co-workers [see eq. (1)].[11] Green–blue **1*** and purple **2*** were isolated by sublimation in 71 and 75% yields, respectively. Purple, low-melting **3*** was obtained in a total yield of 83% by crystallization from hexane (66%) and distillation of the mother liquor (23%). Although alkoxide complexes of the later transition elements are typically unstable with respect to β-H elimination,[14] the copper(II) alkoxides reported here, and some others,[11,12] have good thermal stability; each of **1–3** is sublimed or distilled in $\geqslant$ *ca* 85% recovery between 60–110°C at 10^{-4} torr. The magnetic moments* of **1–3** indicate they are monomeric in solution.

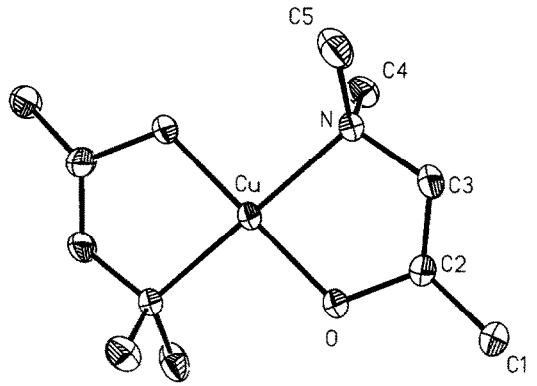

Fig. 1. Structure of $Cu[OCHMeCH_2NMe_2]_2$ (**2**). Selected distances (Å): Cu—O, 1.865(3); Cu—N, 2.052(3). Hydrogen atoms were omitted for clarity.

Crystals of **2** and **3** suitable for X-ray structure determinations were obtained from hexane.† The *trans*, square-planar structure of **2** is shown in Fig. 1, and the distorted square-pyramidal structure of **3** is shown in Fig. 2. The latter geometry results

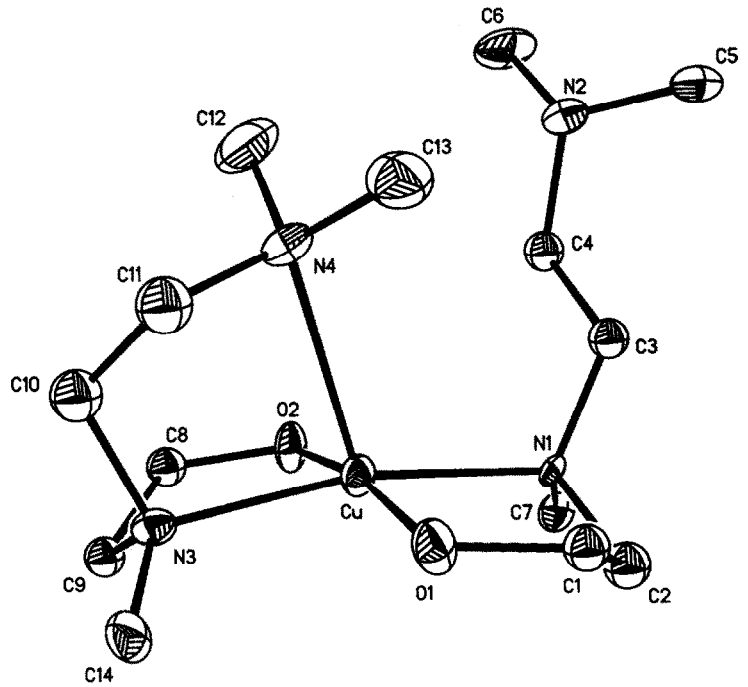

Fig. 2. Structure of $Cu[OCH_2CH_2NMeCH_2CH_2NMe_2]_2$ (**3**). Selected distances (Å): Cu—O(1), 1.892(17); Cu—O(2), 1.887(13); Cu—N(1), 2.113(14); Cu—N(3), 2.102(14); Cu—N(4), 2.598(12). Hydrogen atoms were omitted for clarity.

* *Physical data:* Satisfactory elemental analyses were obtained for **1–3** (C, H, Cu, N). **1**: m.p. 184–185°C dec; sublimed 80°C/10^{-4} torr; μ_{eff} (0.06 M in toluene) 1.82(7) BM. **2**: m.p. 134–135°C dec; sublimed 60°C/10^{-4} torr; μ_{eff} (0.06 M in toluene) 1.76(5) BM. **3**: m.p. 49–51°C; b.p. 110–112°C/10^{-4} torr; μ_{eff} (0.05 M in toluene) 1.81(3) BM.

† Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Centre. Crystal data at ambient temperature: for **2**: space group $P2_1/c$, $a = 5.643(3)$, $b = 10.357(4)$, $c = 11.723(5)$ Å, $\beta = 92.49(5)°$, $D_c = 1.299$ g cm^{-3}, $Z = 2$, final residuals were $R = 0.0407$ and $R_w = 0.0428$. **3**: space group Cc, $a = 16.405(12)$, $b = 10.192(6)$, $c = 12.038(10)$ Å, $\beta = 113.60(7)°$, $D_c = 1.275$ g cm^{-3}, $Z = 4$, final residuals were $R = 0.0578$ and $R_w = 0.0737$.

from one of the $OCH_2CH_2NMeCH_2CH_2NMe_2$ ligands of **3** coordinating in a tridentate fashion, and the other in a bidentate fashion, leaving a terminal NMe_2 group dangling. The axial Cu—N(4) separation of 2.60(1) Å in **3** is considerably longer than the basal Cu—N distances of 2.11(1) Å (av.); these values are typical of the Jahn–Teller-distorted, five- and six-coordinate complexes of copper(II).[15,16] The copper atom sits 0.21 Å above the least-squares basal plane [O(1), O(2), N(1), N(2)], and the Cu—N(4) vector forms a *ca* 72° angle with it. The Cu—O distances of 1.89(2) Å (av.) in **3** are in the short end of the range of corresponding distances (1.89(1)–1.95(1) Å) in a series of alkoxide-bridged, dinuclear copper(II) complexes.[17–20] The Cu—O distances of 1.865(3) Å in **2** and 1.81(1)–1.88(1) Å in a copper(I) alkoxide, $[Cu(\mu\text{-O-}t\text{-Bu})]_4$,[21] are comparable to **3**.

We next sought to establish whether the more volatile compounds **1** and **2** would serve as cupric oxide precursors. In rare mechanistic studies of metal–alkoxide decomposition, Bradley and Faktor determined that $Zr(OR)_4$ compounds pyrolysed to ZrO_2 more readily at atmospheric pressure than at reduced pressure.[8,22] Consequently, we carried out pyrolysis of solid **2** at ambient pressure under a N_2 stream (25–300°C, 2 h), and obtained copper metal as the only phase detected by X-ray powder diffraction. In related work, Jeffries and Girolami recently reported the vapour deposition of metallic copper using $[Cu(\mu\text{-O-}t\text{-Bu})]_4$ as the volatile source.[23] However, pyrolysis of **1** under the same conditions employed for **2** led to a mixture of copper metal, CuO and Cu_2O in a 48 : 33 : 19 ratio, respectively. Thus, the course of thermal decomposition is ligand dependent. Efforts to design a useful CuO precursor through suitable ligand modifications are in progress. The high volatility of **2** suggests it may be a useful source for copper deposition.

INCOMPLETE COORDINATION TO RHENIUM(V) BY A FACULTATIVE QUINQUEDENTATE LIGAND. THE X-RAY CRYSTAL STRUCTURE OF [ReO(OMe){2′-(NC_4H_3-2-CH=N$(CH_2)_3$NMe$(CH_2)_3$CH=N—)C_4H_3NH}]PF_6

(*Received* 26 *September* 1989; *accepted* 12 *October* 1989)

Abstract—The reaction between $Bu_4N[ReOCl_4(H_2O)]$ and the Schiff base ligand $\{HNC_4H_3$-2-CH=N$(CH_2)_3\}_2$NMe in methanol affords the cationic complex [ReO(OMe){2′-(NC_4H_3-2-CH=N$(CH_2)_3$NMe$(CH_2)_3$CH=N—)C_4H_3NH}]PF_6. An X-ray diffraction study of this complex reveals a six coordinate, nearly octahedral rhenium(V) centre coordinated to only four nitrogen donor atoms from the quinquedentate ligand. One terminal pyrrolyl group remains protonated and uncoordinated. The remaining two coordination sites are occupied by the mutually *trans* oxo and methoxide ligands.

Reports of rhenium complexes containing facultative ligands with more than four potential donor atoms are rare.[1] Mazzi and co-workers have reported the complexes $[ReO(N(R)\{(CH_2)_nN$=CH—C_6H_4-2-$O\}_2)]^z$ (R = nothing, $n = 2$ and $z = 0$; R = Me, $n = 3$ and $z = +1$) and have determined the molecular structure of the technetium counterpart of the former, $[TcO(N\{(CH_2)_2N$=CHC_6H_4-2-$O\}_2)]$.[2] More recently we have found that not all potential donor atoms in a facultative ligand may bind to the ReO^{3+} core in rhenium(V) complexes.[3,4] In the complex [ReO(OEt)$\{OC_6H_4$-2-CH=$N(CH_2)_2\}_2$S] the thioether sulphur of the potentially quinquedentate ligand remains uncoordinated,[3] while in [ReO(Cl)$\{OC_6H_4$-2-CH=$N(CH_2)_2$ $OCH_2\}_2$] it is the two ether oxygen atoms of the sexidentate ligand which do not coordinate.[4] Thus, in both of these cases the ligands function as quadridentate although they have the capacity to coordinate further. Wilkinson and co-workers have noted this phenomenon previously[5] but did not present crystallographic data.

In the examples cited above, the finding that the thioether sulphur or ether oxygen donor atoms in polydentate facultative ligands do not bind to the rhenium may not be too surprising. The binding capacities of these non-coordinated atoms would be expected to be rather weak compared to an alkoxide or halide ligand. Certainly when two phenoxide and three nitrogen donors are present in $N(R)\{(CH_2)_nN$=CH—C_6H_4-2-$O\}_2$, five-coordination is achieved.[2] We have now examined the reactions between $[ReOCl_4(H_2O)]^-$ and the potentially quinquedentate ligands $\{HNC_4H_3$-2-CH=N$(CH_2)_2\}_2$NH and $\{HNC_4H_3$-2-CH=N$(CH_2)_3\}_2$NMe which contain terminal pyrrolyl coordinating groups and offer five nitrogen donor sites.

The ligands $\{HNC_4H_3$-2-CH=N$(CH_2)_2\}_2$NH and $\{HNC_4H_3$-2-CH=N$(CH_2)_3\}_2$NMe were prepared by condensation of 2-formylpyrrole with $\{H_2N(CH_2)_2\}_2$NH or $\{H_2N(CH_2)_3\}_2$NMe, respectively. They have been characterized by spectroscopic methods and by elemental analyses. The former ligand reacts with $Bu_4N[ReOCl_4(H_2O)]$ in methanol to produce a red–brown solution. Treatment of this solution with KNCS affords an orange–brown solid, the IR spectrum of which con-

* Authors to whom correspondence should be addressed.

tains bands attributable to $\nu_{C\equiv N}$ and $\nu_{Re=O}$. In addition, a band is observed at 2050 cm^{-1} attributable[6] to N-bound thiocyanate. The ^1H NMR spectrum of the complex is consistent with the presence of a plane of symmetry in the molecule and contains no pyrrolyl-NH signals. The complex is a non-conductor in MeCN solution and the elemental analysis is in accord with the formulation $[ReO(NCS)\{NC_4H_3\text{-}2\text{-}CH{=}N(CH_2)_2\}_2NH]$. A structure consistent with these findings would contain a six-coordinate rhenium centre with the N-bound NCS ligand *trans* to the rhenyl oxo-group. The quinquedentate ligand would occupy the remaining "equatorial" sites with the central —NH— donor group remaining non-coordinated as illustrated in Fig. 1(a).

Treatment of the reaction solution with the non-coordinating anions PF_6^- or ClO_4^- affords species which exhibit appropriate solution conductivities for 1 : 1 electrolytes. It is possible that the central —NH— group of the quinquedentate ligand is bound *trans* to the rhenyl oxo-group in these compounds as illustrated in Fig. 1(b). However, their NMR spectra, in CD_3CN solution, are very similar to that of $[ReO(NCS)\{NC_4H_3\text{-}2\text{-}CH{=}N(CH_2)_2\}_2NH]$. It seems likely, therefore, that a neutral ligand such as MeCN or OH_2 is bound *trans* to the oxo-group in place of NCS^-. Further studies are in progress to establish unequivocally the structure of the cationic complex in these compounds.

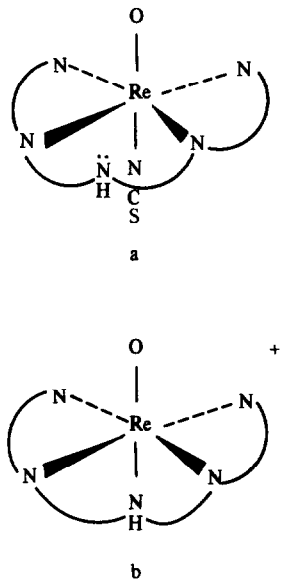

Fig. 1. Schematic representations of possible structures for: (a) $[ReO(NCS)\{NC_4H_3\text{-}2\text{-}CH{=}N(CH_2)_2\}_2NH]$; (b) $[ReO\{HNC_4H_3\text{-}2\text{-}CH{=}N(CH_2)_2\}_2NH]^+$.

The ligand $\{HNC_4H_3\text{-}2\text{-}CH{=}N(CH_2)_3\}_2NMe$ also reacts with $Bu_4N[ReOCl_4(H_2O)]$ in methanol to produce a red–brown solution. However, in this case, treatment with NH_4PF_6 affords a complex with a ^1H NMR spectrum which indicates the absence of a plane of symmetry in the molecule and the presence of a pyrrolyl NH proton. Crystals of this compound which were suitable for an X-ray diffraction study could be obtained, allowing the structure of the complex to be determined. The structure* of the complex cation is illustrated[10] in Fig. 2, which also shows the crystallographic atom numbering scheme used. The ligand and methoxy group bind to the ReO^{3+} core to produce a distorted octahedral geometry, involving three chelate rings, one five-membered and two six-membered. The oxo-group lies *trans* to the oxygen of the methoxy group, similar to previous observations in related complexes,[3,4] and four sequential nitrogen atoms occupy the equatorial sites, producing the *trans*(1, 6) octahedral isomer. One pyrrolyl nitrogen is *trans* to the amine nitrogen and the two imine nitrogen atoms, N(2) and N(4), are mutually *trans*. The remaining pyrrolyl nitrogen is protonated and uncoordinated. The maximum angular distortion from ideal octahedral geometry occurs in the angle N(1)—Re—N(2), 77.7°, which involves the five-membered chelate ring. There are three types of Re—N distances corresponding to the three different bonding geometries at nitrogen. The shortest is that involving the pyrrolic nitrogen at 2.059(10) Å. Next longest are those to imine nitrogens, 2.097(9)

*Crystals of $[ReC_{18}H_{27}N_5O_2][PF_6]$, $M_r = 676.6$ are monoclinic, space group $P2_1/n$, $a = 10.828(2)$, $b = 18.564(2)$, $c = 11.897(2)$ Å, $\beta = 105.47(7)°$, with $Z = 4$, $\mu(Mo\text{-}K_\alpha) = 57.1\ cm^{-1}$. A crystal with dimensions $0.5 \times 0.1 \times 0.2$ mm was mounted on an Enraf–Nonius CAD-4 diffractometer; cell dimensions and intensities were measured by ω–2θ scans with graphite-monochromated Mo-K_α radiation. 3521 unique reflections were scanned within $2 < \theta < 25°$. Three standard reflections measured every 2 h showed no significant alteration in intensity. Lorentz and polarization corrections were applied and 2820 structure amplitudes with $F > 5\sigma(F)$ were considered observed and used in the analysis. The structure was determined[7] by Patterson and Fourier methods and refined[8] by least-squares using anisotropic thermal parameters for the heavier atoms. Hydrogen atoms were placed in calculated positions. An empirical absorption correction was applied to the data using DIFABS.[9] The weighting scheme used was $w = 1/[\sigma_2(F) + 0.00035F^2]$, and the refinement converged to $R = 0.036$, $R' = 0.062$. The residual electron density in a final difference map was within ± 1.1 e $Å^{-3}$.

Atomic coordinates, bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre. See Deposition of Crystallographic Data on p. ii.

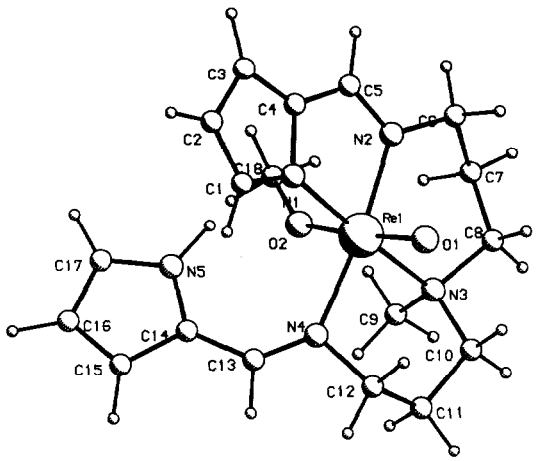

Fig. 2. A view of the complex cation, $[ReO(OMe)\{2'-(NC_4H_3-2-CH{=}N(CH_2)_3NMe(CH_2)_3CH{=}N-)-C_4H_3NH\}]^+$ showing the atom numbering. Selected distances (Å) and angles (°):

Re—O(1)	1.679(7)	Re—O(2)	1.875(6)
Re—N(1)	2.059(10)	Re—N(2)	2.097(9)
Re—N(3)	2.221(8)	Re—N(4)	2.136(9)

O(1)—Re—O(2)	171.8(4)
O(1)—Re—N(2)	90.3(4)
O(1)—Re—N(4)	96.1(4)
N(2)—Re—N(3)	96.2(4)
O(1)—Re—O(2)	171.8(4)
N(2)—Re—N(4)	172.7(3)
O(1)—Re—N(1)	95.6(4)
O(1)—Re—N(3)	88.4(4)
N(1)—Re—N(2)	77.7(4)
N(3)—Re—N(4)	87.5(3)
N(1)—Re—N(3)	172.8(4)

and 2.136(9) Å, for N(2) and N(4), respectively. The longest Re—N distance is the amine nitrogen bond, 2.221(8) Å. The imine nitrogens and the coordinated pyrrole nitrogen are planar, sum of angles; N(2) 360.0, N(4) 359.8, N(1) 359.9°, while the amine nitrogen atom has approximately tetrahedral geometry, angles at N(3) ranging from 103.6(8) to 112.1(7)°.

The angles at N(1), coordinated to rhenium, and N(5), which is bonded to a hydrogen atom, are significantly different; C(4)—N(1)—C(1), 105.6(11)° and C(17)—N(5)—C(14), 110.0(11)°, indicating the difference in bonding at these atoms. A search of the Cambridge Structural Database[11] during August 1989, revealed examples of 18 compounds containing pyrrole coordinated to a metal atom and 131 compounds containing a free pyrrole ring. Calculations showed that the angle C—N—C had a mean value of 105.9(3)° and range from 103.6 to 107.9°, when coordinated to a metal atom, whereas a mean of 109.6(3)° and range from 101.7 to 118.1° was found for the pyrrolyl nitrogen bonded to a hydrogen. These values correlate well with those for this compound.

The Re=O distance of 1.679(7) Å is similar to those reported previously,[4] while the Re—OMe distance, 1.875(6) Å, is shorter than for an alkoxy ligand in the related complex $[ReO(OEt)\{OC_6H_4-2-CH{=}N(CH_2)_2\}_2S]$,[3] in which Re—OEt is 1.947(5) Å. A mutually *trans* arrangement of a rhenyl oxo-atom and another singly-bonded oxygen atom, appears to be favoured in structures of this type.[3,4]

There is a possible intramolecular hydrogen bond interaction between H(N5) and the methoxy oxygen atom; N(5)···O(2) 1.91 Å. There are no short interactions with the PF_6^- counterion.

This structure contrasts with the previously reported examples where not all potential donor atoms in a ligand bind to the metal, in that a terminal rather than an internal ligand donor atom fails to coordinate. Furthermore, it is a nitrogen atom rather than the less basic ether oxygen or thioether sulphur atoms which does not bind. The results obtained by Mazzi and co-workers indicate that with the ligands $N(R)\{(CH_2)_nN{=}CHC_6H_4-2-OH\}_2$ (R = H, n = 2; R = Me, n = 3) changing the internal chelate ring size from five- to six-membered does not preclude binding by all five donor atoms to the ReO^{3+} core. However, in the examples described here the use of quinquedentate ligands forming five- rather than six-membered terminal chelate rings, and having pyrrolyl rather than salicylyl terminal groups, leads to non-coordination of a potential donor atom. It is worthy of note that with first row *d*-block metal ions both quadridentate N(4)[12,13] and sexidentate N(6)[14] ligands can bind to metal ions through all of their nitrogen atoms as exemplified by $[Ni\{NC_4H_3-2-CH{=}N(CH_2)-\}_2(X)]$ (X = nothing or CH_2) and $[Fe\{NC_4H_3-2-CH{=}N(CH_2)_2NHCH_2\}_2]PF_6$.

(*Received* 25 *October* 1989; *accepted* 2 *November* 1989)

Abstract—The new complexes $[Mo(NO)\{HB(Pr^iMeC_3N_2H)_3\}XY]$ (X = Y = CO, I, OMe, OEt; X = I and Y = OMe, OEt, OPr^i, OBu^t, OCH_2SiMe_3, OPh, OC_6H_4-4-Me, NHPh or NHC_6H_4-4-Me) have been synthesized. In the cases where X = I, or where X = Y = CO or I, these compounds were isolated as a mixture of at least two isomers. However, ^1H NMR studies show that the complexes with X = I and Y = OPr^i, OBu^t, NHPh, NHC_6H_4-4-Me undergo rearrangement reactions at elevated temperature to give selectively a single isomer. These reactions involve 1,2-boratropic shifts of the substituted pyrazolyl moieties and appear to be promoted by the more bulky of the co-ligands X and Y.

Since they were first described[1,2] the tripodal hydrotrispyrazol-1-ylborate ligand and its derivative hydrotris(3,5-dimethylpyrazol-1-yl)borate have made important contributions to transition metal chemistry in the development of both coordination compounds[3–5] and organometallic species.[6,7] Much of this work has exploited the analogy between these ligands and the cyclopentadienide ligand and its derivatives. However, there are significant electronic[8] and steric[5] differences between these two types of ligand. Furthermore, the trispyrazolylborate derivates may be functionalized in the 3-position so as to create structured cavities which may enforce unusual coordination geometries on metal ions.[3,9] The possibility also exists of using polar substituents in the 3-position to promote reactions of, or enter into reactions with, co-ligands coordinated to a metal ion incorporated in the cavity created by the tripodal ligand. In the longer term such species may lead to more elaborate models of metalloenzymes[10,11] or offer novel catalytic systems. However, in the shorter term it is necessary to develop the synthesis and chemistry of complexes containing more simply functionalized

* Author to whom correspondence should be addressed.

trispyrazolylborate ligands. As a part of this endeavour we have been studying the synthesis and derivative chemistry of the complex [Mo(NO)$(CO)_2${HB(Pr^{i}Mepz)$_3$}] (where pz = C_3N_2H) and present here a preliminary account of our initial findings.

A sample of [Mo(NO)$(CO)_2${HB(Pr^{i}Mepz)$_3$}] was prepared from $Mo(CO)_6$ and HB(3,5-Pr^{i}Mepz)$_3^-$ using a procedure similar to that used to prepare [Mo(NO)$(CO)_2${HB(3,5-Me_2pz)$_3$}].[12] The ^{1}H NMR spectrum of this compound indicated that two principal isomers were present. In fact six isomers are possible based on the distribution of three methyl and three isopropyl groups among the 3- and 5-positions on the pyrazolyl rings of the tripodal ligand, but it is likely that those with the isopropyl groups predominantly occupying the 3-positions will be preferred.[13]

Again, following the precedent[12] provided by the synthesis of [Mo(NO){HB(3,5-Me_2pz)$_3$}I_2], the reaction of [Mo(NO)$(CO)_2${HB(Pr^{i}Mepz)$_3$}] with iodine produced [Mo(NO){HB(Pr^{i}Mepz)$_3$}I_2].* This compound was initially obtained as a mixture of isomers as indicated by the ^{1}H NMR spectral data. However, after heating at 70°C for 40 h *in vacuo* in the solid state it was found that conversion to a single isomer had occurred. The ^{1}H NMR spectrum of this material contained signals of relative area 1 : 2 at δ_{TMS} = 6.16 and 5.86 attributable to the pyrazolyl-4-H protons. The pyrazolyl methyl protons appeared as singlets of relative area 3 : 6 at δ_{TMS} = 2.57 and 2.29, while the isopropyl methyl signals gave rise to three doublets of relative area 6 : 6 : 6 at δ_{TMS} = 1.30, 1.05 and 0.98 ($^3J_{HH}$ = 7 Hz). In the absence of structural data it is not possible to unambiguously define the distribution of the isopropyl groups in this complex. However, in terms of minimizing steric interactions[13] the most likely structure would place the isopropyl group on the pyrazolyl ring between the two bulky iodide ligands in the 5-position near to the BH group. The other two isopropyl groups would then occupy the 3-positions on the pyrazolyl rings lying between the iodide and nitrosyl ligands as shown in Fig. 1. The only other structure consistent with the NMR data would reverse these positions and place two isopropyl substituents near to the BH group which would not be in accord with the precedents reported so far for this type of complex.[9,13] The rearrangement to produce a single isomer involves a 1,2-

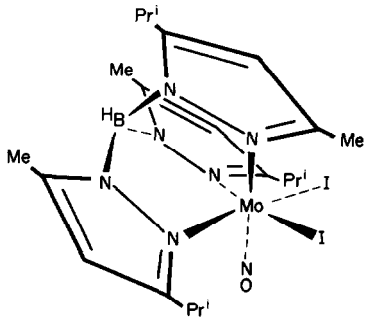

Fig. 1. The proposed structure of [Mo(NO){HB(Pr^{i}Mepz)$_3$}I_2].

borotropic shift of one or more methylisopropylpyrazolyl groups in the ligand. Such rearrangements have been observed previously[13] in cobalt(II) complexes of the ligands HB(3-Pr^{i}Hpz$_2$)$_3$ and HB(3,4-Pr^{i}Brpz)$_3$.

Since the reactions of [Mo(NO){HB(3,5-Me_2pz)$_3$}I_2] with alcohols or organoamines have been found to afford air-stable alkoxide or organoamide derivatives, we were interested in establishing whether a similar derivative chemistry could be developed from [Mo(NO){HB(Pr^{i}Mepz)$_3$}I_2]. Unlike HB(3-Bu^{t}Hpz$_2$)$_3$, HB(3,5-Pr^{i}Hpz$_2$)$_3$ does not enforce tetrahedral coordination geometries on coordinated first row *d*-block metal ions. However, it is apparent that steric interactions occur between the isopropyl groups on the opposing ligands in octahedral cobalt(II) complexes of HB(3-Pr^{i}Hpz)$_3$. This results in a rearrangement to form [Co{HB(3-Pr^{i}Hpz$_2$)$_2$(5-Pr^{i}Hpz$_2$)}$_2$] which is the isomer actually isolated.[13] A similar situation arises with [Mo(NO){HB(Pr^{i}Mepz)$_3$}I_2] in that pseudo-octahedral coordination at the molybdenum atom is tolerated but a facile thermal rearrangement occurs to reduce steric congestion near the large iodide ligands. Replacing iodide by smaller alkoxide ligands such as OMe or OEt might be expected to reduce steric interactions somewhat, while larger alkoxide ligands such as OPr^i or OBu^t might be expected to increase steric congestion.

The reaction between the isomeric mixture of [Mo(NO){HB(Pr^{i}Mepz)$_3$}I_2] and methanol proceeds smoothly over a period of 2 h under reflux. The reaction product was found to be primarily [Mo(NO){HB(Pr^{i}Mepz)$_3$}I(OMe)] contaminated with some [Mo(NO){HB(Pr^{i}Mepz)$_3$}$(OMe)_2$] which could be separated by column chromatography. The ^{1}H NMR spectrum of [Mo(NO){HB(Pr^{i}Mepz)$_3$}I(OMe)] indicated that a mixture of isomers was present and attempts to produce a single isomer by heating the material were unsuccessful. A similar situation was found for the

* The new complexes were characterized by elemental analyses and by IR, mass and ^{1}H NMR (270 MHz) spectroscopy. Some of the compounds could only be obtained as mixtures of isomers as detailed in the discussion.

reaction with EtOH. However, when Pr^iOH or Bu^tOH were used to produce the monoalkoxides $[Mo(NO)\{HB(Pr^iMepz)_3\}I(OR)]$ ($R = Pr^i$, Bu^t) the isomer mixtures which formed initially could be rearranged to a single isomer by heating. Thus the ^1H NMR spectrum of $[Mo(NO)\{HB(Pr^iMepz)_3\}I(OPr^i)]$, for example, contained three resonances of relative area one attributable to the pyrazolyl-4-H protons, three resonances of relative area three attributable to the pyrazolyl methyl protons and eight doublets of relative area three attributable to the isopropyl methyl protons. The effect of placing the sterically bulky group one atom removed from the oxygen was investigated by using the alcohol Me_3SiCH_2OH. In this case a mixture of isomers was obtained which, like the methoxide or ethoxide derivatives, could not be converted to a single isomer on heating.

The reactions between the mixed isomers of $[Mo(NO)\{HB(Pr^iMepz)_3\}I_2]$ and $PhNH_2$ or $4\text{-}MeC_6H_4NH_2$ also afforded products which were mixtures of isomers, but in these cases single isomers were obtained after heating to 70°C for 40 h as revealed by NMR spectral studies. However, the reactions with PhOH and $4\text{-}MeC_6H_4OH$ afforded isomer mixtures which could not be converted to a single isomer by heating. This may reflect the lower steric demands of the oxygen atom as compared to the NH donor group.

The bis-alkoxide complexes $[Mo(NO)\{HB(Pr^iMepz)_3\}(OR)_2]$ (R = Me, Et) could be prepared by the reactions of the respective monoalkoxide mixed isomers with an excess of ROH in the presence of AgOAc. In these cases single isomers were obtained directly. These gave NMR spectra consistent with the presence of a plane of symmetry in the molecule and which contained no additional signals attributable to other isomers.

In conclusion we have found that, with the sterically less demanding ligands, the monoalkoxide complexes $[Mo(NO)\{HB(Pr^iMepz)_3\}I(OR)]$ (R = Me, OEt, CH_2SiMe_3) are isolated as isomeric mixtures which do not rearrange to a single isomer on heating to 70°C for 40 h. In contrast, the more bulky alkoxide ligands OPr^i and OBu^t afford complexes which can be rearranged to single isomers. However, the incorporation of two OMe or OEt ligands in the bis-alkoxide derivatives does lead to the formation of single isomers. There is a difference in behaviour between the aryloxo and arylamido ligands which may reflect steric effects associated with the sizes of the oxygen versus NH donor groups. These systems thus provide novel examples where subtle changes in co-ligand size appear to have a pronounced effect on the relative stability of different isomeric arrangements within the $HB(Pr^iMepz)_3$ ligand. In order to obtain a fully detailed picture of the structural arrangements in these complexes it is necessary to carry out X-ray structural studies of representative compounds. Attempts to obtain suitable crystals and to carry out such studies are in progress.

(*Received* 17 *October* 1989; *accepted* 13 *November* 1989)

Abstract—The pyridine-2-thionato (pyS) bridged compound $[Re_2(pyS)_2(CO)_6]$ reacts with $[Ru_3(CO)_{12}]$ to give various tetranuclear compounds built from $Re(pyS)(CO)_3$ and $Ru(CO)_x$ ($x = 2$, 3 or 4) units: $[ReRu_3(S)(C_5H_4N)(CO)_{14}]$, $[Re_2Ru_2(S)(C_5H_4N)(pyS)(CO)_{13}]$, and $[Re_3Ru(S)(C_5H_4N)(pyS)_2(CO)_{11}]$ as two isomers. X-ray structures of these isomers show that one contains two doubly-bridging pyS ligands and the other one doubly- and one triply-bridging pyS ligands.

The heteroatoms of the pyridine-2-thionato radical (pyS) have potentially seven non-bonding electrons for metal–ligand bonding and by bridging it can make use of three or five of these. However, oxidative addition with C—S bond cleavage would give the strongly bridging sulphur and 2-pyridyl groups which together could donate as many as nine electrons. This high capacity for supplying electrons for metal–ligand bonding and hence to facilitate the aggregation of metal centres is encountered in a reaction we have observed between $[Re_2(pyS)_2(CO)_6]$ and $[Ru_3(CO)_{12}]$.

$[Re_2(CO)_{10}]$ reacts with pyridine-2-thione (pySH) to give high yields of the rhenium dimer $[Re_2(pyS)_2(CO)_6]$ (**1**).[1] Slow scrambling of **1** at room temperature with the 6-methyl substituted analogue $[Re_2(MepyS)_2(CO)_6]$ give an equilibrium involving $[Re_2(pyS)(MepyS)(CO)_6]$ and we argued for the intermediacy of the mononuclear species $[Re(pyS)(CO)_3]$, which may be trapped by various neutral ligands L to give $[Re(pyS)(CO)_3L]$ (L = MeCN, PMe_2Ph etc).[1] Believing that this 16-electron intermediate might react with simple metal carbonyl compounds with electron donation to rhenium and simultaneously from sulphur, we treated **1** with $[Ru_3(CO)_{12}]$ in refluxing *m*-xylene (30 min) to give four products separable by TLC on silica: $[ReRu_3(S)(C_5H_4N)(CO)_{14}]$ (**2**) (32%), $[Re_2Ru_2(S)(C_5H_4N)(pyS)(CO)_{13}]$ (**3**) (31%), and two isomers of $[Re_3Ru(S)(C_5H_4N)(pyS)_2(CO)_{11}]$ (**4**) (9%) and (**5**) (9%). Each compound has been

with two metal–metal bonds in **2** and one each in **3** to **5**. Compounds **4** and **5** are isomers of an interesting and novel type; their X-ray structures (Figs 1 and 2)† are presented here but the structures of **2** and **3** will be reported elsewhere. Each isomer contains the fragments of a pyS ligand formed by C—S bond cleavage: a central four-coordinate sulphur atom linking four metal atoms and a 2-pyridyl ligand bridging a rhenium and a ruthenium atom. The two intact pyS ligands act as five-electron donors. In total the three pyS ligands contribute 19 electrons and with a Re—Ru bond in each (2.902(1) and 2.884(1) Å in **4** and **5**, respectively) and the valence electron count of 70 leads to saturation in each. The isomers differ in the arrangement of the 2-pyridyl and pyS ligands. In **4** the 2-pyridyl ligand bridges a metal–metal bonded edge but in **5** it bridges a non-bonded edge. But the main difference, however, between the isomers is that both pyS ligands are doubly-bridging in **4** as in the parent compound **1**, while in **5** one pyS is doubly-bridging but the other triply-bridges Ru(1), Re(1) and Re(3). Triply-bridging pyS ligands have been found previously. For examples see refs 2 to 4. In spite of these overall geometric differences the metal atoms in each isomer have very similar coordination spheres. Specifying the metal-bonded atoms, both isomers have *fac*-$Re(CO)_3S_2N$ for Re(1) and Re(2), *fac*-$Re(CO)_3NS_2Ru$ for Re(3), and $Ru(CO)_2S_2CRe$ for Ru(1). Figure 3 shows how the cages relate in spite of their overall different shapes and how the μ_4-S atoms are similarly distorted from a tetrahedral geometry. Compound **4** is in principle simply converted into **5** by coordinating N(1) to Re(3) and N(3) to Re(1) instead of the other way round. However, even at high temperatures this conversion does not occur and instead other products are obtained which we are investigating.

These results show that the pyS in mono- or dinuclear complexes can add oxidatively to give strongly bound cages with S and C_5H_4N ligands. Another example is the reaction of $[Ru(pyS)_2(CO)_2]$ with $[Ru_3(CO)_{12}]$ to give $[Ru_5(\mu_4\text{-}S)_2(\mu\text{-}C_5H_4N)_2(CO)_{11}]$ containing a Ru_5S_2 pentagonal bipyramid.[5] We believe this could be a general route from mono- or dinuclear compounds to robust cage compounds.

Springer; Berlin, Heidelberg, New York, Tokyo.

The "Gmelin" treatment of organoiron compounds falls into three series; series A deals with ferrocene derivatives, series B with mononuclear organoiron compounds, and series C with compounds containing two or more iron atoms.

Earlier volumes in series B, up to B10, covered the compounds with ligands bound via 1–4 carbon atoms; B11 and B12 began the consideration of compounds of C_5 ligands, continued in the three latest volumes.

Volume B13 continues the compounds $(C_5H_5)Fe(CO)_2R$, where R is a substituted alkyl, alkenyl, alkynyl, aryl, or other carbocyclic group. As usual in the Gmelin approach, compounds are considered systematically, with quick-reference tables. Taking $(C_5H_5)Fe(CO)_2COCH_3$ as an example of the utility of the book, one can ascertain from one table its appearance; melting point; IR, UV, Mössbauer, ^1H and ^{13}C NMR spectra, as well as the yields from four alternative preparative methods. One can find out much more about this compound from the five pages of text dedicated to it, including details of its reactions and solubility, as well as critical comment on the spectroscopic data. This approach is particularly useful in view of the propensity of some research workers to omit "basic" information like colour, solubility and melting points of compounds, and is especially useful to researchers wishing to repeat the preparations of "known" compounds. Similarly, when an X-ray structure is available, a diagram giving important bond lengths and angles is provided, as for the fluxional $(\eta^5\text{-}C_5H_5)Fe(CO)_2(\eta'\text{-}C_5H_5)$, discussed in some five pages of text.

Volume B14 completes coverage of the $(C_5H_5)Fe(CO)_2R$ compounds, before passing to the related species with substituted cyclopentadienyls, ending up with anionic and cationic species. The volume contains an empirical formula index for both volumes B13 and B14.

Volume B15 starts by covering compounds of the type $(L_5Fe(CO)_3)^+$. The prototype $[(C_5H_5)Fe(CO)_3]^+$, synthesized by oxidation of $[(C_5H_5)Fe(CO)_2]_2$, has an interesting and well-defined "tripod" structure. Other ligands like C_6H_6 and C_7H_9 form related compounds in which only five of the ring carbon atoms are bound to iron. This very thorough treatment consumes some 260 pages of the volume followed by consideration of those compounds with thiocarbonyl and isocyanide groups. The volume has its own empirical formula index.

For all three volumes, literature coverage is complete to at least the end of 1986, but in fact there are many additional references up to 1988, so that these volumes represent extremely up to date treatment of the primary literature.

"Gmelin" is undoubtedly the first choice as a means of rapid access to *all* the published data on a particular compound or family of compounds. The intelligibility of the distilled data within its pages is excellent, helped by the lucidity of the tabulated material. They are, as always, highly recommended.

(*Received* 26 *June* 1989; *accepted* 31 *August* 1989)

Abstract—The interaction of the vitamin B_6 (VB_6) compounds, pyridoxol (P), pyridoxal (PL) and pyridoxamine (PM), with the binary species 2,2′-bipyridyl (BP) of copper(II) has been studied potentiometrically and polarographically at an ionic strength of 0.15 M Cl^-. The potentiometric data at 37°C were assessed by the SUPERQUAD program. The results indicated that BP enhances ternary complex formation with vitamin B_6 compounds, especially with P and PL. The differential pulse polarographic technique further confirmed the formation of ternary species, especially at pHs greater than 5.5. The ternary complex enhancement was discussed in terms of log K_1 (log β_{111i} − log β_{1010} − log β_{011i}) and log K_2 (2 log β_{111i} − log β_{2010} − log β_{0211i}).

VB_6 compounds, P, PL and PM, Fig. 1(a), form various complexes with Cu^{II} of varied stabilities. The order of stability of Cu^{II} with the three ligands for the 1:1 (VB_6–Cu^{II}) species is as follows: CuPM ≫ CuPL > CuP.[1–3] Ternary complexes involving the binary complexes of Cu^{II}–PM with other potential ligands have been investigated.[4–9] Ternary stability enhancement has been shown to occur in these systems. However, ternary systems involving PL and P are rare, although the isolation of a ternary complex involving P, BP[10] and Cu^{II} has been recently reported. On the other hand, BP, Fig. 1(a), forms stable complexes with Cu^{II} in aqueous solution.[11] Ternary complexes involving BP as one of the ligands and other secondary ligands have been the subject of many reports in the last two decades.[12,13] The presence of BP in the Cu^{II} inner sphere usually enhances ternary complex formation.[12] This concept has been tested in this work, especially that the binary complexes of Cu^{II} with PL and P are weak.

chloride (PM·2HCl) (Merck, > 99%) were analytically pure and used without further purification. Stock solutions of P, PL and PM were 0.10 M. BP (Fluka >99%) was used without further purification. The stock solution of BP was 0.10 M in 0.20 M HCl. The ligands stock solutions were kept in the dark at 4°C to avoid any possible photodecomposition. A stock solution of $CuCl_2$ ($\simeq$0.202 M) was prepared and its concentration was checked by EDTA complexometric titration as previously reported.[2] KCl was used to keep the ionic strength of solutions constant at 0.15 M. Carbonate-free KOH titrant (0.0967 M) was used in the titrations.

Measurements

The potentiometric titrations were carried out as previously reported[3] using an Orion Research Ionalyser type 901 in the pH mode. The ion meter was provided with Orion glass (91–01) and calomel (90–05–00) electrodes. It was calibrated before use with two buffers; Merck buffer at pH 6.96 and Radiometer buffer at pH 4.03. The titrant was delivered by the Radiometer autoburette type ABU12 accurate to ± 0.001 cm^3. The titrations were carried out in a thermostated cell at 37°C under the surge of purified nitrogen. The analytical concentration of the ligands (T_{PM}, T_{PL}, T_P) and the metal (T_{Cu}) were $(1.0–3.0) \times 10^{-3}$ M and that for BP (T_{BP}) was $(1.0–4.0) \times 10^{-3}$ M.

Differential pulse polarograms (DPP) were obtained using Metrohm polarocord 156 provided with a three electrode arrangement, dropping mercury indicator electrode, saturated calomel reference electrode and counter platinum-wire electrode. The settings of the polarographs were as follows: the voltage range was either 0.0 to -0.5 or -0.8 to -1.8 V, the pulse amplitude was -40 mV, the drop time was 1 s, the recorder speed was 0.5 mm s^{-1}. The pH range used was $\simeq$2.00–11.20.

The solution was deoxygenated by passing pure humidified nitrogen through before taking the polarograms. The ionic strength was 0.15 M Cl^-. For the binary system the BP concentration was identical to that of the metal ion, whereas in the case of ternary systems, the BP and Cu^{II} concentrations were 1.0×10^{-3} M and that of PM, PL and P were 2.0×10^{-3} M. The polarograms were taken at room temperature (23 ± 1)°C.

Calculations

The formation constants of the binary species of Cu^{II}–BP and the ternary species of Cu^{II}–BP–L (where L = P or PL or PM) system were determined using the SUPERQUAD program.[14] The procedures used to select the correct equilibrium models were similar to those reported previously.[15] In addition, allowance has been made for errors in pH and titrant volume in the range 0.001–0.005 of a pH unit and volume (cm^3). In most cases, the final equilibrium model was not changed except that sigma decreases drastically as the preselected errors increase. The distribution diagrams of the binary and ternary systems as a function of pH were made by using the SPECN program.[16]

RESULTS AND DISCUSSION

pH-metric study

Table 1 depicts the protonation constants of the ligands used in this work together with the formation constants of their Cu^{II} binary complexes. It is worth mentioning that the binary complex formation of Cu^{II}–P and Cu^{II}–PL cannot be easily studied at a wide pH range as in the Cu^{II}–BP and Cu^{II}–PM systems due to the early precipitation of hydrolysed products. However, the addition of BP stabilizes these systems against precipitation up until a pH of $\sim$10.5. It seems that the electron-withdrawing property of BP enhances ternary complex formation with the vitamin B_6 compounds. Although this is true, it is also dependent on the basicity as well as the denticity of the second incoming ligand. The ternary formation constants are shown in Table 2. The larger values of the formation constant of the 1 : 1 : 1 : 0 and 1 : 1 : 1 : 1 species of BP–PM–Cu^{II}–H than those of BP–P (or PL)–Cu^{II} systems indicate a different mode of ligation of the vitamin B_6 compounds to the BP–Cu^{II} system. One should expect that chelation takes place in the BP–PM–Cu^{II} system rather easier than in the other two systems where monodentate ligation of P or PL to the BP–Cu^{II} system is more favourable. The proton in the 1 : 1 : 1 : 1 species is likely to be located on the pyridinic nitrogen of the vitamin B_6 compounds. The order of basicity of this moiety is still the same as in the free ligand, i.e. PM > P > PL, as shown by the protonation constant of the 1 : 1 : 1 : 0 species (= 7.3, 6.6, 5.9 for PM, P and PL containing ternary systems). However, the monodenticity of PM is shown by the occurrence of 2 : 2 : 1 : i (i = 1, 2, 3 or 4) species if it is assumed that BP will remain unprotonated in the ternary complex formation. Moreover, these species emphasize the hexacoordination nature of Cu^{II}. In addition, the strong chelation property of PM over PL and P overcomes the formation of dimerized ternary species, 2 : 2 : 2 : -2 encountered in the BP–P (or PL)–Cu^{II} systems, Fig. 1(b).

It is interesting to notice that the species exhibited

by the BP–P (or PL)–Cu^{II} systems are almost the same with their formation constants close in value. In other words, the presence of the formyl or alcoholic groups in the *ortho* position to the phenoxy group has no effect on the ligation of the P or PL to BP–Cu^{II} binary complexes (if the phenoxy group is assumed to be the ligation site). This finding is true since the formyl group in PL is also thought to add intramolecularly to the alcoholic group to form a hemiacetal,[17] in a wide pH range, Fig. 1(c).

The extent of ternary complex enhancement over binary complex formation for the 1:1:1:0 and 1:1:1:1 may be recognized if one examines the following equilibrium reactions:

$$CuBP + CuPH_i \rightleftharpoons CuBPPH_i + Cu;$$
$$K_1 = \beta_{111i}/\beta_{1010}\beta_{011i} \quad (1)$$
$$Cu(BP)_2 + CuP_2H_i \rightleftharpoons 2CuBPPH_i;$$
$$K_2 = \beta^2_{111i}/\beta_{2010}\beta_{021i} \quad (2)$$

(where $i = 0$, 1 or 2). The charges have been omitted for clarity. Table 3 depicts the values of log K_1 and log K_2 whenever enough information is obtained. Statistically, log K_1 should have a value of −0.6, values markedly greater than this indicate a stabilization of the ternary complex. Actually, positive

values mean that the second ligand prefers to bond to the binary complex rather than to the solvated metal ion. On the other hand, values greater than 0.6 for log K_2 suggests the stabilization of the ternary complexes. The value of log K_2 is dependent on the stabilities of the bis complexes and since these bis complexes are not intermediates in the formation of the ternary complexes, the value of log K_2 may not reflect the stability of the mixed complex. However, log K_2 tends to be less dependent than log K_1 on differences in the charges of the ligands involved in the ternary metal complex formation.[18] It seems that ternary enhancement of the 1:1:1:0 species is favoured more by the systems BP–P–Cu^{II} and BP–PL–Cu^{II} than BP–PM–Cu^{II}, as it is shown by the positive values of log K_1 (the system containing P is assumed to behave similar to that containing PL) for the former systems and the negative value of log K_1 for the latter system. However, the disproportionation of the bis binary complexes to form the 1:1:1:0 species is favoured by all of the three systems exemplified by the positive values of log K_2. On the other hand, the ternary enhancement of the 1:1:1:1 species is not favoured in the reaction of the three systems indicated by their negative values of log K_1. However, disproportionation reaction is favoured for all the three systems as shown by the positive values of log K_2.

The ternary enhancement of species other than 1:1:1:0 and 1:1:1:1 may be similarly explained except that the statistical values of log K_i of various equilibrium reactions will be different from log K_1 and log K_2 depending on the geometry of the formed ternary complexes. It is interesting to notice that the ternary species 2:2:1:i (i = 1, 2, 3 or 4) of the PM containing system is not the product of the disproportionation of the binary species 2:0:1:0 and 0:2:1:i (i = 1, 2, 3 or 4) since their log K's have negative values, but rather by the disproportionation of 2:0:1:0 and 0:2:1:0 species, Table 3. Figure 2(a), (b) and (c) shows the distribution diagrams of the various species for the three systems as a function of pH.

Polarographic study

Binary systems. The DPP of a $CuCl_2$ solution at pH ~3.0 shows two cathodic peaks at E_{max} (the potential at maximum differential faradic current

K_3, K_4, K_5, K_6, K_7, K_8, K_9, K_{10} and K_{11} are for the following equilibrium reactions:
$CuBP + Cu(PL)_2 \rightleftharpoons CuBP(PL)_2 + Cu$; $K_3 = \beta_{1210}/\beta_{1010}\beta_{0210}$
$Cu(BP)_2 + Cu(PL)_2 \rightleftharpoons CuBP(PL)_2 + CuBP$; $K_4 = \beta_{1010}\beta_{1210}/\beta_{2010}\beta_{0210}$
$CuBP + CuP_2H_2 \rightleftharpoons CuBPP_2H + Cu + H$; $K_5 = \beta_{1211}/\beta_{1010}\beta_{0212}$
$Cu(BP)_2 + CuP_2H_2 \rightleftharpoons CuBPP_2H + CuBP + H$; $K_6 = \beta_{1211}\beta_{1010}/\beta_{2010}\beta_{0212}$
$Cu(BP)_2 + CuPL \rightleftharpoons Cu(BP)_2PL + Cu$; $K_7 = \beta_{2110}/\beta_{2010}\beta_{0110}$
$Cu(BP)_2 + Cu(PL)_2 \rightleftharpoons Cu(BP)_2PL + CuPL$; $K_8 = \beta_{2110}\beta_{0110}/\beta_{2010}\beta_{0210}$
$Cu_2(BP)_2(OH)_2 + Cu(PL)_2 \rightleftharpoons Cu_2(BP)_2(PL)_2(OH)_2 + Cu$; $K_9 = \beta_{222-2}/\beta_{202-2}\beta_{0210}$
$2CuBPOH + 2CuPL \rightleftharpoons Cu_2(BP)_2(PL)_2(OH)_2 + 2Cu$; $K_{10} = \beta_{222-2}/\beta^2_{101\ \ 1}\beta^2_{0110}$
$Cu(BP)_2 + Cu(PM)_2 + H \rightleftharpoons Cu(BP)_2(PM)_2H + Cu$; $K_{11} = \beta_{2211}/\beta_{2010}\beta_{0211}$
(charges have been omitted for clarity).

(δ_i) of −64 and −220 mV and one anodic at −348 mV, Fig. 3(a). No appreciable change has been found in these peaks until the precipitating pH is reached. The cathodic peaks have been previously rationalized,[19] using direct current polarography, as being due to the stepwise reduction of Cu^{2+} to Cu as a result of the formation of the more stable chloro complex of Cu^{I}. The anodic peak was also interpreted as due to the further oxidation of the cuprous complex to the cupric state.

On the addition of an equimolar concentration of BP to the $CuCl_2$ solution, considerable changes were observed in the DPP in the potential range of 0.0 to −400 mV, Fig. 3(b). The experimental conditions used imposed the formation of the 1 : 1 species and possibly their hydroxy species in the pH range 2.0–11.0. The DPP of the 1 : 1 (Cu^{II}–BP) solution shows two overlapping cathodic peaks in the pH range 2.7–3.4. The differential faradic current (δ_i) decreases as the pH increases. A new cathodic peak arises above pH 3.4. The E_{max} of the peak shifts regularly to a lower potential as the pH increases up until pH ~5.0 with constant δ_i. The peak stays constant in E_{max} and δ_i over a wide pH range (5.0–11.0). Furthermore, the peak at $E_{max} \sim -80$ mV in the pH range 2.7–3.4 shifts suddenly at pH ≃ 6.8 with an increase in δ_i as the pH increases, Fig. 3(b). Figure 4(a) shows the effect of pH on this peak. If one refers to the distribution diagram of Cu^{II}–BP system, Fig. 5, it may be concluded that the first two overlapping peaks mainly correspond to the reduction properties of the chloro species of the $CuBP^{2+}$ complex with some traces of the chloro species of Cu^{2+}. The anodic peak of $CuCl_2$ vanished in the Cu^{II}–BP–Cl system due to the stabilization effect of BP on the Cu^{II} oxidation state, Table 1. However, BP also stabilizes the Cu^{I} oxidation state.[20] One should obtain two anodic peaks, each corresponding to a single electron reduction step. This may explain the presence of two peaks in the DPP in the pH range 2.7–5.0; one at an E_{max} of −80 mV and the other at $E_{max} \simeq -300$ mV. The change in the peak E_{max} from −80 to −184 mV may be attributed to the reduction of the 1 : 1 : −1 and 2 : 2 : −2 (BP–Cu^{II}–OH) species formed at pH ~6.6. The shift in the last peak as the pH increases above 9.4 may correspond to the formation of other species showing slight different reduction properties. The half-height width ($W_{1/2}$)[21] of the peaks at −80, −184 and −220 mV amounts

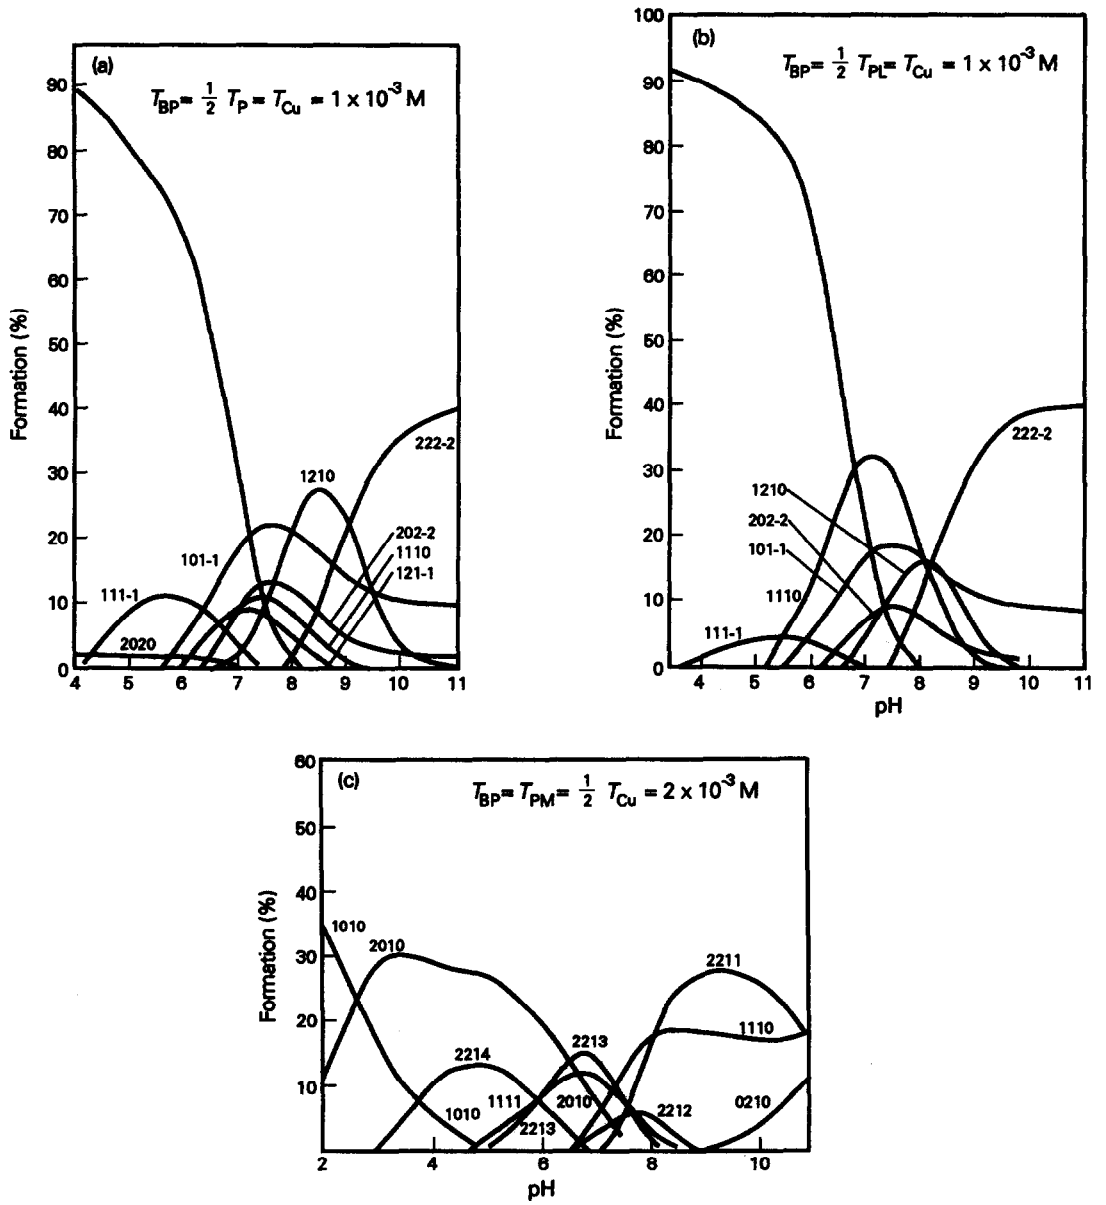

Fig. 2. Distribution diagram of the various species as function of pH. (a) BP–P–Cu^{II}; (b) BP–PL–Cu^{II}; (c) BP–PM–Cu^{II}.

to ~ -84 mV indicating a single electron reduction process.

The DPP's of the P or PL–Cu^{II} system are similar in pattern when the composition ratio of 2 : 1 has been used with one cathodic and one anodic peak, Fig. 3(a), in the pH range 3.0–5.0. At pH's greater than 5 the anodic peak is lost. The cathodic peak has $W_{1/2} \simeq -96$ mV, possibly indicating a single electron step. The DPP's are not affected greatly by variation in the type of the species which may be encountered in solution. This finding emphasizes the weak ligation properties of P and PL to Cu^{II}. On the other hand, the differential pulse polarography of the PM–Cu^{II} system is different from the P or PL–Cu^{II} systems under identical experimental conditions. In the pH range 3.0–4.0 DPP is similar to that of the P or PL–Cu^{II} system exhibiting two peaks, one is cathodic and the other is anodic with approximately the same E_{max}. The anodic peak shifts to more negative potentials as the pH increases from 4.0 to 5.0. However, at pH's greater than 4 the anodic peak is lost and a new cathodic peak appears, Fig. 3(c), which shifts regularly toward more negative potential as the pH increases from 4.0 to 9.0. At pH's above 5.0, a new cathodic peak appears which also shifts regularly to lower potential as the pH increases from 5.0 to 11.0. The first cathodic peak gradually vanishes as the pH

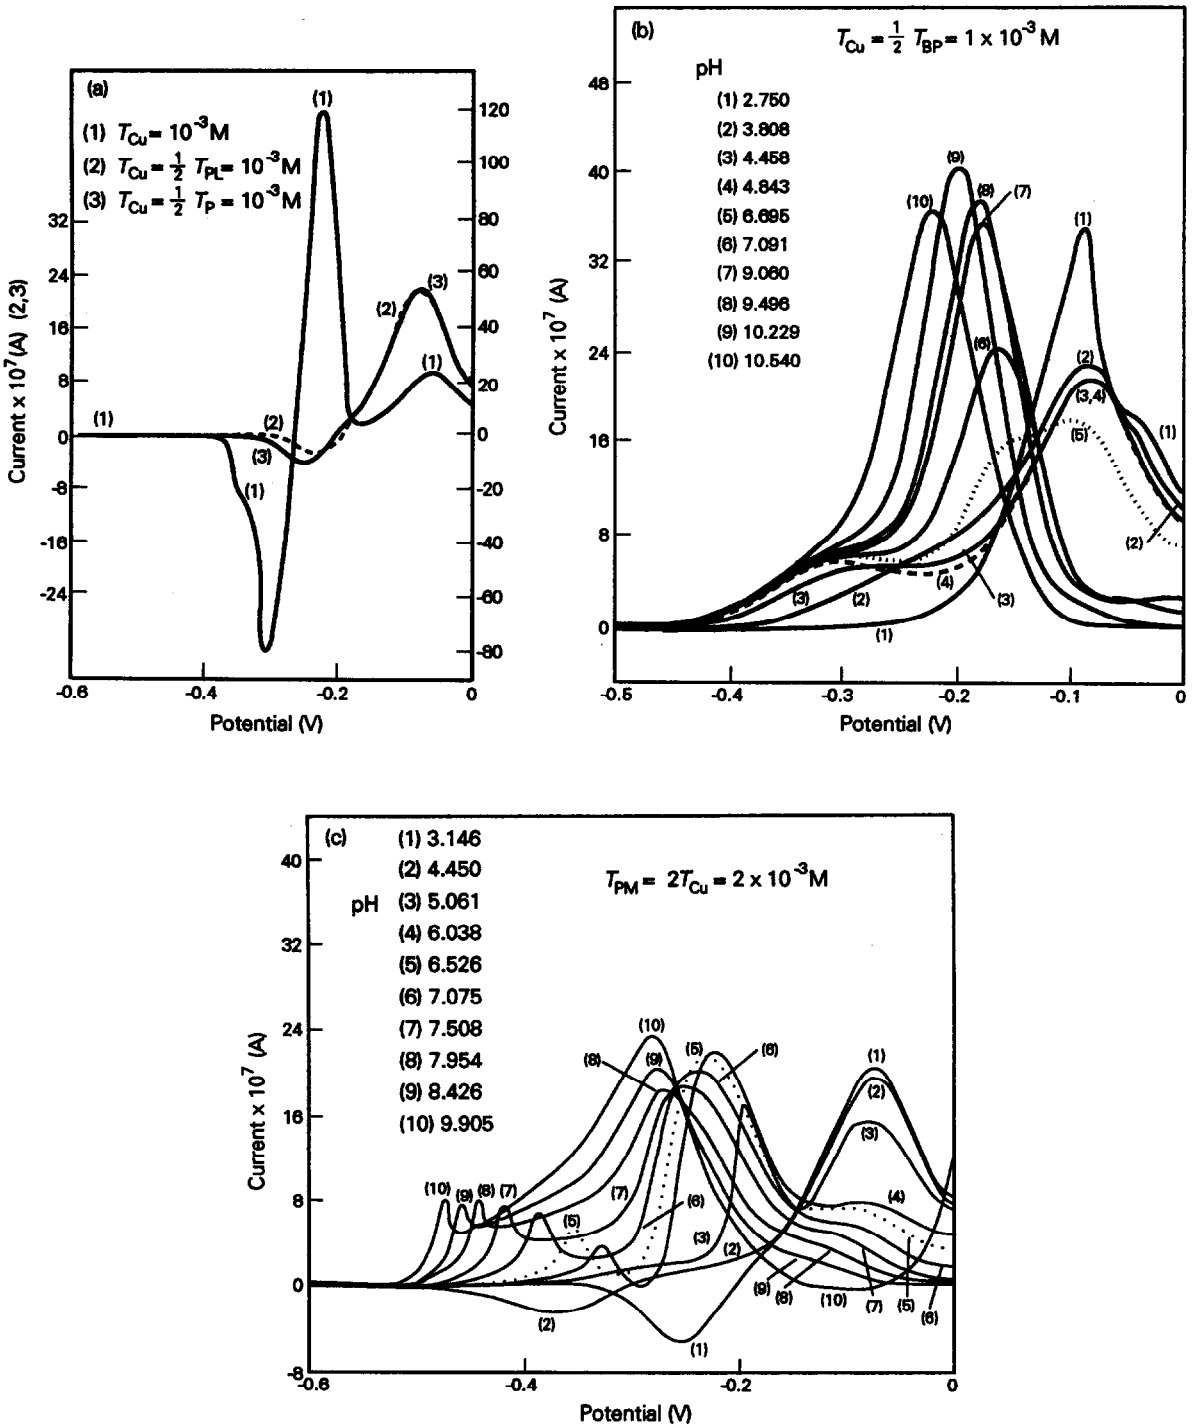

Fig. 3. (a) DPP of $CuCl_2$ solution, Cu^{II}–P and Cu^{II}–PL systems at different pH. (b) DPP of Cu^{II}–BP at various pH. (c) DPP of Cu^{II}–PM at various pH.

increases from 4.0 to 11.0. The first cathodic peak may explain the reduction property of the 1 : 1 : *i* species (*i* = 0, 1 or 2) (PM–Cu^{II}–*i*H) in the pH range 3.0–4.0. However, the 1 : 1 : *i* species (PM–Cu^{I}–*i*H) may be oxidized further to the Cu^{II} species as in the $CuCl_2$ system. The second and third cathodic peaks may correspond to the reduction property of the 2 : 1 : *i* (*i* = 0, 1, 2 or 3) species in the pH range 5.0–11.0. Figure 4(b) shows the effect of pH on the E_{max} of the second and third cathodic peaks. However, the third peak may be due to the reduction of hydrolysed products not detected by potentiometric methods.

Ternary systems. The differential pulse polar-

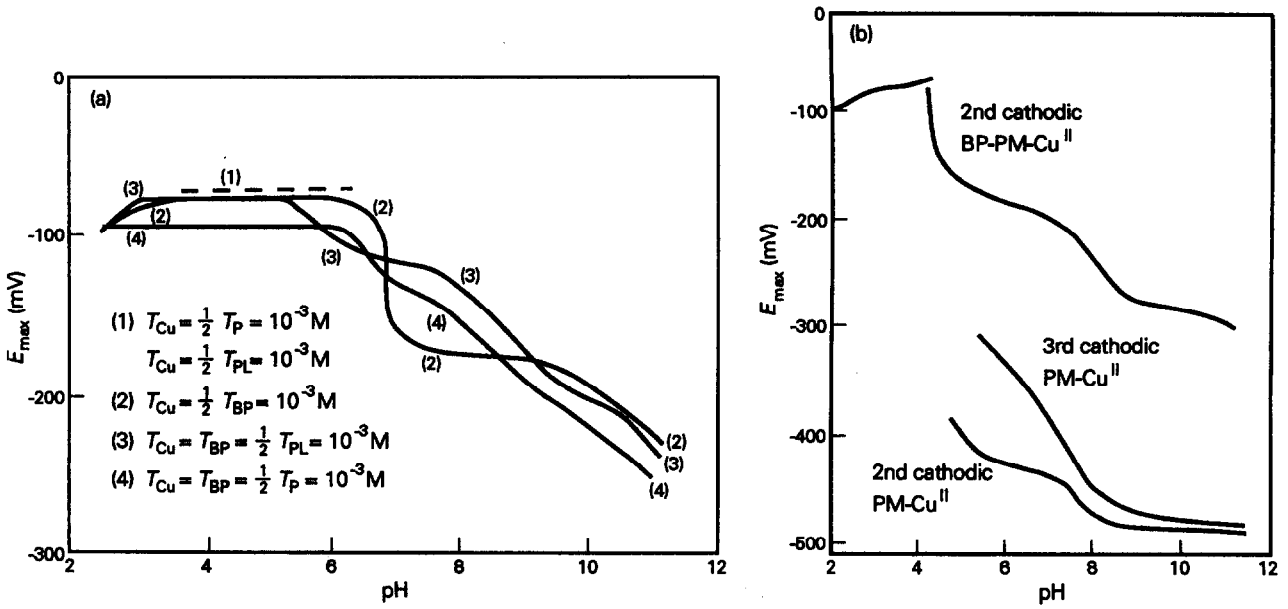

Fig. 4. (a) The DPP E_{max} of BP–Cu^{II}, P–Cu^{II}, PL–Cu^{II}, BP–P–Cu^{II} and BP–PL–Cu^{II} systems. (b) The DPP E_{max} of PM–Cu^{II} and BP–PM–Cu^{II} systems as function of pH.

ography of BP–P or PL or PM–Cu^{II} systems has been taken in the potential range of 0.00 to −2.00 V, Fig. 6(a), (b) and (c). Although the range from 0.9 to −2.00 V was informative and interesting, the presence of the reduction peaks of the ligands complicated the results. The DPP's of the BP–P or PL–Cu^{II} systems are alike except that the E_{max} for the BP–P–Cu^{II} system shifts to more negative potential than the BP–PL–Cu^{II} system, Fig. 4(a). Both systems show different behaviour of E_{max} as a function of pH from the parent binary systems, especially in the pH range 6–11. Figure 4(a) indicates the formation of ternary species of different redox properties. At least two ternary species may be recognized in this pH range. The degree of negativity of E_{max} reflects, somewhat, the stability of the ternary

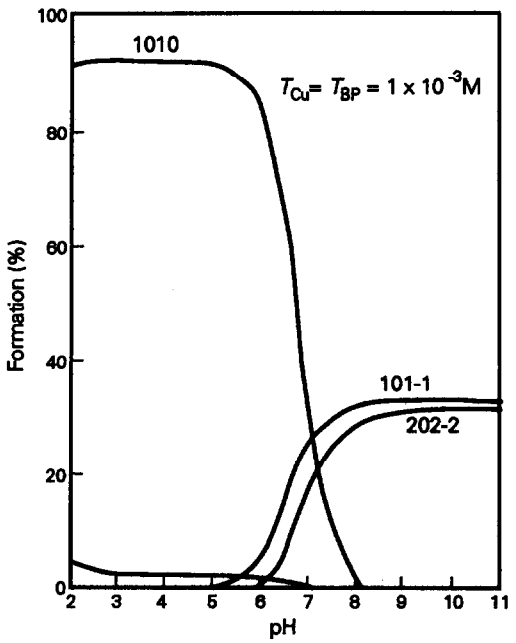

Fig. 5. The distribution diagram of BP–Cu^{II} species as function of pH.

species or the extent of σ and π bonding between the ligands and the metal, being slightly larger in the case of the BP–P–Cu^{II} system.

The DPP of BP–PM–Cu^{II} is different from the former ternary systems and parent binary systems, BP–Cu^{II}, P or PL–Cu^{II} and is characterized by a more negative E_{max}, Fig. 4(b). However, the ternary system still has a less negative E_{max} than that of the binary system PM–Cu^{II}, Fig. 4(b). This may be due to the loss of coplanarity of the ternary complex, assumed to be experienced by the bis complex of PM ($0:2:1:i$), with reduction of electron density on the Cu^{II}, accompanied by facile reduction.

OPTICALLY ACTIVE TRANSITION METAL COMPOUNDS, CHIRAL AT THE METAL CENTRE. SYNTHESIS AND STEREOCHEMICAL STUDIES OF THE CHIRAL CYCLOPENTADIENYL IRON COMPLEXES $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$*

E. CESAROTTI,† M. GRASSI and L. PRATI

(*Received* 31 *March* 1989; *accepted* 18 *September* 1989)

Abstract—The reaction between $[Fe(\eta^5\text{-}C_5H_5)(CO)_2Cl]$ and {(S)-Prolophos}, a chiral chelating ligand without a C_2 axis, yields $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]Cl$ spontaneously and quantitatively; the chelation of the ligand forms a pair of diastereoisomers differing only in the iron configuration. Reprecipitation with NH_4PF_6 leads to $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$ with 83% diastereoisomeric excess (d.e. %) at the iron chiral centre. One recrystallization is sufficient to give the optically pure iron complex whose absolute configuration has been tentatively assigned as *S*. $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$ on UV irradiation in THF splits off the CO ligand to give the highly reactive complex $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(THF)]PF_6$; the iron(tetrahydrofuran) complex regenerates the title compound with an overall retention of configuration upon treatment with carbon monoxide.

Optically active organometallic compounds in which the transition element is the centre of chirality have been available since 1969;[1] most of them are cyclopentadienyl and carbonyl complexes optically stable at the metal centre in the solid state. As far as the behaviour in solution is concerned the compounds can be divided into two groups: those which are configurationally stable at the metal centre and those which are configurationally labile, racemizing or epimerizing with respect to the metal atom prior to any reaction. To the former class of compounds belong optically active iron complexes which have been shown to exert powerful stereocontrol in a wide variety of stoichiometric reactions of attached ligands.[2,3] A general application in the strategy of synthesis of optically active molecules requires, however, that the chiral auxiliary organometallic complex should be in an optically pure form. The synthesis of chiral organometallic compounds usually proceeds with very low or even without stereocontrol at the metal centre; this implies that the availability of reasonable amounts of chiral, not racemic, organometallic compounds is still related to classical, long, tedious and sometimes unsuccessful methods to separate the antipodes.

We describe here the synthesis of cyclopentadienyl carbonyl iron complexes of potential utility in which the centre of chirality, the metal, is generated with a high stereoselectivity (d.e. $\geqslant$ 80%) in high chemical yield. A simple recrystallization leads to one optically pure antipode. UV irradiation splits off the carbonyl generating a highly reactive species.

EXPERIMENTAL

General procedures

Solvents were distilled under an inert atmosphere and stored under nitrogen. Elementary analyses were performed by the Microanalytical Laboratory

* {(S) - Prolophos} = (S) - N - diphenylphosphino - 2-(diphenylphosphinoxymethyl)pyrrolidine.

† Author to whom correspondence should be addressed.

of the Dipartimento di Chimica Organica e Industriale, University of Milan. ^1H and ^{31}P NMR were recorded on Varian XL200 and Bruker NS80 spectrometers, whereas circular dichroism (CD) were recorded on a Jobin–Yvon Dichrographe III instrument using CH_2Cl_2 as a solvent and with concentrations of 0.4–0.5 g dm^{-3}. FAB^+ mass spectra were recorded on a VG-7070 Eq mass spectrometer; M^+ is the peak in the parent multiplet which arises from the most abundant iron isotope.

$[Fe(\eta^5\text{-}C_5H_5)(CO)_2Cl]$ and {(S)-Prolophos}[4] were prepared according to previously published methods.

Preparation of $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$

3.33 g of $[Fe(\eta^5\text{-}C_5H_5)(CO)_2Cl]$ (15.5 mmol) and 9.6 g of {(S)-Prolophos} (20.5 mmol) were thoroughly mixed in a flask under nitrogen followed by the slow addition of 5 cm^3 of THF. The addition gave rise to an immediate and violent reaction and generated a sticky light brown mass which was dissolved in CH_2Cl_2–MtOH 1 : 1 (30 cm^3) and treated with 2.82 g of solid NH_4PF_6 (17.3 mmol). The suspension was then passed through a short column of Florisil to remove NH_4Cl and the solution was evaporated to dryness giving 10 g of yellow microcrystalline $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$ as a 9.2:0.8 mixture of epimers at the iron atom. The diastereoisomeric mixture was dissolved in boiling MtOH (150 cm^3) under nitrogen, and upon standing at 4°C for 24 h the racemic mixture precipitated. The solution was filtered and evaporated giving 6.9 g of optically pure $[CD(-)_{319}Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$; 58% yield based on $[Fe(\eta^5\text{-}C_5H_5)(CO)_2Cl]$. Found: C, 54.6; H, 4.5; N, 1.9. Calc. for $C_{35}H_{34}F_6NO_2P_3Fe$: C, 55.1; H, 4.5; N, 1.8%. M^+(FAB) 618. IR, 1969 cm^{-1}.

Preparation of $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(THF)]PF_6$

500 mg of $[CD(-)_{319}Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$, dissolved in THF (200 cm^3), were placed in a Pyrex Schlenk vessel, degassed with argon for 15 min and irradiated with a Phillips high-pressure Mercury 125-W lamp until the carbonyl band disappeared (6 h). The solution was then evaporated to give a brown residue which was washed with petroleum ether and dried again; the yield is almost quantitative. Found: C, 54.9; H, 5.1; N, 1.6. Calc. for $C_{38}H_{42}F_6NO_2P_3Fe$: C, 56.5; H, 5.2; N, 1.7%. (FAB) $M^+(-THF)$ 590.

RESULTS AND DISCUSSION

In the cyclopentadienyl iron complex $[Fe(\eta^5\text{-}C_5H_5)(CO)_2Cl]$ the two carbonyls are in an enantiomeric relationship; the substitution of one CO with a ligand L gives two enantiomers differing only in the configuration at the metal (Fig. 1, reaction 1). The same result can be obtained when both carbonyls are replaced with a chelating ligand lacking a C_2 axis (Fig. 1, reaction 2).

If the chelating ligand, together with the absence of a C_2 axis, has one or more chiral but not racemic centres, the substitution gives rise to a couple of diastereoisomers which may be resolved into pure enantiomers (with respect to the metal atom).

{(S)-Prolophos}, because it is easily obtainable from the natural (S)-Prolinol in high yield,[4] has a centre of chirality and lacks a C_2 axis. {(S)-Prolophos} reacts immediately and quantitatively with $[Fe(\eta^5\text{-}C_5H_5)(CO)_2Cl]$ (Fig. 2, reaction i) expelling the chloride ion and one carbonyl to give $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]Cl$ as a pale yellow amorphous compound. The treatment of the chloro iron complex with NH_4PF_6 gives the yellow cyclopentadienyl iron complex $[Fe(\eta^5\text{-}C_5H_5)\{(S)\text{-Prolophos}\}(CO)]PF_6$, as a mixture of diastereoisomers **3** and **3′** which differ only in the chirality of the metal atom (Fig. 2, reaction ii).

The complexity of the ligand makes the ^1H NMR spectrum of the mixture rather complicated and not diagnostic for the stereochemistry of the reaction; by contrast the ^{31}P NMR spectrum is extremely useful in determining the stereoselectivity. The ^{31}P NMR spectrum of the ligand {(S)-Prolophos} shows two singlets at δ 113.7 and 46.7 ppm ($CDCl_3$, H_3PO_4 internal standard) assigned, respectively, to the phosphito and aminophosphine groups.[5] Upon coordination the two signals are shifted downfield to around δ 170 ppm for PO and δ 110 ppm for PN. The ^{31}P NMR of the diastereoisomeric mixture, **3**

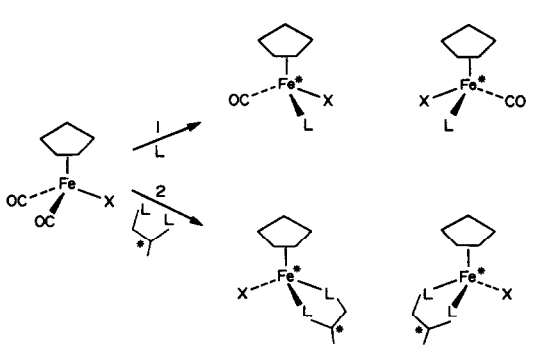

Fig. 1.

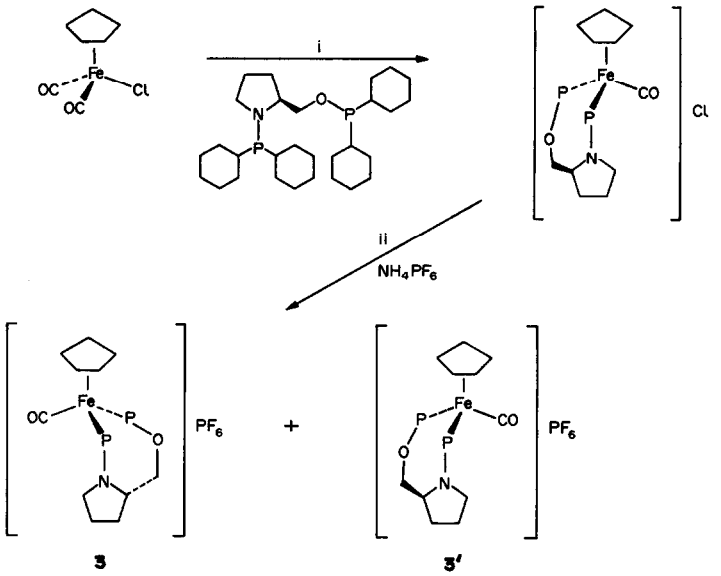

Fig. 2.

and 3', shows only two major doublets at δ 168.2 and 109.6 ppm (J_{PO-PN}, 78.2 Hz) and two doublets of lower intensity at δ 177.2 and 119.0 ppm (J_{PO-PN}, 68.4 Hz) in a 9.2:0.8 ratio, thus indicating that the reaction is chemically quantitative and proceeds with a high diastereoselectivity, close to 83% d.e. (Fig. 3).

A simple recrystallization from methanol gives the more abundant diastereoisomer optically pure; ^{31}P NMR shows the almost complete absence of the two doublets at δ 177.2 and 119.0 ppm. The chemical yield is close to 60% (based on the [Fe(η^5-C_5H_5)$(CO)_2$Cl] loaded). The assignment of the configuration of the metal, usually performed by X-ray crystallographic determination, is not possible as the optically pure diastereoisomer has always been

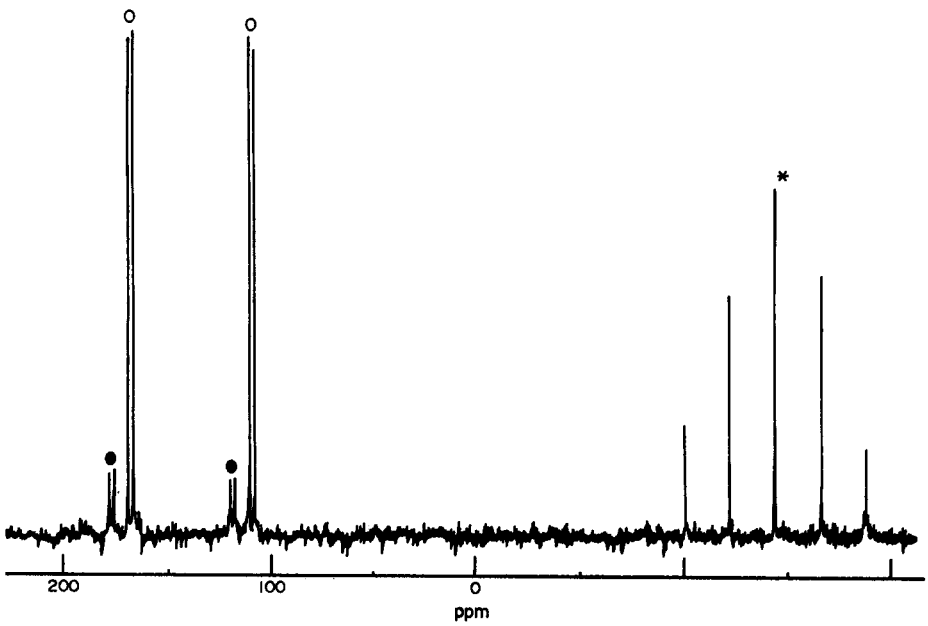

Fig. 3. ^{31}P NMR spectrum of diastereoisomeric [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6; the open circles represent the major diastereoisomer, the solid circles the minor one, the asterisk indicates the counter ion PF_6^-.

obtained as disordered microcrystals; however, we think it is possible to infer the configuration at the metal by correlation of the CD spectra to those of known compounds.

CD spectra of the pure diastereoisomer and of the racemic mixture are recorded in solution and in the solid state (KBr pellets). To normalize the data with respect to both concentration and the optical path, the spectra in Fig. 4(a) and (b) are plotted as $\Delta A/A$(415 nm) where A(415 nm) is the UV absorbance of the solution and of the KBr pellet at 415 nm; a clear analogy between the sign and relative intensities is evident for both the pure diastereoisomer and for the racemic mixture. While the chiral ligand does not show any CD active transition between 300 and 500 nm, the optically pure [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 shows two negative maxima of the same sign and intensity, respectively, at 319 and 415 nm [Fig. 4(a)]. The racemic mixture shows only one negative CD maximum at 415 nm [Fig. 4(b)].

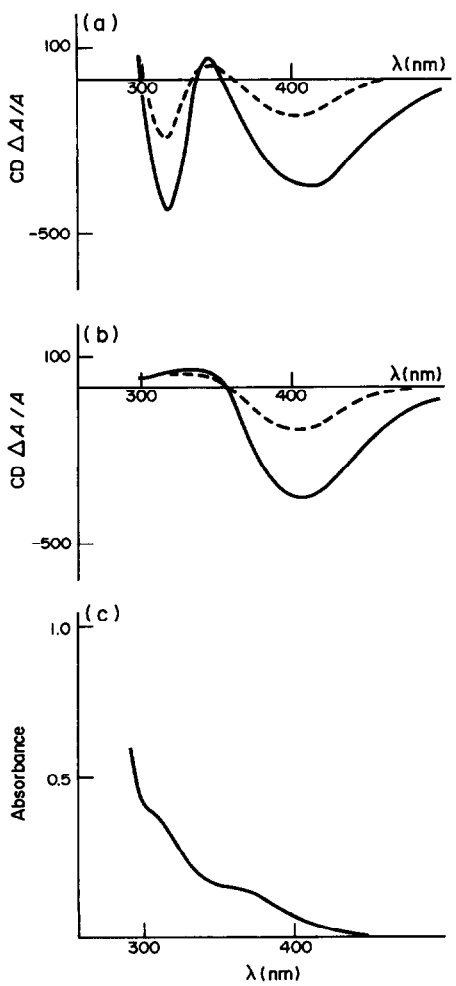

Fig. 4. (a) CD spectra of the optically pure [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 complex in solution (continuous line) and in the solid state (dashed line). (b) CD spectra of the racemic [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 complex in solution (continuous line) and in the solid state (dashed line). (c) UV spectra of the [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 complex in solution.

The complexes [Pd{(S)-Prolophos}Cl_2],[6] [Pt{(S)-Prolophos}Cl_2],[6] [Rh{(S)-Prolophos}(COD)]$^+$ BF_4^- [5] show the same negative CD absorption in the 400–450 nm region. In these complexes the only element of dissymmetry is the chiral centre on the ligand; therefore, by analogy with the negative transitions mentioned above it is possible to assign the 415 nm negative band in the pure diastereoisomer, as well as in the racemic mixture, to a transition mainly due to the chelated diphosphine, its negative band arising from the particular conformation of the metal–{(S)-Prolophos} chelated ring. The transition at 319 nm is very intense in the optically pure [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 whilst almost absent in the racemic mixture. Assignments of the bands in the spectra of pseudo-tetrahedral molecules appear to be very uncertain, but these transitions are thought to be a mixture of *d–d* and metal-to-cyclopentadienyl ligand charge-transfer types.[7] If one accepts that the transition at 319 nm is essentially a Fe–C_5H_5 charge-transfer, it seems logical that this transition should be CD active and intense in the optically pure [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6, but almost absent in the racemic mixture because it reflects the intrinsic chirality of the metal atom. This implies that such a transition can be considered diagnostic to assign the absolute configuration in cyclopentadienyl–iron complexes, as it is for cyclopentadienyl–ruthenium compounds.[8]

The X-ray crystallographic determination of the structure of the complexes [(η^5-C_5H_5)Ru{(S)-Prolophos}Cl],[8] [Rh{(S)-Prolophos}(COD)]BF_4,[5] [(η^3-C_4H_7)Pd{(S)-Prolophos}]PF_6[9] and [Pt{(S)-Prolophos}Cl_2][6] clearly shows that the conformation of the chelating ligand in the solid state is almost the same whatever the metal and the formula of the complex. This is almost certainly due to the presence of the rigid five-membered pyrrolidine ring fused with the seven-membered ring, generated by chelation.

In [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6, independent of the conformation of the chelating ligand in solution, the comparison between the spectra in solution with that in the solid state supports not only that one conformation prevails but also that the conformations are the same; we can conclude, therefore, that it is very probable, even if not proved, that the conformation of the chiral ligand

in the optically pure [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 is the same as that found in the complexes mentioned above.

As an example, Fig. 5 shows the conformation of the chelating ligand determined from the X-ray structures of known complexes with {(S)-Prolophos} and from CPK models. The upper and lower faces of the plane defined by P(O)—M—P(N) atoms are diastereotopic and present a rather general feature: the P(O)—M—P(N) plane bisects the PPh_2—P(O) arm of the ligand disposing the phenyl groups under and above the plane by approximately the same angle; contrary to this, the phenyl rings of the PPh_2—P(N) plane assume an axial and equatorial disposition with the axial phenyl group pointing away from the metal. This implies that in the [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 complex the bulky cyclopentadienyl group may be better located in the upper cavity and the CO group in the lower one. Assuming, operationally that η-$^5C_5H_5$ is a single group, it is possible to refer to [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 as a pseudo-tetrahedral complex and extend to it the Cahn–Ingold–Prelog notation, the priority sequence being: η^5-C_5H_5 > PO > PN > CO.

^{31}P NMR spectroscopy, a defined conformation of the chelating ligand based on a comparison of the CD spectra in solid and in solution with those of different compounds of known structure and the inspection of CPK models led us to conclude that the more probable configuration of the iron atom in the major diastereoisomer **3** is *S*

The configurational stability of [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 is reflected in its lack of reactivity; if the aim is to make available a chiral and stable organometallic reagent, it is necessary to overcome this inertness by transforming the cyclopentadienyl iron complex into a more reactive compound.

Irradiation of optically pure [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 (**3**) in THF leads quantitatively to the replacement of the CO ligand by a tetrahydrofuran molecule. The reaction is rather slow but is easily monitored by IR spectroscopy. The [Fe(η^5-C_5H_5){(S)-Prolophos}(THF)]PF_6 complex has been fully characterized. Elemental analyses and FAB$^+$ MS gave satisfactory results, and ^{1}H NMR clearly shows the coordination of one THF.

^{31}P NMR recorded at room temperature does not give any signal, but on decreasing the temperature to −50°C a complicated pattern of at least five broad triplets appears. Bubbling CO into a solution of [Fe(η^5-C_5H_5){(S)-Prolophos}(THF)]PF_6 immediately and quantitatively regenerates the [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 complex as a mixture of **3** and **3′**; ^{31}P NMR indicates a 62% diastereoisomeric excess, the major diastereoisomer being that obtained in the synthesis of **3** and **3′** from [Fe(η^5-C_5H_5)$(CO)_2$Cl] and {(S)-Prolophos} [two doublets at δ 168.2 and 109.6 ppm ($J_{PO—PN}$, 78.2 Hz) and two doublets at δ 177.2 and 119.0 ppm ($J_{PO—PN}$, 68.4 Hz; 8:2 ratio)].

It is undeniable that the activation process of [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]$^+$ by photocatalysed expulsion of the CO ligand proceeds with a certain loss of steric control, but it appears proven that the entire sequence

$$[CpFe(L—L)(CO)]^+ \xrightarrow{h\nu/THF}$$

$$[CpFe(L—L)(THF)]^+ \xrightarrow{+CO} [CpFe(L—L)(CO)]^+$$

proceeds with partial retention of configuration at the metal atom. Surprisingly when the racemic mixture of [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 is subjected to the same procedure, irradiation in THF followed by CO addition, the final product [Fe(η^5-C_5H_5){(S)-Prolophos}(CO)]PF_6 is regenerated with a 42% diastereoisomeric excess, also in this case the major diastereoisomer (two doublets at δ 168.2 and 109.6 ppm ($J_{PO—PN}$, 78.2 Hz; 7:3 ratio) is that obtained in the direct synthesis of the title compound.

Scheme 1 summarizes the results: the expulsion of the CO ligand gives rise to the 16-electron diastereoisomeric species **4** and **4′** (*vide infra*), which are in fast equilibrium between themselves and the THF-containing complexes **5** and **5′**. This fast exchange is evidenced by the broad signals in the low temperature ^{31}P NMR. The incoming ligand (CO in the present case) reacts rapidly with the coordinatively unsaturated species **4** and **4′** and regenerates **3** and **3′**.

The assumption that the 16-electron complexes **4** and **4′** could exist as a couple of diastereoisomers is suggested by theoretical studies of the dynamic

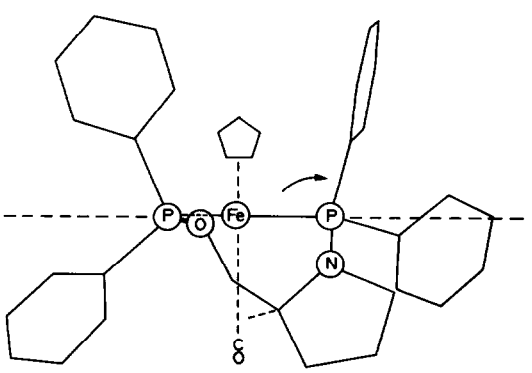

Fig. 5.

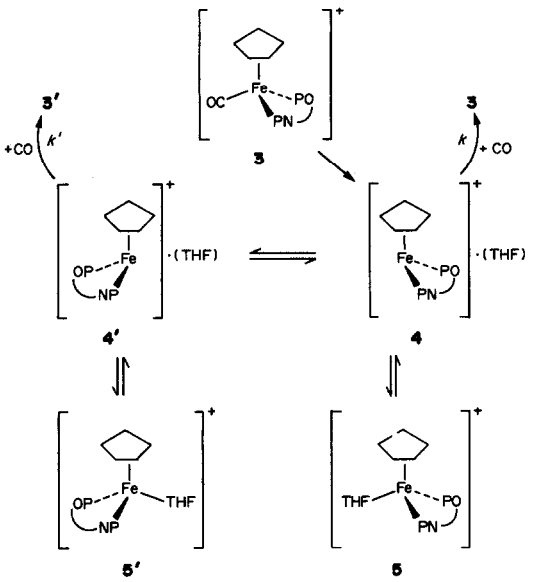

Scheme 1.

behaviour of the 16-electron intermediates $CpML_1L_2$, which concluded that such intermediates can retain a "pyramidal" geometry instead of a "planar" one and may indeed be configurationally stable depending upon the metal and the nature of the ligands L_1 and L_2.[10]

In the present work it is still a matter of speculation if the observed stereoselectivities in the exchange reaction depend on thermodynamic or kinetic effects, i.e. different equilibrium concentrations between **4** and **4'** or a different rate of reaction of **4** and **4'** with the incoming ligand.

Work is currently in progress to elucidate this latter question, as well as studying the reaction with other ligands, particularly with prochiral olefins.

(*Received* 14 *February* 1989; *accepted* 18 *September* 1989)

Abstract—The two molybdenum(IV) hydride complexes $[MoH_4(dppe)_2]$ [dppe = $(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2$] and $[MoH_4(dtpe)_2]$ [dtpe = $(o\text{-}CH_3C_6H_4)_2PCH_2CH_2P(o\text{-}CH_3C_6H_4)_2$] were applied in a process of radiation-catalytic reduction of molecular nitrogen. The yields of ammonia and hydrazine were determined for different concentrations of these complexes in cyclohexane solutions. The mechanism of the reduction of molecular nitrogen by γ-radiation is suggested. It has also been discovered that the $[MoH_4(LL)_2]$ complexes are useful in the process of radiation-catalytic fixation and reduction of nitrogen.

In a previous paper[1] we described a new route to the reduction of molecular nitrogen using the $[MoOCl(dppe)_2]Cl$ complex by γ-radiation. In this paper, intermediate and final products of reduction of N_2 were defined and the mechanism of this process was put forward. In another paper[2] the radiation yields of ammonia in the process, when the gaseous N_2 was passed through the irradiated solutions, were determined. The determined yields of the reduction of N_2[2] ($G_{(NH_4)_2SO_4} = 348$ molecules per 100 eV in a solution of $[MoOCl(dppe)_2]Cl$ of concentration 10^{-1} mol dm^{-3}) supports the conclusion that the process of fixation and reduction of N_2 appears to be a chain reaction. However, the fixation and reduction of N_2 using the $[MoOCl(dppe)_2]Cl$ complex proceeds by a multistep reaction:

(1) reduction of the molybdenum(IV) complex to molybdenum(0);
(2) modification of the coordination sphere and formation of the dinitrogen complex;
(3) reduction of the coordinated nitrogen into hydrazide, hydrazine and finally ammonia;
(4) oxidation of molybdenum(0) to molybdenum(IV) with replacement of the initial coordination sphere.

The purpose of this work is to simplify this process using the molybdenum(IV) hydride complexes $[MoH_4(dppe)_2]$ and $[MoH_4(dtpe)_2]$ instead of $[MoOCl(dppe)_2]Cl$. We used dtpe in order to obtain a complex which is more soluble in cyclohexane. It is well known that in solutions of certain transition metal complexes the following equilibrium occurs: $[MH_4L_4]+N_2 \rightleftharpoons [M(N_2)_2L_4]+2H_2$.[3,4] The complex $[MoH_4(dppe)_2]$ was obtained as a result of passing gaseous H_2 through a $[Mo(N_2)_2(dppe)_2]$ solution.[5] The $[Mo(N_2)_2(dppe)_2]$ complex was obtained in a similar way from the $[MoH_4(dppe)_2]$ solution which was irradiated with UV while simultaneously passing gaseous N_2 through the solution.[6] Therefore, it is expected that under γ-radiation either nitrogen will much more effectively displace hydrogen ions from the coordination sphere or N_2 molecules will fill the released coor-

dination places in the process of molybdenum(IV) reduction. Thus, the process of N_2 fixation and reduction can be simplified. It was assumed that application of the molybdenum(IV) hydride complex would lead to higher H_4N_2 and H_3N yields. Some hydride metal complexes were used earlier by Japanese scientists[7] for reduction of coordinated nitrogen. The complexes that they successfully applied either contained positive or negative charges on the hydrogen atoms. Thus, it can be expected that H^- ions will reduce the Mo=N—NH^+ moieties (and others) under γ-radiation. Consequently, the hydrogen atoms generated by γ-radiation from H^- ions will reduce coordinated nitrogen. Cyclohexane was used as a solvent because hydride complexes are soluble in it without decomposition and, moreover, cyclohexane gives a considerably high yield of hydrogen atoms and e_s^-, necessary for the reduction of the molybdenum(IV) atoms, and cations which are the H^+ ion donors for the Mo—N=N moiety.

EXPERIMENTAL

Dppe was synthesized by the standard method from lithium phosphide and 1,2-dichloroethane. Dtpe was synthesized by the same method from lithium phoshide using $P(o\text{-}CH_3C_6H_4)_3$[8] instead of triphenylphosphine. The complexes $[MoH_4(dppe)_2]$, $[MoH_4(dtpe)_2]$, and $[Mo(N_2)_2(dppe)_2]$ were synthesized in a one-step reaction by reducing the $MoCl_5$ solution in tetrahydrofuran with sodium in the presence of proper phosphine under a H_2 or N_2 atmosphere, respectively.[9] $[Mo(dtpe)_2]$ was obtained by heating the hydride complex under reduced pressure to 80°C until the ν_{Mo-H} vibration disappeared. Other reagents (POCH Gliwice) were purified when necessary, and all solvents were saturated with hydrogen or nitrogen, respectively, before use. The $[MoH_4(dppe)_2]$ complex was dissolved in acidified methanol (H_2SO_4 concentration, 5×10^{-2} mol dm^{-3}). Solutions made in this way were then irradiated by the γ-radiation source "Issledovatiel" (stationary ^{60}Co γ-radiation source) with simultaneous saturation with gaseous, deoxygenated N_2 (dose rate in conversion to methanol was calculated as 4.5×10^{15} eV cm^{-3} s^{-1}). The cyclohexane solutions of the molybdenum(IV) hydride complexes and $[Mo(dtpe)_2]$ were continuously saturated with a 1 : 3 mixture of nitrogen and hydrogen during the irradiation, or with nitrogen only in other experiments. The dose rate was the same as in the case of irradiation in the methanol solutions. The dose rate was calculated on the basis of a Fricke dosimeter. In order to keep the concentration of molybdenum complexes and H_2SO_4 constant the gases were passed through washers filled with methanol or cyclohexane, respectively, before introduction into the irradiated solutions. The generated H_4N_2 and H_3N were absorbed in aqueous solutions of 5×10^{-2} mol dm^{-3} H_2SO_4. Hydrazine was estimated spectrometrically using *p*-dimethylaminobenzaldehyde[10,11] and ammonia was determined by the indophenol test.[12,13]

In the solid phase radiolysis experiment samples of $[Mo(N_2)_2(dppe)_2]$ (0.2 g) and $[MoH_4(dppe)_2]$ (0.2 g) were placed in glass tubes and then the air was pumped out and replaced with hydrogen (nitrogen complex) or hydrogen mixed with nitrogen (hydride complexes). Next, the tubes were placed into the γ-radiation field. The gaseous products of reactions were estimated using a WMS-2 mass spectrometer operating at an ionization energy of 100 eV.

RESULTS AND DISCUSSION

In order to determine the importance of H^- ions in the radiation-catalytic process of reduction of N_2, the yields of H_4N_2 and H_3N were determined either in cyclohexane or methanol solutions of the molybdenum(IV) hydride complexes. The typical curve shapes of dependence of numbers of H_4N_2 molecules on dose for different molybdenum(IV) hydride complex concentrations are shown in Fig. 1.

Similar shapes were also obtained for $N_2H_6SO_4$

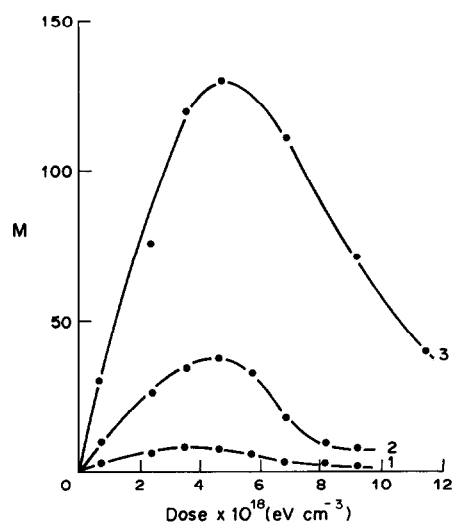

Fig. 1. Dependence of numbers of H_4N_2 molecules on dose for different molybdenum(IV) hydride complex concentrations in cyclohexane: (1) $c = 5\times10^{-4}$ mol dm^{-3} $[MoH_4(dppe)_2]$; (2) $c = 10^{-3}$ mol dm^{-3} $[MoH_4(dppe)_2]$; (3) $c = 10^{-2}$ mol dm^{-3} $[MoH_4(dtpe)_2]$. M—number of H_4N_2 molecules $\times10^{15}$ for (1) and (2) and $\times10^{16}$ for (3).

10^{-2}	37.5	4×10^{-3}	1.4

in $CH_3OH_2^+$. Radiation yields of H_4N_2 and $N_2H_6SO_4$ are presented in Table 1.

It can be seen that removing H^- ions from the coordination sphere of molybdenum(IV) leads to yields of $N_2H_6SO_4$ which are typical for the $[MoOCl(dppe)_2]Cl$ complex.[1] Application of the molybdenum(IV) hydride complex gives much higher H_4N_2 yields. Generation of hydrazine was also evidenced in the radiolysis of the solid $[MoH_4(dppe)_2]$ and $[Mo(N_2)_2(dppe)_2]$ in an atmosphere of N_2 or a mixture of N_2 and H_2. Mass spectra of hydrazine and the gaseous products from the radiolysis of solid $[MoH_4(dppe)_2]$ and $[Mo(N_2)_2(dppe)_2]$ irradiated in an atmosphere of N_2 or a mixture of N_2 and H_2 are presented in Table 2.

The mass spectra of the gaseous products from radiolysis of $[MoH_4(dppe)_2]$ are very similar to the spectrum of hydrazine. In the tubes in which $[MoH_4(dppe)_2]$ was under a N_2 atmosphere, much less hydrazine was observed than in those which were filled with a mixture of H_2 and N_2. This is due to the fact that there was much less of the released hydrogen and hydrogen atoms consequently from the hydride complex. It can also be seen (see Table 2) that coordinated nitrogen was reduced by hydrogen atoms and molecular ions H_2^+ (their yields in gaseous H_2 are, respectively, $G_H = 17.6$[14] and $G_{H_2^+} = 2.75$[15]). The shapes of the curves in Fig. 1 suggest that the process of conversion of H_4N_2 into H_3N takes place. The mechanism of hydrogenation of hydrazine was explained earlier.[1] Dependence of the numbers of H_3N molecules on dose for different molybdenum(IV) hydride complex concentrations is shown in Fig. 2.

There is an induction period in these curves which is connected with the generation of a bis-dinitrogen complex and its subsequent reduction to H_4N_2 and

finally to H_3N. In acidified solutions the induction period is longer and the yields of NH_4^+ are lower (see Table 3). Yields of H_3N and NH_4^+ ions are listed in Table 3.

From the data given in Fig. 2 and Table 3 it can be seen that from the molybdenum(IV) hydride complex solutions saturated with a mixture of N_2 and H_2 the yields of ammonia obtained are independent of the kind of ligated phosphine. Yields of NH_4^+ ions are much lower than yields of H_3N (see Table 3). Comparison of the yields of H_3N ($[MoH_4(dtpe)_2]$ complex dissolved in cyclohexane, $c = 10^{-2}$ mol dm^{-3}) at the same dose rate with the yields of NH_4^+ ions ($[MoOCl(dppe)_2]Cl$ dissolved in acidified methanol, $c = 10^{-2}$ mol dm^{-3}, $G_{NH_4^+} = 25$ ions per 100 eV[2]) shows that the former complex is about 5.2 times more effective than the latter. By considering the overall yield, $G_{H_4N_2} + G_{H_3N} = 168.5$ molecules per 100 eV (see Tables 1 and 3), it can be concluded that the molar ratio of nitrogen reduction products to the molybdenum(IV) hydride complex (the dose rate, as in ref 1, being approx. 3.17×10^{17} eV cm^{-3} s^{-1}) after 1 min of irradiation is about: $([H_3N] + [H_4N_2])/[MoH_4(dtpe)_2] \cong 6.7$. At a dose rate of 4.5×10^{15} eV cm^{-3} s^{-1} this ratio is about 7.8×10^{-2}. In order to define the way in which the dinitrogen complex is being formed (either as a result of displacement of H^- ions for N_2 or by placing N_2 into the released coordination places), the yields of H_3N were stated in cyclohexane solutions of the $[Mo(dtpe)_2]$ complex saturated with N_2 or with a mixture of N_2 and H_2. Results of this experiment are presented in Figs 3 and 4 and in Table 4.

By making a comparison between Figs 2 and 3 and Fig. 4 the same induction period can be noticed but the yields of H_3N are different. It supports the hypothesis that the dinitrogen complex is formed by a process which places N_2 into the free coordination positions (formed by the release of H^- ions). If N_2 displaced H^- ions in the coordination sphere, induction periods in this experiment should be longer. The similar induction periods (see Figs 2, 3 and 4) also suggest that $[Mo(N_2)_2(dtpe)_2]$ is converted into $[MoH_4(dtpe)_2]$ by H_2 generated by γ-radiation in C_6H_{12} or by H_2 supplied to the system. The different yields of H_3N (see Figs 2, 3 and 4) are due to the different overall concentrations of the

Table 3. Radiation yields of H_3N and NH_4^+ ions for different molybdenum(IV) hydride complex concentrations in cyclohexane solutions saturated with the mixture of N_2 and H_2 1:3 and in acidified methanol solutions of the $[MoH_4(dppe)_2]$ (concentrations of $H_2SO_4 = 5 \times 10^{-2}$ mol dm^{-3})

dinitrogen complex in the systems. H^- ions are also presumed to take part in the reduction of coordinated nitrogen (see Tables 3, 4 and Figs 2, 3, 4). Although supplying gaseous H_2 into the irradiated system makes the generation of H atoms and H_2^+ ions more effective, this effect cannot be considered as the only reason responsible for the increase of H_3N molecules in the solutions saturated with a mixture of N_2 and H_2, compared with the solutions saturated with N_2 only. Such a great difference between the yields of H_3N in $[MoH_4(dtpe)_2]$ and $[Mo(dtpe)_2]$ solutions also suggests that H^- ions react with the coordinated nitrogen. In the previous paper[1] it was shown that the yields of H_4N_2 and H_3N are independent to a high degree of the H^+ ions concentration. There are a lot fewer H^+ ions in the $[Mo(dtpe)_2]$ solutions (and fewer H^- ions) than in the solutions of $[MoH_4(dtpe)_2]$. A high yield such as $G_{H_4N_2} + G_{H_3N} = 168.5$ cannot be explained as a result of reduction of the coordinated nitrogen with H_2^+ and $C_6H_{12}^+$ ions and hydrogen atoms (their overall yield is about 30 ions and hydrogen atoms per 100 eV). It seems to be obvious, therefore, that in the system $[MoH_4(LL)_2]$–C_6H_{12} nitrogen is reduced by H_2 in a catalytic process. By considering the charge allocation on the coordinated nitrogen (especially the negative charge on N_β in $Mo—N_\alpha—N_\beta$) the protonation of N_β appears to be the first step in the reduction. Protons are transferred from H_2^+ and $C_6H_{12}^+$ cations ($G_{C_6H_{12}^+} = 5.3$[16]). Another source of protons is the hydrogen atoms which are converted to H^+ ions in the process of the molybdenum(IV) reduction. Free or bound protons are promoted to the acceptors in a very short time according to the tunnel mechanism.[17] Intramolecular proton promotion has been observed earlier.[19–21] Protons from $C_6H_{12}^+$ are promoted to

Concentration of the $[Mo(dtpe)_2]$ complex (mol dm^{-3})	Number of H_3N molecules per 100 eV in solutions saturated with N_2	Number of H_3N molecules per 100 eV in solutions saturated with the mixture of N_2 and H_2 (1 : 3)
2.5×10^{-3}	3.9	6.0
5×10^{-3}	8.6	17.5
10^{-2}	28.0	55.2

the acceptors in a process which is not controlled by diffusion (e.g. the rate constant of the reaction $C_6H_{12}^+ + H_3N \rightarrow NH_4^+ + C_6H_{11}$ is very high, $K_f = 2.4 \times 10^{11}$ dm^{-3} mol^{-1} s^{-1} [21]). The dinitrogen complex, starting from the moment when its concentration is high enough (see Tables 3 and 4), successfully competes for protons along with the molybdenum(IV) hydride complex (H^- ions are also the proton acceptors which converts them into hydrogen atoms). Dinitrogen as a ligand is easier to reach than the H^- ions (because of the symmetry and the distance from the central atom), which makes the reaction of the $[Mo(N_2)_2(dppe)_2]$ complex with protons more probable. The supply of gaseous hydrogen into the irradiated system allows the H^- ion concentration (in the molybdenum(IV) complex solution) to be kept at a level high enough to maintain their ability to react with a Mo=N—NH$^+$ moiety forming the Mo=N—MH$_2$ moiety (or others, or their conversion into hydrogen atoms). Thus, the H^- ions in this way protect the central atom from oxidation to the higher oxidation state. Support for this comes from Tables 3 and 4. Based on the data given in ref. 7, it cannot be excluded that H^- ions react directly with the Mo—N≡N moiety. Generation of $[MoH_4(dtpe)_2]$ as a result of irradiation of the cyclohexane solution of $[Mo(dtpe)_2]$ saturated with a mixture of N_2 and H_2 was evidenced when a substance with characteristic ν_{Mo-H} vibrations at *ca* 1750 and 1809 cm^{-1} was separated from this solution. From the four possible Mo—H vibrations (two B_2 and two E) associated with the $[MoH_4(LL)_2]$ complexes with D_{2d} symmetry, the two δ_{Mo-H} vibrations (*ca* 770 and 636 cm^{-1}) are obscured by phenyl vibrations. The other vibrations in the 400–3000 cm^{-1} range are identical to those from the non-irradiated molybdenum(IV) complex (with dppe). When the $[MoH_4(dtpe)]$ complex was irradiated without saturation with N_2 the ν_{Mo-H} vibrations vanished whilst the other vibrations were left unchanged. Based either on the data gathered in the tables and figures and on the discussion above or on the data from ref. 1, the following mechanism for the radiation-catalytic reduction of N_2 using the molybdenum(IV) hydride complexes can be suggested:

$$C_6H_{12} \rightsquigarrow C_6H_{12}^+, e_s^-, H, M^*, H_2 \quad (1)$$

$$H_2 \rightsquigarrow H_2^+, e^-, H, M^* \quad (1a)$$

$[MoH_4(dtpe)_2]$

$$\begin{array}{l} \xrightarrow[2e_s^-]{2H} [Mo(dtpe)_2] + 2H_2 + 2H^- \\ \xrightarrow[(2H_2^+)]{M^*} [Mo(dtpe)_2] + 2H_2 + M + 2H^- + 2H \end{array} \quad (2)$$

$$[Mo(dtpe)_2] + 2N_2 \longrightarrow [Mo(N_2)_2(dtpe)_2] \quad (3)$$

$$[Mo(N_2)_2(dtpe)_2] \xrightarrow[(C_6H_{12}^+)]{H^+} \left[\begin{array}{c} Mo(dtpe)_2 \\ \| \\ N—NH^+ \end{array}\right] + N_2 + (C_6H_{11}) \quad (4)$$

$$\left[\begin{array}{c} Mo(dtpe)_2 \\ \| \\ N—NH^+ \end{array}\right] \xrightarrow{H^-(H)} \left[\begin{array}{c} Mo(dtpe)_2 \\ \| \\ N—NH_2 \end{array}\right] \quad (5)$$

$$\left[\begin{array}{c} Mo(dtpe)_2 \\ \| \\ N—NH_2 \end{array}\right] \xrightarrow[(H)]{H^+} \left[\begin{array}{c} Mo(dtpe)_2 \\ | \\ HN—NH_2 \end{array}\right]^+ \xrightarrow{H^-} \left[\begin{array}{c} Mo(dtpe)_2 \\ | \\ H_2N—NH_2 \end{array}\right] \quad (6)$$

$$\left[\begin{array}{c} Mo(dtpe)_2 \\ | \\ H_2N—NH_2 \end{array}\right] \xrightarrow[C_6H_{12}^+]{H^+} 2H_3N + [Mo(dtpe)_2]^{2+} + C_6H_{11} \quad (7)$$

$$[Mo(dtpe)_2]^{2+} \xrightarrow[2N_2]{2H} [Mo(N_2)_2(dtpe)_2] + 2H^+ \quad (8)$$

$$[Mo(N_2)_2(dtpe)_2] + 2H_2 \longrightarrow [MoH_4(dtpe)_2] + 2N_2. \quad (9)$$

(*Received* 7 *August* 1989; *accepted* 18 *September* 1989)

Abstract—A series of new 1:1 complexes of formula $Ph_3SnCl \cdot L$ for a range of ligands L, where L_1 = 2-$HOC_6H_4CH{=}NCH_2CO_2Et$, L_2 = 2-$HOC_6H_4C(CH_3){=}NCH_2CO_2Et$, L_3 = $2HOC_6H_4CH{=}NCH(CH_3)CO_2Me$ and L_4 = 2-$HOC_{10}H_6CH{=}NCH_2CO_2Et$, have been prepared and characterized. A full X-ray crystal structure analysis of the compound chlorotriphenyl(ethyl N-salicylideneglycinate)tin(IV) ($Ph_3SnCl \cdot L_1$) has been performed. The crystals are monoclinic, space group $P2_1/n$, $a = 8.191(4)$, $b = 18.575(5)$, $c = 17.983(7)$ Å, $\beta = 101.41(4)°$, $V = 2682.1(18)$ Å^3, $Z = 4$, $D_{calc} = 1.455$ Mg m^{-3}, $\mu = 1.08$ mm^{-1}, final $R = 4.3\%$ for 1174 unique observed reflections. It was found that the ligand behaves as a unidentate and binds to the tin via the phenolic oxygen atom. The complexes have a five-coordinated trigonal bipyramidal geometry with the phenyl groups taking up the equatorial position around the tin atom.

There have been several reports recently concerning the Schiff base complexes of organotin(IV) halides and pseudo-halides, and involving the coordination of the ligands in either their deprotonated or neutral forms.[1–5] We now wish to report the synthesis and characterization of a series of new complexes of general formula $Ph_3SnCl \cdot L$ with a range of biologically-significant Schiff bases in their neutral forms, and the results of an X-ray structural investigation for one of the complexes, $Ph_3SnCl \cdot L$ (L = L_1). The various α-amino acid derivatives used as ligands are shown overleaf.

EXPERIMENTAL

Triphenyltin chloride was purchased from Alfa Inorganics and used without further purification.

Either glycine ethyl ester hydrochloride or alanine methyl ester hydrochloride, in ether, were neutralized by bubbling gaseous ammonia through the stirred solution. The ammonium chloride was filtered off and the neutral α-amino acid ester in ether was used immediately for condensation with either salicylaldehyde or 2-hydroxynaphthaldehyde. After refluxing the mixture for about 1 h, the ether was evaporated and petroleum ether (60–80°C) was added. The mixture was cooled in the refrigerator

$2\text{-}HOC_6H_4CH{=}NCH_2CO_2Et$ L_1

$2\text{-}HOC_6H_4C(CH_3){=}NCH_2CO_2Et$ L_2

$2\text{-}HOC_6H_4CH{=}NCH(CH_3)CO_2Me$ L_3

$2\text{-}HOC_{10}H_6CH{=}NCH_2CO_2Et$ L_4

and the ligands produced were filtered off and recrystallized with ether–petroleum ether (1 : 1). Melting point and analytical data for the ligands are given in Table 1.

The complexes were prepared by refluxing the calculated amount of ligand and triphenyltin chloride in petroleum ether. The complexes crystallized out when the solutions were cooled in the refrigerator overnight. They were filtered off and recrystallized from petroleum ether or ether–petroleum ether (1 : 1). Melting point and analytical data are summarized in Table 2.

Conductance measurements in nitrobenzene were made at room temperature using a Phillips PW 9501 conductivity bridge with a cell constant of 0.71. Molar conductances of the complexes are recorded in Table 2.

The IR spectra of the ligands and complexes were recorded in the region 4000–600 cm^{-1} with a Beckmann Acculab "4" instrument either as neat liquid films or Nujol mulls between NaCl plates or as KBr pellets. For the 600–200 cm^{-1} region, the Beckmann IR4250 spectrophotometer was used.

PMR spectra were obtained using a Perkin–Elmer R12B spectrometer with deuterochloroform as solvent.

Tin was estimated as SnO_2. Microanalyses were carried out by the Chemistry Department, National University of Singapore, Singapore.

Crystal data

Monoclinic, space group $P21/n$, $a = 8.191(4)$, $b = 18.575(5)$, $c = 17.983(7)$ Å, $\beta = 101.41(4)°$, $V = 2682.1(18)$ $Å^3$, $Z = 4$, $D_{calc} = 1.455$ Mg m^{-3}, $\mu = 1.08$ mm^{-1}.

Intensity data

Intensity data were collected with a Nonius diffractometer from a $0.1 \times 0.3 \times 0.3$ mm crystal to 2θ max = 44.8°, using the θ–2θ scan mode and

graphite monochromatized Mo-K_α radiation. A total of 11822 reflections were measured including 3465 which were unique, of which 1174 were considered significant, with $I_{net} > 2.5\sigma$ (I_{net}). No correction was made for absorption [I(Mo-K_α) = 0.70932 Å].

Structure solution and refinement

The structure was solved by Patterson and heavy-atom methods and refined with full-matrix least-squares. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated and were not refined. The final residuals are $R_F = 0.043$ and $R_w = 0.036$ for the significant reflections and $R_F = 0.063$ and $R_w = 0.036$ for all reflections. In the final D-map, the deepest hole showed a density of $-0.690e/Å^3$ and the highest peak, a density of $0.680e/Å^3$. Weights based on counting statistics were used throughout. All calculations were performed with the NRCVAX system of programs.[6] Literature values[7] were used for the scattering factors.*

RESULTS AND DISCUSSION

Regardless of the proportions of ligand and triphenyltin compound used, the complexes all recrystallized with 1 : 1 stoichiometry. Like the ligands, they were all yellow in colour, thermally stable with sharply defined melting points and were found to be soluble in the common organic solvents. Microanalytical and conductance data for the complexes are presented in Table 2. The observed molar conductances in nitrobenzene were in the range 1.4–2.5 Ω^{-1} cm^2 mol^{-1}, indicating that the compounds were non-electrolytes and in each instance, the chloride group is bound to the tin atom. (Molar conductances expected for 1 : 1 or 1 : 2 electrolytes in nitrobenzene are 25–35 and 44–60 Ω^{-1} cm^2 mol^{-1}, respectively.[8])

Comparison of the integrated intensities of the ligand and organotin protons confirms the 1 : 1 stoichiometry of the complexes. The sharp singlet assigned to the azomethine proton of all the ligands ($\delta \sim 8.5$ ppm) was found to be unchanged on coordination, indicating that the nitrogen atom is not coordinated to the metal. On the other hand, the peak due to the phenolic proton for each ligand molecule ($\delta \sim 13$ ppm) was significantly broadened on complex formation. As the ring formed by the intramolecular hydrogen bond of the Schiff base ligand is retained but distorted in the complexes,[9] coordination through oxygen will result in a weakening of the O—H bond, and a strengthening of the C=N---H hydrogen bond, which in turn leads to the observed broadening of the peak due to the phenolic proton. Similar observations have been reported for the dialkytin dichloride complexes of N-arylsalicylideneimines,[10] and of N,N′-bis(salicylaldehyde)ethylenediimine.[11]

The IR evidence (Table 2) also suggests that the ligands are behaving as monodentates via the phenolic oxygen atoms. This is based on the stretching vibration of the phenolic O—H which is lowered and broadened, the Sn—Cl stretching mode which is shifted downfield by some 100 cm^{-1} from its value in triphenyltin chloride,[12] as well as the shift to higher frequency (*ca* 20 cm^{-1}) of the C=N stretching vibration for the triphenyltin complexes. Similar shifts in the C=N stretching frequency for ligands of this type have been found to indicate coordination to the tin atom by oxygen.[9,13] This has been confirmed by the X-ray structural analysis of the complex of triphenyltin chloride with N-4′-methylphenyl-2-hydroxynaphthylideneimine.[5]

In the present instance, the structural implications of the experimental findings outlined above are again confirmed by the X-ray results. A full X-ray crystal structure analysis of the compound chlorotriphenyl(ethyl - N - salicylideneglycinate)tin (IV) ($Ph_3SnCl \cdot L_1$) has been performed. This complex has a trigonal bipyramidal structure, with the three phenyl groups occupying the equatorial positions around the tin atom, while the oxygen atom of the ligand and the chlorine occupy the axial positions.

The structure of the complex and the atomic numbering scheme are shown in Fig. 1. Table 3 lists selected bond distances and angles. The Cl—Sn—O angle is 173.76(13)°, similar to that (173.0(1)°) in the 1,10-phenanthroline complex of triphenyltin chloride.[14] The average Sn—C(Ph) distance of 2.136(8) Å is almost the same as that reported for the picolinic acid complex of triphenyltin chloride (2.135(5) Å)[15] and within the range of Sn—C(Ph) distances (2.105–2.16 Å) reported in the literature.[12,16] The C—C bond lengths in the phenyl groups are all normal. The Sn—Cl bond length of 2.5138(24) Å is similar to that found in the picolinic acid complex (2.515 Å)[15] and within the range (2.32–2.58 Å) of Sn—Cl distances found in other chloro complexes.[12,16] The Sn—O distance of 2.310(5) Å is comparable to that (2.280(4) Å) in the

* Atomic coordinates, thermal parameters, full lists of bond lengths and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

complex of triphenyltin isothiocyanate with N-4′-methylphenyl-2-hydroxynaphthylideneimine.[4]

In view of the similarities in PMR, IR and conductivity data, and in the light of the identical stoichiometries shown by the complexes reported here, they are all assigned trigonal bipyramidal structures analogous to that found for $Ph_3SnCl \cdot L_1$.

ABSORPTION, LUMINESCENCE, IR AND RAMAN SPECTROSCOPY OF A NOVEL POLYNUCLEAR NEODYMIUM COMPOUND: $Nd_2(OH)_3(ClO_4)_3 \cdot 5H_2O$

(*Received* 7 *August* 1989; *accepted* 19 *September* 1989)

Abstract—The novel polynuclear compound $Nd_2(OH)_3(ClO_4)_3 \cdot 5H_2O$ was characterized by different spectroscopic methods. IR and Raman spectra in the 50–4000 cm^{-1} region were measured. The stretching ν(Nd—O) and bending δ(O—Nd—O), as well as ClO_4^- vibrations, are discussed in relation to the crystal structure. Absorption spectra along the crystallographic *c*-axis of a single crystal were recorded at room and liquid helium temperatures. The effect of ion-pair interaction was stated. Oscillator strengths, values and τ_λ parameters were calculated on the basis of Judd theory and compared with those for the aquo-ion. Laser-excited luminescence spectra at low temperatures were measured, and Stark components were determined and energy diagrams for $^4I_{9/2}$ and $^4I_{11/2}$ levels were proposed.

It has been proved that perchlorate ions do not enter the first coordination sphere of lanthanide ions in water solutions even at high concentrations.[1–4] Also, solid perchlorates of formula $M(ClO_4)_3 \cdot 6H_2O$ contain metal ions octahedrally coordinated by water molecules.[5] However, we obtained recently in our laboratory single crystals of $Nd_2(OH)_3(ClO_4) \cdot 5H_2O$ from water solution.

The results of X-ray diffraction studies to be published elsewhere[6] show that neodymium ions are eight-coordinated and perchlorate ions are strongly involved in coordination, acting as bridging bidentate and tridentate units. The IR, Raman and electron spectroscopy studies were undertaken to give the full characterization of this novel compound and to explain how perchlorate coordination can influence its spectroscopic properties.

EXPERIMENTAL

Sample preparation

The preparation of the title compound is described elsewhere.[6] Crystals for all spectroscopic studies were controlled by X-ray diffraction methods.

IR and Raman spectra

IR spectra in the range 50–4000 cm^{-1} were recorded on a Perkin–Elmer 180 grating spectrophotometer. The solid samples were mulled in Nujol and placed between CsBr (middle-IR) or polyethylene plates (far-IR).

Raman spectra in the range 50–1400 cm^{-1} were measured on a Jeol IRS-S1 spectrophotometer equipped with a Coherent Radiation CRS argon ion laser (488 line). Measurements in the 1400–4000

cm^{-1} range were impossible due to the excitation of Nd^{3+} luminescence.

Electronic spectra

Absorption spectra of a single crystal of $Nd_2(OH)_3(ClO_4)_3 \cdot 5H_2O$ along the *c*-direction and of the Nd^{3+} aquo-ion were recorded on a Cary–Varian spectrophotometer over the range 11000–31250 cm^{-1} at room temperature and at 4.5 K. Stark components were determined at 4.5 K; absorption spectra taken at room temperature were used for intensity analysis of the *f–f* transitions. Oscillator strength values for the electronic transitions were calculated throughout the measured spectral range by the graphical integration method. These experimental values were used to calculate the τ_λ parameters from the Judd relation.[7] The calculation procedure is described in ref. 8. Fluorescence spectra were measured at 50 and 5 K; Nd^{3+} ions were excited by means of an argon laser ILA 120 (C. Zeiss Jena) with 488 and 514 nm lines and recorded on a grating double GDM monochromator with an EMI 9684 B type S1 cooled photomultiplier.

RESULTS AND DISCUSSION

IR and Raman data

The IR and Raman spectra of the complex are shown in Fig. 1. The wavenumbers of bands observed, their relative intensities and tentative assignments are presented in Table 1.

The IR and Raman vibrational patterns of the sample studied are very complex due to the structural complexity of this compound arising from the interactions of four molecules in the low symmetry unit cell as well as from alternative roles played by the perchlorate ligands. The crystal structure of the title compound is described by the monoclinic unit cell of the $C2/c = C_{2h}^6$ symmetry and $Z = 4$. Therefore 152 atoms in the unit cell should be taken into account in the vibrational analysis based on the factor group approximation. Such an approach leads to the 456 unit cell modes subdivided into three acoustic and 453 optic modes. In the site group approximation the number of optic modes is reduced to 57 which is very close to the summary number of bands observed in IR and Raman spectra. Therefore, the qualitative discussion of these spectra can be carried out based on the site group approach and ascent in symmetry method.

The central atom in the Nd^{3+} coordination polyhedron is surrounded by eight oxygen atoms. Four of them belong to four different perchlorate ligands and the remaining four oxygens correspond to the hydroxy- and/or aquo-ligands with their statistical distribution to compensate the ion charge. Both oxygen sets form distorted tetrahedrons around the Nd^{3+} cation and together create a strongly distorted dodecahedron. The ascent in symmetry method allows us to describe this figure by D_{2d} symmetry in which the eight ligands are divided into two non-equivalent sets of four in each set. The vibrations of the NdO_8 polyhedron are described by 21 normal modes which for D_{2d} symmetry are divided in the following form:

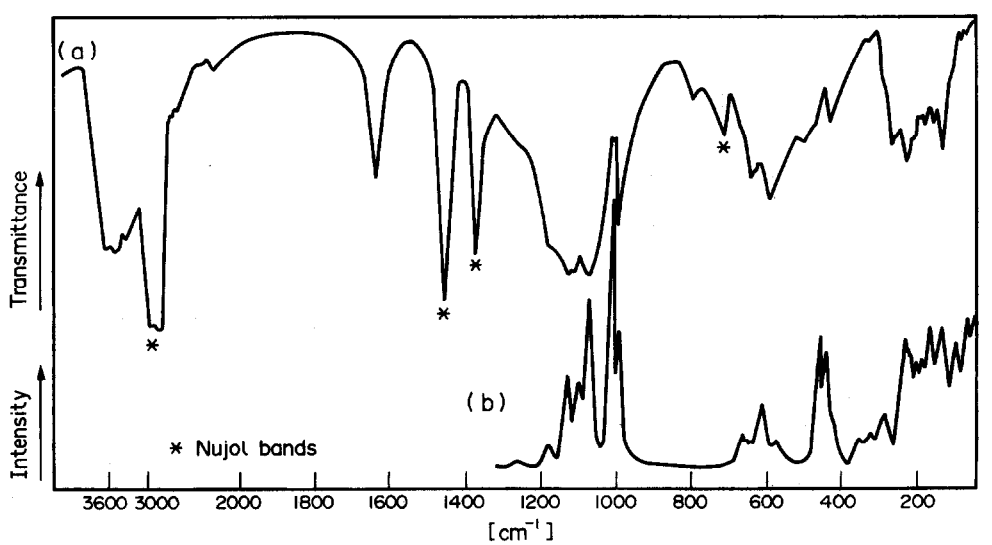

Fig. 1. Vibrational spectra of $Nd_2(OH)_3(ClO_4) \cdot 5H_2O$ in the range 50–4000 cm^{-1}: (a) IR, (b) Raman.

ν—stretching, δ—bending, ρ—rocking, τ—twisting, ω—wagging.

$$\Gamma_{D_{2d}} = 4A_1(RS)+A_2(ia)+2B_1(RS) +4B_2(RS,IR)+5E(RS,IR).$$

Among them four ν(NdO) stretching and five bending frequencies are active in the IR spectrum. The number of Raman active bands is equal to six for stretching and nine for bending frequencies. Since the Nd^{3+} ion occupies the C_1 site, all IR and Raman modes became active in both spectra. Therefore, the multiplets composed of six and nine bands are expected to exist both in IR and Raman spectra corresponding to stretching and bending modes, respectively. This is in accordance with the experimental results. The bands observed in the FIR region at 330, 290, 269, 254, 230, 216 cm^{-1} and in the Raman spectrum at 357, 327, 290, 235, 227, 221 cm^{-1} should be assigned to the stretching ν(NdO) vibrations. Respective bending δ(ONdO) vibrations were detected at 192, 181, 159, 133, 128, 114, 94, 83 cm^{-1} in the IR spectrum and at 203, 185, 170, 160, 137, 110, 104, 77 cm^{-1} in the Raman spectrum. The broad range of energies for these vibrations arises from the distinct variation of the Nd—O distances, which vary between 2.549 and 2.374 Å.[6]

The internal vibrations of the hydroxo- and aquo-ligands appear at the standard frequency regions: ν(OH), 3460; $\nu(H_2O)$, 3350, 3240; δ(HOH), 1640; δ(NdOH), 1000–1200 (partially obscured by $\nu(ClO_4)$ vibrations), $\rho(H_2O)$, 800 and $\omega(H_2O)$, 500 cm^{-1}. The energetic position of these vibrations supports the X ray-structural data[6] which shows that the positive charge excess of the Nd—ClO_4 framework is neutralized by the hydroxyl groups.

The perchlorate ions usually have no tendency to enter the inner-sphere of the Ln^{3+} cations. Praseodymium glutamate perchlorate hydrate, described recently,[9] and the complex under investigation are the only examples grown from water solutions where ClO_4^- groups were found to be directly coordinated to the lanthanide ion. In the title compound perchlorate ligands play a double role as the bridging tridentate and bridging bidentate units. The Cl—O distances are 1.501, 1.461, 1.469, 1.454 Å for Cl(1) and 1.471, 1.472 Å for Cl(2), respectively.[6] The ascent in symmetry method allows us to decribe the vibrations of the perchlorate ligands based on C_{2v} (bidentate) and C_1 (tridentate) point groups. The correlation schemes between the $T_d \rightarrow C_{3v} \rightarrow C_{2v} \rightarrow C_1$ symmetries describe these vibrations as follows:

$$\nu_1: A_1 \rightarrow A_1 \rightarrow A_1 \rightarrow A;$$

$$\nu_2: E \rightarrow E \rightarrow A_1+A_2 \rightarrow 2A;$$

$$\nu_3 \text{ and } \nu_4: F_2 \rightarrow A_1+E \rightarrow A_1+B_1+B_2 \rightarrow 3A.$$

According to refs 10 and 11 the following groups of bands are expected to be active depending on the

symmetry and frequency range:

	900–1300	600–700	400–500 cm^{-1}
C_{3v}	3 (IR,RS)	2 (IR,RS)	1 (IR,RS)
C_{2v}	4 (IR,RS)	3 (IR,RS)	1 (IR,RS)+1(RS)
C_1	4 (IR,RS)	3 (IR,RS)	2 (IR,RS)

Some accidental reduction of this number may appear since the Cl(2) atom of our sample occupies the special C_1 site position and all Cl—O distances are very close to each other. We obtained good agreement between the observed and literature data[12-16] for the last two frequency ranges. However, some discrepancies are observed in the 900–1300 cm^{-1} range where the band positions are significantly shifted in relation to those of other authors[12-16] and there are no IR or Raman lines in the 900–980 cm^{-1} region. The stretching vibration of ClO_2 in bidentate perchlorate is considerably shifted from the standard energy ($\sim$ 930 cm^{-1}). This is not surprising because for known lanthanide compounds only the chelating perchlorates were observed and not the bridging ones, as in our case. The presence of the tribonding bridging perchlorate in lanthanide compounds has not been reported, so we cannot compare our results with any others.

Absorption and luminescence results

The results of crystal studies revealed that in the title compound the perchlorate ions are involved in coordination. It is interesting how this is reflected in the intensity of the *f–f* transitions, especially the hypersensitive one, and in the splitting of levels, and how much these properties differ from those of the aquo-ion.

The absorption spectra of the $Nd_2(OH)_3(ClO_4)_3 \cdot 5H_2O$ single crystal are shown in Fig. 2. The oscillator strength values for the bands observed in its spectra and those of the aquo-ion are listed in Table 2. The band intensities of all the *f–f* transitions are similar, but the intensity of the hypersensitive transition is somewhat higher. Thus

I: $\tau_2 = (2.96 \pm 0.54) \times 10^{-9}$; $\tau_4 = (4.86 \pm 0.49) \times 10^{-9}$; $\tau_6 = (10.58 \pm 0.71) \times 10^{-9}$.
II: $\tau_2 = (2.02 \pm 0.60) \times 10^{-9}$; $\tau_4 = (4.98 \pm 0.55) \times 10^{-9}$; $\tau_6 = (10.36 \pm 0.78) \times 10^{-9}$.

when in a solution, the same form as in the solid state will be present in a small amount, the intensity of the hypersensitive transition would not change significantly.

The existence of this species can explain the results of Breen and Horrocks[3] and Tanaka and Yamashita[4] on the decay time measurements of lanthanide perchlorate solutions. These authors suggested that in solutions with a high excess of ClO_4^-, higher coordination numbers of the aquo-ions are forced to occur, leading to more effective non-radiative de-excitation. If the perchlorate bridges of the Ln—O—Cl—O—Ln type are formed, the energy would be transferred and the decay time would be shorter even when the coordination number of the lanthanide ions remains unchanged. It could be added as a comment, that our compound was obtained at the concentrations Nd ≈ 2 M and ClO_4 ≈ 6 M, and the coordination of Nd^{3+} was eight, i.e. lower than usually accepted for the aquo-ion.[17]

The formula of the compound suggests at least two different environments for the Nd^{3+} ions because of the odd number of OH^- and H_2O. The

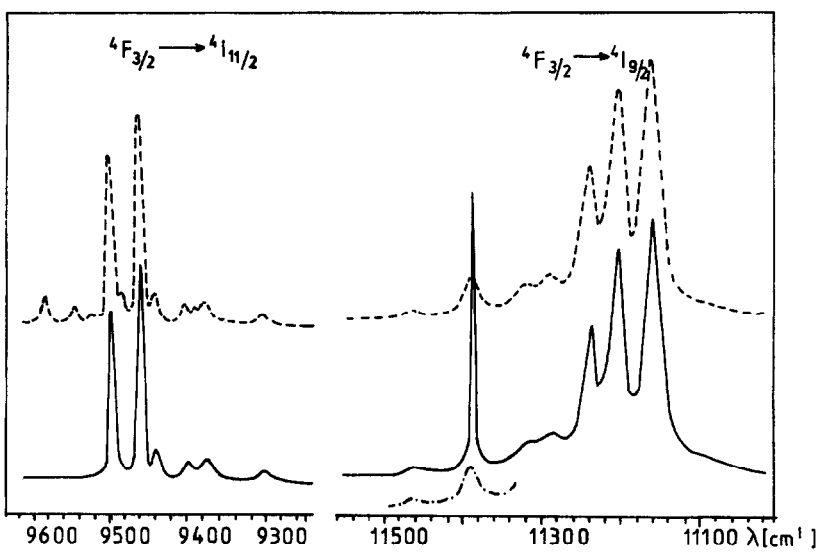

Fig. 3. Fluorescence spectra of $Nd_2(OH)_3(ClO_4)_3 \cdot 5H_2O$ at 5 and 50 K (—, $T = 5$ K, $\lambda_{exc} = 488$ nm; – – –, $T = 50$ K, $\lambda_{exc} = 488$ nm; – · – · –, $T = 5$ K, $\lambda_{exc} = 514$ nm).

crystallographic data, however, suggest the equivalence of all the Nd^{3+} ions. The absorption spectra (at helium temperature) confirm this supposition. The band corresponding to the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition is a singlet. The observed equivalence of the neodymium ions from the crystal structure and spectroscopy is due to the migration of the proton. For the $^4I_{9/2} \rightarrow {}^4G_{5/2}, {}^2G_{7/2}$ band, however, we observed more components than follows from group theory for one structural position. The neodymium atoms are bonded by O—Cl—O bridges and the distance between them is equal to 5.13 Å. This is short enough to make the ion-pair interaction possible. As a consequence we observe a doublet structure of the bands of the hypersensitive transition. Moreover, the vibronic components[18] are observed at the higher energies of this transition (Fig. 2). The detailed analysis of all components observed in the whole spectral region will be given in a following paper.

The luminescence spectra of the $^4F_{3/2} \rightarrow {}^4I_{9/2}$ and $^4F_{3/2} \rightarrow {}^4I_{11/2}$ transitions, at low temperatures, are shown in Fig. 3. At 5 K, five and six components should be expected for these two transitions respectively. However, in the region of $^4F_{3/2} \rightarrow {}^4I_{9/2}$ we observed some additional lines. Since it was found from the absorption spectra that the separation of the two sub-levels of the $^4F_{3/2}$ term is almost equal to the energy of the first Stark component of the ground state, the strong line observed at 11200 cm^{-1} can be probably related to the resonance effect. Another reason for the discrepancy between the theoretical and the observed number of components could be either the ion-pair effect or the vibronic transitions. Furthermore, the intensity of the line at 11,387 cm^{-1} is very sensitive to the energy of excitation at 5 K.

The Stark components of $^4I_{9/2} \rightarrow {}^2P_{1/2}$ and $^4I_{9/2} \rightarrow {}^4F_{3/2}$ transitions, together with the transitions in the luminescence spectrum at 5 K, were used to determine the energy level diagrams (Table 3). Splitting of the ground and first excited states is equivalent to 303 and 196 cm^{-1}, respectively.

Table 3. Energy level diagrams for the ground and first excited states of the Nd^{3+} ion

EQUILIBRIUM CONSTANTS OF METAL AMINO ACID COMPLEXES

F. REY, J. M. ANTELO, F. ARCE* and F. J. PENEDO

Departamento de Química Física, Universidad, 15706 Santiago de Compostela, Spain

(*Received* 15 *June* 1989; *accepted* 21 *September* 1989)

Abstract—The complexation equilibria of the amino acids L-serine and L-leucine with the ions Mg^{2+}, Ca^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} have been studied at 298 K and ionic strength $I = 0.1$ M in various ethanol–water media. The complexes found and their equilibrium constants are discussed in terms of the acid–base characteristics of the amino acids and the properties of the cations.

The properties of metal ions in solutions containing potential ligands, such as nitrogen-bearing compounds, depend to a large extent on the formation of complexes, calculation of whose distribution requires knowledge of their stability constants. Previous studies of complexes between amino acids and divalent cations have been rather sketchy and carried out under very different conditions,[1–8] which hinders meaningful comparison of the reported stability constants and stoichiometries. On the other hand, the stability of these kind of complexes is sensitive to the solvent composition.[9,10] This article describes an investigation of the formation of complexes between the divalent cations Mg^{2+}, Ca^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} and the amino acids L-serine and L-leucine. The solvents considered were water and two water–ethanol mixtures.

EXPERIMENTAL

All reagents were Merck p.a. products. The amino acids were purified by standard procedures and their purity checked by gas chromatography.[11] Solutions of the metal ions were prepared from their nitrates except for Zn^{2+}, for which the chloride was used, and their concentrations were determined by titration against EDTA.[2]

Potentiometric titrations were performed in a 250 cm^3 cell thermostatted at 298.0 ± 0.1 K by a HAAKE D3 thermostat. Nitrogen purified by Fieser solutions and passed through the same solvent as used in the cell was bubbled through the cell solution to provide both stirring and an inert atmosphere. The EMF was measured, as indicated by Bates,[13] using a Crison Digilab 517 pH-meter accurate to ± 0.1 mV equipped with an Ingold electrode.

Amino acid–metal solutions of ionic strength $I = 0.1$ M (controlled with KNO_3) were made up in three solvents (water and water–ethanol with 10 and 25% of ethanol by weight) and titrated against solutions of NaOH in the same solvent at the same ionic strength up to an EMF corresponding to pH = 9. All titrations were performed at least twice, and the replicate values of EMF always agreed to within 0.1 mV. The initial concentrations of the various substances used are listed in Table 1 (solutions with different metal–ligand ratios were studied, the concentrations of metal ions and amino acids always being the same for the eight cations).

Protonation and stability constants were calculated by using the program MINIQUAD 75.[14]

RESULTS AND DISCUSSION

Table 2 lists the values obtained for the protonation constants of L-serine and L-leucine, and the stability constants of their complexes with the metal ions studied. The protonation constants of LH stoichiometries correspond to the proton's binding to the amino group of the most basic form of the ligand. L-Serine is less basic than L-leucine, i.e. its protonation constants are smaller, because

of the electron-withdrawing effect of the neighbouring OH group.

The stoichiometries and stability constants of the complexes formed were determined by trying various possible composition models for the system ($ML+ML_2$, $ML+ML_2+MLH_{-1}$, $ML+ML_2+ML_3$) and using the program MINIQUAD 75 to identify that which, according to χ^2, r factor and sum of squares parameters, best fitted the experimental data. The absence of polynuclear species was shown by an individual analysis of each of the experimental curves obtained for the various concentrations of metal ion and amino acid, since the same stoichiometric indices and stability constants were obtained in all cases. It may be concluded that the only complexes present were those listed in Table 2.

All of the systems studied, except for those involving Mg^{2+}, Ca^{2+} and Pb^{2+}, were found to contain only complexes of the forms ML and ML_2, which agrees with other published findings. The detection of just a single amino acid–magnesium complex may be attributed to the instability of high-order complexes in the working conditions of this study. Moreover, in systems involving Ca^{2+} and Pb^{2+}, MLH_{-1} complexes were formed by the loss of a proton from the ML complexes.

The fact that the L-leucine complexes had greater stability constants than the corresponding complexes between the same metal ion and L-serine may be attributed to L-leucine being the more basic of the two amino acids. That the Ca^{2+} complexes are more stable than Mg^{2+} ones is explicable in terms of the smaller hydration energy of the Ca^{2+} ion,[14] since the formation of ion–ligand bonds requires that ion–solvent bonds are broken first.

The order of stability found for the complexes of the other divalent ions studied ($Cd^{2+} < Co^{2+} < Zn^{2+} < Pb^{2+} < Ni^{2+} < Cu^{2+}$) coincides with that observed for almost all amino acid ligands. Figure 1 shows that $\log\beta_1$ and $\log\beta_2$ increase from Co^{2+} to Ni^{2+} as predicted by ligand field theory, and then drop to Zn^{2+} and Cd^{2+}. The classic sharp maximum for Cu^{2+} is due to the stabilizing contribution of the Jahn–Teller effect, and the ratio $\log\beta_1$ (Ni^{2+})/$\log\beta_1$ (Cu^{2+}) agrees with the value observed in complexes with a wide range of other amino acids.[6] Figure 1 also shows that the variation of $\log\beta_2$ is greater than that of $\log\beta_1$, i.e. the binding of the second ligand is more sensitive to the nature of the metal ion.

The results listed in Table 2 show that the presence of ethanol in the solvent brings about an increase in the stability of the complexes. This confirms that the formation of a metal ion complex in solution is dependent on the competition of ethanol and water for coordination sites around cations.[15,16]

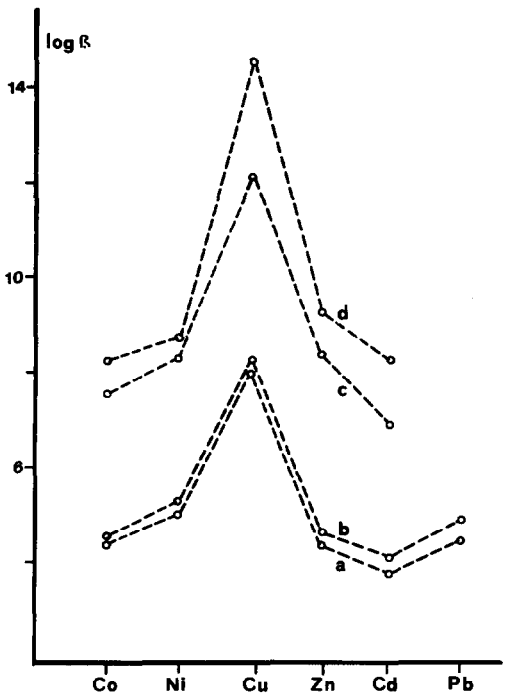

Fig. 1. Variation of stability constants of some divalent metal complexes: (a) $\log\beta_1$ L-serine; (b) $\log\beta_1$ L-leucine; (c) $\log\beta_2$ L-serine; (d) $\log\beta_2$ L-leucine.

Abstract—The reduction of several high oxidation state tungsten halide complexes by lithium organophosphides and primary phosphines is described. Reaction of Cp^*WCl_4 ($Cp^* = \eta 5\text{-}C_5Me_5$) with $t\text{-}Bu_2PLi$ (4 equiv.) results in reduction of the metal and coupling of $t\text{-}Bu_2P$ units to form a mixture of $[Cp^*WCl_2]_2$ and $t\text{-}Bu_2PPt\text{-}Bu_2$ which co-crystallize as $[(Cp^*WCl_2)_2 \cdot (t\text{-}Bu_2PPt\text{-}Bu_2)_2]$ (**1**). There are no close intermolecular contacts between the tungsten(III) chloride-bridged dimer $(Cp^*WCl_2)_2$ and $(t\text{-}Bu_2PPt\text{-}Bu_2)$ in the solid state. In the crystal structure of **1** the diphosphine exists in the *gauche* conformation found in other structurally characterized diphosphines. The $(Cp^*WCl_2)_2$ dimer has all four chloride ligands in bridging positions. Reaction of $[Cp^*WCl_4]_2$ with 2 equiv. of Ph(H)PLi forms the monomeric phosphine adduct $(Cp^*WCl_4)(H_2PPh)]$ (**2**) in 50% yield. The reaction of WCl_6 with excess $t\text{-}BuPH_2$ in dichloromethane gives *trans*-$WCl_4(H_2Pt\text{-}Bu)_2$ (**3**). Reaction of $[(PhN)Cl_3W(PMe_3)_2]$ with $t\text{-}Bu_2PLi$ (2 equiv.) under nitrogen leads to reduction and formation of the $\mu\text{-}N_2$ bridged W(IV) dimer $[\{(PhN)WCl_2(PMe_3)_2\}_2(\mu\text{-}N_2)]$ (**4**) in which the W—N—N—W core is virtually linear. Crystal data for **1**: $C_{52}H_{102}P_4Cl_4W_2$, $M = 1360.8$, monoclinic, $P2_1/n$ (No. 14), $a = 8.309(9)$, $b = 24.50(1)$, $c = 15.117(8)$ Å, $\beta = 95.98(1)°$, $U = 3060.5$ Å^3, $Z = 2$, $R = 0.0385$, $R_w = 0.0474$. Crystal data for **2**: $C_{16}H_{21}PCl_4W$, $M = 569.98$, monoclinic, $P2_1/c$ (No. 14), $a = 8.776(9)$, $b = 16.310(6)$, $c = 16.580(1)$ Å, $\beta = 101.21(6)°$, $U = 2327.8$ Å^3, $Z = 4$, $R = 0.046$, $R_w = 0.069$. Crystal data for **3**: $C_8H_{20}P_2Cl_4W$, M = 503.85, monoclinic, $C2$ (No. 5), $a = 11.136(5)$, $b = 8.218(7)$, $c = 9.832(8)$ Å, $\beta = 93.20(6)°$, $U = 898.29$ Å^3, $Z = 1$, $R = 0.0330$, $R_w = 0.0369$. Crystal data for **4**: $C_{24}H_{46}P_4Cl_4N_4W_2$, $M = 1024.07$, monoclinic, $P2_1/c$ (No. 14), $a = 15.702(2)$, $b = 12.580(2)$, $c = 19.416(4)$ Å, $\beta = 94.41(1)°$, $U = 3823.9$ Å^3, $Z = 4$, $R = 0.043$, $R_w = 0.051$.

The reduction of high valent tungsten halide compounds has been the focus of much research.[1–5] This interest stems in part from the prospect of activating dinitrogen and finding a catalytic cycle by which nitrogen may be functionalized and then released to yield industrially important chemicals.[6] Low valent tungsten and molybdenum complexes have been shown to be effective binding agents for the ligation of molecular nitrogen and, in some cases, the stoichiometric conversion of N_2 to hydrazine or ammonia.[7–10] Traditional reducing reagents such as Na, Mg, Zn are most commonly employed to effect stoichiometric reductions of transition metal centres, however, a number of alternative routes, such as pyridine and tertiary phosphines, have been used in tungsten and molybdenum chemistry.[3–11] In this paper we describe the reactions of a number of high valent tungsten (W^V, W^{VI}) chloride complexes with primary phosphines and lithium di-

† Author to whom correspondence should be addressed.

organophosphides as reducing agents to give lower oxidation state (W^{III} and W^{IV}) products.

As part of our studies of sterically demanding phosphido (R_2P^-) and arsenido (R_2As^-) complexes of the transition metals[1,2] we recently turned our attention to the group 6 metal tungsten for which relatively few phosphido complexes are known. One general route to phosphido complexes which works well for both early and late transition metals is salt elimination reactions involving alkali metal phosphides, e.g.

$$LiPR_2 + L_yMX \rightarrow L_yMPR_2 + LiX$$

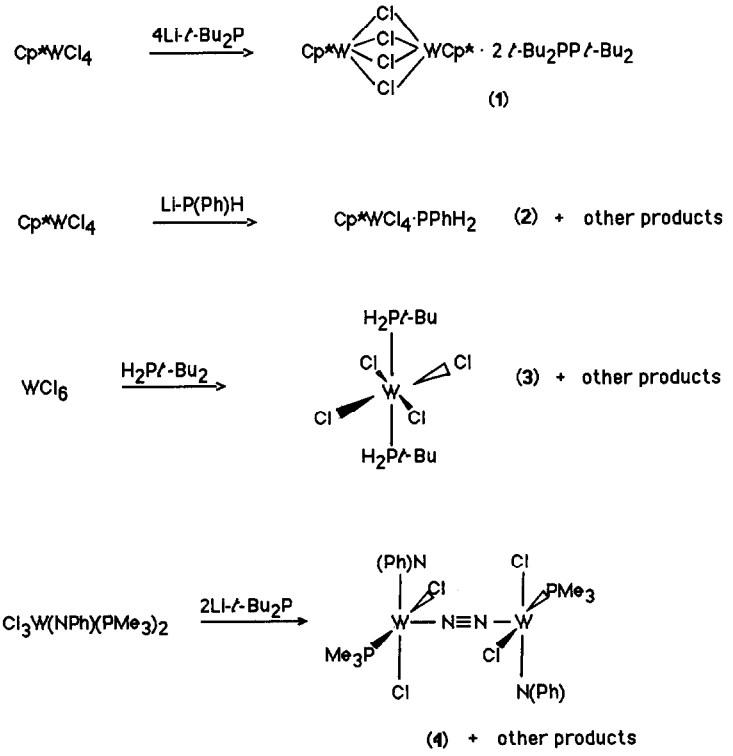
L_y = other ligands, M = transition metal, X = halide.

We therefore investigated the reactions of several high oxidation state tungsten complexes with lithium phosphides with the aim of synthesizing some new phosphido complexes. Reduction of the tungsten occurred with the $LiPR_2$ reagents acting as reducing agents. We were, however, able to isolate and characterize a number of interesting new complexes from these reactions. Thus reaction of Cp^*WCl_4 with t-Bu_2PLi produces a mixture of $[Cp^*WCl_2]_2$ and [t-Bu_2PPt-Bu_2] (1 : 2) (**1**) in which the tungsten(III) dimer $[Cp^*W(\mu\text{-}Cl)_2]_2$ and [t-Bu_2PPt-Bu_2] co-crystallize. There are no close intermolecular contacts between the two molecules in the solid state and the structural characterization of both moieties is of interest. In contrast, a similar reaction of Cp^*WCl_4 with Ph(H)PLi simply produced the phosphine adduct $[(Cp^*WCl_4)(H_2PPh)]$ (**2**) in low yield. This may be a result of disproportionation of Ph(H)PLi into Li_2PPh and H_2PPh. The reaction of t-$BuPH_2$ with WCl_6 in dichloromethane results in the formation of *trans*-$WCl_4(H_2Pt\text{-}Bu)_2$ (**3**). The reduction of tungsten(VI) in this case is effected by the primary phosphine t-$BuPH_2$. Finally the phenylimido tungsten(V) complex $[(PhN)WCl_3(PMe_3)_2]$ reacts with t-Bu_2PLi under a nitrogen atmosphere to give the linear dinitrogen bridged complex $[\{(PhN)WCl_2(PMe_3)_2\}_2(\mu\text{-}N_2)]$ (**4**). The new compounds **1**–**4** have been characterized spectroscopically and their solid-state structures have been determined by X-ray crystallography. The reactions and new compounds are shown in Scheme 1.

RESULTS AND DISCUSSION

Reaction of $[Cp^*WCl_4]_2$ *with* LiPt-Bu_2: $[(Cp^*WCl_2)_2 \cdot (t\text{-}Bu_2PPt\text{-}Bu_2)_2]$ (**1**)

The compound $[Cp^*WCl_4]_2$ was first reported by Schrock and co-workers and has been used for the synthesis of alkyl and hydrido derivatives which are



Scheme 1.

relevant to catalytic CO reduction.[14,15] We initially hoped to synthesize sterically hindered phosphido derivatives of tungsten *via* reactions of $[Cp^*WCl_4]_2$ and other compounds with alkali metal phosphido species. However, these appear to be too powerful reducing reagents and give only reduced tungsten complexes.

Thus reaction of $[Cp^*WCl_4]_2$ with four equivalents of LiP*t*-Bu_2 in THF produces the tungsten(III) product $[Cp^*WCl_2]_2$ as a green microcrystalline solid. If the supernatant liquid remaining from the initial crystallization is concentrated further and cooled (−20°C), brown X-ray quality crystals of formula $[(Cp^*WCl_2)_2 \cdot (t\text{-}Bu_2PPt\text{-}Bu_2)_2]$ (**1**) may be isolated. A single crystal X-ray analysis showed this to be a mixture of co-crystallized $[Cp^*WCl_2]_2$ and $[t\text{-}Bu_2PPt\text{-}Bu_2]$. The origin of the coupled *t*-Bu_2P units is presumably from the reduction of $[Cp^*WCl_4]_2$ to $[Cp^*WCl_2]_2$ and LiCl [eq. (1)]. Of relevance here is the reduction of $MoCl_3$ by LiP*t*-Bu_2 to yield the homoleptic phosphido complex $[Mo(\mu\text{-}t\text{-}Bu_2P)(t\text{-}Bu_2P)]_2$. This reaction also produces $[t\text{-}Bu_2PPt\text{-}Bu_2]$.[16]

$$[Cp^*WCl_4]_2 + 4LiPt\text{-}Bu_2 \rightarrow [Cp^*WCl_2]_2 + 4LiCl + 2[t\text{-}Bu_2PPt\text{-}Bu_2] \quad (1)$$

The ^1H NMR spectrum for **1** shows resonances for both moieties. The protons of the Cp* ligand appear as a singlet (δ 2.4 ppm) and the *t*-Bu protons of the diphosphine appear as a 1 : 2 : 1 triplet (δ 1.35 ppm, $J_{P\text{—}H(apparent)} = 19$ Hz). The ^{31}P NMR shows a singlet at 39.94 ppm which is close to the literature value for free $[t\text{-}Bu_2PPt\text{-}Bu_2]$ ($\delta = 37.40$ ppm).[17]

X-ray structure of **1**

An ORTEP view of the tungsten moiety is shown in Fig. 1 and a ball and stick representation of the diphosphine, down the P—P axis, in Fig. 2. A view of the crystal packing arrangement in the unit cell is shown in Fig. 3. Data collection and crystal structure parameters are given in Table 1 and key bond lengths and angles are in Table 2. There are no close intermolecular contacts between the diphosphine and the tungsten dimer in the solid state. Compound **1** crystallizes in the monoclinic space group $P2_1/n$ with two molecules of $[Cp^*WCl_2]_2$ and four molecules of $[t\text{-}Bu_2PPt\text{-}Bu_2]$ in the unit cell. The

tungsten moiety exists as a dimer in the solid state with all four chlorine atoms occupying bridging positions across a W—W single bond (2.626(1) Å), each tungsten atom thus achieves an 18-electron count. Dimeric structures containing one bridging chloride per metal atom have been proposed for $[Cp^*WCl_4]_2$[13] and $[CpMoCl_4]_2$.[18a] The five-coordinate tungsten atoms have a square-pyramidal coordination geometry if the ring centroids of the Cp* ligands are taken as the apexes of the respective pyramids. There is a crystallographically imposed centre of inversion in the molecule and the C_5Me_5 rings adopt a staggered configuration. The molecule is essentially isostructural with $[Mo(\eta^5\text{-}C_5H_4i\text{-}Pr)(\mu\text{-}Cl)_2]_2$[18b] and the group 5 tantalum species $[Ta(\eta^5\text{-}C_5Me_5)(\mu\text{-}Br)_2]_2$.[18c]

The *t*-Bu_2P units of the diphosphine molecule adopt the semi-eclipsed form also found in $[Cy_2PPCy_2]$.[19] This structural type has also been observed in other P_2X_2 species (X = H, halide) and is thought to be a manifestation of the *gauche* effect.[20] The torsion angle about the eclipsed *t*-Bu_2P units is slightly greater than that found in $[Cy_2PPCy_2]$ (for $[t\text{-}Bu_2PPt\text{-}Bu_2]$; 13.5°, for $[Cy_2PPCy_2]$; 5.5°).[19] The C(25)—P(2)—P(1) angle [121.6(4)°] is also wider than the corresponding bond angle in $[Cy_2PPCy_2]$ [108.0(3) and 107.4(3)°]. Both differences may be ascribed to the greater steric demands of *t*-butyl groups relative to cyclohexyl groups. The P—P distance of 2.233(3) Å is within normal bonding distances for P—P bonded molecules.[21] While the average of the P—C bond lengths $[(P—C)_{av}]$ in $[t\text{-}Bu_2PPt\text{-}Bu_2]$ is slightly longer than that found for the cyclohexyl derivative or the tetramer $[t\text{-}BuP]_4$, there are no unusual distortions and this slight lengthening may again be attributed to the greater steric influences of the *t*-butyl groups (for $[t\text{-}Bu_2PPt\text{-}Bu_2]$; P—$C_{av}$ = 1.92 Å, for $[Cy_2PPCy_2]$; P—C_{av} = 1.88 Å, for $[Pt\text{-}Bu]_4$; P—C_{av} = 1.89 Å).[22]

Reaction of LiPPh(H) *with* $[Cp^*WCl_4]_2$; *synthesis of* $[(Cp^*WCl_4)(H_2PPh)]$ (**2**)

The reaction between LiPPh(H) and $[Cp^*WCl_4]_2$ led to the formation of the 17-electron species $[(Cp^*WCl_4)(H_2PPh)]$ (**2**). Dark brown hydrocarbon soluble crystals of **2** are stable for short periods in air. Paramagnetic behaviour is observed in the solution state ($\mu_{eff} = 0.6$ BM, Evans' method, 23°C, toluene). The source of H_2PPh is presumably from abstraction of a proton from the solvent (THF) or from a disproportionation of LiPHPh. The analogous trimethylphosphine adduct $[Cp^*WCl_4(PMe_3)]$ has been described but no crystal structure has been reported.[14] The paramagnetic product shows only broad resonances in the ^1H and ^{31}P NMR spectra.

X-ray structure of **2**

Crystals of **2** may be crystallized from toluene (−20°C) and an ORTEP view of the molecule is

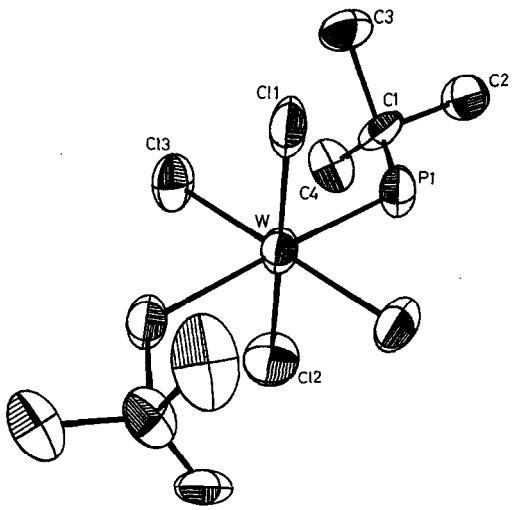

Fig. 5. ORTEP view of **3** showing atom numbering scheme.

shown as Fig. 4. Key bond lengths and angles are given in Table 3. Compound **2** crystallizes in the monoclinic space group $P2_1/c$ with four molecules in the unit cell. The molecule exists as a monomer in the solid state. The molecular geometry may be described as distorted octahedral with the chlorine atoms lying in the equatorial plane. The W—P separation of 2.568(5) Å is clearly indicative of a dative interaction. The hydrogen atoms of the H_2PPh ligand were not located in the X-ray structure, however a ν(P—H) stretch at 2300 cm^{-1} in the IR spectrum confirms their presence. There is a slight but interesting distortion in the W—Cl bond lengths. The chlorine atoms lying underneath the phenyl substituent of the coordinated phosphine have slightly shorter W—Cl bonds [W—Cl(2) = 2.376(7) Å, W—Cl(3) = 2.369(6) Å] than the remaining chloride ligands [W—Cl(1) = 2.412(7), W—Cl(4) = 2.399(6) Å]. This may be a reflection of steric compression exerted on the chloride ligands by the bulky Cp* ligand and the phenyl substituent of the phosphorus ligand. Presumably the steric congestion about the tungsten atom in **2** makes it impossible for two monomers to couple and achieve an electron count of 18 *via* a dimeric structure.

Reaction of WCl_6 *with* t-$BuPH_2$: *synthesis of* trans-$WCl_4(H_2Pt\text{-}Bu)_2$ **(3)**

The reduction of tungsten hexachloride to form WCl_4L_2 derivatives is well known.[10,23,24] This class of molecule has seen broad use as a starting material in the preparation of many tungsten compounds.[4,5,7,11,25–28] To our knowledge no analogous complexes featuring primary phosphines have so far been reported.

Excess t-$BuPH_2$ reacts with WCl_6 in dichloromethane to give a red solution from which the crystalline compound *trans*-$WCl_4(H_2Pt\text{-}Bu)_2$ **(3)** may be obtained in high yield. The compound is paramagnetic in solution (μ_{eff} = 3.11 BM, Evans' method, 23°C, toluene), as is found for other WX_4L_2 complexes,[29] and shows two ν(P—H) stretches in the Raman spectrum 2352, 2369 cm^{-1}). The IR spectrum contains no corresponding absorp-

tions consistent with the *trans* configuration and a centre of symmetry.

X-ray structure of **3**

An ORTEP of **3** is shown in Fig. 5. Crystal structure parameters and key bond lengths and angles are given in Tables 1 and 4, respectively. The compound crystallizes in the monoclinic space group $C2$ (No. 5) with a single molecule in the unit cell. The molecular geometry is pseudo-octahedral and the molecule has a crystallographically imposed two-fold axis of symmetry passing through the Cl(1)—W—Cl(2) vector. The four chlorine atoms are essentially planar and lie in equatorial positions. The two phosphine ligands are *trans* [W—P(1) = 2.540(2) Å]. The steric influence of the *t*-butyl substituents on the phosphorus ligand is reflected in the Cl(3)—W—P(1) angle of 96.58(6)° and the Cl(3)′—W—P(1) angle of 83.44(6)°, the other chloride ligands lie essentially orthogonal to the P—W—P vector.

The structure of **3** may be compared to other structurally characterized tungsten(IV) species. A recent structural analysis of $WCl_4(PPh_3)_2$ also shows *trans*-phosphines coordinated at the apexes of an octahedral tungsten centre.[30] The average of the W—Cl distances (2.33 Å) is the same for both molecules. The W—P bond in **3** [2.540(2) Å] is slightly shorter than that for the triphenylphosphine analogue [W—P = 2.629(6) Å] due to the greater steric influence of the triphenylphosphine ligand. On going to the tris-substituted complex $WCl_4(PMe_3)_3$ the W—Cl bond distances increase by an averge of 0.1 Å, however, the W—P distance (2.55 Å) is still close to that found for **3**.[24]

Reduction of $(PhN)WCl_4(PMe_3)_2$ *with* $LiPt\text{-}Bu_2$: *synthesis of* $[\{(PhN)WCl_2(PMe_3)_2\}_2(\mu\text{-}N_2)]$ (**4**)

The imido ligand $[RN]^{2-}$ has recently seen a renewal of interest due to its ability to bind in a linear or bent fashion as a four- or two-electron donor, respectively.[9] Imido ligands may also bridge two metal centres as four-electron donor ligands. This electronic versatility is often used to create a flexible coordination environment around a metal centre so that certain aspects of its reactivity may be explored. Recent work by Nielson and co-workers has focussed on the synthesis and characterization of a number of high oxidation state organoimidotungsten complexes,[31–34] however, the reaction chemistry of these organoimidotungsten complexes with main group substrates has not received much attention.

From the reaction of $[(PhN)WCl_4(PMe_3)_2]$ and $t\text{-}Bu_2PLi$ we were able to isolate and structurally characterize the $\mu\text{-}N_2$ complex $[\{(PhN)WCl_2(PMe_3)_2\}_2(\mu\text{-}N_2)]$ (**4**). While the fate of the $t\text{-}Bu_2P$ units in this reaction is not known it is likely that coupling occurs to yield the diphosphine species as happens in the reaction of $[Cp^*WCl_4]_2$ with $LiPt\text{-}Bu_2$ (see above). Earlier work using Na/Hg as a reductant in the presence of PMe_3 resulted in the isolation of the monomeric octahedral complex $[W(NPh)Cl_2(PMe_3)_3]$.[33]

X-ray structure of **4**

An ORTEP view of **4** may be seen in Fig. 6. Crystal structure parameters and key bond lengths and angles are given in Tables 1 and 5, respectively. The compound crystallizes in the monoclinic space group $P2_1/c$ (No. 14) with four molecules in the unit cell. The molecular geometry of the tungsten atoms is distorted octahedral with the phosphine ligands at the apexes of the octahedron. The two $[(PMe_3)_2(NPh)WCl_2]$ units are twisted essentially 90° with respect to each other so that steric interactions between pairs of trimethylphosphine ligands is minimized. The dinitrogen ligand is end-on bonded to both tungsten centres with W—N—N angles almost linear [W(1)—N(3)—N(4) = 178(2)°, W(2)—N(4)—N(3) = 173(2)°] as commonly found for bridging N_2 species.[35] W—N and N—N bond lengths [W(1)—N(3) = 1.9(2), W(2)—N(4) = 1.90(2) and N(3)—N(4) = 1.19 Å] favour dative coordination of the N_2 ligand over the recently characterized bis-imido bonding mode $[\mu\text{-}N_2]^{4-}$.[36] The phenyl imido groups are bonded in an almost linear fashion [W—N—C = 167(1)°,

Numbers in parentheses are the ESDs in the least significant digits.

W—N = 1.74(2) Å] suggesting some participation of the nitrogen lone pair in multiple bonding.[37] If the phenyl imido ligands are counted as four-electron donors each tungsten atom attains an electron count of 18. The average W—Cl and average W—P bond lengths ($W—Cl_{av}$ = 2.47 Å, $W—P_{av}$ = 2.51 Å) may be compared with those found in $[W(NPh)Cl_2(PMe_3)_3]$ ($W—Cl_{av}$ = 2.52 Å, $W—P_{av}$ = 2.48 Å).[33]

EXPERIMENTAL

All compounds were prepared under dry nitrogen using standard vacuum-line techniques. Toluene was distilled from sodium metal under nitrogen before use. Hexane and THF were distilled from sodium benzophenone ketyl under nitrogen. $[Cp^*WCl_4]_2$[14] and $[(PhN)WCl_3(PMe_3)_2]$[30] were prepared by the literature methods. Instruments: IR: Perkin–Elmer 1330; NMR (^1H and ^{31}P): GE 300 IR spectra were recorded as KBr disks. NMR spectra were recorded in C_6D_6 at ambient temperature and are referenced to Me_4Si (δ 0.0, ^1H) and 85% H_3PO_4(aq.) (δ 0.0, ^{31}P).

Synthesis of **1**

A suspension of $[Cp^*WCl_4]_2$ (0.34 g, 0.37 mmol) in THF (40 cm^3) was cooled to −78°C. The rapid injection of four equivalents of $LiPt\text{-}Bu_2$ (6.53 cm^3 of a 0.226 M solution) led to a colour change from orange to green to red. The reaction mixture was allowed to warm to room temperature then stirred for an additional 4 h. Removal of solvent *in vacuo* left a green–burgundy residue which was extracted into toluene (2 × 30 cm^3), concentrated (20 cm^3) and cooled (−20°C) to yield X-ray quality crystals of **1**, yield = 0.059 g, 35%. M.p. 237–245°C (dec). IR: 2960 s, 2930 s, 2858 s, 1463 s, 1378 s, 1363 s, 1260 m, 1165 m, 1448 w, 1028 m, 804 m (cm^{-1}). ^1H NMR: δ 2.4 (s, *Me*), δ 1.35 (dd, *t-Bu*). ^{31}P NMR: δ 39.94 (s).

Synthesis of **2**

A suspension of $[Cp^*WCl_4]_2$ (0.43 g, 0.47 mmol) in THF (30 cm^3) was cooled to −78°C, 5.4 cm^3 of 0.19 M LiHPPh/THF was then added dropwise via syringe. The solution turned light green over a period of 5 min then changed to an opaque suspension. The reaction mixture was allowed to stir overnight at room temperature then dried *in vacuo* and extracted with toluene (2×35 cm^3). Cooling of the extract to −20°C gave dark crystals of **3** in low yield. IR (Nujol mull): 1460 s, 1370 s, 1108 w, 1077 w, 1023 w, 922 w, 888 s, 738 s, 730 s, 688 m (cm^{-1}).

Synthesis of **3**

An excess of mono-*t*-butylphosphine (3 cm^3 H_2Pt-Bu) was added to solution of WCl_6 (3 g, 7.58 mmol) in dichloromethane (40 cm^3) at −78°C. The reaction mixture was allowed to warm to room temperature and stirred (12 h). The resulting purple solution was extracted with CH_2Cl_2 (3×20 cm^3). The extract was then concentrated and cooled (−20°C) for 24 h to yield bright red crystals of **1**, yield 2.5 g, 65%. M.p. 120–126°C (dec). IR: 2880 s br, 1640 s, 1568 s, 1459 m, 1440 m, 1374 w, 1354 w, 1310 s, 1254 m, 1195 m, 1153 w, 1088 m, 1050 w, 1067 w, 976 m, 721 w, 690 w, 625 w, 590 w, 523 m, 485 w (cm^{-1}).

Synthesis of **4**

A solution of $Cl_3W(NPh)(PMe_3)_2$ (0.25 g, 0.47 mmol) in THF (30 cm^3) was cooled to −78°C, LiPt-Bu_2 (1.42 cm^3 of a 0.33 M THF solution) was quickly added, whereupon the solution turned dark green after several minutes. After stirring overnight at room temperature the solution became deep burgundy. The reaction mixture was dried *in vacuo* and extracted with toluene (2×30 cm^3). The extract was concentrated (25 cm^3) and cooled to −20°C to yield dark red crystals of **4**, yield 0.117 g, 50%. IR (Nujol mull): 1460 s, 1370 m, 1335 m, 1275 w, 945 s (cm^{-1}).

† P is used in the calculation of $\sigma(I)$ to downweight intense reflections in the least-squares refinement. The function minimized was $\Sigma\omega(|F_o|-|F_c|)^2$, where $\omega = 4(F_o)^2/[\Sigma(F_o)^2]^2$, where $[\Sigma(F_o)^2]^2 = [S^2(C+R^2B)+\{P(|F_o|)^2\}^2]/(L_p)^2$, where S is the scan rate, C is the total integrated peak count, R is the ratio of scan time to background count and L_p is the Lorentz polarization factor.

X-ray experimental for **1–4**

Crystals of **1–4** were sealed in thin-walled glass capillaries under nitrogen. Details of crystal data and a summary of intensity data and collection parameters for all four compounds are given in Table 1. Data were collected on an Enraf–Nonius CAD-4 diffractometer at 23 ± 1°C using graphite monochromated Mo-K_α radiation. All calculations were performed on a Microvax-II computer using the Enraf–Nonius software package "SDP-PLUS".[38] For each structure the data were corrected for Lorentz and polarization effects. The structures were solved by direct methods (MULTAN)[39] or Patterson methods, and successive cycles of difference Fourier maps followed by least-squares refinement. Scattering factors were taken from ref. 40.

For compound **1**. Unit cell parameters were obtained by centering 25 reflections having 2θ values between 28 and 31°. The monoclinic space group $P2_1/n$ (No. 14) was uniquely determined by the systematic absences $0k0$, $k = 2n+1$, $h0l$, $h+l = 2n+1$. The structure was solved using direct methods (MULTAN). Hydrogen atoms were not located but their contributions were included in the final refinements. Data with intensities less than $3\sigma(I)$ and $(\sin\sigma)/\lambda$ less than 0.10 were excluded, and a non-Poisson contribution weighting scheme with an experimental instability factor of P set at 0.08 was used in the final stages of refinement.† The maximum peak in the final difference Fourier map has a height of 2.12 $eÅ^{-3}$ and was located 1.088 Å from tungsten and 1.467 Å from Cl(1).

For compound **2**. The X-ray crystallography for **2** was similar to that of **1** with the following specific details. The 2θ range for unit cell parameters was 28–30°. The structure was solved using Patterson methods. A non-Poisson contribution weighting scheme with $P = 0.07$. Hydrogen atoms were not located. The highest peak in the final difference Fourier map was 1.8 $eÅ^{-3}$.

For compound **3**. The X-ray crystallography for **3** was similar to that of **1** with the following specific details. The 2θ range for unit cell parameters 24–26°. The structure was solved using Patterson methods. A non-Poisson contribution weighting scheme with $P = 0.06$. Hydrogen atoms were not located. The highest peak in the final difference Fourier map had a height of 1.084 $eÅ^{-3}$ and was located 1.03 Å from tungsten.

For compound **4**. The X-ray crystallography for **4** was similar to that of **1** with the following specific details. 2θ range for unit cell parameters 25–28°. The structure was solved using direct methods (MULTAN). A non-Poisson contribution weight-

ing scheme with $P = 0.04$. Hydrogen atoms were not located. The highest peak in the final difference Fourier map had a height of 0.87 eÅ^{-3} and was located close to N(2).†

CRYSTALLOGRAPHICALLY DETERMINED Se---O AND P---O INTERACTIONS IN TRIS(2,4-DIMETHOXYPHENYL) PHOSPHINE SELENIDE AND THE 2,4,6-TRIMETHOXY ANALOGUE. CORRELATIONS OF P—Se BOND LENGTHS WITH ^{77}Se NMR DATA

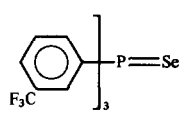
DAVID W. ALLEN,* NORMAN A. BELL, LORRAINE A. MARCH and IAN W. NOWELL†

Department of Chemistry, Sheffield City Polytechnic, Pond Street, Sheffield S1 1WB, U.K.

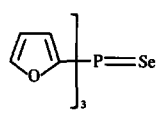
(*Received* 20 *July* 1989; *accepted* 21 *September* 1989)

Abstract—(2,4-Dimethoxyphenyl)$_3$PSe crystallizes in the monoclinic space group $P2_1/n$ with four molecules in the unit cell having dimensions of $a = 9.0660(1)$, $b = 17.2102(3)$, $c = 17.2475(3)$ Å, $\beta = 98.3(2)°$ and refined to $R = 5.2\%$ for 1258 observed reflections. (2,4,6-Trimethoxyphenyl)$_3$PSe is orthorhombic, space group $P2_12_12_1$ with four molecules in the unit cell $a = 18.2983(5)$, $b = 12.3716(1)$, $c = 12.4696(1)$ Å and refined to $R = 6.4\%$ for 1229 observed diffractometer data. In both cases the rings are orientated so that weak P---O interactions take place between one of the *o*-methoxy groups and phosphorus. Similar interactions between selenium and oxygen are also found. These interactions may account for the significant deshielding of the selenium atom in these compounds compared with related triarylphosphine selenides as shown by ^{77}Se NMR data.

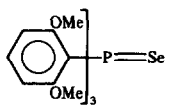
In earlier publications, we have reported studies of the donor properties of heteroaryl- and substituted arylphosphines towards selenium, as indicated by the magnitude of the one-bond coupling constants $^1J(^{77}Se–^{31}P)$ of a series of phosphine selenides,[1] and also recently, by studies of the ^{77}Se chemical shifts for these molecules.[2] It has been shown that the coupling constants increase as the groups attached to phosphorus become more electron-withdrawing, indicating an increased *s*-character for the phosphorus orbital involved in bonding to selenium, in accordance with Bent's rule.[3] Consequently, for electron-withdrawing substituents, the phosphorus–selenium bond would be expected to be shorter than in related molecules bearing less electron-withdrawing groups. Support for this view has been gained from X-ray studies of the phosphine selenides (**1**)[4] and (**2**),[2] in which the phosphorus–selenium bonds show significant shortening compared with that in triphenylphosphine selenide. Our recent studies[2] of ^{77}Se chemical shifts also revealed



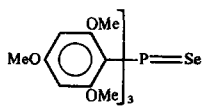
(**1**)



(**2**)



(**3**)



(**4**)

that in **2** the selenium atom is shielded by 86 ppm compared with that in triphenylphosphine selenide, the X-ray study also revealing that each of the three oxygen atoms is arranged about the selenium at an average distance of 3.577 Å. In contrast, it was found that introduction of *ortho* substituents into phenylphosphine selenides causes a deshielding of the selenium. In particular, in **3** and **4**, the selenium is deshielded by, respectively, 222 and 240 ppm compared with that in triphenylphosphine selenide; the coupling constants $^1J(^{77}Se–^{31}P)$ are also reduced, in keeping with the anticipated electron-donating properties of the substituents. In order

† Present address: Robert Gordon's Institute of Technology, Queen's Road, Aberdeen AB9 2PG, Scotland, U.K.

to seek further understanding of the influence of substituents on the selenium shielding and the length of the phosphorus–selenium bond, we have carried out full X-ray studies of **3** and **4**, and now report key aspects of their structures and also draw attention to a possible correlation between phosphorus–selenium bond length and selenium shielding in a number of phosphine selenides.

EXPERIMENTAL

The compounds tris(2,6-dimethoxyphenyl) phosphine selenide (**3**) and tris(2,4,6-trimethoxyphenyl)phosphine selenide (**4**) were prepared as described previously[2] from the corresponding phosphine and selenium and recrystallized from ethanol. Crystals of **3** and **4** were mounted with one axis coincident with the ω-axis of a Stoe Stadi 2 two-circle diffractometer. Data were corrected for Lorentz and polarization effects but absorption corrections were not applied. Details of the crystal data and X-ray data collection are listed in Table 1.

Structure determination and refinement

The selenium coordinates were determined from three-dimensional Patterson maps. The remaining non-hydrogen atoms were located from successive difference Fourier maps. The structure was refined by full-matrix least-squares techniques with all non-hydrogen atoms being assigned anisotropic temperature factors. The hydrogen atoms were included in ideal positions (C—H, 1.08 Å) and given isotropic temperature factors [**3**, 0.102(22) and 0.139(19) Å^2, **4**, 0.036(27) and 0.141(30) Å^2] for the ring and methyl hydrogens, respectively. Complex neutral atom scattering factors[5] were employed throughout the refinements and a non-unit weighting scheme (Table 1) was adopted for both structures. Selected bond distances are listed in Table 2, and selected bond angles in Table 3. Full atomic parameters, thermal parameters, bond lengths and bond angles have been deposited at the Cambridge Crystallographic Data Centre (CCDC). All calculations were performed with an IBM4341 computer using the SHELX computing package.[6]

DISCUSSION

Both **3** and **4** are distorted tetrahedral monomers (Figs 1 and 2) with angles about phosphorus ranging from 102.1(5) to 117.0(4)° for **3** and from 97.8(7) to 118.5(6)° for **4**. The average Se—P—C angles are 111.1(4)° for **3** and 112.8(6)° for **4**, and average C—P—C angles 107.9(6)° for **3** and 106.2(7)° for **4**, all very close to the tetrahedral bond angle.

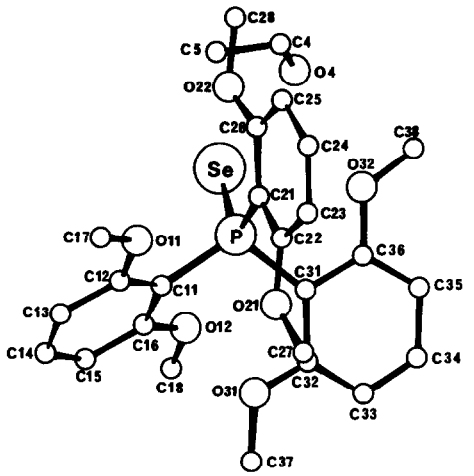

Fig. 1. Structure and atom labelling for tris(2,6-dimethoxyphenyl)phosphine selenide (H atoms omitted for clarity).

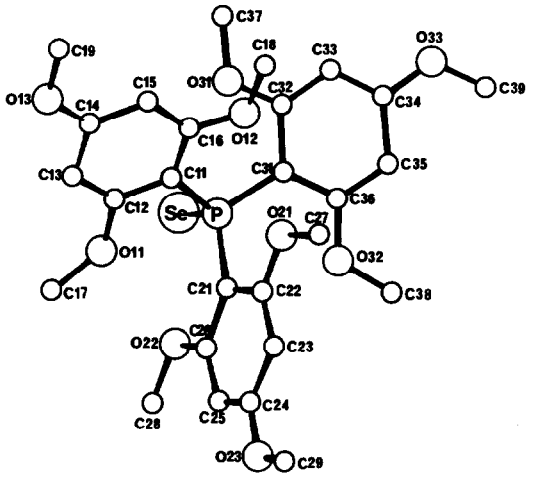

Fig. 2. Structure and atom labelling for tris(2,4,6-trimethoxyphenyl)phosphine selenide (H atoms omitted for clarity).

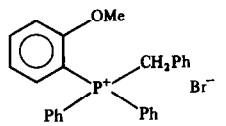
In both compounds the rings are tilted so that, except for ring 3 in **4** where both P---O distances are very similar (2.935, 2.996 Å), one of the two oxygen atoms of the *o*-methoxy groups in each ring lies within the sum of the van der Waals' radii for phosphorus and oxygen (3.35 Å), whereas the other P---O distances are greater than 3.7 Å (Table 2). Thus phosphorus is enclosed in a cage of three carbon and one selenium atoms, with further weak bonding to three oxygen atoms in **3** and four in **4**. The tilting of the rings also results in both smaller P—C—C angles associated with the shorter P---O distances together with correspondingly smaller C—C—O angles, except in ring 3 for both compounds. However, in both cases, the larger

Table 4. Comparison of: P---O, Se---O distances, P—C—C and C—C—O angles for R_3PSe [R = 2,6-$(MeO)_2C_6H_3$, (**3**); 2,4,6-$(MeO)_3C_6H_2$, (**4**)]

	Compound **3** Ring			Compound **4** Ring		
	1	2	3	1	2	3
P---O (Å)	2.873	2.864	2.819	2.838	2.858	2.935
	3.089	3.093	3.154	3.168	3.071	2.996
P—C—C (°)	116(1)	118(1)	115(1)	116(1)	120(1)	119(1)
	125(1)	125(1)	128(1)	127(1)	123(1)	125(1)
C—C—O (°)	117(1)	114(1)	117(1)	116(1)	113(1)	116(1)
	119(1)	118(1)	115(1)	119(2)	116(1)	114(1)
Se---O (Å)	3.254	3.083	3.191	3.311	3.046	3.453

C—C—O angles in ring 3 are compensated by much smaller P—C—C angles, thus enabling oxygen to be involved in a weak interaction with phosphorus (Table 4).

A related interaction between the oxygen of the *o*-methoxyphenyl substituent and phosphorus in the phosphonium salt (5), resulting in a P---O distance of 2.88 Å, has been reported by McEwen and co-workers[7] and attributed to a specific O_{2p}–P_{3d} overlap. However, in a recent related study of the chemistry of *o*-dimethylaminophenylphosphonium salts, Cairns and McEwen[8] have pointed out that it is more appropriate to discuss such interactions from the point of view of hypervalent bonding to phosphorus rather than to a specific 3*d* orbital involvement. If, in the above phosphine selenides, the oxygen atoms are involved in specific hypervalent interactions with the partially positive phosphorus atom (considering the phosphine selenide as a resonance hybrid of the two principal contributing canonical forms, **6** and **7**), then one might expect that this would also influence the extent to which the phosphorus atom is able to become involved in back-donation via $P_{3d\pi}$–$Se_{p\pi}$ overlap with selenium, and result in a lengthening of the phosphorus–selenium bond. In this connection, it is of interest that the phosphorus–selenium distances in **3** and **4** (2.135(3) and 2.119(5) Å, respectively) are longer than that in triphenylphosphine selenide (2.106(1) Å) (although, because of the errors associated with the phosphorus–selenium distance in **4**, the latter increase in length is not *crystallographically significant*).



(5)

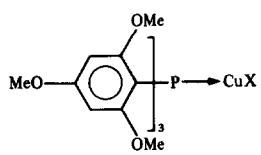
(6) (7)

In both compounds, there are also weak interactions between selenium and one of the oxygen atoms of the *o*-methoxy groups in each ring, resulting in an average Se---O distance in **3** of 3.176 Å and in **4** of 3.266 Å, compared with the sum of the van der Waals' radii for selenium and oxygen of 3.40 Å. As expected, there are no intermolecular interactions involving the methoxy groups in either compound. The *o*-methoxy–selenium interaction noted above may therefore be a factor in explaining the marked deshielding of the selenium observed in our earlier ^{77}Se NMR studies.

The bonding around selenium in **3** is further extended by a weak interaction with a molecule of solvent ethanol (Se---O, 3.338 Å).

A consideration of the data in Table 5 for a range of triarylphosphine selenides reveals a possible correlation between phosphorus–selenium bond length and the NMR shielding of the selenium atoms. The shorter the bond, the greater is the shielding of the selenium. As the bond length increases, the selenium becomes less shielded, but clearly the very marked deshielding observed in compounds **3** and **4** is due to the interactions with nearby oxygen atoms as revealed in the present study.

It is of interest that a recent structural study of the formally two-coordinate copper(I) complexes (**8**) has also revealed a significant interaction



(8) X = Cl or Br

between one *o*-methoxy oxygen and the copper, which results in a distortion of the expected linear geometry at copper.[9]

THE SYNTHESIS, ELECROCHEMISTRY AND THERMAL BEHAVIOUR OF SOME MOLYBDENUM MONONITROSYL COMPLEXES INCORPORATING LONG CHAIN ALKYL SUBSTITUENTS

BENJAMIN J. COE, CHRISTOPHER J. JONES* and JON A. McCLEVERTY

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, U.K.

and

DUNCAN W. BRUCE

(*Received* 25 *August* 1989; *accepted* 21 *September* 1989)

Abstract—The new mononitrosyl complexes $[Mo(NO)LI(OC_6H_4CO_2C_{12}H_{25})]$, $[Mo(NO)LCl(OC_6H_4CO_2C_{12}H_{25})]$, $[Mo(NO)L(OC_6H_4CO_2C_{12}H_{25})_2]$, $[Mo(NO)LI(NHC_6H_4C_{10}H_{21})]$, $[Mo(NO)LCl(NHC_6H_4C_{10}H_{21})]$ and $[Mo(NO)L(NHC_6H_4C_{10}H_{21})_2]$ [L = $HB(3,5\text{-}Me_2C_3N_2H)_3$] have been synthesized and characterized by spectroscopic methods. All undergo one-electron reduction processes at potentials ranging from −0.18 to −1.40 V (SCE). These new compounds have been examined by differential scanning calorimetry. Although these compounds have reduced melting points compared to compounds lacking long alkyl chain substituents, 44°C in the case of the bis-phenoxide derivative, none exhibits liquid crystalline behaviour.

There is considerable current interest in the synthesis of redox-active transition metal complexes which form liquid crystal mesophases.[1–5] Such materials are usually coloured and may undergo electron-transfer processes which lead to a significant change in their optical and magnetic properties. The molybdenum mononitrosyl derivatives [Mo(NO)LXY] (L = hydrotris(3,5-dimethylpyrazol-1-yl)borate, X = Cl, I or Y and Y = phenoxide or arylamide)[6] are redox active,[7,8] strongly coloured and can, in certain cases, exhibit non-linear optical properties.[9] In order to discover whether the incorporation of long chain alkyl substituents into complexes of this type might reduce their melting points and produce materials which exhibit ordering phenomena in the liquid phase, we have synthesized derivatives containing anilide or phenolate ligands carrying long chain alkyl substituents in the 4-position of the aryl ring. Differential scanning calorimetry (DSC) and polarizing hot-stage microscopy studies have been used to establish whether liquid crystalline mesophases are formed by these new compounds.

EXPERIMENTAL

All reagents were used as supplied. $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}I_2]$ and $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl_2]$ were prepared according to previously described methods.[10,11] Solvents used as reaction media were dried according to standard methods and freed of oxygen before use. Silica gel 60 (70–230 mesh) was used as the stationary phase for column chromatography with dichloromethane as eluent. All reactions were carried out under nitrogen but purification procedures were carried out in air. Elemental analyses were carried out by the Microanalytical Laboratory, University of Birmingham.

* Author to whom correspondence should be addressed.

IR spectra were recorded using a PE 297 spectrometer with samples as KBr discs. 270 MHz ^{1}H NMR spectra were obtained from solutions in $CDCl_3$ using a Jeol GX 270 spectrometer. Cyclic voltammetric measurements were made using a PAR 174A polarograph. Solutions in CH_2Cl_2 were *ca* 10^{-3} mol dm^{-3} in complex and 0.2 mol dm^{-3} in $[Bu^n_4N]BF_4$ as base electrolyte. A Pt–bead test electrode was used with a scan rate of 200 mV s^{-1}. An SCE reference electrode was used with ferrocene as an internal standard. Potentials are quoted relative to the SCE and under these conditions E_f for the oxidation of ferrocene was found to be 0.58 V. DSC measurements were carried out using a Perkin–Elmer DSC7 instrument with samples (typically 1.4–3 mg) being hermetically sealed in 10 μl aluminium pans. In all cases heating and cooling rates of 10 K min^{-1} were used. The microscopy studies were carried out using a CZ Scientific Labpol system equipped with a Link-Am PR600 controller and TH600 hot-stage. Heating rates were 10 K min^{-1} unless otherwise stated.

$[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}I(OC_6H_4CO_2C_{12}H_{25})]$

A solution of $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}I_2]$ (0.5 g, 0.74 mmol), *n*-dodecyl-4-hydroxybenzoate (0.5 g, 1.63 mmol) and hexamine (0.05 g, 0.36 mmol) was stirred under reflux in toluene (50 cm^3) for 5 h. The reaction mixture was cooled and filtered, and the filtrate evaporated to dryness under reduced pressure. The resulting brown solid was purified by column chromatography using dichloromethane as the eluant. The major brown fraction was collected and afforded the red–brown product after evaporation. Further purification could be effected by recrystallization from CH_2Cl_2–hexane mixtures (0.35 g, 55%). *Spectroscopic data.* ^{1}H NMR (δ_{TMS} ppm):* aryl protons, 8.07 (2 d $^3J_{HH}$ = 11 Hz), 7.46 (2 d $^3J_{HH}$ = 11 Hz); pyrazolyl-4-H protons, 5.91 (1 s), 5.86 (1 s), 5.85 (1 s); pyrazolyl-3- and 5-Me protons, 2.53 (3 s), 2.45 (3 s), 2.40 (3 s), 2.37 (3 s), 2.28 (3 s), 1.97 (3 s); aliphatic protons, 4.30 (2 t $^3J_{HH}$ = 6.5 Hz), 1.76–0.85 (23 bm); IR: ν_{NO} = 1683, ν_{CO} = 1715 cm^{-1}. [Mo(NO){HB(3,5 - $Me_2C_3N_2H)_3$}[$NHC_6H_4C_{10}H_{21})_2$]

Sodium (0.1 g, 4.35 mmol) was heated under reflux in dry THF (35 cm^3) for 30 min. Naphthalene (0.1 g, 0.78 mmol) was then added and the mixture stirred for 1 h under reflux during which time the solution became dark green. The mixture was then filtered under nitrogen, to remove excess sodium, and 4-decylaniline (0.1 g, 0.43 mmol) was added to the filtrate. After stirring the resulting solution for 30 min at room temperature, [Mo(NO){HB(3,5-$Me_2C_3N_2H)_3$}I($NHC_6H_4C_{10}H_{21}$)] (0.1 g, 0.13 mmol) was added and the mixture stirred for a further 2.5 h. The final dark green mixture was filtered in air to give a dark purple filtrate from which the solvent was removed under reduced pressure. The product was purified by column chromatography using CH_2Cl_2 as eluant, the major purple fraction being collected. Further purification was effected by recrystallization from *n*-pentane (0.11 g, 57%). *Spectroscopic data.* ^1H NMR (δ_{TMS} ppm): amide protons, 8.78 (2 b); aryl protons, 7.19 (4 d $^3J_{HH}$ = 8 Hz), 7.04 (4 d $^3J_{HH}$ = 8 Hz); pyrazolyl-4-H protons, 5.94 (1 s), 5.72 (2 s); pyrazolyl-3- and 5-Me protons, 2.47 (3 s), 2.34 (9 s), 2.24 (6 s); aliphatic protons, 1.54–0.86 (42+12 from pentane bm); IR: ν_{NO} = 1631, ν_{NH} = 3320 cm^{-1}. UV–vis λ_{max}(nm) (ε, mol^{-1} dm^3 cm^{-1}): 549 (12,600), 369 (11,400). Found: C, 64.8; H, 8.5; N, 12.5. $C_{47}H_{74}N_9BMoO \cdot C_5H_{12}$ requires: C, 65.1; H, 9.0; N, 13.1%. *Electrochemical data.* E_f = −1.40 V, ΔE_p = 200 mV, ΔE_p(Fc) = 95 mV.

DISCUSSION

Synthetic studies

The new complexes were synthesized according to established procedures. In the case of the phenoxide derivatives hexamine was used to selectively induce mono-substitution of iodide in [Mo(NO)LI_2] and triethylamine to induce bis-substitution.[11] In forming the bis-arylamide derivative more forcing conditions involving sodium naphthalenide were used to substitute the remaining iodide in [Mo(NO)LI($NHC_6H_4C_{10}H_{21}$)].[12] In the remaining cases, triethylamine was used to consume the HI or HCl liberated in the halide substitution reactions.

All of the new complexes exhibit ν_{BH} at *ca* 2550 cm^{-1} in their IR spectra. In addition, the phenoxide derivatives exhibit ν_{CO} at 1710–1715 cm^{-1} attributable to the carboxylate moiety, while the arylamide derivatives exhibit ν_{NH} at 3260–3320 cm^{-1} due to the amide moiety. It has been found that ν_{NO} in complexes of this type is highly sensitive to the nature of the co-ligands attached to the {Mo(NO)L} moiety. Thus values of *ca* 1680, 1660, 1660 and 1635 cm^{-1} are observed, respectively, for mono-phenoxide, bis-phenoxide, mono-arylamide and bis-arylamide complexes.[6,12] All of the new compounds exhibit ν_{NO} at frequencies in accord with their formulations.

The ^1H NMR spectra of the mono-substituted complexes [Mo(NO)LXY] (X = I or Cl; Y = $OC_6H_4CO_2C_{12}H_{25}$ or $NHC_6H_4C_{10}H_{21}$) exhibit signals attributable to the presence of the aryl and alkyl groups in Y. In addition, the amide complexes exhibit a broad signal at *ca* 13 ppm due to the amide proton. The bis-substituted complexes similarly

contain signals due to the phenoxide or aryl amide ligands but with twice the relative area found for their mono-substituted counterparts. The amide protons in $[Mo(NO)L(NHC_6H_4C_{10}H_{21})_2]$ are substantially shifted from their position in the spectrum of the mono-substituted complex to 8.78 ppm. The signals from the three pyrazolyl-4-H and six methyl protons in the ligand, L, are indicative of the molecular symmetry. In the absence of overlap nine resonances in the area ratio 1 : 1 : 1 : 3 : 3 : 3 : 3 : 3 : 3 should be present for mono-substituted derivatives, whilst the bis-substituted derivatives exhibit signals in the area 1 : 2 : 3 : 3 : 6 : 6. The area ratios observed for the new complexes are in all cases in accord with their formulations. The bis-arylamide complex $[Mo(NO)L(NHC_6H_4C_{10}H_{21})_2]$ could only be isolated in solvated form and both the ^1H NMR and analytical data are consistent with the presence of one mole of pentane in the compound. All attempts to remove this by heating *in vacuo* have failed.

Electrochemical studies

The electrochemical properties of the complexes have been determined by cyclic voltammetry and are in accord with expectations. Previous work has shown that the reduction potentials of the complexes [Mo(NO)LXY] are highly sensitive to the nature of X and Y. Thus for X = halide and Y = phenoxide a reduction potential of *ca* −0.4 V might be expected compared to *ca* −0.8 V for X = halide Y = arylamide.[7] However, the presence of substituents on the aryl ring also has a significant effect on the reduction potentials.[8,13] Thus the ester function on the phenoxide ligand would be expected to give rise to more anodic potentials, whilst the alkyl substituent on the amide ligand should give slightly more cathodic potentials. The observed potentials of −0.18 (X = I, Y = $OC_6H_4CO_2C_{12}H_{25}$), −0.20 (X = Cl, Y = $OC_6H_4CO_2C_{12}H_{25}$), −0.83 (X = I, Y = $NHC_6H_4C_{10}H_{21}$) and −0.87 V (X = Cl, Y = $NHC_6H_4C_{10}H_{21}$) are entirely consistent with this expectation. Similarly, the reduction potentials of bis-phenoxide and bis-arylamide derivatives would be expected to be *ca* −0.8 and −1.3 V, modified by the presence of the substituents on the aryl rings. The observed potentials of −0.44 (X = Y = $OC_6H_4CO_2C_{12}H_{25}$) and −1.40 V (X = Y = $HNC_6H_4C_{10}H_{21}$) are consistent with this expectation. On the basis of the cathodic to anodic peak current ratios these reduction processes appear chemically reversible when the phenoxide ligand is present, but they are not fully reversible in the complexes containing the arylamide ligand.

Thermal studies

Typical melting points for complexes of the type described here, and which contain phenoxide or arylamide ligands with methyl substituents, are in excess of 200°C {e.g. 210–215°C for [Mo(NO)LCl(OC_6H_4-4-Me)] and 250–255°C for [Mo(NO)LCl(NHC_6H_4-4-Me)]}. As expected, the incorporation of the long alkyl chain substituents leads to a marked reduction in the melting points of these materials. In the case of $[Mo(NO)L(OC_6H_4CO_2C_{12}H_{25})_2]$ the melting point is as low as 41–44°C. In order to assess whether these materials exhibit any liquid crystalline behaviour, the complexes were examined by polarizing hot-stage microscopy and DSC.

When viewed under the polarizing microscope $[Mo(NO)LI(OC_6H_4CO_2C_{12}H_{25})]$ showed no changes until the material melted at 106°C. This process appeared to be accompanied by some decomposition. Cooling the freshly melted sample at 10 K min^{-1} failed to show any birefringent textures. The DSC trace revealed two fairly well-resolved endothermic events with a combined enthalpy of 47.9 J g^{-1}. The former had T_{ON} = 107°C (ΔH = 46.6 J g^{-1}) while the latter, which peaked at about 124.5°C, accounted for 1.3 J g^{-1}. Nothing corresponding with this second event could be observed by microscopy and its origin is thus unclear.

In the case of $[Mo(NO)LCl(OC_6H_4CO_2C_{12}H_{25})]$ a melting event was observed at 100°C which corresponded with an endothermic event in the DSC trace with T_{ON} = 104°C (ΔH = 31.13 J g^{-1}). Another event was observed at 122°C and involved a darkening of the sample. This corresponded with an *exothermic* event in the DSC trace with ΔH = −3.95 J g^{-1}. Although the sample appeared birefringent on melting at 100°C, this turned out to be unmelted crystallites in an isotropic environment and so again, no mesomorphic behaviour was observed.

The bis-phenoxide derivative $[Mo(NO)L(OC_6H_4CO_2C_{12}H_{25})_2]$ melted at 43°C corresponding with two poorly resolved events in the DSC trace having T_{ON} = 42.5°C (ΔH = 33.6 J g^{-1}) and T_{peak} = 46°C (ΔH = 20.3 J g^{-1}). Cooling the resulting fluid to −40°C revealed nothing in either the microscopy or the DSC study.

Heating the arylamide derivative, $[Mo(NO)LI(NHC_6H_4C_{10}H_{21})]$, at 10 K min^{-1} revealed the onset of melting at 186.7°C, a possible second event at 189.7°C and finally clearing at 190.5°C. Despite the birefringent appearance of the material between the highest and lowest temperatures this is not a liquid crystalline phase, as evidenced by the melting

of solid crystallites into an isotropic background at the clearing point. On heating the DSC showed two fairly well-resolved events with $T_{ON} = 175°C$ ($\Delta H = 19$ J g^{-1}) and $T_{peak} = 186°C$ ($\Delta H = 18.5$ J g^{-1}), while on cooling the trace was featureless. This suggests that the first event may be a transition between two crystalline modifications while the second is associated with melting, apparently without decomposition. Although the sample solidifies at around 136°C on cooling under the microscope, no thermal evidence of solidification was observed by DSC.

The related complex, [Mo(NO)LCl($NHC_6H_4C_{10}H_{21}$)], melted into an isotropic fluid over a broad range at about 110°C. The DSC study revealed a broad endothermic event with $T_{ON} = 92.6°C$ ($\Delta H = 27$ J g^{-1}). No other events were observed on cooling. The bis-arylamide complex [Mo(NO)L($NHC_6H_4C_{10}H_{21}$)$_2$] could not be freed of solvent and this material became more fluid on heating to 64°C before turning black and decomposing at 74°C. There was no evidence for any liquid crystalline behaviour.

Two of the arylamido complexes melt at higher temperatures than their aryloxo counterparts. This might reflect the presence of opportunities for hydrogen bonding in the amido systems (which appears[14] to greatly increase the melting points of other mesogenic systems) which are not present in the aryloxo systems. However, structural studies have shown that the amide proton is sterically protected to some extent by the bulky ligand L as well as by the aryl groups.[6,15–17] Another feature which emerges from the results is that the replacement of the chloride co-ligand by iodide in the mono-aryloxo complexes appears to have little effect. In contrast, this change produces almost a 100°C increase in melting point for the mono-arylamido systems.

In conclusion, it may be noted that the incorporation of long chain alkyl substituents can be a successful strategy for reducing the melting points of these trispyrazolylborate complexes containing the redox active {Mo(NO)L} moiety. However, the use of co-ligands containing only one aryl ring produces insufficient structural anisotropy to stabilize liquid crystalline mesophases; this may be attributed, in part at least, to the steric bulk of the trispyrazolylborate ligand, L. Work is in progress to assess the effect of using co-ligands of much higher structural anisotropy including hydroxybiphenyl and hydroxystilbene. One final point which may be noted is that the aryloxo complexes appear more suitable when seeking redox active liquid crystalline complexes. Not only are their reduction potentials more accessible than those of their arylamido counterparts, but they also appear to show superior thermal properties.

Acknowledgements—We are grateful to Mr T. Green for technical assistance, to the Royal Society (D.W.B.) and the SERC (B.J.C.) for support. The calorimeter and microscope were purchased with the aid of grants from the SERC, the University of Sheffield and the European Community (Twinning Grant No. ST2J-0387-C).

(*Received* 31 *August* 1989; *accepted* 21 *September* 1989)

Abstract—The bimetallic complexes $[\{Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl\}_2(NHCH_2)_2Z)]$ (Z = nothing, CH_2 or $\{CH_2OCH_2\}_2$), have been synthesized and characterized by spectroscopic methods. The reduction potentials of these compounds were determined by cyclic voltammetry. Although the complexes exhibit irreversible reduction behaviour, their first reduction poentials occur at increasingly more anodic potentials as the size of the α,ω-diamido-bridging ligand is decreased; the values being E_{pc} (V, SCE) = −1.46 (Z = $\{CH_2OCH_2\}_2$, −1.38 (Z = CH_2) and −1.19 (Z = nothing).

The synthesis and electrochemistry of complexes of general formula [Mo(NO)LX(YR)] (L = $HB(3,5\text{-}Me_2C_3N_2H)_3$; X = I or Cl; Y = O, S or NH and R = alkyl or aryl) have been extensively studied in recent years.[1–4] A topic of particular interest has been the way in which the molybdenum mononitrosyl redox centres in bimetallic complexes of the type [Mo(NO)LCl—BL—Mo(NO)LCl] (BL is a bridging ligand) influence one another. Cyclic voltammetric studies have shown that the metal based redox centres do influence one another, as manifest in their electrochemical properties, to an extent which depends upon the nature of BL. Thus when BL is $—NHC_6H_4CH_2CH_2C_6H_4NH—$, a single broadened two-electron reduction wave is observed corresponding with the near simultaneous reduction of both redox centres.[5] However, when BL is $—NHC_6H_4NH—$, two quite separate one-electron reduction processes are observed with the difference between the potentials being 850 mV for mutually *para* —NH— substituents and 450 mV for mutually *meta* —NH— substituents.[6,7] Evidence for a strong interaction between the redox centres is also found with the saturated cyclohexa-1,4-diazyl bridging ligand $—N(CH_2CH_2)_2N—$.[8] As a continuation of these studies we were interested to determine the extent of interaction between {Mo(NO)} redox centres bridged by the single saturated aliphatic chain bridges $—NH(CH_2)_nNH—$ (n = 2, 3). However, because of the tendency for primary alkyl amide derivatives [Mo(NO)LX(NHR)] to exhibit irreversible electrochemistry, we were not optimistic that useful information could be obtained from such systems. Despite this expectation we have synthesized $[\{Mo(NO)LCl\}_2(NHCH_2)_2Z)]$ (Z = nothing, CH_2 or $\{CH_2OCH_2\}_2$) for the sake of completeness and have investigated their electrochemistry.

EXPERIMENTAL

All reagents were used as supplied. $[Mo(NO)\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl_2]$ was prepared according to a previously described method.[9] Silica gel 60 (70–

* Author to whom correspondence should be addressed.

230 mesh) was used as the stationary phase for column chromatography unless otherwise stated. All reactions were carried out under nitrogen but purification procedures were carried out in air. Elemental analyses were carried out by the Microanalytical Laboratory, University of Birmingham.

IR spectra were recorded using a PE 297 spectrometer. ^{1}H NMR spectra were obtained using Varian XL100 (100 MHz) or Jeol GX 270 (270 MHz) at the University of Birmingham or a Bruker WH400 (400 MHz) instruments at the SERC high field NMR service, University of Warwick. Cyclic voltammetric and other electrochemical measurements were made using a Hitek PPR 1 waveform generator and DT 2101 potentiostat or a PAR 174A polarograph. Solutions were *ca* 10^{-3} mol dm^{-3} in a complex and 0.2 mol dm^{-3} in [Bu^{n}N]BF_4 as base electrolyte. A Pt-bead test electrode was used with an SCE reference electrode. Under these conditions the formal electrode potential, E_f, for the Fc/Fc$^+$ couple was found to be at 0.56 V with the cathodic and anodic peak potential separation, $\Delta E_p = 120$ mV. The number of electrons associated with electrode processes was estimated by comparison with [Mo(NO)LCl_2].

[{Mo(NO)LCl(NHCH$_2$—)}$_2$]

A solution containing [Mo(NO)LCl_2] (1.0 g, 2.2 mmol) and 1,2-diaminoethane (0.06 g, 1.0 mmol) in dichloromethane (60 cm^3) was heated under reflux for 3 days in the presence of NaH (0.2 g). The reaction mixture was then filtered and the solvent removed from the filtrate *in vacuo*. The crude product was purified by column chromatography on silica gel using 1% (v/v) tetrahydrofuran in dichloromethane as the eluant, the major orange band being collected. Further purification could be effected by recrystallization from dichloromethane–*n*-hexane mixtures to give an orange solid (0.2 g, 20%). *Spectroscopic data.* 270 MHz ^{1}H NMR $CDCl_3$ (δ_{TMS} ppm):* amide NH 12.20 (2 b); pyrazolyl-4-H 5.87 (2 s), 5.84 (2 s), 5.83 (2 s); NCH_2 CH_2N protons 5.45 (2 m), 4.92 (2 m); pyrazolyl-3- and 5-Me 2.57 (6 s), 2.51 (6 s), 2.38 (6 s), 2.36 (12 s), 2.32 (6 s). IR: $\nu_{NO} = 1655$, $\nu_{NH} = 3290$ cm^{-1}. Found: C, 39.4; H, 5.1; N, 23.0. $C_{32}H_{50}N_{16}B_2O_2Cl_2Mo_2$ requires: C, 39.4; H, 5.1; N, 23.0%.

[{Mo(NO)LCl(NHCH$_2$)}$_2$CH$_2$]

A solution containing [Mo(NO)LCl_2] (2.0 g, 4.4 mmol) and 1,3-diaminopropane (0.15 g, 2.0 mmol) in dichloromethane (60 cm^3) was heated under reflux for 5 days in the presence of NaH (0.2 g). The reaction mixture was then filtered and the solvent removed from the filtrate *in vacuo*. The crude product was purified by column chromatography on silica gel using dichloromethane as the eluant, the major orange band being collected. Further purification could be effected by recrystallization from dichloromethane–*n*-hexane mixtures to give an orange solid (0.6 g, 30%). *Spectroscopic data.* 400 MHz ^{1}H NMR $CDCl_3$ (δ_{TMS} ppm): amide NH 12.54 (1 dd, $^3J_{HH} = 7$ and 10 Hz), 12.31 (1 dd, $^3J_{HH} = 7$ and 10 Hz); pyrazolyl-4-H 5.86 (1 s), 5.84 (1 s), 5.83 (2 s), 5.81 (1 s), 5.80 (1 s); NCH_2 protons 5.42 (2 m), 4.66 (2 m); pyrazolyl-3- and 5-Me 2.59 (3 s), 2.58 (6 s), 2.47 (3 s), 2.44 (3 s), 2.40 (3 s), 2.39 (3 s), 2.38 (3 s), 2.36 (6 s), 2.33 (6 s). IR: $\nu_{NO} = 1655$, $\nu_{NH} = 3230$ and 3290 cm^{-1}. Found: H, 40.0; H, 5.3; N, 21.4. $C_{33}H_{52}N_{16}B_2O_2Cl_2Mo_2$ requires: C, 39.5; H, 5.2; N, 22.3%.

[{Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$]

A solution containing [Mo(NO)LCl_2] (1.0 g, 2.2 mmol) and 1,8-diamino-3,6-dioxaoctane (0.15 g, 1.0 mmol) in dichloromethane (100 cm^3) containing NEt_3 (0.2 cm^3) was heated under reflux for 24 h. The reaction mixture was then filtered and the solvent removed from the filtrate *in vacuo*. The crude product was purified by column chromatography on silica gel using 2% (v/v) tetrahydrofuran in dichloromethane as the eluant, the major red–orange band being collected. Further purification could be effected by recrystallization from dichloromethane–*n*-hexane mixtures to give a red–orange solid (0.41 g, 35%). *Spectroscopic data.* 100 MHz ^{1}H NMR $CDCl_3$ (δ_{TMS} ppm): amide NH 12.52 (2 b); pyrazolyl-4-H 5.80 (5 s), 5.71 (1 s); NCH_2 protons 5.25 (2 m), 4.60 (2 m); N—C—CH_2O protons 3.75 (4 m); OCH_2CH_2O protons 3.56 (4 s); pyrazolyl-3- and 5-Me 2.59 (6 s), 2.48 (3 s), 2.45 (3 s), 2.38 (s 18), 2.33 (6 s). IR: $\nu_{NO} = 1655$, $\nu_{NH} = 3300$ cm^{-1}. Found: C, 41.8; H, 5.9; N, 19.6. $C_{36}H_{58}N_{16}B_2O_4Cl_2Mo_2 \cdot \frac{1}{2}C_6H_{14}$ requires: C, 42.3; H, 5.9; N, 20.3%.

DISCUSSION

The new complexes were prepared following established methods[1,10] in which [Mo(NO)LCl_2] was reacted with the appropriate diamine in the presence of NEt_3 or NaH to consume the HCl liberated during the reaction. All of the compounds exhibited ν_{BH} at 2550 cm^{-1} along with other bands attributable to the presence of the ligand L. The values observed for ν_{NO} were in accord with the

* NMR data relative area and multiplicity given in parentheses; s = singlet, d = doublet, t = triplet, m = multiplet with unresolved couplings, throughout.

formulation of the complexes as monoalkylamide derivatives, and ν_{NH} was observed at *ca* 3300 cm^{-1}. In the case of [{Mo(NO)LCl(NHCH$_2$—)}$_2$] and {Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$] only one NH stretching band was observed but in the case of [{Mo(NO)LCl(NHCH$_2$)}$_2$CH$_2$] two were observed in accord with the ^{1}H NMR results.

The 270 MHz ^{1}H NMR spectrum of [{Mo(NO)L(NHCH$_2$—)}$_2$] was in accord with a structure having a centre of symmetry as found[8] in [{Mo(NO)LCl}$_2${N(CH$_2$CH$_2$)$_2$N}]. This would arise from the {Mo(NO)LClNH—} groups being present in an antiperiplanar configuration with respect to the bridging —CH$_2$CH$_2$— moiety. As in [{Mo(NO)LCl}$_2${N(CH$_2$CH$_2$)$_2$N}] it would appear that the two chiral metal centres are bound sufficiently closely for the diastereoisomer containing two metal centres of opposite chirality to be preferred. Thus the pyrazolyl-4-H protons appeared as three signals, each of relative area two, whilst the pyrazolyl-3 and 5-methyl protons appeared as five signals of relative area 6:6:6:12:6. As required, these findings are consistent with the absence of a plane of symmetry through the {Mo(NO)L} moiety. The diamide —CH$_2$— protons appeared as two unresolved multiplets each of relative area two corresponding with the two diastereotopic sites on the α-carbon. The two-bond and three-bond couplings to CH protons and the three-bond coupling to the adjacent NH proton were not resolved at 270 MHz so that broadened signals were observed. These signals were shifted to low field as a result of their proximity to the formally 16-electron {Mo(NO)}$^{3+}$ core as is now well established.

The odd number of carbon atoms in the central bridge of [{Mo(NO)LCl(NHCH$_2$)}$_2$CH$_2$] precludes the formation of a centrosymmetric molecule and this is reflected in the ^{1}H NMR spectrum which was obtained at 400 MHz. This contains two signals attributable to the NH protons, each appearing as a doublet of doublets as a result of coupling to the two diastereotopic α-protons of the diamido group. The α-protons themselves appear as two complex multiplets as a result of the combination of two-bond coupling to the adjacent diastereotopic CH proton and the three-bond couplings to the NH and central β-CH$_2$ protons. The signal from the central β-CH$_2$ protons lies under the signals from the pyrazolyl-3 and 5-methyl protons and is obscured. The pyrazolyl-4-H protons appeared as five signals in the area ratio 1:1:2:1:1, whilst the pyrazolyl-3 and 5-methyl protons appeared as nine signals of relative area 3:6:3:3:3:3:3:6:6.

