is due to back donation of electron density from filled metal *d*-type orbitals into empty π^*-orbitals of the but-2-yne. Strong, broad bands at ~ 1020 cm^{-1}, ν(BF), are also observed in the IR spectra of **1–7** due to the tetrafluoroborate anion.[18]

The ^{1}H and ^{13}C NMR spectra of **1–7** show there to be a number of isomers in solution. Unsuccessful attempts were made to grow suitable single crystals of **1–7** for X-ray crystallography. One likely structure of **1–7** is shown in Fig. 1, which has iodide *trans*- to a but-2-yne ligand on each tungsten atom. The X-ray crystal structures of [WI(CO)L(dppm)(η^2-MeC_2Me)]$^+$ [L = P(O^{i}Pr)$_3$[16] and $SC(NH_2)_2$[19]] have been determined and have the geometry displayed in Fig. 1, where each of the phosphine atoms of the bidentate bridging phosphine have replaced the tri-isopropylphosphite and thiourea ligands in [WI(CO)L(dppm)(η^2-MeC_2Me)]$^+$ to give the bridging complexes $[W_2I_2(\mu\text{-L—L})(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$.

The reactions of two equivalents of [WI(CO)(NCMe)(dppm)(η^2-MeC_2Me)][BF_4] with one equivalent of L—L {L—L = $Ph_2P(CH_2)_nPPh_2$, n = 1–6 and [Fe(η^5-$C_5H_4PPh_2)_2$]} must initially afford a monodentate phosphine complex of the type [WI(CO)(η^1-L—L)(dppm)(η^2-MeC_2Me)][BF_4] which rather than displacing an iodide to give the dicationic complexes of the type [W(CO)(dppm){$PPh_2(CH_2)_nPPh_2$}(η^2-MeC_2Me)][BF_4]I, the free end of the phosphine reacts with another equivalent of [WI(CO)(NCMe)(dppm)(η^2-MeC_2Me)][BF_4] to give the bimetallic phosphine-bridged compounds **1–7**. It is interesting to note that reaction of the more electron rich and sterically constrained bidentate nitrogen donor ligands N—N (N—N = 2,2′-bipyridine, 1,10-phenanthroline, etc.) with an equimolar amount of [WI(CO)(NCMe)(dppm)(η^2-MeC_2Me)][BF_4] gave the dicationic complexes [W(CO)(N—N)(dppm)(η^2-MeC_2Me)][BF_4]I.[20]

Equimolar quantities of [WI(CO)(NCMe)(dppm)(η^2-MeC_2Me)][BF_4] and dppm shows the series of resonances due to **1**, a single resonance at δ = −21.53 ppm due to uncoordinated dppm. There is also an additional set of low intensity resonances which is likely to be due to the monodentate coordinated complex [WI(CO)(η^1-dppm)(dppm)(η^2-MeC_2Me)][BF_4]. There is com-

Table 4. ^{13}C NMR data for the complex $[W_2I_2(\mu\text{-L—L})(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$

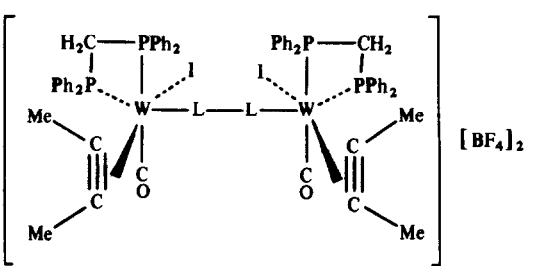

Fig. 1. One possible structure of the bimetallic complexes $[W_2I_2(\mu\text{-L—L})(CO)_2(dppm)_2(\eta^2\text{-MeC}_2\text{Me})_2][BF_4]_2$.

petition from [WI(CO)(NCMe)(dppm)(η^2-MeC_2Me)][BF_4] for both dppm and [WI(CO)(η^1-dppm)(dppm)(η^2-MeC_2Me)][BF_4]. Whereas when a pure sample of **1** is reacted with one equivalent of dppm the ^{31}P NMR spectrum of this mixture displayed only resonances for **1** and free dppm at $\delta = -21.53$ ppm.

The ^{13}C NMR spectra of **2**, **3** and **5** showed a number of resonances above 200 ppm due to both carbonyl ligands and alkyne contact carbon atoms, which again suggests the existence of several isomers in solution. Alkyne contact carbon resonances above 200 ppm indicate[21] that the but-2-yne ligands are utilizing both their filled $p\pi$-orbitals and are formally donating four-electrons each to the tungsten atoms in these compounds.

Acknowledgements—We thank Dr O. W. Howarth for measuring several ^{31}P NMR spectra at the University of Warwick and we thank the SERC for support.

OCTAHEDRAL METAL CARBONYLS—LXXIII.† DISPLACEMENT OF AROMATIC SOLVENTS (SOLV) FROM (SOLV)$Cr(CO)_5$ COMPLEXES GENERATED AFTER FLASH PHOTOLYSIS: MODES OF BONDING AND MECHANISM

SHULIN ZHANG and GERARD R. DOBSON‡

Department of Chemistry and Center for Organometallic Research,
University of North Texas, Denton, TX 76203-5068, U.S.A.

(*Received* 23 *March* 1990; *accepted* 15 *June* 1990)

Abstract—Rates of solvent displacement by 1-hexane (hex) from 17 (solv)$Cr(CO)_5$ transients generated after pulsed laser flash photolysis (solv = aromatic solvent, $C_6H_{6-n}X_n$; X = alkyl, perfluoroalkyl (R, R_f); F, Cl, Br; n = 0–4),

$$(\text{solv})Cr(CO)_5 + \text{hex} \longrightarrow (\eta^2\text{-hex})Cr(CO)_5 + \text{solv},$$

have been determined. Analyses of the rate constants in terms of the steric and electronic properties of solv indicate that the rections take place via initial slow fission of a solv—Cr bond. The data also indicate that for R, R_f and F substituents, solv is coordinated to Cr "edge on" via an isolated C=C bond, while for solv which contain Cl and Br substituents, coordination to Cr takes place through halogenic lone pairs. Aside from influences of the mode of coordination of solv to Cr, rates increase with increasing electron-withdrawing properties and increasing steric bulk of the substituents.

Recent studies have begun to provide an understanding of solvation–desolvation reactions taking place after flash photolyisis of metal carbonyls; in these studies, $Cr(CO)_6$ has been the exemplar. Thus, several groups have investigated the very rapid solvation reactions which take place after coordinatively-unsaturated [$Cr(CO)_5$] is produced,[1] and others have studied the strengths of Cr—alkane bonds by time-resolved photoacoustic calor imetry.[2,3] Still other studies have focused attention on the rates and mechanisms of displacement of solvent molecules such as alkanes,[2,4,5] benzene[6] and chlorobenzene[7] from (solvent)$Cr(CO)_5$ molecules by Lewis bases [L; eq. (1)]:

$$(\text{solvent})Cr(CO)_5 + L \longrightarrow LCr(CO)_5 + \text{solvent}. \quad (1)$$

In this last regard it is interesting to note that evidence suggests two solvent displacement mechanisms [eq. (2)] to be operative. For (*n*-heptane)$Cr(CO)_5$, in which *n*-heptane is coordinated to Cr via an "agostic"[8] C—H—Cr interaction, both the interchange pathway (2a) and the dissociative pathway (2b) have been found to be assessible,[2,4] while for benzene[6] and chlorobenzene[7] as solvents the dissociative pathway is much more pronounced. Moreover, for these last two solvents, modes of bonding also may differ. Thus, strong evidence has been presented which supports coordination of benzene via an "edge-on", isolated double bond.[6] On the other hand, the mode of bonding of chlorobenzene to Group VI-B metals, whether "edge-on" or via coordination through a lone pair of electrons on Cl, has been the subject of some discussion;[9] X-ray structural studies have shown both modes of bonding of substituted benzenes, "edge-on",[10] and coordinate, through a halogenic lone pair,[11] to take place.

† Part LXXII: S. Zhang and G. R. Dobson, *J. Organomet. Chem.*, in press.

‡ Author to whom correspondence should be addressed.

All these observations have prompted a broader investigation of solvent displacement reactions of (solv)$Cr(CO)_5$ complexes according to eq. (1), where solv are aromatic hydrocarbons containing zero or more alkyl, perfluoromethyl, F, Cl or Br substituents and L = 1-hexene. It was of particular interest to study changes in rates of solv displacement from (solv)$Cr(CO)_5$ as a function of the steric and electronic nature of the aromatic solvents since, where linear free energy relationships are observed to exist, it may be concluded that reactions are mechanistically similar.

EXPERIMENTAL

Materials

Chromium hexacarbonyl (Pressure Chemical Co.) was vacuum sublimed before use. Benzene and toluene (Mallinckrodt), *t*-butylbenzene (Eastman), cyclohexylbenzene, cumene, ethylbenzene, 1,2,3,4-tetramethylbenzene, *o*-xylene and *m*-xylene (Aldrich), and mesitylene (Fisher) were all fractionally distilled from sodium under nitrogen. α,α,α-Trifluorotoluene, *o*-bromofluorobenzene and *p*-xylene (Lancaster Synthesis), bromobenzene (Matheson), and chlorobenzene, *o*-dichlorobenzene and fluorobenzene (Aldrich) were fractionally distilled from P_4O_{10} under nitrogen. 1-Hexene (Aldrich) was fractionally distilled from anhydrous $MgSO_4$.

Flash photolysis studies

Flash photolysis studies were carried out employing equipment previously described,[12] except that either a Lumonics TE-430 ($Xe/F_2/He$ gas fill, 351 nm, 10 ns FWHI, 25 mJ/pulse maximum energy) or Tachisto 800 ($Xe/F_2/He$ gas fill, 20 ns FWHI, 200 mJ/pulse maximum energy) excimer laser was employed as the photolysis source. Typically, solutions *ca* 3.5×10^{-3} M in $Cr(CO)_6$, containing at least a 100-fold excess of the 1-hexene "trap" in the aromatic solvent, were employed so that pseudo-first-order reaction conditions were obtained. The observation wavelength was 490 nm, which monitored the disappearance of (solv)$Cr(CO)_5$; the temperature was maintained at 25.00(5)°C through the use of a jacketed cell and an external circulating bath. Depending upon the signal-to-noise ratio observed for a given solvent, pseudo-first-order rate constants obtained from plots of $\ln(A_t-A_\infty)$ vs time were determined from the averages of from one to 10 traces. No significant differences were observed for individual traces obtained after the first or after subsequent flashes, an observation which indicates that flash photolysis of (1-hexene)$Cr(CO)_5$ affords the same photolysis product as does $Cr(CO)_6$, i.e. $[Cr(CO)_5]$. Rate constants were determined employing at least four sets of data taken at different concentrations of 1-hexene. The data were analysed employing in-house, Asyst©-based computer programs designed for the laboratory's 286-based microcomputer. Limits of error are given in parentheses as the uncertainty of the last digit(s) of the cited value to one standard deviation.

RESULTS AND DISCUSSION

Evidence has strongly indicated that the reactions taking place after pulsed laser flash photolysis of $Cr(CO)_6$/bz/hex solutions (bz = benzene; hex = 1-hexene) proceed according to eq. (3):[6]

$$Cr(CO)_6 \xrightarrow[+bz]{h\nu} (bz)Cr(CO)_5 \xrightarrow{+hex} (\eta^2\text{-hex})Cr(CO)_5. \tag{3}$$

Rate data for this reaction obtained over very wide concentration ranges of bz (the solvent) and hex (the "trapping agent"), to [hex] = *ca* 6 M, obey the rate law

$$-d[(bz)Cr(CO)_5]/dt = \frac{k[(bz)Cr(CO)_5][hex]}{[bz]+k'[hex]}. \tag{4}$$

Since [bz], [hex] ≫ $[(bz)Cr(CO)_5]$ (Experimental),

$$k_{obs} = k[hex]/([bz]+k'[hex]). \tag{5}$$

This rate law was interpreted in terms of a dissociative mechanism for benzene displacement, eq. (6):

$$\begin{array}{l} (bz)Cr(CO)_5 \underset{k_{-1}[bz]}{\overset{k_1}{\rightleftharpoons}} [Cr(CO)_5] \\ \qquad\qquad\qquad\qquad \Big\downarrow k_2[hex] \\ \qquad\qquad\qquad\qquad (\eta^2\text{-hex})Cr(CO)_5. \end{array} \tag{6}$$

For this mechanism, assuming a steady-state concentration of $[Cr(CO)_5]$, k [eq. (5)] = k_1k_2/k_{-1} and $k' = k_2/k_{-1}$.

It is reasonable to assume (for the present) that the mechanism given in eq. (6) also applies to other aromatic solvents, such as those investigated here. Under the reaction conditions employed in the present study, [hex] ≪ [solv], and since it has been observed for benzene that $k' < 1$ (*vide infra*), [solv] ≫ k'[hex]. It is also to be noted, since [solv] ≫ [hex], that [solv] will be approximately constant as [hex] is varied, and thus that [solv] ≃ $[solv]_0$, the concentration of the pure solvent. Under these

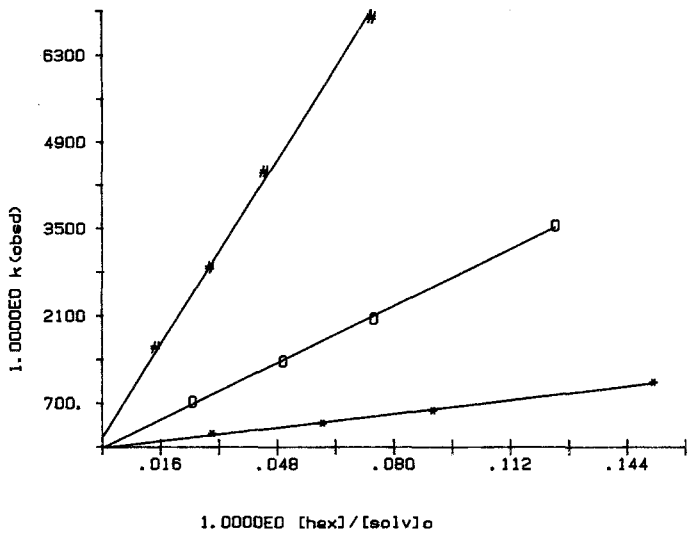

Fig. 1. Plots of k_{obs} vs [hex]/[solv]$_0$ for reactions of (solv)Cr(CO)$_5$ complexes with hex at 25°C (solv = aromatic solvent; hex = 1-hexene). #: solv = cumene; ○: solv = *o*-xylene; *: solv = 1,2,3,4-tetramethylbenzene.

conditions, eq. (5) becomes,

$$k_{obs} \simeq k([hex]/[solv]_0), \quad (7)$$

and plots of the pseudo-first-order rate constants, k_{obs}, vs [hex]/[solv]$_0$ will afford the rate constants, k ($= k_1k_2/k_{-1}$).

Figure 1 exhibits plots of k_{obs} vs [hex]/[solv]$_0$ for three representative solv (cumene, *o*-xylene and 1,2,3,4-tetramethylbenzene) which demonstrate the adherence of these reactions to the rate law given in eq. (7); the other solvents studied also obey this rate law. The rate constants, k, determined at 25.0°C for 17 solv, are presented in Table 1.

For the mechanism shown in eq. (6), of the rate constants which comprise k ($= k_1k_2/k_{-1}$), k_2, the rate constant for interaction of [Cr(CO)$_5$] with hex, is the same for all solvents. Thus, observed changes in rate are attributable to changes in k_1/k_{-1}, the equilibrium constant for desolvation; however, both these rate constants, k_1 and k_{-1}, should be

Table 1. Rate constants for displacement of aromatic solvents from photogenerated (solv)Cr(CO)$_5$ complexes

15	*o*-Bromofluorobenzene, *o*-C_6H_4BrF	0.915(18)
16	1,2,3,4-Tetramethylbenzene, 1,2,3,4-$C_6H_2(CH_3)_4$	0.684(27)
17	Bromobenzene, C_6H_5Br	0.30(3)

influenced by the steric and electronic properties of solv.

The value of k_{-1}, the rate constant for interaction of solv with $[Cr(CO)_5]$, is expected to be very large since available data indicate that solvation of photogenerated $[Cr(CO)_5]$ takes place on the ps–fs time-scale.[2] Thus there should be little solv—Cr bond-making in attaining the transition state, and consequently there is expected to be relatively little influence of k_{-1} on k among various solv. Thus, differences in the values for k, which vary by some 1750-fold, will be determined largely by differences in k_1, the rate constants for solv dissociation.

Turning first to consideration of the data for benzene and nine monosubstituted aromatic solvents (1–4, 6, 7, 9–11, 17; Table 1), rates have been correlated with the "aromatic" substituent constants, σ_m, σ_p and MR, presented by Hansch and co-workers.[13] Bearing in mind that evidence strongly suggests that in $(bz)Cr(CO)_5$, bz is bonded to Cr "edge-on" through a C=C bond[6] and that σ_m and σ_p are electronic substituent constants for adjacent carbons, the sums of these $(\sigma_m+\sigma_p)$ are taken as the electronic substituent constants, E, used for this study. The MR values, taken from molar refractivity data,[14] have been used to represent steric influences. The electronic and steric substituent constants, E and MR respectively, are presented in Table 2. The observed second-order rate constants, k (eq. 7), were correlated with E and MR for the aromatic solvents 1–4, 6, 7, 9–11, 17, through use of the equation:

$$\log k = aE+b(MR)+c, \qquad (8)$$

employing a multilinear regression. This fit afforded a correlation coefficient, R, of 0.072. With the exclusion of the rate constants for arenes 11 and 17 (chlorobenzene and bromobenzene), this fit improves to $R = 0.979$ and obeys eq. (9):

$$\log k = 1.70E+0.069(MR)+5.14. \qquad (9)$$

Equation (9) indicates that rate constants for displacement of monosubstituted aromatic solvents from their $(solv)Cr(CO)_5$ complexes increase with the increasing charge-withdrawing properties of the substituent and also with increasing substituent bulk. On this basis, the rates of dissociation of chlorobenzene and bromobenzene are abnormally slow. Figure 2 exhibits a plot of $\log(k_{calc}-k_{exp})$ vs E, MR. The "spikes" (both positive and negative) thus represent differences between the experimentally-determined rate constants, k_{exp}, and the rate constants calculated by employing eq. (9), k_{calc}. The figure clearly demonstrates the good fit for the rate constants for solv 1–4, 6, 7, 9 and 10, and the poor fit of k for solv 11 and 17, chlorobenzene (CB) and bromobenzene, to eq. (9).

Table 2. Aromatic substituent constants[13]

Substituent (—X)	σ_m	σ_p	E $(=\sigma_m+\sigma_p)$	MR
$-CF_3$	0.42	0.54	0.97	5.02
—F	0.34	0.06	0.40	0.92
$-CH(CH_3)_2$	−0.07	−0.15	−0.22	14.98
—H	0.00	0.00	0.00	1.03
$-C(CH_3)_3$	−0.10	−0.20	−0.30	19.62
$-C_6H_{11}$	−0.07[a]	−0.22	−0.29	26.69
$-CH_2CH_3$	−0.07	−0.15	−0.22	10.3
$-CH_3$	−0.07	−0.17	−0.24	5.65
—Cl	0.37	0.23	0.60	6.03
—Br	0.39	0.23	0.62	8.88

[a] This value is not available in ref. 13; it is assumed to be the same as that for $-CH(CH_3)_2$.

The good correlation of the data for the aromatic solvents 1–4, 6, 7, 9 and 10 indicates that the displacement of each solv in this group from its $(solv)Cr(CO)_5$ complex is mechanistically similar and that coordination of each solv to Cr also is similar in nature. This group of solv includes bz, which is displaced from $(bz)Cr(CO)_5$ via the mechanism shown in eq. (6), and which is coordinated "edge-on" to Cr.[6]

Chlorobenzene also is displaced from its $(CB)Cr(CO)_5$ complex via a dissociative mechanism;[7] the much slower rates of displacement of chlorobenzene and bromobenzene thus are not related to mechanistic differences; they instead are most reasonably attributable to a different mode of bonding to Cr of these solvents, via lone pairs on the halogen atoms rather than through "edge-on" olefinic bonding. This mode of bonding has been widely observed in a number of related systems (*vide supra*).[11]

This supposition was further probed through determination of the rate of displacement of *n*-butyl chloride (BC) by hex from photogenerated $(BC)Cr(CO)_5$. This rate (k, [eq. (7)] $= 2.27(8)\times10^3$ s^{-1}), is slower than is the rate of displacement of CB, as is expected on the basis of the electron-withdrawing nature of $-C_6H_5$ relative to that of $-C_4H_9$, a trend consistent with a similar mode of bonding of both CB and BC to Cr. *n*-Butyl chloride, being aliphatic, *must* bond to Cr via a lone pair of electrons on Cl, since solvents coordinating via a C—H—Cr "agostic" interaction are much more susceptible to solvent displacement.[2,4,5]

On the other hand, fluorobenzene (FB) is a member of the group of eight aromatic solvents which

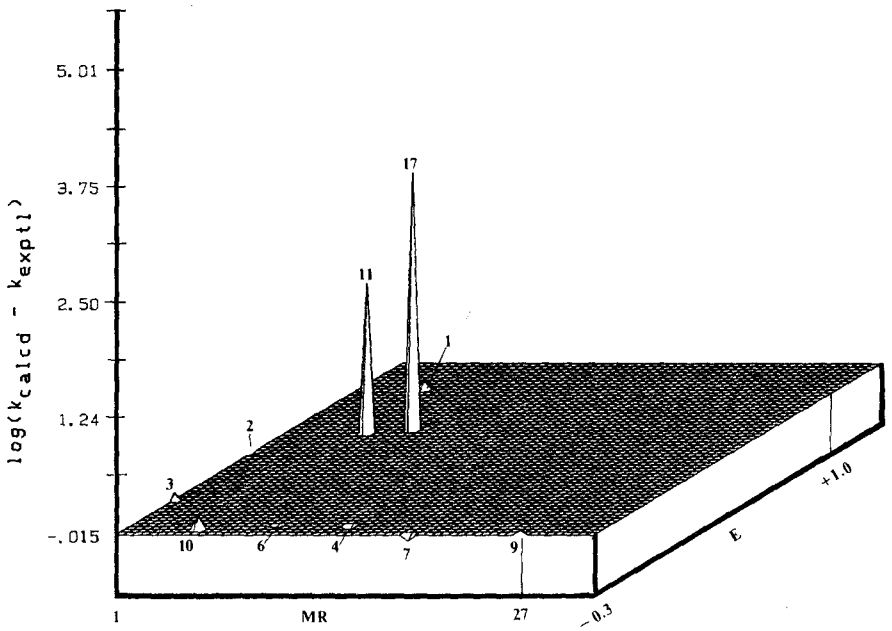

Fig. 2. Plot of $\log(k_{calc}-k_{exp})$ vs E, MR, the electronic and steric parameters (Table 2) for 10 aromatic solvents: 1—α,α,α-trifluorotoluene; 2—fluorobenzene; 3—benzene; 4—cumene; 6—ethylbenzene; 7—*t*-butylbenzene; 9—cyclohexylbenzene; 10—toluene; 11—chlorobenzene; 17—bromobenzene. The numbers refer to Table 1.

the evidence presented above indicates are bonded to Cr via an isolated C=C bond. Oishi has presented evidence which he interprets as indicative of a similar mode of bonding of FB to Cr in (η^6-anisole)(η^2-FB)$Cr(CO)_2$ produced upon photolysis of (η^6-anisole)$Cr(CO)_3$ in FB solution.[15] The "change-over" in the mode of bonding from F to Cl is reasonably attributable to the decrease in electronegativity of X along the series F, Cl, Br; a decrease which would be expected to produce an increase in the coordinating ability of X. Note in this regard (Table 1) that a 12-fold increase in the rate of displacement of solv is observed for chlorobenzene vs bromobenzene.

Relative rates observed for the displacement of aromatic solvents from their (solv)$Cr(CO)_5$ complexes containing the series of five halogenated benzenes (2, 8, 11, 15, 17; Table 1) also are consistent with coordination of Cl and Br to the metal in disubstituted solv containing these substituents (8, 15). As would be expected, these rates increase with the increasing electron-withdrawing abilities of the halogens, i.e. as the coordinating abilities of X decrease.

From Table 1 it can be seen that the solv studied also includes a series of six methyl-substituted benzenes (5, 10, 12–14, 16). It is noted, with the exception of mesitylene, that the rates decrease from that observed for benzene with increasing methyl-substitution, as expected based upon the electron-releasing nature of methyl substituents relative to H and "edge-on" C=C bonding to Cr. The faster rate observed for mesitylene suggests that coordination of arenes to the metal takes place preferentially at an " unsubstituted" double bond in which there is less steric crowding, a bond which mesitylene, alone of these six solv, does not possess. Employing 2 E and 2 MR for the two methyl groups in xylene molecules and eq. (9), the best agreement between the calculated and experimentally-determined rate constants, k_{calc} and k_{exp}, is for *p*-xylene (2.6×10^4 s^{-1} in each case) which suggests Cr–arene bond formation involving the unsubstituted *o*- and *m*-carbons.

CONVERSION OF LONG-CHAIN TERMINAL ALCOHOLS AND SECONDARY AMINES INTO TERTIARY AMINES USING RUTHENIUM(II) TERTIARY PHOSPHINE COMPLEXES AS HOMOGENEOUS CATALYSTS*

SANJOY GANGULY and D. MAX ROUNDHILL†

Department of Chemistry, Tulane University, New Orleans, LA 70118, U.S.A.

(*Received* 9 *April* 1990; *accepted* 15 *June* 1990)

Abstract—$RuCl_2(PPh_3)_3$ acts as a homogeneous catalyst for the condensation reaction between long-chain terminal alcohols and secondary amines to give tertiary amines. Supporting evidence is presented for a pathway involving an intermediate aldehyde which undergoes Schiff base formation with the secondary amine. Small amounts of amine side product are formed from catalysed alkyl group transfer reactions between the amines in the solution. A secondary pathway involving decarbonylation of the aldehyde leads to the formation of alkane and $RuHCl(CO)(PPh_3)_3$. Mechanistic probes are presented and discussed, and the scope of the reaction with secondary alcohols and ketones is presented.

The catalysed synthesis of amines having long-chain alkyl groups is of potential commercial value because of the use of these compounds in the production of detergents. A plausible synthetic approach to these compounds involves the condensation reaction between long-chain terminal alcohols and secondary amines [eq. (1)]:

$$Me(CH_2)_nOH + R_2NH \longrightarrow Me(CH_2)_nNR_2 + H_2O. \quad (1)$$

This reaction has been the focus of considerable study for an extended period of time, and numerous heterogeneous catalysts have been developed for accelerating this reaction.[2] The reaction has received less study as a transformation which can be catalysed under homogeneous conditions, but complexes of ruthenium and other transition metals have been used for similar dehydration reactions.[3] An example of such a process is the use of ruthenium triphenylphosphine complexes as homogeneous catalysts for the conversion of ethylene glycol into both monoamines and diamines.[4] This paper reports our use of ruthenium(II) complexes as homogeneous catalysts for the conversion of long-chain terminal alcohols into tertiary amines by the general condensation reaction shown in eq. (1). Alcohols ranging in carbon chain length from 10 to 18 have been used [$n = 9, 13, 15, 17$ in eq. (1)], and secondary amines have been employed which have methyl, ethyl, 1-propyl and phenyl substituents as the R group in R_2NH.

EXPERIMENTAL

Alcohols and secondary amines were commercial samples and used as supplied. The complexes $RuCl_2(PPh_3)_3$, $RuCl_2(PN)_2$, $RuCl_2(dppe)_2$, $RuCl_2(bipy)_2$ and $RuCl_2(CO)_2(PPh_3)_2$ were synthesized using literature procedures.[5] Triphenylphosphine (Aldrich) and stannous chloride were commercial samples. The catalytic reactions were carried out in a Parr pressure vessel fitted with a 45 cm^3 reaction cup. The reaction cup was heated in an aluminium block, and the reaction mixture stirred by a magnetic stir bar. The cooled reaction mixture was filtered through alumina to remove the ruthenium complexes, and the eluant analysed on a Hewlett–Packard Model 5830 gas chromatograph–mass spectrometer. Prior to the GC–MS analysis, dodecane (0.75 g, 4.4 mmol) was added to a mixture of the alcohol (10 mmol) and secondary amine (10 mmol). The yield of product tertiary amine was obtained by comparing the peak areas of the reac-

† Author to whom correspondence should be addressed.

tant alcohol and product amine with that of the standard dodecane. The relative detector sensitivity for equimolar amounts of terminal alcohol, product amine and dodecane was 1.7:1.3:1 with an accuracy of better than 5%. Our product yields are accurate to approximately 5%, and the selectivity in the majority of cases is greater than 90%. The lowered selectivity in some reactions was reduced because of a catalysed amine scrambling reaction. The yields of other amine products were obtained by GC–MS comparison with dodecane. The complex which was recovered from the reaction at the end of each catalytic run was $RuHCl(CO)L(PPh_3)_2$, where L is a secondary amine. The complex $RuHCl(CO)(PPh_3)_3$ was prepared by the literature procedure and characterized by a combination of IR, ^1H and $^{31}P\{^1H\}$ NMR spectroscopy: $\nu(CO)$ 2020, 1922, 1903 cm^{-1}; ^1H NMR: δ −7.2 [$^2J(PH_{cis}) = 23.7$ Hz, $^2J(PH_{trans}) = 104.9$ Hz]; $^{31}P\{^1H\}$ NMR: δ 13.5s, 39.6s [$^2J(PP)$ 0 Hz].[6] Addition of excess diethylamine to a solution of $RuHCl(CO)(PPh_3)_3$ gave $RuHCl(CO)(HNEt_2)(PPh_3)_2$, which was characterized by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy: ^1H NMR: δ −14.5t [$^2J(PH) = 19.6$ Hz]; $^{31}P\{^1H\}$ NMR: δ 47.6s.

RESULTS

When a terminal alcohol, $Me(CH_2)_nOH$ (n = 9, 13, 15, 17), is reacted with a secondary amine, R_2NH (R = Me, Et, 1-Pr, Ph), at 120°C for 2.5 h in the absence of any catalyst, no observable quantity of tertiary amine $Me(CH_2)_nNR_2$ is formed. When the complex $RuCl_2(PPh_3)_3$ (50 μmol) is added to such a reaction mixture containing an alcohol (10 mmol) and a secondary amine (10 mmol) at 120°C, tertiary amine is formed as the product after 2.5 h reaction time (Table 1). After the reaction is complete the only ruthenium complex which can be detected in the solution is $RuHCl(CO)L(PPh_3)_2$, where L is the secondary amine used as the reactant. When the amine L is removed from this solution by evaporation, the complex $RuHCl(CO)(PPh_3)_3$ is formed.[6] This reaction is readily reversible since we find that the addition of excess secondary amine (L) to $RuHCl(CO)(PPh_3)_3$ gives $RuHCl(CO)L(PPh_3)_2$ [eq. (2)]:

$$RuHCl(CO)L(PPh_3)_2 \underset{L}{\overset{PPh_3}{\rightleftharpoons}} RuHCl(CO)(PPh_3)_3 \quad (L = R_2NH). \tag{2}$$

Table 1. Conversion of terminal alcohols and secondary amines into tertiary amines[a]

Terminal alcohol	Secondary amine[b]	Tertiary amine	Yield (%)[c]	Turnover number[d]

$RuCl_2(PN)_2$	160	15
$RuCl_2(PN)_2 + PPh_3$ (4 moles)	160	72

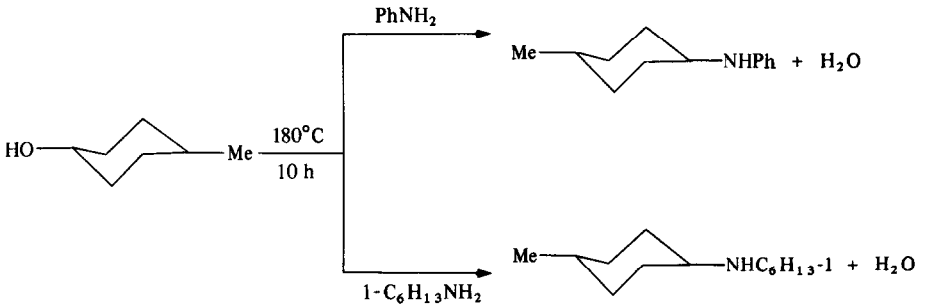
[a] Reaction time 2.5 h; catalyst concentration 0.5%.
[b] Reaction time 30 h.

The complexes $RuHCl(CO)L(PPh_3)_2$ and $RuHCl(CO)(PPh_3)_3$ are inactive as catalysts for reaction (1), and $RuCl_2(PPh_3)_3$ does not catalyse the reverse reaction. At 120°C, the chelate complexes $RuCl_2(PN)_2$ (PN = *o*-diphenylphosphino-N,N-dimethylaniline), $RuCl_2(dppe)_2$, $RuCl_2(bipy)_2$ and the dicarbonyl complex $RuCl_2(CO)_2(PPh_3)_2$ are also inactive as homogeneous catalysts for reaction (1). At the higher temperature of 160°C, $RuCl_2(PN)_2$ will catalyse the formation of $C_6H_{33}NPr_2$ from $C_{16}H_{33}OH$ and $NHPr_2$. When the reaction temperature is lowered to 25°C, $RuCl_2(PPh_3)_3$ is inactive as a catalyst for the formation of $C_{16}H_{33}NPr_2$ over a time period of 30 h, and comparable reaction conditions at 70°C give only a 4% yield of $C_{16}H_{33}NPr_2$ after 30 h (Table 2). Although triphenylphosphine itself is not a catalyst for reaction (1), the addition of 4 moles of triphenylphosphine per mole of $RuCl_2(PPh_3)_3$ to solutions which contain $RuCl_2(PPh_3)_3$ or $RuCl_2(PN)_2$ results in increased yields of amine (Table 2). The complex $RuCl_2(PN)_2$ is not recovered at the end of the catalytic reaction at 160°C under conditions where 4 moles of triphenylphosphine are added. Instead in the $^{31}P\{^1H\}$ NMR spectrum we observe a single resonance at δ 25 due to an unidentified complex. The yield of tertiary amine is dependent on both the alcohol and secondary amine. The highest yields are obtained with $NHMe_2$ and $C_{14}H_{29}OH$ or $C_{18}H_{37}OH$, and the lowest yield with $NHEt_2$ and $C_{18}H_{37}OH$ (Table 1). Secondary and tertiary alcohols do not react; thus in the presence of $RuCl_2(PPh_3)_3$ at 170°C for 2.5 h with dipropylamine, the secondary alcohols 2-propanol, 2-octanol, 4-methylcyclohexanol, *t*-butanol and phenol give no tertiary amine products.

The catalytic reaction with primary alcohols and secondary amines exhibits an induction period of approximately 30 min before significant amounts of tertiary amine product are formed. This induction period is reduced when 4 moles of PPh_3 per mole of $RuCl_2(PPh_3)_3$ are added to the solution. Data collected in Table 3 show that the catalysed reaction between $C_{10}H_{21}OH$ and $NHPr_2$ gives increased yields of $C_{10}H_{21}NPr_2$ with added triphenylphosphine at all times after this 15 min induction period. At the early stages of the reaction the $^{31}P\{^1H\}$ NMR spectrum shows the presence of $RuCl_2(PPh_3)_3$ (δ 45, 60) as the only phosphorus containing ruthenium complex, whereas at the late stages of the catalysis complete conversion to $RuHCl(CO)(NHPr)(PPh_3)_2$ (δ 47.8) has occurred. No other complexes are observed in significant amounts. In the presence of added triphenylphosphine we observe the formation of $RuHCl(CO)(NHPr)(PPh_3)_2$ after 90 min, whereas in the absence of added triphenylphosphine we only observe this compound after 180 min.

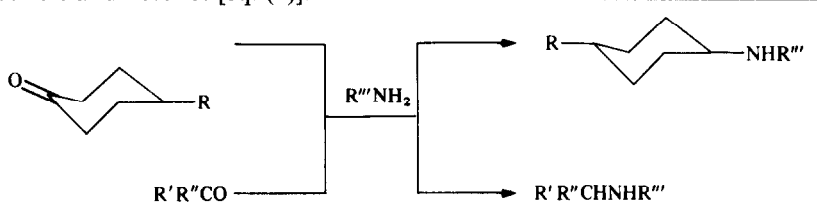
At the higher temperature of 180°C and the longer reaction time of 10 h we observe the

$RuCl_2(PPh_3)_3$ catalysed conversion of secondary alcohols into tertiary amines by condensation with primary amines, but not with secondary amines. Thus after the 10 h reaction time we obtain a 43% yield of 4-methylcyclohexylphenylamine from 4-methylcyclohexanol and aniline, and a 22% yield of 4-methylcyclohexyl hexylamine from 4-methylcyclohexanol and 1-hexylamine [eq. (3)].



(3)

With 4-methycyclohexanol and dipropylamine we observe no product amine after 10 h, but after 16 h reaction time the compound 4-methylcyclohexyldipropylamine is formed in 13% yield. Under catalytic conditions at 120°C we observe no tertiary amine formation from dipropylamine and secondary alcohols or ketones. Previous workers have, however, reported that $RuCl_2(PPh_3)_3$ acts as a homogeneous catalyst for the condensation of aniline with *both* secondary and primary alcohols, therefore we have investigated further the scope of this reaction.[7] Under catalysed conditions at 180°C for 10 h we find that aniline and 1-hexylamine undergo condensation reactions with both cyclic and acyclic alcohols and ketones [eq. (4)].



(4)

(R = H,Me; R' = R'' = C_2H_5; R' = CH_3, R'' = Ph; R' = 1-C_6H_{13}, R'' = CH_3; R''' = Ph, 1-C_6H_{13})

The yields of product amine are generally low (Table 4), especially for the case where a secondary amine reactant is employed.

In the catalysed condensation reactions of aniline with both 3-pentanone and acetophenone, the respective yields of 3-pentylphenylamine and acetophenyl phenylamine are increased by approximately four-fold when the reaction is carried out under a pressure of hydrogen.[8] For the case of secondary amines and ketones the yield of tertiary amine is very low even when the catalyst is composed of $RuCl_2(PPh_3)_3$ with 4 moles of triphenylphosphine under a hydrogen pressure of 1300 psig (Table 5).

In some cases the selectivity of the condensation reaction (1) is lowered by a redistribution reaction, whereby the initially formed amine undergoes alkyl group interchange to give a series of different tertiary and secondary amines. This reaction is observed in the reaction between terminal alcohols and secondary amines (Table 6), secondary alcohols and both primary and secondary amines (Table 7), and ketones and primary amines (Table 8). The data in Tables 6–8 show no particular pattern. For the terminal alcohols we only observe significant redistribution products when dipropylamine is used. In addition to the product $RNPr_2$, the amines R_2NPr, NPr_3 and RNHPr (R = $C_{10}H_{21}$, $C_{14}H_{29}$, $C_{16}H_{33}$, $C_{18}H_{37}$) are formed in varying amounts depending on the alcohol ROH (Table 6). Similar results are found when secondary alcohols are used (Table 7). For the case of ketones we observe no amine redistribution products when the reaction is carried out in the absence of hydrogen, when the amine yield is very low. Under a pressure of hydrogen the yield of amine is increased, and redistribution products are observed (Table 8).

DISCUSSION

The complex $RuCl_2(PPh_3)_3$ acts as a homogeneous catalyst for the condensation of terminal alcohols with secondary amines to give tertiary amines. At the end of the 2.5 h reaction time the complex has been converted completely into

[a] Reaction conditions: 3 h at 120°C; 1.00×10^{-2} moles of 1-decyl alcohol and 1.00×10^{-2} moles of dipropylamine; 5.22×10^{-5} moles of $RuCl_2(PPh_3)_3$ and 2.08×10^{-4} moles of PPh_3.

$RuHCl(CO)(amine)(PPh_3)_2$. Separate experiments with $RuHCl(CO)(PPh_3)_3$ and secondary amine verify that this complex is not itself a catalyst for the condensation reaction. The initial step of the reaction apparently results in the formation of an intermediate alkoxide complex which can undergo β-hydrogen transfer to give an aldehydic intermediate. In the presence of excess secondary amine we do not detect any aldehydic intermediates because of their rapid condensation with amine. Two pieces of evidence support the postulate that intermediate aldehydes are formed. The first supportive evidence is the formation of both $RuHCl(CO)L(PPh_3)_2$ (L = amine) and small quantities of alkane in the catalytic reaction. Well-documented examples exist which show that aldehydes are decarbonylated by platinum metal group complexes to give alkanes and carbonyl metal complexes.[9] The second support comes from a series of separate catalysed and uncatalysed reactions between butyraldehyde and diethylamine at 120°C for 2.5 h reaction time (Table 9). In the absence of catalyst the products of the reaction are the eneal, $CH_3(CH_2)_2CH{=}C(C_2H_5)CHO$, and the eneamine, $CH_3CH_2CH{=}CHN(C_2H_5)_2$, in a 44:1 ratio. In the presence of $RuCl_2(PPh_3)_3$ the products are the eneal and tertiary amine, $(C_4H_9)N(C_2H_5)_2$, in a 8.9:1 ratio. In the presence of hydrogen under a pressure of 1300 psig the catalytic reaction is selective for $(C_4H_9)N(C_2H_5)_2$. These results can be explained by eq. (5)

$$\begin{array}{l} RCH_2CHO \underset{H_2O}{\overset{Et_2NH}{\rightleftharpoons}} RCH{=}CHNEt_2 \xrightarrow{H_2} RCH_2CH_2NEt_2 \\ \quad \Updownarrow \\ RCH_2CH{=}CH(R)CHO \end{array} \qquad (5)$$

$(R = C_2H_5)$,

whereby the condensation reaction to eneamine is in competition with the self-condensation of the aldehyde to give the aldol eneal product. The formation of saturated amine results from the function of $RuCl_2(PPh_3)_3$ as a hydrogenation catalyst for the intermediate eneamine, and the hydrogenation step is accelerated under hydrogen pressure.

At 120°C for 2.5 h we do not observe any catalysed condensation reaction between dipropylamine and secondary or tertiary alcohols. This

Table 9. Reaction products from butyraldehyde and diethylamine

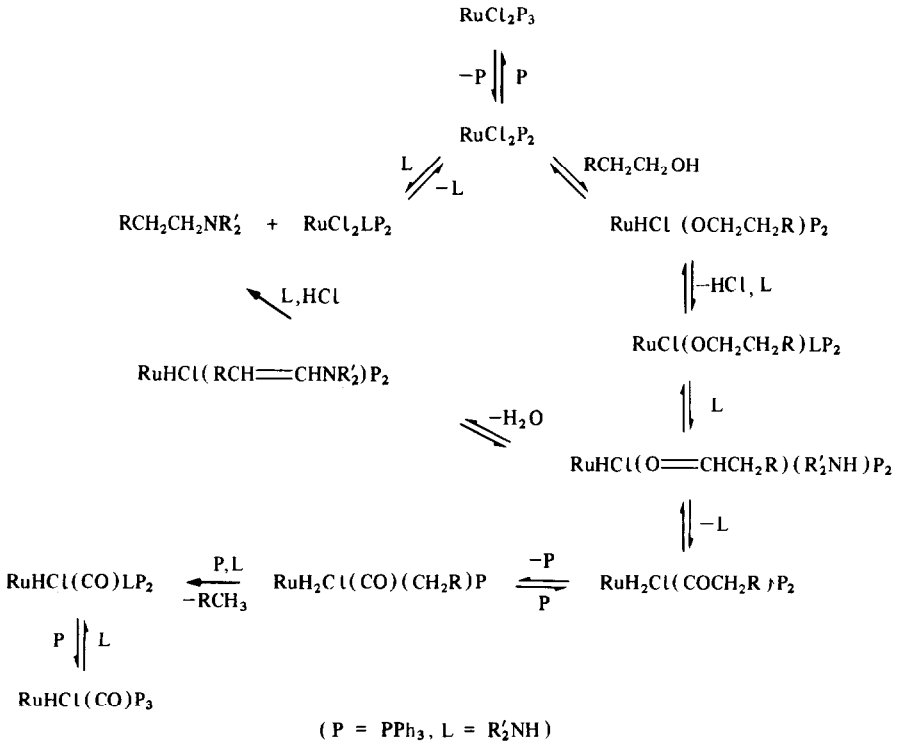
Conditions[a]	Product ratio	Yield (%)
No catalyst	 44 : 1	77
No catalyst (1300 psi H_2)	 1.9 : 1	66
$RuCl_2(PPh_3)_3$	 8.9 : 1	77
$RuCl_2(PPh_3)_3$ (1300 psi H_2)		32

[a] Conditions are 120°C for 2.5 h.

observation may be due to the failure of $RuCl_2(PPh_3)_3$ to catalyse either the dehydrogenation of secondary alcohols to ketones or the hydrogenative condensation of ketones with the secondary amine. Under conditions with $RuCl_2(PPh_3)_3$ for 10 h at 180°C we detect *no* tertiary amine formation with 3-pentanone and dipropylamine, diethylamine or pyrrolidine, or with acetophenone and dipropylamine. Furthermore when the alcohol is 2-octanol, 3-pentanol or cyclohexanol we detect no ketone formation.

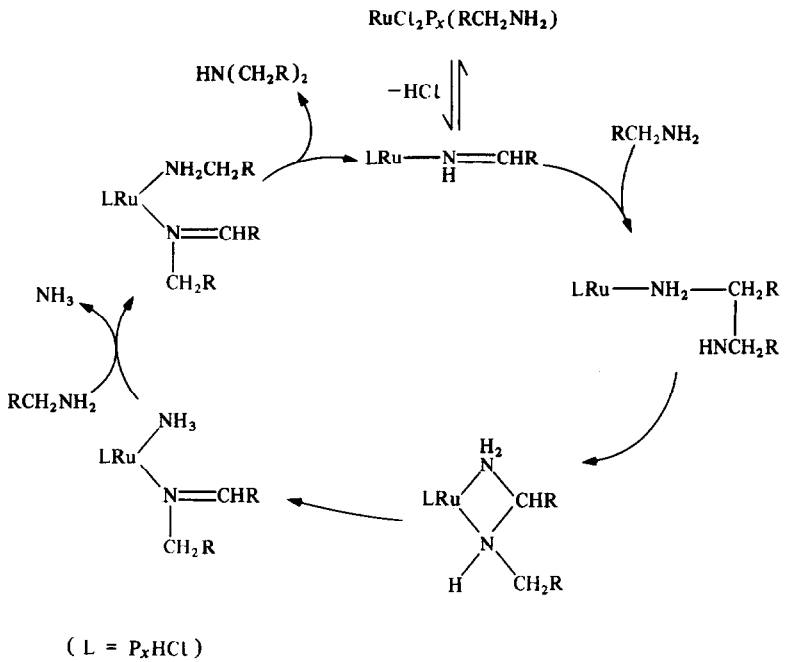
The data in Table 2 show that $RuCl_2(PPh_3)_3$, but not $RuCl_2(dppe)_2$, $RuCl_2(PN)_2$ (PN = 2-diphenylphosphino-N,N-dimethylaniline) or $RuCl_2(bipy)_2$, is a homogeneous catalyst for the condensation reaction between terminal alcohols and secondary amines. The difference between $RuCl_2(PPh_3)_3$ and the other complexes is that $RuCl_2(PPh_3)_3$ is a 16-electron complex, whereas the other complexes have 18-electron configurations. The failure of $RuCl_2(PN)_2$ to catalyse the formation of tertiary amines implies that under our experimental conditions the ligand is not hemilabile, whereby the dimethylamino moiety hinges away from the metal centre to create a vacant coordination site.[5] Adding tin(II) chloride to $RuCl_2(PPh_3)_3$ does not increase its catalytic activity by introducing $SnCl_3^-$ as a good leaving ligand. Adding triphenylphosphine causes an increase in catalytic activity of $RuCl_2(PPh_3)_3$ Triphenylphosphine itself is inactive as a homogeneous catalyst for reaction (1). From the data in Table 3 it is unclear as to the precise function of triphenylphosphine in accelerating the formation of tertiary amines. Since we observe the formation of $RuHCl(CO)(NHPr_2)(PPh_3)_2$ at an earlier stage of the reaction than we do in the absence of triphenylphosphine, it appears that the complete catalytic cycle has been accelerated. Several possibilities can be excluded or considered unlikely. One of these is that chloride ion is replaced by triphenylphosphine to give a catalytically more reactive cationic ruthenium(II) complex. We have eliminated this possibility because solutions of $RuCl_2(PPh_3)_3$ show no increased conductivity upon addition of excess triphenylphosphine. A second possibility is that triphenylphosphine acts to extend the catalyst lifetime of $RuCl_2(PPh_3)_3$; this postulate is disfavoured by the observation that the catalytically inactive complex $RuHCl(CO)NHPr_2(PPh_3)_2$ is formed at shorter reaction times in the presence of added triphenylphospine than is found in comparable catalytic runs in its absence.

The proposed catalytic pathway for the condensation reaction between terminal alcohols and secondary amines is shown in Scheme 1. In this scheme a key step is the Schiff base condensation reaction between secondary amine and the inter-



(P = PPh_3, L = R'_2NH)

Scheme 1.



Scheme 2.

mediate aldehyde formed by β-hydrogen transfer. The tertiary amine product is then obtained by the catalysed hydrogenation of the imine formed in this Schiff base condensation. Two plausible explanations for the accelerating effect of triphenylphosphine are that it displaces the complexed aldehyde ligand to facilitate its reaction in the free state with secondary amine, or that it functions to accelerate the catalytic hydrogenation of imine to tertiary amine.

The condensation reaction between ketones and amines under catalytic conditions with $RuCl_2(PPh_3)_3$ requires a higher temperature than does the condensation reaction between primary alcohols and amines. The primary product is the secondary amine, and the yield is increased under a pressure of hydrogen [eq. (6)].

$$R_2CO + R'NH_2 + H_2 \longrightarrow R_2CHNHR' + H_2O \quad (6)$$

For secondary amines as reactants, tertiary amines are not formed in the absence of hydrogen, and even under 1300 psig hydrogen pressure the yields are very low [eq. (7)].

$$R_2CO + R'_2NH + H_2 \longrightarrow R_2CHNR'_2 + H_2O \quad (7)$$

These results support a pathway whereby the final amine is produced by catalytic hydrogenation of an intermediate imine formed in an equilibrium condensation reaction between the ketone and reactant amine [eq. (8)].

$$R_2CO + R'NH_2 \underset{H_2O}{\overset{-H_2O}{\rightleftharpoons}} R_2C{=}NR' \xrightarrow{H_2} R_2CHNHR' \quad (8)$$

We propose that the catalytic activity of $RuCl_2(PPh_3)_3$ results from its functioning as a hydrogenation catalyst for the intermediate imine. This imine is formed in equilibrium with the ketone and amine, and its catalysed hydrogenation to the product amine drives the equilibrium away from the reactant.

The amine redistribution reaction results in decreased selectivity of the catalysed condensation reactions between amines and either alcohols or ketones. These side products cannot be eliminated from the product because this redistribution reaction occurs subsequent to the formation of the initial amine product. Previous researchers have found that these redistribution reactions are catalysed by a series of different ruthenium complexes.[10] The pathway used to explain these reactions is shown in Scheme 2.

SYNTHESIS OF NEW SYMMETRICAL *MESO*-SUBSTITUTED PORPHYRINS: TETRA-6-QUINOLINE PORPHYRIN, TETRA-6-[N-METHYL(^{13}C) QUINOLINE] PORPHYRIN TETRAIODIDE SALT AND THEIR COPPER(II) COMPLEXES

JAMES D. McCURRY* and JAMES E. ROBERTS†

Lehigh University, Department of Chemistry, Bethlehem, PA 18015, U.S.A.

(*Received* 26 *February* 1990; *accepted* 15 *June* 1990)

Abstract—The synthesis and spectroscopic characterization of a series of *meso*-substituted porphyrins based on a new parent compound, tetra-6-quinoline porphyrin, is described. Successful preparation of the parent compound was accomplished by the synthesis of 6-quinoline carboxaldehyde followed by reaction with pyrrole via the Rothemund condensation. The quinoline nitrogens were then methylated with ^{13}C-methyl iodide to form the uniformly labelled tetra-6-[N-methyl(^{13}C) quinoline] porphyrin tetraiodide salt. Copper(II) complexes of the parent compound and the ^{13}C labelled porphyrin were also successfully prepared and characterized.

Porphyrin compounds have been extensively studied due to their important metabolic role in oxygen transport, electron transport and photosynthesis.[1] Synthetic porphyrins are often used as models to understand the chemistry of naturally occurring porphyrins and have recently found application as structural probes for nucleotides and as tumour imaging agents.[2,3] For our work porphyrins were chosen as model compounds for the investigation of paramagnetic relaxation in solid-state nuclear magnetic resonance. The ability of porphyrins to complex paramagnetic metals and their simple rigid geometry allow simplification of the structural terms in the paramagnetic relaxation equation. In our laboratory, a number of symmetric free base and copper(II) *meso*-tetra-[N-methyl(^{13}C) pyridyl] porphyrin tetraiodide salts have been synthesized. The ^{13}C labelling improved sensitivity and selectivity for the NMR relaxation experiments. These syntheses were performed by the Adler-modified Rothemund condensation of equimolar amounts of pyrrole with pyridylaldehydes.[4,5]

A logical extension of the N-methylated pyridyl porphyrins was the preparation of an N-methylated quinoline porphyrin series, specifically tetra-6-[N-methyl(^{13}C) quinoline] porphyrin (see Fig. 1). Since a number of *meso*-tetra-aryl porphyrins have been prepared via the Rothemund condensation,[6–9] the challenge was finding a method for the synthesis of 6-quinoline carboxaldehyde since it is not commercially available or reported in the literature. The aldehyde synthesis was accomplished by the partial oxidation of 6-methyl quinoline, which is commercially available. Teague and Roe reported a simple preparation of 3-quinoline carboxaldehyde from 3-methyl quinoline using selenium oxide.[10] Once the 6-quiniline carboxaldehyde was prepared, the porphyrin synthesis proceeded analogous to the pyridyl series. The ^{13}C label was introduced to the quinoline nitrogen using ^{13}C-methyl iodide.

EXPERIMENTAL

All synthetic methods were first attempted with non-labelled materials. Products were characterized for structure and purity before proceeding to isotropically enriched syntheses. The following descriptions and results are only reported for the isotropically enriched products when applicable. All solvents and reagents used were reagent grade. Elemental analyses were performed in duplicate and the averages reported. UV–vis spectroscopy was accomplished with a Perkin–Elmer Lambda V spectrometer using 1 cm matched quartz cells, a 0.2 nm slit width and a scan speed of 60 nm min^{-1} from

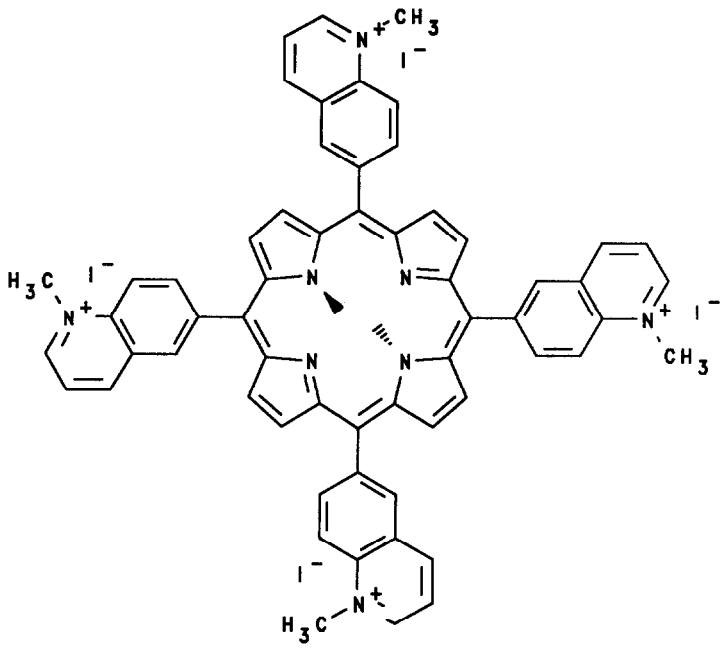

Fig. 1. Structure of tetra-6-[N-methyl(^{13}C) quinoline] porphyrin tetraiodide salt.

700 to 350 nm. ^{1}H NMR spectroscopy was performed with a Bruker AM 500 with resonances referenced to TMS (0.0 ppm). A Matson Sirus 100 FT–IR was used for IR spectroscopy with the sample cast as a film between potassium bromide windows. Gas chromatography–mass spectrometry (GC–MS) analysis was accomplished with a Hewlett–Packard 5970A equipped with a 25 m × 0.25 mm i.d. thin film SP-1 capillary column.

(1) *6-Quinoline carboxaldehyde*

A 500 cm^3 three-necked flask containing 25.0 g (0.18 mol) of 6-methyl quinoline (Aldrich Chemical Co.) was equipped with an immersion thermometer, a powder addition funnel and a magnetic stirring bar. Into the powder addition funnel was placed 20.0 g (0.18 mol) of selenium(IV) oxide. The 6-methyl quinoline was heated to 180°C and the selenium oxide was slowly added to the stirring quinoline.[11] The complete addition of the SeO_2 took approximately 1 h and was controlled so that the temperature never exceeded 210°C. After cooling to room temperature 100 cm^3 of ethyl ether was placed in the flask and a reflux condenser replaced the addition funnel. The ether was refluxed for 20 min, cooled and decanted from the flask, leaving the dark brown tar behind. This procedure was repeated twice more. The combined ether extracts were dried over magnesium sulphate, filtered and the ether removed with a rotary evaporator. A damp yellow solid was recovered and an IR spectrum was taken to confirm the presence of an aldehyde functionality (ν = 1700 cm^{-1}). Further analysis by GC–MS was performed to determine the presence and purity of quinoline aldehyde. The product was further purified by fractional distillation under vacuum to obtain 9.1 g (33% yield) of 6-quinoline carboxaldehyde as a pale yellow solid. The aldehyde was immediately used for porphyrin synthesis before any significant oxidation occurred.

(2) *Tetra-6-quinoline porphyrin* (T6QP)

The quinoline aldehyde (9.1 g, 58.0 mmol) prepared above was placed in a flask and dissolved in 150 cm^3 of propionic acid. After dissolution, freshly distilled pyrrole (4.0 g, 58.0 mmol) was added and the mixture was refluxed for 2 h. After cooling to room temperature, the propionic acid was removed by rotary evaporation leaving a shiny black tar. The tar was dissolved in 100 cm^3 of chloroform. A flash chromatography column (45 cm × 5 cm) was packed with neutral activated alumina (Brockman activity 1, 80–200 mesh) and the chloroform solution containing the tar was placed on the column. The porphyrin was chromatographed on the column with 10% (v/v) pyridine–dichloromethane. Long wavelength UV light was used to follow the porphyrin elution band through the column. Fractions containing the porphyrin were combined and the solvent removed by rotary evaporation. A total of 500 mg of tetra-6-quinoline porphyrin was recovered as dark purple crystals (1% yield). A UV–vis and a ^{1}H NMR spectra were recorded for this novel

compound. A Beer's law analysis was also performed in order to calculate the Soret band extinction coefficient. Found: C, 82.0; H, 4.3; N, 13.4. Calc.: C, 82.1; H, 4.2; N, 13.7%.

(3) *Tetra*-6-[N-*methyl*(^{13}C) *quinoline*] *porphyrin tetraiodide salt* (T6NMQP)

Methylation of the quinoline nitrogens was accomplished by refluxing tetra-6-quinoline porphyrin (0.3 g, 0.37 mmol) and ^{13}C-methyl iodide (5.0 g, 34.3 mmol) in 50% (v/v) chloroform–dimethylformamide for 24 h. After cooling to room temperature, the reaction mixture was mixed with 250 cm^3 of dichloromethane to precipitate the product. The methylated porphyrin salt was recovered by filtration and was washed with 15 cm^3 portions of hot dichloromethane until the filtrate was clear. The result was recovery of 0.51 g of product as a brown solid (99% yield). A UV–vis spectrum and ^{1}H proton NMR spectrum were recorded for this porphyrin. A Soret band extinction coefficient was also calculated from a Beer's law plot. Found: C, 48.5; H, 3.4; N, 7.8. Calc.: C, 48.4; H, 3.3; N, 8.1%.

(4) *Copper–tetra*-6-[N-*methyl*(^{13}C) *quinoline*] *porphyrin tetraiodide salt* (Cu–T6NMQP)

The porphyrin was metallated by mixing methylated quinoline porphyrin (75 mg, 0.05 mmol) and $CuCl_2(H_2O)_2$ (75 mg, 0.44 mmol) in 25 cm^3 of dimethylformamide and refluxing for 1 h. The resulting solution was chilled to 0°C and stored at that temperature overnight to precipitate the product. A total of 62 mg of copper–tetra-6-[N-methyl(^{13}C) quinoline] porphyrin tetraiodide salt was recovered from the solvent by filtration followed by cold (0°C) acetone washings (85% yield). A UV–vis spectrum was taken for this porphyrin with the determination of a Soret band extinction coefficient from the Beer's law plot.

(5) *Copper–tetra*-6-*quinoline porphyrin* (Cu–T6QP)

The tetra-6-quinoline porphyrins are novel compounds so the non-methylated free base porphyrin was metallated with copper in order to complete UV–vis spectral characterization for the series. Starting with tetra-6-quinoline porphyrin (75 mg, 0.09 mmol) and $CuCl_2(H_2O)_2$ (75 mg, 0.44 mmol), 80 mg of copper–tetra-6-quinoline porphyrin was obtained using the metallation procedure described above (100% yield). A UV–vis spectrum was obtained and a Soret band extinction coefficient was determined from the Beer's law analysis.

RESULTS AND DISCUSSION

The successful oxidation of the 6-methyl quinoline to form 6-quinoline carboxaldehyde was initially confirmed by the presence of a carbonyl IR band at 1700 cm^{-1} in the crude reaction product. Further characterization was accomplished by GC–MS. The gas chromatogram shows the presence of two major components in the product. The mass spectra were compared with reference spectra of 6-methyl quinoline and 3-quinoline carboxaldehyde.[12] Analysis of the mass spectra revealed the two components to be methyl quinoline and quinoline carboxaldehyde. Higher oxidation products such as quinoline alcohols and carboxylic acids were not detected. Attempts to rigorously purify the aldehyde were not attempted since the next reaction step, porphyrin condensation, would not be adversely affected by the presence of methyl quinoline while further handling of the reaction product would result in aldehyde losses.

The 6-quinoline porphyrin series represents a new *meso*-substitution. Spectroscopic analyses for these compounds were carried out with UV–vis and NMR. The UV–vis spectrum for the tetra-6-quinoline porphyrin is shown in Fig. 2(A). The features show a strong Soret band at 424 nm with *Q*-bands at 518, 553, 592 and 640 nm. The relative intensities for these features are typical for symmetric *meso*-substituted porphyrins.[1] The copper–tetra-6-quinoline UV–vis spectrum is shown in Fig. 2(B). This spectrum shows the hypso characteristics typical for copper porphyrins where the intensity sequence is Soret $\gg \alpha > \beta$ and the energies are slightly blue shifted.[1] The spectral features and Soret band extinction coefficients for the four quinoline porphyrins are summarized in Table 1.

^{1}H NMR spectroscopy was used to further characterize both free-base porphyrin structures. The tetra-6-quinoline porphyrin ^{1}H NMR in $CDCl_3$ showed resonances in the aromatic region (7.5–9.5 ppm) whose chemical shifts are similar to those reported for 6-quinoline.[13] A large singlet resonance at 8.8 ppm is due to the eight chemically equivalent β-pyrrole protons on the parent porphyrin ring. The only other peak of interest occurred at -2.6 ppm which represented the two protons on the porphyrin core nitrogens. Integration of the quinoline protons and the β-pyrrole protons gave an intensity ratio of 3:1, thus indicating a symmetrically substituted product.

The ^{1}H NMR spectra of the tetra-6-[N-methyl (^{13}C) quinoline] porphyrin in perdeuterated dimethyl sulphoxide was taken in order to determine the extent of methylation and is shown in Fig. 3. A ^{1}H resonance from the N-methyl(^{13}C) protons

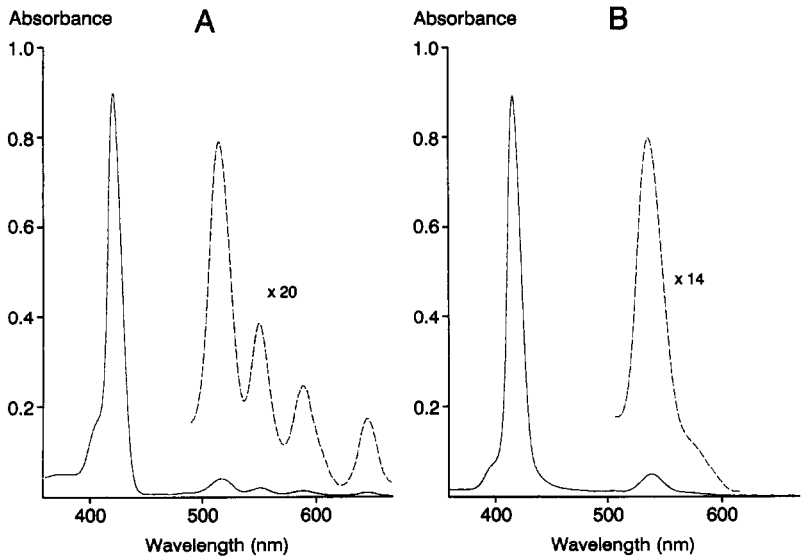

Fig. 2. (A) UV–vis spectrum of tetra-6-quinoline porphyrin in chloroform. *Q*-band expansion: × 20. (B) UV–vis spectrum of copper tetra-6-quinoline porphyrin in chloroform. *Q*-band expansion: × 14. The methylated porphyrins exhibit similar UV–vis spectra, with the observed spectral features summarized in Table 1.

was observed at 5.0 ppm with a ^{1}H–^{13}C *J*-coupling of 145.1 Hz. The doublet appearance of this resonance confirmed all methyl groups originated from the 99% ^{13}C labelled methyl iodide. Integration of the aromatic resonances (8.0–10.0 ppm) and the N-methyl(^{13}C) resonance gave an intensity ratio of 2:1. This indicated complete methylation of the porphyrin. Resonances due to residual water and protonated DMSO were observed at 3.4 and 2.5 ppm, respectively.

Although no rigorous solubility work was performed with these porphyrins, it was observed that the N-methylated iodide salts exhibited distilled water solubilities comparable to the tetra-4-(N-

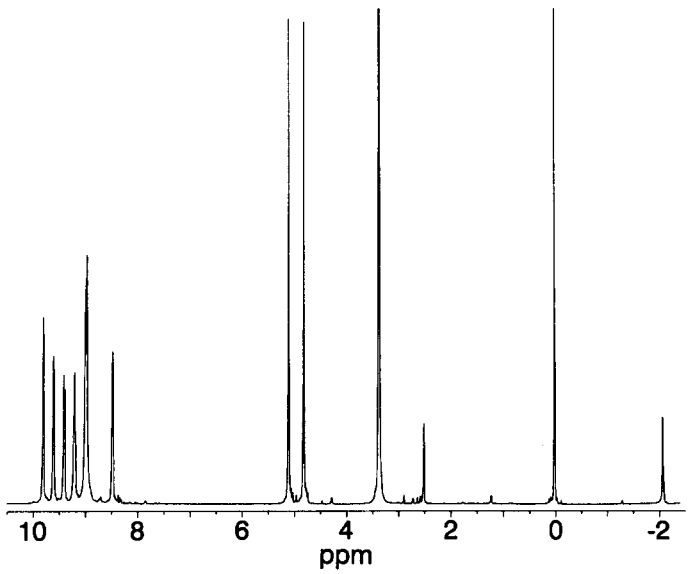

Fig. 3. ^{1}H NMR spectrum of tetra-6-[N-methyl(^{13}C) quinoline] porphyrin tetraiodide salt in perdeuterated dimethylsulphoxide. The resonances resulting from the porphyrins' protons are described in the text. The resonance at 4.4 ppm is due to residual water and the resonance at 2.5 ppm is due to protonated DMSO.

methyl pyridyl) porphyrins. The non-methylated porphyrins were soluble in methylene chloride and chloroform.

CONCLUSIONS

Selenium oxide was shown to be a good reagent for the mild oxidation of 6-methyl quinoline without the formation of higher oxidation products. The yields for this reaction were sufficient to provide enough aldehyde for the porphyrin synthesis. The Adler modified Rothemund condensation of the quinoline aldehyde with pyrrole was successful for the formation of the desired *meso*-substituted porphyrin, however, yields were very low. The four quinoline porphyrins prepared in this work had UV–vis spectra whose features were consistent with symmetric aryl-*meso* substitution on the porphyrin ring. These UV–vis spectra were sufficient for the quantitation and confirmation of product formation.

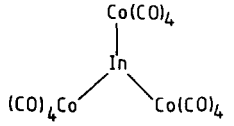
Abstract—The reaction between $InCl_3$ and one equivalent of $K[Co(CO)_3(PPh_3)]$ affords the complex $[InCl_2(PPh_3)\{Co(CO)_4\}]$ (**8**), which was characterized by X-ray diffraction. Compound **8** crystallizes in the triclinic space group $P\bar{1}$ with $a = 15.044(4)$, $b = 10.292(3)$, $c = 16.937(6)$ Å, $\alpha = 89.61(3)$, $\beta = 110.14(3)$, $\gamma = 91.04(2)°$ and $Z = 4$. The structure contains two essentially identical molecules per asymmetric unit and comprises an indium centre bonded to two chlorine atoms, a PPh_3 ligand and a $Co(CO)_4$ fragment in a tetrahedral coordination geometry. The solution state rearrangement of **8** to a complex, **9**, containing $Co(CO)_3(PPh_3)$ fragments is described and discussed. The reaction between $InCl_3$ and two equivalents of $K[Co(CO)_3(PPh_3)]$ affords two complexes. The first was characterized as $[Co(CO)_3(PPh_3)_2][InCl_2\{Co(CO)_4\}_2]$ (**10**) by X-ray crystallography. Compound **10** crystallizes in the triclinic space group $P\bar{1}$ with $a = 13.466(5)$, $b = 14.176(6)$, $c = 16.162(4)$ Å, $\alpha = 75.47(3)$, $\beta = 115.19(2)$, $\gamma = 114.17(3)°$ and $Z = 2$. The structure is a salt containing the $[Co(CO)_3(PPh_3)_2]^+$ cation and the indium-centred anion $[InCl_2\{Co(CO)_4\}_2]^-$. The latter contains an indium centre bonded to two chlorine atoms and two $Co(CO)_4$ fragments in a tetrahedral geometry. Spectroscopic data on the second complex obtained from this reaction indicates the formula $[InCl\{Co(CO)_3(PPh_3)\}_2]$ (**12**). We have also characterized the anion of **10** as its PPN salt (PPN = $Ph_3PNPPh_3^+$), $[PPN][InCl_2\{Co(CO)_4\}_2]$ (**11**). Compound **11** crystallizes in the triclinic space group $P\bar{1}$ with $a = 9.957(2)$, $b = 20.262(3)$, $c = 23.058(5)$ Å, $\alpha = 82.16(2)$, $\beta = 86.13(2)$, $\gamma = 84.00(2)°$ and $Z = 4$. The two crystallographically independent anions are similar in all respects to the anion in **10**. The reaction between $InCl_3$ and three equivalents of $K[Co(CO)_3(PPh_3)]$ affords $[In\{Co(CO)_3(PPh_3)\}_3]$ (**14**), spectroscopic data for which are described and discussed. We have also examined the reaction between InCl and $[Co_2(CO)_6(PPh_3)_2]$ which affords the dicobalt–indium chloride complex $[InCl(PPh_3)\{Co(CO)_3(PPh_3)\}_2]$ (**13**). Spectroscopic and analytical data are presented for all new complexes together with a discussion of their solution state properties which involve partial dissociation and rearrangement reactions.

Many examples exist of compounds containing transition metal–indium bonds.[1,2] In this introduction, however, we shall restrict ourselves primarily to those compounds which contain cobalt and are therefore of most relevance to this work.

One of the earliest such compounds to be described was $[In\{Co(CO)_4\}_3]$ (**1**), prepared by Hieber and Teller[3] from the metallic elements and

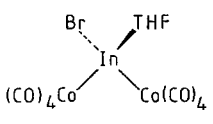


1

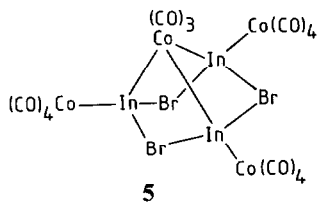
* Author to whom correspondence should be addressed.

CO under high pressure. This compound was later prepared by Schrauzer *et al.*[4] from indium metal, $[Co_2(CO)_8]$ and CO in toluene at high pressure and reported to be a catalyst for the dimerization of norbornadiene, and a subsequent report by Robinson and Schussler[5] presented details of a crystal structure determination which revealed a trigonal planar indium centre bonded to three $Co(CO)_4$ fragments. The reaction between **1** and $[Co(CO)_4]^-$ has been described by Robinson and co-workers[6] and affords the anionic complex $[In\{Co(CO)_4\}_4]^-$ (**2**). The solution state properties of **2** were also reported[6] with regard to dissociation; in CH_2Cl_2 it is essentially undissociated whereas in THF it dissociates to give **1** and $[Co(CO)_4]^-$, whilst in DMSO complete dissociation to $[In]^{3+}$ and $[Co(CO)_4]^-$ is observed. Two further Lewis base adducts with **1** were also mentioned, viz. $[In(OPPh_3)\{Co(CO)_4\}_3]$ and $[Cl(In\{Co(CO)_4\}_3)_2]^-$.

Indium halide fragments coordinated to cobalt have also been known for many years. Graham has described the insertion of InBr into $[Co_2(CO)_8]$ in THF which affords $[InBr(THF)\{Co(CO)_4\}_2]$ (**3**),[7] although the THF is readily lost to give $[InBr\{Co(CO)_4\}_2]$ (**4**), which is presumed to be dimeric. The same reaction, however, if carried out in benzene yields the polynuclear complex $[In_3\{Co(CO)_4\}_3(\mu\text{-}Br)_3\{\mu_3\text{-}Co(CO)_3\}]$ (**5**),[7,8] the structure of which was determined by X-ray crystallography.[8,9] Compound **3** is also produced from the reaction between $InBr_3$ and $2Na[Co(CO)_4]$ in THF and Graham has also described[7b] the synthesis of $[In(acac)\{Co(CO)_4\}_2]$ from **3** and the synthesis of **1** from $InBr_3$ and $3Na[Co(CO)_4]$.

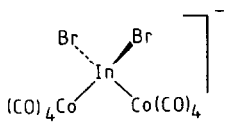


3



5

The anionic complex $[InBr_2\{Co(CO)_4\}_2]^-$ (**6**) has been prepared as the $[NEt_4]$ salt, from the reaction between InBr and $[Co_2(CO)_8]$ in the presence of $[NEt_4]Br$ and structurally characterized,[10] and Hsieh and Mays[11] have described the synthesis of



6

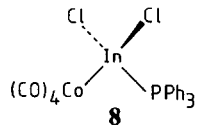
$[InCl\{Co(CO)_4\}_2]$ (**7**) by three methods: (i) $InCl_3 + 2Na[Co(CO)_4]$, (ii) insertion of InCl into $[Co_2(CO)_8]$ and (iii) reaction of InCl with $[Hg\{Co(CO)_4\}_2]$.

Finally, we note that Ruff[12] has reported the reaction between $InBr_3$ and one equivalent of $[PPN][Co(CO)_4]$ which gives the adduct $[PPN][InBr_3\{Co(CO)_4\}]$ and Burlitch *et al.*[13] have described the synthesis of the adduct $[PPN][InPh_3\{Co(CO)_4\}]$ from $[PPN][Co(CO)_4]$ and $InPh_3$ ($PPN = Ph_3PNPPh_3^+$].

Herein we report details of our own work involving the reactions between $InCl_3$ and $K[Co(CO)_3(PPh_3)]$.

RESULTS AND DISCUSSION

The reaction between $InCl_3$ and one equivalent of $K[Co(CO)_3(PPh_3)]$ in THF gave a pale yellow solution from which very pale yellow crystals were obtained after work-up and crystallization from CH_2Cl_2–hexane mixtures. An IR spectrum obtained on a solution of these crystals in THF is shown in Fig. 1(a) with numerical data in Table 1. In order to determine the structure of this complex, an X-ray diffraction study was undertaken, the results of which are presented in Fig. 2 and Table 2. The structure comprises an indium centre in a tetrahedral coordination environment bonded to two chlorine atoms, a $Co(CO)_4$ fragment and a PPh_3 ligand, $[InCl_2(PPh_3)\{Co(CO)_4\}]$ (**8**) and can



8

be described as a phosphine adduct of the neutral, trivalent indium complex, $[InCl_2\{Co(CO)_4\}]$. Two

molecules of **8** are present in the asymmetric unit of the unit cell which are similar in their gross structural form except in the conformations about the In—Co bond. Thus the torsion angle defined by P(1)—In(1)—Co(1)—C(2) differs by about 25° in the two molecules, whereas the orientation of the PPh_3 ligand relative to the $InCl_2$ fragment differs by only 5°. The In—Co bond lengths [In(1a)—Co(1a) 2.540(3), In(1b)—Co(1b) 2.543(3) Å] are in the usual range for such bonds, which we will discuss later, and are axial with respect to the trigonal bipyramidal geometry about cobalt. The In—P lengths are 2.607(5) and 2.611(5) Å which can be compared with a standard single bond value of 2.60 Å derived from the sum of the covalent radii of indium and phosphorus.[14] While phosphine complexes of indium halides are quite common[15] the only published structural data of which we are aware are for the complex $[InCl_3(PPh_3)_2]$[16] for which the In—P bond lengths are 2.701(5) and 2.723(5) Å, slightly longer than those in **8** possibly as a result of increased steric crowding around the indium centre.

Analytical data for **8** are given in Table 1 and are in accord with the formula derived from the X-ray analysis. However, when a sample of **8** was

dissolved in CD_2Cl_2 in order to obtain a ^{31}P NMR spectrum, the initially colourless solution became yellow after a few minutes and a small amount of white solid was precipitated, some of which slowly redissolved. The ^{31}P NMR spectrum obtained on this sample showed signals at 63.4 and 6.4 ppm, the former consistent with PPh_3 bonded to cobalt[17] and the latter with free phosphine or possibly phosphine bonded to indium. Moreover, on removal of the CO_2Cl_2 and after dissolving the resultant yellow oil in THF, the IR spectrum obtained revealed that a rearrangement had certainly taken place [Fig. 1(b)], whilst the peak values ($\nu C{\equiv}O$ 2076w, 2050w, 2021w, 2002w, 1957s cm^{-1}), especially the major, intense absorption at 1957 cm^{-1}, were also suggestive of a $Co(CO)_3(PPh_3)$ fragment.[17] Thus **8** would appear to rearrange in CD_2Cl_2 solution affording a complex in which PPh_3 is bonded to cobalt, presumably of the form $[InCl_2\{Co(CO)_3(PPh_3)\}]$ (**9**). However, crystals of **8** were originally obtained from CH_2Cl_2 solution after work-up of the reaction. It would therefore appear that whilst **9** is the major compound present in solution, and, of course, the anticipated product from this reaction, a small amount of **8** is also present which crystallizes more readily under the conditions employed. The subsequent rearrangement of **8** into **9** after redissolution in CH_2Cl_2 suggests that an equilibrium shown in eq. (1) is present which in CH_2Cl_2 solution lies predominantly to the right. However, as **8** is apparently less soluble than **9**, crystallization affords **8** which progressively shifts the equilibrium in solution to the left-hand side [as represented in eq. (1)]. This cannot be the whole story since the rearrangement of **9** to **8** requires more CO, relative to cobalt and indium, than is originally present in the reaction. We suggest that this accounts for the low isolated yields of **8** (typically 48%) but we have not observed or isolated any carbonyl-deficient compounds from this reaction.

$$[InCl_2(PPh_3)\{Co(CO)_4\}] \quad (\mathbf{8}) \rightleftharpoons [InCl_2\{Co(CO)_3(PPh_3)\}] + CO \quad (\mathbf{9}) \quad (1)$$

As a partial explanation for these results, we note that the observed lability of the PPh_3 ligand on cobalt is in accord with the generally observed substitution lability of ligands in CoL_4 fragments.[18] However, we did not encounter such problems in the chemistry of $K[Co(CO)_3(PPh_3)]$ with antimony or bismuth halides[17] and suggest that the reason for these observations in the system described above is that the Lewis acidic indium centre effectively competes with the cobalt for the phosphine ligand.

In an effort to obtain **8** by another, potentially higher yield route we carried out the following reaction. $InCl_3$ was dissolved in THF together with one equivalent of PPh_3. After stirring for 15 min, one equivalent of $K[Co(CO)_4]$ was added and work-up followed by crystallization from CH_2Cl_2–hexane mixtures afforded a pale yellow crystalline material which analysed correctly for **8**.* When these crystals were dissolved in CD_2Cl_2 a colour change from colourless to yellow was observed and the ^{31}P NMR spectrum was similar to that observed previously for **8** and showed signals at 63.4 and 6.2 ppm. Removal of the CD_2Cl_2 and redissolution in THF gave a yellow solution, the IR spectrum of which was identical to that shown in Fig. 1(b), i.e. that of **9**. The THF solution IR spectrum of the original pale yellow crystals showed a pattern almost ident-

* Found: C, 42.5; H, 2.3. Compound **8** requires: C, 42.7; H, 2.5 (Table 1).

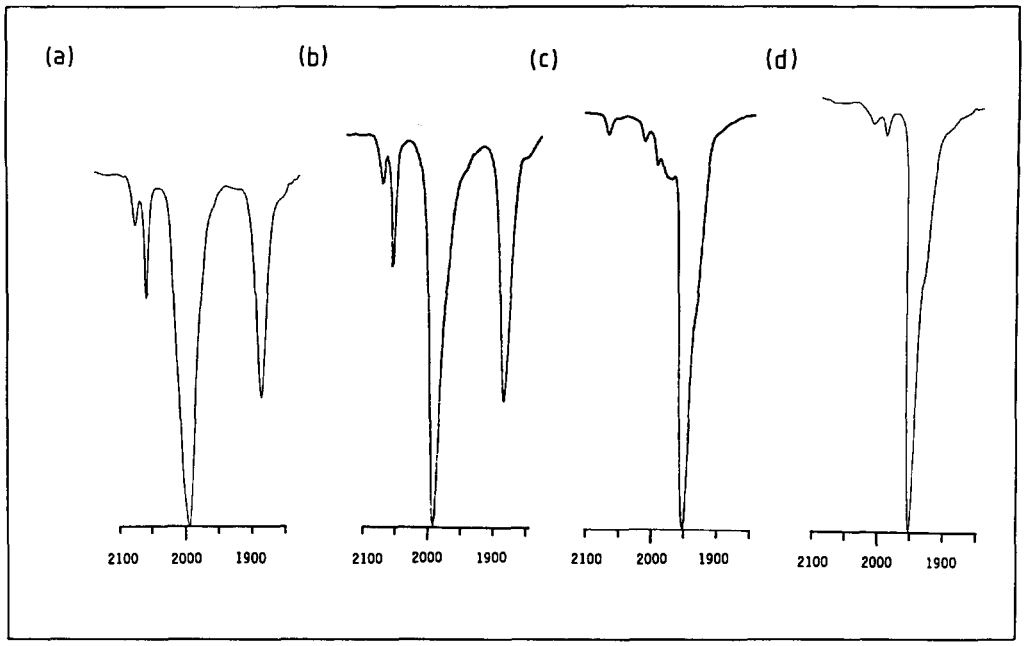

Fig. 3. IR spectra in the carbonyl stretching region, (a) **10**, (b) **11**, (c) **12** and (d) **13**.

ical to that found for **8** [Fig. 1(a)] but with values 2090m, 2075w, 2004s cm^{-1}, i.e. approximately 10–12 cm^{-1} higher in frequency. We have no explanation for this particular observation except to say that we cannot be sure as to whether the solid-state structure found for **8** is also present in THF solution (it is certainly not present in CH_2Cl_2 solution). The pattern of absorptions in the IR spectrum is consistent with a $Co(CO)_4$ group, but the extent to which the phosphine remains coordinated to indium is unclear. It may well be concentration dependent and thereby affect the frequencies observed in the IR spectra but not the number and intensity of the peaks.*

The reaction between $InCl_3$ and two equivalents of $K[Co(CO)_3(PPh_3)]$ is more complex and gives rise to at least two products. Work-up followed by recrystallization from THF–hexane mixtures afforded a heterogeneous sample consisting of yellow plate-like crystals and an orange crystalline powder. An IR spectrum was obtained on a THF solution of the yellow crystals [Fig. 3(a), Table 1] together with a ^{31}P NMR spectrum which showed a singlet at 55.9 ppm (CD_2Cl_2), but in order to ascertain the structure, an X-ray diffraction study was carried out. The results are presented in Figs 4 and 5 and Table 3 and establish the structure as a salt with the formula $[Co(CO)_3(PPh_3)_2][InCl_2\{Co(CO)_4\}_2]$ (**10**). The cation $[Co(CO)_3(PPh_3)_2]^+$ has not been previously characterized by X-ray methods and comprises a trigonal bipyramidal cobalt centre with axial PPh_3 ligands and equatorial carbonyls.[19] The anion $[InCl_2\{Co(CO)_4\}_2]^-$ consists of a tetrahedral indium centre bonded to two chlorine atoms and two $Co(CO)_4$ fragments, the latter adopting a configuration such that the indium occupies an axial site in the trigonal bipyramidal coordination geometry around the cobalt, as was also observed for **8**. The Co—In bond lengths [In(1)—Co(1) 2.617(2) and In(1)—Co(2) 2.608(2) Å] are slightly longer than those observed in **8** but comparable to those observed in the dibromo analogue $[InBr_2\{Co(CO)_4\}_2]^-$ (**6**),[10] [In—Co 2.638(12), 2.644(14) molecule A and 2.637(12), 2.596(14) Å molecule B]. Other In—Co bond lengths of interest are those in **5**[8,9] [terminal $(CO)_4Co$—In 2.532(5), 2.585(5), 2.582(6) Å; μ-$(CO)_3Co$—In 2.573(5), 2.637(6), 2.591(5) Å] and in **1**[5] [In—Co 2.590(3), 2.595(3), 2.597(3) Å]. Clearly, a value of 2.50–2.65 Å is typical for a In—Co single bond though little else of any significance can be gathered from these values. We note, however, that in all cases where indium is bonded to a $Co(CO)_4$ fragment, it resides in an axial position with respect to the cobalt centre.

We will return to the formation of **10** and the nature of the second product shortly but at this stage it is useful to include the results of another

* We have no evidence for the rearrangement of **8** to **9** in THF solution.

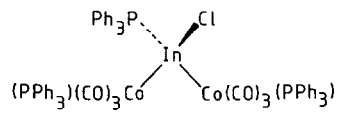
crystal structure determination carried out on the complex $[PPN][InCl_2\{Co(CO)_4\}_2]$ (**11**), obtained from the reaction between $InCl_3$ and two equivalents of $[PPN][Co(CO)_4]$.[20] The results for **11** are presented in Fig. 6 and Table 4 and show that both the crystallographically-independent anions, $[InCl_2\{Co(CO)_4\}_2]^-$, are similar in all respects to **10**. The In—Co bond lengths are *ca* 2.6 Å [In(1)—Co(1) 2.600(4), In(1)—Co(2) 2.621(4); In(2)—Co(3) 2.625(4), In(2)—Co(4) 2.609(4) Å] whilst the Co—In—Co and Cl—In—Cl angles differ by no more than 3.3 and 0.6°, respectively. Moreover, the relative orientations of the $Co(CO)_4$ fragments are also similar as judged by the torsion angles Cl(2)—In(1)—Co(1)—C(11) [−49.2(3)°] and Cl(2)—In(1)—Co(2)—C(23) [−155.3(4)°] in **10** compared with the corresponding angles in **11** of −44.6(10) and −160.6(9)° for molecule A and −50.1(10) and −154.3(12)° for molecule B.

The solution IR spectrum of **11** [Fig. 3(b), Table 1] is very similar to that observed for **10**. Both were obtained in THF but the absorption at 1886 cm^{-1} is characteristic of $[Co(CO)_4]^-$ [20] and therefore indicates that partial In—Co bond heterolysis occurs in this solvent.* Dissociation in polar coordinating solvents is commonly observed in the chemistry of transition metal indium compounds, as cited in the Introduction for **1** and **2**[6] and as reported for related complexes containing $Mo(CO)_3(\eta\text{-}C_5H_5)$[2] and $Mn(CO)_5$[21] fragments (see later).

Turning now to the mechanistic origin of **10**, the lability of the PPh_3 ligands on cobalt is again evident since the cobalt centres bonded to indium have clearly lost the phosphine present in the starting anionic complex, $[Co(CO)_3(PPh_3)]^-$, whereas the cobalt in the counter cation, $[Co(CO)_3(PPh_3)_2]^+$, has an additional phosphine ligand. The formation of **10** under the reaction conditions employed is fully repeatable and this reaction, together with that

* In the spectrum of **10** [Fig. 3(a)], we assume that the signals arising from $[Co(CO)_3(PPh_3)_2]^+$ are masked by the strong absorption at 1995 cm^{-1}.

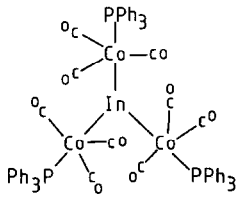
which afforded **8**, were indicative of a situation in which $Co(CO)_3(PPh_3)$ fragments bonded to indium were very prone to phosphine loss. However, the second complex formed in the reaction between $InCl_3$ and two equivalents of $K[Co(CO)_3(PPh_3)]$ does appear, on the basis of spectroscopic data, to contain the $In–Co(CO)_3(PPh_3)$ moiety. This complex, **12**, was isolated as an orange powder and has an IR spectrum in THF solution with an intense absorption at 1952 cm^{-1} and much weaker peaks at 2075, 2021 and 2000 cm^{-1} [Fig. 3(c)] which is characteristic of a $Co(CO)_3(PPh_3)$ fragment. We were unable to obtain enough sample for either microanalysis or a ^{31}P NMR spectrum, however, the similarity between the spectra for **12** [Fig. 3(c)] and **9** [Fig. 1(b)] is readily apparent and provides further evidence for the presence of one, or more, $Co(CO)_3(PPh_3)$ groups. Moreover, we were able to obtain further insight into the nature of **12** due to some results obtained from a different project concerned with the insertion of indium monochloride into metal–metal bonds.[22] Thus the reaction between InCl and $[Co_2(CO)_6(PPh_3)_2]$[23] afforded a yellow crystalline complex, **13**, the THF solution IR spectrum of which is shown in Fig. 3(d), which again comprises a single strong absorption at 1952 cm^{-1} (Table 1). The ^{31}P NMR spectrum of **13** exhibited two broad singlets at 63.4 and 37.5 ppm in an approximate ratio of 2:1, the former attributable to a PPh_3 ligand bonded to cobalt (cf. the signal observed at 63.4 ppm for **9**). The latter signal is not due to free PPh_3 but may well be associated with an additional phosphine bonded to indium. We propose, therefore, the following formula for **13**, $[InCl(PPh_3)\{Co(CO)_3(PPh_3)\}_2]$, and support for this is also provided by the microanalytical data (Table 1). Mass spectra are often difficult to obtain for phosphine complexes due to facile loss of phosphine but an FAB mass spectrum obtained for **13** showed a signal at *m/z* 925 due to the ion $[In\{Co(CO)_3(PPh_3)\}_2]^+$; further details are given in the Experimental.



13

Thus, in summary, we feel that the nature of **13** is fairly well established by the spectroscopic and analytical data and suggest on the basis of the similarity of the IR spectra, that **12** is either the same complex or very closely related; perhaps $[InCl\{Co(CO)_3(PPh_3)\}_2]$.

The reaction between $InCl_3$ and three equivalents of $K[Co(CO)_3(PPh_3)]$ in THF afforded an orange solution from which well-formed orange crystals were obtained after work-up and recrystallization from CH_2Cl_2. Unfortunately these crystals lost solvent very rapidly when removed from the mother liquor and were unsuitable for X-ray diffraction studies. Similar problems were encountered with crystals obtained from other solvents [see Experimental] and as a result it was not possible to obtain an X-ray crystal structure. Nevertheless, an IR spectrum obtained on this material (Fig. 7, Table 1) and microanalytical data (Table 1) were consistent with the anticipated formula, $[In\{Co(CO)_3(PPh_3)\}_3]$ (**14**), a complex analogous to $[In\{Co(CO)_4\}_3]$ (**1**),[5] the probable structure of which is indicated in the diagram below.



14

As we have discussed previously with regard to **9**, **12** and **13**, the appearance of a single strong absorption at *ca* 1940–1960 cm^{-1} is characteristic of a $Co(CO)_3(PPh_3)$ fragment, but the absence of absorptions at or around 1926 and particularly at 1830 cm^{-1}, due to the anion $[Co(CO)_3(PPh_3)]^-$,[20] indicate that **14** does not dissociate in THF, in contrast to the situation observed for $[In\{M(CO)_3(\eta\text{-}C_5H_5)\}_3]$ (M = Mo, W).[2] Spectra obtained for **14** in toluene, CH_2Cl_2 and MeCN are very similar

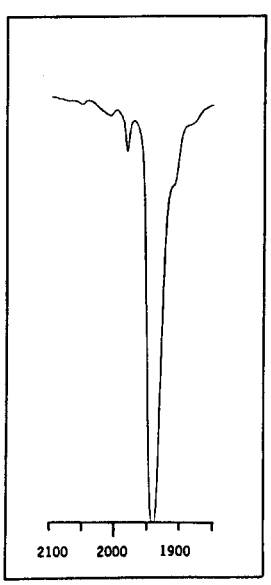


Fig. 7. IR spectrum in the carbonyl stretching region for **14** in THF solution.

to that observed in THF (Table 1), although a small peak observed at 1838 cm^{-1} MeCN is suggestive of a small degree of dissociation in this solvent. The extent to which complexes of the general form $In(ML_n)_3$ dissociate in various solvents is clearly very dependent on the nature of the metal fragment, ML_n, and the solvent system, but we will defer a detailed discussion of this phenomenon to a future publication.

A FAB mass spectrum recorded on a sample of **14** showed a signal at *m/z* 925 corresponding to the fragment ion $[In\{Co(CO)_3(PPh_3)\}_2]^+$ but of greater interest were the ^{31}P NMR spectra which were obtained in CD_2Cl_2 solution. The spectrum observed, at 298 K, on a solution with a concentration of about 3×10^{-2} mol dm^{-3} is shown in Fig. 8(a) with chemical shift data given in Table 5. This spectrum was obtained on a solution derived from a completely homogeneous crop of well-formed crystals of **14** and yet it was evident that a number of phosphine-containing complexes were present in solution. All signals in the range 55–65 ppm are consistent with the presence of cobalt bonded PPh_3 groups with the strong intense signal at 62.2 ppm most likely due to **14**. However, the signals at 37.4 and −4.2 ppm probably arise from indium-bound phosphine and free phosphine, respectively, and thus clearly indicate some form of equilibrium/rearrangement process is present in this solvent. This behaviour was observed and has been discussed for **8**/**9** and is not unexpected, but of further interest is the fact that the spectra obtained are clearly temperature dependent. ^{31}P NMR spectra obtained at 253, 233 and 213 K are shown in Figs 8(b)–(d), respectively, and indicate a number of trends. Firstly it is apparent that the signals at 62.2 and −4.2 ppm (298 K) decrease in intensity relative to those at 56.0 and 35.9 ppm (213 K), and also that the signal at −4.2 (298 K) shifts up field to −10.5 ppm on cooling to 213 K. These changes are reversible on warming the sample to room temperature and clearly indicate the presence of an equilibrium between various species although with the data available, any speculation as to the nature of this equilibrium and the species present would be idle. A concentration dependence is also evident when the spectrum shown in Fig. 8(a) is compared with that obtained at a concentration of *ca* 1.5×10^{-3} mol dm^{-3} at 298 K shown in Fig. 8(e). However, as before, the nature of any equilibria which give rise to these differences is unclear.

In concluding this section of the paper we will merely state that a number of reactions have been carried out within the reaction system defined by $InCl_3 + nK[Co(CO)_3(PPh_3)]$ which give rise to a number of compounds some of which we have been able to characterize fully whilst on the nature of others, we are forced to speculate. An important point to be made, however, is that the structures observed in the solid state are not always those present in solution and also that the anticipated products are often either unobserved or unstable with respect to subsequent rearrangement. An important factor in this latter observation is the lability of PPh_3 on the cobalt centre and the apparent affinity of the indium centre for phosphine.

As will be evident from the foregoing discussion, much of the chemistry described herein at times seemed rather intractable and we were not well disposed towards the idea of an extensive study of the reactivity of any of these complexes. Two reactions were carried out, however, and are worth mentioning at this point. Treatment of a solution of **14** with 0.5 equivalents of $InCl_3$ in THF led to a lightening of the orange colour of the solution, an IR spectrum of which showed a single strong absorption at 1952 cm^{-1}. This observed frequency is the same as that found for **12** and **13** and is there-

Table 5. ^{31}P NMR chemical shift data for **14** at different temperatures and concentrations[a]

Temperature (K)	Chemical shifts (ppm)						
298[b]		63.4	62.2	58.6	55.9	37.4	−4.2
253[b]	63.0	63.7	62.2		55.9	35.5	−7.0
233[b]	62.9	63.5	62.5		55.9	35.7	−9.2
213[b]	63.1	63.4	62.7		56.0	35.9	−10.5
298[c]	64.1	63.4	62.1	58.5	55.9		−4.1

[a]All spectra are ^1H decoupled and referenced to 85% H_3PO_4 (external), positive values to high frequency. Plots of all spectra are displayed in Fig. 8(a)–(e).

[b]Concentration $\approx 3 \times 10^{-2}$ mol dm^{-3}.

[c]Concentration $\approx 1.5 \times 10^{-2}$ mol dm^{-3}.

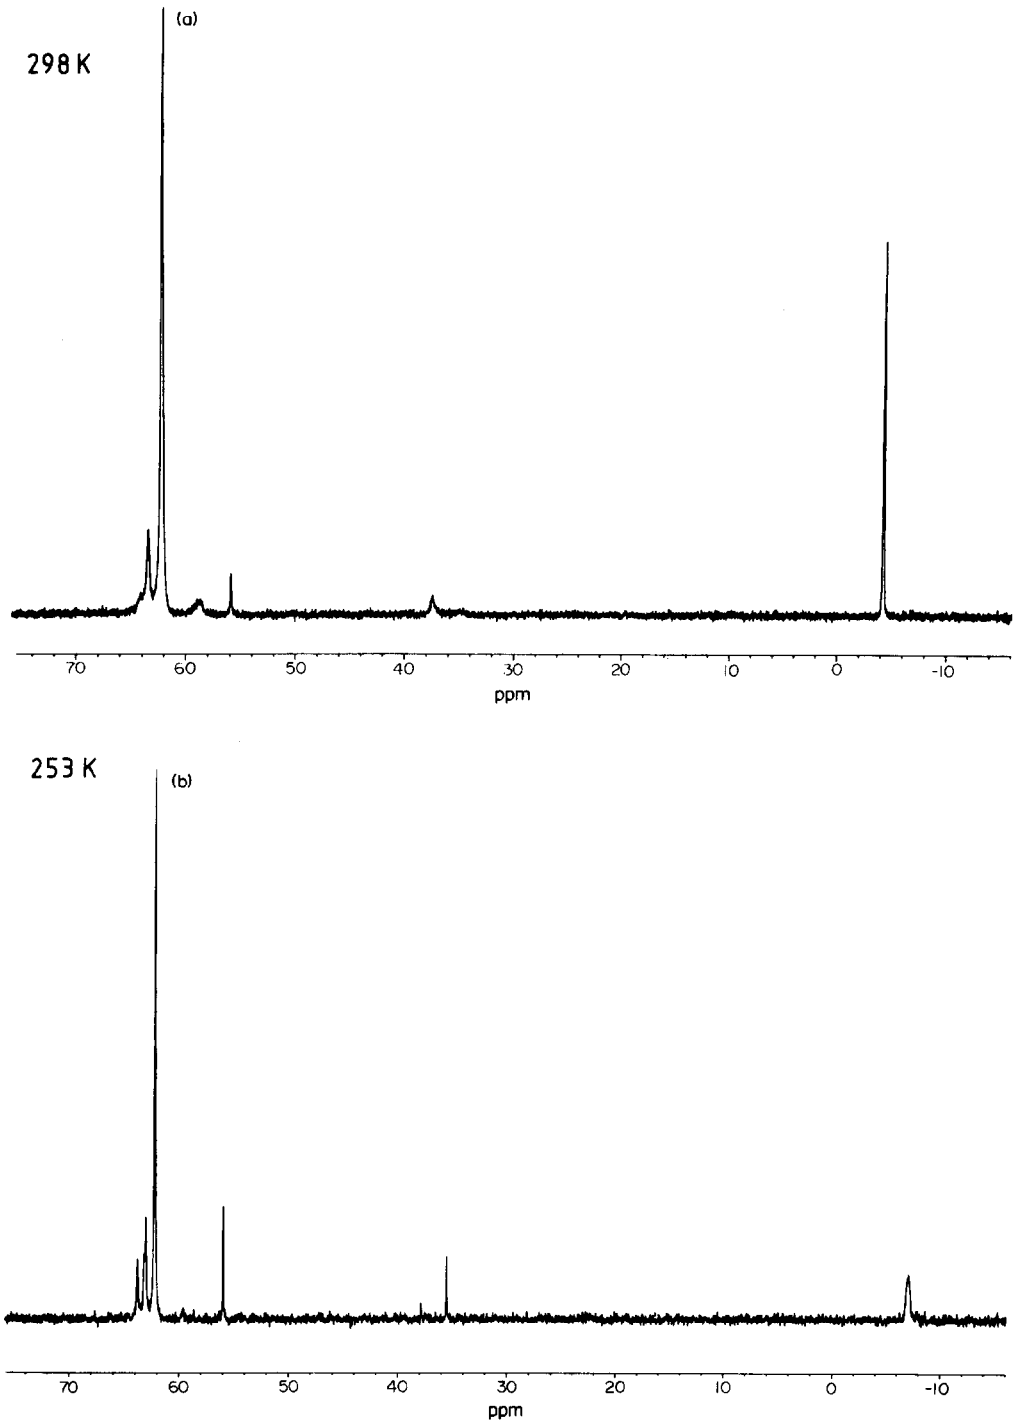

Fig. 8. ^{31}P NMR spectra for **14** measured in CD_2Cl_2 solution. Spectra (a)–(d) were recorded for a solution of approximate concentration 3×10^{-2} mol dm^{-3} at 298, 253, 233 and 213 K, respectively. Spectrum (e) was recorded for a solution of approximate concentration 1.5×10^{-2} mol dm^{-3} at 298 K. Chemical shifts are listed for all spectra in Table 5.

fore consistent with the formation of a dicobalt indium compound as shown in eq. (2):

$$2[In\{Co(CO)_3(PPh_3)\}_3] + InCl_3 \rightleftharpoons 3[InCl\{Co(CO)_3(PPh_3)\}_2]. \quad (2)$$

We have observed similar chemistry in the related system with $[In\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_3]$[24] and also for analogous antimony[25] and bismuth[17,26] complexes.

The second reaction which we carried out was between $[In\{Co(CO)_4\}_3]$ (**1**)[7b] and three equivalents of PPh_3. On work-up, an orange, crystalline material was obtained, the IR spectrum of which was identical to that obtained previously for **14**.

In closing we note that the thallium analogue of **14**, $[Tl\{Co(CO)_3(PPh_3)\}_3]$ (**15**), has been reported, originally by Hieber[27] and more recently by Robinson[28] and Burlitch.[29] The latter report gives IR data for **15** in THF solution (viz. 1987m, 1954s, 1922w sh) which is similar to that observed for **14**. A more detailed discussion of the similarities and differences between indium and thallium in these types of complexes is both interesting and illuminating and we shall have more to say on this matter in a future paper.

EXPERIMENTAL

General procedures

All experiments were performed using standard Schlenk techniques under an atmosphere of dry oxygen-free dinitrogen. All solvents were freshly distilled over appropriate drying agents immediately prior to use. ^1H and ^{13}C NMR spectra were recorded on a Bruker WP200 spectrometer operating at 200.13 and 50.324 MHz, respectively, and are referenced to Me_4Si, positive values to high frequency. ^{31}P NMR spectra were obtained on a Bruker WM300 instrument operating at 121.49 MHz. FAB mass spectra were recorded on a Kratos MS80 spectrometer using a *m*-nitrobenzyl alcohol matrix. IR spectra were recorded on a Nicolet 20 SXB FTIR spectrophotometer, and microanalytical data were obtained at the University of Newcastle.

$InCl_3$, $[Co_2(CO)_8]$, PPh_3 and $[Co_2(CO)_6(PPh_3)_2]$ were procured commercially and used without further purification.

IR and analytical data for the new compounds are presented in Table 1 whilst ^{31}P NMR data are given in the text and Table 5.

Preparations

Preparation of $K[Co(CO)_3(PPh_3)]$. This was prepared in a two stage reaction. $K[Co(CO)_4]$ was prepared according to the procedure given by Edgell[30] and more recently by Ellis[31] from $[Co_2(CO)_8]$ and KOH, whilst $K[Co(CO)_3(PPh_3)]$ was prepared from $K[Co(CO)_4]$ and PPh_3 according to Wojcicki.[18]

Reaction between $InCl_3$ *and* 1 $K[Co(CO)_3(PPh_3)]$. A solution of $K[Co(CO)_3(PPh_3)]$, prepared from $[Co_2(CO)_8]$ (0.105 g, 0.307 mmol) and PPh_3 (0.161 g, 0.614 mmol), in THF (30 cm^3) was added to a stirred solution of $InCl_3$ (0.136 g, 0.614 mmol) in THF (10 cm^3), and cooled to $-78°C$ by means of a dry ice–ethanol bath. During the addition a slight deepening of the yellow colour was observed together with the formation of a very finely dispersed white precipitate. After complete addition, the reaction mixture was warmed to room temperature and stirred for a further 3 h. Removal of all volatiles followed by extraction in CH_2Cl_2 and filtration through Celite afforded a yellow solution from which, after reduction of the solvent volume and slow diffusion of hexane at $-30°C$ over a period of 2–3 days, very pale yellow plate-like crystals of **8** were obtained which were suitable for X-ray diffraction studies (48% yield).

Reaction between $InCl_3$ *and* 2 $K[Co(CO)_3(PPh_3)]$. A solution of $K[Co(CO)_3(PPh_3)]$, prepared from $[Co_2(CO)_8]$ (0.354 g, 1.034 mmol) and PPh_3 (0.542 g, 2.068 mmol), in THF (30 cm^3) was added to a stirred solution of $InCl_3$ (0.229 g, 1.034 mmol) in THF (10 cm^3), pre-cooled to 0°C. During the addition, a marked deepening of the yellow colour was observed ($K[Co(CO)_3(PPh_3)]$ in THF is usually a very pale yellow) together with the formation of a fine white precipitate. After warming to room temperature, the reaction mixture was stirred for a further 1.5 hours. Filtration through Celite, followed by reduction of the solvent volume to 5 cm^3, followed by slow diffusion of hexane (30 cm^3) at $-30°C$ over a period of 5 days afforded small yellow crystals and a white solid (KCl). Repeated recrystallizations from CH_2Cl_2–hexane mixtures afforded X-ray quality crystals of **10**, and an orange powder, **12**.

NMR data for **10**: ^1H (CD_2Cl_2) δ 7.60 and 7.44 (m, phenyls); $^{13}C\text{-}\{^1H\}$ (CD_2Cl_2) δ 134.7 and 131.8 (m, *o*-, *m*-, *p*-phenyls).

Reaction between InCl *and* $[Co_2(CO)_6(PPh_3)_2]$. InCl (0.070 g, 0.466 mmol) and $[Co_2(CO)_6(PPh_3)_2]$ (0.378 g, 0.466 mmol) were stirred in toluene (10 cm^3) at 80°C for 7 h. After this time the toluene was removed *in vacuo* and the resulting yellow powder redissolved in CH_2Cl_2 and filtered through Celite. The solvent from the yellow filtrate was removed *in vacuo* and the resulting yellow solid recrystallized from THF–hexane at $-30°C$, which afforded yellow crystals of **13**.

NMR data for **13**: ^{1}H (CD_2Cl_2) δ 7.75, 7.60, 7.39 (m, phenyls); ^{13}C-{^{1}H} δ 133.8 (m, *o*-C_6H_5), 131.1 (s, *p*-C_6H_5), 129.3 (m, *m*-C_6H_5). Mass spectra (FAB): *m/z* 925, P′ [P′ = In{Co(CO)$_3$(PPh$_3$)}$_2$]; 841, P′ − 3CO; 785, P′ − 5CO; 642, [Co_2(PPh$_3$)$_2$]; 321, [Co(PPh$_3$)]; 114, [In].

Reaction between $InCl_3$ *and* 2 [PPN][Co(CO)$_4$] A solution of $InCl_3$ (0.035 g, 0.160 mmol) in THF (10 cm^3) was added to a stirred solution of [PPN][Co(CO)$_4$][20] (0.302 g, 0.320 mmol) in THF (10 cm^3) at room temperature. The pale yellow solution was stirred for 18 h affording a slightly turbid pale green solution. Purification by column chromatography on Florisil with Et_2O–THF (3:1) as eluant afforded a yellow oil after removal of all voltatiles *in vacuo*. Redissolution in CH_2Cl_2 followed by filtration through Celite gave a clear yellow solution from which, after concentration of the solvent volume and slow diffusion of hexane at −30°C, pale yellow needles of **11** suitable for X-ray diffraction were obtained.

Reaction between $InCl_3$ *and* 3 K[Co(CO)$_3$(PPh$_3$)]. A stirred solution of K[Co(CO)$_3$(PPh$_3$)], prepared from [Co_2(CO)$_8$] (0.748 g, 2.187 mmol) and PPh_3 (1.147 g, 4.374 mmol), in THF (20 cm^3) was cooled to 0°C and maintained at this temperature. To this was added a solution of $InCl_3$ (0.325 g, 1.458 mmol) dropwise over a period of a few minutes, resulting in a turbid yellow solution. After complete addition, the reaction mixture was allowed to warm to room temperature and was stirred for a further 24 h, during which time a colour change from yellow to orange was observed. Filtration through Celite, followed by removal of all volatiles *in vacuo* afforded an orange oil. Extraction in CH_2Cl_2, followed by filtration through Celite gave a clear orange solution from which, after reduction of the solvent volume and slow diffusion of hexane at −30°C, a crude crystalline solid was obtained. Recrystallization from a concentrated solution in CH_2Cl_2 afforded well-formed crystals of **14**. The crystals rapidly lost solvent on removal of the mother liquor and were thus unsuitable for X-ray studies.

Crystallization from 1,2-dichloroethane, chlorobenzene, 1,2-dichlorobenzene, $CHCl_3$, THF–hexane and acetone–hexane gave crystals of varying degrees of visual quality but none proved suitable for X-ray diffraction.

NMR data for **14**: ^{1}H (CD_2Cl_2) δ 7.67-7.27 (m, phenyls); ^{13}C-{^{1}H} (CD_2Cl_2) δ 134.1 (m, *o*-C_6H_5), 131.1 (s, *p*-C_6H_5), 129.3 (m, *m*-C_6H_5). Mass spectra (FAB): *m/z* 925, P′ [P′ = In{Co(CO)$_3$(PPh$_3$)}$_2$]; 896, P′ − 1CO; 841, P′ − 3CO; 785, P′ − 5CO; 757, P′ − 6CO; 667, [Co(CO)$_3$(PPh$_3$)]; 583, [Co(PPh$_3$)$_2$]; 321, [Co(PPh$_3$)]; 262, [PPh$_3$]; 114, [In]; 77, [Ph].

X-ray crystallographic studies

Structure determination of [$InCl_2$(PPh$_3$){Co(CO)$_4$}] (**8**). A pale yellow crystal of approximate dimensions 0.5 × 0.4 × 0.3 mm was mounted in a general position on a glass fibre and coated with acrylic resin. Data were collected at ambient temperatures, using the θ–2θ scan mode, on a CAD4F automated diffractometer with graphite-monochromated X-radiation. Unit cell parameters were determined by refinement of the setting angles ($\theta \geqslant 12°$) of 25 reflections. The standard reflections $\bar{8}06$ and $3\bar{4}5$ were measured every 2 h and after *ca* 5100 data, these showed a catastrophic decrease in intensities. As a result only data to $h = 7$ were obtained (theoretical maximum value for h is 17 where $\theta \leqslant 22.5°$). A decay correction in two linear sections was applied, as were Lorentz–polarization and absorption/extinction (DIFABS)[32] corrections. A total of 5371 measured reflections (θ range 2–22.5°, h 0 → 7, k −12 → +12, l −20 → +20) yielded 5011 independent data, of which 2856 having an intensity $> 2.5\sigma(I)$ were considered observed and used for structure solution and refinement. The distribution of normalized structure factors indicated the centrosymmetric space group $P\bar{1}$, and this was confirmed by successful structure solution and refinement. The structure was solved by direct methods (MITHRIL)[33] and subsequent electron density difference syntheses. The structure consists of two molecules in the asymmetric unit, which are approximately related by the symmetry operation (1/2−x, 1/2+y, 1/2−z), and the structure can be refined in the monoclinic space group $P2_1/n$. The true space group, however, is undoubtedly $P\bar{1}$, for several reasons.

(i) The α and (particularly) the γ unit cell angles differ significantly from 90°.

(ii) Although the zones $h0l$; $h+l = 2n+1$ and $0k0$; $k = 2n+1$ are systematically weak, the Laue symmetry is clearly not monoclinic. A substantial number of reflection pairs hkl and $h\bar{k}l$ differ significantly in intensities, as observed in values for R(merge) [2.7% for $P\bar{1}$ and 17.9% for $P2_1/n$].

The structure was refined using full-matrix least-squares, minimizing the function $\Sigma\omega(|F_o| - |F_c|)^2$. The weighting scheme $\omega = [\sigma^2(F_o)]^{-1}$ was used and judged satisfactory. $\sigma(F_o)$ was estimated from counting statistics. The In, Co, Cl and P atoms were allowed anisotropic thermal motion, the other atoms refined with isotropic thermal parameters. The phenyl groups were refined as rigid groups with idealized geometry (C—C = 1.395, C—H = 1.0 Å) with individually refined isotropic thermal parameters for the carbon atoms, and fixed parameters

(0.05 Å^2) for the hydrogen atoms. Refinement using a total of 227 parameters converged to give the residuals presented in Table 6 with mean and maximum Δ/σ values of 0.004 and 0.064, respectively, in the final cycle. A final electron density difference synthesis showed no chemically significant features (max $\Delta\rho = +1.03$, min $\Delta\rho = -0.55$ eÅ^{-3}). The ESD of an observation of unit weight (S) was 2.12. Neutral atom scattering factors were taken from ref. 34 with corrections applied for anomalous scattering. All calculations were carried out on a MicroVAX 3600 computer using the Glasgow GX suite of programs.[35] The two molecules are similar in general, but differ in some small details (see text). The Co—C bond lengths (*mean* 1.71 Å for molecule A, 1.77 Å for molecule B, ESDs 0.02–0.03 Å) differ somewhat, and the Co(2a)—C(4a)—0(4a) angle of 136(3)° is decidedly non-linear. This is probably an artefact of the poor quality truncated data set, and has no chemical significance.

Structure determination of $[Co(CO)_3(PPh_3)_2][InCl_2\{Co(CO)_4\}_2]$ (**10**). In general, this was performed as described above for **8**. The points of difference are as follows:

(i) Standard reflections 22$\bar{8}$, 7$\bar{4}\bar{7}$ and 351 showed a slight decrease in intensity of *ca* 1.5% in 10,000 reflections.

(ii) A total of 7040 measured reflections (θ range 2–22.5°, h 0 → 14, k −15 → 15, l −17 → 17) yielded 6941 independent data, of which 4763 having an intensity $>3\sigma(I)$ were considered observed.

(iii) All non-hydrogen atoms apart from the aryl carbons were allowed anisotropic thermal motion. The phenyl groups were refined as rigid groups as for **8**.

(iv) Refinement using 343 parameters converged to give the residuals shown in Table 6 with mean and maximum Δ/σ values of 0.0002 and 0.002, respectively, in the final cycle. A final electron density difference synthesis showed no significant features (max $\Delta\rho = +0.66$, min $\Delta\rho = -0.5$ eÅ^{-3}). S was 2.09.

Structure determination of $[Ph_3PNPPh_3][InCl_2\{Co(CO)_4\}_2]$ (**11**). As for **8** except:

(i) Standard reflections 381 and 40$\bar{7}$ showed no significant variations in intensity.

(ii) A total of 12,770 measured reflections (θ range 2–22.5°, h 0 → 10, k −22 → 22, l −24 → 24) yielded 11,945 independent data. Due to the small crystal size and poor diffraction, only 4044 reflections having an intensity $>2\sigma(I)$ were considered observed and used for structure solution and refinement.

(iii) Due to matrix size limitations, the parameter list was divided into two blocks of 272 and 335 parameters, and each refined in separate cycles. The Co, In, Cl and P atoms were allowed anisotropic thermal motion, all other atoms were refined using isotropic thermal parameters. The phenyl rings were refined as rigid groups as for **8**.

(iv) Refinement converged to give the residuals shown in Table 6 with mean and maximum Δ/σ

(*Received* 3 *May* 1990; *accepted* 10 *August* 1990)

Abstract—The new complexes $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3MO_3]$ (M = Re, R = Me or Et; M = Tc, R = Me) have been synthesized from the reaction between $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3]^-$ and MO_4^-. The rhenium complexes may also be prepared by oxidation of $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3Re(CO)_3]$. The oxidation of $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3Mo(CO)_3H]$ affords the dimer, $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3MoO_2]O$, which is also obtained from MoO_4^{2-} and the tripodal ligand. The reaction between WO_4^{2-} and $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3]^-$ affords either the dimer, $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3WO_2]O$ (R = Me, Et), or the monomer, $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3WO_3]^-$ (R = Et). An X-ray diffraction study of $[(\eta^5\text{-}C_5H_5)Co\{P(OMe)_2(=O)\}_3ReO_3]$ confirms that the rhenium has a distorted octahedral coordination geometry consisting of three facial oxygen atoms from the tripodal ligand and three rhenyl oxo-groups [mean Re=O, 1.703(7) Å; mean O=Re=O, 102.5(7)°].

Complexes of rhenium(VII) with polydentate ligands are rare.[1] The compounds [ReO_3Cl(2,2′-bipyridyl)] and [ReO_3Cl(*o*-phenanthroline)] provide well characterized examples of complexes containing bidentate ligands coordinated to the $\{Re(=O)_3\}^+$ moiety,[2] and more recently the complex $[ReO_2(OSiMe_3)_2\{N{=}P(Ph)_2CH_2PPh_2\}]$, which contains the $\{Re(=O)_2\}^{3+}$ moiety, has been reported.[3] However, there has been little work on rhenium(VII) complexes with ligands containing three or more donor atoms. Wieghardt *et al.* have recently described the synthesis and structure of [(1,4,7-triazacyclononane)ReO_3]$^+$.[4] Organometallic derivatives of rhenium(VII) are also known, two examples being methyltrioxorhenium[5] and $[(\eta^5\text{-}C_5Me_5)ReO_3]$.[6] We were interested in establishing whether a high-valent rhenium(VII) chemistry might be developed using tridentate oxygen ligands to bind to an MO_3 (M is an early *d*-block metal) fragment. To this end we have examined the oxidation reactions of $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3M(CO)_3]^z$ (M = Re, $z = 0$; M = Mo, $z = 1-$)[7,8] and the reactions between the uninegative tripodal ligand[9,10] $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3]^-$ (R = Me or Et) and MO_4^x (M = Tc or Re and $x = 1-$; M = Mo or W and $x = 2-$).

* Authors to whom correspondence should be addressed.

The oxidation of $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3Re(CO)_3]$ with peracetic acid affords the rhenium(VII) complex $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3ReO_3]$, which can also be prepared by acidification of a solution containing $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3]^-$ and ReO_4^- [ν(Re=O) 940 and 910 cm^{-1}, R = Me]. The ^1H NMR spectra of these compounds are consistent with the presence of three-fold symmetry in the molecule, and the presence of a distorted octahedral structure about rhenium has been confirmed by the X-ray diffraction study described below. A similar reaction was found to occur with TcO_4^- [ν(Tc=O) 906 and 892 cm^{-1}, R = Me]. The oxidation of $[(\eta^5\text{-}C_5H_5)Co\{P(OEt)_2(=O)\}_3W(CO)_3H]$ ($L_{OEt}W(CO)_3H$) affords the tungsten(VI) dimer $[\{L_{OEt}WO_2\}_2O]$.[11] We have prepared in a similar way the analogous molybdenum(VI) complex and confirmed its oxo-bridged structure by an X-ray crystal structure determination.[12] This compound and its counterpart with R = Me may also be prepared directly by acidification of a solution containing $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3]^-$ (R = Me, Et) and MoO_4^{2-} or, for R = Me, $Mo_2O_7^{2-}$ [ν(Mo=O) 935 and 902 cm^{-1}, R = Me, Et]. The ^1H NMR spectra of these complexes are consistent with the absence of either a three-fold symmetry axis or a plane of symmetry, in accord with the crystallographic results. The compounds are non-conducting in MeOH solution. The reactions of $[(\eta^5\text{-}C_5H_5)Co\{P(OR)_2(=O)\}_3]^-$ (R = Me or Et) with WO_4^{2-} give differing results depending upon the nature of R. In the case where R = Me the compound obtained is non-conducting in MeOH solution and exhibits a ^1H NMR spectrum, which is consistent with the absence of symmetry in the complex [ν(W=O) 950 and 905 cm^{-1}]. Using a shorter reaction time in the case where R = Et affords a product which forms a conducting solution in MeOH and exhibits a ^1H NMR spectrum which shows only one environment for the methyl groups of the ethyl substituents [ν(W=O) 950–broad and 905 cm^{-1}], consistent with the formulation $Na[L_{OEt}WO_3]$. However, crystals grown from this solution have been found, by an X-ray diffraction study, to contain the dimer $[\{L_{OEt}WO_2\}_2O]$.

The crystals of $[(\eta^5\text{-}C_5H_5)Co\{P(OMe)_2(=O)\}_3ReO_3]$ are monoclinic, space group $P2_1/c$ with $a = 8.524(4)$, $b = 15.395(6)$, $c = 47.138(13)$ Å, $\beta = 94.66(4)°$ and $Z = 12$; $D_c = 2.215$ g cm^{-3}, μ(Mo-K_α) = 70.9 cm^{-1}. 5218 reflections measured on an Enraf–Nonius CAD-4 diffractometer in the range $2 < \theta < 23°$ and having $I > 3.5\sigma(I)$ were used in the analysis. The structure was solved by Patterson and Fourier methods and refined[13] by least-squares with anisotropic temperature factors for the heavier atoms and isotropic temperature factors for the oxygen and carbon atoms. Hydrogen atoms were included in calculated positions. The refinement converged (all calculated shift/ESD ratios $< 0.2\sigma$) to R, R_w 0.071, 0.106 with weights $w = 1/[\sigma^2(F)+0.00001F^2]$ and residual electron density within ± 1.95 e Å^{-3}. An empirical absorption correction was applied using DIFABS.[14]

The compound crystallizes with three independent molecules in the unit cell; one of these is illustrated[15]* in Fig. 1. The other two molecules have virtually identical structures. Apart from the cyclopentadienyl ring the molecules approximate

* The atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

to three-fold symmetry. Mean bond lengths are: Re=O, 1.703(7); Re—O, 2.131(10); P=O(Re), 1.537(11); P—O(Me), 1.593(9); P—Co, 2.143(5) Å. The coordination geometry at rhenium is essentially octahedral with maximum angular deviation from ideal values, 18.2°, in an O=Re—O *trans* angle (*trans* angle range 161.8–165.2°, mean 163.5°). The angles between the rhenyl oxo-groups are large [mean 102.5(7)°], presumably due to repulsion between the short electron-rich double bonds. Concomitantly the other *cis* angles are generally less than 90°.

The Co—P bond length is somewhat shorter than the mean lengths of 2.183, 2.175, 2.173 and 2.165 Å found in the crystal structures of $[(\eta^5\text{-}C_5H_5)Co\{P(OMe)_2(=O)\}_2\{P(OMe)_3\}]$,[16] $[(L_{OEt})_2M]$ (M = Sn, Pb)[17] and $[L_{OEt}Rh(CO)_3RhL_{OEt}]$,[18] respectively. The angles subtended at the cobalt atom by the three phosphorus atoms are close to 90° [mean 89.6(4)°]. The cyclopentadienyl rings are all planar to within the limits of experimental error [maximum displacements 0.03(6), 0.01(6) and 0.10(7) Å for the three independent molecules]. The cobalt atom is essentially equidistant from the ring carbon atoms, the relevant distances being in the ranges 2.02(4)–2.07(4), 1.99(4)–2.11(5) and 2.05(4)–2.15(4) Å in $[(\eta^5\text{-}C_5H_5)Co\{P(O)(OMe)_2\}_2\{P(OMe)_3\}]$[16] and $[(L_{OEt})_2M]$ (M = Sn, Pb).[17] The overall average Co—C distance in $[(\eta^5\text{-}C_5H_5)Co\{P(OMe)_2(=O)\}_3ReO_3]$ is 2.07(2) Å, which may be compared with the mean values of 2.096, 2.082 and 2.079 Å in these three molecules.[16,17]

Acknowledgements—We are grateful to Ms C. A. Fletcher for experimental assistance and to the SERC, Amersham International plc and Johnson Matthey plc for support (to H.J.B., W.H. and I.G.E., respectively).

4. CONCLUSIONS 2565

1. INTRODUCTION

A high level of activity in the synthesis and structural characterization of transition metal complexes containing macrocyclic ligands continues unabated. One reason that such systems have aroused interest is their ability to model biological phenomena, such as the binding of small molecules, e.g. O_2 or CO, to iron in various haem systems. Full understanding of this process has been an elusive one for biologists and chemists alike. It is understandable then, why special attention has been paid to synthetic macrocycles which resemble but also differ from the naturally occurring porphyrins. However, the chemistry of metal–macrocycle complexes is also of fundamental interest.

The title macrocyclic ligand, a dianion which is usually abbreviated tmtaa, shares many common characteristics with porphyrins, but it features some important differences. Thus, while it is of bio-inorganic interest, it also has many other characteristics that make it of fundamental interest in its own right. The similarities to porphyrins are as follows: (1) the four nitrogen atoms of H_2tmtaa are confined to a plane, as in the porphyrins (see I); (2) upon metal complexation, the ligand usually

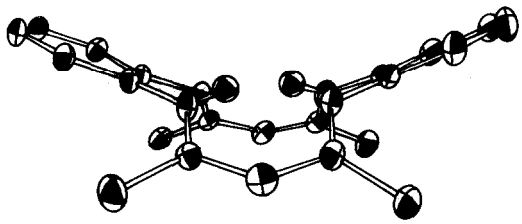

Fig. 1. Side view of H_2tmtaa showing its saddle shape even in the free state.

deprotonates to give a dianion; and (3) tmtaa has a completely conjugated system of double bonds. The differences between tmtaa and the naturally occurring systems, however, account for the non-bio-inorganic interest and hence for the proliferation of new and interesting compounds. The 14-membered ring size of tmtaa, as compared to a 16-membered one in porphyrins, favours shorter metal–nitrogen distances. Secondly, in contrast to the completely delocalized framework of porphyrins, each of tmtaa's two negative charges tends to be localized only over the 2,4-pentanediiminato chelate rings. Lastly, even though tmtaa can be described as conjugated, it is an anti-aromatic ($4n$) system, whereas porphyrins exhibit a $4n+2$ π-electron aromaticity.

Tmtaa was first synthesized by Jäger[1] via a template condensation reaction of *o*-phenylenediamine with 2,4-pentanedione. Its modified synthesis[2] and a crystal structure[3] were reported much later by Goedken and co-workers. It has three special steric features which dictate its reactivity and coordination geometry: (1) Its "core size" is about 1.902 Å, which is about 0.1 Å smaller than that of porphyrins. (2) A saddle shape conformation is produced by the internal steric constraints (e.g. methyl–phenyl repulsions) and this causes displacement of the coordinated metal from the N_4 plane. (3) Because the saddle shape has the *o*-phenylene rings and the diiminate framework displaced in opposite directions, the two remaining coordination sites on the metal centre become chemically inequivalent. Figure 1 shows the saddle shape as it exists even in the free ligand, H_2tmtaa.[3]

The present article provides a concise summary of most of what is known about transition metal–tmtaa complexes. However, we do not attempt to discuss all of them. Rather the most important trends in our judgement will be noted and a few compounds with special features will be emphasized. Tables 1 and 2 list the known tmtaa complexes with information on their properties, including structures in the relatively few cases where these are known. It should be mentioned again that H_2tmtaa itself is structurally characterized.[3]

2. MONONUCLEAR COMPLEXES

2.1. *Early transition metals* (*Groups* IV, V, VI)

General trends. The organometallic chemistry of the early transition metals, although a broad and active field today, mainly depends on such stabilizing ligands as cyclopentadiene and substituted cyclopentadienes.[4] It was not until the early 1980s that the title ligand was introduced to this field as an ancillary ligand for stabilizing M—C functionalities.

In 1982, Goedken and co-workers synthesized Ti(tmtaa)Cl_2[5] and other Ti(tmtaa)$(R)_n$ type compounds (where R = O, S, alkyl groups and n = 1, 2) which were the first examples of a wide group of compounds subsequently synthesized. Since then, the macrocyclic stabilization effect of tmtaa has allowed for a more diverse chemistry of the group IV, V and VI transition metals, to be discussed presently.

There are two efficient synthetic routes employed in the preparation of the M(tmtaa)$(Cl)_n$ (n = 1, 2) type compounds listed in Table 1 for Group IV, V and VI metals. They are as follows: (1) reaction of an early transition metal halide with H_2tmtaa under basic reaction conditions (e.g. in the presence of NEt_3); and (2) reaction of a metal halide with an activated form of H_2tmtaa, Li_2(tmtaa), in tetrahydrofuran (THF). The lithium compound is formed upon reacting n-Bu–Li with H_2tmtaa in a 2:1 ratio at -10°C in THF.

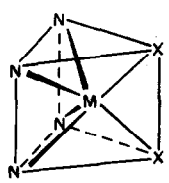
Despite the seemingly disparate character of the compounds listed in Table 1, a number of features tie them all together. First, there is the inherent predisposition of tmtaa to push the metal out of the N_4 plane (see Introduction). Indeed, all the monomeric compounds discussed in this section have the metal located well out of the N_4 plane. The displacements range from 0.435 Å for Cr(tmtaa)Cl[12] to 1.070 Å for $Zr(tmtaa)Cl_2$.[8] The degree of metal displacement is a function of the size of the metal ion: $Zr(tmtaa)Cl_2$, mentioned above, shows the maximum distortion; its first row analogue, $Ti(tmtaa)Cl_2$,[5] on the other hand, shows the smaller distortion of 0.91 Å, consistent with the smaller radius of titanium.[38] The second feature is that most $M(tmtaa)(Cl)_n$ type complexes are easily alkylated with Grignard reagents, often leading to novel M—C functionalities. These alkyl groups are found *cis* to each other,[8] as shown in Fig. 2; this is somewhat unusual in light of the many six-coordinate complexes of the middle transition metals which possess a *trans* ligand arrangement [e.g. Fe(tmtaa)(CO)(py)].[18,19] The axial halides in these early transition metal compounds are themselves found in the *cis* arrangement.

The extent to which the metal atoms are displaced from the N_4 plane is greater for these early transition metals than for any of the later ones. One way to rationalize this is to regard the coordination sphere as a distorted trigonal prism, as shown schematically in **II**. This point of view



II

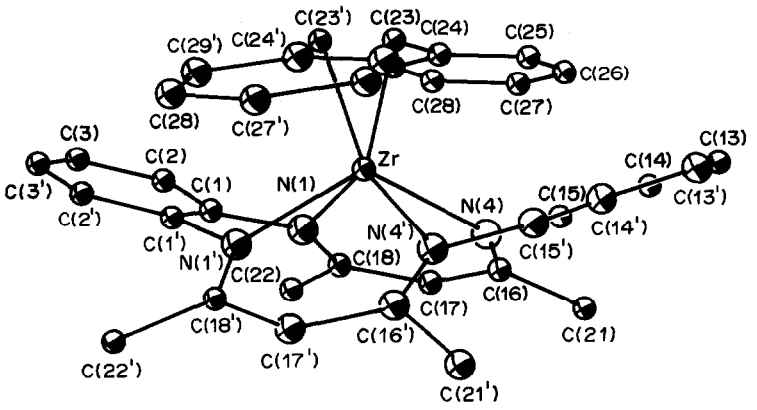


Fig. 2. An ORTEP diagram of the six-coordinate zirconium complex, illustrating the *cis* arrangement of the axial ligands.

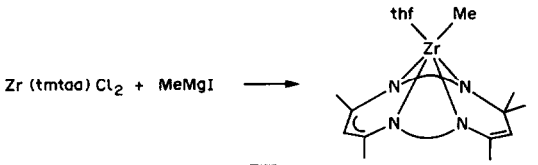
is consistent with the large displacement and with the presence of two X ligands, both on the same side (i.e. *cis*) and is in harmony with Girolami's recent work[4] showing that the trigonal prism is a "natural" geometry for six-coordinate d^0 metal ions.

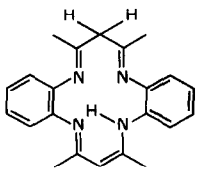
Peculiarities. A zirconium complex, Zr(tmtaa-Me)(Me)(THF),[8] demonstrates that during a substitution reaction occurring at the metal centre, the ligand itself can undergo some transformation, as shown in **III**. Floriani and co-workers report that although the familiar saddle shape



III

of tmtaa is retained in this complex, the ligand no longer behaves as a dianion, but instead acts as a trianion. Although, the exact route to the formation of this compound is obscure, it is clear that the ligand undergoes methylation at the carbon atom of one C=N group. The zirconium(IV) is 1.049 Å out of the N_4 plane, the largest displacement seen to date.

Yet another anomaly worth mentioning is provided by the $M(H_2tmtaa)(CO)_4$ compounds, where M = Mo,[13] W,[13,14] shown in Fig. 3. The metal is bonded to only two of the four nitrogen atoms of tmtaa and the ligand remains neutral upon coordinating to the $M(CO)_4$ moiety. These complexes are obtained by reaction of $M(CO)_6$ with H_2tmtaa at high temperatures. In these reactions, one of the two nitrogen protons migrates to a methine carbon atom so that the ligand can now be represented by **IV**. The saddle shape conformation of this isomeric H_2tmtaa becomes even more pronounced than that of the normal form.



IV

In a very recent report[36a] it has been shown that $(tmtaa)(M)(CO)_4$, where M = Mo and W, can be converted to the cation, $[(tmtaa)M(CO)_3NO]^+$, which may then react with CH_3CN to give the "scorpion" like product shown in Fig. 4. This seven-coordinate cationic complex is quite remarkable, because it contains a tridentate tmtaa moiety. The latter was transformed from a bidentate unit by formation of an imine appendage which in turn resulted from the insertion of an acetonitrile molecule into a C—H bond of the coordinated —N=C—CH_2—C=N— fragment.

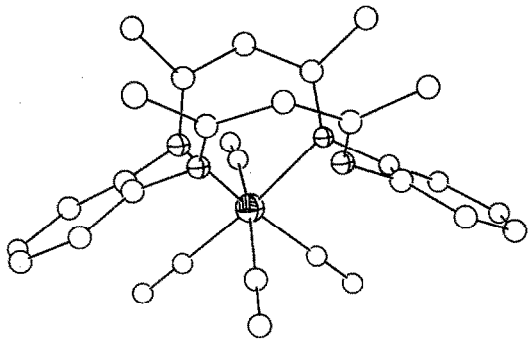


Fig. 3. Side view of the $W(H_2tmtaa)(CO)_4$ complex, illustrating the metal's coordination to only two nitrogen atoms of the ligand.

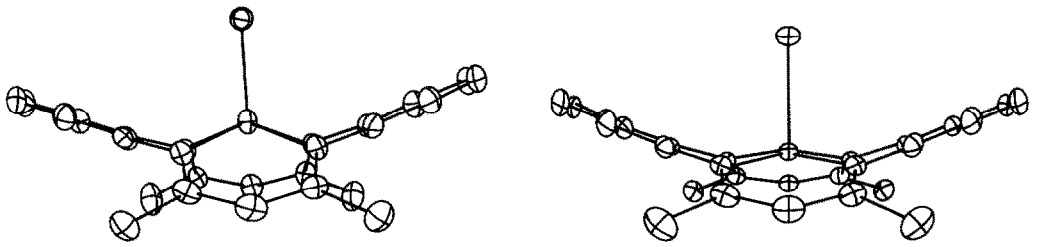

Fig. 5. Side view of Fe(tmtaa)Cl (left) and Co(tmtaa)Cl (right).

The compound (tmtaa)CrCl[12] is of unusual interest as the only known square pyramidal complex of chromium(III). It can be easily prepared in essentially quantitative yield. It has three unpaired electrons, which is in accord with a molecular orbital treatment of the electronic structure. The structure closely resembles that of the analogous iron(III) complex shown in Fig. 5.

2.2. *Middle transition metals* (*Groups* VII, VIII, IX)

General trends. Unlike the early transition metals discussed above, these metals have been found in various macrocyclic systems for over two decades. Study of these systems is especially important because of their potential practical uses. For example, metals such as manganese, iron and cobalt

have long been known to take active parts in many biological functions, i.e. binding of small molecules in haems. The same metals in synthetic macrocycles can provide us, then, with significant clues to the understanding of the natural systems. Such was the motivation behind the extensive study of the middle transition metals with tmtaa, done concurrently by Goedken and Dabrawiak, beginning in the early 1970s.

The first row metals, manganese, iron and cobalt, clearly dominate the list in this section. Their chemistry upon complexation to the macrocyclic ligand is quite similar for all of them despite their differences in ionic radii, oxidation numbers and spin states. First, iron and cobalt form the four-coordinate complexes of the type M^{II}(tmtaa). Fe(tmtaa)[3,18] and Co(tmtaa)[27] are both low spin M^{II} systems with $\mu_{eff} = 3.69$ and 2.86 BM, respectively. Only Fe(tmtaa) has been structurally characterized; there are, however, many features common to the two compounds in terms of their chemical behaviour. These two four-coordinate complexes readily coordinate axial ligands to satisfy their coordinatively unsaturated geometry. Reaction of Fe(tmtaa) with $CHCl_3$ or CCl_4 leads to the five-coordinate, high-spin complex, Fe(tmtaa)Cl.[17,18] Similarly, Co(tmtaa) reacts with X_2 or CHX_3 (X = Cl, Br, I) to give Co(tmtaa)X[27] ($S = 1$ spin configuration). Both structures are shown in Fig. 5.

The displacements out of the N_4 plane for iron(III) and cobalt(III) centres are 0.600 and 0.234 Å, respectively. The redirecting of the N_4 lone pairs towards the metal is much greater in the case of the bigger ion, Fe^{3+}.[38] Manganese forms similar five-coordinate complexes but via a different synthetic route.[16] Mn(tmtaa)X, where X = Cl, Br, I, are high-spin d^4 systems. Although nothing is known about their structures, the compounds are well characterized by IR, ESR and magnetic susceptibility measurements.

There are a number of six-coordinate complexes (mostly of iron and cobalt), all of them containing the axial ligands *trans* to each other. The few crystal structures available establish with certainty the configuration of tmtaa as it accommodates the additional ligands. A good example of such a complex is Fe(tmtaa)(CO)(NH_2NH_2),[19,22] shown in Fig. 6. This octahedral iron(II) complex has the carbon monoxide molecule strongly bound to the iron (C—Fe = 1.75 Å), producing a *trans* effect at the hydrazine site. This, together with the steric interactions between tmtaa and hydrazine, results in an abnormally long iron–nitrogen$_{(base)}$ bond of 2.12 Å. The low-spin Fe^{2+} centre is displaced from the N_4 plane towards the carbon monoxide by 0.11 Å; this displacement is similar to that in the other low-spin Fe^{2+} complex, four-coordinate Fe(tmtaa), discussed earlier.

Although there are other six-coordinate compounds known of metals such as cobalt and ruthenium, useful comparisons cannot be made because of the lack of crystallographic studies. Compounds such as $[Co(L)(py)_2]^+$,[27] Ru(L)$(py)_2$[25] or $[Ru(L)(MeCN)_2]^+$[25] are all well-defined, but by NMR and IR only.

Finally, it ought to be pointed out that the chemistry of the second and third row middle transition metals is quite unexplored. Rhenium, osmium and iridium have yet to play a role in tmtaa chemistry.

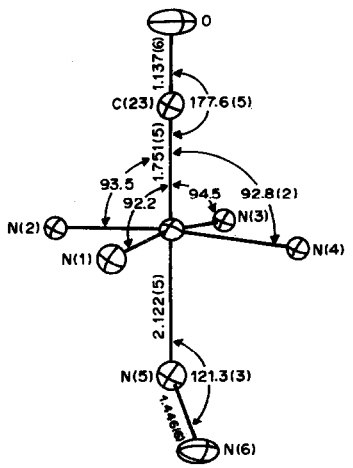

Fig. 6. Bond distances and angles in the six-coordinate Fe(tmtaa)(CO)(NH_2NH_2) complex.

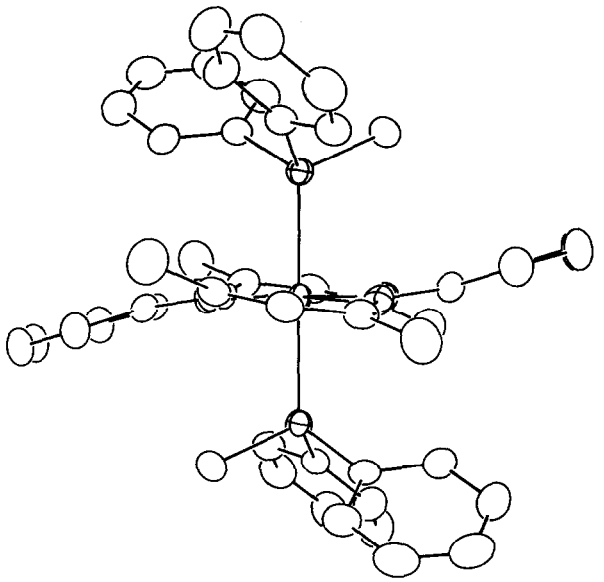

Fig. 7. Side view of the molecule illustrating the step-like shape of the ligand.

Peculiarities. $Ru(tmtaa)(PMePh_2)_2$[26] is a novel complex in which the conventional geometry of the ligand is altered. The octahedral environment of the ruthenium atom consists of four equatorially bound nitrogen atoms of tmtaa and two axially bound phosphorus atoms of $PMePh_2$. The axial, bulky phosphines force the ligand out of the saddle shape and into a "step-like" geometry, with the two benzenoid rings *trans* to each other, relative to the N_4 plane (Fig. 7). This centrosymmetric complex is the only example of a complex in which the saddle shape of tmtaa is destroyed in this fashion. The low-spin t_{2g}^6 electron configuration gives the ruthenium(II) a small enough effective radius to allow it to fit into four nitrogen atoms.

Another complex with unusually interesting features is obtained from a reaction of $Co(tmtaa)(py)_2^+$[24] with acetylene under basic conditions. The final product, Fig. 8, contains the dianionic yet pentadentate tmtaa macrocycle with a vinylide carbon σ-donor occupying one of the two axial sites of the metal. This structure may be compared with that shown in Fig. 4.

The formation of this remarkable product is favoured by a strained coordination environment of the metal ion and the activated character of the methine carbon of tmtaa.

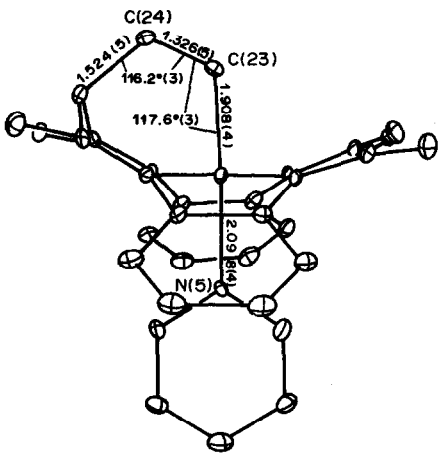

Fig. 8. Side view of $[Co(C_{24}H_{24}N_4)(C_5H_5N)]^+$ illustrating the pentadentate coordination of tmtaa.

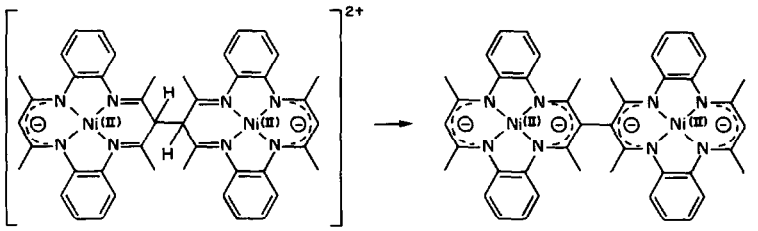
2.3. *The metals nickel, copper and zinc*

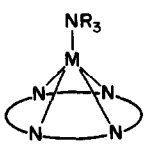
The last class of mononuclear complexes to be discussed is that formed by the late transition metals and zinc. The first report of tmtaa coordination in 1969 mentioned the four-coordinate nickel complex, Ni(tmtaa).[1] Since then, there has been but a handful of other examples, with nickel and copper as the only two late transition metals. Dabrawiak and co-workers[31] found that Ni(tmtaa) undergoes elecrochemical oxidation which leads to the formation of a dimer, **Va**. The two macrocyclic fragments are joined through a carbon–carbon single bond. Under basic conditions this dimeric cation easily loses two protons to give the complex **Vb**. Presumably, a radical mechanism



Va **Vb**

leads to the joining of the two macrocycles, in the end giving the neutral dimer. Its postulated structure is supported by IR and ^{1}H NMR data. (Similar chemistry has been seen with an oxovanadium complex of tmtaa, reported by Goedken and co-workers.)[10]

The element zinc exhibits somewhat different chemical behaviour when coordinated to tmtaa. The complexation of zinc(II) with the macrocycle takes place only in the presence of a base,[16] such as NEt_3 or $N(n\text{-}Pr)_3$, and the resulting product contains a tertiary amine strongly coordinated to the metal centre. The $Zn(tmtaa)(NR_3)$ type complexes are most probably square pyramidal in geometry, as shown by molecular models, with the metal displaced from the N_4 plane thus facilitating the binding of the amine, as shown in **VI**. (Potentially severe steric interactions between the alkyl



VI

groups of the amine and the macrocyclic fragment are diminished when the metal is pushed out of the N_4 plane.)

One can speculate that the displacement of zinc(II) is similar to that for manganese(II) since the ionic radii of the two cations[38] are relatively large and both exceed the hole size of tmtaa. There have been no reports of $M(tmtaa)NR_3$ type complexes with nickel or copper despite some preliminary attempts by Dabrawiak to synthesize the nickel ones.

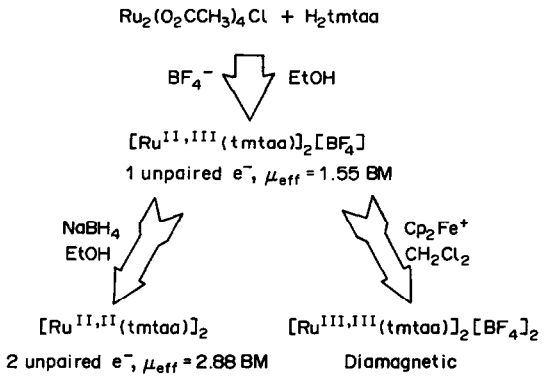
The only copper complex reported is Cu(tmtaa).[32,33] It has one unpaired electron and spectroscopic data are also reported but the structure is unknown. In view of the well-known strong preference of copper(II) for square coordination, this might have a stepped conformation like that in $Ru(tmtaa)(PPh_2Me)_2$.

3. DINUCLEAR COMPLEXES

The chemistry of unbridged $[M(tmtaa)]_2$ type dimers is small in comparison to the large field of monomeric species. These metal–metal bonded complexes with non-bridging macrocycles warrant more study in view of their stability despite the potential steric repulsions of the macrocyclic ligand. Furthermore, these porphyrin-like systems have potential as catalysts in redox processes. Since there is but a handful of $[M(tmtaa)]_2$ complexes known to date, it is worthwhile to consider each of them explicitly.

3.1. *The diruthenium compounds*

The first compounds of the type $[M(tmtaa)]_2$ to be reported were those of ruthenium. In 1978, Warren and Goedken[25] reported the chemistry summarized in the scheme below, **VII**. Unfortunately, no structural data have yet been presented.



VII

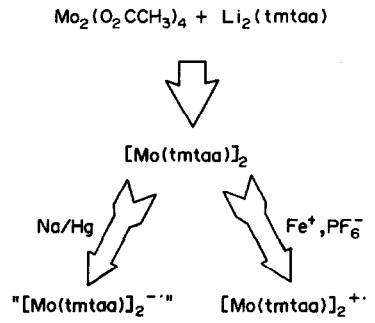
From the magnetic data it can be inferred that the electron configurations for the neutral molecule, the +1 and the +2 ions are, respectively, $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*2}$, $\sigma^2\pi^4\delta^2\delta^{*2}\pi^*$ and $\sigma^2\pi^4\delta^2\delta^{*2}$. These are analogous to those believed to occur in the analogous porphyrin systems.

3.2. *The dirhodium compound*

The compound $Rh_2(tmtaa)_2$ has been prepared and structurally characterized.[37] It has the tmtaa rings in the usual saddle conformation and a Rh—Rh distance of 2.619(6) Å, consistent with a $\sigma^2\pi^4\delta^2\delta^{*2}\pi^{*4}$ configuration and a net single bond. A side view of this molecule showing how the two tmtaa rings are rotated 90° to each other to allow a snug fit is presented in Fig. 9.

3.3. *The dichromium and dimolybdenum compounds*

Several publications[35,36] have appeared dealing with the molybdenum compound and its derivatives. $Mo_2(tmtaa)_2$ is easily prepared by reaction of $Mo_2(O_2CCH_3)_4$ with Li_2tmtaa and it has been shown that it can be both oxidized and reduced, as shown below in **VIII**. The structures of both the



VIII

neutral molecule and the cation have been reported and they are essentially identical except for a change in the Mo—Mo bond distance from 2.175(1) Å for the molecule to 2.221(1) Å for the cation. This change of 0.046 Å upon removal of one δ electron is similar to that found in other cases. Figure 10 shows the structures of both of these species (and the Cr_2 and Rh_2 molecules as well) projected down the M—M axis. Conversely, the side view of the $Rh_2(tmtaa)_2$ structure shown in Fig. 9 is essentially the same for the other three species.

An especially interesting example of a M—M multiply bonded species of tmtaa appeared recently with the synthesis of $[Cr(tmtaa)]_2$.[34,35] Chromium(II) is well-known for forming unusually short Cr—Cr quadruple bonds under certain conditions. Only a few of them, however, exist in unbridged

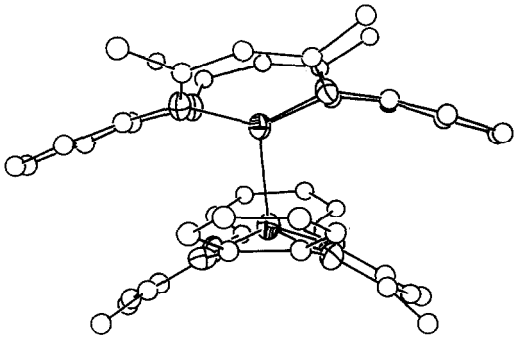


Fig. 9. An ORTEP diagram of the $[Rh(tmtaa)]_2$ molecule showing how the saddle-shaped ligands fit together snugly.

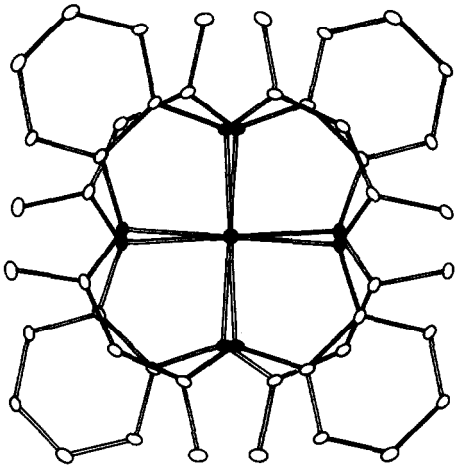

Fig. 10. An ORTEP view of the $[Mo(tmtaa)]_2$ molecule down the M—M axis.

systems. There are all together five efficient ways of synthesizing the $[Cr(tmtaa)]_2$ compound, three reported by one group[34] and two by another.[35]

$$Me_8Cr_2(LiTHF)_4 + 2tmtaaH_2 \xrightarrow{-4CH_4}$$

$$2Mes_2Cr(THF)_3 + 2tmtaaH_2 \xrightarrow{-4MesH}$$

$$2CrCl_2(THF)_2 + 2(tmtaa)Li_2 \xrightarrow{-4LiCl} [(tmtaa)Cr]_2.$$

$$Cr_2(O_2CCH_3)_4 + 2(tmtaa)Li_2 \xrightarrow{-2Li(O_2CCH_3)}$$

$$2Cp_2Cr + 2tmtaaH_2 \xrightarrow{-4CpH}$$

As before, X-ray crystallographic studies show that the two tmtaa fragments possess the saddle-shape geometry and are rotated by nearly 90° relative to one another, as indicated in Figs 9 and 10.

The Cr—Cr distance is 2.101(1) Å in the crystal form that is isomorphous with $Mo_2(tmtaa)_2$. This is short enough to show that a multiple bond exists in the dimer. Calculations[35] show that

there is only a triple bond between the two chromium atoms because metal–ligand interactions lead to a diminished overlap between the δ-bonding $d_{x^2-y^2}$ orbitals. In the molybdenum compound, on the other hand, significant δ-bonding exists.

In summary, unbridged $[M(tmtaa)]_2$ type complexes are stable, despite the steric repulsions of the macrocyclic moieties. There are two main features of the ligand which serve to reduce the potentially severe steric interactions which might have been expected when the macrocyclic fragments are brought together within a bonding distance of the metals. They are, as mentioned in the discussion of monomeric compounds: (1) the ability of the ligand to displace the metal out of the N_4 plane; and (2) its flexibility to adjust the saddle shape according to the size of a metal and axial ligands (another M(tmtaa) fragment, in this case). The limited number of reactions that have been so far investigated in the case of the dimers $[Mo(tmtaa)]_2$, $[Ru(tmtaa)]_2$ and $[Ru(tmtaa)]_2^+$ point to a facile cleavage of Mo—Mo and Ru—Ru bonds. The molybdenum dimer reacts first with tetracyanoethylene (TCNE) and then presumably with some traces of water to produce monomeric $[MoO(tmtaa)][C_3(CN)_5]$.[36b] The ruthenium(II) dimer, on the other hand, dissociates in the presence of CO or pyridine to give monomers of Ru(tmtaa)(CO) and $Ru(tmtaa)(py)_2$. Furthermore, $[Ru(tmtaa)]_2^+$ disproportionates in the presence of carbon monoxide and acetonitrile forming Ru(tmtaa)(CO) and $[Ru(tmtaa)(CH_3CN)_2]^+$.

There is still a lot to be accomplished in the field of unbridged tmtaa dimers. Metals such as vanadium, tungsten, osmium, manganese and iron to mention a few, have the potential for forming these compounds; their synthesis may be simply a matter of time.

4. CONCLUSIONS

The syntheses of unbridged $[M(tmtaa)]_2$ type compounds highlight the fascinating chemistry of the dibenzo[b,i][1,4,8,11]tetraazacyclotetradecine macrocyclic ligand. The latter bears many similarities to porphyrinato systems, but its chemical behaviour seems to be even more diverse. The unique features of tmtaa with regard to electronic delocalization, core size and framework flexibility are responsible for the variety of complexes reported to date. In turn, these complexes give us an insight into the effects of metal electronic configuration, charge and size upon the structure and properties of the macrocyclic framework. These and other matters are of continuing interest to us and other research groups as we discover new "M(tmtaa)" type systems.

ADDENDUM

Since the submission of this manuscript for publication, we have been informed of an interesting compound relevant to this review. J. Guerchais and co-workers synthesized a metal–metal bonded dimolybdenum compound (see below) that is the first of its kind. The $[Mo_2]^{4+}$ core is bonded to only one tmtaa ligand which acts as a bridging ligand for the two metal centres. Two acetate groups are *cis* to each other, also bridging the molybdenum atoms. This dimer has the molybdenum–molybdenum distance of 2.105(1) Å, suggesting a quadruple bond. It will be interesting to see if other compounds with the ligand in this posture can be made.

(*Received* 21 *November* 1989; *accepted* 3 *April* 1990)

Abstract—A series of new mixed cobalt(II) complexes with dipeptide and imidazole, which are dioxygen carriers, was synthesized. The oxygen-free, high-spin octahedral form of the active complex, the reversible dimeric complex with a μ-peroxo bridge as the oxygenated form and the irreversible complex with a μ-superoxo bridge have been examined by spectrophotometric (UV, vis, near-IR), ESR, potentiometric and gas-volumetric methods. Both the electron and the molecular structures have been proposed for each species.

Searching for synthetic models which are close to biological systems capable of reversible oxygen uptake,[1–3] we have investigated a group of mixed-ligand complexes imitating the proximal histidine environment in haemoglobin. The complexes were formed from cobalt(II) ions with dipeptides (dipept) and imidazole (Himid). Related mixed-ligand systems with amino acids (amac) and imidazole[4–7] have proved to be excellent inorganic oxygen and nitric oxide carriers—the considerable influence of the imidazole axial ligand on the thermodynamic stability as well as on inhibition of intramolecular oxidation (auto-oxidation) has been revealed.

The use of peptides instead of amino acids causes some complications due to additional coordination through the deprotonated amide groups. This mode of coordination, very important in metal–peptide complexes in general,[8] is also of essential importance in the oxygen uptake reactions.[9–11] Taking into account the interesting properties of the imidazole-containing systems, we have extended our studies to mixed-ligand complexes with peptides (starting with dipeptides), as a further step towards biological systems.

EXPERIMENTAL

Reagents

All the dipeptides used (glycylglycine, glycyl-L-alanine, L-alanyl–glycine and L-alanyl–L-alanine) were p.a., Fluka AG. Imidazole, p.a., was obtained from Merck. The blue–violet $Co(imid)_2$ polymeric complex was obtained according to the procedure described in ref. 4. For the preparation of the μ-superoxo complex, ceric ammonium nitrate, Merck, p.a., was used. The other reagents (nitric acid, sulphuric acid, sodium hydroxide, potassium nitrate, acetone) were obtained from POCh Gliwice.

* Authors to whom correspondence should be addressed.

Physical measurements

Electronic absorption spectra in the UV–vis and near-IR regions were recorded on a Cary 14 spectrophotometer in a thermostatted cell compartment at 0–1°C, using cuvettes of diameter 0.05, 0.1 and 1 cm. The ESR spectra were recorded on a SE/X 2543 (X band) spectrometer at room-temperature. An external manganese standard was applied. Volumetric measurements were made at ~0°C in an isobaric measurement system described in ref. 11, additionaly provided with a modified double-walled reaction vessel, making possible the introduction of solid $Co(imid)_2$ samples. The pH values were recorded simultaneously by means of a N517 digital pH meter with a combined SAgP-201W electrode. The same pH-meter set-up was used in all other potentiometric measurements.

Preparation of complexes

The solution samples of the active form were synthesized and stored under an oxygen-free atmosphere in order to avoid the formation of oxygenated forms. For spectroscopic investigations we used 0.3 mmol of $Co(imid)_2$ and 0.9 mmol of dipeptide in 1 cm^3 of water—the solution was bubbled with pure N_2 in a gas washer. In the potentiometric and gasometric measurements the total volume of solution amounted to 40 cm^3. For the spectrophotometric measurements the samples of the solution of the active form were prepared directly in a cuvette with a soft silicone stopper according to the procedure mentioned above. Prior to the measurements the reagents were weighed in the cuvette. The water used in the preparation was initially de-aerated in a syringe connected to the cuvette through a needle and then injected into the cell.

The O_2-containing form (μ-peroxo-bridged) was synthesized and stored under a pure oxygen atmosphere at 0°C. The cooled oxygen was bubbled through the sample over *ca* 10 min. For absorption spectra the cuvettes were filled and transported to the spectrophotometer at the same low temperature. The μ-superoxo type complex was prepared in a cool chamber by the addition of 1 cm^3 of the oxygenated form to 1 cm^3 of 0.2 M $(NH_4)_2[Co(NO_3)]_6$ in strongly acidic medium (2 M HNO_3). For ESR measurements a small sample of the solution was collected, maintaining the low temperature, using a syringe with a polypropylene tube into a silica tube. The cuvettes used in the spectrophotometric measurements were filled and transported in a cooled Dewar vessel.

RESULTS AND DISCUSSION

The active form

Most of the systems taking up molecular oxygen reversibly in aqueous solutions are simple metal–ligand systems.[1,3] The studies on O_2 transporters forming a ternary arrangement (Co–chelating ligand–N-base) appear to be much more interesting as closer models of the prosthetic groups. Nevertheless, investigation of the structure of these complexes, as well as of the equilibria involved, is a more complicated problem. The ternary system under study belongs to the most effective dioxygen carriers, since many cycles of the displacement of equilibrium (1) may be accomplished without noticeable loss in efficiency of the system

$$\text{Active form} \underset{N_2}{\overset{O_2}{\rightleftharpoons}} \text{Oxygenated form.} \qquad (1)$$

For all the dipeptides used, very similar spectral curves of the active form have been obtained (Fig. 1), characteristic of high-spin cobalt(II) six-coordinated complexes.[12] The main bands at *ca* 500 nm ($\varepsilon \sim 10$) and *ca* 1100 nm ($\varepsilon \sim 1$) correspond to the quartet spin-allowed transitions $^4T_{1g} \rightarrow {}^4T_{1g}(P)$ and $^4T_{1g} \rightarrow {}^4T_{2g}$, both the bands being strongly asymmetric owing to admixture of the spin-forbidden transitions to doublet states.

The observed rise in pH during dissolution of $Co(imid)_2$ in isoelectric dipeptide medium is due to reaction (2) in which the imidazole molecule—a relatively strong N-base— is released:

$$Co(imid)_2 + \text{dipept}^{\pm} \rightleftharpoons Co(imid)\text{dipept} + \text{Himid}, \qquad (2)$$

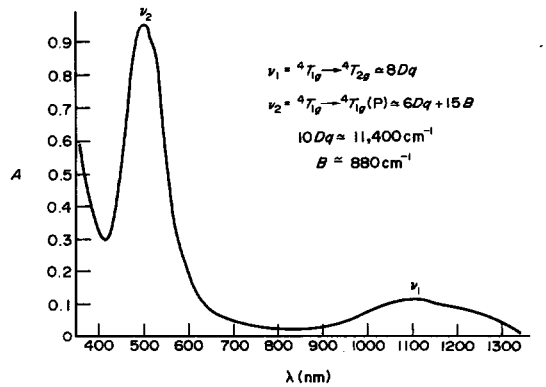

Fig. 1. Visible, near-IR spectrum of the "active" form of the O_2 carrier cobalt(II)–alanylalanine–Himid under N_2: solvent, H_2O; temperature, 0–1°C; *C*, 0.1 M.

where

imid =

$$\text{imid} + \text{H} \rightleftharpoons \text{Himid} \quad (\log K_{1\text{H}} = 14.29 \pm 0.04)^{13}$$

Himid =

$$\text{Himid} + \text{H} \rightleftharpoons \text{H}_2\text{imid} \quad (\log K_{2\text{H}} = 7.03 \pm 0.03)^{13}$$

dipept$^{\pm}$, dipept = dipept^{-}, dipeptH$_{-1}$ denote the neutral, anionic (—NH_3^+ deprotonated) and amide deprotonated forms, respectively.

The appearance of free imidazole was proved by isolation, involving precipitation with acetone of all acetone-insoluble components (complexes and unreacted dipeptide) and then qualitative identification—IR spectra. Reaction (2) is followed by metal-promoted amide deprotonation

$$\text{Co(imid)dipept} \rightleftharpoons \text{Co(Himid)dipeptH}_{-1}. \qquad (3)$$

The correctness of eqs (2) and (3) was confirmed by the results of acid–base titrations (Fig. 2, Table 1); almost 4 mmol of acid per mmol of cobalt were needed to neutralize the solution, which may be explained by the set of equations:

$$\text{Co(Himid)dipeptH}_{-1} + \text{H} \rightleftharpoons \text{Co(dipeptH}_{-1}) + \text{H}_2\text{imid} \qquad (4)$$

$$\text{Co(dipeptH}_{-1}) + 2\text{H} \rightleftharpoons \text{Co} + \text{dipept}^{\pm} \qquad (5)$$

$$\text{Himid} + \text{H} \rightleftharpoons \text{H}_2\text{imid}. \qquad (6)$$

It should be underlined that the proton balance indicates unequivocally a 1 : 1 dipeptide-to-metal ratio.

The oxygenated form

Oxygenation of the active form after stabilization of pH caused a decrease in pH for all the systems (however to a variable extent), Fig. 3. The latter fact may be easily explained by examining the data of quantitative determination of released imidazole during the formation of the oxygenated complex (Table 2). This determination was made after precipitation of the O_2-containing form, in a similar manner as was described earlier for the active form and then by potentiometric titration of the imidazole in the filtrate. Thus we can say that the drop in pH during dioxygen complex formaion (Fig. 3) is due to displacement of equilibria—the greater the shift of equilibrium towards oxygen uptake (i.e. the higher the quantity of imidazole released, Table 2) the lower the decrease in pH.

Hence, the reversible dioxygen fixation consists of replacement of the H_2O molecule by O_2 but this substitution does not influence the pH.

The volumetric measurements indicated the stoichiometry characteristic of μ-peroxo dimers; O_2 : Co = 1 : 2 (Table 3). From the data in Table 3, the maximum of dioxygen fixation occurs at a 1 : 1 dipeptide-to-metal ratio (Fig. 4). This is additional proof for the proposed structure of the active complex.

The increase in concentration ratio above 1 : 1 gives rise to a distinct decrease in dioxygen fixation yield. This should be interpreted as the shift of the complexing equilibria towards the inactive Co(dipept)$_2$ species.

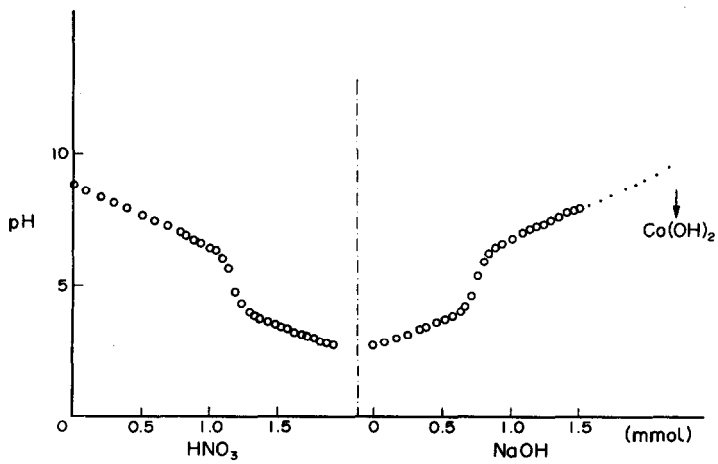

Fig. 2. Acid–base titration of the cobalt(II)–dipeptide–imidazole system under oxygen-free conditions. Gly–ala, 0.9 mmol; Co(imid)$_2$, 0.3 mmol.

L-Ala–L-ala	0.3000	0.9015	1.162	3.873

Dioxygen uptake by the active complex is accompanied by rapid increase in optical density within the near-UV (Fig. 5), the visible region being overlapped by the forming bands up to the near-IR. At the same time the *d–d* transitions characteristic of the active form disappear. These changes in optical density are reflected in the change of colour of the solution from pale pink for the active form to dark red–brown for the oxygenated form.

The position (300–400 nm) and intensity of both LMCT bands in the UV are highly typical of singly-bridged complexes of the μ-peroxo type. The presence of two charge-transfer bands is due to the splitting of π^* antibonding orbitals of the dioxygen molecule into two components (π^*_h and π^*_v) owing to the lack of co-planarity of the Co—O—O—Co moiety.[14] On the lower energetic slope of this band pair we may observe a shoulder at *ca* 500 nm characteristic of the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition in cobalt(III) low-spin complexes.[12] The intensity of the

charge-transfer bands decreases in time, simultaneously with the formation of much weaker *d–d* bands which could be assigned to monomeric, low-spin aquodipeptide cobalt(III) complexes.

The reaction of molecular oxygen uptake by the active form of the complexes under study is very fast. The reverse process, i.e. detachment of the molecule by lowering the O_2 pressure over the solution, is much slower, the rate being highly dependent on temperature. The temperature, however, is an unfavourable factor as it remarkably accelerates the auto-oxidation reactions of the oxygenated form leading to inactive cobalt(III) complexes. Therefore all experiments with the oxygenated form have been carried out at the lowest possible temperature (0–1°C). As was evidenced spectrophotometrically, the auto-oxidation is just moderated enough at this temperature to be neglected during the investigations.

The μ-superoxo form

The μ-peroxo complexes are readily irreversibly oxidated in acidic medium by strong oxidizing agents (Ce^{4+}, Cl_2, MnO_4^-, $HClO_4$) to green–violet products. The electronic spectra of the latter complexes displayed a characteristic charge-transfer band, $d\pi \rightarrow \pi^*_v$, in the near-IR (Fig. 6), typical of cobalt complexes containing a μ-superoxo bridge. The position of this band (*ca* 700 nm), $\varepsilon \sim 10^2$, was almost independent of the type of dipeptide, unlike the related complexes without imidazole (Table 4). The mixed-ligand species were also much more kinetically stable.

By using the mentioned MLCT band we carried out a spectrophotometric titration of the system with Ce^{4+} ions in 1 M HNO_3 medium; the results [0.5 mmol of Ce^{4+} per mmol of Co (Fig. 7)] suggest consumption of one electron per two cobalt ions which confirms the one-electron oxidation of the μ-peroxo bridge to the μ-superoxo bridge.

The presence of the μ-superoxo bridge in the green–violet complexes is indicated by the ESR spectra. For all the investigated systems, isotropic ESR signals were observed (Fig. 8) consisting of a 15-line hyperfine structure arising from symmetric coupling of the unpaired electron with two equi-

valent cobalt ion nuclei of spin 7/2. Both the parameters of the spin Hamiltonian were similar, contrary to the complexes without imidazole (Table 5), thus indicating a considerable unification of structure.

As is the case for numerous dioxygen complexes the small value of the A_{iso} hyperfine splitting constant of order 1 mT, in comparison with 10 mT for simple cobalt(II) complexes,[15] indicates strong delocalization of electron density from the metal to the dioxygen bridge (up to 90%).

CONCLUSIONS

The results presented above suggest that the active (oxygen-free) form is a mixed-ligand complex

of distorted octahedral structure. In the proposed structure the dipeptide molecule chelated through the amine nitrogen, carbonyl oxygen and deprotonated amide group defines the equatorial plane—water and imidazole as the axial ligands (Fig. 9).

