Fig. 10. CISD/DZ energies of the ground state and the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited states of trisilane and n-tetrasilane as a function of the SiSiSi valence angle θ, relative to the energy of the ground state at $\theta = 111.2°$.

to 100° from the equilibrium value of 111.2°. As expected from the behaviour of molecular orbital energies just described, as θ is increased, the energy of the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excited state of both compounds decreases and that of the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited state increases.

In trisilane, the CISD/DZ calculation predicts the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited state to be 2 kcal mol^{-1} lower in energy than the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excited state at $\theta = 100°$, and the opposite ordering with $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excited state lower in energy by 9 kcal mol^{-1} at $\theta = 130°$. In *trans*-n-tetrasilane, the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excited state is predicted to be below the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited state at all valence angles considered here and the separation between the two states increases from 1 to 22 kcal mol^{-1} as θ is increased from 100 to 130°. These results suggest that in the first $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excited state, oligosilanes and most likely also the chromophoric segments of polysilanes have a tendency to become longer by increasing θ.

Previous INDO/S calculations[26] on parent and permethylated oligosilanes containing up to 20 silicon atoms are at variance with these results in that they predict the first $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy to increase as θ increases to 115–120° and then to decrease at larger θ. Previous band gap calculations[37] for infinite chain all-*trans* parent polysilanes, based on a CNDO model Hamiltonian, also disagree. They predict the band gap between the valence and conduction bands to increase as θ is increased from 90 to nearly 120°. While we believe our calculations to be more reliable than the semiempirical ones, more detailed *ab initio* studies using larger basis sets and better model systems are necessary for a definitive understanding of the valence angle effects on excited states.

Experimental evidence available at this time for the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ transition is certainly compatible with the *ab initio* prediction of a red shift with increasing θ, but is only indirect. Three observations may be relevant. (i) In room-temperature solution, poly(di-n-alkylsilanes) with bulkiest alkyl groups are known[38] to have red-shifted absorption peaks relative to those with smaller alkyl groups, and one may be tempted to ascribe this to increased SiSiSi valence angles θ, whose actual magnitudes are however not known, nor are the CSiC valence angles.

(ii) The distance between the next-nearest neighbouring silicon atoms measured by X-ray diffraction experiments[73,74] of stretch-oriented samples of neat polysilanes in their all-*trans* form increases as one proceeds gradually from poly(dimethylsilane) to poly(di-n-alkylsilane)s, with longer alkyl chains. Assuming the SiSi bond length to be constant in all these polysilanes,[22,54] the SiSiSi valence angles, θ, increase along the same series from 111.7 to about 120°. Simultaneously, the first absorption peak observed in the neat solid polymer shifts from about 340 nm for the shortest alkyls to over 370 nm for the longest. Again, this suggests that there is a correlation between θ and the excitation energy, since the electronic effects of the various alkyl groups must be nearly the same. The correlation does not appear to be linear, however, and changes in the size of the CSiC valence angle along the series may play a role as well.

(iii) Finally, one way to account for the red shift of the first intense transition of certain poly(di-n-alkylsilanes) in the all-*trans* ordered neat solid phase (~ 370 nm)[75] relative to the presumably also all-*trans* low-temperature solution phase (~ 350 nm),[76,77] is to postulate that it is due to a higher value of θ in the neat solid phase enforced by the need to accommodate the side chains.[29,37] Recently, the blue shift of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ transition of neat poly(di-n-hexylsilane) with increasing pressure[78,79] has been interpreted in terms of increasing disorder in the silicon backbone. It could also be due to a decrease in the SiSiSi valence angle, θ, with chain compression, since this should be a relatively soft distortion coordinate.

Effects of the SiSiSiSi *twist angle*

As the chain length increases beyond trisilane, conformational effects on the excited states can be explored. As outlined in the introduction, their understanding is critical for the current debate of the nature of the factors responsible for the incomplete delocalization of excitation in polysilane high polymers.

A series of SCF–CISD/DZ calculations were performed on the n-tetrasilane molecule at various

SiSiSiSi twist angles, ϕ, from 0 (planar eclipsed *cis* conformation) to 180° (planar *anti* conformation). For these calculations, the CI active space was restricted to the three highest SCF occupied orbital plus the 13 lowest virtual orbitals, i.e. the minimum basis virtual orbitals. The validity of this restricted CI was checked by performing CI calculations that included the three highest SCF occupied orbitals and all the virtual orbitals at $\phi = 180$, 60 and 0°. The restricted CI calculation was found to reproduce qualitatively the results of the larger CI calculations.

Figure 11 shows the energies of the ground and the first excited states of tetrasilane as a function of ϕ. The *anti* and the *gauche* conformations have nearly identical energy in the ground state and are separated by a 2.2 kcal mol^{-1} barrier for rigid rotation around the central SiSi bond. The top of this conformational barrier is located near a dihedral angle of *ca* 120°. For relaxed rotation, the barrier would be lower still, but its exact value is of limited interest in the present context. The potential energy curve, shown in Fig. 11, is rather flat in the ϕ interval from 60 (*gauche* form) to 0° (eclipsed *cis* form). Previous higher-level *ab initio* calculations for the ground state indicate that the *gauche* form is a local minimum and the eclipsed *cis* form is higher in energy by 1.3 kcal mol^{-1}.[20]

In contrast to the very flat ground state potential energy curve, the first excited singlet state exhibits a strong dependence on ϕ. Its energy minimum corresponds to the planar *anti* conformation ($\phi = 180°$). At this point, the first excited state is of

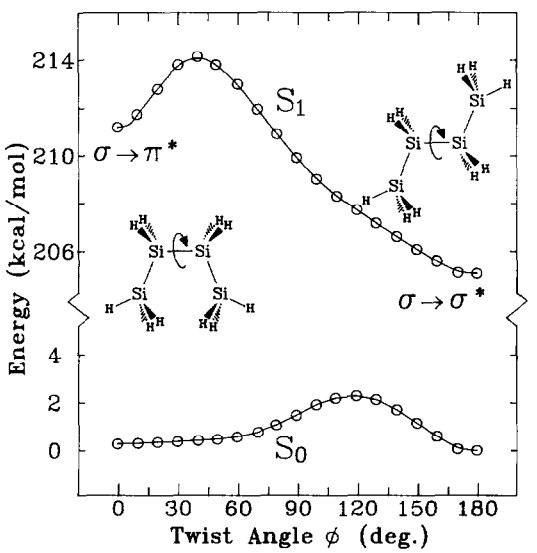

Fig. 11. Energies of the lowest two singlet states, S_0 and S_1, of n-tetrasilane as a function of the SiSiSiSi twist angle ϕ (restricted CISD/DZ, see text), relative to the ground state energy of *trans*-n-tetrasilane.

$\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ (HOMO → LUMO) character. Twisting around the central SiSi bond causes a rapid increase in the excitation energy, which reaches a maximum at $\phi = 35°$, near the *gauche* conformation. Further increase in ϕ lowers the excitation energy again and a local minimum in the first excited state occurs at the *cis* conformation ($\phi = 0°$). At this geometry, the excited state is of $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ character. The presence of two apparent minima in the lowest excited singlet surface as a function of rigid rotation is due to an avoided crossing between the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited states, which occurs near the dihedral angle of 35°. The avoidance is related to the loss of symmetry and of strict distinction between the σ and π symmetries during the conformational change. We have made no attempts to actually optimize the geometry of either minimum. In longer chain polysilanes the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation is not likely to be below the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation even at the *cis* conformation and most likely, these would show only one minimum in the first excited singlet state along the rigid rotation path, at the all-*trans* conformation ($\phi = 180°$).

If polysilane chromophoric segments behave in the same fashion as the model oligosilanes, there is a thermodynamic driving force towards the all-*trans* conformation in the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ singlet excited state and as a consequence, a tendency to convert the approximately *gauche* links terminating the chromophoric segment into *trans* links. Such a process would cause the all-*trans* segment lengths to increase and would appear similar to the process of actual transfer of the excitation energy to a longer segment by the Dexter or Förster mechanism.

The behaviour of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excited state as a function of ϕ is readily rationalized by considering the limits of *anti*-periplanar and *syn*-periplanar orbital interactions.[25-28] The Sandorfy models C and H described earlier provide a qualitative description of the delocalized molecular orbitals of an all-*trans* polysilane chain. In these models, only the effects of vicinal and geminal interactions between the sp^3 hybrid orbitals are considered. Then, a rigid rotation around any Si—Si bond does not affect the σ_{SiSi} bonding and σ^*_{SiSi} antibonding backbone orbitals, because of the cylindrical symmetry of the σ bond. In order to understand qualitatively the effect of conformational changes on the energies of the backbone molecular orbitals one needs to include interactions between more distant non-bonded sp^3 hybrid orbitals, and these can be treated as weak perturbations to the Sandorfy models C and H. Like the vicinal and geminal interactions, a 1–3 interaction is still invariant to a rigid rotation around a Si—Si bond, but a 1–4 interaction is not (Fig. 12).

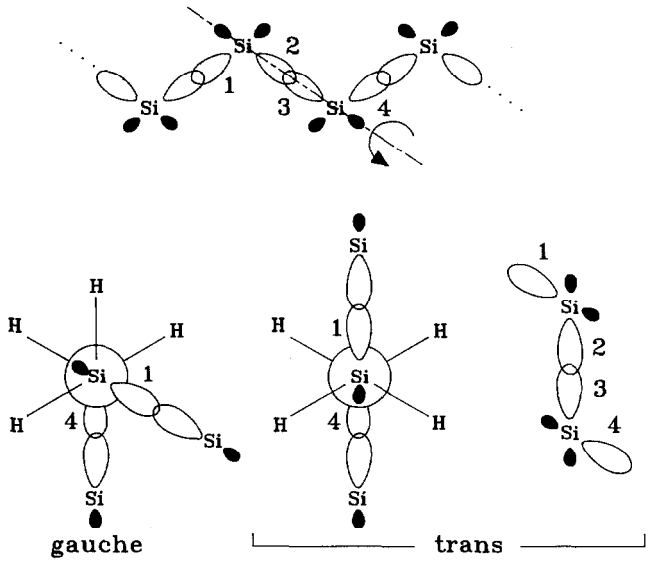

Fig. 12. Relative orientation of silicon sp^3 basis set orbitals 1–4 in *gauche* and *trans* conformations of an oligosilane chain.

In the *trans* planar arrangement of silicon atoms in polysilane, the 1–4 interaction of two sp^3 hybrid orbitals in the silicon chain is *anti*-periplanar in geometry and is dominated by the negative π-type overlap between their p components, which produces a positive resonance integral β_{14}. In the *cis* planar arrangement, π-type overlap between the now *syn*-periplanar orbitals 1 and 4 is positive and the resonance integral β_{14} is negative. It is clear from Fig. 12 that β_{14} must pass through zero partway along the twisting coordinate. When the resonance integrals, β_{14}, are introduced everywhere along the silicon chain, they will perturb the energies of the molecular orbitals in a way dictated by the nodal properties of the latter. Figure 2 shows that the HOMO coefficients have equal signs on every pair of hybrid orbitals that are disposed 1–4 relative to each other, so that a perturbation by a positive β_{14} will cause a destabilization to first-order in perturbation theory. To the contrary, in LUMO the coefficients on hybrid orbitals disposed 1–4 relative to each other differ in sign, so that a perturbation by a positive β_{14} will cause a stabilization.

Upon rotation along the SiSi bond away from the *anti*-periplanar geometry, β_{14} will decrease and go through zero, at which point it will have no destabilizing effect on HOMO nor stabilizing effect on LUMO, and eventually, as the *syn*-periplanar arrangement is reached, β_{14} will attain its most negative value and cause the maximum stabilization of the HOMO and destabilization of the LUMO. The net outcome of this behaviour will be a gradual reduction of the σ_{SiSi}–σ^*_{SiSi} (HOMO–LUMO) gap as one proceeds from the *cis* to the *trans* geometry. The computed reduction of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy along this coordinate is thus readily accounted for. Since only the p-part of the hybrid orbital overlap is angle-dependent, the effects on HOMO should be larger than those on LUMO, which has considerable silicon 3*s* character, and this is indeed observed in the calculations.

Conclusions

Although only qualitative in nature, the results of the *ab initio* SCF–CISD calculations on simple oligosilanes ($n = 2$–5) lead to useful conclusions: (i) for oligosilanes that have more than about five silicon atoms, all Rydberg excitations will be higher in energy than the lowest valence excitations; (ii) for the planar all-*trans* parent oligosilanes with only a few silicon atoms the first valence excited singlet state is of $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ nature, and as the silicon chain is extended, a $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ (HOMO → LUMO) state becomes the lowest; (iii) inclusion of silicon *d* orbitals in the basis set has very little influence on the nature of the calculated low-lying excited states; (iv) the lowest excited state with a large two-photon absorption cross-section is well represented by the SHOMO → LUMO $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ configuration and has essentially no doubly excited character, with the HOMO^2 → LUMO^2 $\sigma^2_{SiSi} \rightarrow \sigma^{*2}_{SiSi}$ configuration entering only into much higher energy states; (v) methylation of oligosilanes reduces the HOMO–LUMO gap by hyperconjugative destabilization of the σ_{SiSi} HOMO by the methyl donor orbitals and decreases the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy; (vi) an increase in the SiSiSi valence angle causes a red shift

in the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy; (vii) the *trans* planar conformation leads to lower $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energies than the *cis* planar conformation; and (viii) conformational changes towards the all-*trans* conformation and an increase in the SiSiSi valence angle are expected upon electronic excitation into the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excited state.

Simple rationalization has been provided for several of these results. In particular, the difference between the nature of the wave functions of the states accessible by two-photon absorption in oligosilanes and in polyenes has been attributed to the absence of even only approximate alternant pairing in the former, and the conformational dependence of the excitation energies has been attributed to *anti*-periplanar secondary interactions in the *trans* form and *syn*-periplanar ones in the *cis* form.

The overall agreement between the current *ab initio* calculations and the semiempirical calculations reported in the literature is reasonably good. The absolute excitation energies obtained from the *ab initio* calculations do not agree well with the experimental ones. The agreement can presumably be improved in the future by using optimized geometries, better basis sets, MCSCF methods to optimize the excited state orbitals and by multi-reference CI procedures that include higher order excitations.

ELECTRON PROPAGATOR THEORY OF BONDING IN SATURATED SILICON CHAINS

J. V. ORTIZ

Department of Chemistry, University of New Mexico, Albuquerque, NM 87131, U.S.A.

Abstract—*Ab initio* electron propagator calculations produce accurate electron binding energies and Feynman–Dyson amplitudes for oligosilanes as a function of bond angle and dihedral angle distortions. Ground state energies are also calculated for equilibrium and distorted structures. While the ground state energies are fairly insensitive to the distortions, changes in electron binding energies can be much larger. Examination of the Feynman–Dyson amplitudes leads to an electronic structure model that is based on phase relationships between bond orbital and antibond orbitals that are localized in Si—Si bond regions. This model is successful in explaining the calculated shifts in electron binding energies and changes in polymer absorption spectra.

INTRODUCTION

In spite of their lack of multiple bonds, lone pairs or *d*-electrons, polysilanes have large oscillator strengths in the near-UV and a rich chemistry in ground and excited states.[1–4] A variety of new applications, including self-developing photoresists,[5] ceramic precursors[6] and photoconducting polymers,[7] has awakened more widespread interest in these polymers.[8] These potentialities are grounded in the electronic structures[9–14] of saturated silicon-containing backbones and how these are influenced by steric effects that are under the control of substituent and environmental factors. To analyse these disparate causes of various electronic properties, *ab initio* calculations on the simplest species, small oligosilanes, are undertaken. These calculations should include no prejudicial assumptions about the locations or types of bonds that may be present. At the same time, the results of the calculations should be produced in a form that lends itself to deep, yet succinct analysis. Electron propagator theory fulfils both of these requirements admirably, for in addition to generating accurate energetic information, it also rigorously produces a one-electron picture that incorporates the effects of electron correlation. Calculations on the electron binding energies of Si_2H_6 will show the origin of a model of electronic structure built on localized bond and antibond functions. As a result of calculations on Si_3H_8, the influence of bond angle changes will be determined and insights into how the localized functions are combined in larger oligomers will be gained. The large influence that dihedral angles can have on electronic structure will be illustrated in calculations on Si_4H_{10} and will show the importance of non-neighbour interactions. Extrapolations of these results will explain how polymer electronic structure can be related to concepts developed through precise work on small oligomers.

METHODS

Gaussian 88[15] is used in the Hartree–Fock and integral transformation steps, and EPT90[16] is used for the propagator calculations.

Structures optimized at the Hartree–Fock double ζ plus polarization level[17,18] are used in calculations with an effective core potential (which excludes the Si 1*s*, 2*s* and 2*p* electrons), its double ζ basis,[19] and a set of *d* functions ($\alpha_d = 0.45$) on each silicon, as well as a double ζ hydrogen basis.[20] This treatment is adequate for the calculation of ionization energies. Electron affinities of small oligomers require diffuse functions. However, the chief purpose of these calculations is the examination of trends in the limit of an infinitely large polymer, where diffuse functions have negligible importance in the conduction band. Therefore, electron affinity calculations are performed with and without a set of diffuse silicon ($\alpha_s = 0.028$, $\alpha_p = 0.026$) and diffuse hydrogen ($\alpha_s = 0.011$) functions. At the geometries under consideration, cor-

relation corrections to the ground state energy are calculated with second-order many-body perturbation theory.[21]

Electron propagator theory[22] is used to generate electron binding energies and corresponding Feynman–Dyson amplitudes. The former, negatives of ionization energies and electron affinities, are obtained with relaxation and correlation corrections that are absent from Koopmans' theorem[23] predictions, the negatives of canonical orbital energies. For every electron binding energy, there is a Feynman–Dyson amplitude (FDA):

$$\int \Psi^*_{N-1}(2,3,4,\ldots,N)\Psi_N(1,2,3,\ldots,N)\, d(2)d(3)d(4)\ldots d(N) = \phi^{FDA}(1),$$

for ionization energies or

$$\int \Psi^*_N(2,3,4,\ldots,N+1)\Psi_{N+1}(1,2,3,\ldots,N+1)\, d(2)d(3)d(4)\ldots d(N+1) = \phi^{FDA}(1),$$

for electron affinities. Because it is a function of the coordinates of one electron, the FDA is an orbital, or more strictly speaking, a spin-orbital. Phase relationships between localized functions and the extent of delocalization are revealed in FDA plots. Unlike representations of total densities or localized molecular orbitals, plots of the FDA show how the electronic structure of the molecule changes upon removing or adding an electron, for they depend on the initial state, Ψ_N, and on the final states, $\Psi_{N\pm1}$. (Total density and localized molecular orbital plots contain information about Ψ_N only.) FDAs have the advantages generally associated with delocalized, canonical molecular orbitals for describing spectra, but they are more general in that they incorporate the effects of electron correlation. Each electron binding energy corresponds to a Feynman–Dyson amplitude in the same way that an energy corresponds to a canonical molecular orbital in Koopmans' theorem. Hartree–Fock molecular orbital theory constitutes the zeroth-order reference for the electron propagator calculations. The present electron propagator calculations utilize the full second-order approximation.[24]

RESULTS AND DISCUSSION

Reliability of the methods

Previous all-electron calculations with larger basis sets and extensive explorations of correlation effects have shown that the diagonal and second-order approximations yield accurate electron binding energies for Si_2H_6, Si_3H_8 and Si_4H_{10} in their equilibrium, ground state geometries.[17,18] For example, Table 1 shows results of a previous study[17] of the ionization energies of Si_2H_6 with various basis sets and propagator approximations. The methods used in this work are equally accurate. As will be discussed below, for Si_3H_8 there are two cationic final states where an electron has been removed chiefly from Si—Si bonding regions. Comparison of the previous calculations[17] with results of this paper (Table 2) shows close agreement among all propa-

gator treatments and photoelectron spectra.[25] All of the predicted electron affinities are negative: the extra electron is not bound. When diffuse functions are added to the basis, this finding is not changed. The additional functions contribute chiefly to diffuse FDAs with negative electron affinities. With increasing chain length, the ordinary valence functions will form FDAs that evolve into the conduction band of the polymer.[10,11] The diffuse functions will continue to contribute to unbound levels embedded in the continuum.

Si_2H_6

In addition to the ionization energies obtained for the equilibrium, D_{3d} geometry of Si_2H_6, propagator results for electron binding energies at a distorted, C_{2h} structure are displayed in Table 3. Note that ionization energies and electron affinities are considered. (A bound final state corresponds to a negative electron binding energy, i.e. a positive ionization energy or electron affinity.) In the distorted structure, two Si—H bonds that are *anti* to each other are elongated by 0.1 Å in order to imitate an Si_2H_4 fragment embedded in a polysilane chain. Destruction of the three-fold axis of symmetry implies breaking the degeneracy of the e_g and e_u FDAs. Changes in the ionization energies are small compared with some of the electron affinity shifts.

Examination of the FDAs reveals the importance of symmetry in understanding how fragments evolve into oligomers and polymers. For the higher cationic states, FDAs with e_g and e_u symmetry are concerned with Si—H bonding and display constructive interference of Si p functions perpendicular to the C_3 axis with neighbouring H s functions. In the e_u case, the Si ps have a π bonding relationship and in the e_g case, they have a π antibonding relationship. These final states are substantially altered when hydrogens are removed in favour of organic substituents.

Of greater interest are the FDAs that pertain to the silicon backbone regions. In the D_{3d} structure, the FDA for the lowest cationic final state is easily described as a σ bond orbital between two silicons. In Fig. 1, contours of this FDA are shown, where solid (dotted) lines are positive (negative) contours and dashed lines designate nodes. Contours are drawn in intervals of 0.015. Nuclear positions are indicated by squares. Note the accumulation of oval contours in the centre of the yz plane, between the two silicon nuclei. Nodes intersect the silicon nuclei and suggest the importance of p_z functions. Contributions from hydrogen s functions, although clearly in evidence from the extrema close to the hydrogen nuclei, are relatively minor. When the symmetry of the molecule is reduced to C_{2h}, this FDA remains virtually the same.

Consideration of the electron affinity FDAs with e_u symmetry shows them to be the Si—H antibonding counterparts of the ionization energy FDAs of the

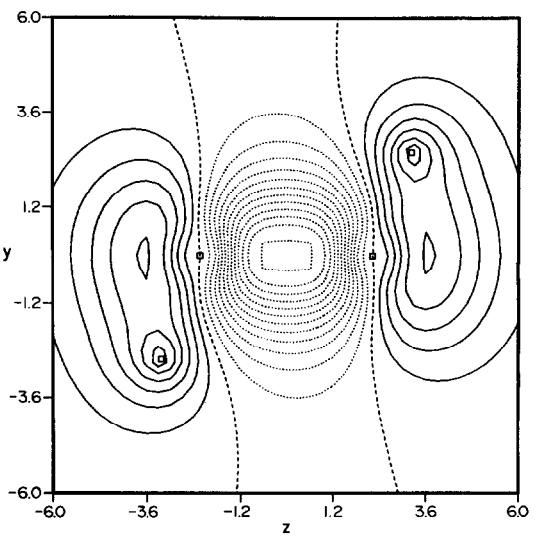

Fig. 1. (D_{3d}) $Si_2H_6^+ {}^2A_{1g}$ Feynman–Dyson amplitude.

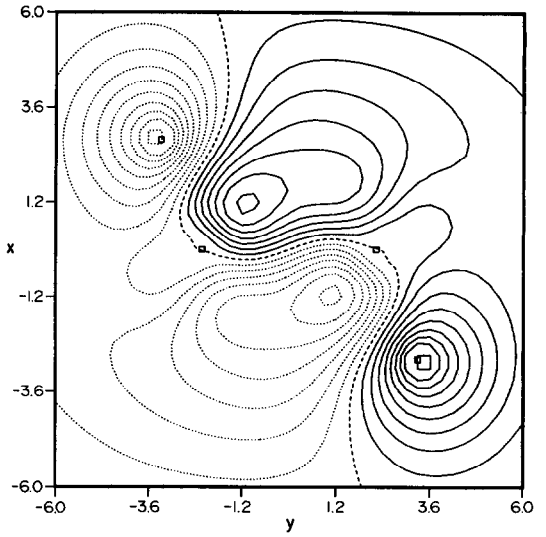

Fig. 4. (C_{2h}) $Si_2H_6^- {}^2B_u$ Feynman–Dyson amplitude.

same symmetry discussed above. Figure 2, a contour plot of an FDA in the xz plane, has nodes along the z axis and extrema in the Si—Si bond region characteristic of a π bonding relationship. Note the presence of four contours surrounded by nodes near values of z corresponding to hydrogen nuclear positions. This suggests an antibonding relationship between the silicons and hydrogens.

Within a trivial amount of energy, 0.02 eV, there is another unbound electron affinity whose FDA has a_{2u} symmetry. Examination of Fig. 3 discloses a wealth of contours in the Si—Si bond region again, but this time with a central node that denotes a σ antibonding relationship. Much of the electron density is therefore pushed to the exterior regions of the molecule. Nodes appear in the vicinity of the hydrogen nuclei.

At this point, it should be re-emphasized that the electron affinity FDAs do not correspond to bound anions. Even when diffuse functions are added to the basis, the largest electron affinity is -1.2 eV. Feynman–Dyson amplitudes for these additional anionic states are non-bonding and are spread over regions remote from the bonds. States such as these are imbedded in the continuum of electron–molecule scattering states.

Breaking the three-fold axis of symmetry in Si_2H_6 allows a_{2u} and e_u FDAs to mix. In the latter degenerate set, one member in C_{2h} symmetry is symmetric with respect to the remaining plane of symmetry and the other is antisymmetric. Group theoretical arguments by themselves cannot tell to what extent mixing takes place between a_{2u} and the symmetric member of the e_u set. From Fig. 4, however, it is evident that the rearrangements are extensive. A lone nodal contour threads its way between the various nuclei in the same plane as that of Fig. 3. (Axis labels have been changed for the lower symmetry calculation, but this is of no consequence.) This FDA, like the FDA in Fig. 2, exhibits much Si—Si π character, but the node connecting the silicons is not straight. It has curves because of contamination from the FDA of Fig. 3. Such interaction produces the local maxima above and to the right of the left-hand silicon nucleus and below and to the left of the right-hand silicon nucleus. Two lobes with opposite sign curl around each other in the Si—Si bond region in resemblance to the Yin–Yang symbol found in the centre of the

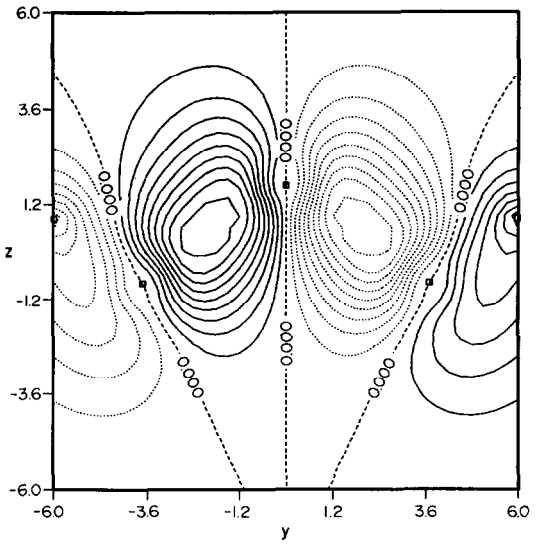

Fig. 7. $Si_3H_8^+ {}^2B_2$ Feynman–Dyson amplitude.

South Korean flag. Such a device has π bonding character and σ antibonding character at once. Because of the presence of the elongated Si—H distances, there is a large deposit of electron density near the two hydrogen nuclei. As shall be seen below, this is an artefact that is obliterated as soon as longer chains are considered.

If two D_{3d} FDAs are mixing, then there must be a remaining combination. This is shown in Fig. 5, where σ antibonding has greater prominence than π bonding. Now the two lobes of Yin–Yang have turned their backs on each other, producing two paisley patterns. Instead of tracing a path perpendicular to this axis, the central node now inclines somewhat because of the π bonding contribution that has been introduced.

These motifs in the broken-symmetry electron affinity FDAs, Yin–Yang and two paisleys, will recur in longer oligomers. These are the antibonding counterparts of the oval bond orbital that occurs in the FDA of the lowest ionization energy.

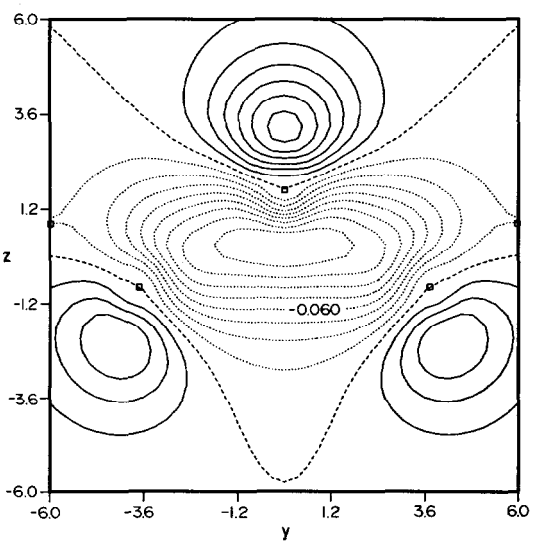

Fig. 6. $Si_3H_8^+ {}^2A_1$ Feynman–Dyson amplitude.

Si_3H_8

If one adopts the bond orbitals as an approximate localized basis for constructing the ionization energy FDAs, then for Si_3H_8 there should be two FDAs of this type. Two bond orbitals in the equilibrium, C_{2v} geometry of Si_3H_8 are related by symmetry and therefore symmetric and antisymmetric combinations are formed. In the former case, constructive interference near the central silicon takes place. Ample confirmation of these suppositions is found in Fig. 6. Negative contours concentrate near the centre of the y axis. An even more obvious success obtains in Fig. 7, where two bond orbitals with opposite signs interfere destructively in the xz plane, as mandated by the b_2 irreducible representation of the FDA.

Because the Si_2H_6 calculations on electron affinity FDAs showed two types of Si—Si antibond orbitals, there is some ambiguity about how the corresponding FDAs of Si_3H_8 should be constructed. Returning to Figs 4 and 5, one notices an important difference between the extrema in the Si—Si bond regions. These extrema are closer to the terminal hydrogens in Fig. 4 than they are in Fig. 5. In the latter FDA, the terminal hydrogen nuclei are within the tails of the paisley lobes. In Si_3H_8, symmetry

projection of these Si—Si antibonding functions produces a total of four combinations. Symmetric combination of two Yin–Yang patterns produces constructive interference in the vicinity of the z axis and three local extrema in the Si—Si bond regions. This combination should be lower in energy than the antisymmetric combination, where destructive interference near the z axis should lead to an antibonding relationship between the Si—Si antibond functions. Two combinations of the paisley patterns can likewise be imagined. A symmetric combination implies constructive interference between the tails of two paisley lobes near the central silicon and along the y axis. For the antisymmetric combination, there is destructive interference between these tails.

Calculations determine the energy ordering and mixings pertaining to these combinations. The qualitative arguments made above are confirmed to a great extent. In the FDA of the largest electron affinity, one sees (Fig. 8) that the most stable combination with a_1 symmetry is built from Yin–Yang lobes instead of paisley patterns. This is reasonable when one considers that in the former case, constructive interference takes place between the Si—Si local extrema near the central silicon, while in the latter case, constructive interference only involves the narrow tails of the paisley lobes. There follows an anionic $^2B_1$ state whose FDA is built from Si—H antibonding combinations of hydrogen s and silicon p_x orbitals; a π bonding relationship prevails among the silicons. In the next FDA, which has b_2 symmetry, interference of paisley patterns is clearly evident (Fig. 9). Note the tails of the paisley lobes that reach over to the terminal hydrogen nuclei.

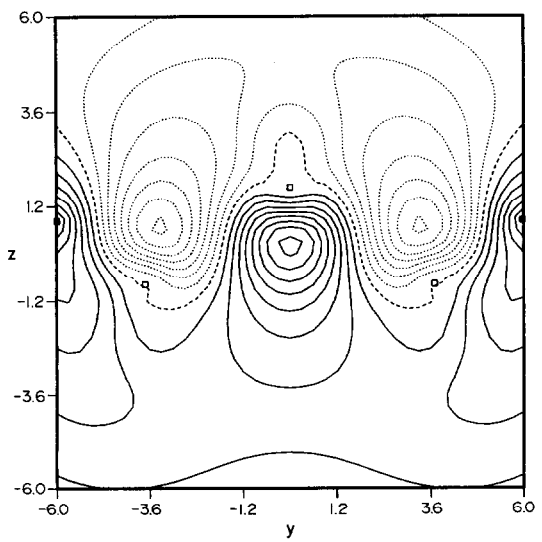

Fig. 8. $Si_3H_8^-$ $^2A_1$ Feynman–Dyson amplitude.

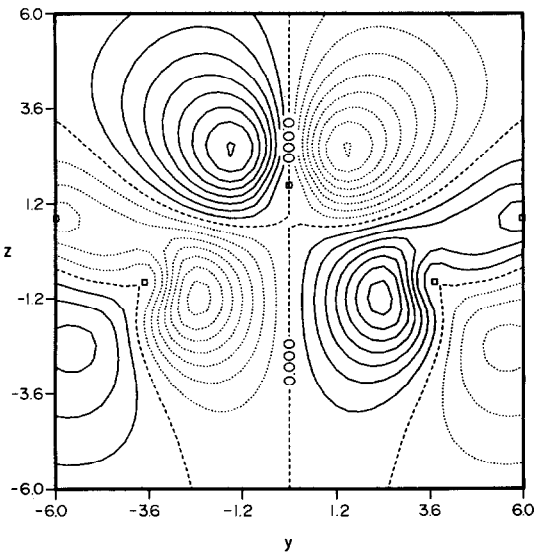

Fig. 9. $Si_3H_8^-$ $^2B_2$ Feynman–Dyson amplitude.

One does not see the tails of the other two paisley lobes because they have destructively interfered with each other near the z axis. Following the same reasoning used for Fig. 8, the lower b_2 combination has less destabilization from destructive interference near the z axis because tails of paisley lobes are involved instead of the thick parts of the Yin–Yang patterns.

Addition of diffuse functions to the basis again produces more anionic states corresponding to negative electron affinities. For the lowest of the new states the electron affinity, -1.1 eV, is nearly the same as its counterpart for the Si_2H_6 case, -1.2 eV. Feynman–Dyson amplitudes for these states are essentially diffuse functions that have been orthogonalized to the valence basis functions.

Si_3H_8 is the simplest possible model for studying the effects of bond angle changes in a silicon backbone. Recent evidence of steric repulsions between bulky side groups producing 120° Si—Si—Si bond angles[26,27] provokes the question as to whether a fundamental change in electronic structure accompanies such distortions. Different hybridization schemes in a valence bond picture may arise from such geometries. To tackle this issue, calculations are repeated for a structure where the central angle is fixed at 120° and where the other geometrical parameters are allowed to relax. The energy difference between the equilibrium and optimized distorted structure is about 0.4 kcal mol^{-1}.[18] (Repeating the same procedure for propane produces an energy difference of 1.3 kcal mol^{-1}.) Electron binding energies shift by about 0.1 eV (Table

Table 4. Si_3H_8 electron binding energies (eV)

	$Si_3H_8^+ {}^2A_1$	$Si_3H_8^+ {}^2B_2$	$Si_3H_8^- {}^2A_1$	$Si_3H_8^- {}^2B_1$	$Si_3H_8^- {}^2B_2$

Distorted	−10.62	−10.00	2.34	3.04	3.25

4). These data do not indicate a fundamental change in electronic structure.

There are, nevertheless, interesting trends that emerge from these calculations. From the equilibrium structure to the distorted structure, the lowest electron binding energy is destabilized, but the next electron binding energy declines. These trends appear to follow from phase relationships between the bond orbitals that contribute to the corresponding FDAs. In the first case, this relationship is constructive and the reduced proximity of the bond orbital maxima implied by the increased bond angle causes the destabilization. The opposite trend obtains when the two bond orbitals have opposite phases. The a_1 electron affinity FDA declines and the next higher level ascends as the bond angle increases. Apparently the relationship between the lobes that interfere just below the central silicon is not as important as that between the lobes which interfere above the central silicon in Figs 8 and 9.

Si_4H_{10}

Dihedral angles can be studied when Si_4H_{10} calculations are performed. Rotations about single bonds have often been invoked as causes for red shifts in polysilane absorption spectra accompanying order–disorder transitions.[28] Steric effects and intermolecular forces determine conformations in the silicon backbone and these conformations affect the spectra. Calculations of ground state energies and electron binding energies as a function of the Si–Si–Si–Si dihedral angle are therefore useful as a model of how conformations influence spectra in organopolysilanes.

First, consider the ground state energies in four conformations: *anti* (180° dihedral angle), *gauche* (60°), *eclipsed*$_{120}$ (120°) and *eclipsed*$_0$ (0°). There is essentially no energy difference between the *anti* and *gauche* forms. Preferences for one form over the other found for related compounds are related to the substituents that may take the place of hydrogen. The two eclipsed structures lie 0.7 and 1.1 kcal mol,$^{-1}$ respectively, above the minima. These results are in excellent agreement with all-electron calculations.[17]

While the potential energy surface for dihedral angle variation is quite flat for the ground state of the neutral, electron binding energies exhibit a much more sensitive dependence. These are summarized in Figs 10 and 11, which plot vertical electron binding energies as a function of dihedral angle. Changes from one conformation to another can be several tenths of an electron-volt. The photoelectron spectrum,[25] because it represents a mixture of isomers, has broad maxima at 9.62, 10.3 and 10.85 eV, where the second energy represents overlapping bands. The present *anti* (−9.45, −10.54, −10.86) and *gauche* (−9.64, −10.17, −10.89) electron binding energies are in excellent agreement.

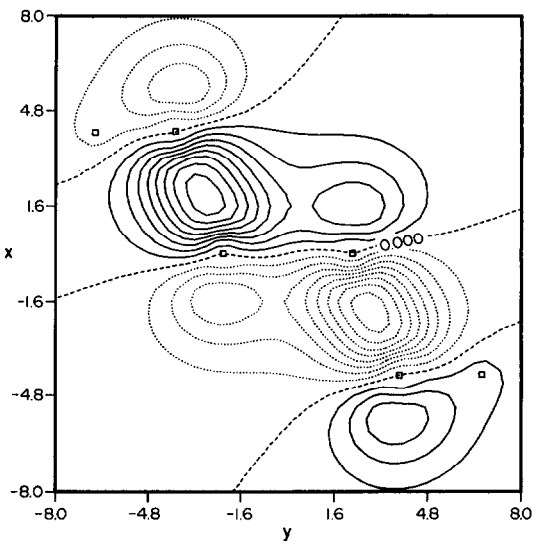

Fig. 13. *Anti* $Si_4H_{10}{}^+ {}^2B_u$ Feynman–Dyson amplitude.

Once again, one can appeal to a qualitative understanding of bond orbitals and antibond orbitals to explain the trends. For the ionization energies, FDAs can be constructed from three bond orbitals. There is always a rotation axis relating the terminal SiH_3 groups to each other, so the FDAs have either *a* or *b* symmetry. (Higher symmetry obtains for the *anti* and *eclipsed*$_0$ cases.) One combination of three bond orbitals has no nodes and *a* symmetry. A *b* symmetry combination has contributions with opposite signs from the terminal bond orbitals. Finally, there should be a combination with alternating signs in the bond functions and *a* symmetry. Another way of classifying these possibilities is to count the number of nodes between bond orbitals: zero, one or two, respectively.

For the *anti* conformation, it is possible to draw contour plots in which all the silicon nuclei are in the same plane. Feynman–Dyson amplitudes for ionization energies are displayed in Figs 12–14. In the first case, constructive interference obtains throughout the silicon backbone region, with a global maximum between the two central silicon nuclei. The long extent of this positive lobe is an excellent indication that all three bond orbitals are contributing to this FDA. In Fig. 13, one sees a node that connects the two central silicons. Two bond orbitals with opposite signs in the terminal Si–Si regions are clearly delineated. In the discussion above of the *b* symmetry combination of bond functions, it was stated that there should be a single node between the two bond orbitals. This node is not perpendicular to the central Si—Si bond axis, but parallel, allowing delocalization of the bond orbitals to occur in such a way as to create a π bonding interaction in the central Si—Si bond region. The curvature of the node in question suggests an alternative formulation where the Yin–Yang antibond orbital contributes in the middle of the molecule. For the FDA corresponding to the lowest ionization energy, one expects three bond orbitals with alternating signs. Figure 14 confirms this conjecture.

To understand the trends in Figs 10 and 11, the opposite extreme in the dihedral angle is considered. Feynman–Dyson amplitudes for the *eclipsed*$_0$ struc-

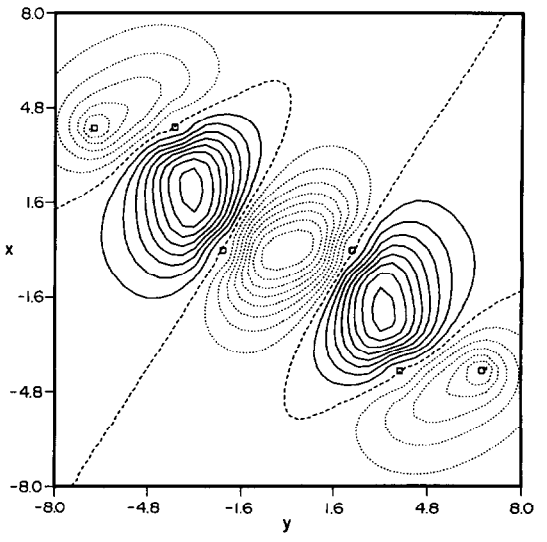

Fig. 14. *Anti* $Si_4H_{10}{}^+ {}^2A_g$ Feynman–Dyson amplitude.

ture also have the representational advantage of coplanar silicon nuclei. In Fig. 15, the analogue of Fig. 12 is displayed. There is still completely constructive interference of bond functions in the silicon backbone region. Note that there are now two extrema instead of just one and that they are displaced away from the central Si—Si bond axis. Of even greater importance is the presence of several negative contours directly connecting the non-neighbour bond orbitals. Such an interaction is not feasible in the *anti* conformation. An in-phase relationship of non-neighbour bond orbitals leads to the stabilization of this level as the dihedral angle decreases. The opposite trend obtains for the next FDA, depicted in Fig. 16. With the closer proximity of the non-neighbour bond orbitals, the FDA is destabilized because the phase relationship is antibonding. In addition, any π bonding that took place between the central silicons in the *anti* geometry has been destroyed. Finally, comparison of Figs 17 and 14 indicates the importance of the non-neighbour interaction. Constructive interference in this case leads to a stabilization of the electron binding energy as the dihedral angle decreases, bringing the non-neighbour bond regions closer to each other.

Based on experience gained in the Si_3H_8 case, the electron affinity FDAs in the *anti* conformation can be constructed from combinations of antibond orbitals. The most stable possibility should retain as many bonding interactions between neighbouring antibond orbitals as possible. Because of the node that is present in the Yin–Yang device in each Si—Si region, the FDA should be antisymmetric with respect to the C_2 axis. Figure 18 confirms these hypotheses and shows three Yin–Yang patterns interfering constructively near the two central silicon nuclei. Consider the patterns near the central silicon nucleus that lies on the positive side of the y axis. Constructive interference takes place between lobes of neighbouring Yin–Yang patterns below and to the left of this nucleus. Tails of the partners of these lobes are also interfering constructively above and to the right of the silicon nucleus. The former type of interference is the reason why one sees four extrema in the silicon backbone region instead of six.

The next issue to arise is the most stable way of arranging three paisley patterns. There is an *a*

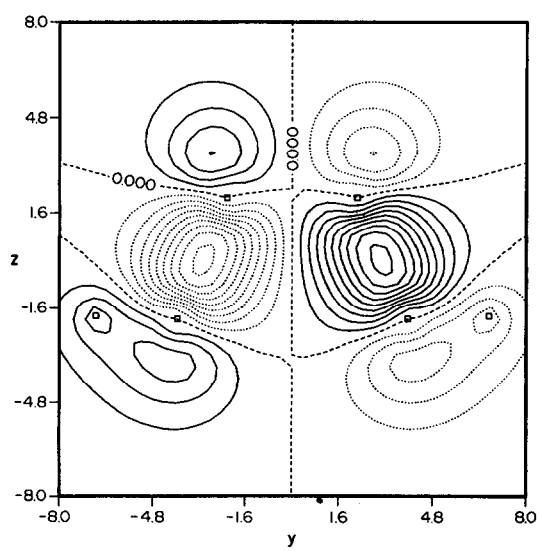

Fig. 16. *Eclipsed*$_0$ $Si_4H_{10}^+$ $^2B_2$ Feynman–Dyson amplitude.

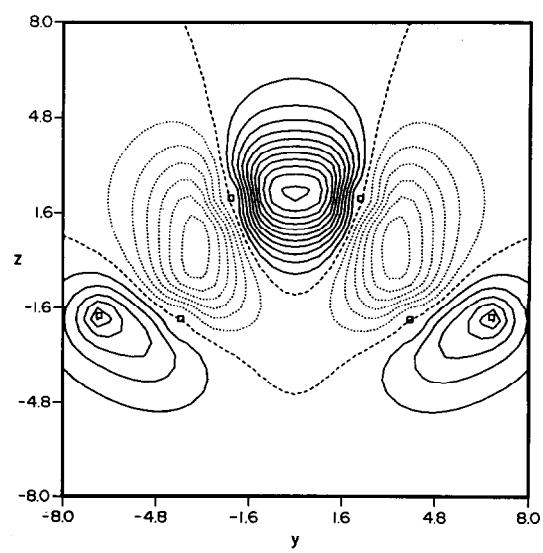

Fig. 17. *Eclipsed*$_0$ $Si_4H_{10}^+$ $^2A_1$ Feynman–Dyson amplitude.

combination formed from paisley patterns on the two terminal Si—Si regions. Two *b* combinations arise from the paisley pattern on the central Si—Si region and the antisymmetric counterpart of the *a* combination. While the *a* combination, through constructive interference of tails, can actually create a bonding interaction in the central Si—Si region, neither of the *b* combinations has anything but antibonding character in this sector of the molecule. The only thing that mixing the two *b* combinations can do is to adjust the nature of the antibonding relationship between the two central silicons. The lowest combination of the three is therefore the one with *a* symmetry. In the FDA shown in Fig. 19, these arguments are verified. Note the somewhat distorted paisley lobes whose tails begin near the terminal hydrogens. The extrema near the terminal silicons of these lobes are more delocalized than their counterparts in previously considered molecules. Near the central silicon nuclei, the wide parts of two paisley lobes are deployed away from the centre of symmetry. Constructive interference between the two tails takes place near the origin.

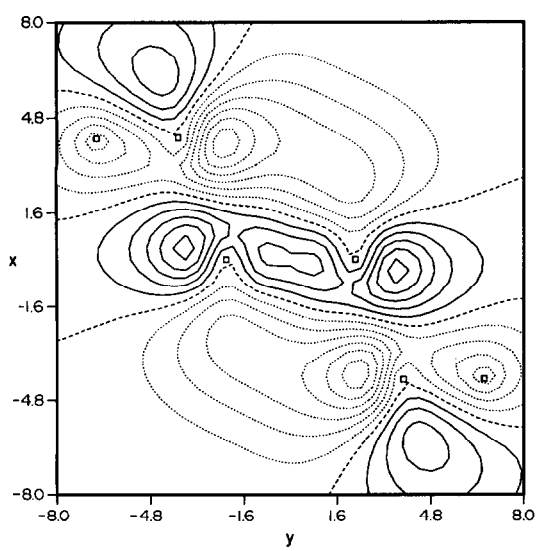

Fig. 19. *Anti* $Si_4H_{10}^-$ ^2A_g Feynman–Dyson amplitude.

Si—H antibonding FDAs that have a_u or b_g symmetry in the *anti* conformation have higher electron binding energies. With only four silicons, the π levels are already above the two lowest electron affinity levels with σ symmetry.

Two reasons underlie the destabilization of the lowest electron binding energy for anionic final states in the *eclipsed*$_0$ form. When the dihedral angle is changed to 0°, the lower of the two anionic FDAs necessarily acquires, because of C_{2v} symmetry, a node that bisects the central Si—Si bond. This is incompatible with the presence of a Yin–Yang form in this region and necessarily introduces more σ antibonding. The other two bond regions are not as drastically affected, but their closer proximity also leads to destabilization, as suggested by their phase relationships. The consequences of these factors for the FDA are shown in Fig. 20, where two Yin–Yang patterns on non-adjacent Si—Si bond regions have opposite signs. Note the distortion of the lobes that lie on the extreme right and left: their local extrema are shifted vertically away from the terminal silicon nuclei. In the central bond region, the pattern is similar to one of the electron affinity FDAs of D_{3d} Si_2H_6. Both of these situations arise from symmetry's enforcement of a central node that is perpendicular to a Si—Si axis.

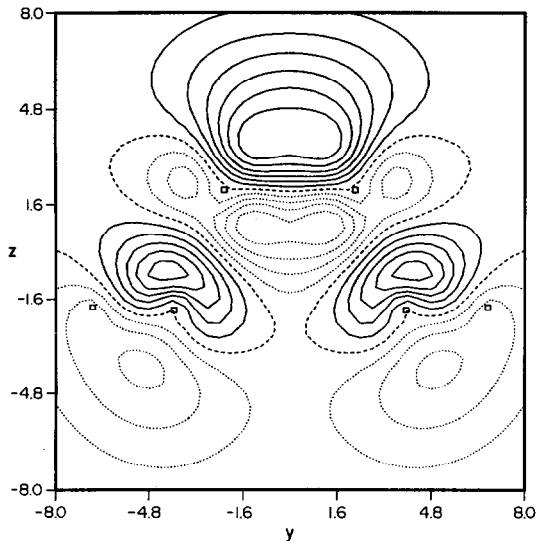

Fig. 21. *Eclipsed*$_0$ $Si_4H_{10}^-$ $^2A_1$ Feynman–Dyson amplitude.

In the remaining FDA, stabilization takes place due to improved constructive interference of paisley lobes from non-adjacent Si—Si bond regions just below the two central silicon nuclei (Fig. 21). One might expect the two remaining paisley lobes to also constructively interfere, but it appears that they have surrounding nodes. The latter pair of lobes is considerably distorted, as evidenced by the locations of their extrema. One might have expected these extrema to lie closer to the z axis. Constructive interference taking place above pushes the extrema to positions just above the terminal silicon nuclei.

Polymers

Based on these findings, one can make some inferences about the valence and conduction bands of a polymer. For the lowest ionization energy, the FDA consists of the most antibonding combination possible of bond orbitals. Alternating phases, one creates the maximum number of nodes. Such an FDA has opposite phases in neighbouring bond orbitals and like phases in first non-neighbour bond orbitals (Fig. 22). As one twists the polymer from an all-*anti* conformation into an all-*gauche* conformation (if the sense of the twist is kept constant, one obtains a helical structure), this FDA is stabilized. For the largest electron affinity, one constructs the corresponding FDA as the most bonding combination possible of antibond, or Yin–Yang orbitals. (Diffuse functions will continue to contribute to unbound anionic states in the polymer.) This FDA exhibits constructive interference about each silicon. An in-phase relationship between neighbouring orbitals and an out-of-phase relationship between first non-neighbour orbitals obtains (Fig. 22). As the dihedral angles decrease, non-neighbour interactions become important, and the electron binding energy is destabilized. In going from a straight chain to a helix, one gets an increase in the ionization energy and a decrease in the electron affinity. Put another way, from helix to straight chain, there is a red shift in the absorption spectrum.

These inferences are confirmed by polymer band calculations.[10,11] In all-*anti* polysilane, the two highest occupied bands exhibit Si—Si σ bonding. The lowest of these states has no nodes along the silicon backbone and the highest has nodes that coincide

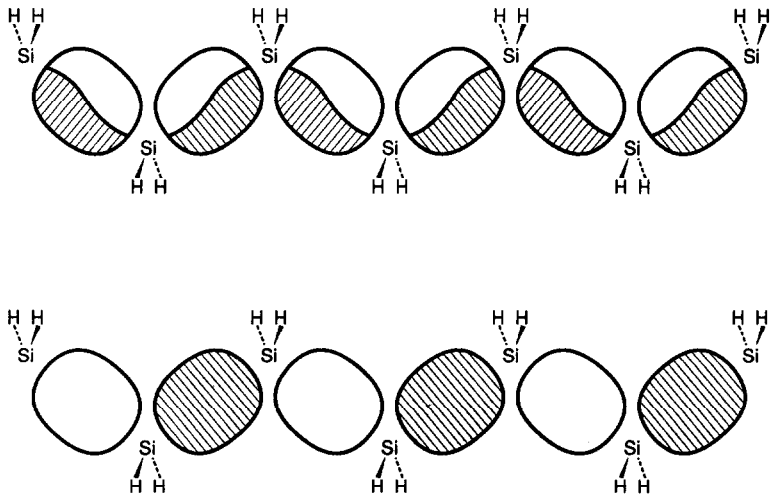

Fig. 22. Feynman–Dyson amplitudes for the lowest ionization energy and highest electron affinity of a polymer.

with each SiH_2 plane. For the lowest state in the conduction band, *sp* hybrids perpendicular to the chain axis have alternating phases on successive silicon nuclei. Phase relationships for the top of the valence band and for the bottom of the conduction band are identical to those in Fig. 22.

CONCLUSIONS

Localized bond orbitals and their antibond counterparts arise in the broken-symmetry FDAs of Si_2H_6. Through application of group theory and criteria of phases and overlap, one can explain how FDAs for larger oligomers are constructed from FDAs of Si_2H_6. A purely localized picture of bonding would be unable to explain how conformations and spectra are related, for there are interactions between neighbouring and non-neighbouring bond and antibond functions that are important. Plots of oligomer FDAs show how localized functions combine to form delocalized states. Phase relationships between the constituent localized orbitals within the FDAs are useful in qualitative predictions of how electron binding energies vary with respect to changes in Si—Si—Si bond angles and Si—Si—Si—Si dihedral angles. Extrapolation to the limit of an infinite polymer shows how shifts in absorption spectra are related to conformational changes.

INTERESTING PROPERTIES OF THE HEAVIER GROUP 14 ANALOGUES OF AROMATIC AND POLYCYCLIC CARBON COMPOUNDS. A THEORETICAL STUDY

SHIGERU NAGASE

Department of Chemistry, Faculty of Education, Yokohama National University, Yokohama 240, Japan

Abstract—This summarizes recent theoretical and experimental studies of the compounds whose skeletons are made of the heavier Group 14 elements. Included are the heavier analogues of benzene and strained polycyclic alkanes of current interest. Several interesting and novel properties of silicon, germanium, tin and lead skeletons are demonstrated by means of *ab initio* molecular orbital calculations. To characterize the properties, the applicability of the concepts such as aromaticity, strain and bonding established in carbon chemistry is discussed.

Carbon compounds have played a central role in organic chemistry. In recent years there has been considerable interest in replacing the skeletal carbons by the heavier Group 14 atoms in the expectation of novel physical and chemical properties. We report here our recent theoretical studies of the heavier Group 14 analogues of aromatic and strained polycyclic carbon compounds, together with the recent experimental data on the successful syntheses and isolations. Our primary concern is to test if the well-established concepts such as aromaticity, strain and bonding in carbon chemistry are also valid and to clarify the characteristics of silicon, germanium, tin and lead skeletons compared with carbon skeletons.

All calculations were carried out by using *ab initio* molecular orbital theory. Geometries were fully optimized at the Hartree–Fock (HF) level. For the geometrical optimization of the compounds with diradical character, the two-configuration self-consistent field (TCSCF) theory was used. Carbon and silicon compounds were calculated using the split-valence *d*-polarized 6-31G(*d*) basis set.[1] Calculations were also carried out with *ab initio* effective core potentials (ECP)[2] on silicon, germanium, tin and lead using the double-zeta (DZ) basis set augmented by a set of six *d*-type polarization functions on each heavy atom [*d* exponents 0.262 (Si), 0.246 (Ge), 0.183 (Sn), 0.164 (Pb), 0.75 (C) and 0.85 (O)].[3,4] The ECPs on tin and lead incorporate the mass–velocity and Darwin relativistic effects.[2] The DZ basis sets of the heavier atoms were obtained by contracting the inner two primitive Gaussian functions in the (3*s*3*p*) sets developed by Wadt and Hay,[2] while those of the second-row atoms such as carbon and oxygen were the standard Huzinaga–Dunning contractions specified by (9*s*5*p*)/[3*s*2*p*];[4] the basis set used for hydrogen was of DZ quality.[5] The effect of electron correlation was calculated using Møller–Plesset (MP) perturbation theory up to full fourth order (MP4).[6] Throughout this report, the symbol "//" means "at the geometry of": thus, single point MP calculations using the DZ(*d*) optimized geometries are labelled MP/DZ(*d*)//HF/DZ(*d*).

AROMATIC COMPOUNDS

As well known, benzene (C_6H_6) is unique among conjugated compounds with respect to its stability and reactivity. This has been attributed to "aromaticity" or the cyclic delocalization of π electrons, as the $(4n+2)$ Hückel rule suggests.

Silicon is contiguous to carbon in Group 14. Thus, it is expected that hexasilabenzene (Si_6H_6) also has an aromatic structure of D_{6h} symmetry since it contains six π electrons. To test this, we undertook the first *ab initio* calculations.[7] As expected, the minimum energy structure of hexasilabenzene was calculated to be planar with D_{6h} symmetry. The optimized Si—Si distance of 2.220 Å was 0.077 Å longer than the Si—Si double bond in $H_2Si{=}SiH_2$, but was 0.162 Å shorter than the Si—Si single bond in $H_3Si{-}SiH_3$, reflecting aromaticity. The planar D_{6h} structure has also been calculated by other research groups.[8,9]

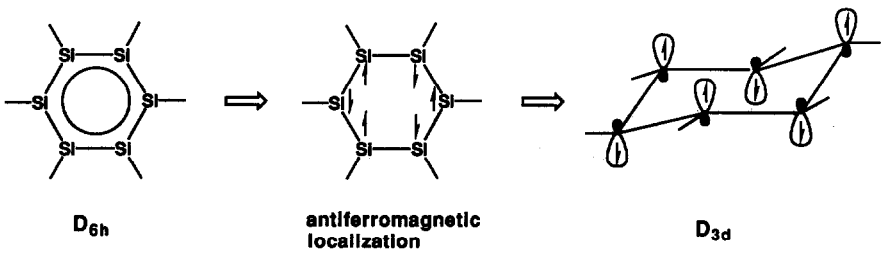

Fig. 1. Deformation of the planar D_{6h} to the non-planar D_{3d} structure in hexasilabenzene.

However, our recent calculations at higher levels revealed that the planar D_{6h} structure is not a minimum on the Si_6H_6 potential energy surface but corresponds to a transition structure with one single imaginary b_{2g} frequency.[10] We have indicated that displacement along the b_{2g} vibrational mode leads to a minimum which is a chair-like puckered structure of D_{3d} symmetry.

As shown in Fig. 1, the skeletal bonding of hexasilabenzene is characterized in terms of a spin density wave (alternative localization of α and β spins); for the HF instability, see ref. 10. A tendency of the antiferromagnetic localization of π electrons onto each silicon atom generates "silyl radical" character at each silicon atom and leads to the preference of the non-planar D_{3d} structure; as well-known, the SiH_3 radical takes a non-planar and pyramidalized structure, unlike the CH_3 radical. The deviation from planarity is however relatively small, as is the gain in energy (*ca* 1 kcal mol^{-1}), probably because π bonding becomes unfavourable upon pyramidalization. The slight preference of the non-planar D_{3d} structure is confirmed also in a subsequent theoretical study at the MCSCF and CI levels.[11]

The non-planar D_{3d} structure is increasingly favoured as the skeletal silicon atoms in hexasilabenzene are replaced by the heavier germanium, tin and lead atoms.[12] Figure 2 shows the optimized D_{6h} and D_{3d} structures of hexagermabenzene (Ge_6H_6), hexastannabenzene (Sn_6H_6) and hexaplumbabenzene (Pb_6H_6) at the

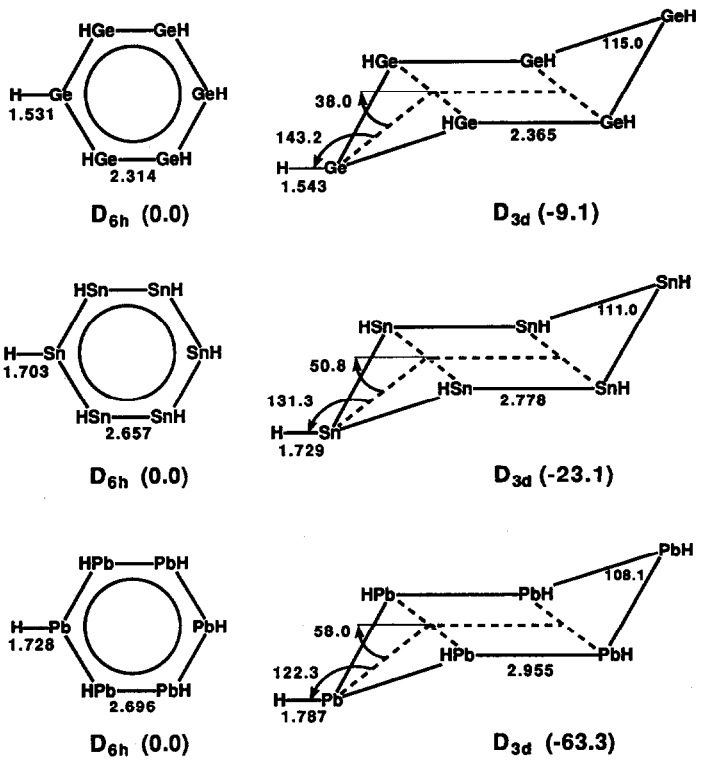

Fig. 2. The optimized D_{6h} and D_{3d} structures (Å and °) of hexagermabenzene, hexastannabenzene and hexaplumbabenzene at the HF/DZ(*d*) level. Values in parentheses are the relative energies (kcal mol^{-1}) at the MP2/DZ(*d*)//HF/DZ(*d*) level.

HF/DZ(*d*) level. The non-planar D_{3d} structures are 9.1 (Ge_6H_6), 23.1 (Sn_6H_6) and 63.3 (Pb_6H_6) kcal mol^{-1} more stable than the planar D_{6h} structures at the MP2/DZ(*d*)//HF/DZ(*d*) level. This suggests that planar hexagonal structures have no special meaning in the heavier analogues, unlike for benzene. The pronounced preference of the non-planar D_{3d} structures in Ge_6H_6, Sn_6H_6 and Pb_6H_6 is due to the increased tendency of the π electrons to localize in an antiferromagnetic way; upon going to GeH_3, SnH_3 and PbH_3 radicals, the pyramidalized structures are progressively favoured. Atomaticity based on electron delocalization is of limited value when it is applied to the heavier analogues of benzene.

It should be noted that the localized nature of π electrons is not characteristic of the heavier analogues. According to spin-coupled valence-bond calculations,[13] the delocalization of π electrons is energetically unfavourable even in benzene. The π electrons are essentially localized in deformed atomic orbitals and the aromatic properties of benzene arise from the symmetric coupling of electron spins. This may suggest that aromaticity is not simply the result of the topological properties of electron count or mode of delocalization. In addition, it has recently been pointed out from the valence-bond correlation diagram and σ–π energy separation that the D_{6h} hexagonal structure of benzene is determined not by the π electrons but by the σ framework, the π electrons themselves preferring a bond-alternated localized D_{3h} structure (a Kekulé structure).[14] We think that the propensity of the π electrons to form singlet pairs alternatively around the ring is analogous in origin to the bond alternation in long polyenes which occurs against the resistance of the σ framework, as known in terms of Peierls distortion in solid physics.

Another interesting point to be noted is the relative stability of the valence isomers.[7] Benzene is 85–130 kcal mol^{-1} more stable than its valence isomers such as Dewar benzene (C_{2v}), benzvalene (C_{2v}) and prismane (D_{3h}). In contrast, the Si_6H_6 valence isomers lie very close in stability to hexasilabenzene and are progressively favoured as the number of double bonds decreases. Thus, hexasilaprismane, being 13.4 kcal mol^{-1} more stable than hexasilabenzene, becomes the most stable Si_6H_6 isomer.[7,10] The preference of prismane structures was also calculated for the heavier Ge_6H_6, Sn_6H_6 and Pb_6H_6 systems.[12] In the heaviest Pb_6H_6 system, even hexaplumbaprismane is not a minimum in D_{3h} symmetry and highly distorted structures were calculated to be more stable. The dramatic differences between the C_6H_6 isomers and their heavier analogues are ascribed to the fact that the heavier atoms have a strong tendency to prefer saturated bonds and are capable of forming less strained compounds.

STRAINED POLYCYCLIC COMPOUNDS

Polycyclic cage compounds $C_{2n}H_{2n}$ such as tetrahedrane ($n = 2$), prismane ($n = 3$) and cubane ($n = 4$) are known as fascinating synthetic targets in carbon chemistry, because of the unusual properties and aesthetic appeal due to high symmetry. As is apparent from the carbon bond angles which deviate greatly from the normal tetrahedral value of 109.5°, they are highly strained. For instance, the strain energies of tetrahedrane and cubane are as large as 140.0 and 154.7 kcal mol^{-1}, respectively, from the experimental evaluation.[15] Summarized in Table 1 are the calculated strained energies of $C_{2n}H_{2n}$ and the silicon analogues $Si_{2n}H_{2n}$ obtained from the homodesmic reactions[16] at the HF/6–31G(*d*) level.[17] The calculated strained energies of tetrahedrane (141.4 kcal mol^{-1}) and cubane (158.6 kcal mol^{-1}) agree well with the experimental values. Thus, comparable accuracy would be expected for the calculated values of the silicon analogues where experimental data are unavailable.

Table 1 reveals an interesting contrast with silicon and carbon compounds.[17] Tetrasilatetrahedrane is as highly strained as tetrahedrane; as the number of four-membered rings increases, however, the strain decreases significantly in silicon compounds while it increases in carbon compounds. Thus, hexasilaprismane is 32 kcal mol^{-1} less strained than prismane, while octasilacubane with only four-membered rings is 65 kcal mol^{-1} less strained than cubane. This suggests that octasilacubane is a reasonable target for synthesis and isolation. In fact, a derivative of octasilacubane (Si_8R_8, R = t-$BuMe_2Si$) has been recently synthesized and its novel properties investigated.[18]

In light of the recent synthesis and structural determination of the bridgehead-coupled cubane, cubylcubane,[19] we have also calculated the silicon-based compound at the HF/6–31G(*d*) level, as shown in Fig. 3.[20] The calculated strained energy of 182.0 kcal mol^{-1}, being somewhat smaller than

Table 1. Strain energies (kcal mol^{-1}) calculated using homodesimic reactions at the HF/6–31G(*d*) level

	X = Si	X = C
Tetrahedrane (X_4H_4; T_d)	140.9	141.4
Prismane (X_6H_6; D_{3h})	113.8	145.3
Cubane (X_8H_8; O_h)	93.5	158.6

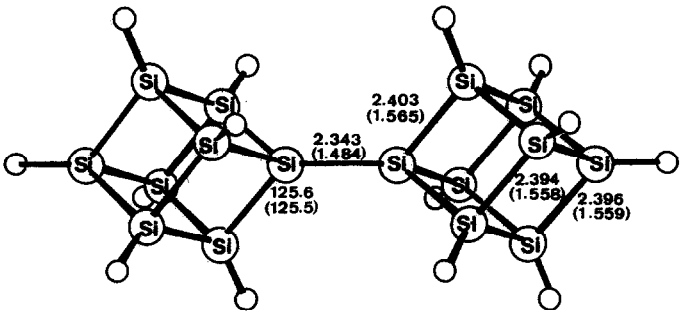

Fig. 3. The HF/6–31G(d) optimized D_{3d} structures of persilacubylcubane and cubylcubane (in Å and °). Values in parentheses are for cubylcubane. The total energies (HOMO and LUMO levels) of persilacubylcubane and cubylcubane are −4630.75593 au (−7.8 and 1.1 eV) and −613.64064 au (−9.6 and 6.0 eV), respectively.

the sum of the strains of two octasilacubanes (2×93.5 kcal mol^{-1}), is 127.8 kcal mol^{-1} smaller than that of 309.8 kcal mol^{-1} for cubylcubane at the HF/6–31G(d) level. This suggests that persilacubylcubane also forms an interesting synthetic target.

Figure 4 shows the optimized structure of larger polycyclic silicon compounds ($Si_{2n}H_{2n}$, n = 5, 6 and 8) at the HF/6–31G(d) level.[20] These were calculated to be minima in D_{nh} symmetry. The calculated strained energies were 82.8 (n = 5), 102.1 (n = 6) and 166.8 (n = 8) kcal mol^{-1}. In the corresponding carbon compounds ($C_{2n}H_{2n}$) known as [n]-prismanes, pentaprismane (n = 5) is the largest that has ever been synthesized.[21] The next largest hexaprismane (n = 6), a formal face-to-face dimer of benzene, is now challenged. However, its synthesis is not yet successful, although the related compound, secohexaprismane, was recently prepared.[22] It is interesting that the strain energies of the silicon-based [n]-prismanes ($Si_{2n}H_{2n}$) are 53.2 (n = 5), 70.1 (n = 6) and 141.0 (n = 8) kcal mol^{-1} smaller than those of 136.0, 172.2 and 307.8 kcal mol^{-1} in [n]-prismanes ($C_{2n}H_{2n}$), respectively;[20] the dimerization of benzene to give hexaprismane was 132 kcal mol^{-1} endothermic, while that of hexasilabenzene to give hexasilaprismane was 153 kcal mol^{-1} exothermic at the HF/6–31G(d) level.

It is also instructive to note that the strain energies of pentasila[1.1.1]propellane (70.2 kcal mol^{-1}) and octasila[2.2.2]propellane (55.7 kcal mol^{-1}) are 34.1 and 40.3 kcal mol^{-1} smaller than those of [1.1.1]propellane (104.3 kcal mol^{-1}) and [2.2.2]propellane (96.0 kcal mol^{-1}) at the HF/6–31G(d) level.[23]

We now discuss the effect of substitution of the skeletal silicon atoms of $Si_{2n}H_{2n}$ (n = 2–4) by heavier atoms such as germanium and tin.[24] As Fig. 5 shows, the substitution has again little effect on the strain energies in the tetrahedrane system.

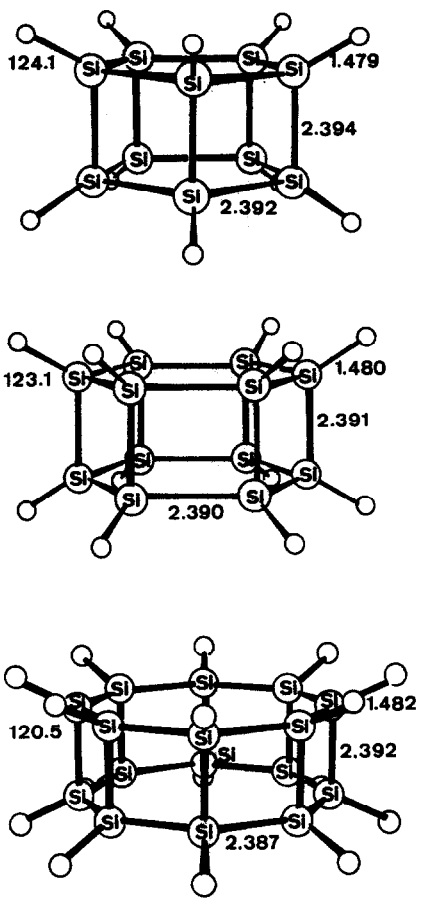

Fig. 4. The HF/6–31G(d) optimized D_{nh} structures of persila[n]prismane ($Si_{2n}H_{2n}$) (in Å and °). The total energies are −2894.98369 (n = 5), −3473.97455 (n = 6) and −4631.91717 (n = 8) au. The HOMO and LUMO levels are −8.6 and 1.3 (n = 5), −8.2 and 1.2 (n = 6), and −8.2 and 1.1 (n = 8) eV, respectively.

This is because three-membered germanium and tin rings are as highly strained as three-membered silicon rings, as is apparent from the fact that the strain energies of cyclotrigermane (39.4 kcal mol^{-1}) and

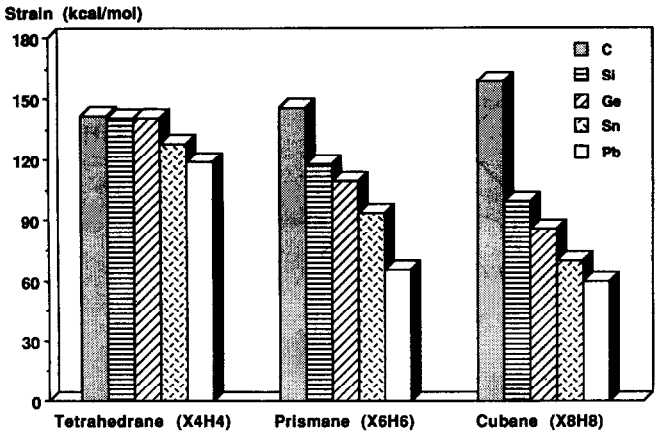

Fig. 5. The strain energies (kcal mol^{-1}) of tetrahedrane, prismane and cubane systems at the HF/DZ(*d*) level.

cyclotristannane (36.6 kcal mol^{-1}) differ little from the strain energy of cyclotrisilane (39.2 kcal mol^{-1}) at the HF/DZ(*d*) level;[24] in addition, these strain energies are all larger than that of cyclopropane (28.7 kcal mol^{-1}).

However, the strain energies of hexasilaprismane and octasilacubane decrease significantly by 9 and 24 kcal mol^{-1} and 13 and 29 kcal mol^{-1}, respectively, upon replacement by the germanium and tin atoms.[24] In this context, it is interesting that a stable hexagermaprismane derivative [Ge_6R_6, R = CH $(SiMe_3)_2$] has recently been synthesized and its X-ray structure determined.[25]

The relief of strain in the prismane and cubane systems is due to the fact that the strain energies of four-membered carbon, silicon, germanium and tin rings decrease successively in the order of cyclobutane (26.7 kcal mol^{-1}), cyclotetrasilane (17.2), cyclotetragermane (15.2), cyclotetrastannane (12.2).[24] These values agree well with the strain energies per four-membered ring in the cubane system: 26.4 (C_8H_8), 16.5 (Si_8H_8), 14.3 (Ge_8H_8) and 11.7 (Sn_8H_8) kcal mol^{-1}. These decreases in strain are due to a stronger reluctance of the heavier atoms to form hybrid orbitals, that is, an increasing tendency to maintain the $(ns)^2(np)^2$ valence electron configurations even in compounds. Apparently, this property of the heavier atoms is favourable for making 90° bond angles with low strain in four-membered rings.[24] However, it becomes unfavourable in forming three-membered rings with bond angles of 60° where hybrid orbitals with sufficiently high *p* character are essential for a description of the bent bond orbitals.[26]

Thus, it is not surprising that a successive decrease in strain due to replacement by the heavier atoms is also seen in the bicyclic compounds consisting of only four-membered rings.[27–29] For instance, the strain energy of bicyclo[2.2.0]hexane decreases by *ca* 20, 25, 30 and 35 kcal mol^{-1}, respectively, upon replacement of the skeletal carbon atoms by the heavier silicon, germanium, tin and lead atoms.[29] In the last 2 years the first synthetic and X-ray structural studies have been made of a derivative of bicyclo[2.2.0]hexasilane.[30] Although the germanium analogues have not as yet been subject to experimental tests, a bicyclo [2.2.0]hexastannane derivative was recently synthesized as the first tin example and its X-ray structure determined.[31] The heaviest analogue, bicyclo[2.2.0]hexaplumbane, is the least strained and prefers a skewed C_2 structure, unlike the lighter analogues of C_{2v} symmetry. However, the energy difference favouring the C_2 over C_{2v} structures is only 0.03 kcal mol^{-1}, despite the considerable geometrical differences between these structures, suggesting that the lead skeleton is remarkably flexible.[29] This structural feature may be ascribable to the fact that lead is most reluctant to form hybrid orbitals with highly directional *p* character because of the inert $(6s)^2$ pair originating from the relativistic effect;[32] lead is most eager to be divalent in compounds.

Reflecting the inert pair, cyclotetraplumbane (c-Pb_4H_8) also tends to take a C_{4h} structure with the hydrogen atoms skewed around the four-membered ring (as shown in Fig. 6) with some divalent character at each lead. The tendency is enhanced in three-membered rings. Thus, cyclotriplumbane (c-Pb_3H_6) adopts a skewed C_{3h} structure, unlike its lighter analogues of D_{3h} symmetry; the energy difference favouring C_{3h} over D_{3h} is as large as 10 kcal mol^{-1} at the MP4/DZ(*d*)//HF/DZ(*d*) level. As suggested in Fig. 7, cyclotriplumbane is best represented as a weak interaction among three singlet plumbylenes (PbH_2). It should be mentioned that skewed-type

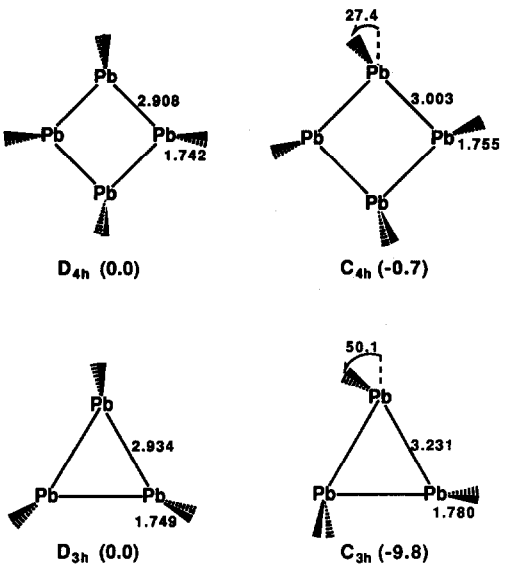

Fig. 6. The HF/DZ(*d*) optimized structures of cyclotetraplumbane (c-Pb_4H_8) and cyclotriplumbane (c-Pb_3H_6) (in Å and °). Values in parentheses are the relative energies (kcal mol^{-1}) at the MP4/DZ(*d*)//HF/DZ(*d*) level.

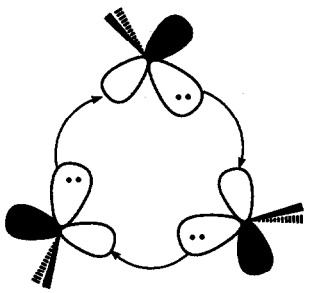

Fig. 7. Interaction of three singlet divalent species (PbH_2).

structures are also favoured in the lighter analogues (c-Si_3H_6, c-Ge_3H_6 and c-Sn_3H_6) when the hydrogens are substituted by the electronegative groups such as fluorine atoms, because the singlet states of the divalent species become much lower in energy than the triplet states.

In an attempt to assess the stability of three-membered and four-membered rings, the energy gain (*E*) due to cyclization from nXH_2 to c-X_nH_{2n} (X = Si, Ge, Sn and Pb) was calculated and compared for $n = 3$ and 4 at the MP4/DZ(*d*)//HF/DZ(*d*) level. As Table 2 shows, the calculated *E* values are larger in forming four-membered rings than in forming three-membered rings, as expected from a lower strain in four-membered rings. The *E* values per "*n*" may measure the strength of the X—X bond in c-X_nH_{2n}. As shown in Table 2, the X—X bonds in the three-membered rings are significantly weaker than those in the four-membered rings.

Table 2. The gain (*E*) in stabilization (kcal mol^{-1}) upon going from nXH_2 to c-X_nH_{2n} at the MP4/DZ(*d*)//HF/DZ(*d*) level

	c-X_4H_8		c-X_3H_6	
X	*E*	*E*/4	*E*	*E*/3
Si	223.4	55.9	142.3	47.4
Ge	164.5	41.1	96.9	32.3
Sn	119.7	29.9	64.1	21.4

	59.6	14.9	30.1	10.0

[a] Values in the second entry are for the skewed structures.

As a consequence, heavier polycyclic compounds constructed only from three-membered rings are subject to "bond stretch" isomerism because of the weaker bonds and higher strain. Thus, tetrasilatetrahedrane, containing four three-membered rings, isomerizes, with no significant barrier, by breaking two Si—Si bonds to form an isomer with one four-membered silicon ring.[33] For the silicon[27,34–37] and germanium[28] analogues of bicyclo[1.1.0]butane containing two fused three-membered rings, two distinctly different structures were located as minima, the isomer with the longer central bond being more stable than the normal bond structure. Upon going to the even heavier tin and lead analogues of bicyclo[1.1.0]butane, only bond-stretch isomers were located at the TCSCF/DZ(*d*) level.[38] As shown in Fig. 8, the central Sn—Sn and Pb—Pb bond distances become 0.832 and 0.986 Å longer than the Sn—Sn and Pb—Pb single bond

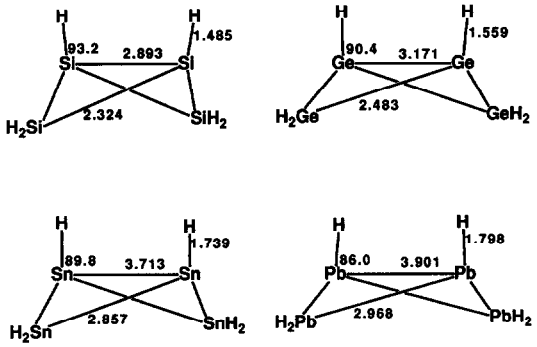

Fig. 8. The TCSCF/DZ(*d*) optimized structures of bond stretch isomers of bicyclic compounds (in Å and °). Interflap angles between the three-membered rings are 138.7 (Si), 140.8 (Ge), 144.0 (Sn) and 151.6° (Pb).

distances in $H_3Sn—SnH_3$ and $H_3Pb—PbH_3$ at the TCSCF/DZ(*d*) level, respectively. The bond-stretch isomers can be viewed as four-membered monocyclic rings with a very weak transannular bond.[28] As is apparent from these results, bond stretching is caused so as to decrease the number of three-membered rings and to create instead less strained four-membered rings.

The silicon analogue of [1.1.1]propellane, containing three fused three-membered rings, undergoes bond-stretching in the central Si—Si bond.[23,39] This was also calculated for the germanium analogue.[40] This theoretical prediction was recently verified by the successful synthesis of 2,2,4,4,5,5-hexakis(2,6-diethylphenyl)pentastanna[1.1.1]propellane.[41] According to its X-ray structure, the central Sn—Sn bond is stretched to 3.367 Å, for which significant singlet diradical character is suggested. Figure 9 shows the optimized structure of the parent compound.[42] The calculated Sn—Sn distances of 3.495 [HF/DZ(*d*)] and 3.502 [TCSCF/DZ(*d*)] Å are *ca* 0.1 Å longer than the value in the X-ray structure of the derivative. This discrepancy may be, in part, ascribed to the presence of the 2,6-diethylphenyl groups on the peripheral tin atoms in the derivative.

The TCSCF wave function (Ψ) of pentastanna[1.1.1]propellane is expressed as

$$\Psi = c_1(\sigma)^2 - c_2(\sigma^*)^2,$$

where σ and σ^* are the bonding and antibonding natural orbitals associated with the central Sn—Sn bond. The closer the square of the c_2 expansion coefficient is to 0.5, the more the wave function corresponds to a singlet diradical. The calculated $(c_2)^2$ value of 0.06 is six times larger than the value of 0.01 in $H_3Sn—SnH_3$: this may support a somewhat diradical character. However, the small value (compared with 0.5) is surprising in light of the stretched central Sn—Sn bond and is comparable with the value of 0.05 calculated for [1.1.1]propellane.[43] In the generalized valence bond approach to the bonding in [1.1.1]propellane, the overlap between the orbitals forming the central C—C bond is calculated to be 0.62.[44] This value is also comparable with the value of 0.59 calculated for pentastanna[1.1.1]propellane.[42] Incidentally, the overlaps were 0.57 and 0.59 in the silicon and germanium analogues, respectively.[42]

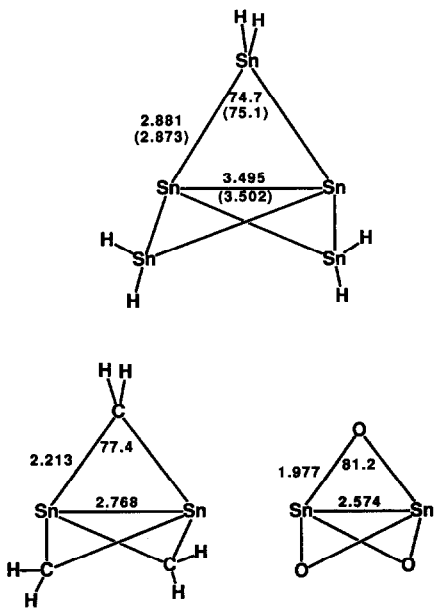

Fig. 9. Pentastanna[1.1.1]propellane and its derivatives at the HF/DZ(*d*) and TCSCF/DZ(*d*) (in parentheses) levels.

It is instructive to view pentastanna[1.1.1]propellane as resulting from a donor–acceptor interaction between SnSn and three SnH_2 units. The SnSn part participates in the interaction as an acceptor, as the negative charge of −0.12e on SnSn suggests. The electron donation into the antibonding π^* vacant orbital of the original SnSn unit may be responsible for the stretching of the central Sn—Sn bond. If this view is correct, electron-accepting substituents at the peripheral positions should significantly suppress the stretching of the central Sn—Sn bond.

As an attempt, the peripheral SnH_2 groups in pentastanna[1.1.1]propellane were all replaced by CH_2 groups because carbon is electronegative to tin. This generated a large amount of positive charge (+0.61e) on each bridgehead tin atom as a result of the increased electron donation from SnSn to three CH_2 units and the decreased back donation into the π^* orbital of SnSn. Thus, the central Sn—Sn bond distance was shortened to 2.768 Å in 1,3-distanna[1.1.1]propellane (Fig. 9). This clearly suggests that the greater the accepting capacity of the peripheral groups, the shorter the central Sn—Sn bond, as emphasized in the silicon and germanium analogues.[23,40]

To confirm this further, we next replaced the CH_2 groups by more electronegative oxygen atoms. The great difference in electronegativity between oxygen and tin leads to the predominance of a π (SnSn) → O forward donation over O → π^*(SnSn) back donation and makes the bridgehead tin atoms more positively charged to 1.37e. The predominance of the forward donation will lead to the formation of a π complex or a three-centre, two-electron bond between SnSn and O. On the other hand, little back donation into the π^* orbital of SnSn and the resultant large charge separation ($Sn^{+1.37}$ and $O^{-0.91}$) and suitable for the proximity of the central bridge-

head tin atoms. Reflecting these, the Sn—Sn bond distance becomes as short as 2.574 Å in 2,4,5-trioxa-1,3-distanna[1.1.1]propellane (Fig. 9).