The ^{1}H NMR spectrum of [{Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$] was obtained at 100 MHz and contains a single, broad signal attributable to the NH protons. The N—CH$_2$— protons again appear as two unresolved multiplets in the region δ 5.1–4.7 ppm, whilst the N—C—CH$_2$O protons appear as a broad unresolved multiplet just to the low field side of the OCH$_2$CH$_2$O protons which appear as a singlet. The pyrazolyl-4-H protons appeared as two signals of relative area 5:1, whilst the pyrazolyl-3 and 5-methyl protons appeared as five signals of relative area 6:3:3:18:6.

The complexes derived from diaminoethane and diaminopropane did not exhibit high mass ions in their mass spectra. However, in the case of [{Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$], isotope envelopes based around $m/z = 932$ and 904 were observed. These may be attributed to the fragment ions {M−(Me$_2$C$_3$N$_2$H+NO)}$^+$ and {M−(Me$_2$C$_3$N$_2$H+2NO)}$^+$.

As expected, the new complexes exhibited only irreversible processes in their cyclic voltammograms. All exhibited irreversible oxidation processes, these being at +1.88 V in the cases of [{Mo(NO)LClNHCH$_2$}$_2$Z] (Z = nothing or CH$_2$) and at +1.68 V in the case of [{Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$]. The reduction processes of [{Mo(NO)LClNHCH$_2$}$_2$Z] were of the greatest interest in view of our previous findings. Each of the three complexes exhibited a reduction process in the region −1.0 to −1.5 V, but in each case these had i_{pa}/i_{pc} values of approximately 0.5 indicating their chemically irreversible nature. The shape parameters, ΔE_p, were also substantially larger than that of the ferrocene reference (120 mV), being in the range 230–440 mV. Despite the irreversible nature of these processes the E_{pc} values do exhibit a trend in accord with our previous findings and indicative of a varying degree of interaction between the metal centres. Thus in [{Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$], where the metal atoms are well separated and may be presumed to have essentially no interaction, a value of $E_{pc} = -1.46$ V was obtained for the only observable reduction process. In the case of [{Mo(NO)LClNHCH$_2$}$_2$CH$_2$] a one-electron reduction was observed at −1.38 V [{Mo(NO)LClNHCH$_2$}$_2$Z], with a second irreversible two-electron process at −2.0 V. A further anodic shift in the first reduction potential was observed in going to [{Mo(NO)LClNHCH$_2$—}$_2$], where $E_{pc} = -1.19$ V, and no second reduction process was observed. These findings are in accord with the second electron-withdrawing {Mo(NO)} centre facilitating reduction of the first as the distance between them is reduced by shortening the aliphatic chain linking the {Mo(NO)LClNH} moieties.

The irreversible character of the reduction

processes precludes any detailed comment. However, the anodic shift of 80 mV in going from [{Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$] to [{Mo(NO)LClNHCH$_2$}$_2$CH$_2$], with a three-carbon atom bridge, compares favourably with the previously determined[5,7] shift of 70 mV in going from [{Mo(NO)LClNHC$_6$H$_4$-4-CH$_2$CH$_2$C$_6$H$_4$-4′-NHMo(NO)LCl] to [1,3-{Mo(NO)LClNH}$_2$C$_6$H$_4$], which also contains a three-carbon atom bridge. Similarly the anodic shift of 270 mV in going from [{Mo(NO)LClNHCH$_2$CH$_2$OCH$_2$—}$_2$] to [{Mo(NO)LClNHCH$_2$—}$_2$], with a two-carbon atom bridge, may be compared with the shift of 280 mV found[8] on going from [Mo(NO)LCl(NC$_4$H$_8$)] to [{Mo(NO)LCl}$_2${N(CH$_2$CH$_2$)$_2$N}], which also contains saturated two-carbon atom bridges. Thus the results described here establish that the effects observed in other bimetallic systems are also present in these compounds containing a bridging single aliphatic chain. Furthermore, the magnitude of the anodic shift in the first reduction potential is sensitive to the length of the chain just as it is to the relative position of disubstitution when aryl bridges are present.[2–5]

HETEROLEPTIC POLYPYRAZOLYLBORATE DERIVATIVES OF THE LANTHANIDE IONS. BIDENTATE LIGAND EXCHANGE REACTIONS OF $[Ln\{HB(C_3N_2H_3)_3\}_2(\beta\text{-DIKETONATE})]$ (Ln = Ce, La, Sm, Eu, Yb, Lu)

MICHAEL A. J. MOSS and CHRISTOPHER J. JONES*

Department of Chemistry, University of Birmingham, PO Box 363, Birmingham B15 2TT, U.K.

(*Received* 21 *August* 1989; *accepted* 9 *October* 1989)

Abstract—The complexes $[LnL_2X]$ [$L = HB(C_3N_2H_3)_3$, X = PhC(O)CHC(Me)O and Ln = Y, La, Ce, Pr, Nd, Sm, Eu, Tb, Ho, Er, Yb, Lu or X = PhC(O)CHC(Ph)O and Ln = Y, La, Ce, Sm, Eu, Tb, Yb, Lu] have been prepared. In selected cases the intermolecular ligand exchange reactions involving the β-diketonate ligand have been studied by ^1H NMR methods. For the sets of complexes $[YbL_2X]$ [X = OC(Ph)CHC(Ph)O or OC(Me)CHC(Me)O] with $[LuL_2X]$ and $[LaL_2X]$ with $[CeL_2X]$, ligand exchange was found to be slow on the ^1H NMR time scale. A time-resolved study of the exchange of β-diketonate ligands between $[SmL_2X]$ and $[EuL_2X]$ gave results which were in accord with a model involving two opposing bimolecular reactions.

Previously we have found that, unlike their homoleptic counterparts $[LnL_3]$ [Ln = lanthanide or Y and L = hydrotris(pyrazolyl)borate] which exhibit rigid structures in solution on the ^1H NMR time scale,[1] the heteroleptic complexes $[LnL_2(acac)]$ [Ln = lanthanide ion, acac = OC(Me)CHC(Me)O] are dynamic.[2,3] These latter compounds exhibit intramolecular ligand reorganization reactions which are rapid on the NMR time scale at room temperature. Similar observations have been made by Takats and co-workers in studies of $[LnL_2(dik)]$ (Ln = Yb, Lu and dik = 3-trifluoroacetyl-D-camphoryl or 2,2,6,6-tetramethyl-3,5-heptanedionyl).[4] We have also found that complexes of the type $[LnL_2X]$ (X^- = β-diketonate) exhibit intermolecular ligand exchange reactions which are slow compared to the intramolecular processes. Such intermolecular exchange processes are of fundamental importance, since they provide a mechanism for the disproportionation of heteroleptic complexes. In particular, heteroleptic organolanthanides such as $[LnL_2R(Sol)]$ (R = hydrocarbyl and Sol = solvent or nothing) may be prone to disproportionation to form $[LnL_3]$ and solvated lanthanide ions if rapid ligand exchange reactions can occur. We report here an investigation of intermolecular co-ligand–ligand exchange in heteroleptic complexes containing the $\{LnL_2\}^+$ moiety.

A previous ligand exchange study involving mixed solutions of $[AsPh_4][Y(tfac)_4]$ and $[AsPh_4][Y(hfac)_4]$ [tfac = OC(CF$_3$)CHC(Me)O and hfac = OC(CF$_3$)CHC(CF$_3$)O] has been reported by Cotton *et al.*[5] The experiments were carried out at −40°C in a NMR spectrometer and five compounds were found in the resulting solution, *viz.* $[Y(hfac)_4]^-$, $[Y(hfac)_3(tfac)]^-$, $[Y(hfac)_2(tfac)_2]^-$, $[Y(hfac)(tfac)_3]^-$ and $[Y(tfac)_4]^-$, the three mixed-ligand complexes being formed by intermolecular exchange. At −40°C eight separate methine proton signals were observed, one for the methine proton of hfac in each of the four molecules in which it occurs and one for the methine proton of tfac in each of the four molecules in which it occurs. In this case coalescence of the methine resonances to give a single resonance for hfac and another for tfac was observed at +40°C.

In order to observe ligand exchange processes in the $[LnL_2X]$ system, chemically equivalent but spectroscopically different ligands are required. The polypyrazolylborate ligands are not easy to modify

* Author to whom correspondence should be addressed.

chemically and, in any event chemical modification leads to profound changes in reactivity. Consequently our initial studies have utilized different β-diketonate co-ligands, and to this end the new complexes [LnL_2X] were prepared where X = PhC(O)CHC(Me)O (bzac) or PhC(O)CHC(Ph)O (dbzm).

SYNTHETIC STUDIES

The complexes [LnL_2X] where X = bzac, Ln = Y, La, Ce, Pr, Nd, Sm, Eu, Tb, Ho, Er, Yb, Lu and where X = dbzm, Ln = Y, La, Ce, Sm, Eu, Tb, Yb, Lu, were prepared using similar procedures to those used in the preparation of [LnL_2(acac)].[3,6] The new complexes are air- and moisture-stable and are soluble in polar organic solvents. They were characterized by IR, ^{1}H NMR and mass spectrometric measurements and by elemental analyses.* The IR spectra of the complexes [LnL_2(bzac)] are superimposable for different Ln in the set, as are the spectra of the complexes [LnL_2(dbzm)]. All of the spectra contain ν_{BH} at 2450–2460 cm^{-1} and $\nu_{C=O}$ at 1600 cm^{-1}, along with characteristic bands attributable to the phenyl and polypyrazolylborate moieties. The [LnL_2(bzac)] and [LnL_2(dbzm)] complexes are volatile and have similar mass spectra to their acac-containing analogues, consisting of a molecular ion of the correct isotopic pattern, and fragment ions including [LnL_2]$^+$ and [LnLpz]$^+$.

The ^{1}H NMR spectra of the [LnL_2(bzac)] and [LnL_2(dbzm)] derivatives presented in Table 1 are similar to those of the related [LnL_2(acac)] complexes containing the same metal.[3,6] All nine complexes containing the three diamagnetic ions (Ln = Y, La, Lu) have very similar pyrazolyl proton chemical shifts, i.e. $\delta_{TMS} = 7.66(\pm 0.02)$, $7.10(\pm 0.05)$ and $5.98(\pm 0.03)$ ppm with $^3J_{HH} = 2$ Hz. The complexes of the paramagnetic ions exhibit pyrazolyl proton resonances which are singlets. The pyrazolyl and methyl proton resonances appear at the same chemical shifts in the spectra of both the acac and the bzac complexes. However, in the spectrum of the bzac complex the methyl resonance integrates for three rather than six protons in accord with the complex formula. The spectra of complexes containing holmium and erbium could not be phased or integrated with sufficient accuracy for unequivocal assignment.

* Supplementary data available. Tables of elemental analyses and kinetic data have been deposited with the Editor.

LIGAND EXCHANGE STUDIES

The ligand exchange process was observed at 20°C by mixing two equimolar $CDCl_3$ solutions, one containing a complex of a paramagnetic ion and the other a complex of a neighbouring diamagnetic ion of similar ionic radius. The 270 MHz ^{1}H NMR spectrum of the mixture was then recorded. Three different mixtures were studied. These contained [YbL_3] and [LuL_2(acac)], [YbL_2(bzac)] and [LuL_2(acac)] and [CeL_2(acac)] and [LaL_2(bzac)]. In each case the spectrum obtained contained signals attributable to four compounds arising, respectively, from the following equilibria:

$$[YbL_3] + [LuL_2(acac)] \rightleftharpoons [YbL_2(acac)] + [LuL_3] \quad (1)$$

$$[YbL_2(bzac)] + [LuL_2(acac)] \rightleftharpoons [YbL_2(acac)] + [LuL_2(bzac)] \quad (2)$$

$$[CeL_2(acac)] + [LaL_2(bzac)] \rightleftharpoons [CeL_2(bzac)] + [LaL_2(acac)]. \quad (3)$$

Monitoring the spectra as a function of time revealed that intermolecular exchange had proceeded to completion during the time required to prepare the sample and acquire the ^{1}H NMR spectrum (*ca* 10 min). In all three reactions there was approximately the same concentration of all four complexes in solution at equilibrium. Therefore the equilibrium constants appear to be close to unity. These qualitative observations indicate that, for [LnL_2X], bidentate ligand exchange processes occur within a period of minutes at room temperature and are slow on the NMR time scale at 270 MHz.

In order to determine whether intermolecular ligand exchange might become fast on the ^{1}H NMR time scale at elevated temperatures trichlorobenzene was used as a solvent. A mixture of [SmL_2(acac)] and [YL_2(acac)] exhibits two methyl resonances, one at 2.00 ppm due to the acac coordinated to yttrium and one at 2.80 ppm due to the acac coordinated to samarium. In trichlorobenzene no broadening of these methyl resonances was observed at 200°C in the ^{1}H NMR spectra recorded at 270 MHz, eq. (4):

$$[SmL_2(acac')] + [YL_2(acac)] \rightleftharpoons [SmL_2(acac)] + [YL_2(acac')]. \quad (4)$$

Thus, even at this temperature, β-diketonate exchange appears to be slow on the ^{1}H NMR time scale. This finding contrasts with the observation of fast ligand exchange at +40°C for $[Y(tfac)_4]^-$/$[Y(hfac)_4]^-$ mixtures using a 60 MHz spectrom-

[b] Spectrum run in CD_2Cl_2.

eter.[5] Even allowing for the difference in field strength between the two experiments, exchange of the β-diketonate ligand is much slower in complexes of the type [LnL_2(acac)] than in [$Y(tfac)_4$]$^-$. This is perhaps not surprising since the steric bulk of the L^- ligands in [LnL_2X], and the presence of only one β-diketonate ligand X, will result in a much smaller fraction of molecular collisions leading to co-ligand exchange.

The co-ligand exchange reaction was found to be very slow at −50°C and could be followed using ^{1}H NMR spectroscopy at sub-ambient temperatures. Time resolved studies were carried out by mixing $CDCl_3$ solutions of [SmL_2(acac)] and [EuL_2(bzac)] at *ca* −50°C, then warming the mixture to a constant −20°C and monitoring the changing composition of the mixture according to eq. (5) as revealed

$$[SmL_2(acac)] + [EuL_2(bzac)] \underset{k_{5'}\ (-20°C)}{\overset{k_5}{\rightleftharpoons}} [SmL_2(bzac)] + [EuL_2(acac)] \quad (5)$$

by the ^{1}H NMR spectrum. Similarly the reverse reaction between [SmL_2(bzac)] and [EuL_2(acac)] according to eq. (6) was studied at −10°C. Under these conditions it was found that equilibration

$$[SmL_2(bzac)] + [EuL_2(acac)] \underset{k_6\ (-10°C)}{\overset{k_{6'}}{\rightleftharpoons}} [SmL_2(acac)] + [EuL_2(bzac)] \quad (6)$$

was essentially complete after 2–5 h. The results obtained indicate the presence of slightly larger concentrations of the complexes with the sterically larger ligand (bzac) coordinated to the larger lanthanide (Sm), and the smaller ligand (acac) coordinated to the smaller lanthanide (Eu), as compared to the other reaction products. Thus the equilibrium constant for the reaction is not exactly unity. In the case of the reaction as written in eq. (5) the final concentrations of the products lead to an equilibrium constant of 1.31. The final equilibrium concentrations for the reaction as written in eq. (6) gave an equilibrium constant of 0.774, the reciprocal of which is 1.29.

Assuming that these reactions can be described as "opposing second-order reactions", and assuming that the same initial concentration of the two starting materials is used, the integrated rate equation (7) can be derived:[7]

$$\ln\{[a-x(1-K^{-1/2})]/[a-x(1+K^{-1/2})]\} = I = 2aK^{-1/2}kt, \quad (7)$$

where a is the initial concentration of one of the starting materials, x is the concentration of one of the products at time t, K is the equilibrium constant and k is the rate of the forward reaction. A plot of the left-hand side of eq. (7), *viz.* I, vs time (t) should give a straight line of slope $2aK^{-1/2}k$ if the mechanism of the two opposing second-order reactions is correct.

The ^1H NMR spectra of the reaction mixtures used are complicated, but in the region between −3 and −4 ppm, the two methyl resonances of acac and bzac coordinated to europium are well separated. Thus these two resonances can be integrated accurately and the relative concentrations of $[EuL_2(acac)]$ and $[EuL_2(bzac)]$ can be calculated. Graphs of the function I against t are linear as shown in Fig. 1 with correlation coefficients of 0.9993 and 0.9975 for the plots from reactions (5) and (6), respectively. The slopes of these plots are $(1.76\pm0.02)\times10^{-4}$ and $(6.2\pm0.1)\times10^{-4}$ s^{-1}, respectively. These values give a forward rate constant for reaction (5) at −20°C (k_5) of $(2.5\pm0.1)\times10^{-3}$ $dm^3\,mol^{-1}\,s^{-1}$ and a forward rate constant for reaction (6) at −10°C ($k_{6'}$) of $(8.8\pm0.4)\times10^{-3}$ $dm^3\,mol^{-1}\,s^{-1}$. The errors of 5% in these rate constants are estimated on the basis of the uncertainty in the concentration since the errors in both the slopes and equilibrium constants are less than 2%. The kinetic data calculated from these two experiments for the reaction as written in eq. (5) can be summarized as follows: $K = 1.30\pm0.01$; $k_5 = (2.5\pm0.1)\times10^{-3}$ $dm^3\,mol^{-1}\,s^{-1}$ and $k_{5'} = (1.9\pm0.1)\times10^{-3}$ $dm^3\,mol^{-1}\,s^{-1}$ at −20°C; $k_6 = (11.4\pm0.6)\times10^{-3}$ $dm^3\,mol^{-1}\,s^{-1}$ and $k_{6'} = (8.8\pm0.4)\times10^{-3}$ $dm^3\,mol^{-1}\,s^{-1}$ at −10°C.

The reaction described by eq. (6) was observed to have essentially reached completion in 2 h at −10°C and so at 20°C it would reach completion in approximately 5 min. In view of this dynamic character the resistance of these heteroleptic complexes to disproportionation is remarkable. It would appear to indicate a thermodynamic preference for the heteroleptic ligand set in $[LnL_2(\beta$-

diketonate)] as compared to a mixture of [LnL_3] and solvated [Ln(β-diketonate)$_3$] or [Ln(β-diketonate)$_4$]$^-$.

EXPERIMENTAL

Synthetic studies

Potassium hydrotris(pyrazol-1-yl)borate was prepared by the literature method.[8] Hydrated lanthanide trichlorides were obtained from Ventron GMBH and acetylacetone, benzoylacetone and dibenzoylmethane were obtained from Aldrich Chemicals Ltd, they were used without further purification. Water was distilled before use. ^{1}H NMR spectra were recorded using Perkin–Elmer R12B (60 MHz), Varian XL 100 (100 MHz) or JEOL JNM GX270 (270 MHz) spectrometers. Deuterated NMR solvents were obtained from Aldrich Chemicals Ltd, and chemical shifts are reported with tetramethylsilane as internal reference at 293 K. IR spectra were recorded using potassium bromide pellets and a Perkin–Elmer 297 spectrometer. Mass spectra were obtained using a Kratos MS80RF mass spectrometer, ions being produced by electron impact.

Benzoylacetonatobis{hydrotris(pyrazol-1-yl)borato} yttrium(III)

K{$HBpz_3$) (0.5 g, 2 mmol), benzoylacetone (0.16 g, 1 mmol), ethanol (20 cm^3) and 0.1 mol dm^{-3} aqueous KOH (10 cm^3) were mixed and the resulting solution added to a stirred solution of $YCl_3 \cdot 6H_2O$ (0.30 g, 1 mmol) in water (5 cm^3). Stirring was continued for 1 h, after which time the white amorphous precipitate produced was collected by filtration (0.61 g, 90%). Recrystallization from CH_2Cl_2–hexane gave white crystals (0.50 g, 74%), m.p. = 232–234°C.

Dibenzoylmethidobis{hydrotris(pyrazol-1-yl)borato} yttrium(III)

This complex was prepared by the same method as the benzoylacetonate complex using dibenzoylmethane (0.22 g, 1 mmol).

The corresponding complexes [Ln{$HBpz_3$}$_2$X] (X = (bzac), Ln = La, Ce, Pr, Nd, Sm, Eu, Tb, Ho, Er, Yb and Lu; and X = (dbzm), Ln = La, Ce, Sm, Eu, Tb, Yb and Lu) were prepared similarly. Details of the amounts of lanthanide starting material used, and of the yields, melting points and colours of the products are given in Table 2.

Ligand exchange experiments

All ligand exchange experiments were carried out using a JEOL JNM GX270 NMR spectrometer. Experiments (1)–(6) relate, respectively, to the reactions shown in eqs (1)–(6). In experiment (4) 1,2,4-trichlorobenzene was used as the solvent, in all other experiments $CDCl_3$ was used. [YbL_3] was prepared by a published method,[9] and other lanthanide complexes were prepared according to previously described methods.[3,5]

Experiment (1). [YbL_3] (40.6 mg, 0.05 mmol) and [LuL_2(acac)] (35.0 mg, 0.05 mmol) were dissolved

in $CDCl_3$ (0.5 cm^3) and an NMR spectrum obtained within 15 min at room temperature (20°C). This spectrum contained the resonances for four previously characterized complexes: $[LnL_3]$ and $[LnL_2(acac)]$, where Ln = Yb and Lu.

Experiment (2). $[YbL_2(bzac)]$ (38.0 mg, 0.05 mmol) and $[LuL_2(acac)]$ (35.0 mg, 0.05 mmol) were treated as in experiment (1), the resulting spectrum again contained resonances for four complexes: $[LnL_2(bzac)]$ and $[LnL_2(acac)]$, where Ln = Yb and Lu.

Experiment (3). $[LaL_2(bzac)]$ (36.3 mg, 0.05 mmol) and $[CeL_2(acac)]$ (33.3 mg, 0.05 mmol) were treated as in experiment (1), the resulting spectrum again contained resonances for four complexes: $[LnL_2(bzac)]$ and $[LnL_2(acac)]$, where Ln = Yb and Lu.

Experiment (4). $[YL_2(acac)]$ (18.4 mg, 0.03 mmol) and $[SmL_2(acac)]$ (20.2 mg, 0.03 mmol) were dissolved in 1,2,4-trichlorobenzene (b.p. = 215°C) and spectra acquired at high temperatures up to a maximum of 200°C, no broadening of the signals was observed.

Experiment (5). A solution of $[SmL_2(acac)]$ (16.8 mg, 0.0249 mmol) in $CDCl_3$ (0.40 cm^3) was placed in a 5 mm NMR tube and cooled to between −60 and −50°C. To this was added a similarly cooled solution of $[EuL_2(bzac)]$ (18.4 mg, 0.0249 mmol) in $CDCl_3$. The mixture was stirred vigorously with a narrow, flat ended glass rod. The NMR spectrometer probe was pre-cooled to −60°C. The cold well-mixed solution was inserted into the spectrometer and warmed to −20°C then held at this temperature. The first spectrum was acquired as quickly as possible and spectra were recorded subsequently at intervals of 10 min. Only the region between −3 and −4 ppm was integrated and printed since this region contains the methyl resonances of acac and bzac attached to europium. Integrations were converted to a ratio of reactant, $[EuL_2(bzac)]$, to product, $[EuL_2(acac)]$.

Experiment (6). The procedure used in experiment (5) was repeated using $[SmL_2(bzac)]$ (18.2 mg, 0.0247 mmol) and $[EuL_2(acac)]$ (16.7 mg, 0.0247 mmol). The equilibration was observed at −10°C in this case, readings being taken at intervals of 5–7 min.

AN NMR STUDY OF THE FLUXIONALITY OF GROUP VI METAL PENTACARBONYL COMPLEXES OF 1,3-DITHIOLANES

EDWARD W. ABEL, KEITH G. ORRELL,* KHURSHID B. QURESHI and VLADIMIR ŠIK

Department of Chemistry, University of Exeter, Exeter EX4 4QD, U.K.

(*Received* 12 *June* 1989; *accepted* 25 *September* 1989)

Abstract—The complexes $[M(CO)_5(\overline{SC_2H_4SC}RR')]$ (M = Cr, Mo or W, R = R′ = H; M = Cr or W, R = R′ = Me, R = H, R′ = Me, Bu^t or Ph) have been synthesized and characterized. Their solution stereodynamics were examined by ^{1}H NMR spectroscopy. Pyramidal inversion of the metal-coordinated sulphur atoms occurs rapidly at ambient temperatures ($\Delta G^{\ddagger}$ (298 K) = 40–44 kJ mol^{-1}). An appreciably slower 1,3-metal–sulphur shift is also evident at temperatures where sulphur inversion is rapid on the proton NMR timescale. For the ligand complexes (R = R′ = H, Me) this shift is purely intramolecular in nature ($\Delta G^{\ddagger}$ (298 K) values ~ 78 kJ mol^{-1}), in contrast to the 2-mono-substituted ligand complexes (R = H, R′ = Me, Bu^t, Ph) where it is accompanied by a dissociation process.

Group VI metal pentacarbonyl complexes with chalcogen ligands are widely known and their solution structures have been rigorously examined by NMR methods.[1] Much of this previous work has been centred around $M(CO)_5$ complexes of cyclic polythioethers such as $\overline{SCH_2SCH_2SCH_2}$,[2,3] $\overline{SCHMeSCHMeSCHMe}$[2–4] and $\overline{SCH_2SCH_2SCH_2SCH_2}$,[5] where in addition to facile pyramidal sulphur inversion and ligand ring reversals, slower 1,3-metal–sulphur shifts occur. Because of the alternating —C—S—C—S— ligand backbone, the $M(CO)_5$ moiety is able to commute freely around these six-membered rings. In five-membered rings, however, this is not possible, as for example in the case of the ligand complexes $[M(CO)_5(\overline{Me_2CCH_2EECH_2})]$ (E = S, Se) where the commutation is restricted to the two adjacent E atoms.[6] Fluxional 1,3-metal shifts restricted to three bonds might be expected to occur in $M(CO)_5$ complexes of the five-membered rings $\overline{SC_2H_4SPPh}$, $\overline{SC_2H_4SP(O)Ph}$ and $\overline{SC_2H_4SP(S)Ph}$, but NMR investigations up to 150°C produced no evidence for such fluxionality, possibly due to the donor in these ligands being the phosphorus, oxygen or exocyclic sulphur atoms rather than the endocyclic sulphur.[7] The 1,3-dithiolanes, $\overline{SC_2H_4SCRR'}$ (R = H, R′ = H, alkyl, aryl), however, can only coordinate via their endocyclic sulphur atoms and so these ligands have been chosen for identifying any 1,3-shifts that might be occurring in five-membered cyclic polythioethers of $M(CO)_5$.

These ligands have recently been shown to form stable palladium(II) and platinum(II) complexes, viz. *trans*-$[MCl_2(\overline{SC_2H_4SCRR'})]$ (R = R′ = H, Me; R = H, R′ = Me, Bu^t, Ph), in which 1,3-metal–sulphur shifts do indeed occur in most cases, usually accompanying pyramidal sulphur inversion or ligand dissociation/recombination.[8,9] This present work therefore serves both to examine the influence of the metal on the fluxional nature of the M → S bond in five-membered ligand ring complexes and also to compare the effect of ligand ring size on 1,3-metallotropic shifts. To this end the following complexes have been synthesized, viz. $[M(CO)_5(\overline{SC_2H_4SCRR'})]$ (M = Cr, Mo, W, R = R′ = H; M = Cr, W, R = R′ = Me, R = H, R′ = Me, Bu^t or Ph), and we report herein their solution structures as evidenced by dynamic ^{1}H NMR spectroscopy.

EXPERIMENTAL

Materials and preparations

Ligands. The preparations of the ligands 1,3-dithiolane, 2-alkyl-1,3-dithiolanes, 2-phenyl-1,3-dithiolane and 2,2-dimethyl-1,3-dithiolane were

* Author to whom correspondence should be addressed.

based on the original method of Gibson.[10] Full details are given in our earlier papers.[8,9]

Metal pentacarbonyl complexes. These were all prepared by reacting the appropriate ligand with $[M(CO)_5THF]$ (M = Cr, Mo, W; THF = tetrahydrofuran). The latter was prepared by UV irradiation of a solution of $[M(CO)_6]$ (0.5 g) in THF (130 cm^3) in an immersion reaction vessel and a 450 W Hanovia medium pressure Hg lamp. The solution was deoxygenated and purged with nitrogen before being irradiated for 12 h to produce a yellow solution of $[W(CO)_5THF]$, or for 40 h to produce a deep orange solution of $[Cr(CO)_5THF]$, or for 88 h to produce a yellow solution of $[Mo(CO)_5THF]$. The irradiated solution was slowly filtered into a Schlenk tube containing a stirred, ice-cold solution of the ligand (1 molar equivalent) dissolved in dichloromethane (20 cm^3). The reaction mixture was stirred for 3 h whilst being allowed to warm up to room temperature. The solvent was removed and the residue dissolved in dichloromethane–petroleum spirit (1 : 1) (20 cm^3) and chromatographed with grade II alumina. The chromatogram was developed using dichloromethane–petroleum spirit (40–60°C) (1 : 1) at room temperature, the product being eluted as a yellow band. The solvents were removed from the yellow fraction under reduced pressure and the yellow complex dried *in vacuo*. Analytical data for the complexes are given in Table 1. The complexes $[M(CO)_5(\overline{SC_2H_4SCHPh})]$ (M = Cr, W) remained as oils and were not isolated as analytically pure crystalline products.

NMR spectra

All spectra were obtained using a Bruker AM250 FT spectrometer operating at 250.1 MHz (^1H). All complexes were examined as solutions in either dichloromethane-d_2 (low temperatures) or 1,1,2,2-tetrachloroethane–nitrobenzene-d_5 mixtures (high temperatures). Proton shifts were measured relative to Me_4Si (internal). Sample temperature variation was achieved by a standard variable-temperature unit, calibrated to read temperatures accurate to at least ± 1°C. Band shape analyses employed the authors' version of the DNMR program of Kleier and Binsch.[11]

IR spectra

The IR-active carbonyl stretching modes of these complexes were measured using a Perkin–Elmer Model 398 spectrophotometer. The complexes were examined as solutions in hexane and data are given in Table 2, where the assignments of the three fundamental stretching modes ($2A_1 + E$) are based on an assumed C_{4v} point group. In most cases an additional band in the region 1975–1990 cm^{-1} was also observed due to the presence of a trace of $M(CO)_6$ in the hexane solutions.

RESULTS

protons and a symmetrical second order AA′BB′ type pattern for the —SCH_2CH_2S— protons. Chemical shift data are given in Table 3. Such a spectral pattern is indicative of rapid inversion of the coordinated sulphur atom which renders the two —SCH_2S— protons isochronous and also removes distinction between the geminal proton pairs of the —SCH_2CH_2S— grouping. This is depicted in Fig. 1, where the two structures represent an enantiomeric pair, with the proton averaging being AB⇌BA and CDEF⇌DCFE. The correctness of this interpretation was confirmed by low-temperature measurements, since on cooling to *ca* −70°C the —SCH_2S— signal split into an AB quartet ($\Delta\nu$ = 129 Hz, $^2J_{AB}$ = 10.4 Hz, for M = W and $\Delta\nu$ = 123 Hz, $^2J_{AB}$ = 10.4 Hz for M = Mo), and the —SCH_2CH_2S— signals became more complex, indicative of four different chemical shifts C,

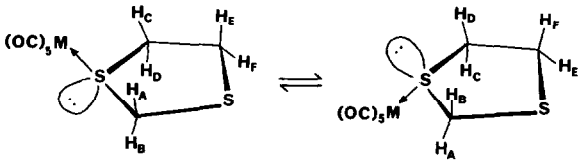

Fig. 1. Enantiomerism in $[M(CO)_5(\overline{SC_2H_4SCH_2})]$ complexes as a result of pyramidal inversion of the coordinated sulphur. The labels A–F on the ring protons refer to the environments, not the identities of the protons.

[a] Relative to Me_4Si; solvent CD_2Cl_2.
[b] Chemical shifts for all AA′BB′ and ABCD spin systems have only been approximately measured.

D, E and F. In the case of the chromium complex, the band shape changes were less clearly defined, probably as a result of accidental near equality of the geminal methylene shifts and the somewhat lower purity of the sample.

Accurate expanded spectra of the $-SCH_2S-$ signals of the molybdenum and tungsten complexes were recorded over the temperature range -25 to *ca* $-90°C$ and the band shapes were computed as exchanging $AB \rightleftharpoons BA$ systems. Good fits of experimental and computed spectra were obtained as shown in Fig. 2 for the complex $[W(CO)_5(\overline{SC_2H_4SCH_2})]$.

Examination of the ^1H NMR spectra of $[W(CO)_5(\overline{SC_2H_4SCH_2})]$ above room temperature revealed further changes in the band shapes due to the $-SCH_2CH_2S-$ protons (Fig. 3). The two methylene multiplets commenced to broaden and proceed towards coalescence at *ca* 115°C as the temperature was raised. However, above *ca* 80°C decomposition became significant but spectra for band shape analysis were acquired up to 105°C (Fig.

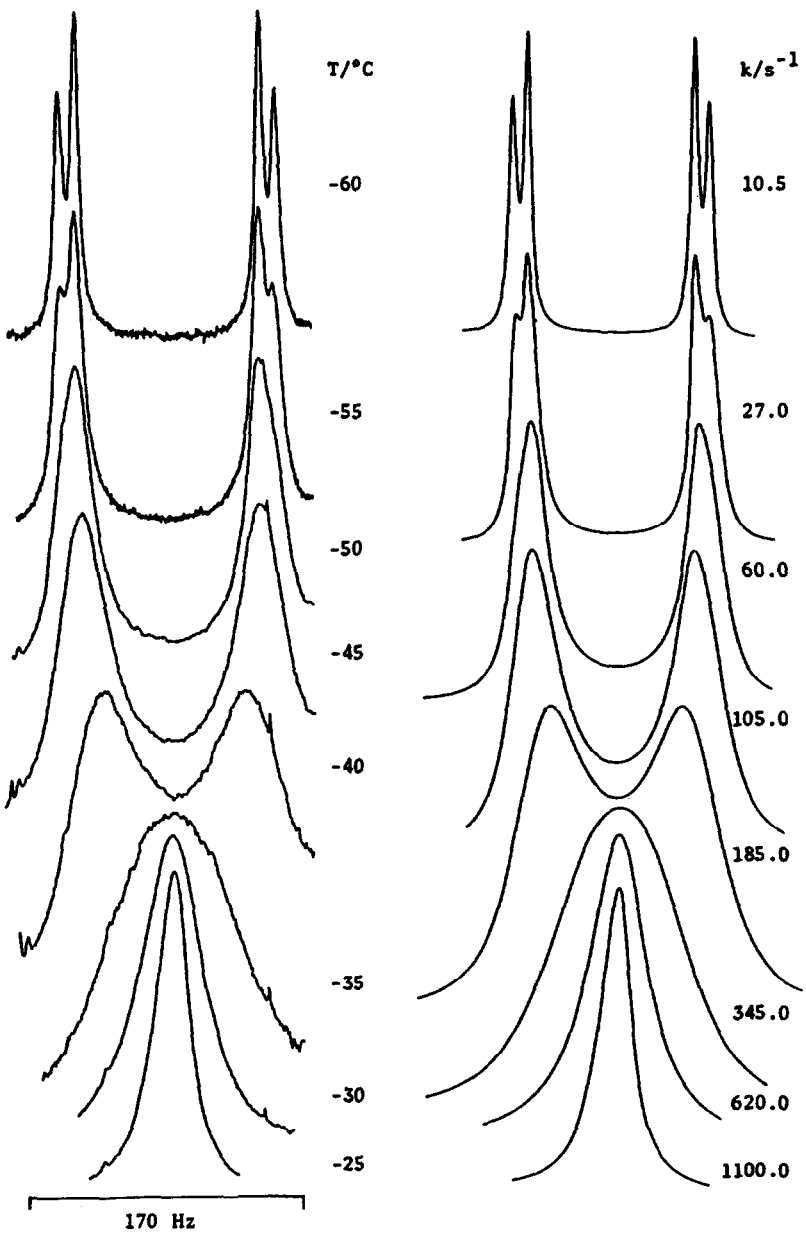

Fig. 2. Variable temperature 250 MHz ^1H NMR spectra of $[W(CO)_5(\overline{SC_2H_4SCH_2})]$ showing the $-SCH_2S-$ region, with the computer synthesized spectra alongside.

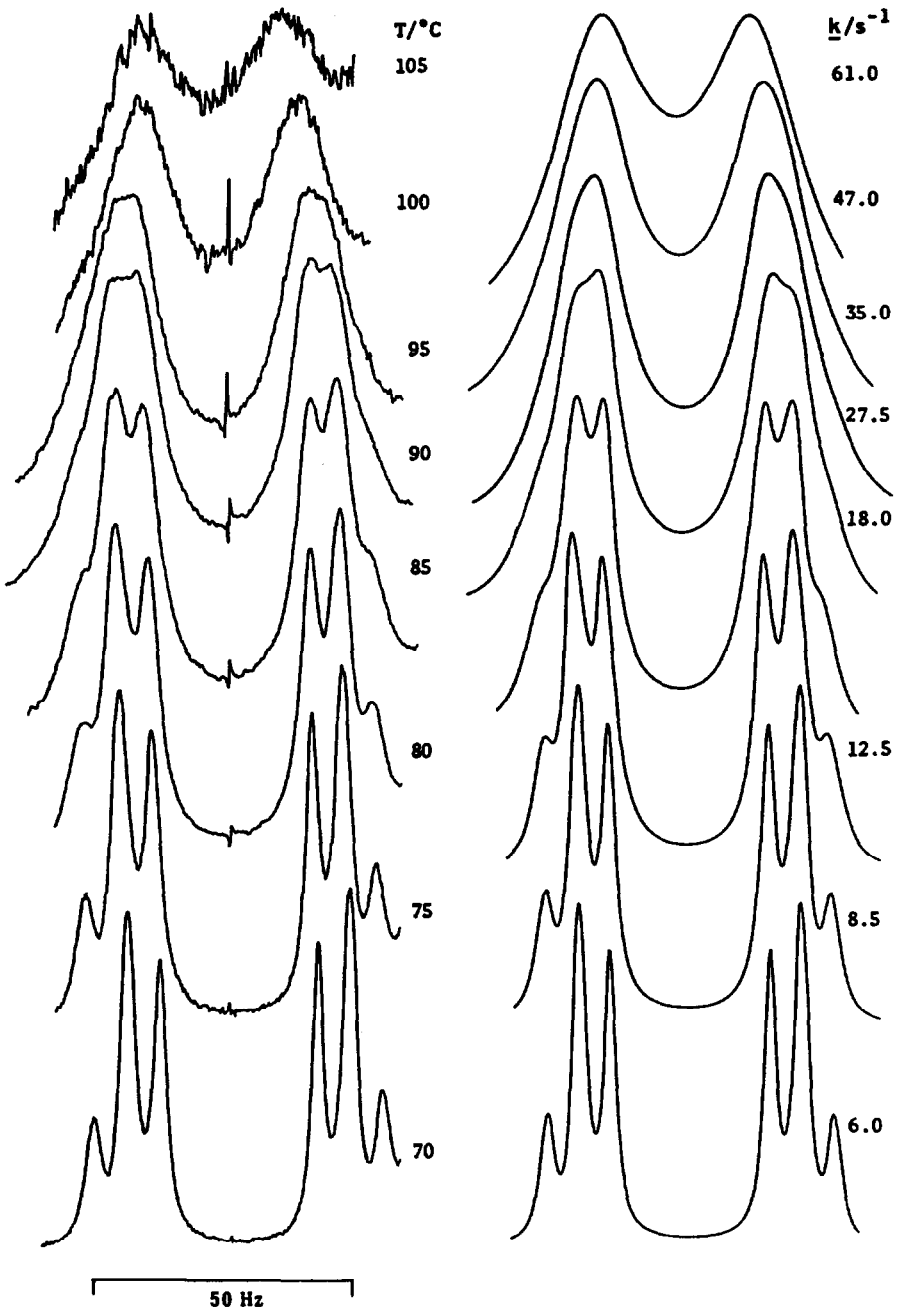

Fig. 3. Variable temperature 250 MHz ^{1}H NMR spectra of $[W(CO)_5(\overline{SC_2H_4SCH_2})]$ showing the $—SCH_2CH_2S—$ region and the effects of the 1,3-shift. Theoretical spectra are shown alongside.

3). Spectra up to *ca* 80°C were fully temperature reversible and clearly indicative of an intramolecular 1,3-shift fluxion which caused averaging of the two ring methylene environments. The kinetics of this process were computed on the basis of an exchanging AA′BB′ ⇌ BB′AA′ spin system where the chemical shifts A, B represent inversion-averaged values ⟨CD⟩ and ⟨EF⟩, respectively. The static parameters used in these calculations are given in Table 4 and the results of the band shape analysis are shown in Fig. 3.

Attempts to repeat these experiments with the chromium complex were unsuccessful due to the production of paramagnetic species, and in the case of the molybdenum complex, because of the very small chemical shift difference $(\nu_A - \nu_B)$, of the adjacent methylene protons.

$[M(CO)_5(\overline{SC_2H_4SCMe_2})]$ (M = Cr, W)

Low and high temperature NMR studies were performed only on the tungsten complex of 2,2-

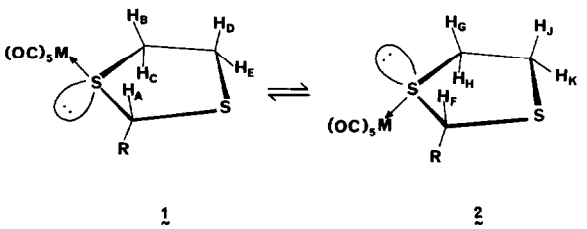
dimethyl-1,3-dithiolane, as the chromium complex was far less stable in solution particularly at ambient temperatures and above. Even in the case of the tungsten complex the band shape changes were less well defined than in the unsubstituted 1,3-dithiolane complexes due to close similarities of chemical shifts. For instance, the geminal C-methyls were only just resolved at < 70°C on a 400 MHz spectrum, whereas the ring methylene signals consisted of an exchange-broadened ABCD type spectrum with three of the shifts very similar. The line widths of the signals were at a maximum at *ca* −70°C (203 K) from which approximate values of the rate constant and $\Delta G^{\ddagger}$ parameter for the pyramidal inversion process at this temperature could be deduced.

At above-ambient temperatures and AA′BB′ system of the —SCH_2CH_2S— protons again broadened due to the onset of the 1,3-shift process and band shape fittings were carried out in an analogous way to that used for the 1,3-dithiolane complexes (See Table 4 for the static parameters used).

$[M(CO)_5(\overline{SC_2H_4SCHR})]$ (M = Cr, W; R = Me, Bu^t, Ph)

In 2-substituted 1,3-dithiolane complexes, the coordinated sulphur is a chiral centre and pyramidal inversion produces a distinct diastereomer (Fig. 4) rather than a mirror-image enantiomer as



1 2

Fig. 4. Diastereomerism in $[M(CO)_5(\overline{SC_2H_4SCHR})]$ complexes as a result of pyramidal inversion of the coordinated sulphur. Structure 1 is the thermodynamically favoured species.

in the case of the unsubstituted 1,3-dithiolanes (Fig. 1). All the ring proton environments in both species are different and thus complex absorption patterns due to these protons are expected.

$[M(CO)_5(\overline{SC_2H_4SCHMe})]$ (M = Cr, W)

At room temperature the ^{1}H NMR spectra of both complexes comprise a methyl 1 : 1 doublet, a methine 1 : 3 : 3 : 1 quartet and a complex symmetrical AA′BB′ type pattern for the ring methylenes (Table 3). On cooling to *ca* −100°C in CD_2Cl_2 solvent, the methylene region changed to a very complex pattern of lines associated with the strongly coupled four-spin systems of each invertomer (Fig. 4). At this limiting low temperature the methyl proton absorption consisted of two doublets in an intensity ratio 63 : 37% for the tungsten complex. The more intense signal was attributed to the *trans* invertomer, i.e. the structure with $M(CO)_5$ *trans* to the ring methyl. The *cis–trans* distinction became less clear on raising the temperature somewhat and the coalescence temperature of the methyl signals was at *ca* −80°C from which an approximate value of $\Delta G^{\ddagger}$ (193 K) was calculated from the Eyring equation.

Warming the complexes to ambient temperatures was expected to change the two ABCD type patterns of the —SC_2H_4S— protons to a single ABCD spectrum, due to rapid inversion of the coordinated sulphur. However, the observed outcome of this temperature elevation was an AA′BB′ pattern of lines. Such a change can only be accommodated by assuming the onset of pyramidal sulphur inversion *and/or* 1,3-metal–sulphur commutation. Such an interpretation implies a considerable lowering of the energy barrier for the 1,3-metal shift process compared to the unsubstituted and 2,2-disubstituted 1,3-dithiolane complexes. An analogous observation was recorded for the 1,3-shifts of the complexes $[M(CO)_5(\overline{SCHMeSCHMeSCHMe})]$ (M = Cr, W)[2-4] compared to the unsubstituted trithian ligand complexes $[M(CO)_5$

($\overline{SCH_2SCH_2SCH_2}$)].[2,3] In that work it was suggested that steric factors confined the ring methyls to equatorial positions and the $M(CO)_5$ to an axial position with respect to the six-membered ring, with the other possible conformational structures unfavoured and undetected by NMR. For the fixed axial $M(CO)_5$ moiety the other sulphur lone pairs were ideally positioned to facilitate a 1,3-metal shift. In contrast, in the unsubstituted $M(CO)_5$–trithian complexes, rapid sulphur inversion and ring reversal alters the relative positioning of $M(CO)_5$ and the sulphur lone pairs and reduces the probability of the 1,3-shift. In the present [$M(CO)_5$ ($\overline{SC_2H_4SCHMe}$)] complexes similar arguments appear valid. In other words, the $M(CO)_5$ moiety adopts a *trans* relationship with respect to the ring methyl and comparable amounts of energy are required to invert the configuration of the coordinated sulphur and to produce a 1,3-metal–sulphur shift without inversion of configuration. The two dynamic processes therefore cannot be separated. The pyramidal inversion process is assumed to proceed via the trigonal planar intermediate,[12] whereas the 1,3-shift must involve a weakly bound pseudo-seven-coordinate metal intermediate which can be most readily envisaged if the five-membered ring adopts a half-chair puckered configuration[13–15] (Fig. 5), although the classical envelope structure or some intermediate between these two extreme forms is almost equally probable.[16] This dual fluxional process is rapid at room temperature for both the chromium and tungsten complexes. Both complexes tended to dissociate at temperatures above *ca* 30°C as evidenced by a colour change from yellow to green and the appearance of free ligand signals in the spectra.

In contrast, in the complexes of $\overline{SC_2H_4SCH_2}$ and $\overline{SC_2H_4SCMe_2}$, where the pyramidal inversion process does *not* produce distinct diastereomers but simply chemical enantiomers, the inversion process proceeds readily, and the 1,3-shifts only occur with relative difficulty at temperatures where the inversion process is rapid, causing the other sulphur lone pair to be less favourably positioned than in the mono-substituted ligand complexes

[$M(CO)_5$($\overline{SC_2H_4SCHR}$)] (M = Cr, W; R = Bu^t, Ph)

These complexes exhibited similar variable-temperature NMR spectral features to the 2-methyl 1,3-dithiolane complexes. The significant difference was that because of the greater steric factors associated with Bu^t and Ph groups compared to Me, only a single solution species was detected at low temperatures. This is confidently attributed to the structure with the $M(CO)_5$ group *trans* to the ring substituent. Since only one invertomer species is thermodynamically favoured, the sulphur inversion process cannot be monitored. The variable-temperature spectra imply that any tendency of the coordinated sulphur atom to invert its configuration leads to a 1,3-shift (via the pseudo-seven-coordinate intermediate, Fig. 5) and/or ligand dissociation.

DISCUSSION

The results of the NMR band shape and coalescence temperature measurements are collected in Table 5. Most of the data refer to tungsten complexes which were most thermally stable in solution. Despite the somewhat limited amount of data certain clear points of discussion arise.

Firstly, for the unsubstituted and symmetrical 2,2-disubstituted 1,3-dithiolanes, sulphur inversion and 1,3-metal shifts are quite separate, uncorrelated processes, $\Delta G^{\ddagger}$ (298 K) values being in the region of 40–44 and 78 kJ mol^{-1}, respectively. Secondly, in the case of 2-substituted 1,3-dithiolane complexes, the steric constraints of the 2-substituent favour the 1,3-shift mechanism and cause

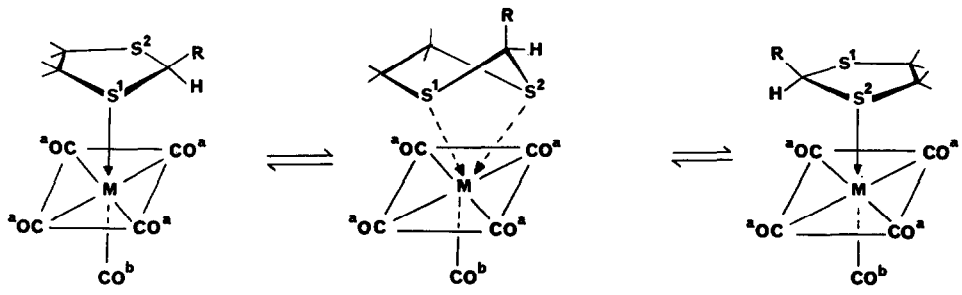


Fig. 5. The proposed mechanism of the 1,3-metal shift fluxion in [$M(CO)_5$($\overline{SC_2H_4SCHR}$)] complexes via the pseudo-seven-coordinate metal intermediate. The carbonyls are labelled to indicate the stereochemical rigidity of the $M(CO)_5$ moiety.

this fluxion to be indistinguishable in NMR terms from the sulphur inversion process. An analogous lowering of the activation energies of 1,3-metal shifts was observed in the six-membered trithian complexes $[W(CO)_5(\overline{SCH_2SCH_2SCH_2})]$ and $[W(CO)_5(\overline{SCHMeSCHMeSCHMe})]$ (Table 5). Thirdly, the significantly lower sulphur inversion energy for the molybdenum complex compared to the tungsten complex is in line with more extensive data[1] which reflect combined metal electronegativity and $(p\text{–}d)\pi$ ligand–metal interactions. In this present work we were unable to measure a sulphur inversion energy for $[Cr(CO)_5(\overline{SC_2H_4SCH_2})]$ due to solution decomposition, but a $\Delta G^{\ddagger}$ value of 44.5 ± 1.5 kJ mol^{-1} has recently been reported elsewhere.[18] This value, however, is of questionable accuracy as it is based on a simplified DNMR analysis of a solution which, the authors claim, consists of both mono- and bis-$Cr(CO)_5$ complexes of 1,3-dithiolane plus free ligand. Nevertheless, the lower limit of this value would bring it in line with the expected trend in inversion energies, namely Mo < Cr < W. Fourthly, no clear dependence of ligand ring size on the inversion energy is apparent in this series of $W(CO)_5$ complexes. This is in contrast to the series $[MX_2\{\overline{S(CH_2)_n}\}_2]$ ($M = Pd^{II}$, Pt^{II}, $n = 3$–5)[19] where a decrease in ring size constrains access to the planar transition state and thus increases the activation energy of sulphur inversion. In the present work the $\Delta G^{\ddagger}$ (298 K) value for $[W(CO)_5\overline{SC_2H_4SCH_2}]$ is anomalously low, but this may simply indicate that comparisons between ligands with different numbers of heterocyclic atoms are not valid. In contrast, the 1,3-shift energies *do* appear to show a clear dependence on ring size, the order being, five-membered < six-membered < eight-membered < open chain. This reflects the previously noted[3,5] dependence on ligand flexibility, although it should be noted that the difference in shift energies between five- and six-membered rings is very slight (Table 5).

A further point of interest in these fluxional complexes concerns the nature of the $W(CO)_5$ moiety, particularly during the 1,3-shifts. This has already been investigated in the cases of the complexes $[W(CO)_5L]$ (L = $MeSCH_2SMe$, $\overline{SCHMeSCHMeSCHMe}$ and $\overline{SC_2H_4SCMe_2}$) by two-dimensional exchange NMR spectroscopy (2D-EXSY).[20] No carbonyl scrambling was noted either in the absence or presence of 1,3-shifts, implying a remarkable stability of the square pyramidal geometry of $W(CO)_5$. Clearly this moiety remains bonded to the ligand in some formal sense throughout the metal shift process (Fig. 5). No evidence for a highly fluxional "naked" $W(CO)_5$ moiety[21] is available and the 1,3-shift can be envisaged as simply a lateral movement of a rigid $W(CO)_5$ moiety.

COPPER(II) COMPLEXES WITH 1-(2-CARBAMYLETHYL)-2-ALKYLIMIDAZOLES

M. CLARA R. M. P. BASTO and ADÉLIO A. S. C. MACHADO*

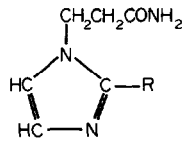
Department of Chemistry, Faculty of Science, University of Oporto,
P 4000 Oporto, Portugal

(*Received* 19 *July* 1989; *accepted* 22 *September* 1989)

Abstract—Complexes of copper(II) and 1-(2-carbamylethyl)-2-alkylimidazoles have been studied. The following have been synthesized and characterized by spectral (vis–UV, IR and EPR) and variable temperature magnetic data: $CuX_2(CIm)_4$ (X = ClO_4, Cl, Br, NCS) and $CuX_2(CMIm)_4 \cdot H_2O$ (X = Cl, Br), tetragonally distorted hexa-coordinated; $CuX_2(CIm)_2$ (X = Cl, Br), square distorted tetra-coordinated or bridged with higher coordination number; and $CuCl_2(CEIm)_2$, whose geometry was not unequivocally characterized.

Complexes of imidazole and derivatives have been thoroughly investigated and are important, for instance, as biochemical, analytical, industrial and anticancer reagents.[1–7] In a project in progress in this department, we have been investigating complexes of 1-(2-carbamylethyl)-2-alkylimidazoles (alkyl = R) both in the solid state[8] and in solution.[9,10] These imidazole derivatives include two

R = H	CIm
R = CH_3	CMIm
R = C_2H_5	CEIm



important coordinating groups in bioinorganic chemistry, imidazole and amide, and three potential coordinating positions: the unsaturated nitrogen atom of the heterocyclic ring and the oxygen and nitrogen atoms of the amide group (however, the literature suggests that the last only coordinates when the amide group is deprotonated[11]). To study the coordinating abilities of these ligands we have tried the preparation of a large variety of their complexes with metals of the first transition series and have studied properties of the synthesized complexes. In the present paper, the study of compounds obtained from the ligands and copper(II) halides or pseudo-halides is reported.

EXPERIMENTAL

Chemicals

CIm was prepared according to Dowbenko *et al.*[5] (m.p. 141–144°C; ref. 5 143–145°C). Analysis: Found (Calc.): C, 51.6 (51.8); N, 30.4 (30.2); H, 6.5 (6.5)%. CMIm and CEIm were synthesized by a similar procedure from acrylamide and the corresponding 2-alkylimidazole. Yields: CMIm, 53%; CEIm, 30%. M.p. CMIm, 162–166°C; CEIm, 120–122°C. Analysis: Found (Calc.): CMIm, C, 54.7 (54.9); N, 27.4 (27.4); H, 7.2 (7.2). CEIm, C, 57.5 (57.5); N, 25.3 (25.1); H, 8.0 (7.8)%.

Commercial copper(II) salts were used without further purification. Copper(II) thiocyanate was obtained in methanol from copper(II) perchlorate and potassium thiocyanate.

Synthesis and analysis of the complexes

The complexes were obtained by the following general procedure. A solution of the copper(II) salt in methanol, dehydrated with 2,2′-dimethoxypropane, was added to a solution of the organic ligand in methanol. When no precipitate was obtained, the solution was concentrated by slow evaporation (IR lamp). The solids were filtered off and dried *in vacuo* (over P_4O_{10}). Some of the compounds are hygroscopic.

In the preparation of $CuBr_2(CIm)_2$ and

Table 1. Analytical data and some properties of the compounds

$CuCl_2(CEIm)_2$, brown oily products (a dark brown solid in the preparation of $CuBr_2(CMIm)_4 \cdot H_2O$) were obtained immediately after mixing the ligand and salt solutions. These were filtered off and discarded. The complexes precipitated upon leaving the mother solution at room temperature.

Carbon, nitrogen and hydrogen microanalysis were performed by the Microanalytical Unit of the Chemistry Department, Surrey University. The copper contents of the complexes were determined by titration with EDTA and the halogen contents by potentiometric titration with silver(I) nitrate, with ion-selective electrodes as indicator electrodes. Analytical results are presented in Table 1.

Physical measurements

The following equipment was used: Pye–Unicam SP700C spectrophotometer for electronic spectra of solid compounds (30–4.5 × 10^3 cm^{-1}) and a Varian–Cary 17DX spectrophotometer for spectra of solutions (30–8.0 × 10^3 cm^{-1}); Perkin–Elmer 457 spectrophotometer for IR spectra (KBr pellets, 4000–250 cm^{-1}); Newport Instruments Gouy balance for magnetic susceptibility determinations in the range from liquid nitrogen to room temperature ($Hg[Co(NCS)_4]$ was used as calibrating agent;[12] molar susceptibilities were corrected for diamagnetism by using Pascal's constants and for temperature independent paramagnetism, TIP = 0.75 mm^3 mol^{-1}[13]); Bruker ER200tt spectrophotometer for X-band EPR spectra (operated at ~9 GHz and 100 kHz field modulation); Metrohm E518 conductivity meter for measurements on methanolic solutions of the complexes (at 25°C).

RESULTS AND DISCUSSION

Synthesis

The colours, melting points and analytical data for the complexes are tabulated in Table 1.

Only bis- and tetrakis-complexes have been obtained. Attempts to prepare hexakis-complexes were unsuccessful, even with anions of very low coordinating tendency like perchlorate. This is not unexpected because copper(II) hexakis-complexes with N-coordinating ligands are rare.[14] Although a hexakis(imidazole)copper(II) nitrate has been reported,[15] no 1:6 copper(II) compounds with N-alkyl-substituted imidazoles[16,17] appear to be described in the literature.

Attempts to prepare copper(II) compounds with iodide and CIm were unsuccessful. Normally, copper(II) is reduced to copper(I) by iodide, but imidazole and N-methylimidazole stabilize the +2

oxidation state.[18,19] In the present case, grey–blue products were obtained from copper(II) and CIm, but their composition was slightly different from that expected for a 1:4 compound and we were unable to purify them. In contrast, unlike the results observed with imidazole or N-alkylimidazoles,[17,20] a thiocyanate copper(II) compound with CIm could be isolated.

Spectral properties of CuX_2L_4 *compounds*

The electronic spectra (Table 2) for $CuX_2L_4 \cdot xH_2O$ compounds are characterized by one broad *d–d* band in the visible region (16–18 × 10^3 cm^{-1}), with a more or less pronounced shoulder on the lower energy side [except for $Cu(NCS)_2(CIm)_4$], whose position is difficult to assign. These spectra are consistent with tetragonal environments for the copper(II) ion, the observed broad bands being assigned, assuming D_{4h} symmetry, to $^2B_{1g} \rightarrow {}^2B_{2g}, {}^2E_g$. Maxima are in the usually observed region for copper(II) compounds with nitrogen donor atoms and weakly coordinated anions[14] and, for the CIm compounds, are in the order $ClO_4^- > Br^- > Cl^- > NCS^-$, expected from decreasing distortion from octahedral symmetry as the anion coordinating power increases. The lower frequencies of band maxima for $CuX_2(CMIm)_4 \cdot H_2O$ are very probably due to the existence of a steric effect of the 2-methyl group (organic ligands being coordinated by the pyridine nitrogen atom of the imidazolic ring).

EPR data also support the tetragonal symmetry and nitrogen ligand coordination. Except for $Cu(NCS)_2(CIm)_4$, the EPR spectra for the powdered compounds, at room and liquid nitrogen temperatures, are all similar (Fig. 1), of axial type with $g_\parallel > g_\perp$, characteristic of monomeric tetragonal copper(II) complexes with a $d_{x^2-y^2}$ ground state. Partially resolved hyperfine structure due to copper is observed in the parallel signal and observed g values are in the ranges usually found for tetragonally distorted copper(II) compounds with four monodentate nitrogen donor ligands and weakly coordinated anions ($g_\parallel = 2.20$–2.30 and $g_\perp = 2.04$–2.09[21]). $Cu(NCS)_2(CIm)_4$ yields a pseudo-isotropic

[a] When not indicated, EPR parameters at 77 K for powdered compounds are equal to the parameters at 293 K.
[b] At 300 K.
[c] Nujol mull.
[d] Slightly magnetic field dependent.

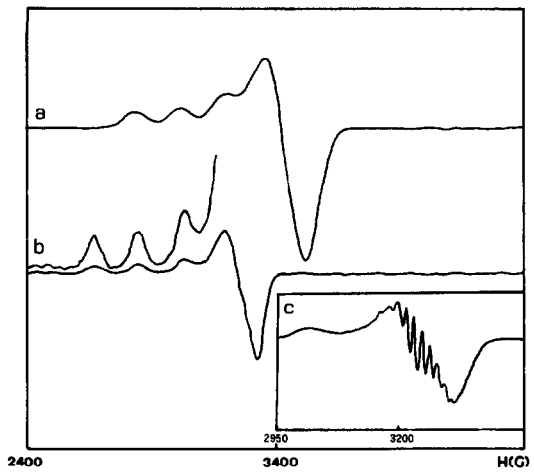

Fig. 1. EPR spectra of: (a) $CuBr_2(CIm)_4$, powder, at 293 K; (b) $CuCl_2(CIm)_4$, in methanol, at 77 K; (c) $CuCl_2(CIm)_4$, in methanol, at 77 K in the $g_\perp$ region.

spectrum, with one unsymmetrical band, probably due to large line widths with respect to the difference between $g_\parallel$ and $g_\perp$ values and the A value.

For tetragonally distorted octahedral copper(II) compounds, the value of $A_\parallel$ decreases and the $g_\parallel$ value increases when the strength of the axial ligands increases.[21] Present results for complexes with CIm are compatible with this order, from the compound with perchlorate to the two halide compounds. However, the observed differences are very small and may be not significant when compared to the experimental error.

The electronic spectra and electrical conductance data in methanol ($\sim 10^{-3}$ M) indicate that the compounds undergo some structural change in this solvent (anion substitution by solvent molecules). Observed molar conductance values are in the range usually found for 1:1 electrolytes ($CuCl_2(CIm)_4$, 114 S cm^2 mol^{-1}; $Cu(NCS)_2(CIm)_4$, 85.0 S cm^2 mol^{-1}) or even 1:2 electrolytes ($CuBr_2(CMIm)_4 \cdot H_2O$, 166 S cm^2 mol^{-1}).

The axial EPR spectra obtained in frozen solutions show (Fig. 1) superhyperfine structure, in the $g_\perp$ region, which indicates coordination of the organic ligands by nitrogen atoms. For complexes with CIm, $A_\parallel$ and $g_\parallel$ values (Table 2) are close to those obtained for powdered compounds, therefore, the interaction with the solvent seems to be unimportant.

Owing to the large number of bands due to the organic ligands and the limited range of the instrument used, IR spectra provided limited information. For $Cu(NCS)_2(CIm)_4$, the only band safely assigned is a band at 2065 cm^{-1} (C—N stretching of the nitrogen coordinated thiocyanate). Bands at 838 (CS stretching), 475 and 467 cm^{-1} (NCS bending) are tentatively assigned by comparison with spectra for $CuX_2(CIm)_4$.

Spectral properties of CuX_2L_2 *compounds*

Band maxima in the spectra of the two $CuX_2(CIm)_2$ compounds (at $15–16 \times 10^3$ cm^{-1}) and the very different spectrum for $CuCl_2(CEIm)_2$ (one shoulder at about 21.7×10^3 cm^{-1} and no visible or near-IR absorption band until 12.5×10^3 cm^{-1}) provide no unequivocal information about the ligand arrangements around copper(II). For $CuX_2(CIm)_2$ compounds, maxima positions are compatible with distorted octahedral geometries, which would imply polymeric structures, but distorted square geometries cannot be excluded. The spectrum of $CuCl_2(CEIm)_2$ is compatible with a pseudo-tetrahedral structure, but a dimeric pentacoordinated copper(II) compound might also be possible.

IR spectra for the CuX_2L_2 compounds, exhibit two well-resolved bands in the region 1550–1700 cm^{-1} with small displacements relative to the corresponding bands of the free ligand, but this alone cannot be taken as evidence of coordination by the amide group.[22,23]

EPR spectra for powdered CuX_2L_2 compounds are all different (Table 2). $CuCl_2(CIm)_2$ shows a three g value spectrum of the rhombic type, without resolved hyperfine splittings. This spectrum indicates a low symmetry environment around copper(II) and the absence of extensive exchange coupling. The X-band EPR spectrum of $CuBr_2(CIm)_2$ is isotropic, showing one broad band.

At room temperature, $CuCl_2(CEIm)_2$ exhibits a very broad EPR spectrum. The spectrum obtained at liquid nitrogen temperature yields three g values in the high field region ($\Delta M_S = \pm 1$) and shows a very weak-intensity feature at the $\Delta M_S = \pm 2$ region, but without any other signals. Therefore it is not characteristic of a dimeric copper(II) compound. In a rhombic type spectrum, the high value for g_1 could point to a distorted tetrahedral stereochemistry.

Magnetic properties

Magnetic results for $CuCl_2(CEIm)_2$ (Table 3) show that the molar magnetic susceptibility depends on temperature accordingly to the Curie–Weiss law. Magnetic moments do not depend on the temperature as expected for an orbitally non-degenerated ground state of a magnetically diluted compound. Therefore, magnetic data provide no

Table 3. Magnetic data for some of the compounds

Compound	T/K	μ (BM) 299.7	251.1	206.3	176.5	156.4	127.2	97.2	Curie–Weiss law[a] $10^5 C$ (m^3 mol^{-1} K)	θ	g

$CuBr_2(CIm)_4$		1.85	1.85	1.85	—	1.84	1.88	1.87	0.5319	2	2.13
$CuCl_2(CIm)_2$		1.82	1.84	1.84	—	1.84	1.85	1.85	0.5236	3	2.11
$CuBr_2(CIm)_2$		1.83	1.84	1.86	1.86	1.85	1.86	1.87	0.5260	4	2.11
$CuCl_2(CMIm)_4 \cdot H_2O$		1.81	1.83	1.83	1.83	1.83	1.85	1.85	0.5208	2	2.10
$CuCl_2(CEIm)_2$		1.91	1.93	1.93	1.93	1.93	1.94	1.93	0.5767	2	2.21

[a] Values of C and θ were obtained by least-squares adjustment of magnetic susceptibility data to the Curie–Weiss law, $\chi = C/(T-\theta)$. Values of the correlation coefficients were always greater than 0.9999 except for $CuCl_2(CMIm)_4 \cdot H_2O$ ($r = 0.9998$).

useful new elements for assignment of stereochemistry to the compound, since the low value for θ suggests no significant magnetic interaction between neighbouring metal ions and no reasonable results were obtained by fitting the magnetic data to the equation derived by van Santen *et al.*[24] (with $J' = 0$ and the g value obtained from the Curie–Weiss law) for dimeric copper(II) compounds. In conclusion, the spectral and the magnetic data neither clearly support a dimeric structure nor exclude the possibility of a monomeric distorted tetrahedral copper(II) compound.

Room temperature magnetic moments for all the compounds (Table 2) are above the spin-only value for a single copper(II) ion. The variable temperature date in the range 90–300 K for some of the $CuX_2L_4 \cdot xH_2O$ compounds (Table 3) show that their magnetic moments do not vary significantly with temperature as would be expected for monomeric tetragonally distorted octahedral copper(II) compounds, and their molar magnetic susceptibilities obey the Curie–Weiss law with very low θ values. Data for polycrystalline samples of $CuX_2(CIm)_2$ compounds show that magnetic moments increase slightly when the temperature decreases, but the positive Weiss constants are very small. Intramolecular magnetic interaction could be present if these compounds were polymeric with bridged halides, but these experimental results show no clear evidence of exchange interaction in the accessible temperature range (additional measurements at lower temperatures may clarify this point).

CONCLUSIONS

The copper(II) compounds with 1-(2-carbamylethyl)-2-alkylimidazoles and halides or thiocyanate, which we were able to synthesize, show two different stoichiometries, $CuX_2L_4 \cdot xH_2O$ and CuX_2L_2. Magnetic and spectral data obtained for the first type of compounds show that they have tetragonally distorted geometries with the organic ligands coordinated by the pyridine nitrogen of the imidazolic group. For $CuX_2(CIm)_2$ complexes, although not confirmed, a polymeric structure with bridged copper(II) ions cannot be ruled out. The properties measured for $CuCl_2(CEIm)_2$ allow no unequivocal conclusion about its stereochemistry.

Abstract—Attempts to prepare the metal tri-isopropoxides $M(OPr^i)_3$ (M = Sc, Y, In, Yb) by various methods always produced the pentanuclear oxoalkoxide clusters $[M_5(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_4(\mu_2\text{-}OPr^i)_4(OPr^i)_5]$ as the stable products. X-ray single crystal diffraction showed (M = In, Yb) the presence of the μ_5-oxygen atom bonded in a square pyramidal configuration to five metal atoms which had terminal isopropoxo groups *trans* to the oxo atom. The μ_3- and μ_2-isopropoxo groups contribute to the distorted octahedral coordination of each metal atom. The scandium, yttrium and ytterbium clusters could be sublimed *in vacuo* and gave mass spectra containing pentanuclear cluster ions. The ^1H NMR spectra for each compound was consistent with the X-ray crystal structure and variable-temperature studies showed fluxionality in the indium complex.

In recent years there has been a resurgence of interest in the application of metal alkoxides as precursors for the deposition of pure metal oxides using either sol–gel or MOCVD techniques.[1] The metal oxides and heterometal oxides are currently of considerable importance in the electronics, ceramics, glass and optical industries.

The alkoxides of yttrium,[2] indium[3] and ytterbium[4] have been known for some time whilst those of scandium[5,6] have received less attention. In attempting to prepare indium tri-isopropoxide from the reaction of indium trichloride with the requisite amount of sodium isopropoxide we obtained a crystalline product which surprisingly had the analysis corresponding to the novel pentanuclear oxoalkoxide $In_5O(OPr^i)_{13}$. Further work established that analogous compounds were given by scandium, yttrium and ytterbium and this was reported in a preliminary communication[7] which included the single crystal X-ray structure of the indium compound. We now report full details of our work including the single crystal X-ray structure of $Yb_5O(OPr^i)_{13}$. Quite independently the yttrium analogue $Y_5O(OPr^i)_{13}$ was discovered and fully characterized jointly by Professor Liliane Hubert-Pfalzgraf at Nice and Professor K. Caulton at Bloomington and their co-workers.[8]

RESULTS AND DISCUSSION

All attempts to prepare the tri-isopropoxides $M(OPr^i)_3$ (M = AC, Y, In, Yb) by a variety of methods resulted in the isolation of the pentanuclear species $M_5O(OPr^i)_{13}$ which were characterized by elemental analyses, NMR spectra, IR spectra and in some cases mass spectra (Sc, Y, Yb) and single crystal X-ray structures (In, Yb). Our results on the yttrium compound are in agreement with the independent work of Hubert-Pfalzgraf and co-workers.[8]

Preparation of $M_5O(OPr^i)_{13}$ (M = Sc, Y, In, Yb)

It was realized that our initial preparation of $In_5O(OPr^i)_{13}$ may have been caused by hydrolysis but repeated preparations using exceptional precautions to exclude water always resulted in the formation of the pentanuclear oxoalkoxide. The indium compound was prepared by reaction of

anhydrous $InCl_3$ with $NaOPr^i$ in a 1 : 3 molar ratio in a benzene–isopropanol mixed solvent. To check whether the isopropanol was implicated in the formation of the oxo species a reaction was carried out in benzene with sodium isopropoxide powder, from which all isopropanol had been removed, but the product was still $In_5O(OPr^i)_{13}$. The yields of $In_5O(OPr^i)_{13}$ were always less than 50% and the precipitated NaCl was heavily contaminated with some insoluble indium compound. When heated to 145°C/10^{-2} mm Hg this "NaCl" gave an off-white sublimate and the volatile products were isopropanol and acetone. This off-white indium-containing sublimate was extraordinarily air-sensitive rendering it practically impossible to characterize. However, an ^1H NMR spectrum (C_6D_6, 80 MHz) was obtained with signals at δ 1.50 (6 H, d, CH_3) and 4.67 (1H, CH) corresponding to a single isopropoxide species in contrast to the complex spectrum of $In_5O(OPr^i)_{13}$. The off-white sublimate contained no chloride and on heating to 130°C/10^{-2} mm Hg gave a small amount of sublimate but the major part decomposed to metallic indium. A solution of the sublimate in toluene at room temperature decomposed to indium within a few hours but was stable for several days at −20°C, during which colourless crystals were deposited. The behaviour of this compound suggests that it may be indium monoisopropoxide which would be expected to have a cubane tetrameric structure $(InOPr^i)_4$ analogous to the thallium(I) alkoxides.[9] In fact, further heating of the original precipitated "NaCl" to 230°C/10^{-2} mm Hg gave a red sublimate of InCl. When the pentanuclear oxo cluster $In_5O(OPr^i)_{13}$ was heated to 80°C/10^{-2} mm Hg some acetone and isopropanol were released but no indium compound was sublimed up to 170°C.

Treatment of anhydrous $ScCl_3$ with $NaOPr^i$ (1 : 3 molar ratio) in isopropanol gave, after removal of sodium chloride and solvent, a white solid which sublimed at 220–280°C/10^{-2} mm Hg accompanied by a more volatile liquid. The sublimate which contained no sodium gave a complex ^1H NMR spectrum, but after recrystallization from isopropanol gave a spectrum consistent with $Sc_5O(OPr^i)_{13}$. The volatile liquid was shown by ^1H NMR to be almost entirely isopropanol contaminated with a scandium species (peaks in the mass spectrum at *m/z*, 355, 281, 207 in addition to OPr^i, 59 and Sc, 45).

In another experiment freshly sublimed $Sc\{N(SiMe_3)_2\}_3$, obtained from the reaction of $ScCl_3$ and $LiN(SiMe_3)_2$,[10] suspended in a benzene–pentane mixture was treated with excess isopropanol under reflux. On cooling, a high yield of $Sc_5O(OPr^i)_{13}$ crystallized out and sublimed at 220–280°C/10^{-2} mm Hg.

The analogous pentanuclear clusters $M_5O(OPr^i)_{13}$ (M = Y, Yb) were obtained from the reaction of the respective metal with isopropanol catalysed by $HgCl_2$, although it had been reported previously that this method gave the metal tri-isopropoxides.[3] Indeed, both compounds could be sublimed at *ca* 220°C/10^{-2} mm Hg which is similar to the sublimation temperatures (Y, 200–210°C/0.1 mm Hg; Yb, 190–200°C/0.2 mm Hg) reported for the "tri-isopropoxides". Addition of excess isopropanol to $Y\{N(SiMe_3)_2\}_3$ at room temperature followed by removal of excess alcohol and $HN(SiMe_3)_2$ *in vacuo* left a solid which gave a ^1H NMR spectrum which was complex and different from that of $Y_5O(OPr^i)_{13}$. It remained unchanged in isopropanol solution for several days at room temperature but upon heating under reflux for 1 h it was converted into the pentanuclear oxoalkoxide. This suggests that $Y(OPr^i)_3$ is thermally unstable and is converted in boiling isopropanol to $Y_5O(OPr^i)_{13}$. It is noteworthy that Hubert-Pfalzgraf and co-workers[8] found that $Y_5O(OPr^i)_{13}$ did not react with aluminium tri-isopropoxide whereas their initial product of the reaction of yttrium and Pr^iOH did react to give the heterometal alkoxide $YAl_3(OPr^i)_{12}$.

It is significant that in spite of exceptional precautions to prevent hydrolysis we have isolated $M_5O(OPr^i)_{13}$ as the thermally stable species and not the previously reported metal tri-isopropoxides. The analytical data presented in Table 1 show that the two types of compound can be distinguished on the basis of their elemental analyses. The comparison of the IR data in Table 2 of $M_5O(OPr^i)_{13}$ and "$M(OPr^i)_3$" compounds shows striking similarities between them. This was also noted for $Y_5O(OPr^i)_{13}$ by Hubert-Pfalzgraf and co-workers.[8] The mechanism of the breakdown of the tri-isopropoxides to give the pentanuclear oxoalkoxides has not yet been elucidated because the presence of isopropanol renders it diffult to identify other volatile products such as propene or di-isopropyl ether. Elimination of alkene is facile for metal tertiary alkoxides[12] but we have found that yttrium tritertiary alkoxides can be prepared under similar conditions of reaction and can be sublimed unchanged.[13] It appears therefore that elimination of di-isopropyl ether may account for the presence of the oxo atom in the pentanuclear clusters:

$$5M(OPr^i)_3 \longrightarrow M_5O(OPr^i)_{13} + Pr^i_2O.$$

Mass spectra of $M_5O(OPr^i)_{13}$

The scandium, yttrium and ytterbium complexes all gave positive ions containing the pentanuclear

cluster (Table 1) but the indium complex was thermally unstable and gave no mass spectrum. For scandium, $[P-OPr^i]^+$ (where $P = M_5O(OPr^i)_{13}$; M = Sc) was the most abundant metal-containing species, whereas for yttrium the highest mass peak was $[P-Me]^+$ but the $[P-OPr^i]^+$ peak was considerably more abundant. For ytterbium, the highest mass peak corresponded to $[P-3(OPr^i)]^+$. In each case the fragmentation pattern was complex and attention was focussed on those peaks closest to the parent molecular ion P^+. The fact that numerous peaks near the parent ion were observed emphasizes the stability of the $M_5(\mu_5\text{-}O)O_{13}$ cluster.

NMR spectra of $M_5O(OPr^i)_{13}$

The ^{1}H NMR chemical shifts are presented in Table 1. The room temperature spectra of the scandium and yttrium clusters in C_6D_6 at 250 MHz were in agreement with the requirements of the single crystal X-ray structures found for $M_5O(OPr^i)_{13}$ (M = In and Yb, which are discussed later), namely four sharp doublets and associated septets in the ratio 4:4:4:1. The scandium compound in $C_6D_5CD_3$ gave a similar spectrum which was unchanged on heating to 90°C, thus showing that the alkoxo ligands were non-fluxional on the NMR timescale and even the terminal groups remained resolved in the 4:1 ratio (basal–apical). On some occasions the spectrum of the yttrium compound at room temperature (C_6D_6) was collapsed into one resolved peak and two broad peaks in the ratio 4:4:5 possibly due to exchange caused by the presence of a trace of isopropanol. In $C_6D_5CD_3$, the 4:4:5 spectrum was always observed and it remained unchanged up to 80°C showing that the μ_3- and μ_2-isopropoxides remained distinguishable from the terminal groups which had collapsed into one signal.

The paramagnetic ytterbium compound at 30°C gave four broad signals between δ +97 and −70 in approximately a 4:4:1:4 ratio due to the methyl groups, and four corresponding peaks for the methine protons between δ +191 and −134. On changing the temperature all of the peaks change in chemical shift due to the paramagnetism but the overall spectrum is unchanged. Thus at 90°C the spectrum covers the range δ +144 to −101. Whilst at −60°C the highest field signal is at δ −169.5 and the lowest field signal is beyond the range of the instrument (i.e. $> \delta$ +200).

By contrast, the ^{1}H NMR spectrum of the indium complex at room temperature showed only two ligand environments in the ratio 8:5. The minor doublet at higher field remained unchanged down to −80°C ($C_6D_5CD_3$, 400 MHz), whereas the major

doublet collapsed at *ca* −30°C (250 MHz) but gave two broad equal peaks at −60°C straddling the minor doublet. This behaviour demonstrated a greater lability of the isopropoxide groups in the indium cluster. Thus the μ_2- and μ_3-ligands were exchanging rapidly above −30°C (ΔG 43–49 kJ mol^{-1}) whilst the terminal ligands were inseparable down to −80°C. This suggests either that the terminal basal–apical exchange is much more facile than μ_2–μ_3 bridging exchange or, more likely, that the chemical shifts of the basal and apical terminal ligands are very close in value.

X-ray crystal structures of $[In_5O(OPr^i)_{13}]$ *and* $[Yb_5O(OPr^i)_{13}]$

We have already reported the molecular structure of $[In_5(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_4(\mu_2\text{-}OPr^i)_4(OPr^i)_5]$ which was determined by single crystal X-ray diffraction.[7] We have now found that the ytterbium analogue $[Yb_5(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_4(\mu_2\text{-}OPr^i)_4(OPr^i)_5]$ is isostructural with the same M_5O_{14} cluster framework. Whilst our work was in progress Hubert–Pfalzgraf and Caulton and their co-workers[8] independently determined the crystal structure of $[Y_5(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_4(\mu_2\text{-}OPr^i)_4(OPr^i)_5]$ and this compound is isostructural with the indium and ytterbium clusters. The structural unit M_5O_{14} is shown in Fig. 1 and the more important bond distances and bond angles are listed in Table 3. In essence, the structure contains a μ_5-oxygen bonded to five metal atoms in a square pyramidal configuration with four μ_2-isopropoxy groups bridging the four basal metal atoms. The four μ_3-isopropoxy groups occupy the triangular faces of the square pyramid. Each metal has one terminal isopropoxy group completing a

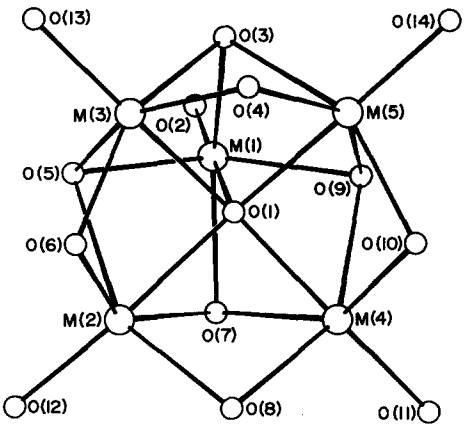

Fig. 1. The metal–oxygen core in $[M_5O(\mu_3\text{-}OPr^i)_4(\mu_2\text{-}OPr^i)_4(OPr^i)_5]$.

distorted octahedral coordination. It is interesting to note that the first example of a structurally characterized cluster molecular containing a μ_5-oxo atom was the organoyttrium methoxo compound $[Y_5(\mu_5\text{-}O)(\mu_3\text{-}OMe)_4(\mu_2\text{-}OMe)_4(C_5H_5)_5]$ reported by Evans and Sollberger.[14] In this case the terminal alkoxo groups have been replaced by η^5-Cp ligands. This reinforces our view that the $[M_5(\mu_5\text{-}O)(\mu_3\text{-}OR)_4(\mu_2\text{-}OR)_4]$ framework (M_5O_9) possesses special stability and must be the driving force for the breakdown of the tri-isopropoxides of scandium, yttrium, indium and ytterbium. Presumably the more stable tritertiary alkoxides[13] cannot attain the M_5O_4 cluster grouping because of steric hindrance and the metals are compelled to adopt a lower coordination number (except Y which gives trinuclear t-butoxide).

The metal–metal distances basal–basal and basal–apical are, respectively, 3.16 and 3.26 Å for indium and 3.26 and 3.38 Å for ytterbium and thus, as expected, there is no evidence for metal–metal bonding within these cluster molecules. The four basal metal atoms are virtually in a square with the μ_5-oxygen atoms slightly above this plane, e.g. 0.16 Å (In) and 0.19 Å (Yb). The apical metal atoms are closer to the μ_5-oxygen (2.21 Å In—O; 2.28 ÅYb—O) than the basal metal atoms (average 2.24 Å, In—O; 2.31 Å, Yb—O). The shortest M—O bonds involve the terminal isopropoxo groups with average bond lengths of 1.96 (In) and 2.00 Å (Yb). The μ_2-isopropoxo groups are symmetrically bonded to the basal metal atoms with average M—O bond lengths of 2.14 (In) and 2.19 Å (Yb). The μ_3-isopropoxy groups have shorter apical M—O bond lengths [average 2.22 (In) and 2.28 Å (Yb)] than the basal M—O bond lengths [average 2.34 (In) and 2.39 Å (Yb)]. The mean bond angles about the μ_5-oxygen are the same for each compound with the mean apical metal–oxygen–basal metal angles of 94.2 ± 0.6 (In) and $94.6\pm0.4°$ (Yb), reflecting the slight displacement of the μ_5-oxygen above the plane of the four basal metals. The angles subtended by the μ_5-oxygen and the basal metals are *cis*: 89.7 ± 0.7 (In) and $89.6\pm0.5°$ (Yb) and *trans*: 171.5 ± 1.1 (In) and $170.7\pm0.9°$ (Yb).

Hubart-Pfalzgraf and co-workers[8] have discussed the structure of $Y_5O(OPr^i)_{13}$ in relation to other cluster alkoxides of yttrium, viz. $[Y_3(OBu^t)_8Cl(THF)_2]$ and $[Y_4O(OBu^t)_{10}Cl_2]^{2-}$ isolated by Evans *et al.*[15] from reactions involving YCl_3 with $LiOBu^t$ or $NaOBu^t$, respectively. The formation of an octahedral configuration for yttrium was considered to be a driving force for the formation of the $Y_5O(OPr^i)_{13}$ structure with the interesting suggestion that the ultimate structure could be the anion $[Y_6O(\mu_2\text{-}OR)_{12}(OR)_6]^{2-}$ containing a μ_6-O octahedrally coordinated to six equivalent metal atoms. It is possible that the sodium salt of such a species is precipitated with NaCl in the reaction between MCl_3 and NaOR. In this respect it is also relevant to note that Andersen *et al.*[16] had earlier reported the neodymium complex chloride isopropoxide $[Nd_6(\mu_6\text{-}Cl)(\mu_3\text{-}OPr^i)_2(\mu_2\text{-}OPr^i)_9(OPr^i)_6]$ which contains a μ_6-Cl at the centre of a trigonal prismatic cluster of neodymium atoms.

EXPERIMENTAL

All operations were performed under an atmosphere of purified nitrogen using Schlenk-style apparatus and a glove box. Solvents were distilled from sodium benzophenone under nitrogen, and isopropanol was initially heated under reflux with CaO (preheated to 700°C) for several hours. Then a small quantity of dried benzene was added and the azeotropes (benzene–isopropanol–water, if still present, then benzene–isopropanol) were removed by fractional distillation; the remaining isopropanol was distilled onto activated 3 Å molecular sieves prior to use. Anhydrous $ScCl_3$ was prepared from the reaction of Sc_2O_3 with concentrated HCl followed by removal of H_2O/HCl *in vacuo*, then heating under reflux for 7 days with $SOCl_2$ (freshly distilled from linseed oil) and finally $SOCl_2$ was removed by distillation *in vacuo*. Anhydrous $InCl_3$ was obtained from commercial sources and heated *in vacuo* for several hours prior to use. Yttrium and ytterbium powder (40 mesh, 99.9%), sodium metal (lumps), and Bu^nLi (solution in hexane), were obtained from commercial sources. Hexamethyldisilazane was prepared by a literature route from reacting Me_3SiCl with ammonia.[11]

^1H NMR spectra were obtained using Bruker WP80 FT, WM250 FT and WH400 FT spec-

trometers; chemical shifts are quoted relative to tetramethylsilane, although calibration was made from the solvent signals from incomplete deuteration. IR spectra were recorded as Nujol mulls between CsI plates in the range 4000–200 cm^{-1} using a Perkin–Elmer 577 spectrophotometer, and mass spectra using a Kratos MS50 TC spectrometer. Metals were analysed gravimetrically as the oxide M_2O_3 by hydrolysis of a sample in a platinum crucible followed by heating in air to 650°C for In and 750°C for the others (for Y and Yb this was followed by heating in a roaring bunsen flame). The isopropoxide analyses were by the method of Bradley *et al.*[17]

(1) $Sc_5O(OPr^i)_{13}$

(a) Sodium (5.0 g, 0.22 mol) was added to isopropanol (250 cm^3) and heated under reflux for 2 h, after which dissolution of metal was complete. This was cooled to room temperature whereupon a solution of anhydrous $ScCl_3$ (11 g, 73 mmol) in

isopropanol (250 cm^3) was added. The mixture was heated under reflux for a further 2 h and then stirred at room temperature for 60 h. The white precipitate was filtered off and the solvent was removed *in vacuo* to leave a white residue. This was heated to 220°C/10^{-2} mm Hg whereupon sublimation began to occur, but was slow, and was therefore continued at up to 280°C/10^{-2} mm Hg; a more volatile liquid was also obtained in a trap held at −196°C (see Results and Discussion). The sublimate was recrystallized from isopropanol to give white needle *crystals* of $Sc_5O(OPr^i)_{13}$ (m.p. > 320°C, 2.5 g, 17% based upon $ScCl_3$). Further washing of the precipitate with isopropanol enhanced the yield slightly.

(b) The $(Me_3Si)_2NH$ (34.6 cm^3, 164 mmol) was cautiously added to Bu^nLi (53 cm^3 of 3.15 M solution, 0.17 mol) and then solvent was removed *in vacuo*. The residue was dissolved in tetrahydrofuran (100 cm^3) and to this a solution of $ScCl_3$ (8.4 g, 56 mmol) in tetrahydrofuran (100 cm^3) was added dropwise. After stirring at room temperature overnight the solvent was removed *in vacuo* and the residue was triturated with pentane (200 cm^3) and any undissolved solid was filtered off. The trituration, etc., was repeated with fresh pentane (200 cm^3) and the two filtrates were combined, concentrated *in vacuo* and held at −25°C, whereupon white crystals of $Sc[N(SiMe_3)_2]_3$ were obtained. These were sublimed at 110°/10^{-2} mm Hg (20.0 g, 69% based upon $ScCl_3$). A sample of the sublimate (8.5 g, 16 mmol) was suspended in benzene (250 cm^3) and isopropanol was added (20 cm^3, ~ fivefold excess), whereupon all the solid dissolved. The contents were heated under reflux for 1 h, then allowed to cool to room temperature, at which point solvents were removed *in vacuo* to leave a white residue. The residue was recrystallized from isopropanol to give white *crystals* of $Sc_5O(OPr^i)_{13}$ (2.1 g, 65% based upon $Sc[N(SiMe_3)_2]_3$).

(2) $Y_5O(OPr^i)_{13}$

To yttrium powder (25 g, 0.28 mol) were added a few small crystals of $HgCl_2$ followed by isopropanol (400 cm^3, large excess), and the contents were heated under reflux for 60 h. By this time most of the metal had dissolved but a small quantity of black solid remained, which was filtered off and discarded. Solvent was removed from the filtrate and a sample of the residue (6 g) was recrystallized from isopropanol to give white *crystals* of $Y_5O(OPr^i)_{13}$ (4.9 g, 7% yield based upon Y). The bulk of the residue was sublimed at 220°C/10^{-2} mm Hg, although presumably some decomposition also occurred since much non-volatile residue remained (sublimed yield of $Y_5O(OPr^i)_{13}$ was 22.2 g, 32% based upon Y). The combined yield of 39% would presumably have been much higher if the whole sample had been recrystallized.

(3) $In_5O(OPr^i)_{13}$

Sodium (34.7 g, 1.48 mol) was added to a mixture of isopropanol (200 cm^3, large excess) and benzene (800 cm^3) and the contents heated under reflux overnight, after which the metal had dissolved. To this was added a solution of $InCl_3$ (106 g, 0.48 mol) in isopropanol (500 cm^3) and the contents were heated under reflux for 2 h, after which they were cooled to room temperature and the white precipitate filtered off. Further extraction from the precipitate was attempted with isopropanol (200 cm^3), and the filtrates were combined and concentrated *in vacuo*, whereupon colourless *crystals* of $In_5O(OPr^i)_{13}$ were obtained (62 g, 48% based upon $InCl_3$). The compound began to turn yellow when heated to 160°C under an atmosphere of nitrogen.

(4) $Yb_5O(OPr^i)_{13}$

To ytterbium powder (10.2 g, 59 mmol) were added a few small crystals of $HgCl_2$ followed by isopropanol (250 cm^3, large excess), and the contents were heated under reflux for 24 h. The residual black solid was filtered off and solvent was removed from the filtrate *in vacuo*. The white residue was sublimed at 215°C/10^{-2} mm Hg as white *crystals* of $Yb_5O(OPr^i)_{13}$ (17.8 g, 86% based upon Yb). M.p. > 300°C.

X-ray crystallography

Crystals of the indium and ytterbium clusters used for the X-ray work were sealed under nitrogen in thin-walled glass capillaries. All crystallographic measurements were performed at 293 K using a Nonius CAD4 diffractometer and graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å), following previously detailed procedures.[18] The structures were solved by direct methods and refined by full-matrix least-squares analysis. For the indium compound all included atoms were refined anisotropically, but due to large thermal motion in the isopropyl groups, C—O and C—C distances were fixed at 1.40 and 1.50 Å, respectively. These distances were also fixed for the ytterbium compound, but in addition all carbon atoms were refined isotropically. No hydrogens were included for either compound.

Details of the crystal data, data collection and refinement are given in Table 4. Computer pro-

(*Received* 24 *July* 1989; *accepted* 27 *September* 1989)

Abstract—The tert-butylisocyanide substituted diethylaminocarbyne complex $I(CO)_2(t\text{-}BuNC)_2W{\equiv}CNEt_2$ (**1**) reacts with one equivalent of HI in CH_2Cl_2 at room temperature to yield a mixture of complexes $(I)_2(CO)_2(t\text{-}BuNC)W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]$ (**2**), major product, and $(I)_2(CO)(t\text{-}BuNC)_2W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]$ (**3**), minor product, separable by column chromatography on silica. The exclusive preparation of compound **3** can be achieved by treating $I(CO)(t\text{-}BuNC)_3W{\equiv}CNEt_2$ (**4**) with one equivalent of HI in CH_2Cl_2 at room temperature. Complexes **2** and **3** contain a 4e-donor alkyne ligand resulting from the proton-induced coupling of one tert-butylisocyanide with the diethylaminocarbyne ligand at a single tungsten centre. Both complexes react with t-BuNC in refluxing CH_2Cl_2 to give quantitatively the cationic alkyne complex $[I(CO)(t\text{-}BuNC)_3W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]]^+I^-$ (**5**). Thermal decarbonylation of this complex in toluene in the presence of t-BuNC at 90°C leads to the carbonyl-free alkyne complex $[I(t\text{-}BuNC)_4W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]]^+I^-$ (**6**). The ionic nature of **5** and **6** has been confirmed by comparison of their conductivity data in 1,2-dichloroethane with $NR_4^+X^-$ salts (R = alkyl; X = PF_6, Br, I). The composition and structure of the alkyne complexes **2**, **3**, **5** and **6** have been determined by total elemental analyses, IR, ^1H NMR and ^{13}C NMR spectroscopies and mass spectrometry. The spectroscopic results indicate a substantial bond delocalization and a hindered rotation of the diethylamino-group in the alkyne ligand. The barrier to this rotation is calculated to be *ca* 13.9–15.3 kcal mol^{-1} for compounds **2**, **3**, **5** and **6**.

Since the discovery of the first compounds containing a metal–carbon triple bond in 1973 by E. O. Fischer and co-workers,[1] considerable progress has been made in the field of transition metal carbyne complexes as shown by the large number of review articles[2–7] and a monograph,[8] which have appeared in the last 14 years. Carbyne complexes are divided into two classes. Class (a) contains compounds of low-valent metals known as Fischer-type carbyne complexes. In these complexes, the electron-rich metal centre is stabilized by good π-acceptor ligands such as CO, e.g. *trans*-$X(CO)_4M{\equiv}CR$ (X = halogen; M = Cr, Mo, W; R = alkyl, aryl).[9] Class (b) includes complexes of high-valent metals known as Schrock-type alkylidyne (carbyne) complexes. In these compounds, the electron-deficient metal is bonded to good π-donors, such as halogen, alkoxy or imido ligands, e.g. $X_3(dme)W{\equiv}C^tBu$ (X = halogen; dme = 1,2-dimethoxyethane).[10–13]

In this context, low-valent complexes containing a diethylamino-group in the carbyne moiety, e.g. $X(CO)_{4-n}L_nW{\equiv}CNEt_2$ (X = halogen; L = 2e-donor ligand; n = 1–4)[14–17] and $(\eta^5\text{-}C_5R_5)(CO)_2W{\equiv}CNEt_2$ (R = H, Me),[18–20] are very attractive because striking differences are observed in the reactivity of these complexes and that of analogous aryl- or alkylcarbyne complexes. Thus, $I(CO)_2L_2W{\equiv}CNEt_2$ (L = PMe_3, MeNC, t-BuNC, $P(OMe)_3$; L_2 = 2.2′-bipy, *o*-phen) and $(\eta^5\text{-}C_5R_5)(CO)_2W{\equiv}CNEt_2$ (R = H, Me) react with I_2 to yield, by partial oxidative decarbonylation, the seven-coordinated, carbonyl-containing compounds $I_3(CO)L_2W{\equiv}CNEt_2$ and $(\eta^5\text{-}C_5R_5)(CO)(I)_2W{\equiv}CNEt_2$, respectively.[19–25] These complexes

are unique because they combine features of both Fischer-type carbyne complexes, such as π-acceptor CO ligands, and Schrock-type alkylidyne complexes, i.e. a high-valent metal centre. In comparison, *trans*-$Br(CO)_4W{\equiv}CR$ (R = Me, CH_2CMe_3, Ph) react with Br_2 in dme to yield the octahedral coordinated, carbonyl-free, Schrock-type alkylidyne complexes $Br_3(dme)W{\equiv}CR$.[26]

Different products are also obtained from the reactions of diethylamino- and aryl- or alkylcarbyne complexes with nucleophiles, e.g. *trans*-$I(CO)_4W{\equiv}CNEt_2$ reacts with PMe_3 by CO elimination to give the mono- or disubstituted carbyne complexes $I(CO)_3(PMe_3)W{\equiv}CNEt_2$ or *cis,trans*-$I(CO)_2(PMe_3)_2W{\equiv}CNEt_2$.[21] However, the reaction of *trans*-$Br(CO)_4W{\equiv}CPh$ with PMe_3 results in addition of the nucleophile to the carbyne-carbon and formation of the ylide complexes $Br(CO)_3(PMe_3)W[C(PMe_3)Ph]$ and $Br(CO)_2(PMe_3)_2W[C(PMe_3)Ph]$.[27]

Nucleophiles induce a carbyne–carbonyl coupling in substituted aryl- or alkylcarbyne complexes to yield η^1- or η^2-ketenyl complexes. Representative examples of this pathway are the reactions of $Cp(CO)_2W{\equiv}CR$ (R = Ph, *p*-C_6H_4Me) with PMe_3 to $Cp(CO)(PMe_3)W[\eta^2\text{-}C(CO)R]$ or $Cp(CO)(PMe_3)_2W[\eta^1\text{-}C(CO)R]$,[28,29] $Br(CO)_2L_2W{\equiv}CR$ (L_2 = 2.2′-bipy, *o*-phen; R = Ph, Me) with KCN to $K[(CN)_2(CO)L_2W(\eta^2\text{-}C(CO)R)]$,[30,31] $[(CO)_2(dppe)W{\equiv}CCH_2Ph]BF_4$ with NaS_2CNMe_2 to $(\eta^2\text{-}Me_2NCS_2)(CO)(dppe)W[\eta^2\text{-}C(CO)CH_2Ph]$[32] and $Cl(CO)_2(py)_2W{\equiv}CPh$ with NaS_2CNEt_2 to $Na[(\eta^2\text{-}Et_2NCS_2)_2(CO)W(\eta^2\text{-}C(CO)Ph)]$.[33] In comparison, a nucleophile-induced carbonylation of the carbyne ligand has not been observed so far for the reactions of substituted diethylaminocarbyne complexes.[34–38]

Reactions of low-valent, substituted aryl- or alkylcarbyne complexes with electrophiles have also been extensively investigated. The electrophile can attack either the carbyne-carbon or the metal centre. Illustrative examples of the former to give carbene complexes are the protonations of $Cl(CO)(PPh_3)_2Os{\equiv}CR$ (R = *p*-C_6H_4Me), $Cp(CO)_2W{\equiv}CR$ (R = Me, *p*-C_6H_4Me) and $Cl(CO)(PMe_3)_3W{\equiv}CR$ (R = C_6H_5, *p*-C_6H_4Me) with HX (X = Cl, I) to $(Cl)_2(CO)(PPh_3)_2Os[C(H)R]$,[39] $Cp(I)(CO)_2W[C(H)R]$[40] and $(Cl)_2(CO)(PMe_3)_2W[C(H)R]$, respectively.[41] Protonation of the metal centre yields hydrido carbyne complexes shown by the reactions of $Cl(PMe_3)_4W{\equiv}CH$, $Cl(dmpe)_2W{\equiv}CR$ (R = H, ^{t}Bu) and $Br(PMe_3)_4W{\equiv}CPh$ with HX (X = Cl, Br) to $(Cl)_2(H)(PMe_3)_3W{\equiv}CH$, $[Cl(H)(dmpe)_2W{\equiv}CR]Cl$[42] and $(Br)_2(H)(PMe_3)_3W{\equiv}CPh$, respectively.[41] In a few cases, electrophile-induced carbon–carbon coupling reactions involving the carbyne ligand are observed, as in the transformation of $Cp(CO)_2W{\equiv}CR$ (R = Me, *p*-C_6H_4Me) by HBF_4 to the dinuclear, alkyne-bridged complex $[Cp_2(CO)_4(\mu\text{-}H)(\mu\text{-}RC{\equiv}CR)W_2]BF_4$[40,43] or by HCl to the η^2-acyl complex $Cp(Cl)_2(CO)W[\eta^2\text{-}C(O)CH_2R]$,[44] and in the carbonylation of $Cl(PMe_3)_4W{\equiv}CH$ in the presence of $AlCl_3$ to the alkyne complex $Cl(CO)(PMe_3)_3W[\eta^2\text{-}HC{\equiv}COAlCl_3]$.[45,46] In comparison, studies involving reactions of low-valent diethylaminocarbyne complexes with electrophiles are limited to a few examples, e.g. the protonation of $Cp(CO)_2W{\equiv}CNEt_2$ with HCl to give the carbene complex $Cp(Cl)(CO)_2W[C(H)NEt_2]$,[47] the addition of CO_2 across the metal–carbon triple bond in $[(CO)_4Mo(\mu\text{-}PPh_2)_2W(CO)_2(CNEt_2)]^-$[34] and the substitution reactions of $I(CO)_nL_{4-n}W{\equiv}CNEt_2$ (n = 1, 2; L = PMe_3, t-BuNC) with MeOTf to give $(OTf)(CO)_nL_{4-n}W{\equiv}CNEt_2$.[48]

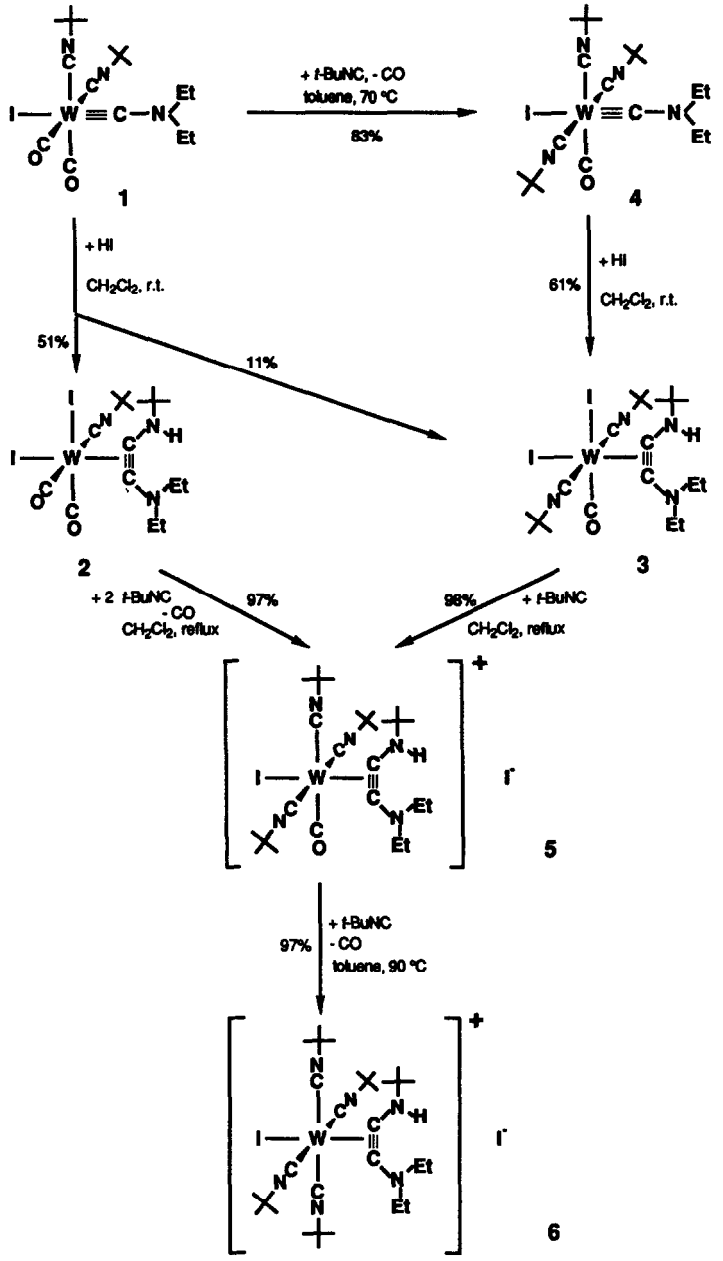
We have, therefore, been interested in the reactivity of electron-rich carbyne complexes towards electrophiles and developed synthetic routes to highly-substituted and carbonyl-free phenyl- and diethylaminocarbyne complexes.[16,17,21,23,49] We studied firstly the reactions of $X(CO)_n(t\text{-}BuNC)_{4-n}W{\equiv}CPh$ (X = Br, I; n = 0, 1) with HX (X = Br, I), found a clean proton-induced coupling reaction of one tert-butylisocyanide with the phenylcarbyne ligand at tungsten to yield an alkyne complex, and then demonstrated the effect of CO ligands on the reaction pathway.[50] These results are important in the context of the reductive coupling of two alkylisocyanide ligands to give a bis(amino)acetylene ligand in seven-coordinated isocyanide complexes of molybdenum and tungsten, reported by Lippard and co-workers.[51–53] They assume for this reaction the intermediate formation of an isocyanide substituted carbyne complex.[54] For rhenium, they have isolated such a carbyne isocyanide complex, but have failed to demonstrate coupling of the two ligands.[55]

In this paper we describe the proton-induced isocyanide–carbyne coupling reaction in diethylaminocarbyne complexes of tungsten. A preliminary report of this work has already been published.[56]

RESULTS AND DISCUSSION

The bis(tert-butylisocyanide) substituted diethylaminocarbyne complex **1** reacts with HI (generated from NEt_4I and $HBF_4 \cdot Et_2O$) to yield a mixture of the alkyne complexes $(I)_2(CO)_2(t\text{-}BuNC)W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]$ (**2**) and $(I)_2(CO)(t\text{-}BuNC)_2W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]$ (**3**) (Scheme 1).

Complex **2**, the major product, is separated from



Scheme 1. Synthesis and reactions of the coupling products **2**, **3**, **5** and **6**.

complex **3**, the minor product, by column chromatography on silica gel at 0°C and is isolated as a red, microcrystalline solid in 51% yield. Complex **3**, a purple microcrystalline solid, is obtained in 11% yield. Complexes **2** and **3** are soluble in CH_2Cl_2, Et_2O and toluene, but insoluble in *n*-pentane. They decompose in a sealed capillary at 95 and 128°C, respectively. Complex **3** can be prepared from **1** following a two-step route. The first step involves the transformation of **1** into the tris(tert-butylisocyanide) substituted carbyne complex **4**. Complex **4** reacts then with HI to form exclusively **3**, which is isolated after purification by column chromatography on silica gel in 61% yield (Scheme 1).

The reaction time for formation of the coupling products with HI is appreciably shorter for **4** than for **1**. This result suggests that an increase in electron density at the tungsten centre accelerates the isocyanide–carbyne coupling reaction.

The reaction of **2** with t-BuNC in refluxing CH_2Cl_2 results in elimination of one CO and one

iodide ligand from the coordination sphere and quantitative formation of the cationic complex **5** (Scheme 1). Complex **5**, which can also be prepared from **3** and t-BuNC in refluxing CH_2Cl_2, reacts further with t-BuNC in toluene at a higher temperature (90°C) to produce quantitatively the carbonyl-free, cationic complex **6** (Scheme 1). Complexes **5** and **6** are isolated as red and purple, microcrystalline solids, respectively, which are very soluble in CH_2Cl_2, sparingly soluble in toluene, but insoluble in Et_2O and *n*-pentane. Complex **6** decomposes in a sealed capillary at 160°C.

Attempts to prepare the neutral, carbonyl-free analogue of **2** or **3** $(I)_2$(t-BuNC)$_3$W[η^2-(t-Bu)HN-C≡C-NEt$_2$] by thermal decarbonylation of **5** in toluene at 90°C have so far failed. The only product isolated is **6** along with decomposition products.[57]

The coupling products **2**, **3**, **5** and **6** are best considered as isocyanide-substituted complexes containing a 4e-donor (tert-butylamino)diethylaminoacetylene ligand. The reality of 4e donation of the alkyne ligand to tungsten is indicated for these complexes by the spectroscopic data (cf. for example ^{13}C NMR spectra, Table 4) and substantiated by their lack of chemical reactivity. They are not only thermally stable, crystalline solids, but also decompose slowly in the presence of atmospheric water and oxygen. These properties are not consistent with a 16e tungsten(II) formulation for complexes **2**, **3**, **5** and **6** counting the alkyne ligand as 2e-donor.[58] The consideration of **2**, **3**, **5** and **6** as complexes containing a 4e-donor alkyne ligand is also supported by the close similarity to the structurally characterized complexes [X(t-BuNC)$_4$M[η^2-(t-Bu)HN-C≡C-NH(t-Bu)]]Y (X = Cl, Br, I, CN; M = Mo, W; Y = Cl, I, BF_4, PF_6) containing a 4e-donor bis(tert-butylamino)acetylene ligand.[52,59] These complexes have been previously prepared by reductive coupling of two isocyanide ligands in the seven-coordinated complexes of the general formula [M(t-BuNC)$_6$X]$^+$ (M = Mo, W) and [Mo(t-BuNC)$_7$]$^{2+}$.[51,53]

The diethylaminocarbyne complexes, **1** and **4**, do not react with NEt_4I. The presence of a proton source (in this case HBF_4) is necessary to initiate the isocyanide–carbyne coupling reaction. We suggest, therefore, that the first step in the reaction sequence, leading from the carbyne complex to the coupling product, involves protonation of the carbyne complex.

Figure 1 illustrates one possible reaction mechanism for this proton promoted carbon–carbon coupling reaction. The initial step involves proton attack on the isocyanide nitrogen to form a cationic bis(aminocarbyne) intermediate (**A**).

This transformation of an isocyanide to an aminocarbyne ligand upon protonation has been previously observed in isocyanide complexes of electron-rich metals, e.g. in the reaction of *trans*-Mo(MeNC)$_2$(dppe)$_2$ with one or two equivalents of $HBF_4 \cdot Et_2O$ to give the cationic aminocarbyne complex *trans*-[(MeNC)(dppe)$_2$W≡CNHMe]BF_4 and the dicationic bis(aminocarbyne) complex *trans*-[(dppe)$_2$Mo(≡CNHMe)$_2$]$(BF_4)_2$, respectively,[60–62] or in the reaction of *trans*-ReCl(RNC)(dppe)$_2$ (R = H, Me, t-Bu) with $HBF_4 \cdot Et_2O$ to yield the cationic aminocarbyne complexes *trans*-[Cl(dppe)$_2$Re≡CNHR]BF_4.[63,64]

The second step (Fig. 1) involves coupling of the two carbynes to a bis(amino)alkyne ligand, a reaction which is possibly promoted by the nucleophile I^-. A similar carbyne–carbyne ligand coupling reaction at a single tungsten centre has previously been proposed to account for formation of the alkyne complex $(Br)_2(CO)(PPh_3)_2W[\eta^2$-CH$_3$-C≡C-C$_6H_5$] from the anionic carbyne complex Li[Br(CO)$_2$(PPh$_3$)(η^1-CH$_3$CO)W≡CC$_6$H$_5$], oxalylbromide and PPh_3,[65] and is in agreement with theoretical predictions on carbyne–carbyne coupling in bis(carbyne) complexes by Hoffmann *et al.*[66]

Other reaction pathways for the proton-promoted isocyanide–carbyne coupling involving proton attack at the carbyne-carbon or at the metal centre to give carbene or hydrido carbyne intermediates should also be considered since the formation of such products has been previously observed in protonation reactions of substituted, low-valent carbyne complexes.[39–42] Currently,

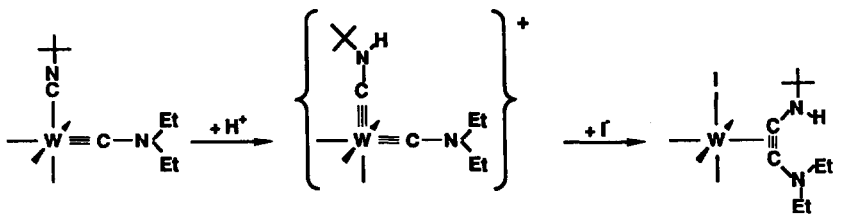


Fig. 1. Possible mechanism for the proton-promoted isocyanide–carbyne coupling reaction.

experimental work is underway in an attempt to trap intermediates to distinguish between the possible pathways for the coupling reaction.

The solution IR spectra of **2**, **3**, **5** and **6** in CH_2Cl_2 show characteristic absorptions for the stretching vibrations of the coordinated tert-butylisocyanide and carbonyl ligands (Table 1). The relative position of these ligands in the coordination sphere is indicated by the number and relative intensity of the ν(C≡N^{t}Bu) and ν(C≡O) absorption bands. Thus, two bands of almost equal intensity are observed for the *cis*-oriented carbonyl ligands in **2** and one band for the two *trans*-positioned tert-butylisocyanide ligands in **3**, resulting, respectively, from the symmetric A_1 and antisymmetric B_1 CO stretching mode in **2** and the A_2 isocyanide stretching mode in **3**.[67] The *trans*-orientation of the four tert-butylisocyanide ligands in **6** gives rise to a strong absorption at 2125 cm^{-1} and a weak, higher energy band at 2175 cm^{-1}, which can be assigned, respectively, to the E and A_1 isocyanide stretching modes.[68]

A shift of the ν(C≡N^{t}Bu) absorptions to lower frequency is observed when the IR data of **2** with **3** or **5** with **6** are compared. This shift can be attributed to an increase in the electron density at the metal and the simultaneous strengthening of the metal–isocyanide back-bonding resulting from substitution of one carbonyl (better π-acceptor) in **2** and **5** by one isocyanide ligand (poorer π-acceptor) in **3** and **6**.[68]

Two IR bands characterize the presence of the (tert-butylamino)diethylaminoacetylene ligand in the coupling products. A ν(N—H) absorption band ~3330 cm^{-1} (complexes **2** and **3**) and ~3230 cm^{-1} (complexes **5** and **6**) (Nujol mull) and another absorption band ~1630 cm^{-1} (CH_2Cl_2 solution), which can be assigned to a ν(C=N) stretching vibration. Similar absorption bands ~1600–1700 cm^{-1} have been previously reported for complexes containing amino-substituted alkyne ligands and have also been assigned to a ν(C=N) and not to a ν(C=C) stretching vibration of the coordinated alkyne ligand (Table 1).[50,51,53] This assignment is supported by the fact that a ν(C≡C) stretching vibration has so far not been observed for alkyl- or aryl-substituted alkyne ligands acting as 4e-donors in d^4 metal complexes.[69,70]

Several resonance forms can be used to describe the metal–alkyne bond in the coupling products **2**, **3**, **5** and **6** and are depicted in Fig. 2. The mesomeric formulas **A**–**D** represent the alkyne ligand acting as a 4e-donor. The complexes **2**, **3**, **5** and **6** thus achieve a closed shell configuration. The fairly high-frequency of the ν(C=N) stretching vibration in **2**, **3**, **5** and **6**, which is comparable with that in immonium cations $(R_2C{=}NR_2)^+$ [ν(C=N): 1640–1690 cm^{-1}],[71] is consistent with a strong contribution of the canonical forms **B**, **C** and **D** to the structure. Its value is, however, lower than for the analogous (tert-butylamino)phenylacetylene complexes $(Br)_2(CO)(t\text{-BuNC})_2W[\eta^2\text{-}(t\text{-Bu})HN\text{-}C{\equiv}C\text{-}C_6H_5]$ and $[I(t\text{-BuNC})_4W[\eta^2\text{-}(t\text{-Bu})HN\text{-}C{\equiv}C\text{-}C_6H_5]]^+PF_6$ (Table 1). Similarly, the ν(C≡N^{t}Bu) and ν(C≡O) stretching vibrations of **3** and **6** are observed at lower frequency than for the analogous (tert-butylamino)phenylacetylene complexes (Table 1), indicating the stronger donor properties of the (tert-butylamino)diethylaminoacetylene ligand.

Variable temperature NMR studies indicate fluxional behaviour for complexes **2**, **3**, **5** and **6**. The fluxionality is best explained by rotation of the diethylamino-group around the C_{alkyne}—N bond in

Table 1. ν(N—H), ν(C≡N^{t}Bu), ν(C≡O) and ν(C=N) stretching vibrations (in cm^{-1}) of the alkyne complexes **2**, **3**, **5** and **6** and of related compounds

the alkyne ligand. Thus, the low temperature limit spectra show two distinct triplets indicating different environments for the methyl protons of the diethylamino-group (Table 2). Two different signals are also observed for the methylene groups. In complexes **3**, **5** and **6** the protons of each methylene group are homotopic and give rise to a quartet. In comparison, complex **2** contains diastereotopic protons in both methylene groups. Therefore a signal of four partially overlapping quartets results for each methylene group (Table 2), which can be assigned to an ABX_3 spin system.

The two distinct signals for the methyl groups broaden upon heating the samples and then collapse to one signal at the coalescence temperature (Table 3). The signals of the methylene protons exhibit similar behaviour as the temperature is raised. The high temperature limit spectra of complexes **3** and **6** have been recorded in CD_2Cl_2 using sealed NMR tubes ($T > 40°C$) and exhibit only one triplet for the methyl and one quartet for the methylene protons indicating an averaged environment for the ethyl groups. The activation barrier for rotation of the diethylamino-group, $\Delta G^{\dagger}(T_c)$, was calculated from the Eyring equation after the Gutowsky–Holm equation was employed to obtain k_{ex} at the coalescence temperature (methyl protons) (Table 3).[72,73]

The signals for the tert-butylisocyanide ligands and the tert-butylamino-group in the alkyne ligand are independent of this dynamic process indicating

Table 2. ^1H NMR spectroscopic data of **2**, **3**, **5** and **6** in CD_2Cl_2; chemical shifts (in δ) relative to the solvent ($CDHCl_2$, $\delta = 5.32$ ppm); relative intensities and multiplicities in parentheses, coupling constants in Hz

Table 3. Rotational activation barriers, $\Delta G^{\dagger}(T_c)$ and coalescence temperatures, T_c, (270 MHz) of complexes **2**, **3**, **5** and **6**

Complex	T_c (K)	$\Delta G^{\dagger}(T_c)$ (kcal mol^{-1})
2	303	14.9
3	278	13.6
5	313	15.3
6	283	13.9

that rotation of the diethylamino-group causes the observed fluxionality. Thus, in the temperature range −80 to +40°C only one singlet is observed for the tert-butyl protons of the two and four, *trans*-oriented isocyanide ligands in **3** and **6**. In **5**, two singlets with a 2 : 1 intensity ratio indicate the *meridional* arrangement of the three tert-butylisocyanide ligands. Moreover, two singlets with a relative ratio of 1 : 9 are observed for all complexes and are assigned, respectively, to the N—H proton and the tert-butyl protons of the alkyne ligand.

Assuming a near coplanarity of the diethylamino-, the tert-butylamino-group and the alkyne-carbon atoms, two isomers (**A** and **B**, Fig. 3) may be expected for complexes **2**, **3**, **5** and **6**, which differ in the relative orientation of the tert-butylamino- and the diethylamino-group in the alkyne ligand. However, ^{1}H NMR spectra show the presence of only one isomer even at low temperature where interconversion of the two possible isomers due to rotation of the tert-butylamino-group around the C_{alkyne}—N bond can be excluded (cf. rotation of the diethylamino-group).

X-ray structures of the related complexes [X(t-BuNC)$_4$Mo[η^2-(t-Bu)HN-C≡C-NH(t-Bu)]]Y (X = Br, I, CN; Y = I, PF_6, BPh_4)[51–53,59] containing a bis(tert-butylamino)acetylene ligand show the presence of only one (isomer **A**) of the three possible isomers depicted in Fig. 4. The molybdenum atom, the halogen ligand, X, and the NCCN atoms of the alkyne ligand are coplanar in the observed isomer **A** (Fig. 4). However, the protons bonded to the nitrogen atoms are distorted out of the plane to diminish the H ··· H steric repulsion that would result if the tert-butylamino-groups were rigidly coplanar with the NCCN fragment.[59] Therefore, the sterically more crowded isomers **B** and **C** are not observed (Fig. 4).

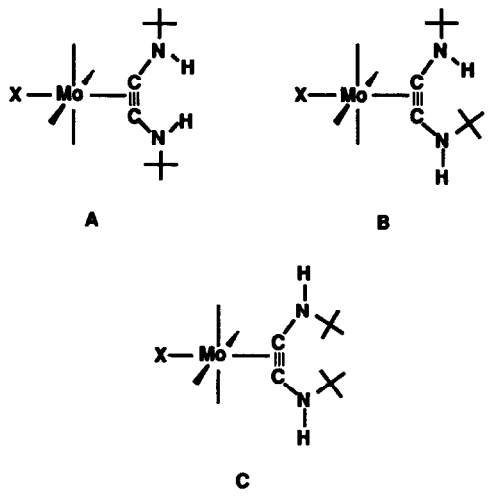

Fig. 4. Three possible isomers for complexes containing a bis(tert-butylamino)acetylene ligand.

Similarly, steric factors have also been used to explain the presence of only isomer **A** (Fig. 5) in the complexes [X(t-BuNC)$_4$W[η^2-(t-Bu)HN-C≡C-C_6H_5]]$^+PF_6^-$ (X = Cl, Br, I) containing a (tert-butylamino)phenylacetylene ligand.[50] In accordance with these data we suggest that in complexes **2**, **3**, **5** and **6** isomer **A** (Fig. 3) is thermodynamically favoured because of steric reasons.

The ^{13}C NMR data of compounds **2**, **3**, **5** and **6** are summarized in Table 4. ^{13}C NMR spectra of the complexes **2**, **3**, **5** and **6** have been recorded below the coalescence temperature. Therefore all complexes exhibit two resonances for the methylene- and two resonances for the methyl-carbon atoms of the inequivalent ethyl groups (Table 4).

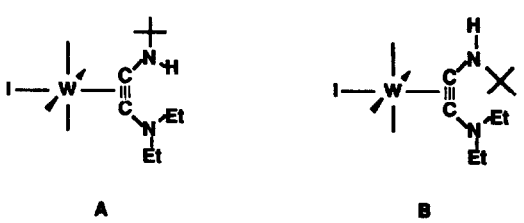

Fig. 3. Two possible isomers for complexes **2**, **3**, **5** and **6** resulting from the relative orientation of the amino-groups in the alkyne ligand.

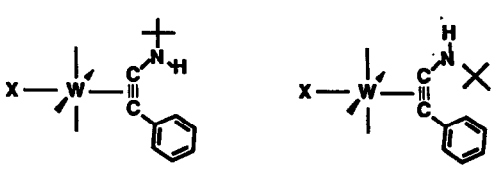

Fig. 5. Two possible isomers for complexes containing a tert(butylamino)phenylacetylene ligand.

[a] Signal for the mutually *trans*-oriented isocyanide ligands.
[b] Signal for the isocyanide ligand with a *trans*-orientation relative to CO.

Two distinct environments are observed for the *cis*-coordinated carbonyl ligands in **2** and the *meridional* arranged isocyanide ligands in **5**. However, the two isocyanide ligands in **3** and the four isocyanide ligands in **6** are *trans*-arranged and therefore chemical shift equivalent. All these results are consistent with a *trans*-orientation of one iodide to the alkyne ligand in the pseudo-octahedral coordinated complexes **2**, **3**, **5** and **6**.

The chemical shift of the alkyne-carbon atoms bound to a metal have been correlated with the extent of donation from the filled alkyne π-orbital to a vacant metal $d\pi$-orbital indicating the electron-donor properties of the alkyne ligand.[74] ^{13}C resonances nearly 200 ppm downfield from Me_4Si are observed for the alkyne carbons in complexes, where the alkyne ligand is acting as a 4e-donor. Their position is ~80 ppm downfield of that observed for alkyne ligands acting as 2e-donors.[69,74–76] A comparison of these results with the ^{13}C resonances observed for the alkyne ligand carbons in **2**, **3**, **5** and **6** (174.9–186.9 ppm, Table 4) and in the structurally related complexes [I(t-BuNC)$_4$W[η^2-(t-Bu)HN-C≡C-NH(t-Bu)]]I (δ_C = 181.5 ppm, $CDCl_3$ solution, RT)[53] and [I(t-BuNC)$_4$W[η^2-(t-Bu)HN-C≡C-C$_6$H$_5$]]PF_6 (δ_C = 193.6 and 206.1 ppm, CD_2Cl_2 solution, RT)[50] suggests a 4e-donation from the alkyne ligand to the metal centre in **2**, **3**, **5** and **6**.

The isocyanide carbons in **2**, **3**, **5** and **6** appear as broad singlets in the range 140–149 ppm because of the quadrupol relaxation of nitrogen. Therefore a ^{13}C–^{14}N coupling cannot be resolved. Comparing the data of **2** with **3** and **5** with **6**, a downfield shift for the isocyanide-carbon resonances is observed. This can be explained by the stronger metal–isocyanide backbonding in **3** than **2** and in **6** than **5** and is consistent with the trend found for the chemical shift of isocyanide carbons in other tungsten complexes.[16,17,22,24,77,78] A similar relationship has been observed in tungsten carbonyl complexes between the strength of the metal carbonyl backbonding and the chemical shift of carbonyl carbons[79] and is apparent in the CO resonances of **2** and **3** (Table 4).

The mass spectral data of **2**, **3**, **5** and **6** are collected in Table 5. The neutral complexes **2** and **3**, under EI conditions, reveal characteristic fragmentation patterns of complexes containing CO and t-BuNC ligands. Loss of CO and t-BuNC, or elimination of isobutene ($Me_2C{=}CH_2$) from the t-BuNC ligand and the tert-butylamino substituent in the alkyne ligand is observed.[16,17,24,25,49,50,77]

Using the SIMS method for the ionic complexes **5** and **6** the parent cations [I(CO)(t-BuNC)$_3$W[η^2-(t-Bu)HN-C≡C-NEt$_2$]]$^+$ (K^+: m/z = 756) and

$[I(t\text{-}BuNC)_4W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]]^+$ (K^+: $m/z = 811$) are observed, respectively, and confirm their ionic composition. The fragmentation patterns of **5** and **6** are the same as that of **2** and **3**. The equivalent conductance, Λ, of 1,2-dichloroethane solutions of **5** and **6** (**5**: $c = 4.8 \times 10^{-4}$ mol dm^{-3}, $T = 19.8°C$, $\Lambda = 35\ \Omega^{-1}\ cm^2\ mol^{-1}$; **6**: $c = 5.3 \times 10^{-4}$ mol dm^{-3}, $T = 19.8°C$, $\Lambda = 40\ \Omega^{-1}\ cm^2\ mol^{-1}$) has been calculated from the ratio of the measured specific conductivity and the equivalent concentration.[80] It has comparable values with the equivalent conductance of $NR_4^+X^-$ salts (R = ^{n}Bu, ^{n}Pr; X = Br, I, PF_6) and other ionic tungsten complexes in 1,2-dichloroethane.[22–24,77,81,82]

CONCLUSION

We have discovered a new reaction path for low-valent, tert-butylisocyanide-substituted tungsten diethylaminocarbyne complexes involving a proton-induced carbon–carbon coupling reaction of one isocyanide with the carbyne ligand to yield an amino-substituted alkyne ligand, and have shown that an increase of the electron density accelerates the isocyanide–carbyne coupling reaction at the tungsten centre. We have further demonstrated that the presence of one or two CO ligands in the coordination sphere of tungsten does not strongly affect the course of the reaction, i.e. formation of the coupling products. In comparison, tert-butylisocyanide-substituted phenylcarbyne complexes have also been previously shown to undergo a proton-induced isocyanide–carbyne coupling reaction, which, however, is dramatically influenced by the presence of even one CO ligand in the coordination sphere.[50] This proton-induced isocyanide–carbyne coupling reaction represents an important step in the recently proposed mechanism by Lippard and co-workers for reductive coupling of two alkylisocyanide ligands at one molybdenum or tungsten centre involving isocyanide-substituted aminocarbyne intermediates.[54] For rhenium they have isolated such a carbyne isocyanide complex but have failed to achieve coupling of the two ligands.[55] The close structural relationship between the coupling products **2**, **3**, **5** and **6** containing a 4e-donor (tert-butylamino)diethylaminoacetylene ligand and the previously reported products from reductive coupling of two tert-butylisocyanide ligands containing a bis(tert-butylamino)acetylene ligand[51–53,59] provides further support for Lippard's mechanistic proposal for the reductive coupling of two isocyanide ligands.

Current experiments are underway to elucidate

the mechanism for the proton-induced isocyanide–carbyne coupling reaction. We have suggested an attractive mechanism involving bis(aminocarbyne) intermediates and have briefly mentioned alternative pathways involving the intermediate formation of isocyanide-substituted carbene or hydrido carbyne complexes. These mechanistic suggestions are based upon known reactivity patterns of low-valent isocyanide and carbyne complexes towards electrophiles.[39–42,47,60–64]

EXPERIMENTAL

$I(CO)_2(t\text{-}BuNC)_2W{\equiv}CNEt_2$ (**1**) and $I(CO)(t\text{-}BuNC)_3W{\equiv}CNEt_2$ (**4**) were synthesized as described previously.[16,22] t-BuNC was prepared according to the literature,[83] distilled and stored under nitrogen. All other reagents were commercially available. All operations were carried out under a nitrogen atmosphere using Schlenk tube techniques. The solvents were dried and purified by standard methods (*n*-pentane, toluene, Et_2O over sodium wire; CH_2Cl_2 over P_4O_{10} and Na/Pb alloy) followed by distillation under an atmosphere of nitrogen. All column chromatography was performed by using silica gel (Merck, 0.063–0.02 mm, activity 1, dried *in vacuo* and stored under nitrogen) as the stationary phase and a thermostated column of 45 cm length and 1.5 cm diameter. Elemental analyses were determined by the Microanalytical Laboratory of this department. IR spectra were obtained with a Nicolet DX 5 FT spectrophotometer. NMR spectra were measured with Jeol GX 270 and GX 400 FT instruments and mass spectra with a Varian MAT CH7 spectrometer using EI conditions for complexes **2** and **3** and the SIMS method for complexes **5** and **6**. Conductance measurements were carried out as described elsewhere.[22,23,77,81,82]

(1) $(I)_2(CO)_2(t\text{-}BuNC)W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]$ (2)

To a yellow solution of **1** (360 mg, 0.58 mmol) in CH_2Cl_2 (60 cm^3) was added first NEt_4I (160 mg, 0.62 mmol) as a solid and then dropwise at $-30°C$ a solution of $HBF_4 \cdot Et_2O$ (0.080 cm^3, 0.58 mmol) in CH_2Cl_2 (10 cm^3). The reaction mixture was slowly warmed to room temperature. After 24 h the solvent was removed *in vacuo* and the oily red residue dissolved in CH_2Cl_2 and purified by column chromatography on silica gel at 0°C. Elution with Et_2O–pentane (3 : 1) afforded a purple band, from which complex **3** was isolated as a purple, microcrystalline solid after crystallization from Et_2O–pentane (50 mg, 11% relative to **1**). Complex **3** was identified by comparison of its IR and NMR spectra with that of an authentic sample [prepared as described under (2)].

Further elution with Et_2O gave a red band, which afforded complex **2** as a red, microcrystalline solid after evaporation of the solvent and crystallization from Et_2O–pentane (220 mg, 51% relative to **1**). (Found: C, 27.8; H, 3.9; I, 33.3; N, 5.5; O, 4.3; W, 24.6. $C_{17}H_{29}I_2N_3O_2W$ (745.09) requires: C, 27.4; H, 3.9; I, 34.1; N, 5.6; O, 4.3; W, 24.7%.)

(2) $(I)_2(CO)(t\text{-}BuNC)_2W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]$ (3)

To a mixture of **4** (240 mg, 0.36 mmol) and NEt_4I (95 mg, 0.37 mmol) was added first CH_2Cl_2 (60 cm^3) and then dropwise at $-30°C$ a solution of $HBF_4 \cdot Et_2O$ (0.048 cm^3, 0.35 mmol) in CH_2Cl_2 (10 cm^3). The colour of the reaction mixture turned from yellow first to orange and then, upon warming to room temperature, to red. After 1 h the solvent was evaporated *in vacuo*, the residue was dissolved in CH_2Cl_2 and purified by column chromatography on silica gel at 0°C. Elution with Et_2O–pentane (3 : 1) gave a purple band, which yielded complex **3** as a purple, microcrystalline solid after evaporation of the solvent and crystallization from Et_2O–pentane (175 mg, 61% relative to **4**). (Found: C, 31.7; H, 4.6; I, 31.2; N, 6.9; O, 2.1; W, 21.9. $C_{21}H_{38}I_2N_4OW$ (800.22) requires: C, 31.5; H, 4.8; I, 31.7; N, 7.0; O, 2.0; W, 23.0%.)

(3) $[I(CO)(t\text{-}BuNC)_3W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]]^+ I^-$ (5) *from* **2** *and* t-BuNC

A solution of **2** (200 mg, 0.27 mmol) and t-BuNC (0.050 cm^3, 0.44 mmol) in CH_2Cl_2 (50 cm^3) was refluxed for 5 h. Evaporation of the solvent *in vacuo* and crystallization of the residue from CH_2Cl_2–Et_2O yielded complex **5** as a red, microcrystalline solid (230 mg, 97% relative to **2**). (Found: C, 35.6; H, 5.6; I, 28.4; N, 8.1; O, 2.0; W, 20.1. $C_{26}H_{47}I_2N_5OW$ (883.35) requires: C, 35.3; H, 5.4; I, 28.7; N, 7.9; O, 1.8; W, 20.8%.)

(4) $[I(CO)(t\text{-}BuNC)_3W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]]^+ I^-$ (5) *from* **3** *and* t-BuNC

A solution of **3** (120 mg, 0.15 mmol) and t-BuNC (0.02 cm^3, 0.18 mmol) in CH_2Cl_2 (30 cm^3) was refluxed for 3 h. The resulting red solution was worked up as described under (3) and complex **5** isolated as a red, microcrystalline solid (130 mg, 98% relative to **3**). Complex **5** was characterized spectroscopically.

$[I(t\text{-}BuNC)_4W[\eta^2\text{-}(t\text{-}Bu)HN\text{-}C{\equiv}C\text{-}NEt_2]]^+ I^-$ (**6**)

A solution of **5** (300 mg, 0.34 mmol) and t-BuNC (0.045 cm^3, 0.4 mmol) in toluene (30 cm^3) was heated at 90°C for 4 h. The solution was reduced in volume and an Et_2O–pentane mixture was added. The almost colourless supernatant solution was removed and the purple microcrystalline solid dried *in vacuo* (310 mg, 97% relative to **5**). (Found: C, 38.6; H, 6.3; I, 26.2; N, 8.9; W, 20.1. $C_{30}H_{56}I_2N_6W$ (938.47) requires C, 38.4; H, 6.0; I, 27.0; N, 9.0; W, 19.6%.)

(*Received* 6 *June* 1989; *accepted* 27 *September* 1989)

Abstract—A crystal structure analysis of $[CuN(CH_2CH_2N{=}CH{-}C_6H_5)_3]^+[BPh_4]^-$ reveals that the complex has approximate three-fold symmetry in the solid state with the copper(I) atom having trigonal-pyramidal geometry. Principal dimensions are Cu—N (apical) 2.232(2), Cu—N(equatorial) 2.004, 2.006 and 2.019(2) Å, N(ap)—Cu—N(eq) 83.7–84.6(1)°. The Cu···H distances to the *ortho*-phenyl hydrogen atoms are too long to be considered agostic. The ^{1}H NMR spectrum is consistent with a similar structure for the copper(I) cation complex in solution.

The structural chemistry of copper(I) and copper(II) complexes of various tripodal ligands has been discussed by Zubieta *et al.*[1] A recent review[2] has also described the X-ray analyses of several divalent transition metal complexes of the potentially heptadentate Schiff base ligand tris-[(4-pyridyl)-3-aza-3-butenyl]amine, $N\{CH_2CH_2N{=}CH(C_5H_4N)\}_3$, abbreviated as py_3tren; other abbreviations are: tren = $N\{CH_2CH_2NH_2\}_3$, $S_3tren = N\{CH_2CH_2N{=}CH(C_4H_3S)\}_3$ and $Ph_3tren = N\{CH_2CH_2N{=}CH(C_6H_5)\}_3$. Our laboratories have undertaken the spectroscopic and structural characterization of copper complexes of new Schiff base ligands derived from tris(2-aminoethyl)amine (tren), and the tripodal nature of the Schiff base ligand, S_3tren, has been reported.[3] This paper describes the coordination geometry of a copper(I) complex of another tren derivative, tris[4-phenyl-3-aza-3-butenyl]amine (Ph_3tren).

The copper(I) complex $[Cu(Ph_3tren)][BPh_4]$ was obtained by adding an excess of $NaBPh_4$ to a stirred acetone solution of $Cu(OAc)_2 \cdot 2H_2O$ and Ph_3tren. $[Cu(S_3tren)][BPh_4]$ can be isolated in an analogous fashion using the preformed Schiff base ligand S_3tren. A series of copper(II) salts, $Cu(S_3tren)X_2$, has been isolated by the reaction of CuX_2 (X = Cl, Br, N_3, NCS, ClO_4) with S_3tren; similar reactions with Ph_3tren are under study.[4]

The structure of $[Cu(Ph_3tren)][BPh_4]$ has been determined crystallographically (Fig. 1).† The geometry about the copper(I) centre is a distorted trigonal pyramid comprised of four nitrogen donor atoms. The Cu—N distances to the equatorial nitrogens [N(1), N(2), N(3)] are 2.019(2), 2.006(2) and 2.004(2) Å, respectively, while the N(1)—Cu—N(2), N(2)—Cu—N(3) and N(1)—Cu—N(3) angles are 112.3(1), 127.8(1) and 116.7(1)°, respectively. The copper atom sits 0.208(1) Å above the plane of the equatorial azomethine nitrogen atoms, while the apical tertiary amine atom (N) lies 2.024(2) Å below that plane; the Cu—N distance is 2.232(2) Å and the

† Crystal data for $C_{51}H_{50}CuN_4B$, $M_r = 793.3$, monoclinic, space group $P2_1/n$, $a = 12.078(4)$, $b = 17.669(2)$, $c = 19.913(3)$ Å, $\beta = 94.32(2)°$, $V = 4238(3)$ Å^3, $Z = 4$, $D_c = 1.24$ g cm^{-3}, $\mu = 5.5$ cm^{-1}, $F(000) = 1672$, Mo-K_α radiation ($\lambda = 0.71073$ Å), $T = 21°C$. 9658 reflections were measured on a CAD4 diffractometer ($2\theta_{max} = 54°$), 9234 were unique and 4277 had $I > 3\sigma(I)$. Lorentz, polarization and Gaussian absorption corrections were applied. The structure was solved using the heavy-atom method. Refinement (with weights derived from the counting statistics) by full-matrix least-squares calculations (with all hydrogen atoms allowed for but not refined) converged with $R = 0.036$ and $wR = 0.042$ for the 4277 observed reflections. An extinction correction was also refined. The final cycle of refinement had 515 variables and maximum shift/error ratio of 0.02. A final difference map had no chemically significant features. Full details of the analysis are available from the Cambridge Crystallographic Data Centre or from the authors.

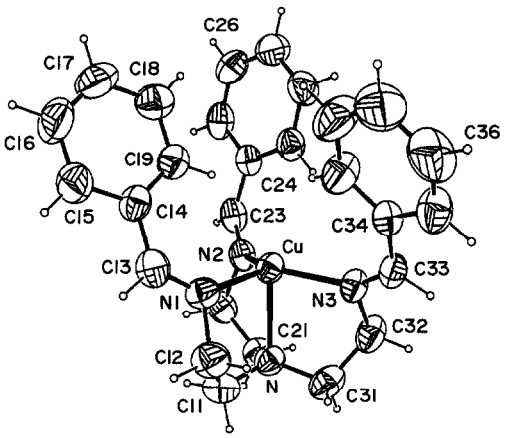

Fig. 1. A view of the $[CuN(CH_2CH_2N{=}CH{-}C_6H_5)_3]^+$ cation with the crystallographic numbering scheme; ellipsoids are at the 50% level.

N—Cu—N(1), N—Cu—N(2) and N—Cu—N(3) angles are 83.9(1), 84.6(1) and 83.7(1)°, respectively. These structural parameters are similar to those reported by Zubieta *et al.*[1] for $[Cu(pmas)]^+$, where pmas is the tripodal ligand $N(CH_2py)(CH_2CH_2SR)_2$: Cu—N(ap) = 2.158(8), Cu—N(py) = 2.035(10) Å, and copper is 0.077 Å from the equatorial plane.

A feature of the cation geometry is the conformation adopted by the complex in the solid state as shown in Fig. 1. The cation has approximate three-fold symmetry and three *ortho*-hydrogen atoms complete a distorted trigonal antiprism around the copper centre, with Cu···H distances 2.55, 2.62 and 2.71 Å, too long to be considered agostic. To accommodate this conformation there is substantial angle opening in the Cu—Nx = Cx3—Cx4—Cx9 (x = 1–3) portion of the molecule (details in Table 1). The Cu—Nx = Cx3 angles have a mean value of 136.6(2)° and the mean Nx = Cx3—Cx4 angle is 125.8(3)°. There are no untoward intermolecular contacts and presumably the conformation adopted in the crystal structure serves to minimize intramolecular and crystal packing forces. This bonding situation is somewhat similar to that exhibited by the pyramidal lithium atom in $[Li(\mu\text{-OAr-2,6-Ph}_2)_3Sn]$, wherein the Li···H distance to one of the *ortho*-hydrogen atoms of one of the aryloxide side-chain phenyl groups was found to be 2.695(9) Å. The authors[5] considered the possibility that very weak agostic interactions to three *ortho*-CH bonds stabilized the electron-deficient lithium atoms. Such two-electron three-centre bonds, represented by C—H→M, have been shown to be widespread in organometallic chemistry[6] and are proposed as precursor species in the skeletal rearrangement of hydrocarbons on metals.[7] A relevant example of an M···H interaction that only arises because of ligand geometry was described by Deeming *et al.*[8] Their X-ray analysis of square-planar $PdCl_2$(mpq), where mpq is (8-methyl-2-quinolylmethyl)di-t-butylphosphine, showed that distortions occurred which drastically reduced the 8Me···Pd and 8Me···Cl interactions. Similarly, the Cu···H dis-

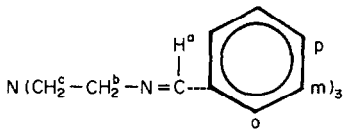
Table 2. ^{1}H NMR data for the ligand and the copper complex

Compound	δ (ppm)[a] and J (Hz)
Ph_3tren[b]	8.08 (H_a), 7.49 (H_o, d, J = 8.0), 7.39 (H_p, t, J = 7.3), 7.34 (H_m, t, J = 7.6), 3.68 (H_b, t, J = 6.1), 2.93 (H_c, t, J = 6.3)
$[Cu(Ph_3tren)][BPh_4]$[c]	8.68 (H_a), 8.17 (H_o, d, J = 8.0), 7.45 (H_p, t, J = 7.3), 7.34 (H, phenyl, m), 6.95 (H_m, t, J = 7.6), 6.92 (H, phenyl, t, J = 7.4), 6.77 (H, phenyl, t, J = 7.2), 4.03 (H_b, t, J = 5.3), 3.29 (H_c, t, J = 5.6)

[a] d = doublet, t = triplet, m = multiplet.
[b] $CDCl_3$ solution.
[c] $(CD_3)_2CO$ solution.



tances in the $[Cu(Ph_3tren)]^+$ cation appear to be influenced by intramolecular forces rather than an agostic interaction. In uncomplexed S_3tren[3], the corresponding C—N=C and N=C—C angles are close to the ideal undistorted value and lie in the ranges 117.7(3)–118.5(3) and 121.9(3)–123.1(3)°, respectively. The tetraphenylborate anion has the usual tetrahedral geometry with B—C 1.634–1.651(4), mean 1.644 Å. Other dimensions in the cation and anion are in accord with anticipated values.

The ^{1}H NMR spectrum of the complex, compared with that of the free ligand (Table 2), clearly shows coordination of all four nitrogen donor atoms by the downfield shift of resonances due to adjacent protons. The shift is most marked for the azomethine protons [(H_a), 0.60 ppm] but still significant (0.35 ppm) for the bridging ethylene protons (H_b, H_c). Resonances due to the phenyl ring protons are also shifted considerably, especially for the *ortho*-protons [(H_o) 0.68 ppm]. These shifts are attributable to electronic effects due to conjugation with the C=N linkage rather than a consequence of any interaction of *ortho*-hydrogen atoms with the copper atom; it is noteworthy that the *ortho*-hydrogen atoms on each ring remain equivalent in the complex, i.e. each phenyl ring undergoes free rotation, at least in solution.

(*Received* 10 *July* 1989; *accepted* 27 *September* 1989)

Abstract—The clean conversion of the complexes $Re_2X_4(LL)_2$ [X = Cl when LL = $Ph_2PCH_2PPh_2$ (dppm) and X = Br when $Ph_2AsCH_2AsPh_2$ (dpam)] to pure *trans*-$Re_2(O_2CR)_2X_2(LL)_2$ occurs when these complexes are reacted with $[(Ph_3P)_2N]O_2CR$ (R = CH_3, C_2H_5, C_6H_4 or 4-C_5H_4N) in CH_2Cl_2 at room temperature. When these same reactions are carried out in refluxing ethanol, the related *cis* isomers are formed when R = CH_3 or C_2H_5; in the case of $Re_2(O_2CC_6H_5)_2Cl_2(dppm)_2$ a mixture of *cis* and *trans* isomers is produced, whereas for $Re_2(O_2C\text{-}4\text{-}py)_2Cl_2(dppm)_2$ (4-py = 4-C_5H_4N) the *trans* isomer is again produced. When *trans*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ (R = CH_3 or C_2H_5) are heated in ethanol for *ca* 3 h, isomerization to *cis*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ takes place. The structure of *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ was established by X-ray crystallography. The crystallographic data for $Re_2(O_2CCH_3)_2Cl_2(dppm)_2 \cdot C_7H_8 \cdot 2H_2O$ are as follows: monoclinic space group $C2/c$, $a = 22.247(7)$, $b = 19.257(7)$, $c = 14.358(4)$ Å, $\beta = 94.73(2)°$, $V = 6129(6)$ Å^3 and $Z = 4$. The structure was refined to $R = 0.042$ ($R_w = 0.056$) for 3110 data with $I > 3.0\sigma(I)$. The molecule contains *trans* dispositions of bridging acetate and dppm ligands. The Cl—Re—Re—Cl unit approaches linearity, with Re—Re—Cl angles of 175.76(6)°. The Re—Re distance of 2.2763(7) Å is consistent with the presence of a Re—Re triple bond.

In an earlier study[1] we showed that the dirhenium(III) complexes $Re_2(\mu\text{-}O_2CR)_4X_2$ (R = CH_3, C_2H_5, or C_6H_5; X = Cl or Br) react with the diphosphine ligand $Ph_2PCH_2PPh_2$ (abbreviated dppm) in refluxing alcohol (methanol or ethanol) to give *cis* and *trans* isomers of the dirhenium(II) complexes $Re_2(\mu\text{-}O_2CR)_2X_2(\mu\text{-}dppm)_2$. The *cis* isomers were obtained conveniently and in moderately high yield when the reactions were carried out for several days with stoichiometric ratios of reactants (dppm: $Re_2(O_2CR)_4X_2$) of *ca* 6:1. Shorter reaction times (1 day or less) and smaller stoichiometric ratios (*ca* 4:1) favoured the formation of the *trans* isomers, but in no instance were we able to isolate the pure *trans* form; these were always present as components of *cis–trans* mixtures. The aforementioned results are important for two reasons. Firstly, the complexes represent the first examples of isomeric metal–metal bonded systems in which the two bridging diphosphine ligands are in *cis* and *trans* arrangements to one another. Secondly, unlike the α- and β-isomeric forms of $Re_2Br_4(depe)_2$ (depe = $Et_2PCH_2CH_2PEt_2$),[2] $Re_2X_4(dppee)_2$ (X = Cl or Br; dppee = $Ph_2PCH{=}CHPPh_2$)[2,3] and $Re_2X_4(dppe)_2$ (X = Cl or Br; dppe = $Ph_2PCH_2CH_2PPh_2$),[3,4] which contain chelating (α) or bridging (β) forms of the bidentate phosphine ligands, the $Re_2(\mu\text{-}O_2CR)_2X_2(\mu\text{-}dppm)_2$ complexes exhibit relatively large differences (*ca* +0.5 V) in

* Author to whom correspondence should be addressed.

the values of the half-wave potentials for the Re_2^{5+}/Re_2^{4+} and Re_2^{6+}/Re_2^{5+} couples.

In order to study these systems in greater detail, we set out to find a more convenient synthetic route to the *trans* isomers. In so doing, we discovered that the dirhenium(II) complexes $Re_2X_4(LL)_2$, where X = Cl or Br and LL = dppm[5] or dpam ($Ph_2AsCH_2AsPh_2$),[6] within which the bridging ligands are already *trans* to one another,[7] react rapidly with the carboxylate salts $[PPN]O_2CR$ ($PPN^+ = (Ph_3P)_2N^+$; R = CH_3, C_2H_5, C_6H_5 or 4-py) in dichloromethane at room temperature to give *trans*-$Re_2(O_2CR)_2X_2(LL)_2$. These same reagents react to give *cis*-$Re_2(O_2CR)_2X_2(LL)_2$ when the reactions are carried out in refluxing ethanol. In addition to describing these synthetic details, we also report the full structural characterization of *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$.

EXPERIMENTAL

Starting materials

The complexes *trans*-$[Re_2(O_2CC_6H_5)_2Br_2(dppm)_2]Br$,[1] $Re_2Cl_4(dppm)_2$[1] and $Re_2Br_4(dpam)_2$[6] were prepared as described previously. Cobaltocene, bis(triphenylphosphine)iminium chloride and the reaction solvents were obtained from commercial sources and were used as received.

Reaction procedures

Syntheses were performed under an atmosphere of dry nitrogen under the overpressure provided by a mineral oil manometer. Solvents were thoroughly deoxygenated prior to use.

(A) *Synthesis of* $[PPN]O_2CR$ (R = CH_3, C_2H_5, C_6H_5 *or* 4-py)

Except for a slight modification in the work-up procedure, the acetate salt was prepared as described in the literature.[8] The other derivatives were prepared and worked up by the use of a similar procedure, the general description of which is as follows. A quantity (1 g) of [PPN]Cl was dissolved in a minimum volume of warm water (60–80°C). A warm concentrated solution of NaO_2CR (usually containing 5–10 g of the salt) was added to the chloride solution with constant stirring. The mixture was cooled to 0°C in an ice-water bath. The precipitate was filtered off, washed with copious amounts of diethyl ether, and dried *in vacuo*. The salt was recrystallized from acetone–diethyl ether. We note that these carboxylate salts are sometimes contaminated with small amounts of [PPN]Cl, but since [PPN]Cl is itself a by-product in the reactions of $Re_2X_4(LL)_2$ with $[PPN]O_2CR$ (*vide infra*), this did not present a problem.

These salts were characterized by IR and NMR spectroscopy. The $[PPN]^+$ cations exhibit bands in their IR spectra at 800 (w), 995 (m), 1113 (s), 1260 (s), 1440 (s) and 1485 (m) cm^{-1}. These values are in accord with those (803, 995, 1115, 1250, 1440 and 1490 cm^{-1}) reported previously.[8] The carboxylate anions display characteristic ν(COO) stretching vibrations in the region 1550–1660 cm^{-1}. Their ^1H NMR spectra (in CD_2Cl_2) display resonances for the phenyl protons of the $[PPN]^+$ cation between δ +7.8 and +7.4. The acetate salt shows a singlet at δ +1.81 for the methyl protons, while the propionate salt exhibits resonances at δ +2.05 (q, —CH_2—) and δ +1.01 (t, —CH_3). Resonances for the phenyl protons of the benzoate anion appear in the region δ +8.2 to +7.2, and the isonicotinate anion exhibits resonances in the region δ +8.5 to +7.4. The ^{31}P NMR spectrum of the $[PPN]^+$ cation (in CD_2Cl_2) displays a singlet at δ +21.6.

(B) *Synthesis of* trans-$Re_2(O_2CR)_2X_2(LL)_2$ (R = CH_3, C_2H_5, C_6H_5 *or* 4-py; X = Cl *or* Br; LL = dppm *or* dpam)

With one exception, these compounds were prepared by application of the following general procedure. Dichloromethane (5 cm^3) was added to a mixture of $Re_2X_4(LL)_2$ (*ca* 0.10 g) and $[PPN]O_2CR$ (2 equiv). The orange solution was stirred at room temperature for 5 min, the solvent was then evaporated under reduced pressure, and the orange residue washed with 2-propanol and dried *in vacuo*. Samples were recrystallized from dichloromethane–diethyl ether. Details relating to the product yield, and the elemental microanalyses for each derivative are given in (a)–(f).

(a) trans-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$. Yield, 68%. Found: C, 46.6; H, 3.8. Calc. for $C_{55}H_{52}Cl_4O_4P_4Re_2$ (i.e. *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2 \cdot CH_2Cl_2$): C, 46.7; H, 3.7%.

(b) trans-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$. Yield, 72%. Found: C, 49.5; H, 4.4. Calc. for $C_{56}H_{54}Cl_2O_4P_4Re_2$: C, 49.5; H, 4.0%.

(c) trans-$Re_2(O_2CC_6H_5)_2Cl_2(dppm)_2$. Yield, 90%. Found: C, 52.3; H, 4.4. Calc. for $C_{64}H_{54}Cl_2O_4P_4Re_2$: C, 52.9; H, 3.7%.

(d) trans-$Re_2(O_2C\text{-}4\text{-}py)_2Cl_2(dppm)_2$. Yield, 74%. Found: C, 51.6; H, 4.1. Calc. for $C_{62}H_{52}Cl_2N_2O_4P_4Re_2$: C, 51.1; H, 3.6%.

(e) trans-$Re_2(O_2CCH_3)_2Br_2(dpam)_2$. Yield, 69%. Found: C, 38.0; H, 3.2. Calc. for $C_{56}H_{54}As_4Br_2$

$Cl_4O_4Re_2$ (i.e. *trans*-$Re_2(O_2CCH_3)_2Br_2(dpam)_2 \cdot 2CH_2Cl_2$): C, 38.1; H, 3.1%.

(f) trans-$Re_2(O_2CC_6H_5)_2Br_2(dpam)_2$. Yield, 67%. Found: C, 41.4; H, 3.0. Calc. for $C_{66}H_{58}As_4Br_2Cl_4O_4Re_2$ (i.e. *trans*-$Re_2(O_2CC_6H_5)_2Br_2(dpam)_2 \cdot 2CH_2Cl_2$): C, 42.0; H, 3.1%.

(g) trans-$Re_2(O_2CC_6H_5)_2Br_2(dppm)_2$. A mixture containing *trans*-$[Re_2(O_2CC_6H_5)_2Br_2(dppm)_2]Br$[1] (0.100 g, 0.062 mmol) and cobaltocene (0.021 g, 0.11 mmol) in acetone (15 cm^3) was stirred at room temperature for 1 h. The red–brown product was filtered off and washed with acetone. The compound was recrystallized from dichloromethane–diethyl ether; yield 0.070 g (74%). Found: C, 49.0; H, 3.8. Calc. for $C_{64}H_{54}Br_2O_4P_4Re_2$: C, 49.8; H, 3.5%.

(C) *Synthesis of* cis-$Re_2(O_2CR)_2X_2(LL)_2$ (R = CH_3, C_2H_5 *or* C_6H_5; X = Cl *or* Br; LL = dppm *or* dpam)

These compounds were prepared through the use of the following general procedure. A suspension of $Re_2X_4(LL)_2$ (*ca* 0.10 g) and $[PPN]O_2CR$ (2 equiv) in ethanol was refluxed for 3 h. The product was filtered off, washed with ethanol and diethyl ether, and dried *in vacuo*.

Note: Attempts to prepare *cis*-$Re_2(O_2C\text{-}4\text{-}py)_2Cl_2(dppm)_2$ with the use of this procedure gave only the *trans* isomer; yield, 63%.

(a) cis-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$. Yield, 48%. The identity of this compound was confirmed by comparison of its electrochemical properties with those of an authentic sample.[1]

(b) cis-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$. Yield, 33%. The identity of this compound was confirmed by comparison of its electrochemical properties with those of an authentic sample.[1]

(c) cis-$Re_2(O_2CC_6H_5)_2Cl_2(dppm)_2$. Yield, 67%. A cyclic voltammogram of this material revealed that it contained *ca* 60% of the *cis* isomer and *ca* 40% of the *trans* isomer. The components of this mixture were identified by comparison of their electrochemical properties with those of authentic samples.[1]

(d) cis-$Re_2(O_2CCH_3)_2Br_2(dpam)_2$. Yield, 61%. Found: C, 40.7; H, 3.5. Calc. for $C_{54}H_{50}As_4Br_2O_4Re_2$: C, 40.7; H, 3.2%.

(e) cis-$Re_2(O_2CC_6H_5)_2Br_2(dpam)_2$. Yield, 49%. A cyclic voltammogram of this material revealed that it contained *ca* 85% of the *cis* isomer and *ca* 15% of the *trans* isomer. A pure sample of the *cis* isomer was obtained upon the slow addition of diethyl ether to a dichloromethane solution of the mixture. Found: C, 43.5; H, 2.9. Calc. for $C_{65}H_{56}As_4Cl_2Br_2O_4Re_2$ (i.e. *cis*-$Re_2(O_2CC_6H_5)_2Br_2(dpam)_2 \cdot CH_2Cl_2$): C, 43.3; H, 3.1%.

(D) *Reactions of* cis- *and* trans-$Re_2(O_2CR)_2Cl_2(dppm)_2$ *with an excess of* $[PPN]O_2CR'$ (R = CH_3 *or* C_2H_5; R′ = CH_3 *or* C_2H_5)

(a) cis-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ *with* $[PPN]O_2CC_2H_5$. A suspension of *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ (0.100 g, 0.075 mmol) and $[PPN]O_2CC_2H_5$ (0.44 g, 0.72 mmol) in ethanol (20 cm^3) was refluxed for 3 h. The product was collected by filtration, washed with ethanol and diethyl ether, and dried *in vacuo*; yield, 0.047 g. ^1H and $^{31}P\{^1H\}$ NMR spectroscopy revealed that the product was a mixture of *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$, *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ and, probably, *cis*-$Re_2(O_2CCH_3)(O_2CC_2H_5)Cl_2(dppm)_2$; a pure sample of the mixed-carboxylate species has not yet been isolated.

(b) cis-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ *with* $[PPN]O_2CCH_3$. This reaction was carried out with the use of a procedure analogous to the one reported in D(a); yield, 0.073 g. NMR spectroscopy revealed that this product contained the same mixture of *cis* isomers as that found in D(a).

(c) trans-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ *with* $[PPN]O_2CC_2H_5$. A mixture of *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ (0.056 g, 0.042 mmol) and $[PPN]O_2CC_2H_5$ (0.260 g, 0.425 mmol) was combined with ethanol (10 cm^3) and heated to reflux. After 3 h, the product was collected, washed with ethanol and diethyl ether, and dried *in vacuo*; yield, 0.028 g. ^1H NMR spectroscopy revealed that this product was a mixture of *cis* isomers and that *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ was the major component.

(d) trans-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ *with* $[PPN]O_2CCH_3$. A mixture containing *trans*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ (0.100 g, 0.073 mmol) and $[PPN]O_2CCH_3$ (0.44 g, 0.74 mmol) in ethanol (20 cm^3) was refluxed for 3 h. The product was collected, washed with ethanol and diethyl ether, and dried; yield, 0.041 g. ^1H NMR spectroscopy again revealed that the product was a mixture of these same *cis* isomers; in this case *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ was the major component.

(E) *Thermolysis of* trans-$Re_2(O_2CR)_2Cl_2(dppm)_2$ *in ethanol*

(a) R = CH_3. A suspension of *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ (0.040 g) in ethanol (10 cm^3) was refluxed for 3 h. The product was filtered off, washed with ethanol and diethyl ether, and dried. The product was shown by cyclic voltammetry to be

cis-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$; yield 0.022 g (55%).

(b) R = C_2H_5. A mixture of *trans*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ (0.045 g) and ethanol (10 cm^3) was refluxed for 3 h. The product was collected by filtration, washed with ethanol and diethyl ether, and dried. The product was shown by cyclic voltammetry to be *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$; yield, 0.022 g (49%).

Preparation of single crystals for a structure determination

Maroon, rhomboidal crystals of *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$, which were suitable for X-ray crystallographic studies, were grown by slow diffusion of toluene vapour into a dichloromethane solution of the complex. The crystals proved to be of composition $Re_2(O_2CCH_3)_2Cl_2(dppm)_2 \cdot C_7H_8 \cdot 2H_2O$.

X-ray crystallography

The structure of a crystal of composition *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2 \cdot C_7H_8 \cdot 2H_2O$ was determined with the use of general procedures that are described elsewhere.[9] A summary of the crystallographic data is given in Table 1. The cell constants are based on 25 reflections with $20 < \theta < 23°$. Three standard reflections were measured after every 5000 s of beam time during data collection. There were no systematic variations in intensity. Calculations were performed on a microVAX II computer using the Enraf–Nonius structure determination package.

The crystal selected for the structure determination belongs to the monoclinic space group $C2/c$ with $Z = 4$. As a check on crystal quality, omega scans of several intense reflections were measured; the width at half-height was 0.89° with a take-off angle of 2.2°, indicating relatively poor crystal quality. The position of the crystallographically unique rhenium atom was determined from a three-dimensional Patterson map with the molecule residing on an inversion centre. The remaining atoms were located in succeeding difference Fourier syntheses. Lorentz and polarization corrections were applied to the data. An empirical absorption correction was applied,[10] the linear absorption coefficient being 42.36 cm^{-1}. No corrections for extinction were applied. The structure was refined in full-matrix least-squares where the function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where w is the weighting factor defined as $w = 1/\sigma^2(F_o)$.

During the course of the refinement, it became apparent that residual electron density at non-bonding distances to the dirhenium complex could be satisfactorily modelled as lattice toluene and water molecules. The toluene molecule was located on a special position. It was disordered about a two-fold axis in such a way that the methyl group could not be refined. The four crystallographically unique carbon atoms of the phenyl ring [C(901)—C(904)] refined with relatively large thermal parameters, implying high thermal motion for the lattice toluene molecule. The crystallographically unique water molecule was present at a general position and refined satisfactorily. Accordingly, the unit cell contains one molecule of

disordered toluene and two molecules of water for each *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ molecule. Hydrogens were not included in the refinement. With the exception of the lattice toluene and water molecules, all non-hydrogen atoms were refined anisotropically; corrections for anomalous scattering were applied to all atoms so refined.[11]

Further details concerning the data set and the structure solution and refinement may be obtained from Dr P. E. Fanwick. Table 2 lists important bond distances and angles.*

Physical measurements. Perkin–Elmer 1420 and 1800 spectrophotometers were used to record the IR spectra of compounds as mineral oil (Nujol) mulls supported on KBr plates in the region 4800–400 cm^{-1}. Electrochemical measurements were carried out by the use of a Bioanalytical Systems Inc. Model CV-1A instrument on dichloromethane solutions that contained 0.1 M tetra-*n*-butylammonium hexafluorophosphate (TBAH) as the supporting electrolyte. A Pt-bead working electrode and a Pt-wire auxiliary electrode were used. $E_{1/2}$ values, determined as $(E_{p,a}+E_{p,c})/2$, were referenced to the silver/silver chloride (Ag/AgCl) electrode at room temperature and are uncorrected for junction potentials. Under our experimental conditions, the ferrocenium/ferrocene couple is at $E_{1/2} = +0.47$ V vs Ag/AgCl. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian XL-200 spectrometer. Proton resonances were referenced internally to the residual protons in the incompletely deuteriated solvent. Phosphorus resonances were referenced externally to 85% H_3PO_4.

Elemental microanalyses were performed by Dr H. D. Lee of Purdue University Microanalytical Laboratory.

RESULTS AND DISCUSSION

(A) *Synthesis of* cis- *and* trans-$Re_2(O_2CR)_2X_2(LL)_2$

The heterogeneous-phase reactions between $Re_2X_4(LL)_2$ (X = Cl or Br; LL = dppm or dpam) and $[PPN]O_2CR$ (R = CH_3, C_2H_5, C_6H_5 or 4-py) in refluxing ethanol afford *cis*-$Re_2(O_2CR)_2X_2(LL)_2$, except in the case of $Re_2(O_2CC_6H_5)_2Cl_2(dppm)_2$ (where a mixture of the *cis* and *trans* isomers is produced) and $Re_2(O_2C\text{-}4\text{-}py)_2Cl_2(dppm)_2$ (where only the *trans* isomer is produced). That *cis*-$Re_2(O_2CR)_2X_2(LL)_2$ is the major product in these reactions is not surprising in the light of our earlier observation that $Re_2X_4(dppm)_2$ (X = Cl or Br) reacts with lithium acetate in refluxing methanol to give *cis*-$Re_2(O_2CCH_3)_2X_2(dppm)_2$.[1] The fact that we see only the *trans* isomer, or a mixture of the *cis*

* Atomic positional and thermal parameters and full listings of bond lengths and angles have been deposited with the Editor and with the Director, Cambridge Crystallographic Data Centre.

and *trans* isomers, in the cases involving aryl carboxylates, is also consistent with the earlier observation that the benzoate derivatives of *trans*-$Re_2(O_2CR)_2X_2(dppm)_2$ (X = Cl, Br) are more stable and more resistant to isomerization (to the corresponding *cis* isomers) than are the corresponding alkyl carboxylate complexes.

When $Re_2X_4(LL)_2$ and $[PPN]O_2CR$ are combined in dichloromethane at room temperature *trans*-$Re_2(O_2CR)_2X_2(LL)_2$ is produced. This is an important result, because this reaction represents the best and most reliable synthetic route to the *trans* isomers. Note that in the work-up of the *trans* isomers care must be taken to exclude oxygen from the system. If not, a purple material is formed whose identity has not yet been fully determined.

We have also shown that *trans*-$[Re_2(O_2CC_6H_5)_2Br_2(dppm)_2]Br$[1] is reduced by cobaltocene to give *trans*-$Re_2(O_2CC_6H_5)_2Br_2(dppm)_2$, with no evidence for isomerization to the *cis* isomer.

(B) *Carboxylate exchange and thermolysis reactions*

Samples of *cis*- and *trans*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ (R = CH_3 or C_2H_5) were reacted with an excess (10 equiv) of $[PPN]O_2CR'$ (R′ = CH_3 or C_2H_5) in refluxing ethanol for 3 h. The reactions involving *cis*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ afford mixtures of *cis*-$Re_2(O_2CR)_2Cl_2(dppm)_2$, *cis*-$Re_2(O_2CR')_2Cl_2(dppm)_2$ and possibly a small amount of *cis*-$Re_2(O_2CR)(O_2CR')Cl_2(dppm)_2$, although a pure sample of the latter species has not been isolated.* A similar distribution of products is obtained in each case. The reactions of *trans*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ with $[PPN]O_2CR'$ also afford a mixture of *cis* isomers, of which the major component is *cis*-$Re_2(O_2CR')_2Cl_2(dppm)_2$. The importance of these results is two-fold: (1) the *cis* isomers undergo carboxylate exchange but do not convert to the *trans* isomers, and (2) the *trans* isomers react with carboxylate ion to give mixtures that contain only the *cis* isomers, the major component of which is the *cis* isomer that contains the alien carboxylate.

When samples of *trans*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ (R = CH_3 or C_2H_5) are heated in refluxing ethanol for 3 h, the corresponding *cis* isomeric form is produced. This result is consistent with our earlier conclusion that the *cis* isomers are the thermodynamically favoured form.[1]

(C) *Spectroscopic and electrochemical properties*

The identities of the newly prepared dpam and isonicotinate derivatives are based upon the close similarity of their electrochemical and NMR spectral properties to those of previously characterized derivatives of this type.[1] The ^1H NMR spectrum of *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$, recorded in CD_2Cl_2, displays resonances for the phenyl protons in the range δ +7.6 to +6.8. The methyl protons of the acetate ligand appear as a singlet at δ + 2.31. The dppm bridgehead methylene protons (—CH_AH_M—) show up as doublets of triplets at δ_A +6.34 and δ_M +4.89. The splitting pattern arises from geminal coupling between H_A and H_M, and further coupling between these protons and two equivalent phosphorus nuclei ($I = 1/2$), with $J(H_A—H_M) \simeq 12$ Hz, $J(H_A—P) \simeq 10$ Hz and $J(H_M—P) \simeq 12$ Hz. The ^1H NMR spectrum of *cis*-$Re_2(O_2CCH_3)_2Br_2(dpam)_2$ (in CD_2Cl_2) is qualitatively similar to that for *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ in that it shows only phenyl resonances (δ +7.7 to +6.9), bridgehead methylene resonances (δ_M +5.76, δ_A +4.51), and a methyl resonance (δ +2.24). However, it differs in that the methylene resonances now appear as doublets with $J(H_A—H_M) \simeq 12$ Hz. The ^1H NMR spectrum of *trans*-$Re_2(O_2C\text{-}4\text{-}py)_2Cl_2(dppm)_2$ (in CD_2Cl_2) shows an unresolved multiplet at δ +5.07, which we assign to the four equivalent bridgehead methylene protons of dppm. The remainder of the spectrum shows the phenyl proton resonances in the range δ +8.7 to +7.1. A doublet at δ +8.70 (with 5.2 Hz splitting) most likely corresponds to the protons *ortho* to nitrogen in the isonicotinate ligands. The $[PPN]^+$ salt of the isonicotinate anion shows a similar doublet centred at δ +8.49 with 5.6 Hz splitting. The $^{31}P\{^1H\}$ NMR spectrum of this particular *trans* species displays a singlet at δ +3.67.

Cyclic voltammetric (CV) data for solutions of these complexes in 0.1 M TBAH/CH_2Cl_2 are listed in Table 3 (all potentials are vs Ag/AgCl). CVs of the new dpam and isonicotinate derivatives resemble quite closely those for the other derivatives, in that they exhibit two reversible one-electron oxidations. However, there is one notable difference, namely, the redox potentials for *trans*-$Re_2(O_2C\text{-}4\text{-}py)_2Cl_2(dppm)_2$ are approximately 0.2 V more positive than the corresponding values for the other *trans* derivatives.

* The identity of the components of these mixtures was established by ^1H and $^{31}P\{^1H\}$ spectroscopy. The ^1H NMR spectral data are reported in section (c) for *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ and in ref. 1 for *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$. The $^{31}P\{^1H\}$ NMR spectra (in CD_2Cl_2) for these two complexes appear as singlets (δ −10.13 for the acetate, δ −10.18 for the propionate).

[b] Numbers in parentheses are ΔE_p values (i.e. $E_{p,a} - E_{p,c}$).

[c] Present study.

(D) *X-ray structure results*

The molecular structure of *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2 \cdot C_7H_8 \cdot 2H_2O$ has been determined by X-ray crystallography. Important bond distances and angles are listed in Table 2. An ORTEP representation of the structure is shown in Fig. 1.

This structure determination is important because it allows us to compare key distances in *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ (**1**) with those for the previously characterized salt *trans*-$[Re_2(O_2CCH_3)_2Cl_2(dppm)_2]PF_6$ (**2**)[1] and the neutral *cis*-$Re_2(O_2CCH_3)_2(dppm)_2$ (**3**).[1] The average Re—P distance is 2.446[4] in **1** and 2.478[1] Å in **2**.* This bond lengthening is statistically significant[12] and presumably reflects a decrease in Re → P π-bonding in going from the neutral to the cationic species. A similar lengthening has been observed in the cases involving $Re_2Cl_4(PMe_2Ph)_4$ and $[Re_2Cl_4(PMe_2Ph)_4]PF_6$,[13] and *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppa)_2$ and *cis*-$[Re_2(O_2CCH_3)_2Cl_2(dppa)_2]PF_6$ (dppa = $Ph_2PNHPPh_2$).[14] The average Re—Cl distance in **1** is 2.571(3) and in **2** it is 2.532(2) Å. These distances are also statistically different and represent a bond shortening from **1** to **2**. This trend can be attributed to contraction of the metal valence orbitals and/or, the increased electrostatic attraction as the metal core charge increases. The average Re—O distances in **1** and **2** are 2.09[2] and 2.06[1] Å, respectively, and are not statistically different. Neither are the Re—Re distances, which are 2.2763(7) for **1** and 2.2748(6) Å for **2**.

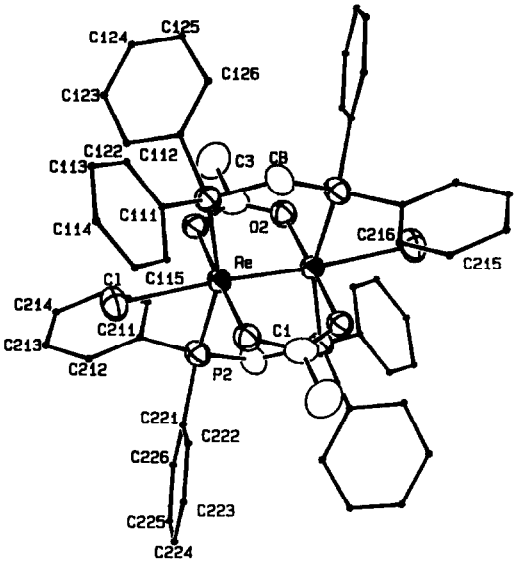

Fig. 1. ORTEP representation of the structure of *trans*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ showing the atomic numbering scheme. The labelled atoms are related to the unlabelled ones by an inversion centre. The thermal ellipsoids are drawn at the 50% probability level.

* The estimated deviation in brackets is calculated as $[\ ] = [\Sigma_n \Delta_i^2/n(n-1)]^{1/2}$, in which Δ_i is the deviation of the ith of n values from the arithmetic mean of the set.

Only two distances change significantly in going from **1** to **3**; these are Re—Re and Re—P. The Re—Re distance in **3** (2.3151(7) Å) is longer than that in **1** (2.2763(7) Å), while the average Re—P distances follow the opposite order (2.446[4] for **1** and 2.396[6] Å for **3**). The conformational demands associated with the two fused five-membered rings P—C—P—Re—Re—P—C—P in these *trans* and *cis* isomers may dictate that the Re—Re and Re—P distances differ between **1** and **3** in this manner.

Abstract—Heptacoordinate trivalent lanthanide complexes containing mixed ligands were prepared and characterized. These complexes were of general structure $M(THD)_3$–IM. In this formula M represents the lanthanide +3 ions of europium, holmium, praseodymium, dysprosium, ytterbium and gadolinium. THD stands for 2,2,6,6-tetramethyl-3,5-heptanedionato and IM for imidazole. The IR spectra of these materials were compared and we have demonstrated that the C—H stretching frequency of the imidazole moiety exhibits a monotonic decrease as a function of increasing size of the lanthanide +3 ion. The N—H stretching frequency for imidazole shows a similar trend, except that the point for the europium occurs at a position quite far above that of the other compounds. These results suggest that the bond strength between the lanthanide ion and the imidazole is sensitive to the radius of the ion and that the chemical reactivity of the imidazole may be influenced by this effect. The crystal and molecular structures of $Eu(THD)_3$–IM have been determined. The following cell constants were found: $a = 19.40(1)$, $b = 10.243(5)$, $c = 21.76(1)$ Å, $\beta = 108.70(5)°$ and $Z = 4$. The space group is $P2_1/n$. The europium ion is seven-coordinate with bonding to the six carbonyl groups of the three THD units and to one of the imidazole nitrogens, thereby forming a capped trigonal prism. Preliminary X-ray data from other members of the series indicate that all are isotructural with the europium compound.

Large chemical shifts are induced in the NMR spectra of certain compounds in the presence of complexes of lanthanide ions with large ligands. The first example of this effect used the dipyridinate of tris(2,2,6,6-tetramethyl-3,5-heptanedionato) europium, $[Eu(THD)_3(PY)_2]$, with cholesterol.[1] Following this landmark paper, a wide variety of other systems were discovered and shown to exhibit similar behaviour.[2] The origin of this dramatic effect has been attributed both to through-space dipolar pseudo-contact interactions[3] and through-bond Fermi contact interactions.[4,5] It is now generally believed that the former are exclusively or nearly exclusively responsible for the observed shifts.[2]

The purpose of the present work is to study the structural differences responsible for the chemical and spectroscopic behaviour of related compounds in a series of organolanthanide shift reagents in the form of their stable seven-coordinate complexes with the nitrogen base, imidazole. In particular, we were interested in the way in which complexation of the imidazole to the shift reagent could modify its chemical reactivity in epoxy resin cure reactions. The series we chose to work with are the $M(THD)_3$–IM chelates. A paper on the preparation of these compounds has been published although the

authors reported only minimal details of the characterization.[6] As part of our present effort, we have examined the X-ray crystal structure of one of the examples of this family of compounds together with the IR spectra of all of these materials. From this information we are able to know, in detail, the precise molecular structure of the complexes and thereby infer relative reactivity relationships.

In addition, we have correlated spectroscopic properties of the complexes with the size of the lanthanide +3 ion. Specifically, we have obtained a measure of the strength of bonding of the imidazole to the metal by use of IR spectroscopy. In related work, we have shown that the reactivity of these different complexes, in an epoxy curing reaction, depends on lanthanide size in the same way that the specroscopic properties do.[7]

EXPERIMENTAL

Preparation of materials

The lanthanide–imidazole complexes were all prepared by the same general route. The following procedure for the europium compound can be utilized for each of the congeners.

A solution of tris(2,2,6,6-tetramethyl-3,5-heptanedionato)europium, [Eu(THD)$_3$] (25.0 g, 0.0356 mol), was prepared in hot methanol (300 cm^3). To this hot, filtered solution was added a solution of imidazole (2.42 g, 0.0356 mol) in hot methanol (100 cm^3). The mixture was boiled for approximately 10 min, and then transferred to a rotary evaporator where the solvent was removed. The crude product was recrystallized from 1,2-dichloroethane (500 cm^3). Yield: 20.9 g (76%). The analytical data and melting points for each of the mixed-ligand complexes are given in Table 1.

Each of the materials was examined by differential scanning calorimetry (DSC) and exhibited a single sharp endothermic peak at the melting point without any evidence of decomposition up to 300°C. The instrument used was a Perkin–Elmer Model 4 Differential Scanning Calorimeter. Standard conditions for the DSC analyses were: heating rate 20° min^{-1}; temperature range, 30–280 or 30–300°C; sample size, 1–5 mg.

Mass spectroscopy was performed on a Hewlett–Packard Model 5985 B instrument. A heated solid sample probe was used to insert the samples into the ionization region.

IR spectra were obtained on a Nicolet MX-1 Fourier Transform Spectrometer in the range from 4000 to 400 cm^{-1}. Samples were prepared as pressed KBr pellets (approximately 1 mg of complex per 100 mg of KBr). Spectra of the M(THD)$_3$–IM complexes are essentially equivalent. Several new absorption lines appear in these complexes and these are summarized in Table 2 together with specific frequencies of the new lines in the europium complex and their comparison with the absorptions in uncomplexed imidazole.

Single crystal X-ray structure determinations were performed on some of these compounds. The experimental details are as follows: A transparent single crystal of Eu(THD)$_3$–IM was mounted on a pin and transferred to the goniometer. From the systematic absences the space group was determined to be the centric $P2_1/n$ type. The data collection and refinement parameters are summarized in Table 3.

Very small crystals of marginal quality resulted in an observed/scanned ratio of 0.40. In addition, obvious disorder and high thermal motion complicated the solution and refinement process. Never-

Table 2. IR absorptions of lanthanide–imidazole complexes

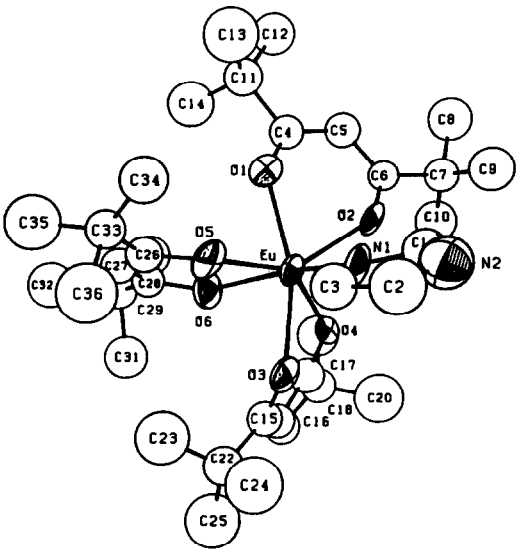

Fig. 1. Molecular structure of $Eu(THD)_3$–IM.

no attempt was made to refine the carbon atoms anisotropically or to locate hydrogen atoms. Refinement of the europium, oxygen and coordinated nitrogen atoms with anisotropic temperature factors led to final values of $R = 0.097$ and $R_w = 0.113$. Selected bond distances and bond angles in $EuC_{36}H_{61}N_2O_6$ are given in Table 4.

Crystals of M = Pr, Gd, Dy, Ho and Yb were examined and preliminary unit cell data were obtained. These cells, their symmetries and space group extinctions match those observed for M = Eu. The best of these, M = Yb, gave $a = 19.355(8)$, $b = 10.225(2)$, $c = 21.765(8)$ Å, $\beta = 108.85(4)°$: with a calculated density of 1.29 g cm^{-3}. A preliminary data set on $Yb(THD)_3$–IM confirmed that it is indeed isostructural with $Eu(THD)_3$–IM.

RESULTS AND DISCUSSION

The preparation of the mixed-ligand complexes is straightforward. It simply requires that the $M(THD)_3$ complex be dissolved with an equimolar amount of imidazole in methanol. Removal of the solvent yields the new complex. In all cases, the crude yields are quantitative and this product can be used as is for most purposes. If purification is necessary it is accomplished by recrystallization from 1,2-dichloroethane with about 70–80% recovery. The melting points we report (Table 1) are between 5 to 14°C higher than those in the literature.[6] Also, the elemental analyses indicate a higher state of purity than those given in the literature.

In our attempts to characterize these materials we undertook a variety of spectroscopic measurements. One of the first approaches was to look at the mass spectrum of these complexes. Using the solid sample insert, and heating from 30 to 300°C

[a] Atomic coordinates have been submitted to the Cambridge Crystallographic Data Centre.

we found no evidence of the molecular ion for the intact complex. The mass peak corresponding to the $M(THD)_3$ substance was found in each case. This result is puzzling since DSC of these compounds exhibits a single sharp endothermic peak at the melting point with no evidence of decomposition even up to nearly 300°C. Apparently, the combination of the high temperature required to vaporize the complexes and the high vacuum in the ionization chamber of the mass spectrometer result in dissociation of the complex and loss of the imidazole portion.

A comparison of the Fourier Transform IR spectra of the $M(THD)_3$ complexes before adding imidazole shows that they are basically very similar, with only small shifts observed for most peaks. When the imidazole complex is prepared several new IR bands appear. Their assignments are given in Table 2 and are based on the spectroscopy of imidazole.[8,9] The largest shift was observed for the N—H stretching frequency of the imidazole and was found to be approximately 500 cm^{-1} from the value in the free ligand. This shift places the N—H frequency close to that for gaseous imidazole[9] (3518 cm^{-1}), and indicates greatly reduced hydrogen bonding in the complexes as compared to that in uncomplexed imidazole.

We noted that there was a small, but perceptible, difference in the measured frequencies of the IR absorption bands for the different lanthanide metal complexes. We surmised that the compounds in the series would be essentially identical in structure except for the effects due to the changing size of the central metal ion. When the N—H absorption frequency and the C—H absorption frequency for the imidazoles in the various complexes were plotted as a function of the size of the lanthanide +3 ion we obtained the results shown in Figs 2 and 3. In the former the monotonic relationship of stretching frequency with ion size is apparent. There is one

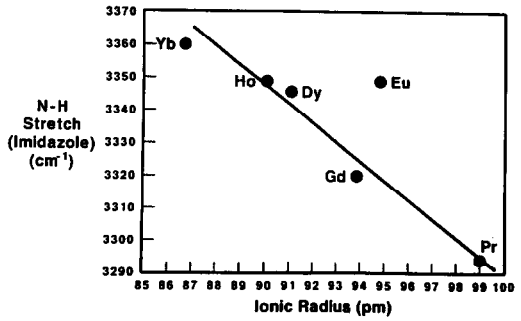

Fig. 2. IR N—H stretching frequencies of imidazole in $M(THD)_3$–IM complexes as a function of the ionic radius of the lanthanide.

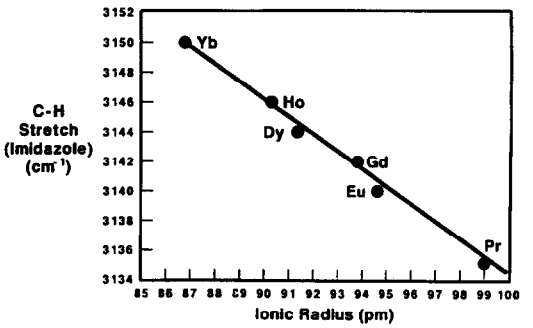

Fig. 3. IR C—H stretching frequencies of imidazole in $M(THD)_3$–IM complexes as a function of the ionic radius of the lanthanide.

exception in this plot. The stretching frequency for the europium compound is higher than it would be for its normal position on the graph. Although we have no adequate explanation for this apparent anomaly, we speculate that the N—Eu bond strength may be influenced by the unusual oxidation–reduction properties of europium. Among the lanthanide metals studied here, europium has the lowest reduction potential, at least 0.3 V lower than the others.[10] This lower reduction potential probably arises from the easy accessibility of the +2 state of europium. The variation of the C—H stretching frequency is monotonic through all compounds tested (Fig. 3).

The variation in the imidazole stretching frequencies in the complexes arises from the variation in the strengths of the metal–nitrogen bonds. The sensitivity of N—H stretching frequencies to cation radius has been previously reported for transition metal complexes of imidazole.[11] The magnitude of this effect will be directly proportional to the electrostatic attraction between the lone pair electrons on the imidazole imino nitrogen and the metal ion. Larger ions result in weaker interactions which appear at lower frequencies in the IR. As we stated above, the anomalous behaviour of the N—H stretching frequency of imidazole in the europium complex is probably attributable to the unusual oxidation states of the europium ion and the manner in which they form bonds with imidazole.

Other shifts observed in the positions of the imidazole bands upon complexation (Table 2) are consistent with shifts observed for imidazole complexes with transition metal (+2) salts.[11] Most absorption bands due to the THD anion are shifted in the order of 0–2 cm^{-1} after complexation. Larger shifts (*ca* 5 cm^{-1}) are observed for the bands associated with the conjugated O=C—C=C—O system[12] in the range 1500–1600 cm^{-1}. The metal–oxygen bond length appears to be unchanged by complexation

as evidenced by the constancy of the absorption bands at 602 and 474 cm^{-1}.[13]

Because of the intriguing chemical possibilities across the lanthanide series using mixed ligands it is important to know the details of the structure of at least one of these compounds. When we recrystallized these $M(THD)_3$–IM materials from 1,2-dichloroethane, crystals were obtained which appeared to the naked eye as being of good enough quality for single crystal X-ray determinations. However, when we attempted to do diffraction studies it was plain that crystal quality was borderline and high R values were obtained, $R = 0.097$ and $R_w = 0.113$.

The structure of the europium compound was solved, however, and the molecular structure is shown in Fig. 1. The europium atom is seven-coordinate with bonding to the six carbonyl units of the β-diketone groups and to one of the nitrogens in the imidazole ring. The five atoms in each of the oxygen-containing rings, O—C—C—C—O are quite planar, and define the least-squares planes in this chelate, and have average deviations from the planes of 0.011, 0.020 and 0.009 Å, respectively. The average Eu—O bond length is 2.33(3) Å (Table 4) which is very similar to the value of 2.35 Å found for the dipyridyl adduct of $Eu(THD)_3$[14] and the value of 2.36 Å found for the bis(dimethylformamide) adduct of $Eu(THD)_3$.[15] The Eu—N bond distance is 2.53(3) Å, which is somewhat shorter than the 2.65 Å found in the dipyridyl adduct[14] but identical to the bond length found for Lu—N in the 3-methylpyridine complex of $Lu(THD)_3$.[16] The long Eu—N bond length in the dipyridyl complex of $Eu(THD)_3$ may be due to the extreme crowding necessitated by the eight-fold coordination around europium. In the present compound, the steric strain is apparently relieved because of the seven-coordinate geometry. The large differences in ionic size of the lanthanides may also play an important role in the bond lengths and bond angles which are observed. A complete study of analogous compounds across the lanthanide series is necessary to elucidate the effect of ionic size. Fortunately, this series of compounds is isostructural for M = Pr–Yb and this will allow a detailed examination of the effect of ionic size on structure when suitable single crystals can be obtained.

CONCLUSIONS

We have prepared and characterized a series of mixed-ligand complexes of the general formula, $M(THD)_3$–IM, where M represents any of the group of lanthanide ions, europium, praseodymium, dysprosium, holmium, gadolinium and ytterbium. The complexes were prepared by mixing solutions of $M(THD)_3$ and imidazole and then removing the solvent. In the IR spectra of these compounds we observed that both the C—H and N—H stretching frequencies of the imidazole group are sensitive to the size of the lanthanide ion. Both bands show a monotonic decrease in frequency as the ionic radii increase.

The single crystal X-ray structure of $Eu(THD)_3$–IM was determined. It is pure seven-coordinate, with six Eu—O bonds and one Eu—N bond, and is best described as being a capped trigonal prism. The three oxygen chelate rings are planar, and bond lengths and bond angles are similar to those found in related compounds. Continued research to obtain quality single crystals for these compounds and thus accurate structural details across this isostructural series is warranted.

η^3-2-METHYLALLYL PHOSPHINE COMPLEXES OF NICKEL(II)

ERNESTO CARMONA,† PILAR PALMA and MANUEL L. POVEDA

Departamento de Química Inorgánica-Instituto de Ciencia de Materiales, Universidad de Sevilla-CSIC, Apartado 553, 41071-Sevilla, Spain

(*Received* 15 *September* 1989; *accepted* 16 *October* 1989)

Abstract—The reaction of $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene) with $2\text{-}MeC_3H_4Cl$ (2-methylallyl chloride), in the presence of different phosphine ligands, has been investigated. PMe_3 furnishes the 16-electron allyl species $[Ni(\eta^3\text{-}2\text{-}MeC_3H_4)Cl(PMe_3)]$ (**1**), while dmpe (dmpe = $Me_2PCH_2CH_2PMe_2$) provides an 18-electron, five-coordinate complex, $[Ni(\eta^3\text{-}2\text{-}MeC_3H_4)Cl(dmpe)]$ (**2**). By contrast, the diphosphines $Ph_2PCH_2PPh_2$ (dppm) and $Me_2PCH_2PMe_2$ (dmpm) form the binuclear complexes $[[Ni(\eta^3\text{-}2\text{-}MeC_3H_4)Cl]_2(\mu\text{-}R_2PCH_2PR_2)]$ (R = Ph, **3**; Me, **4**) containing bridging phosphine ligands. Alkylation of the chloride complex **1** with various Grignard reagents, Mg(R)Cl, allows the isolation of the alkyl–allyl derivatives $[Ni(\eta^3\text{-}2\text{-}MeC_3H_4)R(PMe_3)]$ (R = CH_2SiMe_3, **5**; CH_2CMe_3, **6**; $CH_2C_6H_4$-*o*-Me, **7**). The new compounds have been characterized by analytical and spectroscopic techniques (IR, ^1H, ^{13}C and ^{31}P NMR).

Allyl nickel compounds are key intermediates in a number of catalytic reactions, and have been widely used for the synthesis of complex organic molecules.[1,2] A large number of nickel derivatives containing allyl ligands have been characterized.[3] Many of these compounds contain also a halide, alkyl or aryl group, and in some cases further stabilization is provided by the presence of a donor ligand.[3] As a continuation of previous studies on the chemistry of allyl complexes of nickel,[4] we have now prepared some η^3-2-methylallyl compounds containing mono- and bidentate phosphine ligands. Their synthesis and characterization are the subject of this paper. Analytical and selected ^1H NMR data for the new compounds are reported in the Experimental; ^{13}C and ^{31}P NMR data are collected in Table 1.

RESULTS AND DISCUSSION

(a) 2-*Methylallyl phosphine halide complexes*

The 2-methylallyl halide compounds have been synthesized by a route commonly used for the preparation of this type of compounds, namely by oxidative addition of 2-methylallyl chloride to $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene), in the presence of the phosphine ligand.[3]

Addition of 1 equiv of $2\text{-}MeC_3H_4Cl$ to a cold (−40°C), stirred suspension of $[Ni(cod)_2]$ in Et_2O, in the presence of 1 equiv of PMe_3, produces no apparent reaction, but upon warming at room temperature, the suspended solid is taken up into the solution which then becomes red in colour. When the reaction is complete [eq. (1)], red–orange needles of $[Ni(\eta^3\text{-}2\text{-}MeC_3H_4)Cl(PMe_3)]$ (**1**) can be isolated in high yields. Compound **1** is an air-sensitive solid,

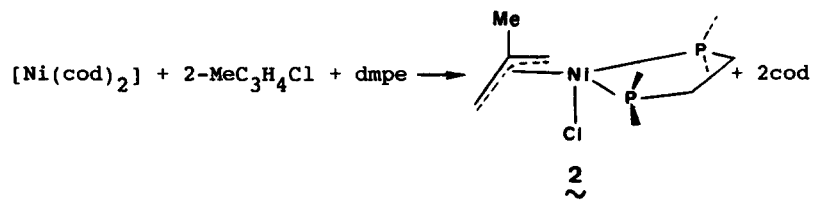
readily soluble in common, non-polar, organic solvents. It is fluxional in solution as evidenced by the appearance of broad, unresolved NMR features in its NMR spectra. The $^{13}C\{^1H\}$ room temperature spectrum shows two rather broad signals at *ca* 65.0 and 41.6 ppm, that can be assigned to the terminal carbon atoms of the allyl ligand.[5] Upon cooling at −70°C (CD_2Cl_2) they convert into two doublets as a result of coupling to the ^{31}P nuclei. This is in accord with the rigid structure shown for this complex in eq. (1). The values of the ^{31}P–^{13}C coupling constants are 23 and 6 Hz for the signals at 65.0 and 41.6 ppm, respectively. Thus, the former is ascribed to the methylene allylic carbon *trans* to the PMe_3 ligand, while the latter corresponds to the other terminal carbon atom. The *meso*-carbon provides a singlet at 119.5 ppm, that remains unchanged with temperature. Above room temperature, the signals at 65.0 and 41.6 ppm further broaden and begin to coalesce. At 65°C only a broad hump is observed at an average chemical shift, and the decomposition of the sample at higher temperatures prevents attainment of the fast-exchange limit. All other resonances, including those associated with the PMe_3 ligand, remain sharp in this temperature range (−70 to +65°C). The fluxional processes responsible for the temperature dependence of the NMR spectra of allyl compounds have been studied in detail.[3,5–7] Since, on the other hand, very limited data are available for compound **1**, this problem has not been investigated any further.

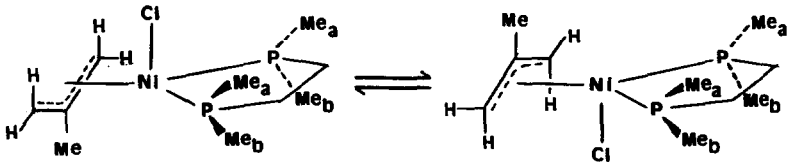
The chelating phosphine dmpe reacts similarly and provides high yields (*ca* 85%) of the five-coordinated species [Ni(η^3-2-MeC_3H_4)Cl(dmpe)] (**2**), as shown in eq. (2). The proposed structure for **2** is in accord with analytical and spectroscopic data, and it is similar to that found by X-ray studies for the analogous complex [Ni(η^3-2-MeC_3H_4)Br(dppe)][8] (dppe = $Ph_2PCH_2CH_2PPh_2$). Com-



2

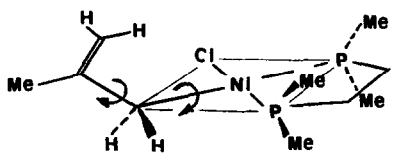
(2)

pound **2** is also fluxional and the available low temperature NMR data indicate the above structure is maintained in solution. Thus, in the slow-exchange limit the terminal allylic carbons are equivalent and produce a virtual triplet at 59.3 ppm ($J_{CP_{app}} \simeq 10$ Hz), as a result of their coupling to two chemically equivalent phosphorus nuclei, i.e. a deceptively simple AXX′ spin system. Interestingly, and again in agreement with the proposed structure, the methyl groups of the diphosphine ligand appear at −85°C as two multiplets that collapse into a virtual triplet at room temperature. The remaining carbon resonances, as well as the ^{31}P resonance characteristic of **2** (see Table 1) show no variation with temperature. ^1H NMR studies indicate that the *syn*- and *anti*-protons of the allyl moiety become equivalent in the fast-exchange limit. These observations can be explained in terms of a rapid exchange between the two degenerate ground structures, **A** and **B** shown below, by means of one or more



A **B**

thermally accessible pathways. A simple mechanistic route that would account for the above changes involves the formation of a four-coordinate, $^1\eta$-allyl intermediate, such as species **C** shown below.



C

We have attempted the synthesis of compounds related to **2** by using other bidentate phosphines such as dppm and dmpm. These, however, display different behaviour. For instance, addition of equimolar amounts of dppm to a 1:1 mixture of $[Ni(cod)_2]$ and 2-MeC_3H_4Cl, provides a dark red species of analytical composition "$Ni(2\text{-}MeC_3H_4)Cl(dppm)_{0.5}$", which seems to be a binuclear species, whose formation takes place as depicted in eq. (3):

$$2[Ni(cod)_2] + 2\,2\text{-}MeC_3H_4Cl + P{-}P \longrightarrow [Ni_2(\eta^3\text{-}2\text{-}MeC_3H_4)_2Cl_2(P{-}P)] \quad (3)$$

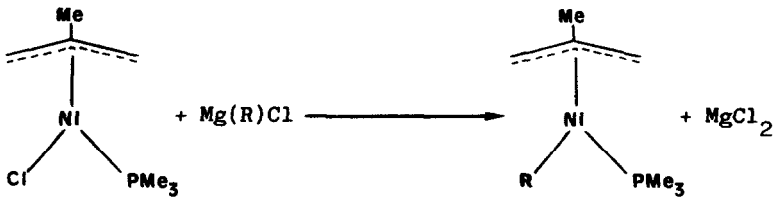
(P—P = dppm, **3**; dmpm, **4**).

A similar reaction using dmpm as the phosphine ligand yields the related complex **4**. Compound **3** exhibits a complex behaviour in solution. The $^{13}C\{^1H\}$ NMR spectrum recorded at 20°C (C_6D_6) shows equivalence of the allyl ligands, the terminal allylic carbons giving rise to a slightly broad singlet centred at 64.6 ppm. We have been unable to attain the slow-exchange spectrum for this complex. On the other hand, the $^{31}P\{^1H\}$ spectrum, recorded at −80°C, consists of several broad resonances that suggest that this compound exists as a mixture of different isomeric species. At room temperature these are in an equilibrium that is fast with respect to the NMR time scale. A definite structural proposal cannot obviously be made with the data available.

The analogous dmpm derivative **4** is sparingly soluble in non-polar organic solvents, although it dissolves readily in acetone and other polar solvents. Attempts to obtain crystalline samples of this material from different solvent mixtures have proved unsuccessful, although the available analytical data are in reasonable agreement with the proposed formulation (see Experimental). The $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ spectra display relatively simple features that remain essentially unchanged with temperature and provide no useful information with regards to the structure of this complex.

(b) 2-*Methylallyl phosphine alkyl complexes*

Some new alkyl–allyl complexes of nickel(II) have been synthesized by the general reaction route outlined in eq. (4), i.e. by alkylation of the chloride derivative **1** with the corresponding Grignard reagent. The new compounds are extremely soluble in all common organic solvents tested. This has prevented us to induce their crystallization even from very concentrated solutions, but they have been isolated as spectroscopically pure oils, with NMR and other properties fully in accord with the proposed formulation. The trimethylsilylmethyl derivative **5** gives rise to two ^{13}C doublets at 55.3 ($^2J_{CP}$ = 5 Hz) and 58.2 ppm ($^2J_{CP}$ = 25 Hz), that can be readily assigned to the two different methylene carbons of the allyl ligand (*cis* and *trans* to the PMe_3 ligand, respectively). The *meso*-carbon



(4)

R= CH_2SiMe_3, 5; CH_2CMe_3, 6

appears at *ca* 119 ppm and exhibits no coupling to the ^{31}P nuclei. On the other hand, the nickel-bound carbon atom of the alkyl group appears also as a doublet as a result of its coupling to the ^{31}P nucleus. The low value of 11 Hz found for this coupling constant is clearly indicative of a *cis* distribution of the alkyl and phosphine ligands. Finally, the non-planarity of the molecules of **5** (and **6**) is clearly manifested by the diastereotopicity of the Ni—CH_2R protons in the ^1H NMR spectra.

We have shown recently[4] that the halide Me-*o*-$C_6H_4CH_2Cl$ oxidatively adds to [Ni(cod)$_2$], in the presence of trimethylphosphine, with formation of an equilibrium mixture of the η^1- and η^3-pseudoallylic complexes [Ni(η^1-$CH_2C_6H_4$-*o*-Me)Cl(PMe_3)$_2$] and [Ni(η^3-$CH_2C_6H_4$-*o*-Me)Cl(PMe_3)], respectively [eq. (5)]:

$$[Ni(cod)_2] + ClCH_2C_6H_4\text{-}o\text{-}Me \xrightarrow{PMe_3} [Ni(\eta^1\text{-}CH_2C_6H_4\text{-}o\text{-}Me)Cl(PMe_3)_2] + [Ni(\eta^3\text{-}CH_2C_6H_4\text{-}o\text{-}Me)Cl(PMe_3)] \quad (5)$$

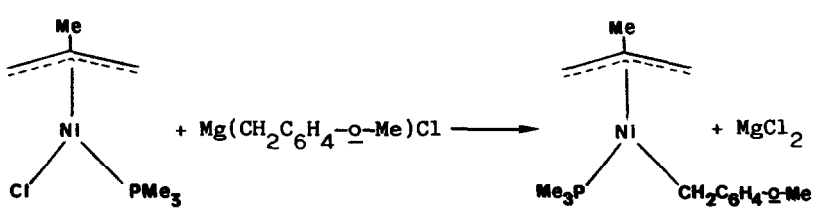
The η^3-allyl complex can be readily prepared by carrying out the above reaction in the presence of equimolar quantities of PMe_3. The facility with which the *o*-methylbencyl group yields η^3-pseudoallylic structures and the fact that compounds of the type [Ni(η^3-allyl)$_2$(PR_3)] are known,[3] prompted us to attempt the synthesis of a mixed allylic complex by reaction of **1** with Mg($CH_2C_6H_4$-*o*-Me)Cl. This interest was further enhanced by the knowledge from the literature that attempts to prepare mixed bis(π-allyl) complexes of nickel, [Ni(η^3-allyl)(η^3-allyl*)], lead[3] to the disproportionation products, i.e. [Ni(η^3-allyl)$_2$] and [Ni(η^3-allyl*)$_2$]. With this aim in mind, the reaction of complex **1** and Mg($CH_2C_6H_4$-*o*-Me)Cl was undertaken. However, as shown in eq. (6), the resulting compound was not the desired mixed bis(allyl), but rather an alkyl–allyl complex **7**, analogous to **5** and **6**. Formation of **7** as an η^1-*o*-methylbencyl species follows from spectroscopic data. They are collected in Table 1 (^{13}C and ^{31}P) and in the Experimental (^1H) and require no further comment.

EXPERIMENTAL

Microanalyses were by Pascher Microanalytical Laboratory, Remagen (F.R.G.), and the Microanalytical Service of the University of Seville. The spectroscopic instruments used were Perkin–Elmer models 557 and 684 for IR spectra and Varian XL-200 for ^1H, ^{13}C and ^{31}P NMR spectra. All preparations and other operations were carried out under oxygen-free nitrogen, following conventional Schlenk techniques. Solvents were dried and degassed before use. [Ni(cod)$_2$] and PMe_3 were prepared according to literature methods.[9,10]

Synthesis of [Ni(η^3-2-MeC_3H_4)Cl(PMe_3)] (**1**)

To a stirred suspension of [Ni(cod)$_2$] (0.82 g, *ca* 3 mmol) in 40 cm^3 of diethyl ether, cooled to −40°C, 0.3 cm^3 of PMe_3 (3 mmol) and 3 cm^3 of a 1 M solution of 2-MeC_3H_4Cl in Et_2O (3 mmol) were added. The reaction mixture was warmed and stirred at room temperature until all the starting material had dissolved (2 h), when a red solution was obtained. The solvent was removed under vacuum, the residue extracted with Et_2O and filtered. Concentration of the resulting solution and cooling at −30°C provided compound **1** as red–orange needles in 85% yield. Found: C, 36.7; H, 7.0. Calc. for $C_7H_{16}PClNi$: C, 37.3; H, 7.1%. ^1H NMR (C_6D_6, 200 MHz): δ 0.92 (d, $^2J_{HP}$ = 8.8 Hz, PMe_3), 1.73 (s, C—Me), 1.38, 1.96, 2.88 and 3.80 (brs, CH_2).



(6)

7

Following a similar procedure the following complexes were prepared: [Ni(η^3-2-MeC_3H_4)Cl(dmpe)] (**2**), orange needles from Et_2O, 85% yield. Found: C, 40.0; H, 7.6. Calc. for $C_{10}H_{23}P_2ClNi$: C, 40.1; H, 7.7%. ^1H NMR (C_6D_6, 200 MHz, 70°C): δ 1.15 (d, $^2J_{HP}$ = 9.6 Hz, P—Me), 1.33 (d, $^2J_{HP}$ = 14.8 Hz, P—CH_2), 1.41 (s, C—Me), 3.23 (brs, allylic CH_2). [$Ni_2(\eta^3$-2-$MeC_3H_4)_2(\mu$-dppm)] (**3**), dark red crystals from Et_2O, 75% yield. Found: C, 58.5; H, 5.9. Calc. for $C_{33}H_{36}P_2Cl_2Ni_2$: C, 58.0; H, 5.3%. ^1H NMR (C_6D_6, 200 MHz, 70°C): δ 1.77 (brs, P—CH_2), 3.05 (s, C—Me), 2.60, 3.45 (brs, allylic CH_2), 6.8–7.7 (m, Ph).

When dmpm is used as the complexing ligand, compound **4** precipitates out of the reaction mixture. After 2 h of stirring at room temperature, the resulting suspension was filtered off and the yellow solid residue washed with Et_2O. Found: C, 34.8; H, 7.1. Calc. for $C_{13}H_{28}P_2Cl_2Ni_2$: C, 35.9; H, 6.4%. ^1H NMR (CD_2Cl_2, 200 MHz): δ 1.5 (brs, P—Me); 1.75 (s, C—Me), 2.70 (brs, P—CH_2), 2.76, 3.43 (brs, allylic CH_2).

Preparation of [Ni(η^3-2-MeC_3H_4)CH_2SiMe_3(PMe_3)] (**5**)

4.1 cm^3 of a 0.8 N solution of Mg(CH_2SiMe_3)Cl in diethyl ether (*ca* 3.5 equiv) were added to a cold (−40°C) solution of complex **1** (0.8 g, 3.5 mmol) in Et_2O (40 cm^3). The colour of the reaction mixture gradually changed from red to yellow and the stirring was continued for 1 h at room temperature. The solvent was then stripped off under reduced pressure and the residue extracted with 25 cm^3 of petroleum ether and centrifuged. Evaporation to dryness gave an oily residue that was shown to be spectroscopically pure **5**. ^1H NMR (C_6D_6, 200 MHz): δ −0.39 (dd, H_A, CH_2Si, $^2J_{AB}$ = 10.5, $^3J_{AP}$ = 13.9 Hz), −0.16 (t, H_B, CH_2Si, $^3J_{BP}$ = 10.4 Hz), 0.08 (s, $SiMe_3$), 1.00 (d, $^2J_{HP}$ = 7.8 Hz, PMe_3), 1.58, (s, C—Me), 1.40, 2.08, 2.36 and 3.03 (H_1, H_2, H_3 and H_4 allylic protons, respectively, d, d, dd and t, $^3J_{H_1P}$ = 2.6, $^3J_{H_2P}$ = 5.9, $^3J_{H_3P}$ = 5.4, $^3J_{H_4P}$ = 4.9, $^2J_{H_AH_B}$ = 3.5 Hz).

The corresponding reactions of **1** with Mg(CH_2CMe_3)Cl and Mg($CH_2C_6H_4$-*o*-Me)Cl, were carried out using a similar procedure, and allowed the isolation of [Ni(η^3-2-MeC_3H_4)CH_2CMe_3(PMe_3)] (**6**) and [Ni(η^3-2-MeC_3H_4)($CH_2C_6H_4$-*o*-Me)(PMe_3)] (**7**) in the form of pure highly soluble oils. (**6**): ^1H NMR (C_6D_6, 200 MHz): δ 0.71 (d, $^2J_{HP}$ = 6.9 Hz, PMe_3), 0.94 (s, CMe_3), 0.81, 1.06 (brs, CH_2CMe_3), 1.33 (s, C—Me), 1.12, 1.95, 2.05 and 3.08 (brs, allylic protons). (**7**): ^1H NMR (C_6D_6, 200 MHz): δ 0.85 (d, $^2J_{HP}$ = 7.8 Hz, PMe_3), 1.33 (d, $^3J_{HP}$ = 2.6 Hz, CH_2Ar), 1.50 (s, C—Me), 2.28 (s, Ar—*Me*), 1.84–2.25 (m, allylic protons), 6.8–7.2 (m, aromatic protons).

Abstract—The preparation of $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ by electrochemical oxidation of zinc and simultaneous reduction of 2-(dimethylamino)ethanethiol disulphide in an acetonitrile solution containing triethylamine is described. The compound crystallizes in the orthorhombic space group $P2_12_12_1$ with $a = 22.010(5)$, $b = 11.313(3)$ and $c = 10.170(3)$ Å. The structure consists of two crystallographically independent neutral monomeric units, which are optical isomers. Each zinc atom is bonded to two nitrogen and two sulphur atoms yielding a distorted tetrahedral coordination geometry. The chelating behaviour of the ligand is also evidenced in the IR and ^1H and ^{13}C NMR spectra.

The X-ray crystal structure of metal complexes of *v*-mercaptoamines has shown that the chelating ability of this family of ligands is a function of the flexibility of the carbon chain linking nitrogen and sulphur donor atoms and also of the metal character. Thus, while 3-amino-1-propanethiol has always behaved as a chelating ligand,[1–3] 3-dimethylamino-1-propanethiol[4–6] and aliphatic cyclic *v*-mercaptoamines[7–9] have preferred coordination via the thiolate group exclusively. The only known examples where 3-dimethylamino-1-propanethiol,[10] 4-mercapto-1-methylpiperidine,[11] 2-(mercaptoethyl)-1-methylpiperidine,[12] 3-(mercaptomethyl)-1-methylpiperidine[13] and 3-(mercaptomethyl)piperidine[10,14] behave as bidentate chelating ligands are restricted to palladium(II) and platinum(II) complexes. Up to now, metal atoms belonging to the first transition series have never yielded chelates. In order to assess the stereochemical constraints imposed by the N-methyl substituted amine function in mercaptoamine ligands, a zinc derivative of 2-(dimethylamino)ethanethiol has been prepared by direct electrochemical synthesis. The crystal and molecular structure of the $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ complex together with the corresponding IR, ^1H and ^{13}C NMR spectra are described in this paper. To our knowledge no complex of the previous ligand with group 12† metals has yet been reported.

EXPERIMENTAL

2-(Dimethylamino)ethanethiol disulphide was obtained from 2-(dimethylamino)ethanethiol by adding an equimolecular amount of NaOH to an aqueous solution of 2-(dimethylamino)ethanethiol hydrochloride (purchased from Fluka) and then distilling the mixture under the open atmosphere. Acetonitrile and methanol were stored over molecular sieves before use. The rest of the reagents were research grade and were not further purified.

Preparation of $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$

A zinc foil (60 × 15 × 0.2 mm) and a platinum wire (10 × 0.5 mm diameter) were placed on the

* Author to whom correspondence should be addressed.
† Refers to the 18-group format of the Periodic Table.

longest opposite faces of a glass cell (75 × 60 × 30 mm) as anode and cathode, respectively. A solution consisting of 2 cm^3 (8.78 mmol) of 2-(dimethylamino)ethanethiol disulphide, 6 cm^3 (43 mmol) of NEt_3 and 0.023 g (0.1 mmol) of Et_4NClO_4 in 50 cm^3 of acetonitrile was added to the cell, which was sealed by means of the corresponding glass lid. A constant voltage of 20 V was applied to the electrodes for 24 h, meanwhile the current intensity varied from the initial 20 mA to the final 5 mA. Then, to the filtered solution, 20 cm^3 of dry diethyl ether were added. This new solution was extracted successively 10 times with 20 cm^3-portions of *n*-hexane. The combined extracts of *n*-hexane were evaporated *in vacuo* down to 5 cm^3 and then the solution was left under a slow stream of nitrogen until a crystalline white solid appeared, which was filtered and dried *in vacuo*. (Found: C, 35.3; N, 10.1; S, 23.3; Zn, 24.2. $C_8H_{20}N_2S_2Zn$ requires C, 35.1; N, 10.2; S, 23.4; Zn, 23.9%.)

This compound is soluble in methanol, ethanol, acetone, diethyl ether, acetonitrile and dichloromethane and slightly soluble in *n*-hexane. It decomposes in water and also in either acid or basic aqueous solutions.

Suitable crystals for X-ray diffraction were obtained by slow evaporation of anhydrous methanolic solutions of the title compound by means of a controlled stream of nitrogen. Analogous attempts with other solvents already mentioned always led to poor quality crystals.

Analyses

Microanalyses were performed by one of the authors (I.C.) with a Carlo Erba NA-1500 analyser. The zinc content was determined by complexometric titration with EDTA.

Physical measurements

IR spectra were recorded from 4000 to 400 cm^{-1} in KBr or between NaCl plates on a Perkin–Elmer 1710 spectrophotometer. The far-IR spectrum of the solid complex was recorded as Nujol mull supported between polythene plates using a Perkin–Elmer 983 apparatus.

^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a Bruker AM-400 in CD_3OD (99.6%) solutions.

Crystallography

Crystal data. $[C_8H_{20}N_2S_2Zn]$, $M = 273.76$, orthorhombic, $a = 22.010(5)$, $b = 11.313(3)$, $c = 10.170(3)$ Å, $V = 2532(2)$ $Å^3$, $Z = 8$, $D_c = 1.436$ g cm^{-3}, $F(000) = 1152$, space group $P2_12_12_1$, $\lambda(\text{Mo-}K_\alpha) = 0.71069$ Å, $\mu(\text{Mo-}K_\alpha) = 22.69$ cm^{-1}, room temperature.

A prismatic white crystal (0.1 × 0.1 × 0.2 mm) was selected and mounted on a Philips PW-1100 four circle diffractometer. Unit-cell parameters were determined from automatic centring of 15 reflections ($4 \leqslant \theta \leqslant 12°$) and least-squares refinement on setting angles. Intensities were collected with graphite monochromatized Mo-K_α radiation, using the ω-scan technique, scan width 0.8°, scan speed 0.03° s^{-1}. 1734 reflections were measured in the range $2 \leqslant \theta \leqslant 25°$; 1050 of which were assumed as observed, applying the condition $I \geqslant 2.5\sigma(I)$. Three reflections were measured every 2 h as orientation and intensity control, no significant intensity decay was observed. Lorentz-polarization but not absorption corrections were made.

Solution and refinement. The structure was solved by direct methods, using the MULTAN system of computer programs[15] and refined by full-matrix least-squares using the SHELX76 computer program.[16] The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where $w = (\sigma^2(F_o) + 0.037|F_o|^2)^{-1}$, *f*. *f'* and *f''* were taken from the *International Tables of X-ray Crystallography*.[17] The positions of hydrogen atoms were computed and refined with an overall isotropic temperature factor, using a riding model. The final *R* factor was 0.053 ($wR = 0.057$) for all observed reflections.* Maximum shift/ESD = −0.2 in *Z* of N8(B), maximum and minimum peaks in final difference synthesis were 0.4 and −0.4 e $Å^{-3}$, respectively.