In the presence of O_2 the water is reversibly replaced by dioxygen and then the diamagnetic, low-spin complexes of cobalt(III) character are formed, with a μ-peroxo (—O_2^{2-}—) bridge. The studied system is a relatively effective dioxygen carrier, capable of oxygen transport in many cycles. As we have observed, this system is less resistant to auto-oxidation than the relative Co–amac–imidazole one, but is more resistant than the Co–dipeptide–OH^- system (without imidazole). The oxygenated form undergoes, in acidic medium, rapid oxygenation to an irreversible cobalt(III) complex with a monoelectron reduced O_2^- bridge of the μ-superoxo type (Fig. 10).

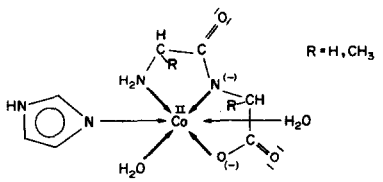

Fig. 9. Proposed structure of the "active" form of the cobalt(II)–dipeptide–imidazole system.

The irreversible μ-superoxo complexes are much more resistant to intramolecular oxidation than the complexes containing the μ-peroxo bridge.

It should be emphasized that for our complexes we have observed a distinct unification of structures, unlike in the complexes without imidazole where a great influence of the primary dipeptide

THE SYNTHESIS AND CHARACTERIZATION OF DI-μ-(METHOXY)-BIS-SQUARATOCOPPER(II)

LINCOLN A. P. M. HALL

Department of Chemistry, The University of the West Indies,
St. Augustine, Trinidad, West Indies

(*Received* 13 *February* 1990; *accepted* 7 *June* 1990)

Abstract—The complex di-μ-(methoxy)-bis-squaratocopper(II), prepared by reacting methanolic solutions of $CuSO_4 \cdot 5H_2O$ and squaric acid in an atmosphere of dry nitrogen, appears to be square planar based on the results of elemental and EXAFS spectroscopic analysis.

Although metal halides have been successfully used in the synthesis of squarates from alcoholic solutions, attempts to prepare a copper(II) squarate from a primary alcohol using copper(II) halides have failed.[1–5] However, if copper(II) sulphate is used, a red–brown complex is formed from methanol. The EXAFS spectroscopic analysis suggests that the complex is square planar. As far as is known, this complex is the first directly synthesized square-planar squarate.

EXPERIMENTAL

Two hundred cm^3 volumes of hot, deaerated 6.5×10^{-3} M squaric acid (obtained from Sigma Chemical Company) and 7.6×10^{-3} M $CuSO_4 \cdot 5H_2O$ methanolic solutions were mixed and allowed to stand in an inert atmosphere. The red–brown complex which formed was collected and dried as described elsewhere.[2] The $CuSO_4 \cdot 5H_2O$ and methanol were of AnalaR grade and obtained from BDH, Poole, U.K. Yield: 0.13 g (40%). Found: C, 28.7; H, 1.7; Cu, 31.1. Calc. for $C_{10}H_8O_{10}Cu_2$: C, 28.9; H, 1.9; Cu, 30.6%.

A sample of the red–brown complex was left exposed to the atmosphere for a few days until it became completely converted to a yellow–green complex. Found: C, 25.1; H, 3.2; Cu, 26.0. Calc. for $C_{10}H_{16}O_{14}Cu_2$: C, 24.6; H, 3.3; Cu, 26.1%.

The IR spectra between 4000 and 600 cm^{-1} were recorded using both Nujol and hexachlorobutadiene as mulling agents. The spectra between 600 and 400 cm^{-1} were recorded using a Nujol mull and AgBr as window material. A reflectance spectrum was taken between 40,000 and 10,000 cm^{-1}. The magnetic susceptibility was determined using $Hg[Co(SCN)_4]$ as calibrant, and the copper content was determined by atomic absorption spectrophotometry.

The EXAFS spectra were measured at 77 K using finely powdered samples of the complex, diluted with boron nitride, and placed in an aluminium sample holder. The synchrotron was operated at 2 GeV energy and an average current of 180 mA. Data collection was carried out at station 9.2 at the SRS, Daresbury Laboratory, using a Si(220) double crystal order-sorting monochromator, with harmonic rejection at 50%. The transmission method of data collection was used. Analysis of the data was carried out using the program "EXCURV88".

RESULTS AND DISCUSSION

The IR spectrum of the complex obtained with the Nujol mull shows the O—H stretch at 3450 cm^{-1}. The very weak absorption at 1780 cm^{-1} is attributed to C=O stretching while the band around 1600 cm^{-1} is assumed to be due to C—C and C—O stretching vibrations.[6] The peaks at 1010 and 1090 cm^{-1} are assigned to the C—O stretching vibrations of the bridging methoxy groups, since similar peaks appear in the spectrum of neat methanol.[7] The absorption at 710 cm^{-1} is a typical squarate band.[8] The absorptions that occur at 520, 440, 430 and 420 cm^{-1}, respectively, have been assigned to Cu—O stretching which is responsible for absorptions at 520 and 435 cm^{-1} in the IR spectrum of $Cu(OMe)_2$.[9] The IR spectrum obtained from the HCB mull showed absorptions at about

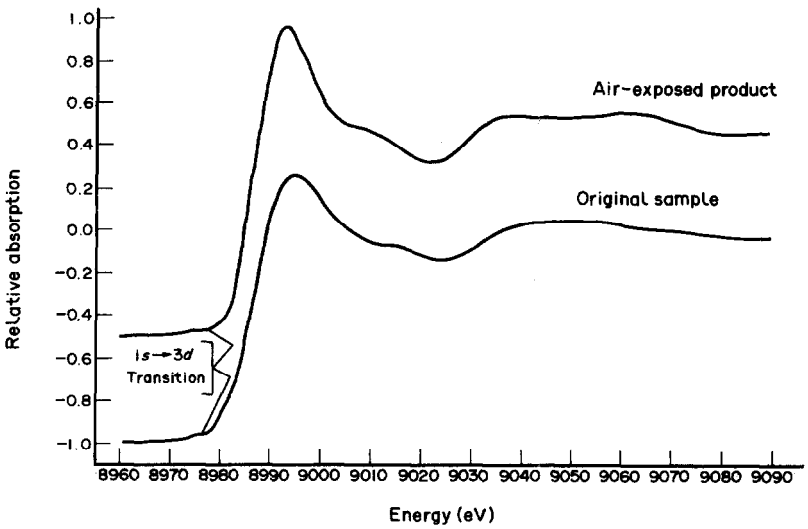

Fig. 1. Comparison of the X-ray absorption spectra of I and II.

1450 and 2930 cm^{-1} which have been identified as CH_3 bands from the bridging methoxy groups.[7]

The UV–vis spectrum shows three absorptions at 10,500–16,000, 19,100 and 20,500 cm^{-1} and is similar to the spectra of the square-planar copper(II) complexes $Cu(DPM)_2$, (DPM represents the anion of 2,2,6,6-tetramethylheptane-3,5-dione) and $Cu(3\text{-}Meacac)_2$ (Meacac represents 3-methylpentane-2,4-dionato).[10,11] $Cu(DPM)_2$, $Cu(3\text{-}Meacac)_2$ and di-μ-(methoxy)-bis-squaratocopper(II) all contain the CuO_4 chromophore. The red–brown squarate (the title compound) is much darker in colour than the yellow–brown copper(II) squarate chloride which apparently has a distorted tetrahedral structure;[3] square-planar copper(II) complexes are frequently red.[12] In addition, the electronic spectrum of copper(II) squarate chloride does not have an absorption at *ca* 19,000 cm^{-1} which is generally present in the spectra of square-planar copper(II) complexes.[10,11]

The EXAFS spectrum (Fig. 1) shows the $1s \rightarrow 3d$ quadrupole transition at 8979 eV which is indicative of the copper(II) oxidation state. The first coordination shell can be fit with four oxygen atoms at 1.93 Å. The EXAFS also shows the presence of a second coordination shell which can be reproduced with either one copper atom at ~ 2.75 Å or two carbon atoms at 2.77 Å (Figs 2, 3 and 4). The copper fit (Debye–Waller factor 0.016) is preferable since the Debye–Waller factor for the two carbon atoms–four oxygen atoms fit (0.002) is rather small.

The edge-width (calculated as the interval between half edge-height and the maximum) of the *K*-edge is 8.6 eV while the edge-width for the air-exposed product is 6.6 eV (Fig. 1). The yellow–

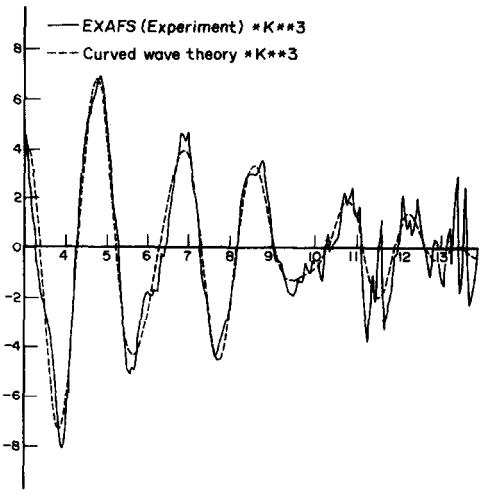

Fig. 2. EXAFS simulation with four oxygen, two carbon and one copper atoms.

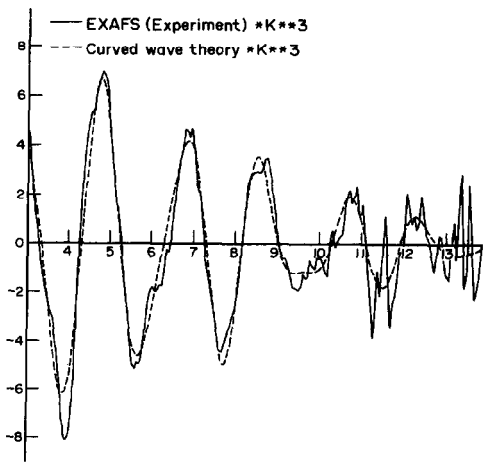

Fig. 3. EXAFS simulation with four oxygen and one copper atoms.

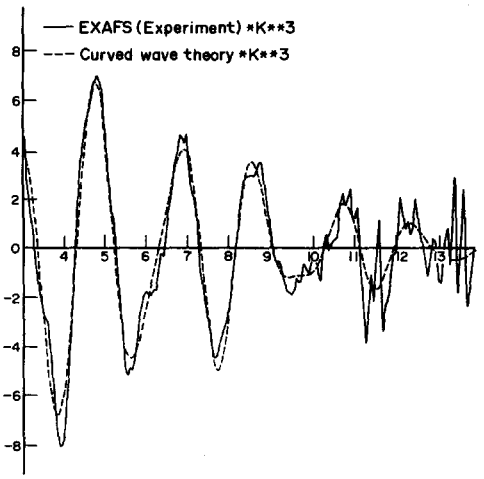

Fig. 4. EXAFS simulation with four oxygen and two copper atoms.

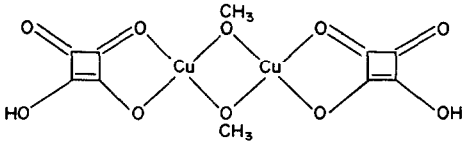
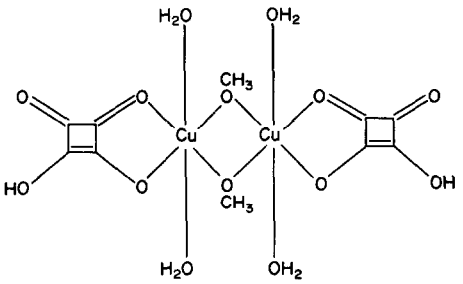
green, air-exposed complex is found to be octahedral from the evidence given later (*vide infra*). The following structures are proposed.



I

Di-μ-(methoxy)-bis-squaratocopper(II).

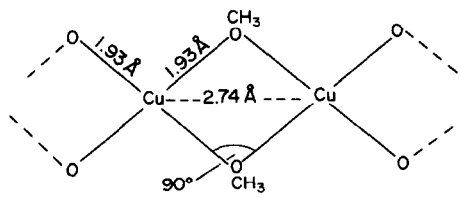


II

Air-exposed product.

The IR spectrum of the air-exposed product shows a number of changes. The O—H stretch at 3450 cm^{-1} in the spectrum of the unexposed complex is replaced by a broad band that extends from 2700 to 3700 cm^{-1}. This is assumed to be due to the O—H stretch in the coordinated water molecules in **II**.[13] The peak at 1010 cm^{-1} observed in the IR spectrum of **I** does not appear in the IR spectrum of **II**, while the peak at 1090 cm^{-1} appears as a multiplet with peaks at 1090, 1110 and 1122 cm^{-1} in the spectrum of **II**. Thus, one of the C—O stretching vibrations of the bridging methoxy groups is lost in **II**. The number of Cu—O absorptions is also reduced. The peak at 520 cm^{-1} does not appear in the spectrum of **II**, while there are only two peaks at 435 and 450 cm^{-1} instead of the three peaks observed in this region in the spectrum of **I**. The reduction in the number of C—O and Cu—O absorptions has been attributed to the higher symmetry of **II**.

The 2 eV change in edge-width in the EXAFS spectra of **I** and **II** suggests that **I** is square planar and **II** octahedral. Bhaskare and Kulkarni[14] illustrated a similar, although greater, difference in edge-width between octahedral copper glutamate (edge-width, 7.58) and square-planar copper oxide (edge-width, 9.98). The Cu—O bond lengths of 1.93 Å in **I** are also consistent with square-planar CuO_4.[15–18] The absence of any pre-edge feature suggests that if there is any axial ligation in **I** the ligands are either > 3 Å or < 2.3 Å from the copper atoms.[18] However, the EXAFS simulation shows no evidence of any ligand at short distance. In addition, any contribution at 2.75 Å should result in a pre-edge feature if there is axial ligation. The evidence, therefore, indicates that **I** is square planar with Cu—O and Cu—Cu distances of 1.93 and 2.74 Å, respectively, and a Cu—O—Cu angle of ~ 90° as shown in the following diagram. The Cu—Cu bond length of 2.74 Å is longer than 2.61–2.65 Å required for direct Cu—Cu bonding.[19]



Analysis of the EXAFS spectrum of the air-exposed product (Fig. 5) suggests that it is most

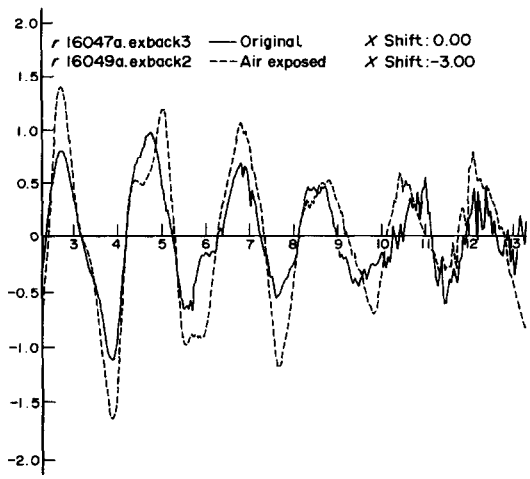


Fig. 5. Comparison of the EXAFS simulations of **I** and **II**.

likely six-coordinate with the fit to the first shell giving six oxygen atoms at 1.93 Å. It is quite likely that the restricted space between layers in the complex forces the copper to adopt an octahedral geometry without the expected Jahn–Teller distortion.

The room temperature magnetic moment of the title complex is 1.84 BM which is consistent with copper(II).

Tetrahedral, five-coordinate and octahedral squarates have been prepared before under anaerobic conditions.[1–5] The square-planar geometry present in this complex completes the list of common geometries shown by first-row transition metal complexes and illustrates the fact that the nature of the solvents and salts used in the preparation of squarates under anaerobic conditions affects the coordination and shape of the complex synthesized.

Acknowledgements—The author wishes to thank Dr S. S. Hasnain and Dr R. W. Strange from the Daresbury Laboratory in Warrington, U.K., for their help in obtaining the EXAFS spectra and the latter for his help in interpreting the EXAFS spectra.

TRIPODAL LIGANDS WITH MIXED DONORS. SYNTHESIS OF 2-DIPHENYLPHOSPHINOMETHYL-2-PHENYLTHIOMETHYL-1-METHOXYPROPANE (PSO) AND ITS TRANSITION METAL COMPLEXES

SHIUH-TZUNG LIU,* CHONG-LUNG TSAO, MING-CHU CHENG and SHIE-MING PENG

Department of Chemistry, National Taiwan University, Taipei, Taiwan 10764, R.O.C.

(*Received* 20 *March* 1990; *accepted* 7 *June* 1990)

Abstract—A tripodal ligand containing phosphorus, sulphur and oxygen donors has been synthesized and its coordination in chromium(0), molybdenum(0), tungsten(0), manganese(I) and palladium(II) complexes has been investigated. X-ray crystal structures of the chromium, tungsten and palladium compounds have been determined, and the conformations of the six-membered chelate rings of these complexes are discussed.

The design of new polydentate ligands for coordination studies has been interesting and challenging work. As part of our interest in tripodal terdentate ligands, we wished to synthesize such species which contain both "soft" and "hard" donor sites. Such ligands could be used to study the selectivity studies toward transition metals. In our early work,[1] we described several tripodal ligands that contain only two different donor sites, **1** and **2**. However, tripodal terdentates containing three different donor atoms would be more attractive for coordination chemists. Only a few such species have been reported,[2,3] and none containing phosphorus. Here, we report the synthesis of a tripodal phosphine ligand with three different donors, 2-diphenylphosphinomethyl-2-phenylthiomethyl-1-methoxypropane (abbreviated as PSO) **3**, and its complexation toward various transition metals.

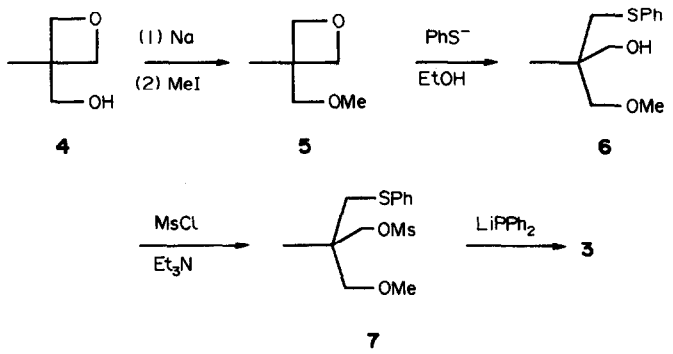
RESULTS AND DISCUSSION

Synthesis of ligand

The synthetic approach to **3** is shown in Scheme 1. From **4**, compound **5** was prepared according to a modification of the reported method.[4] The oxetane ring was opened by the benzenethiolate anion to generate the sulphide–alcohol **6**. Mesylation of the hydroxy function of **6**, followed by treatment with diphenylphosphide anion, produced the desired phosphine compound (±)-**3**, after anaerobic chromatography of the crude product on a column of degassed silica gel. This terdentate was characterized by a spectroscopic method and elemental analysis. The ^{31}P NMR spectrum shows a single peak at −24.78 ppm, upfield from the reference of 85% H_3PO_4, which is the characteristic absorption of a tertiary phosphine.

Group VI *complexes*

The group VI carbonyl complexes, (PSO)M$(CO)_4$, in which M = Cr (**8a**), Mo (**8b**) and W (**8c**), were readily prepared by means of the direct ligand substitution reaction. The complexes **8a**–**8c** were made by the thermal reaction of **3** with the corresponding $M(CO)_6$ in boiling, degassed xylene. Attempts to prepare (PSO)Mo$(CO)_3$ failed. The substitution reaction of Mo(η^6-cyclohepatriene)$(CO)_3$ by PSO led to the isolation of **8b** instead



Scheme 1.

of $(PSO)Mo(CO)_3$. Other thermal substitution reactions or photochemical activation of **8b** were unable to force the oxygen donor to become co-ordinated. All purified tetracarbonyl metal complexes have been identified by both spectroscopic and elemental analyses; their data are summarized in Table 1.

Crystals of **8a** and **8c** were grown from hexane and dichloromethane solvents and are isomorphous. The structure of **8a** shows the chromium centre to have an octahedral stereochemistry with four carbonyls, and the phosphorus and the sulphur donors of PSO bound to the metal (Figs 1 and 2). All bond distances and bond angles are within normal ranges; some selected bond distances and bond angles are given in Table 2. The M—C distances for both **8a** and **8c** *trans* to phosphorus are longer than those *trans* to sulphur; this effect is believed to be a consequence of the presence of metal-to-sulphur π-back-donation.[2,4]

Manganese(I) *complexes*

From the reaction of equimolar **3** and $Mn(CO)_5Br$ in boiling chloroform, a yellow crystalline solid of complex **9** was isolated. The IR spectrum

[a] Coordination chemical shifts ($\Delta_{\delta P}$) = δ_p(complex) − δ_p(free ligand), in ppm.

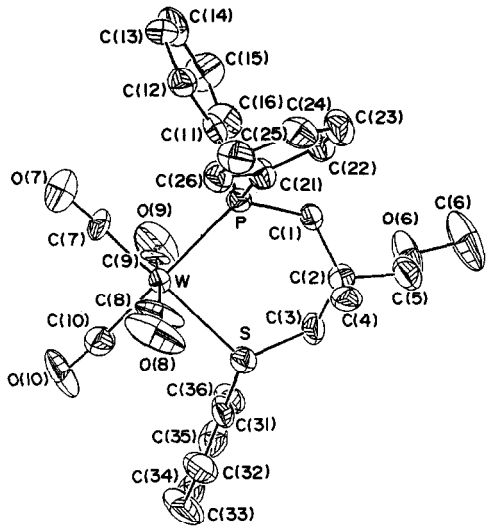

Fig. 1. The ORTEP drawing of **8c**.

(ν(CO) = 2034, 1961, 1907 cm^{-1}) of **9** shows three terminal CO stretches in *fac*-geometry.[5] Both ^{31}P and ^{1}H NMR spectra indicate that phosphorus and sulphur donors bind to the metal centre with the oxygen site uncoordinated. This evidence indicates the structure of **9** to be an octahedral complex with phosphorus, sulphur and bromide in a *fac*-arrangement.

Another way to achieve complex **9** is by the reaction of **3** and $Mn_2(CO)_{10}$ to generate [(PSO)Mn $(CO)_3]_2$ (**10**), followed by treatment with bromine (Scheme 2). It is interesting to note that both IR and ^{1}H NMR spectra of **10** are similar to those of **9**; only the ^{31}P chemical shifts for both complexes have a slight difference (δ 25.66 of **9** vs δ 27.63 of **10**). However, we have not determined the exact structure of **10**.

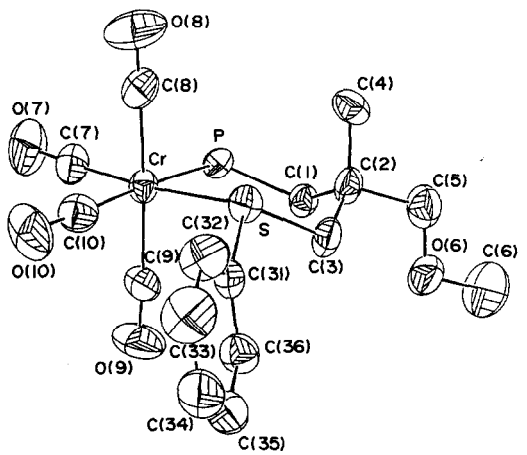

Fig. 2. The ORTEP drawing of **8a** (phenyl groups omitted for clear view).

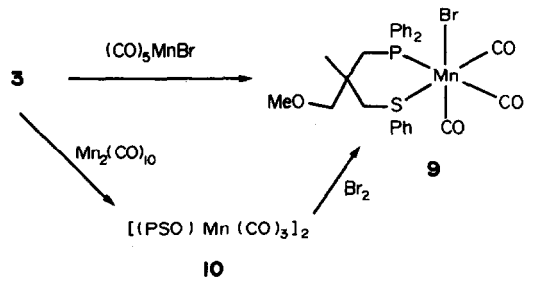

Scheme 2.

Palladium(II) *complex*

The reaction of equimolar amounts of **3** and $PdCl_2$ in acetonitrile afforded the desired complex (PSO)$PdCl_2$ (**11**) as a yellow, crystalline solid upon recrystallization. Both ^{1}H and ^{31}P NMR spectroscopic data of the compound indicate that the potentially terdentate PSO ligand acts in a bidentate mode with phosphorus and sulphur atoms binding to palladium metal in a *cis*-fashion. This structure has been further determined by the single-crystal X-ray diffraction method. Figure 3 shows an ORTEP view of the complex with all non-hydrogen atoms labelled. The coordination geometry around palladium is a square-planar arrangement with the palladium atom slightly [0.197(4) Å] out of the plane defined by S,P,Cl(1),Cl(2). Selected bond dis-

tances and angles are listed in Table 2. The Pd—Cl bond *trans* to the phosphorus atom is longer, as expected, than that *trans* to the sulphur atom, probably due to the "*trans* effect".

Conformational analysis

Table 3 presents all torsional angles around the six-membered chelate rings of the complexes, which also facilitates their comparison. The characteristic $+g$, $-g$ alternations indicate the conformations of the six-membered chelate rings of **8a**, **8c** and **11** to be in chair forms, which are considered the most stable.[6,7] However, these chair conformations are all slightly distorted, especially in the palladium complex (Fig. 3).

In the previous investigation,[1a,1b] we found that the conformations of $(P_2S)Mo(CO)_4$ and $(P_2O)Cr(CO)_4$ were in twist-boat forms mainly due to the steric interactions of substituents along the chelate rings, as shown in Fig. 4(a). Apparently, the trivalent thioether (coordination to the metal) helps to relieve some 1,3-diaxial interactions in the chelate rings of complexes **8a** and **8c**, so that the chelate rings are able to adopt chair forms [Fig. 4(b)].

Table 3. Torsional angles (°) around the six-membered chelate rings of complexes **8a**, **8c** and **11**

	8a M = Cr	**8c** M = W	**11** M = Pd
M—P—C(1)—C(2)	−52.5(3)	−54.1(7)	43.5(3)
P—C(1)—C(2)—C(3)	80.3(4)	81.8(10)	−71.9(4)
C(1)—C(2)—C(3)—S	−81.1(4)	−82.4(10)	67.0(4)
C(2)—C(3)—S—M	57.7(3)	57.6(6)	−34.9(3)
C(3)—S—M—P	−28.8(2)	−28.9(4)	6.4(2)
S—M—P—C(1)	25.4(2)	26.0(4)	−9.9(2)

In contrast to an equatorial position, the phenyl group attached to the sulphur atom is situated in an axial position in the palladium complex **11**. This difference obviously suggests the "eclipsed" interaction of the equatorial phenyl group and the chloride ligand to be larger than the 1,3-diaxial interaction. Of course, another factor contributing to this outcome is that the larger angle of S—Pd—P [97.81(6)°] increases the distance between phosphorus and sulphur, which leads to the decrease of the 1,3-diaxial interaction between the phenyl groups.

The resolution of the chiral ligand PSO and its applications are currently in progress.

EXPERIMENTAL

The general information has been described in detail previously.[1] Compound **4** was prepared according to the reported method.[8]

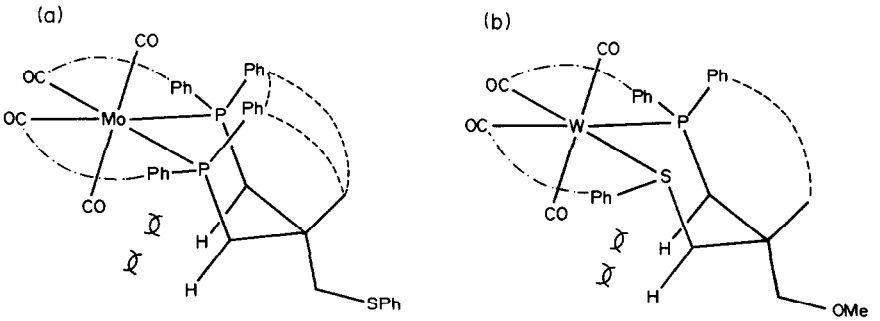

Fig. 4. (a) Three types of major steric interactions of $(P_2S)Mo(CO)_4$ in the chair conformation: (i) 1,3-diaxial interactions (---); (ii) "eclipsed" interactions between apical ligands (CO) and phenyl groups (—·—·—); (iii) interactions between apical ligands and axial hydrogen atoms (𝔍). (b) The steric interaction of $(PSO)W(CO)_4$ in the chair form.

3-Methoxymethyl-3-methyloxetane (**5**)

Freshly-cut sodium metal (3.7 g) was added to a solution of **4** (16.27 g, 0.16 mol) in toluene (40 cm^3). The mixture was heated to reflux overnight. Iodomethane (12 cm^3, 0.16 mol) was added to the above solution, which was then stirred at room temperature for 36 h. The reaction mixture was quenched with water (50 cm^3) and the organic layer was separated. The organic portion was extracted with ether (20 $cm^3 \times 3$). All organic extracts were combined, dried and concentrated. The residue was distilled to give compound **5** (10.0 g, 54%) as a clear liquid: b.p. 138–142°C/760 mm (similar to literature[9]).

2-Hydroxymethyl-2-phenylthiomethyl-1-methoxypropane (**6**)

Freshly-cut sodium metal (4.15 g, 180.4 mmol) was added to ethanol (70 cm^3) under a nitrogen atmosphere. After all the sodium had reacted, thiophenol (18 cm^3, 175.3 mmol) was added to the ethoxide solution slowly, this was then stirred for 30 min. Compound **5** (6.63 g, 57.2 mmol) was transferred into the above solution and the resulting mixture was heated to reflux overnight. Water (20 cm^3) followed by ether (40 cm^3) was added to the reaction mixture. The organic layer was separated, and the aqueous layer was extracted with ether (30 $cm^3 \times 2$). The combined organic extracts were dried and concentrated. The residue was chromatographed on silica (100 g) with elution by 5% ethyl acetate in hexane. The desired compound **6** was obtained as a viscous, yellow liquid (8.08 g, 62%). ^{1}H NMR: δ 7.40–7.00 (m, 5 H), 3.48 (d, $J = 9$ Hz, 1 H), 3.42 (d, $J = 9$ Hz, 1 H), 3.20 (d, $J = 3$ Hz, 2H), 3.15 (s, 3 H), 3.08 (d, $J = 9$ Hz, 1 H), 2.92 (d, $J = 9$ Hz, 1 H), 2.70 (br, 1 H), 0.80 (s, 3 H). Found: C, 63.1; H, 8.1. Calc. for $C_{12}H_{18}O_2S$: C, 63.7; H, 8.1%.

2-Diphenylphosphinomethyl-2-phenylthio-1-methoxypropane (**3**)

The hydroxy compound **6** was transformed into mesylate **7** according to a standard procedure described previously.[1b] To a solution of diphenylphosphine (3.23 g, 17.2 mmol) in THF (100 cm^3) was added a 2.50 M hexane solution of *n*-butyllithium (17.0 cm^3) at ice-cooled temperature. After stirring for 30 min, compound **7** (4.24 g, 13.9 mmol), in a small portion of THF, was added to the phosphide anion solution. The resulting mixture was heated to reflux for 4 h; degassed water (10 cm^3) was then added. The organic layer was separated, dried and concentrated. The crude product was chromatographed on silica (100 g) with elution by 40% ethyl acetate in hexane. The desired tripodal ligand, PSO, was obtained as a viscous, colourless

Preparation of **8a–8c**

The ligand PSO and an equimolar amount of group VI metal carbonyl ($M(CO)_6$, M = Cr, Mo and W) were dissolved in an aromatic solvent (toluene or xylene) and heated to reflux for 8–10 h. The desired complexes were isolated by chromatography on silica. All spectroscopic and analytic data are given in Table 1.

Preparation of (PSO)$Mn(CO)_3Br$ (**9**)

A solution of $BrMn(CO)_5$ (45.7 mg, 0.17 mmol) and PSO (65.5 mg, 0.17 mmol) in chloroform was refluxed for 30 min. After addition of hexane, the solution was allowed to stand for several days. The complex *fac*-(PSO)$Mn(CO)_3Br$ was crystallized as yellowish needles (65.3 mg, 64%). IR: ν(C≡O) 2034, 1961, 1907 cm^{-1}. ^{1}H NMR: δ 7.90–7.30 (m, 15 H), 3.25 (s, 3 H), 3.09 (d, J = 8.84 Hz, 1 H), 3.03 (d, J = 8.84 Hz, 1 H), 2.71 (d, J = 11 Hz, 1 H), 2.64 (d, J = 11 Hz, 1 H), 2.44 (dd, J = 10, 15.3 Hz, 1 H), 2.15 (dd, J = 10, 15.3 Hz, 1 H), 0.61 (s, 3H). ^{31}P NMR: δ 25.66. Found: C, 48.7; H, 4.0. Calc. for $C_{27}H_{27}O_4PSMnBr$: C, 49.1; H, 4.1%.

Preparation of (PSO)$PdCl_2$ (**11**)

This complex was obtained as a yellow, crystalline solid by stirring a mixture of PSO and $PdCl_2$ in acetonitrile, followed by recrystallization from dichloromethane and ethyl acetate, m.p. (dec.) 190°C. ^{1}H NMR: δ 7.94–7.30 (m, 15 H), 3.03 (s, 3 H), 2.97 (d, J = 5 Hz, 1 H), 2.95 (d, J = 5 Hz, 1 H), 2.89 (d, J = 2.7 Hz, 1 H), 2.87 (d, J = 2.7 Hz, 1 H), 2.49 (dd, J = 22.5, 12 Hz, 1 H), 2.09 (dd, J = 22.5, 12 Hz, 1 H), 0.93 (s, 3 H). ^{31}P NMR: δ 17.81. Found: C, 50.1; H, 4.7. Calc. for $C_{24}H_{27}OPSPdCl_2$: C, 50.4; H, 4.8%.

Crystallographic analysis of complexes **8a**, **8c** *and* **11**

Cell parameters were determined on a CAD-4 diffractometer by a least-squares treatment. Atomic scattering factors wee taken from the *International Tables for X-ray Crystallography*.[10] Computation was carried out by using the NRCC SDP VAX package.[11] Relevant data are summarized in Table 4.

ELECTRONIC STRUCTURE OF THIOCHLOROANIONS OF MOLYBDENUM

LUDMIŁA SZTERENBERG

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, F. Joliot-Curie 14, Poland

(*Received* 5 *April* 1990; *accepted* 8 *June* 1990)

Abstract—The electronic structure and bonding properties of the $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3Cl_6]^{2-}$, $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl)_2Cl_6]^{2-}$ and $[Mo_2(\mu\text{-}S_2)_2Cl_8]^{2-}$ ions have been studied using the Fenske–Hall method. On the basis of the two-centre overlap populations, the roles and the strengths of the metal–metal and metal–ligand bonds have been determined.

Metal compounds in which two transition metal elements are joined via the sulphur or halogen atoms and which contain the metal–metal bonds are well known. This class of complexes is of biological and catalytic interest. There is as yet no definitive evidence for the presence of disulphur complexes in biological systems. However, it was suggested that the reaction of xanthine oxidase with cyanide yielding thiocyanate and the inactive disulpho-form of the enzyme involves abstraction of a sulphur atom from a disulphur complex or from a persulphido group.[1–3]

In continuation of our theoretical investigations of the Mo—S clusters model,[4–6] this paper reports the results of the determination of the electronic structure of polynuclear molybdenum thioanions with a structural unit in which both sulphur atoms of the disulphur ligand are bonded to each of the two metal atoms. The electronic structures of the $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3Cl_6]^{2-}$, $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl)_2Cl_6]^{2-}$ and $[Mo_2(\mu\text{-}S_2)_2Cl_8]^{2-}$ ions, as well as of the S_2^{n-} ligand (where $n = 0$–2), were calculated by the parameter-free Fenske–Hall method.

COMPUTATIONAL DETAILS

The semi-quantitative Fenske–Hall LCAO molecular orbital method[7] was applied in our study. The method is an approximate Hartree–Fock–Roothaan SCF LCAO MO molecular orbital approach which involves neither arbitrary nor adjustable parameters, depending only upon the choice of wave functions and atomic coordinates as input data. The operation is self-consistent.

The interatomic distances and angles used for the examined complexes were based upon their structural determinations for $[Mo_3(\mu\text{-}S)(\mu\text{-}S_2)_3Cl_6]^{2-}$, $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl)_2Cl_6]^{2-}$[8] and $[Mo_2(\mu\text{-}S_2)_2Cl_8]^{2-}$[9] (Fig. 1).

RESULTS AND DISCUSSION

The calculated distribution of charges in the studied complex ions is shown in Tables 1 and 2. The results obtained for some energy eigenvalues are given in Table 3 and Fig. 2. As a result of these, four groups of the occupied orbitals were observed. The *s* orbitals of sulphur and chlorine ligands that do not form effective M—L bonds are the lowest occupied ones. The next group of orbitals displays mainly the *p* character of the ligand atoms and the 4*d* character of molybdenum. This group is followed by the π non-bonding ligand orbitals. The highest occupied molecular orbitals are the strongly delocalized, multicentre orbitals having pre-

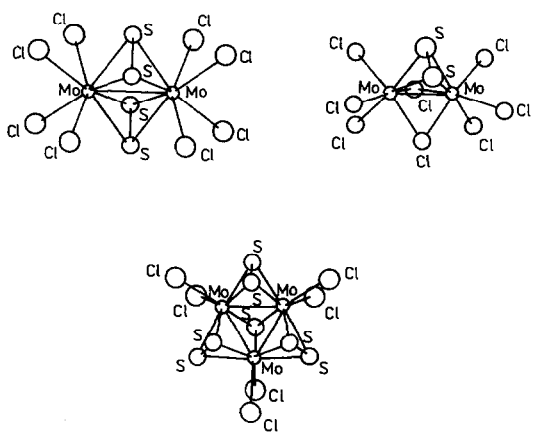

Fig. 1. The geometry of the studied complexes.

Table 1. Calculated atomic charges

dominantly the character of the 4*d* orbitals of molybdenum and of the *p* orbitals of the ligands. The lowest unoccupied molecular orbitals have predominantly the character of the 4*d* orbitals of molybdenum. The description of bonding in the studied system is based on the following sequence of metal–metal orbitals (Fig. 2, Table 3): $\sigma^2(d_{z^2})\sigma^*(d_{z^2})$ for $[Mo_2(\mu\text{-}S_2)_2Cl_8]^{2-}$, $\sigma^2(d_{z^2})^2\delta^1(d_{x^2-y^2})\delta^{*1}(d_{x^2-y^2})\sigma^*(d_{z^2})$ for $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl_2)Cl_6]^{2-}$ and $\sigma^2(d_{z^2})\pi^4(d_{xz})\pi^*(d_{xz})$ for $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3Cl_6]^{2-}$ (where the σ, π and δ orbitals denote the bonding combinations of the valence *d* orbitals of molybdenum, while σ^*, π^* and δ^* are their corresponding antibonding counterparts). For the $[Mo_2(\mu\text{-}S_2)_2Cl_8]^{2-}$

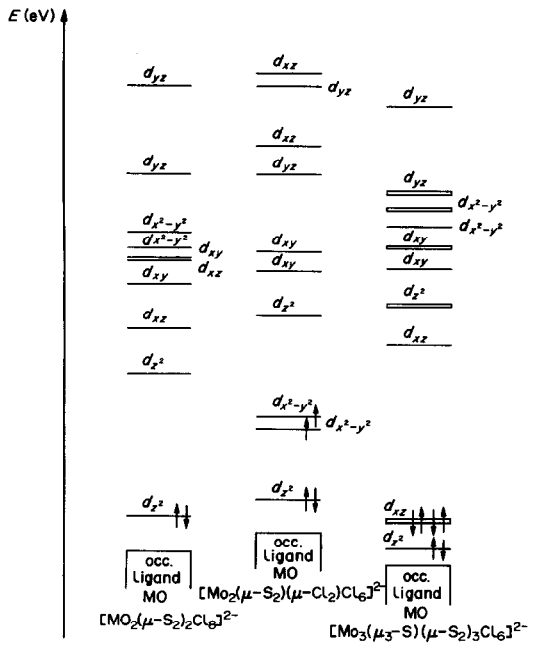

Fig. 2. Molecular orbital diagrams showing the highest filled and lowest unfilled orbitals for the anions investigated.

complex anion the HOMO orbital is occupied by two electrons. The results of calculations for the high- and low-spin systems suggested the presence of the low-spin configuration. The high-spin system proved to be energetically unstable. In such a case the $\sigma^1\sigma^{*1}$ configuration does not form effective Mo—Mo bonding, either. No experimental data on the magnetic properties of the examined system are available, and no temperature-dependent paramagnetism should be expected here, which was also indicated by the $\Delta E_{\text{HOMO-LUMO}}$ splitting value of about 5 eV. Instead, the scheme obtained for the $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl_2)Cl_6]^{2-}$ ion is in good agreement with the magnetic and spectroscopic experimental data, but without contradiction of the existence of σ character in the Mo—Mo bonding. The presence of the chloride bridge atoms is responsible for the appearance of the δ bonding and antibonding orbitals (because of the Mo—Mo interaction) between the σ and σ^* orbitals. Since in all of the three examined cases the σ–σ^* splitting remained of the same order, we could dispel the doubts of Müller and co-workers[8] about the unchanged spectroscopic and magnetic properties of the $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl_2)Cl_6]^{2-}$ ion as compared with those of the monomeric molybdenum(V) complex ions. The magnetically undetectable electrons of the $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl_2)Cl_6]^{2-}$ ion are localized on the Mo—Mo axis in the molecular σ orbital, while the two other electrons occupy the δ and δ^* orbitals. The moderately intensive band at about 12.5×10^3 cm^{-1} in the electronic absorption spectrum of the $[Mo_2(\mu\text{-}S_2)(\mu\text{-}Cl_2)Cl_6]^{2-}$ complex ion was attributed to the $\sigma(d_{z^2}) \rightarrow \delta(d_{x^2-y^2})$ transition, while the shoulder on the intensive band at about 23×10^3 cm^{-1} should be attributed to the $\delta(d_{x^2-y^2}) \rightarrow \sigma^*(d_{z^2})$ one-electron excitation.

More detailed characteristics of bonding are given by Mülliken's overlap populations. Nevertheless, although they are not significant in the absolute scale, comparison of the values for similar systems led to reasonable trends. Taking into account the above-mentioned limitations, the conclusions can be applied to the molybdenum–molybdenum and molybdenum–ligand bonding. The most important overlap populations of the examined complexes are presented in Table 4. The data in Table 4 also confirm a predominant contribution of the $d\sigma$ orbitals to the metal–metal bonding. The contribution of the $d\pi$ and $d\delta$ orbitals is several times lower than those of the $d\sigma$ orbitals. In all of the complexes the Mo—Mo overlap population value is of the same order. Although the Mo—Mo bond plays an important role in electron delocalization, the main contribution to the formation of a stable MoS_2Mo cluster is found to arise from the bonding interaction between the sulphur and the metal atoms, since the former is an electron donor, possessing the capability of strong electron delocalization. In all the studied cases, the two-centre overlap population revealed some consistencies about the metal–ligand bond strengths. The bonding interaction between the d orbitals of

the metal and ligand falls in the oder:

$$P(d\text{Mo–}\mu S_2) > P(d\text{Mo–Cl}_t) > P(d\text{Mo–}\mu\text{Cl}).$$

The strong metal–bridge (μS_2) bonding is evidence for the stability of such systems. The stability is due to the extensive electron delocalization in the Mo—μS_2—Mo arrangement. The negative charge on the sulphur of the free S_2^{2-} ligand decreases drastically in the complexes (Table 5). When S_2^{2-} is a bidentate bridge ligand, the flow of charge π_g,π_u from the disulphur unit to the metal is more effective. Calculations show that the extensive electron delocalization is a general feature of the cluster compounds investigated. It usually appeared as the larger contribution of the π electrons on the μ-S_2 atoms to the free orbitals of the metal. The major contribution of the π bonds, Mo—S_2, is shown in Table 6 by the quantitative molecular orbital scheme for the $[Mo_2(\mu\text{-}S_2)_2Cl_8]^{2-}$ ion.

(*Received* 5 *January* 1989; *accepted after revision* 15 *June* 1990)

Abstract—The crystal structure of $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$ has been determined by single X-ray diffraction: $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$, $Mr = 788.0$, orthorhombic, $P2_12_12_1$, $a = 17.781(2)$, $b = 15.050(2)$, $c = 13.397(1)$ Å, $V = 3585.1(5)$ Å^3, $Z = 4$, $Dx = 1.46$ Mg m^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 14.5$ cm^{-1}, $F(000) = 1608$, $T = 294$ K, $R = 0.056$ for 2620 independent reflections with $I > 3\sigma(I)$. The complex $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$ is essentially square-planar. The bond distance palladium-to-nitrogen *trans* to phosphine of 2.25 Å is the longest observed so far in palladium(II) complexes. The rate of replacement of the nitro-group *trans* to phosphine by piperidine has been studied in the title complex and in *trans*-$[Pd(PPr_3^n)(NO_2)_2Cl][As(C_6H_5)_4]$ at 25°C in dichloromethane. The second order rate constants k_2 (dm^3 mol^{-1} s^{-1}) are, respectively, $(72.8 \pm 1.1) \times 10^3$ and $(36.8 \pm 2.0) \times 10^3$. The enhancement of the relative lability of NO_2 with respect to Cl suggests that the nitro group is either weakly bound to palladium in solution, as in the solid, or is coordinated through oxygen.

We have recently[1] reported that by reaction of the tetrameric complex $[Pd_4(PPr_3^n)_4(NO_2)_8]$ with nucleophiles, anionic complexes of *n*-propylphosphine of the type $[Pd(PPr_3^n)X_3][As(C_6H_5)_4]$ (X = Cl, Br, NO_2, etc.) are obtained. In this paper we report the properties in solid and solution of one of these substances, i.e. $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$. In particular, we describe the structure in the solid compound, as determined by a single-crystal X-ray study, and in order to search for a possible relation between structure and reactivity, we report the kinetics of substitution, by piperidine, of the group X *trans* to PPr_3^n in $[Pd(PPr_3^n)(NO_2)_2X][As(C_6H_5)_4]$ (X = NO_2 or Cl) in dichloromethane at 25°C.

EXPERIMENTAL

The preparation of the complexes $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$ and *trans* $[Pd(PPr_3^n)(NO_2)_2Cl][As(C_6H_5)_4]$ has already been reported.[1] Piperidine was distilled over KOH pellets. All the solvents were of the highest quality commercially available and used as received.

The conductivity measurements were performed with a Radiometer CDM3 conductivity bridge. Ultraviolet–vis. spectra were recorded by using a Perkin–Elmer Lambda 5 spectrophotometer. Infrared spectra in the range 250–4000 cm^{-1} were recorded as Nujol mulls on a Perkin–Elmer 783 spectrometer.

The kinetics were followed with a standard Durrum–Gibson stopped-flow spectrophotometer equipped with a photometric log amplifier model D-131. Absorbance changes, at selected wavelengths, were displayed on a Gould 054100 storage oscilloscope and traces were recorded on a Radiometer REC 61 potentiometric recorder.

In all cases a large excess of reagent was used to provide pseudo-first-order conditions and to force the reactions to completion. Pseudo-first-order rate constants $k_{obs.}$ (s^{-1}) were obtained either from the gradients of the plots $\log(A_t - A_\infty)$ vs time or from non-linear least-squares fit of experimental data to $A_t = A_0 + (A_0 - A_\infty) \exp(-k_{obs.}t)$, where A_0, A_∞ and $k_{obs.}$ were the parameters to be optimized (A_0 = absorbance after mixing of the reagents, A_∞ = absorbance at completion of reaction). The $k_{obs.}$ values were reproducible to better than ±5%.

X-ray data collection and structure refinement

Diffraction data were collected on a Nicolet R3/m diffractometer using graphite-monochromated Mo-K_α($\lambda = 0.71073$ Å) radiation. During the course of the intensity data collection the crystal showed no loss in intensity.

Accurate unit-cell dimensions and crystal orientation matrices were obtained from least-squares refinement of 2θ, ω, χ and ψ values of 25 strong reflections in the range $15° < 2\theta < 30°$. Lorentz and polarization corrections were applied to the intensity data. The structure was solved by using standard Patterson methods, successive least-squares refinements, and difference Fourier maps. Non-hydrogen atoms were refined anisotropically; the carbon atoms of the triphenylarsine cation were refined isotropically. Hydrogen atoms were added at calculated positions and included in the structure factor calculations with a common thermal parameter ($U = 0.08$ Å^2). As usual a general high thermal motion is present in the propyl chains. For this reason some of the C—C bond distances were refined with fixed geometry [d(C—C) = 1.52(2) Å].

Of 5030 independent reflections, measured with a 2θ–ω scan technique in the range $4 < 2\theta < 55$, 2620 having $I > 3\sigma(I)$ were used to refine 237 parameters to final residuals of $R = 0.056$ and $Rw = 0.063$.

The weighting scheme used in the last refinement cycles was: $w = 1.000/(\sigma^2(F_o) + 0.002826F_o^2)$. Reversing the sign of the imaginary anomalous-scattering component of the title compound, which has the non-centrosymmetric space group $P2_12_12_1$, increased R from 0.056 to 0.072. This difference is highly significant, and therefore the model has the correct absolute configuration.

Scattering factors for non-hydrogen atoms were taken from Ref. 2 and for hydrogen atoms from Ref. 3. Anomalous dispersion corrections were taken from Ref. 4. All calculations were performed with SHELX76[5] and PARST[6] set of programs on the IBM 4341 computer at the "Centro di Calcolo dell' Università di Messina". The refined structure was plotted with use of the PLUTO and ORTEP programs (Figs 1 and 2). Atom coordinates, full lists of bond distances and bond angles, anisotropic temperature factors, calculated and observed structure factors are available as supplementary material (Table SI–SIV).

RESULTS AND DISCUSSION

The title compound, obtained by reaction in methanol of the tetrameric complex $[Pd_4(PPr_3^n)_4(NO_2)_8]$, in the presence of $[As(C_6H_5)_4](NO_3)$ 1:10, with excess $NaNO_2$, is a yellow crystalline solid. On the basis of elemental analysis and the IR spectrum the substance can be formulated as $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$. In fact the IR spectrum, besides two bands at 800 and 750 cm^{-1} characteristic of $[As(C_6H_5)]^+$, shows two bands at 1330 and 1398 cm^{-1} assignable to NO stretching.[7] The single crystal X-ray determination of this study confirms that the complex has a square-planar structure with the nitro groups coordinated through nitrogen.

Molecular structure of $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$

The crystal structure of the title compound, depicted in Fig. 1, where the atomic labelling is shown, consists of discrete anion in which the palladium atom is four-coordinated and the $[As(C_6H_5)_4]^+$ cation is separated by normal Van der Waals' interactions. In Fig. 2 a stereoview of the anion is reported. Selected bond distances and angles are given in Table 1.

The local anion geometry is, as expected, square-planar slightly distorted with N3—Pd—P and N1—Pd—N2 bonds angles of 178.3(3) and 178.3(5)°. The weighted mean plane through the four basal donor atoms and the metal atom shows slight distortion from planarity with N1 and N2 deviating by −0.028(10) and 0.034(15) Å, respectively. P and N3 are 0.002(4) and 0.013(9) Å; the palladium atom is −0.015(1) out of this plane. The Pd—P bond distance of 2.263(4) Å is comparable with the value of 2.252(3)Å found in $[Pd_2(PPr_3^n)(NCS)(SCN)_2(\mu\text{-}CN)]$[8] and is not significantly longer than the value of 2.243(5) Å found in $[Pd(PPr_3^n)(NO_2)_2Cl][As(C_6H_5)_4]$,[1] where *n*-propylphosphine is *trans* to the chlorine atom. The two nitro groups *trans* to each other are both bonded to palladium through their nitrogen atoms. The Pd—N1 and Pd—N2 bond distances, are 2.01(1) and 2.01(1) Å, respectively, and are comparable with the corresponding values reported for *trans*-$[Pd(PPr_3^n)(NO_2)_2Cl][As(C_6H_5)_4]$,[1] *trans*-$[Pd(PPhMe)_2(NO_2)_2]$,[9] *trans*-$[Pd(PEt_3)_2(NO_2)_2]$,[9] $[Pd_4(PPr_3^n)_4(NO_2)_8]$[10] and $[Pd(dien)(NO_2)]$.[11] The geometry of these two nitro groups is characterized by an N—O bond length which ranges from 1.16(2) to 1.26(2) Å and by the O—N—O bond angles which are 118(1)° for O22—N2—O21 and 122(1)° for O12—N1—O11. The two nitro group planes are rotated with respect to the palladium coordination plane by 86.9(8) and 92.3(9)° while the rotation of the third nitro group (O31—N3—O32), *trans* to PPr_3^n, significantly deviates from the orthogonality to the metal coordination plane [118.5(12)°]. In addition the bond distance Pd—N3 of 2.25(1) Å

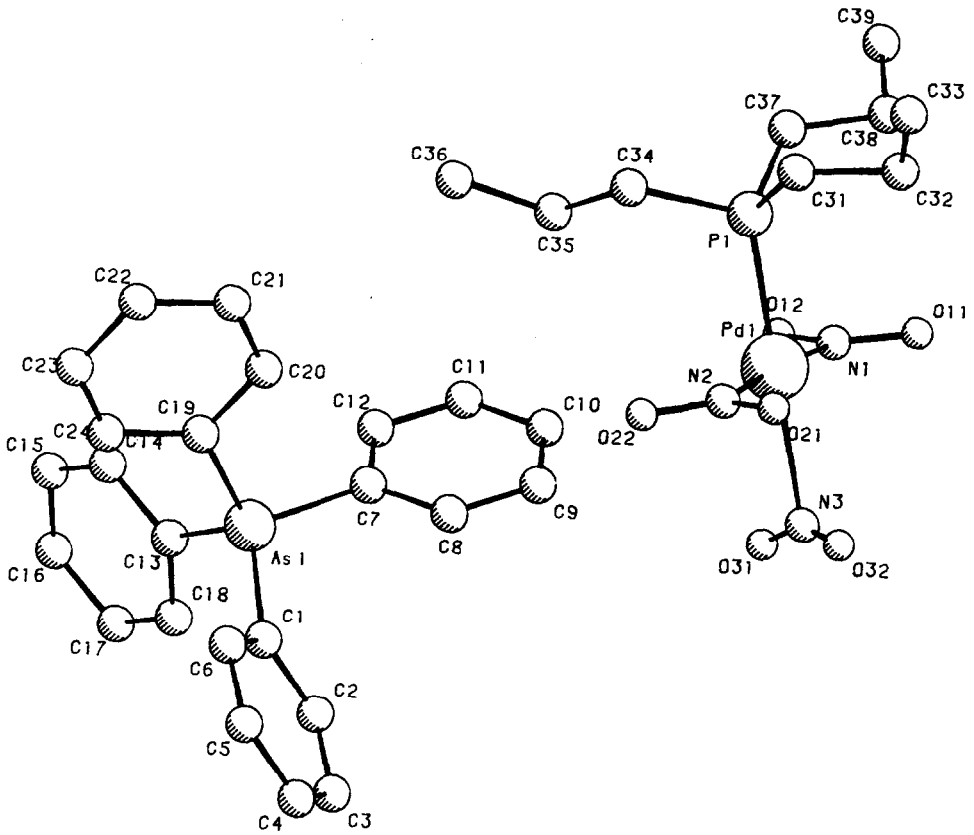

Fig. 1. Perspective view of the $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$ structure.

is, to our knowledge, the longest so far observed for the palladium-to-nitrogen bond. Such an arrangement suggests that some interaction between the oxygen atoms of the nitro group and palladium occurs as in an incipient nitro–nitrito isomerization. It is difficult to explain the Pd—N bond lengthening on the basis of PPr_3^n *trans* influence only and the presence of the adjacent nitro groups has probably to be taken into account.

In the tetraphenylarsonium cation, which has a nearly perfect tetrahedral geometry, the As—C bond distances are as usual and require no special comment.

Conductivity measurements show that $[Pd(PPr_3^n)(NO_2)_3][As(C_6H_5)_4]$ is a 1:1 electrolyte in the common organic solvents. In addition, in solution of coordinating media, the complex undergoes partial solvation. In fact, the shape of the

electronic spectrum of the complex changes on changing concentration. In the presence of free NO_2^-, which should suppress solvolysis, the spectrum of the complex in CH_3CN, MeOH, DMF, etc. overlaps with that recorded, under the same experimental conditions, in poorly coordinating media such as CH_2Cl_2 or $CHCl_3$.

The three nitro groups coordinated to palladium are easily replaced by the common nucleophiles. The process, which is rapid at room temperature, occurs in three observable steps. We have followed, by stopped-flow technique, the kinetics of substitution, by piperidine, of the first nitro group in the title compound and in *trans*-$[Pd(PPr_3^n)(NO_2)_2Cl][As(C_6H_5)_4]$ in dichloromethane at 25°C. As expected on the basis of the large *trans* effect of phosphine,[12] the first leaving group is that coordinated in the *trans* position with respect to PPr_3^n; this can be easily shown by the identity of the electronic spectra after reaction with piperidine, in a ratio 1 : 1, under the same experimental conditions (1) and (2):

$$[Pd(PPr_3^n)(NO_2)_3]^- + pip \rightarrow trans-[Pd(PPr_3^n)(NO_2)_2(pip)] + NO_2^-, \quad (1)$$

$$trans-[Pd(PPr_3^n)(NO_2)_2Cl]^- + pip \rightarrow trans-[Pd(PPr_3^n)(NO_2)_2(pip)] + Cl^-. \quad (2)$$

The kinetics of these reactions, under pseudo-first-order conditions with respect to the complex, obey the simple rate law

$$k_{obs.} = k_2[\text{piperidine}]. \quad (3)$$

The k_2 values (Fig. 3) are $(72.8 \pm 1.1) \times 10^3$ dm^3 mol^{-1} s^{-1} and $(36.8 \pm 2.0) \times 10^3$ dm^3 mol^{-1} s^{-1}, respectively. The lability of NO_2^-, larger than that of Cl^-, is abnormal; usually, in fact, chloride is a much better leaving group than nitrite.[13] These findings could be directly related to the structure

of $[Pd(PPr_3'')(NO_2)_3][As(C_6H_5)_4]$ if we assume that also in solution the nitro group *trans* to phosphine is very weakly bound to palladium. Alternatively, the enhanced lability of NO_2 with respect to Cl could be accounted for assuming that in solution, NO_2 is bonded through oxygen. Nitro–nitrito isomerization is in fact conceivable taking into account that one of the oxygen atoms of the nitro group *trans* to phosphine interact to some extent with palladium already in the solid state. It is unfortunate that spectra in solution were of bad quality so that the bonding mode of NO_2 could not be established. Synthetic work is in progress in order to study to what extent the bond lengthening and the lability enhancement of NO_2 *trans* to palladium may be related to the presence of the adjacent nitro groups.

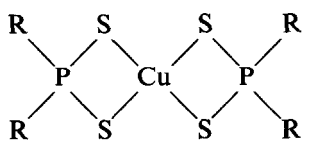
(*Received* 15 *December* 1989; *accepted* 21 *June* 1990)

Abstract—Bis(diethyldithiophosphinato)nickel(II), $[(C_2H_5)_2PS_2]_2Ni$ and bis(di-n-propyl dithiophosphinato)nickel(II), $[(n\text{-}C_3H_7)_2PS_2]_2Ni$, single crystals doped with the corresponding copper(II) complexes have been prepared and studied by EPR spectroscopy. The components of the **g**-tensor, ^{63}Cu hyperfine coupling tensor and ^{63}Cu nuclear quadrupole coupling tensor have been determined. An X-ray crystal structure determination of bis(di-n-propyldithiophosphinato)nickel(II) shows the nickel atom to lie at a centre of symmetry, coordinated by four sulphur atoms at 2.220(4) and 2.230(3) Å.

In the analysis of EPR data for single-crystal systems special attention is paid to the cases where the various tensor axes do not coincide. For transition metal ions in low symmetry sites the anisotropy of the various tensors, in general, is large and any non-coincidence of the tensor axes can lead to large off-diagonal matrix elements. For this reason the first-order treatment gives only qualitative agreement with experiment. Moreover, in the first-order treatment the nuclear quadrupole coupling has no contribution to the allowed transitions. Independently of this, however, some authors use powdered spectra to calculate the quadrupole interaction.[1]

In this paper the results obtained from single-crystal EPR spectra of $^{63}Cu^{II}$ dithiophosphinato complexes, $[Cu(dtph)_2]$ (**I**), magnetically diluted in the corresponding $Ni(R_2\text{-}dtph)_2$ host lattices, are presented and the structural data are compared with those available from X-ray crystal analysis.



R = Et, Pr^n

(I)

The molecular and crystal structure of $Ni(Me_2\text{-}dtph)_2$[2a] and $Ni(Et_2\text{-}dtph)_2$[2b] are known, while the structure of $Ni(Pr^n{}_2\text{-}dtph)_2$, obtained by X-ray analysis, is reported in the present paper.

EXPERIMENTAL

Preparation of the complexes

$(Et_2$-dtph)Na and $(Pr^n{}_2$-dtph)Na have been synthesized according to the methods described.[3] $Ni(R_2$-dtph$)_2$ complexes (R = Et or n-Pr) have been obtained by precipitation of an aqueous solution of the corresponding $Na(R_2$-dtph) and $NiCl_2$. The complexes thus obtained have been recrystallized twice from $CHCl_3$. ^{63}CuO (AERE, Harwell) has been transformed to $^{63}CuCl_2$ through dissolution in HCl followed by evaporation to dryness.

$^{63}Cu/Ni(dtph)_2$ complexes have been prepared by exchange of about 1% of Ni^{II} with $^{63}Cu^{II}$ in $CHCl_3$–water solution, followed by evaporation of the organic phase. The single crystals have been obtained from a chloroform–n-heptane (1 : 1 v/v) solution of $^{63}Cu/Ni(dtph)_2$ by slow evaporation in an open beaker.

EPR measurement and refinement

The single-crystal EPR spectra have been recorded on a Bruker ER 420 X-band spectrometer at room temperature. The microwave frequency has been measured by a Systron–Donner Model 6016 frequency counter with an accuracy of about 50 kHz. The magnetic field has been determined with an accuracy of about 0.5 G by means of a NMR gaussmeter B-H 12. For the orientation of the single crystals in the magnetic field a two-circle goniometer GO-2 has been employed.

The EPR spectra have been recorded by rotation of the single crystals about three mutually perpendicular axes (defining an arbitrary Cartesian reference frame) every 5 or 10°.

The set of experimentally obtained EPR spectra can be described by the spin hamiltonian

$$\mathcal{H} = \beta\vec{H}\cdot\mathbf{g}\cdot\vec{S}+\vec{S}\cdot\mathbf{A}\cdot\vec{I}+\vec{I}\cdot\mathbf{P}\cdot\vec{I}-g_n\beta_n\vec{H}\cdot\vec{I},$$

the various terms in which have their usual meaning. The choice of this spin hamiltonian is based on the facts that the four hyperfine lines are not equally spaced (this inequality varies in a complex way from one spectrum to another) and that in some directions so-called "forbidden" lines appear. To find the components of the various tensors in the chosen reference frame, the method described[4] has been used where perturbation corrections to the energy levels up to second-order are taken into account. In the present study, however, the quantity

$$S = \left\{\frac{1}{(2I+1)n}\sum_{i=1}^{n}\sum_{m+-I}^{I}[h\nu_i - f(i,m,p_1,p_2,\ldots)]^2\right\}^{1/2},$$

where $I = 3/2$ and i runs over all the spectra, was minimized, the parameters p_α (the components of the tensors) being varied simultaneously by means of a modified, simplex procedure.[5] Since this procedure is relatively slow, starting values for the components of the **g** and **A** tensors were taken as those obtained from the first-order treamtent. A value for $S = 0.5\times10^{-4}$ cm^{-1} (which is comparable with the experimental error) has been chosen for goodness of fit. After satisfactory convergence, the **g**, **A** and **P** tensors have been diagonalized and the principal values, as well as the principal directions of them, have been obtained.

Crystallographic study

A prismatically-shaped crystal of $Ni(Pr^n{}_2$-dtph$)_2$ with approximate dimensions, $0.12\times0.08\times0.10$ mm, has been analysed on a computer-controlled Enraf–Nonius CAD4 diffractometer with graphite-monochromatized Mo-K_α radiation. The diffraction data have been collected at a temperature of 292 K, using the ω–2θ scan technique.

The crystals of bis(di-n-propyldithiophosphinato) nickel(II) have been found to be monoclinic, space group $P2_1/n$, $a = 8.165(2)$, $b = 8.706(1)$, $c = 14.935(3)$ Å, $\beta = 103.76(2)°$, $V = 1031.1(7)$ Å^3, $Z = 2$, $D_c = 2.714$ g cm^{-3}, μ(Mo-K_α) = 29.5 cm^{-1}, $F(000) = 888$, $R = 0.053$ for 649 observed reflections with $I > 3\sigma(I)$.

Accurate cell constants have been obtained from a least-squares refinement of the setting angles of 22 reflections in the range $14.05 < \theta < 15.53°$.

A total of 2972 reflections have been collected in the range $\sin\theta/\lambda < 0.527$ (h: −8 to 8, k: −9 to 9, l: −15 to 15) with a zigzag scanning mode. The intensities of equivalent reflections have been averaged. From 1374 unique reflections, only $N_o = 649$ reflections with $I > 3\sigma(I)$ have been used in further calculations.

The structure has been solved by the heavy-atom method. The nickel atom has been located from the three-dimensional Patterson map. The positions of the remaining non-hydrogen atoms have been obtained from subsequent Fourier and difference-Fourier syntheses. The structure has been refined by a geometrically restrained (on P—C and C—C bonds) least-squares fitting, where the function $\Sigma w(|F_o|-|F_c|)^2$ has been minimized with weights w defined as $w = 4F_o^2/[\sigma^2(F_o)]^2$. The highest positive peak in the final difference Fourier map was 2.19 e Å^{-3}. An empirical extinction correction of the form $F_{(corr)} = F/(1+gI)$ with $g = 0.253\times10^{-6}$ has been applied. Atomic scattering factors and anomalous dispersion coefficients for neutral atoms have been taken from *International Tables* (1974). Positional

and thermal parameters have been deposited along with tables of F_o/F_c values.

All calculations have been carried out on a PDP 11/44M computer with a locally modified SDP/PDP V3.0 crystallographic package.

RESULTS AND DISCUSSION

EPR study

Typical EPR spectra of ^{63}Cu/Ni(Pr^n$_2$-dtph)$_2$ and ^{63}Cu/Ni(Et$_2$-dtph)$_2$ single crystals for two different, arbitrarily chosen orientations with respect to the magnetic field are shown in Fig. 1(a) and (b). The EPR spectrum of ^{63}Cu/Ni(Pr^n$_2$-dtph)$_2$ [Fig. 1(a)] is based upon two quartets which shows that the copper(II) occupies two different sites in the crystal, whereas the EPR spectrum of ^{63}Cu/Ni(Et$_2$-dtph)$_2$ [Fig. 1(b)] corresponds only to one site. Each line of a given quartet is further split into three lines (with relative intensities 1:2:1) due to the interaction of the copper(II) unpaired electron with two equivalent ^{31}P nuclei ($I = 1/2$). This superhyperfine splitting is isotropic within experimental error and is of the order of 5.5 G.

The experimentally obtained EPR spectra are in agreement with the crystallographic data for the crystals of Ni(Et$_2$-dtph)$_2$[2b] and Ni(Pr^n$_2$-dtph)$_2$ (reported in the present paper). The number of molecules per unit cell is equal for both compounds ($Z = 2$), but their mutual orientation is different. In accordance with the space group symmetry and atomic coordinates of these compounds, the two molecules in the case of Ni(Et$_2$-dtph)$_2$ are magnetically equivalent, whereas in the case of Ni(Pr^n$_2$-dtph)$_2$ they differ.

The results obtained after digital processing of the EPR data are shown in Tables 1 and 2. In Table 1 the principal values of the **g**, **A** and **P** tensors are presented, and in Table 2 the angles that determine the mutual orientations of the **g** and **A** tensors.

It is seen from Table 2 that the principal directions of the **g** and **A** tensors for ^{63}Cu/Ni(Et$_2$-dtph)$_2$ nearly coincide to within the angle setting error ($\approx 1°$).

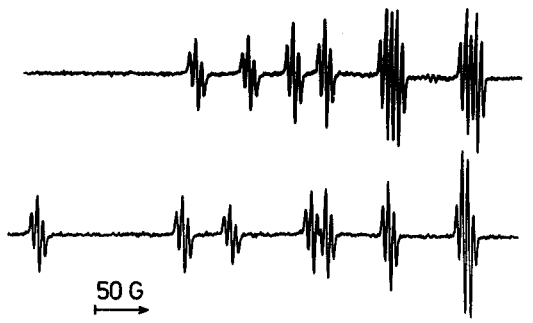

Fig. 1(a). Single crystal EPR spectra of ^{63}Cu/Ni(Pr^n$_2$-dtph)$_2$ for two different arbitrarily chosen orientations of the magnetic field.

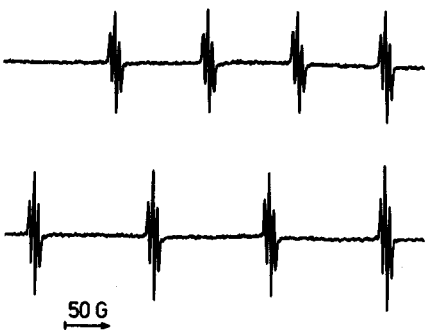

Fig. 1(b). Single crystal EPR spectra of ^{63}Cu/Ni(Et$_2$-dtph)$_2$ for two different arbitrarily chosen orientations of the magnetic field.

For the ^{63}Cu/Ni(Pr^n$_2$-dtph)$_2$ complex, the principal values of the **g**, **A** and **P** tensors (Table 1) for the two different sites are equal (if we keep in mind that $|\Delta g_i| \approx 5 \times 10^{-4}$; $|\Delta A_i|$, $|\Delta P_i| \approx 0.5 \times 10^{-4}$ cm^{-1}). It is seen from Table 2, however, that only the directions of g_3 and A_3 coincide, whereas the directions of A_1 and A_2 are rotated in the plane (g_1, g_2) to an angle of about 10° but in a different direction for each site. One possible reason for this is the fact that the **g** and **A** tensors are close to axial symmetry and consequently the error in the determination of the principal directions in a plane

perpendicular to the principal direction, corresponding to $g_3(A_3)$, is relatively large.

It is assumed that the directions of g_3 and A_3 are perpendicular to the molecular plane (CuS_4 plane). It is seen from Table 2 that the directions of g_3 for the two sites of ^{63}Cu/Ni(Pr^n$_2$-dtph)$_2$ make an angle of 79°. The angle between the molecular-plane normals calculated from the crystallographic data is about 77°, which is very close to the calculated value from the EPR data. This result suggests that the copper(II) complex takes the structure of the host lattice without distorting it. In Table 1 the principal values of the nuclear quadrupole coupling tensor, **P**, are also presented. In magnitude they correspond to the values obtained by other authors for analogous complexes of ^{63}Cu^{II}. It is well known, however, that the determination of the nuclear quadrupole coupling tensor from EPR spectra is not very accurate. As a confirmation of this, Table 3 presents the results obtained by various research groups for the complexes ^{63}Cu(acac)$_2$ as well as ^{63}Cu(dtc)$_2$ (which are analogous to the complexes studied here). The differences in the results for one and the same complex are most probably due to the large relative error in deriving the components of the nuclear quadrupole coupling tensor. Nevertheless, the second-order terms due to the nuclear quadrupole coupling and nuclear hyperfine interaction (the latter vary from 0 to about 5×10^{-4} cm^{-1} depending on the direction of the magnetic field) give a satisfactory explanation of the behaviour of the distances between the hyperfine resonance lines. The magnitude of the difference between the calculated and experimentally obtained values of the magnetic field, at which the hyperfine resonance lines appear, is seldom greater than 1 G and in most cases is less than 0.8 G, i.e. within the experimental error.

Crystallographic study

The molecule of Ni(Pr^n$_2$-dtph)$_2$ along with the atom labelling scheme is shown in Fig. 2. The packing of the molecules within the unit cell is shown in Fig. 3, and selected bond lengths and angles are listed in Table 4.

The nickel atom lies at a centre of symmetry and

is coordinated by four sulphur atoms at 2.220(4) and 2.230(3) Å. The intramolecular Ni···P distance is 2.838(4) Å. The shortest Ni···Ni distances are well "spatially balanced": 8.165(*a*-axis), 8.706(*b*-axis) and 8.768 Å (a half of the unit-cell body diagonal). In a radius of 4.0 Å the nickel atom has intermolecular contacts only with the disordered methyl-carbon atoms C(3a″) (3.59(2) Å) and C(3a′) (4.00(2) Å). The phosphorus atom deviates from the NiS_4 plane by 0.35 Å and has a highly distorted tetrahedral configuration with angle variations from 90(2) to 132(1)°. The average P—S distance of 1.989(5) Å is comparable with the same distances found in bis(dimethyldithiophosphinato) nickel(II) (2.01(1) Å)[2a] and bis(diethyldithiophosphinato)nickel(II) (2.00(1) Å).[2b] A perceptible variation of P—C bond lengths (1.74–1.92 Å) from their average value of 1.85 Å is observed. The disordered propyl groups (Fig. 2) take up predominantly two sets of positions, both with 50% occupancy. The discrete $Ni(Pr^n_2\text{-dtph})_2$ molecules are packed in a zigzag motif and are joined by a van der

(*Received* 29 *March* 1990; *accepted* 21 *June* 1990)

Abstract—Triply-bridged cationic binuclear copper(I) complexes $[Cu_2(\mu\text{-L—L})_2(\mu\text{-PPDMe})]^{2+}$, PPDMe = [3,6-bis(3,5-dimethylpyrazol-1-yl)pyridazine], have been prepared. Treatment in dichloromethane at room temperature of $[Cu_2(\mu\text{-L—L})_2(CH_3CN)_2][BF_4]_2$ with PPDMe in a 1:1 molar ratio gives $[Cu_2(\mu\text{-L—L})_2(\mu\text{-PPDMe})][BF_4]_2$, L—L = bis(diphenylphosphino)methane (dppm) (**1**), 1,1-bis(diphenylphosphino)ethane(mdppm) (**2**) and 2-(diphenylphosphino)pyridine (dppy) (**3**). The crystal structure of **1** has been determined by X-ray diffraction methods. Crystals of **1**, containing dichloromethane molecules of crystallization, are monoclinic, space group $C2/c$, with $Z = 8$ in a unit cell of dimensions $a = 38.100(2)$, $b = 12.7888(7)$, $c = 28.55(1)$ Å, $\beta = 91.79(4)°$. The structure was refined to $R = 0.115$ for 2129 observed reflections, with the tetrafluoroborate anions and the dichloromethane molecules highly disordered. In the binuclear complex **1** the two copper atoms in a distorted tetrahedral arrangement are at a distance of 3.452(7) Å, bridged by two dppm ligands through P atoms and with one PPDMe acting as a dichelate tetradentate ligand through two N pyrazolyl atoms and the two pyridazine N atoms. ^1H and $^{31}P\{^1H\}$ NMR data are discussed.

Binuclear copper(I) and copper(II) complexes form a significant group of derivatives in the coordination chemistry of copper which are currently receiving special attention mainly due to the studies related to the reactivity of dioxygen in biological systems.[1,2] Since it is known[3] that the crystal structure of the active site in deoxyhaemocyanin contains a binuclear copper(I) moiety, particular interest has been focussed on the synthesis of these type of complexes to use as reactivity models for this and other binuclear copper proteins.[4]

We have recently reported[5] a systematic method for the preparation of the scarcely known triple-bridged binuclear copper(I) complexes containing the moieties $Cu_2(\mu\text{-dppm})$ (**A**) and $Cu_2(\mu\text{-dppm})_2$ (**B**), with dppm = bis(diphenylphosphino)methane

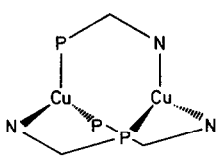
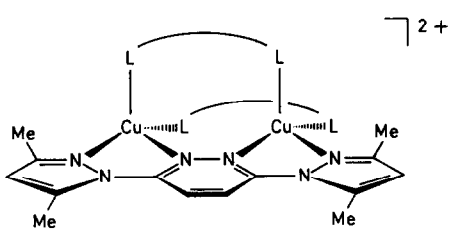
as bridging ligands. These systems have shown to be excellent precursors for the incorporation of one or two L—L anionic bidentate ligands to give binuclear copper(I) complexes with three mixed eight-membered bimetallic rings (L—L = 6-methylpyridin-2-olate, 3,5-dimethylpyrazolate, 1,3-di-*p*-tolyltriazenide or acetate). We have also prepared cationic binuclear copper(I) triply-bridged complexes containing the $Cu_2(\mu\text{-dppy})_3$ moiety [dppy = 2-(diphenylphosphino)pyridine] (**C**).[6]



(C)

The present paper reports the preparation of novel triply-bridged cationic binuclear copper(I) complexes $[Cu_2(\mu\text{-L—L})_2(\mu\text{-PPDMe})][BF_4]_2$, L—L = bis(diphenylphosphino)methane (dppm) (**1**), 1,1-bis(diphenylphosphino)ethane (mdppm) (**2**), 2-(diphenylphosphino)pyridine (dppy) (**3**), containing



L-L = dppm (1), mdppm (2), dppy (3)

3,6-bis(3,5-dimethylpyrazol-1-yl)pyridazine (PPD Me) as a tetradentate bridging group. The X-ray single crystal structure determination of **1** shows the two copper atoms in a distorted tetrahedral arrangement held at a distance of 3.452(7) Å by three bridging ligands, two dppm ligands and one PPDMe acting as a dichelating tetradentate ligand. These complexes can be related to a series of binuclear copper(II) complexes prepared by Thomson *et al.* with PPDMe[7] and similar polydentate bridging nitrogen heterocycles[8] of importance as structural/magnetic probes for the binuclear copper active sites in oxyhaemocyanin and enzymes involved in oxidase and oxygenase activity and reversible oxygen uptake.

RESULTS AND DISCUSSION

Synthesis and spectroscopic characterization

Treatment of a solution of $[Cu_2(\mu\text{-L—L})_2(MeCN)_2][BF_4]_2$ in dichloromethane, at room temperature, with an equimolar amount of PPDMe gives a solution from which the binuclear cationic complexes **1–3** can be isolated as tetrafluoroborate salts

$$[Cu_2(\mu\text{-L—L})_2(MeCN)_2]^{2+} + PPDMe \longrightarrow [Cu_2(\mu\text{-L—L})_2(PPDMe)]^{2+} + 2MeCN. \quad (1\text{–}3)$$

All the complexes are air-stable in the solid state and have been characterized by elemental analyses, conductance measurements in solution and ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. Selected data are given in Table 1. In addition, the structure of complex **1** has been determined by X-ray diffraction. Conductance values of the complexes in acetone show that they are 1 : 2 electrolytes and IR spectra (Nujol) exhibit the expected ν(B—F) absorptions (1000–1100 cm^{-1}) in addition to those characteristic of the bridging phosphine ligands and PPDMe (see Experimental).

^1H NMR spectra in CD_2Cl_2 at room temperature (Table 1) exhibit aromatic, methylene (CH_2P_2 and $HCMeP_2$) and methyl signals of the ligands (PPDMe and mdppm), in accord with the proposed binuclear nature of the complexes and the dichelating coordination of PPDMe. The spectrum of complex **1** shows methylene resonances (CH_2P_2) at δ 3.19 ppm as one unresolved triplet or multiplet showing the (ABXX′) or (AA′BB′X_2) spin system with accidental degeneracy of chemical shifts expected for the two sets of chemically inequivalent protons $CH_aH_bP_2$. This is typical of the binuclear complexes containing the $Cu_2(\mu\text{-dppm})_2$ moiety with boat–boat or boat–chair conformations.[5,9] The corresponding proton and methyl resonances of the pyridazine (pydz) and pyrazolyl (pz) groups appear as singlets [δ 8.7 (pydz), 6.01 (pz), 1.61 and 2.77 (Me) ppm], showing that they are chemically equivalent. This is consistent with the proposed symmetrical dichelate bridging system of PPDMe and in agreement with the X-ray structure deter-

mination (see below), although a small deviation of the two pyrazole rings from planarity is observed.

This unsymmetrical arrangement of the pyrazole rings seems to be more effective in complexes **2** and **3** even in solution, since the proton NMR spectra show two different signals for the pyridazine protons and for the 3-methyl pyrazolyl groups (see Table 1), clearly indicating the chemical inequivalence of these groups, probably due to a larger distortion from the planarity of the heterocycle ligand. This apparently does not affect the 5-methyl groups, located at the opposite position with respect to the copper coordination environment, for which the spectra only show one singlet signal.

$^{31}P\{^1H\}$ NMR spectra at room temperature exhibit a single resonance [δ −7.37 (**1**) and 2.09 (**3**) ppm] showing that all phosphorus atoms in each molecule are chemically equivalent. For complex **3** this appears to indicate a "head to tail" configuration of the dppy ligand, which is consistent also with the aforementioned chemical equivalence of the 5-methyl groups.

Description of the crystal structure of $[Cu_2(\mu\text{-dppm})_2(\mu\text{-PPDMe})][BF_4]_2$ (**1**)

The crystal structure of complex **1** consists of binuclear $[Cu_2(\mu\text{-dppm})_2(\mu\text{-PPDMe})]^{2+}$ cations, BF_4^- anions and dichloromethane molecules of crystallization. The structure of the cation together with the atomic numbering scheme is depicted in Fig. 1 and selected bond distances and angles are collected in Table 2. Although the poor quality of the crystals due to their small size, along with the

high disorder of the tetrafluoroborate anions and the dichloromethane molecules of crystallization, led to a rather high value of R (0.115), structural information of chemical significance can be obtained. In the binuclear cation the two copper atoms are held at a distance of 3.452(7) Å by three bridging ligands, two dppm ligands bonded through the P atoms and one PPDMe molecule acting as a bridge tetradentate ligand via the nitrogen atoms, N(3) and N(4), of the pyridazine group and the N(1) and N(6) atoms of the pyrazolyl groups. Both copper atoms are in a distorted tetrahedral arrangement determined by two P and two N atoms, with N—Cu—N angles of 75(1)° showing the small bite chelating angle of the PPDMe ligand similar to that found[7] in the binuclear square-planar copper(II) complexes $[Cu_2(\mu\text{-PPDMe})(\mu\text{-OH})Cl_2]^+$ and $[Cu_2(\mu\text{-PPDMe})(\mu\text{-OH})(NO_3)_2(H_2O)_2]^+$ [av. 78.1(2)°]. The coordinated heterocycle is not planar, as is shown by the dihedral angle of the two pyrazolyl groups of 28(2)° and the two different angles of each pyrazolyl group with the pyridazine ring [14(1) and 22(1)°]. This contrasts with the essential planarity shown by the PPDMe ligand in the above mentioned binuclear copper(II) complexes.

The conformations of the two PCuCuP bridges are approximately "eclipsed", which is also shown by $[Cu_2(\mu\text{-dppm})_2(\mu\text{-Mepy-O})]^+$ (Mepy-O = 6-

methylpyridin-2-olate)[5] in which the eight-membered Cu(μ-dppm)$_2$Cu ring adopts a boat–boat conformation. Unexpectedly, the structure of complex **1** shows the corresponding dimetallic ring in an approximately boat–chair conformation. The Cu—P and Cu—N distances [av. 2.26(2) and 2.10(3) Å, respectively] are in the range typical of four-coordinated copper(I) complexes.[6,9]

EXPERIMENTAL

Measurements

C, H and N analyses were carried out with a Perkin–Elmer 240 microanalyser. The IR spectra were recorded over the 4000–600 cm^{-1} range on a Perkin–Elmer 1720X FT spectrometer using Nujol mulls between NaCl plates. Conductivities were measured at room temperature with a Jenway PCM 3 conductimeter. NMR spectra were recorded on a Bruker AC300 at 300 MHz (^{1}H) or 121.5 MHz (^{31}P) using $SiMe_4$ or 85% H_3PO_4 as standard references.

Synthesis

All reactions were performed under dry nitrogen and the solvents were dried by standard methods and distilled under nitrogen before use. PPDMe[10] was synthesized according to the reported improved method.[7] The compounds [Cu$_2$(μ-*L*—L)$_2$(MeCN)$_2$][BF$_4$]$_2$ were prepared as described earlier.[6,9]

Preparation of [Cu$_2$(μ-L—L)$_2$(μ-PPDMe)][BF$_4$]$_2$; L—L = dppm (**1**), mdppm (**2**), dppy (**3**)

To a solution of [Cu$_2$(μ-L—L)$_2$(MeCN)$_2$][BF$_4$]$_2$ (0.5 mmol) in CH_2Cl_2 (40 cm^3), PPDMe (0.134 g, 0.5 mmol) was added and the mixture stirred at room temperature for 12 h. After filtration, a solid was obtained by addition of diethyl ether (10 cm^3) to the partially evaporated solution. Yields (%) and colours: **1**, 80, yellow; **2**, 70, orange; **3**, 50, yellow. IR (Nujol mulls, cm^{-1}): **1**, 1450sh, 1430s, 1372w, 1355w, 1100vs,br, 760w, 735m, 710w, 685m; **2**, 1570m, 1300w, 1055s,br, 760m, 735m, 730w, 700m. ^{31}P{^{1}H} NMR (CD_2Cl_2): **1**, −7.37 ppm; **2**, 2.09 ppm.

Crystallographic data collection and refinement of the structure of [Cu$_2$(μ-dppm)$_2$(μ-PPDMe)][BF$_4$]$_2$·4/3CH_2Cl_2 (**1**)

Crystals of **1** (obtained from a mixture of dichloromethane–di-isopropylether by slow diffusion) were small and due to loss of the solvent of crystallization, especially when they are dried *in vacuo*, they gradually become a powder. A yellow crystal of approximate dimensions 0.03 × 0.1 × 0.4 mm was used for the X-ray analyses and was apparently unchanged during the measurements (no decay of intensities was observed). Crystal data are collected in Table 3. Geometric and intensity data were taken on an Enraf–Nonius CAD-4 automated diffract-

ometer equipped with graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation. All reflections measured are in the range $0 \leqslant \theta \leqslant 25°$. The structure was solved by the heavy atom method localizing the rest of the atoms by cycles of DIRDIF[11] and difference Fourier syntheses. Full-matrix least-squares with anisotropic thermal parameters in the last cycles for the Cu and P atoms and unit weights were used for refinement (SHELX76 program).[12] The hydrogen atoms were included in idealized positions (C—H 1.08 Å) with an overall isotropic temperature factor [final value of $U = 0.11(2)$ Å^2]. The phenyl rings, tetrafluoroborate anions and the dichloromethane molecules were refined as rigid bodies. Initially, the structure was solved in the space group *Cc* and changed to *C*2/*c* after a centre of symmetry was found. The tetrafluoroborate anions and the two dichloromethane molecules of crystallization were highly disordered, each molecule of the solvent having an occupancy factor of approximately 2/3. Atomic scattering factors were taken from *International Tables for X-ray Crystallography*.[13]

(*Received* 23 *April* 1990; *accepted* 22 *June* 1990)

Abstract—The stability constants of the dodecaoxohexaphosphate(III) ligand anion with magnesium(II), iron(II), nickel(II) and copper(II) ions were spectrophotometrically determined in aqueous solutions of different ionic strengths (potassium chloride) at room temperature. An optical method based on the measurement of the absorbance ratio at two wavelengths was employed in combination with an equimolar dilution procedure. The logarithmic stability constants of the magnesium, iron(II), nickel and copper complexes with dodecaoxohexaphosphate(III) were, for example at $I = 1$, found to be 5.16, 5.11, 5.39 and 4.76, respectively. Unusual behaviour of the iron(II) complex on the ionic strength dependence of the constant were observed and discussed.

Since the dodecaoxohexaphosphate(III) salt (DOHP) was first synthesized by Blaser and Worms,[1] the structure has been determined by X-ray analysis,[2] and the hydrolytic behaviour[3,4] and the characteristic absorption spectrum[3] have been investigated. For the metal complex formation only the stability constant of the silver complex has been reported.[5] Our preliminary experiments showed that the ring structure characteristic absorption peak at 355 nm shifts to longer wavelengths on complexation with a divalent metal ion. This tendency may be utilized in determining the stability constant. The stability constants of metal–DOHP complexes are in general very large,[6] therefore it may be convenient to use an equimolar metal–ligand dilution method[7] in the analyses. We found that the absorbance measurements at two wavelengths give more accurate results in spite of a considerable overlapping of the spectra of the free ligand and its metal complex.

EXPERIMENTAL

Materials

Potassium, magnesium(II), iron(II), nickel(II) and copper(II) chlorides of commercially available analytical grade were supplied by Kishida Chemicals. DOHP was prepared by the procedure of Blaser and Worms. Double-distilled water was used in all experiments.

Determination of the molar absorption coefficient of DOHP

The molecular weight of prepared DOHP is unknown because of its indefinite hydration

* Author to whom correspondence should be addressed.

number, thus the molar absorption coefficient was determined from the absorbance and the elemental phosphorus analysis of a solution of DOHP sodium salt. The latter was made by decomposition of DOHP with acid into phosphate monomers, followed by absorption measurements using an ordinary molybdenum(VI)–molybdenum(V)[8] method. The molar absorption coefficient of DOHP was evaluated to be 269 ± 0.5 at 355 nm, at room temperature.

Spectral measurements

The pH of a 10–15 cm^3 solution containing potassium chloride and equimolar 5×10^{-3} mmol metal ion and DOHP was adjusted to 7–8.5 in order to minimize hydrolysis of the metal[9] and protonation of DOHP.[10] Then the spectrum of the solution was measured in a 5-cm path quartz cell, using a Spectrophotometer Model U-best 30 (Japan Spectroscopic Co. Ltd). Under these conditions all of DOHP is considered to form the complex with each metal ion due to the high stability of the complex. From the measurements, therefore, the molar absorption coefficients of each metal complex can be determined. This solution was successively diluted with potassium chloride solution of the same concentration to dissociate the complex further. After each dilution a spectral analysis was made. If necessary, the pH was controlled within the pH region by using hydrochloric acid or potassium hydroxide solution. All the calculations were carried out on a personal computer.

RESULTS AND DISCUSSION

When the free ligand DOHP and its one-to-one metal complex are in co-existence, the absorption of the solution is represented by

$$A = \varepsilon^{P}[P]d + \varepsilon^{MP}[MP]d, \tag{1}$$

where ε^{P} and ε^{MP} represent the molar absorption coefficients of free DOHP and its complex, and d represents the cell length. Since the signals from the free ligand and its complex are, in general, not separated, two wavelengths, one of 355 nm for the free ligand peak and the other being an apparent peak wavelength for a ligand–metal complex composite spectrum, were employed. Taking the ratio of absorbances at these two wavelengths,

$$R = \frac{A_{max}}{A_{355}} = \frac{\varepsilon^{P}_{max}[P] + \varepsilon^{MP}_{max}[MP]}{\varepsilon^{P}{}_{355}[P] + \varepsilon^{MP}_{355}[MP]} = \frac{\varepsilon^{P}_{max} + \varepsilon^{MP}_{max}\beta_1[M]}{\varepsilon^{P}_{355} + \varepsilon^{MP}_{355}\beta_1[M]}, \tag{2}$$

where β_1 represents a stability constant

$$\beta_1 = [MP]/[M][P] \tag{3}$$

and P represents the DOHP ligand. When the metal and DOHP are equimolar in the solution, the free metal concentration can be solved as

$$[M] = (-1 + \sqrt{1 + 4\beta_1 C_P})/2\beta_1 \tag{4}$$

where C_P is the total concentration of DOHP,

$$C_P = [P] + [MP]. \tag{5}$$

From eqs (2) and (4) the following equation for analysis of β_1 is derived:

$$\beta_1 = \frac{\left\{1 + \dfrac{2(R\varepsilon^{P}_{355} - \varepsilon^{P}_{max})}{\varepsilon^{MP}_{max} - R\varepsilon^{MP}_{355}}\right\}^2 - 1}{4C_P}. \tag{6}$$

By substituting the molar absorption coefficients and all known quantities into eq. (6), the stability constants can be evaluated.

Since the stability constants of DOHP complexes with divalent metal ions are very high,[6] and an equimolar solution mixture of DOHP and a divalent metal of the appropriate concentrations can give quantitative formation of the one-to-one complexes, the molar absorption coefficient of the complex can be calculated. Figure 1 shows the absorption spectra with molar absorption coefficients for various one-to-one metal complexes of DOHP. As can be seen from the figure, the peak at 355 nm for DOHP shifted by about 10 nm to longer wavelengths on forming the one-to-one complex with a divalent metal ion, while other peaks in the UV region did not shift appreciably. Furthermore, the molar absorption coefficient of the complex at maximum wavelength in general decreased from that of free DOHP. This pronounced change did not occur for iron(II) and alkali metal cations. In the case of calcium, precipitation gradually took place on mixing with DOHP, thus the stability constant of the Ca–DOHP complex could not be determined.

Table 1 provides molar absorption coefficients for DOHP and its complexes at 355 nm, and the individual peak wavelengths. The stability constants calculated from eq. (6), using R values determined after each dilution of equimolar DOHP/metal solution with potassium chloride solution of the same ionic strength, are plotted against the total concentration of DOHP (Fig. 2). The values initially decreased and then became constant at individual ionic strengths. These vlaues in the low concentration range were thus taken as the stability constants of the 1 : 1 metal–DOHP complex, and are tabulated in Table 2.

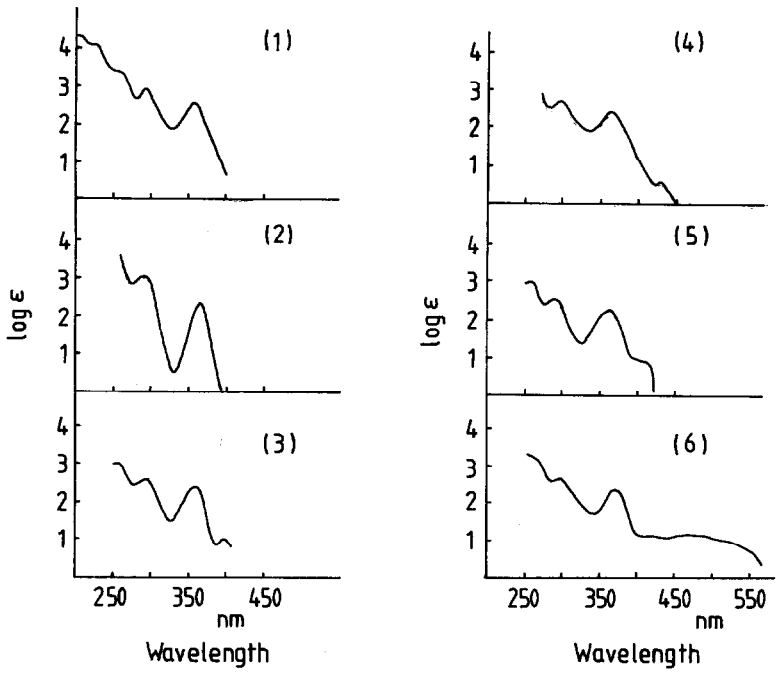

Fig. 1. Absorption spectra of DOHP and equimolar complexes of DOHP with different cations. (1) DOHP only (pH 8.5); (2) Mg–DOHP (pH 8.2); (3) Ca–DOHP (pH 8.3); (4) Fe–DOHP (pH 7.5); (5) Ni–DOHP (pH 8.2); (6) Cu–DOHP (pH 7.0).

To obtain the true stability constants, inert supporting electrolytes such as tetramethylammonium salts may be preferable for the measurements. However, the stability of DOHP complexes is usually too high, therefore dissociation did not appreciably take place even after large dilution. Therefore in our measurements, potassium chloride solution was used to obtain appreciable dissociation by which analyses could be made. Accordingly the values tabulated in Table 2 may be considered to be conditional constants from this point of view. The constants in all cases decreased with increasing ionic strength as expected, although this was not appreciable in the case of the iron(II) complex. Although the plot of $\log \beta_1 \sim \sqrt{I}$ was fairly linear, extrapolation to zero ionic strength may not give a thermodynamic stability constant, because the system may involve ion-pair formation of DOHP with potassium ions.[11] In any case, the order of the stability constant, β_1, was $Fe^{II} < Cu^{II} < Ni \approx Mg$ at lower ionic strengths.

Table 1. Molar absorption coefficients of the complex peak and free DOHP at the longest wavelength

	Wavelength of peak (nm)	ε^{MP}_{max}	ε^{MP}_{355}	ε^{P}_{max}
Mg	365	199	139	97.0
Fe	364	265	219	110
Ni	367	188	112	74.0
Cu	367	205	113	73.5
Ca	361	220	182	150
DOHP	355	—	—	269[a]

[a] Molar absorption coefficient of DOHP only, i.e. (ε^{P}_{355}).

The tendency of decreasing stability constants was almost similar in magnesium, nickel and copper complexes, which may be due to the variation of activity coefficients of each species concerned. Unique behaviour was found for the iron(II) complex, where the stability constants only slightly change in the range studied. The reason may be because the iron(II) complex has a different structure from that of other metal complexes. A free DOHP anion has the possibility to adopt two forms, the chair form or the boat form, although the chair form may be more stable in solution. The complexes with copper, magnesium and nickel probably adopt a boat form so that the four oxygen atoms can bind together to the metal cations. On the other hand, the iron(II) complex probably exists in the chair

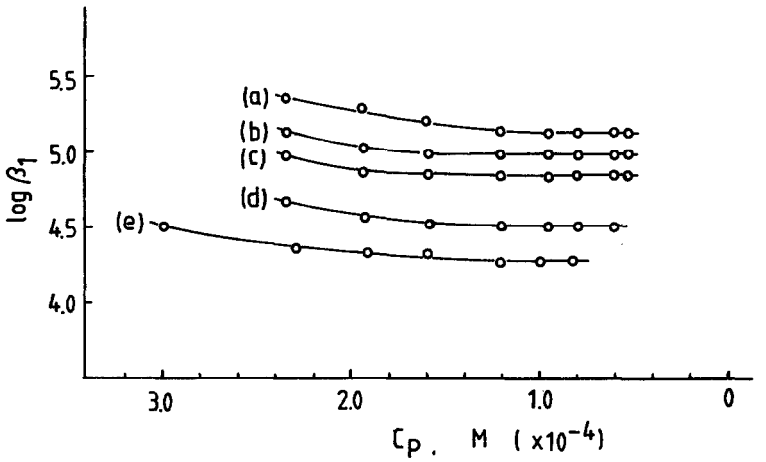

Fig. 2. Stability constants of the Mg–DOHP complex at different dilution stages. (a) $I = 1.0$; (b) $I = 1.5$; (c) $I = 2.0$; (d) $I = 2.5$; (e) $I = 3.0$.

form, therefore the iron(II) ion of coordination number six can retain its ability to accept a chloride ligand. The additional binding of the chloride ligands to the metal in the complex may undoubtedly promote the increase of the conditional stability constant through the enlarged numerator of [MP]/[M][P]. This assumption on the structure may be supported by the fact that the molar absorption coefficient of the iron(II)–DOHP complex, $\varepsilon = 265$ mol^{-1} dm^3 cm, is very close to that of free DOHP ligand, $\varepsilon = 269$ mol^{-1} dm^3 cm.

In addition to the present dual-wavelength method, a conventional single-wavelength method[12] was also applied to the stability constant analyses. However, the latter was more erroneous compared with the former, where two measurable quantities are involved at a given point of the complex system.

Table 2. Dependence of logarithmic stability constants on ionic strength

	Ionic strength					
	0.5	1.0	1.5	2.0	2.5	3.0
Mg	5.77	5.16	4.95	4.82	4.49	4.26
Fe^{II}	5.13	5.11	5.06	5.07	5.09	4.97
Ni	—	5.39	5.21	4.95	4.72	4.60
Cu	5.16	4.76	4.50	—	—	—

Laboratoire de Chimie-Physique, URA n° 405, EHICS, Université Louis Pasteur, 1 rue Blaise Pascal, F-67008 Strasbourg Cedex, France

(*Received* 23 *April* 1990; *accepted* 22 *June* 1990)

Abstract—The bromide complexes of copper(II) were studied spectrophotometrically in acetic acid. This non-dissociating solvent presents secondary equilibria such as perchlorate ⇄ acetate and in the case of copper acetate in acetic acid, monomer ⇄ dimer. A matrix rank treatment of the optical densities identified four mononuclear bromo complexes which are formulated as Cu(OAc)Br, $CuBr_2$, $LiCuBr_3$ and Li_2CuBr_4. The overall stability constants of these species are $\log\beta_1 = 3.2$, $\log\beta_2 = 6.5$, $\log\beta_3 = 7.7$ and $\log\beta_4 = 7.7$. The electronic spectra of the individual species, in this solvent, are reported for the first time. The *d–d* transition band of the tetrabromocuprate is calculated to be at 1120 nm and confirms the structure of a flattened tetrahedron.

According to the classification of the solvents based on the dielectric constant, ε_r, solvents with values of $\varepsilon_r < 15$ are classified as non-dissociating molecular solvents. Acetic acid, $\varepsilon_r = 6.2$, falls under this category and is therefore non-ionic in character and species present in this solvent exist as ion-pairs or ionic aggregates.[1] However, an equilibrium study in this solvent poses a host of theoretical problems which we shall indicate with a concrete example. Having already reported studies of halogenocuprates in different protic and aprotic solvents[2–5] we shall illustrate these problems with the help of results of copper(II) bromides in acetic acid, at 25°C and at a constant molecular environment maintained at 1 mol dm^{-3}.

1. PROBLEM OF THE NATURE OF SALT

In all our previous studies the metal coordinator was introduced into the solution by using a solution of copper(II) perchlorate. However, at low concentration of copper perchlorate in acetic acid, the formation of copper acetate is remarked. Copper perchlorate has a characteristic absorption band at 790 nm, whereas copper acetate absorbs at 680 nm. Eswein *et al.*[6] and Sawada *et al.*[7] have reported the absorption of copper acetate at 670 and 685 nm, respectively. In acetic solutions and at higher concentrations of copper perchlorate, its characteristic maximum is clearly observed at 790 nm. With dilution of the solution this maximum undergoes a hypsochromic effect and shifts to 680 nm, thus indicating the presence of copper acetate. Figure 1(a) and (b) shows the effect of dilution of copper perchlorate solution in acetic acid, respectively, in the presence, as well as in the absence, of lithium perchlorate (1 mol dm^{-3}). There is therefore an equilibrium between perchlorate and acetate:

$$Cu(ClO_4)_2 \rightleftarrows Cu(ClO_4)(OAc) \rightleftarrows Cu(OAc)_2.$$

Copper perchlorate absorbs at 790 nm, copper acetate at 680 nm and, in between, a mixed salt of the two has an absorption maximum at about 720 nm.[10]

Under these conditions a study of the halogeno complexes of copper in acetic acid with copper perchlorate is nearly impossible because the form of the non-complexed copper in the solution is unknown: whether it is in the form of perchlorate or acetate, or in the form of the mixed salt especially when the concentration of copper is low. Furthermore, Fig. 1(a) indicates that even the addition of lithium perchlorate as indifferent electrolyte fails to stabilize copper in the form of copper perchlorate.

* Author to whom correspondence should be addressed.

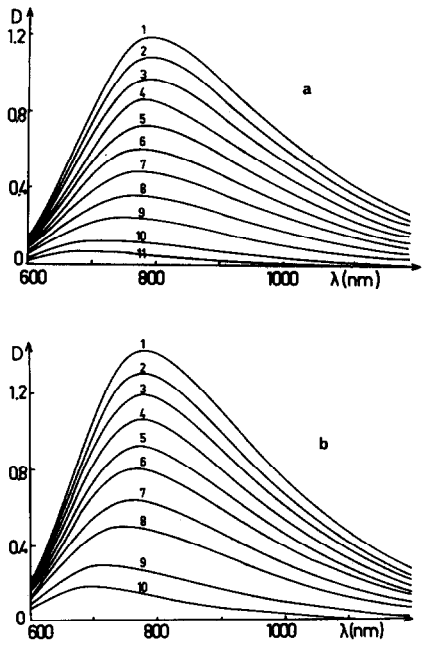

Fig. 1. Dilution of copper(II) perchlorate solution in acetic acid: (a) in the absence of $LiClO_4$; (b) in the presence of $LiClO_4$.

Consequently in a study of the halogeno complexes of copper(II) in acetic acid, copper must be added in the form of copper acetate.

2. MONOMER–DIMER EQUILIBRIUM

The use of copper acetate in acetic acid engenders a different type of problem, that of the existence of a monomer–dimer equilibrium: $2Cu(OAc)_2 \rightleftarrows Cu_2(OAc)_4$. Yamada *et al.*[8] and Martin and Whitley[9] have shown that the absorption band of copper acetate in acetic acid at 365 nm is due to metal–metal bonding in copper acetate which exists as a dimer in solution. Sawada *et al.*[10] have reported this absorption maximum at 370 nm. This band is not observed in our work because of low copper concentration, but it is observed at 372 nm in concentrated solutions of copper acetate $[Cu^{II}] > 4 \times 10^{-3}$ mol dm^{-3}.

The equilibrium constant of the monomer–dimer equilibrium has been determined by Kochi and Bubramanian[11] and is equal to 5×10^{-4}. These authors have also reported the feeble absorption intensity of the dimer band ($\varepsilon < 60$ dm^3 mol^{-1} cm^{-1}). The existence of the monomer and dimer species has been confirmed with the help of magnetic susceptibility measurements by Sawada *et al.*,[7] who have shown that the copper acetate in acetic acid has a dimeric structure, whereas the chloro complexes of copper are monomeric in nature.

Taking into consideration all these factors: (1) the low value of the equilibrium constant of monomer $\rightleftarrows$ dimer, (2) the very low absorption intensity of the dimer, (3) the disappearance of copper acetate in favour of the formation of bromo complexes, in our study, as well as the low concentrations of copper solutions, it can be assumed that copper acetate is in the monomeric form as far as this work is concerned. This hypothesis is further sustained by the fact that addition of small quantities of perchloric acid, which is the case in our study, favours the monomeric species.[11]

3. EQUILIBRIUM OF BROMO COMPLEXES OF COPPER(II) IN ACETIC ACID

In dissociating protic or aprotic solvents, the complexes involved in the equilibrium reaction are either charged or neutral species, generally cations more solvated than anions and sometimes completely unsolvated anions such as CuX_4^{2-}, the electronic spectrum of which was demonstrated as solvent independent.[3]

On the contrary, in the non-dissociating aprotic solvents such as THF[4] or protic solvents such as acetic acid, the species are present as ion-pairs or ion-aggregates and the successive equilibria in solution can be written as:

$$Cu(OAc)_2 + LiBr \rightleftarrows Cu(OAc)Br, LiOAc$$

$$Cu(OAc)_2 + 2LiBr \rightleftarrows CuBr_2, 2LiOAc$$

$$Cu(OAc)_2 + 3LiBr \rightleftarrows LiCuBr_3, 2LiOAc$$

$$Cu(OAc)_2 + 4LiBr \rightleftarrows Li_2CuBr_4, 2LiOAc. \quad (a)$$

However, the so-called non-dissociating solvents are only so by definition in the case of relative permittivity values, ε_r, lower than 15. For acetic acid which has an ε_r of 6.2 there is nevertheless the feeble ionization present. The presence of such voluminous ion-aggregates as $LiCuBr_3$, 2LiOAc or Li_2CuBr_4, 2LiOAc is quite improbable. Consequently, the sequence of the equilibria should be written in the following way:

$$Cu(OAc)_2 + LiBr \rightleftarrows Cu(OAc)Br + LiOAc$$

$$Cu(OAc)_2 + 2LiBr \rightleftarrows CuBr_2 + 2LiOAc$$

$$Cu(OAc)_2 + 3LiBr \rightleftarrows LiCuBr_3 + 2LiOAc$$

$$Cu(OAc)_2 + 4LiBr \rightleftarrows Li_2CuBr_4 + 2LiOAc. \quad (b)$$

As a matter of fact, the equilibrium constants corresponding to formulation (b) are different from those used in ionic media or aprotic dissociating

solvents. This difference is essentially due to the presence of the LiOAc concentration in the numerator. Amuli *et al.*[4] maintained the molecular environment constant in THF by the addition of $LiClO_4$, which enabled its exact analytical concentration to be known. By analogy, LiOAc should be used in these solutions. Unfortunately, copper(II) possesses good coordination ability with lithium acetate, unlike with perchlorate, and would consequently lead to another set of equilibria which overlap with the copper(II) bromides under study. Without addition of LiOAc, calculation of its concentration, taking into account equilibria (b), is quite impossible.

Therefore, the determination of the equilibrium constants of the copper(II) bromo complexes is performed using formulation (a) generalized by:

$$Cu(OAc)_2 + jLiBr \rightleftarrows \text{complex j},$$

with an equilibrium constant $\beta_j = [\text{complex j}]/[Cu(OAc)_2][LiBr]^j$.

4. COPPER(II) BROMIDES IN ACETIC ACID

Keeping in view all the above aspects we report below the results of copper(II) bromo complexes in acetic acid. Eswein *et al.*[6] have already reported the existence of the tri- and tetrabromocuprates in acetic acid absorbing at 625 and 510 nm, respectively. Yatsimirskii and Mal'Kova have calculated the stability constants of the mono- and dibromo complexes ($\log\beta_1 = 2.60$ and $\log\beta_2 = 6.42$) in acetic acid.[12] In another publication, these authors postulated the presence of tetra- and hexabromo complexes in concentrated solutions.[13]

Figure 2 shows the experimental spectra of the copper(II) bromides in the UV–vis and the near-IR regions. As soon as the ligand is added to the copper solutions, the copper absorption band at 260 nm diminishes with the appearance of several maxima:

an absorption band at 285 nm which increases in intensity with concentration and at the same time undergoes a hypsochromic shift until 267 nm for $C = 1.0$ mol dm^{-3};

another maximum at 350 nm, increasing with concentration until $C = 0.01$ mol dm^{-3}, with a bathochromic shift until 370 nm. For $\geqslant 0.03$ mol dm^{-3} this maximum diminishes in intensity and shifts back to 350 nm;

the appearance in the visible range of two absorption bands at 435 and 640 nm following the same evolution pattern as the 350 nm band. In addition to these bands in the visible spectrum, another band appears at 520 nm for ligand concentrations superior to 0.1 mol dm^{-3};

in the near-IR, the maximum at 860 nm increases in intensity until $C = 0.05$ mol dm^{-3} and then diminishes in favour of a large band centred at 1170 nm.

A matrix rank treatment of optical densities was executed to determine the minimum number of species present in the solution,[14] which indicated the presence of at least three complexes. The theoretical expressions and the mathematical treatment have

960 sh	1130(86)	1220(112)	1120(166)

been explained in one of our earlier publications.[3] The computation was performed on the [1,2,3] and [1,2,3,4] theoretical models, i.e. the mono-, di- and tribromo complexes and the mono-, di-, tri- and tetrabromo complexes, respectively. The results are summarized in Table 1.

The quadratic mean $\langle\sigma_t\rangle$ has a significantly lower value for the model with four complexes. Consequently the presence of four mononuclear bromo complexes is concluded and, in acetic acid, they are formulated as Cu(OAc)Br, $CuBr_2$, $LiCuBr_3$ and Li_2CuBr_4. The values of the stability constants are used to determine the specific molar extinction coefficients, ε_j, to calculate the electronic spectra of the individual species represented in Fig. 3. The characteristic charge-transfer bands, as well as the *d–d* transitions for the individual complexes, are reported in the Table 2.

The formation curves of the four complexes are represented in Fig. 4, and it is seen that $CuBr_2$ covers a large range of ligand concentration. Even with a maximum experimental concentration of 1.0 mol dm^{-3}, where 49% of the third and 49% of the fourth complex are formed, small quantities of the dibromo complex are still present.

Our earlier works concerning the structure in solution of the tetrachlorocuprates have demonstrated both the square-planar and flattened tetrahedron configurations depending upon the solvents. As regards the tetrabromo complex, all studies converge to attribute the flattened tetrahedron structure for it. In the solid state, this configuration has a very specific *d–d* transition band at 1111 nm and above. Our calculations show its maximum at 1120 nm and therefore, by comparison with solids, the structure of the tetrabromocuprate, in acetic acid solution, is that of a flattened tetrahedron.

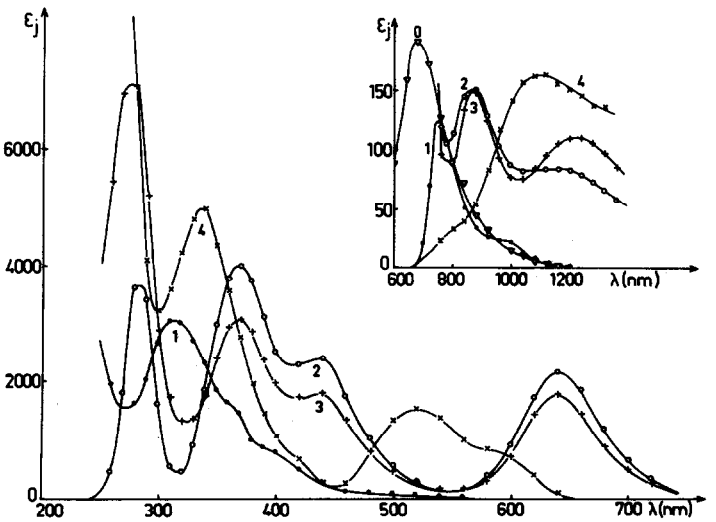

Fig. 3. Calculated electronic spectra of the copper(II) bromo complexes in acetic acid: (0) $Cu(OAc)_2$, (1) Cu(OAc)Br, (2) $CuBr_2$, (3) $LiCuBr_3$, (4) Li_2CuBr_4.

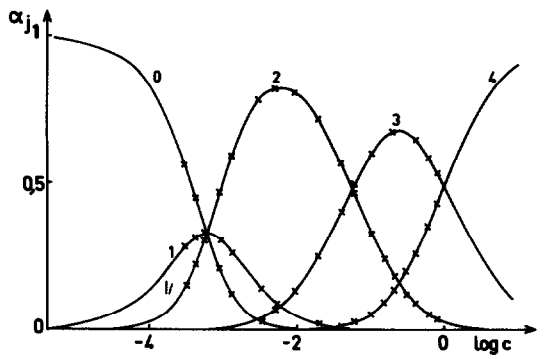

Fig. 4. Degree of formation of the copper(II) bromo complexes in acetic acid, (c is the effective concentration of LiBr); ($\times$) experimental points.

EXPERIMENTAL

Anhydrous acetic acid, pro-analysis (Merck), was used after the addition of a calculated amount of acetic anhydride, p.a. Merck, along with three drops of 0.001 M perchloric acid, 70% p.a. Merck, and then allowing the solution to stand overnight.[1] Copper solutions were prepared from stock solutions of copper(II) acetate, p.a. Merck, and $Cu(ClO_4)_2 \cdot 6H_2O$, p.a. Merck. Lithium bromide, p.a. Merck, and lithium perchlorate, p.a. Fluka, were used without any purification.

The final analytical concentration of copper was 5×10^{-4} mol dm^{-3} for measurements in the UV–vis and 3.75×10^{-3} mol dm^{-3} in the IR region. In these spectral ranges ligand concentrations were varied from 10^{-3} to 1.0 mol dm^{-3} with spectrophotometric cells of 0.5 and 2.0 cm, respectively.

Acetic acid was used as the spectrophotometric reference solution. The final solutions of copper and bromide were prepared just before measurements to avoid any possibility of errors due to instability. The absorption of the solutions was measured with the help of CARY 17D with digital interfacing and a Periferic Zip 30 rapid printer. The numerical analysis was performed on an IBM 3081 D computer.

ROTATIONAL BARRIERS IN DIALKYLAMINOCHLOROSPHINES: STERIC EFFECTS ON THE PREPARATION OF CAGE COMPLEXES

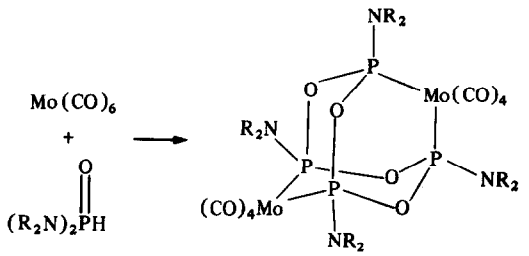
DAVID S. BADER and MARK M. TURNBULL*

Department of Chemistry, Clark University, 950 Main Street, Worcester, MA 01610, U.S.A.

(*Received* 2 *April* 1990; *accepted* 4 *July* 1990)

Abstract—The barrier to rotation about the P—N bond in a series of N,N-dialkylphenylphosphonamidous chlorides has been measured. The barriers fall into two groups based on the alkyl substituents being primary (barrier = 11.6 ± 0.1 kcal mol^{-1}) or secondary (barrier = 13.4 ± 0.2 kcal mol^{-1}). The difference in barrier height is interpreted in terms of the steric requirements of the alkyl substituents. This steric argument is used to explain the observed difference in reactivity of $(R_2N)_2P(O)H$ compounds with $Mo(CO)_6$.

In 1983, Wong *et al.*[1] discovered the thermal condensation reaction between $(^iPr_2N)_2P(O)H$ and $Mo(CO)_6$ to give the cage complex **1** (R = ^{i}Pr), containing the unusual tetraoxatetraphosphorinane ring which binds the two metals centres together [see eq. (1)]:



(1)

(1)

Further work using other phosphine oxides, $(R_2N)_2P(O)H$ (R = cyclohexyl, ethyl, benzyl)[2a] and (R = methyl),[2b] indicated that the yield of cage-like product depended upon the alkyl groups on the amino-substituents; larger groups such as isopropyl and cyclohexyl (= c-hex) gave high yields of the corresponding **1**, while the smaller substituents, methyl, ethyl and benzyl, gave virtually no **1** (detectable spectroscopically, but not isolated).

We interpreted this marked reactivity difference as a steric dependence, where increased steric bulk was somehow responsible for the cage-forming process. This idea was in agreement with the proposed pathway,[3] wherein initial formation of the coordinated phosphinous acid, **2**, is followed by elimination of dialkylamine to generate the coordinated phosphinidene oxide, **3**, which then goes on to form **1** [see eq. (2)]. The existence of the chromium analogue of **3** has been shown by Niecke *et al.*[4] and provides support for this pathway. Relief of steric strain in the conversion of **2** to **3** might provide the driving force for the loss of dialkylamine. It is reasonable that more crowded molecules would undergo this reaction more easily since coordinated phosphinous acids (similar to **2**, but where there are alkyl, aryl or alkoxy substituents in place of the amino groups) are generally isolable, stable species.[5]

We believed that one way to quantify this steric effect would be to examine the barrier to rotation about the P—N bond for the various dialkylamino substituents. Such a relationship would have a useful predictive value for attempting the synthesis of **1** with other amino substituents.

RESULTS AND DISCUSSION

Measurement of the rotational barriers in compounds of the general structure $(R_2N)_2P(O)H$, the actual starting materials for the synthesis of **1**, would provide a direct measure of the steric requirements for the dialkylamino groups involved. However, we were unable to detect any change in the ^{13}C NMR spectrum of $(^iPr_2N)_2P(O)H$ from 330 to 185 K. This was not suprising since the spectrum of $Ph(Me_2N)P(O)Cl$ remains unchanged down to 193 K.[6] Jennings and co-workers, however, had detected the barrier for $Ph(^iPr_2N)P(S)Cl$, which showed coalescence at 208 K,[7] and thus we had hoped that we would be able to detect the barrier for at least the bulky (^{i}Pr and c-hex) oxy-analogues. Because of our inability to study the actual compounds used in the preparation of **1**, we turned to the phenylphosphonamidous chlorides $[Ph(R_2N)PCl]$.

The magnitude of this barrier was first determined by dynamic ^1H NMR spectroscopy of $Ph(Me_2N)PCl$ in 1968.[8] Since that time many workers have studied the phenomenon and the effects of varying the substituents at phosphorus and nitrogen.[9] More recently, Martin and co-workers have examined the P—N bond character of aminophosphines through ^{15}N and ^{31}P NMR chemical shifts and coupling constants.[10] The barrier is attributed to the combined effects of lone pair–lone pair repulsions, N—P double-bond character and steric effects. We felt that in a series of dialkylaminophosphines such as $Ph(R_2N)PCl$ (**4**), where the only variant was the alkyl group, the electronic contributions (lone pair effects and double bond character) would remain reasonably constant. Therefore the difference in the rotational barriers would provide us with a direct measure of the changing steric contribution from the dialkylamino substituents. Dakternieks and Di Giacomo[11] have used similar arguments to explain the effect of varying the P substituents in similar diethylaminophosphines. The barriers to rotation for some of these compounds (R = Me, Et, ^{i}Pr) have been previously reported,[9] but at widely different temperatures, making a direct comparison difficult.

We determined the thermodynamic activation parameters for P—N rotation in the series $Ph(R_2N)PCl$ [R = Me (**4a**), Et (**4b**), Bz (**4c**), ^{i}Pr (**4d**) and c-hex (**4e**)] to see if the steric effects derived therefrom would provide a useful measure of the success of the related $(R_2N)_2P(O)H$ compounds to produce **1**. Compounds **4a–e** were prepared by standard techniques (see Experimental). Treatment of $PhPCl_2$ with two equivalents of the appropriate amine gave the corresponding $Ph(R_2N)PCl$, compound **4**, in 70–90% yield.

$$PhPCl_2 + R_2NH \longrightarrow Ph(R_2N)PCl \quad (3)$$

(4)

^{13}C NMR {H} spectra were obtained for the dialkylaminophosphines (**4a–e**). Spectra were obtained within the liquid range of the solvent, d_6-acetone (200–330 K). Chemical shifts and coupling constants for the low and high temperature limiting spectra are given in Table 1. Rotational frequencies at each temperature were determined by the Complete Bandshape Analysis[12] method for the coalescing doublets of the carbons adjacent to the nitrogen atom for all compounds.

The observed $^2J_{PNC}$ coupling constants for the low and high temperature limiting spectra indicate that the signs of the low temperature couplings must be opposite. For example, $(Me_2N)PhPCl$ shows two doublets with observed couplings of 13 and 35 Hz at 200 K and a doublet with an observed coupling of 11 Hz at 330 K. These values are clearly consistent with couplings of opposite sign as has been observed previously.[9b] Wehrli and co-workers showed the $^2J_{PNC}$ coupling to be dependent upon the dihedral angle between the C—N bond and the phosphorus lone pair; for angles near 0° the value is large and positive and for angles near 180° the value is small and negative. We have assigned our spectra accordingly.

For **4d** and **4e**, the high temperature spectra could not be obtained below the boiling point of the

solvent. Hence, the opposite signs of the observed low temperature coupling constants could not be confirmed, but have been assigned that way by analogy assuming the molecules have similar conformations. However, both **4d** and **4e** show a substantial reduction of the large coupling constant (by about 10 Hz) compared to the primary-alkyl substituted **4a–c**. In addition, the chemical shifts of the large and small coupled doublets in **4d** and **4e** are reversed with respect to **4a–c**, the lower field resonances of **4d** and **4e** having the smaller coupling constants. These effects suggest significant differences in the ground state conformations of **4** as a function of R and thus our assignment of opposite signs to the coupling constants may be inappropriate. Clearly, however, the similarity of spectra within an alkyl type and the differences of the spectra between the alkyl types supports our hypothesis that these compounds constitute two distinct groups.

Standard Eyring plots of $1/T$ vs $\ln k/T$ for each series of spectra yielded $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. These values and the calculated values for $\Delta G^{\ddagger}$ at 298 K are given in Table 2 along with the correlation coefficient for the Eyring plots from which they were derived. Only those spectra not near the high or low temperature limits were used. As has been previously noted,[13] non-linearity was observed at very low and very high rotational rates. Errors introduced by spin–spin coupling and scalar coupling of nuclei are systematic and lead to low values of $\Delta H^{\ddagger}$ and consequently more negative values of $\Delta S^{\ddagger}$, but these are mutually compensating errors, with respect to the calculation of $\Delta G^{\ddagger}$, at the moderate temperatures used in these experiments. In addition, at very low and high rotational rates the errors in comparing the simulated and experimental spectra become significant. At very low rates (< 20–30 Hz), changes of 20% or more produce no visible change in the spectrum. The same is true at high rotational rates (above ≈ 20,000 Hz) and thus these data were not used. A comparison of our results with the literature values is given in Table 3.

Examination of the rotational barriers of **4a–e** shows distinct similarities among compounds with the same type of alkyl group (primary or secondary) and an abrupt break between these groups. Those aminophosphines with primary alkyl groups, **4a–c**, exhibit a barrier of 11.6 ± 0.1 kcal mol^{-1} while those with secondary alkyl groups, **4d** and **4e**, show a barrier of 13.4 ± 0.2 kcal mol^{-1}. We contend that because these are all alkyl-substituted amines, the electronic contribution of the different groups should be relatively constant. Thus the difference in rotational barriers must result from the different steric constraints of the alkyl groups. The absolute difference between the rotational barriers of the two groups is small, 1.8 kcal mol^{-1}, and thus raises the question of how valid conclusions based upon that difference can be. We believe that the even smaller spread of values within each group (0.2 and 0.3 kcal, about 15% of the separation between the groups) supports our hypothesis that the primary or secondary nature of the alkyl group plays the major role in distinguishing the rotational barriers for these compounds.

We are gratified that the two sets of dialkylamino substituents resulting from examination of the rotational barriers correspond to the two sets defined by the reaction of $(R_2N)_2P(O)H$ with $Mo(CO)_6$. We conclude that when R is primary, intermediate **2** in the cage synthesis is too low in energy to undergo the critical elimination reaction to form **3**. Steric crowding in the case of secondary alkyl groups raises the energy of **2**, thus lowering the activation barrier to the production of **3** and thence on to **1**.

The one remaining question is whether the barriers to rotation in **4** and the steric differences derived therefrom, are reasonable models for the interactions occurring in the proposed intermediate **2**. The question is not whether the actual values for

the rotational barriers are comparable, but rather whether the *relative* values are comparable. In the case of **4**, one dialkylamino group is varied with the rest of the structure held constant (phenyl and chloro substituents). In intermediate **2**, the phosphorus atom is tetracoordinate with another dialkylamino group replacing the phenyl substituent, a hydroxyl group in place of chlorine and a $Mo(CO)_5$ fragment coordinated to the phosphorus lone pair. The tetracoordinate nature of the phosphorus atom will clearly change the electronic and lone pair repulsion contributions to the barrier, but the steric requirements will be exaggerated relative to the model compounds, leading to even greater energy differences between the two sets of dialkylamino substituents in **2**.

Further work is in progress to test the predictive power of these results. We intend to vary the steric congestion about the amino group in a regular fashion using the series piperidine, (+)- and (−)-2-methylpiperidine, and 2,6-dimethylpiperidine. The measured rotational barriers for these $Ph(R_2N)PCl$ compounds should allow us to predict the subsequent success of using the diaminophosphine oxides to produce **1**.

EXPERIMENTAL

All procedures were carried out using standard Schlenk techniques under an argon atmosphere. Dichloromethane was distilled from CaH_2. Ether was distilled from Na/benzophenone ketyl. All amines were purchased from Aldrich Chemicals and distilled from KOH. $PhPCl_2$ was purchased from Alfa Products and used without further purification. IR spectra were recorded on a Perkin–Elmer 1330 spectrophotometer and were calibrated against polystyrene. NMR spectra were recorded on a Bruker AC-200 spectrometer (courtesy of the Worcester NMR Consortium) and calibrated against TMS (^1H), solvent (^{13}C) or external Ph_3P (^{31}P). ^{13}C and ^{31}P NMR spectra were broadband proton-decoupled unless otherwise noted. Elemental analyses were performed by MultiChem Laboratories, Inc. Lowell, MA.

$Ph(c\text{-}hex_2N)PCl$ (**4e**)

$PhPCl_2$ (4.07 cm^3, 5.37 g, 30.0 mmol) was dissolved in 50 cm^3 of CH_2Cl_2 and cooled to −78°C. Dicyclohexylamine (11.9 cm^3, 10.9 g, 60.0 mmol) was added dropwise over the course of 10 min with vigorous stirring. The reaction mixture was allowed to warm to room temperature and stirred for 12 h. 50 cm^3 of Et_2O was added, the resulting mixture was filtered and the precipitate washed with 4 × 15 cm^3 of Et_2O. The solvent was removed *in vacuo* from the combined filtrate and washings to give a viscous pale yellow oil, 8.48 g (88%). Found: C, 64.6; H, 7.9; N, 3.6. Calc. for $C_{18}H_{27}ClNP$: C, 66.7; H, 8.4; N, 4.3% (We believe the discrepancy in analysis is due to the compound's susceptibility to hydrolysis. No impurities were detected by NMR spectroscopy and a repeat analysis was not attempted.) IR (neat): 3045m, 2910vs, 2840s, 1060s, 745s, 695s. ^1H NMR: δ 7.74 (br m, 2H, *o*-Ph), 7.43 (br m, 3H, *m*- and *p*-Ph), 3.0 (br, 2H, NCH), 1–2 (br m, 20H, CH_2's). ^{13}C NMR: δ 140.6 (d, $J = 28$ Hz), 131.4 (d, $J = 22$ Hz), 130.2 (s), 129.0 (s), 58.5 (br), 34.8 (br), 26.8 (s), 26.2 (s). ^{31}P NMR: δ 134.

Compounds **4a–d**

These were prepared by procedures analogous to that for **4e**. Isolated material was characterized by comparison of physical properties and ^1H NMR spectra with the literature data.[9] The broadband proton-decoupled ^{31}P NMR spectra at room temperature and high temperature limiting ^{13}C NMR are reported here for reference:

$Ph(Me_2N)PCl$ (**4a**): ^{31}P NMR (d_6-acetone): δ 145. ^{13}C NMR (d_6-acetone): δ 140.2 (d, $J = 27$ Hz), 131.1 (d, $J = 20$ Hz), 130.6 (s), 129.3 (s), 40.4 (d, $J = 11$ Hz). $Ph(Et_2N)PCl$ (**4b**): ^{31}P NMR (d_6-acetone): δ 141. ^{13}C NMR (d_6-acetone) −δ 140.0 (d, $J = 30$ Hz), 131.1 (d, $J = 20$ Hz), 130.5 (s), 129.2 (s), 44.7 (d, $J = 13$ Hz), 14.2 (d, $J = 5$ Hz). $Ph(Bz_2N)PCl$ (**4c**): ^{31}P NMR (d_6-acetone): δ 139. ^{13}C NMR (d_6-acetone): δ 139.6 (d, $J = 30$ Hz), 137.2 (s), 131.3 (d, $J = 22$ Hz), 130.8 (s), 129.2 (s), 129.9 (s), 128.0 (s), 53.5 (d, $J = 12$ Hz). $Ph(^iPr_2N)PCl$ (**4d**): ^{31}P NMR (d_6-acetone): −δ 132. ^{13}C NMR (d_6-acetone): δ 140.3 (d, $J = 19$ Hz), 131.3 (d, $J = 21$ Hz), 130.5 (s), 129.4 (s), 49.4 (br), 24.4 (s), 23.5 (d, $J = 13$ Hz).

Data analysis methods

Fourier transform ^{13}C NMR {H} spectra were obtained for each compound from 200 to 330 K. Samples were prepared at a concentration of 5%. Probe temperatures were determined by calibration against the temperature-dependent chemical shifts of ethylene glycol (above room temperature) or methanol (below room temperature).

Magnetic resonance spectra were simulated by the "Complete Bandshape Method".[12b] The lineshape equation, implemented on an IBM–XT personal computer, was designed to simultaneously simulate two pairs of coalescing resonances and thus accommodated simulation of the exchanging

doublets. In brief, calculated NMR spectra were obtained as follows: experimental frequencies and linewidths, as well as a projected rate constant, were input into the program to yield a set of contracted Lorentzian line-shape functions. The line-shape functions were then multiplied over the experimental frequency range to yield a calculated spectrum whose rate constant and transverse relaxation times could be adjusted to obtain the best fit with the experimental spectrum as determined by eye. We estimate the error in the rotational frequencies to be 5% or less.

(*Received* 22 *June* 1990; *accepted* 5 *July* 1990)

Abstract—The compound $Cr(NBu^t)_2Cl_2$ has been synthesized and converted to $Cr(NBu^t)_2(NHBu^t)Cl$, $Cr(NBu^t)_2(NHBu^t)_2$ and $Li_2Cr(NBu^t)_4$, the latter completing the series of Group 6 compounds, $Li_2M(NBu^t)_4$, M = Cr, Mo, W. The five-coordinate adducts, $Cr(NBu^t)_2Cl_2L$, L = PMe_3, PMe_2Ph and Bu^tNC, have been characterized as well as $[Cr(NBu^t)_2Cl_2]_2(\mu\text{-}Ph_2PCH_2CH_2PPh_2)$ and the six-coordinate $Cr(NBu^t)_2Cl_2$(2,2′-bipyridyl). Chloride substitution reactions of $Cr(NBu^t)_2Cl_2$ lead to the compounds, $Cr(NBu^t)_2(\eta^1\text{-}O_2CMe)_2$, $[Cr(NBu^t)_2(PMe_3)_2](O_3SCF_3)_2 \cdot 0.5MeCN$, $[Cr(NBu^t)_2py_2(\eta^1\text{-}O_3SCF_3)]SO_3CF_3$ and $[Cr(NBu^t)_2(bpy)_2](PF_6)_2$. The isocyanide, $[Cr(NBu^t)_2Cl_2(Bu^tNC)]$, with MeLi gives the η^2-iminoacyl $Cr(NBu^t)_2[\eta^2\text{-}(Bu^tN{=}CMe)]Cl$. Interaction of $Cr(NBu^t)_2Cl_2$ with alkylating agents at low temperatures gives the chromium(V) dimer $[Cl(Bu^tN)Cr(\mu\text{-}NBu^t)]_2$ in a one-electron per chromium reduction and the same product is obtained by reduction of the dihalide with $(\eta^5\text{-}C_5H_5)_2Co$. X-ray structures of compounds listed in the title have been determined.

In previous papers we have described the synthesis, X-ray structures and some reactions of the lithium derivatives of the species $[M(NBu^t)_4]^{2-}$, M = Mo and W,[1] and $[Re(NBu^t)_4]^-$.[1a,2] A preliminary note on the chromium(VI) analogue[3] is now expanded and this paper also includes a number of reactions of $Cr(NBu^t)_2Cl_2$.[3]

We have also previously described the chromium(VI) diaryls, $Cr(NBu^t)_2Ar_2$, Ar = $C_6H_2Me_3$-2,4,6(mesityl, mes), $C_6H_3Me_2$-2,6, the X-ray structures of the mesityl and of the reaction product with Bu^tNC, i.e. $Cr(NBu^t)_2[\eta^2\text{-}mesC{=}NBu^t]mes$; an unstable acyl from the reaction with CO, $Cr(NBu^t)_2(COmes)_2$ was characterized spectroscopically.[4]

After completion of the present study, a recent paper has described $Cr(NBu^t)_2X_2(py)$, X = Cl, Br, some bulky dialkyls, e.g. $Cr(NBu^t)_2(CH_2SiMe_3)_2$, similar to the aryls, and η^5-cyclopentadienyl compounds of the type $Cr(\eta^5\text{-}C_5H_5)(NBu^t)_2R$, R = alkyl or bromide.[5]

Analytical and physical data for new compounds are collected in Table 1. Reactions of $Cr(NBu^t)_2Cl_2$ are summarized in Scheme 1.

RESULTS AND DISCUSSION

(1) *Bis(t-butylimido)dichlorochromium*(VI)

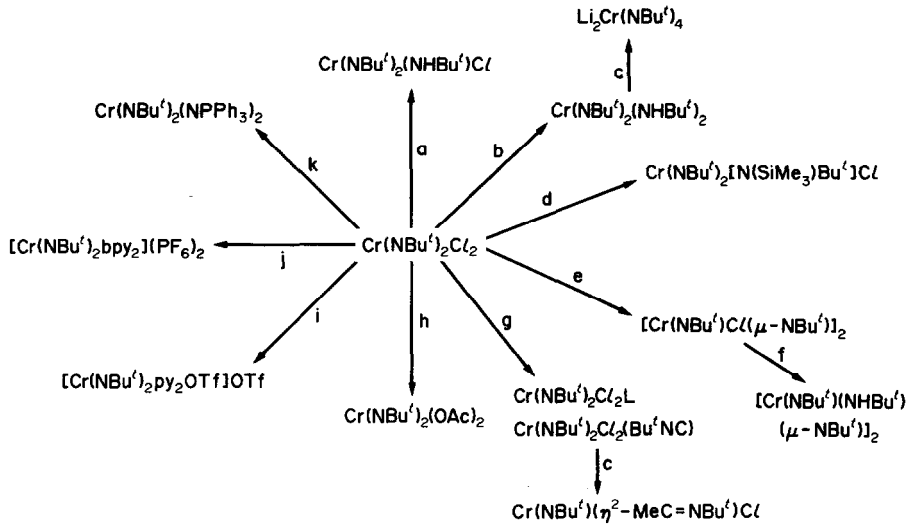
with boron trichloride in dichloromethane, the chloride, $Cr(NBu^t)_2Cl_2$ (**1**), can be prepared in multigram quantities. The reaction is very sensitive to conditions; longer reaction times or higher temperatures than those specified in the Experimental lead to reduced yields, possibly due to polymer formation and/or reduction by chloride ion (cf. reduction of CrO_2Cl_2 by BCl_3[7]). Other main group or transition metal halides ($AlCl_3$, PCl_5, $TiCl_4$, $ZrCl_4$) react similarly but the products are difficult to separate and BCl_3 is the preferred reagent because of the ease of removal of excess chlorinating agent and side products. The chloride (**1**) has been claimed previously,[5,8] but the materials reported were evidently impure oils; our product is a red crystalline solid that can be conveniently purified by sublimation. It is extremely sensitive to moisture; it is less oxidizing than CrO_2Cl_2 as is evident from its reactivity and this is doubtless due to increased π-donation to the metal by the imido group.[6b] The ^1H NMR spectrum is strongly dependent on the nature of the solvent; aromatic solvents induce upfield shifts, possibly due to weak complex formation (cf. the adduct with pyridine[5]). In the $^{13}C\text{-}\{^1H\}$ NMR



Scheme 1. Reactions of $Cr(NBu^t)_2Cl_2$. (a) Bu^tNH_2 or $Bu^tNH(SiMe_3)$; (b) Bu^tNHLi (2 eq); (c) MeLi, Et_2O; (d) $LiN(SiMe_3)(Bu^t)\cdot Et_2O$; (e) $Zn(CH_2CMe_3)_2$, *CpLi or Cp_2Co; (f) Bu^tNHLi; (g) L = PMe_2Ph, PMe_3, Bu^tNC, bpy; (h) AgOAc; (i) $AgSO_3CF_3$+py; (j) bpy, $AgCF_3SO_3$, PF_6^-; (k) $LiNPPh_3$.

spectrum the Δ parameter[6b,9] (Δ = 53 ppm) indicates the presence of electrophilic, probably linear, $MNBu^t$ groups and the high order of the Cr—N bond is supported by the IR stretching frequency.

(2) *Bis(t-butylimido)(t-butylamido)chlorochromium* (VI) (**2**), *bis(t-butylimido)bis(t-butylamido)chromium*(VI) (**3**), *bis(butylimido)[t-butyl(trimethylsilyl)amido]chlorochromium*(VI) (**4**) *and dilithium tetrakis (t-butylimido)chromate*(VI) (**5**)

The interaction of the dichloride with excess Bu^tNH_2 proceeds according to eq. (1):

$$Cr(NBu^t)_2Cl_2 + 2Bu^tNH_2 = Cr(NBu^t)_2(Bu^tNH)Cl + Bu^tNH_3Cl. \quad (1)$$

Further substitution does not occur even under forcing conditions, while the use of less bulky amines gives intractable products.

t-Butylsilylamine reacts similarly only to give the monoamido species (**2**), eq. (2):

$$Cr(NBu^t)_2Cl_2 + Bu^tNH(SiMe_3) = Cr(NBu^t)_2(Bu^tNH)Cl + SiMe_3Cl. \quad (2)$$

Compound **2** is monomeric (mass spectrum) and remarkably inert towards substitution of the chloride by a variety of nucleophiles. Methyllithium gives intractable products and there is no reaction with more bulky alkyl lithium or Grignard reagents. The compound can be recovered after treatment with Na/Hg or Mg in tetrahydrofuran.

The bis-amido compound, $Cr(NBu^t)_2(NHBu^t)_2$ (**3**) is obtained from $Cr(NBu^t)_2Cl_2$ with two equivalents of $LiNHBu^t$ in toluene but in rather low yield evidently because of competing reduction reactions. The bis-amido compound could not be obtained either at elevated temperature or by use of more polar solvents.

Attempts to obtain $Cr(NBu^t)_3$ (the isoelectronic analogue of CrO_3) from **2** via α-elimination of HCl by thermal or photochemical treatment or by interaction with strong neutral (Et_3N, proton sponge) or anionic (Bu^tLi) bases were unsuccessful and the starting material is recovered. A possible alternative route involved synthesis of $Cr(NBu^t)_2[N(SiMe_3)Bu^t]Cl$ (**4**) by interaction of $Cr(NBu^t)_2Cl_2$ with $LiNBu^t(SiMe_3)\cdot Et_2O$ but thermolysis in THF or toluene gives a green material from which, on work-up, only orange crystals of $Cr(NBu^t)_2(NHBu^t)Cl$ can be isolated; the solvent evidently acts as a source of hydride. There was no reaction in hexane.

Deprotonation of **3** with lithium alkyls under conditions similar to those used for synthesis of the molybdenum and tungsten analogues[1c] gives $Li_2Cr(NBu^t)_4$ (**5**).

Although crystals of **5** suitable for X-ray study could not be obtained, the compound is evidently isostructural with the molybdenum and tungsten analogues[1] and can be formulated as $(Bu^tN)_2Cr(\mu\text{-}NBu^tLi)_4Cr(NBu^t)_2$, as the spectroscopic properties of the three compounds are very similar. Thus the ^1H NMR spectrum of **5** has two singlets (ratio 1 : 3)

at 1.60 and 1.30 ppm corresponding to linear and bent metal–imido groups, respectively (cf. W, 1.67, 1.48; Mo, 1.66, 1.47 ppm). The IR bands for linear and bent groups are at 1230 and 1190 cm^{-1}, respectively.

(3) *Adducts and chloride-substituted compounds from* $Cr(NBu^t)_2Cl_2$

(a) *Adducts.* The pyridine compound, $Cr(NBu^t)_2Cl_2(py)$, was obtained from $Cr(NBu^t)_2(OSiMe_3)_2$ by action of HCl in Et_2O followed by pyridine.[5] Interaction of $Cr(NBu^t)_2Cl_2$ with PMe_2Ph, PMe_3 and Bu^tNC readily gives rise to the corresponding mono-adducts (**6**, **7** and **8**), as expected for addition to the 16-electron Lewis acid (**1**). These adducts are insoluble in toluene but are fairly soluble in THF or in CH_2Cl_2 in which they are non-conductors. There is no evidence even in refluxing THF for transfer of an imido group to the phosphine as occurs for the monoimido tetraphenylporphyrin complex of chromium(IV),[10] where the phosphineimide and chromium(II) porphyrin are obtained. Interaction of **1** with $Ph_2P(CH_2)_2PPh_2$ (dppe) formed a dppe bridged dimer (**9**) which again has five-coordinate chromium(VI). The reluctance to give an octahedral species may be attributed to the strong *trans* influence of the imido ligand[6b] which precludes having a phosphorus atom *trans* to it (cf. similar observations for tungsten imido complexes[11]). However, interaction with 2,2′-bipyridyl (bpy) does give a six-coordinate adduct $Cr(NBu^t)_2Cl_2(bpy)$ (**10**) which can be converted to the cation, $[Cr(NBu^t)_2(bpy)_2]^{2+}$, as discussed below.

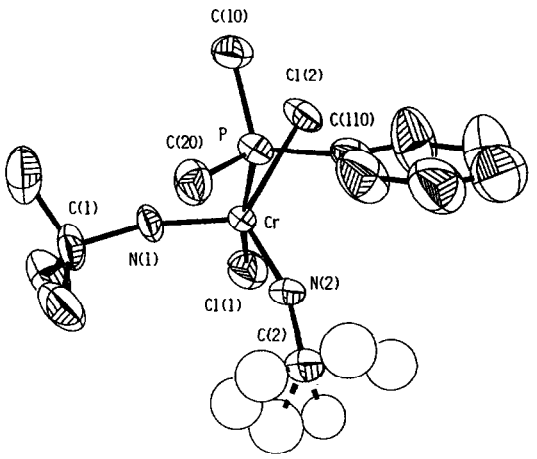


Fig. 1. The structure of $Cr(NBu^t)_2Cl_2(PMe_2Ph)$.

The structure of $Cr(NBu^t)_2Cl_2(PMe_2Ph)$ has been determined by X-ray crystallography.

A diagram of the molecule is shown in Fig. 1 and selected bond lengths and angles are given in Table 2. The geometry is quite clearly best described as trigonal bipyramidal, with the phosphine and one chlorine occupying the axial sites. The Cr—Cl_{ax} and Cr—Cl_{eq} distances are very similar, reflecting the lack of any *d* electrons and Cr—P π-bonding. One surprising feature is that in the equator, the N—Cr—N angle is the smallest, whereas repulsions between the electron density in the imido bonds might be expected to require enlargement of this. A similar feature has been found in the trigonal

bipyramidal $Re(NBu^t)_2Cl_3$.[2] The Cr–imido functions have normal geometries with short Cr—N bonds (1.635 Å) and slight bends of *ca* 14° in the Cr—N—C group. Both imido groups are required to act as 4e donors to provide an 18e configuration at chromium.

(b) *Chloride substitution reactions.* Some of these have been noted above. Interaction of **1** with silver acetate gives $Cr(NBu^t)_2(\eta^1\text{-}O_2CMe)_2$ (**11**) as a low melting solid, readily soluble in organic solvents. The η^1-coordination is in accord with both IR and NMR data.

Interaction of **1** with silver trifluoromethanesulphonate (AgOTf) in acetonitrile removes Cl^- as AgCl and the adduct $Cr(NBu^t)_2(MeCN)_n(OTf)_2$ is obtained, but only as an orange oil that has not crystallized; addition of pyridine or PMe_3 allows isolation of the respective crystalline products, **12**, **13**. In the latter case the analysis corresponds to $[Cr(NBu^t)_2(PMe_3)_2](OTf)_2 \cdot 0.5MeCN$ (**13**) and the presence of MeCN was also confirmed by IR and ^1H NMR spectra. From spectroscopic data the pyridine complex (**12**) is clearly $[Cr(NBu^t)_2py_2(\eta^1\text{-}OTf)](OTf)$, with one η^1-triflate bound to five-coordinate chromium(VI); in MeCN at 25°C the molar conductivity (183 Ω^{-1} cm^2 mol^{-1}) is somewhat higher than usual for a 1 : 1 electrolyte which suggests some dissociation of coordinated triflate in dilute solution. The X-ray structure of the salt is shown in Fig. 2 and bond lengths and angles are given in Table 3.

The geometry of the cation is again suitably described as trigonal bipyramidal, this time with the axial sites occupied by the pyridine donors. The distribution of ligands in the equator reflects that found in the dichloro complex described above,

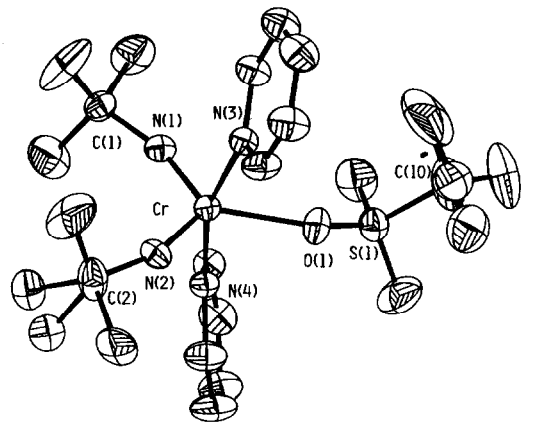

Fig. 2. The structure of the cation in $[Cr(NBu^t)_2(C_5H_4N)_2(\eta^1\text{-}O_3SCF_3)]CF_3SO_3$.

with the smallest angle between the two imido bonds. The Cr—N—C groups are again slightly bent, with angles of *ca* 163°, although normal Cr≡NR interactions are again required to provide an 18e configuration for chromium. It may be noted that a similar tungsten compound $W(NBu^t)_2(NH_2Bu^t)_2(\eta^1\text{-}OTf)_2$ is octahedral with *cis*-η^1-O_3SCF_3 groups.[1b,c]

Interaction of $Cr(NBu^t)_2Cl_2(bpy)$ (**10**) with AgOTf and additional bpy in MeCN leads to the cation $[Cr(NBu^t)_2(bpy)_2]^{2+}$ that can be precipitated as its PF_6^- salt (**14**), which is sparingly soluble in THF and CH_2Cl_2 but very soluble in MeCN in which Λ_M = 250 Ω^{-1} cm^2 mol^{-1} (1 : 2 electrolyte). The solid salt is unaffected by water, methanol or dilute normal acids. The *cis* geometry for the two NBu^t ligands in the octahedral complex is suggested

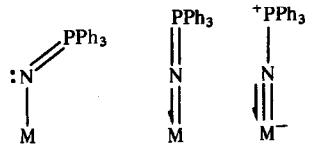
by two types of C_5H_4N rings of the bpy ligands (two N atoms *trans* to NBu^t) according to the NMR data.

The isocyanide complex, $Cr(NBu^t)_2Cl_2(CNBu^t)$ (**8**), was treated with MeLi in diethyl ether in the expectation that nucleophilic attack might lead to a carbene complex. However, the product was the η^2-iminoacyl complex, $[Cr(NBu^t)_2(\eta^2\text{-}Bu^tN{=}CMe)Cl]$ (**15**), that was characterized spectroscopically. A related iminoacyl,[4] characterized crystallographically, was obtained by transfer of a mesityl group in $Cr(NBu^t)_2(mes)_2$ to the carbon atom of Bu^tNC in an "insertion" reaction. The present complex is presumably formed by methyl transfer to the isocyanide carbon atom in an intermediate $Cr(NBu^t)_2Cl(Me)(CNBu^t)$. The IR spectrum has a characteristic $\nu(C{=}N)$ stretch at 1760 cm^{-1} (cf. refs 2 and 4).

The interaction of $Cr(NBu^t)_2Cl_2$ with two equivalents of $LiN{=}PPh_3$ in toluene gives the bisphosphineiminato compound, $Cr(NBu^t)_2(NPPh_3)_2$ (**16**). Although phosphineiminato complexes are well established,[12] the use of $LiNPPh_3$ as a phosphineiminato transfer agent is not common. From the three resonance forms possible for the metal–ligand system, viz.



(I) **(II)** **(III)**

We consider that form **I** contributes more in the present case in view of the IR absorption (1075 cm^{-1}) at the lower limit of the ν(P—N) region, 1050–1200 cm^{-1}.[12]

Complex **16**, although it reacts with high oxidation state oxo compounds like CrO_2Cl_2, $CrO_2(OSiMe_3)_2$, OsO_4 or $MoO_2(S_2CNEt_2)_2$, does not form a nitrido-bridged dimer with elimination of Ph_3PO; such a reaction occurs with free phosphine imines and the oxo species, OsO_4 and OsO_3NBu^t.[13]

(4) *Reduction reactions of* $Cr(NBu^t)_2Cl_2$

The dialkyls[5] such as the neopentyl were obtained by alkylation of $Cr(NBu^t)_2(py)Br_2$ and the authors state that "The choice of alkylating agent is clearly critical in order to prevent reduction". We had independently shown that $Cr(NBu^t)_2Cl_2$ at 0–5°C in diethyl ether with $LiCH_2CMe_3$ and $LiCH_2SiMe_3$ gives the dialkyls identical to those described.[5] However, we find additionally that at low temperatures the diamagnetic chromium(V) dimer, $[(Bu^tN)ClCr(\mu\text{-}NBu^t)]_2$ (**17**), only is obtained; the same product is obtained by reaction of **1** with LiC_5Me_5. An oxo analogue of this imido species is not known. It seems reasonable to assume that reduction (with Li or Mg alkyls acting as one-electron reductants) and alkylation, are competing reactions, with substitution being kinetically favoured, while the thermodynamically preferred product is **17**. (cf. The similar rhenium(VI) compound[2].)

The confirmation of a one-electron reduction process is shown by the reaction of **1** with $(\eta^5\text{-}C_5H_5)_2Co$ [eq. (3)]:

$$2Cr(NBu^t)_2Cl_2 + 2Cp_2Co = 2Cp_2Co^+Cl^- + [Cl(NBu^t)Cr(\mu\text{-}NBu^t)]_2. \quad (3)$$

So far, attempts to reduce $Cr(NBu^t)_2Cl_2$ in the presence of various O, N and P donors, alkenes, etc., by use of Na/Hg or Mg, have given only brown intractable products.

The dimer **17** reacts with $LiNHBu^t$ in diethyl ether to give the first imido amido complex of chromium(V), namely $[Cr(NBu^t)(NHBu^t)(\mu\text{-}NBu^t)]_2$ (**18**); the high solubility of the compound in hexane, even at −78°C, makes isolation in high yields difficult. The ^1H NMR spectrum of the diamagnetic compound consists of six singlets, which on close examination are found to comprise two sets of three singlets. A similar spectrum has been observed for the isoelectronic vanadium analogue,[14] $[V(NBu^t)(NHBu^t)(\mu\text{-}NBu^t)]_2$, which is also highly petroleum soluble. The spectra probably result from the double bond character of the $Cr{=}NHBu^t$ bond which restricts rotation about the Cr—N bond,[15] giving two sets of isomers.

We have been unable to obtain X-ray quality crystals of compounds **17** and **18** due to twinning. However, the structures with bridged NBu^t groups are well established by IR and NMR spectra. The chromium(V) atom is thus four-coordinate in both cases and there could be a metal–metal interaction, although this seems unlikely. The diamagnetism of the compounds is presumably due to superexchange interaction of unpaired electron density on each metal atom via the imido bridge. The situation is thus similar to that found for the rhenium(VI) compound, $[(Bu^tN)_2(\mu\text{-}Bu^tN)Re]_2$, which has been characterized by X-ray diffraction.[2]

EXPERIMENTAL

Experimental procedures and instrumentation have been described.[2,16] The following starting materials were prepared by literature methods:

$Cr(NBu^t)_2(OSiMe_3)_2$,[6a] $Zn(CH_2CMe_3)_2$[17] and $(C_6H_5)_3P{=}NH$,[18] $LiNHBu^t$ was prepared by interaction of Bu^tNH_2 with Bu^nLi in hexane at −78°C and $LiNBu^t(SiMe_3)\cdot Et_2O$ by deprotonation of $Bu^tNHSiMe_3$ with LiMe in Et_2O. In mass spectra (EI at 70 eV) all *m/e* values show appropriate isotopic envelopes due to chromium isotopes. NMR data are in ppm relative to Me_4Si in C_6D_6 unless otherwise stated; ^{31}P spectra are referenced to external H_3PO_4. IR data are in cm^{-1} in Nujol mulls unless otherwise stated.

(1) *Bis(t-butylimido)dichlorochromium*(VI) (**1**)

To a solution of $Cr(NBu^t)_2(OSiMe_3)_2$ (6.0 g, 0.016 mol) in CH_2Cl_2 (60 cm^3) at 0°C was added dropwise with stirring over 5 min a solution of BCl_3 in hexane (32 cm^3 of 1M solution; 0.032 mol). The solution becomes slightly darker in colour and after addition of BCl_3 was allowed to warm to room temperature and stirred for 2 h. Longer reaction times depress the yield. Volatiles were recovered in vacuum leaving an oily residue which after *ca* 1 h in vacuum solidifies. The solid was extracted with hot hexane until the extracts were colourless (*ca* 4×50 cm^3); removal of solvent left a red residue which was sublimed (80–100°C/0.01 mm Hg) to a cold probe. Yield 55–65%.

MS: 264(M^+); 249(M^+-Me); 233(M^+-MeNH_2). NMR ^1H: 1.14s; ($CDCl_3$) 1.60 s; $^{13}C\{^1H\}$ ($CDCl_3$): 30.4, $C(CH_3)_3$; 82.5 $C(Me_3)$. IR: 1258 (NBu^t); 358 (CrCl).

(2) *Bis(t-butylimido)(t-butylamido)chlorochromium* (VI) (**2**)

Method A. A solution of **1** (1.0 g, 3.8 mmol) and $Bu^tNH(SiMe_3)$ (1.45 g, 10 mmol) in hexane (30 cm^3) was refluxed (*ca* 12 h) when the colour changed from dark red to orange–red. After removal of volatiles in vacuum the orange solid was crystallized from hot hexane. Yield: 0.75 g (66%).

Method B. To **1** (0.5 g, 1.9 mmol) in hexane (10 cm^3) was added Bu^tNH_2 (2 cm^3) and the solution refluxed for 8 h. Work-up as above gave 0.2 g (35%) of product, spectroscopically identical with that prepared as above. MS: 301 (M^+); 286 (M^+-Me); 271 (M^+-2Me); 230 (M^+-NBu^t). NMR ^1H: 1.30 [s, 18H, $NC(CH_3)_3$]; 1.21 [s, 9H, $NHC(CH_3)_3$]. IR: 3250 (NH), 1202 (NBu^t), 358 (CrCl).

(3) *Bis(t-butylimido)bis(t-butylamido)chromium*(VI) (**3**)

A toluene (20 cm^3) solution of **1** (0.5 g, 1.89 mmol) at −78°C was added via a cannula to a cold (−78°C) solution of $LiNHBu^t$ (0.3 g, 3.77 mmol) in toluene (20 cm^3) over *ca* 10 min and the mixture allowed to warm over 12 h, during which time the colour changed from orange–red to dark purple. The volatiles were removed and the residue extracted with hexane (3×20 cm^3); the filtered extracts were evaporated and the residue sublimed (80°C/0.05 mm Hg) to give a red–purple crystalline solid. Yield: 0.25 g (40%).

MS: 338 (M^+); 323 (M^+-Me); 308 (M^+-2Me). NMR ^1H: 1.39 [s, 18H, $NHBu^t$]; 1.35 [s, 18H, (NBu^t)].

(4) *Bis(t-butylimido)[t-butyl(trimethylsilyl)amido] chlorochromium* (**4**)

To **1** (0.3 g, 1.13 mmol) in toluene (30 cm^3) at −78°C was added dropwise via a cannula, a solution of $LiNBu^t(SiMe_3)\cdot Et_2O$ (0.26 g, 1.13 mmol) in toluene (20 cm^3) and the mixture allowed to warm to room temperature with stirring (12 h). Removal of volatiles and extraction of the residue with hexane (2×20 cm^3), filtration and evaporation of the solution left a red–purple solid which was sublimed (100°C/0.05 mm Hg). Yield: 0.18 g (*ca* 45%).

NMR ^1H ($CDCl_3$): 1.60 {s, 9H, $N(SiMe_3)[C(CH_3)_3]$}; 1.54 [s, 18H, $NC(CH_3)_3$]; 0.51 [s, 9H, $SiMe_3$].

(5) *Dilithium tetrakis(t-butylimido)chromate*(VI) (**5**)

To a solution of $Cr(NBu^t)_2(NHBu^t)_2$ (0.3 g, 0.9 mmol) in hexane–ether (3 : 1, 20 cm^3) at −78°C was added dropwise a solution of Bu^nLi (0.65 cm^3 of a 2.68 M solution). After stirring for 10 min at −78°C the mixture was allowed to warm (1 h) and then was heated (30°C, 0.5 h), after which volatiles were removed and the residue extracted with hexane (3×10 cm^3); concentration (5 cm^3) and cooling (−20°C, 2 days) gave red crystals which could be recrystallized from Et_2O. Yield: 0.03 g (*ca* 10%).

IR: 1224 (linear $CrNBu^t$); 1184 (bent $CrNBu^t$). NMR ^1H: 1.30 [s, 27H, (bent imido)]; 1.60 [s, 9H (linear imido)]. In $CDCl_3$ values are 1.40 and 1.56.

(6) *Bis(t-butylimido)(dimethylphenylphosphine)dichlorochromium*(VI) (**6**)

To a solution of **1** (0.2 g, 0.75 mmol) in toluene (10 cm^3) was added PMe_2Ph (0.1 cm^3, 1.5 mmol). The resulting mixture was stirred at room temperature for 3 h. The yellow precipitate was collected, washed with hexane and recrystallized from THF at −20°C. Yield: 0.13 g (52%).

NMR ^1H ($CDCl_3$): 1.52 (s, 18H, NBu^t); 2.08 (6H,

d, PMe_2, $^3J_{P-H}$ = 11.95 Hz) and aromatic protons; $^{31}P-\{^1H\}$ ($CDCl_3$): 30.67.

(7) *Bis(t-butylimido)(trimethylphosphine)dichlorochromium*(VI) (**7**)

This was prepared as for **6** from **1** (0.2 g, 0.75 mmol) and PMe_3 (0.075 cm^3) in toluene. Recrystallization from THF at −20°C afforded a yellow microcrystalline solid. Yield: 0.14 g (60%).

NMR ^1H ($CDCl_3$): 1.54 (s, 18H, NBu^t); 1.83 (d, 9H, P*Me*$_3$); $^{31}P-\{^1H\}$ ($CDCl_3$): 28.72.

(8) *Bis(t-butylimido)(t-butylisocyanide)dichlorochromium*(VI) (**8**)

This was prepared as for **6** from **1** (0.2 g, 0.75 mmol) and Bu^tNC (0.1 cm^3) in toluene. Recrystallization from THF–hexane at −20°C gave an orange microcrystalline solid. Yield: 0.12 g (45%).

IR (Nujol and KBr disk): 2237 (NC).

(9) *Bis(t-butylimido)[μ-bis(diphenylphosphino)ethane]tetrachlorodichromium*(VI) (**9**)

This was prepared as for **6** from **1** (0.2 g, 0.75 mmol) and dppe (0.3 g, 0.75 mmol) in toluene. Recrystallization from CH_2Cl_2–hexane gave a yellow microcrystalline solid. Yield: 0.2 g (40%).

NMR ^1H (CD_2Cl_2): 1.32 (s, 36H, NBu^t); 3.38 (m, 4H, *CH*$_2$PPh$_2$); $^{31}P-\{^1H\}$ (CD_2Cl_2): 50.53.

(10) *Bis(t-butylimido)(2,2′-bipyridyl)dichlorochromium*(VI) (**10**)

As for **6** but from **1** (0.29, 0.75 mmol) and 2,2′-bipyridine (0.12 g, 0.75 mmol) in toluene (20 cm^3). Yield: 0.23 g, (75%).

NMR ^1H ($CDCl_3$): 1.62 (s, 18H, NBu^t) and aromatic protons.

(11) *Bis(t-butylimido)di-η^1-acetatochromium*(VI) (**11**)

To a well-stirred suspension of Ag(OAc) (0.25 g, 1.5 mmol) in toluene (10 cm^3) was added $Cr(NBu^t)_2Cl_2$ (0.29, 0.75 mmol) in toluene (10 cm^3). The resulting mixture was stirred at room temperature overnight and filtered. The orange filtrate was evaporated to dryness and the residue extracted with hexane (10 cm^3) which was concentrated (to *ca* 5 cm^3) and cooled at −78°C to give bright orange crystals. Yield: 0.15 g (64%).

MS: 253 ($M^+ - CH_3CO_2$). IR: 1666, 1525, (CO_2). NMR ^1H ($CDCl_3$): 1.55 (s, 18H, Bu^t); 2.15 (s, 6H, C*H*$_3$CO$_2$).

(12) *Bis(t-butylimido)bis(pyridine)-η^1-O-trifluoromethylsulphonatochromium*(VI) (*trifluoromethylsulphonate*) (**12**)

To a solution of **1** (0.2 g, 0.75 mmol) in MeCN (10 cm^3) was added AgOTf (0.4 g, 1.5 mmol) in MeCN (10 cm^3). The mixture was stirred at room temperature for 1 h, filtered, and the orange filtrate evaporated. The residue was extracted with CH_2Cl_2 (20 cm^3), then pyridine (0.13 cm^3, 1.5 mmol) was added and the solution stirred for 3 h at room temperature. On reduction of volume (to *ca* 5 cm^3), excess of Et_2O (25 cm^3) was added; the orange precipitate was collected, washed with Et_2O (2 × 5 cm), and recrystallized from CH_2Cl_2–Et_2O. Yield: 0.34 g (73%).

NMR ^1H (CD_3CN): 1.66 (s, 18H, NBu^t) and aromatic protons.

(13) *Bis(t-butylimido)bis(trimethylphosphine)chromium*(VI) *bis(trifluoromethylsulphonate)*(0.5 *acetonitrile*) (**13**)

This was prepared as for **12** from **1** (0.2 g, 0.75 mmol), Ag(OTf) (0.4 g, 1.5 mmol) and PMe_3 (0.15 cm, 1.5 mmol). Yield: 0.2 g (40%). Λ_M (MeCN 25°C): 200 Ω^{-1} cm^2 mol^{-1}.

NMR ^1H (CD_2Cl_2): 1.61 (s, 18H, NBu^t); 1.92 (d, 18H, $^3J_{P-H}$ = 12 Hz; PMe_3). $^{31}P-\{^1H\}$ (CD_2Cl_2): 31.80.

(14) *Bis(t-butylimido)bis(2,2′-bipyridine)chromium*(VI)*bis(hexafluorophosphate)* (**14**)

To a solution of $Cr(NBu^t)_2Cl_2$(bpy) (0.55 g, 1.3 mmol) in MeCN (10 cm^3) was added 2 equivalents of Ag(OTf) (0.66 g, 2.6 mmol) in MeCN (10 cm^3). The solution was stirred at room temperature for 1 h, filtered and to the filtrate was added another equivalent of bpy (0.2 g). After stirring for an additional 6 h the solution was reduced in volume (5 cm^3) and a saturated methanolic solution of $[Bu^n{}_4N]PF_6$ added. The dark purple precipitate was collected, washed with THF and Et_2O, and recrystallized from MeCN–Et_2O. Yield: 0.4 g (39%).

NMR ^1H (CD_3CN): 1.45 (s, 19H, NBu^t) and aromatic protons.

(15) *Bis(t-butylimido)[η^2-methyl(t-butylimino)methyl]chromium*(VI) (**15**)

To a suspension of the isocyanide adduct (**8**) (0.3 g, 1 mmol) in Et_2O (20 cm^3) at −78°C was added MeLi (3 cm^3, 0.33 M in Et_2O) and the mixture slowly warmed to room temperature. After stirring

overnight the solution was filtered, evaporated to dryness and the residue extracted with hexane ($2 \times 10\ cm^3$). This extract was concentrated (to *ca* 10 cm^3) and cooled at $-20°C$ to give yellow crystals. Yield: 0.15 g (49%).

IR: 1760 (CN). NMR ^1H (C_6D_6): 1.30 (s, 18H, NBu^t); 1.35 (s, 9H, $C{=}NBu^t$); 2.30 (s, 3H, $Me{-}C{=}N$).

(16) *Bis(t-butylimido)bis(triphenylphosphineimino) chromium*(VI) (**16**)

A solution of **1** (0.25 g, 9.5 mmol) in toluene (10 cm^3) was added to a suspension of $LiNPPh_3$ (0.54 g, 1.9 mmol) in toluene (20 cm^3) at $-78°C$. The solution was stirred and allowed to warm overnight; filtration and evaporation of the filtrate gave a residue that was crystallized from Et_2O as dark red needles. Yield: 0.3 g (42%).

IR: 1194 (Bu^tN); 1075 (N=P); 712, 694, aromatic CH bands. NMR ^1H ($CDCl_3$): 1.28 (s, 18H, $NCMe_3$); 7.1, 8.05 (m, 30H, aromatic). $^{31}P\{^1H\}$: 8.93.

(17) *Bis[t-butylimido(chloro)(μ-t-butylimido)]dichromium*(V) (**17**)

Method A. To $Cr(NBu^t)_2Cl_2$ (0.2 g, 0.75 mmol) in toluene (20 cm^3) at $-78°C$ was added dineopentylzinc (0.5 g, 2.5 mmol), when the colour changed from red to orange–yellow. After warming with stirring (2 h), volatiles were removed and the residue extracted with hexane ($3 \times 5\ cm^3$); filtration, concentration and cooling ($-20°C$) gave green–yellow crystals. Yield: 0.06 g (*ca* 35%) based on Cr.

Method B. To a solution of $Cr(NBu^t)_2Cl_2$ (0.2 g, 0.75 mmol) in toluene (10 cm^3) was added $(C_5H_5)_2Co$ (0.15 g, 0.75 mmol) in toluene (10 cm^3). After stirring for *ca* 12 h, the solution was filtered from $(C_5H_5)_2CoCl$ and worked-up as above. Yield: 0.05 g (30%).

MS: 458 (M^+); 443 ($M^+ - Me$); 402 ($M^+ - iso$-

X-ray crystallography

Crystals of both compounds were sealed under argon in glass capillaries. Unit cell and intensity data were obtained using standard procedures on a CAD4 diffractometer. Experimental details are given in Table 4. The structures were solved and developed via the heavy atom method and refined by full-matrix least-squares. Both crystals showed large and variable mosaic spread, indicating lower than preferred crystal quality, and structure refinement was hampered by disorder. Details are given in Table 4. Lists of final coordinates, displacement factor coefficients, bond lengths and angles, together with F_o/F_c values have been deposited as supplementary data with the Editor. Coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

(*Received* 30 *March* 1990; *accepted* 11 *July* 1990)

Abstract—X-ray structure analysis of the complexes $[Ir_2(CO)_2(C_6H_5)(CNC(CH_3)_3)(RC_2R)((C_6H_5)_2PCH_2P(C_6H_5)_2)_2]B(C_6H_5)_4$ (**1**) and $[Rh_2Cl_2(CO)_2(RC_2R)((C_6H_5)_2PC_5H_4N)_2]$ (**2**) ($R = CO_2CH_3$) shows that both contain the RC_2R moiety bound as a dimetallated olefin. The metal–metal separations [**1**: 2.8987(4) Å, **2**: 2.6528(5) Å] indicate that significant metal–metal interaction is present. The results provide confirmation of the presence of a σ-bonded (to iridium) phenyl group in **1**. In both complexes the carbonyl ligands are *trans* to the dimetallated olefin. Complex **1** is monoclinic, $P2_1/n$, $a = 19.901(5)$, $b = 19.416(4)$, $c = 24.138(8)$ Å, $\beta = 100.82(2)°$, $Z = 4$, 6812 reflections [$I \geqslant 3\sigma(I)$], $R = 0.048$, $R_w = 0.066$. Complex **2** is monoclinic, Cc, $a = 20.808(2)$, $b = 12.368(2)$, $c = 20.514(2)$ Å, $\beta = 111.446(8)°$, $Z = 4$, 3361 reflections [$I \geqslant 3\sigma(I)$], $R = 0.038$, $R_w = 0.053$.

In a recent publication[1] we reported that the attempted thermal decarbonylation of $[Ir_2(CO)_3Cl(\mu\text{-}RC_2R)(DPPM)_2]BPh_4$ ($R = CO_2Me$, DPPM = $Ph_2PCH_2PPh_2$) in refluxing THF formed $[Ir_2Cl_2(CO)_2(RC_2R)(DPPM)_2]$ and what was suggested to be $[Ir_2(CO)_2(Ph)(RC_2R)(DPPM)_2]BPh_4$ (**3**) in approximately equal amounts. The latter was proposed to derive from attack of an iridium species on the tetraphenylborate ion. In related work, $[Rh_2Cl_2(\mu\text{-}RC_2R)(Ph_2PC_5H_4N)_2]$ (**4**) ($R = CO_2Me$) has been reported[2] to reversibly add carbon monoxide to form a dicarbonyl adduct. We now report determination of the structures of the more stable *tert*-butylisocyanide adduct of **3** (**1**) and of the carbonyl adduct of **4** (**2**) which confirm the previously proposed compositions.