In contrast to the heavier analogues of [1.1.1]propellane, the heavier analogues of [2.2.2]propellane, consisting of only four-membered rings, have normal central bond distances.[23,42]

For [2.2.2]propellane it was predicted long ago that there are two minima as a result of the crossing in orbital energies of the symmetric (bonding) and asymmetric (antibonding) orbitals of the central C—C bond.[45] The crossing arises from the advantage of through-bond over through-space interactions as the central bond is severely elongated, giving a diradical (see Scheme 1). This was also calculated for the heavier silicon, germanium and tin analogues of [2.2.2]propellane.[42] According to the calculations at the TCSCF/DZ(*d*)//TCSCF/DZ level, normal-bond structures were more stable than diradical structures by 6.0 (Si), 3.0 (Ge) and 2.4 (Sn) kcal mol^{-1}. In addition, the isomerizations of the normal closed-shell structures to diradicals were hindered by significant barriers of 11.5 (Si), 10.2 (Ge) and 9.8 (Sn) kcal mol^{-1}. However, more sophisticated calculations will be essential since these energy values are sensitive to electron correlation.[43]

UNUSUALLY SHORT PHANTOM BONDS

We have recently found that the Si—Si and Ge—Ge distances become unusually short in 2,4,5-trioxa-1,3-disilabicyclo[1.1.1]pentane (**1**)[46] and 2,4,5-trioxa-1,3-digermabicyclo[1.1.1]pentane (**2**),[40] despite the separations between the formally non-bonded atoms. We explained these short distances in terms of a small amount of back donation from the linked oxygen atoms and the resultant large charge separation. In addition, a purely ionic model was also suggested.[47]

Figure 10 shows the optimized structures of the even heavier analogues, 2,4,5-trioxa-1,3-distannabicyclo[1.1.1]pentane (**3**) and 2,4,5-trioxa-1,3-diplumbabicyclo[1.1.1] pentane (**4**), at the HF/DZ(*d*) level. For comparison, **1** and **2** were also calculated at the same level. The optimized Si—Si and Ge—Ge distances of 2.069 and 2.235 Å agree well with our previous values of 2.060 Å [HF/6-31G(*d*)][46] and 2.222 Å [HF/3-21G(*d*)],[40] respectively; the present values are calculated to be only slightly longer.

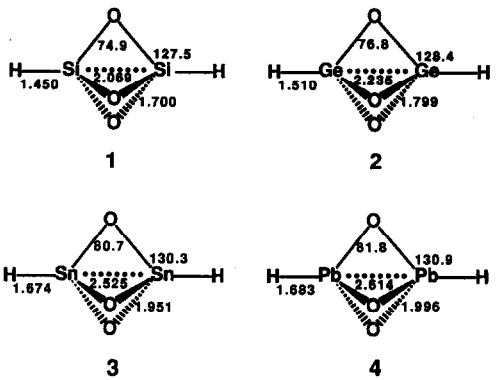

Fig. 10. HF/DZ(*d*) optimized structures of D_{3h} symmetry (in Å and °).

As Fig. 10 shows, **3** and **4** also have very short distances between the formally non-bonded atoms: Sn—Sn = 2.525 Å in **3** and Pb—Pb = 2.614 Å in **4**. These structures of D_{3h} symmetry are indeed energy minima, as shown by all real vibrational frequencies in Table 3. The Sn—Sn and Pb—Pb distances in **3** and **4** are 0.314 (11%) and 0.254 (9%) Å shorter than the Sn—Sn and Pb—Pb single bond distances of 2.839 Å in $H_3Sn—SnH_3$ and 2.868 Å in $H_3Pb—PbH_3$ at the HF/DZ(*d*) level, respectively. These compare favourably with the corresponding Si—Si and Ge—Ge shortenings of 0.275 Å (12%) in **1** from $H_3Si—SiH_3$ and 0.245 Å (10%) in **2** from $H_3Ge—GeH_3$.

Noteworthy is the fact that the Sn—Sn distance of 2.525 Å in **3** is *ca* 0.23 Å shorter than the double bond distances in distannenes ($R_2Sn{=}SnR_2$): 2.768 Å in the X-ray structure of a derivative [R = CH $(SiMe_3)_2$] with a *trans*-bent C_{2h} framework[48] and 2.747 [HF/DZ(*d*)] Å in the parent $H_2Sn{=}SnH_2$ (C_{2h}). The enforced optimization of $H_2Sn{=}SnH_2$ in higher D_{2h} symmetry leads to a shorter Sn—Sn distance of 2.558 Å [HF/DZ(*d*)], but this less stable planar D_{2h} form corresponds to a transition structure for *trans*-bending, as well known for the silicon and germanium analogues.[48,49] The Sn—Sn double bond distances in distannenes exceed the sum of the double bond covalent radii (2.60 Å)[50] and are only slightly shorter than the Sn—Sn single bond distances in distannanes ($R_3Sn—SnR_3$).[48,51] This is because tin is much more reluctant to form distinct double bonds[48,52–54] than silicon and germanium: for a weak dative bond description, see refs 48 and 52; for a σ conjugative interaction, see ref. 53; for a resonating-unshared-pair bond, see ref. 54. In this context, the short Sn—Sn distance in **3** is surprising

[a] Values in parentheses are IR intensities.
[b] Stretching between the central heavy atoms.

since its shortening percentage of 11% (0.314 Å) from $H_3Sn—SnH_3$ differs little from that of 13% (0.192 Å) for the C—C bond from $H_3C—CH_3$ to $H_2C{=}CH_2$.[55] In this sense, **3** is the first example with a "true (?)" double bond distance.

Despite recent great developments in the chemistry of the heavy analogues of alkenes,[56] very little is still known about the heaviest lead analogues, diplumbenes ($R_2Pb{=}PbR_2$). According to the calculations of the parent $H_2Pb{=}PbH_2$, the double bond breaks down even in the *trans*-bent C_{2h} form: its optimized Pb—Pb distance is as long as 3.116 [HF/DZ(*d*)] and 3.026 [MCSCF/DZ(*d*)] Å and becomes much longer than the Pb—Pb single bond in $H_3Pb—PbH_3$. This suggests that lead does not form double bonds.[57] In this connection, the non-

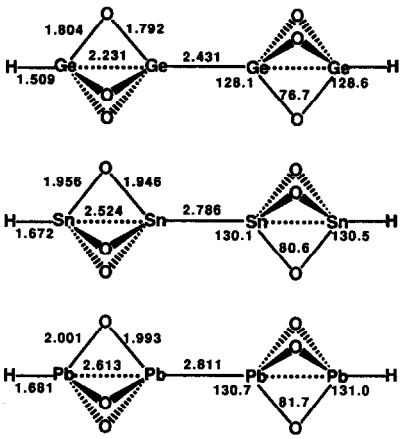

Fig. 11. HF/DZ(*d*) optimized structures of D_{3d} symmetry (in Å and °).

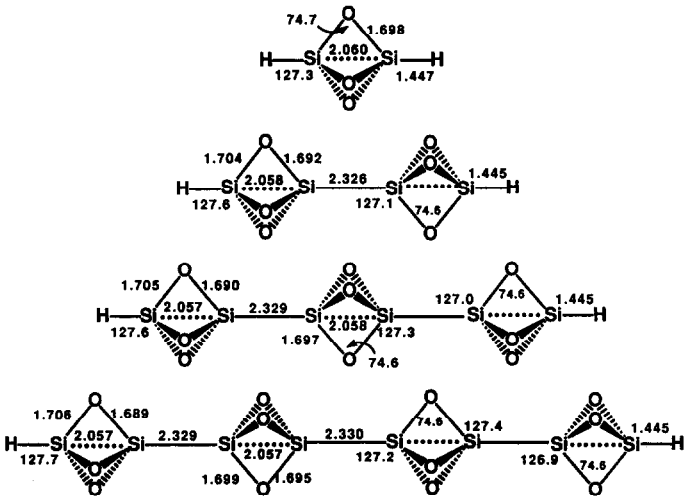

Fig. 12. The HF/6-31(*d*) optimized structure of $H—(Si_2O_3)_n—H$ of D_{3h} (n = 1 and 3) and D_{3d} (n = 2 and 4) symmetry in the staggered forms.

bonded Pb—Pb separation of 2.614 Å in **4** is unprecedentedly short which imitates a double bond distance.

It is interesting that the record distances are kept even in the dimeric forms, as shown in Fig. 11. In addition, it is also interesting to note that the central Ge—Ge (2.431 Å), Sn—Sn (2.786 Å) and Pb—Pb (2.811 Å) single bonds are significantly shorter than the normal single bonds, as in recent topics of the short C—C central single bonds in the cage and bridged ring systems with widened bond angles.[58]

Figure 12 shows the HF/6–31G(*d*) optimized structure of the silicon polymer, H—$(Si_2O_3)_n$—H (n = 1–4).[20] The non-bonded Si—Si separations of *ca* 2.06 Å are considerably shorter than the Si—Si double bond distances of 2.134 Å [HF/6-31G(*d*)] in $H_2Si{=}SiH_2$ and 2.14–2.16 Å in the X-ray structures of the derivatives.[56] No Si—Si triple bond has yet been isolated, although the possible transient existence of *trans*-bent dimethyldisilyne (MeSi≡SiMe) has recently been suggested.[59,60] In this context, it is noteworthy that the non-bonded Si—Si separations in H—$(Si_2O_3)_n$—H compare favourably with the formal Si—Si triple bond distance of 2.083 [HF/6–31G(*d*)] Å in *trans*-bent disilyne (HSi≡SiH). Thus, the silicon skeletons of the polymers having alternatively single and double (or triple) bond distances in the linear chain provide a long-sought polysilene (or polysilyne).

Acknowledgements—This work was undertaken with T. Kudo, M. Nakano and M. Souma in our research group and was, in part, supported by a grant from the Ministry of Education, Science and Culture in Japan. All calculations were carried out at the Computer Room of the Faculty of Education of Yokohama National University and at the Computer Center of the Institute of Molecular Science using the GAUSSIAN 82, 86 and 88 programs.[61–63] Thanks are also due to Dr T. Kudo for the critical reading of the manuscript.

Abstract—The interaction of solid $W_3S_7Br_4$ or $W_3Se_7Br_4$ with Et_4NBr under vibrational mill conditions followed by extraction with acetonitrile resulted in the isolation of $(Et_4N)_2W_3S_7Br_6$ (**1**) and $(Et_4N)_2W_3Se_7Br_6$ (**2**) salts. Treatment of the product of the analogous reaction of $Mo_3Se_7Br_4$ and Et_4NBr with sodium diethyldithiocarbamate (Nadtc) resulted in $[Mo_3Se_7(dtc)_3]dtc$ (**4**). The $M_3Y_7^{4+}$ (Y = S, Se) cluster fragments are retained in all of these reactions. By dissolving **1** in conc. hydrochloric acid and adding PPNCl, the $(PPN)_2W_3S_7Cl_6$ salt (**5**) was obtained, for which an X-ray study has been performed. Selected distances for the cluster anion $W_3(\mu_3\text{-}S)(\mu_2\text{-}S_2)_3Cl_6^{2-}$ are 2.7270(7)–2.7445(6) Å for W—W, 2.360(3)–2.361(3) Å for W—(μ_3-S), 2.032(4)–2.052(4) Å for S—S, 2.429(3)–2.459(2) and 2.493(4)–2.519(3) Å for W—Cl (for *cis* and *trans* positions with respect to μ_3-S, respectively). Rather short distances (3.17–3.21 Å) between the chlorine atoms and sulphur atoms of the μ_2-S_2 ligands of the adjacent anions were noted. The interaction of **2** with 1,2-bisdiphenylphosphine ethane (dppe) is accompanied by elimination of selenium to produce $[W_3Se_4Br_3(dppe)_3]Br$ (**6**).

Although the first cluster chalcogenides of molybdenum of the composition $Mo_3Y_7X_4$ (Y = S, Se; X = Cl, Br) had been synthesized in 1968,[1] the study of their chemical properties was strongly hampered by their low reactivity. X-ray studies of $Mo_3S_7Cl_4$[2] indicated this cluster to have a polymeric structure with the four chlorines being bridging atoms connecting adjacent $Mo_3S_7^{4+}$ units which is described by the crystallochemical formula $[Mo_3S_7Cl_2Cl_{4/2}]_\infty$. The recently obtained thiobromide, $W_3S_7Br_4$,[3] has the same structure also and, apparently, so have all other $M_3Y_7(Hal)_4$ (Y = S, Se; Hal = halogen) compounds.

The known examples of depolymerization of these compounds occurring with breaking of the halogenide bridges to produce molecular complexes take place under rather severe conditions. Thus $Mo_3S_7X_4$ (X = Cl, Br) and $W_3S_7Br_4$ interact with PPh_4X only in melts at 270–300°C to produce the $(PPh_4)_2Mo_3S_7X_6$ (X = Cl, Br) and $(Ph_4P)_2W_3S_7Br_6$ salts in high yields, which have been structurally characterized.[4,5] The interaction of the same chalcohalogenides with Et_4NX in boiling solutions of conc. HX (X = Cl, Br) produces Et_4N^+ salts in very low and poorly reproducible yields.

In the present work we have found that the reactivity of $M_3Y_7(Hal)_4$ considerably increases under the conditions of mechanochemical activation

which opens up new possibilities for the synthesis of complexes of $M_3Y_7^{4+}$ and $M_3Y_4^{4+}$.

EXPERIMENTAL

The synthesis of $W_3S_7Br_4$ from the elements followed ref. 5. Bromine was purified over P_4O_{10}, and the molybdenum and tungsten metals were annealed under H_2O before use. The organic solvents were purified by the standard methods.[6] dppe was synthesized according to ref. 7. All other reagents were of reagent-grade purity and used without further purification. $M_3Se_7Br_4$ compounds were obtained by heating stoichiometric amounts of the elements in evacuated quartz ampoules at 300–350°C for 70–90 h.

Experimental equipment

The IR spectra were recorded on a IFS-113 Fourier spectrometer (Bruker) in polyethylene. The Raman spectra were obtained on a Triplimate-2I spectrometer. The ^1H and ^{31}P NMR spectra were taken on a SXP-4-100 (Bruker) instrument at 290 K. The UV–vis spectra were taken on a "Specord" spectrometer. Mo, W, S and Se were determined gravimetrically as $Mo(C_9H_6NO)_2$, WO_3, $BaSO_4$ and Se, respectively. C, H, N and Br were determined at the Laboratory of Microanalysis, Institute of Organic Chemistry (Novosibirsk). The analytical and spectral data for the synthesized complexes are listed in Table 1.

The mechanochemical synthesis was performed using the apparatus described in ref. 8. The conditions were as follows. The grinding packing (3 mm diam. steel balls of total mass 300 g filling 72% of the reactor volume) and starting crystalline materials were charged into a cylindrical steel reactor (100 cm^3 volume and 50 mm height) fitted with a flange cover. The frequency of the vertical reciprocating motion of the reactor was 23 Hz, the amplitude 6 mm. The activation continued for 3–4 h. Under these conditions the reactor warmed up to 80–90°C within the first hour of activation.

Interaction of $M_3Y_7Br_4$ *with* Et_4NBr *(a typical procedure)*

Approximately equal amounts of the two reagents (charges of 3–6 g) were ground in the vibrational mill, after which the mixture was taken out and extracted with hot acetonitrile. Then ether was added to the extract and the precipitated solid was filtered, washed with alcohol, ether and vacuum-dried. For further purification, **1** can be recrystallized from acetonitrile or concentrated HBr. In contrast to this, the compounds of selenium quickly decompose in solutions which make their purification difficult. The typical yields were 50–60% for $(Et_4N)_2W_3S_7Br_6$ (**1**), 20–25% for $(Et_4N)_2W_3Se_7Br_6$ (**2**) and 30% for $(Et_4N)_2Mo_3Se_7Br_6$ (**3**).*

* Not obtained in analytically pure form.

Synthesis of $[Mo_3Se_7(dtc)_3]dtc$ (**4**)

Complex **3** (0.62 g) and $NaS_2CNEt_2 \cdot 3H_2O$ (1.00 g) in acetonitrile were boiled under argon for 2.5 h. After cooling, the red crystalline precipitate was filtered and extracted with dichloromethane on a filter. By adding ether to the extract, 0.44 g of red, crystalline substance were obtained. Yield: 25% (in terms of the starting molybdenum metal).

Synthesis of $(PPN)_2W_3S_7Cl_6$ (**5**)

Complex **2** (0.20 g) was dissolved in 30 cm^3 of conc. hydrochloric acid under heating. After addition of 1 g of PPNCl the solution was heated until a solid coagulated and then placed into a refrigerator (−5°C). After 12 h of standing the solid was filtered off, washed with alcohol and ether. 0.26 g of a pink powder **5** were obtained (quantitative yield).

Crystals suitable for an X-ray study were obtained by diffusion of ether vapours into an acetonitrile solution of the complex.

Synthesis of $[W_3Se_4Br_3(dppe)_3]Br$ (**6**)

Complex **2** (0.30 g, 0.11 mmol) and dppe (0.40 g, 0.49 mmol) in 25 cm^3 of acetonitrile were boiled under argon. After 2 h, the hot, green solution was filtered and allowed to stand at −5°C for crystallization. The precipitated green crystals were filtered to give 0.06 g of complex **6**. By adding ether to the mother solution, a further 0.16 g of **6** were obtained which were recrystallized with hexane from dichloromethane for purification. Combined mass obtained, 0.22 g. Yield: 55%.

Crystal structure determination of **5**

A well-shaped, dark violet crystal with dimensions $0.25 \times 0.30 \times 0.55$ mm was used. The data were collected on an Enraf–Nonius CAD-4 diffractometer using Mo-K_α radiation (graphite monochromator). The unit cell parameters were determined from a total of 22 reflections ($20.0 < \theta < 22.0$). The details of the X-ray experiment are given in Table 2. Three standard reflections were checked every 3 h during data collection. The intensity variations were less than 1%. The measured intensities were corrected for Lorentz and polarization effects. An empirical correction for absorption was made. The materials decomposition due to the X-rays was not taken into account. The three tungsten atoms were located from a Patterson map and the structure was solved finally by full-matrix least-squares. The positions of the hydrogen atoms were calculated and their contributions added to the structure factors but were not refined. No correction for secondary extinction was made. The atomic scattering factors and the anomalous dispersion coefficients were taken from the SDP/PDP V 3.0 Enraf–Nonius package. All calculations were performed on a PDP 11/44 computer.

RESULTS AND DISCUSSION

The study of the chemistry of molybdenum chalcogenide has shown that the $Mo_3S_7^{4+}$ cluster fragment is stable and shows a distinct tendency to form in systems rich in sulphur. This may be illustrated by the diversity of the synthetic routes to $Mo_3S_7X_4$ thiohalcogenides (X = Cl–I). They may be obtained

from elements, or from MoX_2 or MoX_3 and sulphur, or, vice versa, by heating MoS_3 with bromine[1,9–12] or by thermolysis of MoS_4X_2 (X = Br, I).[1] The cluster thio complex $(NH_4)_2Mo_3S_7(S_2)_3$ was obtained by reduction of $(NH_4)_6Mo_7O_{24}$ with ammonium polysulphide,[13] whereas oxidation of $Mo(CO)_6$ or $K_4Mo_2Cl_8$ with $[R_2P(S)]_2S_2$ (R = Et, Pr, Bu) gives rise to $[Mo_3S_7(R_2PS_2)_3]R_2PS_2$.[14] Maoyu *et al.*[15] obtained $[Mo_3S_7\{(EtO)_2PS_2\}_3]Cl$ by the reaction of K_2MoOCl_5 and P_2S_5 in ethanol. Another molybdenum(V) compound, $MoCl_5$, in the reaction with NaSH forms the $(Et_4N)_3Mo_3S_7Cl_7$ salt in 3% yield.[16]

In the case of $W_3S_7^{4+}$ and $M_3Se_7^{4+}$ clusters the only starting compounds to develop the chemistry are the $M_3Y_7X_4$ chalcogenides and the corresponding selenohalogenides of tungsten have not been described at all. Selenohalogenides of molybdenum, first described in 1968,[9] were obtained by heating di- and trihalogenides of molybdenum with selenium at 300–350°C. We have found that the same samples of $Mo_3Se_7Br_4$ can be obtained from the elements by the ampoule method (heating of stoichiometric amounts of elements in evacuated quartz ampoules at 300–350°C for 70–100 h). In the case of tungsten, heating of stoichiometric amounts of the elements under the above conditions affords a product consisting to a considerable extent of $W_3Se_7Br_4$. Because of the lower reactivity of tungsten and selenium in comparison with molybdenum and sulphur, respectively, the individual product is difficult to obtain; but the selenobromides obtained in this way turned out to be convenient sources of the $M_3Se_7^{4+}$ clusters and presented no problems of separation from the side reaction products.

As a result of the mechanochemical reactions [eq. (1)],

$$M_3Y_7Br_4 + 2Et_4NBr \longrightarrow (Et_4N)_2M_3Y_7Br_6$$

M = W, Y = S (**1**)
M = W, Y = Se (**2**)
M = Mo, Y = Se (**3**) (1)

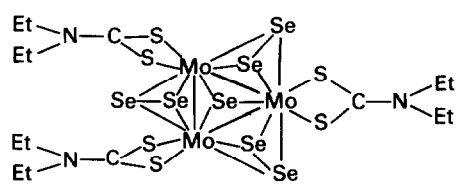
complexes with molecular structure are produced from the polymeric chalcogalogenides. Vibrational spectra of **1** indicate it to be identical to the product produced in low yield in the reaction Et_4NBr with $W_3S_7Br_4$ in boiling, conc. HBr.[5] In the case of selenohalogenides, comparison of the vibrational spectra of the starting $Mo_3Se_7Br_4$ and the products of reaction (1) indicates that the central, structural fragment $M_3Se_7^{4+}$ is retained. Although, in contrast to the thio complexes, the cluster seleno complexes are not practically studied by the vibrational spectroscopy methods (determination of the types and the symmetry of the vibrations, the force constants), the bands in the region 330–310 cm^{-1} in the IR and Raman spectra of **1** and **3** and of the starting $Mo_3Se_7Br_4$ and $W_3Se_7Br_4$ can be suggested to correspond essentially to the valence vibrations of the μ_2-Se_2 ligand and the lower energy bands 270–280 cm^{-1} to be associated with the μ_3-Se ligand. In the IR spectra of $NbSe_2Cl_2$ and $NbSe_2Br_2$[17] the bands at 352 and 343 cm^{-1}, respectively, were attributed to ν(Se—Se). The lower-lying M—M, M—Br and M—(μ_2-Se) vibrations must strongly mix with each other. The spectra of **2** and **4** (Raman and IR) are shown in Fig. 1.

As pointed out above, selenohalogenide complexes cannot be recrystallized without decomposition. Compound **3** could not be isolated in analytically pure form. Therefore, in this case, the product of reaction (1) was transformed to the more stable diethyldithiocarbamate complex [eq. (2)]:

$$Mo_3Se_7Br_6^{2-} + 4\,dtc^- \xrightarrow{\text{acetonitrile}} [Mo_3Se_7(dtc)_3]dtc + 6Br^- \quad (2)$$
(**4**)

Complex **4** is poorly soluble in CH_3CN and CH_3NO_2 but readily dissolves in chlorinated and aromatic hydrocarbons. The ^1H NMR spectrum of **4** shows the following features due to the structure of **4**:

(1) Non-equivalence of the methylene groups of the coordinated and uncoordinated dithiocarbamates (the ratio of the signals 3:1); (2) Non-equivalence of the methylene groups of the coordinated dithiocarbamate (the intensity ratio 1:1) due to the retarded rotation about the C—N bond.[18] As a result, two methylene groups from each ligand occupy different positions with respect to the Mo_3 plane. The $[Mo_3S_7(Et_2PS_2)_3]^+$ dtc^- complex, containing dithiocarbamate as a counterion, has been described in ref. 14. Thus, the following structure can be proposed for the $Mo_3Se_7(dtc)_3^+$ cation:



The easy replacement of the halogen atoms in **1**–**3** is also illustrated by the production of the $W_3S_7Cl_6^{2-}$ salt when **1** is recrystallized from conc. hydrochloric acid. Adding PPNCl to this solution results in the isolation of **5** in quantitative yield.

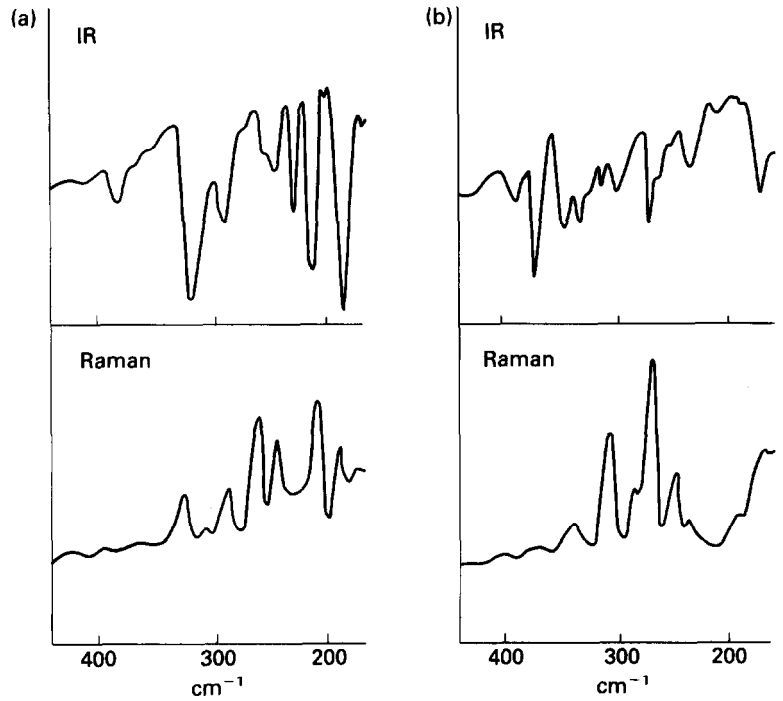


Fig. 1. IR and Raman spectra of (a) $(Et_4N)_2W_3Se_7Br_6$ and (b) $[Mo_3Se_7(dtc)_3]dtc$.

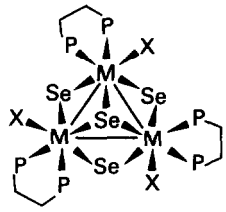
The literature has already described quite a number of examples of transitions from $M_3S_7^{4+}$ to $M_3S_4^{4+}$ derivatives. These reactions consist of the elimination of the equatorial sulphur atoms of the μ_2-S_2 ligand under the action of different nucleophiles.[3,5,19-21] On the whole, the problem of obtaining $Mo_3S_4^{4+}$ and $W_3S_4^{4+}$, both in aqueous and non-aqueous media, can be considered to be solved. In 1985 $Mo_3Se_4^{4+}$(aq) and $Mo_3Te_4^{4+}$(aq) were obtained by Sykes and co-workers[22] by the electrolysis of aqueous solutions of $Mo_2O_4(cys)_2^{2+}$ with a selenium or tellurium cathode. However, no individual solid compounds containing such cluster fragments have been described. Saito *et al.* described[23] the interaction of $Mo_3Se_7Cl_4$ with PEt_3 which probably gives a mixture of several phosphine complexes of $Mo_3Se_4^{4+}$. The $W_3Se_4^{4+}$ derivatives have not been described. We found that **2** readily reacts with dppe upon boiling in acetonitrile to give a bright green solution which crystallizes **6** [eq. (3)]:

$$(Et_4N)_2W_3Se_7Br_6 + 4.5\,dppe \longrightarrow [W_3Se_4(dppe)_3Br_3]Br + 1.5\,dppeSe_2. \quad (3)$$

Complex **6** is soluble in acetonitrile, dichloromethane and chloroform. The electronic spectra of **6** in the visible region contain an absorption band at 645 nm ($\varepsilon = 1070$). Its position and intensity is close to those observed for other $M_3Y_4^{4+}$ chromophores (M = Mo, W; Y = S, Se), indicating, in all appearances, the presence of the $W_3Se_4^{4+}$ chromophore. The ^{31}P NMR spectrum contains two unresolved singlets with an intensity ratio 1 : 1, which indicates the presence of two types of phosphorus atoms coordinated at the tungsten atom in *cis* and *trans* positions with respect to the μ_3-Se ligand. This type of coordination is characteristic of all of the studied complexes $[M_3S_4(\widehat{P\ P})_3X_3]^+$ (M = Mo, W; $\widehat{P\ P}$ = dmpe, dppe; X = Cl, Br, H):[3,18,19,23,24]



The structure of the $W_3S_7Cl_6^{2-}$ *anion*

The crystal structure of two pairs of polymeric chalcogenides and their anionic complexes have been studied in the chemistry of molybdenum and tungsten: $Mo_3S_7Cl_4$,[2,3] $W_3S_7Br_4$,[3] $(Ph_4P)_2Mo_3S_7Cl_6$[4] and $(Ph_4P)_2W_3S_7Br_6$.[5] The structure has been also determined for $(Et_4N)_3Mo_3S_7Cl_7$[16] in which the anion contains μ_3-Cl weakly coordinated by the axial sulphurs of the μ_2-S_2 ligands (d_{S-Cl} = 2.91–2.95 Å). Here we report the structure of $(PPN)_2W_3S_7Cl_6$.

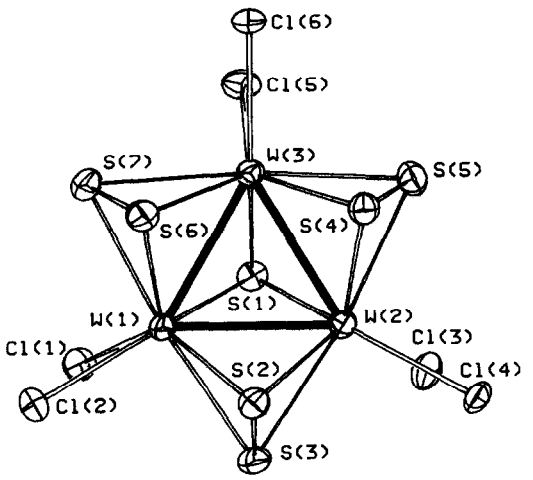


Fig. 2. Structure of $W_3S_7Cl_6^{2-}$ showing the atom labelling scheme.

The structure of the $W_3(\mu_3\text{-}S)(\mu_2\text{-}S_2)_3Cl_6^{2-}$ anion is shown in Fig. 2. There are two independent PPN^+ cations slightly differing in their geometrical parameters but which do not go beyond that typical

for this cation. In Table 3 are listed the interatomic distances in the $W_3S_7Cl_6^{2-}$ anion. The W—W bond length is, on average, 2.739(1) Å; S—S, 2.039(3) Å; and W—μ_3-S, 2.364(3) Å.

The three tungsten atoms defining an equilateral triangle and the three sulphur atoms of the asymmetrically coordinated μ_2-S_2 ligands practically lie in one plane (deviations from the root-mean-square plane do not exceed 0.1 Å, Table 5). In addition to two μ_2-S_2 and one μ_3-S ligands each tungsten is coordinated by two chlorine atoms at different distances. For the chlorine atoms in the *trans* position to the μ_3-S ligand [Cl(2), Cl(4) and Cl(6)] the average W—Cl distance is 2.524 Å, and in the *cis* position [Cl(1), Cl(3) and Cl(5)] it is 2.446 Å. An analogous situation occurs in the previously studied anions. This appears to be due to the steric effects of the μ_2-S_2 ligands which are strongly tilted towards the M_3 plane and all actually lie on the side of the M_3 triangle which is opposite to μ_3-S (Table 4).

The sulphur atoms of the μ_2-S_2 ligands in such compounds are capable of additionally coordinating halogen atoms, as was shown for $Mo_3S_7Cl_7^{3-}$,[16] $[Mo_3S_7\{(EtO)_2PS_2\}_3Cl]$,[15] with the S—Cl distance (2.9 Å) being intermediate between the covalent (1.9–2.0 Å) and van der Waals' (3.65 Å) interactions. The reason for this behaviour is not clear. We have discovered[4] that the $Mo_3S_7Cl_6^{2-}$

anions in the structure of $(Ph_4P)_2Mo_3S_7Cl_6$ are united with centrosymmetric dimers at the expense of the interaction between the chlorine atoms and the sulphur atoms of the μ_2-S_2 ligands (3.12–3.47 Å). Such short S—Cl contacts have also been found by us in the structure of **5** (3.17–3.21 Å).

Acknowledgement—We are grateful to Ms M. P. Primanchuk for halpful discussions.

REDOX AND COORDINATIVE PROPERTIES OF N,N′-DITHIOBISAMINES: OXIDATIVE DESULPHURIZATION BY COPPER(II) IONS AND $Cr(CO)_5[S_2(NR_2)_2]$ COMPLEXES

CARLOS DÍAZ

Universidad de Chile, Facultad de Ciencias, Departamento de Química, Casilla 653, Santiago, Chile

(*Received* 20 *November* 1990; *accepted* 9 *January* 1991)

Abstract—N,N′-dithiobisamines, $R_2N—S—S—NR_2$, NR_2=$N(CH_3)_2$, $N(CH_2CH_3)_2$,  ,  or $N(CH_2—C_6H_5)_2$, are oxidized to SO_2 by copper(II) salts with formation of copper(I) complexes, while from the reaction with pentacarbonyl (tetrahydrofuran)chromium the novel complexes $Cr(CO)_5[S_2(NR_2)_2]$ were isolated. They have been characterized by elemental analysis as well as by spectroscopic methods. The π-acceptor abilities of the sulphur-containing ligands in the $Cr(CO_5)L$ complexes are discussed and compared with those found for their analogous monothio derivatives. Reactivity of the coordinated sulphur compounds towards acids and copper(II) salts is less than that of the free ligands.

Interest in the chemistry of the metal–disulphide interaction has accelerated markedly over the last 50 years, largely because of the importance of this linkage in biological systems.[1,2] Nevertheless, the isolation of metal complexes with organic disulphide is not always facile because certain metal ions cause cleavage of the disulphide bond.[3] The great majority of such studies have been made with disulphide compounds of the type R—S—S—R[3–8] and investigations with disulphides containing bonds other than C—S are scarce.[9–11] As a part of a study of the reactivity and coordination properties of S—N compounds[12–20] we are now investigating the N,N′-dithiobisamines, $R_2N—S—S—NR_2$. These compounds were prepared in 1895[21] but little attention has been paid to their reactivity.[9,22] N,N′-dithiobisamines undergo sulphur–nitrogen fission in reactions with sulphurous acids,[23] thiols[23] and *p*-toluenesulphinic acid,[10] whereas sulphur–sulphur cleavage has been reported in reactions with lithium[24] and chlorine.[9] In spite of the expected coordinative properties arising from the lone electron pairs on the sulphur and nitrogen atoms, to our knowledge the only metal complexes containing N,N′-dithiobisamines as a ligand are the iron(II) and cobalt(II) complexes with N,N′-dithiomorpholine.[25]

Many of the investigations on N,N′-dithiobisamines have been stimulated by their activity as insecticides,[26] fungicides,[26] polymerization catalysts,[27] corrosion inhibitors in lubricating oil[28] and as stabilizers for polyurethane fibres.[29] In addition, much effort has gone into evaluating the usefulness of such disulphides for the vulcanizations of rubber.[30] The extensive use of N,N′-dithiobismorpholine as a catalyst in the vulcanization of natural rubber has prompted a toxicological study on this compound.[31]

Previously we have reported the synthesis and spectroscopic studies of some N,N′-dithiobisamines[32,33] and in this paper we present the results about some of the redox and coordinative behaviour of a series of N,N′-dithiobisamines towards copper(II) salts and the $Cr(CO)_5$ fragment, respectively.

RESULTS AND DISCUSSION

Redox properties of N,N′-*dithiobisamines*

The initial attempt to obtain coordination compounds was made by reaction of copper(II) salts with N,N′-dithiobisamines.

However, we conclude that similar to the behav-

iour of other sulphur–nitrogen compounds,[12,16] N,N′-dithiobisamines reduced copper(II) perchlorate hexahydrate in acetonitrile according to:

$$R_2N—S—S—NR_2 + 6\,Cu(ClO_4)_2 6\,H_2O \xrightarrow{CH_3CN} 6\,[Cu(CH_3CN)_4]ClO_4 + 2\,SO_2 + 32\,H_2O + 4\,HClO_4 + 2\,[R_2NH_2]ClO_4$$

where NR_2 = $N(CH_3)_2$, $N(CH_2CH_3)_2$,  ,  , $N(CH_2—C_6H_5)_2$.

The copper(I) acetonitrile complex[16,34] was identified by IR, ^1H NMR and elemental analysis. The sulphur dioxide evolved from the reaction was detected by the usual method.[16] The corresponding $H_2NR_2^+$ salt was isolated and characterized by IR and ^1H NMR in the case of the reaction with N,N′-dithiobismorpholine and by NMR of the solutions in the case of the other dithiobisamines (see Experimental). Yields of the reactions based on the copper(I) product are similar to those found in the reactions with N,N′-thiobisamines.[16]

On the other hand, from the reaction of N,N′-dithiomorpholine with $CuCl_2 \cdot 2H_2O$ in ethanol, the complex $[Cu_2Cl_3][H_2N$  $O]$[12] and sulphur dioxide were identified. Similar products have been found in the reaction of N,N′-thiobisamines with copper(II) chloride dihydrated in ethanol.[17]

The formation of sulphur dioxide and the respective $H_2NR_2^+$ species from these reactions indicate S—N as well as S—S bond cleavage in N,N′-dithiobisamines. This behaviour is readily understood since it is well established that electrophiles such as H^+, Ag^+, Co^{III} and R^+ can assist in the nucleophilic cleavage of the disulphide bond in R—S—S—R compounds.[3] Thus it is known that copper(II) ions destabilize the S—N bond in thiobisamines.[12,15–17]

Although several Cu—RSSR compounds have been reported,[4,6,7] the difficulty in the synthesis of the metal–disulphide complexes has already been noted.[7] The reaction of copper(II) salts with sulphur compounds in a low oxidation state normally results in the reduction of the metal. The copper(I) oxidation state is usually stabilized by the formation of complexes in which the ligand remains intact and (or) by the formation of $(Cu—SR)_n$ complex polymers. In the case of N,N′-thiobisamines and similar to other S—N compounds,[12,16] copper(I) is stabilized by the solvent (acetonitrile) in the reaction with $Cu(ClO_4)_2 \cdot 6H_2O$ or by the anion of the copper(II) salt in the reaction with $CuCl_2 \cdot 2H_2O$.

Coordinative properties

From the above results it can be concluded that metal ions destabilize the S—S as well as the S—N bonds in the N,N-dithiobisamines studied. Hence we attempted their coordination with a metal in a low oxidation state as the fragment $Cr(CO)_5$.[35] Reaction of the labile intermediate $[Cr(CO)_5(THF)]$ with the sulphur–nitrogen ligands in THF affords the complexes $Cr(CO)_5[S_2(NR_2)_2]$:

$$[Cr(CO)_5(THF)] + S_2(NR_2)_2 \xrightarrow{THF} Cr(CO)_5[S_2(NR_2)_2]$$

NR_2

(1) $N(CH_3)_2$

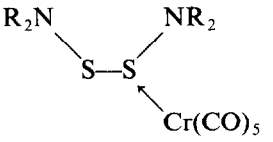
(2) $N(CH_2CH_3)_2$

(3)

(4) 
(5) $N(CH_2—C_6H_5)_2$.

The complexes obtained by this procedure are yellow solids, soluble in organic solvents but unstable both in air and particularly in solution. Compounds **2** and **5** were obtained as yellow oils and all crystallization attempts were unsuccessful.

The IR spectra of the complexes in the carbonyl stretching region show the four bands expected for $Cr(CO)_5L$ complexes where L is a bulky sulphur ligand.[36] The splitting of the *E* mode is not observed as found for other sulphur(II)–nitrogen complexes.[14,20] Values of the ν(C—O) frequencies are presented in Table 1. Bands corresponding to the Cr—C stretch and Cr—C—O bending vibrations have also been assigned. Coordination by $Cr(CO)_5$ causes only small changes in the IR bands of N,N′-dithiobisamines.[32] The S—N bands appear to be split and shifted with respect to the free ligand, as is shown in Table 2. The splitting of the S—N bond may be due to the non-equivalent S—N bonds caused by coordination to one of the sulphur atoms:



Consistent with this, the coordination of $Cr(CO)_5$ to N,N′-thiobisamines causes only a shift of the ν(S—N) frequency as may be expected, and no splitting is observed.[14]

The NMR spectra of the complexes show, in general, the expected signals corresponding to the

coordinated ligands. Small chemical shift differences in the signals in going from the free to coordinated ligand were observed (see Table 2). The spectra of compounds **1** and **5** could not be recorded at room temperature (35°C) due to the extensive decomposition of the samples. The spectrum of complex **1** at low temperatures (−20°C) consists of two singlets of equal intensity at 2.58 and 2.68 ppm. On standing at room temperature, rapid decomposition of the complex with separation of a green, insoluble solid as well as broadening of the signals by loss of resolution was observed. At the same time a signal corresponding to the free ligand[32] formed in the decomposition appears and increases in intensity on raising the temperature. On the other hand, the ^1H NMR spectrum of **5** at low temperature consists of a slightly broadened (nearly two unresolved signals) signal corresponding to methylene protons, giving rise to a sharp singlet at higher temperatures. Simultaneous appearance of a second singlet, attributable to the free ligand,[32] was observed. On standing at room temperature, decomposition of the complex was also observed. We believe that these changes may be caused by a 1,2 metal-shift between the adjacent pair of sulphur atoms, as observed for pentacarbonylchromium derivatives of dialkyldisulphides.[37] However, for complex **1** and **5** unfortunately the 1,2 shift dynamic

process could not be observed because of the rapid decomposition of the sample at higher temperatures. For complexes **2–4**, the spectra do not exhibit any significant change at low temperatures.

The differences in the chemical shift values on going from the free to coordinated ligand are comparable with those found in other organic sulphur(II)–nitrogen ligands ligated to chromium(0) which, as has been established, are evidence for coordination via the sulphur atom.[14,20]

The UV–visible spectra of the complexes show a band at about 400 nm, close to those found in pentacarbonylchromium–sulphur complexes[14,20] and assigned to a $^1A_1 \rightarrow {}^1E$ transition.[38]

Attempts to obtain the mass spectra for the complexes were successful only for **3** and **4**. For these compounds the molecular ion peaks in addition to other fragments can be observed, and the ions are listed in Table 3. The fragments arising from decomposition of the molecular ion were identified with the aid of previous fragmentation studies of dithiobisamines[33] and chromium carbonyl complexes.[39] For compound **3** fragmentation occurs principally by loss of three carbon monoxide molecules to give a $Cr(CO)_2[S_2(N\text{-}C_5H_8)_2]^+$ fragment. Subsequently this undergoes successive loss of sulphur to give the species $Cr(CO)_2[S(N\text{-}C_5H_8)_2]^+$ and $Cr[N\text{-}C_5H_8]_2^+$. Fragmentation arising from the Cr—S bond cleavage of the molecular ion is also evident by the presence of the ions $[Cr(CO)_{5-n}]^+$ $(n = 0–5)$ and $[S_2(N\text{-}C_5H_8)_2]^+$. Consistent with this, the

 and $[C_4H_7]^+$ fragments observed in the mass spectrum of the free ligand[33] were also observed in the mass spectrum of **3**.

For compound **4** the decomposition of the molecular ion occurs principally with Cr—S cleavage. The  ion and its typical decomposition fragments[33] are observed with high intensity.

Information about the donor–acceptor abilities of the N,N′-dithiobisamines towards $M(CO)_5$ fragments (M = Cr, Mo, W) can be obtained using the σ–π parameters of Graham.[40] For complexes **1–5** these were calculated using the Cotton–Kraihanzel[41] force constants for the C—O bonds obtained from the ν(C—O) values reported in Table 1. For comparison the respective π and σ values for the monothiobisamines analogous compounds,[14] as well as for other ligands,[38] have been included in Table 4. By inspection of the π values, it can be seen that N,N′-dithiobisamines are better π acceptors than their corresponding monothio derivatives but they possess a lower π acceptor ability than alcoxythioamines.[20] From the table it can also be

observed that the π values for complexes **1–5** are close to those found for divalent sulphur compounds. The change in the π acceptor capacity in going from the dithio to the monothio derivatives in the S—N compounds is the reverse of that found in disulphide and thioether ligands.[6]

Stability of the complexes and reaction with $Cu(ClO_4)_2 \cdot 6H_2O$

As mentioned before, solutions in common organic solvents were unstable on exposure to air, but the solids were fairly stable, **1** being the most unstable. The complexes are also unstable to acids, and decomposition with hydrogen sulphide evolution was observed. Decomposition in acid media has also been reported for the free ligands.[23] Towards bases, the complexes are fairly stable. Similar to the free ligands, the complexes reduce the copper(II) perchlorate in acetonitrile to give the copper(I)–acetonitrile complex and sulphur dioxide, but in minor yields.

Consequently, it seems possible to suggest that the reactivity of N,N′-dithiobisamines towards acids decreases in going from the free to the coordinated sulphur–nitrogen compound.

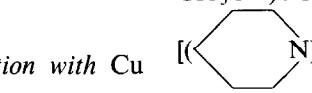
EXPERIMENTAL

N,N′-dithiobisamines were prepared as described previously.[3,2] Commercially available chromium hexacarbonyl (Alfa) was used without further purification. All preparations and manipulations were carried out under purified nitrogen. Spectroscopic measurements were made as described elsewhere.[13–20]

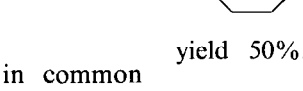
Reactions of N,N′*-dithiobisamines with* $Cu(ClO_4)_2 \cdot 6H_2O$ *in acetonitrile*

Dithiobisamine (1.5–3.5 mmol) in acetonitrile was added to the copper(II) salt solution with stirring and at ambient temperature. The white solid which formed was filtered and dried with a stream of dry nitrogen gas. In some cases a green, basic copper(II) salt was obtained as an impurity which was eliminated by disolution of the solid in hot acetonitrile followed by filtration of the green solid and evaporation of the solvent to afford the white, crystalline product $Cu(CH_3CN)_4ClO_4$.

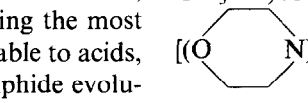
Found: Cu, 19.2. Calc. for $C_8H_{12}O_4N_4ClCu$: Cu, 19.4%. ^{1}H NMR (acetone-d^6, δ from TMS) 2.15 s (CH_3). IR_{max} (KBr) 2300, 2260 m $\nu(C{\equiv}N)$; 1200–1000s, br $\nu(ClO_4)_{asym}$; 922 s $\nu(ClO_4)_s$; 620 m $\delta(ClO_4)$. Amounts of reactants used, yields of the $Cu(CH_3CN)_4ClO_4$ product and ^{1}H NMR data for the $[H_2NH_2]^+$ salts are as follows: $[(CH_3)_2N]_2S_2$, 0.54 g; $Cu(ClO_4)_2 \cdot 6H_2O$ 2.39 g, yield 82%. $[(CH_3CH_2)_2N]_2S_2$, 0.5 g; $Cu(ClO_4)_2 \cdot 6H_2O$, 2.1 g, yield 70%. ^{1}H NMR $[(CH_3CH_2)_2NH_2]^+$ (filtrate CH_3CN): 3.07 (2H, q, CH_2), 1.25 (3H, t, CH_3).



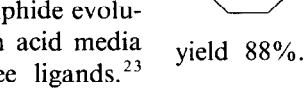
$]_2S_2$ 0.35 g; $Cu(ClO_4)_2 \cdot 6H_2O$ 1.12 g, yield 50%. ^{1}H NMR



(filtrate CH_3CN): 3.0 (4H, m, NCH_2), 1.66 [6H, m, $(CH_2)_3$].



$]_2S_2$ 0.81 g; $Cu(ClO_4)_2 \cdot 6H_2O$ 2.54 g, yield 88%. ^{1}H NMR



(filtrate CH_3CN): 3.86 (4H, m, OCH_2), 3.26 (4H, m, NCH_2). $[(C_6H_5{-}CH_2)_2N]_2S_2$ 0.7 g; $Cu(ClO_4)_2 \cdot 6H_2O$ 1.15 g, yield 90%. ^{1}H NMR $[(C_6H_5{-}CH_2)_2NH_2]^+$ (filtrate, CH_3CN): 7.3 (10H, m, C_6H_5), 3.9 (4H, s, CH_2).

Isolation of  *from reaction with* N,N′*-dithiomorpholine*. After filtration of the white crystals of $Cu(CH_3CN)_4ClO_4$ a second portion of this compound was precipitated by slow evaporation of the solution. Slow evaporation of the solvent of the filtrate at room temperature afforded colourless crystals, soluble in water. ^{1}H NMR (acetone-d_δ δ from TMS): 3.93 (4H, m, OCH_2), 3.53 (4H, m, NCH_2), 3.03 (2H, br, s, NH_2). IR ν_{max} (KBr): 3125 m $\nu(NH_2)_{sym}$; 3060 s $\nu(NH_2)_{asym}$ 2461 m; 1580 s $\delta(NH_2)$.

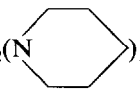
Reaction of N,N′*-dithiomorpholine with copper*(II) *chloride dihydrate*. To a solution of copper(II) chloride dihydrate (1.73 g, 10.16 mmol) in ethanol (previously deoxygenated with nitrogen) dithiomorpholine (2.5 g, 10.16 mmol) in the same solvent was added dropwise. Evolution of sulphur dioxide and the formation of white crystals was observed. The solid product was filtered, washed with ethanol and dried *in vacuo*, m.p. 110–115°C (dec.) (ref. 12, 110–111°C dec). IR_{max} (KBr) 3185 $\nu(NH_2)_{asym}$; 3060 $\nu(NH_2)_{sym}$; 1580 $\delta(NH_2)$; 1100 s $\nu(COC)_{asym}$; 865 s $\nu(COC)_{sym}$.

Synthesis of $Cr(CO)_5[S_2(NR_2)_2]$ *complexes*

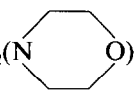
$Cr(CO)_5[S_2(N(CH_3)_2)_2]$ (**1**). A solution of $Cr(CO)_6$ (0.99 g, 4.5 mmol) in *ca* 60 cm^3 of THF was irradiated for 90 min at room temperature. To this a solution of $S_2[N(CH_3)_2]$ (0.6 g, 3.9 mmol) was added and the mixture stirred for 60 min. After removing the solvent *in vacuo* the excess of hexa-

carbonyl was sublimed from the residue *in vacuo* at room temperature. The solid residue was stirred in n-hexane and the solution filtered through Kieselghur. The solution was then concentrated at room temperature *in vacuo* and then placed in the freezer overnight. Filtration of the resulting yellow solid affords **1** (60 % yield), m.p. 53°C. Found: C, 30.2; H, 3.1; N, 7.0. Calc. for $C_9H_{12}O_5N_2S_2Cr$: C, 31.4; H, 3.5; N, 8.0%.

$Cr(CO)_5[S_2(N(CH_2CH_3)_2)_2]$ (**2**). A solution of $[Cr(CO)_5(THF)]$ generated as described for **1** was stirred with the corresponding dithiobisamine (0.82 g, 3.9 mmol) in THF for 1 h. After removing the solvent *in vacuo* the residue was stirred with n-hexane and filtered. Evaporation of the solvent afforded a non-crystallizable, yellow oil which was only spectroscopically characterized (see Tables 1 and 2).



$Cr(CO)_5[S_2(N\quad)_2]$ (**3**). A solution of $[Cr(CO)_5(THF)]$ was stirred with N,N′-dithiobispiperidine (0.8 g, 3.4 mmol) for 1 h. After removing the solvent *in vacuo* the excess of $Cr(CO)_6$ was sublimed under reduced pressure at room temperature. The solid residue was then redissolved in n-hexane, filtered through Kieselghur and the resulting solution was concentrated and placed in a freezer overnight to give **3** as yellow crystals (75% yield), m.p. 92–93°C (dec.). Found: C, 42.1; H, 4.8; N, 6.5. Calc. for $C_{15}H_{20}O_5N_2S_2Cr$: C, 42.4; H, 4.7; N, 6.5%.



$Cr(CO)_5[S_2(N\quad O)_2]$ (**4**). This compound was obtained using the same procedure as for **3**, as yellow crystals (80% yield), m.p. 86–88°C (dec.). Found: C, 36.1; H, 3.8; N, 6.4. Calc. for $C_{13}H_{16}O_7N_2S_2Cr$: C, 36.8; H, 3.8; N, 6.6%.

$Cr(CO)_5[S_2(N(CH_2—C_6H_5)_2)_2]$ (**5**). To a solution of $[Cr(CO)_5(THF)]$ was added N,N′-dithiobisdibenzylamine (1.52 g, 0.33 mmol) in THF at room temperature. The mixture was stirred for 1 h, then the THF was evaporated *in vacuo* and the resulting oil residue dissolved in n-hexane. The yellow solution was filtered, concentrated and cooled to −20°C overnight. After this no crystals were formed. By evaporation of n-hexane, **5** was obtained as a yellow oil which was spectroscopically characterized (see Tables 1 and 2).

Reaction of **4** *with* $Cu(ClO_4)_2 \cdot 6H_2O$ *in acetonitrile*

To a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.754 g, 0.20 mmol) in acetonitrile, **4** (0.0674 g, 0.157 mmol) was added dropwise with stirring at room temperature. Slow evolution of sulphur dioxide was observed and the solution turned green. A small amount of green, insoluble solid formed which was filtered and the solvent evaporated slowly from the solution. From the residue, 0.0213 g of the complex $[Cu(CH_3CN)_4]ClO_4$ was isolated.

(*Received* 9 *July* 1990; *accepted* 24 *January* 1991)

Abstract—New nickel(II) and copper(II) complexes of four Schiff base ligands formed from benzoylacetone and 2-hydroxynaphthaldehyde with S-alkyl esters of dithiocarbazic acid have been prepared and characterized by IR, NMR, ESR and electronic spectroscopic techniques. The Schiff bases yield neutral 1:1 complexes of general formula M(ONS) (ONS^{2-} = dinegatively charged anions of the Schiff base ligands; M = Ni, Cu). Magnetic and spectral evidence support a dimeric structure for these complexes. The complexes, M(ONS)B (B = py, dipy, phen), were also prepared. The complexes, M(ONS)py, are square-planar but electronic and ESR spectroscopic data support a five-coordinate geometry for the Cu(ONS)B (B = dipy, phen) complexes. Based on spectroscopic and magnetic data, a thiolato, sulphur-bridged, octahedral structure is assigned to the Ni(ONS)B (B = dipy, phen) complexes.

Metal complexes of tridentate NNS-bonding ligands have been extensively investigated because of their interesting physicochemical properties and marked biological activities.[1–6] In contrast, comparatively little work has been carried out on metal complexes of chelating agents containing the ONS set of donor atoms. We now report the synthesis and characterization of metal complexes of four new ONS-chelating ligands.

EXPERIMENTAL

Physical measurements and analytical procedures were similar to those described before.[7]

* Author to whom correspondence should be addressed. Present address: Department of Chemistry, University of Brunei Darussalam, Bandar Seri Begawan, Brunei Darussalam.

Preparation of the ligands

The ligands were prepared by heating ethanolic solutions of the appropriate aldehyde or diketone with S-methyl- or S-benzyl-dithiocarbazate. Recrystallization from absolute ethanol afforded pure products.

H_2L^1: $C_{13}H_{12}N_2S_2O$, m.p. 230°C; Found: C, 56.8; H, 4.45; N, 9.8. Calc. for $C_{13}H_{12}N_2S_2O$: C, 56.5; H, 4.4; N, 10.1%.

H_2L^2: $C_{19}H_{16}N_2S_2O$, m.p. 201°C; Found: C, 64.5; H, 4.6; N, 7.9. Calc. for $C_{19}H_{16}N_2S_2O$: C, 64.75; H, 4.6; N, 7.95%.

H_2L^3: $C_{12}H_{14}N_2S_2O$, m.p. 201°C; Found: C, 54.2; H, 5.4; N, 10.5. Calc. for $C_{12}H_{14}N_2S_2O$: C, 54.1; H, 5.3; N, 10.5%.

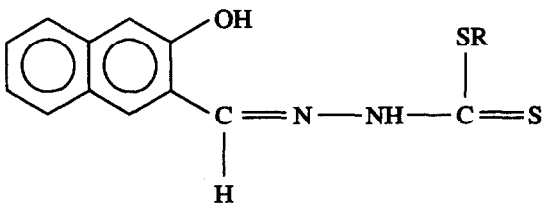
H_2L^4: $C_{18}H_{18}N_2S_2O$, m.p. 128°C; Found: C, 62.9; H, 5.3; N, 7.9. Calc. for $C_{18}H_{18}N_2S_2O$: C, 63.3; H, 5.3; N, 8.2%.

Preparation of the complexes

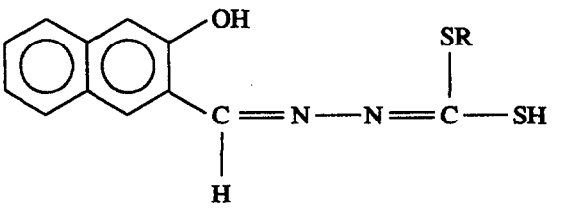
The metal complexes were prepared by heating the ligand and metal acetates in a 1 : 1 molar ratio in ethanol. On cooling, the complexes crystallized as microcrystalline powders. Complexes containing the heterocyclic bases were prepared by heating a mixture of the appropriate Schiff base, metal acetate and base in a 10 : 1 mixture of ethanol and 2,2-dimethoxypropane.

RESULTS AND DISCUSSION

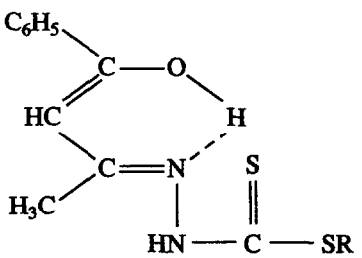
The IR spectra of the solid Schiff bases (Table 1) contain no ν(S—H) band at *ca* 2600 cm^{-1} indicating that they remain as the thioketo forms (**IA** and **IIA**), however, in solution there may be an equilibrium mixture of both the thioketo and thioenol (**IB** and **IIB**) forms.



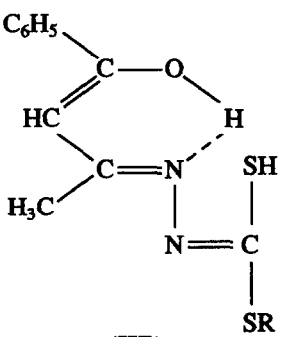
(IA; R = CH_3, H_2L^1; R = $CH_2C_6H_5$, H_2L^2)



(IB)



(IIA; R = CH_3, H_2L^3; R = $CH_2C_6H_5$, H_2L^4)



(IIB)

The ^1H and ^{13}C NMR spectral data for the Schiff bases (Table 2) are consistent with structures **IA** and **IIA** but do not support the thioenol tautomeric structures **IB** and **IIB**. The ν(C=N) band[8] of the free ligands shifts to lower wavenumbers (Table 1) in the complexes suggesting coordination via the azomethine nitrogen atoms. This is further supported by ^{13}C NMR. The spectrum of H_2L^1 displays a ^{13}C resonance at 145.73 ppm, whereas as a result of coordination via the CH=N— nitrogen atom this appears at 153.30 ppm in the spectrum of the nickel(II) chelate. The appearance of ν(M—S) bands at *ca* 300 cm^{-1} in the IR spectra of all the metal complexes supports coordination through the mercapto sulphur atoms.

The mono-ligated nickel(II) complexes, Ni(ONS), are diamagnetic and presumably square-planar. Their electronic spectra (Table 1) show *d–d* bands characteristic of square-planar nickel(II).[9] Since the ligands can provide a maximum of three donor atoms, the Ni(ONS) complexes must dimerize in order to attain a square-planar structure. A thiolato sulphur-bridged dimeric structure is proposed for the monoligated nickel(II) complexes. An oxygen-bridged dimeric structure is unlikely since the phenolic ν(C—O) band occurs at 1520 cm^{-1} which is lower than that found for a bridged C—O group.[10] The IR spectra of Ni(ONS)B (B = py, dipy, phen) (Table 1) suggest that the heterocyclic bases are coordinated to the nickel atom. The diamagnetism and electronic spectra of Ni(ONS)py support a monomeric square-planar geometry. The electronic spectra of Ni(ONS)phen and Ni(ONS)dipy (Table 1) do not resemble the spectra of other five-coordinate nickel(II) complexes,[11] but are similar to those of pseudo-octahedral nickel(II) complexes.[12] The lower values of the room-temperature magnetic moments may be due to inter-

Table 1. Selected IR absorption bands and electronic spectral data

[a] Molar conductance of *ca* 10^{-3} solutions in dimethylsulphoxide.
[b] Calculated values are given in parentheses.

action between the nickel(II) ions in a mercapto sulphur-bridged dimeric structure or to strong in-plane π-bonding and axial ligation, as has been found in the case of some other nickel(II) complexes.[13]

The copper(II) complexes, $Cu(ONS)\cdot xH_2O$ ($x = 0$, 0.5, 1), are insoluble in most common organic solvents suggesting that they are not monomeric structures. The frozen solution ESR spectrum of CuL^1 in DMSO with two g values ($g_\parallel = 2.16$, $g_\perp = 2.06$) supports a tetragonal geometry. A simple phenolic oxygen- or mercapto sulphur-bridged dimeric structure cannot be assigned to CuL^1 since such a bridging arrangement generally leads to antiferromagnetic interactions.[14] The present copper complexes display room temperature moments of 2.10–1.95 BM which do not support dimeric structures. The colour, magnetic moments and electronic spectra of the present copper(II) complexes (Table 3) resemble those of the copper(II) complex of the 5-nitrosalicylaldehyde Schiff base of S-methyldithiocarbazate, for which a tetrameric structure has been proposed.[15] Unfortunately due to the very low solubilities in suitable non-donor solvents, molecular weights of these compounds in solution could not be measured.

The room temperature moments of Cu(ONS)B (B = py, dipy, phen) fall in the range 1.79–2.0 BM. The electronic spectra of the Cu(ONS)py complexes (Table 1) display *d–d* bands which compare well with those of four-coordinate, square-planar copper(II).[16] The frozen solution ESR spectra of the CuLpy complexes with $g_\perp = 2.07, g_\parallel = 2.17$ and $A_\parallel = 160$ G are typical of square-planar copper(II) complexes.[17]

The electronic spectra of CuLdipy and CuLphen (Table 1) contain *d–d* bands at *ca* 758 and 543 nm which do not resemble either square-planar or tetragonal copper(II) complexes but compare well with those of five-coordinate copper(II) species.[18] The ESR spectral data for these complexes (CuL^2 phen: $g_\perp = 2.07$, $g_\parallel = 2.20$; CuL^4phen: $g_\parallel = 2.16$, $g_\perp = 2.04$; CuL^3phen: $g_\parallel = 2.17$, $g_\perp = 2.05$ with $g_\parallel > g_\perp$) support a square-pyramidal rather than a trigonal-bipyramidal geometry.[18]

Acknowledgements—Some of the spectroscopic measurements were performed at the University of Missouri–Columbia by Dr Michael S. Tempesta, thanks to the support of the IOCD, which is gratefully acknowledged. One of us (M.N.) thanks the UNESCO, New Delhi for financial assistance.

(*Received* 24 *July* 1990; *accepted* 24 *January* 1991)

Abstract—2-Methyl-5-nitroimidazole [MNIH, (**1**)] forms the complexes $Cu(MNIH)_2X_2$ [X = Cl (**1a**), Br (**1b**), NO_3 (**1c**), OH (**1d**)] and $Co(MNIH)_2X_2$ [X = Cl (**1e**), OAc (**1f**)]. X-ray crystal structure of **1a** shows a distorted octahedral geometry for the copper(II) ion bonded to two chlorine atoms and two nitroimidazole molecules through N(1) and with a *trans* diaxial coordination to one of the oxygen atoms of the nitro groups. This is the first example of nitroimidazole derivatives in which the nitro group occupies a coordination site. Spectroscopic evidence suggests that for compounds **1b–1f** the preferred coordination site for the metal ion is N(1), with interaction of the nitro group adjacent to it, giving extra stability to the complexes. The copper complexes, **1b** and **1c**, contain six coordinated metal atoms, while **1e** is tetrahedral and **1f** is a carboxylate-bridged dimer. The other ligand, 1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole [metronidazole, HEMNI (**2**)] forms the complexes $Cu(HEMNI)_2X_2$ [X = Cl (**2a**, **2b**), Br (**2c**), OAc (**2d**)] and $Co(HEMNI)_2Cl_2$ (**2e**). An X-ray crystal structure determination on $Cu(HEMNI)_2Cl_2$ (**2a**) shows a centrosymmetric chloro-bridged dimer. The coordination geometry around each copper atom is trigonal bipyramidal with three equatorial chlorine atoms and two axial imidazole molecules. The rest of the metronidazole complexes obtained were shown to be a dimeric compound with bridging

acetates, **2d**, two monomeric octahedral (X = Cl, Br) copper compounds, **2b** and **2c**, and a tetrahedral cobalt compound, **2e**.

Metal ions play a vital role in a vast number of widely differing biological processes. The interaction of these ions with drugs administered for therapeutic reasons is a subject of considerable interest.

Continuing our work in this area[1-3] we have been studying the complexing ability of 2-methyl-5-nitroimidazole [MNIH, (**1**)] and 1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole [metronidazole, HEMNI (**2**)], Fig. 1. Nitroimidazoles are used as chemotherapeutic agents particularly in protozoal and anaerobic microbial infections.[4] They have also been proposed as radiosensitizers, this property being related to the presence of the nitro group.[5] Previous work on metal complexes with **2** is limited to two brief reports on copper complexes[6,7] and the research carried out on its platinum compounds has been focused on their radiosensitization properties.[8-12]

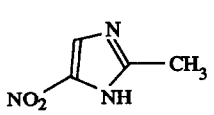
EXPERIMENTAL

Reagents

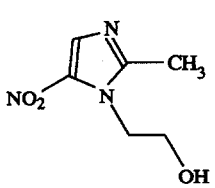
The metal salts, ligands and solvents were obtained from Merck and J. T. Baker as analytical reagents. All reagents were used without further purification.

Physical measurements

IR spectra in the range 4000–600 cm^{-1} were recorded in KBr pellets and as Nujol mulls using CsI plates in the region 600–200 cm^{-1} on a Perkin–Elmer 599B spectrophotometer. Electronic spectra of microcrystalline samples were measured by the diffuse reflectance method on a Cary 17 Varian spectrophotometer over the range 850–350 nm.



1



2

Fig. 1. 2-Methyl-5-nitroimidazole (MNIH) **1** and 1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole (metronidazole, HEMNI) **2**.

Magnetic moments were measured using Evans' technique with a Johnson Mathey balance. Elemental analyses were performed by Butterworth Ltd Laboratories in the U.K. and by the Analytical Chemistry Department, DEPg, Facultad de Química UNAM.

Synthesis: general technique

The copper coordination compounds were prepared using ethanol as solvent and 1:1, 1:2 and 2:1 ligand/Cu^{II} molar ratios were employed (mmol scale). The same products were obtained regardless of the variation in ligand/metal ratio, but the ratio 2:1 gave the best yield. The ligand was dissolved in 50 cm^3 of boiling ethanol and added to a solution of the metal salt in 50 cm^3 of hot ethanol. The reaction mixture was refluxed for *ca* 6 h and then allowed to stand at room temperature for 7 days. The resulting precipitates were filtered, washed and dried.

In the case of the cobalt complexes, the molar ratios and the preparation were the same as described above but acetone was used as solvent. When the metal salts were used in excess, only impure compounds were isolated. For the cobalt chloride complexes of both ligands, oleus blue solutions were obtained and the compounds were precipitated by adding 25 cm^3 of a 1:1 ethanol/hexane mixture. The solid products were filtered and washed with ethanol. With cobalt acetate, the metal salt was added to the ligand **1** (2-methyl-5-nitroimidazole, MNIH) and a fine orange powder precipitated immediately; this was centrifuged and washed with hot ethanol. It was not possible to obtain the cobalt acetate complex with the ligand **2** [1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole, HEMNI].

Preparation of $Cu(MNIH)_2Cl_2$ (**1a**)

Copper(II) chloride dihydrate (0.0852 g, 0.5 mmol) was dissolved in hot ethanol (50 cm^3) and a hot solution of **1** (0.1704 g, 1 mmol) in ethanol was added. The green solution was refluxed for 4 h and then allowed to stand for 4 days. The deep blue crystals were filtered off, dried *in vacuo* and sent for X-ray diffraction study. Storage of the mother liquor after filtration resulted in the formation of a few green crystals which changed back to the original blue crystals on attempting to isolate them.

Preparation of $Cu(HEMNI)_2Cl_2$ (**2a**)

Ligand **2** (0.1710 g, 1 mmol) was dissolved in hot ethanol (50 cm^3) and added to a hot solution of $CuCl_2 \cdot 2H_2O$ (0.0852 g, 0.5 mmol) in 50 cm^3 of ethanol. The reaction mixture was refluxed for 6 h. The green solution was allowed to stand at room temperature for 1 week. The bright green crystals (**2a**) which had grown were filtered off, dried *in vacuo* and sent for X-ray diffraction study. Storage of the mother liquor after filtration resulted in the formation of blue crystals with the formula $[Cu(HEMNI)_2Cl_2] \cdot H_2O$ (**2b**). Unfortunately, the crystals were not suitable for X-ray study.

Crystal structure determination of **1a** and **2a**

The single crystal X-ray data collections, structure resolution and refinements were performed on a Nicolet R3m four circle diffractometer using graphite monochromated Cu-K_α radiation (λ = 1.54178 Å) operating in the θ–2θ scanning mode. The unit cell parameters were established by least-squares adjustment on the setting angles of 25 machine centred strong reflections. The crystal data for compounds **1a** and **2a** are summarized in Table 1. During the data collections two standard reflections were monitored after the measurement of groups of 46 reflections and they showed no significant intensity decay. The data measured were corrected for background, Lorentz and polarization effects as well as for absorption, for which the crystal was considered to have a pseudo-ellipsoid shape. The structures were solved by direct methods using the software package provided by the diffractometer manufacturer using data for which $I \geqslant 3\sigma(I)$. All non-hydrogen atoms were refined anisotropically using the full-matrix least-squares procedure. The hydrogen atoms bonded to carbon atoms were placed at fixed positions (C—H, 1.09 Å) and included in the structure factor calculation with their isotropic contribution. After several full-

matrix least-squares cycles of refinement, the two hydroxyl group hydrogen atoms of **1a** became evident from a difference Fourier synthesis and were included in the structure factor calculation. The least-squares weighting scheme used is $w = 1/\sigma^2(F_o)+G(F_o)^2$, where σ is the standard deviation of observed amplitudes based on counting statistics and G is a variable adjusted after each cycle to minimize the function $\Sigma w(\Delta F)^2$. The final G values and other relevant refinement values are given in Table 1.

RESULTS AND DISCUSSION

The coordination compounds of copper(II) and cobalt(II) with **1** and **2** obtained in this study, **1a**–**1f** and **2a**–**2e**, are listed in Table 2, together with their analytical data. In the reactions of the metal (II) ions with ligands **1** and **2** in ethanol the same products were obtained regardless of the variation in ligand/metal ratio (1 : 1, 1 : 2 and 2 : 1).

Structure of dichloro-bis-(2-methyl-5-nitroimidazole)copper(II) (**1a**)

The crystal structure of **1a** shows two nitroimidazole and two chlorine atoms bonded to the copper(II) ion, Fig. 2 and Tables 3–5, the structure presents a symmetry centre at the metal ion with an octahedral geometry tetragonally distorted and a *trans* diaxial coordination to one of the oxygen atoms of the nitro groups. The O—Cu distance is 2.6 Å indicating weak coordination, which is also evident from the angle deformation of the ligand which allows the oxygen atom to approach the metal ion. Furthermore, the N—O distance of the nitro groups are longer for the oxygen atoms which are coordinated to the metal ions. The same distance was found in a similar complex between an acetate and a copper(II) atom interacting through a four-membered ring.[13] Compound **1a** is the first example in nitroimidazoles derivatives where the nitro group occupies a coordination site. It is noteworthy that in another nitroimidazole platinum complex[14] the nitro group is not interacting with the metal ion (O—Pt distance 3.28 Å). In compound **1a** the distances Cu—Cl and Cu—N have normal values. The formation of a chelate ring produces a change in the angles of the heterocyclic molecule, the C(5)—N(1)—C(2) angle is decreased (105°) and as a consequence Cu—N(1)—C(2) (132.3°) and Cu—N(1)—C(5) (122°) angles are very large.

Ligand **1** presents a tautomerism, Fig. 3, and the metal has the possibility of coordination to any of these tautomers. A rhodium complex of a methylimidazole has been reported,[15] where coordination takes place through the less hindered nitrogen, Fig. 4. In our case it is noteworthy that the copper ion coordinates to the most hindered nitrogen atom, adjacent to the nitro group. This behaviour is explained by stabilization of the structure through coordination of the nitro group to the metal ion.

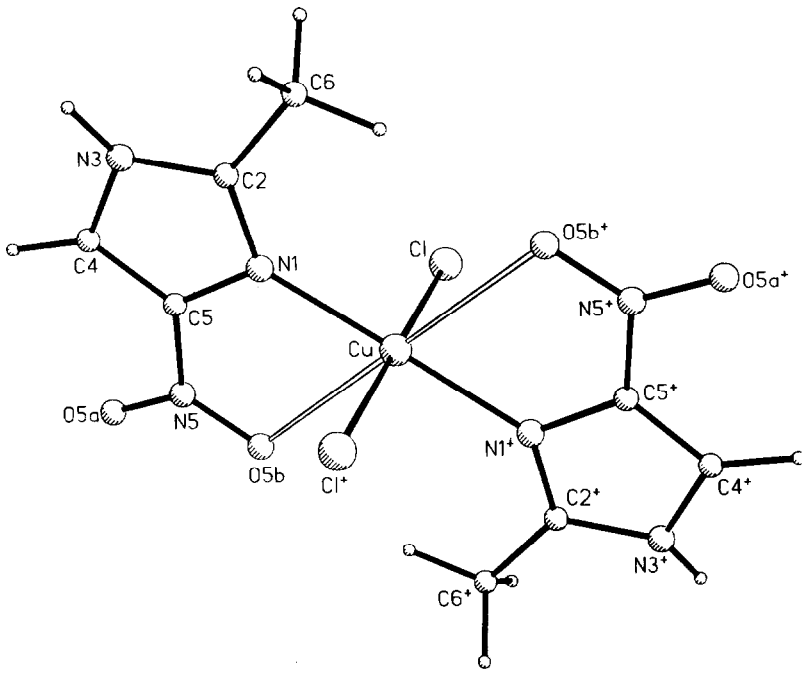

Fig. 2. Crystal structure of **1a**

Structure of bis-[(μ-chloro)chloro-bis-(1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole)copper(II)] (**2a**)

The molecular structure obtained for compound **2a** is a centrosymmetric chloro-bridged dimer, as is shown in Fig. 5. The coordination geometry around each copper atom in the dimer is trigonal bipyramid with three equatorial chlorine atoms and two axial imidazole molecules. Representative bond lengths and angles are given in Tables 6–8. Two different Cu—Cl bond lengths (2.418 and 2.619 Å) in Cu_2Cl_2 appear to be the common feature among the chloro-bridged dimeric complexes of copper(II).[16] The equatorial Cu—Cl bond lengths (2.297 Å) are normal for this type of complex. The angle between the two bridging chlorine atoms and the copper ion is

smaller than expected due to the effect of the four-membered ring, nevertheless the sum of the three equatorial angles is 360°, the remainder of the angles around the copper atoms are normal for a bipyramidal structure. Coordination to the metal ion does not produce any deformation of the ligand angles, as can be appreciated from the X-ray data of the free ligand.[17] The two axial imidazole molecules are bonded to copper through the imine nitrogen with a normal Cu—N distance of 1.993 Å.

Infrared and electronic spectroscopy studies

Copper complexes. The electronic spectrum of the crystalline complex **1a** (Table 9) presents a band indicative of a tetragonally distorted octahedral geometry, Fig. 6. The ν(Cu—Cl) stretching band in the far-IR is as expected for terminal Cu—X (290 cm^{-1}) and its magnetic moment is consistent with this structure. A similar structure is proposed for the complexes **1b** and **1c** (Table 9). In the IR spectra (Table 10), the free heterocyclic ligand (MNIH) has

bands assigned to the ν_{as} and ν_s stretching modes of NO_2 at 1510 and 1385 cm^{-1}, which increased in intensity, became broader and shifted a few wave numbers in complexes **1a**, **1b** and **1c**, supporting the interaction of this group with the metal ion *vide infra*; it is also interesting that a set of bands due to the ligand skeletal vibration modes (825, 815, 790 and 750 cm^{-1}) presents exactly the same pattern in these three complexes indicating that they must share the same coordination mode and structure. The difference in the IR spectrum of compound **1d** indicates that copper(II) has another coordination mode. The compound has a strong symmetric band ν(OH) at 3440 cm^{-1} and another broad band, δ(OH), at 1145 cm^{-1} assigned to a bridging OH^- group. The electronic spectrum characteristic of a distorted octahedral geometry (Table 9) and its low magnetic moment ($\mu = 1.58$) allow the proposal of a polymeric structure with hydroxo bridges.

The 1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole copper complexes, **2a**, **2b**, **2c** and **2d**, have similar IR spectra in which the bands assigned to $\nu_{as}(NO_2)$ and $\nu_s(NO_2)$ remain in the same position as observed in the ligand (Table 10), indicating that this group does not participate as a coordination site, *vide infra*; the bands assigned to the ν(OH) group (3220 cm^{-1}) are shifted to higher wave numbers indicating that the original hydrogen bridge

[d] Not enough sample available.

observed in the ligand[17] is lost in the metal complexes. The blue compound **2b** presents new bands (3120 and 3165 cm^{-1}) in that region, most probably due to a different crystal packing of this compound with respect to the analogous green compound **2a**. There were important changes in the ring vibration region due to N(3) coordination to the metal ion. The electronic spectrum and the magnetic moment of **2a** (Table 9) is characteristic of a pentacoordinated copper(II) ion.[18] The acetate compound, **2d**, has a similar electronic spectrum to **2a**, Fig. 6, and a low magnetic moment (1.49 BM), suggesting the presence of a dimeric structure with a copper–copper interaction.[13] This is supported by the presence of bridging acetates in the IR spectrum, in which vibrations assigned to the COO^- group were at $\nu_{as}(COO^-)$ 1555, $\nu_s(COO^-)$ 1435, $\delta(OCO)$ 650 and $\pi(COO^-)$ 600 cm^{-1}. The structure of this compound is proposed to have a pentacoordinate copper(II) ion with acetate bridges and apical **2**. The electronic spectra of **2b** (blue) Fig. 6, and **2c** are typical of a distorted octahedral geometry (Table 9).

Cobalt complexes. The blue cobalt(II) complexes **1e** and **2e** have magnetic moments and diffuse electronic spectra (Table 9) typical of tetrahedral complexes, Fig. 7, the bands at *ca* 600 nm are assigned to the $^4T_1(P) \leftarrow {}^4A_2(F)$ transition.[19] The low frequency vibrational spectra (Table 10) contain bands assignable to ν(Co—Cl) at 295 and 280 cm^{-1} for **1e** and at 340 and 300 cm^{-1} for **2e**.

The orange compound **1f** has a diffuse electronic spectra, suggesting the presence of a non-centrosymmetric cobalt environment possibly due to a distorted tetragonal arrangement or to a pentacoordinate geometry, with two complex bands at 490 and 510 nm, its magnetic moment ($\mu = 4.75$ BM) is as expected for a cobalt(II) ion. The acetate shows IR bands at *ca* 1545 cm^{-1} [$\nu_a(COO^-)$], 1430 cm^{-1}[$\nu_s(COO^-)$] and 620 cm^{-1} [$\pi(COO^-)$], which are consistent for a carboxylate-bridged cobalt(II) dimer;[20] and most probably has the ligands occupying the terminal positions in the dimer, as has been observed in this type of structure.

Conclusions

Stable complexes with both ligands were obtained. The copper chloride compounds **1a** and

2a, were suitable for X-ray diffraction studies. It is noteworthy that the ligand structure modulates the geometry and the coordination sites in these copper complexes.

The results obtained from the electronic spectra for both groups of complexes showed that the ligand **1** is stronger than the ligand **2**, as can be appreciated from the electronic transitions at higher energies for the 2-methyl-5-nitroimidazole complexes, indicating a stronger ligand field. This is most probably due to the presence of a nitro group adjacent to the preferred coordination site, N(1), giving extra stability to the complexes by its interaction with the metals. These complexes are the first examples of the nitroimidazole derivatives in which an interaction of the metal ions with the nitro group is observed. A study of the biological activity of the compounds obtained in this work is in progress.

(*Received* 9 *November* 1990; *accepted* 21 *January* 1991)

Abstract—The mono(μ-alkylthiolato) complexes, *cis*-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SR)(PMe_3)_2$ (R = Me, **1**; t-Bu, **2**) are obtained as the exclusive products of the reaction of acetone solutions of *trans*-$[PdCl(\mu\text{-}Cl)(PMe_3)]_2$ with the corresponding thiols at 25°C, whereas reaction with stoichiometric amounts of thiophenol gives mixtures of *cis*-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SPh)(PMe_3)_2$ (**3**) and *trans*-$Pd_2Cl_2(\mu\text{-}SPh)_2(PMe_3)_2$ (**5**). Reaction of *trans*-$[PdCl(\mu\text{-}Cl)(PR_3)]_2$ with thiophenol in a 1:2 stoichiometry gives exclusively *trans*-$Pd_2Cl_2(\mu\text{-}SPh)_2(PR_3)_2$ (R = Et, **4**; Me, **5**). The molecular structures of **1**, **2**, **3**·CH_2Cl_2 and **4** have been determined by X-ray diffraction. Complexes **1** and **2** have non-planar geometries with dihedral angles of 140 and 146°, respectively, between the coordination planes of the palladium atoms. By contrast, the μ-arylthiolato complexes are planar with dihedral angles of 180° between the coordination planes of the palladium atoms. The Pd—S bond distances 2.262(2)–2.272(2) Å in complexes **1** and **2** are significantly shorter than the Pd—S distances in **3**, 2.288(2) and 2.301(2) Å, indicating enhanced metal–sulphur bonding in the alkylthiolato complexes. The bent geometries of the alkylthiolato complexes as well as the dichotomy of *cis* and *trans* phosphine geometries preferred by $M_2Cl_2(\mu\text{-}SR)_2(PR'_3)_2$ (M = Pd, Pt) alkylthiolato and arylthiolato complexes, respectively, are discussed in view of the enhanced sulphur–metal donor interactions in the alkylthiolato complexes. The isolation of mono(μ-thiolato) complexes from the reaction of *trans*-$[PdCl(\mu\text{-}Cl)(PMe_3)]_2$ with alkylthiols and not arylthiols is also accounted for by the additional stabilization of the metal–sulphur bonds in the alkylthiolato complexes. Crystallographic data: for **1**, orthorhombic, $Pbc2_1$, $Z = 4$, $a = 11.630(6)$, $b = 11.667(3)$, $c = 12.816(4)$ Å, $V = 1739(1)$ Å^3, $\rho_{calc.} = 1.980$ g cm^{-3}; for **2**, orthorhombic, $P2_1cn$, $Z = 4$, $a = 8.158(3)$, $b = 10.345(3)$, $c = 24.106(6)$ Å, $V = 2035(1)$ Å^3, $\rho_{calc.} = 1.830$ g cm^{-3}; for **3**·CH_2Cl_2, monoclinic $C2/2$, $Z = 8$, $a = 27.38(1)$, $b = 11.477(9)$, $c = 16.506(7)$ Å, $\beta = 124.12(3)°$, $V = 4294(4)$ Å^3, $\rho_{calc.} = 1.924$ g cm^{-3}; for **4**, triclinic $P\bar{1}$, $Z = 2$, $a = 8.694(5)$, $b = 9.570(6)$, $c = 10.203(7)$ Å, $\alpha = 68.72(5)$, $\beta = 76.86(5)$, $\gamma = 85.27(5)°$, $V = 770.3(8)$ Å^3, $\rho_{calc.} = 1.592$ g cm^{-3}.

Dimetallic μ-thiolato complexes of palladium and platinum have been known for many years[1] and a wide variety of these complexes have been prepared.[1–11] However, the factors responsible for their thermodynamically preferred conformations remain poorly understood. One enigma has been the preferred geometries of $M_2Cl_2(\mu\text{-}SR)_2(PR'_3)_2$ complexes: the bis(μ-alkylthiolato) complexes are stabilized as *cis* isomers, while the bis(μ-arylthiolato) complexes are stabilized as *trans* isomers. To account for this dichotomy, Chatt and Hart proposed[2] that the metal–sulphur interaction in the alkylthiolato complexes involved an aromatic, inor-

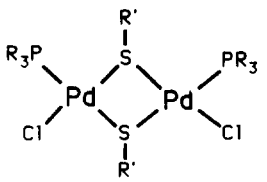
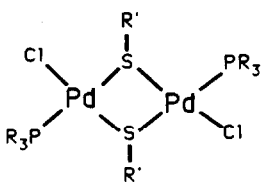
† Author to whom correspondence should be addressed.

ganic $d\pi$–$d\pi$ ring system into which *p*-electrons from the sulphur atoms were delocalized. They speculated that the aromatic ring was somehow stabilized by the *cis*-phosphine geometry. However, in the case of the arylthiolato complexes dipole measurements indicated non-planar coordination about sulphur. This precludes delocalization of sulphur *p*-electrons into an aromatic $d\pi$–$d\pi$ system and provided a rationale for the arylthiolato complexes adopting the more common *trans*-phosphine geometry.



Cis phosphine configuration
when R = alkyl and R' = alkyl.



Trans phosphine configuration
when R = alkyl and R' = aryl.

A subsequent X-ray structure determination of *cis*-$Pt_2Cl_2(\mu\text{-}SEt)_2(PPr_3)_2$ by Owston and coworkers[12] showed the Pt—S—Pt—S ring to be non-planar with a dihedral angle of 130° between the two platinum coordination planes and that the thiolato α-carbon atoms were out of the Pt—S—Pt plane. The existence of an aromatic $d\pi$–$d\pi$ ring system in the bis(μ-alkylthiolato) complex was therefore ruled out by these results. Owston instead attributed the stabilization of the *cis* isomer of the bis(μ-alkylthiolato) to a continuous zigzag chain, P—Pt—S—Pt—P, of strong *cis* bonds involving only one sulphur atom.