RESULTS AND DISCUSSION

Synthesis

The anodic oxidation of zinc and the simultaneous cathodic reduction of 2-(dimethylamino) ethanethiol disulphide is a direct route for obtaining a very pure zinc chelate of formula $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$. The same procedure using either the thiol or the corresponding disulphide as starting materials has already been reported for the synthesis of neutral $[M^{II}(SR)_2]$ compounds (M = Zn, Cd, Hg), for which a polymeric structure has been proposed,[18] and also for the syn-

* Atomic coordinates, thermal parameters, full lists of bond lengths and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

thesis of the anionic cluster $[Zn_4(SPh)_{10}]^{2-}$ whose structure consists of discrete tetrahedra of zinc atoms with four terminal and six bridging thiolate ligands. Despite that, the formula of the complex reported in this work is compatible with a polymeric structure, the ability of the ligand to behave as a chelate has caused formation of discrete mononuclear species, in agreement with the high solubility of $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ in common organic solvents. The main difference in the synthesis of this complex and those mentioned above is that in our case the electrochemical reaction has never attained a 90% yield as has been reported for the other complexes. Even though the amount of pure complex recovered is a function of the number of extractions, its solubility in *n*-hexane accounts for the low yield. On the other hand, evaporation of the acetonitrile–ethereal solution has always led to a yellow solid whose elemental analyses and IR spectrum indicated that it corresponded to a slightly impure zinc complex.

Description of the structure of $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$

The title compound crystallizes in orthorhombic space group $P2_12_12_1$ and contains discrete neutral monomeric units exclusively. The most relevant metrical parameters for the two crystallographically independent molecules, denoted as **A** and **B**, are given in Table 1. The X-ray analysis shows that **A** and **B** differ slightly in bond distances and angles. Molecules **A** and **B** together with the atom numbering scheme are displayed in Fig. 1. In each unit the zinc atom is coordinated to two ligand molecules by means of the nitrogen and sulphur donor atoms. Thus, both aminothiolate ligands give rise to a five-membered chelate ring. The chelate groups are non-planar. The coordination geometry around zinc is that of a flattened tetrahedron as evidenced by the bite angle of the ligands, which is close to 90°C and by the S(1)—Zn—S(2) and N(3)—Zn—N(8) angles, which are about 141 and 116°, respectively (Table 1). The degree of distortion from tetrahedral geometry can also be measured by the dihedral angle determined by the planes defined by S(1), Zn, S(2) and N(3), Zn, N(8) atoms, which is 77.5 and 78.7° for molecules A and B, respectively. Similar distortions from tetrahedral geometry have been reported for ZnN_2S_2 units and five-membered S,N-chelate rings. By comparing $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ with $[Zn\{SC(CH_3)_2CH_2NH_2\}_2]$[20] and $[Zn_2LCl_2]_2$ (L = $^-SCH_2CH_2N(CH_3)CH_2CH_2N(CH_3)CH_2CH_2S^-$),[21] Table 2, it is possible to conclude that: (a) Zn—S and Zn—N bond distances are comparable in the three complexes and agree well with other literature values;[22–24] (b) the bite angle of the ligands, S—Zn—N, and that formed by adjacent donor atoms of different ligands, S—Zn—N′, depend very little on the ligand nature and (c) the geometrical constraints of the $^-SCH_2CH_2N(CH_3)CH_2CH_2N(CH_3)CH_2CH_2S^-$ ligand account for the great S—Zn—S′ and small N—Zn—N′ angles; meanwhile the methyl groups in $^-SC(CH_3)_2CH_2NH_2$ and $^-SCH_2CH_2N(CH_3)_2$ cause the previous angles to vary in the opposite

[a] L = $^-SCH_2CH_2N(CH_3)CH_2CH_2N(CH_3)CH_2CH_2S^-$.
[b] This work.

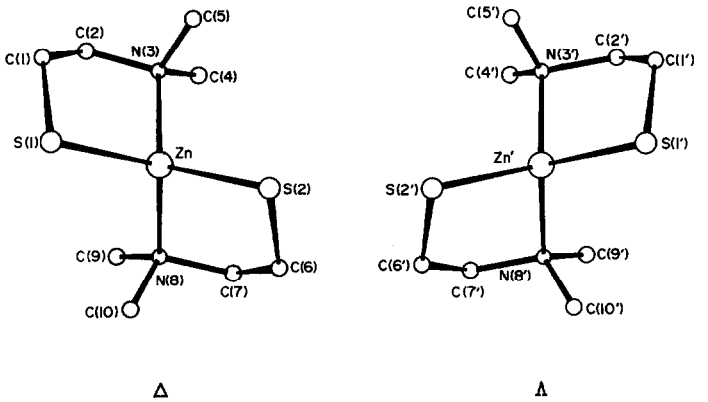
sense as would be expected based on their steric requirements only.

The structure of the $^-SCH_2CH_2N(CH_3)_2$ ligand itself shows no unusual features and compares well with the $^-SC(CH_3)_2CH_2NH_2$ ligand in tetrahedral zinc(II)[20] and cobalt(II)[25] complexes.

The closest distance between two molecules is 3.8 Å which denotes that no chemical forces act between them. The unit cell contains eight molecules, four of each optical isomer of the title compound. The absence of an inversion centre or a plane of symmetry in the molecule accounts for the existence of two enantiomeric forms, Δ and Λ,[26] and consequently for the two crystallographically independent units, **A** and **B**, respectively.

IR data

The comparison of the IR spectrum of the crystalline $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ complex with that of $HSCH_2CH_2N(CH_3)_2$ and the corresponding halohydrates leads to the same conclusions as those drawn from aliphatic ν-mercaptoamine ligands.[11,27] Thus, also in the present case, the 3000–2500 cm^{-1} region indicates unambiguously the ligand behaviour, as displayed in Fig. 2. Meanwhile, free $HSCH_2CH_2N(CH_3)_2$ shows two strong and resolved bands at 2945 and 2780 cm^{-1}, assigned to $\nu(CH_2)$ and $\nu(CH_3—\bar{N})$, respectively, the chelating $^-SCH_2CH_2N(CH_3)_2$ anion only shows one, also strong and resolved, and centred at *ca* 2900 cm^{-1}.



Δ Λ

Fig. 1. View of the two crystallographically independent molecules, **A** and **B**, in $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$, which correspond to Δ and Λ enantiomorphic forms, respectively. The atom numbering scheme is also shown.

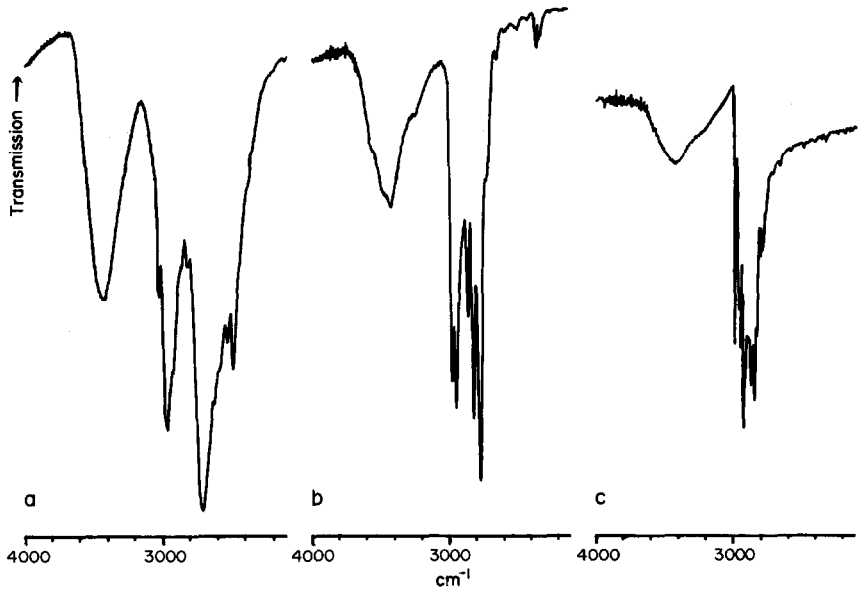


Fig. 2. The 4000–2200 cm^{-1} region of the IR spectra of (a) $HSCH_2CH_2N(CH_3)_2 \cdot HBr$, (b) $HSCH_2CH_2N(CH_3)_2$ and (c) $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$.

Based on the behaviour of *v*-mercaptoamine ligands[11,26] the IR spectrum of complexes where 2-(dimethylamino)ethanethiol is in the anionic form and coordinating through the sulphur atom exclusively should be practically identical to that of the free ligand. In the case of the halohydrates, which is comparable to complexes where the aminothiol is in the zwitterionic form and thus coordinating through the sulphur atom exclusively, $^-SCH_2CH_2\overset{+}{N}H(CH_3)_2$, the band at 2945 cm^{-1} remains, but a new very broad band centred at *ca* 2700 cm^{-1} is also present. This one can be assigned to ν(N—H) according to previous reports.[27] The far-IR spectrum (400–50 cm^{-1}) of $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ shows bands at 377(s), 335(s), 299(m), 270(w), 232(s), 212(m), 169(w), 116(s), 92(m) and 76(m). The corresponding intensities are given in parentheses.

^1H *and* ^{13}C NMR *data*

Peaks observed in the ^1H and ^{13}C, ^1H-decoupled NMR spectra of solutions of $(CH_3)_2NCH_2CH_2SSCH_2CH_2N(CH_3)_2$ and $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ are given in Table 3, together with the corresponding assignments, which have been made based on reported information on aliphatic *v*-mercaptoamine complexes.[11,12,28] By comparing the ^1H NMR spectra of the zinc complex with that of the free disulphide it is observed that in the complexed ligand, the singlet corresponding to the methyl groups shifts 0.16 ppm to lower fields which

is consistent with its chelating behaviour. However, this shift is smaller than that found for palladium(II)[11,12] and platinum(II)[11] complexes of *v*-mercaptoamines, thus indicating that the metal nature plays an important role on the referred displacement.

The main features of the ^{13}C NMR spectra of the above compounds complete the information obtained from the ^{1}H NMR spectra. Thus, the chemical shifts of the peaks assigned to $C(H_2—S)$ and $C(H_2—N)$ differ significantly from the free disulphide to the chelated aminothiolate ligand, while that corresponding to the methyl groups is practically unaffected by metal coordination. The structure found for $[Zn\{SCH_2CH_2N(CH_3)_2\}_2]$ (Fig. 1) may account for these data, as it clearly shows that the aliphatic chain linking nitrogen and sulphur donor atoms becomes rigid by metal chelation, meanwhile the exo-oriented methyl groups are much less affected by coordination.

(*Received* 14 *September* 1989; *accepted* 4 *October* 1989)

Abstract—The polymeric structure of the $\{[Ag_{13}(\mu\text{-}SC_5H_9NHMe)_{16}]^{13+}\}_n$ cation contains $Ag_{10}S_{16}$ units linked by three silver atoms. Each unit consists of a central $Ag_6(\mu\text{-}SR)_6$ core and two $Ag_4(\mu\text{-}SR)_4$ rings, and comprises digonal, trigonal and tetrahedral silver and doubly- and triply-bridging sulphur atoms.

Despite the fact that copper and silver thiolates have been known for many years, their molecular structures are still of considerable interest.[1] Recent reports indicate that the difficulties encountered in obtaining X-ray quality crystals can be overcome either by reacting metal tertiary alkanethiolates, such as $[M(SBu^t)]_\infty$, with triphenylphosphine,[2] or by using sterically hindered (triorganosilyl) methanethioles, $(RR'R''Si)_nCH_{3-n}SH$, as ligands.[3] However, up until now only two non-molecular silver(I) thiolates, $[AgSCMeEt_2]_n$[4] and $[Ag_4\{SCH_2(SiMe_3)\}_3(OCH_3)]_n$,[3] have been characterized structurally. The introduction of the amine function as a solubilizing group in thiol ligands has to be considered as an alternative method for obtaining crystalline silver(I) thiolate complexes. Thus, solution equilibria studies with several aliphatic γ-mercaptoamines in aqueous media have shown that in a wide pH-range they behave as simple thiolate ligands,[5] and they have also led to the structural chacterization of the cation $\{Ag_5[\mu_2\text{-}S\text{-}(CH_2)_3\text{-}NHMe_2]_3[\mu_2\text{-}S\text{-}(CH_2)_3\text{-}NMe_2]_3\}^{2+}$, the first thiolate complex with trigonal bipyramido-M_5-trigonal prismo-S_6 polyhedral stereochemistry.[6]

We report here the synthesis and structure of the polymeric $\{[Ag_{13}(S\text{-}C_5H_9NHMe)_{16}]^{13+}\}_n$ cation (**1**). When a six-fold excess of 4-mercapto-1-methylpiperidine is added to a solution of $AgNO_3$ in water containing $NaClO_4$ (2.3 M), and after the pH is adjusted to 8.5 with $HClO_4$, pale yellow crystals are obtained, whose formula correspond to the perchlorate of **1**. The structure was determined by X-

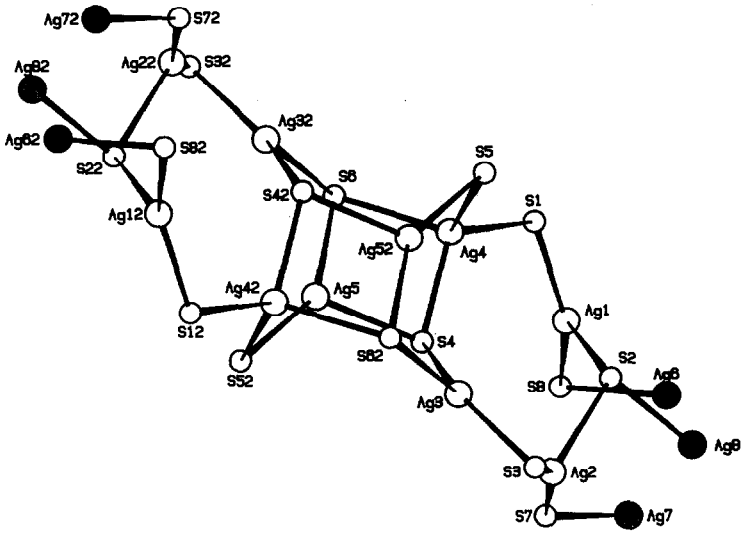

Fig. 1. Skeleton of the $Ag_{10}(\mu\text{-}SR)_{16}$ unit with the atom numbering (all labels ending with 2 mean positions $-x, 2-y, 1-z$). Shaded atoms have an occupancy factor of 0.5. All ligand atoms, except for sulphur have been omitted for the sake of clarity.

ray crystallography.* The anodic oxidation of silver in a $NaNO_3$ saturated acetonitrile solution containing 4-mercapto-1-methylpiperidium nitrate and triphenylphosphine in a 1 : 2 molar ratio, and after diffusion of ether, leads to pale yellow crystals corresponding to the nitrate of **1**. In this case the X-ray crystal structure determination could not be completed because of too much disorder, but the molecular structure very much resembles that of the perchlorate as far as the heavy atoms are concerned. Both the perchlorate and nitrate of **1** are hydrated compounds. However, neither elemental analysis nor crystal structure determination have allowed us to establish unambiguously the degree of hydration.

The $\{[Ag_{13}(\mu\text{-}SC_5H_9NHMe)_{16}]^{13+}\}_n$ cation, as shown schematically in Fig. 1, consists of a central core of Ag_6S_6 atoms from which two eight-membered cycles of alternating silver and sulphur atoms emerge. The Ag_6S_6 core can be described as four fused $Ag_3(\mu\text{-}SR)_3$ cycles, each in a boat conformation, containing two tetrahedral [Ag(4), Ag(42)] and four trigonal-planar [Ag(3), Ag(5), Ag(32),

* Crystal data. $C_{96}H_{208}Ag_{13}Cl_{13}N_{16}O_{52}S_{16}$, triclinic, space group $P\bar{1}$, $a = 21.129(4)$, $b = 20.383(4)$, $c = 15.172(3)$ Å, $\alpha = 121.59(3)$, $\beta = 114.53(4)$, $\gamma = 96.21(3)°$, $Z = 1$, $2\theta_{max} = 50°$, crystal dimensions $0.05 \times 0.05 \times 0.2$ mm. 9492 measured reflections including 4083 observed reflections with $I \geqslant 2.5\sigma(I)$ were collected using a Philips PW-1100 four cycle diffractometer, Mo-K_α radiation, graphite monochromator, ω-scan technique, scan width 0.8°, scan speed 0.03° s^{-1}, 288 K. No absorption corrections were made. The silver and sulphur atoms were located with the MULTAN system of computer programs. The Fourier synthesis of MULTAN revealed three positions, Ag(6), Ag(7) and Ag(8), with an intermediate electronic number between silver and sulphur. Three isotropic refinement cycles confirmed that these three peaks correspond to three silver atoms, with an occupancy factor of 0.5. Carbon, nitrogen and several chlorine atoms were located from a DIRDIF. Subsequent isotropic refinements and difference synthesis revealed the position of more chlorine and oxygen atoms of the perchlorate ions or water molecules. This process was terminated when difference synthesis did not reveal more atoms clearly. At this point 11 ClO_4^- ions (Cl(6) has an occupancy factor of 0.5) and six H_2O (confirmed by hydrogen bonding with nitrogen atoms) had been located as well as two positions [O(w4) and O(w5)] which could be assigned either to H_2O molecules or two chlorine atoms with an occupancy factor of 0.5. The neutrality of the crystal requires two additional ClO_4^- ions which have not been located. We suspect they are in a disordered position. The structure was refined anisotropically by using the SHELX76 computer program. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, where $w = (\sigma^2(F_o) + 0.076|F_o|^2)^{-1}$. The final R factor with the located atoms was 0.093 ($R_w = 0.096$) for all observed reflections. Number of refined parameters = 938. Max. shift/ESD = 0.4 in U_{12} of O(33). Maximum and minimum peaks in a final difference synthesis were 1.7 and -0.8 e $Å^{-3}$, respectively.

Atomic coordinates, bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre (see p. ii at front).

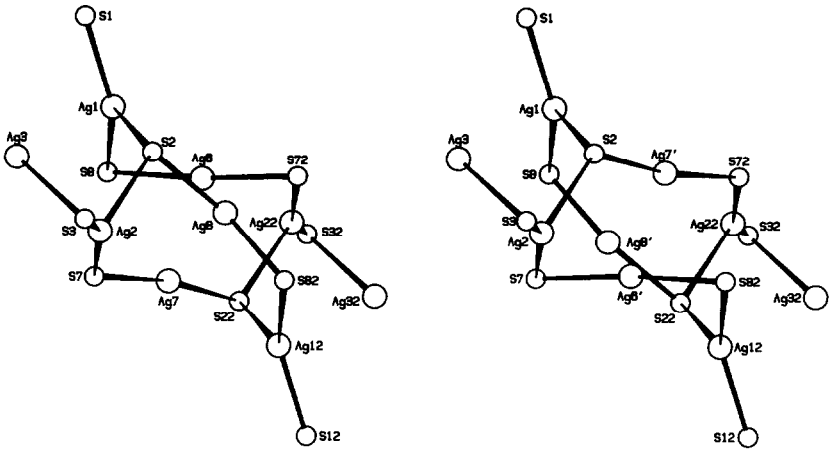

Fig. 2. The two alternative connections for the $Ag_{10}(\mu\text{-}SR)_{16}$ units (symmetry code $' = -x, 1-y, -z$).

Ag(52)] silver atoms and four triply-bridging [S(4), S(6), S(42), S(62)] and two doubly-bridging [S(5), S(52)] sulphur atoms. Ag(3), Ag(4) and S(4), and their symmetry related Ag(32), Ag(42) and S(42), belong simultaneously to a $Ag_4(\mu\text{-}SR)_4$ cycle, respectively, all but the Ag(4) atoms having trigonal-planar coordination. Considering the $Ag_4(\mu\text{-}SR)_4$ rings and ignoring Ag(6), Ag(7) and Ag(8), three sulphur atoms [S(1), S(2), S(3)] are doubly-bridging and two [S(8), S(7)] are terminal. Because of the inversion centre in the Ag_6S_6 core the same applies to the symmetry related sulphur atoms.

The $Ag_6(\mu\text{-}SR)_6$ core and the two $Ag_4(\mu\text{-}SR)_4$ rings just described constitute the unit that repeats in the one-dimensional non-molecular structure. Three disordered and digonally coordinated silver atoms [Ag(6), Ag(7), Ag(8)] are responsible for linking these $Ag_{10}S_{16}$ units, thus accounting for the empirical formula of the $[Ag_{13}(\mu\text{-}SR)_{16}]^{13+}$ cation. The two different ways that the Ag(6), Ag(7), Ag(8) atoms link the $Ag_{10}S_{16}$ units are illustrated in Fig. 2. With either of the two possibilities, sulphur [S(2), S(7), S(8) and their symmetry related] and silver atoms are at normal Ag—S bonding distances. The sulphur atoms describe a distorted octahedron, Fig. 3, where of the three silver atoms, one is in an equatorial and two are in axial edges. By including the disordered silver atoms the previously called terminal sulphur atoms [S(7), S(8)] now become doubly-bridging and the already doubly-bridging sulphur [S(2)] becomes triply-bridging in the crystallographic $Ag_{13}S_{16}$ unit.

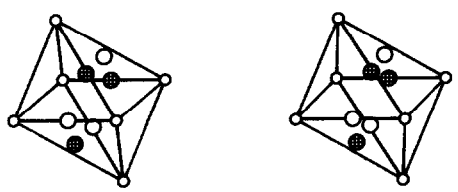

Fig. 3. Stereoview of the S_6-octahedron at the junction of two $Ag_{10}(\mu\text{-}SR)_{16}$ units showing the localization of the three disordered silver atoms (open and marked circles identify both sets).

Mean values of Ag—S bonding distances are as follows: Ag^{dig}—S, 2.40(8) Å; Ag^{trig}—S, 2.50(7) Å; Ag^{tetr}—S, 2.61(9) Å. There is very good agreement with literature values.[1-3] The shortest Ag—Ag distance is 3.00 Å [Ag(6)—Ag(8)], which precludes metal–metal interactions.[2] More details about this structure will be reported in the future.

THE FIRST EVIDENCE FOR REDUCTIVE COUPLING OF TRANSITION METAL SUBSTITUTED HALOGERMANES

G. BARSUASKAS, D. LEI, M. J. HAMPDEN-SMITH* and E. N. DUESLER

Department of Chemistry and Center for Micro-Engineered Ceramics,
University of New Mexico, Albuquerque, NM 87131, U.S.A.

(*Received* 25 *September* 1989; *accepted* 24 *October* 1989)

Abstract—The reduction of 1-(cyclopentadienylirondicarbonyl)-1-bromo-3,4-dimethylgermacyclopent-3-ene (**1**) with lithium metal results in practically quantitative yield of the coupled product (**2**). The formation of a Ge—Ge bond was confirmed by a single crystal X-ray diffraction study. The lithium reduction of **3**, $Br_2Ge[Fe(CO)_2Cp]_2$, results in the formation of the first examples of homoleptic transition metal substituted polygermanes.

The synthesis of small ring cyclopolysilanes and -germanes remained elusive for many years, even though the Wurtz coupling method of preparation for larger cyclopolysilanes was discovered early in the century.[1] However, the realization that the nature of both the organic substituents and the reducing agent are of vital importance ultimately led to the successful synthesis of trisilacyclopropanes,[2,3] disilenes,[4] trigermacyclopropanes[5] and digermenes[6] from R_2EX_2 (E = Si; Ge) species. Lithium naphthalenide has been widely employed as a reducing agent, and sterically demanding substituents, such as 2,6-dimethylphenyl, adamantyl and tert-butyl, have resulted in isolation of surprisingly inert species, such as $Si_3(tert\text{-}Bu)_6$, which is reportedly air stable when heated close to its melting point (180°C).[3] In some cases, heavy carbene analogues have been invoked as the reactive intermediates formed during reductive coupling;[3,7] in other cases, a radical mechanism is more likely. Very recently, the reduction of organo–group 14 trichlorides,[8] or their equivalents, such as $RX_2E—EX_2R$,[9,10] have been studied, and a number of fascinating new polyhedral oligomers have been characterized.

As part of our studies of the chemistry of transition metal–germanium bonds,[11] we are interested in determining whether the germanium–halide bond is susceptible to reductive coupling in the presence of transition metal substituents at germanium, with the ultimate goal of preparing homoleptic transition metal substituted polygermanes. Oligosilanes and -germanes with transition metal substituents have been previously prepared, but generally by salt elimination reactions.[12] We now report our initial findings on the reductive coupling of transition metal substituted halogermanes.

As a starting point, we have examined the reduction of a simple transition metal substituted diorganohalogermane, 1-(cyclopentadienylirondicarbonyl) - 1 - bromo - 3,4 - dimethylgermacyclopent-3-ene (**1**),† with 0.5 equiv. of lithium metal. The reaction proceeded virtually quantitatively according to eq. (1) to produce, after work-up, a crystalline species with spectroscopic and ana-

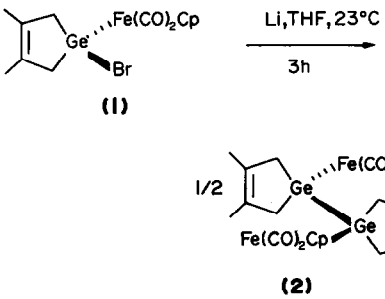
† Complex **1** was prepared by the reaction of 1,1-dibromo-3,4-dimethylgermacyclopent-3-ene with one equivalent of $Na[Fe(CO)_2Cp]$, as described elsewhere (see ref. 11).

lytical data consistent with the formation of the coupled product, **2**.*



(1)

To provide unambiguous evidence for the formation of the Ge—Ge bond, a single crystal X-ray diffraction study was performed.† The molecular structure of **2** is shown in Fig. 1, together with the appropriate bond lengths and angles. The molecule possesses C_i point group symmetry and adopts a staggered conformation about the Ge—Ge bond in which the two sterically demanding —$Fe(CO)_2Cp$

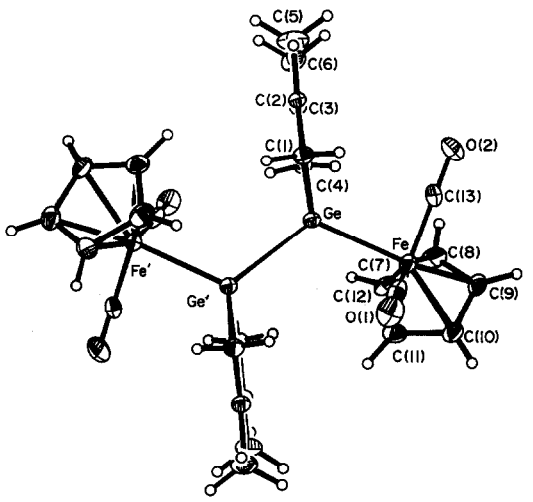


Fig. 1. 25% thermal ellipsoid plot showing the molecular structure of **2**.

Relevant bond distances (Å):

Ge—Ge'	2.448(1)	Fe—C(12)	1.740(6)
Ge—Fe	2.416(1)	Fe—C(13)	1.741(6)
Ge—C(1)	1.986(s)	Fe—Cp	2.093(6)
Ge—C(4)	1.983(1)		(av.)

Relevant bond angles (°):

Ge'—Ge—Fe	115.7(1)
C(1)—Ge—C(4)	91.6(2)
C(4)—Ge—Fe	110.8(2)
C(4)—Ge—Ge'	112.0(2)
C(1)—Ge—Fe	113.1(2)
C(1)—Ge—Ge'	111.1(2)

substituents are *anti* with a slightly enlarged Ge—Ge'—Fe' angle of 115.7(1)°. The Ge—Ge' distance of 2.448(1) Å and the Fe—Ge distances of 2.416(1) Å are in the ranges expected.‡ The germacyclopent-3-ene ring is almost planar, in contrast to 1,1-ditransition metal substituted germacyclopent-3-enes we have structurally characterized previously.[13] Other features of the structure in the present context are unremarkable.

Having demonstrated that the —$Fe(CO)_2Cp$ substituent is inert to the conditions of reductive coupling of Ge—Ge bonds, $[Cp(CO)_2Fe]_2GeBr_2$ (**3**) was reacted with lithium according to eq. (2):

$$[Cp(CO)_2Fe]_2GeBr_2 + Li \xrightarrow{THF,\ 17\ h,\ 23°C} \underset{(3)}{} \quad 1/n\{Ge[Fe(CO)_2Cp]_2\}_n + 2LiBr \quad (2)$$
$$(4)$$

Upon addition of lithium, the pale orange THF solution of **3** became deep red–brown, and the for-

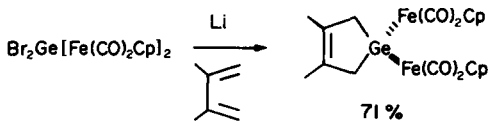
*300 mg of **1** (0.73 mmol) and 3.0 mg (0.5 equivalent) of lithium foil were placed in a 50 cm^3 Schlenk flask under dry nitrogen and 5 cm^3 of THF added. After stirring for 3 h, the initial pale orange solution had become a deep orange–red colour. The THF was removed *in vacuo*, and the dark residue thus obtained was extracted with two 10 cm^3 portions of toluene and filtered. The volume of the solvent was reduced by three-quarters and the solution cooled to −30°C. After 2 days, pale yellow crystals had formed that were isolated by filtration, washed with cold toluene and dried *in vacuo*. Yield of **2**, 200 mg (0.3 mmol), 82.2% yield. Found: C, 47.3; H, 4.4; N, 0.1. Calc: for $C_{13}H_{15}O_2GeFe$: C, 47.0; H, 4.6%. ^1H NMR (250 MHz, C_6D_6, 20°) $\delta = 2.32$, d, $J_{H-H} = 15.7$ Hz, 2H, CH_2; $\delta = 2.09$, d, 2H, CH_2; $\delta = 1.87$, s, 6H, CH_3; $\delta = 4.23$, s, 5H, C_5H_5. $^{13}C\{^1H\}$ NMR (62.9 MHz, C_6D_6, 20°C) $\delta = 19.8$, CH_3; $\delta = 33.8$, CH_2; $\delta = 82.8$, C_5H_5; $\delta = 132.1$, C—Me; $\delta = 215.9$, CO.

† Crystal structure data for **2**: monoclinic, space group $P2_1/n$, $a = 10.340(2)$, $b = 7.0124(12)$, $c = 18.295(4)$ Å, $\beta = 95.99(2)°$, $V = 1319.3(5)$ Å^3, $Q_{calc} = 1.670$ g cm^{-3}, $Z = 4$, 1943 unique reflections collected from $2\theta = 2.0$ to 50.0° with $F_o > 3.0\sigma(F)$. Nicolet R3M/V diffractometer, Mo-K_α radiation, $\gamma = 0.71073$ Å, $T = 20°C$. Solution by direct methods using SHELXTL PLUS (Microvax II) refined by full-matrix least-squares, $R_w = 3.64\%$. Further details are available as Supplementary Material. Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Centre.

‡ D(Ge—Ge) in $(Ph_2Ge)_n$ are $n = 4$, 2.465 Å; $n = 5$, 2.453 Å; $n = 6$, 2.460 Å; L. Ross and M. Drager, *J. Organomet. Chem.* 1980, **199**, 195; D(Fe—Ge) in $Cl_2Ge[Fe(CO)_2Cp]_2$ is 2.357(4) Å, M. A. Bush and P. Woodward, *J. Chem. Soc. A* 1967, 1833.

mation of a colourless precipitate was observed. After work-up, ^{1}H NMR spectroscopy indicated that there was no starting material present and that four new cyclopentadienyl resonances had been produced in the approximate ratio 1:2:4:12.* Elemental analysis of this mixture of products is consistent with the empirical formula: {Ge[Fe $(CO)_2Cp]_2$} (**4**).† Repeating the lithium reduction using solutions of **3** with different concentrations and using sodium naphthalenide as the reducing agent resulted in formation of the same ^{1}H NMR cyclopentadienyl resonances, but in different ratios. We therefore conclude that each resonance corresponds to a single reaction product: $\{Ge(Fe(CO)_2Cp]_2\}_n$.

When the reduction of eq. (2) is carried out in the presence of a large (> 10-fold) excess of 2,3-dimethylbutadiene, eq. (3), 1,1-bis(cyclopentadienylirondicarbonyl) - 3,4 - dimethylgermacyclopent-3-ene (**5**) was isolated in high yield,‡ in addition to oligomers $\{Ge[Fe(CO)_2Cp]_2\}_n$ (**4**) identical to those formed according to the reaction of eq. (2).



(3) (5)

$$+ \{Ge[Fe(CO)_2Cp]_2\}_n \quad (3)$$

(4)

The identity of **5** was confirmed by comparison of its spectroscopic and physical data with those of an authentic sample prepared by independent synthesis.§ No evidence for any other trapping products was obtained. At this stage, we are unable to determine whether the "$Ge[Fe(CO)_2Cp]_2$" moiety generated by the lithium reduction of **3** and trapped by 2,3-dimethylbutadiene is derived from a free transition metal substituted germylene [eq. (4)], or formed via interception of a radical pathway, such as eq. (5):

$$[Cp(CO)_2Fe]_2GeBr_2 \xrightarrow{Li} \text{"}[Cp(CO)_2Fe]_2Ge\text{:"} \longrightarrow \text{oligomerization} \quad (4)$$

$$Br_2Ge[Fe(CO)_2Cp]_2 \underset{-LiBr}{\overset{+Li^\cdot}{\rightleftharpoons}} [Cp(CO)_2Fe]Ge(Li)(Br) \Longrightarrow \text{oligomerization.} \quad (5)$$

In conclusion, this work provides the first evidence that halogermanes can be reductively coupled in the presence of transition metal substituents in high yield and that the —$Fe(CO)_2Cp$ moiety is innocent to the reaction conditions. Further studies concerning the chromatographic separation of the mixture of oligomers, **4**, and determination of their ring size by cryoscopic molecular weight determination in benzene solution are in progress.

*0.5 g of **3** were placed in a 200 cm^3 Schlenk flask under nitrogen, together with 12 mg of lithium foil. 20 cm^3 of THF was added and the mixture stirred for 20 h. During this time, the solution changed colour from pale orange to deep red–brown. The THF was removed *in vacuo*, and the dark residue was extracted with 2 × 20 cm^3 of benzene. The benzene was removed *in vacuo* to give a dark red–brown oil. ^{1}H NMR data (250 MHz, C_6D_6, 20°C): 4.57 ppm (12H), 4.56 (1H), 4.51 (2H), 4.24 (4H). Authentic **3** exhibits a single cyclopentadienyl resonance at 4.29 ppm and did not coincide with any of the peaks above when added to the NMR tube.

† Elemental analysis: Found: C, 39.4; H, 2.2; N, 0.00. Calc. for $C_{14}H_{10}O_4Fe_2Ge$: C, 39.3; H, 2.3%.

‡ To a mixture of **3** (500 mg, 0.85 mmol) and Li (24 mg) was added a mixture of 20 cm^3 of THF and 1 cm^3 of 2,3-dimethylbutadiene. After stirring for 20 h, the volatile components were removed *in vacuo* and the red–brown residue was extracted with 3 × 10 cm^3 of toluene. The volatile components were removed *in vacuo* and the residue extracted with 30 cm^3 of *n*-pentane. The volume of the solution was reduced to about 5 cm^3 *in vacuo* and placed at −30°C. After 16 h, 310 mg (0.61 mmol) of crystalline **5** was recovered (71.7% yield): oligomers, **4**, were obtained from the toluene soluble fraction.

§ ^{1}H NMR data for **5** (250 MHz, C_6D_6, 20°C): δ = 4.31, s, 5H, C_5H_5; δ = 2.43 ppm, q, 2H, J_{H-H} = 1 Hz, CH_2; δ = 1.92, t, 3H, CH_3. ^{13}C NMR (62.9 MHz, C_6D_6, 20°C): δ = 19.5, CH_3; δ = 41.9, CH_2; δ = 83.8, C_5H_5; δ = 131.9, *C*—Me; δ = 216.7, *C*O. SYNTHESIS AND CRYSTAL STRUCTURE DETERMINATION OF TETRAPHENYLARSONIUM *p*-BROMOPHENYLTHIOCHROMATE

WALDEMAR MAZUREK

(*Received* 20 *October* 1989; *accepted* 13 *November* 1989)

Abstract—The initial step in the reaction of $[Cr_2O_7]^{2-}$ with *p*-bromothiophenol in dimethylformamide is the formation of the chromium(VI)–thioester $[p\text{-}BrC_6H_4SCrO_3]^-$, which has been isolated as the $[Ph_4As]^+$ salt and its structure determined by a single crystal X-ray diffraction study, thus confirming the proposed first step in the mechanism for the overall oxidation of thiophenols by dichromate.

In aqueous solution thiols are considered to react rapidly with chromate ions forming "thioesters" ($[RSCr^{VI}O_3]^-$) which then participate in the overall reduction of chromium(VI) to chromium(III) as the thiol is oxidized to a disulphide.[1,2] The orange thioesters are transient species, however, and have only been detected by visible spectroscopy[1,2] (characteristic absorptions at *ca* 420–440 nm), while more recently the chromium(VI)–glutathione thioester has been characterized by ^1H and ^{13}C NMR spectroscopy.[3] Less is known about the subsequent redox chemistry of the systems although the production of a chromium(V) intermediate in the chromate oxidation of glutathione[4] indicates a possible initial step as: $[RSCr^{VI}O_3]^- \rightarrow$ "Cr^{V}" + $RS^{\bullet}$.

While studying the kinetics of dichromate oxidations of thiols in organic solvents we have observed that the addition of an excess of thiol to $Na_2Cr_2O_7$ in dimethylformamide (DMF) results in the formation of species characterized by visible absorptions in the region of 420 nm with extinction coefficients, ε, of *ca* 2000 $mol^{-1}\ dm^3\ cm^{-1}$. This is similar to the behaviour observed in aqueous solution, and these species have been similarly assigned as chromium thioesters.

The subsequent decomposition of such species occurs notably more slowly in DMF than in aqueous solution and this has encouraged our attempts to isolate the products. The addition of a precipitate such as ether to DMF solutions of sodium or ammonium dichromate and various thiols gave only small amounts of paramagnetic material. However when *p*-bromothiophenol was the reductant and $[Ph_4As]^+$ ions were present in the system the addition of ether resulted in the isolation of the compound $[Ph_4As][p\text{-}BrC_6H_4SCrO_3]$.† It was recrystallized from DMF/ether to remove traces of paramagnetic material to yield a diamagnetic compound having $\lambda_{max} = 414$ nm; ε [per Cr] = 2440 $mol^{-1}\ dm^3\ cm^{-1}$ in DMF, the same spectral characteristics as had been obtained when $p\text{-}BrC_6H_4SH$ was initially added to a DMF solution of $Na_2Cr_2O_7$.

* Author to whom correspondence should be addressed.

† Microanalytical data, Found: C, 53.6; H, 3.5; Br, 12.0; S, 4.6. Calc. for $C_{30}H_{24}AsBrCrO_3S$: C, 53.7; H, 3.6; Br, 11.9; S, 4.8%.

The IR spectrum of the salt contains strong bands at 946 and 890 cm^{-1}, which by analogy with $KCrO_3Cl$ correspond to $\nu(Cr—O)_{asym}$ and $\nu(Cr—O)_{sym}$, respectively.[5] Other absorptions around this region indicate the presence of *p*-Br C_6H_4S (1008 and 818 cm^{-1}) and $[Ph_4As]^+$ (977, 741 and 689 cm^{-1}). The absence of bands around 770 cm^{-1} indicate the loss of the μ-oxo bond.[6]

Similar salts have also been isolated with $[(Ph_3P)_2N]^+$ cations and the thioesters derived from thiophenol and its *p*-Br and *p*-NO_2 derivatives.

A crystal structure determination has been made of $[Ph_4As][p\text{-}BrC_6H_4SCrO_3]$ which has confirmed the chromium(VI) thioester assignment.* Figure 1 shows the atomic labelling scheme used and appropriate bond lengths and angles are listed. The structure represents the first example of a chromium(VI)–sulphur compound to have been characterized as well as the first chromium(VI)–thioester compound.

The Cr—O bond lengths are somewhat shorter than the mean bond distance for many chromate anions (1.646(25) Å) and closer to the mean non-bridging Cr—O distances reported for dichromates (1.615(18) Å) and trichromates (1.598(10) Å).[8] The opening of the O—Cr—O angles beyond the tetrahedral value is presumably a result of the incorporation of the large sulphur atom bonded to chromium with a Cr—S bond distance of 2.263(7) Å. This results in an approximate C_{3v} symmetry for the four bond group connected to chromium(VI). The shortening of three Cr—O distances below that of the chromate anion as the fourth chromium–ligand bond lengthens has been noted in the case of a series of polychromates.[8] In two alkali metal $[CrO_3Cl]^-$ compounds the Cr—O lengths are comparable with those in the thioester (1.601–1.613).[9]

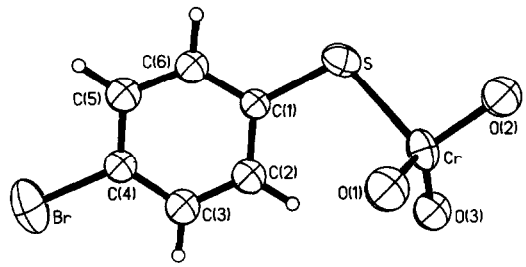

Fig. 1. ORTEP drawing of the $[p\text{-}BrC_6H_4SCrO_3]^-$ anion structure (standard deviations are given in parentheses)

Cr—O(1)	1.609(12)	Cr—O(3)	1.621(12)
Cr—O(2)	1.607(11)	Cr—S	2.263(7) Å

O(1)—Cr—O(2)	114.1(6)
O(2)—Cr—O(3)	112.9(6)
O(1)—Cr—O(3)	112.9(7)
O(1)—Cr—S	107.5(5)
S—C(1)—C(2)	123.1(14)
Cr—S—C(1)	105.1(6)°.

We are currently studying the kinetics of formation and decomposition of such chromium(VI)–thioesters in DMF solution. Whilst they eventually decompose to give chromium(III) and disulphides there is evidence for further transient intermediates and the use of non-aqueous solvents may allow isolation of these species.

(*Received* 15 *March* 1989; *accepted* 31 *August* 1989)

Abstract—Seventeen bis-carboxylate derivatives of bis(methylcyclopentadienyl)titanium have been prepared by the reaction of bis(methylcyclopentadienyl)titanium dichloride with the appropriate sodium salts of substituted benzoates. They have been characterized by elemental analysis, IR and ^{1}H NMR. When treated with electrophilic reagents such as $SOCl_2$, CH_3COCl and HX, $(CH_3C_5H_4)_2TiX_2$ were obtained. The crystal and molecular structure of bis(methylcyclopentadienyl)bis(*o*-methylbenzoate)titanium has been determined by X-ray diffraction. The compound crystallizes in the monoclinic group $P2_1/c$ with four molecules in a cell having $a = 8.098(3)$, $b = 28.747(4)$, $c = 10.374(3)$ Å, $\beta = 95.48(2)°$. The molecules have a distorted tetrahedral structure in which the titanium atom is attached to two η^5-$CH_3C_5H_4$ groups and two monodentate *o*-methylbenzoate ligands (Ti—C, 2.323–2.409 Å; Ti—O, 1.979(3) and 1.961(3) Å; O—Ti—O, 90.5(3)°; (cent-$CH_3C_5H_4$)—Ti—(cent-$CH_3C_5H_4$), 130.1(3)°.

The synthesis, characterization and structure of the complexes $(C_5H_5)_2Ti(O_2CR)_2$ (R = alkyl and aryl) have been reported.[1–4] On account of the biological activity of the complexes, this work has attracted the interest of many researchers.[5–6] One study on $(CH_3C_5H_4)_2Ti(O_2CR)_2$ has been reported, but the structure of this type of complex is still of interest.[1] We report here the synthesis of 17 new complexes of $(CH_3C_5H_4)_2Ti(O_2CR)_2$ (R = aryl) and discuss the IR spectra and ^{1}H NMR of these new complexes. The structure of bis(methylcyclopentadienyl)titanium bis(*o*-methylbenzoate) has been determined by X-ray diffraction and its molecular structure is discussed in detail.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

All reagents were obtained commercially and were not purified before use. Benzene and petroleum ether were dried using sodium/benzophenone. Anhydrous sodium salts of substituted benzoic acids were prepared by reaction of substituted benzoic acids with sodium ethoxide, and were dried. $(CH_3C_5H_4)_2TiCl_2$ was prepared according to the literature method.[8]

Melting points were determined using a Kofler instrument, but the temperature was not calibrated. ^{1}H NMR spectra were recorded with a Bruker FT-80A spectrometer, using $CDCl_3$ as solvent. The chemical shifts were reported in ppm relative to $Si(CH_3)_4$. IR spectra were recorded with an FT-5DX spectrophotometer (in KBr pellets) in the 4000–400 cm^{-1} range. The titanium analyses were

determined gravimetrically as TiO_2. Carbon, hydrogen and nitrogen contents of the complexes were carried out with a 1106-elemental analysis instrument.

Preparation of $(CH_3C_5H_4)_2Ti(O_2CC_6H_4X)_2$

$(CH_3C_5H_4)_2TiCl_2$ (2 mmol) and an excess of the anhydrous sodium salt of the substituted benzoic acid were added to 50 cm^3 of dry benzene and stirred for 12 h at 30°C. The colour of the reactant liquid changed from deep red to orange–red. The precipitated salt was removed by filtration and the filtrate was concentrated under reduced pressure until the remaining liquid was about 10 cm^3. Petroleum ether was added, the solution refrigerated at 0°C overnight, and a crystalline product was obtained. The crystals were washed with petroleum ether. Physical data and elemental analyses of the complexes are listed in Table 1. Complexes **4** and **8** were selected to react with CH_3COCl, $SOCl_2$ and HX (X = Cl, Br, I), respectively, in THF at room temperature. The products $(CH_3C_5H_4)_2TiX_2$ (X = Cl, Br, I) were characterized by ^1H NMR and their melting points.

Structure determination of complex **10**

An orange–red single crystal of complex **10** was obtained by recrystallization from benzene–*n*-hexane (1 : 1). The diffraction experiment was performed on a CAD4 diffractometer with graphite-monochromated Cu-K_α radiation ($\lambda = 1.5418$ Å). A total of 3007 reflections were collected in the range $3 < 2\theta < 110°$, and there were 2176 reflections with $I > 3\sigma(I)$. The crystal data are summarized in Table 2. The structure was solved by direct and Fourier methods, and refined by full-matrix least-squares techniques with the anisotropic temperature factor for non-hydrogen atoms. Hydrogen atoms in calculated positions with isotropic thermal parameters were included in final structure factor calculations. Final $R = 0.055$ and $R_w = 0.058$; all calculations were performed on a PDP11/44 computer with the SDP program package.

RESULTS AND DISCUSSION

The new complexes of $(CH_3C_5H_4)_2Ti(O_2CC_6H_4X)_2$ were synthesized by the reaction of $(CH_3C_5H_4)_2TiCl_2$ with $XC_6H_4CO_2Na$. This method is easy and simple. Complexes **1–17** are stable to dry air at room temperature and have regular melting points. They are soluble in polar organic solvents such as C_6H_6, $CHCl_3$, CH_2Cl_2, CH_3COCH_3, etc., but insoluble in petroleum ether and water.

The molecular structure of complex **10**

An ORTEP drawing of complex **10** is given in Fig. 1. Atoms of the two η^5-methylcyclopentadienyl and two *o*-methylbenzoate ligands are distinguished by a literal subscript. Bond distances and angles in the coordination group are listed in Table 3.

The molecules of complex **10** have a bent metallocene structure in which the titanium atom is attached to two monodentate *o*-methylbenzoate ligands and two η^5-$CH_3C_5H_4$ groups. The centroids of the $CH_3C_5H_4$ and the coordinated oxygen atoms define a distorted tetrahedron with the cent-$CH_3C_5H_4$—Ti—cent-$CH_3C_5H_4$ angle being 130.1° and the O_{2A}—Ti—O_{2B} angle being 90.5°; these figures should be compared with data for the known compound $(C_5H_5)_2Ti(O_2CC_6H_5)_2$ (137.7 and 91.4°).[1] Because C_{6C} and C_{6D} are on the same side and the non-bonded contacts of C_{3C}—C_{3D} (2.93 Å) and C_{4C}—C_{4D} (2.95 Å); C_{2C}—C_{2D} (4.05 Å) and C_{5C}—C_{5D} (4.12 Å) are similar, the two η^5-$CH_3C_5H_4$ rings are eclipsed. The conformation of complex

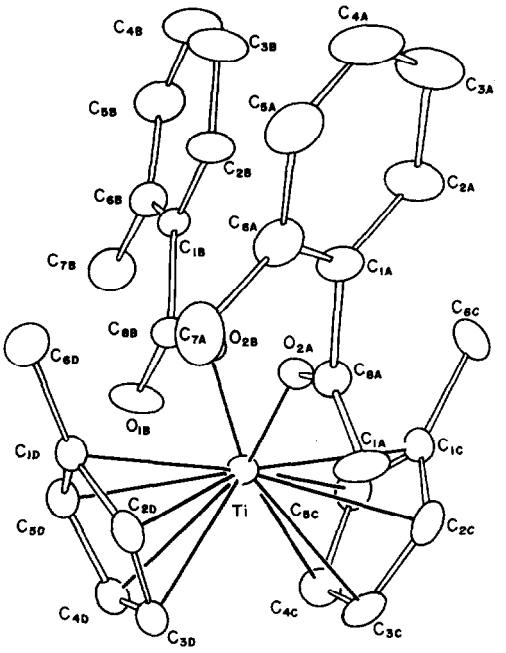

Fig. 1.

10 is also different from $(C_5H_5)_2Ti(O_2CC_6H_5)$[1] but similar to $(CH_3C_5H_4)_2TiCl_2$.[9] The Ti—C distances and the distances from the titanium atom to the centroids of the CH—C—H rings (2.075 Å) are in excellent agreement with the corresponding distances in the other $(CH_3C_5H_4)_2Ti$ structure.[9]

There is considerable crowding in the TiO_2C_{10} coordination group as evidenced by the conformation (eclipsed conformation including methyl groups). Due to crowding, the Ti—O bond lengths (1.979 and 1.961 Å) are relatively longer than the Ti—O bonds in $(C_5H_5)_2Ti(O_2CC_6H_5)_2$ (1.992 and

Table 3. Some important bond distances and bond angles for complex **10**

Bond distances (Å)

Ti—O_{2B}—C_{8B}	137.9(7)	O_{2A}—C_{8A}—C_{1A}	114.5(4)
O_{1A}—C_{8A}—O_{2A}	125.6(4)	O_{2B}—C_{8B}—C_{1B}	114.5(4)

1.930 Å). Fay and co-workers have reported a large Ti—O—C angle and a relatively short Ti—O bond length in the $(C_5H_5)_2Ti(O_2CC_6H_5)_2$ complex, which is formally a 16-electron complex if only Ti—O σ-bonding is considered, achieving an effective 18-electron configuration via Ti—O π-bonding. On comparing the Ti—O—C angles of complex **10** (138.6 and 137.9°) and $(C_5H_5)_2Ti(O_2CC_6H_5)_2$ (148.6 and 147.9°), it is seen that the Ti—O—C angle of complex **10** is less by 10°. Thus, complex **10** may be formally a 16-electron complex because of the smaller Ti—O—C angle and the longer Ti—O bond distance.

IR spectra

The important IR frequencies are given in Table 4. Some characteristic absorptions of the methylcyclopendienyl ring appeared. The C—H stretching frequency at 3090–3114 cm^{-1} is indicative of the methylcyclopentadienyl ring. The frequency at 1370–1415 cm^{-1} is due to the C—C stretching of π-bonding in the methylcyclopentadienyl ring. δ(C—H) in the methylcyclopentadienyl ring is at 1013–1059 cm^{-1} and changes in the order F > Cl > Br > I (the halogen is in the *p*-position of the phenyl ring).

Strong bands are observed at 1626–1650 cm^{-1} and 1295–1345 cm^{-1}, which are characteristic absorptions of the (COO) group. The difference ($\Delta\nu$) between ν_{asym}(COO) and ν_{sym}(COO) is about 290 cm^{-1}. Chandra *et al.*[7] reported the IR spectra of $(CH_3C_5H_4)_2Ti(O_2CC_6H_5)_2$. They suggested that in this compound the ligand is bidentate as in $Cp_2Ti(O_2CR)$ complexes.[10] Fay[1] pointed out that this result may be wrong and our experimental results are also different to those of Chandra. The large difference, $\Delta\nu$ (*ca* 290 cm^{-1}), is indicative that the ligand is monodentate. This result is consistent with the analogous complexes $(C_5H_5)_2Ti(O_2CC_6H_4X)_2$.[2] Our X-ray structure determination of complex **10** further confirms this result.

As indicated in Table 4, some characteristic absorptions of the substituted phenyl ring appeared. The data for complexes **1–17** compare well with the analogous complexes, $(C_5H_5)_2Ti(O_2CC_6H_4X)_2$.[2]

^{1}H *NMR spectra*

Chemical shifts for the protons (δ scale) of complexes **1–17** are given in Table 5. The spectra consist of one sharp peak due to the methyl on the methylcyclopentadienyl ring. The protons of the two methylcyclopentadienyl rings give two groups of asymmetric triplet peaks, the standard AB system. This result is consistent with that for the analogous complexes of $(CH_3C_5H_4)_2Ti^{IV}$.

For complexes **3**, **13** and **6** (*p*-F, *p*-Cl, *p*-Br, respectively, on the phenyl ring), the chemical shift of the methylcyclopentadienyl ring decreases in the order F, Cl, Br. This is very similar to the changes which occur in the compounds $(C_5H_5)_2Ti(p\text{-}XC_6H_4)_2$ (X = F, Cl, Br)[11] and opposite to those

which occur in $(CH_3C_5H_4)_2Ti(OC_6H_4X)_2$ compounds.[12] The reason may be that the Ti—O bond in the complexes has little double bond character, therefore, the ^{1}H NMR spectra indicate that the complexes are more like the phenyltitanocenes than the aryloxytitanocenes. Another characterization in the ^{1}H NMR different from the appropriate aryloxytitanocenes was also observed. The chemical shift of the protons on the methylcyclopentadienyl ring in the carboxylate complexes is lower than the analogous chloride and much lower than the analogous aryloxy complexes.

(*Received* 31 *August* 1989; *accepted* 9 *October* 1989)

Abstract—The boric acid–pyrogallol system has been studied in aqueous solution by means of potentiometric methods. Evidence is given for two adducts of 1 : 1 and 1 : 2 stoichiometry. An analysis of ^{13}C NMR spectra of the 1 : 2 adduct is presented.

In this paper we present the characterization of the boric acid–pyrogallol system by potentiometric and ^{13}C NMR methods. This study is part of general research on the interactions between buffer systems and the medium in which they act; in fact in many cases the importance of these interactions is neglected, even though they can completely distort the results of the systems studied. For example, borate buffer is often used in the study of the enzyme polyphenoloxidase (PPO),[1] but it inhibits the reaction because all substrates of the reactions catalysed by PPO, i.e. L-Dopa, catechol, pyrogallol, chlorogenic, caffeic and gallic acid, strongly interact at pH 8.5 with the buffer itself.

The reaction of boric acid with diols has been extensively studied both for analytical purposes[2–4] (boric acid is transformed into a relatively strong acid by addition of an organic compound containing two or more hydroxy groups and, therefore, can be easily titrated with a strong base) and for structural studies[5,6] (boric acid, interacting only with compounds with two hydroxy groups in the *cis* position or two phenoxy groups in the *ortho* position, distinguishes between *cis*- and *trans*-dihydroxy compounds and between *ortho* and *meta* or *para* compounds).

The existence of only a 1 : 1 complex, or both 1 : 1 and 1 : 2 complexes in such systems has been examined by different authors.[7–9] In this study we have attempted to characterize reliably the boric acid–pyrogallol system by potentiometric and NMR methods.

EXPERIMENTAL

NMR studies

^{13}C NMR spectra were determined in D_2O solution with a CFT-20 Varian Spectrometer at a probe temperature of *ca* 37°C, under an argon atmosphere. Chemical shifts are expressed in ppm relative to internal TMS. Typical Fourier transform conditions under which the ^{13}C results were obtained are as follows: spectral width 6000 Hz, data points 8 K, pulse repetition times 0.8–4.0 s, number of accumulated transients 10,000–40,000.

Potentiometric studies

The titrations were performed on a pH M 84 Radiometer pH meter, equipped with a Dosimat 655 Metrohm automatic titrator, at an ionic strength of 0.1 M (KNO_3) and at 25°C. The standard potential of the electrode and the slope was determined daily by titrations of chloridic acid with

* Author to whom correspondence should be addressed.

NaOH, at an ionic strength of 0.1 M (KNO_3). All titrations using pyrogallol were made under a nitrogen atmosphere to prevent decomposition. The boric acid and pyrogallol concentrations used in the various titrations were in the range 0.003–0.018 M and their ratio varied from 2 : 1 to 1 : 6.

Calculations

Potentiometric data for the electrode standardization were analysed by the Magec program.[10] The ionization constants of boric acid and pyrogallol, and the formation constants of their adducts were calculated by the PSEQUAD program,[11] which we slightly modified to present a graphic display of experimental and calculated data.

The calculations were performed on a PS II/50 IBM personal computer.

Materials

Boric acid, pyrogallol, isopropanol and *sec*-butanol were purchased from Fluka; D_2O and NaOD from Merck.

RESULTS AND DISCUSSION

The potentiometric titrations of H_3BO_3, pyrogallol and of their mixtures in different ratios allow the evaluation of the ionization constants of the two reagents (reported in Table 1) and the proposal of the equilibria:

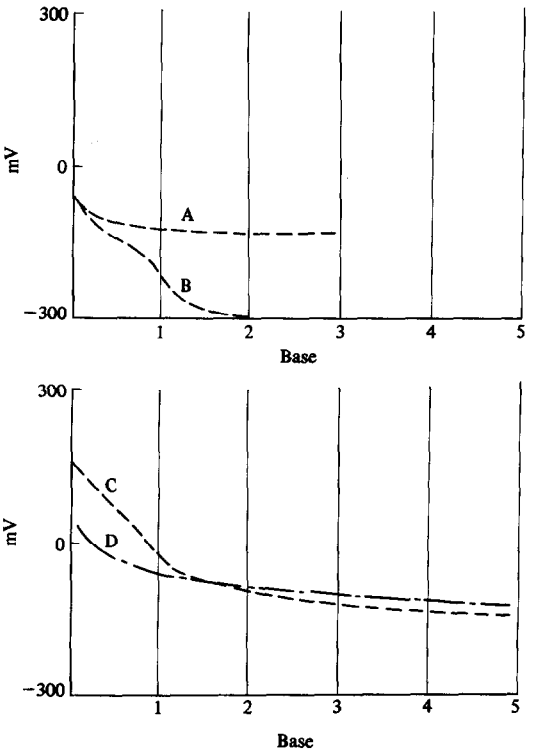

Fig. 1. The titration curves (EMF vs the ratio [base added]/[total pyrogallol] for curve A or [base added]/[total boric acid] for curves B, C and D) are reported for pure pyrogallol 0.003 M (curve A), pure boric acid 0.003 M (curve B) and for the mixtures boric acid 0.022 M–pyrogallol 0.066 M (curve C) and boric acid 0.0033 M–pyrogallol 0.0099 M (curve D).

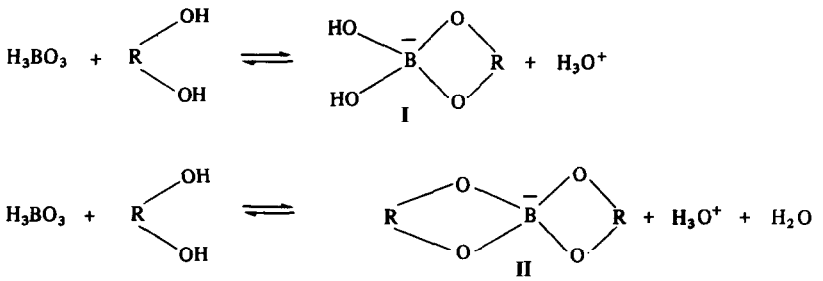

(1)

The relative formation constants are also reported in Table 1 and are in good agreement with those of Antikainen and Katila.[12] Some differences between our results and the literature values[13] for the boric acid ionization constant are noteworthy.

Table 1. pK values for the ionization of boric acid and pyrogallol, and log of formation constants for the reactions in Scheme 1

	K_1	K_2
Boric acid	9.07±0.03	—
Pyrogallol	8.83±0.03	10.81±0.04
Adducts	−6.4±0.01	−2.8±0.1

The titration curves of the mixtures were tentatively fitted with a simple 1 : 1 complexation model, but the fit was significantly poorer than that obtained with the scheme above.

The mixture of boric acid and isopropanol or *sec*-butanol were also examined under the same conditions; their titration curves do not show any significant difference to those of free boric acid. This was expected on the basis of the behaviour of boric acid with simple alcohols, but is also permits the exclusion of medium effects for alcohol concentration on H_3BO_3 titration.

The titration curves in Fig. 1 and the distribution functions in Fig. 2 require some comments:

(1) the titration graphs of the pure compounds,

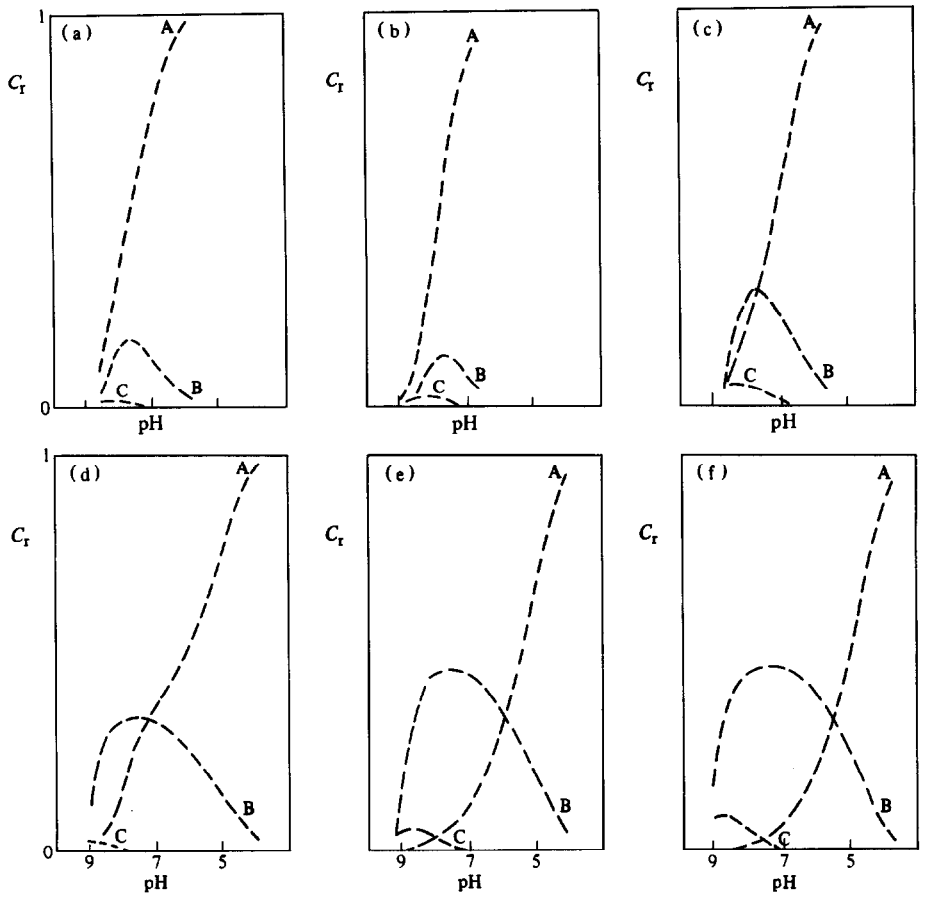

Fig. 2. The ratios [free pyrogallol]/[total pyrogallol] (curves A), [1:2 complex]/[total pyrogallol] (curves B) and [1:1 complex]/[total pyrogallol] (curves C) are reported as a function of pH, calculated with the equilibrium constants reported in Table 1, for the solutions: (a) Boric acid (B.A.) 0.0033 M, pyrogallol (Pyr) 0.0099 M; (b) B.A. 0.0033 M, Pyr 0.0033 M; (c) B.A. 0.013 M, Pyr 0.0066 M; (d) B.A. 0.022 M, Pyr 0.066 M; (e) B.A. 0.066 M, Pyr 0.066 M; (f) B.A. 0.13 M, Pyr 0.066 M.

having similar pK_1 values, look very different because of the second ionization constant of pyrogallol;

(2) opposite to the behaviour with other diols, the addition of pyrogallol eliminates the inflection in the boric acid curve rather than emphasize it. This is ascribed to two reasons:

   (a) the interaction of boric acid with pyrogallol is weaker than with other diols;

   (b) pyrogallol exhibits an acid behaviour which is different from the other diols, and this leads to a flattening of the titration curve when an excess of pyrogallol is titrated. The formation of adducts with pyrogallol, therefore, cannot be exploited for the analytical determination of boric acid. The complexes, as can be clearly seen from the distribution curves in Fig. 2, have a sensible weight at pH values above 5.

In particular, the 1:2 complex, whose existence has been significantly demonstrated by the potentiometric analysis, exists alone at a concentration of 0.07 mol dm^{-3} and pH 7.5. A study by ^{13}C NMR spectroscopy has therefore been possible.

The ^{13}C NMR spectrum of the pure pyrogallol, shown in Fig. 3(a), exhibits four peaks: from off-resonance experiments the two bands at 146.61 and 133.57 ppm were attributed to the three quaternary carbon atoms C(1), C(2) and C(3); in particular, from symmetry considerations, the more intense band at 146.61 to C(1) and C(3) carbon atoms, and that at 133.57 to C(2). By analogous considerations the band at 121.67 can be attributed to C(5) and that at 109.69 to the two equivalent C(6) and C(4) carbon atoms.

By addition of boric acid, in the reported amounts, six new narrow peaks appear well distinct from the four of pure pyrogallol [see Fig. 3(b) and Table 2]. These peaks can be attributed to the complexed form (II) of pyrogallol, in slow exchange with the free form, at the probe temperature of

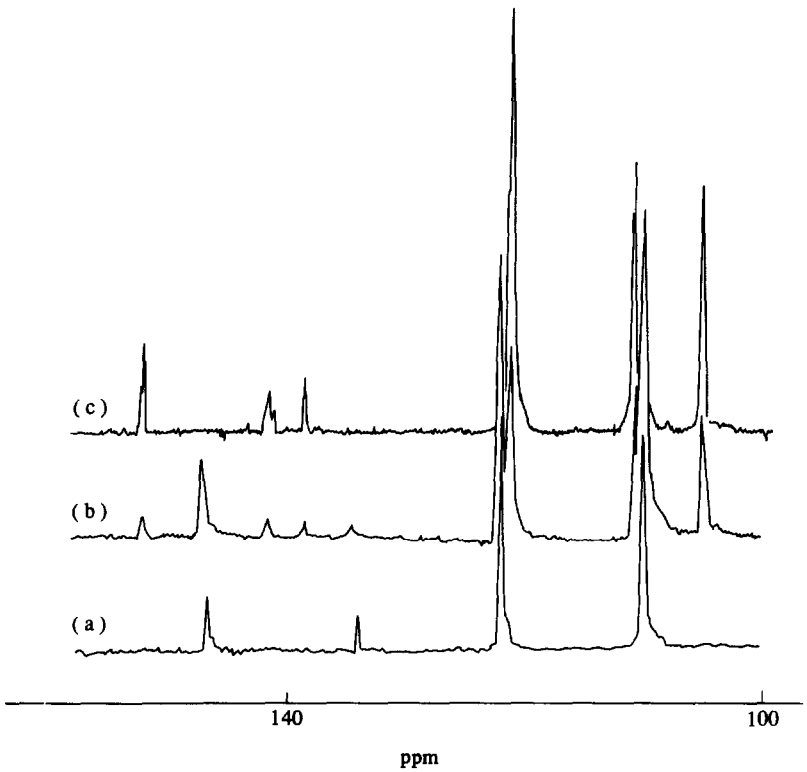

Fig. 3. ^{13}C NMR spectra of pyrogallol from aqueous solutions at pH 7 of (a) pure pyrogallol 0.07 M, (b) pyrogallol 0.07 M–boric acid 0.02 M and (c) pyrogallol 0.07 M–boric acid 0.14 M.

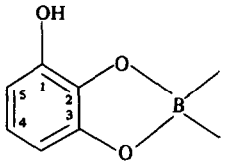
37°C. Their assignment can be made on the basis of shielding effects for the complexation with boric acid; it can, in fact, bind only to two hydroxy groups in the *ortho* position, according to the structure:



The peaks at 151.77 and 138.06 ppm can therefore be attributed to the C(3) and C(2) atoms, for the high-field shifts of 5.16 and 4.49 ppm from the bands of the free pyrogallol; these shifts have been assigned to a deshielding effect caused by binding with boric acid. The C(1) and C(4) atoms, which are one bond apart from C(2) and C(3), exhibit a downfield shift of −5.52 and −5.21 ppm from the peaks of pure pyrogallol, according to the values of transmission of substituent effects along an aromatic molecule.[14]

C(5) and C(6) show a low shift of −0.89 and 0.63 ppm, respectively. The slight high-field shift of C(6), opposite to the expected downfield shift of C(5), can be tentatively explained in terms of resonance effects with the neighbouring OH group on the C(1) atom. These values are in a very good agreement with those reported by Pasdeloup and Brisson[9] for the analogous 1 : 2 complex of boric acid with cat-

Table 2. ^{13}C chemical shifts (in ppm downfield from TMS) of the species present in the solution of boric acid and pyrogallol at pD 7.5

	C(1), C(3)		C(2)	C(5)	C(4), C(6)	
Free pyrogallol	146.41		133.57	121.67	109.69	
	C(3)	C(1)	C(2)	C(5)	C(6)	C(4)
1 : 2 Complex	151.77	141.09	138.06	120.78	110.32	104.48
$\Delta\delta$	+5.36	−5.32	+4.49	−0.89	+0.63	−5.21

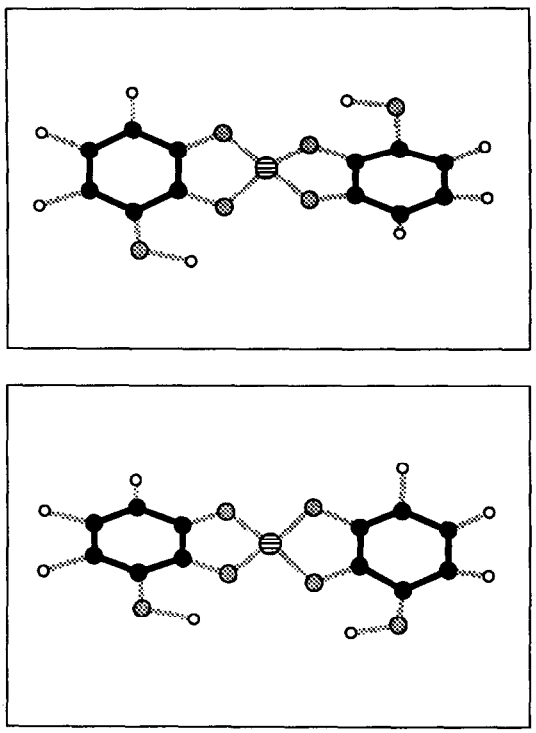


Fig. 4. The enantiomers of the 1 : 2 complex, showing the two possible relative positions of the —OH groups.

echol, and the shifts of C(2) and C(3) agree with the statement[15] that all C—OH carbon atoms are shifted about 6 ppm downfield in the carbohydrate residues of nucleosides. At higher boric acid concentrations the spectrum of pure pyrogallol completely disappears.

At the concentrations used, also with an excess of boric acid, we were not able to detect the resonance of 1 : 1 adducts, but this could also be expected on the basis of the distribution curves.

The spectra of the 1 : 2 complex indicate that the boron forms equivalent bonds with the two pyrogallol moieties in the adduct. In fact no splitting of the signals is observed which implies symmetry of the molecule. The enantiomers of the adduct, recognized as centrally chiral, are shown in Fig. 4, where the two-fold axis of symmetry contains a chiral centre of stereoisomery.[16]

(*Received* 22 *March* 1989; *accepted* 18 *October* 1989)

Abstract—Nine complexes of lanthanide nitrates with 4-benzoyl-3-methyl-1-phenylpyrazol-5-one (BMPP) having the general formula $[Ln(BMPP)_2(NO_3)_3]$ (where Ln = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy and Y) have been synthesized and their IR spectra obtained. In these complexes BMPP acts as a bidentate ligand coordinating through the oxygen of both the carbonyl groups and the nitrate ion acts as a unidentate ligand coordinating through one of the oxygen atoms with the lanthanide ion.

4-Benzoyl-3-methyl-1-phenylpyrazol-5-one forms stable complexes with some transition metals and lanthanides in which BMPP acts as a monobasic bidentate ligand in which both the carbonyl groups (ring and side chain) are participating in coordination.[1,2] As part of our programme for the synthesis and characterization of solid lanthanide complexes,[3–8] we presently report on the isolation and IR spectral studies of nine lanthanide nitrates, in which BMPP acts as a neutral bidentate rather than monobasic bidentate ligand.

EXPERIMENTAL

Reagents

The nitrates of La^{III}, Pr^{III}, Nd^{III}, Sm^{III}, Eu^{III}, Gd^{III}, Tb^{III}, Dy^{III} and Y^{III} were prepared from the respective oxides (99.9% pure) as reported earlier.[5] BMPP was prepared by a modified Jenson method,[2,9] in which ethanol was used as solvent rather than dioxane, and 2 N hydrochloric acid, which had been cooled in ice, was used for neutralization to give a better yield. The crude sample of BMPP was recrystallized from 95% ethanol. The purity of the sample was checked by elemental analysis, IR spectral, TLC and melting point data.

Preparation and analysis of complexes

Lanthanide nitrates (2 mmol) and BMPP (4.1 mmol) were dissolved separately in minimum amounts of hot ethanol and these solutions were mixed together and kept under reflux on a water bath for 2 h. The reaction mixture was then concentrated to obtain a viscous mass, which was stirred vigorously with hot benzene to separate the complex. The complex was collected by removal of the benzene layer and was washed repeatedly with hot benzene to remove excess ligand. All the complexes so isolated were dried *in vacuo* over phosphorus(V) oxide.

The lanthanide contents of the complexes were determined by the oxalate–oxide method.[10] Microanalyses for carbon, hydrogen and nitrogen were performed by the microanalytical unit of the Regional Sophisticated Instrumentation Centre (Central Drug Research Institute, Lucknow, India).

Physical measurements

Molar conductivities of the complexes in acetonitrile and nitrobenzene ($\sim 10^{-3}$ M solutions) were measured at room temperature ($28 \pm 2°C$) using an ELICO type MB2T conductivity unit with dip type cell (Type CC-03) containing platinum electrodes (cell constant = 1.40 cm^{-1}). Magnetic susceptibilities of the complexes were measured at room temperature by the Gouy method using mercury(II) tetrathiocyanatocobaltate(II) as the calibrant. The IR spectra of the ligand and complexes were recorded on a double-beam Perkin–Elmer 397 IR spectrophotometer in the range 4000–400 cm^{-1} using the KBr disc technique. Molecular weights of

the complexes ($\sim 10^{-4}$ M solutions) were determined by the cryoscopic method in nitrobenzene.[11]

RESULTS AND DISCUSSION

All the complexes are non-hygroscopic solids with varying colours (Table 1), which are soluble in polar solvents such as acetone, acetonitrile, ethanol, methanol and nitrobenzene and insoluble in solvents of low polarity such as benzene, carbon tetrachloride, chloroform and diethyl ether. The elemental analysis, magnetic susceptibility, molecular weight and molar conductivity data of the complexes are presented in Table 1. All of these complexes show non-electrolytic behaviour in nitrobenzene and acetonitrile.[12] The lanthanum and yttrium complexes are diamagnetic while all the other complexes are paramagnetic, as expected. The measured magnetic moments (Table 1) are in good agreement with the theoretical values calculated from the Van Vleck formula.[13] These observations suggest that the present series of complexes can be formulated as $[Ln(BMPP)_2(NO_3)_3]$, where Ln = La, Pr, Nd, Sm, Eu, Gd, Tb, Dy and Y.

IR spectra

The important IR spectral bands of the ligand and complexes are presented in Table 2. The observed IR spectral bands of the ligand and lanthanum complex with their tentative assignments are given in Table 3.

The IR spectrum of BMPP exhibits a broad band with a peak maximum at 2550 cm^{-1}, which is attributed to strongly hydrogen bonded ν(OH). The very strong band at 1630 cm^{-1}, observed in the spectrum of BMPP, is due to a stretching vibration of the intramolecular hydrogen bonded side chain carbonyl group. Absence of any stretching band corresponding to the ring carbonyl group in the spectrum of the ligand indicates that the enol form (II) is stabilized in the free ligand as shown in Fig. 1.

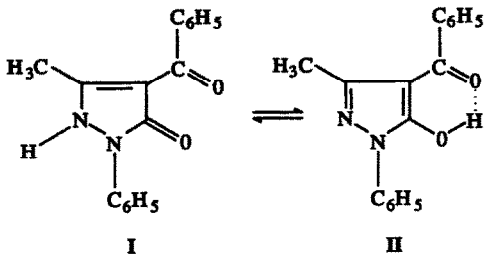

Fig. 1. Keto (I) and enol (II) forms of BMPP.

In the spectra of the complexes the band corresponding to ν(OH) is absent. Instead, a new band is observed at 3160 cm^{-1} in these spectra, assignable to ν(NH), which has no parallel band in the spectrum of the ligand. This shows that the keto form (I) of the ligand is coordinated to the lanthanide ion in the complexes. This is also supported by the appearance of two very strong bands, one at 1620 cm^{-1} and another at 1650 cm^{-1} in the spectra of the complexes, which are attributed to the stretching vibrations of the ring carbonyl and side chain carbonyl groups, respectively. The relative positions of ν(C=O) (ring) and ν(C=O) (side chain) suggest that both the carbonyl groups are coordinated to the metal ion. The apparent lowering of the side carbonyl stretching frequency of the free ligand (1630 cm^{-1}) is due to very strong intramolecular hydrogen bonding by way of forming a six-membered ring as shown in Fig. 1. The observed positions of the ν(C=O) (ring) and ν(C=O) (side chain) modes in the spectra of the complexes (1620 and 1650 cm^{-1}) may be attributed to vibrational

coupling effects. These observations suggest that the free ligand exists in the enol form (**II**) and the coordinated ligand exists in the keto form (**I**). The presence of ν(NH) in the spectra of the complexes shows that BMPP acts as a neutral ligand rather than a monobasic one, in disagreement with the observation made by Okafor.[2] The present observation on the coordination of BMPP towards lanthanides is confirmed by the presence of three nitrate ions in all the complexes (Table 1).

The spectra of the complexes contain four additional bands at 1430, 1300, 1025 and 410 cm^{-1}, which are not present in the spectrum of the ligand. Of these, the first three are assigned to ν_1, ν_4, and ν_2 modes, respectively, of the coordinated nitrate ion. In fact the ν_1 and ν_4 modes of the nitrate

ion are the two split bands of the ν_3 mode of the uncoordinated nitrate ion. The magnitude of splitting of ν_1 and ν_4 is in the order of 130 cm^{-1}. This type of splitting and comparison with recent papers on similar complexes, which have been characterized by X-ray analysis, suggest that the nitrate ions are coordinated unidentately to the lanthanide ions in the present complexes.[14–16] The fourth additional band at 410 cm^{-1} is assigned to stretching vibrations of the Ln—O bond formed out of coordination through the carbonyl groups.

Based on the above discussion and observations, it is concluded that BMPP acts as a neutral bidentate ligand coordinating through both the carbonyl groups, and the nitrate ion acts as a unidentate ligand coordinating through one of the three oxygen atoms with the lanthanide ion. Hence the lanthanide ion has a coordination number of seven in the present complexes.

MONO- AND DINUCLEAR PHOSPHINE COORDINATED 1,4-BIS(DIPHENYLPHOSPHINO)ETHYNE SEVEN-COORDINATE COMPLEXES OF MOLYBDENUM(II) AND TUNGSTEN(II)

PAUL K. BAKER* and ELAINE M. ARMSTRONG

Department of Chemistry, University College of North Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 6 *May* 1989; *accepted* 18 *October* 1989)

Abstract—Equimolar quantities of the seven-coordinate compounds $[MI_2(CO)_3(NCMe)_2]$ (M = Mo and W) and $Ph_2PC{\equiv}CPPh_2$ react in CH_2Cl_2 at room temperature to afford the $Ph_2PC{\equiv}CPPh_2$ phosphine coordinated bridged complexes $[M_2I_4(CO)_6(\mu\text{-}Ph_2PC{\equiv}CPPh_2)_2]$ in good yield. Reaction of $[MI_2(CO)_3(NCMe)_2]$ with two equivalents of $Ph_2PC{\equiv}CPPh_2$ in CH_2Cl_2 at room temperature gives the mononuclear compounds $[MI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$. ^{31}P NMR studies show the $Ph_2PC{\equiv}CPPh_2$ ligand in $[MI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$ to have monodentate phosphine coordination.

In the past the ligand $Ph_2PC{\equiv}CPPh_2$ has been shown to coordinate via the phosphorus atoms to transition metal centres.[1–14] However, in 1970 Ward and Templeton[15] reported the synthesis of the alkyne coordinated 1,4-bis(diphenylphosphino) ethyne complex $[W(CO)(S_2CNEt_2)_2(\eta^2\text{-}Ph_2PC{\equiv}CPPh_2)]$. Very recently, Went and co-workers[16] have studied the chemistry of $[W(CO)(S_2CNEt_2)_2(\eta^2\text{-}Ph_2PC{\equiv}CPPh_2)]$, and interestingly found it could coordinate by either bridging a cobalt–cobalt bond in $[(S_2CNEt_2)_2(CO)W(\mu\text{-}Ph_2PC{\equiv}CPPh_2)Co_2(\mu\text{-}CO)_2(CO)_4]$, or as a bidentate phosphine to molybdenum in $[(S_2CNEt_2)_2(CO)W(\mu\text{-}Ph_2PC{\equiv}CPPh_2)Mo(CO)_4]$.

In recent years we have been studying the reactions of the highly versatile seven-coordinate compounds $[MI_2(CO)_3(NCMe)_2]$ (M = Mo and W).[17] These compounds are prepared by reacting the zero-valent six-coordinate complexes $[M(CO)_3(NCMe)_3]$ *in situ* with one equivalent of iodine at 0°C to give $[MI_2(CO)_3(NCMe)_2]$ in quantitative yield.[17] For example, the complexes $[MI_2(CO)_3(NCMe)_2]$ react either with two equivalents of monodentate ligands (PPh_3, $AsPh_3$ or $SbPh_3$) (L)[18] or one equivalent of bidentate phosphines (L_2)[19] to give the substituted products $[MI_2(CO)_3L_2]$. The complexes $[MI_2(CO)_3(NCMe)_2]$ also react with either one equivalent of alkyne, RC_2R' (M = Mo and W; R = R′ = Me, Ph and CH_2Cl; R = Ph, R′ = Me and CH_2OH; R = Me, R′ = PhS and *p*-MeC_6H_4S) to afford the iodo-bridged complexes $[M(\mu\text{-}I)I(CO)(NCMe)(\eta^2\text{-}RC_2R')]_2$[20] or with two equivalents of RC_2R' (M = Mo and W; R = R′ = Me or Ph; R = Me, R′ = Ph; for M = W only, R = R′ = Me, CH_2Cl and *p*-MeC_6H_4; R = Ph, R′ = CH_2OH) to give the mononuclear bisalkyne complexes $[MI_2(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ and the iodo-bridged molybdenum compound $[Mo(\mu\text{-}I)I(CO)(\eta^2\text{-}MeC_2Me)_2]_2$.[21] In view of this work the ligand $Ph_2PC{\equiv}CPPh_2$ could coordinate to molybdenum or tungsten in $[MI_2(CO)_3(NCMe)_2]$ via either the phosphorus atoms or the alkyne group. In this paper we describe the reactions of $[MI_2(CO)_3(NCMe)_2]$ with $Ph_2PC{\equiv}CPPh_2$.

EXPERIMENTAL

All reactions described in this paper were carried out under an atmosphere of nitrogen using standard Schlenk-line techniques. CH_2Cl_2 was dried and distilled before use. The seven-coordinate compounds $[MI_2(CO)_3(NCMe)_2]$ (M = Mo and W) were prepared by the published method.[17] All chemicals used were purchased from commercial sources.

Elemental analyses (C, H and N) were determined using a Carlo Erba Elemental Analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 197 IR spectrophotometer. ^{13}C and ^{31}P NMR spectra were recorded on a Bruker WH-400 NMR spec-

trometer at the University of Warwick (^{13}C NMR spectra were calibrated against tetramethylsilane; ^{31}P NMR spectra were calibrated against 85% H_3PO_4). Molecular weights of $[M_2I_4(CO)_6(\mu\text{-}Ph_2PC{\equiv}CPPh_2)_2]$ (**1** and **2**) were determined by Rast's method,[22] with camphor as the solvent.

$[Mo_2I_4(CO)_6(\mu\text{-}Ph_2PC{\equiv}CPPh_2)_2]$ (1)

To a stirred solution of $[MoI_2(CO)_3(NCMe)_2]$ (0.2501 g, 0.388 mmol) in CH_2Cl_2 (15 cm^3), under a stream of nitrogen, was added $Ph_2PC{\equiv}CPPh_2$ (0.1530 g, 0.388 mmol). After 3 min, filtration, followed by removal of the solvent *in vacuo* gave orange crystals of $[Mo_2I_4(CO)_6(\mu\text{-}Ph_2PC{\equiv}CPPh_2)_2]$ (**1**), which were recrystallized from CH_2Cl_2, yield of pure product = 0.17 g, 37%. Molecular weight for $C_{58}H_{20}I_4Mo_2O_6P_4$: Found: 1519. Calc: 1656.

In a similar reaction, $[WI_2(CO)_3(NCMe)_2]$ and an equimolar quantity of $Ph_2PC{\equiv}CPPh_2$ gave $[W_2I_4(CO)_6(\mu\text{-}Ph_2PC{\equiv}CPPh_2)_2]$ (**2**). Molecular weight for $C_{58}H_{20}I_4O_6P_4W_2$: Found: 1956. Calc: 1832.

$[MoI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$ (3)

To a stirred solution of $[MoI_2(CO)_3(NCMe)_2]$ (0.1000 g, 0.194 mmol) in CH_2Cl_2 (15 cm^3), under a stream of nitrogen, was added $Ph_2PC{\equiv}CPPh_2$ (0.1529 g, 0.388 mmol). After 10 min, filtration, followed by removal of the solvent *in vacuo* gave orange crystals of $[MoI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$ (**3**), which were recrystallized from CH_2Cl_2, yield of pure product = 0.09 g, 38%.

In a similar reaction, $[WI_2(CO)_3(NCMe)_2]$ with two equivalents of $Ph_2PC{\equiv}CPPh_2$ gave $[WI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$ (**4**).

RESULTS AND DISCUSSION

The seven-coordinate bisacetonitrile complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo and W) react in CH_2Cl_2 at room temperature with an equimolar amount of $Ph_2PC{\equiv}CPPh_2$ to eventually give the seven-coordinate phosphine-bridged dimeric compounds $[M_2I_4(CO)_6(\mu\text{-}Ph_2PC{\equiv}CPPh_2)_2]$ (**1** and **2**). However, reaction of $[MI_2(CO)_3(NCMe)_2]$ with two equivalents of $Ph_2PC{\equiv}CPPh_2$ in CH_2Cl_2 at room temperature gave the monomeric seven-coordinate compounds $[MI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$ (**3** and **4**). The new complexes (**1**–**4**) were fully characterized by elemental analysis (C, H and N) (Table 1), IR (Table 2), ^{13}C and ^{31}P NMR spectroscopy (Tables 3 and 4). The complexes are stable in the solid state when stored under nitrogen, and are soluble in chlorinated solvents such as CH_2Cl_2 and $CHCl_3$.

The reactions of $[MI_2(CO)_3(NCMe)_2]$ with $Ph_2PC{\equiv}CPPh_2$ in a 1:1 ratio should initially give the monoacetonitrile compounds $[MI_2(CO)_3(NCMe)(Ph_2PC{\equiv}CPPh_2)]$. Complexes of the type $[MI_2(CO)_3(NCMe)L]$ [L = PPh_3, PPh_2Cy, $AsPh_3$, $SbPh_3$ and $P(OPh)_3$] have been isolated and fully characterized from reactions of $[MI_2(CO)_3(NCMe)_2]$ with an equimolar quantity of L.[23] The

steric constraints of the ligand $Ph_2PC{\equiv}CPPh_2$ do not allow easy coordination in a bidentate manner to a transition metal centre, compared to a more flexible bidentate phosphine such as $Ph_2P(CH_2)_2PPh_2$ which reacts with an equimolar amount of $[MI_2(CO)_3(NCMe)_2]$ to give $[MI_2(CO)_3\{Ph_2P(CH_2)_2PPh_2\}]$.[19] The monoacetonitrile complexes $[MI_2(CO)_3(NCMe)(Ph_2PC{\equiv}CPPh_2)]$ rapidly dimerize to give the phosphine-bridged dimeric complexes $[M_2I_4(CO)_6(\mu\text{-}Ph_2PC{\equiv}CPPh_2)_2]$ (**1** and **2**). The dimeric nature of **1** and **2** was confirmed by molecular weight measurements by Rast's method[22] (see Experimental). ^{31}P NMR studies (Table 4) show that all four phosphine atoms in each of **1** and **2** are coordinated to the metal (the phosphine resonance in the ^{31}P NMR spectrum of uncoordinated $Ph_2PC{\equiv}CPPh_2$ in $CDCl_3$ at 25°C is −31.19 ppm relative to 85% H_3PO_4).

The reactions of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with $Ph_2PC{\equiv}CPPh_2$ in a 2:1 molar ratio afford the bismonodentate coordinated phosphine complexes $[MI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$. The ^{31}P NMR spectra (Table 4) of **3** and **4** showed resonances due to the coordinated phosphine atoms at δ = +8.44 and +7.18 ppm and due to the uncoordinated phosphine atoms at δ = −32.51 and −33.15 ppm, respectively (uncoordinated $Ph_2PC{\equiv}CPPh_2$ has a single ^{31}P resonance at δ = −31.19 ppm). This evidence confirms that the ligand $Ph_2PC{\equiv}CPPh_2$ is coordinated via one of its phosphorus atoms in **3** and **4**.

The structures of both the dimeric and monomeric complexes are likely to have capped octahedral geometries, since the structure of the dimer $[W(\mu\text{-}Br)Br(CO)_4]_2$[24] and a number of monomeric seven-coordinate complexes of the type $[MX_2(CO)_3L_2]$[25–32] have been determined by X-ray crystallography and shown to have capped octahedral geometry. The IR spectral properties [ν(C≡O)] (Table 2) of **3** and **4** are similar to other seven-coordinate complexes which have been shown to have capped octahedral geometry. Further evidence to support the proposed capped octahedral structures comes from measuring the low temperature (−70°C, CD_2Cl_2) ^{13}C NMR spectrum of **4**. The spectrum shows a carbonyl resonance at very low field (229.13 ppm) (Table 3), which is likely to be due to a carbonyl ligand in the unique capping position from some work of Colton and Kevekordes[33] on the low temperature ^{13}C NMR spectra on related seven-coordinate complexes. However, the existence of four carbonyl resonances suggests there are several isomers in solution. One

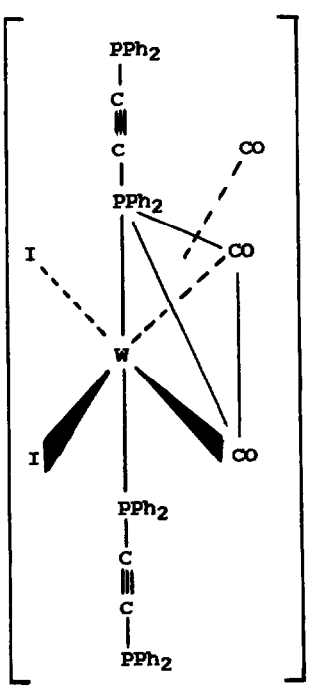

Fig. 1. One possible isomer of $[WI_2(CO)_3(Ph_2PC{\equiv}CPPh_2)_2]$.

likely isomer of **4** is shown in Fig. 1, i.e. with *trans*-phosphine ligands and a carbonyl ligand in the unique capping position. Unfortunately we were unable to grow suitable single crystals for X-ray crystallography of **1–4**.

In conclusion, although the complexes $[MI_2(CO)_3(NCMe)_2]$ have been shown to react with phosphine donor ligands[18,19] and alkynes,[20,21] the reactions of $[MI_2(CO)_3(NCMe)_2]$ with the mixed phosphine/alkyne ligand $Ph_2PC{\equiv}CPPh_2$ give complexes with either one or both phosphine atoms attached to the metal.

Acknowledgements—We wish to thank Dr O. W. Howarth for running the ^{13}C and ^{31}P NMR spectra of complexes **1–4** at the University of Warwick and we thank the SERC for support.

(*Received* 24 *May* 1989; *accepted* 18 *October* 1989)

Abstract—A number of copper(II) complexes of some tridentate O—N—O donors and bidentate O—O and O—N donors in the form of 2,3-disubstituted quinazolin-(3H)-4-ones have been synthesized and characterized based on analytical, conductivity, magnetic, IR, electronic and ESR spectral data. The reaction between copper(II) acetate and tridentate O—N—O donor ligands such as 2-(R)-3-(X)-substituted quinazoline-(3H)-4-ones, where R = methyl/phenyl and X = 2′-hydroxyphenylamino (MHBQ/PHBQ), yielded neutral complexes of the type $Cu(O—N—O)_2$. The bidentate O—O or O—N donor ligands like 2-(R)-3-(X)-substituted quinazoline-(3H)-4-ones, where R = methyl/phenyl and X = carboxymethyl (MCMQ/PCMQ), furylamino (MFQ/PFQ), acetamino (MAQ/PAQ), uramino (MUQ/PUQ) and thiouramino (MTUQ/PTUQ), yielded neutral complexes of the type $Cu(O—O)_2$ or $Cu(O—N)_2(CH_3COO)_2$. The IR spectral data of the metal complexes indicate that the ligands like MHBQ and PHBQ act as uninegative tridentate, MCMQ and PCMQ act as uninegative bidentate and MFQ, PFQ, MAQ, PAQ, MUQ, PUQ, MTUQ and PTUQ act as neutral bidentate ligands. The reflectance spectral studies of these complexes indicate that they contain square-planar or tetragonal geometry around copper(II).

Quinazolones contain both an oxygen on the ring and a nitrogen and oxygen on the substituent at the three-position (Structure I) as donor centres in the proper orientation to chelate with the metal ion. The chelating tendency of these compounds is not very well documented except for a few publications involving similar ligands.[1–4] Spectral studies of copper(II) complexes are of great interest because their ground states orbitally degenerate in regular geometries and non-degenerate in distorted geometries, since an orbitally degenerate configuration is susceptible to a Jahn–Teller distortion. As a result, the ESR studies of copper(II) complexes yield valuable information regarding the nature of bonding between the metal ion and donor atom. Basically, the interpretation of the ESR spectrum of an isolated transition metal ion yields values for two types of parameter: (1) the spectroscopic splitting constants (g-values) which describe the frequencies between the different electron spin states and (2) the hyperfine coupling constants (A) which give a measure of electron spin–nuclear spin interactions. These parameters are affected by the presence of ligands around the central metal ion. In order to discover the nature of the interaction of these ligands with the copper(II) ion, the present study was undertaken. In this paper, complexes of copper(II) with 2-(R)-3-(X)-substituted quinazolin-(3H)-4-ones, where R = methyl/phenyl and X = carboxymethyl (MCMQ/PCMQ), 2′-hydroxy benzylamino (MHBQ/PHBQ), furylamino (MFQ/PFQ), acetamino (MAQ/PAQ), uramino (MUQ/PUQ) and thiouramino (MTUQ/PTUQ), are discussed.

Structure **Ia** and **b**. Structures of the ligands.

EXPERIMENTAL

All the chemicals used were of AR grade. The ligands were prepared by literature methods.[5,6] The purity of these compounds was checked by TLC and melting point determinations.

Preparation of complexes

Copper acetate solution (1 mmol) in acetone was added dropwise to a solution (3 mmol) in acetone with constant stirring. The reaction mixture was refluxed on a water bath for 60–120 min and cooled. The solid thus obtained was filtered and washed several times with water and acetone until the washings were free from excess ligands. These complexes were finally dried *in vacuo* over fused calcium chloride. All the copper(II) complexes are crystalline powders, light or dark green in colour. They are stable to room temperature, non-hygroscopic and insoluble in common organic solvents like methanol, ethanol, acetone and CCl_4, but appreciably soluble in DMF and DMSO.

Physical measurements

The analytical data (C, H, N) for the ligands and their metal complexes were obtained from the Microanalytical Laboratory, Calcutta University, Calcutta, India. The metal content of the complexes after heating to decomposition temperatures was determined using standard procedures. Molar conductivities of the complexes in DMF were measured using a Digisun digital conductivity meter, Model-DI-909 with a Philips dip-type conductivity cell. The magnetic measurements of the complexes in the solid state were made on a Gouy balance at room temperature using $Hg[Co(SCN)_4]$ as calibrant. Diamagnetic corrections were applied using Pascal's constants. The TGA and DTA curves of the complexes were recorded on a Leeds and Nathrup DTA unit (U.S.A.), using calcined alumina as reference material. The experiments were carried out in an atmosphere of static air using Pt/Rh thermocouples, and the rate of heating was maintained at 6°C min^{-1}. The IR spectra of the ligands and their complexes in Nujol and KBr, in the range 4000–200 cm^{-1}, were recorded on a Perkin–Elmer IR spectrophotometer, Model-283. The UV and visible spectra of the complexes in DMF were recorded on a Shimadzu multipurpose recording spectrometer, Model MPS-5000. The reflectance spectra of the complexes were measured on a Perkin–Elmer Lambda-15 spectrophotometer. The ESR spectra of the complexes in solid state and in DMF solutions at liquid nitrogen temperature were recorded on a Varian E-4, X-band spectrometer.

RESULTS AND DISCUSSION

The analytical and physical data for the complexes are listed in Table 1. On the basis of analytical data the metal complexes are found to have 1:2 (metal–ligand) stoichiometry and some complexes are also associated with two acetate molecules. The molar conductance values of the complexes in DMF at 10^{-3} M concentrations are low (10–20 Ω^{-1} cm^2

mol^{-1}) suggesting that they are non-electrolytes.[7]

Decomposition temperatures of the complexes, determined from their thermograms, are given in Table 1. The complexes are thermally stable up until 200°C and are not hydrated. This fact is further confirmed by their DTA curves which do not give endothermic peaks in the 150–200°C region. The sharp decomposition associated with the loss of ligand starts above 230°C. The final products of decomposition above 600°C in all the complexes correspond to metallic oxide. The decomposition temperatures of the complexes are a measure of their thermal stability. The ligands under study form complexes of varying stability in the order MCMQ < PCMQ < PFQ ≃ MAQ < PAQ < MTUQ < MFQ ≃ MUQ < PUQ < PTUQ < PHBQ < MHBQ.

Despite the large amount of work on thermogravimetry, considerable difficulties still exist in rationalizing the increase or decrease in thermal stability of complexes with different ligands. The literature contains various explanations of the relative order of thermal stability of the complexes. For example, thermal stability is said to increase with an increase in π-electron delocalization, the size of the molecule and also the nature of the rings formed.[8] The relative order of stability observed for the present complexes may be accounted for by such factors.

Important IR absorption frequencies of ligands and their complexes, along with their assignments, are listed in Table 2. A strong band corresponding to ν(C=O) of the quinazolone ring at 1700 cm^{-1} is shifted to lower wavenumbers by 40–50 cm^{-1} in the IR spectra of all the complexes, indicating that the carbonyl oxygen is invariably coordinated to copper(II).[9] The bands due to ν(OH) observed in the spectra of MHBQ, PHBQ,[10] MCMQ and PCMQ[11] disappeared completely in the spectra of their complexes confirming the coordination of these ligands by deprotonation. The band at 1640 cm^{-1} due to ν(C=N) of quinazolone remains unaltered in the spectra of complexes, whereas the band at 1600 cm^{-1} due to the benzylamino/furylamino group undergoes a lower shift of 40–50 cm^{-1}, suggesting coordination through this nitrogen.[12]

The ν(N—H) frequency observed at 3300 cm^{-1} in MAQ, PAQ, MUQ, PUQ, MTUQ and PTUQ has shifted to a lower region ($\Delta\nu$ = 50 cm^{-1}) in the

[c] (C=S) of thiouramino group observed at 860 cm^{-1} in MTUQ and PTUQ and at 850 cm^{-1} in their complexes.

complexes, indicating the involvement of the imino-nitrogen in coordination,[13] whereas the bands due to ν(NH_2)[14] (MUQ, PUQ, MTUQ and PTUQ), ν(C=O) (MAQ, PAQ, MUQ and PUQ)[5] and ν(C=S) (MTUQ and PTUQ)[15] at 3400, 1660 and 860 cm^{-1}, respectively, remain unchanged in the complexes, indicating the non-participation of the N/O/S of these groups in coordination. The presence of acetate ion in the coordination sphere in some complexes is also confirmed from their IR data.[16] The mode of coordination is further supported by the appearance of ν(Cu—O) and ν(Cu—N) bands around 400 and 500 cm^{-1}, respectively.[17,18]

The electronic spectral data along with the assignments are presented in Table 3. All the ligands exhibit strong bands around 35,000 and 32,000 cm^{-1} which may be assigned to $\pi^* \leftarrow \pi$ and $\pi^* \leftarrow n$ transitions, respectively. The reflectance spectra of all the copper(II) complexes, except those complexes of MCMQ and PCMQ, exhibit one broad band around 16,000 cm^{-1}, and complexes **3**, **4**, **6** and **7** also show one shoulder around 13,000 cm^{-1}. Due to the Jahn–Teller effect, tetragonal copper(II) complexes involve three transitions, *viz.* $^2B_{2g} \leftarrow {}^2B_{1g}$, $^2E_g \leftarrow {}^2B_{1g}$ and $^2A_{1g} \leftarrow {}^2B_{1g}$, but bands due to these transitions usually overlap to give a broad absorption band. Based on earlier reports, the present complexes are tentatively assigned tetragonal geometry.[19–21] However, the copper(II) complexes of MCMQ and PCMQ display two bands around 15,000 and 20,000 cm^{-1} which may be due to $^2B_{2g} \leftarrow {}^2B_{1g}$ and $^2E_g \leftarrow {}^2B_{1g}$ transitions and are also tentatively assigned square-planar geometry.[22]

All the copper(II) complexes are paramagnetic and possess magnetic moment values equivalent to one unpaired electron. The value is found to be less than 1.9 BM indicating the complexes have tetragonal or square-planar arrangements around the copper(II) ion.[23] But the excess over the spin-only value of 1.73 BM observed (Table 3) in these complexes might be due to spin-orbit coupling.

[a]Broad band indicating overlapping of different transitions.

the solid state and in solutions are given in Figs 1 and 2. The ESR spectral and bonding parameters are listed in Table 4.

The ESR spectra of all the copper(II) complexes in the solid state at liquid nitrogen temperature show two peaks, one of intense absorption at high field and the other of less intensity at low field. From these peaks $g_{\parallel}$ and $G_{\perp}$ have been calculated. However, the ESR spectra of all the copper(II) complexes in solution at liquid nitrogen temperature exhibit a set of four well-resolved peaks in the low field region and intense unresolved peaks in the high field region.

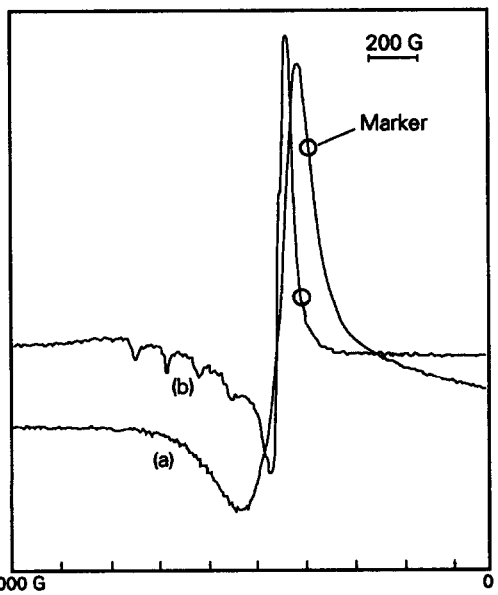

Fig. 1. ESR spectra of copper(II) MFQ complexes at liquid nitrogen temperature: (a) in the solid state; (b) in solution.

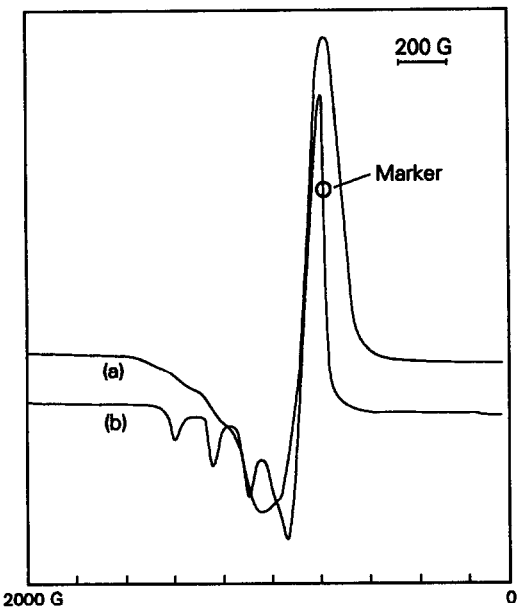

Fig. 2. ESR spectra of copper(II) PFQ complexes at liquid nitrogen temperature: (a) in the solid state; (b) in solution.

The $g_{\parallel}$ and $g_{\perp}$ values have been calculated using Kneubuhl's method.[24] $A_{\parallel}$ and $A_{\perp}$ values were calculated by using one third of the line widths at half maximum and A_0 as 1/3 $(A_{\parallel}+2A_{\perp})$ and g_0 as 1/3 $(g_{\parallel}+2g_{\perp})$.[25] No bands corresponding to Ms = ± 2 transitions were observed in the spectra, ruling out any Cu—Cu interaction.

The g tensor values of copper(II) complexes can be used to derive the ground state.[26] In elongated octahedral (tetragonal) and square-planar complexes, the unpaired electron lies in the $d_{x^2-y^2}$ orbitals giving $^2B_{1g}$ as the ground state with $g_{\parallel} > g_{\perp}$.

IIb

Structure **IIa**: Copper(II) complexes of the (O—N) donor ligands; **IIb**: copper(II) complexes of the (O—O) donor ligands.

In a compressed octahedron, on the other hand, the unpaired electron lies in the d_{z^2} orbital giving $^2A_{1g}$ as the ground state with $g_{\perp} > g_{\parallel}$. From the observed values it is evident that the unpaired electron lies predominantly in the $d_{x^2-y^2}$ orbital. The complexes also show anisotropic ESR spectra with $g_{\parallel} > g_{\perp}$ characteristic of tetragonal or square-planar geometry. Recalling the complexes with the $d_{x^2-y^2}$ ground state, strong interactions along the z axis are accompanied by an increase in the value of $g_{\parallel}$. Strong axial bonding leads to an increase in the length of the bond in the X–Y plane, which results in a decrease of both in-plane covalency and the energy of the $d_{x^2-y^2}$ transition.[27] Both these effects tend to increase the values of $g_{\parallel}$.

$g_{\parallel}$ is the most sensitive function for indicating the covalency, being 2.3 or more for ionic compounds and less than 2.3 for covalent compounds.[28] It is clear from Table 4 that the value of $g_{\parallel}$ obtained is less than 2.3 indicating covalent character of the metal–ligand bond.

Based on the foregoing data all the copper(II) complexes are assigned to the tetragonal or square-planar geometry and are shown in structures **IIa** and **b**.

Acknowledgements—The authors thank the Head, IIT, Bombay, for providing facilities for recording ESR spectra. One of us (B.P.) is grateful to CSIR, New Delhi, for the award of a SRF.

NUCLEAR MAGNETIC RESONANCE STUDIES OF SILICON(IV) COMPLEXES IN AQUEOUS SOLUTION—I. TRIS-CATECHOLATO COMPLEXES

DENNIS F. EVANS,* JONATHAN PARR and ERIC N. COKER

Inorganic Chemistry Laboratories, Imperial College, London SW7 2AY, U.K.

(*Received* 26 *September* 1989; *accepted* 18 *October* 1989)

Abstract—Quantitative data for the reaction $3LH_2 + Si(OH)_4 \rightleftharpoons SiL_3^{2-} + 4H_2O$ in aqueous solution have been obtained by ^1H and ^{29}Si NMR spectroscopy, where LH_2 = catechol, 4,5-dichlorocatechol, 4-nitrocatechol or 3,4-dinitrocatechol. By a suitable choice of LH_2 it is possible to obtain stable solutions of tris-catecholato complexes of silicon(IV), in the presence of $Si(OH)_4$, at pH values ranging from alkaline to as low as 4.1. When LH_2 = 2,3-dihydroxybenzaldehyde or tiron, meridional and facial isomers have been characterized. Mixed complexes containing catechol and 4-nitrocatechol or catechol and 4,5-dichlorocatechol have also been studied. Information has been obtained about the rate of Si—O bond breaking from the ^1H NMR spectra of the tris-complex derived from gallic acid.

There has been considerable interest recently in the biochemistry of silicon.[1] It has been known for many years that organisms such as diatoms and siliceous sponges utilize dissolved silica to produce elaborate structures of amorphous silica, and there is now considerable evidence that active transport of silicon is involved.[2] Since 1972 it has also been realized that silicon is an essential element participating in the normal metabolism of higher animals.[3] However, the mechanism of silicon transport in living organisms is largely unknown, although it seems likely that silicon(IV) complexes will be involved. Silica is quite soluble in aqueous solutions of strong alkalis, and a large number of polysilicate species have been characterized by ^{29}Si NMR spectroscopy.[4] This elegant work is, however, not relevant to the biochemistry of silicon since the polysilicate species are only stable at high pH values. Apart from hydrofluoric acid and the well-known SiF_6^{2-} ion[5] only two classes of ligands have been reliably reported to react to give silicon(IV) complexes from silica in water. In 1931, Rosenheim *et al.*[6] prepared the tris-catecholato silicon(IV) anion by heating freshly prepared "silicic acid" with aqueous alkaline solutions of catechol, followed by crystallization. Subsequently, Muetterties and Wright[7] showed that silicic acid reacted with tropolone in aqueous acid to give the tris-tropolonato silicon(IV) cation. Although stable in acid solution, this cation is rapidly hydrolysed at neutral pH. In the present work, ^1H and ^{29}Si NMR spectroscopy have been used to determine quantitatively the reaction between silica and various catechols in aqueous solution, and also to obtain more detailed information about the species present in solution.

EXPERIMENTAL

Materials

Catechol ($catH_2$) was purified by sublimation, and 4-chlorocatechol[8,9] (4-$ClcatH_2$), 4,5-dichlorocatechol[9] (4,5-Cl_2catH_2), 3,4-dinitrocatechol[10] [3,4-$(NO_2)_2catH_2$] and 4,5-dinitrocatechol[11] [4,5-$(NO_2)_2catH_2$] were prepared by literature methods. The remaining catechols were pure commercial samples. Catechol-d_6 was prepared by heating $catH_2$ (2 g) in D_2O (10 cm^3) with 1 cm^3 of 20% DCl in D_2O in a sealed ampoule under argon at 110°C for 24 h. The solution was taken to dryness *in vacuo*, and the procedure repeated once. The ^1H NMR in D_2O indicated an isotopic purity for the aromatic protons of > 98%. Silicic acid (for chromatography) was obtained from Fluka.

Preparation of solid tris-catecholato complexes

All preparations were carried out under argon until the point of precipitation of the complex.

$(Et_3NH)_2[Si(cat)_3]$ (cf. ref. 12). To a stirred solution of $catH_2$ (3.99 g, 36.2 mmol) in ethanol (25 cm^3), triethylamine (3.4 cm^3, 24.5 mmol) was added, followed by $Si(OEt)_4$ (2.7 cm^3, 12.1 mmol). After 20 min, the white precipitate was filtered, washed with ethanol, then diethyl ether and dried *in vacuo*. Yield: 2.16 g, 32%. Found: C, 64.1; H, 7.9; N, 5.0. $(Et_3NH)_2[Si(cat)_3]$ requires: C, 64.7; H, 7.9; N, 5.0%. The corresponding complexes derived from 4-$ClcatH_2$, 4,5-Cl_2catH_2 and 4-NO_2catH_2 were prepared in a similar manner and gave satisfactory analyses.

$K_2[Si(cat)_3]\cdot xH_2O$. The following procedure was found to be more convenient than that used by Rosenheim *et al.*[6]

To $catH_2$ (5.00 g, 45.4 mmol) in ethanol (20 cm^3), a solution of potassium (1.21 g, 31.1 mmol) in ethanol (20 cm^3) was added. The fine white precipitate formed initially, disappeared on warming to *ca* 50°C and $Si(OEt)_4$ (3.38 cm^3, 18.5 mmol) was added. The reaction mixture was warmed for a further 30 min and then cooled to 0°C. The white precipitate was filtered off, washed with ethanol, then diethyl ether and dried *in vacuo* at 70°C to constant weight. Yield: 5.1 g, 64%. Found: C, 50.9; H, 2.9. $K_2[Si(cat)_3]$ requires: C, 50.2; H, 2.8%. Mass spectra (FAB^+) $m/z = 431$, as $K_2[Si(cat)_3]H^+$. Analyses for carbon and hydrogen, and the loss in weight on heating to 110°C *in vacuo* indicate that samples dried at room temperature contained slightly variable amounts of H_2O, with x being in the range 2–4. (Rosenheim *et al.*[6] report $x = 12H_2O$ for complexes prepared in H_2O.) The potassium salts of the tris-catecholato complexes derived from 4-NO_2catH_2, 4,5-$(NO_2)_2catH_2$, 3,4-$(NO_2)_2catH_2$ and 4,5-Cl_2catH_2 were prepared in a similar manner, and satisfactory analyses were obtained. They were found to be more water soluble than their triethylammonium counterparts.

With 1,2-dihydroxybenzaldehyde (3-$CHOcatH_2$) and 3,4-dihydroxybenzaldehyde (4-$CHOcatH_2$) the extreme insolubility of both K[3-CHOcatH] and K[4-CHOcatH] led to incomplete conversion to the $[Si(3\text{-}CHOcat)_3]^{2-}$ and $[Si(4\text{-}CHOcat)_3]^{2-}$ complexes. Accordingly, the tetramethylammonium salts were prepared, the method of preparation being as for $K_2[Si(cat)_3]$, using a stoichiometric amount of tetramethylammonium hydroxide in place of the potassium ethoxide. Found: C, 60.6; H, 6.9; N, 4.4. $(N(Me)_4)_2[Si(3\text{-}CHOcat)_3]$ requires: C, 59.6; H, 6.2; N, 4.4%.

Equilibrium studies

A solution of the catechol was sealed in a fused silica ampoule under argon with an excess of silicic acid, in a 0.2 M buffer solution. Acetate buffer was used for pH 4.0–5.0; thereafter, 2-(N-morpholino)ethanesulphonic acid (5.1–6.5); piperazine-NN′-bis-2-ethanesulphonic acid (6.6–7.5); N-2-hydroxyethylpiperazine-N′-2-ethanesulphonic acid (7.6–8.0); N-2-hydroxyethylpiperazine-N′-3-propanesulphonic acid (8.1–8.6). The ampoules were shaken for 8 weeks in a water bath at 25.0°C. After an ampoule was opened, the contents were centrifuged, and following a measurement of pH, an aliquot of the supernatant fluid was rapidly taken to dryness.[13] The residue was redissolved in D_2O, and the ^1H NMR recorded before any change in the equilibrium could occur. With 3,4-$(NO_2)_2catH_2$, the ^{29}Si NMR spectrum of the formed tris-complex was measured directly on the aqueous solution after centrifugation, in a 10 mm tube, using a 5 mm insert tube containing D_2O for the lock signal. 3-(Trimethylsilyl)-1-propanesulphonate was used as an internal intensity standard. For the hydrolysis experiments, buffered solutions of $K_2[Si(cat)_3]$ or $K_2[Si(4\text{-}NO_2cat)_3]$ were kept at 25.0°C for 8 weeks in sealed silica ampoules under argon. The solutions remained clear, because of the small size of the silica particles formed. For a 0.05 M solution of $K_2[Si(cat)_3]$ at pH 8.4, which had been allowed to hydrolyse extensively (2 weeks), it was shown, using laser diffraction techniques, that the majority of the particles formed had diameters of 35 ± 3 nm. This is sufficiently large to exclude any appreciable increase in the equilibrium solubility of the silica.[3]

Physical measurements

For NMR measurements of the pure and the mixed tris-complexes, the potassium, triethylammonium or tetramethylammonium salts were used either dissolved directly in D_2O, or if pH control was required, in aqueous buffers, which were then rapidly evaporated, and the residue redissolved in D_2O. Where pH values are quoted for solutions in D_2O, they refer to the pH of the aqueous solution before evaporation and redissolution in D_2O. Reported pD values refer to the observed pD of the solution in D_2O. A number of the triethylammonium salts were only sparingly soluble in water, and in these cases, the solid was stirred with a little water and an excess of Dowex 50-X8 ion exchange resin in the Na^+ form. Solid complexes were not isolated with 4,5-dihydroxybenzene-1,3-disulphonate (tiron) or 3,4,5-trihydroxybenzoic (gallic) acid. Solutions of the tris-complexes were prepared by adding a slight excess of $Si(OEt)_4$ to a buffered solution of the ligand in water, which was then stirred for 18 h. For the determinations of the solubility of silica, silicic acid was shaken, in

polypropylene tubes under argon, with buffer solutions for 8 weeks, at 25.0°C. The dissolved silica was determined colourimetrically, using ammonium molybdate and 4-amino-3-hydroxy-1-naphthalene-sulphonic acid.[14]

^1H NMR spectra were recorded on Bruker WM250 (250 MHz), Jeol GSX270 (270 MHz) and Bruker WM500 (500 MHz) spectrometers. ^{29}Si NMR spectra and ^{13}C NMR spectra were recorded on Bruker WM250 and Jeol FX90Q spectrometers. The relaxation reagent, Na[Cr(dtpa)], which has been used for ^{13}C NMR in aqueous solution,[15] was added (0.08 M) to overcome the problems associated with the long relaxation times and the negative magnetic moment of the ^{29}Si nucleus. Line shape calculations for the gallic acid system were made using a program kindly provided by Dr H. S. Rzepa. Measurements in the slow exchange region showed that $\delta\nu$ varied with temperature, and accordingly extrapolated values of $\delta\nu$ were used in the calculations. Mass spectra were recorded on a Micromass VG 7070E spectrometer in the FAB^+ mode, with the sample suspended in a water–glycerol matrix. Photon correlation spectroscopy for the determination of particle size was carried out using a He/Ne laser and a standard 96 channel Malvern correlator. Raman spectra were recorded using a Spex Ramalog V instrument (488 nm, 150 mW).

IR spectra were measured using a Perkin–Elmer 1720 FT spectrometer.

RESULTS AND DISCUSSION

The solubility of amorphous silica in water has been determined by several groups of workers[2] and is found to be only slightly dependent on pH in the range 1–*ca* 8.5, and equal to *ca* 2×10^{-3} M. The silica is thought to be present as monomeric $Si(OH)_4$.[3] For aqueous solutions containing silica and a catechol, we therefore have equilibrium (1), with an equilibrium constant given by eq. (2):

$$3LH_2 + Si(OH)_4 \rightleftharpoons SiL_3^{2-} + 4H_2O + 2H^+ \quad (1)$$

$$\frac{[SiL_3^{2-}][H^+]^2}{[LH_2]^3[Si(OH)_4]} = K. \quad (2)$$

If excess solid silica is present, then to a reasonable approximation, over the pH range 1–*ca* 8.5,

$$\frac{[SiL_3^{2-}][H^+]^2}{[LH_2]^3} = K' \quad (3)$$

where K' is *ca* 2×10^{-3} K.

We also have the ionization of the catechol [eqs (4) and (5)]:

$$LH_2 \rightleftharpoons LH^- + H^+ = K_1 \quad (4)$$

$$[LH_2] = [LH_2]_{tot}\cdot\frac{[H^+]}{[H^+]+K_1}, \quad (5)$$

where $[LH_2]_{tot}$ = total free catechol, i.e. $[LH_2]+[LH^-]$, if the second ionization constant can be neglected; this is reasonable when $pH < pK_2 - 2$.

Substituting in eq. (3),

$$\frac{[SiL_3^{2-}]([H^+]+K_1)^3}{[LH_2]_{tot}^3[H^+]} = K' \quad (6)$$

or

$$\frac{[SiL_3^{2-}]}{[LH_2]_{tot}} = \frac{K'[H^+]}{([H^+]+K_1)^3}. \quad (7)$$

The left-hand side of eq. (7) is a measure of the extent of formation of the tris-complex, and will have a maximum when

$$pH = pK_1 + 0.301$$

corresponding to the equation

$$2LH^- + LH_2 + Si(OH)_4 \rightleftharpoons SiL_3^{2-} + 4H_2O.$$

For any catechol, this gives the optimum pH, and suggests that to obtain reasonable equilibrium concentrations of the tris-complex at neutral or slightly acid pH, a catechol with an electron-withdrawing group(s) and a consequent value of pk_1 of < 7 might be suitable. Values of pk_1 (and some pk_2 values) are given in Table 1.

Figure 1 shows the ^1H NMR spectrum of a solution obtained from silicic acid and $catH_2$ (initial concentration 0.15 M) at pH 8.35. The $catH_2$ gives a characteristic AA'BB' pattern, while for $[Si(cat)_3]^{2-}$, δ_A and δ_B are almost the same. Chemical exchange between free and complexed $catH_2$ is therefore slow on an NMR time scale, and this was true for all the catechols studied except 4,5-$(NO_2)_2catH_2$. By integration it is possible to obtain the relative values for the concentration of $catH_2$

Table 1. Values of pK_1 and pK_2 for some catechols in water at 25°C

Catechol	pK_1	pK_2
$catH_2$	9.27[a]	*ca* 13[a]
4,5-Cl_2catH_2	7.46[b]	—
4-NO_2catH_2	6.69[a]	10.57[a]
3,4-$(NO_2)_2catH_2$	4.39[c]	8.27[c]

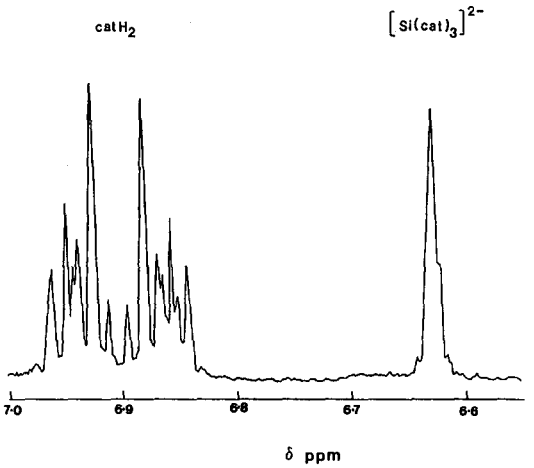

Fig. 1. ^{1}H NMR spectrum (270 MHz, D_2O) of a mixture of $[Si(cat)_3]^{2-}$ and $catH_2$ prepared from silicic acid and $catH_2$ at pH 8.35.

and $[Si(cat)_3]^{2-}$, and from a knowledge of the initial concentration of the $catH_2$, or the tris-complex in the hydrolysis experiments, their absolute magnitudes. Values of K' can then be calculated from eq. (6). For 3,4-$(NO_2)_2catH_2$, at room temperature the tris-complex gave an extremely broad proton resonance, almost lost in the baseline, presumably due to an intermediate rate of fluxionality. Accordingly, the concentration of the tris-complex formed was found from ^{29}Si NMR spectroscopy. The equilibrium data obtained are presented in Table 2, together with the calculated values of K'. Attempts were made to shorten the time taken for equilibration by using $Si(OEt)_4$ (which hydrolyses to form SiO_2) in place of silicic acid. However, after 36 h stirring at 25°C, the amounts of $[Si(cat)_3]^{2-}$ formed were considerably greater (by a factor of *ca* 4) than those obtained in the same pH range (8.0–8.5) for both the formation and decomposition experiments, giving much larger apparent values for K'. This is presumably because the hydrolysis of $Si(OEt)_4$ produces very small particles of SiO_2 which will have a higher free energy and solubility than bulk SiO_2.[3] The solubility of the silicic acid used was found to be 1.78×10^{-3} M at pH 7.41 and 1.91×10^{-3} M at pH 8.35, in good agreement with literature values.[3] An average value of 1.85×10^{-3} was used to calculate the approximate values of the true equilibrium constant K given in the table. The results of the hydrolysis and formation equilibria for both $catH_2$ and 4-NO_2catH_2 indicate that true equilibria have been reached. For any one catechol, there is a scatter in the values of K and K' observed. In addition, for $catH_2$ itself, a possible increase in K and K' with pH may be due to an increase in the solubility of silica in the more alkaline solutions.[3] Nevertheless, the experimental results are reasonably consistent with eqs (6) and (7). As expected, K values increase in the sequence

$$catH_2 < 4,5\text{-}Cl_2catH_2 < 4\text{-}NO_2catH_2 < 3,4\text{-}(NO_2)_2catH_2,$$

which also corresponds to the decrease in pK_1 and pK_2 for the free catechols. It is certainly clear that by an appropriate choice of catechol, stable aqueous solutions of tris-catecholato complexes of silicon(IV) can be obtained in the presence of dissolved silica at pH values ranging from alkaline to as low as 4.1. There have been two previous attempts to obtain values of K for tris-catecholato complexes of silicon(IV) in aqueous solution. Bartels[16] carried out base titrations of a number of catechols in the presence of silicic acid. The concentration of silicic acid was taken as being the total amount added, equivalent to 6.67×10^{-3} M, which considerably exceeds the equilibrium solubility of silica (*ca* 2×10^{-3}). It is also not clear whether true equilibria were obtained during the titrations. It is therefore not surprising that he reported values of K for $catH_2$ (1.3×10^{-11}) and 4-NO_2catH_2 (7.4×10^{-6}) which differ considerably from our values (3.8×10^{-13} and 1.8×10^{-8}, respectively). Baumann[17] used the molybdate reaction to obtain the concentration of "molybdate active silicic acid" in aqueous solutions containing $catH_2$ and excess silicic acid. He derived a value for K of 4.8×10^{-12}, which is still considerably greater than that reported here.

Pichet and Benoit[18] using UV spectrophotometry, have reported values of K for the formation in aqueous solution of a number of tris-catecholato complexes of germanium(IV), which exist in a similar equilibrium to that found for silicon(IV). They also observed a correlation between an increase in K and a decrease in pK_1 and pK_2 for the free catechol. The values of K are much larger, however, which reflects the greater stability of the germanium(IV) complexes.

Facial and meridional isomers

When the catechol is asymmetrically substituted, and the two oxygens become non-equivalent in the dianion, there is the possibility of meridional and facial isomerism in the corresponding tris-catecholato silicon(IV) complex. In the facial isomer, the ligands are equivalent but in the meridional isomer they are all different. The meridional–facial isomer ratio expected on a purely statistical basis is 3 : 1. Figure 2 shows the ^{1}H NMR spectrum of the $[Si(3\text{-}CHOcat)_3]^{2-}$ anion in D_2O. Four peaks of

[a] The initial concentration of the catechols was 0.15 M (0.05 M for the tris-catecholato complexes in the hydrolysis experiments), except for 3,4-$(NO_2)_2catH_2$ (0.3 M).

[b] The value is for $[L_{complexed}]/[L_{free}]$, i.e. $[SiL_3]^{2-}/3[L_{free}]$, where $[L_{free}]$ is the total concentration of the free catechol.

[c] K_{mean} is the mean of the values of K found from hydrolysis and formation reactions, assuming $[Si(OH)_4]=1.83\times10^{-3}$.

[d] Based on the H_6 resonances.

equal intensity are observed for the aldehydic protons, showing the presence of meridional and facial isomers in the statistical ratio, within experimental error. The aromatic resonances are more complex, but for H_6 four overlapping sets of double doublets can be discerned (Fig. 2). The distinction between H_4 and H_6 was made on the basis of a difference NOE experiment, with the aldehydic resonances being irradiated.

In Fig. 3 the ^1H NMR spectrum of the tris-complex derived from tiron and silicic acid is shown. The H_6 resonance consists of three doublets of equal

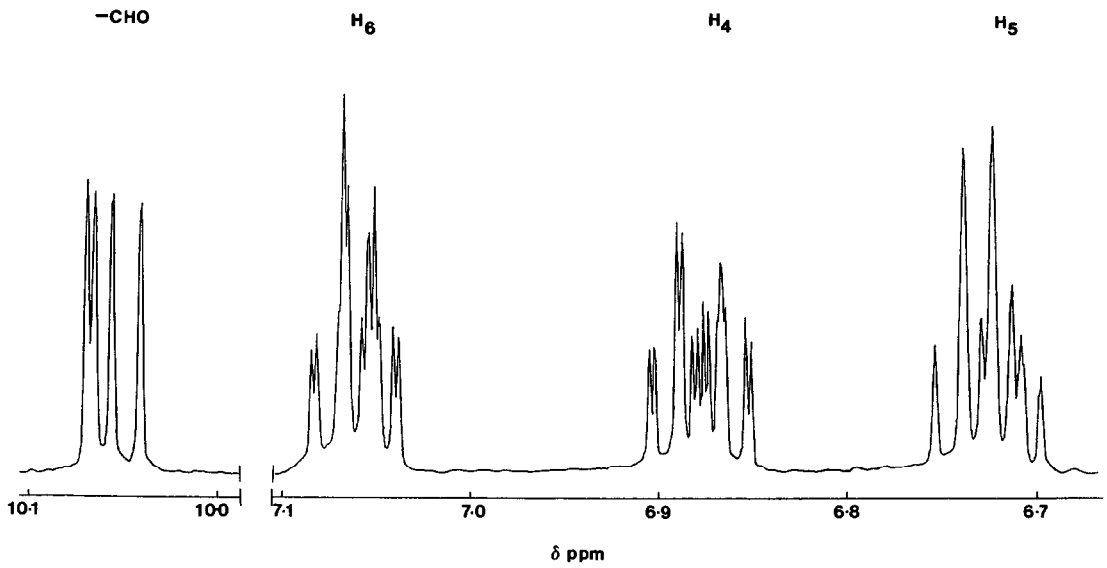

Fig. 2. ^{1}H NMR spectrum (500 MHz, D_2O) of the $[Si(3\text{-}CHOcat)_3]^{2-}$ anion.

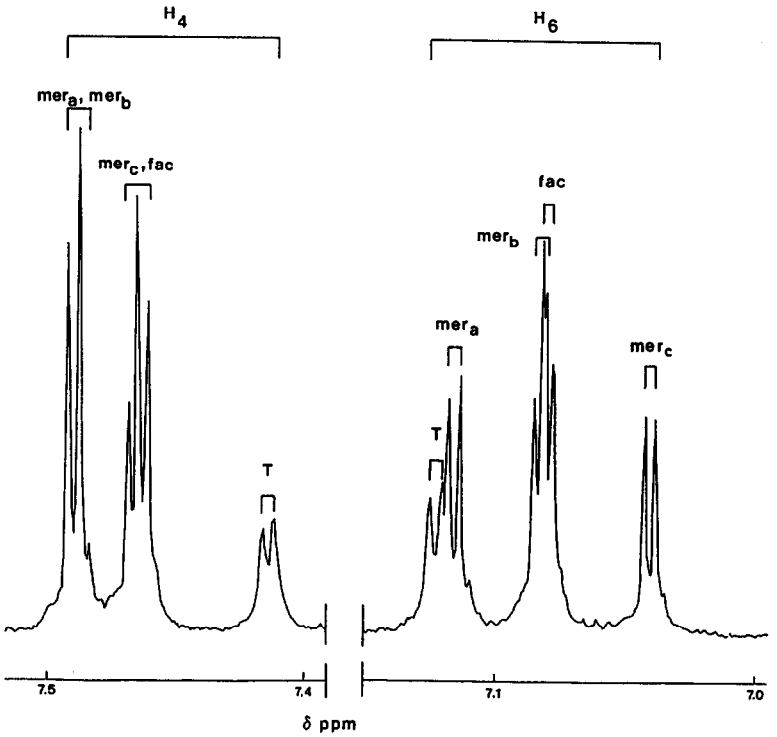

Fig. 3. ^{1}H NMR spectrum (500 MHz, D_2O) of the tris-complex derived from tiron; T = free tiron.

intensity, together with one of greater intensity, which can be assigned to the facial isomer. The meridional–facial ratio is $2.3 \pm 0.2 : 1$. The difference from the statistical value may be due to steric effects associated with the bulky sulphonate groups. The detailed assignment given in Fig. 3 is based on a 2D COSY experiment (500 MHz).

Facial and meridional isomers would also be expected for the tris-complexes derived from 4-substituted catechols. The ^{1}H NMR spectra of $[Si(4\text{-}CHOcat)_3]^{2-}$ and $[Si(4\text{-}NO_2cat)_3]^{2-}$ suggested that meridional and facial isomers were present, but only very limited resolution could be achieved. With $[Si(4\text{-}NO_2cat)_3]^{2-}$, the H_3 resonances comprised two overlapping sets of doublets of equal intensity. Measurements at both 250 and 500 MHz showed

that a chemical shift was involved and not an abnormally large *para*-{^{1}H–^{1}H} coupling. For the free ligand, H_6 consisted of one doublet only. It seems likely that in both complexes two of the meridional resonances and one facial and one meridional resonance have almost identical chemical shifts. The ^{1}H NMR spectra of $[Si(4\text{-}CHOcat)_3]^{2-}$ and $[Si(3\text{-}MeOcat)_3]^{2-}$ also showed no clear resolution of the resonances from the facial and meridional isomers. The presence of a strongly anisotropic group in the 3-position of the catechol ring may therefore be necessary to obtain adequate resolution of the meridional and facial isomers in the ^{1}H NMR spectra.

The ^{1}H resonances of $[Si(3\text{-}CHOcat)_3]^{2-}$ began to broaden at *ca* 50°C, with appreciable broadening at *ca* 80°C, while for $[Si(tiron)_3]^{2-}$, broadening begins at *ca* 40°C with partial collapse at *ca* 70°C. These changes indicate the onset of fluxionality since the resonances of the free ligand remain sharp throughout. Although $[Si(3\text{-}CHOcat)_3]^{2-}$ is rigid on an NMR time scale at room temperature, it is probably fluxional in the time taken to obtain the NMR spectrum since it is unlikely that the solid tetramethylammonium salt used contains the isomers in almost the exact statistical ratio.

Mixed complexes

When freshly prepared 0.1 M solutions of $K_2[Si(cat)_3]$ and $K_2[Si(4\text{-}NO_2cat)_3]$ in D_2O at pH 8.0 were mixed at room temperature, the ^{1}H NMR spectrum measured immediately consisted of a superposition of those of the two complexes. After *ca* 60 min, resonances characteristic of the mixed complexes began to appear, and equilibrium was reached after *ca* 14 h. Ligand exchange was found to be faster at the lower pH of 7.0. For mixed solutions of $(Et_3NH)_2[Si(cat)_3]$ and $(Et_3NH)_2[Si(4\text{-}NO_2cat)_3]$ in dimethyl sulphoxide-d_6 no such complexes could be detected after 24 h, suggesting that in water ligand exchange involves as a first step H^+ attack on a Si—O bond.

Two series of mixed complexes were studied in detail, those formed from $[Si(cat)_3]^{2-}$ and $[Si(4\text{-}NO_2cat)_3]^{2-}$ and those from $[Si(catd_4)_3]^{2-}$ and $[Si(4,5\text{-}Cl_2cat)_3]^{2-}$. The former system is one with both a symmetrical and an asymmetrical catechol, the latter has two symmetrical catechols. $K_2[Si(catd_4)_3]$ was used to obtain the ^{1}H NMR spectra of the mixed complexes involving 4,5-Cl_2catH_2 to avoid interference caused by the resonances of free $catH_2$ formed by hydrolysis during equilibration. The mixed complexes expected are illustrated in Figs 4 and 6, and the observed ^{1}H and ^{29}Si NMR spectra are shown in Figs 5 and 7. For the $[Si(catd_4)_3]^{2-}$ and $[Si(4,5\text{-}Cl_2cat)_3]^{2-}$ systems, the different species can be distinguished in both the ^{1}H NMR and ^{29}Si NMR spectra. The assignment given in Fig. 5 was confirmed by studying a solution prepared from a different initial molar ratio of the pure tris-complexes (1 : 2). As expected, two ^{1}H resonances of equal intensity are observed for the $[Sicatd_4(4,5\text{-}Cl_2cat)_2]^{2-}$ anion. Because of the appreciable hydrolysis that occurred during equilibration, it was not possible to obtain accurate data concerning the position of the equilibrium, although it seems to be close to the statistical value. Three geometrical isomers are expected for the $[Sicat(4\text{-}NO_2cat)_2]^{2-}$ anion (Fig. 6). In the asymmetrical isomer (which has twice the statistical weight of the others) the two 4-NO_2cat ligands are not equivalent. Accordingly, the H_3 resonance for the mixed species should comprise four doublets. Only three are actually observed, with two overlapping to give an apparent triplet. It seems likely that the strong, slightly broad high-field doublet comprises two highly overlapped doublets. The ^{29}Si NMR spectrum (Fig. 7) distinguishes between complexes of different formula, but not between the $[Sicat(4\text{-}NO_2cat)_2]^{2-}$ isomers.

The $[Si(gallate)_3]^{5-}$ *complex*

In this work qualitative information has been obtained from ^1H NMR spectra concerning the rates of a number of processes, i.e. the exchange between free and complexed ligand, the interchange between different ligands and the "scrambling" of meridional and facial isomers. ^1H NMR spectra of the tris-complex derived from gallic acid provides quantitative rate data for another process, the breaking of one Si—O bond to give a five-coordinate complex, which is a plausible first step in these other reactions. If bond breaking in the tris-complex is slow on the NMR time scale then two separate resonances are expected (H_A and H_B in Fig. 8). Fast bond breaking, with concomitant fast proton transfer, will result in a single resonance only. Figure 8 shows the ^1H NMR spectra of the tris-complex in D_2O as a function of temperature, together with the calculated mean lifetimes, τ. The free ligand resonance remains sharp throughout, showing that intermolecular exchange does not contribute appreciably to the observed collapse of the H_A and H_B resonances. The rate of bond breaking is dependent upon the pD of the solution. At a pD of 8.4 (25°C) the mean lifetime, τ, was 0.014 s at 85°C, compared with an interpolated value of 0.008 s at the same temperature and a pD of 7.8. It therefore seems likely that bond breaking is assisted by H^+ attack on one of the Si—O bonds, although the situation is complicated by a probable change in species with pD, arising from the ionization of the free phenolic-OD group. At low temperature and high pH, some additional structure in the H_A and H_B resonances was observed, presumably arising from the presence of meridional and facial isomers. In the corresponding germanium(IV) complex,[19] where bond breaking is slow, this structure is more clearly resolved.

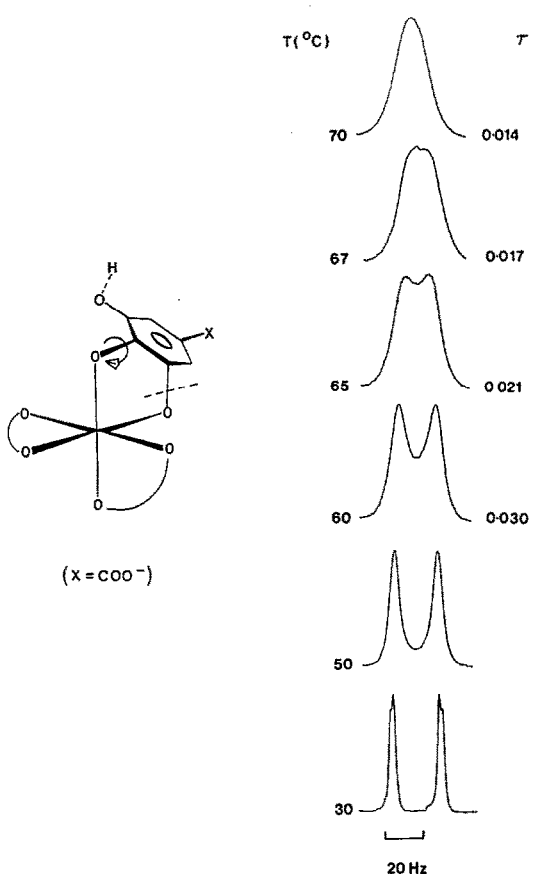

Fig. 8. ^1H NMR spectra (250 MHz, D_2O, pD at 25°C = 7.8) of $[Si(gallate)_3]^{5-}$ at various temperatures, together with the calculated values of the mean lifetimes, τ, for the interchange of H_A and H_B.

^{29}Si and ^{13}C NMR spectra

The ^{29}Si chemical shifts observed for the tris-catecholato complexes are given in Table 3. Cella *et al.*[20] showed that in organic solvents six-coordinate complexes of silicon give much more negative values of δ than do complexes in which the silicon is bound to four oxygens only. For $(Et_3NH)_2[Si(cat)_3]$ in dimethyl sulphoxide-d_6 they report a value for δ of -139.3, in reasonable agreement with our result of -140.3 for $K_2[Si(cat)_3]$ in dimethyl sulphoxide. The more negative value of δ for an aqueous solution (-146.3) presumably arises from solvent effects, possibly due, in part, to hydrogen-bonding from the water to the oxygens in the tris-complex. The main factor affecting the chemical shifts in Table 3 seems to be the electron density on the

cat(4-NO_2cat)$_2$	-143.8

[a] In $(CH_3)_2SO$ with 0.08 M $Cr(acac)_3$.

oxygens, with electron-withdrawing groups leading to deshielding of the ^{29}Si nucleus. For the 4- and 4,5-substituted catechols there is a reasonable correlation between δ and $\Sigma\sigma$, where $\Sigma\sigma$ is the sum of the Hammett σ_m and σ_p values for the substituent, calculated with respect to the oxygens. There are two anomalies, $[Si(4\text{-}Mecat)_3]^{2-}$, where δ is less negative in water (though not in $(CH_3)_2SO$) than that for $[Si(cat)_3]^{2-}$, and $[Si(4\text{-}CNcat)_3]^{2-}$, for which a less negative value would be expected. As with $[Si(4\text{-}Mecat)_3]^{2-}$, the δ value of $[Si(4\text{-}CNcat)_3]^{2-}$ in $(CH_3)_2SO$ is closer to that expected from the relevant Hammett σ values, suggesting that these anomalous results in water may also be largely associated with solvent effects. Quite good additivity of the ^{29}Si chemical shifts is observed in the mixed complexes (Table 3, Figs 5 and 7). The ^{13}C NMR spectrum of the $[Si(cat)_3]^{2-}$ anion in H_2O shows resonances at 152.1 ($C^{1,2}$), 120.4 ($C^{4,5}$) and 113.4 ppm ($C^{3,6}$), compared to 147.7, 123.1 and 118.9 ppm, respectively, for $catH_2$. Griffith *et al.*[21] have reported the ^{13}C NMR spectra of catecholato complexes of molybdenum, tungsten and some platinum metals, which show similar but more marked deshielding of $C^{1,2}$ on coordination of the $catH_2$. For $[Si(4\text{-}NO_2cat)_3]^{2-}$ in H_2O, the ^{13}C resonances were at 169.4 (C^1), 151.6 (C^2), 135.8 (C^4), 124.1 ($C^{3(5)}$), 118.9 ($C^{5(3)}$) and 111.4 ppm (C^6). All ^{13}C resonances were measured relative to internal (trimethylsilyl)propane sulphonate.

Vibrational spectra of the $[Si(cat)_3]^{2-}$ *ion*

The ^1H NMR spectra reported for the meridional and facial isomers, the mixed complexes, and the complexes derived from gallic acid prove that in these cases silicon is octahedrally coordinated in solution. Further evidence for the parent $[Si(cat)_3]^{2-}$ ion is provided by the almost identical Raman spectra of $K_2[Si(cat)_3]$ in the solid state and in aqueous solution (Table 4). The X-ray crystal structure of $(Cu^{II}(en)_2)[Si(cat)_3]$ has been reported[22] and shows that silicon is surrounded by six oxygens, with O—Si—O bond angles close to 90° (88.3 to 94.4°). Table 4 also gives the IR data for solid $K_2[Si(cat)_3]$. The IR and Raman spectra of $K_2[Si(catd_4)_3]$ were also measured, and indicated that the vibrations were highly "mixed". Accordingly, no assignments of the bands in Table 4 are attempted.

Acknowledgements—We thank Mr R. N. Sheppard for the 500 MHz NMR spectra, Mr J. N. Bilton for the mass spectra, and Dr D. Young for the laser diffraction data. One of us (J.P.) thanks the SERC for a grant.

(*Received* 28 *May* 1989; *accepted* 18 *October* 1989)

Abstract—Copper(II) and nickel(II) complexes of tri- and tetrapeptide segments of thymopoietin—ArgLysAspVal (TP4), ArgLysAsp (TP3, LLL, LLD, LDL, DLL) and ArgLys-(Arg)Asp (ETP3)—were studied by potentiometric spectrophotometric, CD and EPR methods. The coordination of terminal amino, two deprotonated amide nitrogens and the β-carboxylate of the aspartic acid residue was proved in all cases. Significant stereoselectivity was not observed in the copper complexes of diastereomeric tripeptides.

Thymopoietin, a 49 amino acid polypeptide, is a hormone of the thymus which influences the differentiation of various cells. The synthetic pentapeptide segment—Arg–Lys–Asp–Val–Tyr (TP5)—was reported to correspond to a biologically-active site of the parent thymopoietin molecule.[1]

Concerning the coordination chemistry of TP5, its various transition metal and lanthanide complexes have so far been studied.[2–4] It was found that TP5 forms stable 1 : 1 complexes with copper(II) in which coordination takes place via the terminal-amino, two deprotonated amide nitrogens and the β-carboxylate group of the aspartic acid residue. On the basis of this result it was stated that during complex formation TP5 acts as a tripeptide, and the aspartic acid present in the third position in the peptide chain is able to hinder the coordination of the fourth and fifth amino acid residues. The same effect of the aspartyl moiety was found in the copper(II) complexes of other peptides containing aspartic acid,[5] while the coordination of four nitrogens (NH_2 and 3 N^-) is characteristic of tetraglycine.[6]

Carbon terminally shortened segments of TP5—ArgLysAspVal, TP4 and ArgLysAsp, TP3—eliciting remarkable immunostimulating effects, are under clinical studies.[7] Taking into account the governing role of the aspartyl residue during complex formation it is worthwhile studying the transition metal complexes of TP4 and TP3 and their diastereomers. This is also supported by literature values, because a significant stereoselectivity can be observed in the copper(II) complexes of diastereomeric dipeptides.[8–10] Namely, $CuAH_{-1}$ complexes of (LL)-dipeptides are more stable than the complexes of (LD)-dipeptides. The difference in stability largely depends on the side-chain disposition, and it is explained by hydrophobic interactions between the side chains. Similar studies for the diastereomeric tripeptides have not been published yet.

In this paper we present the results of potentiometric and spectrophotometric studies for the

copper(II) and nickel(II) complexes of TP4 (LLLL), TP3 (LLL, DLL, LDL, LLD) and ETP3 containing arginyl residues both at the α- and ε-amino groups of lysine, Arg–Lys(Arg)–Asp.

EXPERIMENTAL

The acetate forms of the peptides—Arg–Lys–Asp–Val (TP4, LLLL), Arg–Lys–Asp (TP3 LLL, DLL, LDL, LLD) and Arg–Lys(Arg)–Asp (TP3, LL(L)L)—were synthesized by usual methods. Details of the synthesis will be published elsewhere.

In the pH-metric studies, the ligand concentration varied between 1 and 4×10^{-3} mol dm^{-3}, while the metal ion to ligand ratios ranged from 2:1 to 1:3. The 5 cm^3 samples were titrated with carbonate-free potassium hydroxide, and argon was bubbled through the samples to ensure the absence of carbon dioxide and for stirring the solutions. All pH-metric studies were carried out at 298 K and at a constant ionic strength of 0.2 mol dm^{-3} (KCl). The pH measured was converted to [H$^+$]-ion concentration by the method of Irving *et al.*[11] Measurements were made with a Radiometer pHM84 pH-meter with GK2421C combined electrodes and an ABU80 autoburette. Stability constants defined by the following equation (charges are omitted and "A" denotes the fully deprotonated forms of TP3, TP4 and ETP3)

$$pM + qA + rH \rightleftharpoons M_pA_qH_r$$

$$\beta_{pqr} = \frac{[M_pA_qH_r]}{[M]^p[A]^q[H]^r}$$

were calculated with a general computational program (PSEQUAD) which was published earlier.[12]

Absorption spectra were recorded on a Beckman Acta MIV spectrophotometer and the concentrations were similar to those used in the potentiometric measurements. Circular dichroism (CD) spectra were measured on an automatic spectropolarimeter JASCO-J-20 in the 200–740 nm region, in equimolar solutions. All CD spectra are expressed in terms of $\Delta\varepsilon/(\varepsilon_l - \varepsilon_r)$. EPR spectra of the solution in a glycol–water mixture were taken on a JEOL JES-ME-3X spectrometer at liquid nitrogen temperature and at 9.15 GHz.

RESULTS AND DISCUSSION

The ligands investigated in this study can be classified into two categories. TP4, TP3 and ETP3, containing only L-amino acids, represent one type of ligand, and their protonation constants are summarized in Table 1.

Table 1. Protonation constants of TP3, TP4 and ETP3. $I = 0.2$ mol dm^{-3} (KCl); $T = 298$ K

	TP4	TP3	ETP3
pK_1	10.48±0.03	10.49±0.03	7.84±0.03
pK_2	7.34±0.02	7.44±0.02	7.13±0.03
pK_3	3.89±0.06	4.20±0.05	4.03±0.05
pK_4	3.04±0.05	2.77±0.05	2.67±0.05

It can be seen from Table 1 that all peptides have four dissociable protons in the measurable pH-range. pK_3 and pK_4 belong to the β-carboxylate and C-terminal carboxylate groups of the peptides, respectively. Data reveal that pK_3 and pK_4 values of TP3 and ETP3 are almost the same, but the difference between these values is smaller for TP4, because of the longer distances of the carboxylate groups in the molecule. Deprotonation of the terminal (arginyl) amino group (pK_2) and the side-chain lysyl ε-amino group (pK_1) are well separated in TP4 and TP3. The pK values obtained are similar to each other (and to those of TP5[2]), suggesting that the length of the peptide chain does not significantly influence the deprotonation processes of the amino groups. Both amino groups of the lysyl residue are in amide linkage in ETP3, therefore the ligand can be characterized by two "terminal (arginyl) amino" groups. Deprotonation of these ammonium groups takes place simultaneously, and their difference does not significantly exceed the statistical value (0.6 log unit). The average of pK_1 and pK_2 corresponds well with the deprotonation of the arginyl amino group (pK_2) in TP3 or TP4, supporting the independent deprotonation of the ammonium groups in ETP3.

Stability constants of the copper(II) and nickel(II) complexes of TP4, TP3 and ETP3 are collected in Table 2, while the concentration distribution of the complexes formed in the copper(II)–TP3 system are depicted in Fig. 1.

From Table 2 it can be seen that the same species are present in TP3 and TP4 systems, suggesting the same type of coordination for both ligands. $[CuAH_2]^{2+}$ and $[CuAH]^+$ are present in low concentration in acidic solution where the coordination takes place via the terminal amino and neighbouring carbonyl groups, similar to other oligopeptides.[6] $[CuAH_{-1}]^-$ is the main species between pH 5 and 10, which means that TP3 and TP4 act as tripeptides. Namely, both ligands are coordinated via the terminal amino, two deprotonated amide nitrogens and the β-carboxylate group of aspartic acid, while the ε-amino group of the lysyl residue remains protonated in the $[CuAH_{-1}]^-$ species. Consequently the real composition is

$[CuAH_{-1}]^{-} = [Cu(HAH_{-2})]^{-}$. This type of coordination is supported by the spectrophotometric results: the absorption band of $[CuAH_{-1}]^{-}$ appears at $\lambda = 542$ nm for both peptides with $\varepsilon = 159$ and 165 dm^3 mol^{-1} cm^{-1} for TP3 and TP4, respectively. It corresponds to the coordination of three nitrogens, and is in a good agreement with the absorption spectra of copper(II)–TP5 where the same tripeptide-like coordination was proved.

In basic solution $[CuAH_{-1}]^{-}$ is deprotonated and corresponding pK^{Lys} values are close to the pK value of the ε-amino group of the lysyl residues. There is no change in the absorption spectra in that pH-range, supporting the fact that the lysyl side chain of thymopoietin oligopeptide segments does not take part in coordination. CD and EPR measurements provide more unambiguous proof for the existence of the suggested binding mode, as is demonstrated in Table 3.

It can also be seen from Table 2 that complex formation processes of copper(II) and nickel(II) are very similar to each other. Standard deviations of stability constants of nickel(II) complexes are, however, significantly larger because the formation of square-planar diamagnetic complexes is quite slow (especially for the tetrapeptide). The existence of $[NiAH_2]^{2+}$ species can be excluded because of the higher pH-range of complex formation. Deprotonation of the amide groups takes place in a cooperative manner again, which results in the high concentration of $[NiAH_{-1}]^{-} = [Ni(HAH_{-2})]^{-}$.

Deprotonation of the amide group, therefore, can be characterized by an average pK value (pK') given

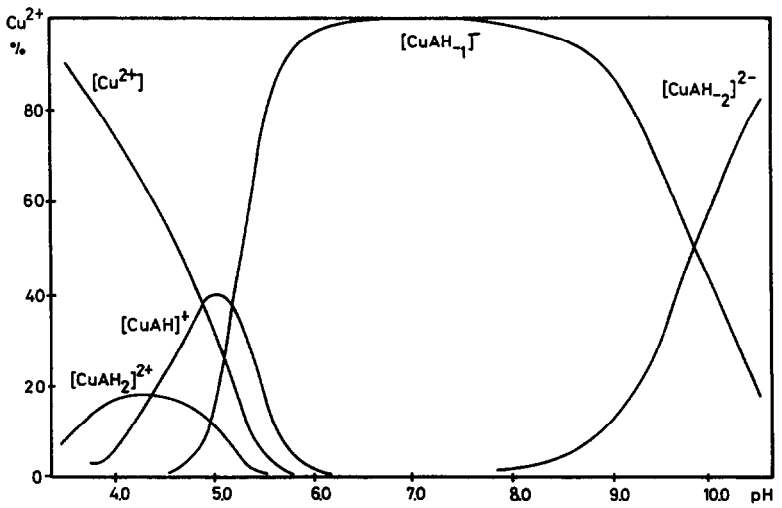

Fig. 1. Concentration distribution of the complexes formed in the copper(II)–TP3 system; $C_{Cu^{2+}} = 1.1 \times 10^{-3}$, $C_{TP3} = 2.9 \times 10^{-3}$ mol dm^{-3}.

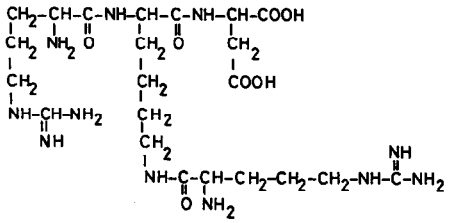
by the equation:

$$[Cu(HA)]^+ \rightleftharpoons [Cu(HAH_{-2})]^- + 2[H^+].$$

The data in Table 2 reveal that amide coordination is more favoured in copper(II) complexes ($\sim$ 1.7 log unit), similar to other peptide complexes. Comparing the pK' values of TP4 and TP3, it can be stated that TP4 forms the more stable complexes both with copper(II) and nickel(II) ($\sim$ 0.5 log unit).

ETP3–Arg–Lys(Arg)–Asp (Structure I) can be regarded as a "doubled" peptide molecule, at least from the coordination chemical viewpoint.



Structure I.

The molecule has the same donor groups as TP3 on one side, but another set of donor atoms is also present with the participation of the peptide bond at the ε-amino group of lysine. Consequently, complex formation processes of ETP3 are much more complicated than those of TP3, and species distribution largely depends on the metal ion to ligand ratios. Figures 2 and 3 show the concentration distribution of the complexes formed in the copper(II)–ETP3 system at 1:2 and 2:1 metal ion to ligand ratios, respectively.

It can be seen from Fig. 2 that in the presence of excess ligand the same species are formed both in copper(II)–TP3 and copper(II)–ETP3 systems. Namely, a stable coordination occurs via the tripeptide part of the ETP3 molecule and the lysyl residue behaves like an independent side chain. Of course, the ratio of $[CuAH_{-1}]^-$ and $[CuAH_{-2}]^{2-}$ is different for the two ligands because the pK of the terminal amino group in ETP3 is much smaller than the pK value of the ε-amino group in TP3. Spectrophotometric results also support the 3N-coordination because spectral parameters above pH 7 (at 1:2 ratio) are almost the same as for copper(II)–TP3 (λ_{max} = 540 nm, ε_{max} = 160 dm^3 mol^{-1} cm^{-1}). Deprotonation of two amide groups takes place simultaneously, and pK' is in a good agreement with TP3.

Figure 3 shows that the peptide bond at the lysyl locus can also be a binding site in the presence of excess copper(II) ion. Formation of $[Cu_2AH_{-2}]$ can be represented by the equation:

$$[CuAH_{-2}]^{2-} + [Cu^{2+}] \rightleftharpoons [Cu_2AH_{-2}].$$

The equilibrium constant for this process is $\log K = 4.73$ which corresponds well to a glycineamide-type coordination with the participation of the amino and carbonyl groups.[13] The amide bond at the ε-amino group deprotonates above pH 6–7 which leads to the formation of $[Cu_2AH_{-3}]^-$. Spectroscopic results also support the existence of two different copper(II) ions around pH $\sim$ 6, because an absorption band can be observed at λ = 540 nm (from the tripeptide coordination) and a shoulder appears between λ = 650 and 700 nm

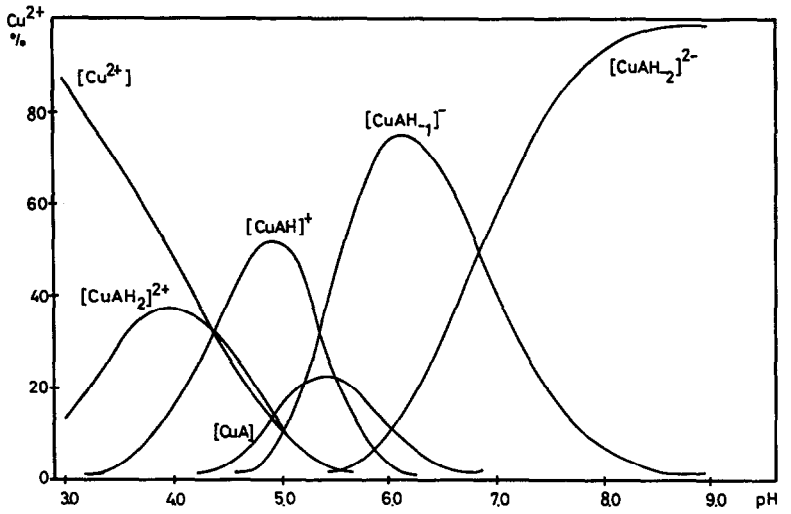


Fig. 2. Concentration distribution of the complexes formed in the copper(II)–ETP3 system; $C_{Cu^{2+}} = 1.04 \times 10^{-3}$, $C_{ETP3} = 2 \times 10^{-3}$ mol dm^{-3}.

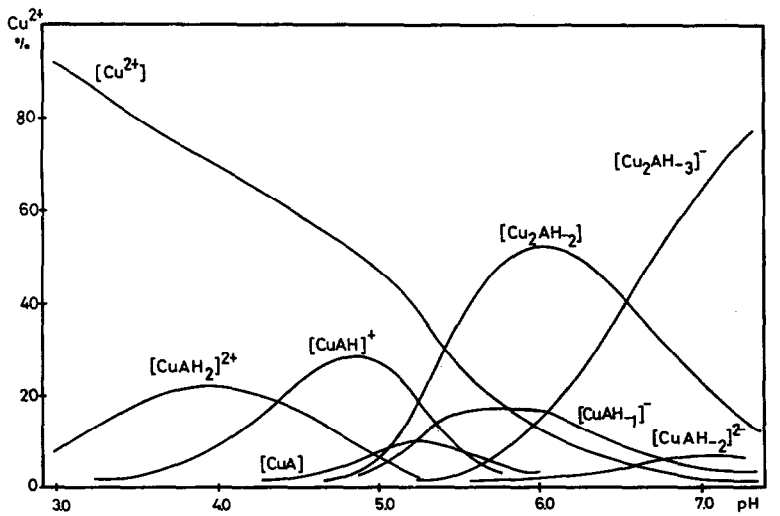

Fig. 3. Concentration distribution of the complexes formed in the copper(II)–ETP3 system; $C_{Cu^{2+}} = 2.45 \times 10^{-3}$, $C_{ETP3} = 1.34 \times 10^{-3}$ mol dm^{-3}.

which is characteristic of glycineamide coordination. Precipitation occurs above pH 7.5 because the bound lysyl peptide is not able to compete with the hydrolysis of excess metal ions. To summarize the results obtained for the complexes of copper(II)–ETP3, it can be stated that the tripeptide-like coordination is the governing factor during complex formation, while the peptide linkage at the ε-amino group represents a weak binding site for metal ions.

Derivatives of TP3 containing one amino acid in the D-configuration (DLL, LDL, LLD) represent the second type of ligands studied in this work. A literature survey shows that pK values of diastereomeric dipeptides differ from each other.[8] Namely, the terminal ammonium is less acidic and the carboxylic group is more acidic in the (LD)-dipeptides than in the pure (LL)-form. In the copper(II) complexes it results in the enhanced stability of [$CuAH_{-1}$] formed with (LL)-dipeptides. Data show that the stability increase is related to intramolecular interaction of the hydrophobic side chains of the dipeptides.[9-10]

Stability constants of the proton and copper(II) complexes of four different diastereomers of TP3 are summarized in Table 4. The data in Table 4 reveal that significant differences can not be observed in the pK values of various diastereomers of TP3. It is probably due to the long distance between the terminal groups in the tri-

pK^{Lys}	9.88	9.79	9.92	10.16

Standard deviations are the same as for TP3(LLL) in Tables 1 and 2.

peptide and the lack of hydrophobic side chains in the molecules. A decrease in the pK value of TP3 (DLL) exceeds the error limit, which probably can be explained by the modification of hydrogen bonds in the (DLL)-form. The pK values of β-carboxylate of aspartic acid show two sets of pK_3. p$K_3 \sim 4.20$ is characteristic for LLL- and DLL-forms, and p$K_3 \sim$ 4.10 for LDL- and LLD-tripeptides. These results correspond well with data obtained for diastereomeric dipeptides, but the extent of the differences is much smaller in this case.

Concerning the complex formation with the copper(II) ion, the existence of the same species can be detected for all diastereomers and the equilibrium data show the same trend as was observed with the pK values. (There is a small difference in the concentration of protonated complexes in the copper(II)–TP3(DLL) system, but they are minor species, and the equilibrium constant can not be easily calculated because of the acetate content of the ligands; pK for acetate is 4.55.) Absorption spectra of various copper(II) complexes exclude the structural differences between the various $[CuAH_{-1}]^{-}$ complexes of TP3 derivatives. Namely, $\lambda_{max} = 542, 540, 542, 540$ nm, and $\varepsilon = 159, 150, 152, 158$ dm^3 mol^{-1} cm^{-1} were obtained for the LLL-, DLL-, LDL- and LLD-forms of TP3, respectively. The lack of stereoselectivity can probably be explained by the presence of hydrophilic side chains and by the existence of a stable tripeptide-like coordination mode. As was mentioned above, deprotonation of two amide groups takes place simultaneously, resulting in the formation of three fused chelate rings. The existence of this fused chelate structure is the governing factor during complex formation with tripeptides, and non-coordinated side chains have only minor effects on the thermodynamic stability. Of course, this conclusion can not be generalized for all metal ions and for other diastereomeric tripeptides, and further investigations are necessary to elucidate the role of side chains during complex formation with various tripeptides.

Abstract—Cadmium complexes of 15 ligands containing sulphur donors in various environments were studied by potentiometric and polarographic methods. Thiol donors were the most effective in cadmium binding in the order of (S,N,O) > (S,N) > (S,O,O) > (S,O) donor sets. Thioamide groups also enhance the stability of the complexes formed, while the disulphide group is ineffective in the presence of amino acid or peptide binding sites.

Thioneins, which are thought to detoxify heavy metals incorporated in biological systems,[1–4] are low molecular weight proteins rich in cysteine residues (one third of the amino acid content). Cysteine residues are very effective ligands for many heavy metal ions, especially the very toxic cadmium ion. Recently two cadmium binding oligopeptides were found in the fission yeast.[5–9] These peptides (cadystins) are also rich in cysteine residues and they can be induced in the fission yeast by several heavy metals, such as copper(II), zinc(II), lead(II), cobalt(II) and mercury(II).[10] The greatest yield from the synthesis of cadystins is, however, induced by cadmium ions. It was intriguing to find that plants are also able to synthesize peptides called phytochelatins, which have the same sequence as cadystins.[11–13] The general structure of this set of peptides is (γ-Glu–Cys)$_n$–Gly (n = 2–8, for cadystins n = 2 and 3).[14,15] It seems likely that all these peptides are synthesized from glutathione or its precursor, γ-Glu–Cys, in a sequential manner.[12,16] Thus, the oligopeptide chelating agents differ in origin from thioneins (primary gene products), though both products may be important in detoxification and homeostasis of heavy metal ions. The

* Author to whom correspondence should be addressed.

molecular biology of metal tolerances of plants in which phytochelatins are involved was discussed recently by Tomsett and Thurman.[17]

The presence of thiol groups significantly changes the binding ability of a peptide molecule as compared to non-cysteine peptides. The available data do not allow us to conclude about the general features of the thiol moiety in peptide ligands, but it is already accepted that its powerful coordination ability is critical for the ligands protecting living organisms against heavy metal ions. Cadmium complexes of simple thiol-containing ligands have already been extensively studied and the data obtained reveal that this metal ion can form very stable chelates with the (S,O) or (S,N) donor sets involved. The formation of the oligonuclear species involving sulphur bridges seems to be a characteristic feature for the thiol-containing systems.[18–20] Not much data on the cadmium interaction with the cysteine-containing peptides including glutathione is available.[21,22] Hence, to be able to conclude more precisely about the stability and structure of the systems containing metal ion–sulphur bonds we have performed potentiometric and polarographic studies on the cadmium complexes with 15 ligands containing different sulphur donors, including thiol, disulphide and thioamide moieties.

EXPERIMENTAL

Polarographic meausurements (d.c.) were performed on a Radelkis OH-105 polarograph using a dropping mercury electrode with a capillary output of 2.61 mg s^{-1} and a drop time of 3.4 s. The saturated calomel electrode was used as a reference electrode. The cadmium ion concentration was equal to 5×10^{-5} or 1×10^{-4} mol dm^{-3}. The ligand concentrations varied from 2×10^{-5} to 5×10^{-4} mol dm^{-3} for L-cysteine (Cys) and from 5×10^{-4} to 2×10^{-2} mol dm^{-3} for D-penicillamine (D-Pen). A constant ionic strength of 0.15 or 3.0 mol dm^{-3} was maintained by means of sodium perchlorate. The measurements were performed at pH 5.5 for Cys and pH 6.5 and 10.5 for D-Pen. The different conditions used for the solutions containing Cys and Pen derived from the fact that cadmium complexes with Cys precipitated very easily. Differential pulse polarographic (DPP) measurements on a hanging mercury drop electrode (HMDE) were carried out on a PA-4 polarographic analyser (Prague). The three electrode system comprised an HMDE, a platinum counter electrode and a saturated calomel electrode. A scan rate of 20 mV s^{-1}, pulse amplitude of 50 mV and potential range from 0 to −1.2 V were applied. Deoxygenated solutions with ionic strength 0.2 M (KNO_3) were measured at 25°C. The stability constants from the polarographic data were estimated from the Ilkovic equation or by the Lingane method.[23] Potentiometric measurements were performed on a Radiometer pHM84 pH-meter with a GK2421C combined electrode and an ABU 80 automatic burette. In the pH-metric studies the ligand concentration varied between 0.001 and 0.01 mol dm^{-3} while the metal ion-to-ligand ratios ranged from 1:1 to 1:5. Nitrogen was bubbled through the samples (10 cm^3) to ensure the absence of oxygen and carbon dioxide and to mix the solutions during titrations with carbonate-free KOH. All titrations were carried out at 25°C and at constant ionic strength (0.2 mol dm^{-3} of KNO_3). The proton concentration calculations from the measured pH and other details of the pH-metric procedure have been described previously.[24] Stability constants, defined by the following equations:

$$pM + qA + rH \rightleftarrows M_pA_qH_r$$

$$\beta_{pqr} = \frac{[M_pA_qH_r]}{[M]^p[A]^q[H]^r}$$

were calculated with PSEQUAD, a general computational program.[25]

RESULTS AND DISCUSSION

The protonation constants of the studied ligands are collected in Table 1. Deprotonation of the carboxylic group ($pK \sim 2$–3.5) is well separated from the other proton dissociations of thiol and/or ammonium groups. The deprotonation of both the latter groups takes place simultaneously and the real acidity of these functions can be characterized by the microconstants, as was shown earlier.[22] The ligands containing disulphide bridges or a thioamide group, which are presented in the lower part of Table 1, may only dissociate protons from the carboxylate and ammonium groups as indicated.

The calculated stability constants of cadmium complexes are given in Table 2. For the cadmium–cysteine system only one species could be detected (by d.c. polarography) because of precipitation. The ligands containing the thiol group, i.e. L-cysteine (Cys), L-cysteine-methylester (CysOMe), N-acetyl-L-cysteine (N-Ac-Cys), D-penicillamine (D-Pen), N-acetyl-D-penicillamine (N-Ac-D-Pen), mercaptopropionylglycine (MPGly), mercapto-succinic acid (MSA), dipeptides Cys–Gly, Ala–Cys and tripeptide Ala–Ala–Cys, form considerably stronger complexes with cadmium ions than the other ligands presented in Table 2. The first four ligands collected in this table form three monomeric species MA, MA_2 and MA_3. Among them, CysOMe is most effectively bound to the metal ion. All these ligands

have only two potential binding sites for cadmium ions, i.e. (S,N) in CysOMe and (S,O) in the other three molecules. The stability constants of these complexes suggest that the (S,N) donor set is distinctly more effective in the binding of cadmium ions than the (S,O) set. This conclusion is also supported by the data obtained for the di- and tripeptide ligands. Since the cadmium ion is not able to deprotonate and bind an amide nitrogen,[22] all three peptides, Cys–Gly, Ala–Cys and Ala–Ala–Cys, also act as the bidentate ligands. Due to the steric effects only one or two species (and their protonated forms) can be detected for these ligands using potentiometric titrations. Again the Cys–Gly ligand which can bind the metal ion using the (S,N) donor set forms more stable complexes than those bound via (S,O) donors (Table 2). Three of the other thiol ligands, D-Pen, Cys and MSA, form the MA species which are even more stable than those just discussed. All these ligands are potentially tridentate and the involvement of three donors makes the equimolar species very stable. The (S,N,O) binding mode which is possible for Cys and D-Pen ligands is more effective than the (S,O,O) coordination which occurs for the MSA ligand (Table 2). The distinct difference in the stability of the MA_2 complexes of the D-Pen and MSA ligands indicates the considerable intermolecular interactions between ligand molecules. The high values of $\log(K_1/K_2)$ clearly support this conclusion (Table 2). The precipitation of the Cd–Cys complexes does not allow evaluation of the stability of the MA_2 species for cysteine. Another characteristic feature of the studied thiol ligands excluding peptides is formation of the oligomeric species which dominate in solution at lower pH (Fig. 1, Table 2). Only in the case of CysOMe is the dimeric species formed, while for the other ligands the trimeric complex gives the best fit in the calculations performed.

In order to obtain more firm evidence that the models assumed for the potentiometric data calculations are realistic, the polarographic techniques were also applied. The stability constants of the respective species which were evaluated from the polarographic data are presented in Table 2 and are in very good agreement with those obtained from the potentiometric titrations. More important evidence was needed to support oligomer formation in the system studied. The DPP reduction peaks of the metal ion in the Cd–CysOMe system are shown in Fig. 2. A similar reduction pattern of the cadmium complexes was obtained for all other systems. Figure 2 indicates that at around pH 5–6 there are two distinct peaks for cadmium reduction simultaneously present. They appear at considerably different potentials than the free metal ion reduction

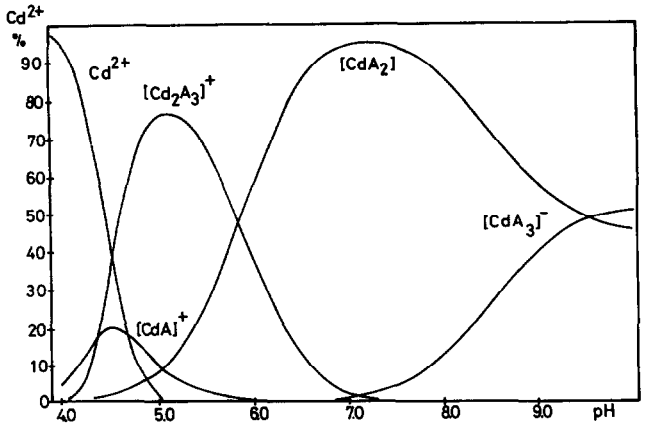

Fig. 1. Concentration distribution of the complexes formed in the Cd–CysOMe system as a function of pH; $c_{Cd} = 1 \times 10^{-3}$ mol dm^{-3}, $c_A = 5 \times 10^{-3}$ mol dm^{-3}.

peak and their relative heights depend on the pH and ligand-to-metal ratios. The interesting variation of these two peaks was observed when the solution studied was diluted with 0.2 M KNO_3 and the pH was kept constant. These changes are presented for the Cd–MSA system in Fig. 3. The 20-fold dilution of the solution leads to the almost complete disappearance of the major peak. The remaining peak indicates that all cadmium ions transfer into one species in diluted solution, which corresponds well with an equimolar complex. The stability constant calculated for this species is in

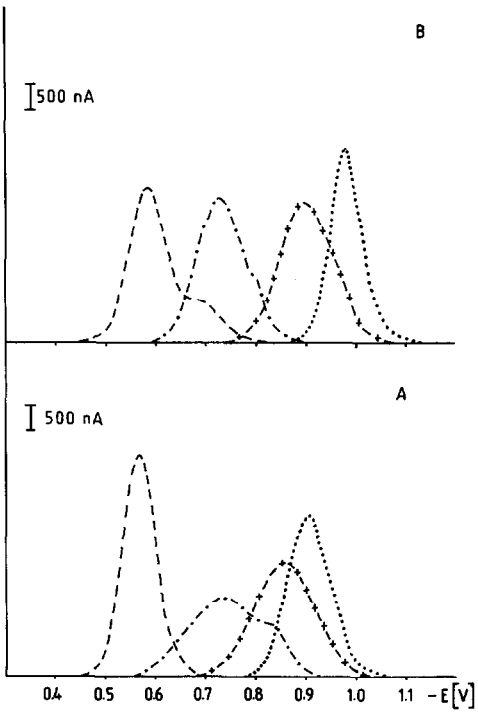

Fig. 2. pH dependence of DPP reduction peak of the cadmium ion for the Cd–CysOMe system, for 1:5 (A) and 1:25 (B) metal-to-ligand ratios; $c_{Cd} = 8 \times 10^{-4}$ M; pH = 3.3 (———); pH = 5.4 (— · — · —); pH = 7.4 (—+—); pH = 12.1 (· · · ·).

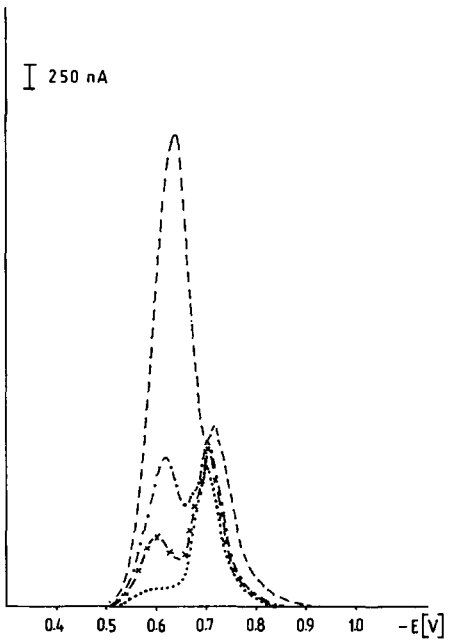

Fig. 3. Dependence of the DPP reduction peak of the cadmium ion of two complexes (M_3A_4, MA) for the Cd–MSA system on dilution with 0.2 M KNO_3. To 10 cm^3 of solution [Cd] = 8×10^{-4} M, [A] = 4×10^{-3} M in 0.2 M KNO_3 (pH = 5.3). 0.2 M KNO_3 was added as follows: 0 cm^3 (———); 35 cm^3 (— · — · —); 70 cm^3 (—+—); 160 cm^3 (· · · ·).

good agreement with the value obtained from potentiometric data (Table 2). According to the potentiometric data calculations the two peaks discussed above could correspond to the MA and oligomeric species. Thus, the dilution presented in Fig. 3 destabilizes the oligomeric complex, as was also found for the strong complexes of silver(I) with thioether amino acids.[26]

The stability of the cadmium complexes with ligands containing a sulphur donor involved in disulphide bridges are much lower than those obtained for the thiol ligands. Comparison of the stability of MA species of Cys–Gly (S,N) coordination and Cys–Gly–disulphide indicates that involvement of the (S,N) donor set in the cadmium ion binding is unlikely in the latter ligand. The (S,N) coordination mode leads to formation of species which are more than six orders more stable than that created by chelation via the (N,O) donor set available in Cys–Gly–disulphide[27] (Table 2).

The thioamide sulphur was shown to be very effective in the binding of copper(II) and nickel(II) ions by several amino acid or peptide derivatives.[28,29] The (NH_2,CS) coordination leads to formation of species which are two or even four orders more stable than the corresponding species with (NH_2,CO) chelation. A comparison of the stability of the MA complexes of, for example, methionine-N-methylamide (Met–NHMe) and of its thioamide analogue clearly indicates that also in the case of cadmium ions, binding of thioamide sulphur stabilizes the complex formed (1.7 log units, Table 2). The distinct stabilization is also observed for complexes of Alat–AlaOMe, containing thioamide as a peptide bond, when compared, for example, with the glycineamide or MetNHMe.

CONCLUSIONS

The sulphur donor is a basic binding site for cadmium ions even in simple ligands containing the thiol group. The presence of such a group leads to formation of very stable complexes, having stability constants several orders higher than respective complexes without a sulphur donor. The thiol donors of the cysteine (or D-Pen) residue are the most effective, although the thioamide sulphur may also stabilize the complexes formed. The (S,N) donor set is a more effective donor set than the (S,O) chelation. The disulphide group seems to be quite ineffective as a potential binding site for cadmium ions, at least in the presence of amino acid moieties. The other characteristic feature of sulphur donation in cadmium complexes is the formation of oligomeric structures as was already found in the case of, for example, nickel(II) complexes.[18–20,22]

(*Received* 7 *September* 1989; *accepted* 20 *October* 1989)

Abstract—Reaction of all asymmetric phenols 2-methyl,6-tert-butylphenol (HOAr-2Me,6Bu^t) and 2,4-dimethyl,6-(α-methylcyclohexyl)phenol (HOAr-2,4Me$_2$,6cyMe) with $Cp_2Zr(CH_2Ph)_2$ at 120°C in toluene leads to the slow formation of the mono-substituted derivatives $Cp_2Zr(OAr\text{-}2Me,6Bu^t)(CH_2Ph)$ (**1**) and $Cp_2Zr(OAr\text{-}2,4Me_2,6cyMe)(CH_2Ph)$ (**2**) along with one equivalent of toluene. A single crystal X-ray diffraction analysis of **2** confirmed the stoichiometry and shows the carbon and oxygen atoms of the benzyl and aryloxide ligands occupying positions about the zirconium atom typical of $Cp_2Zr(X)(Y)$ type compounds. The large Zr—O—Ar angle of 165.3(5)° results in the aryloxide occupying a "wedge-like" space within the coordination sphere. This wedge is oriented within the plane which bisects the metallocene unit, i.e. almost coplanar with the ZrCO plane, and is oriented so that the bulky α-methylcyclohexyl group lies next to the benzyl ligand. The reaction of **1** with Bu^{t}NC also takes place very slowly leading to the η^2-iminoacyl compound $Cp_2Zr(OAr\text{-}2Me,6Bu^t)(\eta^2\text{-}Bu^tNCCH_2Ph)$ (**3**). Despite the steric demands of the bulky aryloxide ligand, the spectroscopic and structural data on **3** show the iminoacyl to be η^2-bonded to zirconium, Zr—N = 2.244(4) Å, Zr—C = 2.208(5) Å. In the solid state the 18-electron compound **3** has the η^2-iminoacyl group lying along the plane bisecting the metallocene unit. Crystal data at 20°C for $ZrOC_{34}H_{42}$ (**2**): $a = 10.201(1)$, $b = 14.372(3)$, $c = 20.365(3)$ Å, $\beta = 95.210(9)°$, $Z = 4$, $d_{calc} = 1.287$ g cm^{-3} in space group $P2_1/n$; for $ZrONC_{33}H_{41}$ (**3**): $a = 9.708(1)$, $b = 10.698(1)$, $c = 27.829(3)$ Å, $Z = 4$, $d_{calc} = 1.284$ g cm^{-3} in space group $P2_12_12_1$.

The demonstrated ability of high valent early *d*-block, lanthanide and actinide metal compounds to inter- and intramolecularly activate carbon–hydrogen bonds has led to numerous synthetic, mechanistic and theoretical studies.[1–6] During our studies of early transition metal aryloxide chemistry we have demonstrated the sometimes facile cyclometallation of 2,6-di-tert-butylphenoxide (OAr-2,6Bu$^t_2$) and 2,6-diphenylphenoxide (OAr-2,6Ph$_2$) ligands at d^0-metal centres, especially in the presence of alkyl leaving groups.[7] Due to the thermal robustness and excellent NMR characteristics of the metallocene unit, Cp_2M, we have argued that cyclometallation of aryloxide ligands in a system such as $Cp_2M(OAr)(R)$ (M = Ti, Zr, Hf) would allow valuable mechanistic studies to be obtained. The cyclometallation of bis(trimethylsilyl)amido ligands in related metallocene systems has been reported by Bradley and Andersen and co-workers.[8,9] In this paper we wish to report on the synthesis and remarkable thermal stability of just such a series of alkyl, aryloxide compounds of zirconium. As aryloxide ligands we have chosen 2-methyl,6-tert-butylphenoxide (OAr-2Me,6Bu^t) and 2,4-dimethyl,6-(α-methylcyclohexyl)phenoxide

(OAr-2,4Me_2,6cyMe) for study. While both of these ligands offer the potential for formation of either five- or six-membered metallacycle rings, the α-methylcyclohexyl substituent of OAr-2,4Me_2,6cy Me also offers both primary and secondary sp^3-CH bonds for activation.

RESULTS AND DISCUSSION

The bis(benzyl) compound $Cp_2Zr(CH_2Ph)_2$[10] fails to react with HOAr-2Me,6Bu^t or HOAr-2,4Me_2,6cyMe in hydrocarbon solvents at ambient temperatures. However, at 120°C in toluene solution, substitution occurs via a protonolysis reaction to yield the mono-alkyl compounds **1** and **2** in excellent yields (Scheme 1). The NMR spectroscopic properties of orange **1** and **2** are very similar, the most striking feature besides the Cp and aryloxide resonances being the characteristic chemical shift of the carbon atom of the remaining Zr—CH_2Ph bond in the ^{13}C NMR spectrum at δ 53.1 and 51.0 ppm, respectively.

A single crystal X-ray diffraction analysis of **2** was undertaken not only to characterize the coordination environment but also to determine the conformation adopted by the aryloxide ligand and in particular the α-methylcyclohexyl substituent. It can be seen (Fig. 1) that the central $Cp_2Zr(O)(C)$ coordination environment appears unexceptional. The Zr—O distance of 1.981(6) Å (Table 1) is comparable to that reported by Lappert and coworkers[11] for $Cp_2Zr(OAr\text{-}2,6Bu^t_2)Cl$, 1.98(2) Å, but is slightly longer than the values of 1.903(4) and 1.936(4) Å reported for the aryloxide ligands in Zr $(OAr\text{-}2,6Bu^t_2)(OAr\text{-}2,6Bu^t_2\text{-}4OMe)(CH_2Ph)_2$.[12] The Zr—C(benzyl) distance of 2.321(9) Å also ap-

pears typical for $Cp_2M(R)(X)$ compounds and can be compared with a value of 2.330(5) Å in $Cp'_2Zr(CH_2C_6Me_5)(Cl)$ ($Cp' = C_5H_4SiMe_3$).[11] However, these distances are slightly shorter than those in $Zr(OAr\text{-}2,6Bu^t_2)(CH_2Ph)_3$, 2.26–2.29(1) Å, and $Zr(OAr\text{-}2,6Bu^t_2)(OAr\text{-}2,6Bu^t\text{-}4OMe)(CH_2Ph)_2$, 2.243(9) and 2.272(8) Å. The large Zr—O—Ar angle of 165.3(5)° is typical of high-valent early *d*-block metal derivatives of these ligands and results in the aryloxide group occupying what can be thought of as a wedge within the coordination sphere.[13] It can be seen (Fig. 1) that this wedge, defined essentially by the plane of the central phenoxy ring, is lying so as to bisect the metallocene unit, i.e. approximately coplanar with the ZrOC plane. A very similar arrangement of the aryloxide ligands in $Cp_2Zr(OAr\text{-}2,6Bu^t_2)Cl$ and $Cp_2Zr(OAr\text{-}2,6Bu^t_2)(NMe_2)$ is observed.[11] However, the asymmetric *ortho*-substitution within the OAr-2Me,6cy Me ligand means that two different conformers can be imagined, either with the smaller methyl or the bulky α-methylcyclohexyl group adjacent to the Zr—CH_2Ph bond. From Figs 1 and 2 it can be seen that compound **2** prefers to orientate itself with the α-methylcyclohexyl group next to the benzyl ligand. Presumably this conformation is sterically favoured over a situation where the bulky group is pushed between the cyclopentadienyl ligands.

The alkyl compound **1** will react with Bu^tNC to produce an η^2-iminoacyl derivative (**3**), although the reaction is very slow, requiring heating in toluene for several hours (Scheme 1). In the ^{13}C NMR spectrum of **3** the η^2-binding of the iminoacyl group is strongly implicated by the chemical shift of the $Zr(Bu^tNCCH_2Ph)$ carbon atom at δ 236.4 ppm, which lies very close to the region reported for other zirconocene η^2-iminoacyl compounds.[14] A single crystal X-ray diffraction analysis of **3** confirmed the η^2-binding of the iminoacyl group (Fig. 3; Table 2) despite the presence of the sterically demanding aryloxide ancillary ligand. As for other structurally characterized η^2-acyl and η^2-iminoacyl compounds of stoichiometry $Cp_2M(\eta^2\text{-}RCX)(Y)$ (M = Ti, Zr, Hf; X = O, NR')[14] the iminoacyl unit in **3** lies along the equatorial girdle of the metallocene unit. In this case the nitrogen atom lies proximal to the aryloxide oxygen atom. An identical conform-

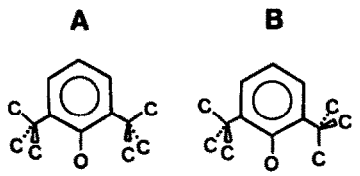
ation is found in the compounds $Cp_2Zr(\eta^2\text{-}MeNCCHPh_2)(Me)$[11] and $Cp_2Hf[\eta^2\text{-}xyNCCH(Ph)(py)](Cl)$ (xy = 2,6-dimethylphenyl).[15] However, the sterically demanding aryloxide ligand does appear to have an impact on the bonding of the iminoacyl group to the metal centre. One measure of the degree of η^2-binding of iminoacyl groups is to consider a parameter Δ, defined as d(M—N)−d(M—C).[14] In compound **3** the Zr—N distance of 2.244(4) Å is longer than the Zr—C distance of 2.208(5) Å yielding a value for Δ of +0.036 Å. In contrast, a value of −0.037 Å is found for $Cp_2Zr(\eta^2\text{-}MeNCCHPh_2)(Me)$, i.e. where the Zr—N distance of 2.210(4) Å is *shorter* than the Zr—C distance of 2.247(5) Å.[11] Similarly, in the compound $Cp_2Hf[\eta^2\text{-}xyNCCH(Ph)(py)](Cl)$ the Hf—N distance is shorter than the Hf—C distance to yield a Δ value of −0.016 Å.[15] A survey of other zirconium and hafnium η^2-iminoacyl compounds, including those containing aryloxide ancillary ligands show that in all cases the M—N distance is shorter than the M—C distance to yield negative values of Δ.[14] We ascribe the elongation of the Zr—N bond in **3** to the extremely crowded coordination sphere. However, it is also possible that a weakening of the Zr—N bond is a consequence of the π-donor properties of the aryloxide ligand in this formally 18-electron compound. The steric congestion in this compound is also indicated by the twisting of the plane of the aryloxide ligand out of the equatorial girdle of the metallocene unit (Fig. 3).

A final point of interest concerning these compounds arises from the conformation adopted by the α-methylcyclohexyl group in **2** (Figs 1 and 2). In the majority of compounds containing 2,6-di-

tert-butylphenoxide ligation the CMe_3 groups are oriented so as to maximize the distance between the metal and the methyl groups. Hence conformation **A** shown in the diagram is typically adopted. However, in a few cases one of the tert-butyl groups is found to be oriented so that a unique methyl group points directly towards the metal centre (conformation **B**).[16] It can be seen that for compound **2** a conformation similar to **A** is adopted so that ZrHC



contacts are minimized. The cyclohexyl group does not have the effect of forcing the methyl group towards the metal. However, due to the presence of the cyclohexyl group it can be seen that a static solution structure identical to that found in the solid state would result in non-equivalent Cp ligands and a diastereotopic Zr—CH_2Ph group. The ^{1}H NMR spectrum of **2** at ambient temperatures shows sharp singlets for both the C_5H_5 and CH_2Ph protons. On cooling toluene-d_8 solutions of **2** to −65°C only negligible broadening of these signals is observed in the ^{1}H NMR spectrum. Hence it appears that there must exist a very low barrier to rotation of the α-methylcyclohexyl group in **2** such that an effective plane of symmetry is generated through the molecule in solution.

EXPERIMENTAL

The HOAr-2,4Me_2,6cyMe ligand was prepared by treating 2,4-dimethylphenol with an excess of 1-methylcyclohexene in the presence of a catalytic amount of H_2SO_4.[17] Purification was achieved after work-up by fractional distillation. The compound $Cp_2Zr(CH_2Ph)_2$ was prepared by published procedures,[10] while 2-methyl,6-tert-butylphenol and Bu^{t}NC were obtained commercially. The methods employed for the manipulation of the air- and moisture-sensitive products have been described previously.[12,13]

Cp_2Zr(OAr-2Me,6Bu^t)(CH_2Ph) (**1**)

To a solution of $Cp_2Zr(CH_2Ph)_2$ (0.68 g, 1.7 mmol) in toluene (25 cm^3) was added HOAr-2Me,6Bu^t (0.33 g, 2.0 mmol). The mixture was heated at 100°C in a sealed flask for 4 h. Removal of the solvent under vacuum yielded a sticky solid which was taken up in a minimum amount of hot toluene. Slow cooling of the solution yielded the product as yellow crystals in 55% yield. Found: C, 70.1; H, 7.1. Calc. for $ZrC_{28}H_{32}O$: C, 70.7; H, 6.8%. ^{1}H NMR (C_6D_6, 30°C): δ 2.58 (s, Zr—CH_2); 1.28 (s, *Bu^t*); 1.99 (s, CH_3); 5.77 (s, C_5H_5); 6.8–7.8 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 53.0 (Zr—CH_2); 112.5 (C_5H_5); 29.9 (2-CH_3); 34.1 (CMe_3); 18.9 (CMe_3).

Cp_2Zr(OAr-2,4Me_2,6cyMe)(CH_2Ph) (**2**)

A mixture of $Cp_2Zr(CH_2Ph)_2$ (1.9 g, mmol) and HOAr-2,4Me_2,6cyMe (1.0 g, mmol) in toluene (15 cm^3) was heated at 120°C in a sealed flask for 4 h. The resulting clear solution was cooled, diluted with hexane (15 cm^3) and placed in a freezer at −15°C, whereupon large yellow crystals of product were obtained. Found: C, 73.8; H, 7.4. Calc. for $ZrC_{35.5}H_{42}O$: C, 74.0; H, 7.3%. The compound crystallizes with 1/2 toluene per zirconium. ^{1}H NMR (C_6D_6, 30°C): δ 2.58 (s, Zr—CH_2); 5.69 (s, C_5H_5); 1.32 (s, α-CH_3); 1.98 (s), 2.24 (s, 2,4Me_2); 1.3–2.0 (series of multiplets, cyclohexyl protons). ^{13}C NMR (C_6D_6, 30°C): δ 50.9 (Zr—CH_2); 110.9 (C_5H_5); 17.5, 19.0, 21.2, 25.0, 35.8, 36.0 (2,4Me_2 and α-methylcyclohexyl).

Cp_2Zr(OAr-2Me,6Bu^t)(η^2-Bu^{t}NCCH_2Ph) (**3**)

To a solution of **1** (0.81 g, 1.7 mmol) in toluene (25 cm^3) was added Bu^{t}NC (1 g, excess). The mixture was heated at 100°C in a sealed flask for 6 h. Removal of solvent and excess Bu^{t}NC *in vacuo* yielded **3** as a crude solid. Crystals suitable for X-ray diffraction studies were obtained by slow cooling of a saturated, hot (100°C) toluene solution. Found: C, 71.4; H, 7.5; N, 2.4. Calc. for $ZrC_{33}H_{41}NO$: C, 70.9; H, 7.4; N, 2.5%. ^{1}H NMR (C_6D_6, 30°C): δ 3.63 (s, CH_2Ph); 1.09 (s, CN*Bu^t*); 2.03 (s, 2*Me*); 1.62 (s, 6*Bu^t*). ^{13}C NMR (C_6D_6, 30°C): δ 236.4 (Bu^{t}N*C*CH_2Ph).

X-ray crystallography

Crystal data and data collection parameters are collected in Table 3. A suitable crystal of each of the two compounds was mounted in a glass capillary in a random orientation. Cell constants were obtained from least-squares refinement using the scattering angles of 25 reflections as measured by the computer-controlled diagonal slit method of centring. Systematic absences and subsequent least-squares refinement indicated the space group $P2_1/n$ for **2** and $P2_12_12_1$ for **3**. The data were collected to a maximum 2θ of 45° in both cases using the ω–2θ

scan technique. Moving crystal, moving counter background counts were made by scanning an additional 25% above and below the scan width. The counter aperture was adjusted as a function of θ. For intense reflections an attenuator (factor 12.9) was automatically inserted in front of the detector. As a check on crystal and electronic stability three standard reflections were measured every 2000 s of beam time. In the case of **2** some decay was observed and an empirical correction was applied. No decay was observed for **3**.

The structures were solved by using the Patterson heavy-atom method to reveal the position of the zirconium atoms. The remaining heavy atoms were then located in succeeding Fourier syntheses. Hydrogen atoms were located and added to the structures but were not refined. In the case of **3** choice of the alternate enantiomorph yielded $R = 0.03097$, $R_w = 0.04116$ and goodness of fit = 1.460.*

CHARGE-TRANSFER COMPLEXES OF 5,6-DIMETHYL-1,3-DIHYDRO-2-TELLURAINDENE WITH QUINONES

ALI Z. AL-RUBAIE* and EMAN A. AL-MASOUDI

Department of Chemistry, College of Science, University of Basrah, Basrah, Iraq

(*Received* 26 *April* 1989; *accepted* 20 *October* 1989)

Abstract—The new 5,6-dimethyl-1,3-dihydro-2-telluraindene was used as a donor to form 1:1 donor–acceptor complexes with *p*-benzoquinone, 1,4-naphthaquinone and 2,3-dimethylanthraquinone, respectively. Solid conductivity, UV–vis, IR, ^{1}H NMR, ESR and mass spectral data are discussed, and it is concluded that the degree of charge-transfer is small. The $[C_{10}H_{12}Te]^+[C_{10}H_6O_2]^-$ complex shows evidence of semiconducting properties.

Recently there has been considerable interest in the studies on the charge-transfer complexes of organotellurium compounds with 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ)[1–4] and chloranil.[3,5]

However, there is no reference in the literature, as far as we aware, concerning the preparation and characterization of charge-transfer complexes with *p*-benzoquinone, 1,4-naphthaquinone or 2,3-dimethylanthraquinone.

The aim of the present work is to synthesize new charge-transfer complexes with 5,6-dimethyl-1,3-dihydro-2-telluraindene, and to clarify the ability of the new cyclic telluride to act as an electron-donor in the reaction with quinones. Physical studies of the new complexes are reported.

EXPERIMENTAL

(a) *Synthesis*

5,6-Dimethyl-1,3-dihydro-2-telluraindene. Sodium borohydride was added to a boiling ethanolic solution of $C_{10}H_{12}TeI_2$[6] (3.0 g) until the orange colour had disappeared. The solution was filtered, then poured into 500 cm^3 of water and extracted with ether (3 × 100 cm^3). The combined ether extracts were dried over $CaCl_2$ and concentrated to dryness on a rotatory evaporator. The yellow plates of 5,6-dimethyl-1,3-dihydro-2-telluraindene which melted at 90–92°C were recrystallized from petroleum ether (60:80). Found: C, 46.0; H 4.6. Calc. for $C_{10}H_{12}Te$: C, 46.2; H, 4.7%.

Synthesis of charge-transfer complexes. All complexes were prepared by the reaction of $C_{10}H_{12}Te$ with the corresponding quinone. The general preparation route is ilustrated by the following example:

Complex of p-*benzoquinone with* 5,6-*dimethyl*-1,3-*dihydro*-2-*telluraindene.* A mixture of 2.16 g (0.02 mol) of *p*-benzoquinone and 5.19 g (0.02 mol) of 5,6-dimethyl-1,3-dihydro-2-telluraindene in dry dichloromethane (50 cm^3) was heated to reflux for 3 h. A small quantity of black–brown crystals was deposited from this reaction on cooling. The precipitate was washed with a small amount of dichloromethane and recrystallized from ethanol, m.p. 100–102°C.

Table 1 lists the 1:1 charge-transfer complexes synthesized, together with their analytical data.

(b) *Physical measurements*

Analytical measurements for C and H were carried out by the Analytical Service Unit, Fakultät für Chemie, Universität Konstaz, F.R.G.: tellurium was determined volumetrically.[7] IR spectra were recorded with KBr discs in the range 4000–200 cm^{-1} on a Beckman TM spectrophotometer. UV–vis spectra were obtained with Pye–Unicam SP3-300S. ^{1}H NMR spectra were recorded on a Bruker WM-250 at 250 Hz using TMS as internal reference. ESR spectra were obtained at room temperature with a Varian E-109 spectrometer. Mass spectral data were determined at 70 eV with a MAT 1125 Finnigan mass spectrometer instrument.

Conductivity measurements. A sample of the $[C_{10}H_{12}Te]^{+}[C_{10}H_6O_2]^{-}$ complex was compressed into a disc of 12 mm diameter and 0.8 mm thickness. Two nickel electrodes were deposited on the disc by evaporation using a special apparatus *in vacuo* (10^{-7} torr). Copper wires were attached by silver paint. The sample was studied over a temperature range of 292–362 K.

RESULTS AND DISCUSSION

The reaction of $C_{10}H_{12}Te$ with quinones (i.e. *p*-benzoquinone, 1,4-naphthaquinone and 2,3-dimethylanthraquinone) in dichloromethane gave complexes of 1 : 1 stoichiometry (Table 1). The changes in their colour from black–brown to yellow, as the number of benzene rings increased, may be attributed to the distribution of the free electron over the benzene rings.

IR spectra of the complexes are compared with the spectra of the components alone; the spectra of the complexes are quite similar to the superposition of the spectra of the components. There are slight shifts in frequency and some alterations in the intensity, which reflect the molecular association. The degree of charge-transfer of the complexes could be monitored by examination of ν(CO) for quinones, similar to ν(CN) in TCNQ complexes.[8] The slight changes in the C=O frequencies may imply a small degree of charge-transfer (Table 2). We particularly

Table 2. Electronic, IR and ESR spectral data for the CT complexes

Compound	λ_{max}[a] (nm)	ν(CO)[b] (cm^{-1})	*g*-Factor (∓0.0009)
$[C_{10}H_{12}Te]^{+}[C_6H_4O_2]^{-}$	242(11,350), 272(7420), 282(5950), 314(2790), 340(1490)	1660	2.0030
$[C_{10}H_{12}Te]^{+}[C_{10}H_6O_2]^{-}$	238(26,900), 244(27,600), 258(20,650), 276(5800), 282(29,500), 336(4400)	1660	2.0029
$[C_{10}H_{12}Te]^{+}[C_{16}H_{12}O_2]^{-}$	242(17,020), 258(17,960), 266(16,960), 282(7730), 328(1580)	1670	2.0029

[a] $CHCl_3$ solution. Molar extinction values (M^{-1} cm^{-1}) are given in parentheses.
[b] $C_{10}H_{12}Te$ gives $\nu(CH_2)$ at 2928 cm^{-1} and ν(Te—C) at 518 cm^{-1}.

noted shifts of $+15\ cm^{-1}$ for $\nu(CH_2)$ which seems reasonable for the more positive tellurium atom.[9]

The electronic spectra of the complexes (I, II and III) show complexity. This is due to the overlapping between charge-transfer, n–π^* and π–π^* transitions. New bands at 314 (I), 276 (II) and 282 (III) nm are also observed (Table 2).

^1H NMR and mass spectra of the complexes are quite similar to the total signals of the components. The ^1H NMR spectra showed downfield signals at 8.64 (I), 10.38 (II) and 9.19 (III) ppm due to the hydroxyl group. This implies that the complexes are dissociated in solution and that hydroquinones were formed due to the presence of H_2O and using DMSO-d_6 as solvent.

Strong, and in general sharp, ESR signals for the solid complexes (I, II and III) were detected. The g-value of the ESR absorption by the unpaired electron for the complexes are close to the free electron value.[10,11] This indicates that each signal arises from unpaired electron density on the quinones (Table 2). It was not possible to observe a resonance from the tellurium cationic radical. This may be a consequence of a large spin–orbital coupling constant leading to increased line width,[12] or it could imply a diamagnetic ground state achieved by dimerization of the radical cations.[3,13]

The powder of complex II was pressed at 11 tons into a disc, and then the conductivity was measured at various temperatures within the range 292–362 K by a direct method. The variation of the resistivity with temperature was found to obey the usual behaviour of an intrinsic semiconductor[14] (see Fig. 1). The activation energy (E_a) was obtained from a plot of $\ln \rho$ against $1/T$ and found to be 0.56 eV.

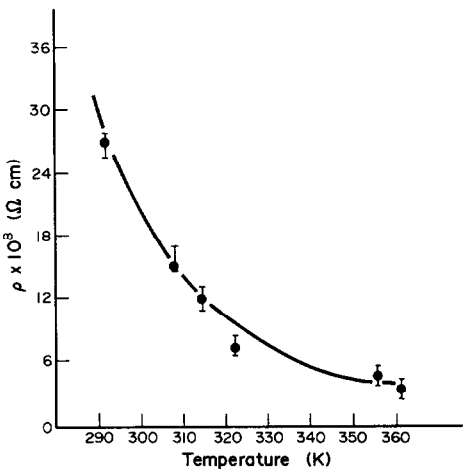

Fig. 1. The relation between specific resistivity (ρ) and temperature.

Acknowledgements—The authors thank Professor Pfleiderer, Professor Brozenjki and Dr N. A. Al-Masoudi, Fakultät für Chemie, Universität Konstanz, F.R.G., for providing C and H analysis, ^1H NMR and mass spectral data. We are grateful to Dr M. T. Mohammod, Department of Physics, for providing the facilities for conductivity measurements, and to Dr A. H. Al-Mawalli for obtaining the ESR spectra.

SYNTHESIS AND LIGAND CHEMISTRY OF BIS[(2-ARYLTELLURO)ETHYL]AMINE AND BIS[(2-ARYLTELLURO)ETHYL]METHYLAMINE—NOVEL (Te, N, Te) DONORS

AJAI K. SINGH,* VINOD SRIVASTAVA and B. L. KHANDELWAL

Department of Chemistry, Indian Institute of Technology, New Delhi—110 016, India

(*Received* 19 *July* 1989; *accepted* 20 *October* 1989)

Abstract—New tridentate ligands, bis[(2-aryltelluro)ethyl]amine (**1** and **2**) and bis[(2-aryltelluro)ethyl]methylamine (**3** and **4**) (aryl = 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$) were synthesized by the reaction of sodium aryltellurolate with bis(2-chloroethyl)amine and bis(2-chloroethyl)methylamine, respectively, and characterized by molecular weight measurements, elemental analyses, IR, ^1H and $^{13}C\{^1H\}$ NMR spectra. Complexes of the type $MCl_2 \cdot L$ (L = **1** or **2**; M = Hg, Pd or Pt) were synthesized by reacting the ligand with $HgCl_2$, $(C_6H_5CN)_2PdCl_2$ and K_2PtCl_4. Mercury complexes were found to be non-ionic and monomeric. ^1H and $^{13}C\{^1H\}$ NMR spectra suggest that the ligands in these complexes coordinate only through two tellurium atoms. Palladium and platinum complexes of **1** and **2** were found to be diamagnetic, monomeric and non-ionic in nitrobenzene. However, they exhibit conductance in acetonitrile and methanol due to solvolysis. ^1H and $^{13}C\{^1H\}$ (recorded for **1** only) NMR spectra suggest that **1** and **2** act as a tridentate ligand in palladium and platinum complexes. On considering their electronic and IR spectral data in conjunction with the various properties, a square pyramidal structure with two chlorine atoms *trans* to each other seems to be most plausible for palladium/platinum complexes.

Bidentate or polydentate hybrid telluride ligands are somewhat rare.[1–3] We have reported recently[4] novel (Te, N) ligands, *viz.* 1-(NMe_2)-2-(TeAr)-4-MeC_6H_3 (Ar = C_6H_5, 4-$MeOC_6H_4$, or 4-$EtOC_6H_4$), and their complexation with palladium(II) and platinum(II). They also behave as unidentate ligands (coordinating through tellurium only) in mercury(II) complexes.[5] In continuation of our studies on the syntheses and ligation of (Te, N) donors we have synthesized bis[(2-aryltelluro)ethyl]amine and bis[(2-aryltelluro)ethyl]methylamine (**1–4**). It was thought worthwhile to explore their complexation with metal ions in detail because their phosphorus analogues have been found to give interesting structures[6] and induce catalytic activities[7] in platinum metal complexes. In the present paper the syntheses of **1–4** and the ligational behaviour of **1** and **2** with mercury(II), palladium(II) and platinum(II) are reported.

EXPERIMENTAL

Published methods were used to synthesize the ditellurides, $(4\text{-}MeOC_6H_4)_2Te_2$ and $(4\text{-}EtOC_6H_4)_2Te_2$,[8] bis(2-chloroethyl)amine and bis(2-chloroethyl)methylamine.[9] Chloride, mercury and tellurium were estimated by standard methods.[10] The C, H and N analyses were carried out with a Perkin–Elmer elemental analyser 240C. ^1H and $^{13}C\{^1H\}$ NMR spectra in $CDCl_3$ were recorded at 25°C on a JEOL FX100 FT-NMR spectrometer at 99.55 and 25 MHz, respectively. IR spectra (Nujol mulls between CsI windows or CsI/KBr discs) in the range 4000–200 cm^{-1} were recorded on a Nicolet 5DX FT-IR spectrometer. Electronic spectra in chloroform were recorded on a Hitachi 300 UV–vis spectrometer. The conductivity measurements were made on *ca* 1 mM solutions in acetonitrile, methanol and nitrobenzene with a Metrohm 660 conductometer. The molecular weights were determined in chloroform solution (~ 10 mmolal) with a Knauer vapour pressure osmometer.

Synthesis of bis[(2-aryltelluro)ethyl]amine and bis[(2-aryltelluro)ethyl]methylamine

Diaryl ditelluride (2.5 mmol) was refluxed in ethanol (30 cm^3) under a nitrogen atmosphere. Sodium borohydride (0.2 g in 2 cm^3 of 1 M NaOH) was added to it dropwise until the refluxing solution became colourless. Bis(2-chloroethyl)amine or bis(2-chloroethyl)methylamine (2.5 mmol) dissolved in ethanol (10 cm^3) was added dropwise to this refluxing solution of sodium aryl tellurolate with vigorous stirring. The resulting pale yellow mixture was further refluxed for 1 h, cooled to room temperature and poured into 200 cm^3 of water. The ligand (**1–4**) was extracted into chloroform (200 cm^3) from this aqueous mixture. The extract was washed with water, dried over anhydrous sodium sulphate and concentrated to ~5 cm^3 under vacuum. The precipitated pale yellow–white crystalline solid was recrystallized from a chloroform–hexane (70 : 30) mixture to give the white crystalline ligand (**1–4**). The yield, melting point, molecular weight, results of elemental analyses, characteristic IR bands, ^1H and $^{13}C\{^1H\}$ NMR data for **1–4** are given below.

Ligand **1**. Yield 75%; m.p. 78°C. Analysis: Found: C, 39.5; H, 4.1; N, 2.5; Te, 46.6. Calc. for $C_{18}H_{23}NO_2Te_2$: C, 40.0; H, 4.3; N, 2.6; Te, 47.2%. Mol. wt: Found: 522.8; Calc.: 540.2. IR (cm^{-1}): 1180m [ν(C—N)]; 3261m [ν(N—H)]; 268mb, 297mb [ν(Te—C(Ar))]. NMR [^1H]: δ, 1.65 (bs, 1H, NH); 2.92 (bs, 8H, NCH_2CH_2Te); 3.78 (s, 6H, OMe); 6.69–6.78 (d, 4H, H^b of phenyl ring *-m* to Te); 7.62–7.71 (d, 4H, H^a of phenyl ring *-o* to Te); [$^{13}C\{^1H\}$]: δ, 10.5 ($TeCH_2$); 49.5 (NCH_2); 55.1 (OMe); 100.4 (C_1); 115.0 (C_3); 140.8 (C_2); 159.6 (C_4).

Ligand **2**. Yield 80%; m.p. 85°C. Analysis: Found: C, 41.7; H, 4.1; N, 2.4; Te, 43.8. Calc. for $C_{20}H_{27}NO_2Te_2$: C, 42.2; H, 4.8; N, 2.5; Te, 44.9%. Mol. wt: Found: 547.0; Calc.: 568.2. IR (cm^{-1}): 1180m [ν(C—N)]; 3261bm [ν(N—H)]; 270mb, 315mb [ν(Te—C(Ar))]. NMR [^1H]: δ, 1.65 (bs, 1H, NH); 2.83 (bs, 8H, NCH_2CH_2Te); 3.80–4.10 (q, 4H, OCH_2); 1.32–1.46 (t, 6H, CH_3); 6.67–6.76 (d, 4H, H^b of phenyl ring); 7.58–7.66 (d, 4H, H^a of phenyl ring); [$^{13}C\{^1H\}$]: δ, 10.4 ($TeCH_2$); 14.7 (CH_3); 49.5 (NCH_2); 63.2 (OCH_2); 100.1 (C_1); 115.5 (C_3); 140.8 (C_2); 158.9 (C_4).

Ligand **3**. Yield 85%; m.p. 58°C. Analysis: Found: C, 40.2; H, 4.2; N, 2.7; Te, 45.7. Calc. for $C_{19}H_{25}NO_2Te_2$: C, 41.1; H, 4.5; N, 2.5; Te, 46.1%. Mol. wt: Found: 530.5; Calc.: 554.2. IR (cm^{-1}): 1180m [ν(C—N)]; 280m, 245m [ν(Te—C(Ar))]. NMR [^1H]: δ, 2.23 (s, 3H, NMe); 3.77 (s, 6H, OMe); 2.78–2.84 (unresolved triplet, 4H, $TeCH_2$); 2.91–2.97 (unresolved triplet, 4H, NCH_2); 6.69–6.78 (d, 4H, H^b of phenyl ring); 7.61–7.69 (d, 4H, H^a of phenyl ring); [$^{13}C\{^1H\}$]: δ, 8.6 ($TeCH_2$); 40.9 (NMe); 55.0 (OMe); 58.0 (NCH_2); 101.3 (C_1); 114.9 (C_3); 140.4 (C_2); 159.3 (C_4).

Ligand **4**. Yield 87%; m.p. 62°C. Analysis: Found: C, 42.5; H, 4.7; N, 2.3; Te, 42.6. Calc. for $C_{21}H_{29}NO_2Te_2$: C, 43.3; H, 5.0; N, 2.4; Te, 43.8%. Mol. wt: Found: 562.4; Calc.: 582.2. IR (cm^{-1}): 1180m [ν(C—N)]; 250w, 280m [ν(Te—C(Ar))]. NMR [^1H]: δ, 2.23 (s, 3H, NMe); 2.78–2.84 (unresolved triplet, 4H, $TeCH_2$); 2.91–2.98 (unresolved triplet, 4H, NCH_2); 1.32–1.46 (t, 6H, CH_3); 3.89–4.10 (q, 4H, OCH_2); 7.60–7.69 (d, 4H, H^a of phenyl ring); 6.81–6.90 (d, 4H, H^b of phenyl ring); [$^{13}C\{^1H\}$]: δ, 8.13 ($TeCH_2$); 14.7 (CH_3); 41.0 (NMe); 58.2 (NCH_2); 63.3 (OCH_2); 101.1 (C_1); 115.6 (C_3); 140.5 (C_2); 158.9 (C_4).

Synthesis of mercury complexes (**5** *and* **6**)

To a solution of $HgCl_2$ (0.3 mmol) in acetone (5 cm^3) was added the solution of the ligand (**1, 2**) (0.3 mmol) in acetone (5 cm^3) with stirring at room temperature. Hexane was added to precipitate the complex (**5** or **6**) as a pale yellow solid which was filtered, washed with acetone (2 cm^3) and dried *in vacuo*. These complexes are soluble in $CHCl_3$, CH_2Cl_2 and CH_3CN. The physical and spectral data are recorded below.

$HgCl_2 \cdot$ **1** (**5**). Yield 67%; m.p. 70°C. Analysis: Found: C, 26.6; H, 2.8; N, 1.7; Cl, 8.7; Te, 31.4; Hg, 24.7. Calc. for $C_{18}H_{23}NO_2Te_2 \cdot HgCl_2$: C, 26.0; H, 2.7; N, 1.7; Cl, 8.1; Te, 30.5; Hg, 24.1%. Mol. wt: Found: 830.8; Calc.: 811.7. IR (cm^{-1}): 1180m [ν(C—N)]; 250m, 290w [ν(Te—C(Ar))]; 3261bw [ν(N—H)]; 325wb (ν(Hg—Cl)]. NMR [^1H]:

δ, 3.76 (s, 6H, OMe); 3.12 (bs, 4H, $TeCH_2$); 3.40 (bs, 4H, NCH_2); 1.67 (bs, 1H, NH); 7.79–7.87 (d, 4H, H^a of phenyl ring); 6.78–6.87 (d, 4H, H^b of phenyl ring); [$^{13}C\{^1H\}$]: δ, 24.8 ($TeCH_2$); 46.1 (NCH_2); 55.2 (OMe); 103.2 (C_1); 115.8 (C_3); 139.6 (C_2); 161.0 (C_4).

$HgCl_2 \cdot$ **2** (**6**). Yield 63%; m.p. 80°C. Analysis: Found: C, 28.5; H, 3.2; N, 1.7; Cl, 8.5; Te, 30.4; Hg, 23.9. Calc. for $C_{20}H_{27}NO_2Te_2 \cdot HgCl_2$: C, 27.7; H, 3.2; N, 1.6; Cl, 7.9; Te, 29.4; Hg, 23.0%. Mol. wt: Found: 855.0; Calc.: 839.7. IR (cm^{-1}): 1180m [ν(C—N)]; 3282bw [ν(N—H)]; 265m, 290w [ν(Te—C(Ar))]; 315m [ν(Hg—Cl)]. NMR [^1H]: δ, 2.00 (bs, 1H, NH); 3.14 (bs, 4H, $TeCH_2$); 3.37 (bs, 4H, NCH_2); 1.30–1.43 (t, 6H, CH_3); 3.84–3.98 (q, 4H, OCH_2); 7.73–7.82 (d, 4H, H^a of phenyl ring); 6.73–6.82 (d, 4H, H^b of phenyl ring); [$^{13}C\{^1H\}$]: δ, 14.6 (CH_3); 24.5 ($TeCH_2$); 46.2 (NCH_2); 63.4 (OCH_2); 103.1 (C_1); 116.3 (C_3); 139.5 (C_2); 160.3 (C_4).

Synthesis of palladium complexes (**7** *and* **8**)

Bis(benzonitrile)palladium dichloride (0.5 mmol) dissolved in chloroform (20 cm^3) was stirred at room temperature with **1** or **2** (0.5 mmol) (added as solid) for 2 h. The resulting orange–yellow solution was mixed with hexane (50 cm^3) with stirring. The orange coloured precipitate of the complex (**7** or **8**) was filtered, washed with hexane, dried *in vacuo* and recrystallized from a chloroform–hexane (75:25) mixture. These complexes are soluble in a wide range of polar organic solvents, *vis.* CH_2Cl_2, $CHCl_3$, CH_3CN, MeOH, EtOH, DMF and DMSO, as well as in H_2O. The physical and spectral data for **7** and **8** are recorded below.