EXPERIMENTAL

The complex $[Ir_2(CO)_2(Ph)(CNC(CH_3)_3)(RC_2R)(DPPM)_2]BPh_4$ (**1**) ($R = CO_2Me$), prepared as previously described,[1] was crystallized by the slow diffusion of hexane and diethyl ether into an acetone solution. A pale yellow needle was wedged into a thin-walled glass capillary containing the mother liquor to retard loss of solvent of crystallization and the capillary was sealed with epoxy cement. Bright orange crystals of **2** were obtained from the slow diffusion of toluene into a CO-saturated 1,2-dichloroethane solution of the complex, prepared *in situ* from $[Rh_2Cl_2(\mu\text{-}RC_2R)(Ph_2PC_5H_4N)_2]$ ($R = CO_2CH_3$)[2] and carbon monoxide. An irregular crystal was secured with epoxy cement in the end of a thin-walled glass capillary containing the mother liquor to retard solvent loss. Intensity data were collected at room temperature on an Enraf–Nonius CAD-4 diffractometer. General procedures for the data collection and refinement have been published,[3] while details specific to the present study appear in Table 1.

Least-squares refinement of 25 reflections ($16.03 \leqslant \theta \leqslant 20.95$ for **1**; $19.94 \leqslant \theta \leqslant 24.65$ for **2**) accurately centred on the diffractometer provided final unit cell parameters. Systematic absences observed in the data collection uniquely determined the space group for **1**, while for **2** either Cc or $C2/c$ was indicated. The choice of Cc was suggested by a density measurement and confirmed

[a] The weighting scheme for the final refinement was $w = 1/(\sigma_F)^2$, where $\sigma_F = \sigma_{F^2}/2F$ and $\sigma_{F^2} = [(\sigma_I)^2 + (pF^2)^2]^{1/2}$.
[b] $R = \Sigma ||F_o| - |F_c|| / \Sigma F_o$.
[c] $R_w = [w(F_o - |F_c|)^2 / \Sigma w(F_o)^2]^{1/2}$.
[d] $GOF = [\Sigma w(F_o - |F_c|)^2 / (N_o - N_v)]^{1/2}$ (N_o, N_v are number of observations and variables, respectively).

by the successful refinement. Both data sets were corrected for an approximately linear decay (**1**: 12.3%; **2**: 0.8%) in the intensity monitors. An empirical absorption correction (ψ scans for six reflections, $83 \leqslant \chi \leqslant 89°$) was also applied for **1**, but not for **2** because of the inaccessibility of suitable reflections. Solution was by direct methods and refinement by full-matrix least-squares (Enraf–Nonius, SDP software package) with hydrogen atoms included as fixed contributions (C—H = 0.95 Å, isotropic thermal parameters 1.3 times that of attached carbon) riding on attached carbon atoms. Solvent of crystallization was found in both crystals. The acetone in **1** was given an occupancy of 0.4 based on a trial refinement of the occupancy factors of the constituent atoms. For **2**, two molecules of 1,2-dichloroethane were found. In the ensuing refinement of **2** the solvent molecules were not well-behaved and the phenyl groups showed very irregular geometries. A degree of disorder was indicated for the solvent by difference maps but could not be resolved. Therefore the refinement was completed employing a restrained refinement[4,5] of the solvent molecules and phenyl groups alternating with normal refinement of the remaining non-hydrogen atoms. The solvent molecules and phenyl rings were closely restrained (±0.02 Å), respectively, to the observed geometry[6] and to planar hexagons (C—C = 1.390 Å). The final difference maps for both structures were essentially featureless. Final crystallographic data have been deposited with the Editor as supplementary material.

DISCUSSION

The crystal structure of **1** consists of well-separated $[Ir_2(CO)_2(C_6H_5)(CNC(CH_3)_3)(\mu\text{-DMAD})(DPPM)_2]^+$ (DMAD = $C_2(CO_2Me)_2$) cations, tetraphenylborate anions and solvent acetone

molecules. A perspective view of the inner coordination sphere of the cation is shown in Fig. 1. The salient feature of the cation is the presence of a phenyl group bonded to iridium, confirming the composition proposed from analytical and spectroscopic data.[1] Pertinent bond distances and interbond angles appear in Table 2, from which it is evident that the coordination about each metal is roughly octahedral with the major distortion resulting from the bonding constraints of the acetylenic ligand. This moiety is clearly bound as a dimetallated olefin, as evidenced by the C(3)—C(4) distance of 1.32(1) Å and the approximately trigonal planar environment about these atoms. The Ir(1)—C(3) and Ir(2)—C(4) distances are slightly different but this is probably not significant. They are significantly longer than those in the precursor $[Ir_2(CO)_3Cl(\mu\text{-DMAD})(DPPM)_2]^+$ (**5**) [2.055(5), 2.077(5) Å][1] but compare favorably with the longer Ir—C distance [2.133(6) Å] found in $[Ir_2Cl_2(CO)_2(\mu\text{-DMAD})(DPPM)_2]$ (**6**)[7] and therefore, are not considered to be unusually long. The Ir(1)—Ir(2) distance of 2.8987(4) Å is somewhat longer than that in **5** [2.8933(2) Å], which likely reflects a greater *trans* influence of the axial phenyl group in **1** as compared to the carbonyl group in **5**. Nevertheless, it is significantly shorter than the intraligand P---P distances [P(1)---P(4) = 3.030(3), P(2)---P(3) = 3.005(3) Å], indicating an attractive interaction between the metal atoms. Although the metal–metal distances in **1** and **5** are rather long for an Ir—Ir bond [c.f. Ir—Ir = 2.7793(3) Å in **6**], significant metal–metal interaction is required to accomodate the observed diamagnetism and the longer distances observed for the former two compared with that in **6** are probably the result of their cationic nature.

Many of the other structural features of **1** can be attributed to steric factors. Thus the plane of the phenyl group on Ir(I) is twisted by only *ca* 7° from the mean equatorial plane. This phenyl ring is substantially sandwiched between those built on C(111) and C(211) and makes close contacts with two *ortho*-hydrogens [C(12)---H(112) = 2.90, C(16)---H(212) = 2.89 Å], which effectively prevent it from assuming another orientation. While all the Ir—P distances are within the range previously found in **5** and **6**, the more typical value for DPPM-bridged di-iridium complexes is 2.32–2.33 Å.[8-10] The longer values seen for Ir(1)—P(2) and Ir(2)—P(4) are probably the result of the contacts H(226)---C(12) (2.67 Å) and H(426)---C(17) (2.82 Å) which involve a phenyl group on each of these phosphorus atoms. These contacts also account for the departure of the axial ligands (phenyl and isocyanide) from collinearity with the metal–metal bond. Both bend towards the DMAD moiety. Finally, as has been noted in **5** and **6**, there is a twist of the two sides of the cation about the Ir—Ir axis of 6.4°.

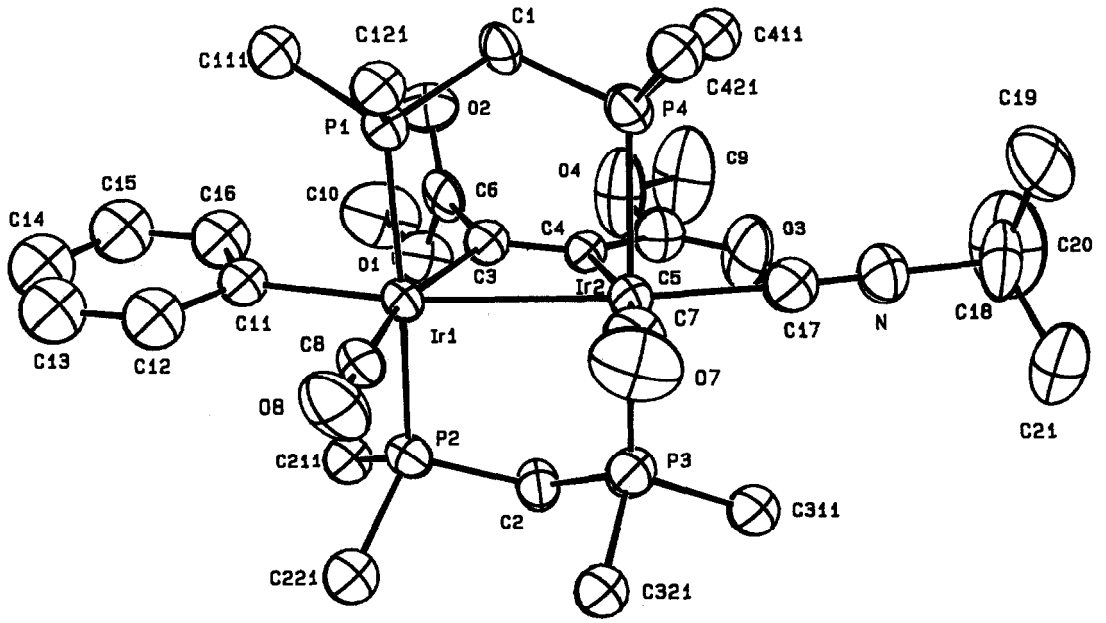

Fig. 1. A perspective view of the inner coordination sphere of the $[Ir_2(CO)_2(C_6H_5)(CNC(CH_3)_3)(\mu\text{-}H_3CO_2CC{=}CCO_2CH_3)((C_6H_5)_2PCH_2P(C_6H_5)_2)_2]^+$ cation (**1**). Thermal ellipsoids are shown at the 50% level and only the *ipso*-carbon atoms of the ligand phenyl rings are shown.

The crystal structure of **2** consists of well-separated $[Rh_2Cl_2(CO)_2(\mu\text{-DMAD})(Ph_2PC_5H_4N)_2]$ molecules and two independent, partially disordered solvent 1,2-dichloroethane molecules. A perspective view of the inner coordination sphere is shown in Fig. 2, while pertinent bond distances and interbond angles appear in Table 3. Again, it is clear from these data that the DMAD moiety is bound as a dimetallated olefin. The Rh(1)—C(17) and Rh(2)—C(11) distances are significantly different but there does not appear to be any obvious reason for this. The former, however, compares well with those found previously in $[(\eta^5\text{-}C_5H_5)Rh(\mu\text{-DMAD})(\mu\text{-}Ph_2PC_5H_4N)Rh(CO)(\mu\text{-Cl})]_2$ (**7**).[11] The Rh(1)—Rh(2) distance of 2.6528(1) Å is midway between the corresponding distances found in **7** [2.661(1) Å] and $[Rh_2Cl_2(CO)_2(NC_5H_4{=}C(CH_3)C_6H_4)_2]$ (**8**) [2.639(2) Å],[12] but is considerably longer than that in $[Rh_2Cl_2(\mu\text{-CO})(Ph_2PC_5H_4N)_2]$ (**9**) [2.612(1) Å].[13] This is not surprising since **2**, **7** and **8** are formally rhodium(II) complexes, while **9** contains rhodium(I). As the metal–metal distance in **2** is significantly less than the intraligand P—N distances [P(1)---N(1) = 2.761(8), P(2)---N(2) = 2.679(8) Å], an attractive interaction is clearly present. The coordination about each metal is approximately octahedral with the primary distortion again being the result of the bonding constraints of the DMAD moiety. The Rh—Cl distances differ only slightly but are significantly longer than the mean value found for **8** [2.464(4) Å]. There does not appear to be an obvious reason for this difference although we note that each chlorine makes a rather close contact with the *ortho*-hydrogen of the adjacent pyridyl group [Cl(1)---H(10) = 2.675, Cl(2)---

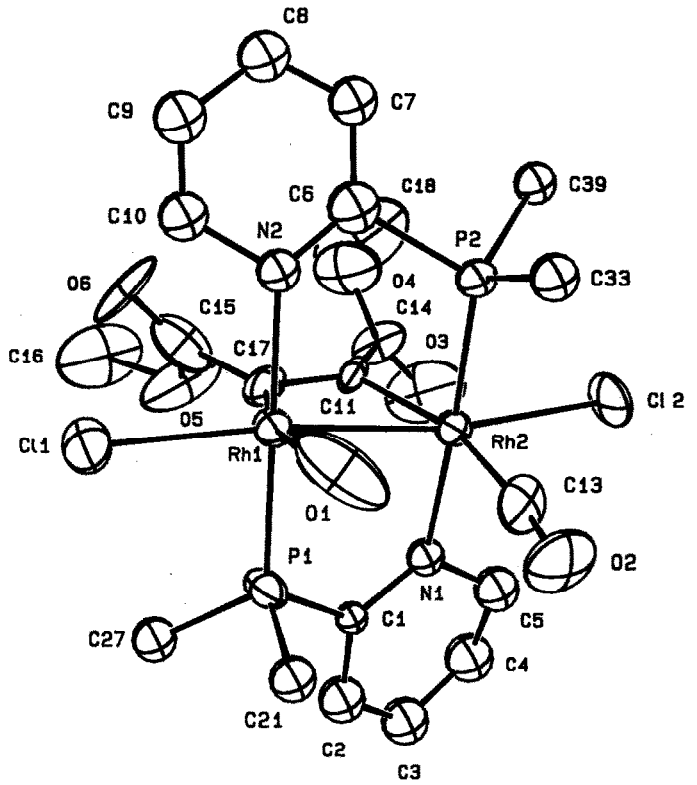

Fig. 2. A perspective view of the inner coordination sphere of $[Rh_2Cl_2(CO)_2(\mu\text{-}H_3CO_2CC{=}CCO_2CH_3)((C_6H_5)_2PC_5H_4N)_2]$ (**2**). Thermal ellipsoids are drawn at the 50% level and only the *ipso*-carbons of the phenyl rings are shown.

Table 3. Bond distances (Å) and interbond angles (°) for $[Rh_2Cl_2(CO)_2(\mu\text{-}H_3CO_2CC{=}CCO_2CH_3)((C_6H_5)_2PC_5H_4N)_2]$ (**2**)

H(5) = 2.537 Å]. It may, therefore, be that the lengthening is due to steric factors and this may also account for the fact that the Rh—Cl bonds are not collinear with the metal–metal axis. The Rh—N distances are significantly shorter than those found in **8** [2.25(1), 2.26(1) Å], consistent with a lower *trans* influence of phosphorus as compared with the σ-bonded phenyl group in **8**. The two sides of the molecule are twisted, with respect to one another, by 14.7°. This is probably largely steric in origin so as to minimize contacts between the phenyl group built on C(39) and the adjacent carbomethoxy group.

The ^{31}P and ^{13}C NMR spectra of **2** were reported to indicate the complex readily exchanges carbon monoxide in solution.[2] The low temperature limiting spectra of freshly prepared **2** indicated the presence of two species, the minor component having a symmetrical ^{31}P spectrum and the major component a spectrum interpreted as the AB portion of an ABXY spin system (X = Y = Rh). The latter was proposed to indicate a structure in which one rhodium had chlorine equatorial and the carbonyl axial, while on the other metal the ligand positions were reversed. The symmetrical spectrum was attributed to a species having the structure found here. The observation that the material isolated by slow crystallization at room temperature in the presence of carbon monoxide is the symmetrical isomer, together with the observed lability of **2** indicates that the latter is presumably the thermodynamically more stable isomer while the unsymmetrical species is formed under kinetic control.

Abstract—Reaction of $FeCl_2$ with one molar equivalent of $[18]aneN_2S_4$ in refluxing MeOH–H_2O for 15 min affords a deep blue solution containing the complex cation $[Fe([18]aneN_2S_4)]^{2+}$. Addition of excess BF_4^- or BPh_4^- counterions gives the complex as a blue solid. A single crystal X-ray structure determination of $[Fe([18]aneN_2S_4)](BPh_4)_2 \cdot 2MeCN \cdot 1/2MeOH$ shows iron(II) bound to all six macrocyclic donor atoms in a distorted octahedral geometry, Fe—N = 2.022(4), 2.037(5), Fe—S = 2.2578(17), 2.2588(16), 2.2673(16), 2.2674(15) Å. The macrocycle binds to give a *rac* configuration with each $SCH_2CH_2NCH_2CH_2S$ linkage bound meridionally to the metal centre. Solutions of $[Fe([18]aneN_2S_4)](BF_4)_2$ show two irreversible, overlapping oxidations at E_{pa} = +0.78 and +0.88 V vs Fc/Fc^+.

We have recently been investigating the coordination chemistry of the potentially hexadentate macrocycles $[18]aneN_2S_4$ (1,4,10,13-tetrathia-7,16-diazacyclooctadecane) and $Me_2[18]aneN_2S_4$ (7,16-dimethyl-1,4,10,13-tetrathia-7,16-diazacyclooctadecane).[1] In the course of this work we have observed that these macrocycles bind readily to transition metal centres, leading to unusual stereochemical and electrochemical properties. Importantly, we have found that $[18]aneN_2S_4$ binds octahedrally to metal centres to give exclusively the *rac* isomer, as originally proposed by Black and McLean.[1,2] As a continuation of these studies we report herein the synthesis and single crystal structure of $[Fe([18]aneN_2S_4)](BPh_4)_2 \cdot 2MeCN \cdot 1/2MeOH$.

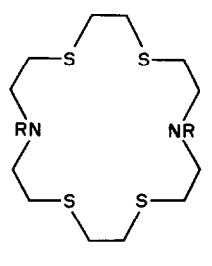
RESULTS AND DISCUSSION

Treatment of $FeCl_2 \cdot 4H_2O$ with one molar equivalent of $[18]aneN_2S_4$ in refluxing MeOH–H_2O (1 : 1 v/v) under N_2 for 15 min affords a deep blue solution. Addition of excess $NaBF_4$ or $NaBPh_4$ yields a blue precipitate, which can be recrystallized



$[18]aneN_2S_4$: R = H
$Me_2[18]aneN_2S_4$: R = Me

Scheme 1.

from MeCN. Prolonged refluxing results in decomposition giving an insoluble orange precipitate.

The IR spectrum of the tetrafluoroborate salt shows peaks at 3240 and 3080 cm^{-1} corresponding to N—H stretching vibrations, ν(N—H), as well as other peaks indicative of the presence of coordinated [18]aneN_2S_4. Peaks at 1050, 535 and 520 cm^{-1} are characteristic of the BF_4^- counterion. The FAB mass spectrum of this product shows molecular ion peaks at $m/z = 469$, 401 and 381, assigned to $[^{56}Fe([18]aneN_2S_4)BF_4]^+$, $[^{56}Fe([18]aneN_2S_4)\cdot H_2O+H]^+$ and $[^{56}Fe([18]aneN_2S_4-H)]^+$, respectively. The ^1H NMR spectrum measured in CD_3NO_2 shows a complex second-order multiplet in the range $\delta = 2.15$–3.85 ppm assigned to the methylene protons of the coordinated macrocycle. The ^{13}C NMR spectrum of the complex, measured in CD_3NO_2 at 298 K, exhibits 12 distinct resonances, indicating the presence of two different isomers in solution in a ratio of roughly 3:2, (δ = 52.26, 51.90, 39.82, 39.46, 33.56 and 32.96 ppm for one isomer; 52.41, 51.80, 38.90, 38.08, 35.46 and 34.94 ppm for the other isomer). These results are consistent with the presence of two alternative forms of the *rac* configuration. These diastereoisomers, **I** and **II**, differ in the relative orientations of the N—H functions (Fig. 1) and each gives rise to six methylene carbon resonances.[3] The UV–vis spectrum of the product shows absorption bands at $\lambda_{max} = 572$ nm ($\varepsilon_{max} = 171$ M^{-1} cm^{-1}), 424 (152) and 344 (103) which are assigned as *d–d* transitions on the basis of the magnitudes of their extinction coefficients and their solvent independence. In addition, there is a much more intense band at 238 nm (19,570) which is assigned tentatively as a S → Fe charge-transfer transition. This evidence, together with microanalytical data, indicates the product to be the low-spin iron(II) species [Fe([18]aneN_2S_4)]$(BF_4)_2$. The corresponding BPh_4^- salt, [Fe([18]aneN_2S_4)]$(BPh_4)_2$, can be prepared by using $NaBPh_4$ in place of $NaBF_4$ in the above synthesis.

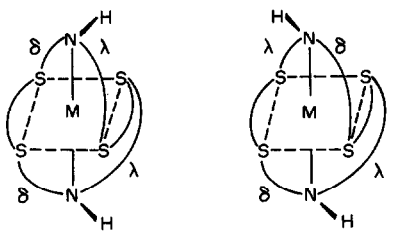


Fig. 1. Isomers **I** and **II** for *rac*-[M([18]aneN_2S_4)]$^{x+}$.

Deep blue, columnar crystals of suitable quality for a single crystal X-ray structure determination were obtained by slow evaporation from a solution of [Fe([18]aneN_2S_4)]$(BPh_4)_2$ in MeCN–EtOH. The structure confirms a *rac* configuration for [Fe([18]aneN_2S_4)]$^{2+}$ (Fig. 2), with all six macrocyclic donor atoms bound to the Fe^{II} centre, Fe—S(1) = 2.2674(15), Fe—S(4) = 2.2673(16), Fe—S(10) = 2.2578(17), Fe—S(13) = 2.2588(16), Fe—N(7) = 2.037(5), Fe—N(16) = 2.022(4) Å. Thus, the two Fe—S bond lengths in one SCH_2CH_2S chain are essentially equal, but different from those in the other SCH_2CH_2S linkage. This is consistent with predictions based on the influence of the N—H functions which give rise to approximate non-crystallographic C_2 symmetry [Fig. 2(b)] and six distinct methylene carbon resonances. Furthermore, the orientations of the two N—H groups confirm that the complex exists as isomer **I** in the crystal selected.[3] The *rac* configuration observed probably reflects the preference for *gauche* torsions at C—S linkages and *anti* torsions at C—N (secondary amine) linkages.[4] There is a small, but significant, tetrahedral distortion of the sulphur-donor atoms out of the least-squares S_4 coordination plane, with S(1) and S(13) lying 0.137 and 0.139 Å, respectively, above the plane, while S(4) and S(10) lie 0.137 and 0.139 Å, respectively, below. The structure also shows that the N—H groups in [Fe([18]aneN_2S_4)]$^{2+}$ participate in strong hydrogen-bonding interactions with the two MeCN molecules: H(7)···N(6S) = 2.079(9) Å, angle N(7)—H(7)···N(6S) = 137.4(5)°, H(7)···N(6S)—C(5S) = 171.1(7)°; H(16)···N(3S) = 2.078(9) Å, angle N(16)—H(16)···N(3S) = 139.4(4)°, H(16)···N(3S)—C(2S) = 166.5(7)°.

Cyclic voltammetry of [Fe([18]aneN_2S_4)]$(BF_4)_2$, measured in MeCN (0.1 M $^nBu_4NBF_4$ supporting electrolyte) at platinum electrodes, shows two overlapping, irreversible oxidations at $E_{pa} = +0.78$ and +0.88 V vs Fc/Fc^+, assigned tentatively to Fe^{II}/Fe^{III} couples for the two *rac* isomers. The irreversibility may be due to deprotonation of the oxidation product. The Fe^{II}/Fe^{III} couple for the related low-spin, bis-trithia and bis-triaza macrocyclic species, [Fe([9]aneS_3)$_2$]$^{2+}$ and [Fe([9]aneN_3)$_2$]$^{2+}$, occur at $E_{1/2} = +0.98$[5] and −0.59 V vs Fc/Fc^+, respectively.[6]

EXPERIMENTAL

IR spectra were recorded as KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–4000 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh

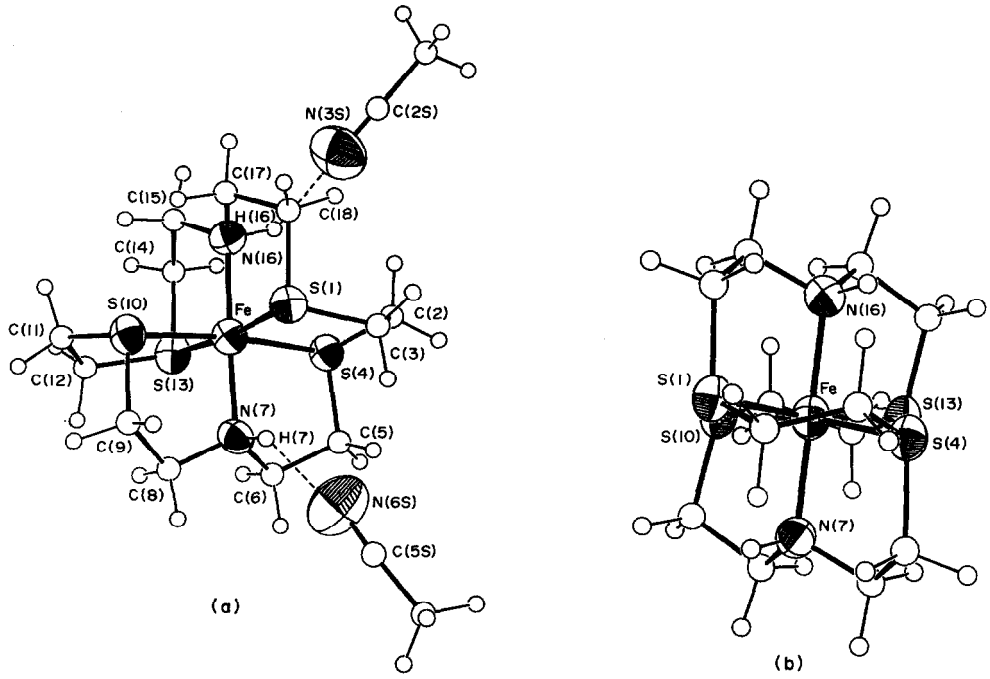

Fig. 2. Two views of the single crystal structure of $[Fe([18]aneN_2S_4)]^{2+}$: (a) showing hydrogen-bonded MeCN solvent molecules, with numbering scheme adopted; (b) view along the approximate, non-crystallographic C_2-axis.

University Chemistry Department Microanalytical service. Electrochemical measurements were performed on a Bruker E310 Universal Modular Polarograph. All readings were taken using a three-electrode potentiostatic system in acetonitrile containing 0.1 M $^nBu_4NPF_6$ or $^nBu_4NBF_4$ as supporting electrolyte. Cyclic voltammetric measurements were carried out using a double platinum electrode and an Ag/AgCl reference electrode. All potentials are quoted vs ferrocene/ferrocenium, Fc/Fc^+. Mass spectra were measured by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer. ^1H and ^{13}C NMR spectra were obtained on Bruker WP80 and WP200 instruments.

(a) *Synthesis of* $[Fe([18]aneN_2S_4)](BF_4)_2$

Reaction of $FeCl_2 \cdot 4H_2O$ (22 mg, 0.107 mmol) and $[18]aneN_2S_4$ (35 mg, 0.107 mmol) in refluxing, degassed MeOH–H_2O (35 cm^3, 1 : 1 v/v), for 15 min under N_2, afforded a deep blue solution. Cooling, reducing the volume to 10 cm^3 and filtering the reaction mixture into a solution of excess $NaBF_4$ in MeOH gave a blue precipitate which was recrystallized from MeCN and diethyl ether (Yield: 40 mg, 83%). Found: C, 26.0; H, 4.8; N, 5.0. Calc. for $[C_{12}H_{26}N_2S_4Fe](BF_4)_2$: C, 25.9; H, 4.7; N, 5.0%. FAB mass spectrum (3-NOBA matrix): Found m/z = 469, 401 and 381. Calc. for $[^{56}Fe([18]aneN_2S_4)BF_4]^+$, M^+ = 469; $[^{56}Fe([18]aneN_2S_4)\cdot H_2O]^+$, M^+ = 400; $[^{56}Fe([18]aneN_2S_4)]^+$, M^+ = 382. UV–vis spectrum (MeCN): λ_{max} = 572 nm (ε_{max} = 171 M^{-1} cm^{-1}), 424 (152), 344sh (103), 238 (19,570). ^1H NMR spectrum (80.13 MHz, CD_3NO_2, 298 K): δ = 2.15–3.85 ppm (m, CH_2, 24H). ^{13}C DEPT NMR spectrum (50.32 MHz, CD_3NO_2, 298 K): δ = 52.26, 51.90 ($2\times NCH_2$); 39.82, 39.46 ($2\times NCH_2CH_2S$); 33.56, 32.96 ppm ($2\times SCH_2CH_2S$) major isomer; δ = 52.40, 51.80 ($2\times NCH_2$); 38.90, 38.08 ($2\times NCH_2CH_2S$); 35.46, 34.94 ppm ($2\times SCH_2CH_2S$) minor isomer. IR spectrum (KBr disc): 3240m, 3080m, 2920m, 1460m, 1420m, 1380w, 1320w, 1295w, 1050vs b, 930w, 790m, 535m, 520m cm^{-1}.

(b) *Synthesis of* $[Fe([18]aneN_2S_4)](BPh_4)_2$

Method as for (a), using $NaBPh_4$ in place of $NaBF_4$. Recrystallization from MeCN–EtOH gave the product as blue crystals. FAB mass spectrum (3-NOBA matrix): Found m/z = 381. Calc. for $[^{56}Fe([18]aneN_2S_4)]^+$, M^+ = 382. IR spectrum (KBr disc): 3180m, 3040m, 2980w, 2920w, 1575m, 1475m, 1460m, 1420m, 1405m, 1380w, 1305w, 1260w, 1170w, 1120w, 1080w, 1060w, 1030w, 990w, 970w, 920w, 840w, 820w, 785w, 755m, 735vs, 710vs, 610vs, 470w cm^{-1}.

Single crystal X-ray structure determination of $[Fe([18]aneN_2S_4)](BPh_4)_2 \cdot 2MeCN \cdot 1/2MeOH$

Slow evaporation from a solution of the complex in a 1:1 v/v mixture of MeCN–EtOH gave deep blue, columnar crystals. The selected crystal ($0.69 \times 0.27 \times 0.27$ mm) was sealed in a glass capillary to prevent solvent loss. Crystal data: $[C_{12}H_{26}N_2S_4Fe]^{2+} \cdot 2(C_{24}H_{20}B^-) \cdot 2MeCN \cdot 1/2MeOH$, $M = 1119.0$, triclinic, space group $P\bar{1}$, $a = 11.8615(8)$, $b = 15.4285(12)$, $c = 17.9412(13)$ Å, $\alpha = 67.301(3)$, $\beta = 78.542(4)$, $\gamma = 76.696(3)°$,

$V = 2925.6$ Å^3 [from 2θ values for 27 reflections measured at $\pm\omega(32 < 2\theta < 35°$, $\lambda = 1.54184$ Å, $T = 298$ K)], $Z = 2$, $D_c = 1.270$ g cm^{-3}, μ(Cu-K_α) = 3.712 cm^{-1}, $F(000) = 1186$.

Data collection and processing. Stoë STADI-4 four-circle diffractometer, graphite-monochromated Cu-K_α radiation, ω–2θ scans using the learnt-profile method.[7] 8245 reflections measured ($2\theta_{max} = 120°$, h $-13 \rightarrow 12$, k $-15 \rightarrow 17$, l $-18 \rightarrow 20$) giving 6110 with $F > 6\sigma(F)$. No significant crystal decay.

Structure analysis and refinement. The iron position was deduced from a Patterson synthesis. Iterative cycles of least-squares refinement and difference Fourier syntheses[8] located the positions of all other non-hydrogen atoms. Corrections for absorption (max. 0.356, min. 0.171) were applied using ψ scans. Two fully-occupied MeCN molecules and one half-occupied MeOH molecule from the solvent were found to be associated with each $[Fe([18]aneN_2S_4)]^{2+}$ cation. Strong hydrogen-bonding interactions between the macrocyclic N—H functions and the two MeCN molecules may account for the well-ordered nature of these solvent molecules, whereas the MeOH molecule is disordered and does not participate in significant hydrogen-bonding interactions. Hydrogen atoms were included in fixed, calculated positions, and the phenyl rings of the BPh_4^- counteranion were refined as rigid groups.[8] Anisotropic thermal parameters were refined for Fe, S, N, B and C atoms. The weighting scheme $w^{-1} = \sigma^2(F) + 0.000509F^2$ gave satisfactory agreement analyses. At final convergence, $R = 0.0668$, $R_w = 0.0947$, $S = 1.232$ for 591 independent parameters, and the final difference Fourier synthesis showed no feature above 0.60 or below -0.61 e Å^{-3}. Illustrations were prepared using ORTEPII,[9] molecular geometry calculations utilized CALC,[10] and scattering factor data were inlaid[8] or taken from ref. 11. Bond lengths, angles and torsion angles are given in Table 1. Fractional atomic coordinates and thermal parameters, together with observed and calculated structure factors have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

DETERMINATION OF *CIS–TRANS* ISOMERS OF AMINE AND PYRIDINE PLATINUM(II) COMPLEXES BY *J*(Pt—H) COUPLING CONSTANTS

T. B. T. HA,* J.-P. SOUCHARD, F. L. WIMMER and N. P. JOHNSON

Laboratoire de Pharmacologie et de Toxicologie Fondamentales du CNRS, 205, route de Narbonne, 31077 Toulouse Cedex, France

(*Received* 14 *March* 1990; *accepted* 4 *July* 1990)

Abstract—The coupling constants ^3J(Pt—H) of $[Pt(Xpy)_2L_2]$ and $[Pt(Xpy)(dmso)I_2]$ complexes (Xpy = pyridine, 4-Me-py, 3,5-diMe-py, 4-Cl-py, 4-CN-py, 4-$HOCH_2$-py, 4-CH_3COO-py; L = Cl, I, Br, ONO_2) have been recorded. The ^3J(Pt—H) values of the *cis* complexes are 42 ± 2 Hz, while those of the *trans* derivatives are 31.5 ± 2.5 Hz. ^2J(Pt—H) of $[Pt(XNH_2)_2L_2]$ complexes (X = CH_3, cyclopropyl, cyclobutyl, cyclopentyl, cyclohexyl, cycloheptyl; L = Cl, I, ONO_2) also have been recorded. The ^2J(Pt—H) values of the *cis* complexes are 66.5 ± 1.5 Hz, those of the *trans* derivatives are 58 ± 2 Hz. These results show that measurement of Pt—H coupling constants is a rapid method of identifying the *cis* and the *trans* isomers of platinum(II) complexes.

Different methods have been used to distinguish *cis* and *trans* isomers of platinum(II) complexes. For identifying *cis*- and *trans*-$[Pt(Xpy)_2Cl_2]$, several chemical tests are available:[1]

—Oxyphenylenetelluronium hydrogen sulphate which gives a red coloration with the *cis* isomer.
—Hydrobromic acid gives a bright yellow precipitate with the *cis* isomer while the *trans* isomer gives a whitish precipitate.
—Silver oxide reacts with the *cis* isomer to give a yellow glassy mass; with the *trans* isomer white needles are formed.
—Kurnakov's test[2–4] which involves addition of thiourea and precipitation of the thiourea complexes.

In addition, several methods are available for analysing mixtures of *cis*- and *trans*-$[Pt(NH_3)_2Cl_2]$. Paper chromatography,[5] TLC and HPLC are employed mainly for detecting one isomer in the presence of the other. Solutions containing *cis*- and *trans*-$[Pt(NH_3)_2Cl_2]$ can also be analysed by measuring optical absorbances before and after controlled reaction with allyl alcohol.[6] However, ^{195}Pt NMR spectroscopy has proved to be insufficiently sensitive at low concentrations, and laser Raman spectroscopy did not yield useful signals.[5]

In this paper, we report the ^3J(Pt—H) coupling constants (Table 1) of 28 complexes of general formulae $[Pt(Xpy)_2Cl_2]$, $[Pt(Xpy)_2I_2]$, $[Pt(Xpy)_2(ONO_2)_2]$ and $[Pt(Xpy)(dmso)I_2]$; (Xpy = pyridine or substituted pyridines). The ^{1}H NMR spectra have been recorded in deuterated acetone, chloroform or dmso. The coupling constants, ^3J(Pt—H), between Pt and H(α) of the pyridines are 42 ± 2 Hz for the *cis* complexes and 31.5 ± 2.5 Hz for the *trans* isomers. In addition the ^2J(Pt—H) values of 21 complexes of general formulae $[Pt(XNH_2)_2I_2]$, $[Pt(XNH_2)_2Cl_2]$ and $[Pt(XNH_2)_2(ONO_2)_2]$ (X = CH_3, cyclopropyl, cyclobutyl, cyclopentyl, cyclohexyl, cycloheptyl) were recorded (Table 2). The difference between the values for the *cis* and *trans* isomers is smaller: 66.5 ± 1.5 Hz for the *cis* and 58 ± 2 Hz for the *trans* complexes.

Thus, the *J*(Pt—H) coupling constants are characteristic of the geometry of the complex. These results may reflect a general *trans* effect on coupling constants in platinum complexes,[7] and their

measurement is an easy and rapid method of distinguishing *cis* and *trans* isomers.

EXPERIMENTAL

Preparation of the complexes

The complexes *cis*- and *trans*-$[Pt(Xpy)_2Cl_2]$ and $[Pt(XNH_2)_2Cl_2]$ were prepared from K_2PtCl_4 by well established methods.[1,8–10]

Cis- and *trans*-$[Pt(Xpy)_2I_2]$ and $[Pt(XNH_2)_2I_2]$ and their nitrato derivatives were prepared according to Souchard *et al.*[11]

Trans-[Pt(dmso)(Xpy)I_2] complexes were prepared according to Ha *et al.*[12]

Spectral measurements

^{1}H NMR spectra were recorded on a Bruker 250 MHz Fourier transform spectrometer at ambient temperature. dmso solutions were prepared immediately prior to measurement. Coupling in pyridine complexes gave distinct satellite peaks, while some broadening due to chemical shift anisotropy was observed for the amine complexes.

TRANSMETALLATION OF A BINUCLEAR COMPLEX OF NICKEL(0): SYNTHESIS AND MOLECULAR STRUCTURE OF [NiPt(μ-CNMe)(CNMe)($Ph_2PCH_2PPh_2$)$_2$Cl][Cl]

KEVIN S. RATLIFF, PHILLIP E. FANWICK and CLIFFORD P. KUBIAK*

Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 21 *May* 1990; *accepted* 16 *July* 1990)

Abstract—The transmetallation of the dinickel complex $Ni_2(CNMe)_3(dppm)_2$ (**1**) with $Pt(dppm)Cl_2$ (dppm = $PPh_2CH_2PPh_2$) yields the heterobimetallic complex [NiPt$(CNMe)_2$ $(dppm)_2$Cl][Cl] (**2**). The structure of **2** was determined by X-ray crystallography. The Ni—Pt bond distance of 2.5892(9) Å indicates a strongly interacting mixed-metal core. In the presence of one equivalent of methyl isocyanide, the chloride bound to platinum can be removed with $TlPF_6$ to form the tris-isocyanide complex [NiPt$(CNMe)_3$ $(dppm)_2$][PF_6]$_2$ (**3**).

The formation of heterobimetallic complexes which alloy different metal atoms is of interest for their potential to exhibit cooperative reactivities and unusual chemical and physical properties. Structurally characterized heterobimetallic complexes having a discrete metal–metal bond between nickel and platinum have not been known previously. Recently, several examples of heterobimetallic complexes have been prepared using metallation and transmetallation techniques. Shaw and co-workers have used a synthetic strategy based on the transmetallation of relatively labile d^{10} metal ions, Cu^I, Ag^I, Au^I or Hg^{II}, by d^8 ions such as Rh^I or Ir^I.[1] We recently reported the metallation and transmetallation of the homobinuclear Ni^0 complex $Ni_2(\mu$-CNMe)(CNMe)$_2$(dppm)$_2$ (dppm = $Ph_2PCH_2PPh_2$), (**1**) with Pd^{II},[2] Au^I,[3] Ni^{II}[4] and Hg^{II}[5] salts. Here we report the transmetallation of **1** with $Pt(dppm)Cl_2$,[6] to form the strongly bonded Ni—Pt heterobimetallic complex [NiPt(μ-CNMe)(CNMe)$(dppm)_2$Cl][Cl] (**2**).

EXPERIMENTAL

Complex **2** was prepared from $Ni_2(CNMe)_3$ $(dppm)_2$ (0.2803 g, 0.27 mmol) and $(dppm)PtCl_2$[7] (0.1807 g, 0.27 mmol) in THF. The solution turned red and a bright red solid precipitated from solution. The solid was collected by filtration and washed with a small amount of THF and then pentane. The solid was dried; yield = 0.2065 g, 0.17 mmol, 65%. ^{1}H NMR (CD_2Cl_2): δ 8.1–7.1 (m, 40H), δ 3.12 (m, 4H), δ 2.83 (s, 6H). $^{31}P\{^1H\}$ NMR (CD_2Cl_2): AA′BB′, $\delta(P_A)$ = 31.0, $\delta(P_B)$ = 23.3; $J(PtP_A)$ = 2716 Hz; $J(PtP_B)$ = 528 Hz. IR(KBr) ν(CN): 2187(s), 1715(s) cm^{-1}.

Crystal data for **2**·2CH_3CN. The complex crystallized with two molecules of acetonitrile in the crystal lattice. $PtNiCl_2P_4N_4C_{58}H_{56}$, FW = 1257.72, monoclinic space group $P2_1/n$, a = 15.324(1), b = 18.354(2), c = 20.190(2) Å, V = 5639(2) Å^3, Z = 4, d_{calc} = 1.481 g cm^{-3}. Crystal dimensions: 0.50 × 0.35 × 0.28 mm. The structure was solved by MULTAN least-squares Fourier methods and was refined to R and R_w values of 0.032 and 0.039, respectively, for 601 variables and 5235 observations with $I \geq 3.0\sigma(I)$ with Mo-K_α radiation. Data were corrected for absorption

empirically, $\mu = 30.85$ cm^{-1}. Further details can be found in the supplementary material.

Complex **3** was prepared from complex **2** (0.250 g, 0.213 mmol) and $Tl(PF_6)$ (0.153 g, 0.44 mmol), in CH_3CN, in the presence of one equivalent of methylisocyanide. The solution turned orange and TlCl precipitated out of solution. The solution was filtered and the solvent removed. The solid was then recrystallized from THF–pentane. Yield = 0.275 g, 0.19 mmol, 90%. ^{1}H NMR (CD_2Cl_2): δ 7.6–7.1 (m, 40H), δ 4.63 (m, 4H), δ 2.67 (s, 6H), δ 2.32 (s, 3H). ^{31}P{^{1}H} NMR (CD_2Cl_2): AA′BB′, $\delta(P_A) = 10.31$, $\delta(P_B) = 6.76$, $J(PtP_A) = 2444$ Hz. IR(KBr) ν(CN): 2230(m), 2194(s), 2143(m) cm^{-1}.[7]

RESULTS AND DISCUSSION

Treatment of a THF solution of **1** with one equivalent of $Pt(dppm)Cl_2$ leads directly to the transmetallated product, **2**, in 65% yield:

$$Ni_2(\mu\text{-CNMe})(CNMe)_2(dppm)_2 + Pt(dppm)Cl_2 \longrightarrow [NiPt(\mu\text{-CNMe})(CNMe)(dppm)_2Cl][Cl] \quad (1)$$

The IR spectrum of **2** exhibits one terminal and one bridging isocyanide ν(CN) band at typical values of 2187 and 1715 cm^{-1}, respectively. The isocyanides, however, are equivalent on the ^{1}H NMR time scale and appear as a singlet at 2.83 ppm. The ^{31}P {^{1}H} NMR spectrum of **2** is an AA′BB′ spin system [$\delta(P_A) = 30.60$ ppm, $\delta(P_B) = 23.36$ ppm] with ^{195}Pt coupling constants of $^1J(PtP_A) = 2781$ Hz and $^2J(PtP_B) = 528$ Hz, thus indicating a Ni—Pt heterobinuclear complex. Crystals of **2** suitable for X-ray diffraction were obtained from slow diffusion of Et_2O into a concentrated acetonitrile solution of **2**. An ORTEP drawing of **2** is presented in Fig. 1. The molecule consists of a strongly bonding Ni—Pt core with d(Ni—Pt) = 2.5892(9) Å. Holah *et al.* have synthesized the heterobimetallic complex $NiPtCl_2(\mu\text{-CO})(dppm)_2$ which possesses a significantly longer Ni—Pt separation of 2.689(2) Å.[8] Compound **2** adopts a distorted "A-frame" geometry with the platinum atom remaining essentially square planar and the nickel atom adopting a distorted tetrahedral geometry. A skeletal view of **2** with selected bond distances and bond angles is shown in Fig. 2. The formation of **2** from $Ni_2(\mu\text{-CNMe})(CNMe)_2(dppm)_2$ and $Pt(dppm)Cl_2$ presumably follows an initial metallation of the dinickel complex with $Pt(dppm)Cl_2$ followed by the expulsion of a Ni^0 fragment.[2]

In the presence of one equivalent of methyl isocyanide, the chloride bound to the platinum atom

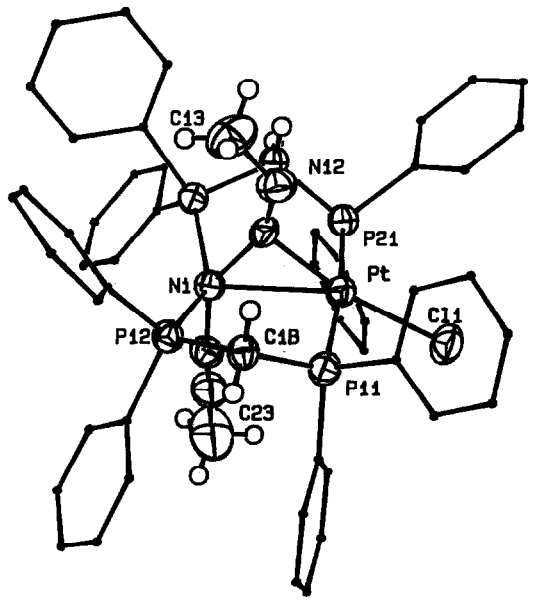

Fig. 1. ORTEP drawing of $[NiPt(\mu\text{-CNMe})(CNMe)(dppm)_2Cl]^+$ (**2**).

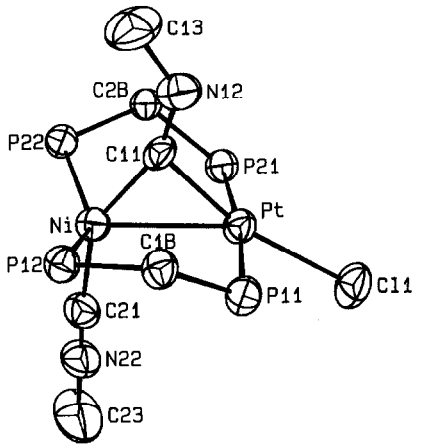

Fig. 2. Skeletal view of **2** with selected bond distances (Å) and bond angles (°): Ni—Pt, 2.5892(9); P(11)—Pt—P(21), 173.47(6); Cl(1)—Pt—C(11), 163.2(2); P(12)—Ni—P(22), 140.65(7); P(12)—Ni—C(21), 103.6(2); P(22)—Ni—C(11), 88.2(2); C(11)—Ni—C(21), 146.7(3).

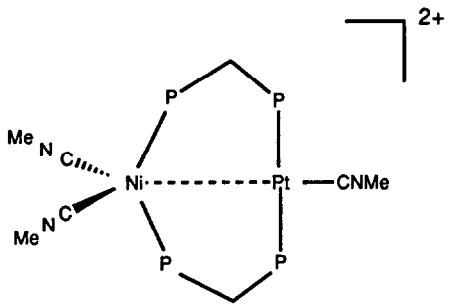
can be removed using thallium(I) salts to form the tris-isocyanide complex, $[NiPt(CNMe)_3(dppm)_2]^{2+}$ (**3**).[7]

$$[NiPt(CNMe)_2(dppm)_2Cl][Cl] + 2Tl(PF_6) + CNMe \longrightarrow [NiPt(CNMe)_3(dppm)_2][PF_6]_2 \quad (2)$$

The latter complex is analogous to the homobinuclear complex $[Ni_2(CNMe)_3(dppm)_2]^{2+}$[9] and the heterobinuclear complex $[NiPd(CNMe)_3$

$(dppm)_2]^{2+}$ [2] which were recently prepared in our laboratories.

The IR spectrum of **3** reveals only terminal isocyanide bands at $\nu(CN) = 2230$, 2194 and 2143 cm^{-1}. The $^{31}P\{^1H\}$ NMR spectrum of **3** is also an AA'BB' spin system with $\delta(P_A) = 10.18$ ppm and $\delta(P_B) = 6.76$ ppm. The spectrum, however, only shows ^{195}Pt coupling to one set of phosphorus atoms, with a coupling constant of $^1J(PtP_A) = 2444$ Hz. The absence of ^{195}Pt coupling to the phosphorus atoms bound to the nickel atom indicates that there is a significant weakening of the metal–metal interaction between the nickel and platinum atoms compared with **2**. The ^1H NMR spectrum reveals two types of methyl isocyanides at δ 2.68 and 2.32 ppm in a ratio of 2 : 1. Attempts at forming X-ray quality crystals have been unsuccessful, however, spectroscopic data as well as previous X-ray structural studies of $[Ni_2(CNMe)_3dppm_2]^{2+}$ and $[NiPd(CNMe)_3dppm_2]^{2+}$ suggest the following weakly metal–metal′ interacting structure.



3

The synthesis of this Ni—Pt complex completes the series of $[Ni—M(CNMe)_3(dppm)_2]^{2+}$ (M = Ni, Pd, Pt) complexes. Further studies on the metallation and transmetallation of $Ni_2(\mu\text{-}CNMe)(CNMe)_2(dppm)_2$ are continuing.

Supplementary material available: atomic coordinates have been deposited with the Director, Cambridge Crystallographic Data Centre.

REACTION OF O_2 WITH $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgCH$_2$Si(CH$_3$)$_3$: FACILE Si—C BOND CLEAVAGE AND FORMATION OF $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgOSi(CH$_3$)$_3$

RUNYU HAN and GERARD PARKIN*

Department of Chemistry, Columbia University, New York, NY 10027, U.S.A.

(*Received* 25 *June* 1990; *accepted* 31 *July* 1990)

Abstract—The reaction of the magnesium trimethylsilylmethyl complex $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgCH$_2$Si(CH$_3$)$_3$ with O_2 gives the trimethylsiloxide derivative $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgOSi(CH$_3$)$_3$ as a result of facile cleavage of the Si—C bond.

The reaction of molecular oxygen with metal alkyl derivatives is of fundamental importance in view of the role that metal-based oxidations play in systems as diverse as industrial and biological processes.[1] We have recently reported the insertion of O_2 into the Mg—C bond of a series of alkyl complexes $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgR [3-Bu^{t}pz = 3-C_3N_2Bu^{t}H$_2$; R = CH$_3$, CH$_2$CH$_3$, CH(CH$_3$)$_2$, C(CH$_3$)$_3$] to give alkylperoxo derivatives $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgOOR [eq. (1)]:[2]

$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgR} + O_2 \longrightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgOOR}. \quad (1)$$

Here we report that the analogous reaction of the trimethylsilylmethyl derivative $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgCH$_2$SiMe$_3$ with O_2 is accompanied by facile Si—C bond cleavage and the formation of the trimethylsiloxide derivative, $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgOSiMe$_3$.

The trimethylsilylmethyl derivatives $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgCH$_2$SiMe$_3$† and $\{\eta^3$-HB(3,5-Me$_2$pz)$_3\}$MgCH$_2$SiMe$_3$† [3,5-Me$_2$pz = 3,5-C_3N_2(CH$_3$)$_2$H] are obtained by metathesis of (Me$_3$SiCH$_2$)$_2$Mg with either Tl$\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$ or K{HB(3,5-Me$_2$pz)$_3$}, respectively [eqs (2) and (3)]:

$$(\text{Me}_3\text{SiCH}_2)_2\text{Mg} \xrightarrow{\text{Tl}\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}} \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgCH}_2\text{SiMe}_3 \quad (2)$$

$$(\text{Me}_3\text{SiCH}_2)_2\text{Mg} \xrightarrow{\text{K\{HB(3,5-Me}_2\text{pz)}_3\}} \{\eta^3\text{-HB(3,5-Me}_2\text{pz)}_3\}\text{MgCH}_2\text{SiMe}_3. \quad (3)$$

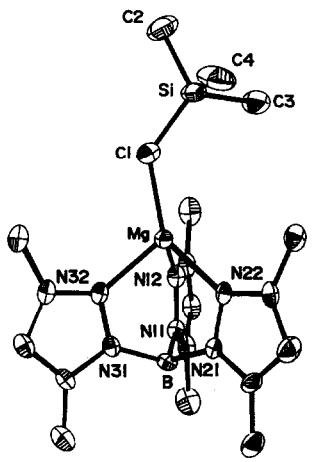

Fig. 1. ORTEP drawing for $\{\eta^3$-HB(3,5-Me$_2$pz)$_3\}$MgCH$_2$SiMe$_3$.

† Selected ^{1}H NMR data (C_6D_6, RT, 200 MHz). $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgCH$_2$SiMe$_3$: δ 1.40 [9H, s, HB{C$_3$N$_2$H$_2$C(CH$_3$)$_3\}_3$], 5.80 [d, 1H, HB{C$_3$N$_2$H$_2$C(CH$_3$)$_3\}_3$], 7.33 [d, 1H, HB{C$_3$N$_2$H$_2$C(CH$_3$)$_3\}_3$], −0.49 [2H, s, MgCH$_2$SiMe$_3$], 0.54 [9H, s, Si(CH$_3$)$_3$]. $\{\eta^3$-HB(3,5-Me$_2$pz)$_3\}$MgCH$_2$SiMe$_3$: δ 2.10 and 2.23 [s, HB{C$_3$N$_2$H(CH$_3$)$_2\}_3$], 5.44 [s, HB{C$_3$N$_2$H(CH$_3$)$_2\}_3$], −0.64 [2H, s, MgCH$_2$SiMe$_3$], 0.51 [9H, s, Si(CH$_3$)$_3$]. $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}$MgOSiMe$_3$: δ 1.44 [9H, s, HB{C$_3$N$_2$H$_2$C(CH$_3$)$_3\}_3$], 5.77 [d, 1H, HB{C$_3$N$_2$H$_2$C(CH$_3$)$_3\}_3$], 7.28 [d, 1H, HB{C$_3$N$_2$H$_2$C(CH$_3$)$_3\}_3$], 0.53 [9H, s, Si(CH$_3$)$_3$].

The molecular structure of $\{\eta^3$-HB(3,5-$Me_2pz)_3\}MgCH_2SiMe_3$ has been determined by single crystal X-ray diffraction, as shown in Fig. 1.*

The reaction of $\{\eta^3$-HB(3,5-$Me_2pz)_3\}MgCH_2SiMe_3$ with O_2 has been examined using ^1H NMR spectroscopy which demonstrates the formation of a complex mixture of products, of which the bis {tris(3,5-dimethylpyrazolyl)hydroborato} derivative $\{\eta^3$-HB(3,5-$Me_2pz)_3\}_2Mg$[3] is a major constituent [eq. (4)]:

$$\{\eta^3\text{-HB(3,5-Me}_2\text{pz)}_3\}\text{MgCH}_2\text{SiMe}_3 \xrightarrow{O_2} \{\eta^3\text{-HB(3,5-Me}_2\text{pz)}_3\}_2\text{Mg} + \cdots \quad (4)$$

In view of the greater stability that may be provided by the more sterically demanding tris(3-t-butylpyrazolyl)hydroborato ligand system, and in particular the inability to form the corresponding bis{tris(3 - t - butylpyrazolyl)hydroborato}magnesium derivative,[3] we examined the reaction of $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgCH_2SiMe_3$ with O_2. The reaction was indeed observed to be much cleaner than the reaction of $\{\eta^3$-HB(3,5-$Me_2pz)_3\}MgCH_2SiMe_3$ with O_2 and the major product (after 1 h at room temperature) was identified as the trimethylsiloxide derivative, $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgOSiMe_3$ [eq. (5)].† Formaldehyde was also observed as a product of this reaction.

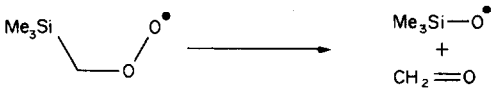
$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgCH}_2\text{SiMe}_3 \xrightarrow{O_2} \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgOSiMe}_3 + (\text{CH}_2\text{O})_n. \quad (5)$$

* Crystal data for $\{\eta^3$-HB(3,5-$Me_2pz)_3MgCH_2SiMe_3$: $C_{19}H_{33}N_6BSiMg$, $M = 408.8$, monoclinic, space group $C2/c$ (No. 15), $a = 23.897(8)$, $b = 8.010(2)$, $c = 30.072(8)$ Å, $\beta = 119.71(2)°$, $U = 5000(2)$ Å^3, $Z = 8$, $D_c = 1.09$ g cm^{-3}, $F(000) = 1760$ electrons, μ(Mo-K_α) = 1.4 cm^{-1}, $T = 295$ K, crystal dimensions 0.18 mm × 0.54 mm × 0.60 mm. Intensity data were collected on a Nicolet R3m diffractometer using monochromated Mo-K_α X-radiation ($\lambda = 0.71073$ Å) and were corrected for Lorentz and polarization effects. A total of 1863 unique reflections were collected in the range $3° < 2\theta < 45°$, of which 1489 with $F_o > 5\sigma(F_o)$ were used in the structure determination. The structure was solved using direct methods and standard difference map techniques. Most of the hydrogen atoms were located in the difference map after all the non-hydrogen atoms were located and refined anisotropically, but hydrogens on carbon were allowed to refine in calculated positions [$d_{C-H} = 0.96$ Å; U_{iso} (H) = $1.2U_{iso}$(C)]. Block-diagonal least-squares refinement converged to $R = 0.0599$ ($R_w = 0.0602$), with the maximum shift-to-σ ratio of 0.023 for the last cycle. The final difference map showed no significant features, with the highest final peak 1.0 e Å^{-3}. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

Characterization of the trimethylsiloxide derivative $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgOSiMe_3$ is also provided by the independent synthesis from $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgCl$ and $KOSiMe_3$ [eq. (6)]:

$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgCl} + \text{KOSiMe}_3 \longrightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgOSiMe}_3 + \text{KCl}. \quad (6)$$

The reaction of $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgCH_2SiMe_3$ with O_2 most likely involves a radical chain process, as proposed for the reactions of $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgR$[2] and other metal alkyl derivatives with O_2.[5] Thus, a potential mechanism for the formation of $\{\eta^3$-HB(3-Bu^{t}pyz)$_3\}MgOSiMe_3$ involves the generation of $Me_3SiO^\bullet$ as a result of the rearrangement of the radical intermediate $Me_3SiCH_2O_2^\bullet$ [eq. (7)]. The formation of a strong Si—O bond would be expected to provide an effective driving force for such a transformation.



(7)

Support for a radical-chain mechanism is provided by the observation of (i) mild inhibition of the reaction of $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgCH_2SiMe_3$ with O_2 in the presence of galvinoxyl, a radical trap, and (ii) crossover products in the reactions of O_2 with mixtures of (a) $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgCH_2SiMe_3$ and $\{\eta^3$-HB(3,5-$Me_2pz)_3\}MgC(CH_3)_3$ [eq. (8)], and of (b) $\{\eta^3$-HB(3,5-$Me_2pz)_3\}MgCH_2SiMe_3$ and $\{\eta^3$-HB(3-Bu^{t}pz)$_3\}MgC(CH_3)_3$ [eq. (9)]:[6]

$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgCH}_2\text{SiMe}_3 + \{\eta^3\text{-HB(3,5-Me}_2\text{pz)}_3\}\text{MgC(CH}_3)_3 \longrightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgOOC(CH}_3)_3 + \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgOSiMe}_3 + \cdots \quad (8)$$

$$\{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgC(CH}_3)_3 + \{\eta^3\text{-HB(3,5-Me}_2\text{pz)}_3\}\text{MgCH}_2\text{SiMe}_3 \longrightarrow \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgOSiMe}_3 + \{\eta^3\text{-HB(3-Bu}^t\text{pz)}_3\}\text{MgOOC(CH}_3)_3 + \cdots \quad (9)$$

Organic products arising from facile cleavage of Si—C bonds of other trialkylsilyl metal derivatives upon autoxidation have been previously observed, and thus provide a precedent for the reactions described here. For example, treatment of the Grignard reagent Me_3SiCH_2MgCl with O_2, followed by hydrolysis, gave significant quantities of Me_3SiOH, $(Me_3Si)_2O$ and CH_2O.[7] Thus, these observations provide further evidence that such cleavage reactions may be a general feature of trimethylsilylmethyl derivatives upon autoxidation.

THE FIRST METAL COMPLEXES CONTAINING TELLURIUM–SULPHUR–NITROGEN ANIONS; X-RAY STRUCTURE OF $[Pt(TeSN_2H)(PMe_2Ph)_2][BF_4]$

PAUL F. KELLY, ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London SW7 2AY, U.K.

(*Received* 21 *May* 1990; *accepted* 10 *August* 1990)

Abstract—Reaction of $Te_3N_2SCl_2$ with *cis*-$PtCl_2(PMe_2Ph)_2$ and 1,8-diazabicylo[5.4.0] undec-7-ene provides the first route to a metal–tellurium–sulphur–nitrogen complex, $Pt(TeSN_2)(PMe_2Ph)_2$ (**1**), the only example of a complex containing the $TeSN_2^{2-}$ ligand. Complex **1** reacts with a dilute solution of $HBF_4 \cdot Et_2O$ to give $[Pt(TeSN_2H)(PMe_2Ph)_2][BF_4]$ (**2**), the X-ray structure of which reveals the first example of a M–Te–S–N ring. Complexes **1** and **2** are air-stable.

Recently we reported the preparation of $Pt(ESN_2)(PR_3)_2$ and $[Pt(ESN_2H)(PR_3)_2][BF_4]$ (E = S or Se).[1,2]† Since these compounds have interesting structural properties we have now developed a synthetic route to the tellurium analogue. This has been achieved by utilizing the only known (though poorly characterized) Te—S—N heterocycle, $Te_3N_2SCl_2$, prepared by reaction of $[(Me_3Si)_2N]_2S$ with $TeCl_4$ in THF.[3] Here we report details of the synthesis of $Pt(TeSN_2)(PMe_2Ph)_2$ (**1**) and $[Pt(TeSN_2H)(PMe_2Ph)_2][BF_4]$ (**2**) and the X-ray crystal structure of **2**.

Reaction of a CH_2Cl_2 solution of *cis*-$PtCl_2(PMe_2Ph)_2$ with $Te_3N_2SCl_2$, in the presence of dbu (dbu = 1,8-diazabicyclo[5.4.0]undec-7-ene), gives, after work-up, a yellow solid which analyses as **1**, the first example of a M—Te—S—N species. We have been unable to resolve the X-ray crystal structure‡ of **1** due to

$$PtCl_2(PPMe_2Ph)_2 + Te_3N_2SCl_2 \xrightarrow[4\,dbu]{CH_2Cl_2} \underset{(1)}{Pt(TeSN_2)(PMe_2Ph)_2} + 4[dbuH]Cl + 2Te \quad (1)$$

$$Pt(TeSN_2)(PMe_2Ph)_2 + HBF_4 \longrightarrow \underset{(2)}{[Pt(TeSN_2H)(PMe_2Ph)_2][BF_4]} \quad (2)$$

disorder problems [as was the case for $Pt(SeSN_2)(PMe_2Ph)_2$]; however **1** is readily protonated [eq. (2)] by HBF_4 to give **2**. The X-ray crystal structure of **2** reveals (Fig. 1) square-planar coordination of the platinum with the metal bonded to the tellurium of the $TeSN_2H^-$ anion. The Pt—P(1) and Pt—P(2) distances [2.313(3) and 2.257(3) Å] are significantly different from each other and reflect the *trans* geometry of the phosphorus atoms with respect to tellurium and nitrogen. However, these distances are the same as those observed in the sulphur and selenium analogues, **3** and **4**.

* Author to whom correspondence should be addressed.

† $Pt(S_2N_2)(PR_3)_2$ complexes are best prepared by reaction of *cis*-$PtCl_2(PR_3)_2$ with $S_4N_4H_4$ and the base dbu, whilst $Pt(SeSN_2)(PR_3)_2$ complexes are made by reaction of the dichloro species with $[Se_2N_2SCl]_2$ in liquid ammonia. The complexes can be readily protonated on the metal-bound nitrogen by the action of acids such as HBF_4.

‡ Crystal data: Complex **1**, monoclinic, $a = 19.810(8)$, $b = 9.677(5)$, $c = 10.972(5)$ Å, $\beta = 107.10(3)°$, space group *Cc* or *C*2/*c*. Due to severe disorder problems the detailed structure could not be resolved.

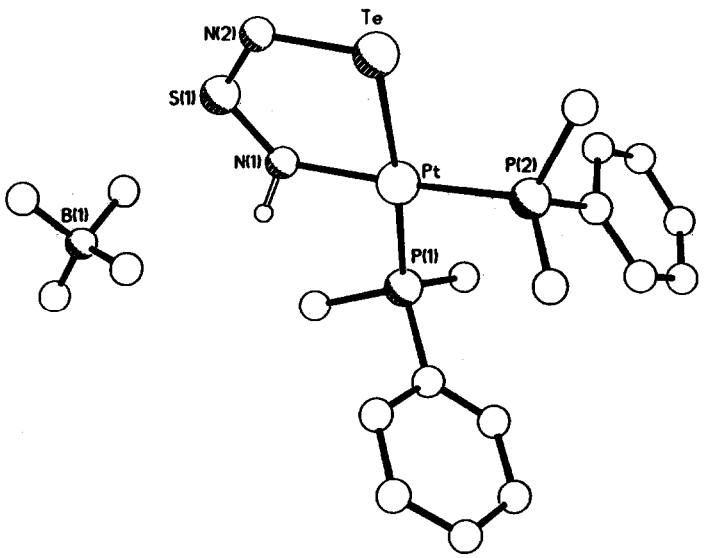

Fig. 1. The X-ray structure of $[Pt(TeSN_2H)(PMe_2Ph)_2][BF_4]$ (**2**) in the crystal. Important bond lengths (Å) and angles (°):

Pt—P(1)	2.313(3)	N(2)—S(1)	1.532(14)
Pt—P(2)	2.257(3)	S(1)—N(1)	1.569(11)
Pt—Te	2.553(1)	Pt—N(1)	2.046(11)
Te—N(2)	1.993(13)		

P(1)—Pt—P(2)	94.5(1)	Te—N(2)—S(1)	120.3(6)
N(1)—Pt—Te	84.9(3)	N(2)—S(1)—N(1)	111.6(6)
Pt—Te—N(2)	95.6(3)	S(1)—N(1)—Pt	127.6(6)

This is consistent with the ^{31}P NMR wherein the $^1J\{^1P-^{195}Pt\}$ coupling constants for the two phosphorus atoms are quite different from each other, but are not greatly changed upon varying E (E = Te, Se, S).* Despite the significantly increased covalent radius of tellurium versus selenium and sulphur and the consequent increase in the Pt—E and E—N(2) bond lengths (E = Te, Se, S) in **2** relative to **3** and **4**, the gross structure of the molecule remains virtually unchanged throughout the series; complexes **2**–**4** being crystallographically isostructural.† The only significant change in the ring geometry other than at E is at N(1) where there is a significant increase in the Pt—N(1)—S(1) angle [127.6(6) in **2**, cf. 122.8(4) and 121.4(4)° in **3** and **4**, respectively]. There are no Te—S—N structures available for comparison. As in **3** and **4**, the cations form infinite stacks in the crystal. Within the stacks of dimer pairs the intradimer $PtTeSN_2$ ring separation is 3.55 Å and the interdimer separation is 4.35 Å.‡ The ^{31}P NMR spectra of $Pt(ESN_2)(PR_3)_2$ (E = S, Se) have characteristic $^{31}P-^{195}Pt$ coupling constants. In **1** there are additional $^2J\{^{31}P-^{195}Te\}$ couplings for P(1) (Fig. 2) and P(2) of 146 and 103 Hz, respectively. To the best of our knowledge there have been no previous reports of a $^2J\{^{31}P-^{125}Te\}$ coupling directed through a metal.

The chemistry of S–N anions such as $S_2N_2^{2-}$ and S_3N^- is well known[4] and, as we have recently demonstrated,[5,6] selenium analogues can also be prepared. The development of Te—N and Te—S—N chemistry has, until now, been limited because of the lack of suitable starting materials (Te_4N_4 is poorly characterized and extremely hazardous). The work reported here demonstrates that Te—S—N species can be stabilized. The ease of synthesis of **1** and **2**, coupled with their ease of handling and stability, should greatly facilitate the development of this hitherto unexplored area of chemistry. We are currently investigating the incorporation of **2**–**4** in molecular metals.

* The $^1J\{^{31}P-^{195}Pt\}$ coupling constants for P(1) and P(2) are 2559, 2687, 2642 and 3240, 3227, 3171 Hz for E = S, Se and Te, respectively.

† The Pt—E, E—N(2) bond lengths (Å) and the Pt—E—N(2) angles (°) are 2.283(2), 2.401(1), 2.553(1); 1.649(8), 1.833(9), 1.993(13); and 104.4(3), 100.2(2), 95.6(3) for the S, Se and Te compounds, respectively.

‡ There are short non-bonded anion–cation contacts between F(1) and S(1) (3.17 Å) and F(1) and N(1) (3.26 Å).

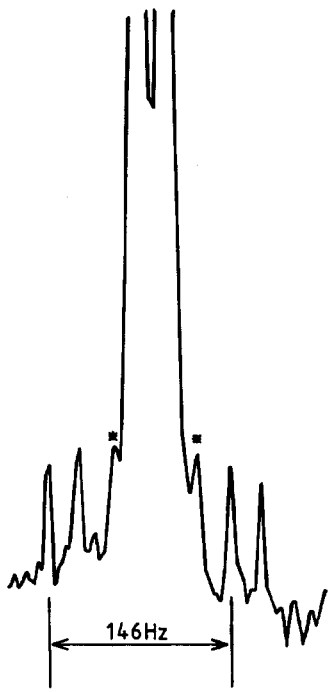

Fig. 2. The ^{31}P NMR spectrum of the phosphorus *trans* to tellurium in complex **1**. Peaks marked with an asterisk (*) are spinning sidebands.

EXPERIMENTAL

$Pt(TeSN_2)(PMe_2Ph)_2$ (1)

A vigorously stirred suspension of $Te_3N_2SCl_2$[3] (0.21 g, 0.41 mmol) and *cis*-$PtCl_2(PMe_2Ph)_2$ (0.22 g, 0.41 mmol) in CH_2Cl_2 (60 cm^3) was treated with excess dbu (*ca* 0.5 cm^3), and the resulting mixture stirred for 4 h. This yielded an orange solution together with large amounts of a finely-divided black precipitate of tellurium which was removed by twice filtering through celite, in air. Removal of the CH_2Cl_2 *in vacuo* gave an orange–brown oil which was triturated with degassed water, yielding a yellowish solid which was filtered, washed with more water, then dried *in vacuo*. Addition of hexane to a CH_2Cl_2 solution of this product yielded pure $Pt(TeSN_2)(PMe_2Ph)_2$ (**1**) (0.21 g, 78%) as a yellow solid. Found: C, 29.7; H, 3.3; N, 4.1. Calc.: C, 29.2; H, 3.4; N, 4.3%. ^{31}P NMR: AX spectrum, δ_a 0.8 ppm [$^1J(^{195}Pt–^{31}P)$ 2786 Hz], δ_x −30.2 ppm (^1J 2839 Hz). IR: 1080 (s), 619 (s), 374 (m) and 349 (m) cm^{-1}.

$[Pt(TeSN_2H)(PMe_2Ph)_2][BF_4]$ (2)

Protonation was achieved by treating a solution of **1** (0.1 g, 0.15 mmol) in CH_2Cl_2 (30 cm^3) with a solution of excess $HBF_4 \cdot Et_2O$ (3 drops) in CH_2Cl_2 (60 cm^3) over a period of 1 min. After stirring for 5 min the volume of the solution was reduced to $\approx$ 5 cm^3 and a reddish solid precipitated with Et_2O (100 cm^3). After drying, the solid was extracted into CH_2Cl_2 (20 cm^3), filtered to remove some residual red solid and tellurium, then slowly treated with hexane, with stirring, to give $[Pt(TeSN_2H)(PMe_2Ph)_2][BF_4]$ (**2**) (95 mg, 84%) as well-formed microcrystals. Crystals suitable for X-ray crystallography were grown by slow hexane diffusion into a dilute CH_2Cl_2 solution of **4**. Found: C, 25.7; H, 3.0; N, 4.2. Calc.: C, 25.7; H, 3.1; N, 3.8%. ^{31}P NMR: AX spectrum, δ_a −1.5 ppm [$^1J(^{195}Pt–^{31}P)$ 2642 Hz], δ_x −35.6 ppm (^1J 3171 Hz). IR: (bands between 100 and 1200 cm^{-1} obscured by vibrations due to BF_4^-), 619 (w) and 315 (w) cm^{-1}.

Crystal data. Complex **2**, $C_{16}H_{23}BF_4N_2P_2PtSTe$, $M = 746.9$, monoclinic, $a = 8.479(2)$, $b = 17.365(5)$, $c = 16.061(7)$ Å, $\beta = 103.79(3)°$, $U = 2297$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 2.16$ g cm^{-3}, μ(Cu-K_α) = 242 cm^{-1}. Refined unit cell parameters were obtained by centring 16 reflections on a Nicolet R3m diffractometer. 3100 independent reflections were measured ($2\theta \leqslant 116°$) with Cu-K_α radiation (graphite monochromator) using ω-scans. 2747 had $|F_o| > 3\sigma(|F_o|)$ and were considered to be observed. Data were corrected for Lorentz and polarization factors and an empirical absorption correction based on 372 azimuthal measurements was applied; maximum and minimum transmission factors: 0.182 and 0.058, respectively. The structure was solved by direct methods. The positions of hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2\ U_{eq}(C)$ and allowed to ride on their parent carbon atoms. Refinement was by block-cascade full-matrix least-squares to $R = 0.054$, $R_w = 0.056$ [$w^{-1} = \sigma^2(F) + 0.00128F^2$]. The maximum and minimum residual electron density in the final ΔF map were 2.52 and −2.01 e Å^{-3}. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system. Further details of the crystal structure can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K. Any request should be accompanied by the full literature citation for this communication.

(*Received* 18 *January* 1990; *accepted* 1 *May* 1990)

Abstract—The coordination of copper(II) chloride to the large linear polyazadioxime molecules 4,4-diaza-3,6-dimethyl-3,5-octadiene-2,7-dione-2,7-dioxime and -4,5,8,9-tetraaza-3,6,7,10-tetramethyl-3,5,7,9-dodecatetraene-2,11-dione-2,11-dioxime (abbreviated, respectively, H_2doxN_2 and H_2doxN_4) has been studied. These polymetallic complexes are an unusual route for bridging paramagnetic ions through a direct polyatomic pathway to give an antiferromagnetic linear chain of the ribbon type. Without available X-ray data the molecular geometries of the polymetallic compounds are characterized by vibrational, electronic and EPR spectroscopy, as well as by magnetic susceptibility measurements between 300 and 4.2 K. The binuclear $Cu_2(H_2doxN_2)Cl_4$ complex shows antiferromagnetic intradimer super exchange, $2J = -38$ cm^{-1}, and the trinuclear $Cu_3(H_2doxN_4)Cl_6$ complex shows antiferromagnetic intratrimer superexchange between neighbouring centres, $2J = -25$ cm^{-1}, propagated through the diaza bonds.

The polymetallic complexes of macromolecules are ubiquitous in conductive materials and biology. They are involved in a large number of processes; electron transport, metal storage or intermediates in redox reactions. In this respect, the interaction of metallic ions with large molecules is currently receiving much attention. Among the large chain molecules of interest, the linear conjugated macromolecules such as polyacetylenes and carotenoids are by far the most studied.[1] Unfortunately, the interactions of these polyene molecules occur only with the low oxidation state of metallic species such as carbonyl complexes. Ligands containing the —N=C—C=N— grouping are among the best known chelating agents, e.g. dimethylglyoxime, biacetyldihydrazone, 2,2′-bipyridine, etc. Larger polyaza chain molecules containing this grouping can be synthesized by condensation reactions between 1,2-diketones and hydrazines. Some polyaza ligands containing two —N=C—C=N— groupings and related metallic complexes have been previously synthesized.[2–14]

Recently, the syntheses and vibrational analysis of larger polyazadioxime oligomers have been reported.

The coordinating properties of the polyaza ligands are expected to differ from the coordinating properties of the corresponding monomeric systems, because of the several possible stereoisomers arising from the conformational changes of the backbone of the ligands.[13,14] The coordination of polyazadioxime molecules to copper(II) chloride was undertaken because the complexes exhibit a bridging route that consists of a polyatomic direct bonding pathway and conjugated bonding throughout the ligand.[13] The nature of

* Author to whom correspondence should be addressed.

magnetic and electronic interactions in magnetically coupled systems is the subject of much speculation,[15-19] but with the rapid growth in the number of reference complexes more information is being obtained. The spectroscopic and magnetic study of the copper(II) complexes of a series of polyazadioxime chain molecules promises to be a useful addition to the study of magnetic coupling propagated via a large polyatomic pathway.

EXPERIMENTAL

Synthesis of the polyazadioxime chain molecules

All chemicals were of reagent grade and were utilized without further purification except dehydration.

Dimethylglyoxime or 2,3-butanedione-2,3-dioxime (abbreviated hereafter H_2dox) was recrystallized from ethanol.

4,4 - *Diaza* - 3,6 - *dimethyl* - 3,5 - *octadiene* - 2,7-*dione*-2,7-*dioxime*, H_2doxN_2 (**2**). This was obtained by a method previously described.[7] Found: C, 49.0; H, 7.2; N, 28.2; O, 16.1. Calc. for $C_8H_{14}N_4O_2$: C, 48.5; H, 7.0; N, 28.3; O, 16.2%. Mass spectrum, *m/z* (%): 198(5); 182(10.8); 181(100); 165(5); 122(13.6); 98(29.4); 68(15.1); 58(32.2); 45(4.3).

4,4-*Diaza*[15]-3,6-*dimethyl*-3,5-*octadiene*-2,7-*dione*-2,7-*dioxime*, $H_2dox^{15}N_2$ (**2**). A solution of $^{15}N_2H_4 \cdot H_2O$ in dry ethanol was obtained from $^{15}N_2H_4 \cdot H_2SO_4$ (95%) (10^{-3} mol) and NaOH (2×10^{-3} mol). The solution of hydrazine hydrate was added dropwise to 0.222 g (2×10^{-3} mol) of 2,3-butanedione dissolved in 50 cm^3 of dry ethanol under vigorous stirring. The mixture was refluxed for 24 h and the volume reduced to 10 cm^3. Then the solution was kept at 0°C. After 24 h the pale yellow solid obtained was filtered and washed with cold methanol and diethyl ether. The product was dried *in vacuo*, yield 80%. Mass spectrum, *m/z* (%): 200(6); 184(150); 183(100); 182(4).

4,5,8,9 - *Tetraaza* - 3,6,7,10 - *tetramethyl* - 3,5,7,9-*dodecatetraene*-2,11-*dione*-2,11-*dioxime*, H_2doxN_4 (**3**). Biacetyldihydrazone or 2,3-butanedione-2,3-dihydrazone was obtained as previously described.[20,21]

0.114 g (10^{-3} mol) of biacetyldihydrazone was dissolved in 50 cm^3 of warm dry ethanol. This solution was added dropwise to 30 cm^3 of a stirred solution of dry ethanol containing 0.222 g (2×10^{-3} mol) of biacetyl monoxime. The mixture was refluxed for 24 h and then cooled to room temperature. After 24 h the yellow–orange microcrystals were filtered off and washed with cold ethanol and diethyl ether. The crystals were dried *in vacuo*, yield 80%. Found: C, 51.9; H, 7.54; N, 30.2; O, 9.9. Calc. for $C_{12}H_{20}N_6O_2$: C, 51.4; H, 7.1; N, 30.0; O, 11.4%. Mass spectrum, *m/z* (%): 280(9); 263(10.2); 204(4.7); 198(8); 182(10.5); 181(100); 163(8.1); 136(5.3); 123(9.4); 98(43); 68(20.1); 58(48).

4,5,8,9,12,13 - *Hexaaza* - 3,6,7,10,11,14 - *hexamethyl*-3,5,7,9,11,13 - *hexadecahexene* - 2,15 - *dione*-2,15-*dioxime*, H_2doxN_6 (**4**).[22] Bis(biacetyl)azine dihydrazone or 4,4-diaza-3,6-dimethyl-3,5-octadiene-2,7-dione-2,7-dihydrazone was obtained as previously described.[2] 0.196 g (10^{-3} mol) of bis(biacetyl)azine dihydrazone was dissolved in 50 cm^3 of warm dry ethanol. This solution was added dropwise to a stirred solution of 0.222 g (2×10^{-3} mol) of biacetyl monoxime in 30 cm^3 of dry ethanol. The mixture was refluxed for 24 h and then cooled to room temperature. After 24 h the yellow–orange microcrystals were filtered off and washed with cold ethanol and diethyl ether. The crystals were dried *in vacuo*, yield 80%. Found: C, 52.7; H, 7.13; N, 30.7; O, 7.1. Calc. for $C_{16}H_{26}N_8O_2$: C, 53.0; H, 7.2; N, 30.9; O, 8.8%. Mass spectrum, *m/z* (%): 362(4.1); 280(12.2); 263(25.4); 198(6.5); 181(43); 164(13.1); 98(100); 81(24.6); 51(11.4).

Poly(1,4-*diaza*-2,3-*dimethyl*-*butadiene*) (**5**). A solution of biacetyl (2×10^{-3} mol) in dry ethanol was added dropwise to N_2H_4 (2×10^{-3} mol) dissolved in 100 cm^3 of dry ethanol under vigorous stirring. The mixture was refluxed for 72 h and then cooled to room temperature. The pasty product obtained was washed with ethanol and diethyl ether. The product was dried *in vacuo*. Found: C, 60.1; H, 9.2; N, 31.2. Calc. for $(C_4H_6N_2)_n$: C, 58.5; H, 7.3; N, 34.1%.

Synthesis of the copper(II) *and zinc*(II) *complexes*

$Cu(H_2dox)Cl_2$ (**6**) *and* $Cu(H_2dox)Br_2$ (**7**). These were obtained as described in the literature.[23] Found: C, 19.3; H, 3.2; N, 11.1; Cu, 26.1; Cl, 28.2. Calc. for $CuC_4H_8N_2O_2Cl_2$: C, 19.2; H, 3.2; N, 11.2; Cu, 25.4; Cl, 28.3%. Found: C, 14.2; H, 2.4; N, 8.3; Cu, 18.7; Br, 46.8. Calc. for $CuC_4H_8N_2O_2Br_2$: C, 14.1; H, 2.4; N, 8.2; Cu, 18.7; Br, 47.1%.

$Cu_2(H_2doxN_2)Cl_4$ (**8**). To 50 cm^3 of a dry solution of hot ethanol containing 0.198 g (10^{-3} mol) of H_2doxN_2 were added dropwise and under vigorous stirring 20 cm^3 of a solution of dry ethanol containing 0.541 g (3×10^{-3} mol) of $CuCl_2$. After 12 h, green crystals separated.

They were collected by filtration, washed with cold ethanol and diethyl ether and dried *in vacuo*, yield 90%. Found: C, 21.9; H, 3.3; N, 11.8; Cu, 26.9; Cl, 29.3. Calc. for $Cu_2C_8H_{14}N_4O_2Cl_4$: C, 21.0; H, 3.0; N, 12.0; Cu, 27.2; Cl, 30.0%.

$Cu_2(H_2doxN_2)Br_4$ (**9**). This was obtained in a similar manner except $CuBr_2$ was used in place of $CuCl_2$, yield 90%. Found: C, 15.0; H, 2.4; N, 8.4; Cu, 19.4; Br, 49.1. Calc. for $Cu_2C_8H_{14}N_4O_2Br_4$: C, 14.9; H, 2.1; N, 8.7; Cu, 19.7; Br, 49.6%.

$Zn_2(H_2doxN_2)Cl_4$ (**10**). 0.198 g (10^{-3} mol) of H_2doxN_2 was dissolved into 50 cm^3 of hot dry ethanol. This solution was added dropwise under vigorous stirring to 20 cm^3 of dry diethyl ether containing 0.410 g (3×10^{-3} mol) of $ZnCl_2$. After 6 h, pale yellow crystals were collected by filtration under dry argon, washed rapidly with dry diethyl ether and dried *in vacuo*, yield 80%. Found: C, 20.8; H, 3.2; N, 11.5; Zn, 26.9; Cl, 30.5. Calc. for $Zn_2C_8H_{14}N_4O_2Cl_4$: C, 20.4; H, 3.0; N, 11.9; Zn, 27.8; Cl, 30.2%.

$Cu_3(H_2doxN_4)Cl_6$ (**11**). 0.280 g (10^{-3} mol) of H_2doxN_4 was dissolved into 60 cm^3 of hot dry ethanol. This solution was added dropwise under vigorous stirring to 20 cm^3 of dry ethanol containing 0.853 g (5×10^{-3} mol) of $CuCl_2$. After 24 h, dark green crystals were filtered off, washed with ethanol and diethyl ether and dried *in vacuo*, yield 90%. Found: C, 21.0; H, 3.1; N, 12.2; Cu, 26.8; Cl, 30.7. Calc. for $Cu_3C_{12}H_{20}N_6O_2Cl_6$: C, 21.1; H, 2.9; N, 12.3; Cu, 27.2; Cl, 31.1%.

Attempt to obtain $Cu_4(H_2doxN_6)Cl_8$ (**12**). The method used is similar to that used for $Cu_3(H_2doxN_4)Cl_6$ (**11**). Unfortunately, even in the presence of an excess of $CuCl_2$, the resulting compound does not correspond to a definite product but to a mixture of $Cu_3(H_2doxN_6)Cl_6$ and $Cu_4(H_2doxN_6)Cl_8$.

Physical measurements

The IR spectra were recorded on a FT–IR Bruker IFS 113V instrument using the KBr disc method of Nujol mulls (4000–500 cm^{-1}) and polyethylene disc method (500–20 cm^{-1}).

The Raman spectra were recorded using a triple monochromator Dilor RTI 30 instrument. The exciting lines used were the radiations of a krypton (647.1 nm) or argon (514.5, 488.0, 457.9 nm) ion laser. Sample spinning cell techniques were used and the absorbing samples were diluted in solid K_2SO_4 and pressed to form pellets.

The electronic spectra were run on a "Jobin et Yvon" DUOSPAC 203 instrument, using Nujol mulls.

EPR spectra were recorded at X-band on a Varian E.109 spectrometer at room and liquid nitrogen temperatures using powder samples. The magnetic field was calibrated with a DPPH marker.

Magnetic measurements were performed on a Faraday type magnetometer equipped with a helium continuous-flow cryostat in the 4–300 K temperature range. $HgCo(NCS)_4$ was used as a susceptibility standard. Diamagnetic corrections for **7** and **10** were taken as -236 and -342×10^{-6} cm^3 mol^{-1}, respectively. The data were also corrected for the temperature independent paramagnetism (TIP) of the copper(II) ions, 60×10^{-6} cm^3 mol^{-1}.

RESULTS

Synthesis of the copper(II) *and zinc*(II) *polyaza complexes*

The polyazadioxime chain molecules are capable of chelating metallic ions through the nitrogen-donor atoms. The coordination capabilities of the polyaza chain molecules depend on the nature of the metallic ion and the counterion.

In the presence of $CuCl_2$, H_2dox forms a well-known complex $Cu(H_2dox)Cl_2$ (**6**)[6] which has been structurally well characterized[24,25] (Fig. 1). The conformational changes in the backbone of the H_2dox ligand result in a torsion of 180° around the N=C—C=N single bond. Upon coordination, the backbone of the ligand changes from the C_{2h} to C_{2v} point symmetry group.

In the presence of MX_2 (M = Cu, Zn; X = Cl, Br), H_2doxN_2 forms binuclear complexes $M_2(H_2doxN_2)X_4$. All the complexes are poorly soluble in dry ethanol. They crystallize immediately without dramatic rearrangement of the backbone of the chain molecule except for torsional motions. Among the possible stereoisomers of the H_2doxN_2 molecule (Fig. 2) the (*E,E,E,E*) s all *trans* conformation is the most probable.[21] When the ligand is dissolved in the presence of an excess of MX_2, the conformational changes of the H_2doxN_2 molecule result in a torsion of 180° around the N=C—C=N single bonds and the coordination constrains the

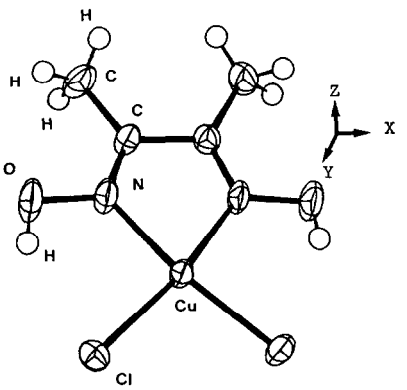

Fig. 1. Molecular structure of $Cu(H_2dox)Cl_2$ (from refs 24 and 25).

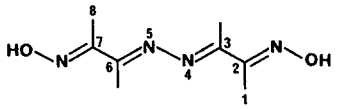

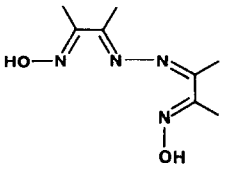

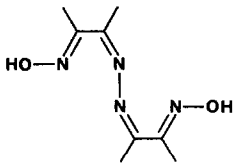

Fig. 2. Possible stereoisomers of the H_2doxN_2 molecule.

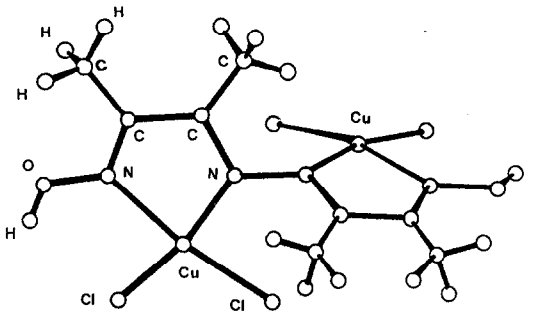

Fig. 3. Idealized molecular geometry of $Cu_2(H_2doxN_2)Cl_4$ (**8**).

(*E,E,E,E*) s *cis*, s *gauche*, s *cis* conformation (Fig. 3). Upon coordination, the backbone of the planar subunits N=C—C=N change from C_{2h} to C_{2v} symmetry. The resulting symmetry of the complex is at the very most C_2.

Unfortunately attempts to obtain suitable crystals for X-ray analysis failed and no definitive structural assignment could be made. Nevertheless the structure of a parent ketazine complex has been reported earlier[13] and supports the reasonable structural assumptions concerning all the complexes under study (Fig. 3). The bridge connecting the two metal centres consists of an azine linkage. The complex is not planar, there is a rotation about the N—N bond to minimize the intra- and intermolecular contacts. To prevent the precipitation of fortuitous compounds such as $M(H_2doxN_2)X_2$, the ligand is introduced dropwise to a vigorously stirred solution containing a large excess of metallic salts. Elemental analyses were undertaken after numerous attempts with different metal–ligand ratios, and are in good agreement with the proposed formulation $M_2(H_2doxN_2)X_4$ with the range [2.5–5] for the metal–ligand ratio.

The geometry of the backbone of the coordinated H_2doxN_2 molecule depends on the counterion X of the metallic compounds MX_2. As previously reported,[14] coordination of H_2doxN_2 with $Cu(ClO_4)_2$ leads to a template rearrangement of the H_2doxN_2 molecule. In the $[Cu(HdoxN_2)]_2[ClO_4]_2$ complex, the $HdoxN_2^-$ anion acts as a planar tridentate ligand with an (*E,E,Z,E*) s *cis*, s *trans*, s *cis* conformation, Fig. 4.

Among the possible stereoisomers of the H_2doxN_4 molecule, the (*E,E,E,E,E,E*) all *trans* conformation is the most probable,[21] Fig. 5. When the H_2doxN_4 ligand is dissolved in the presence of an excess of MX_2 (M = Cu, X = Cl, Br) the conformational modifications of the H_2doxN_4 molecule, upon coordination, arise from a torsion of 180° around the C—C single bonds (Fig. 5) and

the preferred conformation in $Cu_3(H_2doxN_4)Cl_6$ becomes (*E,E,E,E,E,E*) s *cis*, s *gauche*, s *cis*, s *gauche*, s *cis*.

The bridges connecting the three metal centres consist of two azine linkages. The symmetry of the planar N=C—C=N subunits evolves from C_{2h} to C_{2v}. The resulting symmetry of the complex is at the very most C_2 because of the rotation around the N—N bonds to minimize the intra- and intermolecular contacts. The resulting structure of the tricopper complex may be expected to be a non-planar spiral structure rather than a planar zigzag structure.

It should be noted that the elemental analyses concerning the $Cu_3(H_2doxN_4)Cl_6$ compound are in good agreement with the proposed formulation if the metal–ligand ratio is in the [4–7] range.

Attempts to obtain pure tetrametallic complexes, $M_4(H_2doxN_6)Cl_8$, have failed to date, and the numerous elemental analyses are not in good agreement with the proposed formulation in the range [4–8] for the metal–ligand ratio. The elemental analyses likely correspond to a mixture of $Cu_3(H_2doxN_6)Cl_6$ and $Cu_4(H_2doxN_6)Cl_8$ complexes. The conformational changes in the backbone of the $doxN_6$ molecule do not occur for all four subunits before precipitation of the compound. In the same way, if the polycondensation between biacetyl and hydrazine is undertaken under template synthesis conditions, no significant metal content is detected. It is probable that the all s *trans* conformation of the polymer remains, even in the presence of a large excess of $CuCl_2$.

Vibrational spectroscopy

IR and Raman spectroscopies have been used to establish the conformational changes of the ligand backbones during the complexation and the mode of bonding in the coordination sphere of the metallic ions copper(II) and zinc(II). Therefore, the assignments of the most characteristic Raman and IR bands of both polyaza chain molecules and related metallic complexes have been undertaken by comparison between ^{14}N and ^{15}N labelled compounds' spectra, Cl and Br, Cu and Zn derivatives, respectively. The effects of site and crystal in the solid state are probably weak and not resolved with the resolution used to run the spectra at room temperature. So, the spectra are interpreted using the molecular structure hypothesis in the solid state.

The vibrational spectra of all the compounds H_2dox, H_2doxN_2, H_2doxN_4 and H_2doxN_6 are in good agreement with a C_{2h} symmetry group.[21,22,26] Indeed with C_{2h} symmetry, the normal vibrations are either Raman active (A_g+B_g) or IR active (A_u+B_u). It should be noted that the spectra of the polyaza chain molecules are particularly characteristic of the N=C(CH$_3$)C(CH$_3$)=N subunits with planar C_{2h} local symmetry.

The coordination of metallic moieties such as MX_2 (M = Cu, Zn; X = Cl, Br) to subunits, through the two nitrogen atoms, imposes a 180° rotation around the C—C bond to give subunits with C_{2v} symmetry group. The A_1, B_1 and B_2 modes are IR active, whereas all the vibration modes A_1, A_2, B_1 and B_2 are Raman active. The polymetallic complexes of the large polyazadioxime molecules arise from the linkage of two, three or four subunits with C_{2v} local symmetry, the resulting symmetry group is at the most C_2 for all of the compounds.

The band pattern of the spectra of the polymetallic complexes resemble that of the MH_2doxX_2 spectra, therefore assignments can be made in correspondence with the results from the vibrational analysis of the monomeric species. The main Raman and IR peaks of the copper(II) complexes $Cu(H_2dox)Cl_2$, $Cu_2(H_2doxN_2)Cl_4$ and $Cu_3(H_2doxN_4)Cl_6$ are collected in Table 1. The lines observed in the ν(C=N) region are indicative of the skeletal change upon coordination. Indeed, the ν(C=N—OH) and ν(C=N—N) modes are both IR and Raman active for all the metallic compounds under study. These results are in good agreement with local C_{2v} symmetry of the subunits for all the ligands with the all *E* configuration in $[Cu(HdoxN_2)_2][ClO_4]_2$, inducing four bands in the ν(C=N) region which are IR and Raman active. This result is in good agreement with a C_s symmetry of the ligand.[14]

The lines observed in the spectral range 1400–600 cm^{-1}, attributed to deformation, rocking and wagging motions of the methyl groups, indicate poorly the skeletal change of the polyaza molecules upon coordination. The more sensitive indications of the conformational changes are the skeletal deformation and torsion motions which are active

in the far wavenumber range, Table 1, however, the interpretation is not straightforward.

The assignments of the most characteristic vibrational modes of the coordination sphere MN_2X_2 are achieved by comparison with those of $Cu(H_2dox)X_2$ (X = Cl, Br) and the zinc analogue complexes. Among the $4A_1+A_2+B_1+3B_2$ expected vibration modes for the MN_2X_2 moieties, only the intense IR modes ν_{as},ν_s(M—X) and δ(XMX) are unequivocally assigned. Indeed, the weak ν_s and ν_{as}(M—N) stretching modes are masked by the intense bands arising from the MCl_2 vibrations and are only clearly observed with X = Br. Nevertheless, when the complexes contain more than one MN_2X_2 subunit, the Raman and IR bands are broad.

Electronic transitions

The electronic spectra of the copper(II) complexes exhibit several bands at: 270 (s), 310 (s), 350 (sh), 460 (sh), 690 (w) nm for $Cu(H_2dox)Cl_2$; 280 (s), 330 (s), 350 (sh), 470 (sh), 690 (w), 760 (w) nm for $Cu_2(H_2doxN_2)Cl_4$; 320 (s), 370 (s), 350 (sh), 490 (sh), 690 (w), 740 (w), 770 (w) nm for $Cu_3(doxN_4)Cl_6$, with the respective intensities s (strong), sh (shoulder) and w (weak). The assignments of these electronic transitions may be facilitated by comparing the spectra with those of the corresponding free ligand and zinc(II) complex. Indeed the two strong absorptions near 300 nm are observed both in the free ligand and metallic complex spectra. They are attributed readily to internal ligand $\pi \rightarrow \pi^*$ transition. In addition, the weak and broad absorptions around 700 nm are not observed for the zinc(II) analogues and are assigned to $d \rightarrow d$ transitions in copper(II) complexes. The medium absorptions, observed as shoulders near 350 and 470 nm in all the spectra of metallic complexes, probably arise from $d \rightarrow \pi^*$ metal–ligand charge-transfers. The charge-transfer character of the latter transitions can be verified if the Raman spectra of the metallic complexes are carried out at different exciting lines within the contour of the charge-transfer bands. A pre-resonance Raman effect was detected particularly for the Raman bands in the ν(C=N) region, Table 1. The Raman band intensities of the ν_s(C=N) modes are enhanced more and

more if the exciting line wavelength decreases from 647.1, 514.5, 488.0 to 457.9 nm. These features indicate that the orbitals of the C=N group participate in the π^* molecular orbital involved in the charge-transfer transition. It should be noted that the intense Raman band corresponding to the ν(N—N) bond in the free polyaza ligands is not enhanced by resonance effects and may be clearly detected only in the $Zn_2(doxN_2)Cl_4$ complex at 1055 cm^{-1} with off-resonance conditions. The *d–d* bands are too broad to be used as a "criterion of stereochemistry".[27,28] Indeed, four *d–d* transitions are expected for one CuN_2Cl_2 chromophore with C_{2v} local symmetry from $d_{z^2}(a_1)$; $d_{x^2-y^2}(a_1)$; $d_{xz}(b_2)$; $d_{yz}(a_2)$ to the ground state $d_{xy}(b_1)$. $Cu(H_2dox)Cl_2$ exhibits ill-defined absorptions around 700 nm as generally reported for copper(II) complexes with square-planar stereochemistry. For di- and tri-copper(II) complexes, there are two and three CuN_2Cl_2 chromophores and the respective electronic absorption spectra exhibit untractable absorptions near 700 nm for the elucidation of the stereochemistry.

Magnetic susceptibility and EPR spectra

The theory of exchange interactions in copper(II) dimers and trimers has been treated in detail previously.[16,18,19,29]

The crystal structure[24] and magnetic susceptibility[23] of $Cu(H_2doxCl_2)Cl_2$ have previously been reported. The complex consists of dimeric $[Cu(H_2dox)Cl_2]_2$ units that are essentially isolated from each other, although the dimeric moieties are linked together through hydrogen bonds to form an infinite linear chain.[25] The bridging Cu_2Cl_2 unit is constrained to be planar by the presence of the crystallographic inversion centre in the middle of the dimer. The geometry of each copper can be described as a distorted tetragonal-pyramidal arrangement, the bridging chloride occupying the apical site.

Magnetic suspectibility measurements[21] show that the exchange coupling constant was found to be small, $2J = +0.30$ cm^{-1}, where J is defined by the well-known spin-Hamiltonian:

$$H = -2JS_1 \cdot S_2, \qquad (1)$$

for a pair of $S = 1/2$ ions; $-2J$ represents the energy gap between the two low-lying states resulting from the spin coupling. As previously reported,[23] the EPR spectrum of $Cu(H_2dox)Cl_2$, run at room temperature, exhibits a clear resolution of the **g** tensor principal components into a parallel $g_\parallel = 2.21$ and a perpendicular $g_\perp = 2.03$ component. On lowering the temperature to 77 K the spectrum shows a complete **g** tensor anisotropy with $g_x = 2.02$, $g_y = 2.04$ and $g_z = 2.21$. The corresponding bromide derivative $Cu(H_2dox)Br_2$, exhibits a broad quasi-isotropic feature centred at $\langle g \rangle = 2.03$ at room temperature.[23] On lowering the temperature to 77 K, only a weak change is observed in the EPR spectrum. It should be noted that the signals observed for non-dilute powdered samples are only a good estimation of the crystal **g** tensor components rather than the molecular **g** tensor components.

The magnetic susceptibility of the dicopper(II) complex $Cu_2(H_2dox)N_2)Cl_4$ is plotted in Fig. 6 as a function of temperature. The magnetic susceptibility per copper exhibits a broad maximum around 30 K, which rapidly drops as the temperature is lowered. This type of temperature-dependent behaviour is expected for an antiferromagnetically coupled copper(II) binuclear molecule. The magnetic susceptibility per copper may be calculated using the Bleaney–Bowers expression.[30]

$$\chi_{Cu} = N\beta^2 g^2/kT[3+\exp(-2J/kT)]^{-1}[1-\rho] + \rho N\beta^2 g^2/4kT + \chi_{TIP}. \qquad (2)$$

In eq. (2) the symbols have their usual meaning. The formula gives the magnetic susceptibility per mole of copper atom in the coupled system, corrected for TIP and paramagnetic impurities. The curve through the data points in Fig. 6 was obtained from the best fit of the data to eq. (2) with the parameters $g = 2.08 \pm 0.03$, $\rho = 0.08 \pm 0.01$ and $2J = -38.5 \pm 2$ cm^{-1}. The magnetic data of the dicopper(II) complex $Cu_2(H_2doxN_2)Cl_4$ are analogous to those reported previously[13] for the parent complex $Cu_2(pmk)Cl_4$. The magnitude of $-2J$ suggests that the dominant pathway for exchange is superexchange through the Cu—N—N—Cu azine bridge. Earlier magnetic susceptibility measurements show that the exchange couplings through the Cu–Cl–Cu exchange pathway are weak for $[Cu(H_2dox)Cl_2]_2$ and $Cu_2(pmk)Cl_4$[13] compounds. The g value obtained from the magnetic measurements for the $Cu_2(H_2doxN_2)Cl_4$ compound, $g = 2.08 \pm 0.03$, is in good agreement, within the experimental error range, to the isotropic $\langle g \rangle$ value deduced from the EPR data, $\langle g \rangle = 1/3(g_\parallel + 2g_\perp) = 2.1$. At 77 K two components can be observed, $g_\perp = 2.06$ and $g_\parallel = 2.18$, in the EPR spectrum of $Cu_2(H_2doxN_2)Cl_4$. The spectrum appears to be in agreement with a triplet spin state, $S = 1$, by the temperature dependence although any half-field signal is observed. The molecular **g** tensors of the two magnetic sites were found to be identical and analogous to that of the monomeric species $Cu(H_2dox)Cl_2$. It should be noted that the signals remain broad even at low temperature and the zero-

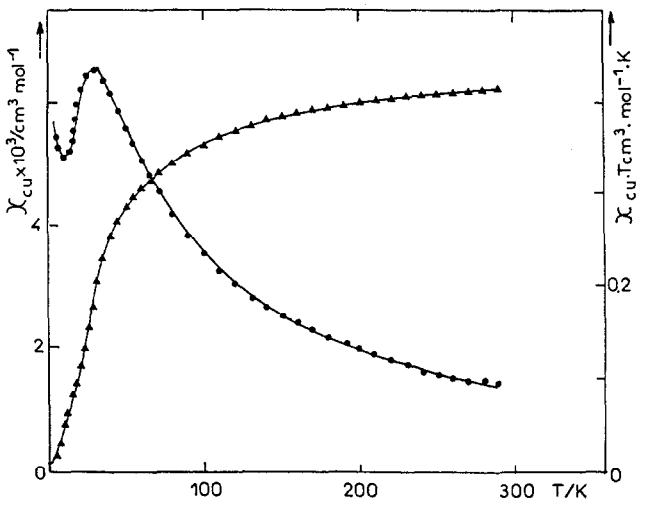

Fig. 6. Magnetic susceptibility per copper (●) and the product $\chi_{Cu}T$ (▲) plotted as a function of temperature for $Cu_2(H_2doxN_2)Cl_4$. The curve through the data is the best fit of the data to eq. (2), as described in the text.

field splitting parameters cannot be drawn out as previously reported for dicopper(II) analogues.[31]

The temperature dependence of χ_{Cu} vs T for $Cu_3(H_2doxN_4)Cl_6$, represented in the form of the product $\chi_{Cu}T$, the magnetic susceptibility per mole of copper multiplied by the temperature, is shown in Fig. 7. The general form of the magnetic data for $Cu_3(doxN_4)Cl_6$ is appropriate for a trimer with dominant exchange interactions between adjacent copper atoms.[32,36] To characterize the exchange interaction in symmetric trimers, the spin-Hamiltonian may be written:

$$H = -2J_{12}(S_1 \cdot S_2 + S_2 \cdot S_3) - 2J_{13}S_1 \cdot S_3. \quad (3)$$

The exchange integral J_{12} refers to two adjacent copper atoms and J_{13} to the interaction between the terminal copper atoms by coupling S_1 and S_3 to give an intermediate spin state S^*, and then coupling S^* to S_2 to give a total spin state S. The low-lying states are a ground doublet state 1/2(0), an excited doublet state 1/2(1) and an excited quartet state 3/2(1) using the notation $S(S^*)$.[32] Different **g** tensor values correspond to the different $S(S^*)$ states according to the relation previously reported.[36] As long as the trinuclear complex has two equivalent ions, the two spin doublets are not mixed and the g values for the various multiplets can be easily expressed as a linear combination of the **g** tensors of the individual ions. Therefore the most general expression for the magnetic susceptibility of a sym-

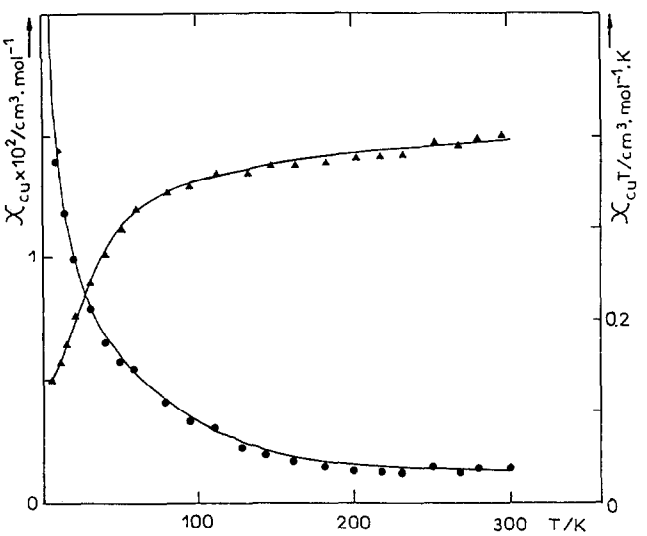

Fig. 7. Magnetic susceptibility per mole of copper (●) and the product $\chi_{Cu}T$ (▲) as a function of temperature for $Cu_3(H_2doxN_4)Cl_4$. The curve through the data is the best fit of the data to eq. (4) as described in the text.

metric trimer is reduced to the following equation[32] if $\mathbf{g}_1 = \mathbf{g}_2 = \mathbf{g}_3 = \mathbf{g}$ and if J_{13} is assumed to be negligible as expected for nearly linear tricopper complexes. It should be noted that neither the nonplanar spiral structure nor the planar zigzag structure exhibits a strictly linear alignment of the Cu_3 system.

$$\chi_{Cu} = N\beta^2 g^2/12kT[X/Y]+\chi_{TIP}$$
$$X = 10\exp[J_{12}/kT]+\exp[-2J_{12}/kT]+1$$
$$Y = 2\exp[J_{12}/kT]+\exp[-2J_{12}/kT]+1. \quad (4)$$

The experimental values of $\chi_{Cu}T$ have been fit to eq. (4) by treating g and J_{12} as adjustable parameters. The resulting best fit is shown as the solid line in Fig. 7. The best fit is achieved with $g = 2.13\pm0.05$ and $2J_{12} = -25\pm3$ cm^{-1}. The reasonable agreement between calculated and experimental $\chi_{Cu}T$ values supports the hypothesis effected and discussed earlier in detail.[32,36] The magnetic data show that the coupling between the internal and the two external copper ions of the trimer is antiferromagnetic, therefore, the **g** tensor of the ground spin doublet is given by[36] $\mathbf{g} = 4/3\mathbf{g}_1 - 1/3\mathbf{g}_2$, where $\mathbf{g}_1 = \mathbf{g}_3$ and $\mathbf{g}_2$ are local **g** tensors for external and internal copper nuclei, respectively. The temperature dependence of the apparent **g** values obtained from powder EPR spectra can be compared to these reported previously for tricopper(II) analogues.[36] Above 77 K the two spin doublets and the spin quartet are populated and the observed spectrum at a given temperature above 77 K would be a thermal average of the spectra of the three multiplets. If the individual local **g** tensors are analogous, as assumed the **g** components obtained at 77 K in the EPR spectrum, $g_x = 2.06$, $g_y = 2.19$, $g_z = 2.23$, are relevant to the doublet ground state with an average value $\langle g \rangle = 2.16$ in accordance with the magnetic data.

DISCUSSION

Without X-ray data for the polymetallic complexes under study, it is not possible to analyse the relationship between the structural and magnetic properties of complexes of the types $Cu(H_2dox)Cl_2$, $Cu_2(H_2doxN_2)Cl_4$ and $Cu_3(H_2doxN_4)Cl_6$. Indeed, even if the gross molecular structures can be reasonably assumed from the experimental data of the present work, they cannot predict the magnetic behaviour since a small modification of the structural parameters may drastically modify the magnetic properties of the polymetallic complexes. However, it is possible from a small number of basic concepts to explain qualitatively the magnetic properties and to deduce some structural evidence.[18,37] The spin–spin coupling in the polycopper(II) complexes under study may be propagated through the Cu—N—N—Cu azine exchange pathway or either of the Cu—Cl—Cu exchange pathways.

If the intermolecular chlorine–copper contacts form a coordination polyhedron close to a tetragonal pyramidal geometry, the exchange interaction between the two copper ions would be weak, as observed previously for $[Cu(H_2dox)Cl_2]_2$ and $Cu_2(pmk)Cl_4$.[13,38,39]

The magnetic orbital lies in the plane determined by the four closest atoms N_2Cl_2. If these atoms lie in a plane, the magnetic orbital would have little density out of the plane and the amount of overlap onto the bridging chlorine would be small. It is important to note that the fitted curves shown in Figs 6 and 7 did not require significant corrections for interdimer magnetic coupling arising from the possible intermolecular chlorine bridging contacts. It is clear from magnetic susceptibility data that chain behaviour is not obtained. By analogy with the $Cu(H_2dox)Cl_2$ complex, the $Cu_2(H_2doxN_2)Cl_4$ and $Cu_3(H_2doxN_4)Cl_6$ complexes would be expected to exhibit negligible exchange interactions via the chloride bridges, and the propagation of magnetic coupling occurs via the direct azine pathway resulting in intramolecular antiferromagnetic superexchange.

The coordination polyhedron of each copper(II) ion in $Cu_2(H_2doxN_2)Cl_4$ and $Cu_3(H_2doxN_4)Cl_6$ is deduced to be nearly planar as reported previously for the $[Cu(H_2dox)Cl_2]_2$ complex.[24,25] In the square-planar environment the most destabilized orbital occupied by the unpaired electron of copper (II) ion is of the d_{xy} type.[18] This points from the metal towards the four nearest neighbours N_2Cl_2 in an antibonding fashion. It can be expected that the main factor governing the magnitude of the antiferromagnetic interaction via the extended azine bridge will be the overlap of magnetic orbitals. Both the orientation and delocalization of the magnetic orbitals favour their overlapping and thus the antiferromagnetic interaction. The possibility of the former method is governed by the torsional angle of the ketazine bond C=N—N=C, which is indicative of the relative orientation of the d_{xy} magnetic orbitals. However, the delocalization depends on the energy gap between the copper(II) orbitals and the ligand orbitals, which depends on the torsional angles of the azine functions. The delocalization in the monomeric subunits is transmitted through the azine bond via the σ molecular orbital system only, according to the assumed dihedral angle between the planar monomeric fragments, the π molecular

orbital system is not delocalized over the entire molecules.

It is tempting to compare the present $2J$ values with those obtained for parent dimeric complexes. The antiferromagnetic coupling constants reported for $Cu_2(pmk)Cl_4$[13] and for $Cu_2(H_2doxN_2)Cl_4$ in the present study are in the same order, -52 and -38 cm^{-1}, respectively. They suggest a dihedral angle between the two planar monomeric fragments of more than 30° in $Cu_2(H_2doxN_2)Cl_4$. Indeed if a coplanar conformation of the two monomeric fragments is constrained through a rigid ligand such as pyridazine-3,6-diformyldioxime, H_2piox, to form the $Cu_2(Hpiox)_2(ClO_4)_2(H_2O)_2$ complex,[40] the magnitude of the antiferromagnetic coupling is very large and close to 500 cm^{-1}. This strong interaction is due to the strict co-planarity of the two magnetic orbitals and to their delocalization through the σ and π systems of the ligands. Analogous conclusions[41,43] can be drawn from earlier reports concerning parent complexes with pyridazine, imidazolato and triazolato bridging ligands.

The knowledge of the magnetic exchange pathway for $Cu_2(H_2doxN_2)Cl_4$ indicates that for the non-planar tricopper complex, $Cu_3(H_2doxN_4)Cl_6$, the magnitude of the superexchange between the two external copper(II) ions is expected to be negligible as is assumed in strictly linear tricopper complexes.[34] The antiferromagnetic coupling constant value between the two adjacent copper(II) ions is of the same order as that observed for the dimer analogue $Cu_2(H_2doxN_2)Cl_4$, -25 and -38 cm^{-1}, respectively. From the results obtained in the present work, it should be reasonable to speculate that the magnitude of the antiferromagnetic coupling between two adjacent copper(II) ions in the linear tetracopper(II) complex, $Cu_4(H_2doxN_6)Cl_8$, or in the copper(II) linear chains of the twisted ribbon type, is in the same range as that measured in $Cu_3(H_2doxN_4)Cl_6$, although these compounds have not been successfully synthesized as yet.

(*Received* 26 *April* 1989; *accepted after revision* 7 *June* 1990)

Abstract—The study of soluble complexes formed in aqueous solution between iron(III) and 5-sulphosalicylic acid (H_3L) has been carried out by means of potentiometric techniques, at 25°C, employing 0.5 mol dm^{-3} $NaNO_3$ as inert ionic media. The results, obtained by a proper numerical analysis of the experimental data, show the formation of the following metal complexes in solution (charges omitted; the values between parentheses correspond to the respective stability constants): FeHL ($\log \beta_{111} = 19.12$), FeL ($\log \beta_{011} = 17.05$), Fe_2L_3 ($\log \beta_{023} = 48.41$), FeL_2 ($\log \beta_{012} = 26.42$) and FeL_3 ($\log \beta_{013} = 32.76$). As seen, in the presence of 5-sulphosalicylic acid, iron(III) forms a polynuclear complex of stoichiometry Fe_2L_3, which has not been reported before.

As a continuation of our interest to study naturally occurring ligands bearing carboxylic groups as complexing agents for iron(III) ions,[1–3] 5-sulphosalicylic acid has been chosen. The ligand has a structural similarity with salicylic acid and higher solubility. Also, the use of 5-sulphosalicylic acid avoids precipitation of ferric hydroxide in aqueous solution.

In the molecule of 5-sulphosalicylic acid, the carboxylic and hydroxylic groups are attached to a benzene ring. This fact brings some different characteristics to 5-sulphosalicylic acid with respect to the previously studied ligands, i.e. increasing the rigidity of the chelating ring as well as the acidic character of the hydroxylic group.

5-Sulphosalicylic acid is used in laboratories as a colorimetric reagent for iron(III) ions.[4] Data for the iron(III)–5-sulphosalicylic acid system reported in the literature and summarized in Table 1, show a general agreement of the proposed models,[5–10] regarding M : L stoichiometries of 1:1, 1:2 and 1:3. Despite this, some important differences are observed between the values of stability constants proposed in ref. 10 with respect to other authors.[7–9] This fact encouraged us to carry out a detailed and systematic study of the complexing equilibria in the iron(III)–5-sulphosalicylic acid system, using 0.5 M NO_3^- as ionic medium. The present work has been thus undertaken in order to obtain precise information on the system iron(III)–5-sulphosalicylic acid by a proper characterization of the chemical reactions involved.

EXPERIMENTAL

The study is based on experimental data including measurements of the free hydrogen ion concentration, h, in a number of aqueous solutions containing iron(III) and 5-sulphosalicylic acid. The method, based on potentiometric titrations, has been described in detail before.[1–3]

For the different experiments, the analytical concentrations of iron(III), B, and 5-sulphosalicylate C, in the test solutions, were varied in the range

0.8–1.0 mmol dm^{-3} and 9.0–25.0 mmol dm^{-3}, respectively. The pH was varied in the range 1.5–7.5.

The experiments were carried out in a thermostatic bath at 25±0.1°C.

RESULTS

Protolytic equilibria of 5-sulphosalicylic acid

By using the potentiometric technique, with test solutions of $B = 0$ the protonation constants of the 5-sulphosalicylic ion were determined at the above mentioned conditions. The results obtained include only mononuclear species (no aggregates were detected in the analysis of data). The constants were evaluated by using a graphical method[12] and later refined with the least-square fitting programs LETAGROP[13] and SUPERQUAD.[14] The final values are given in Table 2. A comparison of these results with those determined by other authors[7,8,10,15,16] has been carried out by a correlation procedure using the specific ionic interaction theory[17] and related coefficients obtained from refs 17 and 18; Fig. 1 gives the results of this correlation. As seen by this treatment, our values give a good correlation with those obtained with diverse ionic media and also fit better than the protonation constants proposed in refs 8 and 10.

Iron(III)–5-sulphosalicylate complexes

The formation of soluble complexes between iron(III) and 5-sulphosalicylate can be expressed by the general equation:

$$pH + qFe + rL \rightleftharpoons H_pFe_qL_r; \quad \beta_{pqr}, \qquad (1)$$

where β_{pqr} represents the formation constant of corresponding p, q, r complex species. Figure 2 shows the experimental data obtained, plotted in the form Z vs $-\log h$ at different B and C levels.

Z represents the number of H^+ bound to the total 5-sulphosalicylate, defined by:

$$Z = (A - h + K_w \cdot h^{-1})/C, \qquad (2)$$

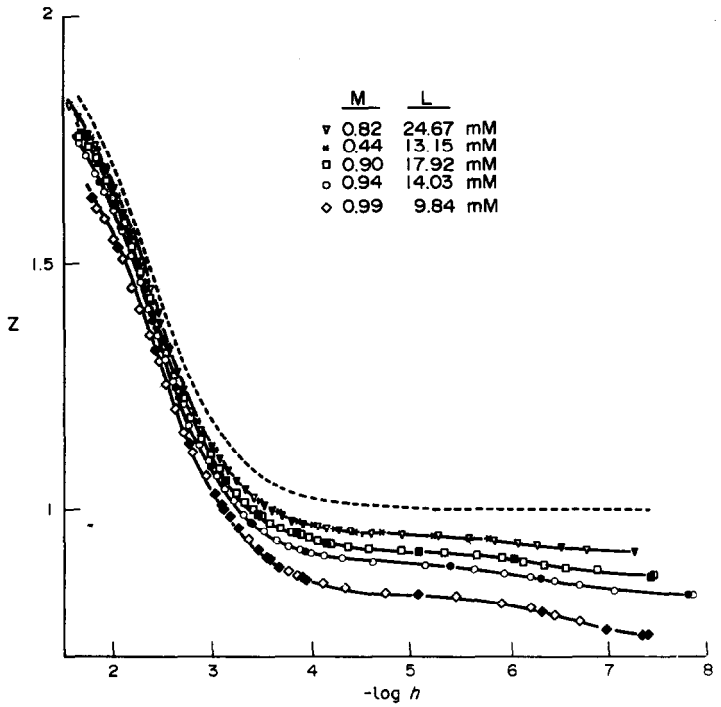

Fig. 2. Z plotted vs $-\log h$ for the different sets of experiments. Full points represent back titrations. Solid lines have been calculated by the model proposed in the present work.

where A represents the analytical concentration of hydrogen ion.

In order to verify our equilibrium data, back titrations were performed using the same analytical composition of the system. These data also are plotted. The good agreement between the forward and back titration data also shows that no irreversible processes take part in the complexation reactions.

The stoichiometry of the complexes as well as the constant β_{pqr} have been determined by means of numerical analysis of the obtained data. For this purpose, the computer programs LETAGROP[13] and SUPERQUAD[14] were used. The results obtained from this treatment are collected in Table 3. As seen, the introduction of a polynuclear species of stoichiometry Fe_2L_3 contributes definitively to the best fit of the model to the experimental data. This species has not been reported before.

Thus, the best fit of the experimental data is obtained when the species FeHL, FeL, Fe_2L_3, FeL_2 and FeL_3 are formed. These results are expressed

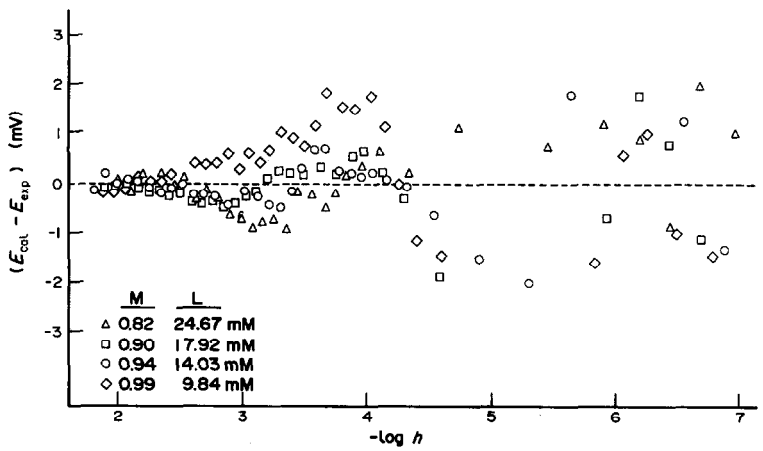

Fig. 3. Residuals $(E_{calc}-E_{exp})$ (mV) values plotted vs $-\log h$ for the different experimental data on the basis of the model proposed by eqs (3)–(7).

The standard deviation σ (mV) is defined as $(U/[N_{p-Nk}\beta])^{1/2}$. N_k is the number of constants to adjust. The error in the constant values is given as $\pm3\sigma$ (log β). When $\sigma(k) > 0.2\beta$, the "best" value of log β and the maximum value, Max, log $[\beta+3\sigma(\beta)]$ are given.

by the following reaction equations; corresponding β_{pqr} values are given:

$$Fe+L+H \rightleftharpoons FeHL;\ \log\beta_{111} = 19.12\pm0.02 \quad (3)$$

$$Fe+L \rightleftharpoons FeL;\ \log\beta_{011} = 17.05\pm0.02 \quad (4)$$

$$2Fe+3L \rightleftharpoons Fe_2L_3;\ \log\beta_{023} = 48.41\pm0.01 \quad (5)$$

$$Fe+2L \rightleftharpoons FeL_2;\ \log\beta_{012} = 26.42\pm0.01 \quad (6)$$

$$Fe+3L \rightleftharpoons FeL_3;\ \log\beta_{013} = 32.76\pm0.02. \quad (7)$$

Using this set of complexes, we systematically considered new complexes by using a statistical process of LETAGROP called "Species Selector".[19] In this sense, taking into account the acidic properties of Fe^{3+}, the new complexes included species of the type $Fe_p(OH)_qL_r$. Altogether, 43 new complexes were tried, but the model expressed by eqs (3)–(7) still gives the best fit of the experimental data.

Figure 3 shows the residual values of $(E_{calc}-E_{exp})$ in mV. As seen, there is no evidence of systematic deviations on the proposed model.

DISCUSSION

The results obtained in the present work correspond to the complex formation between iron(III) and 5-sulphosalicylic acid, in an aqueous solution of 0.5 M $NaNO_3$ ionic medium.

The experimental data have been shown to correspond to the equilibrium state of the system and no irreversible processes have been found to take part in the reactions studied.

The complex species formed are represented by eqs (3)–(7), and Fig. 4 shows the distribution diagrams of the species, calculated by the program HALTAFALL,[20] in the pH range 1.5–8.0. This model is in partial agreement with the results previously reported.[5–10] The mononuclear species FeL, FeL_2 and FeL_3 are reported in most of these studies[7–10] and their stability constants appear to be well-defined in the present work. In the case of the protonated species reported in refs 5 and 6, FeHL, FeH_2L_2 and FeH_3L_3, only one species, FeHL, has been found in our analysis. On the other hand, the numerical treatment of the obtained data has shown that a deprotonated binuclear iron(III)–5-sulphosalicylate complex, Fe_2L_3, is formed and, as seen in Fig. 4, is present in a wide pH interval. This species has not been reported before. This type of result follows the tendency of carboxylic ligands bearing hydroxyl groups to form polynuclear complex species with iron(III).[1]

On the other hand, the model proposed in the present work may be interpreted mechanistically by stepwise addition of deprotonated ligand to the metal ion. The formation of the polynuclear species may also be a consequence of such an addition by following the suggested reaction:

$$2FeL+L \rightleftharpoons Fe_2L_3. \quad (8)$$

The high stability of Fe_2L_3 species could explain

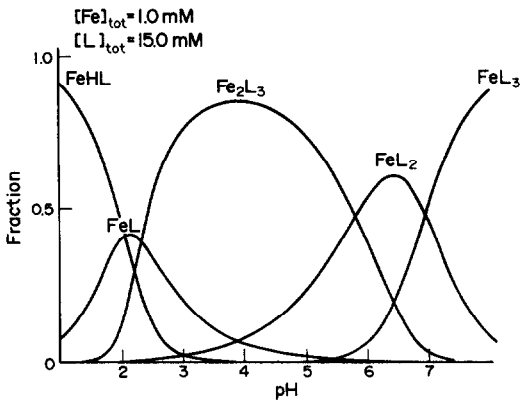

Fig. 4. Fraction diagram of the iron(III)–5-sulphosalicylic acid complexes as a function of $-\log h$.

the possibility of the proposed reaction (8) by compensating for the low acidity of the hydroxyl group.

In Fig. 2, the full lines represent calculated values of Z vs $-\log h$ using the proposed model [eqs (3)–(7)]. The close fit to the experimental values determines a high confidence level of this model.

(*Received* 3 *July* 1989; *accepted after revision* 15 *June* 1990)

Abstract—The kinetics of the ligand substitution reaction of aquo-ethylenediaminetetraacetato ruthenate(III) with 4,6-dimethyl-2-mercaptopyrimidine were studied as a function of ligand concentration, temperature (30–45°C) and pH (1.4–9.0). The reaction proceeds with the formation of a red complex (λ'_{max} = 510 nm) which undergoes a pH dependence change (pK_a = 4.5) to form a violet product (λ_{max} = 560 nm). Activation parameters for both the reactions were calculated and compared with other experimental results under identical experimental conditions. The mechanism of the substitution process was explained in terms of the labilization effect of the coordinated ethylenediaminetetraacetate ligand. An associative interchange (Ia) mechanism was suggested for the substitution reaction of H_2O by the ligand 4,6-dimethyl-2-mercaptopyrimidine followed by the displacement of coordinated carboxylate group in which deprotonation of coordinated ligand and reorganization of the coordination sphere of the metal ion takes place. The sum of acid dissociation and chelation constants for red to violet complex formation computed potentiometrically at 30°C and μ = 0.1 M KCl is 3.58.

Ligand substitution reactions on pentacoordinated chelated ruthenium(III) complexes have long been a subject of much interest.[1–2] Recently, the kinetic behaviour of ethylenediaminetetraacetate and the N-(hydroxyethyl)-ethylenediaminetetraacetate complex of ruthenium(III) with a series of anionic and neutral ligands was reported.[3–4] The remarkable lability of the water molecule in the complexes was explained due to the formation of a hydrogen bond between the free carboxylate oxygen and the coordinated water molecule. The transient coordination of a pendant group also plays an important role which causes the rapid replacement of a coordinated water molecule.[5–6] It was reported recently[7] that 2-mercaptopyridine can behave as a monodentate as well as a bidentate ligand, leading to a mixture of red and green products, respectively. The 2-mercaptopyrimidine ligand can exist in its tautomeric form in aqueous solution with a protonated N-atom.[8] The available thione group, however, is capable of forming a bond with the transition metal ions.[9] The ligand 4,6-dimethyl-2-mercaptopyrimidine[6] is an ambidentate ligand that can coordinate through the sulphur and the ring nitrogen atom. We have, therefore, undertaken the study of the substitution reaction of H_2O in [Ru(Hedta)(H_2O)] with the ligand L in aqueous solution. The reaction proceeds at low pH by the coordination of the 2-mercapto group in the metal ion to give a red complex in the first instant. At higher pH > (4.5) the red complex changes to a violet complex where both S and N of the ligand are combined to the metal ion in a bidentate manner. The equilibrium and rate constants for the formation of the mixed ligand Ru^{III}–EDTA–L

* Author to whom correspondence should be addressed.

complex have been computed by potentiometric and spectrophotometric studies.

EXPERIMENTAL

$K[Ru(H\text{-}edta)(Cl)]\cdot 2H_2O$ was prepared and characterized by following the published procedure.[10,11] It rapidly hydrolyses in aqueous solution to $Ru(H\text{-}edta)(H_2O)$[2,11] (with a $\lambda_{max} = 283$ nm and $\varepsilon_{283}^{max} = 2800$). The composition of the red product complex [ethylenediaminetetraacetato-4,6-dimethyl-2-mercaptopyrimidineruthenium(III)] in solution was determined by recording the spectra of four different solutions in which concentration of metal and ligand was maintained at 1 : 1, 1 : 2, 1 : 3 and 1 : 10, respectively. The pH of each solution was kept fixed at 1. The spectra of the 1 : 1 solution ($\lambda_{max} = 510$ nm and $\varepsilon_{510}^{max} = 2280$) nicely matched with the other solutions containing higher ligand concentrations. The violet compound ethylenediaminetetraacetato - 4,6 - dimethyl - 2 - mercaptopyrimidineruthenium(III) was produced in the solution by treating the red product with a slight excess of NH_4OH ($\lambda_{max} = 560$ nm and $\varepsilon_{560}^{max} = 1750$). The 1 : 1 metal–ligand composition was determined by a similar manner at pH 9.0.

All other chemicals used were A.R. grade. Doubly distilled water was used throughout this study. Acetate, phosphate and borate buffers were used to control the pH and $NaClO_4$ for adjusting ionic strength.

Potentiometric titrations were performed under an argon atmosphere as described elsewhere[12] using a Metrohm 682 titrator in manual mode. Formation constants were computed at 30°C ($\mu = 0.1$ M KCl) by a curve fitting method using the program PKAS.[13]

For recording spectra and other spectrophotometric measurements a Shimadzu UV-160 spectrophotometer equipped with temperature controller TCC-240A was used. The substitution reaction was followed by using a Hi-Tech SF-140 stopped-flow spectrophotometer. The absorbance time plots for the biphasic reaction (formation of red complex and its conversion to violet product) were analysed with the aid of ADS-1 data acquisition and analysis system equipped with the stopped-flow unit. pH measurements were carried out with a Digisun pH meter with an accuracy of ± 0.001 unit. The rate constant data are reproducible within $\pm 4\%$.

RESULTS AND DISCUSSION

Preliminary kinetic experiments demonstrated that the employed buffer component, viz. acetate, phosphate and borate, as well as the medium selected to control the ionic strength of solutions did not react with the Ru^{III} complex. The nucleophilicity of 4,6-dimethyl-2-mercaptopyrimidine is so high that the other potential nucleophiles, used either as buffer or to control the ionic strength of the medium, had no significant effect on the behaviour of the system when these were added to the solution containing entering ligand prior to the mixing with the aquo complex within the stopped-flow mixing chamber.[14]

The substitution reaction of $Ru(H\text{-}edta)(H_2O)$ with 4,6-dimethyl-2-mercaptopyrimidine ligand was studied under pseudo first-order conditions and in contrast with the preceding work performed by Matsubara and Creutz,[2] two successive reactions were detected in this work. The first reaction leading to the red complex was due to the substitution of the water molecule in $Ru(H\text{-}edta)(H_2O)$ by the 4,6-dimethyl-2-mercaptopyrimidine in which the sulphur atom of the ligand is coordinated to the metal ion. The characteristic red colour is due to sulphur to metal charge-transfer.[15] The second reaction was associated with the partial or total conversion of the red complex to a violet complex where the ligand 4,6-dimethyl-2-mercaptopyrimidine acts as a chelate by the coordination of the sulphur atom of 2-mercapto and the ring nitrogen atom.

The observed rate constant for the first reaction in the formation of red complex depends on the ligand concentration of the entering ligand and it increases linearly with the increase of ligand concentration at constant pH, ionic strength and temperature (Fig. 1). As there is no intercept in the plot, it can be assumed that the reverse aquation is not appreciable under experimental conditions. The observed rate constant for the conversion of red complex to violet complex in the second reaction is independent of the entering ligand concentration at a fixed pH and temperature (Table 1). This shows

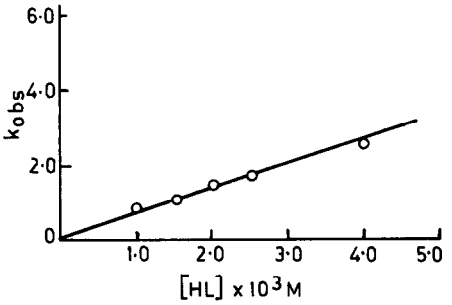

Fig. 1. Effect of [HL] on k_{obs} for the reaction of Ru(edta)$(H_2O)^-$ with 4,6-dimethyl-2-mercaptopyrimidine at pH = 5 (acetate buffer), $\mu = 0.2$ M ($NaClO_4$), [Ru(edta)$(H_2O)^-$] = 1×10^{-4} M, $T = 30$°C.

Table 1. Values of k_{obs} and k'_{obs} as a function of ligand concentration [Complex 1] = 1.1×10^{-4} M, pH = 5, $T = 30°C$, $\mu = 0.2$ M ($NaClO_4$)

[Ligand] (M)	$10^{-1} k_{obs}$ s^{-1}	k'_{obs} s^{-1}
1×10^{-3}	0.78	0.98
1.5×10^{-3}	1.01	1.01
2.0×10^{-3}	1.39	1.00
2.5×10^{-3}	1.68	1.01
4×10^{-3}	2.54	1.03

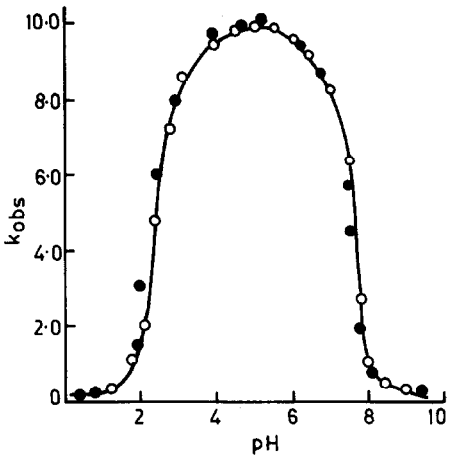

Fig. 2. Variation of k_{obs} with pH at 30°C. [Complex 1] = 1×10^{-4} M, [HL] = 1.5×10^{-3} M, $\mu = 0.2$ M ($NaClO_4$); (○) observed rate constant; (●) calculated by using resolved rate constant.

that the second step involves a deprotonation of the coordinated ligand. The relatively lower values of the observed rate constant for the conversion of red to violet complex reflects that the proton transfer reaction in this step is diffusion controlled[14] and the measured rate cannot be ascribed to a simple acid–base reaction. The deprotonated form of 4,6-dimethyl-2-mercaptopyrimidine is a potentially bidentate ligand. In the formation of the violet complex ethylenediaminetetraacetato-4,6-dimethyl-2-mercaptopyrimidineruthenium(III), the ligand binds through the ring nitrogen by the displacement of a coordinated carboxylate group which would lead to the change in the absorption spectrum from red to violet with an appreciable reorganization of the coordination sphere of the metal ion.[9,15] It is worthwhile to note here that no change in red colour was found when Ru(H-edta)(H_2O) was reacted with 4-mercaptopyridine even at high pH.[7]

The pH dependence of the formation of red complex is associated with the substitution lability of the various Ru^{III}–edta species, viz Ru(H-edta)(H_2O), Ru(edta)(H_2O)$^-$ and Ru(edta)$(OH)^{2-}$. The characteristic pH dependence (Fig. 2) for this substitution reaction can be explained in terms of the following equilibria:

$$\text{Ru(H-edta)}(H_2O) \overset{K_1}{\rightleftharpoons} \text{Ru(edta)}(H_2O)^- + H^+ \quad pK_1 = 2.4,$$

$$\text{Ru(edta)}(H_2O)^- \overset{K_2}{\rightleftharpoons} \text{Ru(edta)}(OH)^{2-} + H^+ \quad pK_2 = 7.6,$$

and the reaction pathways:

$$\text{Ru(H-edta)}(H_2O) + HL \xrightarrow{k_1} \text{Ru(H-edta)(HL)} + H_2O, \quad (1)$$

$$\text{Ru(edta)}(H_2O)^- + HL \xrightarrow{k_2} \text{Ru(edta)(HL)} + H_2O, \quad (2)$$

$$\text{Ru(edta)}(OH)^{2-} + HL \xrightarrow{k_3} \text{Ru(edta)(HL)} + OH^-, \quad (3)$$

where HL represents neutral 4,6-dimethyl-2-mercaptopyrimidine ligand with one protonated N atom.

Now considering the above acid dissociation equilibria among the reactants, the following rate expression was derived:

$$k_{obs} = \frac{k_1[H^+]^2 + k_2K_1[H^+] + k_3K_1K_2}{[H^+]^2 + K_1[H^+] + K_1K_2}[HL]. \quad (4)$$

It is seen from Fig. 2 that the two inflections in the bell-shaped curve occur exactly at pH = pK_1 and pH = pK_2. A similar result was reported by Matsubara and Creutz.[2] At very low pH (< 1) only the Ru(H-edta)(H_2O) species which is less labile than Ru(edta)(H_2O)$^-$ is predominant in the solution and the significant contribution to the rate is due to reaction (1) only. Hence eq. (4) at very low pH reduces to $k_{obs} = k_1[HL]$. At very high pH (>9), only reaction (3) in which Ru(edta)$(OH)^{2-}$ is predominant can be considered. So at high pH, eq. (4) is reduced to $k_{obs} = k_3[HL]$. It can be clearly seen from Fig. 2 that in the pH range $4 < pH < 6$, k_{obs} reaches a maximum limit. In this pH range, almost complete deprotonation of Ru(H-edta)(H_2O) occurs to form the most labile deprotonated Ru(edta)(H_2O)$^-$. Hence, in this pH range k_{obs} can be equated to $k_2[HL]$. The values of k_2 do not change appreciably in the pH range $4 < pH < 6$ as substantiated by plotting the limiting form of eq. (4) as a function of $[H^+]$ at pH < 5 and pH > 5. The

limiting form of eq. (4) can be written as follows:

$$k_{obs} = \left(k_1 + \frac{K_2K_1}{[H^+]}\right)\left(1 + \frac{K_1}{[H^+]}\right)^{-1}, \quad \text{at pH} < 5 \tag{5}$$

and

$$k_{obs} = \left(k_3 + \frac{k_2[H^+]}{K_2}\right)\left(1 + \frac{[H^+]}{K_2}\right), \quad \text{at pH} > 5. \tag{6}$$

The values of k_2 thus obtained, 7.74×10^3 and 7.8×10^3 M^{-1} s^{-1}, at 30°C are significantly larger than $k_1 = 63$ M^{-1} s^{-1} and $k_3 = 50.6$ M^{-1} s^{-1}. An identical rate–pH profile was obtained when k_{obs} (calculated by resolving rate constant values) is plotted against pH. The calculated (theoretical) curve superimposes which substantiates the various assumptions in rate expressions (1)–(3).

In the second reaction it was found that the k'_{obs} (observed rate constant for the conversion of red to violet complex) value increases with the decrease of hydrogen ion concentration in the solution.

The pH dependence (Fig. 3) of the conversion of red complex to violet in the second reaction can be interpreted in terms of the following reversible proton transfer to and from the monodentate red complex and subsequent chelation of the deprotonated red complex to produce chelated violet complex in solution.

$$RH^+ + H_2O \overset{K_a}{\rightleftharpoons} R + H_3O^+, \tag{7}$$

$$R \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} V, \tag{8}$$

where RH^+ and R represent the protonated and deprotonated forms of the red complex, respectively, and V represents the chelated violet complex. Now considering the above acid dissociation equilibrium (7) and chelation step (8), the following rate expression was derived:

$$k'_{obs} = \frac{\{k_{-4}K_a + [H_3O^+]\} + k_4K_a}{K_a + [H_3O^+]}. \tag{9}$$

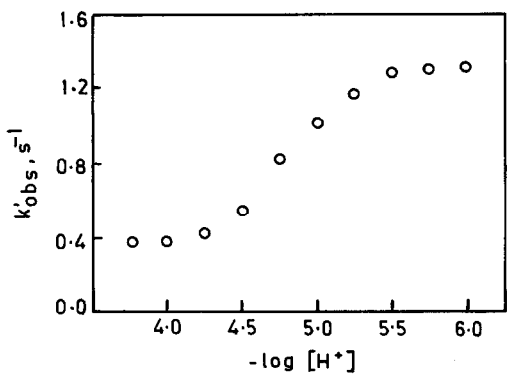

Fig. 3. Variation of k'_{obs} with pH at 30°C. [Complex 1] = 1×10^{-4} M, [HL] = 1.5×10^{-3} M, $\mu = 0.2$ M ($NaClO_4$).

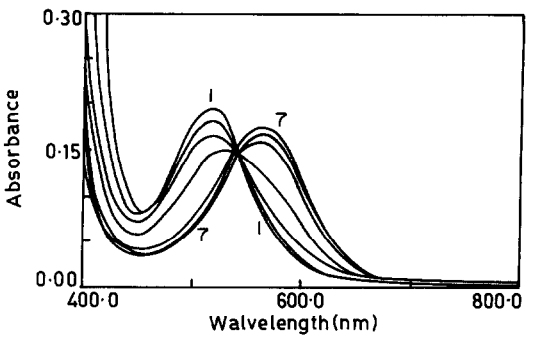

Fig. 4. Electronic spectra of Ru(edta)$(H_2O)^-$ with 4,6-dimethyl-2-mercaptopyrimidine at different pH. [Complex 1] = 1×10^{-4} M = [HL], $T = 30$°C, $\mu = 0.2$ M ($NaClO_4$), pH of (1) 1.42, (2) 2.89, (3) 3.78, (4) 4.45, (5) 5.00, (6) 6.80, (7) 7.89.

It is seen in Fig. 3, the k'_{obs} values are independent of pH in the low acid ($K_a \gg [H_3O^+]$) and high acid ($[H_3O^+] \gg K_a$) regions and go from $k_{obs} = k_{-4}$ at high acid concentration to $k'_{obs} = k_4 + k_{-4}$ at low acid concentration. The values of k_4 and k_{-4} thus obtained are 0.91 and 0.41 s^{-1}, respectively. The pK_a (negative logarithm of the apparent equilibrium constant) value is determined (pK_a = 4.79) by using the values of k_4 and k_{-4} in eq. (9). In this case, the negative logarithm of the equilibrium constant is not strictly speaking a pK_a but rather the sum of the pK_a of RH^+ and log of the chelation equilibrium.

The red and violet complexes co-exist in solution with an isobestic point at 542 nm (Fig. 4). The pK_a value for the conversion of red to violet complex determined spectrophotometrically by plotting absorbance vs pH (Fig. 5) is 4.5.

To determine the acid dissociation constant and the chelation constant for the formation of 1 : 1 Ru(edta)-4,6-dimethyl-2-mercaptopyrimidine complex the potentiometric titrations were carried out at 30°C, $\mu = 0.10$ M KCl.

The free ligand titration of 4,6-dimethyl-2-mercaptopyrimidine [Fig. 6(a)] shows no inflection but only a buffer region between $a = 0$–1. The proton dissociation constant calculated from the program PKAS[14] was $10^{-8.79}$.

The titration curve for 1 : 1 Ru(H-edta)(H_2O) and 4,6-dimethyl-2-mercaptopyrimidine under Ar [Fig. 6(b)] gave two inflections at $a = 1.0$ and 2.0. The plausible reactions in the buffer region between

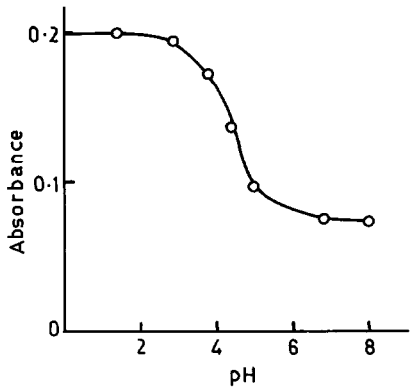

Fig. 5. Change in absorbance at 510 nm with hydrogen ion concentration at 30°C, $\mu = 0.2$ M ($NaClO_4$), [Complex 1] = [HL] = 1×10^{-4} M.

$a = 0$–1 are as follows:

$$MLH \rightleftharpoons ML + H^+,$$

$$K_a = [ML][H^+]/[MLH], \quad (10)$$

$$ML + HA \overset{K_{MLAH}}{\rightleftharpoons} MLAH, \quad (11)$$

where MLH = [Ru(H-edta)(H_2O)] and HA = 4,6-dimethyl-2-mercaptopyrimidine.

The dissociation constant for equilibrium (10) as reported earlier[13] is $10^{-2.36}$. In equilibrium (11), since there is no liberation of proton, the formation constant of MLAH cannot be determined by potentiometry. The formation constant of MLAH obtained by spectrophotometry is $10^{4.75}$. The buffer region between $a = 1$–2 indicates the dissociation of proton from the MLAH species and the following equilibrium is assumed:

$$MLAH \overset{K_{MLA}}{\rightleftharpoons} MLA + H^+, \quad (12)$$

$$K_{MLA} = [MLA][H^+]/[MLAH].$$

The proton dissociation constant for equilibrium (12) calculated by program PKAS is $10^{-6.19}$, dissociation of proton is followed by chelation:

$$MLA \overset{K_{Ch}}{\rightleftharpoons} MLA\,(chelate). \quad (13)$$

From the equilibria (10)–(12) the chelation constant was calculated as $10^{2.61}$.

The sum of the chelation constant [eq. (13)] and dissociation constant [eq. (12)] determined spectrophotometrically, $10^{-4.5}$, agrees with that determined potentiometrically, i.e. $10^{-3.58}$. The difference of 1.0 log K unit may be accounted for by the use of different techniques in elucidating the constants.

The effect of temperature on the substitution reaction was studied under limiting condition, i.e. where a minor change in pH due to change in temperature would not affect the observed rate constants. Rate constant data for both the reactions at different temperatures are shown in Table 2. Activation parameters for both the reactions are shown in Table 3 along with some related data obtained from literature for comparison purposes. It is seen from Table 3 that the low value of $\Delta H^{\ddagger}$ and negative value of $\Delta S^{\ddagger}$ for this substitution reaction clearly support the associative character of the substitution process and are in close agreement with those reported for other substitution reactions. Labilization of water molecules in this reaction may be explained on the basis of hydrogen bonding between the uncoordinated acetic acid moiety [in the case of Ru(H-edta)(H_2O)] and H_2O. Matsubara and Creutz[2] reported the possibility of a dissociative mode of activation resulting from the eventual labil-

ization of the Ru^{III}—OH_2 bond through hydrogen bonding between the pendant carboxylate group and water molecule, but this possibility was recently ruled out by Eldik,[3,4] where a significantly negative volume of activation ($\Delta V^{\ddagger}$) was required for the substitution of Ru(H-edta)(H_2O) by a series of neutral and anionic ligands which is a characteristic of an associative process. The slightly higher value of $\Delta H^{\ddagger}$ as compared to 2-mercaptopyridine[7] may be due to the presence of two methyl groups which cause some steric hindrance in forming activated species, which is also indicated by a larger value of $\Delta S^{\ddagger}$ (Table 3).

A comparatively larger activation energy for the second reaction as compared to the first indicates the displacement of coordinated carboxylate group in the formation of the tetracoordinated EDTA in the complex ethylenediaminetetraacetato-4,6-dimethyl-2-mercaptopyrimidineruthenium(III). It is assumed that the deprotonation of the coordinated mercaptopyrimidine ligand leads to a chelated product ethylenediaminetetraacetate-4,6-dimethyl-2-

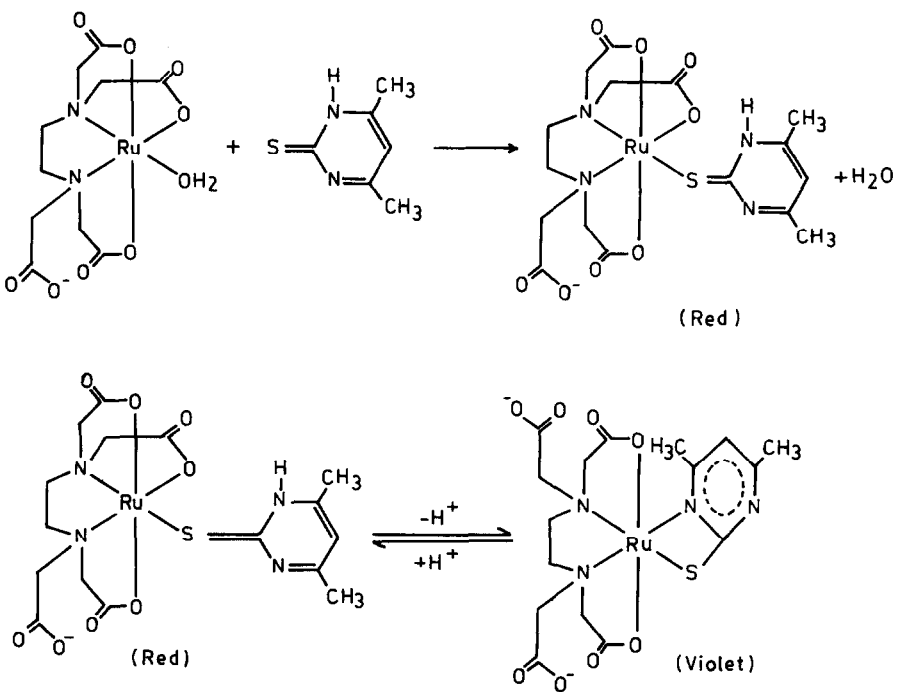

Fig. 7. Mechanism of the substitution of $Ru(edta)(H_2O)^- + HL \rightarrow Ru(edta)(L)^- + H_2O$ (where HL = 4,6-dimethyl-2-mercaptopyrimidine).

mercaptopyrimidineruthenium(III), obtained by the opening of the coordinated carboxylate group by a pH dependent process.

Based on the above mentioned experimental facts, it is suggested that the substitution of water molecules from the ethylenediaminetetraacetate complex of ruthenium(III) proceeds through an associative interchange (Ia) mechanism followed by the conversion of pentacoordinated-EDTA–Ru^{III}–L to tetracoordinated-EDTA–Ru^{III}–L chelated product (Fig. 7).

THE SYNTHESES OF MONO-AROMATIC CARBOXYLIC DERIVATIVES OF BIS(η^5-CYCLOPENTADIENYL)ZIRCONIUM(IV)

YAO-KUN ZHOU* and HONG-MING CHEN

Department of Chemistry, Lanzhou University, Lanzhou, Gansu Province, P.R.C.

(*Received* 16 *January* 1990; *accepted* 21 *June* 1990)

Abstract—Fifteen mono-aromatic carboxylic derivatives of the type Cp_2ZrCl  (where Cp = cyclopentadienyl; X = *o*-Br, *m*-Br, *p*-Br, *o*-Cl, *p*-Cl, *o*-I, *p*-I, *o*-F, *m*-F, *m*-NO_2, *p*-NO_2, *p*-Me, *p*-CN, *o*-NH_2 and H) have been prepared by the reaction of Cp_2ZrCl_2 with the sodium salts of aromatic acids in a 1 : 1 molar ratio in benzene at 30°C. The compositions, structures and coordinative modes of the carboxylate ligands in these derivatives have been characterized by elemental analysis, IR and ^{1}H NMR spectra.

The preparation of bis-aromatic derivatives of bis(η^5-cyclopentadienyl)titanium(IV) was reported as a patent,[1] and it was claimed that they could be used as catalysts in alkene polymerization. Subsequent work[2–4] has shown that some derivatives have physiological activities. A perusal of the literature reveals that most of the work has been restricted to titanium(III and IV), with less work on derivatives of zirconium(IV).[5] We have synthesized and characterized 15 mono-aromatic carboxylic derivatives of bis(η^5-cyclopentadienyl)zirconium (IV) dichloride.

EXPERIMENTAL

All the reaction systems were protected with nitrogen. Benzene was dried by distilling it over the sodium ketyl of benzophenone, petroleum ether (60–90°C) by distilling it over CaH_2 for about 24 h, and bis(η^5-cyclopentadienyl)zirconium(IV) dichloride was prepared by the literature procedures.[6]

Measurement

The carbon, hydrogen and nitrogen analyses were carried out on a 1106 type elemental analytical instrument. Zirconium was determined gravimetrically as ZrO_2.

IR spectra were obtained with a FT-5DX (4000–400 cm^{-1}, KBr) instrument, while ^{1}H NMR spectra were obtained on an FT-80A spectrometer (solvents, $DCCl_3$ or D_3CCCD_3; internal standard, TMS). The melting points were determined using a Kofler melting point apparatus.

Preparation of the sodium salts of aromatic carboxylic acids

All of them were prepared by the reaction of aromatic carboxylic acids with alcoholic sodium in the same molar ratio. The products were dried at constant temperature *in vacuo*.

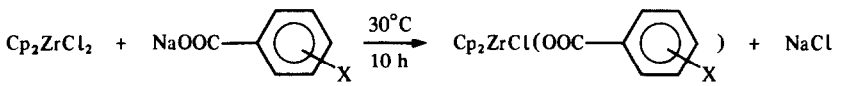
Syntheses of the derivatives

Anhydrous sodium salts of aromatic carboxylic acid (1 mmol), Cp_2ZrCl_2 (1 mmol) and benzene (50 cm^3) were stirred for 10 h at 30°C and the precipitated sodium chloride was filtered off. The filtrate was concentrated to 5 cm^3 under reduced pressure, then the appropriate amount of anhydrous petroleum ether (60–90°C) was added. The white solid obtained was recrystallized from benzene–petroleum ether (60–90°C).

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

The substitution reactions of Cp_2ZrCl_2 with the anhydrous sodium salts of aromatic carboxylic acids were carried out in the same ratio:



(here, Cp = cyclopentadienyl; X = *o*-Br, *m*-Br, *p*-Br, *o*-Cl, *p*-Cl, *o*-I, *p*-I, *o*-F, *m*-F, *m*-NO_2, *p*-NO_2, *p*-Me, *p*-CN, *o*-NH_2 and H).

This reaction occurred readily under these conditions. All the products were obtained in high yields. They are white crystals and are sensitive to moisture. They can be dissolved easily in polar organic solvents like CH_2Cl_2, $CHCl_3$, acetone, etc. However, they are insoluble in n-hexane or petroleum ether. All of them have sharp melting points. The elemental analytical and physical data of the products are given in Table 1.

IR spectra

In the carboxylato complexes, the symmetrical O—C—O stretching frequency (ν_1) and asymmetrical O—C—O stretching frequency (ν_2) are of importance since their position and separation ($\nu_2 - \nu_1$) can help in determining the type of bonding in the metal carboxylate.[7] We referred to the stan-

dard spectra of the sodium salts of aromatic carboxylic acids and found that the separation values ($\nu_2-\nu_1$) are about 190 cm^{-1}. Our experimental results indicated that the separation values ($\nu_2-\nu_1$) for these derivatives are also about 190 cm^{-1} and therefore deduce that the coordinative mode of the carboxylates is the bidentate bridging structure.

Absorption bands indicating the presence of the cyclopentadienyl group appear at ≈ 3100 [ν(C—H)], ~ 1440 [ν(C—C)], ~ 1020 [δ(CH) in-plane] and ~ 810 cm^{-1} [δ(CH) out-of-plane]. All these bands correspond to those of bis(η^5-cyclopentadienyl)zirconium(IV) dichloride. The data indicate that the cyclopentadienyl rings remain delocalized and π-bonded to the metal, and maintain their aromatic nature.

^{1}H *NMR spectra*

In these derivatives, the chemical shifts of the cyclopentadienyl protons are at 6.21–6.43 ppm, which is upfield compared to Cp_2ZrCl_2.[8] The results correspond with the aroxyl bis(η^5-cyclopentadienyl)zirconium(IV).

Comparing with $Cp_2ZrCl(OOC-C_6H_5)$, the higher the electronegativities of the substituting groups in the aromatic rings, the more downfield are the chemical shifts of the cyclopentadienyl protons. However, as the substituting groups (X) are F, Cl, Br and I; *o*-X and *p*-X have different influences on the chemical shifts of the cyclopentadienyl. For *o*-X (X = F, Cl, Br and I), the chemical shifts of the cyclopentadienyl protons are almost the same except for F (F: 6.43, Cl: 6.32, Br: 6.30, I: 6.31). Whereas for *p*-X (X = Cl, Br and I), the chemical shifts are different (Cl: 6.43, Br: 6.24, I: 6.21). The results correspond to those reported by Beachell and Butter in the aromatic carboxylato bis(η^5-cyclopentadienyl)titanium(IV).[9]

(*Received* 29 *March* 1990; *accepted* 21 *June* 1990)

Abstract—The compound of formula $[Cu(C_{14}H_{15}N_3)(N_3)_2]_2 \cdot 2H_2O$ [where $C_{14}H_{15}N_3$ is N-(2′-(6-methyl)pyridyl)methylene-2-(2′-pyridyl)ethylamine (pymep)] has been synthesized and its crystal structure determined by X-ray diffraction methods. The structure consists of centrosymmetric dimeric molecules, $[Cu(pymep)(N_3)_2]_2 \cdot 2H_2O$, in which the water molecules form hydrogen bonds with the azide groups. The geometry of the coordination polyhedron around the copper(II) ion is near to trigonal bipyramid. The X-band ESR powder spectrum shows a weak-intensity signal corresponding to the $\Delta M_s = \pm 2$ forbidden transition, which indicates a magnetic interaction between the copper(II) ions of the dimeric compound.

Many bivalent transition metal ions form complexes of the type $[ML_{III}X_2]$,[1–4] where L_{III} is a tridentate ligand and X is a negatively charged unidentate ion (halide or pseudo-halide). Structural data are available for several $[CuL_{III}X_2] \cdot nH_2O$ compounds [L_{III} is 2,2′:6′,2″-terpyridine (terpy), pyridine-2-aldehyde 2′-pyridylhydrazone (paphy) or N-(2′-(6-methyl)pyridyl)methylene-2-(2′-pyridyl) ethylamine (pymep)] showing the copper(II) ion to be five-coordinate[5–10] or exceptionally, hexacoordinate.[11]

Monomeric $[CuL_{III}X_2] \cdot nH_2O$ complexes can be considered as precursors of the condensed systems. Recently, we have established a synthetic strategy of new one-dimensional systems of copper(II) with tridentate ligands of general formula $[CuL_{III}XY]$ (X = coordinating anion, Y = coordinating or non-coordinating anion) which include bi- and polynuclear species.[12] In this way, the ability and adaptability of the azide ion (N_3^-) as a bridging ligand is well established,[13,14] and two bridge modes, end-on and end-to-end, have been observed in the polynuclear complexes.[14] In this work, we present the crystal structure and a spectroscopic study of the $[Cu(pymep)(N_3)_2] \cdot H_2O$ dimeric complex.

EXPERIMENTAL

Preparation of the $[Cu(pymep)(N_3)_2] \cdot H_2O$

This compound was synthesized by a different method from the one described in the literature.[15] Diluted solutions of $CuCl_2 \cdot 2H_2O$ in water and the N-(2′-(6-methyl)pyridyl)methylene-2-(2′-pyridyl) ethylamine compound in ethanol were mixed in a 1 : 1 molar ratio. The resulting solution was treated with a slight excess of NaN_3 pseudo-halide to give a microcrystalline, dark green precipitate. It was filtered, washed with water and diethyl ether and stored in a desiccator over P_4O_{10} for 48 h. Prismatic crystals were obtained by slow evaporation of an ethanolic solution containing the resulting compound. Found: C, 43.1; H, 4.3; N, 32.6. $[Cu(C_{14}H_{15}N_3)(N_3)_2] \cdot H_2O$ requires: C, 43.0; H, 4.4; N, 32.3%. The thermogravimetric analysis indicates the presence of one water molecule per copper(II) ion. The dehydration of the compound starts at $\approx 80°C$.

X-ray crystallography

A specimen with dimensions $0.17 \times 0.08 \times 0.02$ mm was selected. Preliminary cell dimensions and

space group symmetry were obtained from Weissenberg and oscillation photographs. The crystal was mounted on a Enraf–Nonius CAD-4 diffractometer equipped with graphite-monochromatized Cu-K_α radiation. Accurate cell parameters were obtained by a least-squares refinement of the setting angles of 25 reflections with $16 \leqslant 2\theta \leqslant 30°$.

Crystal data. $[Cu(C_{14}H_{15}N_3)(N_3)_2]\cdot H_2O$, $M = 390.5$, $P2_1/n$, $a = 10.543(2)$, $b = 9.653(1)$, $c = 16.638(3)$ Å, $\beta = 97.90(2)°$, $U = 1677(4)$ Å^3, $Z = 4$, $D_m = 1.57(3)$, $D_x = 1.55$ g cm^{-3}, $\lambda(Cu\text{-}K_{\alpha 1}) = 1.54059$ Å, $\mu(Cu\text{-}K_\alpha) = 21.14$ cm^{-1}, $F(000) = 796$, $T = 294$ K. The density was measured by flotation in a chloroform 1,1,2,2-tetrabromoethene mixture.

A total of 2277 reflections were recorded in the range $2 \leqslant 2\theta \leqslant 80°$ with h: $-8 \rightarrow 8$; k: $0 \rightarrow 8$; l: $-13 \rightarrow 13$, using the ω–2θ scan technique. Three orientation and two intensity control reflections were checked every 50 reflections and every hour, respectively, and showed no significant variation. Data were corrected for Lorentz-polarization effects. No absorption corrections have been made. After averaging of the symmetry-related reflections 1011 unique reflections were obtained, of which 947 had $I \geqslant 2\sigma(I)$. The structure was solved by direct methods, using the MULTAN 84 system,[16] and refined by full-matrix least-squares, using the SHELX 76 program.[17] The function minimized was $\Sigma\omega[|F_o|-|F_c|]^2$, where $\omega = [\sigma^2(F_o)+0.001797(F_o)^2]^{-1}$. Positions of the hydrogen atoms were computed and refined with overall isotropic thermal parameters and the remaining atoms anisotropically. The final R was 0.039 ($R_\omega = 0.043$) for all observed reflections. At the end of the refinement the maximum peak in the final ΔF map was 0.24 e Å^{-3}. Scattering factors were taken from the *International Tables for X-ray Crystallography*.[18] All calculations were carried out on a Microvax Computer at the computer centre of the Basque University. The geometric calculations were made with XANADU[19] and molecular illustrations were drawn with SCHAKAL 88.[20] Further details are presented as supplemenary data, together with thermal parameters, bond lengths and angles, mean average planes and structure factors.

Physical measurements

Water was determined thermogravimetrically using a Perkin–Elmer TGS-1 thermobalance. The IR spectrum was obtained on a Perkin–Elmer 1430 spectrophotometer using KBr pellets. The electronic reflectance spectrum at 298 K was measured with a Perkin–Elmer Lambda-9 UV–vis/NIR spectrophotometer on a powder sample. A Bruker ER 200 tt spectrometer, equipped with a standard low-temperature device, operating at X-band calibrated by an NMR probe for the magnetic field and a HP 5342A frequency counter for the microwave frequency, was used to record the ESR powder spectra of the complex at different temperatures.

RESULTS AND DISCUSSION

Selected bond lengths and angles are given in Table 1. The structure of the compound is shown in Fig. 1, together with the atomic numbering system.

The structure consists of $[Cu(pymep)(N_3)_2]_2\cdot 2H_2O$ centrosymmetric dimeric molecules. The coordination polyhedron around the copper(II) ion is better described as a distorted trigonal bipyramid. The axial sites are occupied by the two outer nitrogen atoms [N(1), N(3)] of the tridentate ligand [Cu—N(1),N(3), 2.039(7), 2.038(6) Å, respectively], while the equatorial sites are occupied by the central nitrogen atom [N(2)] of this ligand [Cu—N(2), 2.080(6) Å] and by two nitrogen atoms [N(4), N(7)] belonging to the azide groups [Cu—N(4), N(7), 2.039(8), 1.986(7) Å, respectively]. In the coordination polyhedron, the average value of the angles N_{axial}—Cu—$N_{equatorial}$ is 90(5)°, while the equatorial angles N(2)—Cu—N(4), N(2)—Cu—N(7) and N(4)—Cu—N(7) are 107.9(3), 122.6(3) and 129.5(3)°, respectively, and the axial angle N(1)—Cu—N(3) is 169.8(4)°. The separation of the copper(II) ion from the plane defined by the N(2), N(4), N(7) atoms is 0.02 Å. Likewise, the distortion of the coordination polyhedron, from trigonal bipyramid ($\Delta = 0$) towards a regular square pyramid ($\Delta = 1$), has been calculated according to the Muetterties and Guggenberger description.[21,22] The value obtained, $\Delta = 0.11$ (Table 2), is in good agreement with a topology near to trigonal bipyramid.

In the dimeric molecule, each water molecule forms intramolecular hydrogen bonds with both the N(4) of one azide group [Ow···N(4), 2.882(9) Å] and the $N(9)^i$ atom of the azide group belonging to the other half of the dimer [Ow···$N(9)^i$, 3.02(1) Å; $i = 1-x, -y, -z$]. The intradimer copper–copper distance is 6.970(2) Å.

The azide groups are found to be linear within experimental error [angles N(4)—N(5)—N(6) and N(7)—N(8)—N(9) are 177.8(7) and 176.5(8)°, respectively]. The values for the angles Cu—N(4)—N(5) and Cu—N(7)—N(8) [119.0(5) and 130.9(5)°, respectively] lie within the expected range for the angle of a trigonally hybridized nitrogen.[13] The different N—N distances in both azide groups support the asymmetry of these groups. In the N(4)—N(5)—N(6)

Table 2. Dihedral angles (°) and distortion (Δ) of the coordination polyhedron for the $[Cu(pymep)(N_3)_2]\cdot H_2O$ compound compared with the ideal geometries trigonal bipyramid (TBP) and regular square pyramid (SPr)

Dihedral angle	TBP	$[Cu(pymep)(N_3)_2]\cdot H_2O$	SPr
δa_1	101.5	97.1	121.8
δa_3	101.5	108.8	121.8
δa_4	101.5	101.6	121.8
δa_6	101.5	105.5	121.8
δa_2	101.5	100.7	73.9
δa_5	101.5	96.6	73.9
δe_1	53.1	58.9	73.9
δe_2	53.1	54.1	73.9
δe_3	53.1	45.9	0
Δ	0	0.11	1

$\Delta = |[(\delta a_1 + \delta a_3 + \delta a_4 + \delta a_6) - 406.0]/182.7| + |[(\delta a_2 + \delta a_5) - 203.0]/248.41| + |[(\delta e_1 + \delta e_2) - 106.2]/187.2| + |(53.1 - \delta e_3)/477.9|$.

azide group, the N—N distances are 1.191(14) and 1.153(15) Å for N(4)—N(5) and N(5)—N(6), respectively. In the other azide group, N(7)—N(8)—N(9), the N(7)—N(8) and N(8)—N(9) distances are 1.179(12) and 1.143(13) Å, respectively. In both cases, the longest N—N distance is closest to the Cu—N bond.

The interest in the IR spectrum of the complex lies mainly on the bands due to the water molecule and azide groups. For the water molecule, only the stretching vibration has been observed at 3340 cm^{-1}. For the azide groups, the crystal structure shows that both groups are crystallographically independent. Thus, two bands are expected to appear in the IR spectrum due to the antisymmetric stretching mode, $\nu_{as}(N_3)$, of the azide groups, and similarly, two further bands are expected to occur corresponding to the symmetric stretching mode, $\nu_s(N_3)$.[23] According to these considerations, four bands can be observed in the IR spectrum. The strong bands at 2055 and 2035 cm^{-1} may be accounted for by the antisymmetric stretching frequency of the azide groups. The symmetric stretching vibrations, much weaker than the antisymmetric stretching vibration, are at 1350 and 1315 cm^{-1}. Two peaks at frequencies 680 and 675 cm^{-1}, corresponding to the bending mode, can also be observed in the IR spectrum.

In the visible region, the reflectance electronic spectrum, at room temperature, exhibits one broad and unresolved band centred around 13,000 cm^{-1}. The position of the intensity maximum in the absorption envelope agrees with the observations of Hathaway and co-workers[24,25] on $[CuN_5]$ chromophores with geometries near to trigonal bipyramid.

The X-band ESR powder spectrum (Fig. 2) shows an orthorhombic signal, which corresponds to the $\Delta M_s = \pm 1$ allowed transition [$g_1 = 2.220$ (2.214), $g_2 = 2.167$ (2.174) and $g_3 = 2.039$ (2.034) at 298 and (110) K]. In addition to this signal, a weak intensity absorption at ≈ 1600 gauss can be observed, which corresponds to the $\Delta M_s = \pm 2$ forbidden transition and indicates a magnetic interaction between the copper(II) ions of the dimeric molecule.

In the title compound, magnetic interactions can be propagated by a superexchange pathway through an extended bridging network formed by two azide groups and one water molecule connected by hydrogen bonds (see Fig. 1). The Cu—Cu^i distance (through the extended bridging network) is 12.3 Å, and for such distance the expected $|J|$ value ranges between 10^{-2} and 10^{-3} cm^{-1}, according to the experimentally determined function for long-range antiferromagnetic superexchange proposed by Coffman and Buettner.[26] However, a direct dipolar interaction, which is known to vary as r^{-3} (r being the interspin distance) can not be assumed negligible in this compound ($D_d = 10^{-2}$ cm^{-1}). It must be pointed out that, for the detection of the magnetic interactions with exchange coupling constants of $|J| < 0.1$ cm^{-1}, the magnetic measurements should be performed at temperatures lower than 2 K.