We have synthesized and determined the crystal structure of several μ-thiolato complexes. From these studies, structural patterns have emerged. We report here the results of our structural studies as well as our insights into the connections between the geometries of the μ-thiolato complexes and the nature of the metal–μ-thiolato bonds.

EXPERIMENTAL

General details

The following were purchased and used without further purification: 2-methyl-2-propanethiol, triethylphosphine (Fluka Chemical Corp.); thiophenol, acetone, chloroform, dichloromethane-d_2 (Aldrich Chemical Co.); trimethylphosphine (Strem Chemicals Inc.) and methyl mercaptan (Matheson). The complexes, *trans*-[PdCl(μ-Cl)$(PR_3)]_2$ (R = Me, Et) were prepared by the method of Chatt and Venanzi.[13]

Caution: Trimethylphosphine and methyl mercaptan are volatile toxins, therefore use of an efficient fume hood is mandatory.

The ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Nicolet NT300 spectrometer at 300 and 122 MHz, respectively. The ^1H NMR data are listed in ppm downfield from TMS at 0.00 ppm. ^{31}P NMR chemical shifts were measured relative to the deuterium resonance of the solvent by using the internal frequency lock of the spectrometer so that the resonance from a capillary of 85% H_3PO_4, centred in a 5 mm NMR tube containing the deuterated solvent, appeared at 0.0 ppm at 20°C. Microanalyses were performed by Oneida Research Services Inc. (Whitesboro, New York).

Preparation of cis-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SMe)(PMe_3)_2$ (1)

Synthesis of **1** has been reported previously.[3] However, we find the following preparation more convenient. A slow stream of methyl mercaptan was passed through a solution of *trans*-[PdCl(μ-Cl)$(PMe_3)]_2$ (1.507 g, 2.97 mmol) in acetone (125 cm^3) at room temperature for 5 min. The initially orange solution became green–yellow. The solution was then stirred at room temperature for 24 h. After reduction of the solvent to 30 cm^3, the resulting green, crystalline product (1.443 g, 93.6% yield) was isolated from the reaction mixture by filtration. The ^1H NMR spectrum of the product was identical with that which has previously been reported[3] for **1**. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 6.0 (s). Found: C, 16.1; H, 3.8. Calc.: C, 16.2; H, 4.0%.

Preparation of cis-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SCMe_3)(PMe_3)_2$ (2)

A solution of *trans*-[PdCl(μ-Cl)$(PMe_3)]_2$ (0.998 g, 1.97 mmol) in acetone (125 cm^3) was treated at room temperature with 2-methyl-2-propanethiol (0.90 cm^3, 7.90 mmol). The initially orange solution became yellow–green within 5 min and was stirred at room temperature for 24 h. After reduction of the solvent to 40 cm^3, the resulting green, crystalline product (0.924 g, 82.5% yield) was isolated from the reaction mixture by filtration. ^1H NMR (CD_2Cl_2): δ 1.71 (s, $SCCH_3$, 9H), 1.66 [d, J_{P-H} = 12.6 Hz, $P(CH_3)_3$, 18H]. $^{31}P\{^1H\}$

NMR (CD_2Cl_2): δ 5.8 (s). Found: C, 21.3; H, 4.7. Calc.: C, 21.4; H, 4.8%.

Preparation of cis-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SPh)(PMe_3)_2$ (**3**)

Method 1. A solution of *trans*-[PdCl(μ-Cl)$(PMe_3)]_2$ (1.011 g, 2.00 mmol) in acetone (100 cm^3) was treated at room temperature with thiophenol (0.205 cm^3, 2.00 mmol). The initially orange solution became yellow within 5 min and was stirred at room temperature for 24 h. After reduction of the solvent to 10 cm^3, the resulting yellow, crystalline solid was isolated by filtration and seen by ^1H NMR to consist of a 85:15 mixture of **3** and **5**. The bis(μ-thiolato) complex was removed by extraction with 150 cm^3 of benzene leaving pure **3** (0.214 g, 18.6% yield). ^1H NMR (CD_2Cl_2): δ 8.13 m, 7.37 m (aromatic, 5H), 1.51 [d, J_{P-H} = 10.2 Hz, $P(CH_3)_3$, 18H]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 5.8 (s). Found: C, 24.3; H, 3.8. Calc.: C, 24.8; H, 4.0%.

Method 2. A solution of *trans*-[PdCl(μ-Cl$)(PMe_3)]_2$ (1.005 g, 2.00 mmol) in acetone (125 cm^3) was treated at room temperature with thiophenol (0.437 g, 4.00 mmol). The initially orange solution became yellow within 5 min and was stirred at room temperature for 24 h. After reduction of the solvent to 20 cm^3, the resulting yellow, crystalline product, **5**, was isolated from the reaction mixture by filtration (1.204 g, 92.0% yield). ^1H NMR (CD_2Cl_2): δ 8.01 m, 7.21 m (aromatic, 10H), 1.28 (d, J_{P-H} = 11.9 Hz, $P(CH_3)_3$, 18H). $^{13}P\{^1H\}$ NMR (CD_2Cl_2): δ −0.9 (s). Found: C, 32.8; H, 4.2. Calc.: C, 33.0; H, 4.3%. The bis(μ-thiolato) complex (0.418 g, 0.64 mmol) was then refluxed in chloroform with an equimolar amount of *trans*-[PdCl(μ-Cl$)(PMe_3)]_2$ (0.324 g, 0.64 mmol) for 1 h. The resulting yellow, crystalline solid was isolated by filtration, 0.583 g, 78.6% yield.

Preparation of trans-$Pd_2Cl_2(\mu\text{-}SPh)_2(PEt_3)_2$ (**4**)

A solution of *trans*-[PdCl(μ-Cl$)(PEt_3)]_2$ (1.012 g, 1.71 mmol) in acetone (125 cm^3) was treated at room temperature with thiophenol (0.35 cm^3, 3.42 mmol). The initially orange solution became yellow within 5 min and was stirred at room temperature for 24 h. After reduction of the solvent to 10 cm^3, the resulting yellow, crystalline product was isolated from the reaction mixture by filtration (1.069 g, 94.6% yield). ^1H NMR (CD_2Cl_2): δ 8.02 m, 7.21 m (aromatic, 10H), 1.64 [dq, J_{P-H} = 10.2 Hz, $P(CH_2CH_3$, 12H)], 1.06 [dt, J_{P-H} = 9.3 Hz, $P(CH_3)_3$, 18H]. $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 30.3 (s). Found: C, 39.0; H, 5.4. Calc.: C, 39.0; H, 5.4%.

Crystallographic studies

Crystals suitable for X-ray diffraction were obtained by slow evaporation of dichloromethane solutions of the respective complexes. The crystals were mounted on glass fibres with epoxy and centred on a Nicolet P3 automated diffractometer. The unit-cell parameters were obtained by least-squares refinement of the setting angles of 20 reflections. Crystal and instrument stability were monitored with a set of three standard reflections measured every 97 reflections; in all cases no significant variations were found. Details of other crystal data and relevant information are summarized in Table 1.

The structures were solved by direct methods using SHELX PLUS computer programs (Nicolet Instrument Corp.) and refined by full-matrix least-squares procedures. All non-hydrogen atoms were refined with anisotropic coefficients. The hydrogen atoms were introduced in fixed, calculated positions and the coordinates and isotropic thermal parameters for hydrogen atoms were allowed to vary in the final cycles of full-matrix least-squares refinement. During the refinement of **3** a group of peaks not associated with the palladium complex became apparent in the difference Fourier maps. The peaks were refined as a methylene chloride solvate. The carbon atom of the solvate lies on a special position about which the symmetry unique chlorine is disordered over two positions which refined with occupancies of 0.765 and 0.235 in the Cl(4) and Cl(4′) sites, respectively.

RESULTS AND DISCUSSION

Syntheses

The mono(μ-thiolato) complexes, *cis*-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SR)(PMe_3)_2$ (R = Me, **1**; t-Bu, **2**; Ph, **3**) are obtained by reaction of acetone solutions of *trans*-[PdCl(μ-Cl$)(PMe_3)]_2$ with thiols at 25°C (Scheme 1). In the case of the alkyl thiols, mono(μ-thiolato) complexes were obtained exclusive of bis(μ-thiolato) complexes even when the reaction is carried out in the presence of excess thiol. Analytically pure $Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SR)(PR'_3)_2$ complexes have previously been obtained only through a disproportionation of $[PdCl(\mu\text{-}Cl)(PR_3)]_2$ and purified $Pd_2Cl_2(\mu\text{-}SR)_2(PR'_3)_2$ complexes.[1,3,9,10] The reaction of *trans*-[PdCl(μ-Cl$)(PMe_3)]_2$ with one equivalent of thiophenol produces a mixture of the mono(μ-thiolato) complex, **3**, and the bis(μ-thiolato) complex, **5** (Scheme 1). Analytically pure **3** could be obtained in high yield only from disproportionation of equimolar amounts of **5** and *trans*-[PdCl(μ-Cl$)(PMe_3)]_2$. The bis(μ-thiolato)

complexes, *trans*-$Pd_2Cl_2(\mu\text{-}SPh)_2(PR_3)_2$ (R = Et, **4**; Me, **5**) are obtained as the exclusive product from the reaction of *trans*-$[PdCl(\mu\text{-}Cl)(PR_3)]_2$ with thiophenol in a 1 : 2 stoichiometry (Scheme 1).

Structures of cis-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SR)(PMe_3)_2$ (R = Me, **1**; CMe_3, **2**; Ph, **3**) *and* trans-$Pd_2Cl_2(\mu\text{-}SC_6H_5)_2(PEt_3)_2$ (**4**)

ORTEP projections of the molecular structures of **1**, **2**, **3** and **4** are shown in Figs 1–4, respectively. Selected bond angles and distances are given in Tables 2–5. The complexes exhibit nearly square-planar geometry about each of the palladium centres. In the mono(thiolato) complexes **1–3**, the phosphine ligands are arranged in a *cis* configuration as was found[10] in the X-ray structure determination of $Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2$ and has been indicated by electric dipole measurements[1] and spectroscopic[3,7–10] analysis to be the preferred configuration of $M_2Cl_2(\mu\text{-}Cl(\mu\text{-}SR)(PR'_3)_2$ (M = Pd, Pt) complexes. By contrast, the phosphine ligands of **4** are arranged in a *trans* configuration as was found in the X-ray structure determination[4] of $Pd_2(SC_6F_5)_2(\mu\text{-}SC_6F_5)_2(PPh_3)_2$ and has been indicated by electric dipole measurements[2] to be the preferred configuration of $M_2Cl_2(\mu\text{-}SR)_2(PR'_3)_2$ (M = Pd, Pt; R = aryl) complexes. As has been found[4–7,12] for other bis(μ-thiolato) complexes, the μ-thiolato groups of **4** are in an *anti* conformation.

Generality of bent vs planar structures of dipalladium alkylthiolato vs arylthiolato complexes

The μ-alkylthiolato complexes, **1** and **2**, have non-planar geometries with dihedral angles of 140 and 146°, respectively, between the coordination planes of the palladium atoms, while the μ-arylthiolato complexes, **3** and **4**, are planar with corresponding dihedral angles of 180°. The non-planar structures as seen for **1** and **2**, appear to be common to all dipalladium and diplatinum complexes containing μ-alkylthiolato groups as $Pd_2(S_2CSCMe_3)_2(\mu\text{-}SCMe_3)_2$,[5,5] *cis*-$Pd_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2$,[10] *cis*-$PtCl_2(\mu\text{-}SEt)_2(PPr_3)_2$,[12] *cis*-$Pt_2(SCH_2Ph)_2(\mu\text{-}SCH_2Ph)_2(PMePh_2)_2$,[6] and (dppe)Pt(μ-SMe)$_2$-Pt $ClMe_3$[7] all been found to have dihedral angles of 130–154° between the coordination planes of the metals. The planar structures of **3** and **4** match that previously found[4] for *trans*-$Pd_2(SC_6F_5)_2(\mu\text{-}SC_6F_5)_2(PPh_3)_2$, thus suggesting that the planar geometry is preferred by μ-arylthiolato complexes. Both bent[14] and planar[15] structures have also been found for bis(μ-chloro)dipalladium and -diplatinum complexes. In the case of the μ-chloro complexes, the planar and bent structures appear to be energetically very similar[16] and it has been suggested[17] that crystal packing forces are responsible for the variation in the solid-state configuration. However, ^1H and ^{31}P NMR spectroscopic studies of *cis*-$Pt_2(SCH_2Ph)_2(\mu\text{-}SCH_2Ph)_2(PMePh_2)_2$[6] and *cis*-$Pt_2X_2(\mu\text{-}SR)_2(PMe_2Ph)_2$ (X = Cl, I; R = Me)[18] indicate these complexes

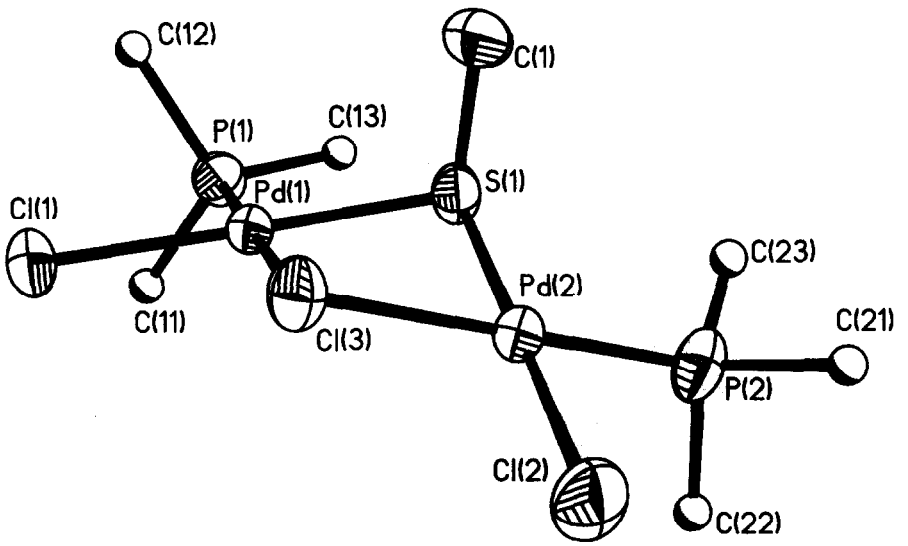

Fig. 1. ORTEP projection of *cis*-$Pd_2Cl_2(\mu\text{-}SMe)(\mu\text{-}Cl)(PMe_3)_2$ (**1**) thermal ellipsoids at 50% probability. The hydrogen atoms have been omitted and PMe_3 carbon atoms given an arbitrary radius for clarity.

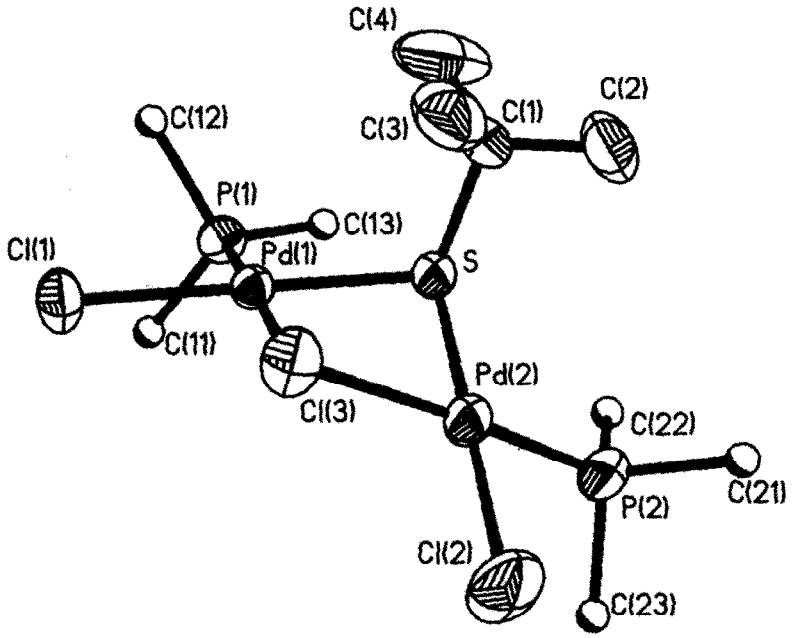

Fig. 2. ORTEP projection of *cis*-$Pd_2Cl_2(\mu\text{-}SCMe_3)(\mu\text{-}Cl)(PMe_3)_2$ (2) thermal ellipsoids at 50% probability. The hydrogen atoms have been omitted and PMe_3 carbon atoms given an arbitrary radius for clarity.

have bent geometries in solution. Therefore, energetic considerations other than solid-state crystal packing forces are responsible for the configurations of these and most likely other bis(μ-thiolato) complexes.

The bending of palladium and platinum μ-alkylthiolato complexes has previously been ascribed to steric interactions.[12] However, comparison of the nearly equal dihedral angles between the coordination planes of **1** and **2** with the planar molecules **3** and **4** demonstrates that electronics rather than sterics are responsible for the geometries of these

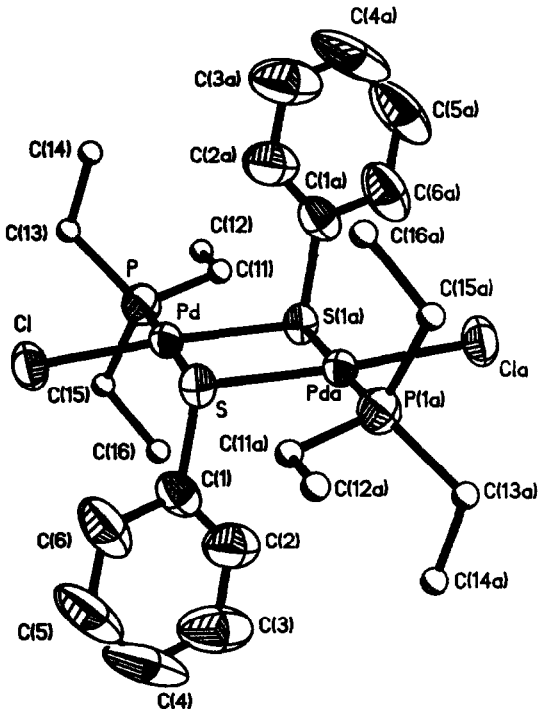

Fig. 4. ORTEP projection of *trans*-$Pd_2Cl_2(\mu\text{-}SPh)_2(PEt_3)_2$ (**4**) thermal ellipsoids at 50% probability. The hydrogen atoms have been omitted and PMe_3 carbon atoms given an arbitrary radius for clarity.

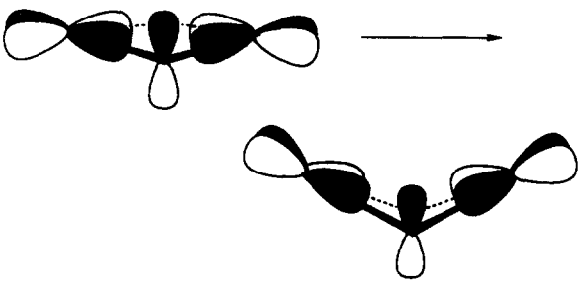
complexes. Finally, the Pd—Pd distances of 3.294(4), 3.208(1), 3.934(3) and 3.463(2) Å in **1**–**4**, respectively, demonstrate the lack of bonding interactions between the palladium atoms and thus metal–metal bonding plays no role in the determination of molecular geometry of these complexes.

The Pd—S bond distances of 2.262(2) and 2.272(2) Å in complexes **1** and **2** are significantly shorter than the Pd—S distances in **3**, 2.288(2) and 2.301(2) Å, indicating enhanced metal–sulphur bonding in the alkylthiolato complexes. One explanation of the consistently bent geometries of the alkylthiolato complexes is that electron-donating alkyl groups, as opposed to electron-withdrawing aryl groups, significantly enhance the donor ability of the thiolato sulphur. As a result, metal–sulphur bonding interactions involving the sulphur p_z orbital and the metal $d_{x^2-y^2}$ orbitals are established thus distorting the complexes from planarity as seen below.



Owston and co-workers proposed[12] that the distortion is favourable to the establishment of a multiple overlap zigzagging P—M—S—M—P chain of π-bonding orbitals. We find no evidence for the involvement of the Pd—P bonds in such a multiple overlap bonding system as the Pd—P bond distances in the mono(μ-arylthiolato) complex **3**, of 2.214(2) and 2.222(2) Å, are within the 2.209(2)–

Effect of metal–sulphur bonding in cis *vs* trans *phosphine geometries*

Dipalladium and diplatinum complexes containing weak σ-donor bridging ligands prefer[14] a *trans*-phosphine geometry. Thus the *trans*-phosphine configuration of **4** and other bis(arylthiolato) complexes is consistent with our model whereby μ-arylthiolato ligands are simple σ-donors. The *cis*-phosphine geometry of $M_2Cl_2(\mu\text{-}SR)_2(PR'_3)_2$ (M = Pd, Pt; R = alkyl) complexes is more problematic. *A priori* it would seem that the alkyl(thiolato) groups should participate in balanced bonding to the metal centres. It would then seem logical for the complex to adopt a *trans*-phosphine geometry whereby the destabilizing *trans* influence of the phosphines would be equally distributed among both thiolato groups. Our model in which the metal–sulphur bonding in the alkylthiolato complexes involves the sulphur p_z and metal $d_{x^2-y^2}$ orbitals provides a new basis for the *cis*-phosphine geometry in the bis(μ-alkylthiolato) complexes. If the additional bonding component involves mainly

the metal $d_{x^2-y^2}$ orbital, this interaction would be effectively disrupted by the strong *trans* influence of a phosphine ligand. Thus the bis(μ-alkylthiolato) complexes prefer a *cis*-phosphine geometry whereby one thiolato group is *trans* to both chlorides and significantly stabilized by an enhanced metal–sulphur bonding interaction.

CONCLUSION

Our results suggest that the establishment of an enhanced metal–sulphur bonding interaction is responsible for the non-planar geometries of dipalladium and diplatinum μ-alkylthiolato complexes. Furthermore, we believe the dichotomy of *cis* and *trans* geometries preferred by $M_2Cl_2(\mu\text{-}SR)_2(PR'_3)_2$ (M = Pd, Pt) alkylthiolato and arylthiolato complexes, respectively, can be explained by the requirement of weak *trans* donors for the stabilization of this enhanced bonding interaction in the alkylthiolato complexes. Finally, the isolation of mono(μ-thiolato) complexes from the reaction of *trans*-$[PdCl(\mu\text{-}Cl)(PMe_3)]_2$ with alkylthiols and not arylthiols can be accounted for by the additional stabilization of the metal–sulphur bonds in the alkylthiolato complexes.

(*Received* 27 *June* 1990; *accepted* 29 *January* 1991)

Abstract—The synthesis of mononuclear complexes $M(HL)_2 \cdot nS$ [M = copper(II), nickel (II) and cobalt(II), S = solvent] and $M'(HL)_2OH \cdot nS$ [M′ = iron(III) and vanadyl(V)] and of the binuclear complexes $M_2L_2 \cdot nS$ [M = copper(II), nickel(II) and cobalt(II)] and $Fe_2L_2(OH)_2 \cdot H_2O$ and $(VO)_2L_2SO_4 \cdot 4H_2O$ derived from 2,2′-dihydroxy-3,3′-diacetyl-5,5′-dichlorodiphenylmethane (H_2L) is reported. Their coordination geometry is discussed on the basis of physico-chemical data. Magnetic measurements at room temperature suggest that no interactions between metal ions are present in the binuclear chelates. Iron(III) and vanadyl(V) complexes were used as catalysts for the oxidation of 3,5-di-t-butyl-1,2-dihydroxybenzene (3,5-DBTC). From the oxidative cleavage, 3,5-di-t-butyl-*o*-quinone (3,5-DTBQ), 3,5-di-t-butyl-1-oxacyclohepta-3,5-diene-2,7-dione (3,5-DTBODD), 3,5-di-t-butyl-5-carboxymethyl-2-furanone (3,5-DTBCF) and 4,6-di-t-butylpyrone-2-one (4,6-DTBP) were isolated and identified by mass, IR and ^{1}H NMR data. The title compound was reacted to give a hexaketone by application of the Wittig method. A polymeric Schiff base was obtained by reaction of the diacetyl derivative with ethylenediamine, also in the presence of nickel(II) perchlorate or boric acid.

In recent years the increased awareness of the potential importance of molecules containing polymetallic centres has developed. The involvement of compounds containing such centres in catalytic processes has been the primary interest, and this is reflected in the growth and development of metal-cluster chemistry. Further stimulus has come from the discovery that many proteins and enzymes require two or more metal ions for their activity, and from the need to understand the nature of the active site and intermetallic interplay in these metallo-species.

Different approaches have been developed for the design and synthesis of polymetallic centres in order to exploit their mentioned potentials. One strategy has been to design and prepare multidentate ligands capable, through the siting of their donor atoms, of coordinating metal ions into juxtaposition (e.g. compartmental,[1] face-to-face,[2] cylindrical macrotricycles,[3] polypodal ligands,[4] etc.). The development of these so-called binucleating ligands has led to the successful synthesis of homo- and heterobinuclear metal chelates which have found application in the area of biomimic chemistry.[5,6]

As a part of our program on polynuclear chelates, we report the synthesis and the properties of the ligand 2,2′-dihydroxy-3,3′-diacetyl-5,5′-dichlorodiphenylmethane and its interactions with metal salts. In addition, a ligand extension via a modified Wittig reaction is reported.

EXPERIMENTAL

Microanalytical data were obtained by the Microanalytical Service of the University of Padova. Mass spectra were run on a VG Micromass 16 F spectrometer, IR spectra on a Nicolet 5DX FTIR

* Author to whom correspondence should be addressed.

spectrophotometer as KBr disks or Nujol mulls and electronic spectra on a Cary 14 spectrophotometer. Magnetic meausurements were carried out using the Gouy technique at room temperature with $HgCo(NCS)_4$ as calibrant. ^1H NMR spectra were recorded on a Jeol FX 900 in $CDCl_3$ solution. Mössbauer effect spectra were recorded at 78 K in a conventional acceleration spectrometer which utilized a room temperature rhodium matrix ^{57}Co source and was calibrated at room temperature with natural abundance α-iron foil. The spectra were fitted to Lorentzian line shapes by using standard least-squares computer minimization techniques.

Preparation of 2,2′-*dihydroxy*-3,3′-*diacetyl*-5,5′-*dichlorodiphenylmethane* (**V**)

The title compound has been prepared by the following two methods.

Method A

Preparation of acetoxy-4-*chlorophenol* (**I**). *p*-Chlorophenol (50 g) was dissolved in acetic anhydride (120 cm^3) and concentrated sulphuric acid (0.5 cm^3) was added. The solution was refluxed for 2 h and after cooling poured into 500 cm^3 of ice-cooled water. The brown oil was extracted with diethyl ether and the organic phase was washed with water, treated with active charcoal and dried over anhydrous sodium sulphate. The solvent was evaporated and the residue distilled at reduced pressure (78°C/1 mm Hg) to give 64 g of a colourless liquid (yield 96%).

Preparation of 4-*chloro*-2-*hydroxyacetophenone* (**II**). Compound **I** (40 g) was mixed with aluminium trichloride (73 g) and the mixture heated at 120°C for 15 min under vigorous stirring. After cooling, the green solid was poured into 500 cm^3 of ice-cooled 2 N hydrochloric acid. The suspension was filtered and the solid washed with water and crystallized from petroleum ether 40–60°C to give 38 g of colourless needles (yield 95%).

Preparation of 2,2′-*dihydroxy*-3,3′-*diacetyl*-5,5′-*dichlorodiphenylmethane* (**V**). Compound **II** (5 g) was dissolved in a solution of sulphuric acid and methanol (2 : 1 v/v) at −5°C. The resulting solution was further cooled down to −10°C and then formalin (38%; 2 cm^3) was slowly added under stirring. The stirring was continued for 2 h at the same temperature. The solution was left to stand overnight and then poured into 500 cm^3 of cool water. The brown solid was filtered, washed with water and dissolved in 300 cm^3 of NaOH (3%). The solution was treated with active charcoal and the solid was again precipitated with 2 N hydrochloric acid. The brown solid was recrystallized from hot ethanol to give a pale green compound (3.2 g; yield 60%; m.p. 202–203°C).

Method B

Preparation of 2,2′-*dihydroxy*-5,5′-*dichlorodiphenylmethane* (**III**). *p*-Chlorophenol (30 g) was dissolved in methanol (70 cm^3) and water (7 cm^3) was added. The resulting solution was cooled to −10°C and then sulphuric acid (120 cm^3) was added dropwise under stirring. Formalin (38%; 9 cm^3) was added under cooling and the mixture was stirred for 2 h. The white suspension was poured into ice (700 g) and stirred for 30 min. The white powder was filtered, washed with water, dissolved into 120 cm^3 of 2 N sodium hydroxide and treated with active charcoal. The clear solution was acidified with 2 N hydrochloric acid and the precipitate that formed was filtered, washed with water and dried at 50°C *in vacuo*. The white solid was recrystallized from ethanol (21.8 g; yield 70%; m.p. 172–175°C).

Preparation of 2,2′-*diacetoxy*-5,5′-*dichlorodiphenylmethane* (**IV**). Compound **III** (10 g) was dissolved in 100 cm^3 of acetic anhydride and 0.5 cm^3 of concentrated sulphuric acid. The solution was refluxed for 1 h, poured into ice-cooled water and then extracted with diethyl ether; the aqueous phase was discharged while the ethereal phase was washed with aqueous sodium bicarbonate (5%; 2×100 cm^3) and distilled water (100 cm^3), treated with active charcoal and then dried over magnesium sulphate. By evaporation of the solution to dryness the product was obtained as a white solid (12.2 g; yield 92%; m.p. 98–100°C).

Preparation of 2,2′-*dihydroxy*-3,3′-*diacetyl*-5,5′-*dichlorodiphenylmethane* (**V**). Anhydrous aluminium trichloride (20 g) and **IV** (10 g), in a 250 cm^3 flask, were heated in an oil bath at 140–150°C to obtain a homogeneous mixture; the temperature was allowed to rise to 170–180°C and maintained for 30 min. After cooling, the solid was added to 400 cm^3 of 2 N hydrochloric acid. The precipitate was filtered, washed with water and dried. The crude mixture was crystallized from ethanol to give a pale green product (4.0 g; yield 40%; m.p. 200–203°C).

Preparation of mononuclear complexes

The metal perchlorate (1 mmol) dissolved in methanol (50 cm^3) was slowly added to a methanolic solution (100 cm^3) of ligand **V** (2 mmol) and lithium hydroxide (2 mmol). The fine suspension which resulted was heated at 50°C under stirring.

The precipitate was filtered, washed with methanol and dried *in vacuo*.

Preparation of binuclear complexes

Ligand **V** (1 mmol) and lithium hydroxide (2 mmol) were dissolved in hot methanol (100 cm^3) and then added to a methanolic solution (50 cm^3) of the metal salt (1 mmol). The resulting mixture was refluxed for several hours. The precipitate so obtained was filtered, washed with methanol and dried *in vacuo*.

Oxidation of 3,5-*di-t-butyl*-1,2-*dihydroxybenzene*

The oxidation of the 3,5-di-t-butylcatechol (3,5-DTBC) was carried out both in air and under an oxygen atmosphere.

In air. Catechol (2.22 g, 10 mmol) was dissolved in the appropriate solvent (50 cm^3) and poured into a 100 cm^3 flask. The solution was stirred and the iron(III) or vanadyl(V) complex (1×10^{-2} mmol) was added. The solution was stirred for several hours, during which the reaction was monitored by thin layer chromatography. After this, the mixture was evaporated to dryness and the residue was eluted on silica gel using chloroform as eluant. The three main fractions recovered were identified as 3,5-di-t-butyl-*o*-quinone (3,5-DTBQ), 3,5-di-t-butyl-1-oxacyclohepta-3,5-diene-2,7-dione (3,5-DTBODD) and 4,6-di-t-butylpyran-2-one (4,6-DTBP) with vanadyl as catalyst and two 3,5-di-t-butylquinone and 3,5-di-t-butyl-5-carboxymethyl-2-furanone (3,5-DTBCF) with iron(III) as catalyst.

In oxygen. A solution (50 cm^3) of catechol (2.22 g, 10 mmol) and the iron or vanadyl complex (1×10^{-2} mmol) in a 100 cm^3 flask was stirred under oxygen (1 atm) for several hours at room temperature. The reaction mixture was evaporated to dryness and the residue chromatographed on silica gel using chloroform as eluant.

Preparation of the hexaketone 3,3′-*methylene bis*(2-*hydroxy*-1-*acetoacetylbenzene*)

Compound **V** (10 mmol) was dissolved in 200 cm^3 of ethyl acetate heated to 50°C and stirred under a nitrogen atmosphere. Metallic sodium (13 mmol) was slowly added over 30 min. Stirring was continued until the yellow sodium salt was precipitated. The reaction was cooled and the sodium salt filtered, washed with ethyl acetate and dried. The solid was added to dilute aqueous acetic acid solution (10%) and the resulting compound extracted with diethyl ether. The ethereal phase was filtered, washed with aqueous bicarbonate (5%) and distilled water, and finally dried over magnesium sulphate. The product was obtained by evaporation of the solution to dryness as a pale yellow solid (3.3 g; yield 75%; m.p. 172–173°C).

Reaction of **V** *with ethylenediamine*

(A) Nickel(II) perchlorate (1 mmol) and ethylenediamine (2 mmol) were dissolved in ethanol (100 cm^3). The solution was stirred for 30 min at 50°C, heated up to reflux, then **V** (2 mmol) in ethanol (50 cm^3) was added dropwise and the reflux continued for 90 min. During the reaction a yellow–green powder precipitated which was filtered and washed with ethanol and diethyl ether. Elemental analysis agrees with the formula $C_{19}H_{17}Cl_2N_2O_2Ni$ (Found: C, 51.9; H, 4.1; N, 6.5; Cl, 15.8; Ni, 13.0. Calc.: C, 52.5; H, 3.9; N, 6.4; Cl, 16.3; Ni, 13.5%.)

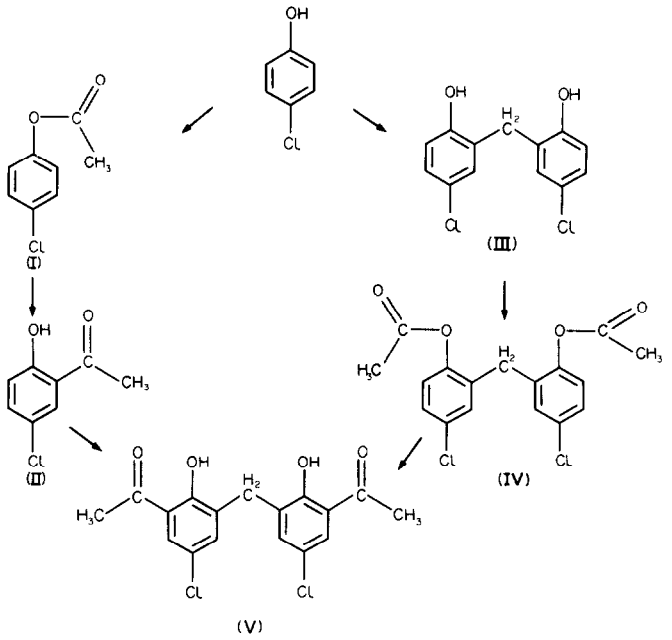
The precipitate was suspended in water and hydrogen sulphide (1 atm) was bubbled through for 30 min. The yellow–black solid was filtered and treated with dimethylsulphoxide to give a black solid and a yellow solution. The solid was filtered and the yellow solution evaporated to dryness to give a solid that was digested in ethanol, filtered, washed with ethanol and diethyl ether and dried *in vacuo*.

(B) Compound **V** (2 mmol) was suspended in methanol and then heated to reflux. Boric acid (1.2 mmol) was added and after 20 min a yellow solution was formed. A methanolic solution of ethylenediamine (2 mmol in 20 cm^3) was added and the reflux was continued for 2 h. During the reaction a yellow solid precipitated, this was filtered, washed with methanol and diethyl ether and dried *in vacuo*.

RESULTS AND DISCUSSION

Compound **V** has been prepared by two different methods according to a modified Erlenmeyer procedure[7] (Scheme 1). The first route seems to be better than the second because it operates at lower temperature; moreover the acetyl derivative (**I**) is liquid and it will mix better with aluminium(III) chloride than the solid diacetyl derivative (**IV**).

Compound **V** has been characterized by elemental analysis (Found: C, 57.6; H, 4.1; Cl, 19.8. Calc. for $C_{17}H_{14}Cl_2O_4$: C, 57.8; H, 4.0; Cl, 20.1%.) and spectral data. The mass spectrum, in addition to the principal fragmentation peaks, shows a strong M^+ peak at 352 *m/z* corresponding to the formula weight of the compound. The ^1H NMR spectrum consists of four signals at 12.43 (phenolic H), 7.58 and 7.37 (aromatic H), 3.95 (CH_2) and 2.60 ppm (CH_3). The hydroxyl IR stretching vibration consists of a broad band centred at *ca* 3050 cm^{-1}. Its



Scheme 1. The two pathways for obtaining V.

position and extreme width (400 cm^{-1}) are compatible with strong intramolecular association. The C=O stretching mode lies at 1638 cm^{-1} and confirms the presence of the intramolecular hydrogen bond.

Interaction with metal ions

Mononuclear complexes. By reacting ligand V with metal perchlorates in a 2:1 molar ratio in methanol, we have obtained mononuclear chelates of the type $M(HL)_2 \cdot nS$ (where S = water or methanol; M = copper(II), nickel(II) and cobalt(II)] and $Fe(HL)_2OH \cdot H_2O$. The synthesis of the vanadyl complex is very sensitive to the reaction conditions; in our case, by reaction of vanadyl(IV) sulphate with the ligand we obtained a compound of vanadyl(V), $VO(HL)_2OH$, even under a nitrogen atmosphere. Almost all the mononuclear compounds are soluble in the common organic solvents and they were crystallized before the analyses (Table 1).

The compounds present similar IR spectra, characterized by a broad band at 3400 cm^{-1} due to the coordinated solvent and a strong band at 1638 cm^{-1} which is also present in the free ligand. The presence of a single absorption for the carbonyl group can be explained assuming that the covalent bond between metal ion and C=O is comparable with a hydrogen bond. This hypothesis is confirmed by the spectra of the mononuclear and dinuclear sodium complexes. In fact, the mononuclear chelate shows two bands due to the C=O groups at 1670 and 1638 cm^{-1}, while the binuclear compound shows only a single band at 1670 cm^{-1}. Since the sodium forms an ionic M—O bond, the first band in the mononuclear chelate can be assigned to a free carbonyl group and the second to the C=O group involved in a hydrogen bond. The C—O phenol stretching frequency at 1323 cm^{-1} in the free ligand is not shifted after the coordination of metal ions, but appears at 1359 cm^{-1} in the sodium compound. A reasonable explanation is connected with an increased electron density on the oxygen atom as a result of increased ionicity of the Na—O bond. The stretching frequencies of the M—O modes, which should occur in the 400–500 cm^{-1} range, cannot be assigned because of the presence of bands due to the free ligand in the same region. The vanadyl complex presents a strong band at 850 cm^{-1} due to the V=O vibration.

The electronic spectra of these complexes show two absorption bands at 255 nm due to the phenyl ring and 350 nm. Since the latter one is present in the free ligand and is insensitive to metal change we assume that it is due to the ligand transition. The copper complex shows a broad band centred at 650 nm comparable with that of copper(II) bis(*o*-hydroxyacetophenonate),[8] suggesting a square-planar geometry. Its magnetic moment (1.80 BM) is that expected for an isolated copper(II) ion. The electronic spectrum of the nickel(II) complex presents a single band (630 nm) in the visible region,

as found for nickel(II) bis(acetylacetonate) and nickel(II) bis(*o*-hydroxyacetophenonate),[9,10] suggesting an octahedral coordination around the nickel(II) ion. This agrees with the room temperature magnetic moment (3.30 BM) typical of octahedral high-spin nickel(II). An octahedral coordination geometry can also be postulated for the cobalt(II) complex on the basis of the magnetic moment (4.90 BM) and electronic spectrum (a band at 600 nm) which are similar to those found for octahedral cobalt(II) bonded to the O_6 chromophore.[10,11] For the $Fe(HL)_2OH \cdot H_2O$ complex obtained by reaction of both iron(II) or iron(III) salts with the ligand under a nitrogen atmosphere, the spectral data suggest the presence of high-spin iron(III). In addition, the magnetic moment (5.90 BM) and the Mössbauer spectra (Fig. 1) are both typical of species containing isolated octahedral high-spin iron(III).[12,13]

Binuclear complexes

The binuclear complexes have been prepared by reaction of the ligand with a slight excess (molar ratio, 1 : 2.2) of the metal salts. The elemental analyses agree with formulae of the type $M_2L_2 \cdot nS$ [where M = nickel(II), copper(II) and cobalt(II)] and $Fe_2L_2(OH)_2 \cdot H_2O$. For the vanadyl ion, the $(VO)_2L_2SO_4 \cdot 4H_2O$ complex has been isolated, as confirmed by elemental analyses (Table 1).

The IR spectra do not differ from the mononuclear complexes as three main bands are present at 3400 (water), 1640 (C=O group) and 1320 cm^{-1} (C—O phenolic). For the vanadyl complex the bands due to ν(V=O) at 868 cm^{-1} and to the coordinated sulphate anion are also present. The electronic spectra of all these complexes are similar to those of the mononuclear chelates and suggest an analogous coordination geometry. The magnetic moments are typical of an isolated metal ion, excluding spin-exchange coupling. The Mössbauer effect spectra of the two iron-containing complexes have been measured at liquid nitrogen temperature and the resulting parameters are reported in Table 2. The spectra (Fig. 1) consist of a single asymmetric quadrupole-split doublet with hyperfine parameters typical of high-spin iron(III) complexes with the metal ion coordinated to six oxygen atoms in a nearly octahedral geometry. No difference can be found between the isomer shift values of the two compounds, and this points to a virtually identical electronic structure. The very small increase of the quadrupole splitting indicates a slightly higher distortion in the coordination of the bis-iron adduct.

Since the X-ray diffraction study[14] of the ligand has shown that the phenyl rings are twisted (Fig. 2), two possible structures for the binuclear complexes can be postulated (Fig. 3): a monomeric (**2a**) or a polymeric one (**2b**). Their low solubilities in coordinating organic solvents and the interactions of the

binuclear complexes with ethylenediamine to give polymeric Schiff bases suggest a polymeric configuration.

Oxidation reactions in the presence of vanadyl(V) *and iron*(III) *complexes*

The binuclear iron(III) or vanadyl(V) complexes were dissolved in a 0.1 M CH_2Cl_2 solution of 3,5-DTBC and then the reaction mixture was stirred at room temperature under oxygen (1 atm) or in air. At the end of the reaction, the 3,5-DTBC disappeared and the oxidation products (Scheme 2) were separated by a chromatography column on silica gel using chloroform as eluant; they were recrystallized and characterized by IR, ^1H NMR and mass spectroscopy (Table 3). All the investigated complexes were effective catalysts for the oxidation of 3,5-DTBC as shown in Table 4.

In presence of the iron(III) complexes isolation

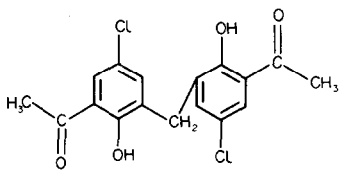

Fig. 2. A schematic view of **V**.

yielded unreacted catechol, a minor amount of lactone 3,5-DTBCF and 3,5-DTBQ as the main product. The results under various conditions are presented in Table 4. While both the mononuclear and binuclear complexes function as catalysts for the formation of 3,5-DTBQ and 3,5-DTBCF, the use of bimetallic complexes decreases the reaction time and increases the percentage of conversion. The same results can be obtained if the reaction is carried out in air even if the reaction time is longer than in an oxygen atmosphere.

adyl complex, 5,5-di-t-butylcatechol is oxidized by molecular oxygen to afford three products: 3,5-DTBODD, 4,6-DTBP and 3,5-DTBQ; no catechol has been recovered. 3,5-DTBODD is the main product of this reaction, indicating that vanadium catalyses cleavage of the catechol incorporating an oxygen atom. This reaction compares well with results reported in the literature for other vanadium compounds.[15,16] The most remarkable feature of these oxygenation reactions, in methylene chloride solutions, is the high catalytic activity of the vanadyl complexes as compared with the iron complexes. As the main product, 3,5-DTBODD is analogous to the intermediate found in enzymatic intra-diol cleavage reactions,[17] suggesting that the vanadium catalyst favours an intra-diol rather than an extra-diol oxidative cleavage. The presence of 4,6-DTBP as a minor product can be attributed to an extra-diol cleavage of the catechol ring and subsequent loss of a CO group.[18] Although the 3,5-DTBQ was an intermediate product in several oxidative ring cleavages,[19,20] it cannot be further oxidized in this reaction just as in the enzyme reaction. However, methanol leads to a poor yield of the oxygenated products (3,5-DTBODD, 4,6-DTBP), while pyridine completely inhibits the oxidation. The same results were obtained when the reactions were carried out in air.

Interaction of the diacetyl derivative (V) *with ethylenediamine*

We have tried to prepare macrocyclic complexes starting from V, using nickel(II) perchlorate or boric acid as template. The compound was reacted in ethanol solution with a stoichiometric amount of ethylenediamine in the presence of metal perchlorate; a yellow precipitate was formed containing the metal ion. It was treated with H_2S to precipitate NiS, and the black residue was extracted with dimethylsulphoxide. The solution was evap-

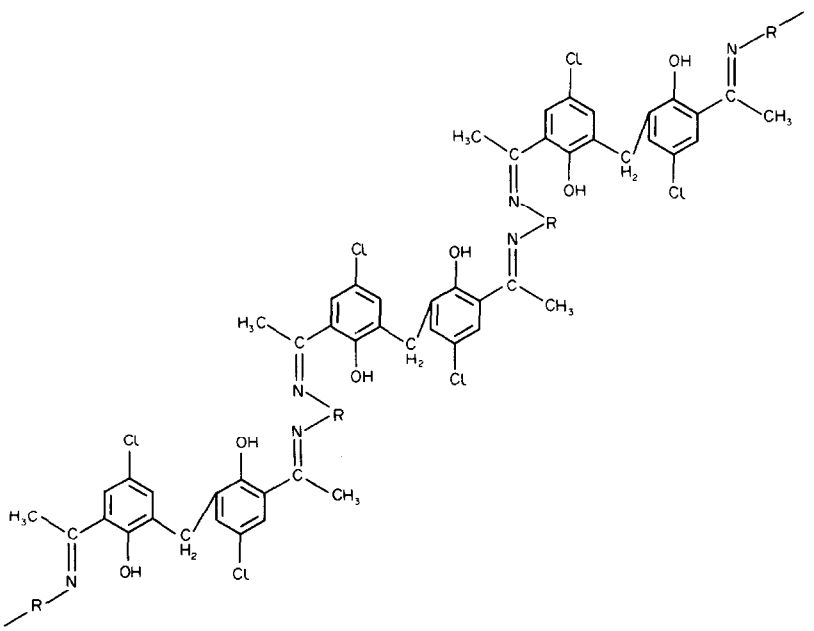

Fig. 4. The polymeric Schiff base obtained from the reaction of V with ethylenediamine.

orated to dryness to give a yellow solid. In the IR spectrum of the compound, the C=O and N—H stretching modes are absent, while a peak at 1605 cm^{-1} is present due to the C=N stretching mode involved in a hydrogen bond. The elemental analysis agrees with this suggestion but the mass spectrum (absence of P^+ at m/z 378 and presence of fragments at higher values m/z) indicates that a polymeric species is present (Fig. 4).

The same result was obtained when **V** was reacted with ethylenediamine in the presence of boric acid.

Interaction of the diacetyl derivative (**V**) *with ethyl acetate*

Compound **V** provides a versatile precursor for polynucleating ligand species or for a hexaketonic array after ligand extension via a modified Wittig condensation. This involves the condensation of the diacetyl derivative with ethyl acetate in the presence of sodium wire. The compound (Fig. 5) was crystallized from hot ethanol to give a pale yellow, microcrystalline powder in good yield. It was characterized by IR, mass (P^+ at $m/z = 437$) and ^1H NMR spectra.

The hydroxyl stretching band of 3,3′-methylene-bis-(2-hydroxyl-1-acetoacetylbenzene) consists of a broad signal, about 400 cm^{-1} wide, centred at 3060 cm^{-1}. This band could result from two overlapping OH absorptions. In the carbonyl region only a band at 1610 cm^{-1} is present, due to a C=O group involved in a hydrogen bond. No bands due to free C=O are present, suggesting that the enol form is predominant in the solid state. The enol tautomer is the major form also in chloroform solution as confirmed by the ^1H NMR spectrum. The principal resonances occur at 2.14, 3.98, 6.20, 12.56 and 14.97 ppm due to CH_3-C, CH_2, phenyl *H*, phenolic O*H* and enolic O*H*, respectively. Other weak signals at 2.30 and 13.65 ppm could be assigned to the keto-methyl and phenolic hydrogen in the keto tautomer. The integrated peak areas are in agreement with these assignments.

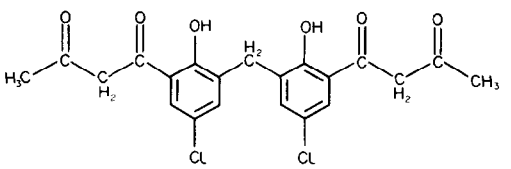

Fig. 5. The hexaketone 3,3′-methylene-bis-(2-hydroxy-1-acetoacetylbenzene).

Work is in progress to prepare complexes with this ligand.

(*Received* 6 *October* 1990; *accepted* 29 *January* 1991)

Abstract—Four five-coordinate copper(II) complexes of deprotonated S-R-β-N-(pyridine N-oxide-2-ylmethylidene)dithiocarbazates (R = methyl, abbreviated SMPDH; R = benzyl, abbreviated SBPDH) with *o*-phenanthroline or 2,2′-bipyridine, were synthesized and characterized by UV, IR spectra and magnetic susceptibilities at room temperature. The X-ray crystal structure of [Cu(SBPD)Phen]ClO_4 was determined. The crystal structure contains a mononuclear unit in which copper(II) displays a distorted square pyramidal geometry.

A large number of transition metal complexes with Schiff bases as ligands containing sulphur and nitrogen atoms have been widely studied, since such complexes of platinum(II), palladium(II), nickel(II), copper(II) and zinc(II) were found to show certain anti-cancer activities.[1–4] Recently, we reported two new tridentate ligands of the above class derived from a Schiff base condensation reaction of S-R-dithiocarbazates (R = methyl and benzyl) with 2-pyridinecarboxaldehyde N-oxide, and their four-coordinate planar copper(II) complexes.[5] As part of our series, four five-coordinate copper(II) complexes of the above two ligands with *o*-phenanthroline or 2,2′-bipyridine are discussed in this paper.

EXPERIMENTAL

Preparation of the copper(II) complexes

The two ligands S-R-β-N-(pyridine N-oxide-2-ylmethylidene)dithiocarbazates (R = methyl, abbreviated SMPDH; R = benzyl, abbreviated SBPDH) have already been reported.[5] A general procedure for preparing copper(II) complexes is as follows. The ligand (1 mmol) was dissolved in ethanol (50 cm^3) with heating and an ethanol solution (10 cm^3) of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol) was added. After refluxing for 10 min, the mixture was added to an equivalent mole of *o*-phenanthroline or 2,2′-bipyridine in ethanol (5 cm^3), and was further refluxed for 5 min, then filtered while hot. Dark green crystals were obtained when the filtrate was cooled to room temperature. Yields and elemental analyses are given in Table 1.

Measurements

UV spectra were obtained using a Shimadzu 240 spectrophotometer. IR absorption spectra from 4000 to 400 cm^{-1} were recorded using a Nicolet 170 SXFT–IR spectrophotometer; samples were prepared as KBr pellets. Magnetic susceptibilities were measured at room temperature by the Gouy method with a CTP-F82 Faraday balance. The corrected magnetic moments and main IR data of the four complexes are listed in Table 2.

X-ray structure determination of [Cu(SBPD)Phen] ClO_4 (3)

Single crystals were obtained by slow diffusion of ether into an acetonitrile solution of the complex.

Crystal data: $CuC_{26}H_{20}ClN_5O_5S_2$, Mr = 645.57, monoclinic, space group $C2/c$, $a = 19.227(5)$, $b = 14.506(3)$, $c = 20.487(4)$ Å, $\beta = 106.00(2)°$, $V = 5493(2)$ Å^3, $Z = 8$, $D_c = 1.56$ g cm^{-1}, μ(Mo-K_α) = 10.83 cm^{-1}, $F(000) = 2567$. Crystal size: a tabular crystal, $0.4 \times 0.5 \times 0.05$ mm.

The unit-cell parameters were determined from 25 reflections with the CHDU program, devised by ourselves for searching reflection peaks automatically. Intensity data were collected with a R3M/E four-circle diffractometer operating in the ω–2θ scan mode, using graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) and $2\theta_{max} = 42°$. A total of 3307 independent reflections were measured and corrected by Lorentz-polarization factors, but not absorption. Only 2360 [$I > 3\sigma(I)$] reflections were used in structural determination and refinement. The structure was solved by direct methods. The 30 non-hydrogen atoms were revealed from the best E-map, the rest were located from the Fourier syntheses. Hydrogen atoms were obtained from a difference Fourier map. The coordinates of all the atoms, anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, were refined by block diagonal least-squares with 441 variables. The final $R = 0.046$, $R_w = 0.046$. Maximum peak in final difference synthesis was 0.48 e/Å^{-3} and minimum peak −0.30 e/Å^{-3}; the largest shift/ESD was 0.068 in O_4 atom.

Lists of atomic coordinates, thermal parameters, calculated hydrogen coordinates, least-square planes and torsion angles have been deposited as supplementary material with the Editor, from whom copies are available on request.

RESULTS AND DISCUSSION

The corrected magnetic moments of polycrystalline samples at 283 K are representative of magnetically dilute copper(II) complexes, compatible with the proposed stereochemistry. The reflectance electronic spectra of the compounds studied exhibit one broad unresolved band at *ca* 24.4 kK, unlike other pentacoordinated copper chromophores.[6] The *d–d* bands in these copper(II)

complexes are not observed, which may result from the charge-transfer absorptions of ligands containing sulphur atoms.

The strong IR bands in the region 1410–1440 cm^{-1} of these complexes are due to the stretching vibrations of C=N bonds. ν(C=N) of complexes **1** and **3** are near 1415 cm^{-1}, whereas those of complexes **2** and **4** are at *ca* 1435 cm^{-1}. Bands appearing at *ca* 1200 cm^{-1} are assigned to ν(N—O) modes, and δ(N—O) modes are found at *ca* 870 cm^{-1}; these

bands are in agreement with literature reports.[7–12] The frequencies of the two ligands decrease by *ca* 22–33 cm^{-1} upon complex formation, indicating N-oxide coordination by two ligands.[13] The ν(C—S) absorption appears near 1043 cm^{-1}, but no stretching vibrations of C=S bonds are observed, which indicates that the two ligands are in the thiolate form in these complexes, similar to those of other metal chelates with S-alkyldithiocarbazates and their derivatives as ligands.[14–16] Very strong bands are found in the range 1079–1101 cm^{-1}, which are assigned to ν(Cl—O) of the ClO_4^- group.

An X-ray study of **3** was carried out. Figure 1 shows the molecular structure with the atomic numbering scheme and selected bond lengths and bond angles are presented in Table 3.

The geometry of the pentacoordinated copper atom is distorted square pyramidal. The basal coordination positions are occupied by the O(1), N(3) and S(1) atoms of the tridentate ligand together with the N(2) atom of *o*-phenanthroline, and the apical position is occupied by the N(1) atom—the other nitrogen atom in the *o*-phenanthroline moiety. The Cu—S(1), Cu—N(2) and Cu—N(3) distances fall within the normal range, corresponding to the bond lengths in [Cu(SMPD)ImH]ClO_4.[5] The axial Cu—N(1) bond, however, is significantly longer (2.220 Å) than the equatorial Cu—N(2) bond (1.985 Å), owing to the coordination of the much larger *o*-phenanthroline group.

The coordination plane composed of Cu N(1) N(2) and N(3), from which the maximum deviation of atoms is −0.0462 Å, has a dihedral angle of 8.8° with the *o*-phenanthroline plane. The pyridine ring of the ligand is planar, and the two connected atoms, C(1) and C(18), are also in the plane with deviations less than 0.0900 Å. The dihedral angle between the pyridine plane and the *o*-phenanthroline plane is 120.5°; it is the spatial resistance of the above two planes that leads to the distorted square pyramidal configuration of the copper atom and the non-coplanarity of the N(2), O(1), N(3) and S(1) atoms. Coordination planes, Cu N(2) N(3) O(1) and Cu S(1) N(1) O(1), with the dihedral angle of 101.1°, are almost perpendicular to that of the Cu N(1) N(2) N(3), the dihedral angles to one another are 91.1 and 89.0°, respectively.

The atoms O(1), N(4), C(17), C(18), N(3), N(5), C(19) and S(1) are all conjugated via the pyridine group, consistent with the case in [Cu (SMPD)ImH]ClO_4.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURES OF $[Me_2NH_2]^+[Al(OSiMe_3)_4]^-$ AND $Al_2(OSiMe_3)_6$

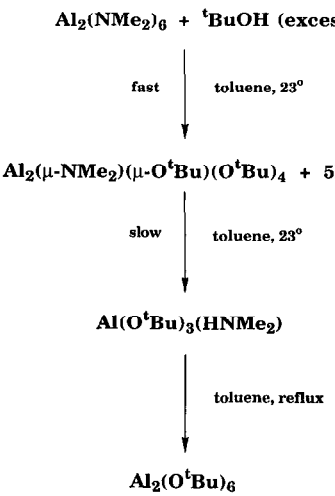
MALCOLM H. CHISHOLM,* JOHN C. HUFFMAN and JODI L. WESEMANN

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 16 *October* 1990; *accepted* 29 *January* 1991)

Abstract—The reaction between $Al_2(NMe_2)_6$ and excess Me_3SiOH in hydrocarbon solvents yields $[Me_2NH_2]^+[Al(OSiMe_3)_4]^-$ (**I**), which has been characterized by X-ray crystallography. Hydrogen bonding occurs between oxygen atoms on the siloxides and hydrogen atoms of the dimethylammonium cations. Under a dynamic vacuum **I** sublimes (50°C, 10^{-2} torr) but with some decomposition to $Al_2(OSiMe_3)_6$ (**II**). The latter compound is better prepared by addition of Me_3SiOH to $Al(OPr^i)_3$. The addition of Me_3SiOH and Me_2NH to hydrocarbon solutions of **II** regenerates **I**. These results are compared with previous studies of the reaction between $Al_2(NMe_2)_6$ and Bu^tOH. The X-ray crystal structure of **II** has been determined at −100°C.

In a previous study we observed that the reaction between $Al_2(NMe_2)_6$ and Bu^tOH in hydrocarbon solvents proceeded to give $Al_2(OBu^t)_6$ by way of two kinetic intermediates, $Al_2(\mu\text{-}NMe_2)(\mu\text{-}OBu^t)(OBu^t)_4$ and $(Me_2NH)Al(OBu^t)_3$[1,2] (see Scheme 1). Both of the kinetic products showed remarkable persistence with respect to the formation of $Al_2(OBu^t)_6$ at 0°C and were isolated and fully characterized by single crystal X-ray diffraction. These findings prompted us to investigate the related reaction between $Al_2(NMe_2)_6$[3] and Me_3SiOH. We describe here results of these investigations together with the single crystal X-ray structure of $Al_2(OSiMe_3)_6$, a compound that has previously been reported in the literature from alternative synthetic procedures.[4,5]



Scheme 1.

RESULTS AND DISCUSSION

Syntheses: $[Me_2NH_2]^+[Al(OSiMe_3)_4]^-$ (**I**) *and* $Al_2(OSiMe_3)_6$ (**II**)

The reaction between $Al_2(NMe_2)_6$ and Me_3SiOH ($\geq$ 6 equiv.) in hydrocarbon solvents proceeds quite differently from the related reaction involving Bu^tOH. The kinetic and thermodynamic product in the reaction is the amine salt, $[Me_2NH_2]^+[Al(OSiMe_3)_2]^-$ (**I**), which is a white, crystalline, hydrocarbon-soluble solid. Although an amine adduct $(Me_2NH)Al(OSiMe_3)_3$ might seem a plausible precursor to **I**, this compound has not been detected. Moreover, addition of Me_2NH to hydrocarbon solutions of $Al_2(OSiMe_3)_6$ does not yield $(Me_2NH)Al(OSiMe_3)_3$ but rather the salt **I** and other unidentified products.

Compound **I** sublimes at 45–50°C, 10^{-2} torr, but with some decomposition. The latter leads to the formation of $Al_2(OSiMe_3)_6$ (**II**), but does not pro-

vide a reliable synthesis of **II**. Compound **II** is best prepared by the addition of Me_3SiOH to $Al(OPr^i)_3$.

The addition of Me_3SiOH and Me_2NH to hydrocarbon solutions of **II** regenerates **I** thereby establishing the equilibrium shown in eq. (1). In view of the fact that compound **I** sublimes *in vacuo* with some formation of **II**, the position of equilibrium in eq. (1) must lie well to the right, under ambient conditions.

$$Al_2(OSiMe_3)_6 + Me_2NH + Me_3SiOH \rightleftharpoons [Me_2NH_2]^+[Al(OSiMe_3)_4]^- \quad (1)$$

Compound **I** shows $\tilde{\nu}$(NH) at 2780 and 2470 cm^{-1} in the IR spectrum. Complete IR, ^1H and ^{13}C NMR data are given in the Experimental. The anion $[Al(OSiMe_3)_4]^-$ has been previously reported in both alkali (M = Li, Na, K)[6] and stibonium $[(SbMe_4)^+]$[7] salts. The Si—O—Al stretch in the IR spectrum has been assigned to a band at 966 cm^{-1} for the Na^+ and K^+ salts.[6] We observe a strong band at 948 cm^{-1} for the $Me_2NH_2{}^+$ salt, **I**.

X-ray crystal structures

A summary of pertinent crystal data for **I** and **II** is given in Table 1.

$[Me_2NH_2]^+[Al(OSiMe_3)_4]^-$ (**I**). In the space group $P2_1/a$ there are two independent ion pairs in the asymmetric unit of the unit cell. They differ little with respect to their metric parameters. A view of one of the ion pairs is shown in Fig. 1 and selected

bond distances and bond angles are given in Tables 2 and 3.

The aluminium atoms are in a pseudo-tetrahedral environment. The Al—O distances span the range 1.73–1.78 Å with the longer Al—O distances being associated with the oxygen atoms that are nearest and hydrogen bonded to the $[Me_2NH_2]^+$ hydrogen atoms. (H atoms were located in the X-ray determination.) The O—Al—O angles span a range from 104 to 113°. The Si—O distances were all essentially equivalent with an average distance of 1.625 Å. The Al—O—Si angles span the range 130–150° with a greater variation being observed in the ion pair containing Al(22). The smaller Al—O—Si angles are for oxygen atoms that are involved in hydrogen-bonding.

$Al_2(OSiMe_3)_6$ (**II**). Selected bond distances and angles for the centrosymmetric dimer are given in Table 4, wherein a comparison is also made with the previously reported alkoxide dimer, $Al_2(OBu^t)_6$.[2] A ball-and-stick drawing of **II** is shown in Fig. 2.

There is considerable motion associated with the methyl groups and a disorder involving the bridging $OSiMe_3$ ligand. There are two alternate positions for Si(13) (50% occupancy) with each sharing a common position for O(12), C(15) and C(16). There

are two 50 : 50 occupancies for C(14) and C(14)′ to complement Si(13) and Si(13)′.

Then crystallographic problems notwithstanding, the present structural determination of **II** reveals the remarkable similarity of the Al_2O_6 core with that seen for $Al_2(OBu^t)_6$. In particular, the Al—O distances are equivalent in the two molecules. The Al—O—Si angles of the terminal siloxide ligands are, however, notably larger than their Al—O—C counterparts in the $Al_2(OBu^t)_6$ molecule. The Al(1)—O(2)—Si(3) angle, for example, is 175°, essentially linear. While the Al—O distances differ by *ca* 0.015 Å, the Si—O bond distances differ by *ca* 0.08 Å. In both instances the distances associated with the bridging oxygen atoms are longer which is explainable in terms of either the hybridization at oxygen or the coordination number of oxygen, 2 vs 3. Comparison of Al—O and Si—O distances is also worthy with those seen in $Al_2(OSiMe_3)_4(acac)_2$[8] which adopts the structure depicted by **A**.

Concluding remarks

Bu^tOH and Me_3SiOH differ in two important ways. (1) The pK_a of the silanol is *ca* 4 units lower, indicating greater acidity of the silanol.[9] (2) Although the Me_3Si group is larger in volume than the Bu^t group, the effective steric pressure at a metal centre is greater for Bu^tO than for Me_3SiO as a ligand. Both of these factors are at work in causing the different behaviour of $Al_2(NMe_2)_6$ towards Me_3SiOH and Bu^tOH. The high formation tendency of the $[Al(OSiMe_3)_4]^-$ anion is favoured by both the greater pseudo-halide character and the

lesser steric demand of the $OSiMe_3$ ligand. The greater acidity and lesser steric demand of Me_3SiOH also presumably works to make species such as $Al_2(\mu\text{-}NMe_2)(\mu\text{-}OSiMe_3)(OSiMe_3)_4$ and $(Me_2NH)Al(OSiMe_3)_3$ kinetically more labile than their Bu^tO analogues. The structure of the Al_2X_6 dimers, where X = OBu^t and $OSiMe_3$, are remarkably similar in their Al_2O_6 cores which testifies to the fact that reactivity differences can only be traced in extreme cases to structural origins. The Al—O and Si—O distances in **I** and **II** for the terminal groups are roughly 0.2 Å smaller than the sum of the covalent radii. In view of the fact that the terminal Al—O distances in $Al_2(OBu^t)_6$ and $Al_2(OSiMe_3)_6$ are essentially identical, the short Al—O distances cannot be due to solely oxygen p_π–Al bonding.

EXPERIMENTAL

All procedures were carried out under nitrogen using air-sensitive techniques. Solvents were dried and degassed using standard procedures, and stored over activated molecular sieves. Glassware was presilylated by heating with hexamethyldisilazane. 99.99% $Al(OPr^i)_3$ was purchased from Aldrich and used without further purification in the preparation of $Al_2(OSiMe_3)_6$.[4] Me_3SiOH was synthesized by water hydrolysis of hexamethyldisilazane in diethyl ether, followed by neutralization with 2 M hydrochloric acid, separation of the aqueous layer, removal of ether and vacuum distillation.[2] $Al_2(NMe_2)_6$[3] was made from $AlCl_3$ and $LiNMe_2$ in hexane and purified by sublimation.

^1H and ^{13}C NMR spectra were obtained on a Varian XL-300 spectrometer, ^1H NMR at 300 MHz, referenced to proton impurities of d_6-benzene at δ 7.15; ^{13}C NMR at 75 MHz referenced also to benzene at δ 128.0. Microanalyses were obtained from Oneida Research Services, Whitesburo, New York, and IR spectra were obtained using a Nicolet FT–IR using KBr pellets.

Preparation of $[Me_2NH_2]^+[Al(OSiMe_3)_4]^-$ (I)

$Al_2(NMe_2)_6$ (0.381 g, 1.197 mmol) was dissolved in *ca* 25 cm^3 of toluene. Me_3SiOH (1.8 cm^3, 16.25 mmol) was added and the solution was heated with stirring to 80°C in an oil bath for 6 h. Toluene was removed *in vacuo* to give a white solid, that subsequently was dissolved in hexane. The solution was filtered. The product crystallized at −30°C with a yield of 0.80 g (78%). NMR data showed some concentration dependence. ^1H NMR (C_6D_6): δ 1.35 (br, 6H, NMe_2), 0.32 (s, 36H, $OSiMe_3$); ^{13}C NMR (C_6D_6): δ 33.04 (NMe_2), 3.45 ($OSiMe_3$); ^{29}Si NMR (C_6D_6): δ 0.27; IR (cm^{-1}): 2957s, 2901m, 2780br, 2470br, 1473m, 1257s, 1022s, 947s, 833s, 750s, 650m, 580m, 555m. Found: C, 39.4; H, 10.3; N, 3.1. Calc. for $AlC_{14}H_{44}NO_4Si_4$: C, 39.1; H, 10.3; N, 3.3%.

Addition of $HNMe_2$ *and* Me_3SiOH *to* $Al_2(OSiMe_3)_6$

Four equivalents of Me_3SiOH (0.285 cm^3, 2.63 mmol) were added to $Al_2(OSiMe_3)_6$ (0.387 g, 0.657 mmol) dissolved in *ca* 15 cm^3 of toluene. Me_2NH was bubbled through the solution for 1 min. The volume was reduced *in vacuo* to *ca* 5 cm^3. The solution was cooled to −15°C and within several hours white crystals had formed. They were isolated and dried *in vacuo* yielding 0.07 g, **I** by NMR data.

Sublimation of I

Compound **I** (0.17 g, 0.40 mmol) was placed in a silylated Schlenk and heated to 40°C in an oil bath. After 5 h a white solid had collected on the cold finger. This was collected and examined by ^1HNMR spectroscopy and thereby found to be a mixture of **I** (δ 1.4 and 0.32) and **II** (δ 0.27 and 0.24). From extended sublimations the residue yielded pure **II** as sublimate, δ 0.27 s, 12H (μ-$OSiMe_3$), 0.23 s, 24H (t-$OSiMe_3$). Found: C, 36.5; H, 8.8; N, 0.0. Calc. for **II**: C, 36.7; H, 9.2; N, 0.0%.

X-ray structural determinations

General operating procedures and listings of programs have been previously given.[10] Data collection, solution and refinement parameters are given in Table 1.

$[Me_2NH_2]^+[Al(OSiMe_3)_4]^-$ (**I**). Colourless, rod-like crystals were obtained from a hexane solution. A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques employed by the IUMSC and cooled to −172°C for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/a$. Subsequent solution and refinement of the structure confirmed this choice. Data were collected in the usual manner using a continuous θ–2θ scan with fixed backgrounds. Data were reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. All hydrogen atoms were clearly visible in a difference Fourier synthesis phased on the non-hydrogen atom parameters. All

hydrogen atoms were refined isotropically and non-hydrogen atoms anisotropically in the final cycles. A final difference Fourier was featureless, with the largest peak being 0.45 e/Å^3. Two independent molecules are present in the structure.

$Al_2(OSiMe_3)_6$. Similar crystals were obtained from both toluene and benzene solutions. When the sample was first transferred to the goniostat and cooled using the standard glove-bag techniques developed by the IUMSC, the crystal went through a violent phase transition, completely fracturing at -150°C. A subsequent crystal was transferred at -70°C, and slow cooling indicated the phase transition occurs near -130°C. A third crystal was then transferred and cooled to -100°C, at which temperature all data were collected. A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/n$. Subsequent solution and refinement of the structure confirmed this choice. Data were collected in the usual manner using a continuous θ–2θ scan with fixed backgrounds. Data were reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. The thermal motion is best described as severe, and in addition, a disorder is present with the bridging-$OSiMe_3$ group. There are two alternate positions for Si(13) with each sharing C(15) and C(16) as well as O(12). C(14) is also 50% occupancy, and a second position C(14)′ completes the alternate Si(13)′ sphere. In spite of the disorder and large thermal parameters, all atoms behaved properly when refined anisotropically. Hydrogen atoms were placed in fixed idealized positions for the final four cycles of refinement. There are no significant peaks in the final difference Fourier, the largest being 0.40 e/Å^3.

Atomic coordinates for compounds **I** and **II** have been deposited with the Cambridge Crystallographic Data Centre.

Abstract—Pulse radiolytic reduction of a series of nitro-substituted tetraaza copper(II) complexes with the aquated electron (e_{aq}) results in formation of nitro radical anions. By contrast, reaction of pendent nitro dithia-diaza copper(II) analogues with e_{aq} achieves exclusive reduction of the metal centre. Oxidation of all tetraaza copper(II) complexes with the hydroxyl radical (OH) resulted in formation of stable copper(III) complexes, whereas no metal-centred oxidation was observed for the corresponding $Cu^{II}N_2S_2$ complexes. The variation in reactivity, effectively evidence for selectivity in reduction with e_{aq} or oxidation with OH, was attributed to the shift in the $Cu^{II/I}$ half-wave potentials going from a tetraaza to a dithia-diaza donor set.

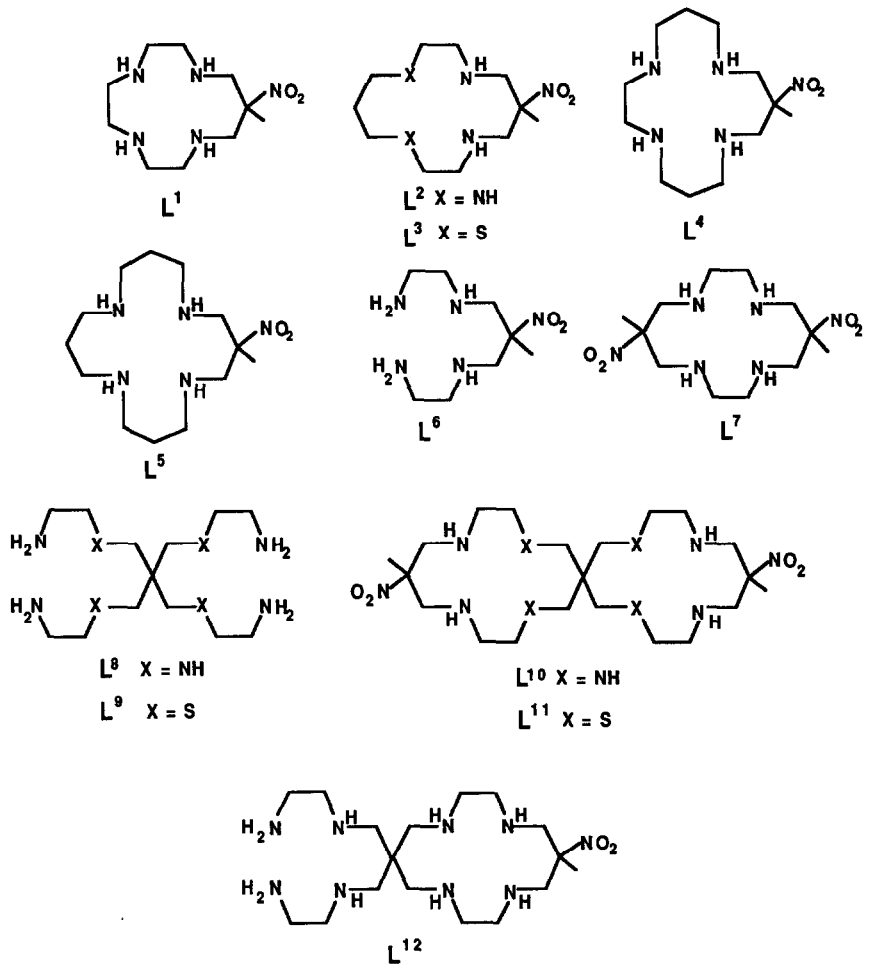
In a previous paper, we reported the pulse radiolysis and electrochemistry of a series of tetraaza macrocyclic and acyclic nickel(II) complexes.[1] Both nickel(I) and nickel(III) derivatives of the precursor complexes were characterized. The electrochemical behaviour of tetraaminecopper(II) complexes is somewhat similar to that displayed by nickel(II) analogues, in that both the copper(I) and copper(III) oxidation states are also accessible from redox reactions of the precursor complexes. Electrochemical studies of the copper(II) complexes of L^1–L^{12} have been reported with their syntheses,[2–6] and a pulse radiolysis study of the products of both one-electron oxidation (with hydroxyl radicals, OH) and one-electron reduction (with aquated electrons, e_{aq}) of these complexes is contained herein.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

The mononuclear copper(II) complexes of the ligands L^1–L^7 were prepared via metal-directed condensation reactions, as described previously.[2–5] The dicopper(II) complexes of the ligands L^8–L^{12} were also prepared according to literature syntheses.[6]

Pulse radiolysis experiments were performed with a Van de Graaf electron accelerator that delivered electron pulses (3 μs) at *ca* 1 MeV (1 eV = 1.60×10^{-19} J) through the thin wall of a 1 cm optical path cell as previously described.[7] Dosimetry was performed with an aerated aqueous solution of KSCN, employing values of $\varepsilon_{480\ nm} = 7600$ M^{-1} cm^{-1} and $G(OH) = G([(NCS)_2^{-}]) = 2.8$; a dose of *ca* 40 Gy was observed. All reductions were effected by e_{aq}, with OH being scavenged by the addition of 2-methylpropan-2-ol (*ca* 0.01 M) to each solution. Oxidation was achieved with OH, with e_{aq} being quenched by purging each solution



with nitrous oxide, which effectively doubled the yield of OH. Formation rate constants for e_{aq} and OH reactions were determined according to previously described methods.[1]

RESULTS AND DISCUSSION

Reductions

Reactions of all copper(II) complexes with e_{aq} resulted in the formation of species at effectively diffusion controlled rates ($\sim 10^{10}\,M^{-1}\,s^{-1}$). The large excess (100-fold) of precursor complex to reductant (e_{aq}) permitted only single electron redox processes. A summary of the electronic spectra and reactivity of each reduced complex is given in Table 1. In all but four cases, those being the copper(II) complexes of L^3, L^8, L^9 and L^{11}, the electronic spectrum of each reduced species exhibited a single maximum in the range 280–290 nm (ε, 2000–4000 $M^{-1}\,cm^{-1}$). Maxima of comparable energy and intensity have previously been shown to be characteristic of nitro radical anions ($-NO_2^{\bullet -}$),[1,8] and since each of the eight complexes displaying a maximum around 290 nm possess a pendent nitro group, a similar assignment is made for the present set. These nitro radical anion complexes decay via first-order processes (Table 1) to a similar copper(II) complex, or dicopper(II) complex.

The dicopper(II) complexes of the acyclic ligands L^8 and L^9 do not possess pendent nitro groups, and therefore only metal-centred reductions are possible for these complexes. The electronic spectrum of the reduced $[Cu_2L^8]^{4+}$ ion did not differ appreciably from that of its precursor complex, nor were large changes in the spectra anticipated upon reduction to the putative $[Cu_2L^8]^{3+}$ ion, which is a mixed-valence Cu^{II}–Cu^{I} complex. The Cu^{I} moiety (d^{10}) of this reduced species would most likely be transparent in the near UV–vis region of the spectrum, and indeed the Cu_{aq}^{+} ion has been shown to exhibit no electronic maxima in this region.[9] Moreover, bleaching of the relatively weak visible absorption maximum of the copper(II) unit, upon reduction, was not great enough to be precisely determined by the present equipment. By contrast, reduction of the thio-ether analogue $[Cu_2L^9]^{4+}$ with e_{aq} resulted in complete bleaching of the intense near-UV

Table 1. Physical properties of one electron reduced species

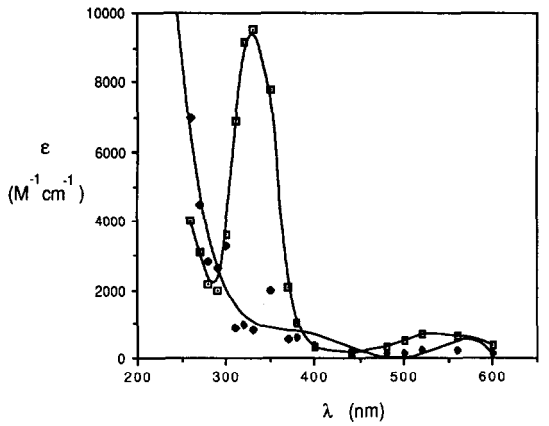

Fig. 1. Electronic spectrum of $[Cu_2L^{11}]^{4+}$ (□) and its one electron reduced product (◆).

maximum (330 nm) characteristic of copper(II) complexes with S-donor ligands.[4] It is apparent that the presence of this maximum is a direct indicator of a copper(II) complex [or dicopper(II) complex], and its disappearance upon reduction or oxidation implies a metal-centred redox reaction. The more intense visible *d–d* maximum exhibited by the N_2S_2 donor complex also allowed the observation of bleaching of this maximum upon reduction. It is notable that the spectrum of the resultant $[Cu_2L^9]^{3+}$ ion displayed no maximum near 330 nm, when one might anticipate a halving of intensity relative to the precursor as a result of a reduction of one of the two metal centres. The origins of this phenomenon are not certain, but it appears that there is definitely a strong intramolecular interaction between the two copper centres upon reduction, despite the absence of π-conjugation in the molecule. Previously we have reported[6] that strong intramolecular dipole–dipole coupling, as defined by EPR spectroscopy, occurs in the dicopper(II) complexes of L^8–L^{12}. The present results indicate a rapid intramolecular exchange of the single "hole" in the saturated mixed-valence d^9/d^{10} $[Cu_2L^9]^{3+}$ ion.

A similar result was obtained when the pendent nitro thio-ether amine complexes $[Cu_2L^{11}]^{4+}$ and $[CuL^3]^{2+}$ were reduced with e_{aq}, where a complete disappearance of the intense maximum at 330 nm (indicative of a metal-centred redox reaction) was found upon reduction of the precursor complex. No evidence of nitro radical formation was found and the resultant spectrum displayed no large maxima in the range 270–600 nm (Fig. 1). Products of the e_{aq} reductions of $[Cu_2L^9]^{4+}$, $[Cu_2L^{11}]^{4+}$ and $[CuL^3]^{2+}$ were stable for the duration of the experiment (*ca* 1 ms). It is generally believed that e_{aq} is an indiscriminant reductant, so the present selectivity in reduction of the pendent nitro groups in the $Cu^{II}N_4$ and $Cu^{II}{}_2N_8$ complexes as opposed to metal-centred reduction of the $[CuL^3]^{2+}$ and $[CuL^{11}]^{4+}$ ions is remarkable. The origins of this selectivity presumably lie in the disparate $Cu^{II/I}$ $E_{1/2}$ values for the $Cu^{II}N_4$ and $Cu^{II}N_2S_2$ systems (Table 1), where reduction of the copper(II) centre in $[Cu_2L^{11}]^{4+}$ and $[CuL^3]^{2+}$ is thermodynamically more viable than nitro group reduction [$E_{1/2}$ (—NO_2) −0.85 V *vs* SHE]. The difference in potential between the $Cu^{II/I}$ couple and the nitro group reduction is not nearly as great in the CuN_4 systems, and the nitro group is apparently reduced in preference to the metal centre, although competition between the metal centre and the nitro group for e_{aq} cannot be discounted, since reduction of the copper(II) centre would not result in a large change in the electronic spectrum (*vide supra*).

Oxidations

Oxidation of all $Cu^{II}N_4$ and $Cu_2{}^{II}N_8$ complexes with OH, like reductions with e_{aq}, occurred at effectively diffusion-controlled rates ($\sim 10^{10}$ M^{-1} s^{-1}), the large excess of precursor complex over oxidant again defining only a primary single electron redox process. Generated species exhibit electronic maxima at 370–400 nm and 280–300 nm (Table 2). These products were stable for at least 1 ms, and the spectrum of the final product retained the features of the initially formed complex. The energies and intensities of these maxima are comparable with those reported for the spectra of complexes

Table 2. Electronic spectra of one electron oxidation products

Precursor complex	λ_{max} (ε) (nm) (M^{-1} cm^{-1})
$[CuL^1]^{2+}$	370 (1400), 300 (3500)
$[CuL^2]^{2+}$	390 (1900), 300 (5200)
$[CuL^3]^{2+}$	No change observed
$[CuL^4]^{2+}$	390 (1600), 280 (6600)
$[CuL^5]^{2+}$	360 (1000), 280 (6000)
$[Cu_2L^8]^{4+}$	380 (500), 300 (2300)
$[Cu_2L^9]^{4+}$	No change observed
$[Cu_2L^{10}]^{4+}$	400 (1900), 290 (6000)
$[Cu_2L^{11}]^{4+}$	No change observed
$[Cu_2L^{12}]^{4+}$	380 (560), 300 (3000)

generated by electrochemical,[10,11] pulse radiolysis[12] and flash photolysis[13] oxidation of copper(II) tetraamines. The stability of the complexes is also consistent with other studies that have found tetraazamacrocyclic copper(III) complexes are stable for several minutes in aqueous solution.[10,11] The origins of these electronic maxima are less certain. It has been suggested,[12] albeit tentatively, that these maxima are both of charge-transfer origin, however one would anticipate at least one *d–d* transition ($^1A_2 \leftarrow {}^1A_1$) by analogy with isoelectronic low-spin d^8 nickel(II) complexes. The situation could not be further resolved, and no definitive assignment is made of the copper(III) spectra.

Metal-centred oxidation of the thio-ether amine complexes $[Cu_2L^9]^{4+}$, $[Cu_2L^{11}]^{4+}$ and $[CuL^3]^{2+}$ was not observed, and the intense maximum at 330 nm present in the precursor complexes did not change significantly upon reaction with OH. It is known that hydrogen abstraction is a competitive reaction to metal-centred oxidation,[14] and evidently such a process is occurring upon reaction of the thio-ether complexes with OH. The absence of metal-centred oxidation of these complexes in contrast to the $Cu^{II}N_4$ species may be explained, again, by reference to the $E_{1/2}$ values for the present complexes. It has already been mentioned that there exists a large difference between the $Cu^{II/I}$ $E_{1/2}$ values for the CuN_4 and CuN_2S_2 systems. Although the $Cu^{III/II}$ couples for the present set of complexes lay outside the potential range within which they could be determined with our equipment, other studies of tetraazamacrocyclic copper(II) complexes have defined $Cu^{III/II}$ $E_{1/2}$ values in the range +1.0–1.2 V *vs* SHE in acidic solution.[10,11,15] Recalling that the $Cu^{II/I}$ couples were some 400 mV more negative for the $Cu^{II}N_4$ complexes relative to their $Cu^{II}N_2S_2$ analogues, a similar shift is anticipated for the $Cu^{III/II}$ couple of the thio-ether complexes, i.e. at least to +1.4 V *vs* SHE. Oxidations with OH are unlikely to occur at such extreme potentials in preference to hydrogen abstraction, where the availability of amine and aliphatic hydrogen atoms offers a ready alternative to metal-centred oxidation.

Conclusions

Selectivity in reduction (e_{aq}) and oxidation (OH) has been shown to occur in redox reactions of copper(II) complexes with different ligand fields. The stronger field tetraazacopper(II) complexes exhibit $Cu^{II/I}$ and $Cu^{III/II}$ couples at significantly more negative potentials than the $Cu^{II}N_2S_2$ analogues. The result of this was found to be a preferential reduction of the copper(II) centre instead of the nitro groups in the $Cu^{II}N_2S_2$ complexes, whereas reduction of the pendent nitro $Cu^{II}N_4$ complexes led to nitro radical anions. Oxidation of the $Cu^{II}N_4$ complexes with OH achieved a metal-centred oxidation in contrast to the $Cu^{II}N_2S_2$ complexes which resulted in hydrogen abstraction.