$PdCl_2 \cdot$ **1** (**7**). Yield 75%; m.p. 125°C. Analysis: Found: C, 30.6; H, 3.4; N, 1.8. Calc. for $C_{18}H_{23}NO_2Te_2 \cdot PdCl_2$: C, 30.1; H, 3.2; N, 2.0%. Mol. wt: Found: 698.2; Calc.: 717.6. IR (cm^{-1}): 3028.8 [ν(N—H)]; 1112m [ν(C—N)]; 270w, 240w [ν(Te—C(Ar))]; 320bw [ν(Pd—Cl)]. NMR [^1H]: δ, 3.83 (s, 6H, OMe); 5.39 (bs, 1H, NH); 2.60–3.70 (broad unresolved multiplet, 8H, NCH_2CH_2Te); 6.90–6.98 (d, 4H, H^b of phenyl ring); 7.97–8.06 (unresolved doublet, 4H, H^a of phenyl ring); [$^{13}C\{^1H\}$]: δ, 16.1 ($TeCH_2$); 55.4 (OMe); 59.1 (NCH_2); 105.6 (C_1); 116.2 (C_3); 138.6 (C_2); 161.6 (C_4).

$PdCl_2 \cdot$ **2** (**8**). Yield 80%; m.p. 155°C. Analysis: Found: C, 31.3; H, 4.1; N, 1.7. Calc. for $C_{20}H_{27}NO_2Te_2 \cdot PdCl_2$: C, 32.2; H, 4.2; N, 1.9%. Mol. wt: Found: 730.4; Calc.: 754.6. IR (cm^{-1}): 3071bw [ν(N—H)]; 1112m [ν(C—N)]; 275w, 243w [ν(Te—C(Ar))]; 320bw [ν(Pd—Cl)]. NMR [^1H]: δ, 5.39 (bs, 1H, NH); 3.95–4.15 (q, 4H, OCH_2); 1.36–1.50 (t, 6H, CH_3); 2.67–3.75 (broad unresolved multiplet, 8H, NCH_2CH_2Te); 7.95–8.01 (unresolved doublet, 4H, H^a of phenyl ring); 6.88–6.96 (d, 4H, H^b of phenyl ring).

Synthesis of platinum complexes (**9** *and* **10**)

To a solution of K_2PtCl_4 (0.5 mmol) in water (15 cm^3) was added **1** or **2** (0.5 mmol) in acetone (10 cm^3). The resulting solution was stirred for 3 h at room temperature and poured into water (100 cm^3). From an aqueous mixture the complex (**9** or **10**) was extracted into chloroform (150 cm^3). The chloroform extract was dried over anhydrous sodium sulphate and the solvent was reduced under vacuum to ~ 5 cm^3. The platinum complex **9** or **10** crystallized as pale yellow crystals on keeping the concentrated solution for 4–5 h at room temperature. They were recrystallized from a chloroform–hexane (80:20 mixture). In CH_2Cl_2, $CHCl_3$, CH_3CN, MeOH, EtOH, DMF and DMSO the platinum complexes are fairly soluble and sparingly in H_2O. The analytical and spectral data for these complexes are given below.

$PtCl_2 \cdot$ **1** (**9**). Yield 80%; m.p. 75°C. Analysis: Found: C, 25.8; H, 2.4; N, 1.7. Calc. for $C_{18}H_{23}NO_2Te_2 \cdot PtCl_2$: C, 26.8; H, 2.9; N, 1.8%. Mol. wt: Found: 830.4; Calc.: 806.3. IR (cm^{-1}): 1110w [ν(C—N)]; 270m, 245m [ν(Te—C(Ar))]; 325m [ν(Pt—Cl)]; 2965.5bw [ν(N—H)]. NMR [^1H]: δ, 3.84 (s, 6H, OMe); 4.93 (bs, 1H, NH); 2.34–3.66 (broad unresolved multiplet, 8H, NCH_2CH_2Te); 6.88–9.97 (d, 4H, H^b of phenyl ring); 7.88–7.96 (d, 4H, H^a of phenyl ring).

$PtCl_2 \cdot$ **2** (**10**). Yield 95%; m.p. 105°C. Analysis: Found: C, 27.6; H, 3.0; N, 1.4. Calc. for $C_{20}H_{27}NO_2Te_2 \cdot PtCl_2$: C, 28.7; H, 3.2; N, 1.7%. Mol. wt: Found: 856.4; Calc.: 834.3. IR (cm^{-1}): 1100m [ν(C—N)]; 285w, 250w [ν(Te—C(Ar))]; 330bm [ν(Pt—Cl)]; 2944.4bw [ν(N—H)]. NMR [^1H]: δ, 4.96 (bs, 1H, NH); 2.26–3.61 (broad unresolved multiplet, 8H, NCH_2CH_2Te); 3.95–4.15 (q, 4H, OCH_2); 1.34–1.48 (t, 6H, CH_3); 6.86–6.95 (d, 4H, H^b of phenyl ring); 7.98–8.15 (bd, 4H, H^a of phenyl ring).

The $^{13}C\{^1H\}$ NMR spectra of **8**, **9** and **10** could not be recorded due to an inadequate solubility problem.

RESULTS AND DISCUSSION

The ligands, bis[(2-aryltelluro)ethyl]amine and bis[(2-aryltelluro)ethyl]methylamine were synthesized by the reactions given in eqs (1)–(3):

$$RN(C_2H_4OH)_2 \xrightarrow[CHCl_3/Reflux]{SOCl_2} RN(C_2H_4Cl)_2 \cdot HCl \xrightarrow{10\%\ NaOH} RN(C_2H_4Cl)_2 \quad (1)$$

$$(4\text{-}R'OC_6H_4)_2Te_2 \xrightarrow[NaOH/N_2\,atm.]{NaBH_4/EtOH} 4\text{-}R'OC_6H_4TeNa \quad (2)$$

$$4\text{-}R'OC_6H_4TeNa + RN(C_2H_4Cl)_2 \xrightarrow[N_2\,atm.,\,1\,h]{EtOH/Reflux} RN(C_2H_4TeC_6H_4\text{-}4\text{-}OR')_2 \quad (3)$$

(1–4)

(R = H or Me; R′ = Me or Et).

The ligands, **1–4**, are white crystalline solids with low melting points. They are more soluble in $CHCl_3$, CH_2Cl_2 and Me_2CO than in MeOH and EtOH. Like other tellurides they also behave as non-electrolytes in solution. ^{1}H NMR spectra of **1–4** exhibit some interesting features. In the spectra of **1** and **2** a broad resonance at 1.65 ppm attributable to the NH group appears, whereas ligands **3** and **4** show a sharp singlet at 2.23 ppm due to the NMe group, concurring with earlier reported values.[11] In **1** and **2** the protons of the "NCH_2 CH_2Te" bridge appear as a broad singlet at 2.92 and 2.83 ppm, respectively [Fig. 1(a)], contrary to the expected triplets for the $TeCH_2$ and NCH_2 protons. But in the spectra of **3** and **4** these CH_2 protons give two partly resolved triplets [Fig. 1(b)], centred at 2.94 and 2.81 ppm for the NCH_2 and $TeCH_2$ groups, respectively. The appearance of a broad singlet for the protons of the "NCH_2CH_2Te" bridge may be explained by considering the ^{1}H NMR spectrum of diethanolamine (precursor of these ligands) in which the NCH_2 and OCH_2 appear as triplets centred at 2.80 and 3.69 ppm, respectively. When oxygen is replaced by a less electronegative tellurium, the protons of the CH_2 group attached to it experience shielding and their signal probably merges with the NCH_2 signal, thereby giving a broad singlet. In **3** and **4** the protons of the NCH_2 group are shielded with respect to the similar protons of **1** and **2** due to the presence of the methyl group on nitrogen and, therefore, partly resolved signals [Fig. 1(b)] for the NCH_2 and $TeCH_2$ groups were observed. The ^{1}H NMR spectra of **1–4** were also recorded in CF_3COOD in which the ligands may exist as $D(R)N(C_2H_4TeAr)_2^+$. The "NCH_2 CH_2Te" bridge in this medium has two magnetically non-equivalent groups of CH_2 protons, i.e. $CH_2(N)$ and $CH_2(Te)$, thereby showing the expected coupling of these protons in the spectra [Fig. 1(c)]. The merging of two CH_2 signals may be partly as a result of the weak N → Te interaction

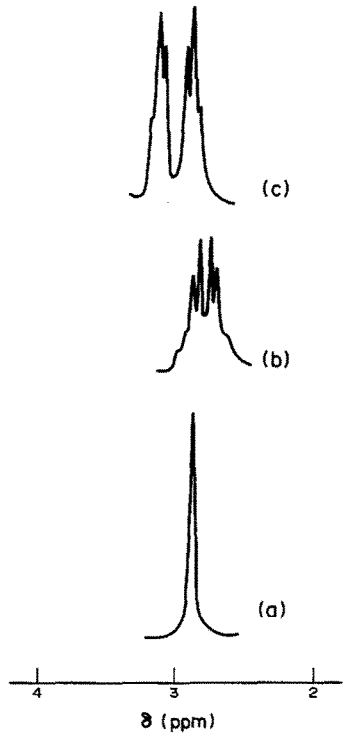

Fig. 1.

which is possible in ligands **1–4**. In acid solution such an interaction breaks down resulting in the expected ^{1}H NMR spectrum for the methylene groups. Moreover, the two tellurium atoms seem to be involved in a dynamic process fast enough on the ^{1}H NMR time scale, in which they interact alternatively with the nitrogen, otherwise protons of the CH_2 groups would have become magnetically non-equivalent, resulting in a complex ^{1}H NMR spectrum. The ring protons H^a and H^b appear as doublets, as expected for a 1,4-substituted phenyl ring. The $^{13}C\{^1H\}$ NMR spectra of **1–4** have been found to be in agreement with ^{1}H NMR spectra as the $CH_2(Te)$ resonances appear between 8 and 10.5 ppm in **1–4**, consistent with the earlier reported values,[12] supporting the shielding of carbon linked to tellurium. The carbon of $CH_2(N)$ in the spectra of these ligands appears between 50 and 58 ppm as reported for such carbons.[11] The carbons of the *p*-ethoxyphenyl and *p*-methoxyphenyl groups linked to tellurium also exhibit signals in agreement with the reported values for such moieties.[13] The two *ν*[Te—C(Ar)] vibrations in the IR spectra of **1–4** at 280–315 and 250–270 cm^{-1} are consistent with the earlier reports on tellurides.[14]

Complexation of **1** *and* **2** *with mercury*(II), *palladium*(II) *and platinum*(II)

The ligands **1** and **2** form complexes with bivalent mercury, palladium and platinum according to eqs

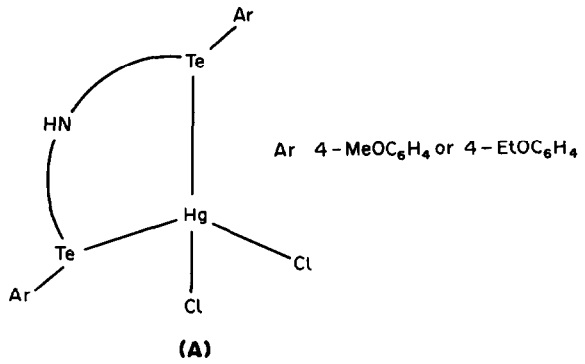
(4)–(6):

$$L + HgCl_2 \xrightarrow[r.t.]{acetone} HgCl_2 \cdot L \quad (5, 6) \qquad (4)$$

$$L + (C_6H_5CN)_2PdCl_2 \xrightarrow[r.t., 2\,h]{CHCl_3} [PdCl_2 \cdot L] \quad (7, 8) \qquad (5)$$

$$L + K_2PtCl_4 \xrightarrow[r.t., 3\,h]{aq.\text{-}acetone} [PtCl_2 \cdot L] \quad (9, 10) \qquad (6)$$

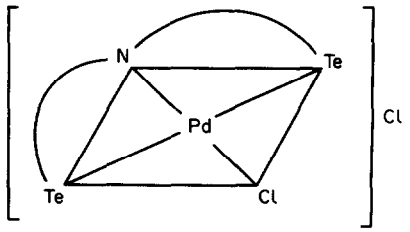
(L = **1** or **2**).



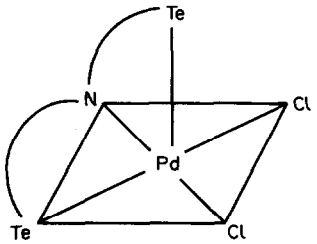
(A)

Molecular weights of mercury complexes indicate that they are monomeric. Their molar conductance values in acetonitrile indicate that they are non-ionic in nature. In the IR spectra of **5** and **6**, two ν[Te—C(Ar)] bands have been found at lower frequency ($\sim$ 15–30 cm^{-1}) in comparison to the similar bands of **1** and **2**. On coordination, ν(C—N) remains unaffected and the shift of ν(N—H) is too insignificant to conclude coordination of the NH group. Thus, probably two tellurium atoms are the only ligating site of **1** and **2** in the mercury complexes. The ^1H NMR spectra of **5** and **6** have two broad singlets due to NCH_2 and $TeCH_2$. This suggests that on coordination, these protons (almost similar in **1** and **2**) become magnetically non-equivalent and therefore appear as two broad singlets. The signal of the NH protons does not show any change in **5** and **6** when compared with that of free ligand, indicating the presence of an uncoordinated NH group in the mercury complexes. The H^a protons of the phenyl ring undergo a greater downfield shift ($\sim$ 0.15 ppm) than the H^b protons ($\sim$ 0.10 ppm). In the $^{13}C\{^1H\}$ NMR spectra of these mercury complexes, carbon signals of CH_2(Te) and C_1(Te) were found to be deshielded by $\sim$ 14.3 and $\sim$ 3.0 ppm, respectively, with respect to the corresponding signals of the free ligands. However, the carbon signal of CH_2(N) appears around 3.5 ppm upfield relative to the free ligand, which supports the possibility of a weak N $\rightarrow$ Te interaction in **1** and **2**. If these spectral observations are considered together they indicate that **1** and **2** probably coordinate with mercury through their two tellurium atoms. On consideration of the spectral data in conjunction with molecular weight and molar conductance values, it is reasonable to presume that structure **A** is most plausible for **5** and **6**.

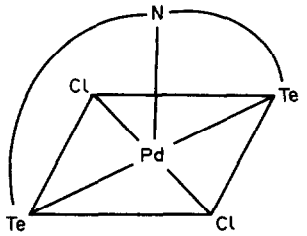
The molar conductances of the solutions of **7–10** in acetonitrile ($\sim$ 1 mM) were found in the range 30–40 Ω^{-1} cm^2 mol^{-1}. These values are lower than those expected for a 1 : 1 electrolyte.[15] The conductances (Λ_M = $\sim$ 100 Ω^{-1} cm^2 mol^{-1}) of **7–10** in methanol ($\sim$ 0.1 mM solution) are very close to that of a 1 : 1 electrolyte and decrease on increasing the concentration (Λ_M for 1 mM solution is $\sim$ 60 Ω^{-1} cm^2 mol^{-1}). In nitrobenzene the conductance is very low (Λ_M = $\sim$ 4 Ω^{-1} cm^2 mol^{-1} at 1 mM concentration) compared to the value expected for a 1 : 1 electrolyte and does not change much on dilution (Λ_M = $\sim$ 10 Ω^{-1} cm^2 mol^{-1} at 0.1 mM concentration). These observations suggest that conductance probably arises from solvolysis of $MCl_2 \cdot$ **1/2** (M = Pt or Pd), and to assume that these complexes are non-ionic is reasonable. Molecular weights of these complexes (**7–10**) in chloroform favour their monomeric and non-ionic nature. In the IR spectra of **7** and **8**, the ν(Te—C) consists of two bands with a red shift of the order of 27–35 cm^{-1}. The ν(C—N) and ν(N—H) are also red shifted by an order of $\sim$ 70 and $\sim$ 200 cm^{-1}, respectively, in comparison to the free ligand, which suggests that **1** and **2** coordinate with palladium through the nitrogen and tellurium atoms. A broad peak at 320 cm^{-1} in the IR spectra of **7** and **8** may be assigned to the ν(Pd—Cl) vibrations.[6,16] The assignment of ν(Pd—Cl) was confirmed by examining the IR spectra of $PdBr_2 \cdot$ **1/2** prepared by the metathetical reaction of $PdCl_2 \cdot$ **1/2** with KBr. The band assigned to ν(Pd—Cl) was absent in the spectra of $PdBr_2 \cdot$ **1/2**. In the ^1H NMR spectra of **7** and **8**, the NH signal was observed $\sim$ 4.7 ppm downfield from its position in the spectra of the free ligand, indicating strong coordination of the NH group with palladium. The H^a protons of the phenyl ring were found to be more deshielded (0.35 ppm) than the H^B protons (0.20 ppm), on formation of palladium complexes. Only the $^{13}C\{^1H\}$ NMR spectrum of **7** could be recorded due to the low solubility of the other complexes. Complex **7** displays carbon signals for the CH_2(Te) and CH_2(N) groups at 5.6 and 9.5 ppm downfield, respectively, relative to the free ligand. The signal of C_1(Te) also moves 5.2 ppm downfield on coordination. On considering the information derived from the IR and NMR spectra together, it appears that in palladium complexes (**7** and **8**) the ligands most probably coordinate through the nitrogen and two tellurium atoms. The



(B)



(C)



(D)

electronic spectra of the palladium complexes which are found to be diamagnetic have three bands at 33.3, 29.4 and 23.8 kK. The first band probably originates from intra-ligand transitions (the electronic spectra of **1** and **2** show only one band at 41.6 kK). The second and third bands suggest that palladium complexes have either square-planar or pyramidal geometry. The bands may be assigned to $^1A_{1g} \rightarrow {}^1E_g$ and $^1A_{1g} \rightarrow {}^1B_{1g}$ transitions.[17] In view of the non-ionic nature of the palladium complexes, the square-planar ionic structure **B** is ruled out. Of the two structures **C** and **D**, the value of ν(Pd—Cl) being somewhat lower than expected for a Cl *trans* to N, favours the *trans* structure **D**.[16] The trigonal bipyramidal geometry around palladium does not seem possible due to steric reasons also.

The IR spectra of **9** and **10** show two ν(Te—C) bands which are red shifted by the order of 20–30 cm^{-1}. The ν(C—N) and ν(N—H) are also red shifted by the order of ~ 70 and ~ 300 cm^{-1}, respectively. The ν(Pt—Cl) bond appears[6,16] around 330 cm^{-1} in the spectra of **9** and **10**, which is supported by the IR spectrum of $PtBr_2 \cdot$ **1/2** (prepared by metathesis) as for the palladium complexes. In the ^{1}H NMR spectra of the platinum complexes (**9** and **10**) the "NCH_2CH_2Te" bridge protons appear as a broad unresolved multiplet compared to a broad singlet for the free ligands, indicating a strong involvement of the nitrogen and both the tellurium atoms of **1** and **2** in coordination to platinum. The signal for H^a protons also undergoes a downfield shift, 0.26 and 0.44 ppm for **9** and **10**, respectively. Similarly, H^b protons undergo a downfield shift of the order 0.20 ppm in **9** as well as in **10**. These trends in the "shifts" indicate that in platinum complexes **1** and **2** probably also coordinate through the nitrogen and two tellurium atoms. The electronic spectra of diamagnetic **9** and **10** show only one band at 29.8 kK which indicates that the platinum complexes are either square-planar or pyramidal. The band may be due to an $^1A_{1g} \rightarrow {}^1E_g$ transition.[17] On considering the above mentioned spectral data and the fact that the conductance behaviour of platinum complexes **9** and **10** is similar to that of palladium complexes, and that they are monomeric, it seems reasonable to presume that the platinum complexes also have a square-pyramidal structure **D** as proposed for palladium complexes (**7** and **8**).

Preliminary investigations have revealed that the palladium complexes (**7** and **8**) have good activity for the homogeneous catalytic hydrogenation of simple olefins, e.g. cyclohexene, which is like the palladium complexes of (P, N, P) ligands.[6]

SYNTHESIS AND CHARACTERIZATION OF LANTHANIDE MORPHOLINE-4-CARBODITHIOATE COMPLEXES

TANG NING, GAN XINMIN, ZHU HAILIANG and TAN MINYU*

Department of Chemistry, Lanzhou University, Lanzhou, P.R.C.

(*Received* 3 *August* 1989; *accepted* 20 *October* 1989)

Abstract—The lanthanide morpholine-4-carbodithioate complexes with the general formula $(MorphH_2)[Ln(MorphCS_2)_4]\cdot H_2O$ (Morph = morpholino, Ln = La, Pr, Nd, Sm, Eu and Gd) have been prepared using anhydrous lanthanide chloride and morpholinium morpholine-4-carbodithioate as reactants. These new complexes were characterized by chemical analyses, IR spectra, electronic spectra, conductivity measurements and TG–DTA techniques. In all the complexes the carbodithioate ligands show bidentate behaviour.

Many complexes of carbodithioates with *d*- and *p*-block metal ions have been investigated,[1–4] while the corresponding type complexes of *f*-block metal ions have been reported much less. According to the "hard and soft" acids and bases rule, carbodithioates are not considered as ligands which prefer to bind to lanthanide ions to form complexes. However recent research has shown that under certain conditions the formation of lanthanide carbodithioate complexes is possible, and most of these complexes are relatively stable and some of them have bacteriostatsis and optical rotation properties.[5–7] Therefore, systematic studies on lanthanide complexes coordinated with organic ligands containing sulphur atoms have important theoretical and practical significance. As an extension of our previous research into the ion-association type complexes of lanthanides with diethyldithiocarbamate,[8] we have recently synthesized the solid complexes of lanthanides with morpholine-4-carbodithioate, and investigated the composition and properties of the new complexes.

EXPERIMENTAL

Preparation of anhydrous lanthanide chlorides

Anhydrous lanthanide chlorides were prepared by a literature method[9] with sulphinyl chloride as the dehydrating agent.

Preparation of the ligand

Morpholinium morpholine-4-carbodithioate ($[\overline{CH_2CH_2OCH_2CH_2NH_2}]\cdot[\overline{CH_2CH_2OCH_2CH_2NCS_2}]$) was obtained according to the literature[10] by the reaction of morpholine and carbon disulphide (molar ratio 2 : 1) in carbon tetrachloride medium. The product was purified by sublimation and then verified by elemental analysis, IR and ^1H NMR spectroscopy.

Preparation of the complexes

Anhydrous lanthanide chloride (0.1 mmol) and the ligand (0.4 mmol) were dissolved in 20 cm^3 of absolute ethanol. After being stirred for 24 h at room temperature the solution was allowed to evaporate spontaneously to dryness. The residual solid obtained was dissolved in 20 cm^3 of anhydrous acetonitrile and then the solution was filtered. To the filtrate was added 100 cm^3 of anhydrous ethyl ether with stirring so that that complex precipitated. The product was isolated by filtration, washed with anhydrous ethyl ether and dried *in vacuo* over P_4O_{10} for 1 week. The complete synthesis of the complexes was carried out in a glove box containing dry nitrogen gas.

Analyses

The metal ion was determined by EDTA titration using xylenol-orange as indicator. Carbon, nitrogen

* Author to whom correspondence should be addressed.

and hydrogen were determined using a Carlo Erba 1106 elemental analyser.

IR measurements

The IR spectra were recorded in the 4000–200 cm^{-1} region using KBr pellets and a 170 SX FTIR spectrometer.

Electronic spectra

The electronic spectra were recorded with a Shimadzu UV-240 spectrophotometer in acetonitrile solution in the 190–400 nm range.

Thermal analyses

Thermal analyses (TG and DTA) were performed on a Dupont 1090 thermobalance. The heating rate was $10^{\circ}C\ min^{-1}$.

Conductivity measurements

These measurements were carried out with a DDS-11A type conductivity bridge for freshly prepared solutions in acetonitrile at 25°C.

RESULTS AND DISCUSSION

Composition of the complexes

The analytical data for the newly synthesized complexes listed in Table 1 indicate that there is one morpholinium ion, one lanthanide ion, four morpholine-4-carbodithioate groups and one water molecule in each of the complex molecules.

IR spectra

The most important IR peaks of the ligand morpholinium salt and the complexes are reported in Table 2.

The presence of a single, strong band due to a ν(CSS) mode in the range 998–1005 cm^{-1} in the spectra of the complexes is strongly indicative of bidentate behaviour of the dithio ligand in the complexes;[3,4] otherwise a doublet is expected in the $1000 \pm 70\ cm^{-1}$ region for the case of monodentate coordination.[11,12] Analysis of the position of the ν(C···N) mode, in the range 1462–1469 cm^{-1}, gives further confirmation of the above suggested behaviour: this band, in fact, undergoes a blue shift in all the complexes, while for unidentate coordination this stretching mode would be shifted towards lower wavenumbers or would remain unchanged at the value of the free carbodithioate sodium salt.[13]

In the far-IR region, the bands of the ligand appear unchanged in the spectra of the complexes; in addition, new bands, absent in the spectra of the starting materials, are present in the 331–358 cm^{-1} range, which may be assigned as the ν(M—S) stretching frequency.[3,14]

In all the IR spectra of the complexes, medium and weak bands are present near 3400 cm^{-1} and in the 1630–1638 cm^{-1} range, respectively, which are clearly due to ν(OH) and δ(HOH), respectively. The absence of the vibrational modes activated by coordination to the metal (wagging, twisting and rocking)

Table 1. Analytical data

Compound[a]	%N Found (Calc.)	%C Found (Calc.)	%H Found (Calc.)	%M Found (Calc.)
$MorphH_2[La(MorphCS_2)_4]\cdot H_2O$	8.0 (7.8)	31.9 (32.2)	5.1 (5.0)	15.6 (15.5)
$MorphH_2[Pr(MorphCS_2)_4]\cdot H_2O$	7.8 (7.8)	32.0 (32.1)	5.1 (4.9)	15.8 (15.7)

$MorphH_2[Gd(MorphCS_2)_4]\cdot H_2O$	7.8 (7.7)	31.6 (31.6)	5.1 (4.9)	17.6 (17.2)

[a] Morph = morpholino ($\overline{CH_2CH_2OCH_2CH_2N}$—).

Table 2. Most important IR bands (cm^{-1})

Compound	ν(CSS)	ν(C···N)	ν(M—S)	ν(O—H) and ν(N—H)	δ(HOH)
$MorphH_2(MorphCS_2)$	984s	1448s		3388w	
$MorphH_2[La(MorphCS_2)_4]\cdot H_2O$	998s	1462s	358w	3388m	1630w
$MorphH_2[Pr(MorphCS_2)_4]\cdot H_2O$	998s	1469s	349w	3402m	1630w
$MorphH_2[Nd(MorphCS_2)_4]\cdot H_2O$	998s	1469s	346w	3409m	1631w
$MorphH_2[Sm(MorphCS_2)_4]\cdot H_2O$	1005s	1462s	331w	3374m	1631w
$MorphH_2[Eu(MorphCS_2)_4]\cdot H_2O$	1005s	1462s	335w	3367m	1638w
$MorphH_2[Gd(MorphCS_2)_4]\cdot H_2O$	1005s	1462s	332w	3367m	1638w

suggests that coordinated water is not present and these results are confirmed by the thermogravimetric studies (see below).

Electronic spectra

The electronic spectra are given in Table 3. All the complexes show three absorption bands due to the chromophore group NCS_2[15] (these absorptions are labelled as Band I, Band II and Band III).

Band I is assigned to an intramolecular charge transfer in the ligand, i.e. a $\pi \rightarrow \pi^*$ transition located mainly in the N···C···S group.[16,17] Band II is attributed to a $\pi \rightarrow \pi^*$ transition of the S···C···S group.[18] This band does not undergo splitting and this fact clearly indicates the equivalence of the C···S bands in the complexes. Band III is a low intensity band assigned to an $n \rightarrow \pi^*$ transition, i.e. a transition of an electron of the lone pair on the sulphur atom to an antibonding π-orbital.[19] It can be seen from Table 3 that Bands II and III, but not Band I, undergo a considerable violet shift upon complexation. This change can be attributed to the formation of M—S bonds and the deviation of the electron cloud around the sulphur atoms, the electron donors, towards the lanthanide ions, which decreases the π–π and p–π conjugate effects in the chromophore group and increases the energy needed for the π–π^* and n–π^* transitions. This results in the absorption bands shifting towards shorter wavelengths.

Thermal analyses

Thermal analysis studies were performed by means of TG and DTA techniques.

The processes of thermal decomposition for all the complexes are almost the same. After the loss of one water molecule in the 27–70°C range, the complexes decompose very rapidly between 126 and 270°C. Then continuous weight loss is detected up to 850°C. At this temperature Ln_2O_3 (Pr_6O_{11} for the praseodymium complex) is formed.

Solubility and molar conductance

All the complexes are hardly soluble in ethyl ether and cyclohexane, but are soluble in methanol, ethanol, acetone and tetrahydrofuran, and are readily soluble in acetonitrile and methylene dichloride. The molar conductance values of the complexes measured in acetonitrile at 25°C lie in the range

Table 3. The electronic spectra (nm)

Compound	Band I	Band II	Band III
$MorphH_2(MorphCS_2)$	211	284	309
$MorphH_2[La(MorphCS_2)_4]\cdot H_2O$	211	274	301
$MorphH_2[Pr(MorphCS_2)_4]\cdot H_2O$	210	272	296
$MorphH_2[Nd(MorphCS_2)_4]\cdot H_2O$	211	271	299
$MorphH_2[Sm(MorphCS_2)_4]\cdot H_2O$	209	269	298
$MorphH_2[Eu(MorphCS_2)_4]\cdot H_2O$	209	268	298
$MorphH_2[Gd(MorphCS_2)_4]\cdot H_2O$	210	268	296

124.4–128.3 Ω^{-1} cm^2 mol^{-1}, which indicates that all the complexes are 1 : 1 electrolytes and that each of the complex molecules dissociates as one cation and one anion in solution.[20]

From the above discussion it can be concluded that the new complexes reported in this paper are ion-association types of coordination compounds. In each of the complexes four carbodithioate groups, acting as uninegative bidentate ligands, are coordinated to a lanthanide ion through eight sulphur atoms to form a complex anion and the morpholinium cation lies outside of the coordination shell. This coordination state was also found in other types of lanthanide carbodithioate complexes.[7,21]

PREPARATION AND STRUCTURAL PROPERTIES OF MONONUCLEAR AND BINUCLEAR RUTHENIUM(II) CYCLOPENTADIENYL COMPLEXES WITH 4-CYANOPYRIDINE AND 4-CYANOPYRIDINE 1-OXIDE

A. MISHRA, K. MISHRA* and U. C. AGARWALA†

Department of Chemistry, Indian Institute of Technology, Kanpur—208016, India

(*Received* 16 *August* 1989; *accepted* 20 *October* 1989)

Abstract—Reactions of $[Ru(\eta^5\text{-}C_5H_5)L_2Cl]$ (L = PPh_3 or $AsPh_3$, L_2 = $Ph_2PCH_2CH_2PPh_2$ or $Ph_2PCH_2PPh_2$) have been carried out with 4-cyanopyridine and 4-cyanopyridine 1-oxide in the presence of suitable anions (PF_6^- or BPh_4^-). The reaction products were found to be cationic mono- and binuclear complexes which have been characterized by elemental analyses, spectroscopic (IR, UV–vis and NMR) and electrochemical studies. Conductivity measurements have also been carried out to confirm the charges on these cationic species.

In extending our studies related to the properties of $[Ru(\eta\text{-}C_5H_5)(EPh_3)_2Cl]$ (E = P, As or Sb) we became interested in the interaction of these molecules with 4-cyanopyridine and its corresponding oxide. Although several detailed reports concerning the complexes of these ligands with metal ions have been published,[1–13] our primary interest in undertaking such a study was (a) to ascertain the relative donor capabilities of these ligands, (b) to examine the nature of the ruthenium(II) orbitals' (d^6) interaction with the low-lying vacant ligand orbitals while the set of "spectator" ligands are also donors, and (c) to investigate the possibility of the formation of cyclopentadienyl-containing ruthenium(II) bi- and/or polynuclear-bridged complexes.

This paper describes the characterized products of the reactions of 4-cyanopyridine and 4-cyanopyridine 1-oxide with $[Ru(\eta^5\text{-}C_5H_5)(EPh_3)_2Cl]$ and $[Ru(\eta^5\text{-}C_5H_5)(L—L)Cl]$ (E = P or As; L—L = dppe or dppm). Their structural properties have been discussed and the influence of the asymmetric nature of these ligands on the structure of the complexes has been assessed.

EXPERIMENTAL

Pure chemicals and dry solvents[14] were used in the reactions. $[Ru(\eta^5\text{-}C_5H_5)Cl(EPh_3)_2]$ and $[Ru(\eta^5\text{-}C_5H_5)(L—L)Cl]$ (E = P or As; L—L = dppe or dppm) were prepared by literature methods.[15–18] 4-Cyanopyridine and 4-cyanopyridine 1-oxide (Aldrich) were purified prior to their use by recrystallization from 95% ethanol. HPLC grade deaerated acetonitrile (distilled over $KMnO_4$ and P_2O_5) for spectral and electrochemical measurements and spectroscopic grade solvents for the study of solvatochromism and conductivity measurements were used.

Analytical, spectral and conductivity data of the products were obtained as described elsewhere.[16] The electronic and ^{13}C NMR spectra of the complexes were recorded on a Shimadzu UV 190 and a JEOL FT-90 spectrophotometer, respectively. Cyclic voltammetry experiments were carried out on a MPI model MP-1042 cyclic voltameter.

Preparation of complexes

Reactions of $[Ru(\eta^5\text{-}C_5H_5)L_2Cl]$ (L = PPh_3 or $AsPh_3$; L_2 = dppe or dppm) with 4-cyanopyridine and 4-cyanopyridine 1-oxide.

(a) *Preparation of the complexes* $[Ru(\eta^5\text{-}C_5H_5)L_2(4\text{-}CNpy)]X$ *and* $[Ru(\eta^5\text{-}C_5H_5)L_2(4\text{-}CNpyo)]X$ (L = PPh_3 *or* $AsPh_3$; L_2 = dppe *or* dppm; X^- = Cl^-, PF_6^- *or* BPh_4^-). In a typical reaction, addition of 4-cyanopyridine (0.57 mmol) or 4-cyanopyridine 1-oxide (0.33 mmol) to a suspension of $[Ru(\eta^5\text{-}C_5H_5)L_2Cl]$ (0.13 mmol) in methanol (50 cm^3), followed by heating under reflux (Table 1), yielded a yellow coloured solution. This was

P = PPh_3; A = $AsPh_3$; dppe = 1,2 bis-diphenylphosphinoethane; dppm = 1,2 bis-diphenylphosphinomethane; 4-CNpy = 4-cyanopyridine; 4-CNpyO = 4-cyanopyridineoxide.

filtered, evaporated to dryness under reduced pressure and the residue was extracted with dichloromethane. Addition of about 50 cm^3 of petroleum ether to the extract yielded a microcrystalline product. This was separated by centrifugation, washed several times with petroleum ether and dried *in vacuo*. The chloro complex thus obtained, was purified by neutral alumina column chromatography (25 cm). The complex was dissolved in methanol (10 cm^3) and passed through the column, and the major band was eluted with a 1 : 1 mixture of methanol and acetone. The resulting solution was evaporated to dryness and the residue was extracted with dichloromethane. From the extract the complex was precipitated by petroleum ether. It was separated by centrifugation, washed several times with petroleum ether and dried *in vacuo*. The complex was analysed as $[Ru(\eta^5\text{-}C_5H_5)L_2(4\text{-}CNpy)]Cl$ (yield, *ca* 40%) or $[Ru(\eta^5\text{-}C_5H_5)L_2(4\text{-}CNpyo)]Cl$ (yield, *ca* 50%).

The corresponding tetraphenylborate and hexafluorophosphate salts of the monomeric cyanopyridine and cyanopyridine 1-oxide complexes were obtained by precipitating the complexes by adding $NaBPh_4$ (0.06 mmol) and NH_4PF_6 (0.12 mmol), respectively, to a solution of the chloro complexes in 20 cm^3 of methanol, followed by brief stirring for about 20 min. These were filtered, and washed several times with methanol and ether. The compounds were purified by dissolving in 5 cm^3 of dichloromethane and eluting on a neutral alumina column (25 cm) with a 1 : 1 mixture of CH_2Cl_2 and acetone. The eluant was dried *in vacuo*, the residue was extracted with CH_2Cl_2 and from the extract the complex was precipitated with petroleum ether. The precipitates after washing and drying were analysed as $[Ru(\eta^5\text{-}C_5H_5)L_2(4\text{-}CNpy)]X$ (yield, *ca* 40%) and $[Ru(\eta^5\text{-}C_5H_5)L_2(4\text{-}CNpyo)]X$ (yield, *ca* 45%) (X = BPh_4^- or PF_6^-).

(b) *Preparation of the dimeric complexes* $[(\eta^5\text{-}C_5H_5)L_2Ru\text{-}4CNpy\text{-}RuL'_2(\eta^5\text{-}C_5H_5)]X_2$ *and* $[(\eta^5\text{-}C_5H_5)L_2Ru4CNpyoRuL'_2(\eta^5\text{-}C_5H_5)]X_2$ (L,L′ = PPh_3 *or* $AsPh_3$; L_2,L'_2 = dppe *or* dppm; X = BPh_4^- *or* PF_6^-). A typical reaction procedure is as follows. $[Ru(\eta^5\text{-}C_5H_5)ClL_2]$ (0.13 mmol) was added to a 50 cm^3 methanolic solution of $[Ru(\eta^5\text{-}C_5H_5)L'_2(4\text{-}CNpy)]Cl$ (0.13 mmol) or $[Ru(\eta^5\text{-}C_5H_5)L'_2(4CNpyo)]Cl$ (0.13 mmol). The resulting mixture was stirred overnight, whereupon the starting complex $[Ru(\eta^5\text{-}C_5H_5)L_2Cl]$ gradually dissolved. The resulting solution was filtered and $NaBPh_4$ (0.12 mmol) was added to the filtrate, followed by stirring for a brief period. The precipitated complex was separated by centrifugation, washed with methanol and purified chromatographically on a neutral alumina column.

The corresponding hexafluorophosphate salt of the binuclear complex was obtained by adding NH_4PF_6 (0.12 mmol) in place of $NaBPh_4$, followed by stirring the solution for 0.5 h. The solution was evaporated to dryness under reduced pressure. The residue was dissolved in CH_2Cl_2 and the PF_6^- complex was precipitated by the addition of petroleum ether to the extract. BPh_4 or PF_6 salts of binuclear cyanopyridine or cyanopyridine 1-oxide were dissolved in about 5–10 cm^3 of CH_2Cl_2 and passed through a neutral alumina column for purification. The major band was eluted with a 1 : 1 mixture of CH_2Cl_2 and acetone. The eluant was evaporated to dryness and the complex was obtained by extracting the residue with CH_2Cl_2 and precipitating with petroleum ether. It was centrifuged, washed several times with petroleum ether and dried *in vacuo*. It was then analysed for $[(\eta^5\text{-}C_5H_5)L_2Ru\text{-}4CNpy\text{-}RuL'_2(\eta^5\text{-}C_5H_5)]X_2$ (yield, *ca* 35%) or $[(\eta^5\text{-}C_5H_5)L_2Ru4CNpyoRuL'_2(\eta^5\text{-}C_5H_5)]X_2$ (yield, *ca* 30%) (X = BPh_4^- or PF_6^-).

RESULTS AND DISCUSSION

Reactions of $[Ru(\eta^5\text{-}C_5H_5)L_2Cl]$ (L = PPh_3 or $AsPh_3$; L_2 = dppe or dppm) with 4-cyanopyridine in the presence of suitable anions (PF_6^- or BPh_4^-) yield reddish-brown mononuclear and maroon-coloured binuclear complexes, and with 4-cyanopyridine-1-oxide, bright yellow mononuclear and yellowish-brown binuclear cationic complexes. Microanalytical data suggest the formulae given in Table 1. They are non-hygroscopic, readily soluble in chloroform, dichloromethane, acetone, acetonitrile, benzene and other organic solvents, but insoluble in light petroleum and diethyl ether. The chloride salts are readily soluble, while those of PF_6^- or BPh_4^- are only slightly soluble in methanol. All the complexes become adsorbed in the cationic ion-exchanger suggesting their cationic nature.

Conductivity measurements

The elecrolyte behaviour of the complexes was determined by their conductivity measurements in nitromethane using the Feltham and Hayter procedure.[19] From the measured values of the equivalent conductance (λ_e) in the concentration range of 10^{-2}–10^{-4} equiv dm^{-3}, λ_0 was determined by extrapolating the straight lines [Fig. 1(b)] and subsequently values of $(\lambda_0 - \lambda_e)$ [Fig. 1(a)] were plotted as a function of $\sqrt{c}$.[20–22] The respective slopes of the mono- (216) and binuclear (420) complexes of the straight lines for the 4-cyanopyridine complexes compared very well with those of the Feltham's values for 1 : 1 and 1 : 2 species in nitromethane.[23,24]

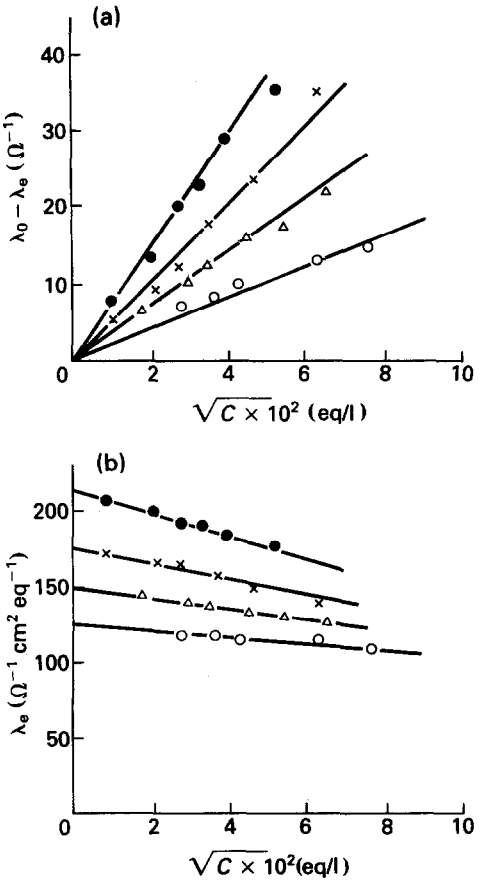

Fig. 1. (a) Plots of $\lambda_0 - \lambda_e$ vs $\sqrt{c}$; (b) plots of λ_e vs $\sqrt{c}$ for the complexes: ○ $[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpy)(PPh_3)_2]PF_6$; × $[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpy)(PPh_3)_4](PF_6)_2$; △ $[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpyO)(PPh_3)_2]PF_6$; ● $[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpyO)(PPh_3)_4](PF_6)_2$.

The corresponding slopes (358 and 728) for 4-cyanopyridine 1-oxide complexes, though a little high, also fall well within the range reported by them for 1 : 1 and 1 : 2 electrolytes.

IR spectra

The shifts in the positions of ν(CN) and the pyridine ring vibrations have been used to elucidate the site of coordination of the cyanopyridines. Coordination through the nitrogen of the nitrile group should result in an increase in ν(CN), while coordination through the pyridine nitrogen should lead to characteristic shifts in the positions of pyridine ring vibrations without much change in the position of ν(CN).

The IR spectra of all mononuclear complexes of cyanopyridine and its oxide exhibited bands of $\nu(C{\equiv}N)$ around 2240 cm^{-1} (Table 1) (ν(CN) for free ligand = 2243 cm^{-1}). Thus suggesting that the linkage of ruthenium is through the aromatic nitrogen of 4-cyanopyridine and through oxygen of the NO group of 4-cyanopyridine 1-oxide, in keeping with earlier observations.[7,11–13,25–28] An insignificant shift (± 3 cm^{-1}) in the positions of ν(CN) is not unexpected and could arise from both resonance and electronic effects (π-backbonding) due to bonding with the metal ion centre. Further support of ruthenium bonding to the aromatic nitrogen of cyanopyridine complexes comes from the blue shifts in the positions of $\nu(C{\cdots}C)$ and $\nu(C{\cdots}N)$ of cyanopyridines in the region 1400–1600 cm^{-1}.[5,7,28]

In monomeric, 4-cyanopyridine 1-oxide complexes the oxygen atom of the N-oxide group having partial negative charge coordinates to the ruthenium(II) nucleus. The contributing resonance structure of 4-cyanopyridine 1-oxide may be shown by a dipolar representation indicating charge separation and the polar character of the N—O bond, where the oxygen atom is regarded as an addition to the molecule of 4-cyanopyridine. The NO stretching vibration in the complexes appeared at higher frequency relative to that in the free 4-cyanopyridine 1-oxide (1280 cm^{-1}) (Table 1). Bands due to ν(NO) in monomeric complexes appeared around 1305 cm^{-1}. The blue shift indicated its coordination to the metal centre. In dimeric complexes in which the uncoordinated CN group of the monomeric complexes coordinates to another ruthenium centre, a decrease in the position of ν(CN) (2232 cm^{-1}) relative to that in the free ligand was observed.[29] The reason for this expected decrease could be attributed to the metal ($d\pi$) → ligand π^*-backbonding.

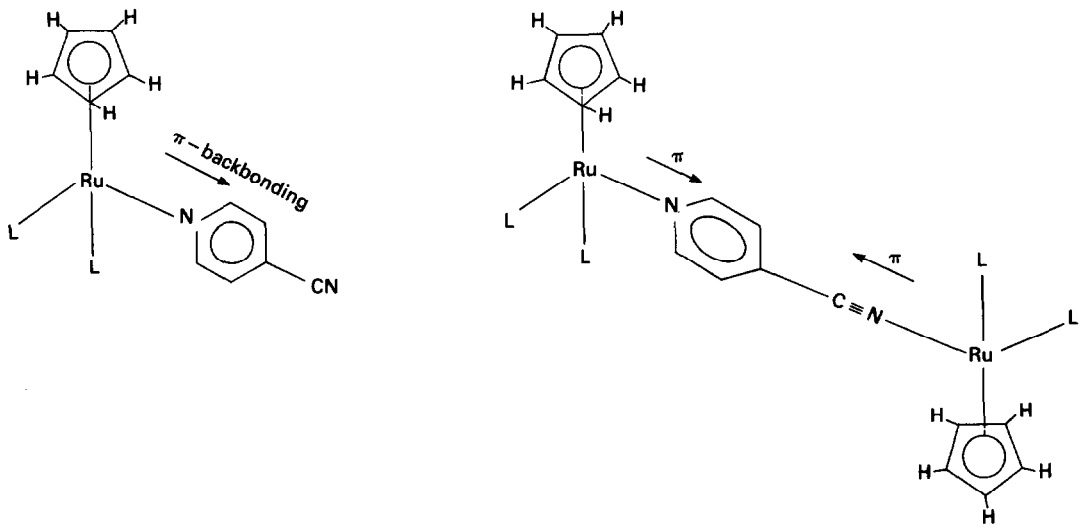
^{1}H NMR spectra

In the ^{1}H NMR spectra of monomeric 4-CNPy and 4-CNPy 1-oxide complexes with $PPh_3/AsPh_3$ as co-ligands, η^5-C_5H_5 protons appeared as a singlet around δ 4.6, whereas in complexes containing dppe or dppm, they occurred around δ 4.9 (Table 1). The downfield shift of η^5-C_5H_5 protons relative to the starting complexes (δ 4.1 in $PPh_3/AsPh_3$; δ 4.5 in dppe/dppm) may result from the change of electron density on ruthenium due to backbonding from metal to 4-CNPy, and more so because of the presence of a strong electron-withdrawing —CN group substituted in the para-position of the pyridine ring. The electron-withdrawing, as well as the conjugative ability of the —CN, pulls the electron density away from the pyridine nucleus towards itself, which affects the electron deficiency on the ruthenium metal. It may consequently lead to a pull of more electrons from C_5H_5 towards the ruthenium centre resulting in deshielding of the C_5H_5 protons.

In binuclear cyanopyridine cationic complexes, η^5-C_5H_5 protons resonate around δ 4.3 and 4.75 as two separate peaks, suggesting a difference in the local electron density on the protons of the two η^5-C_5H_5 molecules present in the binuclear complexes. This could arise because of the difference in the nature of M—L bonding of two ruthenium centres. In complexes of 4-cyanopyridine 1-oxide, the signal for C_5H_5 protons appeared as a broad singlet around δ 4.7 (Table 1). Since the difference in the positions of two signals in binuclear complexes should be sensitive to the nature of L, it is therefore possible that the two resonances in the 4-cyanopyridine 1-oxide complexes should appear in very similar positions, resulting in signal broadening. Furthermore, the signals from binuclear complexes appeared at higher field with respect to those from mononuclear complexes. This behaviour can be anticipated if one considers the fact that the two ruthenium(II) ions in a binuclear complex compete to donate the electron density to 4-cyanopyridine (or 4-cyanopyridine 1-oxide) through π-backbonding both from the cyano nitrogen and the aromatic nitrogen (or through the oxygen of the N → O moiety). This competition would result in the net reduction of the π-bonding effect on the C_5H_5 protons (Structure 1) in binuclear complexes compared to that in mononuclear ones. The signals for the α-protons of the pyridine were observed towards higher field (δ 8.3–8.5) in both mono- and binuclear complexes of 4-cyanopyridine and 4-cyanopyridine 1-oxide relative to ones reported for the free 4-cyanopyridine ligand (δ 9.05).[30–32] This upfield shift is ascribed to the "paramagnetic" anisotropy of ruthenium(II) arising due to temperature independent paramagnetism, as expected of the metal centre.[30] The difference in the signal positions of the cyanopyridine and cyanopyridine 1-oxide complexes may perhaps be caused by the variation in the "paramagnetic" anisotropic effect. It also suggests that a degree of $d\pi$–$p\pi$ backbonding influences the chemical shifts of the hydrogens. The β-protons in the majority of these complexes exhibited shifts towards higher field (δ 7.0–7.9). Since this region was found to be dominated by broad multiplets of aromatic phenyl protons of PPh_3, $AsPh_3$, dppe or dppm co-ligands, the pyridine protons, signals could not be distinguished from them. The experimental observations of upfield shifts of these protons, could again be explained by the higher "shielding" effect caused by the enhanced, stronger π-backbonding from the ruthenium(II) to cyanopyridine group.

^{13}C *NMR*

The ^{13}C NMR spectra of these complexes also support the conclusions drawn from ^1H NMR. The η^5-C_5H_5 carbons in the mononuclear 4-cyanopyridine 1-oxide complexes appeared as a singlet (δ 84.0), towards the downfield side relative to the C_5H_5 carbons (δ 81.5) in the starting complexes. In binuclear complexes with PPh_3/$AsPh_3$ as co-ligands, the spectra exhibited two signals around δ83.0 and 84.5 and in those with dppe/dppm as co-ligands, around δ 81.0 and 82.5. The phenyl carbons in all these complexes exhibited sharp multiplets in the expected region for aromatic carbon (*ca* δ 128–137). The cyanide carbon (—CN) underwent a downfield shift both in mono- and binuclear complexes (δ 119.6, sharp singlet in the mononuclear and δ 121.5 in the binuclear complexes) compared



Structure 1.

to the value in the free ligand (δ 117.6). This downfield shift indicated deshielding of the carbon atoms on coordination to the metal atom. Coordination of 4-cyanopyridine or 4-cyanopyridine 1-oxide resulted in an upfield shift of the pyridine ring carbons (δ 145 and 140) relative to the free ligand (δ 150.5). Though the signals arising from the β- and γ-carbons could not be distinguished from the phenyl carbons in all the complexes, in a few complexes signals due to the γ-carbon appeared in the upfield region with respect to the ones found in 4-cyanopyridine ($\beta = 127$; $\gamma = 121.4$) or 4-cyanopyridine 1-oxide. The shielding of all the carbon atoms on coordination is not unexpected because factors like polarization of the N—C bond due to σ-bonding at the pyridine nitrogen, metal-centred anisotropic diamagnetic currects and increased electron density due to π-bonding will provide net shielding contributions to the carbon atoms of the pyridine ring.

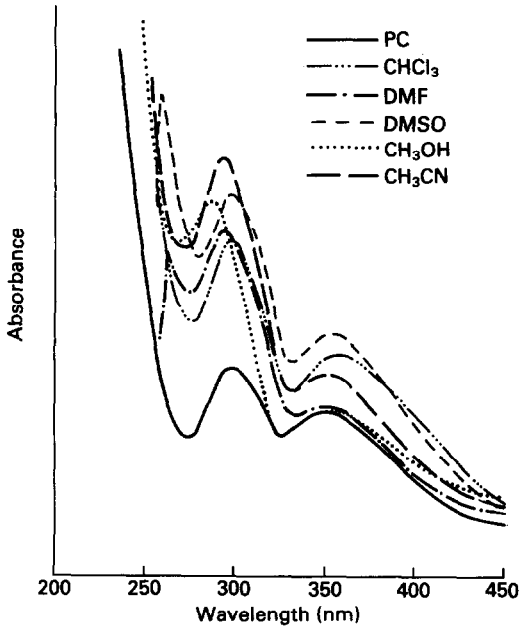


Fig. 2. Electronic absorption spectra of the complex $[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpyO)(PPh_3)_4](PF_6)_2$.

^{31}P *NMR*

^{31}P NMR of the 4-cyanopyridine and 4-cyanopyridine 1-oxide complexes exhibited a single sharp signal around δ 41.5 and 41.9, respectively, for the PPh_3 phosphorus. Similarly, in dppe complexes a single, sharp peak appeared at δ 80.4 for the diphos phosphorus. The deshielding of phosphorus may be caused by relatively less donation of electrons from metal to phosphorus through backbonding. This suggests that the degree of $d\pi$–$p\pi$ backbonding influences the chemical shift of the phosphorus atoms and there exists a competition of the π-electrons between the 4-cyanopyridine or 4-cyanopyridine 1-oxide and other ligands supporting the ^1H and ^{13}C NMR spectral conclusions.

Electronic absorption spectra

The low spin d^6 configuration of both the mono- and binuclear series of complexes provides filled orbitals of proper symmetry on ruthenium(II) which interact with the relatively low-energy unoccupied π^*-orbitals on the pyridine ring of 4-cyanopyridine or 4-cyanopyridine 1-oxide ligands. One should, therefore, expect a band attributable to a MLCT transition ($t_{2g} \rightarrow \pi^*$) in the complexes. Furthermore the energy of these transitions should vary with the nature of the ligand acting as a π-acceptor. The presence of an electron-withdrawing substituent, like a —CN group, in the 4-position of the pyridine and pyridine 1-oxide should decrease the energy of the transition, causing a red shift in the MLCT maximum as well as greater ground state delocalization of the $d\pi$-electron density onto the ligand (π-backbonding), while the electron-donating group on the pyridine ring should increase the transition energy.[34,35] The electronic bands and their assignments for 4-cyanopyridine complexes in various solvents are shown in Table 2. A band around 450 nm has been assigned to a MLCT transition ($t_{2g}Ru^{II} \rightarrow \pi^*$-ligand of 4-cyanopyridine or 4-cyanopyridine 1-oxide). The λ_{max} and the ε_{max} values correlated very well with those of the pyridine bound 4-cyanopyridine complexes of ruthenium(II) and iron(II) in the literature.[5–7] The bonding of ruthenium(II) to the aromatic nitrogen is supported by the fact that the 485 nm band in our complexes appeared at lower energies compared to that in $[(\eta^5\text{-}C_5H_5)Ru(PPh_3)(Py)Cl]$ (465 nm) because of the electron-withdrawing property of the CN group.[34–36] Further support for the bonding is provided by the fact that aromatic nitrogen bonded complexes always absorb at a longer wavelength compared to the nitrile bound complexes.

In the spectra of the binuclear cationic complexes of 4-cyanopyridine there is a slight shift of λ_{max} towards higher frequencies in a few solvents (Table 2). In some solvents λ_{max} remains unaltered. (A slight decrease was also observed in the position of λ_{max} in one or two solvents with respect to the mononuclear cationic 4-cyanopyridine complexes.) This "anomalous" behaviour could be explained on the basis of the asymmetrical nature of the bridging ligand π-backbonding from ruthenium(II)[a] to the pyridine ring must raise the energy of the π^*-orbitals of the nitrile end of the 4-cyanopyridine, while the π-backbonding from the ruthenium(II)[b] to the NC

A = $[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpy)(PPh_3)_2]BPh_4$; B = $[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpy)(PPh_3)_4](BPh_4)_2$; C = $[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpyO)(PPh_3)_2]Cl$; D = $[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpyO)(PPh_3)_4](PF_6)_2$.

group should also raise the energy of the pyridine π^*-orbitals. Because the energy of the MLCT transition is related to that of the LUMO of the ligand, the increase in energy of the π^*-orbital by both electron transfers from the metal centres should result in the shift of the MLCT bands towards higher frequencies with respect to mononuclear complexes.

The MLCT absorptions exhibited a solvatochromic effect. Various parameters, for example, donor number (DN), the Reichardt Dimroth parameter (ET), $1/D_{op}-1/D_s$, E^*_{MLCT}, etc. have been defined[37–40] and correlated with the absorption energies of MLCT transitions. Figures 3 and 4 display these representative plots. They all show an excellent linear correlation between the variation of the MLCT band positions with the solvent polarity. The donor number plots have negative slopes suggesting a decrease in the energy of the transition as the donor property of the solvent increases and the intercepts give the energy of the transition when the compound is dissolved in dichloroethane. Further, a linear relationship is expected between the MLCT band positions and χ_{outer}, assuming the applicability of the Hush model[41–43] in these systems. Accordingly, the energy of the MLCT band which ought to be related to the Frank Condon term (χ_{inner}) and the solvent reorientation properties (χ_{outer}) by the equation $E_{op} = \chi_{inner}+\chi_{outer}+E'_{op}$, should show linearity with χ_{outer}. The χ_{outer} value can be calculated using the relationship $\chi_{outer} = (\Delta e)^2(1/2a_1+1/2a_2-1/r)(1/D_{op}-1/D_s)$, where Δe is charge transferred, D_{op} and D_s are the optic and static dielectric constants of the medium, a_1, a_2 and r, radii of the electron donor, acceptor and distance separating them. Figure 4(b) shows the plot of

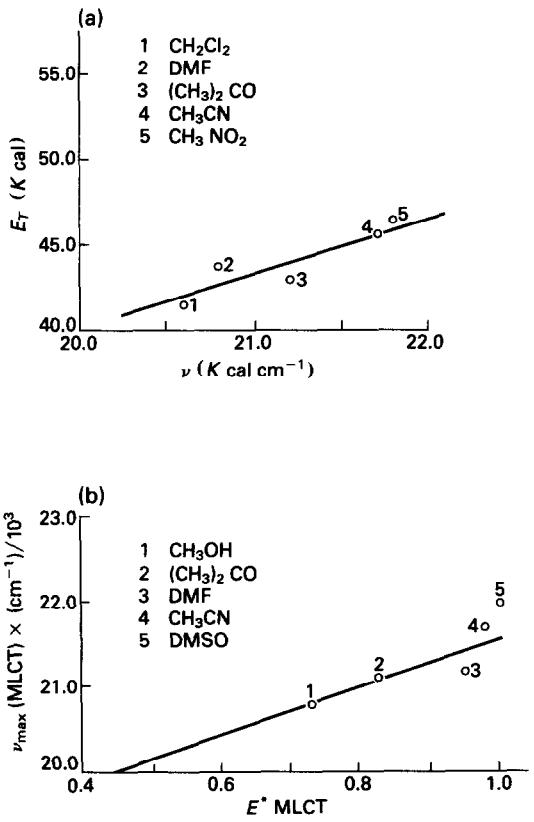

Fig. 3. (a) Plot of E_T vs MLCT for $[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpy)(PPh_3)_4](BPh_4)_2$; (b) plot of MLCT vs E^* MLCT for $[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpy)(PPh_3)_4](BPh_4)_2$.

E_{MLCT} vs $(1/D_{op}-1/D_s)$ for one representative compound. This shows a somewhat satisfactory relationship for both mono- and binuclear 4-cyanopyridine complexes. The generally observed shift to higher energy of the MLCT transition in solvents

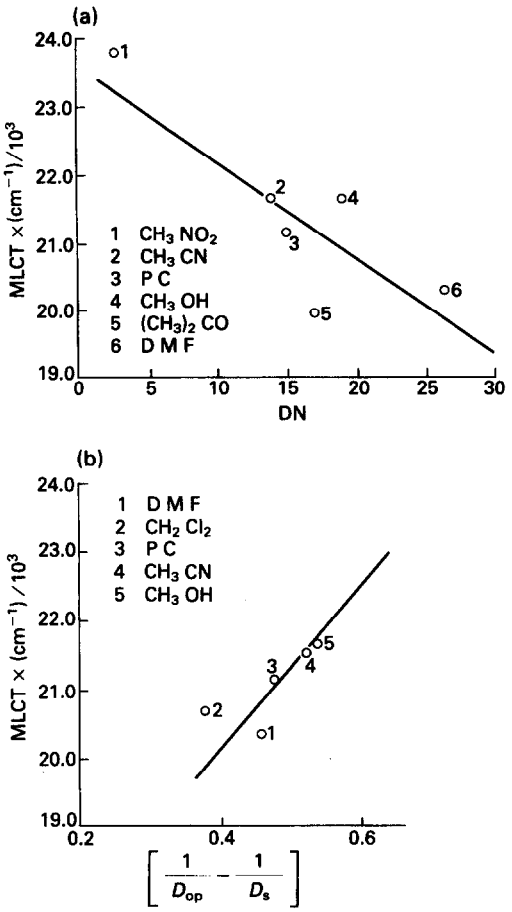

Fig. 4. (a) Plot of MLCT vs DN for $[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpy)(PPh_3)_2]BPh_4$; (b) plot of MLCT vs $[1/D_{op} - 1/D_s]$ for $[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpy)(PPh_3)_2]BPh_4$.

of high polarity has been attributed to the ground state stabilization or the excited state destabilization of non-centrosymmetric complexes in more polar solvents. Furthermore, strong solvatochromism is expected when the dissolved complex is ionic/polar.

The mononuclear and binuclear cationic complexes of 4-cyanopyridine also exhibited broad, medium intensity bands centred around 360 and 350 nm, respectively. These bands are assigned to the metal-to-ligand charge-transfer transition from ruthenium(II) to the antibonding C_5H_5 orbitals. The possibility of these bands arising from other MLCT transitions may be ruled out since the likelihood of transitions appearing from ruthenium(II) to either EPh_3 (E = P, As) or dppe/dppm in the near UV region is obscured. The intraligand $\pi \rightarrow \pi^*$ transitions in 4-cyanopyridine lie in the region < 300 nm (*ca* 250–256 nm). These bands did not show any solvatochromic effect in the 4-cyanopyridine complexes, indicating no change in the dipole moments of the molecule in the ground and excited states.

In mono- and binuclear 4-cyanopyridine 1-oxide complexes there appeared to be a very weak band in the visible region, 400–500 nm, assigned to a metal-to-ligand charge-transfer band. Since this band is very weak and it appears to be masked by the tail of the 350 nm band, no solvatochromic effect could be studied. A band in the region (340–370 nm) was found to be very slightly solvent sensitive, showing a small solvatochromic effect. These bands have been assigned to either a n–π^* transition where one of the p-electrons is excited from the non-bonding orbital of the oxygen atom to an antibonding π^*-orbital or to the MLCT (Ru^{II}) to antibonding C_5H_5 orbitals. Very strong absorption bands appeared in the UV region < 300 nm (Fig. 2) (λ_{max} varies within the range 280–300 nm depending on the solvent used) in the spectra of both the mono- and the binuclear 4-cyanopyridine 1-oxide complexes. These strong bands due to a $\pi \rightarrow \pi^*$ charge-transfer in the pyridine oxide ring, were found to be the most striking feature in these complexes,[44,45] and are very sensitive to the nature of the solvents used. This suggested a strong interaction between the NO group and the π-electrons of the ring. These transitions also showed a distinct blue shift in going from non-polar to polar solvents. In —OH group-containing polar solvents like methanol or isopropyl alcohol there is an average shift of 10–15 nm in λ_{max} towards the higher energy side (Table 2). There hypsochromic shifts could be explained on the basis of stabilization of the ground state by hydrogen bonding between the pyridine 1-oxide ring and methanol or isopropyl alcohol.

Table 3. Values for ruthenium(II) 4-cyanopyridine and ruthenium(II) 4-cyanopyridine-1-oxide complexes vs SSCE at 22+2°C in acetonitrile

Complexes	Process	$E_{1/2}$ (V)
$[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpy)(PPh_3)_2]Cl$	$Ru^{III/II}$	0.52, 1.24
$[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpy)(PPh_3)_4](BPh_4)_2$	$Ru^{III/II}$	0.26, 0.96
$[(\eta^5\text{-}C_5H_5)Ru(4\text{-}CNpy)(PPh_3)_2]Cl$	$Ru^{III/II}$	0.8, 1.16
$[(\eta^5\text{-}C_5H_5)_2Ru_2(\mu\text{-}4\text{-}CNpyO)(PPh_3)_4](PF_6)_2$	$Ru^{III/II}$	0.36, 1.12

Cyclic voltammograms were recorded at 0.2 V s^{-1} in acetonitrile and the values of $E_{1/2}$ (vs SSCE) for the different processes are shown in Table 3, including the corresponding values for related mono- and binuclear species. Both the metal- and ligand-centred redox processes were found to be chemically irreversible. For monodentate 4-cyanopyridine complexes the Ru^{III}/Ru^{II} potential falls in the range consistent with pyridine nitrogen coordination. The C_5H_5- and PPh_3-centred redox processes were also observed,[46] $E_{1/2} = 0.59$ V, in addition to the 4-cyanopyridine-centred redox process.

SYNTHESIS AND REACTIVITIES OF LANTHANIDE–YLIDIC COMPLEXES

WAI-KWOK WONG,* HUA CHEN and FONG-LUNG CHOW

Department of Applied Biology and Chemical Technology, Hong Kong Polytechnic, Hung Hom, Kowloon, Hong Kong

(*Received* 12 *September* 1989; *accepted* 24 *October* 1989)

Abstract—The reaction of $[Li(Et_2O)_2][Cp'_2MCl_2]$ ($Cp' = C_5Me_5$; M = Nd, Sm) with 1 equivalent of $Li(CH_2)(CH_2)PRR'$ (**a**, R = Me, R′ = Ph; **b**, R = R′ = Ph; **c**, R = R′ = Me; **d**, R = R′ = *t*-Bu) produces $Cp'_2M[(CH_2)(CH_2)PPR'] \cdot (LiCl)_2$ (**I**, M = Sm; **II**, M = Nd) in moderate yield. Variable-temperature ^1H NMR studies on $Cp'_2M[(CH_2)(CH_2)P(Me)R] \cdot (LiCl)_2$ (M = Nd, Sm; R = Me, Ph) show that the methyl protons on the phosphorus of the chelating ylide undergo rapid exchange with the bridging methylene protons even at −40°C. A mechanism which is based on a series of metal–carbon bond breaking, rotation and recombination processes has been proposed for the fluxional behaviour. The ylidic complexes react with hydrogen (1 atm) at ambient temperature producing C_5Me_5H and the corresponding phosphonium salts, $[RR'PMe_2]Cl$. ^1H NMR studies on the reactivity of **Ia** towards hydrogen and acid review that the metal–carbon bond formed between the lanthanide metal and the chelating phosphorus ylide is more stable than that formed between the lanthanide metal and the pentamethylcyclopentadienyl ring.

Phosphorus ylides have been shown to possess an extensive coordination chemistry with main group and transition metal atoms and to form metal–carbon σ-bonds of unusual stability.[1] Gilje and coworkers have extended the ylidic chemistry to actinide metals and have synthesized a series of phosphorus ylidic organouranium complexes.[2] Although σ-alkyl organolanthanide complexes have been studied extensively recently, only a few ylidic organolanthanide complexes have been reported.[3] In this paper, we describe the preparation, solution dynamics and reactivities of a series of phosphorus ylidic organolanthanide complexes, $Cp'_2M[(CH_2)(CH_2)PRR'] \cdot (LiCl)_2$, ($Cp' = C_5Me_5$; M = Sm, Nd).

RESULTS AND DISCUSSION

Preparation of chelating phosphorus ylidic organolanthanide complexes

The interaction of $[Li(Et_2O)_2][Cp'_2MCl_2]$ (M = Nd, Sm; $Cp' = C_5Me_5$) with 1 equivalent of $Li(CH_2)(CH_2)PRR'$ in an ether–THF or toluene solution at −78°C gives the corresponding chelating phosphorus ylidic organolanthanide complexes in moderate yield, as shown in eq. (1):

$$[Li(Et_2O)_2][Cp'_2MCl_2] + Li(CH_2)(CH_2)PRR' \xrightarrow[-78°C]{Et_2O\text{–}THF \text{ or toluene}} Cp'_2M[(CH_2)(CH_2)PRR'] \cdot (LiCl)_2 \quad (1)$$

Ia-d or **IIa–b**

I, M = Sm; **II**, M = Nd

a, R = Me, R′ = Ph; **b**, R = R′ = Ph;

c, R = R′ = Me; **d**, R = R′ = *t*-Bu.

Invariably, the organolanthanide complexes always co-crystallize with lithium chloride. The novel organolanthanide complexes are characterized by elemental analyses, NMR and IR spectroscopies. These complexes are insoluble in saturated hydrocarbons, sparingly soluble in toluene and ether, very soluble in THF, and extremely air- and moisture-sensitive. The physical and spectroscopic data are given in Tables 1 and 2.

Both the neodymium- and samarium–ylidic complexes show strong absorption and emission in the visible region. Details of the photochemistry of

these phosphorus ylidic organolanthanide complexes will be reported in a separate paper.

^{1}H *NMR studies*

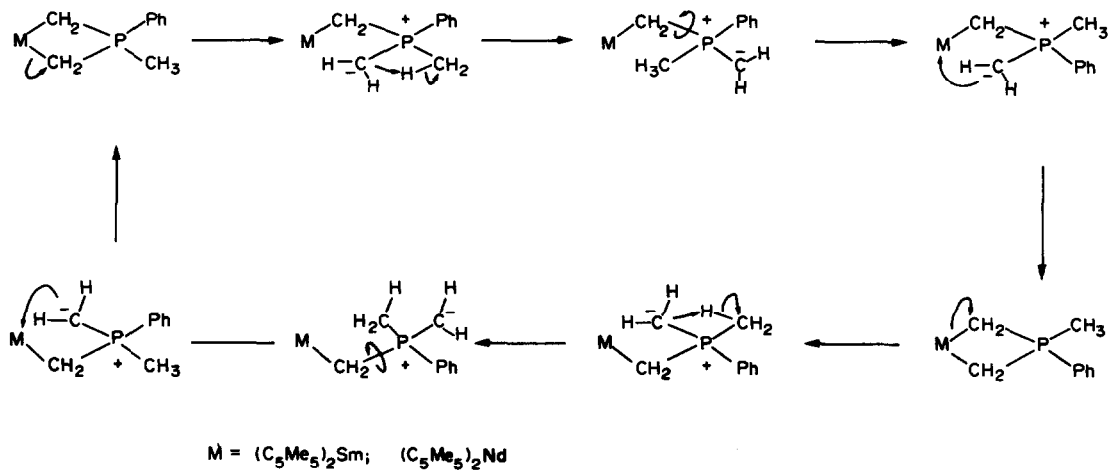
Variable-temperature ^{1}H NMR studies on the chelating phosphorus ylidic organolanthanide complexes review the following:

(i) The chemical shifts of the proton resonances of the novel complexes vary as a function of the temperature. The effect is more pronounced for the neodymium complexes than for the samarium complexes. In the case of the samarium complex, **Ia**, the resonance of the the C_5Me_5 protons shifts from δ 1.60 ppm at -40°C to δ 1.37 ppm at 30°C; whereas the chemical shifts of the methyl, bridging methylenes and phenyl protons remain relatively unchanged over the temperature range -40–30°C. Similar results are also observed for the other samarium complexes, **Ib–d**. In the case of the neodymium complex, **IIa**, the resonance of the C_5Me_5 protons shifts from δ 10.61 ppm at -40°C to δ 8.46 ppm at 30°C, and the resonances of the methyl and bridging methylene protons shift from δ -6.27 ppm at -40°C to δ -3.55 ppm at 30°C. Similar results are also observed for the neodymium complex, **IIb**.

(ii) A facile exchange process takes place between the methyl group and the bridging methylene groups of the phosphorus ylide of $Cp'_2M[(CH_2)(CH_2)P(Me)R]\cdot(LiCl)_2$ (M = Sm, Nd; R = Me, Ph). In $CDCl_3$ at 30°C, the ^{1}H NMR spectrum of **Ia** exhibits a singlet, a doublet and a multiplet of relative intensity 30:7:5 at δ 1.37, 2.08 and 7.55 ppm, respectively. The doublet at δ 2.08 ppm (J = 14.0 Hz) of intensity 7 is assigned to the methyl protons and the bridging methylene protons. The chemical shifts of the methyl protons and the bridging methylene protons of the phosphorus ylide coalesce even at -40°C. Similar results are also observed for **Ic** and **IIa**. For **IIa**, the ^{1}H NMR spectrum in $CDCl_3$ at 30°C exhibits a multiplet centred at δ -3.55 ppm of intensity 7 for the methyl group and the two bridging methylene groups. At -40°C, the resonance shifts to δ -6.27 ppm without any change in intensity. The above observations suggest that the methyl protons undergo a facile exchange with the bridging methylene protons of the phosphorus ylide. The observed fluxional behaviour can be explained by the mechanism shown in Scheme 1, which involves a series of metal–carbon bond-breaking, proton transfer, rotation and recombination processes. A similar mechanism has also been proposed for the fluxional behaviour of the bridging methylene protons of the phosphorus ylide of $Cp'_2M(Cl)[(CH_2)(CH_2)P(Me)(Ph)]$ (M = Th, U).[2]

Reaction with hydrogen

In THF solution, complexes **Ia,b** and **IIa,b** react rapidly with hydrogen (1 atm) at ambient temperature to give C_5Me_5H and the corresponding phosphonium salt, $[Me_2PhPR]Cl$, as the only isolated products. Their identities were confirmed by ^{1}H NMR spectroscopy. Attempts to isolate the organometallic fragments were unsuccessful. ^{1}H NMR studies on the above reaction revealed that the ylidic complexes react rapidly with hydrogen to release C_5Me_5H first, then the phosphonium salt, $[Me_2PhPR]Cl$. For example, the ^{1}H NMR spectrum of **Ia** in $CDCl_3$, after passing hydrogen through it



Scheme 1. Exchange mechanism for the fluxional behaviour of **Ia** and **IIa**.

for 1 min at 1 atm, shows that the intensity of the singlet at δ 1.37 ppm, which corresponds to the $C_5Me_5^-$ resonance, of **Ia** decreases with the concomitant appearance of a broad singlet and a doublet (J = 8.1 Hz) of relative intensity 4:1 at δ 1.79 and 0.99 ppm, respectively. The new resonances are indicative of C_5Me_5H. The intensity of the C_5Me_5H resonances increases as the intensity of the C_5Me_5 resonances of **Ia** decreases. Upon complete disappearance of the singlet at δ 1.37 ppm, a new doublet (J = 14.4 Hz) appears at δ 2.59 ppm. The intensity of this doublet increases as the intensity of the doublet (J = 14.0 Hz) at δ 2.08 ppm, which corresponds to the methyl and bridging methylene protons of the chelating phosphorus ylide, decreases. Eventually, the doublet at δ 2.08 ppm disappears completely, then the intensity of the new doublet at δ 2.59 ppm remains relatively constant. The new doublet at δ 2.59 ppm is identical to the methyl resonance of a genuine sample of $[PhPMe_3]Cl$. The results suggest that the metal–carbon bond formed between the lanthanide metal and the phosphorus ylide is stronger and more stable than that formed between the lanthanide metal and the $C_5Me_5^-$ ring.

Reaction with acid

The relative strength of the metal–carbon bonds is further demonstrated by the reaction of **Ia** with trifluoroacetic acid. A ^1H NMR study of the above reaction shows that when **Ia** is treated with a limited amount of CF_3CO_2H, the intensity of the C_5Me_5 resonances of **Ia** at δ 1.37 ppm decreases with the concomitant appearance of C_5Me_5H resonances. The intensity of **Ia** resonances decreases and that of the C_5Me_5H resonances increases as more CF_3CO_2H is added to the sample. After complete disappearance of the resonance at δ 1.37 ppm, further addition of CF_3CO_2H decreases the intensity of the chelating phosphorus ylide resonance at δ 2.08 ppm (doublet, J = 14.0 Hz) with the concomitant appearance of $[PhPMe_3]Cl$ resonances at δ 2.59 ppm (doublet, J = 14.4 Hz). The intensity of the chelating phosphorus ylide resonances decreases and that of the phosphonium salt resonances increases as more CF_3CO_2H is added to the sample. When excess CF_3CO_2H is added to the sample, the only observable resonances are those of C_5Me_5H and $[PhPMe_3]Cl$. The above ^1H NMR study shows that when **Ia** reacts with acid, C_5Me_5H is liberated first, followed by the corresponding phosphonium salt. This further supports the idea that the metal–carbon bond formed between the lanthanide metal and the chelating phosphorus ylide is more stable than that formed between the lanthanide metal and the $C_5Me_5^-$ ring.

EXPERIMENTAL

Microanalyses were performed by Butterworth (U.K.). IR spectra were obtained on a Perkin–Elmer 983 spectrometer; data given in cm^{-1} for Nujol mulls unless otherwise specified. NMR spectra were recorded on a JEOL FX90Q spectrometer. Chemical shifts were referenced to internal deuterated solvents and then recalculated to TMS = 0.0 ppm. ^{31}P NMR spectra were referenced to external 85% H_3PO_4.

All operations were carried out under nitrogen or *in vacuo*. All chemicals used were of reagent grade. Solvents were dried by standard procedures, distilled and deaerated prior to use. Melting points were taken in sealed capillaries and are uncorrected. $Li[(CH_2)(CH_2)PRR']$[4] and $[Li(OEt_2)_2][Cp'_2MCl_2]$[5] were prepared according to literature methods.

Syntheses

$Cp'_2Sm[(CH_2)(CH_2)P(Me)(Ph)]\cdot(LiCl)_2$ (**Ia**). A solution of $[Li(OEt_2)_2][Cp'_2SmCl_2]$ (1.40 g, 2.2 mmol in 20 cm^3 of a 3:1 mixture of Et_2O–THF) was added to a suspension of $Li[(CH_2)(CH_2)P(Me)(Ph)]$ (0.39 g, 2.4 mmol) in 20 cm^3 of Et_2O at −78°C. The orange solution turned yellow. The reaction mixture was allowed to warm slowly to room temperature and stirred for an additional 30 min. The light yellow solution was filtered and the yellow residue was extracted twice with 10 cm^3 of Et_2O and once with 5 cm^3 of THF. The combined filtrate was cooled to −20°C to give yellow crystals which were filtered and dried under high vacuum. Yield: 0.8 g, 55%; m.p. 196–198°C. [Found (required): C, 51.5 (53.0); H, 6.4 (6.5); P, 4.6 (4.7); Cl, 10.2 (10.8)%.]

$Cp'_2Sm[(CH_2)(CH_2)P(Ph)_2]\cdot(LiCl)_2$ (**Ib**). **Ib** was prepared according to the general procedure outlined above for **Ia** using 0.56 g (0.87 mmol) of $[Li(OEt_2)_2][Cp'_2SmCl_2]$ and 0.23 g (1.05 mmol) of $Li[(CH_2)(CH_2)P(Ph)_2]$. Yellow crystals were obtained. Yield: 0.4 g, 64%; m.p. 226–228°C. [Found (required): C, 55.8 (56.8); H, 6.3 (6.2); P, 4.4 (4.3); Cl, 9.0 (9.8)%.]

$Cp'_2Nd[(CH_2)(CH_2)P(Me)(Ph)]\cdot(LiCl)_2$ (**IIa**). **IIa** was prepared according to the general procedure outlined above for **Ia** using 1.37 g (2.3 mmol) of $[Li(OEt_2)_2][Cp'_2NdCl_2]$ and 0.40 g (2.5 mmol) of $Li[(CH_2)(CH_2)P(Me)(Ph)]$. Blue crystals were obtained from the combined blue filtrate. Yield: 0.9 g, 60%; m.p. 191–193°C. [Found (required): C, 52.5 (53.5); H, 6.3 (6.5); P. 4.8 (4.8); Cl, 10.4 (10.9)%.]

$Cp'_2Nd[(CH_2)(CH_2)P(Ph)_2]\cdot(LiCl)_2$ (**IIb**). **IIb** was prepared according to the general procedure outlined above for **Ia** using 2.30 g (3.6 mmol) of $[Li(OEt_2)_2][Cp'_2NdCl_2]$ and 0.82 g (3.7 mmol) of $Li[(CH_2)(CH_2)P(Ph)_2]$. Blue crystals were obtained from the combined blue filtrate. Yield: 1.7 g, 66%; m.p. 209–210°C. [Found (required): C, 56.5 (57.3); H, 6.1 (6.2); P, 4.5 (4.4); Cl, 9.1 (9.9)%.].

$Cp'_2Sm[(CH_2)(CH_2)P(Me)_2]\cdot(LiCl)_2$ (**Ic**) (*one-pot procedure*). A suspension of Cp'Li (0.95 g, 6.7 mmol) and anhydrous $SmCl_3$ (0.81 g, 3.2 mmol) in 60 cm^3 of THF was refluxed overnight. The resultant orange solution of $[Li(THF)_2][Cp'_2SmCl_2]$ was filtered and kept for later use. MeLi (10 cm^3 of a 1.0 M solution in Et_2O, 10 mmol) was added to a suspension of Me_4PI (0.77 g, 3.5 mmol) in 40 cm^3 of Et_2O at room temperature. During the course of the reaction, the suspension turned clear and then gave white precipitates. After stirring at room temperature for 4 h, the solution was filtered and the white precipitates were washed twice with 20 cm^3 of Et_2O to remove LiI and excess MeLi. The white precipitates were then dissolved in 10 cm^3 of THF at −78°C. The $[Li(THF)_2][Cp'_2SmCl_2]$ solution obtained from above was then added to the $Li[(CH_2)(CH_2)P(Me)_2]$ solution at −78°C. The orange solution turned yellow immediately. The solution was allowed to warm to room temperature and stirred for an additional 2 h before it was filtered. The residue was then extracted with 10 cm^3 of THF. The combinated filtrate was evaporated *in vacuo*. The resultant yellow residue was extracted with CH_2Cl_2 (3×10 cm^3). The solution was filtered, concentrated to *ca* 10 cm^3, and cooled to −20°C to give yellow needle crystals which were filtered and dried *in vacuo*. Yield: 1.2 g, 63%; m.p. 210°C (decomposed). [Found (required): C, 48.6 (48.5); H, 7.1 (6.8); P, 4.8 (5.2); Cl, 11.2 (11.9)%.].

$Cp'_2Sm[(CH_2)(CH_2)P(t\text{-}Bu)_2]\cdot(LiCl)_2$ (**Id**). **Id** was prepared according to the general procedure outlined above for **Ic** using 0.69 g (4.9 mmol) of Cp'Li and 0.61 g (2.4 mmol) of $SmCl_3$ to prepare $[Li(THF)_2][Cp'_2SmCl_2]$, and 6 mmol (6 cm^3 of 1.0 M solution in Et_2O) of MeLi and 0.69 g (2.3 mmol) of $[t\text{-}Bu_2PMe_2]I$ to prepare $Li[(CH_2)(CH_2)P(t\text{-}Bu)_2]$. The resultant yellow solution was filtered, evaporated and the residue extracted with a toluene–CH_2Cl_2 mixture (2×20 cm of a 1 : 1 mixture). The filtered extract was concentrated to *ca* 25 cm^3 and cooled to −20°C to give yellow crystals which were filtered and dried *in vacuo*. Yield: 0.8 g, 51%; m.p. 220°C (decomposed). [Found (required): C, 52.5 (53.1); H, 8.0 (7.7); P, 4.2 (4.6); Cl, 9.8 (10.4)%.]

Reaction with hydrogen

Hydrogen gas (1 atm) was bubbled through a solution of **Ia** (0.40 g, 0.6 mmol) in 20 cm^3 of THF at ambient temperature. After passing hydrogen gas for 5 min, the solution turned cloudy and white solids were precipitated out from the solution. Hydrogen gas was continuously bubbled through the solution for a further 25 min. The solution was then allowed to stir for an additional 2 h at ambient temperature. The solution was filtered and the white precipitates were washed twice with 5 cm^3 of THF. The ^1H NMR spectrum of the white precipitates was identical to that of a genuine sample of $[PhPMe_3]Cl$. Yield of $[PhPMe_3]Cl$ was 0.10 g, 88%. The combined filtrate was evaporated and the residue was extracted twice with 10 cm^3 of Et_2O. Upon removal of the solvent from the Et_2O filtrate, a light yellow oil was obtained. The ^1H NMR spectrum of the oil was identical to that of a genuine sample of C_5Me_5H.

^1H NMR studies

(i) **Ia** *with hydrogen*. 20 mg of **Ia** was dissolved in 0.5 cm^3 of $CDCl_3$ at ambient temperature. Hydrogen gas (1 atm) was bubbled through the solution slowly for 1 min. Then the course of the reaction was monitored by ^1H NMR spectroscopy at 5 min intervals for 1 h.

(ii) **Ia** *with* CF_3CO_2H. 20 mg of **Ia** was dissolved in 0.5 cm^3 of $CDCl_3$ at ambient temperature. CF_3CO_2H was then added to the solution via a microsyringe. The course of the reaction was monitored by ^1H NMR spectroscopy after every addition of 1×10^{-3} cm^3 of CF_3CO_2H to the solution. Addition of CF_3CO_2H was continued until there was no further change in the ^1H NMR spectrum upon addition of more CF_3CO_2H.

CHEMISTRY OF MOLYBDENUM WITH HARD–SOFT DONOR LIGANDS—III. OXOMOLYBDENUM(VI) AND *CIS*-DIOXOMOLYBDENUM(VI) MIXED LIGAND COMPLEXES

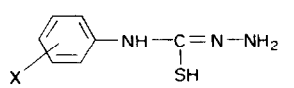
SANCHITA PUROHIT, ADITYA PRASAD KOLEY and SAKTIPROSAD GHOSH*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta—700032, India

(*Received* 19 *June* 1989; *accepted* 2 *November* 1989)

Abstract—The syntheses and characterization of a number of oxomolybdenum(VI) and *cis*-dioxomolybdenum(VI) complexes with 4-substituted thiosemicarbazides in the form of 4-phenyl, 4-(*p*-methylphenyl) and 4-(*p*-chlorophenyl)thiosemicarbazide (represented as LH) as the NS donor metal binding substrates are described. The oxomolybdenum(VI) complexes are of the type $MoO(NS)_2X_2$ and $MoO(NS)_2(O—O)$ (where X = Br or SCN and O—O = oxalate or malonate) with a pentagonal bipyramidal geometry. The *cis*-dioxomolybdenum(VI) complexes are mixed chelate complexes, $MoO_2(NS)L'$, where L'H is either a monoprotic NO donor like oxine, 2-methyloxine or a NS donor such as 2-aminobenzenethiol, 2-aminocyclopent-1-ene-1-dithiocarboxylic acid and its methyl ester. The electrochemical behaviour of these complexes along with *cis*-$MoO_2(NS)_2$ and $MoO(NS)_2Cl_2$ complexes are discussed.

Recently there has been much interest in the chemistry of oxo complexes of molybdenum[1–8] with sulphur, nitrogen and/or oxygen donor ligands due to their relevance to the active sites of certain molybdoenzymes. Thus, design and synthesis of oxomolybdenum complexes have currently become a fascinating field of research in the domain of coordination chemistry. As a part of our ongoing research programme in this area we have recently reported[9] the synthesis and characterization of some *cis*-dioxomolybdenum(VI) complexes of the type MoO_2L_2 and seven-coordinated pentagonal bipyramidal oxomolybdenum(VI) complexes, $MoOL_2Cl_2$, where LH is a monoprotic bidentate NS donor ligand in the form of the 4-substituted thiosemicarbazides (**I**). Here, we present the synthesis and characterization of $MoOL_2Br_2$ (LH = 4-phenyl, 4-(*p*-methylphenyl), 4-(*p*-chlorophenyl) thiosemicarbazides) obtained by the reaction of MoO_2L_2 with HBr and the complexes obtained by direct replacement of the halogens (of $MoOL_2X_2$, X = Cl, Br) by thiocyanate, oxalate and malonate. The redox behaviour of MoO_2L_2, $MoOL_2X_2$ (X = Cl, Br, SCN) and $MoOL_2(O—O)$ (O—O = ox, mal) complexes have been studied by cyclic voltammetry.



X = H, *p*-CH_3, *p*-Cl

I

Although a number of *cis*-dioxomolybdenum(VI) bis-chelate complexes having NS, NO or SS donor atoms have been studied earlier,[9–14] complexes containing two different bidentate ligands have not been investigated adequately. In the present paper, along with the homochelate complexes we also report the synthesis, characterization and electrochemical properties of a number of *cis*-dioxomolybdenum(VI) heterochelate complexes of the type MoO_2LL', where LH is either a 4-phenyl or 4-(*p*-chlorophenyl)thiosemicarbazide and L'H is either a NO donor ligand like 8-hydroxyquinoline (oxine), 2-methyl-8-hydroxyquinoline (2-Me-oxine) or a NS donor ligand like 2-aminobenzenethiol (abt), 2-aminocyclopent-1-ene-

1-dithiocarboxylic acid (acda) and its methyl ester (acdaMe).

EXPERIMENTAL

Molybdenyl acetylacetonate was prepared from ammonium *para*-molybdate (Aldrich Chemicals) by a known[15] method. Analytical reagent grade solvents, distilled and dried by standard methods were used in all cases. All other chemicals were of reagent grade and were employed without further purification. Tetraethylammonium perchlorate (TEAP) was prepared from tetraethylammonium bromide (Fluka AG) using a standard procedure.[16] The ligands 4-phenylthiosemicarbazide (4-PhTSC), 4-(*p*-chlorophenyl)thiosemicarbazide [4-(*p*-Cl)PhTSC] and 4-(*p*-methylphenyl)thiosemicarbazide [4-(*p*-CH_3)PhTSC] were prepared from the corresponding amines using the reported[17] method. The compounds acda[18] and its methyl ester, acdaMe,[19] were prepared following the methods reported earlier.

Synthesis of complexes

$MoOL_2Br_2$ (**2c–e**). To a stirred suspension of MoO_2L_2[9] (1 mmol) in methanol (25 cm^3), concentrated HBr (48%, 0.5 cm^3) was added dropwise over a period of 30 min with constant stirring. The maroon complex slowly dissolved to yield a dark red solution. Stirring was continued for 48 h at room temperature and the volume of the solution was reduced to 10 cm^3 when a dark microcrystalline compound separated out. It was filtered, washed with cold methanol followed by solvent ether and dried *in vacuo*. Yield: 50%.

$MoO(4\text{-PhTSC})_2(SCN)_2 \cdot 2H_2O$ (**3a**). A well stirred solution of 0.258 g (0.5 mmol) of $MoO(4\text{-PhTSC})_2Cl_2$[9] in 25 cm^3 of dry methanol was allowed to react with 0.76 g (1 mmol) of ammonium thiocyanate. The solution turned deep red and was stirred for about 3 h at room temperature. Then the volume of the solution was reduced to about 10 cm^3 when a dark red microcrystalline compound separated out. It was filtered off, washed with ice-cold methanol and dried *in vacuo*. Yield: 40%.

$MoO(4\text{-PhTSC})_2(ox) \cdot 4H_2O$ (**3b**) *and* $MoO(4\text{-PhTSC})_2(mal) \cdot 2H_2O$ (**3c**). These were prepared using the same procedure as above but using oxalic acid and malonic acid, respectively. These complexes were also prepared using $MoO(4\text{-PhTSC})_2Br_2$ as the starting materials.

MoO_2(4-PhTSC) (acda) (**4a**). To a filtered solution of 0.33 g (1 mmol) of $MoO_2(acac)_2$ in 30 cm^3 of dry methanol, a solution of 0.17 g (1 mmol) of 4-PhTSC in 20 cm^3 of dry methanol was added very slowly (over a period of 1 h) with constant stirring at ice-bath temperature when the solution turned deep red. To this solution, 0.16 g (1 mmol) of acda, dissolved in 15 cm^3 of ice-cold methanol, was added over a period of 15 min when a dark microcrystalline compound gradually separated out from the reaction mixture. This was filtered, washed thoroughly with methanol and dried over fused $CaCl_2$ *in vacuo*. Yield: 60%.

MoO_2(4-PhTSC)(acdaMe) (**4c**), MoO_2(4-PhTSC)(abt) (**4e**) *and the corresponding* 4-(*p*-Cl)PhTSC *complexes* (**4b**, **4d** *and* **4f**). These were prepared following the procedure described above. In all cases, dark microcrystalline compounds were obtained in good yield.

MoO_2(4-PhTSC)(oxine) (**4g**). A solution of 0.17 g (1 mmol) of 4-PhTSC in 20 cm^3 of dry methanol was added very slowly to a filtered solution of 0.33 g (1 mmol) of $MoO_2(acac)_2$ in 30 cm^3 of dry methanol with constant stirring at ice-bath temperature. To this solution, 0.16 g (1 mmol) of oxine in 20 cm^3 of dry methanol was added over 0.5 h when a dark maroon microcrystalline compound began to separate out. The stirring was continued for about 4 h at room temperature and the precipitated compound was collected by filtration. It was washed thoroughly with methanol and dried *in vacuo*. Yield: 70%.

MoO_2(4-PhTSC)(2-Me-oxine) (**4i**) *and the corresponding* 4-(*p*-Cl)PhTSC *complexes* (**4h, 4j**). These were prepared in good yield using the same procedure described above.

Physical measurements

Carbon, hydrogen and nitrogen analyses were performed on a Perkin–Elmer 240 C,H,N-analyser. Molybdenum was estimated gravimetrically using oxine as the reagent. The IR spectra were recorded as KBr discs using a Perkin–Elmer 783 spectrophotometer. Electronic spectra of the compounds were recorded on a Pye-Unicam model SP8-150 UV–vis spectrophotometer using spectral grade solvents. Electrical conductance data in solution were obtained on a Philips PR-9500 conductivity bridge fitted with a dip-type cell calibrated with 0.02 M KCl solution. Static susceptibility measurements at room temperature were made with the help of a Princeton Applied Research Vibrating Sample Magnetometer Model 155 using $Hg[Co(SCN)_4]$ as the calibrant. Electrochemical studies were carried out with the help of a PAR Model 370-4 electrochemistry system: 174A polarographic analyser, 175 universal programmer, RE 0089 *X–Y* recorder. All the experiments were carried out under a dry nitrogen atmosphere in a three-electrode con-

figuration. A planar Beckman Model 39273 platinum electrode was used as the working electrode. The results were collected at 298 ± 1 K and are referenced to a saturated calomel electrode (SCE). The reported potentials are uncorrected for junction contribution.

RESULTS AND DISCUSSION

During syntheses of $MoOL_2Br_2$ complexes (**2c–e**) by the reaction of a suspension of MoO_2L_2 in methanol with two equivalents of HBr, the electron-rich oxygen atom undergoes protonation in the first step which is immediately followed by bromide ion inclusion in the metal coordination sphere with simultaneous expansion of coordination number. These are assumed to be two consecutive steps involved in the actual reaction pathway.[20–22] The thiocyanato, oxalato and malonato complexes (**3a–c**) were prepared by the direct replacement of the halide ions from $MoOL_2X_2$ (L = 4-PhTSC, X = Cl, Br). The mixed chelate complexes (**4a–j**) of the type MoO_2LL' have been prepared *in situ* by adding the ligand L'H to a solution of MoO_2(acac)(L) generated in the medium. Thin-layer chromatography (TLC) indicates the presence of a single species in each of these compounds. All the compounds are found to be air-stable.

Results of elemental analysis (Table 1) are in good agreement with the assigned formulations. All the complexes are diamagnetic as expected for the d^0 molybdenum(VI) state. All the oxomolybdenum(VI) complexes (**2c–e**, **3a–c**) are highly soluble in common organic solvents. The com-

Table 1. Analytical data of the complexes

pounds are non-electrolytes in dry acetonitrile. However, it was noted that in a freshly prepared DMF solution of the bromo complexes the conductivity slowly increases, probably due to the partial dissociation[23] of the coordinated bromide ions. It was found that the extent of dissociation of bromide ions is greater than that of the chloride ions in the analogous complexes. Attempts to isolate the solvolysed products yielded dark oils that could not be crystallized. The *cis*-dioxomolybdenum(VI) mixed chelate complexes are highly soluble in DMF and DMSO but are found to have poor solubility in common organic solvents. These are non-electrolytes in DMF.

IR spectra

Analysis of the IR spectra of the complexes indicate that the substituted thiosemicarbazides coordinate exclusively in the enol form via the deprotonated thiol sulphur and the nitrogen atom of the terminal $—NH_2$ group as reported earlier.[9]

In the oxomolybdenum(VI) complexes (**2c–e**, **3a–c**), the strong terminal $\nu(Mo{=}O)$[20,21,24] mode is observed in the region 935–955 cm^{-1}. For the $MoOL_2Br_2$ complexes, the $\nu(Mo—Br)$ bands are observed around 280 cm^{-1}. In the thiocyanato complex, the $\nu(CN)$ vibration is located at 2070 cm^{-1}, indicating that the SCN^- moiety is coordinated to the molybdenum(VI) acceptor centre through the nitrogen atom.[25]

All the *cis*-dioxomolybdenum(VI) heterochelate complexes (**4a–j**) display their characteristic two-band pattern[26,27] in the 900–960 cm^{-1} region. In the acda complexes (**4a**, **b**), the absence of the $\nu(SH)$[18] band of the free ligand (acda) at $\sim$ 2550 cm^{-1} indicates metal–ligand bond formation through the deprotonated thiocarboxylate sulphur. Because of the involvement of the $—NH_2$ group of the free ligand in strong hydrogen bonding, the observed difference in the position of $\nu(NH)$[18] bands in the free ligand and its complexes bonded through the amino group is very small. In the complexes, the $\nu_{as}(CSS)$ stretching of the ligand at 880 cm^{-1} is found to split symmetrically[18] into two bands at 900 and 860 cm^{-1}, respectively and points to unidentate sulphur chelation. Hence, it is expected that in these complexes acda is coordinated to the metal ion through the nitrogen atom of the $—NH_2$ group and the deprotonated thiocarboxylate sulphur. The ligand, acdaMe, is also intramolecularly hydrogen bonded.[28] For this reason, the broad, weak ligand band at 3300 cm^{-1}, assignable to $\nu(NH)$, remains almost unaffected in the complexes (**4c**, **d**). The band due to $\nu(SCH_3)$ in the ligand remains unchanged in the complexes. Two medium intensity bands at 915 and 620 cm^{-1} assignable to $\nu_{as}(CSSCH_3)$ and $\nu_s(CSSCH_3)$, respectively,[28] are slightly shifted ($\sim$ 10 cm^{-1}) to the higher frequency region in these metal chelates. Hence, it may be suggested that in conformity with earlier observations,[28] acdaMe coordinates through the thiocarbonyl sulphur and the deprotonated amino group ($—NH^-$). Disappearance of the ligand (abt) band at 2520 cm^{-1} due to $\nu(SH)$[29] in the IR spectra of the abt complexes (**4e**, **f**) clearly indicates that the ligand coordinates to the metal through the deprotonated thiol sulphur. Shifting of the ligand bands at 3450 and 3355 cm^{-1}, arising due to $\nu_{as}(NH)$ $\nu_s(NH)$,[29] towards lower wave numbers by a margin of $\sim$ 80 cm^{-1} in the complexes points to the involvement of the nitrogen atom of the $—NH_2$ group in coordination. This is corroborated by the fact that the ligand band due to $\delta(NH_2)$ is found to suffer a reduction of 30–40 cm^{-1} in the complexes.

Electronic spectra

For all the complexes the lowest energy band observed in the 450–500 nm region may be assigned to $S(p\pi) \rightarrow Mo(d\pi)$[10,22,30] ligand-to-metal charge-transfer (LMCT) transitions. Other LMCT bands are observed in the region 300–430 nm (Table 2). For the complexes of oxine and 2-Me-oxine (**4g–j**), the bands appearing around 360 and 330 nm may be assigned to the nitrogen-to-molybdenum and oxygen-to-molybdenum charge-transfer transitions,[31] respectively. In the other dioxomolybdenum(VI) complexes it is very difficult to ascertain whether a definite molybdenyl band ($O \rightarrow Mo$ CT) occurs near 330 nm. Even if it is present, this band is probably obscured by the other LMCT bands. For all the complexes, higher energy bands appearing below 300 nm are probably due to internal ligand transitions.

Proposed structures of the complexes

For the seven-coordinated $MoOL_2X_2$ (X = Br, SCN) and $MoOL_2(O—O)$ (O—O = oxalate, malonate) complexes, the most probable structure is a pentagonal bipyramid which has been reported earlier[9,32,33] for the related type of complexes. With one of the two coordinated nitrogen atoms *trans* to the Mo=O bond[9] and the two X groups in *cis* positions,[9] the two possible seven-coordinated pentagonal bipyramid structures are **IIa** and **IIb**. Structures of the $MoOL_2(O—O)$ type complexes can be easily visualized by replacing the two *cis* X ions by an oxalate or malonate moiety.

Structures of the mixed ligand complexes (**4a–j**)

Voltammetric studies

The redox behaviour of some of the MoO_2L_2, $MoOL_2X_2$ (X = Cl, Br, SCN), $MoOL_2$(O—O) (O—O = oxalate, malonate) and MoO_2LL' complexes has been studied using cyclic voltammetry. The results are given in Table 3.

The cyclic voltammogram of MoO_2(4-PhTSC)$_2$ which is typical of all the MoO_2L_2 complexes (**1a–c**) is shown in Fig. 1. For these complexes two irreversible reductive responses are observed near −0.9 and −1.6 V, respectively. On comparing the observed current height at E_{pc}'s with those of the authentic one-electron reductions,[34,35] the first one appears to be a metal-centred one-electron transfer involving the molybdenum(VI) and molybdenum(V) oxidation states:

$$[Mo^{VI}O_2L_2] + e^- \longrightarrow [Mo^{V}O_2L_2]^-.$$

The lack of an anodic response even at high scan rates (500 mV s^{-1}) is evidently due to the instability of the reduced species $[Mo^{V}O_2L_2]^-$.

Electrochemical behaviour of the pentagonal bipyramidal $MoOL_2X_2$ (X = Cl, Br) complexes (**2a–e**) in DMF is complicated but interesting. For these complexes two or more reductive responses are observed (Table 3). All these responses are found to be irreversible which is evidenced by no observable oxidation wave during the reverse anodic scan in the cyclic voltammograms. Irreversible electrochemistry at seven coordinate MoO^{4+} centres results[36] from the fact that the four molybdenum d_{xy} orbital lobes that become singly occupied upon reduction to molybdenum(V) experience unfavourable interactions with the five equatorial bonds

[b] Values in parentheses are coupled oxidation peaks observed with complete CVA cycle.

present in the pentagonal bipyramidal geometry and initiate metal–ligand bond cleavage reactions during charge-transfer. It has been observed for all these complexes that on multiple scan reversal the cyclic voltammogram continuously changes with time until a steady state is reached. It is found that, in the bromo complexes, the first reductive response ~ -0.6 V (Table 3) completely disappears in the second cycle, even when the scan is extended up to +0.5 V. But when the potential is scanned in such a manner as to cycle only the first reductive response, this cathodic peak is found to be reproducible on multiple scan reversal between +0.5 and −0.7 V. Also, the first reductive response is always observed with a fresh scan. It has been noticed that the cyclic voltammograms of the steady state are identical for all the $MoOL_2X_2$ (**2a**–**e**) complexes. The final voltammogram consists of two reductive responses at around −0.85 and −1.55 V (Table 3), respectively, both of which are reproducible on multiple scan reversal. Again, the first response at $E_{pc} \sim -0.85$ V is found to be reproducible when the potential is scanned to cover only the first response and also the E_{pc} value for this peak is almost the same in all cases.

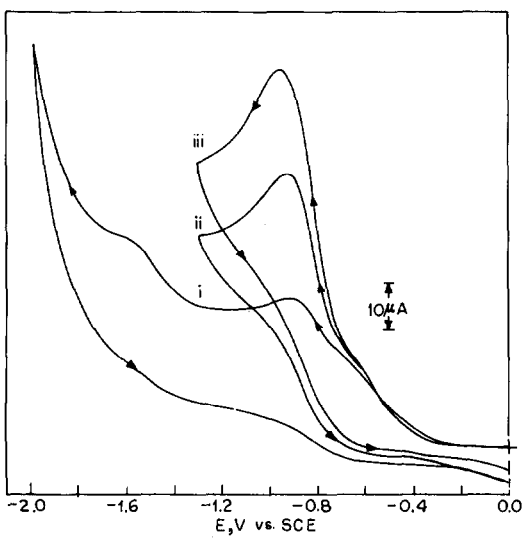

Fig. 1. Cyclic voltammograms for $\sim 1\times10^{-3}$ M MoO_2(4-PhTSC)$_2$ (**1a**) in DMF; scan rates (i) 50, (ii) 100 and (iii) 200 mV s^{-1}.

The course of change of the cyclic voltammogram for MoO(4-(*p*-Cl)PhTSC)$_2Br_2$ is illustrated by Fig. 2. It is noticed that the first reduction wave completely disappears in the second scan, but the current height of the second cathodic peak gradually increases until the steady state is reached. On the other hand, the current height of the third response at around −1.1 V gradually diminishes indicating the decrease in concentration of the species reduced

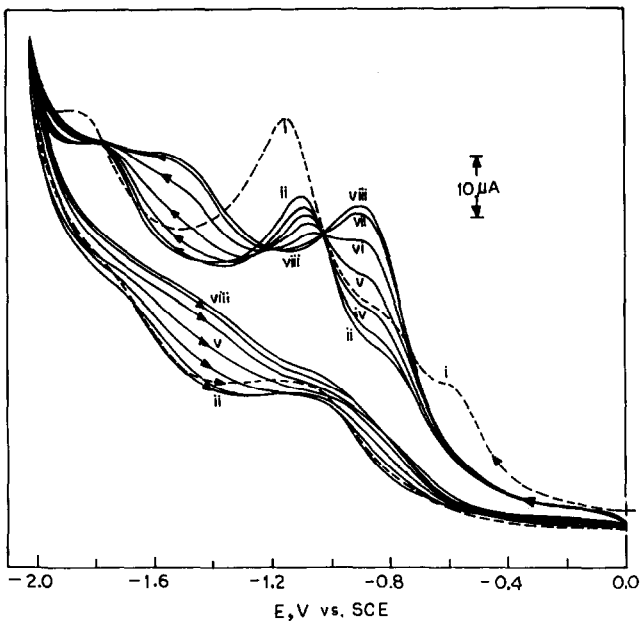

Fig. 2. Cyclic voltammograms for $\sim 1 \times 10^{-3}$ M MoO(4-(*p*-Cl)PhTSC)$_2$Br$_2$ (**2e**) in DMF showing the change with time: (i) initial cathodic scan, (ii) second cycle and (iii) final scan at the steady state.

at this potential and ultimately this response vanishes at the steady state. Also, an anodic shift of the last cathodic wave is observed. The overall process occurring at the electrode may be expressed by the following couples:

is reduced to the corresponding molybdenum(IV) species at ~ -1.1 V, which is ultimately reduced to a molybdenum(III) species with the loss of the remaining halide ion. Thus, the concentration of

$$\begin{array}{ccccc} Mo^{VI}OL_2X_2 & \xrightarrow{+e^-,-X^-} & Mo^{V}OL_2X(DMF) & \xrightarrow{+e^-} & [Mo^{IV}OL_2X(DMF)]^- \\ & & & & \downarrow{\scriptstyle +e^-} \\ [Mo^{VI}OL_2X(DMF)]^+ & \xrightarrow{+e^-} & \uparrow & & \downarrow{\scriptstyle -X^-} \\ [Mo^{VI}OL_2(DMF)_2]^{2+} & \xrightarrow{+2e^-} & Mo^{IV}OL_2(DMF)_2 & \xrightarrow{+e^-} & [Mo^{III}OL_2(DMF)_2]^-. \end{array}$$

It has been confirmed by conductance measurement in DMF that each of the chloro complexes has appreciable conductance ($\Lambda \sim 40\ \Omega^{-1}\ cm^2\ mol^{-1}$), indicating partial dissociation of the chloride ions, while the bromo compounds have conductance values ($\Lambda \sim 100\ \Omega^{-1}\ cm^2\ mol^{-1}$) which lie just above the range of a 1 : 1 electrolyte in DMF. For this reason, all the three possible species $MoOL_2X_2$, $[MoOL_2X(DMF)]^+$ and $[MoOL_2(DMF)_2]^{2+}$ that may be present in the medium, have been taken into active consideration. Here, it is reasonable to guess that the species $[MoOL_2(DMF)_2]^{2+}$, because of its fairly high positive charge, may undergo a facile two-electron reduction at around −0.85 V vs SCE. On the other hand, it is assumed that the halogen-containing species are at first reduced to a molybdenum(V) species, $[MoOL_2X(DMF)]$, which in turn the halide-containing species gradually decreases on multiple scan reversal and finally halogenless species are produced at the steady state when the final species cycles between molybdenum(V), molybdenum(IV) and molybdenum(III) oxidation states. The proposed mechanism, mainly based on the dissociation of the halide ions from the inner coordination sphere of these complexes, receives indirect support from the cyclic voltammetric results (Table 3) of the thiocyanato, oxalato and malonato complexes (**3a–c**), where no change in the cyclic voltammogram (Fig. 3) with time is observed.

Electrochemical behaviour of the MoO_2LL' complexes (**4a–j**) has been examined in deaerated DMSO/0.1 M TEAP within the potential range +0.8 to −2.0 V. Two or more irreversible reductive

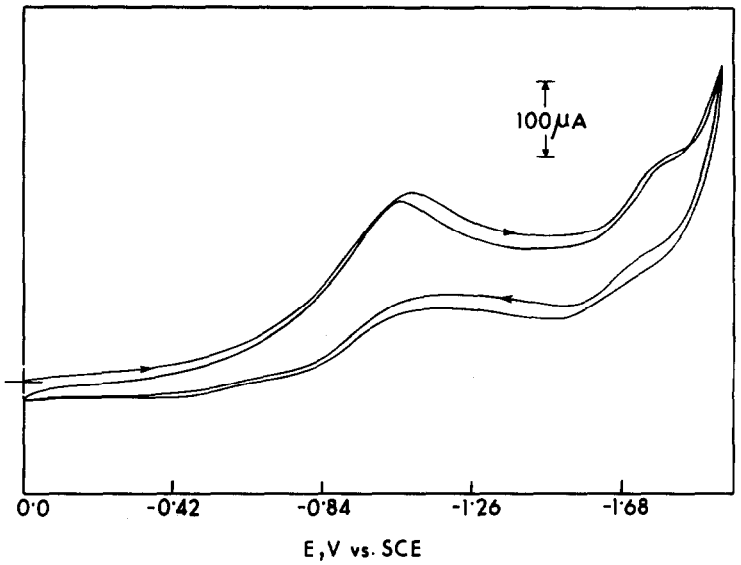

Fig. 3. Cyclic voltammograms for $\sim 1 \times 10^{-3}$ M MoO(4-PhTSC)$_2$(mal)·2H$_2$O (**3c**) in DMF/0.1 M TEAP; scan rate: 50 mV s^{-1}.

responses are observed (Table 3) in the potential range -0.8 to -2.0 V for these complexes [except in the case of oxine compounds (**4g**, **h**)], and that is indicative of either slow electron-transfer kinetics or a chemical process associated with electrochemical reduction. However, on multiple scan reversal the nature of the waves retains their original shapes indicating high reproducibility of the electrode reaction. This suggests that the product of the ECE process, if associated, is not re-oxidized or further reduced in the potential range studied. Electrochemical studies on other *cis*-dioxomolybdenum(VI) complexes have revealed that such complexes[10,23,38,39] generally exhibit irreversible or quasi-reversible behaviour. Spence[13] has shown for a series of molybdenum complexes that molybdenum(V) monomers are not obtainable by electrochemical reduction of the corresponding molybdenum(VI) dioxo complexes. Upon reduction, the dioxomolybdenum(VI) complexes lose an oxo ligand instead of being protonated.[23,40] This oxo loss and subsequent reorganization of the ligand undoubtedly accounts for their irreversible behaviour. A freshly prepared DMSO solution of the complexes (except **4g** and **4h**) exhibits a broad peak/a pair of peaks between -0.8 and -1.1 V (vs SCE). A second broad cathodic peak is observed around -1.72 V for these complexes. At potentials more negative than the second broad peak, another reduction wave, associated with a one- or two-electron transfer process, is observed in the cyclic voltammograms of the 2-Me-oxine compounds (**4i** and **4j**). However, the exact nature of the reduced products cannot be ascertained at this stage due to insufficient data. In this context it may be mentioned here that similar cyclic voltammetric results have been obtained for other *cis*-dioxomolybdenum(VI) complexes.[41,42]

Compared to those of the other MoO_2LL' complexes, the cyclic voltammograms of MoO_2(4-PhTSC)(oxine) (**4g**) and MoO_2(4-(*p*-Cl)PhTSC)(oxine) (**4h**) in DMSO solution are well behaved (Fig. 4) and are highly reproducible. Both compounds undergo two successive reductions near -1.10 and -1.80 V (vs SCE), respectively. These two cathodic peaks produce their corresponding anodic waves near -1.70 and -0.90 V on scan reversal. That the second anodic peak arises only from the first cathodic response and the second couple has no contribution to it, is substantiated by scanning the potential in a manner so as to cycle only the first response. The same current for this second anodic response is obtained irrespective of whether it is scanned taking both the two couples or only the first one. On comparing the current height with that reported[37] for corresponding couples of similar systems, the first step of the reduction process seems to involve one-electron transfer. On multiple scan rates (v = 50, 100 and 200 mV s^{-1}) the overall shape of the voltammograms remains the same. However, the difference in peak potentials increases (peak-to-peak separations, ΔE_p, 160, 180 and 220 mV, respectively) with increasing sweep rate. The difference in peak potentials and the i_{pc}/i_{pa} ratio (which

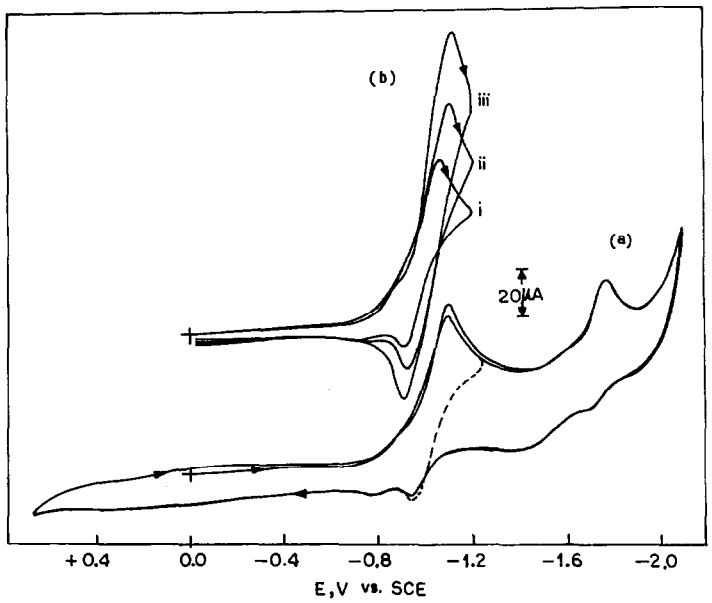

Fig. 4. Cyclic voltammograms for $\sim 1 \times 10^{-3}$ M MoO_2(4-PhTSC)(oxine) (**4g**) in 0.1 M TEAP/DMSO: (a) multiple scan reversal at a scan rate of 50 mV s^{-1}; (b) first cathodic peak at scan rates (i) 50, (ii) 100 and (iii) 200 mV s^{-1}.

deviates slightly from unity) are consistent with a quasi-reversible process characterized by slow electron transfer.[37] The second step involves a complicated process of electron transfer which appears to be irreversible on the cyclic voltammetric time scale. The cathodic peak near −1.80 V has nearly the same current height as that of the cathodic peak of the first couple and this indicates one-electron stoichiometry of this step. The separation between the two peak potentials is 70 mV which refers to a one-electron process. All these results suggest that the dianionic species generated due to reduction is unstable during cyclic voltammetric measurement. The overall electrochemical results for these two complexes can be rationalized as follows.

The compounds (**4g** and **4h**) undergo reduction near −1.10 V forming the corresponding monoanionic molybdenum(V) species. This electrochemically generated molybdenum(V) species is further reduced near −1.80 V to the corresponding dianionic molybdenum(IV) species. The slightly less cathodic current height of this step ($E_{pc} \sim -1.80$ V) compared to the former ($E_{pc} \sim -1.10$ V) is indicative of a chemical reaction that follows the initial one-electron reduction and that prevents a portion of the one-electron reduction product from undergoing a second one-electron reduction step. Again, the observation that the current height of the anodic peak ($E_{pa} \sim -1.70$ V) at which the two-electron reduced product is reoxidized is small, may be explained by the existence of a competing chemical reaction associated with the post electrochemical reaction.

It may be pointed out in this context that major differences are observed in the electrochemical behaviour of MoO_2(oxine)$_2$ and MoO_2(4-PhTSC)(oxine) or MoO_2(4-(*p*-Cl)PhTSC)(oxine). The electrochemistry of the former has been studied[37] in DMSO at a platinum electrode. The reduction of $Mo^{IV}O_2$(oxine)$_2$ occurs in two one-electron steps, with solvent attack of the reduction intermediates and subsequent displacement of the oxinate ligand. The proposal that oxine is a product of $Mo^{VI}O_2$(oxine)$_2$ reduction requires the source of a proton and water present in the solvent (DMSO) has been proposed to be the source of H^+ during the reduction. It has been shown that free oxine is reduced at −1.78 V (vs Ag—AgCl) and the oxinate ion is oxidized at +0.05 V. The absence of any anodic peak around +0.05 V in the cyclic voltammogram of any of the oxine compounds reported in this study indicates that no free oxine is generated during electrolysis. The sharply contrasting behaviour of the above compounds is thus recognized. The reproducibility and reversibility of these electron transfer steps in **4g** or **4h** compared to those in MoO_2(oxine)$_2$ indicates that the presence of 4-substituted thiosemicarbazide ligand within the coordination sphere in place of one of the oxinate ligands, stabilizes the lower valent states.

COMMUNICATION

SYNTHESIS OF A CARBORANYL NUCLEOSIDE FOR POTENTIAL USE IN NEUTRON CAPTURE THERAPY OF CANCER

ABUL K. M. ANISUZZAMAN,† FAZLUL ALAM and ALBERT H. SOLOWAY

College of Pharmacy, The Ohio State University, Columbus, Ohio 43210, U.S.A.

(*Received* 5 *October* 1989; *accepted* 8 *December* 1989)

Abstract—The reaction of 2′,3′-O-(dibutylstannylene)uridine (**1**) with 3-bromopropyne yielded 2′,(3′)-O-(3-propynyl)uridine (**2** and **3**). The mixture of **2** and **3** on acetylation followed by chromatographic purification yielded 3′,5′-di-O-acetyl-2′-O-(3-propynyl) uridine (**4**). Reaction of **4** with bis(acetonitrile)decaborane produced 3′,5′-di-O-acetyl-2′-O-(*o*-carboran-1-ylmethyl)uridine (**5**). Deacetylation of **5** gave 2′-O-(*o*-carboran-1-ylmethyl) uridine (**6**), a boronated nucleoside for potential use in neutron capture therapy of cancer.

The concept of boron neutron capture therapy (BNCT) for the treatment of cancer[1] is based on the nuclear reaction between thermal neutrons and boron-10 to yield alpha particles and lithium-7 nuclei:

$$^{10}_{5}B + {}^{1}_{0}n \longrightarrow [^{11}_{5}B] \begin{cases} \longrightarrow {}^{4}_{2}He + {}^{7}_{3}Li + 2.79\ MeV(6\%) \\ \longrightarrow {}^{4}_{2}He + {}^{7}_{3}Li^{*} + 2.31\ MeV(94\%) \end{cases}$$
$$\downarrow$$
$$^{7}_{3}Li + \gamma + 0.48\ MeV.$$

The high linear energy transfer (LET) alpha particles released in this nuclear reaction have a range in tissue of about 10 μm, approximately equal to the diameter of a single cell. Their destructive effect is, therefore, highly localized to boron-loaded tissue. A key requirement of BNCT is the selective delivery of an adequate concentration of boron-10 to tumors (15–30 $\mu g\,^{10}B/g$ tumor).[2] The lack of boron compounds with the requisite biological properties has been a major limitation for the clinical use of BNCT. Boronated analogues of compounds that are known to localize in various tumors (amino acids, thioruracils, chlorpromazine, nucleosides, antibodies, etc.) have been the focus of compound development in this area.[3] The rationale for the synthesis of boron-containing nucleosides is that such structures would be conserved by rapidly proliferating tumor cells and phosphorylated by cellular kinases to mononucleotides. These may persist "locked-in" within the tumor cell or possibly be converted to the active precursors of nucleic acids, the di- and triphosphate forms.

One boronated nucleoside, 5-dihydroxyboryl-2′-deoxyuridine, containing one boron atom linked at the 5-position, was reported[4] in 1985. We have focused on linking the icosahedral *o*-carborane moiety, containing 10 boron atoms, to various purine and pyrimidine nucleosides. This communication describes the first synthesis‡ of a carboranyl nucleoside.

The alkylation of 2′,3′-O-(dibutylstannylene) uridine[5] (**1**) with 3-bromopropyne yielded a mixture, 2′,(3′)-O-(3-propynyl)uridine (**2** and **3**). The mixture was acetylated and chromatographically purified to give 3′,5′-di-O-acetyl-2′-O-(-3-propynyl)uridine (**4**), in 45% overall yield from **1**, and the structure of **4** was confirmed by ^{1}H NMR, mass spectrometry and microanalysis. Reaction[6] of **4** with the bis(acetonitrile)decaborane yielded the

† Author to whom correspondence should be addressed.

‡ After we had submitted the manuscript for publication, Professor Yoshinori Yamamoto of Tohoku University, Japan, personally communicated that his group had succeeded in synthesizing two nucleoside analogues having the *o*-carborane moiety attached to the pyrimidine base.

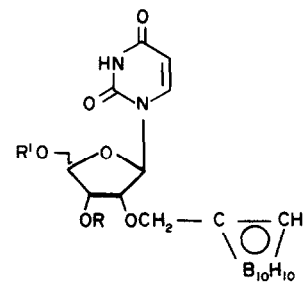
2 R = $-CH_2-C\equiv CH$, R^1, R^2 = H

3 R^1 = $-CH_2-C\equiv CH$, R^1, R^2 = H

4 R = $CH_2-C\equiv CH$, R^1 R^2 = Ac



5 R, R^1 = Ac

6 R, R^1 = H

corresponding carborane-containing derivative **5** (50% yield).

Derivative **5** was quantitatively deacetylated by catalytic amounts of sodium methoxide in methanol at 4°C for 20 h; sodium was removed with cation exchange resin and the solution concentrated. Addition of ether yielded crystalline 2′-O-(*o*-carboran-1-ylmethyl)uridine (**6**) as an ether adduct, m.p. 136–137°C, $[\alpha]_{25}^{D}+4.6°$ (cl, MeOH). The IR spectrum exhibits a strong absorption at 2575 cm^{-1}, characteristic of a B—H stretch and the carbonyl absorption at 1695 cm^{-1}. The ^1H NMR spectrum (in CD_3OD, 250 MHz; δ in ppm downfield from TMS, coupling constant in Hz) exhibits the following peaks: 3.67, 3.80 (ABq, H-5′a, H-5′b; $J_{5'a,5'b}$12.3; $J_{4',5'a}$2.7; $J_{4',5'b}$2.3); 4.64 (bs, carborane C—H); 5.60 (d, H-5; $J_{5,6}$8.1); 5.77 (d, H-1′; $J_{1',2'}$2.7); 8.00 (d, H-6). The peaks due to ether in the solvated **6** occur as a triplet at 1.11 and a quartet at 3.42. The mass spectra (FAB) shows the (M^+ + H) peak at *m/z* 401 as part of the carborane isotopic cluster. Elemental analysis ($C_{16}H_{34}O_7N_2B_{10}\cdot 0.8Et_2O$): Found: C, 39.47; H, 7.09; N, 5.89. Calc.: C, 39.71; H, 7.02; N, 6.09%.

The position of the boron cage on the D-ribofuranose moiety in **6** should not interfere with conformational or hydrogen bonding properties of the pyrimidine base. The biological evaluation of **6** is being undertaken and will be reported separately. The described preparative sequence is applicable to the synthesis of a variety of carborane-containing nucleosides of purines and pyrimidines.

APPLICATION OF MICROWAVE DIELECTRIC LOSS HEATING EFFECTS FOR THE RAPID AND CONVENIENT SYNTHESIS OF COORDINATION COMPOUNDS

DAVID R. BAGHURST, STEPHEN R. COOPER, DAVID L. GREENE, D. MICHAEL P. MINGOS* and SELENA M. REYNOLDS

Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 18 *December* 1989; *accepted* 5 *January* 1990)

Abstract—A wide range of coordination compounds of substitutionally-inert transition metal ions have been rapidly and conveniently synthesized using microwave dielectric loss heating effects. The compounds were synthesized in good yields in a Teflon autoclave, which can sustain temperatures up to 250°C and pressures up to 80 atm. With microwave techniques, reactions requiring 24 h take place in approximately 1 min.

The application of microwave dielectric loss heating effects for accelerating the rates of organic reactions,[1,2] the dissolution of geological samples,[3] organometallic syntheses,[4] intercalation processes[5] and solid-state reactions[6,7] is now well documented. For solution reactions the most dramatic results have been obtained using sealed Teflon containers which can sustain temperatures up to 250°C and pressures up to 80 atm,[8] although alternative methods for refluxing solutions under 1 atm pressure conditions have recently been described.[9] In this communication we describe the application of these techniques to the synthesis of coordination compounds. The synthesis of coordination compounds of substitutionally-inert transition metal ions can frequently be problematical and can lead to long and tedious synthetic procedures. This is particularly true for second- and third-row transition metal complexes which are exceptionally inert in a number of their common oxidation states.

The coordination compounds given in Table 1 represent a range of metals and commonly used ligands, but their syntheses require refluxing conditions for a minimum of 2 h, e.g. $[IrCl_3(9S3)]$, to 1 week for $[RuCl(CO)(bipy)_2]Cl$. Using a sealed Teflon container[8] and a microwave oven operating at 2450 MHz with power levels of 500–650 W, we have found that the coordination compounds listed in Table 1 can be conveniently synthesized in good yields in a matter of minutes. In the reactions 0.2–1.0 g of the metal salts were used with a total reaction volume of *ca* 15 cm^3.

The range of compounds synthesized in this manner, their yields, the reaction mixtures, solvents and reaction times are summarized in Table 1. The work-up procedures for the reactions generally follow those reported in the literature. The dramatic contraction in reaction times is large and parallels that reported previously for organic and organometallic reactions.[1,2,4]

The large decrease in reaction times should not be attributed to specific molecular absorption effects, but rather to macroscopic dielectric loss heating effects associated with the solvents. Water, alcohols and DMF all have high dielectric loss properties and efficiently convert microwave energy into thermal energy.[10] These efficient heating effects rapidly (within a matter of seconds) lead to a "pressure cooker" effect inside the sealed Teflon container due to the volatilities of the solvents. In the case of some of these reactions the formation of gaseous products further increases the pressure build-up. Indeed, in some cases the pressure release mechanism indicated that the pressure was approaching 80 atm before the reaction was complete and it was necessary to allow the reaction

$[Ru(9S3)_2](PF_6)_2$	$RuCl_3 \cdot xH_2O$, 9S3	MeOH	6×25	49	Cannot be synthesized directly	17

[a] DPM = 2,2,6,6-tetramethyl-3,5-heptadionato; 9S3 = 1,4,7-trithiacyclononane; terpy = 2,2′,2″-terpyridine; bipy = 2,2′-dipyridyl.

[b] The reaction product was at times contaminated with $[IrCl_3(CO)(PPh_3)_2]$ which was reduced to $[IrCl(CO)(PPh_3)_2]$ with zinc in DMF.

mixture to cool for 10–15 min before a subsequent exposure to microwaves was made. For example, in Table 1 the entries under reaction time of 2×30 indicate that two exposures of microwaves each of 30 s duration were used.

The synthesis of the crown thioether complex, $[IrCl_3(9S3)]$,[13] which has an octahedral geometry based on the tridentate thioether ligand, required only 16 s to synthesize in virtually quantitative yield. However, the synthesis of this complex is relatively easy using conventional reflux techniques (2 h in MeOH). The synthesis of the related ruthenium complex, $[Ru(9S3)_2](PF_6)_2$, by conventional methods required the prior conversion of $RuCl_3 \cdot xH_2O$ into the labile intermediate $Ru(SO_3CF_3)_3$ or $[Ru(DMSO)_6]^{2+}$.[17] Using the microwave techniques synthesis directly from $RuCl_3 \cdot xH_2O$ required a total of 150 s of microwave exposure (6×25) and gave the product in 49% yield.

The terpyridine complexes of platinum(II) and gold(III) listed in Table 1 have been extensively studied as metallo-intercalation reagents for DNA.[14,15] Both compounds were obtained in good yield using water as the solvent. The synthesis of the gold compound resulted in the formation of small quantities of the complex salt $[Au(terpy)Cl]_2[AuCl_2]_3[AuCl_4]$ which had been previously characterized by Lippard and co-workers.[15]

The heptadionato–chromium complex listed in Table 1 provides an example of a substitutionally-inert first-row transition metal complex which is conveniently made by this technique. It has been widely used as a spin–lattice relaxation reagent in NMR.[11] $[IrCl(CO)(PPh_3)_2]$,[12] Vaska's compound, and $[RuCl(CO)(bipy)_2]Cl$[16] used DMF as the solvent capable of efficiently coupling with the microwaves. In these reactions the DMF also provided the source of the carbonyl ligands.

In summary the application of microwave techniques for the synthesis of coordination compounds has been demonstrated. The technique should open up aspects of the coodination chemistries of second- and third-row transition metals both by facilitating the preparation of known compounds and by providing convenient routes to new compounds.

Acknowledgements—The SERC is thanked for financial support, Johnson Matthey plc for a generous loan of platinum metal salts and Rhode Island College for supporting D.L.G.'s sabbatical leave in Oxford.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry—8th edn. Organotin Compounds, Part 16. By Herbert Schumann and Ingeborg Schumann. Springer, Berlin, Heidelberg, New York, London, Paris, Tokyo, 1988. ISBN 3-540-93581-9; 290 pp. Hard cover DM 1334,–(R).

This text, the sixteenth in the Gmelin series of handbooks on organotin chemistry, deals exclusively with tetravalent compounds which contain two organyl ligands and two oxygen-bonded groups. It should be noted, however, that compounds of the type $R_2Sn(OR')_2$ or $R_2\overline{Sn—O—R—O}$, in which R is an unsubstituted alkyl of four or fewer carbons, were dealt with in earlier volumes (parts 14 and 15) and have consequently been excluded from this one. On the other hand, compounds in which either the two organyl ligands and/or the two O-bonded ligands, are different have been included.

These distinctions are quite arbitrary in any chemical sense and reflect a compartmentalization strategy based upon editorial convenience. Of course, this presents no problem for collectors of substantial portions of the organotin series, but more selective purchasers are advised to examine carefully the scope of each volume.

After a classified list of general literature sources (which includes sections on analysis, toxicology and uses), the main body of the text begins with compounds containing two identical organyl and either two identical O-bonded groups or a single bidentate one. The compounds described contain the following organyl ligands: unsubstituted alkyls from C_5 to C_{10}, although examples of C_{12}, C_{18} and C_{20}, are also included; cyclohexyl; alkyls substituted with aryl, halogen or oxygen, functional groups, of which the most numerous is benzyl; alkenyls; aryls, most commonly phenyl; and finally cyclic organyls with N, O, or S heteroatoms. The oxygen ligands therewith include alkoxides, β-diketonates, carboxylates and dicarboxylates, as well as those containing the linkage Sn—O—G—, where G is B, Si, N, P, As, O, S or Se.

The next section covers compounds in which the two organyls and/or the two O-bonded ligands, are different, as well as the few known compounds of the type $R—Sn(OR')_2$ or $R—O—Sn—O—R$.

In keeping with other volumes in the Gmelin Inorganic Chemistry series, the data provided are comprehensive and meticulously researched. They include synthetic methods, physical properties, structural details, spectroscopic data, and, of particular importance for organotin compounds, uses.

The general presentation follows the format of previous volumes: a large proportion of data is tabulated whilst the more important compounds are further described in the text. Besides the fairly detailed table of contents, finding a specific compound is facilitated by the empirical formula and ligand formula indexes.

In conclusion, therefore, besides the minor but certainly understandable irritation concerning the scope, this volume is yet another example of the excellence of the Gmelin series.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry—8th edn. Re—Organorhenium Compounds, Part 1. Edited by A. Slawisch. Springer, Berlin, 1989. ISBN 3-540-93580-0, ISBN 0-387-93580-0 (Eng.), 612 pp., 89 illustrations, DM 2800.

Gmelin Handbook of Inorganic Chemistry—8th edn. Re—Organorhenium Compounds, Part 2. Edited by A. Slawisch. Springer, Berlin, 1989. ISBN 3-540-93587-8, ISBN 0-387-93587-8 (Eng.), 474 pp., 59 illustrations, DM 2135.

These two Gmelin volumes, the first in a series dealing with organorhenium compounds, cover the literature up to the end of 1987. The material is well organized using the "L and "'D notation, where L represent an organic ligand bonded to rhenium by *n*C atoms and D represents a neutral donor donating *m* electrons.

Mononuclear complexes containing CO and/or "L are described in *Part 1* and compounds are divided into classes according to the type and number of ligands. The first section (24 pp.) deals with non-carbonyls containing ^{1}L ligands, starting with homoleptic alkyls and progressing through oxo- and halohydrocarbyl species (including alkylidenes and alkylidynes) to chelating ^{1}L complexes and reflects the recent upsurge in interest in higher oxidation-state organometallics.

The remaining four major sections successively deal with compounds containing from one to four CO groups (27, 55, 230 and 165 pp.). Sub-division of compounds within these sections is according to the number and type of D ligands and heteronuclear compounds are collected together at the end of each section.

In *Part 2*, the first two sections describe compounds with five (215 pp.) and six (30 pp.) CO ligands, and then six sections are allocated to complexes with from one to six isonitrile ligands (75 pp.). ^{2}L (68 pp.), ^{3}L (24 pp.) and ^{4}L (23 pp.) complexes are covered in the remaining sections. It is worth noting that heterometallic fragments bonded to Re via organic bridges are treated as "L ligands.

This compound classification works well and in each section the systematic listing of compound, method of preparation, properties (physical, spectroscopic etc.) and miscellaneous remarks, in tabulated form whereover possible, is easy to follow. The text and tables are clearly arranged, the figures and diagrams are excellent (complete with bond lengths and angles where appropriate), and empirical formula and ligand formula indexes are provided. Consequently, these volumes are easy to use. I particularly like the footnotes giving the location of references on each page.

The high quality of these volumes is very impressive and, although expensive, their availability in English should attract the previously reluctant Gmelin readers.

(*Received* 28 *September* 1989; *accepted* 24 *October* 1989)

Abstract—The stability constants, $\beta_1[MF^+(aq)]$, for the formation of the monofluoride complexes of zinc(II) and cadmium(II) in aqueous solution have been determined at 25°C and ionic strengths ranging from 0.01 to 3 M ($NaClO_4$) by fluoride ion-selective electrode potentiometry. Despite the difference in size of the zinc(II) and cadmium(II) ions their β_1 values are almost identical. Lack of variation of β_1 at high ionic strengths has been attributed to weak complexing of the metal ions by perchlorate. Measurements with amalgam electrodes at $I = 1$ M ($NaClO_4$) have indicated the existence of a very weak second complex $MF_2^0(aq)$ for both zinc(II) and cadmium(II).

Zinc(II) and cadmium(II) are generally regarded as "borderline" ions in the class A/class B or hard/soft classification systems of Ahrland *et al.*[1] and Pearson.[2] As such, the stability of their halide complexes is of some theoretical interest. On the basis of existing data[3,4] it appears that in aqueous solution zinc(II) ions show class A (hard) behaviour, with overall stability constants (β_n) for the reactions

$$M^{2+} + nX^- \overset{\beta_n}{\rightleftharpoons} MX_n^{2-n} \qquad (1)$$

being in the order $F^- > Cl^- > Br^- > I^-$.[3–5] On the other hand, cadmium(II) shows clear class B character with the overall stability constants of its halide complexes in aqueous solution being $F^- < Cl^- < Br^- < I^-$.[3–5]

However, the differences in the halide stability constants of both ions are not large: a feature often observed for borderline metal ions.[5] Interestingly, closely related lead(II) shows a "mixed" order of $F^- > Cl^- < Br^- < I^-$ in aqueous solution.[5] In non-aqueous solvents such as acetonitrile,[6] DMSO[7,8] and DMF[9] both zinc(II) and cadmium(II) show clear class A behaviour, with halide stability constants $Cl^- > Br^- > I^-$ (the analogous fluoride stability constants have rarely been measured in non-aqueous solvents[5,10]).

Although the zinc(II)– and cadmium(II)–halide systems in aqueous solution have been investigated on many occasions,[3,4] the relatively few studies of the fluoride complexes are not in particularly good agreement and show an uncertain dependence on ionic strength.[10] Since such measurements are also of interest for modelling the behaviour of geological brines,[11,12] seawater[13] and mineral extraction process streams,[14] a thorough study of the fluoride complexes of zinc(II) and cadmium(II) as a function of ionic strength has been undertaken using fluoride ion-selective electrode measurements. Some measurements have also been made with metal amalgam electrodes to look for the possible existence of higher order complexes.

EXPERIMENTAL

Reagents and apparatus

All chemicals used were of reagent grade purity. All solutions were prepared using glass-distilled

* Author to whom correspondence should be addressed.

water and calibrated volumetric glassware. Crude zinc(II) and cadmium(II) perchlorates were prepared by neutralizing the appropriate carbonate or oxide with perchloric acid, followed by removal of water to approximately 50% of the original volume. The crystals so obtained were purified twice by recrystallization from hot water and then vacuum dried (10^{-2} mm Hg) at 110–120°C for at least 24 h. Sodium perchlorate (A.R. grade) was similarly purified. Sodium fluoride (A.R. grade) was purified by the method of Lingane.[15]

Stock solutions of zinc and cadmium perchlorates were standardized against EDTA (BDH Concentrated Volumetric Standard). Stock fluoride solutions were prepared by weight and stored in pre-leached air-tight polyethylene containers. The pH of all solutions was maintained at 5.0–5.5. At this pH the formation of HF and HF_2^-[10] and metal-ion hydroxy species[3,4] may be neglected, as may the OH^- interference with the fluoride ISE.[16]

All measurements were made in a paraffin wax-coated glass cell at 25.00 ± 0.02°C maintained with a circulating thermostat (Haake Model Fe) which was itself cooled by thermostatted (20.0 ± 0.2°C) water.

Free fluoride concentrations were determined by a commercial fluoride ISE (Orion Model 94–09). Zinc and cadmium amalgam electrodes were prepared as described previously.[17,18] All potentials were measured to 0.1 mV with a digital voltmeter (Orion, Models 801A or 901), relative to a Ag/AgCl electrode consisting of a silver wire in contact with solid AgCl.[19] Titrations were performed with a 5 cm^3 Metrohm Mico Hand-burette (Model E457).

The technique of *in situ* calibration and all other details are as described previously.[19] Stability constants reported are the average of at least three and usually more than five independent titrations.

Calculations

(a) *Fluoride electrode measurements.* Assuming that the equilibria in aqueous divalent metal ion–fluoride solutions can be represented as in eq. (1), i.e. there are no "polynuclear" or mixed complexes formed, it is readily shown that if $[M^{2+}]_T \gg [F^-]_T$ (where T denotes the total or analytical concentration):

$$\frac{1}{[M^{2+}]_T}\left\{\frac{[F^-]_T}{[F^-]} - 1\right\} = F_0(X) = \sum_1^n n\beta_n[F^-]^{n-1}, \quad (2)$$

where β_n are the overall concentration stability constants corresponding to the equilibria (1) and $F_0(X)$ is introduced to represent the experimentally-determined left hand side of eq. (2).

(b) *Amalgam electrodes.* Again assuming only the equilibria corresponding to eq. (1) and using the usual mass balance relationships, it can be shown that

$$\frac{1}{[F^-]}\left\{\frac{[M^{2+}]_T}{[M^{2+}]} - 1\right\} = F'_0(X) = \sum_1^n \beta_n[F^-]^n, \quad (3)$$

where $F'_0(X)$ is again introduced for convenience to represent the experimentally determined left hand side of the equation.

If $[F^-]_T \gg [M^{2+}]_T$ then $[F^-] \simeq [F^-]_T$. Alternatively, $[F^-]$ can be obtained iteratively by initially assuming $[F^-] = [F^-]_T$, calculating tentative values of β_n which can then be used to calculate $[F^-]$, etc. Usually two iterations are sufficient to calculate consistent values of β_n and $[F^-]$.[19]

Liquid junction potentials

Cells used for this study may be represented in general terms as

	Reference half cell		Salt bridge		Indicating half cell		
Ag | AgCl	0.1 *I* M ACl 0.9 *I* M AB		*I* M (AB)		*x* M MB_2 *y* M AF (*I* − 3*x* − *y*) M AB		FE or M (Hg)
		E_{j1}		E_{j2}			

(4)

where FE represents the fluoride ISE, M(Hg) a metal amalgam electrode, I ($= 1/2\,\Sigma[i]z_i^2$) the total ionic strength (maintained constant throughout by the addition of a supposedly non-complexing "swamping" electrolyte AB: $NaClO_4$ in the present work) and $E_{j1\text{ and }2}$ are liquid junction potentials (LJPs).

It has been shown[20] that for accurate work LJPs must be taken into consideration even at relatively high ionic strengths. Fortunately, LJPs for the "constant ionic medium" junctions, represented in

cell (4) may be calculated with considerable reliability from the Henderson equation as demonstrated elsewhere.[20] Under typical experimental conditions E_{j1} is essentially constant and may be incorporated into the "standard" cell potential. E_{j2} was calculated for both cell types [i.e. FE or M(Hg)], as described in detail previously.[19,20] The necessary conductivity and transference data for the calculation of E_{j2} were obtained by appropriate interpolation and extrapolation of literature data[21-25] and, in some cases, by direct measurement.[26]

RESULTS AND DISCUSSION

Stability constants at I = 1 M ($NaClO_4$)

Because most of the literature data on metal ion–fluoride complexes have been reported at $I = 1$ M,[5,10] a detailed study at this ionic strength of the zinc(II)– and cadmium(II)–fluoride systems was undertaken using both fluoride and amalgam electrodes. Typical experimental data for the fluoride electrode are presented for the Cd^{II}/F^- system in Table 1. Similar data were obtained for zinc(II) and for both metal ions with the amalgam electrodes. The results obtained at $I = 1$ M are summarized in Table 2.

With the fluoride electrode only the first complex $MF^+(aq)$ is detected, as indicated by the constancy of the $F_0(X)$ values in the right hand column of Table 1 [cf. eq. (2)]. This is not surprising since, in order to maximize the accuracy of the fluoride electrode data,[19] conditions are chosen such that $[M^{2+}] \gg [F^-]$, which means only insignificant amounts of any higher order complexes will be formed.[27] Higher complexes are best detected with

an M^{2+}-responsive electrode where optimal experimental data are obtained when $[F^-] \gg [M^{2+}]$.

In addition to giving values of $\beta_1[MF^+(aq)]$ in excellent agreement with those obtained via the fluoride electrode, M(Hg)-electrode measurements established the existence of a weak second complex $MF_2^0(aq)$ (Table 2) for both metal ions. $CdF_2^0(aq)$ is reasonably well established, having been observed in a number of previous potentiometric and polarographic studies.[3,4,10] However, $ZnF_2^0(aq)$ has not previously been reported probably because of difficulties associated with polarographic study of zinc(II) systems (see below) and also because no previous zinc amalgam measurements appear to have been undertaken.[3,4,10] The $MF_2^0(aq)$ complexes are extremely weak with an overall stability constant approximately equal to that of the first complex (Table 3). That is, the stepwise constant K_2 ($= \beta_2/\beta_1$) for the process

$$MF^+(aq) + F^-(aq) \rightleftharpoons MF_2^0(aq)$$

is very small. No further complexes for either zinc(II) or cadmium(II) were detected even at $[F^-]/[M^{II}]$ ratios up to 1000, consistent with most other studies.[3,4,10]

The stability constants of metal ion–fluoride complexes in aqueous solution have been shown to correlate well with simple electrostatic quantities such as $[Z/(r_{M^{z+}} + r_{F^-})]$.[5] However, it has been noted[5] that the borderline ions do not conform well with this model, having stability constants that are greater than would be predicted by a simple electrostatic model. A plausible explanation of this behaviour is that the borderline cations have higher *effective* charges than other cations because of the inadequate shielding by their inner *d*-electrons.[5]

Whilst $\beta_1[ZnF^+(aq)]$ is greater than $\beta_1[CdF^+(aq)]$, consistent with simple electrostatics, the difference is much less than might be expected given the considerable difference in their size: $r_{Zn^{2+}} = 74$ pm, $r_{Cd^{2+}} = 97$ pm.[28]

[a] Extrapolated using eq. (7); see text.

Variation of stability constants with ionic strength

Measurements at ionic strengths other than 1 M were performed only using the fluoride electrode under conditions where $[M^{2+}] > [F^-]$ and so only the first complex $MF^+(aq)$ was detected. The data obtained are summarized in Table 3 and plotted in Figs 1 and 2 along with literature values.[3,10]

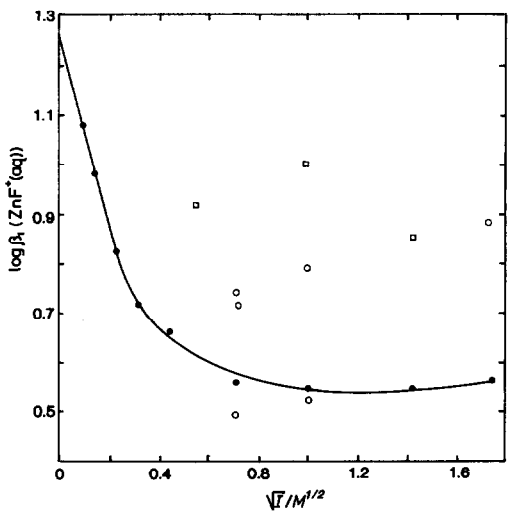

Fig. 1. Comparison of present and literature values for $\log\beta_1[ZnF^+(aq)]$ at 25°C as a function of ionic strength: ●, present results (Table 3); ○, other EMF data; □, polarographic data. Literature values from ref. 10, in $NaClO_4$ or $NaNO_3$ media (see text).

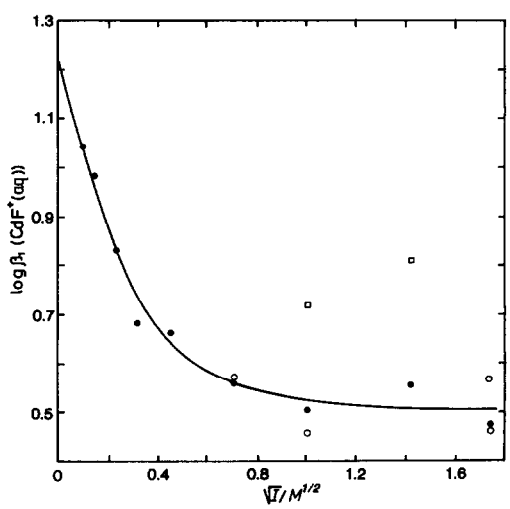

Fig. 2. Comparison of present and literature values for $\log\beta_1[CdF^+(aq)]$ at 25°C as a function of ionic strength. Other details as for Fig. 1.

The present results are the first systematic study of the Zn^{II}/F^- and Cd^{II}/F^- systems as a function of ionic strength.[3,4,10] The Cd^{II}/F^- data are in general in good agreement with previous determinations (Fig. 2). However, the $\beta_1[ZnF^+(aq)]$ results are generally lower than literature values (Fig. 1), although they are in reasonable agreement with previous fluoride electrode studies.[10]

It is apparent from Figs 1 and 2 that most of the higher values for $\beta_1[MF^+(aq)]$ for both zinc(II) and cadmium(II) have been determined polarographically. This technique is generally regarded as somewhat less precise than potentiometry. However, in the absence of complicating factors such as anion adsorption (which should be virtually absent for fluoride systems[29]), polarographic stability constants are usually in good agreement with potentiometric values.[20]

Whilst it is possible to discount the Zn^{II}/F^- data, because of lingering doubts[31] about the reversibility of the polarographic reduction of zinc(II), which would significantly influence the measured β_n values, the cadmium(II) reduction is strictly reversible.[32]

The source of the discrepancy between the polarographic and EMF measurements is not obvious and clearly merits further investigation.

The other remarkable feature of the data in Figs 1 and 2 is the small change in $\beta_1[MF^+(aq)]$ at higher ionic strengths. The stability constants for most equilibria involving ionic species exhibit a characteristic asymmetric U-shaped curve with increasing ionic strength as a result of changing activity coefficients.[19,33,34]

Strictly speaking, the stability constant expression for the formation of the first fluoride complex (eq. (1), $n = 1$) should be written in terms of activities (omitting the aq symbols):[33,34]

$$\beta_1^\theta(MF^+) = \frac{a_{MF^+}}{a_{M^{2+}}a_{F^-}} = \frac{[MF^+]}{[M^{2+}][F^-]} \cdot \frac{\gamma_{MF^+}}{\gamma_{M^{2+}}\gamma_{F^-}}.$$

That is

$$\log \beta_1^\theta = \log \beta_1 + \log\left(\frac{\gamma_{MF^+}}{\gamma_{M^{2+}}\gamma_{F^-}}\right), \qquad (5)$$

where β_1^θ is the "true" or "thermodynamic" constant.

Although activity coefficients for individual ions cannot be measured, their behaviour as a function of ionic strength can be approximated by an appropriate function such as the extended Debye–Huckel, Davies or Pitzer equations.[35] For simplicity the Davies equation[34]

$$\log \gamma_i = -Az_i^2\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right) \qquad (6)$$

will be assumed, where A is the Debye–Huckel constant ($= 0.509$ at 25°C in H_2O).

Combination and rearrangement of eqs (6) and (7) gives

$$\log \beta_1 = \log \beta_1^\theta - 4A\left(\frac{\sqrt{I}}{1+\sqrt{I}} - 0.3I\right), \qquad (7)$$

which accounts for the well-known U-shaped curve: an initial decrease in $\log \beta_1$ at low I, due to the predominance of the first activity coefficient term inside the parentheses, followed by an increase at higher I as the second activity coefficient term becomes dominant. The position of the mimimum in $\log \beta_1$ vs $\sqrt{I}$ curves depends on a number of factors but typically occurs around 0.5–1.0 M.[33–35]

The fact that $\log \beta_1[MF^+(aq)]$ vs $\sqrt{I}$ curves (Figs 1 and 2) do not follow the accepted shape at high ionic strengths indicates that other factors must be taken into consideration. The most likely explanation is competition for the metal ion from the supposedly non-complexing background electrolyte.[36,37] That is, the reaction actually being measured does not correspond to eq. (1) but rather to the competitive equilibrium

$$MClO_4^+(aq) + F^-(aq) \rightleftharpoons MF^+(aq) + ClO_4^-(aq).$$

The effect of such competition is to reduce the dependence of $\log \beta$ on ionic strength at high I values.[36,37]

Although perchlorate is generally regarded as non-complexing in aqueous solution, even a very weak $MClO_4^+$ complex is sufficient to produce the effect seen in Figs 1 and 2.[37] Unfortunately, the data available for the zinc(II)– and cadmium(II)–ClO_4^- systems are rather limited, although at least one conductance study suggests there may be quite strong association.[3] It may also be noted that, unlike most metal ion–fluoride complexes,[37] there does not seem to be much difference between $\beta_n[MF_n^{2-n}(aq)]$ determined in nitrate and perchlorate media.[10] This suggests $\beta_n[M(NO_3)_n^{2-n}(aq)] \simeq \beta_n[M(ClO_4)_n^{2-n}(aq)]$. Since NO_3^- is generally rather more strongly complexing than ClO_4^- this is circumstantial evidence that zinc(II) and cadmium(II) perchlorate complexes are unusually "strong".

Standard state stability constants

The standard state for solutes in solution is arbitrary but is normally taken to be infinite dilution in the solvent.[33] Application of eq. (7) to the low ionic strength $\beta_1[MF^+(aq)]$ data in Table 3 gives $\beta_1^\theta[ZnF^+(aq)] = 15.9 \pm 1.6\ M^{-1}$ and $\beta_1^\theta[CdF^+(aq)] = 15.2 \pm 1.5\ M^{-1}$. The values for $ZnF^+(aq)$ are in good agreement with previous estimates of

13.8 M^{-1} by Cook *et al.* and 18.2 by Connick and Paul.[3,4] No previous estimate of β_1^θ[CdF^+ (aq)] has been made.[3,4,10]

Acknowledgement—The authors thank Dr B. W. Clare of Murdoch University for assistance with the calculations.

(*Received* 28 *July* 1989; *accepted* 2 *November* 1989)

Abstract—The unsaturated complexes $Ru(CO)Cl(CR{=}CHR')(PPh_3)_2$ react rapidly with the sodium salt of the anion 3,3-dimethylacrylate. The family of complexes obtained contains the 3,3-dimethylacrylate ligand η^2-coordinated through the carboxylate group. The structure of the complex $Ru(O_2CCH{=}CMe_2)(CO)(C(CO_2Me){=}CH(CO_2Me))(PPh_3)_2$ was determined by X-ray diffraction. The complex is triclinic, space group $P\bar{1}$, with dimensions of the unit cell of $a = 17.401(1)$, $b = 12.633(3)$, $c = 12.054(1)$ Å; $\alpha = 119.092(4)$, $\beta = 72.423(5)$, $\gamma = 109(7)°$ and $D_{calc} = 1.226$ g cm^{-3} for $Z = 2$. The molecule consists of a ruthenium hexacoordinated with two triphenylphosphines in the apical positions and the rest of the ligands in the equatorial plane of a distorted octahedron.

The carboxylate complexes of ruthenium present interesting catalytic activity in reactions of hydrogenation[1] and hydroformylation.[2] In these reactions the ruthenium atom quickly activates the molecule of H_2 forming hydrides which participate in the catalytic cycle. For this reason we are interested in the reactivity of mononuclear hydrides of ruthenium with unsaturated molecules such as acetylenes and the possible application of products in catalysis. In this way, the unsaturated alkenyl complexes obtained from $RuCl(CO)H(PPh_3)_2$ and acetylenes[3] have been reacted with small molecules like CS_2,[4] acetylenes,[5] pyrazoles,[6] CO[7] and carboxylates.[8] The reaction with CS_2 and acetylenes produces a coupling with the alkenyl ligand; with pyrazoles the alkenyl group is transformed to alkynyl; with CO, a η^2-acyl ligand is formed depending on the alkyne.[7] With carboxylates only saturation of the metal occurs by η^2-coordination.[8] A very interesting reaction is the oxidation of the acyl ligand, obtained from the reaction with CO, with methanol giving rise to an alkenecarboxylate group. The exact nature of the ligand was confirmed by the resolution of the crystal structure of the complex $RuCl(CO)(O_2CC(Me){=}CHMe)(PPh_3)_2$. For a better knowledge of this type of complex we initiated a systematic study of the addition of sodium 3,3-dimethylacrylate to the unsaturated complexes $RuCl(CO)(CR{=}CHR')(PPh_3)_2$.

RESULTS AND DISCUSSION

Previously we have studied the reactivity of the 16-electron complexes $RuCl(CO)(CR{=}CHR')(PPh_3)_2$ toward bidentate anionic ligands such as carboxylates.[8] The results with acetate indicated a fast substitution of the monodentate ligand by a chelating carboxylate. In the same fashion, a methanolic solution of the sodium salt of the anion 3,3-dimethylacrylate reacts with the alkenyl complexes of ruthenium dissolved in dichloro-

* Author to whom correspondence should be addressed.

methane and gives rise to complexes whose elemental analyses are in accordance with the presence of two PPh_3 groups, one molecule of CO, an alkenyl group and a 3,3-dimethylacrylate ligand. The isolated products of formula $Ru(O_2CCH{=}CMe_2)(CO)(CR{=}CHR')(PPh_3)_2$ (with R = R′ = H, Me, Ph and CO_2Me; R = H and R′ = CMe_3, $SiMe_3$, Ph, CO_2Me and CO_2Et) are stable to air and soluble in dichloromethane, but insoluble in alcohols and petroleum ether. The complexes are obtained as yellow microcrystals which can be recrystallized from dichloromethane–methanol mixtures forming suitable crystals for X-ray diffraction studies.

The IR spectrum of the sodium salt of the 3,3-dimethylacrylate ligand presents typical carboxylate group absorptions at 1575 and 1412 cm^{-1} with a $\nu(C{=}C)$ band at 1567 cm^{-1}. The IR spectra of complexes show $\nu(OCO)_{asym}$ at 1515–1567 cm^{-1} and $\nu(OCO)_{sym}$ at 1413–1450 cm^{-1}, characteristic of chelated carboxylate ligands.[9] In some synthesized complexes the $\nu(OCO)_{sym}$ band is obscured by the strong absorptions of the triphenylphosphines making their assignment difficult. This situation also occurred in the complex $RuCl(CO)(O_2CC(Me){=}CHMe)(PPh_3)_2$ which obstructed their spectroscopic identification.[7] The $\nu(CO)$ band appears at 1909–1937 cm^{-1} depending on the alkenyl group and the $\nu(C{=}C)$ is located at $\approx$ 1550 cm^{-1} but is also obscured by the carboxylate absorption.[10] There are no important differences between the $\nu(CO)$ bands of the synthesized products and those of the acetate complexes previously quoted, indicating similar electronic effects on the metal centre. The ^1H NMR spectra of the complexes contain signals due to all the coordinated ligands. The acrylic hydrogen appears at $\approx$ 4.4 ppm and the alkenylic protons —CH= are shifted upfield, while the hydrogens of =CHR′ are shifted downfield with respect to the position of the hydrogens of the unsaturated alkenyl complexes $RuCl(CO)(CR{=}CHR')(PPh_3)_2$. The coupling between the protons in the monosubstituted alkenyl ligands, $\approx$ 16 Hz, indicates that the geometry of the organic group is maintained.[3,11]

All analytical and spectroscopic data of the presented products are in accordance with a structure containing the ruthenium atom coordinated to an η^2-carboxylate (3,3-dimethylacrylate), an η^1-alkenyl, CO and two triphenylphosphine ligands: $Ru(O_2CCH{=}CMe_2)(CO)(CR{=}CHR')(PPh_3)_2$. The majority of similar ruthenium complexes obtained at room temperature contain the two phosphines in *trans* positions. For a complete study of this family of products the structure of the complex $Ru(O_2CCH{=}CMe_2)(CO)(C(CO_2Me){=}CH(CO_2Me))(PPh_3)_2$ (**9**) by X-ray diffraction was undertaken.

The structure of complex $Ru(O_2CCH{=}CMe)_2(CO)(C(CO_2Me){=}CH(CO_2Me))(PPh_3)_2$ (**9**)

The molecular structure of the complex is presented in Fig. 1 and consists of discrete molecules linked by van der Waals' forces. Table 1 lists some selected bond distances and angles. In the molecule the ruthenium atom displays a distorted octahedral geometry where the two phosphines are in the axial sites and C(1), O(2), O(3) and C(2) are in the equatorial plane. The angle formed by the two phosphines and the ruthenium [174.82(4)°], the Ru—P(1) [2.389(1) Å] and the Ru—P(2) [2.386(1) Å] distances are comparable to the values found in other complexes.[3] The carboxylate ligand is η^2-bonded to ruthenium with Ru—O(1) and Ru—O(2) distances of 2.239(4) and 2.161(3) Å, respectively. The observed difference in the distances could be attributed to the positions of the carbonyl and alkenyl ligands with different *trans* effects to the oxygens of the carboxylate ligands.[12] The angle O(1)—C(8)—O(3) of 117.96(48)° produces a distortion of the rest of the angles in the equatorial plane, with a O(1)—Ru—O(2) angle of 59.24(13)°. The C(9)—C(10) double bond of the carboxylate has a length of 1.367(11) Å. The C(1)—O(1) distance of 1.164(5) Å is similar to those observed in other carbonyl complexes of ruthenium.[13] The alkenyl ligand contains two methylcarboxylate groups in a *cis* disposition. The Ru—C(2) distance of 2.034(5) Å lies in the observed range of ruthenium–alkenyl bonds.[13] The C(2)—C(3) bond length of 1.341(7) Å has the same value as in other dimethylcarboxylate alkenyl ligands.[13] Of particular note is the spatial disposition of the α-methylcarboxylate group which is turned to minimize the possible interactions with the ligands.

EXPERIMENTAL

The elemental analyses of carbon and hydrogen were performed with a Perkin–Elmer 240-B analyser. The IR spectra were recorded on a Perkin–Elmer 1710-FT instrument using KBr discs. The ^1H NMR spectra were recorded on a Bruker AM 400 apparatus in $CDCl_3$ solutions and referenced to $SiMe_4$. All preparations were performed under a nitrogen atmosphere using conventional Schlenk techniques. The complexes of departure: $RuCl(CO)(CR{=}CHR')(PPh_3)_2$ were synthesized by published methods.[3,5]

Synthesis of complexes

To a dichloromethane solution of the complexes, $RuCl(CO)(CR{=}CHR')(PPh_3)_2$, a slight excess of sodium 3,3-dimethylacrylate, dissolved in methanol, was added with stirring. The solution turned green and stirring was continued until the liquid became yellow (30 min). The solution was evaporated *in vacuo* and the residue dissolved in dichloromethane. A white solid was separated by filtration and the yellow product was precipitated with hexane. The crystalline complexes were obtained by crystallization from dichloromethane–methanol mixtures.

Complex **1**: $Ru(O_2CCH{=}CMe_2)(CO)(CH{=}CH_2)(PPh_3)_2$. Found: C, 67.5; H, 5.3. Calc. for $C_{44}H_{40}O_3P_2Ru$: C, 67.80; H, 5.13%. IR: ν(CO) 1916, ν(C=C) 1653, 1560, ν(OCO) 1544, 1444 cm^{-1}. ^1H NMR: δ 1.34 (s, 3H), 1.53 (s, 3H), 4.46 (s, 1H), 4.71 (d, $J = 16$ Hz, 1H), 5.01 (d, $J = 8$ Hz, 1H), 7.2–7.8 (m, Ph+1H) ppm.

Complex **2**: $Ru(O_2CCH{=}CMe_2)(CO)(CH{=}CHCMe_3)(PPh_2)_3$. Found: C, 68.6; H, 5.8. Calc. for $C_{48}H_{48}O_3P_2Ru$: C, 69.00; H, 5.75%. IR: ν(CO) 1920, ν(C=C) 1652, ν(OCO) 1496 cm^{-1}. ^1H NMR: δ 0.33 (s, 9H), 1.30 (s, 3H), 1.44 (s, 3H), 4.41 (s, 1H), 4.96 (d, $J = 16$ Hz, 1H), 6.27 (d, $J = 16$ Hz, 1H), 7.2–7.6 (m, Ph) ppm.

Complex **3**: $Ru(O_2CCH{=}CMe_2)(CO)(CH{=}CHSiMe_3)(PPh_3)_2$. Found: C, 66.9; H, 5.7. Calc. for $C_{47}H_{48}O_3P_2SiRu$: C, 66.29; H, 5.64%. IR: ν(CO) 1921, ν(C=C) 1654, ν(OCO) 1498 cm^{-1}. ^1H NMR: δ −0.5 (s, 9H), 1.31 (s, 3H), 1.46 (s, 1H), 4.46 (s, 1H), 4.58 (d, $J = 16$ Hz, 1H), 5.53 (d, $J = 16$ Hz, 1H), 7.2–7.6 (m, Ph) ppm.

Complex **4**: $Ru(O_2CCH{=}CMe_2)(CO)(CH{=}CHPh)(PPh_3)_2$. Found: C, 70.6; H, 5.1. Calc. for $C_{50}H_{42}O_3P_2Ru$: C, 70.36; H, 4.92%. IR: ν(CO) 1922, ν(C=C) 1652, 1558, ν(OCO) 1496 cm^{-1}. ^1H NMR: δ 1.38 (s, 3H), 1.56 (s, 3H), 4.52 (s, 1H), 5.77 (d, $J = 16$ Hz, 1H), 6.4–7.6 (m, Ph), 7.85 (d, $J = 16$ Hz, 1H) ppm.

Table 2. Crystal data and summary of intensity data collection and structure refinement

Crystal data	
Formula	$C_{48}H_{44}O_7P_2Ru$
Crystal habit	Prismatic, yellow–orange
Crystal size	$0.35 \times 0.30 \times 0.26$ mm
Symmetry	triclinic, $P\bar{1}$
Unit cell dimensions	28 reflections, $10 < 2\theta < 45°$
	$a = 17.401(1)$, $b = 12.633(3)$
	$c = 12.054(1)$ Å; $\alpha = 119.092(4)$
	$\beta = 72.423(5)$, $\gamma = 109(7)°$
D_{calc} (g cm^{-3}), M	1.226, 795.474
Z, $F(000)$, μ (cm^{-1})	2, 1026, 13.061
Experimental data	
Scanning range for θ	$2 < 2\theta < 65°$
Number of reflections:	
Measured	6904
Observed	6298 [$I > 2\sigma(I)$] criterion
Final R and R_w	4.9 and 5.3

Atomic coordinates, thermal parameters, full lists of bond lengths and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Complex **5**: $Ru(O_2CCH{=}CMe_2)(CO)(CMe{=}CHMe)(PPh_3)_2$. Found: C, 68.1; H, 5.2. Calc. for $C_{46}H_{44}O_3P_2Ru$: C, 68.42; H, 5.45%. IR: ν(CO) 1909, ν(C=C) 1652, ν(OCO) 1513, 1413 cm^{-1}. ^{1}H NMR: δ 1.03 (d, $J = 4$ Hz, 3H), 1.28 (s, 3H), 1.30 (s, 3H), 1.47 (s, 3H), 4.40 (br, 2H), 7.2–7.7 (m, Ph) ppm.

Complex **6**: $Ru(O_2CCH{=}CMe_2)(CO)(CPh{=}CHPh)(PPh_3)_2$. Found: C, 72.4; H, 5.5. Calc. for $C_{56}H_{48}O_3P_2Ru$: C, 72.20; H, 5.15%. IR: ν(CO) 1920, ν(C=C) 1650, ν(OCO) 1561, 1449 cm^{-1}. ^{1}H NMR: δ 1.28 (s, 3H), 1.53 (s, 3H), 4.31 (s, 1H), 5.84 (s, 1H), 5.9–7.6 (m, Ph) ppm.

Complex **7**: $Ru(O_2CCH{=}CMe_2)(CO)(CH{=}CH(CO_2Me))(PPh_3)_2$. Found: C, 66.2; H, 5.3. Calc. for $C_{46}H_{42}O_5P_2Ru$: C, 65.97; H, 5.02%. IR: ν(CO) 1928, 1671, ν(C=C) 1654, ν(OCO) 1553, 1144 cm^{-1}. ^{1}H NMR: δ 1.33 (s, 3H), 1.56 (s, 3H), 3.36 (s, 3H), 4.27 (s, 1H), 5.45 (d, $J = 16$ Hz, 1H), 7.1–7.7 (m, Ph), 9.60 (d, $J = 16$ Hz, 1H) ppm.

Complex **8**: $Ru(O_2CCH{=}CMe_2)(CO)(CH{=}CH(CO_2Et))(PPh_3)_2$. Found: C, 66.4; H, 5.3. Calc. for $C_{47}H_{44}O_5P_2Ru$: C, 66.29; H, 5.17%. IR: ν(CO) 1924, 1683, ν(C=C) 1652, ν(OCO) 1553, 1138 cm^{-1}. ^{1}H NMR: δ 1.27 (t, $J = 8$ Hz, 3H), 1.53 (s, 3H), 1.76 (s, 3H), 4.02 (q, $J = 8$ Hz, 2H), 4.61 (s, 1H), 5.64 (d, $J = 16$ Hz, 1H), 7.2–7.9 (m, Ph), 9.76 (d, $J = 16$ Hz, 1H) ppm.

Complex **9**: $Ru(O_2CCH{=}CMe_2)(CO)(C(CO_2Me){=}CH(CO_2Me))(PPh_3)_2$. Found: C, 64.3; H, 4.8. Calc. for $C_{48}H_{44}O_7P_2Ru$: C, 64.38; H, 4.91%. IR: ν(CO) 1937, 1705, ν(C=C) 1648, ν(OCO) 1567, 1450, 1209, 1155 cm^{-1}. ^{1}H NMR: δ 1.35 (s, 3H), 1.76 (s, 3H), 3.35 (s, 3H), 3.56 (s, 3H), 4.93 (s, 1H), 4.90 (s, 1H), 7.2–7.7 (m, Ph) ppm.

Structure solution and refinement

The crystal data and a summary of the intensity data collection and structure refinement are given in Table 2. The unit cell dimensions were obtained by least-squares refinement on setting angles of 28 well-centred reflections in the range $10 < 2\theta < 64°$, measured on a diffractometer. Data were collected on a Philips PW 1100 diffractometer using graphite monochromated Cu-K_α radiation and the ω–2θ scan technique.

Two standard reflections were monitored every 90 measurements, no intensity variation was observed. Corrections for Lorentz and polarization effects and absorption[14] were made.

The structure was solved by the heavy-atom method and direct methods. Full-matrix least-squares refinement using F with non-hydrogen atoms anisotropic. The hydrogen atom positions were calculated assuming an idealized geometry

with isotropic thermal parameters equal to those of the atoms to which they are bonded and included in the structure factor calculation. The weighting scheme was chosen so as not to give trends in $\langle \Delta^2 F \rangle$ vs $\langle |F_o| \rangle$ and $\langle \sin\theta/\lambda \rangle$.[15] Scattering factors were taken from the *International Tables of Crystallography*.[16] All calculations were performed with the XRAY76 system,[17] MULTAN,[18] DIFABS[14] and some local programs on a VAX 11/750.

ENZYME INHIBITION BY SODIUM NITROPRUSSIDE

ANTHONY R. BUTLER,* ADRIANNE M. CALSY and IAN L. JOHNSON

Department of Chemistry, The University, St Andrews, Fife KY16 9ST, Scotland, U.K.

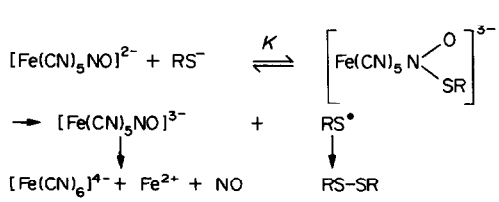
(*Received* 1 *September* 1989; *accepted* 2 *November* 1989)

Abstract—The enzyme which mediates relaxation of arterial muscle, and thus controls blood pressure, is guanylate cyclase, an enzyme with a thiol group at the active site and others elsewhere and a prosthetic haem group. Reaction of nitroprusside, a potent vasodilator, with other enzymes (papain and GAPDH) possessing a thiol group at an active site leads only slowly to enzyme inhibition by formation of disulphide bonds. Computer graphics show that the significant thiol group is accessible to the bulky nitroprusside. With enzymes containing a haem group (lactoperoxidase and catalase) inhibition by, or reaction with, nitroprusside is much faster. This suggests that the rapid vasodilator action of nitroprusside is due to its reaction with the haem group of guanylate cyclase.

It has been suggested by a number of workers that the hypotensive action of nitroprusside is due to reaction with the thiol groups of the enzyme guanylate cyclase.[1–6] In a previous paper[7] the reactions between nitroprusside and a number of low molecular weight thiols (cysteine, N-acetylcysteine, β-methylcysteine, penicillamine, and N-acetylpenicillamine) with formation of intermolecular S—S bonds, were described. The overall anaerobic reaction is shown, non-stoichiometrically, in Scheme 1. A similar reaction with the thiol groups of guanylate cyclase, with formation of a disulphide bond within the enzyme, is possible. Before attempting to investigate this we thought it would be of value to examine the effect of nitroprusside on other enzymes containing thiol groups at the active site, and which were commercially available, e.g. papain and glyceraldehyde-3-phosphate dehydrogenase.

The enzyme papain (EC 3.4.410) is an example of a proteinase with a catalytic thiol group. It is a simple protein of 212 amino acid residues forming one peptide chain. The active site cysteine (cys-25) is the only thiol residue of papain and the reactive intermediate in acyl transfer reactions is a thiol-acylated enzyme. Crystallographic studies[8,9] of papain have revealed the proximity of cys-25 to his-159 and asp-158 in what may be some kind of catalytic triad.

Glyceraldehyde-3-phosphate dehydrogenase (GAPDH, EC 1.2.1.12) is the enzyme that catalyses the oxidation and phosphorylation of D-glyceraldehyde-3-phosphate to 1,3-diphosphoglycerate. The enzyme consists of a tetramer for four identical subunits. Acetaldehyde has been used as a substrate for GAPDH and a thiol group has been implicated in the mechanism as a ^{14}C-labelled thioester is formed after incubation of ^{14}C-labelled acetaldehyde with GAPDH.[10] The essential thiol (cys-149) is, by virtue of a helical configuration, close to the non-reactive thiol of the active site (cys-153). A histidine residue (his-176), also considered to be important to the catalytic mechanism of GAPDH, lies within hydrogen-bonding distance of the essential thiol. The cysteine content of GAPDH varies from one to five for each subunit but it is the essential thiol (cys-149) that is the most reactive. The other thiol of the active site (cys-153), while not generally reactive,[11] can be



Scheme 1.

* Author to whom correspondence should be addressed.

induced to form a disulphide bond with cys-149, thereby permanently inactivating the enzyme, possibly due to irreversible conformational changes.

A well-established[12] aspect of guanylate cyclase activity is that if it is purified so that the haem content is removed the enzyme no longer responds to nitric oxide, nitroprusside, or S-nitrosocysteine in the absence of exogenous haematin. On the other hand, preformed nitrosohaemoglobin produces a substantial increase in enzyme activity. The reaction of nitroprusside and haemoglobins has been examined and, as an extension to this work,[13] we thought it would be of value to examine the reaction of nitroprusside with two commercially available enzymes which are known to contain haem: peroxidase and catalase.

Peroxidase (EC 1.11.17, hydrogen peroxide oxidoreductase) is a haem-bearing enzyme found in a variety of animal and plant tissues. The source used in this study was cow's milk, i.e. lactoperoxidase. Its structure has not been completely determined but the haem environment is thought to be similar to that of horseradish peroxidase.[14] The lactoperoxidase haem iron is in a crevice of the protein molecule and its sixth coordination site is vacant or occupied by a loosely associated water ligand. The inhibition of lactoperoxidase by cyanide, sulphide and fluoride is attributed to attachment of these ions at the coordination site of the haem iron.[15] Lactoperoxidase has 16 cysteine residues, which are thought to form eight disulphide bridges.

The haem-bearing enzyme catalase (EC 1.11.16, hydrogen peroxide oxidoreductase) is present in nearly all aerobically respiring organisms and protects cells from the toxic effect of hydrogen peroxide by catalysing its decomposition. Catalase, in the presence of hydrogen proxide,[17] can effect oxidation of a variety of compounds, including ethanol. The structure of catalase has been determined[18] and it consists of four identical subunits. The sixth coordination site of the haem is vacant but the accessibility of the haem, in a crevice in the protein molecule, is limited by a channel 30 Å long and 15 Å wide.

RESULTS AND DISCUSSION

Papain activity at pH 7.5 was determined by monitoring the hydrolysis of N-benzoyl-L-arginine ethyl ester (BAEE) according to an established procedure.[19] Also, the inhibition of papain by cyanate, a known[20] inhibitor, was recorded. At similar concentrations nitroprusside inhibited papain only marginally and after a long incubation time. However, at higher concentrations of nitroprusside, inhibition was observed (Fig. 1). The reason for the incubation time will be discussed later. At the same concentration nitroprusside is more effective as an inhibitor than nitrite, and both react with thiol groups. This parallels their effect as vasodilators. On the other hand, even at high concentrations (nitroprusside–enzyme molar ratio of 1000:1) nitroprusside did not inhibit the trypsin catalysed hydrolysis of BAEE. That enzyme is known not to have a thiol group as a key part of the active site.

The structure of papain is known and when it was displayed on a screen by the use of Chem-X it was clear that cys-25 is not embedded within the protein structure. To assess the accessibility of cys-25 to nitroprusside the latter was drawn in the same scale as all the atoms within 10 Å (in $\pm x$, $\pm y$ and $\pm z$ directions) of the cys-25 sulphur atom. These graphics demonstrate that there is no steric impediment to the reaction of nitroprusside with the cys-25 of papain. If the sulphur in the active site of guanylate cyclase is similarly accessible it is possible that its action could be inhibited by reaction with nitroprusside.

Glyceraldehyde-3-phosphate dehydrogenase, unlike papain, does not require activation and its interaction with nitroprusside was more readily examined by ^{13}C NMR and ESR spectroscopy. The activity of GAPDH was determined by monitoring the increase in absorbance at 340 nm due to the reduction of NAD. It was found that a 15–20 min incubation of the enzyme solution with nitroprusside prior to initiation of the reaction by addition of the substrate glyceraldehyde-3-phosphate, resulted in significant inhibition of enzyme

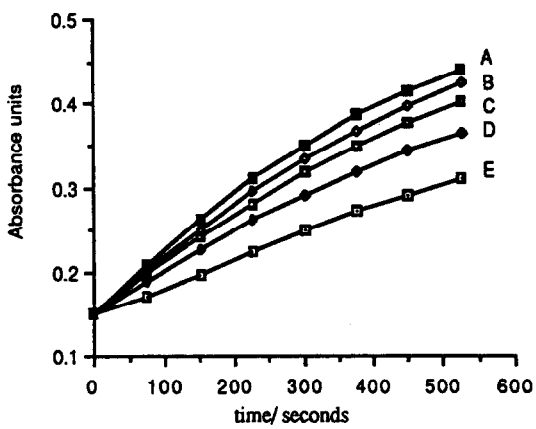


Fig. 1. Hydrolysis of BAEE catalysed by papain in the presence of inhibitors (incubation time, in min, in parentheses): (A) none; (B) 1.5×10^{-4} M nitroprusside (19); (C) 3×10^{-3} M nitrite (23); (D) 3×10^{-3} M nitroprusside (0); (E) 3×10^{-3} M nitroprusside (21). [Papain] = 5.36×10^{-6} M; [BAEE] = 1.24×10^{-3} M.

activity at pH 7.5 (see Fig. 2). The data displayed in Fig. 2 show the general features of the inhibitory effect of nitroprusside. The effects of other vasodilators, nitrite and nitroethane, are also shown; at identical concentrations nitroprusside is more effective. Although not shown, nitroprusside was found to be more effective than nitrate, a known inhibitor of GAPDH.[22] These results provide further evidence that nitroprusside can affect the action of an enzyme containing thiol groups at the active site.

Display of the structure of GAPDH by Chem-X shows that the essential thiol, cys-149, of each subunit is located towards the centre of the enzyme and again not embedded within the protein structure. The accessibility of the active site to nitroprusside was determined by displaying both a window of all atoms within 10 Å (in $\pm x$, $\pm y$ and $\pm z$ directions) of the cys-149 sulphur atom and nitroprusside on the same scale. There is no obvious steric impediment to reaction of nitroprusside at cys-149. The unreactive thiol, cys-153, was also seen, close to cys-149, but clearly remote from the active site.

Not only were we able to show that an enzymatic thiol group can react with nitroprusside but we were able to identify the inorganic product of reaction. The ESR spectra of a degassed solution of nitroprusside added to GAPDH, dissolved in phosphate buffer, were recorded over 1 day. No signal was observed on mixing but after 2 h a strong three-line signal was noted. At the same time the solution, originally clear, became turbid. Five hours later

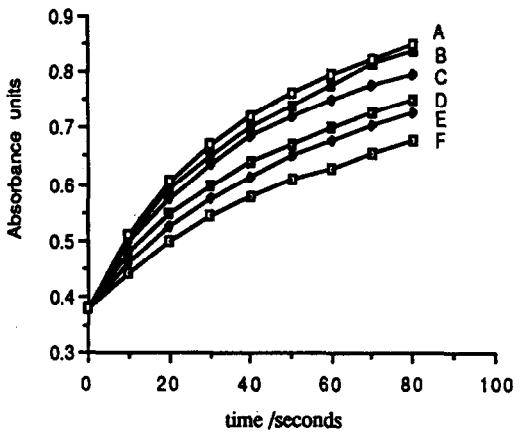

Fig. 2. Late data for the activity of GAPDH due to reduction of NAD in the presence of inhibitors (incubation time, in min, in parentheses): (A) none; (B) 1.66×10^{-2} M nitroethane (20); (C) 1.66×10^{-2} M nitrite (17); (D) 1.66×10^{-3} M nitroprusside (1); (E) 8.3×10^{-3} M nitroprusside (14); (F) 1.66×10^{-2} M nitroprusside (16). [GAPDH] = 2.79×10^{-7} M; [NAD] = 1.50×10^{-3} M.

the signal was unchanged. This three line signal is identical to that observed on reaction of nitroprusside with thiols[7] and corresponds[23] to the species $[Fe(CN)_4NO]^{2-}$.

The ^{13}C NMR spectrum of a solution of ^{13}C-labelled nitroprusside and GAPDH, taken shortly after mixing, showed only the presence of unreacted nitroprusside. However, after several hours turbidity was observed and the spectrum, recorded after filtering and storage under nitrogen, showed a signal at 177.8 ppm corresponding to hexacyanateferrate,[24] as well as the spectrum of unreacted nitroprusside (Fig. 3). Hexacyanoferrate and $[Fe(CN)_4NO]^{2-}$ are known as *in vitro* products of reaction of thiols and nitroprusside, the former the final product and the latter a well-characterized intermediate. Thus, in any attempt to delineate the vasodilator action of nitroprusside via its interaction with guanylate cyclase, it is reasonable to assume that what is known of the reaction of nitroprusside with simple thiols[7] also applies to its reaction with thiol groups within the enzyme.

The turbidity observed in the above experiments suggests denaturation of the enzyme, giving rise to a change in enzyme solubility. It is likely that this arises from formation of disulphide bonds, possibly by reaction of the essential thiol with the adjacent cys-153.[9]

The origin of the apparent time dependence of both papain and GAPDH inhibition by nitroprusside may be due to the formation of intramolecular disulphide bonds. It is known[25] that the first step in the reaction of a thiol, or rather thiolate (RS^-), with nitroprusside is formation of an adduct (Scheme 1). Decomposition of the adduct leads to formation of the short-lived thiyl radical (RS) and possibly the pentacyanonitrosylferrate complex $[Fe(CN)_5NO]^{3-}$. The latter can be oxidized back to nitroprusside by oxygen in the solvent and thus the cycle is repeated. There are other routes by which $[Fe(CN)_5NO]^{3-}$ may decompose and so the cycling does not continue indefinitely.[26] Dimerization of the radical creates the disulphide bond. The rate of disulphide bond formation depends not only upon the rate of dimerization, but also upon the equilibrium constant for adduct formation (K). If, for steric reasons, K is small for thiols within the enzyme, then disulphide bond formation will be slow and significant inhibition of the enzyme occurs only after a long incubation time. This assumes that inhibition is the result of disulphide bond formation.

The activity of lactoperoxidase was measured by the standard assay: oxidation of pyrogallol to purpurogallin by hydrogen peroxide, monitored by the increase in absorbance at 425 nm due to pur-

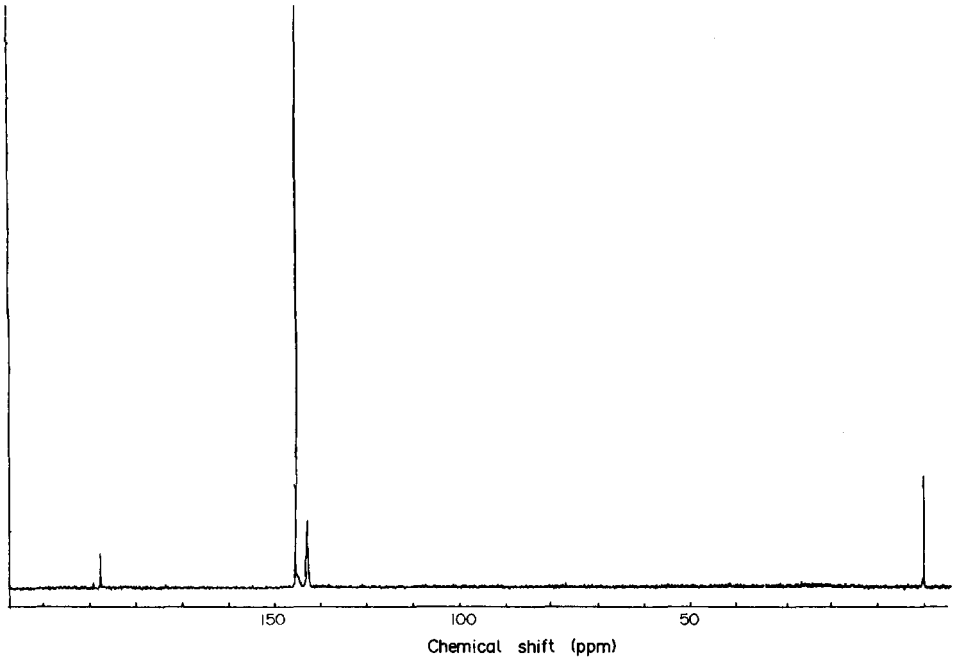

Fig. 3. ^{13}C NMR spectrum after reaction of nitroprusside with GAPDH. [GAPDH] = *ca* 10^{-5} M; [Nitroprusside] = 10^{-3} M.

purogallin formation.[27] Addition of nitroprusside to the enzyme solution, followed by initiation of the reaction with hydrogen peroxide and pyrogallol, led to markedly decelerated purpurogallin formation (Fig. 4). From these data it is clear that nitroprusside is an effective inhibitor for lactoperoxidase but this effect is not dependent on prolonged incubation, as it was with papain and GAPDH.

We could obtain no information on the inhibition of catalase activity because nitroprusside absorbs in the region where disappearance of hydrogen peroxide is monitored (λ_{max} 240 nm). However, spectral changes were observed when catalase and nitroprusside were incubated in phosphate buffer. The resulting spectrum (Fig. 5) corresponded closely to that of a genuine sample of a nitrosyl catalase complex (NO-catalase), prepared from catalase and nitric oxide, and literature values for the absorbance maxima of NO-catalase.[28] The signals due to NO-catalase disappeared over the course of 3 h.

The ESR spectrum of a solution of nitroprusside and catalase was recorded at room temperature and showed a weak three-line signal, identical with that observed on reaction of nitroprusside with simple thiols.[7] There was no signal corresponding to catalase itself or to NO-catalase at room temperature or after cooling the sample to 120 K. Upon warming the sample to room temperature the intensity of the three-line signal was enhanced but the solution in the ESR tube had become turbid, a manifestation of enzyme denaturation. It is known[29] that bovine liver catalase contains eight thiol groups which could have become exposed during warming and reacted with nitroprusside with formation of disulphide bonds. A solution of nitroprusside and catalase at similar concentrations to those of the former

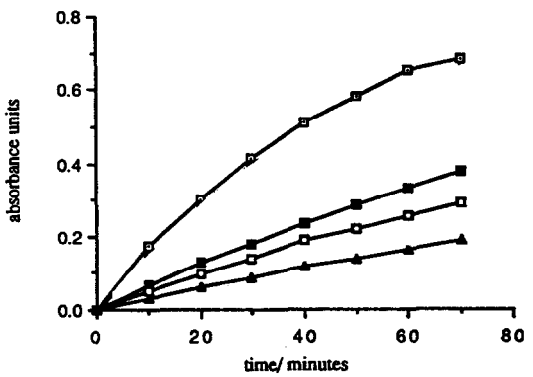

Fig. 4. Formation of purpurogallin catalysed by lactoperoxidase in the presence of inhibitors: (A) none; (B) 1.5×10^{-3} M nitroprusside; (C) 7.6×10^{-3} M nitroprusside; (D) 7.6×10^{-2} M nitroprusside. $[Pyrogallol]_0 = 2.72 \times 10^{-2}$ M; [Lactoperoxidase] = 1.23×10^{-8} M.

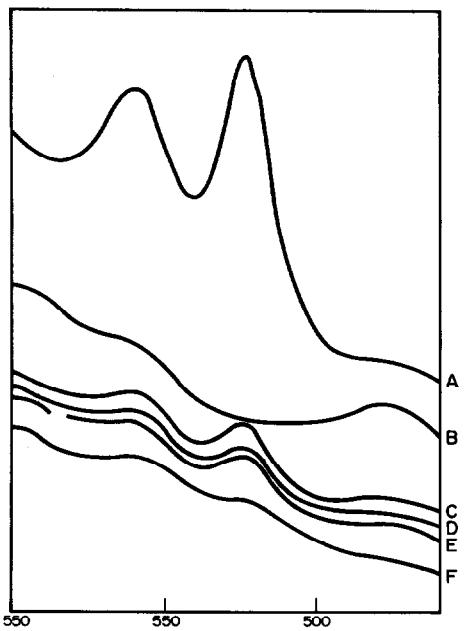

Fig. 5. Spectral changes accompanying the reaction of nitroprusside with catalase: (A) authentic NO-catalase; (B) catalase; (C) spectrum of nitroprusside (5.87×10^{-3} M) and catalase (3.57×10^{-5} M) 5 min after mixing; (D) 20 min after mixing; (E) 30 min after mixing; (F) 3 h after mixing.

experiment but left at room temperature did not become turbid within the same period and the ESR signal remained weak.

The results obtained with lactoperoxidase suggest that inhibition is not due to slow reaction with thiol groups in the enzyme but is consistent with reaction of nitroprusside with haem, possibly a fast electron transfer.[23] The results with catalase present a more complex picture: there is evidence of fast reaction to give NO-catalase and also of reaction with thiols in a much slower process. In view of the rapid vasodilator effect of nitroprusside when used clinically, we tend to favour the former process, i.e. reaction with haem, as the origin of the effective reaction of nitroprusside with guanylate cyclase.

EXPERIMENTAL

Material

Papain, BAEE, dithiothreitol, trypsin (type IX, porcine pancreas), GAPDH (rabbit muscle), NAD (thymol free purified powder), lactoperoxidase (bovine milk, lyophilized powder) and sodium arsenate were obtained from Sigma and used without further purification. DL-Glyceraldehyde-3-phosphate was prepared from the barium salt of DL-glyceraldehyde-3-phosphate diacetal according to the standard procedure.[30] Most other reagents were AnalaR grade. The preparation of ^{13}C-labelled sodium nitroprusside has been described previously.[31] All nitroprusside solutions were protected from light during use. NO-catalase was prepared by a literature method.[32]

Instruments

NMR spectra were recorded on a Brucker AM 300 spectrophotometer. The number of scans was typically 3700 with a pulse width of 2.0 μs and a delay of 1.5 s. For the ESR spectra a Brucker ER 2000 spectrometer was used. UV–vis spectra were recorded on a Pye Unicam SP8 100 spectrophotometer.

Papain assay

Papain activity at 30°C was determined after activation following an established procedure.[19] In a standard experiment papain was eluted from a Sephadex column (G25) with phosphate buffer (pH 7.5, $I = 0.1$ M, containing 10 mM EDTA) following activation of papain (2.5 mg, 60 units) in buffer (0.4 cm^3) with dithiothreitol (2.4 mg) at room temperature for 1 h. The concentration of the enzyme "stock" solution was determined from the absorbance at 278 nm. Temperature-equilibrated stock solution (1 cm^3, 1.34×10^{-5} M) was added to water or inhibitor solution (1 cm^3) and left to incubate. The reaction was initiated by addition of temperature-equilibrated BAEE (0.5 cm^3, 6.2×10^{-3} M) and the change in absorbance at 263 nm, read against a BAEE reference (1.24×10^{-3} M), was recorded.

Trypsin assay

Activity at 30°C was determined by a standard procedure. Nitroprusside (up to 2.7×10^{-4} M) was incubated with trypsin (2.8×10^{-7} M) at 21°C for 20 min in phosphate buffer (pH 7.5, $I = 0.1$ M containing 10 mM EDTA). BAEE (10^{-3} M) was added to initiate the reaction and BAEE hydrolysis was followed as detailed above for the papain assay.

GAPDH assay

The activity of GAPDH at 30°C was determined by monitoring the change in absorbance at 340 nm due to the reduction of NAD. An enzyme "stock"

solution was prepared with GAPDH (105 units, 8.77×10^{-9} mol), NAD (35.8 mg, 4.8×10^{-5} mol) and Na_2HAsO_4 (4.8 cm^3, 1 M) in phosphate buffer (pH 7.32, $I = 0.1$ M containing 10 mM EDTA), total volume 24.8 cm^3. For each experiment, water or a solution of the inhibitor (0.2 cm^3) was added to temperature-equilibrated enzyme "stock" solution (1.9 cm^3) and, following incubation, the reaction was initiated by the addition of temperature-equilibrated glyceraldehyde-3-phosphate solution (0.3 cm^3, 2 mM).

Lactoperoxidase assay

The activity of lactoperoxidase at 18°C was determined by following purpurogallin formation at 425 nm. An enzyme solution was prepared with lactoperoxidase (0.26 units cm^{-3}, 4.07×10^{-8} M) in phosphate buffer (pH 7.0, $I = 0.067$ M). For each experiment, buffer or inhibitor (0.5 cm^3) was added to the temperature-equilibrated enzyme solution (1 cm^3) and buffer (1 cm^3). The reaction was initiated by addition of hydrogen peroxide (0.5 cm^3, 4×10^{-3} M) and pyrogallol (0.3 cm^3, 3×10^{-2} M).

Catalase assay

The activity of catalase at 30°C was determined by following the decrease in absorbance of hydrogen peroxide at 245 nm. An enzyme solution was prepared with catalase (50 units cm^{-3}, 1.96×10^{-8} M) in phosphate buffer (pH 7.00, $I = 0.067$ M). The catalysed decomposition was initiated by addition of hydrogen peroxide (2.9 cm^3, 1.96×10^{-2} M) to the enzyme solution (0.1 cm^3) and buffer or inhibitor (0.1 cm^3, maximum concentration 2×10^{-3} M).

Computer graphics

All atomic parameters and structural data for molecular modelling were obtained from the Daresbury Laboratory Chemical Databank Service. The program Chem-X, developed and distributed by Chemical Design Ltd, Oxford, was used to display and manipulate structures in conjunction with a Tektronics 4107 colour terminal linked to a VAX 11/785 computer.

Abstract—Organometallic feedstocks of cadmium, mercury and tellurium, as well as dopants to create n-type, p-type or diluted magnetic semiconductors, can impose limits on the range of programmable parameters in the MOCVD reactor. The influence of the chosen organometallics on the crystal growth process is critically reviewed.

Binary, ternary and quaternary alloy semiconductors formed from various combinations of elements from groups II and VI of the Periodic Table (or groups 12 and 16 under recent nomenclature) are becoming increasingly important due to their useful electronic, optoelectronic, magneto-optic and piezoelectric properties.[1] MOCVD is an important method of creating II–VI semiconductors in thin films for device applications.[2] In this paper we discuss the benefits and limitations imposed on the MOCVD process and material quality by the currently available organometallics. The recent literature concerning MOCVD of mercury cadmium telluride (MCT), ($Hg_{1-x}Cd_xTe$, $0 \leqslant x \leqslant 1$), n- and p-type extrinsically doped MCT, and zinc or manganese substituted alloys is reviewed. Photo-assisted MOCVD, plasma-enhanced MOCVD and precracking techniques are included. Use of these methods to lower the growth temperature has been intensively studied in order to improve crystalline perfection and control of intentional internal composition gradients which are required in the preparation of heterojunctions. In the case of mercury alloys the equilibrium cation vacancy concentration and the necessary overpressure of mercury during growth can be greatly reduced.[3]

Many interesting patent applications[4–7] concerning growth of MCT by MOCVD contain long lists of possible candidate organometallics, however, experimental MOCVD results have been published for only relatively few compounds. These compounds and some selected possible alternatives are listed in Tables 1–4, together with available data on vapour pressure and thermal stability. Various growth methods which have been employed are indicated in the tables. Conventional growth refers to thermal pyrolysis with hydrogen carrier gas; the substrate is placed on a heated support and this is the only source of energy for cracking the organometallics. A variation of the conventional process is the Interdiffused Multilayer Process (IMP).[6] Photo-assisted growth is generally performed in one of two illumination conditions. Most commonly, the light source impinges directly onto the substrate. Alternatively the light beam is directed through the gas close to and parallel to the substrate. Plasma-enhanced MOCVD and thermal precracking methods also separate the energetic cleavage of the organometallics from the dependence on substrate temperature.

* MOCVD refers to Metal Organic Chemical Vapour Deposition.

[a] A–E are constants in the equations: $\log P = A - B/T$ and $\log P = C - [D/(E+t)]$, where p is the vapour pressure in torr, T is the temperature in Kelvin, and t is the temperature in Celcius.

In compiling Tables 1–4, we found some spread in the values reported for vapour pressures, but more seriously no data were found for some of the compounds used.

Organometallics of zinc, cadmium and mercury (Table 1)

In general, ethyl organometallics are less stable and less volatile than the corresponding methyl compounds. Dimethylzinc could probably be regarded as too volatile and consequently is frequently used diluted in hydrogen. This has the disadvantages of requiring accurate dilution at the manufacturing plant and the possible long-term degradation of dilute mixtures by reaction with residual water and other contaminants in cylinders. For these reasons considerable effort has recently been made to produce adducts which have lower volatility. These have the added advantage of

reduced prereaction due to steric hindrance when H_2E (E = S, Se and Te) are employed as the group VI reagents. Similar adducts of Me_2Cd are also being developed.[61]

Photo-assisted growth of HgTe[22] using divinyl mercury or Me_2Hg occurs at a much lower temperature (165°C) than thermal growth using Me_2Hg[23] (325°C) or Et_2Hg[5] (275°C). Other possible alternative R_2Hg MOCVD sources have been discussed,[28,34] however, many would likely have considerably lower vapour pressures.

Relatively little work has been reported on alternatives to Me_2Hg. It would seem that use of elemental mercury would be preferable on economic, purity and safety grounds, although there are potential prereaction problems caused by the naked mercury atom.[4]

Tellurium organometallics for MOCVD (Table 2)

Considerably more results have been published concerning alternative tellurium sources (Table 2), probably due to the relatively rich MOCVD chemistry known for this element. The bulk of reports concerning MOCVD of MCT employ Et_2Te which exhibits a relatively high onset cracking tempera-

ture. Pyrolysis of this alkyl is autocatalytic[14] and the presence of Me_2Cd reduces the onset temperature for deposition of CdTe by ~ 60°C from the temperature required for growth of HgTe (~ 410°C). Precracking, photo-assistance and plasma-enhancement have all been successfully employed to reduce the growth temperature using Et_2Te. A problem common to all low-temperature techniques is the tendency toward gas-phase nucleation due to the low saturation vapour pressures of tellurium, and MCT. For this reason growth by a surface-selective technique is preferred if significant growth rates are to be achieved. Some branched alkyls are made less stable by the enhanced probability of β-hydrogen elimination as well as reduced activation energy for homolytic radical cleavage due to the more stable radicals.[28] The latter effect is also involved in R_2Te which incorporate ligands offering delocalization of the radical unpaired electron, such as the allyl group. Kinetic simulation studies have shown that heterogeneous decomposition can significantly affect observed cracking temperatures.[62] For photo-assisted growth the liberated ligands should not have significant absorption of the light in order to avoid undesirable side reactions, and the reaction products should have a low sticking probability on the growing crystal surface. Unsaturated products such as butadiene might yield involatile degradation or polymerization products under certain pyrolysis conditions. Long term stability of feedstocks is an important consideration when selecting a source with low cracking temperature, with some commercial sources (e.g. tellurophene, TeC_4H_6) requiring shipment in dry ice.[37]

Good compromise between thermal stability and volatility is offered by Et_2Te and Pr^i_2Te, and both can be used for growth at low temperatures by precracking techniques. The low volatility of some of the other tellurium sources is compensated by enhanced cracking efficiency. Little data are available on carbon incorporation or other possible undesirable effects of using any of the organometallics listed in Table 2.

Organometallics for extrinsic n- and p-type MCT (Table 3)

Although PH_3 and AsH_3 have been employed successfully to dope p-type CdTe and MCT,[63–66] prereaction problems, the low cracking efficiency and necessary extra safety precuations for these compounds have stimulated interest in organometallic dopants. The thermal instability of stibine

would add further difficulties in attempts to use it as a p-type dopant. The very high volatilities of Me_3As and Me_3Sb lead to difficulties in controlling doping levels[43] and their high thermal stabilities would restrict growth of MCT to conventional (410°C) or precracking techniques. The triethyl derivative should be less stable and certainly has a more controllable vapour pressure. Doping of MCT has been reported using Me_3As,[43] however, experience of GaAs growth[40] indicates that substantial carbon incorporation might occur. Other potentially useful arsenic sources with cracking temperatures substantially below that of AsH_3 are listed in Table 3. The volatility of Bu^tAsH_2 and Bu^tPH_2 would necessitate dilution in hydrogen for use as dopants. Recently it has been shown[47] that Bu^tAsH_2 decomposes by the first-order elimination of isobutane, i.e. intramolecular coupling elimination, previously only observed in transition metal systems.

n-Doping of CdTe and MCT using indium alkyls has been reported with the less volatile Et_3In potentially offering better low level doping control and lower growth temperatures. The problems of solid Me_3In delivery have been addressed.[67]

Organometallics of manganese for diluted magnetic semiconductors (*Table* 4)

Methylcyclopentadienyltricarbonylmanganese, $(MeC_5H_4)Mn(CO)_3$, has been used to dope ZnS, ZnSe[49–51,55–58] and CdTe[58] films by the MOCVD process, but a high substrate temperature (500°C) is required for complete cracking. It is possible to grow ZnS–Mn films by MOCVD at substrate temperatures as low as 325°C,[49,50] but at this temperature cracking is incomplete and doping is inefficient. In recent studies,[52,53] a compromise temperature near 400°C has been employed. A number of problems result from the high temperatures required for effective manganese doping. They include poor surface morphology and crystallinity in the deposited film, the promotion of reaction between the II–VI layer and commonly used transparent conducting oxides, hydrogen reduction of the oxides, and enhanced solid-state diffusion rates.[51,55,68]

The problem of the high cracking temperature of $(MeC_5H_4)Mn(CO)_3$ has been partially overcome by thermally precracking the manganese compound at 580°C, or by decomposing it by glow discharge (plasma-enhanced MOCVD). Both techniques allow substantial reduction of the substrate temperature (e.g. to 300°C),[55,56] but each places special requirements on reactor geometry. A further problem with the plasma technique is the liberation of oxygen atoms from the carbonyl complex and the consequent possible incorporation of [O] in the epilayer.

There is yet another problem with $(MeC_5H_4)Mn(CO)_3$. To generate sufficient vapour pressure[49–51] for growth of alloys such as $Cd_{0.7}Mn_{0.3}Te$, it is necessary to keep the bubbler temperature at 120–140°C (probably the high temperature limit for valves used in the stainless steel bubblers). In turn, the tubing, valves and front end of the reactor must also be heated[57] so that there is no condensation in the plumbing on the way to the reactor. Clearly, alternative feedstocks with higher vapour pressure and lower growth temperature are required.

Surprisingly, $(C_5H_5)Mn(CO)_3$ seems not to have been tried as a dopant feedstock. It is an air-stable solid which can be purified[69] by vacuum sublimation at 50°C (0.1 mm). Although little detailed information is available about its mode of thermal decomposition, it is completely decomposed at 280–350°C.

To overcome the problem of oxygen incorporation in the epilayer when $(MeC_5H_4)Mn(CO)_3$ is used in plasma-enhanced MOCVD, dicyclopentadienylmanganese, $(C_5H_5)_2Mn$, has been tried as the manganese source. It was introduced from containers at 75[54] and 140°C,[58] and was decomposed by RF glow discharge at 13.56 MHz. The related compound $(MeC_5H_4)_2Mn$ is more volatile and can be introduced from a bubbler at 5°C.[54]

$(C_5H_5)_2Mn$ may not be the best choice for this work because it is one of the most air-sensitive and least volatile of the $(RC_5H_4)_2Mn$ compounds. Its magnetic properties[70,71] are consistent with a high spin, ionic character $Mn^{2+}(C_5H_5^-)_2$. On heating under nitrogen to 158°C, the brown solid changes to a pale pink solid (phase change?) which melts on further heating to 173°C. Under vacuum (0.1 mm), heating to 100–150°C results in sublimation of the compound.

The alkyl-substituted cyclopentadienyl analogues are more volatile. At room temperature, $(MeC_5H_4)_2Mn$[72] is a low melting solid (m.p. 61–63°C) and the compounds $(RC_5H_4)_2Mn$ (R = Et, Pr^i, Bu^t) are liquids. All can be purified by slow distillation.[71] For example, $(EtC_5H_4)_2Mn$ distils under high vacuum with a bath temperature of only 50–60°C. A detailed study[71] of paramagnetic NMR data for these compounds establishes that low and high spin states are in equilibrium.

Compounds with more highly substituted rings can also be obtained. The pentamethylcyclopentadienyl compound, $(C_5Me_5)_2Mn$,[73] is an example. It has a covalent sandwich structure with

the metal in a low spin state. As the solid, $(C_5Me_5)_2Mn$ is easier to handle than the $(RC_5H_4)_2Mn$ compounds because it is only slowly decomposed in the air. However, its volatility is relatively low, and purification by vacuum sublimation is achieved at 100°C (10^{-5} mm). This detracts from its potential as an MOCVD feedstock.

Other carbonyl-free manganese compounds include dialkyl species, R_2Mn. The simple compounds such as Me_2Mn[74] are rather unstable and some are known to detonate. Moreover, the insolubility of these compounds in organic solvents is consistent with a polymeric composition and their volatility is therefore likely to be low. Higher alkyls including R_2Mn ($R = CH_2CMe_3$ and CH_2SiMe_3) have been more thoroughly characterized.[75] They are dimeric in the solid state, and can be sublimed (e.g. $R = CH_2CMe_3$ at 110°C *in vacuo*). However, these compounds are extremely air sensitive. Stable adducts with N,N,N′,N′-tetramethylethylenediamine (tmed) have been formed,[75] and the 1 : 1 adducts $R_2Mn \cdot tmed$ sublime unchanged at 80°C in vacuum. When the alkyl groups are even bulkier ($R = C(SiMe_3)_3$), monomeric dialkyl compounds MnR_2 are obtained.[76] Further study of the thermal properties of these alkyl–manganese compounds seems warranted.

For low temperature, large area MOCVD growth of doped semiconductors, carbonyl and related derivatives of manganese seem to offer greatest potential as alternative feedstocks. Although it has been suggested[49] that $Mn_2(CO)_{10}$ is not suitable for MOCVD, consideration of its properties[77] indicates that it fulfils many of the requirements. The solid is only slowly decomposed in the air, and it can be kept for very long periods under an inert atmosphere. It is reported to decompose above 110°C to a metallic mirror. The major limitation in its possible use for MOCVD is the relatively low volatility.[48]

A volatile hydrido derivative of manganese carbonyl is known.[78] It is a colourless, malodorous liquid (m.p. −25°C) at room temperature and it rapidly oxidizes in air to regenerate $Mn_2(CO)_{10}$. The parent carbonyl is also formed when the hydride decomposes thermally at about 100°C. It seems probable that this thermal decomposition would be inhibited in a hydrogen atmosphere, and so $HMn(CO)_5$ may be a very good carrier of $Mn_2(CO)_{10}$ under MOCVD conditions. High dopant concentration could be obtained because the vapour pressure of the hydride is 5 mm at room temperature.

The related compounds, $RMn(CO)_5$, are more chemically robust than the hydride, and they display a wide range of volatilities. The methyl derivative $MeMn(CO)_5$ is a volatile solid (m.p. 95°C; vapour pressure at 28.8°C, 3 mm) at room temperature. It is reported[79] to decompose at *ca* 100°C, and we have determined that pyrolysis of the compound in a hydrogen stream does produce a metallic mirror. The ethyl derivative $EtMn(CO)_5$ is a volatile liquid (m.p. −30°C; vapour pressure at 45°C, 3.5 mm) and it is somewhat less thermally stable than the methyl analogue. There is a report in the patent literature[60] covering the suitability of this compound for MOCVD applications. The thermochemical properties of some other $RMn(CO)_5$ compounds have been investigated. The most recent involves the benzyl compound $PhCH_2Mn(CO)_5$ and it establishes[80] that the $Mn\overset{\sigma}{-}R$ bond is more thermally stable than the Mn—CO bonds. We intend to prepare a range of these compounds with different R groups, and to systematically study their thermal properties, including thermal degradation in a hydrogen stream with identification of the products. Recently, we reported[59] growth of $Cd_{1-x}Mn_xTe$ and $Hg_{1-x}Mn_xTe$ using $MeMn(CO)_5$ at low temperatures.

Since manganese is co-deposited with other semiconductor metals in the MOCVD process, there is interest in finding volatile dimetallic complexes in which manganese is bound to mercury, cadmium or tellurium. A number of such compounds are known and two examples are briefly discussed below.

The mercury–manganese compound $Hg[Mn(CO)_5]_2$ is readily prepared,[81] and can be purified by sublimation (100–140°C at 0.1 mm). It decomposes thermally at 155°C, but it is not indicated if total cracking occurs at this temperature. The volatility of this compound is probably too low for convenient use in MOCVD applications.

The direct reaction between manganese carbonyl and dialkyltellurium gives manganese–tellurium species[82] as shown in eq. (1):

$$Mn_2(CO)_{10} + TeR_2 \longrightarrow Mn_2(TeR)_2(CO)_8 \underset{CO}{\rightleftharpoons} 2Mn(TeR)(CO)_5. \quad (1)$$

The monomeric product may be of interest for the controlled formation of MnTe by MOCVD. These and related bimetallic compounds warrant further investigation, particularly since co-metal chemical vapour deposition has been achieved with other mixed-metal compounds. Recent examples include the formation of $FeCo_x$ films from iron–cobalt carbonyl clusters,[83] and of FeTe and $FeTe_2$ from $[(C_5H_5)Fe(CO)(PEt_3)]_2(Te)_n$.[84]

(*Received* 27 *October* 1989; *accepted* 2 *November* 1989)

Abstract—The interaction of lithium alkyls in diethyl ether in the presence of tetramethylethylenediamine (TMED, $Me_2NCH_2CH_2NMe_2$) with cobalt(II) chloride has led to the isolation of four complexes whose crystal structures have been determined. The complexes (TMED)CoR_2, R = CH_2SiMe_3 and CH_2CMe_3, have tetrahedral geometry about cobalt; in $[(TMED)Li]_2[Co(CH_2SiMe_3)_4]$ there are CH_2SiMe_3 groups bridging the lithium and cobalt atoms; in the ionic complex $[(TMED)_2Li][CoCl\{CH(SiMe_3)_2\}_2]$ the geometry about cobalt is trigonal planar. Electron paramagnetic resonance spectra of the complexes and of the products of the reaction with oxygen are reported.

Relatively few cobalt(II) alkyl or aryl compounds are known, either neutral with a donor ligand, CoR_2L_2, or anionic $[CoR_n]^{2-}$ (n = 3, 4), and X-ray data is particularly scanty; some often unstable and air-sensitive lithium alkylate or arylate anions with, for example, CH_3, CH_2SiMe_3, 2,4,6-MeC_6H_2, C_6F_5 and C_6Cl_5, are listed;[1a] no X-ray structures are so far reported although some structures of neutral species, viz. $Co(C_6F_5)_2$(η-toluene) and Co(mesityl)$_2(PEt_2Ph)_2$ are known,[1b] the latter being planar on account of steric blocking of two sites by methyl groups [cf. Co_2(mesityl)$_4$ noted below].

In a preliminary note[2] we briefly reported some lithium alkylate anions of manganese(II), cobalt(II) and uranium(IV) and showed[3] that the manganese trimethylsilylmethyl could be oxidized to a green unstable species believed to be $Mn^{IV}(CH_2SiMe_3)_4$ on the basis of EPR spectra. Oxidation of the similar cobalt species by air led, however, only to decomposition. The present studies are made with the hope that cobalt(IV) species could be identified or isolated on oxidation—without success; so far the only cobalt(IV) alkyl is the tetranorbornyl first made by Bower and Tennant[4] and recently studied in great detail.[5] In the latter work, the cobalt(III) anion $[Co(nor)_4]^-$ was isolated as salts of $[Li(THF)_4]^+$, [Na(18-C-6)]$^+$ and Et_4N^+.

After completion of our present study the first neutral homoleptic cobalt(II) species, bis(μ-mesityl)dimesityldicobalt(II), has been reported.[6] It was made from the previously known $[Li(THF)_4][Co(mes)_3]$ and both compounds have been characterized in detail and the crystal structure of $[Co(mes)_2]_2$ determined.

Our initial attempts to isolate crystalline salts from reactions of lithium alkyls with $CoCl_2$ or $CoCl_2$THF in diethyl ether or tetrahydrofuran solutions were unsuccessful, although the alkylate anions were evidently readily formed. Even the subsequent addition of TMED did not yield tractable products. The best procedure for the lithium compounds and (TMED)$Co(CH_2CMe_3)_2$, described in the Experimental, involves addition of excess lith-

ium reagent in Et_2O to $CoCl_2$ and TMED in Et_2O at −78°C—even so, black solids separated and the final yields of products were low, 20–30%. The neutral species (TMED)Co(CH_2SiMe_3)$_2$ was isolated in a similar manner but using less alkylating agent.

Although attempts to oxidize the alkylate anions chemically led to decomposition, the initial reaction with O_2 could be followed by EPR spectra as discussed later. Cyclic voltammetry in THF showed only irreversible oxidation waves. No evidence for any formation of cobalt(IV) species has been found.

X-ray crystal structures

The structures of the complexes (TMED)CoR_2, R = CH_2SiMe_3 (**1**) and R = CH_2CMe_3 (**2**), are very similar, as would be expected. Diagrams of the two molecules are given in Figs 1 and 2, respectively, whilst selected bond lengths and angles are given in Table 1. The geometry at cobalt is best described as distorted tetrahedral since the planes defined by the metal and the two carbons and the metal and two nitrogens interact at angles of 84.1(2)° (**1**) and 82.1(2)° (**2**), i.e. close to 90°. Nevertheless, there are significant bond angle distortions away from the ideal 109.5°; the N—Co—N angles, constrained by the bidentate nature of the TMED ligand are 83–84°, whilst the expanded C—Co—C angles of 122.3(2) (**1**) and 132.3(4)° (**2**) reflect the large, but differing, steric size of the alkyls. Increased steric effects may also account for the slightly greater Co—C and Co—N distances in the neopentyl.

Table 1. Selected bond lengths and angles for compounds **1** and **2**

Bond lengths (Å)	1	2
C(10)—Co(1)	2.025(7)	2.039(6)
C(20)—Co(1)	2.024(7)	
N(1)—Co(1)	2.179(7)	2.213(5)
N(2)—Co(1)	2.170(7)	
Bond angles (°)		
C(20)—Co(1)—C(10)	122.3(3)	132.2(4)
N(1)—Co(1)—C(10)	113.4(3)	112.7(3)
N(1)—Co(1)—C(20)	106.5(3)	
N(2)—Co(1)—C(10)	108.1(3)	
N(2)—Co(1)—C(20)	116.0(3)	
N(2)—Co(1)—N(1)	84.0(3)	83.2(3)
C(1)—N(1)—Co(1)	111.9(6)	103.2(4)

The cobalt coordination in [(TMED)Li]$_2$ [Co(CH_2SiMe_3)$_4$] (**3**) is also distorted tetrahedral with the Me_3SiCH_2 groups bridging lithium and cobalt atoms. A diagram of the molecule is given in Fig. 3, bond lengths and angles in Table 2. Here the angle of intersection of the two C_2Co planes is 88.8(3)°. The distribution of tetrahedral angles is affected mainly by the lithium bridging which gives closed-down C—Co—C angles of 101.3(4) and 101.7(3)°. The open C—Co—C angles are 110.6(4) and 114.4(5)°. The Co—C distances

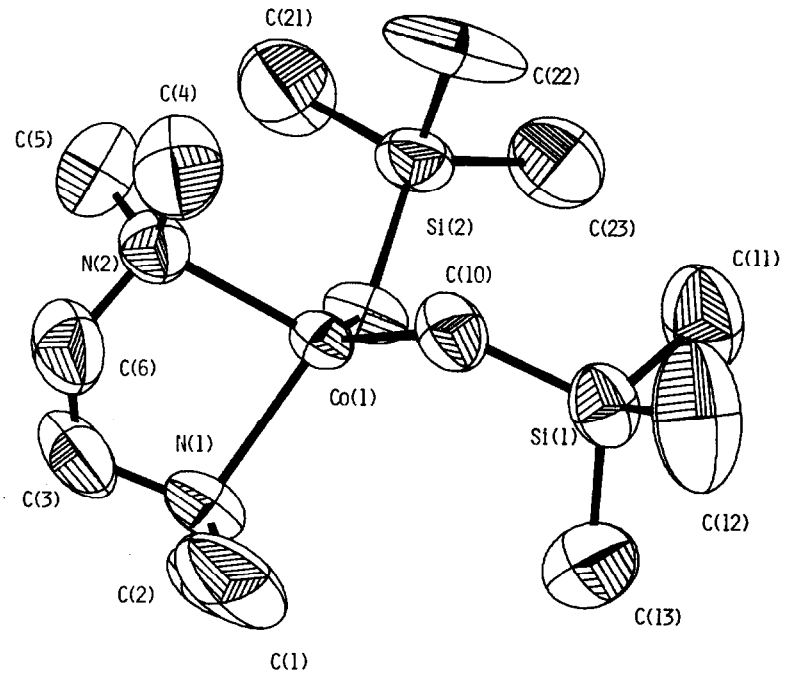

Fig. 1. Structure of (TMED)Co(CH_2SiMe_3)$_2$ (**1**).