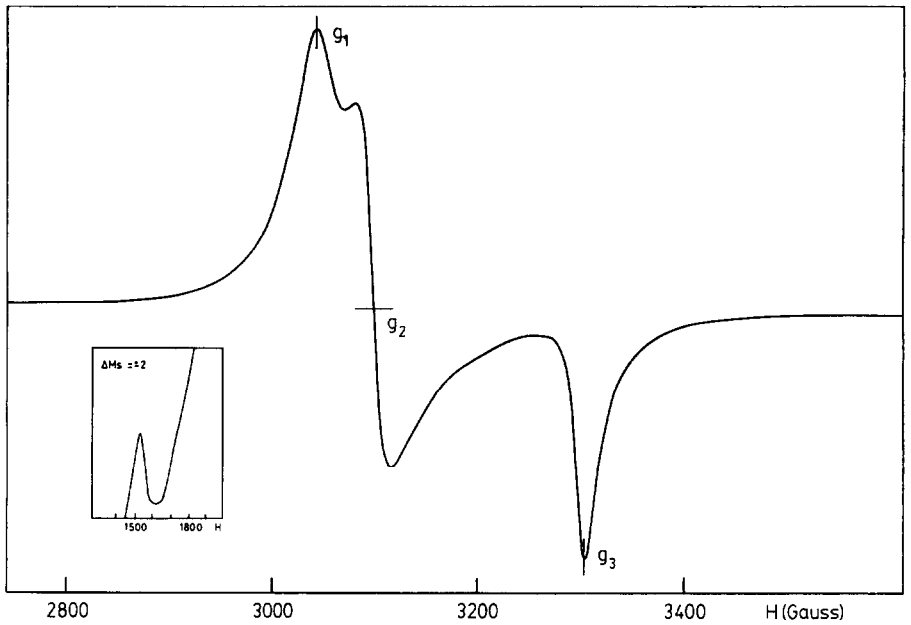

Fig. 2. X-band ESR spectrum of a powdered sample of the [Cu(pymep)(N$_3$)$_2$]·H$_2$O complex at room temperature.

Abstract—The X-ray crystal structure of bis(N-2-pyridinylcarbonyl-2-pyridinecarboximidato)manganese(II) monohydrate, $Mn(BPCA)_2 \cdot H_2O$, has been determined. It consists of discrete neutral $Mn(BPCA)_2$ entities linked two by two through water molecules hydrogen bonded to ligand carbonyl groups. The coordination geometry around the manganese ions can be described approximately as very distorted compressed octahedral. ESR spectra at X- and Q-band are reported for the title compound as well as for manganese(II) doped into $Zn(BPCA)_2 \cdot H_2O$ powder samples. Zero-field splitting parameters, D and E, are calculated at 298 and 130 K. The D values are 0.073 and 0.078 cm^{-1}, respectively, whereas λ ($= E/D$) is far away from zero (0.23 and 0.24 cm^{-1}, respectively) in good agreement with the actual low symmetry of the MnN_6 chromophores.

A part of our research is focused on the study of the interaction between N-donor tridentate rigid ligands (L_{III}) and transition metal ions, and we have recently reported the structural and spectroscopic properties of a series of compounds containing the $Cu(L_{III})_2^{n+}$ entities [L_{III} = BPCA (N-2-pyridinylcarbonyl-2-pyridinecarboximidate anion), $n = 0$; L_{III} = tpt (2,4,6-tris(2-pyridyl)-1,3,5-triazine) or terpy (2,2′:6′,2″-terpyridine), $n = 2$].[1,2] In these complexes the CuN_6 polyhedra can be considered as tetragonally elongated octahedra with a slight orthorhombic component superimposed as a consequence of the rigidity of the tridentate ligands together with the Jahn–Teller effect. Both cases, dynamic and static structures have been observed.[1,2]

We are now studying the behaviour of the BPCA ligand with metallic ions other than copper(II). We report here the crystal structure and spectroscopic studies of the compound $Mn(BPCA)_2 \cdot H_2O$. Since the $Zn(BPCA)_2 \cdot H_2O$ compound is isostructural with the manganese(II) complex, accurate zero-field parameters have been estimated from the ESR spectra on manganese(II)-doped zinc samples.

EXPERIMENTAL

Preparation of $Mn(BPCA)_2 \cdot H_2O$

The HBPCA ligand was isolated as described in ref. 3. Solutions of HBPCA (0.22 mmol) in acetone

* Author to whom correspondence should be addressed.

(2 cm^3) and $Mn(NO_3)_2 \cdot 4H_2O$ (0.11 mmol) in water (15 cm^3) were mixed with stirring. The pH of the resulting orange solution was slowly changed to *ca* 8 (with aqueous NaOH). Red–brown crystals appeared after several hours, these were isolated by filtration, washed with cold acetone and stored in a desiccator over silica gel. Found: C, 54.8; H, 3.4; Mn, 10.4; N, 15.9. Calc. for $C_{24}H_{18}MnN_6O_5$: C, 54.9; H, 3.4; Mn, 10.5; N, 16.0%.

Samples of $Zn(BPCA)_2 \cdot H_2O$ were prepared in the same way but using $Zn(NO_3)_2 \cdot 6H_2O$ instead of manganese(II) nitrate. Doped samples, with a nominal per cent of manganese(II) between 1 and 5, were obtained starting from an adequate mixture of the metallic nitrates.

Physical measurements

IR spectra (KBr pellets) were recorded in the 4000–250 cm^{-1} region using a Pye Unicam SP 2000 spectrophotometer. Diffuse reflectance and solution (chloroform) electronic spectra were recorded on a Perkin–Elmer Lambda 9 UV–vis/NIR spectrophotometer. ESR spectra were recorded on Bruker ER 200D (X-Band) and on Varian E15 (Q-band) spectrometers equipped with a variable temperature device. Water was determined thermogravimetrically by means of a Setaram B70 simultaneous TGA–DTA thermobalance and X-ray powder diffraction patterns ($2° < 2\theta < 50°$) were obtained by means of a Kristalloflex 810 Siemens diffractometer using Cu-K_α radiation and silicon powder as internal reference.

Crystallographic study

Crystal data. Red–brown prismatic crystals of $C_{24}H_{18}MnN_6O_5$, $M = 524.9$, monoclinic, space group $P2_1/c$, $a = 9.192(1)$, $b = 8.821(1)$, $c = 28.920(4)$ Å, $\beta = 97.01(1)°$, $V = 2327(1)$ $Å^3$, $Z = 4$, $D_c = 1.498$ g cm^{-3}, μ(Mo-K_α) = 5.62 cm^{-1}, λ(Mo-K_α) = 0.70926 Å. Manganese and zinc compounds are isostructural and data for the zinc complex have been reported previously.[1]

Data collection. A well-formed crystal of dimensions $0.33 \times 0.20 \times 0.10$ mm was mounted on an Enraf–Nonius CAD-4 diffractometer equipped with a graphite monochromator. The cell dimensions were obtained by least-squares refinement of 25 well-centred reflections. From systematic absences the space group $P2_1/c$ was assumed. Examination of four standard reflections monitored after each 50 reflections showed no substantial intensity decay. A total of 5631 reflections were measured ($2° < 2\theta < 46°$; $-10 < h < 10$, $0 < k < 9$, $0 < l < 31$) with the variable-speed ω–2θ technique; of which 3222 were unique and 1518 with $I > 3\sigma(I)$ were used in the determination of the structure. Lorentz, polarization and absorption corrections (transmission factor range, 0.887–0.951) were applied.

Structure solution and refinement. The structure was solved using direct methods locating the manganese, nitrogen and oxygen atoms. The remaining non-hydrogen atoms were located from successive Fourier syntheses. Refinement of the structure was carried out with the SHELX76 system[4] by weighted anisotropic full-matrix least-squares methods. All hydrogen atoms were calculated assuming C—H = 1.08 Å and were included in the refinement with a fixed isotropic thermal parameter ($B_{iso} = 6$ $Å^2$). The final R_w value was $R_w = 0.056$ (364 parameters refined). $\Sigma w(|F_o| - |F_c|)^2$ was minimized with $w = 1/[\sigma^2(F_o)]$ with $\sigma^2(F_o)$ from counting statistics. In the final difference map the residual maxima were less than 1 e $Å^{-3}$. Atomic scattering factors and corrections for anomalous dispersion for the manganese atom were taken from *International Tables for X-ray Crystallography*.[5] The geometrical calculations were performed with XANADU[6] and DISTAN,[7] and molecular illustrations were drawn with ORTEP.[8] Final atomic coordinates, thermal parameters and F_o/F_c values have been deposited with the Editor as supplementary data.

RESULTS AND DISCUSSION

Crystal structure

Figure 1 shows a perspective view of the $Mn(BPCA)_2$ units with the atomic numbering scheme, and Fig. 2 shows a stereoscopic view of the unit cell. Selected bond distances and angles are listed in Table 1. The structure consists of neutral $Mn(BPCA)_2$ entities linked two by two through hydrogen bonding involving water molecules and carbonyl groups from BPCA ligands, as shown by contact distances listed in Table 1.

Obviating the angular distortions owing to the rigidity of BPCA ligand (see Table 1), the geometry of the MnN_6 polyhedra can be regarded as very distorted compressed octahedral. This compression along the N(2)—Mn—N(5) axis is the result of the rigid structure of the BPCA ligands, which enforce shorter metal–N(central) bond distances.

The N(1), N(2), N(3) and N(5) atoms define a plane (within ±0.10 Å) from which the manganese atom lies 0.07 Å away. The N(2), N(4), N(5) and N(6) atoms, however, deviate more (±0.15 Å) from their least-squares plane, the manganese atom being

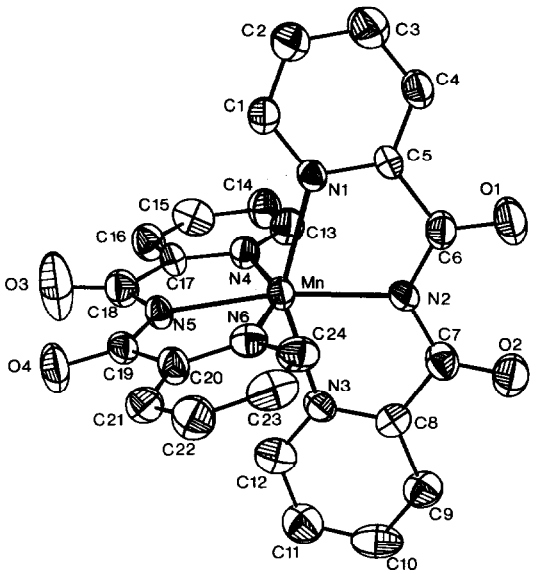

Fig. 1. Perspective view and atomic numbering of the $Mn(BPCA)_2$ units.

only 0.002 Å from this plane. Both mean planes make an angle of 87.0°.

The adaptation of the BPCA ligands to the pseudo-octahedral geometry of the MnN_6 polyhedra requires deformations of the ligand framework. Both ligands are unequivalent and neither of them can be considered planar. In fact, deviations of non-hydrogen atoms from the calculated mean planes are 0.30 Å in one of the ligands and 0.32 Å in the other. Furthermore, it should be noted that the values of the angles around the carbon atoms involved in the carbonyl groups significantly differ from the idealized value of 120°.

Infrared and electronic spectra

The IR spectrum of the title compound shows two noteworthy features, namely the presence of bands at 3550(m) and 3480(m) cm^{-1}, assignable to the O—H stretching vibrations of the water molecule, and that of two intense bands at 1700(vs) and 1685(vs) cm^{-1}, which are due to the C=O stretching vibrations of BPCA carbonyl groups. The shape and position of the ν(OH) bands, in addition to the thermoanalytical data (water is evolved endothermically at low temperature; peak temperature, 80°C), are consistent with water molecules involved in hydrogen bonds of moderate strength.[9] The splitting of the C=O band, which appears as an unique band at 1750(vs) cm^{-1} in the spectrum of the HBPCA ligand,[1,3] might be due to the presence of two different BPCA in the complex, since only one of them is involved in the hydrogen

bonds. This is supported by the observation of an unsplit carbonyl band centred at 1700 cm^{-1} in the IR spectra of the thermally dehydrated $Mn(BPCA)_2$ samples. Similarly, this carbonyl band appears unsplit and centred at 1700 cm^{-1} in the IR spectra of the anhydrous $Ni(BPCA)_2$ complex.[3] Hence the carbonyl groups involved in the hydrogen bonds must be those which produce the absorption at lower wavenumbers, in correspondence to weaker C=O bonds.[1]

Both the reflectance and solution (chloroform) electronic spectra of the compound show only a very strong broad band above 16,000 cm^{-1}, probably due to charge-transfer transitions, which produces the red–brown colour of the samples.

ESR spectroscopy

ESR spectra have been obtained at both X- and Q-band for manganese(II) ions doped into $Zn(BPCA)_2 \cdot H_2O$ at 298 and 130 K. The pure manganese(II) samples give, at room temperature, a strong, broad, symmetrical signal centred at $g_{eff} = 2.00$ and other less intense features at lower and higher magnetic field. This fact suggests a low value for D,[10,11] where D is the axial zero-field splitting parameter in the spin Hamiltonian

$$\mathcal{H} = g\beta HS + D(S_z^2 - 1/3S^2) + E(S_x^2 - S_y^2). \quad (1)$$

The spectra recorded at 130 K [Fig. 3(top)] showed only small changes in the position of the outer signals. An accurate estimation of D and E was not possible at this stage because of the width of the overlapping signals. However, a first evaluation of $0.07\ cm^{-1} < |D| < 0.08\ cm^{-1}$ was made from these spectra. On the contrary, the doped into zinc(II) samples showed a large number of transitions with well-resolved hyperfine structure [Fig. 3(bottom)]. Obviously, the resolution decreases with increasing concentration of manganese(II) in the samples.

The program POWDER[12] was used to calculate the resonance fields by exact diagonalization of the matrix derived from eq. (1) and good agreement with the experimental resonance fields was found with $g = 2.00$ and the data in Table 2. The calculated positions of the signals deviated from the experimental values by less than 25 gauss.

Owing to the small D value and the good resolution of the hyperfine splitting, the sign of D could be determined from the mean spacing of the hyperfine components in the $\pm 3/2 \leftrightarrow \pm 5/2$ transitions, with the magnetic field parallel to z.[13] This

Table 2. Zero-field splitting parameters for $Mn(BPCA)_2 \cdot H_2O$

Temperature (K)	$\lvert D\rvert$ (cm^{-1})	$\lvert E\rvert$ (cm^{-1})	$\lambda\ (= E/D)$
298	0.073	0.017	0.23
130	0.078	0.019	0.24

spacing was greater for the lowest (84 gauss) than for the highest (74 gauss) field observed transition. Assuming that A is negative, as is usually the case for manganese(II), D must be also negative.

The estimated D values indicate that the axial distortion in the MnN_6 chromophores is not very large. This is in full accord with the molecular structure discussed before, since the tetragonality of the chromophore (defined as the ratio between the mean equatorial Mn—N distance and the mean axial Mn—N distance) is only 1.038, if we take the shortest Mn—N distances as the direction of the axial axis. Besides this, the negative D found corresponds to the observed compression of the "octahedra" along an approximate four-fold axis.[10] On the other hand, the λ ($= E/D$) values, near the limiting value of 1/3, fit extremely well with the actual low symmetry of the MnN_6 chromophores.

Finally, it can be noted that the hyperfine parameter A is somewhat lower than found in other manganese(II) complexes.[10,11,14,15] This must be due to the very low symmetry of the MnN_6 chromophores, together with a considerable density of unpaired electrons on the ligands.[1]

PERTURBED ANGULAR CORRELATION STUDIES OF THE Hf–EDTA COMPLEX

S. K. DAS, B. S. TOMAR and SATYA PRAKASH*

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay 400 085, India

(*Received* 23 *April* 1990; *accepted* 22 *June* 1990)

Abstract—The integral perturbed angular correlation (IPAC) technique has been used to determine the stability constant of the Hf–EDTA complex in 4.6 M $HClO_4$. The stability constant ($\log K$) was found to be: 30.1 ± 0.44. The time differential perturbed angular correlation (TDPAC) study of polycrystalline Hf–EDTA was carried out to estimate the quadrupole interaction frequency (w_Q) and the asymmetry of the EFG for the complex, before and after heating at 160°C. These parameters are very similar in these two cases and indicate the possibility of partial polymerization through OH bridging, whereby the immediate chemical surrounding of the hafnium nucleus is expected to remain unchanged.

The perturbed angular correlation (PAC) technique has been effectively used to study hyperfine interactions. Use of this technique in condensed matter physics has been reviewed by Heer and Novey.[1] However, use of this technique in chemistry is relatively recent. Adloff[2] has reviewed several aspects of structural chemistry and solution chemistry, namely, polymerization, complexation, hot atom chemistry, etc., which are amenable to PAC studies. Another review by Rinneberg[3] covers the application of this technique in various fields of research. A report by Lerf and Butz[4] provides data on nuclear quadrupole interactions in several compounds studied by this technique.

Attempts have been made to determine the stability constants of the zirconium complex with EDTA using conventional chemical techniques such as spectrophotometry[5] and ion exchange chromatography.[6] In all these cases the solutions used were made up with low acidity in which zirconium or hafnium is known to polymerize.[7] This restricts these techniques for the direct determination of stability constants, since one has to correct for hydrolysis of the metal ion. While the stability constant of Zr–EDTA at higher acidity (> 3 M), at which zirconium is not polymerized, has been determined,[8] this value for Hf–EDTA has not been determined at higher acidity. Adloff[2] has discussed the potential of IPAC in the determination of stability constants. However, no such attempt has been made so far. In the present work, the sensitivity of the IPAC technique has been exploited in the study of complexation of hafnium(IV) with EDTA and the determination of its stability constant in 4.6 M $HClO_4$.

It is well known from IR data[9] that the Hf–EDTA complex contains four water molecules, of which, two are in the inner sphere and the remaining two are in the outer sphere. The thermal analysis of this complex revealed that at 160°C, 3.6 moles of water are lost. However, there are uncertainties regarding the structure of the complex after removal of the water molecules by heating. In the event of removing the water molecules from the inner sphere, the electronic distribution around the hafnium nucleus would change, resulting in a different EFG. Consequently, the angular correlation pattern would also be altered. To investigate these aspects a TDPAC study has been carried out with polycrystalline Hf–EDTA, before and after heating the sample at 160°C.

EXPERIMENTAL

Sample preparation

Neutron irradiated $HfOCl_2 \cdot 8H_2O$ was dissolved in 5 cm^3 of 6 M HCl to make the stock solution. 0.2 cm^3 aliquots of this solution were transferred to several glass ampoules of 3-mm diameter and dried

* Author to whom correspondence should be addressed.

under an IR lamp. Samples of different Hf : EDTA ratios were made by adding EDTA solutions of determined concentrations prepared in 4.6 M $HClO_4$ in these ampoules. The resultant clear solutions were kept overnight to ensure uniform mixing. These samples were checked for the coincidence of the 133–482 keV cascade at various angles, namely 90, 135 and 180°, using a set-up consisting of two $3'' \times 3''$ NaI(Tl) detectors coupled to a fast–slow coincidence circuit.

For TDPAC measurements Hf–EDTA crystals were prepared following the method described in ref. 9. Nearly 10 mg of inactive hafnium oxychloride was added to an irradiated sample and dissolved in 2 cm^3 of water. This solution was diluted with water to nearly 10 cm^3 and an equimolar quantity of Na_2EDTA was added to this solution with heating. A white precipitate appeared which vanished on further heating. The solution was then evaporated to nearly 1 cm^3 and cooled. The Hf–EDTA complex was crystallized by adding nearly 25 cm^3 of acetone and leaving the solution for 24 h. TDPAC counts were taken for this sample, before and after heating at 160°C, for 4 h at 90 and 180° angles using a set-up consisting of two $1\frac{1}{2}'' \times 1\frac{1}{2}''$ NaI(Tl) detectors coupled to a fast–slow coincidence circuit with a resolving time of 1.4 ns for the above cascade. Nearly 10,000 counts were collected in the peak position of the time spectrum. The detectors were kept at a distance of 14 cm away from the sample so that the solid angle correction was negligible.

RESULTS AND DISCUSSION

Integral measurements

The integral attenuation coefficients A_2G_2 were obtained from the coincidence counts using the formula

$$W(\theta) = 1 + A_2G_2P_2(\cos\theta) + A_4G_4P_4(\cos\theta), \quad (1)$$

where A_k values are the radiation parameters, G_k values are the attenuation factors and P_k values are the Legendre polynomials. The A_2G_2 values as a function of the Hf : EDTA ratio are plotted in Fig. 1. The figure shows that A_2G_2 decreases initially and saturates at a Hf : EDTA ratio close to unity, indicating the formation of a 1 : 1 complex. The stability constant of this complex was then obtained in the following way.

The stability constant of the complex MY in

$$M + Y \rightleftharpoons MY$$

is given by

$$K = [MY]/[M][Y]. \quad (2)$$

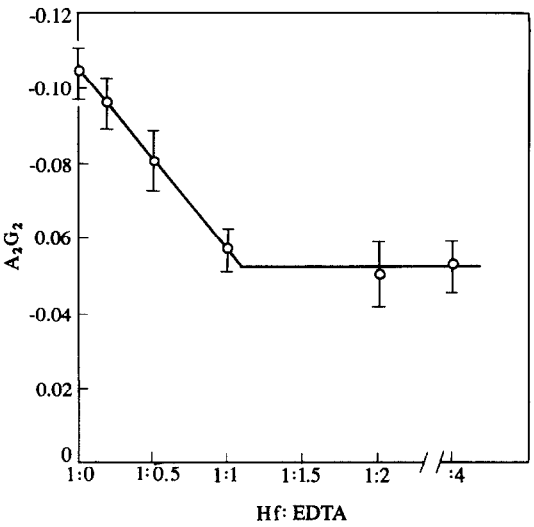

Fig. 1. A_2G_2 vs Hf : EDTA at 4.6 M $HClO_4$.

Alternatively,

$$K = f_A/f_F[Y], \quad (3)$$

where f_A and f_F are the fractions of the complex and the free metal ion, respectively, that is

$$f_A + f_F = 1. \quad (4)$$

For any intermediate value of Hf : Y, the observed attenuation factor can be written as

$$G_2 = f_AG_{2A} + f_FG_{2F}, \quad (5)$$

where G_{2A} and G_{2F} are the integral attentuation factors for the complex and the free metal ion, respectively. G_{2F} is the value of G_2 (Fig. 1) which corresponds to the case when no EDTA is present, and G_{2A} is the saturation value of G_2. f_A and f_F were obtained from eqs (4) and (5).

The free EDTA concentration, [Y], in the medium is obtained from the stepwise dissociation constants of EDTA and is given by

$$[Y] = ([H_4Y]_0 - f_A[M]_0) \Big/ \left(1 + \frac{[H^+]^6}{K_1K_2K_3K_4K_5K_6} + \frac{[H^+]^5}{K_1K_2K_3K_4K_5} + \frac{[H^+]^4}{K_1K_2K_3K_4} + \frac{[H^+]^3}{K_2K_3K_4} + \frac{[H^+]^2}{K_3K_4} + \frac{[H^+]}{K_4}\right), \quad (6)$$

where $[\ ]_0$ represents the initial concentration, and K_5 and K_6 are the dissociation constants for the protonated EDTA species. The dissociation constants for EDTA at the ionic strength (4.6) used in this experiment have been calculated from the extended Debye–Huckel theory using the parameters obtained by fitting the data from ref. 10.

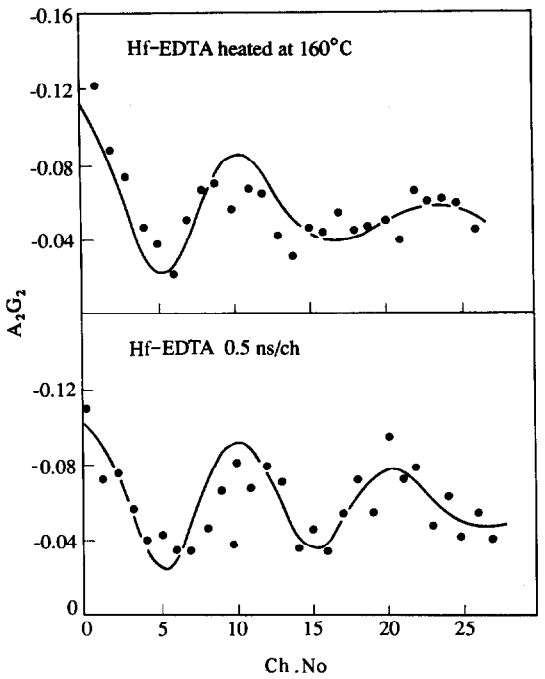

Fig. 2. Time differential perturbed angular correlation spectra for polycrystalline Hf–EDTA.

Substituting [Y] from eq. (6) and the values of f_A and f_F, we obtain the stability constant from eq. (3). The value of the stability constant thus obtained is: $\log K = 30.1 \pm 0.44$.

The present data is in good agreement with the literature data obtained by Caletka *et al.*[8] for Zr–EDTA. The data obtained by Intorre and Martell,[5] Tikhonova,[6] and Morgan and Justus[11] are lower than the present data. This may be attributed to hydrolysis of the metal ion at low acidity.

TDPAC measurements

The A_2G_2 values were obtained from the time spectra at 90 and 180° using expression (1), by neglecting the A_4G_4 term as its magnitude is insignificant compared to A_2G_2. TDPAC patterns for the Hf–EDTA complex, before and after heating at 160°C, are shown in Fig. 2. The continuous curve represents the least-square fit, from which the quadrupole interaction frequency (w_Q), the asymmetry parameter (η) and the width of the frequency distribution (δ) were obtained by using the following equation,[12]

$$G_2(t) = \sum_{n=0}^{3} S_{2n} \cos w_n t \, e^{-(1/2)\delta^2 w_n^2 t^2} \, e^{-(1/2)w_n^2 \tau^2}, \quad (7)$$

where w_ns are the frequencies of the transitions among the m states of the intermediate level. For $\eta = 0$, $w_1 = 6w_Q$, where

$$w_Q = eQV_{zz}/4I(2I-1)\hbar,$$

Q being the quadrupole moment of the intermediate state of spin, I, and V_{zz} is the electric field gradient (EFG). S_{2n} are the amplitudes of the corresponding transitions and are dependent on the asymmetry (η) of the EFG, and τ is the resolving time of the set-up.

Table 1. Time differential angular correlation data for the Hf–EDTA complex

Sample	w_Q (MHz)	η	δ (%)
Unheated	22.9 ± 0.6	0.80	5 ± 1
	21.7 ± 0.5[a]	0.86[a]	—
Heated	20.1 ± 0.6	0.70	9 ± 2

[a] From ref. 13.

Our data are presented in Table 1, along with the literature data for the unheated sample.[13] The quadrupole interaction frequencies for the two cases are almost the same. It is known from the thermal analysis[9] that on the average 3.6 molecules of water are lost at 160°C after prolonged heating. If this evaporation takes place from a single molecule of Hf–EDTA, then firstly, the eight-coordination of hafnium(IV) would have been disturbed and secondly, this would have changed the electron distribution around the hafnium nucleus drastically, resulting in a very different value of w_Q

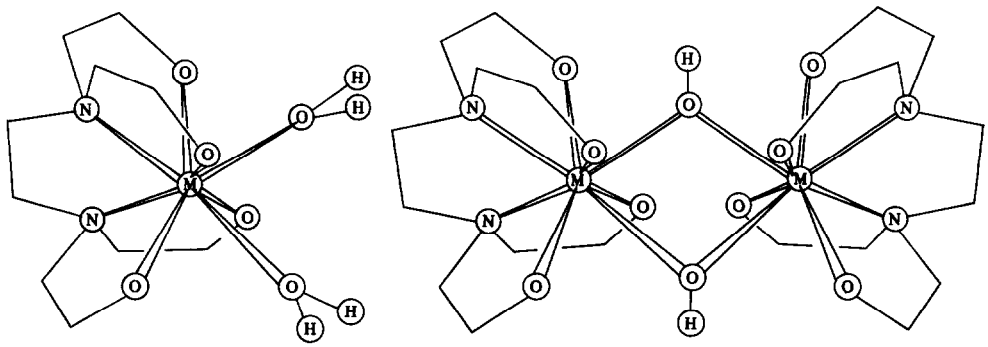

Fig. 3. Structures of monomeric and polymeric Hf–EDTA complexes.[14]

in the two cases. The close values of w_Q observed can be attributed to the probable partial polymerization through OH bridging, as suggested for the Th–EDTA complex[14] (see Fig. 3). This figure shows that the nature of the bonds and the coordination number of the metal ion in the complex, as well as in the polymeric species, remain practically unchanged. Thus the electron distribution around the hafnium nucleus remains almost unchanged, leading to a nearly constant w_Q.

(*Received* 16 *April* 1990; *accepted* 4 *July* 1990)

Abstract—A one-step procedure for the preparation of new mixed-amido halides of niobium and tantalum from their pentahalides and the trimethylsilylamine reagents, Me_3SiNR_2, is described. Thus, high yields of the monokis(amides), $M(NEt_2)Cl_4(OEt_2)$ (**1**, M = Ta; **2**, M = Nb), and the bis(amides), $Ta(NR_2)_2Cl_3(L)$ (**3**, R = Et, L = Et_2O; **4**, R = Et, L = THF; **5**, R = Me, L = THF), can be obtained by this procedure and crystallized as Et_2O or THF adducts. The dimeric niobium amide, $[Nb(NEt_2)_2Cl_3]_2$ (**6**), and the monomeric tris(amide), $Nb(NEt_2)_3Cl_2$ (**7**), are also prepared from Me_3SiNEt_2 and $NbCl_5$ in a single step, under the appropriate conditions. The use of Me_3SiNR_2 compounds as amidation reagents can be extended to prepare the alkoxide amides, $Ta(NEt_2)(DMP)Cl_3(OEt_2)$ (**8**), $Ta(NEt_2)(DIPP)Cl_3(OEt_2)$ (**9**) and $Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (**10**), from the addition of Me_3SiNEt_2 to solutions of the phenoxide compounds, $Ta(DMP)Cl_4(OEt_2)$, $Ta(DIPP)Cl_4(OEt_2)$ and $Ta(DIPP)_2Cl_3(OEt_2)$, respectively (DIPP = 2,6-diisopropylphenoxide, DMP = 2,6-dimethylphenoxide). Complex **10** can be further alkoxylated using $LiDIPP \cdot OEt_2$ to provide base-free $Ta(NEt_2)(DIPP)_3Cl$ (**11**). When **10** is reduced using two equivalents of NaHg in the presence of the appropriate alkyne, the adducts $(PhC{\equiv}CPh)Ta(NEt_2)(DIPP)_2$ (**12**), $(Me_3CC{\equiv}CH)Ta(NEt_2)(DIPP)_2$ (**13**) and $(Me_3SiC{\equiv}CMe)Ta(NEt_2)(DIPP)_2$ (**14**) are formed.

The *selective* preparation of simple amido halides, $M(NR_2)_xCl_y$, of the early transition metals has been difficult to achieve with amidolithium or -sodium reagents unless the ligand is extremely bulky.[1,2] Various strategies to prepare mixed-ligand compounds of smaller amides have been developed, including: (i) the exhaustive amidation of the metal halide, followed by the reaction of the resulting homoleptic complex with a halide source like Me_3SiCl;[3–5] (ii) redistribution reactions of homoleptic or partially substituted complexes;[6,7] and (iii) reactions of the halides with the secondary amine itself, which typically provide adducts $M(NR_2)_xCl_{5-x}(HNR_2)$.[8,9] The disadvantages of these approaches are that they require multiple steps from the pentachlorides or provide adducts in which the coordinated amine may not be labile.

The reaction of early metal halides with silylethers constitutes a convenient method to selectively *alkoxylate* the metal and provide mixed-alkoxy halides.[10–12] For example, Gibson has reported[10] the preparation of $[Nb(OR)Cl_4]_2$ (where R = Me, Et, $SiMe_3$) and we have prepared[11] $[Ta(OR)Cl_4]_2$ and $Ta(OR)Cl_4(OEt_2)$ (where OR = 2,6-dialkylphenoxides) in high yields from the reactions of the pentachlorides with the appropriate trimethylsilyl ethers, Me_3SiOR. Since these and related tantalum alkoxide derivatives are useful precursors to reactive tantalum(III) arene complexes,[11,13] and since π-donor ligands may be singularly important in defining the course of reaction of these compounds,[14,15] we have sought to prepare new amido halides of niobium and tantalum which may exhibit a similar reactivity.

† Author to whom correspondence should be addressed.

Preparations of dialkylamido complexes of the groups 4–6 metals from silylamine reagents and metal halides are known,[16] but typically require the metal fluorides to exploit the formation of a strong Si—F bond (in byproduct Me_3SiF) as a driving force. In this paper, we report the preparation of new niobium and tantalum compounds of the form $M(NR_2)_xCl_{5-x}$, and extend these amidation reactions to include the preparation of alkoxide amides of the type $Ta(NR_2)(OR)_xCl_{4-x}$. The reductions of one of these derivatives, viz. $Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (DIPP = 2,6-diisopropylphenoxide), in the presence of alkynes is also reported.

RESULTS AND DISCUSSION

The transformations observed in this study are summarized in eqs (1)–(6) and in Scheme 1. Spectroscopic data for the compounds are given in the Experimental.

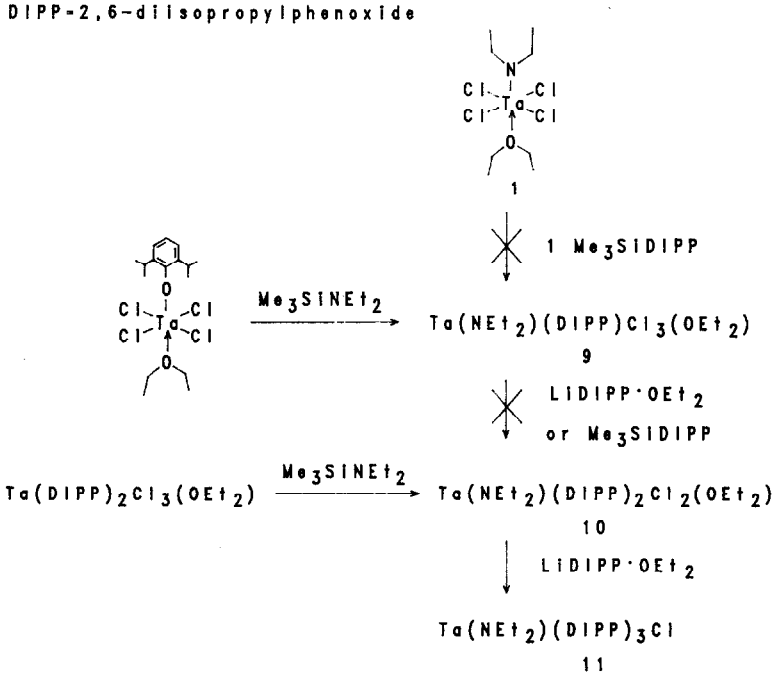
Monokis- and bis(amido) halide complexes

The need to develop routes to a number of *mixed* π-donor ligand complexes[14] has prompted us to explore the use of trimethylsilylamines as selective $-NR_2$ transfer reagents in group 5 chemistry. When one equivalent of Me_3SiNEt_2 reacts with $TaCl_5$ in diethyl ether, an immediate reaction ensues to provide solutions from which $Ta(NEt_2)Cl_4(OEt_2)$ (**1**) can be isolated in high yields, eq. (1). Based upon the single ν(Ta—Cl) mode in its

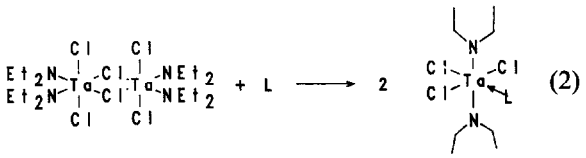
$$MCl_5 + 1\ Me_3SiNEt_2 \xrightarrow{Et_2O} \underset{\substack{1,\ M=Ta\\ 2,\ M=Nb}}{\text{N, Cl, Cl, M, Cl, Cl, O}} \quad (1)$$

far-IR spectrum and the *trans* isomers observed in the monokis-alkoxides, $Ta(OR)Cl_4(OEt_2)$,[11] $Ta(OSi[2\text{-}MeC_6H_4]_3)Cl_4(OEt_2)$[17] and $Ta(OPh)Cl_4L$ (L = pyridine or α-picoline),[18] **1** is formulated as a monomeric, *trans* structure. The analogous niobium complex can be isolated in high yield as purple crystals by the same route, eq. (1).

We have reported previously that excess Me_3SiNEt_2 reacts with $TaCl_5$ (in toluene–Et_2O) to provide dimeric $[Ta(NEt_2)_2Cl_3]_2$ in high yields.[14] This complex was observed to react with pyridine, which disrupted the dimeric structure and provided *cis,mer*-$Ta(NEt_2)_2Cl_3$(pyridine).[14] Oxygen donor solvents, viz. Et_2O or THF, also disrupt the dimeric structure to afford the six-coordinate, monomeric complexes, $Ta(NEt_2)_2Cl_3(OEt_2)$ (**3**) and $Ta(NEt_2)_2Cl_3(THF)$ (**4**) in good yields, eq. (2). Although $[Ta(NEt_2)_2Cl_3]_2$ is itself prepared in a toluene–Et_2O solution, simply removing all of the reaction vola-



Scheme 1.



(2)

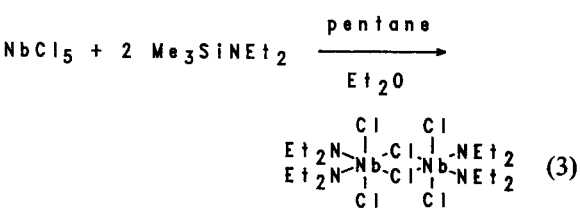
3, L-Et_2O
4, L-THF

tiles from this solution does not afford the etherate **3**.[14] However, by preparing solutions of this dimer in *neat* Et_2O and cooling them to −30°C, high yields of the monoetherate $Ta(NEt_2)_2Cl_3(OEt_2)$ (**3**) are obtainable. The dimethylamido analogue of **4**, viz. $Ta(NMe_2)_2Cl_3(THF)$ (**5**), is readily prepared in a single step from $TaCl_5$, Me_3SiNMe_2 and THF.

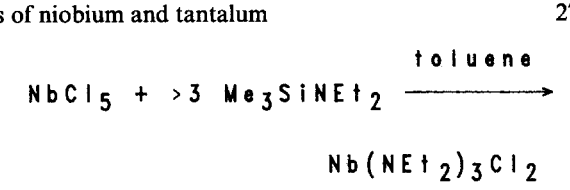
The structures of these complexes of the formula $Ta(NR_2)_2Cl_3$(O-donor) appear to differ from the analogous $Ta(NR_2)_2Cl_3$(N-donor) compounds such as $Ta(NEt_2)_2Cl_3$(pyridine)[14] or $Ta(NMe_2)_2Cl_3(HNMe_2)$.[3] The pyridine and dimethylamine adducts possess a *cis,mer* geometry, as manifested by inequivalent amide ligands in their ^1H and ^{13}C NMR spectra and by a structural determination of the latter complex.[3] The solution *equivalency* of the amide ligands in complexes **3** and **4** requires either the *fac* isomer, or the *trans,mer* geometry, as depicted in eq. (2). Single crystals of the etherate **3** were examined by X-ray crystallography.[19] Although the difference between N and O atoms in the ligands could not be unambiguously distinguished by crystallography, the *mer* arrangement of the NEt_2 and OEt_2 ligands was clearly established.[19] This crystallographic result, in concert with the NMR data, requires the *trans,mer* geometry for **3** as shown in reaction (2). Accordingly, the THF adducts **4** and **5** are also assigned as *trans,mer* structures.

Niobium amido halide complexes

We have extended the utility of this method to the preparation of the dialkyl amides of niobium. Reactions (3) and (4) summarize the syntheses of niobium bis(amide) (**6**) and tris(amide) (**7**) chlorides. Based upon the equivalent amide ligands of **6** in solution, and the presumed relation of this compound to its tantalum analogues, $[Ta(NEt_2)_2Cl_3]_2$[14] and $[Ta(NMe_2)_2Cl_3]_2$,[3] we assign the structure of **6** as shown in eq. (3). However,



(3)



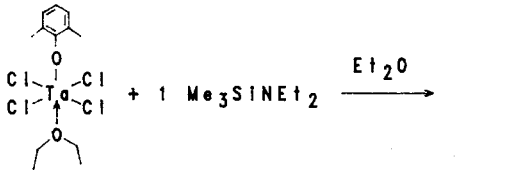
(4)

solution molecular weight measurements of **7** reveal a *monomeric* structure (calc. for monomer: 380. Found: 415 ± 40), unlike its dimeric tantalum analogue $[Ta(NMe_2)_3Cl_2]_2$ reported by Chisholm *et al.*[3] Thus, the equivalency of the diethylamido ligands (by ^1H and ^{13}C NMR spectroscopy) requires that either all three NEt_2 ligands occupy the equatorial positions of a trigonal bipyramid, or more likely, **7** exists as a fluxional five-coordinate structure in solution. Thus, by using the trimethylsilyl-based reagents, controlled amidation of $NbCl_5$ can be effected to afford $Nb(NEt_2)_nCl_{5-n}$ complexes for $n = 1$, 2 or 3.

Our earlier preparation of "base-free" monokis(alkoxides) $[Ta(DIPP)Cl_4]_2$ (DIPP = 2,6-di-isopropylphenoxide) and $[Ta(DMP)Cl_4]_2$ (DMP = 2,6-dimethylphenoxide)[11] prompted attempts to prepare their dialkylamido analogues $[Ta(NR_2)Cl_4]_2$. However, the reaction of $TaCl_5$ in CH_2Cl_2 or $CHCl_3$ solution resulted in the formation of brown solutions from which no tractable products could be isolated.

Amido alkoxides of tantalum

Mixed π-donor ligation may be useful for fine-tuning the reactivity of group 5 intermediates in reduction reactions,[14] therefore we have sought to extend these amidation reactions in order to prepare amido alkoxides. Thus, the monokis(alkoxide) $Ta(DMP)Cl_4(OEt_2)$[11] (DMP = 2,6-dimethylphenoxide) reacts with equimolar Me_3SiNEt_2 to afford $Ta(NEt_2)(DMP)Cl_3(OEt_2)$ (**8**) in *ca* 70% isolated yield, reaction (5). The structure of **8** is most



(5)

8

DMP-2,6-dimethylphenoxide

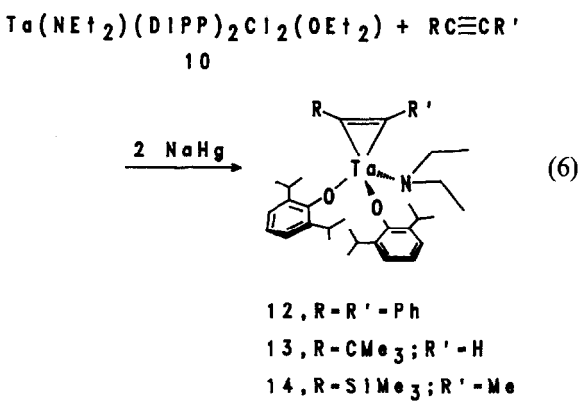
likely characterized by *mer*-chlorides, but whether the π-donor ligands are *trans* as in **3** and **4** or *cis* as in $Ta(NEt_2)_2Cl_3$(pyridine)[14] is not known.

We selected the DIPP compounds to extend this synthetic procedure to higher substituted phenoxide analogues as summarized in Scheme 1. Thus, both

$Ta(NEt_2)(DIPP)Cl_3(OEt_2)$ (**9**) and $Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (**10**) are readily prepared through the reactions of Me_3SiNEt_2 with $Ta(DIPP)Cl_4(OEt_2)$[11] and $Ta(DIPP)_2Cl_3(OEt_2)$,[11] respectively. However, compound **9** has not, in our hands, been prepared from the reaction of **1** with one equivalent of $Me_3SiDIPP$ or $LiDIPP \cdot OEt_2$ in Et_2O, although this preparative route would seem viable, Scheme 1. Likewise, $Ta(NEt_2)(DIPP)_3Cl$ (**11**) is not accessible through the reaction of the tantalum tris(phenoxide), $Ta(DIPP)_3Cl_2(OEt_2)$,[20] with Me_3SiNEt_2, however, **11** can be synthesized from the addition of $LiDIPP \cdot OEt_2$ to **10**, Scheme 1. Finally, compound **10** is not readily available from the reaction of **9** with either $LiDIPP \cdot OEt_2$ or $Me_3SiDIPP$ for reasons which are not readily apparent.

Reactions of amide complexes with alkynes

The reduction of $Ta(OR)_nCl_{5-n}$ complexes in the presence of alkynes may provide alkyne adducts,[14,21] metallacyclopentadienes[14,21] or arene complexes,[11,13] depending upon the nature of the π-donor ligands, including the steric constraints they may place upon the metal. The reactivity of these mixed-ligand compounds with alkynes was initiated with compound **10**, eq. (6). Thus, when **10** is



(6)

reduced using two equivalents of NaHg in the presence of the appropriate alkyne, the adducts $(PhC{\equiv}CPh)Ta(NEt_2)(DIPP)_2$ (**12**), $(Me_3CC{\equiv}CH)Ta(NEt_2)(DIPP)_2$ (**13**) and $(Me_3SiC{\equiv}CMe)Ta(NEt_2)(DIPP)_2$ (**14**) are formed. The $PhC{\equiv}CPh$ and $Me_3SiC{\equiv}CMe$ adducts, **12** and **14**, are readily isolated as crystalline solids, but $(Me_3CC{\equiv}CH)Ta(NEt_2)(DIPP)_2$ (**13**) has not been induced to crystallize, although remarkably clean NMR spectra have been obtained for this compound. In reactions of **10** with smaller alkynes such as $EtC{\equiv}CEt$, only intractable oils were obtained and no evidence for metallacyclopentadienes or higher cyclo-oligomers was obtained.

DISCUSSION

There are few *general* routes to mixed-ligand $M(\pi\text{-donor})_nCl_{5-n}$ complexes which will permit control over the extent of the π-donor substitution based upon anything other than the size of the ligand.[22] This trend has resulted in few early metal compounds $M(L)_x(L')_yCl_z$, where L and L′ are different π-donors. The need for a variety of d^2 "$Ta(\pi\text{-donor})_x$" moieties for use in carbon—carbon bond-forming reactions[23] has prompted the search to control the extent of substitution by *reagent selection* such that reactions with small ligands might be halted at the partially substituted stage. Our need for mixed-alkoxy halides has led to the completion of the series for the compounds $Ta(DIPP)_nCl_{5-n}$ (where $n = 1$–4) in yields of 50–85% which demonstrate this methodology, reactions (7)–(10). Additionally, the trimethylsilyl reagents provide more smooth, clean and controlled reactivity than is usually available from using the protic reagents (viz. HDIPP) which release HCl upon reaction. Therefore, with the precedent provided by the work of Gibson and co-workers,[10,12a] as well as these reactions, we have developed analogous routes to the preparation of new amido halides and amido alkoxides of the group 5 metals, using sterically innocuous amido ligands.

$$TaCl_5 + 1\,Me_3SiDIPP + Et_2O \longrightarrow Ta(DIPP)Cl_4(OEt_2)^{11} \quad (7)$$

$$TaCl_5 + 2\,Me_3SiDIPP \text{ or } 2\,LiDIPP \cdot OEt_2 \longrightarrow Ta(DIPP)_2Cl_3(OEt_2)^{11} \quad (8)$$

$$Ta(DIPP)_2Cl_3(OEt_2) + 1\,LiDIPP \cdot OEt_2 \longrightarrow Ta(DIPP)_3Cl_2(OEt_2)^{20a} \quad (9)$$

$$Ta(DIPP)_2Cl_3(OEt_2) + \text{excess } K^+DIPP^- \longrightarrow Ta(DIPP)_4Cl^{24} \quad (10)$$

We note that the mixed-ligand *fluorides* of niobium and tantalum, $M(NEt_2)_nF_{5-n}$ (for $n = 1$ or 2), have been prepared by Winfield and co-workers in a metathetical reaction between the pentafluorides and the trimethylsilylamine, Me_3SiNEt_2.[16d] However, the tris(amido) fluorides are not available by this route, as $M(NEt_2)_2F_3$ (M = Nb or Ta) are the highest substituted products arising from the reaction between $[MF_5]_4$ and neat Me_3SiNEt_2. Both $M(NEt_2)F_4$ and $M(NEt_2)_2F_3$ have been formulated as polymeric, fluoro-bridged structures based primarily upon their IR spectra.[16d]

EXPERIMENTAL

All experiments were performed under a nitrogen atmosphere either by standard Schlenk techniques[25] or in a Vacuum Atmospheres HE-493 drybox at room temperature (unless otherwise indicated). Solvents were purified under nitrogen by standard techniques[26] and transferred to the drybox without exposure to air. The "cold" solvents used to wash isolated solid products were cooled to *ca* −20°C before use. In all preparations, the Me_3SiNR_2 reagent was weighed (although both the weights and the volumes are recorded for convenience) and the reagent additions were carried out over a period of *ca* 1 min. In all complexes, DIPP = 2,6-diisopropylphenoxide and DMP = 2,6-dimethylphenoxide.

Tantalum(V) chloride and niobium(V) chloride (both resublimed) were purchased from Alfa and used as received. Me_3SiNMe_2 and Me_3SiNEt_2 were obtained from Petrarch and used as received. $Me_3SiDIPP$,[11] Me_3SiDMP,[11] $LiDIPP \cdot OEt_2$,[14] $Ta(DIPP)Cl_4(OEt_2)$,[11] $Ta(DMP)Cl_4(OEt_2)$,[11] $Ta(DIPP)_2Cl_3(OEt_2)$[11] and $[Ta(NEt_2)_2Cl_3]_2$[14] were prepared by our previously reported methods.

^1H (250 MHz) and ^{13}C (62.9 MHz) NMR spectra were recorded at probe temperature (unless otherwise specified) on a Bruker WM-250 spectrometer in C_6D_6 solvent. Chemical shifts (reported downfield of Me_4Si) are referenced internally to C_6D_6 *protio* solvent impurities (δ 7.15) or solvent ^{13}C resonances (δ 128.0). Routine coupling constants are not listed. IR spectra in the region of 600–180 cm^{-1} were recorded as CsI pellets on a Perkin–Elmer PE-983 spectrometer. Molecular weight measurements were determined by vapour pressure osmometry using a device similar to the one previously described.[27] All microanalytical samples were handled under nitrogen and were combusted with WO_3 (Desert Analytics, Tucson, Arizona).

$Ta(NEt_2)Cl_4(OEt_2)$ (1)

Neat Me_3SiNEt_2 (0.17 g, 0.23 cm^3, 1.19 mmol) was added dropwise to a solution of $TaCl_5$ (0.42 g, 1.19 mmol) in 20 cm^3 of diethyl ether. The solution immediately took on a yellow colour, which slowly changed to bright orange over 20 min. The best yields were obtained by allowing the reaction to stir at room temp. for 2 days. The solvent was then removed *in vacuo* to provide the product as an orange solid (0.49 g, 1.04 mmol, 87%) which was sufficiently pure for further reactions. This compound was recrystallized from a minimum volume of diethyl ether at −30°C to provide 0.39 g of analytically pure, orange, crystalline product (0.82 mmol, 79%). ^1H NMR (C_6D_6): δ 4.74 (q, 4 H, OCH_2CH_3), 4.08 (br, 4 H, NCH_2CH_3), 0.96. 0.87 (t, 6 H each, OCH_2CH_3 and NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 67.3 (OCH_2CH_3), 51.1 (NCH_2CH_3), 12.4, 11.7 (OCH_2CH_3 and NCH_2CH_3). IR (CsI): ν(Ta—Cl) = 324 cm^{-1}. Found: C, 20.7; H, 4.4. Calc. for $C_8H_{20}Cl_4NOTa$: C, 20.5; H, 4.3%.

$Nb(NEt_2)Cl_4(OEt_2)$ (2)

To a sample of $NbCl_5$ (0.45 g, 1.70 mmol) dissolved in 15 cm^3 of diethyl ether was added, dropwise, Me_3SiNEt_2 (0.24 g, 0.31 cm^3, 1.70 mmol). Multiple colour changes occurred over 5 min, resulting finally in a purple solution. After stirring this solution for 10 h, the solvent was removed *in vacuo* to afford the product as a purple solid which was washed with pentane and dried *in vacuo*; yield 0.52 g (1.37 mmol, 80%). $Nb(NEt_2)Cl_4(OEt_2)$ obtained in this manner is sufficiently pure for further reactions, but can be recrystallized from diethyl ether at −30°C to yield 0.49 g (1.28 mmol or 76%) of purple crystals. ^1H NMR (C_6D_6): δ 4.50 and 4.10 (q, 4 H each, NCH_2CH_3 and OCH_2CH_3), 1.01 and 0.82 (t, 6 each, NCH_2CH_3 and OCH_2CH_3). ^{13}C NMR (C_6D_6): δ 67.2 (OCH_2CH_3), 55.8 (NCH_2CH_3), 12.4 and 10.3 (NCH_2CH_3 and OCH_2CH_3). IR (CsI): ν(Nb—Cl) = 342 cm^{-1}. Found: C, 25.1; H, 5.4. Calc. for $C_8H_{20}Cl_4NNbO$: C, 25.2; H, 5.3%.

$Ta(NEt_2)_2Cl_3(OEt_2)$ (3)

$[Ta(NEt_2)_2Cl_3]_2$ (0.60 g, 0.69 mmol) was dissolved in 10 cm^3 of diethyl ether and stored at −30°C for 24 h, over which time the etherate crystallized out in 74% yield (0.52 g). ^1H NMR (C_6D_6): δ 3.91 (q, 8 H, NCH_2CH_3), 3.38 (q, 4 H, OCH_2CH_3), 1.08 (t, 6 H, OCH_2CH_3), 0.88 (t, 12 H, NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 65.8 (OCH_2CH_3), 46.5 (NCH_2CH_3), 14.4 (OCH_2CH_3), 12.0 (NCH_2CH_3). Found: C, 28.0; H, 6.2. Calc. for $C_{12}H_{30}Cl_3N_2OTa$: C, 28.5; H, 6.0%.

$Ta(NEt_2)_2Cl_3(THF)$ (4)

Excess THF (1.5 cm^3) was added to a slurry of $[Ta(NEt_2)_2Cl_3]_2$ (0.60 g, 0.69 mmol) in 10 cm^3 of pentane. An immediate reaction ensued to afford a clear, yellow–orange solution. After stirring this solution for 1 h, the reaction volatiles were removed *in vacuo* to yield the product as an orange solid. The product could be washed with cold Et_2O to provide 0.65 g (1.29 mmol, 94%) of $Ta(NEt_2)_2Cl_3(THF)$. The compound was recrystallized from diethyl ether at −30°C in 79% yield (0.54

g, 1.07 mmol). ^{1}H NMR (C_6D_6): δ 4.17 (q, 8 H, NCH_2CH_3), 3.99 (m, 4 H, $O(CH_2CH_2)_2$), 1.21 (m, 4 H, $O(CH_2CH_2)_2$), 1.00 (t, 12 H, NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 73.6 (C_α, THF), 47.0 (NCH_2CH_3), 25.4 (C_β, THF), 11.7 (NCH_2CH_3). Found: C, 28.8; H, 5.6; Cl, 20.2. Calc. for $C_{12}H_{28}Cl_3N_2OTa$: C, 28.6; H, 5.6; Cl, 21.1%.

$Ta(NMe_2)_2Cl_3(THF)$ (**5**)

Neat Me_3SiNMe_2 (1.17 g, 1.53 cm^3, 10 mmol) was added to a solution of $TaCl_5$ (0.90 g, 2.51 mmol) in 20 cm^3 of toluene–diethyl ether (3 : 1), which formed an immediate red–orange colour. After stirring this mixture for 8 h, 2 cm^3 of THF were added, and the reaction volatiles were removed *in vacuo* to afford 0.94 g of the product as an orange powder (2.09 mmol, 84%). Analytically pure samples of $Ta(NMe_2)_2Cl_3(THF)$ were obtained as red crystals in 52% yield by crystallization from THF–pentane solution at −30°C. ^{1}H NMR (C_6D_6): δ 3.92 (m, 4 H, $O(CH_2CH_2)_2$), 3.81 (br s, 12 H, NCH_3), 1.16 (m, 4 H, $O(CH_2CH_2)_2$). ^{13}C NMR (C_6D_6): δ 74.0 (C_α, THF), 48.3 (NCH_3), 25.4 (C_β, THF). Found: C, 21.7; H, 4.6. Calc. for $C_8H_{20}Cl_3N_2OTa$: C, 21.5; H, 4.5%.

$[Nb(NEt_2)_2Cl_3]_2$ (**6**)

To a solution of $NbCl_5$ (0.40 g, 1.48 mmol) in 20 cm^3 of pentane–diethyl ether (1 : 1) was added neat Me_3SiNEt_2 (0.43 g, 0.56 cm^3, 2.96 mmol), which immediately produced a dark brown colour. After 70 min, the solution was filtered and the volatiles were removed from the filtrate *in vacuo* to afford 0.83 g of product as a red–brown solid (1.19 mmol, 80%). This compound was obtained analytically pure in 68% yield (0.69 g, 1.00 mmol of dimer) by recrystallizing from toluene–pentane solution at −30°C. ^{1}H NMR (C_6D_6): δ 3.72 (q, 8 H, NCH_2CH_3), 0.84 (t, 12 H, NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 47.7 (NCH_2CH_3), 11.3 (NCH_2CH_3). Found: C, 28.0; H, 6.0; N, 8.0. Calc. for $C_8H_{20}Cl_3N_2Nb$: C, 28.0; H, 5.8; N, 8.1%.

$Nb(NEt_2)_3Cl_2$ (**7**)

To a stirred suspension of $NbCl_5$ (0.51 g, 1.89 mmol) in 15 cm^3 of toluene was added Me_3SiNEt_2 (1.09 g, 1.40 cm^3, 7.55 mmol), which resulted in a rapid reaction and the formation of a brown solution. After 2 h, the reaction volatiles were removed *in vacuo* to afford a brown solid which was extracted with a minimum of diethyl ether (*ca* 3 cm^3), filtered and the filtrate was cooled to −30°C. The yellow crystals of $Nb(NEt_2)_3Cl_2$ which formed (0.69 g, 0.91 mmol, 48%) were collected and dried *in vacuo*. ^{1}H NMR (C_6D_6): δ 3.83 (q, 12 H, NCH_2CH_3), 1.00 (t, 18 H, NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 47.2 (NCH_2CH_3), 12.1 (NCH_2CH_3). Molecular weight (CH_2Cl_2 soln): Calc. for monomeric $Nb(NEt_2)_3Cl_2$: 380. Found: 415±40. Found: C, 38.1; H, 8.11; N, 11.0. Calc. for $C_{12}H_{30}Cl_2N_3Nb$: C, 38.1; H, 7.9; N, 11.1%.

$Ta(NEt_2)(DMP)Cl_3(OEt_2)$ (**8**)

To a stirred solution of $Ta(DMP)Cl_4(OEt_2)$ (0.77 g, 1.49 mmol) in 15 cm^3 of diethyl ether was added Me_3SiNEt_2 (0.22 g, 0.29 cm^3, 1.51 mmol). After 48 h, the solution was pumped to dryness to yield a yellow solid. This solid was dissolved in a minimum volume (*ca* 3 cm^3) of diethyl ether and the solution was cooled to −30°C to provide 0.59 g of the product as yellow crystals (1.07 mmol, 71%). ^{1}H NMR (C_6D_6): δ 6.87–6.69 (A_2B mult, 3 H, H_{aryl}), 4.44, 3.94 (q, 4 H each, NCH_2CH_3 and OCH_2CH_3), 2.61 (s, 6 H, $OC_6H_3Me_2$), 0.94, 0.86 (t, 6 H each, NCH_2CH_3 and OCH_2CH_3). ^{13}C NMR (C_6D_6): δ 158.3 (C_{ipso}), 130.8 (C_o), 129.3 (C_m), 124.7 (C_p), 66.3 (OCH_2CH_3), 51.8 (NCH_2CH_3), 18.6 ($OC_6H_3Me_2$), 12.4, 12.3 (OCH_2CH_3 and NCH_2CH_3). Found: C, 34.2; H, 5.3. Calc. for $C_{16}H_{29}Cl_3NO_2Ta$: C, 34.6; H, 5.3%.

$Ta(NEt_2)(DIPP)Cl_3(OEt_2)$ (**9**)

To a stirred solution of $Ta(DIPP)Cl_4(OEt_2)$ (0.76 g, 1.32 mmol) in 10 cm^3 of diethyl ether was added Me_3SiNEt_2 (neat) (0.21 g, 0.28 cm^3, 1.44 mmol). After 6 h, the solution was pumped to dryness, the resulting solid was extracted with 1 cm^3 of diethyl ether–pentane (1 : 1) and the solution cooled to −30°C. The yellow crystals of **9** which formed were collected and dried *in vacuo*; yield 0.41 g (0.67 mmol, 51%). ^{1}H NMR (C_6D_6): δ 7.10–6.89 (A_2B mult, 3 H, H_{aryl}), 4.47 (q, 4 H, NCH_2CH_3), 4.00 (spt, 2 H, $CHMe_2$), 3.93 (q, 4 H, OCH_2CH_3), 1.28 (d, 12 H, $CHMe_2$), 0.98, 0.90 (t, 6 H each, NCH_2CH_3 and OCH_2CH_3). ^{13}C NMR (C_6D_6): δ 155.0 (C_{ipso}), 141.3 (C_o), 125.5 (C_p), 124.7 (C_m), 66.2 (OCH_2CH_3), 51.3 (NCH_2CH_3), 26.4 ($CHMe_2$), 25.1 ($CHMe_2$), 12.5, 11.8 (NCH_2CH_3 and OCH_2CH_3). Found: C, 39.0; H, 6.2. Calc. for $C_{20}H_{37}Cl_3NO_2Ta$: C, 39.3; H, 6.1%.

$Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (**10**)

To a solution of $Ta(DIPP)_2Cl_3(OEt_2)$ (1.35 g, 0.46 cm^3, 1.88 mmol) in 15 cm^3 of diethyl ether was added Me_3SiNEt_2 (0.35 g, 0.47 cm^3, 2.41 mmol). After the solution was stirred for 2 h, it was filtered

and the volatiles removed from the filtrate *in vacuo*. Dissolving the resulting yellow solid in Et_2O and cooling the solution to $-30°C$ afforded 1.34 g (1.78 mmol, 94%) of yellow crystals of the product. ^1H NMR (C_6D_6): δ 7.19–6.94 (A_2B mult, 6 H, H_{aryl}), 4.26, 3.60 (q, 4 H each, NCH_2CH_3 and OCH_2CH_3), 4.07 (spt, 4 H, $CHMe_2$), 1.38 (d, 24 H, $CHMe_2$), 1.03 and 0.96 (t, 6 H each, NCH_2CH_3 and OCH_2CH_3). ^{13}C NMR (C_6D_6): δ 155.3 (C_{ipso}), 140.7 (C_o), 124.3 (C_m), 123.9 (C_p), 65.2 (OCH_2CH_3), 49.8 (NCH_2CH_3), 26.3 ($CHMe_2$), 25.4 ($CHMe_2$), 14.1, 10.6 (OCH_2CH_3 and NCH_2CH_3). Found: C, 52.5; H, 7.9. Calc. for $C_{36}H_{64}Cl_2NO_3Ta$: C, 52.3; H, 7.8%.

$Ta(NEt_2)(DIPP)_3Cl$ (**11**)

To a vigorously stirred solution of $Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (0.61 g, 0.81 mmol) in 15 cm^3 of diethyl ether was added solid $LiDIPP \cdot OEt_2$ (0.21 g, 0.81 mmol). After 8 h, the cloudy, pale yellow solution was filtered and the filtrate was pumped to dryness to afford a solid. Extraction of this solid with 3 cm^3 of Et_2O and cooling the solution to $-30°C$ afforded 0.41 g (0.50 mmol, 62%) of product as pale yellow crystals. ^1H NMR (C_6D_6): δ 7.09–6.89 (A_2B mult, 9 H, H_{aryl}), 4.07 (q, 4 H, NCH_2CH_3), 3.63 (spt, 6 H, $CHMe_2$), 1.20 (d, 36 H, $CHMe_2$), 1.01 (t, 6 H, NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 156.7 (C_{ipso}), 138.9 (C_o), 123.9 (C_m), 123.8 (C_p), 50.6 (NCH_2CH_3), 27.2 ($CHMe_2$), 24.5 ($CHMe_2$), 14.9 (NCH_2CH_3). Found: C, 58.6; H, 7.6. Calc. for $C_{48}H_{61}ClNO_3Ta$: C, 58.6; H, 7.5%.

$(PhC{\equiv}CPh)Ta(NEt_2)(DIPP)_2$ (**12**)

To a solution of $Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (**10**) (0.44 g, 0.58 mmol) in 10 cm^3 of diethyl ether was added $PhC{\equiv}CPh$ (0.11 g, 0.60 mmol) and 0.5% NaHg amalgam (0.19 cm^3, 1.16 mmol). After this mixture was stirred for 10 h, the resulting pale yellow solution was filtered through Celite and the filtrate was pumped to dryness. Extracting the resulting solid with 1 cm^3 of pentane and cooling the extract to $-30°C$ afforded white crystals of **12** in 40% yield (0.17 g, 0.23 mmol). ^1H NMR (C_6D_6): δ 7.41 [pseudo d, 4 H, H_o (C_6H_5)], 7.12–6.94 [m, 12 H, H_{aryl} (DIPP) and H_m, H_p (C_6H_5)], 3.99 (q, 4 H, NCH_2CH_3), 3.56 (spt, 4 H, $CHMe_2$), 1.22 and 1.21 (overlapping d, 12 H each, $CHMe_2$), 0.98 (t, 6 H, NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 214.6 (C_{alkyne}), 158.2 (C_{ipso}, DIPP), 142.6 (C_{ipso}, C_6H_5), 137.3 (C_o, DIPP), 128.7, 128.6 (C_o and C_m, C_6H_5), 127.7 (C_p, C_6H_5), 123.6 (C_m, DIPP), 122.5 (C_p, DIPP), 46.4 (NCH_2CH_3), 27.3 ($CHMe_2$), 23.9, 23.8 ($CHMe_2$), 15.0 (NCH_2CH_3). Found: C, 63.8; H, 7.1. Calc. for $C_{42}H_{54}NO_2Ta$: C, 64.2; H, 6.9%.

$(Me_3CC{\equiv}CH)Ta(NEt_2)(DIPP)_2$ (**13**)

To a solution of $Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (**10**) (0.44 g, 0.58 mmol) in 10 cm^3 of diethyl ether was added $Me_3CC{\equiv}CH$ (0.14 cm^3, 1.10 mmol) and 0.5% NaHg amalgam (0.19 cm^3, 1.16 mmol). After stirring this mixture for 8 h, the resulting yellow solution was filtered through Celite and the solvent removed *in vacuo* to afford the product as a yellow oil. The yield of **13** obtained in this reaction was 0.12 g (0.20 mmol, 34%). This compound has not been induced to crystallize, therefore no analyses were attempted. ^1H NMR (C_6D_6): δ 10.95 (s, 1 H; $HC{\equiv}CCMe_3$), 7.08–6.90 (A_2B mult, 6 H, H_{aryl}), 4.00 (q, 4 H, NCH_2CH_3), 3.40 (spt, 4 H, $CHMe_2$), 1.28 and 1.19 (d, 12 H each, $CHMe_2$), 1.09 (s, 9 H, $HC{\equiv}CCMe_3$), 1.06 (t, 6 H, NCH_2CH_3). ^{13}C NMR (C_6D_6): δ 232.4, 196.8 (C_{alkyne}), 157.9 (C_{ipso}), 136.9 (C_o), 123.4 (C_m), 122.2 (C_p), 48.1 (NCH_2CH_3), 30.9 (CMe_3), 27.0 ($CHMe_2$), 24.2, 23.6 ($CHMe_2$), 16.3 (NCH_2CH_3). The resonance for CMe_3 was not observed or is obscured by another signal.

$(Me_3SiC{\equiv}CMe)Ta(NEt_2)(DIPP)_2$ (**14**)

To a solution of $Ta(NEt_2)(DIPP)_2Cl_2(OEt_2)$ (**10**) (0.51 g, 0.62 mmol) in 10 cm^3 of diethyl ether was added $Me_3SiC{\equiv}CMe$ (0.13 g, 1.24 mmol) and 0.5% NaHg amalgam (0.42 cm^3, 1.24 mmol). After this solution was stirred for 8 h, the resulting pale yellow mixture was filtered through Celite and the filtrate was pumped to dryness. Extracting the resulting solid with *ca* 2 cm^3 of pentane and cooling the extract to $-30°C$ afforded the product as pale yellow crystals; yield 0.22 g (0.31 mmol, 45%). ^1H NMR (C_6D_6): δ 7.09–6.90 (A_2B mult, 6 H, H_{aryl}), 3.91 (q, 4 H, NCH_2CH_3), 3.33 (spt, 4 H, $CHMe_2$), 3.01 (s, 3 H, $Me_3SiC{\equiv}CMe$), 1.29, 1.19 (d, 12 H each, $CHMe_2$), 1.03 (t, 6 H, NCH_2CH_3), 0.05 (s, 9 H, $Me_3SiC{\equiv}CMe$). ^{13}C NMR (C_6D_6): δ 230.7, 220.3 (C_{alkyne}), 158.2 (C_{ipso}), 136.8 (C_o), 123.4 (C_m), 122.0 (C_p), 48.4 (NCH_2CH_3), 27.2 ($CHMe_2$), 24.6 ($Me_3SiC{\equiv}CMe$), 23.9, 23.6 ($CHMe_2$), 15.6 (NCH_2CH_3), 0.3 ($Me_3SiC{\equiv}CMe$). Found: C, 55.9; H, 7.8. Calc. for $C_{34}H_{56}NO_2SiTa$: C, 56.7; H, 7.8%.

PREPARATION AND ^{199}Hg NMR STUDY OF SOME MERCURY(II) THIOLATE COMPLEXES

LAURENCE CARLTON* and DAVID WHITE

Department of Chemistry, University of the Witwatersrand, Johannesburg, Republic of South Africa

(*Received* 14 *March* 1990; *accepted* 5 *July* 1990)

Abstract—Mercury-199 NMR parameters are reported for the complexes $Hg(SPr^i)_2$, $Hg(SPh)_2$, $Hg(SCH_2CH_2OH)_2$, $Hg(SCH_2CO_2H)_2$, $Hg(SCH_2CH_2CO_2H)_2$ and $Hg(Sbt)_2$ (Sbt = benzthiazole-2-thiolate) which are readily prepared in moderate to good yield by the reaction of HgO with the free thiol. The ^{199}Hg chemical shift of $Hg(SPr^i)_2$ in a variety of solvents falls in a range −723 to −884 ppm; possible modes of interaction of the solvent with the metal are discussed.

The properties of mercury thiolate complexes are relevant to the study of biochemical systems that interact with the metal[1–3] and the development of antidotes to mercury poisoning.[4–6] Mercury-199 NMR spectroscopy has a potentially useful contribution to make in these areas but, as yet, few studies have reported ^{199}Hg NMR data.[7]

The isotope ^{199}Hg, spin 1/2, occurs in 16.84% natural abundance; relaxation processes (principally chemical shift anisotropy[8] at high magnetic field strengths) are effective and NMR data acquisition can be fairly rapid. The sensitivity of the ^{199}Hg nucleus to changes in its chemical environment is reflected in the observed chemical shift range of over 3000 ppm.[9] This makes ^{199}Hg NMR well suited to the detection of changes in the bonding and conformation of mercury complexes.

EXPERIMENTAL

Reagents were obtained from various sources and used without further purification. THF, pyrrolidine, benzene and toluene were distilled from sodium, dichloromethane was distilled from phosphorus pentoxide, acetone was distilled from potassium carbonate, pyridine, pyrrole, DMF, acetonitile and ether were distilled from calcium hydride and DMSO, n-hexane, isopropylamine, diisopropylamine and triethylamine were dried over calcium hydride. Other solvents were of the highest available purity and used without further treatment. Complexes were prepared under nitrogen.

NMR spectra were recorded at 22°C on a Bruker AC 200 FT spectrometer operating at 200.13 MHz (^{1}H), 50.32 MHz (^{13}C) and 35.84 MHz (^{199}Hg). ^{199}Hg spectra were obtained using a spectral width of 50,000 Hz and acquisition time of 0.33 s.

Preparation of $Hg(SPr^i)_2$[10]

A mixture of mercuric oxide (3.22 g, 14.9 mmol) and isopropyl thiol (2.26 g, 30 mmol) in dichloromethane (80 cm^3) at room temperature was stirred for 2 days. The solution was concentrated and an excess of hexane was added. On standing at −20°C for 12 h bis(isopropylthiolato)mercury was obtained as colourless needles (3.81 g, 10.9 mmol, 73%) Found: C, 20.0; H, 4.0. $C_6H_{14}HgS_2$ requires: C, 20.5; H, 4.0%. ^{1}H NMR (DMSO) δ 3.57 (sept, 1H, J 6.6 Hz), 1.31 (d, 6H, J 6.6 Hz). ^{13}C NMR (DMSO) δ 33.9, 31.0 ppm.

Preparation of $Hg(SPh)_2$[5]

A mixture of mercuric oxide (6.44 g, 29.8 mmol) and thiophenol (6.55 g, 60 mmol) in ethanol (80 cm^3) at room temperature was stirred for 12 h. The product was collected in a sinter, washed with ethanol and dried *in vacuo* to give bis(phenylthiolato)mercury as a white powder (10.51 g, 25.1 mmol, 84%) Found: C, 33.7; H, 2.3. $C_{12}H_{10}HgS_2$ requires: C, 34.4; H, 2.4%. ^{1}H NMR (DMSO) δ

* Author to whom correspondence should be addressed.

7.36 (mult, 2H), 7.11 (mult, 3H). ^{13}C NMR (DMSO) δ 136.9, 131.5, 128.4, 124.5 ppm.

Preparation of $Hg(SCH_2CH_2OH)_2$

A mixture of mercuric oxide (3.22 g, 14.9 mmol) and 2-mercaptoethanol (2.33 g, 30 mmol) in ethanol (80 cm^3) at room temperature was stirred for 12 h. The product was collected in a sinter, washed with ethanol and dried *in vacuo* to give bis(2-hydroxyethanethiolato)mercury as a white powder (1.61 g, 4.5 mmol, 31%) Found: C, 13.0; H, 2.8. $C_4H_{10}HgO_2S_2$ requires: C, 13.5; H, 2.8%. ^{1}H NMR (DMSO) δ 5.24 (s, 1H) 3.33 (t, 3H, *J* 5.9 Hz), 2.87 (t, 3H, *J* 5.9 Hz). ^{13}C NMR (DMSO) 63.3, 30.2 ppm.

Preparation of $Hg(SCH_2CO_2H)_2$[11]

A mixture of mercuric oxide (3.22 g, 14.9 mmol) and thioglycolic acid (2.78 g, 30 mmol) in ethanol (80 cm^3) at room temperature was stirred for 12 h. The product was collected in a sinter, washed with ethanol and dried *in vacuo* to give bis(acetic acid thiolato)mercury as a white powder (5.40 g, 14.1 mmol, 95%) Found: C, 12.7; H, 1.7. $C_4H_6HgO_4S_2$ requires: C, 12.6; H, 1.6%. ^{1}H NMR (DMSO) δ 11.75 (s, 1H) 3.67 (s, 2H). ^{13}C NMR (DMSO) δ 175.5, 29.4 ppm.

Preparation of $Hg(SCH_2CH_2CO_2H)_2$

A mixture of mercuric oxide (3.22 g, 14.9 mmol) and 3-mercaptopropionic acid (3.20 g, 30 mmol) in dichloromethane (80 cm^3) at room temperature was stirred for 12 h. The product was collected in a sinter, washed with dichloromethane and dried *in vacuo* to give bis(propionic acid-3-thiolato)mercury as a white powder (1.71 g, 4.2 mmol, 28%). Found: C, 16.9; H, 2.4. $C_6H_{10}HgO_4S_2$ requires: C, 17.5; H, 2.5%. ^{1}H NMR (DMSO) δ 12 (broad, 1H), 3.05 (t, 2H, *J* 6.8 Hz), 2.56 (t, 2H, *J* 6.8 Hz). ^{13}C NMR (DMSO) δ 174.1, 39.4, 22.1 ppm.

Preparation of $Hg(Sbt)_2$

A mixture of mercuric oxide (3.22 g, 14.9 mmol) and benzthiazole-2-thiol (4.98 g, 30 mmol) in dichloromethane at room temperature was stirred for 3 days. The product was collected in a sinter, washed with dichloromethane and dried *in vacuo* to give bis(benzthiazole-2-thiolato)mercury as a white powder (6.4 g, 12.0 mmol, 81%). Found: C, 29.8; H, 1.5; N, 4.9. $C_{14}H_8HgN_2S_4$ requires: C, 31.5; H, 1.5; N, 5.3%. ^{1}H NMR (DMSO) 7.88 (mult, 1H), 7.61 (mult, 1H), 7.30 (mult, 2H). ^{13}C NMR (DMSO) δ 167.5, 152.7, 137.0, 125.9, 123.8, 121.1, 120.0 ppm.

RESULTS AND DISCUSSION

The complexes $Hg(SR)_2$ are readily prepared in moderate to good yield by the reaction of HgO with the free thiol in dichloromethane or ethanol at room temperature. $Hg(SPr^i)_2$ is soluble in all common solvents except water while $Hg(SPh)_2$, $Hg(SCH_2CH_2OH)_2$, $Hg(SCH_2CO_2H)_2$, $Hg(SCH_2CH_2CO_2H)_2$ and $Hg(Sbt)_2$ are soluble only in DMSO and DMF.

Mercury-199 chemical shifts (Table 1) for the complexes in DMSO solution are found in the range -882 to -1206 ppm relative to $HgMe_2$. This upfield shift may result from the involvement of sulphur lone pair electrons in bonding to the metal. No spin–spin coupling is observed between ^{199}Hg and either hydrogen or ^{13}C, and all ^{199}Hg resonance lines appear as singlets.

From the similarity in the chemical shifts of $Hg(SPr^i)_2$ and $Hg(SCH_2CH_2OH)_2$ it is clear that in the latter the influence of the OH group over four bonds is negligible. For $Hg(SCH_2CH_2CO_2H)_2$, with carboxyl groups positioned a similar distance from the metal, the upfield shift of over 70 ppm relative to $Hg(SPr^i)_2$ must arise from diamagnetic through space shielding by the carbonyls. The closer proximity of the carbonyls to the metal in $Hg(SCH_2CO_2H)_2$ causes a further upfield shift. With aromatic rings positioned at a distance of two bonds from the metal in $Hg(SPh)_2$ and $Hg(Sbt)_2$, the effects of diamagnetic shielding are more pronounced, amounting in the case of Hg(Sbt) to an upfield shift of 324 ppm relative to $Hg(SPr^i)_2$.

[a] Chemical shifts in ppm from neat $HgMe_2$ (external standard), negative values to high field; concentration 0.1 M; temperature 22°C.

[b] ~ 0.05 M (saturated).

Spin–lattice relaxation times, measured by the inversion-recovery method, are short and fall in a narrow range of 0.06–0.15 s. The dominant relaxation effects are likely to be spin-rotation and chemical shift anisotropy.[12] The broadening of the resonance lines of $Hg(SCH_2CO_2H)_2$ and $Hg(Sbt)_2$ suggests that in these compounds spin–spin relaxation processes are also operating; these might be expected to arise from conformational changes involving restricted rotation about the Hg—S or S—C bonds.

The ^{199}Hg chemical shift of $Hg(SPr^i)_2$ in a variety of solvents is shown in Table 2 and appears (with the exception of measurements in THF and methanol) to fall into four groups according to the nature of the solvent: (i) O- and N-donors in which the donor atom is involved in π-bonding (δ −822 to −884); (ii) O- and S-donors in which the donor atom is not π-bonded, Cl-donors (δ −789 to −804); (iii) aliphatic and aromatic hydrocarbons (δ −779 to −783); (iv) aliphatic amines (δ −723 to −749). Groups (i)–(iii) follow an order of decreasing dipole moment but the position of group (iv) on this scale is clearly anomalous. If the coordinating properties of hexane and its contribution to the ^{199}Hg chemical shift can be regarded as minimal (as found for $HgMe_2$[12]) it is possible to draw a number of conclusions.

The interaction between the solvents of group (i) and mercury favours an overall diamagnetic shielding by π-bonded groups of the solvent, i.e. the chemical shifts (relative to that measured in hexane) can be attributed to effects of solvent magnetic anisotropy. The fact that the increasing upfield shift roughly parallels the increase in dipole moment of the solvent suggests that electrostatic forces are involved in the ordering of the solvent in the region close to the metal.

Solvents of group (ii) provide a small diamagnetic shielding while for those of group (iii) there is no significant shielding. The data provide no evidence for an interaction of the π systems of benzene and toluene with the metal; the chemical shift in these solvents is only marginally different from that observed in hexane. This contrasts with the finding of Sens *et al.*[12] for dimethyl mercury, where a shift to high field of 56 ppm was observed on changing from hexane to benzene. The presence of sulphur would seem to discourage the interaction of the metal with the aromatic π system of a non-polar hydrocarbon.

Solvents of group (iv) contribute an overall paramagnetic shielding which is likely to arise from the mixing of atomic orbitals (i.e. nitrogen lone pair and mercury 6*p*) induced by a Lewis acid–base interaction.

(*Received* 21 *May* 1990; *accepted* 5 *July* 1990)

Abstract—The preparation of the ligand 1-(2-hydroxyphenyl)-3-(2-thiomethoxyphenyl)-1,3-propanedione (H_2htmp) is reported along with its physicochemical characterization. The compound is present in the solid state as an unique enol tautomer, while in solution both the enol and the keto tautomers are present. By reaction with metal salts, mononuclear complexes of the type $M(H_2htmp)_2Cl_2$ (M = Pt, Pd) and $M(Hhtmp)_2 \cdot 2H_2O$ (M = Cu, Ni and Co) were isolated and characterized by physicochemical measurements. In addition homo- and heterobinuclear complexes have been prepared.

The design and synthesis of coordination compounds containing two or more different metal ions in adjacent sites are interesting because they provide the path to study multi-electron redox reactions, magnetic exchange interactions and the possible activation of small substrate molecules. Moreover, these complexes can be used to mimic enzymatic metal sites.[1–4]

To obtain heterobinuclear complexes we have prepared and studied the trinucleating ligand 1-(2-hydroxyphenyl)-3-(2-thiomethoxyphenyl)-1,3-propanedione (H_2htmp) which presents three types of reacting sites, one in the centre of the molecule (the β-diketone moiety) and two in the outer sites (the β-ketophenyl and the thioether moiety).

This ligand gives mononuclear and homo- and heterobinuclear complexes allowing, consequently, the synthesis of MM′M″ linear trinuclear compounds that are otherwise difficult to obtain.[5–7]

The present paper reports the preparation of several mono- and binuclear complexes with this ligand. All the compounds described herein are air-stable, both in the solid state and in solution.

EXPERIMENTAL

All the solvents used in the preparation were freshly distilled. Melting points were recorded on a Fisher stage melting point apparatus and are not corrected. IR spectra were recorded on a Nicolet FTIR 5DX spectrometer as KBr pellets or in Nujol mulls. The electronic spectra were recorded on a Cary 17 UV spectrophotometer in DMSO solution and Nujol dispersion. The ^{1}H NMR spectra (200 MHz) were obtained on a Brucker spectrometer in $CDCl_3$ solution.

Preparation of 1-(2-*hydroxyphenyl*)-3-(2-*thiomethoxyphenyl*)-1,3-*propanedione* (H_2htmp)

o-Hydroxyacetophenone (50 mmol) was dissolved in toluene (15 cm^3); two drops of methanol were added and the solution was slowly added to a 60% NaH suspension in toluene (170 cm^3). The resulting yellow suspension was gently refluxed for 15 min. After which, a toluene solution (100 cm^3) of methyl *o*-methylthiosalicylate (55 mmol) was added dropwise. The suspension was refluxed for 6 h, and then allowed to cool down to room temperature. The precipitate was filtered, washed with diethyl ether and dried *in vacuo*. It was added to ice-cooled water, stirred for 10 min, and then acidified to pH = 1 with conc. HCl and the solid extracted with diethyl ether. The organic phase was separated, washed with a 5% $NaHCO_3$ solution and water. After decantation of the aqueous phase, the ethereal phase was dried over Na_2SO_4. Evaporation of the organic solution gave a yellow solid, which upon

* Author to whom correspondence should be addressed.

recrystallization from methanol gave 7.4 g of pure ligand, m.p. 69–70°C (yield, 52%).

Preparation of $M(H_2htmp)Cl_2$ (M = Pd, Pt)

The ligand (2 mmol) was dissolved in benzene (100 cm^3) and the appropriate metal chloride (1 mmol) was added with stirring. The resulting solution was stirred for 48 h. The product was filtered, washed with benzene, ethanol and diethyl ether, and dried *in vacuo*. The same products were obtained when ethanol was used as solvent.

Preparation of $M(Htmp)_2 \cdot nH_2O$ (M = Cu, $n = 0$; M = Ni *or* Co, $n = 2$)

The ligand (2 mmol) was dissolved in ethanol and the appropriate metal acetate or chloride hydrate (1 mmol) was added with stirring. The resulting solution was stirred for 6 h. The obtained precipitate was filtered, washed with ethanol and diethyl ether, and dried *in vacuo*. The same products were obtained when benzene was used as solvent.

Preparation of homobinuclear $M_2(htmp)_2 \cdot H_2O$ *complexes* (M = Ni *or* Co, $n = 4$; M = Cu, $n = 0$)

An ethanolic solution of the ligand (2 mmol) and of lithium hydroxide (4 mmol) was added to a warm ethanol solution of the appropriate metal acetate (1 mmol). The resulting mixture was allowed to reflux for 8 h and then cooled to room temperature. The precipitate was filtered and washed several times with ethanol and diethyl ether, and then dried *in vacuo*.

Preparation of $CuNi(htmp)_2 \cdot 2H_2O$

Lithium hydroxide (2 mmol) was added to an ethanolic suspension of the mononuclear compound (1 mmol) and the solution was stirred at room temperature for 30 min. Then a solution of the metal acetate (1 mmol) in ethanol was added and the mixture refluxed for 8 h. The solid was filtered, washed with ethanol and diethyl ether, and dried *in vacuo*.

Preparation of $PdCu(Hhtmp)_2Cl_2$

The complex can be prepared by reaction of the mononuclear $Cu(Hhtmp)_2$ and $PdCl_2$, or of $Pd(H_2htmp)_2Cl_2$ and copper(II) acetate in an ethanolic solution.

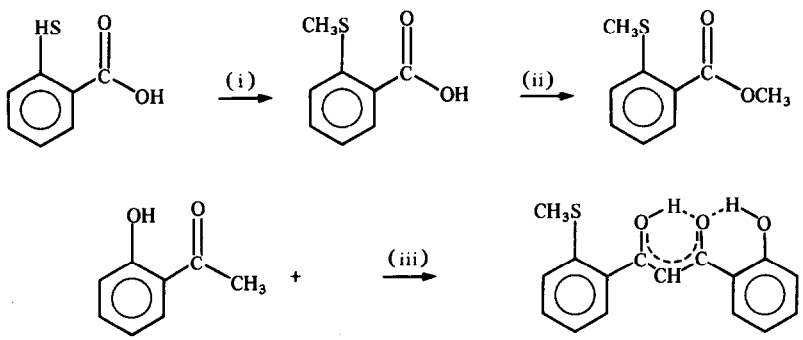
RESULTS AND DISCUSSION

The ligand has been synthesized in three steps (see Scheme 1) starting from thiosalycylic acid. In the first step the thiolo group is methylated by methyl iodide. After conversion into the methyl ester it reacted with *o*-hydroxyacetophenone in the presence of sodium hydride.

The compound gives microanalytical and mass spectral data consistent with the structure; the fragmentation pattern of the compound is reported in Fig. 1. The X-ray structure of the ligand[8] showed that the compound is present, at least in the solid state, only as its enol tautomer (see Fig. 2).

The hydroxyl IR stretching band of the ligand consists of a broad signal (400 cm^{-1} wide) centred at approx. 3050 cm^{-1}; this band may result from two broad, overlapping OH absorptions. Both the position and the extreme width are compatible with strong intramolecular association. In the carbonyl region only one band at 1609 cm^{-1} is present, due to chelating C=O—H, while no band due to free C=O is observed.

The enol tautomer is the major form in $CDCl_3$ solution. A freshly prepared chloroform solution showed the presence of the enol form, together with



Scheme 1. Reaction steps in the preparation of H_2htmp: (i) dimethylsulphate; (ii) thionyl chloride, methanol; and (iii) 60% NaH, toluene.

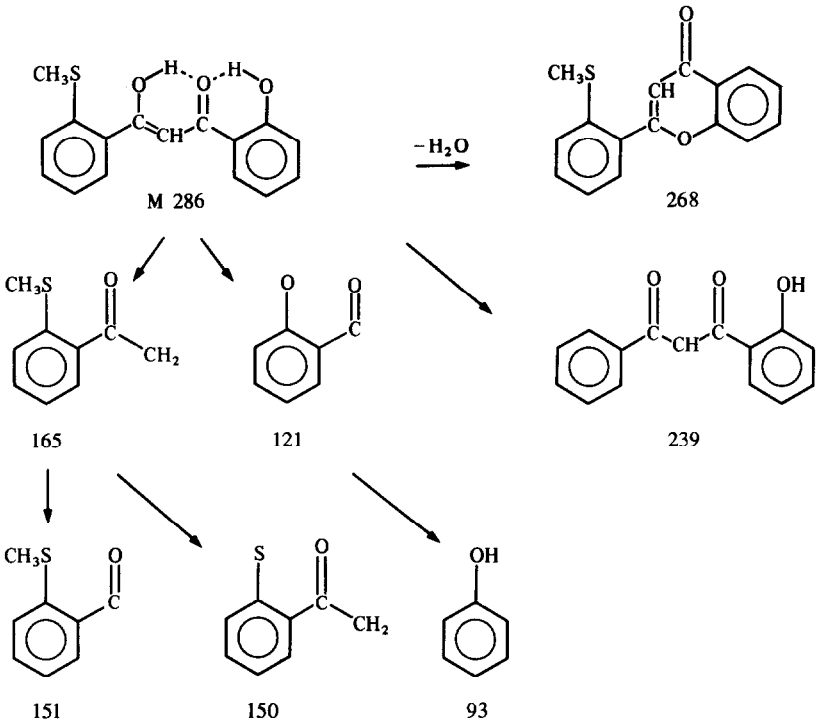


Fig. 1. Fragmentation pattern of 1-(2-hydroxyphenyl)-3-(2-thiomethoxyphenyl)-1,3-propanedione.

extraneous material, amounting to about 18%. The pre-eminent ^{1}H NMR resonances occur at 2.5, 6.75, 12 and 15.45 ppm and have been assigned to the C*H*$_3$S, C*H*, phenolic O*H* and enolic O*H* of the enol form, respectively. Other weak signals are at 2.4, 4.65 and 11.9 ppm and may be assigned to the SC*H*$_3$, methylene and phenolic O*H* of the ketonic tautomer. The integration peak areas are in agreement with these assignments. The other multiple bands in the range 6.9–8.0 ppm are due to aromatic hydrogens.

Interaction with metal salts

Reactions of $PdCl_2$ or $PtCl_2$ with the ligand, in benzene or ethanol solution, gave compounds of the type $M(H_2htmp)_2Cl_2$. Both the cream-coloured platinum(II) and palladium(II) complexes present similar IR spectra; in the 1700–1400 cm^{-1} region there are peaks at 1609, 1578 and 1562 cm^{-1}, present also in the free ligand, which are attributed to the C=O, benzene ring and C=C stretching modes, respectively. The complexes display a band at 385–375 cm^{-1} assigned to the ν(M—S) stretching vibration, since this band is not present in the spectra of the free ligand or of other metal complexes. The two bands at 318 and 301 cm^{-1}, and 328 and 310 cm^{-1}, are assigned to the Pd—Cl and Pt—Cl stretches, respectively. We suggest a coordination geometry of the type shown in Fig. 3(A) for these complexes.

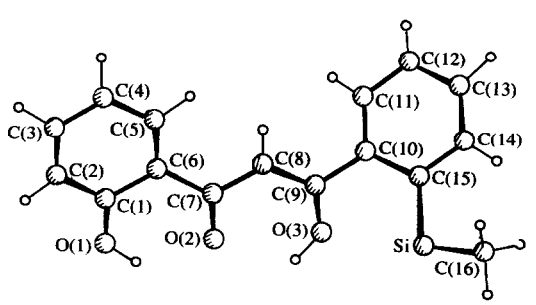

Fig. 2. Molecular structure of $C_{16}H_{14}O_3S$ and the atom labelling scheme.

The ^{1}H NMR spectrum of $Pd(H_2htmp)_2Cl_2$, in d_6-DMSO solution, is virtually identical to that of the free ligand; it shows that the organic moiety is uncoordinated to the palladium, at least in DMSO solution, and involved in a keto–enol equilibrium, where the enol tautomer is predominant. The pre-eminent peaks occur at 2.47 (SC*H*$_3$), 7.13 (C*H*), 11.6 (phenolic O*H*) and 15.75 (enolic O*H*). The 2.40 (SC*H*$_3$), 4.82 (C*H*$_2$) and 11.2 (phenolic O*H*) peaks can be assigned to the keto form. The integrated peak areas are in agreement with these assignments. From this solution a crystalline compound was obtained, and its elemental analysis agrees with the formula $Pd(DMSO)_2Cl_2$.

By reacting the ligand H_2htmp with copper(II), nickel(II) and cobalt(II) metal salts, in benzene or ethanol solution, complexes of the type $M(Hhtmp)_2 \cdot nH_2O$ have been obtained. Their almost identical IR spectra suggest that the same type of coordination is present in all the compounds. Characteristic absorption bands are found in the 1600–1500 cm^{-1} region; on the basis of literature data,[9] we assign the band occurring near 1610 cm^{-1} in both the spectra to the C=O and the band at about 1510 cm^{-1} to the C=C stretching modes of the coordinated acetylacetonate moiety. The absorption band at 3400 cm^{-1} in the complexes containing water molecules is consistent with the analytical data. From these IR data either of the structures shown in Fig. 3(B) or (C) can be proposed for the 1 : 2 chelate.

The room temperature magnetic moments are in the range typical for planar copper(II) and octahedral nickel(II) and cobalt(II) complexes.

The electronic spectrum of the copper(II) shows a band at 670 nm, as expected for a square-planar copper(II) β-diketonate complex. Moreover, this band, which is attributed to the ligand field *d–d* transition, is more similar to that of bis(dibenzoylacetonato)copper(II) than to that of bis(*o*-hydroxyacetophenonato)copper(II) which has two peaks in this region. The nickel complex shows absorption bands between 500 and 1300 nm as expected for octahedral ones. The cobalt(II) com-

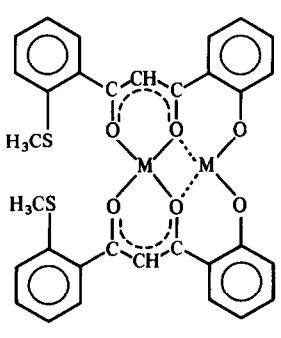
Table 2. Spectroscopic data and magnetic moments

Compound	IR (cm^{-1}) frequency in the 1650–1500 cm^{-1} range			UV (nm)			μ (BM)
H_2htmp	1610	1580	1560				
$Cu(Hhtmp)_2$	1614	1586	1538	670			1.78
$Ni(Hhtmp)_2 \cdot 2H_2O$	1612	1580	1527	680	1110		2.92
$Co(Hhtmp)_2 \cdot 2H_2O$	1600	1571	1516	530	600	1150	4.60
$Pd(H_2htmp)_2Cl_2$	1609	1578	1562	—	—		Diamagnetic
$Pt(H_2htmp)_2Cl_2$	1608	1580	1562	—	—		Diamagnetic
$Cu_2(htmp)_2$	1615	1590	1560	670 broad			1.39
$Ni_2(htmp)_2 \cdot 4H_2O$	1610	1535	1510	650	1115		3.80
$Co_2(htmp)_2 \cdot 4H_2O$	1590	1543	1510	600			6.38
$CuNi(htmp)_2 \cdot 2H_2O$	1612	1585	1500	690	1100		2.59
$PdCu(Hhtmp)_2Cl_2$	1615	1593	1560	670	—		1.82

plex has a low intensity band at *ca* 1150 and two bands at 600 and 530 nm; these features are typical of a weak octahedral field, and the magnetic moment (4.60 BM) is of the same order as those found in other high-spin octahedral cobalt(II) complexes. We suggest that nickel, cobalt and copper are coordinated to the acetylacetone group as shown in Fig. 3(B).

Homobinuclear complexes

These complexes can be obtained by reaction of the ligand with the appropriate metal salts, or by reaction of the mononuclear compound with metal acetate. Their electronic and IR spectra suggest that these complexes are of the type shown in Fig. 4. The IR spectra show bands in the region 1650–1500 cm^{-1}, which are typical of coordinated carbonyl groups and ethylenic C=C bonds. The presence of water is confirmed by a broad band at 3450–3000 cm^{-1}, due to the stretching mode of coordinated water. The electronic spectrum of the copper chelate in DMSO solution or in a Nujol mull, shows a broad band at 670 nm due to the *d–d* transition, as expected for copper(II) acetylacetonate or hydroxyacetophenonate complexes. The nickel(II) compound has very broad bands at 1100 cm^{-1} and at 645 nm, similar to those found for some nickel(II) diketonate complexes.[10] The electronic spectrum of the cobalt complex is very similar to that of $Co(acac)_2 \cdot 2py$[11] and is consistent with octahedral coordination. The magnetic moments, at room temperature, of the dinuclear compounds are lower than the spin-only values, similar to those obtained for analogous adducts in which antiferromagnetic coupling is operative.[12]



M = Cu^{2+}; Ni^{2+}; Co^{2+}

Fig. 4. Probable structure for the linear homobinuclear complexes.

Heterobinuclear complexes

The complexes can be prepared by reaction of the mononuclear complexes with the appropriate metal salts; however, it is necessary to pay attention to the temperature reaction since the copper and nickel mononuclear complexes can be converted into the 2/2 chelate by heating above 60°C. Their IR data are essentially the same as that of the corresponding homobinuclear complexes. The strong band in the 1585–1630 cm^{-1} region is attributable to the coordinated C=O group, and the band in the 1500–1570 cm^{-1} region corresponds to the C=C vibration. Moreover, the $PdCu(Hhtmp)_2Cl_2$ complex shows bands due to the Pd—S and Pd—Cl stretching modes. The magnetic property is explained by assuming that the entire paramagnetism arises from the copper(II) centre; on this basis the magnetic moment is as expected for the isolated d^9 copper(II) ion.

The room temperature magnetic moment of $NiCu(htmp)_2 \cdot 2H_2O$ (2.59 BM) is lower than the

spin-only values, and is similar to those found for analogous complexes in which a magnetic exchange coupling takes place.[13] Work is in progress to prepare the trinuclear chelates.

Abstract—Two aspects of the properties of iron sandwich complexes as molecular reservoir materials are reviewed in a prospective way: (i) electronic properties in the solid state in mononuclear, Jahn–Teller active 19-electron iron(I) complexes and binuclear, 37-electron mixed-valence complexes, showing the coupling between the electronic structure and the lattice; and (ii) solution properties of iron sandwiches as molecular reservoirs of electrons, protons, hydrogen atoms and hydrides.

Iron sandwich complexes have potential as molecular reservoir materials insofar as several oxidation states can be isolated and handled without breakdown. Thermal stability can be obtained in the [FeCp(arene)] series (Cp = C_5H_5) if the arene is permethylated or bulky enough so that the iron(I) radical centre is sterically protected. Binuclear complexes of this series can be linked either via the Cp ligand (fulvalene bridge) or via the arene ligand (bis- or polyarene bridge).

In this short prospective review, we wish to emphasize two aspects of the reservoir properties of these compounds: (i) the solid-state electronic features of the paramagnetic sandwiches in the context of a discoid, monodimensional stacking; and (ii) their function as molecular reservoirs of electrons, protons, hydrogen atoms and hydrides.

The ferromagnetic properties of decamethylferricinium salts disclosed by Miller's group have encouraged organometallic chemists to design the synthesis of complexes with the aim of obtaining new solid-state properties.[1]

Several years ago, it was found that large differences of steric bulk of the two ligands on the iron(I) sandwich complex [FeCp(C_6Me_6)] induce a specific packing arrangement with alternating positions of the arene ligand along the chains[2] (Fig. 1). The

variation of the quadrupole splitting (QS) of the Mössbauer doublet as a function of temperature was assigned to the (Boltzmann) law of thermal population of the upper Kramers' level (Fig. 2). The latter originates from the Jahn–Teller distortion caused by single occupancy of the doubly degenerate e^*_1 orbital.[3] Although this law is valid for dilute iron(I) samples or for sandwiches having comparable steric bulks of the two ligands (disorder in the solid state) such as $[Fe(C_5R_5)(C_6R_6)]$, R = H or Me (Fig. 3), it is no longer true in the solid state. The lattice arrangement induces a specific dynamic cooperative Jahn–Teller distortion responsible for the splitting of the low-temperature Mössbauer

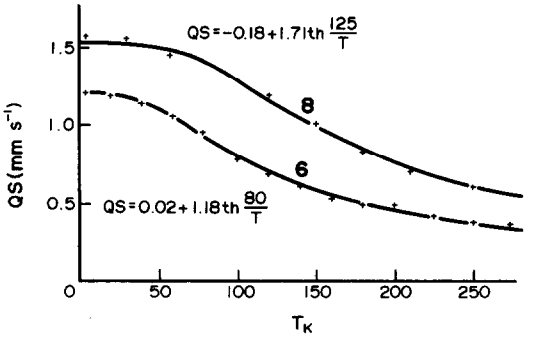

Fig. 2. Variation of QS as a function of temperature in the 19-electron complexes $[Fe(C_5Me_5)(C_6Me_6)]$ (top curve) and $[Fe(Cp)(C_6H_6)]$ (bottom curve). The thermal population of the upper Kramers' level was fitted by the indicated laws (rhombic distortion of the Jahn–Teller-active iron(I) sandwiches). In other iron(I) sandwiches with different ring sizes, phase transitions are observable along these curves [see refs 2 and 7(a)].

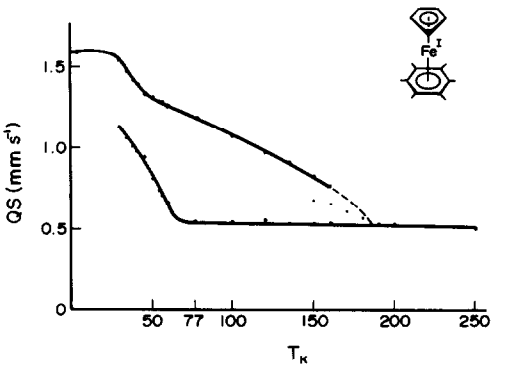

Fig. 3. Splitting of the Mössbauer quadrupole doublet of $[Fe^ICp(C_6Me_6)]$.

doublet of $[FeCp(C_6Me_6)]$ into two doublets (Fig. 4). This phenomenon is accompanied by second-order phase transitions as indicated by the differential thermal analysis and by the breaks in the

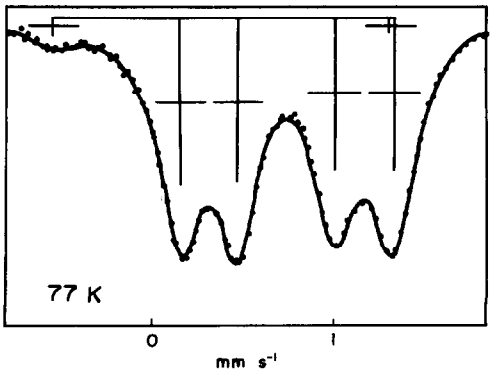

Fig. 4. Mössbauer spectrum of $[FeCp(C_6Me_6)]$ at 77 K. Note the splitting into two equal contributions.

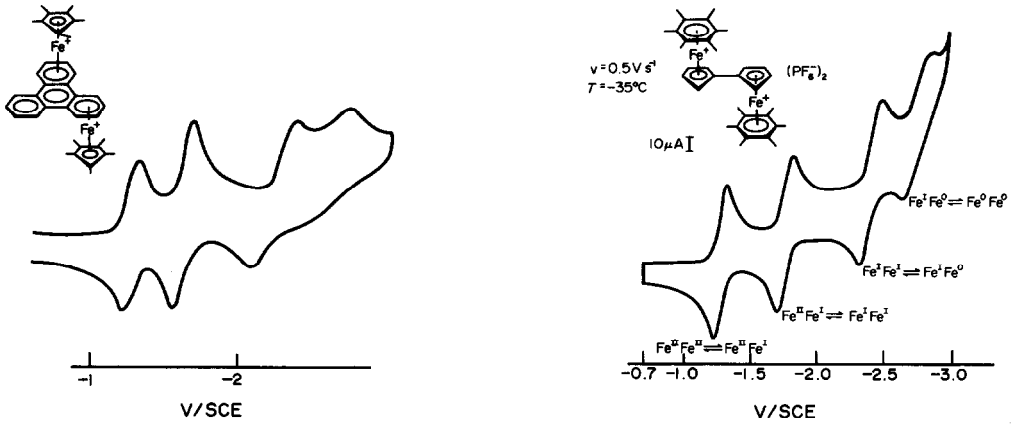

Fig. 5. Cyclic voltammograms of dinuclear iron sandwiches at −30°C (Hg cathode, DMF, $^nBu_4N^+BF_4^-$ 0.1 M; scan rate: 0.1 V s^{-1}).

curve of the variation of the quadrupole splitting as a function of temperature.

These data established the cooperativity between the electronic structure of iron(I) sandwiches and the solid-state lattice.

Cyclic voltammograms of the dinuclear complexes bridged either by the fulvalene or by a polyaromatic ligand show four well separated waves, three of which are chemically and electrochemically reversible (Fig. 5). Only the fourth reduction wave, at very negative potential (around $E_p = -2.5$ V vs SCE), corresponds to a slow electron-transfer in every case (possibly due to a structural change). But three of the five oxidation states are thermally stable and can be isolated: the 36-electron, 37-electron and 38-electron complexes (in the polyaromatic series, the 38-electron species are stable only up to 0°C). The two unpaired electrons in the 38-electron complexes are antiferromagnetically coupled (fulvalene, phenanthrene or pyrene bridges). Systems with biphenyl or dihydrophenanthrene as the bridge are 36-electron complexes with a bicylohexadienylidene bridge. Indeed the voltammograms of the binuclear complexes with a bridge of the biphenyl type show only a two-electron wave (C_5H_5 series) or two close one-electron waves (C_5Me_5 series). In the fulvalene and C_5Me_5 series, 37-electron mixed-valence complexes have been synthesized. Their Mössbauer spectra show the absence of Jahn–Teller activity and delocalization of the electron over the two iron centres, on the Mössbauer time scale (10^7 s^{-1}) down to 4 K.[4] Thus, these compounds can be viewed as models for organometallic conductors with stacked sandwiches, e.g. electron reservoirs in the solid state. The analogy could be extended to vertical stacks with cyclophane bridges (Fig. 6). Stacks with 37-elecron complexes and organic acceptors such

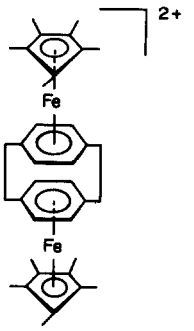

Fig. 6.

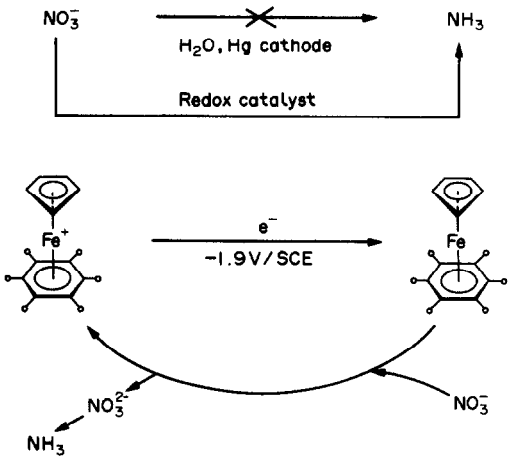
as TCNE or TCNQ would be of interest with respect to their magnetic properties. A diruthenium analogue has recently been made with $TCNQ^-$ by the Dupont group but with a diamagnetic organoruthenium cation.[5]

Remarkably, sandwich complexes, the structures of which are very different from those of redox metalloproteins (except that they have iron in common), are shown to achieve comparable functions of relays to convey electrons, protons and hydrogen atoms in chemical systems.

The stable redox couple $[Fe^{II/I}Cp(C_6Me_6)]^{+/0}$ and its water-soluble derivative $[Fe^{II/I}(CpCO_2)(C_6Me_6)]^{0/-}$ are redox catalysts for the cathodic reduction of NO_3^- to NH_3 in basic media, whereas NO_3^- is not electro-active in such media otherwise[6,7] (Scheme 1).

The ability of the iron(I) sandwich complexes to store electrons has also been recognized in a variety of stoichiometric processes with organic and inorganic acceptors (TCNQ, $TCNQ^-$, phenazine, O_2, H_2O, CO_2, organometallic cations, aldehydes, ketones, alkynes), and the presence of a salt has



Scheme 1. Redox catalysis of the cathodic reduction of NO_3^- to NH_3 mediated by iron sandwiches.

been shown to have a dramatic role on the course of these reductions.[7] Dinuclear complexes such as $[Fe_2Cp_2diphenyl]^{2+/0}$, which can transfer two electrons in one step, are sought after redox catalysts for the reduction of H^+ to H_2 in energy conversion devices. The iron(I) sandwiches are also excellent initiators for electron-transfer chain-catalysed reactions which must be initiated by reducing agents (for instance, ligand exchange reactions,[7b] Scheme 2).

The complexes $[Fe^{II}Cp(arene)]^+$ in which the arene ligand bears one or several methyl substituent(s) are excellent reservoirs of protons. A series of deprotonation–alkylation sequences leads to multiple hexa-alkylation, finishing with the formation of tentacled iron-sandwich complexes with a variety of structures.[8] New discoid molecules are expected using this strategy (Scheme 3).

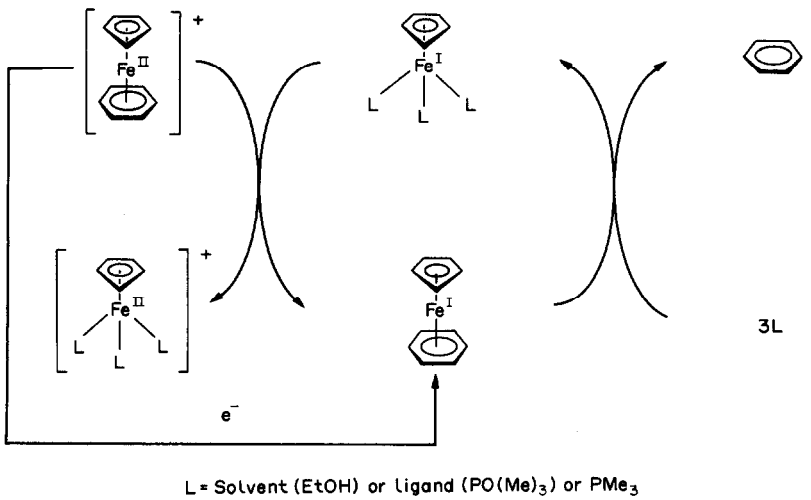
Extensive proton transfers are responsible for the deuteration of the benzylic hydrogens using $D_2O + NaOD$ (1 N).[9]

Hydrogen atom transfers are also possible to and from the 19-electron complex $[Fe^ICp(C_6Me_6)]$. A hydrogen atom is removed by O_2 according to an electron-transfer mechanism followed by proton transfer.[7a] The 18-electron complex formed bears an exocyclic methylene which can trap a hydrogen atom from Pd/H_2 and reforms the 19-electron complex.[10] The latter reacts also with Pd/H_2 at 20°C or with $NaBH_4$ or $LiAlH_4$ to give further hydrogen atom transfer (Scheme 4).

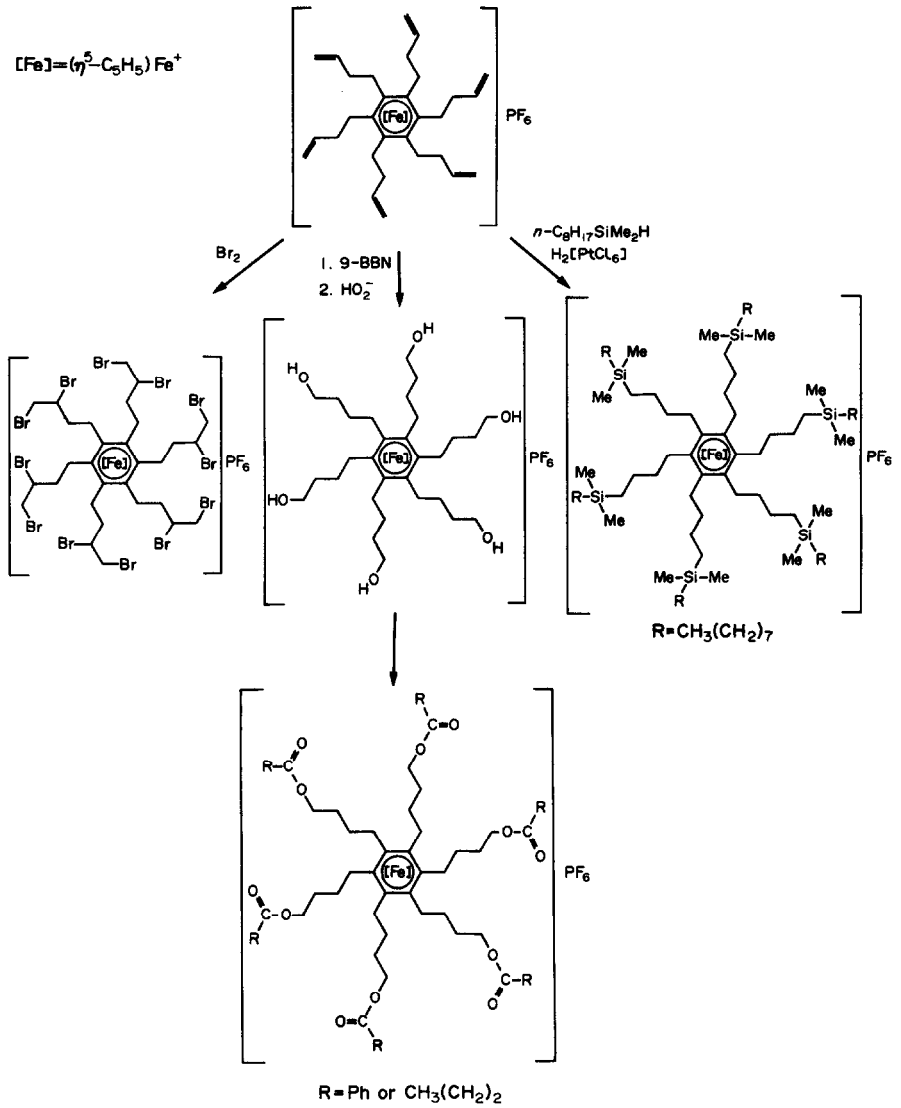
Similarly, the bimetallic phenanthrene and dihydrophenanthrene complexes can transfer several electrons and hydrogen atoms,[11] a function achieved by vitamin K.

The function of iron–arene sandwiches as reservoirs of hydride is useful (for purpose of protection by H^-) in arene activation mediated by temporary complexation to iron. Bis-arene iron dications do not react properly with carbon nucleophiles to form C—C bonds but give electron transfer. However, protection by hydride allows further formation of C—C bonds leading to mono- or heterofunctional cyclohexadienes (Scheme 5). The hydride removal (deprotection) follows an electron pathway as shown by Mandon.[12c,d]

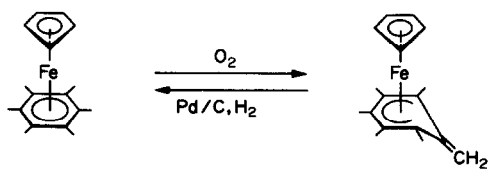
Several transition metal hydrides are able to catalyse the reduction of alkyl halides by $NaBH_4$.[12b]



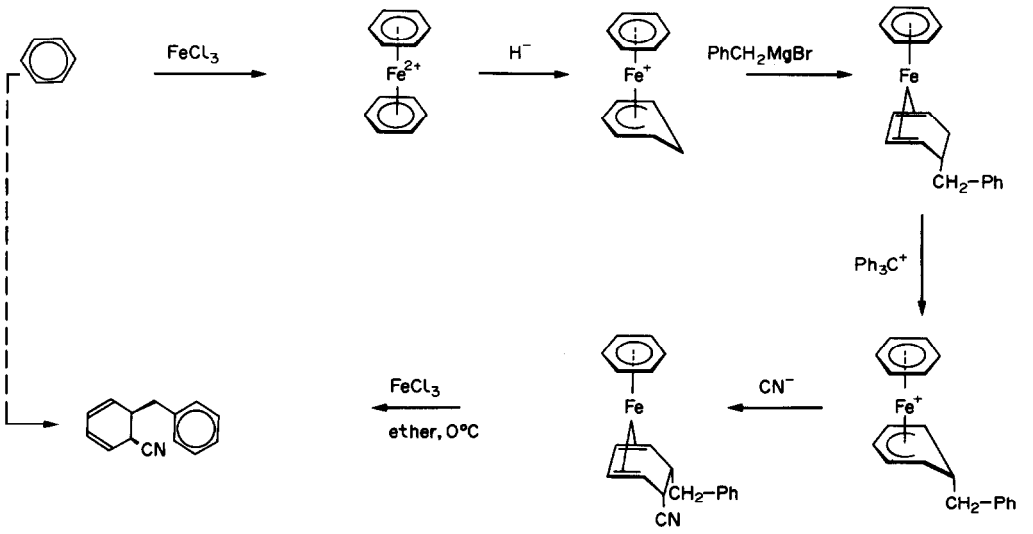
Scheme 2. Mechanism of the electrocatalytic ligand exchange of an arene by three two-electron ligands induced by electrons.



Scheme 3. Syntheses of tentacled iron sandwiches.



Scheme 4. Reversible hydrogen atom transfer in iron sandwiches.



Scheme 5. Hydride reservoir: protection by hydride for the transformation of benzene into heterobifunctional cyclohexadienes.

This is also the case for $[Fe(C_5R_5)(CO)_2H]$ (R = H, Me). These metal–hydride complexes behave as hydride reservoirs rather than as true transition metal catalysts in the sense that the role of the metal is quite ancillary. This is perhaps the limiting case between the two concepts of reservoir (relay) which trans*port* (trans*locate*) small particles with minimal structural change and transition metal catalysts which involve a deep change at the metal centre during the catalytic cycle. Both are needed for artificial as well as for natural processes.

(*Received* 5 *February* 1990; *accepted* 20 *July* 1990)

Abstract—Eight complexes of the anions of monomethyl- and dimethylvioluric acids with the metals ruthenium, rhodium, palladium and platinum have been isolated and characterized by elemental analysis, IR spectroscopy, NMR and thermogravimetry. IR spectra suggest bidentate coordination through the nitroso group and the carbonyl oxygen in position six. Analysis of dehydration processes of rhodium complexes allows us to distinguish between crystallization water, coordinated water and H_3O^+ cations. The crystal structure of hydrogen *fac*-tris(dimethylviolurato)ruthenate(II) heptahydrate has been solved by X-ray diffraction. The existence of ruthenium(II) in this compound instead of ruthenium(III) has been checked by recording its NMR spectra. The metal atom lies on a crystallographic three-fold axis, with three symmetry-related bidentate dimethylviolurato anions in its coordination sphere, defining the *fac* isomer. Water molecules build a very intricate hydrogen-bonding network.

Violuric acids are the 5-isonitroso derivatives of barbituric acid. These compounds show a great ability to form complexes with a large number of metal ions under different conditions of temperature and acidity. They have found immense analytical applications for the identification and determination of several metal ions.[1–6] Acidity constants and metal complexation constants of violuric acids have been studied by several authors.[7–18]

Some complexes of these ligands with transition metal ions have been isolated and characterized by spectroscopic techniques.[19–26] Violurato derivatives show, in these compounds, π-acceptor properties acting as strong-field ligands.[27]

X-ray studies carried out on this type of complex indicate that violurato ligands generally behave as bidentate groups through the nitrogen atom of the oxime group and an oxygen atom from a vicinal carbonyl group.[28–38]

As part of our work on the coordination behaviour of pyrimidine derivatives,[39–41] we report here the synthesis, spectroscopic characterization and thermal behaviour of eight new ruthenium(II), palladium(II), rhodium(III) and platinum(II) complexes of monomethyl- (HMV) and dimethyl- (HDMV) violuric acids, and the crystal structure of the complex hydrogen *fac*-tris(dimethylviolurato) ruthenate(II) heptahydrate.

EXPERIMENTAL

Reagents

Monomethyl- and dimethylvioluric acids were obtained in our laboratory by well-known pro-

* Authors to whom correspondence should be addressed.

cedures.[42,43] Elemental analyses were undertaken by the Technical Services of Granada University using a Perkin–Elmer 240C microanalyser.

Preparation of the ketoximato complexes

$(H_3O)[Ru(DMV)_3]\cdot 6H_2O$ *and* ML_2 *complexes.* The title ruthenium(II) complex and the ML_2 complexes (where M = Pd^{II} or Pt^{II} and L = MV or DMV anions) were prepared by adding 1 mmol of $RuCl_3$, $Na_2[PdCl_4]$ or $(NH_4)_2[PtCl_4]$ to a stirred solution of 2 mmol of HMV or HDMV in 50 cm^3 of distilled water. Yellow palladium complexes or green platinum complexes immediately precipitated. In the case of the ruthenium compound, the dark red solution was held at room temperature for a few days, and small black crystals appeared.

The isolated products were collected and quickly washed with small amounts of water and ethanol and dried in air. Elemental analysis (Calc. in parentheses): $(H_3O)[Ru(DMV)_3]\cdot 6H_2O$: C, 27.7 (27.7); H, 4.1 (4.2); N, 16.8 (16.1)%. $Pd(MV)_2$: C, 25.9 (26.9); H, 1.6 (1.8); N, 18.0 (18.8)%. $Pd(DMV)_2$: C, 30.0 (30.3); H, 2.5 (2.5); N, 18.0 (17.7)%. $Pt(MV)_2$: C, 22.6 (22.4); H, 1.6 (1.5); N, 15.5 (15.7)%. $Pt(DMV)_2$: C, 25.4 (25.6); H, 2.1 (2.1); N, 15.4 (14.9)%.

$Ru(NO)_2(DMV)_2Cl$. The procedure is the same as for the synthesis of $(H_3O)[Ru(DMV)_3]\cdot 6H_2O$, but involves a large excess of $NaNO_2$ adding to the reaction mixture. C, 24.6 (25.5); H, 2.0 (2.1); N, 19.5 (19.8)%.

$(H_3O)[Rh(DMV)_2Cl_2]\cdot 2H_2O$. Commercial $RhCl_3\cdot xH_2O$ (0.2 g) was added to a solution of dimethyl violuric acid (0.4 g) in hot methanol (50 cm^3). The reaction mixture was stirred at 50°C for 15 min. After cooling, the yellow solution was held at room temperature for a few days, when small yellow crystals appeared. The product was washed with methanol and air dried. C, 23.4 (24.1); H, 3.2 (3.2); N, 14.2 (14.1)%.

$[Rh(DMV)_2Cl(H_2O)]\cdot 2H_2O$. The synthesis is analogous to the previous one, but using DMSO as solvent instead of methanol. C, 25.5 (25.7); H, 3.2 (2.9); N, 15.4 (15.0)%.

Physical measurements

Infrared spectra were obtained on a Perkin–Elmer 983G spectrophotometer using KBr (4000–250 cm^{-1}) or polyethylene (600–180 cm^{-1}) pellets.

^1H and ^{13}C NMR spectra were recorded on a Brucker AM300 spectrometer using hexadeuterated dimethylsulphoxide as solvent.

Thermogravimetric measurements were carried out on a Mettler TG-50 thermobalance, using a heating rate of 20°C min^{-1} and a dynamic atmosphere of pure air (100 cm^3 min^{-1}). The nature of the final pyrolysis products was checked by IR spectroscopy.

Data collection and structure determination

A shiny, black, hexagonal, prismatic crystal mounted in open air was used for X-ray work. The unit cell, obtained by usual methods on an Enraf–Nonius CAD-4 diffractometer, shows trigonal or hexagonal symmetry, the first indicated by non-equivalence of hkl and $hk\bar{l}$ reflections. Systematic absences were consistent with space groups $P\bar{3}c1$ and $P3c1$. The structure solved and refined well in $P\bar{3}c1$.

The intensity data were obtained with a Syntex $P\bar{1}$ diffractometer as described earlier,[44] by using graphite-monochromatized Mo-K_α radiation. All hkl and $hk\bar{l}$ reflections within a sphere limited by $2\theta < 50°$ ($0 \leqslant h \leqslant 17$, $0 \leqslant k \leqslant 17$, $-22 \leqslant l \leqslant 22$) were collected. Three standard reflections checked every 47 measurements showed random fluctuation within $\pm 2.6\%$.

A total of 3672 reflections were measured. After averaging, the number of independent reflections reduced to 1840, of which 1279 with $I > 3\sigma(I)$ were used for structure determination. These data were corrected for Lorentz and polarization, but not for absorption ($\mu = 5.82$ cm^{-1}).

The ruthenium atom was located at equipoint 4*d* by means of the Patterson synthesis. All other atoms, including 28 water molecules, were readily located from a ΔF map calculated by the SHELX package.[45] The structure was refined anisotropically by full-matrix least-squares. Individual weights based on counting statistics were applied.

Water oxygen OW(3), initially placed on the two-fold axis (equipoint 4*f*), showed abnormally large thermal motion. It was displaced from the axis, and its three coordinates were allowed to refine (occupancy factor = 1/2). After convergence, more reasonable temperature factors were obtained, indicating that this water molecule was statistically distributed over two symmetry-related sites near the axis.

The methyl hydrogens were also found to be disordered over two equally populated sets of sites. Each set of hydrogen atoms was treated as a semi-rigid body, and a common isotropic temperature factor was refined for the six half-hydrogens of each group. Water hydrogens were not detected. Final agreement factors were $R = 0.036$ and $R_w = 0.045$.

The scattering curves and anomalous dispersion terms for ruthenium were obtained from standard sources.[46,47] The final atomic coordinates and equi-

valent temperature factors are part of the supplementary material, which also includes tables of anisotropic temperature factors, least-squares plane calculations, distances and angles in hydrogen bonds, and structure factor amplitudes.

Crystal data

$(H_3O)[Ru(C_6N_3O_4H_6)_3]\cdot 6H_2O$, FW = 780.6, trigonal, space group $P\bar{3}c1$, $a = 14.007(8)$, $c = 18.333(8)$ Å, $V = 3115.0$ Å^3, $D_c = 1.664$ g cm^{-3}, $Z = 4$, $F(000) = 399$, $\lambda(\text{Mo-}K_\alpha) = 0.71069$ Å (graphite monochromator), $\mu(\text{Mo-}K_\alpha) = 5.82$ cm^{-1}, $T = 293$ K, crystal dimensions (faces): 0.33 mm (001–00$\bar{1}$), 0.28 mm (100–$\bar{1}$00), 0.28 mm (010–0$\bar{1}$0) and 0.28 mm (1$\bar{1}$0–$\bar{1}$10).

RESULTS AND DISCUSSION

Spectroscopic studies

In Table 1, the most important absorption bands of the IR spectra are collected. These values agree well with the literature values for bidentate N(5)—O(6) violurate anions,[48] in which a π-electron delocalization takes place in the five member chelate ring [M—N(5)—C(5)—C(6)—O(6)].

An additional intense, broad band appears in the spectrum of $Ru(NO)_2(DMV)_2Cl$ at 1912 cm^{-1}, clearly assignable to ν(N≡O) of the coordinated nitrosyl groups.[37] This spectrum does not show bands assignable to the existence of nitro groups.

Chlorine-containing compounds show, in the low frequency area, bands due to ν(M—Cl), which suggest that chlorine atoms are in the inner coordination sphere of these complexes.

^{1}H and ^{13}C NMR spectra of $(H_3O)[Ru(DMV)_3]\cdot 6H_2O$ are well solved showing sharp signals, which clearly indicates that the initial ruthenium(III) has been reduced to ruthenium(II). The positions of these signals are the same as reported by Brémard *et al.*[27] for the sodium salt of this complex anion. A complete interpretation of the ^{13}C spectrum has been carried out by these authors.

Thermal behaviour

Thermal decomposition of hydrated compounds begins with the loss of water molecules. This process appears as two or three weight loss effects in the DTG diagram of rhodium complexes, showing the non-equivalence of the present water molecules. A third of them (which is directly coordinated to metal atom or supporting the extra proton) are completely eliminated at about 180°C. In the case of $(H_3O)[Ru(DMV)_3]\cdot 6H_2O$, a single broad weight loss effect is observed for dehydration involving the seven molecules.

The two TG diagrams corresponding to rhodium complexes show, in the 200–360°C temperature range, a new weight loss effect. The corresponding values are in good agreement with the expected values for the elimination of chlorine atoms. After this, pyrolytic decomposition of the organic moiety takes place, finishing around 430°C. This process occurs for the ruthenium complexes in the range 220–380°C, whereas for the palladium and platinum complexes, it occurs between 330 and 420°C (see Table 2).

The final residues were identified by IR spectroscopy. They are PdO or Pt, respectively, for palladium(II) and platinum(II) compounds, with good agreement between experimental and calculated values. For ruthenium and rhodium complexes, the residue is mainly the corresponding metal, but the presence of non-stoichiometric oxides, unburned carbon and even metastable carbonate (in the case of $[Rh(DMV)_2Cl(H_2O)]\cdot 2H_2O$) is observed.

[a] Three steps.

Description of the structure

An ORTEP view of the complex is shown in Fig. 1. The complex consists of discrete anions in which ruthenium is octahedrally coordinated by three dimethylviolurate anions acting as bidentate ligands. The ligand forms a five-membered chelate ring via the oxygen, O(6), and the N(5) atom of the nitroso group. The metal sits on a crystallographic three-fold axis, and the three ligands define the *fac* stereoisomer. The molecules are individually chiral, but the compound is racemic, the Δ and Λ enantiomers being related by the cell inversion centre.

Interatomic distances and bond angles are listed in Table 3. The distances, angles and other features of the coordination sphere are very similar to those of the analogous $[(violurate)_3Ru]^-$ complex,[34] with the difference that the present molecule is closer to idealized symmetry because it lies on a crystallographic three-fold axis. The present Ru—O and Ru—N distances are not significantly different from those found in the above ruthenium(II) viol-

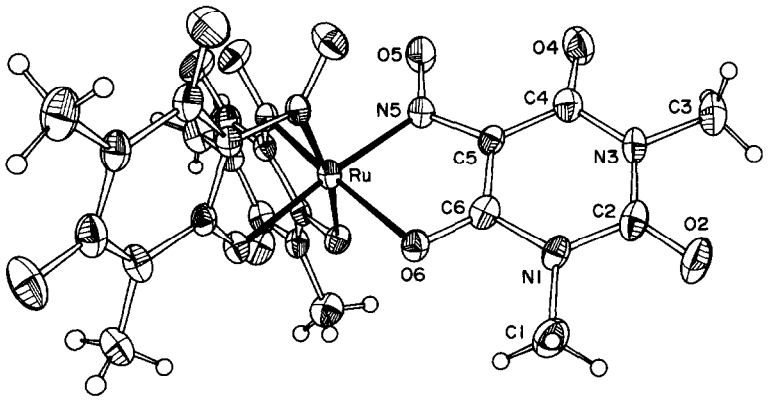

Fig. 1. ORTEP drawing of the *fac*-Ru(dimethylviolurate)$_3$ anion. Ellipsoids are drawn at the 50% probability level. Hydrogen atoms are shown as spheres of arbitrary size. The ligands are related by a crystallographic three-fold axis running through the ruthenium atom.

Table 3. Distances and angles in hydrogen *fac*-Ru(dimethylviolurate)$_3$ · 7H$_2$O

Distances (Å)			
Ru—O(6)	2.099(4)	N(3)—C(4)	1.383(7)

urate compound. The angles around the metal correspond to an octahedron with a trigonal distortion, originating mainly from the small N(5)—Ru—O(6) angle of 80.8(1)° imposed in the chelate ring by the "bite" of the ligand.

Since the crystal structure of dimethylvioluric acid has not been determined, the ligand will be compared with violuric acid,[28,49] assuming that methylation has no dramatic effect. As a logical consequence of deprotonation and greater delocalization in the chelate ring, the C(5)—C(6) and N(5)—O(5) bonds of violuric acid [1.505(8) and

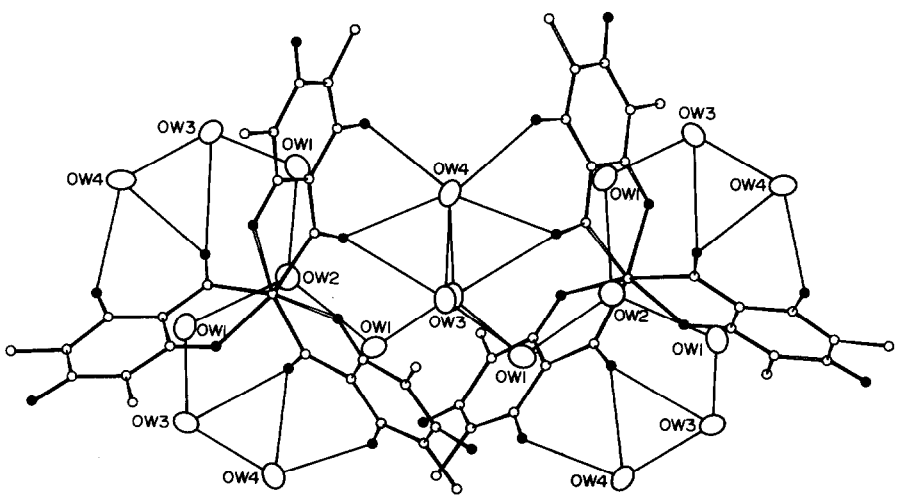

Fig. 2. Hydrogen bonding network in the unit cell. The lines represent hydrogen bonds, but the hydrogen positions could not be determined. The two sites on which OW(3) is disordered are shown in the centre of the drawing. Oxygen atoms are shown as dark spheres and can be identified by comparison with Fig. 1.

Table 4. Distances (Å) between atoms possibly involved in hydrogen bonding

OW(2)—OW(1)	$(x, y, z; 1-y, 1+x-y, z$ and $-x+y, 1-x, z)$	2.800(7)
OW(1)—OW(3)	$(-y, x-y, z)$	2.73(2)
OW(1)—OW(3)	$(y, x, 1/2-z)$	2.47(2)
OW(1)—O(5)	$(x-y, 1-y, 1/2-z)$	2.967(6)
OW(1)—O(4)	$(x-y, 1-y, 1/2-z)$	3.056(7)
OW(3)—OW(4)	(x, y, z)	2.49(2)
OW(3)—O(5)	$(x-y, -y, 1/2-z)$	2.90(2)
OW(4)—O(5)	$(x, y, z$ and $x-y, -y, 1/2-z)$	2.868(5)
OW(4)—O(4)	$(x, y, z$ and $x-y, -y, 1/2-z)$	2.778(6)

1.327(8) Å, respectively][28,49] are shortened in the complex [1.407(6) and 1.258(5) Å, respectively], whereas the C(5)—N(5) and C(6)—O(6) bonds are lengthened [1.274(7) and 1.175(8) Å vs 1.382(7) and 1.266(6) Å, respectively]. Also, the angles around C(5) are severely distorted. The C(6)—C(5)—N(5) and C(4)—C(5)—N(5) angles are 115.1(6) and 125.7(6)°, respectively, in violuric acid. They occur in the opposite order [121.7(4) and 113.1(4)°] for the chelate. No such distortion is detected around C(6). These features are similar to those found in other violurate[32–34,37,50] and dimethylviolurate[35,36] complexes with various metals. The remaining distances and angles are fairly similar to those of violuric acid.

The pyrimidine ring shows significant, but small, deviations from planarity: the largest distances are found for C(2) [0.039(5) Å], N(3) [−0.023(4) Å] and C(4) [0.018(5) Å]. Exocyclic atoms are more displaced, most of them are situated on the same side as the metal atom, which lies at 0.0883(3) Å away from the plane. The largest deviations are found for the nitroso group [N(5), 0.116(4) and O(5), 0.170(3) Å], but O(2) [0.101(4) Å] and the C(1) methyl group [0.103(6) Å] are also appreciably displaced.

The water molecules participate in an intricate network of hydrogen bonds (Fig. 2); details on their geometry are provided in the supplementary material. The distances are collected in Table 4. The unit cell contains, altogether, 28 water molecules: 12 of them [OW(1)] are in general positions, four OW(2) molecules lie on a three-fold axis, whereas the six OW(4) molecules occupy a two-fold axis. Six extra water molecules [OW(3)] are each disordered over two sites slightly off the two-fold axis. Each ligand is connected to this network via the oxygen atoms of the 5-nitroso and 4-carbonyl groups.

The extra proton that balances the charge of the complex anion has not been detected. However, the position of OW(2) on the three-fold axis, its relationship via hydrogen bonding [in which OW(2) must be the donor] with the three nearby OW(1) molecules and the fact that there is one OW(2) per ruthenium atom, lead us to believe that OW(2) actually represents an H_3O^+ cation.

Acknowledgements—We are grateful to Professor F. D. Rochon (Université de Québec à Montréal) for helping in the determination of the cell dimensions and collecting the X-ray diffraction data. We wish to thank the Natural Sciences and Engineering Research Council of Canada and CICYT (research project 402/86) for financial support of this research, and the Spanish Ministry of Education and Science for a scholarship to M.Q.

REACTIVITY OF CYCLOMETALLATED PALLADIUM(II) DIMER COMPLEXES WITH DIPHOSPHINES

JOSE M. VILA,* MIGUEL GAYOSO, JESUS J. FERNANDEZ, JUAN M. ORTIGUEIRA and ANTONIO SUAREZ

Department of Inorganic Chemistry, University of Santiago, 15706 Santiago de Compostela, Spain

(*Received* 13 *June* 1990; *accepted* 25 *July* 1990)

Abstract—The new complexes $[\{Pd(2,3,4\text{-}(MeO)_3C_6HC(H)=NR)\}_2(\mu\text{-}L\text{—}L)(\mu\text{-}O_2CMe)](O_2CMe)$ [where L—L = $Ph_2PCH_2PPh_2$ (dppm), $Ph_2PC(=CH_2)PPh_2$ (vdpp); R = Cy, 2′,4′,6′-$(Me)_3C_6H_2$] were synthesized as 1 : 1 electrolytes by treating the cyclometallated Schiff base palladium(II) acetato-bridged dimers with the appropriate diphosphine in a 1 : 1 molar ratio. These were converted into the analogous halide-bridged complexes by treatment with NaX. Reaction of the palladium(II) cyclometallated halide-bridged dimers with dppm or vdpp in 1 : 1 and 1 : 2 molar ratios gave the dinuclear and mononuclear species, $[\{Pd(2,3,4\text{-}(MeO)_3C_6HC(H)=NR)\}_2(\mu\text{-}L\text{—}L)(\mu\text{-}X)](X)$ and $[Pd\{2,3,4\text{-}(MeO)_3C_6HC(H)=NR\}(L\text{—}L\text{-}P,P)](PF_6)$, respectively, as 1 : 1 electrolytes. The stereochemistry of the complexes is discussed on the basis of spectroscopic data. The compounds were characterized by microanalysis (C, H, N), IR and ^1H and $^{31}P\{^1H\}$ NMR spectroscopy.

Cyclometallation reactions have drawn much attention in the past years and reviews covering them have appeared.[1–4] These reactions have been used as pathways to new products in organic synthesis.[5] We have extensively studied the cyclometallation of differently substituted Schiff bases[6,7] (where the question of regioselectivity has arisen),[8] imidazole ligands[9] and diimines[10] by palladium(II) and manganese (I), which produces dimer and monomer species. The latter were obtained from the dimer complexes by bridge splitting reactions with neutral ligands, such as tertiary phosphines, and anionic ligands, such as acetylacetonate. When we attempted similar reactions with diphosphines of the type $Ph_2PCH_2PPh_2$ (dppm) or $Ph_2PC(=CH_2)PPh_2$ (vdpp), we obtained new dinuclear species with both diphosphine, and halide-bridging ligands and mononuclear species with a chelating diphosphine, depending on the molar ratio used.[11] In the present paper we report a further new type of cyclometallated complex of palladium(II) with Schiff bases, in which the two metal centres are bridged by a diphosphine ligand and an acetato group to give dinuclear 1 : 1 electrolytes. Halide-bridged analogues and mononuclear complexes are also described.

EXPERIMENTAL

Solvents were purified by the standard methods.[12] Chemicals were reagent grade. Palladium(II) acetate and dppm were purchased from Aldrich Chemie and Ventron, respectively; vdpp was made as in the literature.[13] Elemental analyses were carried out on a Perkin–Elmer elemental analyser 240-B. IR spectra were recorded as Nujol mulls or polythene discs on a Perkin–Elmer 180 spectrophotometer. NMR spectra were obtained on $CDCl_3$ solutions and referred to the high frequency of $SiMe_4$ (^1H) or 85% H_3PO_4($^{31}P\{^1H\}$) and were recorded on a Bruker WM-250 spectrometer.

The synthesis of the Schiff base ligands (**a**, **b**), of the acetato-bridged (**1a**, **1b**) and of the halide-bridged (**2a**, **3a**, **2b**, **3b**) dimer complexes has been described by us in an earlier paper.[8]

Synthesis of the complexes

$[\{Pd(2,3,4\text{-}(MeO)_3C_6HC(H)=NCy)\}_2(\mu\text{-}Ph_2PCH_2PPh_2)(\mu\text{-}O_2CMe)](O_2CMe)$ (**4a**). To a solu-

tion of the acetato-bridged dimer **1a** (0.05 g, 0.06 mmol) in acetone (*ca* 10 cm^3), dppm (0.02 g, 0.06 mmol) was added. After stirring for 3 h at room temperature, a precipitate formed which was filtered off and dried *in vacuo*. Recrystallization from dichloromethane–n-hexane afforded the desired complex as a yellow solid. Complexes **5a**, **4b** and **5b** were made similarly.

[{Pd(2,3,4 - $(MeO)_3C_6HC(H)$=NCy)}$_2$(μ - $Ph_2PCH_2PPh_2$)(μ-Cl)](Cl) (**6a**). To a suspension of the chloro-bridged dimer **2a** (0.05 g, 0.06 mmol) in acetone (*ca* 10 cm^3), dppm (0.02 g, 0.06 mmol) was added. The mixture was stirred for 3 h at room temperature and the resulting precipitate was filtered off and dried *in vacuo*. Recrystallization from dichloromethane–n-hexane gave the desired complex as a white solid. Complexes **7–9a** and **6–9b** were made similarly.

[Pd{2,3,4 - $(MeO)_3C_6HC(H)$=NCy}($Ph_2PCH_2PPh_2$-*PP*)](${PF_6}$) (**10a**). To a suspension of the chloro-bridged dimer **2a** (0.05 g, 0.06 mmol) in acetone (*ca* 10 cm^3), dppm (0.05 g, 0.12 mmol) and NH_4PF_6 (0.02 g, 0.12 mmol) were added. The mixture was stirred for 2 h at room temperature, aqueous acetone was added and the resulting solid was filtered off and dried *in vacuo*. Recrystallization from dichloromethane–n-hexane gave the final compound as an orange solid. Complexes **11a**, **10b** and **11b** were made similarly.

RESULTS AND DISCUSSION

In a previous paper[8] we described the preparation and characterization of the acetato-, chloro- and bromo-bridged dimer complexes [(**1–3**)**a**, (**1–3**)**b**] which were the necessary precursors for the synthesis of the compounds in the present paper. The cyclopalladated moiety in the compounds now described bears the same characteristics as the parent dimer compounds. The ν(C=N) stretching band (Table 1) appears at lower frequency than that corresponding to the free imines, in agreement with expected nitrogen coordination.[14] The HC=N ^{1}H NMR resonance in each compound appears shifted to lower frequency by *ca* 0.3–0.4 ppm relative to the free ligand[15] (Table 2). The H(5) proton (see numbering scheme in Fig. 1) appears as a doublet in the phosphine-bridged complexes, and as a doublet of doublets in the phosphine-chelated complexes, by coupling to one or two ^{31}P. The remaining pro-

tons [H(3)′, H(5)′, CH_3, CH_3O] have been assigned unequivocally from chemical shift data and relative intensities (Table 2). The values of the conductivity data (130–155 Ω^{-1} cm^2 mol^{-1} in 10^{-3} mol dm^{-3} solutions in dry acetonitrile) indicate the compounds to be 1 : 1 electrolytes.[16]

Treatment of the acetato-bridged dimer complexes, **1a** and **1b**, with the diphosphines dppm or vdpp in a 1 : 1 dimer–diphosphine molar ratio gave the hitherto unknown complexes **4a**, **5a**, **4b** and **5b**, where one acetato ligand has been replaced by a diphosphine ligand to yield a dinuclear complex with two different bridging ligands. The complexes have been fully characterized by their microanalysis (C, H, N), IR and $^{31}P\{^1H\}$ and ^1H NMR spectroscopy (see Experimental, Tables 1 and 2 and Fig. 1). The IR spectra show the characteristic ν(COO) bands at 1565, 1407 (**4a**), 1575, 1405 (**5a**), 1576, 1400 (**4b**) and 1572, 1405 (**5b**) cm^{-1}; their separation, in each compound, is characteristic of a bridging acetato group.[17] These bands remain when the acetato anion was exchanged for the hexafluorophosphate ion by treatment with NH_4PF_6, showing that they are due to the bridging acetato group. The ^1H NMR spectra show singlets at δ 2.17 (**4a**), 2.13 (**4b**), 0.56 (**5a**) and 0.67 (**5b**) ppm for the O_2CMe(bridging) protons; the lower frequency shift of the latter two resonances is due to the shielding influence of the nitrogen-bonded aromatic ring. The $^{31}P\{^1H\}$ NMR spectra show a singlet, suggesting the two ^{31}P nuclei to be equivalent.

Treatment of the halide-bridged dimer complexes (**2a**, **3a**, **2b**, **3b**) with dppm or vdpp in a 1 : 1 dimer–diphosphine molar ratio gave the complexes (**6–9**)**a** and (**6–9**)**b** where the two metal centres are bridged by a diphosphine ligand and a halogen atom (see Experimental, Tables 1 and 2). These compounds could also be prepared in good yield by treatment of the parent acetato complexes (**4a**, **5a**, **4b**, **5b**) with aqueous sodium chloride or bromide (see Fig. 1). They are 1 : 1 electrolytes (*vide supra*), in contrast to similar compounds reported with bis(diphenylphosphino)ethane (dppe),[18] in which there are two terminal Pd—X bonds and the molecule is not ionic, in accordance with the larger "bite" of dppe as opposed to dppm or vdpp. The IR spectra show only one ν(Pd—X) band for each compound; its rather low frequency suggesting the halogen is *trans* to carbon rather than nitrogen.[19,20] These IR results are in agreement with a parallel disposition

of the Schiff base ligands; in an antiparallel arrangement the halogen atom would be *trans* to the phenyl carbon of one ligand and *trans* to the imine nitrogen of the other, resulting in two different IR ν(Pd—X) bands. The CH_3O[C(4)] NMR resonance is shifted to lower frequency due to the shielding effect of the phosphine phenyl ring.[7] In an antiparallel arrangement one would observe two different resonances for the two inequivalent CH_3O[C(4)] groups, as one of them would not be influenced by the phenyl ring of the phosphine. In a similar complex, the X-ray single crystal determination shows this geometry to be correct.[11]

Reaction of the halide-bridged dimer complexes (**2a**, **3a**, **2b**, **3b**) with dppm or vdpp, and NH_4PF_6, in a dimer–diphosphine 1 : 2 molar ratio affords the mononuclear species **10a**, **11a**, **10b** and **11b**. These can also be made by treatment of (**6–9**)**a** and (**6–9**)**b** with dppm or vdpp, and NH_4PF_6. The final products are identical, whether the chloro or bromo species is used, as the halogen is exchanged by the hexafluorophosphate ion. The $^{31}P\{^1H\}$ NMR shows two doublets for the two inequivalent phosphorus nuclei. The lower frequency doublet is assigned to the phosphorus nucleus *trans* to the phenyl carbon, C(6), and the higher frequency doublet to the phosphorus nucleus *trans* to the imine nitrogen. This is based on the assumption that a ligand of greater *trans* influence shifts the ^{31}P resonance of the phosphorus nucleus *trans* to it to lower frequency.[21] Selective decoupling experiments on compounds **10a**, **11a**, **10b** and **11b** confirm this. *H*(5) gives rise to a doublet of doublets because of coupling to both phosphorus nuclei [^4J(PH) *ca* 11 and 8 Hz]. The HC=N proton resonance (doublet) is coupled only to one phosphorus nucleus [^4J(PH) *ca* 7.5 Hz], presumably that *trans* to it. Selective irradiation of the P_B resonance (assuming this to be the ^{31}P nucleus *trans* to the phenyl carbon atom) reduces the *H*(5) resonance to a doublet [^4J(PH) *ca* 8 Hz], whilst the *H*C=N resonance remains a doublet [^4J(PH) *ca* 7.5 Hz]. Selective irradiation of the P_A resonance reduces the *H*(5) resonance to a doublet [^4J(PH) *ca* 11 Hz] and the *H*C=N resonance to a singlet. Selective irradiation also allows the correct assignment of the $^2J(PCH_2)$ couplings (Table 2).

COPPER COMPLEXES OF 2-THIOURACIL

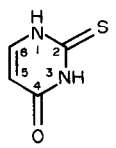
YANG WEI-DA* and HU YIN-PING

Department of Chemistry, East China Normal University, Shanghai 200062, P.R.C.

(*Received* 7 *November* 1989; *accepted* 1 *August* 1990)

Abstract—The preparation of five copper complexes of 2-thiouracil (turH) is described. Their stoichiometric formulae, confirmed by elemental analysis and molecular weight determination in DMSO, are as follows: $Cu(turH)_2Cl$ (**II**), Cu(turH)Br (**III**), $Cu_2(turH)_3Cl_2$ (**IV**), $Cu_4(tur)_4$ (**V**) and Cu(tur)Cl (**VI**). Their tentative structures have been assigned on the basis of IR and electronic spectra, molar conductance and magnetic susceptibility data. The turH acts as a monodentate ligand via its exocyclic sulphur in **II** and **IV**, but is bidentate in **III** and **VI** by using SN(3) and ON(3) donor sets, respectively. However, in tetramer **V** it seems more likely that the deprotonated ligand behaves as a tridentate bridge. In addition, the only copper(II) complex which has been isolated might take the dimeric structure through the oxygen bridges in its crystal lattice.

2-Thiouracil (turH) (**I**) is known as a basic constituent of some t-RNAs[1] and exhibits anti-tumour and anti-thyroid activity because it readily incorporates into nucleic acids.[2] The interactions of various transition metal ions with nucleo-bases have attracted much attention in the past decade. However, little work has been carried out regarding the nature of turH complexes formed with the monovalent copper.[3] In this paper we will report the synthesis and the binding sites which occur in five novel copper complexes based on their various physicochemical properties.



(I)

EXPERIMENTAL

Materials

2-Thiouracil was purchased from the Shanghai Chemical Reagent Factory No. 2, and used after recrystallization from acetone. All the remaining chemicals were reagent grade.

Preparation of the complexes

A warm solution of turH (150 mg, 1.18 mmol) in acetone (150 cm^3) was added dropwise to a methanolic solution (30 cm^3) of $CuCl_2 \cdot H_2O$ (285 mg, 1.68 mmol). After refluxing and stirring for 2 h, light yellow crystals (complex **II**) gradually separated. These were hot filtered off, thoroughly washed with methanol and acetone and finally dried *in vacuo*. The yield obtained was approx. 20%.

Complex **III** was readily prepared by the same procedure except that $CuBr_2$ was used as the appropriate halide. The pale yellow coloured product was isolated in *ca* 35% yield.

Complex **IV** was prepared by dropping a suspension of ligand (320 mg, 2.50 mmol) in warm 6% HCl (10 cm^3) into an aqueous solution (5 cm^3) of cupric acetate (250 mg, 1.25 mmol), with constant stirring. An additional portion of 6% HCl (3–4 cm^3) was subsequently added, until a yellow–green powder resulted from the turbid black coloured solution. After further stirring for 3 h the solution turned light green and the colour of the suspended solid changed to pale yellow. The crude product was filtered and purified in a 4 : 1 (v/v) mixed solvent of acetone and ethanol. The final product was obtained in a 24% yield.

* Author to whom correspondence should be addressed.

The preparation of complex **V** was essentially the same as presented above for the initial reaction, except that rapid filtration followed as soon as the yellow–green solid appeared in the reaction mixture. The precipitate was then purified by the same procedure as described earlier. The resulting solid was ivory coloured, with a yield of *ca* 17%.

The cupric complex **VI** was obtained by the same method as for complex **II** but with a molar ratio of 1:1 (the actual quantity of both reactants used was 0.8 mmol) and simply using methanol as the reaction medium. The resulting compound was a yellow–green microcrystalline product in a yield of *ca* 50%. In this case, the reason why the ligand does not exhibit its reducing power is still obscure.

Physicochemical measurements

IR spectra were recorded on a Perkin–Elmer 580B spectrometer using KBr discs. Electronic spectra were obtained on a Beckman DU-7 spectrometer using DMSO as the solvent. Conductivity measurements were made in 10^{-3} mol dm^{-3} dimethylformamide at 20°C with a DDS-11A conductivity meter. Magnetic susceptibility data were determined by a Faraday's balance, employing Mohr's salt as the calibrant. The molecular weight of each complex was obtained using the Rast method and extrapolating the freezing-point depression data for various concentrations in DMSO as its molality approached infinite dilution. EPR spectra were obtained with a JES-FE2XG spectrometer and g values were calculated using the double calibrant method.[4]

RESULTS AND DISCUSSION

The analytical and some relevant physicochemical data of the title complexes are shown in Table 1. The results from the molecular weight determination show that all the complexes are monomeric in DMSO, except complex **V** which is a tetramer. The magnetic and visible spectral data show that all the copper in **II**–**V** is cuprous, but bivalent in **VI**. The low molar conductivities of the title complexes in DMF indicate non-electrolytic behaviour.[5] The considerable magnitude of Λ_M (34–39 S cm^2 mol^{-1}) obtained may be due to some ligand exchange between the strong polar solvent molecule and the halide group. The small value (*ca* 18 S cm^2 mol^{-1}) for complex **V** probably arises from the partial degradation of the tetramer (which is less soluble in DMF) caused by heating during the preparation of the tested solution.

The characteristic IR data for the free ligand and the complexes are presented in Table 2. It is clear

that thioamide bands I, II and IV for all the complexes shift towards lower frequencies, as compared to the free turH and among these the largest band-shift is noted for thioamide band I. It is reasonable to expect that the thiocarbonyl sulphur of turH (or tur^-) is used in bonding in **II**–**V**, since copper(I) is a soft acid in nature, but their bonding modes seem to be different. If copper(I) is given the common coordination number of three, possible structures for **II** and **IV** may be depicted as shown in Fig. 1(a) and (b). The bathochromic shift of the C=O group, along with the concomitant appearance of the absorption of ν(O—H) (*ca* 3500 cm^{-1}) in the IR spectra for **III** and **V**, implies that N(3) of the pyrimidine ring also coordinates to the metal.[6] Thus the structure for **III** may be illustrated as in Fig. 1(c). Moreover, in the case of **V** a new spectral feature was observed, i.e. splitting of the thioamide band I into a doublet, which shifts to lower wavenumbers (1510 and 1530 cm^{-1}). If compared to the other cuprous complexes, this is presumably a sign that tur^- serves as a tridentate bridge involving a N(1)SN(3) donor set, hence, Fig. 1(d) would be expected for the tentative structure of $Cu_4(tur)_4$. The most informative compound among those reported is the cupric complex, in which the binding sites of the ligand are more likely to be the ON(3) bite rather than the SN(3) ligand coordination sphere, as evidenced by the disappearance of the vibration of the C=O group, and the thioamide band IV remaining constant, which is considered to be mainly due to the contribution from ν(C=S).[7]

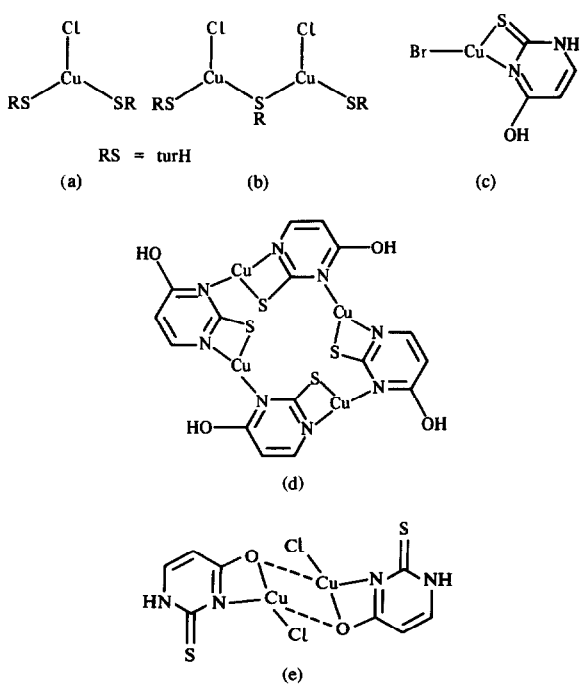

Fig. 1. Postulated structures for the copper complexes: (a) $Cu(turH)_2Cl$, (b) $Cu_2(turH)_3Cl_2$, (c) Cu(turH)Br, (d) $Cu_4(tur)_4$ and (e) dimer of Cu(tur)Cl.

Although complex **VI** is shown to be a monomer by the molecular weight determination, its effective magnetic moment at 77 K (1.34 BM) is considerably lower than in the literature (1.70–2.20 BM),[8] which indicates moderate antiferromagnetic coupling between the adjacent copper(II) centres. The polycrystalline *X*-band EPR data for **VI** are consistent with the magnetic susceptibility measurements mentioned above. In addition to the strong full-field transitions observed (g value of 2.2 at 3100 G), a weak half-field transition signal (corresponding to $\Delta M_s = \pm 2$) with a g value of *ca* 4.3 at 1170 G was also examined. The appearance of the latter signal provides further support to the postulated spin-coupled species in the solid complex.[9,10] Consequently, a dimeric form would be taken in the lattice for the copper(II) complex [Fig. 1(e)]. On account of the magnetic data, an O-bridged structure seems to be preferred to a Cl-bridged structure because of the greater antiferromagnetism normally given by the former in binuclear copper(II) species. Nevertheless, with such stereochemical conditions both the copper(II) and μ-oxygen atoms are forced to form less stable, fused four-membered rings. Con-

sidering the same circumstances as in the molecular weight determination previously discussed, the possibility of complex **III** accepting a dimer form is also not excluded. Attempts to grow single crystals of complex **V** suitable for X-ray study have proved unsuccessful.

Abstract—With the aim of producing redox-active ferrocenyl ligands, the synthesis and characterization of two arylhydrazones, phenyl (**1**) and pyridyl (**2**), of 1,1′-diacetylferrocene (DAF) are reported. The X-ray crystal and molecular structure of **2**, as its acetate salt, has been determined and refined to $R = 0.072$ for 3449 independent reflections; $[FeC_{24}N_6H_{26}]^{2+} \cdot 2[CH_3CO_2]^-$ crystallizes in the triclinic, space group $P\bar{1}$, $a = 15.273(15)$, $b = 17.493(18)$, $c = 11.722(13)$ Å, $\alpha = 97.4(1)$, $\beta = 75.8(1)$, $\gamma = 70.4(1)°$, $U = 2781.5$ Å^3, $Z = 4$. The delocalization of the bonding observed in the substituents on the Cp rings is discussed in comparison with other relevant structures. Similar reactions of DAF with ethylamine, aniline or n-butylamine failed to yield new products.

Attempts to synthesize metal complexes from **1** and **2** failed to yield well characterized materials. In fact, the stability of both complexes in the presence of metal ions was low, with iron(III) species being produced. While not isolated in the pure form, this iron(III) species did not appear to be a ferrocinium derivative.

There is considerable current interest in the production of metal–metal interactions, particularly when these are between two different metals.[1] Of interest to us is the use of organometallic, particularly ferrocenyl, ligands to achieve this goal.[2,3] In addition to the wide variety of substitution patterns available for the ferrocenyl moiety, such molecules have the feature that the ferrocenyl group can, in principle, act as a redox centre.[4] This would permit the electronic "tuning" of a coordinated metal by oxidizing the ferrocenyl group to its ferricinium derivative.[5,6]

A further reason for interest in oxidizable ferrocenyl ligands is the fact that ferricinium ions have anti-tumour activity while the parent ferrocene has not.[7] Also, very recently, reports of the activity of platinum and gold complexes[8,9] of 1,1′-bis(diphenylphosphino)ferrocene (Fdpp) against experimental tumours have appeared. However, complexes of Fdpp do not readily undergo oxidation[10] and we have recently discussed why this should be the case.[11] The synthesis of oxidizable ferrocenyl ligands would allow the design of multifunctional drugs.

It is thus of considerable interest to synthesize ferrocenyl ligands with low oxidation potentials. Due to the acknowledged coordination chemistry of

* Authors to whom correspondence should be addressed.

Schiff's bases[12] we undertook a study of ferrocenyl derivatives with the above aim. We here report the reaction of some primary amines and arylhydrazines with 1,1′-diacetylferrocene (DAF). The stability and suitability of these complexes as ligands is discussed. The crystal and molecular structure of the 2-pyridylhydrazone of DAF is also presented and compared with relevant structures.

EXPERIMENTAL

The melting points are uncorrected. The ^{13}C NMR spectra were obtained on a Bruker WP80 FT spectrometer. The ferrocenyl carbons were numbered conventionally, C(1) being the *ipso*-carbon. The phenyl carbon resonances were numbered similarly and distinguished by primes. For the pyridyl derivatives the pyridine ring is numbered conventionally starting from the N atom. Analysis was performed at the University of Manchester, U.K. Mössbauer data were recorded at 80 K and isomer shifts (δ) are referred to natural iron at room temperature on a spectrometer previously described.[13] All solvents and reagents were used as purchased unless otherwise specified.

Reaction of DAF *and phenylhydrazine* (1)

DAF (1 g, 3.7 mmol) (Aldrich) was dissolved in dried ethanol (using 3 Å molecular sieve) (100 cm^3) and phenylhydrazine (2 cm^3, 20 mmol) (BDH) was added. The solution was refluxed for 1 h and the volume reduced to 25 cm^3. Cooling in ice overnight afforded dark red crystals which were filtered off, dried and stored in a desiccator. Compound **1** was obtained in 59.5% yield (m.p. 115–116°C). IR (cm^{-1}): 1600 ν(C=N). Found: C, 68.8; H, 5.8; N, 11.8. Calc. for $C_{26}H_{26}N_4Fe$: C, 69.3; H, 5.8; N, 12.4%.

1,1′-*Bis(pyridylhydrazone)* (2)

DAF (1 g, 3.7 mmol) (Aldrich) and 2-hydrazinopyridine (1 g, 9.2 mmol) (Aldrich) were dissolved in dried ethanol (100 cm^3) and 1 cm^3 of glacial acetic acid was added. The mixture was refluxed for 1 h and the volume then reduced to 25 cm^3. Cooling in ice overnight afforded dark red crystals which were filtered off, dried and stored in a desiccator. The compound was isolated as the acetate salt. Compound **2** was obtained in 82% yield (3 mmol) (m.p. 128–130°C). IR (cm^{-1}): 1610 ν(C=N). Found: C, 58.0; H, 5.4; N, 13.9. Calc. for $C_{28}H_{32}N_6O_4Fe$: C, 58.7; H, 5.6; N, 14.6%.

Primary amines with DAF

Reactions were tried with ethylamine, aniline and n-butylamine in place of the hydrazines. Changes of solvent to propan-1-ol and toluene and carrying the reaction out under nitrogen were also tried. In all cases no reaction was observed, DAF being recovered quantitatively.

X-ray data collection and structure determination of 2

The crystal structure determination was performed at the University of Reading.

The crystal data for $[FeC_{24}N_6H_{26}]^{2+} \cdot 2[CH_3CO_2]^-$, $M = 578.1$, triclinic, $a = 15.273(15)$, $b = 17.493(18)$, $c = 11.722(13)$ Å, $\alpha = 97.4(1)$, $\beta = 75.8(1)$, $\gamma = 70.4(1)°$, $U = 2781.5$ Å^3, $F(000) = 1200$, $D_m = 1.36$ g cm^{-3}, $Z = 4$, Mo-K_α radiation ($\lambda = 0.7107$ Å), μ(Mo-K_α) = 6.0 cm^{-1}, space group $P\bar{1}$, $R = 0.072$.

A crystal of approximate size 0.25 × 0.3 × 0.3 mm was set up to rotate about the a axis on a Stoe Stadi2 diffractometer and data were collected via variable width w scan. Background counts were 20 s and a scan rate of 0.0333 ° s^{-1} was applied to a width of $(1.5+\sin\mu/\tan\theta)$. 7122 independent reflections were measured, of which 3449 with $I > 3\sigma(I)$ were used in subsequent refinement.

The structure was determined by the heavy-atom method. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms bonded to carbon were in fixed positions. The methyl hydrogen atoms were refined as rigid groups. Hydrogen atoms bonded to the nitrogen atoms were identified in a difference Fourier map and also included in fixed positions.

The structure was given a weighting scheme in the form $w = 1/[\sigma^2(F)+0.003F^2]$. The final R value was 0.072 ($R_w = 0.077$). In the final cycle of refinement all shift/error ratios were $< 0.3\sigma$. The final difference Fourier map showed no peaks greater than 0.8 e Å^{-3}. Calculations were carried out using SHELX76 and some of our own programs on the Amdahl V7 at the University of Reading.

RESULTS AND DISCUSSION

All attempts to prepare Schiff's base type complexes from DAF and primary amines such as ethylamine, aniline and n-butylamine failed to yield new products. In all cases DAF was recovered from the reaction mixtures. However, reactions did occur on replacement of the amines with substituted hydrazines (the phenyl and 2-pyridyl). In the latter case, glacial acetic acid was required for reaction to occur.

The Mössbauer data for the compounds prepared and DAF are presented in Table 1. The quadrupole splitting (QS) of 2.15(1) mm s^{-1} for DAF is in perfect agreement with the previously reported value[14] and indicates that the acetyl groups are electron-withdrawing. The QS increases however when the =O is replaced by either =NNHPh or =NNhPyH$^+$, but the values are still lower than ferrocene itself (QS = 2.37 mm s^{-1}) indicating that electron-withdrawal is still occurring, although to a lesser extent. We have previously shown there to be a linear correlation between QS and oxidation potential.[15] The increase in QS indicates a decrease in the oxidation potential for **1** and **2** compared to DAF.

However, electrochemical investigations revealed these complexes to be unsuitable as redox ligands. Preliminary cyclic voltammetry studies showed that chemical reactions were taking place in solution. In order to identify the reaction products, a controlled potential electrolysis (CPE) experiment was undertaken. CPE of **1** in MeCN at +0.8 V resulted in a dark brown solid which was analysed by Mössbauer spectroscopy. The resulting spectra showed two sites; a ferrocenyl site (86%) and a high-spin iron(II) site ($\delta \sim 1.24$ mm s^{-1}, $\Delta \sim 3.46$ mm s^{-1}) (14%). There was no evidence of a ferrocinium type site. In order to establish if this was an electrochemical reaction, a control experiment was carried out in which a sample of **1** was dissolved in MeCN under N_2 and stirred. Isolation of the resulting solid gave a Mössbauer spectrum very similar to that of the CPE study, indicating that **1** is not stable in solution even under N_2. This was a disappointing result with regard to our initial objectives.

Furthermore, all attempts to prepare metal complexes of **1** and **2** failed to yield well characterized materials. Reaction of **1** with zinc acetate, $ZnCl_2$, $Tl(ac)_2$, $CuCl_2$, $HgCl_2$, $NiCl_2 \cdot 6H_2O$ and $AgNO_3$ were tried. Analysis via ^{57}Fe Mössbauer spectroscopy (for selected data see Table 1) revealed at least two species in the isolated materials; commonly a ferrocenyl site (which sometimes matched those of the starting material although in one case (with $CuCl_2$) the parameters clearly matched those of DAF indicating hydrolysis had occurred), and one or more new sites with parameters around $\delta = 0.49$ mm s^{-1} and $\Delta = 0.82$ mm s^{-1}. These parameters are characteristic of an iron(III) species,[16] but unlike ferrocinium,[17] the most obvious oxidation product. Also the colour, brown, and the fact that under conditions where the only possible oxidant was oxygen, the site was still present would suggest that the species is not a ferrocinium type complex and is a decomposition product of the ferrocenyl moiety. Both **1** and **2** were sensitive to moisture and turned orange–brown (and **1** turned black on one occasion) on standing in air. Mössbauer spectroscopy of these latter materials revealed these samples to contain sites similar to those found with metal salts.

These results would indicate that oxygen is necessary for the formation of the iron(III) materials seen and tentatively suggest them to be μ-oxo iron(III) species,[18] especially as the spectra of these iron(III) species nearly always exhibited symmetric doublets.

The crystal and molecular structure of **2**

Table 2 contains selected bond distances and angles for **2**. The asymmetric unit consists of two independent $[FeC_{24}N_6H_{26}]^{2+}$ cations (A and B) and four independent $[CH_3CO_2^-]_2$ anions. Figure 1 shows the set of the three ions for the salt (A set shown) and includes the numbering sequence. Figure 2 shows a view of a $[C_{12}H_{13}N_3]$ fragment, hydrogen bonded to one acid molecule. Table 3 lists the O···N distances for this pairing. The O···N

distances to the pyridine nitrogen are the shorter, within the range 2.58(2)–2.66(2) Å, with the corresponding distances to the aliphatic NH being in the range 2.94(2)–2.98(2) Å. The hydrogen bond scheme was compatible with the electron density observed in a difference Fourier map. For six of the eight linkages, the hydrogen atom was clearly identified bonded to the nitrogen atom; for the other two [N(30) and N(8B)], a peak was located closer to the nitrogen atom than to the oxygen atom but slightly further than the correct bonding distance. Figure 3 shows a profile view of the ferrocenyl cation alone to demonstrate the relative orientations of the Cp and pyridinium planes (see Table 4). In the acetate group all bond lengths are typical.[19–21]

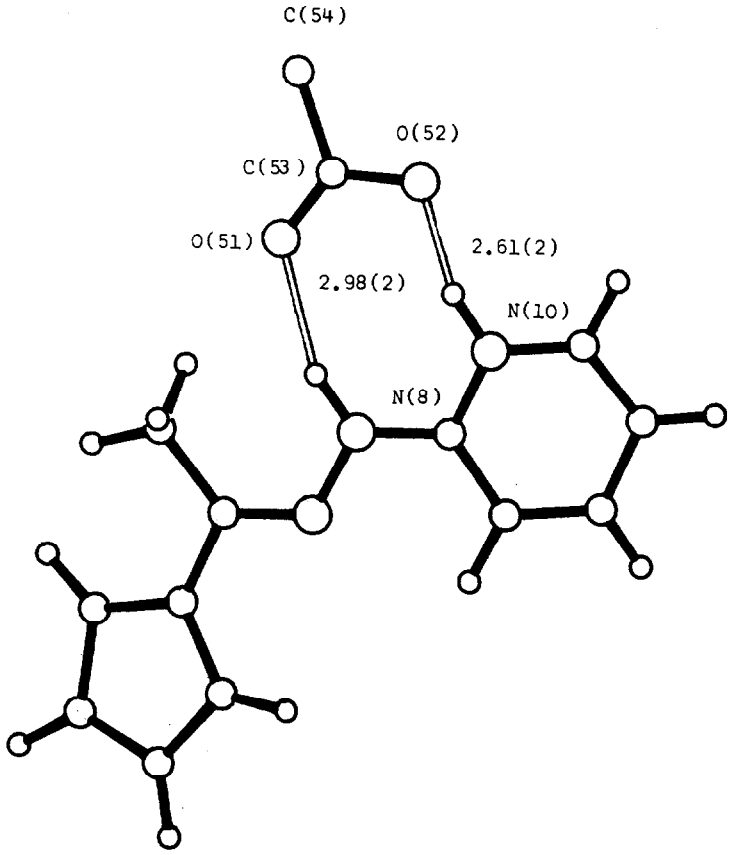

Fig. 2. View of the $[C_{12}H_{13}N_3]$ fragment hydrogen bonded to one acid anion. Hydrogen bonds are shown as unshaded lines.