KINETIC STUDY OF THE REACTION OF *MESO*-TETRAKIS (*p*-TRIMETHYLAMMONIUMPHENYL)PORPHINATODIAQUACOBALT(III) WITH THIOCYANATE AND IODIDE IONS IN AQUEOUS SOLUTION

J. G. LEIPOLDT,* W. PURCELL and H. MEYER

Department of Chemistry, University of the Orange Free State, Bloemfontein, Republic of South Africa

(*Received* 2 *November* 1990; *accepted* 5 *February* 1991)

Abstract—The reaction of *meso*-tetrakis(*p*-trimethylammoniumphenyl)porphinatodiaquacobalt(III) with NCS^- and I^- ions has been studied at 15, 25 and 35°C in 0.1 mol dm^{-3} $[H^+]$ (HNO_3) and $\mu = 1.0$ mol dm^{-3} ($NaNO_3$). The values of the acidity constants, K_{a1} and K_{a2}, for the diaqua complex at 25°C are $3.3(5) \times 10^{-7}$ and $2.0(2) \times 10^{-11}$ mol dm^{-3}, respectively. The reactions are first order in ligand concentration up to 0.9 mol dm^{-3}. The values of the second-order rate constants at 25°C are 89.0(5) and 76.0(4) dm^3 mol^{-1} s^{-1} for NCS^- and I^-, respectively. The values of $\Delta S^{\ddagger}$ for the different incoming ligands are positive or nearly positive, which is indicative of dissociative activation. The value of the activation volume [$\Delta V^{\ddagger} = 18.8(8)$ cm^3 mol^{-1}] indeed points to a dissociative mechanism. The porphine ligand greatly labilizes the cobalt(III). There is about a 10^8-fold increase in the rate constant for substitution compared with that of $[Co(NH_3)_5(H_2O)]^{3+}$. It is proposed that the electron-rich porphine not only labilizes the M^{III} ion (M = Co, Rh and Cr) but also promotes a more dissociative activation mode relative to that of the corresponding $[M(NH_3)_5(H_2O)]^{3+}$ complexes. The extent of labilization depends on the electron-donating ability of the porphine as well as the nature of the central metal ion. It is also shown that the overall charge of the complex, whether positive or negative (as determined by the formal charge of the porphine), plays a minor role in the mechanism of the substitution reaction.

It is well known that the porphine ligand labilizes the axial positions in complexes of cobalt(III), rhodium(III) and chromium(III).[1–8] The extent of labilization is dependent upon the metal ion and the other complex to which it is being compared. For example, the anation reactions of *trans*-$[M(TPPS)(H_2O)_2]^{3-}$ [TPPS = *meso*-tetrakis(*p*-sulphonatophenyl)porphine] are about 10^9, 10^3 and 10^2 times faster than those of $[M(NH_3)_5(H_2O)]^{3+}$, where M = Co, Rh and Cr, respectively.[4–6,9] The extent of labilization also depends on the porphine. The relative rate constants for the anation reactions of $[CoP(H_2O)_2]^{n+}$ complexes are 1, 150 and 225 for P = TMPP, TPPS and TCPP, respectively; TMPP = *meso*-tetrakis(4-N-methylpyridyl)porphine and TCPP = *meso*-tetrakis(4-carboxyphenyl)porphine.[2,4,8] The anation reaction of $[Cr(TPPS)(H_2O)_2]^{3-}$ are, however, only about six times faster than those of $[Cr(TMPP)(H_2O)_2]^{5+}$.[6,7]

The large labilization effect of the porphine ligand, especially in the case of the cobalt(III) complexes, has been explained in terms of a dissociative activation. The electron-rich porphine ligand donates electron density to the central metal ion making the cobalt(III) ion (d^6 species) more like a labile d^7 cobalt(II) ion and also stabilizes the five-coordinated intermediate in a dissociative reaction mode.

Strong support for a dissociative activation was recently obtained from high-pressure studies of the reaction between $[Co(TPPS)(H_2O)_2]^{3-}$ and $[Co(TMPP)(H_2O)_2]^{5+}$ and thiocyanate ions as well as thiourea.[10–12] In an attempt to gain more insight into the mechanism of the substitution reactions of porphine complexes of cobalt(III), rhodium(III)

* Author to whom correspondence should be addressed.

and chromium(III), and to compare the labilization effect of different porphines, we have decided to extend this work to the anation reactions of another water-soluble porphine, *meso*-tetrakis(N-trimethyl ammoniumphenyl)porphine (TAPP), complex of cobalt(III).

EXPERIMENTAL

The iodide salt of TAPP was synthesized as described by Krishnamurthy.[13] The cobalt(III) complex of TAPP was synthesized by heating a solution of the iodide salt (150 mg) and $CoCl_2 \cdot 6H_2O$ (600 mg, a large excess) in 50 cm^3 of water for 2 h on a waterbath while oxygen was bubbled through. During this time all the free porphine was converted into the cobalt(III) complex as was indicated by the visible spectrum of the solution. The solution was filtered to remove all the insoluble impurities and allowed to cool. About 10 drops of concentrated perchloric acid were added. The addition of perchloric acid caused the perchlorate salt, $[Co(TAPP)(H_2O)_2](ClO_4)_5$, to precipitate. The product was filtered, washed with ethanol and ether and allowed to dry in the atmosphere at room temperature. The Soret band for this complex is at 426 nm with a molar absorptivity of 2.01×10^5 mol^{-1} dm^3 cm^{-1}.

A plot of absorbance vs pH at 431 nm (Fig. 1) clearly showed that $[Co(TAPP)(H_2O)_2]^{5+}$ is diprotic. It is obvious that the two steps are sufficiently separated to evaluate K_{a1} and K_{a2} (see Scheme 1) independently. From the equilibrium constant expression, the mass balance and Beer's law equation (1) could be derived. A_a is the absorbance of the acid form and A_b of the basic form. The absorbance vs pH data were fitted to eq. (1) using a non-linear least-squares program.

$$A = (K_a A_b + A_a[H^+]/K_a + [H^+]) \quad (1)$$

The values pK_{a1} and pK_{a2} were determined, respectively, as 6.48 ± 0.08 and 10.70 ± 0.09 at 25°C and $\mu = 1.00$ mol dm^{-3} ($NaNO_3$).

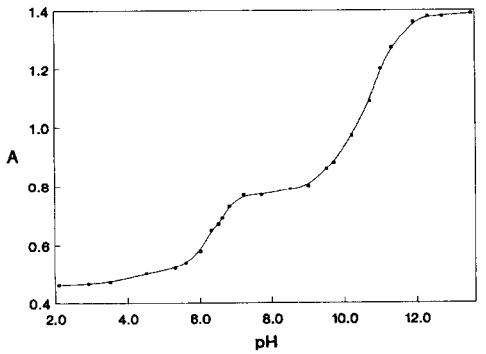

Fig. 1. Change in absorbance as a function of pH at 431 nm.

The values of the stability constants, K_1, for the different incoming ligands at 25°C in 0.1 mol dm^{-3} HNO_3 and $\mu = 1.0$ mol dm^{-3} ($NaNO_3$) were determined spectrophotometrically. The absorbance was measured at different ligand concentrations. From Beer's law, mass balance and the stability constant expression, eq. (2) could be derived:

$$A = (A_r + A_p K_1[L])/(1 + K[L]). \quad (2)$$

A_r is the absorbance of a solution of $[Co(TAPP)(H_2O)_2]^{5+}$, A_p is the absorbance of the product and L is the incoming ligand. The values of K_1 were determined by fitting the absorbance vs [L] data to eq. (2) using a non-linear least-squares program and are listed in Table 1.

The anation reactions between $[Co(TAPP)(H_2O)_2]^{5+}$ and NCS^- and I^- ions were studied at 15, 25 and 35°C in 0.1 mol dm^{-3} HNO_3 and $\mu = 1.0$ mol dm^{-3} ($NaNO_3$). The reaction rates are independent of the $[H^+]$ at $[H^+] > 10^{-3}$ mol dm^{-3}. This clearly indicates that $[Co(TAPP)(H_2O)_2]^{5+}$ is the only reactive species under the experimental conditions. All the kinetic runs were performed under pseudo-first-order conditions, $[L] \gg [Co(TAPP)(H_2O)_2^{5+}]$, where the value of k_{obs} is given by eq. (3), see also Scheme 1:

$$k_{obs} = k_1[L]. \quad (3)$$

Figure 2 is a typical plot of k_{obs} vs [L]. The kinetic results obtained in this way are summarized in Table 1. The activation parameters ($\Delta H^\ddagger$ and $\Delta S^\ddagger$) were calculated by means of a non-linear least-squares fit of the k_1 vs temperature data to the Eyring–Polanyi equation and are also reported in Table 1.

The high-pressure kinetic data for the anation reaction with thiocyanate ions were obtained by means of a thermostatted high-pressure stopped-flow system.[14] The value of $\Delta V^\ddagger$ was calculated from the slope of the linear plot of ln k vs P using eq. (4):

$$\ln k = -\Delta V^\ddagger P/RT. \quad (4)$$

The results are summarized in Tables 1 and 2.

DISCUSSION

The relative high values of pK_{a1} and pK_{a2} {compared with other cobalt(III) complexes like $[Co(en)_2(H_2O)_2]^{3+}$ [15]} indicate that the four nitrogen atoms of TAPP are donating electron density to cobalt(III), since the pK_a values should depend on the electron density on the aqua-oxygen atom and thus also on that on the cobalt ion. The pK_{a1} values

$$[Co(TAPP)(H_2O)_2]^{5+} + L^{n-} \underset{k_{-1}}{\overset{k_1; K_1}{\rightleftharpoons}} [Co(TAPP)(H_2O)L]^{(5-n)+} + H_2O$$

$$K_{a1},\ H^+ \Big\| \Big\downarrow +H^+$$

$$[Co(TAPP)(H_2O)(OH)]^{4+}$$

$$K_{a2},\ -H^+ \Big\| \Big\downarrow +H^+$$

$$[Co(TAPP)(OH)_2]^{3+}$$

Scheme 1. Reaction scheme under the experimental conditions.

of different porphine complexes of cobalt(III) (see Table 3) increase in the order TMPP < TAPP < TPPS < TCPP, which is the expected order since the electron donating ability of the porphines increase in the same order.

The trend in the values of the stability constants (see Table 1; no reaction was observed for Br^- and Cl^- ions as incoming ligands, indicative of very low stability constants for the bromide and chloride complexes) indicates that cobalt(III) behaves as a soft acid. This is also the case for the porphine complexes of rhodium(III) studied so far[5,16] and may be explained in terms of the delocalized electron density in the porphine ligand that is apparently available to the central metal ion. The stability constants for $[Co(TPPS)(H_2O)(NCS)]^{4-}$, 2640 M^{-1} (see ref. 3) and $[Co(TAPP)(H_2O)(NCS)]^{4+}$, 3300 M^{-1} (see Table 1), are about the same, indicating that the overall charge on the complex plays a minor role in determining the stability constants. This may be explained by the fact that the formal charge on the complex is spread over a very large planar surface area, especially since the negatively-charged sulphonato groups (in TPPS) and the positively-charged ammonium groups (in TAPP) are far removed from the positive metal centre. The mode of bonding of the thiocyanate ion is unknown but one would anticipate that the ligand is sulphur bonded because of the apparent softness of cobalt(III).

The reaction of $[Co(TAPP)(H_2O)_2]^{5+}$ with NCS^- and I^- shows no deviation from second-order kinetics up to 0.9 mol dm^{-3} concentration of the incoming ligand. Under our experimental conditions the overall reaction studied can be represented by Scheme 1. The positive values for the entropy of activation is indicative of a dissociative activation. The comparison of the stability and the rate constants also gives an indication of the mode of activation. The stability constants for the NCS^- and I^- complexes differ by a factor of about 35 while the rate constants for these incoming ligands are about the same. This indicates that the rate is not sensitive to the nature of the incoming ligand but sensitive to the nature of the leaving group, which also points to a dissociative activation.

The equilibrium constant, K_1, for the reaction with NCS^- and the $[NCS^-]$ used in the high-pressure study were such that the observed rate constant is given by eq. (3). The pressure dependence of k_1 was therefore calculated from the pressure dependence of k_{obs} at excess NCS^-. The plot of ln k_1 vs pressure was linear and the volume of activation, $\Delta V^{\ddagger}_{expt}$, was calculated from the slope of this line. The large positive value of $\Delta V^{\ddagger}_{expt}$ can also be interpreted as evidence for a dissociative mechanism as

Table 1. Kinetic and equilibrium data for the reaction $[Co(TAPP)(H_2O)_2]^{5+} + L^{n-} \rightleftharpoons [Co(TAPP)(H_2O)(L)]^{(5-n)+} + H_2O$[a]

	NCS^-	I^-
k_1 ($dm^3\ mol^{-1}\ s^{-1}$)	89.0	76.0
K_1 ($dm^3\ mol^{-1}$)	3300	95
$\Delta H^{\ddagger}$ (kJ mol^{-1})	66(1)	63(8)
$\Delta S^{\ddagger}$ (J $mol^{-1}\ K^{-1}$)	14(4)	3(30)
$\Delta V^{\ddagger}$ ($cm^3\ mol^{-1}$)	18.8	—

[a] $[H^+] = 0.1$ mol dm^{-3}, $\mu = 1.0$ mol dm^{-3} ($NaNO_3$). The rate constants are at 25°C.

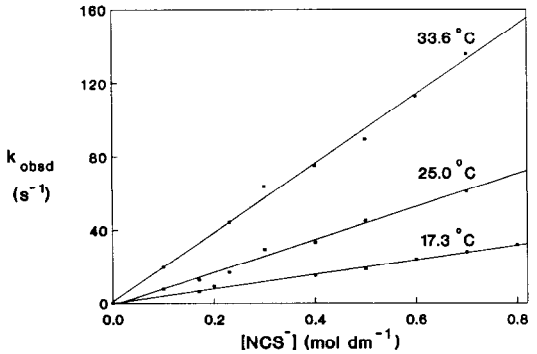

Fig. 2. Plot of k_{obs} vs $[NCS^-]$ at $[H^+] = 0.1$ mol dm^{-3} and $\mu = 1.0$ mol dm^{-3}.

Table 2. k_{obs} as a function of pressure for the anation of [Co(TAPP)$(H_2O)_2]^{5+}$ by NCS^- at 20°C[a]

P (bar)	20	250	500	750	1000
k_1 (dm^{-3} mol s^{-1})	61.2	52.5	42.0	34.5	29.0

[a] $[H^+] = 0.1$ mol dm^{-3} and $[NCS^-] = 0.1$ mol dm^{-3}.

outlined in reactions (5) and (6) :

$$[Co(TAPP)(H_2O)_2]^{5+} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [Co(TAPP)(H_2O)]^{5+} + H_2O \quad (5)$$

$$[Co(TAPP)(H_2O)]^{5+} + NCS^- \xrightarrow{k_3} [Co(TAPP)(H_2O)(NCS)]^{4+}. \quad (6)$$

For this reaction scheme

$$k_{obs} = \frac{k_2 k_3 [NCS^-]}{k_{-2} + k_3 [NCS^-]}, \quad (7)$$

which can be simplified to

$$k_{obs} = \frac{k_2 k_3}{k_{-2}} [NCS^-], \quad (8)$$

since it was observed that plots of k_{obs} vs $[NCS^-]$ were linear with a zero intercept, indicating that $k_{-2} \gg k_3[NCS^-]$ under our experimental conditions.

From eq. (8) it follows that $\Delta V^{\ddagger}_{expt} = \Delta V^{\ddagger}(k_2) + \Delta V^{\ddagger}(k_3) - \Delta V^{\ddagger}(k_{-2})$. It is expected that both k_3 and k_{-2} would be negative since these steps involve bond formation. It may further be assumed that $|\Delta V^{\ddagger}(k_3)| \geq |\Delta V^{\ddagger}(k_{-2})|$ since the molar volume of NCS^- is larger than that of H_2O. This means that $\Delta V^{\ddagger}(k_2)$ should be at least as large as $\Delta V^{\ddagger}_{expt}$, 18.8 cm^3 mol^{-1}, and clearly points to a dissociative mechanism.

Comparison of the volume of activation for the reaction between $[Co(TPPS)(H_2O)_2]^{3-}$ and NCS^- ($\Delta V^{\ddagger}_{expt} = 15.4$ cm^3 mol^{-1} [10]) and that between $[Co(TMPP)(H_2O)_2]^{5+}$ and thiourea ($\Delta V^{\ddagger}_{expt} = 12.6$ cm^3 mol^{-1} [12]) with the volume of activation for the reaction between $[Co(TAPP)(H_2O)_2]^{5+}$ and NCS^- indicates that the overall charge of the porphine complex, as well as the charge of the incoming ligand, do not play a very significant role in determining the volume of activation.

The order of the rate constants for the reaction of thiocyanate ions with the different porphine complexes (TMPP < TAPP < TPPS < TCPP, see

Table 3) is the expected trend, since the electron-donating ability of the different porphines increases in the same order. It is, however, noticeable that this effect of the different substituents on the porphine, as well as the amount of labilization (compared with the pentammineaqua complexes), is much less for the rhodium(III) and especially the chromium(III) complexes, see Table 3. The changes in the volumes of activation of the pentammineaqua complexes to that of the porphine complexes point to a change from an Ia to an Id mechanism for the chromium(III) and rhodium(III) complexes and from an Id to a D mechanism for the cobalt(III) complexes, see Table 3. The central metal ion thus seems to control the extent to which the porphine can modify the reactivity as well as the mode of the substitution process.

Finally, the results of this investigation clearly demonstrate how the presence of the porphine ligand promotes a dissociative reaction mode and thus accounts for the large labilizing effect of the porphine ligand. The electron-rich porphine presumably donates electron density to the cobalt(III) ion making it more like a labile cobalt(II) ion and thus also stabilizes the five-coordinated intermediate in a dissociative mechanism.

Abstract—The interaction of uncharged N-donor ligands with the complex $[Eu(CH_3COO)_2L]Cl\cdot 4(H_2O)$, where L is the macrocyclic ligand $C_{22}H_{26}N_6$, was investigated in solution by NMR spectroscopy and luminescence titration. Both experiments indicated little or no interaction of the N-donor ligands with the metal centre of the macrocyclic complex. Attempts to isolate a 1,10-phenanthroline complex of the europium macrocycle produced instead $\{[Eu(CH_3COO)L]_2(\mu\text{-}CO_3)\}(OH)_2\cdot 7H_2O$, which incorporated atmospheric carbon dioxide. The X-ray crystal structure showed a bis-chelating carbonato group linking two europium macrocycles, each of which was folded in a butterfly configuration towards the external bidentate chelating acetates. Ionic hydroxides and clathrated water molecules completed the structure.

The lanthanide(III) complexes of formula $M(CH_3COO)_2LCl\cdot n(H_2O)$,[1] in which L is the macrocyclic ligand $C_{22}H_{26}N_6$ shown in Fig. 1, afford a unique opportunity to investigate the interaction of the metal centre with external ligands due to the kinetic inertness of the metal–macrocycle moiety. These complexes dissolve in water as well as organic solvents, and are inert to metal release even under acidic or basic conditions, and in the presence of competing ligands. The integrity of the ML entity in solution is confirmed, for both diamagnetic and paramagnetic analogues, by ^1H and ^{13}C NMR spectroscopy.[2,3] In contrast, the exocyclic acetate ligands are labile and easily exchanged; in aqueous solution they are partly replaced by water unless an excess of acetate is present.[4] Because the quasi-equatorial macrocyclic ligand remains bound to the

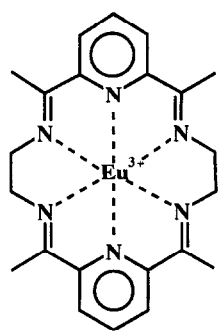

Fig. 1. Schematic formula of the $[Eu(C_{22}H_{26}N_6)]^{3+}$ macrocyclic moiety.

* Author to whom correspondence should be addressed.

metal in solution, the number and geometry of external ligands which may interact with the metal centre are limited. Thus, investigations in solution are greatly simplified by the small number of species which may be present.

The solution behaviour of these complexes is consistent with the solid state structure established for the neodymium,[2] europium,[2] and gadolinium[5] analogues by X-ray crystallography. In these species the metal centre is linked to the six N-donor atoms in a quasi-planar arrangement, while the organic portion of the molecule adopts a folded "butterfly" configuration that minimizes strain. The two bidentate acetates occupy staggered positions on opposite sides of the macrocycle, and an ionic chloride balances the residual charge of the complex.

In the present work, the interaction of the $[M(CH_3COO)_2L]Cl{\cdot}n(H_2O)$ complexes with uncharged nitrogen-donor ligands has been investigated using europium(III) as the metal centre. Europium was chosen because it lends itself to two sensitive and complementary investigative techniques. First, europium(III) retains appreciable Lewis-acidic character in many of its complexes, and can interact with substrates bearing Lewis-basic functionalities to cause paramagnetic shifts and possible broadening of the substrate resonances; certain europium(III) complexes are widely employed as NMR shift reagents.[6] Thus, NMR experiments may serve to determine how the presence of the paramagnetic {EuL} moiety alters the spectral properties of an external ligand. Second, europium(III) exhibits a narrow-band luminescence which arises from electronic transitions within the 4*f* manifold and may be sensitized by the addition of appropriate ligands.[7] Thus, luminescence titration studies can probe the effects of an external ligand on the luminescent behaviour of the europium macrocycle centre. We report here the results of this dual investigation for a series of neutral N-donor ligands including primary amines, as well as monodentate and bidentate chelating heterocycles.

EXPERIMENTAL

Materials and procedures

The complex $[Eu(CH_3COO)_2L]Cl{\cdot}4(H_2O)$ was prepared as previously described.[1] Ligands (1-aminobutane, 2-aminobutane, 2-amino-2-methylbutane, ethylenediamine, aniline, pyridine, 1,10-phenanthroline and 2,2′-bipyridyl) were commercially available and were purified as appropriate before use. Absorption spectra (UV–vis) were obtained with a Beckmann Acta MVIII spectrophotometer. Luminescence measurements were carried out with an SLM-Model 8000 spectrofluorometer. Proton NMR spectra were recorded on a GE QE-300 spectrometer and referenced to TMS.

NMR experiments

Methanol-d_4 (Aldrich) and deuterochloroform (Aldrich) were employed as solvents. In all experiments the ^1H NMR spectrum of a 3.0×10^{-2} M solution of the N-donor ligand was obtained first. An equivalent molar amount of the crystalline europium macrocyclic complex was then added to the NMR tube and the spectrum of the resulting solution was recorded.

Luminescence titrations

All experiments were carried out according to the following general procedure. A set of four solutions was prepared, containing the same concentration (2.0×10^{-4} M) of the $[Eu(CH_3COO)_2L]Cl{\cdot}4(H_2O)$ complex but increasing concentrations of the N-donor ligand (europium–ligand mole ratios = 1 : 1, 1 : 2, 1 : 3 and 1 : 4). Emission and excitation spectra were recorded under identical conditions for each set of solutions and the relative intensities of the $^5D_0 \rightarrow {}^7F_2$ Eu^{III} emission at *ca* 614 nm were compared with the emission of an equimolar solution of the europium complex alone. No appreciable change in either the excitation or emission spectrum was observed for any of the ligands, with the exception of 2,2′-bipyridyl which gave a modest luminescence enhancement for 1 : 1 to 1 : 1.5 mole ratios.

Attempted isolation of solid adducts

Concentration of the stoichiometric 1 : 1 mixtures from NMR experiments, or dilution of the same with diethyl ether, consistently failed to produce any solid (EuL)-(N-donor) adduct. Similarly, no adducts were obtained from bulk solutions (in chloroform or methanol) containing an excess of the N-donor ligands. In each case, only the original complex and the "free" N-donor ligand were recovered. Attempts using a europium–1,10-phenanthroline mole ratio of 1 : 10 in methanol gave, by slow evaporation of the solution in air, minute yields of a yellow crystalline compound of formula $\{[Eu(CH_3COO)L]_2(\mu\text{-}CO_3)\}(OH)_2{\cdot}7H_2O$.

X-ray measurements and structure determination

A transparent pale yellow prismatic single crystal of $\{[Eu(CH_3COO)L]_2(\mu\text{-}CO_3)\}(OH)_2{\cdot}7H_2O$, measuring $0.1 \times 0.22 \times 0.16$ mm, was centred on a four-

circle Philips PW 1100 diffractometer with graphite-monochromated Mo-K_α radiation. The intensity data were corrected for Lorenz-polarization effects and for absorption, following the method of North *et al.*[8] The structure was solved using Patterson and Fourier techniques and refined with full-matrix least squares. Non-hydrogen atoms were allowed to vibrate anisotropically. Carbon-linked hydrogen atoms were introduced at calculated positions and allowed to ride on associated carbon atoms during the least squares refinement ($d_{C-H}=0.98$ Å and $U=0.08$ Å^2). The H atoms of the water molecules, which were disordered among two or three positions, were not introduced. The final difference Fourier map showed a few residuals of the order of 0.6 e/Å^3, close to the water positions and assigned to the disordered hydrogens; two major residuals of about 1 e/Å^3 were present near each europium(III) position. The programs used were SHELX 76[9] for structure solution and refinement, ORTEP[10] and PLUTO[11] for drawings, and PARST[12] for geometrical calculations. Atomic scattering factors were taken from ref. 13.

Crystal data are reported in Table 1, bond lengths and angles in Table 2, and torsion angles in Table 3. Supplementary material (tables of atomic coordinates, atomic vibrations, and calculated structure amplitudes) has been deposited at the Cambridge Data Centre.

RESULTS AND DISCUSSION

Solution studies

The results of the NMR experiments are summarized in Tables 4 and 5. The N-donor ligands investigated in methanol included primary aliphatic and aromatic amines (1-aminobutane, 2-aminobutane, 2-amino-2-methylbutane, ethylenediamine and aniline), as well as nitrogen-containing heteroaromatics (pyridine, 1,10-phenanthroline and 2,2′-bipyridyl). In each case the chemical shifts of the macrocycle protons were sufficiently removed from those of the added ligands so that the two sets of resonances did not interfere. In methanol, a comparison between the spectra of the N-donor ligands alone and the spectra of solutions containing the metal-macrocycle and the

ligand in 1 : 1 mole ratio indicated only minimal metal–ligand association. No significant shift was observed for the resonances of any of the N-donors, even though the ability of $[Eu(CH_3COO)_2L]Cl \cdot 4(H_2O)$ to shift ligand resonances has been demonstrated for a series of carboxylate ligands.[14] The heteroaromatic ligands, which are known to form complexes with "free" europium(III), were also investigated in $CDCl_3$ to minimize solvent competition. Even in this non-coordinating solvent, no significant shifts in the proton NMR spectra were observed. It is reasonable to conclude that the association of the acetate groups with the metal must persist in solution, prohibiting significant interaction of the N-donor ligand with the metal centre.

These conclusions are in full agreement with the results of the luminescence titration experiments. Minimal or no change in the intensity of the typical europium(III) emissions was observed upon addition of the N-donor ligands to the $[Eu(CH_3COO)_2L]Cl \cdot 4(H_2O)$ complex, even with 1,10-phenanthroline or 2,2′-bipyridyl, which are known to form highly luminescent complexes with the "free" europium(III) ion.[15,16] Still more significantly, there was no appreciable shift in the excitation spectrum,

indicating that whatever luminescence was observed arose from the original complex and did not involve energy transfer from the N-donor ligand to the europium(III) centre.

Efforts to isolate solid (EuL)-(N-donor) adducts consistently failed. In one set of experiments with a europium–1,10-phenanthroline ratio of 1 : 10, a novel yellow crystalline complex was obtained as a result of the absorption of atmospheric carbon dioxide by the strongly basic solution. The structure of this unusual complex is described in the following section.

Crystal structure of the carbonato-bridged complex, $\{[Eu(CH_3COO)L]_2(\mu\text{-}CO_3)\}(OH)_2 \cdot 7H_2O$

The compound is ionic, with dimeric complex cations (Fig. 2) consisting of two EuL moieties linked through a bridging as well as chelating carbonate. The two moieties are related by a crystallographic two-fold axis passing through the carbon atom [C(40)] and one of the oxygen atoms [O(3)] of the carbonato bridge. Each europium ion is further linked to a bidentate chelating acetate on the external side of the {Eu—CO_3—Eu} core. Thus the coordination sphere of each europium includes the six nitrogen atoms of the macrocycle in the equatorial plane and two pairs of oxygen atoms, one from the acetate and one from the carbonate, on opposite sides of the macrocycle. An ORTEP view of the asymmetric half-dimer is shown in Fig. 3. Two ionic hydroxides balance the residual charges of the complex cations; clathrated water molecules (seven per dimeric unit) complete the structure. The unit cell is illustrated in Fig. 4.

The two macrocycle moieties of the dimer are folded toward the external acetates and have the "butterfly" configuration found in other lanthanide complexes of this ligand. Each macrocycle consists of two quasi-planar sections containing the pyridine rings and hinged at the —CH_2CH_2— side chains, with an angle of 131.8(2)°. This value is very close to that found in the monomeric $[Eu(CH_3COO)_2L]^+$ moiety of the diacetate chloride complex [132.37(6)°].[2] The torsion angles at the —CH_2CH_2— side chains, −56(1)° [N(2)—C(8)—C(9)—N(3)] and −58(1)° [N(5)—C(19)—C(20)—N(6)], are also nearly identical with the corresponding angles of the diacetate chloride, −55.8(5)° and −58.0(5)°. A ring puckering analysis[17] of the six N-donor atoms showed a minor deviation from planarity, in a twisted boat conformation with puckering constants $Q = 1.00(1)$, $\Theta = 88.3(7)°$, and $\Phi = -138.7(6)°$.

The two acetate ligands of the dimeric complex are staggered with respect to the bridging carbonate and are oriented along the fold line of the respective macrocycle. However, the plane of each acetate is

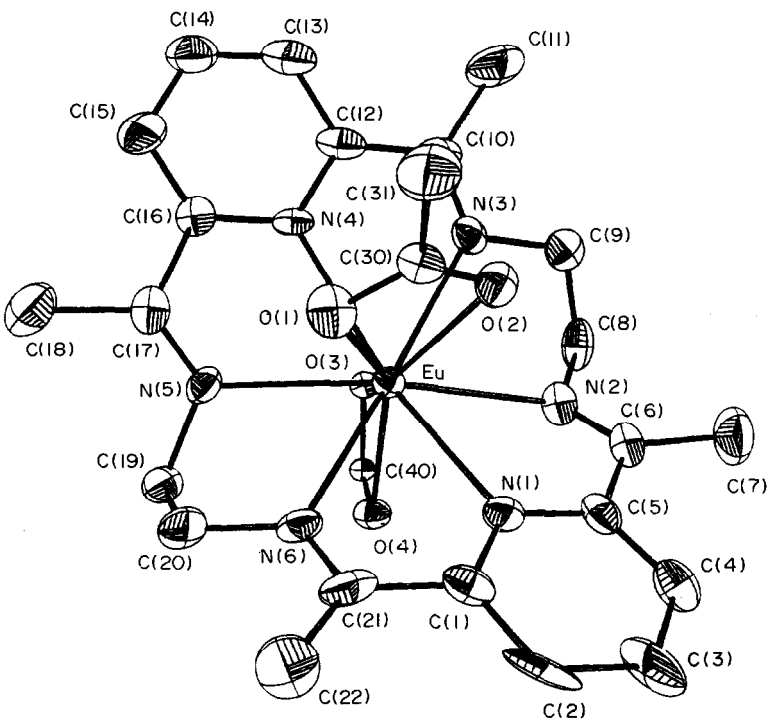

Fig. 3. ORTEP view of the asymmetric half-dimer.

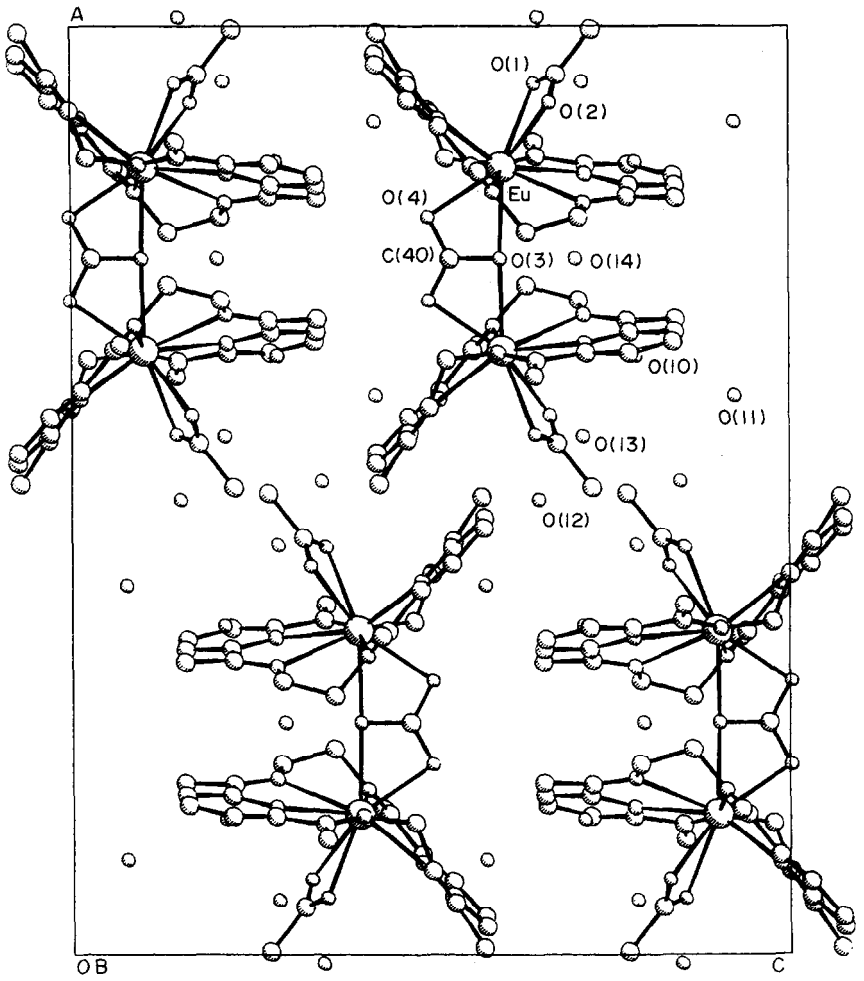

Fig. 4. Unit cell of $\{[Eu(CH_3COO)L]_2(\mu\text{-}CO_3)\}(OH)_2 \cdot 7H_2O$ (PLUTO view down the *b*-axis).

tilted relative to the plane bisecting the macrocycle at the fold. The angle formed by the acetate with the C(9)... N(4)... C(19) section of the macrocycle is 127.0(4)°, whereas the angle formed with the C(8)... N(1)... C(20) section is 78.8(4)°. A similar asymmetry was observed for the acetate ligand on the concave side of the $[Eu(CH_3COO)_2L]^+$ species; the corresponding angles were 102.6(2)° and 55.1(2)°. The dimeric complex Eu—O(acetate) distances are, on average, appreciably longer than the Eu—O(carbonate) distances [2.53(1) versus 2.444(1) Å], and are also somewhat longer than the average Eu—O(acetate) distances [average value 2.48(1) Å] of the $[Eu(CH_3COO)_2L]^+$ complex.[2] This difference between two europium complexes having the same coordination number and containing the same macrocyclic ligand shows that substitution of an acetate by a bridging carbonate influences, either sterically or electronically, the strength of the bonding between the metal and the acetate on the opposite side of the macrocycle. The effect is limited to the anionic axial ligands, since the Eu—N distances are extremely similar in the two complexes.

The features of the bridging carbonate group, although not completely novel, are unusual and deserve comment. A bridging carbonate most commonly exhibits bidentate chelation to one metal centre and monodentate coordination to the other, through the third oxygen atom. In the dimeric complex discussed here the bridging CO_3^{2-} ion acts instead as a chelating ligand to both europium ions and is symmetrically positioned between the two halves of the dimer due to the presence of the crystallographic two-fold axis. Within each half-dimer the Eu—O and C—O distances are rather asymmetric. The Eu—O(3) distance, 2.493(1) Å, is significantly longer than the Eu—O(4) distance, 2.394(8) Å, whereas the C(40)—O(3) distance, 1.34(2) Å, is correspondingly shorter than the C(40)—O(4) distance, 1.27(1) Å. This relationship contrasts with that existing in the carbonato-bridged copper(II) complex $[(CuL)_2(\mu\text{-}CO_3)](ClO_4)_2$

(L = 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene),[18] in which the shorter C—O distances are those corresponding to the shorter Cu—O distances. Both the europium and the copper dimers, however, show the same decrease of the O—C—O angle from the trigonal planar 120° to 117° upon formation of the strained four-atom chelate ring. The C—O distances in the europium complex indicate that the C=O double bond on the side of the shorter Eu—O bond is stabilized. A similar situation was reported for the asymmetric bridging carbonate in the $Rh_2H_2(O_2CO)(PhC{\equiv}CPh)[P(i\text{-}Pr)_3]_2$ dimer,[19] where electronic factors related to the π-bonding ligands may play an important role in determining the C—O bond lengths.

As illustrated in Fig. 4, the unit cell of $\{[Eu(CH_3COO)L]_2(\mu\text{-}CO_3)\}(OH)_2\cdot 7H_2O$ contains a total of nine non-coordinated oxygen atoms per dimeric complex unit. Two of these oxygen atoms must belong to OH^- ions, as required for ionic charge balance; the others belong to clathrated water molecules. Of the nine oxygen atoms, eight form symmetry-related pairs and one, O(14), occupies a unique position in the plane bisecting the complex perpendicular to the Eu—Eu axis. The H-atoms are disordered; thus their positions cannot be defined unambiguously and it becomes difficult to differentiate between the OH^- ions and the water molecules. A possible distinguishing feature is the presence of six pairs of short contact distances [O(14)...O(10) 3.08(2), O(10)...O(11) 2.92(2), O(10)...O(13) 3.12(2) Å, and the symmetry-related pairs] that most likely arise from hydrogen bonding among the water molecules. The two oxygen atoms [O(12) and its symmetry counterpart], which are not involved in hydrogen bonding, may then be assigned to the OH^- ions.

CONCLUSIONS

It is evident from the results of the NMR and luminescence experiments, and also from the unsuccessful attempts to isolate solid adducts, that uncharged N-donor ligands have no tendency to coordinate to the $[Eu(CH_3COO)_2L]^+$ entity, regardless of their type or denticity. This behaviour contrasts with that of the anionic NCS^- ligand, which replaces the acetates readily to yield a molecular complex of the formula $[Eu(NCS)_3L]$, in which the central europium is bound only to nine nitrogen donor atoms.[20] It may be concluded that the lack of interaction between $[Eu(CH_3COO)_2L]^+$ and uncharged N-donor species results from the inability of the latter to replace the negatively charged acetates, rather than from any intrinsic preference of the europium(III) for O-donor ligands.

Abstract—The reaction of cobalt(II) acetate with 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (**L**) in acetonitrile results in the spontaneous assembly of a binuclear double helical complex. The electrochemical behaviour of this compound is complex. The driving force for the assembly of the complex is probably associated with the close stacking contacts between approximately co-planar pyridine rings; there are no direct metal–metal interactions.

Although the coordination chemistry of 2,2′-bipyridine[1,2] and 2,2′:6′,2″-terpyridine[3] has been intensively investigated over the past century, the interactions of the higher oligopyridines with metals has only recently attracted any interest.[3] We have been particularly interested in the coordination behaviour of 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine[4–11] (qpy) and 2,2′:6′,2″:6″,2‴:6‴,2⁗:6⁗,2⁗′-sexipyridine,[12,13] which we have demonstrated to form double- or single-helical binuclear coordination compounds with a range of metals. We have commented elsewhere upon the various factors which control the assembly of a double-helical ligand array.[14,15] In this paper, we wish to describe the formation of a double-helical binuclear complex of qpy with cobalt(II).

EXPERIMENTAL

IR spectra were recorded on a Perkin–Elmer 1710 Fourier transform spectrophotometer, with the samples in compressed KBr discs. Fast atom bombardment (FAB) and electron impact (EI) mass spectra were recorded on a Kratos MS-50 spectrometer, with 3-nitrobenzyl alcohol as matrix for the FAB spectra; ESR spectra were recorded on a Varian E-109 spectrometer as frozen acetonitrile glasses at 90 K. Electrochemical measurements were performed using an AMEL model 553 potentiostat, model 567 function generator and model 721 integrator connected to an *X–Y* recorder via an AMEL model 560/A interface. A conventional three-electrode configuration was used, with platinum bead working and auxiliary electrodes and an Ag/AgCl reference. Ferrocene was added at the end of each experiment as an internal standard. Controlled-potential electrolyses were performed using a cylindrical platinum gauze as working electrode and a smaller, co-axial platinum gauze as auxiliary electrode (separated by a frit). The solvent was acetonitrile in all cases, distilled from CaH_2 and then P_4O_{10} and stored over 4 Å molecular sieve. The base electrolyte was 0.1 M $[Bu^n_4N][BF_4]$, recrystallized twice from methanol/water. Potentials are quoted *vs* ferrocene/ferrocenium couple ($Fc/Fc^+ = 0.0$ V), and all potentials were referenced to internal ferrocene added at the end of each experiment. 2,2′:6′,2″:6″,2‴:6‴,2⁗-Quinquepyridine was prepared by the Krohnke method[16] as we have described earlier,[4–11] cobalt acetate was used as supplied by Aldrich.

Preparation

2,2′:6′,2″:6″,2‴:6‴,2⁗-Quinquepyridine (0.1 g, 0.26 mmol) was added to a solution of $Co(OAc)_2 \cdot 4H_2O$ (0.07 g, 0.28 mmol) in methanol (25 cm^3) and the mixture heated to reflux for 1 h, after which period an orange–brown solution had been obtained. This solution was filtered through Celite and the clear filtrate treated with a methanolic solution of ammonium hexafluorophosphate to yield an orange precipitate. Recrystallization of this solid from acetonitrile by the diffusion of diethyl ether vapour into the solution yielded orange blocks of $[Co_2(qpy)_2(OAc)][PF_6]_3$ (Found: C, 44.7; H, 2.8; N, 9.8. Calc. for $C_{52}H_{37}N_{10}Co_2O_2P_3F_{18}$: C, 45.0; H, 2.7; N, 10.1%) and pink needles of $[Co_2(qpy)_2][PF_6]_4$ (Found: C, 38.9; H, 2.7; N, 9.6. Calc. for $C_{50}H_{34}N_{10}Co_2P_4F_{24}$: C, 39.8; H, 2.5; N, 9.3%).

Crystal structural determination of $[Co_2(qpy)_2(OAc)][PF_6]_3 \cdot 3MeCN$

Orange blocks of the compound were obtained by the diffusion of diethyl ether vapour into an acetonitrile solution of the complex. An orange single crystal was mounted in a glass capillary tube. All geometric and intensity data were taken from this crystal using an automated four-circle diffractometer (Nicolet R3mV) following procedures described previously.[17] Pertinent crystallographic data are given in Table 1. Lattice dimensions were verified by axial photography. Intensity data, gathered by the ω-2θ method were reduced by routine procedures. Calculations were carried out using a Micro-Vax II with the program SHELXTL PLUS.[18] Empirical absorption corrections were applied.

All the non-hydrogen atoms were located by direct methods, and the cobalt, carbon, nitrogen, oxygen and phosphorus atoms refined anisotropically. Pyridine and acetate hydrogen atoms were placed

in idealized positions with fixed isotropic thermal parameters, $U_{py}=0.07$ Å^2, $U_{acetate}=0.16$ Å^2. The hydrogen atoms of the lattice acetonitrile solvent molecules were not located. The PF_6 anions showed positional disorder and were treated as two interlocking octahedra with a common isotropic temperature factor for F and the two positional sets for each anion were refined with occupancies of k and $1-k$. One of the three lattice MeCN molecules exhibited a two-fold positional disorder. The final difference Fourier map had no peaks larger than 0.95 e/Å^3. Selected bond angles and bond distances are given in Table 2.

RESULTS AND DISCUSSION

Upon heating a suspension of qpy with a methanolic solution containing an equivalent amount of cobalt(II) acetate, an orange–brown solution was obtained. Concentration of this solution, followed by the addition of ammonium hexafluorophosphate resulted in the precipitation of a solid. Recrystallization of this product from acetonitrile by the diffusion of diethyl ether vapour into the solution resulted in the formation of two different types of crystal (orange blocks and pale pink needles) which could be separated by hand. Both of these crystalline products were found to lose solvent and collapse to powders upon standing in air or upon drying *in vacuo*. The FAB mass spectra of these two compounds both exhibited peaks at m/z 1327, 1182, 1037, 892 and 446 which may be assigned to the species $\{[Co_2(qpy)_2][PF_6]_3\}^+$, $\{[Co_2(qpy)_2][PF_6]_2\}^+$, $\{[Co_2(qpy)_2][PF_6]\}^+$, $\{[Co_2(qpy)_2]\}^+$ and $\{[Co_2(qpy)]\}^+$, respectively. Partial elemental analyses of the two compounds were in accord with the formulation $[Co_2(qpy)_2][PF_6]_4$ for the pink compound and $[Co_2(qpy)_2(OAc)][PF_6]_3$ for the orange blocks. The IR spectra of the two complexes in the region 1300–1600 cm^{-1} are different, but there are numerous qpy absorptions in this part of the spectrum and it is not possible to unambiguously assign stretching modes to the acetate groups. The orange complex is paramagnetic with a room temperature magnetic moment of 4.90 BM per cobalt centre, which compares favourably with the value of 4.78 BM reported for the mononuclear complex $[Co(ptqpy)Cl_2]$.[19] The ESR spectrum at −196 K of an acetonitrile glass containing the complex exhibits a broad, featureless, apparently isotropic absorption at g_{av} 3.71 which does not show any hyperfine splitting.

The orange compound is electrochemically active and exhibits an unusually rich and complex redox behaviour, in contrast to that observed for the copper[5,6] and nickel[4,8] analogues. The cyclic voltammogram of an acetonitrile solution is presented in Fig. 1. The behaviour is consistent with the pres-

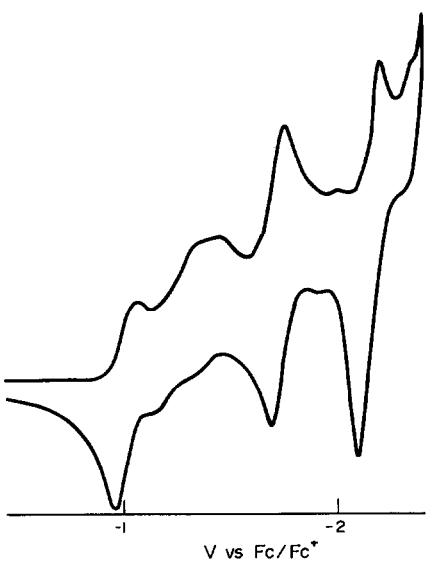

Fig. 1. Reductive cyclic voltammogram of an acetonitrile solution of $[Co_2(qpy)_2(OAc)][PF_6]_3$ (50 mV s^{-1} scan rate, 0.1 M $[^nBu_4N][BF_4]$ supporting electrolyte).

ence of a number of solution species (possibly formed by partial or complete displacement of the acetate by acetonitrile), but it is significant that recrystallization from acetonitrile yields $[Co_2(qpy)_2(OAc)][PF_6]_3$, and so these processes must be reversible or electrochemically initiated. The cyclic voltammogram exhibits reduction processes at -1.10 V (asymmetrical, semi-reversible, $E_a - E_c$ 95 mV), -1.19 V ($E_a - E_c$ 170 mV), -1.37 V ($E_a - E_c$ 130 mV), -1.71 V (reversible, $E_a - E_c$ 90 mV), -1.93 V (very low intensity, but repeatable between various samples, $E_a - E_c$ 90 mV), -2.11 V (return wave amplified by an absorption spike) and -2.30 V (very low intensity) (all potentials quoted *vs* the Fc/Fc^+ couple). The only process that we have been able to unambiguously assign is that associated with the -1.10 V feature; bulk electrolysis at this potential generates a green–brown solution. Coulometry indicates that this wave is associated with the passage of 1.0 ± 0.1 electrons per mole of complex. The assymetry of this peak is scan-rate independent. The ESR spectrum of a frozen acetonitrile glass of this green–brown compound exhibits no absorption close to free-spin, and we can assign the first reduction process to the reduction of the dicobalt(II) complex to a mixed oxidation state (Co^{II}, Co^{I}) species. We have not assigned the remaining processes in the reductive cyclic voltammogram; all of the features are scan-rate dependent and repeatable between different samples of the compound. Perhaps the most surprising feature is the lack of well-defined oxidation processes for the complex. The oxidation of a d^7 cobalt(II) centre to d^6 cobalt(III) should be strongly favoured in a pseudo-octahedral strong ligand field environment. Three small waves are observed at $+0.32$, $+0.53$ and $+0.74$ V, each of which has a small return wave and $E_a - E_c$ values of 80–120 mV (Fig. 2). The reductive feature labelled C in Fig. 2 is only present if the scan includes the oxidative processes (*cf.* Fig. 1) and is a return wave associated with the oxidative processes. Coulometric studies

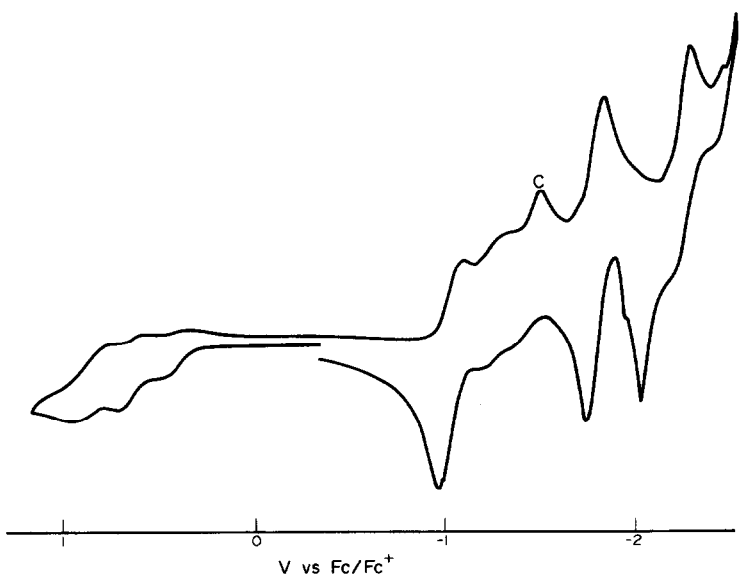

Fig. 2. Full sweep cyclic voltammogram of an acetonitrile solution of $[Co_2(qpy)_2(OAc)][PF_6]_3$ (50 mV s^{-1} scan rate, 0.1 M $[^nBu_4N][BF_4]$ supporting electrolyte).

indicate that the three oxidation processes *combined* are responsible for the transfer of 1.0 ± 0.1 electrons per mole of complex. This observation is in accord with our earlier suggestion of there being a number of solution species. We have been unable to isolate or obtain an ESR spectrum of the oxidized species, which is presumably a mixed oxidation state (Co^{III},Co^{II}) complex.

The X-ray crystal structure of the orange compound has been determined, and the structure of one of the two enantiomers of the cation $[Co_2(qpy)_2(OAc)]^{3+}$ in the complex $[Co_2(qpy)_2(OAc)][PF_6]_3 \cdot 3MeCN$ is shown in Fig. 3. The gross structure of the cation confirms the presence of a binuclear complex with a double helical ligand array about the dicobalt(II) core. The two cobalt centres are both six-coordinate, but are non-equivalent. The structure closely resembles that of $[Ni_2(qpy)_2(OAc)][PF_6]_3 \cdot 3MeCN$ which we recently reported.[8] One of the metal centres [Co(2)] is in a six-coordinate N_6 environment, in which two "2,2′:6′,2″-terpyridyl" portions from the two ligands provide the donor atoms, whilst the second [Co(2)] is in a N_4O_2 environment, provided by the remaining two nitrogen atoms of each qpy ligand presenting a "2,2′-bipyridyl" donor set and the two oxygen donor atoms of a bidentate chelating acetate group. The Co(1)—N bonds show the expected pattern with long contacts to the "terminal" pyridyl rings of the "2,2′:6′,2″-terpyridyl" fragment [2.154(7), 2.177(6), 2.227(6), 2.250(7) Å] and short contacts to the "central" ring [2.054(6), 2.053(7) Å]. In each case, the contact to the central pyridine ring of the ligand is longer than that to the terminal ring. The Co(2)—N and Co(2)—O distances are unremarkable. The N—Co—N bite angles for each "2,2′-bipyridyl" group around Co(1) are unremarkable and are in the range 75.0(3)–76.8(3)°. The corresponding angles about Co(2) are still typical but are slightly larger [77.2(3) and 77.4(3)°] as a consequence of introducing the less sterically demanding acetate ligand, with a bite angle of 60.5(3)°.

There is no significant interaction between the two metal atoms which lie 4.461 Å apart (*cf.* the sum of the *covalent* radii of 2.32 Å). The double helical ligand array is achieved by a series of twists about interannular C—C bonds within each ligand. The major twists occur between the "2,2′-bipyridyl" and "2,2′:6′,2″-terpyridyl" portions of each ligand (59.9° between rings 3 and 4, 58.1° between rings 8 and 9, with the rings numbered according to the

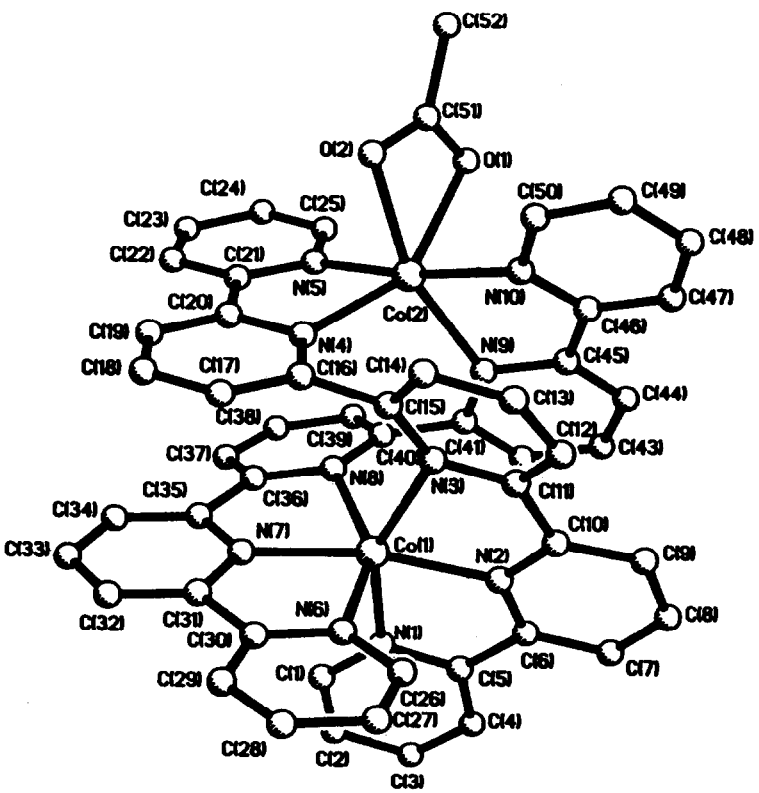

Fig. 3. Structure of one of the two enantiomers of the $[Co_2(qpy)_2(OAc)]^{3+}$ cation in $[Co_2(qpy)_2(OAc)][PF_6]_3 \cdot 3MeCN$ showing the numbering scheme adopted.

numbering of the nitrogen atom). Smaller deviations from planarity are observed between rings 1 and 2 (6.3°), 2 and 3 (17.9°), 4 and 5 (4.9°), 6 and 7 (5.3°), 7 and 8 (14.5°) and 9 and 10 (5.8°). Stacking interactions are observed between approximately parallel rings of the two ligands; rings 4 and 7 make an angle of 2.5° with each other and are separated by an average of 3.307 Å, whilst rings 2 and 9 are twisted by 8.1° and lie 3.389 Å apart. The twisting and the co-planar stacking interactions are emphasised in the projection of the cation presented in Fig. 4.

It is of interest that the reaction of cobalt(II) acetate with qpy results in the high-yield formation of the double-helical binuclear complex, in view of the recent report that the reaction of cobalt(II) chloride with the related ligand 4′,4‴-bis(n-propylthio)-2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (ptqpy) yields a green mononuclear complex in high yield.[19] This is in accord with our observations that double-helical complexes may not always be prepared in the presence of competitive halide ligands. We believe that the change in structure is associated with the presence of halide rather than with the substituents on the ligand; support for this comes from the observation that 4′,4‴-bis(methylthio)-2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (mtqpy) forms a double-helical binuclear complex with nickel(II).[20]

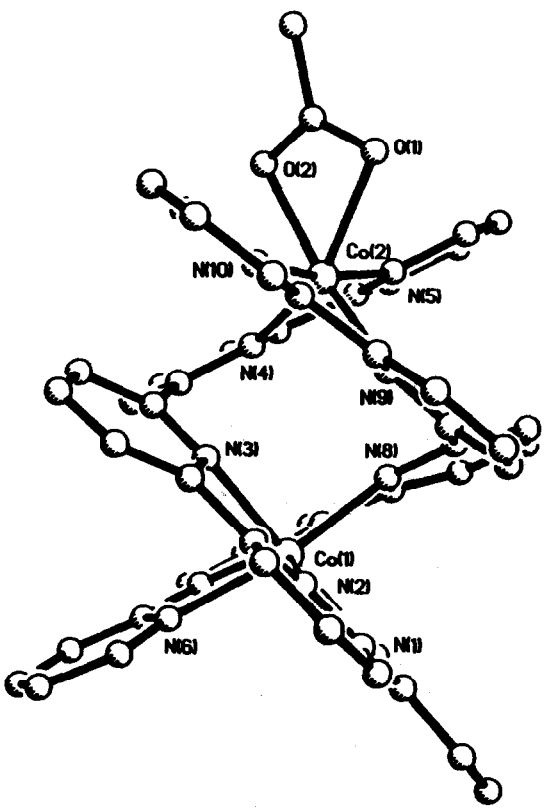

Fig. 4. An alternative view of one of the two enantiomers of the $[Co_2(qpy)_2(OAc)]^{3+}$ cation in $[Co_2(qpy)_2(OAc)][PF_6]_3 \cdot 3MeCN$.

Abstract—In response to a misunderstanding of our presentation of microconstants and microspecies, some of the relations between them and macrospecies and macroconstants are discussed, with specific reference for metal ion binding to catecholamines. For ligands, such as the catecholamines, of high and unknown basicity, either proton displacement constants or conditional stability constants avoid the need to know the ligand pK_a values. The relation between the two formulations is derived.

In a recent paper in this journal, Martell *et al.*[1] commented on our paper dealing with Al^{3+} binding to catecholamines.[2] Their critical comments indicate misunderstandings of our analysis, so we offer this statement clarifying the principles involved.

At issue is an appreciation of the uses of and differences between the macroscopic and microscopic descriptions of a system. Potentiometric methods yield macroscopic equilibrium constants relating macrospecies each of a single overall composition. They may be used to calculate the free metal ion concentration and the total concentration of all microspecies of a given overall composition. All microspecies of a given composition appear as one species in the macroscopic presentation. In many ligand systems there is only one main complex structure referring to each species composition and ambiguities in interpretation do not arise.

In some systems, however, such as the so-called catecholamines, there is more than one microspecies or structure of importance with a given overall macrospecies composition. For example, in DOPA (3,4-dihydroxyphenylalanine) the species of an overall -1 charge consists of several microspecies, the major one of which bears a negative carboxylate group, a protonated ammonium group and one deprotonated, anionic hydroxy group.[3–5] Hence the molecule is better described as an ammonium catecholate.[4] Which of the two catecholate hydroxy groups is the more extensively ionized is not easily determinable nor of concern as the spectrum of the species is a weighted average over the two microspecies. (Ionization from the hydroxy group occurs with $pK_a = 9.54$ in tyrosine and a comparable 9.45 in *meta*-tyrosine.)[6] Moreover, the remaining catecholate proton hydrogen bonds the catecholate oxygen atoms, contributing to the low pK_a of the first and the high pK_a of the second catechol ionizations.[4] It is possible that there is a single potential well with the proton equidistant between the two oxygen atoms, merging the two microspecies.[6,7] In any case, for practical purposes, the writing of a single microspecies for a catecholate monoanion is fully justified.

Loss of the next DOPA proton from the net -1 charged ammonium catecholate is from the ammonium group leaving a -2 charged species with the lone proton hydrogen bonding the catecholate oxygen pair in the main microspecies. Note

* Authors to whom correspondence should be addressed.

that if we consider the -1 charged species to be a catecholamine, there is no ammonium group proton to lose and the macroconstant for the -1 to -2 deprotonation is wrongfully interpreted as being due to ionization of a catechol proton.

In weakly acid and neutral solutions most metal ions bind the -2 charged DOPA species at the catecholate locus with the bridging proton transferring to the amino group.[2,4,8,9] Thus the macroscopic equilibrium constant for metal ion binding to a -2 charged species includes three microscopic equilibrium constants: ionization of the second catecholate proton, protonation of the amino group and metal ion chelation at the catecholate locus. It is often important to resolve the macroconstant into its three component microconstants, for only the last microconstant value should be used when comparing stability constants to other catechols such as catechol itself and tiron.[2]

Since microconstant values are always made consistent with those of macroconstants, exactly the same information is available from microconstants as from macroconstants. Microconstants, however, probe chemical structure more deeply. If one desires molecular and not just phenomenological information in a system such as DOPA, one needs to estimate the microscopic equilibrium constants and hence the relative populations of microspecies. Only then may comparisons among stability constants be made with other ligand systems. Macroconstants contain a mixture of microconstants relating a mixture of microspecies.

Partly due to the intramolecular hydrogen bonding between the catecholate oxygen atoms, but mainly due to the electrostatic effect, the second ionization in catechols yields a high $pK_a \sim 13$.[4] Owing to the high pH region this ionization constant is not known as well as those with lower pK_a values. We determine these high values in separate measurements without added potassium chloride and titrate with concentrated base giving results uncertain to ± 0.2 log units.[10] Since we choose to conduct most of our work in a region of physiological ionic strength, we prefer to include the necessarily higher ionic strengths in the uncertainty of the results for high pK_a values, rather than perform all measurements at a higher ionic strength. Though highly basic pK_a values are quoted to one decimal place, e.g. 13.4 for DOPA, calculations are carried through as if there are two decimal places, i.e. 13.40 in this case.[2] There is no harm in this procedure because the 13.40 value included in log β values cancels out in subsequent manipulation. Since this dissociation in the free ligand occurs to a negligible extent in the pH range of metal complex formation, the greater uncertainty in high pK_a values does not affect the reliability of metal ion stability constants. All log β values were derived from many data points by modern computer methods.

The basis of potentiometric determination of stability constants is the monitoring of proton displacement on a ligand by a metal ion. We write and define the following reactions and equilibrium constants:

$$HL \rightleftharpoons H^+ + L \qquad K_a = [H^+][L]/[HL]$$

$$M + L \rightleftharpoons ML \qquad K_S = [ML]/([M][L])$$

$$M + HL \rightleftharpoons H^+ + ML \qquad K_{SH} = [H^+][ML]/([M][HL]).$$

Most stability constants are expressed as K_S, but if the pK_a is high enough to be uncertain the proton displacement constant, K_{SH}, may be employed. With the acidity constant of the free ligand, K_a, the equations are related by $K_{SH} = K_a K_S$. Martell recommends the proton displacement formulation (third reaction) for ligands with high pK_a values such as catechols. This formulation has been used for years in reactions of metal ions with highly basic ligands such as peptides, where the amide pK_a of *ca* 15 is even greater than that for catechols.[11] Instead of proton displacement constants, in the catecholamine case we used conditional stability constants, which also avoid the use of uncertain, high pK_a values.[2] The conditional stability constant is defined as $K_C = \alpha K_S$, where $\alpha = K_a/([H^+]+K_a)$ is the fraction of free ligand that is deprotonated. Thus in solutions where $[H^+] \gg K_a$, we have $K_C = K_{SH}/[H^+] = [ML]/([M][HL])$ and when $[H^+] \ll K_a$, we have $K_C = K_S$. Once calculated, the conditional stability constant is usable directly at the pH of interest. Conditional stability constants have a long history,[12] accomplish many of the same purposes as proton displacement reactions and have the advantage of being directly applicable at the chosen pH. More applications of and details concerning conditional constants may be found in refs 2, 5 and 13–15. Almost the entire discussion section of our paper deals with conditional constants and Table 2 lists values for several catechol ligands at pH 7.00.[2] Virtually all the criticisms of our paper are met by our use, indeed emphasis, of conditional stability constants.

Microconstants are not only a valid concept but for systems with several microspecies are also useful in ways that macroconstants are not. Microconstants are routinely determined by a combination of potentiometric and spectral absorption, NMR, etc.) methods. It is incorrect to say of microconstants that they are "only accessible through estimative deduction".[16] When an absorption change is used to measure the extent of depro-

tonation of a group in the pH region where a second group also is deprotonating, the pK_a value is not given directly by the usual equations for a single deprotonating group, because the second deprotonation affects the first. Thus one cannot obtain the "true macroscopic pK" by the normal procedure as suggested.[16] It is necessary to use fuller equations developed more than 30 years ago for this purpose.[3,5,17]

Though claimed to be "of theoretical interest only",[16] microconstants are associated with specific structural changes. In larger systems such as proteins, investigators have gone to considerable trouble to identify individual proton and metal ion binding sites by NMR spectroscopy. The microconstants obtained by this and other techniques are not any more "theoretical" nor any less "true" than macroconstants determined wholly potentiometrically.

ASSOCIATION OF TRIS(PENTANE-2,4-DIONATO)COBALT(III) WITH CHLORINATED PHENOLS BY HYDROGEN BONDING

HISANORI IMURA,* SHOICHI KATSUTA and NOBUO SUZUKI†

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980, Japan

(*Received* 8 *May* 1990; *accepted* 12 *February* 1991)

Abstract—Association of tris(pentane-2,4-dionato)cobalt(III) [$Co(acac)_3$] with chlorophenols, dichlorophenols, trichlorophenols and pentachlorophenol in heptane has been studied by the liquid–liquid partition technique in the heptane–0.10 mol dm^{-3} aqueous perchlorate solution system. From the partition equilibrium, the association complexes with the chlorinated phenols(HA) were found to be $Co(acac)_3 \cdot HA$ and $Co(acac)_3 \cdot 2HA$, and the association constants were determined. Existence of the hydrogen bond between the hydroxyl proton of the phenols and $Co(acac)_3$ was evidenced from the ^1H NMR measurement. The relationship between the association constant and the acid-dissociation constant of the phenols is discussed.

In our recent studies, the specific solute–solvent interaction such as coordination and hydrogen bonding has been demonstrated to be an important factor governing the liquid–liquid partition coefficient of metal complexes.[1–4] In the case of tris-pentane-2,4-dionato complexes of aluminium(III), chromium(III) and cobalt(III), the partition coefficient is remarkably lowered probably due to the hydrogen bond interaction between the metal(III) complexes and water molecules.[4] The specific interaction of such tris-pentane-2,4-dionato complexes with chloroform and methanol has been studied by means of the physicochemical measurements of vapour pressure,[5,6] heat of dissolution,[7] IR absorption spectrum,[8] and NMR relaxation rate.[9–11] In those studies, the hydrogen bond interaction was suggested. However, no systematic study on the hydrogen bonding of metal complexes to a series of proton donors has been carried out.

In this paper, we report studies on the association of tris(pentane-2,4-dionato)cobalt(III) [$Co(acac)_3$] with a series of chlorinated phenols which can be considered to be strong proton donors. The chlorinated phenols used are 2-chlorophenol (2-CP), 3-chlorophenol (3-CP), 2,3-dichlorophenol (2,3-DCP), 3,5-dichlorophenol (3,5-DCP), 2,3,5-trichlorophenol (2,3,5-TCP), 2,3,6-trichlorophenol (2,3,6-TCP), 2,4,5-trichlorophenol (2,4,5-TCP), and pentachlorophenol (PCP). Chloroform was also examined as a proton donating solute. The partition equilibrium of $Co(acac)_3$ between heptane and 0.10 mol dm^{-3} aqueous perchlorate solution in the presence of the chlorinated phenols or chloroform were studied in detail, and the composition as well as the equilibrium constant for the association complex of $Co(acac)_3$ with each chlorinated phenol and chloroform in the organic phase were determined. The effect of acidity and steric effects of the chlorinated phenols on the association is discussed. Additionally, the existence of the hydrogen bond between $Co(acac)_3$ and the phenols is examined by the nuclear magnetic resonance (NMR) spectrometry.

EXPERIMENTAL

Materials

Tris(pentane-2,4-dionato)cobalt(III) was obtained from Dojin Chem. Lab., recrystallized from hexane, and dried *in vacuo*. (Found: C, 50.9; H, 6.1. Calc. for: C, 50.6; H, 5.9%.) Chlorinated phenols were commercially obtained: 3-CP, 2,3-DCP, 3,5-DCP, 2,3,5-TCP, 2,3,6-TCP and 2,4,5-TCP

* Present address: Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310, Japan.
† Author to whom correspondence should be addressed.

were of more than 98% purity and further purified by recrystallization from hexane; 2-CP (guaranteed reagent grade) and PCP (99% purity) were used as obtained. The purity of these phenols was checked by their melting points and UV spectra. Chloroform (spectroscopic grade) was used after washing with water several times. Heptane was purified in the usual manner. Carbon tetrachloride used for the NMR measurements was of spectroscopic grade. Water was doubly distilled. Other reagents were of analytical reagent grade and were used without further purification.

To prevent adsorption of the solute onto the wall of the glassware such as extraction vials and pipettes, they were treated with dimethyldichlorosilane before use.

Procedure

Partition coefficient of tris(pentane-2,4-dionato) cobalt(III). An aqueous solution containing 0.010 M perchloric acid, 0.090 M sodium perchlorate, and 4.0×10^{-5}–2.2×10^{-4} M $Co(acac)_3$ was shaken with heptane for 15 min at 25°C. After centrifugation, the aqueous phase was taken out and the absorbance of $Co(acac)_3$ in the aqueous phase was measured at 255.0 nm. Denoting the absorbance of initially prepared aqueous $Co(acac)_3$ solution by $A_{i,aq}$, and that of the aqueous phase after shaking by A_{aq}, the partition coefficient (P_0) of $Co(acac)_3$ was given as follows:

$$P_0=\frac{(A_{i,aq}-A_{aq})V_{aq}}{A_{aq}V_{org}}, \qquad (1)$$

where V_{aq} and V_{org} were the volume of aqueous and organic phase, respectively. The backward partition was also carried out. A heptane solution of $Co(acac)_3$ was shaken with an aqueous phase (0.010 M perchloric acid–0.090 M sodium perchlorate) for 15 min. The absorbance of the organic phase before ($A_{i,org}$) and after (A_{org}) shaking was measured at 257.0 nm, and the partition coefficient was calculated as follows,

$$P_0=\frac{A_{org}V_{aq}}{(A_{i,org}-A_{org})V_{org}}. \qquad (2)$$

The partition coefficients determined by using eqs (1) and (2) agreed well.

Partition coefficient of tris(pentane-2,4-dionato) cobalt(III) in the presence of chlorinated phenols. An aqueous solution (0.0010 M perchloric acid–0.10 M sodium perchlorate or 0.010 M perchloric acid–0.090 M sodium perchlorate) containing 3.2×10^{-5}–6.3×10^{-4} M $Co(acac)_3$ was shaken with a heptane solution containing 9.0×10^{-5}–3.7×10^{-1} M chlorinated phenols (or chloroform as a solute) for 15–60 min. The absorbance of $Co(acac)_3$ in the aqueous phase before and after shaking was measured at 325.0 nm, where the absorbance of the phenols (or chloroform) in the aqueous phase could be ignored. No change in the absorption spectrum and the molar absorption coefficient of $Co(acac)_3$ in the aqueous phase was observed in the presence of the phenols. The partition coefficient (P') of $Co(acac)_3$ was calculated using eq. (1). When the P' value was so high that the absorbance of $Co(acac)_3$ in the aqueous phase could not be directly measured, the aqueous phase was taken out, mixed with a sodium hydroxide solution (to be 0.05 M sodium hydroxide), and shaken with a small volume of chloroform to concentrate $Co(acac)_3$ into the organic phase. The P' value was obtained knowing the absorbance of the organic phase and the molar absorption coefficient (ε) of $Co(acac)_3$ in chloroform: $\varepsilon=8090\pm70$ M^{-1} cm^{-1} at 325.6 nm.

NMR measurement. ^1H NMR spectra of 0.10 M chlorinated phenol in carbon tetrachloride and the mixture of 0.10 M chlorinated phenol with 0.010–0.050 M $Co(acac)_3$ were measured with a 90 MHz NMR spectrophotometer (Varian EM-390) at 35°C. Tetramethylsilane was used as a reference material.

RESULTS AND DISCUSSION

The partition coefficient of $Co(acac)_3$ between heptane and the aqueous perchlorate solution (ionic strength 0.10 M) was determined to be -1.025 ± 0.023 as the logarithmic values for 15 measurements. This value is in good agreement with the literature values, -0.979[12] and -1.036.[13]

The partition coefficient of $Co(acac)_3$ was measured in the presence of a series of chlorinated phenols and chloroform. Figure 1 shows the plots of the partition coefficient (P') of $Co(acac)_3$ against the equilibrium concentration of the chlorinated phenols and chloroform in the organic phase, where the equilibrium concentration can be readily calculated knowing the partition coefficient and the initial concentration of those solutes. The partition coefficients of the chlorinated phenols[14] and chloroform[15] were quoted: the logarithmic values were: 0.785 for 2-CP, -0.273 for 3-CP, 1.333 for 2,3-DCP, 0.416 for 3,5-DCP, 1.953 for 2,3,5-TCP, 1.985 for 2,3,6-TCP, 1.799 for 2,4,5-TCP, 2.990 for PCP, and 1.844 for chloroform. In all of the systems, the partition coefficient of $Co(acac)_3$ rapidly increased with increase in the chlorinated phenol and chloroform concentration in the organic phase. This enhancement effect was remarkably different

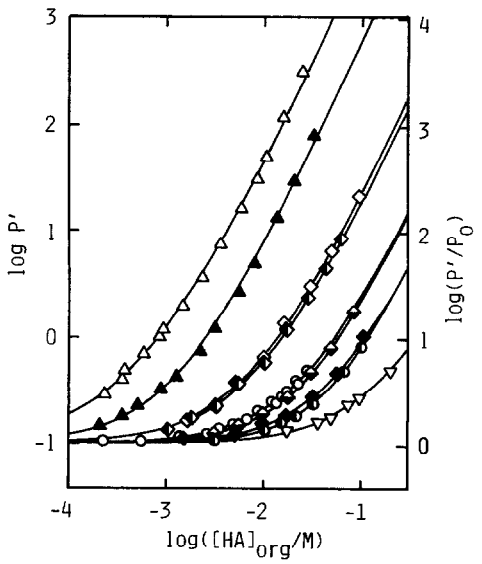

Fig. 1. Effect of chlorinated phenols and chloroform in the organic phase on the partition coefficient of $Co(acac)_3$ between heptane and 0.10 M perchlorate solution. ◆, 2-CP; ▲, 3-CP; ⬙, 2,3-DCP; △, 3,5-DCP; ◐, 2,3,5-TCP; ◑, 2,3,6-TCP; ◇, 2,4,5-TCP; ○, PCP; ▽, $CHCl_3$.

among the chlorinated phenols and increased in the following order: chloroform < 2,3,6-TCP < 2-CP < 2,3-DCP ~ PCP < 2,3,5-TCP ~ 2,4,5-TCP < 3-CP < 3,5-DCP.

Table 1 shows the chemical shift of the hydroxyl proton of each chlorinated phenol in the absence and the presence of $Co(acac)_3$, and the magnitude of the difference in shifts. The data for PCP are not included because its solubility in carbon tetrachloride was so low that the data could not be obtained under the given conditions. In the case of chloroform, the magnitude of the change in chemical shift was as small as 0.04 ppm. The change in chemical shift observed can be explained by hydrogen bonding.[16] In addition, the position of the single peak for the hydroxyl proton indicates the weighted averages of the respective chemical shifts for the free and the hydrogen-bonded phenol molecules. The increasing order of the magnitude of the shift difference is in good agreement with that for the enhancement effect on the partition coefficient of $Co(acac)_3$.

Table 1. NMR chemical shift change for the hydroxyl proton of the chlorinated phenols with $Co(acac)_3$

Chlorinated phenol	δ_0[a] (ppm)	δ[b] (ppm)	$\delta-\delta_0$ (ppm)
2-CP	5.33	5.83	0.50
3-CP	4.77[c]	6.77[c]	2.00[c]
2,3-DCP	5.52	6.22	0.70
2,6-DCP	5.62	5.85	0.23
3,5-DCP	4.77	7.04	2.27
2,3,5-TCP	5.57	6.73	1.16
2,3,6-TCP	5.79	6.16	0.37
2,4,5-TCP	5.37	6.74	1.37

[a] 0.10 M chlorinated phenol in CCl_4.

[b] 0.10 M chlorinated phenol–0.050 M $Co(acac)_3$ in CCl_4.

[c] It was somewhat uncertain because of overlapping of the proton signals.

Association equilibrium

When the association complex of $Co(acac)_3$ with a proton donor (HA) is formed by hydrogen bonding in the organic phase, the apparent partition coefficient (P') of $Co(acac)_3$ in the presence of proton donors can be expressed using the intrinsic partition coefficient (P_0) of $Co(acac)_3$ in the absence of proton donors:

$$P' = \frac{[Co(acac)_3]_{org} + \sum_{n=1}^{m} [Co(acac)_3 \cdot nHA]_{org}}{[Co(acac)_3]_{aq}} \quad (3)$$

$$= P_0\left(1 + \sum_{n=1}^{m} \beta_{ass,n}[HA]_{org}{}^n\right), \quad (4)$$

where the subscripts "org" and "aq" denote the organic and aqueous phase, respectively, and $\beta_{ass,n}$ is the association constant in the organic phase corresponding to the following equilibrium:

$$Co(acac)_{3,org} + nHA_{org} \rightleftharpoons Co(acac)_3 \cdot nHA_{org}. \quad (5)$$

Therefore, the following equation can be derived:

$$\log(P'/P_0) = \log\left(1 + \sum_{n=1}^{m} \beta_{ass,n}[HA]_{org}{}^n\right). \quad (6)$$

Figure 1 also shows the plots of $\log(P'/P_0)$ vs $\log[HA]_{org}$. The plots for 3-CP and 3,5-DCP are almost straight lines with a slope of two in the higher concentration region of the phenols. In other chlorinated phenol systems, such a limiting slope cannot be clearly observed even at the higher concentration region of the phenols (0.1 M), but the slopes of the plots go up to higher than unity. These results mean that the one or two molecules of each chlorinated phenol associate with one molecule of $Co(acac)_3$. From these plots, the association constants, $\beta_{ass,1}$ and $\beta_{ass,2}$ were computed by the least-squares fitting (SALS program, University of Tokyo) based on eq. (6). The association constants obtained are listed in Table 2. In the case of chloro-

Table 2. Association constant of $Co(acac)_3$ with chlorinated phenols and chloroform in heptane at 25°C

Proton donor	log $\beta_{ass,1}$	log $\beta_{ass,2}$	log $K_{ass,2}$[a]
2-CP	1.64 (0.02)	2.57 (0.04)	0.93
3-CP	3.27 (0.03)	5.78 (0.02)	2.51
2,3-DCP	1.87 (0.01)	3.14 (0.01)	1.27

[b] See the text.

form, although the slope of the plots is less than unity even in a higher concentration region of chloroform, the association constant was computed by assuming the formation of the 1 : 1 and 1 : 2 association complexes. Hence, the value for the 1 : 2 complex involves somewhat large uncertainty. The solid lines in Fig. 1 indicate the values computed using these association constants. They are in good agreement with the experimental plots.

Figure 2 shows the correlation between the association constant for the $Co(acac)_3$–chlorinated phenol complexes and the magnitude of the shift difference for the hydroxyl proton of the phenols. A good linear correlation between both parameters is clearly seen, so that it is strongly suggested that the association is caused by the hydrogen bonding of the hydroxyl proton of chlorinated phenols to $Co(acac)_3$.

When the association of $Co(acac)_3$ with the chlorinated phenols is due to the hydrogen bonding as described above, the correlation between the association constant and acid-dissociation constant of the phenols should be expected. The latter can be considered to be a measure for the proton donor ability of the phenols, as cited from the literature.[17] Figure 3 shows the association constant of the $Co(acac)_3$–chlorinated phenol complexes as a function of the acid-dissociation constant of the phenols. A good correlation is found for each group of the chlorinated phenols with the same steric conditions around the hydroxyl group: (1) 2,3,6-TCP and PCP, which possess two chlorine substituents at the 2,6-positions; (2) 2-CP, 2,3-DCP, 2,3,5-TCP and 2,4,5-TCP, which possess one chlorine substituent at the 2-position; (3) 3-CP and 3,5-DCP, which do not possess any chlorine atoms at the 2,6-positions but hydrogen atoms instead. The association constants for these three groups lie at the different regions in Fig. 3 and decrease as follows: group (3) > group (2) > group (1). Since the chlorine atom is more bulky than the hydrogen atom, e.g. the van der Waals volume of the chlorine atom is given to be 12.0 $cm^3\ mol^{-1}$ and that of the hydrogen atom only 2.52 $cm^3\ mol^{-1}$,[18] the chlorine atoms adjacent to the hydroxyl group in the chlorinated phenol molecule may bring about the steric hindrance for the association with $Co(acac)_3$. The

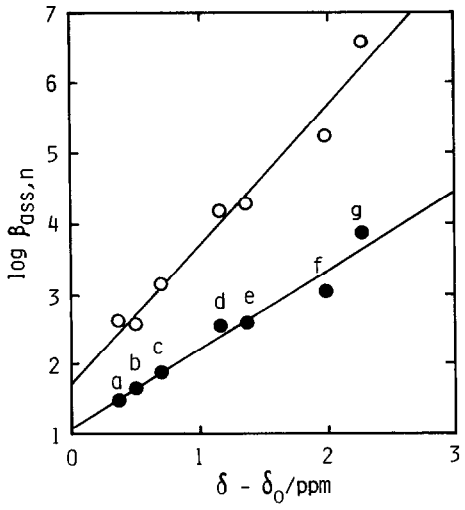

Fig. 2. Correlation between the association constant and the magnitude of the change in NMR chemical shift of the hydroxyl proton of chlorinated phenols. ●, $\beta_{ass,1}$; ○, $\beta_{ass,2}$. a, 2,3,6-TCP; b, 2-CP; c, 2,3-DCP; d, 2,3,5-TCP; e, 2,4,5-TCP; f, 3-CP; g, 3,5-DCP.

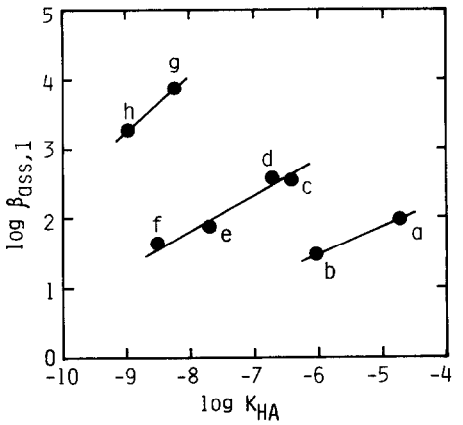

Fig. 3. Correlation between the association constant and the acid-dissociation constant (K_{HA}) of chlorinated phenols. a, PCP; b, 2,3,6-TCP; c, 2,3,5-TCP; d, 2,4,5-TCP; e, 2,3-DCP; f, 2-CP; g, 3,5-DCP; h, 3-CP.

difference in the association constants among the three groups is ascribable to such steric effect.

Consequently, we should discuss the correlation between the association constant and the acid-dissociation constant of chlorinated phenols within each group of the phenols having the same steric structure around the hydroxyl group. In each group, the association constant increases with increase in the acid-dissociation constant of the phenols. This is quite reasonable because the proton donor ability of acids increases with increase in the acid-dissociation constant. Such a linear free energy relationship observed here is also evidence that the association of $Co(acac)_3$ with the chlorinated phenols is attributed to hydrogen bonding.

Tris(pentane-2,4-dionato)cobalt(III) has two open-octahedral faces perpendicular to the C_3 axis of the tris-complex. On each octahedral face, three oxygen atoms from three pentane-2,4-dionato ligands are positioned. The hydrogen bond between $Co(acac)_3$ and the chlorinated phenols can be formed among those oxygen atoms on the octahedral face and the hydroxyl proton of the phenols. Consequently, since two open-octahedral faces of $Co(acac)_3$ can take part in the association, the 1 : 1 and 1 : 2 association complexes should be formed. This model for the association complex is perfectly supported by our experimental results described previously. Such a model has been proposed for the association complex of tris(pentane-2,4-dionato) chromium(III) with chloroform.[5,11]

In conclusion, the existence of the hydrogen bond and the association equilibrium between $Co(acac)_3$ and the chlorinated phenols was clarified. These results revealed that $Co(acac)_3$ acts as a proton acceptor or a base. Such a property of metal complexes is an important factor in their solution chemistry.

SYNTHESIS AND SPECTROSCOPIC CHARACTERISTICS OF BIS-[DIMETHYL(PHENYL)SILYLMETHYL]PLATINUM(II) COMPLEXES WITH PHOSPHORUS DONOR LIGANDS

BERNARDETA C. ANKIANIEC and G. BRENT YOUNG*

Inorganic Chemistry Laboratories, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 19 *November* 1990; *accepted* 18 *February* 1991)

Abstract—A series of bis-[dimethyl(phenyl)silylmethyl]platinum(II) complexes *cis*-$Pt(CH_2SiMe_2Ph)_2L_2$ and $Pt(CH_2SiMe_2Ph)_2(BiL)$ with mono- and bidentate tertiary phosphine ligands {L = PMe_3, PEt_3, PMe_2Ph, $PMePh_2$, PPh_3, $P(4\text{-}C_6H_4CH_3)_3$, $P(2\text{-}C_6H_4CH_3)_3$, $PPh_2(2\text{-}C_6H_4CH_3)$, $PPh_2(2\text{-}C_6H_4CF_3)$; BiL = bis(diphenylphosphino)methane [dppm], 1,2-bis(diphenylphosphino)ethane [dppe], 1,3-bis(diphenylphosphino)propane [dppp], 1,4-bis(diphenylphosphino)butane [dppb], 1,1′-bis(diphenylphosphino)ferrocene [dppf]} has been synthesized by metathetical displacement of the dialkene from $Pt(CH_2SiMe_2Ph)_2(cod)$ or $Pt(CH_2SiMe_2Ph)_2(nbd)$ {cod = cycloocta-1,5-diene; nbd = bicyclo[2.2.1]hepta-2,5-diene}. These new complexes have been characterized by IR and NMR [^1H, ^{13}C and ^{31}P] spectroscopy and their notable features are discussed. The sila-neophyl [sila-neophyl = dimethyl(phenyl)silylmethyl] ligand exhibits a weaker NMR *trans*-influence than its carbon analogue.