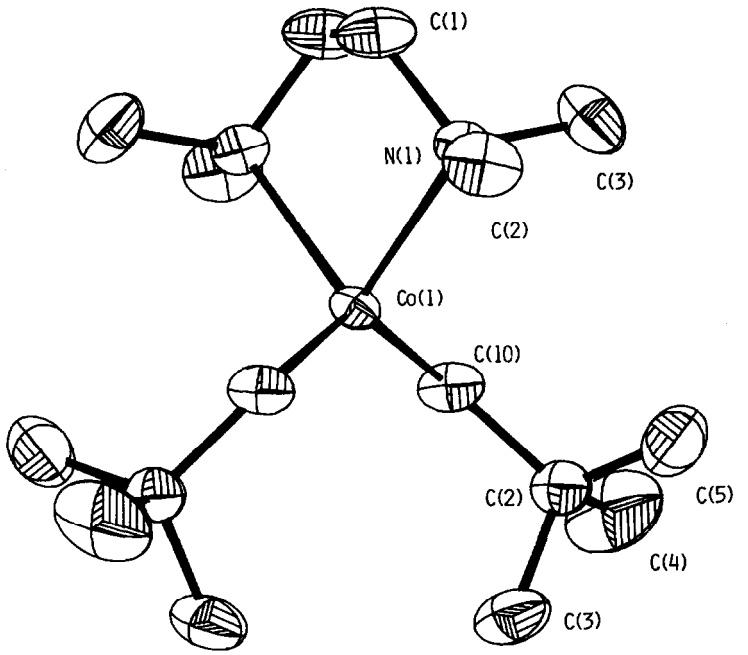

Fig. 2. Structure of (TMED)Co(CH_2CMe_3)$_2$ (**2**).

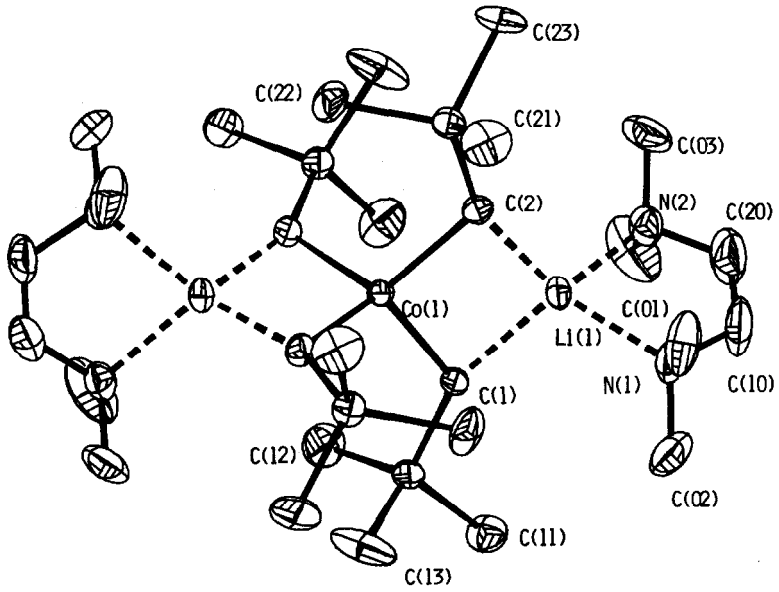

Fig. 3. Structure of [(TMED)Li]$_2$[Co(CH_2SiMe_3)$_4$] (**3**).

are more than 0.1 Å longer than those in the two N_2CoC_2 compounds, possibly affected by the lithium bridging.

For the compound [(TMED)$_2$Li][CoCl{CH(SiMe$_3$)$_2$}$_2$] (**4**) the structure is shown in Fig. 4; bond lengths and angles are in Table 3. The cobalt coordination is trigonal planar (sum of angles = 360.0°) but remarkably, in view of the different ligands, the three angles Cl—Co—C (×2) and C—Co—C are all very close to 120°—119.3(6)–120.8(7)°. A close to planar CoC_3 group has been found[6] in the homoleptic bridged dimer [(mes)Co(μ-mes)]$_2$. Furthermore, there is close similarity to the mononuclear alkoxides and dialkylamides,[7] [Li(THF)$_3$][CoCl(OBu^t$_3$)$_2$], [Li(THF)$_{4.5}$][Co{N(SiMe$_3$)$_2$}(OBu^t$_3$)$_2$] and Li[Co{N(SiMe$_3$)$_2$}(OBu^t$_3$)$_2$], all of which have, however, distorted trigonal planar geometry about cobalt(II). The significant differences in cobalt(II) geometries between the alkyls and the alkoxides and

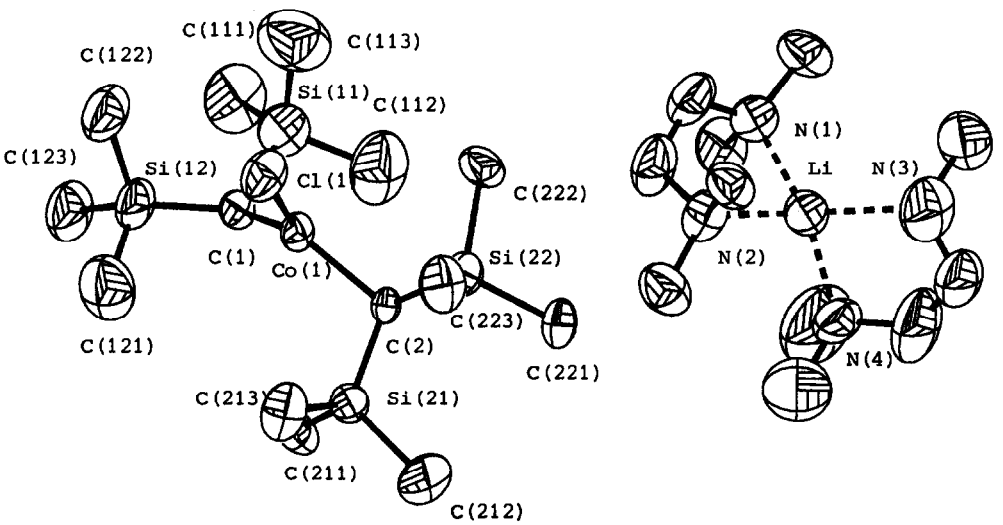

Fig. 4. Structure of $[(TMED)_2Li][CoCl\{CH(SiMe_3)_2\}_2]$ (**4**).

silylamides may well reflect the differing covalent vs ionic character (and therefore stereochemical rigidity) of the metal-to-ligand bonding. Other three-coordinate species are $[Co(NR_2)_2]_2$ (R = $SiMe_3$, Ph) and $Co[N(SiMe_3)_2]_2PPh_3$).

EPR spectra

The X-band EPR spectra of the three tetrahedral cobalt(II) compounds in frozen, degassed toluene at liquid nitrogen temperature (77 K) were typical of such tetrahedral cobalt(II) complexes with large zero-field splittings[8] (Fig. 5). On exposure of solutions to a trace of air followed by rapid freezing, the original cobalt(II) signal was replaced by a signal characteristic of a cobalt(III) dioxygen complex;[9] the colour also changed from blue to brownish. The effective g values for all the dioxygen adducts have $g_z > g_{x,y} \simeq 2.0$ with relatively small A_{iso}^{Co} values, suggesting that the unpaired electron spin density no longer resides on the cobalt metal centre but is delocalized on the dioxygen moiety.[9] The spectrum for $(TMED)Co^{III}(CH_2SiMe_3)_2(O_2)$, Fig. 6, gives the parameters g_x 2.017, g_y 2.067 and g_z 2.341 with ^{59}Co hyperfine constants of 1.49, 1.26 and 6.65×10^{-3} cm^{-1}, respectively. The differences in the EPR spectra of the other dioxygen compounds were very slight. All the species on warming to room temperature decomposed to insoluble brown–black precipitates.

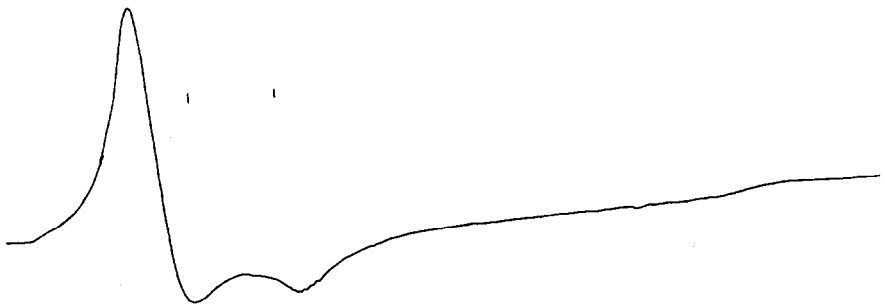

Fig. 5. Typical EPR spectrum of $(TMED)CoR_2$ and $(TMEDLi)_2CoR_4$, R = CH_2SiMe_3 and CH_2CMe_3 at 77 K (scale 100 mT; field increasing to right).

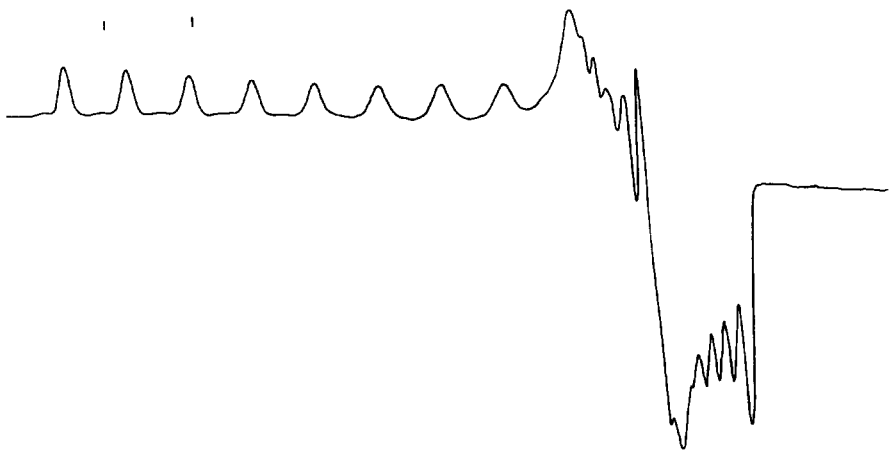

Fig. 6. Typical EPR spectrum of $(TMED)CoR_2$ and $(TMEDLi)_2CoR_4$, R = CH_2SiMe_3 and CH_2CMe_3 after addition of a small amount of oxygen at 77 K (scale 10 mT; field increasing to right).

For the trigonal planar complex $[(TMED)_2Li][CoCl\{CH(SiMe_3)_2\}_2]$ the EPR spectrum was quite different from the others. The spectrum in frozen toluene, Fig. 7, yielded the parameters $g_{\parallel}$ 2.550 and $g_{\perp}$ 2.065. The geometry around the cobalt atom may be approximated to D_{3h}. In this point group, a low spin d^7 ion would be expected to have the configuration $d_{z^2}^2$; $(d_{xz}, d_{yz})^4$; $(d_{x^2-y^2}, d_{xy})^1$ with

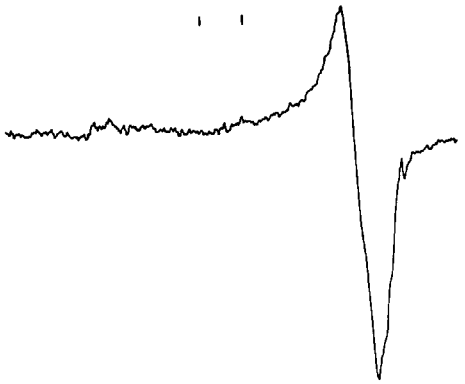

Fig. 7. EPR spectrum of $[(TMED)_2Li][CoCl\{CH(SiMe_3)_2\}]$ at 77 K (scale 10 mT; field increasing to right).

the unpaired electron in a two-fold degenerate E state. However, the relative sharpness of the EPR spectrum indicated a non-degenerate ground state such as might be expected from the more realistic point group of C_{2v}. The observed g values are quite consistent with the d_{xy} ground state, thus predicted if the Co—Cl bond is chosen as the x direction.

On exposure to varying amounts of oxygen the solution became progressively brown giving a decrease in the size of the original EPR signal without showing any new spectrum associated with the cobalt centre.

EXPERIMENTAL

Techniques and instrumentation are similar to those described previously.[10] EPR spectra were obtained at X-band on a Varian E-12 spectrometer. All operations were carried out under N_2 or Ar. Tetramethylethylenediamine was refluxed and distilled over KOH under N_2. Bis(trimethylsilyl)chloromethane was prepared from CH_2Cl_2 and Me_3SiCl;[11] the other halides were from Aldrich. Alkyllithiums were prepared by standard methods from lithium metal and the chlorides in refluxing hexane as for $LiCH_2SiMe_3$;[12] sonification at 50°C using lithium dispersion (2% Na) in a Heat Systems-Ultrasonic Inc. W380 sonicator was also successful. The hexane solution was filtered, evaporated and the residue dissolved in diethyl ether.

(1) $(TMED)Co(CH_2CMe_3)_2$ (2), $[(TMED)Li]_2[Co(CH_2SiMe_3)_4]$ (3) *and* $[(TMED_2Li)][CoCl\{CH(SiMe_3)_2\}_2]$ (4)

For these three complexes the following procedure was used. To a stirred solution of anhydrous $CoCl_2$ (*ca* 0.5 g) and a two-fold excess of TMED in ether at −78°C was added a solution of the alkyllithium in ether (−78°C) in a six-fold excess. The mixture was allowed to warm to room temperature with vigorous stirring. The solution first became red, then green, whilst a black solid deposited. After filtration and evaporation, the residues were dissolved in hexane and blue solutions cooled to −20°C to give blue microcrystalline products in 23% (**1**), 33% (**2**) and 20% (**4**) yields. Recrystallization from hexane gave X-ray quality crystals.

(2) $(TMED)Co(CH_2SiMe_3)_2$ (1)

This was prepared in a manner similar to that described above except that only a four-fold excess of alkyllithium was used and TMED was added to the hexane extract from the reaction of $CoCl_2$ and the alkyllithium. The yield of the crystalline product was 11%.

X-ray crystallography

Crystals of the four compounds were sealed under argon in thin-walled glass capillaries. Following preliminary photographic checks, all subsequent X-ray measurements were made on an Enraf–Nonius CAD4 using the ω–2θ scan mode with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) following previously detailed procedures[13] and standard CAD4 software. The structures were solved via the heavy-atom method and refined by full-matrix least-squares. Non-hydrogen atoms were assigned anisotropic displacement factor coefficients in all cases. Hydrogens were included (in idealized positions with group isotropic displacement factor coefficients) only for compounds **1** and **2**. The crystals of compounds **3** and **4** were very weakly diffracting (cf. proportion of observed data in Table 4), probably as a result of poor crystal packing and both molecular and ligand disorder or thermal motion. Thus, the structure modelling and R values for these two are disappointing, although the identity of the complexes and the molecular configurations are clearly established. No attempts were made to establish a detailed disorder model in view of the paucity of the data. Experimental and other details of the structure analyses are given in Table 4.

Sources of scattering factor data and computer programs used are given in ref. 13; all calculations were made on a DEC VAX 11/750 computer. Lists of atomic coordinates, thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request.

STUDIES ON LANTHANIDE COMPLEXES WITH PYRONIC LIGANDS—III.* SYNTHESIS AND CHARACTERIZATION OF NOVEL COMPLEXES WITH 4-METHYLESCULETIN

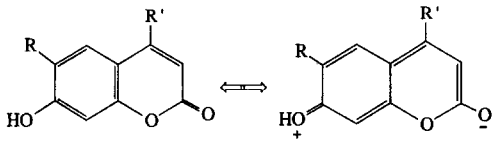
C. BISI CASTELLANI† and O. CARUGO

Dipartimento di Chimica Generale, Università di Pavia, via Taramelli 12, 27100 Pavia, Italy

(*Received* 13 *March* 1989; *accepted* 2 *November* 1989)

Abstract—The novel complexes $Ln(Hmes)Cl_2 \cdot 3H_2O$ (Ln = La, Sm, Eu, Gd, Tb, Dy; Hmes = monodeprotonated 4-methylesculetin) have been synthesized and characterized by elemental and thermogravimetric analysis, and by vibrational and electronic absorption spectra. The ligand, potentially diprotic, is only monodeprotonated. The complexation constants have been determined potentiometrically. Contrary to many other complexes of lanthanides with benzopyrone ligands, the compounds described in this paper do not show metal luminescence promoted by the excited states of the ligand. This behaviour is discussed.

The luminescence of lanthanide cation complexes and its applications are the focus of attention of many researchers.[1] In previous works, we showed that ligands containing the α- or the γ-pyronic rings are able to stimulate the lanthanide ion luminescence.[2] Among the α-pyrone derivatives, the 7-hydroxocoumarins are of relevant interest because of their peculiar electronic structure.[3] The presence of a hydroxy group in the 7-position causes a shift to lower energy of the bands in the electronic absorption spectra, with respect to the parent coumarin. This shift results from mesomeric effects, as shown in Scheme 1.



Scheme 1. H_2mes (4-methylesculetin): R = OH, R′ = Me.

The decrease in electronic transition energy may influence the ability of these molecules to transfer their electronic energy to the lanthanide cations. In order to verify if the 7-hydroxocoumarins behave as good chromophores toward lanthanide ions, like other α-pyrone ligands, we used the 4-methylesculetin as ligand and obtained the novel complexes $Ln(Hmes)Cl_2 \cdot 3H_2O$ [Ln = La, Sm, Eu, Gd, Tb, Dy; Hmes = deprotonated form of 4-methylesculetin (referred to as H_2mes in Scheme 1)]. The compounds were characterized by means of elemental and thermogravimetrical analysis, and electronic and vibrational spectroscopy. The formation constants of all the complexes were determined. No increase in lanthanide cation luminescence was observed in any case.

EXPERIMENTAL

Synthesis

6,7-Dihydroxo-4-methyl-2H-1-benzopyran-2-one (4-methylesculetin) was obtained from Aldrich-Chemie. The lanthanide chlorides were prepared as previously described.[4] An ethanolic solution of H_2mes (1 mmol in 40 cm^3) was added to an aqueous solution of the appropriate lanthanide salt (1 mmol in 15 cm^3). On adjusting the pH to 6.2–6.5 with aqueous NaOH, the product separated from the solution as a brown–orange powder. It was centrifugated, washed with ethanol and water, and dried at 1 mm Hg and room temperature for 3 h.

* For the preceding parts see ref. 2.

† Author to whom correspondence should be addressed.

If kept in contact with the solution, it decomposes in a few hours to a dark pitch.

Physicochemical measurements

IR and electronic spectra were recorded, and TGA measurements performed, as previously described.[5] Emission and excitation spectra were obtained with an Aminco-Baumen MPF spectrophotofluorimeter. Proton–ligand and metal–ligand stability constants were determined using the Calvin–Wilson pH-titration technique,[6] in 1:1 ethanol–water. An E366 Metrohm pH-meter, equipped with a Metrohm glass electrode, was used for pH measurements; the concentrations of the various species were in the range 1×10^{-4}–4×10^{-4} M, temperature 28.0 ± 0.1°C, and $I = 0.1$ M $NaClO_4$. The accuracy in the stability constants determination was not very high, because of the precipitation of the complexes, after addition of a small volume of NaOH 0.05 M. The elemental and thermogravimetric analysis and the stability constants are reported in Table 1.

RESULTS AND DISCUSSION

Some complexes of 4-methylesculetin have already been described; in all cases it was found that the metal cation is bonded by H_2mes in its dianionic form.[7] On the contrary, in the complexes synthesized by us the ligand behaves as a monoanion (Hmes). It is known that the OH group in the 7-position is significantly more acidic than the OH group in the 6-position;[3] thus it seems probable that in our complexes the 7-hydroxy group is deprotonated. The proton of the 6-hydroxy group might be stabilized through hydrogen bonding to one or more of the several oxygen atoms available in the complexes.

The water content of the complexes has been verified by TGA, as reported in Table 1; in each compound all the water molecules are lost in a one-step process at relatively low temperature, indicating that they are not coordinatively bonded to the metal. This fact, together with the well known requirement of the lanthanide cations to reach a high coordination number, might indicate a polymeric structure, with a ligand behaving as a bridge. This hypothesis is supported by the insolubility of the complexes in most common solvents (including DMSO). A polymeric structure has often been observed in lanthanide complexes.[8] Attempts to synthesize complexes with a ligand–metal ratio higher than 1:1 have been unsuccessful, even when operating with a large excess of H_2mes.

The electronic spectra of all the complexes in the solid state are very similar, and quite different from that of H_2mes (Fig. 1). In DMSO they are somewhat different from those in the solid state, indicating partial decomposition of the complexes in solution; therefore it seems more appropriate to compare the spectra in the solid state. The two bands at higher energy are shifted from 198 and 236 nm in the ligand, to 220 and 244 nm in the complexes. The main band at lower energy undergoes a larger shift passing from 340 nm in H_2mes

to 390 nm in the complexes; also its pattern changes noticeably. The decrease in the electronic energy transitions of the complexes with respect to the free ligand could result from an increase of the mesomeric effect (see Scheme 1) after deprotonation and complexation of H_2mes.

This hypothesis is supported by IR spectral data. The H_2mes vibrational spectrum is characterized, in addition to a large ν(OH) band at 3350 cm^{-1}, by a strong signal at 1660 cm^{-1} due to the pyrone ν(C=O) and by two other bands at 1610 and 1560 cm^{-1} assigned to ν(C=C). In the complexes of 4-methylesculetin which have already been described in the literature, the ν(C=O) bond remains unaltered, but the ν(C=C) bonds are very slightly shifted to lower energy (less than 10 cm^{-1}).[7] In the lanthanide complexes described in this work, the pyrone ν(C=O) is located at 1645 cm^{-1} and the ν(C=C) bonds are found at 1575 and 1525 cm^{-1}. These shifts to lower energy with respect to the free H_2mes could indicate that in the complexes the importance of form **II** of the free ligand (see Scheme 1) is increased. However, the IR data might also be indicative of the formation of a coordinative bond between the lanthanide cations and the coumarine carbonyl oxygen atom. Packing effects may also be present.

The formation constants of all the described complexes have been determined, and are reported in Table 1. In order to calculate them, the pK_a of H_2mes was previously determined, and a value of 8.12 ± 0.3 was found. The slight difference from the value (7.90) reported by other authors may be due to different experimental conditions.*[9] The variation of metal–ligand stability constants with increasing atomic number of the cation follows an expected trend.[10] In fact at the Gd level there appears a break, which has often been noted and theoretically studied.[11]

As far as the luminescence is concerned, we recorded the emission spectra of the complexes of 4-methylesculetin with Sm^{III}, Eu^{III}, Tb^{III} and Dy^{III} which are known to be lanthanide cations which can luminesce in the visible region.[12] However, when exciting in the range 300–430 nm, no lanthanide ion luminescence was observed, either in DMSO or in water–methanol (pH 5.5). The ligand fluorescence is reduced to about 70% with respect to the free H_2mes fluorescence. The fact that the metal ions do not luminesce could result from different reasons. For example, we could suppose a very efficient quenching via multiphonon-like processes due to the OH stretching vibrations of water molecules or of the non-deprotonated OH group of the ligand. However, in our opinion, it is more reasonable to suppose that 4-methylesculetin is not effective in transferring energy to luminescent lanthanide cations. In fact, if the metal ion luminescence was quenched by OH stretching vibrations, we should have observed some difference on passing from DMSO to water–methanol as solvent; moreover, some differences had to arise by changing the energy gap between the lowest emitting level and the highest accepting level of the metal; the gaps are 7500, 7800, 12,300 and 14,700 cm^{-1} for Sm^{III}, Dy^{III}, Eu^{III} and Tb^{III}, respectively.[13] Moreover, the brown–orange colour of all the complexes indicates that the first singlet excited state of the ligands is quite low in energy; as a consequence, the first triplet excited state of the ligands, generally involved in the ligand to lanthanide energy transfer,[12] is probably at too low energy to allow an effective energy transfer.

* The experimental conditions are not exhaustively described in ref. 9.

SYNTHESIS, CHARACTERIZATION AND STRUCTURAL ASPECTS OF DIORGANOTELLURIUM(IV) COMPOUNDS CONTAINING (Te—S) BONDS

T. N. SRIVASTAVA and JAI DEO SINGH

Department of Chemistry, University of Lucknow, Lucknow 226007, India

and

SANJAY KUMAR SRIVASTAVA*

School of Studies in Chemistry, Jiwaji University, Gwalior 474011, India

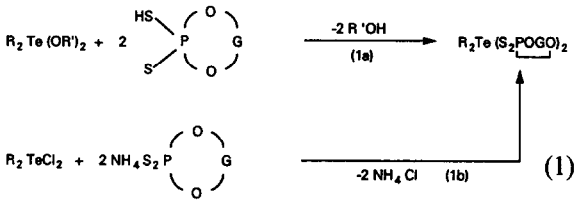
(*Received* 25 *April* 1989; *accepted* 2 *November* 1989)

Abstract—Diorganotellurium(IV) compounds containing (Te—S) bonds of the general formulae $[R_2Te(S_2POGO)_2]$ [R = Ph or *p*-$MeOC_6H_4$; G = —CH(Me)CH(Me)—, —Me_2C—CMe_2—, —$CH_2C(Me_2)CH_2$—, (Me)$CHCH_2C(Me_2)$—, $CH_2C(Et_2)CH_2$—] have been prepared by the reaction of $R_2Te(OR')_2$ (R′ = Me or Et) and corresponding O,O′-alkylene dithiophosphoric acids or by the reaction of R_2TeCl_2 with $[NH_4S_2POGO]$ in anhydrous toluene. The products have been characterized using analytical and spectroscopic (IR, ^1H, ^{13}C, ^{31}P and ^{125}Te NMR) data. The products are monomeric in nature and their possible structures are discussed.

Although several dithiocarbamates containing the (Te—S) bond are well known,[1–4] the analogous dithiophosphate complexes are scarce.[5,6] This may be due to the instability of the products due to their reduction from Te^{IV} to Te^{II} and the formation of the corresponding disulphides. Recently from this laboratory[7–9] and also by other workers,[10,11] it has been reported that diorganotellurium(IV) bis(O,O′-dialkyl dithiophosphates) $[R_2Te\{S_2P(OR')_2\}_2]$ decompose in low boiling solvents into R_2Te^{II} and the disulphides $[(R'O)_2P(S)SS(S)P(OR')_2]$. In view of the increasing interest in (Te—S) bonded compounds,[11,12] we report the synthesis and characterization of $[R_2Te(S_2POGO)_2]$ compounds where the alcoholic (OR′) unit of $[R_2Te\{S_2P(OR')_2\}_2]$ is replaced by the glycolic unit. The stability of $[R_2Te(S_2POGO)_2]$ in comparison to that of $[R_2Te\{S_2P(OR')_2\}_2]$ derivatives is examined.

RESULTS AND DISCUSSION

The diorganotellurium(IV) bis(O,O′-alkylene dithiophosphates) were synthesized by the reaction of diorganotellurium(IV) alkoxides in anhydrous toluene by refluxing and removing the alcohol azeotropically or by stirring a mixture of diorganotellurium(IV) dihalide and the ammonium salt of the O,O′-dialkylene dithiophosphoric acids in 1:2 molar ratio in toluene. Alternatively they may be prepared by the reaction of R_2TeO and corresponding O,O′-alkylene dithiophosphoric acid in



(1)

$CH_2C(CH_3)_2CH_2$—].

2,2′-dimethoxypropane. The yield of the products in the latter case is less than that by the former [eq. (1)]. Similar reactions in benzene gave products

* Author to whom correspondence should be addressed.

which were different than those expected and are characterized as $[R_2Te(S_2POGO)]_2O$ or $[\{R_2Te(S_2POGO)\}_2]\cdot H_2O$. All the reactions [eq. (1)] are facile and are completed by stirring the reactant in toluene (30 min) or by refluxing the reactants in toluene (1 h). The products were obtained in greater than 80% yield in each case. The compounds are yellow, crystalline, sharp melting solids, soluble in all common organic solvents such as MeOH, EtOH, Pr^iOH, C_6H_6, CCl_4, $CHCl_3$, CH_2Cl_2, Me_2SO, Me_2CO, MeCN, etc. They are stable towards atmospheric oxygen and moisture. However, they decompose slowly in low boiling organic solvents according to [eq. (2)]:

$$[R_2Te(S_2POGO)_2] \longrightarrow R_2Te + [OGOP(S)S{-}S(S)POGO] \quad (2)$$

They are completely decomposed by keeping them in solution for 24 h or by refluxing them in low boiling solvents such as CH_2Cl_2, CCl_4, $CHCl_3$, etc. for 10–12 h. The decomposition of the products $[R_2Te(S_2POGO)_2]$ is slower than $[R_2Te\{S_2P(OR')_2\}_2]$ in low boiling solvents. This may be due to the presence of the cyclic ring in the former and an open chain alkoxy group in the latter. The cyclic ring makes the molecules stable.

IR spectra

IR spectra of these new compounds have been examined in KBr as discs and in CS_2 solution in the region 4000–400 cm^{-1}, and tentative assignments have been made on the basis of earlier reports.[13,14] The bands present in the regions 1090–970 and 890–760 cm^{-1} are assigned to ν(P)—O—C and νP—O—(C). A strong to medium band in the region 950–910 cm^{-1} is due to rings. A strong band present in the region 685–620 cm^{-1} in O,O-alkylene dithiophosphoric acids assigned to ν(P=S) does not undergo shifts in the compounds reported in the present study. The bands of medium intensity in the region 510–470 cm^{-1} may be attributed to ν(P—S) vibrations. The IR spectra of the products in KBr discs and in CS_2 solution are almost similar and do not yield any significant information about the nature of coordination of the diothiophosphate ligand.

^{1}H NMR spectra

The ^{1}H NMR spectra of the compounds have been recorded in $CDCl_3$ and the data are given in Table 2. The ^{1}H NMR spectra show the characteristic proton resonances of the corresponding

Table 1. Analytical data for $[R_2Te(S_2POGO)_2]$ derivatives

10	$[(p\text{-}MeOC_6H_4)_2Te\{S_2POCH_2C(Me_2)CH_2O\}_2]$	137	17.1 (17.3)	39.1 (39.1)	4.5 (4.6)	17.2 (17.4)

alkylene as well as aryl groups. A sharp singlet at δ 3.15–3.7 due to the S—*H* protons of free acids is absent in the spectra of the compounds indicating elimination of "H" of the acid derivatives on compound formation.

^{13}C *NMR spectra*

^{13}C NMR spectra of the representative complexes were recorded and the data are summarized in Table 3. The ^{13}C resonances of the compounds show that the two O,O-alkylene dithiophosphate ligands are equivalent.

^{31}P *NMR spectra*

The ^{31}P chemical shift values depend on the size of the glycol ring. In the case of five-membered rings $[S_2POGO]^-$ [G = —$C(Me_2)C(Me_2)$—, —CH(Me)CH(Me)—] the ^{31}P signals are not very different from those in the free ligands, indicating monodentate coordination of the O,O-alkylene dithiophosphate ligand. In the case of the six-membered glycol rings, G = —$CH(Me)CH_2C(Me_2)$—, —$CH_2C(Me_2)CH_2$—, —$CH_2C(Et_2)CH_2$—, a shift of ~ 10–15 ppm in the ^{31}P signals is observed in comparison to that in the free acids. The downfield chemical shift indicates a chelated structure with bidentate alkylene dithiophosphate groups.[15]

^{125}Te *NMR spectra*

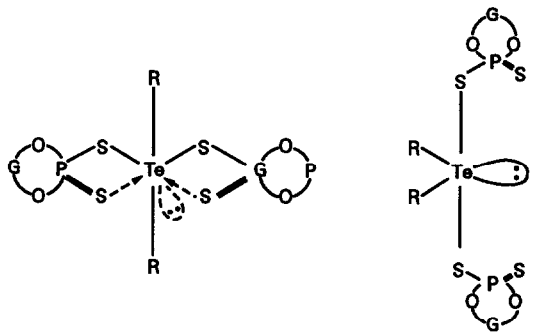
^{125}Te NMR spectra of a few representative compounds have been recorded in C_6H_6 and $CHCl_3$ and are listed in Table 3. Only a single peak was observed. However, at high scans instead of the product signal (^{125}Te chemical shift) another peak was observed at 724.8 ppm in the case of $[(p\text{-}MeOC_6H_4)_2Te(S_2POGO)_2]$ and at 689 ppm in the case of $[Ph_2Te(S_2POGO)_2]$, corresponding to R_2Te (R = p-$MeOC_6H_4$— and Ph) indicating a slow decomposition of the products[16] in solution [$Te^{IV} \rightarrow Te^{II}$].

Structure and bonding

The ^{31}P NMR spectra of the products show that there are two modes of bonding in $[R_2Te(S_2POGO)_2]$ derivatives. Where the glycol unit is five-membered, monodentate bonding of alkylene dithiophosphate ligand is observed, while in the case of six-membered glycol units a bidentate nature of the ligand is indicated.

The change in the bonding may be explained as due to the electron-releasing effect of the alkyl groups in the six-membered ring is more than that in the five-membered ring. Further, the soft nature of the Te^{4+} species and also that of the ligand enables a soft–soft interaction of the metal and ligand atom, the bidentate nature of the ligand more plausible. The unusual behaviour of the two types of ligand (five- and six-membered glycol unit) also seems to be due to stereochemical activity[17] of the lone pair present in the tellurium(IV) species (as observed in many Te—S compounds where the tellurium(IV) lone pair is stereochemically active) or it may be due secondary interactions[18,19] between tellurium and the non-bonded sulphur atom of the ligand.

Thus for $[R_2Te(S_2POGO)_2]$ two possible structures may be suggested for five- and six-membered glycol units of the alkylene dithiophosphate ligands and these are consistent with the reported X-ray crystal structure of R_2TeX_2 derivatives.[12,19]



(R = Ph or p-$MeOC_6H_4$)

G = —$CH_2C(Me_2)CH_2$—,
—$CH(Me)CH_2C(Me_2)$—,
—$CH_2C(Et_2)CH_2$—
G = —CH(Me)CH(Me)—,
—$C(Me_2)C(Me_2)$—

Scheme 1.

EXPERIMENTAL

All manipulations were carried out under a dry nitrogen atmosphere. $TeCl_4$ (BDH) was used as such, and Ph_2TeCl_2 (ref. 20) and $(p\text{-}MeOC_6H_4)_2TeCl_2$ (ref. 21) were prepared according to the established procedures. Solvents were purified and dried by standard procedures. Alkylene dithiophosphoric acids, HS_2POGO, and their ammonium salts were prepared by reported methods[22,23] by passing dry ammonia through a benzene solution of the acids. $R_2Te(OR')_2$ (R = Me or Et) were prepared *in situ* by reaction of R_2TeCl_2 with the corresponding sodium or potassium alkoxides in benzene. ^1H, ^{13}C, ^{31}P and ^{125}Te NMR spectra were recorded on a Jeol Fx 90 Q FT NMR spectrometer and other physicochemical studies were made as

[a] ^{31}P NMR signals for the free ligands.

described earlier.[7] Some representative reactions are described for the preparation of $[R_2Te(S_2POGO)_2]$.

(a) *Reaction of* $(p\text{-}MeOC_6H_4)_2TeCl_2$ *and* $[NH_4S_2POC(Me_2)C(Me_2)O]$

To a stirring suspension of $[NH_4S_2POC(Me_2)C(Me_2)O]$ (4.58 g, 20 mmol) in toluene (25 cm^3) was added a solution of $(p\text{-}MeOC_6H_4)_2TeCl_2$ (4.12 g, 10 mmol) in toluene (50 cm^3). The reaction mixture was stirred for 1 h. Filtration followed by the distillation of the solvent gave the yellow product which was recrystallized from toluene–*n*-pentane (1 : 5 ratio).

(b) *Reaction of* $R_2Te(OR')_2$ *and* $[HS_2POGO]$

In a representative reaction, a mixture of $Ph_2Te(OC_2H_5)_2$ was prepared by the reaction of sodium (0.46 g, 20 mmol) and Ph_2TeCl_2 (3.52 g, 10 mmol) in ethanol. The solution was filtered to remove NaCl, and to the concentrated viscous mass in toluene (20 cm^3) was added $[HS_2POCH_2C(Me_2)CH_2O]$ (3.96 g, 20 mmol) in toluene (10 cm^3). The reaction mixture was refluxed for 1 h and ethanol was removed azeotropically. The solvent was removed under reduced pressure and dried *in vacuo* giving a yellow viscous mass which was recrystallized from a toluene–pentane (1 : 9 ratio) mixture.

(c) *Reaction of* Ph_2TeO *and* $[HS_2POGO]$

Ph_2TeO (2.97 g, 10 mmol) and $[HS_2POCH_2C(Me_2)CH_2O]$ (3.96 g, 20 mmol) were refluxed together in anhydrous benzene (60 cm^3). The water was removed azeotropically. The yellow product thus obtained was identified as $Ph_2Te(S_2POCH_2C(Me_2)CH_2O)_2O$ after several washings with C_6H_6–pet-ether mixture:

$$2Ph_2TeO + 4[HS_2POCH_2C(Me_2)CH_2O] \longrightarrow [Ph_2Te(S_2POCH_2C(Me_2)CH_2O)]_2O + H_2O + 2[HS_2POCH_2C(Me_2)CH_2O].$$

^{31}P NMR signals at δ 91.98 (C_6H_6). Found (%) (Calc.): C, 48.1 (48.2); H, 4.6 (4.7); S, 14.9 (15.1); Te, 14.9 (15.1%). The products are slightly soluble in common organic solvents. When a similar reaction was carried out in methanol and the solution was filtered and allowed to evaporate slowly, yellow crystals of $[\{Ph_2Te(S_2POCH_2CMe_2CH_2O)\}_2O]_2 H_2O$ were produced. ^{31}P NMR signals at δ 91.87 (C_6H_6). Found (%) (Calc.): C, 41.4 (41.5); H, 4.0 (4.2); S, 13.0 (13.0); Te, 25.6 (26.0%); ^1H NMR spectra ($CDCl_3$): δ 7.96–7.22, *m*, 4OH (C_6H_5—Te); 4.20–3.85, *d*, 16H (OCH_2); 1.02, *s*, 24H (CH_3); H_2O, δ 3.35 (br).

SYNTHESIS OF $R_2R'_2C_4B_8H_8$ TETRACARBON CARBORANES FROM (η^6-CYCLOOCTATRIENE)IRON(DICARBAHEXABORANE) COMPLEXES VIA MIXED-LIGAND THERMAL FUSION*

KATHLEEN K. FONDA and RUSSELL N. GRIMES†

Department of Chemistry, University of Virginia, Charlottesville, VA 22901, U.S.A.

(*Received* 1 *September* 1989; *accepted* 6 *November* 1989)

Abstract—Reactions of $(R_2C_2B_4H_4)Fe(\eta^6\text{-}C_8H_{10})$ complexes with $Na^+R'_2C_2B_4H_5^-$ salts ($R = C_2H_5$, $n\text{-}C_4H_9$, $CH_2C_6H_5$; $R' = CH_3$, C_2H_5, $n\text{-}C_4H_9$, $CH_2C_6H_5$) at 150°C in the absence of solvent gave products of the general formula $R_2R'_2C_4B_8H_8$, accompanied in each case by $R_4C_4B_8H_8$ carboranes. ^{11}B, ^1H, and ^{13}C NMR studies of the $R_2R'_2C_4B_8H_8$ clusters indicated that each consists of two isomers consistent with the "open" and "closed" geometries identified in earlier work on $R_4C_4B_8H_8$ clusters, and that the isomer ratios do not change over time in solution at room temperature.

Tetracarbon carboranes of the $R_4C_4B_8H_8$ class were first prepared serendipitously[1] by the low-temperature oxidative fusion of $R_2C_2B_4H_4^{2-}$ ligands in $(R_2C_2B_4H_4)_2MH_x$ complexes ($MH_x = Fe^{II}H_2$ or $Co^{III}H$). Since the original discovery, the ligand fusion reaction has been extensively investigated, as have the chemistry and the unusual cage-fluxionality of the $R_4C_4B_8H_8$ products.[2] The original assumption that the fusion in $(R_2C_2B_4H_4)_2MH_x$ complexes occurred intramolecularly was subsequently demonstrated;[3] for example, oxidation of solutions containing both $(Me_2C_2B_4H_4)_2FeH_2$ and $(Et_2C_2B_4H_4)_2FeH_2$ gave only the homosubstituted species $Me_4C_4B_8H_8$ and $Et_4C_4B_8H_8$, respectively.

Mixed-substituent derivatives of the type $R_2R'_2C_4B_8H_8$ are formed in the simultaneous reaction of $R_2C_2B_4H_5^-$ and $R'_2C_2B_4H_5^-$ ions with $FeCl_2$ followed by air-oxidation.[3] However, such reactions are complicated by the competitive formation of the $R_4C_4B_8H_8$ and $R'_4C_4B_8H_8$ species, which not only lowers the yields of the desired compounds but requires separation of at least three products. In principle, the most efficient approach to the mixed-substituent compounds would entail controlled stepwise addition of dissimilar C_2B_4 carborane units to a metal centre, followed by oxidative fusion to give the desired C_4B_8 product. Since work in this laboratory over several years has demonstrated that $(R_2C_2B_4H_4)Fe(\eta^6\text{-}C_8H_{10})$ complexes readily undergo displacement of the cyclooctatriene ligand by arenes (over $AlCl_3$ in solution, or in thermal reactions) to give $(R_2C_2B_4H_4)Fe$(arene) products,[4] it occurred to us that similar C_8H_{10} displacement might take place at elevated temperatures with small *nido*-carborane ligands. If so, this could provide a controlled route to mixed-ligand $(R_2C_2B_4H_4)FeH_2(R'_2C_2B_4H_4)$ complexes, which in turn could be oxidized to yield the desired $R_2R'_2C_4B_8H_8$ products. An investigation of this approach is the subject of the present report.

RESULTS AND DISCUSSION

Reactions of cyclooctatriene–iron–carborane complexes (1) *with* nido-*dicarbahexaborate*(1−) *salts*

The net process, depicted in Scheme 1, is presumed to involve initial formation of a mixed-ligand bis(carboranyl)iron sandwich (2) as shown, with conversion of the latter species to the observed tetracarbon metallacarborane (3). However, in no case was the proposed intermediate isolated or directly observed. In parallel with previously described arene–$(R_2C_2B_4H_4)Fe(\eta^6\text{-}C_8H_{10})$ thermolyses,[4] all reactions were conducted in glass reactors at 150°C in the absence of solvent; the iron–cyclooctatriene complex is liquid at the reaction

temperature, melting at 88°C. The products were isolated via column and/or plate chromatography in air, and characterized from their ^{11}B, ^{1}H and ^{13}C NMR and mass spectra (see Tables 1–3 and Experimental).

The product yields are presented in Table 4. As can be seen, all reactions examined generated not only the desired mixed-substituent products **3a–d**, but also the corresponding $R_4C_4B_8H_8$ homosubstituted carborane. For comparison, the tetraethyl compound $Et_4C_4B_8H_8$ was prepared by the thermal reaction of $(Et_2C_2B_4H_4)Fe(\eta^6\text{-}C_8H_{10})$ (**1a**) with $Na^+Et_2C_2B_4H_5^-$, which as expected generated a relatively high yield of the target compound (since in this case the main product and by-product are identical). As a control experiment, **1a** was heated alone under conditions identical to the reactions with carborane salts. This afforded $Et_4C_4B_8H_8$ in 33% yield, indicating that thermal decomposition of the reactant complexes **1a–c** may be one source of the $R_4C_4B_8H_8$ by-products listed in Table 4. In another control designed to test the inertness of the reactants to each other at room temperature, **1a** and $Na^+Et_2C_2B_4H_5^-$ in THF solution were stirred for 12 h at room temperature, after which the starting materials were recovered unchanged.

Yields of the isolated heterosubstituted compounds were unfortunately lower than would be required for an efficient synthetic route, probably because of side reactions including decomposition, oligomerization and polymerization of the carborane units occurring at elevated temperature. More efficient experimental arrangements can be envisioned, such as a flow system enabling the trapping of C_4B_8 products as formed. However, the method does provide an apparently general route to heterosubstituted tetracarbadodecaboranes which are accompanied by few soluble side products and hence are easily purified. In a further extension of the synthetic utility of cyclooctatriene displacement, we have recently reported in a collaborative study[5] that reactions of $(R_2C_2B_4H_4)Fe(\eta^6\text{-}C_8H_{10})$ (R = Et, CH_2Ph) with the dihydrodiborole complex $CpCo(Et_2MeHC_3B_2Et_2)$ give novel carborane–dihydrodiborolene triple-decker complexes.

NMR studies

The behaviour of $R_4C_4B_8H_8$ carboranes in solution has been studied in detail by NMR spectroscopy,[1b,6] which revealed that when R = methyl, the solid state consists of one isomer which was shown crystallographically[7] to have a "closed" form (Scheme 1), but when placed in solution a second "open" isomer begins to form and within minutes an equilibrium is established between them. Conversely, when R = ethyl, the solid state is exclusively "open",[6] but in solution the closed isomer is slowly produced until equilibrium is reached. In both cases, evaporation of the solvent causes the compound to revert to its original one-isomer state. In the tetra(*n*-propyl) derivative, both isomeric forms are evidently present even in the solid, but

[a] $CDCl_3$ solution.

[b] Shifts relative to $(CH_3)_4Si$; tentative assignments are given in parentheses. Isomer assignments (**A**, **B**) are given where possible. Cage carbon resonances were not observed. Legend: m = multiplet, s = singlet, d = doublet, dd = doublet of doublets, t = triplet, q = quartet.

there is some change in the open/closed ratio in solution over a period of hours. When R is still larger, e.g. *n*-butyl, the relative amounts of open and closed forms are fixed; in some cases, such as the tetrabenzyl derivative,[8] only the open-cage isomer is seen. These observations, buttressed by kinetic and thermodynamic studies,[6] have been interpreted as reflecting primarily steric effects of the R substituents.

In light of these earlier observations, the solution behaviour of the mixed-substituent compounds **3a–d** was examined via high-resolution NMR spectroscopy as a function of time. Each species was dissolved in dichloromethane and its ^{11}B FT–NMR spectrum recorded within 1–2 min. In all cases, the spectra revealed peaks characteristic of both the open- and closed-cage forms (Table 1), in contrast to the tetramethyl and tetraethyl derivatives referred to above, but consistent with the earlier observations on the tetrapropyl species.[6] Surprisingly, the spectra exhibited no change over time, even on standing for days. For all derivatives, evaporation of the solution to dryness followed by redissolving gave spectra identical to the original.

As is indicated in Table 1, the ratio of open to closed isomers in **3a–d**, as in other examples studied* tends to increase with increasing size of the R substituents, consistent with stabilization of the open form via intramolecular steric repulsion across the open face. The apparent absence of isomer interconversion in solution in the derivatives examined in this work should be interpreted with caution, particularly since the diethyl–dimethyl compound **3a** would not be expected to differ fundamentally from the tetramethyl and tetraethyl derivatives. It is possible that the lowering of symmetry caused by the presence of dissimilar substituents on the two halves of the C_4B_8 cage interferes with the "open"–"closed" interchange process and prevents its occurrence as solvent is removed; this would account for the failure of **3a** to revert to a single isomer in the solid state, in contrast to $Me_4C_4B_8H_8$ and $Et_4C_4B_8H_8$. While the formation of both cage isomers in all four compounds may take place either during synthesis at elevated temperatures or in solu-

* For comparison, the (open isomer)/(closed isomer) equilibrium values[6] for $Me_4C_4B_8H_8$, $Et_4C_4B_8H_8$, and $(n\text{-}C_3H_7)_4C_4B_8H_8$ are, respectively, 0.56, 2.2 and 1.9.

tion during subsequent work-up, the observed open–closed ratios in solution are regarded as equilibrium values since they remain constant over extended periods.

The ^1H and proton-decoupled ^{13}C NMR data on compounds **3a–f** (Tables 2 and 3) further support the characterizations based on ^{11}B spectra as discussed above, and are consistent (as far as can be determined given the complex patterns arising from the organic substituents) with the open–closed isomer ratios which are indicated in the boron NMR data.

EXPERIMENTAL

Materials

n-Hexane and dichloromethane were distilled prior to use and stored over molecular sieves. Tetrahydrofuran (THF) was dried over lithium aluminium hydride and stored over zinc containing titanium tetrachloride as an indicator. Sodium hydride (60% dispersion in mineral oil) and potassium metal were washed three times in dry *n*-hexane prior to each use. Column chromatography was conducted on 70/230 mesh silica gel (EM Science), and preparative-scale plate chromatography was conducted on 250 μm silica gel plates (Merck). *Nido*-2,3-$Et_2C_2B_4H_6$ was prepared by a previously published method,[9] modified in that 3-hexyne and triethylamine were added to the reaction vessel in air and subjected to three cycles of freezing in a liquid nitrogen bath, degassing on the vacuum line and thawing. After addition of B_5H_9 as described earlier,[9] the reactor was stirred for 1 day at 0°C and for 2 days at room temperature, and isolated according to the published procedure. *Nido*-2,3-$Me_2C_2B_4H_6$ was prepared via the literature method[9] except that the B_5H_9 was added over a 10 h period. *Nido*-2,3-(*n*-$C_4H_9)_2C_2B_4H_6$[10] and *nido*-2,3-$(PhCH_2)_2C_2B_4H_6$[4c] were prepared as previously described. $(Et_2C_2B_4H_4)Fe(\eta^6\text{-}C_8H_{10})$[11] (**1a**) and $[(PhCH_2)_2C_2B_4H_4]Fe(\eta^6\text{-}C_8H_{10})$[4c] (**1c**) were synthesized as reported elsewhere.

Instrumentation

^{11}B (115.8 MHz) and ^1H (300 MHz) NMR spectra were acquired on Nicolet NT-360 and GE QE300 spectrometers, respectively. Unit-resolution mass spectra were obtained on a Finnegan MAT 4600 GC/MS spectrometer using perfluorotributylamine (FC43) as a calibration standard. Simulated mass spectra based on natural isotopic abundances were calculated on an AT&T 3B5 computer using the program MASPEC by R. N. Grimes. In all cases, strong parent envelopes were observed, and the calculated and observed unit-resolution spectral patterns were in close agreement.

Synthesis of $[(C_4H_9)_2C_2B_4H_4]Fe(\eta^6\text{-}C_8H_{10})$ (**1b**)

This compound was prepared from Na^+(*n*-$C_4H_9)_2C_2B_4H_5^-$, $FeCl_2$ and cyclooctatetraene by a procedure analogous to that used in the preparation of the C,C′-diethylcarborane homologue[11] and was purified via preparative TLC using 3 : 1 *n*-hexane–dichloromethane eluant and isolated in 13% yield as a red–orange solid, accompanied by a small quantity of $[(C_4H_9)_2C_2B_4H_4]Fe(\eta^6\text{-}C_6H_6)$, identified from its NMR and mass spectra (analogous

iron–benzene by-products have been obtained in previous syntheses of carboranyl iron cyclooctatriene complexes[11a]). ^{11}B NMR at 115.8 MHz (dichloromethane, 25°C, shifts in ppm relative to $BF_3 \cdot OEt_2$, H–B coupling constants in Hz): 9.88 (148), 1B; 4.99 (169), 1B; 2.17 (150), 2B. ^1H NMR at 300 MHz ($CDCl_3$, 25°C, shifts in ppm relative to $SiMe_4$; s = singlet, m = multiplet, q = quartet, t = triplet): 5.37 s (C_6H_6), 2.561 m (α-CH_2), 2.317 m (α-CH_2), 1.575 m (β-CH_2), 1.451 q (γ-CH_2), 0.966 t (CH_3). Mass spectrum: cut-off at m/z 349, corresponding to $^{13}C^{12}C_{17}^{56}Fe^{11}B_4^1H_{32}^+$

Syntheses of $R_2R'_2C_4B_8H_8$ *carboranes*

The procedure followed was the same in all cases; data for specific reactions are given below. In a Pyrex apparatus[12] consisting of upper and lower bulbs separated by a medium-porosity frit and a stopcock, with the upper bulb connected via a Teflon stopcock to an attached tip-tube and the entire apparatus connected to a vacuum line, the $R_2C_2B_4H_6$ reactant was placed in the tip-tube, frozen in liquid nitrogen, and evacuated. An excess of NaH powder was placed together with a stirring bar in the upper bulb, and the iron–cyclooctatriene complex was placed with a stirring bar in the lower bulb. The apparatus was evacuated and the stopcock between the frit and the lower bulb was closed, and 30–40 cm^3 of dry THF was distilled onto the NaH at −196°C. The carborane was added to the NaH–THF mixture via rotation of the tip-tube and the contents were warmed to room temperature and stirred for 1 h, after which the solution of $Na^+R_2C_2B_4H_5^-$ was added through the filter frit to the lower flask containing the iron reagent. The upper flask was rinsed with THF (still *in vacuo*) and the solution added to the lower flask. The lower (reactor) bulb was isolated by closing the stopcock and the bulb was removed from the apparatus and placed in an oil bath at 150°C for *ca* 12 h. After cooling, the flask was opened to the air and the contents were dissolved in dichloromethane and filtered through a few cm of silica gel. The solution was concentrated to a small volume by rotary evaporation and the products purified by preparative layer chromatography. Yields given below are calculated on the basis of the $(R_2C_2B_4H_4)Fe(\eta^6$-$C_8H_{10})$ complex or $Na^+R'_2C_2B_4H_5^-$ consumed, as appropriate.

Reaction of $(Et_2C_2B_4H_4)Fe(\eta^6$-$C_8H_{10})$ *and* $Na^+Et_2C_2B_4H_5^-$

A 0.12 g quantity (0.40 mmol) of the iron reagent and 50 mg (0.41 mmol) of the carborane salt gave 67 mg (0.26 mmol, 65% yield) of $Et_4C_4B_8H_8$, R_f 0.36 in *n*-hexane.

Reaction of $(Et_2C_2B_4H_4)Fe(\eta^6$-$C_8H_{10})$ *and* $Na^+Me_2C_2B_4H_5^-$

A 0.25 g quantity (0.86 mmol) of the iron reagent and 90 mg (0.86 mmol) of the carborane salt gave 74 mg (0.32 mmol, 37%) of $Me_2Et_2C_4B_8H_8$ (**3a**), R_f 0.30 in *n*-hexane, and 12 mg (0.046 mmol, 11%) of $Et_4C_4B_8H_8$, R_f 0.35.

Reaction of $[(C_4H_9)_2C_2B_4H_4]Fe(\eta^6$-$C_8H_{10})$ *and* $Na^+Me_2C_2B_4H_5^-$

A 0.184 g quantity (0.53 mmol) of the iron reagent and 55 mg (0.53 mmol) of the carborane salt gave 20 mg (0.070 mmol, 14%) of $(C_4H_9)_2Me_2C_4B_8H_8$ (**3b**), R_f 0.73 in cyclohexane, and 20 mg (0.054 mmol, 22%) of $(C_4H_9)_4C_4B_8H_8$, R_f 0.64. Also recovered was 15 mg (0.042 mmol, 8%) of the iron complex reagent, R_f 0.17.

Reaction of $(Et_2C_2B_4H_4)Fe(\eta^6$-$C_8H_{10})$ *and* $Na^+(C_4H_9)_2C_2B_4H_5^-$

A 0.32 g quantity (1.1 mmol) of the iron reagent and 21 mg (1.1 mmol) of the carborane salt gave 40 mg (0.13 mmol, 12%) of $(C_4H_9)_2Et_2C_4B_8H_8$ (**3c**), R_f 0.53 in cyclohexane, and 23 mg (0.063 mmol, 12%) of $(C_4H_9)_4C_4B_8H_8$, R_f 0.65. Also recovered was 13 mg (0.044 mmol, 4%) of the iron complex reagent.

Reaction of $[(C_4H_9)_2C_2B_4H_4]Fe(\eta^6$-$C_8H_{10})$ *and* $Na^+Et_2C_2B_4H_5^-$

A 0.134 g quantity (0.39 mmol) of the iron reagent and 53 mg (0.40 mmol) of the carborane salt gave 23 mg (0.073 mmol, 20%) of $(C_4H_9)_2Et_2C_4B_8H_8$ (**3c**, identical with the product of the preceding reaction), and 7 mg (0.026 mmol, 13%) of $Et_4C_4B_8H_8$, R_f 0.48 in cyclohexane. Also recovered was 7 mg (0.02 mmol, 5%) of the iron complex reagent.

Reaction of $(Et_2C_2B_4H_4)Fe(\eta^6$-$C_8H_{10})$ *and* $Na^+(PhCH_2)_2C_2B_4H_5^-$

A 0.219 g quantity (0.75 mmol) of the iron reagent and 0.192 g (0.75 mmol) of the carborane salt gave 21 mg (0.055 mmol. 8%) of $(PhCH_2)_2Et_2C_4B_8H_8$ (**3d**), R_f 0.46 in cyclohexane, and 13 mg (0.050 mmol, 13%) of $Et_4C_4B_8H_8$. Also recovered was 18 mg (0.060 mmol, 8%) of the unreacted iron complex.

Reaction of $[(PhCH_2)_2C_2B_4H_4]Fe(\eta^6\text{-}C_8H_{10})$ *and* $Na^+Et_2C_2B_4H_5^-$

A 0.15 g quantity (0.36 mmol) of the iron reagent and 43 mg (0.33 mmol) of the carborane salt gave 22 mg (0.057 mmol, 17%) of $(PhCH_2)_2Et_2C_4B_8H_8$ (**3d**, identical with the product of the preceding reaction) and 5 mg (0.02 mmol, 12%) of $Et_4C_4B_8H_8$. Also recovered was 9 mg (0.022 mmol, 6%) of the unreacted iron complex.

STRUCTURE OF SODIUM DINEOPENTYLDIOXORHENIUM(V)

SHIANG CAI, DAVID M. HOFFMAN* and DERK A. WIERDA

Department of Chemistry, Harvard University, 12 Oxford Street, Cambridge, MA 02138, U.S.A.

(*Received* 23 *August* 1989; *accepted* 6 *November* 1989)

Abstract—Sodium dineopentyldioxorhenium(V), $[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]$, $C_{12}H_{25}NNaO_2Re$, $M_r = 424.53$, triclinic, $P\bar{1}$ (No. 2), $a = 14.209(3)$, $b = 14.631(3)$, $c = 11.144(2)$ Å, $\alpha = 97.80(1)$, $\beta = 104.69(2)$, $\gamma = 64.54(1)°$, $V = 2022.5(7)$ Å^3, $Z = 2$, $D_x = 1.39$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 61.04$ cm^{-1}, $F(000) = 796$, $T = 233(1)$ K, final $R = 0699$ for 3216 unique reflections with $F_o > 6\sigma(F_o)$ and 308 variables. There are two independent molecules of $[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]$ in the asymmetric unit. In the solid state the compound is polymeric having $\{[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]\}_2$ repeating units. The $\{[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]\}_2$ units are eight-membered rings of composition $Re_2O_4Na_2$, which are connected via Na—O bonds thereby forming the polymer. The $[ReO_2(CH_2CMe_3)_2]^-$ anions within the repeating units have distorted tetrahedral geometries with open O—Re—O (av. 136°) and closed C—Re—C (av. 83°) angles. The planes defined by O—Re—O and C—Re—C are perpendicular (90.6° and 90.0° for Re(1) and Re(2), respectively). Average Re—O multiple bond and Re—C single bond distances ae 1.72 and 2.11 Å, respectively. A comparison of the structures of related d^0, d^1 and d^2 MO_2R_2 (R = alkyl and aryl) compounds is presented. The structural changes which occur as a function of electron count in these compounds are explained in the context of an earlier MO study.

We recently reported the synthesis and spectroscopic characterization of the lithium, sodium and tetraethylammonium salts of the d^2 $[ReO_2(CH_2CMe_3)_2]^-$ anion, and X-ray structures of the lithium and tetraethylammonium salts.[1] In both of the structurally characterized compounds the anions have severely distorted tetrahedral geometries with open O—Re—O and closed H_2C—Re—CH_2 angles. Herein we report the X-ray structure determination of the sodium salt and compare its structure to the other members of the series and some related compounds.

† Lists of atom coordinates, complete bond distances and angles, anisotropic thermal parameters, hydrogen atom parameters and structure factors, as well as a packing diagram, have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

Structure of sodium dineopentyldioxorhenium(V)

The molecular structure and atom-numbering scheme for $[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]$ are presented in Fig. 1. An extended structure is presented in Fig. 2 in order to clarify the polymeric nature of the compound in the solid state. Selected bond lengths and angles are given in Table 1.† There are two crystallographically independent molecules of $[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]$ in the asymmetric unit. The two independent $[ReO_2(CH_2CMe_3)_2]^-$ anions differ only by a twist of the neopentyl t-butyl groups; all chemically equivalent distances and angles are equal by the 3σ criterion. A few angles about the two sodium ions, however, do differ by more than 3σ.

As Fig. 2 illustrates, the compound is polymeric in the solid state with $\{[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]\}_2$ repeating units linked via Na—O

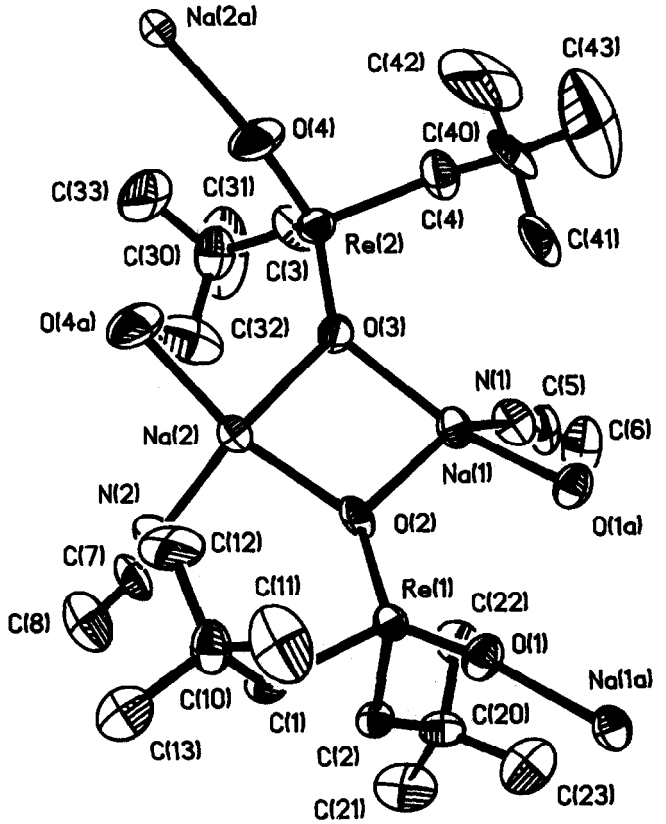

Fig. 1. The molecular structure of $[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]$, $C_{12}H_{25}NNaO_2Re$ (ORTEP, 30% probability level).

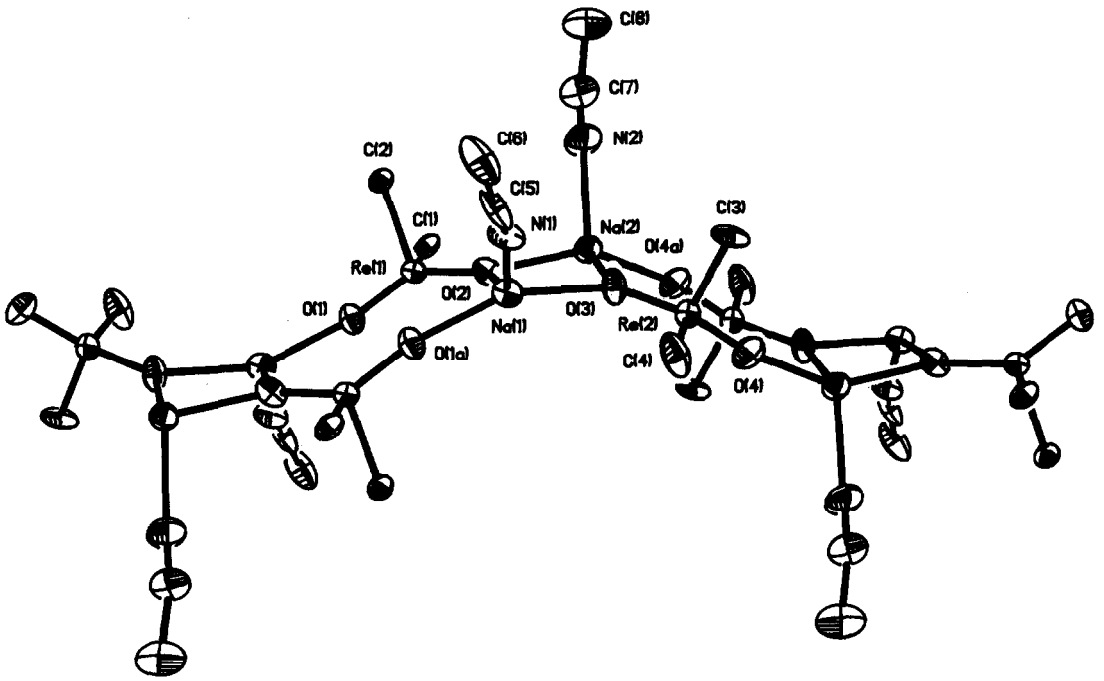

Fig. 2. A different view of the $[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]$ structure highlighting the $Re_2O_4Na_2$ rings and polymeric nature of the compound (ORTEP, 30% probability level). The t-Bu groups of the neopentyl ligands have been omitted for clarity.

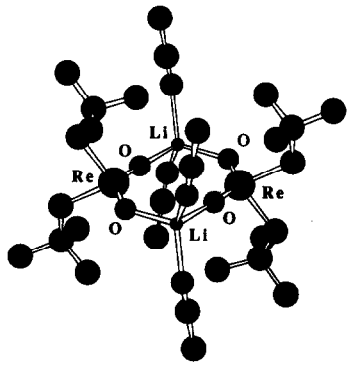
bonds. The $\{[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]\}_2$ repeating units, which each contain one half of the crystallographically unique atoms, are eight-membered $Re_2O_4Na_2$ rings. The rings are nearly planar with the largest deviation from the least-squares plane being Re (0.2 Å).

An analogous eight-membered ring structure was also found in $[Li(CH_3CN)_2][ReO_2(CH_2CMe_3)_2]$ (**I**).[1] The lithium and sodium structures differ, however, in how the cations fill their four coordination sites and in the number of cations bound to the oxo ligands. In the present structure, each sodium is coordinated to three oxo ligands, one each from two separate (but crystallographically equivalent) $[ReO_2(CH_2CMe_3)_2]^-$ anions that are part of the $Re_2O_4Na_2$ ring and an oxo ligand that is part of an adjacent ring, and a terminal acetonitrile; thus, one oxo ligand from each $[ReO_2(CH_2CMe_3)_2]^-$ anion



$\{[Li(CH_3CN)_2][ReO_2(CH_2CMe_3)_2]\}_2$

[a] Angle between the OMO and CMC planes.
[b] A and B designate crystallographically independent molecules.
[c] Crystallographic two-fold axis.

is bound to two cations and the other to only one. The lithium structure, on the other hand, consists of discrete $Re_2O_4Li_2$ eight-membered rings. The four Li^+ ligation sites are occupied by two bridging oxo ligands and two terminal acetonitrile molecules; thus, each oxo ligand is bound to only one lithium cation.

The sodium cation coodination geometry is best described as flattened tetrahedral with the two open angles being O(2)—Na—N(1) and O(3)—Na—O(1a) for Na(1), and O(3)—Na—N(2) and O(2)—Na—O(4a) for Na(2). The six Na—O distances in the structure are equivalent by the 3σ criterion. It is not clear why the sodium cations do not have normal tetahedral geometries. These are, however, two possible interactions, C(41)···Na(1) = 3.11 Å and C(12)···Na(2) = 3.47 Å (cf. to 2.98 Å, the sum of the van der Waals' radius for a CH_3 group and the Na^+ ionic radius), that may be involved in the cation distortions.

The $[ReO_2(CH_2CMe_3)_2]^-$ anions in the sodium salt have distorted tetrahedral geometries with open O—Re—O (av. 136°) and closed C—Re—C (av. 83°) angles. The planes defined by O—Re—O and C—Re—C are perpendicular (90.6° and 90.0° for Re(1) and Re(2), respectively). The Re—O multiple bond and Re—C single bond distances are within 3σ of those observed in $[NEt_4][ReO_2(CH_2CMe_3)_2]$ and $[Li(CH_3CN)_2][ReO_2(CH_2CMe_3)_2]$.

In Table 2 is presented a comparison of M—O and M—C distances, O—M—O and C—M—C angles, and OMO/CMC plane dihedral angles for four-coordinate dioxo–dialkyl and dioxo–diaryl compounds. Most notable is the difference between d^0 MoO_2(mesityl)$_2$ and the d^1 and d^2 compounds.[2-5] The d^0 MoO_2(mesityl)$_2$ complex displays a nearly undistorted tetrahedral geometry,[5] whereas the d^1 and d^2 MO_2R_2 complexes all have open O—M—O and closed C—M—C angles.[1-4] Importantly, the d^1 compounds are less distorted (i.e. are closer to tetrahedral) than the d^2 compounds.

The smooth progression of distortion from a tetrahedral geometry on going from d^0 to d^1 to d^2 is entirely consistent with our earlier extended Hückel theoretical analysis of distorted d^2 $[ReO_2(CH_2CMe_3)_2]^-$.[1] As part of the theoretical analysis we examined both d^0 and d^2 MO_2R_2 complexes. For the d^0 case, the opening or closing of the O—M—O and C—M—C angles from 109° gave a relatively "soft" energy surface; that is, the d^0 MO_2R_2 complex did not show a strong electronic preference for a tetrahedral geometry. On this basis it was predicted that d^0 MO_2R_2 compounds should have geometries with angles close to 109° if the alkyls or aryls were not too sterically demanding.

HOMO
II
Scheme 2.

In contrast to the d^0 case, the theoretical analysis indicated that the distortions in d^2 $[ReO_2(CH_2CMe_3)_2]^-$ are strongly electronically driven and HOMO controlled. The HOMO, which is schematically illustrated in **II**, has primarily *d*-orbital character and is M–O π-antibonding. Orbital **II** and the complex were stabilized by opening the O—Re—O and closing the C—Re—C angles. In both cases the stabilization resulted from a reduction in Re—O π-antibonding. The strong preference of the HOMO in the d^2 compounds for distortion is tempered only by the weaker electronic and steric factors which favour a geometry with angles near 109°.

Because the HOMOs for all of the d^1 and d^2 compounds listed in Table 2 are similar to **II**, the theoretical results discussed above are generally applicable and, in particular, the analysis explains the large structural differences between the d^0 and d^2 compounds. The lesser distortions observed in the d^1 MO_2R_2 compounds are also readily explained: for the d^1 compounds only one electron in the HOMO is stabilized by the distortions whereas in the d^2 compounds, two are stabilized.*

CONCLUSION

The structures of the $[ReO_2(CH_2CMe_3)_2]^-$ anions in $[Na(CH_3CN)][ReO_2(CH_2CMe_3)_2]$ are similar to those in $[NEt_4][ReO_2(CH_2CMe_3)_2]$ and $[Li(CH_3CN)_2][ReO_2(CH_2CMe_3)_2]$. All have distorted tetrahedral geometries with open O—Re—O and C—Re—C angles. Analogous d^1 rhenium aryls, $ReO_2(Ar)_2$, and d^2 osmium aryls, $OsO_2(Ar)_2$, have similarly distorted tetrahedral geometries, but the d^0 complex MoO_2(mesityl)$_2$ is close to a normal tetrahedral geometry. All of the structural variations are readily explained in the context of a previously reported theoretical study.

* See also ref. 3, wherein a related MO based explanation of the structural differences between the d^1 and d^2 compounds is presented.

EXPERIMENTAL

$Na[ReO_2(CH_2CMe_3)]$ was prepared according to our literature method.[1] Dark green crystals were grown by low temperature crystallization from a saturated acetonitrile solution (−20°C; 2 days). The crystals were handled under a nitrogen atmosphere saturated with acetonitrile.

A crystal of dimensions $0.20 \times 0.20 \times 0.40$ mm was mounted on a glass fibre. Lattice parameters were obtained by a least-squares refinement of 24 selected reflections, including 12 Friedel pairs ($20° < 2\theta < 25°$). Collection data: Nicolet R3m/V diffractometer equipped with an LT-1 low-temperature device, graphite-momochromated Mo-K_α radiation; θ–2θ scan mode, scan width (1.8+dispersion)°; range $4° < 2\theta < 45°$; 5741 reflections measured, 5326 unit ($R_{int} = 0.0597$), 3216 observed [$F_o > 6\sigma(F_o)$]. Index range: $-15 \leqslant h \leqslant 14$, $-15 \leqslant k \leqslant 15$, $0 \leqslant l \leqslant 12$. Three intensity control reflections were monitored every 60 reflections of data collection; an average 8% crystal decay was observed. Lorentz-polarization and empirical absorption (ψ-scans) corrections were applied. The structure was solved from Patterson and difference syntheses. An extinction correction was applied.

Non-hydrogen atoms were refined anisotropically by full-matrix least-squares methods. Hydrogen atoms were placed in idealized positions [C—H = 0.96 Å; $U(H) = 1.2U_{eq}(C)$]. The function $w(\Delta F)^2$ was minimized ($w = [\sigma^2(F) + 0.0103F^2]^{-1}$). Final $R = 0.0699$, $wR = 0.0752$, $S = 0.9061$, $\Delta/\sigma(\text{max.}) = 0.014$. The final difference map contained three peaks with heights of 1.58, 1.34 and 1.30 e Å^{-3} located within 0.96 Å of the rhenium atoms. All other peaks were less than 0.99 e Å^{-3}; min. = −1.24 e Å^{-3}. Scattering factors were from the *International Tables for X-ray Crystallography*.[6] Computer programs used: SHELXTL+ programs[7] and PSICOR (public domain).

Abstract—Treatment of the tantalum dichloride compounds $Ta(OAr\text{-}2,6Me_2)_3Cl_2$ or $Ta(OAr\text{-}2,6Pr^i_2)_3Cl_2$ ($OAr\text{-}2,6Me_2$ = 2,6-dimethylphenoxide; $OAr\text{-}2,6Pr^i_2$ = 2,6-diisopropylphenoxide) with phenyl lithium (2 equiv) leads to the formation of the bis-phenyl compounds $Ta(OAr\text{-}2,6Me_2)_3(C_6H_5)_2$ (**1**) and $Ta(OAr\text{-}2,6Pr^i_2)_3(C_6H_5)_2$ (**2**), respectively, in moderate yields. Single crystal X-ray diffraction analyses of both **1** and **2** show them to be isostructural. In both compounds a trigonal bipyramidal environment about the metal centre is evident with *trans*, axial aryloxide oxygen atoms. Short Ta—O distances in the range of 1.848(5)–1.881(3) Å and almost linear Ta—O—Ar angles are present. The central coordination environments in **1** and **2** are strikingly similar to those found for the bis-cyclometallated compound $Ta(OC_6H_3Ph\text{-}C_6H_4)_2(OAr\text{-}2,6Ph_2)$. Combining the structural data for **1** and **2** with those of other alkyl, aryloxide compounds of niobium(V) and tantalum(V) shows that the M—OAr distances span a narrow range of 1.85–1.95 Å, while the corresponding M—O—OAr angles vary from 135 to 180° with no correlation between the two parameters. Crystal data for $TaO_3C_{36}H_{37}$ (**1**) at 19°C: a = 19.313(3), b = 11.652(1), c = 15.288(1) Å, β = 113.13(1)°, Z = 4, d_{calc} = 1.446 g cm^{-3} in space $C2/c$; for $TaO_3C_{48}H_{61}$ (**2**) at 21°C: a = 11.955(2), b = 19.585(2), c = 19.337(2) Å, β = 103.742(9)°, Z = 4, d_{calc} = 1.309 g cm^{-3} in space group $P2_1/n$.

The last 15 years has seen an explosion of interest in the organometallic chemistry of tantalum.[1] This interest was initially stimulated by the demonstrated ability of this metal to undergo multiple bonding to carbon ligands, generating the first examples of stable metal alkylidene and alkylidyne functionalities.[2] These developments rapidly led to a better mechanistic understanding of the olefin metathesis reaction.[3] Recently, attention has been focussed on the importance of π-donor ligation such as alkoxide and aryloxide groups in promoting such reactivity.[4] Hence, for this and other reasons there has been a recent interest in the structure/reactivity relationship of organometallic compounds of tantalum containing oxygen donor ligation.[5–7] During our studies of the organometallic chemistry of niobium and tantalum surrounded by sterically demanding aryloxide ligation we have recently synthesized two new mixed aryloxide, phenyl compounds of tantalum. We wish to report here on their solid-state structures and comment on the known structural types reported for niobium(V) and tantalum(V) mixed alkyl, aryloxide compounds, focusing particular attention on the metal–aryloxide bonding.

RESULTS AND DISCUSSION

The dichloride compounds $Ta(OAr\text{-}2,6Me_2)_3Cl_2$ and $Ta(OAr\text{-}2,6Pr^i_2)_3Cl_2$ ($OAr\text{-}2,6R_2$ = 2,6-dialkylphenoxide) can be readily obtained in high yields

* Author to whom correspondence should be addressed.

by the treatment of $TaCl_5$ with 3 equiv of either HOAr-2,6Me_2 or LiOAr-2,6Pr^i_2 in hydrocarbon solvents.[6,8] Treatment of either substrate with phenyl lithium in benzene leads to the formation of the corresponding diphenyl compounds Ta(OAr-2,6Me_2)$_3$$Ph_2$ (**1**) and Ta(OAr-2,6Pr^i_2)$_3$$Ph_2$ (**2**) in moderate yields. Exposure of solutions of **1** or **2** to an excess of LiPh causes substitution of aryloxide ligands to take place leading initially to the formation of triphenyl derivatives.[9] Further reaction leads to dark solutions containing decomposition products presumably formed via the unstable, homoleptic [$TaPh_5$].[8] The spectroscopic properties of **1** and **2** are as one would predict. The new Ta—C_6H_5 groups are readily detected in the NMR spectra by the characteristic downfield multiplet in the ^{1}H NMR spectrum of the hydrogen atoms *ortho* to the Ta—C bond and the downfield resonance of the Ta—*C*(*ipso*) carbon atom in the ^{13}C NMR spectrum.[10]

Single crystal X-ray diffraction analyses of **1** and **2** show the molecules to adopt almost identical geometries in the solid state. In the case of the 2,6-dimethylphenoxide complex (**1**) a crystallographically imposed two-fold axis is present (Fig. 1) through the pseudo-trigonal-bipyramidal coordination sphere, so that the unique equatorial aryloxide ligand has a linear Ta—O—Ar bond angle. In both molecules (Figs 1 and 2) the phenyl groups bound to tantalum lie within the equatorial plane. Some selected bond distances and angles are collected in Tables 1 and 2. Compounds **1** and **2** represent new members in a now extensive series of five-coordinate organometallic derivatives of niobium(V) and tantalum(V) containing aryloxide ligation. In Table 3 are collected certain structural data

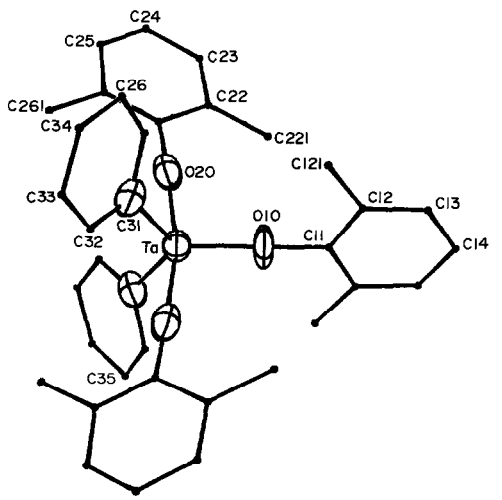

Fig. 1. ORTEP view of Ta(OAr-2,6Me_2)$_3$$Ph_2$ (**1**).

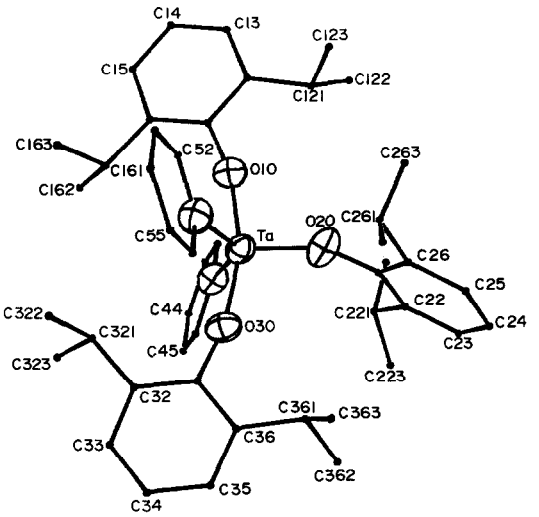

Fig. 2. ORTEP view of Ta(OAr-2,6Pr^i_2)$_3$$Ph_2$ (**2**).

for those compounds that have been the subject of a crystallographic study. For all compounds both the M—C and M—O distances can be seen to lie in a very narrow range of 2.136–2.248 Å and 1.85–1.95 Å, respectively. For the metal–alkyl (aryl) bonds the largest distances are found for the unique methyl groups in Ta(OAr-2,6Bu^t_2)$_2$$Me_3$ and Ta(OAr-2,6Bu^t_2-4OMe)$_2$$Me_3$, where steric pressure from the aryloxide ligands leads to a significant lengthening.[11] Both the M—O and M—C distances appear to be insensitive to whether they are terminal or contained within metallacycle rings formed by aryloxide cyclometallation.

Another interesting feature of the compounds contained in Table 3 concerns the bonding of the aryloxide ligands to the metal centre. All compounds are five-coordinate, formally containing a 10-electron count for the central metal core. The electron deficiency of the metal centre can be relieved by oxygen-*p* to metal-*d* π-bonding, and this argument is normally used to account for the short M—O distances.[16] Consistent with this picture are the results of two studies that show an excellent correlation between Nb—OAr[12] and W—OAr[17] distances and the formal electron count at the metal centre. However, it was also pointed out that the M—O—Ar angle, which theoretically could also be a measure of the amount of π-donation to the metal centre, did not correlate at all with the electron deficiency of the metal.[12,17] This fact is highlighted by the data in Table 3 (Fig. 3) for aryloxide compounds of niobium(V) and tantalum(V). Although the M—OAr distances only vary over the range

Table 1. Selected bond distances (Å) and angles (°) for $Ta(OAr\text{-}2,6Me_2)_3Ph_2$ (1)

Ta—O(10)	1.848(5)	Ta—O(20)	1.879(4)
Ta—C(31)	2.180(6)		
O(10)—Ta—O(20)	96.1(1)	O(10)—Ta—C(31)	115.8(2)
O(20)—Ta—O(20)	167.7(2)	O(20)—Ta—C(31)	87.3(2)

Ta—O(20)—C(21)	175.5(4)		

1.85–1.95 Å, the M—OAr angles vary from 135 to 180°. Furthermore, there is no correlation between the two parameters; i.e. the M—O—Ar angle does not open up as the M—OAr distance falls. Hence, based upon data in this study (Fig. 3) as well as previous studies,[12,17] it can be concluded that the M—O—Ar angle in early *d*-block transition metal aryloxide compounds is an extremely flexible parameter giving little insight into M—OAr bonding.

This situation contrasts markedly with that found for aryloxide derivatives of the Group 14 metals germanium and tin and the later *d*-block transition metals. In these cases terminal M—O—Ar angles appear to be more confined into a narrow range of 120–130°.[18]

EXPERIMENTAL

The chloride compounds $Ta(OAr\text{-}2,6Me_2)_3Cl_2$ and $Ta(OAr\text{-}2,6Pr^i_2)_3Cl_2$ were obtained by published procedures. Phenyl lithium was prepared as a precipitate from a Bu^nLi/C_6H_5Br mixture in hexane/toluene. After washing with hexane the compound was dried and stored in the Dri-Lab prior to use. All solvents were dried by refluxing over sodium benzophenone before being distilled under nitrogen.

$Ta(OAr\text{-}2,6Me_2)_3Ph_2$ (1)

To a yellow solution of $Ta(OAr\text{-}2,6Me_2)_3Cl_2$ (3.0 g, 4.88 mmol) in benzene (75 cm^3) was slowly added LiC_6H_5 (0.82 g, 9.8 mmol) as a powder over a period of 30 min. The resulting dark brown solution was stirred for 3 h, filtered and the filtrate evaporated *in vacuo*. Extraction of the crude product with hexane followed by slow cooling of the solution yielded yellow crystals of the pure product in 35% yield. Found: C, 62.7; H, 5.6. Calc. for $TaC_{36}H_{37}O_3$: C, 61.9; H, 5.3%. ^1H NMR (C_6D_6, 30°C): δ 8.11 (m, *ortho*-C_6H_5), 2.12 (s, OAr-2,6Me_2), 6.8–7.5 (m, aromatic). ^{13}C NMR (C_6D_6, 30°C): δ 192.2 (Ta—*C*), 18.2 (CH_3).

$Ta(OAr\text{-}2,6Pr^i_2)_3Ph_2$ (2)

An essentially identical procedure to that described above only using $Ta(OAr\text{-}2,6Pr^i_2)_3Cl_2$ (0.5 g, 0.78 mmol), benzene (25 cm^3), and LiC_6H_5 (0.16 g, 1.9 mmol) yielded the product as pale crystals from hexane. Found: C, 66.3; H, 6.9. Calc. for $TaC_{48}H_{61}O_3$: C, 66.5; H, 7.1%. ^1H NMR (C_6D_6, 30°C): δ 8.28 (m, *ortho*-C_6H_5), 1.41 (d, $CHMe_2$), 3.41 (m, $CHMe_2$), 6.8–7.5 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 193.8 (Ta—*C*), 18.2 ($CHMe_2$), 2.43 ($CHMe_2$).

[a] All compounds adopt an approximately trigonal bipyramidal geometry about the metal centre with *trans*, axial *aryloxide* ligands, except $Ta(OAr\text{-}2,6Me_2)_4Me$ which is square pyramidal.

X-ray crystallography

Crystal data and data collection parameters are collected in Table 4. A suitable crystal of each of the two compounds was mounted in a glass capillary in a random orientation. Cell constants were obtained from least-squares refinement using the scattering angles of 25 reflections as measured by the computer-controlled diagonal slit method of centring. Systematic absences and subsequent least-squares refinement indicated the space group $C2/c$ for **1** and $P2_1/n$ for **2**. The data were collected to a maximum 2θ of 45° in both cases using the ω–2θ scan technique. Moving crystal, moving counter background counts were made by scanning an additional 25% above and below the scan width. The counter aperture was adjusted as a function of θ. For intense reflections an attenuator (factor 12.9) was automatically inserted in front of the detector. As a check on crystal and electronic stability three standard reflections were measured every 2000 s of beam time. In both cases some decay was observed and

SYNTHESIS AND SOLID STATE STRUCTURE OF SOME 2,6-DIPHENYLPHENOXIDE DERIVATIVES OF RHODIUM(I) AND IRIDIUM(I)

DIEGO E. CHEBI, PHILLIP E. FANWICK and IAN P. ROTHWELL*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 22 *September* 1989; *accepted* 6 *November* 1989)

Abstract—Treatment of the carbonyl dimer $Rh_2Cl_2(CO)_4$ with 2 equivalents of LiOAr-2,6Ph_2 (OAr-2,6Ph_2 = 2,6-diphenylphenoxide) produces the aryloxide bridged dimer $[(CO)_2Rh(\mu\text{-OAr-2,6}Ph_2)_2Rh(CO)_2]$ (**1**) in excellent yield. Compound **1** shows two, equal intensity carbonyl stretching frequencies at 2090 and 2006 cm^{-1} in the IR spectrum (Nujol mull) consistent with a solid state structure consisting of two edge shared square planes. A single crystal X-ray diffraction analysis of **1** confirmed this formulation showing no evidence for π-bonding by the side chain aryl groups to the 16-electron metal centre. Treatment of the dimer $Ir_2Cl_2(COD)_2$ (COD = 1,5-cyclooctadiene) with LiOAr-2,6Ph_2 yielded a mixture of products. Eventually sparingly soluble crystals of a salt $[(COD)Ir(\eta^5\text{-HOAr-2,6}Ph_2)]^+[(COD)Ir(OAr\text{-2,6}Ph_2)_2]^-$ (**2**) were obtained in very minor yield. The presence of a 2,6-diphenylphenol ligand η^5-bound through the central phenoxy ring to the iridium metal centre was confirmed by a single crystal X-ray diffraction analysis of **2**. The distances Ir—C to the COD ligand in the cation in **2**, 2.10(2)–2.16(2) Å, are slightly shorter than the distances of 2.25(2)–2.35(2) Å to the five carbon atoms of the central phenoxy ring. The *ipso* carbon attached to the hydroxyl group is non-bound. The anion in **2** contains two terminal aryloxide ligands bound approximately *trans* to the two iridium–olefinic bonds of the COD group yielding a structure best described as square planar. Crystal data at 20°C for $Rh_2O_6C_{40}H_{26}$ (**1**): $a = 10.750(2)$, $b = 28.307(5)$, $c = 11.311(2)$ Å, $\beta = 96.21(1)°$, $Z = 4$, $d_{calc} = 1.569$ g cm^{-3} in space group $P2_1/n$; for $Ir_2Cl_6O_3C_{72}H_{58}$ (**2**) $2CHCl_3$: $a = 13.428(2)$, $b = 22.838(3)$, $c = 20.937(2)$ Å, $\beta = 92.775(9)°$, $Z = 4$, $d_{calc} = 1.624$ g cm^{-3} in space group $P2_1/n$.

There has been a dramatic increase in recent years in the study of alkoxide and aryloxide derivatives of the electron-rich later transition elements.[1–4] These studies have focussed not only on the types of compounds available but also upon the reactivity of the M—OR and M—OAr bonds. During our studies of the early *d*-block metal chemistry associated with sterically demanding aryloxide ligation[5] we have identified a range of coordination modes for the ligand 2,6-diphenylphenoxide (OAr-2,6Ph_2).[6,7] Besides simple terminal aryloxide bonding, this ligand may also chelate to the metal centre either via a π-interaction or via metallation of the substituent aryl rings.[6,7] Furthermore, a simple non-chelated η^6-interaction with one of the side chain phenyl rings is seen in the compound $(\eta^6\text{-}C_6H_5\text{-HOAr-Ph})Mo(CO)_3$.[8] In this paper we wish to report our preliminary investigation of the later transition metal derivatives of OAr-2,6Ph_2 ligation, focusing on derivatives of rhodium(I) and iridium(I). Although initially anticipated compounds involving chelation via an η^x-interaction ($x < 6$) with the substituent side chain rings were not observed, a new bonding mode for this ligand involving an iridium–η^5-interaction with the central phenoxy ring has been characterized.

RESULTS AND DISCUSSION

Treatment of the carbonyl dimer $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$ with LiOAr-2,6Ph_2 (≥ 2 equiv)

* Author to whom correspondence should be addressed.

OAr = 2,6–Diphenylphenoxide

in hydrocarbon solvents leads to the formation of orange solutions of $[(CO)_2Rh(\mu\text{-}OAr\text{-}2,6Ph_2)_2Rh(CO)_2]$ (**1**) (see Diagram). Recrystallization of **1** from toluene solution yields large yellow blocks suitable for X-ray diffraction analysis. The ^1H NMR spectrum of **1** shows a series of multiplets in the δ 6.8–7.5 ppm region characteristic of the OAr-2,6Ph_2 ligand. The absence of any resonances in the ^1H NMR spectrum upfield of the aromatic region indicates the lack of any π-interaction of the rhodium metal centre with the substituent aryl rings.[7,8] In the ^{13}C NMR spectrum the Rh—*C*O carbon atoms are found to resonate at δ 179.4 ppm with a typical $^1J(^{103}Rh\text{–}^{13}C)$ coupling constant of 76 Hz. In the IR spectrum of **1** as a Nujol mull, two equal intensity bands at 2090 and 2006 cm^{-1} are observed. The complexity observed in the carbonyl region of the IR spectrum of $[(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2]$[9] is missing for **1**, consistent with the solid state structure consisting of a planar $C_2Rh(\mu\text{-}O)_2RhC_2$ unit.

A single crystal X-ray diffraction analysis of **1** confirmed this postulate (Fig. 1). Some selected bond distances and angles are collected in Table 1. The aryloxide groups in **1** adopt a bridging mode holding together two square-planar rhodium units. There are no close contacts between the substituent aryl group and the rhodium metal centres. There are no distortions evident in the solid state structure of **1** involving a bending of the two square-planar units about the bridging oxygen atoms. A significant dihedral angle is present in the chloro-bridged dimer $(CO)_2Rh(\mu\text{-}Cl)_2Rh(CO)_2$ about the Cl—Cl vector.[9] Presumably the sterically demanding aryloxide ligands in **1** preclude close packing of the dimeric units in the solid state so that weak electronic interactions between adjacent molecules cannot take place.

In contrast to this straightforward reactivity, the reaction of LiOAr-2,6Ph_2 with the iridium dimer, $[(COD)Ir(\mu\text{-}Cl)_2Ir(COD)]$, leads to a complex mixture of products as indicated by the ^1H NMR spectrum of the reaction mixture. Simple, dimeric, phenoxide and alkoxide bridged compounds of the type $[(COD)Ir(\mu\text{-}OR)_2Ir(COD)]$ have been reported in the literature.[10] The preferred synthetic route to these compounds involves a combination of parent phenol or alcohol with sodium carbonate reacting with the chloro-bridged dimer.[10] In our hands a mixture of $[(COD)Ir(\mu\text{-}Cl)_2Ir(COD)]$/HOAr-2,6$Ph_2$/$Na_2CO_3$ failed to react. The complexity of the reaction mixture formed by the use of LiOAr-2,6Ph_2 may be a consequence of nucleophilic attack taking place by the phenoxide ion on the coor-

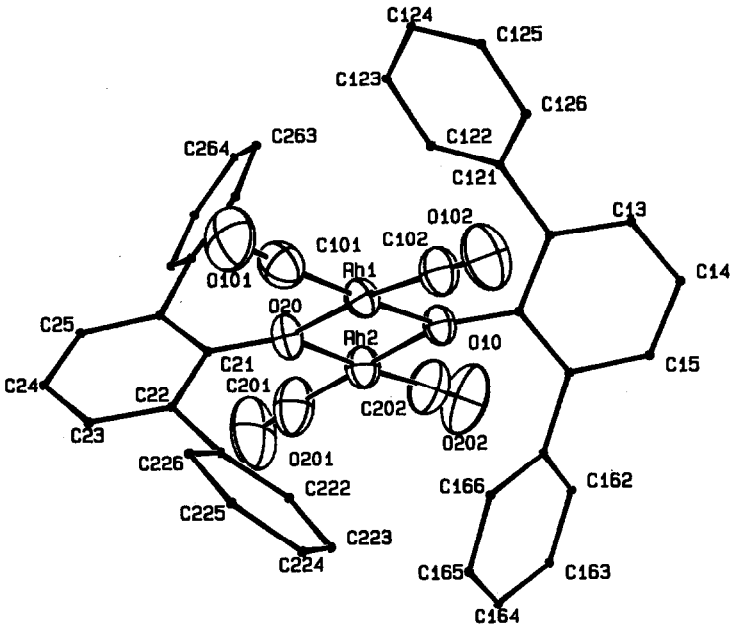

Fig. 1. ORTEP view of $[(CO)_2Rh(\mu\text{-}OAr\text{-}2,6Ph_2)_2Rh(CO)_2]$ (**1**).

dinated COD ligands. This reaction may be competing with a simple exchange process. Repeated attempts at recrystallization of the complex reaction mixture did eventually yield a few crystals of an iridium compound (**2**) from chloroform. A single crystal X-ray diffraction analysis of **2** (Figs 2 and 3) shows the compound to be a salt, with both an iridium-containing cation and anion (see Diagram). Some selected bond distances and angles are collected in Table 2. The anion in **2** can be seen to consist of an iridium(I) metal centre coordinated to a chelating COD molecule and two $OAr\text{-}2,6Ph_2$ ligands. The central coordination sphere in $[(COD)Ir(OAr\text{-}2,6Ph_2)_2]^-$ is best described as a typical square-planar arrangement of the two olefinic parts of the COD and two aryloxide oxygen atoms (Fig. 2). The Ir—O distances of 2.08(1) and 2.09(1) Å in the anion **2** compare favourably with the distance of 2.049(4) Å in the neutral iridium(I) compound *trans*-$Ir(PPh_3)_2(CO)(OPh)$.[11] The cation

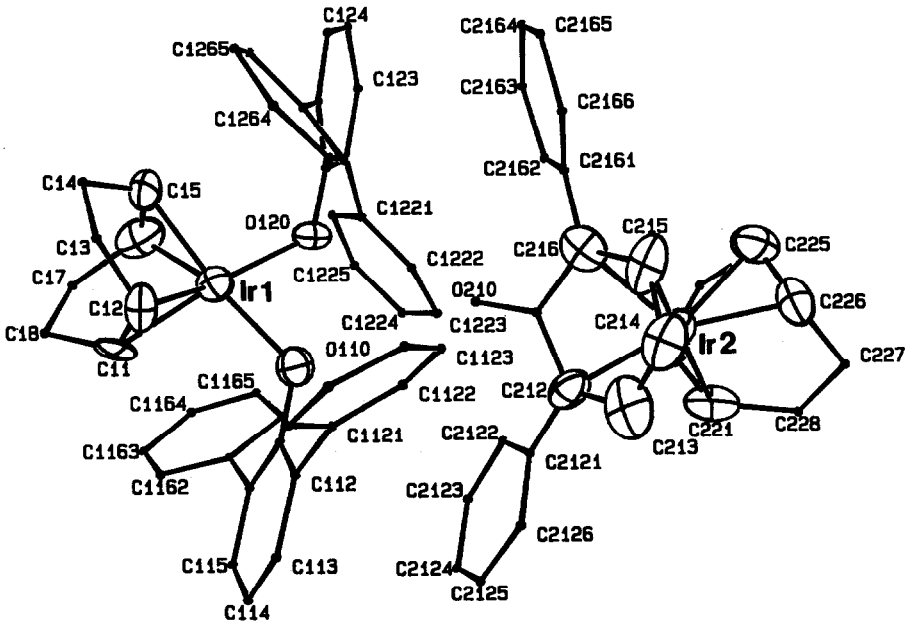

Fig. 2. ORTEP view of the mutual packing of the anion and cation within **2**.

in **2** can be thought of as an $Ir(COD)^+$ unit π-bound to the central phenoxy ring of 2,6-diphenylphenol (presumably generated by partial hydrolysis). The iridium metal centre can be seen to be interacting with the central ring in an η^5-fashion leading to a formal 18-electron count for the metal (Fig. 3). The carbon atom attached to the hydroxide group is bent away leading to a non-bonding distance between it and the metal centre. The π-binding of phenoxide rings to transition metal centres is well established. A considerable number of η^6-phenol and η^6-phenoxide compounds have been reported and structurally characterized.[4,12,13] The compound $[Rh(\eta^5\text{-OAr-2,6Bu}^t_2)(PPh_3)_2]$ was synthesized by Lappert and co-workers and the η^5-cyclohexadienonyl ligand confirmed by a single crystal X-ray diffraction study.[14] In compounds **2** the η^5-HOAr-2,6Ph_2 group can best be described as a protonated η^5-cyclohexadienonyl ligand (see Diagram). Consistent with this picture is the short C—OH distance of 1.26(2) Å compared to values of 1.31(3) and 1.37(2) Å for the O-bound aryloxide ligands contained within the anion.

EXPERIMENTAL

The reagent lithium 2,6-diphenylphenoxide (LiOAr-2,6-Ph_2) was prepared by treating the commercially obained 2,6-diphenylphenol with one equivalent of n-butyl lithium in hexane. Purification was achieved by successive hexane washes of the white powder. The compounds $[(CO)_2Rh(\mu\text{-Cl})]_2$ and $[(COD)Ir(\mu\text{-Cl})]_2$ were obtained by published procedures.[9,15] The methods employed for the manipulation of the air- and moisture-sensitive products have been described previously.[7]

$[(CO)_2Rh(\mu\text{-OAr-2,6Ph}_2)_2Rh(CO)_2]$ (1)

To a solution of $[(CO)_2Rh(\mu\text{-Cl})]_2$ (0.15 g, 0.39 mmol) in benzene (15 cm^3) was added LiOAr-2,6Ph_2 (0.21 g, 0.82 mmol). The mixture was stirred for 40 min. Removal of solvent under vacuum yielded a pale yellow powder which was taken up in 10 cm^3 of toluene. Slow cooling of the solution in the freezer at −15°C for 12 h yielding the product as large yellow crystals in 60% yield. ^1H NMR (C_6D_6, 30°C): δ 6.7–7.2 (m, aromatics). ^{13}C NMR ($CDCl_3$, 30°C): δ 179.4 (Rh—*C*O), $^1J(^{103}Rh\text{–}^{13}C) = 76$ Hz. IR (Nujol mull): ν(CO) = 2090, 2006 cm^{-1}.

$[(COD)Ir(\eta^5\text{-HOAr-2,6Ph}_2)]^+[(COD)Ir(OAr\text{-}2,6Ph_2)_2]^-$ (2)

A mixture of $[(COD)Ir(\mu\text{-Cl})]_2$ (0.20 g, 0.30 mmol) and LiOAr-2,6Ph_2 (0.16 g, 0.65 mmol) in benzene (15 cm^3) was stirred for 4 h and filtered. The filtrate was evaporated under vacuum, and the resulting solid was washed with hexane and dissolved in chloroform. After cooling the solution for 48 h at −15°C, a few crystals of **2** suitable for X-ray crystallography were obtained.

X-ray crystallography

Crystal data and data collection parameters are collected in Table 3. A suitable crystal of each of the two compounds was mounted in a glass capillary in a random orientation. Cell constants were obtained from least-squares refinement using the scattering angles of 25 reflections as measured by the computer-controlled diagonal slit method of centring. Systematic absences and subsequent least-squares refinement indicated the space group $P2_1/n$ for both **1** and **2**. The data were collected to a maximum 2θ of 45° in both cases using the ω–2θ scan technique. Moving crystal, moving counter background counts were made by scanning an additional 25% above and below of θ. For intense reflections an attenuator (factor 12.1) was automatically inserted in front of the detector. As a check on crystal and electronic stability three standard reflections were measured every 5000 s of beam time. No decay was observed in either case. The structures were solved by using the Patterson heavy-atom method to reveal the position of the rhodium atoms for **1** and iridium atoms for **2**. The remaining heavy atoms were then located in succeeding Fourier syntheses. Hydrogen atoms were located and added to the structures but were not refined.

THE CRYSTAL STRUCTURE OF LYSIDINE·$HAu(CN)_2$—A MODEL COMPOUND OF A WEAK-BASE ANION-EXCHANGE RESIN LOADED WITH GOLD CYANIDE

(*Received* 18 *September* 1989; *accepted* 13 *November* 1989)

Abstract—The crystal structure of lysidine·$HAu(CN)_2$ was determined so that the influence of steric hindrance at the active site of weak-base imidazoline resins could be established. These resins, which have alkyl groups attached to the basic nitrogen, have lower basicities, and are also eluted more slowly, than imidazoline resins that have no substituents at the active site. The crystal structure of lysidine·$HAu(CN)_2$ (a model compound for one of the unsubstituted resins) consists of two interpenetrating hydrogen-bonded networks that are perpendicular to each other. The structure suggests that the presence of an alkyl substituent on the basic nitrogen of an imidazoline weak-base resin could hinder the approach of a hydrogen atom and the gold cyanide anion to the basic nitrogen in the functional group, thus lowering the basicity of the amine. However, the crystal structure does not explain the steric effects that have been postulated as causing the rate of elution of disubstituted imidazoline resins to be slower than that of monosubstituted imidazoline resins.

Weak-base anion-exchange resins can be used for the extraction of gold cyanide from cyanide leach liquors. The metal anion can be adsorbed onto the resin owing to the interaction of the negative charge of the anion with the positive charge on the functional group of the resin. A weak-base resin is positively charged only when it is protonated. The basicity of the resin (i.e. the pH value at which it protonates) therefore determines the pH value at which the resin can extract gold cyanide—a resin with a higher basicity can extract gold cyanide at a higher pH value.[1]

The loaded resin can be eluted by contact of the resin with a basic solution. The deprotonation of the resin's functional groups results in the removal of the positive charge on the resin, and hence the means by which gold cyanide is adsorbed. The gold cyanide is washed out of the bed of resin, and the gold metal can be recovered by electrowinning.[2]

Gold cyanide is adsorbed onto the resin by the following mechanism:

$$P{-}NR_2 + H^+ \rightleftharpoons P{-}NR_2H^+ \xrightarrow{Au(CN)_2^-} P{-}NR_2H^+ {}^-Au(CN)_2,$$

where P is the polymer matrix and R is the substituent attached to the basic nitrogen.

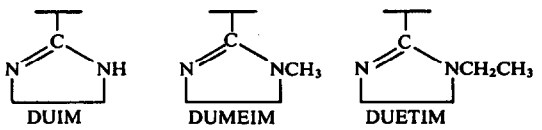
The elution of gold cyanide from a resin occurs as follows:

$$P{-}NR_2H^+ {}^-Au(CN)_2 + OH^- \rightleftharpoons P{-}NR_2 + H_2O + Au(CN)_2^-.$$

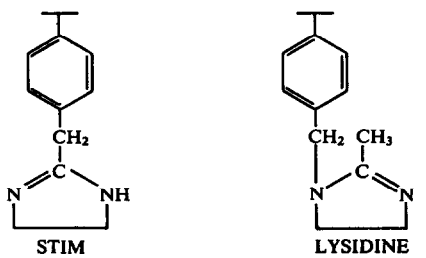
The basicities of resins that have alkyl groups attached to the basic nitrogen (e.g. DUMEIM and

* Author to whom correspondence should be addressed.

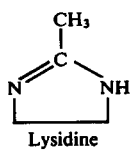
DUETIM) are lower than those of resins with hydrogen atoms as the substituents[3] (e.g. DUIM). This is in contrast to what would be expected from purely inductive effects, and is probably due to an increase in steric hindrance caused by the larger substituent on the basic nitrogen in the resin's functional group:



The elution of resins with disubstituted imidazoline functional groups (LYSIDINE, DUMEIM and DUETIM) is also slow in comparison with that of the monosubstituted resins[4] (DUIM and STIM). It was considered that steric hindrance to the approach of hydroxyl anions, which deprotonate the loaded amine groups, could retard the rate of elution:



It was considered that the investigation of the orientation of the gold cyanide anion relative to the protonated amine group could provide evidence that would either substantiate or discount the importance of steric effects. Consequently, a crystal of lysidine·$HAu(CN)_2$, a model compound for the resin DUIM, was prepared, and the structure was determined:



The ion-exchange reaction occurs in an aqueous environment and hence the preferred solvent for the growing of crystals is water. However, since water hydrolyses lysidine,[4] methanol was used as the solvent.

The crystals were grown from two different solutions that contained potassium aurocyanide and lysidine in the molar ratios of 1.0 and 0.5, respectively. An excess of lysidine was used in the second solution because the molar ratio of functional group to gold cyanide in a loaded resin is less than unity (about 0.1).

The crystals grown from the two solutions consisted of needle- and unneedle-like forms, both of which had the same point group symmetry (established from oscillation and Weissenberg photographs). Analyses of the crystals by energy-dispersive spectroscopy (EDS) using a scanning electron microscope showed that they all had a gold cyanide-to-lysidine ratio of unity. The shape of the crystal used for the determination of the crystal structure was therefore not important. However, a needle form was used for the sake of ease of alignment in the instrument.

Lysidine·$HAu(CN)_2$ did not readily crystallize in forms suitable for single-crystal X-ray techniques. Imperfect, twinned and several small crystals were obtained in spite of the long crystallization time allowed. The crystals were also brittle, and broke easily when handled. A different solvent could not be used because potassium aurocyanide is insoluble in other organic solvents that have properties (such as polarity) that are similar to those of the resin phase.

Attempts to crystallize potassium argentocyanide with the lysidine group from methanolic solutions were unsuccessful.

EXPERIMENTAL

The compound $C_4H_9N_2^+ \cdot Au(CN)_2^-$ (M_r = 334.13) was crystallized from a methanolic solution at pH 7. A needle-shaped crystal was used for the determination of the crystal structure. The cell dimensions were determined by the least-squares refinement of 25 high-angle reflections measured on an Enraf–Nonius CAD4 single-crystal diffractometer. The intensity data were measured at room temperature in the range $3 \leqslant \theta \leqslant 30°$ with an incident-beam graphite-crystal monochromator (λ(Mo-K_α) = 0.70169 Å). The total number of reflections recorded was 1941. The cut-off criterion was $F > 4\sigma(F)$. A variable scan speed in the ω–2θ mode was used. The scanning speed, which was adjusted in terms of the intensity during a pre-scan, did not exceed 5.5° min^{-1}, and the time for the measurement of each reflection was not less than 1 min. Data reduction consisted of correction for Lorentz factor, polarization and absorption; μ = 68.88 cm^{-1}.

The structure was solved by the Patterson method, and refined by the full-matrix least-squares method (101 parameters) by means of the SHELX program.[5] Convergence was attained, with a residual of 0.036 after the last cycle of full-matrix least-squares refinement including anisotropic temperature factors for all the non-hydrogen atoms. The hydrogen atoms on the carbon atoms were

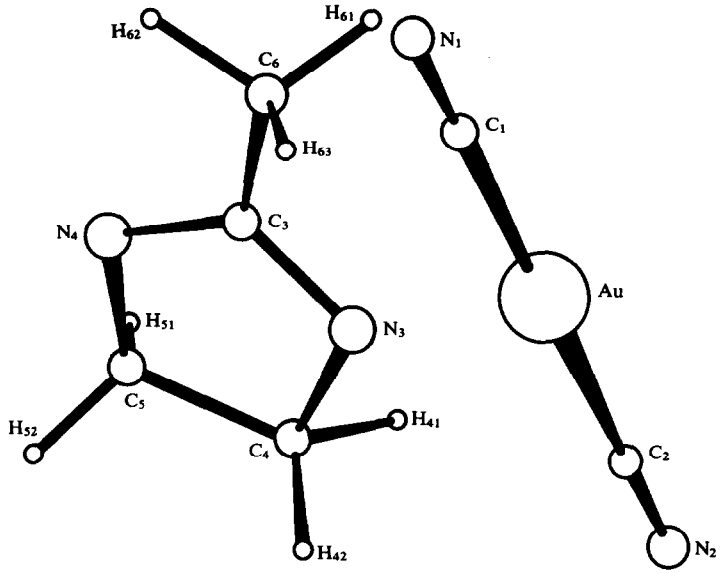


Fig. 1. The asymmetric unit of lysidine·$HAu(CN)_2$.

placed in their calculated positions (d(CH) = 1.08 Å), and were then refined with a common isotropic factor. The hydrogen atoms on the nitrogen atoms were not observed in the difference Fourier synthesis.

The crystal structure of lysidine·$HAu(CN)_2$ is monoclinic, and the space group is $P2_1/c$. This was shown by the systematic absence of reflections in the oscillation and single-crystal data, i.e. $h0l$: $l = 2n$ and $0k0$: $k = 2n$. The unit cell constants are as follows: $a = 10.754(1)$, $b = 13.962(2)$ and $c = 6.324(1)$ Å; $\beta = 109.65(1)°$, $U = 894.23$ Å^3, $Z = 4$, $F(000) = 608$.

RESULTS AND DISCUSSION

The bond lengths and angles involving the atoms (numbered according to Fig. 1) in the asymmetric unit calculated after the last cycle of refinement are listed in Table 1.

The crystal structure consists of two interpenetrating hydrogen-bonded networks. These networks are identical, and are mutually perpendicular. The crystal structure can therefore be described with reference to the structure of one network (Fig. 2), and the orientation of two networks relative to each other. A stereoscopic diagram of the crystal structure is shown in Fig. 3.

In each network, the nitrogen atoms in the gold cyanide are linked, by hydrogen bonds, to two lysidine groups. The gold cyanide anions in the network are parallel to one another. On one side of the gold cyanide anions is a chain of bifurcated hydrogen bonds while, on the other side, a centre of symmetry relates the two lysidine groups to two gold cyanide anions. These four moieties round the centre of symmetry are linked by hydrogen bonds. The rings round the centres of symmetry are perpendicular to the planes formed by the other molecules in the network.

The gold atoms of the two networks are superimposed, possibly because the ionic radii of the gold

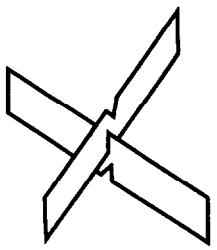
atoms are the smallest in the structure. The stacking of the planes in the networks can therefore be represented as follows:



where each network is represented by

The distance between the gold atoms in the two networks is 3.25 Å—almost as short as that of a metal–metal bond. The hydrogen bonds between the lysidine groups and gold cyanide anions are strong, and should consequently be fairly stable. Solvation is probably not essential for stabilization, and, therefore, the absence of methanol molecules in the crystal is not surprising. The hydrogen bonds at the chain of bifurcated bonds and at the centre of symmetry are similar in length, and are therefore almost identical in strength.

CONCLUSIONS

The crystal structure of lysidine · $HAu(CN)_2$ suggests that, as proposed, the presence of an alkyl substituent on the basic nitrogen in the resin's functional group could hinder the approach of a proton and a gold cyanide anion, thus weakening or eliminating the hydrogen bond between the amine and the gold cyanide anion. The positively charged species on the resin would be less stable, and the basicity of the amine could be relatively lowered.

The results of the investigation did not discount or prove the part played by steric effects in the relatively slower rate of elution of disubstituted imidazoline resins compared with that of monosubstituted imidazoline resins. The elution of disubstituted imidazoline resins would, from a consideration of the crystal structure, be expected to proceed more easily than that of monosubstituted imidazoline resins because only one strong hydrogen bond is formed with the gold cyanide anion. The hydrogen bond at the other end of the gold cyanide anion could be weak or totally absent.

Gold cyanide anions could have different orientations with respect to protonated disubstituted imidazoline and monosubstituted imidazoline (i.e. lysidine) groups. Confirmation of the existence of steric effects that would be expected to influence the elution of resins with disubstituted imidazoline

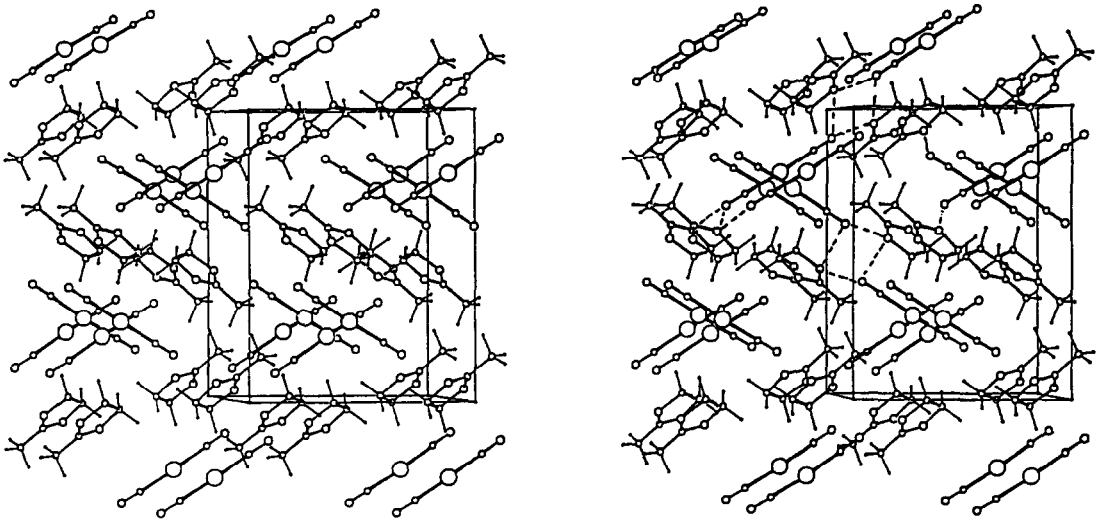


Fig. 3. A stereoscopic diagram of the crystal structure of lysidine · $HAu(CN)_2$.

groups would require the determination of the structure of a crystal grown with benzyllysidine or an alkyllysidine.

Abstract—Following our earlier reports on copper(I) mixed-ligand complexes with heterocyclic thiones and triphenylphosphine, we now report the isolation of 12 new complexes of the general formula [$Cu(PPh_3)_2$(L)X] [L = 1-methyl-1,3-imidazoline-2-thione (meimtH), 5-methyl-2-benz-1,3-imidazoline-2-thione (mebzimtH_2), purine-6-thione (pur6SH), quinoline-2-thione (qn2SH) and X = Cl, Br, I], and their characterization by various physicochemical methods. The crystal structure of the complex [$Cu(PPh_3)_2$(meimtH)Br] is also reported. Crystals are prisms, space group $P\bar{1}$ with $a = 9.988(3)$, $b = 10.212(2)$, $c = 21.066(5)$ Å, $\alpha = 94.86(2)$, $\beta = 91.70(2)$, $\gamma = 119.16(2)°$ and $Z = 2$. The metal ion has a distorted tetrahedral geometry with bond lengths Cu—S = 2.375(1), Cu—Br = 2.509(0), Cu—P(1) = 2.268(1) and Cu—P(2) = 2.281(1) Å. The structure has been solved by single-crystal X-ray diffraction methods with a final R of 0.0330 for observed reflections with $F_o \geqslant 6.0\sigma(F_o)$.

In recent years the ligating properties of heterocyclic thiones have been extensively studied and an increasing number of mononuclear and dinuclear copper(I) complexes with trigonal or tetrahedral copper(I) are presented.[1] Our present research has been concerned with the mode of ligation of such ligands in connection with the presence of nucleophilic reagents, e.g. triphenylphosphine. In order to investigate the influence of bulky ligands (PPh_3) upon the environment of copper(I) we prepared and structurally characterized the complexes [$Cu(PPh_3)_2$(py2SH)Br],[2] (py2SH = pyridine-2-thione) and [$Cu(PPh_3)_2$ (tzdtH)$_2$]NO_3[3] (tzdtH = 1,3-thiazolidine-2-thione). To supplement our present knowledge we report in this paper results of the preparation and characterization of a new series of mononuclear complexes of the general formula [$Cu(PPh_3)_2$(L)X].

EXPERIMENTAL

Physical measurements

IR, electronic and NMR spectra, conductivities, magnetic susceptibility measurements and elemental analyses of carbon, nitrogen, hydrogen and copper were performed as described previously.[3] Thermogravimetric analyses were performed on a Rigacu DTA/TG thermobalance in flowing air, with a heating rate of 10°C min^{-1}. Sample sizes were *ca* 15 mg.

Starting materials

All thione ligands, supplied by EGA or Aldrich, were purified by recrystallization from ethanol. Copper(I) halides, triphenylphosphine and all solvents were of reagent grade and were used without further purification.

Preparation of the complexes

A suspension of CuX in 20 cm^3 of THF was treated with a 50 cm^3 solution of 1 mmol of the appropriate thione and 2 mmol of PPh_3 in the same solvent. The reaction mixture was stirred for 2 h at 40°C, filtered and allowed to evaporate slowly at room temperature. The microcrystalline solid thus formed was collected by filtration, washed with small amounts of ethanol and ether and dried *in vacuo*.

Collection and reduction of intensity data

Complete crystal and intensity collection data are reported in Table 1. Preliminary oscillation and Weisenberg photographs indicated the space group $P\bar{1}$. Unit cell dimensions were derived from least-squares refinement of the setting angles of 15 automatically-centred reflections in the range $21° < 2\theta < 23°$ on a Syntex $P2_1$ diffractometer. The intensities of three standards monitored after every 67 reflections were stable, with a scatter of less than 3% from their respective means. Lorentz and polarization corrections were applied and the data were reduced using the SHELX 76 program.[4]

Solution and refinement of the structure

The positional coordinates of copper, bromine, sulphur and phosphorus atoms were deduced by

the direct methods using the SHELX 76 program.[4] The rest of the non-hydrogen atoms were revealed by subsequent ΔF calculations. Refinement was carried out by blocked full-matrix least-squares, in which $\Sigma w\Delta^2$ was minimized. The hydrogen atoms of the phenyl groups were calculated as riding on carbon atoms at a distance of 0.98 Å. Non-hydrogen atoms were refined using anisotropic and hydrogen atoms using isotropic temperature factors. Seven reflections showing poor agreement were given zero weight during final refinement cycles. Atomic scattering factors were taken from *International Tables for X-ray Crystallography*.[5]

RESULTS AND DISCUSSION

Earlier reports from this laboratory showed[2,3] that some heterocyclic thiones reacts with PPh_3-containing copper(I) compounds such $[Cu(PPh_3)X]_4$, where X = Cl, Br, I, and $[Cu(PPh_3)_2NO_3]$ to give dimeric or monomeric complexes of the general formula $[Cu(PPh_3)(L)X]_2$ and $[Cu(PPh_3)_2(L)]NO_3$, respectively. Although, attempts to isolate complexes of the type $[Cu(PPh_3)_2(L)X]$ by reaction of the dimers with excess of PPh_3 were unsuccessful, these complexes can be achieved via the direct reaction of copper(I) halides with thiones in the presence of triphenylphosphine.[6]

The influence of the stereochemical bulkiness and the π-acidity of PPh_3 was demonstrated in the crystal structure of $[Cu(PPh_3)_2(py2SH)Br]$ and $[Cu(PPh_3)_2(pymtH)Br]$, where we showed that the stereochemistry on copper in both complexes became nearer to tetrahedral geometry than in the case of other copper(I) thione complexes wherein no PPh_3 is involved.[7,8]

The obtained coordination compounds, together with their melting points and elemental analyses, are listed in Table 2. The analytical data show good agreement with the suggested formulae. All the isolated complexes are diamagnetic, as would be expected for d^{10} species and their solutions show a non-electrolytic nature.

The predominant tautomeric form of the ligands investigated may be deduced from their IR spectra. They show the absence of ν(SH) at 2500 cm^{-1} and the presence of ν(NH), as well as the characteristic four "thioamide bands"[9,10] demonstrating that the thione form appears to be the predominant tautomer, in the solid state.

In the spectra of the complexes, the N—H stretching frequency is lowered to 3125–3180 cm^{-1} from 3180–3210 cm^{-1} for the solid free ligands. Such shifts are usually regarded as signifying that the ligand is non N-bonded to the metal.[11]

Analysis of the thioamide bands has been used in the past to differentiate between M—N and M—S contacts for various thione ligands.[12,13] Of the four thioamide bands, those showing the most significant changes upon coordination are I and IV, but in the present compounds they are partly masked by strong triphenylphosphine absorptions and therefore diagnostically useless. Thioamide II and thioamide III show in the spectra of the present complexes negative shifts ranging from 10 to 60 cm^{-1} which indicate that coordination occurs through the thione-S atom.

The new bands around 350 cm^{-1} in the far-IR

[a] Calculated values in parentheses.

spectra are in the range previously reported for analogous copper(I) complexes[3] and can be assigned to Cu—S vibration.[14] In addition, there is no indication of any absorption for these complexes in the region where ν(Cu—N) generally lies. This fact further supports the monodentate nature of the ligands, although no activity assigned to the Cu—S vibration is observed in the cases of [Cu $(PPh_3)_2$(pur6SH)Cl] and [$Cu(PPh_3)_2$(meimtH)Cl].

All the complexes reported here exhibit electronic spectra typical of tetrahedrally-coordinated copper(I). Two strong absorptions are observed in the 260–285 and 315–385 nm ranges, respectively, which can be assigned as intraligand transitions.

The ^{1}H NMR spectra of the complexes in $CDCl_3$ solution also provided proof that ligands are (NH)-protonated. The presence of a peak for the NH-group at 10–14 ppm (sometimes very broad), together with the absence of any evidence for the thiol (SH)-proton (at δ = 3–5 ppm), indicate the thione tautomer as the dominant species in the complexes studied.

Thermal analysis in flowing air shows the complexes decompose in three or four stages. Figure 1 illustrates TG and DTG data curves for the complex [$Cu(PPh_3)_2$(qn2SH)Br]. The thermal decomposition of this compound is a typical example of a four-stage process. The first stage (195–260°C) is connected with a strong endothermic effect and involves a 62.5% mass loss, consistent with the evolution of two PPh_3 molecules (theoretical mass loss 63.2%). The burning of the ligand is accompanied by two exothermic peaks (275–330°C) suggesting the fractional decomposition of the heterocyclic thione and involves a 15% mass loss, corresponding to one chinoline molecule, C_9H_7N (theoretical mass loss 15.5%). The final stage (420–470°C) involves loss of the halogen atom.

Description of the structure

An ORTEP[15] diagram of the molecule is given in Fig. 2. Table 3 lists selected interatomic distances and valence angles.

The structure of [$Cu(PPh_3)_2$(meimtH)Br] is closely related to those of the other two analogous complexes [$Cu(PPh_3)_2$(py2SH)Br][2] and [$Cu(PPh_3)_2$(pymtH)Br],[6] which crystallize in the space group $P2_1/n$. The angles at the copper atom are nearly tetrahedral. This result is a consequence of the approximately equal steric factors near the copper coordination sphere.

The Cu—S bond length is 2.375 Å, as usually found for tetrahedrally-coordinated copper(I) with thione-S donors.[3,7,16] The Cu—P(1) and Cu—P(2) distances of 2.268(1) and 2.281(1) Å, respectively, are in agreement with the distances in [$Cu(PPh_3)_2$Br].[17] The Cu—Br distance of 2.509(0) Å is significantly longer than that observed in [$Cu(PPh_3)_2$Br] (2.35 Å), but similar to those found in two complexes of the type [$Cu(PPh_3)_2$(L) Br], where L = pyridine-2-thione and pyrimidine-2-thione.

For comparison purposes, selected interatomic distances and angles of the three related complexes [$Cu(PPh_3)_2$(py2SH)Br], [$Cu(PPh_3)_2$(pymtH)Br]

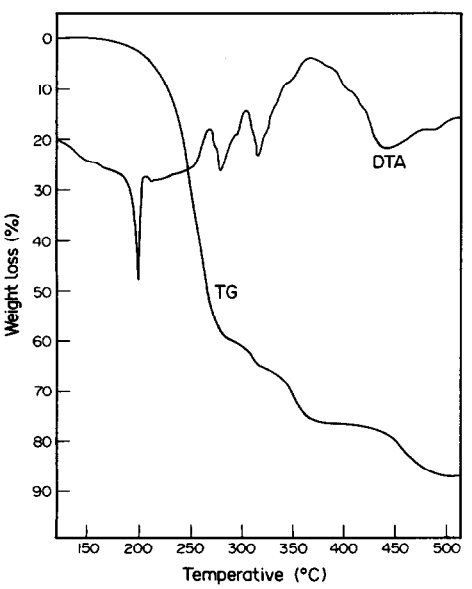

Fig. 1. TG and DTG curves for [$Cu(PPh_3)_2$(meimtH)Br].

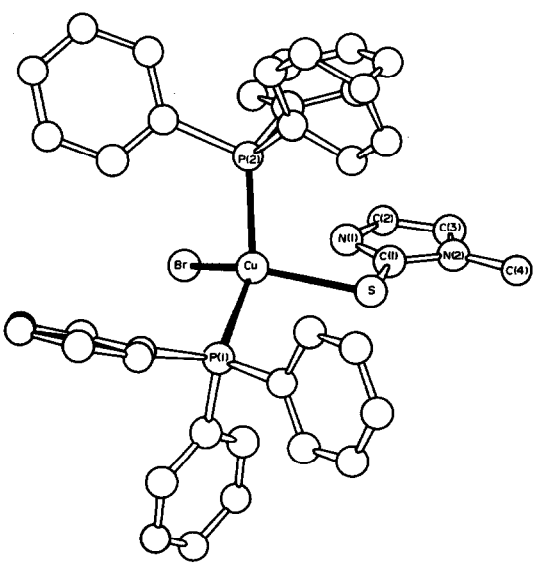

Fig. 2. Molecular structure of [$Cu(PPh_3)_2$(meimtH)Br].

and $[Cu(PPh_3)_2(meimtH)Br]$ are included in Table 4. Three of the angles around copper in the two known complexes, as well as in the present, are nearly those of a regular tetrahedron. The P(1)—Cu—P(2) angle deviates considerably from the tetrahedral value of 109.47°. A possible explanation for the large value is the steric interaction between the PPh_3 group and the CuSBr entity; but as the angle has opened up considerably, these steric interactions are not likely to be the sole cause for the distortion.

The general trend of decreasing Cu—P bond lengths with the increasing P(1)—Cu—P(2) bond angle, as has been reported for the compounds $[Cu(PPh_3)_2X]$, is not evident in these complexes. In comparison with the pyridine-2-thione complex it is seen that the Cu—S distance is lengthened upon coordination, which suggests that the π-character in this bond is reduced.

Geometries within the phosphine and thione ligands are standard. The average P—C (1.823 Å) and S—C (1.685 Å) bond lengths are close to those found in other similar complexes. It appears that the exchange of the six-membered ring with a five-membered ring produces no significant changes in the $CuSP_2Br$ core.

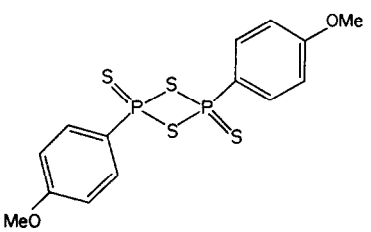
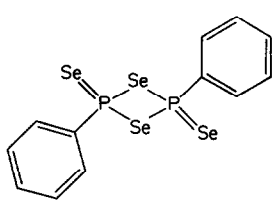
(*Received* 28 *September* 1989; *accepted* 13 *November* 1989)

Abstract—The reaction of the selenium analogue of Lawessons reagent, Ph(Se)PSe_2P(Se)Ph (**1**), with *cis*-$PtCl_2(PR_3)_2$ in either THF or liquid ammonia gives *cis*-$Pt(Se_3PPh)(PR_3)_2$ (**2–5**), the first examples of molecules containing a $PtSe_2P$ ring. Compounds **2–5** were characterized by ^{31}P-{^1H} NMR, IR, mass spectrometry and, in the case of PR_3 = 1/2 dppe (**2**), X-ray crystallography. Compound **2** has square-planar platinum coordination and a folded $PtSe_2P$ ring (dihedral angle 13.2°).

The coordination chemistry of phosphorus–sulphur species such as $R_2PS_2^-$ has been widely investigated. More recently, ourselves and other groups have studied the reaction of organoperthiophosphinic acid anhydride dimers (Lawessons reagent) with transition metal complexes.[1–3] We have recently reported the preparation of a selenium analogue of Lawessons reagent, Ph(Se)PSe_2P(Se)Ph (**1**), from the reaction of $(PhP)_5$ with selenium.[4] Here, we report on the preparation of $Pt(Se_3PPh)(PR_3)_2$, the first examples of complexes containing the $RPSe_3^{2-}$ ligand. The new compounds have been characterized by IR, NMR, microanalyses, and in the case of PR_3 = 1/2 dppe, X-ray crystallography.



Lawessons reagent



(1)

EXPERIMENTAL

$PtCl_2(PR_3)_2$ and $(PPh)_5$ were prepared as described in the literature.[5,6] All manipulations were carried out under argon or oxygen-free nitrogen, and all solvents were dried before use. THF and ethoxyethane were distilled from sodium/benzophenone and dichloromethane from calcium hydride. ^{31}P-{^1H} NMR were recorded on a JEOL FX90Q spectrometer, operating at 36.21 MHz, and are referred to an external standard of 85% H_3PO_4. IR spectra were obtained from KBr discs using a Perkin–Elmer 1720X spectrometer. Elemental analyses were performed by the microanalytical service of Imperial College.

Preparation of Ph(Se)PSe_2P(Se)Ph (1)

Degassed toluene (25 cm^3) was added to $(PPh)_5$ (1.35 g, 12.5 mmol) and grey selenium (1.97 g, 25 mmol). The suspension was heated, with stirring, and reflux maintained for 6 h. After cooling to room

* Author to whom correspondence should be addressed.

temperature, a red solid was filtered off, washed with toluene (4×10 cm^3) and dried *in vacuo*. Yield 1.86 g, 71%.

Preparation of Pt{$Se_2P(Se)(Ph)$}(dppe) (**2**)

Method 1. $PtCl_2$(dppe) (133 mg, 0.2 mmol) was dissolved in degassed THF (25 cm^3). $(PhPSe_2)_2$ (106 mg, 0.2 mmol) was then added and the suspension stirred at room temperature. After 15 min the $(PhPSe_2)_2$ had dissolved to give a yellow solution. On further stirring a cream–brown precipitate was deposited. After 2.5 h stirring the solid was filtered off, washed with further THF (2×15 cm^3) and dried *in vacuo*. Crystals suitable for X-ray analysis were obtained by slow diffusion of ethoxyethane into a CH_2Cl_2 solution of **2**. Yield 0.185 g, 70%. Compounds **3**–**5** were obtained by similar procedures.

Method 2. $(PPhSe_2)_2$ (60 mg, 0.11 mmol) was added to liquid ammonia at −78°C to generate a red solution/suspension. $PtCl_2(PR_3)_2$ (1 mmol) was then added and the solution stirred for 1/2 h at −78°C. The ammonia was then allowed to evaporate slowly as the solution warmed to room temperature. The solid was extracted with CH_2Cl_2 (5 cm^3). Filtering through a celite/glass-wool plug gave compounds **2**–**5** in *ca* 45% yield after the addition of *n*-hexane.

Crystal data

$C_{32}H_{29}P_3Se_3Pt \cdot CH_2Cl_2$, $M = 1023.4$, monoclinic, $a = 9.466(4)$, $b = 16.874(7)$, $c = 22.351(14)$ Å, $\beta = 101.35(5)°$, $U = 3500$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 1.94$ g cm^{-3}. Straw-coloured, air-stable prisms, dimensions $0.6 \times 0.1 \times 0.4$ mm, μ(Cu-K_α) = 142 cm^{-1}, λ = 1.54178 Å, $F(000)$ = 1944.

Data collection and processing

Nicolet R3m diffractometer, ω-scan method, graphite monochromated Cu-K_α radiation; 4720 independent measured reflections ($2\theta \leqslant 116°$), 4244 observed [$|F_o| > 3\sigma(|F_o|)$], corrected for Lorentz and polarization factors; numerical absorption correction (face-indexed crystal). Maximum and minimum transmission factors 0.438 and 0.150, respectively.

Structure analysis and refinement

The structure was solved by direct methods and all the non-hydrogen atoms refined anisotropically. A ΔF map revealed the presence of a dichloromethane molecule. The positions of the hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.20$Ueq(C) and allowed to ride on their parent carbons. Refinement was by block-cascade full-matrix least squares to $R = 0.50$, ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.052$ ($w^{-1} = \sigma^2(F) + 0.00081F^2$). The maximum and minimum residual electron densities in the final ΔF map were 1.92 and −1.63 e Å^{-3} and the mean and maximum shifts/error in the final refinement cycle were 0.001 and 0.004, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[7]

RESULTS AND DISCUSSION

Reaction of **1** with *cis*-$PtCl_2(PR_3)_2$ proceeds at room temperature as shown in eq. (1):

$$cis\text{-}PtCl_2(PR_3)_2 + Ph(Se)PSe_2P(Se)Ph \longrightarrow Pt(Se_3PPh)(PR_3)_2 + Ph(Se)PCl_2. \quad (1)$$

Apart from compounds **2**–**5** in the ^{31}P NMR we also observed a resonance at 73.6 ppm ($^1J\{^{31}P$–$^{77}Se\}$ 825 Hz) in the crude reaction mixtures from organic solvents and at 52.5 ppm (^1J 760 Hz) from the reactions in liquid ammonia and we assign this to the other product from the reactions, $Ph(Se)PCl_2$ and $Ph(Se)P(NH_2)_2$, respectively. The new metal complexes have been characterized by microanalyses, NMR (Table 1), mass spectrometry and IR spectroscopy. Their ^{31}P NMR spectra consist of

two singlets each with platinum satellites with the expected coupling constants. In general, the ^2J $\{^{31}P-^{195}Pt\}$ couplings in **2–5** are higher in magnitude than in their sulphur analogues[4] (e.g. in the case of $PR_3 = PEt_3$ the values are 217 and 210 Hz for the sulphur and selenium cases, respectively). The IR spectra are dominated by the phosphine and aryl bands and it is not possible to assign the P—Se vibrations. The mass spectra of **2** and **3** (EI mode) reveal the parent ion and $\{M—P(Se)Ph\}^+$ ions with the expected isotopic distributions.

As was the case for the sulphur analogues[4] we noticed that **2–5** are somewhat air-/moisture-sensitive in solution. Thus, the ^{31}P NMR of a $CDCl_3$ solution of **4** following exposure to air revealed a new compound (δ −19.1 ppm, ^1J 3157 Hz, δ 38.2 ppm, ^2J 256 Hz) which appears to be of a similar type to **4**. The NMR data suggests that the terminal selenium has been replaced by oxygen to give P=O as part of a $PhPSe_2O^-$ ligand.

The X-ray structure of **2** reveals (Fig. 1, Table 2) square-planar coordination of the platinum by the dppe and a bidentate $Ph(Se)PSe_2^-$ ligand and is similar to that seen in the analogous $Pt\{S_2P(S)C_6H_4OMe\}(PPh_3)_2$ (**6**).[2] The ligand shell of the platinum [Pt, Se(1), Se(2), P(2) and P(4)] has a maximum deviation from planarity of 0.04 Å for Pt. The Pt—P distances in **2** (2.253(2) and 2.249(2) Å) are noticeably shorter than those in **6** (2.291(2) and 2.293(2) Å)[2] reflecting the difference in the *trans* donor atom (Se vs S). The dihedral angle between the $PtSe_2$ and PSe_2 planes is 13.2° compared to 19.4° in **6**. A consequence of this dihedral angle is that P(1) is displaced 0.21 Å from the ML_4 plane. The substituents on P(1) adopt a pseudo axial/equatorial

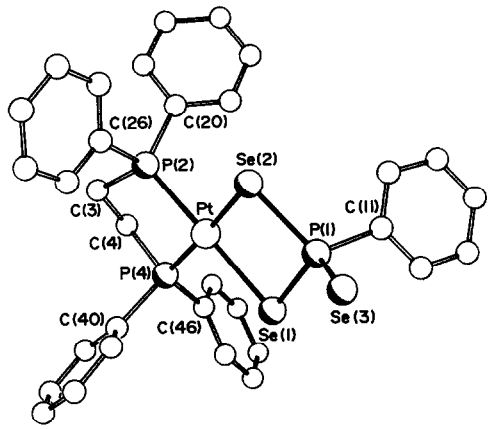

Fig. 1. The X-ray crystal structure of **2**.

conformation with respect to the PtP_2Se_2 coordination plane (Se equatorial). As was observed for the P—S distances in **6** the exocyclic P=Se bond length in **2** is only *ca* 0.1 Å shorter than those in the $PtSe_2P$ ring, thus implying substantial delocalization in the ring. The transannular Pt···P(1) and Se(1)···Se(2) distances are 3.27 and 3.34 Å, respectively. There are no significant short intermolecular contacts.

X-RAY CRYSTAL STRUCTURE ANALYSIS AND REACTIVITY OF (2-CHLOROPHOSPHININE)PENTACARBONYLTUNGSTEN COMPLEXES

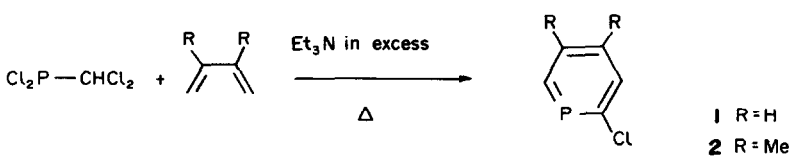
PASCAL LE FLOCH, LOUIS RICARD and FRANÇOIS MATHEY*

Laboratoire de Chimie du Phosphore et des Métaux de Transition DCPH,
Ecole Polytechnique, 91128 Palaiseau Cedex, France

(*Received* 4 *October* 1989; *accepted* 13 *November* 1989)

Abstract—The X-ray crystal structure analysis of (2-chlorophosphinine)pentacarbonyltungsten shows that the 2-chloro-substituent enhances the electronic cyclic delocalization within the ring by comparison with the parent phosphinine and its pentacarbonylmolybdenum complex. No nucleophilic substitution of this chloro-substituent is observed upon reaction with a variety of nucleophiles: $BuNH^-$, $i\text{-}Pr_2N^-$, HO^-, MeO^-, Me^-, Bu^-. In each case, a (2-chloro-1,6-dihydrophosphinine)pentacarbonyltungsten complex is obtained instead via initial attack at phosphorus. The subsequent reactions of $BuNH^-$, MeI and HCl with (2-chloro-4,5-dimethylphosphinine)pentacarbonyltungsten leads to (2-chloro-4,5,6-trimethylphosphinine)pentacarbonyltungsten.

In a previous paper, we described a very simple one-step synthesis of 2-chlorophosphinines,[1] eq. (1):



1 R=H
2 R=Me

(1)

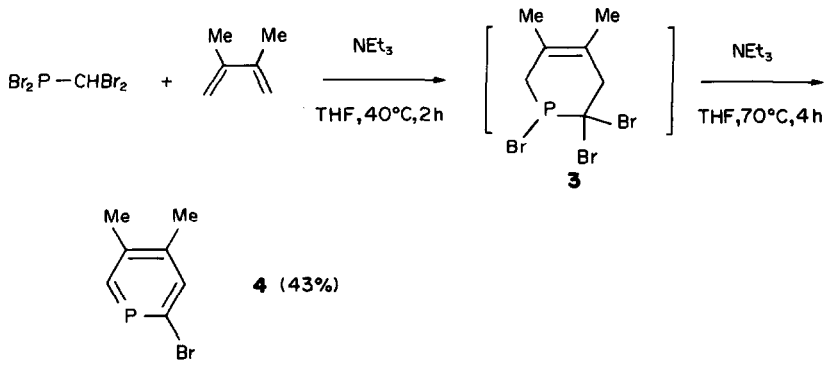
The simplicity of this synthesis prompted us to investigate in more depth the properties of the resulting original and weakly substituted products.

RESULTS AND DISCUSSION

A series of experiments was first performed with the free phosphinines themselves. We tried without notable success to take advantage of the presence of a C—Cl bond. Thus, **1** and **2** were allowed to react with lithium, sodium and potassium in THF at room temperature, and red, paramagnetic, intractable products were obtained. No reaction was observed with magnesium in refluxing THF under ultrasonic irradiation. The zinc–copper couple in dimethylformamide at 140°C slowly converted **2** into the already described 3,4-dimethylphosphinine.[2] The formation of this compound was monitored by ^{31}P NMR analysis: δ +189 ppm [t, ^2J(P—H) = 34.2 Hz]. From this series of observations, it appears that the chloro-substituent of **1** and **2** stabilizes the phosphinine ring to a great extent (compare the thermal stability of **1** with the relative instability of the parent phosphinine[3]), but is practically unreactive. In order to enhance the reactivity of the halo substituent, we first decided

* Author to whom correspondence should be addressed.

to prepare a 2-bromophosphinine, eq. (2):



(2)

The intermediate product, **3**, gives a ^{31}P resonance at +74.7 ppm. As expected, the NMR parameters of the 2-bromophosphinine, **4**, are closely similar to those of **2** apart from a substantial shift of the ^{31}P resonance to low fields: δ ^{31}P (**4**) +194.6 ppm (hexane), $\Delta\delta$ (**4**−**2**) +15 ppm. Unfortunately, **4** proved to be as inert as **1** and **2**. In order to find an explanation for the stability of these 2-halophosphinines, we performed an X-ray crystal structure analysis of the P—$W(CO)_5$ complex of **1** (**5**).[1] The most significant structural parameters of **5** are collected in the caption of Fig. 1. A comparison of the ring parameters is made in Table 1 between **5**, $(C_5H_5P)Mo(CO)_5$,[4] and the parent phosphinine.[5] It must be recalled here that we have demonstrated, on the basis of chemical experiments,[6] that the aromaticity of the phosphinine ring is somewhat reduced when the phosphorus atom is complexed by a $M(CO)_5$ group. When comparing the data of C_5H_5P and $(C_5H_5P)Mo(CO)_5$, this loss of aromaticity can be monitored by a decrease of the P—C bond lengths from 1.73 to 1.70 Å (the P—C bonds acquire a higher double bond character and become able to give [2+4] cycloadducts with conjugated dienes[6]) and a decrease of the C—C bond lengths from 1.40 (mean) to 1.38 Å. The data in Table 1 show a striking structural similarity between **5** and the free phosphinine. It is quite clear that **5** is more aromatic than $(C_5H_5P)Mo(CO)_5$. Thus, the role of the 2-chloro-substituent is to enhance the electronic cyclic delocalization (and, hence, the stability) of the phosphinine ring. Only theoretical calculations could fully rationalize this phenomenon. Apparently, this stabilizing interaction between the halo-substituent and the phosphinine ring is specific of the 2-position. Märkl and Hock have indeed shown that 3-chlorophosphinines are able to react with strong nucleophiles such as lithium amides to give the corresponding 3-aminophosphinines.[7] We thus decided to investigate the reaction of **2** and its P—$W(CO)_5$ complex **6** with BuNHLi. A complex and intractable mixture were obtained with **2**, but **6** reacted very cleanly. However, no substitution took place at the C—Cl bond. A classical attack at phosphorus

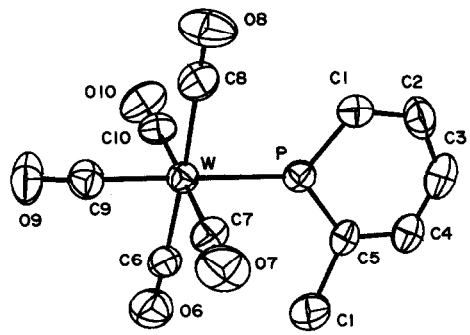


Fig. 1. ORTEP drawing of one molecule of **5**. Vibrational ellipsoids are scaled to enclose 50% of the electron density. Hydrogen atoms are omitted for clarity.

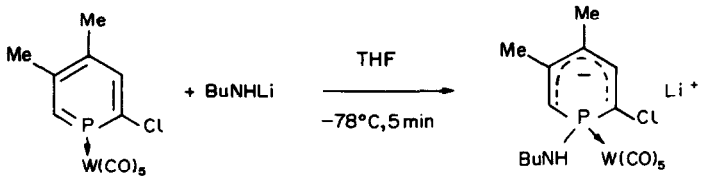
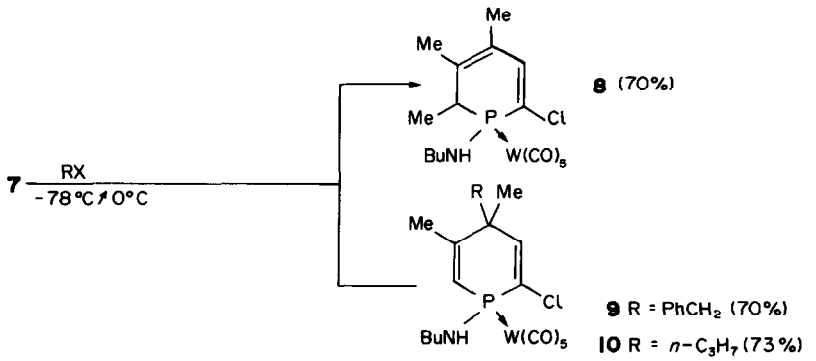
was observed instead, eq. (3):



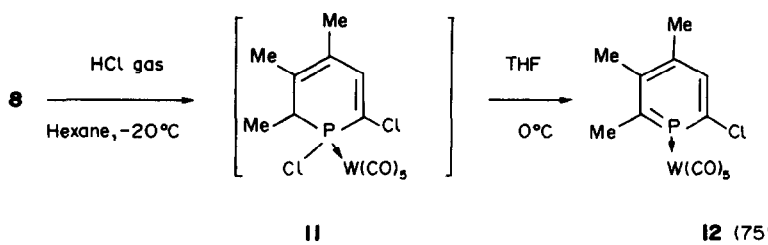
6 7 (3)

The delocalized anion **7** thus obtained was alkylated at the α-unsubstituted position by methyl iodide and at the γ-position by benzyl bromide or propyl iodide, eq. (4):



(4)

Treating **8** with HCl gave the corresponding phosphinine complex **12**, eq. (5):



11 12 (75%) (5)

The formation of the intermediate dichloro complex **11** was monitored by ^{31}P NMR spectroscopy: δ ^{31}P (**11**) + 101.6 ppm. The compound is very unstable and spontaneously loses HCl in THF at 0°C. The aromaticity of 2-chlorophosphinine complexes is thus well evidenced. This two-step scheme (BuNHLi,IMe, then HCl) is a convenient method for methylating the 6-position of 2-chlorophosphinines. We also investigated the reaction of the more bulky lithium diisopropylamide with **6**. Our

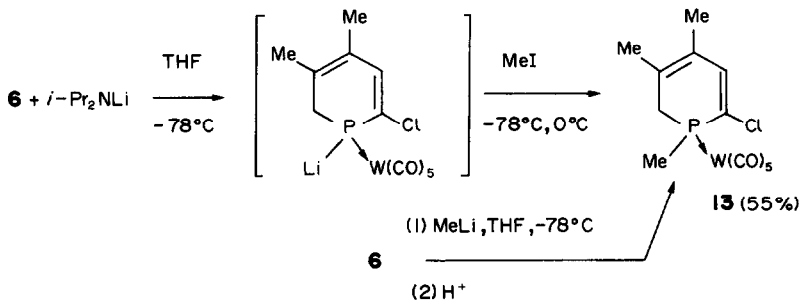
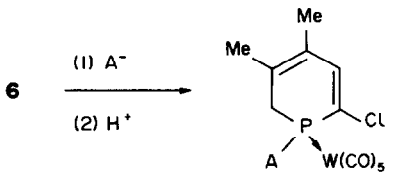
hope was to block attack at phosphorus by steric hindrance and to observe a substitution at C_2. In fact, the attack also took place at phosphorus but the amide acted as a masked lithium hydride, eq. (6):



(6)

Complex **13** was independently synthesized by reaction of **6** with MeLi. We also investigated the reaction of **6** with other nucleophiles (HONa, MeONa, *n*-BuLi) and always observed an initial attack at phosphorus, eq. (7):



14, A = HO (95%)
15, A = MeO (85%)
16, A = *n*-Bu (95%)

(7)

These experiments clearly suggest that the 2-chloro- is less reactive than the 3-chloro-substituent on a phosphinine ring. The study of these interesting 2-halophosphinines is currently continuing.

EXPERIMENTAL

NMR spectra were recorded on a Bruker AC 200 SY spectrometer operating at 200.13 MHz for ^1H and 50.32 MHz for ^{13}C and on a Bruker WP 80 SY spectrometer operating at 32.44 MHz for ^{31}P. Chemical shifts are expressed in parts per million downfield from internal TMS (^1H and ^{13}C) and external 85% H_3PO_4 (^{31}P). Mass spectra were obtained at 70 eV with a Shimadzu GC–MS QP 1000 instrument by the direct inlet method. IR spectra were recorded with a Perkin–Elmer Model 297 spectrometer. Elemental analyses were performed by the "Service d'analyse du CNRS", at Gif-sur-Yvette, France. Silica gel (70–230 mesh) was used for chromatographic separations. All commercially available reagents were used as received from the suppliers.

4,5-*Dimethyl-2-bromophosphinine* (**4**)

Dibromomethyldibromophosphine (3.6 g, 10 mmol), triethylamine (2 g, 20 mmol) and 2,3-dimethylbutadiene (8.2 g, 10^{-1} mol) were heated in 60 cm^3 of THF at 40°C. After 2 h, triethylamine (5 g, 50 mmol) was added and the mixture heated at 70°C for 4 h. After evaporation of the solvent and the excess of amine and diene, the residue was dissolved in 100 cm^3 of hexane and then filtrated. After evaporation, the final product was quickly chromatographed on dry silica gel with hexane as eluent. Yield 0.86 g (43%).

4: colourless oil; ^{31}P NMR (hexane): δ +194.7 ppm; ^1H NMR ($CDCl_3$): δ 2.2 (s, 6H, CH_3), 7.82 (d, 1H, ^3J(H—P) = 4.3 Hz, H_3), 8.14 (d, 1H, ^2J(H—P) = 39.4 Hz, H_6); ^{13}C NMR ($CDCl_3$): δ 22.08 (s, CH_3), 22.8 (d, ^3J(C—P) = 2.7 Hz, CH_3), 140 (d, ^2J(C—P) = 14.2 Hz, C_3), 141.3 (d, ^2J(C—P) = 10.9 Hz, C_5), 141.6 (d, ^3J(C—P) = 10.2 Hz, C_4), 149.1 (d, ^1J(C—P) = 63 Hz, C_2), 157.1 (d, ^1J(C—P) = 53.5 Hz, C_6) ppm.

(1 - n - *Butylamino* - 2 - *chloro* - 4,5,6 - *trimethyl* - 1,6 - *dihydrophosphinine*)*pentacarbonyltungsten* (**8**)

Lithium *n*-butylamide (2.2 mmol in 2 cm^3 of THF) was added at −78°C to a solution of complex **6** (1 g, 2 mmol) in 10 cm^3 of dry THF. After a few minutes, methyl iodide (0.3 g, 2.2 mmol) was added and the reaction mixture was allowed to warm to room temperature. After evaporation of the solvent, the residue was chromatographed with hexane–CH_2Cl_2 (4 : 1) as eluent. Yield 0.8 g (70%).

8: yellow solid; m.p.: 108°C; ^{31}P NMR ($CDCl_3$): 70.5 ppm, $^1J(^{31}P-^{183}W)$ = 258.8 Hz; ^1H NMR ($CDCl_3$): δ 0.8 [t, 3H, CH_3 (butyl)], 1–1.5 (m, 6H), 1.65 (s, CH_3), 1.7 (s, CH_3), 2.8 (m, 2H, CH_2), 3.3 (m, 1H, N—H), 6.25 (d, ^3J(H—P) = 17.3 Hz, H_3); ^{13}C NMR ($CDCl_3$): δ 12.9 (d, ^2J(C—P) = 13.2 Hz, CH_3), 13.8 (s, CH_3), 16.65

(1-n-Butylamino-2-chloro-4-benzyl-4,5-dimethyl-1,4-dihydrophosphinine)pentacarbonyltungsten (**9**)

Lithium *n*-butylamide (2.2 mmol in 2 cm^3 of THF) was added at −78°C to a solution of complex **6** (1 g, 2 mmol) in 10 cm^3 of THF. After a few minutes, benzyl bromide (0.5 g, 3 mmol) was added and the reaction mixture was allowed to warm to room temperature. After evaporation of the solvent, the residue was chromatographed quickly with hexane–CH_2Cl_2 (6:1) as eluent. Yield 0.9 g (70%).

9: colourless oil; ^{31}P NMR ($CDCl_3$): δ +24.48 ppm, $^1J(^{31}P-^{183}W)$ = 268.6 Hz; ^1H NMR ($CDCl_3$): δ 0.8 [t, 3H, CH_3 (butyl)], 1.21 (s, CH_3), 1.2–1.4 (m, 4H, $2CH_2$), 2.02 (s, CH_3), 2.5–2.9 (m, 4H, $2CH_2$), 5.64 (d, 1H, ^2J(H—P) = 23.4 Hz, H_6), 6.17 (d, 1H, ^3J(H—P) = 16 Hz, H_3), 6.9–7.3 (m, 5H, C_6H_5); ^{13}C NMR ($CDCl_3$): δ 13.8 (s, CH_3), 19.9 (s, CH_3), 21.9 (d, ^3J(C—P) = 11.9 Hz, CH_3), 26.45 (s, CH_2), 33.6 (s, CH_2), 43 (d, ^2J(C—P) = 10 Hz, N—CH_2), 46.54 (d, ^3J(C—P) = 5.6 Hz, C_4), 47.1 (s, CH_2), 121.9 (d, ^1J(C—P = 51.9 Hz, C_6), 127 [s, CH *para* (C_6H_5)], 128.55 [s, CH *meta* (C_6H_5)], 128.73 (d, ^1J(C—P) = 55.7 Hz, C_2), 129.88 [s, CH *ortho* (C_6H_5)], 136.1 [s, C *ipso* (C_6H_5)], 144.89 (d, ^2J(C—P) = 6.7 Hz, C_3), 153.06 (s, C_5), 196.55 (d, ^2J(C—P) = 11.8 Hz, CO *cis*), 199.7 (d, ^2J(C—P) = 22.1 Hz, CO *trans*) ppm; IR (decalin): ν(CO), 2090, 1950 cm^{-1}; mass spectrum (^{184}W): *m/z* 646 (M, 13), 618 (M−CO, 8), 562 (M−3CO, 66), 506 (M−5CO, 15), 343 (506−BuNH−$PhCH_2$, 98); Found: C, 43.5; H, 3.9. Calc. for $C_{23}H_{25}NO_5PWCl$: C, 42.8; H, 3.9%.

(1-n-Butylamino-2-chloro-4-n-propyl-4,5-dimethyl-1,4-dihydrophosphinine)pentacarbonyltungsten (**10**)

The same procedure as for **9** was used: lithium *n*-butylamide (2.2 mmol), 1 g of complex **6** and 0.5 g (3 mmol) of propyl iodide. The residue was chromatographed with hexane–CH_2Cl_2 (4:1) as eluent. Yield 0.87 g (73%).

10: colourless oil; ^{31}P NMR ($CDCl_3$): δ 26.59 ppm, $^1J(^{31}P-^{183}W)$ = 273.4 Hz; ^1H NMR ($CDCl_3$): δ 0.6–0.8 (m, 6H, $2CH_3$), 0.8–1 (m, 2H, CH_2), 1.12 (s, 3H, CH_3), 1.1–1.7 (m, 6H, $3CH_2$), 1.82 (s, 3H, CH_3), 2.52 (m, 2H, CH_2—N), 5.64 (d, 1H, ^2J(H—P) = 24.3 Hz, H_6), 6.09 (d, 1H, ^3J(H—P) = 15.75 Hz, H_3); ^{13}C NMR ($CDCl_3$): δ 13.8 (s, CH_3), 14.3 (s, CH_3), 18.5 (s, CH_3), 19.9 (s, CH_2), 21.2 (d, ^3J(C—P) = 11.8 Hz, CH_3), 27.6 (s, CH_2), 33.6 (s, CH_2), 43.0 (d, ^3J(C—P) = 10.4 Hz, N—CH_2), 43.27 (s, CH_2), 46.15 (d, ^3J(C—P) = 5.4 Hz, C_4), 121.7 (d, ^1J(C—P) = 52.8 Hz, C_6), 128.9 (d, ^1J(C—P) = 39.9 Hz, C_2), 145.46 (d, ^2J(C—P) = 6.6 Hz, C_3), 153.0 (s, C_5), 196.55 (d, ^2J(C—P) = 7.6 Hz, CO *cis*), 199.7 (d, ^2J(C—P) = 22.5 Hz, CO *trans*) ppm; IR (decalin): ν(CO) 2090, 1950 cm^{-1}; mass spectrum (^{184}W): *m/z* 597 (M, 34) 569 (M−CO, 13), 513 (M−3CO, 47), 485 (M−4CO, 6), 457 (M−5CO, 72), 341 (M−$BuNH_2$−C_3H_7, 100); Found: C, 38.4; H, 4.1. X-ray structure determination for **5**

Crystals of **5**, $C_{10}H_4ClO_5$ PW, were grown at −18°C from a pentane solution of the compound. Data were collected at 3 ± 1° on an Enraf–Nonius CAD4 diffractometer. The crystal structure was solved and refined using the Enraf–Nonius supplied SDP package. The compound crystallizes in space group *Pbca*, $a = 8.770(1)$, $b = 13.190(1)$, $c = 22.689(2)$ Å; $V = 2624.58(72)$ $Å^3$; $Z = 8$; $d_{calc} = 2.710$ g cm^{-3}; Mo-K_α radiation ($\lambda = 0.71073$ Å) graphite monochromator; $\mu = 93.7$ cm^{-1}; $F(000) = 2008$. A total of 3731 unique reflections were recorded in the range $2° \leqslant 2\theta \leqslant 60.0°$, of which 1643 were considered as unobserved [$F^2 < 3.0\sigma(F^2)$], leaving 2088 for solution and refinement. The structure was solved by Patterson methods, yielding a solution for the tungsten and phosphorus atoms. The hydrogen atoms were included as fixed contributions in the final stages of least-squares refinement while using anisotropic temperature factors for all other atoms. A non-Poisson weighting scheme was applied with a *p* factor equal to 0.08. The final *R* factors were $R = 0.034$, $R_w = 0.057$, G.O.F. = 1.20.

THE CHEMISTRY OF SIMPLE CERAMIC GLAZES—I. ^{57}Fe MÖSSBAUER STUDIES OF IRON-CONTAINING GLAZES AND GLASSES

NASSIF J. ALI, PETER A. GILLESPIE and WILLIAM R. McWHINNIE*

Department of Chemical Engineering and Applied Chemistry, Aston University, Aston Triangle, Birmingham B4 7ET, U.K.

(*Received* 25 *September* 1989; *accepted* 4 *December* 1989)

Abstract—A simple feldspathic glaze which matures at 1280°C and which contains iron as a colouring agent was examined by ^{57}Fe Mössbauer spectroscopy. When fired in air, oxidation of the iron (added as iron(II) oxalate) was complete and the iron(III) occupied a distorted octahedral site. By contrast a soda–lime–silica glass, fired under the same conditions, showed two iron sites, one octahedral [iron(III)], the other tetrahedral, although the oxidation state is uncertain. Firing under dinitrogen produced glazes containing iron(II) and iron(III); the iron was added as iron(II) oxalate or as a mixture of iron and Fe_2O_3. The chemical environment of the iron in the matured glaze was shown to be a function of the way in which the element is introduced into the raw batch, to the firing conditions, and may also be influenced by the replacement (gradual or complete) of $CaCO_3$ with $SrCO_3$ or $BaCO_3$. Using this simple glaze, good reproduction of Chinese "mirror black" and celadon were achieved by firing under dinitrogen and manipulating the form in which iron was added. Preliminary studies of iron–vanadium glazes are reported. Vanadium(IV), or VO^{2+}, was identified in the matured feldspathic glaze by ESR. The addition of iron (as metal) produced glazes, the ESR spectra of which were dominated by contributions from iron(III). The Mössbauer spectrum of a glaze containing 6% iron confirmed the presence of iron(III) but also revealed the presence of another iron site. The data are discussed in terms of an "FeO^{2+}" species.

The modern ceramic industry with its capacity for the manufacture of long runs of sophisticated and often intricate ware represents one of the triumphs of materials science. Craft pottery, whilst not untouched by advances in materials science remains a free form of expression in the sphere of ceramic art. The kiln of the craft potter is a cauldron in which much fascinating inorganic chemistry progresses. The potter, whilst able to exercise some control over the final result, often finds that serendipity remains an important ingredient of the process.

The reactant systems are complex, but it occurred to us that the examination of the chemical changes occurring during the firing of a simple glaze would provide a challenge which could be addressed via the resonance spectroscopies, in particular Mössbauer and solid-state magic angle spinning NMR (MASNMR). We recently attempted to demonstrate the power of the techniques by presenting our studies of the thermolysis of iron-containing minerals illite and montmorillonite[1] by ^{57}Fe Mössbauer spectroscopy and of the iron-free clays hectorite and laponite by ^{29}Si and ^{23}Na MASNMR spectroscopy.[2] In this paper we present some of our results on some iron-containing glazes of simple composition (together with data on simple glasses for comparison); we also investigate methods of obtaining glazes containing iron(II) other than by firing under a reducing atmosphere.

EXPERIMENTAL

Firing of specimens

Specimens were fired to temperatures up to 1280°C in a silicon carbide lined carbolyte MFHT furnace with a gas inlet facility to enable some firing

* Author to whom correspondence should be addressed.

to be carried out under a dinitrogen atmosphere. For such experiments the crucible containing the specimen was covered with a quartz sagger with a side arm which was attached to the gas inlet system. Samples were fired in platinum or unused porcelain crucibles. Materials were of reagent grade but some, for example, feldspar α-quartz and whiting were natural. All materials were subjected to XRD examination prior to use.

Physical measurements

X-ray diffraction (XRD) measurements were made on two instruments using Cu-K_α (1.54 Å) (JEOL) or Co-K_α (1.791 Å) (Philips) radiation. Exposure times of up to 4 h were necessary and identification of species was achieved via the powder diffraction file. Mössbauer spectra were obtained with a Centronic constant acceleration spectrometer as described by Fernandopulle,[3] other specimens were examined using the system recently described.[1] Spectra were computer fitted using a program written by Stone and co-workers[4] adapted for an ICL 1904S and HARRIS H800. The Gaussian non-linear regression method was used and the χ^2 criterion was used as a measure of the acceptability of fit. Spectra were recorded at room temperature. Electron spin resonance (ESR) spectra were measured with a JEOL PE-1X spectrometer using a Mn^{2+}/MgO standard.

RESULTS

Materials

XRD examination of starting materials gave the following results: reagent grade silica (amorphous), reagent grade sodium carbonate (amorphous), reagent grade calcium carbonate (calcite + aragonite), quartz (α-quartz), potash feldspar (no major impurity), whiting (calcite).

Firings in air

Iron was added as iron(II) oxalate dihydrate to both a simple soda glass and simple feldspathic glaze of the following composition:

GLASS I		GLAZE Ia	
10.9%	Na_2CO_3	54.4%	potash feldspar, $K_2O \cdot Al_2O_3 \cdot 6SiO_2$
11.1%	$CaCO_3$	19.1%	quartz (SiO_2)
58.1%	SiO_2	10.3%	whiting ($CaCO_3$)
19.9%	$Fe(COO)_2 \cdot 2H_2O$	16.2%	$Fe(COO)_2 \cdot 2H_2O$

Tables 1(a) (glass) and (b) (glaze) summarize the results of XRD and ^{57}Fe Mössbauer studies of specimens of the preceding composition fired to the indicated temperature. Heating rates were 400°C h^{-1}.

Observations from the data in Table 1 led to the design of experiments in which reagent grade calcium carbonate was heated in turn with X-ray amorphous silica and with α-quartz. The temperature was held at 1000°C for 2 h, after which the crucible was quenched. In both cases the composition was: 49.2% $CaCO_3$ (reagent grade); 50.8% silica (amorphous) *or* α-quartz. The results of XRD analyses are shown in Table 2.

Further experiments were carried out to assess the influence, if any, of the nature of the added alkaline earth ion, i.e. the substitution of Ca by Sr or Ba. One set of data (Table 3) were obtained for a glass, the other (Table 4) for the glaze, the compositions of which are recorded in the tables.

Firings under dinitrogen

"Reduced" glazes, i.e. those in the case of iron-containing glazes which might contain some iron(II), are usually formed by manipulation of the kiln atmosphere. We carried out two sets of experiments in one of which iron(II) was added to the initial glaze which was then fired under dinitrogen and in the other iron metal was added to the raw glaze. The results of the experiments are presented in Tables 5 and 6. The glaze compositions relevant to Table 5 are (weight %):

	Ia	Ib	Ic
Potash feldspar	55.0	55.0	55.0
Quartz	18.8	18.8	18.8
Whiting ($CaCO_3$)	10.7	7.2	3.6
Strontium oxalate	—	3.6	7.2
Iron(II) oxalate	15.5	15.4	15.4

For Table 6 the relevant compositions are:

DISCUSSION

Potash feldspar (orthoclase, $K_2O \cdot Al_2O_3 \cdot 6SiO_2$) can form the basis of many ceramic glazes. For this investigation we took a composition (**Ia** in Results section) which fires to an attractive opaque glaze maturing at 1280°C and which can be modified by the addition of various transition metal oxides to introduce colour to the final glaze. The frequency with which iron is used as a colouring oxide, and the availability of Mössbauer spectroscopy, make it an attractive element to study.

Iron glazes and glasses fired in air

The initial experiments were designed to compare the behaviour of iron in a feldspathic glaze and in a soda–lime–silica glass, both fired to the same maximum temperature of 1280°C. Iron was added as iron(II) oxalate (for consistency with subsequent experiments in which firings were carried out under dinitrogen). The glass components were laboratory reagent grade materials; the silica proved amorph-

ous to X-rays, whereas the calcium carbonate was shown by XRD to be a mixture of calcite and aragonite. By contrast, the whiting used in the glaze was pure calcite. Table 1 details the thermal history of the glass and glaze batches on firing to 1280°C in air.

Aragonite is lost from the glass batch between 400 and 600°C, this is in accord with published data which specifies a temperature of 510°C for the aragonite–calcite phase transition.[5] Calcite undergoes decomposition around 800°C and iron(II) oxalate has completely decomposed to haematite, α-Fe_2O_3, by 400°C. It is clear that additional reactions begin to occur around 800°C since weak unresolved Mössbauer features are seen to be superimposed on the central region of the dominant α-Fe_2O_3 sextet. Attempts to deconvolute this region were ultimately abandoned when no satisfactory χ^2 values were obtained, this presumably means that a range of iron(III) sites co-exist. At 900°C, XRD evidence for the formation of some β-$CaSiO_3$ is obtained consistent with the weight per cent of CaO and SiO_2 employed.[6,7] According to the Mössbauer data, haematite persists until 1100°C, but at 1280°C a glass has been formed and two iron sites are detected. The chemical isomer shift ($\delta = 0.32$ mm s^{-1}) of one site is consistent with the presence of iron(III) in an octahedral "FeO_6" environment. The fact that $\Delta > 0$ illustrates that the "octahedral" site must be distorted. The second site with $\delta = 0.03$ mm s^{-1} is of more interest. Tetrahedral iron(III) generally gives less positive values of δ,[8] but the value of 0.03 mm s^{-1} seems low even for the extended range of δ values seen in vitreous as opposed to crystalline systems.[9–14] Indeed it approaches the value, 0.01 mm s^{-1} w.r.t. iron metal, observed by Gallagher and Kurkjian[15] for the 700°C phase in their study of the thermal decomposition of $Sr_3[Fe(oxalate)_3]$, $2H_2O$ and attributed to iron(IV). Given that later in this paper evidence for iron(IV) in a glaze firing is presented, we suggest that this interpretation of the $\delta = 0.03$ mm s^{-1} resonance cannot be disregarded. Thus the second iron environment is probably stereochemically a distorted "FeO_4" site, however the oxidation state of the iron is not clearly defined by the Mössbauer technique.

By contrast, the feldspathic glaze (Table 1) seems more straightforward. Haematite persists until 1100°C, but even at that temperature there is evidence for the incorporation of some iron in a glassy matrix. By 1280°C all the iron has been incorporated into distorted octahedral sites which, within the cited errors, are very similar to the octahedral site in the soda–lime–silica glass. No evidence for a second iron site was obtained. A further difference between the glass and glaze firings is the identification of XRD of β-$CaSiO_3$ in the glass (but not glaze) batches fired to 800–1000°C. Table 2 reports experiments carried out on mixtures of $CaCO_3$ with amorphous silica and α-quartz. Firing to 1000°C produces β-$CaSiO_3$ in the former, but not in the latter case. This then is a kinetic phenomenon where the smaller particle size and greater surface activity of the amorphous material induces a more rapid reaction.

Table 3 investigates the influence of alkaline earth carbonates on the reaction between α-quartz and α-Fe_2O_3. Apparently no reaction occurs at 1280°C in the presence or absence of $CaCO_3$, however, $SrCO_3$ and $BaCO_3$ produce new iron species at that temperature. For $SrCO_3$ the parameters are consistent with iron(III) in a distorted octahedral environment, but the large value of $\Gamma_{1/2}$ suggests that a spectrum of environments is present. The value of δ for the barium system however (0.20 mm s^{-1}) could certainly indicate a tetrahedral site—the values of both Δ and $\Gamma_{1/2}$ are smaller then in the Sr case suggesting a narrower range of environments and suggesting the possibility of a barium ferrate(III) phase.

Substitution of $SrCO_3$ for $CaCO_3$ in glaze **I** (Table 4) produces a less positive isomer shift, but greater quadrupole splitting on firing to 1280°C, however, $\Gamma_{1/2}$ is again large suggesting once more that a spectrum of micro-environments is available to the iron(III). The substitution by $BaCO_3$ produces an even less positive value of δ but, within the errors, Δ is the same—$\Gamma_{1/2}$ at 0.74 mm s^{-1} is even larger. The sites are suggested to be tetrahedral, certainly the values of δ are consistent with this view,[8] and recently others have cited quadrupole splittings > 1.0 mm s^{-1} for tetrahedral sites in iron–silica glasses.[16] Thus it would appear, in the case of glaze **I**, that the alkaline earth cation may have a significant influence on the ultimate environment of the iron. This may occur via modification of the glass structure[17] or, as implied in Table 3, the precipitation of "ferrate(III)" phases.

Firing under dinitrogen

Many stoneware glazes have greater aesthetic impact if they are fired under reducing conditions. We decided to explore the possibility by adding, in this instance, iron in a lower oxidation state [iron(II) or iron(0)] and firing in an inert atmosphere to examine if "reduced" effects could be obtained. Table 5 contains experimental data for our basic feldspathic glaze (**Ia**) fired under nitrogen; also glazes **Ib** and **Ic** explore the influence of partial replacement of $CaCO_3$ by $SrCO_3$. Even at 400°C a magnetic hyperfine spectrum is seen for **Ia** but it

arises from magnetite, Fe_3O_4, rather than haematite. Magnetite persists to 1200°C but by 1280°C the iron has been incorporated into the matured glaze—octahedral iron(II) ($\delta = 1.06$ mm s^{-1}, $\Delta = 1.99$ mm s^{-1}) and iron(III) sites ($\delta = 0.29$ mm s^{-1}, $\Delta = 1.16$ mm s^{-1}); within the cited errors, the iron(III) site is clearly similar to that observed on firing in air (Table 1). The matured glaze fired in air to 1280°C is green, whilst that fired under nitrogen is mirror black. XRD showed the presence of α-quartz and potash feldspar in the mature black glaze (as was the case for firings in air); also XRD measurements confirmed, for batches fired to lower temperatures, that the oxide of iron present was indeed magnetite.

One of the summits of ceramic art was reached in the Chinese Sung Dynasty.[18] Hedges[19] has made Mössbauer studies of some authentic glazes from this period, the following comparison of parameters is of interest:

Glaze **Ia** (under N_2)		Chinese "Mirror Black"[19]	
δ	Δ	δ	Δ
0.29 ± 0.03	1.16 ± 0.03	0.30	1.29
1.06 ± 0.03	1.99 ± 0.03	1.08	2.02

The similarity is striking.

The partial replacement of $CaCO_3$ by $SrCO_3$ has little effect on the ultimate fate of the iron when **Ib** and **Ic** are fired in air, a single octahedral iron(III) environment being seen (Table 5). When fired under dinitrogen the Mössbauer parameters seem more sensitive to the substitution. Thus the iron(III) chemical isomer shift becomes less positive and comparable to that observed for glaze **II** in Table 4, thus the suggestion must again be made that, in the presence of strontium iron(III) prefers a tetrahedral environment. Although δ for iron(II) is not greatly influenced by the strontium for calcium substitution, Δ which is reduced to ~ 1.76 mm s^{-1}, is apparently sensitive to the change. This is unlikely to be an electronic effect, hence a modification of the site symmetry is implied.

Glazes **IVa** and **IVb** (Table 6) differ in that **IVa** contained, initially, both α-Fe_2O_3 and iron(0), whereas **IVb** contained iron metal as the sole source of the element. Bhatt *et al.*[20] have demonstrated the possibility of forming an iron(II) glass by mixing equimolar portions of iron and iron(III) oxide in the batch. Firing **IVa** under dinitrogen gave no evidence of reaction up to 800°C when XRD evidence for the continued presence of iron(0) and α-Fe_2O_3 was obtained. At 1280°C the glaze matured and a single iron(II) site was identified; the colour was a rich blue. The same iron(II) spectrum was in fact seen at 1000 and 1200°C even though the glaze was not mature. Although the isomer shift of the iron(II) resonance is similar to that of the iron(II) site in glaze **Ia** fired under dinitrogen, Δ is significantly larger suggesting that the ultimate location of the iron(II) is a function, amongst other variables, of the way in which the iron is introduced. When glaze **IVb** is fired in air, Mössbauer parameters essentially identical to those in Table 1 are obtained. This is not surprising since XRD shows that iron(II) oxalate decomposes to α-Fe_2O_3 by 400°C and that iron metal has completely oxidized to α-Fe_2O_3 by 1000°C, thus in both cases haematite is the effective source of iron. Firing under dinitrogen produces an iron(II) glaze with parameters closely similar to those obtained for **Ib** and **Ic** (Table 5). The matured glaze is pale green, again comparison with the data of Hedges[19] is instructive:

	δ	Δ
Pale green celadon glaze[19]	1.12	1.81
Glaze **IVb** under N_2	0.99 ± 0.03	1.78 ± 0.03

Hedges also reported a second site which he described as tetrahedral, but no evidence for a second iron site was found for **IVb**.

The colour of the "mirror black" glaze presumably arises from iron(II)/iron(III) charge-transfer between adjacent ions, whilst that of the celadon is typical of an $Fe^{II}O_6$ environment. The blue colour of **IVa** fired under N_2 is then probably a function of the more distorted ligand field apparent from the larger value of Δ, which gives some absorption in the red. Great variety may therefore be achieved from the same basic glaze composition by subtle variation in the firing conditions and in the manner of introduction of the iron.

Mixed iron–vanadium glazes

Glaze **Va** (see Results section) is similar to **Ia** except that V_2O_5 replaces iron(II) oxalate. The matured glaze is a creamy colour but it gives a well resolved ESR spectrum showing parallel and perpendicular components with evidence of hyperfine splitting (^{51}V has spin 7/2). The spectrum is characterized by $g_\parallel < g_\perp$ and $A_\parallel > A_\perp$. Early work by Bamford[21] predicted that vanadium should be incorporated in glasses primarily as vanadium(V) and vanadium(III), but others[22,23] allowed the possibility of vanadium(IV) also. Bandyopadhyag[24] has used ESR to detect the VO^{2+} ion in borate glass.

Fortunately a considerable body of experimental data exists for ESR studies of vanadium(IV); some useful comparative data are set out in Table 8. It is apparent that the spectrum of glaze **Va** is most similar to those in which the VO^{2+} ion is present

Table 8. Some comparative experimental data—ESR parameters for vanadium(II) in oxygen coordination environments

Ion	$g_{\parallel}$	$g_{\perp}$	$A_{\parallel}$	$A_{\perp}$	Reference	Interpretation
V^{4+} in tridymite	1.968	2.00	58	22	25	Tetrahedral
V^{4+} in TiO_2	1.957	1.915	142	37	26	Octahedral—weak tetragonal distortion
VO^{2+} in borosilicate glass	1.931	1.967	165.8	58.4	24	Octahedral sites with strong tetragonal distortion, i.e. VO^{2+} ion
VO^{2+} in lead silicate glass	1.906	1.969	170	60	27	
VO^{2+} in glaze **Va**	1.959	1.986	163	78.6	Present work	

as a network modifier. Thus it is clear that *some* vanadium(IV), probably in the form VO^{2+}, is present in the mature glaze **Va**; however, the colour of the final glaze suggests the concentration of VO^{2+} is small.

Glaze **Vb** and **Vc** contain iron; introduced as the metal **Vb** matures to an attractive blue violet colour and **Vc** to a lustrous brown. The ESR spectra are dominated by contributions from iron(III). Some ESR studies of Fe–V borosilicate glasses[24] have been published and the loss of hyperfine structure from the vanadium component was also noted; it was suggested that strong interactions between vanadium(IV) and iron(III) were responsible. Even the relatively low iron concentration that characterizes **Vb** results in the loss of the vanadium hyperfine structure, however, the use of a piece of glaze rather than the powdered glaze to record the spectrum did reveal some vanadium hyperfine structure superimposed on the broad high-field resonance, thus confirming, in our view, the continued presence of some vanadium(IV). The main spectral feature was at an apparent g value of 4.15. This feature is commonly observed in iron-containing minerals and glasses and is usually taken to arise from iron(III) in a rhombically distorted environment.[28] The iron content of **Vb** proved too low for a satisfactory Mössbauer spectrum to be obtained.

The ESR spectrum of **Vc** was very similar to that of **Vb**, hence there was the expectation that iron(III) in a distorted environment would be detected in the Mössbauer spectrum. In the event a most peculiar spectrum was obtained (even for this sample the iron content is not great and the spectral quality was poor). Four peaks only were seen and we pair these as indicated in Table 7. The anticipated distorted iron(III) site is, on this basis, tetrahedral ($\delta = 0.13$, $\Delta = 1.31$ mm s^{-1}). The second iron site is characterized by an isomer shift of -0.59 mm s^{-1} which is compatible with iron(IV),[8,9] however, the quadrupole splitting is massive (4.10 mm s^{-1}). A possible explanation is that the iron(IV) substitutes for vanadium(IV) in the VO^{2+} sites within the glaze, i.e. the implication is that a "FeO^{2+}" species must be considered. If such a species exists in the glaze it has been trapped on formation and the stability must be kinetic. There is no doubt that the Fe/V glass system will repay further investigation.

COMMUNICATION

HOMOLEPTIC *t*-BUTYLIMIDO COMPOUNDS OF OSMIUM(VIII) AND CHROMIUM(VI)

ANDREAS A. DANOPOULOS and GEOFFREY WILKINSON*

Johnson Matthey Laboratory, Chemistry Department, Imperial College, London SW7 2AY, U.K.

(*Received* 16 *January* 1990; *accepted* 30 *January* 1990)

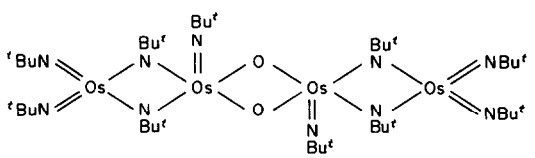
Abstract—The homoleptic imido compounds $Os(NBu^t)_4$ and $Li_2Cr(NBu^t)_4$ have been synthesized, the former by interaction of OsO_4 and $Bu^tNH(SiMe_3)$ where a tetrameric oxoimido compound $Os_4(NBu^t)_6(\mu\text{-}Bu^t)_4(\mu\text{-}O)_2$ is also formed, and the latter by methyllithium deprotonation of $Cr(NBu^t)_2(NHBu^t)_2$.

We recently described the first syntheses of homoleptic imido compounds, namely those of tungsten and rhenium, $Li_2W(NBu^t)_4$ and Li(TMED) $Re(NBu^t)_4$ (TMED = tetramethylethylenediamine). Details of the rhenium compound and of a second homoleptic compound of rhenium(VI), $[(Bu^tN)_2Re(\mu\text{-}NBu^t)]_2$ have been given.[2] X-ray structures of the three compounds were reported,[1,2] while the synthesis of the molybdenum analogue $Li_2Mo(NBu^t)_4$ has been described.[3]

We noted[1] that the only other similar transition metal imido compound was the non-homoleptic $Os(NBu^t)_3(Ntos)$ (tos = *p*-toluene sulphonate) made by K. B. Sharpless, details of which are not available.[4]

We now report the synthesis of $Os(NBu^t)_4$ and of $Li_2Cr(NBu^t)_4$, the latter completing the series of compounds for chromium, molybdenum and tungsten.

The osmium compound is obtained in *ca* 20% yield by interaction of OsO_4 in refluxing neat $Bu^tNH(SiMe_3)$ or, in lower yield using $Os(NBu^t)O_3$. Other compounds are formed and one of these, a red crystalline compound, m.p. 120°C, formed in *ca* 10% yield, has been fully characterized by analyses, spectra and by X-ray crystallography[5] as having the oxoimido formulation (**1**).



(1)

$Os(NBu^t)_4$ is an orange–brown, moisture-sensitive, low melting solid (m.p. *ca* 30°C; b.p. 90–100°C/0.01 mm Hg) that has correct analysis and cryoscopic molecular weight. The NMR spectra are invariant over the range −80 to +80°C: ^1H, 1.48 ppm (NBu^t); $^{13}C\text{-}\{^1H\}$, 30.25 ppm, $C(CH_3)_3$, 72.61 ppm, CMe_3. The mass spectrum shows the molecular ion (476) with structure due to osmium isotopes and peaks at lower mass due to loss of NBu^t and CH_3 groups. We have, so far, been unable to grow X-ray quality crystals.

The chromate(VI) analogue, $Li_2Cr(NBu^t)_4$, is made by a route similar to that used[3] for $Li_2Mo(NBu^t)_4$, starting from $Cr(NBu^t)_2(OSiMe_3)_2$[6] namely the sequence:

$$Cr(NBu^t)_2(OSiMe_3)_2 \xrightarrow[CH_2Cl_2]{BCl_3} Cr(NBu^t)_2Cl_2$$

$$\downarrow \text{LiNHBu}^t,\ \text{toluene}$$

$$Li_2Cr(NBu^t)_4 \xleftarrow[Et_2O/\text{hexane}]{MeLi} Cr(NBu^t)_2(NHBu^t)_2$$

* Author to whom correspondence should be addressed.

Satisfactory analyses were obtained for all the chromium compounds. The red $Li_2Cr(NBu^t)_4$, $d > 250°C$, forms crystals suitable for X-ray diffraction from diethyl ether. The ^1H NMR indicates that the structure is similar to that of the tungsten[1] and molybdenum[3] compounds having bands for linear and bent imido groups at 1.30 (9H) and 1.60 (27H) ppm, respectively. The intermediates were also fully characterized: $Cr(NBu^t)_2Cl_2$, m.p. 68–70°C, mass spectrum *m/e* 264 (M^+), ^1H NMR δ 1.60 ppm; $Cr(NBu^t)_2(NHBu^t)_2$, m.p. 57–60°C, IR ν(N—H) 3350, ^1H NMR δ 1.39 ppm (18H, $NHCMe_3$), mass spectrum *m/e* 338 (M^+).

Acknowledgements—We thank the SERC for support and Johnson Matthey plc for the loan of osmium.

BINUCLEAR DIOXOMOLYBDENUM(VI) COMPLEXES CONTAINING BRIDGING DIOXIME SCHIFF BASE LIGANDS

R. N. MOHANTY and K. C. DASH*

Department of Chemistry, Utkal University, Vani Vihar, Bhubaneswar-751004, India

(*Received* 29 *August* 1989; *accepted* 2 *November* 1989)

Abstract—$MoO_2(acac)_2$ reacts in EtOH with polydentate dioxime-based Schiff base ligands obtained by the condensation of biacetylmonoxime with ethylenediamine (H_2DMED), propylenediamine (H_2DMPD), diethylenetriamine (H_2DMDT) and triethylenetetramine (H_2DMTT) to form binuclear, ligand-bridged, six-coordinated *cis*-dioxomolybdenum(VI) complexes—[(acac)MoO_2(L)O_2Mo(acac)]. All the ligands essentially act as bridging tetradentate ligands. The complexes are characterized by analytical, conductivity, IR and NMR (^1H and ^{13}C) spectral measurements.

The biological activity of molybdenum mostly involves the molybdenum(VI) state, the coordination chemistry of which is to a large extent based on oxo complexes which are of importance for their role in oxidation catalysed by metals.[1,2] Among the transition metal oxocations, the oxovanadium(IV)[3] and dioxomolybdenum(VI)[4] have attracted particular attention. In the structural chemistry of molybdenum(VI) the MoO_2^{2+} has received wide attention and a near octahedral structure with *cis*-dioxo groups is a constant feature. $MoO_2(acac)_2$ is a good source of MoO_2^{2+} and is very convenient to prepare.[5,6] The reaction of $MoO_2(acac)_2$, in suitable solvents, with the multidentate Schiff bases obtained by the condensation of biacetylmonoxime with ethylenediamine (H_2DMED), propylenediamine (H_2DMPD), diethylenetriamine (H_2DMDT) and triethylenetetramine (H_2DMTT) results in the formation of binuclear, mixed-ligand, six-coordinated, *cis*-dioxomolybdenum(VI) complexes, [(acac)MoO_2(L)O_2Mo(acac)], by the partial displacement of the acetylacetone group from the starting $MoO_2(acac)_2$.

EXPERIMENTAL

Materials and methods

FT–IR spectra in KBr phase and electrolytic conductance were obtained as reported earlier.[7] All NMR measurements in DMSO-d_6 medium were performed on a JEOL FT–NMR instrument operating at 270.05 MHz for ^1H and 67.80 MHz for ^{13}C. $MoO_2(acac)_2$ was prepared[5] from $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (Merck) and acetylacetone (BDH). The multidentate Schiff bases, H_2L (H_2L = H_2DMED, H_2DMPD, H_2DMDT and H_2DMTT), were obtained by the condensation[7–9] of biacetylmonoxime (Loba Chemie) with ethylenediamine, propylenediamine, diethylenetriamine or triethylenetetramine in Et_2O or *i*-Pr_2O medium. The metal was estimated after digesting the complex in 3:4 vol/vol conc. HNO_3 and conc. H_2SO_4, extracting the residue in H_2O and precipitating as oxinate. C, H, N microanalyses were carried out by CDRI, Lucknow.

Synthesis of [(acac)MoO_2(L)O_2Mo(acac)] *complexes*

All these complexes were synthesized by a general synthetic technique. The solid ligand (H_2L) (1 mmol) was added in small amounts to a hot, stirred solution of $MoO_2(acac)_2$ (1 mmol) in EtOH (10 cm^3) and a white or pale yellow solid was formed. The mixture was further stirred under reflux for 8 h for completion of reaction. The solids were then collected on a glass frit, washed with small aliquots of EtOH followed by Et_2O and dried *in vacuo* at room temperature. Variation of the metal-to-ligand

ratio did not affect the stoichiometry of the complexes. The compounds were obtained in 70–75% yield.

RESULTS AND DISCUSSION

The chemistry of molybdenum(VI) is dominated by complexes containing the MoO_2^{2+} core,[2,10] the vast majority of which are six-coordinate with a distorted octahedral structure with the two Mo—O_t bonds *cis* to each other. In addition to the monomeric complexes, some polymeric structures are also known which have the Mo—O_t distances and O_t—Mo—O_t angles similar to those found in the mononuclear complexes. Complexes with MoO_2^{2+} core structures are prepared by using Na_2MoO_4, $(NH_4)_6Mo_7O_{24}$ or $MoO_2(acac)_2$ as the starting materials.[5,11] $MoO_2(acac)_2$ is a convenient starting material as one or both of the acac groups may be replaced by suitable ligands in a convenient reaction medium. The complexes formed may be mononuclear or binuclear containing the MoO_2^{2+} core or may also be binuclear containing the Mo_2O_3 and MO_2O_5 structures.[12,13] The polydentate oxime-based Schiff base ligands—the tetradentate H_2DMED, H_2DMPD; the pentadentate H_2DMDT and the hexadentate H_2DMTT—may coordinate to a single metal centre[9,14] or to two metal centres.[7,15,16] $MoO_2(acac)_2$ reacts with these ligands in EtOH medium to form stable, binuclear, diamagnetic, six-coordinated dioxomolybdenum(VI) complexes. That only one acac group is displaced from each $MoO_2(acac)_2$ is confirmed by the isolation of $Cu(acac)_2$ quantitatively from the filtrate after the reaction of $MoO_2(acac)_2$ with H_2L (H_2L = H_2DMED, H_2DMPD, H_2DMDT, H_2DMTT). Further confirmation of this is obtained from IR and NMR (^1H and ^{13}C) evidence as discussed below. The ligands, H_2L, behave as doubly-deprotonated tetradentate ligands bridging two $MoO_2(acac)^+$ centres. A similar partial displacement of acac groups from $MoO_2(acac)_2$ has also been observed in several complexes containing the MoO_2^{2+} core,[11,17,18] the VO^{2+} core[19] and in complexes of the type Co(acac)(Salen).[20]

The complexes isolated are reported in Table 1. They are rather poorly soluble in common organic solvents precluding the determination of molecular weight and isolation of a good quality crystal for structural determination. However, dilute solutions (10^{-4} M) in DMSO confirm their non-electrolytic behaviour.[21] All the complexes, [(acac)MoO_2 (L)O_2Mo(acac)], exhibit IR bands characteristic of the *cis*-MoO_2^{2+} core, the Schiff base ligands and the acac groups. In the complexes, a fairly sharp band in the 1580–1620 cm^{-1} region is assigned to the ν(C=N) of the Schiff base ligands.[22] The ν(N—O) in the complexes at 1140–1150 cm^{-1} suggests the oximes to be N-coordinated.[23] The ν'(N—O) and δ(N—O) bands appear at 1080 and 820 cm^{-1}, respectively. ν(C=O) for the coordinated acac group appears[24] at 1580 cm^{-1} and the methine C—H bending vibration is seen as a weak band at 1190 cm^{-1}. The formation of Mo—O bonds with acac groups and Mo—N bonds of the Schiff bases results in the appearance of a few medium-to-strong stretching frequencies in the 550–650 cm^{-1} region, which are absent in the free ligands. As for the *cis*-MoO_2^{2+} groups, the IR spectrum manifests itself in the form of an intense two-band pattern corresponding to the symmetric and antisymmetric Mo=O stretching vibrations[25] in the 880–920 cm^{-1} region. The *trans*-MoO_2^{2+} complex would have given only one absorp-

tion band. That one or two secondary amine (—NH) functions remain uncoordinated in the complexes with the pentadentate H_2DMDT and the hexadentate H_2DMTT ligands is seen from the appearance of ν(NH) at *ca* 3150 cm^{-1}. This is further substantiated on the basis of the ^{1}H NMR spectra discussed below.

The ^{1}H and ^{13}C NMR spectra establish in a complementary way the disposition of the non-oxo ligands in the complexes. The ^{1}H NMR spectra of the Schiff base ligands and the complexes show two sharp signals due to the two non-equivalent CH_3 groups in the 1.7–2.0 ppm region and the CH_2—CH_2 signals at 3.3–3.9 ppm.[26] The ^{13}C NMR spectrum of the ligands have two ^{13}C signals due to the non-equivalent —CH_3 groups at 8.6 and 12.9–13.4 ppm which shift downfield in the complexes to *ca* 10.4 and 18.4 ppm, respectively. The CH_2—CH_2 carbons resonate in the 48.9–52.32 ppm region in the free ligands and shift to 42.5–48.9 ppm in the complexes. The carbons (C^c and C^d) in the diacetylmonoxime skeleton resonate at 156.48 and 164.1–165.1 ppm for the free ligands, respectively, and shift only slightly downfield in the complexes. Additional signals at *ca* 2.0 and 5.4 ppm in the ^{1}H NMR spectrum and at 30.6, 98.7 and 196.7 ppm in the ^{13}C NMR spectrum unequivocally demonstrate the presence of coordinated acetylacetonate[27] groups in all the complexes. The NH— proton signals in pentadentate H_2DMDT and the hexadentate H_2DMTT ligands appear at 8.3 ppm and in the complexes they shift to 10.5 ppm, providing proof for the presence of free NH— groups. The ^{1}H NMR and ^{13}C NMR data are presented in Tables 2 and 3, respectively, and Fig. 1 depicts the ^{13}C NMR of a typical complex.

[a] All measurements in DMSO-d_6; all values in ppm relative to internal DMSO-d_6 exhibiting a heptet centred at 39.6 ppm downfield from TMS.

The thermal analysis measurements clearly reveal the decomposition patterns of the complexes with increasing temperature, and ultimately in the 650°C region MoO_3 is formed as the stable end-product.[28] The analytical data, IR, ^1H and ^{13}C NMR spectral measurements establish the formation of binuclear, ligand-bridged, mixed-ligand, six-coordinated dioxomolybdenum complexes where each molybdenum(VI) is surrounded by two oxo-ligands, one bidentate acac group and two N-donor atoms (oxime N and imine N) of the Schiff bases. The potential pentadentate H_2DMDT and the hexadentate H_2DMTT ligands essentially function as bridging tetradentate ligands (like the tetradentate H_2DMED or H_2DMPD) with one or two secondary amine groups (—NH) remaining uncoordinated in the complexes. Similar observations have been previously[16] made by us for thorium(IV) and dioxouranium(VI) complexes.

Acknowledgements—The authors are grateful to Professor A. Schmidpeter, Munich University, Munich, F.R.G., for the FT–NMR (^1H and ^{13}C) spectra and to Dr C. R. Panda, Chemical Centre, Lund University, Sweden, for the FT–IR measurements. One of the authors (R.N.M.) thanks the Government of Orissa for leave of absence.

Abstract—3-Methyl-5-(2-pyridyl)- and 3-methyl-5-(6-methylpyrid-2-yl)-1,3,4-thiadiazolidine-2-thiones have been synthesized and characterized by spectroscopic techniques. The thiadiazolidine-2-thiones react with nickel(II), zinc(II) and cadmium(II) acetates producing intensely-coloured, stable metal complexes. Conductance, magnetic and spectroscopic evidences indicate that the rearrangement of the thiadiazolidine-2-thiones to the corresponding Schiff bases occurs. The complexes have been characterized by magnetic and spectroscopic techniques.

The phenomenon of tautomerization of the condensed products of thiolamines and carbonyl compounds to Schiff bases, promoted by metal ions, is well-known[1–4] and we report several further examples. The parent compounds (Fig. 1) and their metal complexes were prepared by extensions of standard methods.[4,5]

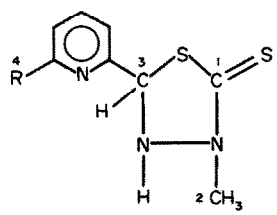

Fig. 1. R = H or CH_3.

EXPERIMENTAL

All the physical measurements and analytical methods were as described before.[6]

RESULTS AND DISCUSSION

The general structural formula of the two thiadiazolidine-2-thiones prepared in the present study is shown in Fig. 1 and their physical properties and characterization data are shown in Table 1.

The thiadiazolidine-2-thiones readily react with nickel(II), zinc(II) and cadmium(II) acetate salts producing stable complexes whose properties and other characterization data are summarized in Table 2. The magnetic and spectroscopic data in Table 2 support an octahedral geometry for the nickel complexes. The IR spectra of [Cd(NNS)ac] and [Cd(MeNNS)ac] show bands at *ca* 1540 and 1410 cm^{-1}, suggesting the presence of bridging acetate ligands.[9] The cadmium complexes most

COMPLEXES OF IRON AND COBALT TETRASULPHONATED PHTHALOCYANINES WITH HORSERADISH PEROXIDASE PROTEIN

ŁUCJA OSTROPOLSKA

Institute of Chemistry, University of Wrocław, Poland

(*Received* 3 *November* 1988; *accepted after revision* 13 *November* 1989)

Abstract—The interaction between the iron and cobalt tetrasulphonated phthalocyanines and the horseradish peroxidase protein leads to the formation of artificial peroxidase containing phthalocyanine derivative in place of protohaem. Such a modification has also been carried out by replacement of the haem in peroxidase by metal tetrasulphonated phthalocyanine. The complexes are not formed with apo-peroxidase previously modified by carboxymethylation at histidines. This suggests that the binding site of iron and cobalt phthalocyanines is a histidine residue, as is the case of the haem in the native peroxidase.

The visible absorption spectra show the main peak of the iron compound at 658 nm and that of the cobalt compound at 680 nm. The position of the main band and the properties of the cobalt compound suggest three oxidation states of the cobalt ion. It is shown by circular dichroism (CD) experiments that incorporation of $Fe^{III}L$ or $Co^{III}L$ into the peroxidase protein leaves the helical content of the protein virtually unchanged in spite of their larger sizes. It is, however, markedly lower than that of the native enzyme, which points to the lower stability of the model complexes. Molecular weight results indicate that the synthesized compounds are monomers. Both phthalocyanine-modified peroxidases are reduced by dithionite and ferrocytochrome *c* to give iron(II) and cobalt(II) complexes which are able to undergo reversible oxygen binding. Artificial peroxidases exhibit minimal enzymic activity and for this reason they cannot be regarded as physiological models of the native peroxidase.

The important role of metalloenzymes in the biological processes has led to the synthesis and study of their model analogues. One of the most important classes of metalloenzymes constitute the haem proteins. They are formed by conjugation of proteins with iron porphyrin which plays the role of the prosthetic group.[1] The interaction between the haem group and the surrounding protein is critical for the functional design of haem proteins.[2,3] The interaction has been investigated by comparing the reactivity of the physical properties of model systems with those of the proteins.[4,5]

The effect of metal substitution on peroxidase conformational stability and the effect of the protein on the haem centre have been reported for the following metallosubstituted peroxidases: Co–HRP, Cu–HRP, Mn–HRP and V–HRP.[6–9] Also, the effect of chemical modification of the porphyrin side chain and the role of peripheral substituents of the porphyrin in metalloporphyrin–apo-peroxidase complexes have been studied.[10–13] According to these results, the major role in the restoration of the helical content of a protein is played by the porphyrin ring itself, not by the metal component. For functionally active peroxidase a hydrophobic environment of the prosthetic groups is required.

The compounds which closely resemble metal-

Abbreviations:

$Co^{II}L$: cobalt(II) tetrasulphonated phthalocyanine.
$Co^{III}L$–apo-peroxidase: cobalt(III) tetrasulphonated phthalocyanine complex with peroxidase protein.

loporphyrins are metal tetrasulphonated phthalocyanines. Recently it has been shown that iron and cobalt tetrasulphonated phthalocyanines are able to displace haem in haemoglobin and myoglobin to give complexes with properties resembling those of haemoglobin and myoglobin.[14,15] Iron and cobalt phthalocyanine-substituted cytochrome *c* has also been synthesized. The conformation of the protein in those compounds is significantly altered compared to that in the native cytochrome *c*. These phthalocyanine-substituted compounds are low-spin species with the metal ions in the trivalent state.[16,17]

In this article we report the results concerning the preparation, structure and properties of artificial peroxidase obtained by incorporation of iron and cobalt tetrasulphonated phthalocyanines into the haem binding site of the peroxidase protein.

EXPERIMENTAL

Materials and methods

Horseradish peroxidase, type I, was purchased from Sigma Chemical Co. and the isoenzyme *C* was separated and purified by the method of Shannon *et al.*[18] The purity index ($A_{403\,nm}:A_{278\,nm}$) of this enzyme was 3.4. The apo-peroxidase was prepared from horseradish peroxidase by a modification of Teale's acid butanone technique reported by Yonetani.[19] The concentration of the solutions was assayed spectrophotometrically using absorption coefficients, based on separate dry weight determinations: 9.2×10^4 M^{-1} cm^{-1} at 403 nm for the native protein and 1.3×10^4 M^{-1} cm^{-1} at 278 nm for the apo-protein. The preparation of the carboxymethylhistidine derivatives of apo-peroxidase was performed by iodoacetylation at pH 5.5 according to the method described previously.[20]

The preparation and purification of iron and cobalt tetrasulphonated phthalocyanines have been described by Fallab and co-workers.[21] The stock solution was obtained by weighing an appropriate amount of the solid and dissolving the latter in 100 cm^3 of an appropriate buffer.

Synthesis of the metal tetrasulphonated phthalocyanine-substituted peroxidase

The apo-peroxidase in 0.01 M Tris, pH = 8.4, was adjusted to 0.2 mM, mixed with a two-fold excess of iron or cobalt tetrasulphonated phthalocyanine, and allowed to stand at 4°C for 2 days. The mixture was passed through a DEAE–cellulose column equilibrated with 10 mM potassium phosphate buffer, pH = 7.4. The complexes of $Fe^{III}L$ and $Co^{II}L$ with the apo-peroxidase were not adsorbed on DEAE–cellulose, whereas free iron and cobalt tetrasulphonated phthalocyanines were firmly bound to this adsorbent. The complex fraction of the chromatographic separation was concentrated by lyophilization and stored at 0°C. The concentrations of the phthalocyanine complexes in the solutions were determined from the molar absorption coefficients: $Fe^{III}L$–apo-peroxidase $\varepsilon_{658} = 2.4\times10^4$ M^{-1} cm^{-1} and $Co^{III}L$–apo-peroxidase $\varepsilon_{680} = 3.8\times10^4$ M^{-1} cm^{-1}. Solid samples were obtained by lyophilization of the water solutions of the complexes.

The reduced forms of the complexes were prepared by addition of a few milligrams of sodium dithionite to their buffered solutions and removal of the reductant excess on a Sephadex G-50 column. All the chemicals used in the studies were of analytical purity. Absorption spectra and difference spectra were recorded on a Cary 15 spectrophotometer with a cell compartment thermostatically controlled at 4°C or on a Specord spectrophotometer.

Molecular weight measurements of the model complexes were carried out by gel-filtration on a Sephadex G-75 column according to the method of Andrews.[22] The following proteins were used as reference substances: cytochrome *c* (mol. wt 12,400), myoglobin (mol. wt 17,800), chymotrypsinogen (mol. wt 25,000), ovalbumin (mol. wt 45,000), serum albumin (mol. wt 67,000) and γ-globulines (mol. wt 160,000).

Circular dichroism spectra were recorded on a model ORD/UV-5 Japan Spectropolarimeter with CD attachment. The solutions of the complexes were prepared by dissolving the appropriate amount of lyophilized preparation in phosphate buffer, pH = 7.4.

Enzyme assay

Peroxidase activity was measured spectrophotometrically by following the change in absorbance at 460 nm due to *o*-dianisidine oxidation in the presence of H_2O_2 and the complexes.[23]

RESULTS

The reaction of $Fe^{III}L$ and $Co^{II}L$ with peroxidase indicates that haem is partially displaced by phthalocyanine compounds. This is shown by the difference spectra presented in Fig. 1. In both cases the Soret band at 403 nm, which is characteristic of peroxidase, disappears. The formation of phthalocyanine complexes is monitored by the appearance of a new characteristic band in the region of phthalocyanine absorption at 658 and 680 nm, respec-

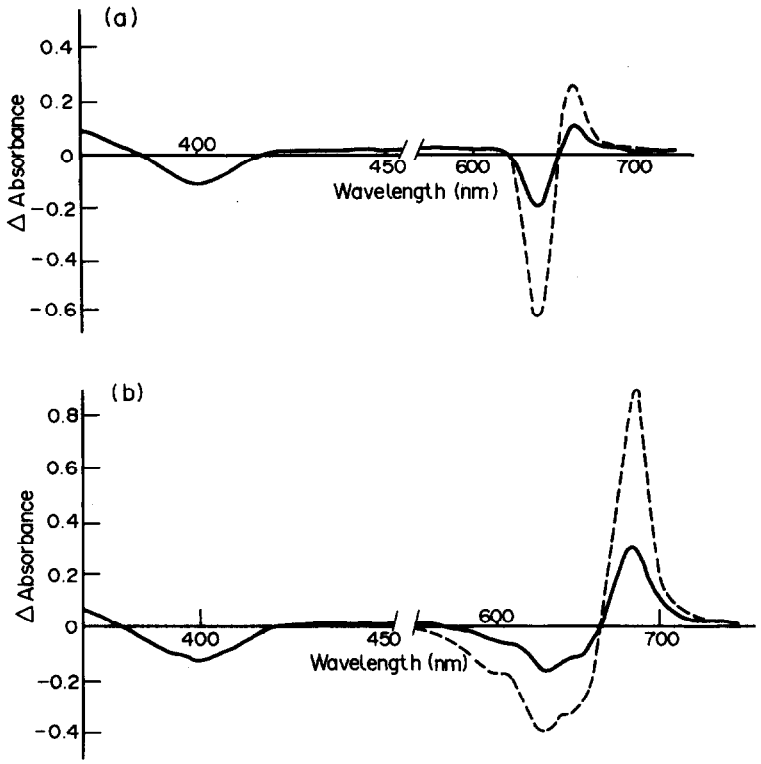

Fig. 1. Difference spectra of the mixture of HRP with (a) $Fe^{III}L$ and (b) $Co^{II}L$ against the same solution mixed (——). Difference spectra of (a) $Fe^{III}L$+apo-peroxidase and (b) $Co^{II}L$+apo-peroxidase mixtures against the same solution unmixed (– – –). Spectra were recorded after 24 h of the reaction run in 5 mM phosphate buffer, pH = 7.5. Concentrations: HRP = apo-peroxidase = 1×10^{-5} M, $Fe^{III}L = Co^{II}L = 2 \times 10^{-5}$ M.

tively, for iron and cobalt protein complexes. At the same time the characteristic absorption of $Fe^{III}L$ at 635 nm and $Co^{II}L$ at 625 nm decreases. The reaction of haem displacement in peroxidase by phthalocyanine derivatives was investigated in the pH range 4.5–9.5. The optimal pH for this reaction appeared to be 5.5. This fact suggested that displacement of haem by phthalocyanine was dependent on dissociation of the peroxidase into haem and apo-protein.[24] It is known from previous investigations[25] that tetrasulphonated phthalocyanine exists in aqueous solution in two forms: dimeric and monomeric. The stability of the dimers was found to decrease in the following way: $Fe^{III}L > Co^{II}L$. This could explain the higher displacement reaction rate in the case of $Co^{II}L$ than that of $Fe^{III}L$ and confirms previous suggestions that the monomer is a species which displaces haem from haemoproteins.[26]

Combination of $Fe^{III}L$ *and* $Co^{II}L$ *with peroxidase protein*

The reaction between metal tetrasulphonated phthalocyanine and apo-peroxidase was demonstrated by a difference absorption spectroscopy experiment (Fig. 1). The difference spectra of both systems in the visible region correspond closely to those of the systems with the native peroxidase. It is evident from these spectra that in the reaction of peroxidase apo-protein with phthalocyanine compounds new complexes are formed which are identical to those arising in the haem displacement process.

In contrast to free $Co^{II}L$, its complex with apo-peroxidase has very little ability to undergo reversible oxygen binding, which suggests that insertion of $Co^{II}L$ into the apo-protein under aerobic conditions leads to oxidation of the cobalt ion to its trivalent state.

Spectroscopic titration of an apo-peroxidase with $Fe^{III}L$ and $Co^{II}L$ points to a 1 : 1 molar ratio of the reagents. The new apo-peroxidase complexes were isolated as green–blue solids by separation of the reaction mixture on DEAE–cellulose and by lyophilization. The solids were stable for 4 weeks.

The incubation of iron and cobalt tetrasulphonated phthalocyanines with a carboxymethylhistidine derivative of the apo-peroxidase did not lead to the formation of the complexes.

This fact suggests that the metal phthalocyanine binding site in apo-peroxidase is the histidine group.

Properties of the $Fe^{III}L$*–apo-peroxidase and* $Co^{III}L$*–apo-peroxidase complexes*

The reduction of the $Fe^{III}L$–apo-peroxidase with dithionite involves direct attack of the reductant on the iron(III) atom. The spectrum of the reduced form of this complex exhibits a characteristic band at 690 nm. No degradation of the phthalocyanine ring is observed in this spectrum in contrast to that of free $Fe^{II}L$ where disappearance of the phthalocyanine characteristic bands occurs.[14] The results presented above suggest that the $Fe^{III}L$–apo-peroxidase compound is located deeply inside the protein.

A solution of $Fe^{II}L$–apo-peroxidase exhibits reversible combination with oxygen. Absorption spectra of this compound in argon and oxygen are shown in Fig. 2.

The reduction of $Co^{III}L$–apo-peroxidase with dithionite in argon results in the disappearance of the band at 680 nm and increased absorptivity at 635 nm. Bubbling oxygen through the solution gives rise to a new band at 690 nm. At the same time the band at 635 nm disappeared. In an argon atmosphere the reaction reverses. These results indicate that the reduced form of the $Co^{II}L$–apo-peroxidase complex is able to undergo reversible oxygen binding. The band at 690 nm corresponds to the oxygenated form of the complexes and that at 635 nm to its deoxygenated form. The oxygen displacement from the oxygenated form of the iron complex is more difficult than in the case of the cobalt complex, which suggests a stronger metal–oxygen bond in the iron complex.

The difference spectrum presented in Fig. 2 shows that $Fe^{III}L$–apo-peroxidase is able to oxidize ferrocytochrome *c* under anaerobic conditions. The increase in absorptivity at 406 nm and its decrease at 417 nm points to the transformation of ferrocytochrome *c* to ferricytochrome *c*. The simultaneous decrease of absorptivity at 658 nm and its increase at 690 nm indicates that $Fe^{III}L$–apo-peroxidase is reduced to $Fe^{II}L$–apo-peroxidase.

Both model complexes reacted slowly with hydrogen peroxide to form "peroxide compounds" with characteristic absorption bands at 662 and 682 nm for $Fe^{III}L$–apo-peroxidase and $Co^{III}L$–apo-peroxidase, respectively (Fig. 3). When catalase was added to the solution, H_2O_2 was decomposed and the original spectrum of $Fe^{III}L$–apo-peroxidase and $Co^{III}L$–apo-peroxidase was regenerated. This suggests that H_2O_2 coordinates to the metal atoms. However, the intensities of these spectra diminish with time, which is indicative of slow auto-oxidation of the phthalocyanine ligand. The purified $Fe^{III}L$–apo-peroxidase and $Co^{III}L$–apo-peroxidase gave activities of 500 and

Fig. 2. 350 mol min^{-1} mg^{-1}, respectively, in the standard *o*-anisidine assay.

The results of the molecular weight estimation using Sephadex G-100 gel-filtration techniques demonstrated that the molecular weight of the iron complex is aproximately 42,500 and that of the cobalt one is 42,000. These values are comparable with that of peroxidase, which indicates that the model complexes are monomers.

To obtain information about whether the metal tetrasulphonated phthalocyanine incorporation in the peroxidase protein brings about perturbation of its helical structure, the UV CD spectra of the appropriate mixtures were taken. The results of these experiments, presented in Table 1, indicate that the helical content of the peroxidase apo-protein is virtually unchanged due to metal phthalocyanine coordination. CD spectra of the metal phthalocyanine-modified peroxidases exhibit molar ellipticities close to that of the peroxidase apo-protein. However, they are markedly lower than that of the native peroxidase.

Table 1. Comparison of CD results of the complexes. The medium contained 5 mM phosphate buffer, pH = 7.5

CONCLUSIONS

Interaction between the iron and cobalt tetrasulphonated phthalocyanines and peroxidase protein results in the formation of the complexes $Fe^{III}L$–apo-peroxidase and $Co^{III}L$–apo-peroxidase with characteristic absorptivities at 658 and 680 nm, for iron and cobalt complexes, respectively. The same complexes were obtained by haem displacement in the native peroxidase with $Fe^{III}L$ and $Co^{II}L$. This suggests the same binding site on the protein for haem and phthalocyanine derivatives. The stoichiometry of this process was found to be 1 : 1 in the systems with both phthalocyanine complexes but the reaction rate was higher when $Co^{II}L$ was used. This suggests a different mechanism for the process with the cobalt complex. The position of the main absorption band of the cobalt phthalocyanine-modified peroxidase, as well as its lack of ability to undergo reversible oxygen binding, which is characteristic for free $Co^{II}L$, points to three oxidation state of the cobalt ion in this compound. According to the suggestions of Hoffman and Petering[27] reconstitution of the cobalt-substituted haemoglobin and the other haemoproteins depends markedly on the cobalt ion oxidation state. It is possible that in the case of the cobalt phthalocyanine-modified peroxidase, oxidation of the cobalt ion of $Co^{II}L$ results in its incorporation into the protein in the proper orientation at the haem binding site. Carboxymethylation of the histidyl residues of the peroxidase apo-protein renders it completely inactive towards metal tetrasulphonated phthalocyanine, which suggests that, like in the case of haem,[28] the histidine group constitutes the

phthalocyanine binding site. As is shown by molecular weight estimation, both phthalocyanine-modified peroxidases are monomers with molecular weights close to that of the native enzyme.

Incorporation of the metal tetrasulphonated phthalocyanines into the haem crevice of the peroxidase protein virtually does not change its helical conformation, in spite of their larger size. On the other hand, the helical content of the examined model complexes is markedly lower than that of the native peroxidase, which points to their lower stability.[29-31]

Both phthalocyanine-modified peroxidases reduced with dithionite under anaerobic conditions are able to undergo reversible oxygen binding to give oxygenated compounds. The cobalt oxygen adduct, however, is unstable and undergoes slow auto-oxidation with degradation of the phthalocyanine ring. Both model complexes exhibit extremely low activity toward H_2O_2 and *o*-dianisidine, which indicates that they cannot fulfill the physiological function of the native peroxidase and cannot be regarded as its model in this respect. In conclusion, it can be stated that the haem crevice of the peroxidase closely fits to the natural prosthetic group, to give a conformation which is essential for the physiological function of the enzyme.

SYNTHESIS AND ELECTROCHEMICAL STUDIES OF A MACROCYCLIC COMPLEX OF NICKEL(II) BEARING A PYRROLE UNIT

RANDHIR SINGH

Department of Chemistry, Gurukula Kangri University, Hardwar, India

(*Received* 16 *November* 1988; *accepted after revision* 13 *November* 1989)

Abstract—A saturated 13-membered C-substituted macrocycle containing a N-substituted pyrrole group and its nickel(II) complex have been synthesized and characterized. During electrochemical studies, electropolymerization of the macrocyclic complex was observed by cyclic voltammetry using a glassy carbon electrode in acetonitrile.

Since the publication of the first report on polypyrrole films, electrode surface deposition of redox polymers has received much attention.[1–4] In spite of the much lower conductivity of N-substituted polypyrrole films compared to polypyrrole itself,[5] one of the most appealing means of incorporating a catalytic species into an electroactive film[6,7] is by covalently linking the molecular electrocatalyst to pyrrole via its nitrogen atom. Recently, interesting work on ferrocene[8,9] and a few other complexes of nickel(II) and copper(II) has been published.[10,11] Keeping in view the interesting electrocatalytic properties of Ni^{II}(cyclam)$^{2+}$ and analogous complexes,[12–14] it has been planned to synthesize and carry out electrochemical studies of a [13]ane-N_4 macrocycle bearing a pendant pyrrole unit [Fig. 1(a)] and its nickel(II) complex.