As is apparent from Fig. 2, the $[FeC_{24}N_6H_{26}]^{2+}$ $[CH_3CO_2^-]_2$ grouping has approximately C_2 symmetry. The Fe—C distances are as expected for a ferrocene derivative,[22] ranging from 2.026(15) to 2.135(17) Å. The two Cp rings are staggered (all *trans* C—Fe—C angles are within 4° of 180°). This is quite unusual for a ferrocene derivative. We have surveyed a large number of substituted ferrocenes and have found the most common configuration to be eclipsed.[22] Previous studies of 1,1′-disubstituted ferrocenes, such as diacetylferrocene[23] and ferrocenedicarboxylic acid,[24] have

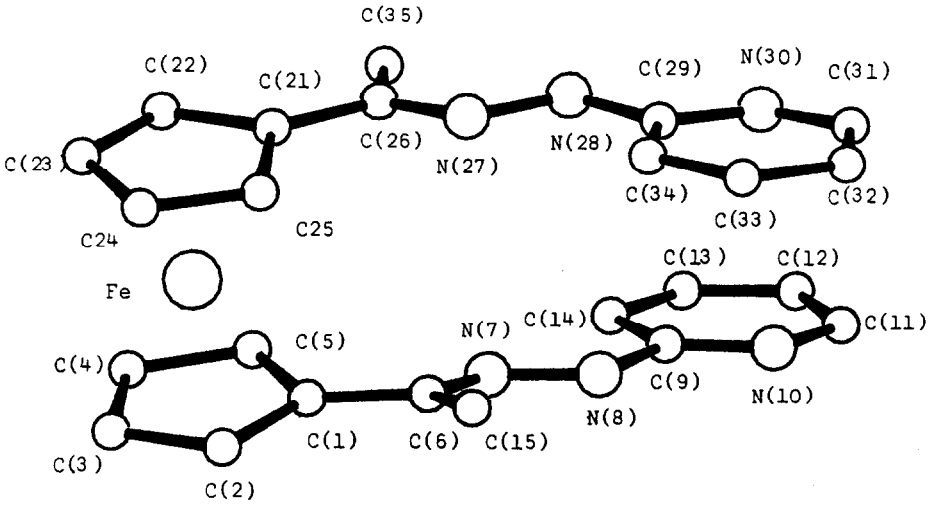

Fig. 3. Profile view of $[FeC_{24}N_6H_{26}]^{2+}$ showing the atomic numbering scheme.

eclipsed conformations with twist angles of 4.7° for the former and 1.6° for the latter.

The cyclopentadienyl rings in both molecules A and B are planar, as are the pyridine rings (see Table 3). The ring-tilt between the two Cp rings is small at 1.6 and 2.4° in A and B, respectively, giving a mean of 2.0°. The two pyridine rings are inclined at 10.3 and 2.2° with respect to each other for A and B. The angle α between the plane defined by the Cp and pyridine rings of each side chain exhibits a wide range, from 13.1 to 30.6°. The largest pair of angles are present in molecule A, with angles of 19.5 and 30.6°. There appears to be little chemical non-equivalence between the two substituent arms and hence these differences are probably due to packing forces.

Palenik *et al.*[25] have reported the structures of 5-hydroxy-2-formylpyridine thiosemicarbazone (5OH2FPTSC) and acetone thiosemicarbazone (ATSC). It is interesting to note that the former compound exhibits an *E* configuration as does the hydrazone prepared here. These authors also compared these structures with other semicarbazones and semicarbazides.[25] They showed that ATSC and various semicarbazides had a significantly longer average N(1)—N(2) bond length at 1.404(8) Å than did the semicarbazones (excluding ATSC) at 1.372(3) Å. They attributed the shortening as being due to the interaction of the N—N bond with the group attached to the sp^2 carbon of the C=N bond, concluding that aryl thiosemicarbazones could be treated as extensively delocalized systems.

Table 5 lists the structural parameters found by Palenik *et al.*,[25] with the corresponding distances for **2**. All the bond lengths and angles in **2** are typical, although the N—C bond at 1.377 Å is clearly the longest in the series and may reflect the fact that sulphur and not carbon is present as the terminal atom in the side chain of the thiosemicarbazones.

The average N—N distances of 1.384 Å in **2** indicates some interaction with the Cp ring, which is in accordance with the view of Palenik *et al.*[25] However, this is at the upper limit for such distances and suggests that the interaction is small.

^{13}C *NMR data*

The ^{13}C NMR data for the hydrazones and parent hydrazines appear in Table 6. The assignments of the phenyl resonances in the phenylhydrazones were made using the known additivity factors.[26] A similar approach was used for the 2-pyridyl carbons.[27] For the latter, good agreement was found between the observed and calculated shifts for the neutral pyridinyl substituent. This finding is at variance with the X-ray structure which shows an acetate molecule bound to hydrogens of the pyridinium and secondary amine nitrogen atoms. Such binding, however, must be weak and is disrupted in polar solvents such as acetone.

The cyclopentadienyl carbons C(3),C(4) (β) are deshielded relative to the C(2),C(5) (α) carbons, indicating electron-withdrawal by the hydrazone substituent. The β position in ferrocene shows similar effects to the *para* position in benzene,[28] the chemical shifts of which appear to be largely controlled by charge density. The C(3),C(4) resonances are about 2 ppm upfield from those of diacetylferrocene,[29] which supports the conclusion from the Mössbauer data that electron-withdrawal by the hydrazino group is less than that for the acetyl group. For the ferrocenylphenylhydrazone, the shift of the *para* [C(4)′] carbon is almost identical to that of phenylhydrazine itself, which suggests

Table 6. ^{13}C chemical shifts of hydrazones[a]

that the lone pair on the nitrogen atom of the secondary amine is not appreciably delocalized around the imine grouping. One point of particular interest is the geometry of the imine group. The above X-ray analysis clearly shows an *E* configuration. It has been demonstrated[30] that the stereochemistry of the imino group can be unambiguously determined in solution by the ^{13}C shifts of the carbon atoms in the α-position to the imine (in our case the methyl group). Thus hydrazones of *E* geometry have the α-carbon shifted upfield by 12–15 ppm relative to the parent ketone, whereas a *Z* geometry causes only a 3–6 ppm upfield shift. For both ferrocenylhydrazones in this study upfield shifts of about 14 ppm are found, showing that the *E* geometry is preserved in solution.

CONCLUSIONS

The instability of the hydrazones of DAF, reported here, precludes their use as organometallic ligands. This instability was not due to hydrolysis, resulting in DAF, as might have been expected, but the formation of an iron(III) product, which was not a ferrocinium type complex. We tentatively suggest, from Mössbauer data, that these species are μ-oxo iron(III) complexes. More importantly, however, these hydrazones did not show promise as ligands. Also, they did not appear to undergo the typically reversible ferrocene–ferrocinium oxidation, the second feature we were trying to achieve for the complexes. We note that while this manuscript was in preparation, reports of lanthanide complexes of the condensation products of formylferrocene and ferrocenylformyl acetone with benzoylhydrazine[31] and ethylenediamine,[32] respectively, were made. However, neither study investigated the possible redox behaviour of the complexes. In the latter case[32] Mössbauer data were reported and the QS for the series ranged from 2.24 to 2.27 mm s^{-1}. These values are relatively low and would indicate a high potential for the ferrocenyl oxidation in these complexes. We are continuing to investigate suitable redox-active ligands.

Abstract—The inelastic neutron scattering (INS) spectrum of $[(\mu_2\text{-H})_2Os_3(CO)_{10}]$ has been recorded; bands due to M—H vibrations are clearly seen and evidence has been found for a direct interaction between the two hydrogen ligands.

Inelastic neutron scattering (INS) has long been used as a tool in the study of metal–hydrogen interactions in bulk metal hydrides[1] but, apart from an early communication by White and Wright,[2] the technique has not been exploited in the investigation of hydrido-ligands in transition metal cluster complexes. This is somewhat surprising, given the difficulties encountered in investigating M—H modes using IR and Raman spectroscopy due to their inherently weak intensities and large band widths. Conventionally, the detection and assignment of such bands relies on their preferential sharpening at lower temperature.[3] Even with such sharpening, however, overlap with other bands is still considerable, making band assignment and detailed modelling formidable tasks.

The triosmium cluster, $[(\mu_2\text{-H})_2Os_3(CO)_{10}]$, is unusual in that it contains 46 valence electrons and, consequently, is one of the relatively few examples of an unsaturated, low nuclearity cluster. Both single crystal X-ray and neutron diffraction studies have been carried out[5] and show that the central triangular osmium core contains one Os—Os distance which is considerably shorter (264 pm) than the other two (288 pm). This short edge is spanned

by the two bridging hydrogen ligands and as such provides a rare example of a μ_2-H bridging system of the type observed in the molecular structure of diborane. We now wish to provide information which we believe provides evidence for a substantial H—H interaction of the type recently found for a number of mononuclear dihydrogen complexes.

In Fig. 1 is shown the INS spectrum of $[(\mu_2\text{-}H)_2Os_3(CO)_{10}]$ which has been obtained on the TFXA spectrometer at the ISIS pulsed neutron facilities of the Rutherford Appleton Laboratory. The physics of the neutron scattering process in general, and the "intensity optimized" nature of TFXA in particular, means that the only motion expected to be represented strongly in this spectrum is that due to the hydrogen atoms.[4] From previous work on hydrido-clusters,[6,7] we expect to and indeed do find modes in the 600–1600 cm^{-1} region; these are due mainly to M—H vibrations. In addition, there are two strong INS bands below *ca* 650 cm^{-1}. These bands are found at frequencies normally associated with M—C stretching and carbonyl bending vibrations (650–300 cm^{-1}); and M—M stretches and metal–carbon deformations (< 250 cm^{-1}), respectively. However, they are expected to couple with the M—H vibrations, thereby gaining intensity and consequently appearing in these regions of the INS spectrum. Lastly, the weak features found near 1400 cm^{-1} and above 1600 cm^{-1} may be assigned to overtones and combinations arising from the main M—H vibrations.

Quantitative calculations are in progress using the data analysis package CLIMAX, specially developed for INS spectra,[8] and the results have indicated the following noteworthy points.

(i) In the analysis of the M—H vibrations, interactions between the hydrogen ligands are found to be very important. For example, if such interactions are ignored then the two strongest peaks seen in the INS spectrum at *ca* 650 cm^{-1} would be expected to collapse into one. These interactions have been quantitatively modelled to provide an excellent fit with the INS data. Significantly, it is this observation which provides the first, clear example of H—H interactions of the type recently found in mononuclear dihydrogen complexes. These interactions are also of interest in the modelling of the behaviour of hydrogen on metal surfaces.

(ii) The bands below *ca* 650 cm^{-1} should allow a detailed investigation of hydrogen dynamics in response to carbonyl motion. This could have important implications for those interested in hydrogen migration in hydrido-clusters and in modelling the bulk–metal hydride bond[9] using hydridocarbonyl cluster compounds.

(iii) The availability of data on combinations and overtones will enable us to build up a detailed model of the anharmonic hydrogen local potential, which will eventually allow comparison with work along a similar direction on hydrogen potentials in bulk metals.[10]

We have also measured the INS spectrum of $[(\mu_2\text{-}H)_4Os_4(CO)_{12}]$ (Fig. 2). Although the structure of this material is known and μ_2-bridging hydrido-ligands suggested from a consideration of the Os—Os bond lengths,[11] the positions of the hydrogen atoms have not been resolved with certainty. Bearing in mind that INS is primarily a probe of local hydrogen dynamics, the striking similarity of the spectra of $[(\mu_2\text{-}H)_2Os_3(CO)_{10}]$ and $[(\mu_2\text{-}H)_4Os_4(CO)_{12}]$ immediately supports the assignment of μ_2-bridging hydrido-ligands to this structure. Detailed analysis of this spectrum using CLIMAX is also in progress.

In summary, we have shown that the technique

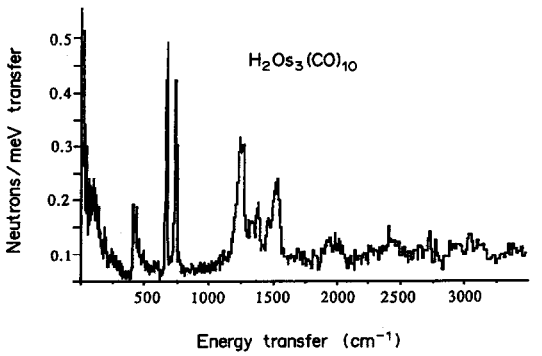

Fig. 1. The inelastic neutron scattering spectrum of $[(\mu_2\text{-}H)_2Os_3(CO)_{10}]$. The strongest bands in the 600–1600 cm^{-1} region are due to Os—H vibrations. Other bands are assigned in the text.

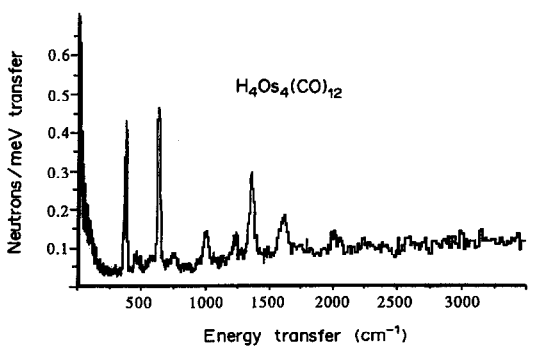

Fig. 2. The inelastic neutron scattering spectrum of $[(\mu_2\text{-}H)_4Os_4(CO)_{12}]$. The similarity with the spectrum in Fig. 1 strongly suggests the presence of μ_2-bridging hydrido-ligands in this material.

of INS spectroscopy is extremely useful in the detection and assignment of vibrational modes in hydridocarbonyl metal clusters. In particular we have indicated that, in $[(\mu_2\text{-H})_2Os_3(CO)_{10}]$, the interactions between the two hydrogen ligands are important and can be modelled quantitatively.

NEW SYNTHETIC PATHWAYS INTO THE ORGANOMETALLIC CHEMISTRY OF GALLIUM

MALCOLM L. H. GREEN,* PHILIP MOUNTFORD, GEOFFREY J. SMOUT and S. ROBERT SPEEL

Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3AQ, U.K.

(*Received* 23 *July* 1990; *accepted* 4 *September* 1990)

Abstract—Ultrasonic irradiation of gallium metal with di-iodine and alkyl iodides, RI, rapidly gives high yields of $[RGaI_2]$ via a reactive intermediate material "GaI". "GaI" also inserts into the metal–iodine bonds of $[Fe(\eta\text{-}C_5H_5)(CO)_2I]$ and $[Mo(\eta\text{-}C_5H_4Me)(CO)_3I]$ as witnessed by the synthesis of $[Fe(\eta\text{-}C_5H_5)(CO)_2Ga(\eta^1\text{-}C_5H_4Me)_2\cdot$pyridine] and $[Mo(\eta\text{-}C_5H_4Me)(CO)_3GaI_2\cdot Et_2O]$, whose crystal structures have been determined.

We report an improved and very convenient synthesis for monoalkylgallium di-iodide compounds $[RGaI_2]$. Previous routes to these compounds have involved the exchange reaction between the reactive and costly Me_3Ga and GaI_3,[1] or prolonged thermal reaction (1–2 weeks) between Ga and I_2 or thermally prepared "GaI" with RI.[2] A metal vapour synthesis route gave mixtures of the mono- and di-alkylated derivatives.[3]

We have found that sonication of liquid gallium metal with di-iodine and alkyl iodides (RI) rapidly gives high yields of the monoalkylgallium di-iodides $[RGaI_2]$. Typically, gallium metal (0.70 g, 10 mmol), di-iodine (1.27 g, 5 mmol) and the alkyl halide (*ca* 2 cm^3) in toluene (10 cm^3) were sonicated under N_2 using a Heat-Systems Ultrasonics cell disruptor direct immersion horn sonicator, supplying *ca* 375 W, 20 kHz.[4]

The mixture was warmed to melt the gallium (m.p. 30°C) before sonication. Upon sonication the gallium metal dispersed, the initially purple mix becoming first grey and then, after 2–8 min, turning into a colourless solution. Recrystallization of the products from toluene gave high yields of white crystalline $[RGaI_2]$ [**1(a)**; R = Me (70%) (**b**); R = Et (82%) (**c**); R = ^{n}Pr (80%) (**d**); R = ^{i}Pr (55%) (**e**); R = ^{n}Bu (90%) (**f**); R = n-pentyl (76%); **1e**, **1f** liquid at room temperature]. Cryoscopic molecular weight determinations in *p*-xylene for **1a–c** indicate a degree of association of 1.6–1.9 (for *ca* 0.06–0.3 M in monomer equivalents).

Many Lewis adducts are known for alkylgallium dichlorides,[5] but adducts of $[RGaI_2]$ are confined largely to those of $MeGaI_2$ with R′SH (R′ = Me, Et, ^{n}Pr and ^{t}Bu).[6] Therefore, we have explored further reactions of $[RGaI_2]$.

Treatment of **1a–f** with Lewis bases [Et_2O, THF, pyridine, acridine, PMe_3, PPh_3, $P(OPh)_3$ and $AsPh_3$] gave 1:1 adducts, characterized by ^{1}H NMR and IR spectroscopy and mass spectrometry, all adducts showing a band near 540 cm^{-1} in the IR spectrum associated with ν(Ga—C). The adducts of **1b** with PPh_3 and $AsPh_3$ dissociate on subjection to EI mass spectrometry, but cryoscopic molecular weight determinations in *p*-xylene showed them to be essentially monomeric in this solvent.

Sonication of gallium metal and di-iodine in toluene in the absence of alkyl iodide gave a pale green powder "GaI" (**2**). This material is surprisingly reactive and behaves as a monovalent gallium system. Thus treatment of **2** with excess RI and stirring at room temperature overnight or sonicating for a few minutes gave the monoalkylgallium di-iodides (**1**). Treatment of **2** with toluene solutions of tetrahydrofuran or PPh_3 gave apparent disproportionation to products that analysed as $GaI_2\cdot$THF and $GaI_3\cdot PPh_3$, respectively,

* Author to whom correspondence should be addressed.

together with the corresponding quantity of gallium metal.*

The "GaI" prepared by sonication has a powder diffraction pattern that does not correspond either to that reported previously by Corbett or Chadwick and their co-workers,[7,8] or to those for low-valent gallium iodides reported by Gerlach *et al.*[9] It may, however, be similar to the thermally-prepared "GaI" of Wilkinson and Worral, which they showed to contain at least Ga, Ga_2I_3 and Ga_2I_4 by Raman spectroscopy.[2] Their "GaI" reacted much more slowly than our sonicated "GaI" with RI, possibly due to particle size effects. We were interested to see whether "GaI" (**2**) would undergo oxidative addition reactions with metal–iodine bonds. Room temperature reaction with [Fe(η-C_5H_5)$(CO)_2$I] and recrystallization of the product from ether gave [Fe(η-C_5H_5)$(CO)_2GaI_2\cdot(Et_2O)_n$] (**3a**). A similar but heated reaction of **2** with [Mo(η-C_5H_4Me)$(CO)_3$I] gave large amber crystals of [Mo(η-C_5H_4Me)$(CO)_3GaI_2\cdot Et_2O$] (**4a**). [Mo(η-C_7H_7)$(CO)_2$I] and [Mo(η-C_5H_4Me)$(CO)_3]_2$ gave [Mo(η-C_7H_7)$(CO)_2GaI_2\cdot$THF] (**5**) and [(Mo(η-C_5H_4Me)$(CO)_3)_2$GaI] (**6**) by essentially analogous reactions. The adducts **3a** and **4a** readily lose some ether, although the last traces are retained tenaciously. As with the simple alkylgallium di-iodides, both **3a** and **4a** readily undergo displacement of Et_2O to form 1 : 1 adducts with pyridine (**3b**, **4b**).

Treatment of **3a** with 2 equivalents of NaC_5H_4Me followed by reaction with pyridine

4a: 4.72 (d, 4H, η-C_5H_4Me), 3.80 (q, 4H, $(MeCH_2)_2O$), 1.59 (s, 3H, η-C_5H_4Me), 0.92 (t, 6H, $(MeCH_2)_2O$). **4b**: 9.03 (d, 2H, pyridine), 6.42 (t, 1H, pyridine), 6.16 (t, 2H, pyridine), 4.91, 4.84 (AA′, BB′, 4H, η-C_5H_4Me), 1.69 (s, 3H, η-C_5H_4Me).

5: 4.69 (s, 7H, η-C_7H_7), 3.95 (t, 2H, THF), 1.21 (m, 2H, THF).

6: 4.88, 4.77 (AA′, BB′, 4H, η-C_5H_4Me), 1.47 (s, 3H, η-C_5H_4Me).

7: 8.28 (d, 2H, pyridine), 6.71 (t, 1H, pyridine), 6.43 (br. s, 4H, η^1-C_5H_4Me), 6.41 (br., 2H, pyridine), 5.74 (br. s, 4H, η^1-C_5H_4Me), 4.35 (s, 5H, η-C_5H_5), 2.25 (s, 6H, η^1-C_5H_4Me).

gives pale diamond-shaped crystals of [Fe(η-C_5H_5)$(CO)_2$Ga(η^1-$C_5H_4Me)_2$·pyridine] (**7**) in modest yield.

The crystal structures of **4a** (Fig. 1) and **7** (Fig. 2) have been determined* and they confirm the presence of a transition metal–gallium bond in each compound. The Ga—Fe bond length of 2.4272(9) Å in **7** is comparable to those in [$(CH_2{=}CH)$Ga(THF)$Fe(CO)_4]_2$ of 2.510(1) and 2.521(2) Å.[10]

In conclusion, we have shown that sonication is a most convenient way of making alkylgallium diiodides. Sonochemically-produced "GaI" behaves as a highly-reactive monovalent gallium system and can provide a new route to compounds containing transition metal–gallium bonds.

*Crystal data for **4a**: $C_{13}H_{17}GaI_2MoO_4$, crystal dimensions *ca* $0.3\times0.4\times0.5$ mm, triclinic, space group $P\bar{1}$, $a = 12.570(5)$, $b = 10.049(14)$, $c = 11.919(18)$ Å, $\alpha = 138.47(7)$, $\beta = 91.12(7)$, $\gamma = 94.31(7)°$, $3 \leqslant 2\theta \leqslant 46°$, $V = 988.9$ Å^3, $D_c = 2.209$ g cm^{-3}, $Z = 2$, $\mu = 50.84$ cm^{-1}, $F(000) = 612$, $R = 0.068$, $R_w = 0.061$ for 2071 observed reflections [$I > 3\sigma(I)$].

Crystal data for **7**: $C_{24}H_{24}FeGaNO_2$, crystal dimensions *ca* $0.2\times0.2\times0.4$ mm, triclinic, space group $P\bar{1}$, $a = 9.828(2)$, $b = 10.134(3)$, $c = 12.955(7)$ Å, $\alpha = 121.29(3)$, $\beta = 96.34(3)$, $\gamma = 90.13(2)°$, $3 \leqslant 2\theta \leqslant 48°$, $V = 1093.1$ Å^3, $D_c = 1.474$ g cm^{-3}, $Z = 2$, $\mu = 19.15$ cm^{-1}, $F(000) = 496$, $R = 0.045$, $R_w = 0.057$ for 2303 observed reflections [$I > 3\sigma(I)$].

Data were collected using an Enraf–Nonius CAD4-F diffractometer employing graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). The heavy-atom positions were located using direct methods and the other non-hydrogen atoms located from subsequent difference syntheses. The structures were refined using full-matrix least-squares procedures with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were placed in calculated positions (C—H = 0.96 Å) with an isotropic thermal parameter of 1.3 times that of their supporting carbon atom, and refined riding on that carbon atom. Crystallographic calculations were carried out using the Oxford CRYSTALS package.[11] Atomic coordinates, bond lengths and angles, observed and calculated structure factors, and thermal parameters have been deposited at the Cambridge Crystallographic Centre.

1. INTRODUCTION

This review is mostly concerned with the chemistry of a class of coordinatively unsaturated cluster complexes of platinum and, to a lesser extent, palladium, and with a study of the relationship of this chemistry to that which is known or thought to occur on a platinum surface during chemisorption and catalysis. The relationship of the chemistry of coordinatively unsaturated clusters† with the chemistry of a metal surface was not fully appreciated until about 15 years ago.[1,2] Prior to this, the development of organometallic chemistry and heterogeneous catalysis had proceeded much more independently of one another, but it is remarkable how platinum has played a dominant role in both fields. A brief historical outline to illustrate this point is given below.

1.1. *Historical perspective*

The phenomenon now known as catalysis was first reported by H. Davy who observed the flameless combustion of coal gas in the presence of a platinum wire in 1817. The first commercial application of catalysis was in Dobereiner's lighters, which were based on his observation of the spontaneous combustion of hydrogen in the presence of a finely divided platinum catalyst in 1823. From such modest beginnings, heterogeneous platinum metal catalysis is now of major significance. Some applications still involve combustion catalysis and related effects, with applications in catalytic converters, afterburners and heaters for example, but there are also major uses in the oxidation of ammonia and in the reforming (platforming) of petroleum for fuels and petrochemicals.[3]

Just as platinum was the first heterogeneous catalyst discovered, so it was also a constituent of the first organometallic compound to be reported. The compound was Zeise's salt $K[PtCl_3(C_2H_4)]$ which was discovered in 1827, just 10 years after Davy's discovery and 9 years before Berzelius in 1836 coined the term catalysis to describe this new phenomenon.[3,4] The first metal carbonyl was also a platinum complex, $[\{PtCl_2(CO)\}_n]$, prepared by Schutzenberger in 1868. Alkylplatinum and hydridoplatinum complexes were prepared by Chatt in the 1950s, and it was in this period also that the bonding in Zeise's salt and related compounds was described in the general terms which are now used. The mechanisms of many reactions of organoplatinum complexes have been determined and have contributed to our understanding of the mechanisms of homogeneously catalysed reactions.

It is now recognized that chemisorption and the reactions occurring in heterogeneous catalysis are forms of coordination chemistry and organometallic chemistry of the metal surface. There are analogies with transition metal chemistry both in terms of the reactions involved and the structures of the surface species. For example, in terms of reactions of metal surfaces and complexes, respectively, non-dissociative chemisorption is like coordination, and dissociative chemisorption is like oxidative addition.[1,2,5] When carbon monoxide binds to a platinum(111) surface, it can bind at on-top (terminal) or two-fold (doubly bridging) sites and perhaps also at three-fold (triply bridging) sites; the surface mobility of carbon monoxide is due to easy migration between these sites (Fig. 1).[6,7] Such metal–carbonyl bonding modes are also common in metal cluster complexes, and the mobility of carbon monoxide on metal surfaces is analogous to carbonyl fluxionality.[1,2,5] Similarly, the dissociative chemisorption of dihydrogen on a metal surface is analogous to the oxidative addition of dihydrogen to a metal cluster complex. In each case, the H—H bond is cleaved and the resulting hydrogen atoms usually bind in bridging positions between two or three metal atoms.[1,2] Many other examples will be considered below.

1.2. *The chemical problems and strategy*

1.2.1. *Coordinatively unsaturated clusters.* In designing coordinatively unsaturated clusters to mimic surface reactions, the late transition elements and particularly rhodium, iridium, palladium and platinum are most attractive since, in the lower oxidation states, these elements often form

† For the purpose of modelling surface reactions it is advantageous to have all metal atoms in the cluster complex coordinatively unsaturated but, in more general terms, a single site of coordinative unsaturation is all that is required.

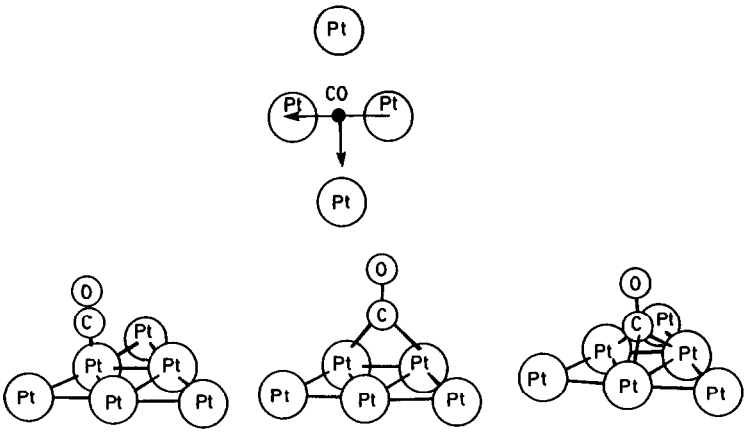

Fig. 1. The binding modes of carbon monoxide on a platinum(111) surface and, above, a top view indicating how a small motion can transform a doubly bridging CO to a terminal or triply bridging CO.

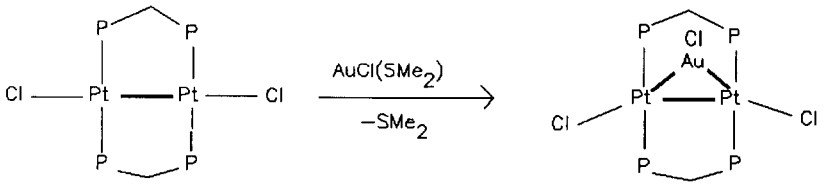
complexes in which the metal has the 16-electron configuration.[4] For example, the square planar mononuclear d^8 complexes have a vacant p_z orbital, and this feature is often carried over to the binuclear and cluster complexes of these elements. In contrast, the transition elements in the centre of the periodic table usually adopt the 18-electron configuration and their cluster complexes are usually coordinatively saturated [e.g. $Os_3(CO)_{12}$] or have a single site of unsaturation [e.g. $Os_3H_2(CO)_{10}$].[8–10] Cobalt and nickel also tend to form coordinatively saturated clusters.[11] The coordinatively unsaturated binuclear and cluster complexes of rhodium and iridium have played an important rôle in the mimicry of surface reactions,[1,2,12–17] but this review will treat only such complexes of palladium and platinum.

1.2.2. *Preventing cluster fragmentation.* The major problem in developing the cluster–surface analogy with the late transition elements is that the metal–metal bonds in their binuclear or cluster complexes are not sufficiently robust to resist cluster fragmentation during many chemical reactions.[18–23] The first studies of platinum clusters were made by Chatt and Chini, who found that the clusters $[Pt_3(\mu\text{-}CO)_3L_4]$ reacted with excess phosphine ligand (L) to give the mononuclear complexes $[Pt(CO)L_3]$ or $[PtL_4]$.[18] Nevertheless, despite this problem, an impressive chemistry of the clusters $[M_3(\mu\text{-}L)_3L'_3]$ and $[M_3(\mu\text{-}L)_3L'_4]$, where L = CO or SO_2 and L′ = tertiary phosphine, has been developed in which the cluster nuclearity is maintained or increased,[18–23] and much of this chemistry has been reviewed.[19,20,24] For example, Farrar and coworkers showed that, with bulky phosphine ligands, the complexes $[Pt_3(\mu\text{-}CO)_3L_3]$ undergo phosphine ligand exchange at a rate much greater than the rate of cluster fragmentation, and that the reactions proceed by reversible formation of $[Pt_3(\mu\text{-}CO)_3L_4]$.[21] Mingos and coworkers showed that carbonyl groups of these cluster complexes could be replaced by sulphur dioxide to give $[Pt_3(\mu\text{-}SO_2)_3L_3]$, while isocyanides could displace both the carbonyl and the phosphine ligands.[19,22,25] The electron-rich clusters $[Pt_3(\mu\text{-}CO)_3L_3]$ can also act as Lewis bases, forming complexes to Lewis acids such as M^+, LM^+ (M = Cu, Ag, Au, L = phosphine ligand), Hg or Hg^{2+};[26–31] examples of the product clusters are $[Au\{Pt_3(\mu\text{-}CO)_3(PPh_3)_3\}_2]^+$ and $[Pt_3(\mu_3\text{-}AuPCy_3)(\mu\text{-}CO)_3(PCy_3)_3]^+$. This combination of electrophilic and nucleophilic character of the platinum(0) clusters is promising in terms of catalytic behaviour. There are excellent accounts of structure and bonding in these complexes, which rationalize their dual character.[32–35]

In order to stabilize cluster complexes with respect to fragmentation, it is desirable to use bridging ligands which bind more strongly than the μ-CO, μ-RNC, μ-SO_2 or μ-H ligands which are typically present in palladium and platinum cluster complexes.[19,20] The ligand $Ph_2PCH_2PPh_2$, dppm, has proved to be one of the most useful bridging groups and its use in stabilizing binuclear complexes has been reviewed.[36–38] It is important to note here that much of the chemistry of the binuclear complexes $[M_2Cl_2(\mu\text{-dppm})_2]$, M = Pd or Pt, can be considered to mimic the chemistry occurring at a two-fold site on a metal surface. Many small unsaturated molecules insert into the metal–

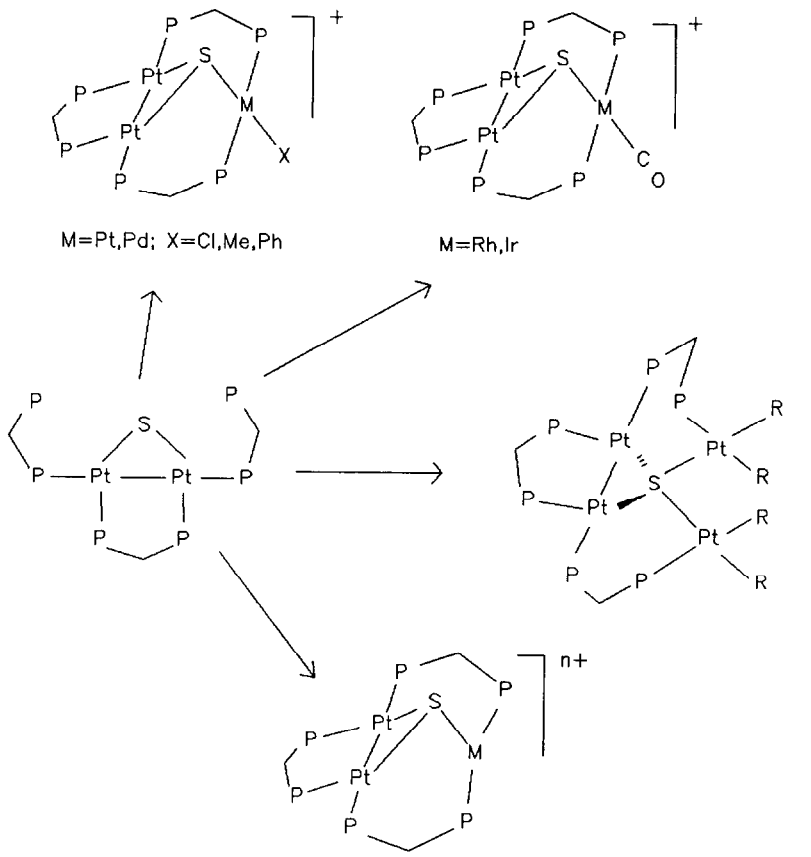
metal bond, and the metal centres are susceptible to attack by both nucleophilic and electrophilic reagents.[36–38] Where the nucleophile or electrophile is metal-centred, these reactions can lead to formation of heteronuclear cluster complexes (eq. 1).[39–45]



(1)

More robust Pt_3 and Pt_2M clusters could be prepared by reaction of $[Pt_2(\mu\text{-S})(\mu\text{-dppm})(\eta^1\text{-dppm})_2]$ with suitable Lewis acids, as shown in Scheme 1. The product complexes contain a μ_3-S or μ_4-S bridge as well as three μ-dppm ligands, and are therefore inert towards fragmentation. A typical structure is shown in Fig. 2.[46] However, these complexes were inert towards reaction with most organic ligands and attempts to form additional metal–metal bonds in the clusters were unsuccessful.[47]

Fortunately, the strategy of locking three metal atoms together in a triangle by μ-dppm ligands to give reactive, coordinatively unsaturated clusters was ultimately successful and this review describes the chemistry which has been developed so far.



Scheme 1. R = Me or Ph.

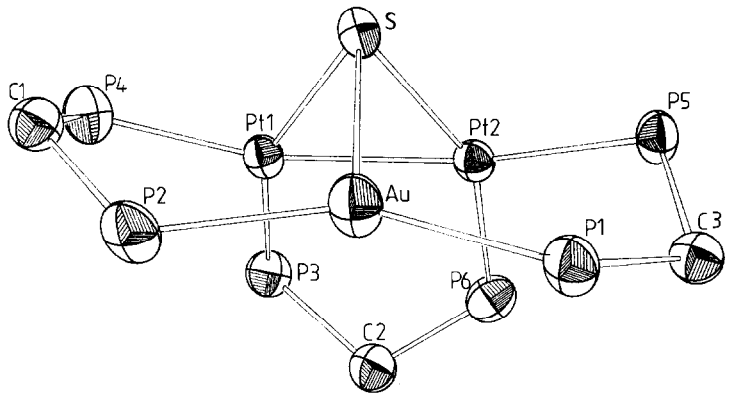


Fig. 2. A view of the $[Pt_2Au(\mu_3\text{-}S)(\mu\text{-}dppm)_3]^+$ cation. Distances are Pt—Pt = 2.61(1) Å, and Pt—Au = 3.25(1) and 3.11(1) Å. The Pt—Au distances are non-bonding.

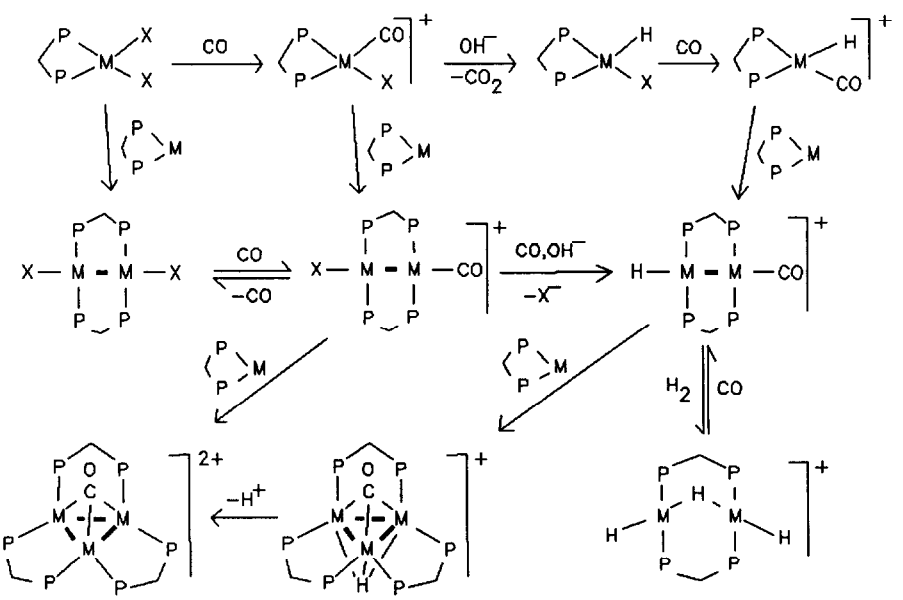
2. THE SYNTHESIS OF COMPLEXES $[M_3(\mu_3\text{-}CO)(\mu\text{-}DPPM)_3]^{2+}$

The cluster complex cations were prepared by reaction of $[M(O_2CCF_3)_2(dppm)]$ with carbon monoxide in aqueous acetone, according to eq. (2), M = Pd or Pt, X = CF_3CO_2:

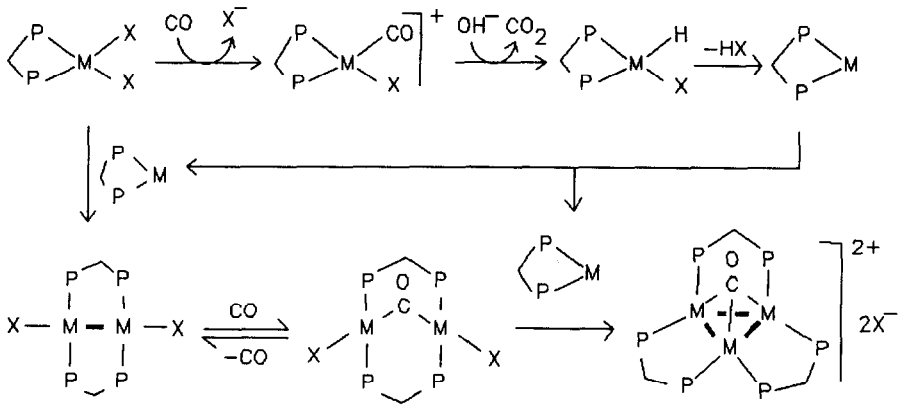
$$3[MX_2(dppm)] + 3CO + 2H_2O \longrightarrow [M_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]X_2 + 4HX + 2CO_2. \quad (2)$$

For M = Pd, the reaction occurs at room temperature[48,49] but, for M = Pt, a temperature of 100°C is needed.[50] When M = Pd, the reaction was shown to proceed by way of dipalladium(I) intermediates $[Pd_2(O_2CCF_3)_2(\mu\text{-}dppm)_2]$ and $[Pd_2(\mu\text{-}CO)(O_2CCF_3)_2(\mu\text{-}dppm)_2]$.[49] For M = Pt, the major intermediate species was the diplatinum(I) hydride $[Pt_2H(CO)(\mu\text{-}dppm)_2]^+$. This reaction mixture gave efficient catalysis of the water gas shift reaction and, when much H_2 was produced, the complex hydride $[Pt_2H_3(\mu_3\text{-}dppm)_2]^+$ was also identified in the reaction mixture.[51] For M = Pt, the reduction was studied for a wider variety of ligands $R_2PCH_2PR_2$. The clusters $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}R_2PCH_2PR_2)_3]^{2+}$ were formed when R = Ph, 4-MeC_6H_4 or 3,5-$Me_2C_6H_3$, but reduction led only to $[Pt_2H(CO)(\mu\text{-}R_2PCH_2PR_2)_2]^+$ when R = 2-MeC_6H_4, probably due to steric hindrance by the 2-MeC_6H_4 substituents.[51]

The mechanism of reaction is believed to involve formation of shortlived M^0(dppm) species according to Scheme 3, followed by sequential reaction to give the binuclear and trinuclear complexes according to Scheme 2 (M = Pt) and Scheme 3 (M = Pd).[49,51]



Scheme 2.



Scheme 3.

Finally, reduction does not always stop at the M_3 stage. When M = Pt, further reduction can occur to give $[Pt_4(\mu\text{-H})(\mu\text{-CO})_2(\mu\text{-dppm})_3(\eta^1\text{-dppm})]^+$ which can be oxidized to give $[Pt_4(\mu\text{-H})(\mu\text{-CO})_2(\mu\text{-dppm})_3\{Ph_2PCH_2P(O)Ph_2\}]^+$ or $[Pt_4(\mu\text{-CO})_2(\mu\text{-dppm})_3\{Ph_2PCH_2P(O)Ph_2\}]$.[51–53] This step does not occur if the reduction of $[Pt(O_2CCF_3)_2(dppm)]$ is carried out in the presence of some free acid CF_3CO_2H.[54] Indeed, the Pt_4 clusters are decomposed by acid or by Ag^+ to give back the parent cation $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$.

The structure of a trinuclear complex, $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ (**1**), is shown in Fig. 3.[50] It contains a triangular Pt_3 cluster, with Pt—Pt distances [2.613(1), 2.638(1) and 2.650(1) Å] indicative of platinum–platinum single bonds (2.58–2.80 Å).[55–57] The edges of the Pt_3 triangle are spanned by three dppm ligands to form an approximately latitudinal (planar) Pt_3P_6 skeleton. One face of the Pt_3 triangle is capped by a carbonyl group coordinating the metal centres in a symmetrical triply bridging mode [Pt—C 2.080(9), 2.089(8) and 2.095(9) Å]. This is the first example of a cluster complex containing a $Pt_3(\mu_3\text{-CO})$ group. Even the largest platinum clusters studied previously contain only terminal and μ_2-CO ligands.[19,20] In **1**, the bulky phenyl and methylene groups of the dppm ligands form a fence around each face of the latitudinal Pt_3P_6 skeleton, so that the metal centres are easily accessible only from above and below the Pt_3 plane. This structural feature, illustrated in Fig. 4,[58] is retained in many crystallographically characterized adducts of **1** with small molecules and ions.

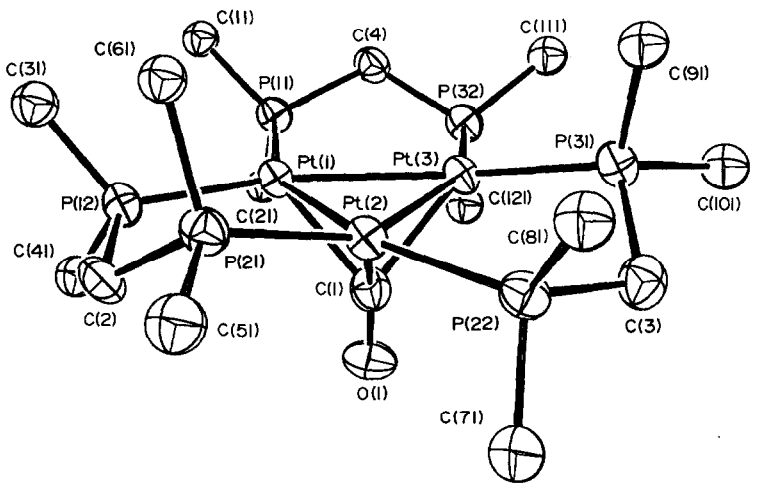


Fig. 3. A view of the $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ cation. In each phenyl ring only the carbon atom attached to phosphorus is shown. Reproduced by permission from *Organometallics* 1986, **5**, 345.

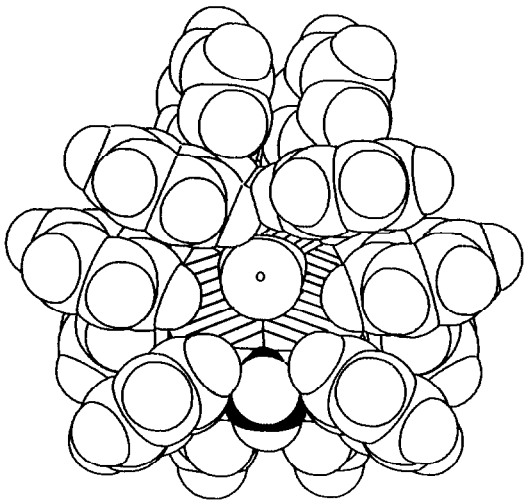

Fig. 4. A space-filling model of the $[Pt_3(SCN)(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^+$ cation showing the steric environment of the μ_3-CO group which lies in a cavity bounded by six phenyl groups. Platinum atoms are cross-hatched and methylene carbon atoms are shaded. Reproduced by permission from *Inorg. Chem.* 1986, **25**, 4192.

3. STRUCTURE AND BONDING IN THE CLUSTER CATIONS

The bonding in $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ has been modelled, using EHMO analysis, by considering it to be formed from a planar (latitudinal) Pt_3L_6 unit and CO^{2+}. Calculations have been based on $Pt_3(CO)_6$ and $Pt_3(\mu\text{-}H_2PCH_2PH_2)_3$ units as models for the $Pt_3(\mu\text{-}dppm)_3$ unit,[33,35] and a typical MO correlation diagram is given in Fig. 5.[35] The highest energy filled orbitals a_1 and e are

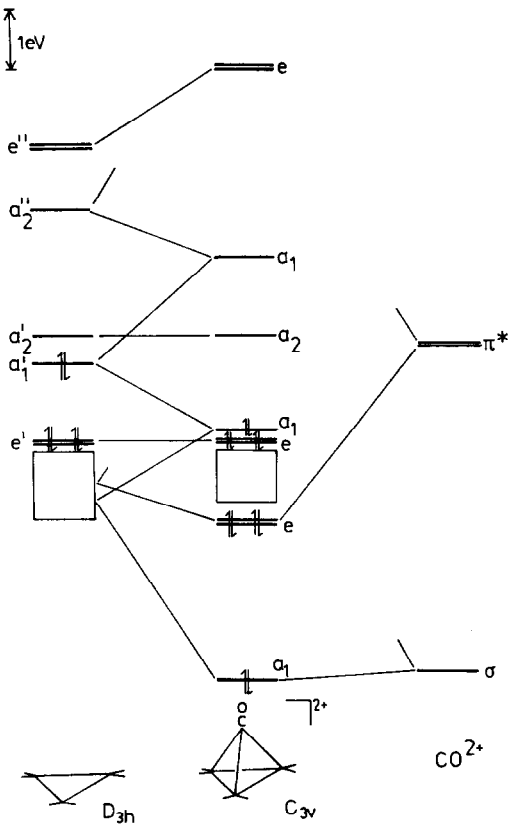

Fig. 5. An interaction diagram for the $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ cation, considering it to be formed from $[Pt_3(\mu\text{-}dppm)_3]$ and CO^{2+}.

metal–metal bonding and are analogous to the Walsh orbitals in cyclopropane. These are the orbitals which will be used when the cluster interacts with Lewis acids. Of the lowest energy unoccupied orbitals, a_2 is metal–metal antibonding while a_1 and e are combinations derived mostly from the empty $6p_z$ orbital on each platinum atom and therefore have mostly metal–metal non-bonding character. Since Lewis bases will normally approach from below the Pt_3L_6 plane, the initial interaction will be with the a_1 or e levels of the cluster and this should not affect the metal–metal bonding to a great extent. However, if a ligand can migrate to an edge of the cluster and hence interact with the metal–metal antibonding orbital a_2, cleavage or weakening of a metal–metal bond is expected to occur.[32–35]

It is, of course, the presence of the empty $6p_z$ orbitals (a_1 and e) on platinum which gives the clusters their coordinatively unsaturated character. In terms of electron counting, the $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ cluster has 42 electrons in the valence shell and, in principle at least, it could reach coordinative saturation by adding three extra 2-electron donor ligands to give the 48-electron count. In practice, one or two ligands can be added to give 44e, 46e and perhaps even 48e clusters, as discussed in the next section.

4. COORDINATION CHEMISTRY OF THE CLUSTERS

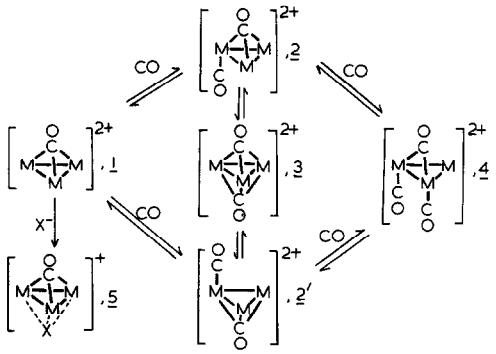
In this section, the chemistry of the cluster complexes $[M_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$, M = Pd or Pt, with 2-electron and 4-electron donor ligands will be described. It will be seen that added ligands can bind at terminal or bridging sites on the M_3 triangle and that they can influence the mode of coordination of the carbonyl ligand. There are some unique forms of fluxionality of these complexes, and the mechanism of ligand substitution in the clusters is made clear by the direct study of the adducts.

4.1. *Reactions with carbon monoxide*[59]

This chemistry is illustrated in Scheme 4.

The clusters **1**, M = Pd or Pt, add carbon monoxide rapidly and reversibly to give **2** or **3** and, when M = Pt, a second carbonyl can be added to give **4**. Exchange between all these species was rapid on the NMR time scale at room temperature, but the equilibria involving addition or loss of carbon monoxide could be frozen out at −80°C. However, for the 1 : 1 adduct, the NMR spectra indicated that the molecule had D_{3h} symmetry even at −90°C, and hence suggested structure **3**, whereas the IR spectra indicated that both terminal and bridging carbonyls were present and hence suggested structure **2**. It was therefore proposed that fluxionality involving **2** ⇌ **3** is rapid even at −90°C. EHMO calculations suggest very similar energies for **2** and **3**, consistent with the experimental observations.[35]

This work is significant for two reasons. Firstly, it shows how terminal, μ_2 and μ_3 carbonyl groups can be close in energy when coordinated to a Pt_3 triangle, and that the resulting fluxionality can mimic the easy migration of CO on a platinum surface.[6,7] Secondly, the sequence of reactions **1** ⇌ **2** ⇌ **3** ⇌ **2′** ⇌ **1** of Scheme 4 illustrates very clearly how carbonyl substitution can occur very easily by reversible addition of carbon monoxide. Indeed exchange of carbon monoxide in **1** by ^{13}CO occurs very rapidly at room temperature.[59]



Scheme 4.

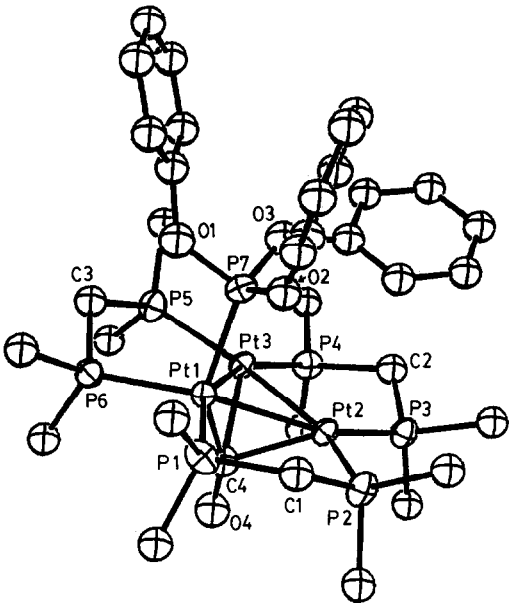


Fig. 6. The structure of the $[Pt_3(\mu_3\text{-CO})\{P(OPh)_3\}(\mu\text{-dppm})_3]^{2+}$ cation.

4.2. *Reactions with phosphine and phosphite ligands*[60,61]

The cluster $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ adds monodentate phosphine or phosphite ligands (L) to give $[Pt_3(\mu_3\text{-CO})L(\mu\text{-dppm})_3]^{2+}$ (**5**), and the structure of the adduct with $L = P(OPh)_3$ is shown in Fig. 6. This structure reveals that the phosphite ligand adds to a single platinum centre, Pt(1). It is also interesting to note that the carbonyl ligand is no longer in a symmetrical μ_3-bridging mode, but is bound more strongly to Pt(1) than to the other two platinum atoms. Pertinent bond lengths are shown in Table 1. They can be rationalized by considering that CO^{2+} acts as an acceptor ligand for the Pt_3L_7 fragment so that it binds preferentially to the most electron-rich platinum centre, i.e. to the PtL_3 centre. As can be seen in Fig. 6, the adducts are sterically crowded and their formation

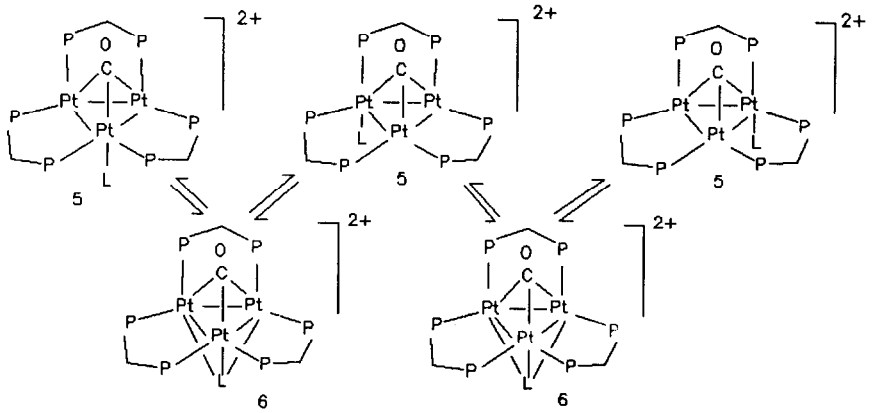
[a] As discussed in the text, these complexes may be considered to have 48 electrons counts if the halide acts as a 6-electron ligand.

[b] There is Cl—CO disorder, and the two sets of Pd—C distances correspond to two positions of the disordered CO ligand.

[c] One $CF_3CO_2^-$ oxygen weakly binds to Pd(1) [Pd(1)—O(1) 2.83 Å], and the other bridges Pd(2)—Pd(3) [Pd(2)—O(2) 2.77 Å, Pd(3)—O(2) 2.92 Å].

becomes less favourable for more sterically demanding phosphines. The limit appears to be reached with PPh_3 which forms a complex in solution at −90°C. At room temperature, however, this complex is essentially fully dissociated.

A remarkable property of these complexes is that the added ligand L can migrate around the Pt_3 ring, according to eq. (3), at a rate fast enough to cause NMR fluxionality. The transition state is thought to be the triply bridged species **6**. For the adduct with $L = PF_3$, the NMR spectrum, even at −90°C, is that expected for a complex with three-fold symmetry and it is possible that bridging PF_3 groups could be present in the ground state.[61] These are the first observations of phosphine fluxionality in transition metal cluster complexes.[62] The ligands PH_3 and PF_3 are also thought to bind as terminal ligands when adsorbed onto platinum(111) or nickel(111) surfaces.[63]

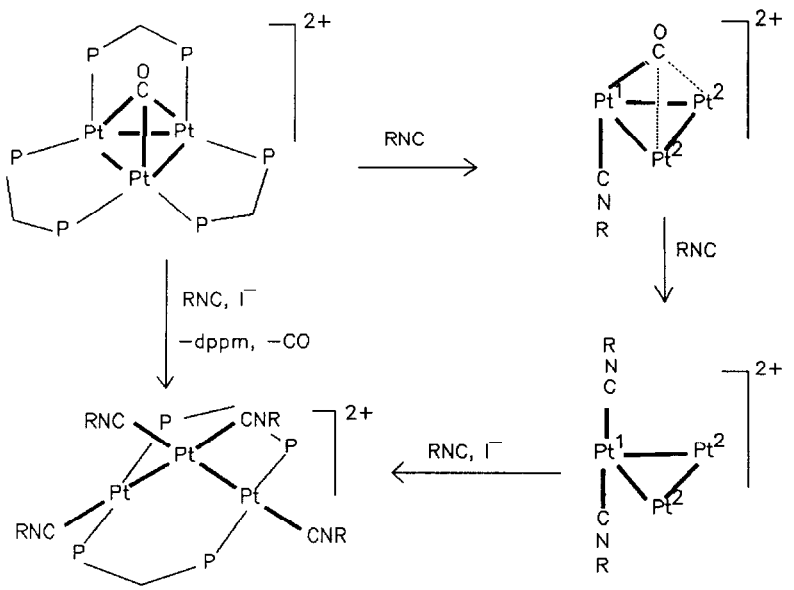


(3)

4.3. *Reactions with isocyanide ligands*[64]

The chemistry of the bulky isocyanide ligands RNC, R = t-Bu, Cy or 2,6-$Me_2C_6H_3$, with the platinum cluster **1** is shown in eq. (4). Again, the first equivalent of RNC adds as a terminal ligand, but a second equivalent may then displace the carbonyl ligand.

Remarkably, the product contains two terminal isocyanide ligands bound to the same platinum atom, as shown in Fig. 7. These molecules may also exhibit fluxional behaviour, of the type described for the phosphine adducts. In terms of the surface analogy, MeNC is adsorbed onto platinum(111) in a mixture of terminal (linear MeNC) and μ_2 (bent MeNC) bonding modes.[64] In neither the surface nor the cluster reactions is there evidence for the presence of $Pt_3(\mu_3\text{-CNR})$ groups, except possibly as intermediates in the fluxional process.



(4)

4.4. *Reactions with* SnX_3^- *ligands*

Like the isocyanides, the anions SnX_3^-, X = F^- or Cl^-, can form 1 : 1 adducts with $[Pt_3(\mu_3\text{-}CO)(\mu\text{-dppm})_3]^{2+}$ and can also add a second equivalent with replacement of carbonyl.[65,66] However, unlike the phosphines or isocyanides, the SnX_3^- ligands bind to the Pt_3 cluster in a triply bridging

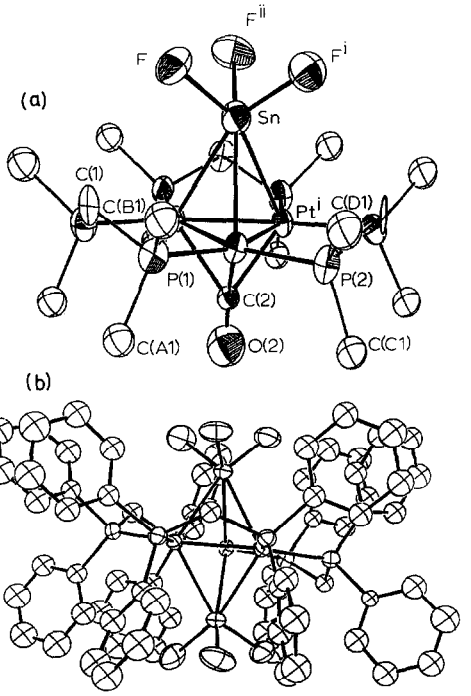

Fig. 8. The structures of μ_3-SnF_3 complexes. (a) $[Pt_3(\mu_3\text{-}CO)(\mu_3\text{-}SnF_3)(\mu\text{-dppm})_3]^+$. Reproduced by permission from *J. Chem. Soc., Chem. Commun.* 1989, 161. (b) $[Pt_3(\mu_3\text{-}SnF_3)_2(\mu\text{-dppm})_3]$.

mode to form trigonal bipyramidal $Pt_3(\mu_3\text{-}CO)(\mu_3\text{-}SnX_3)$ and $Pt_3(\mu_3\text{-}SnX_3)_2$ linkages in $[Pt_3(\mu_3\text{-}CO)(\mu_3\text{-}SnF_3)(\mu\text{-}dppm)_3]^+$ and $[Pt_3(\mu_3\text{-}SnF_3)_2(\mu\text{-}dppm)_3]$ (Fig. 8). The $Pt_3(\mu_3\text{-}Sn)$ linkages in $[Pt_3(\mu_3\text{-}CO)(\mu_3\text{-}SnF_3)^-(\mu\text{-}dppm)_3]^+$ and $[Pt_3(\mu_3\text{-}SnF_3)_2(\mu\text{-}dppm)_3]$ are essentially covalent, the Pt—Sn bond lengths [2.699(2)–2.830(2) Å] lying within the accepted range for platinum–tin single bonds (2.6–2.8 Å).[67,68]

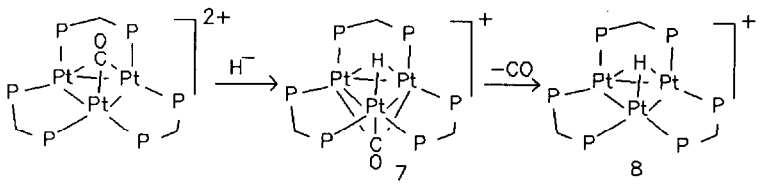
A complex in which SnX_3^- is the only triply bridging ligand $[Pt_3\{\mu_3\text{-}SnMe_2(O_2PF_2)\}(\mu\text{-}dppm)_3]^+$ was prepared in a different way, by reaction of Me_2SnH_2 with $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3][PF_6]_2$.[65] The structure of this complex [Pt—Sn 2.702(3)–2.766(2) Å] is closely similar to that of the parent cation (Fig. 3), from which it can be considered derived by replacement of the carbon monoxide ligand by a $SnMe_2(O_2PF_2)^-$ ion.

It is noteworthy that the ligands PR_3 and SnX_3^- are isolobal and yet they give quite different ground state structures on addition to $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$. The ground state structure of the tin complexes, containing a $Pt_3(\mu_3\text{-}CO)(\mu_3\text{-}SnX_3)$ unit, probably corresponds to the transition state (**6**) for fluxionality of the phosphine and phosphite complexes [eq. (3)].

It is possible to use the above results to predict that SnX_3^- ligands will bind at triply bridging sites on a platinum surface, and that such groups may be present in some important heterogeneous bimetallic platinum, tin catalysts.[65]

4.5. *Reaction with hydride*[69]

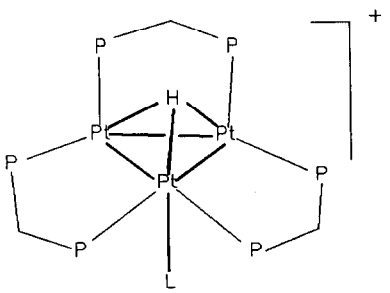
This reaction occurs according to eq. (5), the source of H^- being $Na[BH_4]$. Whilst there is little doubt that complex **8** has the structure shown, with an unusual $Pt_3(\mu_3\text{-}H)$ group, the structure of **7** is less certain. The NMR spectra at low temperature indicate three-fold symmetry and hence structure **7**, but the IR spectrum has $\nu(CO) = 1982\ cm^{-1}$ which suggests a terminal carbonyl group. Given the easy fluxionality of several related complexes, as discussed previously, it is obviously possible that **7** has a structure of lower symmetry in the ground state, such as $[Pt_3(\mu_3\text{-}H)(CO)(\mu\text{-}dppm)_3]^+$, where the carbonyl ligand is terminal.



(5)

The complex **8** readily undergoes inversion of the $Pt_3(\mu_3\text{-}H)$ group and it has been suggested that this occurs by way of a planar $Pt_3(\mu_3\text{-}H)$ transition state. This is then related to the mechanism by which hydrogen atoms are thought to migrate from the surface to the bulk phase in metallic platinum or palladium. Hydrogen atoms on the platinum(111) surface may be present as PtH, $Pt_2(\mu_2\text{-}H)$ or $Pt_3(\mu_3\text{-}H)$ groups, but $Pt_3(\mu_3\text{-}H)$ groups are most stable.[70]

The hydride complex **8** can also add phosphite ligands to give the complexes $[Pt_3(\mu_3\text{-}H)L(\mu\text{-}dppm)_3]^+$ with $L = P(OR)_3$; R = Me, Et or Ph. Evidence from NMR spectroscopy indicates the structure **9**, with an asymmetric $Pt_3(\mu_3\text{-}H)$ bridge. Again, the stronger bond of hydrogen to the platinum atom with the highest coordination number can be rationalized by considering the complex to be formed from Pt_3L_7 and H^+, with the proton binding most strongly to the most electron-rich metal centre.[71]



9

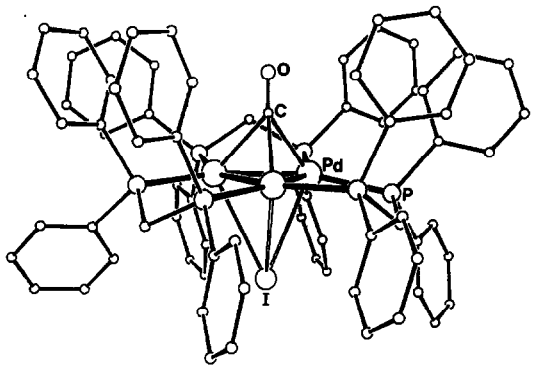


Fig. 9. The structure of the cation $[Pd_3(\mu_3\text{-}I)(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^+$.

4.6. *Reactions with halide and related ligands*[72,73]

The complexes $[M_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ with M = Pd or Pt add halide ligands to give $[M_3(\mu_3\text{-}CO)X(\mu\text{-}dppm)_3]^+$ and, for M = Pd, the halide is triply bridging, as illustrated by the structure of Fig. 9.[72] The complexes readily undergo halide for halide substitution reactions. The structures of the palladium adducts with X = Cl or I, characterized crystallographically, show that the halide occupies the second capping site of the Pd_3 triangle and thus completes a trigonal bipyramidal $Pd_3(\mu_3\text{-}X)(\mu_3\text{-}CO)$ unit (Fig. 9).[72,73] The finer structural details of this unit are obscured in the chloride adduct by μ_3-CO/Cl disorder. However, in the iodide adduct, which is not disordered, the iodide ligand is roughly equidistant from the metal atoms, with Pd—I distances of 2.951(1), 3.031(1) and 3.083(1) Å. These distances are substantially longer than those considered typical of normal Pd—I σ-bonds (about 2.6 Å).[74,75] It is then possible that the $Pd_3(\mu_3\text{-}I)$ interaction is largely electrostatic in origin, although weak covalent character is indicated by the UV–vis spectra. A $\mu_3\text{-}X^-$ ligand could be considered as a 6-electron donor and, on that assumption, the complexes $[M_3(\mu_3\text{-}X)(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^+$ would have a coordinatively saturated 48-electron configuration. Ligand addition does not much affect the Pd—Pd distances as shown by the data in Table 1.

The pseudohalide SCN^- also forms 1 : 1 adducts with the complexes $[M_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$.[58] However, in $[Pt_3(SCN)(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^+$ the thiocyanate acts as a terminal ligand (Figs 10 and 4), as is obvious from the Pt—S [2.656(4) Å] and Pt···S [3.243(4) and 3.380(4) Å] distances, which can be compared with those normally found for covalent Pt—SCN bonds (2.3–2.4 Å).[76] Addition of the terminal SCN^- ligand, which occupies a longitudinal position with respect to the Pt_3 triangle,

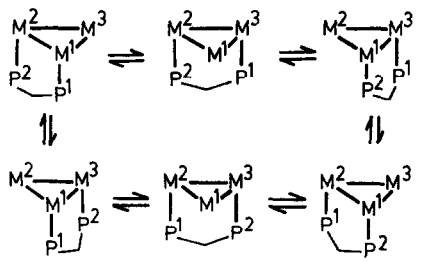
causes a slight slippage of the μ_3-CO ligand towards the SCN^- substituted platinum atom, as is evident from the Pt—C bond lengths shown in Table 2. The rapid fluxionality of this complex, observed even at −80°C, indicates that the terminal $\rightleftharpoons$ μ_3-thiocyanate transformation occurs very easily.

4.7. *Reactions with diphosphine ligands*[77,78]

The complexes $[M_3(\mu\text{-CO})(\mu\text{-dmpm})_4]^{2+}$, M = Pt or Ni, dmpm = $Me_2PCH_2PMe_2$, are prepared by reaction of $[Pt_2(\mu\text{-dmpm})_3(PPh_3)]$ with carbon dioxide and water, or by reduction of nickel(II) salts with $NaBH_4$ in the presence of carbon dioxide and dmpm, respectively.[77,78] They can be considered as adducts of the unknown clusters $[M_3(\mu_3\text{-CO})(\mu\text{-dmpm})_3]^{2+}$ with the bidentate ligand dmpm. The arrangement of the fourth dmpm ligand and the carbonyl group, with respect to the latitudinal $M_3(\mu\text{-dmpm})_3$ fragment in the two adducts, is shown in Fig. 11. In both complexes the fourth dmpm ligand is bonded to the M_3 cluster in an edge-bridging longitudinal mode. The carbonyl ligand forms a distorted μ_3-CO bridge in the nickel complex,[78] but in the platinum complex it acts primarily as a μ_2-ligand bridging the same platinum atoms to which the fourth longitudinal dmpm ligand is also attached (a semi-bridging interaction with the third platinum centre is possible).[77] In both cases the carbonyl binds most strongly to the metal centres with highest coordination number. This is consistent with the explanation given for distortions in monodentate phosphine adducts in section 4.2. The complex $[Ni_3(\mu_3\text{-CO})(\mu\text{-dmpm})_4]^{2+}$ is the first example of a 46-electron Ni_3 cluster; nickel clusters are usually coordinatively saturated.

Whilst $[Pt_3(\mu\text{-CO})(\mu\text{-dmpm})_4]^{2+}$ adopts a rigid structure,[77] the nickel analogue is fluxional in the sense that the fourth dmpm ligand can migrate around the Ni_3 triangle as shown in eq. (6).[78] More remarkable is the observation that $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ can reversibly add a fourth dppm ligand to give $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_4]^{2+}$. This complex, which must be subject to very severe steric effects, is fluxional even at −90°C, as shown by eq. (6).[79]



(6)

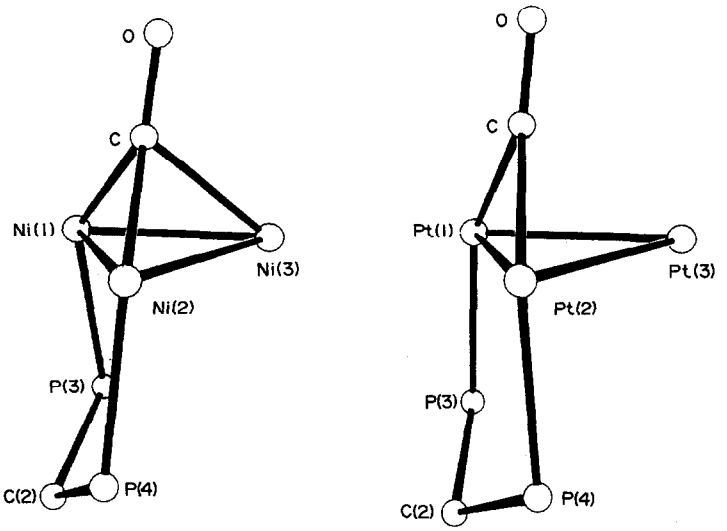


Fig. 11. The structures of the cations $[Ni_3(\mu\text{-CO})(\mu\text{-dmpm})_4]^{2+}$ and $[Pt_3(\mu\text{-CO})(\mu\text{-dmpm})_4]^{2+}$.

4.8. *Reactions with other bidentate ligands*[80]

The dithio ligands, $R_2NCS_2^-$ and R_3PCS_2, form similar complexes of formula $[Pt_3(\mu\text{-CO})(\mu\text{-}S_2CNR_2)(\mu\text{-dppm})_3]^+$ or $[Pt_3(\mu\text{-CO})(\mu\text{-}S_2CPR_3)(\mu\text{-dppm})_3]^{2+}$. From the structure of the adduct shown in Fig. 12, it is obvious that, on addition of N,N-dimethyldithiocarbamate to $[Pt_3(\mu_3\text{-CO})(\mu\text{-}$

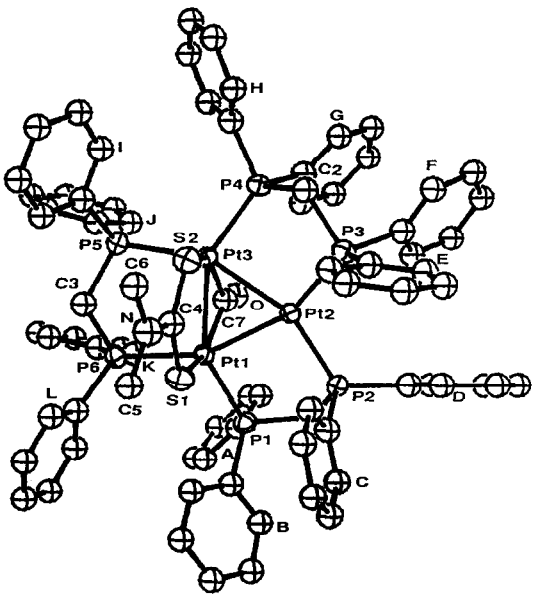

Fig. 12. The structure of the cation $[Pt_3(\mu\text{-CO})(\mu\text{-}S_2CNMe_2)(\mu\text{-dppm})_3]^+$.

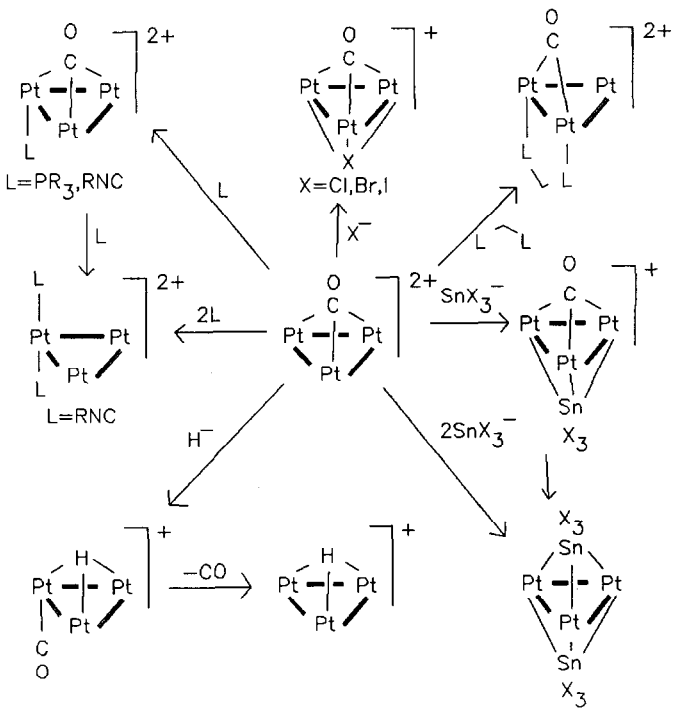
dppm)$_3$]$^{2+}$, the carbonyl ligand has slipped from the symmetrical μ_3-bonding mode to bridge two platinum atoms only, and they are the same atoms to which the μ-$S_2CNMe_2^-$ ligand is also bonded. Even at low temperature, the ^{31}P NMR spectra indicate three-fold symmetry and so fluxionality analogous to that of eq. (6) is obviously very easy in these complexes.

4.9. *Summary of coordination chemistry*

Molecular structures of many cluster complexes discussed above have been determined by X-ray crystallography. Selected structural data are presented in Tables 1 and 2. The coordination chemistry of the complexes with M = Pt is summarized in Scheme 5. It is now obvious that the complexes [$M_3(\mu_3$-CO)(μ-dppm)$_3$]$^{2+}$, M = Pd or Pt, can add one or two 2-electron donor ligands or a bidentate 4-electron donor ligand to give 44-electron and 46-electron clusters. When the additional ligand is a weakly bound halide or trifluoroacetate it can be argued that the cluster valence electron count may even reach 48-electron.

The complexes discussed so far contain a triangular M_3 cluster and a $M_3(\mu$-dppm)$_3$ fragment in which the M_3P_6 unit adopts a planar, latitudinal conformation. In most complexes the M_3 triangle is close to equilateral and, where small differences in the individual M—M bond lengths are observed, no correlation with the electronic properties of the cluster is usually obvious. Thus, in [$Pt_3(\mu_3$-CO)(μ-dppm)$_3$]$^{2+}$, where all three metal centres are electronically identical, the Pt—Pt distances vary from 2.613(1) to 2.650(1) Å, whereas in [Pt_3(SCN)(μ_3-CO)(μ-dppm)$_3$]$^+$, where the thiocyanate ligand interacts with one metal atom only, the Pt—Pt distances are virtually constant, at 2.620(1)–2.625(1) Å. However, the latitudinal M—P bonds tend to lengthen with increase in the coordination number of the metal atom. In [$Pt_3(\mu$-S_2CNMe_2)(μ-CO)(μ-dppm)$_3$]$^+$, for example, the Pt—P bonds range from 2.244(3) to 2.357(3) Å, the shorter bonds involving the four-coordinate platinum atom and the longer ones involving the two six-coordinate platinum atoms which are bridged by $S_2CNMe_2^-$ and carbon monoxide ligands. In the complexes [$M_3(\mu_3$-CO)(μ-dppm)$_3$]$^{2+}$ and their adducts with anionic ligands the mean Pt—P distances [2.28–2.29 Å] are slightly shorter than the mean Pd—P distances [2.31–2.32 Å], and this may reflect the harder acid character of palladium compared with that of platinum.[81]



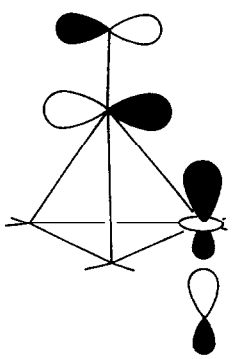
Scheme 5.

Of particular interest is the observation that the mean M—M bond lengths show little variation in these complexes. Thus, mean Pt—Pt distances vary only from 2.61 to 2.64 Å; mean Pd—Pd distances are slightly shorter, 2.59–2.60 Å, reflecting the difference in the Pauling metallic radii (Pt 1.295, Pd 1.283 Å).[82] It is therefore clear that the additional ligands bind to $[M_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ using the empty $6p_z$ orbitals of the metal atoms rather than empty metal–metal σ^* orbitals of the cluster, and this conclusion is supported by theoretical considerations.[33,35]

The additional ligands can interact with one, two or all three metal centres in the $[M_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ complexes (Scheme 5). Most monodentate ligands add as terminal groups, but the halides and SnX_3^- ligands form $M_3(\mu_3\text{-X})$ and $M_3(\mu_3\text{-SnX}_3)$ linkages. Isocyanide and SnX_3^- are also capable of replacing the carbonyl group.

The added ligands can affect the geometry of the $M_3(\mu_3\text{-CO})$ unit, and symmetrical μ_3-, asymmetrical μ_3- and symmetrical μ_2-bonding modes are all represented (Tables 1 and 2). The two extreme bonding modes are found in $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ and $[Pt_3(\mu_2\text{-S}_2\text{CNMe}_2)(\mu\text{-CO})(\mu\text{-dppm})_3]^+$, for example. In complexes where the additional ligands interact with one metal centre only, one short and two long M—C bonds are observed, the short bond involving the metal atom with higher coordination number. Similar slippage is apparent in the $[Pt_3(\mu_3\text{-H})(L)(\mu\text{-dppm})_3]^+$ complexes, where the hydride ligand binds more strongly to the platinum atom with higher coordination number.

The degree of slippage of the carbonyl group from the symmetrical μ_3-bridging mode, judged by the r.m.s. deviations of the M—C distances from their mean value (Tables 1 and 2), reflects the donor ability of the added ligand, increasing along the series $\mu_3\text{-I} < \mu_3\text{-}\eta^2\text{-}CF_3CO_2^- < SCN^- < P(OPh)_3$. The C—O bond lengths also appear to increase with donor ability of the added ligand, suggesting an increase in carbon monoxide π^* orbital occupancy, but this observation must be considered tentative in view of the high standard deviations for some of the observed C—O distances. We and Evans considered the carbonyl derivatives and suggested that π-backbonding to carbon monoxide was stronger from the platinum atom with higher coordination number as shown in **A** below, and that this effect led to the shorter Pt—CO distance involving the same platinum atom (Fig. 6).[35,58,77]



A

However, this rationalization obviously cannot be applied to the hydride derivatives. A more general, simple way to understand the observations is to consider that the complexes are formed by interaction of the $[Pt_3(L)(\mu\text{-dppm})_3]$ fragment with CO^{2+} or H^+, each of which has a vacant σ-acceptor orbital. Therefore the CO^{2+} or H^+ will bind preferentially to the platinum atom with highest electron density, i.e. the platinum atom with highest coordination number. The π-backbonding component in the Pt—CO bonding would then be a secondary effect, rather than the primary effect responsible for the observed distortions of the $Pt_3(\mu_3\text{-CO})$ group. The μ-CO bonding mode in the complexes $[Pt_3(\mu\text{-CO})(\mu\text{-LL})(\mu\text{-dppm})_3]^{2+}$ can be rationalized in an analogous fashion, i.e. by considering the CO^{2+} electrophile interacting with the hypothetical $Pt_3(\mu\text{-dppm})_3(\mu\text{-LL})$ unit.

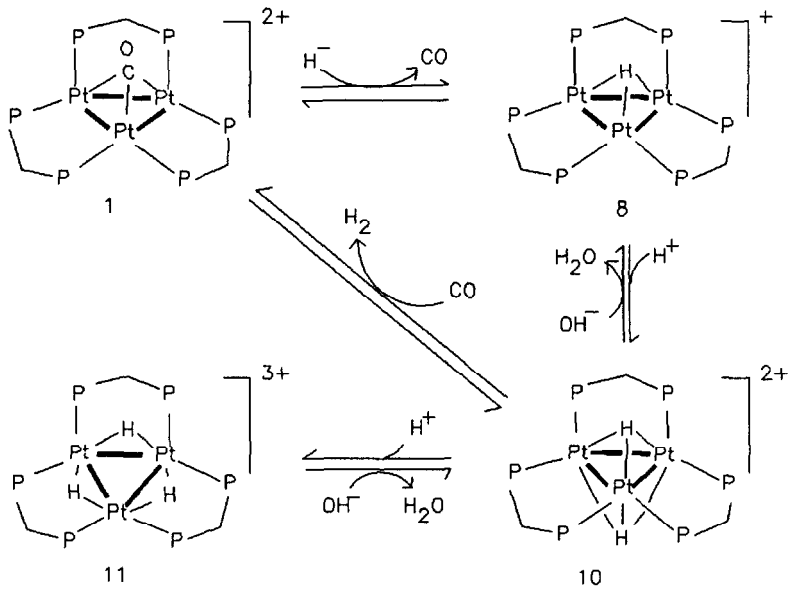
Finally, the ligand binding modes and fluxionality involving ligand migration between platinum centres are similar in many ways to the processes thought to occur on a platinum surface and, when known, the activation energies are also similar. In both the cluster and surface chemistry, the key

property in this respect is the similarity in the energies of the PtL, $Pt_2(\mu\text{-L})$ and $Pt_3(\mu_3\text{-L})$ groups. As an example, the activation energy for carbon monoxide migration on platinum(111) is estimated as 7 kcal mol^{-1}, while the activation energy for fluxionality can be estimated as < 10 kcal mol^{-1}.[7,59]

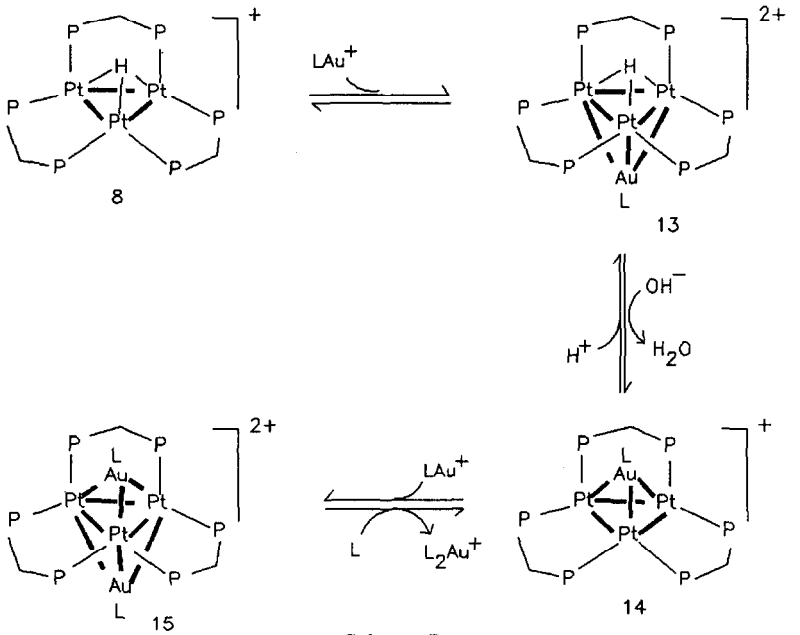
5. REACTIONS WITH ELECTROPHILES[83]

The cluster $[Pt_3(\mu_3\text{-H})(\mu\text{-dppm})_3]^+$ (**8**) can act as a base in reactions with electrophilic reagents, as illustrated in Schemes 6 and 7. It can add one proton to give $[Pt_3(\mu_3\text{-H})_2(\mu\text{-dppm})_3]^{2+}$ (**10**) and then another proton to give $[Pt_3(\mu_2\text{-H})_3(\mu\text{-dppm})_3]^{3+}$ (**11**). These reactions are reversible, so that addition of base gives back the parent cluster (Scheme 6).

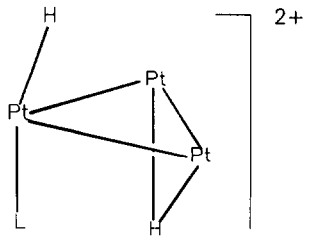
Complex **10** reacts with carbon monoxide with loss of H_2 to give back the cluster $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ but phosphine and phosphite ligands add to give $[Pt_3H_2(L)(\mu\text{-dppm})_3]^{2+}$, which are thought, on the basis of NMR studies, to have structure **12**.



Scheme 6.



Scheme 7.



12

The fragment LAu^+ is isolobal with H^+, and similar chemistry results from its reaction with $[Pt_3(\mu_3\text{-}H)(\mu\text{-}dppm)_3]^+$, as shown in Scheme 7. These reactions also give a clear picture of how electrophilic substitution reactions can occur at the Pt_3 face of the cluster, i.e. by addition of an electrophile at one face followed by loss of an electrophile from the other face.

In terms of electron-counting, addition or loss of H^+ or LAu^+ does not affect the formal coordinative unsaturation at the Pt_3 centre but, in complexes such as **10**, **13** or **15** in which both faces of the Pt_3 triangle are capped, both electrophiles are competing for the electron density of the same a_1 bonding orbital of the Pt_3 fragment, and so the ligands are more weakly bound than in complexes such as **8** or **14** in which only one face of the Pt_3 triangle is capped. This is shown by dramatic reductions in the coupling constants ^1J(PtH) or ^2J(PtAuP) for the bis(capped) clusters.[83]

6. REACTION WITH PLATINUM(0) COMPLEXES AND WITH MERCURY(0)[52,53,71]

The addition of electrophilic d^{10} gold fragments to the Pt_3 clusters leads to cluster expansion as shown in section 5, and it was of interest to compare the corresponding chemistry of nucleophilic d^{10} species such as platinum(0) complexes. The complex $[Pt(CO)_2L_2]$, L = PPh_3, reacts with $[Pt_3(\mu_3\text{-}H)(\mu\text{-}dppm)_3]^+$ to give $[Pt_4(\mu\text{-}H)(\mu\text{-}CO)_2(L)(\mu\text{-}dppm)_3]^+$. A similar complex with L = η^1-dppm is often a by-product during the synthesis of $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ (see section 2), and its formation probably occurs by addition of a platinum(0) fragment to a Pt_3 cluster. In both complexes the Pt_4 clusters have the butterfly structure, as shown in Fig. 13, which is expected for 58-electron clusters of platinum. The cluster can be considered to be formed from the $Pt(CO)_2L$ fragment acting as a 2-electron donor to the Pt_3 triangle of **1**, and in this sense it is an example of ligand addition (section 4). In this case, the extra platinum bridges an edge of the Pt_3 triangle and, consistent with the trend discussed in section 4, the hydride ligand moves to bridge the same edge. The Pt_4 complexes are fluxional and the mechanism shown in eq. (7) has been established. This fluxionality leads to effective

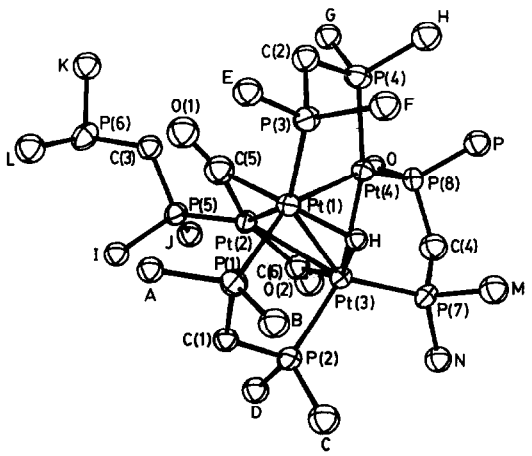


Fig. 13. The structure of the cation $[Pt_4(\mu\text{-}H)(\mu\text{-}CO)_2(\mu\text{-}dppm)_3(\eta^1\text{-}dppm)]^+$. For each phenyl ring only the carbon atom attached to phosphorus is shown. Reproduced by permission from *J. Chem. Soc., Chem. Commun.* 1988, 150.

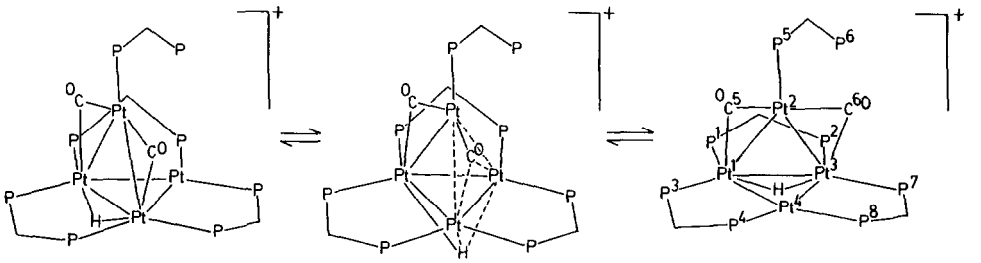
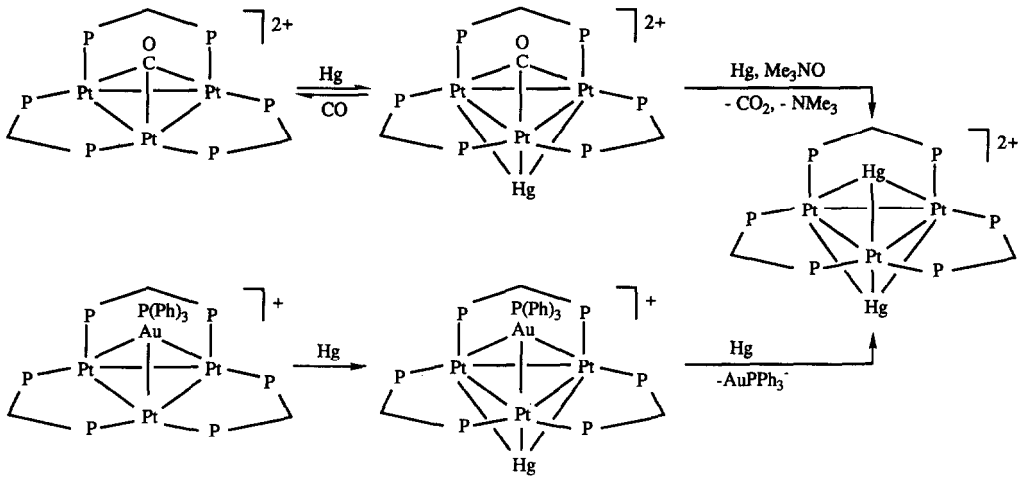
three-fold symmetry of the clusters, since the hydride and the $LPt(CO)_2$ fragments can move rapidly from edge to edge of the $Pt_3(\mu\text{-dppm})_3$ triangle.[53]



(7)

Elemental mercury reacts easily with $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ to give $[Pt_3(\mu_3\text{-CO})(\mu_3\text{-Hg})(\mu\text{-dppm})_3]^{2+}$ and, in the presence of Me_3NO whose rôle is to abstract carbon monoxide from platinum, to give $[Pt_3(\mu_3\text{-Hg})_2(\mu\text{-dppm})_3]^{2+}$ (Scheme 8). In these complexes, EHMO calculations indicate that the mercury atom acts as a weak donor using its $6s^2$ electron pair and a weak π-acceptor using its vacant $6p_\pi$ orbitals and so remains essentially neutral. There is an analogy with the tin(II) complexes discussed in section 4.4, since tin(II) also has the s^2 configuration, and the mercury adducts can also be considered as coordination complexes. Similar complexes with Hg or Hg_2 bridging two Pt_3 units are known, but no other simple Pt_3Hg clusters are known. A structure is shown in Fig. 14, and the



Scheme 8.

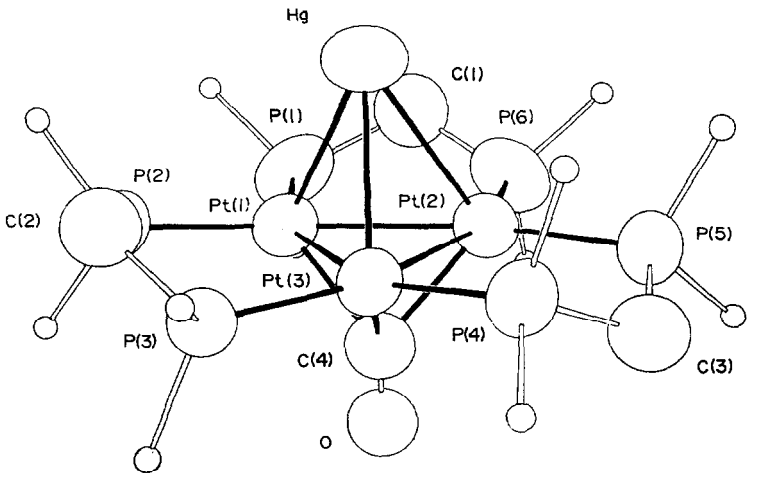


Fig. 14. The structure of $[Pt_3(\mu_3\text{-CO})(\mu_3\text{-Hg})(\mu\text{-dppm})_3]^{2+}$.

Pt_3Hg unit can be considered as a likely model for mercury on a platinum(111) surface. The adsorption of mercury atoms on metal surfaces is difficult to study because of the extreme ease of amalgamation.

7. OXIDATIVE ADDITION REACTIONS

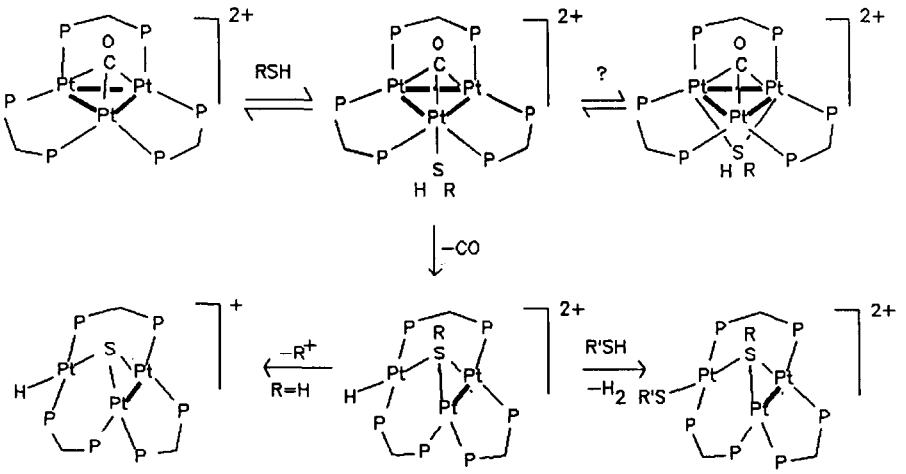
In the clusters $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ or $[Pt_3(\mu_3\text{-}H)(\mu\text{-}dppm)_3]^{+}$, the oxidation state of each platinum is formally +2/3 and oxidation by two units leads to a mean oxidation state of +4/3 for each platinum. In these products the three-fold symmetry is lost and they are easily identified as $Pt^{I}_2Pt^{II}$ complexes, in which the Pt^{II} centre is bound to the Pt^{I}_2 unit only by the two μ-dppm ligands and by an extra bridging group introduced during the reaction. In some cases, the Pt^{II} centre breaks away completely. For example, the reaction of $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ with HCl gave $[Pt_2Cl_2(\mu\text{-}dppm)_2]$ and $[PtCl_2(dppm)]$, whilst reaction with hydrogen gave $[Pt_2H_2(\mu\text{-}H)(\mu\text{-}dppm)_2]^{+}$ as the only detectable product. This section will describe in detail only those reactions which occurred without cluster fragmentation.

7.1. *Reactions with* H—S *and* H—Se *bonds*[84–86]

The chemistry of $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ with reagents H_2E or REH (E = S or Se) is illustrated in Scheme 9. It is likely that in all cases a coordination complex $[Pt_3(\mu_3\text{-}CO)(EHR)(\mu\text{-}dppm)_3]^{2+}$ is formed, and this step has been monitored for R = Et or Ph, E = S and R = Ph, E = Se. Next, oxidative addition of the E—H bond occurs with loss of carbon monoxide and cleavage of two metal–metal bonds to give $[Pt_3H(\mu_3\text{-}ER)(\mu\text{-}dppm)_3]^{2+}$. When R = H or t-Bu, loss of R^+ then occurs to give $[Pt_3H(\mu_3\text{-}E)(\mu\text{-}dppm)_3]^{+}$ or, when R = Ph, reaction with more REH can give hydrogen and $[Pt_3(EPh)(\mu_3\text{-}EPh)(\mu\text{-}dppm)_3]^{2+}$. The palladium cluster reacts in a similar way, but the Pd—H bond formed is more reactive. The structure of $[Pt_3H(\mu_3\text{-}S)(\mu\text{-}dppm)_3]^{+}$ (Fig. 15) shows clearly the $Pt^{I}_2Pt^{II}$ formulation with just one metal–metal bond [Pt^{I}—Pt^{I} 2.597(4) and $Pt^{I}\cdots Pt^{II}$ 3.574(2), 3.678(7) Å].[84,85] Another approach is to consider these as 46-electron clusters in which the extra four electrons resulting from the oxidative addition reaction occupy metal–metal anti-bonding molecular orbitals, thus leading to cleavage of two metal–metal bonds.

These reactions are of interest as models for poisoning of platinum or palladium catalysts, and much work has been carried out to understand the heterogeneous reaction between platinum and hydrogen sulphide. On a platinum(111) surface, hydrogen sulphide first forms a coordination complex, then undergoes dissociation to give H and HS groups on the surface, and finally loses hydrogen to give adsorbed sulphide present as $Pt_3(\mu_3\text{-}S)$ groups.[86] This chemistry is then very similar to that observed with the model complex $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$.

An unusual reaction of $[Pt_3H(\mu_3\text{-}S)(\mu\text{-}dppm)_3]^{+}$ occurs with $[AuCl(PPh_3)]$ and $AgNO_3$ to give



Scheme 9.

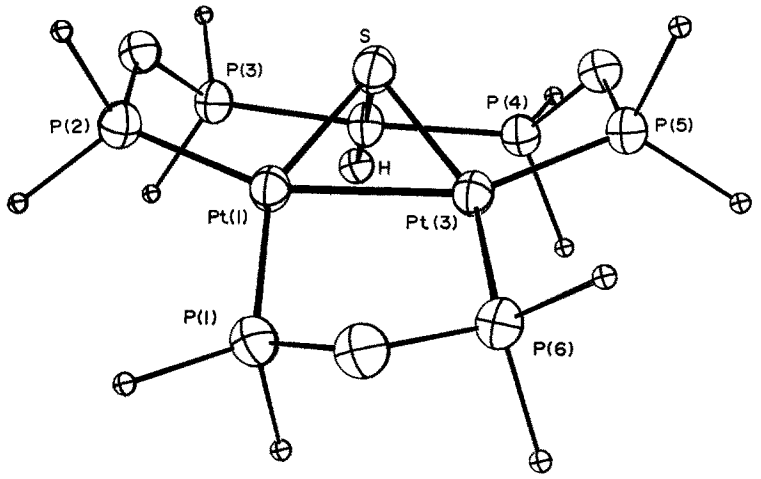


Fig. 15. The structure of the cation $[Pt_3H(\mu_3\text{-}S)(\mu\text{-dppm})_3]^+$. Reproduced by permission from *J. Chem. Soc., Chem. Commun.* 1986, 1809.

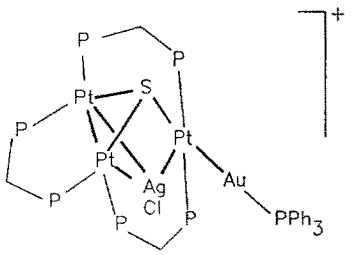
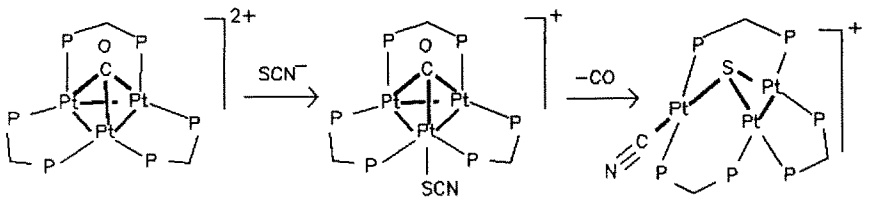
$[Pt_3(AuPPh_3)(\mu_3\text{-}S)(\mu_3\text{-}AgCl)(\mu\text{-dppm})_3]^+$ and HNO_3.[87] The structure of the heterometallic product (**16**) is shown in Fig. 16. It can be considered derived from that of the parent complex by replacement of H^+ with isolobal $AuPPh_3^+$, and addition of an AgCl unit to the vacant capping site of the Pt_3 triangle, to form a $Pt_3(\mu_3\text{-}Ag)$ unit [Pt—Pt 2.615(3), 2.619(3), Pt···Pt 3.631(2)–3.726(2), Pt—Ag 2.768(4)–2.861(4) Å].† A notable feature of this complex is the presence of a short Pt—Au bond not supported by bridging groups [2.577(3) and 2.575(3) Å].[45,88–90]



16

7.2. *Reactions with* C=S *bonds*

As discussed in section 4.5, the thiocyanate ligand forms complexes $[M_3(\mu_3\text{-}CO)(SCN)(\mu\text{-dppm})_3]^+$, M = Pd or Pt, but these rearrange either thermally or photochemically with cleavage of the sulphur–carbon bond to give $[M_3(CN)(\mu_3\text{-}S)(\mu\text{-dppm})_3]^+$, eq. (8).[58]



(8)

† In the crystal structure of $[Pt_3(AuPPh_3)(\mu_3\text{-}AgCl)(\mu_3\text{-}S)(\mu\text{-dppm})_3][PF_6]$ the asymmetric unit comprises two cations and two anions.

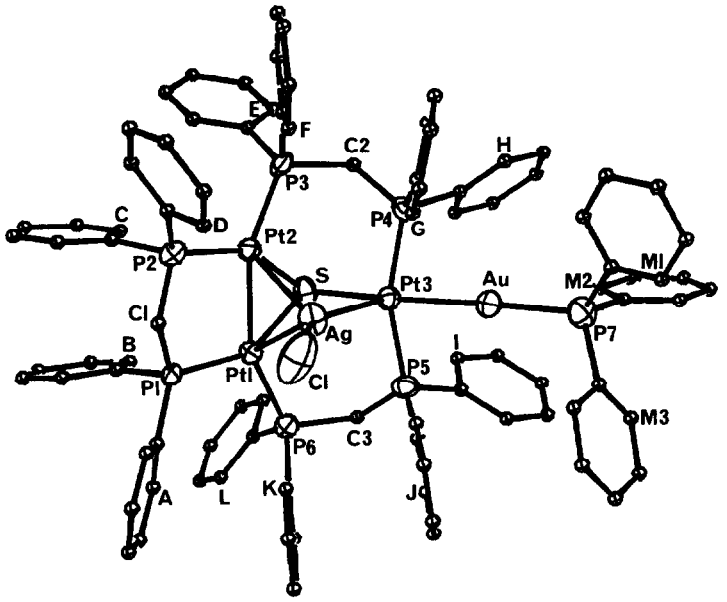


Fig. 16. The structure of one of the two crystallographically independent $[Pt_3(\mu_3\text{-}S)(AuPPh_3)(\mu_3\text{-}AgCl)(\mu\text{-}dppm)_3]^+$ cations. The structure of the second cation differs from that shown above only slightly. Reproduced by permission from *Inorg. Chem.* 1988, **27**, 4516.

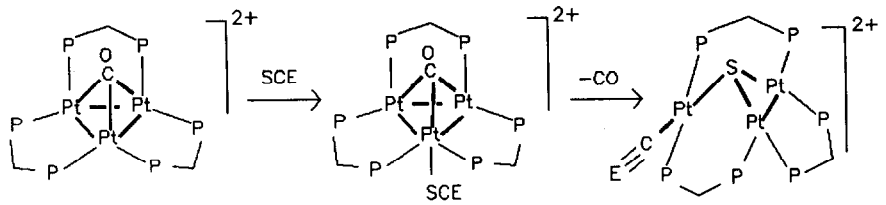
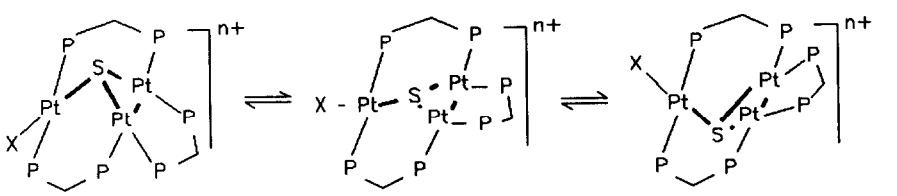
When M = Pt, similar reactions occur with the neutral reagents COS, CS_2 and RNCS to give $[Pt_3(\mu_3\text{-}CO)(SCE)(\mu\text{-}dppm)_3]^{2+}$ and then $[Pt_3(CE)(\mu_3\text{-}S)(\mu\text{-}dppm)_3]^{2+}$, E = O, S or RN [eq. (9)].[91]



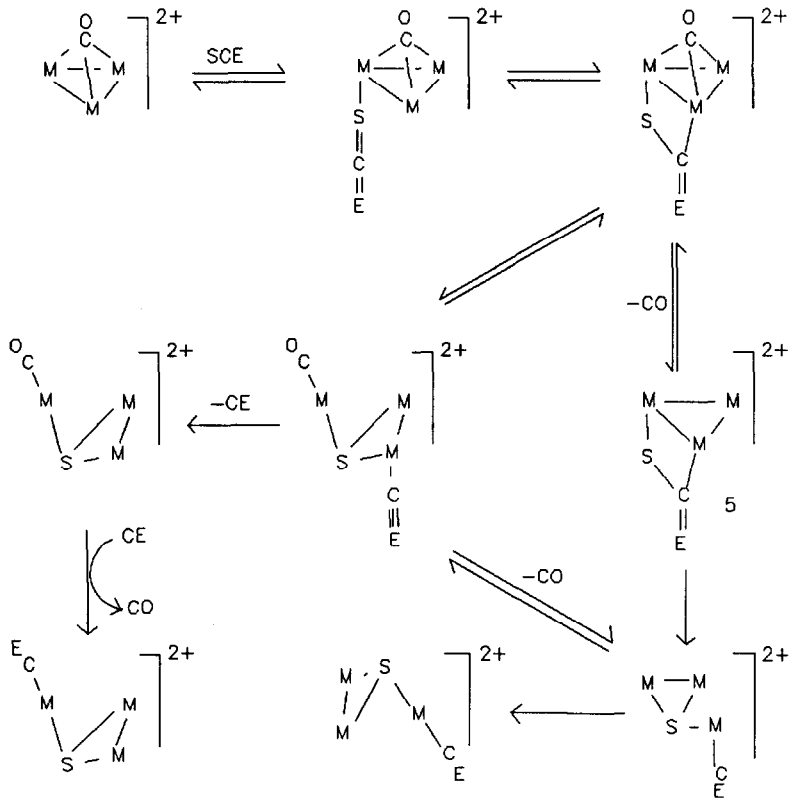
(9)

Mechanistic studies on these reactions have been carried out. The reactions with SCN^- and CS_2 are retarded by free carbon monoxide, but no long-lived intermediates could be detected. However, the reactions of $[Pt_3(\mu_3\text{-}C^*O)(\mu\text{-}dppm)_3]^{2+}$ with both COS and RNCS gave $[Pt_3(C^*O)(\mu_3\text{-}S)(\mu\text{-}dppm)_3]^{2+}$ as kinetic product, with loss of carbon monoxide and RNC, respectively, and in the isothiocyanate reactions, subsequent displacement of C*O by RNC gave the thermodynamic product $[Pt_3(CNR)(\mu_3\text{-}S)(\mu\text{-}dppm)_3]^{2+}$. Thus there appear to be two mechanistic pathways possible for these reactions, as illustrated in Scheme 10.

An interesting property of the μ_3-S complexes described in sections 1.2, 7.1 and 7.2 is the fluxionality, involving inversion about the sulphur atom, which leads to an effective plane of symmetry containing the $Pt_3(\mu_3\text{-}S)(\mu\text{-}dppm)_3$ unit [eq. (10)].[46,47,85,97]



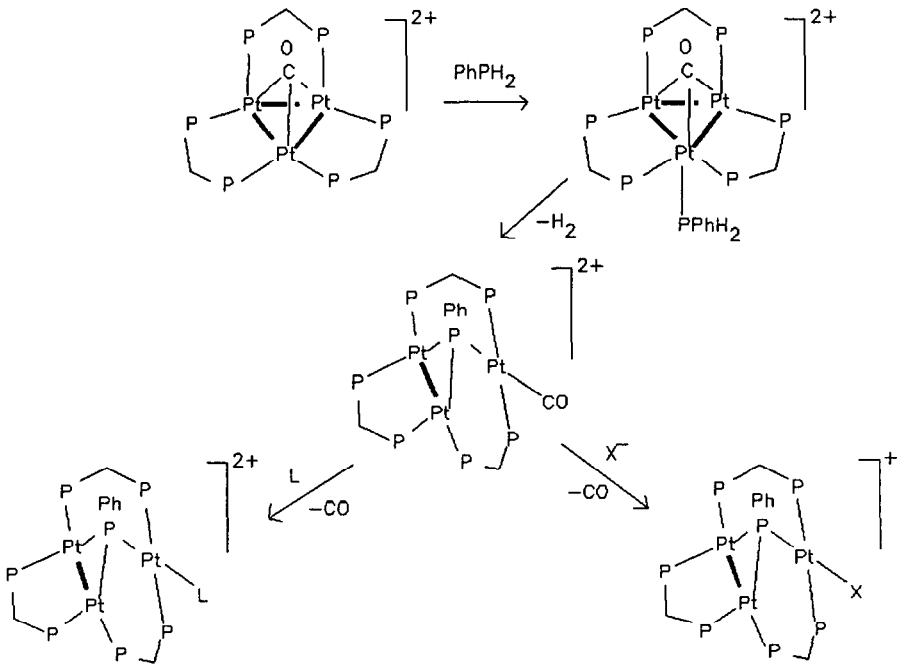
(10)



Scheme 10.

7.3. *Reactions with* P—H *bonds*[92]

The complex $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^{2+}$ reacts with $PhPH_2$ to give $[Pt_3(CO)(\mu_3\text{-}PPh)(\mu\text{-}dppm)_3]^{2+}$ and hydrogen. The carbonyl ligand in this phosphinidene bridged cluster is labile and is easily displaced by many other ligands, as shown in Scheme 11. It is not known why hydridoplatinum



Scheme 11.

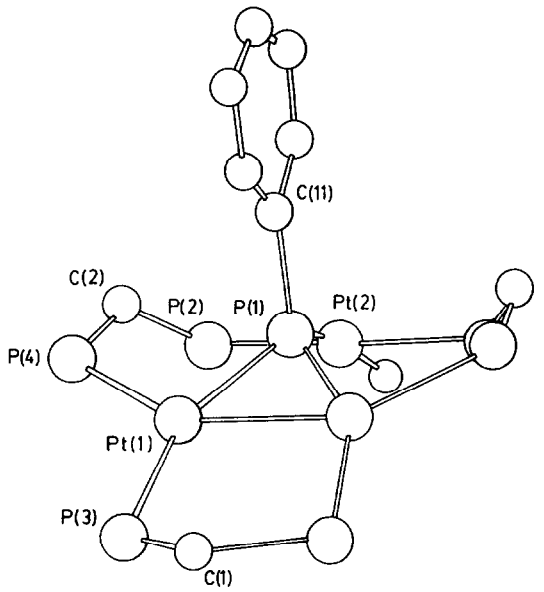


Fig. 17. The structure of the $[Pt_3(\mu_3\text{-PPh})(OH)(\mu\text{-dppm})_3]^+$ cation.

complexes are not formed in these reactions (compare with Scheme 9). However, the reasons are kinetic in origin since the complex $[Pt_3H(\mu_3\text{-PPh})(\mu\text{-dppm})_3]^+$ (Scheme 11) can be prepared though it is reactive. A typical structure is shown in Fig. 17.

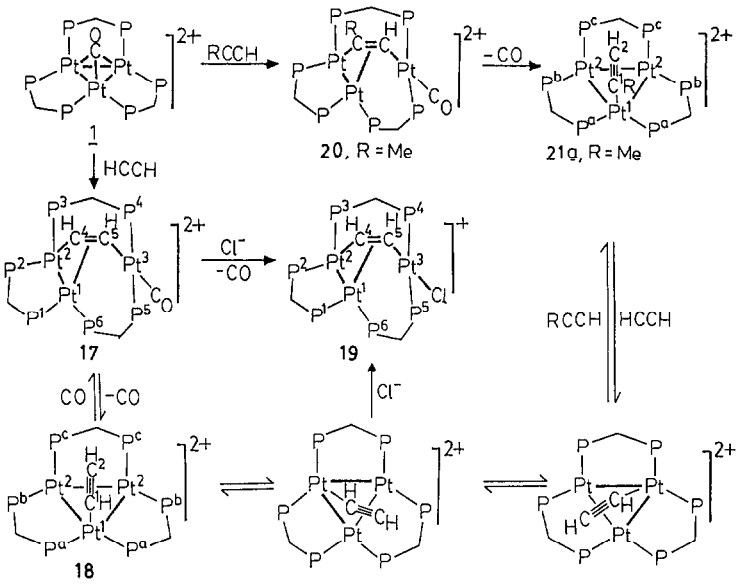
In a similar reaction, excess PH_3 gives $[Pt_3(PH_3)(\mu_3\text{-PH})(\mu\text{-dppm})_3]^{2+}$, an unusual example of a μ_3-PH group. On a platinum(111) surface PH_3 adsorbs as a terminal ligand at low temperature and then loses all hydrogen to give adsorbed phosphide, $Pt_3(\mu_3\text{-P})$, while the surface chemistry of $PhPH_2$ has not been studied.[63] There are obvious similarities and differences when compared to the cluster chemistry. Certainly, the cluster complex reactions proceed by way of an intermediate coordination complex $[Pt_3(\mu_3\text{-CO})(L)(\mu\text{-dppm})_3]^{2+}$, L = PH_2Ph or PH_3, which then loses hydrogen by a stepwise reaction sequence. This is similar to the surface science.

8. REACTIONS WITH ALKYNES

8.1. *Reactions of* $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$

The reactions of acetylene and some derivatives of acetylene with $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^{2+}$ are shown in Scheme 12. The reactions give initially the carbonyl(alkyne) complexes **17** or **20**, but these easily lose carbon monoxide to give **18** or **21**, or undergo displacement of carbon monoxide by other ligands to give complexes such as **19**. The structure of the complex **19** is shown in Fig. 18, which shows that the acetylene adopts the μ_3-(η^2-||) bonding mode and that there is just one metal–metal bond. The acetylene is a 4-electron ligand, and so **19** is a 46-electron cluster. The structure is similar to those found for the oxidative addition products with $Pt_3(\mu_3\text{-S})$ or $Pt_3(\mu_3\text{-PPh})$ groups (section 7), rather than to the complexes with simple donor ligands (sections 4.7 and 4.8), and so it is perhaps most reasonable to consider the acetylene addition as a form of oxidative addition. Thus the acetylene forms σ-bonds to Pt(2) and Pt(3) and the resulting dimetallated ethylene acts as a 2-electron donor to Pt(1).[93]

The complexes **18** and **21** are characterized spectroscopically as containing acetylene in the less common μ_3-(η^2-⊥) bonding mode. The complex **18** is fluxional, as shown in Scheme 12, such that the acetylene can migrate around the Pt_3 triangle. Both complexes are coordinatively unsaturated, with the 44-electron configuration, and ligand addition and alkyne-for-alkyne exchange occur readily. The presence of two metal–metal bonds in **18** and **21** is predicted on the basis of the NMR data, and is consistent with the theoretical prediction for a 44-electron cluster of platinum. Thus Wade's



Scheme 12.

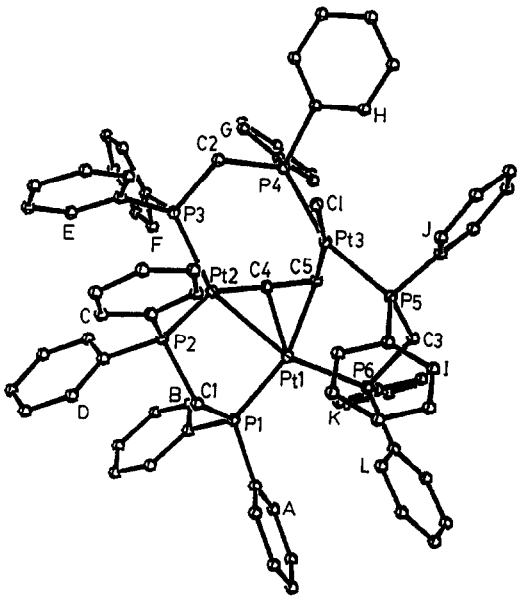


Fig. 18. The structure of the cation $[Pt_3Cl(HC{\equiv}CH)(\mu\text{-dppm})_3]^+$, illustrating the μ_3-(η^2-||) coordination of the acetylene [C(4) and C(5)] to the Pt_3 unit.

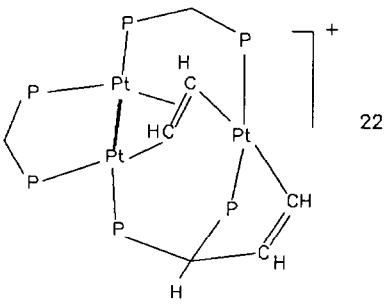
rules (modified for the platinum atoms preferring a 16-electron count) predict an *arachno* or *hypho* structure (Fig. 19) for the Pt_3C_2 core in **18** or **19**, respectively.

Reaction of sodium acetylide with $[Pt_3(\mu_3\text{-CO})(\mu\text{-dppm})_3]^+$ or, better, with complex **17** or **19** gave the complex **22**. This complex contains an acetylene ligand in the μ_3-(η^2-||) bonding mode and an unusual bis(diphenylphosphino)propenyl ligand, formed by formal insertion of acetylide into a C—H bond of a μ-dppm ligand. The structure of **22** is shown in Fig. 20.[94]

In all of the reactions described above, the acetylene does not rearrange to vinylidene or other possible structures.



22

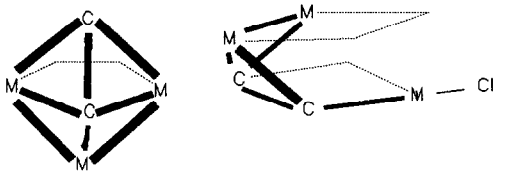


Fig. 19. A depiction of the M_3C_2 cores of the cations $[Pt_3(HCCH)(\mu\text{-dppm})_3]^{2+}$, **18**, and $[Pt_3Cl(HCCH)(\mu\text{-dppm})_3]^{+}$, **19**, showing the proposed relation to a pentagonal bipyramid and a square antiprism, respectively.

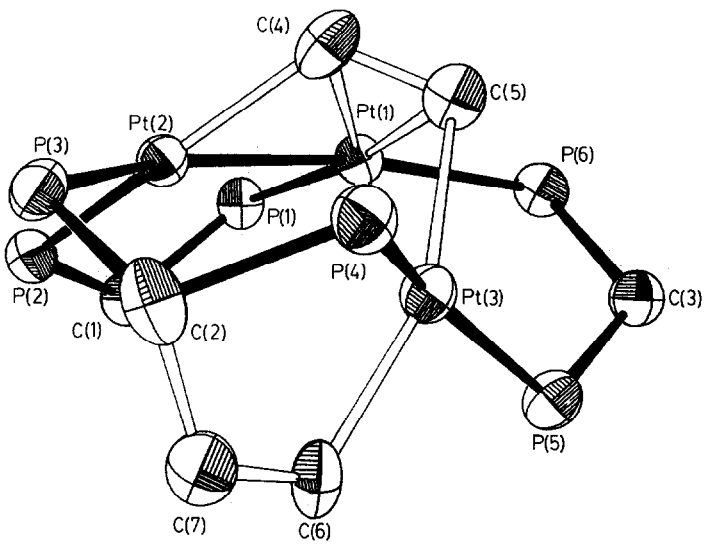

Fig. 20. The structure of the cation $[Pt_3(HCCH)(\mu\text{-dppm})_2\{\mu_2\text{-}\eta^3\text{-}(Ph_2P)_2CHCH{=}CH\}]^{+}$ with all phenyl groups omitted for clarity. The acetylene ligand [C(4), C(5)] bridges the M_3 unit in the $\mu_3\text{-}(\eta^2\text{-}\|)$ fashion also shown in Fig. 18. In this structure a CCH^{-} ion has inserted into a C(2)—H bond to give a $(Ph_2P)_2CHCH{=}CH$ ligand which is bonded to Pt(3) through C(6). Reproduced by permission from *J. Am. Chem. Soc.* 1989, **111**, 745.

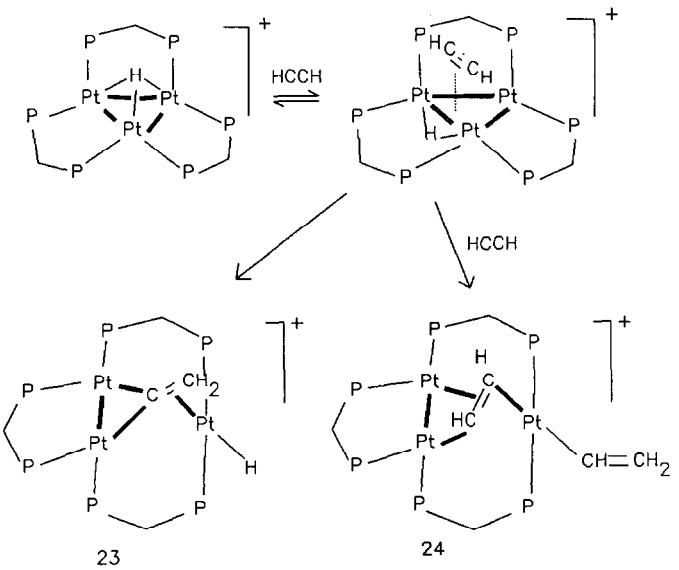
8.2. *Reactions with* $[Pt_3(\mu_3\text{-H})(\mu\text{-dppm})_3]^{+}$

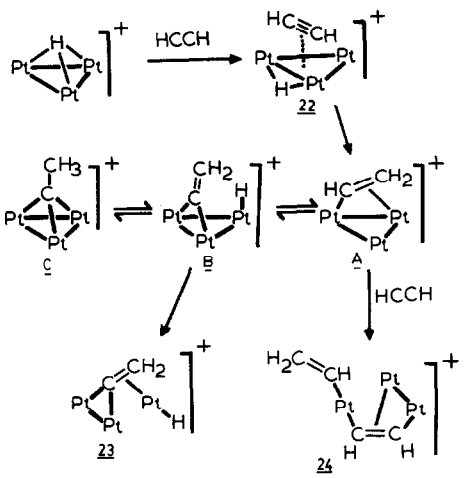
These reactions are shown in Scheme 13. The reaction of HCCH with $[Pt_3(\mu_3\text{-H})(\mu\text{-dppm})_3]^{+}$ at $-80°C$ gave a weak acetylene complex, which reacted further, in the absence of excess acetylene, to give the vinylidene complex, **23**, or, in the presence of excess acetylene, to give the vinyl(acetylene) complex, **24**.[95,96] Complex **23** did not react with excess acetylene to give **24**.



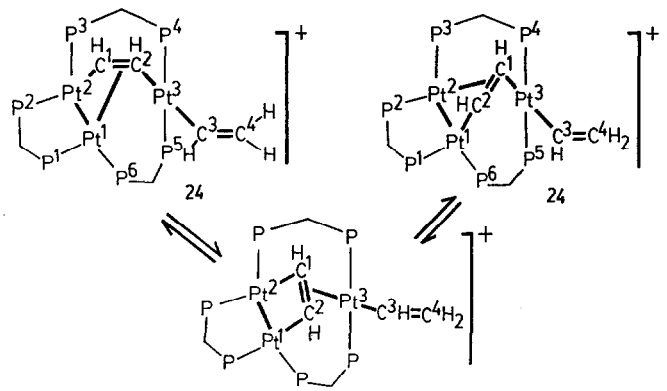
Scheme 13.

Some light was shed on the mechanism of these reactions by labelling studies, using combinations $Pt_3D + HCCH$ or $Pt_3H + DCCD$. It was found that H,D scrambling occurred between the hydride and vinylidene sites of **23** and that H,D scrambling occurred between the hydride and all vinyl sites of **24**, but that no H,D scrambling occurred in the acetylene ligand of **24**. These results, and the observation that **23** could not be converted to **24**, were interpreted in terms of the mechanism of Scheme 14. It is assumed that the acetylene adduct $[Pt_3(\mu\text{-H})(\mu\text{-dppm})_3(HCCH)]^+$ first rearranges to the intermediate 44-electron vinyl cluster **A**, and that there is then a very rapid scrambling between vinyl complex **A**, vinylidene(hydride) complex **B** and ethylidyne complex **C**, all of which are 44-electron clusters. This process naturally leads to H,D scrambling. Finally, the stable 46-electron clusters **23** and **24** are formed by isomerization of **B** or by reaction of **A** with excess acetylene, respectively.[96]

The acetylene complex **24** is analogous to complexes such as **19**, except that the acetylene is *trans* to vinyl instead of chloride. This difference is sufficient to lead to fluxionality of the HCCH ligand in **24** but not in **19**. The vinyl group probably labilizes the *trans* bond, and the resulting mechanism of fluxionality is shown in eq. (11).



Scheme 14.



(11)

8.3. *Comparison to the surface chemistry of* HCCH[97,98]

Acetylene adsorbs to the platinum(111) surface at low temperature in the μ_3-(η^2-||) bonding mode, but then rearranges on warming. On the platinum(111) surface, the stable species is thought to be the ethylidyne, $Pt_3(\mu_3\text{-}CCH_3)$, but on lower symmetry surfaces the vinylidene, μ_3-η^2-C=CH_2, is thought to be present. The extra hydrogen atom needed to form ethylidyne is presumably provided by dissociation of acetylene, initially to CCH and H, on the surface. Species such as CCH, CH, or C are thought to be present on other metal surfaces as major products, and there is some evidence also for vinyl groups on the surfaces, at least as intermediates. On the platinum(111) surface, it has been suggested that the sequence of reactions for formation of ethylidyne is $Pt_3(\mu_3\text{-}\eta^2\text{-HCCH}) \rightarrow Pt_3(\mu_3\text{-}\eta^2\text{-C=}CH_2)H \rightarrow Pt_3(\mu_3\text{-}CCH_3)$, and that H,D exchange between adsorbed hydrogen and ethylidyne involves reversible isomerization $Pt_3(\mu_3\text{-}CCH_3) \rightleftharpoons Pt_3(CH\text{=}CH_2)$, with the H,D exchange step occurring in the vinyl group.[97-99]

In the model cluster systems, no rearrangement of acetylene groups, $Pt_3(HCCH)$, to vinylidene, $Pt_3(C\text{=}CH_2)$, or other groups occurred unless a hydride ligand was present on the cluster (sections 8.1 and 8.2), and this suggests that acetylene rearrangement on a metal surface may require at least catalytic amounts of surface hydrogen. In the model systems, the first step involves combination of hydride and acetylene ligands to give vinyl. At this stage there is good evidence for H,D exchange processes and these may well involve reversible formation of vinylidene and ethylidyne groups analogous to steps proposed to occur on a platinum(111) surface.[99] The vinylidene group may be stable in the clusters as may a terminal vinyl group. However, ethylidyne, which appears to be the most stable species on the platinum(111) surface,[97-99] is at best a reaction intermediate in the model cluster complexes.

9. CATALYSIS OF THE WATER GAS SHIFT REACTION[51,52]

While the major efforts described above have been to mimic chemisorption and related phenomena on metal surfaces, it would obviously also be useful to mimic the catalytic activity of metal surfaces. The latter aim has not been realized, but the cluster $[Pt_3(\mu_3\text{-}CO)(\mu\text{-dppm})_3]^{2+}$ is a useful catalyst for the water gas shift (WGS) reaction, $CO + H_2O \rightarrow CO_2 + H_2$.

From a kinetic point of view, the catalysis is first order in cluster complex and inverse first order in pressure of carbon monoxide (Fig. 21). The reaction occurs more rapidly in aqueous methanol containing higher H_2O–MeOH ratios provided that solubility is sufficient. The mechanism of Scheme 15 is thought probable. All of the individual steps in the proposed catalytic cycle have been shown to occur readily, with the exception of the step involving attack of hyroxide on $[Pt_3(\mu_3\text{-}CO)(\mu\text{-dppm})_3]^{2+}$ to give carbon dioxide and $[Pt_3(\mu_3\text{-}H)(\mu\text{-dppm})_3]^{+}$, which is suggested to be rate determining. There are good precedents for attack of hydroxide on cationic carbonyls of platinum, but a terminal carbonyl may be necessary. The inhibition of catalysis by excess carbon monoxide may be due to the parallel formation of $[Pt_3(CO)_2(\mu\text{-dppm})_3]^{2+}$ or $[Pt_3(CO)_3(\mu\text{-dppm})_3]^{2+}$ (section 4.1), which may be less reactive to attack by hydroxide.

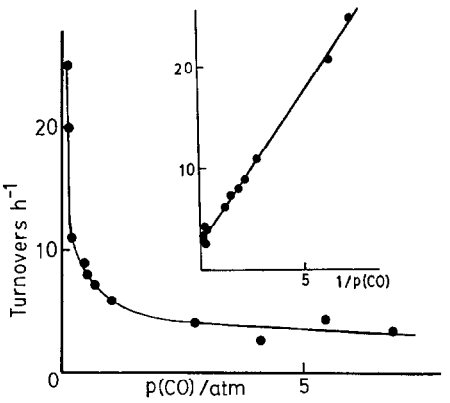


Fig. 21. Dependence of turnover rate for the WGS reaction catalysed by $[Pt_3(\mu_3\text{-}CO)(\mu\text{-}dppm)_3]^+$ in aqueous methanol at 100°C on the pressure of carbon monoxide. The inset shows the corresponding plot of turnover rate versus $1/p(CO)$.

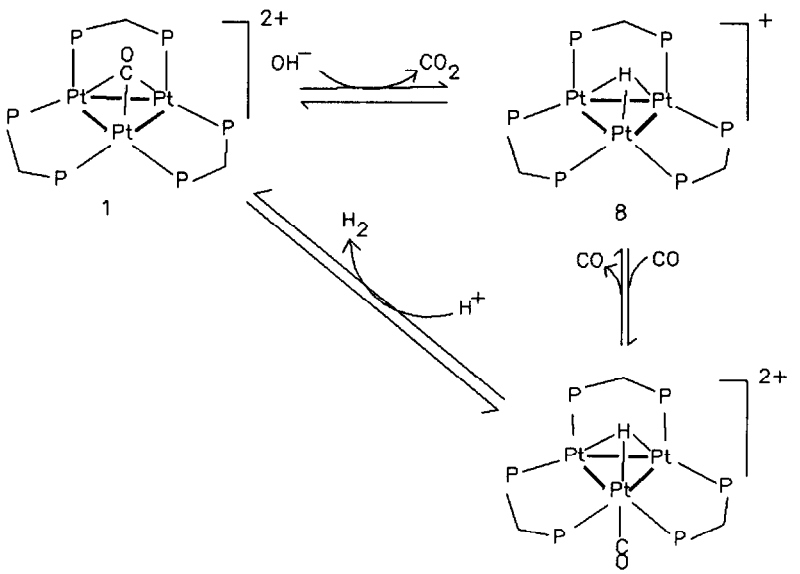

Scheme 15.

10. CONFORMATIONS OF dppm LIGANDS

Molecular structures of nearly all complexes discussed here contain a $M_3(\mu_3\text{-dppm})_3$ fragment in which the metal atoms form a triangular arrangement edge-bridged by three dppm ligands. In most complexes the metal atoms form three M—M bonds, and such complexes contain an approximately latitudinal M_3P_6 unit. In the complexes where only one M—M bond is observed, the M—P bonds are substantially bent out of the M_3 plane.

When a dppm ligand bridges a M—M bond a five-membered M_2P_2C ring is formed. Crystallographic studies have shown that, in the cluster complexes discussed here, such rings usually adopt an envelope shape with the CH_2 group at the flap. This conformation of the M_2P_2C rings permits a near-zero P—M—M—P torsion angle, required by the latitudinal M_3P_6 core, and M—P—C—P torsion angles, w_1 and w_2, corresponding to nearly staggered conformations of the dppm ligands around the P—CH_2 bonds. A correlation plot[100] of w_1 and w_2 angles observed in

different complexes (Fig. 22) thus shows a cluster of points centred on $w_1 = -w_2 = 50°$, characterizing a symmetrical envelope conformation of the M_2P_2C rings. The plot also shows combinations of w_1 and w_2 values consistent with M—M separation of 2.60 Å in rings of average dimensions (M—P = 2.30 Å, P—C = 1.83 Å, M—P—C = 109° and P—C—P = 111°). In such rings $w_1 = -w_2 = 50°$ represents the dppm conformation of lowest energy, corresponding to the smallest distortions from staggering ($w_1 = -w_2 = 60°$) about the P—CH bonds, allowed by the constraint M—M = 2.60 Å. For dppm ligands bridging two metal atoms which are not directly bonded to each other, the observed M—P—C—P torsion angles are typically $w_1 = 65°$ and $w_2 = -40°$ (Fig. 22). Thus the rupture of the M—M bonds and the increase in M···M separations to 3.1–3.6 Å causes a relatively small change in conformation of the dppm ligands, the w_1 and w_2 torsion angles changing typically by about 10–15°. This analysis therefore shows that dppm ligands can bridge a pair of metal atoms at M—M separations of 2.58–3.60 Å without adopting energetically unfavourable conformations, irrespective of whether or not the metal atoms are bonded to each other. It is then not surprising that the dppm ligands are capable of preventing fragmentation of these trinuclear complexes into binuclear and/or mononuclear species.

In the complexes which contain three M—M bonds, and therefore three envelope shaped M_2P_2C rings, two conformations of the *triangulo*-$M_3(\mu\text{-dppm})_3$ fragment are observed: (A) all three CH_2 flaps lie above the same face of the M_3 triangle, and (b) two CH_2 flaps lie above and one below the M_3 triangle. In type (A) complexes six equatorial phenyl groups project above the M_3 triangle and six axial phenyl groups project below it (Fig. 23). In type (B) complexes four equatorial plus two axial, and two equatorial plus four axial, phenyl groups lie above the opposite faces of the M_3 triangle. Therefore, in both types of complexes the two faces of the M_3 cluster are exposed to sterically different environments, the steric hindrance increasing with the number of axial phenyl groups (Fig. 24). The observed molecular structures of these complexes illustrate clearly that ligands adding to the $M_3(\mu\text{-dppm})$ fragment show a preference for the M_3 face with the greater number of equatorial phenyl groups.

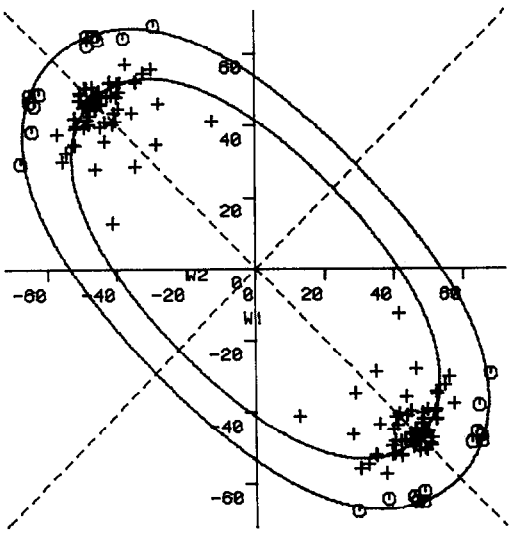

Fig. 22. Conformational map for dppm ligands in complexes with $M_3(\mu\text{-dppm})_3$ skeletons. The M—P—C—P torsion angles, w_1 and w_2, for each ligand are plotted against each other. Crosses correspond to ligands bridging M—M bonds and open circles to ligands bridging two metal atoms which are not bonded to each other (M···M 3.1–3.6 Å). Also shown are the combinations of w_1 and w_2 corresponding to M—M = 2.60 Å (inner curve) and 3.00 Å (outer curve) for a M_2P_2C ring with M—P = 2.30 Å, P—C = 1.83 Å, M—P—C = 109° and P—C—P = 111°. The diagonal broken lines $w_1 = w_2$, and $w_1 = -w_2$ are lines of mirror symmetry in the map, and relate isometric ligand conformations. The clustering about $w_1 = -w_2 = 50°$ (or $w_2 = -w_1 = 50°$) for rings with M—M bonds is especially obvious.

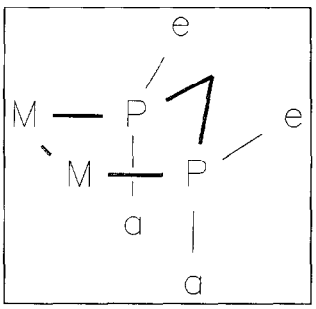

Fig. 23. The symmetrical envelope conformation of an M_2P_2C ring. Axial (a) and equatorial (e) substituent positions are also shown.

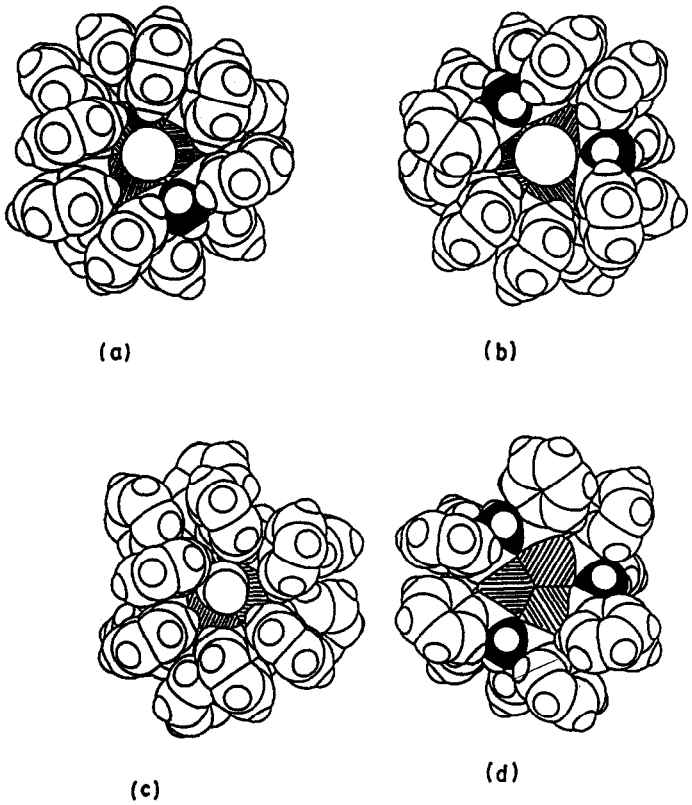

Fig. 24. The steric environments of M_3 faces in *triangulo*-$M_3(\mu\text{-dppm})_3$ complexes illustrated by space-filling models. Metal atoms are hatched and dppm methylene carbon atoms are shown in black. In all cases the complex is viewed along normal to the M_3 plane. (a) $[Pd_3(\mu_3\text{-I})(\mu_3\text{-CO})(\mu\text{-dppm})_3]^+$ viewed from the μ_3-CO side. The carbonyl is surrounded by two equatorial phenyl groups (adjacent to methylene carbon) and four axial phenyl groups. (b) The same cation viewed from the μ_3-I side. The iodo ligand is surrounded by four equatorial and two axial phenyl groups. Rotation of (a) by 180° about the vertical axis gives (b). (c) $[Pt_3(\mu_3\text{-CO})\{P(OPh)_3\}(\mu\text{-dppm})_3]^{2+}$ viewed from the μ_3-CO side. The carbonyl ligand is surrounded by six axial phenyl groups but the asymmetry in the $(\mu_3\text{-CO})Pt_3$ bonding does not appear to be caused by steric effects. (d) The same cation rotated 180° about the vertical axis to show the face to which the phosphite ligand is attached. The phosphite ligand is not shown. All phenyl groups are equatorial. Comparison of (a)–(d) suggests that steric hindrance above the M_3-face increases along the series (d) < (b) < (a) < (c).

11. CONCLUSIONS

The results described above show that coordinatively unsaturated cluster complexes, which are stabilized with respect to cluster fragmentation, can mimic some of the properties of a metal surface. Perhaps the most important property of the clusters is the ability to coordinate small molecules under very mild conditions in ways that mimic adsorption on a metal surface at low temperature. Such coordination compounds can typically be formed at $-80°C$ in solution and can be characterized by multinuclear NMR techniques. Where the molecules are stable at room temperature, they can be crystallized and characterized crystallographically. The best mimics for the structures of surface bound molecules have been based on derivatives of the iron group clusters, such as $[M_3(CO)]_{12}$, M = Fe, Ru or Os.[1,2,8–11] However, these are coordinatively saturated and must undergo carbonyl dissociation in order to bind small molecules. Since carbonyl dissociation is not usually easy, the coordination of small molecules often requires forcing conditions. In this sense, the coordinatively unsaturated clusters of the late transition metals are better mimics of a coordinatively unsaturated metal surface, particularly in terms of reactivity and reaction mechanism.

The ligands bound to the Pt_3 clusters may adopt terminal, μ_2 or μ_3 bonding modes and the energy differences between these different forms is evidently small in many cases. This frequently leads to very easy fluxionality. For example, the unique fluxionality of phosphine and diphosphine ligands is clearly a result of this phenomenon and is directly related to the coordinative unsaturation of the clusters. The fluxionality then gives useful mimicry of the mobility of coordinated molecules on a metal surface.

The oxidative addition of small molecules to the clusters mimics dissociative chemisorption on a metal surface and typically involves the preliminary step of simple coordination, mimicking low temperature non-dissociative chemisorption, as described above. It is in these cases of oxidative addition that metal–metal bonds are usually broken, and hence when the rôle of the μ-dppm ligands in preventing cluster fragmentation is particularly useful. The coordination and rearrangement of acetylene on the Pt_3 clusters, and the use of the clusters as catalysts for the WGS reaction, are further examples of processes where the dppm ligands prevent cluster fragmentation.

In summary, these clusters are very crude models for a metal surface but they are able to mimic many of the chemical properties of a platinum(111) surface. Clearly, the design, synthesis and study of coordinatively unsaturated clusters can also be a productive and worthwhile area of research in its own right.

(*Received* 4 *April* 1989; *accepted after revision* 15 *June* 1990)

Abstract—The stereoisomerization of complexes with polydentate aminochelate ligands dien (diethylenetriamine), trien (triethylenetetramine), tetraen (tetraethylenepentamine) and cyclam (1,4,8,11-tetraazacyclotetradecane) were investigated by ^{59}Co NMR in aqueous solutions. Their structure and preference of certain isomeric formations were studied. It was found that for the $[Co(dien)(NO_2)_2NH_3]Cl$ complex, out of four geometric isomers observed, those with *mer*-configuration dominate. *Trans*-complexes with tetradentate ligand (trien), configurationally are more labile than *cis*-complexes and the stability of geometric isomers increases in the order *trans* $< \alpha < \beta$. While when the cyclic tetradentate ligand (cyclam) coordinates to cobalt, mainly complexes with *trans*-configuration are formed. Formation of all four alternative geometric isomers for Co^{III} complexes containing pentadentate ligand (tetraen) is found.

Different stereoisomeric forms are possible for octahedral Co^{III} complexes with polydentate amine ligands. These forms will differ in the nitrogen atom binding with the central atom of cobalt.

In Co^{III} complexes with polydentate amines there are several sources of asymmetry (complex configuration, conformation of chelate cycles, asymmetric character of donor nitrogen atoms) resulting in the appearance of complicated diastereoisomeric forms. Therefore, to determine the absolute configuration of these isomers is rather difficult, although, undoubtedly, attractive. High sensitivity of the Co^{III} nucleus to structural changes allows (using ^{59}Co NMR) the existence of different types of isomerism to be determined in the solutions of Co^{III} complexes with chelate ligands.

This work was aimed at investigating, by ^{59}Co NMR, the stereoisomerization reaction of Co^{III} complexes containing polydentate amine ligands: dien, trien, tetraen and cyclam.

EXPERIMENTAL

The cobalt(III) complex compounds were synthesized according to known procedures: $[Co(dien)(NO_2)_2NH_3]Cl$,[1] $[Co(NH_3)_3(NO_2)_2Py]Cl$,[2] $[Co(trien)X_2]Y_{1;3}$,[3,4] $[Co(cyclam)X_2]Y_{1;3}$,[5,6] ($X = NO_2^-$, NH_3, Cl^-; $Y = Cl^-$, ClO_4^-). Solutions, containing *trans*-$[Co(trien)(OH)_2]^+$ and $[Co(cyclam)(OH)_2]^+$ were obtained by passing *trans*-$[Co(trien)Cl_2]Cl$ and *trans*-$[Co(cyclam)Cl_2]Cl$; $[Co(tetraen)X]Y_{1;3}$[7] ($X = NH_3$; OH^-, Cl^-, H_2O; $Y = Cl^-$, ClO_4^- and $ZnCl_4^{2-}$) through an ion-exchange column (form-OH). ^{59}Co NMR spectra of the fresh aqueous solutions with a concentration of 0.05–0.1 mol dm^{-3} were recorded on a Bruker AM-400 (resonance frequency 94.45 MHz) at room temperature. Chemical shifts are given relative to $[Co(NH_3)_6]Cl_3$.

RESULTS AND DISCUSSION

Octahedral Co^{III} complexes containing one molecule of tridentate ligand (dien) can exist in two isomeric forms (*mer*- and *fac*-).[8–12]

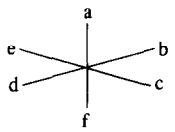
The presence of different monodentate ligands in the coordination sphere leads to an increase in the number of geometric isomers. Four resonance signals corresponding to isomers (Table 1) were found in the ^{59}Co NMR spectrum of an aqueous solution of $[Co(dien)(NO_2)_2NH_3]Cl$.

Intensity ratios of signals show that for Co^{III} complexes (with one molecule dien) the formation

* Author to whom correspondence should be addressed.

Table 1. ^{59}Co NMR spectra of $[Co(dien)(NO_2)_2NH_3]Cl$ aqueous solutions after 10 min

Isomers' assignment		δ ^{59}Co (ppm)	Line widths ($\Delta\nu 1/2$ Hz)	Relative intensity
fac-	aed,bf,c	−1430	280	6.12
	aed,cf,b	−1480	310	3.22
mer-	edc,ab,f	−1530	420	33.05
	edc,af,b	−1550	650	56.78



of the *mer*-configuration is preferable compared with the formation of *fac*-isomers.

It should be noted that for the bis-complex of diethylenetriamine $[Co(dien)_2]^{3+}$, which is realized in the form of three topological isomers: S-*fac*, u-*fac* and *mer*,[13–16] meridional coordination of dien over facial coordination is also preferable. However, as was shown by Keene and Searle,[17] when PO_4^{3-} or SeO_3^{2-} oxyanions are present in the solution, the equilibrium shifts to the preferred formation of *fac*-isomers (S-*fac* > u-*fac* > *mer*). They assume that an enhanced proportion of the *fac*-isomers is responsible for the differential specific associations between the oxyanions and the three isomeric cations.

When triethylenetetramine is coordinated to cobalt the formation of three geometric isomers α-*cis* (S-*cis*), β-*cis* (u-*cis*) and *trans*- is possible.[18] We found the formation of the above geometric isomers for complexes $[Co(trien)X_2]^{n+}$ (where $X = NO_2^-$, NH_3, OH^-) (Table 2).

Presence of two asymmetric nitrogen atoms—NH-group—in the ligand trien increases the number of possible isomers.[3,18] Analysing the stereomodels of the geometric isomers mentioned, Buckingham *et al.*[19] showed that two enantiomers, Δ (SS) and Λ (RR), are possible in the case of the α-*cis* configuration of the complex. For the complexes of β-*cis* configuration the possibility of four stereoisomers, Λ (SS), Λ (SR), Δ (RR) and Δ (RS), was considered, but for the *trans*-complex the presence of two optical isomers (SS), (RR) and *meso*-form (SR) was considered. However, wide lines in the ^{59}Co NMR spectrum for the dinitro-complex $[Co(trien)(NO_2)_2]Cl$ [Fig. 1(a)] evidently do not allow the observation of diastereoisomers in the solution caused by insignificant structural effects. Substitution of the nitro-group by an ammonia molecule or hydroxo-group in tetramine Co^{III} complexes makes the resonance signals in the ^{59}Co NMR spectrum noticeably narrow. Thus, a low intensity signal (−665 ppm) is present in the spectrum of the freshly prepared *trans*-$[Co(trien)(NH_3)_2]Cl_3$ as a result of *trans*-(R,S)-*meso*-form formation [Fig. 1(b)] besides an intense signal corresponding to the sum of optical isomers R,R (S,S) of *trans*-configuration. Intensity ratios of signals show that for *trans*-complexes with triethylenetetramine, SS- and RR-configurations are much preferable because in the case of R,S-species formation all three five-member cycles reveal different conformations (λ, ε, δ), as was assumed by Shibata,[4] which, evidently, requires a higher strain of the chelate rings. It should be noted that in solutions of *trans*-$[Co(trien)X_2]^{n+}$ in all cases α- and β-*cis* isomers were present as a result of *trans* → *cis* isomerization. Isomerization of *trans* $\rightleftharpoons$ α-*cis* $\rightleftharpoons$ β-*cis* at pH = 7 at 25°C proceeds spontaneously and in time equilibrium shifts to the formation of α- and β-*cis* isomers. Timed ^{59}Co NMR spectra analyses for $[Co(trien)X_2]^{n+}$ complexes leads to the conclusion that the stability of geometric isomers increases in the order *trans* < α < β-*cis*. The presence of two broad signals (Fig. 2) in the $[Co(trien)(NH_3)OH]^{2+}$ spectrum is a result of the dimer complexes existence in the solution bonded to each other through a bridging OH-group. In the formation of

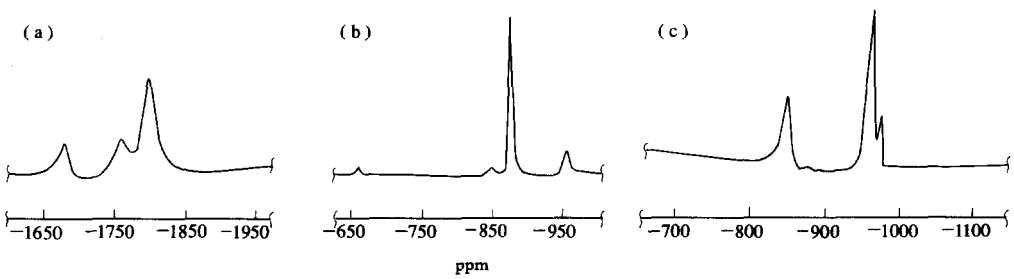


Fig. 1. ^{59}Co NMR spectra of (a) $[Co(trien)(NO_2)_2]Cl$, (b) *trans*-$[Co(trien)(NH_3)_2]Cl_3$, and (c) *cis*-$[Co(trien)(NH_3)_2](ClO_4)_3$ in aqueous solution after 15 min. The assignments of the lines are given in Table 2.

Table 2. ^{59}Co NMR data of isomers' assignments for $Co(trien)X_2^{n+}$ complexes ($X = NO_2^-$, NH_3, $n = 1,3$)

Complex	Absolute configuration	δ ^{59}Co (ppm)	$\Delta\nu 1/2$ (Hz)

dimer complexes all four geometric isomers can participate (Table 3).

It is known[5] when the cyclic tetramine ligand—cyclam—is coordinated to cobalt, complexes with *trans*-configuration are mainly formed. Whereupon, all four nitrogen atoms can be asymmetric centre. That is why the possibility of five diastereoisomers RRRR, RSRR, SSRR, RSSR and RSRS was considered with regard to the orientation of hydrogen atoms.[6]

The possible existence of such isomers was discussed in the literature,[5,6,20–22] but the formation of more than two isomers for *trans*-complexes was never mentioned.

$[Co(cyclam)(NH_3)_2]Cl_3$ obtained as a result of reaction of *trans*-$[Co(cyclam)Cl_2]Cl$ with liquid ammonia gives one resonance signal (−620 ppm) in aqueous solutions, so out of five possible isomers only one *trans*-form is stable (Table 4). No other isomers appeared when the pH or temperature of the solution were changed. In the solution of *cis*-$[Co(cyclam)(NH_3)_2]^{3+}$ spontaneous *cis* → *trans* isomerization was observed. Increase of the basicity (pH > 10) favoured *cis* → *trans* isomerization and the complex with the *trans*-configuration dominated in the solution.

Evidently, this is the result of the amine ligands deprotonation in basic solutions which makes the chelate rings inversion easier in turn. Formation of all five configuration isomers was observed in the solution of *cis*-$[Co(cyclam)(OH)_2]^+$ (Table 4). The presence of a dihydroxo-complex of *cis*-configuration was proved. In the spectrum of this solution in the presence of optically active anions of *d*-tartaric acid, the signal (993 ppm) assigned to *cis*-$[Co(cyclam)(OH)_2]^+$ shifted to higher field and split into two (987 and 981 ppm) as a result of diastereoisomers $\Lambda d \rightleftharpoons \Delta d$ formation. Since the *cis*-complex has no symmetry plane, only this complex can exist in two enantiomeric Λ- and Δ-forms.

Earlier authors[23] succeeded in separating optically the active isomer *cis*-Λ-$[Co(cyclam)en]Cl_3$. So, for Co^{III} complexes with cyclam only, complexes with the *trans*-configuration are more stable in solution. While only one form out of five possible diastereoisomers is mainly formed as follows from the intensity ratios of signals for *trans*-complexes, but not three, as was assumed on the basis of the model compound calculations.[20]

One could assume as well, the existence of all five types of diastereoisomers for *cis*-complexes. However, *cis*-complexes are formed as a racemic compound of two enantiomers Λ-SSSS (Δ-RRRR) in which five- and six-member chelate cycles have more stable gauche- and chair-conformations, therefore steric hindrance must be minimal.

Dissolving *β*-$[Co(tetraen)Cl](ClO_4)_2$ in 10% aqueous solution of ammonia led to the formation of a

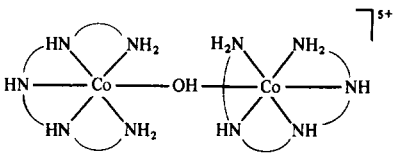
both complexes being formed in all four possible isomeric forms (Table 5).[24–27]

A wide signal in the region −380 to −460 ppm consisting of several overlapping lines [Fig. 3(a)] indicated the hydroxo- complexes' dimerization through the bridging OH-group. As all four types of hydroxo-complex could participate in the dimer formation, various combinations of isomeric forms are possible (for example, α- and β- and so on).



α β

Each combination of the complex must produce two separate resonance signals in the ^{59}Co NMR spectrum. Evidently, the complicated shape of the signal from binuclear hydroxo-complexes is thus explained. ^{59}Co NMR data for similar binuclear μ-peroxo-O_2 complexes $[Co(tetraen)_2]O_2^{4+}$ are given in Refs 30 and 31. On making the solution acid, the bridging bond in [(tetraen)Co-OH-Co(tetraen)]$^{5+}$

is easily broken resulting in the formation of mononuclear water complexes.

In the literature discussing the symmetry of all the four considered geometric isomers, opinions differ. In some reports[28,29] it was assumed that all four isomers must be asymmetric. However, later it was proved[25,32] that out of the four isomers, the α-isomer has the plane of symmetry and cannot exist in optically active form. Other authors[25] succeeded in separating Λ- and Δ-enantiomers and proved the existence of optically active forms for the β-isomer. In the type of complexes discussed, besides the chiral configuration of the chelate rings there is one more source of optical activity—three asymmetric atoms of the secondary nitrogen.

It was found by X-ray analysis[26] that the β-isomer is realized in two stable diastereoisomeric forms differing by the orientation of the hydrogen atoms bonded to the nitrogen atom (NH-group) on *trans*-coordination with the NH_2-group (—NH—Co—NH_2—). Moreover, for bedcf, the existence of four diastereoisomers is assumed on the basis of stereo-models of these complexes, but for aedfc,b and aedcf,b the formation of only one form was discussed.[26] It is necessary to note that in all the considered amine ligands, the nitrogen atoms participating in complex formation are four coordinated, i.e. they have tetrahedral surrounding and are configurationally stable. So, different orientations of hydrogen atoms predetermine the conformation of chelate cycles—the curve of the ligand chain where carbon atoms not participating in complex formation are placed.

The presence of optical isomers dependent on the different Λ- and Δ-configurations of the complexes was found for two geometric isomers. In the spec-

trum of the aqueous solution [Co(tetraen)OH] $(ClO_4)_2$ in the presence of *d*-tart^{2-} [Co : (*d*-tart)$^{2-}$ = 1 : 6] all four signals were slightly shifted to a higher field and two signals corresponding to β-(bedfc,a) and (bedcf,a) isomers, having neither a plane nor a symmetry centre, were split because of the binding of optically active anions in the second coordination sphere with the formation of Λ-*d* and Δ-*d* diastereoisomers [Fig. 3(b)]. No formation of diastereoisomers was found due to the different orientation of hydrogen atoms at the secondary nitrogen atoms, which in the case of tetradentate ligands (trien and cyclam) contribute to the shielding of the cobalt(III) central atom. It is known[33,34] that for Co^{III} complexes with anions of ethylenediaminetetraacetic acid where asymmetric nitrogen atom with different substituents is also present. However, consideration of the chelate cycles' geometry showed that nitrogen can have only S-configuration. Evidently, formation of geometric isomers with pentadentate ligand (tetraen) also requires such a curve of the chelate cycles when only a definite orientation of the hydrogen atom is stabilized.

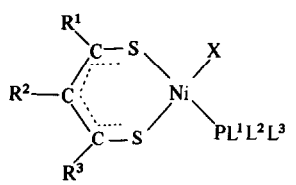
Abstract—The dimerization of butenes by a catalyst system derived from (pentane-2,4-dithionato)chlorotri-n-butylphosphinenickel(II) and diethylaluminium chloride in chlorobenzene has been investigated. The data are consistent with the presence of two catalytic species in solution. The concentrations of the catalysts appear to decrease with time, at a rate which is first-order in catalyst concentration, and the initial oligomerization rate appears to be second-order in olefin concentration.

The catalytic oligomerization of low molecular weight olefins has been practised commercially for about 50 years.[1] It remains a reaction of considerable industrial significance, and is utilized today in the production of fuels and specialty chemicals. A number of catalyst types have been used, and new catalysts are still being developed. The interest in new catalysts derives from the requirements of higher selectivity accompanying high activity. Although complexes of many transition metals are active as oligomerization catalysts,[2,3] nickel-based systems have received perhaps the greatest attention.[4–7] Both Shell's higher olefin process and IFP's Dimersol™ process utilize nickel-based catalyst precursors.[8,9]

The air-stable, 16-electron compounds Ni(R^2–R^1sacR^3sac)($PL^1L^2L^3$)Cl (R^j, L^j = alkyl or aryl, sacsac$^-$ = $C_5H_7S_2^-$ = dithioacetylacetonate anion = pentane-2,5-dithionate anion) form extremely active olefin oligomerization catalysts when activated by a suitable co-catalyst.[10–15]



I

These systems are extremely active, oligomerizing ethylene at turnover numbers greater than 1000 mol of ethylene per mole of nickel per second at atmospheric pressure and room temperature. Catalysts derived from compounds **I** are also extremely active olefin double bond shift isomerization catalysts. The high rates of reactions observed in these systems make the study of the catalytic reaction extremely difficult. However, manageable reaction rates can be obtained using butenes as substrates. This may be a consequence of the low thermodynamic equilibrium concentration of 1-butene at ambient temperatures. Internal olefins appear to be oligomerized less rapidly than terminal olefins by catalysts derived from **1**. 1-Butene or *cis*- or *trans*-butene substrates are rapidly isomerized to close to the thermodynamic equilibrium mixture.

We have previously reported on the kinetics of,

* Paper presented at the Symposium on Applied Organometallic Chemistry, Pokolbin, NSW, Australia, 10–12 July 1989.

† Authors to whom correspondence should be addressed.

and product distributions from, a series of reactions between butenes and catalysts derived from **I** ($R^1 = R^3 = CH_3$, $R^2 = H$) with different phosphine ligands.[13] An empirical mathematical model was developed for the latter stages of the reaction ($t > ca$ 3/4 h). This model was able to describe the catalyst performance with a high degree of accuracy. For all of the catalysts tested, the butene concentration varied non-linearly with time, and was found empirically to obey the relationship

$$\ln(m_b) = A\exp(Bt) + C, \quad (1)$$

where m_b is the mass of residual butene, and A, B and C are empirical constants specific to individual catalysts. This equation was shown to be of the same form as equations developed by Dumas and Hsu to describe the kinetics of butadiene polymerization catalysed by homogeneous nickel-based species.[16] Dumas and Hsu showed that the behaviour described by eq. (1) is consistent with the "instantaneous" activation of a single catalytic species such that the polymerization reaction is first-order in both substrate and catalyst concentrations [eq. (2)], and that the disappearance of the active form of the catalyst is first-order in catalyst concentration [eq. (3)].

$$\delta m_b/\delta t = -k_b m_b m_c \quad (2)$$

$$\delta m_c/\delta t = -k_c m_c \quad (3)$$

In these expressions m_b and m_c are the masses of residual butene and catalyst, respectively, and k_b and k_c are the oligomerization and catalyst disappearance rate constants, respectively. Our analysis was limited to the latter stages of the reaction, and the fit of our model to the data over that period was excellent. However, a systematic deviation of our data from the model was observed during the initial period of the reaction. The precision of the data during the initial period did not allow a more complete analysis of the reaction during this phase of the reaction.

We have now refined the experiment by the addition of automated data acquisition. This has enabled us to collect a significant data population during the initial reaction period. An analysis of the catalyst behaviour during the initial reaction period is presented herein.

RESULTS AND DISCUSSION

In this study, we have concentrated on the catalysts derived from Ni(sacsac)(PBu_3)Cl and Et_2AlCl in chlorobenzene. The similarity of the behaviour of all of the catalysts reported in our previous study suggests that the behaviour observed for this catalyst system is probably obeyed by all catalysts **I**. We have shown previously, that the initial rate of propylene oligomerization in reactions at constant propylene pressure is proportional to the concentration of nickel precursor, provided that the nickel : Et_2AlCl ratio is high.[14] Within the concentration limits available, a similar first-order

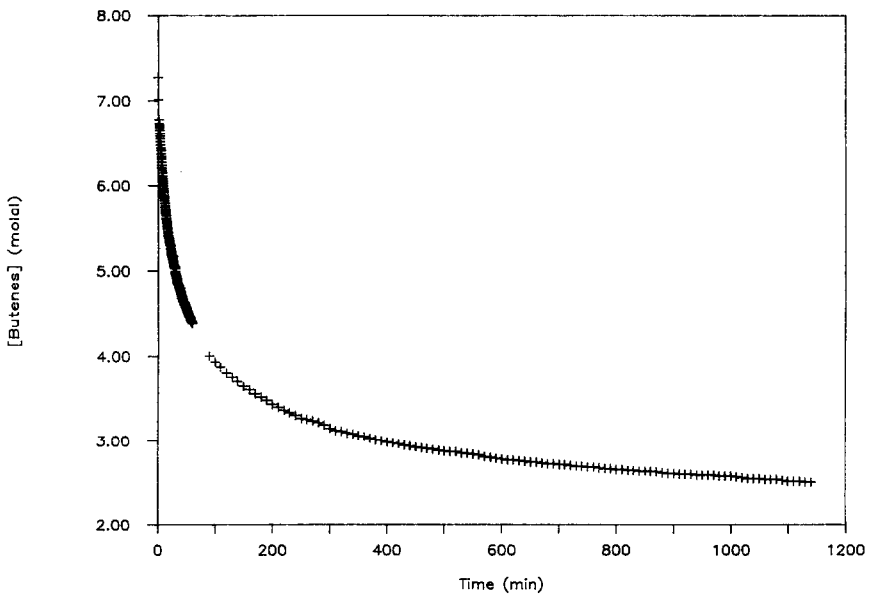


Fig. 1. Time dependence of butene concentration. Initial concentrations (molal): Ni, 0.005626; Al, 0.1824; C_4H_8, 7.19.

dependence of the initial rate on the Ni(sacsac) (PBu_3)Cl concentration is suggested in the present system.

Figure 1 illustrates the concentration of residual butene as a function of time for a typical reaction. There is an initial rapid decrease in the butene concentration, followed by a slower consumption of the remaining butene. The data can be divided into an initial ($0 \leqslant t \leqslant 1$ h) and an advanced ($4.5 \leqslant t \leqslant 19$ h) stage of the reaction.

Figure 2 shows that the data obtained during the latter period of the reaction can be modelled extremely well by eqs (1)–(3), as we have shown previously[13] (we note, however, that reasonable fits at these slow reaction rates can also be obtained from alternative models). The regression is characterized by an index of determination of 0.999, and is statistically significant at a probability level greater than 99.99%. This behaviour is consistent with a model in which the oligomerization reaction is first-order in the concentrations of both butene substrate and the catalyst, and in which the amount of active catalyst decreases at a rate which is first-order in catalyst concentration.

It is clear, however, from Fig. 2, that the reaction cannot be described by this model at short reaction times.

The data obtained during the initial reaction period is best accommodated by an empirical regression function of the form

$$1/m_b = D\exp(Et)+F, \qquad (4)$$

where, again, m_b is the mass of residual butene, and D, E and F are empirical constants specific to the catalyst. The fit of this function to the decrease in butene concentration, as a function of time, during the initial period is illustrated in Fig. 3. The regression of Fig. 3 also has an index of determination larger than 0.999 (statistical significance higher than 99.99%). No simple regression has been found for the transition period between 1 and 4.5 h of the reaction time. This is indicated by the systematic deviations of the experimental points from the linear regressions in both Figs 2 and 3.

It can be demonstrated that the form of eq. (4) is consistent with a kinetic model which is first-order with respect to catalyst concentration and second-order with respect to butene concentration [eq. (5)], with the disappearance of catalyst described by eq. (6)

$$\delta m_b/\delta t = -k'_b m_b^2 m_{c'} \qquad (5)$$

$$\delta m_{c'}/\delta t = -k'_c m_{c'}, \qquad (6)$$

where $m_{c'}$ is the mass of residual catalyst, and k'_b and k'_c are the oligomerization and catalyst disappearance rate constants, respectively, for this reaction stage. The values of the constants of eq. (4) are then

$$D = -(k'_b/k'_c)(m_c)_0 \qquad (7)$$

$$E = -k'_c \qquad (8)$$

$$F = 1/(m_b)_0 - D. \qquad (9)$$

Here, $(m_c)_0$ and $(m_b)_0$ are the initial amounts of catalyst and butene, respectively.