Recently, we reported that bis-(trimethylsilylmethyl)platinum(II) complexes *cis*-$Pt(CH_2SiMe_3)_2L_2$ with phosphorus donor ligands, L, undergo a novel thermolytic rearrangement involving β-carbon migration from silicon to platinum.[1] This reactivity contrasts with those of the analogous palladium and nickel complexes, which favour thermolytic reductive C—C elimination,[2] and also with those of related, d-block trimethylsilylmethylmetal systems featuring, for example, ruthenium,[3] osmium,[4] rhodium[5] and iridium,[5,6] where γ-hydrogen transfer reactions afford 2,2-dimethyl-2-silametallacyclobutanes. Corresponding neopentylmetal derivatives, including those of platinum,[7] generally undergo similar cyclometallations. Neophylmetal complexes, too, may be susceptible to cyclometallation, this time via aromatic δ-C—H activation; we have elucidated some of the reaction controls in platinum(II) systems *cis*-$Pt(CH_2CMe_2Ph)_2L_2$, with both nitrogen- and phosphorus-donor ligands, L.[8] Preliminary investigations of sila-neophylplatinum† complexes, *cis*-$Pt(CH_2SiMe_2Ph)_2L_2$ with N-donor L, have revealed a thermolytic preference for a cyclometallation path analogous to the neophylplatinum species.[9] In view of the unusual reactivity of *cis*-$Pt(CH_2SiMe_3)_2(PR_3)_2$,[1] however, it was of clear interest to investigate the corresponding sila-neophylplatinum derivatives with P-donor ancillary ligands. Here, we describe their syntheses and some notable spectroscopic characteristics.

EXPERIMENTAL

General and instrumental

Elemental analyses were determined by Imperial College Microanalytical Laboratories. NMR spectra were recorded on Brüker WM250 (^1H, 250.13 MHz; ^{13}C, 62.9 MHz), Jeol GSX270 (^1H, 270.17 MHz; ^{13}C, 67.9 MHz) and Jeol FX90Q (^1H, 89.55 MHz; ^{31}P, 36.21 MHz) spectrometers. IR data were collected on a Perkin–Elmer 683 or a Perkin–Elmer 1720 FT instrument as 4% KBr dispersions.

All reactions were carried out under argon, using standard anaerobic techniques. All apparatus was flame dried before use.[10] Solvents were distilled under nitrogen prior to use: diethyl ether and *n*-

† Sila-neophyl = dimethyl(phenyl)silylmethyl.

hexane from sodium–benzophenone; toluene from sodium.

Cycloocta-1,5-diene, bicyclo[2.2.1]hepta-2,5-diene, phosphorus trichloride, diphenylchlorophosphine, triphenylphosphine, bis(1,2-diphenylphosphino)ethane, bis(1,3-diphenylphosphino)propane, and bis(1,1′-diphenylphosphino)ferrocene were all used as supplied by Aldrich Chem. Co. Trimethylphosphine, triethylphosphine, dimethylphenylphosphine and diphenylmethylphosphine, supplied by Strem Chemicals, were stored under argon but used without further purification. Bis(diphenylphosphino)methane and bis(1,4-diphenylphosphino)butane were also used as supplied by Strem Chemicals.

Syntheses

$Pt(CH_2SiMe_2Ph)_2$(cod) and $Pt(CH_2SiMe_2Ph)_2$(nbd) were prepared as described previously.[9]

Preparation of tri-4-tolylphosphine.[11] A solution of $Mg(C_6H_4\text{-}4\text{-}CH_3)Br$ (50 mmol) in diethyl ether (15 cm^3) was added to a stirred solution of PCl_3 (2.00 g, 14.6 mmol) in diethyl ether (40 cm^3). The mixture, which had turned cloudy, was refluxed for 24 h, then cooled to −20°C and quenched with saturated aqueous ammonium chloride (30 cm^3). The organic layer was separated and the aqueous phase washed with diethyl ether (2 × 10 cm^3). The combined ether extracts were dried over anhydrous $MgSO_4$, decolourized with charcoal and filtered. Removal of the ether *in vacuo* yielded a pale yellow solid, which was recrystallized from the minimum amount of hot ethanol (7 cm^3) affording colourless crystals of tri-4-tolylphosphine. (Yield: 2.93 g, 9.6 mmol, 66%.) [^{31}P: $\delta = -6.90$ ppm, s.]

Preparation of diphenyl-2-tolylphosphine.[11] To a stirred solution of PPh_2Cl (2.00 g, 9.1 mmol) in diethyl ether (15 cm^3) cooled to 0°C was added dropwise a solution of $Mg(C_6H_4\text{-}2\text{-}CH_3)Br$ in diethyl ether (50 cm^3). Upon addition, the reaction mixture was stirred vigorously for 24 h then cooled to −25°C and quenched with saturated ammonium chloride solution (30 cm^3). The organic layer was separated and the aqueous phase repeatedly washed with diethyl ether (3 × 15 cm^3) until the washings were colourless. The ether extracts were combined, dried over anhydrous $MgSO_4$, decolourized with activated charcoal, filtered and evaporated to dryness *in vacuo*, yielding a pale yellow crystalline solid. The solid was dissolved in hot ethanol (10 cm^3) and cooled slowly to ambient temperature. The white crystalline solid was filtered, washed with cold ethanol (2 × 4 cm^3) and dried *in vacuo*. (Yield: 2.26 g, 8.2 mmol, 90%.) [^{31}P: $\delta = -14.1$ ppm, s.]

Preparation of diphenyl-2-trifluoromethylphenylphosphine.[12] Diphenyl-2-trifluoromethylphenylphosphine was prepared as a white crystalline solid by the reaction of excess $Li(C_6H_4\text{-}2\text{-}CF_3)$ and PPh_2Cl by a method analogous to that used for diphenyl-2-tolylphosphine. (Yield: 2.12 g, 6.4 mmol, 71%.) [^{31}P: $\delta = -11.4$ ppm, q; $J_{P\text{-}F} = 53.2$ Hz.]

Preparation of cis-*bis-(sila-neophyl)-bis-(trimethylphosphine)platinum*(II). $Pt(CH_2SiMe_2Ph)_2$(cod) (0.20 g, 0.33 mmol) was dissolved in toluene (10 cm^3) and trimethylphosphine (100 μl, 0.76 mmol) added by microsyringe. The reaction mixture was heated to 60°C for 14 days. The toluene was removed *in vacuo* to give a white solid, which was recrystallized from toluene (1 cm^3) and *n*-hexane (0.5 cm^3) and cooled to −20°C to give colourless crystals of $Pt(CH_2SiMe_2Ph)_2(PMe_3)_2$. (Yield: 0.19 g, 0.29 mmol, 89%.) IR: 1421 m, 1283 m, 1258 wm, 1250 m, 1233 s, 1102 s, 967 s, 961 s, 946 vs, 936 s, 809 vs, 763 s, 729 s, 714 s, 539 m.

Preparation of bis-(sila-neophyl)[bis-(diphenylphosphino)methane]platinum(II). $Pt(CH_2SiMe_2Ph)_2$(nbd) (0.20 g, 0.34 mmol) was dissolved in toluene (8 cm^3) and dppm (0.131 g, 0.34 mmol) added. After 10 days at 60°C, the toluene was removed *in vacuo* affording a pale yellow crystalline solid. Recrystallization from dichloromethane (2 cm^3) and methanol (1 cm^3) gave the product as a white crystalline solid. (Yield: 0.27 g, 0.31 mmol, 91%.) IR: 1485 wm, 1438 s, 1426 wm, 1265 m, 1242 m, 1109 s, 1031 m, 831 vs, 819 vs, 729 vs, 702 vs, 694 vs, 585 m, 502 s, 478 m.

Prepared according to the same procedure were:

Bis-(sila-neophyl)[1,4-*bis(diphenylphosphino)butane]platinum*(II). Product: white crystalline solid from dichloromethane and *n*-hexane. (Yield: 0.16 g, 0.17 mmol, 85%.) IR: 1485 wm, 1438 s, 1426 m, 1265 m, 1238 m, 1109 s, 1097 s, 1031 m, 839 s, 811 vs, 745 s, 729 s, 702 vs, 533 m, 506 s.

Bis-(sila-neophyl)[1,3-*bis(diphenylphosphino)propane]platinum*(II). Product: white crystalline solid from dichloromethane and methanol. (Yield: 0.26 g, 0.29 mmol, 85%.) IR: 1489 wm, 1438 s, 1426 m, 1265 m, 1241 m, 1109 s, 839 vs, 815 vs, 718 m, 737 s, 702 vs, 666 m, 518 vs.

Preparation of cis-*bis-(sila-neophyl)-bis-(dimethylphenylphosphine)platinum*(II). $Pt(CH_2SiMe_2Ph)_2$(nbd) (0.20 g, 0.34 mmol) was dissolved in diethyl ether (6 cm^3), dimethylphenylphosphine (120 μl, 0.70 mmol) added and the solution allowed to stand at ambient temperature for 7 days. The solvent was removed *in vacuo*, dissolved in the minimum of benzene (1 cm^3) and *n*-hexane (0.5 cm^3) added. Cooling to −20°C produced colourless crys-

tals of the product. (Yield: 0.25 g, 0.32 mmol, 95%.) IR: 1440 m, 1302 m, 1240 s, 942 s, 917 s, 906 m, 837 vs, 815 vs, 765 s, 753 s, 543 s, 504 s, 489 m, 430 s.

Prepared according to an analogous procedure were:

Cis-*bis*-(*sila-neophyl*)-*bis*-(*diphenylmethylphosphine*) *platinum*(II). Product: colourless crystals from *n*-hexane. (Yield: 0.23 g, 0.26 mmol, 76%.) IR: 1433 m, 1330 m, 1236 s, 939 s, 910 s, 904 s, 839 s, 831 vs, 811 vs, 762 s, 747 s, 726 s, 706 m, 539 s, 494 m, 424 s.

Cis-*bis*-(*sila-neophyl*)-*bis*-(*triethylphosphine*)*platinum*(II). Product: colourless crystals from *n*-hexane. (Yield: 0.23 g, 0.315 mmol, 93%.) IR: 1575 m, 1457 m, 1426 m, 1379 m, 1265 m, 1242 m, 1113 s, 1038 s, 1031 s, 835 s, 819 vs, 772 vs, 741 vs, 721 s, 709 vs, 635 m, 475 m.

Cis-*bis*-(*sila-neophyl*)-*bis*-(*triphenylphosphine*)*platinum*(II). Product: white crystalline solid from benzene and *n*-hexane. (Yield: 0.34 g, 0.33 mmol, 98%.) IR: 1482 m, 1476 m, 1431 s, 1247 m, 1103 m, 1092 s, 828 s, 806 s, 763 m, 737 s, 722 s, 692 vs, 544 m.

Cis-*bis*-(*sila-neophyl*)-*bis*-(*tri*-4-*tolylphosphine*)*platinum*(II). Product: white crystalline solid from benzene and *n*-hexane. (Yield: 0.42 g, 0.38 mmol, 89%.) IR: 1504 s, 1430 m, 1402 wm, 1191 m, 1113 s, 1101 s, 831 s, 806 vs, 726 s, 680 s, 628 s, 524 vs, 514 vs, 499 m, 448 m.

Cis-*bis*-(*sila-neophyl*)-*bis*-(*diphenyl*-2-*tolylphosphine*)*platinum*(II). Product: white crystalline solid from benzene and *n*-hexane. (Yield: 0.28 g, 0.27 mmol, 79%.) IR: 1481 wm, 1438 s, 1246 m, 1113 s, 1101 s, 829 s, 805 vs, 747 s, 728 s, 698 vs, 540 m, 529 s, 499 m, 473 s.

Bis-(*sila-neophyl*)[1,2-*bis*(*diphenylphosphino*)*ethane*] *platinum*(II). Product: white solid from toluene and *n*-hexane. (Yield: 0.31 g, 0.35 mmol, 93%.) IR: 1432 m, 1402 wm, 1259 wm, 1236 m, 1102 s, 828 m, 803 vs, 762 m, 748 s, 741 m, 730 m, 699 vs, 524 s.

Bis-(*sila-neophyl*)[1,1′-*bis*(*diphenylphosphino*)*ferrocene*]*platinum*(II). Product: amber crystalline solid from toluene and *n*-hexane. (Yield: 0.28 g, 0.27 mmol, 78%.) IR: 1485 m, 1438 s, 1430 m, 1265 m, 1109 s, 1101 s, 1042 m, 1031 s, 835 s, 811 vs, 749 m, 733 s, 702 vs, 643 m, 553 m, 498 s, 471 s.

Preparation of cis-*bis*(*sila-neophyl*)-*bis*-[*diphenyl* (2-*trifluoromethylphenyl*)*phosphine*]*platinum*(II). To $Pt(CH_2SiMe_2Ph)_2$(nbd) (0.20 g, 0.34 mmol) dissolved in diethyl ether (7 cm^3) was added excess diphenyl-2-trifluoromethylphenylphosphine (0.45 g, 1.36 mmol). The solution was allowed to remain at ambient temperature for 21 days. After this time, the reaction had reached 75% completion as established by ^{31}P NMR. Unreacted $Pt(CH_2SiMe_2Ph)_2$ (nbd) and excess phosphine were removed by column chromatography at 0°C (neutral alumina, 30 cm) using *n*-hexane as eluent. The product was then obtained using toluene as the eluent. Removal of the solvent *in vacuo* afforded a white solid.

^{31}P NMR showed that the sample was 30% contaminated with the rearranged species. The desired product is very labile and rearranges quickly at ambient temperature in non-polar solvents.

RESULTS AND DISCUSSION

Synthesis

Reaction of the diene complexes with stoichiometric amounts of tertiary phosphines, yielded a series of *cis*-bis-(phosphine)platinum(II) dialkyls in essentially quantitative yields in most cases. With the exception of $Pt(CH_2SiMe_2Ph)_2$(dppf) which is yellow, the remainder are colourless crystalline solids. Where L = PEt_3 and PPh_2Me, some problems were encountered in obtaining crystalline samples. Substitution was generally complete within 14 days at either 60°C or ambient temperature, depending on the diene complex and solvent employed. These air inert solids do not decompose in deoxygenated hydrocarbons. They do react slowly with chlorocarbon solvents, affording *cis*-$PtCl_2(PR_3)_2$; the reaction is accelerated at higher temperatures and in the presence of oxygen. All have satisfactory elemental analyses (Table 1), except *cis*-$Pt(CH_2SiMe_2Ph)_2(PPh_2C_6H_4\text{-}2\text{-}CF_3)_2$ which was not isolated pure.

Spectroscopic studies

Infrared. Selected IR data are listed in the experimental section. These complexes show the same characteristic vibrations in the sila-neophyl skeleton as those previously described.[9] Additionally, the band at 1090 cm^{-1} is a characteristic P—Ph "X-sensitive" band and bands occurring at 545–520 cm^{-1} are out of plane C—H bending modes typical of phosphine bound phenyl groups.

^1H *NMR.* The site designations used in the ensuing discussions appear in Fig. 1. A general feature

Table 1. Analytical data for bis-(sila-neophyl)platinum(II) complexes with P-donor ligands

Complex	Colour	Found (calculated), % C	H
$Pt(CH_2SiMe_2Ph)_2(PMe_3)_2$	White	44.5 (44.6)	6.9 (6.9)
$Pt(CH_2SiMe_2Ph)_2(PEt_3)_2$	White	49.5 (49.4)	7.8 (7.8)
$Pt(CH_2SiMe_2Ph)_2(PMe_2Ph)_2$	White	53.0 (53.0)	6.3 (6.3)
$Pt(CH_2SiMe_2Ph)_2(PPh_2Me)_2$	White	59.3 (59.4)	6.0 (5.8)
$Pt(CH_2SiMe_2Ph)_2(PPh_3)_2$	White	63.8 (63.7)	5.5 (5.5)
$Pt(CH_2SiMe_2Ph)_2(P\text{-}4\text{-}tol_3)_2 \cdot \frac{1}{2}C_6H_6$	White	66.2 (66.3)	6.3 (6.3)
$Pt(CH_2SiMe_2Ph)_2(PPh_2\text{-}2\text{-}tol)_2$	White	64.0 (64.3)	5.7 (5.8)
$Pt(CH_2SiMe_2Ph)_2$(dppm)	White	58.6 (58.8)	5.5 (5.5)
$Pt(CH_2SiMe_2Ph)_2$(dppe)	White	59.0 (59.2)	5.5 (5.6)

$Pt(CH_2SiMe_2Ph)_2$(dppb)	White	59.9 (60.0)	5.9 (6.0)
$Pt(CH_2SiMe_2Ph)_2$(dppf)	Amber	59.6 (59.6)	5.0 (5.2)

of all these spectra (Table 2) is the multiplet obtained from the hydrogens of the methylene group bound to platinum, typified by *cis*-$Pt(CH_2SiMe_2Ph)_2(PMe_3)_2$. This second order resonance arises from an $A_2A_2'MRR'X_9X_9'$ system [A = $^1H_{CH_2}$, M = ^{195}Pt, R = ^{31}P and X = $^1H_{P\text{-}CH_3}$]. In practice it generates an apparent quartet with platinum satellites. This multiplet exhibits considerable broadening for several of the complexes in spectra measured at 250 MHz but a well resolved quartet is usually observed at lower field. This phenomenon has been attributed to more efficient relaxation of the ^{195}Pt nucleus by increasing field gradient anisotropy.[13]

Similar general observations have been noted for related *cis*-PtR_2L_2 [R = neophyl, trimethylsilylmethyl, ethenyldimethylsilylmethyl; L = PEt_3, PPh_3 dppe].[8,14-16] Comparisons with bis-(neophyl) analogues show that $^2J_{Pt\text{-}H}$ values are 5–15 Hz larger for sila-neophyl derivatives. Also, the magnitude of $^2J_{Pt\text{-}H}$ coupling constants are consistently *ca* 10 Hz smaller for phosphine complexes than for corresponding nitrogen donor derivatives, implying less *s*-orbital character in the Pt—C—H skeleton and reflecting the generally stronger *trans*-influence of P-donor ligands.[17]

Characteristic patterns-are also observed for the hydrogens on phosphine substituents. These often emerge as doublets of "triplets" due to coupling to both ^{31}P and ^{195}Pt nuclei. An exception is $Pt(CH_2SiMe_2Ph)_2$(dppf), where H_2 and H_6 of the phenyl group generate a very broad singlet at room temperature and the four cyclopentadienyl protons H_Y, $H_{Y'}$, H_Z, $H_{Z'}$ display slightly broadened but unresolved resonances (Fig. 2). Lowering the temperature initially broadens each of these signals, then subsequently they become resolved into doublets. Rate constants (k_c) for the processes responsible for this exchange can be determined from the linewidths at half-height ($\Delta\nu$) at each coalescence point. These rate constants were used to determine the free energies of activation ($\Delta G_c^{\ddagger}$, Table 3) at the coalescence temperature, T_c.[18]

The complex lacks a plane of symmetry unless the phosphine adopts a syn-eclipsed conformation on chelation,[19] resulting in conformers which are enantiomeric. H_Y and $H_{Y'}$ are now magnetically inequivalent, as are H_Z and $H_{Z'}$, and generate distinct resonances. Assuming that there is negligible coupling between hydrogens on different cyclo-

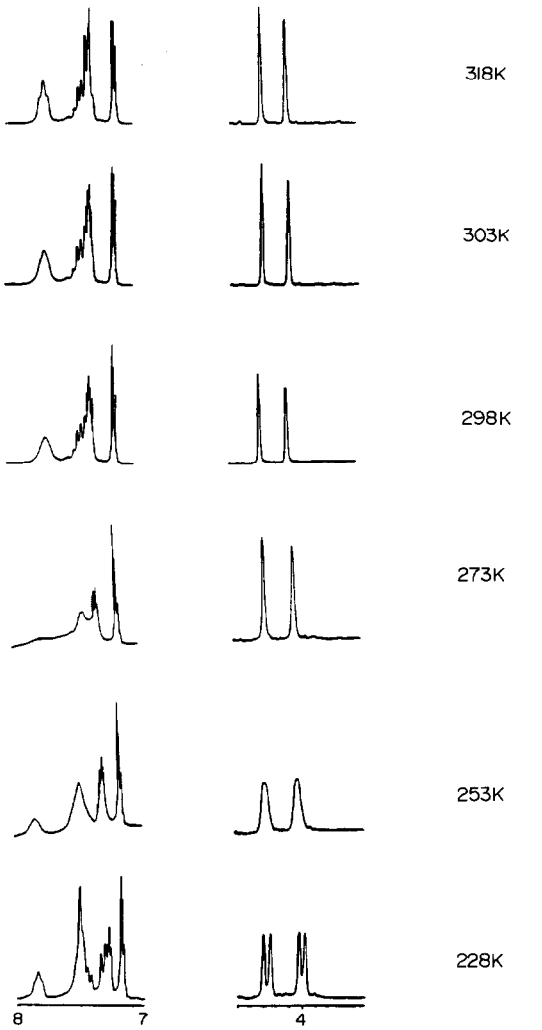

Fig. 2. Temperature-dependence of ^{1}H NMR spectrum of $Pt(CH_2SiMe_2Ph)_2(dppf)$.

pentadienyl rings, the observed low temperature spectrum (representing, ideally, an $A_2B_2C_2D_2$ system) may be explained by slow exchange of these conformers. At high temperatures, rapid exchange gives rise to a time-averaged spectrum ($A_2A_{2'}B_2B_{2'}$) in which H_Y, $H_{Y'}$ and H_Z, $H_{Z'}$ exhibit single resonances. Similarly the two phenyl substituents on each phosphorus are magnetically non-equivalent. Although all the phenyl hydrogens exhibit this type of behaviour, it is most prominent in the resonances due to H_2 and H_6 which collapse forming a broadened triplet at higher temperatures.[20] Assuming that the values of $\Delta G_c^{\ddagger}$ derive from the same process, then $\Delta H_c^{\ddagger}$ is estimated at 43.0 ($\pm$1.0) kJ mol^{-1} and $\Delta S_c^{\ddagger}$ at -43.4 ($\pm$2.0) J K^{-1} mol^{-1}. These values are very similar to those observed previously for related systems[16] indicating that the process is essentially independent of the nature of the alkyl group.

^{31}P NMR. The $^{31}P\{^1H\}$ NMR data for bis-(silaneophyl)bis-(phosphine)platinum(II) complexes appear in Table 4. Spin–spin coupling of ^{31}P to ^{195}Pt results in the expected "triplet" observed for all of these complexes. For L = PPh_2-2-$C_6H_4CF_3$ a "triplet" of quartets due to coupling of three ^{19}F nuclei to ^{31}P was anticipated, instead, a broad "triplet" was observed. The ^{19}F NMR, however, showed the expected doublet with $^4J_{P\text{-}F} = 4.4$ Hz. With the exception of $Pt(CH_2SiMe_2Ph)_2(dppm)$, the $^1J_{Pt\text{-}P}$ coupling constants are in the range 1950–2065 Hz, typical for *cis*-bis-(phosphine)platinum(II) dialkyl compounds.[1,8,16] The especially low value of 1615 Hz for $Pt(CH_2SiMe_2Ph)_2(dppm)$ is a general coordination feature of this ligand and can be ascribed to angular constraints around Pt and P due to the four-membered ring.[21]

Phosphorus nuclei incorporated in chelate rings display a ring contribution, Δ_R, to their chemical shift change upon coordination. The magnitude and direction of Δ_R depend on ring substitution and size.[22] The ring contribution, defined as $\Delta_R = \Delta - \Delta_{R^\circ}$ [where Δ is the difference in the chemical shift upon coordination (δP–δF) and Δ_{R° is a standard ring contribution] has been determined for the series of bidentate phosphine complexes (Table 5). The four-membered ring has a shielding effect

[e] $J_{P\text{-}F}$ = 4.4 Hz.

relative to *cis*-$Pt(CH_2SiMe_2Ph)_2(PPh_2Me)_2$, whilst the five-membered ring has a deshielding effect. These values are in good agreement with those obtained for other PtR_2L compounds (L = dppm, dppe, dppp, dppb; R = Me, $CH_2SiMe_2CH_2$:CH_2, CH_2SiMe_3)[1,16,22].

Also noteworthy is the magnitude of $^1J_{Pt\text{-}P}$, which is consistently 300–400 Hz greater in sila-neophyl than in neophyl analogues. The same trend has been observed in comparison of analogous neopentyl and trimethylsilylmethyl derivatives (cf. Fig. 3).[14]

^{13}C NMR. $^{13}C\{^1H\}$ NMR characteristics of sila-neophyl complexes are presented in Table 6. Assignments have been made by comparison with the free ligand, by the magnitude of Pt—C coupling constants, on the basis of peak intensities and (in some cases) ADEPT measurements, and are in accord with those noted elsewhere.[8,15,16,23] Typically, carbon atoms on coordinated phosphine show coupling to both ^{31}P and ^{195}Pt producing a doublet of "triplets". $^3J_{Pt\text{-}C}$ coupling is observed to the silicon-bound methyl carbons and to C_1 of the aromatic ring, of magnitude 20–30 Hz. Notably, for unhindered monodentate phosphines, the value of $^3J_{Pt\text{-}C}$ for Si—CH_3 groups is noticeably larger than for Si—C_1. As the steric bulk of the ligand is increased, a decrease in $^3J_{Pt\text{-}C_{methyl}}$ and a corresponding increase in $J_{Pt\text{-}C_1}$ are observed—presumably reflect-

[e] Measured at −10°C.

ing changes in *s*-orbital contributions to the Pt—CH_2—Si—C skeleton. Relatedly, a corresponding increase in the magnitude of $^1J_{Pt\text{-}C}$ from PMe_3 (524 Hz) to $PPh_2C_6H_4$-2-CF_3 (587 Hz) is also observed.

Just as $^1J_{Pt\text{-}P}$ is larger (*vide supra*), the magnitude of $^1J_{Pt\text{-}C}$ for sila-neophyl derivatives is characteristically 130–160 Hz smaller than that for the analogous neophyl complexes and is very similar to those for corresponding *cis*-$Pt(CH_2SiMe_3)_2L_2$[23] and *cis*-$Pt(CH_2SiMe_2CH_2:CH_2)_2L_2$.[16] Comparing, for instance, $Pt(CH_2SiMe_2Ph)_2(dppe)$ with its carbon equivalent, a reduction of 133 Hz in $^1J_{Pt\text{-}C}$ is matched by an increase in $^1J_{Pt\text{-}P}$ of 370 Hz. The extent of change in the two couplings is—perhaps fortuitiously—similar (*ca* 24%), and typical for analogues for which comparative data are available; notably, the methylplatinum homologue exhibits intermediate values (Fig. 3). These variations may be attributed to a greater carbon 2*s*-orbital contribution to Pt—C bonding in the presence of the more electronegative (and, perhaps, sterically more demanding) β-carbon, which, as has been discussed by us elsewhere,[16,23] affects the disposition of the platinum 6*s*-orbital in the linear C—Pt—P skeleton.

These observations are further substantiation of an apparently weaker *trans*-influence for the β-silaalkyl than for the analogous carbon ligand—and, by conventional wisdom, stronger Pt—C bonds involving the latter. Ancillary ligand dissociation is often a prerequisite for thermolytic rearrangements

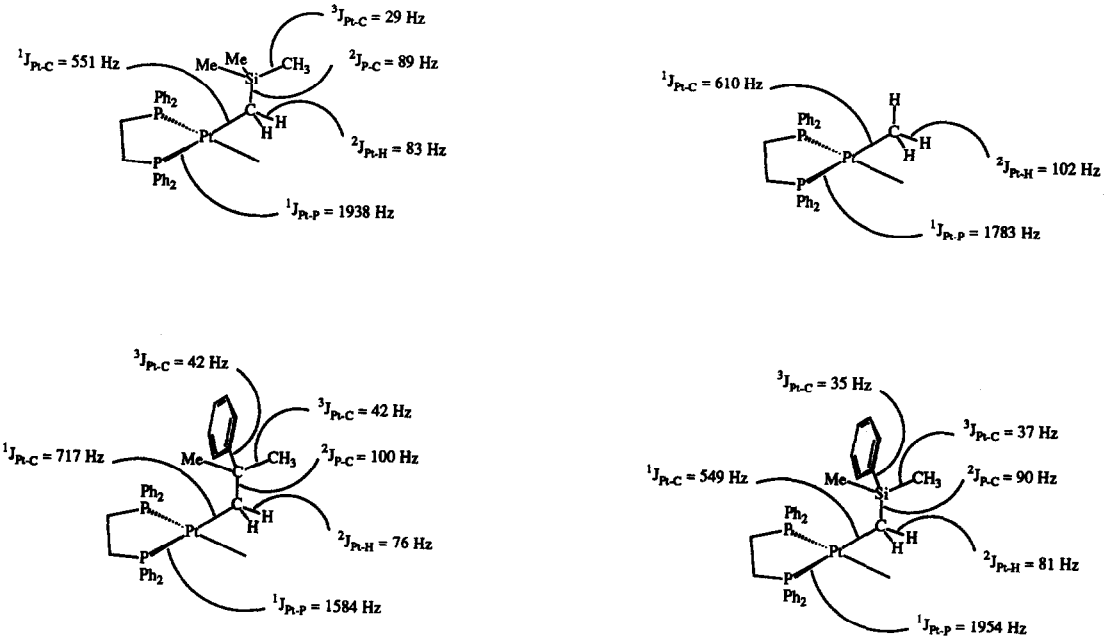

Fig. 3. Selected NMR spin–spin coupling constants for $PtR_2(dppe)$.

of this type of complex (see ref. 8, and references cited therein) and, therefore, such a difference in ground state energies may have a kinetic influence on lability, perhaps contributing to the (usually) readier reactivity of neophyl (and related) complexes compared to silicon-bearing analogues. We are engaged in other studies to evaluate more fully the internal energetics of these systems. As will emerge,[24] however, while Pt—P scission is generally a mechanistic prerequisite in both cases, the preferred modes of reactivity for corresponding silaneophyl- and neophylplatinum(II) complexes may differ completely.

Acknowledgements—We thank Dick Sheppard and Sue Johnson for high field NMR measurements and Ms D. J. Wilkes for an experimental contribution at the outset of this work. The award of a studentship by the SERC (to B.C.A.) is also acknowledged gratefully. As ever, we are greatly indebted to Johnson-Matthey plc for their continuous support via generous loans of platinum.

(*Received* 10 *December* 1990; *accepted* 20 *February* 1991)

Abstract—The interaction of $Re(NBu^t)_3Cl$ with dicobalt octacarbonyl in hexane gives rise to the cluster $ReCo_3(NBu^t)_2(CO)_{10}$ that has the metal atoms with a "butterfly" type core together with two (μ_3-NBu^t) and two (μ-CO) groups. The rhenium atom has three CO terminal groups, and the two wingtip cobalt atoms have two terminal CO groups.

The interaction of $Re(NBu^t)_3Cl$[1] and $Co_2(CO)_8$ in hexane leads to the isolation of dark red–violet crystals of a compound of stoichiometry $ReCo_3(NBu^t)_2(CO)_{10}$. The compound is moderately air and moisture sensitive and is soluble in common organic solvents. Spectroscopic data are not instructive but the ^1H NMR spectrum has a singlet at 0.88 pm for the NBu^t group, while the IR spectrum has a complicated carbonyl region. The structure of the molecule which has mirror symmetry was determined by X-ray crystallography and is shown in Fig. 1. Bond lengths and angles are given in Table 1.

The geometry is best described in terms of a butterfly[2] structure with the wing fold along the vector Re...Co(1) which lies on the crystallographic mirror plane. In each $ReCo_2$ wing triangle the Re—Co distances are very similar [2.581, 2.602(5) Å] and the Co—Co distance of 2.435(6) Å seems to indicate equivalent strength. The capping imido function bonds slightly asymmetrically, with Co—N distances of 1.98(1) Å[Co(1)] and 1.89(1) Å[Co(2)] and Re—N 2.02(1) Å. On the other hand, the CO bridging across the Co(1)...Co(2) edge is almost symmetrical, with Co—C distances of 1.94(2) and 1.96(2) Å. The Co(2)...Co(2a) distance between wingtips is 3.571(7) Å. If the imido functions act as four electron donors, then the total electron count is 62 e and the structure is then immediately classified as an arachno derivative of an octahedral parent (for electron counting schemes see ref. 2, p. 1068).

There are several precedents for μ_3-NR groups in cluster chemistry, e.g. for tungsten,[3b] where π overlaps in the NPh bridge are discussed and for ruthenium.[3c] Gold compounds[3d] have PhN bridging separate $AuPR_3$ groups. As far as we are aware no μ_3 bridged species of rhenium have previously been reported.

EXPERIMENTAL

To a solution of $Re(NBu^t)_3Cl$ (0.35 g, 0.80 mmol) in hexane (30 cm^3) at −78°C was added a solution of $Co_2(CO)_8$ (0.42 g, 1.2 mmol) in hexane (10 cm_3), and the solution allowed to warm. After 5 h stirring, filtration from black insoluble matter, concentration (to *ca* 7 cm^3) and cooling (−20°C) gave dark red–violet crystals. Yield: 0.2 g (33%). m.p.: 178–180°C. [Found: C, 28.1; H, 2.6; N, 3.7; O, 18.7; $C_{17}H_{18}Co_3N_2O_9Re$ requires C, 27.5; H, 2.3; N, 3.6; O, 20.4%.] MS(EI). The spectrum

X-ray crystallography

The crystal used for X-ray work was sealed in a thin-walled glass capillary. Following preliminary photography, unit cell dimensions and intensity data were obtained using standard procedures and a CAD4 diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) operating in the $\omega/2\theta$ scan mode. The structure was solved by direct methods and refined by full matrix least-squares. All atoms were refined with anisotropic displacement factor coefficients; no hydrogens were included. Experimental details are as follows.

Crystal data. $C_{18}H_{18}N_2O_{10}Co_3Re$, $M_r = 785.36$, monoclinic $a = 8.764(2)$, $b = 16.822(3)$, $c = 9.225(2)$ Å, $\beta = 116.71(2)°$, $V = 1214.9$ Å^3, space group $P2_1/m$, $Z = 2$, $D_c = 2.14$ g cm^{-3}, μ(Mo-K_α) = 64.5 cm^{-1}, $F(000) = 752$.

Data collection. $1.5 \leqslant \theta \leqslant 23.0°$, $0 \leqslant h \leqslant g$, $0 \leqslant k \leqslant 18$, $-10 \leqslant l \leqslant 10$, 1886 data collected, 1752 unique, 1371 observed [$F_o > 3\sigma(F_o)$]. *Lp* and empirical absorption corrections based on psi-scans.

Refinement. 163 Parameters, weights = $[\sigma(F)^2 + 0.01F_o]^{-1}$, $R = 0.059$, $R_w = 0.063$. All calculations made using SHELX 80 installed on a T800 transputer hosted by an IBM/AT clone.

ORGANOCHROMIUM π-COMPLEXES—V.† COMPOUNDS CONTAINING η^4-1,3-DIENE AND η^2-ALKYNE MOLECULES

P. W. JOLLY‡ and U. ZAKRZEWSKI

Max-Planck-Institut für Kohlenforschung, D-4330 Mülheim a.d. Ruhr, F.R.G.

(*Received* 10 *December* 1990; *accepted* 20 *February* 1991)

Abstract—$Cr(PMe_3)_2Cl_2$ reacts with active-Mg and butadiene or Mg(butadiene) in a stepwise manner to give initially $(\eta^4\text{-}1,3\text{-}C_4H_6)Cr(PMe_3)_2Cl$ which reacts further to $(\eta^4\text{-}1,3\text{-}C_4H_6)_2CrPMe_3$. Related compounds are formed in the presence of PMe_2Ph or 2,3-dimethylbutadiene. $Cr(PEt_3)_2Cl_2$ reacts to give the dimeric species $[(\eta^4\text{-}2,3\text{-dimethylbutadiene})Cr(PEt_3)Cl]_2$, whereas in the presence of the bidentate ligand bis(diisopropylphosphino)ethane, $(\eta^4\text{-}1,3\text{-}C_4H_6)Cr(Pr^i_2PC_2H_4PPr^i_2)$ is formed. Related reduction of $CrCl_2$-derivatives in the presence of alkynes leads to the formation of $(\eta^2\text{-}R'C{\equiv}CR')_2Cr(PR_3)_2$ (R′ = Me, Ph) and $(\eta^2\text{-}PhC{\equiv}CPh)_3CrPMe_3$.

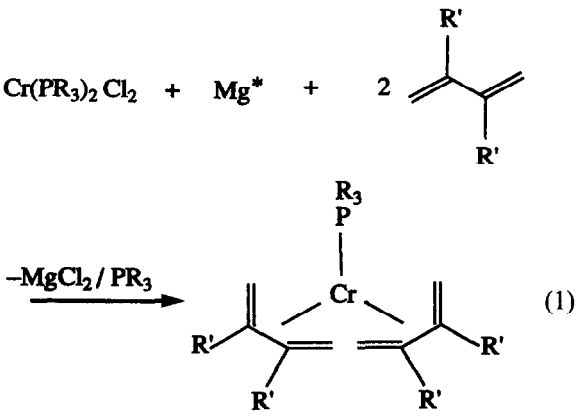
Although it is assumed that complexes containing metal-bonded 1,3-diene or alkyne molecules play a role in the chromium-catalysed oligomerization of dienes[2] and cyclotrimerization of alkynes,[3] examples of carbonyl-free compounds are apparently limited in the first case to a few chromium(I)-compounds, e.g. $Cp(\eta^4\text{-}1,3\text{-}C_4H_6)CrPR_3$[4] and $(\eta^4\text{-}1\text{-}EtC_4H_5)(\eta^3\text{-}C_3H_5)Cr(Me_2PC_2H_4PMe_2)$;[5] the zerovalent chromium compounds, $(\eta^4\text{-}1,3\text{-}C_4H_6)Cr(Me_2PC_2H_4PMe_2)_2$[6] and $(\eta^4\text{-}1,3\text{-}C_4H_6)Cr(PF_3)_4$;[7] in the second to $(\eta^2\text{-}PhC_2Ph)Cr(Me_2PC_2H_4PMe_2)$[6] and $Cp_2(\eta^2\text{-}CF_3C_2CF_3)Cr$;[8] and a dinuclear species formulated as $(HC_2H)[Cr(Ph_2PC_2H_4PPh_2)_2]_2$.[9]

Here, we describe the preparation of further examples of both types of compound by reducing $CrCl_2$-derivatives with active-Mg in the presence of a diene or alkyne.

RESULTS AND DISCUSSION

It has been shown that commercially available magnesium is sufficiently reactive to reduce some transition metal halides. For example, $CrCl_3$ in the presence of trimethylphosphine and dinitrogen reacts to give $Cr(PMe_3)_4(N_2)_2$,[10] while $FeCl_2$ in the presence of the same phosphine reacts to give $Fe(PMe_3)_4$.[11] In other cases, activation of the magnesium with anthracene has proved advantageous, and this variation has been used to prepare complexes of a variety of transition metals including iron, cobalt and palladium.[12–15]

Our initial attempts to prepare organochromium compounds by reducing $CrCl_2$ with magnesium failed: for example, $Cr(PMe_3)_2Cl_2$ does not react with butadiene and commercial magnesium activated with methyl iodide at −30°C, while at 0°C uncontrolled reduction takes place to give metallic chromium and a brown oil. Reduction can, however, be successfully carried out at −30°C using a highly active magnesium powder (Mg*) produced by the thermolysis of MgH_2[15] and compounds **1**–**4** have been isolated by reacting the appropriate $Cr(PR_3)_2Cl_2$ species with the active-Mg in the presence of butadiene or 2,3-dimethylbutadiene [eq. (1)]:



(1)

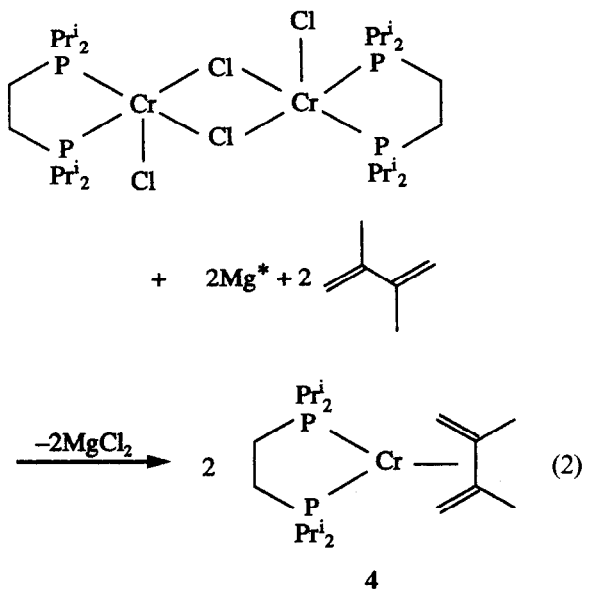
1 (R=Me, R'=H); **2** (R=Me, R'=Me); **3** (R_3=Me_2Ph, R'=Me)

† For part IV, see ref. 1.

‡ Author to whom correspondence should be addressed.

The green, paramagnetic compounds **1–3** decompose in ether at *ca* 0°C, and their structure follows from the elemental analysis and mass spectra while the protolytic decomposition of **2** is accompanied by the quantitative release of 2,3-dimethylbutadiene.

An analogous reaction carried out in the presence of the bidentate ligand $Pr^i_2PC_2H_4PPr^i_2$ does not lead to a diamagnetic bis(η^4-diene)Cr(L–L)-species but instead the mono(η^4-diene)Cr-species, **4**, is formed [eq. (2)]:

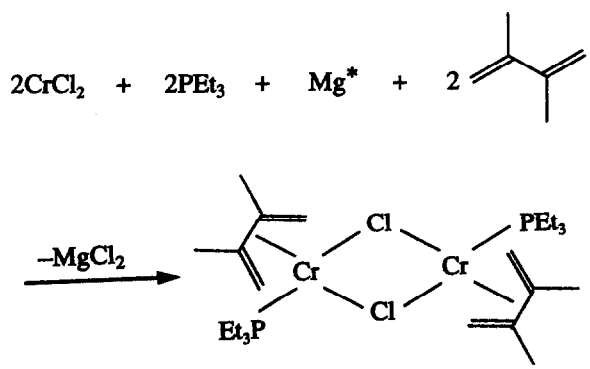


(2)

4

Compound **4** is a violet solid which decomposes above −20°C and inflames in the air.

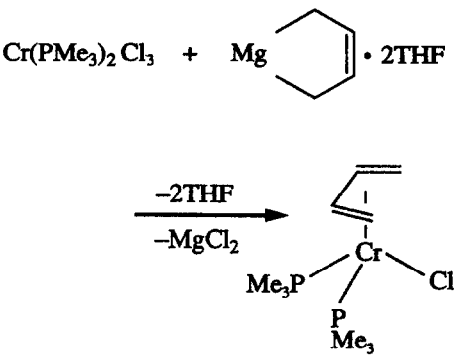
The attempted extension of the method to $Cr(PEt_3)_2Cl_2$ in the presence of 2,3-dimethylbutadiene produced a brown, crystalline compound whose elemental analysis and molecular weight suggest that a partial reduction has occurred to give the dinuclear (η^4-1,3-diene)Cr^I-species, **5** [eq. (3)]:



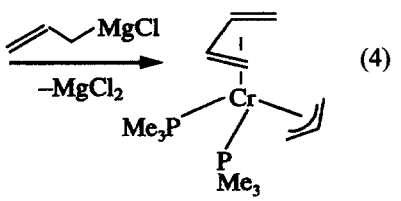
5 (3)

Compound **5** disproportionates in the mass spectrometer to give $CrCl_2$ and fragments assignable to (η^4-2,3-dimethylbutadiene)$_2$CrPEt$_3$. We were, however, unable to make preparative utility of this observation.

A further (η^4-1,3-diene)Cr^I-species, **6**, could be prepared by reacting $Cr(PMe_3)_2Cl_2$ or $Cr(PMe_3)_2Cl_3$ with magnesium–butadiene and it is also formed in low yield upon reacting $Cr(PMe_3)_2Cl_2$ with one equivalent of active-Mg and butadiene [eq. (4)]:



6



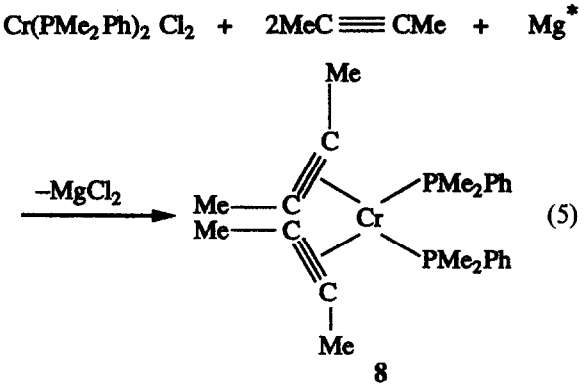
(4)

7

Molecular weight determinations confirm that **6** is monomeric. Compound **6** reacts further at room temperature in a vacuum to give **1** and can be used in the synthesis of further organochromium species. For example, the product of the reaction with allylmagnesium chloride is **7**. Interestingly, the dinuclear-Cr^ICl compound, **5**, does not react with the Grignard reagent.

In contrast to the behaviour of $FeCl_2$, which reacts to give initially an (η^4-1,3-diene)$Fe(PR_3)_3$ species from which P-donor ligands are displaced by a second diene molecule,[13] the results described above suggest that the $CrCl_2$-derivatives are reduced in a stepwise manner in the presence of 1,3-dienes.

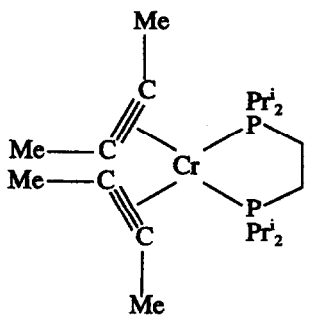
The use of active-Mg in the preparation of π-complexes from $CrCl_2$-derivatives is not limited to (η^4-1,3-diene)Cr-species and compounds containing η^2-bonded alkyne molecules can also be synthesized. For example, the reduction of $Cr(PMe_2Ph)_2Cl_2$ in the presence of 2-butyne leads to the formation of the green, crystalline compound, **8** [eq. (5)]:



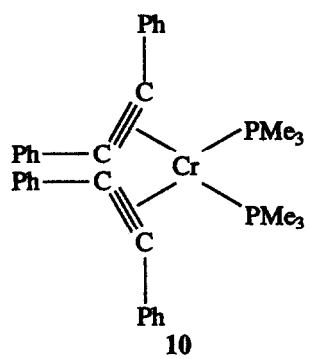
(5)

8

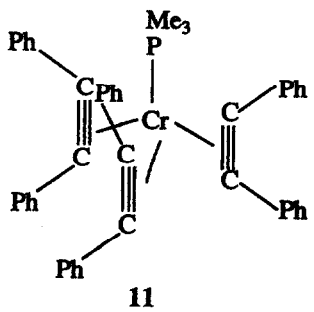
Compound **8** is surprisingly stable and can even be handled briefly at room temperature. The compound is diamagnetic, and the presence of an absorption at 1665 cm^{-1} in the IR spectrum is typical for species in which the alkyne is acting as a 4-electron donor to the metal.[16] The related compounds, **9** and **10**, have been prepared analogously and in the case of **10** the alkyne-C atoms are assigned to a singlet at 212.5 ppm in the ^{13}C NMR spectrum.[17,18]



9



10



11

Compound **10** reacts further in diethyl ether at 0°C to give the orange–yellow, crystalline compound, **11**. The suggested pseudo-tetrahedral structure (C_{3v}-symmetry) in which the three alkyne groups donate 10 electrons to the metal atom is supported by the observation of an absorption at 1700 cm^{-1} in the IR spectrum and of two singlets at 205.0 and 186.4 ppm in the ^{13}C NMR spectrum measured at −80°C which are assigned to the alkyne C-atoms. Rotation about the chromium–alkyne axis leads to broadening of these signals at −30°C, while at higher temperatures decomposition with the release of hexaphenylbenzene is observed. Mass spectral evidence suggests that a related species (*m/z* 290, M^+) is formed upon reacting $Cr(PMe_3)_2Cl_2$ with active-Mg and 2-butyne, but the compound was contaminated with hexamethylbenzene and could not be isolated pure. A CO-stabilized analogue to **11** has been mentioned,[19] and related compounds are known for molybdenum, tungsten and rhenium.[16,20] An MO-description of the bonding has been developed and need not be reiterated here.[19,21,22]

EXPERIMENTAL

The experimental conditions and the preparation of the $CrCl_2$-derivatives have been described earlier.[23] The active-Mg (Mg*) [composition Mg (96.65%), C (0.98%), H (0.19%), Fe (1.21%) and Cl (0.90%)] was prepared by the thermolysis of MgH_2, and was kindly provided by Professor B. Bogdanović and his co-workers.[15] Mg-butadiene was prepared from magnesium and butadiene.[24]

(η^4-1,3-C_4H_6)$_2$CrPMe$_3$ (1)

A suspension of $Cr(THF)Cl_3$ (1.89 g, 9.7 mmol) and PMe_3 (1.1 cm^3, 10 mmol) in diethyl ether (100 cm^3) was cooled to −30°C and treated with liq. 1,3-butadiene (3.5 cm^3, 30 mmol) and active-Mg (0.5 g, 20.8 mmol). The reaction mixture was stirred at −30°C for 24 h and the resulting brown–green mixture filtered and evaporated to dryness. The residue was extracted with precooled hexane at −30°C, and the green extract cooled to −78°C to give the compound as dark green crystals which were washed with precooled hexane at −78°C and dried at −30°C. Yield: 1.1 g (48% theory). Found: C, 56.0; H, 9.0; Cr, 21.8; P, 13.2. Calc. for $C_{11}H_{21}CrP$: C, 56.9; H, 9.0; Cr, 22.0; P, 13.1%.

MS (70 eV, 70°C): *m/z* 236 (M^+), 182, 128, 76. IR (KBr): *ν* 3040, 1470, 1420, 1280, 960 cm^{-1}.

(η^4-2,3-*Dimethyl*-1,3-*butadiene*)$_2$CrPMe$_3$ (**2**)

Prepared as above as a dark-green crystalline solid (m.p. 85°C dec.) in 48% yield from Cr(THF)Cl$_2$, PMe$_3$, active-Mg and 2,3-dimethyl-1,3-butadiene. Found: C, 61.5; H, 10.3; Cr, 17.7; P, 10.7. Calc. for $C_{15}H_{29}CrP$: C, 61.6; H, 10.0; Cr, 17.8; P, 10.6%.

MS (70 eV, 40°C): *m/z* 292 (M^+), 210, 128, 82. IR (KBr): *v* 3026, 1480, 1420, 1280, 940 cm^{-1}. Treatment of the compound with HCl leads to the release of 2,3-dimethyl-1,3-butadiene (70% theory, GC).

(η^4-2,3-*Dimethyl*-1,3-*butadiene*)$_2$CrPMe$_2$Ph (**3**)

Prepared as above as a dark-green crystalline solid (m.p. 120°C dec.) in 51% yield from Cr(THF)Cl$_2$, PMe$_2$Ph, active-Mg and 2,3-dimethyl-1,3-butadiene. Found: C, 66.6; H, 9.2; Cr, 15.0; P, 9.1. Calc. for $C_{20}H_{31}CrP$: C, 67.8; H, 8.8; Cr, 14.7; P, 8.7%.

MS (70 eV, 70°C): *m/z* 354 (M^+), 272, 216, 190, 138, 134. IR (KBr): *v* 3025, 1485, 1430, 1295, 940 cm^{-1}.

(η^4-2,3-*Dimethyl*-1,3-*butadiene*)Cr(Pr$^i_2$PC$_2$H$_4$PPr$^i_2$) (**4**)

A suspension of [Cr(Pr$^i_2$PC$_2$H$_4$PPr$^i_2$)Cl$_2$]$_2$ was prepared from Cr(THF)Cl$_2$ (1.37 g, 7.03 mmol) and Pr$^i_2$PC$_2$H$_4$PPr$^i_2$ (1.85 g, 7.04 mmol) in diethyl ether (70 cm^3), cooled to −30°C and treated with active-Mg (0.5 g, 20.8 mmol) and 2,3-dimethyl-1,3-butadiene (0.8 ml, 7.1 mmol). The reaction mixture was stirred at −30°C for 24 h, filtered and evaporated to dryness. The residue was extracted with precooled pentane at −30°C and the extract cooled to −78°C to give the compound as violet crystals which were washed with pentane at −78°C and dried at −30°C. Yield: 1.07 g (38% theory). Found: C, 60.6; H, 10.5; Cr, 13.4; P, 15.6. Calc. for $C_{20}H_{42}CrP_2$: C, 60.6; H, 10.7; Cr, 13.1; P, 15.6%.

IR (KBr): *v* 3020, 1460, 1230 cm^{-1}.

[(η^4-2,3-*Dimethyl*-1,3-*butadiene*)Cr(PEt$_3$)Cl]$_2$ (**5**)

A suspension of Cr(THF)Cl$_2$ (1.52 g, 7.8 mmol) and PEt$_3$ (1.2 ml, 8.0 mmol) in diethyl ether (70 cm^3) was cooled to −30°C and treated with active-Mg (0.48 g, 20.0 mmol) and 2,3-dimethyl-1,3-butadiene (1.1 cm^3, 10.0 mmol) and stirred for 24 h at −25°C. The reaction mixture was filtered at −20°C and evaporated to dryness in high vacuum. The residue was extracted with pentane at −10°C and the extract cooled to −78°C to give the compound as red–black crystals which were isolated and washed with precooled pentane (10 cm^3) at −78°C and dried at −30°C. Yield: 1.07 g (48% theory). Found: C, 49.8; H, 9.2; Cl, 12.1; Cr, 18.0; P, 10.9. Calc. for $C_{24}H_{50}Cl_2Cr_2P_2$: C, 50.1; H, 8.8; Cl, 12.3; Cr, 18.1; P. 10.8%.

MW(cryoscopic): 594 g mol^{-1} (calc. 575 g mol^{-1}). IR (KBr): *v* 3016, 1458, 1039 cm^{-1}. Magn. suscept.: μ_B 4.9.

(η^4-1,3-C$_4$H$_6$)Cr(PMe$_3$)$_2$Cl (**6**)

A suspension of Cr(THF)$_3$Cl$_3$ (2.46 g, 6.6 mmol) and PMe$_3$ (1.4 cm^3, 13.5 mmol) in THF (50 cm^3) was cooled to −78°C and treated with (C$_4$H$_6$)Mg(THF)$_2$ (1.56 g, 7.0 mmol). The reaction mixture was stirred for 3 h at −30°C, filtered at −20°C and the solution evaporated to dryness under oil-pump vacuum. The residue was extracted at −10°C with precooled pentane and the extract cooled to −78°C to give the compound as red–black crystals (m.p. 85°C dec.). Yield: 1.6 g (83% theory). The compound can also be prepared by reacting preformed Cr(PMe$_3$)$_2$Cl$_2$ with either (C$_4$H$_6$)Mg(THF)$_2$ (yield 42%) or active-Mg and 1,3-butadiene (yield 19%). Found: C, 40.8; H, 8.3; Cl, 12.2; Cr, 17.6; P, 20.9. Calc. for $C_{10}H_{24}ClCrP_2$: C, 40.9; H, 8.2; Cl, 12.1; Cr, 17.7; P, 21.1%.

MW(cryoscopic): 223 g mol^{-1} (calc. 293.7 g mol^{-1}). IR (KBr): *v* 3030, 1480, 1420, 1280, 950 cm^{-1}.

(η^4-1,3-C$_4$H$_6$)(η^3-C$_3$H$_5$)CrPMe$_3$ (**7**)

(η^4-1,3-C$_4$H$_6$)Cr(PMe$_3$)$_2$Cl (**6**) (1.0 g, 3.4 mmol) was dissolved in diethyl ether (50 cm^3) at −30°C and ethereal allylmagnesium chloride (11 cm^3 of a 0.33 mol soln, 3.6 mmol) was added slowly. The green reaction mixture was stirred for 24 h at −30°C, filtered and evaporated to dryness. The residue was dissolved in hexane (20 cm^3) at −30°C, filtered and the filtrate cooled to −78°C to give the compound as green crystals. Yield: 0.84 g (83% theory). Found: C, 52.8; H, 10.0; Cr, 16.6; P, 19.8. Calc. for $C_{13}H_{29}CrP_2$: C, 52.2; H, 9.8; Cr, 17.4; P, 20.7%.

MS (70 eV, 50°C): *m/z* 299 (M^+), 245, 233, 204, 169. IR (KBr): *v* 3020, 1470, 1420, 1280, 1215, 940 cm^{-1}.

(η^2-MeC≡CMe)$_2$Cr(PMe$_2$Ph)$_2$ (**8**)

A suspension of Cr(PMe$_2$Ph)$_2$Cl$_2$ was prepared from Cr(THF)Cl$_2$ (1.03 g, 5.3 mmol) and PMe$_2$Ph (1.6 cm^3, 11.0 mmol) in diethyl ether (50 cm^3), cooled to −30°C and active-Mg (0.48 g, 20.0 mmol) and 2-butyne (1.2 cm^3, 15 mmol) were added. The

reaction mixture was stirred for 24 h, filtered at −20°C and evaporated to dryness at −30°C under high vacuum. The residue was extracted with pre-cooled pentane at −20°C, the extract concentrated, hexane (10 cm^3) added and the solution cooled to −78°C. The compound was deposited as green crystals which were isolated, washed with pentane at −78°C and dried in high vacuum at −30°C; m.p. 75°C dec. Yield: 1.3 g (56% theory). Found: C, 66.2; H, 7.8; Cr, 11.6; P, 14.3. Calc. for $C_{24}H_{34}CrP_2$: C, 66.0; H, 7.9; Cr, 11.9; P, 14.2%.

MS (70 eV, 73°C): 436 (M^+), 328, 190. IR (KBr): ν 1675, 1665, 1430, 1265, 930 cm^{-1}. ^1H NMR (d_8 THF, −30°C): δ 7.20 (m, Ph), 2.62 (d, MeC≡), 1.40 [d, MeP, J(P,H) 6.8]. ^{31}P NMR (d_8 THF, −30°C): δ 78.83.

(η^2-MeC≡CMe)$_2$Cr($Pr^i_2PC_2H_4PPr^i_2$) (**9**)

Prepared as above as a green crystalline solid (m.p. 85°C dec.) in 57% yield from Cr(THF)Cl_2, $Pr^i_2PC_2H_4PPr^i_2$ active-Mg and 2-butyne in diethyl ether. Found: C, 62.5; H, 10.8; Cr, 12.2; P, 14.6. Calc. for $C_{22}H_{44}CrP_2$: C, 62.5; H, 10.5; Cr, 12.3; P, 14.7%.

IR (KBr): ν 1653, 1460, 1240 cm^{-1}. ^1H NMR (d_8 THF, −30°C): δ 2.77 [d, MeC≡, J(P,H) < 1], 2.03 (m, PCH_2), 1.83 [(m, CH, J(P,H) 7); 0.78/0.61] [dd, Me, J(P,H) 10.8/13.4]. ^{31}P NMR (d_8 THF, −30°C): δ 146.0.

(η^2-PhC≡CPh)$_2$Cr(PMe_3)$_2$ (**10**)

Prepared as above as a red crystalline solid in 55% yield from Cr(THF)Cl_2, PMe_3 active-Mg and diphenylacetylene in diethyl ether. Found: C, 71.9; H, 6.6; Cr, 8.8; P, 10.2. Calc. for $C_{34}H_{38}CrP_2$: C, 72.8; H, 6.8; Cr, 9.3; P, 11.1% (PMe_3-dissociation occurs at 0°C).

IR (KBr): ν 1670, 1650, 1440, 1295, 940 cm^{-1}. ^1H NMR (d_8 THF, −30°C): δ 7.25 (m, Ph), 1.10 [d, PMe, J(P,H) 7.5]. ^{13}C NMR (d_8 THF, −10°C): δ 212.5 (C≡C), 144.7/128.8/127.5/126.1 [Ph, J(C,H) 0/159/159/160], 23.1 [PMe, J(C,H) 128]. ^{31}P NMR (d_8 THF, −30°C): δ 56.34.

(η^2-PhC≡CPh)$_3$CrPMe$_3$ (**11**)

(η^2-PhC≡CPh)$_2$Cr(PMe_3)$_2$ (**10**) (1.5 g, 2.7 mmol) was dissolved in diethyl ether (100 cm^3) and the solution stirred at room temperature for 24 h. The colour changed from red to yellow. The solution was filtered and cooled to −78°C to give the compound as orange crystals which were isolated, washed with pentane at −30°C and dried. Yield: 0.46 g (39% theory). Found: Cr, 7.9; P, 4.5. Calc. for $C_{45}H_{39}CrP$: Cr, 7.9; P, 4.7%.

IR (KBr): ν 1700, 1440, 950 cm^{-1}. ^1H NMR (d_8 THF, −30°C): δ = 7.6–6.5 (m, Ph), 1.45 [d, PMe, J(P,H) 10]. ^{13}C NMR (d_8 THF, −80°C): δ 205.0/186.4 [d, C≡C, J(P,C) 12.5/38.1], 147.9/143.3/129.5/128.5/128.3/126.7/126.0/125.8 (Ph), 18.5 [PMe, J(P,C) 20.9, J(C,H) 128]. ^{31}P NMR (d_8 THF, −30°C): δ 33.34.

(*Received* 12 *December* 1990; *accepted* 20 *February* 1991)

Abstract—Linear plots of standard enthalpies of formation of homoleptic metal halides, MX_m, against the standard enthalpies of formation of the gaseous hydrogen halides, HX, were used to assess a large number of literature data and to gain a better understanding of the correlations themselves. The method is extremely simple, and enables the estimation of new data.

Enthalpies of formation of organic substances can be estimated through several well known methods.[1–5] These so-called "schemes", which rely on the additivity of bond enthalpies or group contributions and have been refined to account for second order effects such as strain and resonance,[6] yield reliable data for a large number of molecules. A much less favourable situation occurs for inorganic compounds. The wide variety of elements and bonds, together with experimental difficulties in probing the energetics of many inorganic materials, has limited the size of the thermochemical data bank and hindered the development of prediction methods. Efforts in this direction have only become available in recent years, thanks to the work of several groups.[7–14]

In two early papers[7,8] we described a method to estimate enthalpies of formation of inorganic and organometallic molecules, both in their standard reference states (i.e. their stable physical states at 298.15 K and 1 bar) and in the gas phase.[7,8] The method consists of linear correlations between the enthalpies of formation of a given family of compounds, MX_nL_m, and the enthalpies of formation of ligands L or LH [eq. (1)]. As the latter quantities are usually available with good accuracies, the correlations can be used to derive unknown values of $\Delta H_f^\ominus(MX_nL_m,rs/g)$ or even to assess experimental data.

$$\Delta H_f^\ominus(MX_nL_m,rs/g) = a\Delta H_f^\ominus(LH,rs/g)+b. \quad (1)$$

Another good feature of the linear correlations represented by eq. (1) is their apparent physical meaning. Although any empirical method which enables predicting enthalpies of formation of inorganic compounds is itself rather valuable, some understanding of *why* the method works is also desirable. Interesting conclusions, concerning, for example, the trends of metal–ligand and ligand–hydrogen bond disociation enthalpies, were inferred from the above linear relationship.[8] This early discussion revealed, however, some less understood features of the correlation. One of them is related to the slope, a, in eq. (1), which, according to the simple thermochemical model used (see below), should be equal to the number of ligands, L, bonded to the metal atom. Yet, it is observed that a is often different from that number of ligands. In order to gain new insights into this problem we decided to

apply the method to analyse the fairly comprehensive thermochemical data of homoleptic metal halides, MX_n. In addition to some general patterns that have emerged from this exercise, the analysis was also used as an assessment of tabulated data and to help in the selection of several controversial values.

DESCRIPTION OF THE METHOD

Consider Scheme 1, which represents an hypothetical reaction involving the metal halide, MX_m. Here, ΔH_1 and ΔH_2 are the enthalpies of reaction with MX_m in the standard reference state (usually solid) and in the gas phase, respectively, and ΔH_V are vaporization (or sublimation) enthalpies.

$$\begin{array}{ccccc} MX_m(rs)+(m/2)H_2(g) & \xrightarrow{\Delta H_1} & M(c)+mHX(g) \\ \downarrow \Delta H_{V1} \quad \downarrow 0 & & \downarrow \Delta H_{V2} \quad \downarrow 0 \\ MX_m(g)+(m/2)H_2(g) & \xrightarrow{\Delta H_2} & M(g)+mHX(g) \end{array}$$

Scheme 1.

As shown in the next section, there is a linear correlation between $\Delta H_f^\ominus(MX_m,g)$ and $\Delta H_f^\ominus(HX,g)$ [eq. (2)]. The implications of this relationship can be derived by expressing ΔH_2 in terms of M—X and H—X bond dissociation enthalpies [eq. (3)].

$$\Delta H_f^\ominus(MX_m,g) = a\Delta H_f^\ominus(HX,g)+b, \quad (2)$$

$$\Delta H_2 = \Delta H_f^\ominus(M,g)+m\Delta H_f^\ominus(HX,g) - \Delta H_f^\ominus(MX_m,g) = m[\bar{D}(M—X) - D(H—X)]+(m/2)D(H—H). \quad (3)$$

It is easily concluded that if eq. (2) is observed and $m = a$, then ΔH_2 is constant for a given metal and so is the difference between the metal–halogen *mean* bond dissociation enthalpy and the halogen–hydrogen bond dissociation enthalpy. This parallel trend of $\bar{D}$(M—X) and D(H—X) had been noted before by ourselves[8] and by Bercaw and co-workers,[15] and its use for predicting new values of metal–ligand bond dissociation enthalpies has been suggested. If the slope a of the empirical correlation [eq. (2)] equals the number of ligands m, then $\bar{D}$(M—X) $-\bar{D}$(M—Y) = D(H—X) $-D$(H—Y) for any pair of halogens X,Y. In the most general case, however, $a \neq m$ and the difference $\bar{D}$(M—X) $-\bar{D}$(M—Y) is related to D(H—X) $-D$(H—Y) through eq. (4). In turn, this implies that in the sequence F → Cl → Br → I [i.e. $\Delta H_f^\ominus(HX,g) < \Delta H_f^\ominus(HY,g)$] the correction term will be positive when $a > m$ and negative when $a < m$. In other words, the parallel trend holds but the differences $\bar{D}$(M—X) $-\bar{D}$(M—Y) may be higher or lower than D(H—X) $-D$(H—Y), depending on the ratio a/m. This obvious conclusion is not restricted to X,Y = halogen: it holds for any ligands L,L′ from a given family (i.e. that belong to the same correlation). It is therefore important to know the value of a whenever the difference D(L—H) $-D$(L′—H) and $\bar{D}$(M—L) [or D(M—L)] are used to estimate M—L′ bond dissociation enthalpy.

$$\bar{D}(M—X)-\bar{D}(M—Y) = D(H—X)-D(H—Y) +[\Delta H_f^\ominus(HX,g)-\Delta H_f^\ominus(HY,g)](1-a/m). \quad (4)$$

Let us go back to Scheme 1 in order to address a final point. As shown below, the linear correlations do not hold just for the enthalpies of formation of MX_m and HX in the *gas phase*, but they are usually observed (and often have better statistical fits) when the enthalpies of formation of MX_m in their *standard reference states* (usually solid) are used. This second empirical relationship can be compared with eq. (5), which was derived with the help of Scheme 1. As ΔH_{V2} is constant for a given metal, the correlation between $\Delta H_f^\ominus(MX_m,rs)$ and $\Delta H_f^\ominus(HX,g)$ implies that the enthalpy of vaporization of MX_m, ΔH_{V1}, which of course varies with X, is itself a linear function of $\Delta H_f^\ominus(HX,g)$.

$$\Delta H_f^\ominus(MX_m,rs) = m\Delta H_f^\ominus(HX,g) - m[\bar{D}(M—X)-D(H—X)] - \Delta H_{V1}+\Delta H_{V2}-(m/2)D(H—H). \quad (5)$$

BRIEF ANALYSIS OF LITERATURE DATA

The method described above will now be applied to review the literature data of homoleptic metal halides of groups 1–12. Included are also the values for thorium and uranium halides. It is stressed that this survey is not comprehensive. One of the points of doing such an exercise was to analyse the values recommended in the two most currently used thermochemical tables for inorganic compounds, JANAF and NBS tables.[16,17] Occasionally, however, data from other sources were included in the discussion. Whenever possible, JANAF tables were preferred over NBS, since they usually provide uncertainty intervals. $\Delta H_f^\ominus(HX,g)$ were taken from the latter compilation, viz. −271.1, −92.307, −36.4 and 26.48 kJ/mol, respectively for X = F, Cl, Br, and I.

Correlations similar to eq. (2) were analysed through a standard least-squares program and the results are shown in Tables 1 and 2. The error bars indicated for the slopes and the intercepts are standard deviations.

Table 1. Parameters for the least-squares fits of $\Delta H_f^{\ominus}(MX_m,c/l)$ vs $\Delta H_f^{\ominus}(HX,g)$

Group 1

Although the experimental uncertainties of the enthalpies of formation of solid alkaline metal halides are less than 2 kJ/mol, the correlations for these families are not as good as could have been anticipated, a fact that is likely to reflect a limitation of the method itself. Nevertheless, it is observed that in one of the worst cases (KX) the data are fitted within *ca* 6 kJ/mol. Of similar quality are the correlations for the gas phase enthalpies of formation (Table 2) despite their higher experimental uncertainties (up to *ca* 13 kJ/mol). It is worth noting that the fit for NaX in Table 2 relies on three points only, since JANAF tables do not recommend a value for $\Delta H_f^{\ominus}$(NaI,g). An estimate of −106.1±1.7 kJ/mol, obtained by using the correlation together with $\Delta H_f^{\ominus}$(HI,g), disagrees with the value given in NBS tables, −79.5 kJ/mol. Even considering the risk of a long extrapolation, the discrepancy indicates that the value quoted in NBS tables for gaseous sodium iodide is fairly inconsistent with the remaining sodium halide data, which, incidentally, are similar in both tables (within 4 kJ/mol).

An interesting point that is also observed for other groups addressed below, concerns the variation in the slope of the correlations in Table 1: *a*

decreases with increasing atomic number. The trend is not so smooth for the values in Table 2, but this probably results from experimental errors of the individual values of the enthalpies of formation.

Group 2

Uncertainties of 1–6 kJ/mol are assigned to the enthalpies of formation of most solid alkaline earth metal halides. A noticeable exception is found for BeI_2 (−189±21 kJ/mol). Good linear fittings of these data are seen in Table 1. For the gaseous species, on the other hand, although the error bars are considerably larger, the correlations are even better (Table 2). As noted for Group 1, a decrease of *a* with the atomic number is also observed in this group (Fig. 1).

Group 3

The three enthalpies of formation of solid scandium halides used to derive the correlation in Table 1 were taken from NBS tables. The experimental uncertainties are not available, but the errors in *a* and *b* indicate some inconsistency in the data. A value of −490±22 kJ/mol is predicted for $\Delta H_f^{\ominus}(ScI_3,c)$.

A better correlation is observed for YX_3,

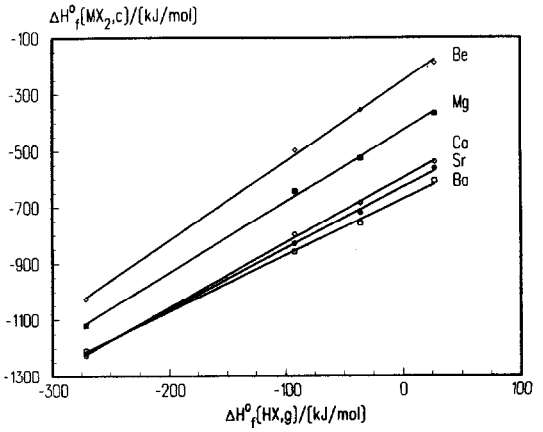

Fig. 1. Enthalpies of formation of solid metal halides from Group 2 against the enthalpies of formation of gaseous hydrogen halides.

obtained from three values (Cl, Br, I) reported by Fuger and co-workers.[18] The NBS values (F, Cl, I) lead to $a = 3.729 \pm 0.217$ and $b = -693.1 \pm 36.0$. Our method is of course unable to assess absolute values (e.g. the discrepancy between the values recommended for $\Delta H_f^\ominus(YI_3,c)$ in the two publications is 24 kJ/mol) but the data fitted in Table 1 look more consistent.

Group 4

The plots of $\Delta H_f^\ominus(MX_m,g)$ vs $\Delta H_f^\ominus(HX,g)$ (M = Ti, Zr; m = 1–4) are illustrated in Figs 2 and 3. They rely on JANAF data, with the exception of $\Delta H_f^\ominus(ZrCl_m,g)$, m = 1–3, which were quoted from a recent work by Efimov *et al.*[19] These values lead to significantly better correlations than the $\Delta H_f^\ominus(ZrCl_m,g)$ data taken from JANAF tables. Despite this improvement, it is observed in Fig. 3 (or in Table 2) that the plot involving ZrX molecules is far from satisfactory, even by excluding from the fit the value recommended by JANAF for $\Delta H_f^\ominus(ZrI,g)$, which looks too high. The worst correlation in the case of the titanium halides is for TiX_2, which is not surprising, given the large uncertainties (13–42 kJ/mol) assigned to the experimental values. The error bars are also large for $\Delta H_f^\ominus(TiX,g)$, *ca* 42 kJ/mol, but the data seem fairly consistent.

The correlations for TiX_m and ZrX_m (m = 3, 4) in their standard reference state are poorer than the gas phase plots. As the uncertainties of both sets of data are similar, this could be related to the trend of ΔH_{VI} with $\Delta H_f^\ominus(HX,g)$ [see the discussion before eq. (5)]. More likely, however, it merely results from inaccuracies of experimental values. Note, for example, that the plots involving solid state enthalies of formation of TiX_2 and ZrX_2 are better than those made with the gas phase values. In addition, the trend in the slopes (a) for TiX_4 and ZrX_4 (Tables 1 and 2) is opposite to what could be expected.

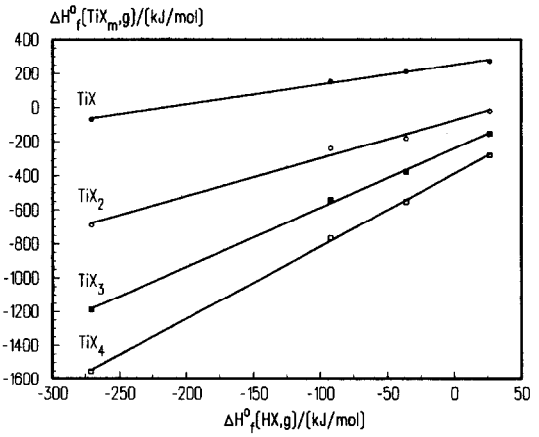

Fig. 2. Enthalpies of formation of gaseous titanium halides against the enthalpies of formation of gaseous hydrogen halides.

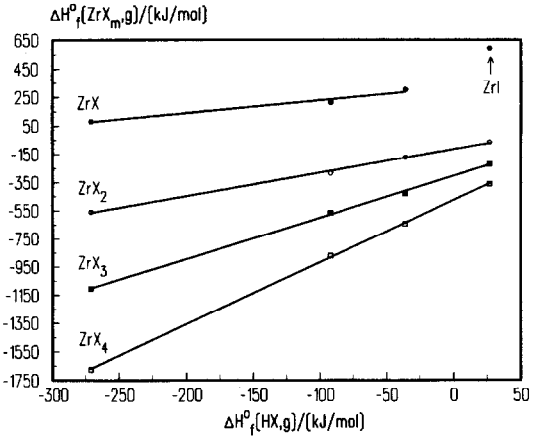

Fig. 3. Enthalpies of formation of gaseous zirconium halides against the enthalpies of formation of gaseous hydrogen halides.

Group 5

The excellent three-point correlation of $\Delta H_f^\ominus(VX_3,c)$ lends some confidence to the estimated value for $\Delta H_f^\ominus(VF_3,c)$, -1047 ± 1 kJ/mol, which is not reported in NBS tables. Probably less reliable is the predicted value for $\Delta H_f^\ominus(VF_2,c)$, -769 ± 13 kJ/mol. This latter three-point plot relies on NBS data for X = Br, I and on a new value for $\Delta H_f^\ominus(VCl_2,c)$, -457.3 ± 1.1.[20]

The correlations for NbX_5 and TaX_5 are less satisfactory, particularly those involving the solid state data. The gas phase plot of the enthalpies of formation of NbX_5 (Table 2) can be used to predict $\Delta H_f^\ominus(NbI_5,g)$, -65 ± 34 kJ/mol. The same exercise for $\Delta H_f^\ominus(TaX_5,g)$ leads to $\Delta H_f^\ominus(TaI_5,g) \approx -124 \pm 21$ kJ/mol. The three points that define this latter correlation were taken from three literature sources.[17,21,22]

Group 6

The correlation for CrX_3 (Table 1) does not include $\Delta H_f^\ominus(CrBr_3,c)$, which is not available but can be estimated as -396 ± 19 kJ/mol. The inconsistency of gas phase enthalpies of formation of CrX_2, on the other hand, is apparent by the error bars in Table 2. Better is the plot involving $\Delta H_f^\ominus(CrX_2,c)$, Table 1. For the analogous MoX_2 molecules, both gas phase and solid three-point plots are very good, allowing estimation of the missing

data: $\Delta H_f^\ominus(MoF_2,c) = -552 \pm 13$ kJ/mol and $\Delta H_f^\ominus(MoCl_2,g) = 89 \pm 1$ kJ/mol. It is worth mentioning that the NBS value for $\Delta H_f^\ominus(MoBr_2,c)$, -261.1 kJ/mol, seems inconsistent with the remaining data. The value recommended in JANAF tables, -202.9 ± 25 kJ/mol, was preferred to define the correlation.

The uncertainties assigned to most of the available enthalpies of formation of solid and gaseous MoX_3 are large, but both three-point plots are reasonable, yielding the following estimates, the first being much less reliable than the second, which is an interpolation: $\Delta H_f^\ominus(MoF_3,c) = -790 \pm 54$ kJ/mol and $\Delta H_f^\ominus(MoCl_3,g) = -141 \pm 16$ kJ/mol.

The inconsistency of JANAF data for the enthalpies of formation of gaseous MoX_4 is reflected by the poor fit seen in Table 2. A better plot is obtained when the three available solid state values are considered (Table 1). This correlation leads to $\Delta H_f^\ominus(MoF_4,c) = -1007 \pm 17$ kJ/mol.

Some of JANAF data for gaseous and standard reference state enthalpies of formation of WX_6 are rather uncertain. This and also the large slope of these plots justify the huge error bars in *a* and *b* seen in Tables 1 and 2. The picture is somewhat similar for the fit involving $\Delta H_f^\ominus(WX_5,c)$, Table 1, which also relies on three experimental values, but here one (WF_5) is an estimate (-1457 kJ/mol) by Burgess *et al.*[23]

Large uncertainties (13–42 kJ/mol) are assigned to the three available $\Delta H_f^\ominus(MoX,g)$ values, but the plot (Table 2) is better than could be anticipated. The missing value, $\Delta H_f^\ominus(MoCl,g)$, is estimated as 414 ± 3 kJ/mol. Not surprisingly, the analogous correlation for WX is worse, reflecting the rather high uncertainties (42–84 kJ/mol) that affect the experimental data. The error bars in *a* and *b* are not as large because the slope is small and because the $\Delta H_f^\ominus(WX,g)$ values are fairly consistent. This three-point correlation leads to an estimate for $\Delta H_f^\ominus(WI,g)$: 648 ± 11 kJ/mol.

Group 7

Only the values of $\Delta H_f^\ominus(MnX,g)$ are available to define a linear correlation (Table 2).

Group 8

JANAF and NBS data had to be used together to yield the parameters displayed in Tables 1 and 2 for FeX_3. The solid state correlation relies on three points only and enables estimation of $\Delta H_f^\ominus(FeI_3,c)$, -32 ± 40 kJ/mol. The high uncertainty is likely to indicate poor quality of experimental data. Recent values reported for $\Delta H_f^\ominus(FeCl_3,c)$, -395.3 ± 0.7 kJ/mol,[24] and $\Delta H_f^\ominus(FeBr_3,c)$, -262.6 ± 0.2 kJ/mol,[25] make small (*ca* 5 kJ/mol) differences from those tabulated in JANAF and NBS tables. This suggests that the value recommended for $\Delta H_f^\ominus(FeF_3,c)$, -1042 ± 13 kJ/mol,[16] may be the source of the inconsistency and is probably too low.

The correlation for gaseous FeX_3 (Table 2) is fairly good and so are those obtained for FeX_2 (Tables 1 and 2). A slight improvement to that involving $\Delta H_f^\ominus(FeX_2,g)$ is achieved if the JANAF values for X = Cl, Br are replaced by the data measured by Efimov and Evdokimova,[24,25] used together with the sublimation enthalpies taken from JANAF.

Values of RuX_3 from the JANAF (Br, I) and NBS (Cl) tables look very consistent and lead to -414 ± 4 kJ/mol for $\Delta H_f^\ominus(RuF_3,rs)$.

Group 9

Data for $\Delta H_f^\ominus(CoX_2,c)$ chosen to define the correlation in Table 1, were taken from JANAF (F, Cl) and NBS (Br, I) tables and seem quite reliable. The values for the chloride and the iodide were remeasured by Lavut *et al.* (-311.1 ± 0.3 kJ/mol),[26] and Efimov and Evdokimova (-215.4 ± 0.3 kJ/mol),[27] respectively, and support that idea. A small improvement of the fit is, however, obtained if the last value is used instead of the NBS result (-220.9 kJ/mol).

Group 10

The three-point fit of $\Delta H_f^\ominus(PtX_4,c)$ data is excellent and leads to an estimate for $\Delta H_f^\ominus(PtF_4,c)$, -471 ± 1 kJ/mol. There is, however, a controversy around this quantity. The above prediction is some 210 kJ/mol higher than a value quoted in a recent paper![28] As stated above, our method is unable to decide for an absolute value. The only valid comment on that discrepancy is that NBS data for PtX_4 are totally inconsistent with the lower number (-681 ± 25 kJ/mol)[28] for the tetrafluoride. One can also speculate on the slope of the PtX_4 correlation in Table 1. Despite the consistency, the slope appears too small, since a higher value could be expected (compare, for example, with the slopes for the correlations involving NiX_2 and PdX_2). Thus, it may well be possible that the observed consistency of NBS data is fortuitous.

Excellent and unsatisfactory correlations are observed for $\Delta H_f^\ominus(NiX_2,c)$ and $\Delta H_f^\ominus(PdX_2,c)$, respectively (Table 1). The latter is a three-point (Cl, Br, I) fit.

Group 11

The parameters derived from the enthalpies of formation of gold halides (Table 1) rely on data for the fluoride, chloride and bromide. On this basis, the value of $\Delta H_f^{\ominus}(AuI_3,c)$ is predicted as 35 ± 7 kJ/mol (it is noted, however, that the slope in Table 1 seems too small, suggesting that this estimate is a lower limit). A similar exercise made for $\Delta H_f^{\ominus}(CuI_2,c)$, by using the three-point fit in Table 1, leads to -25 ± 13 kJ/mol.

The slopes of the correlations for copper, silver and gold mono-halides are in the expected trend, but the consistency of data is not very good, particularly for AuX. In this case, the fit was defined with three points (Cl, Br, I).

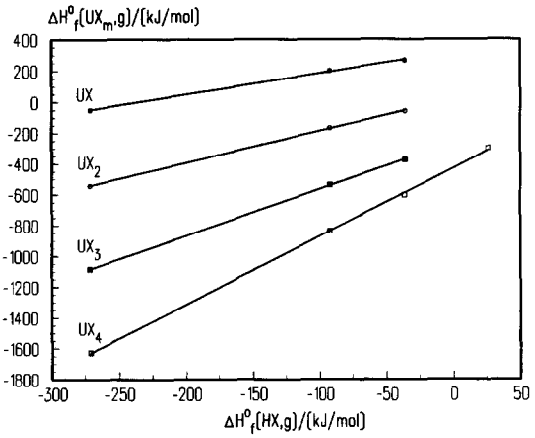

Fig. 4. Enthalpies of formation of gaseous uranium halides against the enthalpies of formation of gaseous hydrogen halides.

Group 12

Data for zinc, cadmium and mercury dihalides in their standard reference states lead to the correlations shown in Table 1. The HgX_2 plot relies on values for the chloride, bromide and iodide, and indicates that $\Delta H_f^{\ominus}(HgF_2,c) = -404 \pm 6$ kJ/mol.

A three-point fit involving $\Delta H_f^{\ominus}(ZnX_2,g)$, Table 2, was obtained from NBS data together with the enthalpies of sublimation of $ZnBr_2$ and ZnI_2 quoted from a different source.[29] In the case of CdX_2, also a three-point correlation, the NBS data were coupled with the enthalpies of sublimation of $CdCl_2$, $CdBr_2$, and CdI_2.[30] Finally, the plot of HgX was obtained with NBS data (F, Cl, I) and a value for $\Delta H_f^{\ominus}(HgBr,g)$ taken from a survey by Hepler and Olofsson.[31]

Thorium

Enthalpies of formation of the solid and gas phase ThX_4 given in NBS compilation must be fairly reliable, as indicated by the correlations in Tables 1 and 2, and by a comparison of some values with more recent literature data. For example, Lau and Hildenbrand determined $\Delta H_f^{\ominus}(ThF_4,g)$ and $\Delta H_f^{\ominus}(ThCl_4,g)$ as -1759 ± 4 kJ/mol and -962 ± 4 kJ/mol, respectively.[32,33] These values differ by 10 and 4 kJ/mol from those recommended by the NBS tables.