EXPERIMENTAL

The macrocycle [Fig. 1(a)] and its nickel(II) complex were prepared by suitable modifications of published methods.[15,16] The combination of triethylene tetraamine and substituted diethylmalonate resulted in the 3-(4-amino-*n*-butyl)-1,5,8,11-tetraazacyclotridecane macrocycle which was then treated with *cis*-but-2-ene-1,4-diol in the presence of palladium black. This reaction mixture was stirred magnetically at 100°C for about 36 h under an inert atmosphere. The macrocycle was separated chromatographically as a white compound in very low yield. Found: C, 66.2; H, 10.3; N, 22.4. Calc. for $C_{17}H_{33}N_5$: C, 66.4; H, 10.3; N, 22.8%. The complex was prepared in good yield by mixing requisite amounts of macrocycle A and $Ni(ClO_4)_2 \cdot 6H_2O$ in MeOH. After filtering and drying *in vacuo*, a yellowish powder of the nickel(II) complex was obtained.

Cyclic voltammetry onto glassy carbon electrode vs SCE was performed in CH_3CN solution (deoxygenated by bubbling nitrogen gas) using a Cyclic Voltameter Princeton Applied Research Model 155 and tetrabutylammonium perchlorate, as supporting electrolyte.

RESULTS AND DISCUSSION

After the chromatographic separation the compound was characterized by ^{1}H NMR spectroscopy in CD_3OD and the characteristic pattern of the pyrrolic subunit showed two multiplets at δ 6.02 and 7.66. Cyclic voltammetric (CV) measurements have shown that redox potential values were found very close to those of Ni(cyclam)$^{2+}$.[17] The redox couples $Ni^{III}/Ni^{II}/Ni^{I}$ for the nickel(II) macrocyclic complex in CH_3CN showed E^0 values of +0.96 and −1.40 V, respectively. An irreversible and multielectronic oxidation of the pyrrolic group also gave a value of 1.34 V, which is close to N-substituted pyrroles.[18] In CH_3CN the macrocyclic complex showed electropolymerization by repeated cyclic scanning of the potential between 0.2 and 1.2 V on a glassy carbon electrode. The formation and growth of a polymer film on the electrode surface was observed with the increase in size of the CV peaks, Fig. 1. The redox couple Ni^{III}/Ni^{II}, to which the main electrochemical process corresponds, showed a peak separation of 100 mV. The peak current intensity is proportional to the potential sweep rate over a wide range (10–150 mV s^{-1}), as

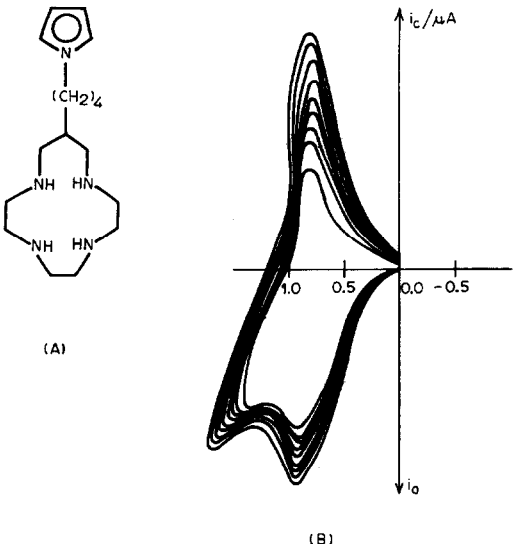

Fig. 1. Cyclic voltammogram showing polymerization of a macrocyclic complex of nickel(II) on to a glassy carbon electrode in acetonitrile using 0.1 M TBAP with a sweep rate of 50 mV s^{-1}.

expected for an electroactive compound which has deposited on the surface of an electrode.

The film becomes, interestingly, insulating as soon as a cathodic potential is applied. One point to be noted is that the present example deals with a non-aromatic electroactive species. The Ni^{II}/Ni^{I} redox couple involves a metal-localized redox processes.[19–21] It is well known that the nickel(II) cyclam-modified polypyrrole film does not lead to a redox process involving the Ni^{II}/Ni^{I} couple which may prevent its use in electroreduction processes. The reversibility of the redox couple Ni^{III}/Ni^{II} might be useful in the present polypyrrolic film for use in oxidative electrocatalysis.

THREE DIFFERENT COPPER(II) COORDINATION POLYHEDRA IN THE CRYSTAL STRUCTURE OF BIS(4-PICOLINE)DITHIOCYANATO COPPER(II) COMPLEX, $[Cu(4\text{-pic})_2(NCS)_2]$; EXPERIMENTAL EVIDENCE OF A NEW TYPE OF MUTUAL INFLUENCE OF LIGANDS IN COMPLEXES

Z. KOŽÍŠKOVÁ, J. KOŽIŠEK* and M. KABEŠOVÁ

Department of Inorganic Chemistry, Slovak Technical University, CS-812 37 Bratislava, Czechoslovakia

(*Received* 17 *August* 1989; *accepted* 13 *November* 1989)

Abstract—The crystal structure of bis(4-picoline)dithiocyanato copper(II) is reported. The compound crystallizes in space group $P2_1$, with $a = 9.808(6)$, $b = 26.752(10)$, $c = 9.927(4)$ Å, $\beta = 107.89(4)°$, $U = 2478(1)$ Å^3, $Z = 6$, $D_m = 1.48(2)$, $D_x = 1.47$ g cm^{-3}, μ(Cu-K_α) = 4.13 mm^{-1}, $F(000) = 1122$, $T = 293$ K. Final R is 0.043 ($R_w = 0.043$) for 2400 observed reflections. The complex compound exhibits three different pseudo-octahedral coordination polyhedra for copper(II). The polyhedra differ in the degree of their tetragonal distortion. While two of them show "symmetrical" shortening and elongation, respectively, the third presents both an elongated and a shortened axial bond.

Among others, the donor–acceptor properties of neutral ligands are factors influencing the coordination mode of the thiocyanate ligand in heterogeneous thiocyanate complexes.[1–3] Norbury[3] has generalized this knowledge for all transition metals by applying the π-bonding hypothesis. As we have shown,[4,5] the validity of the assumed hypothesis depends on the strength of the π-acceptor neutral ligand properties in conditions of the coordination sphere with various central atoms. Thiocyanato copper(II) complexes show an increasing sensitivity in this direction. This fact may be correlated with the plastic properties of their coordination polyhedra.[6,7] It was found that the ligands having different π-acceptor properties in thiocyanato copper(II) complexes can influence the bonding properties of thiocyanate ligands in several ways. For example, they cause changes in their coordination mode,[5] influence their interatomic distances to the copper(II) central atom[8] and they also affect the thermal properties in thiocyanato copper(II) complexes.[9] It was the differing thermal decomposition of compounds $[CuL_2(NCS)_2]$, where L = pyridine and all isomeric forms of picolines,[9,10] which led us to examine the crystal structure of $[Cu(4\text{-pic})_2(NCS)_2]$.

EXPERIMENTAL

Preparation

Dark green prism-shaped crystals of $[Cu(4\text{-pic})_2(NCS)_2]$ were prepared by the reaction of an aqueous solution of $CuSO_4$ with 4-picoline and ammonia, and an aqueous solution of KNCS (2 M), in the molar ratio of $[Cu^{II}]:[NH_3]:[4\text{-pic}]:[NCS^-] = 1:4:2.5:2$. Found: Cu, 17.3; N, 15.3; C, 45.9; H, 3.8. Calc: Cu, 17.4; N, 15.3; C, 45.9; H, 3.9%.

Crystal data

$[Cu(NC_6H_7)_2(NCS)_2]$, $M = 366.00$, monoclinic, space group $P2_1$, with $a = 9.808(6)$, $b = 26.752(10)$, $c = 9.927(4)$ Å, $\beta = 107.89(4)°$, $Z = 6$, $D_m = 1.48(2)$, $D_x = 1.47$ g cm^{-3}, Cu-K_α, $\lambda = 1.54178$ Å, graphite monochromator, $\mu = 4.13$ mm^{-1}, $F(000) = 1122$, room temperature.

The cell parameters were refined with a SYNTEX $P2_1$ diffractometer by the least-squares method

* Author to whom correspondence should be addressed.

using the angles of 10 selected reflections. The orientation matrix obtained was employed for further intensity measurements carried out within the range of $0 < 2\theta < 100°$ by applying the θ–2θ scanning technique with a variable scan rate ranging from 4.88 to 29.3° min^{-1}. The scan range for each reflection was from $2\theta(Cu\text{-}K_{\alpha 1}) - 1°$ to $2\theta(Cu\text{-}K_{\alpha 2}) + 1°$. Two standard reflections were re-measured after every 98 reflections.

The original total reflections were reduced to 2400 by rejecting reflections with $F < 4\sigma(F)$, $R_{Int} = 0.030$ for 376 reflections. Intensities were corrected for the Lorentz and polarization factors but not for absorption effects. The structure was solved by Patterson and Fourier methods.[11] Positional and thermal parameters for all non-hydrogen atoms were refined by the least-squares procedure. The hydrogen atoms located on Fourier synthesis were included in the F_c calculations with an idealized position and a fixed isotropic thermal parameter. Full-matrix least-squares refinement on F leads to $R = 0.043$ and $R_w = 0.043$ for the 568 parameters varied and 2400 observed reflections ($w^{-1} = k(\sigma^2(F) + gF^2)$, $k = 0.26$, $g = 0.00110$). Isotropic extinction correction, $F_c^* = F_c(1 - xF_c^2/\sin\theta)$ ($x = 2.7(6) \times 10^{-6}$) was carried out. The maximum residual electron density, max. $\Delta\rho = +0.50$ e $Å^{-3}$ and minimum, min. $\Delta\rho = -0.55$ e $Å^{-3}$. Scattering factors and anomalous dispersion corrections were obtained from *International Tables for X-ray Crystallography* (1974).

RESULTS AND DISCUSSION

The symmetry-independent section of the unit cell of the $[Cu(4\text{-pic})_2(NCS)_2]$ crystal structure exhibits three types of coordination polyhedra (Fig. 1). In

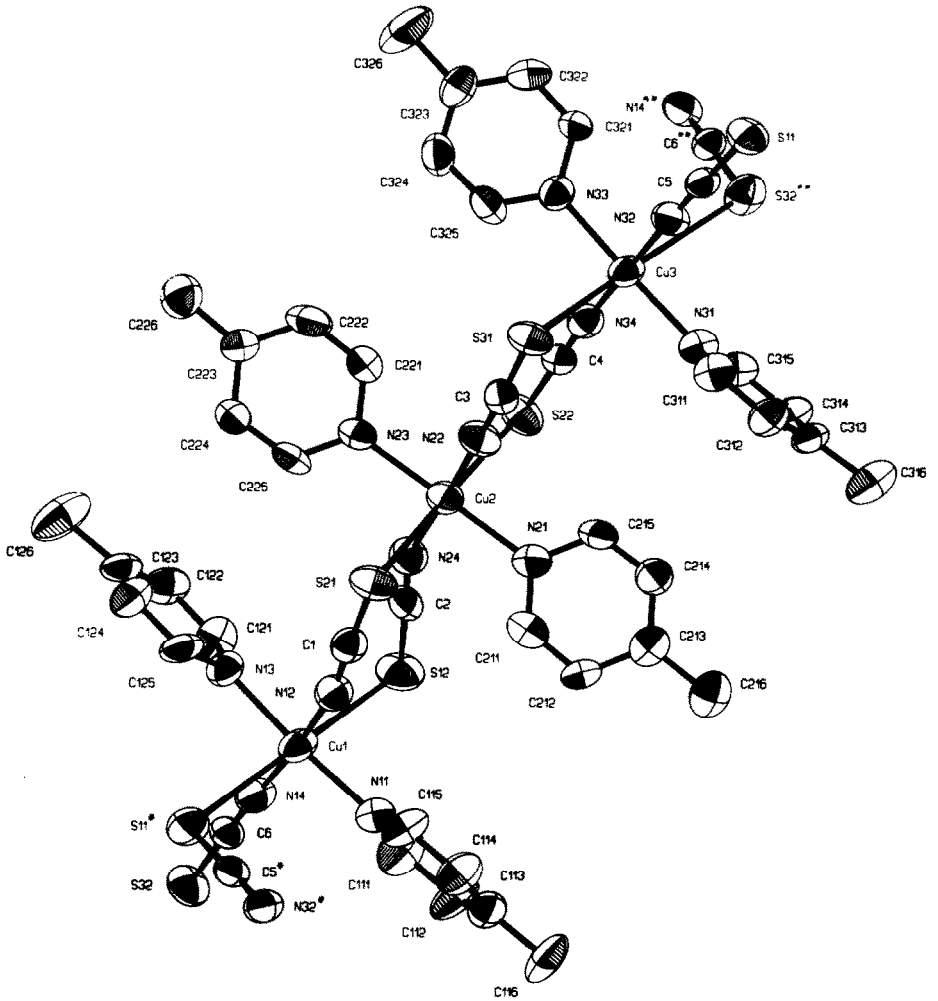

Fig. 1. An ORTEP drawing of the structure of $[Cu(4\text{-pic})_2(NCS)_2]$ and the atom numbering. The ellipsoids are drawn at the 50% probability level. The hydrogen atoms have been omitted. Symmetry code: (*) $1-x, -1/2+y, 1-z$; (**) $1-x, 1/2+y, 2+z$.

all three cases the central copper(II) atom appears to be octahedrally coordinated with the same ligand arrangement in the coordination sphere. Four nitrogen atoms are found in the equatorial planes of copper(II) coordination polyhedra; two of them are from the thiocyanate ligands (in *trans*-positions), while the other two are from the 4-picoline ligands. There are two sulphur atoms from the bidentate bridging thiocyanate ligands coordinated in axial positions of copper(II). The coordination mode found for copper(II) is analogous to that found in the crystal structure of $[Cu(py)_2(NCS)_2]$,[12] which, however, shows in its symmetry-independent section only one coordination polyhedron of copper(II).

The axial Cu—S distance in the crystal structure of $[Cu(py)_2(NCS)_2]$ is equal to 3.043(10) Å. Two of the three symmetry-independent copper(II) coordination polyhedra in the crystal structure of $[Cu(4\text{-pic})_2(NCS)_2]$ exhibit different values. The first polyhedron [Cu(1) central atom] shows a "symmetrical elongation" of this bond [3.109(4) and 3.124(4) Å] when compared with that of the pyridine complexes. In the second polyhedron [Cu(2) central atom] the Cu—S bond lengths remain constant [2.968(4) and 3.005(4) Å]. For the third polyhedron [Cu(3) central atom] one bond was found to be elongated [3.258(4) Å], while the other one remained unchanged [2.977(4) Å]—an "asymmetrical distortion". Based on the data obtained from electronic spectra, the differences in the degree of axial distortions in the copper(II) coordination polyhedra for the $[Cu(py)_2(NCS)_2]$ and $[Cu(4\text{-pic})_2(NCS)_2]$ compounds were expected.[13] The ligand-field band for $[Cu(py)_2(NCS)_2]$ with its maximum at 15,600 cm^{-1} was shifted and split for $[Cu(4\text{-pic})_2(NCS)_2]$. The maximum values were observed at 16,600 and 13,400 cm^{-1}.

In symmetry-independent coordination polyhedra the interatomic distances of Cu—N(NCS) and Cu—N(L) show minimal differences (Table 1). In all cases, however, the thiocyanate ligands in the equatorial plane are coordinated more strongly than the molecules of the heterocyclic base. This result is in good agreement with the published values for valence vibrations of ν(Cu—N)(NCS) = 321 cm^{-1} and ν(Cu—N)(4-pic) = 216 cm^{-1} observed in the IR spectra.[8] A comparison of the bonding properties of Cu—N(NCS) in the crystal structure both with 4-picoline and with pyridine indicates that the different bonding properties of heterocyclic ligands occur with no change in the coordination mode of the thiocyanate ligand and with only small differences in the strength of this bonding. As expected, the interatomic distance of Cu—N(L) in the coordination compound with 4-picoline is slightly greater than with pyridine.

The presence of the methyl substituent on the pyridine ring manifests itself significantly on the overall arrangement of structural units in the crystal structures. While the crystal structure of $[Cu(py)_2(NCS)_2]$ (Fig. 2) exhibits linear chains, that of $[Cu(4\text{-pic})_2(NCS)_2]$ (Fig. 2) shows chains of "zig-zag" form.

The numerical data (Table 1) indicating significant differences in the axial interatomic distances of Cu—S, are also in a good agreement with the known preferential sensitivity of axial bonds in copper(II) coordination polyhedra.[14]

In the three symmetry-independent structure units in the crystal structure of $[Cu(4\text{-pic})_2(NCS)_2]$, differences were also found in the orientation of the heterocyclic rings of 4-picoline (Table 2). The planes through the 4-picoline atoms and the equatorial plane of the copper(II) "symmetrically elongated" coordination polyhedron form dihedral angles of 151 and 126°, respectively.

The dihedral angles in coordination polyhedra with unchanged axial bonds have the values of 52 and 44° in accordance with the orientation of the pyridine rings in $[Cu(py)_2(NCS)_2]$.[12] It should be

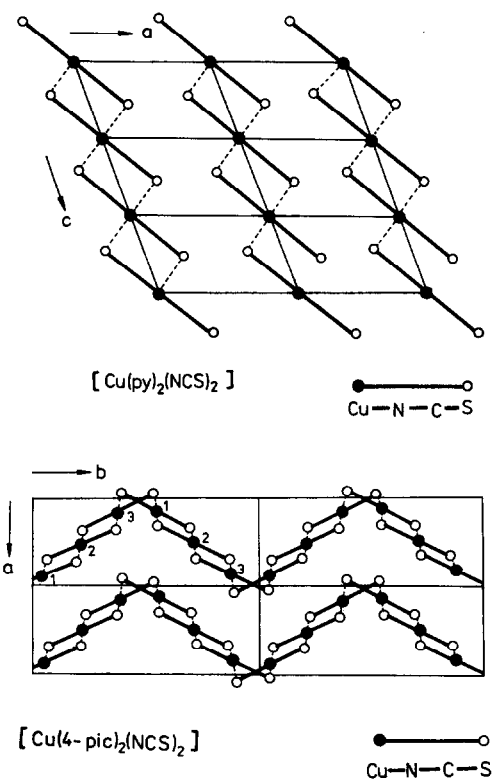

Fig. 2. Schematic representation of the chains of formula units in crystals of $[Cu(py)_2(NCS)_2]$ and $[Cu(4\text{-pic})_2(NCS)_2]$.

noted, that for the case of the coordination polyhedron with "asymmetrically distorted" axial bonds one value of the dihedral angle (130°) is between the dihedral angles of the "symmetrically-elongated" coordination polyhedron, while the other one (46°) is in the range of dihedral angles observed in unchanged coordination polyhedra of copper(II).

The results obtained by solving the crystal structure of $[Cu(4\text{-pic})_2(NCS)_2]$ have shown, however, that for copper(II)–cyanato complexes not every change in neutral ligand π-acceptor properties manifests itself in the bonding properties of thiocyanate ligands. In the case of $[Cu(4\text{-pic})_2(NCS)_2]$ the different π-acceptor properties of 4-picoline compared with those of pyridine in $[Cu(py)_2(NCS)_2]$ are shown in the changes of the degree of tetragonal distortion of the copper(II) coordination polyhedron.

The crystal structure of the complex compound under investigation exhibits three symmetry-independent coordination polyhedra of copper(II). They differ from each other in the values of the Cu—S interatomic distances and probably in the character of the molecular orbitals of Cu—N(4-picoline ring) due to the different orientation of the 4-picoline rings to the equatorial plane of copper(II) coordination polyhedron. The positions of the heavy atoms, copper and sulphur, are determinated very precisely, together with the position of the 4-picoline plane. Hence, it seems reasonable to assume that there is some connection between the changes in orientation of the 4-picoline rings and the values of Cu—S interatomic distances.

In connection with the conception of equatorial–axial interactions in complexes as a manifestation of the mutual influence of ligands,[14] it is possible to say, that the orientation of the 4-picoline rings

corresponds to the values of Cu—S interatomic distances, and vice versa. The 4-picoline rings have C_{2v} symmetry and have no steric hindrances to rotation around the Cu—N bond. They occupy a position with minimum energy and, in this way, affect the electronic properties of the nitrogen atom of the Cu—N bond. These changes via the central atom give rise to changes in the values of the Cu—S interatomic distances.

The above is experimental evidence of a new type of mutual influence of ligands in complexes.

Abstract—The energetic results from molecular orbital calculations on fragments of boron hydrides and hydrocarbons illustrate the fundamental differences in bonding between these two types of compounds. Combining the results for boranes with an extension of Lipscomb's topological approach yields a procedure for constructing potentially stable boranes and understanding their bonding characteristics.

Bonding in boranes is often seen as rather unusual. For example, the regularity of carbon chemistry, and also of much of main group chemistry, with clearly defined bond types of approximately constant length and with predictable geometries does not hold for boranes. A number of schemes have been developed to account for the structure and bonding in boranes. Broadly speaking these can be divided into those based on molecular orbital (*mo*) arguments and those based on topological (connectivity) arguments. Philosophically the differences between these two types of approach lies in the fact that *mo*'s are delocalized over the whole molecule whereas topological approaches use localized bonds between nearest neighbour atoms. The idea of boranes being held together by a mixture of two- and three-centre bonds was first developed by Longuet-Higgins[1] and has been fruitfully exploited, in particular in the topological approach (TA) of Lipscomb *et al.*[2] and the work of Wade,[3] to rationalize the observed geometries of boranes. Some support for the topological approaches has come from calculations on various boranes and carboranes[4] where the electron density maps support the concepts of two- and three-centre bonds in boranes. In principle, an accurate *mo* calculation can always be performed, and in some cases symmetry constraints on *mo*'s enable *mo* theory to be used simply and semi-quantitatively to determine stable cluster geometries. Wade's rules[3] for *closo*-boranes are the classic example of this. However, this is by no means always the case. Recent thereotical work[5] on boranes has focused on rationalizing the geometry and reactivity of particular boranes using various semi-empirical *mo* formalisms. As with Wade's rules, wider applicability of these results rests on symmetry arguments, so for less symmetric boranes or fragments of boranes we still rely on the TA.

It is the aim of this work to develop, using *mo* calculations on simple boron hydride systems, an energetic rationale for the rules summarized in the TA, thus complementing it with a basis for choosing between different geometries for which localized bonding schemes can be proposed. In addition some extra rules are developed which simplify the application. The result is a scheme whereby potentially stable boranes can be "built" from component atoms, rather than the existence of known structures simply being rationalized or answers restricted to a limited series of compounds.

We shall begin by comparing the bonding in boron and carbon compounds to see why boron bonding does not accord with the chemists idea of "normal" bonding. We shall follow molecule formation by following how the molecular orbitals of atoms or groups of atoms change when they join to form molecules. Although individual *mo*'s have

* Author to whom correspondence should be addressed.

no reality in themselves, the changes in the orbitals of a molecular fragment upon molecule formation indicate how the wavefunction, and hence the electron density and bonding, changes upon molecule formation. The bonding of A to B can be understood in much the same manner as that of diatomic molecules. The *mo*'s of a molecule AB, composed of fragments A and B, can be expressed as linear combinations of A and B molecular fragment orbitals (*mfo*'s). The most important A and B *mfo* contributors to a given *mo* will be of comparable energy with significant overlap.[6] The main changes upon molecule formation are therefore due to occupied *mo*'s of AB which have a large component of unoccupied *mfo*'s—i.e. those resulting from the interaction of higher occupied *mfo*'s and lower unoccupied *mfo*'s, and often of the highest occupied (*ho*) and lowest unoccupied (*lu*) *mfo*'s. We denote a singly-occupied *mfo* (i.e. an orbital which is both *lu* and *ho*) as *somfo*, and a singly occupied *mo* as *somo*.

The calculations used in this work have been performed using MICROMOL,[7] which is an implementation for IBM PC's of a subset of a standard *ab initio* quantum chemistry program CADPAC.[7] This program performs self-consistent field (SCF) energy calculations using the Hartree–Fock–Roothan Linear Combination of Atomic Orbitals (HFRLCAO) method, i.e. the wavefunction is expressed as a single antisymmetrized product of molecular orbitals. These molecular orbitals are found as optimum LCAO's, which are represented by contracted Gaussian basis functions. MICROMOL also calculates the gradient of the energy of the molecule with respect to nuclear displacements, and so it is possible to calculate an optimized geometry for the molecule with a given basis set.

Unless otherwise noted, all the orbital energies presented in this work are results of MICROMOL calculations carried out with a double zeta basis set (i.e. two contracted Gaussian functions per orbital in the valence space) at the geometry optimized using MICROMOL with this basis set. A double zeta basis set SCF calculation is a very simple *ab initio* quantum chemical calculation, and one cannot hope to obtain quantitative accuracy: the basis set has little flexibility, and one is completely ignoring correlation (i.e. the instantaneous interaction between the electrons). However, we are concerned only with relative energies and with trends over a series of similar calculations on simple molecules, and so we believe that the qualitative picture given by these calculations should be adequate for our purposes.[8] (It should be noted that for open-shell species the orbital energies are not uniquely defined, though the total energy is.)

BORON AND CARBON COMPOUNDS

In this section we shall briefly look at the types of bonding which one might expect to be favourable for boron and why it differs from that for carbon. Boron and carbon are both first-row main group atoms with similar valence orbitals available for combining into molecular orbitals. The main differences between B and C which affect their bonding capabilities are that (i) carbon's orbitals are lower in energy than boron's, which affects the extent of interaction with heteroatoms, and (ii) carbon has one more electron than boron, which affects orbital occupancy. It is perhaps unfair to attach the somewhat derisory label "electron deficient" to boron compounds—they simply utilize fewer electrons than carbon compounds in the most efficient manner possible. Some results of these differences are illustrated by the simple molecules and fragments of molecules whose orbital energies and bond lengths are given in Figs 1 and 2.

Analysis of the results of the MICROMOL calculations enable the bonding and structure of boranes and their differences from hydrocarbons to be at least qualitatively understood. We shall proceed by first examining B_2H_6 and C_2H_6 systems in some detail, thus providing the groundwork for us to "build" stable boranes from component parts.

Ethane and diborane

A_2H_4 has the same optimized geometry for A = B or C, whereas the experimental structures for A_2H_6 are different for diborane and ethane (cf. Fig. 3). Let us consider the effect of adding two H atoms to A_2H_4. The H 1*s* *somo* has a bonding (and hence stabilizing) interaction with all occupied A_2H_4 orbitals (since less than half the valence *mo*'s of A_2H_4 are occupied). It is therefore apparent why C_2H_6 adopts the ethane structure: the *lumo* of C_2H_4 (which becomes a major component of the *homo* in both bridged and non-bridged C_2H_6) is a C—C antibonding π-orbital, $2\pi_g^*$, that has no interaction with a bridging H, but a stabilizing one with a terminal H.

The situation for B_2H_6 is less clear cut. The stabilizing nature of the interaction of H with all B—B orbitals ensures that each H, whether bridging or terminal, has nearly "two electrons-worth" ($\approx$ 2e) of electron density. In the non-bridged structure this means there is little valence electron density between the borons, so the electronic stabilization from having the B's close together (say < 2 Å) is not a sufficiently large contribution to the total energy to overcome the B—B internuclear repulsion at that distance. As a result the optimized non-

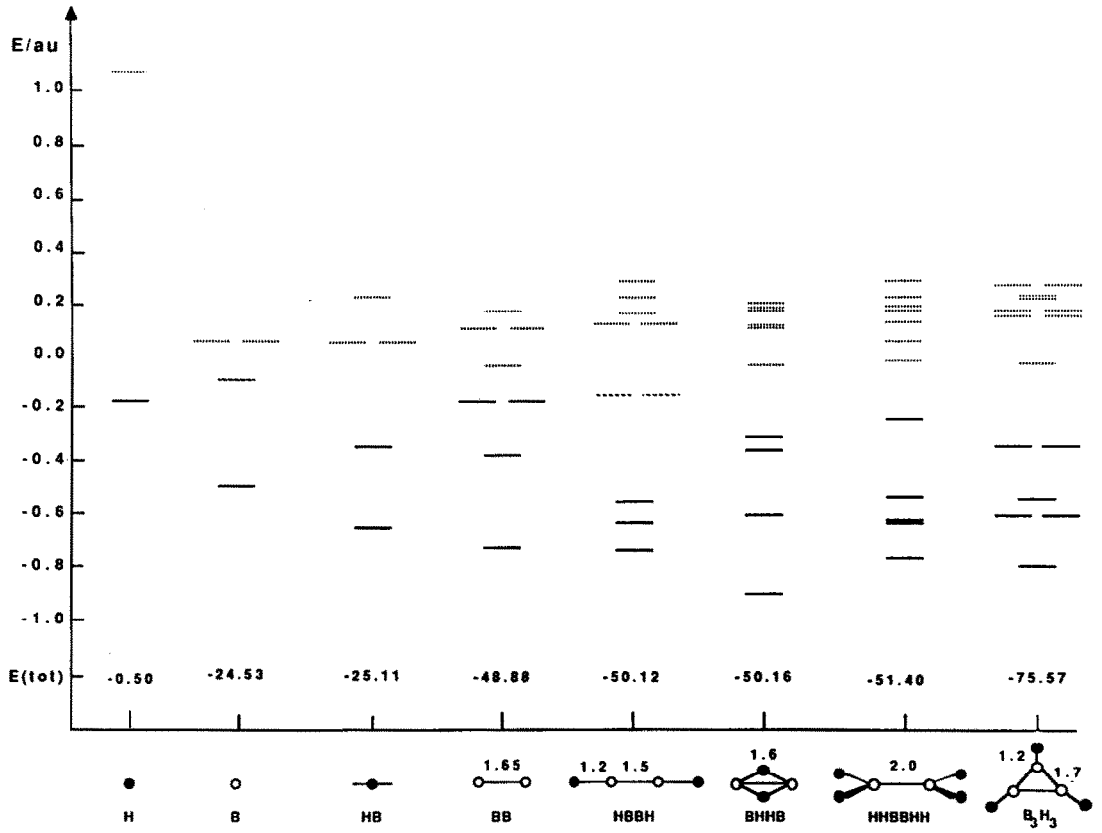

Fig. 1. Geometries and *mo* energy levels for some boron hydride fragments.

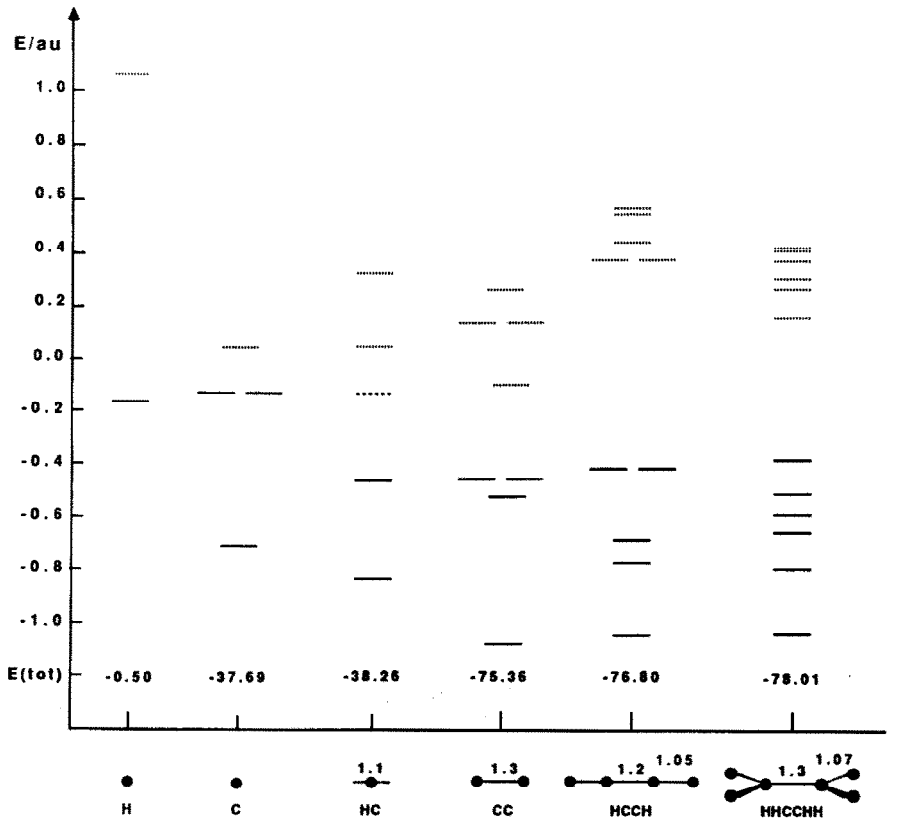

Fig. 2. Geometries and *mo* energy levels for some hydrocarbon fragments.

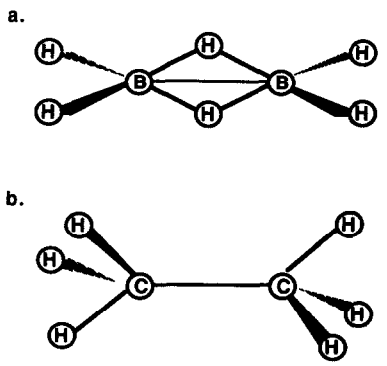

Fig. 3. Geometries of diborane and ethane.

bridged structure at the level of accuracy of our calculations did not converge. If however a bridged geometry is adoped, the electron density involved in boron-bridging hydrogen bonding is also involved in B—B bonding. Their combined stabilizing effect results in a B—B bond and a stable system.

In conclusion we can somewhat simplistically say that diborane adopts a geometry with two H bridges because it then gets both B—H and B—B bonding stabilization when there is insufficient electron density for a two electron/two atom bond. Equivalently this can be viewed as a consequence of the number of valence electrons and the variation principle (the more *ao*'s contributing to an *mo* the lower its energy is). Ethane on the other hand has sufficient electrons to have stabilizing contributions from six terminal C—H bonds and also one C—C bond. It should be noted that the calculations (Fig. 4) indicate that the comparative stability of the bridged structure of diborane is not as obvious as familiarity might lead one to believe. The whole of boron chemistry only just happens.

BUILDING BORANES

If a larger molecule is formed from diborane by replacing an H with a substituent A, similar types of bonding would be retained if A and H have *ho* and *lu* orbitals of similar energy and symmetry and A has ~ 1e available for bonding. If A does not satisfy

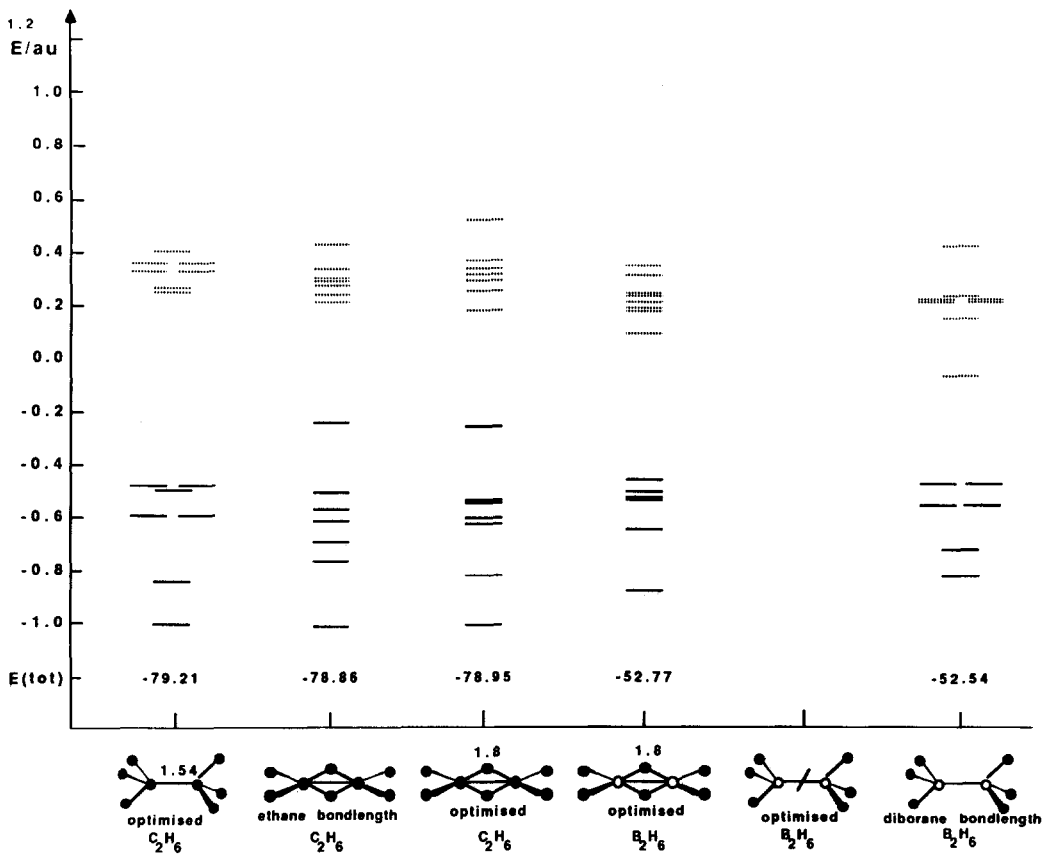

Fig. 4. *Mo* energy levels for possible geometries of diborane and ethane. (To make semi-quantitative deductions from orbital energy level diagrams it is best to compare different geometries with the same bond lengths so that the nuclear repulsion energy is the same.)

these criteria then a different bonding scheme, resulting in an ethane-type structure or two dissociated fragments, is almost certainly more stable. Both BH_2 and CH_3 fit these criteria so larger boranes (and carboranes) could in principle be built by substituting for H's in diborane resulting in additional BB and CB or BBB and BCB (by analogy with BHB) bonds. It should be noted that a particular geometry which one might build in this manner may never be observed experimentally if an alternative geometry is more stable, thus B_3H_7 with 6BH, 1BHB, and BBB is not observed since B_3H_9 with 6BH, 3BHB is more stable than $B_3H_7+H_2$.

Although somewhat artificial, it is helpful to consider the relative stabilities of two geometries to be determined by two factors: (i) the relative stabilities of the bonds which are formed, and (ii) steric considerations (i.e. does the proposed geometry force two nuclei so close together that repulsion due to overlapping electron clouds occurs). The artificiality of this situation is most obvious when one realizes that steric constraints can cause the distance between nearest neighbour (nn) atoms to be increased which in turn decreases the strength of the bond.

From the variation principle, and also from the results of *mo* calculations on borane fragments collected in Figs 1 and 2, one might expect contributions to borane stability to be in the order BBB $\geqslant$ BHB $\geqslant$ BB $\geqslant$ BH, with bonds which share an edge being less stable. This would be particularly true for BB or BH bonds so that any one nn link can be taken to have at most one two-centre bond. Each B of a BBB bond can notionally be seen to contribute $\sim$ 2/3e, since electron density in excess of $\sim$ 2e will be antibonding. Similarly, a B contributes $\sim$ 1/2e to a BHB, and $\sim$ 1e to a BB or BH (cf. ref. 3). Electron density can, however, easily be transferred between nn. Thus stable boranes will be held together by a mixture of two- and three-centre bonds, the ratio being such as to ensure all valence electrons are (at least nominally) bonding. The greater stability of three-centre bonds suggests that borane polyhedra with triangulated faces and as many bridging H's as possible are energetically desirable. We shall return to this below.

Let us first consider boranes whose B_p polyhedra are "convex", i.e. have each B such that other vertices lie on or beneath a tangential plane. This automatically limits the B polyhedron to having B's with at most six nn B's. In addition it excludes from our immediate consideration the polyhedra, which are in fact found for B_p, $p > 12$, where two convex boron fragments share an edge or a vertex. We denote a B vertex with i nn B's as B(i).

From the preceding discussion we can deduce stable bonding schemes for each vertex in a neutral borane, assuming each B has 3e to use in bonding. B(6) is most stably connected to its nn B's by 3BBB, so 1BH is required to use up its valence electrons (assuming no large charge displacements). The best bonds for connecting a B(5) to its nn B's are 2BBB and 1BHB, but steric factors preclude the additional BH or 2BHB then required. Thus B(5) is most stably bonded by 3BBB (two sharing an edge) and 1BH, or 2BBB, 1BB and 1BH. Thus both B(5) and B(6) are expected to always have a terminal H atom. Similarly B(4) is expected to have at least one terminal H, and probably no more. Ideally a B(3) would have 2BHB, 1BB and 1BH. Other combinations, some with 2BH, are possible and in fact more probable due to the requirements of the nn of a B(3) (see examples below). A B(2) will be most stable with 2BHB and 2BH.

Boranes with a net negative charge (a net positive charge is unlikely) must have more bonds than neutral boranes, thus fewer three-centre bonds. BHB bonds use least B valence electron per B per bond so are less likely in negatively-charged systems than in neutral systems. As charge increases one would expect first to lose BHB's, then gradually open out the triangulated faces to squares. In the limit of one or more extra electron per boron atom, were such a system able to exist, geometries like those in carbon chemistry might be expected.

The situation is somewhat different for the B atoms which are shared by two polyhedral fragments to make a larger borane than is possible with a single fragment. The nn of such a B are not restricted to one side of a plane containing the B, so for example, a B(5) can accommodate bridging H's. Borons of connectivity seven or higher will not have a terminal H as they do not have sufficient valence electron density. A B(6) or B(5) may have a terminal H. Alternatively they may have a bridging H.

At this stage it is appropriate to summarize the TA. The topological approach is based on the following assumptions: (i) in any borane 2e are required to make a stable bond to a terminal H, 2e per BHB bond, 2e per BBB bond and 2e per BB bond; (ii) each B has at least one terminal N and all B's, whose distance indicates a bond, are connected by one two-centre bond or one three-centre (BBB or BHB) bond or two three-centre bonds, and (iii) all B valence orbitals are involved in the bonding. Our previous discussion provides a semi-quantitative justification of these assumptions. As noted by Wade,[3] B's which connect two "convex" B polyhedral fragments do not necessarily have a terminal H. To be complete we therefore follow Wade and consider $B_{p+r}H_{p+q}^{c-}$, where r is the number of B's without a BH. Simple arithmetic to

balance electrons and orbitals gives

$$n_{BBB} = p+r-n_{BHB}-c \geqslant 0, \quad (1)$$

where n_{BBB} is the number of BBB, etc.

$$n_{BB} = n_{BHB}+r/2-q/2+3c/2 \geqslant 0. \quad (2)$$

For known or postulated single fragment boranes Lipscomb *et al.* determined all possible assignments of three-centre and two-centre bonds that satisfy their criterion. This provides a bonding scheme for B geometries and enables electron distribution, bond lengths and so on to be determined if the possible bond assignments are weighted in some way (usually equally in their work). Considering the weighting of assignments as a variational procedure (rather than an *ad hoc* average) supports the suggestion[2b] that greater stability corresponds to larger numbers of resonance structures. However, to make a significant contribution to the total electron density a given assignment of bonds must not be energetically unfeasible due to significant distortion of the charge distribution in the molecule.

Our extension to the TA (ETA) involves application of the preceding energetic arguments and the introduction of the additional structure parameters, n_e, the number of nn B—B links, i.e. polyhedral edges, n_d the number of edges shared by two three-centre bonds, and n_2 the number of B's with two BH's. We can then write:

$$n_d = n_{BB}+3n_{BBB}+n_{BHB}-n_e \geqslant 0$$
$$= 3p-n_{BHB}-3c/2-q/2-n_e \geqslant 0 \quad (3)$$
$$n_2 = q-n_{BHB}. \quad (4)$$

Closo-*boranes*

Let us consider boranes whose B_p polyhedra are *closo*, so $n_e = 3p-6$. A B(6) is not possible for $p = 7$ since the B—B bonds of a single vertex cannot be coplanar. For $p > 7$, B(6) is unfavourable relative to other options as it forces both small and large angles on the molecule. Thus one would expect a B(6) only in B_{11} polyhedron since a triangulated 11 vertex *closo*-polyhedron must contain at least one B(6) (10 B(5) and one B(4) cannot be formed into a *closo*-triangulated polyhedron). For structures between B_5 and B_{11} all vertices will then be B(5) or B(4). This dictates the polyhedra adopted to be the ones indicated in Fig. 5. For B_{12} we would expect an icosahedral boron polyhedron.

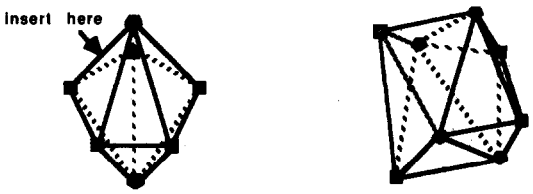

Fig. 6. Illustration of the insertion of an additional B atom into a boron polyhedron.

As an aside we note that the relationships between the polyhedra favoured by boranes is interesting as one can envisage synthesizing the *closo*-boranes in this manner. From $p = 4$ to $p = 11$ the successive triangulated polyhedra of Fig. 5 can be constructed from the preceding one by inserting an atom between nn B's as illustrated in Fig. 6. Insertion along an edge involves loss of only one stabilizing B—B contact so is most favourable. The choice of insertion point is, from the above discussion, that which, if possible, causes two of the B(4) (or B(3) for $p = 4$, 5) atoms to become B(5) [or B(4)] (Fig. 6). For $p = 11$ a B(6) is created, and as no B_{11} *closo*-polyhedron can be constructed without a B(6) it remains. If the same construction is followed to go from B_{11} to B_{12} two B(6) result.

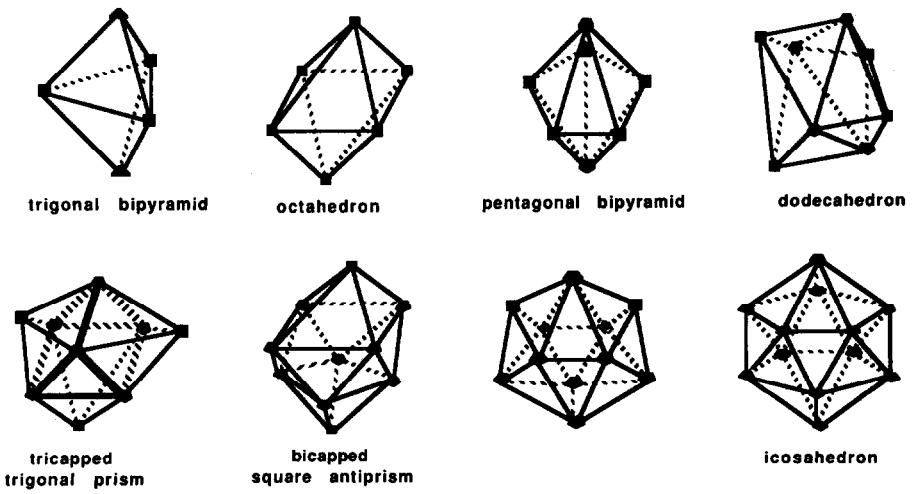

Fig. 5. B_p polyhedra.

The comparatively small curvature of the B_{11} polyhedron means that an alternative insertion point between the B(6), 2B(4) and 3B(5) atoms is possible. This gives the more stable icosahedron. Higher nuclearity "convex" *closo*-polyhedra either have lots of B(6) centres or low triangularity, so it is energetically more favourable to couple fragments of smaller polyhedra together for $p > 12$.

We have now deduced the geometries of the *closo*-borane polyhedra. We also know that each B will have one and only terminal H for $p > 5$. It remains only to determine c and hence the types of bonds. The stability of pairs of electrons in bonding orbitals suggests that $c = 0$, 2 or 4.

If $c = 0$, $n_{BBB} = p$, $n_{BB} = 0$, $n_d = 6$ and there is a total of $2p$ bonds. If $c = 2$, $n_{BBB} = p-2$, $n_{BB} = 3$, $N_d = 3$ and there is a total of $2p+1$ bonds. If $c = 4$, $n_{BBB} = p-4$, $n_{BB} = 6$, $n_d = 0$ and there is a total of $2p+2$ bonds. Now if BBB and BB were similar in energy, then the bond (or orbital) energy would favour $c = 4$, i.e. more bonds, and if they are quite different ($E_{BBB}/E_{BB} > 1.5$, where E denotes stabilizing energy) then bond energy favours $c = 0$. For some values of p, the required number of bonds for each c cannot be assigned[9] so one would not expect those to be observed. In those cases where more than one assignment is possible the following considerations apply. From Figs 1 and 3 it can be deduced that $E_{BBB}/E_{BB} > 1.5$ for unsubstituted boranes, where E denotes stabilizing energy. Thus bond energies favour $c = 4$. However, electron interaction terms are significantly different for molecules of different charge, and a minimum for neutral species. The observed value of $c = 2$ for *closo*-boranes is consistent with these conflicting trends. Thus $c = 2$, $n_{BBB} = p-2$, $n_{BB} = 3$, $n_d = 3$. The situation is different in substituted boranes, cf. ref. 9.

It is not possible to construct $B_4H_4^{2-}$ with the required types of bonds. Various other geometries, such as tetrahedral $B_4H_4^{4-}$ with 6BB+4BH, or $B_4H_8^{2-}$ with 2BBB+1BB+8BH, or $B_4H_7^-$ with 3BB+7BH are possible, however, only a small distortion of the tetrahedron takes the boron polyhedron to a butterfly shape. B_4H_{10}, which adopts this shape, has 4BHB, 6BH and 1BB, and is more stable than the other options.

Neutral boranes

A neutral borane has fewer electrons available for bonding than the negatively charged *closo*-boranes. This makes BHB bonds desirable. To construct a stable neutral borane, B_pH_{p+q}, one therefore considers p atom fragments of the *closo*-triangulated polyhedra illustrated in Fig. 5 and adds terminal and bridging H's. The maximum possible, though not necessarily desirable, number of bridging H's is determined by the space available in the "hole" of the polyhedron. Thus the removal of a single atom from the icosahedron does not leave enough room for bridging H's, so no B_{11} cluster whose B polyhedron is a fragment of an icosahedron exists. (Neutral B_{11} clusters are composed of two smaller fragments linked along a B—B edge.)

The B_p fragments which need be considered for a given p can be limited by the energetic considerations developed above. Firstly, those with nearest neighbour atoms missing will usually result in the most stable molecules as triangular faces are then retained. Which atoms are removed in forming a fragment is determined by two competing factors: (i) the creation of as many fragment edges as possible to enable the maximum number of bridging H's to be accommodated, and (ii) the retention of as many triangular faces as possible to maximize the number of BB links and hence maximize n_{BBB}. (i) Can be expected to dominate the formation of *arachno*-polyhedra, as more potential H bridging sites are created than BBB bonds lost. However, for *nido*, *hypo*, etc., polyhedra (ii) can be expected to dominate as few if any additional H bridging sites are created when the second or third B is removed. Thus the first atom removed from a *closo*-polyhedron will be one of highest connectivity. Subsequently, atoms of lowest connectivity are removed.

A BHB uses the least valence electron density from a boron atom, so a maximum value for n_{BHB} enables the formation of the largest total number of stabilizing bonds. Thus, unless it leads to an inconsistent result, we assume stability relates to the maximum number of BHB's possible for a given boron polyhedron fragment. By way of contrast a BH is expensive in electrons, so a minimum value of n_2 is usually appropriate, i.e. n_2 usually equals the number of B(2) in neutral boranes.

To construct stable neutral boranes we therefore proceed as follows. (i) For a given number of B's, construct all different boron fragment polyhedra from higher order *closo*-polyhedra by removing first a vertex of maximum connectivity and subsequently ones of minimum connectivity. (Molecular models considerably simplify this process. Cocktail sticks and small pieces of plastic tubing with holes punched in it are ideal.) (ii) Determine n_2(min) = the number of B(2), n_e and n_{BHB}(max) for each fragment. (iii) Starting with n_{BHB}(max) and n_2(min) determine n_{BB}, n_{BBB} and q for each n_{BHB} and n_2 until a consistent set of values is obtained. (iv) Determine whether the required number of BB and BBB bonds can be assigned in the proposed geometry, i.e. does

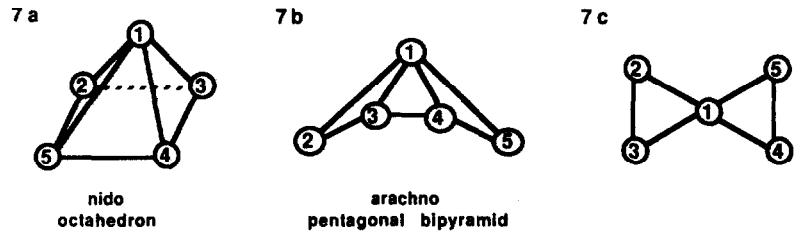

Fig. 7. The possible triangulated topologies for B_5.

each B—B link have 1BB, or 1BHB, or 1BBB, or 1BHB+1BBB, or 2BBB (ensuring n_d is correct facilitates this process). If an assignment cannot be made then one would not expect to observe the structure. (v) If all possible bond assignments lead to a significant distortion of the charge distribution from that represented by the unbonded atoms in the same shape, then that structure is energetically unfeasible. (Equations (1)–(3) only consider the total electron count—this is a more localized consideration.) (vi) Final determination of the most stable structure is made by considering the number of bonds of each type in a molecule. (It should be noted that in comparing stability of different structures with different numbers of H's, the energy of H—H bonds of the extra H's must be included where appropriate.) Step (iv) is precisely the topological approach of Lipscomb *et al.*[2] It is also the most tedious and error-prone step, which would be much simplified by implementation of the programs developed by Lipscomb *et al.* The main feature of the ETA compared with previous ones is the coupling of a topological approach used iteratively (previously done by Wade to a limited extent[3]) with a semiquantitative energetic discussion which enables potentially stable structures to be identified and unstable ones to be eliminated.

The following examples illustrate this procedure.

B_5H_{5+q}

The possible triangulated topologies for B_5 are illustrated in Fig. 7. The first is a *nido*-octahedron, and the second an *arachno*-pentagonalbipyramid.

The **7a** polyhedral fragment has $n_e = 8$, $n_2(\text{min}) = 0$, and $n_{\text{BHB}}(\text{max}) = 4$. If $n_{\text{BHB}} = 4$, then $n_2 = 0$ (for steric reasons), $n_{\text{BBB}} = 1$, $n_{\text{BB}} = 2$ and $n_d = 1$, and the molecular formula is B_5H_9. The bonds can be assigned as in Fig. 8(a). The average B charge assignment between the four equivalent bond assignments is 2.83e for B^2, B^3, B^4 and B^5, and 3.66e for B^1. Although B^+ has a nominal charge significantly above two, the balance of charge lies in its nn so a significant charge displacement is not in fact required to form the bonds of Fig. 8(a), and one might expect to observe this molecule, as is the case.

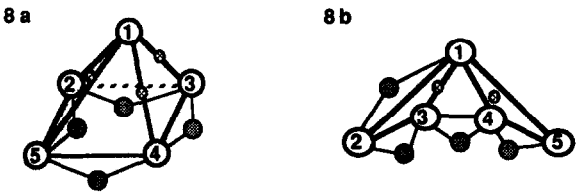

Fig. 8. The two possible neutral B_5 boranes.

The **7b** polyhedral fragment has $n_e = 7$, $n_2(\text{min}) = 2$, and $n_{\text{BHB}}(\text{max}) = 4$ (for steric reasons only one of the B(4)—B(2) edges can accommodate a BHB). If $n_{\text{BHB}} = 4$, and $n_2 = 2$ then $n_d = 1$, $n_{\text{BBB}} = 1$, $n_{\text{BB}} = 2$, and the molecular formula is B_5H_{11}. The bond assignment associated with this geometry is illustrated in Fig. 8(b). A "resonance" between this geometry and its mirror image would have additional stability since little or no geometry distortion is required. This derivation of the geometry of B_5H_{11} illustrates the usefulness of deriving borane geometries from first principles. When considering B_5H_{11}, Irving and Lipscomb assumed that the fourth bridging H was terminal on B^1. Although it is possible to derive a bond assignment for this geometry the electron distribution is more distorted than nn sharing can correct, and it does not correspond with the experimental bond lengths.[2b]

The two possible neutral B_5 boranes illustrated in Fig. 8: $B_5H_9+H_2$ with 4BHB+1BBB+2BB+5BH+1HH, $n_d = 1$, and B_5H_{11} with 4BHB+1BBB+BB+7BH, $n_d = 1$ are expected to be of comparable stability. A more quantitative analysis is required to differentiate between them. The existence of both molecules is consistent with this.

B_8H_{8+q}

B_8 systems are of sufficient complexity to illustrate how one should deal with the larger systems. Using the criteria for fragment formation given above we are able to limit our consideration to the fragment polyhedra illustrated in Fig. 9. They are,

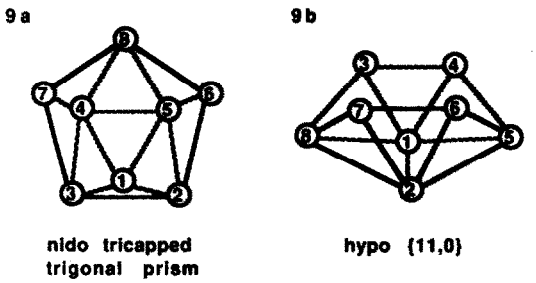

Fig. 9. The possible B_8 fragment polyhedra.

respectively, a *nido*-tricapped trigonal prism $\{9,-1\}$ or an *arachno*-bicapped antiprism $\{10,-2\}$, and a structure which can be viewed as either $\{11,-3\}$ or $\{12,-4\}$.

The polyhedral fragment of Fig. 9(a) has $n_e = 16$, $n_2(\text{min}) = 0$. $n_{BHB}(\text{max}) = 5$, however, this results in an odd number of electrons. So consider $n_{BHB} = 4$ and $n_2 = 0$, in which case $n_{BBB} = 4$, $n_{BB} = 2$ and $n_d = 2$. Although bond assignments can be made, all involve significant distortion of the electron distribution so are energetically unfavourable. If $n_2 = 2$ or 1 the geometries are also either electrostatically unfavourable or sterically crowded. So although in principle possible, such a geometry is unlikely to be energetically feasible.

The polyhedral fragment of Fig. 9(b) has $n_e = 15$, $n_2(\text{min}) = 0$. $n_{BHB}(\text{max}) = 6$, but eq. (3) then results in a negative value for n_d. $n_{BHB} = 5$, for steric reasons has $n_2 = 0$ and thus an odd number of electrons. So consider $n_{BHB} = 4$. If $n_2 = 0$, $n_{BBB} = 4$, $n_{BB} = 2$ and $n_d = 3$. The two possible assignments of BHB's for this B_8H_{12} cluster which both require only nn charge redistribution are illustrated in Fig. 10(b). If $n_{BHB} = 4$ and $n_2 = 2$, $n_{BBB} = 4$, $n_{BB} = 1$ and $n_d = 2$. Again two possible bond assignments for this B_8H_{14} cluster requiring only nn charge redistribution are possible, Fig. 10(c). We can therefore conclude that both of these clusters are feasible molecules and of comparable energy.

Charged boranes

Charged hydrogen-bridged boranes are observed when other factors overcome the repulsive electron interaction terms. For negatively-charged systems energetically feasible bond allocations may have a B requiring more than 3e for bonding to its nn's, however any positive charge must be able to be accounted for by nearest neighbour redistribution.

We considered above the neutral B_8 boranes which may be able to be synthesized. The first non-*closo*-B_8 borane to be observed was in fact $B_8H_{13}^-$. It has $n_e = 16$, $n_{BBB} = 4$, $n_{BB} = 2$, $n_{BHB} = 3$, $n_2 = 2$ and $n_d = 2$. Thus the additional electron makes a geometry with fewer BHB's favourable.

Another example is provided by $B_{10}H_{14}$ which is stable as an icosahedral or, equivalently, dodecaborane fragment with $n_2 = 0$ and four bridging H's (cf. figure). The bridged hydrogens are somewhat sterically crowded, and a small geometric distortion alters the position of two of the bridging H's to terminal positions on B(3)'s, and two to positions across the long bonds of the original structure. As B(3)'s in neutral boranes do not favour two BH's, additional electrons help stabilize this new geometry and it is found in both neutral and charged forms. Charged hydrogen-bridged boranes

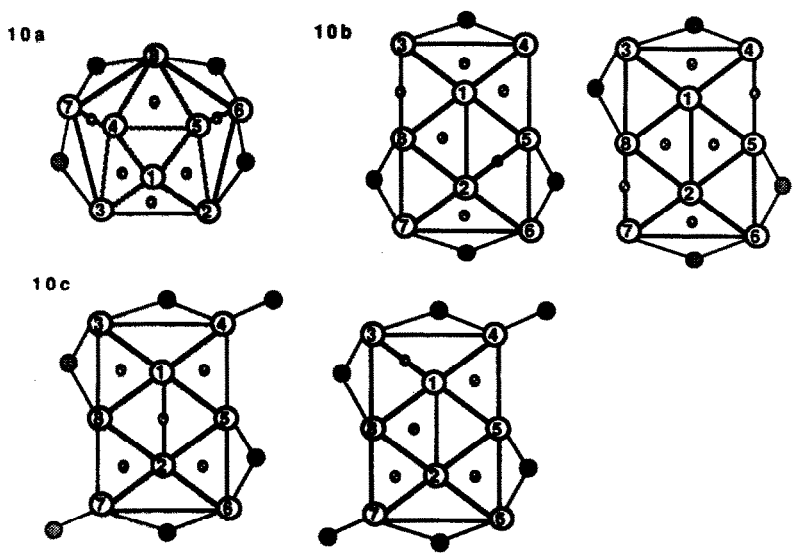

Fig. 10. Possible neutral B_8 boranes.

in fact often have more than one BH on a B(3) [or even on a B(4)].

CONCLUSION

By beginning our study of boron hydride clusters with small collections of B and H atoms and the corresponding C and H molecular fragments we were able to see why the bonding in boranes and organic molecules differs. This then enabled the development of a procedure to construct potentially stable boranes from component atoms. Much of the procedure coincided with the topological approach to borane bonding developed by Lipscomb *et al.*[2] The main differences are as follows.

(i) We are able to proceed by generating feasible boron hydride cluster frameworks from a knowledge of the atomic composition of a molecule.
(ii) The calculations on boron hydride fragments enabled comparisons of the stability of topologically feasible structures to be made.
(iii) Explicit inclusion of the number of bonds sharing edges facilitated the analysis.
(iv) The nearest neighbour charge redistribution discussion gives a rationale for weighting bond assignments in the determination of bond-lengths (cf. the work of Williams[10]).

The generality of our approach means that it does not always provide the final choice between a few remaining possible geometries. A more detailed analysis such as that of O'Neill and Wade on *closo*-structures with n, $n+1$ or $n+2$ skeletal electron pairs may then need to be undertaken.

SULPHURATING AND COORDINATING PROPERTIES OF N,N′-THIOBISMORPHOLINE TOWARDS IRON CARBONYLS

CARLOS DIAZ*

Departamento de Química, Facultad de Ciencias, Universidad de Chile, Casilla 653, Santiago, Chile

(*Received* 9 *October* 1989; *accepted* 30 *November* 1989)

Abstract—The reactions of N,N′-thiobismorpholine, $S(N\bigcirc O)_2$, with $Fe(CO)_5$, $Fe_2(CO)_9$, $Fe_3(CO)_{11}$ and $[(\eta^5\text{-}C_5H_5)Fe(CO)_2THF]BF_4$ were examined. Thiobismorpholine undergoes desulphurization towards $Fe(CO)_5$ with formation of $Fe_3(CO)_9S_2$, while the novel complex $Fe(CO)_4S(N\bigcirc O)_2$ was isolated and characterized from the reaction with $Fe_2(CO)_9$. On the other hand, thiobismorpholine is somewhat unreactive towards $Fe_3(CO)_{11}$ but it undergoes S—N fission with $[(\eta^5\text{-}C_5H_5)Fe(CO)_2THF]BF_4$.

N,N′-thiobisamines, $(R_2N)_2S$, are known to be quite unreactive compounds.[1] They react neither with water nor with alcohols, but in the presence of H^+, ion metals or Lewis acid, redox[2,3] and substitution processes occur.[4] The low reactivity of N,N′-thiobisamines has been frequently explained by the diminished nucleophilicity of the sulphur and nitrogen atoms, arising from double bond character in the S—N linkage.[5] In spite of the expected coordinative properties arising from the lone electron pairs on the sulphur and nitrogen atoms the only metal complexes with N,N′-thiobisamines as ligands reported are $[M(CO)_5S(NR_2)_2]$ (M = Cr, Mo, W).[6] As part of our investigation of the coordinative properties of S^{II}—N compounds,[6,7] we now report the reaction of N,N′-thiobismorpholine with iron pentacarbonyl, enneacarbonyldiirons and triiron dodecacarbonyl.

RESULTS AND DISCUSSION

Reaction of $(O\bigcirc N)_2S$ *with* $Fe(CO)_5$

When iron pentacarbonyl was irradiated (UV) with N,N′-thiobismorpholine in methanol for 3 h at room temperature, dark red needles were produced. This compound was identified by elemental analysis, IR and mass spectroscopy as $Fe_3S_2(CO)_9$.[8] Its IR spectra were identical with those reported in the literature.[8–10] The mass spectrum of this compound showed the parent ion and the fragments arising from stepwise loss of all the carbonyl groups. Peaks at *m/z* 176, 144 and 120, corresponding to $Fe_2S_2^+$, Fe_2S^+ and FeS_2^+ fragments, were also observed.

The sulphur-transfer behaviour of N,N′-thiobismorpholine toward iron pentacarbonyl is unexpected but not surprising in view of the desulphurization behaviour shown by other organic sulphides toward iron carbonyls.[9,10] Furthermore, the compound $Fe_3S_2(CO)_9$ is a common product in the reaction of iron carbonyls with sulphur compounds.[9–11]

Reaction of $(O\bigcirc N)_2S$ *with* $Fe_2(CO)_9$

Reaction of diiron nonacarbonyl with N,N′-thiobismorpholine in THF at room temperature proceeds smoothly according to

$$(O\bigcirc N)_2S + Fe_2(CO)_9 \longrightarrow Fe(CO)_4S(N\bigcirc O)_2 + Fe(CO)_5.$$

* Present address: Departamento de Quimica Organometalica, Universidad de Oviedo, 33071 Oviedo, Spain.

The tetracarbonyliron (N,N′-thiobismorpholine) complex is a brown–orange solid, unstable to air. The compound was fully characterized by analysis, mass spectrometry as well as by IR, ^{1}H NMR and Mössbauer spectroscopy.

The IR spectrum of the complex $Fe(CO)_4S(N\bigcirc O)_2$ showed four terminal carbonyl bands with frequency and intensity values similar to those found for $Fe(CO)_4L$ complexes, where L is a sulphur-donor ligand.[12,13] Data for $Fe(CO)_4S(N\bigcirc O)_2$ and other $Fe(CO)_4L$ complexes are shown in Table 1.

In $Fe(CO)_4L$ complexes the ligand L could occupy an axial or equatorial site of the locally trigonal-bipyramidal geometry at iron. Quantitative group theoretical arguments indicate that axially-substituted $Fe(CO)_4L$ complexes (C_{3v} symmetry) should exhibit three IR-active CO stretching frequencies ($2A_1+E$), while equatorially substituted compounds (C_{2v} symmetry) should exhibit four such bands ($2A_1+B_1+B_2$). However, structural assays based solely on IR data could be misleading because, as pointed out by Darensbourg *et al.*,[14] the E mode of axially-substituted $Fe(CO)_4L$ compounds is often split, thus yielding a total of four distinct ν(CO) bands. An X-ray study of $Fe(CO)_4$(1,3-dithiane)[15] shows that the sulphur ligand adopts an axial site in a trigonal-bipyramidal array at iron.

In the complexes $Fe(CO)_4L$, with L = pyridine, pyrazine,[16] triphenylphosphine,[17] trimethylarsine and trimethylstibine,[18] the ligand also occupies an axial position in a trigonal-bipyramidal array. Given the similarity of the ν(CO) IR data of compound $Fe(CO)_4S(N\bigcirc O)_2$ with those for $Fe(CO)_4$(1,3-dithiane) and the other $Fe(CO)_4L$ compounds of known structure, it is reasonable to assume the persistence of the C_{3v} skeletal geometry in the N,N′-thiobismorpholine complex.

The $\nu(S—N)_{as}$ band which in the free ligand is observed at 950 cm^{-1},[19] is lowered to 940 cm^{-1} in the complex by coordination effects. Similar ν(N—S) shifts are observed in the $M(CO)_5S(N\bigcirc O)_2$ complexes.[6]

The ^{1}H NMR spectra of the complex $Fe(CO)_4S(N\bigcirc O)_2$ shows the expected signals slightly shifted downfield due to the coordination.

Mass spectral data provide support for the structure of the complex $Fe(CO)_4S(N\bigcirc O)_2$. The m/z fragments corresponding to the molecular ion, ions showing successive loss of CO, $S(N\bigcirc O)_2^+$, as well as other fragments expected from the proposed structure, are observed. An interesting feature of the spectrum of the tetracarbonyl(thiobismorpholine)iron complex is the apparent loss of morpholine from the fragment $Fe(CO)_2S(N\bigcirc O)_2^+$ to give an intense ion of m/z 232 and formulated as $Fe(CO)_2S—N\bigcirc O^+$.

[a] Intensities values in parentheses relative to the strongest band as 10, using a per cent transmission scale.

Confirmation of the trigonal-bipyramidal structure of the complex $Fe(CO)_4S(NC_4H_8O)_2$ arises from its ^{57}Fe Mössbauer spectrum which is shown in Fig. 1. The spectrum consists of a single quadrupole splitting. The large quadrupole splitting value QS = 3.1 mm s^{-1} is typical of $Fe(CO)_4L$ complexes with a trigonal-bipyramidal structure, QS = 2.3–2.9 mm s^{-1}.[20,21] This result discards a binuclear structure of the type $Fe_2(CO)_6L_2$ for which QS = 0.6–1.4 mm s^{-1}, the other possible product found in the reaction of iron carbonyl with sulphur ligands. The isomer shift value, IS = 0.23 mm s^{-1}, is characteristic of iron(0) carbonyl derivatives.[20,21] The increase in the IS values in going from $Fe(CO)_5$, QS = 2.5mm s^{-1}, to $Fe(CO)_4S(NC_4H_8O)_2$ can be interpreted as a descrease in the σ-donor ability of N,N″-thiobismorpholine with respect to carbon monoxide. This is consistent with the weak nucleophilic character of N,N′-thiobisamines concluded from the IR[22] and structural data studied.[23] The highest value of the QS parameter for the $Fe(CO)_4S(NC_4H_8O)_2$ complex compared with those of $(Me_3N)_3PFe(CO)_4$, QS = 2.22, $PPh_3Fe(CO)_4$, QS = 2.44, $Ph_3SbFe(CO)_4$, QS = 2.63, $Ph_3AsFe(CO)_4$, QS = 2.68 and (*o*-Me $C_6H_4)_3AsFe(CO)_4$, QS = 2.93 mm s^{-1},[20] indicates a weaker π-acceptor ability than the phosphine, arsine and stilbine ligands. This agrees with the weak π-acceptor ability of N,N′-thiobisamines suggested from IR data of the $M(CO)_5S(NR_2)_2$ complexes.[6] We also find that the IS and QS values for the complex $Fe(CO)_4S(NC_4H_8O)_2$ occur in the poor π-acceptor region of the Collins–Pettit graph.[24]

Stability of the $Fe(CO)_4S(NC_4H_8O)_2$ *complex*

Similar to other $Fe(CO)_4L$ complexes where L = sulphur-donor ligand,[13] the complex $Fe(CO)_4S(NC_4H_8O)_2$ is very unstable. Mass and Mössbauer spectroscopic data indicate that this complex decomposes on standing to a mixture of $Fe_3S_2(CO)_9$[8] and $S(NC_4H_8O)_2$. The difficulty of preparing $Fe(CO)_4L$ complexes with L = nitrogen-donor ligand has been mentioned previously.[16] On the other hand, few examples of tetracarbonyl iron complexes with sulphur-donor ligands are known.[12–15] Hence the synthesis of the tetracarbonyl(thiobismorpholine)iron complex is relevant from the point of view of Fe—S compounds as well as from the coordination properties of S—N compounds

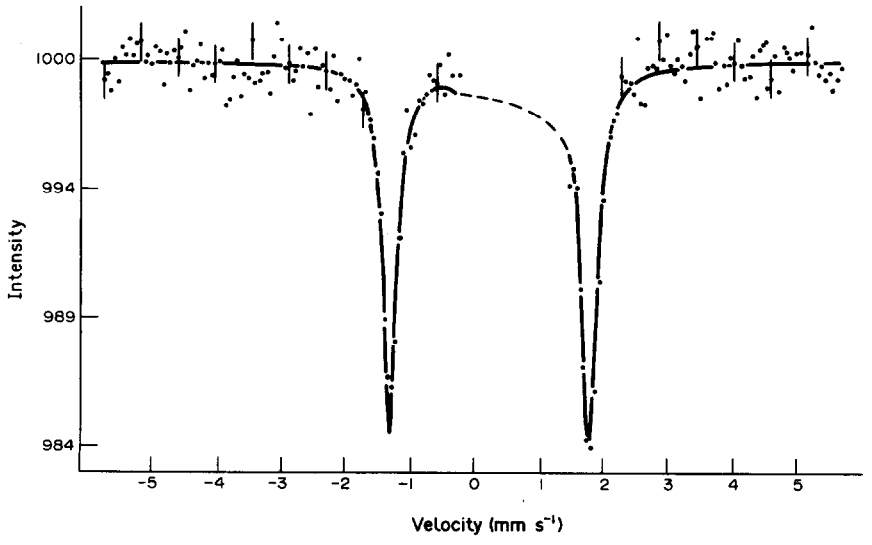

Fig. 1. The Mössbauer spectrum of $Fe(CO)_4S(NC_4H_8O)_2$. A small absorption (----) due to decomposition of the sample was subtracted (see text).

Reaction of S(N O)$_2$ *with* $Fe_3(CO)_{11}$

From the reaction of triiron dodecacarbonyl with thiobismorpholine in THF at 60°C, unchanged thiobismorpholine and a dark brown solid material were obtained. NMR spectroscopic examination of this product revealed the presence of thiobismorpholine and an unidentified carbonyl species. IR bands in the range 3600–3200 and at 2350 and 800 cm^{-1} [3] also suggest some S—N bond cleavage of the ligand.

Reaction of $[(\eta^5\text{-}C_5H_5)Fe(CO)_2THF]BF_4$ *with* S(N O)$_2$

From the reaction of (dicarbonyl)(η^5-cyclopentadienyl)(tetrahydrofuran)iron tetrafluoroborate[25] with thiobismorpholine a brown solid was isolated. Cleavage of the S—N linkage of the ligand is indicated by their IR spectrum which shows, among others, bands at 3410, 3290, 2040 and 1565 cm^{-1} typical of [O NH$_2$]X salts.[3] Similar behaviour leading to S—N cleavage has been reported in reactions of N,N′-thiobisamines with H^+ and with copper(II) salts.[2,3] Hence the S—N bond fission of thiobismorpholine in the presence of the $(\eta^5\text{-}C_5H_5)Fe(CO)_2THF^+$ cation, which is known to act as a Lewis organometallic acid,[26] is no surprise.

EXPERIMENTAL

Materials and general procedures

N,N′-thiobismorpholine[1] and $[(\eta^5\text{-}C_5H_5)Fe(CO)_2THF]BF_4$[25] were prepared according to literature methods. The iron carbonyls $Fe(CO)_5$ (Alfa), $Fe_2(CO)_9$ (Fluka) and $Fe_3(CO)_{11}$ (Fluka) were procured commercially and used without subsequent purifications. All solvents were carefully dried prior to use. All operations were performed under an inert atmosphere. Photochemical irradiation was carried out using a UV lamp, Hanau medium pressure, 150 W and a standard irradiation cell.

Spectroscopic measurements

IR spectra were obtained on a Perkin–Elmer 621 instrument. ^{1}H NMR spectra were measured on Varian T-60 apparatus. The mass spectra were determined on a Varian MAT 711 mass spectrometer at an ionizing voltage of 70 eV. The Mössbauer spectrum was determined using a constant acceleration drive system and the data were collected on a Canberra multichannel analyser. The source was ^{57}Co diffused in palladium and sodium nitroprusside was used as standard.

Reaction of S(N O)$_2$ *with* $Fe(CO)_5$

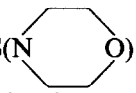
$Fe(CO)_5$ (4.37 g, 22.3 mmol) and S(N O)$_2$ (1.8 g, 8.8 mmol) in CH_3OH were irradiated for 3 h at room temperature. The solvent was then removed *in vacuo* and the residue chromatographed on a Florisil column and eluted with *n*-hexane. The resulting red solution was cooled to −20°C overnight to give dark red needles (0.5 g, 25% yield), m.p. 113–114°C (Refs 8, 9, 114°C). Found: C, 22.4. Calc. C, 22.3%. IR (*n*-hexane) 2060, 2045, 2024, 1985 cm^{-1}. Mass spectrum *m/z* 484 (M^+ 5%), 456 (M−CO) 428 (M−2CO) 400 (M−3CO), 372 (M−4CO), 344 (M−5CO) 316 (M−6CO), 288 (M−7CO), 260 (M−8CO) 232 (M−9CO), 176 (M−9CO−Fe), 144 (M−9CO−Fe−S).

Synthesis of $Fe(CO)_4$S(N O)$_2$

To $Fe(CO)_9$ (2.12 g, 5.82 mmol) was added a solution of S(N O)$_2$ (1.1 g, 5.4 mmol) in 50 cm^3 of THF. The mixture was stirred under a static argon atmosphere for 14 h and then solvent and $Fe(CO)_5$ were removed at room temperature *in vacuo*. The residue was extracted with *n*-hexane and after filtration the red–brown solution was cooled to −30°C overnight to give brown–orange solid (0.6 g, 30% yield), m.p. 69–70°C. Found: C, 38.9; H, 4.7; N, 7.9. Calc. for $C_{12}H_{16}O_6N_2SFe$: C, 38.7; H, 4.3; N, 7.5%. IR (*n*-hexane) 2050(s), 1972(s), 1948(vs), 1935(vs) cm^{-1}. NMR ($CDCl_3$) 3.66 (m, 4H, CH_2O), 3.33 ppm (m, 4H, CH_2N). Mass spectrum *m/z* 373 (M^+), 345 (M−CO), 316 (M−2CO), 232 (M−2CO−HN O) 176 (M−4CO−HN O).

Attempted reaction of $Fe_3(CO)_{11}$ *with* S(N O)$_2$

A solution of $Fe_3(CO)_{11}$ (1.15 g, 2.28 mmol) and



(0.60 g, 2.93 mmol) in THF were stirred at 60°C for 2 h, during which it assumed a red–brown colour. The solvent was removed under reduced pressure. The residue was dissolved in *n*-hexane and the solution filtered through Kieselguhr and cooled to −30°C overnight to give brownish-coloured crystals identified by IR and ^{1}H NMR as unreacted N,N′-thiobismorpholine (0.11 g). Following this the solution was evaporated to dryness to give a dark brown oil which solidified on standing. NMR ($CDCl_3$) 3.7 (m, 8H, OCH_2), 3.3 ppm (m, 8H, NCH_2). IR 3600–3200 (m, br), 3000 (m), 2350 (w), 2100–1850 (vs, br), 1600–1400 (m, br), 1260 (s), 1100 (vs), 1060 (vs), 1020 (vs), 920 (m), 800 (s).

Attempted reaction of $[(\eta^5\text{-}C_5H_5)Fe(CO)_2THF]BF_4$ *with* 
To a solution of $[(\eta^5\text{-}C_5H_5Fe(CO)_2THF]BF_4$[25] in CH_2Cl_2 (prepared from $\eta^5\text{-}C_5H_5Fe(CO)_2I$ and $AgBF_4$), was added  (1.1 g, 5.38 mmol) and stirred for 1 h. The reaction mixture changed from a red to brown–red colour. The resulting solution was evaporated *in vacuo* to dryness, and the solid redissolved in a mixture of *n*-hexane–CH_2Cl_2, filtered and cooled at −30°C. The brown solid residue was dried *in vacuo*. Found: C, 31.7; H, 4.1; N, 4.2. NMR [$(CD_3)_2CO$] 5.46 (s, 5M, C_5H_5), 3.91 (m, 6H), 3.43 (m, 10H). IR (KBr) 3410 (m), 3290 (m), 2420 (w), 2040 (vs), 1990 (vs), 1565 (m), 1430 (m), 1310 (m), 1150–1000 (vs, br), 905 (m), 890 (m), 880 (m), 873 (s), 610 (m, br).

Acknowledgements—I would like to thank Dr N. Yutronic and Dr R. Latorre for obtaining the mass and Mössbauer spectra.

(*Received* 5 *September* 1989; *accepted* 20 *November* 1989)

Abstract—The dimethyl compounds M(OAr-2,6Ph$_2$)$_3$(CH$_3$)$_2$ (M = Nb, Ta; OAr-2,6Ph$_2$ = 2,6-diphenylphenoxide) undergo the thermal loss of methane in hydrocarbon solvents to generate the monocylometallated compounds M(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(CH$_3$) (M = Nb, **1**; Ta, **2**). Kinetic studies show the reactions to be first-order with activation parameters $\Delta H^{\ddagger} = 25.3 \pm 0.8$ kcal mol^{-1} and $\Delta S^{\ddagger} = -15 \pm 5$ cal mol^{-1} K^{-1} for the tantalum compound. The use of the labelled compound Ta(OAr-2,6Ph$_2$)$_3$(CD$_3$)$_2$ shows no change in the rate of metallation and also the absence of a methylidene intermediate for the reaction. Attempts to generate a bis(*n*-butyl) compound by treatment of Ta(OAr-2,6Ph$_2$)$_3$Cl$_2$ with LiBu^n (2 equivs) led instead to the immediate formation of the metallated compound Ta(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(Bu^n) (**3**) along with butane. Thermolysis of the bis(*p*-methylbenzyl) compound Ta(OAr-2,6Ph$_2$)$_3$(CH$_2$C$_6$H$_4$-4Me)$_2$ also leads to a monocyclometallated compound (**4**) and *p*-xylene. However, attempts to obtain a corresponding niobium bis(*p*-methylbenzyl) compound by treatment of Nb(OAr-2,6Ph$_2$)$_3$Cl$_2$ with Mg(CH$_2$C$_6$H$_4$-4Me)$_2$ led instead directly to the monocyclometallated derivatives Nb(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(Cl) (**5**) and Nb(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(CH$_2$C$_6$H$_4$-4Me) (**6**). Single-crystal X-ray diffraction studies of **2**, **3** and **5** show the molecules to be similar in the solid state. A trigonal bipyramidal environment about the metal atom is observed with *trans*,axial oxygen atoms. The new M—C(aryl) bond is chelated to an oxygen atom in one of the axial positions. Crystal data for TaC$_{64}$H$_{50}$O$_3$; **2**·3/2C$_6$H$_6$ at −155°C: $a = 13.497(3)$, $b = 17.033(6)$, $c = 10.744(2)$ Å, $\alpha = 94.76(1)$, $\beta = 96.34(1)$, $\gamma = 79.80(1)°$, $Z = 2$, $d_{calc} = 1.444$ g cm^{-3} in space group $P\bar{1}$; for TaC$_{64}$H$_{53}$O$_3$; **3**·C$_6$H$_6$ at −130°C: $a = 18.202(5)$, $b = 17.930(3)$, $c = 15.282(3)$ Å, $\beta = 96.05(2)°$, $Z = 4$, $d_{calc} = 1.408$ g cm^{-3} in space group $P2_1/c$; for NbC$_{54}$H$_{38}$ClO$_3$; **5** at 20°C: $a = 18.830(4)$, $b = 11.2856(9)$, $c = 20.725(5)$ Å, $\beta = 102.8(1)°$, $Z = 4$, $d_{calc} = 1.335$ g cm^{-1} in space group $P2_1/c$.

One of the most exciting recent developments in early transition metal organometallic chemistry has been the recognition that high valent, d^0-metal alkyl and related functional groups have the ability to intra- and intermolecularly activate carbon–hydrogen bonds under mild conditions.[1–6] A common

* Author to whom correspondence should be addressed.

feature of these reactions has been the need to carry out careful labelling studies in order to determine the actual pathway leading to C—H bond activation.[1-6] During our studies of the early transition metal chemistry associated with sterically bulky aryloxide ligation we have characterized a number of reactions involving the cyclometallation of 2,6-di-*tert*-butylphenoxide ligands.[7] A series of mechanistic studies of the reaction at tantalum(V) has shown that these reactions may proceed via indirect and sometimes competing reaction pathways.[8,9] More recent work has focussed on the related cyclometallation chemistry of 2,6-diphenylphenoxide ligands at various *p*- and *d*-block metal centres.[10,11] In this paper we wish to report on the cyclometallation of this ligand at niobium(V) and tantalum(V) metal centres, focussing on the mechanistic aspects of the reactivity as well as the structure of the metallated products.

$$M(OAr)_3(CH_3)_2 \longrightarrow M(OC_6H_3Ph{-}C_6H_4)(OAr)_2(CH_3) + CH_4$$

M = Nb (1); Ta (2)

OAr = 2,6-diphenylphenoxide

Scheme 1.

RESULTS AND DISCUSSION

The dimethyl compounds $M(OAr\text{-}2,6Ph_2)_3(CH_3)_2$ (M = Nb, Ta; OAr-2,6Ph$_2$ = 2,6-diphenylphenoxide) can be readily obtained in high yield from the corresponding dichloride.[12] Thermolysis of the alkyl compounds in hydrocarbon solvents at temperatures above 120°C leads to the formation of corresponding monocyclometallated compounds, **1** and **2**, and one equivalent of methane (Scheme 1). The reactions can be readily monitored in toluene-d_8 solution in sealed 5 mm NMR tubes by ^{1}H NMR spectroscopy. Although the aromatic region of the spectra is rather uninformative, the sharp M—CH_3 resonance of the dimethyl compound at δ +0.18 (Nb) and −0.21 ppm (Ta) is replaced by a new methyl resonance of **1** and **2** at δ −0.05 and −0.39 ppm, respectively, along with a corresponding peak for methane. In the ^{13}C NMR spectra of **1** and **2** highly characteristic resonances at δ 190.9 (Nb) and 199.9 ppm (Ta) can be assigned to the M—*C*(*ipso*) carbon atom of the new metallacycle ring. A single-crystal X-ray analysis of **2** confirms the stoichiometry of the compound as well as its mononuclearity (Fig. 1). Some selected bond distances and angles are collected in Table 1. The environment about the metal atom in **2** can best be described as trigonal bipyramidal with two axial oxygen atoms. The oxygen atom of the six-membered metallacycle ring occupies one of the axial sites while the new Ta–C bond lies in an equatorial position leading to a chelate bite at the metal of 80.8(2)°. As with other six-membered metallacycle rings formed by cyclometallation of aryloxide ligands, this small bite angle is readily accommodated with little puckering of the six-membered ring due to the large Ta—O—C angle, in this case 141.4(4)°.[7] The Ta—O distances of 1.883(4)–1.909(4) Å and Ta—C distances of 2.125(7) (alkyl) and 2.215(5) Å (aryl) are well within the range reported for related aryloxyl alkyl or aryl derivatives of tantalum(V).[13] The overall structure of **1** bears a close resemblance to that found for the monocyclometallated compound $Ta(OC_6H_3Bu^tCMe_2CH_2)(OAr\text{-}2,6Bu^t_2)(Ph)_2$ (OAr-2,6Bu$^t_2$ = 2,6-di-*tert*-butylphenoxide).[9]

A kinetic study of the formation of **2** was carried out by monitoring changes in the ^{1}H NMR spectrum in toluene-d_8 solution upon heating. The ring closure reaction was found to obey first-order kinetics over 3–4 half-lives yielding the following rate constants $10^5 k/s^{-1}$ at various temperatures (T/°C): 4.15(120); 10.1(130); 9.75(130); 18.0(139); 50.0 (151). These data yield activation parameters for the reaction of $\Delta H^{\ddagger} = 25.3(8)$ kcal mol^{-1} and

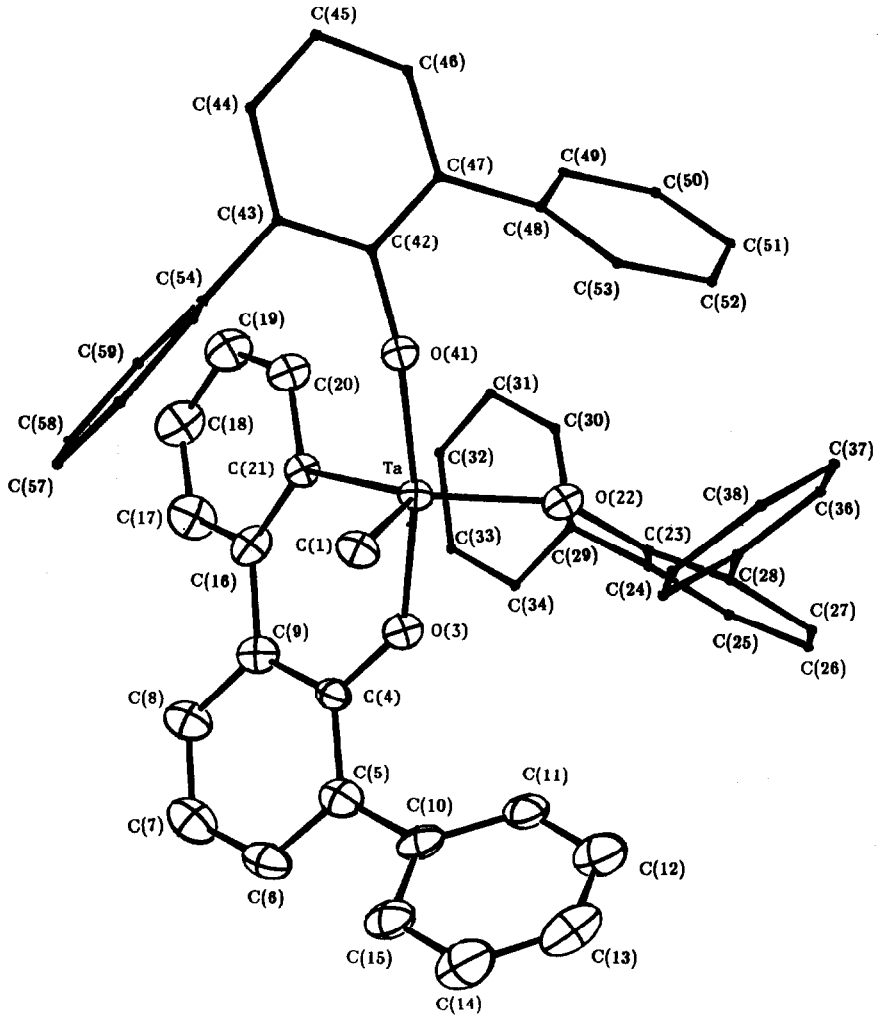

Fig. 1. ORTEP view of Ta(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(CH$_3$) (**2**) emphasizing the central coordination sphere.

$\Delta S^{\ddagger} = -15(5)$ cal mol^{-1} K^{-1} (Fig. 2). The moderately large and negative entropy of activation for the reaction compares favourably with the other values reported for related reactions and appears to be a consistent characteristic of such cyclometallation reactions.[7]

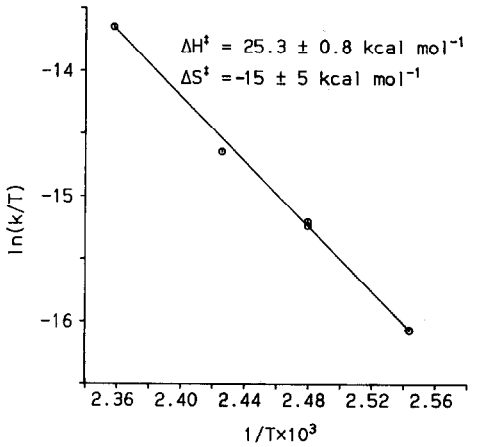

Fig. 2. Activated complex theory plot for the formation of **2** from Ta(OAr-2,6Ph$_2$)$_3$(CH$_3$)$_2$.

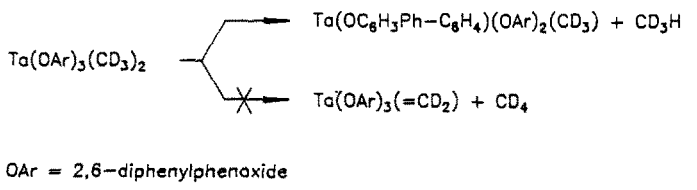
An important aspect of high-valent early transition metal alkyl chemistry is the possible formation of stable or intermediate alkylidene functional groups by α-hydrogen abstraction processes.[5,8,14,15] It is possible that the formation of **2** from Ta(OAr-2,6Ph$_2$)$_3$(CH$_3$)$_2$ proceeds via initial formation of a methylidene intermediate, [Ta(OAr-2,6Ph$_2$)$_3$(=CH$_2$)], which then undergoes rapid addition of the aromatic C—H bond to the tantalum methylide double bond to generate the product. This pathway has to be taken seriously given the fact that alkylidene compounds of the type Ta(OAr)$_2$(X)(=CHR) (X = OAr, CH$_2$R) have been isolated[13,16] and that a photogenerated tantalum methylidene intermediate was found to rapidly activate the aliphatic C—H bonds of OAr-2,6Bu$^t_2$ ligands.[8,17] In order to check this possibility



Scheme 2.

the compound $Ta(OAr\text{-}2,6Ph_2)_3(CD_3)_2$ was synthesized by reacting the dichloride with $LiCD_3$. Thermolysis of this compound in toluene was found to yield the monocyclometallated compound **2**. Analysis of this product by mass spectrometry clearly indicated the presence of only **2**-d_3. A simulation of the mass spectrum indicated < 5% of **2**-d_2, i.e. containing $TaCHD_2$, to be present. Hence, thermolysis of the labelled compound leads to loss of CD_3H and formation of only **1**-d_3. No loss of CD_4 to generate an intermediate $[Ta(OAr\text{-}2,6Ph_2)_3(=CD_2)]$ was detected in this experiment. Hence, it appears that the methyl leaving group in these reactions combines directly with the hydrogen of the aromatic C—H bond to yield the product **2** (Scheme 2). On the basis of work by many groups this process is believed to occur via a four-centre, four-electron transition state.[1–7]

Attempts to isolate a bis-*n*-butyl compound by treatment of $Ta(OAr\text{-}2,6Ph_2)_3Cl_2$ with Bu^{n}Li (2 equivs) led instead to the isolation of the monocyclometallated compound $Ta(OC_6H_4Ph\text{-}C_6H_4)(OAr\text{-}2,6Ph_2)_2(Bu^n)$ (**3**) in moderate yields. The dark brown reaction mixture contained numerous other unidentified components. Pale yellow crystals of **3** could be obtained from the reaction mixture by slow cooling of toluene solutions. The ^{13}C NMR spectrum of **3** clearly shows the Ta—*C*(*ipso*) resonance at δ 199.3 ppm along with the four non-equivalent Ta—$CH_2CH_2CH_2CH_3$ resonances. However, the ^1H NMR spectrum of **3** appears very complicated in the aliphatic region. In particular, a series of overlapping multiplets are observed in the δ −0.5 to +1.0 ppm region. This complexity of the Bu^n resonances can be explained by the molecular structure of **3** which lacks a plane of symmetry through the Ta—Bu^n bond, hence making all of the three methylene groups diastereotopic.

A solid-state structural analysis of **3** by single-

crystal X-ray diffraction methods shows a molecular geometry almost identical to that of **2** (Fig. 3). Some selected bond distances and angles are collected in Table 2.

Treatment of the dichloride Ta(OAr-2,6Ph$_2$)$_3$Cl$_2$ with Mg(CH$_2$C$_6$H$_4$-4Me)$_2$ (where CH$_2$C$_6$H$_4$-4Me = 4-methylbenzyl) allows the isolation of the corresponding dialkyl compound in high yield.[12] Thermolysis of this compound at 120°C also leads to the formation of a monocyclometallated compound Ta(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(CH$_2$C$_6$H$_4$-4Me) (**4**) along with one equivalent of *p*-xylene. In contrast, treatment of Nb(OAr-2,6Ph$_2$)$_3$Cl$_2$ with Mg(CH$_2$C$_6$H$_4$-4Me)$_2$ is found to initially yield the monocyclometallated chloro compound Nb(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6-Ph$_2$)$_2$(Cl) (**5**), which then undergoes further reaction to produce the *p*-methylbenzyl compound (**6**) (Scheme 3). Compounds **1**, **5** and **6** are of interest as they represent the first reported examples of cyclometallated aryloxide compounds of niobium. A single-crystal X-ray diffraction study of **5** was carried out for comparison with the related tantalum compounds (Fig. 4). Some selected bond distances and angles are collected in Table 3. Again a geometry about the central metal atom is found in **5** that is extremely close to those observed for **2** and **3**. In fact a comparison of the overall geometries of **2**, **3** and **5**, as well as the conformations adopted by the non-

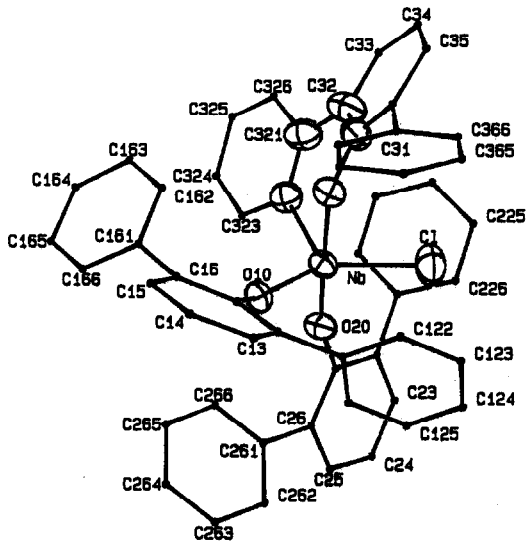

Fig. 4. ORTEP view of Nb(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(Cl) (**5**).

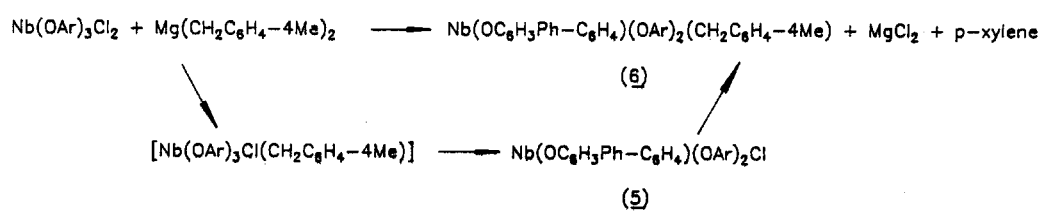
metallated OAr-2,6Ph$_2$ ligands, shows a close similarity (Figs 1, 3 and 4).

Although variable-temperature analyses of the kinetics of the ring closure reactions of Nb(OAr-2,6Ph$_2$)$_3$(CH$_3$)$_2$ and Ta(OAr-2,6Ph$_2$)$_3$(CH$_2$C$_6$H$_4$-4Me)$_2$ were not carried out, first-order kinetics were found to be obeyed for the disappearance of both compounds at 120°C. Hence the following three half lives for the cyclometallation reactions are



Scheme 3.

available for comparison:

Compound	Half-life (min at 120°C)
$Nb(OAr\text{-}2,6Ph_2)_3Me_2$	22(2)
$Ta(OAr\text{-}2,6Ph_2)_3Me_2$	280(20)
$Ta(OAr\text{-}2,6Ph_2)_3(CH_2C_6H_4\text{-}4Me)_2$	65(5)

Hence it can be seen that cyclometallation occurs much faster at niobium than at tantalum for the same set of ligands. The difference in rates between the two metals, more than an order of magnitude, is much more pronounced than that observed for the cyclometallation of 2,6-di-*tert*-butylphenoxide ligands at titanium and zirconium. In that study a rate difference of only three (Ti > Zr) was found.[7,18] It can also be seen from the data that benzyl ligands are superior leaving groups to methyl ligands at tantalum. This difference in the rate may be attributable to the fact that early *d*-block metal bonds to benzyl ligands have been consistently found to be weaker than corresponding metal–methyl bonds.[19] Furthermore, this and related observations[7,9] may explain why treatment of $Nb(OAr\text{-}2,6Ph_2)_3Cl_2$ with $Mg(CH_2C_6H_4\text{-}4Me)_2$ leads to monocyclometallated **5** (Scheme 3). This reaction will initially produce the mono(benzyl) compound $Nb(OAr\text{-}2,6Ph_2)_3(CH_2C_6H_4\text{-}4Me)(Cl)$. Presumably cyclometallation occurs rapidly in this compound before further substitution can take place. The fact that the niobium bis(methyl) and tantalum bis(benzyl) compounds are isolable must be due to the slower rates of cyclometallation. A very similar situation was found for the reaction of $Ta(OAr\text{-}2,6Bu^t_2)_2Cl_3$ with LiPh, where rapid formation of a monocyclometallated compound $Ta(OC_6H_3Bu^tCMe_2CH_2)(OAr\text{-}2,6Bu^t_2)Cl_2$ was followed by the formation of corresponding phenyl derivatives.[9]

EXPERIMENTAL

All operations were carried out either under a dry nitrogen atmosphere or *in vacuo* using a Vacuum Atmosphere Dri-Lab or by standard Schlenck techniques. Hydrocarbon solvents were dried by distillation from sodium benzophenone and stored under DRY nitrogen. The compounds $M(OAr\text{-}2,6Ph_2)_3Cl_2$, and $M(OAr\text{-}2,6Ph_2)_3(CH_3)_2$ (M = Nb, Ta) were prepared by reported procedures.[12]

$Nb(OC_6H_3Ph\text{-}C_6H_4)(OAr\text{-}2,6Ph_2)_2(CH_3)$ (1)

A solution of $Nb(OAr)_3(CH_3)_2$ (0.20 g) dissolved in toluene (5 cm^3) was heated at 120°C for 2 h in a closed flask. Cooling and removal of solvent under vacuum yielded the product as a yellow powder. Yield = 0.18 g (90%). ^1H NMR (C_6D_6, 30°C): δ 6.60–7.85 (aromatics), −0.05 (s, Nb—CH_3). ^{13}C NMR (C_6D_6, 30°C): δ 190.9 (Nb—*C*), 62.0 (Nb—*C*H_3). Found: C, 78.4; H, 5.0. Calc. for $NbC_{55}H_{41}O_3$: C, 78.4; H, 4.9%.

$Ta(OC_6H_3Ph\text{-}C_6H_4)(OAr\text{-}2,6Ph_2)_2(CH_3)$ (2)

A solution of $Ta(OAr)_3(CH_3)_2$ (0.25 g) in toluene (5 cm^3) was heated for 7 h at 120°C in a closed flask. Removal of solvent under vacuum yielded the product as a pale white powder. The crude product was dissolved in a minimum amount of benzene. Slow evaporation of the benzene solvent inside the Dri-lab yielded colourless crystals of the product suitable for X-ray analysis. Yield = 0.24 g (87%). ^1H NMR (C_6D_6, 30°C): δ 7.74, 6.90 d, 7.4–6.4 (aromatics), −0.39 (s, Ta—CH_3). ^{13}C NMR (C_6D_6, 30°C): δ 199.9 (Ta—*C*), 64.3 (*C*H_3). Found: C, 72.8; H, 5.3. Calc. for $TaC_{65}H_{50}O_3$: C, 73.4; H, 4.8%.

$Ta(OC_6H_3Ph\text{-}C_6H_4)(OAr\text{-}2,6Ph_2)_2(Bu^n)$ (3)

To a solution of 20 g (2.0 mmol) of $Ta(OAr)_3Cl_2$ dissolved in 10 cm^3 of benzene was added, 2.0 cm^3 of a 2.2 M *n*-BuLi solution in hexane over 10 min. The mixture was cooled with an ice bath throughout

the *n*-BuLi addition. The reaction mixture was stirred for 40 min before being warmed to room temperature. A white precipitate that formed during stirring was filtered off, and the solvent was evaporated from the filtrate. The resulting crude solid was redissolved in a minimum amount of benzene, and crystals of product slowly formed over 24 h. Yield = 0.55 g (28.3%). Additional product could be obtained by concentrating the supernatant. ^{1}H NMR (C_6D_6, 30°C): δ 7.87 d, 7.82 d, 7.73 d, 7.35–6.20 (aromatics), 1.35 to −0.50 (m, Ta—C_4H_9). ^{13}C NMR: δ 199.3 (Ta—*C*), 87.3, 31.3, 28.8, 13.6 (Ta—C_4H_9). Found: C, 72.5; H, 4.9. Calc. for $TaC_{64}H_{53}O_3$ **3**·C_6H_6: C, 73.1; H, 5.1%.

Ta(OC$_6$H$_3$Ph - C$_6$H$_4$)(OAr - 2,6Ph$_2$)$_2$(CH$_2$C$_6$H$_4$ - 4Me) (**4**)

A solution of 0.25 g of Ta(OAr)$_3$(CH$_2$C$_6$H$_4$Me)$_2$ dissolved in toluene (5 cm^3) was heated at 120°C for 6 h in a sealed tube. The solvent was evaporated *in vacuo* to yield the crude product as a yellow solid. ^{1}H NMR (C_6D_6, 30°C): δ 0.71 (d), 2.39 (d, Ta—CH_2), 5.51 (d), 6.38 (d), 6.5–8.4 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 200.7 (Ta—*C*), 86.6 (Ta—CH_2), 2.16 (4*Me*). Found: C, 72.0; H, 4.7. Calc. for $TaC_{62}H_{47}O_3$: C; 72.9; H, 4.6%.

Nb(OC$_6$H$_3$Ph-C$_6$H$_4$)(OAr-2,6Ph$_2$)$_2$(Cl) (**5**)

To a solution of Nb(OAr-2,6Ph$_2$)$_3$Cl$_2$ (1.50 g) in benzene (15 cm^3) was added Mg(CH$_2$C$_6$H$_4$-4Me)$_2$ (0.14 g) in small portions. The resulting mixture was stirred for 1 h, filtered and the deep red filtrate concentrated, whereupon deep-red crystals of the product were obtained. Yield = 1.1 g (78%). Found: C, 74.1; H, 4.6; Cl, 4.8. Calc. for $NbClO_3C_{54}H_{38}$: C, 75.1; H, 4.4; Cl, 4.1%. ^{1}H NMR (C_6D_6, 30°C): δ 6.6–7.8 (m, aromatics). ^{13}C NMR (C_6D_6, 30°C): δ 192.1 (Nb—*C*).

Nb(OC$_6$H$_3$Ph - C$_6$H$_4$)(OAr - 2,6Ph$_2$)$_2$(CH$_2$C$_6$H$_4$ - 4Me) (**6**)

To a solution of **5** (0.30 g) in benzene (15 cm^3) was added Mg(CH$_2$C$_6$H$_4$-4Me)$_2$ (0.05 g). The solution was stirred for 4 h, filtered and concentrated to yield

CORRELATIONS OF CARBONYL STRETCHING FREQUENCIES AND ^{31}P AND ^{95}Mo NMR PARAMETERS FOR *FAC*-[$Mo(CO)_3(bipy)(PR_3)$] COMPLEXES

ELMER C. ALYEA,* ROBERT A. GOSSAGE, JOHN MALITO and ZURAIDAH A. MUNIR

Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario N1G 2W1, Canada

(*Received* 11 *September* 1989; *accepted* 4 *December* 1989)

Abstract—Several complexes of the type [$Mo(CO)_3(bipy)(PR_3)$] [where bipy = 2,2′-dipyridine, R = *n*-Bu, Me, *p*-C_6H_4-X; X = F, Cl, H, CH_3, OCH_3, $N(CH_3)_2$] were synthesized and characterized by ^{31}P NMR, ^{95}Mo NMR and IR spectroscopy. Relationships are drawn between the bonding nature of the ligands and the ^{95}Mo and ^{31}P NMR chemical shifts and the $\nu(C{\equiv}O)$ values. Correlations of $\delta(^{95}Mo)$, $\Delta\delta(^{31}P)$ and $\nu(C{\equiv}O)$ to various parameters such as ligand pK_a, ligand cone angle (Θ), and the Kabachnik parameter ($\Sigma\sigma^{\phi}$) are discussed and indicate the interrelationship of the donor abilities of C≡O, dipy and the phosphine ligands. The importance of steric effects in influencing net metal electron density is demonstrated by the results.

IR data for the carbonyl region has been central to studies of the structural and electronic properties of transition metal carbonyl complexes for almost three decades.[1] Carbonyl stretching force constants were among the first parameters used to relate the σ-donor and π-acceptor ability of ligands in metal carbonyl complexes.[2] With the advent of Fourier transform NMR techniques, however, the bonding properties of ligands containing carbon (e.g. C≡O) or phosphorus [e.g. $P(C_6H_5)_3$] could be easily observed directly in terms of the NMR chemical shift.[3] Metal–ligand NMR coupling constants between the NMR active nuclei in the ligand (e.g. ^{31}P) and an NMR active nucleus of the central metal atom (e.g. ^{183}W) have also been widely employed to study metal–ligand interactions, especially for phosphorus donor ligands.[4] Metal–phosphorus bond properties are of great fundamental importance due to the widespread use of phosphorus-containing ligands in metal complexes used in various catalytic processes.[5]

The development of routine metal NMR spectroscopy has recently provided a direct probe of the metal environment[6] and enables one to observe metal–phosphorus coupling constants of metal nuclei which are difficult to observe via ^{31}P NMR spectroscopy (e.g. ^{95}Mo).[7] Studies in our laboratory over the past few years have centred on probing the effects of a number of ligand systems on the molybdenum metal centre in diamagnetic molybdenum metal complexes via ^{95}Mo NMR spectroscopy. ^{95}Mo NMR spectroscopy is well established as a sensitive probe of the molybdenum metal atom in several oxidation states.[8] Our studies on molybdenum(0) carbonyl complexes have shown the chemical shift range for $Mo(CO)_5L$ (L = P, As, Sb or N donating ligand) to exceed 400 ppm[9] and to exceed 800 ppm for $Mo(CO)_4L_2$ complexes.[10] Our recent study on $Mo(CO)_5L$ complexes (L = substituted pyridine ligands) have shown a direct correlation between the σ-bonding ability, as portrayed by the pK_a of the pyridine ligands, and the ^{95}Mo NMR chemical shift [$\delta(^{95}Mo)$] over a range of almost 70 ppm.[11] In contrast, $\delta(^{95}Mo)$ values were surprisingly similar for some [$Mo(CO)_5(p$-X-$C_6H_4)_3P$] complexes involving phosphines of varying basicity.[9] To investigate these effects further we have chosen the system $Mo(CO)_3(bipy)L$ (where bipy = 2,2′-bipyridine and L = various phosphine donor ligands). By systematically changing L, we hoped to probe the nature of the bonding between a d^6 metal centre in a low valent oxidation state, and carbon monoxide, a bidentate α-diimine ligand and various phos-

* Author to whom correspondence should be addressed.

phorus donor ligands. The reasons for choosing this system involve the fundamental importance of CO, α-diimine and phosphine ligands to coordination, catalytic and electrochemical chemical processes.[12,13] The ability of several commonly accepted parameters (e.g. cone angle (Θ), χ electronic parameter, pK_a, Kabachnik's $\Sigma\sigma^{\phi}$ values, etc.) in quantitatively describing the nature of metal–phosphorus bonding was also the subject of critical scrutiny[14] during this investigation.

EXPERIMENTAL

All reactions and manipulations were carried out under a dry oxygen-free dinitrogen atmosphere. The solvents used were all reagent grade. $Mo(CO)_6$, PMe_3, 2,2′-bipyridine, PBu_3 and trimethylamine oxide dihydrate (TMNO) were purchased from Aldrich Chemical Co. PPh_3 was purchased from Pressure Chemical Co. Tetrabutylammonium iodide (Bu_4NI) was purchased from Fisher Scientific Co. P(*p*-Me-C_6H_4)$_3$, P(*p*-N(CH_3)$_2$-C_6H_4)$_3$, P(*p*-F-C_6H_4)$_3$ and P(*p*-Cl-C_6H_4)$_3$ were acquired from Strem Chemical Co. and P(*p*-OCH_3-C_6H_4)$_3$ was bought from Columbia Organic Co. Inc. All were used without further purification. NMR measurements were performed in septum-capped 10 mm NMR tubes on freshly prepared samples at room temperature (23 ± 2°C). ^{31}P NMR spectra were recorded in CH_3CN solutions on a Bruker WH-400 spectrometer operating at 161.92 MHz. Chemical shifts are reported as positive to high frequency of external 85% phosphoric acid. ^{95}Mo NMR spectra were recorded on the same instrument or on a Bruker CXP-200 NMR spectrometer, operating at 26.08 or 13.04 MHz, respectively, from naturally abundant ^{95}Mo using saturated CH_3CN solutions. Chemical shifts are relative to external aqueous 2 M K_2MoO_4 at pH 11. Duplicate ^{95}Mo results were obtained at both operating fields, so field effects are termed to be negligible for this series. IR spectra were recorded on a Nicolet 20 DXC FT–IR spectrometer from CH_2Cl_2 solutions in 0.5 mm NaCl solution cells and are accurate to ±0.5 cm^{-1}. $Mo(CO)_4$bipy was prepared by a published method.[15] In a typical synthesis, 0.3 g of $Mo(CO)_4$ bipy in 20 cm^3 CH_3CN was heated to reflux for 15 min with an equimolar quantity of TMNO[16] or a catalytic amount of Bu_4NI and an equimolar quantity of the desired phosphine ligand. As the PPh_3 derivative of this series is known,[17] the species studied were not isolated but observed entirely *in situ* using at least duplicate repetitions. Note that although the reactions were carried out in CH_3CN, at no time was [$Mo(CO)_3$(bipy)(CH_3CN)] observed by IR spectroscopy, so it is assumed to be a short-lived intermediate in the decarbonylation–phosphine addition process.[18] The complexes synthesized are all the thermodynamically stable facial isomers as indicated by their IR spectra.[2]

RESULTS AND DISCUSSION

The ^{31}P NMR and reference data for the free phosphines and complexes appear in Table 1. For the complexes, the carbonyl stretching frequencies and the ^{95}Mo NMR data appear in Table 2. Several trends can be seen. First, the value of the CO stretching frequency representative of the A_1 mode does not greatly change throughout the series. In fact, any electronic differences between P(*p*-Me-C_6H_4)$_3$ and P(*p*-OCH_3-C_6H_4)$_3$ are not resolved by the A_1 mode. The sum of all CO stretching vibrations [$\Sigma\sigma$(CO)] may, in fact, be a better reflection of the net effect on the CO ligands of varying the phosphine.

Relationships between the measured values for ν(C≡O), $\Delta\delta(^{31}P)$ and $\delta(^{95}Mo)$ run from good to excellent within the series. The $\Delta\delta(^{31}P)$ values relate to the $\delta(^{95}Mo)$ values (correlation coefficient $r = 0.902$) and to the changes in the $\Sigma\nu$(C≡O) values ($r = 0.992$). In turn, the $\Sigma\nu$(C≡O) values relate well to the $\delta(^{95}Mo)$ values ($r = 0.962$). This trend is expected when the steric bulk of the phosphorus ligand remains constant,[21] as is the case here.

The $\Delta\delta(^{31}P)$ chemical shift values show a general decrease with increasing ligand substituent electron-donating ability, indicating less net electron donation by the phosphine with increasing ligand Brönsted basicity. This trend has also been observed for other molybdenum(0) carbonyl complexes.[22(a)] Electron density around the molybdenum atom, as indicated by $\delta(^{95}Mo)$, is not greatly affected by the changes in the electronic

properties of the phosphine since the δ(^{95}Mo) values span a range of only about 6 ppm. This slight shift is not adequately explained by plotting δ(^{95}Mo) vs the phosphine ligand pK_a (Table 1) (correlation coefficient (r) is only 0.880) nor by the Tolman χ_i value (r = 0.908).[13] This lends support to two conceptual ideas, one of which we discuss here, while the other has been discussed previously.[23] Firstly, the lack of good correlation with Tolman's χ_i values lends support to our idea that $\Sigma\nu$(CO) is a better reflection of the effect of the nature of PR$_3$ then the A_1 stretching mode is alone, since χ_i values are based solely on the A_1 stretching mode of various Ni(CO)$_3$L (L = phosphorus ligands) complexes.[13] Secondly, the lack of correlation with the measured value of the ligand's pK_a supports the argument that pK_a values are not an appropriate measure of the interaction between phosphines and soft acid species such as low-valent transition metal centres.[23] The justification here lies in the fact that pK_a values are dependent on the interaction between the phosphine and the hard acid, H^+. An acceptable correlation (r = 0.957) is found between δ(^{95}Mo) and the Kabachnik $\Sigma\sigma^\phi$ parameter (Fig. 1), indicating that $\Sigma\sigma^\phi$ may be the better experimental parameter for this type of series. The Kabachnik substituent parameters,[20] derived from ionization data of phosphorus acids using a Hammett-type relationship, have been noted by other workers[13,19] to be good measures of electronic effects for phosphines. The Mo—P coupling constants are basically uniform throughout the series indicating that molybdenum–phosphorus σ-bonding character is essentially the same throughout the series. Since the phosphines must be donating different amounts of electron density in total, as measured by $\Delta(\delta^{31}P)$,

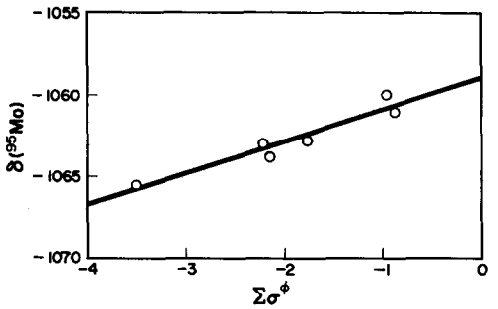

Fig. 1. Plot of δ(^{95}Mo) vs $\Sigma\sigma^\phi$ for [Mo(CO)$_3$(bipy){P(X-C$_6$H$_4$)$_3$}] complexes.

the other ligands present in the system must be serving in some way to compensate for the difference. A plot of $\Sigma\sigma^\phi$ vs $\Sigma\nu$(CO) yields an excellent correlation (r = 0.998) (Fig. 2), indicating that the electronic differences of the phosphines are adequately measured by summing the CO stretching frequency vibrations. This trend has been observed previously for a series of Mo(CO)$_5$(py-R)

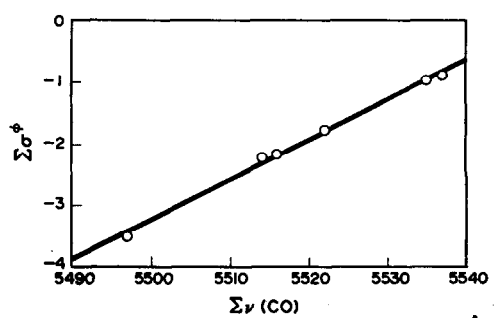

Fig. 2. Plot of $\Sigma\sigma^\phi$ vs $\Sigma\nu$(CO) for [Mo(CO)$_3$(bipy){P(X-C$_6$H$_4$)$_3$}] complexes.

(py-R = substituted pyridine ligand) complexes.[24] The $\delta(^{95}Mo)$ value is directly affected by the different electronic nature of $P(p\text{-}X\text{-}C_6H_4)_3$ and this trend is also reflected by the net change on the CO ligands (Fig. 3), but phosphorus σ-donor character is not significantly changed. This result tends to indicate that the CO ligands are responsible for compensating for the lesser or greater donating ability of $P(p\text{-}X\text{-}C_6H_4)_3$ compared to PPh_3. The effect of the bidentate α-diimine ligand, 2,2′-bipyridine, is likely uniform within this series since $\Sigma\sigma^{\phi}$ relates directly to $\Sigma\nu(CO)$. The general compensation of overall metal electron density by CO regardless of X in $P(p\text{-}X\text{-}C_6H_4)_3$ has the possibility of steric hindrance as its basis. The bulkiness of PPh_3 ($\Theta = 145°$),[13] compared to many other phosphine ligands, may not allow the phosphine to get close enough to the molybdenum centre for its full electronic character to greatly influence the metal's electron sphere. To test if this was indeed the case, we synthesized two other complexes $[Mo(CO)_3(bipy)(PMe_3)]$ and $[Mo(CO)_3(bipy)(PBu_3)]$, where the ligand PR_3 had a smaller steric size than PPh_3 but electronic capabilities, measured by $\Sigma\sigma^{\phi}$, within the same range.

The PBu_3 complex [ν(CO): 1908, 1806, 1784 cm^{-1}; $\delta(^{31}P)$: +3.70, $\Delta\delta(^{31}P) = 34.0$ ppm; $\delta(^{95}Mo) = -1071.2$ ppm, $^1J_{MoP} = 125$ Hz] produces a more pronounced effect on the molybdenum centre, shielding it by a further 5.7 ppm over the $P(p\text{-}NMe_2\text{-}C_6H_4)_3$ complex. PBu_3 is producing virtually the same net electronic effect on the CO ligands ($\Sigma\nu(CO) = 5498$) as compared to $P(p\text{-}NMe_2\text{-}C_6H_4)_3$ ($\Sigma\nu(CO) = 5497$) which is not unexpected since the $\Sigma\sigma^{\phi}$ values for these two ligands, −3.66 and −3.51,[20] respectively, are very similar. The further effects of PBu_3 over the PPh_3 derivatives in shielding the metal centre may therefore be a result of the smaller steric size of PBu_3 ($\Theta = 132°$) over PPh_3. This allows PBu_3 to move closer to the metal centre and hence produce stronger overall molybdenum shielding. This is also seen with the PMe_3 complex [ν(CO): 1910, 1810, 1785 cm^{-1}; $\delta(^{31}P)$: −15.2, $\Delta\delta^{31}P = 45.8$ ppm; $\delta(^{95}Mo) = -1076.8$ ppm, $^1J_{MoP} = 130$ Hz]. The poorer electron donor PMe_3 ($\Sigma\sigma^{\phi} = -2.88$ vs −3.66 for PBu_3), still puts considerably more electron density on the metal centre than does PPh_3 [$\delta(^{95}Mo) = -1062.8$ ppm, $\Sigma\sigma^{\phi} = -1.77$].

Thus, the CO ligands appear to restabilize net metal electron density only to some maximum extent, dictated not only by phosphine electronic but by steric properties. Only when the phosphine is small enough to get close to the metal centre can its electronic capabilities be seen to truly influence net metal electron density to a significant extent. This "push–pull" mechanism between phosphine σ-donor ability and steric ligand bulk is of great fundamental importance since it will greatly influence the design of metal catalytic molecules. The relative importance of steric vs electronic effects on molybdenum(0) carbonyl complexes has also been demonstrated in several earlier NMR studies by Gray and others.[21,22]

An interesting anomaly in this series is the fact that $P(p\text{-}OCH_3\text{-}C_6H_4)_3$ shields the molybdenum nucleus to a lesser extent than $P(p\text{-}CH_3\text{-}C_6H_4)_3$. This observation is also seen for the $Mo(CO)_5PR_3$ complexes,[9] although the shielding difference in that case is a more pronounced one. The reason for this is currently unclear, since steric effects in both cases are obviously uniform. It does indicate, however, that various groups may be less able to affect the metal nucleus than their $\Sigma\sigma^{\phi}$ (or pK_a) values would indicate. This dictates caution in describing metal electron density based solely on measured parameters of the free ligands only.

Our attempts to correlate relative shielding of the molybdenum metal nucleus to the Mo—P bond length have proved ineffective. The Mo—P bond lengths for $Mo(CO)_5PPh_3$ and $[Mo(CO)_5P(p\text{-}CH_3\text{-}C_6H_4)_3]$ are virtually identical, being 2.560 and 2.562 Å, respectively,[25,26] but $\delta(^{95}Mo)$ values differ by 7 ppm,[9] similar to the difference between $[Mo(CO)_3(bipy)\{P(p\text{-}CH_3O\text{-}C_6H_4)_3\}]$ and $[Mo(CO)_3(bipy)(PBu_3)]$. This similarity of bond lengths was noted in the recent related study of several iron(II) phosphine complexes where bond lengths and σ-donor/π-acceptor ability of the phosphine ligands do not appear to correlate.[14(a)]

Our results also show one other important factor. Giering and co-workers state in their discussion of the relative bonding ability of phosphine ligands that: "Undoubtedly, the terminal carbonyl stretching frequencies {of their $[(\eta^5\text{-}C_5H_5)Fe(CO)(COCH_3)(PR_3)]$ complexes} are directly dependent on the electron density of the metal to which the CO is bonded".[14(a)] However, we have clearly

shown, by comparing the $\delta(^{95}Mo)$ values of $[Mo(CO)_3(bipy)(PBu_3)]$ and $[Mo(CO)_3(bipy)\{P(p\text{-}NMe_2\text{-}C_6H_4)_3\}]$, both of which have virtually identical CO stretching frequencies, that their statement is not universally valid. Thus, the best probe of metal electron density is not by observation of the surrounding ligands but by observing the metal centre itself.

Related ^{95}Mo NMR studies currently underway in our laboratory are centred around further probing the nature of the effects of phosphines and phosphites on molybdenum environments.

Abstract—2-Furanthiocarboxyhydrazide (Hfth), salicylaldehyde-2-furanthiocarboxyhydrazone (H_2L) and N-salicyl-N′-2-furanthiocarboxyhydrazine (H_2sfth) form complexes of the composition $[Fe(Hfth)_2Cl_2]Cl$, $Fe(fth)_3$, $[Fe(H_2sfth)_2Cl_2]Cl$, $Fe(HL)Cl_2$ and Fe(HL)L, which have been characterized on the basis of their elemental analyses, magnetic susceptibility, Mössbauer, UV–vis and IR spectral studies. The compounds $[Fe(Hfth)_2Cl_2]Cl$, $[Fe(H_2sfth)_2Cl_2]Cl$ and $Fe(fth)_3$ are all octahedral with coordination through sulphur and nitrogen. The compound $[Fe(H_2sfth)_2Cl_2]Cl$ exists in spin isomeric forms, $S = 5/2$ and $S = 1/2$, at room temperature as well as at liquid nitrogen temperature. The compound $Fe(HL)Cl_2$ is high-spin tetrahedral while the compound Fe(HL)L is low-spin octahedral.

Complexes of a number of metal ions with the condensation products of pyridine-2-carboxaldehyde and both S- and N-substituted dithiocarbazates have been reported.[1,2] These ligands react with iron to form a variety of high- and low-spin complexes of both iron(II) and iron(III)[2–4] and are potentially tridentate with an NNS donor atom set.

The basic SN chelate ring is similar to that of the thiosemicarbazide moiety, $=NNHCSNH_2$, which coordinates in most cases via the hydrazinic nitrogen and the sulphur to give a five-membered chelate ring. Thiosemicarbazones have long been known to constitute a class of compounds with a wide range of pharmacological activity which is thought to be connected to their chelation of trace metal ions.[5]

The iron(III) complexes of some α-N-heterocyclic carboxaldehyde thiosemicarbazones have recently been receiving attention in chelation therapy. A number of such thiosemicarbazones have strong antineoplastic activity,[6] while others show antimalarial action.[7] The role of chelation by metal ions in the mechanism of the action of such compounds has been discussed both by French and co-workers[8] and by Petering and co-workers.[9] Some iron(II) complexes of 5-substituted 2-formylpyridine and 1-formyl isoquinoline thiosemicarbazones are cytotoxic to tumour cells both *in vivo* and *in vitro*.[10–12]

Similarly, complexes of 2-formylpyridine thiosemicarbazone with iron(II) and other metal(II) ions have significant antitumour activity against Erhlich ascytes carcinoma and L1210 leukemia in mice.[13,14]

It is a logical extension of this work to prepare thiohydrazide and thiohydrazone complexes and to investigate their activity since they contain the same basic chelate ring =NNHCS— as thiosemicarbazones. We have previously reported the synthesis and properties of a few of these compounds[15–17] and now wish to report the synthesis and spectral properties of some iron(III) complexes of 2-furanthiocarboxyhydrazide (Hfth), salicylaldehyde-2-furanthiocarboxyhydrazide (H_2sfth) and N-salicyl-N′-2-furanthiocarboxyhydrazine (HL) (see Fig. 1).

Fig. 1. Structures of ligands.

EXPERIMENTAL

All the chemicals used were BDH or reagents of similar quality. The ligands were prepared as previously described.[15–17]

The compound $[Fe(Hfth)_2Cl_2]Cl$ was obtained by mixing chloroform solutions of anhydrous iron(III) chloride and the ligand in a 1:2 ratio at room temperature and with constant stirring. The compound $[Fe(fth)_3]$ was prepared by digesting a mixture of an ethanolic solution of ferric chloride and the ligand in a 1:3 molar ratio together with *ca* 1 g of sodium acetate. The precipitate was filtered and washed with a hot ethanol–water mixture.

The compound $[Fe(H_2Sfth)_2Cl_2]Cl$ was obtained by refluxing a chloroform solution of anhydrous iron(III) chloride with a suspension of H_2sfth in the same solvent, in a 1:2 molar ratio, for about 3 h. The complex $Fe(HL)Cl_2$ was prepared by mixing chloroform solutions of anhydrous iron(III) chloride and HL in a 1:1 molar ratio at room temperature. Stirring ethanolic solutions of iron(III) chloride and HL at room temperature for about 15 min, on the other hand, gave Fe(HL)L on evaporation of the solvent at room temperature.

The complexes were analysed for iron using a standard procedure[18] after first destroying the organic ligand with a mixture of nitric and hydrochloric acids followed by sulphuric acid. Sulphur was determined as $BaSO_4$. Carbon, hydrogen and nitrogen were determined by microanalysis using a Perkin–Elmer Analyser model 240C. The analytical data are shown in Table 1.

Electrical conductance was measured at room temperature on a WTW conductivity meter. Room temperature magnetic susceptibility was determined by the Faraday method using $HgCo(NCS)_4$ as calibrant and molar susceptibilities were corrected for diamagnetism.[19] The electronic reflectance spectra were recorded at room temperature on either a Cary 14 or a Perkin–Elmer model 330. The IR spectra were recorded on a Perkin–Elmer model 783. The Mössbauer spectra were measured using a Cryophysics microprocessor controlled spectrometer calibrated against iron foil. The spectra were fitted using a least-squares program developed by F. Woodham and supplied by Cryophysics.

RESULTS AND DISCUSSION

The analytical data on the complexes isolated are shown in Table 1 together with the colours, melting

point, magnetic moments and molar conductances in solution. The compound $Fe(HL)Cl_2$ is soluble in non-polar as well as polar organic solvents, while the other complexes are only soluble in polar organic solvents such as DMF and DMSO.

The IR spectra of both ligands and complexes were studied over the range 4000–200 cm^{-1} (see Table 2). Bands in the range 3400–3140 cm^{-1} due to ν(NH) modes show small negative shifts on coordination, indicating the involvement of the terminal hydrazine nitrogen in coordination to the metal. The largely ν(C=S) band of the ligands in the region 900–800 cm^{-1} is appreciably shifted to lower values in the spectra of the complexes confirming coordination through the thione sulphur. The ν(OH) and ν(C=O) bands in the spectrum of $Fe(H_2sfth)_2Cl_3$ appear at slightly higher frequencies than in the free ligand, indicating that neither the phenolic oxygen nor the carbonyl oxygen of this ligand is coordinated to the metal.

The room temperature magnetic moment of $Fe(Hfth)_2Cl_3$, 3.61 μ_B, would suggest either a strong magnetic interaction between coupled high-spin iron(III) ions or, less likely, an intermediate spin state, $S = 3/2$. However, all presently known well-characterized $S = 3/2$ species are five-coordinate and have Mössbauer spectra characterized by large quadrupole splittings with values greater than 2 mm s^{-1}, which is clearly not so in the present case (see Table 3). The molar conductance of $Fe(Hfth)_2Cl_3$ (see Table 1) lies in the range expected for a 1 : 1 electrolyte[20] if we assume that it is in fact a monomer, i.e. it should be formulated $[Fe(Hfth)_2Cl_2]Cl$. While a dimer structure $[Fe(Hfth)_2\text{-}\mu\text{-}Cl_2\text{-}Fe(Hfth)_2]Cl_4$ would account for the magnetic moment it is incompatible with the conductivity data. Furthermore, the far-IR band assigned to ν(Fe—Cl) at 315 cm^{-1} lies in the range expected for terminal Fe—Cl bands in six-coordinate species. The single ν(Fe—Cl) band indicates a *trans* structure. The Mössbauer isomer shift (Table 3) leaves no doubt that the compound contains iron(III). Unfortunately the decrease in isomer shift and quadrupole splitting at liquid nitrogen temperature suggests a crystal phase change and offers no real help. The compound obtained from Hfth in ethanolic solution, $Fe(fth)_3$, is a non-electrolyte with a magnetic moment of 3.22 μ_B. Thus its formulation as a six-coordinate ("octahedral") low-spin monomer is in little doubt. The far-IR bands assigned to ν(Fe—N) and ν(Fe—S) show the expected change, i.e. a decrease in the former and increase in the latter compatible with the bond rearrangement in the chelate ring. The *d–d* bands like those of $Fe(Hfth)_2Cl_3$ are characteristic of "octahedral" iron(III) coordination compounds with similar ligands.[21]

The compound $Fe(H_2sfth)_2Cl_3$ is a 1 : 1 electrolyte in DMF suggesting the formulation $[Fe(H_2sfth)_2Cl_2]Cl$. The Mössbauer data (Table 3) indicate the presence, both at room temperature and at liquid nitrogen temperature, of both high- and low-spin states, the latter characterized by its smaller isomer shift and much larger quadrupole splitting. The isomer shifts and quadrupole splittings are very similar to those found by Ablov, Goldanskii and their co-workers for iron(III) thiosemicarbazones and mixed complexes.[22] There are, however, two important differences. Firstly, the iron(III) species examined by Ablov and co-workers all contained iron(III) in the octahedral anionic form FeL^{2-} or $FeL'L^-$ and, secondly, only in one case, that of a mixed salicylaldehyde thiosemicarbazone–pyruvic acid species, $[FeL'L]^-$, did they observe both high- and low-spin states to be present at a detectable level at 300 K. Zelentsov and his co-workers have also discussed in detail the structural features and magnetic properties of iron(III) complexes of substituted salicylaldehyde thiosemicarbazones in the region of the $^6A_1$–$^2T_2$ spin crossover.[23] It is significant in the case of $[Fe(H_2sfth)_2Cl_2]^+$ that the hydrazine nitrogen is only mono-substituted —NH—NH— instead of —NH—N= in the case of salicylaldehyde thiosemicarbazones, and that the —OH group in the salicyl moiety is not involved in coordination. The far-IR and *d–d* spectra (Tables 2 and 4) of $Fe(H_2sfth)_2Cl_3$, $Fe(Hfth)_2Cl_3$ and $Fe(fth)_3$ are not greatly different, so that the crystal-field factors affecting spin crossover must be quite subtle. In fact the isomer shift values at room temperature of $Fe(Hfth)_2Cl_3$ and of the high-spin form of $Fe(H_2sfth)_2Cl_3$ are identical within experimental error and the difference in quadrupole splittings is relatively small.

The two complexes formed by the ligand H_2L are quite different. The compound $Fe(HL)Cl_2$ is high spin with $\mu = 6.0$ μ_B. The ν(NH) band is missing from the IR spectrum of the complex, indicating thioenolization of the ligand and coordination of the sulphur in the thiolato form. The Mössbauer data (Table 3) are compatible with a distorted tetrahedral geometry (low isomer shift combined with $\mu = 6.0$ μ_B and a relatively large quadrupole splitting) but not with a five-coordinate geometry which might be expected if the phenolic oxygen were also coordinated to the iron as well as the nitrogen and sulphur atoms. The positive shifts in the thioamide bands [β(NH) + ν(CN) and ν(CN) + β(NH)] and the ν(NN) band can be interpreted as support for bonding through the hydrazine nitrogen.[24] Consequently the ligand must be coordinated through nitrogen and sulphur and not through the phenolic oxygen.

Table 4. Electronic spectral band positions and assignments

Compound	Band positions	Assignments	Geometry
$[Fe(Hfth)_2Cl]Cl_2$	11,300, 14,700, 24,670, 32,300	*d–d* transitions; CT	Octahedral
$[Fe(H_2sfth)_2Cl_2]Cl$	10,000, 11,300, 14,300, 19,000, 20,300, 28,700	*d–d* transitions; CT	Octahedral (low and high spin)
$Fe(HL)Cl_2$	14,000, 18,000, 21,700, 33,300, 36,700	*d–d* transitions; CT	Tetrahedral (high spin)
Fe(HL)L	11,000, 13,700, 21,000, 27,700	*d–d* transitions; CT	Octahedral (low spin)
$Fe(fth)_3$	11,000, 15,000, 20,700, 24,700, 29,000	$^2T_{2g} \rightarrow {}^4T_{1g}(^4G)$; $^2T_{2g} \rightarrow {}^4T_{2g}(^4G)$; $^2T_{2g} \rightarrow {}^2A_{2g}$; CT	Octahedral (low spin)

The *d–d* spectrum is compatible with a roughly tetrahedral geometry with the first band at 14,000 cm^{-1} (cf. Fe(HL)L where the first band occurs at 11,000 cm^{-1}). In methanol the compound is a 1 : 2 electrolyte but this probably results from solvent displacement of the chlorides. The compound Fe(HL)(L) is low spin with Mössbauer parameters which correspond well with those expected for a low-spin "octahedral" species, cf. the low-spin species of $[Fe(H_2sfth)Cl_2]Cl$ (see Table 3). The *d–d* (Table 4) and IR spectra (Table 2) support this formulation. (It is a non-electrolyte in MeOH and DMF as would be expected.) The donor atom set of each coordinated ligand must be SNO but the L^{2-} ligand must be in the thioenolato form, whereas the HL^- must be in the thionato form. In fact ν(OH) and ν(NH) bands are both missing from the IR spectrum.

ISOTOPE EFFECTS IN THE ACID-CATALYSED REACTIONS OF HYPOPHOSPHOROUS ACID

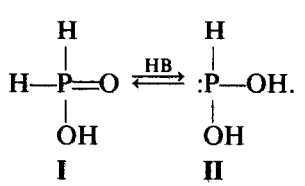
JOHN W. LARSON

Department of Chemistry, Marshall University, Huntington, WV 25755-2520, U.S.A.

(*Received* 8 *August* 1989; *accepted* 8 *December* 1989)

Abstract—Rate constants for four isotope exchange reactions and four oxidation reactions were measured at 25°C for protonated and deuterated hypophosphorous acid. For the acid-catalysed, rate-determining tautomerization of inactive $H_2PO(OH)$ to active $HP(OH)_2$, primary kinetic isotope effects (k^D/k^H) of 0.36 for the forward reaction and 0.24 for the reverse reaction were obtained. The secondary isotope effect was determined to be 1.45. These isotope effects are consistent with a transition state in which proton attachment occurs with a bond order of 0.2. This bond order is used, along with the Marcus theory of proton transfer, to calculate a free energy of tautomerization of 62 kJ.

The rate constants for a variety of acid-catalysed reactions involving the P—H bond of hypophosphorous acid are all approximately 3.5×10^{-3} M^{-1} s^{-1} at room temperature. These reactions range from simple isotope exchange with the solvent[1,2] to the oxidation of hypophosphorous acid with over 12 different oxidizing agents.[3–6] The common mechanism proposed to explain these rates involves the general acid-catalysed conversion of the inactive tautomer **I** to the active intermediate, tautomer **II**[1,2,5]



I II (1)

The present study involves examination of isotope effects on both the exchange reactions and the oxidation reactions with I_3^-. Detailed analysis of these isotope effects can reveal considerable information about the mechanism of the reaction and the structure of the transition state. Of particular interest is the fraction of protonation that occurs in the transition state structure as deduced from the isotope effect, α_I, and that deduced from the Brønsted coefficient,[5] α_B. No previous study of isotope effects on the reactions of hypophosphorous acid has been carried out.

Small but significant discrepancies also exist between the rates obtained for exchange versus oxidation reactions. In order to compare these results, a detailed experimental and theoretical analysis of the isotope effects is needed.

The larger temperature range and the better precision of the present study of the isotope exchange rates provides a more solid backdrop for interpretation of future kinetic experiments. In particular, this work was a necessary prelude to a planned quantitative study of Lewis acid catalysis of the isotope exchange reaction.

EXPERIMENTAL

Sodium hypophosphite monohydrate obtained from Fisher Scientific was analysed by heating to 200°C *in vacuo* followed by titration after elution from a strong acid ion exchange column. Hydrochloric and acetic acids were obtained commercially in the highest purity available and analysed by standard acidometric methods. The 99.8 atom % D_2O used was obtained from Aldrich.

Phosphorous magnetic resonance spectra were obtained using a Varian XL-200 spectrometer. Mole fractions of the $H_2PO(OL)$, $HDPO(OL)$ and $D_2PO(OL)$ species calculated from the spectra were generally reproducible to better than 2%. L is the symbol used for either H or D. Temperatures were controlled to within ±0.3°C. Temperature calibration was carried out with a mercury thermometer.

RESULTS AND DISCUSSIONS

Equilibrium isotope effect

Fifteen kinetic experiments were allowed to run to completion at stoichiometric mole fractions of deuterium between 0.1 and 0.9. Measurement of areas under the D_2PO_2 quintet, the $HDPO_2$ doublet of triplets and the H_2PO_2 triplet resulted in equilibrium constants for reactions (2) and (3) of $K_2 = 1.12 \pm 0.08$ and $K_3 = 0.305 \pm 0.015$:

$$DOL_l + H_2PO_2L_{aq} = DHPO_2L_{aq} + HOL_l \quad (2)$$

$$DOL_l + DHPO_2L_{aq} = D_2PO_{2aq} + HOL_l. \quad (3)$$

This value of K_2 is in good agreement with the value of $K_2 = 1.1 \pm 0.2$ obtained from the base-catalysed reaction.[7] K_2 and K_3 are consistent with statistical factors of 2 and 0.5, respectively, along with the deuterium fractionation factor, defined[8] by eq. (4), of $\phi_{PH} = 0.59 \pm 0.03$:

$$\phi_{PH} = (D—P/H—P)/(D—O/H—O)_{aq}. \quad (4)$$

A theoretical value for the deuterium fractionation factor may be estimated from bond stretching frequencies of 2400 cm^{-1} for P—H and 3300 cm^{-1} for O—H.[9] The estimated zero-point energy difference[8] of 132 cm^{-1} gives a value of ϕ_{PH} of 0.53 at 25°C, in good agreement with the measured value.

A value of 0.0176 for K_D, the acid ionization constant of $H_2PO(OD)$ in D_2O, is calculated from the PH coupling constants in various solutions following a previously discussed method.[10] The ratio of $K_D/K_H = 0.36$ is typical of that obtained for other acids in D_2O.[8] This ratio is equal to l^3/ϕ_{POH} where l is the fractionation factor for the hydronium ion and has a value of 0.69.[8] The calculated fractionation factor for the POH hydrogen of 0.9 is close to the value of 1.0 expected for a neutral OH group.

Determination of the rate constants for isotope exchange

The rate of disappearance of H_2P isotopic species at any particular acid concentration, ionic strength, isotope concentration and temperature is given by eq. (5):

$$d(H_2P)/dt = k_2(H_2PO_2L)(X_D) - k_{-2}(HDPO_2L)(1-X_D), \quad (5)$$

where X_D is the mole fraction of deuterated solvent. Dividing eq. (5) by the total hypophosphite concentration gives eq. (6):

$$dX_{H_2P}/dt = k_2F\,X_{H_2P}\,X_D - k_{-2}F\,X_{HDP}(1-X_D), \quad (6)$$

where F is the fraction of total hypophosphite in the acid form as determined from the PH coupling constant,[10] X_{H_2P} and X_{HDP} are the fractions of total P in these forms, and k_2 and k_{-2} represent the pseudo first-order rate constants obtained for the forward and reverse reaction (2). Similar expressions may be written for the rate of disappearance of $HDPO_2L$ and D_2PO_2L. The relations among k_2, k_{-2}, k_3 and k_{-3} are known from the equilibrium fractionation factors to be given by eq. (7):

$$k_2 = 2\phi_D k_{-2} = 2k_3 = k_{-3}\phi_D. \quad (7)$$

Experimental values of the mole fractions of the three L_2PO_2L species as a function of time were used to obtain k_2 by numerical integration of eq. (6). An example of typical results is shown in Fig. 1.

General acid catalysis of the exchange reaction means that k_2 is a sum of the products of individual acid rate constants and concentrations of acids LB, eq. (8):

$$k_2 = \Sigma k_2^{LB}(LB). \quad (8)$$

Even in the simplest system, involving only aqueous hypophosphorous acid, there are eight different, but related, rate constants that differ in the direction of the reaction, the acid catalysing the reaction, and the isotopic form of the acid. In this work, the subscript will indicate the isotope reaction taking place and the superscript indicates the catalytic acid for the reaction. Thus the acid-catalysed, pseudo first-order rate constant, k_{-3}, for the disappearance of D_2PO_2H in pure H_2O is given by eq. (9):

$$k_{-3} = k_{-3}^{H}(H_3O^+) + k_{-3}^{H_3PO_2}(H_3PO_2). \quad (9)$$

Dividing by (H_3O^+) yields eq. (10):

$$k_{-3}/(H_3O^+) = k_{-3}^{H} + k_{-3}^{H_3PO_2}(H_3PO_2)/(H_3O^+). \quad (10)$$

The values for the left-hand side of eq. (10) are plotted against $(H_3PO_2)/(H_3O^+)$ to give a straight line as shown in Fig. 2 for measurements made at 45°C and ionic strengths of 0.2 and 0.5. Values of k^H are obtained from the intercept and $k^{H_3PO_2}$ from the slope.

In making experimental measurements over a variety of temperatures and with various acids, it is necessary to use a considerable range of ionic strengths. As observed in Fig. 2, there is no appreciable dependence on ionic strength. This is expected from the fact that the transition state for the reaction will involve the same charge type species as the reactants.

In addition to the study of PD to PH exchange at 0, 25, 45 and 65°C, rates of disappearance of

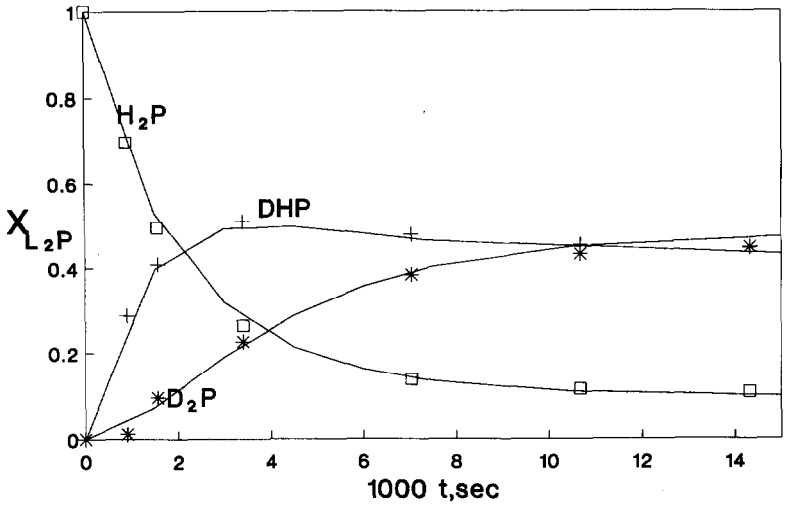


Fig. 1. Experimental and calculated mole fractions of H_2PO_2, $DHPO_2$ and D_2PO_2 as a function of time for Run No. 11, 25°C, $(H^+) = 0.077$ M, $(H_3PO_2) = 0.682$ M, $(H_2PO_2^-) = 0.581$, $X_D = 0.793$. $k_2 = 5.8 \times 10^{-4}$ used in calculating solid lines.

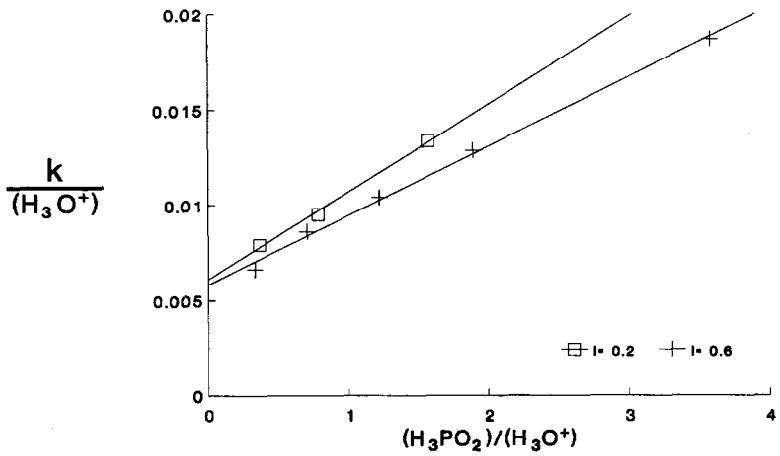

Fig. 2. Analysis of results at 45°C for the reaction $D_2PO_2 \rightarrow H_2PO_2$ via eq. (10) at ionic strengths of 0.2 and 0.6.

H_2PO_2L in pure D_2O were studied at these temperatures to obtain the values reported in Table 1.

The rate constants for the reverse exchange reactions in the same solvent system may be calculated from the relationships given in eq. (7). The four unique exchange rate constants for the L_3O^+-catalysed reactions at 25°C are summarized in the top half of Table 2. The uncertainties in these rate constants are ±15%.

Kinetic isotope effects for the oxidation reaction at 25°C and the mechanism of reaction

To assist in the detailed mechanistic analysis of the isotope effects, the rate of oxidation of hypophosphorous acid by I_3^-, eq. (11), was measured:

$$L_2O + L_2PO_2L + I_3^- = 3I^- + LPO_3L_2 + 2L^+. \quad (11)$$

The time dependence of oxidation was monitored from integration of the ^{31}P NMR of H_2PO_2 and HPO_3. Analysis of the results followed the method of Griffith *et al.*[5] Because of the changing pH during reaction (11), the experimental rates for the oxidation reaction were not precise enough to extract two independent rate constants as was done from the corresponding exchange rates. The experiments were therefore carried out under conditions where the reaction was predominantly catalysed by the hydronium ion, and the hydronium ion-catalysed rate constants were calculated by estimating the

Table 1. Measured rate constants[a] for exchange reactions

Temperature (°C)	Ionic strength	$k^{H}_{D\to H}$	$k^{D}_{H\to D}$	$k^{HL_2PO_2}_{D\to H}$	$k^{DL_2PO_2}_{H\to D}$
		($\times 10^3$ Ms)			
0	0.6–1.2	—	0.24	—	(0.12)[b]
25	0.2–1.0	1.19	4.09	1.01	1.87
45	0.2–0.6	11.0	27.6	6.14	17.9
65	0.8–1.4	—	(223)[b]	—	48.0

[a] Numerical subscripts have been replaced by explicit indication of the P bonding reaction being measured so that $k_{H\to D}$ indicates that PH is reacting to give PD and is equal to k_2.
[b] Extrapolated value.

Table 2. Measured and calculated rate constants for exchange and oxidation reactions at 25°C

Rate constant	Experimental value ($\times 10^3$ Ms)	Literature value ($\times 10^3$ Ms)	Expression for rate constant	Calculated value ($\times 10^3$ Ms)
$k^{H}_{H\to D}$	0.70		$k^0(k^{D}_{-13}/k^{H}_{-13})$	0.78
$k^{D}_{H\to D}$	4.09	4.62[a]	$k^0(K^{D}_{12}/K^{H}_{12})$	4.73

[c] Value from ref. 2 corrected to 25°C.

hypophosphorous acid rate constant as being equal to 0.5 that of the rate constant for the hydronium ion-catalysed reaction. This ratio of 0.5 is equal to that determined in the isotope exchange work presented earlier and to the previously measured ratio[5] in the oxidation of H_2PO_2 by I_3^-. The values of the four rate constants obtained for the oxidation reactions from this work are given in Table 2. The total uncertainty in these rate constants is ±30%.

The data from the oxidation reactions reveal in a straightforward way the expected trends.[8,11-13] The primary isotope effect is to retard the reaction of PD relative to PH. The secondary or solvent isotope effect results in the reaction being faster in D_2O compared to H_2O, in accordance with the deuterium ion being a stronger acid in D_2O than the hydronium ion is in H_2O. The analysis of the exchange results is not as straightforward because it involves two different primary isotope effects, as will be shown by the following analysis.

Previous work[14] indicates hypophosphorous acid is protonated in a fast equilibrium, eq. (9), with $K_{12} = 0.02$. The fact that the reaction involves general acid catalysis suggests that the rate-determining step involves the conjugate base of the acid. This implies a mechanism classified[11] as A2 (Scheme 1). In this scheme H, D and L are used to indicate

$$H{-}P{=}O + LB \rightleftharpoons \overset{+}{H}{-}P{=}O{-}L + B \quad (12)$$

$$H{-}P{=}\overset{+}{O}{-}L + B \rightleftharpoons [B{\cdots}H{\cdots}P{=}O{-}L] \longrightarrow HB + :P{-}O{-}L \quad (13)$$

$$:P{-}O{-}L + \text{Oxidant} \longrightarrow [\,] \longrightarrow HO{-}P{-}OL \text{ (fast)} \quad (14)$$

$$:P{-}O{-}L + DB \longrightarrow D{-}P{=}\overset{+}{O}{-}L + B \quad (15)$$

$$D{-}P{=}\overset{+}{O}{-}L + B \longrightarrow D{-}P{=}O + LB \text{ (fast)}, \quad (16)$$

Scheme 1.

the three different hydrogens which may affect the reaction rate. The PH and the POH bonds that do not react are not shown in eqs (12)–(16).

Using the steady-state approximation, the concentration of the active tautomer is given by eq. (17):

$$(:POL) = \frac{k_{13}(B)(HPOL^+)}{k_{-13}(HB)+k_{14}(Ox)+k_{15}(DB)}. \quad (17)$$

Oxidation reactions. The overall rate for the oxidation is given by k_{14}(:POL)(Ox). Substituting for (:POL) under the conditions that k_{14}(Ox) is much greater than either of the two other terms in the denominator of eq. (17) and making use of the equilibrium constant to express the concentration $HOPOL^+$ and B in terms of K_{12}, the rate expression becomes eq. (18):

$$\text{rate} = k_{13}K_{12}(LB)(H_3PO_2). \quad (18)$$

If we designate k^0 as the value of $k_{13}K_{12}$ when all hydrogens are protons, we can express the rate constants of the other three oxidation reactions in terms of this value and the isotope effects on k_{13} and K_{12} as indicated in Table 2.

Exchange reactions. For the proton to deuterium exchange reactions, the overall rate is given by eq. (19):

$$\text{rate} = k_{15}(DB)(:POL). \quad (19)$$

Substituting for the active intermediate and rearranging yields eq. (20) for the rate and eq. (21) for k_2:

$$\text{rate} = \frac{k_{13}k_{15}K_{12}(H_3PO_2)(LB)X_D}{k_{-13}(1-X_D)+k_{15}X_D} \quad (20)$$

$$k_2 = \frac{k_{13}k_{15}K_{12}(LB)}{k_{-13}(1-X_D)+k_{15}X_D}. \quad (21)$$

Solving this in the limits of X_D equal to 0 and 1, with $k_{15} = k^D_{-13}$, gives two of the exchange expressions in Table 2. The two additional expressions are obtained in an identical manner by considering the deuterium to hydrogen exchange reaction.

Values of the individual kinetic isotope parameters, $K^D_{12}/K^H_{12} = 1.45$, $k^D_{13}/k^H_{13} = 0.36$ and $k^D_{-13}/k^H_{-13} = 0.24$, along with $k^0 = 3.26 \times 10^{-3}\ M^{-1}\ s^{-1}$, are obtained by best fit of the calculated to the experimental rate constants in Table 2.

Isotope effects and transition state structure

Following the procedure given by Schowen,[12] BH and PH bond orders in the transition state of eq. (13) may be estimated from the isotope effect on k_{13}. This procedure involves a linear interpolation from the maximum calculated isotope effect which is assumed to occur when the PH bond is half broken and the BH bond order is half formed. Bond orders of 0.83 and 0.17 are calculated for the BH and PH, respectively. A useful symbolism is to designate the PH bond order as α_I, the fraction of protonation of the transition state as determined by the kinetic isotope effect. Repeating the calculation for the reverse reaction from the k_{-13} isotope effect gives a value of $\alpha_I = 0.22$.

Extraction of the value of K^D_{12}/K^H_{12} from the experimental rates results in all isotope effects other than those involved indirectly in the P—H—B bond entering into this value. The theoretical estimate of these secondary isotope effects for hydronium ion catalysis will involve considering the fate of the three hydrogens from this ion as they are involved in the transition state.[15] Two of these are in the water molecule that serves as the base in eq. (13), and one is attached to the phosphorous oxygen in step (12). If the BH bond order is given as x, the extent to which the two water protons resemble the original OH^+ protons is also x and the extent to which the POH proton resembles OH^+ is $1-x$. The secondary isotope effect is calculated from the expression:

$$I^{2x}I^{1-x}/I^3,$$

where x is equal to $1-\alpha_I$. For $x = 0.8$, a solvent effect of 1.55 is calculated in good agreement with the experimental value of 1.45.

The fraction of transition state protonation determined for the kinetic isotope effect, α_I, is quite different from the fraction determined from the slope of the graph of $\ln(k)$ against the pK_a of the catalysing acid, α_B, the Brønsted coefficient. Griffith *et al.*[5] have determined the latter value to be 0.52. The value of α_I appears to give a more realistic indication of the transition state in that it is consistent with the Hammond postulate[16] that the transition state in the "uphill" reaction (13) should most closely resemble the product, **II**, which has zero proton transfer from the acid.

The Marcus theory[17,18] of proton transfer provides both a basis for analysing the reason for the discrepancy between the two α values and a method of estimating the free energy of tautomerization of hypophosphorous acid. The latter will be analysed first. The Marcus theory involves two key equations, eqs (22) and (23), that may be applied to eq. (13):

$$\Delta G^* = w_r + 1/4\lambda(1+\Delta G^0/\lambda)^2 \quad (22)$$

$$\alpha = (1+\Delta G^0/\lambda)/2. \quad (23)$$

For the hydronium ion-catalysed reaction, the solvation energy change on bringing the reactants of

eq. (13) together, w_R, should be approximately zero because the base is the solvent, water. The free energy of activation in eq. (22) is $\Delta G^{\ddagger}_{13} = 77$ kJ which is known from the difference in the overall free energy of activation (88 kJ) and ΔG^{0}_{12} (11 kJ). Using this activation energy and $\alpha = \alpha_I$, $\Delta G^{0}_{13} = 51$ kJ is calculated from eqs (22) and (23). The free energy of tautomerization, ΔG^{0}_{I}, is then obtained by adding ΔG_{12} to ΔG_{13} to obtain 62 kJ. This value is in excellent agreement with values estimated by very different methods of < 68[19] and 59 kJ.[20]

The large value of α_B in relation to α_I can be rationalized by some combination of three effects. (i) For negatively charged bases, w_R may be considerable; (ii) as the basicity of B in eq. (13) approaches that of :POH, ΔG^0 will decrease leading to a larger α; (iii) determination of α is made difficult by the fact that competing reactions become increasingly important as the pH increases, and part of the differences in these values may be due to the experimental error in α_B. Albery *et al.*[18] have discussed the first two effects in relation to a different reaction. Experimental support for the importance of these first two factors was obtained by measuring the rate of the exchange reactions at 45°C catalysed by acetic acid. The values obtained were $k^{AcOH}_{D\rightarrow H} = 3.4 \times 10^{-5}$ M^{-1} s^{-1} and $k^{AcOD}_{H\rightarrow D} = 3.0 \times 10^{-4}$ M^{-1} s^{-1}. A value of $k^{AcOH}_{H\rightarrow OH} = 3.1 \times 10^{-4}$ M^{-1} s^{-1} is calculated at 45°C from a measured value at 30°C.[5] Together these rate constants would indicate isotope effects of $K^{D}_{12}/K^{H}_{12} \sim 1$ and $k^{H}_{13}/k^{D}_{13} \sim 9$. This latter value is close to the maximum isotope effect possible which would occur at a value of $\alpha_I = 0.35$. The uncertainty in the acetic acid-catalysed rate constants is high ($\pm 30\%$) because over 50% of the reaction is still catalysed by H_3O^+ and H_3PO_2.

Temperature dependence of rate constants

The kinetic isotope expressions given in Table 2, along with the values of the parameters determined in this work, have been used to calculate k^0 from the rate constants for the exchange reactions. These are shown in Fig. 3 as a function of $1/T$ along with the directly measured rate constants for oxidation reactions. The rate constants for the tritium exchange reaction[2] were taken to apply to the rate of exchange of T_2PO_2 with H_2O and not $HTPO_2$ with H_2O as cited in the literature.[1,6] The original article seems to indicate that the statistical factor of two had been applied in order to arrive at the former rate constant. The good agreement of the values of k^0 obtained from the various oxidation reactions and those obtained from the exchange reactions confirm reaction (1) as the common rate-determining step in these reactions.

The energy of activation from all of these measurements is 81 kJ, in good agreement with the value of 84 kJ obtained by the careful work of Griffith *et al.*[5]

CONCLUSIONS

Experimental determinations were made of the isotope effects on both deuterium–hydrogen exchange of hypophosphorus acid and the oxidation of hypophosphorous acid with tri-iodide. Deuteration of either the hypophosphorous acid or the water reveals a primary isotope effect that decreases the exchange reaction rate constant. A secondary isotope effect is determined that indicates that the deuterium ion is more effective than the hydronium ion in catalysing the reaction.

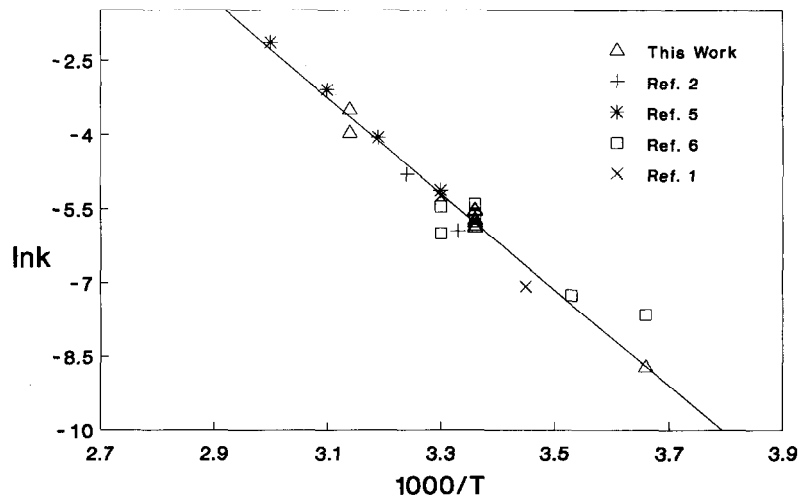

Fig. 3. Arrhenius analysis of kinetic results of this work and previous kinetic studies involving hypophosphorous acid.

The interpretation of these effects indicates that the rate-determining step of the reaction is the attack of a base on the PH proton of the protonated phosphorous acid. The theoretical calculation indicates that when the base is water the transition state occurs when the PH bond order is 0.2.

The Marcus theory is used to calculate a value of the free energy of tautomerization of hypophosphorous acid from $H_2PO(OH)$ to $HP(OH)_2$ as 62 kJ.

(*Received* 15 *September* 1989; *accepted* 8 *December* 1989)

Abstract—A convenient synthetic scheme that utilizes readily available starting materials and leads to the isolation of the linear, stereospecific NSNN tetradentate ligand, *N*-(2-aminoethyl)-2-[(2-aminoethyl)thio]acetamide (egeH, **6**), as its dihydrobromide salt is reported. Ligand **6** deprotonates and forms octahedral complexes with cobalt(III) of only one geometric isomer, for example, $[Co(ege)(NO_2)_2]\cdot 4H_2O$ (**7**). Compound **7** crystallized in the monoclinic space group $I2/c$, $a = 25.83(2)$, $b = 7.896(6)$, $c = 15.703(8)$ Å, $\beta = 90.36(5)°$, $V = 3202(3)$ Å^3, $Z = 8$. Refinement was based on 3105 reflections and converged at $R = 0.038$, $R_w = 0.047$. The structural determination reveals that the geometry of the backbone ligand is *cis*-β. In addition, the structures of $[Co(egpy)(NO_2)_2]$ (**8**) (where egpyH = *N*-(2-aminoethyl)-2-[(2-pyridylmethyl)thio]acetamide) and $[Co(eee)(NO_2)_2]Br$ (**9**) (where eee = 1,8-diamino-3,6-dithiaoctane), which also contain stereospecific ligands, were also determined. Compound **8** crystallized in the monoclinic space group $P2_1/c$, $a = 7.628(3)$, $b = 12.347(4)$, $c = 16.433(8)$ Å, $\beta = 108.39(3)°$, $V = 1470(1)$ Å^3, $Z = 4$. Refinement was based on 2249 reflections and converged at $R = 0.034$, $R_w = 0.042$. Compound **9** crystallized in the monoclinic space group $P2_1/a$, $a = 12.719(9)$, $b = 13.855(4)$, $c = 8.033(6)$ Å, $\beta = 111.32(4)°$, $V = 1319(1)$ Å^3, $Z = 4$. Refinement was based on 2300 reflections and converged at $R = 0.029$, $R_w = 0.035$. The tetradentate ligand in the former adopts the *cis*-β conformation, while for the latter, the expected *cis*-α geometry is observed. The structural parameters are compared and the origins of the attendant stereospecificities are discussed in terms of the nature of the internal donor atoms of the tetradentate ligands.

Over the years, octahedral cobalt(III) complexes containing flexible, linear tetradentate ligands have been intensely studied.[1–3] Previous investigations of their reaction chemistry have centred upon the activation of coordinated amino acid derivatives, proteins, thiolates and related compounds.[1,4,5]

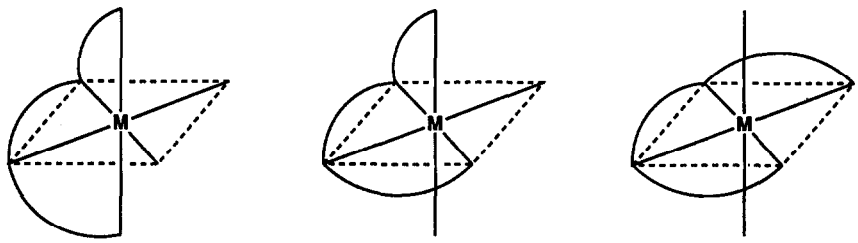

Fig. 1. The three possible coordination geometries for a flexible, linear tetradentate ligand in an octahedral metal complex.

Since three geometrical isomers (*cis*-α, *cis*-β and *trans*; see Fig. 1) are possible for such complexes, the synthetic design of ligands of high stereoselectivity, if not stereospecificity, is of special interest. The judicious incorporation of asymmetric centres into the backbone of the tetradentate ligand has met with varying degrees of success;[2,6,7] however, the exact geometry obtained has been difficult to predict and subsequent rearrangements under different reaction conditions have remained problematic.[8,9] We note that further isomers may result due to stereochemical considerations about planar, internal secondary amino donor atoms in linear chelating ligands such as triethylenetetramine (trien).[10]

Here we report on the synthesis and isolation of *N*-(2-aminoethyl)-2-[(2-aminoethyl)thio]acetamide (egeH). This compound is a linear, tetradentate ligand with an NSNN donor set containing internal thioether and amido groups, that belongs to the same class of ligands as egpyH (*N*-(2-aminoethyl)-2-[(2-pyridylmethyl)thio]acetamide), pygeH (*N*-[(2-pyridyl)methyl]-2-(2-aminoethyl)thioacetamide) and geeH (*N*-{2-[(2-aminoethyl)-thio]ethyl}-2-aminoacetamide), which coordinate to cobalt(III) with concomitant deprotonation of the amide moiety.[1]

It has been previously demonstrated[1] that each of these NSNN ligands, with the exception of egpy, generates a series of chemically interconvertible octahedral cobalt(III) complexes for which only one geometrical isomer is isolated in each case, as elucidated from ^{1}H and ^{13}C NMR spectroscopies. The lack of symmetry in the backbone ligands precludes identification of the gross geometry of the complexes by spectroscopic techniques. X-ray diffraction studies of $[Co(gee)(NO_2)_2]\cdot H_2O$[1] and $[Co(pyge)(NO_2)_2]\cdot H_2O$[11] have determined the stereochemistry as *cis*-β for complexes of these two ligands. In order to establish the geometry of cobalt(III) ege and egpy complexes, we have undertaken the structural determinations of $[Co(ege)(NO_2)_2]\cdot 4H_2O$ and $[Co(egpy)(NO_2)_2]$. In addition, the structure of $[Co(eee)(NO_2)_2]Br$, which is already known to adopt the *cis*-α geometry,[12,13] is reported for comparison. The chemical structures of the ligands in this article are depicted in Fig. 2.

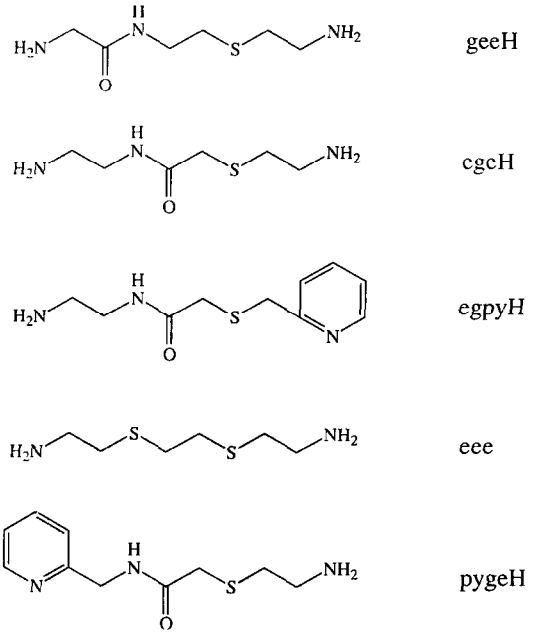

Fig. 2. Structural representations of the ligands in the present study.

EXPERIMENTAL

Materials and methods

^{1}H and ^{13}C NMR spectra were obtained on a Varian XL-300 spectrometer at 299.943 and 75.429 MHz, respectively. Spectra obtained in $CDCl_3$ or Me_2SO-d_6 solution were referenced to tetramethylsilane, while spectra obtained in D_2O solution were referenced to 3-(trimethylsilyl)propionic acid, sodium salt (^{1}H) or dioxane (^{13}C). A Varian DMS-80 spectrophotometer was utilized for visible

spectra at ambient temperature. All melting points are uncorrected. Elemental analyses were determined by Atlantic Microlabs Inc. (Atlanta, Georgia).

Preparation of compounds

Unless otherwise noted, all starting materials and solvents were obtained from standard sources and used without further purification.

N - {2 - [(*benzyloxy*)*carbonyl*]*aminoethyl*} - 2 - S-(*benzyloxy*)*carbonyl*]*mercaptoacetamide* (**2**)

A solution of benzyl chloroformate (17.93 g, 105 mmol) in toluene (25 cm^3) was added to a solution of *N*-(2-aminoethyl)-2-mercaptoacetamide (**1**)[1,14] (6.7 g, 50 mmol) in water at 0–5°C, followed quickly by a solution of $NaHCO_3$ (8.4 g, 100 mmol) in water (50 cm^3). The reaction was stirred vigorously for 35 min. Diethyl ether (20 cm^3) was added and the organic solvents removed on a rotary evaporator to give the white product in essentially quantitative yield. The material decomposed (turned pink) at 120–124°C without truly melting. An analytical sample was obtained from 95% ethanol as the monohydrate. Found: C, 57.33; H, 5.54. Calc. for $C_{20}H_{24}N_2O_6S$: C, 57.13; H, 5.75%. ^1H NMR ($CDCl_3$): δ 7.36 (broadened s, 10 H, aryl), 6.72 (br s, 1 H, NH), 5.26 (s, 2 H, OCH_2), 5.15 (br s, 1 H, NH), 5.11 (s, 2 H, OCH_2), 3.50 (s, 2 H, SCH_2CO), 3.36 (m, 4 H, NCH_2CH_2N). ^{13}C NMR ($CDCl_3$): 170.69, 168.56, 156.92, 136.38, 134.56, 128.79, 128.69, 128.54, 128.48, 128.16, 128.11, 70.00, 66.87, 40.64, 40.30, 34.48.

N - {2 - [(*benzyloxy*)*carbonyl*]*aminoethyl*} - 2 - *mercaptoacetamide* (**3**)

Sodium (1.27 g, 55.2 mmol) was dissolved carefully in absolute methanol (100 cm^3). Protected amino thiol (**2**) (20 g, 49.8 mmol) was added, along with methanol (200 cm^3). The reaction mixture was stirred for 3 h to give a light orange–pink solution. The methanol was removed on a rotary evaporator; then water (*ca* 100–150 cm^3) was added with stirring and the mixture was acidified to pH 3 by dropwise addition of conc. HCl. The off-white product was collected, washed well with water and petroleum ether and dried. Yield 7.88 g (59%); m.p. 109–111°C. Found: C, 53.89; H, 6.09. Calc. for $C_{12}H_{16}N_2O_3S$: C, 53.71; H, 6.01%. ^1H NMR ($CDCl_3$): δ 7.35 (broadened s, 5 H, aryl), 7.09 (br s, 1 H, NH), 5.25 (br s, 1 H, NH), 5.10 (s, 2 H, OCH_2), 3.38 (m, 4 H, NCH_2CH_2N), 3.16 (d, 2 H, SCH_2CO), 1.83 (t, 1 H, SH). ^{13}C NMR ($CDCl_3$): 170.17, 157.13, 136.38, 128.57, 128.24, 128.11, 66.92, 40.72, 40.59, 28.24.

N - {2 - [(*benzyloxy*)*carbonyl*]*aminoethyl*} - 2 - {(2 - [(*benzyloxy*)*carbonyl*]*aminoethyl*)*thio*}*acetamide* (**5**)

To a solution of NaOH (0.362 g, 9.1 mmol) in methanol–water (10 cm^3 : 2.5 cm^3) was added thiol (**3**) (2.43 g, 9.1 mmol) followed by 2-{[(benzyloxy)-carbonyl]amino}ethyl chloride (**4**)[15] (1.93 g, 9.1 mmol). The reaction mixture was heated at reflux for 2 h, then cooled to room temperature. The product precipitated and was collected and washed well with water. The crude product was recrystallized from hot absolute ethanol. Unoptimized yield, 1.21 g (30%); m.p. 131–133°C. Found: C, 58.99; H, 6.07. Calc. for $C_{22}H_{27}N_3O_5S$: C, 59.31; H, 6.11%. ^1H NMR ($CDCl_3$): δ 7.33 (broadened s, 10 H, aryl), 7.19 (br s, 1 H, NH), 5.38 (br s, 2 H, NH), 5.08 (s, 4 H, OCH_2), 3.36 (m, 6 H, NCH_2), 3.18 (s, 2 H, SCH_2CO), 2.65 (t, 2 H, SCH_2CH_2N). ^{13}C NMR ($CDCl_3$): 169.41, 156.61, 136.38, 128.53, 128.18, 128.10, 66.88, 40.91, 40.40, 40.10, 35.98, 33.36 (some accidental equivalences due to the similar environments of the (benzyloxy)carbonyl groups).

N - (2 - *aminoethyl*) - 2 - [(2 - *aminoethyl*)*thio*] *acetamide dihydrobromide* (egeH · 2HBr) (**6**)

Protected egeH (**5**) (1.11 g, 2.5 mmol) was stirred in 32% HBr–acetic acid (12.5 cm^3) for 1 h. At this time, diethyl ether (50 cm^3) was added, and the product collected. The crude material was stirred in absolute ethanol overnight, collected and washed with a little diethyl ether and dichloromethane. Yield 0.42 g (50%); m.p. 158–160°C. Found: C, 21.91; H, 5.13. Calc. for $C_6H_{17}Br_2N_3OS$: C, 21.25; H, 5.05%. ^1H NMR (D_2O): δ 3.55 (t, 2 H, CH_2NDCO), 3.39 (s, 2 H, SCH_2CO), 3.24 (t, 2 H, $SCH_2CH_2ND_2$), 3.17 (t, $D_2NCH_2CH_2ND$), 2.92 (t, 2 H, $SCH_2CH_2ND_2$). ^{13}C NMR (D_2O): 174.04, 39.85, 38.90, 38.01, 35.20, 30.03.

$Co(cge)(NO_2)_2$ (**7**)

To a solution of NaOH (0.05 g, 1.25 mmol) in methanol–water (3 cm^3 : 1.5 cm^3) was added **6** (0.22 g, 0.65 mmol). A solution of $NaNO_2$ (0.09 g, 1.30 mmol) in water (1.5 cm^3) was then added to the reaction mixture, followed by $CoCl_2 \cdot 6H_2O$ (0.15 g, 0.63 mmol). Air was bubbled through the solution for 4 h; after scratching and seeding, the orange product was collected. Yield 0.08 g (39%). Visible (H_2O) and ^{13}C NMR spectra (Me_2SO-d_6) were essentially identical to literature values.[1] ^1H NMR (Me_2SO-d_6): δ 5.60 (br s, 1 H, NH), 4.71 (br s, 1

Crystals

Crystals of $[Co(ege)(NO_2)_2] \cdot 4H_2O$ (**7**), $[Co(egpy)(NO_2)_2]$ (**8**)[1] and $[Co(eee)(NO_2)_2]Br$ (**9**)[12] were obtained by slow evaporation of saturated aqueous solutions.

Structure determinations

Unique data sets ($h\ k\ \pm l$) were measured at ~ 295 K using a Syntex $P2_1$ four-circle diffractometer (graphite monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å; 2θ–θ scan mode), yielding N independent reflections, N_0 with $I > 3\sigma(I)$ being considered "observed" and used in the full-matrix least-squares refinement after analytical absorption correction. Anisotropic thermal parameters were refined for the non-hydrogen atoms; for hydrogen atoms, x, y, z were refined in **8** and **9** (U_{iso} constrained) while for **7** all of (x, y, z, U_{iso})$_H$ were constrained at estimated values. Residuals at convergence are quoted on $|F|$; statistical weights derivative of $\sigma^2(I) = \sigma^2(I_{diff}) + 0.0005\sigma^4(I_{diff})$ were used. In no case was refinement of extinction necessary. Neutral atom complex scattering factors were employed;[16] computation used the X-RAY 76 program system[17] implemented by S. R. Hall. Crystallographic and refinement data for **7**, **8** and **9** are compiled in Table 1. Atomic positional parameters, anisotropic thermal parameters, complete tables of bond lengths and angles, hydrogen atom parameters, and tables of observed and calculated structure factors are available from the Editors or Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

New synthesis of the ligand, EgeH

The ligand, egeH (**6**), has been previously synthesized in solution by one of us,[1] but not isolated. The known amino thiol (**1**)[1,14] (Scheme 1) was protected at each terminus with benzyl chloroformate to give protected amino thiol (**2**). All attempts to introduce a (benzyloxy)carbonyl cap only at the amino end, with just one equivalent of protecting reagent, were not successful under various conditions of reaction. However, the desired protected thiol (**3**) could be obtained from **2** by selective cleavage of the thiocarbonate by sodium methoxide and subsequent work-up.

Thiol (**3**) was combined with the known protected alkyl chloride (**4**)[15] under basic conditions to give the protected egeH (**5**). The (benzyloxy)carbonyl caps on **5** were cleaved off with 32% HBr–acetic

acid to provide **6**, from which **7** was prepared in good purity and modest yield.

Structural results

The ligands ege and egpy in this study are designed to coordinate only in the *cis-β* fashion in octahedral cobalt(III) complexes; on the other hand, the symmetrical eee is known to bind only in the *cis-α* mode from spectroscopic studies.[12,13] The control of geometry in these cases originates from the stereochemical preferences of the internal donor atoms of the tetradentate ligand.[1] Thioether donors overwhelmingly tend to coordinate in a pyramidal fashion when situated at the junction of two five-membered chelate rings, in which at least one of the adjacent donor atoms is nitrogen or oxygen.[12,13] This empirical observation likely stems from the longer metal-to-sulphur bond lengths due to the larger radius of sulphur vs nitrogen or oxygen. On the other hand, the atoms in the neighbourhood of a coordinated deprotonated amide nitrogen-donor atom have a strong proclivity for remaining in the same plane in order not to disturb electron delocalization into the carbonyl function.[18] Thus, these two propositions should lead us to anticipate the *cis-β* geometry for the NSNN lignds in this study and explains the previously observed *cis-α* stereochemistry for cobalt(III) eee complexes,[12] which have the NSSN donor set. We point out that for the ligands in the present study, no additional isomers can arise due to the nature of the internal donor atoms (amido or thioether).

The molecular structures of **7**, **8** and **9** are depicted in Figs 3, 4 and 5, respectively. For each of the three structure determinations, one formula unit comprises the asymmetric unit of the centrosymmetric unit cell. The ligand disposition in both **7** and **8** is *cis-β*, while in **9** it is *cis-α* as expected. The geometries of the cobalt environments are col-

lected in Table 2; for the *cis*-β complexes, these are very similar, requiring the opposition of N(1) to S(7) and N(4,10) to N(b,a). For these latter, the geometrical parameters (Table 2) are generally very similar to those of $[Co(pyge)(NO_2)_2]\cdot H_2O$ (**10**)[11] and $[Co(gee)(NO_2)_2]\cdot H_2O$ (**11**).[1] Unusually large discrepancies noted are: (i) a large spread in the N(10)—Co—N(1,4) angles, presumably at least partly consequent upon the aliphatic or aromatic nature of N(10) and the presence or absence of H(94) in proximity to the hydrogen atom on N(1); (ii) an abnormally large N(1)—Co—N(b) angle in **10**[11] (compared to **7**, **8** or **11**) again presumably a consequence of the hydrogen atom *ortho* to the nitrogen atom of the aromatic ring in proximity to O(b2). Consistent large differences in Co—N(1) and Co—N(4) for compounds **7**, **8**, **10** and **11** are found throughout. It is notable that N(1) and N(4) are opposed to thioether and nitro ligating atoms, respectively; in addition, N(4) is deprotonated, which might lead to an anticipated shorter bond length.[1] As might be expected, the results for the ege derivative, **7**, most closely parallel those previously obtained for the gee analogue, **11**,[1] with the most significant differences being the angles N(4)—Co—N(10,a) (ege, 92.2(1), 88.9(1)°; gee, 90.5(1), 91.9(1)°).

The Co—NO_2 distances in **7** and **8** are within the usual range found in analogous cobalt(III) complexes.[19] The difference in Co—N(a,b) in the gee

[b] Reference 11.

adduct (**11**) (1.941(2), 1.920(2) Å)[1] parallels that observed in **7** and **8**, possibly reflecting slightly different *trans* effects of amine and amide nitrogens.

The eee cation in **9** is potentially of C_2 symmetry;[13] this is reflected in the geometry of Table 2. Relative to the other complexes, significant elongations are noted in both the average Co—S and Co—NO_2 bond lengths, which now lie *trans* to each other.

In each complex, there is considerable strain in the vicinity of the coordinated thioether atom(s), as evidenced by small Co—S—C (97.9–104.4°) and C—S—C (101.4–104.2°) angles. Ligand torsion angles for **7**–**9** are provided in Table 3. The relative planarity about N(4) is quite apparent in these values. In addition, a possible explanation for why the egpy derivative (**8**) is less robust than the ege (**7**), pyge (**10**) and gee (**11**) complexes can be put forth. Previous work[1] had determined that **8** can not be derivatized like **7**, **10** and **11** with concentrated HCl to give violet $[Co(L)Cl_2]$ (L = tetradentate ligand). In the egpy case, green solutions resulted, suggesting that possibly the pyridyl donor was being displaced. The pyridyl donor in **8** causes the out-of-plane chelate ring to flatten by the nature of the aromatic ring. This presumably causes further strain around the coordinated thioether atom as evidenced by the torsion angles involving S(7). In the concentrated acid, this angular strain can be relieved by substitution and protonation of the pyridyl group by the HCl.

Of course, the in-plane chelate ring in the pyge analogue (**10**) is also flattened by the pyridyl donor here.[11] However, the other in-plane chelate ring is already very planar due to the constraints invoked by the deprotonated amide, N(4) (*vide supra*), so that apparently this additional flattening causes very little extra strain about N(4).

UV-VISIBLE AND IR SPECTRA OF IRON(II) PHTHALOCYANINE POLYMER COMPLEXES LINKED BY BIS-PYRIDINATO LIGANDS

KARIFA BAYO and GUY VENANCE OUEDRAOGO

I.N.C. Université de Ouagadougou, Burkina Faso

and

GEORGES TERZIAN and DAVID BENLIAN*

Laboratoire de Chimie de Coordination, Université de Provence D22,
Av. Escadrille Normandie-Niemen, 13397 Marseille Cedex 13, France

(*Received* 20 *September* 1989; *accepted* 8 *December* 1989)

Abstract—The spectra of iron(II) phthalocyanine polymer complexes $(FePcL)_n$ with bis-pyridinato bridging ligands, where L = 44′-bipyridine (bpy), *trans*-1,2-(4-pyridyl)ethylene (bpe), 1,2-bis-(4-pyridyl)ethane (bpa), are discussed in comparison with the spectra of $Fe^{II}Pc$ and $FePcL'_2$, where L′ = pyridine, 4-cyanopyridine (4CNpy), in reference to the π back-donation to the macrocycle.

Phthalocyaninato iron(II) is a widely investigated porphyrin-like molecule which exhibits a strong tendency to axial ligation. A former study of many of its adduct complexes with pyridine and substituted pyridines gave a consistent view of the axial and equatorial π-bonding in the series.[1,2]

Recently, many papers have reported on linear FePc polymers in which iron atoms are axially linked by conjugated π-electron-containing bridging ligands.[3–6] The main objective is to create conducting materials based on a linear chain arrangement of transition-metal centred molecules. However, the electronic properties of the iron atom in such complexes has to be completely established in relation with the observed spectral data.

We report on UV-vis and IR spectrometric results of $(FePcL)_n$, where L = bpy, bpe, bpa, and we compare them with the spectra of $Fe^{II}Pc$, $FePc(py)_2$ and $FePc(4CNpy)_2$. New information is provided on the interplay of axial and equatorial back-donation from the metal.

EXPERIMENTAL

The reagents for the syntheses are commercial grade and the solvents used in spectrometric experiments are spectral grade.

$Fe^{II}Pc$ and $FePcL'_2$ (L′ = py, 4CNpy) were prepared as previously described.[2]

Two routes were followed to prepare $(FePcL)_n$: L = 44′-bipyridine (bpy), *trans*-1,2-(4-pyridyl) ethylene (bpe), 1,2-bis(4-pyridyl)ethane (bpa).

(i) 0.5 g of $Fe^{II}Pc$ and 0.5 g of L were mixed in 50 cm^3 of acetonitrile and the mixture refluxed for 3 h. Then, the initially green solution became colourless and a blue solid compound precipitated. The solid was collected and washed several times.

(ii) A ground mixture of 0.5 g of FePc and 3 g of L were fused at 260°C and heated at this temperature for 3 h. After cooling, the blue solid residue was ground, washed several times with distilled water and ethanol and dried.

UV-vis spectra were recorded on a Philips PU 8800 spectrometer using the second derivative recording in saturated DMSO solutions or finely ground solid dispersed in KBr.

IR spectra were recorded on Nicolet FT 20SXB and 20F spectrometers, using KBr and PE pellets, collecting 128 scans at 1 cm^{-1} resolution.

RESULTS AND DISCUSSION

Both routes to $(FePcL)_n$ yield the same compound identified by IR, UV-vis and Mössbauer spectra. Analogous procedures have been used to

* Author to whom correspondence should be addressed.

prepare pyrazine (pyz) derivatives of FePc.[4] The Fe content of our compounds determined by atomic absorption spectroscopy agrees neither with $FePcL_2$ nor $(FePcL)_n$ with a defined n value. We think these compounds may be a mixture of different polymer species. However, Mössbauer spectroscopy revealed only one site for Fe nuclei in this type of compound.[6,7]

ELECTRONIC ABSORPTION SPECTRA

The electronic data are grouped in Table 1. We have compared, where possible, our spectra of finely ground solid dispersed in KBr to solution spectra of the same compound and observe an agreement within 2–3 nm for the band maxima.

The characteristic π–π^* transition band is observed both for $(FePcL)_n$ and $(FePcL'_2)$ at *ca* 652 nm except for L = bpe in which it appears at 680 nm.

Compared to FePc, several supplementary bands appear between 400 and 590 nm in all spectra. $FePc(py)_2$ and $(FePcbpa)_n$ show one band at 415 nm in the spectra while two bands are observed at 415 and 500 nm in the spectra of $FePc(4CNpy)_2$, $(FePcbpy)_n$ and $(FePcbpe)_n$.

In a previous study of an extended series of $FePcL'_2$ (L′ = py and substituted pyridine),[2] we showed that the band at 410 nm, initially attributed to an Fe–L′ charge-transfer band, is in fact L′–Pc CT *via* Fe d_π bonds. We also have attributed the band at 500 nm to Fe–L′ CT as it only appeared in the spectra of complexes where the axial pyridine is markedly "π-acceptor".

Our results on bridged polymers confirm these assignments. Besides, M–L charge-transfer bands have been observed with this type of bidentate ligand used in this work. As one needs a suitable basis for the comparison of their electronic overlap properties, we can use the data collected on carbonyl or ammine complexes of the same ligands which have been extensively investigated (M = Cr, Fe, Co, W, Ru, etc.). All these complexes have CT bands at 450–500 nm assigned to metal to ligand transfer.[8–11] In a similar way, M–L CT bands have been reported at 400–600 nm in axially substituted (Fe, Ru, Os) porphyrins[12–16] or porphyrin-type macrocyclic iron complexes.[17] Recent MO calculations have shown that ring π back-donation is stronger in $Fe^{II}Pc$ than in Fe^{II} porphyrins explaining the relatively easy oxidation of the latter.[18] In the case of axially coodinated FePc the charge transfer to the d_π (d_{xz}, d_{yz}) orbitals appears to be strong enough to increase the back-bonding from the metal to the ring LUMO. The extent of back-bonding in $FePcL_2$ is stronger than in $Fe^{II}Pc$.[18]

According to these considerations, our electronic absorption results are in good agreement with an analysis based on π back-donation in the $(FePcL)_n$ and $FePcL'_2$ compounds. The conjugation in the bpy and bpe ligands makes the pyridine rings behave, each with regard to the other, as a withdrawing group like the 4-cyano groups. However the CN group is a stronger π-electron acceptor than the pyridine ring. As 4CNpy is only linked to the metal by the ring nitrogen, there is no chain formation.[7,19]

We have shown in our previous Mössbauer studies that substituted pyridines behave mainly as "σ donors".[8] It seems that the conjugation in bpy and bpe does not markedly perturb this property, as the spectra of $(FePcbpy)_n$ and $[FePcbpe)_n$ exhibit a L–Pc CT band at 415 nm like those of $(FePcbpa)_n$ and $FePc(py)_2$. The position of this band at 406 nm in the spectrum of $FePc(4CNpy)_2$ is consistent with the stronger electron withdrawing property of the cyano group.

The band at 500 nm in the spectra of $(FePcbpy)_n$, $(FePcbpe)_n$ and $FePc(4CNpy)_2$ does not exist in the spectra of $Fe^{II}Pc$, $FePc(py)_2$ and $(FePcbpa)_n$. There is no conjugation between the two pyridine rings of bpa. Hence this ligand acts as two linked, but independent, pyridine molecules explaining the fact that the spectra of $(FePcbpa)_n$ and $FePc(py)_2$ are similar and only exhibit the L–Pc CT band.

INFRARED SPECTRA

Infrared high-frequency and low-frequency data are listed in Tables 2 and 3.

The similarity between the IR spectra of phthalocyanine (H_2Pc) and metallophthalocyanines in the 1800–400 cm^{-1} region allows us to attribute the numerous vibrational bands to the macrocycle vibrational modes. All these bands consist of strongly coupled νCC, νCN, δCH and δCCN modes. Important modifications are noted in the 800–700 cm^{-1} region which corresponds to the CH deformations of the benzene and pyridine rings.[21–23]

The frequencies and the intensities of the peripheral CH deformation bands are sensitive to the stacking in the lattice. When the polymer is formed, the Pc molecules lie apart from each other with much less interaction than, for instance, in any crystalline modification of FePc.

The axially substituted species show bands of the ligands between 1600 and 1200 cm^{-1}. The strong band at 1590 cm^{-1} in the spectra of free ligands is slightly low shifted for $FePc(py)_2$ while it remains almost constant in frequency in the spectra of $(FePcbpy)_n$ and $(FePcbpe)_n$. An important loss of intensity in all the cases is the main feature.

We focus on two bands at 1332 and 1288 cm^{-1} in the Fe^{II} spectrum. In the $(FePcL)_n$ series the band at 1288 cm^{-1} appears to remain almost constant in frequency and intensity while the band at 1332 cm^{-1} varies in two ways: down shift to 1328 cm^{-1} and loss of relative intensity. We relate this effect to the π overlap in the chain. This influence on π bonding sensitive vibrations in the series of ligands can be referred to the similar effect observed in the spectra of $(CO)_5W$–L–$W(CO)_5$,[9] in which bpe appears to be the most effective in delocalizing the π charges between the $W(CO)_5$ moieties.

The remaining FePc bands are kept nearly constant except the group below 1110 cm^{-1} which derives from the composite band at 1081 cm^{-1} in $Fe^{II}Pc$. Under axial substitution, this band is split in 1098–1070 cm^{-1} in bpe, 1097–1071 cm^{-1} in

bpy, 1095–1081 cm^{-1} in bpa and 4CNpy through π coupling. The constancy is confirmed at 912, 820, 779, 753 and 730 cm^{-1}.

In the 500–50 cm^{-1} region, $Fe^{II}Pc$ has four characteristic bands (Table 3). Low frequency spectra are sensitive to the charge densities around the metal and supply useful data on the core structure of phthalocyanines.[24] The result of axial ligation of pyridine bases is a supplementary band at *ca* 400 cm^{-1} easily assigned to the ring deformations of L. Out of plane deformation modes of Pc assigned at 365 and 435 cm^{-1} remain nearly constant and show no obvious dependence on the ligands. On the other hand, the Fe–N_4 stretching at 308 cm^{-1} shifts largely towards the high frequencies in the spectra of axially substituted compounds. The observed shift is bpa > bpy > bpe for $(FePcL)_n$ and py > 4CNpy for $FePcL'_2$. This trend of variation follows the overall donor capacity of the bridging ligands. This mode of vibration involves the relative positions of Fe and ligand atoms in an almost constant "σ skeleton". The movement of Fe makes the π bonding region between Fe d_π orbitals and equatorial and axial π orbitals change markedly. The interplay of axial versus equatorial back-bonding determines the charge distribution in the complex.

Consequently the frequency of this vibrational mode is related to the importance of the π overlaps. Then the variation of νFe–N_4 is in good agreement with that of the Fe–L CT band in $(FePcL)_n$ electronic absorption spectra.

CONCLUSION

UV-vis and IR data on our homogeneous series of $(FePcL)_n$ polymers show evidence for three features depending on the conjugation of π bonds in the bridging ligands L:

(i) An Fe–L CT band near 500 nm is observed with bpa > bpy > bpe, showing that the π acceptor capacity is modulated by the extent of conjugation in the bridge.

(ii) The IR high-frequency bands of the axially substituted complexes of FePc remain almost constant except for the 1332 cm^{-1} absorption which shows strong dependence on the π overlaps between axial and equatorial systems through the d_π orbitals of Fe.

(iii) The Fe–N_4 stretching band at 308 cm^{-1} in FePc is remarkably sensitive to the interplay between axial and equatorial back-bonding as shown by the good correlation with the Fe–L CT electronic absorption.

A SCHIFF BASE DERIVED REDOX-RESPONSIVE RECEPTOR MOLECULE AND RELATED COMPOUNDS WITH POTENTIAL AS NON-LINEAR OPTICAL MATERIALS

PAUL D. BEER* and HARRISON SIKANYIKA

Department of Chemistry, University of Birmingham, P.O. Box 363, Birmingham B15 2TT, U.K.

(*Received* 31 *October* 1989; *accepted* 8 *December* 1989)

Abstract—A new Schiff base redox-responsive receptor molecule (**8**) containing a ferrocene redox-active centre and a benzo-15-crown-5 metal cation binding unit is reported. The reversible redox couple of **8** shifts anodically on addition of Na^+, K^+ and Mg^{2+} guest cations. The synthesis and electrochemical properties of two related ferrocenyl Schiff base compounds (**9** and **10**) possessing electron-donor and -acceptor moieties which have potential as non-linear optical materials are also reported.

We and others[1] have demonstrated that reducible[2–4] or oxidizable[5–7] redox-active macrocyclic receptor molecules can electrochemically recognize[1] cationic (metal, ammonium[8]) and anionic (bromide)[9] guests either "through space" electrostatic perturbation and/or via various conjugated bond linkages linking the heteroatoms of the ionophore to the redox centre. The magnitude and type (one- or two-wave) of the shift in the respective couple of these host systems produced by charged guest binding is dependent upon a combination of many factors[1] including: (i) redox-active host–guest complementarity; (ii) the charge/radius ratio or polarizing power of the guest; (iii) proximity of host binding site to redox centre; (iv) nature of redox centre; and (v) nature of bond linkage from host binding site to redox centre. With respect to studying the latter factor we report here the synthesis, coordination and electrochemical properties of a new redox-responsive receptor molecule (**8**) in which a ferrocene redox-active centre is linked to a benzo-15-crown-5 cation binding unit via a conjugated Schiff base covalent bond and two related compounds (**9** and **10**) possessing electron-donor and -acceptor moieties which have potential as new non-linear optical (NLO) materials.

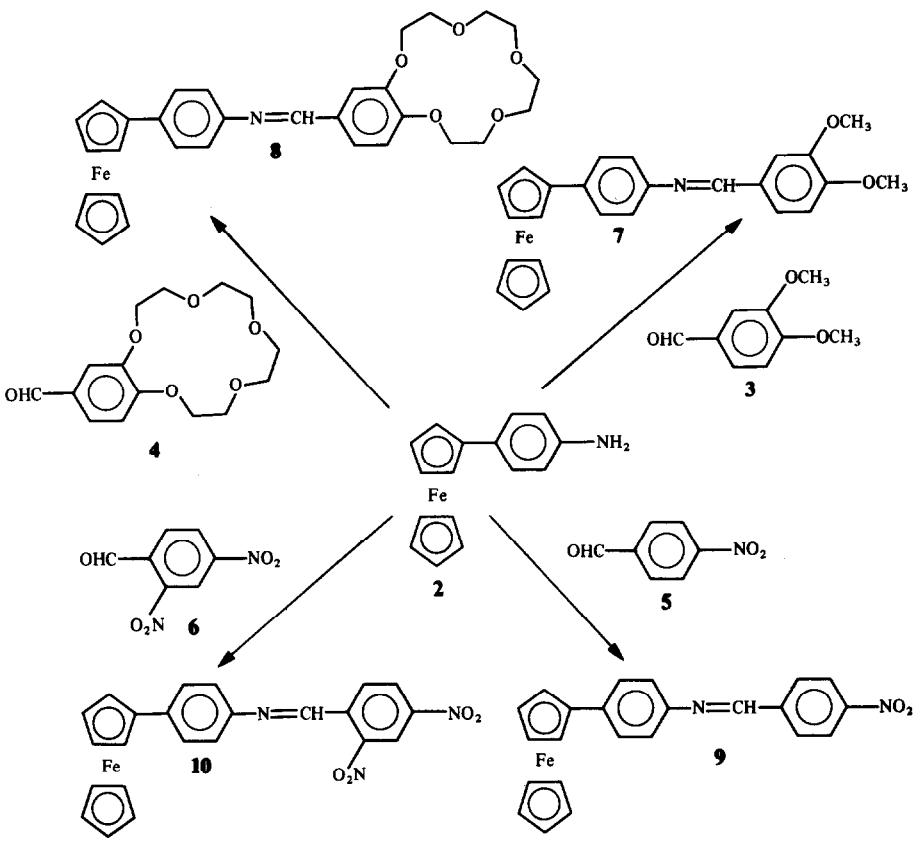
RESULTS AND DISCUSSION

4-Ferrocenylaniline (**2**) was prepared via the Sn/HCl reduction of 4-ferrocenylnitrobenzene (**1**).[10] Condensation of **2** with 3,4-dimethoxybenzaldehyde (**3**), 4-formylbenzo-15-crown-5 (**4**),[11] *p*-nitrobenzaldehyde (**5**) and 2,4-dinitrobenzaldehyde (**6**) gave the respective Schiff base products, **7**–**10**, in generally excellent yields (Scheme 1). The new, air-stable compounds were characterized by elemental analyses, fast atom bombardment mass spectrometry (FABMS), IR and ^1H NMR spectroscopy (see Experimental).

The elecrochemical properties of **7**–**10** were investigated using cyclic voltammetry in anhydrous acetonitrile with $[n\text{-}Bu_4N]BF_4$ as supporting electrolyte and the results are presented in Table 1. Each compound exhibits a reversible redox oxidation wave in the range +0.40 to +0.50 V (vs SCE) typical of a substituted ferrocene derivative. Comparing these values it is surprising that electrochemically the powerful electron-withdrawing nitro groups present in **9** and **10** have very little effect on the ferrocenyl redox couple of each compound, suggesting that inductive communication through the Schiff base bond linkage is extremely weak. Cyclic voltammograms were also recorded after progressive addition of stoichiometric molar equivalents of Na^+, K^+ and Mg^{2+} cations to the electrochemical solutions of **7** and **8**. The addition of any of the



Scheme 1.

three metal cations to **7** had negligible effect on the ferrocene/ferricinium redox potential ($\Delta E_{1/2} \leqslant 5$ mV). The redox couple of **8**, however, shifted anodically by 10, 20 and 60 mV on addition of four equivalents of K^+, Na^+ and Mg^{2+} cationic guests, respectively. The magnitudes of these shifts reflect the differing polarizabilities of the bound metal cations, Mg^{2+} possessing the largest charge/radius ratio produces the greatest value of anodic shift, and K^+ the smallest. These findings are in agreement with those found with the *cis* and *trans* olefinic-linked ferrocene-benzo-15-crown-5 ionophores (**11a** and **11b**) in which K^+, and Na^+ produce modest shifts of 20 and 30 mV, respectively, whereas with Mg^{2+} a $\Delta E_{1/2}$ value of 70 mV is observed.[12] It is noteworthy that although compared to **11** receptor **8** contains an extended conjugated Schiff base bond linkage from the ferrocene redox centre to the benzo-crown-ether binding unit, the magnitude of $\Delta E_{1/2}$ values produced by metal cation binding are similar.

Table 1. Electrochemical data

Compound	$E_{1/2}$ (V)[a]	ΔE_p (mV)[b]
7	+0.44	80
8	+0.44	80
9	+0.46	80
10	+0.46	80

[a] Obtained in acetonitrile solution containing 0.2 M $[n\text{-}Bu_4N]BF_4$ as supporting electrolyte. Potentials were measured with reference to SCE at 24 ± 1°C at 0.2 V s^{-1} scan rate.

[b] Separation between anodic and cathodic peak potentials of cyclic voltammograms; values for ferrocene under the same conditions ranged from 75 to 85 mV.

Interestingly, addition of one equivalent of Mg^{2+} to **9** led to an unexpected anodic shift of 50 mV in the ferrocene/ferricinium redox couple accompanied by a large decrease in the peak current. Additional equivalents of Mg^{2+} did not induce any further shift in the redox potential but resulted in a progressive decrease in the peak current. These observations infer the Mg^{2+} cation interacts with the remote nitro group of **9** with the metal cation influencing the charge distributions of the respective canonical representations shown in Fig. 1.

Considerable interest is currently being shown in the synthesis of new materials with NLO properties

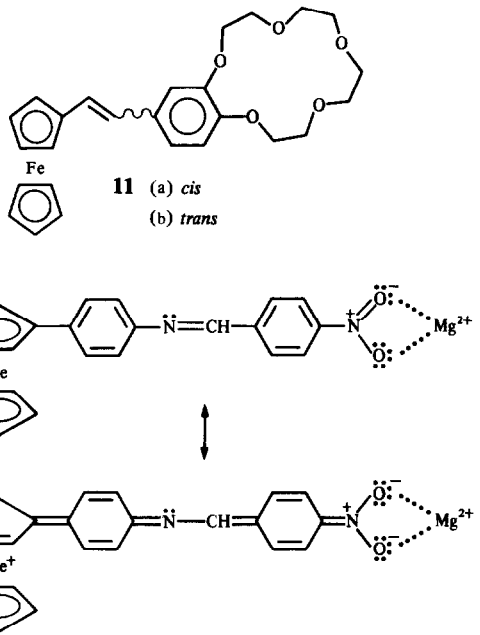


Fig. 1. Proposed interaction of Mg^{2+} with **9**.

which have applications in laser technology, telecommunications and integrated optical devices.[13] Non-centrosymmetric, highly polarizable organic[14] and organometallic[15] conjugated molecular systems bearing a donor group at one end and an acceptor group at the other have been shown to produce materials displaying large macroscopic optical nonlinearity.

Compounds **9** and **10** possess some of these features and an initial indication of potential NLO behaviour can be elucidated from solvation effects on solution UV–vis spectra. The UV–vis spectrum of **10** is markedly affected by varying the solvent. In hexane two absorptions at 390 and 530 nm are observed, whereas in N,N′-dimethylformamide large hypsochromic shifts to 380 and 500 nm are observed. In contrast, the analogous UV–vis spectra of the crown compound **8** was expectedly unaffected by solvent variation. As a result of this solvatochromic behaviour of **10** it is currently being screened for second-harmonic generation (SHG) and the results will be reported in a future paper.

EXPERIMENTAL

General

^{1}H NMR spectra were recorded at 400 and 270 MHz using TMS as internal standard. IR spectra were obtained on a Perkin–Elmer 297 instrument as KBr discs. Electrochemical measurements were carried out using a PAR 174 polarographic analyser.

4-Ferrocenylnitrobenzene (**1**)[10] and 4-formylbenzo-15-crown-5 (**4**)[11] were prepared according to literature methods. All elemental analyses were performed at the University of Birmingham's Microanalytical Department.

Syntheses

Preparation of 4-*ferrocenylaniline* (**2**). A three-necked, 500 cm^3, round-bottomed flask was equipped with a mechanical stirrer and a reflux condenser. To this, a solution of 4-ferrocenylnitrobenzene (1.88 g, 6.12 mmol) in concentrated HCl (25 cm^3) and absolute ethanol (40 cm^3) was added, followed by tin granules (4.5 g, 37.82 mmol), and the mixture was heated under reflux (N_2 atmosphere) for 4 h. The reaction mixture was allowed to cool to room temperature; water (200 cm^3), dichloromethane (200 cm^3) were added and the mixture basified with 40% NaOH to pH 14. The mixture was filtered through celite, extracted with dichloromethane and filtered again to remove residual $Sn(OH)_2$. After drying (Na_2SO_4) and removal of the solvent, the residue was recrystallized from dichloromethane–petroleum ether (60–80°C) to give **2** as orange crystals in 94.5% yield; m.p. 154–156°C; *m/z* 277; IR 1620 (—N—H bend), 3375, 3475 cm^{-1} (—N—H stretch); ^{1}H NMR ($CDCl_3$) δ: 3.45 (s, broad, 2H, NH_2), 4.0 (s, 5H, FcH), 4.21 (t, J = 1.8 Hz, 2H, FcH), 4.50 (t, J = 1.8 Hz, 2H, FcH), 6.50 (d, J = 9 Hz, 2H, ArH), 7.50 (d, J = 9 Hz, 2H, ArH).

Preparation of **7**. To a solution of **2** (0.30 g, 1.08 mmol) in dry toluene (150 cm^3) was added 3,4-dimethoxybenzaldehyde (0.18 g, 1.08 mmol), one drop of concentrated HCl and the mixture was refluxed under N_2 overnight using a Dean and Stark apparatus to azeotrope off the water formed during the reaction. The reaction mixture was allowed to cool to room temperature and the solvent removed *in vacuo*. The residue was chromatographed on an alumina column eluting with a petroleum ether (40–60°C)–dichloromethane gradient. The orange band was collected. After removal of the solvent mixture, recrystallization from *n*-hexane gave **7** as orange crystals, 0.37 g (80.4%); *m/z* 425; IR 1620 (—C=N— stretch), 1575, 1325 cm^{-1} (NO_2 asym. and sym. stretches, respectively); ^{1}H NMR ($CDCl_3$)δ: 3.94 (s, 3H, OCH_3), 3.98 (s, 3H, OCH_3), 405 (s, 5H, FcH), 4.30 (t, J = 1.8 Hz, 2H, FcH), 4.62 (t, J = 1.8 Hz, 2H, FcH), 6.88–7.65 (m, 7H, ArH), 8.41 (s, 1H, —N=CH—). Found: C, 67.3; H, 6.0; N, 3.2. Calc. for $C_{25}H_{23}O_2NFe \cdot H_2O$: C, 67.7; H, 5.6; N, 3.2%.

Preparation of **8**, **9** *and* **10**. Compounds **8**, **9** and **10** were prepared by slight modification of the above procedure for **7**. Thus, after removal of the solvent from the reaction mixture, the residue was exhaustively extracted with boiling hexane. Removal of the hexane gave the crude product which was recrystallized from dichloromethane–*n*-hexane to give the pure products in yields ranging from 55 to 94%.

Compound **8**: yield, 55%; m.p. 155–157°C; *m/z* 555; IR 1620 (—C═N— stretch), 1300–1100 cm^{-1} (C—O—C stretch); ^1H NMR ($CDCl_3$)δ: 3.75–4.20 (m, 16H, crown-H), 4.00 (s, 5H, FcH), 4.30 (t, $J = 1.8$ Hz, 2H, FcH), 4.66 (t, $J = 1.8$ Hz, 2H, FcH), 6.85–7.59 (m, 7H, ArH), 8.40 (s, 1H, —N═CH—). Found: C, 64.7; H, 5.2; N, 2.4. Calc. for $C_{31}H_{33}O_5NFe \cdot H_2O$: C, 64.9; H, 6.1; N, 2.4%.

Compound **9**: yield, 94%; m.p. 241°C (dec); *m/z* 410; IR 1620 (—C═N— stretch), 1575, 1340 cm^{-1} (NO_2 asym. and sym. stretches, respectively); ^1H NMR ($CDCl_3$)δ: 4.05 (s, 5H, FcH), 4.36 (t, $J = 1.8$ Hz, 2H, FcH), 4.68 (t, $J = 1.8$ Hz, 2H, FcH), 7.20 (d, $J = 9$ Hz, 2H, ArH), 7.55 (d, $J = 9$ Hz, 2H, ArH), 8.10 (d, $J = 9$ Hz, 2H, ArH), 8.35 (d, $J = 9$ Hz, 2H, ArH), 8.64 (s, 1H, —N═CH—). Found: C; 67.1; H, 4.2; N, 6.5. Calc. for $C_{23}H_{18}O_2N_2Fe$: C, 67.3; H, 4.4; N, 6.8%.

Compound **10**: yield, 71.4%; m.p. 206°C (dec); *m/z* 455; IR 1595 (—C═N— stretch), 1520, 1340 cm^{-1} (NO_2 asym. and sym. stretches, respectively); ^1H NMR ($CDCl_3$)δ: 4.08 (s, 5H, FcH), 4.38 (t, $J = 1.8$ Hz, 2H, FcH), 4.62 (t, $J = 1.8$ Hz, 2H, FcH), 7.32 (d, $J = 9$ Hz, 2H, ArH), 8.60 (t, $J = 0.9$ Hz, 2H, ArH), 8.94 (t, $J = 0.9$ Hz, 1H, ArH), 9.10 (s, 1H, —N═CH—). Found: C, 55.6; H, 4.0; N, 8.6. Calc. for $C_{23}H_{17}O_4N_3Fe \cdot 2H_2O$: C, 56.2; H, 4.3; N, 8.6%.

A MODIFIED SYNTHESIS OF RUTHENIUM(II) HEXAAQUA SALTS

PAUL BERNHARD,* MARGRET BINER and ANDREAS LUDI†

Institut für Anorganische Chemie, Universität Bern, CH-3000 Bern 9, Switzerland

(*Received* 31 *October* 1989; *accepted* 8 *December* 1989)

Abstract—An efficient preparation of ruthenium aqua ions starts from the hydrated dioxide. Oxidation by periodate produces ruthenium tetroxide which is reduced by metallic lead to $[Ru(H_2O)_6]^{2+}$. Ion exchange and crystallization affords pure $[Ru(H_2O)_6](tos)_2$ (tos = *p*-toluenesulphonate) in 70–80% yield.

Some time ago we reported the first preparation of solid salts of the ruthenium aqua ions[1] as model systems for electron transfer[2] and ligand exchange[3] studies. The ruthenium(II) salt in particular was recognized as a very versatile and promising starting reagent for the synthesis of a wide variety of coordination compounds.[4] Surprisingly, this aqua ion could also be employed for very facile and efficient preparations of organoruthenium species, especially sandwich and half-sandwich compounds.[5] This reactivity of $[Ru(H_2O)_6]^{2+}$ toward unsaturated organic molecules evoked the interest of polymer chemists and stimulated its successful application as a catalyst in polymerization reactions.[6] Despite this remarkably rich chemistry the actual use of ruthenium aqua salts is rather limited owing to the quite difficult and tedious synthesis starting from ruthenium metal.[1] In order to make this potentially very useful compound more readily available, we have simplified the procedure as much as possible. This paper reports an improved and more efficient preparation of solid $[Ru(H_2O)_6]^{2+}$ salts.

EXPERIMENTAL

The overall reaction is summarized by the following equation

$$RuO_2 \xrightarrow[H_2SO_4]{NaIO_4} RuO_4 \xrightarrow[H_2SiF_6]{Pb} [Ru(H_2O)_6]^{2+}$$

$$\xrightarrow{\text{Ion exchange}} [Ru(H_2O)_6](tos)_2$$

$$\downarrow$$

$$PbSO_4$$

(tos = *p*-toluenesulphonate). Deionized water was used throughout. Chemicals were from Fluka, $RuCl_3 \cdot aq$ was a loan from Johnson Matthey.

(1) *Generation and reduction of* RuO_4

The complete arrangement displayed in Fig. 1 was swept with Ar for 20 min. H_2SO_4 was added over 1 h under continuous stirring of A and B and

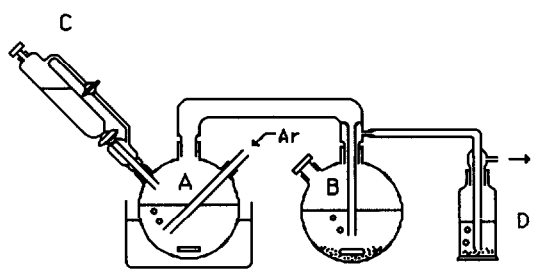

Fig. 1. Production of $[Ru(H_2O)_6]^{2+}$ solution. A: 500-cm^3 flask with 5 g of $RuO_2 \cdot aq$ and 25 g of $NaIO_4$ in 200 cm^3 of H_2O; B: 500-cm^3 flask containing 330 cm^3 of 1 M H_2SiF_6 and 35 g of Pb grains activated in 50 cm^3 of 50% HNO_3. A and B are stirred magnetically. C contains 100 cm^3 of icc-cold 50% H_2SO_4, D contains 70 cm^3 of 1 M H_2SiF_6 and 5 g activated Pb. Distance between A and B is as short as possible and all joints are without grease.

* Present address: CIBA–GEIGY AG, 1701 Fribourg, Switzerland.

† Author to whom correspondence should be addressed.

slow Ar bubbling (1 bubble per second). Formation of RuO_4 was indicated by a yellow colour in A. The Ar-stream was then increased three-fold until a dark colour appeared in B, then doubled in intensity. After complete addition of H_2SO_4, A was allowed to reach room temperature and Ar bubbling was continued until this solution was virtually colourless, which required about 2 days. If this did not occur another portion of 3 g of $NaIO_4$ was added. The colour in B should now be a deep purple–red. If it had a brownish tint another portion of 10 g of freshly activated Pb was added to B. The stirring of both solutions was continued for another day while A was gently warmed to 40°C.

Caution: Owing to the toxicity and sensitivity of RuO_4 the whole operation was carried out in a well ventilated, dark hood.

(2) *Removal of* $PbSO_4$, *ion exchange and crystallization*

The solution in B (Fig. 1) was decanted into an Ar-filled 1 dm^3 flask containing 100 cm^3 of Ar-saturated 2 M H_2SO_4 and stirred under Ar bubbling for 30 min. After standing for 15 min the mixture was quickly passed through a large ($\gtrsim$ 10 cm) G4 frit, and the filtrate was diluted to 4 dm^3 with Ar-saturated water. Ion exchange was then carried out under Ar using Schlenk techniques[7] (Fig. 2) adapted to the appropriate scale. After flushing the whole configuration with Ar connecting dropping funnel to collecting vessel (a to f in Fig. 2) maintained a constant Ar atmosphere throughout the ion-exchange process. The loaded column was washed first with 300 cm^3 of water and then with 700 cm^3 of 0.1 M Htos. Elution was achieved with 1.8 M Htos at a rate of about two drops per second. The resulting red solution ($\sim$ 400 cm^3) was rotatory concentrated at $\lesssim$ 40°C until precipitation of a solid began, i.e. to approximately 200 cm^3. Cooling to 0°C for 2 days afforded a crystalline mass which was collected on a G3 frit, thoroughly washed with ethyl acetate to remove solid Htos, then with ether, and dried *in vacuo* for 2 h. Yield: 12.98 g $[Ru(H_2O)_6](tos)_2$ (79%). Found: C, 30.6; H, 4.9; S, 11.2; H_2O, 19.7. Calc.: C, 30.5; H, 4.7; S, 11.6; H_2O, 19.6%.

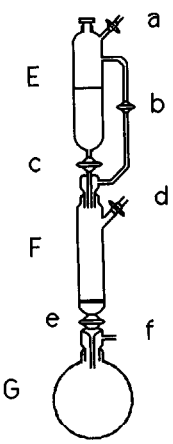

Fig. 2. Ion exchange of $[Ru(H_2O)_6]^{2+}$. E: 4000-cm^3 dropping funnel. F: ion-exchange column (30 × 3 cm) with G2 frit, 50 g of Dowex WX8 in H^+ form, Cl^- free by Ag^+ test. G: 1000-cm^3 flask. a, b, c, d, e: stopcocks.