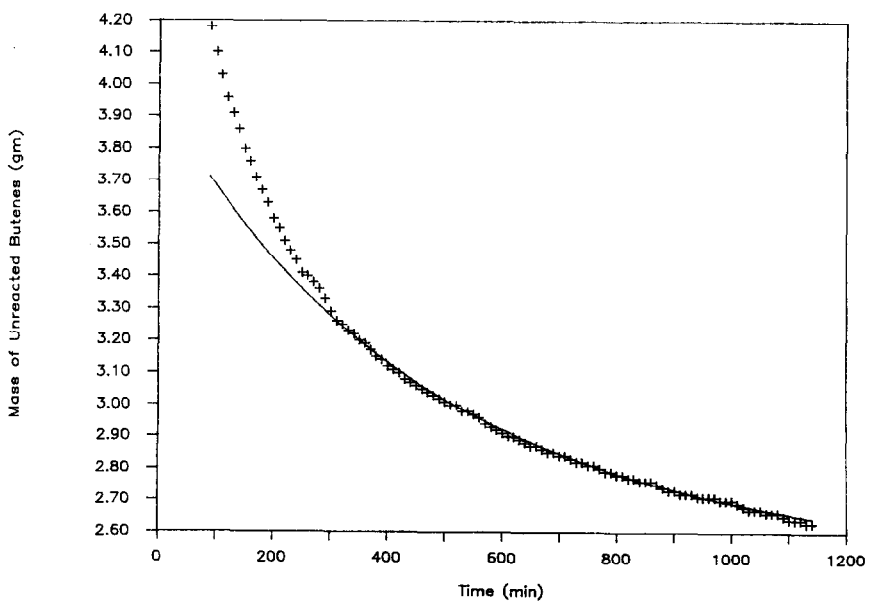

Fig. 2. Fit (solid line) to experimental data (points) during the latter period of butene oligomerization.

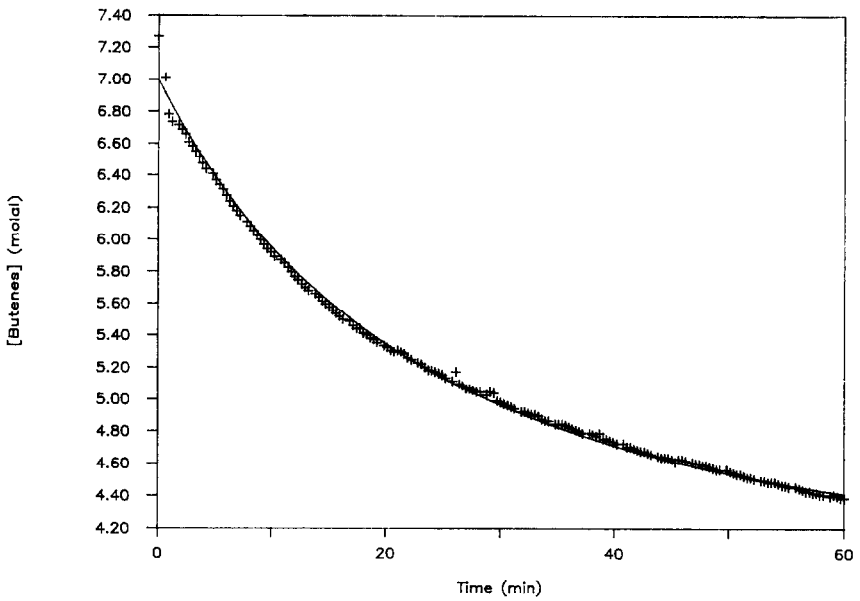

Fig. 3. Fit (solid line) to experimental data (points) during the initial period of butene oligomerization.

The data then suggest a system in which there are two catalytic species, **A** and **B**, in solution, both oligomerizing butene and both being consumed at rates which are first-order in catalyst concentration. However, the reaction order with respect to butene concentration during the initial reaction period during which catalyst **A** dominates, may differ from that during the advanced reaction period, during which catalyst **B** dominates. The detailed natures of catalysts **A** and **B** are at present unknown. Our analysis does not discriminate between models in which (a) one catalyst is generated more rapidly than the other, (b) the first catalyst "decomposes" into the second, or (c) both catalysts are generated "instantaneously". With the assumption of option (c), a comparison of reaction rates for the initial and advanced reaction stages indicates that initially the two reaction rates differ by about a factor of three, with catalyst **A** predominating. After about 1 h, the two reaction rates are about equal, and after about 4 h the two reaction rates differ by about a factor of 20, with catalyst **B** predominating. This change in the ratio of reaction rates agrees very well with the observed transformation from one reaction phase into the other.

Propylene oligomerization, catalysed by other nickel complex/aluminium haloalkyl systems, has been reported to be first-order in nickel, and second-order in olefin concentrations.[17,18] However, relatively short reaction times were used in these studies. Both first- and second-order kinetics with respect to olefin concentration can be accommodated by the conventional mechanism involving a nickel–hydride intermediate and a sequence of olefin coordination, olefin insertion and β-hydride elimination steps.[5,19] If the insertion of the second olefin molecule into the nickel–alkyl bond is rate-determining, the reaction order with respect to olefin will depend on the reversibility of the insertion of the first olefin molecule into the nickel–hydride bond.

We have conducted numerous experiments varying the concentrations of the reagents and the reaction times and have found the behaviour described above to be quite general. A mechanism involving two parallel, coupled catalytic cycles involving two different catalysts has been postulated previously to describe the oligomerization of 1-butene by the catalyst derived from (C_8H_{13})Ni(acac) ($acac^-$ = 2,4-pentanedionato anion.)[20]

Some care is required in interpreting the experimental data in terms of rate constants derived from the relationships above. Although the initial concentrations of the Ni(sacsac)(PBu_3)Cl and Et_2AlCl precursors are known, the true concentrations of actual catalysts in the reaction are not. There is no guarantee that the precursor and catalyst concentrations are related by a simple direct proportionality, nor that the proportionality factor approaches unity. Moreover, we, and others, have demonstrated that the role(s) of the alkylaluminium and other co-reactants can be non-trivial.[13,14,17,18] Accordingly, we prefer to use the present data to provide a qualitative, rather than quantitative, description of the system.

The nature of the catalyst consumption process

is also unknown at present. However, we have observed that the addition of an extra aliquot of Ni(sacsac)(PBu_3)Cl to the reactor after the reaction had practically ceased resulted in additional butene consumption. The revival of the reaction was observed regardless of whether both Ni(sacsac)(PBu_3)Cl and Et_2AlCl were injected simultaneously, or whether only Ni(sacsac)(PBu_3)Cl was added. The addition of Et_2AlCl alone had no apparent effect.

These reactions are highly selective ($\geq 95\%$) for dimerization. A small fraction of higher oligomer products is formed. We have observed that the C_{16} fraction of the reaction products is almost always significantly larger than the C_{12} fraction. Thus, it seems that the dimerization of octenes is favoured over the addition of butene to the octenes.

The amounts of hexenes produced increase with the concentration of Et_2AlCl. This behaviour is consistent with the suggestion that the active catalyst may be in equilibrium with excess Et_2AlCl.[14]

EXPERIMENTAL

All manipulations were carried out in an inert atmosphere of argon or butenes using standard vacuum manifold techniques. Solvents were AR grade and were dried and distilled under argon before use. Diethylaluminium chloride (Merck and Aldrich) was used as received. The compound Ni(sacsac)(PBu_3)Cl was prepared from Ni(sacsac)$_2$ and $NiCl_2(PBu_3)_2$ by the method reported previously,[21,22] and its identity confirmed by NMR spectroscopy. *trans*-2-Butene (Matheson technical grade) was used as received. The presence of small amounts of 1-butene, and *cis*-2-butene in the *trans*-2-butene was established by gas chromatographic analysis. No other impurities were detected by this technique. Gas chromatographic analyses were performed on an SGE 25m QC2/BP1 0.25 mm capillary column using a Hewlett Packard 5890A gas chromatograph equipped with an FID and a Hewlett Packard 3393A integrator.

Butenes were oligomerized in batch experiments in a magnetically stirred stainless steel tubular reactor system. The temperature inside the reactor was monitored and maintained constant by immersion of the reactor in a stirred, controlled temperature bath at 25.0 ± 0.2°C. The oligomerization experiments were conducted as described previously,[13] except that the temperature and pressure were monitored via a thermocouple and a calibrated pressure transducer (Sensym, Inc. (U.S.A.) SSX100A) respectively, connected to a data logger (Data Electronics (Australia) DATATAKER DT100). The pressure transducer was calibrated over the range 0–600 kPa using both the known pressure–temperature dependence for butenes, and direct pressure measurements by a mercury manometer. The logging program enabled the collection of data in regular preselected intervals. Typically, data were logged every 20 s for about 1 h, and every 10 min thereafter. The logged values were averages of readings over the logging interval. Data analysis was as described previously,[13] but used a reduced population of the experimental data, particularly for the latter period of the reaction. The reliability of the final results could be shown to be unaltered by this data reduction. The yield predicted from the time–pressure–temperature analysis was checked by a careful mass balance and gas chromatographic analyses of the reaction products. The useful range of catalyst concentrations available with this method is limited by two factors. Firstly, the relatively slow rate of butene oligomerization limits the lower range of catalyst concentrations effective in producing manageable reaction rates. Secondly, the potential contribution to the partial pressure of any ethane produced by decomposition of Et_2AlCl limits the higher range of catalyst concentrations. In general, the useful range of concentrations is between $5–60 \times 10^{-4}$ molal for Ni(sacsac)(PBu_3)Cl, and up to 9×10^{-2} molal for Et_2AlCl.

Abstract—The preparation and characterization of species in which $[H_nFeCo_3(CO)_{12}]^{n-1}$ ($n = 0, 1$) are supported on partially dehydroxylated silica and on aminated silica are reported. $[HFeCo_3(CO)_{12}]$, deposited onto aminated silica, yields the cluster anion, $[FeCo_3(CO)_{12}]^-$, bound to the surface. However, when $[HFeCo_3(CO)_{12}]$ is loaded onto partially dehydroxylated silica, deprotonation does not occur and the surface species is the cluster hydride. The cluster anion, as $K^+[FeCo_3(CO)_{12}]^-$, can be deposited onto both supports. The cluster anion, as $PrNH_3^+[FeCo_3(CO)_{12}]^-$, can also be loaded onto partially dehydroxylated silica. All depositions occur without the formation of other IR detectable carbonyl-containing species and with the metal framework remaining intact. The supported clusters are precursors of active catalysts for the Fischer–Tropsch reaction at 1 atm. The catalysts, derived from the precursors by thermal activation under hydrogen, are active for at least 120 h. The order of activity is as follows: $[HFeCo_3(CO)_{12}]$/partially dehydroxylated silica $< K^+[FeCo_3(CO)_{12}]^-$/partially dehydroxylated silica $\approx K^+[FeCo_3(CO)_{12}]^-$/aminated silica $\ll PrNH_3^+[FeCo_3(CO)_{12}]^-$/partially dehydroxylated silica $\approx [HFeCo_3(CO)_{12}]^-$/aminated silica. Only the catalysts derived from the last two precursors contain significant amounts of nitrogen. This is consistent with the formation of metal nitride phases in these catalysts and may correlate with their higher activity. Moreover, this formation of nitride phases occurs only when the nitrogen is in close association with the metal cluster. During the thermal activation of all the catalysts there was no loss of metal and the iron to cobalt ratio remained at 1 : 3. The effects of operational parameters on product distribution and CO conversion rates obtained with the catalyst produced from $[HFeCo_3(CO)_{12}]$ deposited onto aminated silica are also reported.

Transition metal carbonyl cluster compounds have attracted increasingly greater interest as possible models of metal surfaces[1,2] and as precursors of supported metal catalysts.[3,4] These clusters often have been absorbed onto partially dehydroxylated metal oxide supports,[5] and confined to the surface either by tight ion pairing with ionic support moieties,[5] or by bond formation via reaction between the cluster and surface hydroxyl groups.[6,7] Alternatively, metal carbonyl compounds have been immobilized on functionalized metal oxide surfaces by appropriate ligating or ionic groups bound to the surface as chemical anchors.[8]

Immobilized catalysts derived from mixed-metal carbonyl clusters have been claimed to exhibit more desirable behaviour than catalysts prepared from

either a mixture of metal salts, or a mixture of carbonyl clusters of the same metal stoichiometry.[9] Choplin *et al.*[10] showed that thermal decomposition of supported heterometallic carbonyl clusters yields very small heterometallic particles which have the same bulk composition as that of the starting cluster. In contrast, mixtures of homometallic carbonyl clusters supported on metal oxides appear to decompose into separate metallic phases.[11]

Hemmerich *et al.*[12,13] reported the deposition of $[HFeCo_3(CO)_{12}]$ onto an amine-modified silica support. This is a rare example of the utilization of the acid–base chemistry of an amine group in cluster anchoring. Thermal activation of this supported cluster was reported to produce a catalyst which contained dimetallic particles of the same stoichiometry as $[HFeCo_3(CO)_{12}]$. This catalyst was active in the Fischer–Tropsch reaction, showing reasonable reaction rates and a remarkable selectivity to gasoline-range products. Recently, we reported our initial comparisons[14] of this catalyst system to the work of Hemmerich.[12,13] The structure of the metal carbonyl cluster bonded to the silica surface after loading is easily characterized for this system. However, the surface species, which is produced by thermal activation of the carbonyl cluster and is the active Fischer–Tropsch catalyst, has not been identified. We present, here, further work investigating the nature of the species produced on the surface when $[H_nFeCo_3(CO)_{12}]^{n-1}$ ($n = 0, 1$) are deposited onto modified silica. Results of the Fischer–Tropsch reaction with these species as catalyst precursors are also reported.

EXPERIMENTAL

All synthetic manipulations were carried out in an air-free dry argon atmosphere using Schlenk techniques. Dichloromethane and acetone were dried by distillation from calcium hydride and potassium carbonate, respectively. Silica gel 40 (surface area 675 $m^2\ g^{-1}$, 35–70 mesh) was obtained from Merck. The 3-aminopropyltriethoxysilane (Dynamit Nobel Chemie, Dynasylan AMEO™) was obtained from Plastral Trading and distilled before use under argon. Dicobaltoctacarbonyl (Strem) and iron pentacarbonyl (Aldrich) were used as received. $[HFeCo_3(CO)_{12}]$, $K^+[FeCo_3(CO)_{12}]^-$ and $PrNH_3^+[FeCo_3(CO)_{12}]^-$ were prepared by the methods of Chini *et al.*[15]

Supports

Partially dehydroxylated silica. Silica gel 40 (15 g) was heated *in vacuo* at 300°C for 3 h to produce approx. 13 g of partially dehydroxylated silica.

Aminated silica. Partially dehydroxylated silica (10 g) was refluxed with AMEO (13 g) in toluene (100 cm^3) for 6 h. The solution was filtered and the solid was washed with toluene for 24 h in a Soxhlet extractor. The aminated silica was finally dried *in vacuo*. Yield: approx. 16 g.

Catalyst precursors

$[HFeCo_3(CO)_{12}]$/*aminated silica* (*catalyst precursor* **A**). $[HFeCo_3(CO)_{12}]$ (1.0 g, 1.8 mmol) was dissolved in acetone (50 cm^3) and stirred at room temperature for 2 h with aminated silica (4 g). The solvent was removed *in vacuo*, and the resultant solid was washed with pentane (50 cm^3). The solid was then dried overnight *in vacuo*. Analyses: wt% of element before (after) catalysis—Fe 1.7(2.3), Co 5.2(6.3), N 1.89(0.80), Co/Fe 2.9(2.6).

$[HFeCo_3(CO)_{12}]$/*partially dehydroxylated silica* (*catalyst precursor* **B**). $[HFeCo_3(CO)_{12}]$ (1.0 g, 1.8 mmol) was dissolved in dichloromethane (50 cm^3) and stirred at room temperature for 2 h with partially dehydroxylated silica (4 g). The solvent was removed *in vacuo* and the resultant solid was dried overnight *in vacuo*. Analyses: wt% of element before (after) catalysis—Fe 1.8(2.0), Co 5.5(6.3), Co/Fe 2.9(3.0).

$K^+[FeCo_3(CO)_{12}]^-$/*partially dehydroxylated silica* (*catalyst precursor* **C**). $K^+[FeCo_3(CO)_{12}]^-$ (1.0 g, 1.6 mmol) was dissolved in acetone (50 cm^3) and stirred at room temperature for 2 h with partially dehydroxylated silica (4 g). The solvent was removed *in vacuo*, and the resultant solid was washed with pentane (50 cm^3). The solid was then dried overnight *in vacuo*. Analyses: wt% of element before (after) catalysis—Fe 1.6(1.8), Co 4.9(5.5), Co/Fe 2.9(2.9).

$K^+[FeCo_3(CO)_{12}]^-$/*aminated silica* (*catalyst precursor* **D**). $K^+[FeCo_3(CO)_{12}]^-$ (1.0 g, 1.6 mmol) was dissolved in acetone (50 cm^3) and stirred at room temperature for 2 h with aminated silica (4 g). The solvent was removed *in vacuo*, and the resultant solid was washed with pentane (50 cm^3). The solid was then dried overnight *in vacuo*. Analyses: wt% of element before (after) catalysis—Fe 1.6(2.1), Co 4.8(6.8), N 1.80(0.11), Co/Fe 2.8(3.1).

$PrNH_3^+[FeCo_3(CO)_{12}]^-$/*partially dehydroxylated silica* (*catalyst precursor* **E**). $PrNH_3^+[FeCo_3(CO)_{12}]^-$ (1.0 g, 1.6 mmol) was dissolved in acetone (50 cm^3) and stirred at room temperature for 2 h with partially dehydroxylated silica (4 g). The solvent was removed *in vacuo*, and the resultant solid was washed with pentane (50 cm^3). The solid was then dried overnight *in vacuo*. Analyses: wt% of element before (after) catalysis—Fe 1.6(2.0), Co 5.0(6.3), N 0.40(0.39), Co/Fe 3.0(3.0).

Testing of catalysts

Catalysts were tested for Fischer–Tropsch activity at atmospheric pressure in a fixed-bed reactor as previously described.[16] The catalyst precursors were activated in a stream of hydrogen (space velocity 500 h^{-1}) at 200°C for 2 h. A hydrogen–carbon monoxide–water vapour mixture (total space velocity 500 h^{-1}) was used as the feed gas, and was preheated to 200°C prior to entering the stainless steel reaction vessel (10 cm × 1 cm i.d.) which was maintained at constant temperature. The products of the reaction were monitored for a minimum of 12 h.

Carbon monoxide conversion rates, carbon dioxide selectivity, and C_1 and C_2 hydrocarbon selectivity were monitored at approx. 20 min intervals with a Shimadzu 8AIT gas chromatograph fitted with a thermal conductivity detector and a packed column (10 ft × ⅛ in i.d., Chromosorb 102, S.G.E., Australia) and were continuously data-logged.

Variable temperature and gas feed composition experiments were performed sequentially on the same sample. Time was allowed for these systems to come to "steady state" before data-logging recommenced.

Full product distributions (C_1–C_{29} hydrocarbons and oxygenates) were obtained at least once during the reaction period using a Hewlett–Packard 5890A gas chromatograph equipped with a flame ionization detector and a fused silica capillary column (50 m × 0.02 mm i.d., EP-5, S.G.E., Australia). The error in the percentage of diesel and wax obtained from a catalyst test is greater than for the lower hydrocarbons due to retention of these products on the catalyst support. The long reaction times used in these experiments, however, should minimize these errors. Comparison of the results obtained from the continuous monitoring system (Shimadzu gas chromatograph) and the full product distribution (Hewlett–Packard gas chromatograph) for the selectivity to C_1 and C_2 hydrocarbons indicated that the magnitude of this error was low in all cases.

Metal analyses were obtained by atomic absorption spectroscopy. C, H and N analyses were determined by combustion using a Leco CHN600 analyser. Fourier transform IR spectra of catalyst precursors were obtained using a Digilab FTIR FTS20/80 spectrophotometer. Diffuse reflectance IR spectra of $[HFeCo_3(CO)_{12}]$/aminated silica (catalyst precursor **A**) under activation conditions were obtained using a Mattson Cygnus 100 spectrophotometer. The sample was contained in a Harrick environmental cell.

RESULTS AND DISCUSSION

The supports used in this study were partially dehydroxylated silica and aminated silica. The former was prepared from silica gel 40 (35–70 mesh) by heating *in vacuo* for 3 h. Aminated silica was synthesized by the condensation of AMEO onto silica with the elimination of ethanol.[17] The same cluster loadings and catalytic results were obtained irrespective of whether or not ethanol was removed via a Dean Stark apparatus.

$[HFeCo_3(CO)_{12}]$ was loaded onto aminated silica by evaporation of an acetone solution of the cluster to form catalyst precursor **A**. The IR spectrum of the resultant catalyst precursor (Table 1) showed

five bands in the region 2200–1600 cm^{-1}. These data are consistent with the deprotonation of $[HFeCo_3(CO)_{12}]$ to form the carbonyl anion, $[FeCo_3(CO)_{12}]^-$,[15] deposited onto the surface. The anion is formed by the acid–base reaction of the hydride cluster, $[HFeCo_3(CO)_{12}]$, with ultimate transfer of the hydride to the amine anchor [eq. (1)]. The deposition of the cluster onto the support is quite easily followed by IR spectroscopy, the clusters $[HFeCo_3(CO)_{12}]$ and $[FeCo_3(CO)_{12}]^-$ exhibiting distinct and different spectra[15] in the region of the carbonyl stretching frequencies.

$$SIL{-}(CH_2)_3NH_2 + [HFeCo_3(CO)_{12}] \longrightarrow SIL{-}(CH_2)_3NH_3^+[FeCo_3(CO)_{12}]^- \quad (1)$$

SIL = Surface≡Si

There appears to be a small shift in the bridging carbonyl stretching frequency to lower frequencies. The shift is monotonic with increasing cluster loading. For small cluster loadings, this difference is at the limit of experimental significance, but is consistently observed. Tight ion pairing interactions between bridging carbonyls of supported anionic clusters and cationic surface species are detectable by a shift of the bridging carbonyl IR absorption to lower frequencies.[5,18] However in the present case, this shift is also observed for the anion on supports without this amine anchor (Table 1). Thus, this shift in the bridging carbonyl IR absorption cannot be attributed necessarily to an interaction of the anion with the alkylammonium anchor or the support, analogous to that postulated for supported $[Fe_3(CO)_{11}]^-$.[5]

The IR spectrum of $[HFeCo_3(CO)_{12}]$ deposited onto aminated silica (catalyst precursor **A**) indicated that no new carbonyl species, other than supported $[FeCo_3(CO)_{12}]^-$, were formed during the deposition process. In particular, Choplin *et al.*[19] reported the deposition of $[HFeCo_3(CO)_{12}]$ onto partially dehydroxylated magnesia. The hydride cluster was deprotonated by the magnesia surface and bound as $[FeCo_3(CO)_{12}]^-$. These authors postulated that $[Co(CO)_4]^-$ was a possible decomposition product accompanying the formation of the anionic cluster on the surface.[19] We have no IR evidence of any surface confined $[Co(CO)_4]^-$ in our product (no absorption at $\simeq$ 1890 cm^{-1}).[20]

Elemental analysis of catalyst precursor **A** showed $\simeq$ 7% metal by weight and an iron to cobalt ratio of 1 : 3, the same ratio as for the original cluster. Temperature-programmed reduction (TPR) experiments of this supported cluster under hydrogen showed no peaks due to reduction of metal species. The IR, TPR and elemental data are consistent with deposition of the metal cluster onto the silica surface without any detectable metal oxidation and with the preservation of the cluster metal framework.

IR spectra were obtained from the $[HFeCo_3(CO)_{12}]$/aminated silica system (catalyst precursor **A**) at a variety of temperatures and under conditions which mimic the thermal catalyst activation process. Upon heating to 110°C in a stream of 1 : 1 carbon monoxide–hydrogen, complete loss of carbonyl ligands from the cluster was observed. Cooling the sample in a carbon monoxide stream does not regenerate the starting supported cluster, nor any other carbonyl-containing species detectable by IR spectroscopy. For this catalyst precursor the elemental analysis of the solid obtained after catalyst activation (and use) shows the same total metal content and the same iron to cobalt ratio as before activation. This contrasts with the work of Czekaj and Geoffroy[21] who have recently shown that bulk $[HFeCo_3(CO)_{12}]$ is volatilized at about 80°C in a carbon monoxide stream. Furthermore, these authors suggest that under these conditions, $[HFeCo_3(CO)_{12}]$ decomposes to $Fe(CO)_5$, $Co_4(CO)_{12}$ and H_2.[21] Thus, cluster decomposition to yield volatile $Fe(CO)_5$ does not occur in our system, in which thermal degradation of the precursor apparently yields metal domains with the same overall stoichiometry as those of the starting supported cluster. This is consistent with the results of Choplin *et al.*[10,19] who established that $[FeCo_3(CO)_{12}]^-$, deposited onto partially dehydroxylated magnesia, starts to decompose at 50°C, and when thermally degraded at 400°C in a stream of hydrogen gives very small bimetallic particles. The individual particles were shown to have the same bulk composition as that of the starting $[HFeCo_3(CO)_{12}]$.

Results of the Fischer–Tropsch testing of the catalyst system derived from precursor **A** are collected in Tables 2 and 3. This catalyst shows activity in the Fischer–Tropsch reaction and remains active for long periods (at least 120 h). Methane production, whilst not excessive, is undesirably high and under all conditions the products follow a typical Shultz–Flory distribution with α-values (propagation probabilities)[22] of around 0.7. The olefin content of the product is high, especially in the range C_3–C_5, and the oxygenate content is low. The overall product distribution does not change appreciably with time. Aminated silica with no loaded metal cluster showed no carbon monoxide conversion under the same activation and testing processes.

Table 2 contains the variance with temperature of the product parameters over the range 220–280°C. Carbon monoxide conversion rates increase with

Conditions: temperature—240°C.

increasing temperature and the catalyst is inactive below 210°C. A calculation of the energy of activation of the Fischer–Tropsch reaction for this catalyst, using the Arrhenius equation, gives a result of 82(±9) kJ mol^{-1}. This compares with values of 108 kJ mol^{-1} for iron and 112 kJ mol^{-1} for cobalt, both deposited onto alumina.[23] The product distribution also changed with temperature over the temperature range studied. Carbon dioxide production increased with temperature from 3 to 19%, as did the amount of methane which rose from 11 to 27%. The petrol fraction was reduced with increasing temperature. Changes in the selectivity to olefins were not systematic with the temperature rise. Thus the desirable increase in carbon monoxide conversion rate at higher temperatures is offset by an undesirable increase in methane and carbon dioxide production.

Table 3 summarizes the changes in the carbon monoxide conversion rate and product selectivity in the Fischer–Tropsch reaction with changes in the gas feed composition. The carbon monoxide conversion rate increases with increasing hydrogen content of the feed gas. The production of carbon dioxide decreases with an increase in the hydrogen content. This decrease is due, in principle, to the shift in the equilibrium position in the water–gas shift reaction. An increase in the hydrogenation of surface species (i.e. increase in methane produced and decrease in olefin fraction) is also observed with rising hydrogen content.

Amine modification of the silica surface appears to be necessary to anchor $[FeCo_3(CO)_{12}]^-$ to silica by solution processes using $[HFeCo_3(CO)_{12}]$. If unmodified silica is used as a support, the silica remains almost colourless after contact with a solution of $[HFeCo_3(CO)_{12}]$, and only a weak IR absorption is observed at 2004 cm^{-1}.[24] We have deposited $[HFeCo_3(CO)_{12}]$ on partially dehydroxylated silica by evaporation from its dichloromethane solution to yield catalyst precursor **B**. The IR spectrum (Table 1) clearly indicates the

presence of the hydrido cluster rather than the anionic cluster, $[FeCo_3(CO)_{12}]^-$, on the support. By contrast, $[HFeCo_3(CO)_{12}]$ is readily bound to alumina or magnesia as the anion.[10,19,24] Elemental analysis of the silica supported catalyst precursor **B** showed that the iron to cobalt ratio of 1:3 was maintained.

The $[HFeCo_3(CO)_{12}]$/partially dehydroxylated silica system (catalyst **B**) is also active in the Fischer–Tropsch reaction (Table 4), but the rate of carbon monoxide conversion is more than an order of magnitude lower than that of the $[HFeCo_3(CO)_{12}]$/aminated silica system (catalyst **A**). The product distribution was found to be similar in both cases. Partially dehydroxylated silica with no loaded metal cluster showed no carbon monoxide conversion under the same activation and testing processes. Elemental analysis of the used catalyst showed no loss of metal and the same iron to cobalt ratio as for the catalyst precursor. The reasons for this dramatic loss of activity are unclear at present. However, it appears that for good carbon monoxide conversion rates, the surface bound catalyst precursor must be the cluster anion.

The anionic metal cluster, $[FeCo_3(CO)_{12}]^-$, was loaded onto partially dehydroxylated silica by evaporation of an acetone solution of $K^+[FeCo_3(CO)_{12}]^-$ to produce catalyst precursor **C**. The IR spectrum (Table 1) and elemental analysis of this supported species indicate that the cluster was deposited as the anion with its metal framework intact. The catalyst derived from this precursor (catalyst **C**) also showed a carbon monoxide conversion rate substantially lower than that observed for the catalyst prepared from $[HFeCo_3(CO)_{12}]$ loaded onto aminated silica (catalyst **A**). However, the reaction rate for catalyst **C** was higher than that of the material derived from hydride cluster deposited onto partially dehydroxylated silica (catalyst **B**). Elemental analyses of catalyst **C** showed no loss of iron or cobalt. Hemmerich *et al.*[12] have suggested that the amine anchors react with the clusters under Fischer–Tropsch conditions to form metal nitride phases. The nitrogen content for the $[HFeCo_3(CO)_{12}]$/aminated silica species after catalysis (catalyst **A**) was still significant at 1.5 nitrogen atoms per $FeCo_3$ unit. However, the nitrogen content for aminated silica (with no loaded metal cluster), after it was tested as a catalyst, indicated that the amine anchors were lost in the absence of loaded metal cluster. This is consistent with the formation of metal nitride phases during activation. Schultz *et al.*[25] showed that iron nitrides have a greater activity in the Fischer–Tropsch reaction than do simple iron phases. This work of Schultz *et al.*[25] supports the view that the increased activity of catalyst **A** is due to the presence of metal nitrides.

$K^+[FeCo_3(CO)_{12}]^-$ was also deposited onto aminated silica by this "incipient wetness" technique with acetone as the solvent, to prepare catalyst precursor **D**. This system showed a low carbon monoxide conversion rate compared with that obtained for $[HFeCo_3(CO)_{12}]$ on aminated silica (catalyst **A**). The carbon monoxide conversion rate and product distribution for catalyst **D** (Table 4) are similar to those observed for this anion loaded onto partially dehydroxylated silica (catalyst **C**). Elemental analysis showed the iron to cobalt ratio before and after catalysis to be 1:3 as expected. The nitrogen content for catalyst **D** was 0.2 nitrogen atoms per $FeCo_3$ unit, compared with the result for $[HFeCo_3(CO)_{12}]$ on aminated silica (catalyst **A**) of 1.5 nitrogen atoms per $FeCo_3$ unit. Thus, despite the presence of surface nitrogen in the catalyst precursor, metal nitrides were not formed during activation of catalyst **D**. This fact is consistent with its activity being low. Therefore, even though the amine anchor may be present, as in catalyst precursor **D**, the available nitrogen must form a close association with the metal cluster anion for the production of metal nitride phases.

The cluster anion was therefore loaded onto partially dehydroxylated silica as $PrNH_3^+[FeCo_3(CO)_{12}]^-$ to yield catalyst precursor **E**. The propylammonium countercation was chosen to mimic the charged amine anchor. The carbon monoxide conversion rate for the catalyst produced from this precursor (catalyst **E**) was high and is similar to the value obtained using the catalyst derived from $[HFeCo_3(CO)_{12}]$ deposited onto aminated silica (catalyst **A**). The nitrogen content for catalyst **E** is high (0.8 nitrogen atoms per $FeCo_3$ unit), indicating the presence of metal nitride phases and is consistent with the observation of higher carbon monoxide conversion rates. The product distributions of catalysts **A** and **E** show a large difference only in the carbon dioxide and diesel selectivity. The other fuel product selectivities and the selectivity to olefin and to oxygenate are quite similar for these two catalysts.

SYNTHESIS OF HETEROGENEOUS OLEFIN-OLIGOMERIZATION CATALYSTS USING HOMOGENEOUS NICKEL-CHELATE COMPLEXES AS A BASIS*

ALISON M. A. BENNETT, GARY A. FOULDS† and DAVID A. THORNTON

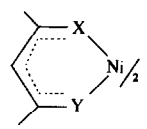
Departments of Chemistry and Chemical Engineering, University of Cape Town, Rondebosch 7700, South Africa

(*Received* 6 *July* 1990; *accepted* 17 *July* 1990)

Abstract—The synthesis and characterization of two nickel(II) catalyst precursors are described. The first is derived from cross-linking of the bis(glycidyl ether) of bis(1-*p*-hydroxyphenyl-1,3-butanedionato)nickel(II) with 1,2-diaminoethane and the second is obtained from polystyrene-supported chloro-2,4-pentanedithionatotriphenylphosphine-nickel(II). The compounds and their homogeneous precursors have been examined for their activity in catalysing the oligomerization of 1-hexene using triethylaluminium and ethylaluminiumdichloride as co-catalysts. Results obtained indicate that the polymeric complexes are active when $AlEtCl_2$ is used as a co-catalyst, but not when $AlEt_3$ is used. Furthermore, oligomerization is accompanied by isomerization, while a high selectivity for dimers is observed. Analysis of the complexes after catalytic runs reveals that some leaching of the nickel ions from the polymers has taken place.

Olefin oligomerization is a fundamental reaction in the upgrading of low molecular weight olefins to high value chemicals and synthetic fuels. Oligomerization may be effected using homogeneous or heterogeneous catalysts and industrial processes have been based on both systems. Examples of these are SHOP[1] and DIMERSOL,[2] which are homogeneous, and MOGD,[3] which is heterogeneous. Both systems have their advantages and disadvantages. Homogeneously-catalysed reactions are generally more efficient, specific and reproducible than those catalysed heterogeneously. However, heterogeneous catalysts are chemically and thermally more stable and also obviate the separation problems encountered in homogeneously-catalysed processes.

In combination with a suitable Lewis acid, almost any soluble nickel compound will show activity for olefin oligomerization. Compounds with oxidation states ranging from zero to two have been used and several comprehensive reviews cover the subject.[5–7] The oligomerization activity of β-ketoenolate and related complexes, **I**, has been extensively studied.[8–13] In particular, bis(2,4-pentanedionato)nickel(II) exhibits high activity in the presence of various Lewis acids and shows remarkable selectivity to linear oligomers if AlR_3 (R = alkyl) is used as co-catalyst.[10]



X = Y = O[8]
X = O, Y = NH[13]

(I)

Closely related to the β-ketoenolate complex catalysts are the systems reported by Cavell and Masters,[14–17] in which the β-ketoenolate ligand has been replaced by its dithio analogue, **II**. In addition, the introduction of the phosphine moiety has a pronounced effect, both on reactivity and selectivity.[16,18] Some of these complexes are among the most active oligomerization catalysts known.

(II)

The aim of the present work is to exploit the advantages of both systems by heterogenizing the most promising of the soluble nickel-complex catalysts. We have chosen $[Ni(acac)_2]_3$ (Hacac = 2,4-pentanedione) and [Ni(sacsac)(PPh_3)Cl] (Hsac sac = pentane-2,4-dithione) as a basis for preparing polymeric analogues, the former for its selectivity in forming linear isomers when used with AlR_3 (R = alkyl) and the latter for its high activity. We have investigated the reactions of 1-hexene with the polymeric complexes, **IV** and **V**, and their monomeric homogeneous precursors, **III** and **II** (X = Cl, R = Ph), respectively, in a series of batch experiments, using $AlEt_3$ and $AlEtCl_2$ as co-catalysts. 1-Hexene was chosen as the reactant olefin for its manageable reactivity and ease of handling. In addition, since the lower olefins are more reactive,[4] complexes that oligomerize 1-hexene should certainly be active for the oligomerization of lower olefins.

EXPERIMENTAL

All reactions were performed using standard Schlenk tube techniques under dry argon. 1-Hexene and toluene were dried over sodium wire and freshly distilled under dry nitrogen before use. The starting materials $[Ni(PPh_3)_2Cl_2]$[19] and $[Ni(sacsac)_2]$[20] were prepared using methods described in the literature. Polystyrene polymer, 2% cross-linked with divinyl benzene and functionalized with PPh_3 at a concentration of 0.00306 mol PPh_3/g polymer, was purchased from Aldrich. Triethylaluminium (25% w/w in toluene) and ethylaluminium dichloride (25% w/w in toluene) were purchased from Aldrich and used as supplied.

Preparation of bis(p-*hydroxyphenyl*-1,3-*butanedionato*)*nickel*(II) (**III**) *and the polymeric nickel complex* **IV**

Bis(*p*-hydroxyphenyl-1,3-butanedionato)nickel(II) (**III**) and the polymeric nickel compound, **IV**, which is derived from complex **III**, were prepared according to the reaction scheme depicted in Fig. 1.[21] The detailed experimental procedure relating to each reaction sequence and the charac-

terization of each intermediate are reported elsewhere.[22]

Preparation of [Ni(sacsac)(PPh_3)Cl]

[Ni(sacsac)(PPh_3)Cl] was prepared in a similar manner to that described previously.[23] [Ni(sacsac)$_2$] (0.48 g, 1.5 mmol) and [$NiCl_2(PPh_3)_2$] (0.98 g, 1.5 mmol) were dissolved in deoxygenated benzene (40 cm^3) and refluxed for 3 h under nitrogen. The resultant solution was filtered while hot. Removal of the solvent from the filtrate yielded a black oily residue. This residue was taken up in the minimum of acetone. Slow addition of n-heptane, with scratching, yielded black crystals. Recrystallization in this manner was repeated until microanalytical purity was established.

Preparation of the polymeric nickel complex **V**

[Ni(sacsac)(PPh_3)Cl] (2.181 g, 4.47 mmol) was dissolved in deoxygenated benzene (50 cm^3). Sufficient PPh_3-functionalized polystyrene polymer (2.0 g) was added to the solution, which was then refluxed for 48 h. The dark brown, polymeric, supported nickel complex, **V**, was filtered and washed with benzene until the washings were colourless.

Analyses of complexes

The purity and composition of the compounds were determined by microanalysis (C, H and N) and Energy Dispersive X-ray analysis (EDX) (Ni) (Table 1). Further characterization was achieved using ^1H and ^{13}C NMR spectroscopy, IR spectroscopy and thermogravimetry. NMR spectra were run at ambient temperature on a Varian ZX 200 spectrometer using CH_3OD or $CDCl_3$ as solvent and TMS as reference. IR spectra were determined as Nujol mulls (4000–1500 and 1300–300 cm^{-1}) or hexachlorobutadiene mulls (4000–1700 and 1500–1300 cm^{-1}) between CsI plates on a Perkin–Elmer 983 spectrophotometer, and as Nujol mulls between polyethylene plates (500–80 cm^{-1}) on a Digilab FTS-16 B/D interferometer. Thermogravimetric analysis was performed on a Stanton Redcroft thermal analyser.

1-*Hexene oligomerization*

Oligomerization was carried out in batch mode using a magnetically-stirred glass reactor. To exclude the presence of any water associated with the nickel catalyst, each was dissolved or slurried in toluene, transferred to the reactor and azeotroped

Table 1. Analytical data

for several hours under argon (concentration of nickel in toluene = 10^{-3} mol nickel/60 cm^3 toluene). The reactor, heated by a thermostatted oil bath, was allowed to stabilize at 40°C, before injecting the co-catalyst (25% w/w in toluene) into the reactor via a septum (Ni : Al ratio 1 : 1 for $AlEt_3$ and 1 : 10 for $AlEtCl_2$). The reaction temperature, which was monitored throughout, rose intitially (45°C) before slowly returning to 40°C. The reactor was maintained under a positive pressure of argon and samples (1 cm^3) were taken with a syringe at regular time intervals. The samples were immediately mixed with methanol to quench the reaction by catalyst deactivation.

Product analysis

The liquid products were filtered (to remove deactivated nickel complex precipitate) and analysed by gas–liquid chromatography, using methanol as an internal standard. Product analysis was determined using a Varian 3600 GC with a 0.531 mm i.d., 30 m long, fused silica megabore column, coated with a 1.5 μm film of DB 101 (100% methylpolysiloxane). Products have been reported as mass % :

$$\text{mass \% (olefin } i) = \frac{(\text{Peak area olefin } i)R_{fi}}{\sum_{i=1}^{n} [(\text{Peak area olefin } i)R_{fi}]}$$

where n = number of olefins present
R_{fi} = response factor of olefin i*.

* The response factor of an olefin with a carbon number greater than five is taken as unity.

RESULTS AND DISCUSSION

IR spectra

Selected bands from the IR spectra of compounds **II**, **III**, **IV** and **V** are listed in Table 2. The carbonyl stretch, ν(C═O), occurs at 1610 cm^{-1} for *p*-hydroxybenzoylacetone and a shift of 10 cm^{-1} to lower wavenumber is an indication that complexation with nickel(II) to yield the monomeric complex **III** has occurred. This vibration is also present in the polymeric complex **IV** and occurs at 1590 cm^{-1}. Of particular interest are the metal–ligand vibrations, ν(Ni—O), which occur at 435 and 271 cm^{-1} for the monomer, **III**, and at 429 and 276 cm^{-1} for the cured epoxy polymer, **IV**. These bands have been assigned by comparison with the spectrum of *trans*-$[Ni(acac)_2(H_2O)_2]$[24] and by metal-ion substitution studies.[24] The bands at 3281 and 3164 cm^{-1} are assigned to the asymmetric and symmetric N—H stretches in the cured polymer **IV** which do not, of course, occur in the spectrum of the monomer **III**. In addition, the presence of ν(N—H) indicates that

Table 2. Characteristic bands (cm^{-1}) in the IR spectra of the polymeric complexes and their homogeneous precursors

	III	**IV**	[Ni(sacsac)(PPh_3)Cl]	**V**
ν(C═O)	1600	1590		
ν(Ni—O)	435	429		
	271	276		
$\nu(N—H)_{as}$		3281		
$\nu(N—H)_s$		3164		
ν(C═S)			715	710
ν(Ni—S)			382	393
			290	
ν(Ni—Cl)			332	338

only a degree of cross-linking has been achieved, while the absence of any bands which may reasonably be assigned to ν(Ni—N) eliminates the possibility of coordination of ethylenediamine.

In considering the spectra of [Ni(sacsac)(PPh_3)Cl] (**II**; R = Ph, X = Cl) and the polymer **V**, the bands which impart important structural information are ν(C=S), ν(Ni—S), ν(Ni—P) and ν(Ni—Cl). The ν(C=S) band occurs at 715 cm^{-1} in the complex [Ni(sacsac)(PPh_3)Cl] and is shifted to 710 cm^{-1} in the spectrum of the polymer **V**. Assignment of ν(Ni—S) has been made with reference to a recent study[24] in which the IR spectrum of [Ni$(sacsac)_2$] was analysed. The ν(Ni—Cl) band was assigned on the basis of halide substitution.[24] The assignment of ν(Ni—P) is as yet unclear. However, a detailed IR study of the complexes **II** is presently being undertaken with a view to assigning ν(Ni—P).

Finally, the fact that the metal–ligand bands are not significantly shifted when the monomeric complexes are converted into their polymeric derivatives strongly suggests that the square-planar environment of the nickel(II) ion is unchanged.

^{1}H *and* ^{13}C *NMR spectra*

Due to their limited solubility, the NMR spectra of the complexes **III**, and the polymers **IV** and **V** could not be determined. ^{1}H and ^{13}C NMR spectra confirmed the identity of [Ni(sacsac)(PPh_3)Cl] (Table 3).

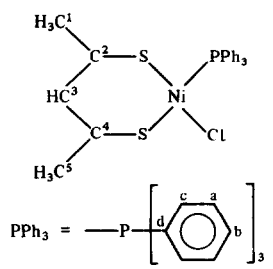

Table 3. ^{1}H and ^{13}C NMR spectra of [Ni(sacsac)(PPh_3)Cl][a]

C^3H	Obscured	C^3	130.84
		C^a	128.13 (doublet)
Ph	7.4–7.9	C^b	130.53
	(multiplet)	C^c	135.04 (doublet)
		C^d	Not observed

[a] Spectra were run at ambient temperature using $CDCl_3$ as solvent and TMS as reference.
J_{CCP} = 9.8, J_{CCCP} = 10.2.

The chemical shifts are similar to those reported for [Ni(sacsac)(PEt_3)Cl].[23] At ambient temperature the methyl resonances are magnetically equivalent. This equilibration has been attributed to phosphine or halide exchange.[23] As also found for the complex [Ni(sacsac)(PEt_3)Cl], the relaxation time of the quaternary carbon atoms is insufficiently short for these resonances to be observed.

TGA/DTA studies

The TGA/DTA curves for the polymeric complexes **IV** and **V** are shown in Figs 2 and 3, respectively. It is clear that the polymer **V** is stable to over 200°C, whereas the epoxy polymer **IV** exhibits a mass loss at much lower temperatures. A total mass loss of 80% is observed for polymer **V**, with the final residue being NiO. Consequently, 14.5% of the polymer mass is nickel, which is consistent with the EDX analysis which yielded 14.3% by mass of nickel. A total mass loss of 76% is observed for the epoxy polymer **IV**. However, the residue is not NiO, but a more complex acid-insoluble material.

1-*Hexene oligomerization*

In the oligomerization studies, it was decided not only to investigate the effect of catalyst, but also the

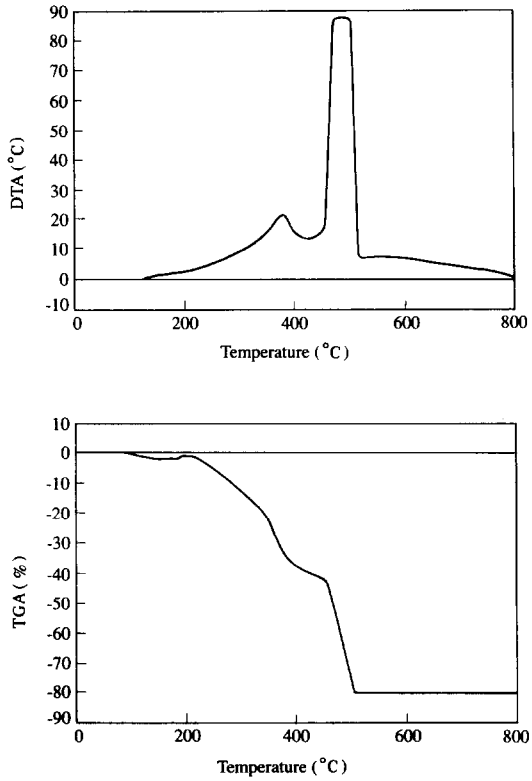

Fig. 2. TGA/DTA curves for polymer **IV**.

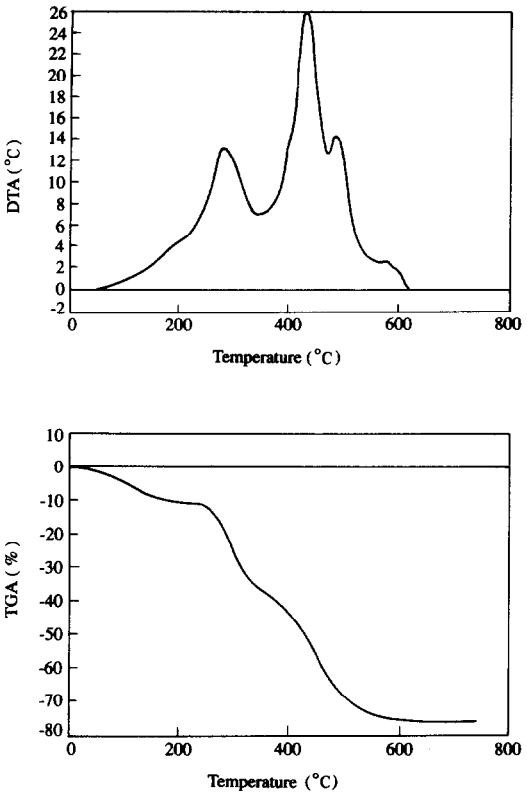

Fig. 3. TGA/DTA curves for polymer **V**.

effect of co-catalyst on the activity and selectivity of the reaction. We have utilized $AlEt_3$ and $AlEtCl_2$ co-catalysts, because firstly, the order of reactivity for the chloride-containing Lewis acids is $AlEt_2Cl < Al_2Et_3Cl_3 < AlEtCl_2$[22] and secondly, because a unique selectivity for linear product formation is obtained when $AlEt_3$ is used in a 1:1 ratio with bis(β-ketoenolato)nickel(II) complexes in "chloride-free" solvents.[10,25] The latter phenomenon is illustrated in Figs 4 and 5 where 1-hexene

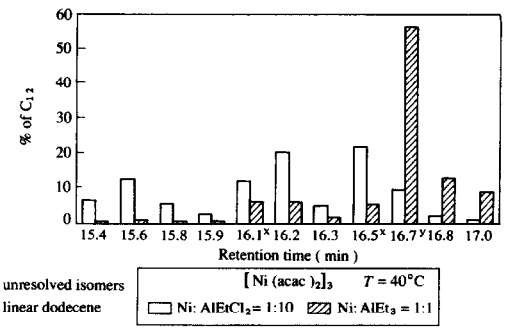

Fig. 5. C_{12} isomer distributions using $[Ni(acac)_2]_3$ with $AlEt_3$ and $AlEtCl_2$ as co-catalysts.

has been oligomerized by $[Ni(acac)_2]_3$ in the presence of an equimolar amount of $AlEt_3$ and a 10-fold excess of $AlEtCl_2$. Clearly, $AlEtCl_2$ has the higher activity, but Fig. 5 reveals the striking difference in C_{12} selectivity.

Compounds **III**, **IV** and **V** were not active when tested with an equimolar amount of $AlEt_3$. These complexes are insoluble and it is possible that the stability of the complexes, coupled with their insolubility, may preclude the formation of the active species in the presence of the weak Lewis acid.

The polymeric nickel complex, **IV**, and its monomeric precursor, **III**, are both active as oligomerization catalysts when a 10-fold excess of $AlEtCl_2$ is utilized as co-catalyst. As is commonly found in these systems, oligomerization is accompanied by isomerization to internal olefins.[26]

Figure 6 shows the conversion of 1-hexene using the monomeric complex, **III**, as catalyst. This complex, which is suspended in toluene, dissolves on the addition of $AlEtCl_2$ and the reaction thus proceeds in a homogeneous manner. As for other homogeneous catalysts of this type, the monomeric complex, **III**, exhibits high initial activity and is, in fact,

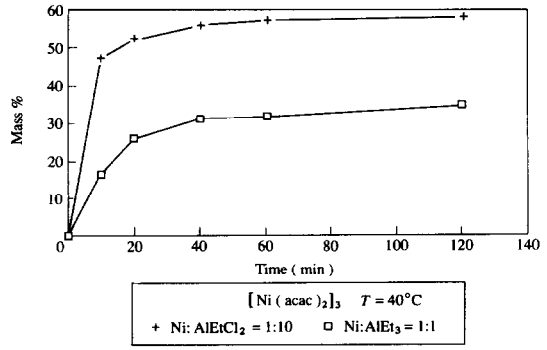

Fig. 4. Dimerization of 1-hexene using $[Ni(acac)_2]_3$ with $AlEt_3$ and $AlEtCl_2$ as co-catalysts.

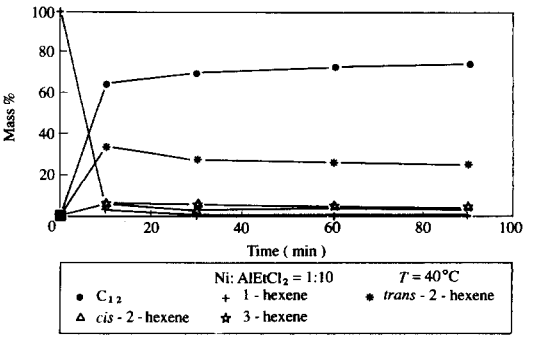

Fig. 6. Conversion of 1-hexene using complex **III** with $AlEtCl_2$ as co-catalyst.

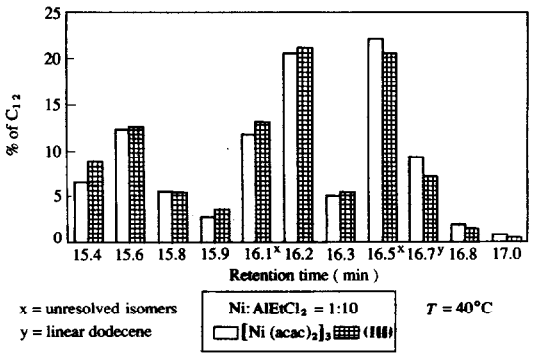

Fig. 7. C_{12} isomer distributions using $[Ni(acac)_2]_3$ and complex **III** with $AlEtCl_2$ as co-catalyst.

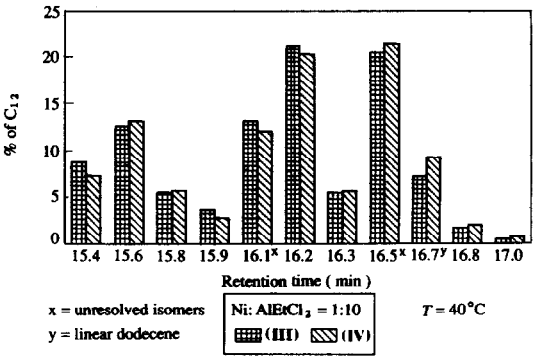

Fig. 9. C_{12} isomer distributions using complex **III** and polymer **IV** with $AlEtCl_2$ as co-catalyst.

more active than $[Ni(acac)_2]_3$ (Fig. 4). This may be due to the electronic effect of the ligand which now has a *p*-hydroxyphenyl substituent replacing a methyl group. The C_{12} isomers produced by the monomeric complex, **III**, and $[Ni(acac)_2]_3$ are shown in Fig. 7. It is clear that they are very similar and it is likely that a similar reaction mechanism is involved.

The nickel polymer, **IV**, exhibits a different trend from that observed for its monomeric homogeneous precursor, **III** (Fig. 8). Although conversion is still rapid, the isomerization reaction predominates in the early stages producing a large percentage of *cis*- and *trans*-2-hexene and 3-hexene. That oligomerization proceeds at a slower pace is probably due to the fact that the internal C_6 olefins have to be converted to the α-olefin. This is evident from a concomitant decrease in the internal C_6 olefins as C_{12} dimers are produced. No active species have been presented in the literature to describe the activity of supported catalysts. However, the similarity in C_{12} isomer distribution for both the polymeric complex and its homogeneous precursor is clearly illustrated in Fig. 9, implying that both systems comprise a similar active species. In addition, both monomer **III** and polymer **IV** produce dimers only, with no higher oligomers being formed.

Turning to [Ni(sacsac)(PPh_3)Cl] and the phosphine supported polymer, **V**, the situation is similar to the system described above in that the supported catalyst is initially less active than its homogeneous precursor (Figs 10 and 11). Similarly, C_6 isomerization is dominant in the early stages but is followed by increasing oligomerization. As observed by Cavell and Masters,[14] who studied the oligomerization of propylene using [Ni(sacsac)(PPh_3)Cl] and a polymer-supported analogue, the oligomer (C_{12}) isomer distribution is similar when the homogeneous catalyst is heterogenized onto an organic support (Fig. 12). This is indicative of the operation of a similar active species in both systems. Comparison of the C_{12} isomer distribution formed by the polymeric complexes, **IV** and **V**, respectively, reveals substantial differences between the two systems (Fig. 13). These differences can probably be ascribed to the influence of the phos-

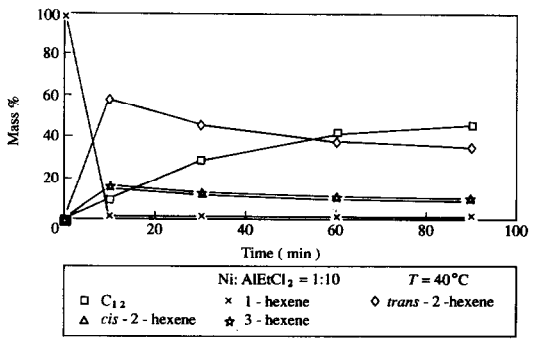

Fig. 8. Conversion of 1-hexene using polymer **IV** with $AlEtCl_2$ as co-catalyst.

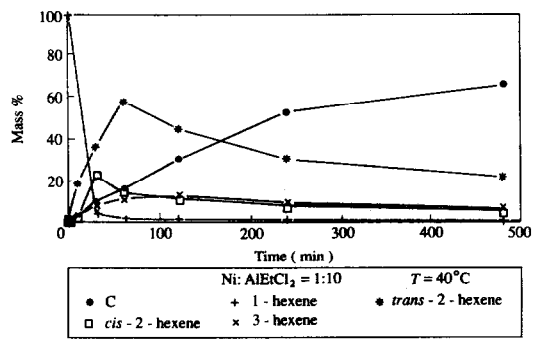

Fig. 10. Conversion of 1-hexene using polymer **V** with $AlEtCl_2$ as co-catalyst.

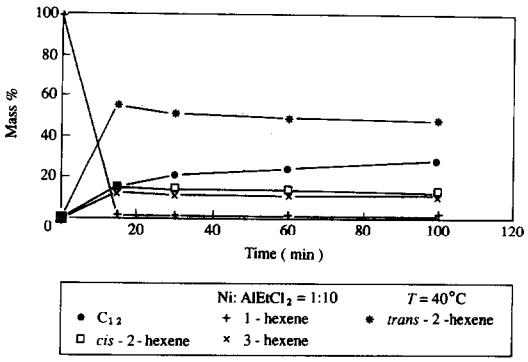

Fig. 11. Conversion of 1-hexene using [Ni(sacsac)(PPh$_3$)Cl] with AlEtCl$_2$ as co-catalyst.

phine ligand on the reaction.[18] Analysis of the polymer **V**, after reaction, revealed that the percentage nickel had decreased from 6.2% to less than 1%. This suggests excessive weeping and some doubt exists as to whether only polymer-bound nickel was responsible for oligomerization. As a result of the excessive weeping, the polymer **V** could not be used for successive runs, a major drawback of this system.

In conclusion, the epoxy polymer, **IV**, shows promise as an olefin oligomerization catalyst, particularly in view of its thermal and chemical stability.[21] However, the non-selectivity towards yielding a linear product and the fact that only dimers are formed, are two factors that require further investigation. We are presently examining the synthesis of nickel(I) complexes and methods for their polymerization, since a number of these complexes have been shown to be active for the homogeneous oligomerization of olefins to linear products.[12] In addition, it also obviates the use of a co-catalyst.

Abstract—Reactions of $[Cu(PPh_3)_4]ClO_4$ with heterocyclic thiones (L) [L = pyridine-2-thione (py2SH), pyrimidine-2-thione (pymtH), 1,3-thiazolidine-2-thione (tzdtH), 1-methyl-1,3-imidazoline-2-thione (meimtH), benz-1,3-imidazoline-2-thione ($bzimtH_2$), benz-1,3-thiazoline-2-thione (bztzH), 5-nitro-2-benz-1,3-imidazoline-2-thione ($nbzimtH_2$) 5-methyl-2-benz-1,3-imidazoline-2-thione ($mebzimtH_2$) and quinazolinone-2-thione ($qnotH_2$)] yield mononuclear complexes of the general formula $[Cu(L)_2(PPh_3)_2]ClO_4 \cdot 2CHCl_3$. The complexes have been characterized by elemental analysis, IR, UV–vis and NMR spectroscopy. The crystal structure of $[Cu(py2SH)_2(PPh_3)_2]ClO_4 \cdot 2CHCl_3$ has been determined by single-crystal X-ray diffraction methods. The copper atom has S_2P_2 tetrahedral coordination with Cu—S 2.363, 2.377(1) Å and Cu—P 2.301, 2.315(1) Å.

There has been considerable interest during the past few years in complexes of heterocyclic thiones and transition metals, stemming from the similarity of these ligands with thiolated nucleosides.[1] Notably, major interest has grown in copper complexes due to the biological importance of copper–sulphur interactions in Cu^I/Cu^{II} redox systems.[2]

Recently the structures of a number of simple complexes of copper(I) with heterocyclic thiones, and also of mixed complexes with heterocyclic thiones and triphenylphosphine ligands, have been reported.[3–5] As part of our continuing investigation into the synthesis and chemical structural properties of copper(I) complexes, we report here the preparation and characterization of a new series of complexes of the general formula $[Cu(L)_2(PPh_3)_2]ClO_4$.

EXPERIMENTAL

Physical measurements

Elemental analyses of carbon, nitrogen, hydrogen and copper, IR, electronic and NMR spectra, conductivities and magnetic susceptibility measurements were performed as described previously.[5]

Starting materials

$[Cu(PPh_3)_4]ClO_4$ was prepared from $CuClO_4$ and PPh_3 as described in the literature.[6] All thione ligands, supplied by EGA or Aldrich, were used after recrystallization from ethanol. Triphenylphosphine, copper(II) perchlorate and all solvents were of reagent grade and were used without further purification in the synthetic work.

Preparation of the complexes

$[Cu(PPh_3)_4]ClO_4$ (1 mmol) was dissolved in 30 cm^3 of chloroform and treated with 20 cm^3 of a 1 mmol solution of the appropriate ligand in the same solvent. The reaction mixture was refluxed for 2 h, filtered and cooled to room temperature. Slow evaporation of the solvent at room temperature gave the microcrystalline solid, which was filtered off, washed with ether and dried *in vacuo*.

Collection and reduction of intensity data

Complete crystal and intensity collection data are reported in Table 1. Unit cell dimensions were derived from least-squares refinement of the setting angles of 15 automatically centred reflections in the range $13 < 2\theta < 24°$ on a SYNTEX $P2_1$ diffractometer. The intensities of three standards monitored after every 67 reflections were stable, with a scatter of less than 3% from their respective means. Lorentz and polarization corrections were applied.

Solution and refinement of the structure

The positional coordinates of copper, chlorine, sulphur and phosphorus atoms were deduced by direct methods using the SHELX 76 program.[7] The rest of the non-hydrogen atoms were revealed by subsequent ΔF calculations. The difference map showed the existence of two solvent molecules (chloroform) in the asymmetric unit, one of them being disordered. The difference map shows two positions, A and B, for the disordered $CHCl_3$. The

[b] $R_w = [\Sigma w(\Delta F)^2/\Sigma w|F_o|^2]^{1/2}$.

site occupancies of the positions A and B were refined, keeping the sum of the two constant at 1.0, and the Cl—Cl and C—Cl distances constrained to 2.84(1) and 1.73 Å. The occupancy refined to 0.809(3) Å for the A position. Refinement was carried out by blocked full-matrix least-squares, in which $\Sigma w\Delta^2$ was minimized. The hydrogen atoms were calculated as riding on carbon atoms at 1.02 Å. Non-hydrogen atoms were refined using anisotropic temperature factors and hydrogen atoms isotropic temperature factors. Atomic scattering factors were taken from the *International Tables for X-ray Crystallography*.[8]

RESULTS AND DISCUSSION

It is well known that copper(I) complexes with heterocyclic thiones have a wide variety of stoichiometries and structure types depending on both the thione ligand and the counter ion. Generally, the number of ligands bound to the univalent metal seems to be influenced by both the chemical nature of the ligands and the geometry they impose. In fact, in the absence of triphenylphosphine, three or four ligand molecules are present in pyridine-2-thione complexes for nitrate[9] and perchlorate[10] derivatives. However, in the presence of triphenylphosphine it seems that the counter ion does not change the core geometry and a distorted tetrahedral coordination about the copper atom is obtained.

The crystal structure of mononuclear or binuclear halide complexes, e.g. [Cu(py2SH)$(PPh_3)_2$Br] and $[Cu(py2SH)(PPh_3)Br]_2$[3] shows that coordination about copper involves the halogen atom. Interestingly, the reaction of $[Cu(PPh_3)_2NO_3]$ with heterocyclic thiones results in the formation of the complexes $[Cu(L)_2(PPh_3)_2]NO_3$ in which the anion is not coordinated to copper.[5]

The reaction of $[Cu(PPh_3)_4]ClO_4$ with these heterocyclic thiones (L) yields a variety of crystalline products. These products fall into two general groups corresponding to either a 1:1 or to a 2:1 ligand-to-metal ratio; no species containing more than two heterocyclic thione ligands per copper ion have been observed. On changing the solvent, products of different composition have been isolated, but their analytical results were poor and irreproducible.

All the complexes described herein are air- and moisture-stable solids, but their solutions are oxidized within a few days. They are diamagnetic, as would be expected for d^{10} species, and behave as 1:1 electrolytes in acetonitrile solutions. Table 2 lists the compounds we have isolated with their colours, melting points and analytical data. The

results of the elemental analyses show good agreement with the suggested formulae.

Description of the structure

Relevant distances and angles are listed in Table 3. Figure 1 contains a labelled diagram of the cation with an adjacent perchlorate group.

The pyridine-2-thione acts as a monodentate ligand coordinating through the sulphur atom. The $Cu_2X_2L_2$ core geometry is very similar to that of the complex $[Cu(py2SH)_2(PPh_3)_2]NO_3$. The coordination of copper(I) is distorted tetrahedral, with a mean distance of 2.370 Å for Cu—S and 2.308 Å for Cu—P. The Cu—S distances are somewhat shorter than the sum of the covalent tetrahedral radii for copper and sulphur (2.39 Å); they are not sufficiently short to suggest appreciable metal–sulphur multiple bonding.

The Cu—P(1) and Cu—P(2) bond lengths [2.301(1) and 2.315(1) Å, respectively] are in good agreement with the distances in $[Cu(PPh_3)_2(BF_4)]$[11] and $[Cu(PPh_3)_2(pymtH)Br]$.[3]

The angles at the copper atoms are nearly tetrahedral. This result is a consequence of the approximately equal steric factors near the copper coordination sphere. However, the P—Cu—P angle of 121.5° deviates considerably from the tetrahedral value of 109.47°, but falls in the range of values

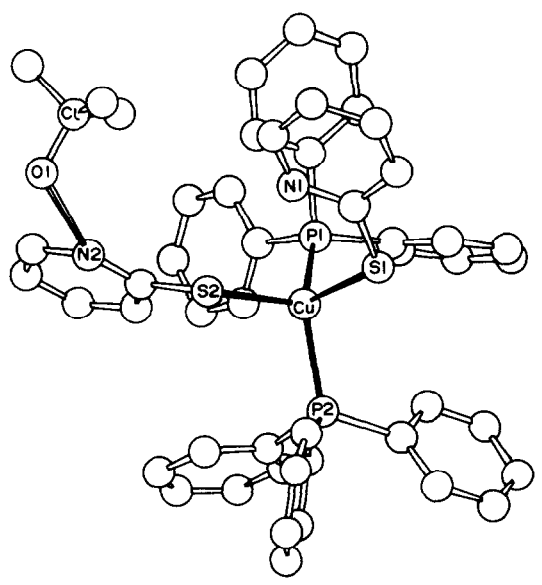

Fig. 1.

reported for other bis(triphenylphosphine)copper(I) compounds.[12]

It is suitable to present the results as a comparison between the compounds $[Cu(tzdtH)_2(PPh_3)_2]NO_3$ (**I**)[5] and $[Cu(py2SH)_2(PPh_3)_2]ClO_4$ (**II**). The interatomic parameters associated with each of the molecules **I** and **II** are similar, which indicates that the molecules are very nearly identical. A difference between the two molecules is found in the interaction of S(1) with copper atoms, namely, Cu—S [2.377(1) and 2.363(1) Å for molecule **I**, and 2.373(1) and 2.382(1) Å for molecule **II**] and associated S(1)—Cu—S(2) angles of 101.3(0) and 115.4(0)°, respectively.

A slightly greater difference is observed in the Cu—P distances [2.301(1) and 2.315(1) Å for molecule **I**, and 2.292(1) and 2.310(1) Å for molecule **II**], which is associated with a small increase in the angle P—Cu—P [121.5(0)° for molecule **I** and 123.2(0)° for molecule **II**].

Electronic spectra

The UV–vis spectra of the complexes in $CHCl_3$ at ambient temperature, as expected, show no *d–d* transitions but consist of two strong absorption bands with maxima at ~360 and ~280 nm, which can be assigned as intraligand transitions.

IR spectra

IR spectra of the studied complexes are in agreement with the X-ray diffraction data with respect to the monodentate sulphur donating character of the ligands investigated. In fact, only small changes upon coordination can be observed in the 3400–3100 cm^{-1} region for bands assigned to N—H stretching vibrations, suggesting that the nitrogen atoms are not involved in bonding.[11]

The pattern of vibrations and the directions of the shifts in the position of the four "thioamide" bands[12,13] are very similar to those observed for the analogous nitrate complexes[4] in which the coordination also takes place through the thione sulphur atom.

The monodentate nature of the ligands is further confirmed by the presence of new bands around 350 cm^{-1}, which can be assigned to the ν(Cu—S) vibration,[12] and the absence of the corresponding ν(Cu—N).

Ionic perchlorate is indicated by the presence of an intense broad band at 1090 cm^{-1}, as well as a band of medium intensity at 620 cm^{-1}, in the solid state IR spectra of all the complexes.[14,15]

Supplementary material

Lists of observed and calculated structure factors, of positional and anisotropic thermal parameters of the non-hydrogen atoms, of positional and isotropic thermal parameters of the hydrogen atoms are available from the authors on request. Atomic coordinates have been deported with the Cambridge Crystallographic Data Centre.

(*Received* 20 *March* 1990; *accepted* 25 *July* 1990)

Abstract—New pyrazole-derived ligands, 3,5-bis(2-pyridyl)pyrazole (HL), 2-(6-methyl) pyridyl-2-pyridyl-3,5-pyrazole (HL^1) and 3,5-bis-2-(6-methyl)pyridyl-3,5-pyrazole (HL^2), are reported. Complexes of formulae $[ML(NO_3)]\cdot xH_2O$ (M = Co^{II}, Ni^{II}, Zn^{II} and Cd^{II}), $[ML(NCS)]\cdot H_2O$ (M = Co^{II}, Ni^{II}, Zn^{II} and Cd^{II}), $[ML^1(NO_3)]\cdot H_2O$ (M = Ni^{II} and Co^{II}), $[M_2L^2(NO_3)_2(OH)]\cdot H_2O$ (M = Ni^{II} and Co^{II}), $[M_2L^1Cl_2(OH)]$ (M = Co^{II} and Ni^{II}) were synthesized and characterized by IR and UV–vis spectroscopies and magnetic susceptibility measurements. Dinuclear compounds containing a di-μ-pyrazole bridge are found in nitrate and thiocyanate complexes with the first two ligands, while mixed μ-hydroxo, μ-pyrazole-bridged structures are found in chloride complexes with the second ligand and nitrate complexes with the last ligand.

Research on the coordination chemistry of pyrazole-derived ligands has progressed very rapidly in the last years. The synthesis of metallocycles of the type $M(pz)_nM'$, where pz is the pyrazole or pyrazole-derived ligand, is one of the major areas of interest.[1] Very recently, the interest in this $M(pz)_nM'$ metallocycle type of compounds has increased due to the possibility of the synthesis of mixed μ-OH, μ-pz-bridged compounds of rhodium(III), nickel(II), palladium(II) or platinum(II). These compounds are very interesting due to the enhanced nucleophilicity of the OH group. The high-field ^1H NMR[2,3] observed for the —OH proton supports this assumption.

Trofimenko in his extensive and well documented review[1] inspires further studies on these $M(pz)_nM'$ metallocycles. Both metal ions are close enough to undergo synchronous or stepwise reactions with small molecules, possibly of a catalytic nature. Numerous double pz-bridged bimetallic complexes, $M(pz)_2M'$, are known, commonly with monodentate or bidentate ligand groups completing the coordination of the metal ions. With few exceptions, the $(AA)M(pz)_2M'(AA)$ complexes have a boat configuration, in which the $M(pz)_2M'$ core is not planar. In the unusual $(C_5H_5)_2Ti(pz)_2Ti(C_5H_5)_2$ complex, the two pz rings are coplanar, but the Ti atoms lie 0.4 Å above and below the central ring plane, resulting in an overall chair conformation.[4] This non-planarity sometimes causes difficulty in synthesizing compounds with interesting catalytic and physical properties. The puckered nature of the $M(pz)_2M'$ core and the non-planarity of the whole complex is generally due to the non-rigid complex skeleton and the exo-nature (pyrazole independent) of the ligands used to complete the coordination of the metal ions.

In a recent paper[5] we reported an interesting pz-derived ligand affording strictly planar, dinuclear di-μ-pz-bridged complexes. The 3,5-bis(2-pyridyl)pyrazole (HL) has proved to be an excellent tetradentate, dinucleating ligand giving dinuclear

complexes with first row transition metal ions. The nickel complex of this ligand, $[Ni_2L_2(MeOH)_4]Cl_2 \cdot 2H_2O$, has a molecular structure in which both ligand molecules and both metal ions are coplanar.[5] Furthermore, four solvent molecules complete the hexacoordination of the nickel(II) ion. On the other hand, the copper(II) complex shows an interesting tetrahedral tetramer structure, cubane-like, involving $\pi(h^5)$ Cu^{II}–pz dimer–dimer interactions.[6] In this paper we report on two new, closely related 3,5-bis(2-pyridyl)pyrazole-derived ligands (Fig. 1) and their comparative coordination chemistry toward the first transition metal series and group 12 metal ions.

EXPERIMENTAL

General

All reagents were commercial grade materials and were used without further purification. All solvents (methanol, ethanol) were previously deoxygenated in a vacuum line and all reactions were routinely carried out under nitrogen atmosphere.

Analyses (C, N, H) were performed in our microanalytical laboratory on a Perkin–Elmer 240-B instrument. IR spectra were run on a Perkin–Elmer FT spectrophotometer as KBr pellets or Nujol films. Electronic spectra were run on a Kontron UV–vis spectrophotometer in the solid state (KBr pellets). ^1H and ^{13}C NMR were recorded on a Brucker AM 400WB spectrometer.

Magnetic susceptibility measurements were made using a Faraday type balance equipped with a liquid nitrogen cryostat. Diamagnetic corrections were calculated from Pascal Tables and direct diamagnetic susceptibility measurements of the ligands. No TIP (temperature independent paramagnetism) corrections were used in the calculations. From the Curie–Weiss plot of the magnetic measurements, the Curie constant, C, was calculated and the g value was derived by the equation $C = 0.125 \times g^2 \times S(S+1)$, where S is the spin value of the corresponding metal ion.

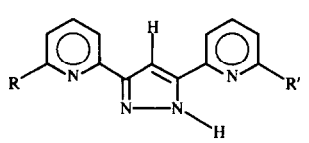

Fig. 1. Pyrazole-derived ligands: R = R′ = H: HL; R = CH_3, R′ = H: HL^1; R = R′ = CH_3: HL^2.

Materials

The compound 6-methyl-2-picolinic acid[7] was prepared by previously reported procedures. The ligand molecule, 3,5-bis(2-pyridyl)pyrazole (HL), was synthesized as previously described.[5]

Synthesis of the ligands

Preparation of methyl-6-methyl-2-picolinate. A 500-cm^3 round-bottom flask, equipped with a reflux condenser and addition funnel, was charged with 6-methyl-2-picolinic acid (11.4 g, 83.1 mmol) and methanol (25 cm^3). H_2SO_4 (12.5 cm^3) was slowly added (1 h) through the funnel. The resulting solution was then gently refluxed for 2 h, allowed to cool to room temperature and then poured into a mixture of 10 g of ice in 90 cm^3 of water. The solution was neutralized (Na_2CO_3), and then filtered and extracted with several portions of ethyl ether (50 cm^3 each). The extract was dried overnight (anhydrous Na_2SO_4) and filtered. The solvent was eliminated by rotary evaporation and the residue placed on the vacuum line at 80°C to eliminate the last traces of water. Yield: 10.3 g; 82%. IR spectrum (KBr): ν(C=O) 1723 cm^{-1}; ν(C=C) 1593 cm^{-1}. ^1H NMR (d_6-dmso, ppm): 2.6 (s, 3, CH_3—py); 4.0 (s, 3, CH_3—CO); 7.53 (t, 1, *H*—py); 7.9 (d, 2, *H*—py). ^{13}C NMR (d_6-dmso, ppm): 23.6, CH_3—py; 52.0, CH_3—CO; 121.8, 126.5, 137.24, 146.79, 158.26 (C_5H_5N); 165.28 (*C*O). Found: C, 63.2; H, 5.6; N, 8.7. Calc. for $C_8H_9NO_2$: C, 63.6; H, 6.0; N, 9.3%.

Preparation of 2-pyridyl-2-(6-methyl)pyridyl-1,3-propanedione. Under a dinitrogen atmosphere, a 250-cm^3 Schlenk flask was charged with sodium (0.67 g, 28.0 mmol). Ethanol (20 cm^3) was added and the mixture was stirred until all the sodium was consumed. The ethanol was eliminated *in vacuo*. Dry toluene (25–30 cm^3), methyl-6-methyl-2-picolinate (4.39 g, 29.0 mmol) and pyridyl-methyl-ketone (4.95 g, 40.9 mmol) were added in this order, always slowly, to the white residue of sodium ethanolate. The mixture was stirred until a yellowish precipitate separated (0.5 h), then it was gently warmed until the sodium salt of the β-diketone was formed (6 h). The salt was filtered and dried. The resulting solid was slowly added to a vigorously stirred solution of acetic acid (30 cm^3), water (30 cm^3) and ice (100 g), yielding a solid which was filtered and dried *in vacuo*. Yield: 4.5 g; 64.6%. IR spectrum (KBr): ν(C=O) 1615 cm^{-1}; ν(C=C) 1564 cm^{-1}. ^1H NMR ($CDCl_3$, ppm): 2.58 (s, 3 CH_3—py); 4.8 [$H_2C(C{=}O)_2$]; 7.1–8.1 [m, 7, *H*—py, *H*C=C(O)]; 8.6 (s, 1, *H*—py): Found: C,

69.4; H, 4.9; N, 11.1. Calc. for $C_{14}H_{12}N_2O_2$: C, 69.0; H, 5.0; N, 11.7%.

Preparation of 2-(6-*methyl*)*pyridyl*-2-*pyridyl*-3,5-*pyrazole* (HL^1). A 100-cm^3 Schlenk flask connected to a Dean–Stark apparatus was charged with 2-pyridyl-2-(6-methyl)-pyridyl-1,3-propanedione (1 g, 4.2 mmol) and hydrazine (0.24 g, 7.5 mmol). Benzene (70 cm^3) was added, and the mixture was then refluxed for 18 h, allowed to cool to room temperature and then filtered. Yield: 0.9 g; 91.5%. IR spectrum (KBr): ν(N—H) 3283 cm^{-1}; ν(C=C), ν(C=N) 1581–1562 cm^{-1}. ^1H NMR ($CDCl_3$, ppm): 2.50 (s, 3, CH_3—py); 7.0 (d, 1, *H*—py); 7.1 (d, 1, *H*—py); 7.35 (s, 1, *H*—pyrazole); 7.5–7.8 (m, 3, *H*—py); 7.90 (d, 1, *H*—py); 8.6 (s, 1, *H*—py); 10.4 [b, 1, *H*—N(pyrazole)]. ^{13}C-NMR ($CDCl_3$, ppm): 158, 149, 136, 122.7, 122.4, 120, 112 (C_5H_3N); 149, 101 (C_3HN_2); 24.4 (CH_3). Found: C, 71.2; H, 5.1; N, 23.4. Calc, for $C_{14}H_{12}N_4$: C, 71.2; H, 5.1; N, 23.7%.

Preparation of 1,3-*bis*[2-(6-*methyl*)*pyridyl*]-1,3-*propanedione*. Under a dinitrogen atmosphere, a 250-cm^3 Schlenk flask was charged with sodium (0.63 g, 27.4 mmol). Deoxygenated absolute ethanol (20 cm^3) was added and the mixture was stirred until all the sodium was consumed. The ethanol was eliminated *in vacuo* to yield a white solid. Dry toluene (25–30 cm^3), methyl-6-methyl-2-picolinate (4 g, 26.5 mmol) and 6-methylpyridyl-2-methyl-ketone[8] (3.61 g, 26.7 mmol) were added in this order, always slowly, to the white residue of sodium ethanolate. Upon stirring the mixture overnight, a pale orange precipitate separated, which was filtered and dried. The resulting solid was slowly added to a vigorously stirred solution of acetic acid (20 cm^3), water (20 cm^3) and ice (70 g), yielding a white solid which was filtered and dried *in vacuo*. Yield: 3.1 g; 46.0%. IR spectrum (KBr): ν(C=O) 1614 cm^{-1}; ν(C=C), ν(C=N) 1581 cm^{-1}. ^1H NMR ($CDCl_3$ ppm): 2.54 (s, 6, CH_3—py); 4.67 [s, $H_2C(C{=}O)_2$]; 7.1 [s, *H*C=C(O)]; 7.13 (d, 2, *H*—py); 7.57 (t, 2, *H*—py); 7.8 (d, 2, *H*—py). ^{13}C NMR ($CDCl_3$, ppm): 184.7 (*C*=O); 158.5, 152, 136, 126, 118 (C_5H_3N); 94.5 [H*C*=C(py)]; 24.5 (CH_3). Found: C, 70.0; H, 5.5; N, 10.7. Calc for $C_{15}H_{14}N_2O_2$: C, 70.8; H, 5.6; N, 11.0%.

Preparation of 3,5-*bis*-2-(6-*methylpyridyl*)-3,5-*pyrazole* (HL^2). A 100-cm^3 Schlenk flask connected to a Dean–Stark apparatus was charged with 1,3-bis-[2-(6-methyl)pyridyl]-1,3-propanedione (1 g, 3.9 mmol) and hydrazine (0.20 g, 6.1 mmol). Benzene (60 cm^3) was added and the mixture was then refluxed for 18 h. Upon cooling, a solid separated which was filtered and vacuum dried. Yield: 0.7 g; 69.2%. IR spectrum (KBr): ν(N—H) 3293 cm^{-1}; ν(C=C), ν(C=N) 1579–1562 cm^{-1}. ^1H NMR ($CDCl_3$, ppm): 2.58 (s, 6, CH_3—py); 7.1 (d, 2, *H*—py); 7.35 (s, 1, *H*—pyrazole); 7.61 (t, 2, *H*—py); 7.67 (d, 2, *H*—py); 11 [b, 1, *H*—N(pyrazole)]. ^{13}C NMR ($CDCl_3$, ppm): 158, 148, 136, 122, 117 (C_5H_3N); 147, 101 (C_3HN_2); 24.4 (CH_3). Found: C, 69.1; H, 5.5; N, 21.1. Calc for $C_{15}H_{14}N_4 \cdot 0.5H_2O$: C, 69.5; H, 5.8; N, 21.6%.

Synthesis of the metal complexes

Synthesis of the nitrate complexes $[ML(NO_3)] \cdot xH_2O$ (M = Co^{II}, Ni^{II}, Zn^{II} *and* Cd^{II}). These complexes were synthesized as previously described.[5]

Synthesis of the thiocyanate complexes $[ML(NCS)] \cdot H_2O$ (M = Co^{II}, Ni^{II}, Zn^{II} *and* Cd^{II}). The appropriate thiocyanate salt (9×10^{-4} mol: $Ni(NCS)_2$, 0.16 g; $Co(NCS)_2 \cdot 3H_2O$, 0.21 g; $Zn(NCS)_2$, 0.16 g; $Cd(NCS)_2$, 0.216 g) in solid was added to a solution of the ligand (0.1 g; 4.5×10^{-4} mol) in ethanol (99%, 20 cm^3). The resulting mixture was stirred for 6 h and the clear solution obtained left to stand at room temperature for 24 h. All operations were carried out at room temperature, but in the case of the cadmium complex, the reaction was carried out under refluxing conditions. A crystalline precipitate appeared in all cases, which was filtered, washed with ethanol and vacuum dried.

Synthesis of the nitrate complexes $[ML^1(NO_3)] \cdot H_2O$ (M = Ni^{II} *and* Co^{II}). The appropriate metal salt (8.4×10^{-4} M: $Ni(NO_3)_2 \cdot 6H_2O$, 0.24 g; $Co(NO_3)_2 \cdot 6H_2O$, 0.24 g) was added to a solution of the ligand (0.1 g, 4.2×10^{-4} mol) in EtOH (99%, 40 cm^3). The mixture was concentrated and a crystalline precipitate appeared, which was filtered, washed with ethanol and vacuum dried.

Synthesis of the nitrate complexes $[M_2L^2(NO_3)_2(OH)] \cdot H_2O$ (M = Ni^{II} *and* Co^{II}). The appropriate metal salt (4×10^{-4} mol: $Ni(NO_3)_2 \cdot 6H_2O$, 0.12 g; $Co(NO_3)_2 \cdot 6H_2O$, 0.12 g) was added to a solution of the ligand (0.05 g, 2×10^{-4} mol) in ethanol (99%, 40 cm^3). The mixture was heated and carried to dryness. The resulting solid was treated with tetrahydrofurane and ethyl ether. Finally, a crystalline solid precipitate was obtained, which was filtered, washed with THF and ether and vacuum dried.

Synthesis of the chloride complexes $[M_2L^1Cl_2(OH)]$ (M = Co^{II} *and* Ni^{II}). The appropriate metal salt (8.4×10^{-4} mol: $CoCl_2 \cdot 6H_2O$, 0.20 g; $NiCl_2 \cdot 6H_2O$, 0.20 g) was added to a solution of the ligand (0.1 g, 4.2×10^{-4} mol) in ethanol (99%, 40 cm^3). The mixture was heated at 60°C for 2 h and then left to stand at room temperature. A crystalline solid precipitate was obtained, which was filtered, washed with ethanol and ether and vacuum dried.

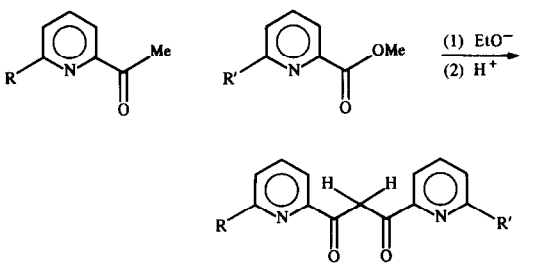
[a] Calculated analytical values are given in parentheses.

Table 1 reports the analytical and physical data for all the reported compounds.

RESULTS AND DISCUSSION

The β-diketone compounds, 1,3-bis[2-(6-methyl) pyridyl]-1,3-propanedione and 2-pyridyl-2-(6-methyl)pyridyl-1,3-propanedione, have been synthesized following a Claisen condensation of the appropriate ketones and esters. Equation (1) schematically represents this reaction.



(1)

Further treatment of these β-diketone compounds with hydrazine in benzene yielded the expected pz-derived ligands, 3,5-bis-2-(6-methyl) pyridyl-3,5-pyrazole and 2-(6-methyl)pyridyl-2-pyridyl-3,5-pyrazole.

In chloroform solution the β-diketones described here are in equilibrium with the corresponding keto-enols. These last species are dominant, in an approximate ratio of 20% β-diketone: 80% keto-enol.

IR spectra of the nitrate complexes

The IR spectra of the nitrate-containing complexes are a valuable tool to elucidate their stereochemistry. Frequently, such studies are based on the behaviour of the $\nu_3(E', D_{3h})$ band, which is very sensitive to the coordination mode of the nitrate group. In general there are several bands which are due to the organic ligands in the N—O stretching mode region, which makes the analysis of the ν_3 band difficult. Lever and Mantovani[9] have dem-

Table 2. Selected IR absorption bands (cm^{-1})

onstrated the utility of the $\nu_1+\nu_4(E', D_{3h})$ combination band for structural purposes. This band appears near 1750 cm^{-1} and is not generally overlapped by other ligand bands. Table 2 shows the IR absorptions in the $(\nu_1+\nu_4)$ combination band region for the complexes synthesized.

The cobalt and zinc complexes of the ligand HL show one single band in this region, indicating ionic behaviour of the nitrate group. The nickel(II) complex exhibits two bands, shifted only 13 cm^{-1}, in the same region. This splitting is not typical for a real unidentate nitrate group,[9] but could be explained by considering that either the two ionic nitrate groups are placed in different lattice sites or is induced by non-symmetric intermolecular hydrogen bond interactions with the water molecules in the crystal. Moreover, all these compounds exhibit one single, strong band in the ν_3 mode region at 1385 cm^{-1}, as is expected for an ionic nitrate group.[10]

The complex compounds of the ligand HL^1 exhibit three bands in the combination band region, shifted by only 9–10 cm^{-1} between them. This behaviour could also be explained by assuming ionic character of the nitrate group. The splitting and the difference in position of these bands with respect to the complexes of the ligand, HL, could be explained by assuming that relatively strong but rather symmetric intermolecular lattice or hydrogen bond interactions exist in the crystal. Consequently, with this hypothesis all these compounds exhibit only one strong band in the ν_3 mode region, as is expected for an ionic nitrate anion.

The complexes of the ligand HL^2 present two clear and well defined bands separated by 28–36 cm^{-1}. This behaviour is typical for a monodentate nitrate group.[9] In addition, these compounds exhibit two bands in the N—O stretching mode region at 1456, 1299 (Ni) and 1456, 1289 (Co) cm^{-1}, as is expected for a monodentate nitrate group.[10] The cadmium compound of the ligand HL also exhibits two well defined bands at 1767 and 1743–1733 cm^{-1}, similar to the aforementioned complexes of the ligand HL^2, indicating a similar monodentate coordination mode of the nitrate group in this complex. The second band is split into two components separated by only 10 cm^{-1}, but this splitting is probably due to non-symmetrical intermolecular lattice forces in the crystal.

IR spectra of the thiocyanate complexes

We have synthesized four thiocyanate complexes of the ligand HL of general formula $[MLNCS\cdot H_2O]$. The cobalt, nickel and zinc thiocyanate complexes exhibit only one band in the ν(CN) mode region at 2078, 2093 and 2076 cm^{-1}, respectively. On the contrary, the cadmium(II) complexes exhibit two bands in the same region at 2070 and 2130 cm^{-1} (Table 2). N-thiocyanate complexes have been reported in the literature where the ν(CN) band appears at similar frequencies: $[Co(NCS)_4]^{2-}$ (2065 cm^{-1}), $[Ni(NCS)_4]^{2-}$ (2112, 2103 cm^{-1}), $[Zn(NCS)_4]^{2-}$ (2072 cm^{-1}).[10] Even though our compounds are not tetrahedral, we could tentatively assign a nitrogen coordinated mode for all of them except the cadmium(II) compound, which is probably sulphur coordinated.[11]

Electronic spectra

Good electronic spectra for the complexes with the ligand HL [Ni^{II} and Co^{II}] were obtained by diffuse reflectance methods. Both nickel(II) compounds show two bands in the visible region, one at 560 nm $[NiL(NO_3)]\cdot H_2O$ or 550 nm $[NiL(NCS)]\cdot H_2O$, $[\nu_3{}^3A_{2g} \rightarrow {}^3T_{1g}(P), O_h]$ and a second band split into two components at 794 and 750 nm $[NiL(NO_3)]\cdot H_2O$ or 790 and 756 nm $[NiL(NCS)]\cdot H_2O$ $[\nu_2{}^3A_{2g} \rightarrow {}^3T_{1g}(F), O_h]$. These

spectra are characteristic of an octahedral nickel(II) complex[12] with a tetragonal distortion splitting the ν_2 band. Both cobalt(II) compounds show two bands as a shoulder of an intense charge-transfer band, at 693 and 500 nm $[CoL(NO_3)]\cdot 2H_2O$ or 650 and 500 nm $[CoL(NCS)]\cdot H_2O$, typical for an octahedral cobalt(II) complex.[13] The similarity of the electronic spectra of the thiocyanate and nitrate complexes of nickel(II) and cobalt(II) confirms the coordination mode of the thiocyanate group through the nitrogen in all of the complexes.

Magnetic susceptibility data

Magnetic susceptibility data for the compounds studied have been run from room temperature down to 77 K. Table 3 displays only relevant data at two temperatures. The nickel nitrate and nickel thiocyanate complexes of ligand HL and HL^1 display Curie–Weiss behaviour in the temperature interval studied and show values for the magnetic moment at room temperature typical of octahedral nickel(II) complexes.[14] The slight variation with temperature could be explained by assuming an antiferromagnetic interaction between both nickel(II) ions in the dinuclear molecule. The higher values observed in the hydroxo compounds of ligands HL^1 and HL^2 suggest distorted tetrahedral coordination of the nickel(II) ions in the compound.[14] Also, in this case, antiferromagnetic interactions between the metal ions could be assumed.

The cobalt nitrate compounds of ligands HL and HL^1 also show Curie–Weiss behaviour down to 77 K. The magnetic moment values and their variation are typical for an octahedral coordinated cobalt(II) ion.[14] The smaller values of the magnetic moment for the μ-OH compounds suggest a distorted tetrahedral coordination for the cobalt(II) ion.[14] In all cases, a slight antiferromagnetic interaction between the cobalt(II) ions could be assumed, being smaller in the case of the hydroxo compounds. The practically Curie behaviour of the μ-OH compounds suggests a small effective spin–orbit coupling constant. This small value explains the spin-only value of the magnetic moment (3.89 BM) found in these compounds.[15] The cobalt thiocyanate compound exhibits an anomalous low magnetic moment.

Table 3. Magnetic susceptibility measurements

	MB (77 K)	MB (293 K)	g
$[CoL(NO_3)]\cdot 2H_2O$	4.07	4.74	2.61

CONCLUSIONS

Di-μ-pyrazole-bridged complexes

Nitrate and thiocyanate complexes of ligands HL and HL^1 exhibit a metal–ligand stoichiometry of 1:1. The IR spectra of the nitrate complexes show ionic behaviour of the nitrate group for all the complexes, except for the cadmium(II) compound. IR spectra of the thiocyanate complexes show a nitrogen coordination mode for the thiocyanate group. We could assign a dinuclear, di-μ-pz-bridged structure (Fig. 2) to these compounds, similar to that found in the nickel(II) compound $[Ni_2L_2(MeOH)_4]Cl_2\cdot 2H_2O$.[5] Solvent molecules or nitrate groups complete the coordination of the metal ions in the nitrate complexes, and solvent molecules and —NCS groups in the thiocyanate complexes, in agreement with the magnetic measurements.

Mixed μ-hydroxo,μ-pyrazole-bridged complexes

The nitrate complexes of the ligand HL^2 and the chloride complexes of the ligand HL^1 show a metal–ligand stoichiometry of 2:1. IR spectra of the nitrate complexes display monodentate coordinated nitrate groups. We could assign a mixed μ-OH, μ-pz-bridged structure (Fig. 3) to these compounds, with nitrate ions coordinated to the metal ions $[(NO_3)M(\mu\text{-}OH)(\mu\text{-}L^2)M(NO_3)]\cdot H_2O$. A similar mixed bridged structure is assigned to the chloride complexes of ligand HL^1. Distorted tetrahedral coordination could be assigned to the metal ions in

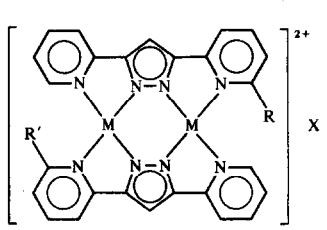

Fig. 2. Diagrammatic drawing of the proposed structure of the di-μ-pyrazole complexes. R = R′ = H: HL; R = CH_3, R′ = H: HL^1; R = R′ = CH_3: HL^2.

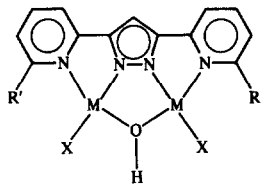

Fig. 3. Diagrammatic drawing of the proposed structure of the mixed μ-hydroxo, μ-pyrazole complexes. R = R′ = H: HL; R = CH_3, R′ = H: HL^1; R = R′ = CH_3: HL^2.

these latter compounds, due to the voluminous OH group, according to the magnetic measurements.

Steric problems due to the methyl groups probably do not allow coordination of the two ligand molecules in the dimethylated HL^2 compound. In the case of the monomethylated ligand HL^1, the *trans* disposition of the methyl groups from each ligand allows the metal–ligand stoichiometry of 1:1. The non-methylated ligand, HL, seems to favour di-μ-pz-bridged complexes, but with the dimethylated ligand, HL^2, only stoichiometric relations, metal–ligand 2:1, are found. The monomethylated ligand, HL^1, forms di-μ-pz complexes with poor coordinating anions like NO_3^-, but with strong coordinating ones, like Cl^-, mixed bridged structures are formed.

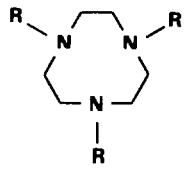
(*Received* 18 *June* 1990; *accepted* 25 *July* 1990)

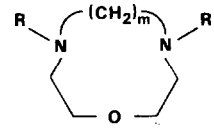
Abstract—Some 9- and 10-membered oxa-diaza macrocyclic ligands and their N-acetate derivatives have been synthesized and their protonation patterns studied by ^{1}H NMR and potentiometric techniques. The stability constants of the complexes formed by these ligands with several alkaline–earth and first-series transition metal ions, zinc, cadmium and lead, were determined by potentiometry and the values were compared with those formed with the analogous 9-membered tri-aza macrocyclic ligands and with 12-membered oxa-triaza ligands. The substitution of one nitrogen by an oxygen atom in the backbone of the macrocyclic ring has pronounced effects both on the kinetics of the complexation reactions (faster equilibration) and on the stability of the metal complexes formed (decreased stability). The differences in this last case are analysed for two pairs of cyclic amines ([9]aneN$_3$/[9]aneN$_2$O and [12]aneN$_4$/[12]aneN$_3$O) with the first transition metal ions and for the corresponding N-acetate derivatives with the first transition and alkaline–earth metal ions.

A large number of macrocyclic compounds have been synthesized and their metal complexes studied in the past three decades. However, less attention has been paid to the tridentate macrocyclic compounds, recently reviewed,[1,2] with the exception of compound **I**, 1,4,7-triazacyclononane, and some of its N-functionalized derivatives, namely the triacetate (**II**).



I: R ≡ H—1,4,7-triazacyclononane
II: R ≡ CH_2COOH—1,4,7-triazacyclononane-N,N′,N″-triacetic acid (NOTA)

With the aim of investigating the effect of substitution of a nitrogen atom by an oxygen donor atom in the ring of macrocyclic ligands on the behaviour and selectivity of their metal complexes with some divalent metal ions, we decided to study the compounds listed below (**III–VI**).



III: $m = 2$, R ≡ H—1-oxa-4,7-diazacyclononane ([9]aneN$_2$O)
IV: $m = 2$, R ≡ CH_3—4,7-dimethyl-1-oxa-4,7-diazacyclononane (N-Me$_2$[9]aneN$_2$O)
V: $m = 2$, R ≡ CH_2COOH—1-oxa-4,7-diazacyclononane-4,7-diacetic acid (N-ac$_2$[9]aneN$_2$O)
VI: $m = 3$, R ≡ H—1-oxa-4,8-diazacyclodecane ([10]aneN$_2$O).

In view of the propensity of most divalent transition metal ions for the coordination number 6 in their complexes, most tridentate macrocycles coordinate to metal ions so that they occupy three facial sites on the coordination sphere of the metal. Furthermore, 2:1 ligand to metal complexes are possible with ligands **III**, **IV** and **VI**, whilst ligand **V** seems ideally suited to wrap around the metal ions.

EXPERIMENTAL

Reagents

All the ligands were synthesized and purified in our laboratories. The chemicals used were of reagent grade and organic solvents were purified by standard methods.

Synthesis and characterization of the ligands

The cyclic amine **III** was synthesized by Richman–Atkins procedure,[3] involving the condensation of 0.05 mol (18.40 g) of the disodium salt of ethylenediamine ditosylate and 0.05 mol (20.72 g) of ditosylated diethyleneglycol at 110°C in dry dimethylformamide. The ditosylated cyclic amine obtained, after recrystallization from benzene–*n*-hexane (yield: 75%), was refluxed with a mixture of glacial acetic acid, 48% hydrobromic acid and phenol for 28 h. The required product (**III**) was precipitated with ether, filtered, and washed with acetone. Recrystallization was carried out with methanol–acetone, and the pure product was obtained in 71% yield; m.p. 167–169°C.

The methylated amine (**IV**) was obtained by refluxing the dihydrobromide [9]aneN_2O with formic acid and formaldehyde for 24 h.[4] The pure product was obtained, as an oil, by vacuum distillation and was characterized by ^{1}H NMR spectroscopy and potentiometric titration.

The N-acetate derivative (**V**) was prepared by reaction of 4.6 mmol (1.33 g) of **III** (in the dihydrobromide form) with 9.2 mmol (1.28 g) of bromoacetic acid and 4.9 mmol (1.13 g) of $BaCl_2 \cdot 2H_2O$ in aqueous alkaline solution. The temperature was kept between 25–30°C and the pH below 8.6, for 10 days. After the reaction the pH was adjusted to 1.4 with 5 M H_2SO_4, the mixture concentrated and the precipitated inorganic salts filtered off. The product was recrystallized from methanol–acetone and purified by anion-exchange chromatography using a Dowex 1-X8 (20–50 mesh) resin in the OH^- form, by elution with formic acid, 0.1 M. Yield: 62%; m.p. 200–202°C. ^{1}H NMR (D_2O–DSS and pD*† 0.20): δ 4.033 ppm (4H, triplet), δ 3.764 ppm (4H, singlet), δ 3.549 ppm (4H, triplet). Elemental analysis for the molecular formula $C_{10}N_2O_5H_{19}Cl$ (Mol. wt = 282.73): Found: N, 9.9; H, 6.8; C, 42.5. Calc.: N, 10.2; H, 6.6; C, 42.7%.

† Operational pD, i.e. value measured with a pH meter standardized with conventional aqueous pH 4 and 7 buffer solutions.

Compound **VI** was prepared by a procedure similar to that used for the synthesis of [9]aneN_2O, using 0.05 mol (19.12 g) of the disodium salt of trimethylenediamine ditosylate and 0.05 mol (20.72 g) of ditosylated diethyleneglycol. The resulting product was recrystallized from methylene chloride–methanol (yield: 59%) and characterized by ^{1}H NMR spectroscopy ($CDCl_3$–TMS): δ 7.7–7.3 ppm (8H, multiplet); δ 3.76 ppm (4H, triplet): δ 3.24 ppm (8H, multiplet), δ 2.43 ppm (6H, singlet) and δ 2.42 ppm (2H, multiplet).

The detosylation was achieved by the method described above and the recrystallization was carried out with methanol–acetone. Yield: 74%, m.p. = 237–239°C, ^{1}H NMR (D_2O–DSS): δ 3.97 ppm (4H, multiplet), δ 3.37 ppm (8H, multiplet) and δ 2.17 ppm (2H, multiplet).

Equipment

For the potentiometric titrations a Crison Digilab 517 measuring instrument was used together with an Ingold U1330 glass electrode and a Radiometer K401 saturated calomel reference electrode described previously.[5] Titrations were carried out in a thermostatted cell at 25.0 ± 0.1°C and the ionic strength of the solutions kept at 0.01 M with KNO_3.

The pH measurements for the NMR titrations were made using a pH M64 Digilab Radiometer (or a Crison micropH 2002) instrument fitted with a combined Ingold 405 M3 microelectrode.

^{1}H NMR spectra were recorded at 100 MHz and probe temperature in a JEOL JNM 100 PTF spectrometer coupled to a JEOL 980A computer.

Solutions

Analytical grade metal nitrates were used and the metal content of the solutions checked by titration with EDTA. The CO_2-free potassium hydroxide solution was prepared as described before.[5] Solutions of the ligands for NMR measurements ($\approx$ 0.01 M) were made up in D_2O (99.8 atom % deuterium from Merck) and the pD* was adjusted by adding DCl or CO_2-free KOD. In all cases sodium 3-(trimethylsilyl)-1-propane sulphonate (DSS) was used as internal reference.

Calculations

The protonation and the stability constants were determined from the potentiometric titrations using the Superquad program.[6] The results were obtained from a minimum of two titrations for which the C_M–C_L ratios were 1 : 1, 1 : 2 and, in some cases, 2 : 1. The errors quoted were calculated by propagation

rules from the standard deviations of the overall constants obtained for about 50 readings in each set of titrations, given by the program, and do not represent the total experimental errors.

It was found that copper(II) and zinc(II) solutions equilibrate with the cyclic amines (**III, IV** and **VI**) during the course of titrations within 5 min of each addition of titrant; cobalt(II) needed 15 min to equilibrate with ligand **III**, and 10 min with ligands **IV** and **VI**, but nickel(II) reacted very slowly, requiring up to 15 min with ligand **VI**, 30 min with ligand **III** and far more with ligand **IV**. With this last ligand it was not possible to perform automated titrations; an out-of-cell technique would be required for the purpose, but it was not undertaken in the present work. Ligand **V** equilibrates more rapidly in the reactions with metal ions, requiring only 90 s for Mn^{2+}, Zn^{2+}, Pb^{2+} and Fe^{2+}, but 5 min with Co^{2+} and 15 min with Ni^{2+}.

The fractions of protonation were obtained from the experimental NMR titration curves using a multiple linear regression program.[7]

RESULTS AND DISCUSSION

Protonation constants and sequence of protonation

The protonation constants of the ligands studied in the present work or obtained from the literature for the same set of ligands are summarized in Table 1. Other ligands are included in this table for comparison.

The first protonation constant for [9]aneN_2O is similar to that of [9]aneN_2S, and also to those of linear amines, a situation not usually found with other macrocyclic compounds,[1] for which $\log K_1$ is generally higher than for the linear amines (this tendency can be seen in Table 1, comparing compounds [9]aneN_3 and diethylenetriamine). The values of the table agree with the interpretation of the higher values of $\log K_1$ being due to the formation of internal hydrogen bonds within the ring cavity, the magnitude of which decreases in the series N ≫ O > S.[1,13]

The values of the second protonation constants

Table 1. Protonation constants ($\log K_i$)[a] for some oxa-diaza, thia-diaza and triaza cyclononane derivatives and some similar linear derivatives ($T = 25°C$)

[i] From ref. 14, $I = 0.1$ M.
[j] From ref. 15, $I = 0.1$ M $NaNO_3$.

($\log K_2$) for the cyclic amines are lower than those of the linear amines. This decrease of basicity can be explained in terms of the electrostatic repulsions between two closely neighbouring ammonium nitrogens, i.e. between the incoming protons and those already bound to the neighbouring nitrogen atoms. This effect decreases with the distance between the two nitrogen atoms, as shown by the value of $\log K_2$ for [10]aneN_2O, where the two nitrogen atoms are separated by a propane chain. Hancock *et al.*[13] suggested that the decreasing values of $\log K_2$ in the series [9]aneN_3 (6.82), [9]aneN_2O (5.45) and [9]aneN_2S (3.98) is probably due to the involvement of the donor atoms in a cooperative stabilization of the attached proton by hydrogen bonding. In fact, with similar linear ligands the $\log K_2$ values do not vary much with the change of the central donor atom from nitrogen, to oxygen or to sulphur, indicating that the inductive effects are not important.[13] Lower than expected values and in the same order also result if the addition of the second proton involves breaking of the hydrogen bonds previously formed since this represents an unfavourable contribution to the heat of the reaction.[16]

More difficult to explain is the value for the first protonation constant of the dimethylated amine (**IV**). In fact, the inductive effect of the methyl groups should make this value higher than that of the parent amine (**III**), as it happens for N-Me_3[9]aneN_3 compared with [9]aneN_3, but this is not the case.

Similar arguments explain the higher value of $\log K_1$ of compound **V**. In this case, the possible formation of hydrogen bonds between the protonated nitrogen and the carboxylate groups help to stabilize the protonated species and contribute to higher $\log K_1$ values.

The explanation of the values of protonation constants of the N-acetate derivative is not straightforward (exception made for $\log K_1$); likewise, it is not immediately evident which are the following basic centres to be protonated, the carboxylate groups or the other nitrogen atom, as it happens with the diaza[16] and triaza[11] macrocycles. However, following the titration by NMR spectrometry measurements, it is possible to understand the sequence of the protonation.

For a quantitative treatment of the sequence of protonation, it is helpful to have a model compound which adopts configurational structures similar to the compound to be studied and whose titration curves are easy to interpret.[7,11,16–19] Compound **IV**, the methylated amine, seems to have the required conditions.

Indeed, the titration curves obtained by NMR measurements of this compound are very simple. The spectrum at pD* 4.92 can be seen in Fig. 1. For

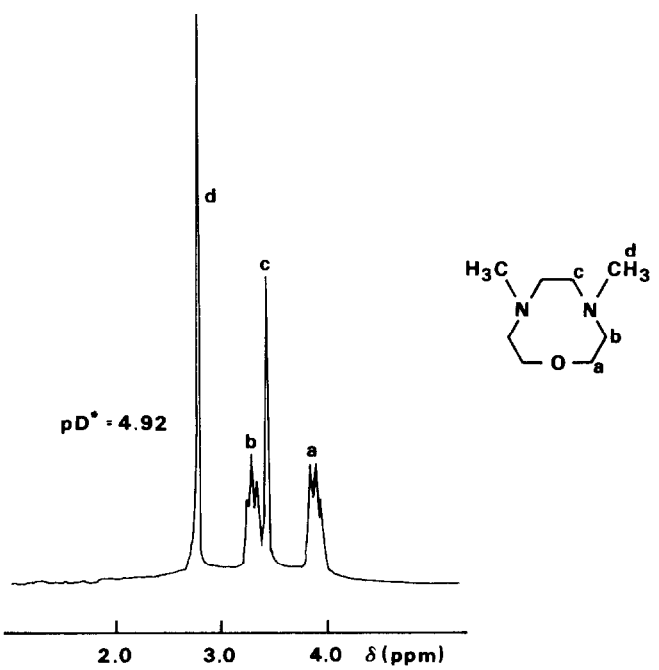

Fig. 1. ^{1}H NMR spectrum of N-Me_2[9]aneN_2O (**IV**) at pD* 4.92.

values of pD* < 8 the spectra present four resonances, although the resonances of the methylenic protons *b* and *c* are indistinguishable for higher pD* values. The assignment of the resonances is straightforward: methylenic protons *a* and the methyl protons *d* are singlets, which can be distinguished by the area ratio 2:3; methylenic protons *a*, deshielded by the electronegative oxygen atom nearby, appear at lower field. The assignment of methylenic protons *b* is made by double-resonance experiments, irradiating the methylenic protons *a*.

The titration curves present two net inflexions, with all the resonances shifting to lower field. One of them, in the pD* range 10.5–7.5, corresponds to the protonation of 50% of the nitrogen atoms, and the second one, in the pD* range 7.0–3.0 corresponds to the protonation of the remaining nitrogen groups.

For $n = 1$ and $n = 2$ (n being the number of equivalents of acid added to the ligand completely deprotonated), it is possible to use Sudmeier and Reilley's quantitative approach[17] to determine the values of the shielding constants (C_{ij}):

$$\Delta\delta_i = \sum_{j=1}^{N} C_{ij} f_j \qquad (1)$$

$$\sum_{j=1}^{N} \alpha_j f_j = n, \qquad (2)$$

where $\Delta\delta_i = \delta_i^{obs} - \delta_i^{o}$, δ_i^{obs} is the observed shift of the i non-labile proton of a methylenic group and δ_i^{o} the intrinsic shift of the fully deprotonated form of the ligand; f_j is the protonation fraction of the various neighbouring basic groups, usually expressed as percentage of protonation (the contributions of the different basic sites being additive); α_j is the number of equivalent sites of protonation and N is the number of basic sites.

C_{ij} represents the $\Delta\delta_i$ value of the methylenic proton i caused by full protonation of a given basic site j. In the present work we refer by C_N the shielding constant relative to the α methylenic protons caused by the protonation of a nitrogen atom and by $C_{N'}$ the corresponding value for the β methylenic protons; C_{COO^-} is the shielding constant relative to the methylenic protons caused by the protonation of a carboxylate group.

The values of C_{ij} determined for the model compound, N-Me_2[9]aneN_2O, are summarized in Table 2.

From this table it can be seen that the values of C_N and $C_{N'}$ are different for the various methylenic protons and increase with the value of pD* (except $C_{N'}$). The variation of the shielding constants with pD*, also found for all other macrocyclic compounds studied before[7,11,16,18,19] has been ascribed to different conformations of the macrocyclic ring.

With these shielding constants it is possible to calculate the fractions of protonation f_j for the N-acetate derivative (**V**), from the experimental δ_i^{obs} obtained by the titration curves, by the combination of equation (2) and four equations of type (1) (one equation for each methylenic proton of the molecule). The set of simultaneous linear equations can be solved using a multiple linear regression program.[7] Naturally, it is necessary to assign previously the various resonances of compound **V**.

In Fig. 2 is shown the spectrum of N-ac_2[9]ane N_2O at pD* 0.2 and the titration curves for the entire pD* range. The spectra exhibit four different resonances at low pD* (< 7) and only three resonances for pD* values higher than 7 (resonances *b* and *c* being superimposed), that can be assigned by the methods already described for the methylated amine. The methylene protons *c* and *d* are singlets, whilst *a* and *b* are triplets; the two triplets can be easily assigned by double-resonance experiments, the protons *a* appearing at lower field due to the deshielding effect of the adjacent oxygen atom. The methylene protons *c* are also easily assigned since they are affected by the same basic centre as *b* and have a similar titration profile. The methylene protons *d* appear at a lower field and have a completely different titration profile, being sensitive to the titration of the two centres (1 and 2).

The titration curves exhibit a pronounced inflexion in the pD* range 12–9, when all the resonances shift downfield; this probably corresponds to the protonation of 50% of the nitrogen atoms (by potentiometric studies it can be seen that in this

Table 2. Shielding constants (C_N and $C_{N'}$) determined from N-Me_2[9]aneN_2O (in ppm)

pD* = 7.46 (n = 1)				pD* = 2.55 (n = 2)			
$C_{N'}$[a]	C_N[b]	$(C_N - C_{N'})$[c]	C_N[d]	$C_{N'}$[a]	C_N[b]	$(C_N + C_{N'})$[c]	C_N[d]
0.35	0.82	0.92	0.67	0.32	0.93	1.17	0.72

pD* range there is only one protonation step). For lower pD* values, between 5–1.5, resonances *b* and *c* move slightly to low field, but methylenic protons *d* have a more pronounced shift, whilst methylenic protons *a* practically do not shift. It seems that, in this pD* range, the carboxylate groups are being protonated, as the potentiometric measurements indicate two protonation steps at this pD* region (cf. Table 1), but the shift of protons *b* and *c* can only be understood if hydrogen bonds between carboxylated groups and protonated nitrogen are formed. For very low pD* values (below 2) there is a continuous shift of all the resonances indicating that full protonation of the last centre is not achieved.

The application of Sudmeier and Reilley's quantitative approach to this compound, assuming that the shielding constants listed in Table 2 are appropriate for this ligand and considering $C_{COO^-} = 0.20$ ppm (the value generally adopted[19]), leads to the protonation fractions shown in Table 3.

All the values in Table 3 seem coherent with our comments above. The value of f_{COO^-} for $n = 4$ is too high, because it was assumed that for the last pD* value of the titration (pD* = 0.19) the fourth equivalent of acid was completely added, which is not true. Indeed, it appears that only about 80% of protonation of the nitrogen atoms is achieved, the carboxylate groups being protonated before the last nitrogen.

So it is possible to conclude that the first proton added to the completely deprotonated compound **V** will protonate one of the indistinguishable nitrogen atoms, the second and third protonate the carboxylate groups, and the last equivalent of acid added protonates the last nitrogen up to about 80% for pD* ≈ 0. N-ac$_2$[9]aneN$_2$O is therefore one

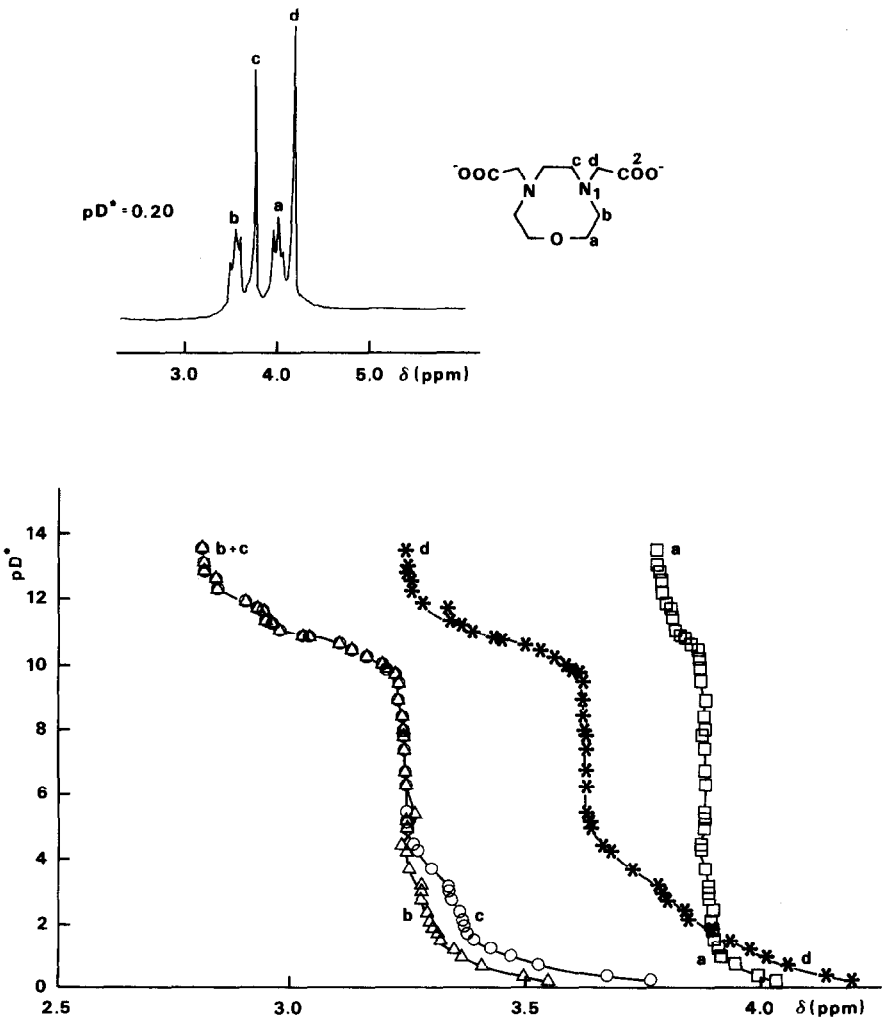

Fig. 2. ^{1}H NMR spectrum of N-ac$_2$[9]aneN$_2$O (**V**) at pD* 0.20 and titration curves pD* versus δ (ppm).

Table 3. Protonation fractions (%) for N-ac$_2$[9]aneN$_2$O

pD*	n	f_N	f_{COO^-}
7.42	1	50±4	0±4
3.17	2	48±2	52±2
1.48	3	54±4	96±4
0.19	4[a]	83±4	117±4

[a] At the end of the titration.

more macrocycle whose nitrogen atoms are less basic than the carboxylates, contrary to what happens with the linear complexones.[7,11,18,19]

It is now easy to explain the protonation constants of this compound, listed in Table 1. Log K_2 is a normal value for the protonation of a carboxylate group linked to a non-protonated nitrogen atom. The protonation of the second carboxylate is counteracted by the positive charge of the nitrogen atom and the possible breaking of the hydrogen bond $^+HN\cdots{}^-OOC—$, hence the protonation constant is lower (1.8). The last protonation constant is a very low value ($\log K < 1$) because it corresponds to the protonation of a nitrogen atom at short distance from the other protonated nitrogen, the electrostatic repulsion being even stronger given the relatively rigid structure of the ring.

It is curious to note that subsequent to the protonation of the first nitrogen, formation of hydrogen bonds between carboxylate groups and protonated nitrogen possibly occurs; for $n = 2$ the protonated carboxylate can also form hydrogen bonds with the non-protonated nitrogen. It might be thought that the model compound, the corresponding methylated amine, would not be a good model since it cannot form this type of hydrogen bond, as in the case of the similar 12-membered compounds.[19] The difference derives from the simpler NMR spectrum of the compound studied in the present work due to its symmetry, hence a smaller number of equations result for the system of equations (1) and (2) and the problem did not arise.

The comparison of the protonation constants of N-ac$_2$[9]aneN$_2$O and NOTA (I) is interesting. In fact, the second acid equivalent added to NOTA still protonates a nitrogen atom but the total posi-

[e] From ref. 20, $I = 0.1$ M $NaNO_3$.

tive charge spreads over the three nitrogens of the ring[11] and a higher $\log K_2$[12] than that found for V is obtained. The third proton added goes to a carboxylate but $\log K_3$ is smaller than expected for the protonation of such a group, due to the repulsion of the partially charged nitrogen to which it is bonded.

Stability constants with some metal ions

The values of the stability constants of some metal complexes studied in this work together with some values found in the literature for the same complexes are summarized in Table 4.

The 1:1 complexes of [9]aneN_2O and [10]aneN_2O have coordinated water molecules which ionize for pH > 6 giving hydroxo species. The constants (pK) corresponding to the equilibrium: $ML \rightleftarrows MLOH + H^+$ are listed below:

Metal ions	[9]aneN_2O	[10]aneN_2O
Mn^{2+}	9.59	—
Co^{2+}	8.93	7.68
Cu^{2+}	7.22	7.20
Zn^{2+}	8.40	7.64

As expected, the values of pK for the complexes of [10]aneN_2O are lower since the complexes of this ligand are less stable and hydrolyse at lower pH.

Some stability constants of the complexes of the ligand N-Me_2[9]aneN_2O were also determined, and the constants obtained for the ML species were: 5.76 ± 0.07 for Co^{2+}, 7.76 ± 0.02 for Cu^{2+} and 6.58 ± 0.06 for Zn^{2+}. With Cu^{2+} and Zn^{2+} hydroxo complexes are also formed. The values for this ligand are smaller than those obtained for [9]aneN_2O, and only ML species are formed, which means that the steric hindrance of the methyl substituents prevents the formation of ML_2 species.

In Table 4 the values obtained by Hancock *et al.* for [9]aneN_2O, and by Ewin and Hill for N-ac_2[9]aneN_2O are also indicated. Our values are in good agreement with those of Hancock *et al.* for Cu^{2+} and Zn^{2+}, but not with those for Ni^{2+}. The equilibrium of formation of Ni^{2+} complexes with [9]aneN_2O is slow to attain (cf. Experimental section) and discrepancies can easily arise. It is worth noting that the substitution of a nitrogen atom for an oxygen in the ring of the macrocycle increases the rate of formation of the complex. Indeed, Zompa found that 3–4 months were necessary to reach the equilibrium of metal–ligand solutions of triaza cyclic amines.[10,21] A similar situation was found with the 12-membered macrocycles,[5] making the mixed oxygen–nitrogen macrocyclic compounds more attractive for applications, as already referred by Hancock *et al.*[8]

However, the values for N-ac_2[9]aneN_2O obtained by Ewin and Hill for the alkaline–earth metal ions are significantly different from ours, especially in the case of Mg^{2+}. These authors performed their measurements in a different medium, $NaNO_3$, but no complex formation with Na^+ appears to occur with this ligand. The discrepancy may therefore result from the different method used by these authors, i.e. calorimetric measurements.

It is interesting to note that in all systems studied in the present work the analysis of the titration data indicate the absence of protonated complex species, even for low pH values. This is an indication of the particularly favourable conformations of these compounds as tridentate chelating ligands.

The Irving–William's order of stability is obeyed for all the ligands, but some Cu^{2+} complexes are less stable than expected, namely the Cu^{2+}–N-ac_2[9]aneN_2O complex which has a stability constant lower than that of EDDA and even than that of DACODA, a N-acetate diazamacrocycle with propane chains separating the nitrogen atoms (see Table 5).

The increase of the size of the ring of the amines, from 9- to 10-membered, leads to a decrease in the stability of the complexes with the transition metal ions studied. This does not happen with the analogous triazamacrocycles, for which the Co^{2+} complex of [10]aneN_3 is more stable than that of [9]aneN_3, and the Cu^{2+} and Zn^{2+} complexes of the two ligands have similar stabilities (although the values published present some dispersion[1,2]).

We can see from Table 4 that the values for log K_{ML_2} for the cyclic amines are only slightly lower than those of log K_{ML}, evidence of the easy addition of the second ligand in facial arrangement to form a hexacoordinated complex. This does not occur with the analogous linear ligands, e.g. ODEN, listed in Table 5.

Comparing the values of stability constants of metal complexes for N-ac_2[9]aneN_2O (Table 4) with those of ethylenediaminediacetic acid (EDDA; Table 5), a linear ligand with the same four donor atoms, it can be seen that the values for the macrocyclic ligand are slightly higher than those for the linear ligand, except for Ni^{2+} and especially Cu^{2+}, whose complexes are considerably less stable than those of EDDA.

More interesting is the comparison of the 9- and 12-membered ligands as to the replacement of one nitrogen for an oxygen atom in the macrocyclic ring. Table 6 summarizes the results of stability constants for the amines and Table 7 the results for the N-acetate derivatives.

[a] Values from Table 5.
[b] Values from Table 4.
[c] Values from ref. 25, DOTA = N-ac$_4$[12]aneN$_4$.
[d] Our values, submitted for publication.
[e] Our values, ref. 5.
[f] Our values, not published.
[g] Difference in log units between stability constants of NOTA and N-ac$_2$[9]aneN$_2$O.
[h] Difference in log units between stability constants of DOTA and N-ac$_3$[12]aneN$_3$O.

There are few values in the literature for [12]aneN$_4$ due to the slow kinetics of formation of the complexes, but the values summarized in Table 6 seem to indicate that for the ML complexes there is a decrease of 4–5 log units in the values of stability constants when a nitrogen atom of the macrocyclic ring is replaced by an oxygen atom. This difference is verified for the 9- and 12-membered macrocycles. The Cu^{2+} complex of the 12-membered macrocycles is an exception, the difference being of about 9 log units. For the ML_2 complexes of the 9-membered ligands the same difference is about 2–4 log units. Note that the basicities of the two ligand pairs are very similar.

However, when we compare the corresponding complexones (N-acetate derivatives of the two families of ligands—Table 7) the differences are more pronounced. For the alkaline–earth metal ions, except Mg^{2+} that seems to prefer the NOTA ligand, the value of Δ is larger for the 12-membered system but decreases with the ionic potential of the metal ion for the two systems. For the 9-membered ligands the difference for the first transition series metal ions is of about 5–6 log units, whilst for the 12-membered ligands the difference is only about 2 log units (equal to the difference in basicities of the two ligands) except for Mn^{2+}, Fe^{2+} and Pb^{2+} complexes for which the difference is about 4 log units (as it is for Ca^{2+}).

The smaller difference of Δ for the transition metal ions of the complexes for the 12-membered ligands that have 8 and 7 potential donor atoms, was explained before[5] by the fact that some of the donor atoms may not be involved in the coordination to the metal ion due to the strict stereochemical requirements for covalent bonding. When all the donor atoms are involved in the coordination, as is the case of the alkaline–earth metal ions and Pb^{2+}, the differences between the two families of ligands are 3–4 log units and cannot be explained in terms of differences of basicity. The electronic structure of these cations allows an optimal adjustment to all donor atoms of DOTA to maximize the electrostatic interactions.[5] The same seems to happen with the complexes of NOTA with Ca^{2+} and, particularly, with Mg^{2+}, due to the smaller size of this latter ion. These effects are reflected in the enthalpy and entropy changes of formation o the alkaline–earth metal complexes with these ligands collected in Table 8.

Table 8. Enthalpy and entropy changes for the formation of 1 : 1 metal-to-ligand complexes of alkaline–earth ions and cyclic complexes (values from the literature). Units: ΔH, kcal mol^{-1}; ΔS, cal mol^{-1} K^{-1}

Metal ion	N-ac$_2$[9]aneN$_2$O[a]			N-ac$_3$[9]aneN$_3$ (NOTA)[b]			N-ac$_3$[12]aneN$_3$O[c]			DOTA[d]		
	log K[e]	ΔH	ΔS	log K	ΔH	ΔS	log K	ΔH	ΔS	log K	ΔH	ΔS

[a] From ref. 9.
[b] From ref. 15.
[c] From ref. 19, our values.
[d] From ref. 26, our values.
[e] From ref. 9, not our values, for coherence of the results in this Table.

From the values of this Table it can be seen that the increase in stability of the NOTA complexes when compared with N-ac$_2$[9]aneN$_2$O seems to be due to both more favourable heats and entropies of reaction. The same happens when we compare N-ac$_3$[12]aneN$_3$O and DOTA, but the higher stability of the alkaline–earth metal complexes of the latter ligand is now clearly due to more favourable entropies of reaction, which shows the involvement of its four acetate groups and argues again in favour of a "cage" coordinating structure.

SYNTHESIS AND X-RAY STRUCTURAL CHARACTERIZATION OF A (η^3-PHOSPHAALLYL)TUNGSTEN P-OXIDE

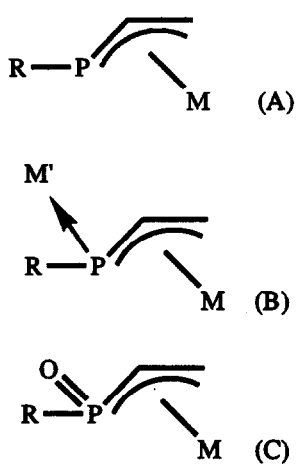
FRANÇOIS MERCIER, LOUIS RICARD and FRANÇOIS MATHEY*

Laboratoire de Chimie du Phosphore et des Métaux de Transition, DCPH,
Ecole Polytechnique, 91128 Palaiseau Cedex, France

(*Received* 9 *July* 1990; *accepted* 4 *September* 1990)

Abstract—The oxidation of (η^3-1-aryl-1-phosphaallyl)(η^5-cyclopentadienyl)dicarbonyltungsten (Ar = 2,4,6-^{t}Bu$_3$C$_6$H$_2$) by hydrogen peroxide affords the corresponding P-oxide which retains the phosphaallyl η^3-coordination according to X-ray crystal structure analysis.

Today numerous phosphorus analogues of unsaturated hydrocarbon π-complexes are known.[1] These products have been described either with a free lone pair or with an additional η^1-complexation at phosphorus. All the attempts at obtaining the corresponding P-oxides have been unsuccessful until now. Some theoretical studies have been performed on various η^5-phosphacyclopentadienyl complexes.[2] They show that the energetic gap between the HOMO and the lone pair orbital is sufficiently large to explain why it is difficult to oxidize these products at phosphorus while retaining the η^5-complexation of the ring. The situation is similar with the η^3-1-phosphaallyl complexes. They exist either with a free lone pair (**A**)[3] or with additional complexation at phosphorus (**B**).[4] The corresponding P-oxides (**C**) are unknown. We wish to describe the first product of type **C** which is also the first representative of the phosphoryl analogues of unsaturated hydrocarbon π-complexes.



Complex **1**,[3a] as a mixture of two isomers, was oxidized by aqueous hydrogen peroxide in benzene to afford the corresponding isomers of P-oxide (**2**) [eq. (1)].

* Author to whom correspondence should be addressed.

The two isomers of **2*** separately crystallized in hexane–dichloromethane (90 : 10). The X-ray crystal structure analysis of the major isomer, **2a**, was carried out (Fig. 1).† The structural features of the phosphaallyl unit [PC(1)C(2)] are absolutely normal. The P=O bond length is also in the normal range. The overall structure of **2a** is similar to the *anti* structure of the previously described molybdenum[4c] and cobalt complexes,[3b] with the *ipso*-carbon of the P-substituent [C(3)] lying in the PC(1)C(2) plane and outside of the PC(1)C(2) angle. The C(2)—C(1)—P—O(1) dihedral angle (47.4°) is close to the corresponding C(2)—C(1)—P—M′ angle in the molybdenum complex (55.2°).[4c] If the structural parameters of **2a** are surprisingly normal, on the contrary, the strong electron-withdrawing effect of the phosphoryl group drastically alters the spectroscopic parameters. The CO stretching frequencies are shifted to higher values (1962 and 1888 cm^{-1} in **2a** vs 1935 and 1850 cm^{-1} in **1**[3a]). Similarly, the C(1) carbon is substantially shielded [δ C(1) 25.5 in **2a** vs 69.7 in **1a**[3a]] suggesting a strong polarization of the C(1)—C(2) bond. We ascribe the stability of **2** to the use of the very bulky supermesityl substituent at phosphorus.[5] In addition, the gap between the HOMO and the lone pair orbital in complexes such as **A** is probably smaller than in η^5-phosphacyclopentadienyl complexes.

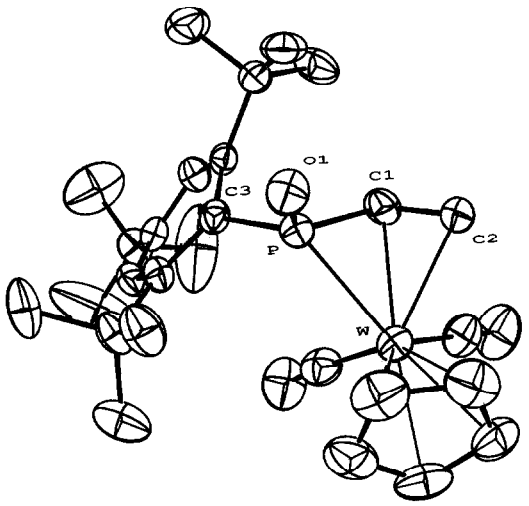

Fig. 1. Structure of **2a** in the crystal.[6] Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Important bond distances (Å) and angles (°):

W—P—O(1)	118.9(1)	C(1)—P—C(3)	105.1(2)
W—P—C(1)	64.0(1)	P—C(1)—C(2)	111.5(4)

EXPERIMENTAL

Complex **1** (0.61 g, 1 mmol), as a mixture of two isomers, was heated at 60°C for 5 min with aqueous hydrogen peroxide (20%, 0.5 cm^3, 4 mmol) in benzene (3 cm^3). After evaporation, extraction of the residue with dichloromethane, drying with Na_2SO_4 and evaporation of CH_2Cl_2, the resulting crude product was chromatographed on silica gel 70–230 mesh. Some impurities were removed with dichloromethane, then complex **2** was eluted with ethyl acetate–methanol (90 : 10) as a mixture of isomers. Yield 0.24 g (*ca* 40%). The two isomers separately crystallized in hexane–dichloromethane (90 : 10).

FORMATION OF MOLYBDENUM–TIN HETEROBIMETALLIC COMPLEXES. REACTIONS OF NEW [(phen){P(4-XC_6H_4)$_3$}Mo(CO)$_3$] (X = Cl, F, CH_3, OCH_3) COMPOUNDS WITH TIN(IV) HALIDES AND ORGANOHALIDES

M. CANO*

(*Received* 24 *August* 1990; *accepted* 17 *September* 1990)

Abstract—The preparation of [(phen){P(4-XC_6H_4)$_3$}Mo(CO)$_3$] (X = Cl, F, CH_3, OCH_3) complexes and their characterization by IR and ^{31}P NMR spectroscopies have been studied. The reactions of the above compounds with R_nSnCl_{4-n} (R = C_6H_5, CH_3; n = 0, 1) are also described.

Tin tetrahalides and organohalides have been found to react readily with several substituted carbonyl group VIB compounds to yield heterobimetallic M—Sn complexes.[1–4]

In a previous paper from this laboratory,[5] we have shown that the reactions of [(bipy){P(4-XC_6H_4)$_3$}Mo(CO)$_3$] with tin derivatives, $SnCl_4$ and R_nSnCl_{4-n} (R = C_6H_5, CH_3; n = 0, 1), give the seven-coordinate complexes [(bipy){P(4-XC_6H_4)$_3$}Mo(CO)$_2$(Cl)(R_nSnCl_{3-n})] or [(bipy)Mo(CO)$_3$(Cl)(R_nSnCl_{3-n})] depending on the tin derivative and phosphine employed. These complexes contain a Mo—Sn bond.

On the other hand, it has recently been reported that the reaction of M(CO)$_3$(NN) fragments [M = Mo, W; NN = 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen)] with mercury halides can be interpreted as the insertion of the former between the atoms of the Hg—X bonds, and this was demonstrated by the isolation of trimetallic complexes X—M—Hg—M′—X (M′ = Mo, W).[6] The same type of reaction has been reported using [Fe(SnX_3)(CO)$_2$(η^5-C_5H_5)] or [(bipy)M(Cl)($SnCl_3$)(CO)$_3$] (X = Cl, Br, I; M = Mo, W) as probes to react with the [M(CO)$_3$(bipy)(NCMe)] complexes (M = Mo, W) giving trimetallic arrays through the insertion of the M(CO)$_3$(bipy) fragments into Sn—X bonds.[7]

Our bimetallic compounds described above could be considered as containing the Mo(CO)$_3$(bipy) unit acting as a bridge between the chloride and tin atoms. However, this behaviour can only be considered as proof of the formation of the dicarbonyl phosphine complexes [(bipy){P(4-XC_6H_4)$_3$}Mo(CO)$_2$(Cl)(R_nSnCl_{3-n})] if the unit [{P(4-XC_6H_4)$_3$}Mo(CO)$_2$(bipy)] is inserted into the Sn—X bonds.

As an extension of the above results and to clarify this behaviour, we are studying the related reactions between [(phen){P(4-XC_6H_4)$_3$}Mo(CO)$_3$] and $SnCl_4$, $C_6H_5SnCl_3$ and CH_3SnCl_3. In this paper we

describe the new [(phen){P(4-XC_6H_4)$_3$}Mo(CO)$_3$] compounds and some of their reactions with tin derivatives.

Refluxing mixtures of (phen)Mo(CO)$_4$ and P(4-XC_6H_4)$_3$ in acetone in the molar ratio 1 : 1 gave, in all cases, the tricarbonyl complexes [(phen){P(4-XC_6H_4)$_3$}Mo(CO)$_3$] which have been characterized by analytical data [Found: C, 54.8; H, 2.7; N, 3.9. Calc. for $C_{33}H_{20}N_2O_3PClMo$: C, 54.7; H, 2.8; N, 3.9% (X = Cl). Found: C, 58.7; H, 3.01; N, 4.2. Calc. for $C_{33}H_{20}N_2O_3PFMo$: C; 58.6; H, 3.0; N, 4.1% (X = F). Found: C, 65.1; H, 4.4; N, 4.2. Calc. for $C_{36}H_{29}N_2O_3PMo$: C, 65.1; H, 4.4; N, 4.2% (X = CH_3). Found: C, 60.4; H, 4.0; N, 3.9. Calc. for $C_{36}H_{29}N_2O_6PMo$: C, 60.7; H, 4.1; N, 3.9% (X = OCH_3)], IR and ^{31}P NMR spectroscopies (Table 1).

The new complexes are microcrystalline, air-stable solids, soluble in organic solvents. Their IR spectra in CH_2Cl_2 solution show, in all cases, three strong carbonyl stretching bands. This has been attributed to the formation of a *fac*-isomer,[8] but there are slight ambiguities in the literature and the IR data may not always conclusively distinguish between the *fac*- and *mer*-isomers.[9–13] The ^{31}P NMR data (when X = F, CH_3, OCH_3) are consistent (Table 1) with the above suggestion; however, when X = Cl an additional signal at 24.35 ppm could be attributed to the presence of a new isomer.

Recently we reported the formation of a mixture of *fac*- and *mer*-isomers for [Mo(CO)$_3$(η^2-NN)(η^1-dppm)] [NN = phen, 2,9-dimethyl-1,10-phenanthroline (dmp); dppm = bis(diphenylphosphino) methane].[14] The ^{31}P NMR data for the phen derivative, δ 20.3 (*mer*-isomer) and 28.7 ppm (*fac*-isomer), are very similar to those displayed by [(phen){P(4-ClC_6H_4)$_3$}Mo(CO)$_3$], δ 38.3 and 24.35 ppm, and, therefore, a similar *fac–mer* mixture could be suggested in this case.

The ν(CO) frequencies and $\Delta(\delta^{31}P)$ chemical shift values show a general increase with decreasing phosphine ligand basicity[15] (Table 1). This has previously been found for other molybdenum(0) carbonyl complexes.[16]

We have also started to study the reactivity of the above complexes with tin derivatives and we describe the results of the reactions of one of these compounds.

The tricarbonyl complex [(phen){P(4-ClC_6H_4)$_3$}Mo(CO)$_3$] reacts with $SnCl_4$, $C_6H_5SnCl_3$ and CH_3SnCl_3 in a refluxing acetone–dichloromethane mix-

Table 2. Analytical and IR data for [(phen){P(4-ClC_6H_4)$_3$}Mo(CO)$_2$(Cl)(R_nSnCl_{3-n})] (R = C_6H_5, CH_3; n = 0, 1)

R	Analysis (%)[a] C	H	N	IR data (cm^{-1}) ν(CO)[b]

ture in a 1:1 mol ratio. Evolution of CO was observed and new Mo—Sn complexes [(phen){P(4-$ClC_6H_4)_3$}$Mo(CO)_2(Cl)(R_nSnCl_{3-n})$] were formed in all cases. Therefore, insertion of the [(phen){P(4-$ClC_6H_4)_3$}$Mo(CO)_2$] units into the Sn—Cl bonds could be suggested to explain this behaviour.

The complexes isolated are microcrystalline, air-stable solids, and have been characterized by their analytical data and IR spectroscopy (Table 2). The IR spectra confirm the existence of Cl—Mo—Sn arrays,[7] but the low solubility of the compounds precluded good NMR spectral data. Mössbauer spectroscopy is probably the best method for knowing the nature of coordination around the tin atom in these types of compound and we are trying to obtain additional information. We are also preparing a new series of Mo—Sn compounds with the rest of the tricarbonylphosphine complexes.

NEW BINUCLEATING AMIDO LIGANDS, SYNTHESIS AND STRUCTURES OF COPPER(II) AND MANGANESE(III) COMPLEXES

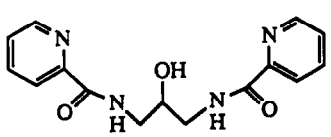
KAREN BERTONCELLO, GARY D. FALLON and KEITH S. MURRAY*

Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia

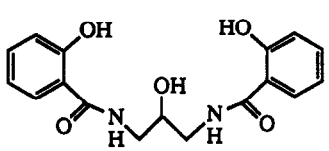
(*Received* 28 *August* 1990; *accepted* 27 *September* 1990)

Abstract—New binucleating ligands containing μ-alkoxo backbones and amido-pyridyl or amido-phenol "end" groups have been synthesized. The syntheses and structures of mononuclear Cu^{II} and binuclear (Cu^{II}—Cu^{II} and Mn^{III}—Mn^{III}) complexes are described. The crystal structure of a novel doubly-bridged Mn^{III}—Mn^{III} complex shows that each six-coordinate manganese is bridged by endogenous μ-alkoxo and exogenous μ-acetato groups. Chemical or electrochemical oxidations will be required to obtain higher oxidation state metallo species.

We are in the process of developing new binucleating ligand systems of the types shown, LH_3 and $L'H_5$, which differ from the well studied Schiff-base[1] or tripodal amino-pyridyl[2] analogues in so far as the salicylideneimine or amino-pyridyl end groups of the latter are replaced by amido-pyridyl or amido-phenol groups. The endogenous μ-alkoxo backbone remains common to all classes. These types of ligands are being used to prepare binuclear (or higher nuclearity) Cu—Cu, Ni—Ni, Fe—Fe and Mn—Mn complexes primarily to use as models for polymetallic bio-sites of these metal ions, for example in Type 3 copper-containing proteins,[3] iron oxo-proteins[4] or the manganese–water oxidation centre (W.O.C.) of Photosystem II.[5] It was felt that incorporation of chelating amido fragments of the type shown, especially in deprotonated forms could potentially stabilize high oxidation state metal ion combinations such as Cu^{II}—Cu^{III}, Cu^{III}—Cu^{III}, Mn^{III}—Mn^{III}, Mn^{III}—Mn^{IV}, etc., some of which have been postulated to be important in the biological systems mentioned above. Studies by other groups[6–8] and our own[9] on related mononuclear amido-chelate species have shown that these oxidation states can be obtained. It was also felt that the planar-deprotonated —CON^-— groups might impose geometric features at the metal ions and the endogenous bridging moiety different to those observed in the Schiff-base and tripodal-pyridyl analogues.



LH_3



$L'H_5$

The ligands LH_3 and $L'H_5$ were synthesized by reaction of 1,3-diaminopropan-2-ol with the corresponding ester of the 2-carboxypyridine or 2-carboxyphenol precursor, and were fully characterized by analytical and spectroscopic methods. Variations have been made, for instance, in the length and symmetry of the diamine backbone. Macro-

Table 1. Mononuclear and binuclear complexes of amido-pyridyl (LH_3) and amido-phenol ($L'H_5$) ligands

Complex	Colour	μ_{eff} (BM) at 295 K (per M ion)
Ligand LH_3		
$Mn(LH_3)Cl_2$	Colourless	5.81
$Cu(LH_3)(ClO_4)_2$	Pale blue	1.63
$Cu(LH)\cdot 2H_2O$	Violet	1.92
$Ni(LH)\cdot H_2O$	Orange	0
$Cu_2L(OAc)\cdot 2.5H_2O$	Blue	1.61[a]
$Cu_2L(CF_3CO_2)\cdot 4H_2O\cdot MeOH$	Blue	1.61
Ligand $L'H_5$		
$[Mn_2L'(OAc)py_4]py\cdot H_2O$	Dark green	4.82
$Mn_2L'(OAc)(MeOH)_4$	Dark green	4.63

[a] A value of 1.70 BM was obtained on a sample obtained by heating, *in vacuo*, the sample used for crystallography, *viz.* $Cu_2L(H_2O)(OAc)\cdot 0.5DMF$. The DMF is easily lost at 295 K.

cyclic analogues of these open-chain amido ligands are also currently being explored. There is an early report of a related macrocyclic system based on the 4-methylphenol-2,6-dicarboxy backbone.[10]

Transition metal ions can readily be incorporated into these ligands and some results were noted which did not always accord with preconceived notions of the relative pK_a values of the various donor groups on the ligand, and probably relate to a subtle interplay of acidity, stability, solubility, hydrogen bonding and nature of solvent. Thus, reaction of LH_3 with metal salts in methanol in the ratio 1 : 2, in the absence of base, yielded crystalline 1 : 1 "adducts" such as $Cu^{II}(LH_3)(ClO_4)_2$ and $Mn^{II}(LH_3)Cl_2$ (Table 1). Similar adducts were obtained by Vagg and co-workers[11] using related non-binucleating pyridyl-amide ligands and polymeric structures were postulated for such species in the solid state. Addition of a base such as NaOH, to a 1 : 1 or 1 : 2 mixture of LH_3 and $Cu(CF_3CO_2)_2$, yielded the violet-coloured complex $Cu(LH)\cdot 2H_2O$, in which the ligand acted as a tetradentate chelate and still retained the protonated, non-bonded alcohol moiety but had undergone deprotonation of the amido NH groups. A crystal structure determination* confirmed the planar CuN_4 coordination imposed by LH^{2-} on copper [Fig. 1(a)] and showed hydrogen-bonded lattice interactions involving water molecules and amide-oxygen or alcohol-oxygen atoms. The Cu—N(amido) and Cu—N (pyridyl) distances are normal.[12] The analogous square-planar $Ni(LH)\cdot H_2O$ complex was likewise obtained and displayed IR, ^1H NMR and mass spectral data compatible with the copper(II) structure.

Binuclear μ-carboxylate copper(II) complexes of LH_3 were obtained using a 2 : 1 copper carboxylate-to-ligand ratio with DMF or MeCN as preferred solvents. FAB mass spectral measurements clearly show the $Cu_2L(RCO_2)$ parent ion. A low temperature crystal structure determination† of Cu_2L

*Crystal data on $Cu(LH)\cdot 2H_2O$: $C_{15}H_{18}CuN_4O_5$, fw = 397.9, monoclinic, $a = 7.998(2)$, $b = 22.696(6)$, $c = 9.463(3)$ Å, $\beta = 109.94(2)°$. Space group: $P2_1/a$, $Z = 4$, $D_c = 1.64$ g cm^{-3}, $D_M = 1.64(1)$ g cm^{-3}, $F(000) = 820$, μ(Mo-K_α) = 1.39 mm^{-1}, λ(Mo-K_α) = 0.71073 Å, $T = 20(1)°C$. Structure solved by Patterson and Fourier methods and refined by full-matrix least-squares (positional and anisotropic thermal parameters for Cu, O, N and isotropic thermal parameters for all other atoms). $R = 0.061$, $R_w = 0.072$ for 152 parameters and 1905 observed [$F > 6\sigma(F)$] data from 3716 measured. The limits of data collection were $3.5 \leqslant 2\theta \leqslant 55°$.

†Crystal data on $Cu_2L(H_2O)(OAc)\cdot 0.5DMF$: $C_{18.5}H_{21.5}Cu_2N_{4.5}O_{6.5}$, fw = 538.0, triclinic, $a = 8.662(1)$, $b = 10.010(1)$, $c = 12.833(2)$ Å, $\alpha = 83.27(1)$, $\beta = 73.61(1)$, $\gamma = 79.35(1)°$. Space group: $P\bar{1}$, $Z = 2$, $D_c = 1.71$ g cm^{-3}, $F(000) = 548$, μ(Mo-K_α) = 2.08 mm^{-1}, λ(Mo-K_α) = 0.7107 Å, $T = -100(1)°C$. Structure solved by Patterson and Fourier methods and refined by full-matrix least-squares (positional and anisotropic thermal parameters for Cu and isotropic thermal parameters for all other atoms). $R = 0.045$, $R_w = 0.052$ for 147 parameters and 2716 observed [$F > 6\sigma(F)$] data from 3680 measured. The limits of data collection were $3.5 \leqslant 2\theta \leqslant 50°$. DMF is disordered about the origin. C(8) is also disordered above and below the C(7), C(9), O(2) plane.

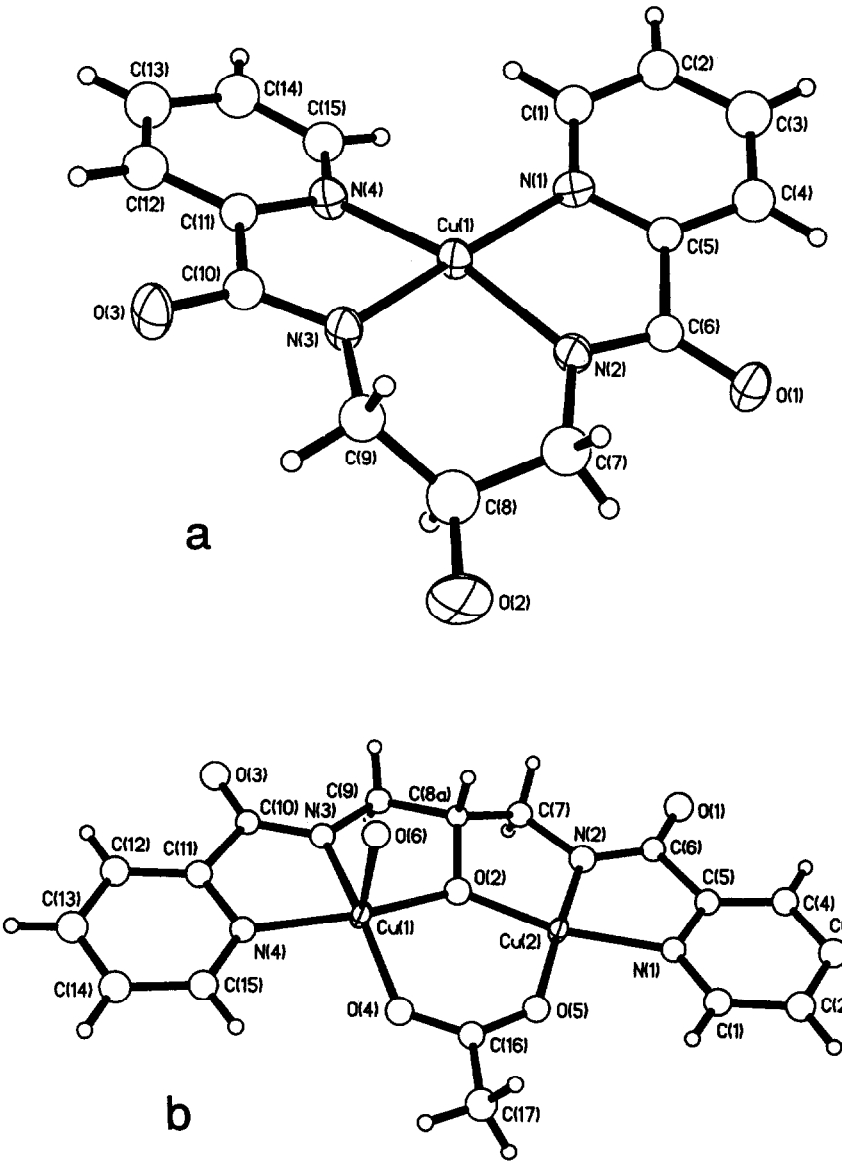

Fig. 1. (a) ORTEP drawing of $Cu(LH)\cdot 2H_2O$. The solvated H_2O molecules are not shown. Selected bond lengths (Å): Cu(1)—N(1) = 2.064(5); Cu(1)—N(2) = 1.956(5); Cu(1)—N(3) = 1.949(5); Cu(1)—N(4) = 2.026(6); Cu(1)—O(1) = 2.533; C(6)—O(1) = 1.257(8); C(6)—N(2) = 1.291(9); C(10)—O(3) = 1.259(9); C(10)—N(3) = 1.309(9). Hydrogen-bonded contacts: O(1)···O(5) = 2.78; O(2)···O(5) = 2.69; O(3)···O(4) = 2.80; O(3)···O(4′) = 2.82; O(4)···(5) = 2.72 [where O(4) and O(5) are water oxygens]. (b) ORTEP drawing of $Cu_2L(H_2O)(OAc)0.5DMF$. The solvated DMF molecules not shown. C(8) is disordered, only the site above the C(7), C(9), O(2) plane is shown. Selected bond lengths (Å): Cu(1)—N(3) = 1.913(4); Cu(1)—N(4) = 2.003(4); Cu(1)—O(2) = 1.907(4); Cu(1)—O(4) = 1.963(3); Cu(1)—O(6) = 2.344(4); Cu(2)—N(1) = 1.992(4); Cu(2)—N(2) = 1.899(5); Cu(2)—O(2) = 1.874(3); Cu(2)—O(5) = 1.923(4); C(6)—O(1) = 1.250(6); C(6)—N(2) = 1.317(6); C(10)—O(3) = 1.258(6); C(10)—N(3) = 1.312(6). Cu(1)···Cu(2) = 3.416. Selected bond angle (°): Cu(1)—O(2)—Cu(2) = 129.2(2).

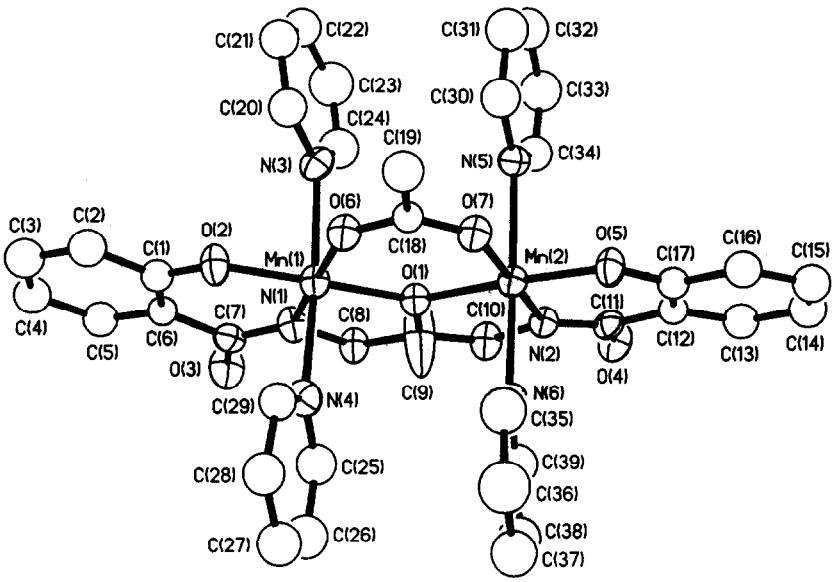

Fig. 2. ORTEP drawing of $[Mn_2L'(OAc)py_4]py \cdot H_2O$. The solvated py and H_2O molecules are not shown. Selected bond lengths (Å) and angles (°): Mn(1)—O(1) = 1.938(5); Mn(1)—O(6) = 1.995(5); Mn(1)—O(2) = 1.848(5); Mn(1)—N(1) = 1.919(6); Mn(1)—N(3) = 2.362(6); Mn(1)—N(4) = 2.389(7); Mn(2)—O(1) = 1.942(4); Mn(2)—O(7) = 1.977(5); Mn(2)—O(5) = 1.851(5); Mn(2)—N(2) = 1.927(6); Mn(2)—N(5) = 2.410(6); Mn(2)—N(6) = 2.389(7). Mn···Mn = 3.552(2); Mn(1)—O(1)—Mn(2) = 132.5(2).

$(H_2O)(OAc) \cdot 0.5DMF$ confirmed that the binucleating ligand had been fully deprotonated and that the two CuN_2O_2 planar moieties were coplanar and were bridged, as desired, by the endogenous μ-alkoxo-oxygen atom and the exogenous $\eta^1:\eta^1:\mu_2$-bridging acetate group. One of the copper atoms has an axially-bonded water molecule [Fig. 1(b)]. A Cu—Cu distance of 3.416 Å and Cu—O(R)—Cu angle of 129.2(2)° were generally in accord with the observed magnetic moment of 1.70 BM (at 295 K), which in turn is indicative of weak antiferromagnetic coupling. Interestingly, Okawa and co-workers[13] have recently observed weak ferromagnetic coupling in a μ-acetato-bridged Cu^{II}—Cu^{II} complex of another binucleating amido ligand system which contains a μ-pyrazolato endogenous bridging group. Unfortunately, no structural data were obtainable which could be compared with those for $Cu_2L(H_2O)(OAc) \cdot 0.5DMF$.

Crystalline μ-pyrazolate-bridged complexes such as $[Cu_2L(3,5\text{-}Me_2\text{-}pyz)]$ were obtained using $Cu(ClO_4)_2$ in the presence of NaOH and ligand. Na^+ and ClO_4^- ions were incorporated into the lattice of some of these derivatives. This is a feature sometimes observed in metal–amido chelate compounds[6,9] and is related to the ability of amide oxygen atoms to bind to Na^+ as well as to the chelated metal.

One of the most interesting groups of binuclear complexes is that formed from manganese(III) and the ligand $L'H_5$. These complexes are of general formula $Mn_2L'(OAc)(B)_4$, where B = pyridine, γ-picoline and methanol, and are formed by reacting $[Mn_3O(OAc)_6py_3](ClO_4)$[14] or $Mn(OAc)_3$, in air, with $L'H_5$ using the neat pyridine base or methanol as solvent. Such conditions are basic enough to cause removal of five protons from $L'H_5$. The molecular structure* of the pyridine derivative, shown in Fig. 2, consists of two octahedrally-coordinated manganese(III) ions bridged by both

*Crystal data on $[Mn_2L'(OAc)py_4]py \cdot H_2O$: $C_{44}H_{43}Mn_2N_7O_8$, fw = 907.7, triclinic, $a = 9.218(3)$, $b = 13.637(4)$, $c = 17.291(5)$ Å, $\alpha = 99.50(2)$, $\beta = 91.44(2)$, $\gamma = 100.14(3)°$. Space group: $P\bar{1}$, $Z = 2$, $D_c = 1.43$ g cm^{-3}, $F(000) = 940$, μ(Mo-K_α) = 0.63 mm^{-1}, λ(Mo-K_α) = 0.71073 Å, $T = 20(1)°C$. Structure solved by Patterson and Fourier methods and refined by full-matrix least-squares [positional and anisotropic thermal parameters for Mn, O, N and C(7) through C(11) and isotropic thermal parameters for all other atoms]. $R = 0.062$, $R_w = 0.079$ for 355 parameters and 3456 observed [$F > 6\sigma(F)$] data from 5489 measured. The limits of data collection were $4.0 \leqslant 2\theta \leqslant 45°$. The stereochemistry around C(9) is trigonal but should be tetrahedral and is, therefore, disordered. An attempt to refine C(9) as occupying two sites, above and below the C(8), C(10), O(1) plane, was unsuccessful.

the μ-alkoxo-oxygen atom of $(L')^{5-}$, with a Mn—O—Mn angle of 132.5(2)°, and by a $\eta^1:\eta^1:\mu_2$-bridging acetate group. The Mn—Mn distance is 3.552(2) Å. A doubly-bridged Mn^{III}_2 structure of this, or any other type, is quite rare in the general context of models for the polynuclear manganese site in the W.O.C. or in manganese catalase enzymes.[5] The whole of the binucleating $(L')^{5-}$ ligand moiety is remarkably planar, presumably through a combination of favourable geometry around the manganese atoms and incorporation of deprotonated amide fragments along the backbone. It is interesting to note that the Mn—O and Mn—N distances provided by $(L')^{5-}$ are similar to those recently deduced from EXAFS for the W.O.C. of Photosystem II, whereas the Mn—N(pyridine) and Mn···Mn distances are longer than those obtained from fits of the first and second shell EXAFS peaks.[15]

The room temperature magnetic moment, per manganese, of $[Mn_2L'(OAc)py_4]py \cdot H_2O$ is 4.82 BM, which is close to the uncoupled $S = 2$ value. Similar weak coupling has been observed recently in other doubly- and triply-bridged Mn^{III}—Mn^{III} systems.[5] An irreversible oxidation wave, observed in the cyclic voltammogram of DMF solutions of this complex at +1.1V (reference to SCE), is assigned to $Mn^{III} \rightarrow Mn^{IV}$. Thus, in contrast to other recently reported mononuclear amido-manganese chelates,[7,8] a stronger oxidant than air is required to obtain Mn^{IV} or Mn^{V} species.

Studies of reactivity, electrochemistry and variable temperature susceptibility are in progress on the various compounds described here.

Supplementary data. Tables of atomic coordinates, thermal parameters, bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre.

(*Received* 11 *December* 1989; *accepted* 20 *July* 1990)

Abstract—The potassium salt of *o*-aminophenol-N,N,O-triacetic acid (APTA) and $KMnL \cdot H_2O$, $KCoL \cdot 3H_2O$, $KNiL \cdot 3H_2O$, $KZnL \cdot 3ZH_2O$, $Co(CoL)_2 \cdot 7H_2O$ and $Ni(NiL)_2 \cdot 8H_2O$ (L^{3-} : anion of APTA) have been synthesized and characterized by elementary analysis, thermogravimetric analysis, molar conductance, IR spectra, magnetic measurements and electronic spectra. The coordination environments of these metal ions have been discussed on the basis of these studies. The single crystal structure of cobalt(II)–APTA has been determined as $CoL \cdot 0.5Co(H_2O)_6 \cdot 4H_2O$, which contains two types of cobalt(II). One type of cobalt(II) is coordinated with six water molecules to form $Co(H_2O)_6^{2+}$, the other is chelated by APTA to form a distorted octahedron and linked into an infinite chain anion $[CoC_6H_4(OCH_2COO)N(CH_2COO)_2^-]_n$, in which each cobalt(II) atom is linked with neighbouring cobalt(II) atoms through two carboxylate oxygen atoms of the phenoxyacetate group. Water molecules occupy interstices in the structure.

Amino carboxylates, as one type of organic ligand, have found wide uses in many important fields as a result of their excellent coordination abilities. *o*-Aminophenol-N,N,O-triacetic acid (APTA) is a new kind of ligand in which iminodiacetic acid is incorporated into the *ortho* position on the ring of phenoxyacetic acid. It is interesting to study the derivatives of phenoxyacetic acid, not only for their special physiological action[1,2] but also for their potential coordination ability,[3,4] especially the coordination behaviour of ethereal oxygen.[5,6] Generally, isolated ethereal oxygen is weakly linked to metal ions or not bonded at all. However, when a strong coordination group is introduced adjacent to an ethereal oxygen, the coordination ability of the ethereal oxygen is greatly increased due to the chelate effect. Therefore the title ligand and its complexes with manganese(II), cobalt(II), nickel(II) and zinc (II) were synthesized and characterized by thermal analysis, IR spectra, electronic spectra and magnetic moments, and the single crystal structure of the cobalt(II) complex determined. On the basis of the physicochemical measurements, the coordination stereochemistry of complexes has been discussed in view of the nature of APTA and the central metal ions.

EXPERIMENTAL

Preparation of compounds

Monopotassium salt of APTA (KH_2L)[7]

o-Aminophenol (0.25 mol) was added to an aqueous solution of $ClCH_2COOK$ (1 mol). The mixture was heated under N_2 with continuous stirring and the pH was maintained above 10 using 5 mol dm^{-3}

* Author to whom correspondence should be addressed.

KOH. After $1\frac{1}{2}$ h, $ClCH_2COOK$ (0.25 mol) was added to ensure the reaction was complete and the mixture was allowed to continue refluxing until the pH of the solution remained constant. The solution was then acidified to pH 3.3 with 6 mol dm^{-3} HCl after cooling and the mixture was allowed to stand overnight. The product was recrystallized twice from deionized water to give the white microcrystalline monopotassium salt of APTA (KH_2L, L^{3-} = anion of APTA). Melting point: 208°C (dec.). Found: C, 44.8; H, 3.8; N, 4.3. Calc. for $C_{12}H_{12}NO_7K$: C, 44.9; H, 3.8; N, 4.4%.

$KM^{II}L \cdot xH_2O$

(a) $KMnL \cdot H_2O$. $MnCO_3$ (1 mmol) was added to KH_2L (1 mmol) in 10 cm^3 of H_2O and the mixture was stirred under N_2 until the pH of the mixture reached 6. 15 cm^3 of ethanol was added to the filtrate and the product was recrystallized with water–ethanol (1 : 1).

(b) $KCoL \cdot 3H_2O$, $KNiL \cdot 3H_2O$ *and* $KZnL \cdot 3H_2O$. $M^{II}CO_3$ (1 mmol) was added to KH_2L (1 mmol) in 20 cm^3 of H_2O and the mixture was mildly heated with stirring until the pH of the mixture reached 6. The filtrate was evaporated on a 70°C water bath until the microcrystalline product appeared on the surface of the solution, then an equal volume of ethanol was added. The complex salt precipitated from solution after a few hours and was recrystallized from water–ethanol (1 : 1).

$M^{II}(M^{II}L)_2 \cdot xH_2O$ (M = Co, Ni)

KH_2L (1 mmol) was added to 40 cm^3 of an aqueous solution containing $M^{II}(NO_3)_2$ (1.5 mmol). The pH of the solution was adjusted to 3.5 with dilute NaOH. The solution was then evaporated until the microcrystals precipitated from solution. The product was recrystallized from water and dried at 60–70°C.

$CoL \cdot 0.5Co(H_2O)_6 \cdot 4H_2O$

The microcrystals of $Co(CoL)_2 \cdot 7H_2O$ were dissolved in water and this was allowed to evaporate at room temperature. The single crystal obtained from solution was used for X-ray analysis without being dried at temperatures higher than room temperature.

The results of elementary analysis, molar conductivity and thermogravimetric analysis of these complex salts are listed in Tables 1, 2 and 3, respectively.

Apparatus

Microanalyses for C, H and N were performed with a Perkin–Elmer 2400C elementary analyser. Metal analyses were carried out by EDTA complexation titration. Molar conductance measurements were obtained in deionized water using a DDS-11A conductivity apparatus. The thermogravity measurements were performed using a LCT-2 differential thermal analyser in an air atmosphere and at a heating rate of 5°C min^{-1}. IR spectra were recorded using a IFS113V IR Fourier spectrometer and KBr discs. The electronic spectra of aqueous solution in the UV–vis region were recorded on a Shimadzu 240 UV–vis spectrophotometer, and in the near-IR region on a Hitachi 330 IR spectrophotometer. The absorption spectra of solid compounds in the UV–vis region were monitored with a Hitachi 557 UV–vis spectrophotometer. Magnetic susceptibilities were determined at room temperature by the Gouy method using $(NH_4)_2Fe(SO_4)_2 \cdot 5H_2O$ as a calibrant, and the diamagnetic corrections for ligand and H_2O were applied. The X-ray intensity data from a single crystal were collected on a CAD4 diffractometer with Mo-K_α radiation using the ω–2θ scan mode. A total of 3565 independent reflections in the range $\theta \leqslant 25$ were measured, of which 2363

$Ni(NiL)_2 \cdot 8H_2O$	135.3

reflections with $I \geqslant 3\sigma(I)$ were considered to be observable. An Lp correction was applied. The structure was solved by direct methods and difference Fourier syntheses. The positions of hydrogen atoms were calculated. The refinements were carried out by full-matrix least-squares procedures with anisotropic temperature factors for non-hydrogen atoms and isotropic temperature factors for hydrogen atoms. The final R is 0.063. The calculations were performed on a PDP 11/44 using the SDP program. Atomic scattering factors were taken from the *International Tables for X-ray Crystallography* (1974).

RESULTS AND DISCUSSION

Structure of $[CoC_6H_4(OCH_2COO)N(CH_2COO)_2] \cdot 0.5[Co(H_2O)_6] \cdot 4H_2O$

$[CoC_6H_4(OCH_2COO)N(CH_2COO)_2] \cdot 0.5[Co(H_2O)_6] \cdot 4H_2O$, $Mr = 989.45$, orthorhombic, *Pbnm*, $a = 9.343(2)$, $b = 18.447(3)$, $c = 24.100(5)$ Å, $Z = 4$, $V = 4153.5$ Å^3, $D_c = 1.582$ g cm^{-3}, $\mu = 6.591$ cm^{-1}, $R = 0.063$ for 2363 observed reflections. The bond lengths and angles are listed in Tables 4 and 5. A view of $[CoC_6H_4(OCH_2COO)N(CH_2COO)_2]^-$ is shown in Fig. 1. There are two different coordination environments of cobalt(II) in the complex. One kind of cobalt(II) is chelated by APTA and linked into an infinite chain anion $\{[CoC_6H_4(OCH_2COO)N(CH_2COO)_2]^-\}_n$, and the other kind of cobalt(II) is coordinated by six water molecules to form $[Co(H_2O)_6]^{2+}$.

In the anion group, the central cobalt atom is bonded to N, O(1), O(3), O(5), O(6) and O(7) to form a severely distorted octahedron, in which O(6) is another carboxylate oxygen atom of the phenoxyacetate group in an adjacent Co^{II}–APTA unit, and

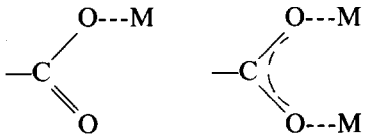
the discrete units of Co^{II}–APTA are linked through two carboxylate oxygen atoms of phenoxyacetate to form an infinite chain polynuclear complexing-anion, in which the cobalt atoms are arranged in a zigzag mode. Here, APTA acts as a hexadentate ligand and the phenyl group—C(1), C(2), C(3), C(4), C(5) and C(6), amine nitrogen N, ethereal oxygen O(5), phenoxyacetate group–C(11), C(12), O(6), O(7) and cobalt atom are roughly co-planar within 0.08 Å. The Co^{II}—N bond length in Co^{II}–APTA is longer than that in Co^{II}—HBATA (HBATA : *o*-hydroxybenzylamine-N,N,O-triacetic acid, one of the analogues of APTA), but the Co^{II}—O(ether) bond length is shorter than that in Co^{II}—HBATA[8] [Co—N, 2.120 Å; Co—O(ether), 2.233 Å]. Obviously, the longer bond length of Co^{II}—N in Co^{II}—APTA can be ascribed to the weaker basicity of the aromatic amine nitrogen of APTA due to the p–π conjugation system. The comparatively shorter bond length of Co^{II}—O(ether) in Co^{II}—APTA may be rationalized as being due to the higher electron density on the ethereal oxygen of APTA as a result of more extensive electronic delocalization on the conjugated system (in APTA the delocalized π bond is π_8^{10}, while in HBATA is π_7^8). Since the weak coordinating ability of ethereal oxygen is generally accepted, it is quite natural that the Co^{II}—N bond length (2.120 Å) is shorter than that of Co^{II}—O(ether) (2.233 Å) in Co^{II}—HBATA. However, the sequence of bond lengths in Co^{II}—APTA is reversed, but if referred to the structural parameters of the protonated complex of cobalt(II) with APDA (*o*-aminophenol-N,N-diacetic acid),[9] in which the Co^{II}—N bond length (2.156 Å) is quite close to that of Co^{II}—O(phenol) (2.154 Å), the above structural character is not abnormal. Firstly, the formation of the phenoxyacetate chelate ring reinforces the interaction between cobalt(II) and oxygen(ether) and secondly, unlike HBATA in which the C—N bond can revolve freely to reach the most stable steric arrangement, the co-plane of the benzene ring with the nitrogen atom makes APTA more rigid in the steric adjustment. So the least tension framework is attained only by adjusting the bond lengths of Co^{II}—N and Co^{II}—O (ether). Consequently, while the Co^{II}—O(ether) bond is strengthened, the Co^{II}—N bond is weakened. For the same reason, in Co^{II}—APTA

there is more space left for the sixth coordination atom, which makes it possible for Co^{II}—APTA to adopt a chain polynuclear structure.