Uranium

Values of a and b for UX_5 in Table 1 rely on a three-point correlation (F, Cl, Br) defined with NBS data. The error bars are considerable, probably indicating lack of consistency of those data. A slight improvement of the fit is achieved when the NBS value for $\Delta H_f^{\ominus}(UCl_5,c)$, -1059 kJ/mol, is replaced by a result taken from another source, -1042 ± 2 kJ/mol.[34]

Some controversy surrounds the experimental value of $\Delta H_f^{\ominus}(UF_4,c)$. NBS tables recommend -1914.2 kJ/mol, but O'Hare's estimate is -1897 ± 6 kJ/mol.[35] While the fitting parameters in Table 1, relying on NBS data, cannot judge the discrepancy, a significantly better correlation is obtained when O'Hare's estimate and his experimental value for $\Delta H_f^{\ominus}(UCl_4,c)$, -1022.8 ± 3.8 kJ/mol, are used ($a = 4.657 \pm 0.114$, $b = -623.9 \pm 16.6$, $r = 0.9994$).

The correlation defined for $\Delta H_f^{\ominus}(UX_3,c)$, Table 1, is good, and much better are those shown in Table 2 and in Fig. 4, involving the gaseous halides UX_m ($m = 1$–4). With the exception of UX_4, all rely on data obtained by Lau and Hildenbrand for the fluorides, chlorides, and bromides.[36–38] The NBS value for $\Delta H_f^{\ominus}(UI_4,g)$ was included in the fit of $\Delta H_f^{\ominus}(UX_4,g)$.

FINAL REMARKS

The previous, somewhat tedious, analysis of some literature values of standard enthalpies of formation of metal halides illustrated how an extremely simple method can be used to assess or to estimate new data. As emphasized above, the latter exercise has to be done with caution, since the linear correlations assess the internal consistency of a set of data, rather than absolute magnitudes. In addition, examples were found where good linear fits, indicating consistent values, yield slopes which are perhaps too different from the number of ligands bonded to the metal atom (see, for example, the comments for PtX_4). Incidentally, it is sur-

prising that the correlations hold so well for solid compounds.

The data surveyed are not enough to draw firm conclusions on the variation of the slope throughout the Periodic Table, but, as noted above, a seems to decrease with increasing atomic number for a given group. The most obvious parameter to relate with this change would be the electronegativity of the metal, χ_M, and indeed a qualitative trend is apparent. On the other hand, when Pauling's original equation for his electronegativity scale[39] is introduced in eq. (4), the complex equation obtained indicates also a relationship between a and metal–metal bond dissociation enthalpy, D(M—M).[40] A qualitative trend is observed in this case, for Group 1. Bond order is another parameter that may be related with the slope of the correlations and this possibility is presently being investigated. Further reliable *gas phase* data are, however, probably necessary in order to try a more thorough discussion about the meaning of a.

STUDIES OF THE *CIS–TRANS* ISOMERISM OF SOME SQUARE-PLANAR PLATINUM(II) NITROIMIDAZOLE COMPLEXES

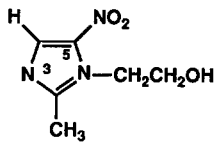
FIONA M. MACDONALD and PETER J. SADLER*

Department of Chemistry, Birkbeck College, University of London, Gordon House and Christopher Ingold Laboratory, 29, Gordon Square, London WC1H 0PP, U.K.

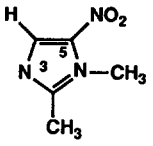
(*Received* 14 *December* 1990; *accepted* 20 *February* 1991)

Abstract—*Cis–trans* isomerism reactions of *cis*-$Pt(MNZ)_2X_2$ complexes, where MNZ is metronidazole [1-(2′-hydroxyethyl)-2-methyl-5-nitroimidazole] and X = Cl, Br or I, occur in both the solid-state and in solution, and were studied by differential scanning calorimetry and multinuclear NMR spectroscopy. For the solid-state process, enthalpies of isomerization ranged from −21 to −49 kJ mol^{-1}. First order rate constants were determined from ^{195}Pt NMR measurements in solution; consideration of the effects of added halides and free ligand suggests that the reaction mechanism involves associative processes.

The stereochemistry of platinum(II) complexes is often of critical importance to their biological activity. For example, the *cis* isomer of $PtCl_2(NH_3)_2$ is an active antitumour agent, whereas the *trans* isomer is inactive.[1] In contrast, the *cis* isomer of $PdCl_2(NH_3)_2$ is inactive.[2] This can be attributed to the rapid *cis–trans* isomerism of palladium(II) complexes in solution, whereas for platinum(II), although the *trans* isomer is 13 kJ mol^{-1} more stable than the *cis* isomer,[3] the isomerization takes place very slowly.



MNZ



DMZ (4)

The relative stabilities of the isomers are determined largely by the nature of the ligands, but *trans* isomers of platinum(II) complexes are frequently more thermodynamically stable than their *cis* isomers. Thus *trans*-$PtCl_2(py)_2$, where py is pyridine, is *ca* 21 kJ mol^{-1} more stable than the *cis* form.[4] For complexes of the type $Pt(NRZ)_2X_2$ (where X is halide) the *trans* isomer is thermodynamically more stable but the *cis* isomer is the kinetically favoured product. In certain cases a *cis–trans* isomerization process may be observed—this may occur spontaneously or be induced thermally, photochemically or in the presence of a nucleophile.[5] Once formed, the *trans* isomer cannot revert to the *cis* configuration. The reverse situation, where the *cis* isomer is the thermodynamic product and the *trans* is the kinetic product, is rarer but in a few cases *trans–cis* isomerism has been observed. An example is provided by $Pt(dialkylsulphoxide)_2Cl_2$ complexes.[6]

Isomerization reactions may occur in the solid state as well as in solution. We report here studies of the isomerization of platinum(II) nitroimidazole complexes in the solid state and in solution using differential scanning calorimetry (DSC) and NMR spectroscopy. The complexes are of interest because of their potential ability to sensitize tumour cells towards radiation damage and could therefore be useful in cancer treatment.[7–11]

EXPERIMENTAL

Metronidazole (MNZ) and dimetridazole (DMZ) were supplied by Rhône Poulenc (Dagenham), and the platinum(II) complexes were prepared by the routes described previously.[8] NMR

solvents were purchased from Aldrich, and glycerine formal from Fluka.

Samples for DSC measurements were ground up using a pestle and mortar, and one sample of *cis*-$Pt(MNZ)_2Cl_2$ was subjected to a commercial milling procedure by Rhône Poulenc (sample B).

DSC

DSC thermograms were obtained on a Perkin–Elmer DSC-2 instrument. Samples were prepared by weighing out milligram quantities of sample into aluminium pans which were then sealed with lids. An empty sealed pan was used as a reference. Unless otherwise stated, samples were run at a heating rate of 10°C min^{-1}, chart speed 10 mm min^{-1} and range setting of 2 mcal (8.368 mJ) s^{-1}. The temperature ranges depended on the complex being studied. A sample with a known heat of fusion (indium; $\Delta H_{fus} = 6.793$ cal g^{-1}) was used for calibration. The areas under the peaks were measured using a planimeter. All runs were carried out in triplicate.

NMR

Information regarding the kinetics of the isomerization reaction in solution was obtained from the rates of disappearance of the ^{195}Pt-$\{^1H\}$ NMR peak for the *cis* isomer and of the appearance of the peak for the *trans* isomer.

^{195}Pt-$\{^1H\}$ NMR spectra at 85.7 MHz were obtained on a Bruker WH 400 spectrometer equipped with a 10 mm broad band probe and a B-VT-1000 variable temperature unit. For each experiment a series of spectra were collected using the same parameters: 500 transients, 0.4 s acquisition time, 0.6 s relaxation delay, 45° flip angle together with broad band decoupling. The chemical shift reference was Na_2PtCl_6 (1 M in D_2O, external).

A means of measuring accurately the temperature inside the probe was required. The temperature dependence of ^{195}Pt chemical shift is well documented (Pregosin, 1982) and so it was decided to calibrate the probe by monitoring the ^{195}Pt chemical shift of the complex under investigation—this, in effect, produced a "platinum thermometer" which provided a rapid means of determining the temperature over the range 300–380 K.

The calibration was achieved by means of a coaxial arrangement involving a 125 mM solution of *cis*-$Pt(MNZ)_2Cl_2$ in glycerine formal in a 5 mm o.d. tube, ethylene glycol plus a trace of HCl in an 8 mm o.d. tube within a 10 mm o.d. tube containing DMSO-d_6 for lock. The temperature was adjusted in steps of 15°C with 45–60 min allowed for equilibration. The probe temperature was measured via the ^1H spectrum of ethylene glycol using the decoupler coils of the broad-band probe. The chemical shift of the ^{195}Pt sample was then recorded, followed by a second check on the probe temperature. This procedure was repeated over the temperature range 300–375 K. Linear relationships between temperature and $\delta(^{195}Pt)$ were obtained (Table 1). The probe temperature was calculated from the separation ($\Delta\nu$ in Hz) between the —OH and CH_2— resonances of ethylene glycol, according to the equation given by van Geet (400 MHz ^1H NMR).[12]

$$T = 466 - 0.254\,\Delta\nu.$$

Table 1. ^{195}Pt NMR chemical shifts of $Pt(MNZ)_2X_2$ at 301 and 373 K in glycerine formal

Complex	$-\delta$ (ppm) 301 K	373 K	$d\delta/dT$
cis-$Pt(MNZ)_2Cl_2$	2070	2031	+0.54
trans-$Pt(MNZ)_2Cl_2$	2069	2021	+0.66
cis-$Pt(MNZ)_2Br_2$	2403	2368	+0.49
trans-$Pt(MNZ)_2Br_2$	2444	2412	+0.44
cis-$Pt(MNZ)_2I_2$	3313	3304	+0.13
trans-$Pt(MNZ)_2I_2$	3371	3352	+0.27

The isomerization reaction was studied in glycerine formal (commercial solvent mixture; 75% 5-hydroxy-1,3-dioxan, 25% 4-hydroxymethyl-1,3-dioxolan) at a temperature of 378 K. Samples were prepared by dissolving the platinum complex in glycerine formal (2 cm^3) to give concentrations of up to 250 mM. The probe was preheated to the specified temperature and the sample inserted. Accumulation was started immediately using a microprogram which enabled a series of spectra to be collected. First order rate constants were obtained from plots of isomer concentration versus time using a computer fitting routine.[13]

RESULTS AND DISCUSSION

Solid state isomerization

Thermograms were obtained for the following complexes: *cis*-$Pt(MNZ)_2Cl_2$, *trans*-$Pt(MNZ)_2Cl_2$, *cis*-$Pt(MNZ)_2Br_2$, *cis*-$Pt(MNZ)_2I_2$ and *cis*-$Pt(DMZ)_2Cl_2$. In the case of *cis*-$Pt(MNZ)_2Cl_2$, two samples were studied: one which had been subjected to a commercial milling procedure (sample A), and one which had been ground in a pestle and mortar (sample B). The two thermograms are shown in Fig. 1. Calculated values for ΔH_f and ΔH_{isom} are listed in Table 2.

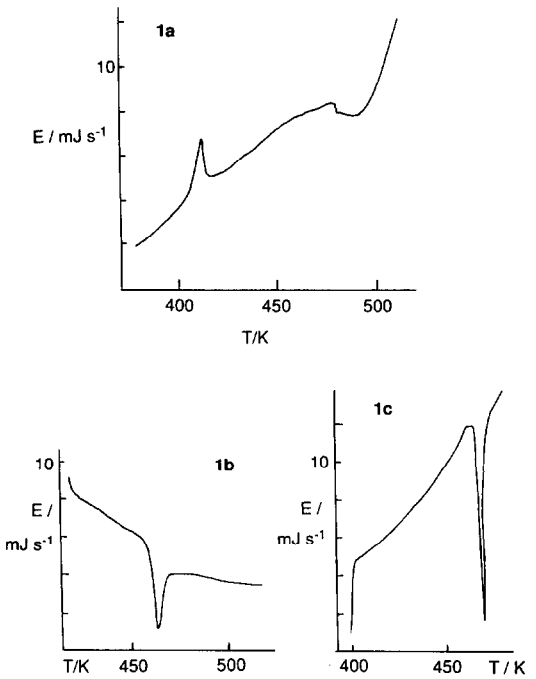

Fig. 1. DSC Thermograms of (a) *cis*-Pt(MNZ)$_2$Cl$_2$ (sample A) (b) *cis*-Pt(MNZ)$_2$Cl$_2$ (sample B) and (c) *cis*-Pt(MNZ)$_2$Br$_2$.

Investigation of *cis*-Pt(MNZ)$_2$Cl$_2$ (sample A) by DSC indicated two endothermic events occurring at 452 and 523 K. The first endotherm correlates with the melting point of the *cis* isomer, and thin layer chromatography of a sample heated to 453 K proved *cis–trans* isomerization to have occurred during this time. This process was found to be irreversible. The second endotherm at 523 K corresponded to the melting of the *trans* isomer, and was followed by a very broad exotherm characteristic of a decomposition process.

Melting transitions are usually endothermic and decompositions exothermic. The observation of an apparently endothermic isomerization is unusual, in that previously such processes have been reported to be exothermic for square-planar platinum(II) complexes. The fact that, in this case, isomerization is accompanied by extensive melting may account for this. A repeat experiment using sample B showed an endo–exotherm [Fig. 1(b)], a trace which is similar to results from previous reports of platinum complexes.[14,15] It is not clear why sample A yielded anomalous results; it can only be inferred that the much smaller particle size has a profound effect on solid state reactions. Endo–exotherms were observed for all the remaining complexes.

Table 2. Values for ΔH_f and ΔH_{isom} obtained from DSC measurements (in kJ mol^{-1})

Complex	ΔH_f	ΔH_{isom}
cis-Pt(MNZ)$_2$Cl$_2$		
Sample A[a]	+26.3	—
Sample B[b]	+7.1	−49.9
cis-Pt(MNZ)$_2$Br$_2$	+12.3	−32.2
cis-Pt(MNZ)$_2$I$_2$	+8.3	−21.3
cis-Pt(DMZ)$_2$Cl$_2$	—	−31.7

[a] Ground with mortar and pestle.
[b] Commercial milling procedure.

In previous studies of the isomerism of platinum(II) complexes using thermal analysis, Nikolaev[16] obtained a sharp exotherm for *cis*-Pt(NH$_3$)$_2$Cl$_2$ prior to the endothermic dissociation peak, a phenomenon not seen for the *trans* isomer. He concluded that this exothermic transition corresponded to an isomerization process. Further proof was provided by a determination of the heats of formation of the two isomers:[17]

$$\textit{cis}\text{-Pt(NH}_3\text{)}_2\text{Cl}_2, \quad \Delta H_f = -483 \text{ kJ mol}^{-1};$$

$$\textit{trans}\text{-Pt(NH}_3\text{)}_2\text{Cl}_2, \quad \Delta H_f = -496 \text{ kJ mol}^{-1}.$$

Similar exothermic effects have been reported for several related square-planar complexes, *cis*-Pt(α-picoline)$_2$Cl$_2$ and *cis*-Pt(β-picoline)$_2$Cl$_2$;[18] *cis*-Pt(pyridine)$_2$X$_2$.

DTA studies on a series of palladium(II) and platinum(II) phosphine complexes have previously given rise to an interesting range of effects.[19] The thermogram of *cis*-Pd(PhPEt$_3$)$_2$Cl$_2$ indicated three thermal events: two endotherms corresponding to the melting points of the *cis* and *trans* isomers, and, shortly after the first endotherm, an exothermic transition. This represented the simultaneous solidification and isomerization of the *cis* isomer. As solidification is an exothermic process, it is difficult to determine whether the isomerization process itself is endo- or exothermic. For the propyl analogue, *cis*-Pd(PhPr$_2$P)$_2$Cl$_2$, only one endotherm was seen and this corresponded to the melting point of the *cis* isomer. On cooling, analysis of this sample revealed that, in fact, the *trans* isomer had been formed—evidently melting and isomerization had occurred simultaneously. The platinum complex, *cis*-Pt(*n*-Bu$_3$P)$_2$Cl$_2$, provided a clearer example: endothermic melting of the *cis* isomer was seen followed by a broader endotherm, subsequently found to correspond to isomerization.

The reverse situation, where the *cis* isomer is the thermodynamic and the *trans* isomer is the kinetic product, has not been so widely studied. Two examples involving *trans*-Pt(pentamethylenesulphide)$_2$

Cl_2[20] and *trans*-$Pt(CO)(NH_2R)Cl_2$[15] have both shown the isomerism process to be exothermic and to be distinct from the melting of the *trans* isomer.

Based on studies of the Pd—N symmetric and antisymmetric stretching bands of *cis*-$PdCl_2(NH_3)_2$ and the bromo analogue, Durig and Mitchell[21] have proposed mechanisms involving intermediates with either trigonal pyramidal geometry (axial Cl^-) or intermolecular association (via Pd---Cl). Some support for the latter comes from the early observation that the following transformation occurs:

$$[PtCl_4]^{2-} [Pt(NH_3)_4]^{2+} \rightarrow 2\ trans\text{-}Pt(NH_3)_2Cl_2.$$

Although intermediates involving tetrahedral geometries have also been proposed,[22] they are unlikely to be favourable for d^8 complexes in their ground states.

Thus for bis(5-nitroimidazole) platinum(II) complexes, the *trans* isomer is likely to be the more thermodynamically stable and the small endotherm can be attributed to melting of the *cis* isomer; it is possible that rapid molecular motion is a requirement for isomerization to occur. The crystal structure of *cis*-$Pt(MNZ)_2Cl_2$[8] shows head-to-tail stacking of the complex in the unit cell, a configuration which could lead to ligand exchange via the associative mechanism.

Isomerizations of $Pt(MNZ)_2X_2$ complexes appear to be less exothermic in the order X = Cl > Br > I (Table 2), which implies that the difference in stability between *cis* and *trans* isomers is smallest for the iodo complex.

Isomerization in solution

A typical series of ^{195}Pt-$\{^1H\}$ NMR spectra, obtained during the isomerization of *cis*-$Pt(MNZ)_2Br_2$ are shown in Fig. 2. Plots of *cis* isomer concentration versus time for the different reaction conditions are given in Figs 3(A), 3(B) and 3(C), and the first order rate constants calculated from these data are listed in Table 3. The temperature coefficients for ^{195}Pt shifts decrease in the order Cl > Br > I (Table 1) and are similar in size to those observed for other platinum(II) complexes, consistent with an increase in the paramagnetic contribution to the chemical shift.

Firstly, the effect of added free ligand, MNZ, on the isomerization rate was studied [Fig. 3(B)]. No species other than the *cis* or *trans* isomers were detected in the ^{195}Pt spectrum. After completion of the reaction, a small sample was withdrawn and checked by ^1H NMR, but only *trans*-$Pt(MNZ)_2Cl_2$ and metronidazole were observed. Addition of metronidazole causes a dramatic increase in reaction rate: by more than a factor of 10 in the presence of 1 mol equiv. (Table 3).

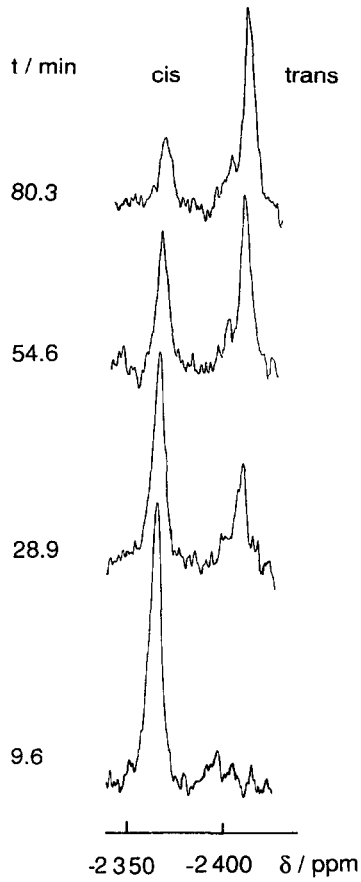

Fig. 2. ^{195}Pt-$\{^1H\}$ NMR spectra of *cis*-$Pt(MNZ)_2Cl_2$ at various times (t) after heating at 378 K in glycerine formal showing the formation of the *trans* isomer.

The effects of added halides on the rate of isomerization were also studied. When LiCl was added to *cis*-$Pt(MNZ)_2Cl_2$ in a mol ratio of 1 : 1 and 2 : 1, again no species other than the *cis* and *trans* isomers were detected during the reaction. The observed increase in isomerization rate may be due to an

Table 3. First order rate constants for the *cis–trans* isomerization reactions of $Pt(MNZ)_2X_2$ at 378 K

Experiment	Rate constant, k (min^{-1})
cis-$Pt(MNZ)_2Cl_2$	4.15×10^{-3}
+0.1 mol equiv. MNZ	6.80×10^{-3}
+0.5 mol equiv. MNZ	4.59×10^{-2}
+1.0 mol equiv. MNZ	5.54×10^{-2}
+1.0 mol equiv. Cl^-	7.00×10^{-3}
cis-$Pt(MNZ)_2Br_2$	1.66×10^{-2}
cis-$Pt(MNZ)_2I_2$	0.29

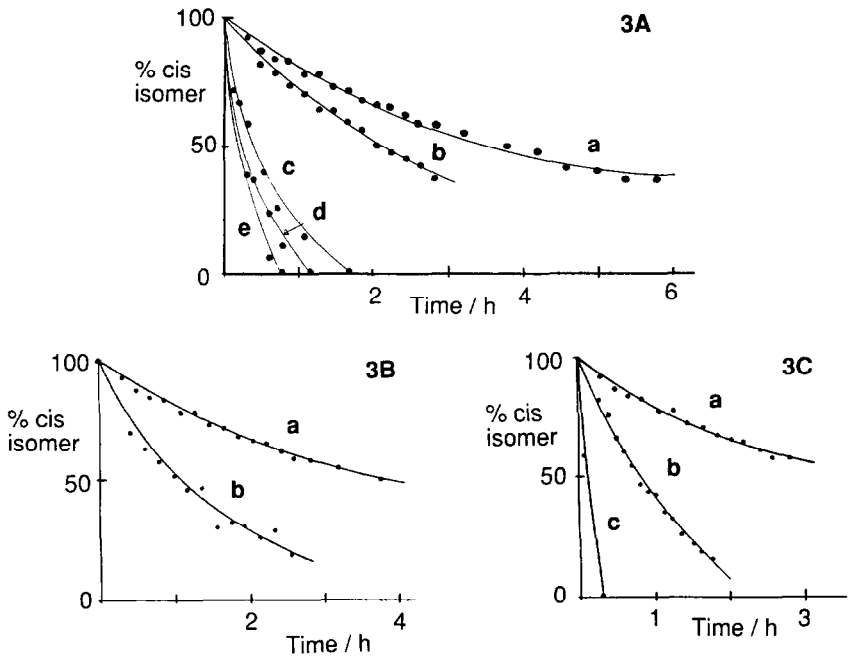

Fig. 3. Plots showing the concentration of the *cis* isomer versus time at 378 K for: (A) *cis*-Pt(MNZ)$_2$ Cl_2 (a), and in the presence of 0.1 (b), 0.5 (c), 1.0 (d) and 2.0 (e) mol equiv. of free ligand MNZ; (B) *cis*-Pt(MNZ)$_2Cl_2$ (a), and in the presence of 1 mol equiv. of LiCl (b); (C) *cis*-Pt(MNZ)$_2Cl_2$ (a), *cis*-Pt(MNZ)$_2Br_2$ (b) and *cis*-Pt(MNZ)$_2I_2$ (c). The initial concentration of each platinum complex was 250 mM.

ionic strength effect since Cl^- should inhibit the reaction if breaking of a Pt—Cl bond is involved in the rate-determining step. An increase in reaction rate with increase in ionic strength is usually observed when an ionic intermediate is involved in the reaction.[23] This was verified by addition of $KAsF_6$, a non-coordinating salt.

A 1 : 1 mixture of *cis*-Pt(MNZ)$_2Cl_2$ with LiBr was prepared in glycerine formal and heated on an oil bath at 420 K for 4 h. After cooling to room temperature, the ^{195}Pt-{^{1}H} NMR spectrum showed three peaks at −2041.4, −2223.7 and −2431.3 ppm with relative intensities of 1 : 1.4 : 0.5. The latter peak is assigned to *trans*-Pt(MNZ)$_2Br_2$ (see Table 1), and that at −2041.4 ppm as *trans*-Pt(MNZ)$_2Cl_2$. The most intense peak is likely to be [Pt(MNZ)$_2$ClBr], probably also a *trans* complex. These results suggest that *cis–trans* isomerism has a step involving halide attack on the *cis* complex.

Isomerization mechanisms have been considered in detail for the case of *cis*-Pt(PEt_3)$_2Cl_2$ in benzene. Although the *cis* complex is indefinitely stable at room temperature, it rapidly isomerizes to the *trans* form on the addition of a trace of free triethylphosphine.[24] Thermodynamic data show that the increased stability is the result of an increase in entropy. This arises from the stronger solvation of the highly polar *cis* isomer, such that isomerization to the *trans* form is accompanied by the release of benzene. Two hypotheses concerning the mechanism have been proposed. The first proposed by Haake and Pfeiffer[25] involves association of the free ligand to give a distorted five-coordinate intermediate [PtL_3X_2] which undergoes a fluxional change, enabling isomerization to occur. Cooper and Powell[26] have suggested an alternative scheme which includes the formation of an ionic intermediate, $[PtL_3X]^+X^-$, in a multistage double displacement mechanism. Experimental evidence lends support to both theories, and it appears that the choice of reaction pathway for such systems depends on the metal, solvent, anion, steric hindrance of the ligands, basicity and catalytic effects.[27]

The uncatalysed isomerization reaction of *cis*-[Pt(PEt_3)$_2$(*o*-MeC_6H_5)Cl] has also been studied[28,29] and a dissociative reaction mechanism proposed. Usually square-planar platinum(II) complexes have been found to favour associative mechanisms, but in this case steric hindrance from the aryl ligand forces a change to a three-coordinate intermediate.

In the present case the evidence points to an associative mechanism involving an ionic intermediate. However, candidate complexes such as $[Pt(MNZ)_3Cl]^+$ are likely to be short-lived and no

species other than the *cis* and *trans* isomers were detected by ^{195}Pt NMR during isomerization reactions. It would have been interesting to examine the effect of solvent polarity on reaction rate, but unfortunately the solubilities of the complexes used here are poor in alternative solvents. Three-coordinate intermediates are unlikely to be favoured in the present case since the isomerization was not retarded by added chloride. However, mechanisms involving pseudorotation of a five-coordinate intermediate to form the *trans* isomer are more difficult to rule out.

PRESSURE EFFECT ON THE HYDROLYSIS VELOCITY OF α- AND β-CHLOROTETRAETHYLENEPENTAAMINECOBALT(III) CATIONS

YOICHI KITAMURA,* SHINJI MATSUZAKI and TOURU BUTOU

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790, Japan

(*Received* 3 *January* 1991; *accepted* 20 *February* 1991)

Abstract—Activation volumes obtained for the title reactions are −3.6 and 42 $cm^3\ mol^{-1}$ for aquation and base hydrolysis of the α-cation, and −1.7 and 35 $cm^3\ mol^{-1}$ for aquation and base hydrolysis of the β-cation. These magnitudes are consistent with the interchange mechanism of aquation or with the S_N1 CB mechanism of base hydrolysis.

We have recently investigated the activation volume for the hydrolysis reaction of a cobalt(III) complex and consider that the magnitude of the activation volume can provide good mechanistic information on the dissociative-associative character of a reaction or the existence of a pre-equilibrium.[1–3] In the present report, we are interested in the effect of the size of a non-labile ligand on the magnitude of the activation volume and study the effect of pressure on the velocity of the title reactions which proceed via two pathways, i.e. aquation [eq. (1)] and base hydrolysis [eq. (2)].[4] Activation volumes for aquation ($\Delta V_{aq}^{\ddagger}$) and base hydrolysis ($\Delta V_b^{\ddagger}$) are calculated therefrom and are discussed in comparison with those of analogous reactions of chloropentaaminecobalt(III).

$$\alpha\text{- or }\beta\text{-[Co(tetren)Cl]}^{2+} + H_2O \xrightarrow{k_{aq}} \alpha\text{-[Co(tetren)OH}_2\text{]}^{3+} + Cl^- \quad (1)$$

$$\alpha\text{- or }\beta\text{-[Co(tetren)Cl]}^{2+} + OH^- \xrightarrow{k_b} \alpha\text{-[Co(tetren)OH]}^{2+} + Cl^-, \quad (2)$$

where tetren = $H_2N(CH_2)_2NH(CH_2)_2NH(CH_2)_2NH(CH_2)_2NH_2$.

The configurations of the α- and β-complexes are shown in Fig. 1.

$$\Delta V_{aq}^{\ddagger} \equiv -RT\frac{d\ln k_{aq}}{dP}$$

$$\Delta V_b^{\ddagger} \equiv -RT\frac{d\ln k_b}{dP}.$$

The activation volume for the aquation of $[Co(NH_3)_5Cl]^{2+}$ at high ionic strength has also been obtained.

EXPERIMENTAL

α- and β-[Co(tetren)Cl]$ZnCl_4$ were obtained according to the literature and identified by elemental analysis and UV–vis absorption spectra.[5] $[Co(NH_3)_5Cl](ClO_4)_2$ was obtained as in previous work.[1] Aliquots of the reaction solution were taken out at certain time intervals and analysed spectrophotometrically.[6]

RESULTS AND DISCUSSION

Experimental first-order rate constants (k_{obs}) are summarized in Table 1. For $[Co(tetren)Cl]^{2+}$, k_{obs} is composed of two contributions:

$$k_{obs} = k_{aq} + k_b[OH^-] = k_{aq} + \frac{k_b K_w}{[H^+]},$$

where K_w is the ionization constant of water. At $[HClO_4] = 1.0$ M, the contribution from base hydrolysis is negligible and $\Delta V_{aq}^{\ddagger}$ can be calculated

M = mol dm^{-3}.

using

$$\Delta V_{aq}^{\ddagger} = -RT\frac{d \ln k_{obs}}{dP}.$$

In the hydrolysis of the α-complex at $[HClO_4]$ = 0.01 M, $\Delta V_b^{\ddagger}$ is calculated by

$$\Delta V_b^{\ddagger} = -RT\frac{d \ln (k_{obs}-k_{aq})}{dP} - \Delta V_w + RT\frac{d \ln (\gamma_{2+}/\gamma_{+}^2)}{dP}, \quad (3)$$

where k_{aq} is assumed to be equal to k_{obs} for this complex at $[HClO_4]$ = 1.0 M. The reaction volume (ΔV_w) for the autoprotolysis of water is estimated as -30.5 cm^3 mol^{-1} at 80°C:[7]

$$\Delta V_w = -RT\frac{d \ln K_w}{dP}.$$

γ_{2+} and γ_+ denote the activity coefficients of a 2+ and a 1+ charged ion, respectively. Their pressure dependence is estimated according to the Debye–Hückel approximation and the last term in eq. (3) equals 2.4 cm^3 mol^{-1}.[8] In the hydrolysis of the β-complex at $[HClO_4]$ = 0.01 M, $\Delta V_b^{\ddagger}$ is calculated by

$$\Delta V_b^{\ddagger} = -RT\frac{d \ln k_{obs}}{dP} - \Delta V_w,$$

where the contribution from aquation and the pressure dependence of the activity coefficients are neglected. ΔV_w is estimated as -24.8 cm^3 mol^{-1} at 60°C,[7] and the resultant activation volumes are summarized in Table 2. From the table, the following can be inferred.

(1) $\Delta V_{aq}^{\ddagger}$ for $[Co(NH_3)_5Cl]^{2+}$ does not depend significantly on the ionic strength (μ) or temperature (t). Therefore, we assume generally that $\Delta V_{aq}^{\ddagger}$ for a chloropentaaminecobalt(III) complex, $[Co(N_5)Cl]^{2+}$, is independent of the reaction conditions.

(2) The magnitude of $\Delta V_{aq}^{\ddagger}$ is within the range -8 to ~ -2 cm^3 mol^{-1}. This magnitude may be interpreted by the interchange mechanism, as has been discussed for $[Co(NH_3)_5Cl]^{2+}$ and *trans*-

Table 2. Activation volume for the hydrolysis of the chloropentaaminecobalt(III) complex

Complex	$\Delta V_{aq}^{\ddagger}$ (cm^3 mol^{-1})	t (°C)	μ (M)	Reference	$\Delta V_b^{\ddagger}$ (cm^3 mol^{-1})	t (°C)	μ (M)	Reference

$[Co(en)_2(NH_3)Cl]^{2+}$.[2,3] It can be noted that the value of $\Delta V_{aq}^{\ddagger}$ is somewhat large for a complex containing a bulky, non-labile N_5 ligand. In the case of the limiting dissociative mechanism, the transition state is long-lived so that the surrounding solvent molecules can equilibrate and the volume effect of a bulky N_5 ligand will cancel out in the transition state and in the initial state.[12] On the other hand, in the case of the interchange mechanism, the transition state is not long-lived enough for the solvent molecules to equilibrate and the effect of a bulky N_5 ligand does not cancel out in both states. Thus, the observed dependence of the magnitude of $\Delta V_{aq}^{\ddagger}$ on the size of a pentaamine ligand is consistent with the interchange mechanism of aquation.

(3) The magnitudes of $\Delta V_b^{\ddagger}$ are large and positive and can be explained by the S_N1 CB mechanism, where the volume change of the pre-equilibrium

$$[Co(N_5)Cl]^{2+} + OH^- = [Co(N_5—H)Cl]^+ + H_2O \quad (4)$$

may amount to *ca* 22 $cm^3\ mol^{-1}$.[13] The N_5—H represents the conjugate base of a N_5 ligand. Except for the β-tetren complex, the magnitude of $\Delta V_b^{\ddagger}$ appears to be independent of the size of the N_5 ligand. This is consistent with the limiting dissociative character of the S_N1 CB mechanism. One explanation for the relatively large $\Delta V_b^{\ddagger}$ value of the β-tetren complex is that the reaction volume of pre-equilibrium (4) is large at a temperature of 80°C. This is surmised from the reaction volume ($-\Delta V_w$) of an analogous neutralization reaction

$$H^+ + OH^- = H_2O$$

which is large at higher temperatures.[7]

COMMUNICATION

THE TRIS((*R*)-CYSTEINESULPHINATO-N,S)COBALTATE(III) ION: A CONVENIENT AND RELIABLE RESOLVING AGENT

R. D. GILLARD

School of Chemistry and Applied Chemistry, University of Wales College of Cardiff, P.O. Box 912, Cardiff CF1 3TB, U.K.

(*Received* 5 *December* 1990; *accepted* 4 *April* 1991)

Abstract—The use of the triply-charged resolving agent tris((*R*)-cysteinesulphinato-N,S) cobaltate(III) for the convenient, reliable and reproducible resolution of triply-charged cations is summarized, following ill-founded criticism.

The utility of potassium tris-fac-Δ-[(*R*)-cysteinesulphinato-N,S)cobaltate(III)] hydrate [synthesized from natural-*R*-cysteine and hexamminecobalt(III) salts in two steps, following simple directions] as a clean resolving agent for triply-charged cations $[M(NN)_3]^{3+}$ has been shown repeatedly.[1] Here, M = Cr, NN = bipy,[1c,d,h] phen,[1c,d] en,[1a] 5,5′-dimethylbipy;[1a] M[1a] = Co, NN = en, pn, bipy, phen; M = Rh,[1a] NN = bipy, phen. Mixed complexes and chelates have also been resolved this way, including, for example, $[Rh(phen)_2(NH_3)_2]^{3+}$ [1a] and the series[1b] from $[Co(phen)_3]^{3+}$ to $[Co(en)_3]^{3+}$. The agent has been sold since 1983 by a Swiss company,[2] quite independently of this laboratory.

Our synthesis[1] starts from hexaamminecobalt(III) salts, and our typical overall reported yield[1c] is 21%.

The characterization of our product as a single, pure compound rests on (i)[1c] the failure of determined efforts via ion-exchange chromatography to separate isomers (the chiroptical properties of leading and trailing parts were identical); (ii)[1c] the constancy during 20 years of the CD of our many samples; and (iii)[1a,b,c] the very clean optical resolutions through its salts. The assignment of linkage isomerism (N,S) stems from that in the green precursor $[Co(cys)_3]^{3-}$ which is, *inter alia*, readily oxidized by hydrogen peroxide (the other known linkage isomer[1d] S,O-bonded, does not undergo this oxidation). Our assignment of the *facial* structure rests essentially on the magnetic resonance spectra. The assignment of handedness [Δ or $R(C_3)$] at the cobalt(III) ion rests on an empirical relation for the lowest energy spin-allowed *d–d* transition.

We have drawn attention[1a,e] to properties which may cause potential difficulties—the photolability of $[Co(R\text{-}cysSO_2)_3]^{3-}$; its thermal lability [particularly via the formation of cobalt(II) species]; the kinetic control of some routes to isomers. However, the route[1a,e] to the versatile and useful resolving agent $[Co(R\text{-}cysSO_2)_3]^{3-}$, arrived at after much experience, is very dependable.

These compounds and their potential isomerism must be described as extremely well known:[3] they have even formed the subject of undergraduate courses.[3b] Nonetheless, a recent paper[4] comments on the earliest work reported from here, but in ignorance of the extensive reported work since 1973,[1b–h] with the strange exception that a single remark in a published lecture[1e] is quoted. (Ironically, that lecture[1e] drew attention again to the possible difficulties[1a] arising from kinetic control: these have been noticed yet again[4] by Arnold and Jackson). In consequence chiefly of that ignorance, the tenor of the short paper[4] by Arnold and Jackson is (in the extensive areas of apparent overlap with our published work[1]) critical. In particular, the final paragraph of their text[4] says: "the inference is that if one intends to use the Δ-tris-(cysteinate) tri-anion (sic) as a resolving agent, the material should be carefully recrystallized to remove the more soluble form . . . *which may well have been present*". The green tris-cysteinate itself is not, of course, yet used as a resolving agent (it is too unstable) but, taking the sense, the quoted extract[4] must refer to the peroxide-oxidized yellow sulphinate compound, so often recommended[1] as a resolving agent. If one

intends to use that as a resolving agent, all that is required is to follow the published directions[1] properly. The comment[4] is otiose. The present note puts the matter straight: the criticism (overt or implied)[4] is incorrect.

Singling out some remarks:[4]

(i) "The ^{13}C NMR spectrum[16] has not been published previously (sic), but Gillard[21] has described it as 'remarkably simple'.[11]" That reference 21 is to a lecture (the present reference 1e) at a summer school, summarizing principles of diastereoisomeric interactions and dissymmetric transformations. Reference 16 in this quotation is to a footnote,[4] giving, for our resolving agent, albeit not made by our method, in D_2O at 25°C (although the experimental section of the paper[4] says 18°C!), values of δ (relative to dioxane): 107.15, −0.46, −13.18. These agree well with the *two* sets of values previously published from here (both recorded with reference to tetramethylsilane). Accepting the value[5] for dioxane relative to TMS, of +67.40, our values were 107.87,[1b] −0.73, −9.46 and 109.1,[1c] 1.3, −8.9.

(ii)[4] "The peroxidized derivative $[Co((R)\text{-cysSO}_2\text{-N,S})_3]^{3-}$ appears[14] to be a useful resolving agent, *and the success of resolutions using this ion could hinge critically on the diastereoisomeric purity*". (My italics.) Reference 14 in this quotation is the present ref. 1a. The methods given[1] remove any such implied problem. Our prescribed synthesis of the solid resolving agent gives[1] a single diastereoisomer which works well as described.[1]

(iii)[4] ". . . the yellow $[Co((R)\text{-cysSO}_2\text{-N,S})_3]^{3-}$ anion, . . . the Δ isomer, the Λ isomer, or a mixture might be obtained . . . accordingly, we have repeated (sic) Dollimore and Gillard's experiments[14] using not only the Δ form but also the Λ and the . . . 1 : 1 mixture . . .". Reference 14 is the present ref. 1a.

The results[4] on the Δ form (the one we always use[1]) fully confirm our own.[1] We have done no experiments on the other forms, so they cannot be repeated.

(iv) The reaction of L-cysteine with cobalt ions, in varied forms, gives[3a] various products. For example, the red isomer $[Co((R)\text{-cis-O,S})_3]^{3-}$ is made[1g] (following Schubert[6]) from cobalt(II) nitrate by air oxidation (typically in 60% yield).

The green isomers (sometimes a diastereo-isomeric mixture) may also be made in a similar way (Schubert's original route[6]) through air oxidation of cobalt(II) reagents. This is the route used[4] (with others) by Arnold and Jackson, who have been able to obtain at least two green isomers *in solution* and who have studied their interconversions. We recommend[1] and use another quite distinct route via $[Co(NH_3)_6]^{3+}$, and our recorded yields (e.g.[1c] 21%) and many other comments[1] make it clear that the word "stereospecific" relates to the final *solid* product $K_3\text{-fac-}\Lambda\text{-}[Co(R\text{-cysSO}_2)_3]nH_2O$. This usage of the word is said[4] to be "erroneously based on . . . the isolated material".

(v) The recent work[4] has confirmed that "the Δ-*RRR*" isomer is much the more abundant under equilibrium conditions". Indeed,[4] "we could detect no Λ-*RRR* isomer by ^{13}C NMR spectroscopy". Rather oddly in view of that (correct) finding, Arnold and Jackson then say in their very last sentence of text[4] "The material should be routinely checked for the presence of the other diastereomer by a technique such as ^{13}C NMR spectroscopy".

In conclusion, the recent paper[4] reports some new facts about the green tris-cysteine compound, intermediate in our synthesis. Otherwise, in covering much of the same ground[1] as that studied by Dollimore and by Cartwright and Sillanpaa with me, Arnold and Jackson have confirmed the following facts:[1] the stereoselectivity of formation of the green compound, in solution and as a crystalline potassium salt; the purity of the single isomer of the peroxide-oxidation product, the spectroscopic properties of this latter, and its structure. They have apparently not attempted to confirm any resolutions: others[1h,2] of course have.

The recent paper[4] implies that its findings show substantial disagreement with our work.[1] It[4] actually confirms all that has been said[1] previously from this laboratory. That confirmation has become concealed, chiefly through ignorance of our extensive work published since 1973.

In much the same way, in his reply to criticisms and misquotation[7] by Jackson of his earlier work (in a field quite distinct from the present one) Brown said[8] "on examination . . . shows that there is no disagreement between our two approaches. Any apparent disagreements have to do with the language employed". The failure by Arnold and Jackson to acknowledge relevant, prior work extends in the present case to the structural work[9] of Okamoto and collaborators. In establishing (by X-ray diffraction) the absolute configuration of $(+)^{CD}_{600}$-bis[tris(L-cysteinato-N,S)cobaltate(III)-μ-S,μ-S′,μ-S″]cobalt(III) nitrate pentahydrate, they too had gone over the question of the stereoselectivity of the formation of green $\Delta_{LLL}\text{-}fac(S)\text{-}[Co(L\text{-cys-N,S})_3]^{3-}$ but were able to agree in full with our earlier work.[1]

(*Received* 16 *January* 1991; *accepted* 21 *March* 1991)

Abstract—Interaction of anhydrous iridium trichloride and 2,4,6-trimethylphenyl (mesityl)lithium in diethyl ether forms the tetrahedral iridium(IV) tetramesityl that has been characterized by electron paramagnetic resonance spectroscopy and by X-ray diffraction.

The interaction of $RhCl_3(THT)_3$ (THT = tetrahydrothiophen) with 2,4,6-trimethylphenyllithium in tetrahydrofuran–diethyl ether has been shown[1] to give the rhodium(III) compound, Rh(mesityl)$_3$, whose structure was found to be quasi-*fac*-octahedral (3C,3H) due to agostic interaction of three hydrogen atoms of three *o*-methyl groups on the aryl with the metal atom.[1] By contrast, the interaction of $IrCl_3(THT)_3$ under similar conditions with mesityllithium led to no isolable product. However, anhydrous $IrCl_3$ [made from iridium trichloride trihydrate (Johnson Matthey) by dehydration with thionyl chloride] in diethyl ether on reaction with mesityllithium in ether in four-fold excess at room temperature, led, after evaporation, extraction of the residue with hexane and crystallization at −20°C to Ir(mesityl)$_4$ as brown crystals, m.p. 138–139°C (dec), in about 15% yield. The formation of an iridium(IV) compound from $IrCl_3$ may be due to a disproportionation reaction, but no other product could be isolated and the residue after hexane extraction is black and insoluble in organic solvents. The tetramesityl compound is stable in air as the solid and in hexane solutions, but these decompose on heating in air to give a green, diamagnetic material, characterized analytically and spectroscopically as Ir(mesityl)$_3$(O_2).

The structure of the tetramesityl compound has been determined by X-ray crystallography† and is shown in Fig. 1. The geometry is reasonably described as distorted tetrahedral, with C—Ir—C angles varying from 89.0(4) to 123.9(5)°. The Ir—C bond lengths range from 1.99(1) to 2.02(1) Å. With a low-spin d^5 iridium(IV) system, the origin of the distortion will not be electronic and must therefore be steric, with the ligands distributed and oriented so as to minimize interligand non-bonding interactions. It is therefore not surprising that the

† Crystal data: $C_{36}H_{44}Ir$, M = 668.97, monoclinic, a = 12.192(3), b = 18.876(2), c = 13.223(2) Å, β = 107.09(5)°, V = 2908.7 Å, space group = $P2_1/c$, Z = 4, D_c = 1.53 g cm^{-3}, μ(Mo-K_α) = 44.2 cm^{-1}, F(000) = 1348. Data were collected using an Enraf–Nonius FAST area detector diffractometer and graphite monochromated Mo-K_α radiation. With a diffractometer swing angle of 24.97° and a crystal-to-detector distance of 40.7 mm, data corresponding to slightly more than one hemisphere were scanned. Of the 22,081 data measured, 12,297 were observed and merged (R = 0.06) to give 4001 unique data. The structure was solved via the heavy atom method and refined by least squares to R = 0.052.

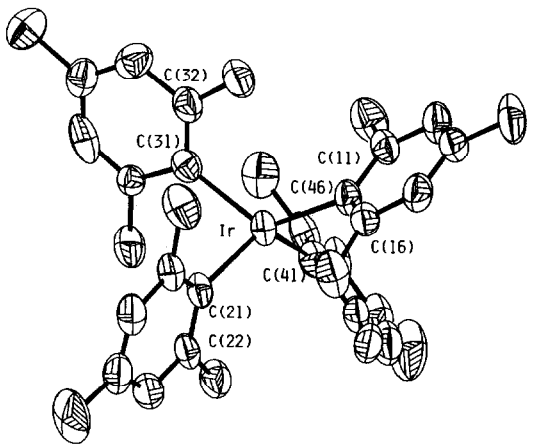

Fig. 1. The structure of Ir(2,4,6-$Me_3C_6H_2)_4$. Selected bond lengths and angles are: Ir—C(11) 2.04(1), Ir—C(21) 1.99(1), Ir—C(31) 2.04(1), Ir—C(41) 2.03(1) Å; C(11)—Ir—C(21) 123.9(5), C(11)—Ir—C(31) 122.0(5), C(11)—Ir—C(41) 92.2(5), C(21)—Ir—C(31) 89.0(4), C(21)—Ir—C(41) 117.0(5), C(31)—Ir—C(41) 115.1(5); Ir—C(11)—C(12) 119(1), Ir—C(11)—C(16) 121(1), Ir—C(21)—C(22) 124(1), Ir—C(21)—C(26) 117(1), Ir—C(31)—C(32) 118(1), Ir—C(31)—C(36) 125(1), Ir—C(41)—C(42) 123(1), Ir—C(41)—C(46) 115(1)°.

geometry of this complex is similar to that found[2] for $[Li(THF)_4][LuAr_4]$ (Ar = 2,6-$Me_2C_6H_3$), in which the Lu—C interaction is likely to be predominantly ionic.

The structure was solved via the heavy-atom method and refined by full-matrix least-squares. The data were corrected for absorption at the isotropic refinement stage using the DIFABS procedure, and the final R, Rw values were 0.052, 0.071, respectively with all carbon atoms and iridium refined anisotropically. No hydrogen atoms were included.

The X-band EPR spectrum in toluene at 77 K agrees with that expected for a tetrahedral molecule with $g_{\parallel} = 2.437$, $g_{\perp} = 2.005$: hyperfine structure due to Ir^{191} and Ir^{193} isotopes (38 and 61% abundance, respectively) is observed.

In cyclic voltammetry in dichloromethane, two reversible, one-electron reduction waves at -0.44 and -1.12 V vs the ferrocene/ferricenium standard were observed.

This mesityl is the first monomeric neutral homoleptic iridium(IV) compound to be synthesized. This now gives hope for the synthesis of compounds with other ligands such as RO, RS, R_2N and R_2P with bulky alkyl or aryl groups.

Acknowledgements—We thank Johnson Matthey plc for loan of iridium and the SERC for X-ray facilities.

ELECTRONIC STATES OF HOT IONS AND THE REACTIVITY OF [$MoOCl_3$(dppe)] TOWARDS SOLVATED ELECTRONS IN TRI-n-BUTYLPHOSPHATE

J. O. DZIĘGIELEWSKI* and K. FILIPEK

Department of Inorganic and Radiation Chemistry, Institute of Chemistry, Silesian University, 9 Szkolna Street, 40006 Katowice, Poland

(*Received* 19 *July* 1990; *accepted* 13 *December* 1990)

Abstract—The reactivity of molybdenum(V) ions towards solvated electrons (e_s^-) was studied by spectroscopic analysis. The crystal-field parameters, $Dq = 2470\ cm^{-1}$, $Ds = -6710\ cm^{-1}$ and $D\tau = 370\ cm^{-1}$, for the complex [$MoOCl_3$(dppe)] were determined and the energy terms were calculated. The mechanism of the reaction, involving the formation of the hot ion of $[d_{xy}]^1[d_{yz}]^1$ and $[d_{xy}]^1[d_{x^2-y^2}]^1$ configuration was suggested. The rate constant of the reaction of e_s^- with [$MoOCl_3$(dppe)] [dppe = 1,2-bis-diphenylphosphineethane] was calculated as $4.5 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$. The higher reactivity of such a complex of *cis*-symmetry towards e_s^- was explained.

In our recent works[1–4] we examined the reactivity of molybdenum complexes towards solvated electrons (e_s^-). We explained these phenomena as due to higher symmetry complexes having different structural features. We have described the complexes of the general formula $MoAB_3L_2$, and these compounds, according to the Bailar's analysis,[5] could have three isomers. We have also described in detail the reaction of t-$MoOCl_3(PPh_3)_2$ with e_s^-.[4]

The aim of the present work is to determine the reactivity of *cis*-[$MoOCl_3$(dppe)] (i.e. the *mer*-isomer regarding the positions of the Cl ligands) towards e_s^- in TBP (tri-n-butylphosphate) solutions.

The *cis* complexes are known to differ from the *trans* isomers taking into account their thermodynamics and kinetic stabilities. The *cis* isomers are more reactive, for example in reactions with the absorbent media forming hydrogen bonds or in hydrolysis reactions.[6–9] In *cis*-[$M(N_2)_2(PMe_2Ph)_4$] the yields of protonation of dinitrogen groups by the central atoms are much higher than in the *trans* isomers.[10] The biological activity of the *cis*-platinum(II) complexes has been established also.[11,12] However, the rate constants of the reactions of $[Co(en)_2Cl_2]^+$ and $[Cr(C_2O_4)_2(H_2O)]^-$ with e_s^- have been calculated as 7.1×10^{10} and $1.3 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$, respectively, and these values were equal for both *trans* and *cis* isomers.[13] The bidentate ligands such as dppe are known to prefer complexes of lower symmetry.[14] On the other hand, the chelating effect of dppe, abolishing the symmetry requirements, could increase the reactivity of the complex.[15]

EXPERIMENTAL

[$MoOCl_3$(dppe)] (red form, *cis* isomer, *mer*) was prepared according to the literature.[16] TBP (puriss p.a., Fluka) was extracted with 10% KOH, then washed with distilled water and distilled *in vacuo*.

The irradiations were made at 300 K and 77 K. Solutions of [$MoOCl_3$(dppe)] in TBP were saturated with argon or N_2O for 15 min, irradiated in a cobalt source Issledovatel (USSR) using a dose rate of $0.4 \times 10^{16}\ eV\ cm^{-3}\ s^{-1}$ (determined with a Fricke dosimeter and converted into the electron density of TBP). In addition, the solutions saturated with argon were frozen at 77 K then irradiated in a cryostat. In frozen solutions the appearance and decay of the absorption bands as a function of temperature were recorded. In irradiations (at room temperature) of solutions of the molybdenum(V) complex in TBP the changes of the band intensities in the UV–vis region were measured. These spectral measurements were made using a Beckman 5240

spectrophotometer. The changes in the magnetic susceptibility due to the irradiation of the solutions examined were determined by the ^1H NMR method described by Evans[17] using a Varian FT-80 A multinuclear spectrometer.

RESULTS AND DISCUSSION

Absorption bands of $[MoOCl_3(dppe)]$ in TBP are shown in Fig. 1 and the band characteristics are presented in Table 1. It is easy to notice that the number of bands attributed to *d–d* transitions is higher than for the *trans* complexes of this type,[18] however, this is in agreement with the spectral characterization of the lower symmetry complexes of the type $[MoOCl_3(LL)]$.[19,20] Assuming C_2 symmetry of the tested complex, the ligand-field parameters, *Dq*, *Ds* and D_τ, were determined and the energies of the terms were calculated as shown in Fig. 2.

Due to the high value of ε and the width of the band at 730 nm one could assume that the *d–d* transition is partially affected by the $Cl^- \rightarrow d_{xy}$ transition (see Fig. 2). The latter transition makes the probability of the $d_{xy} \rightarrow d_{yz}$ transition more likely, therefore the band at 465 nm increased in intensity.

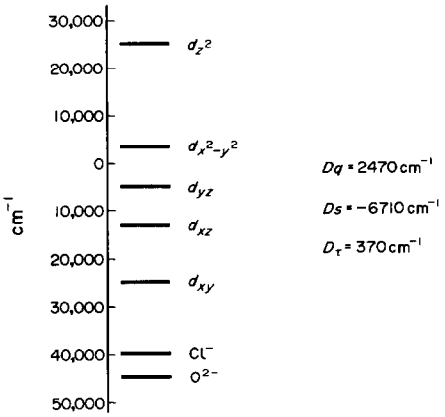

Fig. 2. Ligand-field parameters and the energy level diagram of the central atom orbitals for the complex $[MoOCl_3(dppe)]$.

On the basis of the results presented (see Fig. 2), the absorption bands appearing as a result of irradiation of the frozen solution of $[MoOCl_3(dppe)]$ in TBP were interpreted (Fig. 3). The

465	550	$d_{xy} \longrightarrow d_{yz}$
730	80	$d_{xy} \longrightarrow d_{xz}$ ($\pi_{Cl} \longrightarrow d_{xy}$, a small contribution)

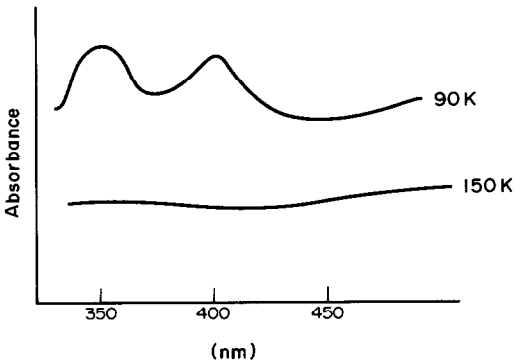

Fig. 3. Absorption bands appearing after the irradiation of the frozen solution of the molybdenum(V) complex in TBP ($C = 5 \times 10^{-3}$ M, dose $= 2 \times 10^{18}$ eV cm^{-3}).

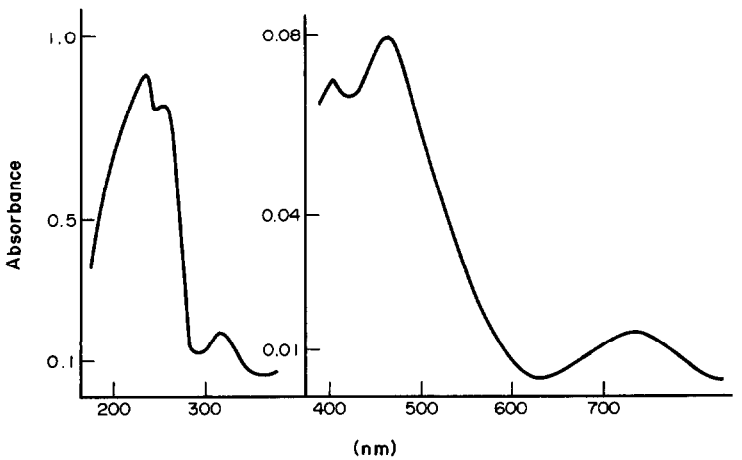

Fig. 1. Absorption bands of $[MoOCl_3(dppe)]$ in TBP.

bands at 350 and 400 nm appearing at 80 K and disappearing at 150 K (the non-irradiated complex solution was used as reference) were assigned as $(d_{xy})^1(d_{yz})^2 \rightarrow (d_{xy})^1(d_{z^2})^1$ and $(d_{xy})^1(d_{x^2-y^2})^1 \rightarrow (d_{xy})^1(d_{z^2})^1$, respectively. Thus, the electronic state of the hot ion, as the immediate product of the molybdenum(V) complex reaction with e_s^-, is $(d_{xy})^1(d_{x^2-y^2})^1$ and $(d_{xy})^1(d_{yz})^1$. The excited state, formed as a result of the direct acceptance of e_t^- and/or the decay of the hot ion could not be observed. The transitions $(d_{xy})^1(d_{xz})^1 \rightarrow (d_{xy})^1(d_{yz}, d_{x^2-y^2})^1$ and $(d_{xy})^1(d_{xz})^1 \rightarrow (d_{xy})^1(d_{xz})^1$ attributed to the excited state are at 300 and 880 nm and are impossible to record due to the significant scattering. The energetic neighbourhood of the $d_{x^2-y^2}$ and d_{yz} levels and their equal electron acceptor abilities are the reason for the similar thermal stability of the bands at 400 and 350 nm in the frozen solutions. According to common views, the higher energy electronic states usually have less thermal stability.

The final, molybdenum(IV), stable product of the molybdenum(V) ion reduction with e_s^- has the configuration $(d_{xy})^2$ and, according to the magnetic susceptibility measurements, is diamagnetic. The effective magnetic moment, after *ca* 40 min of irradiation of the complex solution, was reduced to 0 BM. After irradiation, no changes were found in the intensities of the bands at 235 and 255 nm, while the other bands were decreased. The decrease was proportional to the dose of irradiation and the difference between the intensities of the bands in solutions saturated with Ar and N_2O was significant. Thus, it can be assumed that the molybdenum(V) complex was reduced by e_s^- and, according to the decrease in the band intensity at 315 nm, Cl^- ions were simultaneously liberated from the coordination sphere of the complex. The detailed mechanism of the type of reaction described was presented earlier.[4] The number of reduced molecules of the complex vs dose and concentration were presented in Figs 4 and 5. These were calculated for the band at 730 nm. The number of liberated Cl^- ions vs dose and concentration of the complex solution are presented in Fig. 6. The calculated yields of reduction are presented in Table 2.

The main reactions in the system examined are:

$$TBP \longrightarrow e_s^-, TBP^+, R, \ldots \quad (1)$$

$$[MoOCl_3(dppe)] + e_s^- \longrightarrow [MoOCl_3(dppe)]^- \quad (2)$$

$$TBP + e_s^- \longrightarrow \text{radiolysis products} \quad (3)$$

$$[MoOCl_3(dppe)]^- + TBP \longrightarrow [MoOCl_2(dppe)(TBP)] + Cl^-. \quad (4)$$

By applying the steady-state approximation to reac-

2.0	5.75	5.09	0.66	
3.1	5.84	5.13	0.71	
4.1	5.94	5.17	0.77	
5.0	5.99	5.19	0.80	

G = number of molecules per 100 eV (= radiation yields).

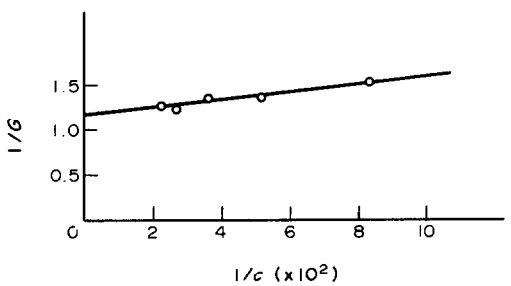

Fig. 7. Dependence of the reciprocal of ΔG on the reciprocal of the concentration of the molybdenum(V) complex.

tions (1)–(3) the following relationship was derived:

$$\frac{1}{\Delta G} = \frac{1}{G_{e_s^-}} + \frac{k_3[\mathrm{TBP}]}{k_2 G_{e_s^-}[\mathrm{Mo^V}]}$$

where $\Delta G = G_{Ar} - G_{N_2O}$, k_2 = rate constant of reaction (2) and k_3 = rate constant of reaction (3). Figure 7 shows G^{-1} as a function of the reciprocal of molybdenum(V) concentration.

From Fig. 7, the values of $G_{e_s^-} = 0.83$ and $K_3[\mathrm{TBP}]/k_2 G_{e_s^-} = 0.5 \times 10^{-3}$ were found. Thus, assuming $k_3 = 5 \times 10^6$ dm^3 mol^{-1} s^{-1} which was determined earlier,[21] we found $k_2 = 4.5 \times 10^{10}$ dm^3 mol^{-1} s^{-1}. On the basis of the results in Table 2, i.e. the yields of the Mo—Cl bond cleavage, the values $G_{e_s^-} = 0.80$ and $k_4 = 4.9 \times 10^{10}$ dm^3 mol^{-1} s^{-1} were calculated in a similar manner. Hence, our expectations concerning the liberation of Cl^- ions from the coordination sphere of the molybdenum complex as a result of molybdenum(V) reduction are confirmed. The calculated rate constant of the reaction of $[MoOCl_3(dppe)]$ with e_s^- is a few times higher than in the case of the reaction of $[MoOC_3(PPh_3)_2]$ with e_s^-.[4] This result and, as a consequence, the greater reactivity of the former complex is due to its lower symmetry and the greater number of orbitals which could accept electrons. Thus, there is no doubt that the symmetry and number of acceptor levels of the central atom in the complex compounds must not be neglected in the reactions with electrons.

MONO-ORGANOMERCURY AND DIORGANOTHALLIUM DERIVATIVES OF RHODANINE: CRYSTAL STRUCTURE OF DIMETHYL(RHODANINATO)THALLIUM(III)

NURIA PLAYÁ, ALEJANDRO MACÍAS,* JOSÉ Ma VARELA, AGUSTÍN SÁNCHEZ, JOSÉ S. CASAS* and JOSÉ SORDO

Departamento de Química Inorgánica, Universidade de Santiago de Compostela, 15706 Santiago de Compostela (A Coruña), Spain

(*Received* 28 *September* 1990; *accepted* 24 *January* 1991)

Abstract—The complexes HgR(Rd) and $TlR_2(Rd)$ (R = Me, Ph; HRd = rhodanine) have been prepared from the reaction of the ligand with the appropriate organometallic hydroxide (Tl) or acetate (Hg). The crystal structure of $TlMe_2(Rd)$ was obtained and shows that the thallium atom is coordinated by two oxygen atoms and a sulphur atom from three different ligands, as well as the two carbon atoms of the methyl groups. The compound crystallizes, forming a planar association along the plane defined by the crystallographic axes *ac*. Comparison of this compound with $TlPh_2(Rd)$ and HgR(Rd) was undertaken using mass, IR, and multinuclear (^1H, ^{13}C, ^{199}Hg, ^{205}Tl) NMR spectra.

The reaction of TlR_2^+ in basic media with heterocyclic ligands (HL) that can have the tautomeric equilibrium

$$—NH—C(S)— \rightleftharpoons —N=C(SH)—, \quad (1)$$

gives metallated compounds in which the ligand only partially changes to the thiolic form, the strongest ligand–metal bond forms across the nitrogen atom, although the sulphur atom also takes part in thallium coordination.[1,2]

Furthermore, the tendency of the thallium atom to take coordination numbers of 5 or more produces intermolecular associations in $TlMe_2L$; across bridging sulphur atoms if there are no other donor groups apart from those implicated in the equilibrium [eq. (1)],[1] or, across these groups if they are present in the ligand molecules.[2] The structures are very different from those formed by HgR^+ cations with the same ligands.[1,3]

In the light of these facts, it would be expected that the reaction of dimethylthallium(III) hydroxide with rhodanine (HRd) ought to give a complex showing a coordinative situation for the thallium atom similar to that found in dimethyl(2-thiouracilato)thallium(III),[2] given the similar donor groups and tautomeric possibilities of the two ligands. Nevertheless this work has shown that the compounds are markedly different, indicating the complexity of coordination chemistry of the TlR_2^+ cations.

At the same time, comparing $TlR_2(Rd)$ with HgR(Rd) has revealed unusual spectroscopic differences in solution in DMSO, that distinguish rhodanine from other heterocyclic ligands studied previously.[1–3]

As far as we know, this is the first X-ray diffraction structural study of a complex of the rhodaninate anion Rd^-, although adducts of rhodanine and 3-methylrhodanine have been studied.[4]

EXPERIMENTAL

Rhodanine (Ega-Chemie), and methylmercury and phenylmercury acetates (Merck) were used without prior purification. Dimethylthallium and diphenylthallium hydroxides were obtained from the corresponding iodide and bromide compounds[5] using freshly prepared Ag_2O. Analytical data of the mercury compounds were obtained from Galbraith Lab. Inc. (Knoxville, TN, USA); thallium compounds were analysed in a Perkin–Elmer 240-B

apparatus. The IR spectra, in nujol suspensions or KBr tablets, were obtained in a Perkin–Elmer 180 spectrometer. ^1H and ^{13}C NMR were recorded on a Bruker WM-250 apparatus except for $TlPh_2$(Rd) for which a Varian CFT-80A apparatus was used. ^{199}Hg (at 44.8 MHz) and ^{205}Tl (at 230.8 MHz) NMR spectra were recorded, in 10 mm o.d. tubes, on a Bruker WM-250 and a Bruker AM-400 spectrometers, respectively. Mass spectra were made on a Kratos MS50TC spectrometer connected to a DS-90 data system, and operating in EI conditions (direct insertion probe, 70 eV, 250°C). All the fragments included in Table 3 were identified using DS-90 software.

Synthesis of $TlMe_2$(Rd)

An aqueous solution containing 2.00 g (7.8 mmol) of $TlMe_2$(OH) was slowly added with stirring to 1.06 g (7.8 mmol) of rhodanine (HRd) dissolved in methanol. After 24 h of stirring a white–violet solid formed that was isolated by filtration and vacuum dried over calcium chloride. A few white–violet crystals, with the same analytical composition as the first solid, were obtained from the mother liquor. They were used in the X-ray diffraction study; m.p. 187-189°C. (Found: C, 16.4; H, 2.1; N, 3.9. $C_5H_8NOS_2Tl$ requires C, 16.3; H, 2.2; N, 3.8%.)

Synthesis of $TlPh_2$(Rd)

An aqueous solution containing 1.28 g (3.4 mmol) of diphenylthallium hydroxide was added to an equimolar amount of rhodanine (0.46 g) dissolved in methanol. After 4 h of stirring, a white solid appeared, which was separated by filtration and vacuum dried over calcium chloride. Dec. pt 170°C. (Found: C, 36.8; H, 2.1; N, 2.9. $C_{15}H_{12}NOS_2Tl$ requires C, 36.7; H, 2.4; N, 2.8%.)

Synthesis of HgMe(Rd)

An aqueous solution of 1.18 g (4.3 mmol) of methylmercury acetate was added to a methanolic solution of rhodanine (0.57 g, 4.3 mmol). The white solid formed was separated by filtration, recrystallized using an ethanol–acetone mixture and vacuum dried over calcium chloride; m.p. 125°C. (Found: C, 13.8; H, 1.5; N, 4.0. $C_4H_5NOS_2Hg$ requires C, 13.8; H, 1.4; N, 4.0%.)

Synthesis of HgPh(Rd)

A solution in ethanol–water (5:2) of 1.22 g (3.7 mmol) of phenylmercury acetate was slowly added with stirring to a solution of rhodanine (0.50 g, 3.7 mmol) in methanol. The white solid that formed was separated by filtration and vacuum dried over calcium chloride; m.p. 130°C. (Found: C, 26.0; H, 1.6; N, 3.3. $C_9H_7NOS_2Hg$ requires C, 26.4; H, 1.7; N, 3.4%.)

Crystal structure determination

Suitable white–violet crystals of $TlMe_2$(Rd) were obtained as described above.

Crystal data. $C_5H_8NOS_2Tl$, M = 366.62, monoclinic, $a = 7.474(2)$, $b = 7.655(1)$, $c = 15.830(4)$ Å, $\beta = 95.45(2)°$, $U = 901.6$ Å^3 (by least-squares refinement on diffractometer angles for 25 automatically centred reflections, $\lambda_{Mo\text{-}K_\alpha} = 0.71073$ Å), space group $I2/m$ (alt. $C2/m$, No. 12), $Z = 4$, $D_c = 2.701$ g cm^{-3}. Crystals of irregular shape. Maximum and minimum dimensions: 0.25 and 0.20 mm, μ(Mo-K_α) = 184.85 cm^{-1}.

Data collection and processing. CAD4 diffractometer, ω–θ mode with scan width and scan speed variables, graphite-monochromated Mo-K_α radiation, 3522 reflections measured ($3 < \theta < 32°$), 1761 unique [merging $R = 0.032$ after empirical absorption correction[6] (max. and min. transmission factors 1.283, 0.612)], giving 849 with $I > 3\sigma(I)$. The standards varied $\pm 3.5\%$ over the course of data collection.

Structure analysis and refinement. Heavy atom method (thallium atom) followed by subsequent Fourier difference syntheses. The hydrogen atoms were not found in the maps and were not included in the model. Full-matrix least-squares refinement with anisotropic thermal parameters for all atoms, and an extinction correction of the form $F_{corr} = F_c(1 + kF_c^2/\sin 2\theta)^{0.25}$, with $k = 3.6803 \times 10^{-8}$, converged for 59 variable parameters to $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.041$ and $R' = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.048$, $w^{-1} = \sigma^2 F_o$). A final difference Fourier map showed some peaks of maximum density 1.265 e Å^{-3} all located at < 1.2 Å from the thallium atom, as previously detected in other dimethylthallium(III) complexes.[2,7,8] Scattering factors and anomalous dispersion corrections were taken from parts (a) and (b) of ref. 9, respectively. Data processing was performed on a DECMicro VAXII computer using the SHELXS-86[10] and VAX-SDP[11] software packages.

RESULTS AND DISCUSSION

Crystal structure

Selected interatomic distances and bond angles for $TlMe_2(Rd)$ are shown in Table 2. The thallium atom is coordinated by two oxygen atoms and a sulphur atom from three different ligands, as well as the two carbon atoms of the methyl groups (Fig. 1). These five atoms form a pseudo-octahedral

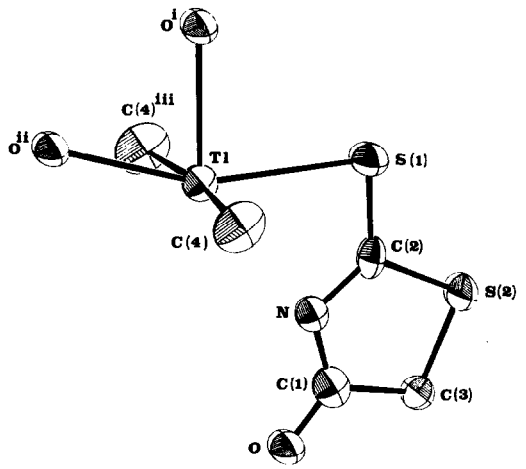

Fig. 1. The environment of the thallium atom in $TlMe_2(Rd)$ and numbering scheme of the compound.

N—Tl—C(4)	91.2(3)	S(2)—C(3)—C(1)	104.5(6)

Numbers in parentheses are estimated standard deviations in the least significant digits. Superscipts i, ii, and iii represent the equivalent positions ($x-1$, y, z), ($1-x$, $-y$, $-z$) and (x, $-y$, z), respectively.

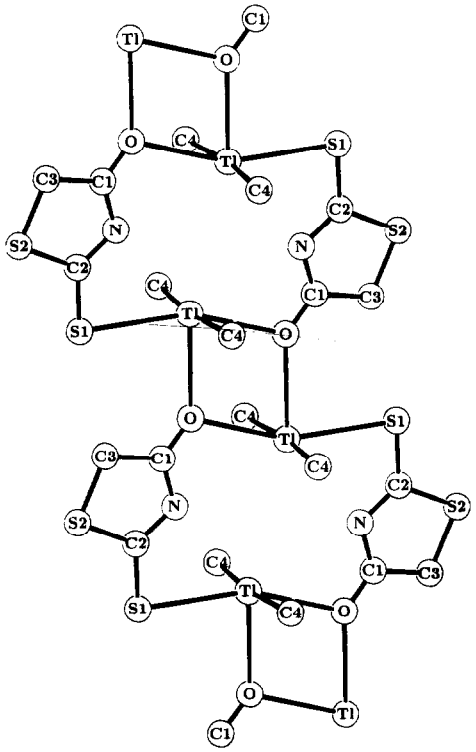

Fig. 2. Polymerization of $TlMe_2(Rd)$ following the crystallographic plane *ac*.

arrangement around the metal atom, with one site of the octahedron vacant. Another thallium atom lies in the approximate direction of the empty site at a distance from the first thallium atom [3.918(1) Å] in the limit of the sum of van der Waals radii (3.92 Å[12]).

The shortest Tl—O distance [2.659(7) Å] is greater than in complexes with the anionic ligands DL-tryptophanate[7] and 1-oxidopyridinium-2-thiolate,[13] which also have asymmetric bridging oxygens, but less than the length of the weak Tl···O bond of dimethyl(2-thiouracilato) thallium(III).[2] The biggest Tl—O distance [2.723(7) Å] is similar to that of the derivative of 2-thiouracil.[2] Similarly, the Tl—S distance [2.949(3) Å] is of the same order as that found in $TlMe_2SCOCH_3$,[14] but greater than those found in other 2-mercapto derivatives[2,8,13] or thiosemicarbazates.[15] The Tl—C distances and the C—Tl—C angle are normal.

That thallium–oxygen and thallium–sulphur distances are greater than those found previously in other compounds of the dimethylthallium(III) cation may come, not so much from the intrinsic donor character of the rhodaninate anion, as from the requirements of the considerably symmetrical laminar configuration of the compound (Fig. 2) (*vide infra*).

The modifications of the rhodanine ring with respect to the free ligand[16] are observed mainly in the C(1)—N and C(2)—N bonds, which shorten in the thallium complex, while the C(2)—S(1) lengthen slightly. These changes suggest that the negative charge of the anion is delocalized along the annular part formed by the atoms O—C(1)—N—C(2)—S(1), strengthening the two nitrogen–carbon bonds and maintaining a high multiplicity in the exocyclic bonds.

The concurrence of two $TlMe_2(Rd)$ units allows the formation of a planar dodecagonal "ring". From this ring protrude the S(2) and C(3) atoms of each rhodanine ring (Fig. 2). It should be noted that the Tl—N distance in these "rings" [3.134(7) Å] is less than the sum of the van der Waals radii (3.51 Å[12]), although the mutual orientation of these two atoms seems ill-suited for a donor interaction to be established by the nitrogen. A pair of weak Tl···O interactions unite each dodecagonal "ring" with its neighbours, forming a planar association along the plane defined by the crystallographic axes *ac*, with the two methyl groups emerging from above and below the plane.

Mass spectra

The spectral behaviour of $TlMe_2(Rd)$ (Table 3) is similar to that observed before in dimethyl(2-thiouracilato)thallium(III),[3] although the molecular ion is less abundant in the present case (0.3% of the base peak). The spectrum shows signals of other fragmentation products with very low intensities ($\leqslant 0.1\%$ of the base peak) and a greater mass than the molecular ion (e.g. *m/z* 450). Although these species could have been generated by an ion–molecule reaction, an origin in the associated character of the compound cannot be excluded.

The spectrum of HgMe(Rd) is clearly different. In the first place, the relative abundance of the molecular ion suggests that the mercury compound is more stable, which agrees with previous thermodynamic studies in solution of the interaction of $HgMe^+$ and $TlMe_2^+$ with sulfhydrilated aminoacids.[17]

Secondly, the HgMe(Rd) spectrum contains minor signals that, judging from their isotopic profile, correspond to the concurrence of two or more ions of related mass. Some of these signals [*m/z* (abundance): 275(14.7) and 260(7.6)] could correspond to the ions [$OCCH_2SHg$]/[OCCHSHg] and [NCSHg]/[MeSHgMe], respectively. The presence of these metallated fragments of the ligand,[18] that are formed in a fragmentation pathway where the

Table 3. Mass spectra (EI) of $TlMe_2(Rd)$[a] and HgMe(Rd)[a]

[a] Only ions containing thallium or mercury included. [HL] and ligand fragments were also observed.

[b] For the bimetallic species the value of the most intense cluster peak is quoted. In monometallic ions, nominal values are calculated using the most abundant isotope ^{205}Tl or ^{202}Hg.

cleavage of the rhodanine ring precedes the cleavage of the S—Hg bond, demonstrates the high stability of this bond. Finally, the number and intensity of the signals corresponding to binuclear ions in this spectrum (Table 3) are considerable.

The information apported by the spectra of the phenyl derivatives is more restricted. The molecular ion was not detected at all. The ions at higher m/z were [M—Ph] (2.4 referred to $[Ph^+H]$ as base peak) and $[Ph_2Hg]$ (11.5 referred to [Ph] as base peak) for $TlPh_2(Rd)$ and HgPh(Rd), respectively. No Hg—S bond retaining ions have been observed.

IR spectra

Table 1 shows the most significant bands in the IR spectra of the ligand and its complexes. The assignments of the ligand bands are based on previous data.[19,20]

Both ν(N—H) bands of the ligand disappear in the complexes, which corresponds to its deprotonation. In $TlMe_2(Rd)$ the coordination of the C=O and C=S groups to the metal was established on the basis of the X-ray diffraction data (*vide supra*). This coordination strongly shifts the 1705 cm^{-1} band of the ligand, ν(C=O), and the 1080 cm^{-1} band, ν(C=S), to lower wavenumbers. The pattern shown (Table 1) is indicative of similar participation of these groups in the coordination to the metal in the $TlPh_2(Rd)$ complex, whereas in the HgR(Rd) complexes the situation is different. Although ν(C=O) also undergoes slight shifts to lower wavenumbers in this case, these are a consequence of the ligand deprotonation and electron rearrangement due to the C=S group coordination.[19] This coordination is confirmed in HgPh(Rd) from the strong shift of the 1080 cm^{-1} band, which indicates a more pronounced thione---thiol evolution in this complex than in the thallium complexes; in HgMe(Rd) the lack of a strong band in this zone could be indicative of a thiol structure for the ligand in the complex.

On the other hand, the shifts to higher wavenumbers seen for the ν_{as}(C—N—C) band could be based on C—N bond reinforcement or, additionally, on a weak N—M interaction.

A strong band located in the free ligand at 1435 cm^{-1} seems to disappear under complexation. Nevertheless, it might be present as a weak absorption in the complexes as there are several weak bands in the range 1500–1300 cm^{-1}. The lack of intensity of this band on coordination (and also deprotonation) of the ligand can be explained if its assignment previously suggested[21] to ν(C—N—C)+δ(N—H) is considered. The ν(C—S_{ring}) located at 680 cm^{-1} in the free ligand remains in the same position in all the complexes, indicating non-participation of this sulphur atom in the coordination.

With respect to the organometallic fragment, $\rho(CH_3)$ in $TlMe_2(Rd)$ and HgMe(Rd) strengthen the ligand band near 800 cm^{-1}, and the positions of ν(C—Tl—C) and ν(Hg—C) are close to those found in related systems.[13,22]

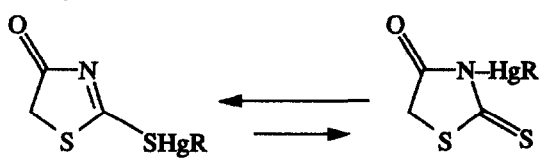
[c] Not observed.

[d] One of the peaks of the doublet associated with this carbon is masked by other phenyl carbon signals.

[e] This coupling was not resolved under the experimental conditions used.

NMR spectra

The behaviour of the HgR(Rd) derivatives in solution in DMSO is conventional (Table 4). The C(2) signal is shielded strongly, as expected for the evolution of the ligand to the thiolic form, as a result of the complexation.[23] The carbons C(4,5) are deshielded, possibly due to the combination of the tautomeric change and the inductive effect of the metal. The values of the coupling constant $^2J(^1H–^{199}Hg)$ and the chemical shift of the mercury-bonded carbon of the methyl group, are a little lower and higher, respectively, than values usually observed in thiolated derivatives of methylmercury(II).[24,25] Furthermore, the chemical shift of the metallic nuclide is somewhat less negative than in other neutral compounds with an R—S—HgMe bond.[3,26] These results suggest that there is a dynamic equilibrium in solution between the thiolic S-metallated form and a small fraction of the organomercury N-bonded cation:



The phenylmercury(II) compound has analogous properties to those of HgMe(Rd).

Surprisingly, the positions of the ligand signals in the ^{13}C NMR spectra of the TlR_2(Rd) compounds (Table 4) are similar to those for HgR(Rd) (see Figs 3 and 4), when, looking at the structure of $TlMe_2$(Rd) in the solid state (*vide supra*), there should be a clearcut difference, at least in the position of the C(2) carbon given the poor thiolic evolution of the ligand in the thallium complex. This apparent anomaly is resolved by considering the proton coupled ^{13}C NMR spectra (insert in Figs 3 and 4). The signal of the C(4) of the carbonyl group is split by the coupling with the hydrogens of the $C(5)H_2$ group, which allows C(4) to be unequivocally identified. Its signal is more shielded than that of the C(2) in HRd (Table 4), and this relative position is maintained in TlR_2(Rd), although both signals are at lower field as a consequence of the coordination to the metal. In HgR(Rd), however, the thiolic evolution of the ligand shields C(2) so much that it changes its relative position with respect to C(4), such that the signal of the latter is placed at lower field in the spectrum. These results suggest that, in DMSO solution, the organothallic derivatives contain the ligand in the keto-thione

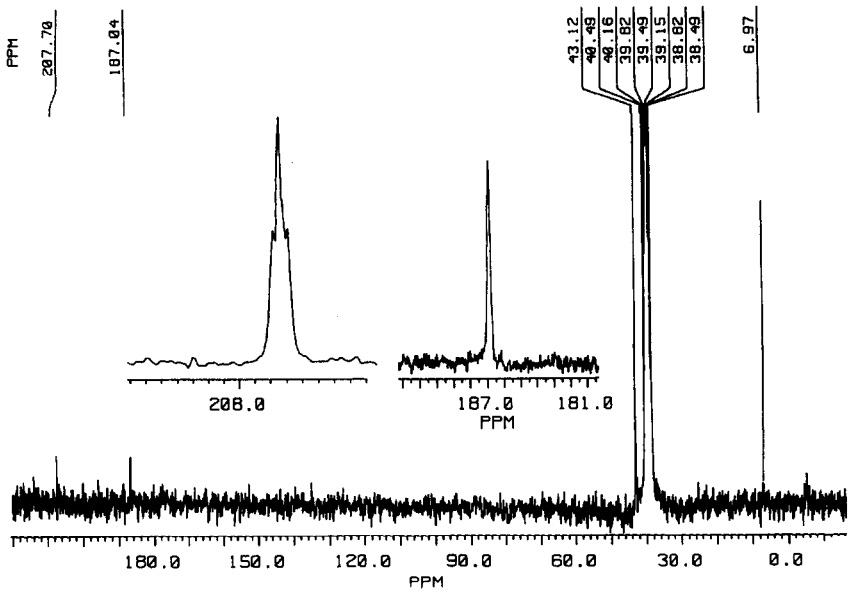


Fig. 3. ^{13}C NMR spectrum of HgMe(Rd) (the insert shows the proton coupled low field signals).

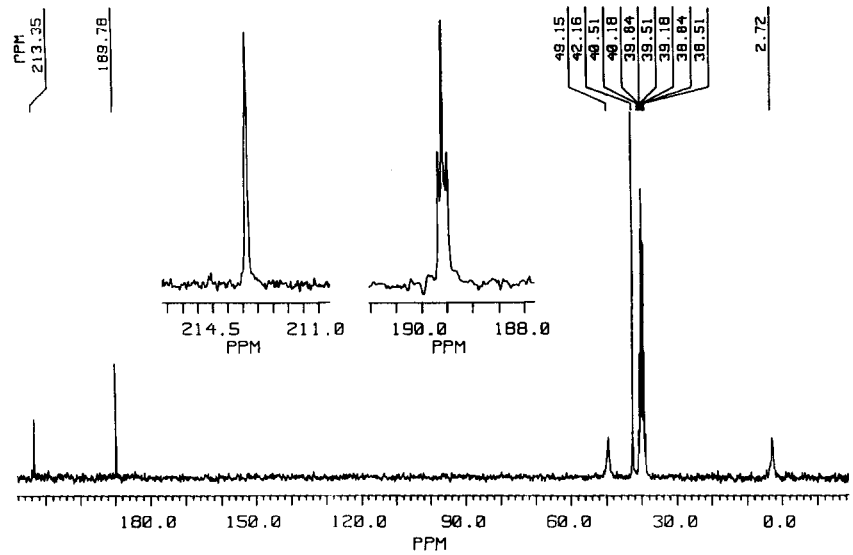

Fig. 4. ^{13}C NMR spectrum of $TlMe_2$(Rd) (the insert shows the proton coupled low field signals).

form as observed in the solid state. Furthermore, the spectral parameters $^2J(^1H-^{205}Tl)$, $^1J(^{13}C-^{205}Tl)$ and the ^{205}Tl chemical shift for $TlMe_2$(Rd) suggest a rather saline behaviour for this compound (i.e. for $TlMe_2ClO_4$ in DMSO, the above mentioned parameters are 438 ± 2.7 Hz, 2918.2 Hz (0.4 M solution) and 3455 ppm (0.4 M solution), respectively).[27]

STRUCTURAL CHARACTERIZATION OF THE PLATINUM(II)–PENICILLIN COMPLEXES

T. GROCHOWSKI* and K. SAMOCHOCKA

Department of Chemistry, Warsaw University, Zwirki i Wigury 101, 02-089 Warsaw, Poland

(*Received* 22 *February* 1990; *accepted* 5 *February* 1991)

Abstract—In the reaction of K_2PtCl_4 with penicillin V and penicillin G, two novel platinum(II) complexes were obtained. The structure of these complexes was determined by using IR and NMR spectroscopy. The structure of natural penicillin was found to be retained in the complex. A new, five-membered ring results from the chelation of the Pt^{2+} ion by the amide and thioether groups of the penicillin moiety. Based on the ^{13}C NMR spectra, the isomerism of the penicillin side chain is established.