Depending on the availability of starting materials the following adaptions can be made:

(i) Commercial $RuCl_3 \cdot aq$ (7.3 g) is heated in 300 cm^3 of 5 M NaOH to 60°C (30 min) then stirred at room temperature overnight. The extremely fine black powder is washed Cl^--free and used for the reaction with $NaIO_4$. Based on the Ru content of $RuCl_3(aq)$, yields for $[Ru(H_2O)_6](tos)_2$ are in the 50 to 70% range.

(ii) Ru sponge (3 g) is fused with 12 g of Na_2O_2 in a Ni crucible to red glow for 5 min. After cooling, the product is dissolved in 200 cm^3 of water to form a deep orange solution which is used to start the reaction with $NaIO_4$. Yields are between 70 and 75%.

DISCUSSION

General properties of $[Ru(H_2O)_6](tos)_2$

$[Ru(H_2O)_6](tos)_2$ is obtained as pink prismatic crystals. A simple test of sample purity is made by measuring the UV–vis spectrum of a freshly prepared solution under Ar in 0.5 M trifluoromethanesulphonic acid. The two ligand-field bands show the following absorption maxima and extinction coeffcients, respectively: 534 and 394 nm, with 12 and 15 $M^{-1}\,cm^{-1}$. Virtually identical values are measured in 0.5 M H_2SO_4.[4] Extinction measurements have to be made immediately after dissolving the solid complex salt in order to avoid errors owing to partial oxidation and subsequent hydrolysis of the ruthenium(III) species. Pink $[Ru(H_2O)_6]^{2+}$ is easily oxidized by atmospheric oxygen to yellow $[Ru(H_2O)_6]^{3+}$ (λ_{max} = 390 nm, ε = 30 $M^{-1}\,cm^{-1}$[4]). The corresponding reduction potential is 0.21 V. Crystalline $[Ru(H_2O)_6](tos)_2$ is surprisingly stable and is best stored under Ar at 0°C. No decomposition is observed for several weeks even at ambient conditions.

Since the tosylate salt of $[Ru(H_2O)_6]^{2+}$ is only very sparingly soluble in MeOH, EtOH and THF, it can be easily converted to the $CF_3SO_3^-$ salt by

ion exchange under Ar. After rotatory evaporation of the resulting $CF_3SO_3^-$ solution at 50°C to constant volume, cooling to −20°C for 2 days produces a pink–red precipitate which was collected by filtration and compressed with a glass stopper to remove occasionally occurring colourless crystals (presumably CF_3SO_3H hydrates). The solid was washed with a small amount of ice-cold ether, transferred into an Ar filled Schlenk vessel and stored at −20°C. This salt is stable at −20°C only for a few days but exhibits considerably higher solubility in non-aqueous solvents. The Tutton salt and its spectroscopic properties have also been reported.[8]

The conventional starting reagent in preparative ruthenium chemistry, $RuCl_3 \cdot aq$, is an ill-defined compound with varying composition and oxidation state. Syntheses are thus not very reproducible and produce low yields, quite often sacrificing organic ligands for the preparation of low-valent ruthenium–organic compounds. In contrast $[Ru(H_2O)_6](tos)_2$ and its $CF_3SO_3^-$ analogue are well defined ruthenium(II) species with a substitution lability[3] adapted for a variety of elegant synthetic routes.

Acknowledgements—We thank Johnson Matthey for a loan of ruthenium chloride, the Swiss National Science Foundation (Grant No. 20-5370.87) for support, and CIBA–GEIGY AG for the elemental analyses.

CARBONYL AND HALOCARBONYL COMPLEXES OF MOLYBDENUM AND TUNGSTEN WITH OXYGEN DONOR LIGANDS

P. PLANINIĆ* and H. MEIDER

Rudjer Bošković Institute, Department of Physical Chemistry, Zagreb, Croatia, Yugoslavia

(*Received* 20 *November* 1989; *accepted* 8 *December* 1989)

Abstract—Halogen oxidation of trisubstituted carbonyl complexes of molybdenum(0) and tungsten(0) containing bis[(diphenylphosphinyl)methyl]phenylphosphine oxide (RPPh) and methylenebis[diphenylphosphine oxide] (MDPO) under controlled conditions afforded diamagnetic, seven-coordinate compounds: $[M(CO)_3(RPPh)X_2]$ and $[M(CO)_3(MDPO)X_2]$, where M = Mo, W and X = Br, I. The reaction of molybdenum and tungsten hexacarbonyls with bis[(diphenylphosphinyl)methyl]ethyl phosphinate (RPOEt) was also investigated. Complexes of the type *cis*-$[M(CO)_4(RPOEt)]$ were isolated, which by treating with iodine released one molecule of carbon monoxide to give metal(II) derivatives, $[M(CO)_3(RPOEt)I_2]$.

Seven-coordinate complexes of molybdenum(II) and tungsten(II) continue to be an area of considerable interest. Amongst these, much attention has been paid to halocarbonyl derivatives containing amine, phosphine, stibine or arsine mono- and polydentate ligands.[1] Up until now, very few studies of analogous compounds with phosphine oxides as attached ligands have been conducted. The only hitherto known seven-coordinate halocarbonyl complexes of molybdenum and tungsten containing a phosphine oxide ligand have been those reported recently by Baker and Kendrick.[2] They prepared iodo-derivatives of molybdenum(II) and tungsten(II) with monodentate triphenylphosphine oxide starting from the corresponding highly reactive bis-acetonitrile diiodo tricarbonyl species.

In recent years we have investigated the synthesis and complexing ability of different organophosphorus ligands.[3–6] As a continuation of our work on metal carbonyl chemistry, in this paper we describe the preparation and properties of the new seven-coordinate halocarbonyl complexes of molybdenum(II) and tungsten(II) containing the following bidentate and potentially tridentate phosphine oxides: methylenebis[biphenylphosphine oxide] (MDPO), bis[(diphenylphosphinyl)methyl] phenylphosphine oxide (RPPh) and bis[(diphenylphosphinyl)methyl]ethyl phosphinate (RPOEt). We also report on the new molybdenum(0) and tungsten(0) tetracarbonyl complexes with the RPOEt ligand.

RESULTS AND DISCUSSION

Starting materials for the preparation of halocarbonyl complexes were trisubstituted carbonyl compounds $M(CO)_3(RPPh)$ and $M_2(CO)_6(MDPO)_3$[6] and tetracarbonyl species $M(CO)_4(RPOEt)$ (M = Mo, W). By halogen oxidation of the above complexes under controlled conditions the following compounds were isolated: $M(CO)_3(RPPh)X_2$, $M(CO)_3(MDPO)X_2$ and $M(CO)_3(RPOEt)I_2$ (M = Mo, W; X = Br, I) (Table 1).

Due to the insolubility of the starting carbonyl species or their highly unstable nature in most solvents, they were dispersed in a suitable solvent prior to halogen oxidation. Iodine or bromine dissolved in benzene or CCl_4 was then added dropwise into the suspension of the corresponding carbonyl complex in *n*-heptane or CCl_4 at temperatures below 0°C. The colour of the suspension began to change immediately with the addition of small portions of halogen. When all of the oxidizing agent had been added, the reaction mixture was additionally stirred

in the cold until the halogenated products were free from unreacted tricarbonyl or tetracarbonyl derivatives. The course of the reaction was followed by IR spectroscopy. The MDPO halocarbonyls were also prepared by a modified procedure using toluene as a solvent and a dispersing agent. As the complexes formed are soluble in toluene they were isolated by precipitation with *n*-heptane.

It has to be noted that further oxidation with expulsion of all the carbon monoxide occurs under more vigorous conditions yielding species of molybdenum and tungsten with higher oxidation states. Consequently, the preparation of bromocarbonyl derivatives proved to be extremely difficult. Very low temperatures are necessary to avoid oxidative decomposition of the reaction products.

The tetracarbonyl complexes $Mo(CO)_4(RPOEt)$ and $W(CO)_4(RPOEt)$ were prepared by allowing the RPOEt ligand to react with molybdenum and tungsten hexacarbonyls in toluene and xylene, respectively, under reflux for several hours. Tricarbonyl complexes like those obtained with RPPh[6] could not be isolated.

All of the new complexes are diamagnetic solids, yellow to brown in colour. The halocarbonyls are insoluble in aliphatic hydrocarbons, diethylether, benzene, CCl_4, but soluble in a variety of polar solvents such as $CHCl_3$, CH_2Cl_2, acetone, nitromethane or nitrobenzene, stable only for a limited period of time in solution. The tetracarbonyls, however, cannot be dissolved in any solvent without decomposition. The isolated complexes are also air-sensitive and thermally unstable, but they can be stored under argon at 0°C for several weeks. Generally, bromides are less stable than iodides, and molybdenum complexes are less stable than tungsten ones.

IR spectra

The most significant absorption bands in the spectra of the ligands and of the isolated complexes are listed in Tables 2 and 3.

Some representative IR spectra of the halocarbonyl complexes are shown in Fig. 1. It can be seen that the halocarbonyls, regardless of the attached ligand, exhibit three characteristic ν(CO) stretching modes at approx. 1900–1930, 2000–2020 and 2070–2090 cm^{-1} in the IR spectra. The highest

[a] From ref. 6.

energy band varies in intensity from medium to very weak, on going from one complex to another, suggesting to some extent different rigidity of the molecule in particular cases. The lowest of the three ν(CO) bands often has a shoulder, or as with $Mo(CO)_3(MDPO)X_2$ a resolved doublet (Fig. 1). Local site symmetry effects in the solid state can account for this difference, as the doublet disappears in solution. In general, the spectra are virtually identical whether measured using KBr pellets or using the substances in solution, and are consistent with the suggested structure which involves the $M(CO)_3$ moiety in a seven-coordinate arrangement. A similar IR pattern including both shape and position of the bands was obtained for analogous seven-coordinate species having different S-, N- or O-donor ligands,[2,7–9] although the frequencies are somewhat higher in the complexes studied indicating a higher bond order for the carbonyl groups. Generally, in these halocarbonyl species there is a shift of ν(CO) on oxidation by *ca* 150–200 cm^{-1} to higher energies compared with the tricarbonyl complexes in zero oxidation state. This shift is in accord with the expected decrease in metal-to-ligand π-backbonding as the positive charge at the metal centre increases by forming a M—X bond. The CO stretching frequencies in molybdenum complexes are slightly higher than in their tungsten analogues, compatible with a more effective π-electron donation from tungsten to the antibonding orbitals of the carbonyl ligands. Regarding halogens, as expected, the ν(CO) decreases in the following order: bromo complexes > iodo complexes.

It should be mentioned that the destroying of the $M(CO)_3$ moiety leading to the eventual formation of dicarbonyl species was not observed in any of the complexes studied, neither by aging of the samples nor by dissolution. Moreover, the initial IR pattern of the carbonyl region was preserved with-

out any shift of the absorption bands until the complete loss of carbon monoxide occurred, which takes place in particular complexes if kept in air. Similarly, the halocarbonyl species having IR spectra with the highest ν(CO) band extremely weak, especially RPOEt complexes, can not be considered as dicarbonyls since dicarbonyl species have distinct IR spectra with the absorption at lower frequencies. In addition, the highest energy band of the complexes under consideration becomes ordinarily more intense for solutions.

Absorption bands relating to the M—Br stretching modes in the bromocarbonyl complexes were found, as expected,[10] at ~ 250 cm^{-1} (Table 2). M—I stretching modes occur below 200 cm^{-1} and could not be observed.

The phosphoryl oxygen stretch, ν(PO), shifts by approximately 35–40 cm^{-1} to lower wavenumbers in comparison with the free ligands, which indicates the formation of a strong M—O(P) bond[11] in these complexes, in contrast to a weaker M—O(P) bond in the starting tricarbonyl species.[6]

The zerovalent tetracarbonyl complexes with the RPOEt ligand, $Mo(CO)_4$(RPOEt) and $W(CO)_4$(RPOEt) show four absorption bands in the CO stretching region of the spectra (2100–1800 cm^{-1}; Table 3) indicating a C_{2v} local symmetry around the metal.[12] Vibrations were assigned to $2A_1$, B_1 and B_2 modes in the order of decreasing frequency and force constants were calculated by use of approximations developed by Cotton and Kraihanzel.[13–15] The higher C—O stretching force constants obtained for the RPOEt complexes, in comparison to the RPPh complexes (Table 3), were ascribed to a more positive effective nuclear charge on the metal which is due to the different chemical nature of the substituent on the central phosphorus atom of the ligand.

Instead of three bands being present in the phosphoryl region of the spectrum of RPOEt at 1245, 1220 and 1190 cm^{-1}, only one intense, rather broad, absorption band is present in the spectra of its tetracarbonyl complexes. The ν(PO) is shifted to ~ 1175 cm^{-1} for molybdenum and to ~ 1165 cm^{-1} for tungsten complexes as a consequence of a strong M—O(P) bond which exists in these compounds, in contrast to the weaker M—C(O) bonds.

^{1}H *NMR spectra*

The ^{1}H NMR spectra of the halocarbonyl complexes show a downfield shift of the methylene proton signals as well as a slight downfield shift of the phenyl proton signals relative to those from the free ligands (Table 4). Phenyl proton resonances are, however, much less informative than the aliphatic proton signals because of the complexity of their patterns and the insensitivity towards structural changes. Thus, in the spectra of RPPh and MDPO, resonances due to phenyl protons appear as multiplets at ~ 7.5 ppm and shift in the spectra of their complexes to ~ 7.7 ppm.

Table 4. ^{1}H NMR (δ) data[a] for RPPh and MDPO and their complexes

Compound	$\delta(CH_2)$ (ppm)	$\delta(C_6H_5)$ (ppm)
RPPh	3.79 (t)	7.53 (m)
$W(CO)_3$(RPPh)I_2	4.14 (m)	7.75 (m)
MDPO	3.53 (t)	7.73–7.34 (m)
$Mo(CO)_3$(MDPO)I_2	4.42 (t)	7.99–7.46 (m)

[a] Spectra recorded in $CDCl_3$ at 22°C and referenced to TMS; t = triplet, m = multiplet.

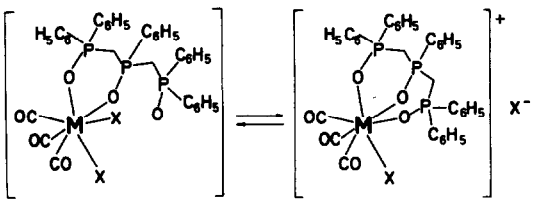
The RPPh ligand shows fluxionality in solution by giving rise to a single PCH_2P resonance in the ^{1}H NMR spectrum at ambient temperatures, which appears as a triplet at 3.79 ppm. In the spectrum of the $W(CO)_3$(RPPh)I_2 complex, the CH_2 protons exhibit a multiplet centred at ~ 4.14 ppm. Had RPPh acted as a bidentate ligand two different CH_2 signals in a ratio of 1 : 1 should be present. If all three P=O groups were engaged in the same way only one CH_2 signal would arise. The appearance of a multiplet consisting of three triplets in a ratio of $\sim 2:1:1$ in the ^{1}H NMR spectrum of $W(CO)_3$(RPPh)I_2 indicates the presence of two different species in solution.

The CH_2 signal for the free MDPO ligand appears as a triplet at 3.53 ppm and shifts to 4.42 ppm in the spectrum of the $Mo(CO)_3$(MDPO)I_2 complex. This value is firmly associated with the chelating MDPO ligand.[16]

Other measurements and concluding remarks

RPPh *complexes.* During some previous investigations several types of transition metal complexes with this ligand were isolated, thus showing that RPPh can act as bidentate and tridentate complexing agents.[3–5] Since the bromocarbonyl complexes with RPPh are non-electrolytes in nitrobenzene and nitromethane solutions (Table 2) they are formulated as $[M(CO)_3(RPPh)Br_2]$ (M = Mo, W) rather than $[M(CO)_3(RPPh)Br]Br$. Thus, with regard to seven-coordination, presumably only two P=O groups from the ligand are attached to the metal in these species. The iodocarbonyl derivatives in nitrobenzene show conductance values which are

too high for non-electrolytes but too low for 1 : 1 electrolytes (Table 2). IR spectroscopy alone has been insufficient for distinguishing between bidentate or tridentate RPPh in the complexes studied, although only one main P=O stretching band is present (Table 2, Fig. 1). However, as the IR spectra of the iodocarbonyls are virtually identical to those of the bromo-derivatives it is very likely that the iodocarbonyls exist in the solid state as neutral complexes as well, i.e. $[M(CO)_3(RPPh)I_2]$. It is known that iodide ligands are more easily displaced than bromide ligands from neutral organotransition metal complexes due to a weaker M—I bond strength. Accordingly, there exists a probability that the third P=O group from RPPh re-enters the coordination sphere of the metal in solution via displacement of the weakly bound iodide ligand leading to the following equilibrium:



Evidence to support this hypothesis comes also from the ^1H NMR spectra discussed above.

Therefore, it is likely, as far as the halocarbonyls in the solid state are concerned, that RPPh behaves as a bidentate rather than tridentate complexing agent. It seems that the steric effects are predominant in determining the geometry of the molecule.

MDPO *complexes*. The isolated halocarbonyls containing MDPO ligand are essentially non-electrolytes (Table 2) in agreement with their formulation as $[M(CO)_3(MDPO)X_2]$. The ^1H NMR spectra confirmed MDPO to be bonded as a bidentate ligand. Molecular weight measurements for the molybdenum iodocarbonyl complex (in CH_2Cl_2) gave a value of $M_r = 829$, which is consistent with the formula $Mo(CO)_3(MDPO)I_2$ ($M_{theor.} = 850$). Neither spectral nor other evidence was found for the existence of a complex which would contain two ligand molecules. It is obvious that halogen oxidation under given circumstances causes the cleavage of the weak M—O(P) bridging bonds in the parent carbonyls liberating MDPO, according to the following equation:

$$M_2(CO)_6(MDPO)_3 \xrightarrow{2X_2} 2M(CO)_3(MDPO)X_2 + MDPO.$$

RPOEt *carbonyl and halocarbonyl complexes*. The formation of disubstituted neutral carbonyl species only, by reaction of RPOEt with the corresponding hexacarbonyls, implies presumably a bidentate nature of the RPOEt ligand in these six-coordinate complexes (Table 3). Under the same circumstances RPPh readily afforded trisubstituted compounds.[6] Electronic factors can account for the difference in the donor ability of the two structurally similar ligands.

cis-$Mo(CO)_4$(RPOEt) and *cis*-$W(CO)_4$(RPOEt) in reaction with iodine released one molecule of carbon monoxide, to give metal(II) derivatives, $M(CO)_3(RPOEt)I_2$, whose properties are listed in Tables 1 and 2. They are diamagnetic non-electrolytes, unstable to light and air, and according to the IR spectra certainly similar to the seven-coordinate complexes with RPPh and MDPO described above. Although the complexes $Mo(CO)_3(RPOEt)I_2$ and $W(CO)_3(RPOEt)I_2$ do not show initial conductance in nitrobenzene and nitromethane (Table 2) they do undergo dissociation to a certain degree since the conductivity increases slightly on standing of the solutions. At the same time in the IR spectra the solvent causes no significant shifts of the carbonyl frequencies.

The geometries of most seven-coordinate halocarbonyl complexes can be described in terms of a C_{3v} capped octahedron.[17] However, when the ligands are inequivalent and the actual symmetry lower, the assignment of a structure is ambiguous. Since the IR spectral properties of our $M(CO)_3(ligand)X_2$ complexes closely resemble the analogous seven-coordinate compounds it is likely that they will also have a capped octahedral structure, most of them probably with *Cs* local symmetry.

EXPERIMENTAL

Materials

The ligands, MDPO, RPPh and RPOEt, were prepared by literature procedures.[18,19]

Metal hexacarbonyls were purchased from commercial sources. The tricarbonyls, $M(CO)_3(RPPh)$ and $M_2(CO)_6(MDPO)_3$ (M = Mo, W), were prepared by reacting the metal hexacarbonyls and the corresponding ligand under reflux in appropriate solvent as described previously.[6]

Solvents were purified and dried in the usual manner and freshly distilled under argon before use. All reactions were carried out in an atmosphere of dry argon.

Physical measurements

IR spectra on nitromethane solution and KBr pellets were recorded in the region 4000–200 cm^{-1}

using a Perkin–Elmer Model 580B spectrometer. Far-IR samples were prepared as Nujol mulls supported between rigid polyethylene plates.

^{1}H NMR spectra were recorded on a JEOL FX90Q Fourier Transform spectrometer using tetramethylsilane as an internal standard.

Conductivity measurements were carried out at 25°C on 10^{-3} M nitrobenzene solutions using a Tacussel conductivity bridge, type Cd7.

Magnetic susceptibilities were measured at room temperature by the Gouy method with $CuSO_4 \cdot 5H_2O$ as calibrant. All the complexes were diamagnetic.

The molecular weight of the $Mo(CO)_3(MDPO)I_2$ complex was determined using a modified Signer's method.[20]

Preparation of complexes

Freshly prepared disubstituted or trisubstituted metal(0) carbonyl complexes[6] were dispersed in a suitable solvent. Adequate amounts of halogen dissolved in benzene, toluene or CCl_4 were added dropwise into the suspension under a stream of dry argon and with stirring at temperatures below 0°C. Completion of the reaction was monitored by IR spectroscopy. The resulting substances were filtered off, washed with appropriate solvent and dried over P_4O_{10} *in vacuo*.

$Mo(CO)_3(RPPh)Br_2$. To $Mo(CO)_3(RPPh)$ (0.184 g, 0.25 mmol) dispersed in 25 cm^3 of CCl_4, at −20 to −30°C with continuous stirring under a stream of dry argon, was added bromine (0.045 g, 0.28 mmol) dissolved in 5 cm^3 of benzene, over 1 h. The reaction mixture was stirred for a further 1/2 h and then the precipitate was filtered off, washed with a small amount of dry CCl_4 and dried over P_4O_{10} *in vacuo*. The yield was 0.157 g (70%).

$Mo(CO)_3(RPPh)I_2$. A suspension of the complex $Mo(CO)_3(RPPh)$ (0.147 g, 0.20 mmol) in CCl_4 (15 cm^3) was treated with iodine (0.061 g, 0.24 mmol) in CCl_4 (40 cm^3) over 4 h under argon with continuous stirring at −5°C. The orange product (0.170 g, 86%) was filtered off, washed with CCl_4 and dried.

$W(CO)_3(RPPh)Br_2$. To a suspension of $W(CO)_3$ (RPPh) (0.205 g, 0.25 mmol) in *n*-heptane (40 cm^3) at −30°C with continuous stirring under dry argon was added bromine (0.045 g, 0.28 mmol) in benzene (5 cm^3), over 2 h. After stirring for a further 1/2 h, the resulting orange–yellow precipitate was filtered off (0°C), washed with a small amount of cold heptane and dried in vacuum. The yield was 0.169 g (69%).

$W(CO)_3(RPPh)I_2$. The complex $W(CO)_3(RPPh)$ (0.164 g, 0.20 mmol) was dispersed in 10 cm^3 of CCl_4 at −10°C. Iodine (0.056 g, 0.22 mmol) in CCl_4 (30 cm^3) was added over 4 h under continuous stirring in a stream of dry argon. After the addition of iodine the reaction mixture was stirred for a further hour and then the complex (190 mg, 89%) was filtered off, washed with CCl_4 and dried.

$Mo(CO)_3(MDPO)Br_2$. To a suspension of $Mo_2(CO)_6(MDPO)_3$ (0.241 g, 0.15 mmol) in CCl_4 (20 cm^3) was added bromine (0.072 g, 0.45 mmol) in 20 cm^3 of the same solvent at −20 to −30°C over 1 h. The reaction mixture was stirred under dry argon. After completion of the reaction, the precipitate (0.180 g, 80%) was filtered off, washed with a few cm^3 of CCl_4 and dried.

$Mo(CO)_3(MDPO)I_2$. A CCl_4 solution (40 cm^3) of iodine (0.089 g, 0.35 mmol) was added dropwise into a suspension of the complex $Mo_2(CO)_6(MDPO)_3$ (0.241 g, 0.15 mmol) in CCl_4 (15 cm^3) under argon at −10°C over 4 h. The reaction mixture was vigorously stirred and after all the iodine had been added, it was left overnight. The orange–brown product was filtered off, washed and dried as usual. The yield was 0.216 g (85%).

$W(CO)_3(MDPO)Br_2$. Treatment of a suspension of $W_2(CO)_6(MDPO)_3$ (0.178 g, 0.1 mmol) in *n*-heptane (30 cm^3) with bromine (0.045 g, 0.28 mmol) dissolved in 6 cm^3 of benzene, with continuous stirring under argon at −25°C over 1 h, afforded 0.145 g (86%) of the orange–yellow complex $W(CO)_3(MDPO)Br_2$, which was filtered off, washed and dried as above.

$W(CO)_3(MDPO)I_2$. $W_2(CO)_6(MDPO)_3$ (0.178 g, 0.1 mmol) dispersed in 20 cm^3 of CCl_4 was treated with a solution (25 cm^3) of iodine (0.056 g, 0.22 mmol) in the same solvent with stirring under argon at −10 to −15°C over 3 h. The resulting precipitate (0.140 g, 75%) was filtered off, washed with a few cm^3 of CCl_4 and dried.

MDPO complexes were also obtained by an alternative procedure. As an example the preparation of $Mo(CO)_3(MDPO)I_2$ is given below.

$Mo(CO)_3(MDPO)I_2$. $Mo_2(CO)_6(MDPO)_3$ (0.161 g, 0.1 mmol) was dispersed in 20 cm^3 of toluene. Iodine (0.056 g, 0.22 mmol) in 30 cm^3 of toluene was added dropwise at −10°C. After stirring the reaction mixture for 2 h the oxidized products which separated on the sides of the flask were removed by filtration. Addition of a three-fold excess of *n*-heptane to the filtrate afforded a good yield (0.120 g; 70%) of orange $Mo(CO)_3(DMPO)I_2$, which was filtered off, washed with a small amount of toluene and dried as above.

$Mo(CO)_4(RPOEt)$. This was obtained by refluxing a mixture of $Mo(CO)_6$ (0.198 g, 0.75 mmol) and RPOEt (0.262 g, 0.5 mmol) in 20 cm^3 of toluene for 5 h. The brown product was collected by filtration from hot solution, washed with a few cm^3 of toluene and dried. The yield was 52% (0.190 g).

$W(CO)_4RPOEt$. A mixture of $W(CO)_6$ (0.176 g, 0.5 mmol) and RPOEt (0.157 g, 0.3 mmol) in 20 cm^3 of xylene was boiled under reflux for 4 h. The complex was collected from a hot solution as described above with a yield of 0.160 g (65%).

$Mo(CO)_3(RPOEt)I_2$. Freshly prepared $Mo(CO)_4$ (RPOEt) (0.146 g, 0.2 mmol) was dispersed in 20 cm^3 of *n*-heptane. An excess of iodine (0.35 mmol, 0.090 g) dissolved in 30 cm^3 of CCl_4 was added dropwise to the suspension over 4 h. The reacting mixture was stirred and cooled to $-20°C$. The resulting precipitate (0.128 g; 65%) was filtered off and washed with a few cm^3 of diethyl ether.

$W(CO)_3(RPOEt)I_2$. This was obtained in a yield of 70% using the same solvents and the same relative ratio of the reacting components as the analogous molybdenum complex described above.

All of the prepared RPOEt complexes are very sensitive and tend to loose carbon monoxide rather quickly if kept in air at room temperature.

ACTIVATION OF AROMATIC C—H BONDS BY ZEROVALENT RUTHENIUM COMPLEXES OF BIS(DIMETHYLPHOSPHINO)METHANE

PILAR PALMA-RAMIREZ, DAVID J. COLE-HAMILTON,* PETER POGORZELEC (in part) and JUAN CAMPORA (in part)

Chemistry Department, University of St Andrews, St Andrews, Fife KY16 9ST, Scotland, U.K.

(*Received* 8 *December* 1989; *accepted* 15 *December* 1989)

Abstract—Reaction of $[RuCl_2(PPh_3)_3]$ with excess bis(dimethylphosphino)methane (dmpm) in petroleum produces *trans*-$[RuCl_2(dmpm)_2]$, whilst a similar reaction using $[OsCl_2(PPh_3)_3]$ in toluene produces only $[OsCl_2(dmpm)_2(PPh_3)_2]$ with *trans*-chlorine atoms or, under reflux in the presence of excess dmpm, $[OsCl_2(dmpm)_3]$. Reduction of $[RuCl_2(dmpm)_2]$ with sodium–potassium alloy in benzene or toluene produces *cis*-$[RuHR(dmpm)_2]$ (R = Ph or C_6H_4Me), together with small amounts of unidentified products, one of which is paramagnetic. The hydrido aryl complexes are characterized spectroscopically and the exchange of *cis*-$[RuHPh(dmpm)_2]$ with C_6D_6 is described.

Although zerovalent complexes of ruthenium containing tertiary phosphine ligands should be sufficiently electron rich to promote intermolecular activation of C—H bonds, their use in these reactions has been bedevilled by the tendency for internal metallation of C—H bonds of the phosphine to occur. This is especially true for triphenylphosphine complexes,[1,2] but even $[Ru(dmpe)_2]$ (dmpe = 1,2-bis(dimethylphosphino)ethane), although it does activate some C—H bonds,[3] also undergoes metallation reactions,[4] albeit intermolecularly.[5]

During studies[6] of zerovalent complexes of ruthenium containing bidentate phosphines, we noted that the rate of *ortho*-metallation of a phosphorus bound phenyl group was strongly dependent upon the length of the carbon chain separating the two phosphorus atoms. Thus, [Ru(styrene)(P—P)$_2$] could not be isolated for P—P = 1,3-bis(diphenylphosphino)propane (dppp), the only product of reactions of $[Ru(styrene)_2(PPh_3)_2]$ with dppp was $[RuH(C_6H_4P(Ph)(CH_2)_3PPh_2)(dppp)]$. For P—P = 1,2-bis(diphenylphosphine)ethane (dppe), [Ru(styrene)(dppe)$_2$] could be isolated but *ortho*-metallation occurred on standing in solution at room temperature for several hours, whilst for P—P = bis(diphenylphosphino)methane (dppm), [Ru(styrene)(dppm)$_2$] was stable to *ortho*-metallation even in refluxing toluene or on photolysis in benzene for 4 days.

We reasoned, therefore, that if $[Ru(dppm)_2]$ could be generated, it should be stable towards *ortho*-metallation reactions and should activate external C—H bonds. We now report studies aimed at generating this species, and the related $[Ru(dmpm)_2]$ (dmpm = bis(dimethylphosphino)methane) and show that the latter is capable of activating aromatic C—H bonds.

Certain dmpm complexes of ruthenium, including $[Ru(dmpm)_3]$ have been isolated[7] and during the course of this work it was shown[8] that the tetradentate phosphine, tris-3-(dimethylphosphino)propylphosphine (PP_3), which is also stabilized towards *ortho*-metallation, allows the production of a ruthenium(0) species which activates C—H bonds in aromatic compounds to give *cis*-[RuHPh(PP_3)].

RESULTS AND DISCUSSION

Preparation of $[RuCl_2(dmpm)_2]$

Attempts to prepare $[RuCl_2(dmpm)_2]$ by reaction of excess dmpm with $[RuCl_2(MeCN)_4]$, $[RuCl_2(DMSO)_4]$ (DMSO = dimethylsulphoxide) or the

* Author to whom correspondence should be addressed.

blue solution of chloro complexes of ruthenium(II), which can be generated by H_2 reduction of $[RuCl_3 \cdot xH_2O]$ in methanol, all failed to produce $[RuCl_2(dmpm)_2]$. $[RuCl_2(dmpm)_2]$ was successfully prepared, however, by the method pioneered by Stephenson[9] of phosphine exchange with $[RuCl_2(PPh_3)_3]$. Thus, stirring $[RuCl_2(PPh_3)_3]$ with excess dmpm* in petroleum produces a yellow solid from which pure $[RuCl_2(dmpm)_2]$ can be isolated on recrystallization from tetrahydrofuran (THF). Spectroscopic properties (Tables 1 and 2) indicate that this complex has *trans* stereochemistry.

Although ^{31}P NMR studies of the yellow solid obtained from petroleum show that it contains only *trans*-$[RuCl_2(dmpm)_2]$ and PPh_3, reasonable yields can only be obtained for small scale reactions (starting from *ca* 3 g of $[RuCl_2(PPh_3)_3]$) and even then substantial amounts of ruthenium remain in solution after recovering *trans*-$[RuCl_2(dmpm)_2]$.

Interestingly, the reaction of $[OsCl_2(PPh_3)_3]$ with dmpm did not lead to complete displacement of the triphenylphosphine ligands even under reflux. The isolated product was $[OsCl_2(dmpm)(PPh_3)_2]$ with *trans*-chlorine atoms (Tables 1 and 2). Using a large excess of dmpm, the product was similar, but spectroscopic properties suggested the formulation $[OsCl_2(dmpm)_3]$, containing two unidentate and one bidentate dmpm ligands. This compound was not obtained free from contaminating PPh_3.

Reduction of $[RuCl_2(dppm)_2]$ *and* $[RuCl_2(dmpm)_2]$

Attempts to reduce $[RuCl_2(dppm)_2]$ with sodium in refluxing toluene or potassium in refluxing benzene generally led to red solutions from which no clean products could be isolated. This was also the case for $[RuCl_2(dmpm)_2]$, but when sodium–potassium alloy, which is a liquid at room temperature, was employed as the reducing agent, cleaner reactions of $[RuCl_2(dmpm)_2]$ were observed and orange oily products could be isolated. Carrying out the reaction with benzene, 40–70°C, two products were observed, one of which was almost insoluble in light petroleum and the other was soluble. The petroleum-insoluble compound, which was obtained from toluene or benzene by precipitation with petroleum gave broad, temperature invariant, NMR signals and, although there were broad resonances in the phenyl and hydride regions of the ^1H NMR spectrum, we were unable fully to characterize the compounds but believe that they are paramagnetic complexes, possibly of ruthenium(I).

By contrast, the petroleum-soluble compounds, which were generally obtained as yellow–orange oils and were sometimes contaminated with small amounts of the paramagnetic species, described above, gave sharp NMR spectra and were identified spectroscopically as *cis*-$[RuHR(dmpm)_2]$ (R = Ph or C_6H_4Me), although they could not be obtained in an analytically pure state.

The phenyl and hydride resonances from the ^1H NMR spectrum of *cis*-$[RuHPh(dmpm)_2]$ are shown in Fig. 1. In the phenyl region separate resonances with the expected multiplicities are observed for the *ortho-*, *meta-* and *para*-protons of the coordinated phenyl group. Since all four phosphorus atoms are inequivalent,† the hydride resonance would be

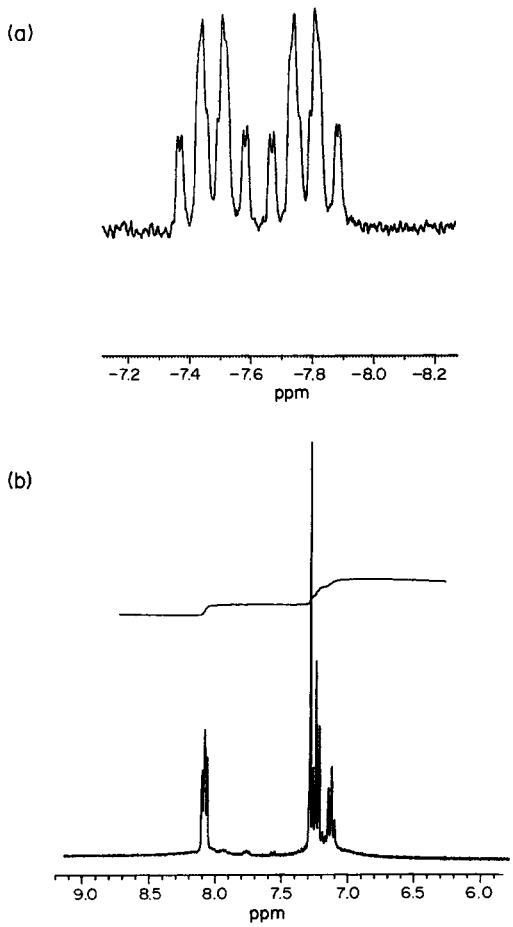

Fig. 1. 300 MHz ^1H NMR spectrum of *cis*-$[RuHPh(dmpm)_2]$ measured in C_6D_6: (a) hydride region and (b) phenyl region—the large singlet at δ 7.3 is from C_6D_5H and C_6H_6 and increases with time at the expense of the other resonances shown in A and B. Resonances are not drawn to scale.

*Carrying out this reaction in ethanol gives $[Ru(dmpm)_3]Cl_2$.[7]

†The mutually *trans*-phosphorus atoms are inequivalent by virtue of their being bound via the methylene groups to phosphorus atoms *trans* to H and *trans* to Ph, respectively. A similar non-equivalence also exists in, for example, *cis*-$[RuH(CO)(dppe)_2]^+$.[10]

expected to be a doublet of doublets of doublets of doublets with one coupling of *ca* 100 Hz (from the *trans*-phosphorus atom) and three couplings of 20–30 Hz (from the *cis*-phosphorus atoms). This is exactly what is observed (Table 1), but there is an extra small coupling (4 Hz) which we have not been able to assign. It is possible that this coupling is either to another phosphorus atom, in which case the complex must not be mononuclear, although even with dinuclear species it is difficult to see how this particular coupling pattern or the observed ^{31}P NMR spectrum (see below) could be obtained. An alternative explanation is that the small coupling arises from coupling to a hydrogen atom. Being a four-bond coupling, this is not likely to be large but may be significant if the H—Ru—P—C—H skeleton holds a W configuration. The only such configurations possible in [RuHPh(dmpm)$_2$] are to two of the CH_3 hydrogen atoms and, although one of these methyl groups appears from models to be in such a position that steric crowding may restrict its rotation, we cannot be certain that this is responsible for the coupling.

Attempts to verify that this small coupling observed in the hydride resonance is to a dmpm methyl proton have been hampered by problems associated with the ready exchange of the complex with C_6D_6 (see below) which leads to loss of the relevant hydride signal, and by the complexity of the ^1H NMR spectrum in the methyl region.

As expected for a *cis*-bis(bidentate phosphine) complex in which the two other ligands are not identical, the ^{31}P NMR spectrum for *cis*-[RuHPh(dmpm)$_2$] is complex. However, it can be simulated and is totally consistent with the formulation proposed. The chemical shifts and coupling constants of the phosphorus atoms are collected in Table 2.

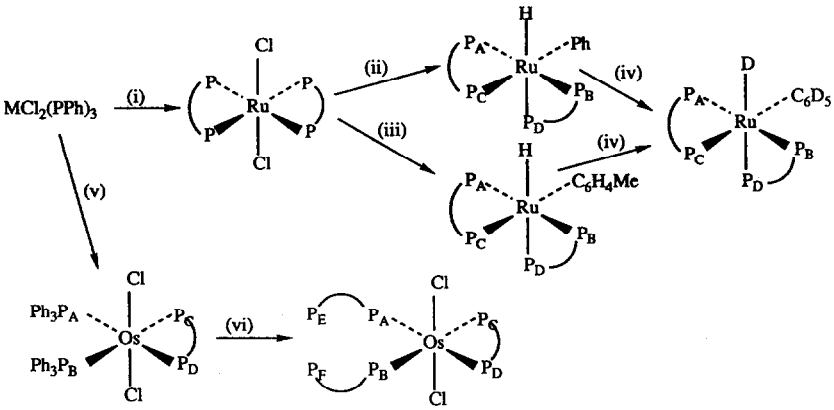
The petroleum-soluble compound obtained from reduction of [$RuCl_2$(dmpm)$_2$] in toluene has very similar spectroscopic properties of those of *cis*-[RuHPh(dmpm)$_2$], except that a more complex aromatic region is observed. From the signals in the region where the aromatic protons *ortho* to the metal resonate, it is possible to determine that the complexes in which the metal has added *para* to the methyl group (dd at 7.87 ppm, intensity 2), *ortho* to the methyl group (d at 7.7 ppm, intensity 1) are obtained in approximately equal amounts but that the product with the metal *meta* to the methyl group (d at 7.53 ppm intensity ~ 0.1, other dd not observed) is only a minor product. The assignment of the protons *meta* and *para* to the metal is complicated by signals from free toluene, which grow with time, presumably because of exchange with d^6-benzene. Once again this compound is contaminated with a paramagnetic species similar to that described above.

Reaction of cis-[RuHPh(dmpm)$_2$] *with* C_6D_6

On standing in C_6D_6 at room temperature for several hours, the signals from the hydride and the phenyl hydrogen atoms of *cis*-[RuHPh(dmpm)$_2$] diminish in intensity, whilst the residual benzene peak increases in intensity. No change is observed in the ^{31}P NMR spectrum so we interpret these observations as arising from an exchange of RuPhH with C_6D_6. Integration of the ^1H NMR spectrum after partial exchange has occurred shows that the ratio of Ph to H is still 1 : 1, suggesting that the exchange occurs via a concerted mechanism. All the reactions described are collected in Scheme 1.

EXPERIMENTAL

Microanalyses were by the University of St Andrews Materials Analysis services. IR spectra were obtained on Nujol mulls between ceasium iodide plates on a Perkin–Elmer 1310 spectrometer and



Scheme 1. Formation and reactions of dmpm complexes of ruthenium and osmium: (i) excess dmpm, M = Ru, petroleum, 20°C, 2 h; (ii) NaK, benzene; (iii) NaK, toluene; (iv) standing in C_6D_6 for several hours; (v) 3 mol dmpm, M = Os, toluene, 20°C, 20 min; (vi) excess dmpm, toluene, reflux, 3 h.

NMR spectra on a Bruker Associates A.M. 300 spectrometer working in the Fourier Transform Mode with (for ^{31}P) noise proton decoupling. All solvents were dried by distillation from sodium diphenylketyl and all manipulations were carried out under dry, deoxygenated nitrogen using standard Schlenk line and catheter tubing techniques. The petroleum used had boiling range 40–60°C.

$[RuCl_2(PPh_3)_3]$,[11] $[OsCl_2(PPh_3)_3]$[12] and dmpm[13] were synthesized by standard literature methods.

Sodium–potassium alloy

Sodium (0.5 g) and potassium (0.5 g) were suspended in THF (10 cm^3) and pressed together with a glass rod. The solvent was decanted and the liquid alloy washed with propan-2-ol (5 cm^3) to remove metal oxides and hydroxides. After decanting the propan-2-ol, the shiny alloy was washed with THF (2×5 cm^3) and the solvent to be used in the subsequent reaction (2×5 cm^3).

(1) trans-*Dichlorobisbis(dimethylphosphino)methaneruthenium*(II)

$[RuCl_2(PPh_3)_3]$ (2.9 g) was suspended in petroleum (30 cm^3) and dmpm (1.5 cm^3) was added. After stirring for 2 h, the yellow solid was collected by filtration, washed with petroleum (3×50 cm^3) and diethyl ether (1×20 cm^3) and dried *in vacuo* (yield *ca* 60%). Well-formed orange crystals of the product were obtained by dissolving the yellow solid in a minimum quantity of THF at room temperature and cooling to −30°C for 16 h. Yield. 30%. Analysis: Found: C, 27.2; H, 6.4. $C_{10}H_{28}Cl_2P_4Ru$ requires: C, 27.0; H, 6.3%. IR (λ_{max}/cm^{-1}) 288 (νRu—Cl). There are also medium features at 328 and 350 cm^{-1}.

(2) trans-*Dichlorobis(dimethylphosphino)methanebistriphenylphosphineosmium*(II)

A solution of $[OsCl_2(PPh_3)_3]$ (0.48 g, 0.5 mmol) in toluene (10 cm^3) was treated with dmpm (0.2 g, 1.5 mmol) and stirred for 20 min. The resulting yellow–green solution was evaporated to 1 cm^3 and treated with petroleum (30 cm^3). After filtration, the resulting yellow solid was washed with petroleum (2×20 cm^3) and dissolved in toluene (10 cm^3). The yellow solution was evaporated to 2 cm^3 and held at −30°C for 16 h. The yellow crystals so formed were collected and dried *in vacuo*. Yield *ca* 60%. Found: C, 53.6; H, 4.8. $C_{41}H_{44}Cl_2OsP_4$ requires: C, 53.4; H, 4.8%. IR (λ_{max}/cm^{-1}), 340 br, ν(Ru—Cl).

(3) trans-*Dichlorotrisbis(dimethylphosphino)methaneosmium*(II)

A solution of $[OsCl_2(PPh_3)_3]$ (0.48 g, 0.05 mmol) in toluene (5 cm^3) was refluxed with dmpm (0.41 g, 3 mmol) for 3 h. All of the osmium complex dissolved to give a yellow solution which was held at 50°C for 16 h. After evaporation to dryness, the product was extracted into petroleum (30 cm^3). Undissolved PPh_3 was removed by filtration and more PPh_3 crystallized on standing for 3 days. This was removed by filtration and the yellow solution evaporated to dryness. The product was obtained as yellow crystals by recrystallization from methanol at −30°C. ^{31}P NMR studies showed that, although the complex was the major product, it

still contained substantial quantities of PPh_3 (δ −6 ppm) and other impurities, the most important of which gave a singlet at δ −75.5.

(4) cis-*Bisbis(dimethylphosphino)methanehydridophenylruthenium*(II)

(i) $[RuCl_2(dmpm)_2]$ (0.67 g) in benzene (30 cm^3) was transferred onto a suspension of sodium–potassium alloy (1.0 g) in benzene (10 cm^3). The resulting suspension was stirred for 24 h using external heating from an oil bath at 70°C. The resulting deep red–orange suspension was filtered to remove NaK and metal chloride and evaporated to dryness to give a red–brown oil. This oil was extracted with petroleum (4 × 50 cm^3) to give a yellow solution and a pale brown solid. On evaporation to dryness, the yellow solution gave an orange oil which was identified as largely *cis*-$[RuHPh(dmpm)_2]$ by its ^{31}P and ^1H NMR spectra. The pale brown solid gave only broad signals in the ^1H and ^{31}P NMR spectra.

(ii) As above but at 60°C for 24 h.

(iii) As above but at 40°C for 42 h (contaminated with two other hydrido products, quintet at δ −16.17, J_{PH} = 20.3 Hz; quintet of triplets at δ −8.5, J_{PH} = 21q and 4.5t Hz).

(iv) As above but at 20°C for 5 days.

(5) cis-*Bis(bisdimethylphosphinomethane)hydridotolylruthenium*(II)

Was prepared as in (ii) above but using toluene (40 cm^3 total volume).

Acknowledgements—We thank the British Council for a Fleming Fellowship (P.P.R.), the British Council and the Spanish Ministerio de Educacion y Ciencias for funding of an Integrated Action programme (P.P.R. and J.C.) and the SERC for a grant to purchase the NMR spectrometer. We are also indebted to Johnson Matthey plc for generous loans of ruthenium salts.

SYNTHESIS AND REACTIONS OF ARENE–RUTHENIUM COMPLEXES CONTAINING NITROGEN-DONOR LIGANDS; CRYSTAL STRUCTURE OF (p-cymene)$_2$Ru$_2$Cl$_2$(N$_3$)$_2$

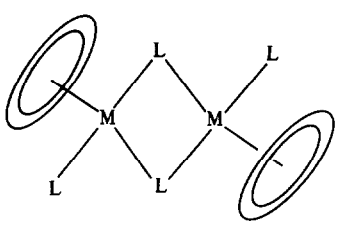
RICHARD S. BATES, MICHAEL J. BEGLEY and ANTHONY H. WRIGHT*

Chemistry Department, University of Nottingham, Nottingham NG7 2RD, U.K.

(*Received* 30 *October* 1989; *accepted* 21 *December* 1989)

Abstract—A range of nitrogen bases have been reacted with [(arene)RuCl$_2$]$_2$ complexes. The reaction with simple amines to give monomeric addition compounds (arene)RuCl$_2$NR$_3$ has been made rapid and quantitative using ultrasound. Steric factors predominate in determining the extent of the reactions. Trimethylsilylazide has been found to be a particularly suitable source of the azide ligand, generating the new dimer [(arene)Ru(μ-N$_3$)Cl]$_2$ which has been structurally characterized. This complex has been shown to undergo dimer cleavage and halide loss reactions.

The dimeric complexes of type **1** are very common and may be subdivided into two groups depending on whether the bridging ligands contribute two or three electrons.[1]



1

The reactivity of the former dimers, such as [CpFe(CO)$_2$]$_2$, is well established.[2] By comparison, the latter group of dimers such as [(arene)RuCl$_2$]$_2$ is much less understood.[3] We have begun a programme investigating the reactivity of these complexes, initially examining the range of different nitrogen-donor ligands that may be introduced to the metal centre.

Extensive investigations of the reactions of these dimers with oxygen-based ligands have been reported,[4] and the reaction with soft nitrogen-based ligands such as pyridine and acetonitrile has been investigated, particularly as sources of the [(arene)Ru]$^{2+}$ fragment.[5]

RESULTS AND DISCUSSION

Reactions with amines

One of the problems associated with using the dimers [(arene)RuCl$_2$]$_2$ (**1**), and especially the benzene-containing dimer, lies in the insolubility of these substrates in non-coordinating solvents. This can be readily overcome by carrying out the reactions at room temperature using a simple ultrasound bath.

Both aliphatic and aromatic primary amines react rapidly with [(C$_6$H$_6$)RuCl$_2$]$_2$ at room temperature when subjected to ultrasound in non-polar solvents (Scheme 1). The products are yellow crystalline solids and the initial product in each case is that of simple addition resulting in dimer cleavage (**2**, **3** and **4**). Analogous products such as (MeC$_6$H$_4$CHMe$_2$)RuCl$_2$(NH$_2$CMe$_3$) (**10**) can be obtained using substrate dimers containing other arenes.

In the case of p-toluidine, addition of excess ligand and longer reaction periods leads to increasing amounts of the product containing two amine ligands (**5**), resulting from subsequent halide substitution. The further substitution that is only observed with aromatic amines, indicates that in these reactions the softness (HSAB theory) of the nucleophile plays a more important role than basicity.

This conclusion is supported by the results of reactions with aliphatic secondary or tertiary

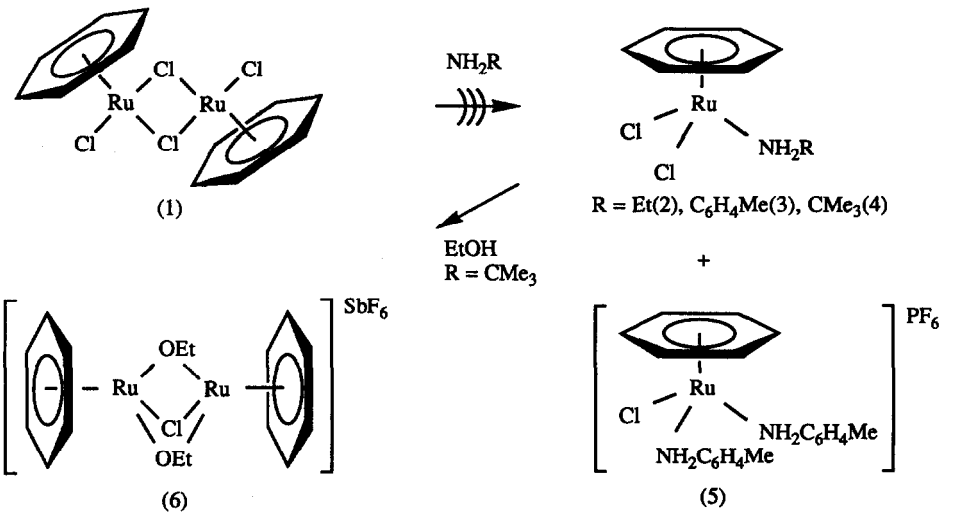


Scheme 1. Reactions of $(C_6H_6)_2Ru_2Cl_4$ with amines.

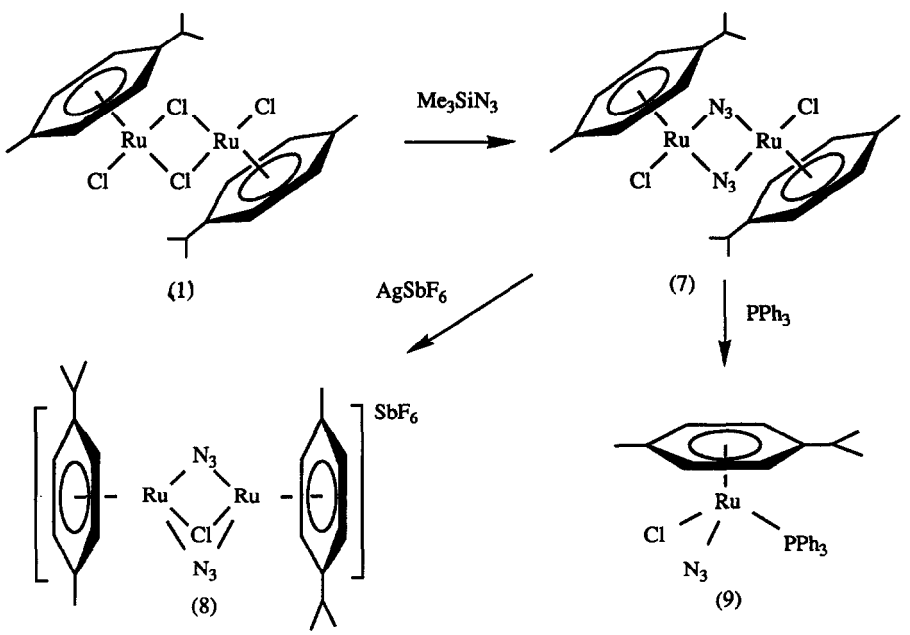
amines in which no addition reactions were observed. This result contrasts with the well-established reactions of the same substrates with tertiary phosphines and indicates that steric factors are much more important with the relative hard amines which are poorer ligands for the ruthenium centre. Softer nitrogen bases such as pyridine undergo the same reaction giving the addition product in the first step.

The recent report of addition reactions of primary aliphatic amines and a range of phosphine nucleophiles to the dimer adds further support for the reactivity pattern described.[6]

The relative weakness of the Ru—N bonds that are formed is illustrated in the reaction of $(C_6H_6)RuCl_2(NH_2CMe_3)$ with $AgSbF_6$ in ethanol, in which the only product that was detected was the triply-bridged cation **6**. In other reactions the only products isolated involve loss of the amine ligand.

Azide ligands

The azide ligand is a non-sterically demanding nitrogen-based pseudohalide. The reagent Me_3SiN_3 provides an excellent source of the azide moiety



Scheme 2. Synthesis and reactions of $(cymene)_2Ru_2Cl_2(N_3)_2$.

and reacts rapidly with $[(cymene)_2RuCl_2]_2$ to give orange crystals of $[(cymene)_2Ru(N_3)Cl]_2$ (**7**).

IR spectra of **7** contain a single absorption assignable to the azide ligand and a single Ru—Cl stretch is observed. The ^1H NMR spectrum contains the absorption associated with a cymene ligand in only one environment. An X-ray crystal structure was carried out to confirm the dimeric nature of the product, Fig. 1.

No product involving further substitution of the chlorides has been detected. This result contrasts with the related reaction of $[(C_5Me_5)_2RhCl_2]_2$ with sodium azide, in which the product involving monosubstitution could only be obtained by limiting the amount of nucleophile to a 1 : 1 stoichiometry.[7]

A second difference between the related complexes lies in the thermal instability of the ruthenium complex. When **7** was heated in toluene, rapid loss of the arene ligand occurred (detected by NMR spectroscopy) and a brown product precipitated from solution that detonated on handling.

Unlike the amine ligands, the azide ligands remain in the coordination sphere when simple reactions are carried out. For example, addition of triphenylphosphine leads to simple bridge cleavage and formation of $(cymene)Ru(N_3)Cl(PPh_3)$ (**9**). The ^1H NMR spectrum of the product contains three sets of signals assignable to cymene ligands indicating that the complex exists in non-polar solutions in three conformations and there is steric hindrance to rotation of the arene ring.

Chloride rather than azide loss occurs when dimer **7** is reacted with $AgSbF_6$, leading to formation of the mixed ligand triply-bridged product **8**.

Structure of (p-*cymene*)$_2$Ru$_2$Cl$_2$(N$_3$)$_2$ (**7**)

The X-ray crystal structure determination of **7** shows that the molecule is dimeric with the two azide ligands bridging the two metals (Fig. 1), and bond lengths and angles are given in Table 1. The only crystallographically-imposed symmetry is an inversion centre midway between the metal atoms.

The surprising feature of the structure is that the ligating nitrogens are pyramidally coordinated, not planar, with the angles about the nitrogen summing to 351.6°. The ruthenium atoms and ligating nitrogens lie in a plane and N(2) and N(3) lie 0.514(2) and 0.992(3) Å, respectively, out of the plane. An examination of non-bonding interactions and a space filling model of the molecule failed to reveal any steric interactions that might cause the bending. Reactions aimed at exploring any reactivity associated with a lone pair on the ligating nitrogen were, however, unsuccessful. A related rhodium complex also contains a bridging azide ligand and has the same overall geometry, but in this case the angles about the ligating nitrogen do not differ significantly from those required for planarity.[7]

The cymene ring is essentially planar and the distance from the ring to the metal is 1.657(3) Å, a distance very similar to that found in $[(C_6Me_6)RuCl_2]_2$.[8] Likewise, the Ru—Cl distance of 2.395(1) Å is very close to that determined for the hexamethylbenzene complex.

EXPERIMENTAL

All reactions were carried out under nitrogen or argon using standard Schlenk techniques. Characterization of new compounds was achieved by means of elemental analysis, IR and NMR spectroscopy and mass spectrometry. Microanalytical data were obtained from the University of Nottingham's Microanalytical Laboratory. IR spectra were recorded on a Perkin–Elmer 983G spectrometer as Nujol mulls on CsI plates. NMR spectra were recorded on a Bruker 250 MHz spectrometer. A 500 W biological cell disruptor from Sonics and Materials Inc. was used for the experiments involving ultrasound.

Ruthenium trichloride was obtained from Johnson Matthey Chemicals Ltd and $[(C_6H_6)RuCl_2]_2$

and $[(cymene)RuCl_2]_2$ were prepared by literature methods.

$(C_6H_6)RuCl_2(NH_2Et)$ (2)

$[(C_6H_6)RuCl_2]_2$ (150 mg, 0.3 mmol) was suspended in THF (10 cm^3) and a solution of NH_2Et (100 mg, 2.2 mmol) in THF (5 cm^3) was added and subjected to ultrasound for approximately 90 min. The reaction mixture was allowed to stand at room temperature for 10 min and the yellow precipitate was collected and recrystallized from a dichloromethane–ethanol mixture to give $(C_6H_6)RuCl_2(NH_2Et)$ (71 mg, 40%). Found: C, 31.9; H, 4.3. Calc. for $RuC_8H_{13}Cl_2N$: C, 32.5; H, 4.4%. ν(NH) 3277, 3206 cm^{-1}, ν(RuCl) 273 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 5.63 (s, 6H, C_6H_6), 3.2 (q, 2H, CH_2), 1.23 (t, 3H, CH_3).

$(C_6H_6)RuCl_2(NH_2C_6H_4Me)$ (3)

$[(C_6H_6)RuCl_2]_2$ (150 mg, 0.3 mmol) was suspended in THF (10 cm^3) and a solution of *p*-toluidine ($NH_2C_6H_4Me$) (230 mg, 2.2 mmol) in THF (5 cm^3) was added and subjected to ultrasound for approximately 90 min. The reaction mixture was allowed to stand at room temperature for 10 min and the yellow precipitate was collected and recrystallized from a dichloromethane–ethanol mixture to give $(C_6H_6)RuCl_2(NH_2C_6H_4Me)$ (162 mg, 76%). Found: C, 43.9; H, 4.35. Calc. for $RuC_{13}H_{15}Cl_2N$: C, 43.7; H, 4.2. ν(NH) 3255, 3223 cm^{-1}, ν(RuCl) 276 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 7.32–7.14 (m, 4H, C_6H_4), 5.33 (s, 6H, C_6H_6), 2.33 (s, 3H, CH_3).

$[(C_6H_6)RuCl_2(NH_2CMe_3)]\cdot NH_2CMe_3$ (4)

Yield, 207 mg, 87%. Found: C, 42.3; H, 7.7. Calc. for $RuC_{14}H_{28}Cl_2N_2$: C, 42.4; H, 7.1%. ν(NH) 3273, 3215 cm^{-1}, ν(RuCl) 275 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 5.72 (s, 6H, C_6H_6), 1.34 [s, 9H, $C(CH_3)_3$ (coord)], 1.11 [s, 9H, $C(CH_3)_3$ (free)].

$[(C_6H_6)RuCl(NH_2C_6H_4Me)_2]PF_6$ (5)

This product may also be isolated from the reaction described for **3**. The yield is increased if NH_4PF_6 is added to the reaction mixture to give $[(C_6H_6)RuCl(NH_2C_6H_4Me)_2]PF_6$. ν(NH) 3028 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 7.34–7.06

(m, 8H, C_6H_4), 5.01 (s, 6H, C_6H_6), 2.29 (s, 6H, CH_3).

$(MeC_6H_4CHMe_2)RuCl_2(NH_2CMe_3)$ (**10**)

This compound was made using the method described for **2** (104 mg, 85%). Found: C, 44.2; H, 6.8. Calc. for $RuC_{14}H_{25}Cl_2N$: C, 44.3; H, 6.64%. ν(NH) 3266, 3209 cm^{-1}, ν(RuCl) 273 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 5.50–5.43 (m, 4H, C_6H_4), 3.05 (sept, 1H, CH), 2.26 (s, 3H, $C_6H_4CH_3$), 1.33 (s, 9H, $C(CH_3)_3$), 1.29 and 1.26 (d, 3H, $CH(CH_3)_2$).

$[(C_6H_6)_2Ru_2Cl(OEt)_2]SbF_6$ (**6**)

$[(C_6H_6)RuCl_2(NH_2CMe_3)]\cdot NH_2CMe_3$ (300 mg, 0.76 mmol) was dissolved in MeCN (20 cm^3) and a solution of $AgSbF_6$ (286 mg, 0.84 mmol) in MeCN (5 cm^3) was added and the mixture stirred for 30 min. The precipitated AgCl was removed by filtration and the product precipitated as an orange solid by the gradual addition of EtOH to give $[(C_6H_6)_2Ru_2Cl(OEt)_2]SbF_6$ (96 mg, 35%). Found: C, 26.5; H, 3.1. Calc. for $Ru_2C_{16}H_{22}ClF_6O_2Sb$: C, 26.7; H, 3.1%. ν(RuCl) 258 cm^{-1} (Nujol mull).

$[(MeC_6H_4CHMe_2)_2Ru_2Cl_2(N_3)_2]$ (**7**)

$[(MeC_6H_4CHMe_2)RuCl_2]_2$ (200 mg, 0.33 mmol) was dissolved in dichloromethane (5 cm^3) and N_3SiMe_3 (530 mg, 4.6 mmol) was added dropwise and the mixture stirred for 30 min. An orange crystalline solid was obtained by addition of hexane and reduction of the volume under reduced pressure. Recrystallization was carried out from CH_2Cl_2–EtOH to give $[(MeC_6H_4CHMe_2)_2Ru_2Cl_2(N_3)_2]$ (186 mg, 90%). Found: C, 37.9; H, 4.5. Calc. for $Ru_2C_{20}H_{28}Cl_2N_6$: C, 38.4; H, 4.5%. ν(NN) 2057 cm^{-1}, ν(RuCl) 281 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 5.33–5.22 (m, 4H, C_6H_4), 2.92 (sept., 1H, CH), 2.24 (s, 3H, $C_6H_4CH_3$), 1.28 and 1.25 (d, 3H, $CH(CH_3)_2$).

$[(MeC_6H_4CHMe_2)_2Ru_2Cl(N_3)_2]SbF_6$ (**8**)

$[(MeC_6H_4CHMe_2)_2Ru_2Cl_2(N_3)_2]$ (250 mg, 0.4 mmol) was dissolved in MeCN (10 cm^3) and $AgSbF_6$ (151 mg, 0.44 mmol) in MeCN, was added. The solution was stirred and then filtered to remove the AgCl precipitate. The product was crystallized by addition of ethanol to give $[(MeC_6H_4CHMe_2)_2Ru_2Cl(N_3)_2]SbF_6$ (208 mg, 63%). Found: C, 28.9; H, 3.5. Calc. for $Ru_2C_{20}H_{28}ClF_6N_6Sb$: C, 29.1; H, 3.4%. ν(NN) 2062 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 5.57–5.36 (m, 4H, C_6H_4), 2.75 (sept., 1H, CH), 2.23 (s, 3H, $C_6H_4CH_3$), 1.29 and 1.28 (d, 3H, $CH(CH_3)_2$).

$[(MeC_6H_4CHMe_2)RuCl(N_3)PPh_3]$ (**9**)

PPh_3 (450 mg, 1.7 mmol) in CH_2Cl_2 (15 cm^3) was added dropwise to a stirred solution of $[(MeC_6H_4CHMe_2)_2Ru_2Cl_2(N_3)_2]$ (150 mg, 0.24 mmol) in CH_2Cl_2 (15 cm^3). A red solid was collected after treatment of the reaction mixture with hexane and the volume reduced under reduced pressure giving $[(MeC_6H_4CHMe_2)RuCl(N_3)PPh_3]$ (234 mg, 85%). Found: C, 58.8; H, 5.1. Calc. for $RuC_{28}H_{29}ClN_3P$: C, 58.5; H, 5.1%. ν(NN) 2039 cm^{-1}, ν(RuCl) 294 cm^{-1} (Nujol mull); ^1H NMR ($CDCl_3$) 5.50–4.80 (m, 4H, C_6H_4), 2.82 (sept., 1H, CH), 1.86–1.81 (s, 3H, $C_6H_4CH_3$), 1.29–1.08 (d, 6H, $CH(CH_3)_2$).

Crystal data

$C_{20}H_{28}Cl_2N_6Ru_2$, $M = 625.52$ g mol^{-1}, triclinic, $a = 7.586(2)$, $b = 8.376(2)$, $c = 9.689(2)$ Å, $\alpha = 101.40(1)$, $\beta = 87.00(1)$, $\gamma = 102.54(2)°$, $U = 589.07(3)$ $Å^3$, space group $P\bar{1}$ (No. 2), $Z = 1$, $D_c = 1.76$ g cm^{-3}, $F(000) = 312$, graphite-monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 14.97 cm^{-1}, crystal dimensions $0.5 \times 0.25 \times 0.05$ mm.

Structure determination

Cell dimensions and their standard deviations were obtained by least-squares refinement of diffractometer setting angles for 12 centred reflections close to 13° in θ. Intensities of 3442 independent reflections ($1° < \theta < 25°$) were measured on a Hilger and Watts Y290 diffractometer in a ω–2θ scan mode.

The structure analysis used 3203 reflections with $I < 3\sigma(I)$ after correction for Lorentz and polarization factors. No correction was made for absorption.

Solution by Patterson and difference syntheses was followed by full-matrix least-squares refinement with anisotropic thermal parameters for all atoms except hydrogen using the CRYSTALS suite of programs. All the hydrogen atoms were located in difference maps and included, but not refined. The refinement for 192 parameters converged to $R = 0.039$ and $R_w = 0.046$, employing a weighting scheme based on Chebyshev polynomials. A final difference map contained no significant features. Complex neutral-atom scattering factors were cal-

culated from the analytical approximation and the coefficients given in ref. 9.*

Acknowledgements—We thank the SERC for support to R.S.B., the EEC for financial support and Johnson Matthey for the loan of ruthenium trichloride.

* Atomic coordinates, thermal parameters, full bond length and angle data and structure factor values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

(*Received* 9 *November* 1989; *accepted* 21 *December* 1989)

Abstract—The new heteroleptic yttrium tris-pyrazolylborate complexes $[Y\{HB(C_3N_2H_3)_3\}_2(O_2CC_6H_4\text{-}p\text{-}Z)]$ (Z = NMe_2 and NO_2) and $[Y\{HB(C_3N_2H_3)_3\}(O_2CC_6H_4\text{-}p\text{-}Bu^t)_2]_2$ have been synthesized and characterized by spectroscopic methods, elemental analyses and solution molecular weight determinations.

As part of an investigation of heteroleptic lanthanide complexes containing the $\{LnL_2\}^+$ moiety (Ln = a lanthanide element or yttrium, L = hydrotris(pyrazol-1-yl)borate) we have prepared[1–5] the complexes $[YL_2X]$ (X = OC(Me)CHC(Me)O, $O_2C_7H_5$, O_2CMe and O_2CPh). The mass spectrum of the acetate complex suggested that this compound is oligomeric and solution molecular weight measurements made by Reger *et al.*[6] indicate a trimeric formulation $[YL_2(O_2CMe)]_3$ in CH_2Cl_2 solution. However, the related ytterbium benzoate complex, $[YbL_2(O_2CPh)]$, has been shown to be monomeric in the solid state containing a bidentate benzoate ligand.[4] This finding is somewhat unusual since those lanthanide carboxylate complexes which have been structurally characterized tend to be oligomeric, containing some bridging carboxylate ligands. In the case of acetate ligands the larger lanthanide ions form mono-, sesqui- and dihydrated tris(acetato) complexes, while the tetrahydrates predominate for the smaller lanthanide ions from samarium to lutetium.[7] Among the latter series $[Ln(O_2CMe)_3(H_2O)_2]\cdot 2H_2O$ (Ln = Ho, Er and Gd) have been structurally characterized.[8,9] These complexes consist of nine-coordinate lanthanide ions surrounded by three bidentate acetate ions, two water molecules and one oxygen of an acetate ligand bound to a neighbouring lanthanide ion. In the case of benzoate ligands several lanthanide complexes have been reported[10] but $[Dy(\mu\text{-}O_2CPh)(\kappa^1\text{-}O_2CPh)_2(H_2O)_4]\cdot H_2O$ is the only unsubstituted benzoate complex which has been structurally characterized.[11] The structure of this complex consists of eight-coordinate dysprosium ions bound to two monodentate benzoate ligands, four water molecules and two bridging benzoate ligands which lead to the formation of infinite chains.

Amongst the heteroleptic complexes, the bis(cyclopentadienyl)lanthanide acetates, benzoates and formates have been found to be dimeric,[12] as were the bis(cyclopentadienyl)ytterbium carboxylates $[(\eta^5\text{-}C_5H_5)_2Yb(O_2CR)]_2$ (R = Me, C_6F_5 and C_5H_4N).[13] The pentamethylcyclopentadienyl derivatives, $[(\eta^5\text{-}C_5Me_5)_2Yb(O_2CR)]$ were reported to be monomeric when R = CF_3 but oligomeric when R = Bu^t,[14] whilst the complexes $[(\eta^5\text{-}C_5Me_5)_2Yb(O_2CR)]_2$ (R = Ph, C_6F_5) are doubly benzoate bridged dimers.[13,15] Reger *et al.* have recently reported[6] the solid-state structure of $[YL(\mu\text{-}O_2CMe)_2]_2$ which contains four bridging acetate ligands linking two seven-coordinate yttrium ions. We have now synthesized three *para*-substituted benzoate complexes of yttrium which also contain the ligand L to further explore the heteroleptic tris-pyrazolylborate derivative chemistry of this element.

EXPERIMENTAL

Potassium hydrotris(pyrazol-1-yl)borate was prepared by the literature method.[16] Hydrated yttrium trichloride was obtained from Ventron

GMBH. Water was distilled before use. ^{1}H NMR spectra were recorded using a JEOL JNM GX270 spectrometer. Deuterated NMR solvents were obtained from Aldrich Chemicals Ltd, and chemical shifts are reported with tetramethylsilane as internal reference at 293 K. IR spectra were recorded using potassium bromide pellets and a Perkin–Elmer 297 spectrometer. Mass spectra were obtained using a Kratos MS80RF mass spectrometer, ions being produced by electron impact. Elemental analyses were performed by the Microanalytical Service of the School of Chemistry, University of Birmingham, and osmometric solution molecular weight determinations by Ms S. Bradshaw, Department of Chemistry, University of Sheffield.

p-*Nitrobenzoatobis{hydrotris(pyrazol-1-yl)borato}yttrium*(III)

KL (0.75 g, 3 mmol), *p*-nitrobenzoic acid (0.25 g, 1.5 mmol), 0.1 mol dm^{-3} aqueous KOH (15 cm^3) and ethanol (15 cm^3) were mixed and added to a stirred solution of $YCl_3 \cdot 6H_2O$ (0.45 g, 1.5 mmol) in water (15 cm^3). The resulting white precipitate was collected by filtration, dried and recrystallized from CH_2Cl_2–hexane (yield, 0.50 g; 49%). M.p. 253–255°C. Found: C, 43.7; H, 3.4; N, 26.9. $C_{25}H_{24}B_2N_{13}O_4Y$ requires: C, 44.1; H, 3.5; N, 26.7%. IR spectrum: ν(BH) = 2460 cm^{-1} $\nu(NO_2)$ = 1540 cm^{-1}, also bands at 1605 and 1590 cm^{-1}; ^{1}H NMR spectrum:* pyrazolyl protons, δ_{TMS} = 7.67d(6), 7.16d(6), 6.01t(6) ppm ($^3J_{HH}$ = 2 Hz), phenyl protons δ_{TMS} = 7.60d, 7.05d ppm ($^3J_{HH}$ = 8 Hz). Mass spectrum: $\{[YL_2(O_2C\text{-}C_6H_4\text{-}NO_2)]-1\}^+$ m/z = 680 (7%), $\{[YL_2(O_2C\text{-}C_6H_4\text{-}NO_2)]-pz\}^+$ m/z = 615 (27%), $[YL_2]^+$ m/z = 515 (100%).

p-(*Dimethylamino*)*benzoatobis{hydrotris(pyrazol-1-yl)borato}yttrium*(III)

KL (0.50 g, 2 mmol), *p*-(dimethylamino)benzoic acid (0.17 g, 1 mmol), 0.1 mol dm^{-3} aqueous KOH (10 cm^3) and ethanol (15 cm^3) were mixed and added to a stirred solution of $YCl_3 \cdot 6H_2O$ (0.30 g, 1 mmol) in water (10 cm^3). The resulting white precipitate was collected by filtration, dried and recrystallized from CH_2Cl_2–hexane (yield, 0.38 g; 56%). M.p. 265–270°C. Found: C, 47.5; H, 4.2; N, 26.6. $C_{27}H_{30}B_2N_{13}O_2Y$ requires: C, 47.7; H, 4.4; N, 26.8%. IR spectrum: ν(BH) = 2460 cm^{-1}, also bands at 1604 and 1570 cm^{-1}. ^{1}H NMR spectrum: pyrazolyl protons δ_{TMS} = 7.64d(6), 7.13d(6), 5.98t(6) ppm, ($^3J_{HH}$ = 2 Hz), phenyl protons δ_{TMS} = 8.00d(2), 6.62d(2) ($^3J_{HH}$ = 9 Hz), methyl protons, δ_{TMS} = 2.98s(6). Mass spectrum: $[YL_2(O_2C\text{-}C_6H_4\text{-}NMe_2)]^+$ m/z = 697 (20%), $[YL_2]^+$ m/z = 515 (100%).

Hydrotris(pyrazol-1-yl)boratobis{p-(*tertiarybutyl*)*benzoato*}*yttrium*(III)

KL (0.75 g, 3 mmol) and *p*-(tertiarybutyl)benzoic acid (0.27 g, 1.5 mmol), 0.1 mol dm^{-3} KOH (15 cm^3) and ethanol (30 cm^3) were mixed and added to $YCl_3 \cdot 6H_2O$ (0.45 g, 1.5 mmol) in water (15 cm^3) with stirring. The resulting white precipitate was collected by filtration and dried (crude yield, 0.45 g; 91% with respect to *p*-Bu^t-C_6H_4-CO_2H), and recrystallized from CH_2Cl_2–hexane to give a white crystalline solid (yield, 0.22 g; 45%). M.p. 292–293°C. Found: C, 57.0; H, 5.6; N, 13.3. $C_{31}H_{36}BN_6O_4Y$ $[YL(O_2C\text{-}C_6H_4\text{-}Bu^t)_2]$ requires: C, 56.7; H, 5.5; N, 12.8%. IR spectrum: ν(BH) = 2460 cm^{-1}, also bands at 1630 and 1560 cm^{-1}. ^{1}H NMR spectrum: pyrazolyl protons, δ_{TMS} = 7.95d(3), 7.78d(3), 6.08t(3) ($^3J_{HH}$ = 2 Hz), phenyl protons, δ_{TMS} = 7.61d(4), 7.09d(4) ($^3J_{HH}$ = 8 Hz), methyl protons δ_{TMS} = 1.19s(18).

RESULTS

The new complexes could be precipitated in crude form by adding alkaline aqueous solutions containing KL and the appropriately substituted benzoic acid derivative in a 2:1 molar ratio to $YCl_3 \cdot 6H_2O$. They were isolated as colourless air- and moisture-stable solids which could be purified by recrystallization from CH_2Cl_2–hexane mixtures. All exhibited signals in their NMR spectra are attributable to the presence of the substituted benzoate ligand and the tripod ligand L. The ^{1}H NMR spectrum and elemental analyses of the tertiary-butylbenzoate complex were in accord with a formulation $[YL(O_2CC_6H_4\text{-}p\text{-}Bu^t)_2]$, involving only one ligand L but two benzoate ligands. This contrasts with the other two substituted benzoate ligands which afforded complexes of 1:2 benzoate:L stoichiometry as used in the synthesis procedure. The IR spectra of the new compounds contained ν(BH) at 2460 cm^{-1} in addition to bands attributable to the carboxylate moiety. In the cases of $[YL_2X]$ (X = NMe_2, NO_2) two bands were observed at *ca* 1605 and 1570–1590 cm^{-1}. However, in the case of the *p*-tertiary-butylbenzoate complex a band was observed at 1630 cm^{-1}. By analogy with $[YL(O_2CMe)_2]_2$ which was shown[6] to be a dimer,

*s, singlet; d, doublet; t, triplet; relative areas of signals are given in parentheses.

it might be expected that $[YL(O_2CC_6H_4\text{-}p\text{-}Bu^t)_2]$ might also be a dimer containing bridging benzoate groups. The dimeric nature of this complex was confirmed by an osmometric solution ($CHCl_3$) molecular weight determination which gave a value of 1423 compared with an expected value of 1312 for $[YL(O_2CC_6H_4\text{-}p\text{-}Bu^t)_2]_2$. The monocarboxylate complexes $[YL_2(O_2CC_6H_4\text{-}p\text{-}NMe_2)]$ and $[YL_2(O_2CC_6H_4\text{-}p\text{-}NO_2)]$ were expected to be monomeric by analogy with their structurally characterized[4] analogue $[YbL_2(O_2CPh)]$. This was again confirmed by osmometric solution ($CHCl_3$) molecular weight determinations which gave values of 646 and 699 compared with the respective values of 679 and 681 expected for the monomers.

The reason for the difference in benzoate : L stoichiometries found in these complexes is not entirely clear. The $—NMe_2$ and $—NO_2$ substituents lie at opposing extremes of the Hammett substituent parameter scale[17] yet afford similar products. Thus electronic factors do not appear to be involved. Similarly, steric effects do not offer a suitable explanation since the substituents are located well away from the metal ion and, in any event, although smaller than Bu^t, $—NMe_2$ and $—NO_2$ are nonetheless quite bulky. One possible explanation may lie in the solubility properties of the complexes. The hydrophobic $—Bu^t$ group may confer particularly low solubility on the complex $[YL(O_2CC_6H_4\text{-}p\text{-}Bu^t)_2]_2$ resulting in its rapid removal from the aqueous reaction medium and shifting the equilibrium distribution to favour this product. In the other cases it may be that the bis-carboxylate complex is not significantly different in properties from the mono-carboxylate so that the reactant stoichiometry is expressed in the product. ^1H NMR studies have shown[18] that facile intermolecular ligand exchange processes occur in complexes of this type so that the rapid removal of a 1:2 benzoate : L complex from solution may stimulate disproportionation of any 2 : 1 complex present.

Acknowledgements—We are grateful to Professor W. J. Evans for helpful discussions, to Dr D. W. Bruce and Ms S. Bradshaw for the molecular weight determinations, to the SERC and BP Chemicals for support (to M.A.J.M.) and to NATO for the provision of travel grant No. 175/84.

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho 7-1, Chiyoda-ku, Tokyo 102, Japan

(*Received* 13 *November* 1989; *accepted* 22 *December* 1989)

Abstract—The complexes, CpCo(cod), $CpCo(CO)_2$, $CpCo(CO)PPh_3$ and CpRh(cod), react with 1,4-dithiins having electron-attracting groups to give the title dithiolato complexes [$CpM(S_2C_2X,Y)$; M = Co or Rh]. 2-Nitro-3,5-diphenyl-1,4-dithiin reacts with $CpCo(CO)_2$ to afford selectively $CpCo(S_2C_2Ph,H)$.

The development of a facile synthetic method for (η-cyclopentadienyl)(1,2-disubstituted 1,2-ethylenedithiolato)cobalt(III) complexes [$CpCo(S_2C_2X,Y)$] in a one-pot reaction of $CpCo(CO)_2$ or CpCo(cod) (cod = 1,5-cyclooctadiene) with alkynes (X—C≡C—Y) and elemental sulphur[1] has enabled us to prepare a variety of dithiolatometal complexes of this type and to elucidate their unique physical and chemical properties.[2] Recently, Vollhardt and Walborsky found that trinuclear cobalt biscarbyne clusters react with elemental sulphur to give dithiolatocobalt complexes.[3] In this paper, we report that $CpM(S_2C_2X,Y)$ (M = Co or Rh) (**3**) complexes are formed in the reactions of CpM(I) complexes [CpM(cod), $CpM(CO)_2$ and $CpCo(CO)PPh_3$] with 1,4-dithiins (**2**).[4]

Only a few reports have appeared concerning the reactions of transition metal complexes with 1,4-dithiins or 1,4-diselenins. The reported reactions are those between $Fe_2(CO)_9$ and tetraphenyl-1,4-dithiin or its diselenin analogue to give the (dichalcogenato)(hexacarbonyl)diiron, together with ferracycle complexes, via the presumed expulsion of diphenylacetylene.[5,6]

Equimolar mixtures of CpM(cod) or $CpCo(CO)_2$ and 1,4-dithiins (each *ca* 0.37 mmol) in toluene (25 cm^3) were reacted at room temperature or at appropriate temperatures under an atmosphere of argon. The products were separated by means of silica gel column chromatogaphy (column, Wako Gel C300; eluent, hexane–dichloromethane) or preparative

[a] In benzene.
[b] 2,4-Dinitro-3,6-diphenylthiophene was obtained in a 50% yield.

HPLC (apparatus, LC-08 manufactured by Japan Analytical Industry Co. Ltd) which employed a column of GPC (eluent, chloroform). The products were identified spectroscopically (MS, NMR, and IR).*

The results in the reactions of CpM(cod) or $CpCo(CO)_2$ with 1,4-dithiins are summarized in Table 1.

The complex CpCo(cod) reacts with **2a** at room temperature for 5 h to give (η-cyclopentadienyl)(1,2-dicyano-1,2-ethylenedithiolato)cobalt(III) (**3a**-Co) and 2,3,4,5-tetracyanothiophene (**4a**) in 23 and < 1% yields, respectively. In the reaction of CpCo(cod) with **2a** at 110°C for 5 h, the yields of **3a**-Co and **4a** rise to 27 and 8%, respectively. The formation of thiopene, a by-product, was enhanced with an increase of temperature. The complex CpRh(cod) does not react with **2a** at room temperature but reacts at 110°C to afford $CpRh(S_2C_2(CN)_2)$ (**3a**-Rh) (17%) and **4a** (6%). However, CpIr(cod) does not react with **2a** even at 110°C, perhaps because of the strong coordination of cod to iridium atom. Thus, the reactivities of CpM(cod) for the formation of dithiolato complexes $[CpM(S_2C_2(CN)_2)]$ in the reaction between CpM(cod) and 2,3,4,5-tetracyano-1,4-dithiin are in the order of CpCo (cod) > CpRh(cod) ≫ CpIr(cod). This order is similar to the reactivities for the formation of the dithiolato complexes in the reactions of CpM(cod) with alkyne and S_8.[1] The complex CpIr(cod) gives no dithiolato complex in the reaction with dimethyl acetylenedicarboxylate and S_8 under similar conditions.

As seen in Table 1, the reactivities of symmetrically-substituted 1,4-dithiins with CpCo(cod) or $CpCo(CO)_2$ for the formation of dithiolato complexes increase with increasing electron-attracting abilities of substituents (X and Y) in the following order: X = Y = CN > X = NO_2, Y = Ph ≫ X = *p*-C_6H_4—Cl, Y = H > X = Ph, Y = H.

The leaving ligands also affect the reactivities of the complexes toward 1,4-dithiins. In the reaction with **2b** (at 140°C for 5 h), $CpCo(CO)PPh_3$ showed higher activity (4.4%) than CpCo(cod) or $CpCo(CO)_2$.

The reaction of the unsymmetrically-substituted 1,4-dithiins (**2e** and **2f**) is of interest. How fast do they react with $CpM(CO)_2$? Which moiety of 1,4-dithiins is incorporated in the dithiolatometal complexes as the ligand?

2-Nitro-3,6-diphenyl-1,4-dithiin (**2e**) reacts with $CpCo(CO)_2$ faster than 2,5-diphenyl-1,4-dithiin (**2b**): At 110°C, **2b** reacts with $CpCo(CO)_2$ only

* The novel complexes were identified by elemental analysis, MS, NMR and IR. $CpCo(S_2C_2PhCl,H)$ (**3c**-Co): m.p. 142–143°C; ^1H NMR ($CDCl_3$) δ = 5.38 (5H, s, Cp), 8.97 (^1H, s, dithiolene H), 7.72 (2H, d, J = 8.79 Hz), 7.28 (2H, d, J = 8.79 Hz); ^{13}C NMR ($CDCl_3$) δ = 79.41 (Cp); MS (70 eV) m/z 324 (M^+). Found: C, 48.2; H, 2.9. Calc. for $C_{13}H_{10}CoS_2Cl$: C, 48.1; H, 3.1%. $CpCo(S_2C_2Ph,NO_2)$ (**3d**-Co): m.p. 175–176°C; ^1H NMR ($CDCl_3$) δ = 5.51 (5H, s, Cp), 7.2–7.3 (2H, m, phenyl H), 7.3–7.4 (3H, m, phenyl H); ^{13}C NMR ($CDCl_3$) δ = 80.9 (Cp), 162.7 and 173.0 (dithiolene C); MS (70 eV) m/z 335 (M^+). Found: C, 46.3; H, 2.9; N, 4.0. Calc. for $C_{13}H_{10}CoO_2S_2N$: C, 46.6; H, 3.0; N, 4.2%. $CpRh(S_2C_2(CN)_2)$ (**3a**-Rh): m.p. 208–209°C; ^1H NMR [$(CD_3)_2CO$] δ = 6.22 (5H, s, Cp); IR (KBr) 2210 cm^{-1} (s) ν(—C≡N); MS (70 eV) m/z 308 (M^+). Found: C, 35.1; H, 1.6; N, 9.0. Calc. for $C_9H_5S_2N_2Rh$: C, 35.1; H, 1.6; N, 9.1%. Other dithiolato complexes (**3a**-Co and **3b**-Rh) were identified in a similar manner.

slightly, while **2e** reacts with $CpCo(CO)_2$ even at 50°C [eq. (2)]. The electron-attracting NO_2 should promote the reactivity of the dithiin. Interestingly, the moiety containing NO_2 is not incorporated in the dithiolato complex and $CpCo(S_2C_2Ph,H)$ is formed selectively. Similar results were obtained in the reaction of 2-nitro-3,6-di(*p*-chlorophenyl)-1,4-dithiin (**2f**) with $CpCo(CO)_2$: the nitro group in 1,4-dithiin accelerates the reaction, but the less electronegative moiety is incorporated in the dithiolato complex [eq. (3)].

In the reaction of **2e** with $CpCo(CO)PPh_3$, the benzene derivative which would be formed in the trimerization of 1-nitro-2-phenylacetylene under the catalyst of the phosphine-coordinated species was detected by MS, together with the increase of the yield of $CpCo(S_2C_2Ph,H)$ (about 20%) [eq. (4)].

The reactions of CpM(cod) or $CpCo(CO)_2$ with 1,4-dithiins afford a convenient method for the preparation of some new dithiolato complexes, such as $CpCo(S_2C_2Ph,NO_2)$, $CpCo(S_2C_2C_6H_4Cl(p),H)$, and $CpCo(S_2C_2(CN)_2)$, which could not be synthesized in the reactions of CpM(cod) with S_8 and alkynes (X—C≡C—Y) owing to the difficulty in the preparation of X—C≡C—Y.[1]

SYNTHESIS AND CHARACTERIZATION OF A PYRIDINE ADDUCT OF BIS(IRONTETRACARBONYL)GERMANIUM(IV)

D. LEI, M. J. HAMPDEN-SMITH* and E. N. DUESLER

Department of Chemistry and Center for Micro-Engineered Ceramics,
University of New Mexico, Albuquerque, NM 87131, U.S.A.

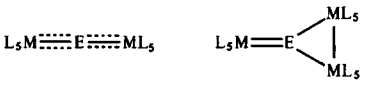
(*Received* 8 *November* 1989; *accepted* 9 *January* 1990)

Abstract—The reaction of $[(CO)_4FeGeBr_2]_2$ (**1**) with $Na_2Fe(CO)_4$ (**2**) in the presence of pyridine results in the formation of $[\{(CO)_4Fe\}_2Ge \cdot 2py]$ (**3**) in high yield. A single crystal X-ray diffraction study of **3** reveals that the local environment around germanium is severely distorted from tetrahedral coordination.

The chemistry of transition metal compounds containing bonds to heavier Group 14 elements has been extensively studied.[1] Multiply-bonded species, particularly of the types shown in **I** and **II** below that can be written in a form containing a formal transition metal–Group 14 element "double bond", (**I**), or as an ylide (**II**), are also well known.[2]

I **II**

The chemistry of *homoleptic* transition metal multiply-bonded Group 14 complexes has recently been reviewed[3] and is limited to the species of type **III**[4,5] and **IV**[4,6] below, where ML_5 represents $[W(CO)_5]$ or $[Mn(CO)_2Cp]$ and E = Ge or Sn. Type **III** species, where $ML_5 = Mn(CO)_2Cp$, contain Mn—E partial triple bonds, which accounts for their facile internal rotation about the Mn—E—Mn axis.[7] The metal–metal multiple bonds in these species seem to be surprisingly inert toward further oligomerization, probably as a result of coordinative saturation at the transition metal centres involved.



III **IV**

Zybill *et al.*[8] have recently reported the synthesis and structure of $[Si(Fe(CO)_4)_2] \cdot 2(Me_2N)_3PO$ prepared by the reaction of $SiCl_4$ with two equivalents of Collman's reagent. Here we report the high yield synthesis and characterization of a multiply-bonded homoleptic germanium–iron cluster, which can formally be considered as a base stabilized inorganic analogue of allene.

Treatment of a diethyl ether solution of **1** with a pyridine–diethyl ether solution of Collman's reagent **2**, according to eq. (1), resulted in the formation of a deep red–orange solution with the concomittant precipitation of sodium bromide.

After filtration, removal of the volatile components *in vacuo*, extraction into toluene, and crystallization at −30°C, red–orange crystals of **3** were isolated in 67% yield. Compound **3** was identified by its elemental analysis, NMR, IR and mass spectroscopic data.† The position of the germanium

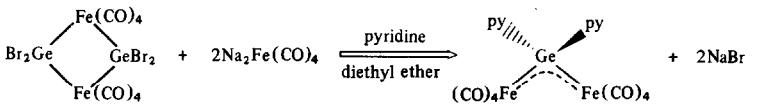
† ^1H NMR data (250.13 MHz, 20°C, C_6D_6): 8.67 ppm, s. br; 6.68 ppm, s. br; 6.38 ppm, s. br. ^{13}C NMR data (62.9 MHz, 20°C, C_6D_6): 126.1, 141.6, 146.8, 216.3 ppm. IR data (KBr disc, cm^{-1}): ν(C—O) 2036, m; 2011, s; 1914, s; ν(N—C) 1607, w; 1451, w; ν(M—C) 615. Mass spectral data (30 eV): no molecular ion observed, highest mass m/z 409 = $[Ge(Fe(CO)_4)_2]$ (10% relative abundance) then m/z = 381, 353, 325, 297, 269, 241, 213 and 185 corresponding to CO loss. Base mass m/z = 139 with Ge isotope distribution pattern. Elemental analysis: Found: C, 37.9; H, 1.7; N, 5.1. Calc. for $C_{18}H_{10}O_8N_2Fe_2Ge$: C, 38.1; H, 1.8; N, 4.9%.



1 2 3 (1)

atom was assigned to an axial iron coordination site based on the observation of three IR active carbonyl stretching modes at 2036, 2011 and 1914 cm^{-1} in the solid state, characteristic of local C_{3v} symmetry ($2A_1 + E$) at each iron centre.[9] However, the single carbonyl resonance observed in the ^{13}C NMR spectrum indicates that the molecule is stereochemically non-rigid in solution on the NMR timescale.*

To unambiguously determine the ground state structure of this species, a single crystal X-ray diffraction study was carried out. Compound **3** crystallizes in the space group *Pccn* with two independent molecules in the unit cell, one type in a general position, and the other on a two-fold axis.† The structural parameters for both molecules are very similar, so only one type will be discussed in detail. The molecular structure of **3** is shown in Fig. 1, together with relevant bond distances and angles. Compound **3** possesses approximate C_{2v} molecular symmetry and local C_{3v} symmetry about the iron atoms with the germanium atom in axial positions, analogous to the structure adopted by $(CO)_4FeGeR_2 \cdot L$ species. The coordination environment about germanium is significantly distorted, with an enlarged Fe—Ge—Fe angle of 131° and a reduced N—Ge—N angle of 89°. The average Fe—Ge bond distances of 2.35 Å are over 0.1 Å shorter than the value expected for an Fe—Ge single bond.[10]

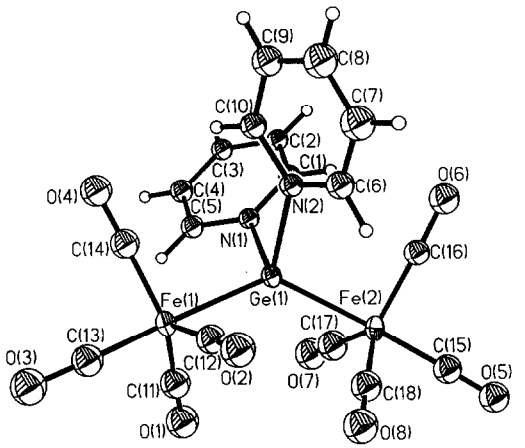


Fig. 1. Thermal ellipsoid plot of **3** emphasizing the enlarged Fe—Ge—Fe angle.

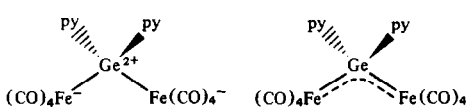
Relevant distances (Å):

Fe(1)—Ge(1)	2.339(4)	Fe(1)—C(11)	1.71(2)
Fe(2)—Ge(1)	2.351(3)	Fe(1)—C(12)	1.77(2)
Ge(1)—N(1)	2.05(1)	Fe(2)—C(15)	1.73(2)
Ge(1)—N(2)	2.08(1)	Fe(2)—C(16)	1.71(2)
Fe(1)—C(13)	1.69(3)	Fe(2)—C(17)	1.74(3)
Fe(1)—C(14)	1.74(2)	Fe(2)—C(18)	1.73(3)

Relevant angles (°):

Fe(1)—Ge(1)—Fe(2)	131.0(1)
N(1)—Ge(1)—N(2)	89.4(6)
N(2)—Ge(1)—Fe(1)	105.4(4)
N(2)—Ge(1)—Fe(2)	108.8(4)
N(1)—Ge(1)—Fe(1)	108.6(4)
N(1)—Ge(1)—Fe(2)	105.8(4)
Ge(1)—Fe(1)—C(13)	178.6(8)
Ge(1)—Fe(2)—C(15)	177.6(7)

These data are consistent with the representation of this species in either of the two canonical forms shown below: a double ylide (**V**) or as a base stabilized inorganic analogue of allene (**VI**).



V **VI**

* No change in the ^{13}C NMR carbonyl resonance was observed on cooling a toluene-d_8 solution of **3** to −90°C.

† The red-orange crystal used for the X-ray study (0.092 × 0.184 × 0.575 mm) was sealed in a glass capillary under nitrogen. Crystal data: Empirical formula $C_{27}H_{15}N_3O_{12}Fe_3Ge_{1.5}$, orthorhombic space group Pccn, a = 23.840(5), b = 15.528(3), c = 17.977(4) Å, Z = 8. A total of 3113 independent reflections were measured on a Nicolet R3m/v diffractometer (293 K) using graphite monochromated Mo-K_α radiation, λ = 0.71073 Å, with ω scan node. 2θ max = 40°. The structure was solved by direct methods using SHELXTL PLUS (Microvax II) and was refined using full-matrix least-squares method. Positions of iron and germanium were refined anisotropically, other non-hydrogen atoms were refined isotropically and hydrogen atom positions were fixed. The final agreement factors were R = 10.11 and R_w = 6.94% for 2070 reflections having $F > 3.0\sigma(F)$. A final difference Fourier was featureless with the largest peak being 1.08 eÅ^{-3}. No unusual intermolecular interactions are observed. Atomic coordinates and equivalent isotopic displacement coefficients are available as supplementary material.

Considering this species as a derivative of inorganic allene {i.e. $[(CO)_4Fe{=}Ge{=}Fe(CO)_4]$ (**4**)} is consistent with the well-established isolobal analogy between $[:CH_2]$ and $[:Fe(CO)_4]$.[11] This explanation is also consistent with (i) the small N—Ge—N angle resulting from the donation of the pyridine lone pair into two empty, mutually orthogonal *p*-orbitals, (ii) the shortened Fe—Ge bonds, and (iii) the large Fe—Ge—Fe angle. The double ylide form (V) can be considered in two ways: either with the positive charge localized on Ge^{IV} or localized at the nitrogen centres analogous to a pyridinium salt. If this canonical form is dominant, tetrahedral geometry at germanium is expected.

The synthesis of this compound can be rationalized in terms of the rapid Ge—Fe bond homolysis in the presence of Lewis bases that has previously been observed in other systems containing four-membered rings,[12] together with a simple metathesis reaction. In the absence of pyridine, the reaction of eq. (1) results in the formation of a gel, which can be dried to form an orange polymeric material. The characterization and properties of this polymer will be reported separately.[13]

Thus far, we have been unable to isolate **4** by removing the pyridine ligands thermally from **3**.* Isolation and characterization of the ground state structure of **4** to determine the linearity of the Fe=Ge=Fe framework, the local coordination environment about iron (C_{2v} or C_{3v}), the relative orientation of the $[Fe(CO)_4]$ fragments, and the barrier to rotation about the Fe=Ge bonds, is of primary importance in understanding the chemistry of these species.

Further studies are in progress.

Acknowledgements—We thank Dr D. Doughty and Professor Vince Ortiz for helpful discussions, Eva Quesnell for typing this manuscript, the Sandia-University Research Program for Financial Support, and NSF for the purchase of a high-field NMR spectrometer.

* Thermal removal of pyridine has been demonstrated in the $(CO)_4FeER_2 \cdot py$ systems, see ref. 12(a).

SYNTHESIS AND CHARACTERIZATION OF ALKOXYCARBONYLRHENIUM(III) COMPLEXES

A. HUGO KLAHN† and CAROLINA MANZUR

Instituto de Química, Universidad Católica de Valparaíso, Casilla 4059, Valparaíso, Chile

(*Received* 24 *July* 1989; *accepted* 6 *November* 1989)

Abstract—The reaction of the cationic complexes $[(\eta^5\text{-}C_5Me_5)Re(CO)_3X]^+$ (X = Cl, Br and I) with alkoxide anions in alcohol or dichloromethane results in the formation of the alkoxycarbonylrhenium(III) complexes, *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2(I)(COOR)$ (X = Cl and Br, R = Me and X = I, R = Me, Et and *i*-Pr). The *trans* orientation of the carbonyl groups in these complexes was assigned by IR spectroscopy.

Alkoxycarbonyl complexes of transition metals (i.e. metalloesters) have been proposed as intermediates in important catalytic reactions,[1,2] and more recently as "abnormal" insertion products in the reaction of metal–alkyl complexes with CO_2.[3] These compounds have usually been synthesized by reacting carbon monoxide coordinated to neutral or cationic complexes with alcohols or alkoxide anions. Some recent examples of alkoxycarbonyl complexes reported are: $[M(CO)_4(COOMe)]^-$ (M = Fe, Ru, Os);[4] $(\eta^5\text{-}C_5R_5)Re(CO)(N_2Ar)(COOR')$ (R = Me and H, R' = Me and *i*-Pr);[5] $(\eta^5\text{-}C_5Me_5)Ru(CO)_2(COOR)$ (R = Me, Et, *i*-Pr and *t*-Bu)[6] and $[Fe(CO)(PMe_3)_2(CNC_6H_{11})(C(Me){=}NHC_6H_{11})(COOMe)]^+$.[7] Nucleophilic attack at the CO ligand has been suggested in all cases.

In previous publications we described the synthesis of cationic pentamethylcyclopentadienyltricarbonylhalide complexes $[Cp^*Re(CO)_3X]^+$ ($Cp^* = \eta^5\text{-}C_5Me_5$, X = I[8] and X = Br and Cl).[9] We now wish to report the results of nucleophilic attack of RO^- on a carbonyl group of these cationic complexes. To our knowledge these reactions are the first examples of rhenium(III) cationic complexes possessing a four-legged pianostool type of structure where one of the CO groups has been transformed into an alkoxycarbonyl ligand. The assignment of the stereochemistry and the reaction of the alkoxycarbonyl complexes with HBF_4 are also included in this report.[10]

† Author to whom correspondence should be addressed.

EXPERIMENTAL

All reactions were carried out under nitrogen using Schlenk apparatus connected to a double manifold providing a low vacuum or nitrogen atmosphere. IR spectra were measured in solution (KBr cells) on a Perkin–Elmer 599 instrument. ^1H NMR spectra were recorded at 60 MHz on a Varian EM 360 instrument. Mass spectra (Hewlett–Packard model 5985), 400 MHz ^1H NMR spectra (Bruker WM-400) and elemental analyses were obtained using the Chemistry Department facilities at the Simon Fraser University, Canada.

Alcohols were distilled under nitrogen prior to use. $Cp^*Re(CO)_3$ was synthesized from $Re_2(CO)_{10}$ according to a literature procedure.[11]

Preparation of trans-$Cp^*Re(CO)_2(I)(COOR)$ (R = Me *and* Et)

The complex $[Cp^*Re(CO)_3I]I_3$ (about 200 mg), prepared by reacting $Cp^*Re(CO)_3$ with an excess of I_2 in hexane,[8] was dissolved in the corresponding alcohol (5.0 cm^3) and then treated with 0.1 cm^3 of NEt_3 at 0°C. The solution changed slowly from dark red to orange. After 1 h the alcohol was pumped off and the orange residue extracted with hexane (3 × 10 cm^3). Crystallization from hexane at −10°C yielded orange–yellow crystals of the corresponding alkoxycarbonyl complex (38% yield). In both cases (R = Me and Et) the complexes decomposed above 95°C without melting. Elemental analysis for $C_{14}H_{18}O_4IRe$: (R = Me) Found:

C, 30.1; H, 3.3. Calc.: C, 29.8; H, 3.2%. For $C_{15}H_{20}O_4IRe$: (R = Et) Found: C, 31.0; H, 3.5. Calc.: C, 31.1; H, 3.5%.

Preparation of trans-Cp*Re(CO)$_2$(I)(COOCHMe$_2$)

[Cp*Re(CO)$_3$I]I$_3$ (100 mg) was dissolved in 5.0 cm^3 of CH_2Cl_2 and cooled to 0°C. To this red solution, sodium isopropoxide (Alfa) (10 mg) dissolved in 2.0 cm^3 of isopropanol was slowly added and stirred for 2 h. Solvent evaporation *in vacuo*, extraction and crystallization in hexane yielded 22 mg (35%) of orange–yellow crystals, which decomposed without melting above 90°C. Elemental analysis for $C_{16}H_{22}O_4IRe$: Found: C, 32.3; H, 3.7. Calc.: C, 32.5; H, 3.7%.

Preparation of trans-Cp*Re(CO)$_2$(X)(COOMe) (X = Cl *and* Br)

A procedure similar to that described for the preceding compound, gave the chloro- and bromomethoxycarbonyl complexes as a crystalline yellow solid, in about 30% isolated yield. Both complexes decomposed without melting above 80°C. Elemental analysis for $C_{14}H_{18}O_4ClRe$: Found: C, 35.5; H, 3.7. Calc.: C, 35.6; H, 3.8%. For $C_{14}H_{18}O_4BrRe$: Found: C, 32.5; H, 3.4. Calc.: C, 32.5; H, 3.5%.

The spectroscopic data of these complexes are listed in Table 1.

Reaction of trans-Cp*Re(CO)$_2$(X)(COOMe) (X = Cl, Br, I *with* HBF$_4$)

The methoxycarbonyl complex *trans*-Cp*Re(CO)$_2$(X)(COOMe) (50 mg) was dissolved in 5.0 cm^3 of dry Et_2O and an excess (0.5 cm^3) of a 50% ether solution of HBF_4 (Alfa) was slowly added through a syringe, at room temperature with stirring. The precipitate of [Cp*Re(CO)$_3$X]BF$_4$ formed was washed three times with ether and dried *in vacuo*.

The isolated yields and melting points of the [Cp*Re(CO)$_3$X]BF$_4$ complexes are: X = I, 97%, > 140°C d.; X = Br, 96%, > 100 d.; X = Cl, 94%, > 80°C d.

RESULTS

The reaction of the cationic complex [Cp*Re(CO)$_3$X]$^+$ (X = Cl, Br and I) with alkoxide ions (as a solid, or generated *in situ* from the corresponding alcohol and Et_3N) as in eq. (1), yields after work-up, single orange–yellow crystals, characterized as the alkoxycarbonyl complexes *trans*-Cp*Re(CO)$_2$(X)(COOR) (X = Cl and Br, R = Me; X = I, R = Me, Et and *i*-Pr). The spectroscopic parameters are listed in Table 1.

Br	Me	2050 s 1965 vs	1635	2.00[e]	3.60
Cl	Me	2065 s 1970 vs	1635	1.93[e]	3.58

[a] Measured in CH_2Cl_2 solution. s = strong; vs = very strong; m = medium.
[b] Terminal CO.
[c] Metalloester CO.
[d] Measured in $CDCl_3$ at 400 MHz.
[e] Measured in $CDCl_3$ at 60 MHz.

The IR spectrum (CH_2Cl_2 solution) of these complexes exhibits ν(CO) absorptions at *ca* 2065 and 1960 cm^{-1}, which can be attributed to two terminal CO groups in a neutral complex (see below), and a medium intensity absorption at about 1640 cm^{-1} assigned to the ν(C═O) of a metalloester group (—CO_2R). The latter value is in good agreement with the frequencies for this group observed in other related complexes.[4–7] The presence of the alkyl group of the alkoxycarbonyl ligands was also confirmed by ^1H NMR (see Table 1).

As a solid, the complexes decompose without melting at about 90°C. At room temperature under nitrogen atmosphere, they do not survive for periods longer than 3 days, the iodo derivatives being the most stable. The observed decomposition products (by IR), are the $Cp^*Re(CO)_3$ and $Cp^*Re(CO)_2X_2$ complexes (2:1). Similar decomposition products were observed for the iodo series by ^1H and ^{13}C NMR during an overnight run in $CDCl_3$ solution. The electron-impact MS do not show any parent peak even at 14 eV. Instead, the spectra show the presence of the tricarbonyl and $Cp^*Re(CO)_2X_2$ complexes. In spite of the thermal instability of the complexes at room temperature, they can be stored as solids at −10°C, under nitrogen, for months without visible deterioration.

As expected, an electrophilic attack on the alkoxy oxygen was observed in the reaction of the alkoxycarbonyl complexes with HBF_4 in ether solutions. The parent cationic complex, as a BF_4^- salt, could be isolated almost quantitatively as a red–orange (X = I) or orange–yellow (X = Cl and Br) solid, $\nu(BF_4)$ 1060 cm^{-1} (in CH_2Cl_2 solution). Evidence for the stereochemistry of the alkoxycarbonyl complexes was obtained from analysis of the intensity ratio of the symmetric and antisymmetric CO stretching vibrations of the terminal CO ligands, ν_s(CO) and ν_{as}(CO), respectively. The IR spectrum in each case consists of only two ν(CO) absorptions in the 1950–2070 cm^{-1} region, of which the lower frequency band [ν_{as}(CO)] is much more intense. Using this criterion, as well as the correspondence between our IR values and those reported for *trans*-$CpRe(CO)_2X_2$ (Cp = η^5-C_5H_5, X = Br and I[12]) and *trans*-$Cp^*Re(CO)_2X_2$ (X = Cl, Br and I[8]) we consider our products to be also the *trans* isomers.

We have used the relative ν(CO) IR intensities to calculate the angle between the CO groups using the relationship[13] $\tan^2\theta = I_{as}/I_s$, where I_{as} and I_s are the areas under the antisymmetric (at lower frequency) and symmetric (at higher frequency) bands, respectively, and 2θ is the angle between the two CO groups. The angles thus determined by this method are close to 130° in all cases, in accordance with their postulated *trans* or diagonal structure. It is important to note that angles between 104 and 147° have been determined by X-ray crystallography and by estimation from the ν(CO) intensities in the complexes containing a four-legged piano-stool type structure.[14]

DISCUSSION

The production of the dicarbonyl alkoxycarbonyl complexes, *trans*-$Cp^*Re(CO)_2(X)(COOR)$, from the tricarbonyl cations $[Cp^*Re(CO)_3X]^+$ evidently results from straightforward attack of the nucleophile on the relatively electrophilic carbonyl carbon atom in these cations.[15] These results are those expected according to Angelici's predictions[16] that carbonyl-containing compounds with $\nu(CO) > 2000$ cm^{-1} should yield these types of complexes. It is worth noting that possible products, which were *not* observed in these reactions, are the dicarbonyl alkoxides, $Cp^*Re(CO)_2(X)(OR)$, resulting from direct CO substitution or the tricarbonyl complex $Cp^*Re(CO)_3$ formed by reductive elimination of the halide ligand. Even though the tricarbonyl complex was not observed during the formation of the alkoxycarbonyl complexes it is the major decomposition product of these compounds. The manner in which these complexes are able to generate the tricarbonyl and dihalide complexes, $Cp^*Re(CO)_3$ and $Cp^*Re(CO)_2X_2$, when they decompose, is a matter of some interest but one about which presently we have no mechanistic information.

The exclusive appearance of the *trans* isomer in these rhenium alkoxycarbonyl complexes is not completely understood at the present time. Recently, we undertook a vibrational study of the cationic complexes[17] with the aim to determine which of the CO group (*cis* and *trans* to the halide ligand) is more likely to react with nucleophiles.

Acknowledgements—The authors express their gratitude to Professor D. Sutton and Ms Z. Xiaoheng for remaking some of the complexes and obtaining the NMR, MS and EA data at the Chemistry Department facilities of Simon Fraser University, Canada. The support of this research by D.G.I., Universidad Católica de Valparaíso and FONDECYT through operating grants to A.H.K., 125.709/87 and 155/89, respectively, are also appreciated.

ELECTROCHEMICAL OXIDATION OF TETRA-(*S*)-MANDELATODIRHODIUM(II) AND TETRAFORMATODIRHODIUM(II)

A. SZYMASZEK and F. P. PRUCHNIK*

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 9 *October* 1989; *accepted* 30 *November* 1989)

Abstract—Rhodium complexes $[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4]$ and $[Rh_2(O_2CH)_4]$ were investigated by electrochemical and spectral techniques in organic solvents and results were compared with those for $[Rh_2(O_2CCH_3)_4]$. The complexes were reversibly oxidized to yield Rh^{II}–Rh^{III} dimers. The half-wave potentials for $[Rh_2(O_2CR)_4L_2]$ (R = H, CH_3, $CH(OH)C_6H_5$) were found to bear a linear relationship with the RCOOH acid dissociation constant. The oxidation process becomes more favourable as the donor number of axial ligand increases. Electronic and ESR spectra of Rh^{II}–Rh^{III} complexes were investigated.

The binuclear rhodium(II) carboxylate complexes are widely studied, because of the interest in the theory of their electronic structure, reactivity and catalytic properties.[1,2] They also exhibit cytostatic and anticancer activity.[1–3]

Electrochemical investigations of the $[Rh_2(OORC)_4L_2]$ complexes allowed better recognition of their electronic structure and reactivity. Rhodium(II) carboxylates oxidate reversibly to Rh^{II}–Rh^{III} complexes, while their reduction is irreversible.[4–6] Oxidation potentials of $[Rh_2(OOCR)_4L_2]$ were discovered to decrease with an increase in the electron-donor properties of the R groups, and to decrease with an increase of the donor number of ligands, L, bound along the Rh—Rh axis (Fig. 1).

The rhodium(II) complexes with the chiral carboxylates are interesting from the point of view of their application in the asymmetric synthesis of the organic compounds. The interest in rhodium(II) chiral carboxylates has been maintained in recent years by their potential applications in chiral organic syntheses. Tetra-(*S*)-mandelatodirhodium catalyses cycloaddition reactions of dimethyl diazomalonate to 1-alkenes to give chiral cyclopropane compounds.[7]

The $[Rh_2(PhCHOHCOO)_4]$ and $[Rh_2(PhCHOHCOO)_2(N\text{-}N)_2Cl_2]$ (Ph = C_6H_5, N-N = 2,2′-bipyridine, 1,10-phenanthroline) complexes are precursors of the effective catalysts for reduction of olefins and ketones.[8] The $[Rh_2(O_2CR)_4]$ complexes also catalyse the oxidation of olefins and alkyl aromatic hydrocarbons.

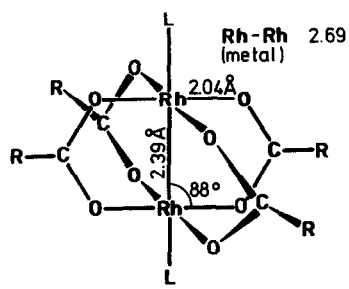

Fig. 1. Structure of tetracarboxylatodirhodium(II).

It seemed interesting to study the electrochemical oxidation of tetramandelatodirhodium(II) and compare its electrochemical properties with that of $[Rh_2(O_2CR)_4]$ dirhodium(II) carboxylates. Prior to this, we have examined the electrochemical properties of rhodium(II) mandelate in methanol.[9] To our knowledge, electrochemical properties of rhodium(II) formate were not investigated.

EXPERIMENTAL

$[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4(H_2O)_2]$,[10] $[Rh_2(O_2CCH_3)_4(H_2O)_2]$,[11] and $[Rh_2(O_2CH)_4]$,[12] were synthesized by the literature methods. All complexes were stored over molecular sieves (3 Å), at room temperature. Tetra-*n*-butylammonium tetrafluoroborate, $n\text{-}Bu_4NBF_4$ (Fluka), used as supporting

* Author to whom correspondence should be addressed.

electrolyte, was recrystallized from an acetone–ether (1 : 1) mixture and dried *in vacuo*. The solvents were dried over molecular sieves. Tetrahydrofuran (THF) and dimethylformamide (DMF) were distilled *in vacuo* over CaH_2 and dichloromethane and acetonitrile over P_4O_{10}. For both electrochemical and spectroscopic experiments all solvents contained 0.1 M *n*-Bu_4NBF_4. Measurements were performed on a Polarographic Analyser PA-4 (Laboratorni Pristroje) using a three-electrode system. The working electrode was a planar platinum electrode ($s = 0.98\ cm^2$). A coiled platinum wire served as the counter-electrode. Potentials were measured relative to a saturated calomel electrode (SCE), which was separated from the examined solution by a bridge filled with electrolyte. The solution in the bridge was periodically exchanged. Ferrocene ($Fecp_2^+/Fecp_2$)[13] was used as an internal standard. Coulometric measurements were made with a Radelkis OH-404 apparatus. The anode was platinum foil ($s = 6.5\ cm^2$), the cathode—mercury ($s = 8\ cm^2$). The coulometric electrolyses were carried out in an electrolyser with cells separated by a glass sinter (G-4). The reference electrode (SCE) was separated from the oxidation solution by means of an electrolytic bridge. Solutions in both cells were stirred magnetically. All measurements were performed at room temperature ($20 \pm 2°C$) in solutions deaerated by a stream of argon (p.a. grade).

Electronic absorption spectra were recorded on a Cary 14 spectrophotometer. The ESR spectra were measured at liquid nitrogen temperature, on a Jeol 3JSMX spectrophotometer.

RESULTS AND DISCUSSION

The cyclic voltammogram of the $[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4(H_2O)_2]$ solution in DMF on the platinum electrode vs SCE is shown in Fig. 2. In the potential range 0–1.5 V it shows a single wave, corresponding to one-electron oxidation (Fig. 2). Analogous voltammograms were obtained for $[Rh_2(C_6H_5CHOHCOO)_4]$ in CH_2Cl_2, CH_3CN and THF solutions and for $[Rh_2(O_2CH)_4]$ and $[Rh_2(O_2CCH_3)_4]$ in DMF solution. During the electro-oxidation of all dirhodium(II) carboxylates in each solution the potential separations ($E_{p,c} - E_{p,a}$) were in the range 60–70 mV, at the cyclic sweep rates $v = 0.02$–$0.5\ V\ s^{-1}$ (Table 1). The ratios of the

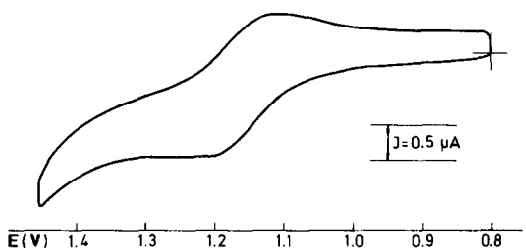

Fig. 2. Cyclic voltammogram of 6×10^{-4} M $[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4(H_2O)_2]$ in DMF/0.1 M *n*-Bu_4NBF_4 on the platinum electrode vs SCE, scan rate 200 mV s^{-1}.

Table 1. Electrochemical data for oxidation of $[Rh_2(O_2CR)_4(H_2O)_2]$ in DMF (0.1 M *n*-Bu_4NBF_4) on the platinum electrode (vs SCE); $v = 0.2\ V\ s^{-1}$

Compound	$E_{p,a}$[a] (V)	$E_{p,c} - E_{p,a}$ (mV)	$E_{1/2}$ (V)	Coulometric determination of the number of electrons transformed/ Mol of $[Rh_2(O_2CR)_4L_2]$
$[Rh_2(O_2CCH_3)_4L_2]$[b] (0.5 mM)	1.015	70	0.990	0.97 ± 0.05
$[Rh_2\{(S)\text{-}C_6H_5CHOHCO_2\}_4L_2]$ (0.5 mM)	1.200	70	1.170	0.97 ± 0.05
$[Rh_2(O_2CH)_4L_2]$[c] (0.1 mM)	1.240	70	1.215	0.95 ± 0.05

[a] Present potentials were determined at the presence of $Fecp^+/Fecp$ in the same electrolyte ($E_{formal}Fecp^+/Fecp = 0.540$ V vs SCE).

[b] Oxidation potential of $[Rh_2(O_2CCH_3)_4L_2]$ in DMF (0.1 M *n*-Bu_4NBF_4) is 40 mV lower than the literature value for oxidation of $[Rh_2(O_2CCH_3)_4L_2]$ in H_2O,[5] and 20 mV lower than its oxidation in 0.1 M H_2SO_4 given by Wilson and Taube.[4] $[Rh_2\{(S)\text{-}C_6H_5CHOHCO_2\}_4L_2]$ is insoluble in water.

[c] $[Rh_2(O_2CH)_4L_2]$ is slightly soluble in DMF.

$L = H_2O$.

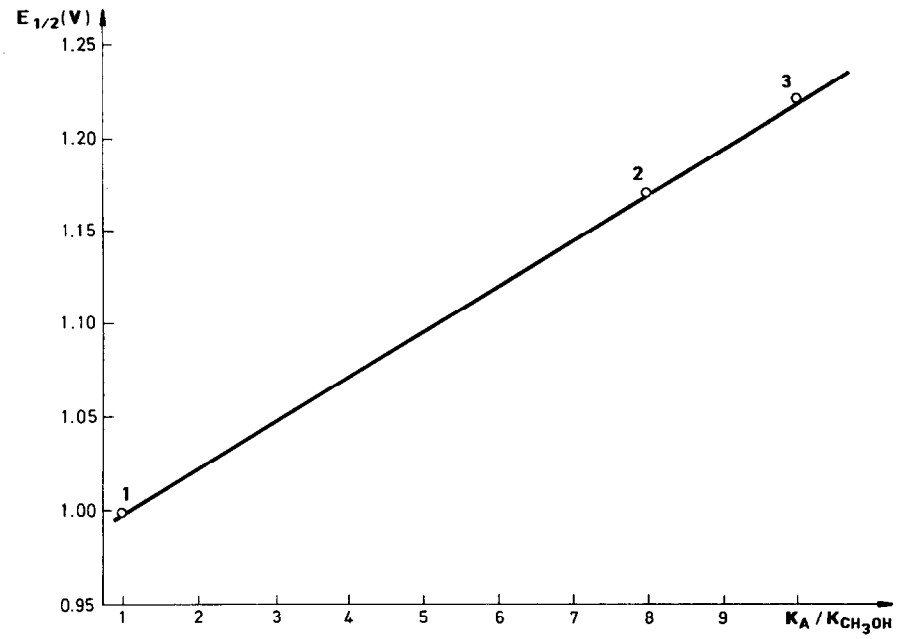

Fig. 3. Plot of the half-wave potentials (V) measured for electro-oxidation of $[Rh_2(O_2CR)_4(H_2O)_2]$ in DMF/0.1 M n-Bu_4NBF_4 vs the K_A/K_{CH_3COOH}: (1) R = CH_3; (2) R = PhC(OH)H; (3) R = H.

cathodic to the anodic peak currents, $i_{p,c}/i_{p,a}$, were close to unity at all scan rates, indicating the absence of coupled chemical reactions.[14] Moreover, the potentials of the anode peak ($E_{p,a/2}$) and formal potentials of all the complexes were independent of the scanning rate: the $i_{p,a}/v^{1/2}$ ratio was constant over the range of scan rates. Such properties are indicative of a one-electron diffusion-controlled Nernstian oxidation. Thus, the electrochemical oxidation of rhodium(II) mandelate and rhodium(II) formate proceed as for the other $[Rh_2(O_2CR)_4]$ complexes.

The stability of rhodium(II) carboxylato complexes, $[Rh_2(O_2CR)_4L_2]$, depends on dissociation constants of RCOOH acids. This is proved by the linear relationship of half-wave potentials with dissociation constants, K_{HA}, or with ratio K_{HA}/K_{CH_3COOH} (Fig. 3). The oxidation potentials are higher for complexes with stronger acids, which, therefore, stabilize the lower oxidation states of the metal.

The effect of axial ligand complexation on the electrode reactions was investigated. It was found that the half-wave potentials decrease with increasing donor number of the solvent (Fig. 4).[15] The donor number can be taken as a measure of the interaction of the axial ligand with the central atoms. The oxidation process becomes more favourable as the interaction of the axial ligand becomes stronger. The shift of the oxidation potential with strength of the axial ligand–rhodium bond indicates that the HOMO levels are destabilized with increasing binding ability of ligands. The differences in the peak potentials, $E = E_{p,c} - E_{p,a}$, for each solvent are near the theoretical value of

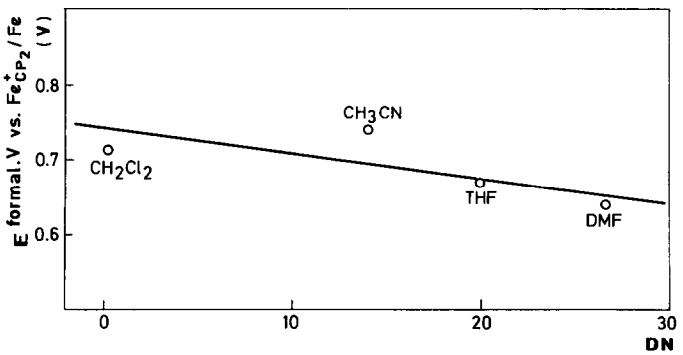

Fig. 4. Dependence of the formal electrode potential of $[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4(H_2O)_2]$ on the donor number of the solvent.

58 mV, corresponding to the reversible transfer of one electron.

$[Rh_2(O_2CR)_4]$ (R = H, Me, PhCHOH) were oxidized coulometrically at potentials 100 mV more anodic than $E_{1/2}$ (Table 1). The complete coulometric oxidation of complexes $[Rh_2(O_2CCH_3)_4(H_2O)_2]$ and $[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4(H_2O)_2]$ in DMF was followed by the change of colour of the solutions from blue to light brown. For $[Rh_2(O_2CCH_3)_2(H_2O)_2]$ the complex regained the blue colour after 24 h. Somewhat different behaviour occurred with $[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4(H_2O)_2]$. The colour of this solution also turned light brown after complete oxidation, but about 20 min after electrolysis was complete, the colour changed to yellow–celadon, under argon atmosphere. After 24 h the reduction process was almost completed and the solution changed to the original blue colour. Reversibility of the oxidation process of rhodium(II) formate, acetate and mandelate was confirmed by the complete reduction of $[Rh_2(O_2CR)_4]^+$ complexes at a potential of +0.6 V.

Similar to electro-oxidation, the consumption of 1.0 electron/dimer was observed, and the cyclic voltammetry of the obtained species gave identical current–voltage curves to those obtained from the original neutral complex.

During the coulometric oxidation of $[Rh_2(O_2CCH_3)_4(H_2O)_2]$ and $[Rh_2\{(S)\text{-}C_6H_5CHOHCOO\}_4(H_2O)_2]$ in DMF (0.1 M n-Bu_4NBF_4) the ESR and absorption spectra were recorded. The resulting absorption spectra are given in Figs 5 and 6 and in Table 2.

The absorption electronic spectra of the $[Rh_2(O_2CR)_4]$ type complexes consist of two weak bands in the visible region, band I (620–500 nm) and band II (450–425 nm). Whereas band II remains almost constant, band I is strongly influenced by changes in the axial ligands and shifts to lower wavelengths depending on the donor atom in the following sequence: I > Br > Cl > O > S > N ⩾ As > P.[1,2,8,10c,16–19] The electronic absorption spectra of the $[Rh_2(O_2CR)_4L_2]^+$ complexes, in addition to the band in the range 400–500 nm, exhibit a new band in the 600–800 nm range. The energy of the latter also depends on the type of ligands coordinated along the Rh—Rh axis. For $[Rh_2(O_2CCH_3)_4(H_2O)_2]^+$,[16–22] the band occurred at 770 nm and was assigned to the $\delta(RhRh) \rightarrow \delta^*(RhRh)$[21] transition. Whereas, in the $[Rh_2(O_2CCH_3)_4(NH_3)_2]^+$ complex this band is located at 570 nm.[22] Since in the spectra of $[Rh_2(O_2CR)_4(DMF)_2]^+$ (R = CH_3, PhCHOH) complexes the band is observed at 770 nm, the DMF molecules should be regarded as coordinated via the oxygen and not the nitrogen atom. In the latter case the strong shift of this band to lower wavelengths should be observed.

The $Rh^{II}Rh^{III}$ complexes in DMF solutions undergo reduction to $[Rh_2(O_2CR)_4]$, both in a

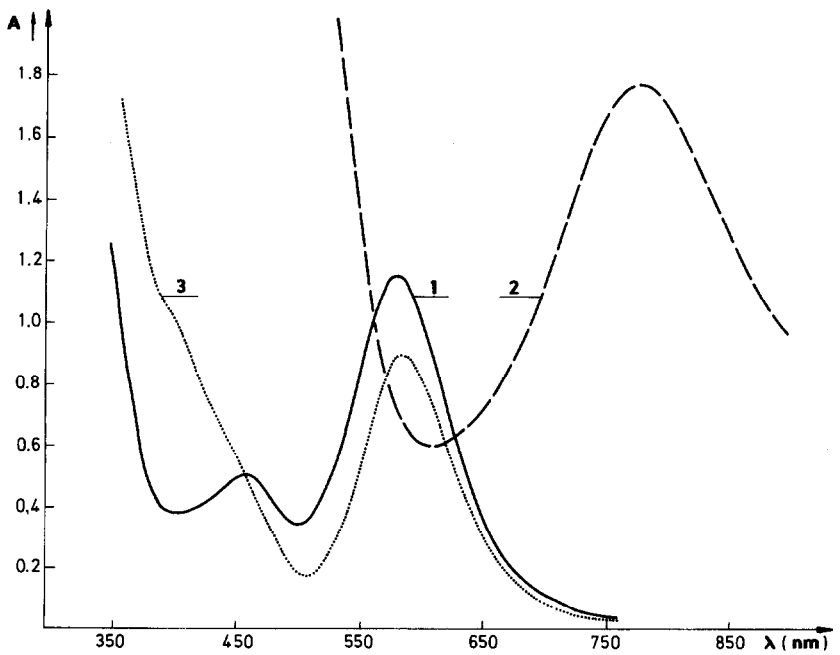

Fig. 5. Electronic absorption spectra obtained during the oxidation of 1×10^3 M $[Rh_2(O_2CCH_3)_4(H_2O)_2]$ in DMF/0.1 M n-Bu_4NBF_4, E_{app} = +1.1 V/SCE: (1) before electrolysis; (2) after electrolysis; (3) 24 h after electrolysis.

L = H_2O.

neutral atmosphere and in air. The rate of this process for the mandelate complex exceeds that for the acetate complex. The faster reduction of the mandelate complex is expected because the oxidation potential of the $[Rh_2(O_2CCHOHPh)_4(DMF)_2]^+$ is higher and this complex undergoes partial reduction after 20–30 min, while $[Rh_2(O_2CCH_3)_4(DMF)_2]^+$ is more stable, and even after 24 h its reduction was not complete (Figs 5 and 6).

HETEROCYCLIC TELLURIUM COMPOUNDS AS LIGANDS; SOME COMPLEXES OF RHODIUM(III) AND RHODIUM(I)

ALI Z. AL-RUBAIE,* YASSIN N. AL-OBAIDI and LINA Z. YOUSIF

Department of Chemistry, College of Science, University of Basrah, Basrah, Iraq

(*Received* 17 *May* 1989; *accepted* 8 *December* 1989)

Abstract—The synthesis and characterization of new rhodium(III) complexes containing tellurium heterocyclic ligands are described. All complexes have the general formula of $RhCl_3L_3$ (where L = C_4H_8Te, $C_4H_8TeI_2$, C_4H_8OTe, C_5H_8Te, $C_6H_{10}Te$, C_8H_5ClTe, $C_{10}H_{12}Te$ and $C_{16}H_{10}Cl_2Te$). Reactions of $RhCl_3L_3$ complexes with carbon monoxide are shown to replace only one cyclic telluride by carbon monoxide under mild conditions. Reactions of square-planar rhodium(I) complexes with tellurium heterocycle ligands are reported.

Rhodium complexes containing organotellurium compounds, namely diphenyltelluride and dimethyltelluride, as donors have been previously prepared and characterized.[1–3]

Our current interest in heterocyclic tellurium compounds[4–7] together with the fact that heterocyclic tellurium compounds, as far as we are aware, have not been used as ligands with rhodium(III) compounds.[8] This prompted us to prepare and investigate properties of a number of new heterocyclic tellurium–rhodium complexes.

EXPERIMENTAL

(a) *Synthesis*

Reactions were carried out in a dry oxygen-free, nitrogen atmosphere. Solvents were dried and distilled before use.

Preparation of ligands. 1-Telluracyclopentane,[5] 1,1-diiodo-telluracyclopentane,[5] 1-oxa-4-telluracyclohexane,[6] 3-methyl-2,5-dihydrotellurophene,[9] 3,4-dimethyl-2,5-dihydrotellurophene,[9] 3-chloro-4,5-benzotellurophene,[10] 2-(chlorovinyl)-3-chloro-4,5-benzotellurophene,[10] di-μ-chlorobis(η^4-1,5-cyclooctadiene)dirhodium(I)[11] and chlorotris(triphenylphosphine)rhodium(I)[12] were prepared by reported methods.

Synthesis of 5,6-*dimethyl*-1,3-*dihydro*-2-*telluraindene*. This new telluride was prepared by the following method. To a suspension of $C_{10}H_{12}TeI_2$ (4.75 g, 7.5 mmol) (this orange compound was prepared by reaction of 1,2-bis(chloromethyl)-4,5-dimethylbenzene with tellurium powder and NaI in 2-butoxyethanol) in 250 cm^3 of ethanol was added dropwise a solution of hydrazine (0.88 g, 2.75 mmol) in 30 cm^3 of ethanol. The resulting solution was warmed gently until the red colour disappeared. The reaction solution was then poured into 1 dm^3 of water and extracted with ether (3 × 200 cm^3). The combined ether extracts were washed with water, dried over $CaCl_2$, and concentrated to dryness on a rotary evaporator. The resulting yellow powder was recrystallized from ethanol to give yellow flakes, m.p. 90–92°C. Found: C, 46.1; H, 4.5. Calc. for $C_{10}H_{12}Te$: C, 46.2; H, 4.7%.

Synthesis of rhodium(III) *complexes*, $RhCl_3L_3$. These complexes were all prepared by the reaction of rhodium(III) chloride trihydrate with the corresponding heterocyclic tellurium compounds. The general preparation route is illustrated by the following example.

Trichlorotris(5,6-*dimethyl*-1,3-*dihydro*-2-*telluraindene*)*rhodium*(III). Rhodium trichloride trihydrate (0.79 g, 3.0 mmol) in dry ethanol (50 cm^3) was added to an ethanolic solution of 5,6-dimethyl-1,3-dihydro-2-telluraindene (2.34 g, 9.0 mmol). The mixture was stirred at room temperature for 24 h. On cooling, a brownish-red solid was obtained, filtered off, washed with ethanol and dried *in vacuo*.

The rhodium(III)–heterocyclic tellurium complexes (along with melting points and elemental

* Author to whom correspondence should be addressed.

analyses), which were prepared by the above general route, are listed in Table 1.

Synthesis of carbonyltrichlorobis(1-telluracyclopentane)rhodium(III), $[RhCl_3(CO)(C_4H_8Te)_2]$. Carbon monoxide was passed through a chloroform solution of $RhCl_3(C_4H_8Te)_3$ (0.46, 4.4 mmol) for 4 h. The solution was filtered and evaporated to dryness. The product was washed several times with hexane to give a brown solid, m.p. 170°C.

Synthesis of carbonyltrichlorobis(3-chloro-4,5-benzotellurophene)rhodium(III), $[RhCl_3(CO)(C_8H_5ClTe)_2]$. Carbon monoxide was passed through a toluene solution of trichlorotris(3-chloro-4,5-benzotellurophene)rhodium(III) (1.32, 5.0 mmol) for 10 h. The solution was filtered and evaporated to dryness. Recrystallization from hexane gave a brown solid, m.p. 152°C.

Synthesis of chloro(η^4-1,5-cyclooctadiene)(1-telluracyclopentane)rhodium(III), $[Rh(COD)(C_4H_8Te)Cl]$. An excess of 1-telluracyclopentane (0.46 g, 2.5 mmol) was added to a solution of $[RhCl(COD)]_2$ (0.25 g, 0.5 mmol) in 30 cm^3 of hexane. The mixture was stirred for 24 h at room temperature. The yellowish-brown product was filtered, washed with hexane and dried *in vacuo*, m.p. 110°C.

Synthesis of di - μ - chloro - bis(1 - oxa - 4 - telluracyclohexane)bis(triphenylphosphine)dirhodium (I), $[Rh(C_4H_8OTe)(PPh_3)Cl]_2$. 1-Oxa-4-telluracyclohexane (0.30 g, 1.5 mmol) was added to 0.46 g (0.5 mmol) of chlorotris(triphenylphosphine) rhodium(I) dissolved in 45 cm^3 of toluene. The mixture was stirred for 12 h at room temperature. The yellowish-brown solid which formed was filtered, washed with dry toluene and dried *in vacuo*, m.p. 156°C.

Table 1. Analytical data, colours and conductivity of the new rhodium(III) complexes

Compound	Colour	Melting point (°C)	Analysis (%)[a] C	H	Conductivity[b] (Ω^{-1} cm^2 mol^{-1})
$RhCl_3$ 	Orange	190	18.3 (18.9)	3.5 (3.2)	2.3
$RhCl_3$ 	Orange	300	17.9 (17.8)	2.9 (2.9)	1.0
$RhCl_3$ 	Red–brown	156	28.5 (28.8)	1.5 (1.5)	3.9

$RhCl_3$ 	Brown	250	9.6 (9.5)	1.7 (1.6)	25.7

[a] Calculated values are in parentheses.
[b] In DMSO solution at 10^{-3} M.

(b) *Physical measurements*

IR spectra were recorded as KBr pellets or Nujol mulls in the range 4000–200 cm^{-1} using a Pye–Unicam SP3-300 IR spectrophotometer. ^1H NMR data were obtained with a Bruker WH-90DS spectrometer using DMF-d_7 as solvent and TMS as internal standard. UV–vis spectra were recorded on Pye–Unicam SP8-200 UV-vis spectrophotometers. Molar conductance of the complexes at 10^{-3} M dilution in DMSO was measured with a WTW conductivity meter LBR, using a standard conductivity cell with cell constant of 0.80.

Microanalyses for carbon and hydrogen were carried out by Heraeus, computer, H.P. 85. Tellurium analysis was carried out as described by Thavornytikarn[13] by use of a Pye–Unicam Spy flameless atomic absorption spectrometer. Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected.

RESULTS AND DISCUSSION

Rhodium(III) *complexes*

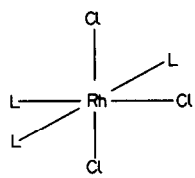
Rhodium(III) chloride trihydrate reacted readily in ethanolic solution with tellurium-donor heterocycles (metal : ligand ratio varied between 1 : 6 and 1 : 3) to give complexes of the general formula $RhCl_3L_3$, which agrees well with previous reports.[2,3] All complexes are coloured solids and mostly soluble in DMF and DMSO. Their physical properties and elemental analyses are listed in Table 1.

Conductance measurements have been made for $RhCl_3L_3$ complexes (**1–7**) in DMSO and the low value of molar conductance (below 4 Ω^{-1} cm^2 mol^{-1}) reveals the non-electrolytic nature of these complexes. Complex **8** is an electrolyte (Table 1), thus it might be expected to dissociate into $RhCl_3$ and $C_4H_8TeI_2$ (see the discussion of the NMR spectra). So it seems probable, that in DMSO, the ligand has dissociated:

$$C_4H_8TeI_2 \rightleftharpoons C_4H_8TeI^+ + I^-.$$

On the other hand, the conductance behaviour of complex **8** could be due to its existence as $[C_4H_8TeI^+]_3[RhCl_3I_3]^{3-}$, since it is well known that dihaloheterocyclic tellurium compounds undergo monohalogen exchange reactions.[14,15a] Further support for this formula was obtained from the thermogravimetric study of complex **8** and some related complexes.[15b]

The IR spectra of complexes **1–8** show some characteristic bands between 320 and 385 cm^{-1} due to the terminal ν(Rh—Cl),[16] Table 2. The appearance of a medium band near 345 cm^{-1}, typical of asymmetric stretching vibration of a linear Cl—Rh—Cl group, indicates a *trans* arrangement of chlorine atoms.[17,18,19] Thus on the basis of the above evidence, the following structure can be assigned for these complexes:



L = Heterocyclic tellurium ligands.

The weakness of the corresponding ν(Te—C) modes precludes direct verification of the proposed tellurium bonding. The essentially unchanged ν(C=C) in **5**, **6** and **7** (telluraindene is regarded as a special case of substituted 2,5-dihydrotellurophene)

of the heterocycle in complexes vs the free ligands supports tellurium bonding in these complexes. Moreover, the unchanged positions of the symmetric and non-symmetric C—O—C stretching modes of the heterocycle in the complex $RhCl_3(C_4H_8OTe)_3$ (**2**) vs the free ligands support Te-bonding,[20] see Table 2.

^1H NMR spectra of complexes **1**, **2**, **5**, **6** and **7** have been recorded in DMF-d_7 and show signal patterns similar to those shown by the free ligands (Table 3). This may be attributed to the dissociation of the ligands in solution. Furthermore, if these ligands coordinate, the α-protons become non-equivalent and we would expect an AB pattern.[4]

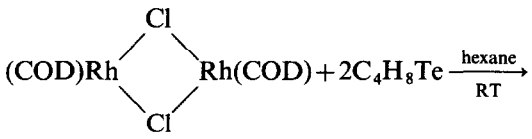
The electronic spectral data of complexes **1–8** are given in Table 4, with molar extinction values. The bands with lower molar extinction values could be assigned to *d–d* transitions and those with higher extinction values are assigned to charge-transfer transitions.[21] The electronic spectra of complex **2** are very different in $CHCl_3$ and DMSO (Table 4), which may be due to the existence of different species in the two solvents.

Carbonyl complexes

Bubbling carbon monoxide at atmospheric pressure through a chloroform solution of complex **1** for 4 h and through a toluene solution of complex **3** for 10 h gave $[RhCl_3(CO)(C_4H_8Te)_2]$ and $[RhCl_3(CO)(C_8H_5TeCl)_2]$ complexes, respectively (Table 5). The IR spectra of the complexes **9** and **10** exhibit strong bands at 2030 and 2060 cm^{-1}, respectively, assigned to the new ν(CO) group of rhodium(III) complexes.[3,19] The IR band at 325 cm^{-1} (in both complexes) is assigned to ν(Rh—Cl) (*trans* to CO) asymmetric stretching (Table 5). The relatively high value of ν(CO) observed for complex **10** (2060 cm^{-1}), as compared with complex **9** (2030 cm^{-1}), indicates an increased π-acidity of 3-chloro-4,5-benzotellurophene.[3]

Rhodium(I) *complexes*

The air-stable complex $[(COD)RhCl(C_4H_8Te)_2]$ was prepared by a bridge cleavage reaction analogous to the reaction of $SePPhMe_2$[22] and $P(p\text{-}C_6H_4F)_3$[23] with $[(COD)RhCl]_2$, as shown in the following equation:



$$2(COD)RhCl(C_4H_8Te).$$

The stoichiometry of this complex has been deter-

mined by IR and elemental analyses (Table 5). The IR spectrum of complex **11** exhibits a band at 340 cm^{-1} which is probably due to Rh—C_8H_{12} stretching mode,[12a] and bands at 270 and 280 cm^{-1} due to the monomeric rhodium(I) complex, which is slightly higher than the bridging Rh—Cl frequency in $[RhCl(COD)]_2$ (Table 5).[12]

Reaction of C_4H_8Te with $[RhCl(PPh_3)_3]$ produced complex **12** as a dimeric rhodium(I) complex (Table 5). This could be attributed to the displacement of one triphenylphosphine molecule by the telluride ligand and loss of another triphenylphosphine in the organic solvent to form complex **12**, as it is well known that $[RhCl(PPh_3)_3]$ loses one molecule of triphenylphosphine and the dimeric complex of the formula $[RhCl(PPh_3)_2]_2$ can be isolated.[12]

EXTRACTION EQUILIBRIUM OF COBALT(II) FROM SULPHATE SOLUTIONS BY DI(2-ETHYLHEXYL) PHOSPHORIC ACID DISSOLVED IN KEROSENE

TING-CHIA HUANG* and TEH-HUA TSAI

Department of Chemical Engineering, National Cheng Kung University, Tainan, Taiwan 70101, Republic of China

(*Received* 18 *October* 1989; *accepted* 8 *December* 1989)

Abstract—The distribution of cobalt(II) between 0.5 kmol m^{-3} aqueous sulphate medium and kerosene solutions of di(2-ethylhexyl)phosphoric acid (HDEHP) has been studied at 25°C. The extraction equilibrium is influenced by the total extractant concentration, equilibrium pH value and total metal concentration in the aqueous phase. The distribution data have been analysed both graphically and numerically. The results show that the species extracted into the organic phase have the composition $\overline{CoR_2(HR)_2}$ and $\overline{CoR_2(HR)_3}$. The stability constants of HSO_4^-, $NaSO_4^-$ and $CoSO_4$ in sulphate solutions have also been estimated from the extraction data.

Di(2-ethylhexyl)phosphoric acid (abbreviated as HDEHP or simply HR) has been studied extensively as an extraction reagent in hydrometallurgical processes for the separation and purification of a number of metals. It extracts first-row transition metals such as copper, cobalt, nickel and zinc, as well as uranium and rare earths in familiar nuclear fuel reprocessing, in a wide range of operating conditions.[1–7]

The extraction of cobalt with HDEHP has been studied by many investigators. Madigan[8] studied the distribution of cobalt between an aqueous sulphate solution and a solution of HDEHP in kerosene, and proposed that CoR_2 compounds are formed in the organic phase. Brisk and McManamey,[9] working in sulphate media, found that a single dimeric acid molecule was formed by the extracted species in aliphatic diluent. Grimm and Kolařík[10] and Komasawa *et al.*,[11] using both aliphatic and aromatic diluents, explained the extraction of Co^{2+} from nitrate medium by assuming the formation of $CoR_2(HR)_2$. Sato and Nakamura[12] proposed the extraction of $CoR_2(H_2O)_2$ after spectroscopic studies on the solid compound obtained by loading the metal in the organic phase. Komasawa *et al.*[13] studied the effect of diluents on extraction from nitrate media and showed the existence of $CoR_2(HR)_2$ formed in alcohol diluents and non-polar or weak polar diluents.

Further experimental studies seem necessary to clarify the uncertainties regarding species composition. In this work, the extraction of cobalt by HDEHP is studied in detail to determine the composition of the species extracted by HDEHP in kerosene. In order to obtain a complete understanding of the system, the extraction of cobalt was

Nomenclature

D: Distribution ratio (−); K_a: acid dissociation constant of monomeric HDEHP in the aqueous phase (kmol m^{-3}); K_d: distribution constant of monomeric HDEHP between the organic and aqueous phases (−); K_2: dimerization constant of HDEHP in the diluent (m^3 $kmol^{-1}$); K_{mpq}: equilibrium constant of cobalt–HDEHP complexes; m: degree of aggregation of the extracted species (−); p: number of R group except HR molecule involved in the extracted species (−); q: number of free monomeric HDEHP involved in the extracted species (−); Co^{II}: metal species; U: error square sum (−); $[]_t$: total concentration of the species in the brackets (kmol m^{-3}).

Greek letters

β: Stability constants of sulphate complexes (m^3 $kmol^{-1}$); σ: standard deviation (−).

Superscripts

$\overline{\quad}$: Denotes the organic phase species or organic phase concentration.

Subscripts

min: Minimum value.

studied first by graphic and slope analysis, which assumed no complexes were in the aqueous phase. Then, by numerical analysis of the experimental data, values for the stability constants of the HSO_4^-, $NaSO_4^-$ and $CoSO_4$ complexes in the aqueous sulphate solutions can be obtained.

EXPERIMENTAL

Reagents and solutions

Di(2-ethylhexyl)phosphoric acid used in this work was the product of Daihachi Chemical Ind. Co. Ltd., Osaka, Japan. A purity of 95% was found by potentiometric titration with NaOH in ethanolic medium. HDEHP was further precipitated as a copper complex from toluene and acetone solution, and then dissolved in toluene and a 4 kmol m^{-3} sulphuric acid solution, following the procedure of McDowell *et al.*[14] Kerosene (Chinese Petroleum Co., Taiwan, R.O.C.) was washed twice with 1/5 volume 98% H_2SO_4, then with distilled water until it was neutral.[15] The other inorganic chemicals were analytical reagent grade supplied by Hayashi Pure Chemical Ind. Ltd., Osaka, Japan. Metal solutions were always prepared by weighing the appropriate volumes of the stock solution and making up with diluent.

Procedure

Twenty millilitres of the organic solution and an equal volume of aqueous solution were mixed in glass flasks with ground glass stoppers and shaken by a mechanical shaker for at least 30 min at 25.0 ± 0.2°C. Preliminary experiments have shown the time needed to reach equilibrium to be less than 15 min. The organic solutions containd a 0.01–0.35 kmol m^{-3} monomeric form of HDEHP in kerosene. The aqueous phase consisted of 0.5 kmol m^{-3} $(Na^+, H^+, Co^{2+})SO_4^{2-}$. The total anion concentrations were kept constant. The concentrations of cobalt ion in the initial aqueous solutions ranged from 8.5×10^{-4} to 1.7×10^{-2} kmol m^{-3}. The two phases were separated after they had been allowed to settle for 4 h in a thermostat at 25.0 ± 0.2°C.

After phase separation, the equilibrium hydrogen ion concentration was measured by a pH meter. The concentration of cobalt was measured with a IL-551 atomic absorption spectrophotometer (Instrumentation Laboratory Inc.) at a wavelength of 240.7 nm, coupled with background correction. Cobalt in the organic phases was stripped with 4 kmol m^{-3} sulphuric acid, and the metal concentration in the acidic solution was analysed by AAS. The process had been shown to be quantitative and the mass balance for the metal was always within ±2%.

RESULTS AND DISCUSSION

Extraction equilibrium of cobalt

Metal complexes of HDEHP tend to form very large polymeric species in a fully loaded organic phase. These polymers are strongly depolymerized in the presence of free HDEHP molecules and ethylene glycol.[16] Thus, it is necessary to assume that cobalt is extracted as an *m*-merized complex into the slightly loaded organic phase. The extraction of cobalt(II) with HDEHP can be represented by the following general reaction:

$$m\mathrm{Co}^{2+} + m(p+q)/2\overline{\mathrm{H_2R_2}} \rightleftharpoons \overline{(\mathrm{CoR}_p(\mathrm{HR})_q)_m} + mp\mathrm{H}^+ \quad (1)$$

where

$$K_{mpq} = \frac{\overline{[(\mathrm{CoR}_p(\mathrm{HR})_q)_m]}[\mathrm{H}^+]^{mp}}{[\mathrm{Co}^{2+}]^m[\overline{\mathrm{H_2R_2}}]^{m(p+q)/2}} \quad (2)$$

is the stoichiometric equilibrium constant referring to 0.5 kmol m^{-3} $(Na,H)SO_4$ with kerosene as diluent, and the bar indicates the species in the organic phase.

The distribution ratio of cobalt is defined as

$$D_{\mathrm{Co}} = \frac{[\overline{\mathrm{Co}^{\mathrm{II}}}]}{[\mathrm{Co}^{\mathrm{II}}]}. \quad (3)$$

Substituting eq. (2) into (3), we obtain

$$D_{\mathrm{Co}} = \frac{m\overline{[(\mathrm{CoR}_p(\mathrm{HR})_q)_m]}}{[\mathrm{Co}^{2+}]} = mK_{mpq}[\mathrm{Co}^{2+}]^{m-1}[\overline{\mathrm{H_2R_2}}]^{m(p+q)/2}[\mathrm{H}^+]^{-mp}. \quad (4)$$

At constant concentrations of HDEHP and low distribution ratio, $[Co^{2+}]^{m-1}[\overline{H_2R_2}]^{m(p+q)/2}$ will be approximately constant. Thus, a plot of $\log D_{Co}$ vs pH will give a straight line with a slope of *mp*. Figure 1 shows the relationships between D_{Co} and pH with HDEHP concentration as parameter for 0.5 kmol m^{-3} $(Na,H)SO_4$ and $[Co^{II}]_t = 0.0017$ kmol m^{-3} at 25°C. The straight lines have slopes = 2, i.e. $mp = 2$. Thus, eq. (4) can be simplified to

$$[\overline{\mathrm{Co}^{\mathrm{II}}}][\mathrm{H}^+]^2 = mK_{mpq}[\mathrm{Co}^{2+}]^m[\overline{\mathrm{H_2R_2}}]^{m(p+q)/2}. \quad (5)$$

At constant concentrations of HDEHP, the degree of aggregation of the cobalt–HDEHP complex in the organic phase, *m*, is obtained from the plot of $\log[\overline{Co^{II}}][H^+]^2$ vs $\log[Co^{2+}]$. The experimental results are shown in Fig. 2 for various HDEHP concentration and 0.5 kmol m^{-3} (Na, H)SO_4 at 25°C. The straight lines have unit slopes in Fig. 2.

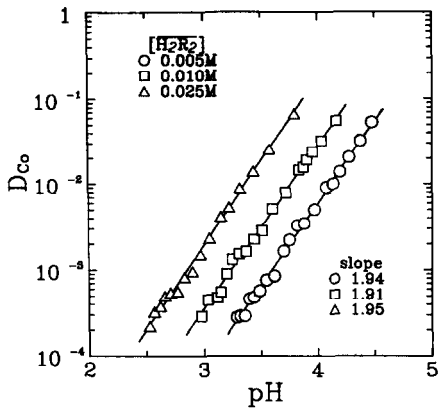

Fig. 1. Effect of pH on the extraction of cobalt between 0.5 kmol m^{-3} $(Na,H)SO_4$ and kerosene at 25°C. $[Co^{II}]_t = 0.0017$ kmol m^{-3}. (○) $[\overline{H_2R_2}] = 0.005$ kmol m^{-3}, slope = 1.94; (□) $[\overline{H_2R_2}] = 0.010$ kmol m^{-3}, slope = 1.91; (△) $[\overline{H_2R_2}] = 0.025$ kmol m^{-3}, slope = 1.95.

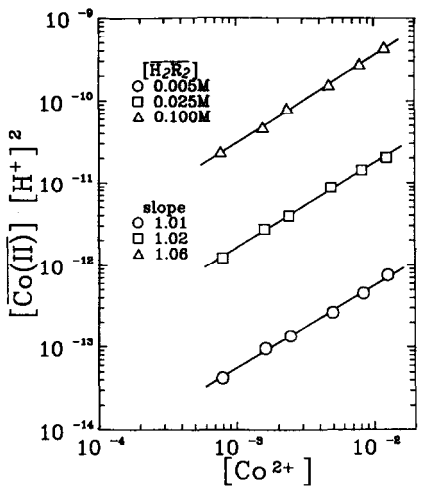

Fig. 2. Extraction of cobalt between 0.5 kmol m^{-3} $(Na,H)SO_4$ and kerosene at constant concentrations of HDEHP and 25°C. (○) $[\overline{H_2R_2}] = 0.005$ kmol m^{-3}, slope = 1.01; (□) $[\overline{H_2R_2}] = 0.025$ kmol m^{-3}, slope = 1.02; (△) = $[H_2R_2] = 0.10$ kmol m^{-3}, slope = 1.06.

Therefore, the extracted species is monomeric, i.e. $m = 1$. And then $p = 2$. Thus, eqs (2) and (4) can be simplified to

$$K_{2q} = \frac{[\overline{CoR_2(HR)_q}][H^+]^2}{[Co^{2+}][\overline{H_2R_2}]^{(2+q)/2}} \quad (6)$$

and

$$D_{Co} = K_{2q}[\overline{H_2R_2}]^{(2+q)/2}[H^+]^{-2}. \quad (7)$$

Rearranging eq. (7), it follows that

$$\log D_{Co} - 2\,pH = \log K_{2q} + (2+q)/2 \log[\overline{H_2R_2}]. \quad (8)$$

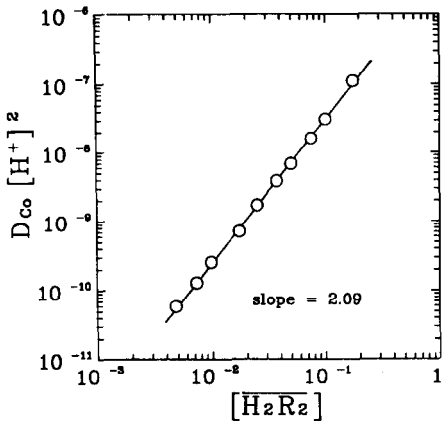

Fig. 3. Effect of HDEHP concentrations on the extraction equilibrium of cobalt between 0.5 kmol m^{-3} $(Na,H)SO_4$ and kerosene at 25°C. $[Co^{II}]_t = 0.0017$ kmol m^{-3}, slope = 2.09.

First, it could be assumed that only species of the type $\overline{CoR_2(HR)_q}$ are formed. Thus, a plot of $\log D_{Co}[H^+]^2$ vs $\log[\overline{H_2R_2}]$ would give a straight line with an intercept equal to K_{2q} and a slope equal to $(2+q)/2$.

Figure 3 shows the relationship between $D_{Co}[H^+]^2$ and $[\overline{H_2R_2}]$ for 0.5 kmol m^{-3} $(Na, H)SO_4$ and $[Co^{II}]_t = 0.0017$ kmol m^{-3} at 25°C. In Fig. 3, a straight line with a slope of 2.09 is obtained, i.e. $q = 2$. Thus, the species formed in the organic phase is $\overline{CoR_2(HR)_2}$. From Fig. 3, the intercept is -5.42, i.e. $K_{22} = 3.84 \times 10^{-6}$.

Reconfirmation of extraction equilibrium formation by slope analysis

Next, assuming two species are formed in the organic phase, e.g. $\overline{CoR_2(HR)_2}$ and $\overline{CoR_2(HR)_3}$, eq. (3) could be expressed as

$$D_{Co} = \frac{[\overline{CoR_2(HR)_2}] + [\overline{CoR_2(HR)_3}]}{[Co^{2+}]}. \quad (9)$$

Using eq. (6), eq. (9) becomes

$$D_{Co}[H^+]^2 = K_{22}[\overline{H_2R_2}]^2 + K_{23}[\overline{H_2R_2}]^{5/2} \quad (10)$$

or

$$\frac{D_{Co}[H^+]^2}{[\overline{H_2R_2}]^{5/2}} = K_{22}\frac{1}{[\overline{H_2R_2}]^{1/2}} + K_{23}. \quad (11)$$

Now, a plot of $D_{Co}[H^+]^2/[\overline{H_2R_2}]^{5/2}$ vs $[\overline{H_2R_2}]^{-1/2}$ would give a straight line with a slope equal to K_{22} and an intercept equal to K_{23}. Figure 4 shows the effect of HDEHP concentrations on the extraction equilibrium of cobalt between 0.5 kmol m^{-3} $(Na,H)SO_4$ and kerosene for $[Co^{II}] = 0.0017$ kmol m^{-3} at 25°C. In Fig. 4, a straight line with a

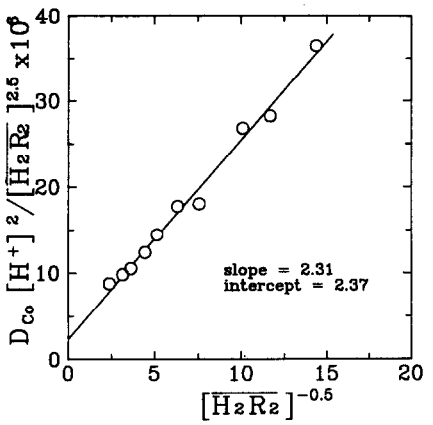

Fig. 4. Effect of HDEHP concentrations on the extraction equilibrium of cobalt between 0.5 kmol m^{-3} (Na,H)SO_4 and kerosene at 25°C. $[Co^{II}]_t = 0.0017$ kmol m^{-3}, slope = 2.31, intercept = 2.37.

slope of 2.31 and an intercept of 2.37 is obtained, i.e. $K_{22} = 2.31 \times 10^{-6}$ and $K_{23} = 2.37 \times 10^{-6}$ (kmol $m^{-3})^{-1/2}$.

Reconfirmation of extraction equilibrium formation by computer treatment

Numerical treatment of the data was performed by modifying the LETAGROP-DISTR program[17] in order to apply it to the five-component system in this work. The aim of these calculations was to confirm the results obtained with the previous graphic analysis and to refine the values of the equilibrium constants.

In this calculation, the computer searches for the best set of equilibrium constants that would minimize the error squares sum defined by

$$U = \sum (\log D_{calc} - \log D_{exp})^2 \qquad (12)$$

where D_{exp} is the distribution ratio of cobalt measured experimentally and D_{calc} is the corresponding value calculated by the program obtained by solving the mass balance equations for Co^{2+}, H_2R_2, SO_4^{2-}, Na^+, using a given set of complexes and their equilibrium constants. The optimal model is the one which minimizes the error squares sum function and gives the lowest mean standard deviation $\sigma(\log D)$, defined by

$$\sigma(\log D) = (U/Np)^{1/2} \qquad (13)$$

where Np is the degree of freedom, approximately equal to the number of data points.

The equilibrium constants for the different HDEHP species between 0.5 kmol m^{-3} (Na,H)SO_4 and kerosene system used in the present work are given from Huang and Juang[4] and shown in Table 1. Table 2 summarizes the results obtained with some of the models tried.

Table 1. Equilibrium constants for the different HDEHP species in the 0.5 kmol m^{-3} (Na,H)SO_4/HDEHP–kerosene system[4]

Reaction	Constant
$HR \rightleftharpoons R^- + H^+$	$pK_a = 1.27 \pm 0.03$
$HR \rightleftharpoons \overline{HR}$	$\log K_d = 3.54 \pm 0.02$
$2\overline{HR} \rightleftharpoons \overline{H_2R_2}$	$\log K_2 = 4.42 \pm 0.04$

Figure 5 presents the plot of U_{min} vs q for models I–VII given in Table 2; the optimal q values are between 2 and 3. And then, two species formed in organic phase (models VIII–XV) were tried, the result showed the optimal one turns out to be the set of species (p,q) equal to (2,2) and (2,3). Furthermore, several more than two species calculations were carried out to investigate the possibility of finding other complexes which could improve the fit of the experimental data (summarized as models XVI and XVII). From Table 2, the optimal fit for sulphate systems was obtained when the species were the same as those suggested by the graphic treatment, i.e. $\overline{CoR_2(HR)_2}$ and $\overline{CoR_2(HR)_3}$ with $\log K_{22} = -5.56 \pm 0.04$ and $\log K_{23} = -5.65\,\max - 5.37$.

The experimental data for the above numerical calculation are given in Figs 1, 2 and 3. The mass balance equation for H_2R_2 in the optimal model is given by

$$[\overline{H_2R_2}]_t = [\overline{H_2R_2}] + 1/2K_2^{-1/2}[\overline{H_2R_2}]^{1/2} + 2K_{22}[Co^{2+}][\overline{H_2R_2}]^2[H^+]^{-2} + 5/2K_{23}[Co^{2+}][\overline{H_2R_2}]^{5/2}[H^+]^{-2}. \qquad (14)$$

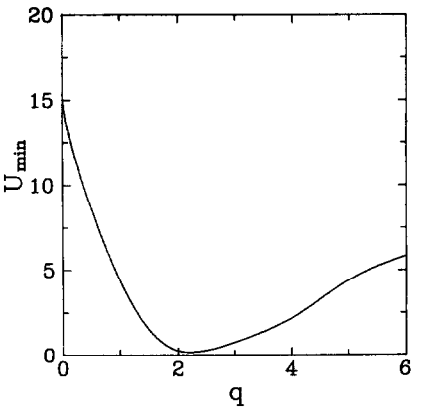

Fig. 5. Variation of U_{min} with number of free monomeric HDEHP involved in the extracted species. (Table 2 models I–VII.)

* Rejected species.

[a] The error given corresponds to $3\cdot\delta(\log K)$.

[b] The value after max corresponds to $\log[K+3\sigma(K)]$.

Complexation of cobalt in sulphate solutions

In the sulphate medium, the equilibrium constants obtained are a sort of "conditional" constant, since cobalt is complexed by sulphate ions. Considering also the species SO_4^{2-}, eq. (9) should be written as follows:

$$D_{Co} = \frac{K_{22}[\overline{H_2R_2}]^2[H^+]^{-2} + K_{23}[\overline{H_2R_2}]^{5/2}[H^+]^{-2}}{1+\beta_1[SO_4^{2-}]} \tag{15}$$

where the stability constant of $CoSO_4$ is defined by

$$\beta_1 = \frac{[CoSO_4]}{[Co^{2+}][SO_4^{2-}]}. \tag{16}$$

$[SO_4^{2-}]$ can be calculated from the mass balance expression for the sulphate concentration as given by eq. (17)

$$[SO_4^{2-}]_t = [SO_4^{2-}]+[CoSO_4] + \beta_2[Na^+][SO_4^{2-}]+\beta_3[H^+][SO_4^{2-}] \tag{17}$$

where β_2 and β_3 are the stability constants of $NaSO_4^-$ and HSO_4^-, respectively, defined by

$$\beta_2 = \frac{[NaSO_4^-]}{[Na^+][SO_4^{2-}]} \tag{18}$$

and

$$\beta_3 = \frac{[HSO_4^-]}{[H^+][SO_4^{2-}]}. \tag{19}$$

The values of $\log\beta_1$, $\log\beta_2$ and $\log\beta_3$ were taken to be 2.4, 1.06 and 1.99 at zero ionic strength.[18] Table 3 summarizes the results of the graphic and computer calculations. However, in the 0.5 kmol m^{-3} $(Na^+, H^+, Co^{2+})SO_4^{2-}$ system, the ionic strength is not zero. Therefore, for minimizing error square sum calculations, the best log values of K_{23}, K_{24}, β_1, β_2 and β_3 were obtained and shown in Table 3.

The published values for the equilibrium constants are compiled in Table 4.

Figure 6 represents the distribution diagram of Co^{II} as a function of the total HDEHP concentration at various total concentrations of cobalt and pH values. It is worth noting the increasing predominance of the $\overline{CoR_2(HR)_2}$ species as the total concentration of HDEHP is increased.

Table 3. Equilibrium constants for species $\overline{CoR_2(HR)_2}$ and $\overline{CoR_2(HR)_3}$ calculated by different methods for sulphate solutions

[a] $\log\beta_1 = 2.4$, $\log\beta_2 = 1.06$ and $\log\beta_3 = 1.99$ obtained from Morel.[18]

[b] The optimal values of stability constants from calculation were $\log\beta_1 = 2.01\pm0.20$,[c] $\log\beta_2 = 1.06\pm0.19$ and $\log\beta_3 = 1.79$ max 3.00.

[c] The value after max corresponds to $\log[K+3\sigma(K)]$ and the error given corresponds to $3\cdot\sigma(\log K)$.

CONCLUSION

For the sulphate system, the cobalt distribution data could be best explained by assuming the formations of two species: $\overline{CoR_2(HR)_2}$ and $\overline{CoR_2(HR)_3}$. Graphic and computer modelling of the data excluded the existence of the species $\overline{CoR_2}$. It could also be established that the existence of these two species together gives the best fit for the distribution data, whereas the assumption that either of them exists alone gives a considerably worse fit.

Grimm and Kolařík[10] and Komasawa *et al.*[11] also reported the existence of the $\overline{CoR_2(HR)_2}$ we identified, although the aqueous phase contained nitrate solutions. However, in the sulphate solutions, $\overline{CoR_2(HR)_3}$ existed at the same time from the above graphic and numerical analysis.

On the other hand, the numerical values of the "conditional" equilibrium constants determined for these two species depend on the composition of the aqueous phase. This is due to the possible complexation of cobalt in the aqueous phase. In this work, we adopted two approaches for considering the existence of $CoSO_4$, $NaSO_4^-$ and HSO_4^- complexations. In the first approach, computer calculations on all sulphate system data were performed by introducing the values of the stability constants of the sulphates in the literatures. In the second approach, the equilibrium constants of Co–

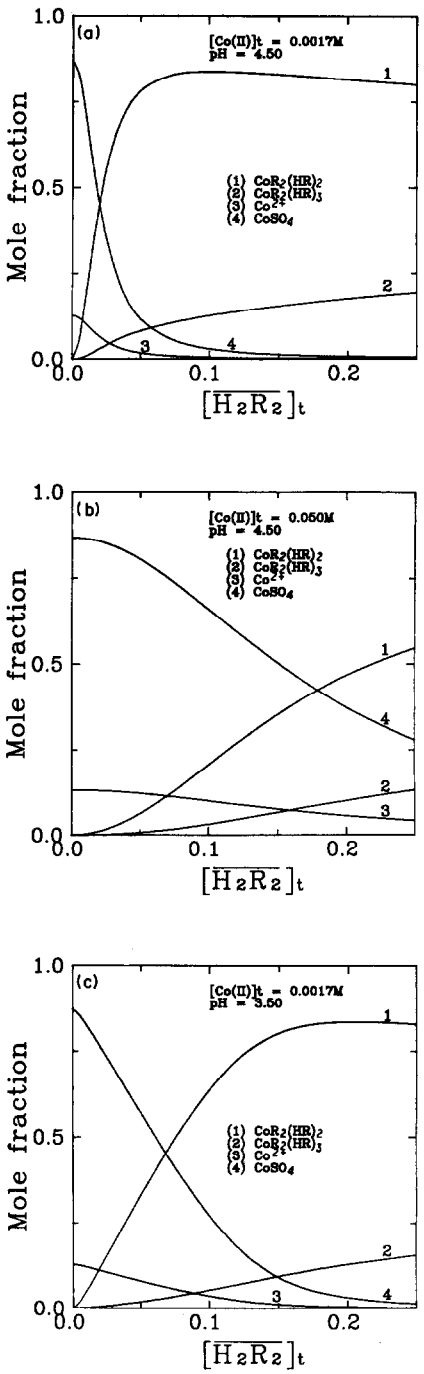

Fig. 6. Cobalt distribution diagrams as a function of the total HDEHP concentration at two different total concentrations of cobalt and two different pH values. Lines 1, 2, 3 and 4 represent $\overline{CoR_2(HR)_2}$, $\overline{CoR_2(HR)_3}$, Co^{2+} and $CoSO_4$, respectively. (a) $[Co^{II}]_t = 0.0017$ kmol m^{-3}, pH = 4.50; (b) $[Co^{II}]_t = 0.05$ kmol m^{-3}, pH = 4.50; (c) $[Co^{II}]_t = 0.0017$ kmol m^{-3}, pH = 3.50.

HDEHP complexes and sulphates were calculated at the same time. New values of K_{22}, K_{23}, β_1, β_2 and β_3 were calculated and are given in Table 3. As can be seen in Table 4, the value of K_{22} obtained agrees

(*Received* 20 *October* 1989; *accepted* 8 *December* 1989)

Abstract—The reaction of the monodentate ligand thioethane with $(C_6H_5)_4PBr$ and Cu_2O in organic solvents results in the crystallization of two new homoleptic polynuclear copper(I) thiolates: $[(C_6H_5)_4P^+]_2[Cu_4(C_2H_5S^-)_6]\cdot 0.5C_2H_6O_2$ (**1**) and $[(C_6H_5)_4P^+][Cu_7(C_2H_5S^-)_8]$ (**2**). Both compounds have been characterized by X-ray crystallography, thermal analysis, luminescence spectroscopy and IR spectroscopy. Compound **1** is triclinic, space group $P\bar{1}$ with $a = 12.066(5)$, $b = 13.824(5)$, $c = 19.112(3)$ Å, $\alpha = 90.82(2)$, $\beta = 101.85(2)$, $\gamma = 93.53(3)°$ and $Z = 2$. Compound **2** is monoclinic, space group $P2_1/c$ with $a = 19.208(3)$, $b = 16.975(4)$, $c = 16.394(6)$ Å, $\beta = 108.68(2)°$ and $Z = 4$. The structure of **1** is built up by $[(Cu_4(RS^-)_6)^{2-}]$ adamantane-type cluster units, separated by $[(C_6H_5)_4P^+]$ cations. Compound **2** consists of copper(I) thiolate chains, also separated by $[(C_6H_5)_4P^+]$ cations. In **2**, structural units of the stoichiometry $Cu_7(C_2H_5S^-)_{10}$ are connected by common sharing of four sulphur atoms, leading to a chain of the stoichiometry $Cu_7(C_2H_5S^-)_8$. The shortest Cu—Cu distance is 2.692(1) Å in **1** and 2.736(2) Å in **2**. Excitation at 450 nm of **1** in the solid state results in a weak emission at 665 nm, compound **2** exhibits in the solid state an intense luminescence at 591 nm upon excitation at 365 nm.

The coordination chemistry of thiolates, a fundamental ligand type in transition metal chemistry,[1,2] is of much current interest in view of forming appropriate model compounds of active sites in metalloproteins.

We are interested in crystallizing metal-rich copper(I) thiolates as model compounds of copper(I) thioneins. Metallothioneins (MT) are believed to play a role in the metabolism and in the detoxification of a number of essential and non-essential trace metals in animals and plants, mainly of the metals zinc, cadmium, mercury and copper.[3] They are characterized by an unusually high cysteinate content of the peptide and a metal-to-cysteinate ratio of 1:3 for Zn– and Cd–MT. In copper(I) thioneins, the metal content found is even higher. In the case of only copper(I)-containing MTs, cluster core types of the stoichiometries Cu_6S_9 and Cu_8S_{12} are often suggested.[4,5] A copper-to-sulphur ratio of 2:3 seems to be a characteristic feature of Cu^I–MTs as well as of synthetic polynuclear copper(I) complexes with mono- or bidentate thiolates.[6,7] The MT with the highest metal content is a fungal MT found in *Neurospora crassa* with a copper(I)-to-cysteinate ratio of 6:7.[8] Syntheses of copper(I) thiolates with *mono*dentate ligands RS^- revealed species that contain core units of the stoichiometries Cu_4S_6 ($R = C_6H_5, CH_3$), Cu_5S_6 ($R = (CH_3)_3C$) and Cu_5S_7 ($R = C_6H_5$).[9] The most favoured Cu_4S_6 "adamantane" type can also be obtained with *bi*dentate ligands ($^-SRS^-$) like 1,2-dithioethane, 1,3-dithiopropane or *o*-xylene-α-α′-dithiol.[10,11] In addition, the formation of core units of the type Cu_3S_6, Cu_8S_{12} and $Cu_{10}S_{16}$ has been observed with bidentate dithiol ligands.[12–14] Our syntheses using the monodentate ligand thioethane (TE) revealed two new homoleptic polynuclear copper(I) thiolates: One with the well-known adamantane-type Cu_4S_6 cluster, the other with a non-molecular one-dimensional Cu_7S_8 chain structure. In both structures, all the copper atoms are trigonally coordinated by

bridging thiolates. We report here on synthesis, structure, spectroscopical and thermoanalytical data of these new copper(I) thiolates.

EXPERIMENTAL

Syntheses and thermal analysis

Thioethane (TE), $(Ph)_4PBr$ and Cu_2O were purchased from Fluka AG, Buchs/Switzerland and used without further purification. The 1 M solution of NaOMe was obtained by adding 23.0 g (1 mol) of sodium to 1000 cm^3 of methanol, stirred on an ice bath. The syntheses were performed in a Schlenk-type apparatus in a nitrogen atmosphere. Thermogravimetric (TG) data in the temperature range 30–700°C were recorded in a flowing N_2-atmosphere, using heating rates of 10°C min^{-1} and sample weights of 4–15 mg on a Perkin–Elmer TGS-2 thermobalance. X-ray powder diffraction diagrams of the final products were produced by a Guinier-type camera with a Johansson monochromator (Cu-$K_{\alpha 1}$ radiation).

$[(C_6H_5)_4P^+]_2[Cu_4(TE^-)_6]\cdot 0.5C_2H_6O_2$ (**1**)

To a solution of 3.34 g (7.8 mmol) of $(Ph)_4PBr$ in ethylene glycol (20 cm^3), MeOH (33 cm^3) and 1 M NaOMe/MeOH (7 cm^3), 1.05 g (16.9 mmol) of TE was added. After warming up to a reaction temperature of 55°C and addition of 400 mg (2.8 mmol) of Cu_2O, a clear yellow solution was obtained. Slow evaporation at room temperature first yielded dark red bulky crystals of **1**. Later on, yellow crystals of compound **2** could also be isolated from the same solution. The red crystals of **1** were separated manually. Found: C, 54.2; H, 5.6; Cu, 20.1 (TG analysis); S, 15.1. Calc. for $C_{61}H_{73}Cu_4OP_2S_6$ (1330.8): C, 55.1; H, 5.5; Cu, 19.1; S, 14.5%.

$[(C_6H_5)_4P^+][Cu_7(TE^-)_8]$ (**2**)

To a solution of 2.5 g (6.0 mmol) of $(Ph)_4PBr$ in ethylene glycol (20 cm^3), MeOH (33 cm^3) and 1 M NaOMe/MeOH (8 cm^3), 1.11 g (17.9 mmol) of TE was added. After addition of 400 mg (2.8 mmol) of Cu_2O, the solution was kept at 60°C for 30 min until it became clear yellow. Slow evaporation at room temperature yielded yellow crystals of **2**. Found: C, 37.7; H, 4.9; Cu, 34.6 (TG analysis). Calc. for $C_{40}H_{60}Cu_7PS_8$ (1273.8): C, 37.7; H, 4.7; Cu, 34.9%.

X-ray crystallography

Symmetry, preliminary cell parameters and space groups of the complexes investigated were established by precession and Weissenberg photography. Final lattice parameters and crystal orientations were obtained from least-squares refinement of the θ values of 25 reflections on an Enraf–Nonius CAD-4 diffractometer.

Intensity data were collected by using graphite-monochromated Mo-K_α radiation. Four standard reflections lying in different regions of the reciprocal space were monitored periodically. A total loss in intensity of −2.3% (**1**) and −1.3% (**2**) was observed and corrected for in data reduction. The intensities were reduced to F_o by applying corrections for Lorentz and polarization effects. A numerical absorption correction based on carefully indexed crystal faces was carried out for both compounds.

The structure of **1** was solved by using the Patterson interpretation routine in SHELXS-86[15] and by conventional Fourier techniques, and refined with full-matrix least-squares methods including anisotropic temperature factors for copper, sulphur, phosphorus and the carbon atoms of the ligands. The phenyl rings were refined as rigid groups with free varying isotropic temperature factors. The atoms of the inserted solvent molecule were also treated with isotropic temperature factors. Due to a disordered arrangement of the terminal carbon atom C(22), the C(21)—C(22) distance was treated with a constrained length in the refinement. The positions of the hydrogen atoms of the phenyl rings and of the ligand molecules were calculated, and the hydrogen atoms were included as fixed contributions in the refinement.

The structure of **2** could be solved with direct methods using 937 negative quartets in SHELXS-86. For the structure refinement of **2** (full-matrix least-squares methods including anisotropic temperature factors for copper, sulphur, phosphorus and the carbon atoms of the ligands) it was not necessary to fix the phenyl ring atoms. These carbon atoms were used with free varying isotropic temperature factors. Due to a disordered arrangement, some of the terminal carbon atoms [C(52), C(62), C(72), C(82)] of the thiolate ligands were treated with a constrained bond length to the adjacent carbon atom in the refinement. The position of all the hydrogen atoms was calculated and the hydrogen atoms included as fixed contributions in the refinement.

The structure of **1** was finally refined with unit weights. The weighting scheme for **2** was $w = 1.0/\sigma^2(F)$. Interatomic distances and angles have

been calculated with the ORFFE3 program.[16] The calculations were performed with the programs SHELXS-86 and SHELX-76[17] on an IBM 3033 and a NAS AS/XL V60 computer at the University of Zürich. Crystal parameters, data collection details, and results of the refinements are summarized in Table 1.

Atomic coordinates and thermal parameters for the two structures have been deposited with the Editor as supplementary material, from whom copies are available on request.

Luminescence spectroscopy

Emission spectra were recorded on a Perkin–Elmer Model 204 fluorescence spectrophotometer using a Xenon lamp as exciting source. Powder samples were fixed on a quartz plate with a non-fluorescing glue.

IR spectroscopy

Solid-state IR spectra in the range 400–180 cm^{-1} were obtained on a Perkin–Elmer spectrophotometer type 983. Spectra were run on Nujol mulls between CsI or polyethylene plates.

RESULTS AND DISCUSSION

The structures of $[(C_6H_5)_4P^+]_2[Cu_4(C_2H_5S^-)_6]\cdot 0.5C_2H_6O_2$ **(1)** *and* $[(C_6H_5)_4P^+][Cu_7(C_2H_5S^-)_8]$ **(2)**

The structure of **1** is built up by $[(Cu_4S_6)^{2-}]$ adamantane-type cluster units, separated by bulky $[(C_6H_5)_4P^+]$ cations, as shown in Fig. 1. The structure of the cluster anion can be considered as a tetrahedron of copper atoms inscribed in a distorted octahedron formed by six μ_2-sulphur atoms (Fig. 2). This cluster type is very common for copper(I) thiolates.[1,2,9] The Cu—Cu distances range from 2.692(1) to 2.780(1) Å, with a mean distance of

2.725 Å. The 12 crystallographically-independent Cu—S distances range from 2.248(3) to 2.309(3) Å, with a mean distance of 2.281 Å (Table 2). Five of the six Cu—S—Cu angles range from 72.6(1) to 73.8(1)°, whereas an increased angle of 75.1(1)° is observed at the sixth sulphur atom as a consequence of a hydrogen bond linking this sulphur atom to the solvate molecule.

The two $[(Cu_4S_6)^{2-}]$ clusters within the unit cell are linked by two hydrogen bonds of the type S···H—O to the ethylene glycol solvate molecule at the inversion centre in the middle of the cell. The corresponding S(4)···O acceptor–donor distance is 3.170(7) Å. The hydrogen atom of the hydroxy group of the inserted solvate molecule could be located in a difference Fourier map. The resulting distances, O—H of 1.05 Å (with a C—O—H angle of 108.1°) and S···H of 2.27 Å, are within the range found for solvate molecules linked to metal coordinating thiolates.[18,19] The O—H···S angle of 142.4° is comparable with values found in a neutron diffraction study.[20]

The structure of **2** consists of copper(I) thiolate chains parallel to the *c*-axis (see Figs 3 and 4) separated by bulky $[(C_6H_5)_4P^+]$ cations. The shortest Cu—Cu distance within the chain is 2.736(2) Å. Structural units of the stoichiometry $Cu_7(TE^-)_{10}$ are connected by common sharing of four sulphur atoms, leading to a chain of the overall stoichiometry $Cu_7(TE^-)_8$. Adjacent units within the chain are generated by a glide-plane operation. This structure type is unique within copper(I) thiolates,

and it can obviously only be realized with the ligand molecule ethanethiolate. On the one hand, the terminal C_2H_5 group of this ligand is able to separate and stabilize the well-known $[(Cu_4S_6)^{2-}]$ cluster found in **1**, on the other hand, this ligand seems to have an optimal size and flexibility to favour the building of the chain structure found in **2**. Using the smaller CH_3S^- molecule as a ligand, the adamantane-type $[(Cu_4S_6)^{2-}]$ is the only structure realized.[21] Syntheses with the more space-filling ligands 2-propanthiolate $[(CH_3)_2CH—S^-]$ or $^tBuS^-$ thiolate with copper(I) under the same reaction conditions always lead to the well-known $[Cu_5(RS^-)_6]$ cluster,[10,22] albeit several enlarged molecular clusters and one-dimensional chain structures are known with $^tBuS^-$ or with even more

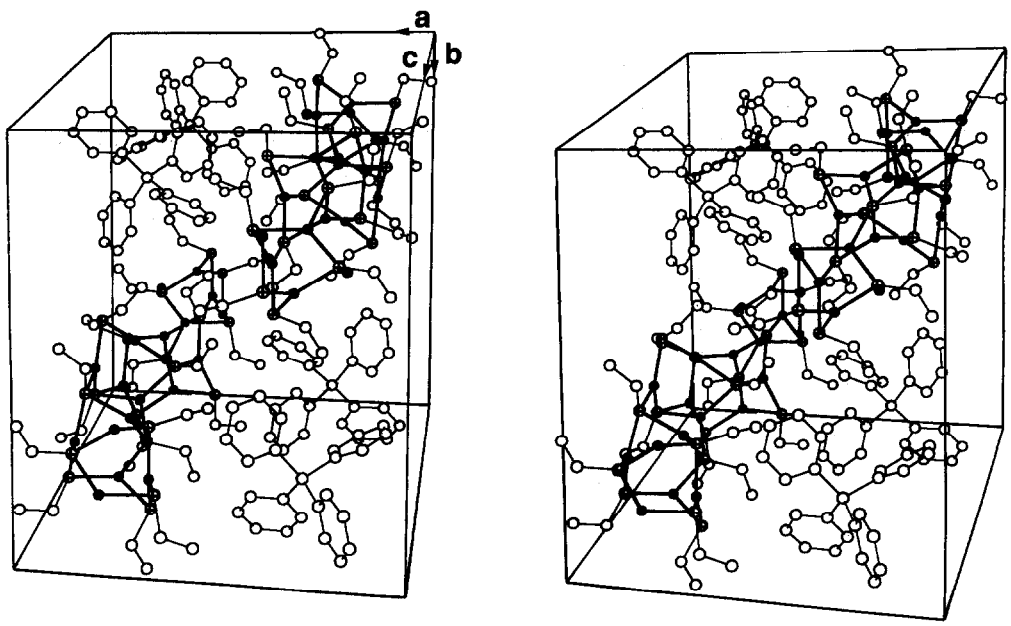

Fig. 3. Stereoview of the unit cell of **2**.

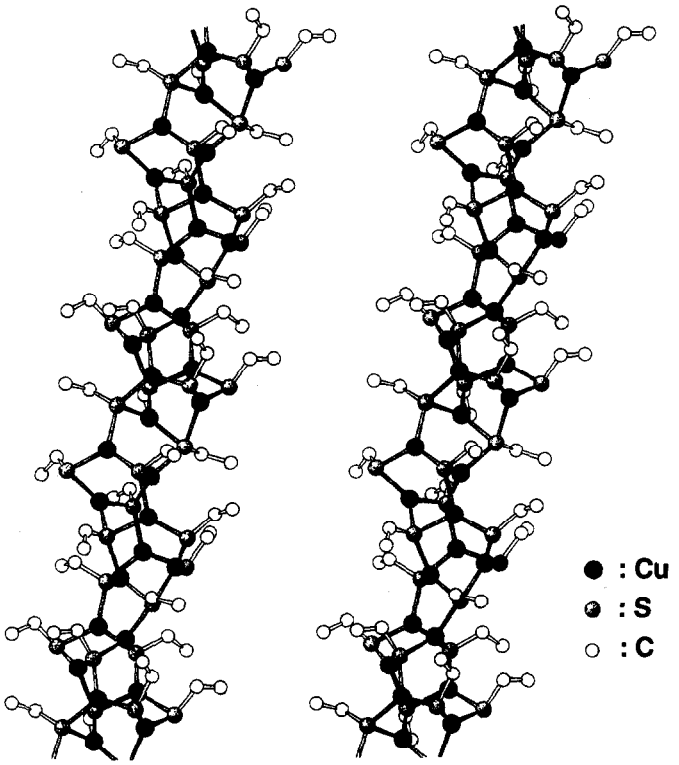

Fig. 4. Stereoview of the $[(Cu_7(TE^-)_8)]_\infty$ chain in **2**.

space-filling thiolates in the case of cadmium(II), silver(I) and other metals.[1,23]

The copper(I) thiolate chain in **2** exhibits two different types of thiolates, involving μ_2- and μ_3-bridging RS^- (see Fig. 5). The latter μ_3-$S(Cu)_3$ unit, exhibiting a RS^- bridging three copper atoms with an approximately tetrahedral C—$S(Cu)_3$ arrangement, is only rarely reported in pure copper(I) thiolates.[13,24] The mean value of all Cu—(μ_3-S)—Cu angles is 99.3°; the mean value of the corresponding angles around the μ_2-S atoms is 79.9°. The μ_2-S—Cu bond distances range from 2.206(4) to 2.247(4) Å, with a mean distance of 2.230 Å, whereas the μ_3-S—Cu bond distances range from 2.246(4) to 2.359(3) Å, with a mean distance of 2.287 Å (Table 2).

Using an alternative description of the structures of **1** and **2**, the CuS_3 group is regarded as a rigid triangle with the copper atoms located a little above or below the S_3 plane. The geometry of these triangles in both structures is determined by a set of three S—Cu—S angles which range from 102.9(1) to 137.3(2)°, with a mean value of 119.9°, and by three Cu—S distances ranging from 2.206(4) to

2.359(3) Å, with a mean value of 2.274 Å (Tables 2 and 3). Table 3 summarizes the deviation of the copper atoms from the corresponding S_3 plane. Using this point of view, the structure of **1** is built up by four CuS_3 groups, each triangle being linked by corner-sharing to the three other triangles. All copper atoms in **1** are systematically displaced from the plane through the three sulphur atoms in a direction away from the centroid of the cage. The connection in structure **2** is similar with the restriction that three triangles instead of two only may be linked by corner-sharing (Fig. 6). The Cu_4S_6 structural entity of **1** can be found in an expanded form as a Cu_5S_8 substructure in **2**. The four-triangle polyhedron of the Cu_4S_6 core is modified by breaking the linkage of two corner-shared S_3 triangles and by insertion of an additional S_3 triangle. A similar transformation is observed in the formation of the M_5S_7 cage ($M = Ag^I$, Cu^I) from a M_4S_6 polyhedron by replacing a sulphur vertex by a linear S—Cu—S bridge.[23,25]

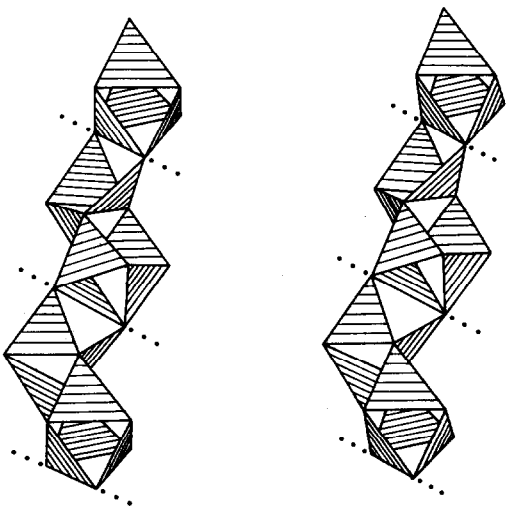

Fig. 6. Schematic stereoview of the $[(Cu_7(TE^-)_8)]_\infty$ chain in **2**. Each hatched triangle represents a CuS_3 unit with the sulphur atoms at the corner of the triangle and the copper(I) lying slightly above or below the S_3 plane. The structural units are separated by dotted lines.

A summary of interatomic bond distances and angles involving the μ_2- and μ_3-sulphur atoms in **1** and in **2** is given in Table 4.

In both structures, the geometry of the $[Ph_4P^+]$ cations as well as of the terminal C_2H_5 groups of the ligands shows no unusual features. The P—C distances range from 1.779(13) to 1.812(13) Å, and the C—P—C angles give no indication for a distinct distortion of the tetrahedral environment about the phosphorus atoms. The C—C bond lengths range

from 1.407(16) to 1.482(16) Å, the S—C—C angles are between 108.0(10) and 115.9(14)°.

Thermal analytical results

Thermogravimetric investigations allow a characterization referring to the stoichiometry of the compounds investigated and to possible decomposition mechanisms. For different copper(I) thiolate clusters, the final product of the degradation is $Cu_{1.96}S$, as identified by X-ray powder diffraction. The patterns were in agreement with those reported in ref. 26 for a synthetic form of Chalcocite, $Cu_{1.96}S$.

The thermal decomposition of $[Ph_4P^+]_2[Cu_4(TE^-)_6]\cdot 0.5C_2H_6O_2$ (1) can be described as a two-step reaction. Within the first step in the range 100–180°C, the inserted solvate molecule is evolved. The second step, partly overlapping with the first one, involves the decomposition of the solvent free species $[Ph_4P^+]_2[Cu_4(TE^-)_6]$ and leads to the final product $Cu_{1.96}S$. Because this degradation is not dependent on the Cu^I—S score type,[9] the thermal decomposition of $[Ph_4P^+][Cu(TE^-)_8]$ (2) shows a pattern very similar with the second decomposition step of $[Ph_4P^+]_2[Cu_4(TE^-)_6]$. The thermal stability of copper(I) ethanethiolates is much smaller than those of copper(I) thiophenolates. The final decomposition temperatures of both compounds investigated are about 270°C, compared to 340–

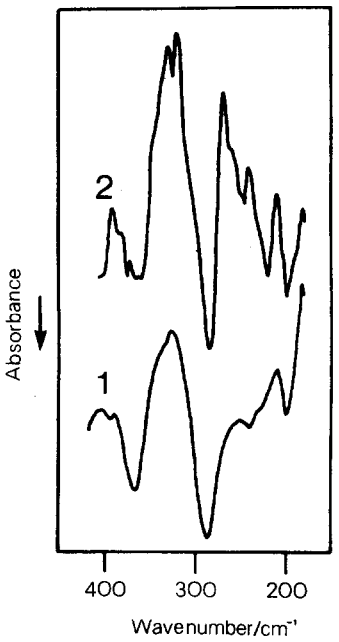

Fig. 7. IR spectra of **1** and **2**.

390°C for copper(I) thiophenolates decomposed under the same reaction conditions.

Spectroscopic results

Copper-containing metallothioneins have been found to exhibit significant luminescence which is related to the copper(I) thiolate chromophore.[27,28] Excitation of the *Neurospora crassa* Cu—MT at 305 nm leads to luminescence at 565 nm.[8] A similar luminescence in the visible region results in a maximum at 609 nm upon excitation of yeast Cu—MT with UV light.[7] This luminescence from copper(I)-containing species at room temperature in solution is highly unusual and is a further remainder of the remarkable coordination properties of MT.

Luminescence emission is well known for d^{10} systems, with most reports concerning solids. Investigations of the luminescence properties of copper(I) species showed that luminescence in the range 500–700 nm is related in solution as well as in the solid state, to the triplet–singlet emission observed for isolated Cu^+ ions.[29–32]

The colour and intensity of the emission of the two homoleptic copper(I) complexes, **1** and **2**, differ considerably. Excitation at 450 nm of **1** in the solid state at about −50°C results in a weak emission at 665 nm. Compound **2** exhibits in the solid state an intense luminescence at 591 nm upon excitation at 365 nm. This emission can be seen at room temperature by the naked eye whilst the luminescence appearance of **1** is only weak even at liquid nitrogen temperature. The intensities increase while cooling the samples. The emission spectra of both compounds are broad and structureless.

The IR spectra in the range 420–180 cm^{-1} of **1** and **2** are given in Fig. 7. The bands above 420 cm^{-1} can be assigned to internal vibrations of the thiolate ligand and of the $[Ph_4P^+]$ ion. The bands in the range given in Fig. 7 are expected to arise mainly from metal–ligand vibrations, e.g. copper–sulphur stretching, $\nu_{(Cu-S)}$.[33] The two spectra differ considerably. The spectrum of **2** (symmetry group of the Cu—S core: C_1) reveals at least two bands more than the spectrum of **1** (symmetry group of the Cu—S core: approximately T_d) (see Table 5). This difference could be a consequence of the different symmetries as well as of the different bridging types of sulphur atoms within the two structures.

Supplementary material including tables of observed and calculated structure factors and of anisotropic thermal parameters may be obtained on request from one of the authors (E.D.).

STRUCTURAL AND SPECTROSCOPIC STUDIES ON THE TRINUCLEAR CLUSTERS $Re_3Cl_9(PMe_3)_3$ AND $Re_3Cl_9(\eta^1\text{-dppm})_3$ (dppm = $Ph_2PCH_2PPh_2$)

SYLVIA M. V. ESJORNSON, PHILLIP E. FANWICK and RICHARD A. WALTON*

(*Received* 10 *October* 1989; *accepted* 14 *December* 1989)

Abstract—The reactions of the trinuclear cluster Re_3Cl_9 with various phosphine ligands in ethanol have been used to prepare the new complexes $Re_3Cl_9(PMe_2Ph)_3$, $Re_3Cl_9(\eta^1\text{-dppm})_3$, $Re_3Cl_9(dmpm)_{1.5}$, $Re_3Cl_9(\eta^1\text{-arphos})_3$ and $Re_3Cl_9(arphos)_{1.5}$, where dppm = $Ph_2PCH_2PPh_2$, dmpm = $Me_2PCH_2PMe_2$ and arphos = $Ph_2PCH_2CH_2AsPh_2$. The ^1H and $^{31}P\{^1H\}$ NMR spectra of several of these complexes and of $Re_3Cl_9(PMe_3)_3$ and $Re_3Cl_9(PMePh_2)_3$ are described, including studies of the dissociative ligand exchange in $Re_3Cl_9(\eta^1\text{-dppm})_3$. The structures of $Re_3Cl_9(PMe_3)_3$ and $Re_3Cl_9(\eta^1\text{-dppm})_3$ have been established by X-ray crystallography. Crystallographic data for $Re_3Cl_9(PMe_3)_3$: hexagonal space group $P6_3/m$, $a = b = 11.614(1)$, $c = 11.209(2)$ Å, $\alpha = \beta = 90$, $\gamma = 120°$, $V = 1309.4(5)$ Å^3 and $Z = 2$. The structure was refined to $R = 0.038$ ($R_w = 0.064$) for 524 data with $I > 3.0\sigma(I)$. Crystallographic data for $Re_3Cl_9(\eta^1\text{-dppm})_3 \cdot C_7H_8$: triclinic space group $P\bar{1}$, $a = 11.883(3)$, $b = 18.233(4)$, $c = 20.102(5)$ Å, $\alpha = 103.32(1)$, $\beta = 99.18(1)$, $\gamma = 95.88(1)°$, $V = 4139(3)$ Å^3 and $Z = 2$. The structure was refined to $R = 0.039$ ($R_w = 0.050$) for 7190 data with $I > 3.0\sigma(I)$. Both structures resemble that of the previously reported $Re_3Cl_9(PEt_2Ph)_3$, with Re—Re double bond distances spanning the narrow range of 2.471(1)–2.488(1) Å. The Re—P bond lengths are 2.634(4) Å for the Me_3P complex, and between 2.693(3) and 2.727(3) Å for $Re_3Cl_9(\eta^1\text{-dppm})_3$; the presence of three monodentate dppm ligands is confirmed in the latter structure.

Trinuclear derivatives of the type $Re_3X_9(L)_3$ are known to form readily when the rhenium(III) halides are treated with donor molecules.[1–3] In the case of monodentate tertiary phosphine ligands, the complexes $Re_3Cl_9(PR_3)_3$ (PR_3 = PMe_3, PEt_2Ph, $PMePh_2$, $PEtPh_2$, PPh_3, 3-methyl-1-phenylphosphole and 3,4-dimethyl-1-phenylphosphole) and $Re_3Br_9(PR_3)_3$ (PR_3 = PEt_2Ph and PPh_3) have been prepared[4–11] but in only one instance, viz. $Re_3Cl_9(PEt_2Ph)_3$,[12] has the structure been established by X-ray crystallography. While several polydentate phosphines have been reacted with Re_3Cl_9, the products are generally not very well defined structurally,[13] although in the case of the insoluble complex $Re_3Cl_9(dppe)_{1.5}$ (dppe = $Ph_2PCH_2CH_2PPh_2$) it seems likely that intermolecular dppe bridges link Re_3Cl_9 units in the solid state.[14]

In the present report we describe the synthesis and characterization of the complexes $Re_3Cl_9(PMe_3)_3$ and $Re_3Cl_9(PMe_2Ph)_3$, as well as $Re_3Cl_9(\eta^1\text{-dppm})_3$ (dppm = $Ph_2PCH_2PPh_2$); the latter is the first example of a structurally characterized complex that contains three pendant dppm ligands. Other reactions studied include those of Re_3Cl_9 with $Me_2PCH_2PMe_2$(dmpm) and $Ph_2PCH_2CH_2AsPh_2$ (arphos) which afford $Re_3Cl_9(dmpm)_{1.5}$, $Re_3Cl_9(\eta^1\text{-arphos})_3$ and $Re_3Cl_9(arphos)_{1.5}$. The ^1H and ^{31}P NMR spectra of these complexes and of the previously reported complex $Re_3Cl_9(PMePh_2)_3$[9] provide the first such spectroscopic data on phosphine complexes of the Re_3X_9 halides with the exception of $Re_3Cl_9(PMe_3)_3$.[11]

EXPERIMENTAL

Starting materials

Rhenium(III) chloride was prepared from $Re_2(O_2CCH_3)_4Cl_2$ by the published procedure.[15] The ligands PMe_3, PMe_2Ph, $PMePh_2$, $Me_2PCH_2PMe_2$(dmpm), *cis*-$Ph_2PCH{=}CHPPh_2$ (*cis*-dppee), and $Ph_2PCH_2CH_2AsPh_2$(arphos) were purchased from Strem Chemicals; $Ph_2PCH_2PPh_2$(dppm), was purchased from the Pressure Chemical Company.

Reaction procedures

A. *Reactions of* Re_3Cl_9 *with monodentate phosphines.* (i) $Re_3Cl_9(PMe_3)_3 \cdot 0.5EtOH$. A solution of Re_3Cl_9 (0.169 g, 0.19 mmol) in 10 cm^3 of absolute ethanol was purged of oxygen by the freeze–thaw method of degassing. This solution was then frozen in a Schlenk tube immersed in liquid nitrogen. A quantity of trimethylphosphine (0.70 cm^3, 6.8 mmol) was introduced via syringe onto the frozen solution and the reaction tube removed from the liquid nitrogen and allowed to warm. Just as soon as the ethanol solution had melted, the mixture was agitated briefly, and a red precipitate formed. This precipitate was quickly filtered off, washed with diethyl ether, and dried *in vacuo*; yield 0.143 g (70%). The pale red filtrate did not yield additional product and was discarded. Found: C, 10.9; H, 3.0. Calc. for $C_{10}H_{30}Cl_9O_{0.5}P_3Re_3$: C, 10.6; H, 2.7%. The presence of lattice ethanol in this product was confirmed by ^1H NMR spectroscopy. $Re_3Cl_9(PMe_3)_3$ is soluble in dichloromethane, chloroform and benzene, soluble with some decomposition in acetone and acetonitrile, and insoluble in methanol, ethanol, diethyl ether, hexane and water.

(ii) $Re_3Cl_9(PMe_2Ph)_3 \cdot 2EtOH$. This complex was prepared in a manner analogous to that described in section A(i); Re_3Cl_9 (0.20 g, 0.2 mmol) was reacted with dimethylphenylphosphine (0.15 cm^3, 1.0 mmol) to afford a red powder; yield 0.236 g (80%). Found: C, 24.8; H, 3.1. Calc. for $C_{28}H_{45}Cl_9O_2P_3Re_3$: C, 24.3; H, 3.3%. The presence of lattice ethanol was confirmed by ^1H NMR spectroscopy.

(iii) $Re_3Cl_9(PMePh_2)_3$. This complex was prepared with the use of a procedure similar to that described in section A(i). A small quantity of Re_3Cl_9 (0.071 g, 0.08 mmol) was reacted with methyldiphenylphosphine (0.25 cm^3, 1.3 mmol) to yield a red powder; yield 0.088 g (75%). Found: C, 31.3; H, 2.7. Calc. for $C_{39}H_{39}Cl_9P_3Re_3$: C, 31.7; H, 2.7%.

B. *Reactions of* Re_3Cl_9 *with bidentate phosphines.* (i) $Re_3Cl_9(dmpm)_{1.5}$. A procedure similar to that described in section A(i) was used to react Re_3Cl_9 (0.102 g, 0.12 mmol) with 0.7 cm^3 of a 0.73 M toluene solution of dmpm (4.5 equivalents). This afforded a red insoluble product; yield 0.035 g (28%). Found: C, 8.3; H, 2.7. Calc. for $C_{7.5}H_{21}Cl_9P_3Re_3$: C, 8.3; H, 2.0%.

(ii) $Re_3Cl_9(dppm)_3 \cdot C_7H_8$. A solution of Re_3Cl_9 (0.102 g, 0.12 mmol) in 10 cm^3 of absolute ethanol was purged of oxygen by the freeze–thaw method of degassing. After the third cycle, a quantity of dppm (0.147 g, 0.38 mmol) dissolved in 5 cm^3 of deoxygenated toluene was added and the mixture frozen. When this mixture was allowed to slowly warm, a red solution resulted. The quick addition of an equal volume of hexanes, followed by centrifugation, yielded a pink solid (0.128 g). Upon allowing the supernate to stand for *ca* 10 min, an additional quantity of solid was obtained (0.043 g); the combined yield was 70%. Found: C, 47.1; H, 3.7. Calc. for $C_{82}H_{74}Cl_9P_6Re_3$: C, 46.4; H, 3.5%. Lattice toluene was evident in the structural analysis of a single crystal of this complex as well as in the ^1H NMR spectrum. $Re_3Cl_9(dppm)_3$ is soluble in dichloromethane but insoluble in acetone, ethanol, diethyl ether and benzene.

When a reaction mixture comprising Re_3Cl_9 (0.066 g, 0.075 mmol) dissolved in EtOH, and dppm (0.134 g, 0.35 mmol) dissolved in toluene was not treated with hexanes, a mixture of compounds slowly precipitated. When the resulting solid was washed with diethyl ether, $Re_3Cl_9(dppm)_3$ remained undissolved on the filter pad; yield 0.016 g (10%). The red filtrate was allowed to stand for *ca* 1 h, whereupon a red solid precipitated; yield 0.050 g. This material was sparingly soluble in acetone, but it was insoluble in dichloromethane. Elemental carbon and hydrogen microanalyses were consistent with a composition between that for $Re_3Cl_9(dppm)_3$ and $Re_3Cl_9(dppm)_2$. Found: C, 40.0; H, 3.4%.

(iii) $Re_3Cl_9(arphos)_3$. An ethanol solution (10 cm^3) of Re_3Cl_9 (0.120 g, 0.14 mmol) was added dropwise to a solution of arphos (0.5 g, 1.1 mmol) in diethyl ether (10 cm^3). After the addition of only one third of the rhenium chloride solution, a red precipitate had already formed. This solid was separated from the solution by filtration, washed with ethanol and diethyl ether and dried; yield 0.088 g. Found: C, 42.0; H, 3.4; Cl, 14.9. Calc. for $C_{78}H_{72}As_3Cl_9P_3Re_3$: C, 42.5; H, 3.3; Cl, 14.5%. $Re_3Cl_9(arphos)_3$ is soluble in dichloromethane but insoluble in ethanol and diethyl ether.

The remaining portion of the Re_3Cl_9 was then added to the arphos in the reaction filtrate. No precipitate was observed initially, but after *ca* 1 h a

second red solid precipitated from this red solution; yield 0.077 g. Elemental carbon and hydrogen microanalyses were fairly close to those expected for $Re_3Cl_9(arphos)_2$. Found: C, 37.3; H, 3.0%. This product is insoluble in dichloromethane, acetone and diethyl ether.

When a different synthetic strategy was used, whereby Re_3Cl_9 (0.021 g, 0.02 mmol) and arphos (0.032 g, 0.08 mmol) were combined as solids to which the solvent EtOH (8 cm^3) was then added, the insoluble product appeared to be of the stoichiometry $Re_3Cl_9(arphos)_{1.5}$; yield 0.030 g (80%). Found: C, 30.2; H, 2.3. Calc. for $C_{39}H_{36}As_{1.5}Cl_9P_{1.5}Re_3$: C, 30.4; H, 2.3%.

Crystallography

Preparation of single crystals for structure determinations. Single crystals of $Re_3Cl_9(PMe_3)_3$ were obtained by the slow evaporation of CD_2Cl_2 from a solution of this complex contained in a 5-mm quartz NMR tube that had been kept under a dinitrogen atmosphere for a period of 1 week. Single crystals of $Re_3Cl_9(dppm)_3$ were obtained by the slow evaporation of the solvent from an ethanol–toluene reaction filtrate under a gentle stream of nitrogen gas over a period of *ca* 4 h.

X-ray data collection and structure refinement. The structure of crystals of composition $Re_3Cl_9(PMe_3)_3$ and $Re_3Cl_9(dppm)_3\cdot C_7H_8$ were determined by standard procedures. A summary of the crystallographic data for these two structures is given in Table 1. The cell parameters are based on 25 reflections with $21.9 < \theta < 22.4°$ for $Re_3Cl_9(PMe_3)_3$ and $17.9 < \theta < 19.5°$ for $Re_3Cl_9(dppm)_3\cdot C_7H_8$. Three standard reflections were measured every 5000 s of beam time during data collection and displayed no systematic variations in intensity. Calculations were performed on a MicroVAX II computer using the Enraf–Nonius structure determination package.

(i) $Re_3Cl_9(PMe_3)_3$. The crystal selected for the structure determination belonged to the hexagonal space group $P6_3/m$ with $Z = 2$. The position of the crystallographically unique rhenium atom was determined from a three-dimensional Patterson map. The molecule resides about the special position 2/3, 1/3, 1/4 which has site symmetry $\bar{6}$. The molecule possess C_{3h} point symmetry where one carbon on each PMe_3 ligand lies in the $Re_3(\mu\text{-}Cl)_3P_3$ plane. One hydrogen, attached to this carbon, was constrained by symmetry to lie in the $Re_3(\mu\text{-}Cl)_3P_3$ plane as well. One other hydrogen, in a methyl group not on the mirror plane, was uniquely determined. The positions of these hydrogens were idealized, and the remaining hydrogen positions were calculated assuming idealized geometry and a C—H bond distance of 0.95 Å. The value of B[H], i.e. the isotropic equivalent thermal parameter, was assumed to be 4 $Å^2$. Scattering factors for hydrogens in these idealized positions were used as a fixed contribution to F_{calc}; the hydrogens were not included in the least-squares refinement (their relative positions were fixed and did not vary as a result of refinement). Lorentz and polarization corrections were applied to the data. An empirical absorption correction was applied,[16] the linear absorption coefficient being 151.35 cm^{-1}. No correction for extinction was applied. The structure was refined in full-matrix least-squares where the function minimized was $\Sigma w(|F_o|-|F_c|)^2$, and w is the weighting factor defined as $w = 1/\sigma^2(F_o)$.

All non-hydrogen atoms were refined anisotropically; corrections for anomalous scattering were applied to all atoms so refined.[17] The highest peak in the final difference Fourier map was 1.54 e $Å^{-3}$; this is a ghost of the rhenium atom.

(ii) $Re_3Cl_9(dppm)_3\cdot C_7H_8$. The crystal of this complex belonged to the triclinic space group $P\bar{1}$ with $Z = 2$. Consequently there was no crystallographically-imposed symmetry for the trirhenium molecule. The positions of the three rhenium atoms were determined from a three-dimensional Patterson map. The remaining atoms were located in succeeding difference Fourier syntheses. The presence of lattice toluene, which was observed in the ^1H NMR spectrum, was confirmed by the crystal structure analysis. Both the trirhenium molecule and the toluene reside in general positions. Lorentz and polarization corrections were applied to the data. An empirical absorption correction was applied,[16] the linear absorption coefficient being 48.85 cm^{-1}. No correction for extinction was applied.

The Re, Cl, P, and bridgehead C atoms were refined anisotropically. Corrections for anomalous scattering were applied to these atoms.[17] The phenyl ring carbon atoms and the carbon atoms in the toluene were refined isotropically. Hydrogen atoms were not refined. The highest peak in the final difference Fourier map was 1.88 e $Å^{-3}$ and did not appear to be of any chemical significance.

Further details concerning the data sets and the structure solutions and refinements may be obtained from Dr P. E. Fanwick. Tables 2 and 3 list important bond distances and angles.*

* Atomic positional and thermal parameters and full listings of bond lengths and angles have been deposited with the Editor and with the Director, Cambridge Crystallographic Data Centre.

[b] See ref. 16.

[c] $R = \Sigma \| |F_o| - |F_c| \| / \Sigma |F_o|$.

[d] $R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(F_o)$.

[e] Goodness-of-fit $= [\Sigma w(|F_o| - |F_c|)^2 / (N_{obs} - N_{param})]^{1/2}$.

Physical measurements. IR spectra (4000–150 cm^{-1}) were recorded as Nujol mulls with a Perkin–Elmer 1800 Fourier transform spectrometer. Electronic absorption spectra were recorded on an IBM Instruments 9420 UV–vis (900–200 nm) spectrophotometer. ^{1}H NMR spectra were recorded on a Varian XL-200 spectrometer. Resonances were referenced internally to the residual protons in the incompletely deuteriated solvent. $^{31}P\{^1H\}$ spectra were recorded on a Varian XL-200 spectrometer operating at 80.98 MHz with an internal deuterium lock using aqueous 85% H_3PO_4 as an external standard.

Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University Microanalytical Laboratory.

RESULTS AND DISCUSSION

(a) *Synthesis and preliminary characterization*

The reactions of Re_3Cl_9 with PMe_3 and PMe_2Ph in ethanol to afford $Re_3Cl_9(PMe_3)_3$ and $Re_3Cl_9(PMe_2Ph)_3$ complete the series of complexes $Re_3Cl_9(PMe_{3-x}Ph_x)_3$ ($x = 0$–3). A recent report that also describes the isolation of $Re_3Cl_9(PMe_3)_3$ used the reaction between $Re_3Cl_9(THF)_3$ and PMe_3 in dichloromethane.[11] A similar reaction between Re_3Cl_9 and bis(diphenylphosphino)methane in an ethanol–toluene mixture gave pure $Re_3Cl_9(\eta^1\text{-dppm})_3$ when the product was isolated quickly from the cold reaction mixture by the addition of hexanes. Slow precipitation of the product at room temperature afforded a material whose composition was between those expected for $Re_3Cl_9(dppm)_3$ and $Re_3Cl_9(dppm)_2$, thereby indicating that polymerization through intermolecular dppm bridges was beginning to occur. An analogous reaction between Re_3Cl_9 and dmpm in ethanol–toluene gave $Re_3Cl_9(dmpm)_{1.5}$ as the only reproducibly identifiable product, i.e. a product in which polymerization through dmpm bridges appears to be complete. This compound probably bears a close structural relationship to $Re_3Cl_9(dppe)_{1.5}$.[14] In the case of the reactions between Re_3Cl_9 and dppee and 1,2-$C_6H_4(PPh_2)_2$ (dppbe), the insoluble red or purple solids that were formed had compositions (based upon carbon and hydrogen microanalyses) approximating to $Re_3Cl_9(dppee)_2$ and $Re_3Cl_9(dppbe)_{0.75}$, respectively; this indicates that polymerization through phosphine ligand bridges and/or incomplete coordination at the three acceptor sites per cluster had occurred.

When a solution of Re_3Cl_9 in ethanol is added to a large excess of arphos in diethyl ether the red 1:3 adduct $Re_3Cl_9(arphos)_3$ is formed. Reactions between Re_3Cl_9 and arphos in ethanol under conditions where the arphos ligand was not present in such a large excess gave a product that analysed as $Re_3Cl_9(arphos)_{1.5}$.

In the preceding syntheses, the isolations of $Re_3Cl_9(PMe_3)_3$, $Re_3Cl_9(PMe_2Ph)_3$ and $Re_3Cl_9(PMePh_2)_3$ were carried out at low temperatures to avoid the possibility of contamination by the dirhenium derivatives $Re_2Cl_4(PR_3)_4$ ($PR_3 = PMe_3$ or PMe_2Ph) and $Re_2Cl_5(PMePh_2)_3$ that can be formed by disruption of the Re_3 cluster unit under more forcing reaction conditions.[9] In the case of $Re_3Cl_9(dppm)_3$ and $Re_3Cl_9(arphos)_3$, the reaction conditions were adjusted so as to favour the coordination of these ligands in a monodentate η^1-fashion. The isolation of $Re_3Cl_9(\eta^1\text{-dppm})_3$ can be compared with our earlier success in preparing *trans*-$ReCl_4(\eta^1\text{-dppm})_2$.[18] We have observed previously the ability of arphos to bind in a monodentate or bridging bidentate fashion to rhenium as in the complexes *trans*-$ReCl_4(\eta^1\text{-arphos})_2$ and [*trans*-$ReCl_4(arphos)]_\infty$.[18]

The electronic absorption spectra of the complexes (Table 4) are typical of derivatives of the Re_3X_9 halides,[12,14,19] the transitions being primarily metal-based.[20] The spectra of $Re_3Cl_9(PMe_3)_3$ in deoxygenated solutions of dichloromethane and in benzene, were unchanged over a period of 30 min, whereas solutions in acetone and acetonitrile were much less stable. The low-frequency IR spectra of each of these derivatives show a very similar group of bands below *ca* 350 cm^{-1} that, in turn, resemble the spectra of other complexes of Re_3Cl_9.[19] The bands between 360 and 300 cm^{-1} are primarily due to ν(Re—Cl) modes.

(b) *Crystal structures of* $Re_3Cl_9(PMe_3)_3$ (**1**) *and* $Re_3Cl_9(\eta^1\text{-dppm})_3$ (**2**)

The structures of these two complexes have been confirmed by X-ray crystallography. ORTEP representations of the structures are shown in Figs 1 and 2, while important bond distances and angles are listed in Tables 2 and 3. A close similarity with the previously reported structure of $Re_3Cl_9(PEt_2Ph)_3$ is revealed. Of importance is our finding that the Re—Re distances for **1** and **2** encompass the narrow range of 2.471(1)–2.488(1) Å, and are similar to the distance of 2.493(4) Å reported for $Re_3Cl_9(PEt_2Ph)_3$.[12]

The Re—P bond lengths of 2.634(4) Å for **1** and 2.693(3)–2.727(3) Å for **2** are not significantly different from the value of 2.700(19) Å for $Re_3Cl_9(PEt_2Ph)_3$.[12] The constancy of the latter

values supports the notion that these long distances are a consequence of steric crowding about the rhenium atoms. The slightly shorter Re—P bonds of **1** are doubtless a reflection of the greater basicity of the PMe_3 ligand (compared to PEt_2Ph and dppm) together with some slight relief of steric pressure. These Re—P bond lengths can be contrasted with those of 2.401(6) and 2.458(6) Å reported for *mer*-$ReCl_3(PMe_2Ph)_3$.[21] The effect of reducing the steric compression is seen in the structure of the bis(phosphine) complex $Re_3Me_9(PEt_2Ph)_2$.[22] In this molecule, the Re—Re distances of 2.433(1)–2.474(1) Å are still compatible with Re—Re double bonds, but the Re—P distances are now considerably shorter (2.546(3) and 2.569(3) Å).

The terminal Re—Cl bonds are, as expected, shorter than the Re—Cl bridging bonds (e.g. 2.310(3) vs 2.418(4) Å for **1**), a trend that is also seen in the structure of $Re_3Cl_9(PEt_2Ph)_3$. The angular distortions in all three molecules are generally very similar and will not be discussed further.