From the crystal structures of Co^{II}—APTA and Co^{II}—HBATA, it can be predicted that although the coordination ability of ethereal oxygen is relatively weak, it would greatly increase when a strong coordination group adjoins to the ethereal oxygen and forms a chelate ring with it; it would be so, especially when the adjacent group would affect the electronic effects on ethereal oxygen.

Infrared spectra

The most characteristic bands in the IR spectra of KH_2L and its complexes are given in Table 6.[10] The characteristic absorptions of coordinated APTA in complexes shift toward lower or higher frequency as compared with uncoordinated APTA, which indicates that APTA is coordinated to the metal ion through the carboxylate oxygen, ethereal oxygen and aromatic amine nitrogen. Generally, when a carboxylate group is coordinated to a metal in the form of (a), the stronger the interaction, the larger the $\Delta\nu_{(a)}$ [$\Delta\nu = \nu_{as}(-COO^-) - \nu_s(-COO^-)$], while in the form of (b), $\Delta\nu_{(b)}$ is smaller than $\Delta\nu_{(a)}$.[11]



(a) (b)

The results reveal a different order ($\Delta\nu$: $KZnL \cdot 3H_2O < KNiL \cdot 3H_2O < KCoL \cdot 3H_2O < KMnL \cdot H_2O$) to the Erving and Williams M^{II} stability order ($Zn^{II} < Ni^{II} < Co^{II} > Mn^{II}$) which may probably be attributed to the existence of the (b) coordination pattern in the cobalt(II) complex.

Table 7. Magnetic moments of complexes of APTA with Co^{II}, Ni^{II} and Mn^{II} at room temperature

Complex	μ_{eff} (BM)
$KCoL \cdot 3H_2O$	4.71
$KNiL \cdot 3H_2O$	3.16
$KMnL \cdot H_2O$	5.88
$Co(CoL)_2 \cdot 7H_2O$	4.79[a]
$Ni(NiL)_2 \cdot 8H_2O$	3.26[a]

[a] Values are corrected for the paramagnetism of $Co(H_2O)_6^{2+}$ and $Ni(H_2O)_6^{2+}$.

Magnetism

The magnetic moments of complexes are collected in Table 7. All compounds except $KZnL \cdot 3H_2O$ are high spin. Usually, μ_{eff} values for high-spin octahedral cobalt(II) complexes range from 4.8 to 5.2 BM.[12] The μ_{eff} value for Co^{II}—APTA is slightly lower than 4.8 BM, which implicates that the coordination geometry around each cobalt atom is a distorted octahedron,[13] as illustrated in Fig. 1. The μ_{eff} value for Ni^{II}—APTA falls within the normal range (2.9–3.4 BM[12]), which indicates the octahedral arrangement around nickel(II) in its high-spin APTA complexes. The μ_{eff} value for Mn^{II}—APTA is close to the $\mu_{s.o.}$ value, which provides no more information than that APTA is a weak-field ligand. The thermogravimetric analysis, however, shows that there is one water molecule coordinated to manganese(II),

therefore manganese(II) is probably located in the central area of a distorted octahedron.

Electronic spectra

The electronic spectra of complexes are given in Table 8. The similarity of the absorption spectra of $KCoL \cdot 3H_2O$ or $KNiL \cdot 3H_2O$ and $Co(CoL)_2 \cdot 7H_2O$ or $Ni(NiL)_2 \cdot 8H_2O$ in solution or in the solid state suggests that the structure of the complex anion in both states is independent of the counter-ion. The main features of these spectra are consistent with the octahedral geometry around cobalt (II) and nickel(II). The absorption bands were assigned and approximate *Dq*, *B* and β were evaluated for an ideal octahedron (see Table 8). Both β values are less than one, which suggests the existence of some electron delocalization in cobalt (II) and nickel(II) complexes. Since the zinc(II) complex is colourless and antimagnetic, the absorption spectrum of the cobalt(II)-dopped zinc(II) complex was recorded in order to gain some insight into the coordination geometry around zinc(II). It gives an absorption peak around 535 nm, which is similar to Co(II)—APTA in its appearance and red shifts about 15 nm in its location. So the zinc(II) atom is probably octahedrally coordinated to APTA.

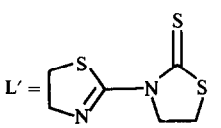
Abstract—Reaction of 1,3-thiazolidine-2-thione with tellurium(IV) in hydrobromic acid medium gave the hexabromotellurate, $[C_6H_9N_2S_3]_2^{2+}[Te^{IV}Br_6]^{2-}$ (**3**). Reaction of 1-methylimidazoline-2-(3H)-thione (L″) with tellurium(IV), in hydrobromic acid medium, gave the mixed-ligand tellurium(II) complex $[Te^{II}L''_3Br]^+Br^-$ (**4**). The structures of $[C_6H_9N_2S_3]_2^{2+}$ $[Te^{IV}Br_6]^{2-}$ (**3**) and $[Te^{II}L''_3Br]^+Br^-$ were determined by single crystal X-ray diffraction methods. In **3** the unit cell contains $[TeBr_6]^{2-}$ anions and two $[C_6H_9N_2S_3]^+$ cations. There is no direct bonding between the metal atom and the cations. In the anion only slight angular deviations from the perfect octahedral geometry are observed. The lone pair of electrons on tellurium(IV) is found to be stereochemically inert. In the cation the two five-membered heterocyclic rings adopt different conformations. In complex **4**, in the solid state, the planar $[Te^{II}L''_3Br]^+$ cation and Br^- anion are held together by ionic interactions. In the cation, L″ is bonded to the central tellurium atom through the sulphur atom.

The heterocyclic thioamides, 1,3-thiazolidine-2-thione (L) and 1-methylimidazoline-2(3H)-thione (L″), are ambidentate ligands in that they can coordinate through the heterocyclic nitrogen or the exocyclic sulphur atom.[1–5] Thiols are capable of undergoing reductive complexation reactions with tellurium(IV) and selenium(IV).[6–9] The interaction of thiols, like 3-mercaptopropionic acid, cysteine, etc., has led to the isolation of the bis(thiolato) complex of tellurium(II) and selenium(II). Interaction of L with transition metals like palladium, cadmium, etc., have resulted in the formation of complexes in which the ligand L remains intact.[10,11] Kubiak and Glowiak[12] on trying to prepare the zinc complex of L, noticed the formation of a new compound of overall composition, $[L'H]^+[ZnCl_3(H_2O)]^-$;



Ainscough *et al.*[13] noticed the formation of $Cu^IL'Cl_2$ during the interaction of L with copper(II) in nitromethane as solvent. Earlier, with selenium(IV), we observed the formation of the hydrobromide of L′.[14] The disulphide, 2,2′-dithiobis[4,5-dihydrothiazole], formed by the oxidation of L is known to rearrange on acid catalysis giving the

* Author to whom correspondence should be addressed.

thiocarbonyl derivative, L′.[15] Complexes of L″ with the metal ions Cr^{III},[16] Co^{II},[17] Ni^{II},[18] Cu^{I},[19,20] Zn^{II},[21] Pd^{II},[22] Pt^{II},[23] Cd^{II},[24] Pb^{II}[25] have been reported. Reaction between copper(II) salts and L″ produced a wide variety of compounds whose composition was dependent on the nature of the solvent, the coodinating properties of the counter ion as well as the molar ratios of the reactants. Agnus *et al.*[26] have reported a Cu^{I}–Cu^{II} cluster featuring the mercaptide anion of L″. Two structures have also been reported which involve an oxidized form of L″, namely 1,1′-dimethyl-2,2′-dimidazolylmonosulphide.[27,28] During the interaction of copper(II) salts with L″, copper(II) is reduced by L″ to copper(I), while L″ is oxidized to the corresponding disulphide. L″ is also known to form 1 : 1 charge-transfer complexes with di-iodine.[29] During the interactions of the thioamides, L and L″, with tellurium(IV) in acid media, attempts to isolate bis(thiolato) complexes of tellurium(II) were made.

The interaction of L with tellurium(IV) in acid media, such as HCl, H_2SO_4, etc., did not yield any isolable crystalline products. However, on employing HBr medium, the formation of the hexabromotellurate (**3**) was observed. The mixed-ligand tellurium(II) complex, $[Te^{II}L''_3Br]^+[Br]^-$ (**4**) was obtained during the interaction of L″ with tellurium(IV) in HBr medium. In this paper, we report the syntheses and crystal structure determinations of **3** and **4**.

EXPERIMENTAL

Preparation of bis[2-(2-*thioxo*-1,3-*thiazolidin*-3-*yl*)-4,5-*dihydro*-1,3-*thiazolium*]*hexabromotellurate*(IV) (**3**)

Ligand L (0.48 g, 4 mmol) was dissolved in 15 cm^3 of methyl alcohol. To this was slowly added tellurium dioxide (0.159 g, 1 mmol) in 5 cm^3 of 4 N hydrobromic acid. The solution gradually turned yellow. After about 24 h, a mixture of orange–red coloured solid and yellow needles of L′ (the thione derivative) were formed. To this, 20 cm^3 of acetonitrile were added, stirred for 15 min and filtered. The filtrate was deep red in colour. The filtrate on slow evaporation at room temperature yielded small, red, transparent crystals of **3**. Found: C, 13.6; H, 1.7; N, 5.7; S, 17.9; Br, 46.4; Te, 11.9. $TeC_{12}H_{18}N_4S_6Br_6$ requires: C, 14.2; H, 1.8; N, 5.5; S, 18.9; Br, 47.1; Te, 12.5%. IR (cm^{-1}): 1575 (s, C=N); 1360 (m, C⋯N); 1040 (m, C=S). ^1H NMR (DMSO-d_6): δ 3.25–3.45 (d, —CH_2—S—C=S); 3.50–3.70 (d, —CH_2S); 3.80–4.10 (d, —CH_2—N—C=S); 4.60–4.80 (d, —CH_2—N—).

Preparation of bromotris(1-*methylimidazoline*-2-(3H)-*thione*)*tellurium*(II) *bromide* (**4**)

Ligand L″ (0.33 g, 3 mmol) was dissolved in 10 cm^3 of methyl alcohol. To this was slowly added tellurium dioxide (0.08 g, 0.5 mmol) in 5 cm^3 of 4 N hydrobromic acid. A deep red colour was produced. The solution on slow evaporation at room temperature yielded small, red, transparent crystals of **4**. The yield was nearly quantitative. Found: C, 21.8; H, 2.5; N, 12.8; Br, 24.8; Te, 19.8. $TeC_{12}H_{18}N_6S_3Br_2$ requires: C, 22.9; H, 2.9; N, 13.1; Br, 25.4; Te, 20.3%. IR (cm^{-1}): 3270–3110 (b, —NH); 1560 (s, C=N); 1395 (s, C⋯N); 960 (m, C⋯S). ^1H NMR (DMSO-d_6): 3.5 (s, —CH_3); 6.7 (d, —CH); 7.1 (d, —CH); 12.2 (b, —NH).

X-ray structure determination of **3** *and* **4**

Crystal data and data collection parameters for **3** and **4** are given in Tables 1 and 2, respectively. The intensity data were corrected for Lorentz and polarization effects. The structures were solved by the heavy-atom method. The positions of tellurium and bromine were obtained from the respective Patterson map. Successive difference Fourier maps revealed the positions of all the remaining non-hydrogen atoms. Non-hydrogen atoms were refined anisotropically by the full-matrix least-squares method using SHELX 76.[30] The scattering factors for tellurium were obtained from Cromer and Mann.[31] Refinement was continued using a weighting scheme of $w = 1/[\sigma^2(F_o)+g|F_o|^2]$ (g being 0.0075 for **3** and 0.0267 for **4**) until the $(\text{shift/ESD})_{max}$ in non-hydrogen parameters was less than 0.01. For both **3** and **4**, the hydrogen atoms did not appear in the final difference Fourier map and their positions were geometrically fixed and not refined. Maximum electron densities in the final difference Fourier map were 2.76 for **3** and 4.35 $eÅ^{-3}$ for **4**, but were rejected due to their proximities to tellurium.

DISCUSSION

Formation aspects of complex **3**

The hexabromotellurate, $[C_6H_9N_2S_3]_2^{2+}[Te^{IV}Br_6]^{2-}$, presents an interesting example of some subtle aspects of coordination. Tellurium(IV) exhibits borderline behaviour from the concept of HSAB[31] theory. Therefore the thione sulphur of L′ would have been expected to coordinate to tellurium(IV). However, bromide, which is a relatively harder base, is coordinated to

tellurium. This can be explained on the basis of the effect of the cation in stabilizing the huge anion, $[TeBr_6]^{2-}$. The formation of the title compound can be explained by the oxidation of L, **1**, in air to the corresponding disulphide, **2**, which in hydrobromic acid medium undergoes rapid intramolecular rearrangement with the extrusion of one sulphur to give the corresponding thione derivative $[L'H]^+$, which brings out the anion from the solution to give **3** as given in Scheme 1.

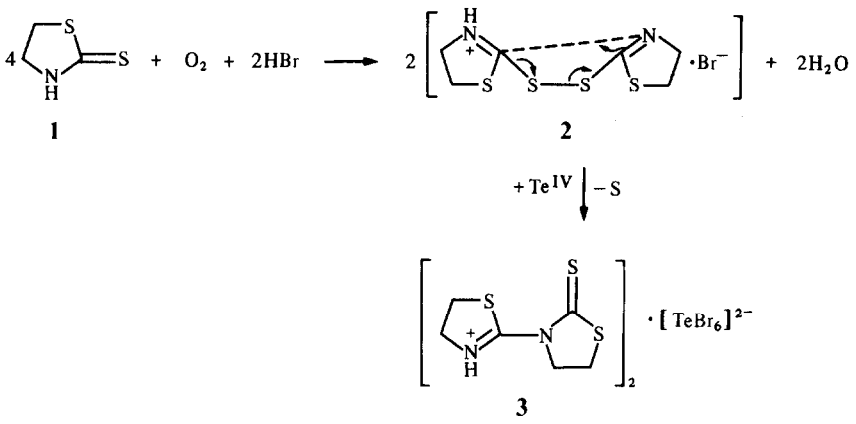

Scheme 1.

Structure of complex **3**

Selected bond lengths and angles are given in Table 3. Figure 1 shows the PLUTO[32] plot of the molecule, while Fig. 2 shows the packing of the molecules in the unit cell.

According to VSEPR[33] theory, a distorted octahedral configuration is expected for systems of the type TeX_6^{2-} (X = Cl, Br, I) which contain six bonding electron pairs and one non-bonding electron pair in the valence shell of tellurium(IV). However, structural investigations on many TeX_6^{2-} anions show a regular octahedral structure. It is observed that the location of tellurium on an inversion centre always produces an undistorted or very slightly distorted octahedron. Highly distorted octahedrons are found with the tellurium atom in a non-centrosymmetric point symmetry group (Table 4). According to Pearson,[34] only small deviations from ideal $m\bar{3}m$ symmetry will be allowed when the point group is of lower symmetry than $m\bar{3}m$.

The hexabromotellurate (**3**) crystallizes in the centrosymmetric space group $P2_1/c$. Only half the molecule is unique, the other half being related by an inversion centre. The tellurium atom of the $[TeBr_6]^{2-}$ anion is at the inversion centre and the $TeBr_6$ octahedron shows slight deviations from the perfect octahedral requirements, with the Br(1)—Te—Br(2) angle being 87.2(2)°. The geometry of the anion is similar to that observed in other centrosymmetric systems. In the cation, the bond parameters are similar to those observed in the hydrobromide of L′. One of the five-membered rings, i.e. the dihydrothiazole ring, adopts the half chair conformation, while the other five-membered ring, namely the thiazolidine thione ring, adopts the envelope conformation.

Te—Br(1)	2.700(1)	Br(1)—Te—Br(2)	87.2(2)
Te—Br(2)	2.708(1)	Br(1)—Te—Br(3)	89.8(3)
Te—Br(3)	2.691(1)	Br(2)—Te—Br(3)	89.9(3)

The nature of interaction of L″ *with tellurium*(IV)

Tellurites are good oxidizing agents for thiols as indicated by the E_0 values for the two redox systems:

$$RSH + 2H^+ + 2e^- \rightleftharpoons 2RSH; \quad E_0 = 0.07 - 0.03\,V$$

and

$$TeO_3^{2-} + 6H^+ + 4e^- \rightleftharpoons Te^0 + 3H_2O;$$

$$E_0 = 0.53\,V.$$

But the observed reaction is not the reduction of tellurium(IV) to tellurium(0), but the stabilization

of the intermediate and the uncommon oxidation state of +2 of tellurium by thione and bromide complexation. There are two interesting aspects which have to be highlighted. Firstly, this is the first instance in planar tellurium(II) chemistry wherein a three sulphur–one halogen coordination of ligands is reported. Secondly, $[TeL''_3Br]^+Br^-$ forms even in presence of excess ligand, L'', under these conditions formation of $[TeL''_4]^{2+}$ is to be expected. The competitive ligating abilities of thione and bromide have resulted in the formation of a complex which involves both ionic and coordinated bromide. During the reductive complexation reaction with tellurium(IV), L'' becomes oxidized. The first oxidation product should be the disulphide, as is well known in the reactions of excess thioureas and enolizable thiones with tellurium(IV) in acid medium.[40] The fate of the oxidation products of L'' in the solution phase is being investigated.

Structure of complex **4**

Selected bond lengths and angles are given in Table 5. Figure 3 shows the PLUTO plot of the molecules, while Fig. 4 shows the packing of the molecules in the unit cell.

The ligands L'' are monodentate and bonded through the sulphur atom to tellurium, with an average Te—S bond length of 2.659 Å. The tellurium atom in the +2 oxidation state, surrounded by three sulphur atoms and a bromide atom, exhibits a characteristically planar geometry.[41] The three sulphur atoms of the ligands, S(1), S(2) and S(3), and the bromine, Br(2), define an approximate plane with deviations of 0.119(5), 0.103(5), −0.149(4) and −0.124(2) Å out of this plane, respectively. The tellurium atom lies 0.05(1) Å out of this plane. The angles subtended at the central tellurium range from 81.5(4) to 94.0(1)° and their sum is 360.4(3)°. The bonding can be explained on the basis of two linear three-centre systems involving p_x and p_y orbitals of tellurium(II) with two ligand σ-orbitals.[42] The angles S(2)—Te—S(1) = 173.4(1) and Br(2)—Te—S(3) = 169.1(4)° show that the two three-centre systems are approximately linear. One of the Te—S distances, Te—S(3) = 2.575(3) Å, is shorter than the other two Te—S distances of 2.712(3) and 2.690(3) Å, probably reflecting the *trans* influence of the bromide atom on S(3). All the L'' ligands are planar and their dimensions are essentially the

Table 4. Comparison of TeX_6^{2-} octahedra

same amongst themselves and are as found in the complexes of L″ with zinc(II), nickel(II), cobalt(II) and lead(II). In the ligands the C—S and C—N bond distances show extensive delocalization in the thioamide moiety. The C—N distances involving the ethylenic carbon atoms are longer than those within the thioamide portion of the ligands. The Te—S—C angles of 99.5(3), 101.8(3) and 102.7(3)° show that the sulphur atoms are essentially sp^3 in character with the $\rangle C^+—S^-$ canonical structure dominating in the coordinated ligand. Two adjacent L″ groups are above the plane defined by tellurium, three sulphur atoms and one bromine atom, while the other L″ group is situated below this plane.

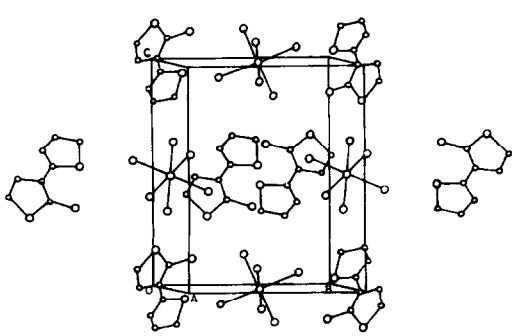

Fig. 4. Packing of the molecules in the unit cell.

Atomic coordinates, thermal parameters, full lists of bond lengths and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

COORDINATION CHEMISTRY OF CHELATING NITROGEN LIGANDS WITH TUNGSTEN CARBONYL NITRILES

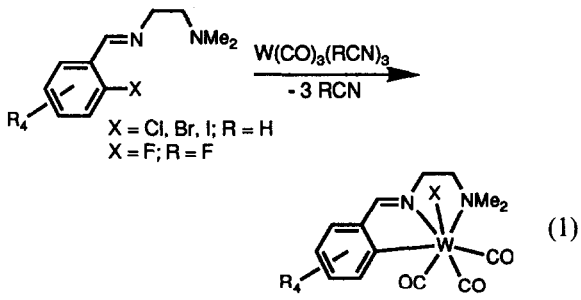
BRIAN P. BUFFIN* and THOMAS G. RICHMOND†

Department of Chemistry, University of Utah, Salt Lake City, UT 84112, U.S.A.

(*Received* 3 *June* 1990; *accepted* 2 *August* 1990)

Abstract—The reactions of a series of Schiff base ligands (**1–4**) prepared by condensation of pyridine-2-carboxaldehyde and 2-X-anilines (X = F, Cl, Br, OMe) with $W(CO)_3(RCN)_3$ results in the formation of deeply coloured complexes $W(CO)_3$(**1–4**)(NCR) which readily react with carbon monoxide to afford $W(CO)_4$(**1–4**). The ligand **5**, prepared from pyridine-2-carboxaldehyde and N,N-dimethylethylenediamine, coordinates to $W(CO)_3$ through the conjugated pyridine–imine chelate to afford complexes with a pendant dimethylamino group which reacts with electrophiles. Of the ligands studied, only the *bis*-amine, pyridine ligand **8**, coordinates to $W(CO)_3$ in a tridentate manner. These reactions provide insight into the geometric and electronic factors which influence coordination of nitrogen containing ligands at a *fac*-tricarbonyl metal centre.

Recent work from our laboratory involves the investigation of the metal carbonyl coordination chemistry of multidentate nitrogen donor ligands with pendant aryl halide groups. This research led to the discovery of chelate assisted carbon–halogen bond activation at a tungsten carbonyl metal centre, including the observation of the first well defined oxidative addition of carbon–fluorine bonds under mild conditions at a transition metal centre.[1]



(1)

Suitably designed ligands also control the regiochemistry of this process.[2]

In order more fully to understand the coordination chemistry of "hard" nitrogen based chelating ligands with tungsten carbonyl nitrile starting materials, we chose to explore the chemistry of a number of related Schiff base ligands. Since we were interested in the possibility of aryl halide coordination[3] as a possible intermediate in the aforementioned oxidative addition reactions, we have investigated the chemistry of several Schiff base ligands derived from pyridine-2-carboxaldehyde and *ortho*-substituted anilines (X = F, Cl, Br, OMe). A number of chelate stabilized complexes of aryl halides have been noted in the literature.[3,4] At very electrophilic metal centres, monodentate aryl and alkyl halides function as ligands.[5] Examples of aryl ether coordination in chelate structures have also been reported.[6] Although ligands **1–4** readily coordinate to tungsten as bidentate N-bound donors, no interactions of the pendant group X with the metal centre could be detected. Accordingly, we examined the coordinating properties of the ligand **5** derived from pyridine-2-carboxaldehyde and N,N-dimethylethylenediamine, which contains a very basic dimethylamino group and is known to coordinate in a tridentate manner to several transition metals.[7] Surprisingly, this ligand functions only as a bidentate donor. Only the reduced ligand **8** behaves as a tridentate donor in a tungsten tricarbonyl compound.

This work provides insight into the coordination chemistry of hard, nitrogen based donor ligands at

octahedral metal centres containing a *fac*-tricarbonyl moiety. This research is also relevant to the growing interest in the behaviour of classical nitrogen[8] and oxygen[9] donor ligands at low valent metal centres.

EXPERIMENTAL

All manipulations were carried out under a nitrogen atmosphere by employing standard Schlenk or glove box techniques unless stated otherwise.[10] Solvents were dried in the indicated manner and distilled prior to use: dichloromethane (P_2O_5), toluene (Na), hexanes (Na/Ph_2CO), acetonitrile (3 Å molecular sieves), $CDCl_3$ (3 Å molecular sieves), DMSO-d_6 (Na). All other reagents were obtained from commercial suppliers and used as received. A literature recipe was used to prepare $W(CO)_3(RCN)_3$ and $W(CO)_4(RCN)_2$ (R = Et, Pr).[11] Schiff base ligands were prepared by condensation of aldehyde and amine in ethanol followed by vacuum distillation, and the expected signals were observed in IR and NMR spectra. Crude **5** was reduced by treatment with excess $NaBH_4$ (4 eqn.) in refluxing methanol, followed by aqueous workup and vacuum distillation to afford **8** in 69% yield.

NMR spectra were obtained on a Varian XL-300 spectrometer. All chemical shifts are reported in δ (ppm) units with the following abbreviations: d = doublet, m = multiplet, s = singlet, and t = triplet. Proton and carbon spectra were referenced to tetramethylsilane by using solvent peaks as internal standards. Fluorine NMR chemical shifts were referenced to internal CCl_3F. Phosphorus chemical shifts were referenced to external 85% H_3PO_4. IR spectra were recorded on a BioRad model FTS-40 FTIR spectrometer operating with a resolution of either 1.0 or 2.0 cm^{-1}. Solution spectra were obtained in 0.1 mm CaF_2 cells. Thin films of liquid ligands and mineral oil mulls of solids were placed between KBr plates for spectral acquisition. Visible spectra were recorded on a Varian CARY 2200 UV–vis spectrophotometer in 1.00 cm quartz cuvettes and a 450 W low pressure mercury lamp filtered through Pyrex was employed for irradiations. Microanalyses were performed by Desert Analytics (Tucson, AZ).

$W(CO)_4$(1)

A 100 cm^3 Schlenk flask equipped with a magnetic stir bar was charged with 4.0 g (9.2 mmol) of $W(CO)_4(PrCN)_2$ and 1.8 g (9.2 mmol) of **1** and then flushed with nitrogen. Methylene chloride (30 cm^3) was added by syringe producing a deep blue–green solution almost immediately. Carbon monoxide gas was then bubbled through the solution for 15 min to afford an intense purple solution reminiscent of the aqueous permanganate ion. The solution was then filtered through a Celite plug, and hexane (30 cm^3) was layered on top of the CH_2Cl_2 solution. After allowing the solvents to diffuse for about 12 h, the methylene chloride was partially removed under reduced pressure. Isolation of the precipitated solid by filtration and washing with pentane gave 3.5 g (7.1 mmol, 77% yield) of a dark purple, air-stable, solid after vacuum drying. IR(CH_2Cl_2): ν_{CO} = 2010s, 1904vs, 1890sh, 1842s cm^{-1}. ^1H NMR ($CDCl_3$, 20°C): δ 9.143 (1H, d, 5.4 Hz), 8.684 (1H, d, 2.5 Hz, J_{W-H} = 7 Hz), 7.778 (1H, app. t, 1.5 Hz), 7.764 (1H, d, 1.1 Hz), 7.354 (1H, m), 7.263 (1H, m), 7.118 (3H, m). $^{13}C\{^1H\}$ NMR($CDCl_3$, 20°C): δ 218.49, 214.10, 197.46, 165.73, 155.19, 152.89 (d, J_{CF} = 249 Hz), 136.43, 129.28 (d, J_{C-F} = 8 Hz), 128.89, 127.21, 125.85, 124.65 (d, J_{C-F} = 4 Hz), 116.81, 116.68 (d, J_{CF} = 20 Hz). ^{19}F NMR($CDCl_3$, 20°C): δ −127.91 (m, br). λ_{max} (toluene) = 581 nm. Found: C, 38.8; H, 1.7; N, 5.5. Calc. for $C_{16}H_9FN_2O_4W$: C, 38.7; H, 1.8; N, 5.6%.

$W(CO)_3(CH_3CN)$(2)

A 100 cm^3 Schlenk flask was charged with 1.9 g (4.4 mmol) of $W(CO)_3(EtCN)_3$ and flushed with nitrogen. Acetonitrile (40 cm^3) was added by syringe to produce a brown–yellow solution which precipitated $W(CO)_3(CH_3CN)_3$ within 10 min. Addition of 0.95 g of **2b** in CH_3CN resulted in an immediate colour change to deep turquoise blue. Removal of solvent under reduced pressure followed by recrystallization from CH_2Cl_2–hexanes gave 1.4 g (2.7 mmol, 61% yield) of purple crystals. IR(CH_3CN): ν_{CO} = 1909vs, 1799s, br cm^{-1}. Found: C, 38.2; H, 2.3; N, 7.9. Calc. for $C_{17}H_{12}ClN_3O_3W$: C, 38.8; H, 2.3; N, 8.0%.

$W(CO)_4$(2)

Carbon mononoxide gas was bubbled through the blue methylene chloride solution left from the recrystallization of $W(CO)_3(CH_3CN)$(**2**). A colour change from blue to deep purple was observed. Crystallization from hexanes afforded 0.32 g (0.62 mmol) of air-stable lavender solid. Including the above product, this accounts for 75% of the W starting material. IR(CH_2Cl_2): ν_{CO} = 2010s, 1904vs, 1890sh, 1844s cm^{-1}. ^1H NMR($CDCl_3$, 20°C): δ 9.199 (1H, d, 5.4 Hz), 8.693 (1H, s, J_{W-H} = 4 Hz), 7.822 (2H, d, 4.7 Hz), 7.338 (3H, m), 7.143 (2H, m). $^{13}C\{^1H\}$ NMR($CDCl_3$, 20°C): δ 218.87, 213.99, 197.52, 165.64, 155.07, 152.97,

136.32, 133.84, 130.50, 128.86, 128.48, 127.57, 127.20, 124.63, 119.00. λ_{max} (toluene) = 580 nm. Found: C, 37.4; H, 2.0; N, 5.7. Calc. for $C_{16}H_9ClN_2O_4W$: C, 37.5; H, 1.8; N, 5.5%.

$W(CO)_4$(3)

$W(CO)_4$(**3**) was prepared in an analogous manner to the complex derived from **1** to afford a 65% yield of a dark purple air-stable solid. IR(CH_2Cl_2): ν_{CO} = 2010s, 1905vs, 1891sh, 1844s cm^{-1}. ^1H NMR($CDCl_3$, 20°C): δ 9.912 (1H, d, 5.4 Hz), 8.682 (1H, s, J_{W-H} = 6 Hz), 7.829 (2H, m), 7.556 (1H, d, 7.9 Hz), 7.311 (3H, m), 7.086 (1H, m). $^{13}C\{^1H\}$ NMR($CDCl_3$, 20°C): δ 218.85 (J_{W-C} = 18.8 Hz), 214.01, 197.64 (J_{W-C} = 11.5 Hz), 165.69, 155.03, 152.98, 150.49, 136.35, 133.63, 128.89, 128.69, 128.25, 127.23, 124.53, 114.04. λ_{max} (toluene) = 581 nm.

$W(CO)_4$(4)

$W(CO)_4$(**4**) was prepared in a similar manner to the complex derived from **1** in 73% yield as an air-stable dark purple solid. IR(CH_2Cl_2): ν_{CO} = 2008s, 1900vs, 1882sh, 1836s cm^{-1}. ^1H NMR($CDCl_3$, 20°C): δ 9.300 (1H, d, 5.9 Hz), 8.792 (1H, s, J_{W-H} = 5 Hz), 7.903 (2H, m), 7.319 (3H, m), 7.046 (2H, m), 3.870 (3H, s). $^{13}C\{^1H\}$ NMR($CDCl_3$, 20°C): δ 218.96, 214.88, 198.30, 164.90, 155.43, 152.86, 150.37, 141.20, 136.27, 128.83, 128.32, 126.75, 123.70, 120.68, 112.22, 55.76. λ_{max} (toluene) = 568 nm. Found: C, 39.9; H, 2.3; N, 5.5. Calc. for $C_{17}H_{12}N_2O_5W$: C, 40.2; H, 2.4; N, 5.5%.

$W(CO)_4$(5)

A 100 cm^3 Schlenk flask equipped with a magnetic stir bar was charged with 4.00 g (8.42 mmol) of $W(CO)_3(PrCN)_3$ and then flushed with nitrogen. Methylene chloride (30 cm^3) was added by syringe, and the resulting brown solution was degassed and flushed with nitrogen. Addition of 1.49 g (8.42 mmol) of **5** by pipette under a positive flow of nitrogen immediately produces a bright royal blue solution. Carbon monoxide was then bubbled through the solution for 15 min during which time the solution colour changed to a deep red–purple. The flask was then charged with carbon monoxide gas, sealed, and the solution stirred for 12 h to complete conversion to the tetracarbonyl compound. The solution was then filtered through a Celite plug, and hexanes (20 cm^3) were layered on top of the methylene chloride solution. After letting the solvents diffuse for 3 h, methylene chloride was partially removed under reduced pressure on a rotary evaporation apparatus. The solid formed was isolated by filtration and washed with pentane. After vacuum drying, 3.18 g (6.74 mmol, 80% yield) of an air-stable brown solid was isolated. IR (CH_2Cl_2): ν_{CO} = 2008s, 1897s, 1883sh, 1834s cm^{-1}. ^1H NMR($CDCl_3$, 20°C): δ 9.200 (1H, d, 5.9 Hz), 8.678 (1H, s), 7.890 (1H, m), 7.786 (1H, m), 7.350 (1H, m), 4.193 (2H, app. t, 5.9 Hz), 2.946 (2H, app. t, 5.9 Hz), 2.294 (6H, s). $^{13}C\{^1H\}$ NMR($CDCl_3$, 20°C): δ 216.85, 215.01, 198.33, 163.62, 155.39, 152.77, 136.49, 127.39, 126.43, 63.82, 60.18, 45.57. λ_{max} (toluene) = 538 nm. Found: C, 35.5; H, 3.1; N, 8.8. Calc. for $C_{14}H_{15}N_3O_4W$: C, 35.5; H, 3.2; N, 8.9%.

[9][BF_4]

A nitrogen atmosphere drybox was utilized to transfer 0.34 g (2.3 mmol) of trimethyloxonium tetrafluoroborate into a 100 cm^3 Schlenk flask. After removing the flask from the drybox, methylene chloride (25 cm^3) was added under a positive nitrogen flow, and the flask was cooled to −78°C. A solution of 1.0 g (2.1 mmol) of $W(CO)_4$(**5**) in 25 cm^3 CH_2Cl_2 was slowly added by syringe to the solution. Allowing the mixture to warm to room temperature and stirring for 24 h resulted in formation of a red–orange precipitate. Filtration and vacuum drying afforded 1.06 g (1.84 mmol, 88% yield) of crude solid. Crystallization with CH_3CN–Et_2O gave analytically pure red–brown crystals. IR(CH_3CN): ν_{CO} = 2013s, 1901vs, 1883sh, 1835s cm^{-1}. ^1H NMR(CD_3CN, 20°C): δ 9.122 (1H, m), 9.038 (1H, s), 8.071 (2H, m), 7.543 (1H, m), 4.543 (2H, app. t, 8.0 Hz), 3.807 (2H, app. t, 8.0 Hz), 3.214 (9H, s). $^{13}C\{^1H\}$ NMR(CD_3CN, 20°C): δ 215.93, 215.02, 199.07, 170.96, 155.54, 153.57, 139.02, 129.86, 128.78, 66.60, 59.09, 54.76. λ_{max} (CH_3CN) = 502 nm. Found: C, 31.3; H, 3.1; N, 7.3. Calc. for $C_{15}H_{18}BF_4N_3O_4W$: C, 31.3; H, 3.2; N, 7.3%.

[9][I]

No precautions were taken to exclude atmospheric oxygen or moisture in this synthesis. $W(CO)_4$(**5**) (0.20 g, 0.42 mmol) was dissolved in 5 cm^3 CH_2Cl_2, and methyl iodide (0.35 g, 2.47 mmol) was added to the solution. After 5 min an IR spectrum indicated that a reaction had occurred. Allowing the solution to stand for 15 h resulted in the formation of 0.10 g (0.16 mmol, 38% yield) of air-stable metallic grey crystals. IR(CH_3CN): ν_{CO} = 2012s, 1900vs, 1881sh, 1835s cm^{-1}. ^1H NMR(CD_3CN, 20°C): δ 9.215 (1H, s), 9.134 (1H, m), 8.076 (2H, m), 7.549 (1H, m), 4.580 (2H, app.

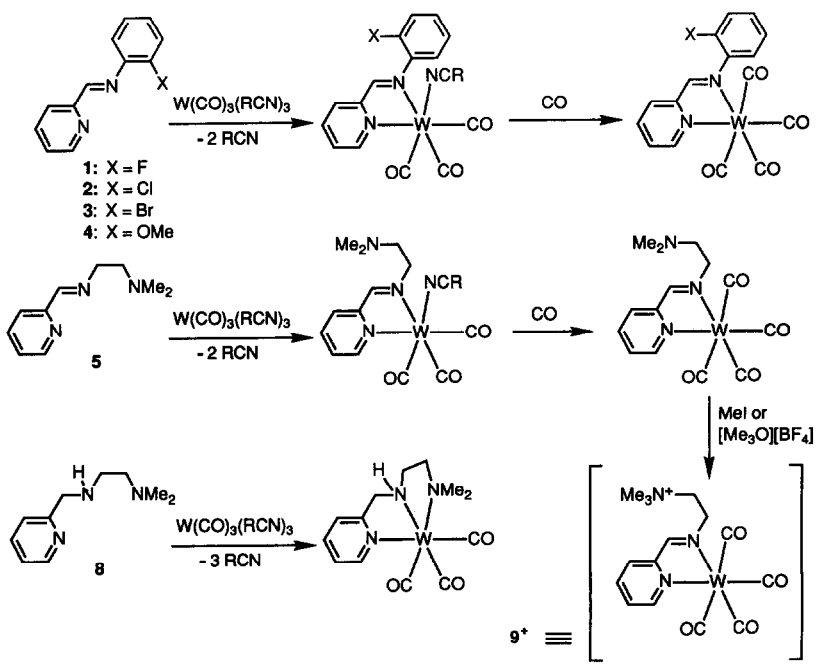
t, 8.0 Hz), 3.879 (2H, app. t, 8.0 Hz), 3.241 (9H, s). $^{13}C\{^1H\}$ NMR(CD_3CN, 20°C): δ 215.89, 215.00, 199.07, 170.90, 155.51, 153.61, 138.97, 129.86, 128.77, 66.44, 58.98, 54.86. λ_{max} (CH_3CN) = 502 nm. Found: C, 29.1; H, 2.9; N, 6.7. Calc. for $C_{15}H_{18}IN_3O_4W$: C, 29.3; H, 2.9; N, 6.8%.

$W(CO)_3$(**8**)

A 100 cm^3 Schlenk flask equipped with a magnetic stir bar was charged with 2.0 g (4.6 mmol) of $W(CO)_3(EtCN)_3$ and flushed with nitrogen. Acetonitrile (20 cm^3) was added by syringe to produce a yellow–brown solution which precipitated $W(CO)_3(CH_3CN)_3$ within 5 min. Slow addition of **8** (0.83 g, 4.6 mmol) in 20 cm^3 CH_2Cl_2 under a positive flow of nitrogen resulted in the immediate precipitation of a bright orange solid. The mixture was stirred for 12 h, at which time the precipitate was removed by filtration. Washing with methylene chloride and vacuum drying afforded 1.7 g (3.8 mmol, 82% yield) of a bright orange solid. IR (CH_3CN): ν_{CO} = 1892s, 1760s, br cm^{-1}. ^1H NMR(DMSO-d_6, 20°C): δ 8.840 (1H, m), 7.916 (1H, m), 7.530 (1H, m), 7.359 (1H, m), 6.125 (1H, br), 4.252 (2H, s), 3.105 (1H, m), 2.821 (3H, s), 2.604 (1H, m), 2.254 (1H, m), 2.147 (3H, s), 1.828 (1H, m). $^{13}C\{^1H\}$ NMR(DMSO-d_6, 20°C): δ 225.78, 225.57, 224.57, 161.58, 151.13, 137.89, 123.84, 122.06, 59.57, 59.29, 55.24, 51.21, 49.43. Found: C, 34.5; H, 3.7; N, 9.4. Calc. for $C_{13}H_{17}N_3O_3W$: C, 34.9; H, 3.8; N, 9.4%.

RESULTS

Schiff base ligands were prepared by condensation of aldehyde and amine components in ethanol and purified as oils by vacuum distillation. A deep blue solution was formed upon addition of the ligands **1**–**4** to a CH_2Cl_2 solution of $W(CO)_3(RCN)_3$ indicative[12] of coordination of the ligands as at least bidentate nitrogen donors (see Scheme 1). Of particular interest was the possibility of X-group interaction with the metal. In the case of **2**, $W(CO)_3$(MeCN)(**2**) was prepared in acetonitrile solution and characterized by elemental analysis after recrystallization from CH_2Cl_2–hexanes. That this material maintains its integrity upon recrystallization in the absence of acetonitrile is consistent with nitrile coordination to the metal centre, rather than a solvate. In addition a weak C≡N stretch assigned to coordinated acetonitrile is observed in a mineral oil mull at 2272 cm^{-1} (free CH_3CN in mineral oil absorbs at 2256 cm^{-1}). This increase in frequency is as observed for $W(CO)_{5-x}(CH_3CN)_x$ complexes.[13] A combination band,[14] arising from the symmetrical C—H deformation and the C—C stretch, at 2306 cm^{-1} (CH_3CN at 2293 cm^{-1}) is also detected. The expected two band pattern in the carbonyl region for the pseudo C_{3v}



Scheme 1.

tricarbonyl arrangement (ν_{CO} = 1909s, 1799s, br cm^{-1}) is observed.

Numerous other attempts to promote X-group coordination to the metal centre utilizing ligands **1–4** in the absence of carbon monoxide or excess RCN invariably resulted in some decomposition and eventual scavenging of carbon monoxide and formation of the tetracarbonyl products $W(CO)_4$(**1–4**). A more convenient synthesis of the tetracarbonyl complexes was effected by addition of carbon monoxide to solutions of the tricarbonyl complexes or utilizing $W(CO)_4(RCN)_2$ as a starting material. These were fully characterized by IR and NMR spectroscopic methods and elemental analysis. The deep purple colours [λ_{max} (toluene) = 568–581 nm] are consistent with literature precedent for coordination of conjugated pyridine–imine ligands.[12] Diagnostic of ligand coordination is the down field shift of the *ortho*-proton on the pyridine ring by 0.4–0.6 ppm upon coordination to the $W(CO)_4$ centre. Tungsten-183 satellites of 4–8 Hz were detected on the imine protons of the coordinated ligands.

Attempts to remove a carbonyl ligand photochemically were unsuccessful, resulting in decomposition of the complexes to colourless solutions at long irradiation times under vacuum or nitrogen purge in toluene solution. As expected,[15] carbon monoxide substitution was observed in the presence of 1 eqiv. PPh_3 to afford the green (λ_{max} = 656 nm) complex $W(CO)_3(PPh_3)$(**1**) which is characterized by its isosbestic formation from $W(CO)_4$(**1**) and its ^{31}P NMR spectra showed δ = 32.64 with $^1J_{WP}$ = 27 Hz.

Addition of ligand **5** to a CH_2Cl_2 solution of $W(CO)_3(RCN)_3$ resulted in a royal blue solution (ν_{CO} = 1904s, 1790vs, br) assigned to $W(CO)_3(RCN)_3$(**5**) as illustrated in Scheme 1. High solubility and rapid scavenging of carbon monoxide to afford the deep red–purple $W(CO)_4$(**5**) precluded isolation of $W(CO)_3(RCN)$(**5**). The structure of $W(CO)_4$(**5**) is assigned on the basis of its spectroscopic properties and elemental analysis. The down field shift of the *ortho*-proton on the pyridine of 0.58 ppm and the deep colour of the complex are indicative of bidentate ligand coordination, but tungsten satellites could not be resolved on the slightly broad imine proton.

Decomposition resulted upon attempted photochemical dissociation of carbon monoxide to generate $W(CO)_3$(**5**). Treatment of **5** with (cycloheptatriene)$W(CO)_3$ in hexanes results in an ill-defined solid which is poorly soluble in CH_2Cl_2 or CH_3CN with ν_{CO} = 1964s, 1896s, br, 1832s cm^{-1}. These bands are compatible with a dimeric or oligomeric structure or perhaps a *mer*-$W(CO)_3$(**5**) complex but are inconsistent with a *fac*-$W(CO)_3$(**5**) structure.

The chemical reactivity of the non-coordinated dimethylamino group is as expected for a free amine. Alkylating agents $[Me_3O][BF_4]$ or MeI react rapidly to afford the cationic complexes $[\mathbf{9}]^+$ in excellent and fair yields, respectively. The CO stretching frequencies increase by 4–6 cm^{-1} upon alkylation. Appropriate integration and a *ca* 1 ppm downfield shift are observed for the transformation from NMe_2 to $[NMe_3]^+$ groups. Protonation of **5** in CH_3CN with CH_3COOH, CF_3COOH, HPF_6(aq) or HCl(aq) afforded $[H(\mathbf{5})]^+$ characterized by ν_{CO} = 2012s, 1900vs, 1882sh and 1837s, and λ_{max} (CH_3CN) = 502 nm red shifted by 13 nm from **5** in CH_3CN. No attempts were made to isolate salts of $[H(\mathbf{5})]^+$.

Tridentate coordination was finally achieved utilizing the ligand **8** prepared by reduction of **5** with $NaBH_4$. Addition of **8** to a MeCN solution of $W(CO)_3(RCN)_3$ resulted in immediate precipitation of the bright orange solid $W(CO)_3$(**8**) characterized by ν_{CO} = 1892s and 1760s, br cm^{-1}, ^1H and ^{13}C NMR spectroscopic methods and elemental analysis.

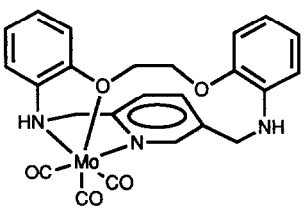
DISCUSSION

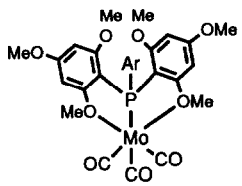
Attempts to promote coordination of weakly basic X-groups to the $W(CO)_3$ using the pyridine–imine ligand systems **1–4** proved unsuccessful although, as expected from literature precedent,[12] the ligand systems readily bind to yield $W(CO)_3$(**1–4**)(NCR) complexes. Although the remaining nitrile is quite labile with a half-life for exchange in related systems of the order of seconds at room temperature,[16] no interaction of the X-group was detected. The lability of the nitrile ligand, which is in contrast to the somewhat related phosphine based complex $W(CO)_3(NCMe)(\eta^2\text{-}Ph_2PCH_2PPh_2)$,[17] is also apparent in the facile scavenging of carbon monoxide to afford $W(CO)_4$(**1–4**). Photolysis of these complexes in toluene solution also failed to provide any evidence for X-group coordination. The expected entropic advantage for coordination of the X-group in the chelate complex does not appear to be sufficient to compete with acetonitrile as a ligand. Molecular models suggest that the ligand system is not flexible enough to enable the X-group to coordinate readily to afford a facial tridentate donor. The conjugation of the imine with the aryl ring would tend to favour planarity for the ligand system.

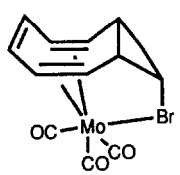
Perhaps the most surprising result of this research is the failure of the ligand **5**, which contains the flexible pendant N,N-dimethylaminoethyl group in addition to the pyridine–imine functionality, to fully chelate upon reaction with $W(CO)_3(RCN)_3$.

The deep purple colour is consistent with coordination through the pyridine–imine chelate, rather than through an amine–imine chelate. Alkylation of the free dimethylamino group provides conclusive evidence for this mode of coordination. Apparently the π-acceptor ability[12,18] of the observed chelate is dominant in determining the regiochemistry of coordination rather than the higher base strength of the potential amine–imine regioisomer. Tridentate binding is observed only in the saturated ligand system **8** which has sufficient flexibility to fully coordinate to the *fac*-$W(CO)_3$ moiety. Comparison of the ligands **5** and **8** shows that the coordinating ability of the pendant dimethylamino group relative to acetonitrile depends markedly on the geometry of the ligand system. In spite of its much higher protonic basicity, the dimethylamino group cannot compete effectively with acetonitrile as a ligand in the geometry imposed by pyridine–imine chelate. Photochemical removal of carbon monoxide from $W(CO)_4$(**5**) also did not induce the NMe_2 group to coordinate.

It is clear that in order to observe chelation of weakly basic X-groups, ligand geometry is crucial, particularly in octahedral complexes enforced by the *fac*-$W(CO)_3$ group. As illustrated by the contrasting behaviour of **5** and **8**, this is true even for quite basic ligands. Two recently reported examples[6] of chelate stabilized aryl ether coordination at $Mo(CO)_3$ provide rather diverse models for the desired interaction, as does the structure of a complex containing a bicyclic triene ligand with a pendant bromocarbon coordinated to $Mo(CO)_3$.[19]







(2)

The contrasting behaviour of these ligands emphasizes the predominance of steric over electronic factors in these systems. Only flexible ligands capable of assuming a facial arrangement are able to coordinate in a tridentate manner. The choice of starting material may also influence the success of attaining coordination of weak X-groups. Our choice of $W(CO)_3(RCN)_3$ allows for direct comparison with our previous studies, but at the expense of introducing competitive nitrile ligands which may hinder observation of halide,[20] perhaps alkoxide,[6] but probably not dimethylamino group interactions with a metal centre. Interestingly, we note that our C—X activating systems[1] are characterized by relatively rigid ligand backbones which may actually disfavour non-productive halocarbon coordination and thus promote metal insertion into C—X bonds.

THE COMPLEXES OF IRON(III) WITH D-GLUCOPYRANOSYL ESTERS OF GLYCINE

M. TONKOVIĆ, Š. HORVAT, J. HORVAT, S. MUSIĆ and O. HADŽIJA*

Ruđer Bošković Institute, 41000 Zagreb, Yugoslavia

(*Received* 5 *April* 1990; *accepted* 6 *August* 1990)

Abstract—The complexes of iron(III) with unprotected, partially protected and fully protected glycine glycosides were prepared and characterized. The dependence between the protection level of the ligands and the composition of the complexes was observed, i.e. molecular weight of the complexes decreases with increasing level of ligand protection.

In recent years, research concerning synthesis of glycopeptides has been directed towards the development of highly receptor selective and specific derivatives for clinical use. The promising results obtained by incorporation of sugar moieties into biologically active peptides[1,2] and the increasing evidence that the carbohydrate moieties in glycoproteins are involved in recognitive and other biological regulative mechanisms[3] led us to examine the chelating properties of some simple model compounds in which N-acylated or free amino acids are linked by the glycosidic ester bond to a protected or unprotected carbohydrate molecule.

Previous studies[4–6] have shown that glucopyranosyl esters of amino acids, although readily hydrolysed, may also undergo transesterification and transamination reactions through nucleophilic attack at the 1-ester carbonyl group. Since the reactions mentioned point out the enhanced electrophilic properties of the 1-ester carbonyl carbon, it seemed of interest to study the complex formation of iron with this type of ligand.

Many papers concerning formation, preparation and characterization of the complexes of iron(III) with amino acids, sugars and polysaccharides appear in the literature,[7–19] but to our knowledge, complexes with amino acid glycosides have not been described so far. Therefore, in this paper we report the preparation and physicochemical properties of such complexes and on the basis of the analytical data, the probable structures are proposed.

Methods of preparation

D-Glucopyranosyl esters of glycine (GGT, AcGGT, AcGGTBoc) have been synthesized by the procedure reported earlier.[20]

Iron(III) complexes of GGT, AcGGT and AcGGTBoc were prepared by mixing 0.1 M aqueous iron(III) nitrate with solid ligands in 1 Fe^{III}: 2 dm^3 molar ratio. The solid complexes were obtained by evaporation of these solutions *in vacuo* and dried in a desiccator over silica gel. Redissolution of the complexes in water yielded brown solutions, except the iron(III)–AcGGTBoc complex where a white precipitate was formed. The precipitate was removed by filtration and the clear solution was lyophylized.

Methods of analyses

Carbon, hydrogen, nitrogen and iron were estimated by standard microanalytical methods. IR spectra were recorded on a Perkin–Elmer spectrophotometer, model 580B. ^{57}Fe Mössbauer spectroscopy was performed using a commercial spectrophotometer (Wissenschaftliche Elektronik GmbH, F.R.G.) with a $^{57}Co/Rh$ source, and the chemical shift is given with respect to metallic iron. Thermogravimetric analyses were performed using Cahn RG electrobalance (U.S.A.). Molecular weights were determined by gel filtration on a Sephadex G-25 column (0.9 × 20 cm) in 0.01 M acetic acid by comparing the elution volumes of the complexes with those of standards: bacitracin (mol. wt 1450) and phenylazobenzyloxycarbonyl-Pro-Leu-Gly-Pro-D-Arg (mol. wt 777). Blue Dextran 2000 was used for the void volume determination. Homogeneity of the complexes was established by thin layer chromatograhy on silica gel, using visualization of spots with: 10% sulphuric acid, ninhydrin–HBr and by inspection under UV light. Paper electrophoresis was performed on Whatman No. 1 paper, at room temperature, with a voltage gradient of 30 V cm^{-1} in Tris–HCl buffer (pH 7.2). Visualization of the complex was performed by peptide reagent and a 2% solution of potassium hexacyanoferrate(II).

RESULTS AND DISCUSSION

In Table 1 the results of chemical analyses and physicochemical measurements of the complexes are presented. The complexes are amorphous and

soluble in water giving a pale brown solution. Thin layer chromatography showed the spots migrating differently from the ligands and iron(III) ion. The molecule of the complex consists of a carbohydrate moiety and the inorganic part consists of iron, nitrate and water. It is known[21] that when heated carbohydrates lose the first molecule of water at 120–190°C, the second and third ones at 165–250°C. Thermal decomposition of iron nitrate starts at 127°C. All three complexes showed by TGA a significant decomposition in the temperature range from room temperature to 342–347°C. In that range all water molecules were evaporated, including those in the carbohydrate moiety, while the decomposition of nitrate began; decarboxylation of the molecule takes place in that temperature range also. The complexes are decomposed completely at 727–811°C. From the IR spectra characteristic bands of the ligands and the complexes are summarized in Table 2. The bands at 830–840 and 390–400 cm^{-1}, which appeared only in the IR spectra of the complexes, corresponding to Fe—O, Fe—OH stretching vibrations, confirmed the existence of such complexes. The bands at about 830 cm^{-1} may be due to inorganic nitrate also.[22,23] The bands at 590–610 cm^{-1} present in the spectra of ligands and complexes, but being much stronger and of different shape in the latter, also can be attributed to the Fe—O stretching vibration. Medium intensity bands in the range 1465–1200 cm^{-1} assigned to —CCH, $—CH_2$ and —COH bending vibrations exhibit shifts to higher frequencies which can be attributed to complexation. The opposite phenomenon is observed in the range 1770–1735 cm^{-1} which is probably due to the coordination with iron. The bands at 1680–1640 and 1465–1420 cm^{-1} assigned, respectively, to the asymm (COO—) and sym (COO—) modes of carboxylate group with differences of about 200 cm^{-1}, indicate bidentate coordination via carboxylate oxygen.[12,19] All spectra of ligands and complexes exhibit bands with maxima at 3380–3480 cm^{-1} originating from O—H stretching vibration which can be ascribed to hydroxy groups of ligands and/or to adsorbed and coordinated water molecules. In the electrophoresis all three complexes moved toward the cathode indicating positive charge. Approximate molecular weight determination showed that iron(III)–AcGGT has a molecular weight >1450, and iron(III)–AcGGTBoc molecular weight between 1450–777.

On the basis of the results of elemental analyses the following formulae of the complexes can be proposed: $Fe_3OL_6(NO_3)_7(H_2O)_5$ for iron(III)–GGT; $Fe_2O_2L_4(NO_3)_2(H_2O)_{20}$ for iron(III)–AcGGT; and $FeL(NO_3)_3(H_2O)_7$ for iron(III)–AcGGTBoc.

It appears that the coordination of the carboxyl group to a trimeric iron unit (Fe_3O) is a general feature for the coordination of amino acids, namely, the coordination to an oxygen is more strongly favoured where iron(III) is involved, than the coordination to the nitrogen of the amino group.[12] The overall structure of these molecules is that of a central oxygen atom bonded to three iron atoms, which are bonded to oxygens of the carboxyl groups

of the amino acid residues. The structures of the complexes formed are consistent with a basic iron(III)–acetate structure.[27] On the basis of analytical data it seems very likely that iron(III)–GGT complex, where the ligand, having non-protected glucose, is linked glycosidically with glycine trifluoroacetate, has a structure essentially the same as described above. The trifluoroacetate of the amino acid glycoside is present as a zwitter-ion and the amino nitrogen is not involved in iron ligand bonding.

Experimental data indicate some differences in the structures of iron(III)–AcGGT and iron(III)–AcGGTBoc complexes.

Even though AcGGT has the structure very similar to GGT, i.e. zwitter-ion capable for complexation with iron(III) by the same manner, elemental analysis and molecular weight indicate the formula $Fe_2O_2L_4(NO_3)_2(H_2O)_{20}$ which presumes an oxo bridging of two irons. This presumption is supported by the IR spectrum where bands of: 835s, 610mb and 390mb cm^{-1} can be attributed to oxo bridges between two iron atoms.[28] Resembling structures are found by crystallographic studies of natural iron–protein complexes.[29–31]

The molecular weight of the iron(III)–AcGGTBoc complex indicates a monomeric structure. This structure, supported by elemental analysis, may be realized by bidentate coordination via two carbonyl oxygens forming a seven-membered ring. Four coordination sites of iron are completed with water molecules. The results of Mössbauer spectroscopy support the above presumption. The values of isomer shift, δ (0.370 mm s^{-1}), quadrupole splitting, ΔE (0.732 mm s^{-1}), and line width Γ (0.403 mm s^{-1}), show that iron is present only in the form of iron(III) and is in the octahedral position. However, a relatively high value of quadrupole splitting indicates that the octahedral structure of the Fe^{III} ion is distorted, which can be ascribed to the asymmetric position of the ligands. These results point out the enhanced electrophilic properties of the 1-ester carbonyl carbon in the fully protected ligand, and may be related to the observed susceptibility of protected β-D-glucopyranosyl esters of amino acids toward nucleophilic attack.[6] The likely structures of the complexes resulting from the above data are presented in Fig. 2, indicating that the structure differences are determined by the protection level of the ligands.

Abstract—The phosphine ligands $PhP(C_5Me_4H)_2$, **I**, and $Ph_2P(C_5Me_4H)$, **II**, can be prepared via the interaction of $PhPCl_2$ and Ph_2PCl with two and one equivalent(s) of $(C_5Me_4H)Li$, respectively. At ambient temperature, $C_7H_8Mo(CO)_4$ reacts with **I**–**II** to give the corresponding $Mo(CO)_5L$ complex, **III**–**IV** [**III**, $L = PhP(C_5Me_4H)_2$; **IV**, $L = Ph_2P(C_5Me_4H)$], in moderate yield (60–65%). In refluxing hexane, $C_7H_8Mo(CO)_4$ reacts with **II** to give $(\eta^5\text{-}C_5Me_4H)Mo(CO)(\mu\text{-}PPh_2)_2Mo[(\eta^5\text{-}C_5Me_4)P(O)Ph_2](CO)\cdot 1/4C_6H_{14}$, **V**, in low yield (10%). Structures of **IV** and **V** have been determined by X-ray crystallography.

The (diphenylphosphino)cyclopentadienyl anion, $Ph_2P(C_5H_4)^-$, has been shown to be a very versatile reagent in organometallic synthesis. Its use as a difunctional reagent to bring two hetero metal centres in close proximity has received considerable attention.[1] Although the chemistry of the anion has been investigated extensively, relatively few studies have been done on its parent compound, $Ph_2P(C_5H_5)$. Recently, we have demonstrated that coordinated $Ph_2P(C_5H_5)$ ligands in *cis*-$Mo(CO)_4[Ph_2P(C_5H_5)]_2$ underwent Diels–Alder dimerization to produce the 1,3-bis(diphenylphosphino) dicyclopentadiene ligand.[2] In this paper, we wish to report the preparation and reactivity of the tetramethylcyclopentadienyl analogues $PhP(C_5Me_4H)_2$, **I**, and $Ph_2P(C_5Me_4H)$, **II**.

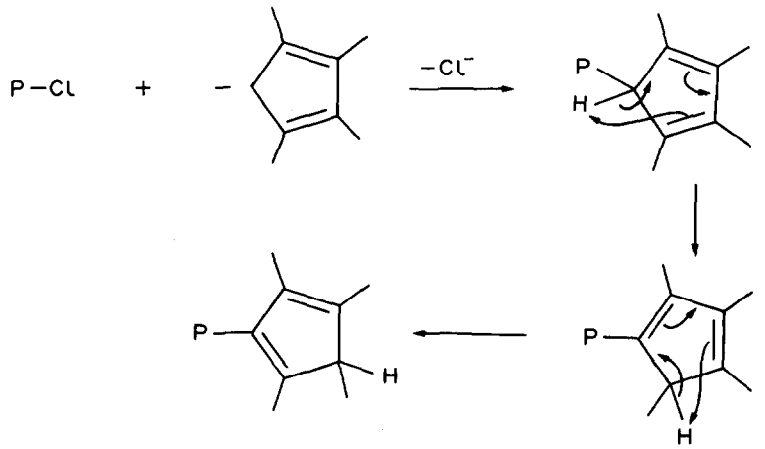
RESULTS AND DISCUSSION

Preparation of phosphine ligands

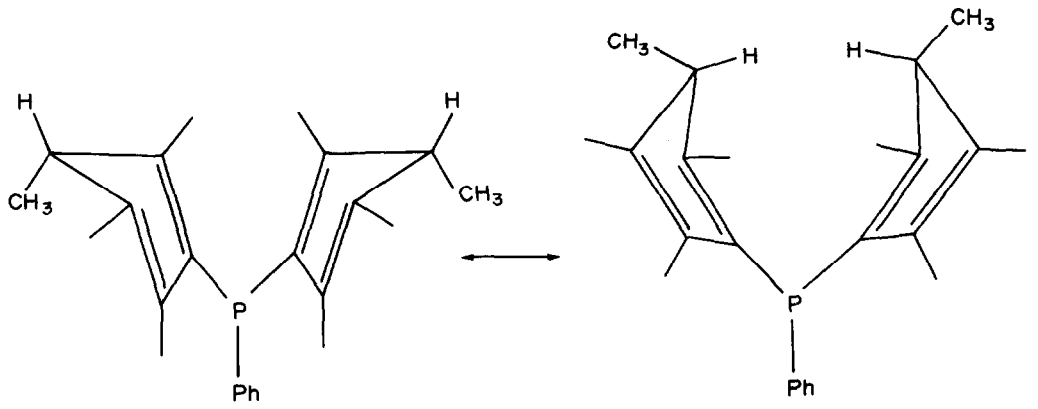
(i) $PhP(C_5Me_4H)_2$, **I**. The interaction of $PhPCl_2$ with two equivalents of $(C_5Me_4H)Li$ in hexane produced a pale orange viscous oil from which white crystalline needles, **I**, were obtained upon cooling to −20°C. The mass spectrum of the white needles shows the highest peak at *m/z* 350, corresponding to the molecular ion $M^+[PhP(C_5Me_4H)_2]^+$, and a peak at *m/z* 229 corresponding to the $[M-(C_5Me_4H)]^+$ fragment. The $^{31}P\{^1H\}$ NMR spec-



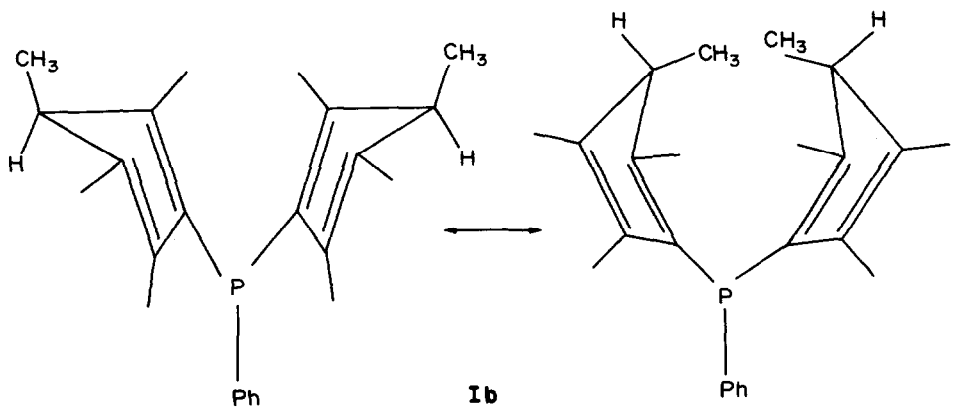
Scheme 1.

trum of **I** shows a singlet at δ 12.5 ppm. The ^{1}H NMR spectrum exhibits a multiplet of relative intensity 5, centred at δ 7.24 ppm for the phenyl protons; a broad singlet of relative intensity 2 at δ 3.92 ppm for the unique protons of the two C_5Me_4H rings; and three broad singlets of relative intensities 6:6:12 at δ 2.08, 1.75 and 1.61 ppm, respectively, for the methyl protons of the two C_5Me_4H rings. The resonance of the unique protons at δ 3.92 ppm corresponds to aliphatic rather than olefinic protons. The above spectroscopic evidence indicates that **I** is bis(2,3,4,5-tetramethylcyclopenta-1,4-dienyl)phenylphosphine which is formed via a series of proton migrations as shown in Scheme 1.

Two structures are possible for **I**. These are **Ia** and **Ib** as shown below:



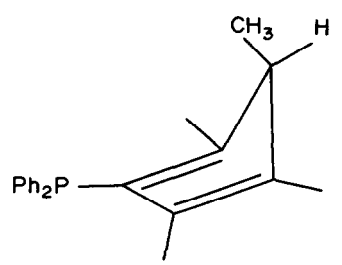
Ia



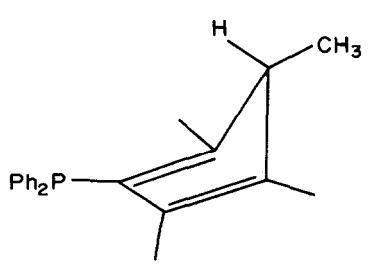
Ib

As shown in the resonance structures, steric interaction between the two C_5Me_4H rings is less in **Ia** than in **Ib**. Thus, structure **Ia** is assigned to **I**.

(ii) $Ph_2P(C_5Me_4H)$, **II**. The interaction of Ph_2PCl with one equivalent of $(C_5Me_4H)Li$ in hexane produced a thick yellow oil, **II**. The mass spectrum of **II** shows the highest peak at *m/z* 306, corresponding to the molecular ion, M^+ $[Ph_2P(C_5Me_4H)^+]$, and an intense peak at *m/z* 122, corresponding to the fragment $(C_5Me_4H_2)^+$. The $^{31}P\{^1H\}$ NMR spectrum of **II** exhibits two singlets of equal intensity at δ −24.6 and 0.8 ppm, indicating the presence of equal amounts of the two isomers of **II**. The ^1H NMR spectrum exhibits a complex multiplet of total intensity 10 centred at δ 7.27 ppm for the phenyl protons, two broad singlets of equal intensity of total intensity 1 at δ 3.69 and 2.64 ppm for the unique proton of the C_5Me_4H ring, and a set of broad singlets of total intensity 12 range δ 1.54–1.91 ppm for the methyl protons of the C_5Me_4H ring. The appearance of two resonances at δ 3.69 and 2.64 ppm for the unique proton further demonstrates the presence of two isomers of **II**. The chemical shifts of the unique protons correspond to aliphatic protons. The above spectroscopic evidence indicates that **II** is (2,3,4,5-tetramethylcyclopenta-1,4-dienyl)phosphine. Structures **IIa** and **IIb** can be assigned to the two isomers of **II** as shown below:



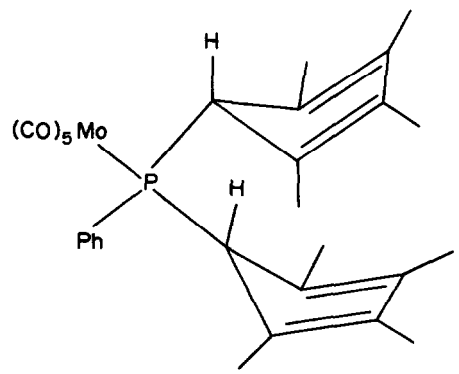
IIa



IIb

Interaction of $C_7H_8Mo(CO)_4$ *with the phosphine ligands*

(i) When $C_7H_8Mo(CO)_4$ was treated with two equivalents of $PhP(C_5Me_4H)_2$ at room temperature in hexane, white crystals of stoichiometry $Mo(CO)_5[PhP(C_5Me_4H)_2]$, **III**, were obtained in moderate yield (60%). The infrared spectrum (KBr) of **III** exhibits three absorptions at 2067s, 1979s, and 1927vs (br) cm^{-1} at the terminal carbonyl region. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at δ 40.8 ppm. The ^1H NMR spectrum exhibits two multiplets of relative 2 : 3 intensity centred at δ 7.56 and 7.28 ppm, respectively, for the phenyl protons; a doublet of relative intensity 2 centred at δ 4.18 ppm (J_{P-H} = 10.5 Hz) for the unique protons of the C_5Me_4H rings; and three broad singlets of relative intensity 6 : 12 : 6 at δ 2.17, 1.69 and 1.50 ppm, respectively, for the methyl protons of the C_5Me_4H rings. The ^1H NMR chemical shift and the splitting pattern of the unique proton of the C_5Me_4H rings of **III** is similar to that of **IV** which has been confirmed by X-ray crystallography (vide infra) to be at the carbon α to the phosphorus. Based on the above data, the following structure can be assigned to **III**.

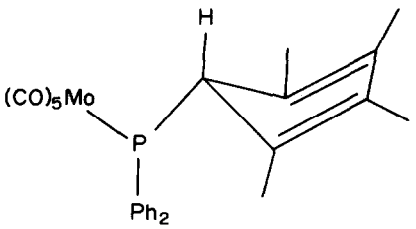


III

Compound **III** is probably formed via a series of proton migrations as shown in Scheme 1 but in the reversed direction. The formation of coordinated bis(2,3,4,5 - tetramethylcyclopenta - 2,4 - dienyl) phenylphosphine reflects that in the complexed form, the 2,3,4,5-tetramethylcyclopenta-2,4-dienyl derivative is probably less sterically hindered than the 2,3,4,5 - tetramethyl - cyclopenta - 1,4 - dienyl analogue.

(ii) When $C_7H_8Mo(CO)_4$ was treated with two equivalents of $Ph_2P(C_5Me_4H)$ at room temperature in hexane, white crystals of stoichiometry $Mo(CO)_5[Ph_2P(C_5Me_4H)]$, **IV**, were obtained in moderate yield (65%). The IR spectrum (KBr) of **IV** exhibits three absorptions at 2070s, 1983s, and 1927vs (br) cm^{-1} at the terminal carbonyl region. The $^{31}P\{^1H\}$ NMR spectrum of **IV** shows a singlet at δ 37.0 ppm. The ^1H NMR spectrum exhibits two multiplets of relative intensity 4 : 6 centred at δ 7.68 and 7.24 ppm, respectively for the phenyl protons; a doublet

of relatively intensity 1 centred at δ 4.23 ppm (J_{P-H} = 15.3 Hz) for the unique proton of the C_5Me_4H ring; and three broad singlets of relative intensity 3:3:6 at δ 1.76, 1.73 and 1.42 ppm, respectively, for the methyl protons of the C_5Me_4H ring. The ^1H NMR chemical shift and splitting pattern of the unique proton suggests that the proton is an aliphatic proton and is attached to the carbon α to the phosphorus. The above spectroscopic evidence indicates that the phosphine ligand is a (2,3,4,5-tetramethylcyclopenta - 2,4 - dienyl)diphenylphosphine ligand. Thus, the following structure can be assigned to **IV**:



IV

The structure of **IV** was confirmed by X-ray crystallography. Crystals suitable for the diffraction study were grown from hexane. The crystal data and other parameters for the X-ray structural analysis are listed in Table 1. A perspective drawing of **IV** is shown in Fig. 1. Selected bond lengths and bond angles are given in Table 2. The cyclopentadienyl group is a planar five-membered ring (within $\pm$0.006 Å). The P(1)—C(31)—C(32) angle of 111.8(4)°, together with the C—C distances of 1.52(1) Å for C(31)—C(32) and C(31)—C(35) as well as 1.35(1), 1.46(1) and 1.36(1) Å for C(32)—C(33), C(33)—C(34) and C(34)—C(35), respectively, indicate that the phosphine is indeed a (2,3,4,5-tetramethylcyclo-2,4-pentadienyl)diphenylphosphine ligand. The molybdenum atom in complex **IV** retains the octahedral coordination of its parent $Mo(CO)_6$.[3] The X-ray structural analysis showed that there are two distinctly different Mo—C distances in complex **IV**. The carbonyl is *trans* to the $Ph_2P(C_5Me_4H)$ ligand and has a Mo—$C_{ax.}$ bond of 1.989(8) Å which is significantly shorter than the Mo—C bonds involving the equatorial carbonyl groups [av. Mo—$C_{eq.}$ = 2.050(9) Å]. This structural feature has been observed in analogous complexes such as $Mo(CO)_5P(CH_2CH_2CN)_3$ and $Mo(CO)_5PPh_3$.[4] The Mo—P bond of 2.555(2) Å is comparable to that found in $Mo(CO)_5PPh_3$[4] [2.560(1) Å] but is significantly longer than those in $Mo(CO)_5P(CH_2CH_2CN)_3$[4] [2.506(1) Å] and $Mo(CO)_5[P(CH_2)_6N_3]$[5] [2.479(5) Å]. As expected, one of the

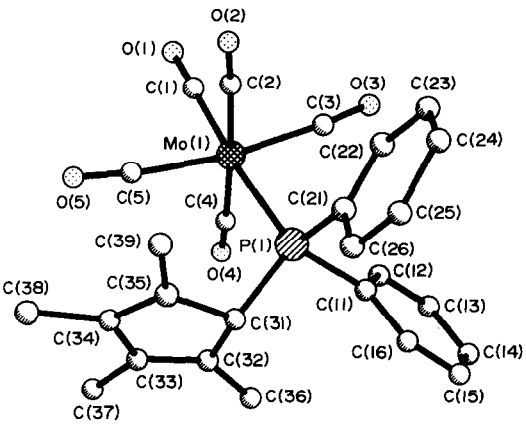


Fig. 1. A perspective view of the molecular structure of **IV**.

phenyl groups of $Ph_2P(C_5Me_4H)$ is oriented so that the P(1)—C(11) bond lies approximately over the bisector of an equatorial C—Mo—C angle to minimize the steric interactions, which can be quantitatively expressed by the torsion angles C(3)—Mo(1)—P(1)—C(11) = −43.8(4)° and C(4)—Mo(1)—P(1)—C(11) = 49.3(4)°.

(iii) When $C_7H_8Mo(CO)_4$ was treated with two equivalents of **I** in refluxed hexane for 3 days, dark red crystals of **V** were obtained in low yield (10%). The IR spectrum of **V** in KBr exhibits two absorptions at 1891s and 1820s cm^{-1} at the terminal carbonyl region. The $^{31}P\{^1H\}$ NMR spectrum of **V** exhibits two singlets of relative intensity 2:1 at δ 83.6 and 20.6 ppm, respectively. The ^1H NMR spectrum exhibits two multiplets and a broad singlet of relative intensity 4:8:18, centred at δ 7.72, 7.42 and 7.25 ppm, respectively, for the phenyl protons; a broad singlet of relative intensity 1 at δ 5.63 ppm in the olefinic region for the unique proton of the C_5Me_4H ring; and a broad singlet, two singlets, a multiplet and a singlet of relative intensity 3:3:12:3:3, centred at δ 1.91, 1.63, 1.53, 1.25 and 1.08 ppm, respectively, for the methyl protons of the C_5Me_4H rings.

The structure of **V** was determined by an X-ray diffraction study of its hexane solvate, $\mathbf{V} \cdot 1/4C_6H_{14}$. The crystal data and other parameters for the X-ray structural analysis are listed in Table 1. A perspective drawing of **V** is shown in Fig. 2. Selected bond lengths and bond angles are given in Table 3. The structure can be formulated as (η^5-C_5Me_4H)Mo(CO)(μ - PPh_2)$_2$Mo[(η^5 - C_5Me_4)P(O)Ph_2](CO) and is consistent with the spectroscopic data. Thus, the ^{31}P chemical shifts at δ 83.4 and 20.6 ppm of relative intensity 2:1 can be assigned to the two phosphido-bridged ligands and

the phosphine oxide, respectively. The dimer can be considered as a Mo^{II}—Mo^{II} compound. For the two molybdenum atoms to obey the 18-electron rule, a double bond should exist between them. This is reflected by the shorter Mo—Mo distance of 2.744(1) Å in comparison with those in the analogous P-bridged complexes $M_2(CO)_8(\mu\text{-}PEt_2)_2$[6] (M=Mo, 3.06 and M=W, 3.05) and the unbridged complex $Mo_2(CO)_6(\eta^5\text{-}C_5H_5)_2$[7] [3.235(1) Å]. The coordination polyhedron around each Mo atom can be described as a distorted tetrahedron if the metal–metal bond is neglected, which is similar to that in $Mo_2(\eta^5\text{-}C_5H_5)_2(\mu\text{-}PPh_2)_2(CO)(O)$.[8] The coordination geometries of the Mo atoms in these two complexes differ markedly in that the Cp(1)—Mo(1)—Mo(2)—Cp(2) moiety in complex **V** is approximately linear with angles of 165.8(2)° and 179.3(2)° for Cp(1)—Mo(1)—Mo(2) and Cp(2)—Mo(2)—Mo(1), respectively, but the corresponding angles in $Mo_2(\eta^5\text{-}C_5H_5)_2(\mu\text{-}PPh_2)_2(CO)(O)$ are 124.4(2)° and 148.5(2)°, respectively. The Mo_2P_2 core in **V** has the same planar

(within ± 0.082 Å from the least-squares plane) configuration as found in other analogous phosphido-bridged complexes.[6,8] The two carbonyl groups are *trans* to each other and approximately perpendicular to the Mo_2P_2 plane. Both cyclopentadienyl rings are planar conjugated groups with sp^2 hybridized C atoms and normal C—C bond lengths [av. 1.428(8) Å], which is in accord with the ^1H NMR results.

EXPERIMENTAL

Microanalyses were performed by Butterworth (U.K.). IR spectra were recorded on a Perkin–

[a] Cp(1) is the centre of the ring composed of carbon atoms C(3)—C(7), and Cp(2) is the centre of C(8)—C(12) ring.

Elmer 983 spectrometer; data given in cm^{-1} in KBr pellets. NMR spectra were recorded on a JEOL FX90Q spectrometer. Chemical shifts of ^1H NMR spectra were referenced to internal deuterated solvents and then recalculated to TMS = 0.0 ppm. ^{31}P NMR spectra were referenced to external 85% H_3PO_4. Mass spectra were obtained on a VG7070F spectrometer.

All operations were carried out under nitrogen or *in vacuo*. All chemicals used were of reagent grade. Solvents were dried by standard procedures, distilled, and deaerated prior to use. Melting points were taken in sealed capillaries and are uncorrected.

$C_5Me_4H_2$[9] and $C_7H_8Mo(CO)_4$[10] were prepared according to literature methods.

Preparation of $PhP(C_5Me_4H)_2$, **I**

A three-necked round-bottom flask (250 cm^3) fitted with a gas inlet, magnetic stirring bar and pressure-equalizing addition funnel was charged with 1,2,3,4-tetramethylcyclopentadiene (5.4 g, 44.3 mmol). Anhydrous tetrahydrofuran (100 cm^3) was syringed into the flask. The solution was then cooled to about −5°C, and *n*-BuLi (26 cm^3, 1.6 M, 41.6 mmol) was added dropwise to the solution over a period of 1 h. During the period, a white precipitate was formed. The reaction mixture was then warmed to room temperature slowly and allowed to stir overnight. The mixture was cooled to −78°C. Dichlorophenylphosphine (2.8 cm^3, 20 mmol) was then added dropwise to the solution. The white precipitate gradually disappeared and the solution changed to clear yellow. The solution was then warmed to room temperature and stirring was continued for another 2 h. The solvent was removed *in vacuo*. The residue was extracted with hexane (2 × 50 cm^3). The combined hexane filtrate was evaporated *in vacuo* to give a pale orange viscous oil from which white needles were obtained upon

cooling to −20°C. Yield (pale orange oil): 5.6 g, 80%.

^{1}H NMR ($CDCl_3$): δ 7.24 (m, 5H), 3.92 (br s, 2H), 2.08 (br s, 6H), 1.75 (br s, 6H), 1.61 (br s, 12H); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 12.5(s) IR(neat, cm^{-1}): 3053m, 2963s, 2912s, 2855s, 2738w, 1955w, 1813w, 1584w, 1544w, 1479w, 1433s, 1378s, 1326w, 1302w, 1253w, 1215m, 1183m, 1140m, 1109m, 1088m, 1068m, 1025m, 976s, 897w, 844m, 794w, 744s, 710m, 696s, 633w, 566m, 539m, 514m, 486m. MS: *m/z* 350. The purity of the pale orange oil was judged to be 95% by $^{31}P\{^1H\}$ NMR.

Preparation of $Ph_2P(C_5Me_4H)$, **II**

The procedure was the same as the preparation of **I**. $C_5Me_4H_2$ (4.1 g, 33.6 mmol), *n*-BuLi (1.6 M, 20 cm^3, 32 mmol) and Ph_2PCl (7.0 g, 31.7 mmol) were used. A pale orange oil was obtained. Yield: 8.0 g, 72%. ^{1}H NMR ($CDCl_3$): δ 7.27 (m, 1.0 H), 3.69 and 2.64 (two br s of total 1H), 1.54–1.91 (sets of s, 12H); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ −24.6 and 0.8 (two s of equal intensity). IR (neat, cm^{-1}): 3068m, 3052m, 2963s, 2916s, 2872s, 1948w, 1883w, 1808w, 1750w, 1583m, 1478m, 1431s, 1327m, 1304m, 1274w, 1216m, 1181m, 1156m, 1130m, 1093s, 1068m, 1026m, 999s, 980s, 895m, 846m, 791w, 740s, 696s. MS: *m/z* 305. The purity of the pale orange oil was judged to be 90% by $^{31}P\{^1H\}$ NMR.

Preparation of $Mo(CO)_5[PhP(C_5Me_4H)_2]$, **III**

A solution of $C_7H_8Mo(CO)_4$ (1.15 g, 3.8 mmol) in hexane (50 cm^3) was added dropwise to a solution of **I** (2.8 g, 7.9 mmol) in hexane (20 cm^3). The solution was allowed to stir at room temperature for 18 h. The solution was filtered. The filtrate was concentrated to *ca* 20 cm^3 and chromatographed on silica gel under nitrogen atmosphere using hexane as eluent. A pale yellow band was separated. The solution was concentrated to *ca* 20 cm^3 and cooled to −20°C to give white needles which were filtered and dried *in vacuo*. Yield: 1.3 g, 60%; m.p. 113–115°C [Found (required): C, 59.6(59.4); H, 5.4(5.3); P, 5.2(5.3)]. ^{1}H NMR ($CDCl_3$): δ 7.56 (m, 2H), 7.28 (m, 3H), 4.18 (d, J_{P-H} = 10.5 Hz, 2H), 2.17 (br s, 6H), 1.69 (br s, 12H), 1.50 (br s, 6H); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 40.8(s). IR in KBr, ν_{CO}: 2067s, 1979s and 1927vs (br) cm^{-1}.

Preparation of $Mo(CO)_5[Ph_2P(C_5Me_4H)]$, **IV**

A solution of $C_7H_8Mo(CO)_4$ (1.7 g, 5.7 mmol) in hexane (50 cm^3) was added dropwise to a solution of **II** (3.6 g, 11.6 mmol) in hexane (20 cm^3). The solution was allowed to stir overnight at room temperature, upon which a brown solution was obtained. The solution was filtered and the filtrate was evaporated to dryness *in vacuo*. The residue was then dissolved in a minimum amount of toluene and then chromatographed on silica gel using toluene as eluent. A brown band was collected. The solution was evaporated to dryness *in vacuo*. The residue was re-dissolved in a minimum amount of toluene and chromatographed on silica gel using hexane–toluene (10:1) mixture as eluent. A light yellow band and a crimson band were obtained. The solvent of the light yellow band was removed *in vacuo*. The residue was dissolved in a minimum amount of toluene, and hexane was added until it started to turn cloudy. At this point, a small amount of toluene was added to make the solution clear again. The resultant solution was then cooled to −20°C to give white crystals which were filtered and dried *in vacuo*. Yield: 2.0 g, 65%; m.p. 152–154°C (decomp.) [Found (required): C, 57.6(57.6); H, 4.3(4.2); P, 5.2(5.7)]. ^{1}H NMR ($CDCl_3$): δ 7.68 (m, 4H), 7.24 (m, 6H), 4.23 (d, J_{P-H} = 15.3 Hz, 1H), 1.76 (br s, 3H), 7.24 (m, 6H), 4.23 (d, J_{P-H} = 15.3 Hz, 1H), 1.76 (br s, 3H), 1.73 (br s, 3H), 1.42 (br s, 6H); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 37.0 (s). IR in KBr, ν_{CO}: 2070s, 1983s, 1927vs (br) cm^{-1}.

Attempts to isolate products from the crimson band were unsuccessful.

Preparation of **V**

A solution of $C_7H_8Mo(CO)_4$ (0.9 g, 3.0 mmol) in hexane (50 cm^3) was added dropwise to a solution of **II** (2.0 g, 6.5 mmol) in hexane (20 cm^3). The solution was refluxed for 3 days. A dark solution with dark precipitate was obtained. The solution was filtered. Attempts to isolate crystalline product from the filtrate were unsuccessful. The dark precipitate was dissolved in a minimum amount of toluene, and chromatographed on silica gel using toluene as eluent. An orange–red band was obtained. The solvent of the orange–red band was evaporated to dryness *in vacuo* to give a dark red residue. The residue was then re-dissolved in a minimum amount of methylene chloride, and hexane was added until it started to turn cloudy. At this point, a small amount of methylene chloride was added to make the solution clear again. The resultant solution was allowed to evaporate slowly in air. After two days, dark red prisms of stoichiometry $C_{56}H_{55}O_3P_3Mo_2 \cdot 1/4(C_6H_{14})$ were formed. They were filtered and dried *in vacuo*. Yield: 0.2 g, 12%; m.p. > 300°C [Found (required): C, 64.0(63.8); H, 5.7(5.4); P, 8.2(8.6)]. ^{1}H NMR ($CDCl_3$): δ 7.72 (m, 4H), 7.42 (m, 8H), 7.25 (br s, 18H), 5.63 (br s, 1H),

1.91 (br s, 3H), 1.63 (s, 3H), 1.53 (s, 12H), 1.25 (m, 3H), 1.08 (s, 3H); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 83.6 (s, 2P), 20.6 (s, 1P). IR in KBr, ν_{CO}: 1891s and 1820s cm^{-1}.

X-ray crystallography

Raw intensities collected on a Nicolet R3m/V four-circle diffractometer at room temperature (294 K) were processed with the profile-fitting procedure of Diamond[11] and corrected for absorption using ψ-scan data.[12] Details of data collection and processing for complexes **IV** and **V** are listed in Table 1.

(i) *Complex* **IV**. Patterson superposition yielded the positions of all non-hydrogen atoms which were subjected to anisotropic refinement. The hydrogen atoms were generated geometrically (C—H bonds fixed at 0.96 Å) and allowed to ride on their respective parent C atoms; all hydrogen atoms were assigned appropriate isotropic temperature factors and included in the structure-factor calculations.

(ii) *Complex* **V**. The Mo_2P_2 core was located by direct phase determination and the coordinates of the other non-hydrogen atoms were derived from successive difference Fourier syntheses. A disordered *n*-hexane solvent molecule located about a crystallographic inversion centre was found on a subsequent difference Fourier map, and interatomic distance constraints of 1.500(2) and 2.490(2) Å were applied to pairs of adjacent and alternate carbon atoms, respectively. The occupancies of these carbon atoms were fixed at 1/2 in the refinement to be compatible with reasonable values of their temperature factors. All non-hydrogen atoms were subjected to anisotropic refinement. Hydrogen atoms except those of the solvent molecule were generated geometrically (C—H bonds fixed at 0.96 Å) and allowed to ride on their respective C atoms; they were assigned appropriate isotropic temperature factors and included in the structure-factor calculations.

Computations were performed using the SHELXL-PLUS program package[13] on a DEC MicroVAX-II computer. Analytic expressions of atomic scattering factors were employed, and anomalous dispersion corrections were incorporated.[14]

(*Received* 10 *May* 1990; *accepted* 6 *August* 1990)

Abstract—Reaction of L {L = [24]aneS$_8$, [28]aneS$_8$} with two molar equivalents of $[Cu(NCMe)_4]X$ ($X^- = ClO_4^-$, BF_4^-, PF_6^-) in MeCN affords the white binuclear copper(I) complexes $[Cu_2(L)]^{2+}$. A single crystal X-ray structure determination of $[Cu_2([24]aneS_8)](BF_4)_2$ shows two tetrahedral copper(I) centres, each of which is coordinated to four thioether sulphur-donors, Cu—S(1) = 2.263(3), Cu—S(4) = 2.363(3), Cu—S(7) = 2.349(3), Cu—S(10) = 2.261(3) Å. The Cu···Cu distance is 5.172(3) Å. A single crystal X-ray structure determination of $[Cu_2([28]aneS_8)](ClO_4)_2$ shows that this complex also contains two tetrahedral copper(I) centres, each coordinated to four thioether sulphur-donors, Cu—S(1) = 2.278(5), Cu—S(4) = 2.333(5), Cu—S(8) = 2.328(5), Cu—S(11) = 2.268(5) Å. The Cu···Cu distance of 6.454(3) Å is greater than in $[Cu_2([24]aneS_8)]^{2+}$, reflecting the greater cavity size in $[Cu_2([28]aneS_8)]^{2+}$. Cyclic voltammetry of $[Cu_2([24]aneS_8)]^{2+}$ and $[Cu_2([28]aneS_8)]^{2+}$ at platinum electrodes in MeCN (0.1 M $^nBu_4NPF_6$) shows irreversible oxidations at E_{pa} = +0.88 V, +0.92 V vs Fc/Fc^+, respectively, at a scan rate of 200 mV s^{-1}. Coulometric measurements in MeCN confirm these oxidations to be two-electron (one electron per copper) processes to give binuclear copper(II) species. Oxidation of the binuclear copper(I) precursors with H_2SO_4 or HNO_3 affords ESR-active copper(II) species which presumably incorporate SO_4^{2-} and NO_3^- bridges.

The study of mono- and binuclear $Cu^{II/I}$ complexes as models for copper-containing metallo-enzymes is well established.[1] Several biological systems involve copper coordinated to sulphur,[2] and this has led several groups to investigate the incorporation of $Cu^{II/I}$ centres into thioether crowns.[3–8] Rorabacher and co-workers have reported a series of studies on the complexation of copper(II) and copper(I) by polythia macrocyclic ligands.[3,5,6] The single crystal X-ray structure of $[Cu([15]aneS_5)]^{2+}$ shows a square-based pyramidal stereochemistry, Cu—S_{eq} = 2.289(2), 2.315(2), 2.331(2), 2.338(2), Cu—S_{ap} = 2.398(2) Å with the copper atom 0.41 Å out of the basal plane.[5] Reduction of $[Cu([15]aneS_5)]^{2+}$ affords $[Cu([15]aneS_5)]^+$, in which the copper(I) centre has a distorted tetrahedral geometry in the solid state, Cu—S = 2.243(5), 2.245(5), 2.317(5), 2.338(5) Å; the fifth sulphur-donor is non-bonding and is disordered over two sites, Cu···S = 3.442(12) and 3.560(11) Å. The self-exchange electron-transfer rate constant for $[Cu([15]aneS_5)]^{2+/+}$ is very rapid ($k = 3 \times 10^4$ M^{-1} s^{-1}).[5] Cooper and co-workers have reported[7] a similar, rapid Cu—S bond cleavage on reduction of $[Cu([18]aneS_6)]^{2+}$. $[Cu([18]aneS_6)]^{2+}$ shows a tetragonally elongated octahedral stereochemistry, Cu—S = 2.323(1), 2.402(1), 2.635(1) Å. Reduction of this complex affords $[Cu([18]aneS_6)]^+$ which, like $[Cu([15]aneS_5)]^+$, shows a tetrahedral stereochemistry at the metal centre, Cu—S = 2.245(2), 2.253(2), 2.358(2), 2.360(2) Å.[7] The interconversion of $Cu^{II/I}$ centres with [15]aneS$_5$ and [18]aneS$_6$ com-

*[24]aneS$_8$: 1,4,7,10,13,16,19,22-octathiacyclotetracosane; [28]aneS$_8$: 1,4,8,11,15,18,22,25-octathiacyclooctacosane.

† Author to whom correspondence should be addressed.

plexes therefore leads to the formation and breaking of one and two Cu—S bonds, respectively.

These results suggested that tetrahedral coordination of copper(I) to thioether crowns was preferred, as would be expected for a d^{10} metal centre. We have been interested in the synthesis of binuclear copper complexes of thioether macrocycles and have reported previously the synthesis of the binuclear copper(I) species $[Cu_2(L)(NCMe)_2]^{2+}$ {L = [18]aneS$_6$,[4] Me$_2$[18]aneN$_2$S$_4$[9]}. In these systems, however, the 18-membered rings are too small and lack sufficient sulphur-donors to encapsulate two copper(I) centres tetrahedrally. As a result, a solvent MeCN molecule completes the tetrahedral coordination sphere at each copper(I) centre. We argued that larger ring S$_8$-donor crowns would be capable of encapsulating two copper(I) ions tetrahedrally to give a binuclear, homoleptic thioether product. We report herein the synthesis and single crystal X-ray structure determination of two such complexes, $[Cu_2(L)]^{2+}\cdot 2X^-$ {L = [24]aneS$_8$, $X^- = BF_4^-$; L = [28]aneS$_8$, $X^- = ClO_4^-$}.

RESULTS AND DISCUSSION

Reaction of L {L = [24]aneS$_8$, [28]aneS$_8$} with two molar equivalents of $[Cu(NCMe)_4]X$ (X^- = ClO_4^-, BF_4^-, PF_6^-), in MeCN under reflux, affords the white, binuclear copper(I) complexes $[Cu_2(L)]^{2+}\cdot 2X^-$. This assignment of the products is based on IR, NMR and FAB mass spectroscopy and elemental analysis. In order to confirm the connectivity and stereochemistry at the copper(I) centres, and also the conformation of these coordinated large-ring thia macrocycles, single crystal X-ray structure determinations were carried out. Although examples of coordination compounds with these octathia ligands have been described previously,[10,11] none has been characterized crystallographically.

A single crystal X-ray structure determination on $[Cu_2([24]aneS_8)](BF_4)_2$ confirms [Fig. 1(a) and (b)] the complex to be a genuine binuclear copper(I) complex. The two copper(I) centres are related by a crystallographic inversion centre and are each coordinated to four thioether sulphur-donors, Cu—S(1) = 2.263(3), Cu—S(4) = 2.363(3), Cu—S(7) = 2.349(3), Cu—S(10) = 2.261(3) Å. These bond lengths are comparable with Cu—S distances in related copper(I)–thioether complexes.[4-8] The Cu···Cu distance of 5.172(3) Å indicates that the two copper(I) centres are non-interacting. The angles at the copper(I) centres are distorted from those values expected for a tetrahedron, ∠S(1)CuS(4) = 94.54(10), ∠S(1)CuS(7) = 120.20(11),

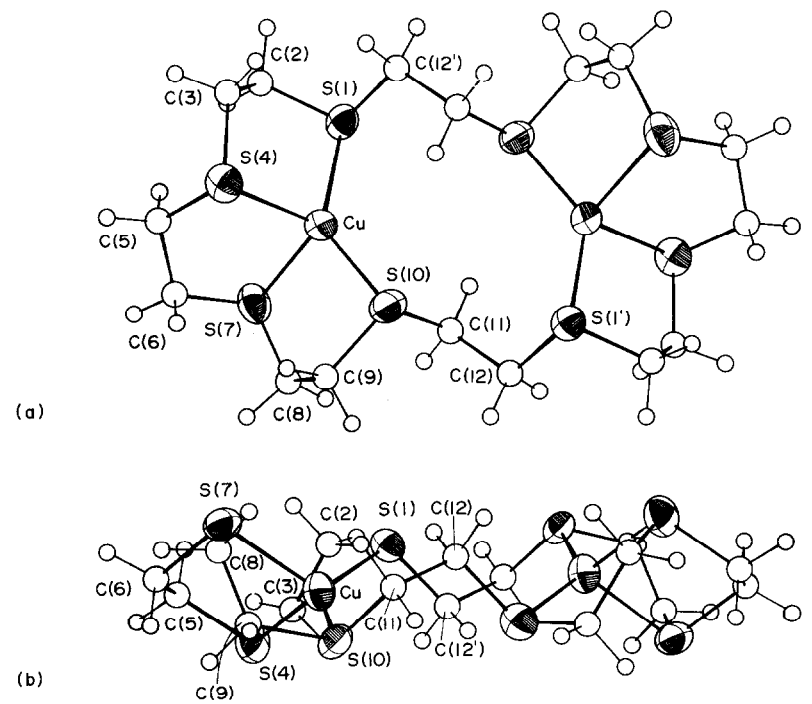

Fig. 1. (a) View of the $[Cu_2([24]aneS_8)]^{2+}$ cation with atom numbering scheme adopted; (b) Orthogonal view showing the conformation of the macrocycle.

∠S(1)CuS(10) = 133.86(11), ∠S(4)CuS(7) = 91.81(10), ∠S(4)CuS(10) = 116.39(10), ∠S(7)CuS(10) = 93.57(10)°. The structure of $[Cu_2([28]aneS_8)](ClO_4)_2$, the analogous complex with the larger, 28-membered ring macrocycle, shows similar features: a single crystal X-ray structure determination of this species [Fig. 2(a) and (b)] also shows two tetrahedral copper(I) centres each coordinated to four thioether sulphur-donors, Cu—S(1) = 2.278(5), Cu—S(4) = 2.333(5), Cu—S(8) = 2.328(5), Cu—S(11) = 2.268(5) Å, ∠S(1)CuS(4) = 93.69(19), ∠S(1)CuS(8) = 108.78(19), ∠S(1)CuS(11) = 133.39(20), ∠S(4)CuS(8) = 105.66(18), ∠S(4)CuS(11) = 119.79(19), ∠S(8)CuS(11) = 93.25(18)°. The Cu···Cu distance of 6.454(3) Å is greater than in $[Cu_2([24]aneS_8)]^{2+}$, reflecting the greater cavity size of $[28]aneS_8$.

These results confirm that the 24- and 28-membered ring ligands are large enough to encapsulate two isolated tetrahedral metal centres. Interestingly, we have found that $[24]aneS_8$ and $[28]aneS_8$ can also complex two palladium(II) ions to give the $[Pd_2(L)]^{4+}$ species.[12,13] The coordination geometry at palladium(II) in these complexes is likely to be square-planar. Thus, the binucleating octathia ligands, $[24]aneS_8$ and $[28]aneS_8$, are capable of complexing both tetrahedral *and* square-planar metal centres. This opens up the possibility of unusual redox capabilities; for example, reduction of the square-planar, binuclear platinum(II) complexes $[Pt_2(L)]^{4+}$ should afford the platinum(0) species $[Pt_2(L)]$ in which the metal centres are tetrahedral. Control of this four-electron reduction couple should lead to interesting substrate activation reactions such as O_2 reduction, although ligand oxidation reactions may be a problem in this case.

Cyclic voltammetry of $[Cu_2(L)]^{2+}$ at platinum electrodes in MeCN (0.1 M $^nBu_4NPF_6$) shows irreversible oxidations at $E_{pa} = +0.88$ V {L = $[24]aneS_8$} and $E_{pa} = +0.92$ V vs Fc/Fc^+ {L = $[28]aneS_8$}, at a scan rate of 200 mV s^{-1}. Coulometric measurements confirm these oxidations to be two-electron processes (one electron per copper) to afford green $Cu^{II/I}$ products, $\lambda_{max} = 428$ {L = $[24]aneS_8$}; 560, 406 nm {L = $[28]aneS_8$}. The fact that these oxidations are electrochemically irreversible is not surprising since the resultant copper(II) centres would be expected to tend towards octahedral or at least five coordination, and would therefore require extra ligation. We have, therefore, undertaken a preliminary study of the chemical oxidation of $[Cu_2(L)]^{2+}$ with, for example, $NOBF_4$, HNO_3 and H_2SO_4. Oxidation of the complexes affords stable, coloured paramagnetic species, the ESR spectra of which suggest that the two copper(II) centres are non-interacting.

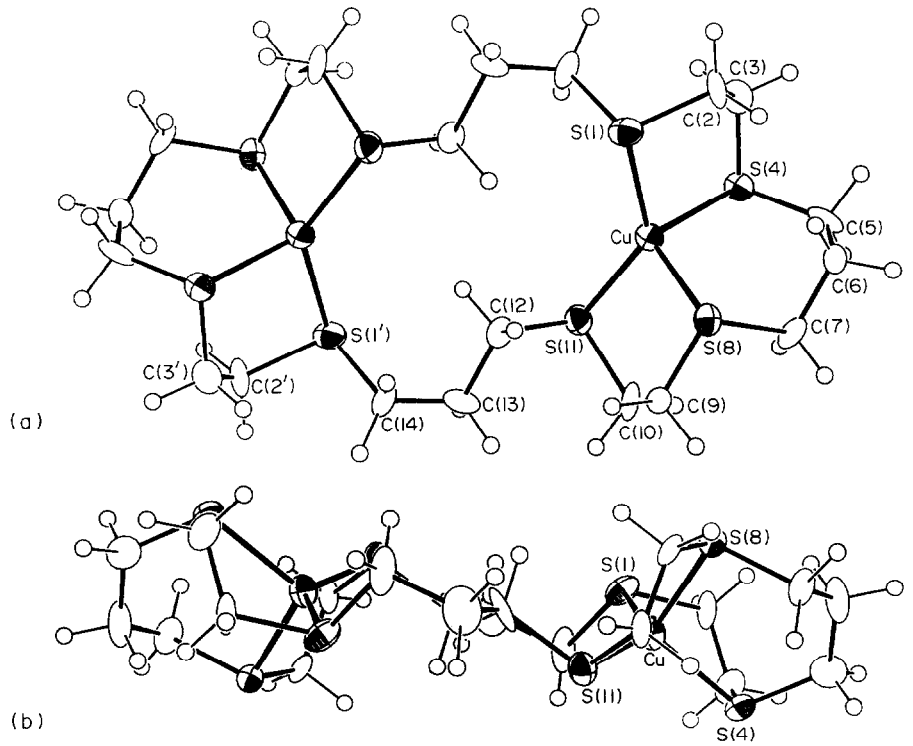

Fig. 2. (a) View of the $[Cu_2([28]aneS_8)]^{2+}$ cation with atom numbering scheme adopted; (b) Orthogonal view showing the conformation of the macrocycle.

Current work is aimed at elucidating the structures and chemistry of these binuclear copper(II) complexes, and to study the redox chemistry of the binuclear copper(I) precursors with small molecule substrates.

EXPERIMENTAL

IR spectra were measured as Nujol mulls, KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–4000 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh University Chemistry Department microanalytical service. ESR spectra were recorded as solids or as frozen glasses down to 77 K using a Bruker ER200D X-band spectrometer. ^1H and ^{13}C NMR spectra were recorded at 200.13 and 50.32 MHz, respectively, on a Bruker WP200 spectrometer. Electrochemical measurements were performed on a Bruker E310 Universal Modular Polarograph. All readings were taken using a three-electrode potentiostatic system in acetonitrile containing 0.1 M $^nBu_4NPF_6$ or $^nBu_4NBF_4$ as supporting electrolyte. Cyclic voltammetric measurements were carried out using a double platinum electrode and a Ag/AgCl reference electrode. All potentials are quoted versus ferrocene/ferrocinium, Fc/Fc^+. Mass spectra were run by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer.

Synthesis of $[Cu_2([24]aneS_8)](PF_6)_2$

To a solution of [24]aneS$_8$ (0.192 g, 0.4 mmol), dissolved in refluxing MeCN (20 cm^3), was added $[Cu(NCMe)_4]PF_6$ (0.298 g, 0.8 mmol). The solution was refluxed for 2 h, filtered and the volume reduced to 5 cm^3. Addition of Et_2O and cooling to −20°C afforded a white precipitate which was recrystallized from acetone–Et_2O to give the desired complex in 78% yield. Found: C, 21.2; H, 3.6. Calc. for $C_{16}H_{32}Cu_2S_8P_2F_{12}$: C, 21.4; H, 3.6%. IR spectrum (KBr disc): 2980, 2920, 1420, 1395, 1320, 1290, 1255, 1210, 1170, 1150, 1130, 1120, 1080, 1050, 920, 840, 740w, 680, 660w, 630w, 610w, 560 and 455 cm^{-1}. FAB mass spectrum (3-NOBA matrix): Found: $M^+ = 753$, 607. Calc. for $[^{63}Cu_2([24]aneS_8)PF_6]^+$: $M^+ = 753$; $[^{63}Cu_2([24]aneS_8)-H]^+$: $M^+ = 607$, with correct isotopic distributions. ^1H NMR spectrum (CD_3CN, 298 K, 200.13 MHz): $\delta = 2.93$–2.97 ppm (32H). ^{13}C NMR spectrum (CD_3CN, 298 K, 50.32 MHz): $\delta = 32.54$ ppm (CH_2).

The complex $[Cu_2([24]aneS_8)](BF_4)_2$ can be prepared in 72% yield by the same method by using $[Cu(NCMe)_4]BF_4$ as a starting material. Found: C, 24.7; H, 4.1. Calc. for $C_{16}H_{32}Cu_2S_8B_2F_8$: C, 24.6; H, 4.1%. IR spectrum (KBr disc): 2980, 2920, 1425, 1410, 1285, 1255, 1200w, 1170w, 1050br, 920w, 910w, 890w, 850, 820, 770, 680, 620w, 520, 455 and 415 cm^{-1}. FAB mass spectrum (3-NOBA matrix): Found $M^+ = 694$, 606. Calc. for $[^{63}Cu_2([24]aneS_8-H)BF_4]^+$: $M^+ = 694$; $[^{63}Cu_2([24]aneS_8)-2H]^+$: $M^+ = 606$, with correct isotopic distributions. ^1H NMR spectrum (CD_3CN, 298 K, 80.13 MHz): $\delta = 2.93$–2.13 ppm (32H).

Crystal structure determination of $[Cu_2([24]aneS_8)](BF_4)_2$

[1,4,7,10,13,16,19,22 - octathiacyclotetracosane - (S^1, S^4, S^7, S^{10})(S^{13}, S^{16}, S^{19}, S^{22})dicopper(I)]$^{2+}$ · $2BF_4^-$. A colourless plate, 0.85 × 0.36 × 0.035 mm, grown by diffusion of Et_2O vapour into a solution of the complex in MeCN, was mounted on a Stoë STADI-4 four-circle diffractometer.

Crystal data. $C_{16}H_{32}Cu_2S_8^{2+} \cdot 2BF_4^-$, $M = 781.5$, monoclinic, space group $P2_1/n$ (alt. $P2_1/c$, No. 14), $a = 6.480(6)$, $b = 20.040(11)$, $c = 11.327(6)$ Å, $\beta = 91.84(5)°$, $U = 1470$ Å^3 [from 2θ values of 22 reflections measured at $\pm\omega(2\theta = 24$–$26°$, $\bar{\lambda} = 0.71073$ Å), $T = 298$ K], $Z = 2$, $D_{calc} = 1.765$ g cm^{-3}, $\mu = 2.014$ mm^{-1}, $F(000) = 792$.

Data collection and processing. STADI-4 diffractometer, graphite-monochromated Mo-K_α X-radiation, $T = 298$ K, ω–2θ scans using the learnt-profile method,[14] 2231 unique data collected ($2\theta_{max}$ 45°, h $-6 \rightarrow 6$, k $0 \rightarrow 21$, l $0 \rightarrow 12$), giving 1468 with $F \geqslant 4\sigma(F)$ for use in all calculations. No significant crystal decay was observed.

Structure solution and refinement. A Patterson synthesis located the copper atom and iterative cycles of least-squares refinement and difference

Fourier synthesis located the remaining non-hydrogen atoms. At isotropic convergence, corrections (min. 0.750, max. 1.615) for absorption were applied using DIFABS.[15] Disorder in the BF_4^- counter-anion was modelled by two fully-occupied and four half-occupied fluorine atoms. Refinement (by least-squares on F[16]) with anisotropic thermal for all ordered non-hydrogen atoms and with hydrogen atoms in fixed, calculated positions converged at R, $R_w = 0.0652$, 0.0827, respectively, $S = 1.141$ for 157 refined parameters, and the final ΔF synthesis showed no feature above 0.79 e $Å^{-3}$. The weighting scheme, $w^{-1} = \sigma^2(F) + 0.000264F^2$, gave satisfactory agreement analyses and in the final cycle $(\Delta/\sigma)_{max}$ was 0.072. Bond lengths, angles and torsion angles are listed in Tables 1–3.

Synthesis of $[Cu_2([28]aneS_8)](PF_6)_2$

To a solution of [28]aneS$_8$ (0.215 g, 0.4 mmol) dissolved in refluxing MeCN (25 cm^3) was added $[Cu(NCMe)_4]PF_6$ (0.298 g, 0.8 mmol). The solution was refluxed for 2 h, filtered and the volume reduced to 5 cm^3. Addition of Et_2O and cooling to −20°C afforded a white precipitate which was recrystallized from acetone–Et_2O to give the desired complex in 82% yield. Found: C, 25.2; H, 4.2. Calc. for $C_{20}H_{40}Cu_2S_8P_2F_{12}$: C, 25.2; H, 4.3%. IR spectrum (KBr disc): 2980, 2920, 1440, 1430, 1420, 1410, 1340w, 1300, 1290, 1255, 1245, 1210w, 1140, 1130, 1020, 935, 840, 740, 660 and 555 cm^{-1}. FAB mass spectrum (3-NOBA matrix): Found: $M^+ = 809$, 663. Calc. for $[^{63}Cu_2([28]aneS_8)PF_6]^+$: $M^+ = 809$; $[^{63}Cu_2([28]aneS_8)-H]^+$: $M^+ = 663$, with correct isotopic distributions. ^{1}H NMR spectrum (CD_3CN, 298 K, 200.13 MHz): $\delta = 2.75$–3.10 ppm (28H). ^{13}C NMR spectrum (CD_3CN, 298 K, 50.32 MHz): $\delta = 33.60$, 31.50, 25.56 ppm (CH_2).

The complex $[Cu_2([28]aneS_8)](ClO_4)_2$ can be prepared in 80% yield by the same method by using $[Cu(NCMe)_4]ClO_4$ as a starting material. Found: C, 27.5; H, 4.6. Calc. for $C_{20}H_{40}Cu_2S_8Cl_2O_8$: C, 27.4; H, 4.7%. IR spectrum (KBr disc): 2960, 2920, 2850, 1440, 1405, 1340w, 1300w, 1255, 1240, 1140, 1090, 940w, 920, 910, 850, 840, 805w, 635 and 625 cm^{-1}. FAB mass spectrum (3-NOBA matrix): Found: $M^+ = 763$, 663. Calc. for $[^{63}Cu_2([28]aneS_8)^{35}ClO_4]^+$: $M^+ = 763$; $[^{63}Cu_2([28]aneS_8)-H]^+$: $M^+ = 663$, with correct isotopic distributions. ^{1}H NMR spectrum (CD_3CN, 298 K, 200.13 MHz): $\delta = 2.72$–2.97 ppm (28H). ^{13}C NMR spectrum (CD_3CN, 298 K, 50.32 MHz): $\delta = 33.14$, 31.23, 26.10 ppm (CH_2).

[a] Primed atoms are related to their unprimed equivalents by inversion through $(2-x, 1-y, 1-z)$.

Data collection and processing. STADI-4 diffractometer, graphite-monochromated Mo-K_α X-radiation, T = 173 K, ω–2θ scans using the learnt-profile method,[14] 2727 data collected ($2\theta_{max}$ 45°, h $-7\rightarrow7$, k $0\rightarrow21$, l $0\rightarrow12$), 1799 unique (R_{int} 0.071), giving 1039 reflections with $F\geqslant4\sigma(F)$ for use in all calculations. Linear isotropic crystal decay (*ca* 21%) corrected for during data reduction, no absorption correction.

Structure solution and refinement. A Patterson synthesis located the metal atom and iterative cycles of least-squares refinement and different Fourier synthesis located the remaining non-hydrogen atoms: these were then refined (by least-squares on F[16]) with anisotropic thermal parameters for all non-hydrogen atoms and with hydrogen atoms in fixed, calculated positions. At final convergence R, R_w = 0.0656, 0.0784, respectively, S = 0.947 for 182 refined parameters, and the final ΔF synthesis showed no feature above 0.74 e Å^{-3}. An isotropic extinction parameter refined to $6(4)\times10^{-8}$. The

COPPER THIOETHER CHEMISTRY: THE SYNTHESIS AND SINGLE CRYSTAL X-RAY STRUCTURES OF $[Cu_2([18]aneS_6)(NCMe)_2](ClO_4)_2$ AND $[Cu([9]aneS_3)(AsPPh_3)](ClO_4)$

ALEXANDER J. BLAKE, ROBERT O. GOULD, ALAN J. HOLDER, AIDAN J. LAVERY and MARTIN SCHRÖDER*

Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh EH9 3JJ, Scotland, U.K.

(*Received* 5 *June* 1990; *accepted* 10 *August* 1990)

Abstract—Reaction of $[18]aneS_6$ with two molar equivalents of $[Cu(NCMe)_4](ClO_4)$ in CH_2Cl_2–MeCN affords the binuclear copper(I) complex $[Cu_2([18]aneS_6)(NCMe)_2](ClO_4)_2$. The single crystal X-ray structure of the complex shows a centrosymmetric cation with two tetrahedral copper(I) centres each coordinated to three thioether S-donors of $[18]aneS_6$, Cu—S(1) = 2.3200(15), Cu—S(4) = 2.3415(16), Cu—S(7) = 2.3250(15) Å, and to one MeCN molecule, Cu—N(1) = 1.939(5) Å, to give an overall NS_3-donation at the metal centres. Additionally, S(7′) shows a long-range interaction, Cu···S(7′) = 3.318(2) Å thus distorting the coordination geometry of the metal ion towards trigonal bipyramidal. The metal–metal separation of 4.428(2) Å suggests that there is no significant interaction between the copper centres of the dimer. Reaction of $[9]aneS_3$ with one molar equivalent of $[Cu(NCMe)_4](ClO_4)$ in refluxing MeCN in the presence of ligands, L, affords the adducts $[Cu([9]aneS_3)L]^+$ (L = PPh_3, $AsPh_3$). The single crystal X-ray structure of the complex $[Cu([9]aneS_3)(AsPh_3)](ClO_4)$ shows tetrahedral AsS_3 coordination at copper(I) with $[9]aneS_3$ bound facially to the metal centre, Cu—S = 2.303(6), Cu—As = 2.322(4) Å.

The bioinorganic chemistry of copper is dominated by mono- and binuclear $Cu^{II/I}$ complexes which may model the stereochemical, electronic and redox properties of certain metalloproteins.[1] Several biological systems incorporate copper coordinated to sulphur,[2] and this has led to the study of $Cu^{II/I}$ complexes of thioether crowns, and a series of mononuclear species have now been synthesized including $[Cu([9]aneS_3)_2]^{2+}$,[3] $[Cu([9]aneS_3)I]$,[4] $[CuCl_2([12]aneS_3)_2]$,[5] $[Cu([14]aneS_4)]^+$,[6] $[Cu(OClO_3)_2([14]aneS_4)]$,[7] $[Cu([15]aneS_5)]^{2+/+}$[8] and $[Cu([18]aneS_6)]^{2+/+}$.[9] More recently, $Cu^{II/I}$ complexes of thiophene-containing crowns have also been reported.[10] However, few examples of binuclear copper complexes of thioether macrocycles have been described. The minicycle $[9]aneS_3$ has been shown by Cooper and co-workers to form the binuclear copper(I) species $[Cu_2([9]aneS_3)_3]^{2+}$ which incorporates one bridging and two facially bound trithia ligands.[11] Similarly, $[16]aneS_4$ has been found to bridge $CuCl_2$ fragments in $[Cu_2Cl_4([16]aneS_4)]$,[12] and more recently we have established that the larger ring octathia crowns $[24]aneS_8$ and $[28]aneS_8$ can fully encapsulate two copper(I) centres in a tetrahedral manner.[13] However, the intermediate ring $[18]aneS_6$, the sulphur analogue of 18-crown-6 ($[18]aneO_6$), is too small and lacks sufficient S-donors to fully encapsulate two copper(I) centres in the same way. Although a series of mononuclear transition metal complexes of $[18]aneS_6$ have been reported,[16] we thought it possible that $[18]aneS_6$ could still act as a binucleating ligand to copper(I) centres if external ligation were available. We report herein the synthesis and structure of the binuclear copper(I) complex $[Cu_2([18]aneS_6)(NCMe)_2]^{2+}$[14] and the related monomeric fragments $[Cu([9]aneS_3)(L)]^+$ (L = NCMe, PPh_3, $AsPh_3$).[15]

RESULTS AND DISCUSSION

Addition of two molar equivalents of $[Cu(NCMe)_4](ClO_4)$ to a solution of $[18]aneS_6$ in CH_2Cl_2–MeCN, followed by warming the solution to 35°C for 0.5 h under N_2 affords a pale yellow solution. Addition of $NaClO_4$ to the cooled solution gives the binuclear copper(I) complex $[Cu_2([18]aneS_6)(NCMe)_2](ClO_4)_2$. If the metal insertion is carried out under more vigorous conditions, the mononuclear species $[Cu([18]aneS_6)]^+$ is isolated.[9] $[Cu_2([18]aneS_6)(NCMe)_2](ClO_4)_2$ can be recrystallized from MeCN to afford pale brown crystals of the complex. $[Cu_2([18]aneS_6)(NCMe)_2](ClO_4)_2$ crystallizes with imposed $C_i(\bar{1})$ symmetry. A single crystal X-ray structure determination of the complex shows (Fig. 1) a centrosymmetric cation with two identically bound copper(I) centres. Each copper(I) is coordinated to three thioether S-donors of $[18]aneS_6$, Cu—S(1) = 2.3200(15), Cu—S(4) = 2.3415(16), Cu—S(7) = 2.3250(15) Å, and to one MeCN molecule, Cu—N(1) = 1.939(5) Å, to give overall NS_3-donation at the tetrahedral metal centres, ∠S(1)CuS(4) = 92.05(5), ∠S(1)CuS(7) = 114.69(5), ∠S(1)CuN(1) = 120.55(14), ∠S(4)CuS(7) = 91.59(5), ∠S(4)CuN(1) = 122.85(14), ∠S(7)CuN(1) = 110.89(14)°. S(7′) shows a long-range interaction to the copper centre, Cu···S(7′) = 3.318(2) Å, thus distorting the coordination geometry of the metal ion towards trigonal bipyramidal. The Cu···Cu separation of 4.428(2) Å suggests that there is no significant interaction between these centres, although S(7) and S(7′), which are separated by nine bonds within the coordinated macrocycle, approach one another to a distance of 3.635(3) Å. The S-atoms of the hexathia ring adopt a chair-like conformation with the S-donors coordinated to copper forming a plane 0.98 Å from the plane of the S-donors coordinated to copper; each copper(I) centre lies 1.08 Å above its coordinated S_3-plane.

$[Cu_2([18]aneS_6)(NCMe)_2](ClO_4)_2$ is the first example of a binuclear copper complex with $[18]aneS_6$, although several binuclear organometallic species such as $[Rh_2(C_5Me_5)_2Cl_2([18]aneS_6)]^{2+}$ and $[M_2(arene)_2Cl_2([18]aneS_6)]^{2+}$ (M = Ru, Os) in which the hexathia ligand is bound in an *exo*, bidentate manner to each metal fragment have been reported.[16,17] Similar *exo* coordination has been proposed in a series of binuclear molybdenum carbonyl complexes.[18] Solutions of $[Cu_2([18]aneS_6)(NCMe)_2]^{2+}$ in MeCN and $MeNO_2$ are stable to the atmosphere, reflecting the stabilization of copper(I) afforded by the NS_3-donor set. However, in dmf or on addition of N-donor ligands such as py, oxidation of the complex occurs to afford intractable copper(II) materials.

The above results confirm the preferred tetrahedral coordination for copper(I) thioether complexes and suggested that related tetrahedral species $[Cu([9]aneS_3)(L)]^+$ (L = PR_3, AsR_3) should be isolable.[14,19] Reaction of $[9]aneS_3$ with one molar equivalent of $[Cu(NCMe)_4](ClO_4)$ in refluxing MeCN affords a colourless solution of $[Cu([9]aneS_3)(NCMe)]^+$. $[Cu([9]aneS_3)(NCMe)]^+$ does not appear to react with CO in MeCN, while reaction with py and PEt_3 affords ill-defined air-sensitive products.[4] However, reaction with ligands, L, in warm MeCN affords the adducts $[Cu([9]aneS_3)L]^+$ (L = PPh_3, $AsPh_3$). The single crystal X-ray structure of $[Cu([9]aneS_3)(AsPh_3)](ClO_4)$ shows (Fig. 2) the cation located on a crystallographic three-fold axis with imposed C_3 symmetry. Distorted tetrahedral AsS_3 coordination is observed at the copper(I) with $[9]aneS_3$ bound facially to the metal centre, Cu—S = 2.303(6), Cu—As = 2.322(4) Å. Coordination of $[9]aneS_3$ to tetrahedral metal centres is rare,[4,11,20] with the ∠SCuS angle of 94.5(2)° being substantially reduced from the values

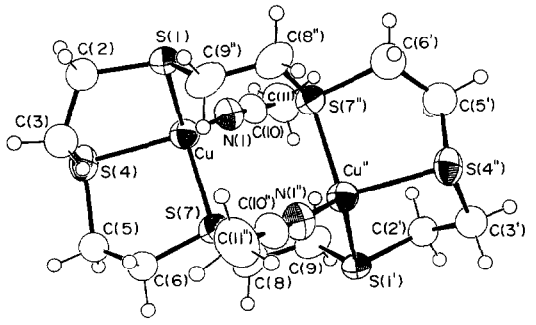

Fig. 1. Structure of $[Cu_2([18]aneS_6)(NCMe)_2]^{2+}$ with numbering scheme adopted. Left side shows major conformation, right side minor conformation.

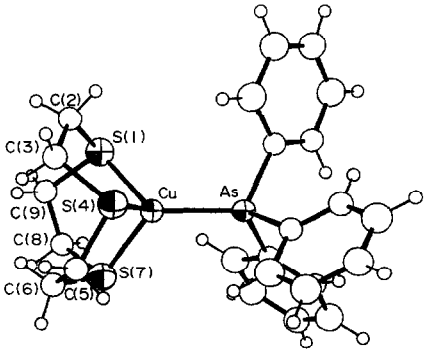

Fig. 2. Structure of $[Cu([9]aneS_3)(AsPh_3)]^+$ with numbering scheme adopted.

expected for a tetrahedral metal centre; this reflects the small bite of facially coordinated [9]aneS$_3$, $\angle$SCuAs = 122.0(2)°. During the course of this work,[15] Wieghardt and co-workers reported the synthesis of [Cu([9]aneS$_3$)I] directly from CuI and [9]aneS$_3$.[4] The structure of [Cu([9]aneS$_3$)I] shows tetrahedral copper(I), Cu—S = 2.329(1), 2.331(1), 2.343(1) Å, Cu—I = 2.490(1) Å, $\angle$S(1)CuS(2) = 92.6(1), $\angle$S(1)CuS(3) = 93.1(1), $\angle$S(2)CuS(3) = 93.9(1), $\angle$S(1)CuI = 128.6(1), $\angle$S(2)CuI = 121.3(1), $\angle$S(3)CuI = 118.7(1).[4] These structural features are therefore quite similar to those of [Cu([9]aneS$_3$)(AsPh$_3$)]$^+$.

We are currently investigating the oxidative chemistry of [Cu$_2$([18]aneS$_6$)(NCMe)$_2$]$^{2+}$ and related binuclear copper(I) thioether complexes such as [Cu$_2$(L)]$^{2+}$ (L = [24]aneS$_8$, [28]aneS$_8$), and of the mononuclear species of type [Cu([9]aneS$_3$)L]$^+$ in the presence of small molecule substrates.

EXPERIMENTAL

IR spectra were measured as Nujol mulls, KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–400 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh University Chemistry Department microanalytical service. Mass spectra were run by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer. ^{1}H NMR spectra were recorded at 80 MHz on a Bruker WP80 spectrometer.

Synthesis of [Cu([18]aneS$_6$)(NCMe)$_2$](ClO$_4$)$_2$

[Cu(NCMe)$_4$](ClO$_4$) (0.09 g, 2.78×10^{-4} mol) was added to a solution of [18]aneS$_6$ (0.05 g, 1.38×10^{-4} mol) in CH$_2$Cl$_2$–MeCN (20 cm^3, 1:1 v/v) under N$_2$. The reaction mixture was warmed gently for 0.5 h to afford a pale yellow solution. Addition of NaClO$_4$ to the cooled solution gave a pale yellow product which was recrystallized from MeCN to give [Cu$_2$([18]aneS$_6$)(NCMe)$_2$](ClO$_4$)$_2$ in up to 50% yield. Found: C, 24.9; H, 3.8; N, 3.8. Calc. for [Cu$_2$([18]aneS$_6$)(NCMe)$_2$](ClO$_4$)$_2$: C, 25.0; H, 3.9; N, 3.6%.

X-ray structure determination of [Cu$_2$([18]aneS$_6$)(NCMe)$_2$](ClO$_4$)$_2$

A colourless crystal (0.75 × 0.5 × 0.2 mm) suitable for X-ray analysis was obtained from MeCN solution.

Crystal data. $C_{16}H_{30}Cu_2N_2S_6^{2+}2ClO_4^-$, M = 768.7, triclinic, space group $P\bar{1}$, a = 9.184(6), b = 9.317(3), c = 9.598(7) Å, α = 81.18(4), β = 73.07(6), γ = 67.93(3)°, V = 727.2 Å^3, D_c = 1.76 g cm^{-3} [from setting angles of 12 reflections (2θ = 16–22°, $\bar{\lambda}$ = 0.71073 Å)], Z = 1; F(000) = 392, $\bar{\lambda}$(Mo-K_α) = 0.71073 Å, μ = 2.11 cm^{-1}.

Data collection and processing. Enraf–Nonius CAD4 four-circle diffractometer, ω–2θ scans, 2539 reflections measured to 2θ = 50°, giving 1926 with $F \geqslant 6\sigma(F)$. No significant crystal decay.

Strucure analysis and refinement. The copper atoms were located using a Patterson synthesis, and application of DIRDIF[21] gave positions for all other non-hydrogen atoms, showing the cation to contain two copper atoms bonded to one macrocycle arranged about a centre of symmetry. On refinement,[22] unrealistic bond lengths, angles and high thermal parameters indicated significant disorder at C(2), C(3), C(5) and C(6). This was resolved into two alternative conformations which refined eventually to site occupancies of 0.55 and 0.45. Hydrogen atoms bonded to all carbon atoms were included in calculated positions and not refined. The ClO$_4^-$ ion is disordered mainly about a molecular three-fold axis. After absorption corrections using DIFABS[23] (maximum correction 20%), anisotropic thermal parameters were refined for all non-hydrogen atoms except the disordered methylene region. In the final cycles, the extensively correlated positional and thermal parameters for the ClO$_4^-$ ion were held constant. At convergence, R and R_w = 0.044 and 0.056, respectively, for 128 parameters, giving a maximum Δ/σ of 0.2. A final difference synthesis showed no peaks or troughs greater than ±0.8 eÅ^{-3}. Bond lengths, angles and torsion angles are given in Table 1.

Synthesis of [Cu([9]aneS$_3$)(PPh$_3$)](ClO$_4$)

Reaction of [Cu(NCMe)$_4$](ClO$_4$) (0.23 g, 7.03×10^{-4} mol) with [9]aneS$_3$ (0.13 g, 7.22×10^{-4} mol), in refluxing MeCN (30 cm^3) under N$_2$, affords a yellow solution which after 1 h turns colourless. PPh$_3$ (0.21 g, 8.1×10^{-4} mol) in MeCN (5 cm^3) was added and the reaction mixture warmed to 40°C for 0.5 h. On cooling a white product crystallized from solution. The complex was recrystallized from MeNO$_2$ (5 cm^3) to give [Cu([9]aneS$_3$)(PPh$_3$)](ClO$_4$) in 70% yield. Found: C, 46.9; H, 4.4. Calc. for [Cu([9]aneS$_3$)(PPh$_3$)](ClO$_4$): C, 47.6; H, 4.5%. IR spectrum (KBr disc): 3040, 1478, 1437, 1404, 1328, 1303, 1279, 815, 748, 709, 695, 620, 529, 502 and 440 cm^{-1}. ^{1}H NMR spectrum (80 MHz, CD$_3$NO$_2$, 298 K): δ = 7.5 (m, 15H, PPh$_3$), 3.06 pm (m, CH_2, 12H).

$\bar{\lambda} = 0.71073$ Å, $T = 295$ K), $Z = 12$, $D_c = 1.870$ g cm^{-3}, $\mu = 2.53$ mm^{-1}, $F(000) = 2274$.

Data collection and processing. Stoë STADI-4 diffractometer, graphite-monochromated Mo-K_α X-radiation, $T = 295$ K, ω–2θ scans using the learnt profile method,[24] 3424 unique reflections ($2\theta_{max}$ 45°, h −9 to 10, k 0 to 11, l 0 to 40) collected, assuming space group $P\bar{3}$, giving 1137 with $F \geqslant 6\sigma(F)$. No significant crystal decay or movement was apparent. All significant data had $(-h + k + l) = 3n$ or $(h - k + l) = 3n$ and the data were analysed as those for a rhombohedral twin. The 1721 data meeting one of these conditions included 673 from the obverse twin, 655 from the reverse twin, 33 common to both with the same indices ($l = 0$ or $h = k = 0$) and 360 ($l = 3n$) containing symmetry-independent contributions from the two twins. Scaling difficulties made it impossible to use the third and fourth classes of data. The first two classes were scaled together after altering the indices for the reverse twin to those for the corresponding obverse axes (hkl to $-h-kl$), and gave a total of 716 data with a merging R of 0.054: of these, 416 with $F \geqslant 6\sigma(F)$ were used to solve and refine the structure.

Structure solution and refinement. The copper and arsenic atoms were located from a Patterson function and subsequent difference maps located all other non-hydrogen atoms of the cation, which is essentially ordered with imposed 3 (C_3) symmetry. The two independent perchlorate ions have imposed $\bar{3}$ (S_6) symmetry. The oxygen atoms are extensively disordered, but refined reasonably well with a single atom for each group in a general position with a site occupancy of 2/3. The non-hydrogen atoms of the cation were then refined anisotropically; hydrogen atoms were refined in fixed, idealized positions with C—H = 1.08 Å, tetrahedral or trigonal geometry as appropriate, and fixed temperature factors of $U_{iso} = 0.05$ Å^2 in the phenyl ring and 0.10 Å^2 in the macrocycle.[22] At final convergence R and $R_w = 0.052$ and 0.064, respectively, $S = 1.06$ for 116 refined parameters: in the final ΔF synthesis the maximum residuals were ± 0.80 eÅ^{-3} near the heavy atoms or perchlorate ions and ± 0.25 eÅ^{-3} elsewhere. No extinction or absorption corrections were made. The weighting scheme $w^{-1} = \sigma^2(F) + 0.0017F^2$ gave satisfactory agreement analyses and in the final cycle $(\Delta/\sigma)_{max}$ was 0.05. Bond lengths, angles and torsion angles are given in Table 2.

Atomic scattering factors were inlaid[22] or taken from ref. 25, molecular geometry calculations utilized CALC[26] and the figures were produced by ORTEPII.[27]

(*Received* 27 *April* 1990; *accepted* 29 *August* 1990)

Abstract—Reaction of $[Rh(H_2O)_6]^{3+}$ with one molar equivalent of [18]aneN$_2$S$_4$ in refluxing MeOH–H_2O (1:1 v/v) for 12 h affords an orange solution from which the complex $[Rh([18]aneN_2S_4)](PF_6)_3$ can be isolated upon addition of NH_4PF_6. A single crystal X-ray structure determination shows a distorted octahedral geometry at rhodium(III) involving the four thioether and two aza-donors of the macrocycle. The complex cation adopts a *rac*-configuration via meridional coordination of the two $SCH_2CH_2NCH_2CH_2S$ linkages.

We have been investigating the synthesis, structures and redox properties of transition metal complexes incorporating polythia and polyaza macrocyclic ligands.[1] Recently, we have extended our interests to the coordination chemistry of the potentially hexadentate macrocycles [18]aneN$_2$S$_4$ and Me$_2$[18]aneN$_2$S$_4$.[2] In their original report on the synthesis of [18]aneN$_2$S$_4$, Black and McLean proposed that this macrocycle would coordinate to first row transition metal ions to give octahedral complexes with the *rac*-configuration (Fig. 1):[3] our studies have confirmed this suggestion.[2,4] These results contrast with those obtained for the hexathia analogue, [18]aneS$_6$, which coordinates octahedrally to a range of transition metal ions to give the *meso*-configuration exclusively.[5] Importantly, we have also shown that substitution of N—H for N—Me in these macrocycles results in dramatic changes to the stereochemical and electrochemical properties of their copper(II) and palladium(II) complexes: [18]aneN$_2$S$_4$ facilitates generation of a mononuclear palladium(III)—N$_2$S$_4$ ionophore, while Me$_2$[18]aneN$_2$S$_4$ stabilizes palladium(I).[2] We wished to extend this study to the binding of [18]aneN$_2$S$_4$ to rhodium(III) centres, and we report herein the synthesis and single crystal X-ray structure of $[Rh([18]aneN_2S_4)](PF_6)_3 \cdot 3H_2O$. The related octahedral macrocyclic rhodium(III) complex $[Rh([9]aneS_3)_2]^{3+}$ and its reduction to unusual mononuclear rhodium(II) and rhodium(I) species has been described.[6]

RESULTS AND DISCUSSION

Treatment of $[Rh(H_2O)_6]^{3+}$ with one molar equivalent of [18]aneN$_2$S$_4$ in refluxing MeOH–H_2O for *ca* 12 h affords a bright orange solution containing the complex cation $[Rh([18]aneN_2S_4)]^{3+}$. Addition of excess NH_4PF_6 yields the complex as an orange precipitate which can be recrystallized from H_2O. The IR spectrum of the complex shows N—H stretching vibrations, ν(N—H), at 3240 and 3080 cm^{-1}, as well as other bands characteristic of coordinated [18]aneN$_2$S$_4$ and PF_6^- counterions. The FAB mass spectrum exhibits molecular ion peaks at $M^+ = 719$, 573 and 427: these are assigned to $[^{103}Rh([18]aneN_2S_4)(PF_6)_2]^+$, $[^{103}Rh([18]aneN_2S_4\text{-}H)PF_6]^+$ and $[^{103}Rh([18]aneN_2S_4\text{-}2H)]^+$, respectively. This evidence, together with microanalytical data, confirms the formulation $[Rh([18]aneN_2S_4)](PF_6)_3$ for the product. The complex can also be isolated as the BPh_4^- salt by using $NaBPh_4$ in place of NH_4PF_6 in the above preparation. The ^{1}H NMR spectrum of $[Rh([18]aneN_2S_4)](BPh_4)_3$ confirms a ratio of three BPh_4^- counterions to one [18]aneN$_2$S$_4$ macrocycle.

Single crystals of $[Rh([18]aneN_2S_4)](PF_6)_3 \cdot 3H_2O$ suitable for X-ray analysis were obtained by slow concentration of an aqueous solution of the complex. The structure of $[Rh([18]aneN_2S_4)]^{3+}$ shows (Fig. 2) the d^6 rhodium(III) ion coordinated by all six donor atoms of the macrocycle, with the N-donors occupying mutually *trans* positions. The observed bond lengths [Rh—S(1) = 2.3289(14), Rh—S(4) = 2.3416(14), Rh—S(10) = 2.3353(14), Rh—S(13) = 2.3349(14), Rh—N(7) = 2.083(4), Rh—N(16) = 2.101(5) Å] are similar to those in the related macrocyclic complexes $[Rh([9]aneS_3)_2]^{3+}$ [Rh—S = 2.3316(14), 2.3335(12), 2.3335(12) Å][6] and $[Rh([9]aneN_3)_2]^{3+}$ [Rh—N = 2.065(19), 2.073(21), 2.058(18) Å].[7] Consistent with other structurally characterized octahedral transition metal complexes $[M([18]aneN_2S_4)]^{x+}$ ($M = Ag^I$, $x = 1$; $M = Ni^{II}$, Fe^{II}, Hg^{II}, $x = 2$; $M = Co^{III}$, $x = 3$),[4] $[Rh([18]aneN_2S_4)]^{3+}$ adopts a *rac*-configuration involving meridional coordination of the two $SCH_2CH_2NCH_2CH_2S$ linkages to the central rhodium(III) ion. Angles around the rhodium(III) ion deviate considerably from ideal octahedral values and there is a significant tetrahedral distortion of the thioether-donor atoms out of the least-squares S_4 coordination plane, with S(4) and S(10) both lying 0.175 Å above this plane, and S(1) and S(13) lying 0.174 and 0.176 Å below. This tetrahedral distortion is likely to originate from the restricted bite angle of the $SCH_2CH_2NCH_2CH_2S$ chains of the macrocycle. The magnitude of this distortion in $[Rh([18]aneN_2S_4)]^{3+}$ is less than in $[Ag([18]aneN_2S_4)]^+$, consistent with the smaller ionic radius of rhodium(III) (66.5 pm) compared with silver(I) (115 pm).[8] To our knowledge, $[Rh([18]aneN_2S_4)]^{3+}$ represents the first characterized complex involving encapsulation of rhodium(III) by an 18-membered ring macrocyclic ligand.

The $[Rh([18]aneN_2S_4)]^{3+}$ cation participates in significant hydrogen-bonding through the N—H functions of the macrocycle, H_2O solvent molecules and fluorine atoms of the PF_6^- counterions: H(7)···O(1S) = 1.888(7) Å, angle N(7)—(H7)···O(1S) = 166.9(5)°; H(16)···O(2S) = 1.726(8)

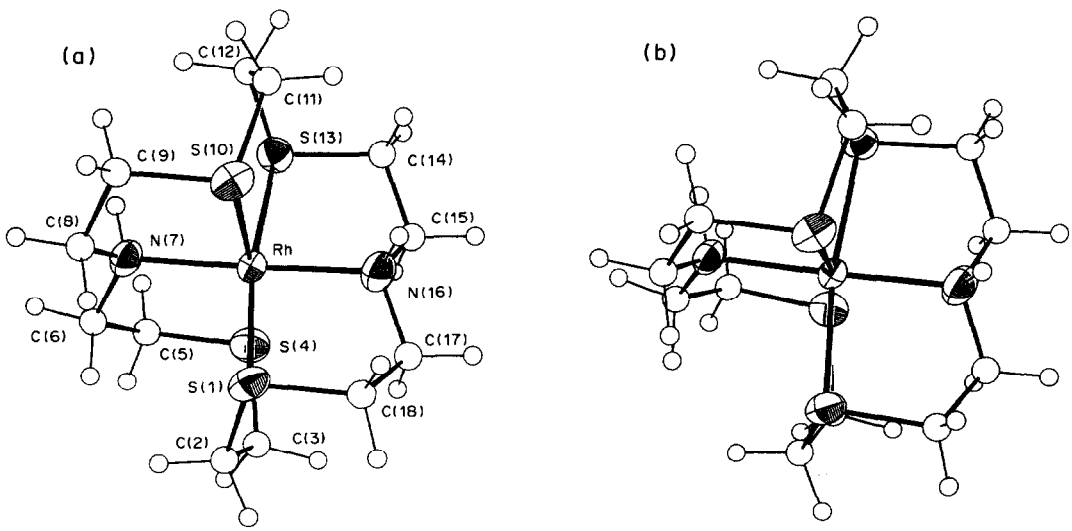

Fig. 2. Two views of the $[Rh([18]aneN_2S_4)]^{3+}$ cation: (a) with numbering scheme adopted and (b) orthogonal view showing the configuration adopted.

Å, angle N(16)—H(16)···O(2S) = 170.9(5)°; F(28)···O(3S) = 2.822(15) Å and O(2S)···O(3S) = 2.655(11) Å.

Since $[Rh([18]aneN_2S_4)](PF_6)_3$ dissolves only very sparingly in organic solvents such as MeCN, $MeNO_2$ and Me_2CO, all electrochemical measurements were performed using the much more soluble BPh_4^- salt. Cyclic voltammetry of $[Rh([18]aneN_2S_4)](BPh_4)_3$ in MeCN (0.1 M $^nBu_4NBPh_4$ supporting electrolyte) at platinum electrodes shows an irreversible reduction. At 298 K, this occurs at $E_{pc} = -1.34$ V vs Fc/Fc^+ (scan-rate = 180 mV s^{-1}). Upon lowering the temperature to 238 K and increasing the scan-rate to 400 mV s^{-1}, the reduction shifts cathodically to −2.02 V vs Fc/Fc^+ but remains irreversible. Coulometric measurements show that this process, which generates a yellow solution, corresponds to a two-electron reduction. These data suggest that the reduction corresponds to the formation of a d^8 rhodium(II) $[Rh([9]aneS_3)_2]^{2+}$ ($E_{1/2}$ for rhodium(III)/thia macrocyclic complex, $[Rh([14]aneS_4)]^{4+}$, has been reported previously.[9] Importantly, the trithia macrocycle $[9]aneS_3$ stabilizes both the d^7 rhodium(II) $[Rh([9]aneS_3)_2]^{2+}$ ($E_{1/2}$ for rhodium(III)/(II) = −0.71 V vs Fc/Fc^+) and the d^8 rhodium(I) complex $[Rh([9]aneS_3)_2]^+$ ($E_{1/2}$ for rhodium(II)/(I) = −1.08 V vs Fc/Fc^+).[6] Such stabilization is not achieved in the analogous tri-aza complex $[Rh([9]aneN_3)_2]^{3+}$ which shows two irreversible reductions at much more cathodic potentials, $E_{pc} = -1.93$ and −2.32 V vs Fc/Fc^+.[7]

EXPERIMENTAL

IR spectra were recorded as KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–4000 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh University Chemistry Department Microanalytical Service. Electrochemical measurements were performed on a Bruker E310 Universal Modular Polarograph. All readings were taken using a three-electrode potentiostatic system in acetonitrile containing 0.1 M $^nBu_4NPF_6$ or $^nBu_4NBPh_4$ as supporting electrolyte. Cyclic voltammetric measurements were carried out using a double platinum electrode and an Ag–AgCl reference electrode. All potentials are quoted vs ferrocene/ferrocenium, Fc/Fc^+. Mass spectra were run by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer. ^1H and ^{13}C NMR spectra were obtained on Bruker WP80 and WP200 instruments.

(a) *Synthesis of* $[Rh([18]aneN_2S_4)](PF_6)_3$

A fresh solution of $[Rh(H_2O)_6]^{3+}$ was prepared by treatment of $RhCl_3$ with three molar equivalents of $AgNO_3$ in refluxing H_2O. Reaction of $[Rh(H_2O)_6]^{3+}$ (0.140 mmol) with $[18]aneN_2S_4$ (45 mg, 0.138 mmol) in refluxing MeOH–H_2O (30 cm^3, 1:1 v/v) for 12 h afforded an orange solution. Addition of excess NH_4PF_6 gave an orange solid which was filtered, recrystallized from H_2O and dried *in vacuo* (yield: 71 mg, 54%). Found: C, 16.4; H, 2.9; N, 3.4. Calc. for $[C_{12}H_{26}N_2S_4Rh](PF_6)_3$: C, 16.7; H, 3.0; N 3.2%. FAB mass spectrum (3-NOBA matrix): Found: m/z = 719, 573 and 427. Calc. for $[^{103}Rh([18]aneN_2S_4)(PF_6)_2]^+$: m/z = 719, $[^{103}Rh([18]aneN_2S_4)PF_6]^+$: m/z = 574, $[^{103}Rh([18]aneN_2S_4)]^+$: m/z = 429: IR spectrum (KBr disc): 3240m, 3080w, 2980w, 2880w, 1465m, 1420m, 1380w, 1290w, 1230w, 1210w, 1175w, 1140m, 1065w, 1020w, 1000w, 970w, 840vs, 740m, 555vs, 495w cm^{-1}.

Single crystal structure determination of $[Rh([18]aneN_2S_4)](PF_6)_3 \cdot 3H_2O$. Recrystallization of the complex from aqueous solution yielded orange plates (0.62 × 0.62 × 0.15 mm) suitable for a single crystal X-ray crystallographic study.

Crystal data. $[C_{12}H_{26}N_2S_4Rh](PF_6)_3 \cdot 3H_2O$, M = 918.2, monoclinic, space group $P2_1/n$, a = 11.7097(12), b = 13.9470(11), c = 19.1954(17) Å, β = 107.048(6)°, V = 2997.2 $Å^3$ [from 2θ values of 35 reflections measured at $\pm\omega$ ($34 < 2\theta < 35°$, λ = 0.71073 Å, T = 298 K)], D_c = 2.035 g cm^{-3}, Z = 4, μ(Mo-K_α) = 1.118 mm^{-1}, F(000) = 1832.

Data collection and processing. A Stoë STADI-4 four-circle diffractometer, graphite-monochromated Mo-K_α radiation and ω–2θ scans using the learnt-profile method[10] were used. Of 4424 unique reflections measured ($2\theta_{max} = 45°$, h −12 → 12, k 0 → 14, l 0 → 20) 4125 with $F > 6\sigma(F)$ were used in all calculations. There was no significant crystal decay and no absorption correction was applied.

Structure analysis and refinement. The rhodium atom was located from a Patterson synthesis and the structure was developed by iterative cycles of least-squares refinement and difference Fourier synthesis.[11] During refinement some disorder of one of the PF_6^- counterions was observed. This was modelled successfully using partial F atoms, which integrated to six F atoms per P atom. Three fully occupied H_2O solvent molecules were found to be associated with each cation, although the H atoms on these could not be located. Anisotropic thermal parameters were refined for Rh, S, P, O, N and all fully occupied F atoms. Macrocyclic H atoms were included in fixed, calculated positions. The weighting scheme $w^{-1} = \sigma^2(F) + 0.007342F^2$ gave satis-

MERCURY MACROCYCLIC COMPLEXES: THE SYNTHESIS OF $[Hg([18]aneN_2S_4)]^{2+}$ AND $[Hg(Me_2[18]aneN_2S_4)]^{2+}$. THE SINGLE CRYSTAL X-RAY STRUCTURE OF $[Hg([18]aneN_2S_4)](PF_6)_2 \cdot 4/3H_2O$

ALEXANDER J. BLAKE, GILLIAN REID and MARTIN SCHRÖDER*

(*Received* 18 *June* 1990; *accepted* 13 *August* 1990)

Abstract—Reaction of $HgSO_4$ with one molar equivalent of L{L = [18]aneN$_2$S$_4$ (1,4,10,13-tetrathia-7,16-diazacyclooctadecane) or Me$_2$[18]aneN$_2$S$_4$ (7,16-dimethyl-1,4,10,13-tetrathia-7,16-diazacyclooctadecane)} in refluxing MeOH–H_2O for 15 min affords a colourless solution containing the complex cation $[Hg(L)]^{2+}$. Addition of excess PF_6^- counterion gives the complex $[Hg([18]aneN_2S_4)](PF_6)_2 \cdot 4/3H_2O$ as a cream coloured solid. A single crystal X-ray structure determination shows mercury(II) bound to a severely distorted octahedral arrangement of the six macrocyclic donor atoms, Hg—S = 2.655(5), 2.735(4), 2.751(4), 2.639(5) Å, Hg—N = 2.473(11), 2.472(17) Å. The cation is in a *rac* configuration with the two $SCH_2CH_2NCH_2CH_2S$ linkages bound meridionally to the metal centre.

In the course of our continuing study of the coordination chemistry of the potentially hexadentate macrocycles [18]aneN$_2$S$_4$ and Me$_2$[18]aneN$_2$S$_4$, we have observed that these large ring systems readily bind to a range of transition metal ions, and that the resultant complexes can often exhibit unusual stereochemical and electrochemical properties.[1] Importantly, we have found that [18]aneN$_2$S$_4$ binds octahedrally to first and second row transition metal centres to give the *rac* isomer exclusively, thus confirming the original proposals by Black and McLean.[2] We were interested to determine whether coordination of [18]aneN$_2$S$_4$ to a large third row metal ion would result in a different configuration for the macrocycle or in distortion from a regular octahedral *rac* configuration. We therefore extended this study to the complexation of mercury(II) with these macrocyclic ligands and report herein the synthesis of $[Hg([18]aneN_2S_4)]^{2+}$ and $[Hg(Me_2[18]aneN_2S_4)]^{2+}$. The single crystal structure of $[Hg([18]aneN_2S_4)](PF_6)_2 \cdot 4/3H_2O$ is also described. Few examples of macrocyclic mercury thioether complexes have been reported. The dimeric species $[Hg_2([14]aneS_4)Cl_4]$ involves exodentate coordination of two thia-donors, with two Cl^- ligands completing the tetrahedral environment at each mercury(II) ion,[3] while we have previously reported the synthesis and structure of $[Hg([9]aneS_3)_2]^{2+}$. This complex cation involves facial coordination of each trithia macrocycle to give a centrosymmetric, tetragonally compressed stereochemistry, Hg—S_{ap} = 2.638(3), Hg—S_{eq} = 2.728(3), 2.712(3) Å.[4]

RESULTS AND DISCUSSION

Treatment of $HgSO_4$ with one molar equivalent of [18]aneN$_2$S$_4$ in refluxing MeOH–H_2O (1 : 1 v/v)

* Author to whom correspondence should be addressed.

for 30 min affords a colourless solution. Addition of excess NH_4PF_6 yields a cream coloured precipitate which was recrystallized from MeCN. The IR spectrum of this product shows a peak at 3295 cm^{-1} corresponding to an N—H stretching vibration, ν(N—H), as well as other peaks indicative of the presence of coordinated [18]aneN$_2$S$_4$ and PF_6^- counterion. The FAB mass spectrum exhibits molecular ion peaks at $m/z = 672$ and 527 assigned to $[^{202}Hg([18]aneN_2S_4)PF_6-H]^+$ and $[^{202}Hg([18]aneN_2S_4)-H]^+$, respectively. The ^1H NMR spectrum measured in CD_3NO_2 at 298 K shows a broad multiplet in the range $\delta = 2.25-3.90$ ppm assigned to the methylene protons of the coordinated macrocycle, as well as a broad resonance at 7.05 ppm due to the N—H functions. These data, together with microanalytical data, indicate the formulation $[Hg([18]aneN_2S_4)](PF_6)_2$ for the product.

Colourless crystals were obtained by vapour diffusion of diethyl ether into a solution of $[Hg([18]aneN_2S_4)](PF_6)_2$ in MeCN. The structure shows (Fig. 1) mercury(II) bound via all six macrocyclic donor atoms, Hg—S(1) = 2.655(5), Hg—S(4) = 2.735(4), Hg—S(10) = 2.751(4), Hg—S(13) = 2.639(5), Hg—N(7) = 2.473(11), Hg—N(16) = 2.472(17) Å, and confirms a *rac* configuration for $[Hg([18]aneN_2S_4)]^{2+}$. This result is consistent with all other structurally characterized octahedral complexes of [18]aneN$_2$S$_4$.[1] The Hg—S bond lengths observed are similar to those in $[Hg([9]aneS_3)_2]^{2+}$.[4] Two alternative diastereoisomers of *rac*-$[M([18]aneN_2S_4)]^{x+}$ are possible: these differ in the relative orientations of their N—H groups (Fig. 2).[5] Each isomer has C_2 symmetry and therefore should give rise to six different ^{13}C NMR resonances. Our single crystal X-ray study shows that $[Hg([18]aneN_2S_4)]^{2+}$ exists as a distorted form isomer **II** in the crystal selected.

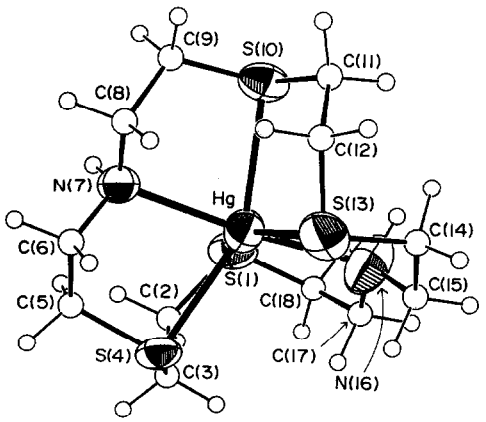

Fig. 1. Single crystal structure of $[Hg([18]aneN_2S_4)]^{2+}$ with numbering scheme adopted.

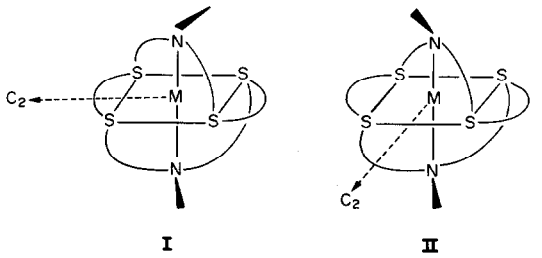

Fig. 2. Isomers I and II for *rac*-$[M([18]aneN_2S_4)]^{x+}$.

Interestingly, our single crystal structure determinations on a range of first row metal complexes *rac*-$[M([18]aneN_2S_4)]^{x+}$ have usually shown these to exist as isomer **I**, although ^{13}C NMR studies on the complexes where M = iron(II) or rhodium(III) have clearly shown that both isomers are present in solution.[1] The ligand conformation and M–donor bond lengths observed in the crystal structure of $[Hg([18]aneN_2S_4)]^{2+}$ lead to approximate, non-crystallographic C_2 symmetry. The structure of $[Hg([18]aneN_2S_4)]^{2+}$ also reveals a severe tetrahedral distortion of the S-donor atoms out of the best S_4 coordination plane, with S(1) and S(13) lying 0.658 and 0.664 Å, respectively, above the plane, while S(4) and S(10) lie 0.670 and 0.652 Å, respectively, below. It is likely that this distortion is a consequence of the fact that the radius of the mercury(II) ion (102 pm)[6] is too large for the macrocyclic cavity, especially with the limited bite angle of the $SCH_2CH_2NCH_2CH_2S$ chains.

The di-N-methylated complex $[Hg(Me_2[18]aneN_2S_4)](PF_6)_2$ has been prepared by a route analogous to that employed for $[Hg([18]aneN_2S_4)](PF_6)_2$, and characterized by microanalyses, IR, ^1H NMR spectroscopy and FAB mass spectrometry. By analogy with our earlier studies on $[Pd(L)]^{2+}$, $[Cu(L)]^{2+}$ and $[Ag(L)]^+$ [1] we propose that $[Hg(Me_2[18]aneN_2S_4)]^{2+}$ is in a *meso* configuration involving facial binding of the $SCH_2CH_2NCH_2CH_2S$ chains, due to the steric effect of replacing NH by the bulkier NMe groups. Studies are currently underway to confirm these proposals.

Cyclic voltammetry of $[Hg([18]aneN_2S_4)](PF_6)_2$ measured in MeCN (0.1 M $^nBu_4NPF_6$ supporting electrolyte) at platinum electrodes shows an irreversible reduction at $E_{pc} = -1.16$ V vs Fc/Fc^+. Subsequent scans lead to the generation of new waves, suggesting the formation of daughter products. Cyclic voltammetry of $[Hg(Me_2[18]aneN_2S_4)](PF_6)_2$ under the same conditions shows an irreversible reduction at $E_{pc} = -0.60$ V vs Fc/Fc^+. Subsequent scans lead to the appearance of a chemically-reversible reduction at

$E_{1/2} = -0.46$ V vs Fc/Fc^+. These results indicate that reduction of the mercury(II) complexes is followed by some chemical reaction, possibly involving formation of solvated species which exhibit a different electrochemistry. In both cases, reduction to mercury metal occurs over a period of a few seconds. $[Hg([9]aneS_3)_2]^{2+}$ shows a chemically-reversible reduction at $E_{1/2} = -0.15$ V vs Fc/Fc^+.[4]

EXPERIMENTAL

IR spectra were recorded as KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–4000 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh University Chemistry Department Microanalytical service. Electrochemical measurements were performed on a Bruker E310 Universal Modular Polarograph. All readings were taken using a three-electrode potentiostatic system in acetonitrile containing 0.1 M $^nBu_4NPF_6$ or $^nBu_4NBF_4$ as supporting electrolyte. Cyclic voltammetric measurements were carried out using a double platinum electrode and an Ag/AgCl reference electrode. All potentials are quoted vs ferrocene/ferrocenium, Fc/Fc^+. Mass spectra were run by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer. ^1H and ^{13}C NMR spectra were obtained on Bruker WP80 and WP200 instruments.

(a) *Synthesis of* $[Hg([18]aneN_2S_4)](PF_6)_2$

Reaction of $HgSO_4$ (30 mg, 0.101 mmol) and $[18]aneN_2S_4$ (35 mg, 0.107 mmol) in refluxing $MeOH–H_2O$ (35 cm^3, 1 : 1 v/v) for 15 min under N_2 afforded a colourless solution. Cooling, reducing the volume to 10 cm^3 and filtering the reaction mixture into a solution of excess NH_4PF_6 in MeOH gave a cream precipitate which was recrystallized from MeCN and diethyl ether (Yield : 60 mg, 73%). Found: C, 17.7; H, 3.4; N, 3.5; S, 16.3. Calc. for $[C_{12}H_{26}N_2S_4Hg](PF_6)_2$: C, 17.6; H, 3.2; N, 3.4; S, 15.7%. FAB mass spectrum (3-NOBA matrix): Found $m/z = 672$ and 527. Calc. for $[^{202}Hg([18]aneN_2S_4)PF_6]^+$ $m/z = 673$; $[^{202}Hg([18]aneN_2S_4)]^+$ $m/z = 528$. ^1H NMR spectrum (80.13 MHz, CD_3NO_2, 298 K): $\delta = 2.25$–3.90 (m, b, CH_2, 24H), 7.05 ppm (b, NH, 2H). ^{13}C DEPT NMR (50.32 MHz, CD_3NO_2, 298 K) suggests fluxional behaviour in solution: two sets of resonances in a ratio of approximately 3 : 1; major component $\delta = 45.41$ (NCH_2), 30.57, 27.52 ppm ($2\times SCH_2$); minor component $\delta = 43.57$ (NCH_2), 29.05, 28.94ppm ($2\times SCH_2$). IR spectrum (KBr disc): 3295m, 2920m, 2860m, 1465m, 1420m, 1320w, 1280w, 1100m, 1040w, 1000w, 940w, 840vs, br, 740w, 555vs cm^{-1}.

Single crystal X-ray structure determination on $[Hg([18]aneN_2S_4)](PF_6)_2 \cdot 4/3H_2O$. Colourless tablets suitable for single crystal X-ray analysis were obtained by vapour diffusion of diethyl ether into a solution of the complex in MeCN. The selected crystal ($0.39 \times 0.21 \times 0.12$ mm) was sealed in a glass capillary tube to prevent solvent loss.

Crystal data. $[C_{12}H_{26}N_2S_4Hg]^{2+} \cdot 2PF_6^- \cdot 4/3H_2O$, $M = 841.1$. Monoclinic, space group $C2/c$, $a = 22.904(8)$, $b = 10.141(4)$, $c = 26.516(9)$ Å, $\beta = 121.544(24)°$, $V = 5249$ Å^3 [from 2θ values for 48 reflections measured at $\pm\omega$ ($23.9 < 2\theta < 25.8°$, $\lambda = 0.71073$ Å, $T = 298$ K)], $Z = 8$, $D_c = 2.129$ g cm^{-3}, μ(Mo-K_α) = 6.334 cm^{-1}, $F(000) = 3232$.

Data collection and processing. Stoë STADI-4 four-circle diffractometer, graphite-monochromated Mo-K_α radiation and ω–2θ scans using the learnt-profile method[7] were used. 4496 reflections measured ($2\theta_{max} = 45°$, h $-24 \rightarrow 15$, k $0 \rightarrow 10$, l $0 \rightarrow 28$) giving 2500 with $F > 6\sigma(F)$. Initial corrections for absorption (min. 0.1833, max. 0.3412) were made by means of ψ-scans. Crystal decay (30%) was approximately linear and isotropic.

Structure analysis and refinement. The mercury position was deduced from a Patterson synthesis. Iterative cycles of least-squares refinement and difference Fourier syntheses[8] located the positions of all other non-hydrogen atoms. Final corrections for absorption (max. 1.624, min. 0.921) were made using DIFABS.[9] During refinement the bond linking C(17) to C(18) was observed to be unusually short. Thus, the bond lengths, C(17)–C(18) and C(17)—N(16) were constrained to be 1.50 Å. Two mutually incompatible 2/3-occupied H_2O solvent molecules were found per $[Hg([18]aneN_2S_4)]^{2+}$ cation. Hydrogen atoms were included in fixed, calculated positions. Anisotropic thermal parameters were refined for Hg, S, N, P, F and C atoms. The weighting scheme $w^{-1} = \sigma^2(F) + 0.000277F^2$ gave satisfactory agreement analyses. At final convergence $R = 0.0490$, $R_w = 0.0615$, $S = 1.104$ for 302 independent parameters, and the final difference Fourier synthesis showed no feature above 0.86 or below -1.71 eÅ^{-3}: this trough lies close to the mercury ion. Illustrations were prepared using ORTEPII,[10] molecular geometry calculations utilized CALC,[11] and scattering factor data were inlaid[5] or taken from ref. 12. Bond lengths, angles and torsion angles are given in Table 1. Fractional atomic coordinates, thermal parameters, together

with observed and calculated structure factors, have been deposited with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

(b) *Synthesis of* $[Hg(Me_2[18]aneN_2S_4)](PF_6)_2$

Method as for (a) above, using $HgSO_4$ (30 mg, 0.101 mmol) and $Me_2[18]aneN_2S_4$ (35 mg, 0.099 mmol). Product isolated as a pale green solid (yield: 56 mg, 67%). Found: C, 19.7; H, 3.6; N, 3.2. Calc. for $[C_{14}H_{30}N_2S_4Hg](PF_6)_2$: C, 19.9; H, 3.6; N, 3.3%. FAB mass spectrum (3-NOBA matrix): Found $m/z = 574$. Calc. for $[^{202}Hg([18]aneN_2S_4)H_2O]^+$ $m/z = 574$. ^1H NMR spectrum (80.13 MHz, CD_3NO_2, 298 K): $\delta = 2.60$–3.65 (m, b, CH_2, 24H), 2.43 ppm (s, CH_3, 6H). IR spectrum

Abstract—The compound di-μ-cyanato-bis[{cyanato(N,N-dimethylethylenediamine)}copper(II)] was synthesized, and studied by IR spectroscopy and X-ray diffraction. It is dimeric with bridging and terminal cyanate groups, and the copper atoms show a square-based pyramid coordination geometry.

One of our research lines relates to the synthesis, reactivity and solid-state structural characterization of copper compounds with nitrogen-based ligands.[1–3] Recently, we synthesized an azido complex with a bidentate amine,[4] whose structural features prompted us to extend the investigation to copper(II) cyanato complexes. The structural parameters that emerge from the copper–pseudohalogen amine complexes merit attention, since they may be related to those of biological interest, such as copper-containing proteins.[5] In addition, it must be pointed out that the pseudohalogens bonded to copper may be made to react with organic nitrogen-based ligands present at the metal's coordination sphere, in analogy to other metal-induced organic synthesis. It is also a fact that lesser attention has been given to cyanate than to other pseudohalogen copper complexes, and we consider it desirable to fill in this gap. We therefore prepared $[Cu(NCO)_2(diMeen)]_2$ (diMeen = N,N-dimethylethylenediamine) and subjected this complex to a full IR and X-ray crystallographic characterization.

EXPERIMENTAL

Synthesis of $[Cu(NCO)_2(diMeen)]_2$

To a solution of 0.681 g (2.82 mmol) of $Cu(NO_3)_2 \cdot 3H_2O$ in 25 cm^3 of methanol was added 0.30 cm^3 (2.82 mmol) of diMeen, followed by a dropwise addition of 0.49 g (6.05 mmol) of KNCO in 3.5 cm^3 of water. The mixture was stirred for 30 min and the solid obtained was filtered, washed with ether and dried *in vacuo*. Recrystallization from methanol gave blue crystals suitable for X-ray analysis. The elemental analysis results were in agreement with the proposed formula.

IR spectrum

The IR spectrum of the title complex was recorded as CsI pellets on a Carl Zeiss Specord 75 IR spectrophotometer.

Crystal structure determination of $[Cu(NCO)_2(diMeen)]_2$

Crystal data: $C_{12}H_{24}Cu_2N_8O_4$, $M = 471.08$, monoclinic, space group $P2_1/c$, $a = 12.216(2)$,

$b = 10.662(1)$, $c = 14.997(4)$ Å, $\beta = 96.09(3)°$, $V = 1942.29(9)$ Å^3, $Z = 4$, $D_c = 1.61$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 21.44$ cm^{-1}, $F(000) = 968$.

A dark-blue single crystal of approximate dimensions 0.125 × 0.3 × 0.3 mm was used in data collection on an Enraf-Nonius CAD-4 diffractometer, using graphite monochromated Mo-K_α radiation. Twenty-five reflections ($12 < \theta < 19°$) were used for least-squares determination of the cell constants, and 2286 reflections with $I > 3\sigma(I)$ were used in the structure determination and refinement. The structure was solved by direct methods[6] and difference Fourier synthesis,[7] using atomic scattering factors from reference 8. Refinement by least-squares minimized $\Sigma_w(|F_o| - |F_c|)^2$; atomic coordinates, anisotropic thermal parameters and scale factor refined; isotropic thermal parameters for H atoms located geometrically.[7] Final $R = 0.0429$. Lists of atomic parameters, observed and calculated structure factors, and anisotropic thermal coefficients for all atoms have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

The IR spectrum of $[Cu(NCO)_2(diMeen)]_2$ showed absorption bands for coordinated cyanate groups[9–11] at 2210w, 2170s, νCN; 1185m, νCO; 645m and 615w, δNCO, cm^{-1}. In the spectrum, the occurrence of two bands assignable to the νCN vibrational mode suggested the presence of cyanate groups with differing modes of coordination. In particular the large splitting of 30 cm^{-1} observed for δNCO indicated the presence of at least one bridging cyanate group.

The X-ray diffraction study confirmed that the title compound is in fact dimeric. The structure of the complex molecule with the atom-numbering scheme is shown in Fig. 1. Selected bond lengths and bond angles are given in Table 1. Each copper atom is surrounded by five nitrogen atoms belonging to two bridging cyanates, one terminal cyanate and two diMeen nitrogens. The coordination geometry for each metal is that of a square-based pyramid, with the bridging cyanato nitrogens occupying the apical positions in both cases. The copper atoms are displaced from the basal planes made up of N(1), N(2), N(3), N(4); and N(5), N(6), N(7), N(8) by only 0.161(1) and 0.194(1) Å, respectively, and although the basal planes are crystallographically parallel, the two halves of the dimer are not related by a centre of symmetry. The angles between the apical and the basal nitrogens of the pyramids vary from 82.2° to 102°, about the theoretical value of 90°. These angles and those within the metal and the nitrogens of the basal plane relate closely to those found in the complex $[Cu(N_3)_2(tMeen)]_2$, where the geometry around the copper atoms is similar.[12]

It is instructive at this point to compare the different polyhedra formed by the metal and the nitrogen atoms of the title compound and those of the related $[Cu(N_3)_2(tMeen)]_2$ and $[Cu(N_3)_2(diEten)]_2$. In the tMeen complex two azido groups bridge the metals in an "end-to-end" fashion resulting in a very long Cu...Cu distance of 5.004 Å, whereas for the diEten compound[4] two N_3 groups are "end-on" bridging with a short Cu...Cu distance of 3.37 Å. Unlike the present complex, $[Cu(N_3)_2(diEten)]_2$ displays a centre of symmetry, and its overall structure is better understood if the copper atoms are placed in the centre of trigonal bipyramids, with the nitrogen of the bridging azide and that of the NH_2 end of diEten at the axial sites. In this complex the Cu...NH_2 distance is smaller than the Cu...NEt_2 distance, which is the opposite of that expected if purely inductive effects were taken into account, and it is interesting that the same trend is again observed for $[Cu(NCO)_2(diMeen)]_2$. In this latter complex, the presence of cyanate rather than azido groups forced such a distortion that the compound entirely lost its centre of symmetry by allowing the NH_2 ends of the diMeen ligands to be on the same side of the dimer. This effect may be of electronic origin, caused by the replacement of the azide by cyanate as the pseudohalogen, rather than by the change from diEten to diMeen as the chelating ligand. Curiously, the net effect is a further shortening of the Cu...Cu distance in $[Cu(NCO)_2(diMeen)]_2$ to 3.2464(9) Å; this fine interplay of electronic effects caused by pseudohalide substitution might be further enlightened by the structural details of a mixed

azido–cyanato copper dimer which is presently under investigation.[13]

As to other cyanato complexes, $[Cu(NCO)_2(diMeen)]_2$ shows longer Cu...N distances for the nitrogens of the bridging groups, but the distances compare well with those of another copper complex which contains 2,2-lut[14] and to those of the interesting $[Cu_2(C_{17}H_{22}N_4O)(C_2H_3O_2)(NCO)][PF_6]$.[15]

Abstract—Toluene solutions of $M_2(NMe_2)_6$ (M = Mo, W) react with mesitylene selenol (Ar'SeH) to give $M_2(SeAr')_6$ complexes. $Mo_2(OR)_6$ (R = ^{t}Bu, $CH_2{}^t$Bu) react with excess (> 6 fold) Ar'SeH to give $Mo_2(SeAr')_6$, whilst $W_2(OR)_6(py)_2$ (R = ^{i}Pr, $CH_2{}^t$Bu) react with excess (> 6 fold) Ar'SeH to give $W_2(OR)_2(SeAr')_4$. Reaction of $Mo_2(OPr^i)_6$ with Ar'SeH produces $Mo_2(OPr^i)_2(SeAr')_4$ which crystallizes in two different space groups. These arene–selenato complexes are air-stable and insoluble in common organic solvents. X-ray crystallographic studies revealed that the $Mo_2(SeAr')_6$ and $W_2(SeAr')_6$ compounds are isostructural in the solid state and adopt ethane-like staggered configurations with the following important structural parameters, M—M (W—W/Mo—Mo) 2.3000(11)/2.2175(13) Å, M—Se 2.430 (av.)/2.440 (av.) Å, M—M—Se 97.0° (av.)°. In the solid state $W_2(O^iPr)_2(SeAr')_4$ adopts the anti-configuration with crystallographically imposed C_i symmetry and W—W 2.3077(7) Å, W—Se 2.435 (av.) Å, W—O 1.858(6) Å; W—W—Se 100.27(3)°, 93.8(3)° and W—W—O 108.41(17)°. $Mo_2(OPr^i)_2(SeAr')_4$ crystallizes in both $P\bar{1}$ and $A2/a$ space groups in which the molecules are isostructural with each other and the tungsten analogue. Important bond lengths and angles are Mo—Mo 2.180(24) Å, Mo—Se 2.432(av.) Å, Mo—O 1.872(9) Å, Mo—Mo—Se 99.39(9)°, 94.71(8)°, Mo—Mo—O 107.55(28)°.