Coordination of transition metal ions to the deprotonated nitrogen atom in the amide or peptide bond is a subject of considerable current interest.[1] Relatively few such complexes of platinum(II) have been reported.[2–5] A survey of the literature indicates that the coordination of the amide nitrogen to the Pt^{2+} ion is facilitated if formation of a five-membered ring is involved. However, many platinum complexes with chelating thioether ligands have been investigated[6–14] using spectroscopic techniques and X-ray structural analysis. Among those compounds an important group are complexes with ligands of biological significance. The latter compounds were investigated as models of platinum complexes bonded to proteins.[8–11] An interesting group of bioligands, which feature the amide and thioether functional groups, are penicillins. From a variety of those β-lactam antibiotics, we chose two typical penicillins, penicillin V (PenV) and penicillin G (PenG) (Fig. 1), which are stable in aqueous solution over a wide range of pH. In this study, the complexes of penicillin V and penicillin G with the Pt^{2+} ion were synthesized and isolated. To our knowledge, these are the first platinum complexes of penicillins to be reported. Their structures were determined by NMR and IR spectroscopy.

EXPERIMENTAL

Materials

K_2PtCl_4 was obtained[15] from the analytical grade K_2PtCl_6 (POCh Gliwice, Poland). Penicillins V and G (potassium salts) were supplied by Tarchomin Pharmaceutical Works (POLFA), Poland. The purity of the penicillins was checked by HPLC.

NMR measurements

The 500 MHz ^1H and 125 MHz ^{13}C NMR spectra were recorded with a Bruker 500 spectrometer.

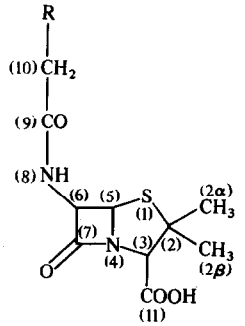

Fig. 1. General structural formula for the penicillin molecule with numbered atoms: R = C_6H_5O for PenV; R = C_6H_5 for PenG.

The 100 MHz ^{1}H NMR spectra were recorded on a Tesla 100 MHz spectrometer. All substances were dissolved in DMSO-d_6. TMS was used as the internal standard for all spectra. An internal lock on deuterium of the solvent was used in ^{1}H and ^{13}C measurements. Spectra of the ^{13}C nucleus were ^{1}H decoupled. The assignments of the ^{13}C signals were confirmed by the DEPT technique.

IR measurements

The IR spectra (3800–400 cm^{-1}) were recorded with an UR-20 IR spectrophotometer (Carl Zeiss Jena) for substances dispersed in KBr disks.

Synthesis of Pt^{2+} *complexes of* PenV *and* PenG

A solution of K_2PtCl_4 (208 mg, 0.5 mmol) in 5 cm^3 of water was added to 5 cm^3 of an aqueous solution of PenV (194 mg, 0.5 mmol) or PenG (186 mg, 0.5 mmol). The change in colour from reddish to yellow was complete within 15 min. The solution was kept at 50°C for 3 h. A yellow precipitate was filtered, rinsed with ethanol and dried over P_4O_{10}. Found: C, 32.8; H, 3.4; S, 5.7; Cl, 4.7; Pt, 32.4. Pt(PenV)(OH)ClPt$C_{16}H_{18}O_6N_2SCl$ requires: C, 32.2; H, 3.0; S, 5.4; Cl, 5.9; Pt, 32.6%. Found: C, 33.4; H, 3.4; S, 5.3; Cl, 5.0; Pt, 32.7. Pt(PenG)(OH)ClPt$C_{16}H_{18}O_5N_2SCl$ requires: C, 33.0; H, 3.1; S, 5.5; Cl, 6.1; Pt, 33.5.

RESULTS AND DISCUSSION

Substitution of chloride by PenV or PenG (Fig. 1) leads in both cases to the formation of a yellow product which precipitates from aqueous solution. The ^{1}H and ^{13}C NMR data for these products are listed in Tables 1 and 2; the IR data are listed in Table 3. The penicillin molecule has three functional groups, i.e. the thioether, amide and carboxylic group, capable of coordinating to the Pt^{2+} ion. It has been shown [2–5] that the formation of a five-membered ring, or a larger chelate containing such a ring, facilitates coordination through the amide group. The formation of a larger, six-membered ring, which involves the amide group, does not occur.[8] Upon coordination, the amide group undergoes deprotonation.[2–5] As shown in Fig. 2, the five-membered ring is formed in the case of the platinum complex with the penicillin molecule. Chelation by the amide group is evident in the IR spectra (Fig. 3): the absence of the amide band II related to the N—H deformational vibrations[16] (1570–1515 cm^{-1}) and the absence of a band related to the N—H stretching vibrations[16] (3300–3100 cm^{-1}). The ^{1}H NMR spectra confirm coordination by the

amide group. Since signals related to the amide proton in the spectra of free penicillins were sharp and well integrable, the *ca* 10-fold decrease of these signals in the spectra of the complexes shows the deprotonation of the amide group caused by coordination. The amide proton undergoes rather slow exchange with deuterium from the solvent (DMSO-d_6), because there is no evidence of this process in the spectra of free penicillin ligands. The presence of the prevailing single ^{13}C NMR signals related to the thiazolidine and β-lactam carbon atoms [C+(2), C(2α), C(2β), C(3), C(5), C(6), C(7)] proves that one major isomer is formed in the reactions of K_2PtCl_4 with PenV or PenG.

The substitution reactions were carried out in aqueous solutions of the penicillin salts at an initial pH of about 10 (pK_a of penicillins varies from 4.5 to 5). Under such conditions, in addition to substitution of two chloride ligands by the thioether and amide groups, the hydrolysis of the remaining Pt—Cl bonds may occur.[11,17,18] The presence of hydroxyl hydroxide ligands in these complexes is confirmed by the IR spectra. Broad bands in the range 3600–3300 cm^{-1} are related to the O—H stretching vibrations.[16] The elemental analysis shows that on average one chloride ligand is replaced.

The ^1H NMR spectra of the complexes Pt—PenV and Pt—PenG indicate the presence of some side products. These substances can be identified as chelate complexes coordinated by the thioether and carboxylic groups.[11] The downfield shift of the signals for the methine [H(3)] proton is analogous to the downfield shift of the signals for such protons in Pt—methionine complexes coordinated by thio-

ether and carboxylic groups. The presence of signals of low intensity, for the amide N—H proton confirms the existence of such coordinated Pt^{2+} complexes.

Conformation of the penicillin thiazolidine ring and orientation of the Pt—S *bond*

There are two different conformations of the thiazolidine five-membered ring, of which one is typical for natural penicillins [Fig. 4(a)], and the other is found in penicillin sulphoxides [Fig. 4(b)]. Since, the oxidation of the thioether group to the sulphoxide results in a change of ring conformation, the possibility of such an effect during complexation of the Pt^{2+} ion should be considered. The distinction between two conformers can be made on the basis of ^1H NMR data for the two isomers of N-phtalimide–penicillinic acid.[19] For this compound, a transition from structure **4a** to **4b** is evidenced by the downfield shift of the ^1H NMR signal of the 2α-CH_3 protons ($\Delta\delta = -0.16$ ppm) and by the smaller upfield shift of the signal of the 2β-CH_3 protons ($\Delta\delta = +0.02$ ppm). These differences illustrate an interaction between the axial methyl group and β-lactam ring at either the *syn* [Fig. 4(a)] or *anti* [Fig. 4(b)] position.

In the ^1H NMR spectra of Pt—PenG and Pt—PenV complexes dissolved in DMSO, two signals of the 2α-CH_3 and 2β-CH_3 protons are predominant. In both cases, there is no more than a 0.01 ppm downfield shift with respect to the analogous signals of the free ligands. Since both of the penicillins used for synthesis have the thiazolidine ring conformation of type **4a**, the conclusion is drawn that the original **4a**-type conformation of the thiazolidine ring is retained upon complexation of the Pt^{2+} ion.

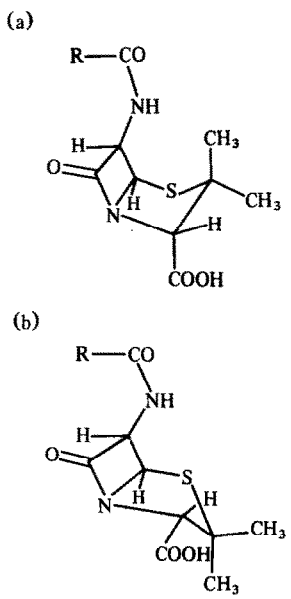

Fig. 4. Conformations of the five-membered thiazolidine ring: (a) typical for prevailing penicillins and (b) typical for penicillin sulphoxides.

Equatorial or axial orientation of the Pt—S bond in the platinum(II)–penicillin complex is possible because of the presence of two lone-pairs of electrons on the thiazolidine sulphur atom. The geometry of the chelate complex **2**, which exhibits the **4a**-type conformation of the thiazolidine ring, determinates the equatorial orientation of the Pt—S bond (Fig. 5). This type of orientation is confirmed by the ^1H and ^{13}C NMR data. Upfield shifts of the C(3) and H(3) NMR signals upon coordination indicate the screening effect along the Pt—S bond.[11]

Conformation of the penicillin side chain

The amide group has a nearly planar structure with restricted rotation around the C—N bond. Two different arrangements are possible when the amide group coordinates the Pt^{2+} ion (Fig. 6). Differences in the arrangements of the substituents at the C(9)—C(10) bond are observed in the ^1H NMR spectra of the free penicillins, in which the signals of the CH_2 protons form the AB pattern. The multiple signals related to the side chain carbon atoms are observed in the ^{13}C NMR spectra of the Pt^{2+} complexes of penicillins. The intensities of these signals are very similar. While β-lactam and thiazolidine carbon atoms produce single NMR signals, the presence of the multiple signals of the side chain atoms proves the existence of the isomeric structures of the penicillin side chain. However, the conformational analysis of the penicillin side chain given above should be considered as preliminary and needs confirmation from further spectroscopic studies of the entire class of similar complexes.

Conclusions

The two novel Pt^{2+} complexes with ligand molecules of biochemical interest were obtained and

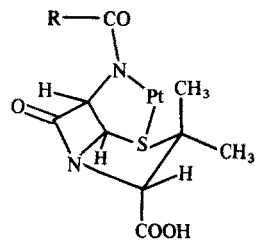

Fig. 5. The conformation of the Pt^{2+}–penicillin complex.

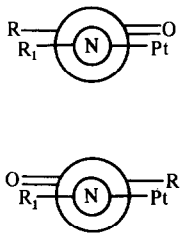

Fig. 6. Two different arrangements of the substituents at the C—N amide bond: R = $C_6H_5OCH_2$ (PenV) or $C_6H_5CH_2$ (PenG); R_1 = penicillin moiety.

their structure was determined by IR and NMR techniques. Coordination of the Pt^{2+} ion in platinum(II)–penicillin complexes involves the amide and thioether groups, and, as a result of the chelation, a new five-membered ring is formed. The structures of the complexes confirm an experimental rule[8] that the formation of five-membered rings involving the amide nitrogen is facile.

The two complexes have *cis* structures and the conformation of the parent penicillin is retained upon complexation. The isomerism of the penicillin side chain was identified in a complex by ^{13}C NMR spectroscopy.

Acknowledgements—Professor Edward Grochowski is thanked for supplying the penicillin samples. This contribution was, in part, supported by grant CPBP 01.17.

STUDIES ON THE STABILIZATION OF TERBIUM(IV) IN AQUEOUS TETRAMETAPHOSPHATE SOLUTION

XIAOJING LI,* WENJI DONG, YULANG QI, DONGMEI WANG and RUDONG YANG

Department of Chemistry, Lanzhou University, Lanzhou 730000, R.O.C.

(*Received* 16 *October* 1990; *accepted* 12 *February* 1991)

Abstract—Terbium(IV) was obtained by oxidation of trivalent terbium in an alkaline aqueous solution of sodium tetrametaphosphate with ozone. The concentration of terbium(III), the pH and the temperature of the solution all greatly affected the generation and stabilization of terbium(IV). Studies showed that the reduction of terbium(IV) (presumably by water) in alkaline solution was a pseudo first-order reaction. The characteristic absorption spectrum, the molar absorptivity, the rate constants and the activation energy of the reduction reaction of terbium(IV) are reported.

It is well-known that the tetravalent oxidation states of cerium, terbium and praseodymium can exist in the solid state.[1] However, terbium(IV) and praseodymium(IV) are unstable in normal aqueous solutions, since the formal reduction potentials of the Ln^{IV}/Ln^{III} couples (e.g. +3.1 V for terbium[2] in 1 M H^+) are so high that they are reduced by water. As the formal reduction potential of the Ln^{IV}/Ln^{III} couple is a function of the ratio of the stability constants of the lanthanide(IV) and lanthanide(III) compounds, a precipitating or complexing agent should enable the stable compound of lanthanide(IV) to form at a more favourable potential in aqueous solution. The chemical oxidation of terbium(III) in phosphotungstate,[3] tellurate,[4] condensed phosphate[5] and potassium hydroxide solution[6] has been reported. Hobart *et al.*[7] have stabilized terbium(IV) in carbonate solution by means of electrochemical oxidation. A precipitate of terbium(IV) was obtained by photoxidation in pyrophosphate solution.[8]

In the present work, terbium(III) in an aqueous solution of sodium tetrametaphosphate was oxidized by ozonolysis and the colour of the solution changed from colourless to a dark reddish-brown. A study was undertaken to find favourable conditions to produce and stabilize terbium(IV) in the aqueous solution. In addition, further studies of the kinetic properties of terbium(IV) in tetrametaphosphate solution were carried out and it was found that the reduction of terbium(IV) was a pseudo first-order reaction. The rate constants, the half-life and the activation energy of the terbium(IV) reduction have been determined and calculated. As far as we know, these studies have not been previously reported.

EXPERIMENTAL

Apparatus

Spectra were recorded with a Model UV-730 rapid-scan spectrophotometer and a Model 751-G UV spectrophotometer (fitted with constant temperature equipment). The pH of the solution was measured with Model PHS-3 acidometer (precision of 0.01 pH).

Reagents

A $Tb(NO_3)_3$ solution was prepared by dissolving Tb_4O_7 (> 99.9%) in nitric acid and diluting with distilled water. $Na_4P_4O_{12}\cdot 4H_2O$ was prepared according to ref. 9 and the X-ray diffraction, IR spectroscopy, thermal analysis and composition of the product were measured in the same manner as in ref. 9. Ozone (of a content of 20–25 mg dm^{-3}) was generated by passing oxygen at a speed of 0.40

* Author to whom correspondence should be addressed.

$dm^3\ min^{-1}$ through an ozonator. All other reagents were A.R. grade.

Analytical approach

The terbium(IV) concentration was determined by iodimetry.[10] The total concentration of terbium was titrated with EDTA when phosphorus was absent or with DTPA and zinc chloride when phosphorus was present.[11]

Procedure

Solid $Na_4P_4O_{12}\cdot 4H_2O$ was dissolved in an aqueous solution of trivalent terbium nitrate in which the concentration of the terbium ion was 10^{-2}–10^{-1} mol dm^{-3}. When the ratio of the moles of $P_4O_{12}^{4-}$ to the moles of terbium(III) ion was less than 1.5, a white precipitate appeared in the solution. However, the precipitate disappeared gradually and the solution became clear when the ratio was greater than 1.5. The hydroxide ion concentration in the solution was adjusted to *ca* pH = 12 by addition of sodium hydroxide solution. The solution was then cooled with water–ice and oxidized for a few hours to ensure sufficient oxidation of terbium(III) by bubbling ozone through the solution. During the oxidation process, the colour of the terbium solution changed from colourless to yellow to dark reddish-brown.

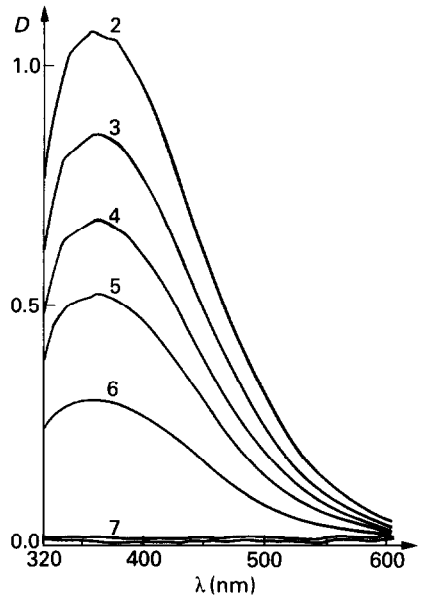

Fig. 1. Absorption spectra of terbium(III) and terbium(III) oxidized by ozone: (1) Tb^{III}–$P_4O_{12}^{4-}$ solution (pH = 12.2); (2) solution 1 was oxidized for 1.5 h (pH = 11.8); (3)–(6) solution 2 was standing for 1, 2.1, 3.3, 5.6 h, respectively; (7) solution 2 was reduced by hydrogen peroxide.

RESULTS AND DISCUSSION

Chemical properties of the terbium(IV) *solution*

The reddish-brown terbium(IV) solution, which is stable for quite a long period (about 2 weeks) in alkaline medium at room temperature, is reduced by water and the colour fades immediately in acid medium. It also oxidizes I^-, Cr^{3+} or Mn^{2+} to I_2, $Cr_2O_7^{2-}$ or Mn^{3+} in acid medium. When an excessively concentrated base (such as sodium hydroxide or potassium hydroxide) is added to the solution, a yellow precipitate of $Tb(OH)_4$ appears.

Spectrum of the terbium(IV) *solution*

The spectrum of the dark reddish-brown terbium(IV) tetrametaphosphate solution is shown in Fig. 1. It is characterized by a broad-band absorption centred at *ca* 365 nm. In comparison, the spectrum of the terbium(III) tetrametaphosphate solution has no absorption peak in the region of *ca* 320–365 nm. When the terbium(IV) solution is left standing for a length of time or some reductants (such as H_2O_2, $NH_2OH\cdot HCl$) are added to the solution, the reddish-brown colour fades and the absorption peak at 365 nm is reduced or disappears (see Fig. 1). Finally, the colour and spectrum of the terbium(IV) solution become the same as that of terbium(III) solution. It is shown that although the formal reduction potential of the Tb^{IV}/Tb^{III} couple is very high in non-complexing, neutral or acidic, aqueous solutions, terbium(IV) can be generated by oxidation by ozone and stabilized by forming a stable complex with a tetrametaphosphate anion in alkaline, aqueous solution. The absorption at 365 nm is the characteristic absorption peak of the terbium(IV) tetrametaphosphate complex solution, and its molar absorptivity is estimated to be $1.7\times 10^3\ dm^3\ mol^{-1}\ cm^{-1}$.

Factors affecting the oxidation of terbium(III)

(a) *The pH of the solution.* In this study it was found that the hydroxide ion concentration of the solution has a great affect on the oxidation of terbium(III). When the pH of the solution is between 11 and 12.7, the oxidation rate of terbium(III) and the stability of terbium(IV) increase with increasing hydroxide ion concentration. If the pH < 11, terbium(III) cannot be oxidized by ozone in the solution, since the formal potential of the Tb^{IV}/Tb^{III} couple is still very high at pH < 11. At pH > 13, the complex of ter-

bium(III) tetrametaphosphate becomes unstable and a great amount of $Tb(OH)_4$ is precipitated from the solution, and the oxidation of terbium(III) becomes difficult (see Fig. 2).

During the reaction, the oxidation of terbium(III) and the reduction of terbium(IV) occur simultaneously in solution. At the beginning of the reaction the rate of oxidation is faster than the rate of reduction; then the reduction rate increases with increasing terbium(IV) concentration and the oxidation rate increases with decreasing terbium(III) concentration in solution. Finally, the oxidation rate and the reduction rate become equal. That is, the oxidation reaction reaches an equilibrium. The lower the initial pH of the solution, the faster the equilibrium. If ozone is bubbled through the solution for too long, the oxidation rate of the reaction will decrease slowly (see Fig. 2).

(b) *The initial concentration of terbium*(III). It is found that when the molar ratio of $[Tb^{III}]/[P_4O_{12}^{4-}]$ in the solution is fixed, the oxidation rate decreases with increase in the initial concentration of terbium(III). The reason is that although the terbium(III) concentration has been increased, the concentration of ozone bubbled through the solution is fixed and therefore the concentration of terbium(IV) produced is not increased.

(c) *The temperature of the solution.* A study was performed to find a correlation between the temperature of the solution and the oxidation of terbium(III). The result shows that the oxidation rate of terbium(III) is decreased with increase in temperature (see Fig. 3). When the temperature is higher than 50°C, the oxidation of terbium(III) is impossible, because at this temperature the $P_4O_{12}^{4-}$ is degraded. The terbium(IV) tetrametaphosphate complex becomes unstable and the reduction rate of terbium(IV) is increased in the solution. It can be seen from Fig. 3 that although the low temperature is beneficial to the oxidation of terbium(III), it reduces the redox rate of reaction and more time is therefore needed to reach the redox equilibrium.

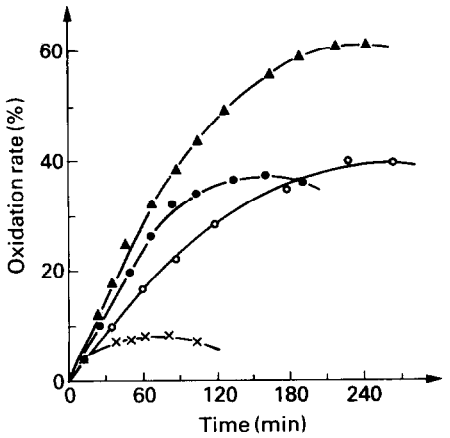

Fig. 2. Correlation of oxidation rate of terbium(III) with pH: $[Tb^{3+}] = 4.91 \times 10^{-3}$ mol dm^{-3}; $[Tb^{3+}]:[P_4O_{12}^{4-}] = 1:4$; $T = 14.0$°C; ▲—pH = 12.56, ●—pH = 12.00, ○—pH = 12.98 (precipitate occurred as ozone was bubbling through the solution), ×—pH = 11.50.

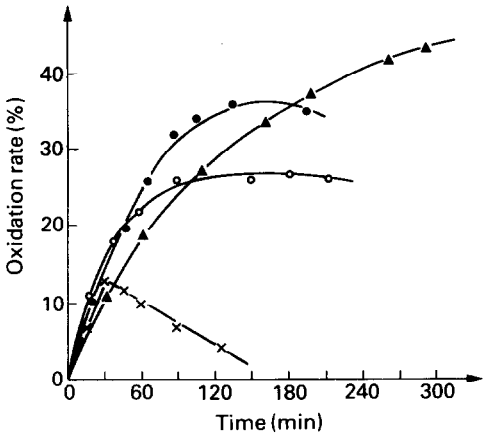

Fig. 3. Correlation of oxidation rate of terbium(III) with temperature: $[Tb^{3+}] = 4.91 \times 10^{-3}$ mol dm^{-3}; $[Tb^{3+}]/[P_4O_{12}^{4-}] = 1:4$; pH = 12.00; ▲—0°C, ●—14.0°C, ○—25.0°C, ×—35.0°C.

(d) *The concentration of tetrametaphosphate.* Our experiments also showed that the concentration of the complexing agent has less influence on the oxidation of terbium(III) than have the initial concentration of terbium(III), the pH and the temperature of the solution.

Study of the reduction kinetics of the terbium(IV) *complex*

The terbium(IV) complex is not very stable and reduces spontaneously at a slow rate in the aqueous solution. A possible equation for the reduction reaction in the alkaline aqueous solution is

$$2Tb^{IV} + 2OH^- \rightarrow 2Tb^{III} + 1/2O_2 + H_2O. \quad (1)$$

Because water is abundant and $[OH^-] \gg [Tb^{IV}]$ in the solution, the concentration of $[OH^-]$ and $[H_2O]$ can be treated as constants. Therefore, reaction (1) is regarded as a pseudo first-order reaction and the kinetics equation is shown below:

$$dC/dt = kC \quad \text{or} \quad \log \frac{C_0}{C} = \frac{k}{2.303} t, \quad (2)$$

where C_0 and C are the concentrations of terbium(IV) at initial time ($t = 0$) and at any time

Table 1. Rate constants of terbium(IV) in solutions of various pH-values[a]

pH of solution	Rate constants 10^6k (s^{-1})
11.20	60.8
11.40	22.8
12.00	5.42
12.56	3.57

[a] $[Tb]/[P_4O_{12}^{4-}] = 1:4$, $t = 15°C$, $[Tb^{IV}] = 2.26 \times 10^{-4}$ mol dm^{-3}.

Table 3. Rate constants of terbium(IV) in solutions of various concentrations of ligand[a]

$[Tb]/[Na_4P_4O_{12}]$	Rate constants 10^6k (s^{-1})
1:2	5.20
1:4	5.42
1:6	5.90

[a] pH = 12.0, $T = 15.0°C$, $[Tb^{IV}] = 2.26 \times 10^{-4}$ mol dm^{-3}.

(t), respectively. As the terbium(IV) complex has a characteristic absorption peak at 365 nm and the terbium(III) complex has no absorption at that wavelength, C_0 and C in eq. (2) can be replaced by the absorbancy, D_0 (at initial time, $t = 0$) and D (at any time, t), of the terbium(IV) complex at 365 nm. Therefore, eq. (2) can be written as

$$\log \frac{D_0}{D} = \frac{k}{2.303}t \quad \text{or} \quad t_{1/2} = 0.693/k, \qquad (3)$$

where $t_{1/2}$ is the half-reduction period of the terbium(IV) complex. The stability of terbium(IV) in the solution can be determined by measuring the change of terbium(IV) absorbancy (D) with change in time (t). The plot of values of log D_0/D against time is linear and it can be shown that the reduction of terbium(IV) in the solution obeys first-order kinetics.

The factors affecting the stability of terbium(IV)

(a) *The* pH *of the solution.* The results given in Table 1 show that the stability of the terbium(IV) complex is greatly increased with increase in the pH of the solution. The main reason is that the coordination of $P_4O_{12}^{4-}$ is influenced by the alkaline nature of the solution. In a certain range of pH, the more basic the solution is, the higher will be the coordination of $P_4O_{12}^{4-}$, the more stable the terbium(IV) complex, and the lower the potential of the Tb^{IV}/Tb^{III} couple. Therefore, the half-reduction period increases with increasing pH.

(b) *The temperature of the solution.* When the pH of the solution is not changed, the stability of the terbium(IV) complex is greatly affected by the temperature. As the temperature increases, the tendency for the terbium(IV) complex to reduce increases (see Table 2), which is similar to the oxidation of terbium(III). The present studies therefore show that a lower temperature is beneficial for the generation and stabilization of the terbium(IV) complex.

In addition, according to the Arrhenius equation:

$$\log k = \frac{E}{2.303RT} + B, \qquad (4)$$

the activation energy (E) of the terbium(IV) tetrametaphosphate complex can be obtained from the slope of log K against $1/T$; $E = 56$ kJ mol^{-1}.

(c) *The concentration of tetrametaphosphate.* It is shown in Table 3 that when the temperature, pH and concentration of the terbium ion are fixed, the influence of the tetrametaphosphate concentration on the stability of terbium(IV) in the solution is not great.

Table 2. Rate constants of terbium(IV) at various temperatures[a]

Temperature (°C)	Rate constants 10^6k (s^{-1})
53.0	85.5
44.0	59.2
36.0	27.7
27.5	10.8
15.0	5.42
6.5	3.33

[a] $[Tb]/[P_4O_{12}^{4-}] = 1:4$, $[Tb^{IV}] = 2.26 \times 10^{-4}$ mol dm^{-3}, pH = 12.00.

SUBSTITUENT EFFECT ON LIGAND PROPERTIES AND ^{3}MLCT BEHAVIOUR IN RUTHENIUM(II) DIIMINE COMPLEXES†

ADNAN ATFAH, AHMED H. TUHL and TALAL S. AKASHEH‡

Chemistry Department, Yarmouk University, Irbid, Jordan

(*Received* 16 *October* 1990; *accepted* 12 *February* 1991)

Abstract—New derivatives of 3,6-di(2′-pyridyl)pyridazine (dppn) were used to prepare complexes of the type $[Ru(L)_3]^{2+}$ (where L = dppn or one of its derivatives). The complexes are evaluated as possible solar energy conversion materials.

More effort and interest is concentrated on the study of ruthenium(II) complexes because of their value as photosensitisers for solar energy conversion[1–6] involving the luminescent ^{3}MLCT (metal-to-ligand charge-transfer) excited state that is capable of electron transfer reactions.[7–10] No doubt theoretical methods are needed to predict which ligands would serve our purposes best. In the words of Ernst and Kaim,[11] we are about to "...enter an era in which the first question is not which ligands are available but which ones are desirable". However, the HMO model, thus far utilized,[11–15] needs further refinement and must be combined with experimental data such as basicity of the ligands, cyclic voltammetry data and luminescence properties to make correct predictions regarding photosensitization and photoactivity of the complexes as well as σ and π activities of the ligands. Typically, while ligands with extended π systems (with lower π^* orbitals) are desirable in order to lower MLCT transitions and hopefully ensure the success of photosensitization, 2-(2′-pyridyl)quinoline and 2,2′-biquinoline yield a tris complex that is non-luminescent at room temperature and too photoactive[16] compared with the star of the show, $[Ru(bpy)_3]^{2+}$.[1–10] Recent work shows that the ^{3}MLCT is only reductively quenched by EDTA in the study of the production of hydrogen from water via the methyl viologen cation radical ($MV^{+\cdot}$), provided that the ^{3}MLCT state has a reduction potential, $^*E(2+/1+)$, greater than *ca* 1 V, which applies to the complex $[Ru(bpz)_2(dpq)]^{2+}$ [where bpz = 2,2′-bipyrazine and dpq = 2,3-di(2′-pyridyl)quinoxaline].[16]

The key to the behaviour of ruthenium(II) diimine complexes lies in the properties of the excited ^{3}MLCT state. The redox potentials of this state, largely determined by the relative stability of the metal HOMO t_{2g} orbitals (in octahedral microsymmetry) and the ligand LUMO π^* orbitals, control the probability of the photosensitized electron transfer processes. Electron transfer quenching has to compete with unimolecular processes of the ^{3}MLCT state, such as emission, radiationless decay and photoreactivity via thermal population to a closely lying *d–d* state.[1–10] Needless to say, metal–ligand interactions and, in particular, σ-donor and π-acceptor tendencies of the ligand determine such properties.[7,8,17–20] It is thus not surprising that ligand bonding properties are derivable from ground state and ^{3}MLCT state properties.

Substitution on the ligand is often a good means to finely tune the properties of the excited state.[21,22] Variation of the ligand itself has been attempted[23–25] and even a cage-ligand (ref. 26 and refs therein) has recently been found to protect against photochemistry.

In this work we report the synthesis and properties of new ruthenium tris-diimine complexes where the ligands are derived from 3,6-di(2′-pyridyl)pyridazine (dppn, see Fig. 1).

EXPERIMENTAL

Materials and equipment

The solvents used in this study were Aldrich HPLC grade. Synthesis of the salts (as PF_6^- salts)

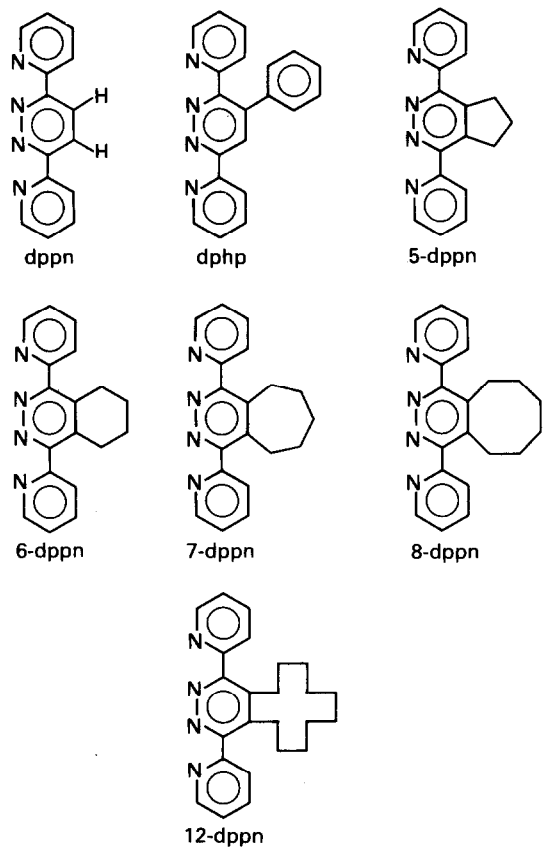

Fig. 1. Structure of the ligand.

was carried out according to standard procedures and is described below. Column chromatography over alumina in acetonitrile was used for purification and characterization was effected by elemental analysis, IR and UV–vis spectroscopy and conductivity measurements. The purity of the samples was checked by the quality of luminescence spectra and lifetime measurements. Cyclic voltammetry, against an SSCE, on a platinum working electrode (and a platinum counter electrode) in DMF (reductions) and acetonitrile (oxidations), with tetra-n-butylammonium hexafluorophosphate (0.1 M) as the supporting electrolyte, was performed on a Hi-Tech potentiostat. A Varian 2300 series UV–vis spectrophotometer and a Perkin–Elmer MPF-44B fluorescence spectrometer were used for recording the spectra in acetonitrile. Lifetimes were measured on an Applied Photophysics K347 laser flash spectrometer in the emission mode, with excitation from a spectron Nd:yAG laser at 355 nm, and/or an Edinburgh Model 199M photon counting system.

Synthesis of ligands and complexes

The dipyridyl pyridazines (dppn and dphp) were prepared according to Butte and Case.[27] The other ligands were prepared according to the procedure described by Atfah.[28]

The tris complexes were prepared by a general procedure. A suspension of $Ru(dmso)_4Cl_2$ (0.27 mmol)[29] or $RuCl_3 \cdot H_2O$ (0.1 g, 0.38 mmol, BDH) in 30% ethanol in water (30 cm^3) was added over an hour to the stoichiometric amount of the ligands in 70 cm^3 of ethanol/water. The mixture was refluxed until the starting ligand disappeared on a TLC plate (3–24 h). The complex was precipitated by adding NH_4PF_6 (2–3 g) in 5 cm^3 of water and cooled in a refrigerator overnight. The vacuum-collected solid was dried after washing in cold water and ether. Dissolution in a small amount of acetonitrile and precipitation by ether (for initial purification) was followed by column chromatography over neutral alumina in dry acetone or acetonitrile. The high quality fractions that were checked by TLC and luminescence spectra were combined, rotatory evaporated to a small volume and precipitated with dry ether. The complexes were characterized by elemental analysis (MHW laboratories P.O. Box 15149, Phoenix, Arizona, USA), in addition to the previously mentioned methods. Data for these are deposited with the Editor and are available from the authors upon request.

RESULTS AND DISCUSSION

Tables 1–3 list the absorbance cyclic voltammetry and excited state characteristics of the complexes as well as some characteristics of the ligands. The excited state redox potentials, $^*E_{1/2}(3+/2+)$ and $^*E_{1/2}(2+/1+)$, were calculated assuming that entropy changes (and thus geometries) upon excitation from the ground state to the ^{3}MLCT are minimal,[8] and the following relations were used:

$$^*E_{1/2}(3+/2+) = E_{1/2}(3+/2+) - E_m$$

and

$$^*E_{1/2}(2+/1+) = E_{1/2}(2+/1+) + E_m.$$

The asterisk labels the excited state, while $E_{1/2}$ is the ground state half-wave potential. While E_m should, in principle, be the 0–0 emission energy, it is usually approximated by the lowest wavelength maxima at 77 K and this gives a lower limit to the energy gap.

Figures 2–4 give typical UV–vis, emission spectra and cyclic voltammograms, respectively.

The UV–vis spectra of the ligands show two features in the range 210–290 nm. The effect of substitution of the electron-releasing phenyl and cyclic alkyl groups leads to a blue shift, resulting from destabilization of the π^* orbitals. This is often accompanied (though not always) by a decrease in

the extinction coefficients. Generally, the effect of complexation leads to red shifts of varying extents of the low energy band due to the general stabilization effect on bonding. The high energy ligand band shows a blue shift for dppn and dphp only.

Complexation largely increases the extinction coefficient of the ligand-centred (LC) bands, which are slightly shifted from those of the ligands. This leads to a definite π,π^* assignment (n,π^* bands should weaken or disappear on complexation). The remaining bands in the complexes are assignable to MLCT bands. In particular, the broad feature around 475 nm is usually considered to be a HOMO metal (d) to LUMO ligand (π^*) transition. Again, electron-releasing effects of the substituents lead to slight blue shifts. The shifts vary between 4 and 7 nm in this band. It has been established that in metal carbonyl complexes of chromium, molybdenum and tungsten containing one diimine ligand[13] and in ruthenium diimine complexes,[11] the extinction coefficient of this band bears a linear relationship with the squared HMO coefficients

($C_N{}^2$) at the chelating nitrogen centres. The lifetimes of the ^{3}MLCT state follow a similar relationship.[11,13] Thus it is not surprising that ε_{CT} (the extinction coefficients for the lowest energy band) and τ are empirically correlated.[30] In our case, some values of ε_{CT} increase as τ (Table 3) increases. Nevertheless, such a correlation for all the data points could not be established. This could be due to a number of reasons. One reason, apart from their approximate nature, HMO calculations that are restricted to the π-system should be insensitive to cyclic alkyl substitution. Moreover, the MLCT bands in question are broad and may involve transitions to the second LUMO π^* orbital.[31,32] The long tail usually accompanying the MLCT band has been assigned to the luminescent ^{3}MLCT excited state[8] and could add to the poor correlation.

In Table 2 cyclic voltammetry results are presented. Kaim *et al.*[11–15] have found a linear relationship between the basisity of the ligand (pK_{BH^+}: dissociation of the protonated form) and the halfwave potential, $E(3+/2+)$. Since σ-donation largely determines the relative stability of the HOMO metal orbitals,[7,8,17,23,33,34] the pK_b of the ligand (a measure of σ-donation) would naturally affect the redox potential which gauges the metal HOMO orbital stability. The calculated pK_{BH^+} values shown in the table indicate that cycloalkyl substitution leads to more basic ligands with better σ-donation, and this is naturally reflected in the destabilization of the metal orbitals in complexes containing the substituted ligands. 12-dppn exhibits the largest effects, while the other 5, 6, 7 and 8 substituents have very close oxidation potentials. The most stable metal orbital occurs in $Ru(dphp)_3{}^{2+}$.

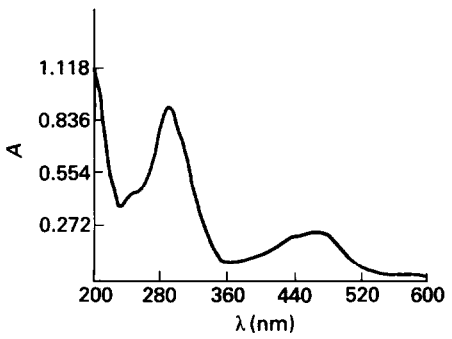

Fig. 2. UV–vis spectrum of $[Ru(12\text{-dppn})_3]^{2+}$ (1×10^{-5} M in acetonitrile).

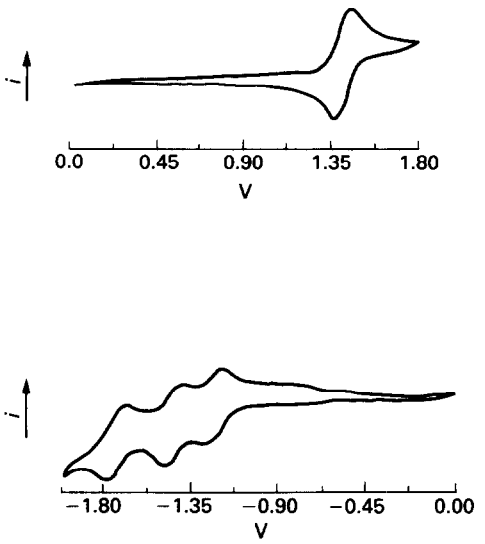

Fig. 3. Cyclic voltammogram of $[Ru(7\text{-dppn})_3]^{2+}$: (a) oxidation in acetonitrile and (b) reduction in DMF.

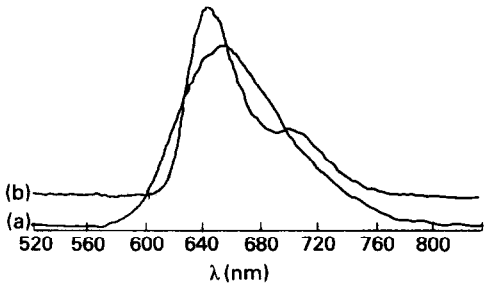

Fig. 4. Emission spectra of $[Ru(5\text{-dppn})_3]^{2+}$ in acetonitrile at (a) room temperature and (b) 77 K.

The cyclic voltammetry results also show three consecutive, reversible or quasi-reversible one-electron peaks which indicate that each reducing electron is localized on one ligand.[8,9,23,25,35] The ligand reduction peaks (Table 2) show mostly irreversible peaks and indicate about a 1 V stabilization of the LUMO π^* orbital upon complexation. We have obtained a linear fit of the complexes' half-wave first reduction potential and that of the ligand (slope = 0.42, correlation coefficient = 0.90), thus substantiating the localized reduction electron picture in the complexes. The first reduction potential largely reflects the stability of the π^* orbitals.[7,8,17,23,33,34] Thus the differences between this reduction peak and the oxidation peak should correlate well with the low energy MLCT absorption band and the ^{3}MLCT emission maximum. The relationship $E_{op} = E_{ox} - E_{red} + A$ (where A is the solvation and reorganization free energies factor) holds well for our complexes, as in other typical complexes.[11-15,23,36] However, in the present study the emission maximum at 77 K correlates much better (correlation coefficient = 0.95) than the lowest energy MLCT absorption maximum (correlation coefficient = 0.83) probably for the same reasons given above for the ε_{cT} and τ values.

The variation of the first reduction potentials of the complexes in the series n-dppn (n = 5–8, 12) show small variations, thus indicating similar π^* stability and thus similar π-accepting properties. The more negative reduction potentials in the series compared with dppn indicate a less stable π^* orbital. Nevertheless, E ($= E_{ox} - E_{red}$) for dppn and n-dppn (n = 5–7) does not vary, thus stressing that π-back-donation is similar for these ligands despite the stronger σ-donation of n-dppn. For n = 8 and 12, slightly stronger σ-donation and weaker π-acceptance are indicated by the redox potentials.

The large metal orbital stability and the slightly larger E for $[Ru(dphp)_3]^{2+}$ give a strong indication that electron-withdrawing phenyl substitution leads to poorer σ-donation but stronger π-acceptor ability than in dppn. In short, σ-donation follows the trend 12-dppn > 8-dppn $\geqslant$ n-dppn > dppn > dphp (n = 5–7), while the π-acceptor trend is dphp > dppn $\approx$ n-dppn $\geqslant$ 8-dppn $\approx$ 12-dppn.

Figure 4 shows the vibrational splitting of the emission spectrum upon cooling to 77 K. Such a result is typical for the ruthenium(II) diimine complexes, in which the rigid medium seems to favour some specific dipole orientations over others. In Table 3, the ^{3}MLCT characteristics are included. The lifetimes are all relatively long and would favour electron-transfer quenching which is necessary for solar energy conversion. The good correlation between the emission maxima and E (mentioned earlier) is indicative of localization of the excited electron on one ligand in the emissive ^{3}MLCT state. The redox potentials for this state can be compared with $[Ru(bpy)_3]^{2+}$ (bpy = 2,2′-bipyridine) which has an $^*E_{1/2}(3+/2+)$ value of -0.83 V and an $^*E_{1/2}(2+/1+)$ value of 0.76 V. All our complexes have better oxidizing excited states than this complex. However, only dppn and dphp have values of $^*E(2+/1+)$ which are close to the minimum (1.03 V) required for quenching by EDTA.[16] Whereas $[Ru(bpy)_3]^{2+}$ is a better reducing agent in the excited state than the complexes reported in this work.

MIXED LIGAND COMPLEXES OF LANTHANIDE IONS WITH ACETONE FERROCENECARBONYLHYDRAZONE AND 1,10-PHENANTHROLINE

HAN XIAOJUN* and WANG XINTANG

Department of Chemistry, Xinjiang University, Wulumuqi 830046, P.R.C.

(*Received* 22 *October* 1990; *accepted* 12 *February* 1991)

Abstract—A new ligand, acetone ferrocenecarbonylhydrazone (HL), and 15 mixed ligand complexes of the type $Ln(HL)(Phen)_2Cl_3 \cdot nH_2O$ (Ln = lanthanide and Y; Phen = 1,10-phenanthroline; $n = 4$ and 5) have been prepared by the reaction of hydrated lanthanide chlorides with HL and Phen in ethanol solution. The IR, NMR, UV, molar conductance and thermogravimetry data of the ligands and their complexes are discussed.

Due to their biological activity, especially as potent inhibitors for many enzymes, the coordination chemistry of aroylhydrazines and related compounds has been the subject of extensive investigation.[1,2] Edwards[3] and co-workers have shown that the replacement of the aromatic group by the ferrocenyl moiety in penicillins and cephalosporins improves their antibiotic activity. Therefore, recently a series of hydrazones containing the ferrocenyl moiety and their complexes with anhydrous lanthanide chlorides have been investigated.[4–8] The mixed ligand complexes of hydrazones containing the ferrocenyl moiety with hydrated lanthanide chlorides and other ligands have not, however, been reported as yet. In the present work, acetone ferrocenecarbonylhydrazone (HL) and the mixed ligand lanthanide complexes of it containing 1,10-phenanthroline (Phen) were studied.

EXPERIMENTAL

Ferrocenecarbonylhydrazine was prepared according to the literature.[9] Hexahydrated lanthanide chlorides were prepared from the respective oxides and hydrochloric acid. The other chemicals were analytical reagent grade.

Preparation of acetone ferrocenecarbonylhydrazone

A mixture of ferrocenecarbonylhydrazine and acetone with a molar ratio of 1:1 was reacted in anhydrous ethanol under reflux for 5 h. After filtering, the filtrate was concentrated to dryness, recrystallized from benzene, and the orange crystals were collected on a Buchner funnel, washed twice with cold benzene and dried *in vacuo*; yield, 75% (m.p. 162.5–164°C). Found: C, 59.8; H, 5.8; N, 10.1. Calc. for $C_{14}H_{16}FeN_2O$: C, 59.2; H, 5.6; N, 9.9%.

Preparation of the complexes

Acetone ferrocenecarbonylhydrazone (1.4 mmol) and 1,10-phenanthroline (1.4 mmol) were dissolved in 30 cm^3 of anhydrous ethanol under heating. Hexahydrated lanthanide chlorides (0.7 mmol) in ethanol (8 cm^3) were added dropwise to the above solution. The mixture was maintained under reflux for 8 h. After filtration, the filtrate was concentrated to 10 cm^3 and ether (20 cm^3) was added with stirring. The precipitate which formed was collected, washed four times with 1:4 ethanol/ether and twice with ether and dried *in vacuo*; yield, above 60%. The complexes are listed in Table 1 together with their decomposition temperature and elemental analyses.

Spectral measurements

IR spectra were recorded with a FTS-40 spectrometer using KBr discs in the region 4000–400 cm^{-1}. NMR spectra were obtained on an AC-80 spectrophotometer using deuterodimethyl sulphoxide as solvent and TMS as an internal standard. UV spectra were measured with a Hitachi U-3400 UV–vis spectrophotometer in the region 215–500

[a] Calculated values are given in parentheses.

nm using a solution in methanol. Electrolytic conductance measurements were made with a DDS-11A molar conductometer and methanol as solvent at 25°C. Thermal characterization studies were carried out with a PE-DTA 1700 thermal analyser in an argon atmosphere.

RESULTS AND DISCUSSION

The lanthanide complexes are amorphous, reddish-orange solids. They are soluble in methanol, ethanol, DMSO and DMF, sparingly soluble in diethyl ether, benzene and water, but insoluble in petroleum ether. Their elemental analyses show that the formula of these complexes is $Ln(HL)(Phen)_2Cl_3 \cdot 4\text{–}5H_2O$.

IR spectra

The important IR frequencies of the ligands and their complexes together with their relative assignments are given in Table 2.

Table 2. Important IR absorption bands (in cm^{-1}) of the ligands and their complexes

s, singlet; d, doublet; t, triplet; m, multiplet.
HL = $C_5H_5FeC_5H_4CONHN{=}C(CH_3)_2$
[a] The signal of this proton disappears after adding D_2O.
[b] The signal of these protons is overlapped with that of the protons in deuterodimethyl sulphoxide.

The IR spectra of the complexes are similar. Compared with the IR spectra of ligand HL, ν(C=O)(amide I) and ν(C=N) were shifted to lower frequencies by *ca* 20 and 50 cm^{-1}, respectively, whereas the ν(N—N) and δ(N—H)(amide II) were shifted to higher frequencies by *ca* 2 and 23 cm^{-1}, respectively. These changes show that the HL ligand coordinates with lanthanide ions in the keto form, with the oxygen atom of the carbonyl group and the nitrogen atom of the azomethine.[4-8] Compared with the IR spectra of the Phen ligand, δ(C—H) were shifted to lower frequencies by *ca* 8 and 5 cm^{-1} and ν(C—H) was shifted to higher frequencies by *ca* 6 cm^{-1}. These changes show that Phen participates in coordination.[10] Two new bands observed at *ca* 543–549 cm^{-1} and 415–419 cm^{-1} are attributed to ν(Ln—N) and ν(Ln—O), respectively.[11]

Table 4. Important UV spectral data of the ligands and their complexes

Complex	Ln^{3+}	Absorption bands (log ε) (nm, λ_{max})			
HL		218.9(4.38)		263.5(4.04)	450
Phen			229.6(4.72)	263.7(4.54)	
HL+Phen			228.2	263.5	450
I	La	225.2(5.05)	229.3(5.03)	265.0(4.88)	450
II	Ce	225.0(5.09)	229.0(5.07)	265.6(4.92)	450
III	Pr	225.8(5.06)	229.1(5.06)	264.6(4.90)	450

VII	Gd	224.9(5.02)	229.5(5.03)	264.0(4.82)	450
VIII	Tb	224.6(5.04)	229.3(5.03)	264.3(4.84)	450
IX	Dy	224.3(5.01)	229.4(4.99)	265.1(4.83)	450
X	Ho	225.0(5.03)	229.4(5.01)	264.7(4.83)	450
XI	Er	225.5(5.02)	229.8(5.02)	264.0(4.84)	450
XII	Tm	224.5(4.97)	230.4(4.94)	265.1(4.80)	450
XIII	Yb	225.9(5.12)	229.9(5.11)	264.3(4.93)	450
XIV	Lu	225.2(5.05)	229.7(5.01)	264.7(4.82)	450
XV	Y	224.6(4.97)	229.3(4.96)	264.3(4.79)	450

[a] Concentrations: HL = 9.75×10^{-5}M, Phen = 3.96×10^{-5}M, HL+Phen·HL = 2.44×10^{-5}M, Phen = 3.96×10^{-5}M, Complex = approx. 2.00×10^{-5}M.

The IR spectra of the HL ligand show medium, sharp peaks of ν(N—H) at 3240 cm^{-1}, whereas the spectra of the complexes exhibit a strong, broad peak of ν(O—H) at *ca* 3300 cm^{-1}. In addition, the characteristic frequencies of the ferrocenyl moiety appear[12] at *ca* 1452, 1026, 822 and 488 cm^{-1} and the bands at *ca* 1378 cm^{-1} are attributed to $\delta(CH_3)$ in the HL ligand and in all the complexes.

NMR spectra

The NMR spectra of the ligands and their complexes are shown in Table 3.

The protons on the two cyclopentadienyl rings, methyl, the nitrogen atom and all the protons on Phen are shifted downfield. These changes are caused by the deshielding effect which occurs after forming the complexes. This also shows that the HL ligand coordinates with lanthanide ions in the keto form and that the molar ratio HL/Phen in the complexes is 1 : 2.

UV spectra

The UV spectra of the ligands and their complexes in methanol are shown in Table 4 and Fig. 1. It can be seen that the UV spectra of the complexes are similar, but they are somewhat different from those of the ligands. The *K* band (π–π^* transition) of the HL ligand is observed at 219 nm, but in the complexes, a bathochromic shift of *ca* 6 nm occurs resulting from the chelation of the ligand with lanthanide ions, and the band appears at 225 nm.

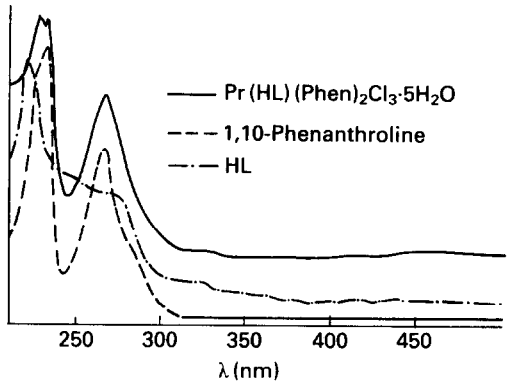

Fig. 1. UV spectra of the ligands and their complexes.

The shoulder peak at 263.5 nm arising from the *B* band of the cyclopentadienyl ring in this ligand changes into a sharp peak at *ca* 265 nm and overlaps with the *B* band of Phen in the complexes. The broad band near 450 nm in the HL ligand and the complexes is attributed to charge-transfer in the ferrocenyl group (transition of the three electrons on iron to either the non-bonding or antibonding orbitals of the cyclopentadienyl ring). The band at 229 nm shows that Phen participates in coordination.

Table 5. Thermal analysis data of the ligands and their complexes

Complex	Ln^{3+}	Decomposition temperature (°C)	Leaving group	Weight loss Found (Calc.)
HL		164–365	Substituent	29.3(34.9)

		262–579		
		up to 579	Residue (Fe+Lu+3Cl)	32.3(33.2)

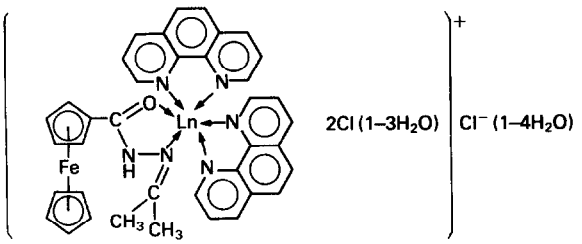

Fig. 2. Structure of these complexes.

Thermal analysis

The thermal analysis data of the ligands and their complexes are listed in Table 5.

It can be seen that the water in these complexes exists in two different forms, crystal and coordinated. The number of coordinated water molecules decreases with a change of lanthanide from light to heavy, i.e. the coordination number of central ions decreases progressively due to the lanthanide contraction. From the start and end temperatures of decomposition, we can see that the thermal stability of the complexes is increased much more than that of the ligands after forming complexes, and that the thermal stability of these complexes is decreased with a change of lanthanide from light to heavy.

Molar conductance

Deep red solutions are obtained by dissolving the complexes in methanol. The molar conductance values of HL, Phen and the complexes are 18.4, 15.0 and 81.7–103.9 $\Omega^{-1}cm^2mol^{-1}$, respectively. These values indicate that in methanol solution HL and Phen are non-electrolytes but the complexes are 1 : 1 electrolytes.[13]

Conclusions

Acetone ferrocenecarbonylhydrazone and 1,10-phenanthroline are bidentate ligands. One molecule of HL (in the keto form), two molecules of Phen, two chloride ions and one to three molecules of water coordinate with one lanthanide ion. The water in these complexes exists in two different forms, crystal and coordinated, and the coordination number is variable (11–9). Therefore, we have established a structure for these complexes shown in Fig. 2.

PERALKYLATED 1,4-DIBORA-2,5-CYCLOHEXADIENES—FORMATION AND REARRANGEMENT INTO PERALKYLATED *NIDO*-2,3,4,5-TETRACARBAHEXABORANES(6)

BERND WRACKMEYER* and GERALD KEHR

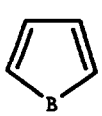
Laboratorium für Anorganische Chemie, Universität Bayreuth, Postfach 101251, D-8580 Bayreuth, F.R.G.

(*Received* 3 *January* 1991; *accepted* 20 *February* 1991)

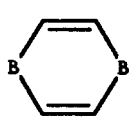
Abstract—Peralkylated 1,4-dibora-2,5-cyclohexadienes (DBCH) (**3a,b**) and a pentaalkylaryl derivative (**3c**) are formed in high yield at low temperature (−78 to −30°C) via the reaction between 1,5,7,11-tetramethyl-2,3,4,8,9,10-hexaisopropyl-3,9-dibora-6-stanna-1,4,7,10-spiro[5.5]undekatetraene (**8**) and organoboron dihalides ($MeBBr_2$, $^iPrBBr_2$, $PhBCl_2$). In contrast with claims in the literature for stable peralkylated DBCH derivatives, compounds **3** rearrange between −30 and +25°C into the *nido*-2,3,4,5-tetracarbahexaboranes(6) (**5**). The specific arrangement of the substituents in the 2,3,4,5-position (Me, ^{i}Pr, Me, ^{i}Pr) is noteworthy. This indicates, together with the formation of carboranes (e.g. **5a** from **3a**) in which substituents at the boron atoms must have been exchanged, that cleavage of the DBCH derivatives (**3**) into borirenes (**1**) is involved at least to some extent. Attempts to prepare a borirene (1-methyl-2,3-ditert-butyl-borirene, **1a**) by the reported reaction between the system $C_8K/MeBBr_2$ and ditert-butylethyne have failed. All reactions were monitored by ^{1}H, ^{11}B, ^{13}C, and ^{119}Sn NMR spectroscopy and the same methods served for the final structural assignment of the DBCH derivatives **3** and the carbaboranes **5**.

The relationship between unsaturated cyclic organoboranes, such as borirenes (**1**), boroles (**2**) and 1,4-dibora-2,5-cyclohexadienes (DBCH, **3**), is of considerable interest, both from a preparative and a theoretical point of view. It has been suggested that the dimerization of **1** leads to **3**[1] and insertion of alkynes into the B—C= bond should give **2**.[1] The reaction of the dianion of **2** (2^{2-}) with boron dihalides does not lead to **3** but to the highly dynamic bicyclic compound **4**[2] which, in the absence of boron ligands with π donor properties, adopts the carborane structure **5**. The carboranes **5** are valence isomers of **3**.

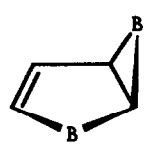
1



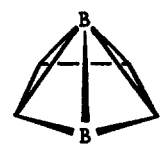
2



3



4



5

Although, derivatives of **4** are potential dimerization products of **1**, the formation of **4** has not been seriously considered[1] since the boron acceptor orbitals are not fully utilized in the dimerization process. On the other hand, the apparently straightforward intramolecular rearrangement of planar **3** into **5** by forming a new C(3)—C(5)— or C(2)—C(6) bond is symmetry forbidden. Inspite of the numerous routes leading to carboranes **5**,[2–7] a direct link between **3** and **5** is still missing. So far, the existence of few derivatives of **3**, mainly species with B—F[8] or B—O[9] bonds, has been proved conclusively. In fact, compound **6**[9] is the only example of a stable DBCH with organyl groups and hydrogen as substituents.

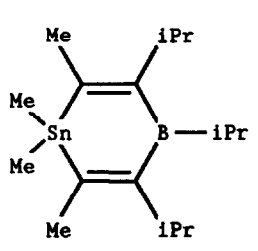
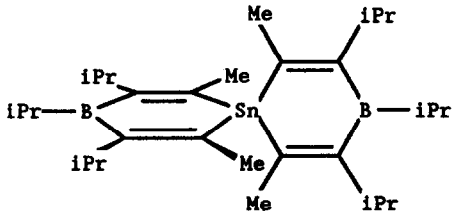
6 [Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$-]

The successful synthesis of hexaalkyl-1,4-dibora-2,5-cyclohexadienes was claimed[10] but extensive attempts to reproduce that work failed.[7] Some time ago, as part of a theoretical approach,[1] the claim for stable peralkylated DBCH derivatives has been renewed in the form of a footnote.[11] However, to the best of our knowledge, the experimental details promised have not been published as yet. Based on this unpublished evidence, it has been concluded[1] that "*hexaalkyl derivatives of both* **3** *and* **5** *have been reported and show no evidence of isomerization reactions*". This statement,[1] together with the insufficient experimental evidence,[10] has led to an unsatisfactory situation which prompted us to start a further investigation of this problem.

Firstly, we tried to use the $C_8K/MeBBr_2$ reagent (the "*suitable methylborylene generator*"[10]) and its reaction with ditert-butylacetylene, for preparing and studying the reactivity of the stable[10,12] 1-methyl-2,3-ditert-butyl-borirene (**1a**). Secondly, we reinvestigated the reaction of the peralkylated 1-stanna-4-bora-2,5-cyclohexadiene (**7**) with $MeBBr_2$[6] under very mild reaction conditions, as a potential route to peralkylated DBCH derivatives. The results of the latter study forced us to synthesize and to use the spiro-cyclic compound **8** instead of **7**, in order to prevent side reactions.



7



8

RESULTS AND DISCUSSION

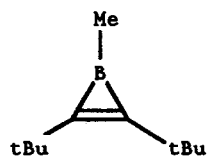
Attempted synthesis of 1-*methyl*-2,3-*ditert-butyl-borirene* (**1a**)

As in the previous attempts[7] at reproducing results for the system $C_8K/MeBBr_2$/alkynes, we have used different types of potassium graphite. A well-ordered C_8K-phase (**A**) was prepared and characterized by X-ray diffraction, and a poorly ordered material (**B**) was prepared *in situ*,[13] which apparently has also been used in the original work.[10] All reactions were carried out in hexane (which proved to be inert against both types of "C_8K") and monitored by ^{11}B NMR.

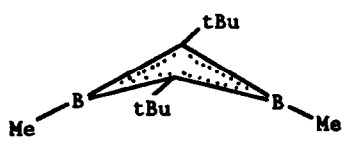
(**A**) After 2 days of stirring the reaction mixture, containing $C_8K/MeBBr_2$/ditert-butylacetylene, at ambient temperature, the ^{11}B NMR spectrum did not show new signals in addition to that of $MeBBr_2$ ($\delta^{11}B$ 63.0). When the mixture was heated to reflux for 24 h, new weak signals at $\delta^{11}B$ 35.4, 41.9, 70.4 and 76.7 had appeared. After heating to reflux for a further 72 h, all $MeBBr_2$ was consumed and major ^{11}B NMR signals appeared at $\delta^{11}B$ 33.3 [presumably $(MeBO)_3$], 42.0, 70.4, 76.8. The signal-to-noise ratio of the ^{11}B NMR spectra was poor in comparison with previous spectra of the same mixture, indicating that most boranes must have been converted into insoluble material.

(**B**) The reaction mixture was treated and monitored as for **A**. Finally, the ^{11}B NMR spectrum showed the same signals in approximately the same ratio as for **A** and, in addition, weak signals at $\delta^{11}B$ 16.6, 13.4, −43.9, −44.0, indicating the presence of some *nido*-2,3,4,5-tetracarbahexaborane(6) derivatives.

Owing to the questionable $\delta^{11}B$ data for **1a**[14a] (**1a** and **9** are reported[10b,12] to be the products of the reaction between $C_8K/MeBBr_2$ and ^{t}Bu—C≡C—^{t}Bu), it is difficult to compare our results with those reported in the literature.[10,12] The $\delta^{11}B$ data for both compounds ($\delta^{11}B$ for **9**: 41.2[14b]) should be in the range $\delta^{11}B$ +35 to +45.[14,15] In



1a



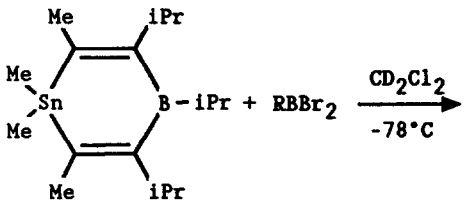
9

any case, the yield of these reactions was very low (no yield has been reported[10b,12]) and we were not able to isolate any definite boron compound from the reaction mixture. Therefore, a study of the reactivity of **1a** towards alkynes (as an interesting route

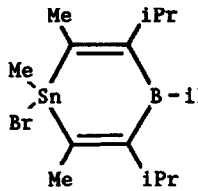
to borole derivatives **2**) and organoboron halides (ring opening and further reactions) had to be postponed.

Reactions of the peralkylated 1-*stanna*-4-*bora*-2,5-*cyclohexadiene* (**7**) *with alkylboron dibromides*

Compound **7** has been reported[6] to react with $MeBBr_2$ to give Me_2SnBr_2 and a mixture of peralkylated *nido*-2,3,4,5-tetracarbahexaborane(6) derivatives (**3**). We have studied this reaction again with $MeBBr_2$ and $^iPrBBr_2$, using ^1H, ^{11}B, ^{13}C and ^{119}Sn NMR at variable temperature (−78 to +25°C). The reaction starts according to eq. (1), with the Me/Br exchange, leading mainly to **10a** and the dialkylboron bromide, accompanied by a small amount of the DBCH derivative **3a,b** (sub-

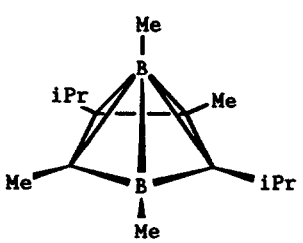


7 R = Me; iPr

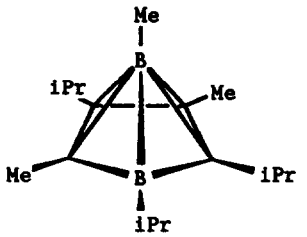


10a

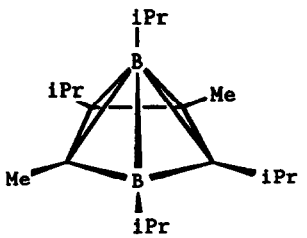
sequently identified, *vide infra*). By warming the samples slowly to room temperature, the amount of **3a,b** did not increase but NMR signals for a mixture of carboranes, as noted previously,[6] appeared and grew rapidly. For both R = Me, ^iPr, a mixture of the carboranes **5a,b** was obtained. Since there can be no doubt as to the distribution of the 2,3,5,6-substituents in **7**, the specific arrangement of the 2,3,4,5-substituents in **5a,b** is remarkable. It is also noteworthy that we did not find an isomer of **5b** with apical ^iPrB— and basal MeB moieties.



5a



5b



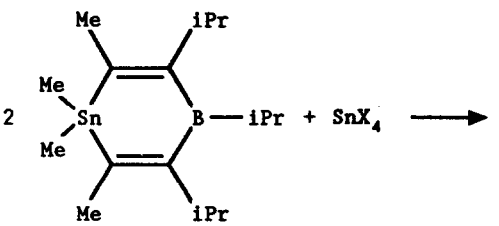
5c

Neither did we observe **5c** (from **7** and $^iPrBBr_2$) in appreciable quantity.

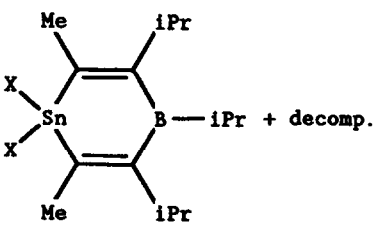
Considering the finding that exocyclic exchange [eq. (1)] is the preferred starting reaction, the whole system becomes exceedingly complex and any discussion of a mechanism leading to **5a,b** as the major, final products would be highly speculative. In order to circumvent the problem of exocyclic exchange [eq. (1)], the spiro-cyclic compound **8** is the better choice for exchange reactions with boron halides.

Synthesis of the spiro-heterocyclic stannane **8** *and its reaction with organoboron dihalides*

The reaction between 2 equivalents of **7** and SnX_4 (X = Cl, Br) does not lead to **8**, but affords only small amounts of **10b,c** [eq. (2)], accompanied by extensive decomposition, including the formation of SnX_2.



7

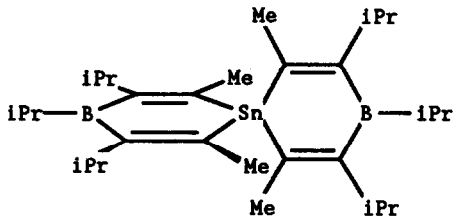


10 b, c

X = Cl, Br

Therefore, we have studied the organoboration[16,17] of tetrakis(alkynyl)stannanes. In the case of the propynide, $Sn(C{\equiv}C{-}Me)_4$, and triisopropylborane [eq. (3)], this has led to the spiro-cyclic compound **8** in high yield.

$$Sn(C{\equiv}C{-}CH_3)_4 + 2\ B(iPr)_3 \longrightarrow$$

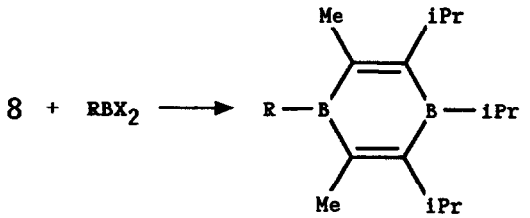


(3)

8

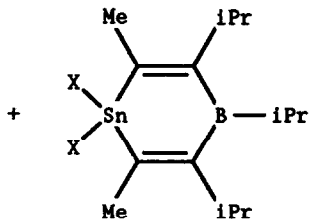
Compound **8** is obtained as a slightly greenish, air-sensitive solid, readily soluble in hexane, benzene, toluene and dichloromethane. It is fully characterized by its NMR data (see Table 1).

The reactions of **8** with $MeBBr_2$, $^iPrBBr_2$ and $PhBCl_2$ in dichloromethane were studied by ^1H, ^{11}B, ^{13}C and ^{119}Sn NMR between -78 and $+25°C$. In all cases, the reaction started [eq. (4)] to give the 1-stanna-4-bora-2,5-cyclohexadienes (**10b,c**) and the corresponding DBCH derivatives (**3a,b,c**). The reactivity towards the boron halides decreased in the order $MeBBr_2 \gg {}^iPrBBr_2 \approx PhBCl_2$.



3 a, b, c

R = Me, iPr, Ph



(4)

10 b, c

X = Cl, Br

All NMR data (Table 2), in particular the whole set of ^1H and ^{13}C NMR signals, are consistent with the proposed structures of **3**. An alternative structure of **3b**, with a different arrangement of the 2,3,5,6-substituents, can be ruled out, since there are two

sets of ^1H and ^{13}C NMR signals for the ^{i}PrB groups in **3b**.

Between −78 and −30°C, no carborane was present [see Fig. 1(a)]. A slight excess of compound **8** was used to ensure that all of the boron halide was consumed, in order to suppress its potential influence on the stability of DBCH derivatives (see the complex behaviour of **7** towards boron halides). The rearrangement of **3** into the carboranes **5** starts by warming the reaction solutions from −30°C to room temperature and is almost (> 80%) complete after 48 h for the reactions (**8**+$MeBBr_2$) and (**8**+$PhBCl_2$). In the case of the reaction (**8**+$^{i}PrBBr_2$), a mixture of **3b** and **5c** (*ca* 40:60) is left after 48 h at room temperature, which can be purified by distillation (*ca* 50°C/10^{-4} torr) to give pure **5c**.

The reaction of **8** with $MeBBr_2$ affords pure **3a**

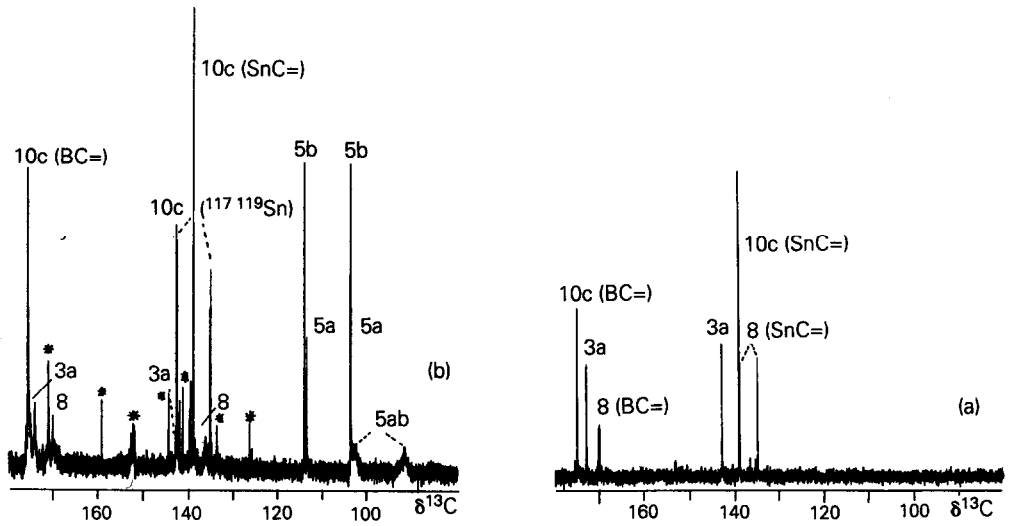

Fig. 1. (a) 75.5 MHz $^{13}C\{^1H\}$ NMR spectrum (233 K, CD_2Cl_2): Reaction between compound **8** (excess) and $MeBBr_2$, showing the region for the olefinic carbons and the carborane cage carbons. Owing to fast quadrupolar relaxation at low temperature, the ^{13}C(B—C=) resonances are fairly sharp[15] and easy to observe. The signals for excess **8**, **10c** and **3a** are readily assigned. The high-field ^{13}C(B—C=) signal of **3a** is on top of the $^{117/119}Sn$ satellites of the ^{13}C(2,6) signals of **10c** [see also Fig. 1(b)]. (b) 75.5 MHz $^{13}C\{^1H\}$ NMR spectrum (300 K, CD_2Cl_2): The same reaction as described in Fig. 1(a), after 2 days at room temperature. In addition to the signals assigned in Fig. 1(a) for **8**, **10c** and **3a**, signals for the cage-carbon atoms of the carboranes **5a** and **5b** are observed. ^{13}C NMR signals for the boron-bonded carbon atoms are broad at room temperature.[15] The ^{13}C(SnC=) resonance signal of **8** is broadened owing to intramolecular dynamic processes. A number of unidentified ^{13}C resonances (marked *) appear in the olefinic region.

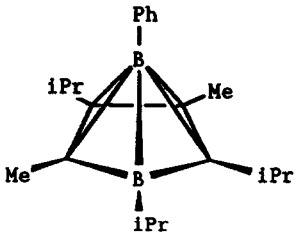
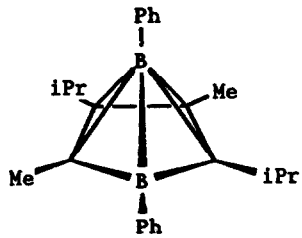
at low temperature [see Fig. 1(a)]. However, when the reaction solution is warmed to room temperature a mixture of the carboranes **5a,b** is present [Fig. 1(b)]. Additional ^{13}C NMR signals in the olefinic region indicate that further unknown species have been formed. Selective ^{13}C-{^{11}B} decoupling experiments[6] have shown that there are two different apical BMe groups (**5a,b**) but only one basal BMe (**5a**) and one basal B^{i}Pr group (**5b**). There is no indication of an apical B^{i}Pr group.

Similarly, compound **8** reacts with ^{i}PrBBr$_2$ to give solely **3b** and **10c**. At room temperature, the typical NMR signals for a single carborane **5c** grow.

The NMR spectra for the reaction mixture (**8**+PhBCl$_2$), containing **3c**, **10b** and a small amount of **8**, change slowly at room temperature to a more complex pattern from which the formation of mainly two carboranes, **5d,e**, is evident, accompanied by a small amount of **5c**.



5d



5e

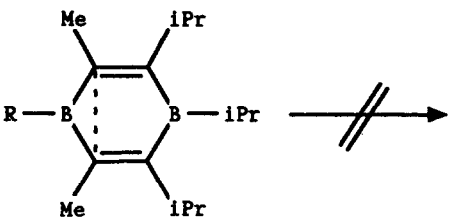
Interconversion between DBCH *derivatives* **3** *and carboranes* **5**

There are mainly two open questions pertinent to the mechanism of the rearrangement of **3** into **5**:

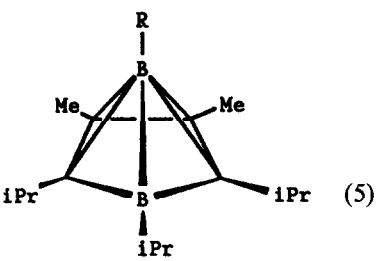
(i) Why does the rearrangement of pure **3a** and pure **3c** lead to mixtures of **5a,b** and **5c,d,e**, respectively?

(ii) How can we explain the specific arrangement of the substituents in the 2,3,4,5-positions of the carboranes **5**?

The experimental evidence relevant to (i) and (ii) rules out the deceptively simple intramolecular process [eq. (5)] which is forbidden by symmetry, anyway. An intermolecular process would either require the rather unlikely reaction between two molecules of DBCH, both loaded with fairly bulky substituents, or the breakage of the six-membered ring into two borirenes [eq. 6(a)]. Recombination of the borirenes could lead back to the starting material (or isomers thereof). However, this would again require the synchronous reaction between sterically crowded centres. Alternatively, derivatives of **4** can be formed from two borirenes [eq. 6(b)] or directly from the DBCH derivatives [eq. 6(c)] via an intramolecular process (*vide infra*) different from that shown in eq. (5). The subscript *n* in eq. (6) denotes that the identity of the substituent is no longer defined.

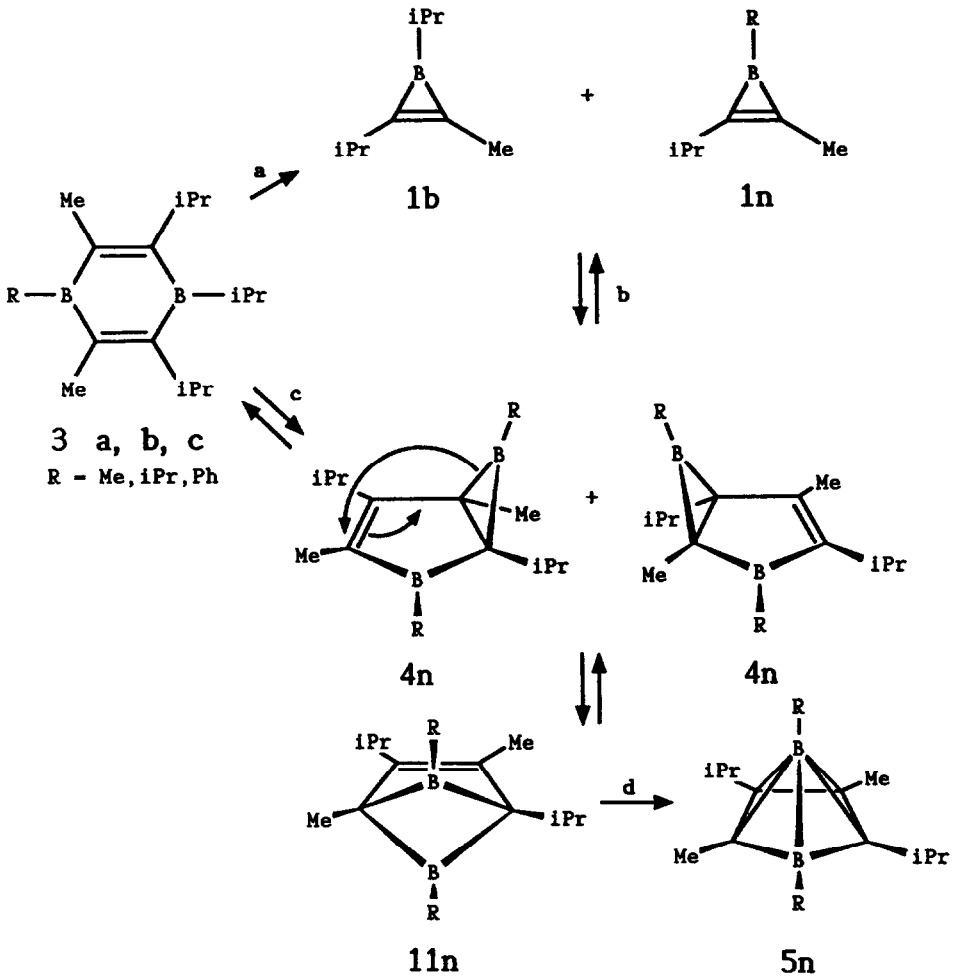


3



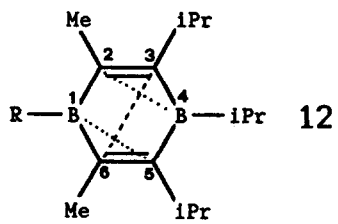
5 (5)

From the derivatives of **4**, there is either a route back to **3** [eq. 6(c)] or the carboranes **5** are formed irreversibly [eq. 6(d)]. The dimerization of the two borirenes to **4** is sterically much less congested if the carbon substituents are alternately ^{i}Pr, Me, ^{i}Pr, Me (in agreement with the experimental data) rather than ^{i}Pr, Me, Me, ^{i}Pr or Me, ^{i}Pr, ^{i}Pr, Me. Since the intermediate **11** has to be considered for the interconversion between **4** and **5**, it is *a priori* unpredictable which RB unit ends up in the apical or basal position. The proposed intramolecular process leading to the intermediate **4**, involving twisted, half-chair or chair conformations of the DBCH derivatives, is symbolized in **12** [dotted lines indicate new B—C bonds and the dashed line indicates a new C—C bond; the B(1)—C(6) and B(4)—C(5) bonds are broken in this process]. Such conformations may be preferred in the presence of bulky substituents such as ^{i}Pr groups on boron as well as on carbon atoms of DBCH. Therefore, both processes [eqs 6(b) and (c)] can be involved in the rearrangement from DBCH derivatives **3** into the carboranes **5**.



(6)

We have been looking for NMR spectroscopic evidence for the intermediacy of the borirenes **1b,c,d**. There were always weak ^{13}C NMR signals in the olefinic as well as in the aliphatic region which could not be assigned. In the ^{11}B NMR spectra, we find weak signals (see Fig. 2) at $\delta^{11}B+34$ to $+35$, or around $\delta^{11}B+40$ which are in the range expected for borirenes (these signals do not belong to oxidation products, since ^{1}H and ^{13}C resonances for B—O—CH— or $BOCH_3$ groups are missing). However, firm evidence is still missing.



12

EXPERIMENTAL

All compounds were handled in N_2 or Ar atmosphere in carefully dried solvents and dry glassware. The starting materials $BiPr_3$,[18] $MeBBr_2$,[19] $PhBCl_2$[19] and $Sn(C{\equiv}C{-}Me)_4$[20] were prepared according to literature procedures. The reaction between BBr_3 and Sn^iPr_4 (1 : 1) in the absence of solvent gave pure $^iPrBBr_2$ in high yield (89%). [$^iPrBBr_2$: 300 MHz ^1H NMR in C_6D_6 (300 K) δ^1H 0.93 d, 6H, ^{i}Pr; 1.59 sp, 1H, BCH; 96.3 MHz ^{11}B NMR, $\delta^{11}B$ 66.5; 75.5 MHz ^{13}C NMR, $\delta^{13}C$ 19.2 ^{i}Pr; 32.6 (br), BCH.] Potassium graphite has been prepared and characterized as described previously.[7] Mass spectra were recorded with a Varian MAT CH 7 instrument. NMR spectra were obtained with JEOL FX 90Q and Bruker AC 300 spectrometers, both equipped with a multinuclear unit. For further experimental details see the footnotes to Tables 1–3 and Figs 1 and 2.

1,5,7,11-*Tetramethyl*-2,3,4,8,9,10-*hexaisopropyl*-3,9-*dibora*-6-*stanna*-1,4,7,10-*spiro*[5.5]*undecatetraene* (8)

A solution of tetrapropinylstannane (8.2 g, 30 mmol) in 120 cm^3 of toluene was cooled to $-78°C$. After adding triisopropylborane (12.6 cm^3, 90 mmol), the solution was allowed to warm up to room temperature and then heated to 60°C for 12

h. The solvent and the excess of triisopropylborane were removed *in vacuo*, and recrystallization of the residue from hexane at −20°C gave 13.3 g (80%) of **8** as a light green solid (> 180°C decomp.). Fig. 2. 96.3 MHz $^{11}B\{^1H\}$ NMR spectrum (300 K, CD_2Cl_2): Reaction between **8** (slight excess) and $^iPrBBr_2$ after 24 h at room temperature. The ^{11}B resonances of **10c**, on top of ^{11}B NMR signal for excess **8**, of the DBCH derivative **3b**, and of the carborane **5c** can be assigned unambiguously. Two signals (marked *) were not assigned (see text).

1.5 cm^3 of CD_2Cl_2. All reactions were monitored by NMR spectroscopy. Depending on the borane, formation of the 1,4-stannabora-2,5-cyclohexadienes (**10b,c**) and DBCH was observed at −40°C (**3a**) or close to room temperature (**3b,c**). In the latter cases the resonances for the DBCH derivatives were always accompanied by resonances for the carboranes (**5**). Except for **3c**/**5de** (decomposition), fractional distillation gave mixtures of the carboranes together with the DBCH derivatives [**3a**/**5ab** (1 : 10) b.p. 50°C/3 × 10^{-4} torr; **3b**/**5c** (1 : 5) b.p. 85°C/3 × 10^{-4} torr]. Chromatography of the mixtures (10 cm SiO_2 column) with hexane gave the pure carborane, whereas the DBCH derivatives decomposed. The reactions between **7** and the organoboron dihalides were carried out by the same method.

300 MHz ^1H NMR in CD_2Cl_2 (300 K): δ^1H [$^nJ(^{119}Sn^1H)$] **10a** = 0.79 [57.2] s, 3H, SnMe; 0.98 d, 6H, B^{i}Pr; 1.22 d, 6H, ^{i}Pr; 1.25 d, 6H, ^{i}Pr; 1.60 sp, 1H, BCH; 2.20 [64.9] s, 6H, =C—Me; 2.93 sp, 2H, =C—CH; **10b** = 1.10 d, 6H, B^{i}Pr; 1.30 d, 12H, ^{i}Pr; 1.98 sp, 1H, BCH; 2.28 [92.0] s, 6H, =C—Me; 2.98 [3.8] sp, 2H, =C—CH; **10c** = 1.06 d, 6H, B^{i}Pr; 1.26 d, 12H, ^{i}Pr; 1.73 sp, 1H, BCH; 2.23 [92.8] s, 6H, =C—Me; 2.94 [4.7] sp, 2H, =C—CH; (see Table 2 for $\delta^{119}Sn$, $\delta^{13}C$ and $\delta^{11}B$ NMR data).