(c) *NMR spectroscopic properties*

The ^1H NMR spectra of $Re_3Cl_9(PMe_3)_3$ in CD_2Cl_2 and C_6D_6 consist of a virtual triplet at δ +1.57 and +1.06, respectively, with $J_{P-H} = 8.4$ Hz. This compares well with the data reported by Wilkinson and co-workers[11] for a solution of $Re_3Cl_9(PMe_3)_3$ in CD_2Cl_2 (δ +1.50(t) with $J_{P-H} = 8.3$ Hz). In the case of $Re_3Cl_9(PMe_2Ph)_3$ and $Re_3Cl_9(PMePh_2)_3$, singlets at δ +1.80 and +2.08, respectively, were observed for CD_2Cl_2 solutions, together with phenyl resonances (showing the correct relative intensities) between δ +7.4 and +7.6. The $^{31}P\{^1H\}$ NMR spectra of these three complexes (recorded in CD_2Cl_2) show singlets at δ −35.2, −30.8 and −20.6, respectively, which are shifted downfield of the free phosphines (δ −63,

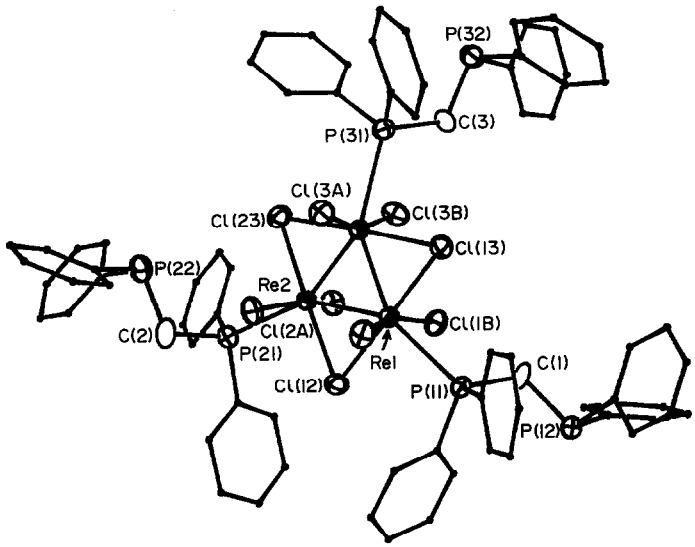

Fig. 2. ORTEP representation of the structure of $Re_3Cl_9(\eta^1\text{-dppm})_3$ showing the atomic numbering scheme for the non-phenyl group atoms. The thermal ellipsoids are drawn at the 50% probability level.

-47 and -28);[23] a previous citation of the $^{31}P\{^1H\}$ NMR spectrum of $Re_3Cl_9(PMe_3)_3$ reported a singlet at δ -38.38.

The NMR spectral properties of $Re_3Cl_9(dppm)_3$ are of interest in view of the monodentate coordination of the dppm ligands. The ^1H NMR spectrum of the crystals of stoichiometry $Re_3Cl_9(dppm)_3 \cdot C_7H_8$ in CD_2Cl_2 at $+20°C$ exhibits a fairly narrow phenyl multiplet centred at δ $+7.25$, a broad singlet at δ $+3.10$ due to the bridgehead —CH_2— groups of the dppm ligands (P—H coupling is not resolved), and a sharp methyl resonance at δ $+2.32$ arising from the lattice toluene molecule. At $-60°C$ the spectrum is little changed, with the exception that the phenyl resonances now display a much more complex pattern as the conformational changes resulting from rotation about the CH_2—P bonds are slowed, as is the dissociative exchange of the dppm ligands (*vide infra*). At $+20°C$, the $^{31}P\{^1H\}$ spectrum shows no discernible features with the exception of two extremely broad humps near δ -14 and -26. As the temperature is lowered to $-50°C$ in 10 degree intervals, the spectral changes shown in Fig. 3 occur with the growth of multiplets centred at δ -12.7 and -27.4 that are assigned to the bound and free phosphorus atoms, respectively. These features are characteristic of a fluxional process such as that involving exchange of bound and free phosphorus ligand atoms; in the present case coalescence occurs just above room temperature. In view of the coordinative saturation at the rhenium atoms of this trinuclear cluster, this process must involve the dissociative exchange of dppm [eq. (1)]:

$$Re_3Cl_9(dppm)_3 \rightleftharpoons Re_3Cl_9(dppm)_2 + dppm \quad (1)$$

with a rate of *ca* 2700 s^{-1} (calculated from rate $= \pi\Delta\nu/\sqrt{2}$, with $\Delta\nu = 1200$ Hz).[24]

In a separate NMR experiment, additional dppm was added to a CH_2Cl_2–CD_2Cl_2 solution of $Re_3Cl_9(dppm)_3$. At room temperature, three broad

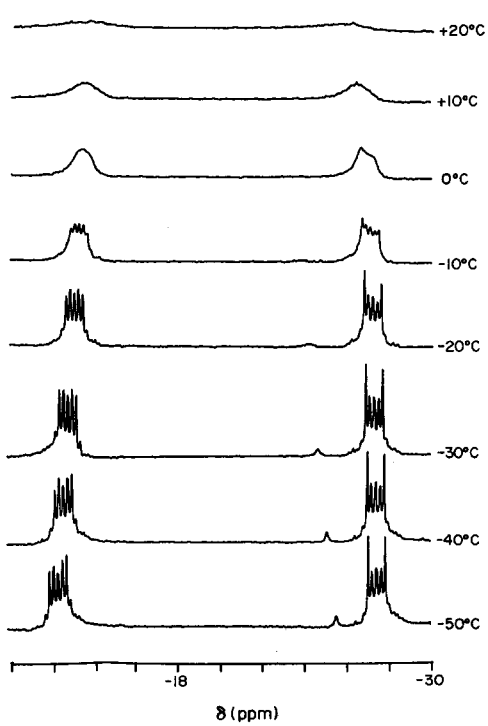

Fig. 3. $^{31}P\{^1H\}$ NMR spectrum of $Re_3Cl_9(\eta^1\text{-dppm})_3$ recorded in CD_2Cl_2 over the temperature range $+20°$ to $-50°C$.

^{31}P signals were observed that correspond to the coordinated (δ −14) and dangling (δ −27) phosphorus atoms of the complex as well as the phosphorus atoms of free dppm (δ −23). These signals, while broad, were considerably sharper than the signals observed at room temperature in the absence of added dppm. This result suggests that, in the presence of excess dppm, the equilibrium of eq. (1) lies well to the left.

Finally, we note that in the room temperature $^{31}P\{^1H\}$ NMR spectrum of $Re_3Cl_9(\eta^1\text{-arphos})_3$ (recorded in CD_2Cl_2), the phosphorus signal at δ −9.0 is downfield of free arphos (δ −12.6 in CD_2Cl_2). While we cannot rule out the presence of small amounts of arsenic-bound arphos in this product, the major species apparently contains phosphorus-bound ligands.

(d) *Concluding remarks*

The reactions of Re_3Cl_9 with the ligands $R_2PCH_2PR_2$ (R = Me or Ph), $Ph_2PCH_2CH_2PPh_2$ and $Ph_2PCH_2CH_2AsPh_2$ have been shown in the present study, and in earlier investigation,[14] to afford polymeric complexes of the type $Re_3Cl_9(LL)_{1.5}$, in which the Re_3Cl_9 cluster units are linked by L—L bridges (LL = $Me_2PCH_2PPh_2$, $Ph_2PCH_2CH_2PPh_2$ and $Ph_2PCH_2CH_2AsPh_2$). For the first time, we have isolated complexes of the type $Re_3Cl_9(\eta^1\text{-LL})_3$ in the case of LL = $Ph_2PCH_2PPh_2$ and $Ph_2PCH_2CH_2AsPh_2$, and confirmed the monodentate nature of these ligands through a single crystal X-ray structure analysis of $Re_3Cl_9(\eta^1\text{-}Ph_2PCH_2PPh_2)_3$. This structure, and that of $Re_3Cl_9(PMe_3)_3$, resemble the previously determined structure of $Re_3Cl_9(PEt_2Ph)_3$.[12]

A STUDY OF THE ANATION REACTION OF $[Cr(NH_3)_6][C_2O_4]_{1.5} \cdot 2H_2O$ IN THE SOLID STATE

PAUL O'BRIEN* and NIGEL B. SELLERS

Department of Chemistry, Queen Mary and Westfield College, University of London, Mile End Road, London E1 4NS, U.K.

(*Received* 14 *September* 1989; *accepted* 15 *December* 1989)

Abstract—The crystalline oxalate salts of chromium(III) and cobalt(III) hexaammines $[M(NH_3)_6][C_2O_4]_{1.5} \cdot 2H_2O$ have been prepared. The chromium salt readily dehydrates and deamminates at 140°C losing four equivalents of ammonia to yield an amorphous product, $[Cr(NH_3)_2(C_2O_4)_{1.5}]$, in which bridging oxalates are coordinated to chromium.

The anation reactions of trivalent metal complexes are amongst the most widely studied of solid-state reactions of coordination complexes.[1–4] As such they have been widely used in discussions of the mechanisms of such reactions, on the whole such debate has tended to ignore solid-state effects. It is unusual for any information on the crystallinity of the reaction product to be reported and mechanisms are usually interpreted in terms of SN 1 (D) or SN 2 (A) processes at the metal centre.[1–4] However, LeMay and Babich[1] have pointed out many of the difficulties in determining mechanisms due to the effects of procedural variables, and House[5] has emphasized the importance, in controlling anation reactions, of defects in the solids.

We have, for some time, been interested both in the reactions of various coordination complexes in the solid state,[6–9] and in the coordination chemistry of chromium(III).[10–14] We were keen to study a system in which a well-defined salt of a cationic chromium(III) complex reacted in the solid state with an anionic chelating ligand, present as the counter ion, but salts of this kind have proved difficult to synthesize. However, the oxalate salts of both chromium and cobalt hexaammines were easy to prepare; in this paper we report on their solid-state reactivity.

RESULTS AND DISCUSSION

Preparation and characterization of the hexaammine salts

The oxalate salts of the hexaammines were prepared by the direct reaction of a cold solution of the nitrate salt of the hexaamine with a solution of potassium oxalate (see Experimental). The oxalate salts of both of the hexaammines were microcrystalline and isomorphous. Many attempts to crystallize the salts, e.g. by diffusion methods, were made and although crystalline material could be obtained the compounds formed as "star bursts" of very fine needles unsuitable for a single-crystal X-ray structure determination.

The IR and electronic spectra of the chromium salt with oxalate are summarized in Tables 1 and 2. The IR spectra (Fig. 1) of the salt before heating is close to an addition of that of the oxalate dianion (e.g. as in $K_2C_2O_4$) and the metal hexaammine; the main bands can be assigned by reference to the parent compounds and the literature,[15] Table 1. The ligand-field strength, as judged from the electronic spectrum,[16] is similar to that in other hexaammine salts of chromium(III) (Table 2), indicating that no anation has occurred during the preparation of the complex. The magnetic moment is typical of that found for a monomeric chromium(III) complex, Table 2.

Thermal analysis of the chromium salt (10°C min^{-1}, N_2 25 cm^3 min^{-1}) gave a single mass loss (120–180°C) of 30%, which is close to that theoretically required for the loss of two molecules of water and four of ammonia (32%). The product and kinetics of the decomposition are discussed later in this paper. Differential thermal analysis of the chromium salt (10°C min^{-1}, static air) resulted in a single endotherm concurrent with deammination and dehydration, $\Delta H = 22(\pm 3)$ kJ mol^{-1} (110–164°C, extrapolated onset temperature 108°C).

The cobalt(III) salt had analogous spectroscopic properties to that of chromium(III), but thermal decomposition took place in three steps: 10.5%,

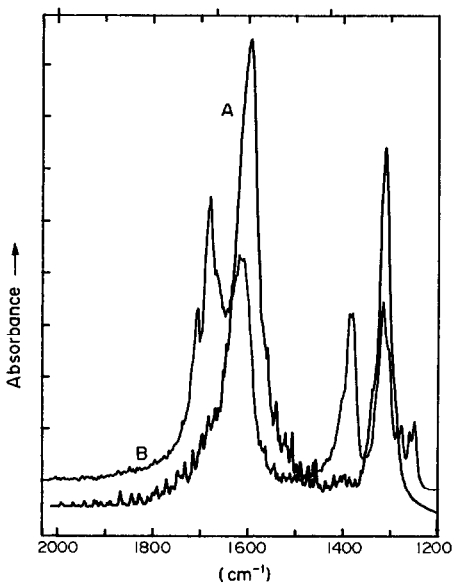

Fig. 1. The IR spectrum of $[Cr(NH_3)_6][C_2O_4]_{1.5}\cdot 2H_2O$ and the product of deammination. The spectra were obtained as KBr disks (1% 100 mg); the spectrum of the salt (A) was first recorded, then the disk was placed in an oven at 140°C for 45 min and spectrum (B) was recorded after the disk had cooled. The results are similar to those obtained for a sample decomposed in an oven, Table 1.

Table 2. Electronic spectra[a]

107–145°C ($2H_2O$, 10.9%), 41%, 155–290°C ($6NH_3+CO$, 40%) and 20.5% up to 500°C ($CO+CO_2$, 21.9%) (10°C min^{-1}, N_2 25 cm^3 min^{-1}). The oxalate anion decomposed concurrent with deammination and the deammination did not lead to a simple reaction of the oxalate with the metal centre; further studies of this compound were not undertaken. However, it is interesting to note

the difference in the reactivity of these isomorphous salts.

Characterization of the reaction product

The product of the deammination of the chromium complex was always found to be amorphous. In the product of the reaction the antisymmetric stretch of the COO^- group is shifted from a single peak at 1596 cm^{-1}, in the salt, to a series of peaks between 1708–1660 cm^{-1}; the new bands are consistent with coordination of the carboxylate function to the metal[15] and resemble the antisymmetric carboxylate stretches in trisoxalatochromate(III). The symmetric carboxylate stretches are also more complicated in the reaction product (Table 1) but show no obvious resemblance to the frequencies in the tris-oxalate. The separation of the symmetric and antisymmetric oxalate stretches is greater than in the chelating oxalates of chromium(III); this observation may suggest bridging oxalate groups in the reaction product.[15,16] A new band is observed at 408 cm^{-1} and may be assigned tentatively as an M—O stretch.[15]

The electronic spectra of various complexes with chromophores from CrN_6 to CrO_6 are summarized in Table 2; the lowest energy *d–d* transition ($^4A_{1g} \rightarrow {}^4T_{2g}$ in *Oh* symmetry) gives an approximate measure of the ligand-field strength.[17] The initial product of the reaction can be assigned as a CrN_2O_4 chromophore. The fact that the lowest energy transition is not split suggests a single product (or products with remarkably similar ligand-field strengths) and that a *cis* arrangement of similar donor atoms predominates.[13,18] The magnetic moment of the salt is slightly below that expected for a monomeric chromium(III) complex (Table 2), supporting the suggestion made above that the product involves bridging ligands.

On dissolution of the product in water the resulting solution had a conductivity of 56 Ω^{-1} cm^2 mol^{-1} (per chromium), typical of a 1 : 1 electrolyte. On standing for 3–4 h the conductivity of the solution gradually increased to 213 Ω^{-1} cm^2 mol^{-1} consistent with a 2 : 1 electrolyte. Solutions of the product separated into two bands on a Sephadex A-25 anion-exchange column, a rapidly moving purple band and a more firmly bound green fraction. The two fractions were characterized by bands in the electronic spectra at 18.5 and 25.0×10^3 cm^{-1} and 17.5 and 24.4×10^3 cm^{-1}, respectively, suggesting CrN_3O_3 and CrO_6 chromophores.

The product of the reaction is probably a chromium(III) complex involving bridging oxalates; a structure such as the neutral dimer $[(NH_3)_2(C_2O_4)Cr(C_2O_4)Cr(C_2O_4)(NH_3)_2]$ with a catenaoxalate bridge fits well with all of the spectroscopic properties of the product, but fails to explain the facile hydrolysis in aqueous solution. A more random polymeric structure involving extended chains of singly (μ) bridging oxalato ligands is more likely. Structures involving two different chromium chromophores seem unlikely as the electronic spectrum of the product has a symmetrical band at low energy.

Isothermal kinetic studies

Isothermal studies of the decomposition were then carried out to determine the mechanism of the solid-state reaction. In order to determine the most appropriate rate law the kinetic results were investigated using various models.[6,9,19,20] Reduced time plots,[21] in which progress of the reaction (α) is plotted against $t/t_{0.5}$ (α, fraction of reaction, $\alpha = 1$, 100% reaction, corresponding to the loss of two molecules of water and four of ammonia from each hexaammine, $t/t_{0.5}$ the absolute time divided by the estimated half-life), are a useful way of assessing the appropriate rate law. Results from a range of temperatures may be compared on a single plot; Fig. 2 shows a reduced time plot. The reaction profile is close to that required for a reaction which obeys the concept of an order (usually for a solid-state process 1, 0.5 or 0.333). Closer inspection of various reduced time plots, and the fitting of the results to these various rate laws as previously described (Table 3),[6,18,19] strongly supports a first-order model. The activation energy, derived from an Arrhenius plot of the first-order rate constants, is 84(±5) kJ mol^{-1}.

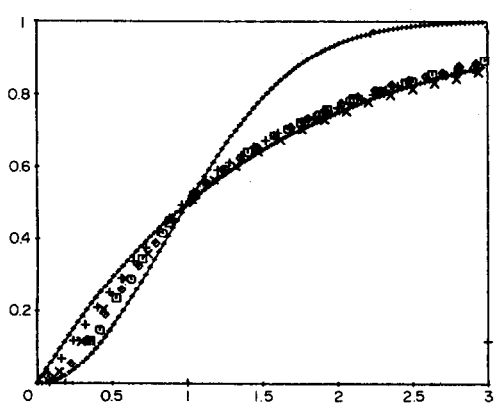

Fig. 2. Reduced time plot. The graph incorporates data at the following temperature (°C): +, 117; ×, 125; ◇, 136; □, 142; ○, 147. The solid lines are the theoretical curves for (a) a first-order process and (b) nucleation and growth in two-dimensions (Avrami/Eroveev kinetics, see refs 20 and 21).

Table 3. First-order rate constants

Temperature (°C)	$10^4 k$ (s^{-1})	
117	8.5	
125	16.8	$\Delta H = 22(\pm 3)$ kJ mol^{-1}
129	17.2	$\Delta H^{\ddagger} = 80(\pm 5)$ kJ mol^{-1}
136	29.2	$\Delta S^{\ddagger} = -100(\pm 25)$ J K^{-1} mol^{-1}
142	45.0	
147	52.5	

The overall process models as a single first-order process. The most logical explanation for this observation is that we are following a random process within the solid in which the loss of various constituents occurs with a single rate-determining step, probably Cr—N bond breaking. Our experience has indicated that genuine first-order reactions are rare in the solid state, but the majority of reactions we are aware of involve crystalline products and reactants. One reason for the lack of a crystalline product may be the large volume change in this reaction, the loss of six molecules overall and the substitution of a chelating ligand into the first coordination sphere of chromium producing too much structural change for the retention of crystallinity.

Consequently it is difficult to draw firm conclusions from our kinetic study, especially as procedural variables can have a marked effect on activation parameters.[4] However, the results do clearly indicate:

(1) a first-order rate,
(2) a modest enthalpy of activation and entropy of activation.

The reaction may proceed by a dissociative mechanism in which the rate-determining step is the loss of ammonia molecules from the ammine complex and resembles the reaction of glycine with $[Cr(NH_3)_6]^{3+}$, in a melt[14] ($\Delta H^{\ddagger}$ 106 kJ mol^{-1}).

EXPERIMENTAL

Materials

All reagents were purchased from BDH Chemicals Ltd. $[Cr(NH_3)_6](NO_3)_3$ and $[Co(NH_3)_6](NO_3)_3$ were prepared by the literature method.[22,23]

Synthesis of $[M(NH_3)_6][C_2O_4]_{1.5}\cdot 2H_2O$ (M = Co *or* Cr)

$[M(NH_3)_6](NO_3)_3$ (1.0 g) was dissolved in cold water (10 cm^3) and 5 cm^3 of a saturated solution of potassium oxalate was added with continuous stirring. A bright yellow microcrystalline precipitate formed almost immediately, the solid was air-dried and stored in a deep freeze. The chromium complex effloresced in air losing one water of hydration. Major *d*-spacings (Å) are as follows for $[Cr(NH_3)_6][C_2O_4]_{1.5}\cdot 2H_2O$, (Co): 4.39, (4.36), 4.15, (4.06), 2.83, (2.80), 2.32, (2,30), 2.23, (2.27), 1.89, (1.86), 1.76, (1.76), 1.40, (1.49), 1.38, (1.35). Both salts gave satisfactory microanalysis: $[Cr(NH_3)_6][C_2O_4]_{1.5}\cdot 2H_2O$ %C 11.1 (11.4), %H 6.8 (6.7), %N 26.0 (25.7); $[Co(NH_3)_6][C_2O_4]_{1.5}\cdot 2H_2O$: %C 10.9 (10.8), %H 6.7 (6.5), %N 25.5 (24.4).

Physical measurements

Electronic spectra were recorded with a Perkin–Elmer 330 spectrophotometer; IR spectra were recorded on a Mattson Polaris FT–IR spectrometer; as Nujol mulls or KBr disks (*ca* 2%, 100 mg). Magnetic moments were measured with an Evans' Balance (Sherwood Scientific, Cambridge, U.K.). Thermogravimetric studies were carried out using a Stanton Redcroft TG-750 (in static air). Differential thermal analysis was undertaken using a DTA 671B, calibrated with high purity indium metal. Activation parameters were calculated as described by Edwards *et al.*[24]

Abstract—The redox behaviour of the ligand 2-mercaptobenzoic acid has been studied in dimethylsulphoxide. The combination of the dianion of the ligand with manganese(II) in a 1:2 mole ratio forms a colourless complex whose stability constant has been determined polarographically as 2.8×10^9 M^{-2}. Oxidation of this complex at -0.45 V vs SCE yields a red complex of manganese(III) whose stoichiometry is also 1:2. The complexes have been characterized by cyclic voltammetry, controlled-potential electrolysis, optical spectroscopy and magnetic susceptibility measurements. The formation constant of the $[Mn^{III}(2\text{-MBA})_2]^-$ complex has been evaluated spectrophotometrically as 9.3×10^7 M^{-2}. These results may be relevant to the development of an adequate model for the active centre of acid phosphatases.

The coordination chemistry of manganese in the +2, +3 and +4 oxidation states is useful for understanding the structure and reactivity of manganese sites in biological systems. It is now well established that manganese plays an important role in numerous redox processes: at least superoxide dismutase,[1,2] acid phosphatases,[3] pseudo-catalase[4] and the photosynthetic oxygen-evolving complex[5–7] contain manganese in their catalytic centre. Therefore, an important area of investigation of the bioinorganic chemistry of manganese is the study of the structure and reactivity of manganese complexes with biologically relevant heteroatom donor ligands.

Previous papers from our group have been concerned with the redox properties of manganese complexes to serve as models for the centre that catalyses the oxidation of water to dioxygen in Photosystem II of green-plant photosynthesis.[8–11] Transition metal dithiolate complexes have also attracted our attention[12] because of the common occurrence of metal–sulphur bonding in biological systems.[13–15] Therefore, we have undertaken the study of the redox chemistry of the ligand 2-mercaptobenzoic acid (2-MBA) and its complexes with manganese in order to determine their stability and stoichiometry, as well as the possibility of stabilizing higher oxidation states of the metal. This ligand represents an analogue of a cysteine residue—with a second coordinating group to enhance the stability of the complexes. It is thus of interest to determine the properties of its complexes with manganese to mimic the ligation properties of cysteinyl residues in proteins.

EXPERIMENTAL

Equipment

A three-electrode potentiostat (Tacussel Model PRT 20-2X potentionstate/galvanostat with Model GSTP wave generator) was used for the cyclic voltammetric and controlled-potential electrolysis experiments.

A current integrator based on operational amplifiers was used as coulometer in the controlled-potential electrolyses.

Cyclic voltammograms were recorded on a Hewlett–Packard Model 7004 A X–Y recorder. The electrochemical cell was equipped with a Beckman platinum-inlay working electrode (area 0.23 cm^2), a platinum coil auxiliary electrode, and an Ag/AgCl

* Author to whom correspondence should be addressed.

reference electrode filled with an aqueous tetramethylammonium chloride solution and adjusted to 0.00 V vs SCE.[16] The latter was contained in a Pyrex tube with a soft-glass cracked tip; this electrode was placed inside a Luggin capillary. For controlled-potential electrolysis, a platinum-mesh working electrode was employed.

A Beckman Model ACTA CV spectrophotometer was used for UV–vis spectrophotometric measurements. The magnetic susceptibility measurements were made with a Varian XL-100 NMR spectrometer by the method of Evans[17] as modified by Retting.[18] Diamagnetic corrections were made.[19]

Air-sensitive compounds were handled in a glove bag (Aldrich) under a nitrogen atmosphere and the oxygen content was monitored with a Beckman Model Monitor II Oxygen Analyser.

Reagents

The reagents for the investigation and syntheses included $Mn(ClO_4)_2 \cdot 6H_2O$ (G. Frederick Smith), tetraethylammonium hydroxide (TEAOH) (25% in methanol, Eastman), tetramethylammonium chloride (Aldrich) and tetraethylammonium perchlorate (TEAP) (G. Frederick Smith). The ligand 2-mercaptobenzoic acid was obtained from Aldrich and was purified by sublimation.

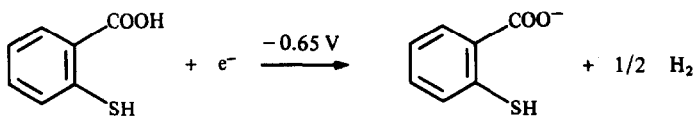
Burdick and Jackson Laboratories "distilled-in-glass" grade solvents were used without further purification for all of the experiments. High purity argon was used to deaerate solutions.

Because the solvation water of the $Mn(ClO_4)_2 \cdot 6H_2O$ salt interfered with the stoichiometric formation of the complexes under study, $[Mn^{II}(DMU)_6][ClO_4]_2$ (DMU = dimethylurea)[20] was used in all the experiments in which the manganese(II) complexes were formed *in situ*. As a source of manganese(III) $[Mn^{III}(urea)_6][ClO_4]_3$[21] was used in all the experiments.

RESULTS AND DISCUSSION

A preliminary study of the ligand showed that this compound is very sensitive to air, and is oxidized by molecular oxygen to the corresponding dimer. Therefore, it was purified by sublimation at reduced pressure. White crystals were obtained whose purity was verified by controlled potential coulometry.

Figure 1 shows the cyclic voltammograms of solutions of 2-MBA in dimethylsulphoxide. In Fig. 1(A) it is observed that in a negative scan a reduction peak at −0.65 V vs SCE appears corresponding to the following process:

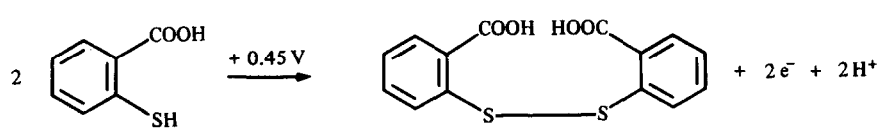


(1)

A study of the peak current as a function of the square root of the scan rate indicates that this is a diffusion-controlled process, and controlled-potential electrolysis at −0.90 V vs SCE allowed us to determine that one equivalent of charge per mole of ligand has been transferred in this process. Peak 1b can be assigned to the oxidation of hydrogen that has been produced in process (1) and that remains at the electrode. In this case the peak current does not show a linear dependence with the square root of the scan rate. This phenomenon is commonly observed in aprotic solvents and has been reported in a study of the activation of molecular hydrogen at a platinum disc electrode in non-aqueous solvents.[22]

The positive scan [Fig. 1(B)] shows an anodic peak (peak 1c) at 0.45 V vs SCE, which corresponds to the oxidation of the ligand in solution to the corresponding dimer according to process (2). The electron stoichiometry of this process has been confirmed by controlled-potential electrolysis.

Peaks 1d and 1e are the reductions of the dimeric species generated before. The first peak (1e) overlaps with process (1) and therefore it cannot be observed very easily. However, peak 1d allows the determination of the purity of the ligand because the absence of this peak in a negative scan indicates the absence of oxidized ligand.



(2)

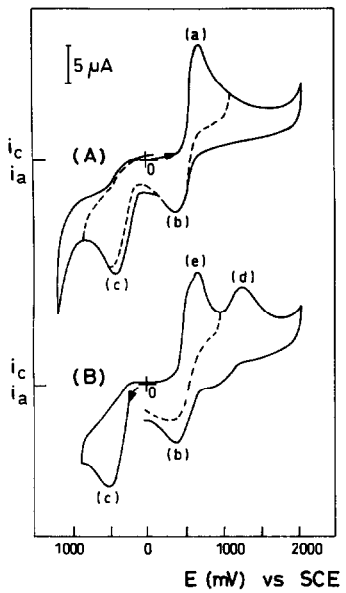


Fig. 1. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1$ V s^{-1}) of a solution that is 1 mM in 2-MBA. (A) initial negative scan; (B) initial positive scan.

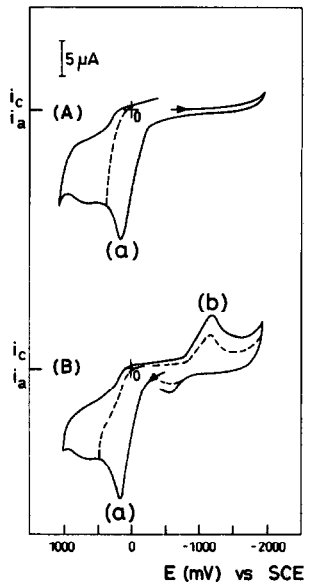

Fig. 2. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1$ V s^{-1}) of a solution that is 1 mM in 2-MBA and 1 mM in base (TEAOH). (A) initial negative scan; (B) initial positive scan.

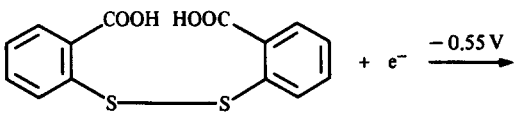
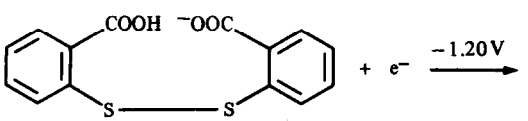
The two reduction steps of the dimeric species are illustrated by processes (3) and (4). In these cases the electron stoichiometries of the reactions have been confirmed by controlled-potential electrolysis.



(3)

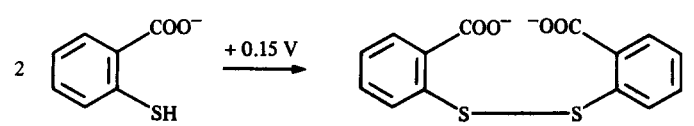


(4)

Figure 2 shows the voltammetric study of the ligand in the presence of one equivalent of base. In a negative scan [Fig. 2(A)] no reduction peak is observed which confirms that process (1) is equivalent to the neutralization of a proton of the ligand.

In the monoanionic species in this case, the proton that remains in the molecule is shared between the carboxylate and the mercapto groups, as a consequence of the *ortho*-effect present, weakening the S—H bond and facilitating its oxidation to produce the dimeric species, as can be inferred by the appearance of peak 2a. In this case the oxidation takes place at a less positive potential than when neutral 2-MBA is present.

On the other hand, the potential of peak 2b is equivalent to that of peak 1d, which would confirm that the ligand is oxidized in 2a to the corresponding disulphide according to process (5), indicating that the protons generated in this process permit the obtention of the species that is reduced in 1d.



(5)

Figure 3 shows the voltammograms corresponding to a solution of 2-MBA in the presence of two equivalents of base. The most relevant observation in this case is that the oxidation to the cor-

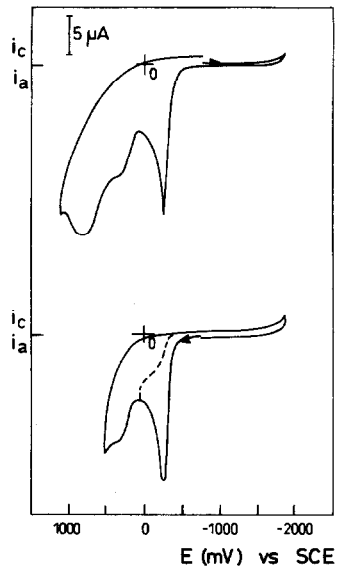


Fig. 3. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1$ V s^{-1}) of a solution that is 1 mM in 2-MBA and 2 mM in base (TEAOH). (A) initial negative scan; (B) initial positive scan.

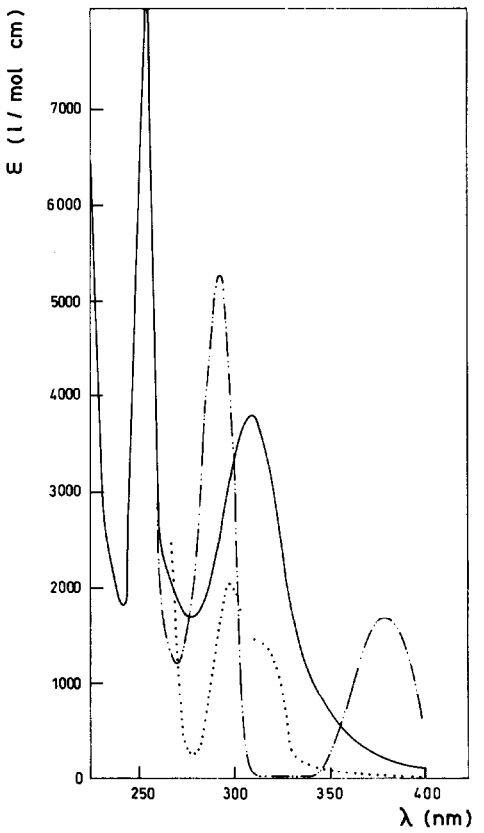

Fig. 4. UV spectra in Me_2SO of solutions that are: (——) 1 mM in the dianion of 2-MBA; (–·–·–·–) 1 mM in the monoanion of 2-MBA; (·····) 1 mM in the neutral form of 2-MBA.

responding disulphide becomes even easier because the dianionic species are now in solution. The absence of cathodic processes when the potential is scanned in any direction should also be noted. This confirms the above mentioned reduction processes for the oxidized ligand because they cannot take place when both protons have been neutralized.

Figure 4 shows the absorption spectra of solutions of 2-MBA in its neutral, monoanionic and dianionic forms. The neutral protonated form presents an absorption maximum at 295 nm ($\varepsilon = 2100$ M^{-1} cm^{-1}) with a sort of shoulder at 315 nm, which may be due in part to the *B* band of the benzene ring of the ligand. The addition of one equivalent of base causes a bathochromic shift due to the presence of the unshared electrons of the monoanion. Therefore, the E_2 band of the ligand is observed at 290 nm ($\varepsilon = 5350$ M^{-1} cm^{-1}), whereas the *B* band shows up at 380 nm ($\varepsilon = 1670$ M^{-1} cm^{-1}). The dianion of the species shows a hypsochromic shift with a great increase in the extinction coefficients. The absorption maximum corresponding to the E_2 band of the benzene ring of the ligand appears at 260 nm ($\varepsilon = 8000$ M^{-1} cm^{-1}) and the *B* band at 310 nm ($\varepsilon = 3700$ M^{-1} cm − 1).

Finally, with respect to the study of the ligand, it should be stated that the observed behaviour in the presence of base is analogous to that found when the protons are removed by previous controlled-potential electrolysis [Process (1)]. This indicates that the amount of water produced upon chemical neutralization of a proton does not affect the above mentioned processes. However, it is very important to avoid the presence of oxygen in the system as the anionic ligand oxidizes very easily to the corresponding disulphide [Process (2)].

The addition of manganese(II) to the ligand, both in its neutral and monoanionic forms, does not produce any change either in the spectra or the cyclic voltammograms of the latter. Only the reduction processes corresponding to the free metal are observed to be independent of the electrochemical behaviour of the ligand. Therefore, we can conclude that under these conditions no complex is being formed.

The voltammetric behaviour of the ligand upon addition of two equivalents of base and in the presence of manganese(II) is illustrated in Fig. 5. In this case a 1 : 2 complex is formed, because the reduction of free manganese(II) is observed when a stoichiometric ratio of 1 : 1 is used [Fig. 5(C)]. In the latter case the free manganese(II) is in excess with respect to the ligand.

The cyclic voltammogram of a solution of the complex [Fig. 5(B)] shows a fairly reversible couple

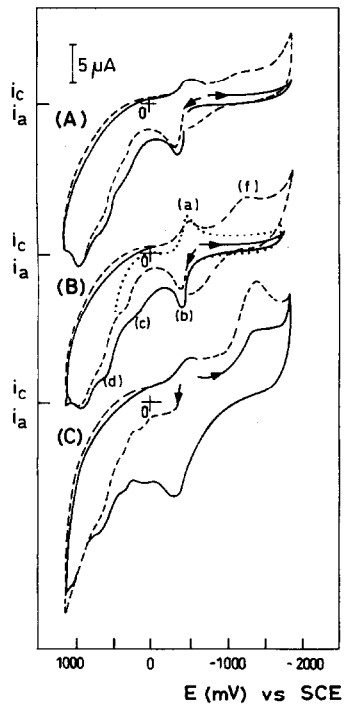

Fig. 5. Cyclic voltammograms in Me_2SO (0.1 M TEAP; $v = 0.1$ V s^{-1}) of solutions that are 1 mM in the dianion of 2-MBA plus: (A) 1/3 mM Mn^{2+}; (B) 1/2 mM Mn^{2+}; and (C) 1mM Mn^{2+}. The metal ion has been added as $[Mn^{II}(DMU)_6](ClO_4)_2$.

(peaks 5a and 5b) when an initial negative scan is made. On the other hand, when the initial scan is made positive, the reduction of free manganese(II) at -1.25 V vs SCE is observed clearly only if the potential scan is reversed after peaks 5d or 5e. Therefore, we can conclude that the processes corresponding to these two peaks are oxidations of the ligand with the subsequent destruction of the complex.

On the other hand, peak 5b corresponds to an oxidation process that leads to another complex. Controlled-potential electrolysis at -0.2 V vs SCE produces a red species with one equivalent of charge being transferred per mole of metal ion. Therefore, this result indicates that this voltammetric peak corresponds to the oxidation of manganese(II) to manganese(III). Controlled-potential electrolysis of a solution of the red complex at -0.7 V vs SCE yields a colourless solution which shows the same voltammetric behaviour as the initial one. In this case, one equivalent of charge per mole of metal ion is transferred in the reduction process. The voltammetric behaviour of these solutions indicates that the following process is reversible:[23]

$$[Mn^{II}(2\text{-MBA})_2]^{2-} \underset{-0.50\,V}{\overset{-0.45\,V}{\rightleftharpoons}} [Mn^{III}(2\text{-MBA})_2]^{-} + e^{-}. \quad (6)$$

Figure 6(A) illustrates the UV spectra of the solutions of the complexes of manganese with 2-MBA. In the case of manganese(II) an absorption maximum is observed at 300 nm ($\varepsilon = 3300$ M^{-1} cm^{-1}) which is probably the same *B* band of the benzene ring of the ligand that has shifted hypsochromically by the interaction of the metal ion with the electrons of the donor groups. In the presence of manganese(III) this band is not observed

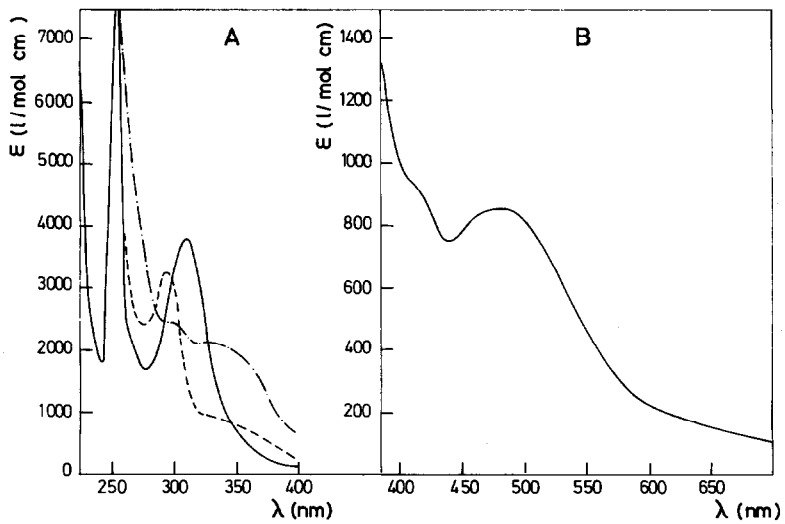

Fig. 6. (A) UV spectra in Me_2SO of solutions that are: (——) 1 mM in the dianion of 2-MBA; (– – – –) 1 mM in the dianion of 2–MBA plus 0.5 mM $[Mn^{II}(DMU)_6](ClO_4)_2$; (–·–·–) 1 mM in the complex of manganese(III) obtained by oxidation at -1.2 V vs SCE. (B) Visible spectrum of a solution 1 mM in the complex of manganese(III).

probably because it has shifted further to shorter wavelengths as a consequence of stronger interaction of these electrons with the oxidized metal. In the visible region, only the red species shows an absorption maximum at 480 nm ($\varepsilon = 840$ M^{-1} cm^{-1}) which could be due to a *d–d* transition in the metal ion, and this is illustrated in Fig. 6(B).

The spectrophotometric behaviour of the red complex of manganese(III) allowed the determination of its formation constant by Job's method (9.3×10^7 M^{-2}). The stoichiometry of the complex was confirmed.

For the manganese(II) complex the determination of the formation constant by this method was not possible because both the ligand and the complex present absorption maxima that are too close to each other. Therefore, its value was evaluated polarographically[24] as 2.8×10^9 M^{-2}.

Finally, the magnetic susceptibility of solutions of these complexes was measured using Evans' method in order to confirm the oxidation state of the metal ion. The colourless solution gave a value of 5.89 BM which indicates that it is manganese(II), whereas the red complex gave a value of 5.28 BM which is closer to the theoretical value for manganese(III).

The oxidation state of the metal ion in the red complex was further confirmed by preparing a solution using $[Mn^{III}(urea)_6(ClO_4)_3]$ as starting material. This solution presented the same voltammetric, spectrophotometric and magnetic behaviour as the one obtained by oxidation of the manganese(II) complex.

These results may be relevant for the development of a model system for the active centre of acid phosphatases. It is believed that this enzyme—isolated from plants such as sweet potato[3] and spinach[25]—appears to contain a mononuclear manganese(III) site with thiolate (cysteine) and phenoxide (tyrosine) ligation.[3,26]

REACTION OF THE $M(CO)_3(NN)$ FRAGMENTS (M = Mo, W; NN = bipy, phen, dipyam) WITH SOME ORGANOMETALLIC HALOTIN DERIVATIVES. POLYNUCLEAR COMPLEXES CONTAINING Sn–M–X MOIETIES (X = Cl, Br, I)

(*Received* 8 *September* 1989; *accepted* 15 *December* 1989)

Abstract—The compounds $[Fe_2(\mu\text{-}SnX_2)(CO)_4(\eta^5\text{-}C_5H_5)_2]$ and $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ (X = Cl, Br, I) were used as probes to react with the $[M(CO)_3(bipy)(NCMe)]$ complexes (M = Mo, W; bipy = 2,2′-bipyridine). The results show that only the trihalide species interact to produce trimetallic complexes $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnX_2)M(X)(CO)_3(bipy)]$. These new substances were characterized by IR and electronic spectroscopy. The reaction can be interpreted as an insertion of the $M(CO)_3(bipy)$ fragments into Sn—X bonds to give Fe—Sn—M—X arrays. Complexes of similar formula (X = Cl) are obtained when bipy is replaced either by phen (1,10-phenanthroline) or dipyam (di-2-pyridylamine). The mono-insertion also was verified in other organometallic systems containing SnX_3 groups. In particular, the $[M(Cl)(SnCl_3)(CO)_3(bipy)]$ complexes yield only the trinuclear compounds $[(bipy)(OC)_3(Cl)M(\mu\text{-}SnCl_2)M'(Cl)(CO)_3(bipy)]$ (M′ = Mo, W) when they react with $[M(CO)_3(bipy)(NCMe)]$.

Previous papers from this laboratory[1,2] have shown that the reaction of the $M(CO)_3(NN)$ fragments [M = Mo, W; NN = 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen), ethylenediamine (en)] with mercury halide derivatives, can be interpreted as the insertion of the former into the mercury–halide bonds. This characteristic was demonstrated by isolating the trimetallic complexes X—M—Hg—M—X and Fe—Hg—M—X (X = halide), using as source of the insertion fragments the $[M(CO)_3(NN)(NCMe)]$ complexes.

In this paper we describe the extension of the above insertion concept to metal centres different from mercury, with the aim to clarify a new route for preparing multinuclear organometallic complexes. Accordingly, in this work we chose to apply this property to compounds with transition metal—tin—halide bonds. The tin selection was done taking into account the recently reported[3] reaction of the $[Mo(CO)_3(bipy)(phosphine)]$ complexes with organotin halides $SnCl_3R$ (R = Cl, CH_3, C_6H_5) to produce, depending upon the phosphine, the tricarbonyl complexes $[Mo(Cl)(SnCl_2R)(CO)_3(bipy)]$. These bimetallic compounds have the $Mo(CO)_3(bipy)$ unit acting as a bridge between the chloride and tin atoms.

For the present study, the tin halide derivatives $[Fe_2(\mu\text{-}SnX_2)(CO)_4(\eta^5\text{-}C_5H_5)_2]$ and $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ were used as probes to react with the $[M(CO)_3(NN)(NCMe)]$ complexes. It was observed that the insertion occurs solely with the complexes $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ to give only trimetallic arrays. A possible explanation for this behaviour and the results using as an additional probe the complexes $[M(Cl)(SnCl_3)(CO)_3(bipy)]$, is also reported herein.

RESULTS AND DISCUSSION

Refluxing mixtures of $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ (X = Cl, Br, I) and $[M(CO)_3(bipy)(NCMe)]$ (M = Mo, W) in methanol in the molar ratio 1:1 or more gave, in all cases, only the trimetallic complexes $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnX_2)M(X)(CO)_3(bipy)]$ according to the reaction:

$$[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)] + [M(CO)_3(bipy)(NCMe)] \longrightarrow [FeM(\mu\text{-}SnX_2)(X)(CO)_5(bipy)(\eta^5\text{-}C_5H_5)] + MeCN. \quad (1)$$

[a] Required values are given in parentheses.
[b] KBr discs.

The new compounds are air-stable, but decompose slowly in the solid state and in solution in the presence of light. They are orange to dark red crystalline solids, with the colour darkening through the sequence X = Cl < Br < I.

The behaviour in solution of the $[FeM(\mu\text{-}SnX_2)(X)(CO)_5(bipy)(\eta^5\text{-}C_5H_5)]$ complexes depends on the metal M. The tungsten derivatives are soluble in organic solvents such as methylene chloride, chloroform or acetone. The molybdenum analogous are unstable in solution. In addition, they react with donor solvents or Lewis bases (L) to produce the complexes $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ and $[Mo(CO)_3(bipy)L]$. Hence, the following equilibrium seems to be operative:

$$[FeM(\mu\text{-}SnX_2)(X)(CO)_5(bipy)(\eta^5\text{-}C_5H_5)] + L \longrightarrow [Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)] + [Mo(CO)_3(bipy)L]. \quad (2)$$

The IR spectra of the $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnX_2)M(X)(CO)_3(bipy)]$ complexes in the CO stretching region (Table 1, compounds **1a–f**) show bands assignable to the $(\eta^5\text{-}C_5H_5)(OC)_2FeSn$[4] and $SnM(X)(CO)_3(bipy)$[3] moieties. Thus, it is concluded that the insertion into the Sn—X bonds has occurred to give the Fe—Sn—M—X arrangements.

The dihalotin derivatives $[Fe_2(\mu\text{-}SnX_2)(CO)_4(\eta^5\text{-}C_5H_5)_2]$ fail to react with the $[M(CO)_3(bipy)(NCMe)]$ complexes. These and the above results showing that the insertion occurs only once, can be understood by considering adduct formation[5] as the initial step of the reaction and the Lewis acid character of the tin atom. The tin acidity decreases in the series of compounds $[(\eta^5\text{-}C_5H_5)(OC)_2Fe]_nSnX_{4-n}$ (n = 1–4) by replacing the halide atoms for the metal groups $(\eta^5\text{-}C_5H_5)(OC)_2Fe$.[6] Then, it would be expected that the strongest acid–base interaction involves the trihalide complexes $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$.

The visible spectra of the solution-stable complexes $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnX_2)W(X)(CO)_3(bipy)]$ were recorded in CH_2Cl_2. They present a unique band localized in the 400–500 nm region. The position of this broad band is related to the X electronegativity, since it is shifted to shorter wavelength in the order Cl(λ_{max} = 440 nm) > Br (λ_{max} = 450 nm) > I(λ_{max} = 440 nm). This absorption is characteristic of the $W(X)(CO)_3(bipy)$ moiety and is associated to the metal ligand charge transfer transition bipy (π^*) ← W($d\pi$)[2].

The complexes $[M(CO)_3(NN)(NCMe)]$ [NN = phen, di-2-pyridylamine (dipyam)] were also found to react with $[Fe(SnCl_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ to yield only trimetallic species $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnCl_2)M(Cl)(CO)_3(NN)]$ (Table 1, compounds **1g–j**).

The above results prompted us to check the syn-

thetic applicability of the insertion reaction in organometallic systems containing SnX_3 groups by using the $[M(Cl)(SnCl_3)CO_3(bipy)]$ complexes. The insertion takes place and again the reaction is stopped affording only trimetallic complexes $[(bipy)(OC)_3(Cl)M(\mu\text{-}SnCl_2)M'(Cl)(CO)_3(bipy)]$ (M′ = Mo, W). The IR spectra (Table 1, compounds **2a–c**) confirm the existence of M—Sn—M′ arrays[2] and the low solubility of these compounds precluded the measurement of the electronic spectra.

EXPERIMENTAL

All operations were carried out in a nitrogen atmosphere using standard Schlenk line techniques. The starting materials, $[Fe(SnCl_3)(CO)_2(\eta^5\text{-}C_5H_5)]$,[7] $[Fe_2(\mu\text{-}SnCl_2)(CO)_4(\eta^5\text{-}C_5H_5)_2]$,[7] $[M(Cl)(SnCl_3)(CO)_3(bipy)]$,[8] $[M(CO)_4(bipyam)]$,[9] $[M(CO)_3(NN)(NCMe)]$[1] [M = Mo, W; NN = 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen), di-2-pyridylamine (dipyam)] were prepared by similar methods to those described in the literature. The $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ complexes (X = Br, I) were precipitated by treating an acetonitrile solution of $[Fe(SnCl_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ with an excess of KI salt dissolved in water or with a HBr solution respectively; the crystalline solids were filtered off and washed with water. The IR spectra were recorded on a Perkin–Elmer 577 spectrophotometer. The electronic spectra were registered on a Carl–Zeiss DMR 22 instrument.

Synthesis of $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnX_2)M(X)(CO)_3(bipy)]$ (M = Mo, W; X = Cl, Br, I)

The complexes were obtained from the reaction of equimolar quantities of $[Fe(SnX_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ and $[M(CO)_3(bipy)(NCMe)]$ in refluxing methanol. The following procedure is typical. $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnCl_2)W(Cl)(CO)_3(bipy)]$: a methanol solution of $[Fe(SnCl_3)(CO)_2(\eta^5\text{-}C_5H_5)]$ (69.1 mg, 0.172 mmol) and freshly prepared $[W(CO)_3(bipy)(NCMe)]$ (80 mg, 0.172 mmol) was refluxed under nitrogen in the dark for 0.25 h. The red crystals were collected by filtration, washed repeatedly with methanol and dried *in vacuo* (90 mg, 63.3% yield). The results of the elemental analysis are presented in Table 1 (compounds **1a–f**).

Synthesis of $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnCl_2)M(Cl)(CO)_3(NN)]$ (M = Mo, W; NN = phen, dipyam)

The same above procedure was used to prepare the $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnCl_2)M(Cl)(CO)_3(phen)]$ complexes. To isolate the $[(\eta^5\text{-}C_5H_5)(OC)_2Fe(\mu\text{-}SnCl_2)M(Cl)(CO)_3(dipyam)]$ compounds the reaction was carried out at room temperature with stirring for 1 h. Then, the solvent was partially evaporated off to give the orange precipitate. The colours and analytical data for all the complexes are given in Table 1 (compounds **1g–j**).

Synthesis of $[(bipy)(OC)_3(Cl)M(\mu\text{-}SnCl_2)M'(Cl)(CO)_3(bipy)]$ (M,M′ = Mo, W)

A similar method was used to prepare these complexes by refluxing for 0.25 h a methanol solution of the starting materials $[M(Cl)(SnCl_3)(CO)_3(bipy)]$ and $[M'(CO)_3(bipy)(NCMe)]$. The precipitate was filtered off, washed with methanol and then dried *in vacuo*. The analytical data are given in Table 1 (compounds **2a–c**).

STUDY OF COMPLEX FORMATION EQUILIBRIA OF PAMOATE ION WITH COPPER(II) ION IN A DIOXANE–WATER SOLUTION

E. CASASSAS* and A. IZQUIERDO-RIDORSA

Department of Analytical Chemistry, University of Barcelona, Av. Diagonal 647, 08028 Barcelona, Spain

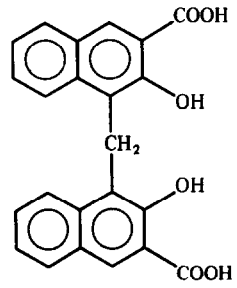
(*Received* 1 *March* 1989; *accepted* 21 *December* 1989)

Abstract—Protonation constants of the carboxylate groups in pamoic acid and stability constants of copper(II) complexes with pamoic acid have been determined from EMF data in a 50% (v/v) dioxane–water solution at 25°C and 0.1 M KNO_3, and protonation constants for the hydroxyl groups have been determined spectrophotometrically in 1 M KCl aqueous medium. The values obtained for the constants are: protonation constants for the carboxylate groups: $\log\beta_1 = 4.352 \pm 0.001$ and $\log\beta_2 = 7.706 \pm 0.001$; for the hydroxyl groups: $\log K_1 = 14.80 \pm 0.24$ and $\log K_2 = 13.05 \pm 0.065$. For the complex-forming reactions $Cu^{II} + nH_2pam \rightleftarrows Cu(pamH)_n + nH$ ($n = 1$ or 2), the equilibrium constants are: $\log\beta_{11-1} = -1.96 \pm 0.02$ and $\log\beta_{21-2} = -5.28 \pm 0.02$. An insoluble 3:2 copper(II)–pamoate complex is identified.

The study of the acid–base properties of aromatic *ortho*-hydroxycarboxylic acids and that of their complex formation equilibria with several metallic ions is important due to the great application that these compounds have in very different fields; they are considered some of the most important model compounds in the study of humic and fulvic acids,[1,2] they are the main constituents in many mordent dyes,[3] they have a very wide pharmaceutical application due to the anti-inflammatory properties of some of their copper(II) complexes,[4–7] and they find a diversity of applications in analytical chemistry.[8,9]

Since many natural compounds contain the aromatic *ortho*-hydroxycarboxylic grouping more than once in their structure, it seems interesting to study model molecules which derive from the most simple aromatic *ortho*-hydroxycarboxylic acids (salicylic acid and 3-hydroxy-2-naphthoic acid) but which contain two such groupings. One of these compounds is 2,2′-dihydroxy-3,3′-dicarboxy-1,1′-dinaphthylmethane (pamoic acid).

In this work, the acid–base properties of pamoic acid and its complex formation equilibria with copper(II) ions were studied. While protonation constants for both hydroxyl groups in pamoic acid must be determined in aqueous medium and at high ionic strength in order to attain pH values high enough to have a measurable amount of deprotonated hydroxyl groups, protonation constants for the carboxylic groups and stability constants for the copper(II) complexes must be determined in dioxane–water mixtures due to the low solubility in water of the neutral ligand and of its metallic complexes.



Pamoic acid

EXPERIMENTAL

Reagents and solutions

Pamoic acid disodium salt (Eastman AR), nitric acid (Merck AR) and copper(II) oxide (Merck AR) were used without further purification. Potassium nitrate (Probus AR) and potassium chloride (Probus

* Author to whom correspondence should be addressed.

AR) were purified by recrystallization in water. CO_2-free potassium hydroxide (Merck AR) solutions were prepared and standardized as usual.[10] Doubly-distilled freshly boiled water was used for the preparation of the solutions. In the potentiometric study the mixed solvent used was prepared from dioxane (Carlo Erba, RPE) purified by Eigenberger's method.[11]

In the spectrophotometric study, aqueous ligand solutions and potassium hydroxide solutions were prepared at 1 M ionic strength adjusted with potassium chloride. In the potentiometric study, ligand solutions, metal ion solutions, nitric acid solutions and potassium hydroxide solutions were prepared in dioxane–water (1 : 1, v/v) mixtures, at 0.1 M ionic strength adjusted with potassium nitrate. Metal ion solutions were standardized iodometrically and by the electrodeposition procedure. Nitric acid solutions were standardized volumetrically with tris(hydroxymethyl)aminomethane.

A flow of N_2 (previously purified with vanadous perchlorate and barium hydroxide) was bubbled continuously through the solution in the potentiometric cell.

Apparatus

(a) Beckman DU-7 single-beam spectrophotometer, equipped with 1-cm silica cells thermostatized at 25.0 ± 0.1°C.

(b) Radiometer PHM 64 pH-Meter equipped with a wide-range glass electrode (Radiometer G202B) and a silver–silver chloride electrode, prepared as described by Brown,[12] in a Wilhelm-type salt bridge.[13] The titrant was added with a Metrohm 655 Multi-Dosimat automatic burette with 1.0 and 5.0 cm^3 exchanging units. Sample solutions were titrated in a double-walled vessel maintained at 25.0 ± 0.1°C by circulating water and stirred magnetically under a continuous flow of N_2. The potentiometric assembly was controlled by an HP 9816 microcomputer via an HP 3421A data acquisition control unit (for details see ref. 14).

(c) IR spectra (KBr pellets) were recorded on a Perkin–Elmer 1330 spectrophotometer.

(d) EPR spectra (of solid samples and DMSO solution) were recorded on a VARIAN E-109 E Spectrometer. The spectra in solution were recorded in capillary quartz tubes of 1 mm diameter (Wilmad, Cat. Nr. 800).

(e) ^{1}H NMR spectra were recorded on a GEMINI 200 (200 MHz) spectrometer. In the ^{1}H NMR experiments, deuterated DMSO was used as solvent, because it provided adequate solubility without proton transfer.

Procedure

(a) *Spectrophotometric determination.* The protonation constants of both hydroxyl groups in pamoic acid were determined by the spectrophotometric method, in 1 M KCl aqueous medium. The spectrophotometric determination was carried out from the absorbance readings taken, between 230 and 275 nm at 5 nm increments, for different solutions of pamoic acid (concentration between 1.6×10^{-4} and 4.2×10^{-6} mol dm^{-3}) in 1 M KCl, in which the pH was varied, between 11.3 and 13.8, by addition of a measured volume of a titrant solution of potassium hydroxide in 1 M KCl. The pH of the solutions was calculated from the known amount of potassium hydroxide added and the value of the autoprotolysis constant of the working medium[15] ($pK_w = 13.93$).

(b) *Potentiometric determinations.* The protonation constants of both carboxylate groups in pamoic acid and the stability constants of its copper(II) complexes have been determined from EMF data obtained according to the previously described method.[16] The calibration parameters (standard potential of the cell, pH dependence of the liquid junction potential and value of the ionic product of the medium) were obtained from a strong acid–strong base titration by the Gran method,[17] using a multiparametric data-fitting procedure.[18] This calibration procedure allows direct correlation of the EMF reading with the hydrogen ion concentration. In a 1 : 1 v/v dioxane–water medium, with 0.1 M ionic strength at 25°C, the value of the ionic product of the medium is: $-\log K_w = 15.322 \pm 0.001$. In this medium, the liquid junction potential, $E_j = j_H[H]$, must be taken into account in acid solutions of $pH < 3.0$: $j_H = -435 \pm 4$ mV M^{-1}.

Protonation curves were obtained at several ligand concentrations, and complex formation curves were obtained at several metal ion concentrations and different ligand-to-metal ion concentration ratios. The experimental conditions of the titrations performed are listed in Table 1. When the ligand–metal ion ratio is 10 : 1 or lower, there is formation of a red precipitate at pH values near 5. When the ligand–metal ion ratio is higher than 10 : 1, the titration with potassium hydroxide can be performed up to basic pH values without any precipitation.

Data treatment

The numerical analysis of the experimental spectrophotometric data has been carried out with the program SQUAD,[19] which determines sim-

ultaneously the stability constants of the formed species and their individual molar absorptivities in the whole working wavelength range.

The numerical analysis of the experimental EMF data has been performed with the computer programs SUPERQUAD[20] and MINIGLASS.[18] The SUPERQUAD program indicates the goodness of the results by the value of the parameter SIGMA, which is the ratio of the root-mean-square of the weighted residuals to the estimated error in our working conditions (0.001 cm^3 for the autoburette volume readings and 0.1 mV for the EMF readings), and by the value of the statistic parameter, χ^2, which is based on weighted residuals of EMF readings.[20] The reliability of the results obtained with the MINIGLASS program is indicated by the standard deviation of the residuals either with respect to added volumes or with respect to measured $[H^+]$, and by the sum of squared residuals.

RESULTS AND DISCUSSION

The values for the protonation constants of both hydroxyl groups in pamoic acid, obtained in aqueous solution at 1 M KCl ionic strength and 25°C are: $\log K_1 = 14.80 \pm 0.24$ and $\log K_2 = 13.05 \pm 0.065$. The standard deviation of the residuals in absorbance units is 2.05×10^{-2} and the sum of residual squares is 1.09×10^{-1}. The calculated individual absorption spectra are given in Fig. 1.

The values for the protonation constants of both carboxylate groups in pamoic acid and for the formation constants of the copper(II) complexes of pamoic acid, obtained in dioxane–water (1 : 1, v/v) solution at 0.1 M KNO_3 ionic strength and at 25°C, are given in Tables 2 and 3, respectively, together with the resulting statistical parameters.

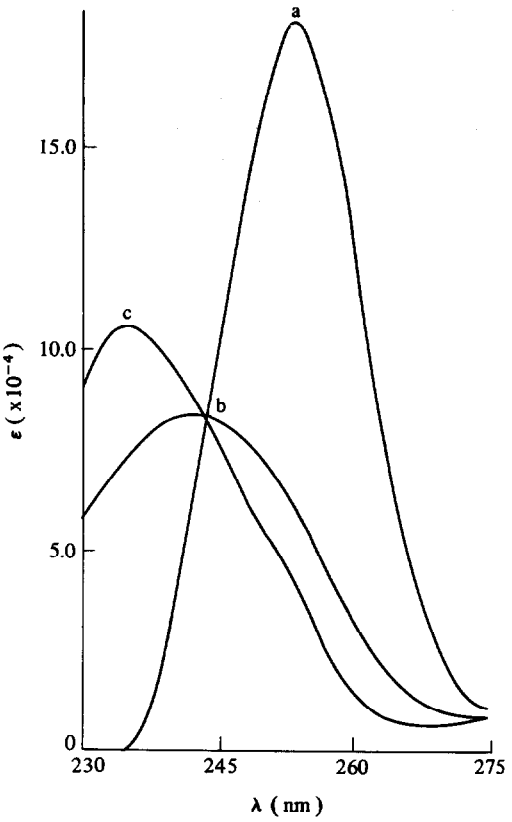

Fig. 1. Individual absorption spectra of (a) pam, (b) Hpam and (c) H_2pam species, where pam refers to the fully deprotonated pamoate ligand.

In the complexation study, the best fits were found with the model containing the species 1 : 1 and 1 : 2 metal ion–ligand. From the values of the constants obtained, the distribution of species which contain copper(II) as a function of pH was evaluated (Fig. 2).

Although pamoic acid contains two *ortho*-hydroxycarboxylic groupings in its molecule, they cannot coordinate simultaneously to a single metal ion due to the steric features of the ligand molecule, where both naphthalene rings lay in different planes because of the sp^3 hybridization of the bridging $-CH_2-$. So, the complexation behaviour of pamoic acid can be compared with that of other related ligands which contain only once the *ortho*-hydroxycarboxylic grouping, like salicylic acid and 3-hydroxy-2-naphthoic acid.

Previous studies on complexation of the copper(II) ion with salicylic acid[16,21] and 3-hydroxy-2-naphthoic acid[14] also show the formation of the 1 : 1 and 1 : 2 metal ion–ligand complexes. A comparison between the values obtained for the 1 : 1 complexes with these ligands show that there is a relationship between the stability of the 1 : 1 complexes and the acidic character of the

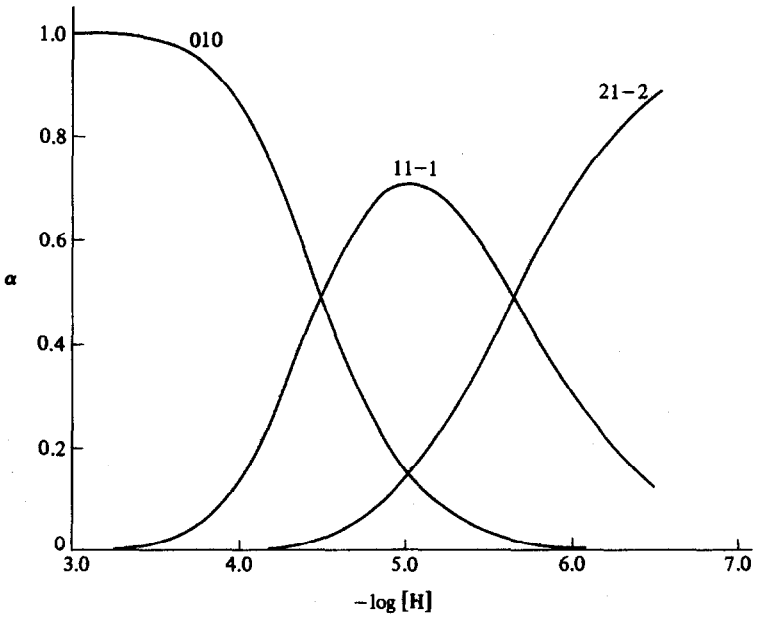

Fig. 2. Distribution plot as a function of $-\log[H]$ for the species which contain copper(II) ion in the Cu^{II}–pamoate system. Alpha is the ratio of each species concentration to the total copper(II) concentration. In the figure, 010, 11−1 and 21−2 refer, respectively, to Cu^{II}, Cu(Hpam) and $Cu(Hpam)_2$. Ligand concentration = 5.3×10^{-3} mol dm^{-3}; metal concentration = 2.6×10^{-4} mol dm^{-3}.

[b] This work.

hydroxyl group of the ligand; the more acidic this group is, the less stable is its related 1 : 1 copper(II) complex (see Table 4). The stability of the 1 : 1 complex with pamoic acid, however, compared with that with salicylate, is much lower than would be expected from only the acidities of the hydroxyl groups of the respective ligands, probably due to the effect of steric hindrance, which must have a certain influence with the pamoate ligand.

The 1 : 2 metal ion–ligand complexes with salicylate and 3-hydroxy-2-naphthoate ions show the same order of stability as the 1 : 1 complexes. With the pamoate ligand, however, the 1 : 2 complex is even more stable than the 1 : 2 copper(II)–salicylate complex. Part of this additional stabilization must be attributed to entropic effects related with the change in electric charge associated with complex formation; while with salicylate and 3-hydroxy-2-naphthoate the 1 : 2 species is formed from a neutral 1 : 1 species, with pamoate both 1 : 1 and 1 : 2 complexes are negatively charged due to the second *ortho*-hydroxycarboxylic grouping which does not participate in complexation.

Studies of the complexation of copper(II) ions with salicylate or 3-hydroxy-2-naphthoate ions showed, at certain conditions of pH and certain ligand-to-metal ion concentration ratios, the formation of a precipitate consisting of the neutral 1 : 1 metal ion–ligand species. In the copper(II)–pamoate system, however, when the concentration ratio copper(II)–pamoate ion is 1 : 10 or lower, there is formation of a precipitate of a different nature at pH values higher than 4. In order to determine the nature of this precipitate, the elemental analysis for several samples obtained at total concentrations much higher than those used in the potentiometric experiments has been carried out. Their IR, EPR and ^1H NMR spectra have also been obtained.

Elemental analysis

The experimental values for %Cu, %C and %H of samples obtained at different working conditions are given in Table 5. The dispersion obtained in the experimental results is due to the critical conditions at which there is precipitation; coprecipitation of copper(II) hydroxide can take place simultaneously. If a somewhat lower pH is used, coprecipitation of pamoic acid occurs. The average percentages are in agreement with the calculated ones for the 3 : 2 copper(II)–pamoate complex, which are also included in Table 5. The 3 : 2 complex with all the hydroxyl groups deprotonated is a negatively-charged species. So, the precipitate must have two hydroxyl groups that do not participate in complexation, or be the sodium salt of the complex. The dispersion of the results does not allow a decision to be made in this respect.

IR absorption spectra

A comparison of the IR absorption spectrum of the insoluble complex and that of pure pamoic acid shows the variation of some IR bands due to complexation. The most characteristic is the disappearance of the acute band at 3600 cm^{-1}, which is due to the —OH stretching vibrations in the free

hydroxyl groups that participate in intramolecular hydrogen bonds. There is also variation in the bands between 1300 and 1700 cm^{-1} and those between 700 and 900 cm^{-1}.

EPR absorption spectra

The EPR experiments have been performed on the powder obtained and on its DMSO solution.

The solution yields a highly asymmetrical EPR spectrum where, of the four bands due to the hyperfine splitting, only the one that appears at higher magnetic field is well defined. This spectrum is characterized by a g_{av} value around 2.13. The bulk of the copper(II) complexes influences the asymmetry of the spectral shape; the more bulky the complex is, the more difficult is its tumbling in solution and the relaxation must go through a spin–spin process which yields asymmetric spectra.

The fact that for the studied copper(II) complex an EPR spectrum is observable indicates the presence of an odd number of copper(II) ions in the insoluble complex, which is, therefore, consistent with the assigned 3:2 copper(II)–pamoate compound.

In order to ascertain if there is any interaction between the copper(II) ions, which could lead to a triplet state, the EPR spectrum of the powder has been obtained. This spectrum exhibits parallel and perpendicular features typical of copper(II) ions in an axial ligand field with tetragonal distortion by elongation along the axial direction. It is composed of an acute band at $g_\perp = 2.003$ and two broad bands at lower magnetic field with an approximated $g_\parallel$ value of about 2.15–2.20. The poor resolution of this region of the spectrum could be due to the presence in the studied compound of more than one copper(II) ion having similar but not identical surroundings. For this studied solid no EPR spectrum is observable in the region between 600 and 2600 G (i.e. in the forbidden transition region with $\Delta M_s = 2$, where the appearance of an EPR spectrum would characterize a triplet state), and thus, there is no evidence of a dipole–dipole interaction between two copper(II) ions in the compound. In the proposed 3:2 copper(II)–pamoate structure the three copper(II) ions lie in different planes due to the sp^3 hybridization of the methylene bridge in the pamoate ligands, and they probably cannot interact with each other.

^{1}H NMR absorption spectra

The ^{1}H NMR resonance technique has been used by several authors to study the binding of copper(II) ions to different ligands by following the broadening effects of the paramagnetic copper(II) ions on the ligand proton resonances.[23,24] Only when a diamagnetic dimeric copper(II) species is formed is no broadening effect observed.[25] For the copper(II)–pamoate insoluble complex all the proton resonance bands of the pamoate ligand are severely broadened, which indicates the paramagnetism of the studied complex.

CONCLUSIONS

The complexing behaviour of pamoate ion with copper(II) ion is very similar to that of other *ortho*-hydroxycarboxylic acids, like salicylic acid and 3-hydroxy-2-naphthoic acid, which is in accordance with the fact that they have the same

active coordination centres in front of metal ions. Due to the steric features of the pamoate ligand, both *ortho*-hydroxycarboxylic groupings lie in different planes and cannot coordinate simultaneously to a single metal ion. The differences observed in the stability of their metal complexes are mainly attributed to the different molecular dimensions and to the indirect effect of the second *ortho*-hydroxycarboxylic grouping in the pamoate molecule.

The insoluble complex formed at certain working conditions has been identified as a 3 : 2 copper(II)–pamoate species and it could be assigned to the second ($n = 1$) member of a series of *core-and-links* complexes with the general formula $(Cu_2PX)(CuPX)_n$, where P is the fully deprotonated pamoate ligand and X is H or Na.

(*Received* 29 *November* 1989; *accepted* 21 *December* 1989)

Abstract—Selenium dibromide prepared from Se and $SeBr_4$ in acetonitrile shows a singlet at 1496 ppm in the ^{77}Se-NMR spectrum and Raman lines at 291, 265, and 105 cm^{-1}. Selenium dibromide which is in equilibrium with Se_2Br_2 and Br_2 reacts with titanocene-pentasulphide at 20°C in CS_2 to give SeS_5 which partly dimerizes to give 1,2-Se_2S_{10} and 1,7-Se_2S_{10}. Raman spectra of Se_2S_{10} and $Se_2S_{10}\cdot CS_2$ are reported and their formation from SeS_5 is discussed. Other products of the $SeBr_2$-titanocenepentasulphide reaction are 1,2-Se_2S_5 (from Se_2Br_2), S_{10} (from Br_2), 1,2-Se_2S_6, 1,5-Se_2S_6, and 1,2,5,6-Se_4S_4.

Selenium and bromine form three binary compounds: $SeBr_2$, Se_2Br_2, and $SeBr_4$.[2] While the molecular structure, spectra, and chemical reactions of Se_2Br_2 are well known the other two compounds are less well studied which may be explained by their thermal instability. $SeBr_4$ exists as solid phases (two allotropes) only and completely decomposes both in solution in various solvents[3,4] and in the vapour phase[5] according to eq. (1):

$$SeBr_4 \longrightarrow SeBr_2 + Br_2. \quad (1)$$

Selenium bromide, on the other hand, has never been prepared as a pure substance but exists only in solutions[6] and the vapour phase[5,7] in equilibrium with Se_2Br_2 according to eq. (2):

$$2SeBr_2 \rightleftharpoons Se_2Br_2 + Br_2. \quad (2)$$

The equilibrium constant $K_2 = [Se_2Br_2][Br_2]/[SeBr_2]^2$ has been determined by spectrophotometric measurements at room temperature as 0.0252 for a solution in carbon tetrachloride[3] and as 0.014 for acetonitrile.[6] The lower value observed for CH_3CN indicates some solvent/solute interaction. However, since SCl_2 interacts only weakly with CH_3CN[8] the same is likely for $SeBr_2$. The dissolved $SeBr_2$ has so far only been detected directly by Raman spectroscopy. Milne[6] observed three Raman lines at 290, 260, and 96 cm^{-1} and, using polarization measurements, assigned them to the asymmetric and symmetric stretching and the bending modes of the C_{2v} molecule $SeBr_2$, respectively. No Raman lines due to Br_2 or Se_2Br_2 were observed for acetonitrile solutions with an Se : Br ratio of 1 : 2.

The aim of the present work was to confirm the Raman data of $SeBr_2$, to measure for the first time the ^{77}Se-NMR spectrum of this molecule, and to check whether $SeBr_2$ reacts with titanocene-

pentasulphide in a similar fashion as sulphur and selenium chlorides do, i.e. according to eq. (3):

$$(C_5H_5)_2TiS_5 + SeBr_2 \longrightarrow SeS_5 + (C_5H_5)_2TiBr_2. \quad (3)$$

SCl_2 is known to react with $(C_5H_5)_2TiS_5$ to give a mixture of mainly S_6 and some S_{12},[9] while S_2Cl_2 yields S_7,[9] and Se_2Cl_2 reacts to give primarily 1,2-Se_2S_5 which then slowly decomposes according to eq. (4):[10]

$$2\ 1,2\text{-}Se_2S_5 \longrightarrow SeS_5 + 1,2,3\text{-}Se_3S_5. \quad (4)$$

The two selenium sulphides 1,2-Se_2S_5 and 1,2,3-Se_3S_5 contain the Se atoms in neighbouring positions as has been shown by X-ray crystallography of single crystals as well as by ^{77}Se-NMR spectroscopy.[10–13]

EXPERIMENTAL

Materials

Carbon disulphide (CS_2; tech. grade) and acetonitrile (CH_3CN; tech. grade) were purified by distillation from phosphorus pentoxide (P_4O_{10}; anal. grade). Grey elemental selenium (Fluka; 99.5%) and bromine (Merck; anal. grade) were used as received. Orange selenium tetrabromide (β-$SeBr_4$),[14] diselenium dibromide (Se_2Br_2),[14] and titanocenepentasulphide (Cp_2TiS_5; Cp = η^5-C_5H_5)[15] were prepared according to literature methods. Methanol used as an eluent for HPLC was distilled from anhydrous magnesium sulphate and degassed in a vacuum immediately prior to use. A solution of $SeBr_2$ was obtained by adding 0.88 g of grey Se (11.1 mmol) to a solution of 4.43 g $SeBr_4$ (11.1 mmol) in 15 cm^3 acetonitrile and stirring until the Se had dissolved quantitatively.[6] If the reaction proceeded quantitatively according to eq. (5), this solution would contain 1.48 mol $SeBr_2$ per litre.

$$SeBr_4 + Se \longrightarrow 2SeBr_2. \quad (5)$$

Procedures

^{77}Se-NMR spectra were recorded with a Bruker WM 360 spectrometer equipped with Aspect 3000 computer for spectrometer control and data processing (frequency 68.679 MHz; temperature 23°C; sample tube diameter 20 mm). Raman spectra were obtained with an Instruments S.A. spectrometer which is based on a Jobin Yvon U 1000 double monochromator and controlled by a MAC 80 computer. Raman scattering was excited with a Spectra Physics krypton ion laser (647.1 nm) and measured by a Hamamatsu R943-02 GaAs photomultiplier. The wavenumbers were reproducible to within ± 1 cm^{-1}. To prevent the Raman samples from thermal or photolytic decomposition during the measurements they were usually cooled to well below 0°C using a self-made cryostat in which the vapour of liquid nitrogen was used as a coolant. Evaporation of the nitrogen by an electric heater was controlled by a Pt 100 temperature sensor placed next to the sample which was contained in a glass capillary inside a glass Dewar vessel.

High pressure liquid chromatography (HPLC) was performed with the following equipment: Perkin–Elmer Liquid Chromatograph (Series 2 with two pumps), Rheodyne Syringe Loading Injector (Model 7125 with 10 μl sample loop), Waters–Millipore Radial-Pak column cartridges filled with C18 phase for reversed-phase chromatography (column length 10 cm, inner diameter 8 mm; particle size 5 or 10 μm) and contained in a RCM-100 compression module, Perkin–Elmer LC75 UV spectrophotometer with autocontrol (variable wavelength detector with deuterium lamp), Hewlett–Packard 3390A electronic integrator with integrated recorder and printer.

To measure UV absorption spectra of chromatographically separated substances during the continuing HPLC analysis a Waters 990 diode-array detector with NEC APC III computer was employed (array of 512 diodes, range 190–800 nm). This equipment does not result in spectra distorted due to photodecomposition of the solute in the methanolic liquid phase as has repeatedly been observed when the stopped-flow technique was used.

RESULTS AND DISCUSSION

^{77}Se-*NMR spectrocopy*

Selenium compounds may be analysed by NMR-spectroscopy[16] since the isotope ^{77}Se (natural abundance 7.6%) has $I = 1/2$. However, the sensitivity of ^{77}Se is relatively low and in the case of selenium bromides the nuclear quadrupole moments of ^{79}Br and ^{81}Br ($I = 3/2$; natural abundance *ca* 50% each) create additional difficulties due to line broadening. We nevertheless succeeded in recording a ^{77}Se-NMR spectrum of a solution of $SeBr_2$ in acetonitrile obtained as described above.

In the range 1050–1700 ppm (relative to dimethyl selenide) only one signal was observed at 1496 ppm, which we assign to $SeBr_2$. The known resonance of Se_2Br_2 at 1176 ppm[17] was not detected which is in agreement with the low equilibrium concentration of this species as mentioned in the Introduction.

The half-width of the line at 1496 ppm was 860 Hz which is much larger than in the case of Se_2Br_2. The reason may be the interactions with both the two bromine nuclei and the nitrogen nuclei ($I = 1$) of the coordinated acetonitrile molecules. The larger chemical shift of $SeBr_2$ compared to Se_2Br_2 is caused by the two bromine atoms attached to one selenium atom but may also be influenced by solvation. These results show that NMR spectroscopy is a suitable technique to analyse selenium bromide solutions.

Raman spectroscopy

Raman spectra of $SeBr_2$ (in CH_3CN), Se_2Br_2 (neat), and β-$SeBr_4$ (solid) were recorded; the results are listed in Table 1. The data obtained for Se_2Br_2 agree with the literature spectra[2] and therefore are not shown. In the case of $SeBr_2$ we agree with Milne[6] as far as the stretching vibrations are concerned. However, we find the bending mode at 105 cm^{-1} rather than at 96 cm^{-1} which may be a plasma line of the krypton laser used by Milne. The Raman spectrum of $SeBr_4$ has so far been known only at > 130 cm^{-1} (allotrope not specified);[18] our data in this region agree with the previously reported values. The spectrum shows the typical lines[19] of $SeBr_3^+$ which is present in both α- and β-$SeBr_4$ and the site symmetry of which is approximately C_s.[20]

Reaction of $SeBr_2$ with titanocene pentasulphide

To follow this reaction by ^{77}Se-NMR spectroscopy 500 mg Cp_2TiS_5 (1.47 mmol) were dissolved in 20 cm^3 CS_2 and reacted with 1 cm^3 of the $SeBr_2$ solution described above (1.48 mmol dm^{-3} $SeBr_2$). After stirring for 10 min the CS_2 phase was filtered into an NMR tube, 0.1 cm^3 each of cyclohexane and deuterobenzene were added and the spectrum recorded immediately in the ranges 502–848 and 999–1302 ppm which are typical for cyclic selenium sulphides. The five signals observed could all be assigned by comparison with literature data.[11-13] The results (Fig. 1; Table 2) show SeS_5 as the major product accompanied by 1,2-Se_2S_5 and three eight-membered SeS rings in small concentrations. The formation of 1,2-Se_2S_5 can be explained from the reaction of Se_2Br_2 with Cp_2TiS_5 which should proceed analogously to the above mentioned corresponding reaction of Se_2Cl_2:

$$Se_2Br_2 + Cp_2TiS_5 \longrightarrow 1,2\text{-}Se_2S_5 + Cp_2TiBr_2. \quad (6)$$

The occurrence of Se_4S_4 and of the two isomers of Se_2S_6 will be discussed below.

To confirm the NMR spectroscopic results the reaction mixture has been analysed also by HPLC. The retention times of cyclic selenium sulphides reflect the ring size and atomic arrangement in a characteristic manner.[21-23] To 53 mg Cp_2TiS_5 (156 μmol) dissolved in 50 cm^3 CS_2 were added 7 cm^3 $SeBr_2$ solution (20 mmol l^{-1}) formally containing 141 μmol $SeBr_2$ (a slight excess of Cp_2TiS_5 is necessary to avoid free selenium bromides which would react with the methanol eluent and result in additional chromatographic peaks). After stirring for 10 min the solution was injected into the HPLC apparatus without further dilution. Most of the chromatographic peaks observed could be assigned using reference substances prepared by literature methods.[10,11,21-26] In addition to SeS_5, 1,2-Se_2S_5, and eight-membered selenium sulphide rings the chromatograms show the presence of S_{10} and of two 12-membered SeS rings (see Table 3, Fig. 2), which may arise from the following reactions:

$$2Br_2 + 2Cp_2TiS_5 \longrightarrow S_{10} + 2Cp_2TiBr_2 \quad (7)$$

$$2SeS_5 \longrightarrow Se_2S_{10}. \quad (8)$$

The concentrations of SeS_5 and 1,2-Se_2S_5 were high enough to measure their UV absorption spectra for the first time. The results are shown in Fig. 3 together with the spectra of the corresponding sulphur rings S_6 and S_7;[27] also shown are the spectra of 1,2,3-Se_3S_5 and S_8. All spectra apply to chromatographically pure substances dissolved in methanol recorded using diode-array detectors. As can

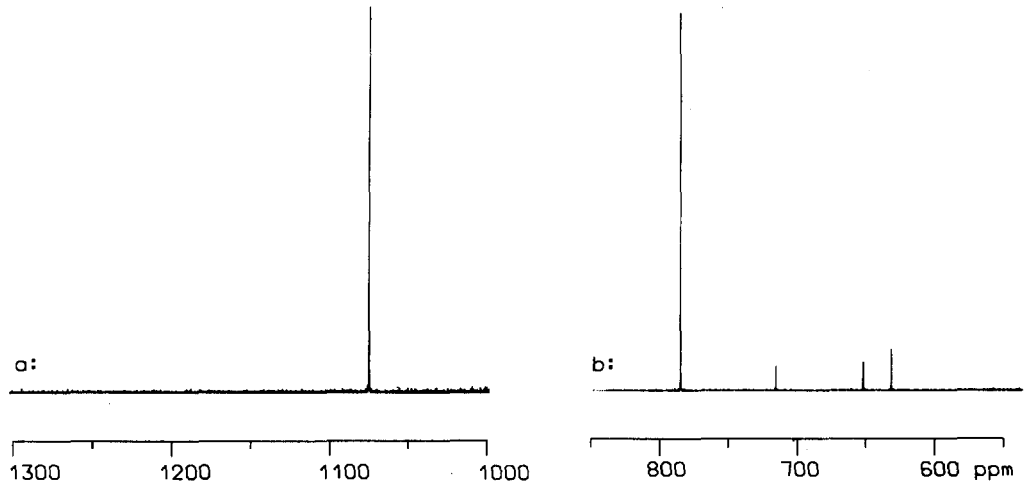

Fig. 1. ^{77}Se-NMR spectra of the reaction mixture of $SeBr_2$ and titanocenepentasulphide showing the presence of 1,2-Se_2S_5 (a) and of SeS_5, 1,5-Se_2S_6, 1,2-Se_2S_6, and 1,2,5,6-Se_4S_4 (b). For details see Table 2.

be seen from Fig. 3 the substitution of S by Se shifts the maxima to higher wavelengths and increases the absorbance at most wavelengths compared to the maximum near 220 nm; the spectra of species of identical ring size are similar. However, S_8 is an exception since this molecule exhibits a rather unique double absorption maximum near 280 nm which is not observed for eight-membered Se–S rings.

To determine the composition and to measure the Raman spectra of the chromatographically detected Se_nS_{12-n} rings a larger sample was prepared. Five grams of Cp_2TiS_5 (14.8 mmol), dissolved in 50 cm^3 CS_2 were reacted with 10 cm^3 $SeBr_2$ solution (14.8 mmol) at 20°C by stirring for 15 min. The precipitate formed was isolated and shown to consist of Cp_2TiBr_2 with traces of six-, seven- and eight-membered selenium sulphide rings (IR spectrum, HPLC analysis, CH content by combustion analysis). The filtrate was separated into CH_3CN and CS_2 phases and the latter cooled to −60°C for 15 h. The precipitate formed (1.42 g) was isolated, washed with a little dried pentane, and analysed by HPLC and IR spectroscopy which showed a mixture of Cp_2TiS_5, Cp_2TiBr_2, Se_nS_{8-n} and Se_xS_{12-x}. To isolate the latter in a pure state the mixture was extracted by 50 cm^3 CH_2Cl_2 for 2 h and the residue (118 mg) by 35 cm^3 CS_2 for 30 min at 20°C. Cooling of the CS_2 extract to −18°C for 15 h resulted in yellow

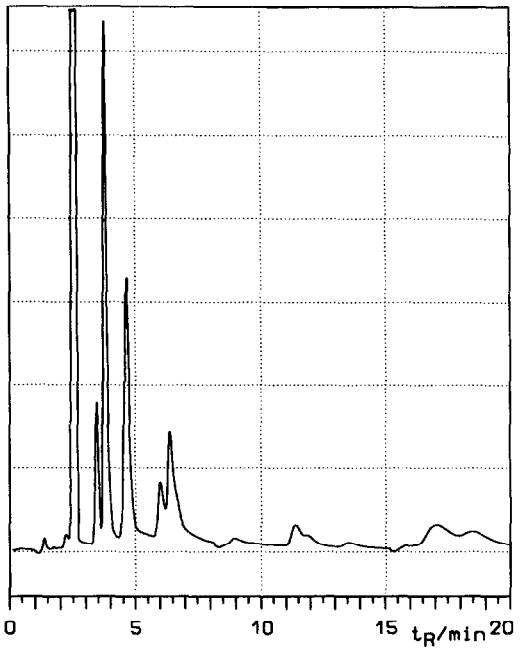

Fig. 2. Chromatographic separation of the products of the reaction between $SeBr_2$ and titanocenepentasulphide showing the presence of rings of sizes 6–12 (see Table 3). t_R retention time, ordinate: absorbance at 254 nm.

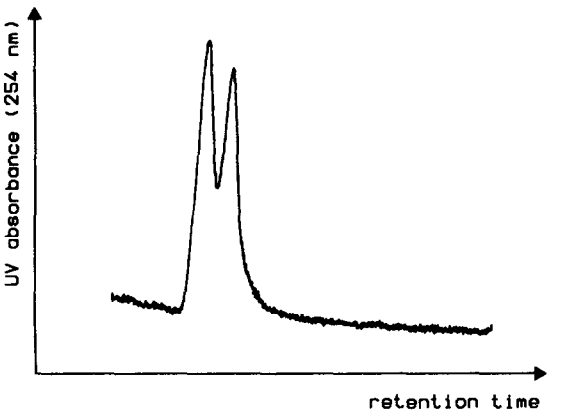

Fig. 4. Chromatographic separation of two isomeric 12-membered rings Se_2S_{10} (retention times see Table 4).

crystals, the HPLC analysis (Fig. 4) and Raman spectra (Fig. 5) of which showed that almost pure 12-membered selenium sulphide rings had been obtained. The analytical composition of several of the Se_xS_{12-x} crystals was determined by energy-dispersive X-ray spectroscopy. Only lines due to S and Se were detected, and using ZnS and elemental selenium as reference materials the atomic ratio S:Se was determined as 5.29:1 resulting in a formula of $Se_{1.89}S_{10}$. Obviously, the compound prepared is Se_2S_{10}. The crystals formed right parallelepipeds.

The HPLC chromatogram of the Se_2S_{10} sample shows two peaks with an intensity ratio of *ca* 1:1 (peak areas). The retention times of a number of sulphur and selenium sulphide rings measured under identical conditions are shown in Table 4. From this table and literature data[21–23] it can be seen that the retention times depend on

(a) the ring size,
(b) the selenium content, and
(c) the number of SeS bonds per molecule.

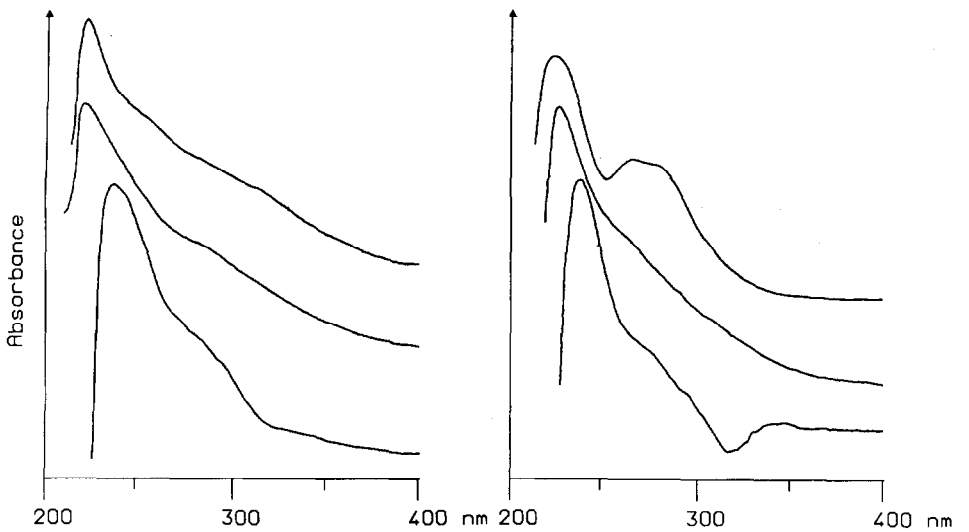

Fig. 3. Left: UV absorption spectra of SeS_5 (bottom), 1,2-Se_2S_5 (centre), and 1,2,3-Se_3S_5 (top). Right: UV spectra of S_6 (bottom), S_7 (centre), and S_8 (top) for comparison. All spectra were recorded with a diode array detector using methanol as a solvent.

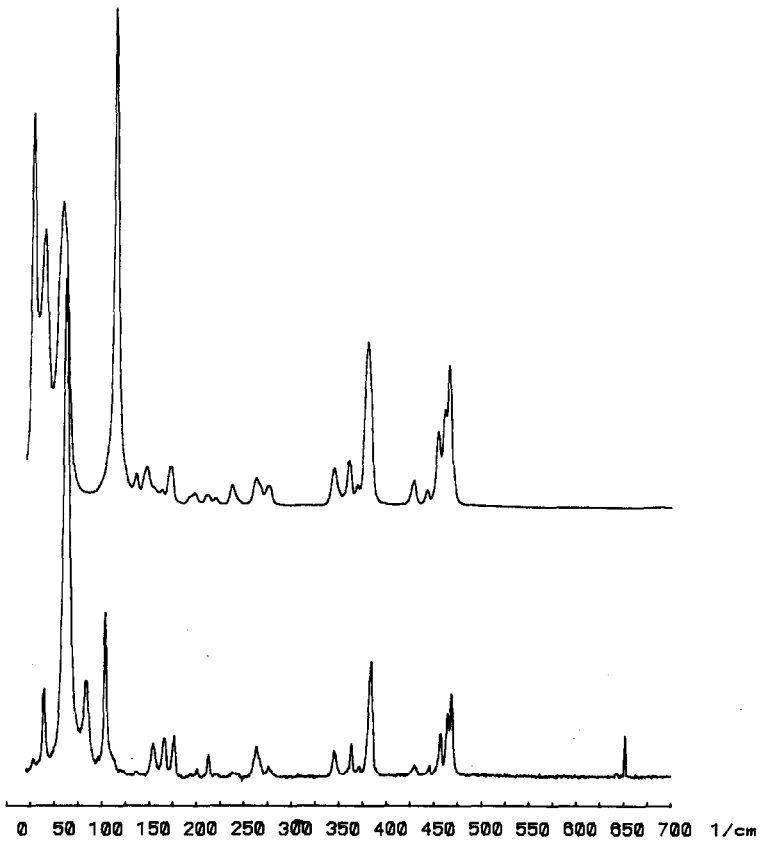

Fig. 5. Raman spectra of solid samples of Se_2S_{10} (top) and $Se_2S_{10} \cdot CS_2$ (bottom). For wavenumbers see Table 5.

While an increase of (a) or (b) enhances the retention time (t_B), an increase of (c) lowers t_B. The two Se_2S_{10} rings prepared in this work show t_B values of which one is distinctly lower than that of S_{12}, while the other one is slightly higher (almost identical) than that of S_{12}. We interpret the first peak as caused by 1,7-Se_2S_{10} (compare 1,4-Se_2S_4 vs S_6) and the second as caused by 1,2-Se_2S_{10} (compare 1,2-Se_2S_5 vs S_7). Both retention times are too different from those of S_{11} (calc. t_B: 13.3 min) and S_{13} (calc. t_B: 20.4 min)[28] to justify any other ring size than 12. A chromatograhic separation of 1,2- and 1,7-Se_2S_{10} on a preparative scale seems to be impossible due to the extremely low solubility of both compounds in methanol.

A dimerization of SeS_5 may result in either

Table 4. Retention times t_B (min) of two Se_xS_{12-x} rings and of 12 reference compounds to illustrae the dependence of t_B on ring size, selenium content, and number of SeS bonds per molecule

Ring size	Increasing t_B
6	1,4-Se_2S_4: 3.38 SeS_5: 3.46 S_6: 3.60

9	S_9: 8.80
10	S_{10}: 10.76
12	1,7-Se_2S_{10}: 15.66 S_{12}: 16.41 1,2-Se_2S_{10}: 16.52

Flow: 2 cm^3 min^{-1}; dead time: 1.41 min; eluent: CH_3OH/H_2O: 95/5 v/v.

1,2-Se_2S_{10} or 1,7-Se_2S_{10}. Assuming an analogous molecular structure for 1,7-Se_2S_{10} as is known for S_{12}[29] the latter heterocycle may exist as two isomers since the atomic positions in the 12-membered ring are not all equivalent (S_{12}: two sets of 6 equivalent atoms each; symmetry D_{3d}). Therefore, the two atoms in 1,7-Se_2S_{10} may be both in the central plane of the molecule (isomer 1) or one in the upper and one in the lower of the three parallel planes of atoms (isomer 2). Both isomers are of C_{2h} symmetry, while 1,2-Se_2S_{10} is of C_1 symmetry (Fig. 6).

The Raman spectra of the yellow Se_2S_{10} crystals, when still wet from CS_2, and of the dried sample are listed in Table 5. S_{12} forms a stoichiometric solid solution with CS_2, the crystal structure[29] and Raman spectrum[30] of which are known and are distinctly different from those of pure S_{12}. A similar behaviour is to be expected for Se_2S_{10} molecules. The crystals obtained from CS_2 show the symmetrical stretching vibration of the structural CS_2 at 651 cm^{-1} and its strongest ^{34}S satellite at 642 cm^{-1} indicating that they consist of $Se_2S_{10}\cdot CS_2$ (Table 5). The corresponding wavenumbers of liquid CS_2 are 654 and 645 cm^{-1}. There are five Raman lines to be assigned to SS stretching modes (500–400 cm^{-1}), four in the region typical for SeS stretching modes (390–330 cm^{-1}), and a number of bending modes below 250 cm^{-1}. The two relatively weak lines at 276 and 262 cm^{-1} may be assigned to either SeSe stretching or SSS bending vibrations (see the vibrational spectra of S_8,[30] S_{12}[30] and Se_nS_{8-n}[31]). If an equimolar mixture of 1,2- and 1,7-Se_2S_{10} was present, only one out of 24 bonds was an SeSe bond resulting in a very weak Raman line for the SeSe stretching mode.

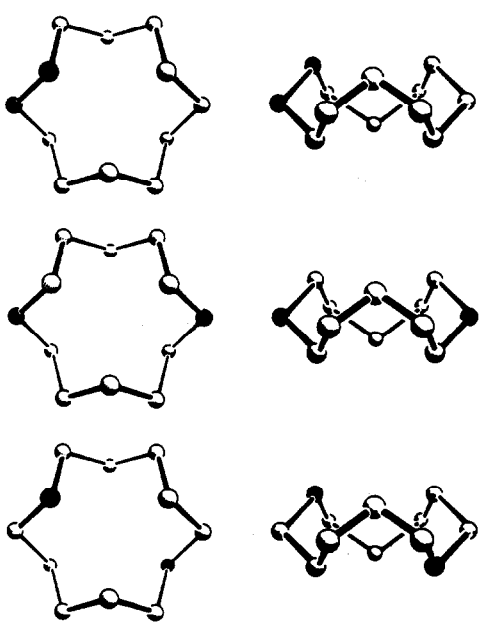

Fig. 6. Likely molecular structures of 1,2-Se_2S_{10} (top) and of two isomers of 1,7-Se_2S_{10} (centre and bottom; black balls = selenium atoms).

On storage of $Se_2S_{10}\cdot CS_2$ in air the Raman spectrum changes to that of Se_2S_{10} which has its most intense line at 114 cm^{-1} (Table 5). This line observed at 127 cm^{-1} for S_{12}, at 117 cm^{-1} for $S_{12}\cdot CS_2$, at 114 cm^{-1} for Se_2S_{10}, and at 103 cm^{-1} for $Se_2S_{10}\cdot CS_2$ has to be assigned to the totally symmetrical ring bending vibration.[30,32] Its position is a function of both the ring size[33] and the Se content, and its high Raman intensity may be utilized to detect these ring molecules in mixtures.

The striking similarities between the spectra of S_{12} and Se_2S_{10} on one hand and of $S_{12}\cdot CS_2$ and $Se_2S_{10}\cdot CS_2$ on the other hand demonstrate that these species do not only agree in molecular structure but the crystal structures must also be analogous. In fact, Weiss *et al.*[34] have prepared solid solutions of S_{12} and Se_xS_{12-x} which crystallize from benzene as orthorhombic needles; the maximum selenium content of 29% (by weight) corresponds to the formula $Se_{1.7}S_{10.3}$. On the other hand, Kutoglu[35] determined the structure of $Se_2S_{10}\cdot CS_2$ by X-ray diffraction at 25°C and found it extremely similar to that of $S_{12}\cdot CS_2$. Both compounds crystallize in space group $R3m-D_{3d}^5$ with $Z = 3$. The lattice constants of $Se_2S_{10}\cdot CS_2$ were $a = 1086.9(3)$ and $c = 1177.9(3)$ pm resulting in a cell volume of 1205.1(9) pm^3. It is not known whether the samples investigated by Weiss *et al.* and by Kutoglu also consisted of isomeric Se_2S_{10} molecules as our sample does. But as has been observed for a large number of eight-membered rings Se_nS_{8-n}, the atomic positions in the crystals of both $Se_{1.7}S_{10.3}$ and $Se_2S_{10}\cdot CS_2$ are occupied statistically by S and Se due to rotational disorder of the ring molecules. The shape of the 12-membered rings agrees with that of S_{12}.

The proposed dimerization of SeS_5 with formation of 1,2- and 1,7-Se_2S_{10} may proceed by two different mechanisms:

(1) Via a hypervalent intermediate as has been proposed before for the interconversion of sulphur rings[36] and for the formation of SeS_5 and 1,2,3-Se_3S_5 by decomposition of 1,2-Se_2S_5.[10] The first step will be an insertion of an Se atom of one molecule into the weakest bond (Se—S) of the second molecule:

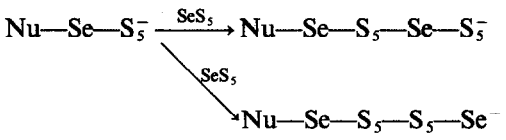
[a] For symbols, see Table 1.

The intermediate may decompose by formation of a bond between S^1 and S^2 at the expense of the two SeS bonds S^1Se and S^2Se in which case 1,2-Se_2S_{10} is formed. On the other hand, the atoms S^3 and Se^2 may combine with rupture of bonds S^3Se^1 and Se^1Se^2 in which case 1,7-Se_2S_{10} is formed. Quantum chemical calculations on model compounds have shown that the two axial bonds in hypervalent species of this type are extremely weak;[37] their dissociation may therefore require very little energy.

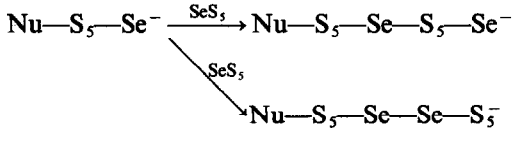
This mechanism does not explain the formation of the eight-membered rings observed as side products (see Table 2).

(2) By nucleophilic attack and ring opening followed by formation of new rings of stable sizes like eight- and 12-membered species.[36,38] In this case the SeS_5 molecule is opened up by attack from a nucleophilic impurity (Nu) in the solution and the zwitterion formed attacks a second molecule. The weakest bond of the molecule will be broken easiest and several products are to be expected:

(a) $Nu + SeS_5 \longrightarrow$



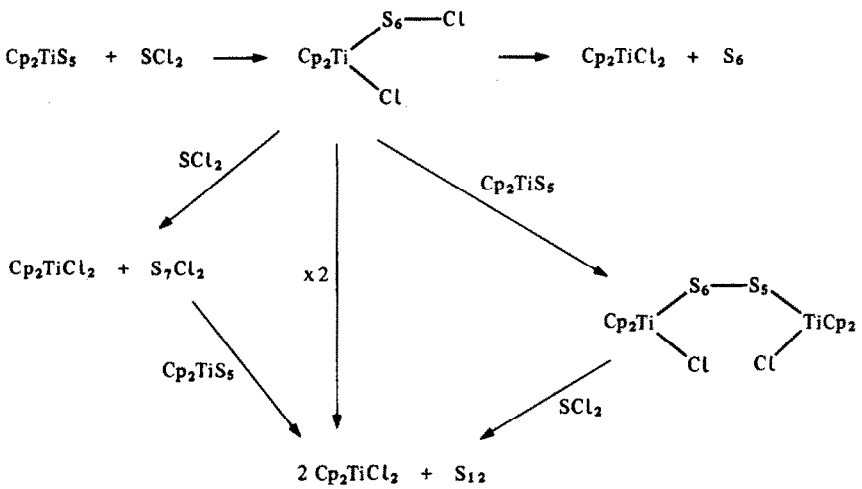
(b) $Nu + SeS_5 \longrightarrow$



The four species of composition $NuSe_2S_{10}$ may

dissociate into Nu and Se_2S_{10} and it can be seen that only 1,2-Se_2S_{10} and 1,7-Se_2S_{10} are formed. If the $NuSe_2S_{10}$ species split off an eight-membered ring by attack of the tail on the chain the following species could form: SeS_7 from reaction (a) and 1,3-Se_2S_6 as well as 1,2-Se_2S_6 from reaction (b). Only the last of these rings has been observed (Table 2). This may indicate that reactions (a) and (b) proceed with a different rate, but additional and presently unknown reactions must occur to explain the products 1,5-Se_2S_6 and 1,2,5,6-Se_4S_4. In general, it is likely that other reactive species present in the reaction mixture like 1,2-Se_2S_5 take part in the above discussed interconversion reactions.

Another route to explain the formation of Se_2S_{10} takes the formation of S_{12} from SCl_2 and Cp_2TiS_5 into consideration. The first product from this reaction may either split off S_6 or react as follows:



Applied to the reaction of $SeBr_2$ with Cp_2TiS_5 the only product would be 1,7-Se_2S_{10} which is in contrast to the observation of 1,2-Se_2S_{10}. We therefore believe that at least this 12-membered ring results from the dimerization of SeS_5.

The present work shows that the combination of HPLC and NMR analysis provides complete information about the species present in reaction mixtures of selenium sulphides. The higher sensitivity of HPLC allows the detection of species present in low concentration or of low solubility, while the very specific dependence of the ^{77}Se chemical shift on ring size and neighbouring atoms helps to identify the species involved provided a sufficiently high solubility.

(*Received* 21 *August* 1989; *accepted* 2 *January* 1990)

Abstract—Tetrahalodimolybdate(II) complexes with pyridine (PY), 3-methylpyridine (3PIC), 4-methylpyridine (4PIC), 3,4-dimethylpyridine (34LUT) and 4-tert-butylpyridine (4TBP) have been spectroscopically characterized. Additionally, the X-ray diffraction structure of the complex $Mo_2Br_4(4TBP)_4 \cdot 2C_6H_6$ is reported and compared to the previously reported structure of the complex $Mo_2Br_4(4PIC)_4 \cdot CHCl_3$. The 4TBP complex crystallizes in the $P2_1/n$ space group ($a = 9.143(3)$, $b = 15.305(5)$, $c = 18.766(4)$ Å, $\beta = 93.46°$, $V = 2621.9(9)$ Å^3, $Z = 4$) in the eclipsed conformation, giving the complex an overall D_{2h} symmetry. The Mo—Mo bond distance is 2.148(2) Å. These structural features are very similar to those found in $Mo_2Br_4(4PIC)_4 \cdot CHCl_3$ according to the published atomic coordinates rather than the depicted complex geometry. A plot of the $\delta \rightarrow \delta^*$ transition energy versus ligand gas-phase basicity shows that the $\delta \rightarrow \delta^*$ transition energy varies with respect to the position and type of alkyl substituent on the pyridine ring.

There is presently little spectroscopic or structural data available for dimolybdenum complexes containing substituted pyridine ligands. This is surprising when one considers that the variability in both the ligand basicity and steric bulk makes the substituted pyridines excellent ligands for probing the nature of the quadruple metal–metal bond and its interactions with such ligands. To our knowledge, the only structural study reported to date for this class of complex is of the tetrakis(4-methylpyridine)tetrahalodimolybdate(II) complexes.[1] This study showed that both chloride and bromide forms exist in the eclipsed conformation with overall D_{2h} symmetry. The coordination about each molybdenum atom was reported to be square-planar. The authors speculated that, based on IR data, $Mo_2Cl_4(4PIC)_4 \cdot CHCl_3$ underwent a structural rearrangement from D_{2h} to D_{2d} symmetry upon loss of chloroform.

Recently, Cotton *et al.*[2] reported on the influence the π-acidity of various phosphine ligands in $Mo_2Cl_4(PR_3)_4$ have on the electronic spectra of these complexes. They showed that there is a correlation between the $\delta \rightarrow \delta^*$ transition energy and the π-acidity for 15 phosphine ligands. In a related paper Hanselman and Smith[3] studied the relationship between spectroscopic properties of $Mo_2Cl_4(PR_3)_4$ complexes and their electrochemical behaviour. They reported that the $Mo_2Cl_4(PR_3)_4$ complexes became more difficult to oxidize as the $\delta \rightarrow \delta^*$ transition energy decreased due to the increased π-acidity of the phosphine ligands. They noted that with more strongly electron-withdrawing phosphine ligands Mo—P backbonding will primarily affect the $\delta \rightarrow \delta^*$ transition energy, while with trialkyl phosphines the $\delta \rightarrow \delta^*$ transition energy is more dependent on the electron-donating ability of the phosphine ligand.

‡ Author to whom correspondence should be addressed.

In a previous paper[4] the preparation of tetrahalodimolybdate(II) complexes with the ligands 3-methylpyridine, 3,4-dimethylpyridine, 3,5-dimethylpyridine and 4-tert-butylpyridine was reported. The current thrust of this work is in determining which factors, electronic or steric, play the predominant role in determining the complex geometry and spectroscopic characteristics. In similar fashion to Cotton[2] and Smith[3] the $\delta \rightarrow \delta^*$ transition energy of the pyridine complexes is evaluated with respect to the change in ligand gas-phase basicity.

EXPERIMENTAL

Synthesis

The complexes were prepared from $Cs_3Mo_2Cl_8H$ and $Cs_3Mo_2Br_8H$ as described by San Filippo *et al.*[5] All solvents and ligands were dried and distilled via literature methods under nitrogen. The dimolybdenum complex containing 2-methylpyridine, the most sterically restrictive ligand, was not isolable. Instead, a brown solid which did not exhibit the characteristic electronic absorption attributable to the $\delta \rightarrow \delta^*$ transition was obtained. This suggests that the resulting product is monomeric in nature, formation of which is due to decomposition of the sterically unstable dimer.

Slow recrystallization of $Mo_2Br_4(4TBP)_4$ from a benzene–pentane solution at 0°C resulted in the formation of a mixture of blue and green crystals. Recrystallization from tetrahydrofuran or excess ligand (4TBP) led to an almost exclusive formation of the green crystals. The green crystals were found to change back to the blue material upon leaving under argon for about a month. X-ray structural data are reported for the blue crystalline form, while X-ray quality crystals of the green form have yet to be obtained.

Spectroscopic measurements

Visible spectra of Nujol mulls of the complexes were recorded on a Cary 219 spectrophotometer with an Apple IIC computer interface. Raman spectra were recorded as described elsewhere.[6]

X-ray crystallography procedures

A crystal (0.12 × 0.17 × 0.37 mm) of the blue form of $Mo_2Br_4(4TBP)_4 \cdot 2C_6H_6$ (red by transmitted light) was sealed in epoxy cement and mounted on a glass fibre. The space group, $P2_1/n$, was uniquely determined from systematic absences. Unit cell parameters were derived from a least-squares fit of the angular settings of 25 reflections ($22° \leqslant 2\theta \leqslant 26°$). The data were corrected for absorption by an empirical method (max/min transmission = 0.198/0.181); R(int) = 0.024. Pertinent crystal data and parameters are collected in Table 1.

The structure was solved by direct methods (SOLV–SHELXTL) which located the molybdenum and two bromine atoms. The remaining non-hydrogen atoms were located from subsequent difference Fourier synthesis. The asymmetric unit consists of 1/2 of the Mo_2 complex (an inversion centre is midway in the Mo—Mo bond) and a molecule of benzene (the recrystallization solvent).

All non-hydrogen atoms were refined with anisotropic thermal parameters, with hydrogen atoms treated as idealized isotropic contributions (d(C—H) = 0.96 Å) and the benzene molecule as a rigid hexagon (d(C—C) = 1.395 Å). Selected bond distances are given in Table 2. Additional crys-

RESULTS AND DISCUSSION

Structure of $Mo_2Br_4(4TBP)_4 \cdot 2C_6H_6$

The structure, as well as the atomic numbering scheme are shown in Fig. 1, bond distances and angles are presented in Table 2. The molecule crystallizes in the $P2_1/n$ space group exhibiting features common to dimolybdenum complexes containing an Mo—Mo quadruple bond.[7] It possesses an eclipsed conformation about the quadruple bond with two 4TBP ligands on each molybdenum atom *trans* to one another giving the complex an overall D_{2h} symmetry. The unit cell contains two molecules of the complex along with four molecules of benzene solvate arranged as shown in Fig. 2. The Mo—Mo and Mo—N bond lengths, 2.148(2) and 2.35(9) Å, respectively, are virtually the same as the Mo—Mo and Mo—N bond lengths found[1] in $Mo_2Br_4(4PIC)_4$. The average Mo—Br bond length, 2.571(2) Å, is slightly longer than that reported for the 4PIC complex, being closer to the Mo—Br (terminal) bond length of 2.57 Å in $MoBr_3$.[8]

Brencic *et al.*,[1] reported that in the $MoBr_2(4PIC)_2$ moiety, the two ring nitrogen atoms, two bromide atoms and the molybdenum atom were in a common plane, while the 4PIC ring was tilted 35° out of this plane. In the 4TBP complex, both the bromide ions and pyridine ligands are bent away from the quadruple bond forming Br(1)—Mo—Br(2) and N(1)—Mo—N(2) angles of 144.5(1) and 155.4(1)°, respectively. Initially, the difference between the geometry of the two complexes was thought to be due to steric interactions between opposing 4TBP groups. However, using Brencic's original published atomic coordinates,[1] the structure of $Mo_2Br_4(4PIC)_4 \cdot CHCl_3$ was re-examined. It was determined that the original structural rep-

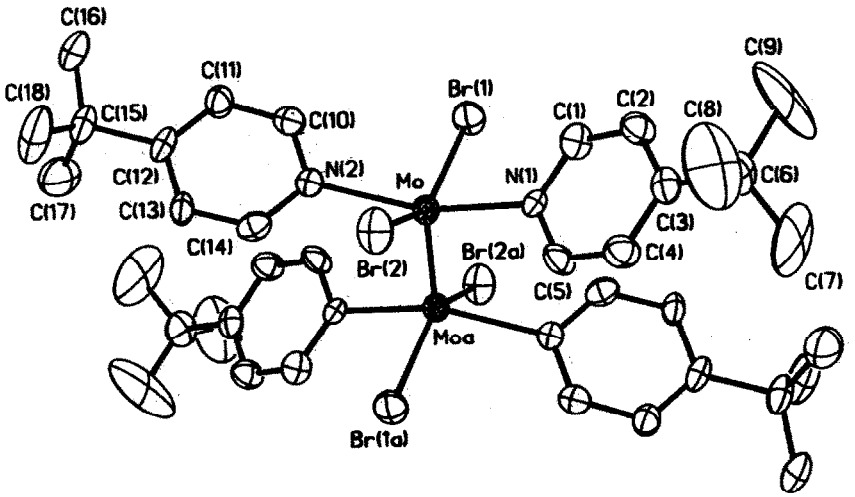

Fig. 1. Molecular structure and labelling scheme for $Mo_2Br_4C_{36}H_{52}N_4$ with 35% probability ellipsoids and the crystallographic numbering scheme. Hydrogen atoms omitted for clarity.

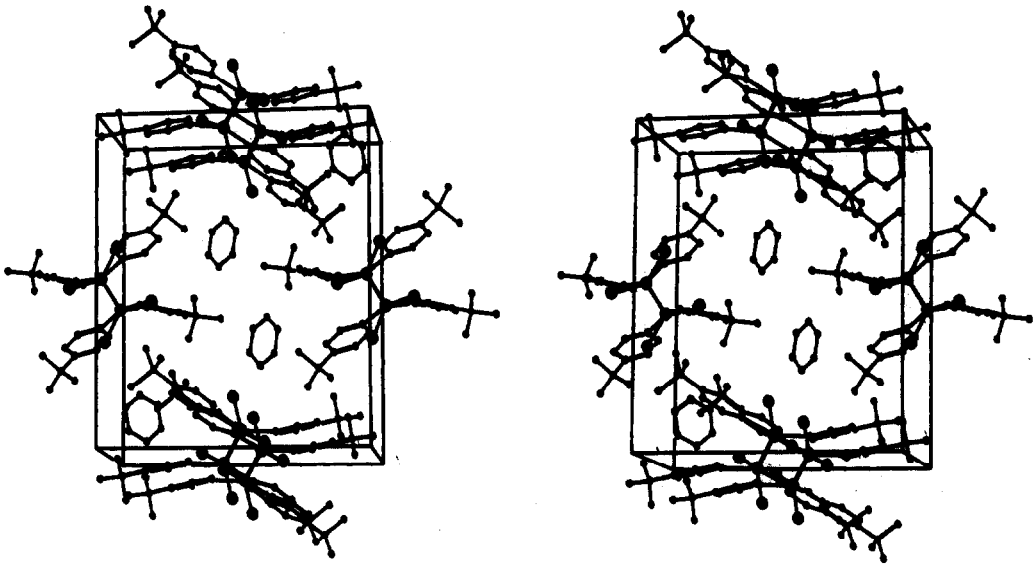

Fig. 2. Stereoview of the unit cell for $Mo_2Br_4(4TBP)_4 \cdot 2C_6H_6$ as viewed down the *a* axis (*b*, vertical; *c*, horizontal).

resentation was in error (see Fig. 2 in ref. 1). Comparison of the structures for the 4PIC and 4TBP complexes (this work) shows these complexes to be isostructural. This indicates that the complex geometry is unaffected by the presence of the bulky tert-butyl group on the pyridine rings.

Both blue and green forms of $Mo_2Br_4(4TBP)_4$ possess identical IR spectra but have different solid-state visible spectra. In the visible region where the absorption due to the $\delta \rightarrow \delta^*$ transition usually appears,[7] the blue form has its lowest energy electronic transition at 17,544 cm^{-1}, while the green form has this transition at 17,182 cm^{-1}. Similarly, $Re_2(N_2CPh_3)_2Cl_4$ crystallizes from tetrahydrofuran as a mixture of ruby red and dark purple crystals.[9] An X-ray study of both crystalline forms show the ruby red complex has a totally eclipsed conformation while the dark purple complex exhibits a 6° twist from the eclipsed conformation. It was proposed that this twist in the Mo—Mo quadrule bond was due to coordination of tetrahydrofuran to one of the rhenium atoms. Elemental analysis of the green form† of $Mo_2Br_4(4TBP)_4$, recrystallized from a 4TBP/hexane mixture, indicates the presence of an additional 4TBP ligand in the molecule. Hence the formula of the green form is best represented as $Mo_2Br_4(4TBP)_4 \cdot L$, where L = 4TBP. The conformation about the quadruple bond may be twisted due to axial coordination of 4TBP to one of the molybdenum atoms in the dimer. This would cause the energy of the $\delta \rightarrow \delta^*$ transition to be lower in the green form than in the blue form, as is observed.

†Found: C, 45.5; H, 5.6; N, 5.4; Br, 28.8. Calc. for $C_{45}H_{65}N_5Br_4Mo_2$: C, 45.5; H, 5.5; N, 5.9; Br, 27.0%.

Spectral data

It is known[10] that the $\delta \rightarrow \delta^*$ transition energy is dependent upon the degree of departure from the eclipsed conformation, as determined by the twist angle χ. The twisting of the quadruple bond can be brought about via torsional forces exerted by bridging bidentate phosphine ligands such as bis(dimethylphosphino)ethane. More recently, the $\delta \rightarrow \delta^*$ transition energy has been shown to vary with either the π-acidity[2] or basicity[3] of different phosphine ligands. In this light, the complexes $Mo_2Cl_4L_4$, where L = PY, 3PIC, 4PIC, 34LUT, 35LUT and 4TBP (blue form), have been studied to determine whether electronic or steric factors primarily affect the $\delta \rightarrow \delta^*$ transition energy.

As shown in Table 3, the measured $\delta \rightarrow \delta^*$ transition energy varies in the order: 35LUT > 4TBP (blue form) > 34LUT > 3PIC > 4PIC < PY. Both the 4PIC[1] and 4TBP (blue form) complexes possess an eclipsed conformation indicating negligible steric interaction across the quadruple bond. The frequencies of the metal–metal stretch in the Raman spectra of the PY, 3PIC, 34LUT and 35LUT complexes (Table 3) are all within 7 cm^{-1} of that for the 4PIC and 4TBP complexes, indicating an eclipsed conformation[7] for all complexes. This evidence suggests that the variation in the $\delta \rightarrow \delta^*$ transition

energy over the range of ligands employed is not due to a twisting of the quadruple bond.

Therefore, electronic factors associated with the different ligands are expected to be of primary importance in determining the spectroscopic properties of the complexes. Because the electronic spectrum of each complex is measured in a Nujol mull, solvation effects would appear to be insignificant. Furthermore, since the differences between the two known crystal structures (i.e. the 4PIC[1] and 4TBP (this work), which are crystallized from two different solvents) are minimal, it seems reasonable to rule out differences due to crystal lattice effects. In Table 3 are listed the gas-phase basicities[11] of the ligands and the measured $\delta \rightarrow \delta^*$ transition energies. In Fig. 3 a plot of the $\delta \rightarrow \delta^*$ transition energy vs the ligand gas-phase basicity indicates that as the gas-phase basicity increases the $\delta \rightarrow \delta^*$ energy generally increase for all complexes. Also, the transition energy is dependent upon the position of alkyl substituents on the pyridine ring.

The variation in the $\delta \rightarrow \delta^*$ energies with respect to both the donor strength of the ligand and

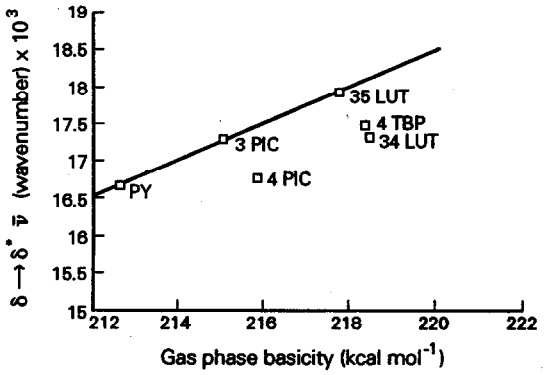

Fig. 3. Plot of the ligand gas-phase basicity of the ligand L = PY, 3PIC, 34LUT, 35LUT and 4TBP in $Mo_2Cl_4L_4$ vs the $\delta \rightarrow \delta^*$ transition energy.

location of the alkyl substituent suggests a complex bonding scenario with at least two possible explanations. Metal-*d* to ligand-*d* backbonding in the complexes $Mo_2X_4(PMe_3)_4$, X = Cl, Br, I, has been proposed[12] to affect the ease of oxidation and difficulty of reduction in the order Cl < Br < I. This order is the opposite to what one would expect based on simple electronegativity arguments. Smith[3] noted that in the trialkyl phosphine complexes, $Mo_2Cl_4(PR_3)_4$, variation in ligand basicity strongly affects the $\delta \rightarrow \delta^*$ transition energy, while in phosphines containing more electronegative substituents Mo(δ) to P(*d*) backbonding has more of an effect on the $\delta \rightarrow \delta^*$ energy.

In the current system, the empty ligand π^*-orbitals with local b_2 symmetry span b_{2g} (δ) symmetry in a D_{2h} complex (note the centre of symmetry in the molecule), allowing for δ-to-ligand π^* backbonding.[13] Assuming δ to ligand π^* backbonding does occur throughout the present series of complexes, the observed $\delta \rightarrow \delta^*$ transition energy is actually a transition between linear combinations of the δ and ligand π^*-orbitals, $\delta + \pi_L^* \rightarrow \delta - \pi_L^*$. Thus, as the σ-basicity of the ligand increases, the effective nuclear charge of the molybdenum is reduced causing the 4*d* orbitals to expand allowing increased δ to π_L^* overlap. As in previous work,[2,3] the observed $\delta \rightarrow \delta^*$ transition energy increases with ligand basicity, but in this case it is due to an increase in the δ-to-ligand π^* overlap. In the case of the 4-alkyl substituted pyridine ligands, hyperconjugative electron release[14] by the 4-methyl, and to a lesser exent the 4-tert-butyl groups will decrease the δ to π_L^* overlap. This will cause a decrease in δ to π_L^* overlap making the observed $\delta \rightarrow \delta^*$ transition lower than expected based on σ-donation arguments alone. Physical manifestation of the δ to π^* backbonding is shown in Fig. 4. Here each tert-butylpyridine ring in $Mo_2Br_4(4TBP)_4 \cdot 2C_6H_6$ is twisted 30° from the plane perpendicular to the metal–metal bond. The analogous 4PIC[1] complex also shows a 30.9° (av.) twist angle, which is not significantly different from the angle found in the 4TBP complex; this twisting of the ligands probably allows for stronger interaction to occur between the δ and ligand π^*-orbitals. A second explanation for the anomalous behaviour of the four-substituted pyridine complexes is that their π-acidity is greater than that of the other pyridine ligands. While data is scarce, Drago and coworkers[15] determined the π-acidity of pyridine and 4PIC to be the same based on observation of the CO stretching frequencies of (B)$Rh_2(pfb)_4(CO)$ (pfb = $O_2C_4F_7^-$, B = pyridine, 4PIC).

Cotton *et al.*[2] have shown that there is a linear relationship between the π-acidity parameters, delta

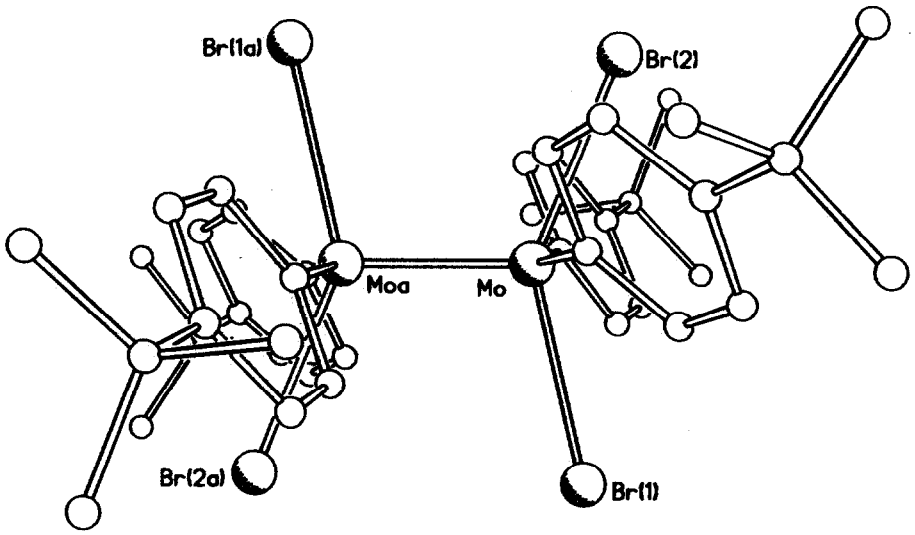

Fig. 4. View of $Mo_2Br_4(4TBP)_4 \cdot 2C_6H_6$ along the *b* axis showing the 30° twist of the pyridine rings with respect to a plane perpendicular to the metal–metal bond.

δ(CO) and $\bar{\nu}$(CO), with the $\delta \rightarrow \delta^*$ transition energy for the complexes $Mo_2Cl_4(PR_3)_4$, where the R group is varied producing 20 different compounds. The data suggest that, as the phosphine's ability to remove electron density increases, the $\delta \rightarrow \delta^*$ energy difference decreases. This effect should then be accompanied by a weakening of the δ bond. However, as the authors point out, it is difficult to estimate the contributions of electron correlation and relaxation effects. Furthermore, the deviation of the phosphines PMe_3, PH_2Ph and $PHPh_2$ from the other ligands presented in previous work[2] is not clearly understood, though perhaps the R group size may play a role.

By way of comparison to previous work,[2] this work has considered the electron-donating ability of the ligand unencumbered by solvent effects and, as it turned out, any steric effects. Thus presumably, as the ability of the ligand to donate electron density increases, the δ to π_L^* overlap increases, consequently increasing the observed $\delta \rightarrow \delta^*$ transition energy as seen in Table 3. However, as was pointed out above, the effect of the position of the R group on the pyridine ring can cause deviation in the expected $\delta \rightarrow \delta^*$ transition energy. Perhaps some mechanism similar to that proposed in this work, encompasing the R groups on the phosphines that show aberrant behaviour may be involved.

Lastly, if electron donation strengthens the δ bond, or if electron back donation weakens it,[2] it would be expected that this would be reflected in the metal–metal fundamental vibration if bond length and bond strength are directly proportional. The Raman spectral data in Table 3 show no significant change or trend, as compared to the gas-phase basicity data. Here again, as previously pointed out,[2] it is difficult to assess the contributions of the many factors to the metal–metal quadruple bond such as electron correlation and relaxation effects.

In conclusion, the results of this study indicate that the spectroscopic behaviour of these complexes is predominately determined by electronic, rather than steric effects. It is shown that the $\delta \rightarrow \delta^*$ transition energy varies with respect to the ligand gas-phase basicity as well as the position of the alkyl substituent on the pyridine ring. The structure of $Mo_2Br_4(4TBP)_4 \cdot 2C_6H_6$ has been determined and found to be isostructural with $Mo_2Br_4(4PIC)_4 \cdot 2CHCl_3$.

DIBENZO[b,i][1,4,8,11]TETRA-AZACYCLOTETRADECINE COMPLEXES—I. $W(CO)_4$(tmtaa)

F. ALBERT COTTON* and JOANNA CZUCHAJOWSKA

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 6 *November* 1989; *accepted* 2 *January* 1990)

Abstract—The title compound (which has been previously reported and an unusual structure postulated) has been prepared by essentially the previous method and its structure determined by X-ray crystallography. It has the previously proposed structure in which there is a diimide group, —N=C(CH_3)CH_2C(CH_3)=N— coordinated to *cis* positions of the $W(CO)_4$ group. The other side of the macrocycle takes on the —NHC(CH_3)CHC(CH_3)NH— structure and is not bonded to the $W(CO)_4$ group. Crystal data: space group *Pcab* (No. 61) with $a = 16.387(8)$, $b = 21.435(8)$, $c = 14.529(5)$ Å, $V = 5104(3)$ Å^3, $Z = 8$.

This report is concerned with the structure of a novel complex of the title ligand, whose normal structure[1] is that shown as **I**, and which may be abbreviated tmtaa. The conventional role played by this ligand[2] is that of a tetra-aza macrocyclic dianion. However, there are a few reports of compounds in which this ligand is believed to behave differently, and one of these struck us as being sufficiently novel as to merit further study. In 1975 Bell and Dabrawiak[3] prepared the two compounds $M(CO)_4$(tmtaa) (M = Mo, W) and proposed, on the basis of spectroscopic evidence the type of structure represented schematically in **II**. Although we saw no reason to doubt the conclusion of Bell and Dabrawiak, we thought it worth establishing with certainty and at a quantitative level of structural detail the occurrence of such an unconventional mode of coordination of tmtaa. It should be noted that in **II** the ligand remains neutral, but has undergone a proton shift from one of the nitrogen atoms to a ring carbon atom, thus generating a —N=C(CH_3)—CH_2—C(CH_3)=N— chain, a 1,3-diimino propane unit, which is the entity that coordinated to the metal atom.

We have prepared the tungsten compound, $W(CO)_4$(tmtaa), and shown that it does indeed have a structure of type **II**. The structure determination and structural details are reported here.

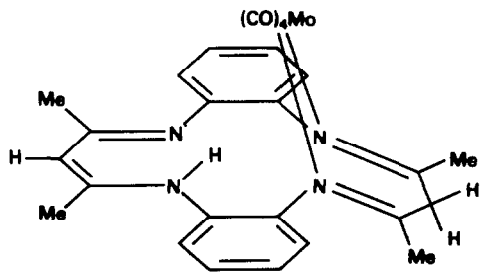
I



II

EXPERIMENTAL

All manipulations were carried out under an argon atmosphere, using standard vacuum-line and Schlenk techniques. The solvents were freshly distilled under nitrogen from the appropriate drying agents. $W(CO)_6$ was obtained from the Pressure Chemical Company and tmtaa[4] was prepared according to the literature.

Preparation

Equimolar quantities of tungsten hexacarbonyl (0.08 g, 0.23 mmol) and tmtaa (0.08 g, 0.23 mmol) were mixed and refluxed in toluene (18 cm^3) for 48 h. The yellow, crystalline product was isolated by layering the reaction solution with hexanes. The product is air-stable. It displayed four IR peaks at 2000, 1890, 1872 and 1830 cm^{-1}, in good agreement with the original paper.

X-ray crystallography

The unit cell determinations and collection of intensity data were carried out by following routine procedures which have been previously described elsewhere.[5] The intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction based upon azimuthal scans of six reflections near $\chi = 90°$ was applied to the data. Pertinent crystallographic data are given in Table 1.

Inspection of the systematic absences led to the inference that the correct space group would be *Pcab*, a non-standard setting of *Pbca* (No. 61). Successful solution and refinement confirmed that choice.

The positions of tungsten, carbonyl groups and the entire macrocyclic ligand were located from the Patterson map. All hydrogen atoms were located from difference Fourier maps and refined with an

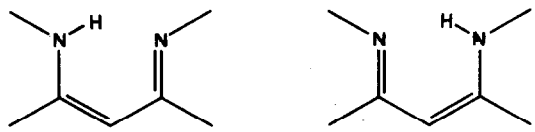
overall isotropic temperature factor. In the later stage, restraints were put on four C—H interatomic distances and added to least-squares refinements. Finally, three models were created to test the position of H(1) with respect to the two nitrogens, N(3) and N(4). In model 1, H(1) was located by the difference Fourier map and refined to convergence at a distance of *ca* 0.9 Å from N(3). In model 2, a hydrogen atom, H(1′), was added to a calculated position at *ca* 0.9 Å from N(4). The atoms H(1′) and H(1) were assigned a fractional occupancy factor of 0.5 and refined to convergence. In model 3, H(1) was deleted, leaving H(1′) at a multiplicity of one. All these models pointed to the fact that, in reality, H(1) and H(1′) have a fractional occupancy factor of 0.5, as described in model 2. The results of model 2 are reported here.

RESULTS AND DISCUSSION

ORTEP drawings of $W(CO)_4$(tmtaa) are shown in Figs 1 and 2, which also define the atomic numbering scheme used in the tables and the following discussion.

The molecule resides on a general position in the unit cell, but has idealized C_s symmetry, with the mirror plane passing through W, C(25)—O(3), C(23)—O(1), C(2) and C(11). If the hydrogen atom spent 100% of its time at either of the nitrogens, N(3) or N(4), then we should see an appropriate shortening of some C—C and C—N bonds, as shown schematically below.



In our case however, H(1) and H(1′) are bonded to N(3) and N(4) respectively, at a distance of *ca* 0.7 Å. We observe a superposition of both of these structures, which explains why the entire C(9)—N(3)—C(10)—C(11)—C(12)—N(4)—C(13) group shows no bond alternation, as would be expected for either one of the above structures. Finally, H(1) and H(1′) participate in hydrogen bond interactions to N(4) and N(3), respectively, with H(1)—N(4) and H(1′)—N(3) distances of 1.964 and 2.024 Å.

The metal atom is indeed bonded to only two of the four nitrogens of tmtaa, N(1) and N(2). Interestingly enough, the ligand remains neutral upon coordinating to the $W(CO)_4$ moiety, due to the migration of one of the nitrogen protons to the methine carbon, C(2). The resulting 1,3-diimino propane unit displays shortened N—C distances of 1.28(1) Å for N(2)—C(3) and N(1)—C(1).

Finally, tmtaa takes on the familiar saddle-shape conformation, but much more pronounced than in the free ligand. Large dihedral angles between planes defined by atoms: (i) N(2)—C(4)—C(5) and C(3)—N(2)—C(4), and (ii) C(1)—N(1)—C(18) and N(1)—C(18)—C(17) of 72.98 and 74.50°, respec-

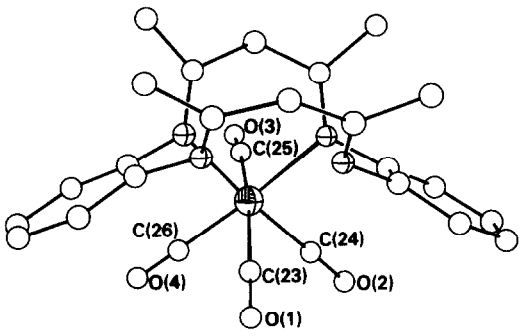

Fig. 2. An ORTEP diagram of $W(CO)_4$(tmtaa) showing the side-view of the molecule.

tively, show a 30° increase as compared to the free tmtaa.

This report established with certainty an unconventional mode of coordination of tmtaa to tungsten, as previously postulated by Bell and Dabrawiak. Tmtaa is also capable of taking on other, equally interesting coordination geometries as shown by some further studies carried out in our laboratory, to be reported presently.

DIBENZO[b,i][1,4,8,11]TETRA-AZACYCLOTETRADECINE COMPLEXES—II. Ru(tmtaa)($PMePh_2$)$_2$

F. ALBERT COTTON* and JOANNA CZUCHAJOWSKA

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 13 *November* 1989; *accepted* 2 *January* 1990)

Abstract—The title compound has been prepared via an unusual synthetic route and structurally characterized. The compound crystallizes in space group $P\bar{1}$ with unit cell dimensions $a = 10.928(3)$, $b = 11.030(2)$, $c = 10.035(3)$ Å, $\alpha = 116.70(1)$, $\beta = 113.10(2)$, $\gamma = 85.94(2)°$, $V = 985.7(5)$ Å^3 and $Z = 1$. This ruthenium monomer is the first Ru–tmtaa compound to be crystallographically characterized. The usual saddle-shape geometry of the macrocyclic ligand is destroyed due to the presence of bulky $PMePh_2$ phosphines. This complex is the first example of such an occurrence.

The title macrocyclic ligand[1] has long been known to take on a characteristic saddle-shape geometry both as the free ligand and upon coordination to a metal atom. The inherent predisposition of tmtaa to adopt such a geometry is due to steric interactions of the methyl groups with the benzenoid rings.[2] There are numerous examples of early[3] and late[4] transition metal complexes with this macrocyclic ligand in which the saddle-shape geometry is evident. The largest observed displacement of the metal out of the N_4 plane is 1.070(2) Å for tmtaa^{2-}, [Zr(tmtaa)Cl_2][4] and 1.5 Å for tmtaa^0, [W(CO)$_4$(tmtaa)].[5]

This report is concerned with the synthesis and crystallographic characterization of a novel Ru–tmtaa complex in which the conventional geometry of the ligand is destroyed. Reaction of $Ru_2(O_2CCH_3)_4$ with tmtaa, in the presence of $PMePh_2$ phosphine, gives a monomeric species, Ru(tmtaa)($PMePh_2$)$_2$. The octahedral environment of the ruthenium atom consists of four equatorially bound nitrogen atoms of tmtaa and two axially bound phosphorus atoms of $PMePh_2$. Presumably, the axially bound, bulky phosphines force the ligand out of the saddle-shape and into a "step-like" geometry, with the two benzenoid rings *trans* to each other, relative to the N_4 plane.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

All manipulations were carried out under an argon atmosphere, using standard vacuum-line and Schlenk techniques. The solvents were freshly distilled under nitrogen from the appropriate drying agents. Starting materials, $Ru_2(O_2CCH_3)_4$[6] and tmtaa[1] were prepared according to the literature. $PMePh_2$ was purchased from Strem, Inc. The UV–vis spectrum was measured on a Cary 17D spectrophotometer at room temperature. The ^{1}H NMR was run on a Varian XL-200A spectrophotometer.

Preparation

A solution of $Ru_2(O_2CCH_3)_4$ (0.06 g, 0.13 mmol) and tmtaa (0.09 g, 0.26 mmol) in ethanol (15 cm^3) was refluxed for 2 h. To this hot solution, $PMePh_2$ (0.20 cm^3, 1.06 mmol) was quickly added. After an additional 12 h of vigorous refluxing, the reaction solution was evaporated to dryness and the remaining solid was dissolved in benzene (12 cm^3). After 12 h, the tube was shaken and green, block-like crystals formed over several hours. The material is air-sensitive, becoming brown within minutes upon exposure to air. Yield: 0.12 g; 60%. Visible spectrum (benzene, λ, nm) of Ru(tmtaa)($PMePh_2$)$_2$: 670, 456, 358 (sh). ^{1}H NMR (C_6D_6, 298 K): δ 8.02–7.10 (m, 10H, $PCH_3(C_6H_5)_2$), 6.051 (m, 8H, Ar*H*), 3.88 (s, 2H, γ-C*H*), 2.31 [s, 3H, $PCH_3(C_6H_5)_2$] and 1.74 (s, 12H, CH_3).

X-ray crystallography

General procedures that have already been fully described elsewhere[7] were used to determine the crystal structure. Information about data collection and structure refinement for the compound is given in Table 1. The intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction based upon azimuthal scans of six reflections near $\chi = 90°$ was applied to the data.

The position of the ruthenium atom in the unit cell (space group $P\bar{1}$) was determined by the Patterson method; it resides on a crystallographic inversion centre. The subsequent development of the structure was done by an alternating sequence of least-squares refinements and difference Fourier maps. All hydrogen atoms were found the same way and refined freely.

Table of positional and isotropic equivalent displacement parameters, anisotropic displacement parameters, observed and calculated structure factors, as well as full lists of bond distances and angles, have been deposited as supplementary material with the Editor.

RESULTS AND DISCUSSION

Figures 1 and 2 show ORTEP drawings of $Ru(tmtaa)(PMePh_2)_2$ and define the atomic numbering scheme used in the tables and the following discussion. Important interatomic dimensions are presented in Table 2.

The ruthenium atom resides on a crystallographic inversion centre and thus is constrained to be in the plane of the four nitrogen atoms of tmtaa. The metal is in an octahedral environ-

ment, with the two phosphines in axial positions. The Ru—P distance, 2.382(1) Å, is not atypical, and the Ru—N distances are also normal and equal to 2.029(2) and 2.032(1) Å. These parameters may be compared with those of the structurally characterized ruthenium tetraphenylporphyrinato complex,[8] Ru(TPP)(PPh$_3$)$_2$, in which the Ru—P and Ru—N distances are 2.428 and 2.050 Å, respectively. The NMR data agree well with the crystal structure of our compound, clearly showing the retention of structure with its dianionic ligand and the two equivalent PMePh$_2$ phosphines, in solution.

As mentioned in the introduction, the conventional saddle-shape geometry of tmtaa is destroyed in this ruthenium monomer. The phenyl groups of each axially bound phosphine sterically interact with the benzenoid ring directly below it. This benzenoid ring is being pushed downwards to minimize the steric crowding. That, in turn, causes the two methyl groups of tmtaa, C(10) and C(11), to direct themselves the opposite way to avoid steric interaction with the benzenoid ring. What results is a "step-like" geometry of the macrocycle, in which the two benzenoid rings are *trans* to each other, relative to the N_4 plane. This is clearly seen in Fig. 2.

This report provides a new entry into the formation of novel Ru–tmtaa complexes. It establishes with certainty an unconventional geometry of tmtaa, as it takes on a "step-like" shape to minimize steric crowding with other ligands. We believe that

the axially bound phosphines can be easily replaced by other σ-donating groups. Such chemistry has been seen with $Ru(TPP)(PPh_3)_2$ and $Ru(OEP)(PPh_3)_2$.[8] Finally, it is of interest to see if a less sterically demanding phosphine like PMe_3, can also destroy the saddle-shape of tmtaa. Chemistry of this kind is presently under investigation.

(*Received* 9 *November* 1989; *accepted* 15 *January* 1990)

Abstract—Dinuclear molybdate complexes of alditols have been studied in aqueous acidic solution by ^{95}Mo and ^{13}C NMR. Their formation constants were determined by potentiometry. In all complexes, the dimolybdate group was chelated by four vicinal hydroxyls. Two types of complexes were characterized by NMR, depending on the *erythro* or *threo* configuration of the central diol group. Their structures were precised using literature crystal data. A single asymmetrical complex of the first type was formed by symmetrical *erythro* ligands (erythritol, galactitol), while the asymmetrical D-arabinitol and D-mannitol formed pairs of isomeric species of this type. Ligands with complexing sites involving a central *threo* group (DL-threitol, xylitol) were complexed in a symmetrical manner. D-Glucitol formed four complexes as pairs of each type. Rules relating the stabilities of the complexes to the structures of the ligands are presented.

In aqueous acidic solution, molybdate ions MoO_4^{2-} react with many polyhydroxy organic compounds to form soluble complexes. Sugars and alditols form a particular class of dinuclear anionic complexes, as demonstrated by a series of polarimetric and potentiometric studies.[1–4] The enhancement of optical rotation of alditols by molybdate has been used for their identification[1] and determination,[5] and sugars were separated by paper electrophoresis in molybdate solution.[2] The crystal structures of D-mannitol complexes have been described.[6] Monosaccharide complexes in solution have been studied by ^1H and ^{13}C NMR. Some aldoses have been shown[7–10] to complex with molybdate in cyclic structures as tridentate donors. ^{95}Mo NMR has been used to demonstrate the presence of two non-equivalent Mo atoms[11] in complexes of aldoses of the *lyxo–manno* series, which chelated molybdate as tetradentate donors.

While our work on homologous complexes of alditols, including ^{95}Mo NMR spectroscopy, was in progress, a paper was published describing a ^1H and ^{13}C NMR investigation on such compounds.[12] It was stated that "alditols form four types of dinuclear molybdate complexes in which they serve as tetradentate donors with four vicinal hydroxyl groups". Although our results were mainly in agreement, important differences are presented in this paper. Several alditols were found to form small proportions of complexes unreported or poorly characterized up to now, allowing us to compare the stabilities of complexes involving various chelating sites. A specificity of our approach was the simultaneous determination of both the structures and the formation constants of the complexes, in order to establish correlations between their stabilities and the configurations of the ligands.

EXPERIMENTAL

Materials

A stock solution of disodium molybdate (Prolabo, 0.1 mol dm^{-3}) was prepared and kept in polyethylene bottles. All products were of analytical grade. Commercial alditols (Fluka or Aldrich) were used as received. Water was de-ionized in a Millipore apparatus. Potentiometric measurements were made at constant ionic strength (KCl, 0.1 mol dm^{-3}). The acid used either in potentiometric or NMR experiments was HCl.

Determination of formation constants

They were measured by potentiometry according to a procedure described previously,[11] based on the determination of the half-equivalence $pH_{1/2}$ values in acidimetric titrations of molybdate–alditol mixtures.

NMR experiments

All 1-D and 2-D NMR spectra were recorded on a Bruker AM 400 spectrometer equipped with a 5 mm multinuclear probe. Solution samples were prepared by dissolving weighed amounts of alditol (0.5 mmol) and disodium molybdate dihydrate (1.5 mmol) in 0.5 cm^3 of D_2O. Then HCl (0.75 mmol) was added. The samples were stable for several weeks at 4°C in the dark. The ^{95}Mo NMR experiments were made as before.[11]

For the ^{13}C NMR experiments, the proton coupled and decoupled spectra were obtained with nuclear overhauser enhancement. The chemical shifts were determined by the substitution method[13] using the TMPS reference signal in D_2O. 2-D heteronuclear experiments were classically performed[14] with polarization transfer from ^{1}H to ^{13}C, the number of experiments being 64×1 K. Initial assignment of ^{1}H spectra in the case of mixtures of complexes, made necessary 2-D homonuclear experiments (COSY-45).[15,16]

RESULTS

^{95}Mo *NMR*

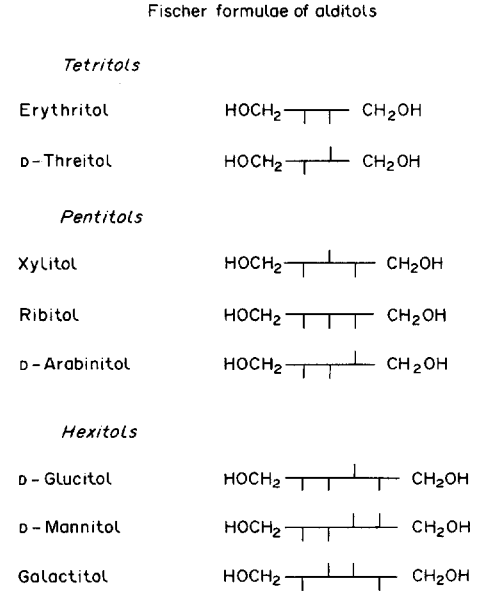
Using an excess of molybdate, the spectra of alditol–molybdate–HCl mixtures were recorded for a series of tetritols, pentitols and hexitols, showing in every case the sharp signal of free molybdate at $\delta \simeq 0$ ppm and a new broad signal ($\Delta\nu \geqslant 270$ Hz) attributed to the complex(es) (Table 1). No individual signals could be characterized in these spectra, contrary to those of complexes of some aldoses which displayed two sharper signals[11] attributed to the dinuclear Mo core. The broader signals were given by hexitol complexes, which could be a consequence of their larger molecular radii and/or of the formation of a mixture of species giving unresolved spectra. It is shown below that while galactitol formed a single complex, D-mannitol and D-glucitol formed at least two complexes. Similarly, the broad signal of the D-arabinitol complex, compared to other pentitols, can result from the formation of two different complexes.

Table 1. 26.076 MHz ^{95}Mo NMR chemical shifts and linewidths in molybdate–alditol complexes; n is the number of complexes[a]

Alditol	δ (ppm)	$\Delta\nu$ (Hz)	n
Erythritol	33.5	290	1
DL-Threitol	22.5	270	1
Ribitol	34	290	1
Xylitol	21	350	1
D-Arabinitol	29.5	450	2
D-Mannitol	31	530	2
D-Glucitol	33	730	4
Galactitol	34	550	1

Reference: Na_2MoO_4 in D_2O. Accuracy: $\delta \pm 1$ ppm.
[a] From ^{13}C NMR data.

The range of chemical shifts for all the complexes was narrow, $\delta = 21$–34 ppm, in agreement with molybdenum being in the +VI oxidation state.[17]



Scheme 1.

In fact, two polyols, namely DL-threitol and xylitol, were characterized by δ values lower than other alditols (22.5 and 21 ppm respectively) and probably formed complexes of a distinct structural type. Besides, the complexes of all other alditols had δ values varying between 29.5 and 34 ppm, which is the same range as one signal given by the complexes of aldoses of the *lyxo–manno* series[11] (two signals at 30 ± 4 ppm and 42 ± 1 ppm). The aldose 42 ppm signal had been attributed to the Mo atom bound to the anomeric HO-1 and neighbouring hydroxyls, which obviously was not possible with alditols.

It was remarked that DL-threitol and xylitol, which gave Mo signals at $\delta \simeq 22$ ppm, did not possess *erythro* diol groups, while D-mannose and D-lyxose, which gave signals at $\delta \simeq 30$ ppm, possessed an *erythro* diol group at C-2,3. This suggested that alditols giving rise to signals at $\delta \simeq 30$ ppm had a related complexing site involving also an *erythro* diol group.

^{13}C *NMR*

The spectrum of an alditol possessing *n* carbon atoms showed at most *n* signals, depending on the molecular symmetry. The assignments were readily made from literature.[18] The addition of molybdate and acid gave rise to new signals, the number and intensity of which indicated the number and relative proportions of complexes formed. Depending on the stabilities of the complexes, signals of the uncomplexed ligand could also be observed in variable proportions.

When the molybdate/alditol ratio varied from 3 to 10, the complex/free ligand ratio increased, but the chemical shifts and relative intensities of the signals remained unchanged, indicating that the ratio of the complex species and their nature was not modified.

In agreement with a previous work,[12] it was found that erythritol, ribitol, xylitol and galactitol gave only one complex each. The same result was obtained with DL-threitol. Besides, D-arabinitol and D-mannitol were found to give two complexes each, in unequal proportions, and up to four complexes were identified in the case of D-glucitol. This contrasted with the same reference[12] in which only one complex was reported for D-mannitol and three for D-glucitol.

The principle of the ^{13}C NMR identification of the chelating sites of the ligands lies on the important deshielding effect on carbons bearing the hydroxyls bound to molybdate.[7–12] These carbons also show increased direct coupling constants $^1J_{CH}$. Consequently, our study required the assignment of the different carbons in the complexes, which was achieved through 2-D heterocorrelated C–H NMR experiments. In every case, the comparison of the spectra of the free and complexed alditol demonstrated that four vicinal carbons were deshielded. The variations of chemical shifts due to complexation ($\Delta\delta$) were calculated and are given in Tables 2–5. The assignments were confirmed by the corresponding variations of the direct coupling constants $^1J_{CH}$. Unless contrary mention, the results were in agreement with literature data.[12]

Galactitol. The spectra (Table 2) of the single complex showed that the characteristic signals of the CH_2OH groups were almost unchanged, proving that complexation involved the four central secondary hydroxyls, which were in a symmetrical (*meso*) configuration. However, the ligand symmetry was destroyed in the complex, since the chemical shift for C-4 (+19.7 ppm) was much higher than those for C-2,3,5 (+7.9–11.8 ppm). This result was unexpected, because the dinuclear Mo core also had a symmetrical structure. Possible reasons for this finding are presented in the Discussion.

Erythritol. This tetritol formed a single asymmetrical complex involving all four hydroxyls. A comparison (Table 2) with the $\Delta\delta$ values calculated for the CHOH groups of galactitol showed a strong analogy, which was not unexpected because both alditols have a central *erythro* diol group. It was remarked that the deshielding effect of complexation on a carbon of the chelating site was nearly the same, whether it bore a central secondary or a terminal primary hydroxyl.

Ribitol. The formation of an asymmetrical complex was expected for this pentitol, because one of the terminal hydroxyls must be involved in complex formation. Accordingly, carbons C-2,3,4,5 were deshielded (Table 2) and displayed increased coupling constants. As in the galactitol and erythritol complexes, one carbon was more strongly deshielded than the others ($\delta \simeq 17$ ppm for C-4), suggesting the ribitol complex to belong to the same type.

Xylitol. Like ribitol, this symmetrical *meso* pentitol formed an asymmetrical complex involving one terminal hydroxyl (Table 3). The chelating site involved carbons C-1,2,3,4. Contrary to that found in the above complexes, the central carbons C-2,3 were equally deshielded ($\Delta\delta \simeq 10.3$ ppm) but less than the lateral carbons C-1,4, which were also equally deshielded ($\Delta\delta \simeq 12.5$ ppm).

DL-*Threitol.* This compound formed a single complex which has not been described heretofore. Data in Table 3 showed a strong analogy with the xylitol complex, when carbons C-1,2,3,4 having related positions were compared. The internal C-4 of xylitol had a $\Delta\delta$ value (> 12 ppm) close to that

of the terminal C-4 of threitol, i.e. higher than the typical value ($\simeq$ 10 ppm) for other CHOH groups. Thus the deshielding effects were similar for a CHOH or CH_2OH group in related position, as in galactitol and erythritol complexes. Moreover, the similar deshielding effects at C-1,4 ($\Delta\delta$ = 12.2 ppm) and C-2,3 ($\Delta\delta$ = 9.8 ppm) indicated that the ligand was complexed in a symmetrical fashion, contrary to galactitol and erythritol. The same was probably true for the above xylitol complex.

These results indicated the existence of at least two types of molybdate complexes, depending on the alditol configurations. One type corresponded to *threo* compounds (xylitol and DL-threitol). The second type was obtained with *erythro* compounds, typically erythritol and galactitol, and probably included ribitol.

D-*Arabinitol.* Two complexes in 60 : 40 ratio were detected in the ^{13}C NMR spectrum, in accordance with literature results. The first one, symbolized as A_1 was that previously identified,[12] involving C-2,3,4,5, since the C-1 signal remained almost unchanged (Table 4). A comparison with the chemical shifts in the galactitol complex showed a striking similarity, indicating an analogous structure of both ligands, as expected because of the identical configurations of the three carbons C-2,3,4. The second minor complex, noted A_2, which had not been characterized in literature, was formed by the same tetritol group, C-2,3,4,5 (the C-1 signal was slightly modified) but the chemical shifts were different from those of the major A_1 complex. The most striking feature was that the more deshielded carbon ($\Delta\delta \simeq 20$ ppm) was C-3 in A_2 instead of C-4 in A_1 and that the overall deshielding patterns were reversed, the variations of chemical shifts

[a] $^{1}J_{CH}$ = 141 Hz for all carbons of uncomplexed D-glucitol. δ assigned from literature.[18] ND: not determined. Accuracy: $\delta \pm 0.1$ ppm; $J \pm 1$ Hz.

being related in the sequences C-2,3,4,5 in A_1 and C-5,4,3,2 in A_2.

D-*Mannitol.* Two complexes in 70:30 ratio, which were called M_1 (major species) and M_2, could be identified (Table 4). Both species involved the tetritol group at C-3,4,5,6 and were analogous to those described for D-arabinitol, in accordance to the related configurations of C-2,3,4 of arabinitol and C-3,4,5 of mannitol.

This makes surprising the report that only one complex (the M_1 species) was formed by D-mannitol, while both A_1 and A_2 species had been detected for D-arabinitol in the same study.[12] Such discrepancies may be due to the difference in techniques for preparing the complexes, since we used sodium molybdate acidified with varying amounts of HCl instead of ammonium molybdate.

D-*Glucitol.* The spectrum of this hexitol in acidified molybdate showed 24 new signals in addition to those of uncomplexed ligand, due to the formation of four complexes referred as G_1 (32%), G_2 (26%), G_3 and G_4 (21% each) (Table 5). The spectra of species G_1 (molybdate bound to C-1,2,3,4) and G_2 (molybdate bound to C-3,4,5,6) have been already reported in literature, a third complex being believed to involve all secondary hydroxyl groups, from the products of its periodate oxidation.[12] The patterns of variations of chemical shifts were typical of the "xylitol type" for G_1 and of the "arabinitol type" for G_2

Unambiguous assignments for the G_3 and G_4 complexes were not possible because homonuclear ^1H 2-D experiments were precluded, owing to the large number of overlapping signals. However, using only ^{13}C NMR data, we found that the G_3 species was characterized by two unchanged signals for the CH_2OH groups, and therefore involved C-2,3,4,5 as the chelating system. The G_4 species had one unchanged CH_2OH signal and since only one complex could be imagined when C-1 was involved (the "xylitol type" G_1), the complexed hydroxyl was assigned to C-6. Thus G_4 had the same complexing site as G_2 at C-3,4,5,6 (arabinitol-like configuration) and the G_2–G_4 couple corresponded to the homologous couples of complexes observed with D-arabinitol and D-mannitol.

Tentative assignments for G_4 were made by considering that the C-3,4,5 systems had the same configurations in D-glucitol and in D-mannitol. Thus the variations of chemical shifts were assumed to be similar in complexes M_2 and G_4, as they were in the M_1–G_2 pair.

Possible assignments for G_3 were proposed by analogy with the xylitol-type complex G_1, since the chelating sites of both species involved the same *xylo* group at C-2,3,4.

Formation constants of the complexes

The potentiometric determination of the formation constants was made according to the method described previously.[11] Two equilibria were observed in molybdate–alditol(L)–H^+ systems:

$$2MoO_4^{2-} + L + 2H^+ \rightleftharpoons (2,1,2)^{2-}$$

$$2MoO_4^{2-} + L + 3H^+ \rightleftharpoons (2,1,3)^{-}.$$

The corresponding equilibrium constants K_{212} and K_{213} defined the formation constants of the complexes in the classical way.[11] The equilibrium between the (2,1,2) and (2,1,3) species was characterized by the pK_a value relative to reaction:

$$(2,1,3)^- \rightleftharpoons (2,1,2)^{2-} + H^+.$$

The values of the formation constants are presented in Table 6. Good agreement was observed with literature values[19–21] when available.

DISCUSSION

This part will be devoted to the examination of factors governing the relative stabilities of the molybdate complexes, with emphasis on those related to the structures of the ligands. Only the (2,1,2) species will be considered, since the acidic (2,1,3) complexes were not characterized by NMR. However, the stabilities of both series of complexes should be strongly related, because the corresponding pK_a values show little differences.

The first problem to be considered was the origin of the different behaviours of the homologous tetritols, erythritol and threitol, which differed only by the configuration of one CHOH group. It resulted in two important effects, first the existence of a symmetrical complex with threitol, while the erythritol one was asymmetrical, and second the higher stability of the erythritol complex. The former result was surprising because both ligands have symmetrical structures. The relationship between stabilities and structures is not simple and is discussed below. Besides, the problem of symmetry, which concerned also pentitols and hexitols, was discussed using available literature data[6,23–26] on the structures of related molybdate complexes.

Molybdate complexes of D-lyxose[23] and polyols[6,26] possess a dinuclear core bridged by three oxygen atoms, two of them being triply-bonded. Each molybdenum atom is also bound to one oxygen atom of the ligand. This unusual dimolybdate group is not typical of carbohydrate complexes, as similar structures have been reported for some complexes of quinones[24] and catechol[25] derivatives. The geometry of the acceptor site can be

Table 6. Formation constants of molybdate–alditol complexes (KCl 0.1 M, 25°C) determined by potentiometry. $\log K_{xyz}$ refers to the formation of the (x,y,z) species from x MoO_4^{2-} y alditol and z H^+. K_a is the acidity constant of the (2,1,3) complex

schematized by projecting, perpendicularly to the medium plane of the dimolybdate core, the four bonded oxygens which form either a stretched diamond[6,23,26] or a parallelogram (naphthalenediol complex[25]) as shown in Fig. 1. The fitting of this quadrilateral with the figure drawn by the donor groups of a ligand was checked using molecular models.

A first type of complex was characterized with alditols possessing a complexing site involving a central *erythro* group (erythritol, galactitol, ribitol). As established by NMR, D-mannitol and D-arabinitol belonged to this type, corresponding to types *A* and *C* in the literature.[12] The known crystal structures of the D-mannitol[6] and erythritol complexes[26] could then be used as models for the whole series. The four carbons of the complexing site must adopt a sickle arrangement allowing their four hydroxyls to point in the same direction, forming a trapeze which did not match exactly the acceptor site. Accordingly, the molecule must twist at one internal carbon as shown in Fig. 1(a). It agreed with the NMR result that one of the central carbons in the ligands was more strongly deshielded (Tables 2 and 4) than the other one.

In fact, we observed that two ligands (D-mannitol, D-arabinitol) formed a pair of complexes, with reversed deshielding patterns, involving the same chelating site: C-2,3,4,5 for arabinitol complexes A_1–A_2 and C-3,4,5,6 for mannitol complexes M_1–M_2. Accordingly, the scheme in Fig. 1(a) predicted that two isomers could be formed when the lateral carbons of the complexing site bore different substituents R and R′, depending on the site of twisting. Their proportions were not equal, the favoured isomer being that in which the more deshielded carbon bore the shortest side chain, i.e. a CH_2OH group. In contrast, one isomer only could be formed by symmetrical ligands (R = R′) like erythritol and galactitol.

Ribitol was remarkable among ligands forming asymmetrical complexes of the *erythro* type, since it gave a single complex instead of two. It was assumed that one complex was much less stable than the other, for reasons similar to those invoked in the case of D-arabinitol. Moreover, the existing complex had a low stability because in the sickle arrangement of the C-2,3,4,5 complexing site, an unfavourable steric interaction existed between C-1 and C-5. The high $\Delta\delta$ value at C-2 (Table 2) may reflect some strain due to this interaction, which did not occur in the D-arabinitol complex possessing the opposite C-2 configuration.

Considering that types *A* and *C* differed only by the possible substitution of one external carbon, which was not associated with a particular deshielding effect, no reason was found to make a distinction between them.

A second type of complex was formed by ligands possessing only *threo* diol groups (DL-threitol and xylitol) which had a carbon chain in a zig-zag arrangement. They were referred to as type *B* and type *D* in the literature.[12] Four hydroxyls already point towards the four tops of a parallelogram, which could not match the acceptor site described above for the *erythro* series. Considering the symmetry of the complexation site, demonstrated by NMR, it seemed likely that the acceptor

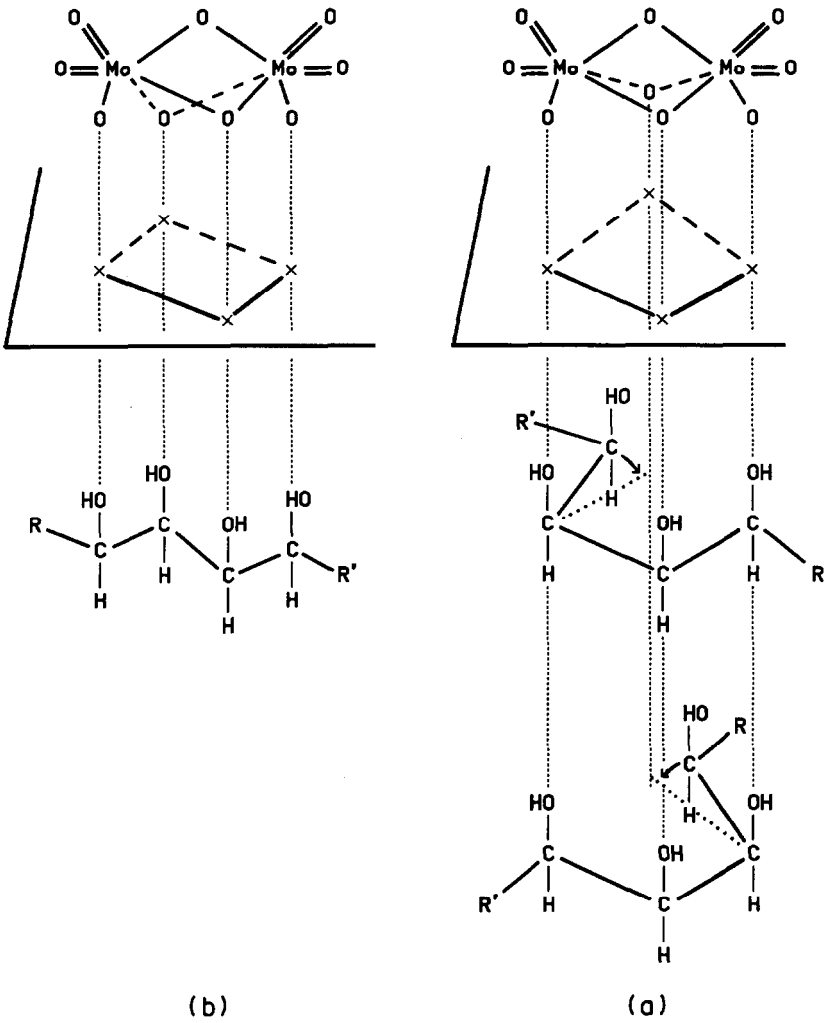

Fig. 1. Schematic representation of the chelation of the dimolybdate core by four vicinal hydroxyls of an alditol molecule. R and R′ are either H or CH_2OH groups. (a) Complexes of *erythro* type, showing the formation of a pair of isomers depending on the site of twisting. The dimolybdate structure is that reported in the D-mannitol,[6] D-lyxose[23] and erythritol[26] complexes. (b) Complex of *threo* type. The proposed symmetrical dimolybdate structure is that observed in the naphthalene-2,3-diol[25] complex.

site had rather a parallelogram shape (in planar projection), allowing the ligands to complex molybdate without appreciable loss of symmetry. The proposed structure, which had never been characterized by X-ray studies in literature, was in agreement with NMR data. Figure 1(b) shows that the triply-bonded oxygens are borne by the internal carbons of the ligand complexing sites, and that the doubly-bonded oxygens are borne by the external carbons. Accordingly, these pairs of carbons were found to be respectively equally deshielded.

Finally, there is no more reason to differentiate between types *B* and *D* than between types *A* and *C*. Moreover, ^{95}Mo NMR afforded a supplementary criterion to distinguish between both types, since complexes of the *threo* type (*B–D*) gave a Mo signal at $\simeq$ 22 ppm while those of the *erythro* type (*A–C*) gave a Mo signal at $\simeq$ 30–34 ppm.

D-Glucitol had a unique behaviour, forming complexes belonging to both types in comparable proportions. All four possible complexes allowed by the structure of this hexitol were detected by ^{13}C NMR:

(1) A *threo* complex G_1, in which the complexing site involved C-1 and the C-2,3,4 *xylo* system.

(2) and (3) A pair of *erythro* complexes G_2 and G_4, in which the complexing site involved C-6 and the C-3,4,5 *arabino* system.

(4) A *threo* complex G_3, involving the four internal CHOH (the *gluco* system) at C-2,3,4,5.

Thus three different sites competed to complex molybdate, and formed species of comparable stabilities. The following discussion examines the relationship between the formation constants and the structural types of the various complexes.

In the *erythro* series, the stability order was: erythritol < ribitol < arabinitol < mannitol < galactitol. The favourable effect of increasing the chain length was correlated with the replacement of CH_2OH groups by CHOH groups in the chelating site. Among hexitols, the highest stability of the galacticol complex was attributed to the favourable configurations of C-2,5, which orientated the terminal CH_2OH groups far away from the complexing site. Such influence of the C-2 configuration also accounted for the relative stabilities of pentitol complexes: D-arabinitol > ribitol. The D-arabinitol complexes were almost as stable as the D-mannitol ones, probably because their complexing sites differed only by the size of the substituent on a lateral carbon.

Thus two rules appeared to govern the stabilities of *erythro* complexes. Rule 1: complexing sites in which the lateral carbons bore secondary hydroxyls gave more stable complexes than those using terminal CH_2OH groups, because of corresponding entropy gain.[22] Rule 2: alditols possessing lateral CHOH groups orientated *threo* with respect to the central *erythro* groups formed complexes of higher stabilities than those with lateral groups orientated *erythro*, since no steric interaction took place between the complexing site and the uncomplexed side chains.

In the *threo* series, the order of stabilities of the complexes xylitol > threitol, was in agreement with Rule 1. The presence of a *threo–threo* system in xylitol resulted in a high stability of the complex, indicating that Rule 2 probably applied. However, the corresponding enhancement of the formation constants (Table 6) seemed more important in this series than in the *erythro* one, making the xylitol complex almost as stable as the D-arabinitol ones. It was concluded that Rules 1 and 2 were also valid in the *threo* series.

We also examined the relative stabilities of complexes belonging to both series. An essential result was that the erythritol complex was more stable than the threitol one, suggesting that an *erythro* diol group had a stronger affinity towards molybdate than a *threo* group. In this respect, the reactions of D-arabinitol and D-mannitol afforded an interesting comparison of the reactivities of *erythro* and *threo* diol groups borne by the same ligand. Both alditols formed two complexes, but none involved the *threo* group in the central position of the four chelating hydroxyls. The complexing sites in both pairs of complexes had a central *erythro* group (C-3,4 in arabinitol and C-4,5 in mannitol). In the case of D-mannitol, the *threo* type complex, involving C-2,3,4,5, was not detected, although it would involve only CHOH groups and should be stabilized according to Rule 1.

These results were formulated as Rule 3: complexes involving a central *erythro* group were generally of higher stabilities than those involving central *threo* groups.

The combined effects of Rules 2 and 3 were unfavourable to the formation of complexes of the *threo* series: when a ligand bore simultaneously an *erythro* group and a *threo* group, (a) complex(es) in which the complexing site(s) involved a central *erythro* group and a lateral *threo* group was stabilized with regard to complexes with a central *threo* group and a lateral *erythro* group. Only in the case of D-glucitol, we were able to detect a complex involving an *erythro–threo* system with the *threo* group in the central position. This G_3 species was expected to have a higher stability, because its complexing site C-2,3,4,5 did not involve any CH_2OH group (Rule 1). Therefore a complexing site of *gluco* configuration (*erythro–threo–threo*) had probably a low affinity for molybdate. Besides, in D-mannitol, the complexing site C-2,3,4,5 of *manno* configuration (*erythro–threo–erythro*) had even lower affinity for molybdate, in agreement again with predictions made by combining Rules 2 and 3.

Finally, the formation constants showed a close correlation with those reported for homologous tungstate complexes,[22] molybdate complexes being about three orders of magnitude less stable. This stability difference did not depend on the nature of the ligand and was ascribed[11] to the easier dimerization of tungstate. Consequently, it was concluded that the structural characteristics of an alditol similarly affected the stabilities of the complexes of both elements.

ALCOHOLS AS SOURCES OF HYDROGEN IN HYDROFORMYLATION OF ALKENES

JOANNA K. MacDOUGALL and DAVID J. COLE-HAMILTON*

Chemistry Department, University of St Andrews, St Andrews, Fife KY16 9ST, Scotland, U.K.

(*Received* 1 *February* 1990; *accepted* 14 *February* 1990)

Abstract—Heating hex-1-ene in the presence of alcohols, CO and $[RhH(PEt_3)_3]$ gives, as the major products, heptanol and 2-methoxyhexanol with the hydrogen source being the alcohol.

In successful catalysed reactions of alkenes with CO in the presence of alcohols, the normal products are esters formed by Reppe type chemistry [eq. (1)][1]

$$RCH{=}CH_2 + CO + R'OH \longrightarrow RCH_2CH_2COOR'. \quad (1)$$

We have recently demonstrated that certain group 8 metal complexes are highly efficient for the dehydrogenation of alcohols,[2–4] and have extended the investigation to the use of such catalysts in reactions of alcohols with alkenes in the presence of CO. We now report for the first time, the selective formation of higher alcohols from alkenes, the extra carbon atom coming from CO and the hydrogen from the alcohol solvent. The only related reactions that have been reported are those in which alcohols act as hydrogen sources in the formation of diethylketone from ethene, CO and the alcohol [eq. (2)][5]

$$2C_2H_4 + CO + R''_2CHOH \longrightarrow Et_2CO + R''_2CO. \quad (2)$$

Water has been used as a hydrogen source in rhodium-catalysed hydroformylation reactions, and alcohols can be the major products,[6] although in these systems addition of excess base is essential.

Table 1 lists the products formed when various alcohols are heated with hex-1-ene in the presence of CO and $[RhH(PEt_3)_3]$. In all cases, the major products are heptanol and 2-methylhexanol. The formation of alcohols rather than aldehydes has also been observed[7] in conventional hydroformylation reactions, carried out in alcohol solvents, catalysed by $[RhH(PEt_3)_3]$.

The formation of heptanol from the reaction of hex-1-ene, CO and alcohols can be represented by eq. (3). 2-Methylhexanol is formed similarly by Markownikoff addition across the double bond

$$C_4H_9CH{=}CH_2 + CO + 2RCH_2OH \longrightarrow C_4H_9CH_2CH_2CH_2OH + 2RCHO. \quad (3)$$

Examination of Table 1 shows that the yield of C_7 alcohol decreases as the steric bulk of the donor alcohol increases, whilst the selectivity to straight-chain C_7 alcohol (heptanol) increases. Adding excess PEt_3 to the reaction using alcohols as the hydrogen source generally has little effect on the straight-branched selectivity of the reaction, although in all cases the yield of C_7 alcohol increases. This observation, together with the finding that the conversion also increases as the CO pressure is reduced at least above 20 atm (see Table 2), suggests that the most active catalytic species has a high PEt_3 content and a low CO content.

Although for linear donor alcohols, C_7 aldehydes are only observed in trace amounts in this reaction, other products are present mostly in $< 10\%$ yield although their yields are higher in the presence of excess PEt_3 than in its absence. For ethanol, these products include the Reppe products, ethyl heptanoate (EH) and ethyl(2-methyl)hexanoate

(E2MH) and straight and branched isomers of heptylheptanoate (HH), as well as heptyl ethanoate (HE) and 2-methylhexylethanoate (2MHE). The origin of the last two products is less certain, but is currently under active study. One other type of product, ethylethanoate in the case of ethanol, is also produced, in quite high yield if excess PEt_3 is present. It is probable that this product arises from acetaldehyde, formed from the dehydrogenation of ethanol.

Detailed speculation on the mechanisms of these unusual reactions is not possible at this stage, but the observation that the rate of reaction is low for propan-2-ol, which is normally considered to be the best of the hydrogen donors, but substantially higher for methanol, the least good hydrogen donor studied, suggests that steric effects may be very important in determining the rate of the reaction. This and other mechanistic aspects are currently under active investigation.

Table 2. Effect of pressure on yield and selectivity for C_7 alcohols[a]

	Pressure (CO)	Temperature (°C)	C_7 alcohols (%)	$n:i$ Ratio

PREPARATION OF $[Mo_2(O_2CCH_3)_4]$ AND $[CrMo(O_2CCH_3)_4]$ FROM M^{II} DERIVATIVES (M = Cr, Mo)

JOSÉ C. MENEZES and CARLOS C. ROMÃO*

Laboratório de Química Inorgânica, Instituto Superior Técnico, Av. Rovisco Pais, 1096 Lisboa Codex, Portugal

(*Received* 7 *November* 1989; *accepted* 27 *February* 1990)

Abstract—The compounds $[Mo_2(O_2CCH_3)_4]$ and $[CrMo(O_2CCH_3)_4]$ are conveniently prepared in 40–50% yields from acetic acid/acetic anhydride solutions and, respectively, $[Mo_2Br_4(CO)_8]$ or a mixture of $[Mo_2Br_4(CO)_8]$ and $CrCl_2$. An improvement in the preparation of $[Mo_2(O_2CCH_3)_4]$ from $Mo(CO)_6$ and acetic acid is also described.

In the course of a project aimed at the study of the chemistry of $[Mo_2(Allyl)_4]$ and the possible preparation of the heteronuclear analogues $[CrMo(Allyl)_4]$ and $[MoW(Allyl)_4]$,[1] we were faced with the repeated preparation of $[Mo_2(O_2CCH_3)_4]$ (**1**) and $[CrMo(O_2CCH_3)_4]$ (**2**). As Cotton and other workers pointed out,[2] the classical preparation of **1**, from $Mo(CO)_6$ and acetic acid,[3] gives rather low yields. The use of carefully purified diglyme as solvent improves the yield of this synthetic method, but is rather time consuming.[4] We also found that the preparation of **2**, by the original method of Garner and Senior[5] gave erratic and low yields well below the 30% originally reported.

Recently, Cotton and Poli reported a new approach to the formation of Mo≡Mo bonds starting from molybdenum(II) carbonyl complexes, namely $[Mo_2X_4(CO)_8]$ (X = Cl, Br, I).[6] In the following we describe our results on the use of this method for the preparation of **1** and **2**, which also led to a very simple and effective improvement of the classical preparation of **1**.

RESULTS AND DISCUSSION

A mixture of acetic acid (HOAc) and acetic anhydride (Ac_2O) was added to freshly prepared $[Mo_2Br_4(CO)_8]$ (**3**), at −40°C, and the resulting slush warmed to room temperature, stirred overnight and finally refluxed for 4 h. After concentration and filtration, **1** was isolated as yellow microcrystals in 57% yield. This convenient preparation of **1** from a molybdenum(II) complex, formally a $MoBr_2$ derivative, suggested that the heteronuclear analogue **2** could be prepared from **3** and $CrCl_2$. A mixture of freshly prepared **3** and a six-fold excess of $CrCl_2$ was therefore treated with HOAc at −40°C, warmed and further refluxed for 2 h. Sublimation of the solid residue left after solvent evaporation allowed the isolation of **2** in 11% yield. However, we found out that this yield can be easily and reproducibly increased to 40% if the cold reaction mixture is brought from −40°C directly into a pre-heated silicone bath at 120°C and left at reflux for 2 h. The better yield and the much shorter reaction time needed make this a very convenient preparation of the heteronuclear complex $[CrMo(OAc)_4]$ (**2**).

Interestingly, a similar effect of the sudden temperature rise was observed in the already mentioned classical preparation of **1**. Indeed, when the suspension of $Mo(CO)_6$ in $HOAc/(Ac)_2O$ is brought directly from room temperature into a pre-heated silicone bath at 120–130°C, the yield of recovered **1** increases from the normal 15–25%,[2] obtained through gradual heating of the reaction mixture, to a reproducible 52–53% yield. Using a 20 g scale of $Mo(CO)_6$, the yield can only be kept at the latter level if a small amount of toluene is added to the

* Author to whom correspondence should be addressed.

reaction mixture in order to wash the sublimed hexacarbonyl back into the reaction vessel.

The origin of the influence of the sudden temperature jump upon the observed yield is unclear. It certainly reflects the existence of a balance between thermodynamically and kinetically controlled reaction pathways for the evolution of the reaction intermediates. In fact, the complexity of this reaction system is confirmed by the wide variety of by-products that have been isolated from it.[2b] However, the organometallic literature provides examples of the clean preparation of $[Mo_2(O_2CR)_4]$ from $[Mo(\eta^6\text{-}C_7H_8)(\eta^3\text{-}C_3H_5)_2]$ and $[Mo(\eta^6\text{-}C_7H_8)(\eta^3\text{-}C_3H_5)X]_2$ (X = Cl, O_2CR) and the corresponding carboxylic acids.[7] The yields exceed 80% and the chemistry seems to imply the formation of a stabilized "$Mo(O_2CR)_2$" fragment, $[Mo(\eta^6\text{-}C_7H_8)(O_2CR)_2]$, that decomposes at room temperature to give $[Mo_2(O_2CR)_4]$.

It is therefore tempting to speculate that the sudden temperature rise favours the formation of a carbonyl stabilized "$Mo(O_2CR)_2$" species, e.g. "$Mo(O_2CR)_2(CO)_4$" (or the carboxylato bridged dimer $[\{Mo(CO)_4\}_2(\mu\text{-}O_2CCH_3)_2]$) and/or a rapid decarbonylation of these species to give $[Mo_2(O_2CR)_4]$. In either case the formation of side products is expected to be disfavoured.

A similar effect can be present when one starts from **3** in which case, to the further advantage of the Mo≡Mo bond formation process, a pre-existing bridging situation between the two molybdenum atoms already exists. The likely formation of halide bridges between chromium and molybdenum in the mixture of **3** and $CrCl_2$ can possibly improve the formation of the heteronuclear quadruple Cr—Mo bonds in **2**.

EXPERIMENTAL

All reactions were performed under an argon atmosphere using standard vacuum line and Schlenk techniques. Solvents were dried by standard techniques and distilled under argon atmosphere.

Samples of $[Mo_2(O_2CCH_3)_4]$,[3] $[CrMo(O_2CCH_3)_4]$[5] and $[Cr_2(O_2CCH_3)_4]\cdot(H_2O)_2$[8] were prepared according to published procedures. Anhydrous $CrCl_2$ was prepared from dehydrated $[Cr_2(O_2CCH_3)_4]\cdot(H_2O)_2$ by bubbling dry gaseous HCl through a suspension in CH_2Cl_2 for 4 h. The white precipitate was filtered, washed with CH_2Cl_2 and dried *in vacuo*. $[Mo_2Br_4(CO)_8]$ was prepared according to the published procedure.[9] After addition of Br_2 to $Mo(CO)_6$ the solvent (CH_2Cl_2) was evaporated at low temperature and the residue used immediately without further purification.

Perkin-Elmer 457, 683 and 1330 IR spectrometers were used to record the IR spectra of the compounds in KBr pellets prepared under Argon. Mass spectra were obtained on a Varian Mat 112S apparatus.

Preparation of $[Mo_2(O_2CCH_3)_4]$ (**1**)

(a) *From* $[Mo_2Br_4(CO)_8]$ (**3**). Acetic acid (110 cm^3) and acetic anhydride (40 cm^3) were added to solid **3**, at −40°C, freshly prepared from $Mo(CO)_6$ (1 g, 3.8 mmol). The mixture was stirred, left to warm to room temperature overnight and finally refluxed for 4 h. Upon slow cooling to room temperature a fine yellow precipitate formed. The mixture was further concentrated to *ca* 1/4 of the initial volume and filtered. The residue was washed several times with benzene and dried *in vacuo*. It was identified as $[Mo_2(O_2CCH_3)_4]$ by its IR and mass spectra. The yield was 0.46 g, 57% referred to $Mo(CO)_6$.

(b) *From* $Mo(CO)_6$. A mixture of $Mo(CO)_6$ (20 g, 76 mmol), acetic acid (100 cm^3), acetic anhydride (70 cm^3) and toluene (10 cm^3) was made at room temperature. The Schlenk tube containing this reaction mixture was fitted with a reflux condenser and transferred to a pre-heated silicone bath at 120°C. Reflux was maintained for 20 h. The reaction mixture was cooled to room temperature and concentrated to 1/2 of the original volume. A brownish precipitate was filtered off and thoroughly washed with CH_2Cl_2 and dried *in vacuo*. The yield of pure $[Mo_2(O_2CCH_3)_4]$ was 8.5 g or 52% referred to $Mo(CO)_6$.

Preparation of $[CrMo(O_2CCH_3)_4]$ (**2**)

To a Schlenk tube containing freshly prepared $[Mo_2Br_4(CO)_8]$ (0.28 g, 0.4 mmol), a six-fold excess of $CrCl_2$ (0.56 g, 4.6 mmol) was added. Acetic acid (100 cm^3) was added to this mixure at −40°C. The flask was then transferred to a pre-heated silicone bath at 120°C and left to reflux gently for 2 h with stirring. After cooling to room temperature the reaction mixure was taken to dryness and the solid residue sublimed *in vacuo*. The pale yellow product, sublimed at 170–200°C and 10^{-2} torr, was resublimed to give 0.12 g (40% referred to molybdenum) of pure $[CrMo(O_2CCH_3)_4]$, identified by comparison of the IR and mass spectra with those of an authentic sample.

Acknowledgement—We thank Professor A. Ferrer Correia of the Universidade de Aveiro for the use of mass spectral facilities.

RUTHENIUM(II)–BIPYRIMIDINE COMPLEXES: CHARACTERIZATION, SPECTROSCOPY AND PHOTOANATION STUDIES

MIRZA M. TAQUI KHAN,* RAMESH C. BHARDWAJ and CHHAYA BHARDWAJ

Central Salt & Marine Chemicals Research Institute, Bhavnagar—364 002, India

(*Received* 13 *April* 1989; *accepted* 2 *November* 1989)

Abstract—Preparation, characterization and photoanation studies of ruthenium(II) complexes with bipyrimidine are reported. Fluorescence and electrochemical studies have also been conducted. The quantum yield has been calculated for photoanation studies of the complex $[Ru(bipym)_3](PF_6)_2$.

The photochemistry and photophysics of the $Ru(bpy)_3^{2+}$ cation have been intensely investigated[1] during the past decade with a view to develop suitable solar energy conversion catalysts. The study of this species in the excited state has contributed greatly to the understanding of other related photocatalytic molecules[2,3] such as $Ru(bpz)_3^{2+}$ (bpz = bipyrazyl) cation. The $Ru(bipym)_3^{2+}$ (**1**) (bipym = bipyrimidine) cation, which is analogous to $Ru(bpy)_3^{2+}$, is also an excellent photocatalyst[4] and has an added advantage over $Ru(bpy)_3^{2+}$ and $Ru(bpz)_3^{2+}$ as there is no quenching[3] of its emission by molecular oxygen. As in the case of $Ru(bpz)_3^{2+}$ the emission of $Ru(bipym)_3^{2+}$ is quenched by protons at pH < 1, indicating a slightly enhanced basicity of its excited state compared to the ground state. There is, however, no change[4] in the emission of **1** at pH 4.5–8; the formal reduction potential of $Ru(bipym)_3^{2+}$. The presence of the bipyrimidine ligand thus shifts the redox potential to a more positive value compared to the corresponding bipyridine and bipyrazine complexes.

Protonation studies of bipyridine, bipyrazine and their ruthenium(II) complexes have been reported.[3] Recently, protonation of 1,10-phenanthroline in aqueous dioxane was conducted by Ishiguro *et al.*[5] Protonation of 2-pyrimidyl and the 2-pyrazylpalladium(II) complex was reported by Crociani *et al.*[6]

The complexes of bipyrimidine, therefore, have the inherent potential to be better oxidizing photocatalysts than the analogous complexes of bipyridine and bipyrazine. Besides, protonation of bipyrimidine is expected to yield species with even more positive oxidizing potentials than the neutral species, providing a handle to change its redox behaviour in suitable photoreactions.

In this paper we report the synthesis, characterization, fluorescence and electrochemical studies and photoanation (quantum yield) studies of ruthenium(II)–bipyrimidine complexes.

RESULTS AND DISCUSSION

The elemental analysis and conductivity of the complexes are given in Table 1. The conductivity of the acetonitrile complexes shows that complexes **1** and **2** are 1:2 electrolytes, complex **5** is a 1:1 electrolyte and complexes **3**, **4** and **6** are non-electrolytes.

The IR spectra of the complexes show a weak peak at 480–495 cm^{-1} assigned to the (Ru—N) stretching frequency. The absence of a peak at 310 cm^{-1} in complexes **1** and **2** suggests that the chlorides are in the outer coordination sphere of the metal ion. The peaks at 320 and 310 cm^{-1} in complex **3** can be assigned to the (Ru—Cl) stretching of *cis*-chlorides. The peak at 510 cm^{-1} in **3** can be assigned to the (Ru—P) stretching. The ^{31}P NMR of **3** gives a singlet at 21.49 ppm suggesting a *trans* disposition of the coordinated triphenylphosphine. Complex **4** exhibits a single peak at 315 cm^{-1} corresponding to the (Ru—Cl) stretching of *trans*-

chlorides. Complex **5** exhibits (Ru—Cl) at 315 cm^{-1}. The IR spectral data are given in Table 2.

The electronic spectra of complexes **1–6** show low-energy bands in the visible region at 24,271 cm^{-1} assigned to ruthenium(II) to bipyrimidine MLCT charge-transfer. The higher energy bands at 30,120 and 40,650 cm^{-1} are π–π^* transitions within the bipyrimidine molecule. The band at 22,123 cm^{-1} in the spectrum of complex **1** is a *d* π–π^* MLCT transition. Similar bands were reported for analogous ruthenium(II) bipyridyl complexes.[7] The two major peaks in the UV spectra are essentially independent of the nature of the complex and are assigned to π–π^* transitions within the bipyrimidine rings. The weaker absorption near 40,650 cm^{-1} can be assigned to a higher energy MLCT. The major shoulder near 22,123 and 24,271 cm^{-1} can be either a *d–d* band or a second MLCT transition. The results are tabulated in Table 2.

Luminescence studies

Luminescence spectra of the complexes were taken in aqueous solution and are uncorrected. The

Key: s = strong; vs = very strong; w = weak and m = medium.

emission spectra of complex **1** shows a strong intensity peak at 611 nm which seems to be $d\pi^*$ in origin. The substitution of chloride by PF_6 shows a blue shift of the λ_{em} maximum which is observed at 602 nm with slightly lower intensity. The emission intensity of complexes **1** and **2** does not change in the pH range 4.5–8. At lower pH the emission intensity rapidly decreased and no emission was observed below pH 1, indicating a slightly enhanced basicity of the excited state of $Ru(bipym)_3^{2+}$. Complex **3** gave λ_{em}(max) at 546 nm which is due to replacement of two bipyrimidine molecules, responsible for fluorescence. The removal of one bipyrimidine molecule has shown a blue shift in complex **4**, where λ_{em}(max) is at 533 nm. The addition of CH_3CN and Cl to the coordination sphere of the metal ion in complex **5** shows a red shift for the emission wavelength at 644 nm. Addition of NO_2 also exhibits a red shift at 750 nm. The red shift in the emission wavelength is very important because the energy utilized for the excitation wavelength is also less. This fact is helpful for the utilization of these complexes in the visible part of the solar spectrum (with less energy) to realize the harnessing of solar energy. The λ_{em} maximum of complexes **1–6** is given in Table 3.

Electrochemical studies

Polarographic $E_{1/2}$ data for ruthenium(II) bipyridimine complexes in aqueous solution with SCE as reference electrode in 0.1 M KNO_3 as supporting electrolyte are compared with those of their bipyridyl analogues. The $E_{1/2}$ value of $Ru(bipym)_3^{2+}$ with bipyrimidine results in a shift of the reduction potentials to more positive values by about 0.5 V. Similar results were reported when bipyridyl was replaced by bipyrazyl ligand.[8] The replacement of bipyrimidine in complex **4** by CH_3CN or NO_2 shows a less positive (more negative) reduction potential because of good σ-donor and poor π-acceptor behaviour of CH_3CN and NO_2 compared to Cl^-, PPh_3 or bipyridine. The shift of the reduction potential to negative values by the replacement of a halogen with good σ-donor groups was reported earlier by Crutchley and Lever.[7] We did not notice the solvolysis of complex **4**.

The diffusion currents for complexes **1–6** were calculated using differential pulse polarography and the results are tabulated in Table 4. As expected, higher diffusion currents were observed in complexes **5** and **6** by the replacement of halogen or bipyrimidine in the coordination sphere of the metal ion by the strong σ-donor CH_3CN or NO_2 groups. The more positive potentials of complexes **1–4** compared to **5** and **6** are due to the presence of less σ-basic or π-acidic ligands like bipyrimidine, PPh_3 and Cl ligands. The π-acidities decrease in the order PPh_3 > bipyrimidine > Cl^-. This is reflected in the increase of i_d for complexes **1–4** in the order **3** < **1** < **2** < **4**.

Photoanation studies

Photoanation studies of $[Ru(bipym)_3](PF_6)_2$ (**2**) in acetonitrile shows the formation of $[Ru(bipym)_2(CH_3CN)(Cl)]PF_6$ (**5**) which corresponds to a quantum yield of 0.14. The results can be compared with the reports of Jones and Cole-Hamilton[9] for the photoanation of the ruthenium(II)–tris-(bipyridyl) dication, $Ru(bipy)_3^{2+}$, by chloride ion in acetonitrile. The only photoproduct reported[9] was $[Ru(bpy)_2(CH_3CN)(Cl)]Cl$ with a maximum quantum yield of 0.01. In solvents of lower polarity such as acetone and CH_2Cl_2 the photoproduct formed was $Ru(bpy)_2Cl_2$ with a slightly higher quantum yield of 0.02.[10,11] These facts are suggestive of an ion-paired mechanism for photoanation. The mech-

anism of photoanation of $Ru(bipym)_3^{2+}$ by analogy to that of $Ru(bpy)_3^{2+}$ is believed to be dissociative, resulting in a five-coordinate intermediate with an end-bonded bipyrimidine ligand. Monodentate bipyridyl intermediates have been isolated and their electronic spectra recorded.[12,13] However, these intermediates are unstable and it is probably that in the case of $Ru(bipym)_3^{2+}$, the formation of a monodentate bipyrimidine complex is not detected spectrophotometrically because of its rapid conversion of $Ru(bipym)_3^{2+}$ to $[Ru(bipym)_2(CH_3CN)(Cl)]^+$. As soon as the five-coordinate intermediate is formed, anation results from the Cl^- associated in the ion pair. The difference in the quantum yields of $Ru(bipym)_3^{2+}$ ($\phi = 0.14$) and $Ru(bpy)_3^{2+}$ ($\phi = 0.01$) may be due to the conversion of the latter species to $[Ru(bpy)_2(solvent)(Cl)]^+$ in solution as observed by Van Houten and Watts.[12]

Our interest in the bipyrimidine(II) species is in the design of the highly photo-oxidizable photocatalyst and it is pertinent that the redox couples associated with $Ru(bpy)_3^{2+}$ do shift to positive values in sulphuric acid by a significant amount.[14] The excited state protonation studies using fluorescence spectroscopy are also of interest to us and are under investigation. The electrochemical properties of these complexes and the replacement of Cl^- by ligands such as NCS, Br_2, I_2, oxalate etc. also falls under our future interest of work.

EXPERIMENTAL

Preparation of complexes

(1) *Tris(bipyrimidine)ruthenium*(II) *dichloride.* The complex was prepared by refluxing $Ru(Me_2SO)_4Cl_2$ (0.4 g) and bipyrimidine (0.8 g) in water (50 cm^3) for 20 h. The reaction mixture was filtered and evaporated to dryness. The residue was washed with acetone and chloroform and again with acetone. The crude product (0.6 g) was dissolved in water (10 cm^3) and filtered. To the boiling filtrate was added slowly a 1:2 mixture of ethanol and propanol (20 cm^3). On cooling the solution, reddish crystalline $[Ru(bipym)_3]Cl_2$ precipitated out (0.55 g); yield: 80%.

(2) *Tris(bipyrimidine)ruthenium*(II) *hexafluorophosphate.* A solution of $[Ru(bipym)_3]Cl_2$ (0.4 g in water to cm^3) was heated to boiling. To this was added an aqueous solution of 0.2 M (50 cm^3) NH_4PF_6 and an orange precipitate was immediately formed. The solution was allowed to cool to room temperature and then filtered. The crude product was washed with water and recrystallized with acetone–ethanol solution to give the orange-coloured crystalline $[Ru(bipym)_3](PF_6)_2$; yield: 76%.

(3) *Dichlorobis(triphenylphosphine)bipyrimidineruthenium*(II). A solution of $RuCl_2(PPh_3)_2$ (0.6 g) and bipyrimidine (0.36 g) in acetone (50 cm^3) was refluxed for 6 h to give a reddish-brown precipitate which was filtered and dissolved in chloroform (100 cm^3). The solution was concentrated to 20 cm^3 and $[Ru(bipym)(PPh_3)_2Cl_2]$ crystallized out on cooling. The complex was recrystallized from chloroform; yield: 42%.

(4) *Dichlorobis(bipyrimidine)ruthenium*(II). The complex was prepared by refluxing $RuCl_3\cdot xH_2O$ (0.25 g) and bipyrimidine (0.3 g) in DMF (20 cm^3) for 2 h. The purple solution obtained was filtered and evaporated to dryness in a roto-evaporator. The dry mass was dissolved in 50 cm^3 of acetonitrile and concentrated to 10 cm^3, when black crystalline $[Ru(bipym)_2Cl_2]$ was obtained. The complex was recrystallized from water; yield: 62%.

(5) *Chlorobis(bipyrimidine)acetonitrileruthenium*(II) *hexafluorophosphate.* To a solution of [Ru(bipym)$_3$](PF$_6$)$_2$ (0.3 g) in CH$_3$CN (100 cm^3) was added slowly over 30 min, tetrabutyl ammonium chloride (TBA)Cl (0.07 g). The solution was irradiated at 350 nm when the orange-coloured solution started to turn deep red. After 3 h the excess of acetonitrile was removed over a roto-evaporator and the crude product was digested in boiling propanol. The residue was dissolved in acetone (20 cm^3), and on cooling dark red crystalline [Ru(bipym)$_2$(CH$_3$CN)(Cl)]PF$_6$ separated out. The complex was recrystallized from water; yield: 37%.

(6) *Bis(dinitrito)bis(bipyrimidine)ruthenium*(II). A solution of Ru(bipym)$_2$Cl$_2$ (0.2 g) and NaNO$_2$ (0.4 g) in a 1:1 ethanol–water mixture (30 cm^3) was refluxed for 8 h and the orange solution turned deep red. The deep red solution was concentrated and the complex precipitated by an excess of acetone, when red crystals of [Ru(bipym)$_2$(NO$_2$)$_2$]·0.5 H$_2$O were obtained. The complex was recrystallized from a water–alcohol mixture; yield: 78%.

Acetonitrile was distilled over anhydrous AlCl$_3$ and P$_2$O$_5$. Tetrabutylammonium chloride was used without purification. Bipyrimidine and tetrabutylammonium chloride was used as purchased from Lancaster Chemicals and Aldrich without further purification. RuCl$_2$(Me$_2$SO$_4$) was prepared as reported earlier.[15] Photoanation studies were conducted using a 450 W Xenon lamp from Applied photo physics in a quartz cell of 1 cm path length. All the solutions were made in double-distilled water or acetonitrile. Fresh stock solutions were prepared for spectroscopic studies.

Electrochemical studies were conducted on a PAR Model 174 electrochemical analyser using DME. The solutions contained 9×10^{-4} M ruthenium complex in 0.1 M KNO$_3$ as the supporting electrolyte. All measurements were performed at 26°C in degassed (N$_2$) aqueous solution and all potentials are reported against a SCE.

Electronic spectra of all the complexes were recorded with a Beckman DU-7 UV–vis spectrometer. IR spectra were recorded on a Nicolet 200 SX FT–IR spectrophotometer. Fluorescence emission spectra were recorded on a Hitachi Model 650 Fluorometer with microprocessor. Irradiation of a vacuum degassed solution of [Ru(bipym)$_3$](PF$_6$)$_2$ (8.0×10^{-5} M) and (TBA)Cl (2×10^{-4} M) was carried out in a 1 cm quartz cell under N$_2$. The light source was a 450 W xenon lamp with an interference filter of 436 nm for photoanation of **2**. The light intensity was calculated using ferrioxalate actinometry.[16] The photolysis was interrupted periodically and the absorption spectra recorded. Quantum yields were calculated on the basis of the

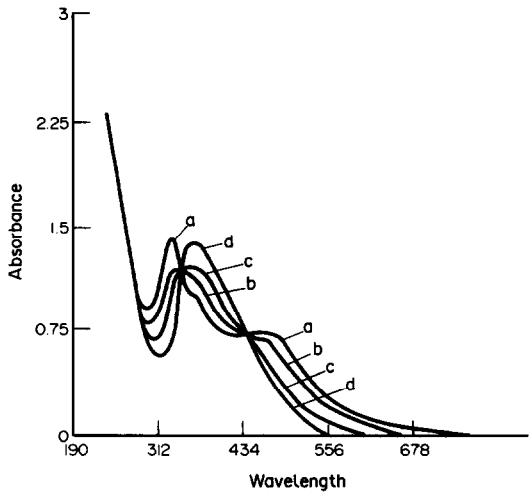

Fig. 1. Absorption spectrum of photoanation studies, Ru(bipym)$_3^{2+}$ (10^{-5} M) and (TBA)Cl (10^{-4} M) in acetonitrile: (a) without illumination; (b) 5 min; (c) 30 min; (d) 45 min for illuminated.

disappearance of the peak corresponding to Ru(bipym)$_3^{2+}$ at 30,120 cm^{-1}.

For the photoanation studies a solution of the complex [Ru(bipym)$_3$](PF$_6$)$_2$ (**2**) in acetonitrile is relatively stable when irradiated at $\lambda = 436$ nm even in the presence of Cl$^-$. However, on irradiation at 350 nm in the presence of Cl$^-$, photoanation takes place as shown in Fig. 1. Figure 1 shows the spectrum of a typical photoanation experiment. The presence of two isobestic points at 356 and 456 nm suggests the formation of two intermediates but only one photoproduct could be isolated. Photolysed solutions of **2** in the presence of Cl$^-$ were extracted with hexane. The UV–vis spectrum before and after hexane extraction showed no change in the position of MLCT bands and a drop in intensity and a narrowing of the ligand π–π^* bands. The hexane extract was evaporated and the melting point and UV–vis spectrum of the residue confirmed the product to be bipyrimidine. The elemental analysis of the photoproduct agrees with the formation [Ru(bipym)$_2$(CH$_3$CN)(Cl)]PF$_6$.

The photolysis at 359 nm seems to give rise to an ion-paired five-coordinate intermediate [Ru(bipym)$_2$bipy)]$^+$Cl$^-$ (**1**), where one of the bipyrimidines is monodentate. This intermediate then collapses to the product [Ru(bipym)$_2$(CH$_3$CN)(Cl)]PF$_6$ (**5**). Irradiation at 350 nm seems to be essential to obtain **1** since irradiation at 450 nm cannot give the photoanation product.

Abstract—Lanthanide complexes from La to Yb with $[PW_{11}O_{39}]^{7-}$ ligands were studied by ^{17}O, ^{31}P and ^{183}W NMR methods. The complexes are non-labile on the NMR time scale, and their 1:2 composition in solution was confirmed by ^{31}P NMR. Contact and dipolar contributions to the lanthanide induced shift (LIS) of ligand nuclei have been estimated. The geometry of the ligand was shown to change in the lanthanide series and the dipolar contribution to LIS increases compared to the contact contribution, as the distance from the lanthanide ion increases.

Lanthanide(III) complexes, known as lanthanide shift reagents (LSR), are tools for the simplification and interpretation of NMR spectra and the structural analysis of organic molecules in solution.[1] On the other hand, ^{17}O and ^{183}W NMR can give some information about the structure of polytungstates in solution.[2–4] Comparison of X-ray and ^{17}O NMR data shows a change of bond length in heteropolyanions (HPA) of tungsten and molybdenum on dissolution. Equivalent bonds of NPA become more equal in solution than in the crystal.[2,4] ^{17}O and ^{183}W NMR studies of the lanthanide complexes of $[PW_{11}O_{39}]^{7-}$–HPA (PW_{11}) were expected to give additional information about the structure and NMR spectra of HPA.

The inorganic tetradentate macroligand PW_{11} is known[5] to form $Ln(PW_{11})_2$ complexes with lanthanide ions, which are HPA with two heteroatom types. We are not aware of structural or NMR ^{17}O studies which can give structural information[3] on these HPA. In the present paper ^{17}O, ^{31}P and ^{183}W NMR spectra of $Ln(PW_{11})_2HPA$ and their constitution in aqueous solution were studied for all stable lanthanides.

EXPERIMENTAL

The $Ln(PW_{11})_2$ complexes were prepared with solid chloride or nitrate lanthanide salts added to a 0.3 M aqueous solution of the sodium salt of $PW_{11}HPA$ in the ratio $Ln:PW_{11} = 1:2$. The natural abundance of ^{31}P, ^{17}O and ^{183}W NMR spectra was recorded with a Bruker CXP-300 spectrometer at 121.47, 40.7 and 12.5 MHz, respectively. Chemical shifts (CS) in δ scale are given to external references H_2O (^{17}O), 85% H_3PO_4 (^{31}P)

and 2 M solution of Na_2WO_4 in H_2O (^{183}W). About 10,000 accumulated scans were used for ^{183}W NMR spectra with a delay of 3–5 s. Correction of CS for magnetic susceptibility of samples was made using the ^{14}N NMR CS of the NO_3^- ion, neglecting its paramagnetic shifts. LIS values are taken as the difference between the CS of the atom of interest in paramagnetic and diamagnetic complexes. For ^{31}P NMR the last value for a given Ln was changed from −11.9 (La) to −13.2 ppm (Lu) proportional to the number of *f*-electrons of Ln. ^{31}P and ^{17}O NMR data are listed in Table 1.

RESULTS AND DISCUSSION

The stoichiometry of the $Ln(PW_{11})_2$ complexes was established in solution by the ^{31}P NMR method as follows. After addition of a stoichiometric amount of lanthanide salt to the solution of PW_{11}HPA the ^{31}P NMR peak of PW_{11} diminished and the $Ln(PW_{11})_2$ peak complex increased. Dissolution of half of the amount of Ln gave two NMR peaks of equal intensity arising from free ligand PW_{11} ($\delta = -10.7$ ppm) and the ligand in the complex. The existence of two peaks means a slow exchange of ligand (or absence of exchange). The life-time of the ligand in the complex, as estimated from NMR spectra, is more than 10–100 ms depending on the Ln.

A study of any salt HPA $Ln(PW_{11})_2$ structure is lacking. A unique X-ray crystal structure determination of the relative HPA (ref. 6) has shown that the two anions α-$GeW_{11}O_{39}^{8-}$ (see Fig. 1) form an oxygen square antiprism around the central atom. In the crystal the square facets of the antiprism differ from each other, and the sides of each square facet differ by about 10%. If this distortion of HPA was present in solution, ^{31}P peaks of different P atoms of the complex should be resolved, especially for a complex with a large LIS. The single peak of ^{31}P NMR demonstrated a uniform construction and connection of the ligands to the lanthanide ion.

LIS of nucleus *i* of the ligand upon coordination to the Ln^{3+} ion is known to be expressed as the sum of the contact shift Δ^c (the first term) and the pseudocontact (dipolar) shift Δ^{pc} (the other terms):

$$\delta_i = \Delta^c + \Delta^{pc} = 2\pi\beta\langle S_z\rangle A_i/3kTh\gamma_N + D'(3\cos^2\theta - 1)r_i^{-3} + D''\sin^2\theta\cos 2\phi_i r_i^{-3}, \quad (1)$$

where $\langle S_z\rangle$ is the Golding constant[7] and A_i the hyperfine coupling constant. Factors D' and D'' are anisotropy components of the magnetic susceptibility tensor, r, θ, ϕ are the spherical coordinates of the observed nucleus with respect to Ln^{3+} at the origin and with the principal magnetic axis as the z axis (Fig. 1). The $\langle S_z\rangle$ value is characteristic of the Ln^{3+} ion only and defines the contact term Δ^c.

The dependence of Δ^{pc} on the Ln^{3+} ion characteristics is defined by the Bleany factor C_B,[9] and LIS must follow C_B along the lanthanide series, if

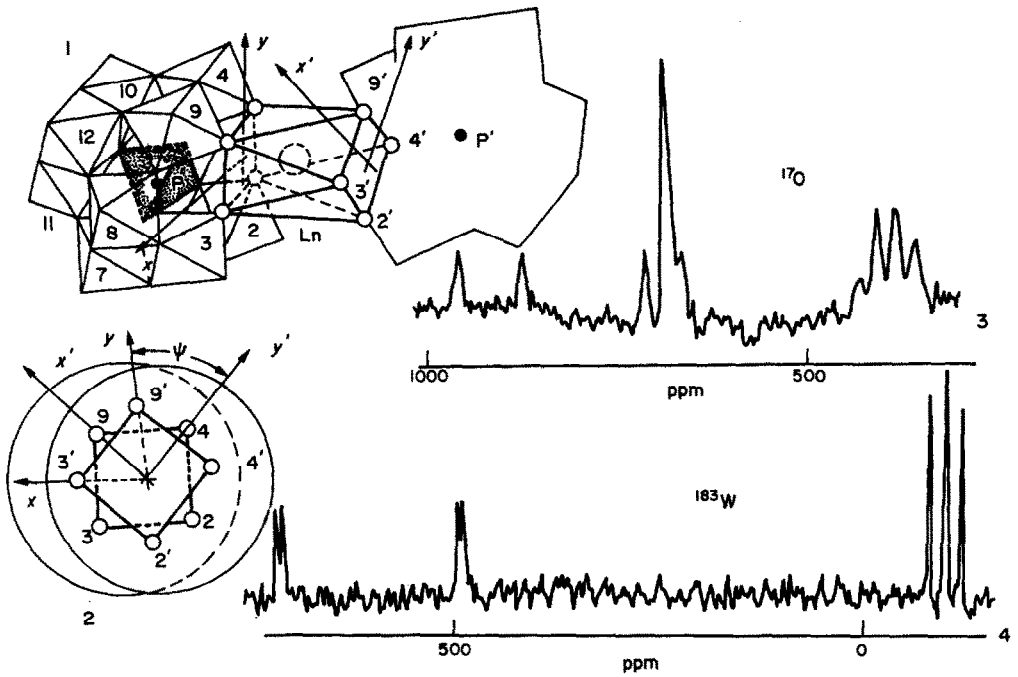

Fig. 1. (1) Schematic representation of the $Ln(PW_{11}O_{39})_2^{11-}$ complex. (Figures denote tungsten atom numbers.) (2) Side view of the complex showing the rotation angle ϕ. (3) ^{17}O NMR spectrum of $Pr(PW_{11}O_{39})_2^{11-}$ at 323 K. (4) ^{183}W NMR spectrum of the same complex.

structural changes are absent. As usual, Δ^{pc} predominates in LIS of atoms further than four bonds away from a paramagnetic ion. Atom P is four bonds away from Ln; furthermore, the W—O—P bond is longer (244 pm[10]) than other W—O bonds (190–192 pm), and the Δ^c value must be less than that of other atoms four bonds away from Ln. Comparison of the C_B and LIS dependences of $Ln(PW_{11})_2$ complexes on Ln shows an appreciable, if not predominant, Δ^{pc} value in LIS.

The geometry of the coordination sphere of the Ln^{3+} ion can change along the lanthanide series.[8] If Δ^c is small in comparison to Δ^{pc} and if structural changes are negligible, we must expect a linear dependence between LIS and C_B values.[8] We did not observe a linear dependence of these values either between light Ln-HPA or heavy Ln-HPA, or even the Ce–Pr–Nd series. Gadolinium HPA LIS is contact in nature, and its ^{31}P value is about 10 ppm. The Δ^c value of Ce-, Pr- and Nd-HPA must be less than in Gd-HPA, therefore a dipolar Δ^{pc} contribution predominates in ^{31}P LIS of Ce-, Pr- and Nd-HPA. This means that the HPA structure changes along the lanthanide series.

The P atoms are equivalent and situated symmetrically with respect to Ln in HPA $Ln(PW_{11})_2$, because only one ^{31}P peak is observed. Estimation of the difference in Ln—P distances in HPA with maximal LIS (Tb- or Tm-HPA) gives a value of less than 0.1 pm, taking into account the cubic dependence of LIS on the Ln—P distance and a linewidth for ^{31}P NMR of 200 Hz.

The Δ^{pc} contribution depends on the coordinates of the nucleus of interest only in the given complex. Variation of Δ^{pc} from one nucleus of PW_{11} to another can be estimated from the coordinates of the HPA atoms (from ref. 6) as a first approximation. Supposing the LIS ^{31}P of HPA to be fully dipolar, we calculated maximal values Δ^{pc} in LIS for other nuclei and used them to determine the character of LIS of each nucleus.

^{17}O NMR spectra of $Ln(PW_{11})_2HPA$ consist of a set of peaks of terminal O=W atoms (725–685 ppm) and a set of W—O—W bridging atom peaks (430–350 ppm, see Fig. 1). They are situated near their position in the free ligand spectrum.[11] Diamagnetic and paramagnetic HPA spectra differ insignificantly except in the peaks for Ln—O—W bridging atoms. Peaks for terminal and bridging O atoms change position negligibly along the lanthanide series.

As is known,[3] the down-field shift of ^{17}O NMR peaks of O=W terminal atoms of polytungstate corresponds to a shortening of the O=W— bond. The average bond length increases from 163 to 183 ppm in the series $O{=}W_{4,9}$, $O{=}W_{5,8}$, $O{=}W_{2,3}$,

O=$W_{6,7}$, O=$W_{10,12}$, O=W_{11}, as follows from structural data.[6] CS ^{17}O of O=$W_{4,9}$ must change along the Ln series, because their LIS is significant. Apparently, the down-field 710 ppm peak belongs to O=$W_{5,8}$ atoms, taking into account that the ^{183}W CS of the $W_{5,8}$ atom changes insignificantly along the Ln series.

Water molecules do not enter the coordination sphere of Ln in HPA, as follows from comparison of ^{17}O CS of water in the solution studied {$\delta(H_2O)$, Table 1, [Ln] = 0.3 M} and a 0.1 M solution of $Ln(NO_3)_3(\delta_{aq})$. Therefore, the coordination sphere of Ln in $Ln(PW_{11})_2$–HPA consists of $O_{2,3,4,9}$ atoms of the PW_{11} ligand only, which are connected with $W_{2,3,4,9}$ atoms. The NMR ^{17}O peaks of $O_{2,3,4,9}$ atoms are not observed for all Ln. These peaks are situated between a set of peaks of O=W terminal atoms and a set of peaks of W—O—W bridging atoms of the MPW_{11} complex (ref. 12, M = M^+, M^{2+}, M^{3+}).

LIS ^{17}O of Ln—O—W atoms depend on the magnetic properties of Ln and the structural parameters of the coordination sphere of Ln (e.g. Ln radius). ^{17}O NMR peaks of Ln—O—W atoms in Ce-, Pr-, Nd-HPA are shifted more than 100 ppm from their position in $Ln(PW_{11})_2$, and these shifts are mainly paramagnetic. LIS of Ln—O—W atoms increase successively in the series Ce, Pr, Nd and do not correlate with C_B. ^{17}O NMR peaks lie near the peaks of La- and Lu-HPA. Oxygen-17 peaks of Ho-, Er- and Tm-HPA, which are situated between the peaks of terminal and bridging atoms (Table 1), apparently belong to O atoms W_4—O—W_{10}, W_9—O—W_{12} and so on, or W_4—O—W_9, W_2—O—W_3 atoms, because ^{183}W LIS of the HPA $W_{2,3,4,9}$ atoms are much more than LIS of those atoms of Ce-HPA (Table 2) and LIS of Ho- and Tm-HPA Ln—O—W atoms must be more than LIS of analogous atoms of Ce-HPA.

The contributions Δ^c and Δ^{pc} for P atoms and $W_{4,9}$—O—Ln and $W_{2,3}$—O—Ln oxygen atoms in Ce-, Pr- and Nd-HPA were calculated using eq. (1) and LIS ^{31}P and ^{17}O with the projection of the Ln atom on O_2, O_3, O_4, O_9 plane taken as the origin of coordinates. The non-linear minimization program LISMIN[13] was explored and calculated results are listed in Table 3.

If k nuclei are taken, a system of k equations arises with j unknowns, which are the Cartesian coordinates of nuclei x, y, z, susceptibility tensor anisotropy constants D' and D'' and the hyperfine coupling constant A. The system is solved if $j < k$. As usual one supposes that x, y, z and A are equal in LIS complexes of light or heavy lanthanides, and the system is solved with a definite number of Ln. This approach is not suitable in this case due to insufficient experimental data. Therefore, a minimization procedure with the minimum criterion R was used

$$R = \left[\sum_k (\delta_{\mathrm{calc},k} - \delta_{\mathrm{obs},k})^2 \Big/ \sum_k (\delta_{\mathrm{obs},k})^2\right]^{1/2},$$

where δ_{calc} was calculated from eq. (1) and δ_{obs} was the observed LIS. Because of the non-linearity of eq. (1), the existence of several minima is possible,