The synthesis of metal–metal multiply bonded compounds has been extensively explored, especially for molybdenum and tungsten.[1] Indeed M_2R_6 (M = Mo, W) compounds are formed for a range of ligands R = alkoxy, amido, thiolate and various mixed species of general formula $M_2R'_2R_4$, e.g. $M_2Cl_2(NMe_2)_4$.[2–4]

Previously, there have been a few reports of Cr, Mo and W aryl selenolate complexes.[5] Two examples which contain μ_2 bridging SePh ligands have been structurally determined by X-ray crystallography,[6,7] namely, $(C_7H_7)Mo(\mu\text{-SePh})_3Mo(CO)_3$ and $(\eta^5\text{-}C_5H_5)(NO)Cr(\mu\text{-SePh})_2Cr(NO)(\eta^5\text{-}C_5H_5)$. Aryl selenium and tellurium complexes of general formula $[M(C_5H_5)_2(EPh)_2]$ (M = Ti, V, Nb, Mo, W; E = S, Se, Te) have been characterized by elemental analysis and IR spectroscopy and are thought to have terminal aryl-chalcogen ligands.[8] One tungsten compound containing an aryl-selenolate ligand has been studied by X-ray crystallography, $(\eta^7\text{-}C_7H_7)W(CO)_2(SePh)$, and contains a terminal aryl-selenide ligand.[7]

Homoleptic complexes supported by selenolate ligands are known[9–14] for mercury $[Ph_4P][Hg(SePh)_3]$, lead $[Ph_4As][Pb(SePh)_3]$, tin $[Sn(SePh)_4]$ and silicon $[(Si(SePh)_3)_2]$. These species are suggested to have only terminal selenolate ligands. Molybdenum and tungsten compounds of formulation $[OM(SePh)_4]$ and $[M_2O_2(ER)_6OMe]^-$ (R = S, Se; R = aryl) have been made and characterized by UV–vis, EPR and elemental analysis.[14,15] An X-ray crystal structure of the thiolate derivative indicates that the dinuclear species has one bridging μ_2 thiolate group and two μ_2 oxo species, with the remainder of the ligands being terminal.[16,17] The selenide derivatives of these complexes have inferred structures based upon the thiolato chemistry.

Here we report the synthesis and characteriz-

* Author to whom correspondence should be addressed.

ation of homoleptic molybdenum and tungsten multiply bonded compounds supported by mesitylene selenol ligands. The choice of the mesityl group was influenced by considerations of steric bulk and C—S bond cleavage.[3,4] The preparations of $M_2(OR)_2(SeAr')_4$ (M = Mo, W) are also presented. To our knowledge these are the first examples of homoleptic transition metal selenolate complexes.[5,18]

RESULTS AND DISCUSSION

Syntheses and characterization

$M_2(SeAr')_6$ and $M_2(SeAr')_4(OR)_2$ compounds. All the reactions were performed at room temperature in toluene or toluene–hexane mixtures. Reaction of $M_2(NMe_2)_6$ (M = Mo, W) with excess (> 6 fold) Ar'SeH produced the completely substituted $M_2(SeAr')_6$ complex, eq. (2) (N.B. Ar', here and after is used for the mesitylene ligand; 2,4,6-trimethyl benzene):

$$M_2(NMe_2)_6 + 6Ar'SeH = M_2(SeAr')_6 + 6HNMe_2. \quad (1)$$

$Mo_2(OR)_6$ (R = ^{t}Bu, $CH_2{}^t$Bu) also reacts with Ar'SeH to give complete substitution, eq. (2). The alcohol generated can be detected in the ^{1}H NMR spectra of the filtrate:

$$Mo_2(OR)_6 + 6Ar'SeH = Mo_2(SeAr')_6 + 6HOR. \quad (2)$$

Surprisingly, reaction of $W_2(OR)_6 \cdot py_2$ (R = $CH_2{}^t$Bu, ^{i}Pr), $W_2(O^t Bu)_6$ or $Mo_2(OR)_6$ (R = ^{i}Pr, ^{c}Hex) with excess (> 6 fold) of mesitylene selenol does not produce the fully substituted species, but rather the tetrasubstituted species $M_2(OR)_2(SeAr')_4$, eq. (3):

$$W_2(OR)_6py_2 + 4Ar'SeH = W_2(OR)_2(SeAr')_4 + 4HOR + 2py \quad (3a)$$

$$Mo_2(OR)_6 + 4Ar'SeH = Mo_2(OR)_2(SeAr')_4 + 4HOR. \quad (3b)$$

The reason for the complete substitution in the amide case for both Mo and W [eq. (1)], when compared to the analogous sulphur chemistry is not obvious.[3] One explanation could be the complete insolubility of the products in eq. (3) in common organic solvents, thus providing a driving force for the reaction.

The reaction of $M_2(OR)_6$ with a six-fold excess of mesitylene selenol leads to complete substitution at room temperature in the case of some molybdenum compounds (OR = ^{t}Bu, $CH_2{}^t$Bu) but stops at the tetrasubstituted tungsten species. The complete substitution at room temperature in the molybdenum case (OR = ^{t}Bu, $CH_2{}^t$Bu) is surprising in the light of the corresponding thiolate chemistry where forcing conditions (80°C) are required. Possibly the larger covalent radius of selenium compared with sulphur (0.09 Å) is sufficient to alter the relative reactivity of the intermediate $M_2(EAr')_x(OR)_{6-x}$ (x = 1–5) compounds (E = S, Se). The increased acidity of a selenol compared with a thiol would also facilitate the generation of the selenolate.

In general, the reaction to form the $Mo_2(SeAr')_6$ species occurs faster for amide [eq. (1)] than alkoxide replacement [eq. (2)]. The rate of reaction (as judged by the rate of product precipitation) is dependent on the bulk of the alkoxide with the ^{t}OBu derivative requiring less time for reaction than the $OCH_2{}^t$Bu derivative [eq. (2)]. This indicates a degree of steric control in the reaction. The tungsten reaction to form $W_2(OR)_2(SeAr')_4$ is much slower than the reaction to form the fully substituted molybdenum species. At room temperature little reaction occurs between $W_2(OBu^t)_6$ and mesitylene selenol after 6 days in hydrocarbon solvents. However a reaction time of 2 weeks in THF followed by cooling to −20°C for 30 days allowed isolation of $W_2(O^tBu)_2(SeAr')_4$.

Reaction of $Mo_2(OR)_6$ (R = ^{t}Bu, $CH_2{}^t$Bu) with Ar'SeH goes to complete substitution and formation of $Mo_2(SeAr')_6$ [eq. (2)], whilst for R = Pr^i and cyclohexyl (^{c}Hex), the tetrasubstituted species $Mo_2(SeAr')_4(OR)_2$ are formed. This is probably due to the solubility of the tetrasubstituted derivative. For R = ^{i}Pr and ^{c}Hex the tetrasubstituted species are very insoluble, whilst a purported $Mo_2(SeAr')_4(OR)_2$ (R = ^{t}Bu, $CH_2{}^t$Bu) species would be expected to be more soluble (based on the relative solubilities of $Mo_2(OBu^t)_6$, $Mo_2(OCH_2{}^tBu)_6$ and $Mo_2(O^cHex)_6$ in hydrocarbon solvents).

Treatment of a solution of $Mo_2Cl_2(NMe_2)_4$ in toluene with excess mesitylene selenol also leads to $Mo_2(SeAr)_6$ formation, eq. (4). The yields of the product are comparable to those obtained by the other routes, although the microanalysis is slightly inferior.

$$Mo_2Cl_2(NMe_2)_4 + 6HSeAr' = Mo_2(SeAr')_6 + 2HCl + 4HNMe_2. \quad (4)$$

The $M_2(SeAr')_6$ and $M_2(OR)_2(SeAr')_4$ (M = Mo, W) compounds were characterized by IR spectroscopy, melting points and X-ray crystallography. Unfortunately, the insolubility precluded an NMR study of the $M_2(SeAr')_6$ product. However,

the mixed alkoxide/selenolate species $M_2(OR)_2(SeAr')_4$ are slightly soluble in THF, chloroform or toluene to about 15 mg in 100 cm^3 of solvent.

The homoleptic compounds $M_2(SeAr')_6$ are relatively air-stable and show little detectable physical changes (IR/m.p./colour) even when stored in the light over 5 months. They are insoluble in and show no decomposition by water. Addition of 6 M HNO_3 to the hexaselenolates causes slow decomposition but requires a long time for reaction due to the high crystallinity of the sample. These physical properties are probably attributable to the hydrophobic exterior presented by the mesitylene ligands.

The IR spectra of the hexaselenolates exhibit the expected ligand vibrations due to coordinated mesitylene selenol and a stretch at low frequency at *ca* 285 or 260 cm^{-1} (in the molybdenum and tungsten cases, respectively), which can be assigned to M—Se vibrations. The mixed $M_2(SeAr')_4(OR)_2$ species exhibit vibrations due to both the selenolate and alkoxide ligands.

The ^1H NMR spectra of $M_2(SeAr')_4(OR)_2$ (M = Mo, R = Pr^i, cyclohexyl; M = W, R = Pr^i, Bu^t, neopentyl) measured at room temperature show the expected resonances for both the selenolate and alkoxide ligands in the correct integral ratios and are consistent with the anti-rotamer. The spectra required a long accumulation time because of the low solubility of the materials.

$M_2(SeAr')_2(NMe_2)_4$. The reaction between $M_2Cl_2(NMe_2)_4$ and mesitylene selenium Grinard Ar'SeMgBr in THF leads to the precipitation of yellow crystals, $M_2(SeAr')_2(NMe_2)_4$ in a 40% yield based on eq. (5). These compounds are slightly soluble in THF–toluene and chloroform, and are air and light sensitive, especially in solution. The ^1H NMR spectrum of $M_2(ScAr')_2(NMe_2)_4$ in benzene reveals only the anti-rotamer. The corresponding thiolate $Mo_2(SAr')_2(NMe_2)_4$ adopts an ethane staggered geometry about the metal–metal triple bond with the aryl thiolato ligands in an anti-configuration in the solid state. Attempts to obtain an X-ray determination of the selenolate derivative were hampered by problems of twinning. The IR spectra of $M_2(SeAr')_2(NMe_2)_4$ have bands directly assignable to the amide and coordinated selenolate ligands.

$$M_2Cl_2(NMe_2)_4 + 2Ar'SeMgBr = M_2(SeAr')_2(NMe_2)_4 + 2MgBrCl. \quad (5)$$

Attempted preparations of phenylselenolates. The reactions between $M_2(NMe_2)_6$ or $M_2(OR)_6 \cdot L_2$ (M = Mo, W, L = py, $HNMe_2$) and selenophenol (HSePh) at room temperature in hydrocarbon solvents produce a purple precipitate for molybdenum and a black solid for tungsten. The reactions with $M_2(NMe_2)_6$ produce ammonium salts as evidenced by the IR spectra of both the molybdenum and tungsten products. In the molybdenum case the reaction is extremely rapid and the product formulated as having an empirical formula $[Mo_4(SePh)_{10}Se_2]H_2NMe_2$ on the basis of microanalysis and IR spectroscopy. The latter showed vibrations associated with the selenophenol ligand as well as the $Me_2NH_2^+$ ion at 2700 and 2400 cm^{-1} ($\bar{\nu}$ NH) for the complex.[18] The product is also air-stable (no change in IR spectrum over 1 month at room temperature in air) and insoluble in organic solvents. The reaction between $Mo_2(O^tBu)_6$ and phenylselenol also produces a purple solid which has a very similar IR to $[Mo_4(SePh)_{10}Se_2]H_2NMe_2$, but missing the vibrations associated with the $Me_2NH_2^+$ ion. However, new bands at 3200 and 1630 cm^{-1}, as well as OBu^t vibrations suggest hydrogen bonding involving $[H_2O^tBu]^+$.

The reaction between $W_2(NMe_2)_6$ and selenophenol proceeded in an analogous manner to the molybdenum compounds and produced a black solid, the microanalysis and IR of which are consistent with the empirical formula $[W_4Se_4(SePh)_{10}]H_2NMe_2$. This material is insoluble in common solvents once isolated. If the reaction to form this material is performed in THF the tungsten species is not precipitated until after 2 days, compared with 3 h for reactions in hydrocarbon solvents.

The solubility of the compounds produced in the reaction of non-sterically protected selenophenols with tungsten and molybdenum amides and alkoxides was not improved by the use of *para*-substituted selenophenols such as *p*-$EtOC_6H_6$—SeH.

Solid state structures of $M_2(SeAr')_6$ (M = Mo, W)

Crystal data for the $M_2(SeAr')_6$ compounds are given in Table 1; selected bond lengths and angles in Table 2. An ORTEP view of the molecule showing the atom numbering scheme used in the tables is shown in Fig. 1 for $W_2(SeC_6H_2Me_3)_6$, and a view down the Mo—Mo axis in $Mo_2(SeC_6H_2Me_3)_6$ is given in Fig. 2.

The sample of $W_2(SeAr')_6$ that was examined crystallographically, crystallized from the reaction involving $W_2(NMe_2)_6$ and Ar'SeH on standing at room temperature for 4 days. No included solvent was present and the compound formed with a crystallographically imposed centre of symmetry in the space group $P\bar{1}$.

The sample of $Mo_2(SeC_6H_2Me_3)_6$ used for X-ray analysis, crystallized from the reaction solution involving $Mo_2(O^tBu)_6$ with excess mesitylene

selenol in toluene at room temperature overnight. The molybdenum compound was isostructural with the tungsten analogue.

A comparison of the parameters associated with the central $X_3M{\equiv}MX_3$ core in structurally characterized homoleptic alkyls, amides, alkoxides and thiolates has been made previously.[4] For related molecules the W—W distance is longer by *ca* 0.08 Å than the Mo—Mo distances.[3,4] This difference is found in the $M_2(SeAr')_6$ compounds.

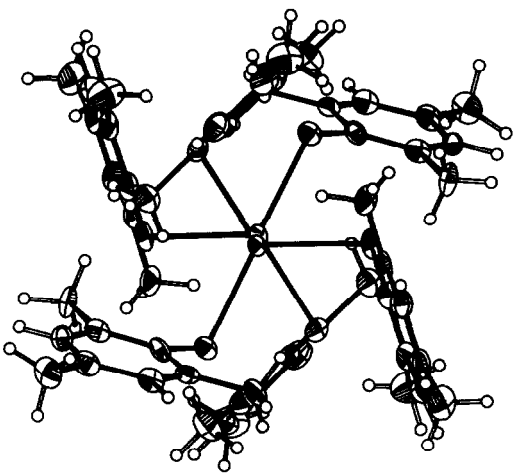

Fig. 2. ORTEP view down the Mo—Mo axis in $Mo_2(SeAr')_6$.

The M—Se distance in $M_2(SeAr')_6$ is (within the 3 σ criteria) the same for Mo and W, 2.43(av.) Å. This M—Se distance is significantly shorter than that observed in the mononuclear $(\eta^7\text{-}C_7H_7)W(CO)_2SePh$ complex, 2.588(2) Å, and the dimeric $(C_6H_7)Mo(\mu\text{-}SePh)_3Mo(CO)_3$ complex, *ca* 2.56 (av.) Å.[6,7] The metal–selenium bond lengths are also shorter than that in the "diselenide complex" $[W_2(CO)_{10}Se_4][SbF_4]_2$, 2.626(2) and 2.631(2) Å,

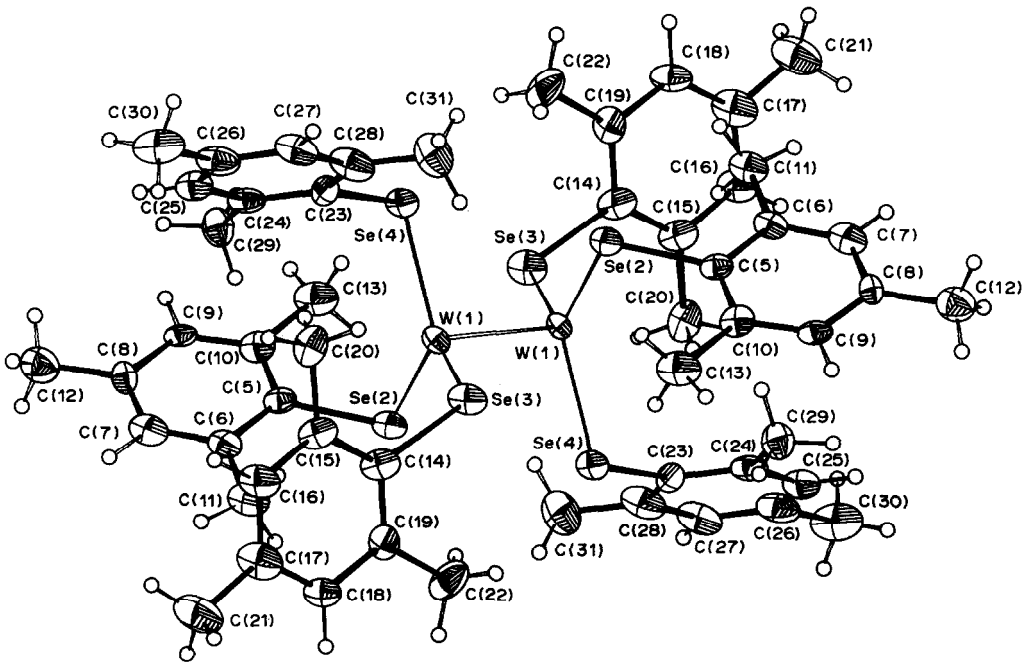

Fig. 1. ORTEP view of $W_2(SeAr')_6$.

respectively.[16] Although these distances are not directly comparable due to differing electronic and steric effects produced by different sets of ligands, the relative shortness of the M—Se bonds in the $M_2(SeAr)_6$ complexes is suggestive of metal–selenium π-bonding. The presence of the methyl groups on the mesitylene ligand probably help to stop bridge formation in the $M_2(SeAr)_6$ complexes.

The M—M—X angles in $M_2(SeAr')_6$ span a small range 96.4–98.2°, and are essentially the same for both the tungsten and molybdenum complexes. These angles are more acute than those in the homoleptic alkyl, amide or alkoxide M_2R_6 complexes, where 100–103° is the normal.[1] The thiolate $M_2(SAr')_6$ complexes[4] have M—M—X angles of comparable magnitude to the selenolate complexes; Mo—Mo—S = 96.6(2)°, W—W—S = 97.4(av.)°. The smaller angles for the selenates and thiolates can be explained in terms of the arrangement of all six mesityl groups, which are distal with respect to the central M—M core. In a typical alkoxide case, e.g. $Mo_2(OCH_2Bu^t)_6$,[1] four groups are distal and two are proximal generating larger and smaller M—M—X angles, with the average angle being larger than the thiolate or selenolate case.

The Mo—Mo distance in $Mo_2(SeAr')_6$ of 2.2176(13) Å is typical of those found in $(Mo{\equiv}Mo)^{6+}$ containing compounds (d = 2.15–2.23 Å) and slightly shorter than the corresponding $Mo_2(SAr')_6$ complex at 2.228(1) Å. The W—W bond in $W_2(SeAr')_6$ is also typical of a $(W{\equiv}W)^{6+}$ moiety at 2.300 Å, and is further significantly shorter (0.012 Å) than the corresponding thiolate analogue.[4]

The M—Se distances are longer (by 0.11 Å) in $M_2(SeAr')_6$ than the M—S bond lengths in $M_2(SAr')_6$ complexes. This is not surprising as selenium has a larger covalent radius than sulphur (1.11 Å compared with 1.02 Å). For the $M_2(SAr')_6$ molecules a case of substantial M—S π-bonding has been forwarded on the basis of the short Mo—S distances observed when compared with the relevant covalent radii.[3] The case for selenium to metal π-bonding can be similarly made, especially since sulphur and selenium have the same electronegativities on the Pauling scale.[20] In general, the covalent radius of selenium is 0.09 Å greater than for sulphur in analogous compounds. The M—S distances in the thiolate analogues $M_2(SAr')_6$ are 0.15 Å shorter than those expected on the basis of covalent radii. This has led to the suggestion of substantial π character in the metal to sulphur bond.[3,4] In the $M_2(SeAr')_6$ species, the M—Se bond lengths are 0.11 Å longer than the sulphur analogue. This indicates that there is a contraction of 0.13 Å in the M—Se bond lengths [0.15+0.09−0.11] in the homoleptic species that may be attributable to the existence of Se-to-M π-bonding. Other reported M—Se bond lengths include 2.512(3) Å in $Sn(SePh)_4$ and 2.727(1) Å in $[Ph_4As][Pb(SePh)_3]$.[11,12]

$M_2(SeAr')_4(O^iPr)_2$

Crystal data for the $M_2(SeAr')_4(O^iPr)_2$ molecules are given in Table 1; selected bond lengths and angles in Table 3. An ORTEP view of the tungsten derivative showing the atom numbering scheme used in the tables is given in Fig. 3, and a stereo-

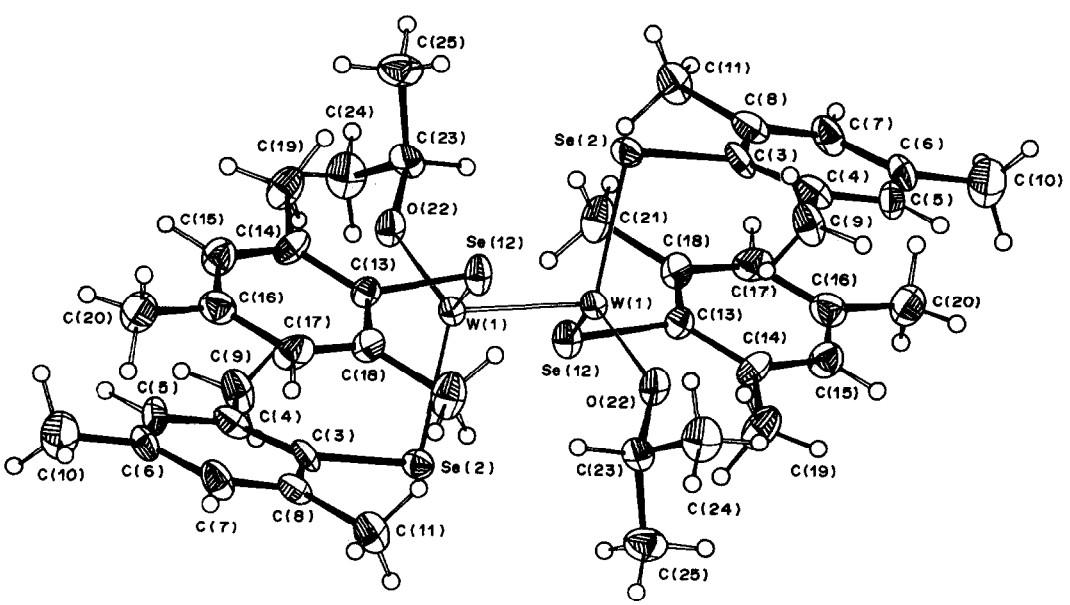

Fig. 3. ORTEP view of $W_2(SeAr')_4(OPr^i)_2$.

[a] Yellow plates.
[b] Orange–red needles.

view of the molecule looking down the Mo—Mo bond axis is given in Fig. 4.

The crystal used for X-ray analysis crystallized from the reaction solution of $W_2(OPr^i)_6(py)_2$ with excess ArScH on standing at room temperature. The molecule has a crystallographically imposed centre of inversion in the space group $P\bar{1}$. The mesityl and isopropyl groups are with respect to the W—W bond distal and proximal, respectively, and the structure is very similar to that adopted by $Mo_2(OPr^i)_2(SAr)_4$.

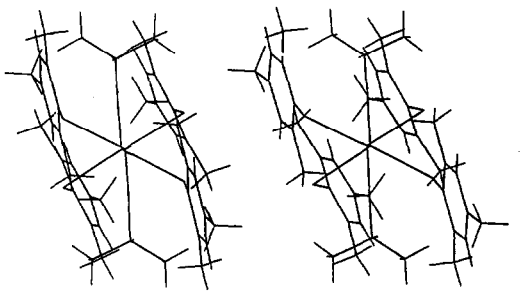

Fig. 4. Stereo-view of $Mo_2(SeAr')_4(OPr^i)_2$ down the Mo—Mo axis.

The crystals of $Mo_2(SeAr')_4(O^iPr)_2$ used for the analysis are crystallized out of the reaction solution of $Mo_2(O^iPr)_6$ with excess (> 6-fold) mesitylene selenol, on cooling the reaction to −20°C after 10 days at room temperature. Two types of crystals were observed from the reaction mixture, yellow plates (10%) and red–orange needles (90%). Both samples were examined crystallographically and found to be $Mo_2(SeAr')_4(O^iPr)_2$. The molecules have a centre of symmetry and were found to be isostructural with each other and the tungsten species $W_2(SeAr')_4(O^iPr)_2$.

The W—W distance of 2.3077(7) Å in $W_2(SeAr')_4(O^iPr)_2$ is typical of a W—W triple bond although slightly longer than the bond length observed in $W_2(SeAr')_6$. The W—Se bond lengths are comparable within the 3σ criteria to those observed in the homoleptic compound. The W—O bond lengths at 1.858(6) Å are slightly shorter than those normally observed in multiple bonded tungsten compounds supported by alkoxide ligands (*ca* 1.94–1.89(av.) Å).[1] This difference is not considered significant as it is comparable to the difference between the bond lengths in $Mo_2(OCH_2{}^tBu)_6$.[1,21]

Thus, the substitution of four alkoxy groups by four areneselenolate ligands has little overall effect on the RO-to-M bonding. As was observed for the homoleptic compounds the W—Se and Mo—Se bond lengths are shorter than expected on the basis of covalent radii, suggestive of Se-to-M π-bonding.

The W—W—O angle at 108.41(17) is close to those observed for other alkoxides. The two W—W—Se angles are significantly different at 93.85(3) and 100.27(3)°, respectively. This pattern was observed for the similar compound $Mo_2(O^iPr)_2(SAr')_4$ which had angles of 95.4(0) and 99.8(0)°.[4]

The Mo—Mo bond distances 2.2192(17) and 2.2180(24) Å in $Mo_2(SeAr')_4(O^iPr)_2$ are normal for triple bonds between molybdenum atoms and equivalent to that in $Mo_2(SeAr')_6$. The other bond lengths and bond angles are essentially the same as those in the tungsten analogue $W_2(SeAr')_4(O^iPr)_2$.

EXPERIMENTAL

All reactions were performed under a nitrogen atmosphere in degassed and distilled solvents. The preparation of $M_2(NMe_2)_6$ (M = Mo, W), $M_2(OR)_6$ (M = Mo, W ; R = $CH_2{}^tBu$)$_3$, ^tBu, ^iPr, ^cHex and $W_2(OR)_6(py)_2$ (R = ^iPr, $CH_2{}^tBu$; L = py, $HNMe_2$) were as previously described.[21-24] Phenyllithium, mesitylene magnesium bromide and selenium metal were purchased from Aldrich Chemical Co. Mesitylene selenol was prepared from the reaction of mesityl Grinard and elemental selenium as described below. ^{1}H NMR spectra were obtained in d^8-THF, $CDCl_3$ or C_6D_6 on a Nicolet 360 spectrometer operating at 360.12 MHz and referenced to internal residual protio THF, chloroform and benzene at 1.73, 7.24 and 7.15 ppm, respectively. Mass spectra were obtained on a Kratos MS450. IR spectra were recorded either as KBr discs or Nujol mulls using a Perkin–Elmer 283 spectrophotometer. Elemental analyses were obtained from Oneida Research Services (Whiteborough, New York).

Mesitylene Selenol

To a solution of mesitylene magnesium bromide (50 cm^3 of 1 M solution in THF) was added over 1 h with stirring grey selenium powder (4.0 g, 50 mmol). The solution was stirred overnight at room temperature with all the selenium dissolving to produce a light-green solution. The solution was hydrolysed by the cautious dropwise addition of water (20 cm^3) followed by 20 cm^3 of 6 N HCl. The upper orange THF layer was collected and dried over anhydrous $MgSO_4$ for 24 h. After filtration from the $MgSO_4$ the THF was removed *in vacuo* to leave a yellow oil (6.8 g, 34.4 mmol, 69%) which was purified by distillation (*ca* 55°C, 1.10^{-4} torr). MS: M^+ = 199; ^{1}H NMR (C_6H_6): δ = 6.67 (s, 2H), 2.18 (s, 6H), 2.04 (s, 3H). IR (KBr plates): 3000br, 2930s, 2900s, 2850sh, 2300w, 1540m, 1435s, 1370m, 1350w, 1270w, 1025s, 870w, 840s, 680s, 540s, 340m cm^{-1}. (Introduction of air helps to provide formation of mesitylene diselenide which crystallizes from the oil on standing.) $(C_6H_2Me_3Se)_2$; MS: M^+ = 396, ^{1}H NMR: δ = 6.69 (s, 4H), 2.31 (s, 12H), 2.03 (s, 6H).

Phenyl Selenol

To a solution of phenyllithium (25 cm^3, 1.8 M solution in cyclohexane–diethyl-ether 80:20) was added THF (5 cm^3) and powdered grey selenium (3.55 g, 0.045 mol). The reaction was stirred for 18 h at room temperature with all the selenium dissolving to give a light-green solution. The solution was hydrolysed by the cautious dropwise addition of water (15 cm^3) (very exothermic reaction), followed by 6 N HCl (15 cm^3). The upper orange layer was decanted and dried over anhydrous $MgSO_4$. Removal of the solvent under vacuum gave selenophenol (4.42 g, 0.27 mmol, 60%), which was purified by distillation at 57°C/8 torr.

[*Caution*: Phenyl and mesitylene selenol are very malodorous and all operations should be performed in a well ventilated hood. The glassware is best cleaned after the reaction by soaking in sodium hypochlorite (4% solution) for 1 day, decanting off the liquid then adding to a KOH–EtOH bath.]

$W_2(SeAr')_6$

$W_2(NMe_2)_6$ (0.100 g, 0.158 mmol) was dissolved in toluene (20 cm^3) at room temperature. Mesitylene selenol (0.250 g, 1.25 mmol) was added dropwise to the stirred solution causing an immediate darkening in colour from yellow to red. The stirring was continued for 5 min then the solution allowed to stand at ambient temperature for 3 days, during which time dark-red–brown crystals of $W_2(SeAr')_6$ (0.154 g, 0.0985 mmol, 62.3%) formed. These were collected by filtration, washed with hexane (20 cm^3) and THF (20 cm$_3$) and air dried. Found: C, 41.7; H, 4.3; N, 0.0. Calc.: C, 42.2; H, 4.2%. IR (KBr disc): 3000m, 2945m, 2895m, 1585w, 1552w, 1520w, 1442vs, 1420vs, 1360m, 1290s, 1161w, 1080w, 1015sh, 1002vs, 940w, 866w, 835vs, 716w, 690w, 554w, 535m, 455w, 400w, 325sh, 315m, 245s cm^{-1}. M.p. = 162–164°C, decomp. These crystals were suitable for X-ray analysis as described below.

$Mo_2(SeAr')_6$

Mesitylene selenol (0.40 g, 2.01 mmol) was dissolved in toluene–hexane (10 : 10 cm^3) and stirred for 0.5 h at room temperature. Solid $Mo_2(NMe_2)_6$ (0.100 g, 0.122 mmol) was added to produce an immediate colour change in the solution to dark-red and after 10 min with stirring, to dark-brown with a red precipitate. The mixture was stirred overnight and the solid collected by filtration and washed with hexane (20 cm^3), THF (30 cm^3), toluene (20 cm^3) and diethyl-ether (20 cm^3); $Mo_2(SeAr')_6$ (0.186 g, 0.134 mmol, 61%). IR (KBr disc): 3000m, 2960m, 2900m, 2840m, 1708w, 1588w, 1552w, 1535w, 1520w, 1442vs, 1430vs, 1390sh, 1368s, 1290s, 1162m, 1080w, 1016s, 1002vs, 940m, 865m, 838vs, 716m, 690s, 556m, 540s, 460w, 410w, 331m, 320sh, 285vs cm^{-1}. M.p. 168–172°C, decomp. Found: C, 46.9; H, 4.7; N, 0.0. Calc. for $Mo_2(SeAr')_6$: C, 47.0; H, 4.8%.

Alternative procedure 1. To a solution of $Mo_2(OBu^t)_6$ (0.100 g, 0.159 mmol) in toluene (20 cm^3) at room temperature was added excess mesitylene selenol (0.25 g, 1.26 mmol). The solution was stirred for 5 min, causing an intense dark-red colour. This was allowed to stand at room temperature for 5 days to produce dark-red crystals of $Mo_2(SeC_6H_2(CH_3)_3)_6$ (0.148 g, 0.107 mmol, 67%). Found: C, 47.7; H, 4.8; N, 0.0. Calc.: C, 47.0; H, 4.8%. IR and melting points were identical to the compounds made above. The crystals were of X-ray quality and the structure was determined as outlined above.

The reaction can also be repeated with the same procedure, reaction scale and conditions, but using $Mo_2(OCH_2{}^tBu)_6$ instead of $Mo_2(OBu^t)_6$ to give $Mo_2(SeAr')_6$ (0.095 g, 0.068 mmol, 43%).

Alternative procedure 2. To a solution of $Mo_2Cl_2(NMe_2)_4$ (0.035 g, 0.08 mmol) in toluene (35 cm^3) at room temperature was added mesitylene selenol (0.20 g, 1.00 mmol) to generate a dark-red coloured solution. The solution was stirred for 5 min and then left to stand overnight (10 h) to produce brown–red crystals. The crystals were filtered and washed with THF (10 cm^3), ethanol (15 cm^3), toluene (15 cm^3) and diethyl-ether (10 cm^3); $Mo_2(SeAr')_6$ (0.035 g, 0.025 mmol, 33%). Found: C, 47.5; H, 4.7; N, 0.10. Calc.: C, 47.0; H, 4.8%.

$W_2(SeAr')_4(O^iPr)_2$

Solid $W_2(OPr^i)_6(py)_2$ (0.100 g, 0.114 mmol) was added to a stirred solution of mesitylene selenol (0.40 g, 2.0 mmol) in toluene (20 cm^3) at room temperature generating a dark-red solution. The solution was stirred by a magnetic follower for 10 min and then allowed to stand for 3 days at room temperature. This produced red crystals of $W_2(SeAr')_4(O^iPr)_2$ (0.068 g, 0.077 mmol, 67%) which were collected by filtration and washed with pentane (20 cm^3) and THF (20 cm^3). Found: C, 39.5; H, 4.5; N, 0.0. Calc.: C, 39.4; H, 4.5%. IR (KBr disc): 3000w, 2945m, 2895m, 2845sh, 1580w, 1560w, 1430vs, 1410s, 1380sh, 1362m, 1350m, 1310m, 1380m, 1150m, 1090s, 1005s, 960vs, 845m, 832s, 710m, 695w, 600m, 550w, 530w, 460m, 440m cm^{-1}. M.p. 135°C darkens, does not melt below 360°C. ^1H NMR at 22°C in $CDCl_3$: $\delta = 6.85$ (s, 8H), 4.03 (br, 2H), 2.35 (s, 24H), 2.24 (s, 12H), 1.28 (s, 12H).

$W_2(SeAr')_4(OCH_2{}^tBu)_2$

Solid $W_2(OCH_2{}^tBu)_6(py)_2$ (0.091 mg, 0.087 mmol) was added to a stirred solution of mesitylene selenol (0.20 g, 1.00 mmol) in toluene (20 cm^3) at room temperature to form a dark-red solution. The solution was allowed to stand at room temperature for 8 days and then cooled to −20°C for 3 days to produce red crystals of $W_2(SeAr')_4(OCH_2{}^tBu)_2$ (0.040 g, 0.29 mmol, 33%). IR (KBr disc): 3000w, 2940s, 2900m, 2840s, 1455s, 1435m, 1385m, 1365m, 1355m, 1285m, 1170w, 1030vs, 940w, 930w, 860w, 840s, 745w, 725m, 685vs, 605w, 605w, 550w, 535w, 460w, 445w, 410w, 390w, 310w, 270w cm^{-1}. ^1H NMR at 22°C ($CDCl_3$): $\delta = 6.85$ (s, 8H), 3.33 (s, 4H), 2.31 (s, 24H), 2.24 (s, 12H), 0.84 (s, 18H).

$W(O^tBu)_2(SeAr')_4$

Mesitylene selenol (0.20 g, 1.0 mmol) was added dropwise to a stirred solution of $W_2(O^tBu)_6$ (0.050 g, 0.062 mmol) in THF (10 cm^3) at room temperature. This caused an immediate darkening of the solution to dark red. The mixture was allowed to stand at room temperature for 2 weeks and then cooled to −20°C for 30 days. This produced lustrous red crystals of $W_2(O^tBu)_2(SeAr')_4$ which were obtained by decanting the solution and washing with hexane (5 cm^3), toluene (5 cm^3) and THF (5 cm^3) (0.021 g, 0.016 mmol, 26%). ^1H NMR at 26°C (C_6D_6): $\delta = 6.68$ (s, 8H), 2.182 (s, 24H), 2.042 (s, 12H), 1.036 (s, 18H). IR (KBr disc): 2958s, 2900sh, 1450s, 1365m, 1351m, 1288w, 1225m, 1150s, 1010s, 960vs, 900w, 835s, 690w, 600w, 540s, 460s, 410s, 390s, 315w, 270s cm^{-1}. Found: C, 40.6; H, 4.4; N, 0.0. Calc.: C, 40.5; H, 4.7%.

$Mo_2(SeAr')_4(O^cHex)_2$

Mesitylene selenol (0.20 g, 1.00 mmol) was added dropwise with stirring to a slurry of $Mo_2(O^cHex)_6$ (0.05 g, 0.064 mmol) in toluene (20 cm^3). The solu-

tion turned dark red, and after 10 min with stirring all the $Mo_2(O^cHex)_6$ has reacted and dissolved. The solution was allowed to stand at room temperature for 24 h, during which time red crystals were precipitated. The crystals were collected by filtration and washed with hexane (10 cm^3) and toluene (10 cm^3) to give $Mo_2(SeAr')_4(O^cHex)_2$ (0.026 g, 0.21 mmol, 33%). IR (KBr disc): 3000m, 2920s, 1595w, 1560w, 1440s, 1400w, 1370m, 1350m, 1335w, 1290m, 1245w, 1230w, 1160w, 1140w, 1080w, 1035vs, 1005vs, 965s, 945m, 880w, 860w, 840vs, 790s, 720w, 700vs, 630sh, 600w, 555w, 540w, 500w, 460w, 450w, 410w, 375w, 345w, 330w, 315w, 295m, 274w, cm^{-1}. ^1H NMR at 25°C (C_6D_6): $\delta = 6.54$ (s, 8H), 2.24 (s, 24H), 2.15 (s, 12H), 1.6 (br, 10H), 0.85 (br, 12H).

$Mo_2(SeAr')_4(O^iPr)_2$

$Mo_2(O^iPr)_6$ (0.050 g, 0.092 mmol) was dissolved in toluene (20 cm^3) at room temperature to generate an orange solution. Mesitylene selenol (0.30 g, 1.5 mmol) was added dropwise with stirring generating a dark-red colour in solution. The mixture was allowed to stand at room temperature for 3 days and then cooled to −20°C for 2 days to produce a mixture of red needles (90%) and yellow plates (10%), both of which were $Mo_2(O^iPr)_2(SeAr')_4$ (0.035 g, 0.032 mmol, 35%). The crystals were collected by decanting the solution and washing with 10 cm^3 of both pentane and diethyl-ether. The filtrate was combined with pentane (10 cm^3) and cooled to −20°C to produce a fine orange–red precipitate of $Mo_2(O^iPr)_2(SeAr')_4$ (0.015 g, combined yield 45%). Found: C, 46.2; H, 4.7; N, 0.0. Calc.: C, 45.7; H, 5.3%. ^1H NMR (C_6D_6): $\delta = 6.93$ (s, 2H), 6.89 (s, 4H), 6.86 (s, 2H), 4.07 (scpt, 2H), 2.41 (s, 6H), 2.32 (s, 6H), 2.29 (s, 12H), 1.29 (d, 12H). IR (KBr disc): 2995m, 2942s, 2895s, 2835m, 1580w, 1445s, 1425s, 1360m, 1350m, 1310m, 1275m, 1160w, 1150m, 1115m, 1090s, 1020m, 1004m, 960vs, 835s, 720w, 690w, 600m, 550w, 535w, 460m, 440m, 330w, 290s cm^{-1}.

$M_2(NMe_2)_4(SeAr')_2$ (M = Mo, W)

Mesitylene magnesium bromide (0.46 cm^3, 1 M soln in THF) was added to THF (10 cm^3) at room temperature. Solid elemental grey selenium (0.36 g, 0.46 mmol) was added and the mixture stirred for 0.5 h until all the selenium had dissolved leaving a clear colourless solution. Solid $Mo_2Cl_2(NMe_2)_4$ (0.100 g, 0.27 mmol) was added and the solution rapidly stirred for 1 min, generating a clear yellow solution. The solution was allowed to stand overnight producing yellow needle-like crystals. The solution was filtered and the crystals washed with *n*-pentane (10 cm^3) and diethyl-ether (10 cm^3) to give $Mo_2(SeAr')_2(NMe_2)_4$, (0.060 g, 0.086 mmol), 32%). The filtrate was cooled to −20°C to produce a second crop (0.012 g, 0.0156 mmol overall yield 38%). The crystals were air sensitive and insoluble in hexane, acetone, THF and water. IR (Nujol mull) 1440sh, 1380w, 1233m, 1125m, 1028m, 1010m, 940vs, 937vs, 837m, 710w, 695w, 650w, 550m, 540m, 460w, 440w, 335m. ^1H NMR (C_6D_6): $\delta = 6.79$ (s, 4H), 4.38 (br, 12H), 2.54 (s, 12H), 2.09 (br, 18H). Analogous reaction conditions and reaction scale gave for tungsten; $W_2(SeAr')_2(NMe_2)_4$ (yield 0.061 g, 0.065 mmol). IR (Nujol mull): 1440sh, 1380w, 1335m, 1160w, 1130m, 1110m, 1060m, 1030m, 1010m, 945vs, 840m, 710m, 695m, 550m, 540m, 380w, 340 cm^{-1}. ^1H NMR (C_6D_6): $\delta = 6.82$ (s, 4H), 4.38 (br, 12H), 2.54 (s, 12H), 2.13 (br, 18H). Found: C, 33.2; H, 4.4; N, 4.9. Calc.: C, 33.2; H, 4.9; N, 5.9%.

Reactions involving selenophenol with $M_2(NMe_2)_6$ *and* $M_2(OR)_6$ *compounds* (M = Mo, W)

Molybdenum

To $Mo_2(NMe_2)_6$ (0.05 g, 0.11 mmol) dissolved in toluene (10 cm^3) was added selenophenol (0.25 g, 0.15 mmol), generating a purple colour in solution and a purple precipitate. The reaction was allowed to stand at room temperature for 3 days, and the purple precipitate isolated by filtration, washed with THF (5 cm^3), hexane (5 cm^3) and toluene (5 cm^3). The solid (0.076 g) was insoluble in common solvents, air-stable and seemingly inert to hydrolysis. Found: C, 35.2; H, 2.6; N, 0.7. Calc. for $[Mo_4(SePh)_{10}Se_2]H_2NMe_2$: C, 34.7; H, 2.9; N, 0.6%. IR (KBr disc): 3020br, 2920m, 2700m br, 2400m br, 1550m, 1530m, 1460m, 1450m, 1425m, 1370m, 1310w, 1285w, 1240w, 1165w, 1140w, 1090w, 1055m, 1005m, 1005s, 990m, 930w, 875m, 835m, 800w, 725s, 680s, 655m, 600sh, 550sh, 510sh, 455m, 410w, 395w, 340w, 310w, 295w cm^{-1}. [Reaction of $Mo_2(O^tBu)_6$ with selenophenol under the same conditions produces a purple solid which has similar IR bands to the above save no stretch at 2700, 2400 and 1450 cm^{-1}, but stretches at 1630 and 3200 cm^{-1}.]

Tungsten

To $W_2(NMe_2)_6$ (0.050 g, 0.08 mmol) dissolved in toluene (10 cm^3) at room temperature was added selenophenol (0.25 g, 1.59 mmol). This produced an intermediate darkening of the solution to red.

After 1 day at room temperature a black precipitate is produced, which was collected by filtration (after 3 days), washed with hexane (10 cm^3), toluene (10 cm^3) and diethyl-ether (15 cm^3). The precipitate is slightly soluble in THF, air-stable and seemingly inert to hydrolysis. Found: C, 27.7; H, 1.7; N, 0.6. Calc. for $[W_4(SePh)_{10}Se_4]H_2NMe_2$: C, 28.0; H, 2.1; N, 0.5%. IR (KBr disc): 3020br, 2920m, 2650m br, 2310m br, 1550m, 1530m, 1460m, 1450m, 1425m, 1370m, 1310w, 1285w, 1240w, 1165w, 1140w, 1090w, 1055m, 1005m, 1005s, 990m, 930w, 875m, 835m, 8002, 725s, 680s, 655m, 600sh, 550sh, 510sh, 455m, 410w, 395w, 340w, 310w, 295w cm^{-1}. Reaction involving $W_2(O^iPr)_6 \cdot (HNMe_2)_2$ with selenophenol under the same conditions gave the same product.

X-Ray Structure Determinations

General operating facilities, procedures and programmes have been previously described.[25] A summary of the crystal data is given in Table 1.

$W_2(SeAr')_6$

A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques employed by the IUMSC and cooled to -155°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located no symmetry or systematic absences, indicating a triclinic space group. Subsequent solution and refinement of the structure confirmed the centrosymmetric choice, $P\bar{1}$.

Data were collected in the usual manner using a continuous θ–2θ scan with a fixed background. Data were reduced to a unique set of intensities and associated σ in the usual manner. The structure was solved by a combination of direct methods (MULTAN 78) and Fourier techniques. A different Fourier synthesis revealed some but not all, hydrogen atoms. All hydrogen atoms positions were therefore calculated using idealized geometries and d(C—H) = 0.95 Å. These calculated positions were fixed for the final cycles of refinement.

Data were corrected for absorption. A final difference Fourier was featureless, with the largest peak being 1.19 e/Å^3 at the metal site.

As shown in the figures and tables, the molecule lies at a crystallographic centre of inversion.

$Mo_2(SeAr')_6$

Mounting and cooling were performed identically to the tungsten analogue.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with no symmetry or systematic absences, indicating a triclinic space group. The morphology was essentially the same as the tungsten analogue, and examination of the reciprocal space revealed that the structures are indeed isomorphous.

Data were collected in the usual manner using a continuous θ–2θ scan with a fixed background. Data were reduced to a unique set of intensities and associated σ in the usual manner. The heavy atom coordinates from the tungsten analogue were used as a starting point for the refinement. All hydrogen atoms were clearly visible in a difference Fourier synthesis phased on the non-hydrogen parameters. All hydrogen atoms were refined isotropically and non-hydrogen atoms anisotropically in the final cycles.

A final difference Fourier was featureless, with the largest peak being 0.45 e/Å^3. No absorption correction was performed.

$W_2(O^iPr)_2(SeAr')_4$

A crystal of suitable size was mounted using silicon grease and was transferred to a goniostat where it was cooled to -155°C for characterization and data collection. A search of limited hemisphere of reciprocal space revealed no symmetry or systematic absences. An initial choice of space group $P\bar{1}$ was confirmed by the successful solution of the structure. Following intensity data collection and correction for absorption, data processing gave a residual of 0.010 for 145 unique intensities which had been measured more than once. Four standards measured every 300 data showed no significant trends.

The structure was solved by a combination of direct methods (MULTAN 78) and Fourier techniques. The tungsten and selenium positions were obtained from an E-map. Subsequent iterations of least-squares refinement and different Fourier revealed all of the remaining non-hydrogen atoms. Hydrogen atoms were placed in fixed calculated positions to improve the refinement of the non-hydrogen atoms. Hydrogen thermal parameters were fixed at one plus the isotropic thermal parameter of the atom to which they were bonded.

In the final cycles of refinement all non-hydrogen atoms were refined with anisotropic thermal parameters to a final $R(F) = 0.033$. The final difference map was reasonably clean. There were heavy atom residuals of 0.81–1.67 e/Å^3. All other residual peaks were 0.76 e/Å^3 or less. The centre of the molecule is at a crystallographic centre of symmetry.

$Mo_2(O^iPr)_2(SeAr')_4$

The sample consisted of reddish-orange needles and a minor component (estimated 10%) of yellow plate-like crystals. Both components were examined and transferred to the gonistat where they were cooled to $-155°C$ for characterization and data collection. For the major component a systematic search of limited hemispherical reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to a monoclinic space group. It was later discovered that an *A*-centring was present, the system was not reindexed, leading to the choice of $A2/a$ (standard setting $C2/c$).

Data were collected using a continuous θ–2θ scan with fixed background. Data were reduced to a unique set of intensities and associated σ in the usual manner. The structure was solved by a combination of direct methods (MULTAN 78) and Fourier techniques. A different Fourier synthesis revealed the location of some but not all hydrogen atoms. All hydrogen atoms were assigned idealized geometries d(C—H) = 0.95 Å. These calculated positions were fixed for the final cycles of refinement. The structure is essentially the same as the tungsten complex above.

The minor component (yellow plates) was also isostructural with the major component (orange–yellow needles). A structure analysis using the same procedure as above was based on a triclinic unit cell with $P\bar{1}$ symmetry.

Department of Inorganic Chemistry, The University of Bristol, Bristol BS8 1TS, U.K.

(*Received* 21 *June* 1990; *accepted* 10 *August* 1990)

Abstract—The complex $[MoW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_2B_9H_{10}Me)]$ reacts with diazomethane in Et_2O containing EtOH to afford the dimetal compound $[MoW(OEt)(\mu\text{-}CH_2)\{\mu\text{-}C(C_6H_4Me\text{-}4)C(Me)O\}(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_2B_9H_{10}Me)]$. The structure of this product was established by X-ray diffraction. The Mo—W bond [2.778(4) Å] is bridged by a CH_2 group [μ-C—Mo 2.14(3), μ-C—W 2.02(3) Å] and by a $C(C_6H_4Me\text{-}4)C(Me)O$ fragment [Mo—O 2.11(3), W—O 2.18(2), Mo—$C(C_6H_4Me\text{-}4)$ 2.41(3), W—$C(C_6H_4Me\text{-}4)$ 2.09(3), Mo—C(Me) 2.26(3) Å]. The molybdenum atom is η^7-coordinated by the C_7H_7 ring and the tungsten atom is η^5-coordinated by the open pentagonal face of the *nido*-icosahedral $C_2B_9H_{10}Me$ cage. The tungsten atom also carries a terminally bound OEt group [W—O 1.88(3) Å]. The ^1H and $^{13}C\text{-}\{^1H\}$ NMR data for the dimetal compound are reported and discussed.

As part of a continuing study[1] of the ligating properties of the C≡W bonds in the salts $[X][W(\equiv CR)(CO)_2(\eta^5\text{-}C_2B_9H_9R'_2)]$ [X = $N(PPh_3)_2$, NEt_4 or PPh_4; R = alkyl, aryl or alkynyl; R′ = H or Me] we have recently prepared the electronically unsaturated 32 valence electron dimetal complex $[MoW(\mu\text{-}CC_6H_4Me\text{-}4)(CO)_2(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_2B_9H_{10}Me)]$ (**1**) by treating $[NEt_4][W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta^5\text{-}C_2B_9H_{10}Me)]$ with $[Mo(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)][BF_4]$ in CH_2Cl_2.[2] Compound **1** reacts with $PHPh_2$ to afford $[MoW(\mu\text{-}PPh_2)\{\mu\text{-}C(OH)C(C_6H_4Me\text{-}4)\}(CO)(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_2B_9H_{10}Me)]$ (**2**), a complex having a very unusual structure.[3] In further studies on the reactivity of species of type **1** with nucleophilic reagents, we report herein a novel dimetal compound resulting from the reaction between **1** and diazomethane. We have previously shown that the latter reagent readily adds CH_2 groups to heteronuclear dimetal compounds with bridging alkylidyne groups, but having cyclopentadienyl $\eta^5\text{-}C_5R_5$ (R = H or Me) ligands attached to the Mo or W centres instead of an $\eta^5\text{-}C_2B_9$ cage, as in **1**.

RESULTS AND DISCUSSION

Treatment of a Et_2O solution of **1** with an excess of CH_2N_2 resulted in an immediate colour change of the solution from red to orange–brown. Column chromatography of the mixture on alumina removed several products formed in such trace amounts that they could not be identified. However, continued elution of the column led to the recovery of significant amounts of an orange crystalline solid **3**. Although the IR and NMR data for this species did not allow structural characterization, nevertheless it was apparent that an unusual compound had formed. Thus the IR spectrum revealed the absence of any CO groups. Moreover, the ^1H and $^{11}B\text{-}\{^1H\}$ NMR spectra showed that no B—H→Mo bridge-bond was present, as occurs in the precursor **1**. The $^{13}C\text{-}\{^1H\}$ NMR spectrum displayed no resonances attributable to CO ligands nor to a μ-C alkylidyne carbon-nucleus, although peaks were observed indicating that the C_7H_7 ring and the $C_2B_9H_{10}Me$ cage were present. An X-ray diffraction study on the complex **3** was evidently necessary. Although the crystals were twinned, it was possible to establish the structure, and in this manner **3** was identified as the dimetal compound $[MoW(OEt)(\mu\text{-}CH_2)\{\mu\text{-}C(C_6H_4Me\text{-}4)C(Me)O\}(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_2B_9H_{10}Me)]$.

Selected bond distances and angles are listed in Table 1, and the molecule is shown in Fig. 1. The Mo—W bond [2.778(4) Å] is bridged by a CH_2 group [Mo—C(40) 2.14(3), W—C(40) 2.02(3) Å], and also by a $C(C_6H_4Me\text{-}4)C(Me)O$ fragment. The oxygen atom of the latter is bonded to both metal centres [Mo—O(2) 2.11(3), W—O(2) 2.18(2) Å], as is the carbon atom C(30) of the $C(C_6H_4Me\text{-}4)$ group [Mo—C(30) 2.41(3), W—C(30) 2.09(3) Å]. However, the carbon atom C(20) of the CMe moiety is linked only to the molybdenum [Mo—C(20) 2.26(3) Å]. As expected, the latter carries the C_7H_7 ring, while the carbaborane cage is η^5-coordinated via its open pentagonal face to the tungsten atom. Unexpectedly, the tungsten is bonded to an OEt group. The W—O(1) distance [1.88(3) Å] is appreciably shorter than the W—O(2) separation, implying a degree of multiple bonding in the former linkage, as depicted in the structural formula for **3** displayed, with the ligand functioning formally as a three-electron donor. The electron contributions from the various ligands, as well as the presence of the metal–metal bond, allow both metal centres to acquire filled 18 electron shells, so that the compound is electronically saturated with 34 valence electrons.

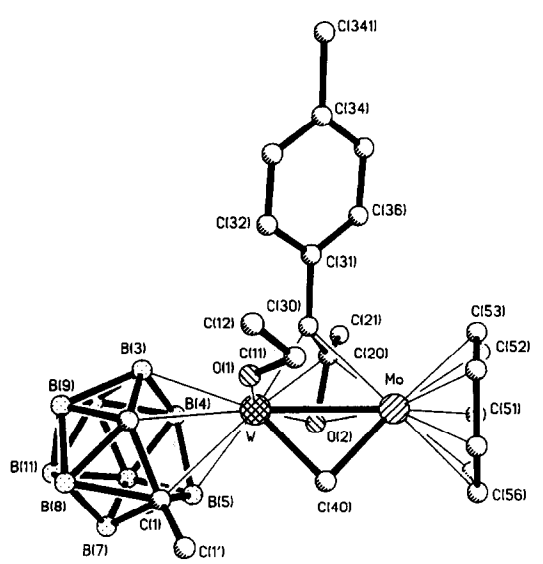

Fig. 1. The molecular structure of $[MoW(OEt)(\mu\text{-}CH_2)\{\mu\text{-}C(C_6H_4Me\text{-}4)C(Me)O\}(\eta^7\text{-}C_7H_7)(\eta^5\text{-}C_2B_9H_{10}Me)]$ (**3**) showing the atom-numbering scheme.

The origin of the ethoxy group in compound **3** derives from ethanol used in the generation of diazomethane (see Experimental section). In an attempt to increase the yield of **3**, typically *ca* 15%, ethanol was added to the reaction mixture, but this produced no advantageous result. Having established the molecular structure of complex **3**, it was possible to interpret satisfactorily all the NMR data.

The $^{11}B\text{-}\{^1H\}$ NMR spectrum showed seven peaks at δ 4.2, 1.1, −6.7, −7.9, −8.8, −10.1 and −14.2 ppm. The signals at −8.8 and −10.1 ppm each corresponded in intensity to two boron nuclei, while each of the remaining resonances was of an intensity expected for one boron nucleus. The peaks at δ 4.2 and 1.1 ppm became doublets [J(BH) 130 Hz] in a fully-coupled ^{11}B NMR spectrum, confirming that they are attributable to BH groups with two-centre two-electron bonds. The fully-coupled ^{11}B spectrum was measured because the observed chemical shifts at 4.2 and 1.1 ppm fall into the region where signals due to exo-polyhedral three-centre two-electron B—H→Mo groups are often seen. However, in a fully-coupled ^{11}B NMR spectrum these groups, if present, have resonances with $^1H—^{11}B$ couplings of *ca* 80 Hz, e.g. for compound **1** the B—H→Mo signal is at δ 11.7 ppm, with J(BH) 77 Hz.[2]

The ^1H and $^{13}C\text{-}\{^1H\}$ NMR spectra of complex **3** are also in agreement with the structure revealed by X-ray diffraction. In the ^1H spectrum the signal for the $\mu\text{-}CH_2$ group occurs as an AB pattern at δ 5.64 and 5.77 with J(AB) 10 Hz, while in the $^{13}C\text{-}\{^1H\}$ spectrum the resonance for the $\mu\text{-}CH_2$ ligand is at δ 147.9 ppm, and shows $^{183}W—^{13}C$ satellite peaks [J(WC) 40 Hz]. Compounds with metal–metal bonds bridged by methylene groups commonly have ^{13}C resonances in the range δ 100–200 ppm,[5] and thus complex **3** is no exception.

The $^{13}C\text{-}\{^1H\}$ NMR spectrum of compound **3** shows the expected signals for all the other groups

Table 1. Selected bond distances (Å) and angles (°) for the complex [MoW(OEt)(μ-CH$_2$){μ-C(C$_6$H$_4$Me-4)C(Me)O}(η^7-C$_7$H$_7$)(η^5-C$_2$B$_9$H$_{10}$Me)] (**3**)

present. Thus diagnostic resonances for the cage-carbon nuclei of the carbaborane ligand occur at δ 77.1 (CH) and 62.9 ppm (*C*Me), both peaks being broad due to unresolved ^{11}B—^{13}C coupling. Signals for the ethoxide ligand occur at δ 78.7 (OCH_2) and 17.1 ppm (OCH_2*Me*). A specific assignment of peaks for the CMe moiety of the C(C_6H_4Me-4)*C*(*Me*)O fragment is not possible since they occur with the resonances for the C_6H_4Me-4 group. Thus signals at 138.2 and 138.0 ppm are ascribed to one or other of the C^4(C_6H_4) and *C*(Me)O nuclei, and a pair of resonances at δ 21.6 and 21.2 ppm can be assigned to the C(*Me*)O and Me-4 groups. The resonance for the C*Me* group of the carbaborane ligand is seen at δ 32.1 ppm, a characteristic chemical shift for such a group. Remaining resonances in the ^{13}C-{^1H} NMR spectrum of **3** are observed at 164.5 [C^1(C_6H_4)], 129.7, 129.2 (C_6H_4), 128.5 (*C*C_6H_4Me-4) and 90.8 ppm (C_7H_7). These assignments correlate with those observed for these groups in earlier work.

The μ-C(C_6H_4Me-4)C(Me)O fragment present in compound **3** has been found previously in the complexes [WMn{μ-C(C_6H_4Me-4)C(Me)O}(CO)$_5$(η-C_5H_5)] (**4**) and [MoW{μ-C(C_6H_4Me-4)C(Me)O}(CO)$_4$(η-C_5H_5)$_2$] (**5**).[6] The bridge bonding in **3**, with the oxygen atom linked to both metal centres, is similar to that present in **4**. In contrast, in complex **5** the C(Me)O moiety is η^2-coordinated to the tungsten atom, and there is no Mo—O bond.

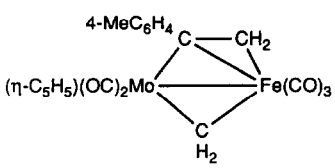
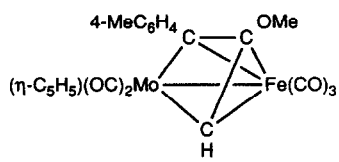
(5)



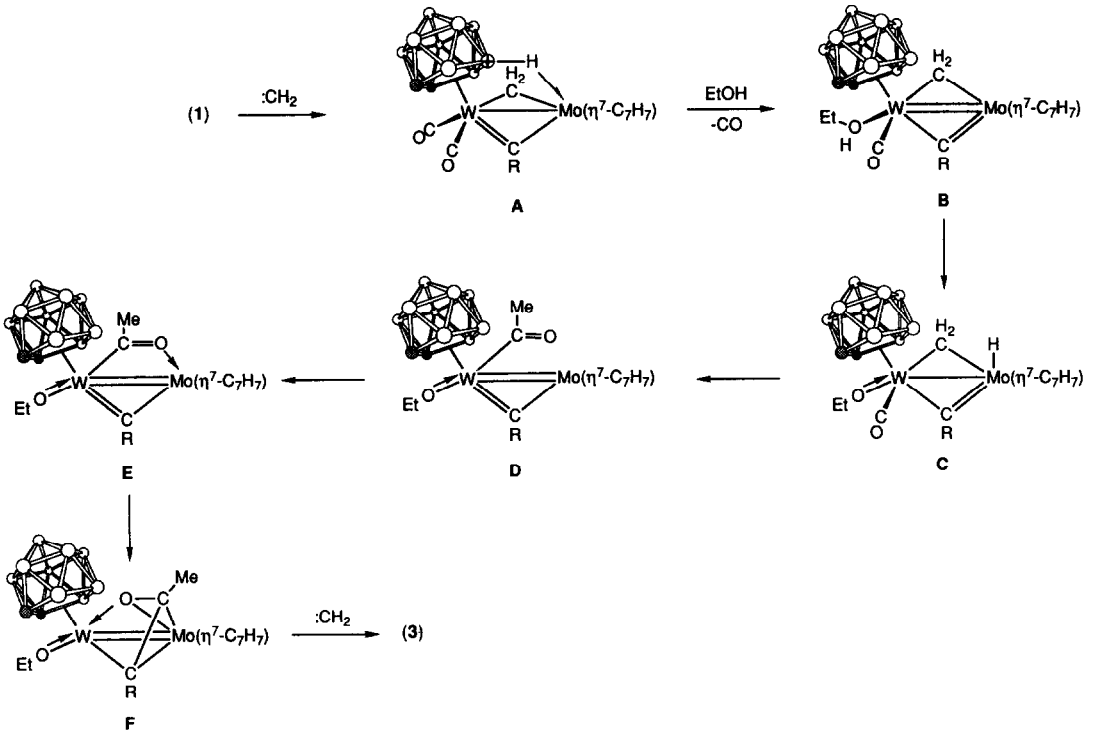
(6)



(7)

Compounds **4** and **5** are obtained from reactions between [W(≡CC_6H_4Me-4)(CO)$_2$(η-C_5H_5)] and [MnMe(CO)$_5$] and [MoMe(CO)$_3$(η-C_5H_5)], respectively. Both species result from a coupling of the *p*-tolylmethylidyne group in the tungsten reagent with an acyl group, very probably generated at the manganese or molybdenum centres. The formation of the μ-C(C_6H_4Me-4)C(Me)O ligand in **3** is clearly complex and must involve several steps; thereby accounting both for the relatively low yield and the observation of trace amounts of unidentified products. The synthesis of **3** from **1** requires reaction of the latter with two CH_2 fragments in a stepwise fashion. A double addition of methylene groups is unusual, but there is precedent in the formation of the compounds [MoFe(μ-CH_2){μ-σ:η-C(C_6H_4Me-4)=CH_2}(CO)$_5$(η-C_5H_5)] (**6**) and [MoFe{μ-C(C_6H_4Me-4)C(OMe)CH}(CO)$_5$(η-C_5H_5)] (**7**) from [MoFe(μ-CC_6H_4Me-4)(CO)$_6$(η-C_5H_5)] and CH_2N_2.[4c] Some possible intermediates in the synthesis of **3**, modelled on earlier work, are shown in Scheme 1.

As mentioned earlier, compound **1** is electronically unsaturated, and intermediate **A** is therefore reasonable based on the known facile addition of CH_2 groups across the metal–metal bonds of many such species.[4,5,7–11] The transformation from **A** into **B** involves a lifting of the B—H→Mo bond, concomitant with coordination of an ethanol molecule at the tungsten centre. The ability of η^5-C_2B_9 cage-systems to adopt either a spectator rôle as in **B** or a non-spectator rôle as in **A**, thereby filling a dual rôle as either a four- or a six-electron donor at a dimetal centre, is well established.[1–3] The oxidative addition of ethanol at a dimetal centre, step **B** to **C**, so as to generate a molecule with the elements (EtO)W—Mo(H) has ample precedent in the work of Chisholm *et al.*[12] on the reactions of the compounds [1,2-M_2R_2(NMe_2)$_4$] (M = Mo or W, R = alkyl) with alcohols. Intermediate **C** would



Scheme 1. R = C$_6$H$_4$Me-4; ○BH, ◎CH, ●CMe, ⊕ B.

readily generate a Me group,[8] and the latter by migrating to a molecule of CO could afford the acyl species **D**. The final steps **D** → **E** → **F** involve the acyl ligand adopting a μ-η^2 bonding mode,[13] followed by coupling with the *p*-tolylmethylidyne fragment, as observed previously.[6] Several of the postulated steps in the reaction scheme require transformations between structures with multiple or single metal–metal bonds. We have encountered this process in the reactions of alkynes at dimolybdenum centres,[14] and it probably results from a need for the metal atoms to attain where possible a filled 18-electron valence shell, as implied by some of the intermediates depicted in Scheme 1.

EXPERIMENTAL

Solvents were rigorously dried before use, and all reactions were carried out in Schlenk tubes under oxygen-free nitrogen. Alumina used for chromatography was BDH aluminium oxide (Brockman activity II). The compound [MoW(μ-CC$_6$H$_4$Me-4)(CO)$_2$(η^7-C$_7$H$_7$)(η^5-C$_2$B$_9$H$_{10}$Me)] (**1**) was prepared as previously described.[2] The NMR measurements were made with JEOL JNM GX270 and GX400 spectrometers. The ^{11}B-{^{1}H} NMR chemical shifts are positive to high frequency of BF$_3$·Et$_2$O (external).

Synthesis of the complex [MoW(OEt)(μ-CH$_2$){μ-C(C$_6$H$_4$Me-4)C(Me)O}(η^7-C$_7$H$_7$)(η^5-C$_2$B$_9$H$_{10}$Me)]

A solution of compound **1** (0.20 g, 0.30 mmol) in Et$_2$O (10 cm^3) was treated with an excess of CH$_2$N$_2$ [*ca* 10 mmol in Et$_2$O (10 cm^3), generated using an Aldrich Chemical Co. Diazald kit which employs an EtOH–H$_2$O–Et$_2$O mixture as solvent]. Following addition of CH$_2$N$_2$, the red solution immediately became orange–brown in colour. Solvent was removed *in vacuo*, and the residue was dissolved in a mixture of CH$_2$Cl$_2$–hexane (*ca* 5 cm^3, 2 : 1) and chromatographed (column 2 × 25 cm). Elution with CH$_2$Cl$_2$–hexane (1 : 4) removed traces of inseparable fractions. Continued elution and increasing the concentration of CH$_2$Cl$_2$ removed an orange band. Evaporation of solvent *in vacuo* followed by crystallization of the residue from CH$_2$Cl$_2$–hexane (1:4) afforded orange microcrystals of [MoW(OEt)(μ-CH$_2$){μ-C(C$_6$H$_4$Me-4)C(Me)O}(η^7-C$_7$H$_7$)(η^5-C$_2$B$_9$H$_{10}$Me)] (**3**) (0.032 g, 15%) (Found: C, 38.7; H, 6.0%. C$_{23}$H$_{37}$B$_9$MoO$_2$W requires C, 38.2; H, 5.2%). NMR (in CD$_2$Cl$_2$): ^{1}H, δ 1.11 [apparent triplet, 3 H, OCH$_2$*Me*, *J*(HH) 7], 2.31, 2.46, 2.54 (s × 3, 9 H, CMe and Me-4), 3.60 [s br, 1 H, CH(C$_2$B$_9$H$_{10}$Me)], 3.81–4.00 (m, 2 H, OC*H*$_2$Me), 5.29 (s, 7 H, C$_7$H$_7$), 5.64, 5.77 [(AB), 2 H, μ-CH$_2$, *J*(AB) 10], 6.99, 7.12 [(AB)$_2$, 4 H, C$_6$H$_4$,

J(AB) 7 Hz]; ^{13}C-{^{1}H}, δ 164.5 [C^{1}(C_6H_4)], 147.9 [μ-CH_2, J(WC) 40 Hz], 138.2, 138.0 [C^{4}(C_6H_4) and O*C*Me], 129.7, 129.2 (C_6H_4), 128.5 (*C*C_6H_4Me-4), 90.8 (C_7H_7), 78.7 (O*C*H_2Me), 77.1 [br, *C*H($C_2B_9H_{10}$Me)], 62.9 [br, *C*Me($C_2B_9H_{10}$Me)], 32.1 [C*Me*($C_2B_9H_{10}$Me)], 21.6, 21.1 (Me-4 and C*Me*), 17.1 ppm (OCH$_2$*Me*); ^{11}B-{^{1}H}, δ 4.2 (1 B), 1.1 (1 B), −6.7 (1 B), −7.9 (1 B), −8.8 (2 B), −10.1 (2B), −14.2 ppm (1 B).

Crystal structure determination for **3**

Diffracted intensities were collected at 298 K from a crystal of dimensions *ca* 0.45 × 0.30 × 0.20 mm on a Siemens R3m/V four-circle diffractometer. Of the 5182 unique reflections collected (θ–2θ scans, $3° \leqslant 2\theta \leqslant 50°$), 2506 had $F \geqslant 10\sigma(F)$, and only these were used for structure solution and refinement. The data were corrected for Lorentz and polarization effects, and for X-ray absorption, the latter by an empirical method based on azimuthal scan data.[15]

Crystal data. $C_{23}H_{37}B_9MoO_2W$, $M = 722.6$, monoclinic space group $P2_1/n$, $a = 11.724(6)$, $b = 17.12(1)$, $c = 14.87(1)$ Å, $\beta = 100.07(5)°$, $U = 2939(2)$ Å^3, $Z = 4$, $D_c = 1.64$ g cm^{-3}, $F(000) = 1408$ electrons, Mo-K_α X-radiation (graphite monochromator), $\bar{\lambda} = 0.71073$ Å, μ(Mo-K_α) = 44.3 cm^{-1}.

The structure was solved by first locating the metal atoms by direct methods, and then using successive difference Fourier syntheses to locate the remaining atoms except hydrogens. The latter were included in calculated positions (C—H 0.96 and B—H 1.10 Å),[16] with fixed isotropic thermal parameters. Only the metal atoms, and O(2), C(20), and C(21) were refined anisotropically. Poor quality data resulted from crystal twinning, as revealed by the peak profiles. Refinement by full matrix least squares led to $R = 0.10$ ($R' = 0.10$). A weighting scheme of the form $w^{-1} = [\sigma^2(F) + 0.005|F|^2]$ gave a satisfactory analysis of variance. The final electron-density difference synthesis showed one peak of 5.7 eÅ^{-3} near the W atom; this high value being due to the poor quality of the data. Calculations were performed on a DEC micro-Vax II computer with the SHELXTL PLUS system of programs,[15] scattering factors with corrections for anomalous dispersion were taken from ref. 17.

Additional material available from the Cambridge Crystallographic Data Centre comprise the atom coordinates, thermal parameters, and remaining bond distances and angles.

(*Received* 29 *June* 1990; *accepted* 12 *August* 1990)

Abstract—Transamination reactions utilizing the compound mercuric bis(trimethylsilyl)amide, $Hg\{N(SiMe_3)_2\}_2$, in tetrahydrofuran (THF), and the metals Na, Mg, Ca, Sr, Ba and Al have been investigated. Thus the THF solvated compounds $Na[N(SiMe_3)_2] \cdot THF$ and $M[N(SiMe_3)_2]_2 \cdot 2THF$, M = Mg, Ca, Sr and Ba (**1–4**), have been prepared. The X-ray crystal structures of **1** and the related manganese compound $Mn[N(SiMe_3)_2]_2 \cdot 2THF$ (**5**) are reported. Interaction of the silylamides, **2–4**, with a range of crown ethers apparently proceeded with elimination of silylamine, $(Me_3Si)_2NH$, and novel ring opening of the crown ethers, generating species containing a donor alkoxide ligand with a vinyl ether function, presumably, $—O(CH_2CH_2O)_nCH{=}CH_2$ (n = 3–5). The silylamides **2–4** were also cleanly converted to the corresponding alkoxides (from ^1H NMR data) in reactions with stoichiometric quantities of 3-ethyl-3-pentanol.

The utility of σ-organomercury(II) compounds in redox transorganylation reactions is well established.[1] We have observed that mercury bis(trimethylsilyl)amide may be employed similarly for the amination of metals from groups 1 and 2 but not 3. In this paper we present details of these transamination reactions including the crystal and molecular structure of one of the products and of the analogous manganese compound. We also include a preliminary account of the reactions of the new silylamides with a range of crown-ethers and the alcohol, 3-ethyl-3-pentanol.

RESULTS AND DISCUSSION

Mercuric silylamide, $Hg[N(SiMe_3)_2]_2$, was prepared in the manner described by Burger,[2] and transamination reactions [eq. (1)]

$$n/2\,Hg[N(SiMe_3)_2]_2 + M \xrightarrow{THF} M[N(SiMe_3)_2]_n \cdot xTHF + n/2\,Hg \quad (1)$$

$$M = Na \quad n = 1, x = 1$$

$$M = Mg, Ca, Sr \text{ and } Ba \quad n = 2, x = 2$$

were explored for metals from groups 1–3 with decreasing electropositive character. Thus while the reaction with sodium proceeded smoothly at room temperature and the alkaline earth metals Mg, Ca, Sr and Ba reacted slowly in refluxing THF, there was no reaction with aluminium turnings even when surface cleaning agents like mercuric chloride were employed. It is noteworthy that attempted direct reactions between the alkaline earth metals Ca, Sr and Ba and the silylamine, $(Me_3Si)NH$, were unsuccessful despite the presence of catalytic quantities of mercuric chloride.

The new compounds **1–4** were isolated as colourless or pale cream crystalline solids. They showed

* Authors to whom correspondence should be addressed.

good thermal stability, with melting points decreasing down the group, but were extremely sensitive to air. The presence of two coordinated THF molecules was indicated by ^{1}H NMR spectroscopy. Surprisingly, the chemical shift of the single resonance observed for the trimethylsilyl protons was insensitive to the nature of the central metal atom for compounds **2**–**4**. The variable temperature NMR spectra recorded for the strontium compound, **3**, in the temperature range 293–203 K showed that the single resonance persisted although it was somewhat broadened at lower temperatures. A monomeric tetrahedral structure was confirmed by X-ray crystallography for the magnesium and related manganese compounds $M[N(SiMe_3)_2]_2 \cdot 2THF$. Mass spectra could only be obtained for $M[N(SiMe_3)_2]_2 \cdot 2THF$ (M = Mg, Mn). For the magnesium compound the highest mass peak observed (*m/z* 488) corresponded to the three-coordinated species, $\{Mg[N(SiMe_2)_2]_2 \cdot THF\}^+$, whereas for the manganese compound a species corresponding to the four-coordinated complex, $\{Mn[N(SiMe_3)_2]_2 \cdot 2THF\}^+$, was observed together with some fragment ions. Wannagat and co-workers had previously isolated the unsolvated species and the monomeric monoetherate, $Mg[N(SiMe_3)_2]_2 \cdot OEt_2$, from the reaction between diethylmagnesium and the silylamine, $(Me_3Si)_2NH$.[3,4] The crystal structures of the unsolvated manganese dimer, $\{Mn[N(SiMe_3)_2]_2\}_2$, the solvated three-coordinate manganese monomer, $Mn[N(SiMe_3)_2]_2 \cdot THF$, and the solvated samarium species, $Sm[N(SiMe_3)_2] \cdot 2THF$, have been mentioned in the literature.[5,6] It is noteworthy that the THF in compounds **2** and **5** could be replaced by pyridine giving stable bis-pyridine complexes, $M[N(SiMe_3)_2]_2 \cdot 2py$ (M = Ca, Mn). The manganese complex has been shown by single crystal X-ray diffraction to have a distorted tetrahedral structure.*

Crystal structures

The structure of the compounds $M[N(SiMe_3)_2]_2 \cdot 2THF$ (M = Mg, Mn) is given in Fig. 1 and substantial deviation from ideal tetrahedral geometry is apparent. The crystal data are given in Table 1 and selected bond lengths and angles are collected in Table 2. While the difference in the M—O bond lengths closely parallel the difference in the ionic radii (with Mg^{2+} 0.66 Å and Mn^{2+} 0.80 Å), the M—N distances are remarkably

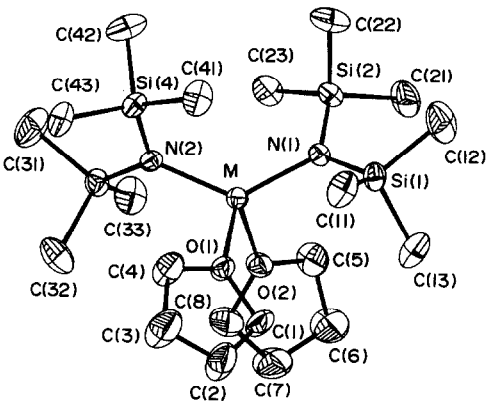

Fig. 1.

similar and apparently long—cf. Al—N 1.78 Å in $Al[N(SiMe_3)_2]_3$.[7] At the same time the N—Si distances in the Mg^{2+} and Mn^{2+} structures are short, a feature previously correlated with the ionic character of the $—N(SiMe_3)_2$ ligand,[8,9] although here the Si—N—Si angles are not particularly wide. This, together with the long M—N bonds, probably reflects severe interligand repulsions. Both complexes exhibited some tetrahedral flattening, with the dihedral angle between the planes described by O,M,O and N,M,N atoms wider than that expected for tetrahedral geometry.

Reactions between the compounds $M[N(SiMe_3)_2]_2 \cdot 2THF$ *and cyclic ethers*

Crown ethers form 1 : 1 complexes with alkali metal silylamides[10] but have been reported to stabilize the ionic products of the disproportionation equilibria said to be present in solutions of dialkylmagnesium and diorganoaluminium halides.[11] The reactions of the alkaline earth bis-silylamides, **2**–**4**, with the cyclic ethers, 12-crown-4, 15-crown-5 and 18-crown-6, in a 1 : 1 molar ratio, were explored in the expectation that similar equilibrium products might be detected. The reactions in fact proceeded with elimination of the silylamine, $(Me_3Si)_2NH$, and the formation of species containing an alkoxide ligand bearing the vinyl ether function, presumably, $—O(CH_2CH_2O)_nCH{=}CH_2$, n = 3–5. The reactions were followed by ^{1}H NMR spectroscopy, where the appearance of the vinyl ether residue was an unmistakable feature in every case. The elimination of silylamine was confirmed by a trapping experiment. For the most part the products were isolated as pentane-insoluble, colourless oils having free cyclic ether, as well as the ring-opened ether product present, and these were not further purified. An extremely air-sensitive, colourless solid, however, was obtained from the 18-crown-

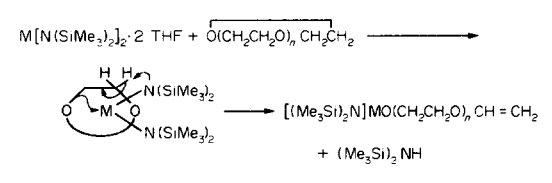
6/barium silylamide reaction and this was recrystallized from toluene, affording very solvent dependent needle-like crystals. The ^{1}H NMR spectrum indicated the presence of a species containing the pentaoxoduodeca-1-ene oxide along with silylamide and cyclic ether, to which we tentatively assigned the composition $[(Me_3Si)_2N][BaO(CH_2CH_2O)_5CH{=}CH_2]$[18-crown-6]. The isolation of polyoxaalkane-eneoxide-containing products suggested a mechanism (Scheme 1) involving proton abstraction from coordinated crown-ether by the silylamide anion, with subsequent C—O bond cleavage and generation of the vinyl ether



Scheme 1.

residue and donor alkoxide linkage. The free silylamide anion has not been isolated or detected but a linear structure is probably the most stable conformation for this species. The potassium compound $KN(SiMe_3)_2(dioxane)_2$ adopted a structure with the widest observed Si—N—Si angle (136.3°) suggesting a high degree of ionic character, although the K—N distance (2.70 Å) suggested that this species may at best be viewed as a tight ion pair.[8] The related free amide ion, $[Ph_3SiNSiPh_3]^-$, has an Si—N—Si angle of 154.9(3)°.[20] This type of ring-opening reactivity is to our knowledge unprecedented for crown ethers but similar base-promoted ring-opening has recently been observed for a range of crown-thioether complexes, $[M([9]aneS_3)_2]^{3+}$, M = Co, Rh, Ir.[12]

The THF solvated alkaline earth silylamides, **2–4**, were recovered unchanged from solutions in dioxane. There was, in addition, no apparent reaction between mercuric silylamide and 18-crown-6 ether. Implicit in these observations, and the fact that alkali metal silylamides form 1 : 1 complexes with crown ethers, is that the ring opening reaction requires a multidentate coordinating ether and a metal silylamide which is at least divalent and has a high degree of ionic character.

Reactions with 3-ethyl-3-pentanol

Metal silylamides are widely used as precursors for a range of other metallo-organic species including metal alkoxides.[13,14] Group II metal alkoxides are generally obtained by direct reaction with primary alcohols, but reaction with tertiary alcohols is sluggish.[15] The availability of the group 2 bis-silylamides offered a convenient route to the corresponding metal tertiary alkoxides and this was demonstrated by their reactions with 3-ethyl-3-pentanol. The series of compounds $[M(OCEt_3)_2]$, M = Ca, Sr and Ba (**6–8**), was isolated as colourless (Ca and Sr) or pale orange (Ba) solids. Their ^1H NMR spectra showed pronounced second-order effects at 80 MHz, but simple first-order spectra were obtained at 250 MHz and these indicated a single alkoxide environment. The single magnetic environment persisted at −10°C, below which temperature solubility problems were encountered.

EXPERIMENTAL

Synthetic work was carried out using standard Schlenk procedures. Solvents were dried over and distilled from the sodium ketyl of benzophenone, or molecular sieves. The spectroscopically pure silylamides consistently gave low carbon and nitrogen analyses despite several attempts to obtain these in each case from two different analytical services. Microanalytical data were obtained from the Butterworth and University College London services. Instruments: NMR, Bruker WP80 and WM-250, data were referenced to the C_6D_5H signal at 7.2 ppm, or the C_3D_5HO signal at 2.05 ppm, or the C_7D_5H signal at 2.1 ppm; Mass spectrometer, Kratos MS-902, E I, recorded at 70 eV; IR, Perkin–Elmer Grating Infrared spectrometer 225 and FTIR 1720 × (selected data are given in Table 3); UV–vis, Beckman DK 2 spectrometer.

$Na[N(SiMe_3)_2] \cdot THF$[16] *from* $Hg[N(SiMe_3)_2]_2$ *and sodium metal*

Freshly cleaned sodium metal (0.26 g, 11.3 mmol) was treated with a solution of mercuric silylamide (3.03 g, 5.82 mmol) in THF (25 cm^3). The stirred reaction mixture was held at room temperature for several hours and mercury metal was deposited from the resultant green solution. After 18 h the mixture was filtered and the solvent evaporated. The residual white solid was crystallized from a toluene–pentane mixture giving the white microcrystalline product (1.06 g, 37%). ^1H NMR (C_6D_6): 0.15 [s, 18H, $N(SiMe_3)_2$], 1.2 (m, 4H, THF), 3.54 (m, 4H, THF).

$Mg[N(SiMe_3)_2]_2 \cdot 2THF$ (**1**)

This compound was prepared from magnesium turnings (0.37 g, 15.02 mmol) and mercuric silylamide (4.02 g, 7.68 mmol) in refluxing THF (25 cm^3). The work-up given for sodium silylamide above afforded large transparent flakes from toluene–hexane (1 : 2) (2.8 g, 75%). ^1H NMR (C_6D_6): 0.27 [s, 36H, $N(SiMe_3)_2$], 1.2 (m, 8H, THF) 3.54 (m, 8H, THF). Mass spectrum: *m/z* 488 (1%) $[M-THF]^+$, 344 (2.3 %) $[Mg(N(SiMe_3)_2)(N(SiMe_3))]^+$.

$Ca[N(SiMe_3)_2]_2 \cdot 2THF$ (**2**)

This compound was prepared from mercuric silylamide (7.8 g, 15 mmol) and calcium metal (0.65 g,

16 mmol) in refluxing THF (100 cm^3) over 10 h. The solvent was evaporated and the pentane-soluble product filtered twice. The concentrated solution was cooled at −25°C affording colourless needles (6.6 g, 86%), m.p. 151–153°C. ^1H NMR (C_6D_6): 0.38 [s, 36H, $N(SiMe_3)_2$], 1.2 (m, 8H, THF), 3.6 (m, 8H, THF). Found: C, 45.5; H, 10.2; N, 5.3; Ca, 8.7. Calc. for $CaN_2Si_4C_{20}H_{52}O_2$: C, 47.5; H, 10.4; N, 5.5; Ca, 7.9%.

$Sr[N(SiMe_3)_2]_2 \cdot 2THF$ (**3**)

Prepared in the manner described for **2**, from mercuric silylamide (5.93 g, 11.4 mmol) and strontium metal (1 g, 11.4 mmol) in refluxing THF (150 cm^3). Isolated as colourless needles from pentane at −25°C (4.8 g, 76%), m.p. 128–130°C. ^1H NMR (C_6D_6): 0.38 [s, 36H, $N(SiMe_3)_2$], 1.32 (m, 8H, THF), 3.6 (m, 8H, THF). Found: C, 40.7; H, 9.5; N, 4.4; Sr, 17.1. Calc. for $SrN_2Si_4C_{20}H_{52}O_2$: C, 43.4; H, 9.5; N, 5.0; Sr, 16.0%.

$Ba[N(SiMe_3)_2]_2 \cdot 2THF$ (**4**)

Prepared in the manner described for **2**, from mercuric silylamide (3.64 g, 7 mmol) and barium metal (1 g, 7.3 mmol) in refluxing THF. Isolated as colourless needles (2.63 g, 53%), m.p. 88–90°C. ^1H NMR (C_6D_6): 0.33 [s, 36H, $N(SiMe_3)_2$], 1.32 (m, 8H, THF), 3.6 (m, 8H, THF). Found: C, 37.7; H, 8.5; N, 4.7; Ba, 23.1. Calc. for $BaN_2Si_4C_{20}H_{52}O_2$: C, 39.9; H, 8.7; N, 4.7; Ba, 22.8%.

$Mn[N(SiMe_3)_2]_2 \cdot 2THF$ (**5**)

The procedure described[5] for the synthesis of the dimer $\{Mn[N(SiMe_3)_2]\}_2$ was followed and the bis-tetrahydrofuranate was obtained on recrystallization of the product from THF. Mass spectra: *m/z* 578 (12%) $[M-H]^+$. UV–vis cm^{-1} (dm^3 mol^{-1} cm^{-1}) (THF): 20,400 (sh), 22,200 (0.5); 23,700, 25,600 (0.25), 27,300, 30,100. Magnetic susceptibilities (Gouy balance) over a temperature range (298–123 K) obeyed the Curie–Weiss law ($\theta = -12$ K) with average $\mu_{eff} = 6.06 \pm 0.02$ BM.

$Ca[N(SiMe_3)_2]_2 \cdot 2pyridine$

To a stirred solution of **2**, in THF at room temperature, was added pyridine (excess). This mixture was stirred for 2 h and the solvents removed under reduced pressure. Pale yellow leaf-like crystals were obtained from pentane solutions of the product. ^1H NMR (C_6D_6): 0.4 [s, 36H, $N(SiMe_3)_2$], 6.7 (m, C_5H_5N), 6.86 (m, C_5H_5N), 8.72 (m, C_5H_5N). Found: C, 49.3; H, 8.9; N, 9.9. Calc. for $CaN_4Si_4C_{22}H_{46}$: C, 50.9; H, 8.9; N, 10.8%.

*Reactions with crown-ethers**

Typically, a THF solution of the metal silylamide, $M[N(SiMe_3)_2]_2 \cdot 2THF$ (M = Ca, Sr or Ba) (0.5 g in 50 cm^3), was treated with one molar equivalent of crown-ether (one of 12-crown-4, 15-crown-5 or 18-crown-6) in THF (25 cm^3). The resultant mixture was stirred at room temperature for approximately 2 days. The volatiles were removed under reduced pressure and the residual material washed several times with pentane. Oils were generally obtained but a solid product was isolated from the reaction between 18-crown-6 ether and compound **4**. This solid was recrystallized from toluene giving colourless solvent-dependent needles; proposed composition $[(Me_3Si)_2N]BaO(CH_2CH_2O)_5CH{=}CH_2$(18-crown-6). ^1H NMR (C_7D_8) of (18-crown-6/compound **4** reaction product): 0.3 [s, 18H, $N(SiMe_3)_2$], 3.4–3.95 [m, 44H, $-O(CH_2CH_2O)_5$ and $\overline{O(CH_2CH_2O)_5CH_2CH_2}$],

3.95 (dd, 1H, ),

4.2 (dd, 1H, ),

6.43 (q, 1H, )

$^3J_{ac} = 14$ Hz, $^3J_{ab} = 7$ Hz, $^2J_{bc} = 2$ Hz.

$[Ca(OCEt_3)_2]$ (**6**)

A stirred solution of **2** (2.9 g, 5.7 mmol) in benzene (200 cm^3) was treated with 3-ethyl-3-pentanol (1.33 g, 11.4 mmol). The mixture was held at the reflux temperature for 10 h and subsequently stirred at room temperature for 48 h. The solvent was evaporated and the colourless residual solid washed several times with pentane affording the product (1.2 g, 74%), m.p. > 350°C dec. ^1H NMR (C_3D_6O): 0.83 (t, 18H, $-CH_3$), 1.4 (q, 12H, $-CH_2$). Found: Ca, 15.0. Calc. for $CaO_2C_{14}H_{30}$: Ca, 14.8%.

*A full account of this work will be presented elsewhere.

$[Sr(OCEt_3)_2]$ (7)

This compound was prepared in the manner described for the calcium compound above from **3** (3.0 g, 5.4 mmol) and 3-ethyl-3-pentanol (1.27 g, 11.0 mmol) giving a white solid (1.3 g, 77%), m.p. > 300°C. ^{1}H NMR (C_3D_6O): 0.85 (t, 18H, —CH_3), 1.45 (q, 12H, —CH_2). Found: Sr, 28.7. Calc. for $SrO_2C_{14}H_{30}$: Sr, 27.5%.

$[Ba(OCEt_3)_2]$ (**8**)

This compound was prepared as described for the calcium derivative above from **4** (3 g, 4.9 mmol) and 3-ethyl-3-pentanol (1.2 g, 10.3 mmol) giving an orange solid (1.32 g, 72%). ^{1}H NMR (C_3D_6O): 0.85 (t, 18H, —CH_3), 1.43 (q, 18H, —CH_2). Found: C, 43.7; H, 8.3; Ba, 37.2. Calc. for $BaO_2C_{14}H_{30}$: C, 45.7; H, 8.2; Ba, 37.3%.

Crystallography

Measurements were made on crystals sealed under nitrogen in glass capillaries using a CAD4 diffractometer operating in the ω–2θ scan mode with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) as previously described.[17] The intensity data were corrected for absorption empirically using psi-scan profiles. The structures were solved using standard heavy-atom procedures and refined using full-matrix least-squares methods[18] with scattering factors calculated from data obtained from reference 19. Non-hydrogen atoms were refined with anisotropic displacement factors; hydrogen atoms were included in idealized positions and refined with group isotropic displacement factors.

Acknowledgements—We thank the SERC and Queen Mary and Westfield College for grants and equipment and one of us (A.C.S.) thanks the SERC for an Advanced Fellowship. The Sudan Government and the British Council are thanked for support to A.A.I. We are also grateful to Mr Greg Coumbarides for the NMR spectra, and Mr Peter Cook for mass spectra.

Abstract—The reaction of {$HB(Me_2pz)_3$}Mo(NCS)(S_4) [$HB(Me_2pz)_3^-$ = hydrotris(3,5-dimethylpyrazolyl)borate anion] with dicarbomethoxyacetylene in refluxing toluene results in the formation of the brown, diamagnetic complex {$HB(Me_2pz)_3$}Mo(NCS){$S_2C_2(CO_2Me)_2$} (**1**) (the reactants above also yield **1** upon prolonged reaction in dichloromethane at 25°C), which has been characterized by X-ray crystallography. The mononuclear pseudo-octahedral complex contains a facially tridentate $HB(Me_2pz)_3^-$ ligand, a monodentate N-bound NCS^- ligand, and a bidentate $S_2C_2(CO_2Me)_2^{2-}$ ligand having a near planar MoS_2C_4 fragment and a SC=CS bond distance of 1.342(15) Å. Solutions of **1** are unstable in air and decompose to produce {$HB(Me_2pz)_3$}MoO_2(NCS) and {$HB(Me_2pz)_3$}MoO$(NCS)_2$.

The reactions of *cis*-{$HB(Me_2pz)_3$}MoO_2X (X = F^-, Cl^-, Br^-, NCS^-) complexes with sulphiding agents result in the formation of the tetrasulphidomolybdenum(IV) complexes {$HB(Me_2pz)_3$}$MoX(S_4)$.[1] NMR and X-ray crystallographic studies of these complexes indicate that the S_4^{2-} ligand possesses a degree of dithiolene-like character unprecedented in tetrasulphidomolybdenum complexes. Thus, in {$HB(Me_2pz)_3$}$MoCl(S_4)$ the S_4^{2-} ligand is planar with very short Mo—S bond distances and alternating S—S distances, indicative of $d\pi$–$p\pi$ bonding between molybdenum and sulphur and multiple bonding between the two uncoordinated sulphur atoms. In all the complexes, a methyl group on one of the pyrazole rings resides near and perpendicular to the centroid of the MoS_4 ring; this group exhibits a very shielded ^{1}H NMR signal (δ *ca* 0) due to its residence within a shielding zone presumably associated with the MoS_4 fragment. Previously characterized tetrasulphidomolybdenum complexes exhibit puckered MoS_4 rings which possess varying degrees of bond distance alternation.[1] Due mainly to their biological relevance, the reactions of polysulphido ligands with cyanide, phosphines and activated acetylenes have received considerable attention. Polysulphido complexes of Ti,[2] V,[2] Mo[3] and Fe[4] react with activated acetylenes to produce 1,2-dithiolene complexes. These reactions are reminiscent of the first synthesis of a dithiolene complex from diphenylacetylene and nickel sulphide.[5,6] In one case, the reaction of $[Mo_2O_2(\mu\text{-}S)_2(S_2)_2]^{2-}$ with dicarbomethoxyacetylene, an unusual molybda-2,3-dithiacyclopent-4-ene ring complex was formed.[7] We have now explored the reactivity of the tetra-

sulphido ligand of $\{HB(Me_2pz)_3\}Mo(NCS)(S_4)$ with dicarbomethoxyacetylene and our results are reported herein.

EXPERIMENTAL

Materials and methods

The complex $\{HB(Me_2pz)_3\}Mo(NCS)(S_4)$ was prepared according to the method of Young *et al.*[1] Dicarbomethoxyacetylene was used as obtained from Aldrich Chemical Company. All solvents used were carefully dried, distilled and deoxygenated prior to use. Unless otherwise stated, all reactions were performed under an atmosphere of pure dinitrogen, employing standard Schlenk line techniques. Microanalyses were performed by Atlantic Microlabs. IR spectra were obtained on a Perkin–Elmer 1430 Ratio Recording IR spectrophotometer using pressed KBr discs with polystyrene as reference. NMR spectra were obtained using a Jeol JNM FX-200 Fourier transform spectrometer and were referenced against chloroform. Mass spectra were provided courtesy of Dr Sydney Middleton of Monash University. Column chromatography was performed on a 50 cm column using Merck Art. 7734 Kieselgel 60. TLCs were run on Merck Art. 5735 DC-Plastikfolien Kieselgel 60 F_{254}.

Synthesis of $\{HB(Me_2pz)_3\}Mo(NCS)\{S_2C_2(CO_2Me)_2\}$ (1)

A solution of $\{HB(Me_2pz)_3\}Mo(NCS)(S_4)$ (0.2 g, 0.345 mmol) and dicarbomethoxyacetylene (0.21 cm^3, 1.71 mmol) in toluene (10 cm^3) was heated at 60°C for 1 day. The fine brown crystals formed were filtered in air, washed with toluene (5 cm^3) and dried *in vacuo*. Yield 0.151 g (66.8%).

Found: C, 40.0; H, 4.2; N, 14.9; S, 14.6. Calc. for $C_{22}H_{28}BMoN_7O_4S_3$: C, 40.2; H, 4.3; N, 14.9; S, 14.6%. IR (KBr): 2960m, 2565m, 2040vs, 1730s, 1720s, 1535s, 1460s, 1440s, 1430s, 1415s, 1385s, 1355s, 1230s, 1185s, 1065s, 1045s, 1025s, 965m, 900m, 855s, 810s, 790m, 755m, 705m, 690m, 645m, 465m, 370m and 295m cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.38 and 2.60 [s, 2 × 3H, 2 × CH_3 of $HB(Me_2pz)_3^-$], 2.39 and 2.63 [s, 2 × 6H, 4 × CH_3 of $HB(Me_2pz)_3^-$], 3.86 (s, 6H, 2 × CH_3 of ester groups), 5.57 [s, 1H, CH of $HB(Me_2pz)_3^-$], 5.88 [s, 2 × 1H, 2 × CH of $HB(Me_2pz)_3^-$]. Electronic spectrum (CH_2Cl_2) λ_{max}, nm (ε, M^{-1} cm^{-1}): 655 (900), 520 (1960), 403 (6730), 330 (12,000, sh), 285 (16,850). Mass spectrum, *m/z* (%) for $[1]^+$: 652 (8), 653 (48), 654 (21), 655 (53), 656 (74), 657 (84), 658 (79), 659 (100), 660 (37), 661 (42), 663 (13), 664 (5).

Reaction of $\{HB(Me_2pz)_3\}Mo(NCS)(S_4)$ *and* $C_2(CO_2Me)_2$ *in dichloromethane*

A solution of $\{HB(Me_2pz)_3\}Mo(NCS)(S_4)$ (0.15 g, 0.26 mmol) and dicarbomethoxyacetylene (0.035 cm^3, 0.28 mmol) in dichloromethane (20 cm^3) was stirred for a period of 2 months. The green coloration slowly dissipated and a brown solution was produced. TLC showed a good yield (estimated 70%) of **1** was present. Further stirring for 3 months led to a red solution. Column chromatography yielded a single orange fraction. Yield 0.09 g. The substance was shown to be a mixture of $\{HB(Me_2pz)_3\}MoO(NCS)_2$[8] (*ca* < 5%) and $\{HB(Me_2pz)_3\}MoO_2(NCS)$[9] by comparison with spectroscopic data from authentic samples.

Crystal structure determination of 1

Crystals suitable for X-ray diffraction studies were grown anaerobically by slow diffusion of hexane into a saturated dichloromethane solution of complex. Intensity data were measured at room temperature on an Enraf–Nonius CAD-4F diffractometer fitted with Mo-K_α radiation, $\lambda = 0.7107$ Å. The ω–2θ scan technique was employed to measure

the intensities of 4856 reflections (θ_{max} 23.5°); the data were corrected for Lorentz and polarization effects but not for absorption. Of the reflections measured, 4329 were unique of which 2405 satisfied the $I > 2.5\sigma(I)$ criterion of observability and were used in the subsequent analysis. Relevant crystal data and details of the refinement are listed in Table 1. The structure of **1** was solved from the interpretation of the Patterson synthesis and refined by a full-matrix least-squares procedure based on F.[10] Non-carbon, non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were included in the model at their calculated positions. After the introduction of a weighting scheme of the form $w = k/[\sigma^2(F)+g|F|^2]$ (k = 1.55, g = 0.0011), the refinement was continued until convergence. Refinement was performed with the SHELX 76[10] suite of programs installed on a SUN4/280 computer. Selected interatomic parameters are given in Table 2 and the numbering scheme employed (drawn with ORTEP II[11]) is shown in Fig. 1. Scattering factors for neutral molybdenum corrected for f' and f'' were from ref. 12 and those for the remaining atoms were as incorporated in the SHELX 76 program. Material deposited comprises fractional atomic coordinates, thermal parameters, hydrogen atom parameters, all bond lengths and angles and structure factor tables.

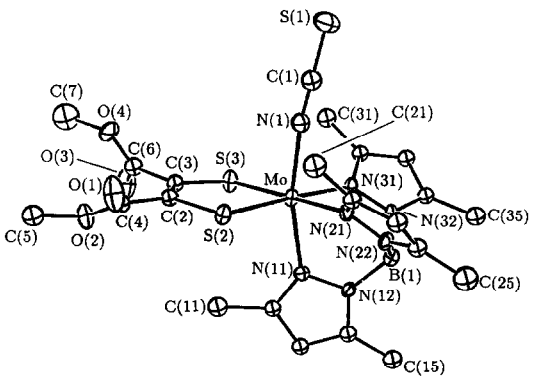

Fig. 1. Molecular structure and crystallographic numbering scheme employed for **1**.

RESULTS AND DISCUSSION

We have explored the reaction of $\{HB(Me_2pz)_3\}$ $Mo(NCS)(S_4)$ and dicarbomethoxyacetylene under various conditions and have thoroughly characterized the major product thereof as $\{HB(Me_2pz)_3\}Mo(NCS)\{S_2C_2(CO_2Me)_2\}$ (**1**). At room temperature in dichloromethane a very slow reaction took place and after a period of months the initial green solution had changed to brown. Chromatographic investigation of the reaction mixture indicated a *ca* 70% yield of **1**. Column chromatography of the reaction mixture after 6 months yielded an orange fraction which

contained $\{HB(Me_2pz)_3\}MoO_2(NCS)$[9] contaminated by a small amount of intensely coloured $\{HB(Me_2pz)_3\}MoO(NCS)_2$.[8] The source of the oxygen in the final product must arise from adventitious air, consistent with the independent observation that solutions of **1** are air sensitive. The reaction of $\{HB(Me_2pz)_3\}Mo(NCS)(S_4)$ with dicarbomethoxyacetylene, in refluxing toluene, results in the relatively rapid formation of **1**, which precipitates as brown crystals from the reaction mixture. The above reactions result in the formation of a dithiolene ligand, $S_2C_2(CO_2Me)_2^{2-}$, and sulphur (initially) through reaction of the tetrasulphido ligand with the activated acetylene. The possible mechanisms of this type of reaction have been discussed,[3b] but our observations shed no light on the mechanism of our reaction. We have been unable, for example, to prepare $\{HB(Me_2pz)_3\}MoX(S_2)$ complexes in order to test their reactivity with dicarbomethoxyacetylene, as support for the conversion of S_4^{2-} to S_2^{2-} (plus sulphur) prior to the concerted reaction of the S_2^{2-} ligand with acetylene. Examination of space-filling molecular models indicates that although sterically encumbered due to the $HB(Me_2pz)_3^-$ ligand, the coordinated sulphurs of the S_4^{2-} ligand are also able to undertake direct nucleophilic attack on the acetylenic carbons prior to expulsion of sulphur.

Complex **1** has been characterized by elemental analysis, IR, electronic and ^1H NMR spectroscopy, mass spectrometry and X-ray crystallography. Besides the many bands characteristic of the $HB(Me_2pz)_3^-$ ligand, the IR spectrum of **1** exhibits a strong band at 2040 cm^{-1}, which may be assigned to the NCS^- ligand, and bands at 1730, 1720 and 1230 cm^{-1}, which may be assigned to the bidentate $S_2C_2(CO_2Me)_2^{2-}$ ligand.[3] The ^1H NMR spectrum of **1** indicates that the molecule has C_s symmetry in solution, with the methyl and methine resonances of the facially coordinated $HB(Me_2pz)_3^-$ ligand having intensity ratios of 3 : 3 : 6 : 6 and 1 : 2, respectively. Only one resonance is observed for the methyl groups of the $S_2C_2(CO_2Me)_2^{2-}$ ligand. Thus, the mirror plane bisects the dithiolene ligand and contains the molybdenum atom and NCS^- ligand. The electronic spectrum of **1** is dominated by intense bands assigned to charge-transfer transitions. The mass spectrum of **1** exhibits a parent $[1]^+$ ion cluster with m/z 659.0; the calculated isotope pattern for $[1]^+$ closely matches that of the observed parent ion.

The X-ray crystal structure of **1** has been determined. The pseudo-octahedral complex (Fig. 1) is composed of a facially tridentate $HB(Me_2pz)_3^-$ ligand, a bidentate $S_2C_2(CO_2Me)_2^{2-}$ ligand and a monodentate N-bound thiocyanate ligand. The equatorial girdle composed of the S(2), S(3), N(21) and N(31) atoms is co-planar with the molybdenum atom with a maximum atom deviation of 0.10(1) Å [for N(31)] in the five-atom equatorial plane. The N(1) and N(11) atoms are 2.05(1) and 2.151(8) Å, respectively, from the equatorial plane, and the Mo—N(1,11) vectors are both tilted away from the dithiolene ligand; consequently, the N(1)—Mo—N(11) angle is only 165.1(3)°. The Mo—S distances are an average 2.357 Å and the average Mo—S—C angle is 106.5(4)°. The S—C bond distances of the dithiolene ligand are 1.75(1) and 1.70(1) Å and the C(2)—C(3) distance is 1.342(15) Å. The $S_2C(CO_2Me)_2$ fragment of the dithiolene ligand is planar with a maximum atom deviation from the plane of 0.07 Å [for C(4) and C(6)]; the molybdenum atom is 0.2376(9) Å out of the plane of this fragment and the dihedral angle between the ligand plane and the Mo,S(2),S(3) plane is 7.78°. The geometry and metrical parameters for the dithiolene ligand are very similar to those reported for related molybdenum dithiolene complexes.[3,5,13,14] The Mo—N bond distances of the $\{HB(Me_2pz)_3\}Mo$ fragment are identical within experimental error and average 2.173 Å. The metrical data for the NCS^- and $HB(Me_2pz)_3^-$ ligands are similar to those reported for related complexes.[15,16]

HIGH-SPIN ↔ LOW-SPIN TRANSITION IN [Fe(NCS)$_2$(4,4′-BIS-1,2,4-TRIAZOLE)$_2$](H$_2$O). X-RAY CRYSTAL STRUCTURE AND MAGNETIC, MÖSSBAUER AND EPR PROPERTIES

Abstract—The Fe^{II} ion in [Fe(NCS)$_2$(4,4′-bis-1,2,4-triazole)$_2$](H$_2$O) has distorted tetragonal symmetry with two *trans*-oriented NCS$^-$ ligands. It shows a very abrupt high-spin ↔ low-spin transition at 123.5 K on cooling and 144.5 K on warming. The compound is rather stable *in vacuo* at room temperature; however, samples which have passed the spin transition once lose their water of hydration above 240 K *in vacuo*. The dehydrated substance does not show a spin transition; it is high spin in the whole temperature range. Mössbauer ligand-field spectra and magnetic behaviour of both the hydrated and non-hydrated compounds are discussed.

The spin transition has been followed by EPR measurements with the aid of traces of Cu^{2+} ions which could be substituted for Fe^{2+} in the tetragonal structure. In the high-spin phase the EPR signal is very broad and featureless; in the diamagnetic low-spin phase it is very sharp and resolved in hyperfine and superhyperfine structures. This unusual method to follow the spin transition was shown to be quite generally applicable.

In the crystal structure of Fe(NCS)$_2$(C$_4$H$_4$N$_6$)$_2$(H$_2$O) the distances Fe—NCS are 2.125(3) Å, and Fe—N(ligand) 2.180(3) and 2.188(2) Å. The water molecule is connected to the non-coordinating ligand N-atom by hydrogen bonding.

Thermally induced high-spin ↔ low-spin transitions of six-coordinated Fe^{II} and a few other first-row transition metal ions with d^4 to d^7 electron configurations, have been studied for many years. Several techniques are available to investigate this phenomenon. Mössbauer spectroscopy, magnetic measurements, heat capacity data, X-ray diffraction techniques and UV–vis and IR spectrometries, have been mainly used and the results were discussed in several review articles on the subject.[1–4]

Until now, only a few examples of iron compounds with triazole ligands, exhibiting a spin-crossover, have been described. [Fe(trz)

$(Htrz)_2](BF_4)$ (Htrz = 1,2,4-triazole)[5] is a low-spin iron compound at room temperature. A transition to high-spin occurs upon heating to 105–107°C. A hysteresis of 32 K was observed. A polynuclear structure was proposed for this complex.

$[Fe_3(4\text{-ethyl-}1,2,4\text{-triazole})_6(H_2O)_6](CF_3SO_3)_6$ contains differently coordinated iron atoms.[6] It has been shown that only the central iron atom, having a N(6) coordination, shows a spin transition.[7] Several other iron(II) compounds showing spin transition with 1,2,4-triazole and 4-amino-1,2,4-triazole as ligands have been described by Larionov and coworkers.[8]

Furthermore, a series of iron(II) compounds with the chelating bidentate ligand 5-(2′-pyridyl)-1,2,4-triazole has been described.[9] These compounds also exhibit a temperature-induced spin transition.

Recently, a series of isomorphous compounds has been described with general formula $[M(NCS)_2(btr)_2](H_2O)$ (M = Fe, Co or Ni, btr = 4,4′-bis-1,2,4-triazole).[10] A crystal structure determination, carried out on the cobalt compound,[11] revealed that the compounds have a two-dimensional structure with the metal atoms bridged by the btr ligands, coordinating through their N(1) and N(1′) atoms. Two *trans*-oriented thiocyanate anions form the axial ligands. With manganese, a similar two-dimensional structure has been observed for the nitrate: $[Mn(btr)_2(H_2O)_2](NO_3)_2$.[12] Surprisingly, $Mn(NCS)_2$ does not give a two-dimensional structure with btr. A compound of composition $[Mn(NCS)_2(btr)(H_2O)_2]\cdot 2H_2O$ appeared to be a btr-1,1′-linked linear chain.[13]

The iron compound, $[Fe(NCS)_2(btr)_2](H_2O)$, was reported to show a spin transition.[11] This spin transition is highly unusual because the ligand btr is not a very strong ligand; it is, for instance, weaker than 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen). $[Fe(btr)_6]^{2+}$ in the three-dimensional lattice of $[Fe(btr)_3](CF_3SO_3)_2$ is high-spin at all temperatures[14] (Dq = 1120 cm^{-1}). Moreover, there is no report so far on a spin transition in iron(II) compounds with *trans*-oriented thiocyanate groups. In contrast, numerous iron(II) compounds with *cis*-oriented NCS^- groups are well known to exhibit such a spin transition from high-spin to low-spin on cooling, e.g. $Fe(NCS)_2L_2$, L = bipy or phen.[1,2] The very few iron(II) *trans*-thiocyanate compounds which are known[15–18,34,35] do not exhibit a spin transition, they are high-spin in the whole temperature range. It also appears that $[Fe(NCS)_2(btr)_2](H_2O)$ is the first spin transition compound with a two-dimensional structure.

The ligand field of $[Fe(NCS)_2(btr)_2](H_2O)$ shows a Dq value of 1160 cm^{-1}, which is at the lower limit of the range of Dq values (1160 < Dq < 1340 cm^{-1}), given by Robinson *et al.*[19] for iron(II) compounds in which spin-crossover should occur.

Since the iron atoms in this compound have a site symmetry close to D_{4h}, it seemed appropriate to prepare a copper(II) dope in the iron compound. It has been shown that it is quite possible to detect the HS–LS transition in an iron compound by focusing on the variable temperature EPR spectra of doped species, which acts as a probe to get information about the spin state of the host lattice.[20–22]

In the present paper this method of detecting spin transitions in iron compounds will be described in more detail. A preliminary communication about the detection of the spin transition was published before.[21] The spin transition of $[Fe(NCS)_2(btr)_2](H_2O)$ will be discussed first.

These investigations on the compound made it more desirable to carry out the X-ray structure determination on the iron compound itself, since it is clear that there might be some differences with the isomorphous cobalt compound. Unfortunately, low-temperature single-crystal structure determination will not be possible since the crystals disintegrate upon passing the spin transition. The room temperature single crystal structure determination of the compound is described at the end of this paper.

EXPERIMENTAL

Synthesis

The synthesis of the compound and the dopes containing Cu^{II} and Mn^{II} have been described elsewhere.[11,20] The elemental analyses for the doped substances were done by using atomic absorption. The copper dope gave Fe–Cu = 1 : 0.011 and the manganese dope Fe–Mn = 1 : 0.010.

Measurements

Magnetic measurements have been carried out on polycrystalline samples weighing about 6 mg with a Faraday type magnetometer equipped with a helium continuous-flow cryostat from Oxford Instruments working in the 2–295 K temperature range (Orsay) or on an automatic Faraday balance in the temperature range 80–295 K operating *in vacuo* (Leiden).

The variable temperature EPR spectra of the copper-doped $[Fe(NCS)_2(btr)_2](H_2O)$ were obtained from a Bruker ER 200D spectrometer equipped with an Oxford Instruments continuous-flow cryostat.

Mössbauer spectra were obtained with a constant

Table 1. Crystallographic data[a] for $[Fe(NCS)_2(btr)_2](H_2O)$

Chemical formula $C_{10}H_{10}FeN_{14}OS_2$	$T = 20°C$
$f_w = 462.259$	λ(Mo-K_α) = 0.71073 Å
Space group $C2/c$	$\rho_{obs} = 1.60(2)$ Mg m^{-3} $\rho_{calc} = 1.59$ Mg m^{-3}

	Number of independent reflections 4389
	Number of significant reflections 1368

[a] Estimated standard deviations in the least significant digits are given in parentheses.

acceleration spectrometer, which uses a ^{57}Co in Rh source. Isomer shifts are reported relative to the NBS standard $Na_2[Fe(CN)_5NO](H_2O)_2$. The measured spectra were fitted with calculated subspectra consisting of Lorentzian-shaped lines by varying the Mössbauer parameters in a non-linear, iterative minimization routine. UV–vis spectra were obtained using a Perkin–Elmer 330 spectrophotometer, applying the diffuse reflectance technique at room temperature with MgO as a reference.

Collection and reduction of X-ray intensity data

A bar shaped single crystal of $[Fe(btr)_2(NCS)_2](H_2O)$, btr = $C_4H_4N_6$, was selected and mounted on an Enraf-Nonius CAD-4 automatic four-circle diffractometer (graphite-monochromated Mo-K_α radiation; $\lambda = 0.71073$ Å), applying the ω–2θ scan technique at room temperature. The obtained diffraction data, which showed no systematic decay of intensity due to deterioration of the crystal (checked periodically every 90 min by using selected intensity standards), were corrected for Lorentz and polarization effects. Absorption correction, using the Monte Carlo method,[23] led to a value for R_{int} of 0.01. Atomic scattering factors for neutral atoms were taken from the literature.[24] Details on crystal data and intensity collection are listed in Table 1.

Solution and refinement of the structure

The structure was solved in space group $C2/c$. For the refinement, the atomic parameters of the non-hydrogen atoms of the isomorphous cobalt compound were used.[11] Successive cycles of least-squares refinement and difference Fourier syntheses based on 1368 significant reflections (with $I > 2\sigma_I$) did not yield the hydrogen positions, therefore the ligand hydrogens were placed at 0.98 Å and refined in the subsequent cycles with one overall isotropic temperature factor. The function minimized was $\Sigma[w(|F_o| - |F_c|)^2]$ with $w = 1/\sigma_{F^2}$ (σ_{F^2} from counting statistics). All non-hydrogen atoms were given individual anisotropic thermal parameters in the refinement. None of the remaining electron densities could be assigned to the water hydrogen atoms due to hydrogen bonding.

The final values for the discrepancy indices defined by $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ where $R = 0.039$ and R_w 0.049 with the significant set of reflections. The atomic positional parameters, and listings of F_o and F_c values and anisotropic thermal parameters for the non-hydrogen atoms are available as supplementary material.[25]

RESULTS AND DISCUSSION

Spin-crossover observations

The high-spin ↔ low-spin transition in $[Fe(NCS)_2(btr)_2](H_2O)$ has been followed by measuring the molar magnetic susceptibilities χ_M as a function of temperature T.

At first, the data were recorded from 80 to 295 K, and vice versa, under helium atmosphere at 10 mm Hg (1.3 kPa) pressure. A very broad hysteresis of more than 30 K was found *initially*, i.e. $T_c\downarrow = 123$ K, $T_c\uparrow \approx 153$ K, but after heating up to room temperature a second time and subsequently cooling down again no transition occurred. Nevertheless, the transition could be repeated many times in a test tube at normal pressure when the sample is cooled down in liquid nitrogen and heated up again. In this experiment the transition can be detected

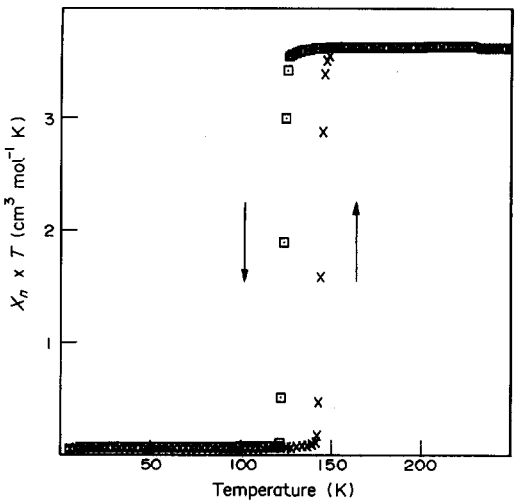

Fig. 1. The χT vs T curves of $Fe[(MCS)_2(btr)_2](H_2O)$ at increasing (×) and decreasing (⊡) temperatures, 0–250 K.

visually, because of the white-to-purple and vice versa colour change associated with the spin transition. The basic difference between this simple experiment and the magnetic measurements is the difference in pressure.

Analysis of the weight of the sample during the magnetic measurements revealed a loss of 3.9% of weight in the temperature region from 240 to 280 K. This loss closely corresponds to one mole of water per molecular unit. Afterwards, the weight remained constant. Therefore it is concluded that, at temperatures above 240 K and at 10 mmHg (1.3 kPa) pressure, the compound looses its non-coordinated water molecule. The loss of water became also clear from the disappearance of the bands characteristic of water in the IR spectra recorded after the magnetic measurements.

Subsequently, the magnetic measurements have been carried out on another sample in the temperature range 10–240 K, and under the same pressure conditions. The $\chi_M T$ vs T curves are given in Fig. 1. The weight of the sample remains constant over the whole temperature range. A hysteresis of 21 K appeared for this sample, $T_c\downarrow = 123.5$ K, $T_c\uparrow = 144.5$ K.

It is clear from these results that the loss of the water molecules present in the lattice induces the disappearance of the spin-crossover phenomenon in the system under investigation.

The high-spin ↔ low-spin transition of this compound was also studied by Mössbauer spectroscopy. At 295 K the isomer shift and the quadrupole splitting are 1.30 and 2.83 mm s^{-1}, respectively. Below the transition temperature the isomer shift is fairly constant at 0.76 mm s^{-1}, and any quadrupole splitting was not observed (line width 0.32 mm s^{-1}). The hysteresis effect can be seen from Fig. 2 in which Mössbauer spectra at various temperatures around T_c are presented. The transition temperature and the hysteresis are in good agreement with the results obtained from magnetic data. It is remarkable that the quadrupole splitting in the low-spin phase is (close to) 0 mm s^{-1}.

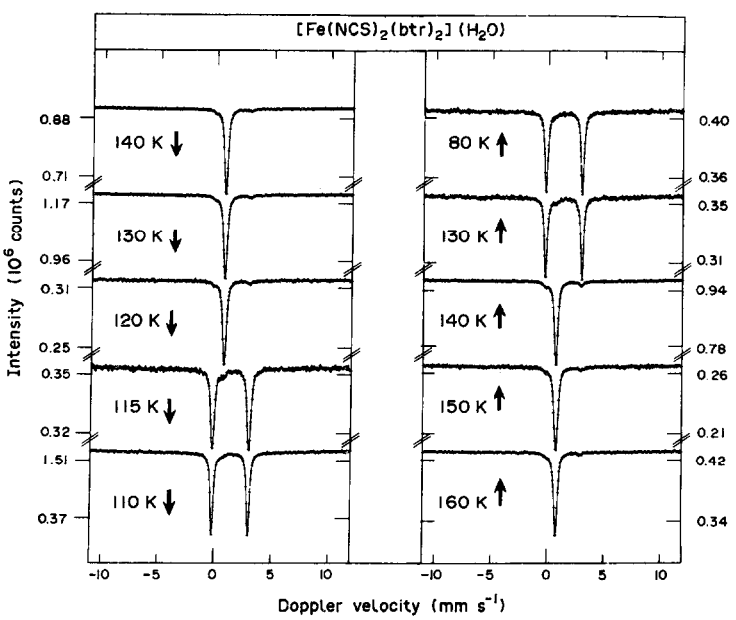

Fig. 2. Mössbauer spectra of $Fe[(MCS)_2(btr)_2](H_2O)$ at indicated temperatures: ↓ indicates decreasing temperatures, ↑ indicates increasing temperatures.

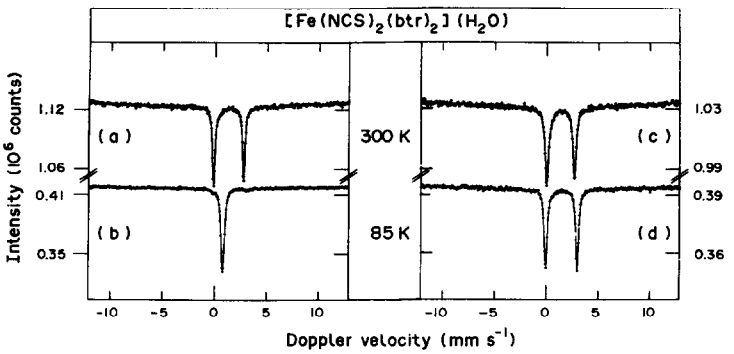

Fig. 3. Mössbauer spectra of $Fe[(MCS)_2(btr)_2](H_2O)$ at indicated temperatures: (a) and (b) unperturbed samples, (c) and (d) dehydrated samples.

Such small values are to be expected for iron(II) in a highly symmetric coordination sphere, e.g. hexakisligand systems.[3] Apparently, the tetragonal distortion of octahedral symmetry is rather small in the low-spin phase.

Dehydrated compound

Mössbauer spectra of a dehydrated sample have been recorded at room temperature and at 85 K (Fig. 3). No low-spin species could be detected at low temperature. The isomer shift (1.33 mm s^{-1} at 295 K, 1.43 mm s^{-1} at 85 K) and the quadrupole splitting (2.62 mm s^{-1} at 295 K, 2.99 mm s^{-1} at 85 K) of the dehydrated samples differ from those for the non-evacuated sample. This indicates a change in the local symmetry of the iron atom upon dehydration. Differences have also been observed in the ligand-field spectra of these samples. The *Dq* value of the dehydrated sample is 80 cm^{-1} lower than that of the hydrated one. This is clearly below the before mentioned range to give spin-crossover phenomena.[1,2,19] A further broadening of the ligand-field absorption is observed in the dehydrated sample indicating a tetragonal distortion of the iron atoms.

The previously reported partial spin transition of $[Fe(NCS)_2(btr)_2](H_2O)$[11] can now be explained by the above described disappearance of the spin transition upon dehydration. The partial dehydration of a sample apparently results in a partial overall spin transition.

EPR measurements

The above applied techniques, as well as other methods used to investigate HS–LS transitions all focus either on the metal species, which undergoes the transition, i.e. its electronic and magnetic properties, or on species which are present in the compound, i.e. ligands and eventually counterions and solvent molecules, or on structural changes accompanying the spin crossover, as revealed by heat capacity data and X-ray diffraction and/or spectral absorption patterns. It has been shown that it is possible to introduce a guest species in the compound, the behaviour of which is drastically changed when the host compound undergoes the spin transition, and to focus on that species with variable temperature physical measurements to detect the spin transition. In this way the crossover phenomenon can be observed indirectly.

$[Fe(NCS)_2(btr)_2](H_2O)$ is the first spin-transition iron compound with *trans*-oriented thiocyanate groups and ligand-bridged iron atoms. Because weak magnetic interaction might exist between the metal ions, it is to be expected that the spin transition of the iron ions will affect the magnetic properties of doped metal ions, such as Cu^{II} and Mn^{II} and thus, the EPR spectrum of the compound. A copper dope and a manganese dope of $[Fe(NCS)_2(btr)_2](H_2O)$ have therefore been synthesized. The doped species exhibit the same magnetic behaviour as observed for the undoped species, i.e. a very abrupt and complete spin transition and a large hysteresis.

The EPR spectra of the copper-doped iron compound recorded at variable temperatures have been reported previously.[20] It was shown that in the paramagnetic phase above T_c the EPR spectrum is very poorly resolved due to exchange broadening. In contrast, at T_c and below, a beautifully resolved spectrum was observed corresponding to a magnetically isolated Cu^{II} ion in an elongated tetragonal environment with hyperfine as well as superhyperfine structures. See Fig. 4.

To confirm that the features in the EPR spectra appeared because of the spin transition, EPR spectra have been recorded of the sample after dehydration, which induces the loss of the spin tran-

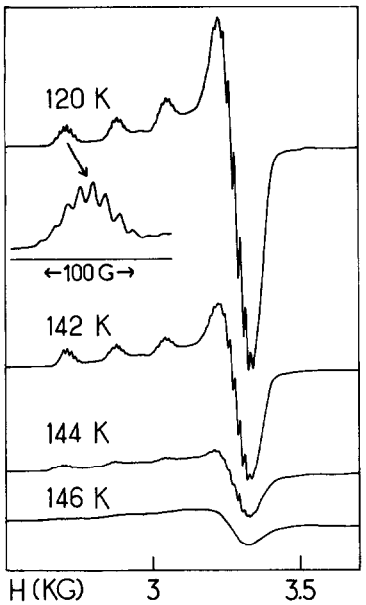

Fig. 4. EPR spectra of copper-doped Fe[$(MCS)_2(btr)_2$] (H_2O), at increasing temperatures.

sition behaviour as described above. Both at room temperature and at 77 K only a broad signal was observed around $g = 2$. At 77 K only very weak hyperfine splitting was observed, as shoulders on the broad signal, with $g = 2.3$ and $A = 165$ G. Furthermore an absorption appears at $g = 4.3$, which has also been observed in the unperturbed sample at room temperature.

These results clearly confirm the conclusion that the superhyperfine and hyperfine structures can be observed in the EPR spectra of the copper dope of $[Fe(NCS)_2(btr)_2](H_2O)$, because of the diamagnetic character due to the low-spin state of the host lattice.

The magnetic susceptibility curves for the manganese(II)-doped sample also closely resemble those of the pure compound. $T_c\downarrow$ is slightly lower, 120.5 K, and the hysteresis effect seems to be larger. A lowering of T_c is generally observed for doped compounds exhibiting a temperature-induced spin transition.[1,26–29] The variable temperature powder EPR spectra of the manganese(II) dope show only very broad signals above T_c, whereas small but abrupt changes occur at T_c. The spectrum is sharpened, though still not well resolved, in the diamagnetic phase and is essentially constant in the whole temperature range below T_c.

Rao *et al.*[30] detected the HS ↔ LS transition with EPR spectroscopy on a guest ion, by preparing manganese-doped $[Fe(phen)_2(NCS)_2]$ and $[Fe(pic)_3]Cl_2 \cdot EtOH$ [pic = 2-(amino-methyl)pyridine]. A broadening of the EPR resonance lines at the transition temperature was observed. A linewidth vs temperature curve for the composition $[Mn_{0.01}Fe_{0.99}(pic)_3]Cl_2 \cdot EtOH$ yielded a maximum at the transition temperature. This effect was explained by assuming a longer lifetime for iron(II) high-spin states in the critical temperature region.

The present study shows that it is quite possible to detect the HS–LS transition in an iron compound by focusing on the EPR spectrum of a doping ion, which acts as a "spy" to get information about the spin state of the host lattice. Both divalent copper and manganese appeared to be useful, although the effect in the copper dope expressed more pronounced.

As is shown by Ozarowski *et al.*[21] this doping technique is also useful for the study of other systems. So, a comparable effect was described for copper(II) and manganese(II) dopes in [Fe(1-propyltetrazole)$_6$]$(BF_4)_2$, known to exhibit high-spin ↔ low-spin transition as well.[31,32] The changes of the EPR spectra indicated the existence of two different diamagnetic phases, depending on the cooling rate.

DESCRIPTION OF THE STRUCTURE

The description of the isomorphic analogous cobalt compound,[11] already showed that the coordination around iron is a distorted octahedron with two thiocyanate N atoms *trans* to each other. The now found distances are Fe—NCS 2.125(3) Å and Fe—N(ligand) 2.180(3) and 2.188(2) Å (Table 2). These last distances are at the lower part of the range of high-spin Fe^{II}—N(triazole ligand) distances (2.29–2.167 Å)[14] and in fact in the range (2.1–2.2 Å) of values of compounds of high-spin Fe^{II} that change to low-spin upon cooling.[33] An ORTEP drawing of the structure showing the relative position of the iron atoms in the two-dimensional grid, the numbering of the atoms in the asymmetric unit and the hydrogen bonding between the water molecule and the ligand is shown in Fig. 5.

Compared with the isomorphic cobalt(II) compound the Fe—N distances are 0.03–0.05 Å longer which is quite normal. Compared with other two-dimensional iron(II) compounds of triazoles with *trans*-NCS^- ions, it is found that the mean distance is about the same or less: in $[Fe(NCS)_2(1,2,4\text{-triazole})_2]$[34] 2.15 and 2.24 Å, in $[Fe(NCS)_2(tp_2)]$ (tp = [1,2,4]triazolo[1,5-*a*]pyrimidine)[35] 2.25 and 2.33 Å. These two compounds do not change their spin state on cooling, although geometry and ligand type are the same. The difference can be explained by the fact that in these two compounds the triazole rings are *bidentate*, whereas in the btr compounds each triazole ring coordinates to only one metal

ion. The electronic effect of a second metal ion diminishes the strength of the ligand just enough to prevent spin change.

The compound differs further from the isomorphous cobalt compound by the fact that the sulphur atoms of the thiocyanate groups are not disordered. The Fe—N—C angle is 153.7(3)°, which deviates even more from 180° than in the cobalt compound. However, in all other characteristics the two structures are essentially the same, even in the hydrogen bonding system between the water molecule and the non-coordinating nitrogens of the btr ligand. As the cobalt compound is not easily dehydrated *in vacuo* one may conclude that the easy dehydration of the iron compound is caused by a structural phase change accompanying the spin transition that causes the crystals to crack and on warming up to pulverize. The dehydration occurs from the pulverized high-spin phase.

CONCLUDING REMARKS

As already observed with several compounds[1,36,37] the spin transition vanishes upon removal of lattice water of crystallization. As discussed above, removal of part of the water molecules results in partial spin transition.

To obtain more insight into the mechanism of the spin transition, the cooperative effect playing a rôle in it, it would be worthwhile to further investigate this compound. One might study the influence of Co^{2+} substitution on the transition behaviour. Insight into the interaction of the water molecules with the bridging ligands might be obtained if (crystalline) preparations of the same compound without water or with other solvent molecules (methanol, ethanol) were successful.

It appeared to be possible to get monocrystals seemingly intact through the spin transition into the low-spin phase, however, when mounted for a single crystal experiment no single crystal reflections could be obtained. On warming up to room temperature the crystals appear to be transformed to powder. This behaviour indicates that a crystalline phase transition accompanies the spin transition. At the same time it does not exclude that an intermediate unstable diamagnetic phase may be present for a short time after (rapid) cooling as suggested by Ozarowski *et al.*[21]

As shown above, detecting spin transition via EPR spectroscopy was not restricted to ligand-bridged compounds. In fact, the limiting factor seems to be the preparation of real dopes of the probe ions (Cu^{2+}, Mn^{2+}) in the iron compound lattice; the existence of compounds of copper(II) or manganese(II) isomorphous to the iron(II) compound to be doped is not essential. It is worthwhile to investigate whether this technique is also valid for iron thiocyanate compounds with the more common *cis*-configuration of the thiocyanate anions, especially of those of which detailed crystal structure analyses above and below T_c are available. If the EPR spectrum changes at T_c this method might give valuable information on the environment of the iron atoms above and below the transition temperature.

Abstract—Two new Schiff bases (SMPDH and SBPDH) of S-methyl- and S-benzyl-dithiocarbazate with 2-pyridinecarboxaldehyde N-oxide were prepared and confirmed by elemental analyses and IR spectra. Four copper(II) complexes of the above two Schiff base ligands with imidazole and pyridine were obtained and characterized spectroscopically. The crystal structure of $[Cu(SMPD)ImH]ClO_4$ was determined by X-ray diffraction analysis. The geometry of the copper atoms in these complexes is square planar with an unsymmetrical environment.

Transition metal ion complexes of ligands containing sulphur and nitrogen as donor atoms in Schiff bases were extensively studied, owing to their certain antitumour, antimalarial and antibacterial activity.[1–3] These types of ligand are commonly the products derived from the Schiff base condensations of S-alkylhydrazine carbodithioate and S-alkyldithiocarbazate with some ketones and aromatic aldehydes.[4] Here we report two new tridentate ligands of the above class via the condensation of S-R-dithiocarbazate with 2-pyridinecarboxaldehyde N-oxide (R = methyl, L = SMPDH; R = benzyl, L = SBPDH). A number of metal complexes with these two ligands were prepared and characterized by magnetic properties, UV and IR spectra, as well as elemental analyses, and crystal structures of some complexes have been determined by X-ray diffraction. As part of our series, four copper(II) complexes are studied in this paper.

EXPERIMENTAL

Preparation

(1) *Ligands.* 2-Pyridinecarboxaldehyde N-oxide,[5] S-methyldithiocarbazate[6] and S-benzyldithiocarbazate[7] were prepared and confirmed by elemental analyses.

A solution of S-R-dithiocarbazate (20 mmol) in absolute ethanol (50 cm^3) was added to a hot solution of 2-pyridinecarboxaldehyde N-oxide (20 mmol) in absolute ethanol (50 cm^3). The mixture was stirred and refluxed for 30 min, then cooled to room temperature and filtered. Yellow crystals were obtained and recrystallized from hot ethanol.

(2) *Complexes.* All copper(II) complexes were prepared by the following method: a solution of ligand (1 mmol) and $Cu(ClO_4)_2 \cdot 6H_2O$ in ethanol (60 cm^3) was refluxed for 5 min, then imidazole or pyridine (2 mmol) in ethanol (10 cm^3) was added. After refluxing for 10 min, the mixture was filtered when hot. The filtrate was then kept at room temperature and green crystals were obtained.

Measurements

UV spectra were recorded using a Shimadzu 240 spectrophotometer. IR absorption spectra from 4000 to 400 cm^{-1} were obtained on a 170SX FT–IR instrument, with samples prepared as solid KBr pellets. Magnetic susceptibility measurements were carried out in the solid state at room temperature (283.2 K) using a Gouy balance with $[Ni(en)_3]S_2O_3$ as calibrant. Table 1 gives the elemental analyses and yields of the ligands and copper(II) complexes. Selected spectroscopic data and magnetic moments for the complexes are shown in Table 2.

Crystallographic analysis

Single cystals of [Cu(SMPD)ImH]ClO_4 were obtained by a diffusion method in an acetonitrile and ether system. A dark green crystal ($0.2 \times 0.4 \times 0.6$ mm) was used for data collection. Unit cell and intensity data were obtained using a R3M/E four-circle diffractometer and graphite-monochromatized Mo-K_α radiation, ω–2θ scan mode. Data correction for Lorentz and polarization factors was made, but not for absorption effects. The structure was solved by direct methods, refinement was by full-matrix least-squares cal-

culations, initially with isotropic and later with anisotropic thermal parameters. All hydrogen atoms were located on the difference Fourier map. Crystal data are given in Table 3.

Lists of atomic coordinates, thermal parameters, calculated hydrogen coordinates and torsion angles have been deposited as supplementary material with the Editor, from whom copies are available on request.

RESULTS AND DISCUSSION

The corrected magnetic moments for all of the complexes at room temperature are within the normal values for copper(II) complexes in a square planar tetracoordinated environment. The *d–d* bands in the electronic spectra exhibit broad absorptions in the range 16,660–17,250 cm^{-1}, consistent with those of the square copper(II) complexes reported by Ali and Tarafdar,[7,8] the other absorptions at approx. 19,000 cm^{-1} may be shielded by the charge-transfer absorptions of the ligands.

In the IR spectra of two ligands, medium bands at 3100–3106 cm^{-1} are assigned to ν(N—H). Due to the existence of conjugation in the molecule, the vibration of the C=N bond moves to lower wavenumbers compared with that of the C=N bond in general Schiff bases; both SMPDH and SBPDH have a very strong band at 1480–1485 cm^{-1} assigned to ν(C=N). Two strong bands appearing in the ranges 1221–1231 cm^{-1} and 870–880 cm^{-1} are assigned to the ν(N—O) and δ(N—O) modes, which are in agreement with those of similar ligands.[9] Bands which are considered to derive some intensity from the C=S bond appear at approx. 1090 cm^{-1}.

In the IR spectra of the complexes, the ν(C=N) and ν(N—O) frequencies of the ligands decreased by *ca* 45–56 cm^{-1} and 17–31 cm^{-1}, respectively, upon complex formation, indicating the co-ordinated nitrogen atom of the C=N bond and oxygen atom of the N—O bond. In comparison with the free ligands, ν(C=S) disappears, whereas ν(C—S) appears at approx. 1045 cm^{-1}, which shows the coordinated ligand is in the thiolate form, similar to analogous ligands.[6,10] All complexes have a very strong ν(Cl—O) absorption in the region 1060–1090 cm^{-1}. Complexes **3** and **5** produce a band at 3270–3335 cm^{-1}, which is assigned to ν(N—H) of the additive imidazole, different from that of the ligand which disappears when the complex forms.

The structure of [Cu(SMPD)ImH]ClO_4 is shown in Fig. 1, together with the atomic numbering scheme. Figure 2 is a view of the unit cell illustrating the molecular packing. Selected bond lengths and bond angles are given in Table 4.

The copper atom in one molecule is planar, tetracoordinated by the S(1), N(4) and O(1) atoms of the ligand and one nitrogen atom of the imidazole. The Cu—S, Cu—N and Cu—O distances fall in the normal range, and the N(1)—Cu—O(1), O(1)—Cu—N(4), N(4)—Cu—S(1) and S(1)—Cu—N(1) bond angles are 87.5, 91.1, 86.2 and 95.1°, respectively.

Like other copper(II) complexes of pyridine N-oxide, the O(1) atom is not only coplanar with the binding pyridine group, but also has a normal O(1)–

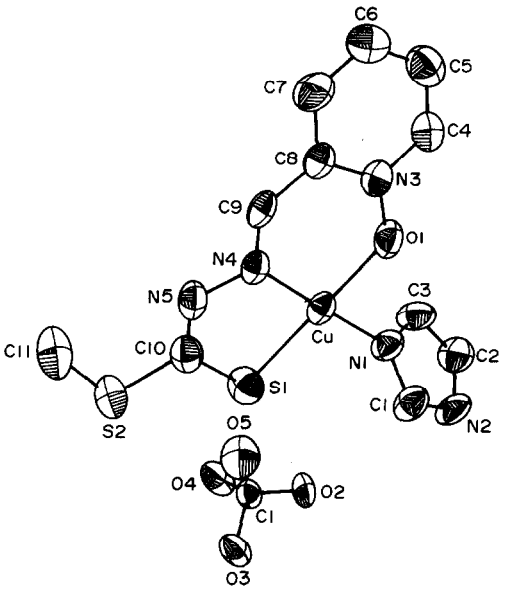

Fig. 1. The structure of $[Cu(SMPD)ImH]ClO_4$.

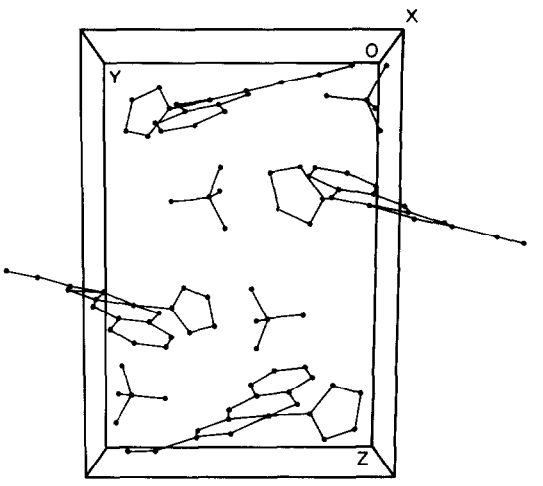

Fig. 2. View of the unit cell illustrating the molecular packing.

N(3) bond length (1.312 Å).[11] The O(1)—N(3), N(3)—C(8), C(8)—C(9), C(9)—N(4), N(4)—N(5), N(5)—C(10) and C(10)—S(1) bond lengths indicate that all these atoms are conjugated with each other via the pyridine group. Two least-squares planes composed of CuN(4)C(8)C(9)N(3)O(1) and CuN(4) N(5)C(10)S(1) are parallel to each other, but almost perpendicular to the imidazole ring to decrease spatial repulsion. The whole molecule has low symmetry, resulting from the presence of the large imidazole group which leads to a longer distance between molecules and prevents possible

dimer formation via the potential bridging group O(1) atom or S(1) atom of the ligand.

It is expected that the ligand is deprotonated to be uninegative on complex formation and the crystal structure of the complex confirms this.

SOME ACTINIDE COMPLEXES OF PYRIDIN-, PYRROL-, FURAN- AND THIOPHEN-ALDAZINE SCHIFF BASES*

MAHMOUD M. DAWOD, FAWWAZ I. KHALILI and AFIF M. SEYAM†

Department of Chemistry, University of Jordan, Amman, Jordan

(*Received* 11 *April* 1990; *accepted* 29 *August* 1990)

Abstract—Actinide chloride complexes with pyridinaldazine (PAA), pyrrolaldazine (PyAA-H_2), furanaldazine (FAA), and thiophenaldazine (TAA): $An(L)Cl_n \cdot m\text{-}H_2O$, where An = Th, UO_2; L = PAA, PyAA-H_2, FAA, TAA; $n = 2, 4$; $m = 0, 2, 3, 5$ (also, mononuclear with 2L, dinuclear and trinuclear complexes) have been prepared by the reaction of $ThCl_4$, UO_2Cl_2 or $UO_2(Ac)_2 \cdot 2H_2O$ with PAA, PyAA-H_2, FAA or TAA and characterized by spectral data, electrical conductance, thermal and elemental analysis.

Recently, we reported the synthesis and characterization of some lanthanide chloride complexes of pyridinaldazine and pyrrolaldazine Schiff bases.[1] It has been found that pyridinaldazine (PAA) and pyrrolaldazine (PyAA-H_2) form metal complexes of different stoichiometries.[1,2] Transition metal complexes of PAA[2], furanaldazine (FAA)[3,4] and thiophenaldazine (TAA)[4] are reported. In the complexes of FAA and TAA with transition metals, they behave in a monodentate fashion.[4] In this paper, we report the synthesis and characterization of some actinide complexes of PAA, PyAA-H_2, FAA and TAA.

EXPERIMENTAL

Physical and analytical measurements

Proton nuclear magnetic resonance (^{1}H-NMR) spectra were recorded on a varian T-60A spectrometer in methanol-d_4. Chemical shifts are reported relative to internal $Si(CH_3)_4$. IR spectra were recorded on a Perkin–Elmer (577) spectrometer as KBr discs or Nujol mulls pressed between two NaCl discs or two polyethylene sheets. Conductivity measurements were carried out using 10^{-3} M solution in methanol on a Philips PW 9059 digital conductivity meter at 25°C. UV–vis spectra were recorded on a Beckman Du-7 spectrophotometer. Thermogravimetric analyses (TGA) were recorded on a Mettler TG 10A TA processor using a Mettler Tg-50 thermobalance. Microanalyses were performed by Dr Franz Pascher/ Ellen Pascher Microanalysis laboratory (Bonn, F.R.G.). Thorium analyses were determined by titration with EDTA[5] after decomposition of the sample with HNO_3. The titration method was confirmed by analyses of the metals as the corresponding oxide. Uranium was determined as U_3O_8 using the ammonia method.[6] Chloride was determined gravimetrically as AgCl.[6]

Materials and methods

All procedures were performed using techniques for air sensitive compounds. Pyrrole-2-carboxyaldehyde (BDH) was purified by stirring over active carbon in methanol; pyridine-2-carboxyaldehyde (Fluka) and furan-2-carboxyaldehyde (Kock-Light) were purified as in the literature;[1,7] thiophene-2-carboxyaldehyde and hydrazine (Riedel- de- Haen) thorium tetrachloride, uranyl acetate dihydrate and uranyl chloride (BDH) were used without further purification. The ligands PAA, PyAA-H_2, FAA and TAA were prepared according to Stratton's method.[8]

Complexes with PAA, I

To a filtered solution of the metal salt, $ThCl_4$ or $UO_2(Ac)_2 \cdot 2H_2O$ (4.76 mmol) in methanol (15 cm^3), a solution of PAA (1.0 g, 4.76 mmol) in methanol (30 cm^3) was added (only 0.5 g, 2.38 mmol

of PAA in the case of U^{VI} salt). The mixture was stirred for 48 h in the case of Th^{IV}, and 3 h in the case of U^{IV} at room temperature to give the complex as a precipitate. The precipitate was filtered, washed with cold methanol and diethyl ether, and dried *in vacuo* over P_4O_{10}. Both complexes are insoluble in most common solvents but hydrolyse in water.

Complexes with PyAA-H_2, **II**

To a stirred solution of the metal salt, $ThCl_4$ or UO_2Cl_2 (2.38 mmol) in a mixture of methanol–acetone (1:4; 15 cm^3), a solution of the ligand PyAA-H_2 (2.38 mmol) in a mixture of methanol–diethyl ether (1:10; 30 cm^3) was added. The reaction mixture was stirred overnight to give the complex as a precipitate. The complex was filtered, recrystallized from a mixture of methanol–acetone–diethyl ether (1:3:5), washed with acetone and diethyl ether and dried *in vacuo* over P_4O_{10}. Both complexes are soluble in methanol and ethanol, and partially soluble in acetone, THF, DMF and water.

Complexes with FAA *and* 2-TAA, **III** *and* **IV**

To a hot solution of the metal salt, $ThCl_4$ or UO_2Cl_2 (3.54 mmol) in methanol (80 cm^3), FAA or TAA (3.54 mmol) was added. The reaction mixture was refluxed for 3 h in the case of FAA, and 48 h in the case of TAA, then cooled to 40°C and the solvent was removed *in vacuo*. The residue was washed with diethyl ether (2 × 50 cm^3). The residue was extracted with THF (4 × 50 cm^3) at 40°C and the solvent was removed *in vacuo* to give the complex. The complexes are soluble in DMF, methanol and ethanol, and partially soluble in THF and acetone, but hydrolyse in water.

RESULTS AND DISCUSSION

The new actinide complexes of PAA, PyAA-H_2, FAA and TAA (Table 1) were prepared and characterized. Work-up procedures involved filtration and crystallization; yields are generally high (45–87%). The complexes gave satisfactory analytical data (Table 1). The complexes are air stable, usually yellow-coloured microcrystalline solids, complexes **II–IVa,b** are soluble in methanol and ethanol, and partially soluble in tetrahydrofuran and acetone, whilst complexes **Ia,b** are insoluble in most common solvents. Complexes **Ia,b**, **IIIa,b** and **IVa,b** hydrolyse in water, whilst **IIa,b** are soluble in water. Elemental analysis showed that the ratio of metal–ligand in the complexes is 1:1, except in complex **IIb** it is 1:2, and in complexes **IIa** and **IVb** it is 3:2.

TGA data (Table 1) show that water of hydration is lost around 95°C and helps in assigning the number of water molecules of hydration in these complexes. Conductivity data (Table 2) show that these

[b] Y = O, S.

complexes behave as 1 : 2 electrolytes in methanol, whilst complex **IIIb** behaves as a 1 : 1 electrolyte.

^{1}H NMR (Table 2) of the complexes shows that the resonances are as expected for diamagnetic Th^{IV} and U^{VI} species. The presence of tetrahydrofuran in complex **IIIa** was confirmed by ^{1}H NMR as a multiplet at δ 3.7 ppm and a multiplet at δ 1.8 ppm, whilst complex **IIIb** shows a quartet at δ 1.3 ppm (methyl protons of Et_2O) indicating the presence of diethyl ether.

UV–vis data (Table 2) show that the electronic spectra of the complexes are dominated by ligand absorption bands with a hyperchromic effect, this is similar to what has been observed with Ln^{3+}[1] with PAA and PyAA-H_2.

IR data (Table 3) for the complexes **Ia**, **IIIa**, **IIIb** and **IVa** show a distinct splitting of the C=N group stretching bands and of the ring breathing vibrational bands characteristic of the tridentate ligand. The ligand is coordinated through the heteroatoms of the two rings and one nitrogen of the C=N groups. In complex **Ib**, the ligand PAA acts as a tetradentate one, to two uranyl ions, and due to the different environment around each uranyl ion {a bidentate acetate group to one uranyl ion [ν_{as}(COO) at 1550, ν_s(COO) at 1445 cm^{-1}] is suggested which is in accord with the literature[9]}, a splitting of the C=N group stretching bands and of the ring breathing vibrational bands occurs. A similar situation exists in complexes **IIa** and **IVb**, but the environment of the two heterocycles in each ligand is the same, so there are no changes in the ring breathing vibrational bands. The uranium complex of PyAA-H_2 (**IIb**) shows a splitting of the C=N vibrational bands similar to PyAA-H_2·HCl, with changes in the ring breathing vibrational band and the N—H stretching vibrational band. All this suggests that the ligand PyAA-H_3^+ is acting as a monodentate ligand probably through the pyrrole nitrogen.

The uranyl stretching vibration of complexes **I**–**IVb** gave rise to a very strong-intensity absorption at 928 or 915 cm^{-1}.[10] In the U^{VI} complex (**Ib**) a very strong band is observed at 1325 cm^{-1} which can be assigned to a bridging hydroxyl group,[11] and this might explain at least the dimeric nature of this complex.

Therefore, suggested formulae (Table 1), based on spectral data, electrical conductance, thermal and elemental analysis, show that in complexes **II**–**IVa** and **IVb** the coordination number is eight, whilst for complexes **Ia** it is nine, **Ib** and **IIb**, seven, and for **IIIb** it is six, and this is expected for the actinides.[12]

B

Barium
cryptand complex, 1143
diaminepolycarboxylate complex, 2693
mixed metal oxides, 1615
tetracycline complexes, 189
Benzene complexes
chromium, 1589
chromium(0), 1135
Benzenethiolate, indium, 763
Benzil complexes
molybdenum(VI), 2915
Benzoates
cobalt(II), copper(II), 2395
lanthanides, 555
molybdenum(VI), 2915
nickel(II), 2395
titanium(IV), 1844,1846
Benzo-15-crown-5 complex
thallium(I), 2115
Benzohydroxamate complexes
molybdenum(IV), 29
Benzoin complexes
molybdenum(VI), 2915
Benzoin oxime complexes
molybdenum(VI), 2473
Benzonitrile complexes
rhenium(I), 1872
Benzophenone, 653
Benzoquinonedioxime complexes
ruthenium(II),(III), 851
Benzotriazole complexes
antimony(III), 581
N-Benzoylalaninate, -glycinate, -leucinate, -valinate complexes, nickel(II), 1329
Benzyls
nickel(II), 285,2449

tantalum(V), 341
zirconium, 77
6-Benzyl-2,2'-dipyridyl, 6-benzyl-4,4'-dimethyl-2,2'-dipyridyl complexes, zirconium, 77
Benzylisocyanide complexes
tungsten(II), 827
6-Benzyl-1,10-phenanthroline complexes, zirconium, 77
Beryllium
aminoacid hydroxide complexes, 2017
iodate water complex, 357
tetracycline complexes, 189
Bicarbonate complexes
cobalt(III), 2389
Bicyclo-2,2,1-hepta-2,5-diene complexes, rhodium(I), 167
Biguanidine complexes
copper(II), 7
Binucleating pentadentate ligand, copper(II) complex, 2513
Biomineralisation, iron oxides, 149
Biphasic catalysis, review, 407
2,2'-Bipyrazine complexes
molybdenum(0), 921
ruthenium(II), 2615
3,3'-Bipyridazine complexes
molybdenum(0), 921
ruthenium(II), 2615
2,2'-[&4,4'-]Bipyrimidine complexes, molybdenum(0), 921
1,4-Bis(2-butyltellurophenyl)-2,3-diazabuta-1,3-diene complexes
Pd(II), Pt(II), 2769
1,6-Bis(2-butyltellurophenyl)-2,5-diazahexa-1,5-diene complexes
Pd(II), Pt(II), Rh(I), 2769
Bis(3-dicyclohexylphosphino)propyl(phenyl)phosphine complexes
iridium, 1903
Bis(2-diethylaminoethyl)amido complexes, Cr(III), Ti(III), V(III), 1457
1,2-Bis(diethylphosphino)ethane complexes, Cr(II), 1821
Bis(2-diethylphosphinoethyl)-amido complexes
vanadium(III), 1339,1767
zirconium(IV), 1767
Bis(2-diethylphosphinoethyl)phosphido complexes, Zr(IV), 1767
1,2-Bis(dimethylarsino)benzene complexes, osmium(I), 1537
Bis(2-dimethylarsinoethyl)amido complexes, zirconium(IV), 1767
Bis-3-(dimethylphosphino)dipropylamine complexes
Ni(II), Pd(II), Pt(II), 25
1,2-Bis(dimethylphosphino)ethane complexes
chromium(II), 1821
nickel(II), 1069
niobium(I), 1784
rhenium(V), 959
technetium(V), 1879
titanium(0), 1611
vanadium(II),(IV), 1784
zirconium, 1601
Bis(2-dimethylphosphinoethyl)-amido complexes
vanadium(III), 1339,1767
zirconium(IV), 1767
Bis(2-dimethylphosphinoethyl)-phosphido complexes
zirconium(IV), 1767
Bis(4,6-dimethylpyridylimino)isoindoline complexes, Mo(II), 2359
1,2-Bis(diphenylarsino)ethane complexes, Re(II),(III), 1733
Bis(diphenylphosphino)amine complexes, palladium(I), 1045
1,2-Bis(diphenylphosphino)benzene complex, rhenium(V), 1689
1,4-Bis(diphenylphosphino)butane complexes
nickel(0), 13
platinum(II), 433
1,2-Bis(diphenylphosphino)ethane complexes
cobalt(II), 749
molybdenum, 1595
molybdenum(0), 1463,1810,2599
molybdenum(II), 1751,2599

rhenium, 1595
rhenium(I), 1872
ruthenium, 695
technetium(I), 1201
tungsten, 1595
vanadium(II),(IV), 1784
Bis(2-diphenylphosphinoethyl)phenylphosphine complexes, molybdenum(II),(IV), 1756
1,1'-Bis(diphenylphosphino)ferrocene complexes, Pt(II), 433
Bis(diphenylphosphino)methane complexes
aluminium, 1497
cobalt(II), 749
molybdenum(0), 1810
nickel(0), 13
osmium(I), 1537
platinum(II), 433
rhenium(II),(III),(IV), 1689
1,3-Bis(diphenylphosphino)propane complexes
cobalt(II), 749
nickel(0), 13
platinum(II), 433
Bis(diphenylphosphinoyl)methane complexes, aluminium, 1497
Bis[(diphenylphosphinyl)methyl]-phenylphosphine oxide complexes, Mo(0), W(0), 627
1,2-Bis(di-*i*-propylphosphino)ethane complex, Ir(III), 1945
Bis(2-di-*i*-propylphosphinoethyl)-amido complexes, Zr(IV), 1767
Bis(di-*i*-propylphosphino)methane complexes, platinum(II), 2169
1,3-Bis(2-hydroxyphenyl)propane-1,3-dionate complexes, Cd, Co(II), Ni(II), Zn, 2743
Bis(3-hydroxypropyl)thiourea, 1891
1,3-Bis(1-methylcyclohexyl)cyclopentadienyl complex, W(II), 1804

1,7-Bis(5-methyl-4-imidazolyl)2,6-dithiaheptane complexes, Co, Cu, Mn, Ni, 1965
Bis[2-(1-methylimidazolyl)methyl]-amine complex, copper(II), 659
Bismuth(III)
arylamide, 1579
carboxylate, 2941
diimine halide complexes, 2937
dithiocarbamates, 1891
dithiophosphate, 483
phosphonate complexes, 1307
Bis(phosphiranyl)oxide complexes
tungsten(0), 2671
Bis(pyridylimino)isoindoline complexes, molybdenum(II), 2359
2,3-Bis(2-pyridyl)pyrazine complexes, ruthenium(II), 2615
3,6-Bis(2'-pyridyl)-1,2,4,5-tetrazine complex, molybdenum(0), 921
1,9-Bis(2-pyridyl)-2,5,8-triazanonane complexes, copper(II), nickel(II), 909
Bis(triaza)diphosphine complexes
platinum(II), 2485
N-Bis(trifluoromethyl)nitroxyiminophosphine, 379
Bis(trimethylsilyl)cyclopentadienyl complexes,
hafnium(IV), 1774
niobium(IV), 1848
titanium(III), 1883
zirconium(III), 1882
zirconium(IV), 1774
Bis(trimethylsilyl)methyl complexes, La, Lu, 1850
Bis(triphenylphosphonium)methane salt, 1293

molybdenum(IV) amine phenoxide complex, 1971
molybdenum(IV) cyclopentadienyl mercaptopyridine complex, 2439
molybdenum(IV) cyclopentadienyl tetraselenide complex, 1999
molybdenum(IV) thio niobium(IV) complex, 1762
molybdenum(V,VI) methoxide oxo isopolyanion, 537
molybdenum(VI) alkoxide carboxylate dienolate diketal hydroxide oxo complexes, 2915
molybdenum(VI) alkoxide oxo complex, 1213
molybdenum(VI) benzoin oxime oxo salicylaldoxime salicylhydroxamate complexes, 2473
molybdenum(VI) carbazone chloride oxo thiocarbazone complexes, 677
molybdenum(VI) diolate oxo complex, 519
molybdenum(VI) erythritol oxo complexes, 1571
molybdenum(VI) oxo peroxide water complexes, 541
molybdenum(VI) oxo triamine cobalt(II) iron(III) complexes, 1675
neodymium diketonate hydroxide complex, 2183
nickel(0) carbonyl phosphine complex, 1351
nickel(II) acetate polypyridine helical complex, 2551
nickel(II) alkyl pyridine cyclometallated complex, 1069
nickel(II) aminoacid water complexes, 1329
nickel(II) aminoethanethiolate, 2837
nickel(II) benzyl phosphine complexes, 2449
nickel(II) carboxylate water complexes, 39
nickel(II) diimine nitrate water complexes, 689
nickel(II) methanol salicylaldimine complex, 2321
nickel(II) nitrate oxime pyridine complex, 305
nickel(II) phenanthroline complex, 2649
nickel(II) thiolate, 1253
nickel(II) thiosemicarbazonate, 727
niobium(IV) cyclopentadienyl thio molybdenum(IV) complex, 1762
niobium(V) alkylimide chloride cyclopentadienyl, 1819
niobium(V) hydride phenoxide complex, 1607
niobium(V) thio thiophenoxide complex, 1797
osmium alkynyl carbonyl tungsten complex, 2003
osmium carbonyl thio complex, 1437
osmium(II) diimine complex, 367
osmium(VI) carboxymethyl methoxide oxo complex, 597

palladium(I) chloride diphosphine complex, 1045
palladium(II) chloride nitrite phosphine complexes, 161
palladium(II) chloride phosphine thiolate complexes, 2151
palladium(II) chloride sulphurdiimide complex, 91
palladium(II) diimine phosphine complex, 1989
palladium(II) polytelluride complex, 701
phosphaalkene, 2087
phosphonium salts, 1039,1293
phosphorane iminato complexes, 716
phosphorus(V) aminoacid fluoride phenyl compounds, 731
platinum alkylidyne carbonyl Fe(II) Mo complex, 2265
platinum(0) carbonyl diene iron(0) complexes, 2521
platinum(II) amido phosphine complexes, 1979
platinum(II) aryl dipyridyl binuclear complex, 2209
platinum(II) arylamide phosphine complex, 2507
platinum(II) bis(triaza)diphosphine chloride phosphine complex, 2485
platinum(II) chloride diphosphine phosphidophosphine complexes, 2169
platinum(II) cyanide disulphurdiimide complexes, 841
platinum(II) phosphine selenium - nitrogen complexes, 2215
platinum(II) phosphine telluro complex, 701
platinum(II) phosphine thionylimino complex, 835
platinum(IV) bromide phosphine complex, 893
platinum(IV) chloride phosphine sulphur - nitrogen complex, 997
polyselenide complexes, 1995
potassium crown ether complex, 2051
potassium crown ether iron(II) complex, 879
potassium thioethercarboxylate, 2147
rhenium(I) chloride diphosphine nitrile complex, 1872
rhenium(II),(III) chloride diarsine complexes, 1733
rhenium(V) chloride methyl oxo phosphine complex, 959
rhenium(VI) alkylimide, 2657
rhenium(VII) alkylimido aryl chloride siloxide complexes, 2657
rhodium(I) carbonyl chloride complex, 2119
rhodium bromide nitrosyl phosphine complex, 2565
rhodium(I) chloride diphosphine phosphine complex, 1575
rhodium(I) cyanide phosphite complex, 2415
rhodium(I) diene diphosphine zirconium(IV) complex, 1760
rhodium(I) diene perrhenate complex, 375
rhodium(II) acetate diketonate pyridine complex, 1117
rhodium(II) carbonyl chloride triphosphine complex, 2119
rhodium(III) bromide nitrate phosphine complex, 2565
rhodium(III) chloride hydride phosphine thioether thiolate complexes, 613
rhodium(III) phenyl phosphine quinaldinate trifluoroacete water complex, 2727
ruthenium alkyne carbonyl phosphine thio complexes, 1123
ruthenium alkynyl carbonyl tungsten complex, 2003
ruthenium carbene carbonyl thio tungsten complex, 2351
ruthenium carbonyl diphosphine vinyl tungsten complex, 695
ruthenium(II) acetate carbonyl complex, 597
ruthenium(II) pyridine quinone oxime complex, 103
ruthenium(II,III) acetate phosphine oxide complex, 2571
samarium(II) cyclopentadienyl ether complexes, 1007
silver(I) amine thioether macrocyclic complex, 2951
silver(I) crown thioether complexes, 513
silver(I) polyselenide complexes, 1139
silver(I) polysulphide complex, 2379
sodium phosphine oxide thiocyanate complexes, 215
tantalum(V) alkyl amido imido imine iminoacyl phenoxide complexes, 341
technetium(II) chloride diimine complexes, 1879
technetium(V) diimine diphosphine halide nitride complexes, 1879
thallium(I) carboxylate carboxylic acid thioether complex, 793
tin(II) catechol ether complex, 2933
tin(IV) alkyl chloride dithiocarbamate complex, 1413
tin(IV) chloride phenyl vanadium(IV) complexes, 1753
tin(IV) phenyl thiocyanate complex, 1897
tin(IV) tetraselenide complex, 1999
titanium(III) carbonyl chloride complex, 1883
titanium(III) chloride cyclopentadienyl complexes, 1780
titanium(III) chloride ether complex, 2013
titanium(IV) carboxylate carboxylic acid chloride oxo complexes, 1841
titanium(IV) chloride

cyclopentadienyl oxo pyridine complex, 1804
titanium(IV) cyclopentadienyl ether hydroxide methyl water complexes, 1838
tungsten carbonyl chloride cyclopentadienyl phosphinoalkenyl complex, 1807
tungsten carbonyl cyclopentadienyl vinyl ruthenium complex, 695
tungsten carbonyl thio ruthenium complex, 2351
tungsten(0) carbonyl cyclopentadienyl antimony complex, 2495
tungsten(0) carbonyl phosphine thioether complex, 1876
tungsten(0) carbonyl phosphirane complex, 2671
tungsten(II) chloride phosphine complex, 1261
tungsten(III) alkylidyne carbonyl cyclopentadienyl methyl complex, 2035
tungsten(IV) alkene arylimido carbonyl chloride oxo phosphine complex, 1261
tungsten(VI) alkylimido amine sulphonate complex, 2947
tungsten(VI) alkylimido arylimido chloride oxo complexes, 1788
tungsten(VI) bromide hydroxide oxo triamine complexes, 1675
uranium(IV) phenoxide, 1247
uranium(VI) ketophosphonate nitrate oxo complexes, 1357
vanadium(II) acetic acid chloride water complexes, 1823
vanadium(III) alkylamido phenyl complex, 1457
vanadium(III) cyclopentadienyl thio complex, 2763
vanadium(IV) chloride oxo thione water complex, 87
vanadium(IV) oxo salicylaldimine tin(IV) complexes, 1753
ytterbium benzoate pyrazolylborate, 551
ytterbium cyclopentadienyl phosphine oxide complex, 1983
yttrium acetate hexadentate macrocycle water complexes, 1923
yttrium tetramine thiocyanate macrocyclic complex, 2157
zinc methoxide nitrate pyrrolidone mercury complexes, 1913
zirconium alkyl alkylamido borohydride chloride cyclopentadienyl diphosphine iminoalkene phenoxide complexes, 1601
zirconium alkyl cyclopentadienyl rhodium(I) complex, 1760
zirconium carboxylate chloride cyclopentadienyl complex, 929
zirconium diimine phenoxide complex, 77
zirconium phenoxide pyrazolylborate complex, 845
X-ray diffraction
aluminophosphates, 819
beryllium iodate water complex, 357
cadmium mercury borates, 1567
clay minerals pyrolysis, 2709
copper(II) acetate oxime pyridine water complex, 1077
ferrihydrite - goethite conversion, 149
iridium(III) chloride pyridine complex, 2245
magnesium hydroxide nitrate, 1061
molybdenum cyanide nitrosyl complexes, 2897
vanadium(IV) oxo Schiff base complexes, 1790
2,6-Xylylmethylidyne complexes
Cr, Fe, Mo, W, 179

Y

Ytterbium
carboxylate pyrazolylborate, 555
chloride pyridine pyrrole Schiff base water complexes, 21
crown ether complex, 1561
cyclopentadienyl ether indenyl complexes, 17
cyclopentadienyl furfuralkoxide salicylaldehydate complexes, 2109
cyclopentadienyl phosphine oxide complex, 1983
formylferrocene benzoylhydrazone complex, 2105
oxalate pyrazolylborate, 2367
polyaminepolycarboxylate, 1425
pyrazolylborate tropolonate complexes, 117
Yttrium(0)
arene complexes, 1641
Yttrium(III)
acetate hexadentate macrocycle water complexes, 1923
carboxylate pyrazolylborate, 555
coordination numbers, 2431
formylferrocene benzoylhydrazone complex, 2105
nitrate pyridine Schiff base water macrocyclic complex, 1217
oxalate pyrazolylborate, 2367
tetramine thiocyanate macrocyclic complex, 2157

Z

Zeolite, molybdenum(V)
dithiocarbamate in, 1817
Ziegler - Natta catalysis, 1867
Zinc
amide cytosine halide phosphine oxide urea complexes, 1093
chloride pyridine complexes on silica gel, 2901
chloride theobromine complex, 2593
diaminepolycarboxylate dicarboxylate complexes, 2693
diisocyanide complex, 317

diketonate pyridine complexes, 2743
diketonate thiodiketonate water complexes, 2305
dithiocarbamates, 1891
insulin complexes, 2065
methoxide nitrate pyrrolidone mercury complex, 1913
phosphonate complexes, 1307
polyselenide complexes, 1995
pyridinedicarboxylate complexes, 745
Zirconium(0)
arene carbonyl complexes, 1641
carbonyl triphosphine complexes, 1611
Zirconium(III)
alkyl chloride cyclopentadienyl fulvalenide hydride phosphinoalkyl complexes, 1758
alkylphosphido cyclopentadienyl complexes, 1774
chloride cyclopentadienyl ether phosphine complexes, 1882
Zirconium(IV)
alkoxide cyclopentadienyl methyl Nb(III) Ta(III) complexes, 2189
alkyl alkylamido borohydride chloride cyclopentadienyl diphosphine iminoalkene phenoxide complexes, 1601
alkyl cyclopentadienyl phosphinoalkyl complex, 1758
alkyl cyclopentadienyl rhodium(I) complex, 1760
alkyl diimine phenoxide complexes, 77
alkylphosphido cyclopentadienyl diphosphanate triphosphanate complexes, 1774
carboxylate chloride cyclopentadienyl complex, 929
chloride diphosphinoamido diphosphinophosphido complexes, 1767
chloride ether salicylaldimine complex, 1717
cyclopentadienyl metallathiazenes, 1729
diaminopolycarboxylate complexes, 1365
dicarboxylate peroxide pyridine-*N*-oxide complex, 977
edta peroxide phosphine oxide succinate complexes, 109
hydroxycarboxylate oxalate peroxide complexes, 1371
phenoxide pyrazolylborate complexes, 845
phthalocyanine, 1631