3a = 0.81 s (br), 3H, BMe; 1.00 d, 6H, B^{i}Pr; 1.21 d, 12H, ^{i}Pr; n.o. BCH; 1.89 s, 6H, =C—Me; 2.95 sp, 2H, =C—CH; **3b** = 1.00 d, 6H, B^{i}Pr; 1.10 d, 6H, B^{i}Pr; 1.21 d, 12H, ^{i}Pr, n.o. B(1)CH; n.o. B(6)CH; 1.94 s, 6H, =C—Me; 2.97 sp, 2H, =C—CH; **3c** = 1.16 d, 6H, B^{i}Pr; 1.29 d, 12H, ^{i}Pr; 1.89 s, 6H, =C—Me; 2.10 sp, 1H, BCH; 3.07 sp, 2H, ^{i}Pr; 7.30–7.60 m, 5H, BPh (see Table 3 for relevant ^1H, ^{11}B and ^{13}C NMR data of the carboranes **5**).

Me(^{i}Pr)B—Br in CD_2Cl_2 (300 K): 300 MHz ^1H NMR δ^1H = 1.07 d, 6H, B^{i}Pr; 1.16 s, 3H, BMe; 1.86 sp, 1H, BCH; 96.3 MHz ^{11}B NMR $\delta^{11}B$ = 79.8; 75.5 MHz ^{13}C NMR $\delta^{13}C$ = 16.4 (br), BMe; 18.6, B^{i}Pr; 33.5 (br), BCH.

THE SYNTHESIS AND CHARACTERIZATION OF PYRIMIDINE-2-THIONE COMPLEXES OF PALLADIUM(II)

DIMITRA KOVALA-DEMERTZI* and PARASKEVI KYRKOU

(*Received* 25 *April* 1990; *accepted* 22 *February* 1991

Abstract—Complexes of palladium(II) with pyrimidine-2-thione and the thiolate anion were synthesized and characterized. The complexes were prepared in methanolic or aqueous media. The neutral ligand acts as monodentate and exhibits S-coordination in acidic medium or in methanolic solution. In neutral and basic media the thiolate anion of pyrimidine-2-thiol exhibits S,N-ligation through the ring nitrogen and exocyclic sulphur atoms, in the production of an asymmetric, four-membered, chelated ring.

Pyrimidine derivatives containing sulphur in their structure are known to act as potent inhibitors[1] and as antimetabolites.[2] Pyrimidine thiones were found to inhibit the synthesis of t-RNA under certain conditions and thus act as antitumour and antithyroid agents.[3–10] A similar inhibitory behaviour has been found for pyrimidine-2-thione and the compound also shows pronounced *in vitro* bacteriostatic activity.[10,11] The studies on metal complexes of heterocyclic thio derivatives is an area of great interest, as indicated by Raper in a recent review.[12] The thiopyrimidines such as pyrimidine-2-thione have the potential to bind to a single metal through sulphur,[13] nitrogen[14] or one nitrogen and the sulphur atom.[15] Such binding will leave a potential donor free, since it is not feasible for all three donors to bind to the same metal atom. As part of our systematic investigation on the coordination chemistry of pyrimidine derivatives[16–20] and on the study of complexes of platinum group metals,[16–23] we report the preparation and characterization of palladium(II) complexes with pyrimidine-2-thione, abbreviated as LH, and their structural studies by spectral (IR, ^{1}H NMR spectra), thermal and conductivity measurements.

EXPERIMENTAL

$PdCl_2$, K_2PdCl_4 and pyrimidine-2-thione were purchased from Fluka Chemical Company. All the solvents and chemicals used were of high purity. Elemental analysis of the samples was performed at the N.S. Kurnakov Institute, Academy of Sciences, Moscow (U.S.S.R.). The IR spectra were recorded on a Bruker IFS 113 v Fourier transform spectrophotometer using KCl (4000–500 cm^{-1}) and polyethylene (500–40 cm^{-1}) pellets. ^{1}H NMR spectra in d_6-DMSO were recorded at 90 MHz on a Varian EM-390 spectrometer with Me_4Si as internal standard. Thermogravimetric (TG) data have been obtained on a Du Pont R90 instrument equipped with a 951 thermogravimetric analyser. Analyses were carried out using published methods.[16,18,22]

Synthesis

$[Pd(LH)X_2]_2$ *and* $[Pd(LH)_2X]_2X_2$ (*where* X = Cl, Br). The complexes were prepared by mixing methanolic solutions of the ligand LH and lithium tetrahalogenopalladate(II) prepared *in situ* from $PdCl_2$ and 2LiX (1.5:3 and 4:2 ligand-to-metal molar ratio). The reaction mixture was stirred for 24 h at room temperature and then left in the refrigerator for 1 day. The powders were filtered off, washed with cold methanol and ether and dried *in vacuo* over silica gel. They were redried at 90°C *in vacuo* over P_4O_{10}.

$PdL_2 \cdot 3H_2O$ *and* $[PdL(OH)]_2 \cdot 2H_2O$. A solution of the ligand LH in 0.2 N KOH was added dropwise, with stirring to a solution of the metal halide, $PdCl_2$, in 0.2 N HCl (4:2 and 1:1.7 ligand-to-metal molar ratio for the complexes $PdL_2 \cdot 3H_2O$ and $[PdL(OH)]_2 \cdot 2H_2O$, respectively). The reaction mixture was stirred for 24 h at room temperature. The powder was then filtered off and washed with cold water, acetone and ether and dried as before.

RESULTS AND DISCUSSION

The analytical data and molar conductivity values are given in Table 1. The complexes are microcrystalline or powders stable in atmospheric conditions. Complexes **1**, **2**, **5** and **6** are insoluble in all common solvents, but complexes **3** and **4** are insoluble in polar solvents and soluble in DMF and DMSO. Because of the insolubility of the prepared complexes in suitable solvents, we could not grow crystals for single crystal X-ray structural analysis. The conductivity values of complexes **3** and **4** are within or near the 110–170 Ω^{-1} cm^2 mol^{-1} range indicated for 1:2 electrolytes in DMF,[24] Table 1.

Complexes **1–4** were formed according to eqs (1)–(4), in methanolic solutions or in aqueous solutions in the pH range 1.0–3.5:

$$Li_2[PdX_4] + LH \xrightarrow{CH_3OH} Pd(LH)X_2 + 2LiX \quad (1)$$

$$Li_2[PdX_4] + 2LH \xrightarrow{CH_3OH} Pd(LH)_2X_2 + 2LiX \quad (2)$$

$$H_2[PdX_4] + LH \xrightarrow{H_2O} Pd(LH)X_2 + 2HX \quad (3)$$

$$H_2[PdX_4] + 2LH \xrightarrow{H_2O} Pd(LH)_2X_2 + 2HX. \quad (4)$$

Complexes **5** and **6** were obtained according to eqs (5) and (6), in basic media in the pH range 4–9:

$$H_2PdCl_4 + LH + 2H_2O \longrightarrow PdL(OH) \cdot H_2O + 4HX \quad (5)$$

$$H_2PdCl_4 + 2LH + 3H_2O \longrightarrow PdL_2 \cdot 3H_2O + 4HX. \quad (6)$$

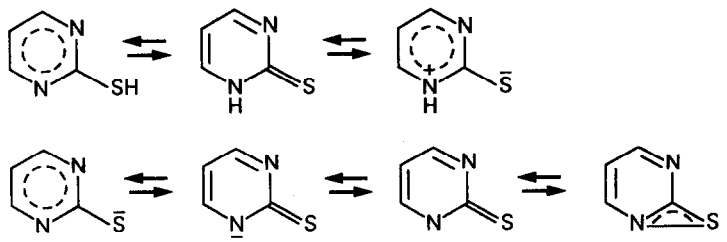

Fig. 1. Tautomeric forms of (a) neutral and (b) anionic forms of pyrimidine-2-thione.

Attempts to isolate complexes in highly acid conditions were unsuccessful.

Tautomeric forms of LH are presented in Fig. 1.

Tautomeric equilibria are modified in solution by changing pH. In highly acid media fully protonated species are likely and may appear to have all available coordination sites blocked. With a pK_a value[25] of 7 deprotonation in the presence of palladium(II) is apparent over a wide pH range, 4–9. Tautomeric equilibria of the thiol–thione type (Fig. 1) are of considerable interest in many areas of chemistry and biochemistry.[26–28]

The principal IR bands of interest are given in Table 2. As a general remark we must emphasize that some stretching modes are coupled, so that the proposed assignments must be regarded as approximate descriptions of the vibrations.[29–31] The assignment for LH is supported by recent normal coordinate treatment.[29] A very broad band at *ca* 2500 cm^{-1} is taken to represent the ν(NH---S) mode due to intermolecular hydrogen bonding. The presence of strong ν(C=S), π(C=S) and δ(C=S) vibrations in LH indicates that the hydrogen atom from the mercapto group migrates to N(1) or N(3) of the ring and the ligand may be better formulated as a pyrimidine-2(1H)-thione rather than as a thiolate,[32]

[a] ν(C—S) band appears at 628(s) cm^{-1}.

[b] $\nu(OH)_b$ band appears at 1260(s) cm^{-1} and $\delta(OH)_b$ at 942(s) cm^{-1}.

but a structure determination would be necessary to decide this. The ν(S—H) band does not appear either in the spectra of the pure ligand or in the spectra of the complexes, indicating that LH and the complexes exist in their thione form. In the free ligand the C=N and C=C bands are observed at 1602 and 1560 cm^{-1} and remain unchanged in the spectra of complexes **1–4** indicating that the cyclic N(1) or N(3) atom is not involved in coordination, while the strong bands at 1207 and 750 cm^{-1} [predominantly the ν(C=S) mode] decrease dramatically and shift to lower frequency upon coordination. All the evidence is consistent with the ligand LH behaving in a monodentate fashion through the sulphur atom of the thione group with no enthiolization process. Since the shifts in complexes **1–4** are in the same direction, the bonding pattern is deduced to be the same for these complexes. The significant change in the ligand bands in complexes **5** and **6** is the absence of the high frequency ν(NH) and δ(NH) bands [great δ(NH) character] at 3090, 1480 and 1320 cm^{-1}, respectively. A new, strong band at 628 cm^{-1} is taken to represent the ν(C—S) vibration. The C—S stretching frequency generally appears in the region 710–570 cm^{-1} [33] and in 4,6-dimethyl-2-mercaptopyrimidine the band at 630 cm^{-1} was attributed to the ν(C—S) vibration.[30] The presence of the bridging hydroxy groups in complex **6** is supported by the appearance of the $\nu(OH)_b$ mode at 1260 cm^{-1} and the bridging OH bending mode at 942 cm^{-1}.[34] In complexes **5** and **6** the band at 1600 cm^{-1} is split and is shifted to higher frequencies, indicating an increase in double bond character of the C=C and C=N links and coordination through the endocyclic nitrogen atom.[12,35]

The far-IR spectra of the complexes (Table 3) give insight into the structure and bonding in the solid state. The far-IR spectra of complexes **1** and **2** are indicative of the presence of both terminal and bridging Pd—$X_{(halogen)}$ bonds, suggesting a dimeric or polymeric structure. The *trans*-planar $M_2L_2X_4$-type compound (C_{2h}) exhibits three IR-active (Bu) ν(MX) modes, one $(MX)_t$ and two $(MX)_b$. For the latter two, the higher frequency band corresponds to $\nu(MX)_b$ *trans* to X, whereas the lower frequency band is assigned to $\nu(MX)_b$ *trans* to L, since it is sensitive to the nature of L.[34] From comparison with the free ligand spectra, a medium and broad absorption in the 320–340 cm^{-1} range could be tentatively attributed to ν(Pd—S)[12,36,37] in the case of the chloro complexes **1** and **3**; this band is masked by ν(Pd—Cl) which has already been assigned. The lower value of ν(Pd—S) obtained for the bromide compounds agrees with the HSAB theory.[18,38,39] The factors affecting the hardness of acids, are size, charge, oxidation state, electronic structure and the nature of attached groups, halogens in this case. The Pd—S bond is stronger when palladium(II) is bonded to chloride since it is more electronegative than bromide and the amount of positive charge on palladium(II) is greater.[18,38,39] The lower value of ν(Pd—S) for the bromide compounds also agrees with the *trans*-influence.[18,34] A slight increase in the position of the ν(M—S) band in complexes **5** and **6**, relative to the corresponding value for the neutral complexes **1–4**, suggests some strengthening of the metal–sulphur bond.[40] The spectra of complexes **5** and **6** differ from those of **1–4** due to the appearance of a band at *ca* 380–390 cm^{-1} attributable to the ν(Pd—N) vibrations.[12,18]

Table 3. Metal–ligand vibrations of the complexes

Compound	$\nu(Pd—X)_t$	$\nu(Pd—X)_b$	ν(Pd—S)	ν(Pd—N)
1	338vsbr	285sh 278m		
2	279ms	212s 202sh	323ms 312sh	
3		280mbr 245m	335mbr 320sh	
4		222ms 215m	322sh 315m	
5			332s 320sh	391s 380sh
6[a]			328m 317sh	379m 369w

[a] $\nu(Pd—O)_b$ appears at 276m (br) cm^{-1}.

The ^{1}H NMR spectrum of LH in d_6-DMSO contains a triplet at 6.87 ppm downfield from TMS assigned to the C(5)H proton, a peak at 8.30 ppm assigned to NH and a peak at 8.38 ppm assigned to the C(4)H and C(6)H protons. The absence of any evidence for the thiol-SH proton (δ 2–5 ppm) confirms the thione tautomer as the dominant species of LH in d_6-DMSO solution, as in the solid state. The ^{1}H NMR spectra of complexes **3** and **4** display peaks at 7.40 ppm assigned to the C(5)H protons, at 8.60 ppm assigned to the NH proton and at 8.75 ppm assigned to the C(4)H and C(6)H protons. The ^{1}H NMR spectra of the complexes **3** and **4** also confirm the participation of the sulphur atom in metal coordination. The spectra of complexes **1**, **2**, **5** and **6** could not be recorded because of their insolubility in d_6-DMSO and other common NMR solvents.

The thermal decomposition of complexes **5** and **6** was studied using TG and DTG techniques. From the data obtained, it can be seen that two

main processes occur—dehydration and pyrolytic decomposition. The thermal decomposition of complex **6** after dehydration is characterized by the complex degradation mechanism without the formation of a stable intermediate. Complex **5** releases water in two steps, as revealed by the appearance of two DTG maxima and an inflection in the TG curve. The presence of a TG plateau after water loss indicates that a stable, anhydrous intermediate is formed. The anhydrous PdL_2 complexes undergo decomposition in two distinct steps, between 250 and 340°C and 350 and 405°C, which corresponds exactly to the release of one L molecule per metal ion. From TG data the following thermal decomposition mechanism has been proposed:

$$PdL_2 \cdot 3H_2O \xrightarrow[endo]{70^\circ C} PdL_2 \cdot H_2O \xrightarrow[endo]{141^\circ C}$$

$$PdL_2 \xrightarrow[exo]{312^\circ C} PdL \xrightarrow[exo]{368^\circ C} PdO.$$

Conclusions

The effect of pH on the coordination properties of the ligand in the presence of the palladium(II) ion has been studied. In methanolic or aqueous acid media (pH = 1–4), complexes of the type $[Pd(LH)X_2]_2$ and $[Pd(LH)_2X]_2X_2$ (where X = Cl, Br) are formed. A sulphur-donating ligand, in the thione form, is proposed. Sulphur donation is also reported for the same ligand in $Pt(LH)_4Cl_2$ and $[Pt(LH)_4] \cdot [PtCl_6]$.[13] In neutral or basic aqueous media $PdL_2 \cdot 3H_2O$ and $[PdL(OH)]_2 \cdot 2H_2O$ complexes are formed. The monoanionic ligand L, in the thiolate form, exhibits bidentate sulphur and nitrogen coordinating behaviour. The involvement of the nitrogen and sulphur atoms in the coordination of L suggests either a bridging or chelated role for the thiolate anion. Some authors described the anion of heterocyclic thiones as S,N-bridging,[40,41] however S,N-chelation has also been proposed for *cis* square palladium and platinum complexes, ML_2 (where L = benzo-1,3-thiazoline-2-thione),[42] and for $[WL_4]$[15] and $[FeL_3]$[32] (where L = the thiolate anion of pyrimidine-2-thiol).

The most plausible structures for the new, isolated complexes based on the above results are dimeric for $[Pd(LH)X_2]_2$ with terminal and bridging halogen atoms and dimeric for $[Pd(LH)_2X]_2X_2$ with bridging halogen atoms. The $[PdL(OH)]_2 \cdot 2H_2O$ complex is described as dimeric with bridging hydroxy groups and chelated S,N-coordinated ligand, while the $PdL_2 \cdot 3H_2O$ complex is described as polymeric with S,N-bridging or monomeric with S,N-chelated thiolate anion (Fig. 2).

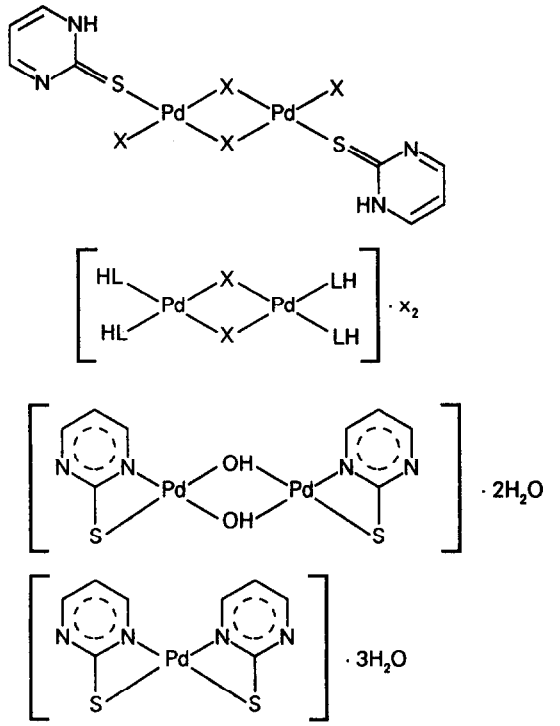

Fig. 2. The proposed geometry for the $[Pd(LH)X_2]_2$, $[Pd(LH)_2X]_2X_2$, $[PdL(OH)]_2 \cdot 2H_2O$ and $PdL_2 \cdot 3H_2O$ complexes

ORGANODIPALLADIUM(II) CYCLOMETALLATES OF THE SCHIFF BASE N,N′-DIETHYL-2,6-DIALDIMINOBENZENE

SUKLA CHAKLADAR, PARIMAL PAUL and KAMALAKSHA NAG*

Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta 700 032, India

(*Received* 18 *September* 1990; *accepted* 22 *February* 1991)

Abstract—Syntheses and reactions of dipalladiobenzene derivatives have been reported. $Li_2[PdCl_4]$ reacts with N,N′-diethyl-2,6-dialdiminobenzene (H_2L) to form the cyclometallated compound, $[Pd_4L_2Cl_4]$, in which metallation occurs at the 3,5-carbon atoms of the aromatic ring. The tetrachloro compound can be converted to a dinuclear precursor complex, $[Pd_2L(MeCN)_2(ClO_4)_2]$, which reacts with pyridine, 4-methylpyridine, pyrazole and imidazole (B) to produce complexes of the type $[Pd_2L(B)_4](ClO_4)_2$, and with 2,2′-bipyridine to produce $[Pd_2L(bpy)_2](ClO_4)_2$. A tetranuclear neutral complex $[Pd_4L_2(pz)_4]$ is formed when the precursor complex interacts with pyrazole and triethylamine. A series of neutral chelate compounds $[Pd_2L(AB)_2]$ has been obtained by reacting the precursor with sodium salts of acetylacetone, ethylacetoacetate, N-methylsalicylaldimine (HAB) and N,N′-dimethyldithiocarbamic acid (HAB). The compounds have been characterized from their ^1H NMR spectra.

Palladium(II), which is classified as a typical electrophile[1–3] for the activation of C—H bonds in hetero-substituted organic molecules, undergoes cyclometallation reactions with remarkable ease and the chemistry of cyclopalladated compounds, especially those derived from N-donor ligands, is very rich.[4–12] In particular, *ortho*-palladated compounds have been extensively studied because of their potential utility in organic synthesis.[13,14] Although the literature abounds with *ortho*-palladated compounds containing one Pd—C linkage per aromatic ring, to our knowledge, there exists only a single report[15] dealing with the formation of *ortho*-metallated dipalladiobenzene derivatives. These compounds have been obtained from N,N,N′,N′-tetraalkyl-*p*-xylene-α,α-diamines and N,N,N′,N′-tetraalkyl-*m*-xylene-α,α-diamines. As part of our interest in exploring the chemistry of 3,5-dipalladiocyclometallates we have recently reported[16] the formation of tetranuclear complexes $[Pd_4L_2(OAc)_4]$ with N,N′-dialkyl-2,6-dialdiminobenzenes (H_2L). These μ-acetato complexes undergo interesting reactions with a variety of nucleophiles. The present study is concerned with the reactions of the dinuclear complex $[Pd_2L(MeCN)_2(ClO_4)_2]$.

EXPERIMENTAL

Physical measurements

IR spectra were recorded on a Perkin–Elmer model 783 IR spectrophotometer with KBr pellets or Nujol mulls. ^1H NMR spectra [δ (ppm)] were recorded at 270 MHz on a Bruker WH 270 spectrometer in $CDCl_3$ or Me_2SO-d_6 with Me_4Si as an internal standard. A Philips PR 9500 bridge was used for conductivity measurements. Carbon, hydrogen and nitrogen analyses were performed on a Perkin–Elmer model 240C elemental analyser. Palladium was estimated gravimetrically as the dimethylglyoximate.

Materials

$PdCl_2 \cdot xH_2O$ was obtained from Johnson Matthey, and 1,3-diformylbenzene was prepared by

some minor modifications of the method described in the literature.[17]

The Schiff base N,N′-diethyl-2,6-dialdiminobenzene (H_2L) was prepared by refluxing a benzene solution (50 cm^3) of 2,6-diformylbenzene (2.7 g, 20 mmol) and ethylamine [3.2 cm^3 70% (w/w) aqueous solution, 40 mmol] in a Dean–Stark apparatus for 4 h. The solvent was removed on a rotary evaporator and the oily residue was evacuated to 0.1 torr. The ligand thus obtained was substantially pure and used directly for cyclometallation reactions.

Silver perchlorate was prepared by digesting "silver carbonate" (BDH) with dilute $HClO_4$ to leave some of the carbonate undissolved. The filtrate was evaporated to dryness on a steam bath. The solidified mass after drying over P_4O_{10} *in vacuo* was recrystallized from boiling benzene.

CAUTION! Silver perchlorate and other perchlorate salts described below are potentially explosive. Although $AgClO_4$ was recrystallized in gram quantities without any difficulty, **extreme caution should be exercised in handling this material.**

Preparation of the complexes

$[Pd_4L_2Cl_4]$ (**1**). $Li_2[PdCl_4]$ (2.62 g, 10 mmol) and H_2L (0.94 g, 5 mmol) were stirred in MeOH (100 cm^3) for 5 h. The product deposited was collected by filtration and washed with MeOH and Et_2O; yield 60%.

$[Pd_2L(MeCN)_2(ClO_4)_2]$ (**2**). A stirred suspension of **1** (0.94 g, 1 mmol) in MeCN (30 cm^3) was treated with small portions of $AgClO_4$ (0.83 g, 4 mmol). After 1 h, AgCl was removed by filtration and the filtrate was concentrated to a small volume on a rotary evaporator. The product deposited on cooling at −5°C was collected by filtration and washed with Et_2O; yield quantitative.

$[Pd_4L_2X_4]$ [Z = Br (**3**), N_3 (**4**)]. To a MeCN solution (50 cm^3) of **2** (0.68 g, 1 mmol) was added dropwise, with stirring, an aqueous solution (10 cm^3) of LiBr (0.2 g, 2.4 mmol) or NaN_3 (0.16 g, 2.4 mmol). The product precipitated immediately and after additional stirring for 0.5 h was collected and washed successively with H_2O, MeOH and Me_2CO; yield quantitative.

$[Pd_2L(py)_4](ClO_4)_2$ (**5**). A Me_2CO solution (50 cm^3) of **2** (0.68 g, 1 mmol) was slowly treated with pyridine (0.5 cm^3). The white, crystalline product that deposited on standing was collected by filtration and recrystallized from MeOH; yield 80%.

$[Pd_2L(4\text{-}Mepy)_4](ClO_4)_2 \cdot 0.5CHCl_3$ (**6**). This compound was prepared by the same method as **5** and recrystallized from MeOH–$CHCl_3$; yield 80%.

$[Pd_2L(Hpz)_4](ClO_4)_2$ (**7**). A Me_2CO solution (30 cm^3) of **2** (0.68 g, 1 mmol) and pyrazole (0.27 g, 4 mmol) was stirred for 1 h. The solution was then evaporated to a small volume and stirred with Et_2O to precipitate the product. The compound was recrystallized from MeOH–Et_2O; yield 80%.

$[Pd_2L(Him)_4](ClO_4)_2$ (**8**). The method of preparation of this compound is the same as for **7**.

$[Pd_4L_2(pz)_4]$ (**9**). A solution (30 cm^3) of **2** (0.68 g, 1 mmol) in MeCN was treated dropwise, with stirring, with a solution (10 cm^3) of pyrazole (0.126 g, 2 mmol) and Et_3N (0.2 g, 2 mmol) in MeCN. The product deposited was collected by filtration and washed with MeOH and Me_2CO; yield 80%.

$[Pd_2L(bpy)_2](ClO_4)_2$ (**10**). A MeCN solution (30 cm^3) of **2** (0.68 g, 1 mmol) and an MeOH solution (20 cm^3) of 2,2′-bipyridine (0.31 g, 2 mmol) were mixed together and stirred for 2 h. During this period the colourless solution became intense yellow. The solution was evaporated on a rotary evaporator and the residue triturated with Et_2O. The product was recrystallized from MeOH–Et_2O; yield 90%.

$[Pd_2L(acac)_2]$ (**11**). To a stirred suspension of **2** (0.68 g, 1 mmol) in $CHCl_3$ (40 cm^3) was added an MeOH solution (10 cm^3) of acetylacetone (0.2 g, 2 mmol) and metallic sodium (0.046 g, 2 mmol). The filtrate, on concentration, afforded a yellow, crystalline product which was recrystallized from MeOH–$CHCl_3$; yield 80%.

$[Pd_2L(etacac)_2]$ (**12**). To a stirred suspension of **2** (0.68 g, 1 mmol) in $CHCl_3$ (40 cm^3) was added an EtOH solution (10 cm^3) of ethylacetoacetate (0.26 g, 2 mmol) and KOH (0.11 g, 2 mmol). After 2 h, the solution was filtered and the filtrate was concentrated to *ca* 25 cm^3. The product which deposited on standing was collected by filtration and recrystallized from CH_2Cl_2; yield 80%.

$[Pd_2L(msalmine)_2]$ (**13**). An MeOH solution (10 cm^3) of N-methylsalicylaldimine, obtained by refluxing salicylaldehyde (0.24 g, 2 mmol) and methylamine [0.3 cm^3 40% (w/w) aqueous solution] for 0.5 h, was cooled to room temperature and then added to a stirred suspension of **2** (0.68 g, 1 mmol) in $CHCl_3$ (30 cm^3). After 1 h the filtrate was concentrated to crystallize out the product, which was recrystallized from MeOH–$CHCl_3$; yield 80%.

$[Pd_2L(Me_2dtc)_2]$ (**14**). A freshly prepared MeOH solution (10 cm^3) of sodium dimethyldithiocarbamate[18] (2 mmol) was added in small portions to a solution of **2** (0.68 g, 1 mmol) in Me_2CO (20 cm^3). After 1 h the product was collected by filtration and recrystallized from MeOH–$CHCl_3$; yield 90%.

Analytical data and ^1H NMR spectroscopic data for the complexes are given in Tables 1 and 2, respectively.

Table 1. Analytical data[a] for the complexes

Complex	Colour	Analysis (%) C	H	N	Pd
$[Pd_4L_2Cl_4]$ (1)	Light yellow	31.0(30.6)	3.2(3.0)	5.8(6.0)	45.6(45.3)

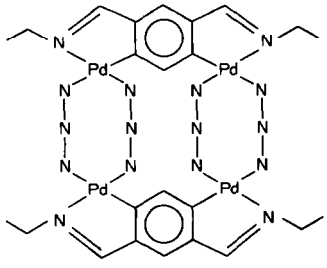
RESULTS AND DISCUSSION

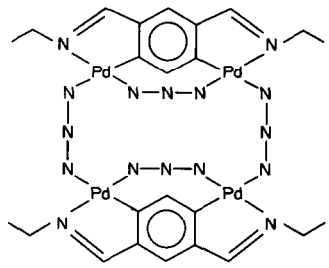
The reaction between N,N′-diethyl-2,6-dialdiminobenzene (H_2L) and $Li_2[PdCl_4]$ in MeOH affords $[Pd_4L_2Cl_4]$ (**1**) in good yield. In this compound metallation occurs simultaneously at the 3- and 5-carbon atoms of the aromatic ring. We have already shown[16] that complex **1** and its analogues can be obtained by the metathetical reaction between the tetra-μ-acetato cyclopalladates, $[Pd_4L_2(OAc)_4]$, and LiCl. The tetranuclear composition of these compounds has been established by determining molecular weights of soluble derivatives.

Although the ability of Schiff bases to form *ortho*-palladated compounds was recognized quite early[18–20] and recent studies[21–25] have covered their important structural aspects, the potential of 2,6-dialdiminobenzenes to form 3,5-dipalladiometallocycles has not been previously investigated. Since *ortho*-palladated compounds derived from Schiff bases have found important applications in organic synthesis,[13,14] we considered that a 3,5-dipalladiometallocyclic derivative of H_2L might widen the scope of synthesis. However, to be useful for reactions such as vinylation or carbonylation, the precursor cyclopalladate should be soluble in organic solvents and contain labile donors. For this purpose **1**, which is practically insoluble in common organic solvents, can be readily converted to a colourless, soluble complex of composition $[Pd_2L(MeCN)_2(ClO_4)_2]$ (**2**) by treating it with four equivalents of $AgClO_4$ in MeCN. The IR spectrum of **2** shows characteristic $\nu(C{\equiv}N)$ due to MeCN at 2250 cm^{-1}. The ν_3 band due to ClO_4^-, which is split into three components with peaks at 1150, 1105 and 1065 cm^{-1}, suggests perchlorate coordination[26] in the solid state. The molar conductivity of **2** in MeCN (250 Ω^{-1} cm^2 mol^{-1}) is in the Λ_M range consistent with a 2:1 electrolyte.[27]

Complex **2** reverts to **1** on treatment with chloride ion. Complexes $[Pd_4L_2Br_4]$ (**3**) and $[Pd_4L_2(N_3)_4]$ (**4**) can be obtained by the same manner. The presence of the 1,3-azido bridge in **4** is indicated by the observation of $\nu_{as}[N_3^-]$ at a higher frequency (2080 cm^{-1}) relative to that of the terminal azide (2050 cm^{-1}).[28,29]



(I)



(II)

Complex **4** can be structurally represented either by **I** or **II**, but **I** seems to be more appropriate.

A number of dinuclear cyclopalladates have been derived from **2**. For example, pyridine and 4-methylpyridine afford $[Pd_2L(py)_4](ClO_4)_2$ (**5**) and $[Pd_2L(4\text{-}Mepy)_4](ClO_4)_2$ (**6**), respectively. The ^1H NMR spectrum of **5** (Fig. 1) shows an interesting feature in that the singlet due to 4-CH of the cyclometallated phenyl ring is strongly shielded (δ 4.94) with respect to 1-CH (δ 7.50). Construction of molecular models for **5** revealed that the two pyridine rings which are *trans* with respect to the Pd—N bonds do not lie in the same plane of the cyclometallated aromatic ring. In the sterically favoured configuration the 4-CH proton is exposed to the strong, diamagnetic, anisotropic shielding effect of the adjacent pyridine rings. Inasmuch as the two pyridine rings bound to each palladium are in chemically distinct environments, corresponding hydrogen atoms on each would be expected to resonate at different fields. Indeed Fig. 1 shows that the unresolved multiplets due to 9-CH and 9′-CH appear at δ 7.42 and 7.53, respectively, and also the chemical shifts due to 8-CH (8.76) and 8′-CH (8.88) are different. However, the chemical shifts due to 10-CH and 10′-CH, both being farthest from the metal centre, are least affected by the orientation of the rings and are observed as a triplet at δ 7.96. Complex **6** also shows similar ^1H NMR spectral features (Table 2). In this case the δ values for 4-CH and 1-CH are 5.28 and 7.52, respectively. The relatively stronger shielding of 4-CH in **5** compared with that in **6** can be rationalized in the following way. In **6**, to avoid steric interaction of the methyl substituents the pyridine rings are more tilted which leads to diminution of shielding of 4-CH.

Pyrazole and imidazole also form similar colourless complexes, $[Pd_2L(Hpz)_4](ClO_4)_2$ (**7**) and $[Pd_2L(Him)_4](ClO_4)_2$ (**8**). On the other hand, when **2** is treated with two equivalents of pyrazole and triethylamine, a light yellow complex (**9**) of composition $[Pd_2L(pz)_2]$ is obtained. Complex **9** is not soluble enough for molecular weight determination, nevertheless, the above composition is unlikely in view of the normal stereochemical preferences of

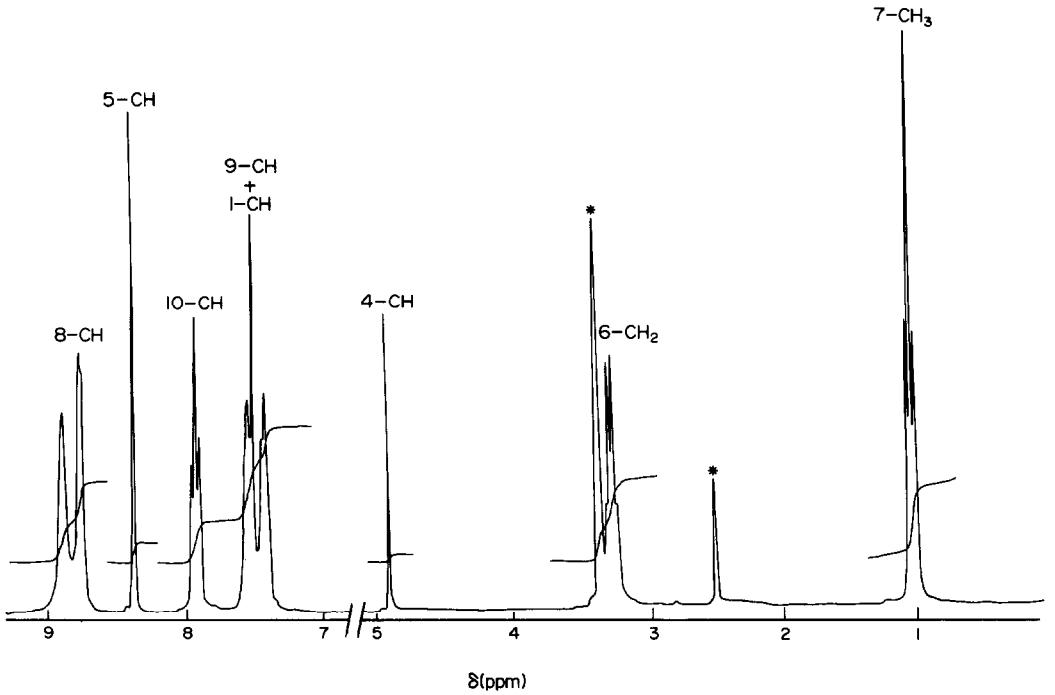


Fig. 1. ^{1}H NMR spectrum of **5** in Me_2SO-d_6. The signal due to the solvent is marked by *.

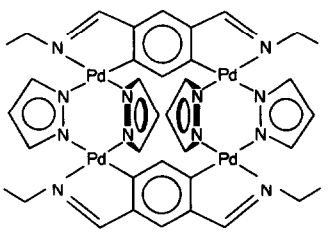
palladium(II). It is more likely that **9** has the tetranuclear composition $[Pd_4L_2(pz)_4]$ with the structural arrangement shown in **III**.



(III)

With 2,2′-bipyridine complex **2** produces $[Pd_2L(bpy)_2](ClO_4)_2$ (**10**). The ^{1}H NMR spectral features of **10** (Table 2) show some interesting changes with respect to those of **5** and **6**. Firstly, the aliphatic protons of **10** are shifted to lower field compared with those of **5** and **6**. Secondly, unlike **5** or **6**, in **10** 4-CH is more deshielded than 1-CH. These changes are plausibly due to more extensive π-electron delocalization in the 2,2′-bipyridine case.

Complex **2** reacts with monoprotic, bidentate ligands (HAB) to form neutral chelate complexes $[Pd_2L(AB)_2]$. $[Pd_2L(acac)_2]$ (**11**) and $[Pd_2L(etacac)_2]$ (**12**), prepared in this way, are identical to those previously obtained by us[16] from the tetranuclear precursor. The ^{1}H NMR spectrum of $[Pd_2L(msalmine)_2]$ (**13**), shown in Fig. 2, is consistent with the structure in which the phenolic oxygen of N-methylsalicylaldimine is *trans* to the Pd—N bond. Similar to **10**, in this case also the aliphatic protons are relatively more deshielded and 4-CH is more deshielded (δ 7.63) compared with 1-CH (δ 7.10). Again this is due to strong electron delocalization in the msalmine chelate ring. A similar observation was also made[16] for **11** and **12**.

Table 3, which summarizes the δ values due to azomethine protons in three ionic and three neutral complexes, discloses an interesting feature. Compared with the ionic complexes for which the chemical shift due to CH=N varies between δ 8.42 and 8.62, in the neutral chelates the chemical shifts remain almost invariant (δ *ca* 7.83) and are appreciably more shielded. The greater shielding of

Table 3. Chemical shifts (δ) due to CH=N

13	7.83

[a] Data taken from ref. 16.

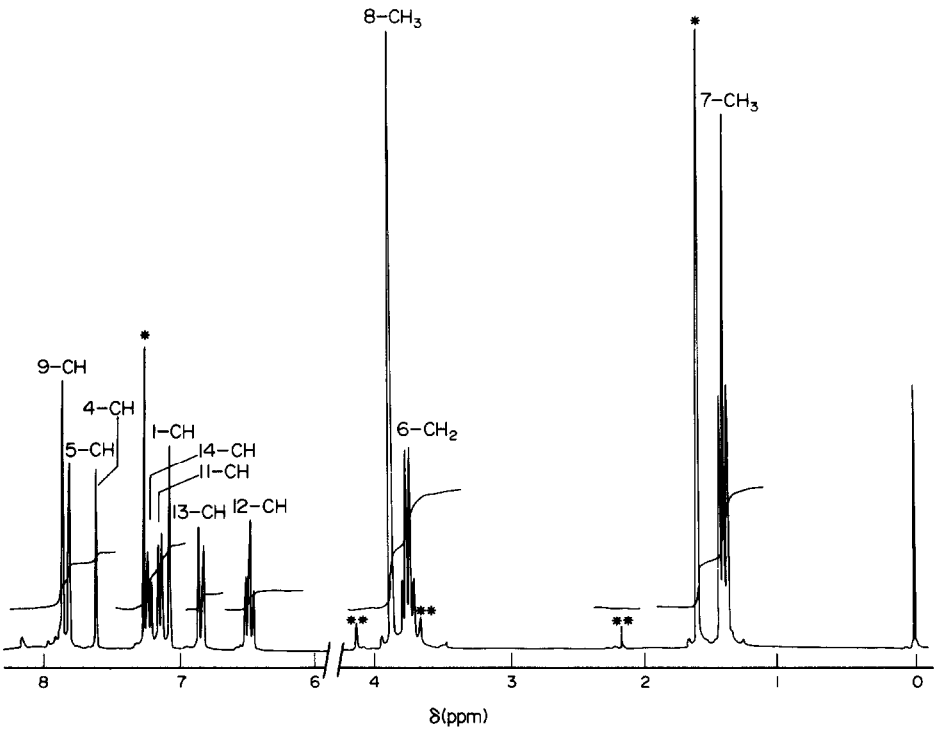

Fig. 2. ^{1}H NMR spectrum of **13** in $CDCl_3$. The signals due to the solvent are marked by * and ** indicates trace impurities.

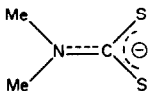
CH=N in the neutral chelates is a consequence of the quenching of the electrophilicity of palladium.

Finally, complex **2** with N,N′-dimethyldithiocarbamate produces disulphur chelated species, $[Pd_2L(Me_2dtc)_2]$ (**14**). This compound exhibits characteristic IR frequencies due to delocalized



at 1500 [ν(C=N)], 1240 [$\nu_{as}(CS_2^-)$] and 980 cm^{-1} [$\nu_s(CS_2^-)$].

In conclusion, **2** is a useful precursor for the generation of a variety of air-stable, cyclometallated, dipalladiobenzene derivatives. The usefulness of this compound in organic synthesis is currently under investigation.

Abstract—Bis-phosphine 1,3-bis(diphenylphosphinoacetyl)benzene (LH_2) is obtained in high yield by reacting Ph_2PCl with bis(lithium anolate) derived from 1,3-diacetylbenzene in tetrahydrofuran. Its oxidation by air gives quantitatively the corresponding double β-ketophosphine oxide. The ligand LH_2 reacts with $[(o\text{-}C_6H_4CH_2NMe_2)PdCl]_2$ to give the binuclear complex $[\{(o\text{-}C_6H_4CH_2NMe_2)PdCl\}_2(\mu\text{-}LH_2)]$ in which the bis-phosphine behaves as a bridging ligand. The latter complex is conveniently converted by prolonged treatment with sodium hydride in tetrahydrofuran into the bis-enolato complex $[\{(o\text{-}C_6H_4CH_2NMe_2)Pd\}_2(\mu\text{-}L)]$ in which the bridging ligand L contains two chelating subunits. Reaction of LH_2 with $[Pd(acac)_2]$ leads to oligomeric material of formula $(PdL)_n$. Mass spectroscopic measurements suggest the presence of a tetrameric species, $(PdL)_4$, present in the reaction mixture.

There is currently renewed interest in the design and synthesis of binucleating ligands possessing two chelating subunits. Such systems have frequently been used to maintain two metals in close proximity, a situation which, by virtue of reciprocal steric and electronic forces between the metal centres, may induce new physical properties as well as enhanced stoichiometric or catalytic reactivity.[1] More recently, some attention has been focused on ligands with two chelating subunits which are separated by a rigid spacer and therefore cannot bind the same metal centre. This allows the preparation of molecular assemblies built around two distinct metal ions. Such a strategy has been applied, *inter alia*, to the synthesis of dinuclear complexes suitable for the incorporation of bifunctional substrates.[2] Another interesting aspect of binucleating ligands results from the property that the selective chelation of one coordinating subunit may control the orientation of the second one and help to induce predictable organized geometries.[3] In this paper we present a convenient synthesis of 1,3-bis(diphenylphosphinoacetyl)benzene, a ligand with two potentially chelating *P,O* subunits as well as that of the corresponding bis-(phosphine oxide). Some polynuclear palladium complexes obtained from LH_2 are also presented.

EXPERIMENTAL

General procedures

The preparation of the phosphines and the complexes was conducted under an atmosphere of dry

* Author to whom correspondence should be addressed.

dinitrogen by use of standard techniques and equipment (Schlenk flasks, etc.), that of the phosphine oxide LH_2O_2 was performed in air. IR spectra were recorded on a Perkin–Elmer 398 or a IFS 66 Brucker spectrophotometer as KBr pellets. The ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded at 200 and 81 MHz, respectively, on a Bruker WP 200 SY instrument, and the $^{13}C\{^1H\}$ NMR spectra were recorded at 100.6 MHz on a FT Bruker AM 400 spectrometer. ^1H and ^{13}C chemical shifts (in ppm) are given relative to external $SiMe_4$ and those for ^{31}P relative to external H_3PO_4. The mass spectra of the ligands LH_2 and $L^{OMe}H_2$ were recorded on Kratos MS 80 and Finnigan MAT TSQ-70 spectrometers, respectively. The FAB mass spectra of $(PdL)_n$ were recorded on a ZAB HF VG analytical, using *p*-toluenesulphonic acid as protonating agent. The complex $[\{o\text{-}C_6H_4CH_2NMe_2)Pd(\mu\text{-}Cl)\}_2]$[4] and 3,5-diacetylanisole[5] were obtained by literature methods.

Preparation of 1,3-*bis*(*diphenylphosphinoacetyl*) *benzene*

A 1.6 M solution of n-BuLi (12.5 cm^3, 20.0 mmol) was added dropwise to a solution of di-isopropylamine (2.024 g, 20.0 mmol) in tetrahyrofuran (THF) (20 cm^3) at −78°C. The mixture was stirred for 0.5 h and a solution of 1,3-diacetylbenzene (1.622 g, 10.0 mmol) in THF (50 cm^3) was subsequently added with the temperature kept at −78°C. After stirring the viscous purple mixture, a solution of Ph_2PCl (4.413 g, 20.0 mmol) in THF (50 cm^3) was added slowly. The temperature was then raised and the mixture was stirred for 15 h. After removal of the solvent *in vacuo*, the residue was treated with toluene and the resulting suspension was filtered to remove LiCl. The filtered solution was evaporated to dryness and the product was chromatographed on a column containing 450 g of Kieselgel (Kieselgel 60, Merck) using a mixture of CH_2Cl_2/*n*-hexane/AcOEt (450 cm^3 : 550 cm^3 : 50 cm^3) as eluent (yield 4.138 g, 78%). The compound LH_2 eluted first ($R_f = 0.8$ with AcOEt/hexane, 45:55 v/v). Found: C, 76.8; H, 5.5. Calc. for $C_{34}H_{28}O_2P_2$: C, 77.0; H, 5.3%. MS (electron impact) $M_r = 530.54$: 530 (8% M), 386 (8%, $M-2C_6H_5$), 345 (100%, $M-PPh_2$). IR (KBr): 1672 s cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.80 [s, 4H, PCH_2, $^2J(PH) = 0$ Hz], 7.29–7.52 (21H, aromatic H), 8.08 [dd, 2H, H(4) and H(6) of central ring system, $^3J = 8$ Hz, $^4J = 1.5$ Hz], 8.45 [t, 1H, H(2), $^4J = 1.5$ Hz]. $^{31}P\{^1H\}$ NMR (toluene/C_6D_6): δ −16.0 (s). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 40.58 [d, PCH_2, $^1J(PC) = 22$ Hz], 128.56–137.11 (aromatic C), 196.30 [d, C=O, $^3J(PC) = 8$ Hz].

Preparation of LH_2O_2

A solution of LH_2 (0.531 g, 1.0 mmol) in CH_2Cl_2 (50 cm^3) was vigorously stirred in a beaker for 72 h. The solvent was removed *in vacuo* and the product was then recrystallized from CH_2Cl_2/pentane (0.435 g, 82%). Found: C, 72.6; H, 5.2. Calc. for $C_{34}H_{28}O_4P_2$: C, 72.6; H, 5.0%. IR (KBr): 1672 vs [ν(C=O)], 1176 vs [ν(P=O)] cm^{-1}. ^1H NMR ($CDCl_3$): δ 4.30 [d, 4H, PCH_2, $^2J(PH) = 15$ Hz], 7.47–9.21 (24 H, aromatic H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 27.2 (s).

Preparation of 3,5-(*diphenylphosphinoacetyl*) *anisole* (L^{OMe})

This compound was prepared using a similar procedure to that described for LH_2 but starting from 3,5-diacetylanisole (0.640 g, 3.33 mmol). The product was chromatographed on Kieselgel (Kieselgel 60, Merck, 100 g) using a mixture of AcOEt/*n*-hexane (25:75 v/v) as eluent ($R_f = 0.45$ with AcOEt/*n*-hexane, 20:80 v/v) (0.300 g, 16%). Found: C, 74.8; H, 5.7. Calc. for $C_{35}H_{30}O_3P_2$: C, 75.0; H, 5.4%. MS (negative ion chemical ionization) $M_r = 560.579$: 592 (6%, M+2O), 576 (34%, M+O), 560 (100%, M). (The peaks due to oxidation of the phosphine could not be avoided.) IR (KBr); 1676 vs [ν(C=O)] cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.77 [s, 4H, PCH_2, $^2J(PH) = 0$ Hz], 3.83 (s, 3H, Me), 7.30–7.49 (20H, aromatic H), 7.61 [d, 2H, H(2) and H(6) of anisole ring, $^4J = 1.5$ Hz], 8.05 [t, 1H, H(4) of anisole ring, $^4J = 1.5$ Hz]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 15.8 (s). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 40.77 [d, PCH_2, $^1J(PC) = 22$ Hz], 55.63 (s, Me), 117.88–160.01 (aromatic C), 196.27 [d, C=O, $^3J(PC) = 8$ Hz].

Preparation of $[\{(o\text{-}C_6H_4CH_2NMe_2)Pd(\mu\text{-}Cl)\}_2(\mu\text{-}LH_2)]$ (**1**)

To a solution of $[\{(o\text{-}C_6H_4CH_2NMe_2)Pd(\mu\text{-}Cl)\}_2]$ (0.182 g, 0.33 mmol) in CH_2Cl_2 (10 cm^3) was added a solution of LH_2 (0.175 g, 0.33 mmol) in CH_2Cl_2 (10 mmol). After 5 min stirring, the solution was concentrated to *ca* 10 cm^3 and the product was precipitated with pentane as a white powder, which was recrystallized from CH_2Cl_2/pentane (0.304 g, 85%). Found: C, 57.8; H, 4.9; N, 2.5. Calc. for $C_{52}H_{52}Cl_2N_2O_2P_2Pd_2$: C, 57.7; H, 4.8; N, 2.6%. IR (KBr): 1675 vs [ν(C=O)] cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.75 [d, 12H, NMe_2, $^4J(PH) = 2.5$ Hz], 4.02 [d, 4H, NCH_2, $^4J(PH) < 1$ Hz], 4.55 [d, 4H, PCH_2, $^2J(PH) = 11$ Hz], 6.28–8.29 (32H, aromatic H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 29.9 (s).

Preparation of $[\{(o\text{-}C_6H_4CH_2NMe_2)Pd\}_2(\mu\text{-}L)]$ **(2)**

A solution of complex **1** (0.190 g, 0.18 mmol) in THF (20 cm^3) was stirred with NaH (0.010 g, 0.40 mmol) for 72 h. The solution was evaporated to dryness. Toluene was added and the resulting suspension was filtered through a frit. Addition of pentane to the filtered solution gave **2** as a white powder (0.169 g, 93%). Found: C, 61.6; H, 4.9; N, 2.8. Calc. for $C_{52}H_{50}N_2O_2P_2Pd_2$: C, 61.9; H, 5.0; N, 2.8%. IR (KBr): 1507 vs and 1494 vs [ν(C—O)+ν(C=C)] cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.95 [d, 12H, NMe_2, $^4J(PH) = 2$ Hz], 4.00 [d, NCH_2, $^4J(PH) = 1.5$ Hz], 4.94 [d, 2H, PCH, $^2J(PH) = 2.5$ Hz], 6.69–8.39 (22H, aromatic H). $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 32.1 (s).

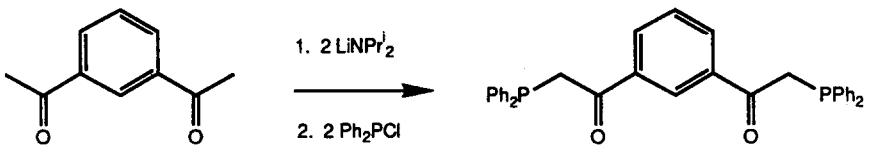
Reaction of LH_2 *with* $Pd(acac)_2$

A solution of LH_2 (0.570 g, 0.93 mmol) in THF (1000 cm^3) was added dropwise to a vigorously stirred solution of $Pd(acac)_2$ (0.283 g, 0.93 mmol) in THF (200 cm^3). The solution instantly turned yellow–green and when *ca* 50% of LH_2 had been added, the solution became turbid. After 1 h stirring, the solution was concentrated to half and filtered through a glass frit. The precipitate was washed several times with Et_2O (0.650 g). The material is only sparingly soluble in THF, CH_2Cl_2 or $CHCl_3$. Found: C, 63.2; H, 4.3. Calc. for $C_{34}H_{26}O_2P_2Pd$: C, 64.3; H, 4.1%. IR (KBr): 1516 vs br and 1509 sh [ν(C—O)+ν(C=C)] cm^{-1}. ^1H NMR ($CDCl_3$): this spectrum was of poor quality because of the low solubility of the compound; a broad signal at δ 4.68 ppm unambiguously reveals the presence of PCH enolate protons. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 37.4 (s).

RESULTS AND DISCUSSION

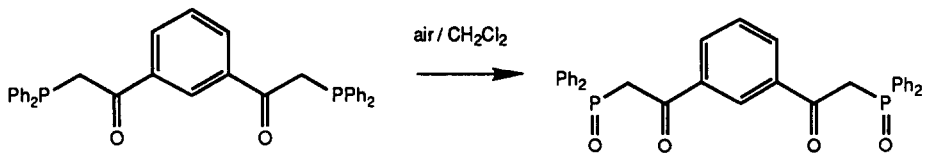
The diphosphine LH_2 was prepared according to the reaction sequence shown in eq. (1), by using THF as solvent. After purification by column chromatography, LH_2 was obtained as a white powder in *ca* 85% yield (see Experimental). Its $^{31}P\{^1H\}$ NMR (toluene/C_6D_6) spectrum displays a single peak at −16.0 pm, a value typical for β-ketophosphines of the type $Ph_2PCH_2C(O)R$.[6] The ketone functions are characterized by (a) a strong absorption band at 1672 cm^{-1} in the IR spectrum and (b) the presence in the $^{13}C\{^1H\}$ NMR spectrum of a doublet at 196.30 ppm [$^2J(PC) = 8$ Hz]. Other characterizing data are given in the Experimental and Table 1. Reaction of air with a dichloromethane solution of LH_2 gave complete conversion into the corresponding bis(phosphine oxide), LH_2O_2 [eq. (2)], after 48 h.

The IR spectrum of LH_2O_2 in KBr shows a typical ν(P=O) absorption band at 1176 cm^{-1}. The ν(C=O) vibration appears at 1672 cm^{-1}, as for the starting compound. We note also that the PCH_2 groups appear as a doublet [$^2J(PH) = 15$ Hz] at 4.30 ppm in the ^1H NMR ($CDCl_3$) spectrum, whereas for LH_2 they appear as a singlet [$^2J(PH) = 0$ Hz] at 3.78 ppm. The spectroscopic data of both ligands clearly indicate that no enol form is present.



(1)

LH_2



(2)

LH_2 **LH_2O_2**

Another binucleating diphosphine, L_{OMe}, was also prepared according to the procedure used for LH_2 (see Experimental). The spectroscopic data concerning the phosphinoacetyl fragment of this ligand are very similar to those of LH_2 (Table 1 and Experimental) and will not be discussed further.

The ligand LH_2 reacts with the palladium dimer $[(o\text{-}C_6H_4CH_2NMe_2)PdCl]_2$ to yield the binuclear

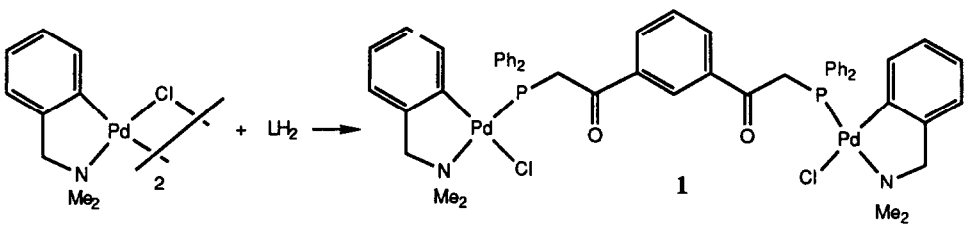
Table 1. Important spectroscopic data for LH_2, LH_2O_2, $L^{OMe}H_2$, **1** and **2**

Compound	^1H NMR, ppm ($CDCl_3$) δ PCH_2 or PCH [^2J(PH), Hz]	$^{31}P\{^1H\}$ NMR, ppm[a]	ν(C=O), cm^{-1} (KBr)
LH_2	3.80 [0]	−16.0	1672
LH_2O_2	4.30 [15]	27.2	1672
$L^{OMe}H_2$	3.77 [0]	−15.8	1676
1	4.55 [11]	29.9	1675
2	4.94 [2.5]	32.1	1507, 1494

[a] Solvent: $CDCl_3$ except for LH_2, toluene/C_6D_6.

complex **1**, in which the phosphine acts as a bridge between the two palladium atoms [eq. (3)]. Spectroscopic data characteristic of this formulation include the presence of a single ^{31}P NMR signal (29.9 ppm) and a strong ν(C=O) absorption band at 1675 cm^{-1} in the IR spectrum.

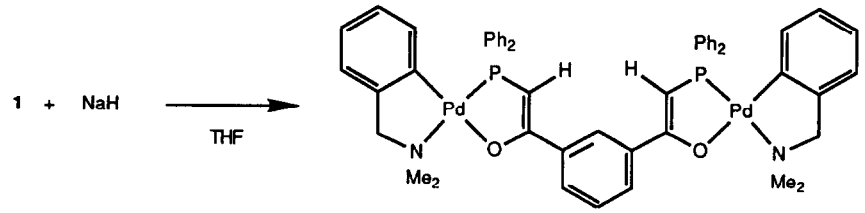
When LH_2 was reacted with one equiv. of Pd $(acac)_2$ in THF a sparingly soluble, yellow–green material was obtained (see Experimental). Its IR (KBr) spectrum shows the presence of a strong absorption band at 1516 cm^{-1}, unambiguously showing that the ligand LH_2 has been deprotonated



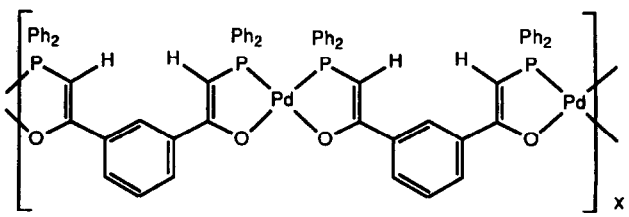
(3)

Treatment of complex **1** with NaH for 72 h quantitatively leads to the bis(enolato) complex **2** [eq. (4)]. The formation of enolato ligands from the two ketone functions is unambiguously demonstrated by the appearance of strong absorption bands at 1507 and 1494 cm^{-1} in the IR spectrum which may be assigned to the ν(C=C)+ν(C—O) vibration.[7] The NMR spectrum of **2** displays a doublet [^2J(PH) = 2.5 Hz] for the PCH protons at 4.94 ppm.

to give the enolato form L. This is also confirmed by the presence of a broad signal at 4.68 ppm (vs 4.94 pm for **2**) in the ^1H NMR spectrum. The $^{31}P\{^1H\}$ NMR ($CDCl_3$) spectrum displays a single peak at 37.4 ppm. This chemical shift, when compared with that found for the complex *cis*-[$\{Ph_2PCH{=}C(O)Ph\}_2Pd$] (37.7 ppm[8]) indicates that each palladium centre is bonded to two phosphorus atoms occupying *cis* positions.



(4)



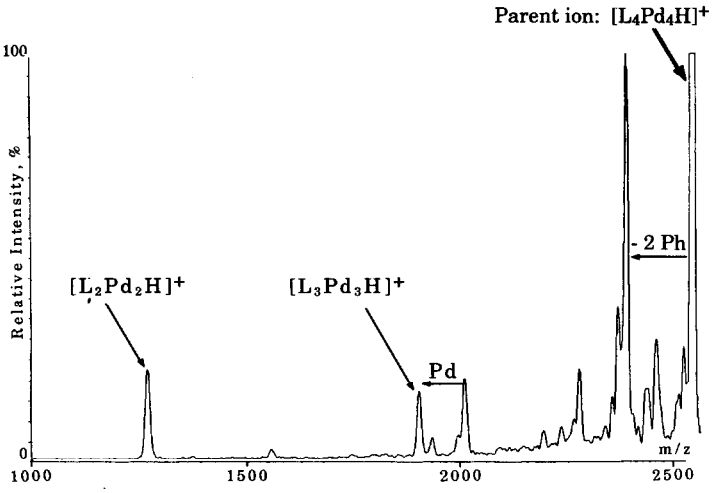


Fig. 1. Mass analysed ion kinetic energy spectrum (MIKES) of the ion at $m/z = 2541 \pm 3$ in the FAB spectrum of the crude reaction mixture. The main fragments observed confirm the tetrameric structure of ion 2541. Dimeric and trimeric species are formed from the parent ion ($[Pd_2L_2H]^+$ at $m/z = 1271$ and $[Pd_3L_3H]^+$ at $m/z = 1905$). The ion at $m/z = 2011$ corresponds to a trimeric species with four palladium atoms and probable loss of a proton to yield a singly-charged ion. The parent ion loses two phenyl groups and yields the ion at $m/z = 2388$.

The FAB–MS spectrum at 1000 resolution of the crude product displays an intense ion at $m/z = 2541.5$ corresponding to a protonated molecular ion $[(PdL)_4H]^+$ (expected value, 2540.8). Two other intense ions appear at $m/z = 1905.9$ and 1270.9 which indicate, respectively, the presence of the fragments $[(PdL)_2H]^+$ (expected value, 1270.9) and $[(PdL)_3H]^+$ (expected value, 1905.7) possibly generated from the ion at $m/z = 2541.5$. The ions at 1905.9 could also partially correspond to a trimeric complex, $(PdL)_3$, present in the crude reaction product. No ion was detected at $m/z = 3175.8$, which would correspond to a pentameric complex, $(PdL)_5$. To confirm that the ion at $m/z = 2541.5$ corresponds to a tetrametallic complex of formula $(PdL)_4$, a MIKES analysis of this ion was performed. In this technique, the molecular isotopical cluster at $m/z = 2541 \pm 3$ was selected using the first sector of the mass spectrometer and its decomposition ions measured with the second sector. This experiment clearly showed (Fig. 1) fragmentation of the selected ion into $(PdL)_3$ ($m/z = 1905$) and $(PdL)_2$ ($m/z = 1271$).

Due to the low solubility product which excludes a detailed NMR study, the question of whether the polymeric material obtained contains only the tetramer $(PdL)_4$ or a mixture of assemblies of formula $(PdL)_n$ cannot be answered at the present time. We are currently investigating this question.

In conclusion, the binucleating ligand LH_2 is conveniently obtained as a P—C coupling product by reacting the bis-enolate, $1,3\text{-}LiCH_2C(O)(C_6H_4)C(O)CH_2Li$, with Ph_2PCl. This ligand allows the synthesis of binuclear complexes containing either a bridging LH_2 moiety or the binucleating L_2 double chelate. The design of this new ligand appears to be of particular interest for the synthesis of new, oligomeric, organometallic materials.

Acknowledgements—We are grateful to Professor M. Leroy, EHICS-Strasbourg, for providing us with facilities to carry out this work and to R. Huber (Service de Spectrométrie de Masse, Université Louis Pasteur) for measuring the mass spectra.

(*Received* 23 *April* 1990; *accepted* 28 *February* 1991)

Abstract—The complexes of cyclo-tri-, cyclo-tetra- and cyclo-hexaphosphate with aluminium in solution were studied using ^{31}P and ^{27}Al NMR spectrometry. For the 1 : 1 Al^{3+}–$P_3O_9^{3-}$ complex, only a four-membered bidentate binding complex was found. For the 1 : 1 Al^{3+}–$P_4O_{12}^{4-}$ complex, on the other hand, three kinds of the complex isomers (four-membered, six-membered and eight-membered bidentate binding) were found. For the 1 : 1 Al^{3+}–$P_6P_{18}^{6-}$ complex, four kinds of isomers (four-membered bidentate, six-membered bidentate, 10-membered bidentate and eight-membered tridentate binding) were found. The discovery of new binding isomers is based on the assignment of the ^{31}P or ^{27}Al NMR resonances observed as separate peaks despite the existence of a complexation equilibrium. Furthermore, the stability constants or micro-stability constants and the isomerization constants for the 1 : 1 complexes were evaluated: $K^1_{free} = 1.1 \times 10^3$ for the cyclo-triphosphate complex; $K^1_{free} = 3.3 \times 10^4$, $K^{1-2}_1 = 0.29$ and $K^{1-3}_{1-2} = 6.7$ for cyclo-tetraphosphate complexes; and $K^{1-2}_1 = 8.4$, $K^{1-4}_{1-2} = 0.91$ and $K^{1-3-5}_{1-4} = 0.62$ for cyclo-hexaphosphate complexes, at an ionic strength of 0.1 and 20°C.

Although a large number of papers concerning the equilibrium analysis on metal complexes of cyclo-polyphosphate anions and the hydrolysis of cyclo-polyphosphate has been published,[1–7] an investigation on their binding structure in solution has not so far been reported. Since a cyclo-polyphosphate anion has a large number of donor oxygen atoms, it can coordinate to a metal ion by a variety of binding modes to form various isomers in equilibrium simultaneously. In the conventional equilibrium study only compositional information was given, but the structure of the complexes and the equilibrium distribution of the binding isomers were not given.

Very recently we found the co-existence of two binding modes for chromium–phosphinate complexes and for aluminium–monomeric phosphate complexes in solution by ^{31}P NMR and Raman spectroscopies.[8,9] One of these was a non-chelating mode in which the ligand coordinates to a metal ion with a single oxygen atom and the other was a four-membered chelating mode in which the ligand coordinates with two oxygen atoms.

In this work a distinction between various binding isomers and a quantitative analysis on the equilibrium distribution of these binding isomers in aluminium–cyclo-triphosphate, –cyclo-tetraphosphate and –cyclo-hexaphosphate complex systems were attempted by using ^{31}P and ^{27}Al NMR spectroscopy. The NMR method seemed the most powerful for these purposes, since the aluminium–

* Author to whom correspondence should be addressed.

phosphorus oxoanion complexes are moderately inert and the NMR resonances were observed as separate peaks for each complex in equilibrium.

EXPERIMENTAL

Reagents

The sodium salts of cyclo-triphosphate, $Na_3P_3O_9 \cdot 6H_2O$, cyclo-tetraphosphate, $Na_4P_4O_{12} \cdot 4H_2O$, and cyclo-hexaphosphate, $Na_6P_6O_{18} \cdot 6H_2O$, were prepared by the procedure described in previous papers.[9-11] Aluminium nitrate and other chemicals were of commercially available reagent grade. The acidity of the aluminium nitrate stock solution was maintained at 0.1 M with nitric acid to avoid hydroxo complex formation.

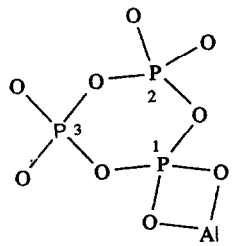
NMR measurement

The sample solutions were adjusted to an ionic strength of 0.1 with $N(CH_3)_4Cl$ and to pH 3 with nitric acid or sodium hydroxide. The NMR spectra were recorded on a FT JEOL spectrometer JNM-GX400 operating at 161.86 MHz for ^{31}P NMR and at 104.4 MHz for ^{27}Al NMR, respectively, at 20°C using a 10 mm i.d. spinning sample tube. The chemical shift was referenced to an external standard of 85% H_3PO_4 for the ^{31}P NMR spectrum and a solution containing 1 M hydrochloric acid for the ^{27}Al NMR spectrum, a positive shift being downfield. The peak area ratio of the complex species and free ligand or free aluminium in the spectrum was determined by measuring the paper weight proportional to each resonance area recorded. When necessary, a Lorentzian curve-fitting computer analysis was employed to resolve the resonance overlapping.

RESULTS AND DISCUSSION

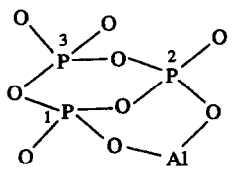
^{31}P *and* ^{27}Al *NMR study of the aluminium–cyclo-triphosphate complex system*

The ^{31}P and ^{27}Al NMR spectra of a series of solutions containing equimolar $Al(NO_3)_3$ and $Na_3P_3O_9$ were measured (Fig. 1). In the ^{31}P NMR spectrum, resonance a_P was due to the free cyclo-triphosphate anion, whereas resonances b_P, c_P, d_P and e_P could be assigned to the aluminium complexes. In the ^{27}Al NMR spectrum, resonance a_{Al} was due to the free Al^{3+} ion and resonances b_{Al} and c_{Al} could be assigned to the complexes. The b_P and c_P resonances in ^{31}P and b_{Al} in ^{27}Al NMR were assigned to a 1 : 1 complex, AlP_3O_9, since they were observed in a sufficiently low concentration range. The presence of two resonances in the ^{31}P NMR spectrum of this complex indicates that the phosphate group exists in two different states in the molecule, one being coordinated and the other uncoordinated. The c_P resonance with a large, upfield coordination shift from the resonance of the free ligand (−10.5 ppm) can be assigned to the aluminium-coordinating phosphate group, while b_P, which has a very small upfield coordination shift (−0.8 ppm), may be assigned to the uncoordinated group in the complex. The b_P resonance is a doublet and its peak area is always twice that of c_P, and b_{Al} is a doublet split by the phosphorus atom of the coordinated phosphate group. Therefore the 1 : 1 aluminium–cyclo-triphosphate complex should exist as structure **I** from the three forms indicated below.



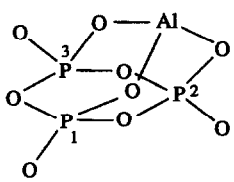
AlP_3O_9 (1)

(I)



AlP_3O_9 (1–2)

(II)



AlP_3O_9 (1–2–3)

(III)

The presence of a single oxygen-binding form in the single phosphate group-binding complex (structure **I**) could also not be denied, as has been previously found in the monomeric phosphate complexes of chromium or aluminium.[8,9] However, the difference in the chemical shifts between the non-chelating and chelating forms may become too small for the polyphosphate complexes to give separate peaks due to perturbation by other uncoordinated phosphate groups in the complex. Therefore, the predominance of the chelate form can be expected, as explained for the monomeric ligand complexes.[9]

The d_P, e_P and c_{Al} resonances can be assigned to a 1 : 2 complex, $Al(P_3O_9)_2^{3-}$, existing as structure **IV** due to the fact that c_{Al} is a triplet and the inten-

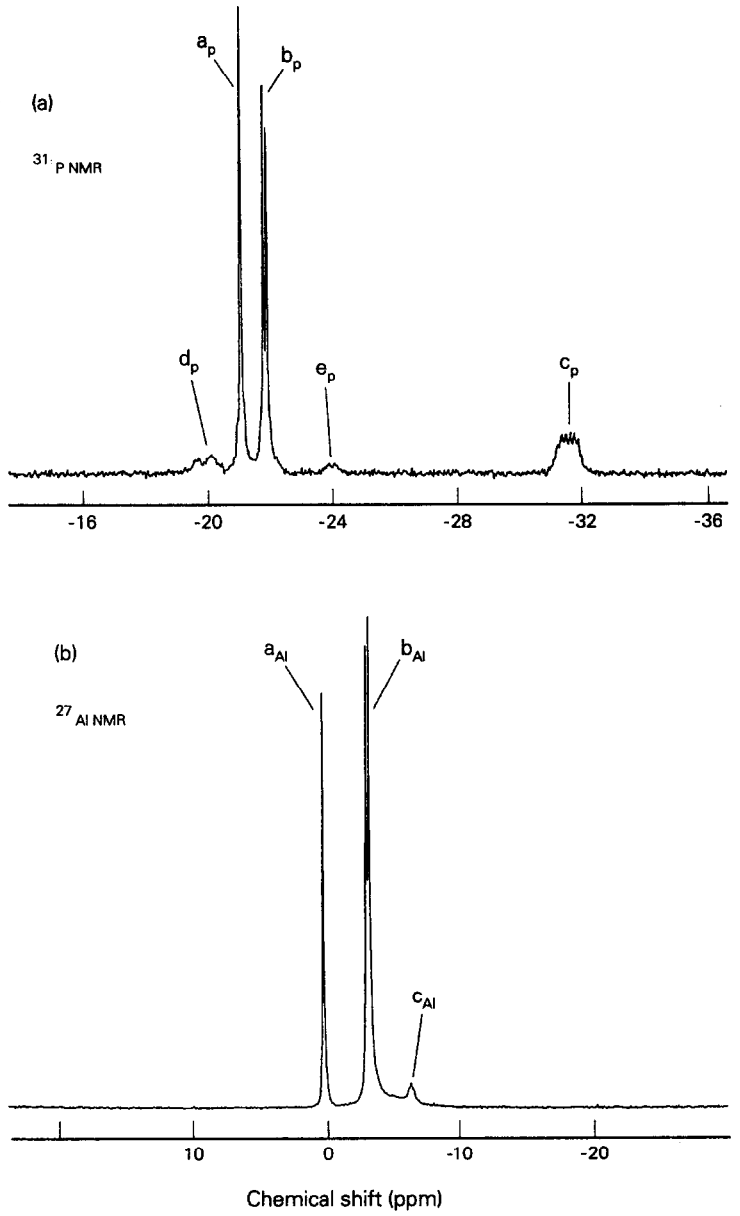


Fig. 1. ^{31}P and ^{27}Al NMR spectra of the solution containing equimolar 2.5×10^{-2} M $Al(NO_3)_3$ and $Na_3P_3O_9$ at pH 3 and 20°C.

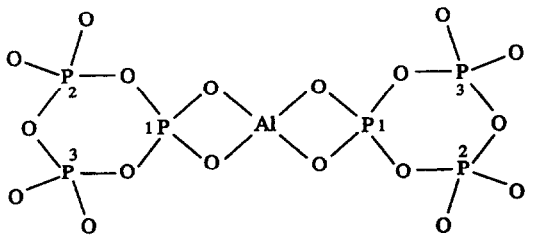
sities of these signals increase with increasing ligand concentration, and that the intensity ratio of d_P/e_P remains constant. On the other hand, the 2 : 1 aluminium–cyclo-triphosphate complexes were not detected even in the solution containing excess aluminium ion.



$Al(P_3O_9)_2^{3-}$ (1,1)

(IV)

^{31}P *and* ^{27}Al *NMR study of the aluminium–cyclo-tetraphosphate complex system*

Figure 2 shows examples of ^{31}P and ^{27}Al NMR spectra of the solution containing equimolar $Al(NO_3)_3$ and $Na_4P_4O_{12}$. In the ^{31}P NMR spectrum [Fig. 2(a)], resonance a_P is due to the free cyclo-tetraphosphate ion and the other resonances are

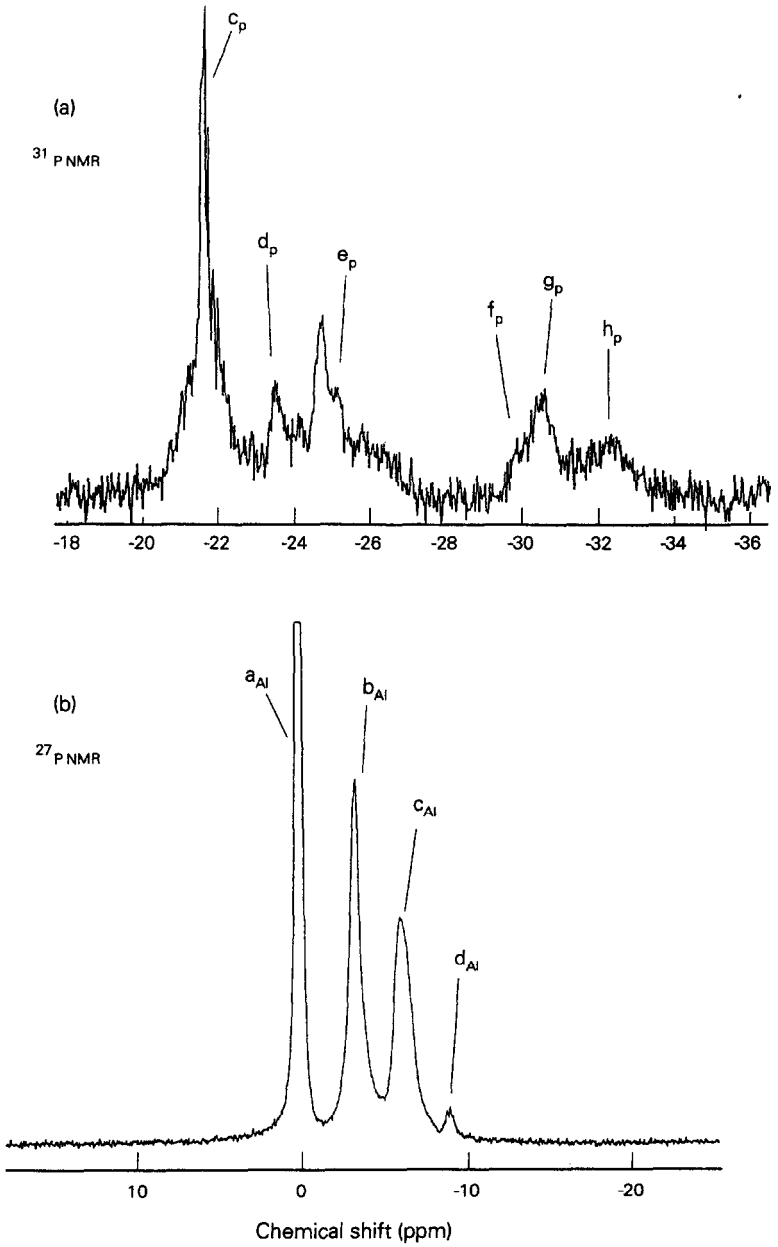


Fig. 2. ^{31}P and ^{27}Al NMR spectra of the solution containing equimolar 4×10^{-3} M $Al(NO_3)_3$ and $Na_4P_4O_{12}$ at pH 3 and 20°C.

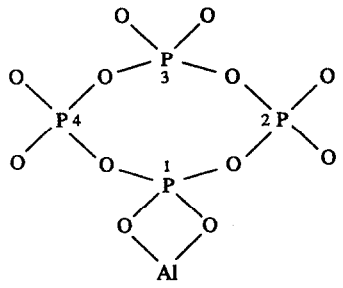
due to the aluminium complexes. As the peak area ratio for these complexes did not vary in the lower concentration range, they may be assigned to the 1 : 1 complexes. Resonances g_P, f_P and e_P with large upfield coordination shifts (−6.7, −5.1 and −4.5 ppm) may be assigned to the coordinated phosphate groups, and resonances b_P, c_P and d_P with small coordination shifts (+0.1, −1.3 and −2.0 ppm) may be assigned to the uncoordinated phosphate groups in the complexes, due to the reasons described above. Therefore, there should be at least three types of coordinated phosphate group and three types of uncoordinated phosphate group for the 1 : 1 complexes.

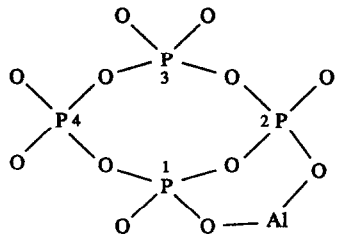
The binding isomers, **V**, **VI** and **VII**, are expected to exist in the Al^{3+}–$P_4O_{12}^{4-}$ complex system, which is different to the Al^{3+}–$P_3O_9^{3-}$ complex system where only the one 1 : 1 complex **I** was formed because of the larger ring size and the presence of more oxygen atoms in the $P_4O_{12}^{4-}$ anion. Cyclotetraphosphate anions coordinate to the aluminium ion by one phosphate group to form four-membered, bidentate binding in complex **V**, and by two phosphate groups to form six-membered

bidentate binding (**VI**) or eight-membered bidentate binding (**VII**).



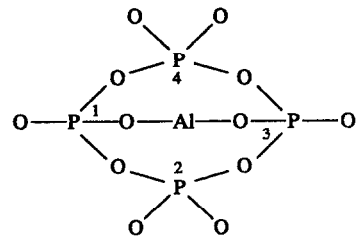
$AlP_4O_{12}^-$ (1)

(V)



$AlP_4O_{12}^-$ (1–2)

(VI)



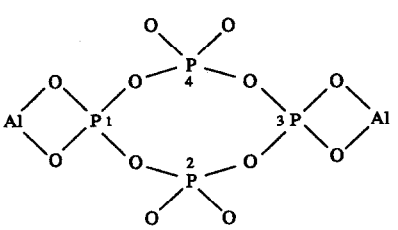
$AlP_4O_{12}^-$ (1–3)

(VII)

It can be considered that a stronger interaction between the phosphate group and aluminium ion should, in general, cause a greater ^{31}P NMR coordination shift. Thus the shift of the coordinated phosphate group may increase with a decrease in the number of phosphate groups coordinating to the aluminium ion, and the shift of the uncoordinated phosphate group decreases with an increase in the distance from the metal ion. The largest upfield shift, g_P, and the smallest shift, b_P, may be assigned to P(1) and P(3) of complex **V**, respectively. Resonance c_P (doublet) may be assigned to P(3) and P(4) of complex **VI**, and resonance e_P, which has the same area as c_P, may be assigned to P(1) and P(2) of complex **VI**. Resonance d_P may be due to overlapping peaks of P(2) and P(4) of complex **VII** with P(2) and P(4) of complex **V**. Therefore, it was concluded that there are three binding isomers for the $AlP_4O_{12}^-$ complex.

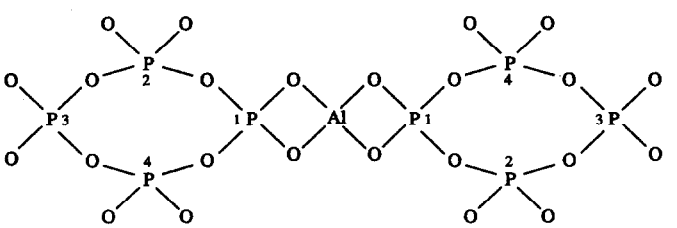
In the ^{27}Al NMR spectrum [Fig. 2(b)], resonance a_{Al} is due to the free Al^{3+} ion and resonances b_{Al} and c_{Al} are due to the 1 : 1 complexes. It is expected that the more phosphate groups coordinating to an aluminium ion the larger the shift from the free aluminium ion in the ^{27}Al NMR spectrum. Thus resonance b_{Al} can be assigned to complex **V** and c_{Al} to complexes **VI** and **VII**. Since the chemical shift difference between complexes **V**, **VI** and **VII** is considered to be small, the resonances for the complexes undergo considerable overlapping.

It was observed that the intensities of resonances a_P and b_P decreased and a new resonance with a coordination shift of −11.5 ppm appeared with an increase in the $Al(NO_3)_3$ concentration, when the concentration ratio of $Al(NO_3)_3$ to $Na_4P_4O_{12}$ was larger than unity, reflecting the formation of a 2 : 1 complex. This complex is presumably of structure **VIII** on consideration of the strong repulsion between the two aluminium ions bound to the $P_4O_{12}^{4-}$ anion and the low relative formation of six-membered bidentate binding in the 1 : 1 complex. When cyclo-tetraphosphate is in excess, a new resonance, d_{Al}, with a coordination shift of −6.8 ppm, which is almost the same as that of the $Al(P_3O_9)_2^{3-}$ complex (**IV**), was observed in the ^{27}Al NMR spectrum (Fig. 3). This may be assigned to the 1 : 2 complex (**IX**).



$Al_2P_4O_{12}^{2+}$ (1,3)

(VIII)



$Al(P_4O_{12})^{5-}$ (1,1)

(IX)

^{31}P *and* ^{27}Al *NMR study of the aluminium–cyclohexaphosphate complex system*

In this system more isomers can be expected. The ^{31}P and ^{27}Al NMR spectra are shown in Fig. 4. Three resonances were observed for the 1 : 1 complexes in the ^{27}Al NMR spectrum [Fig. 4(b)]. On

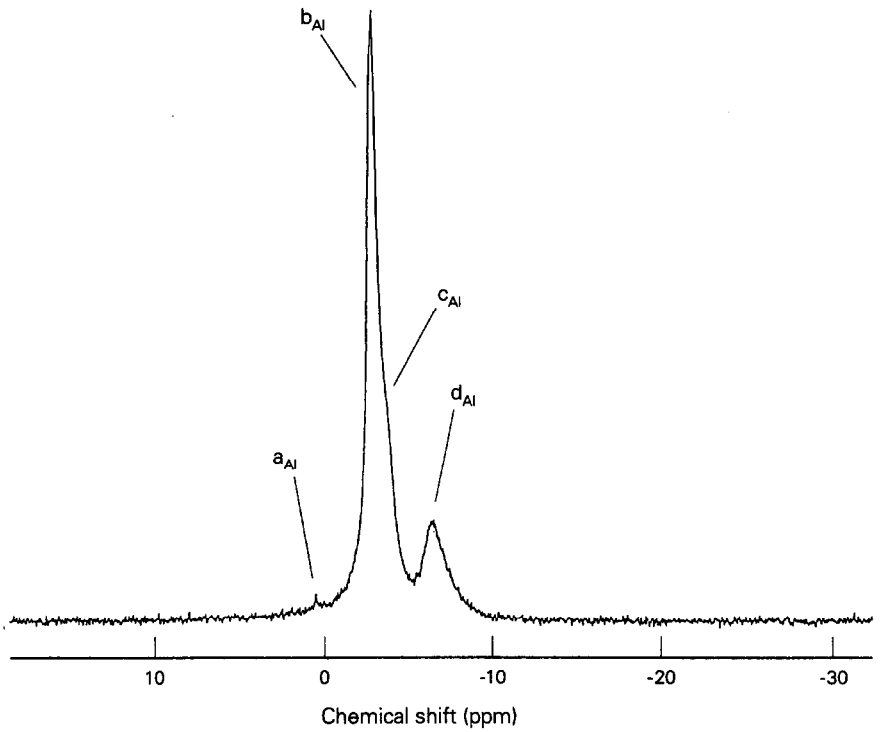


Fig. 3. ^{27}Al NMR spectrum of the solution containing 4×10^{-3} M $Al(NO_3)_3$ and 8×10^{-3} M $Na_4P_4O_{12}$ at pH 3 and 20°C.

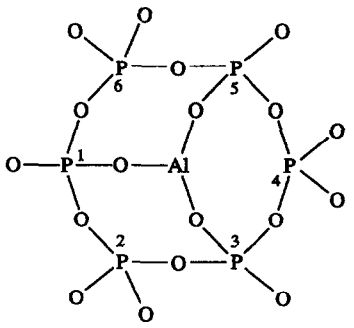
the basis of the coordination shift of the resonance and the splitting pattern observed, b_{Al}, c_{Al} and quartet d_{Al} may correspond to a single-phosphate group coordinated isomer, a two-phosphate groups coordinated isomer and a three-phosphate groups coordinated isomer, respectively.

More detailed information can be obtained from the ^{31}P NMR spectrum [Fig. 4(a)]. Resonance a_P is due to the free anion and all the other resonances are due to the 1 : 1 complexes. Similar to the cyclotetraphosphate complex system, e_P, f_P and g_P resonances with large upfield coordination shifts (−4.6, −10.2 and −10.5 ppm from the unprotonated free anion) can be assigned to the coordinated phosphate groups, and b_P, c_P and d_P resonances with smaller upfield coordination shifts (−1.0, −2.0 and −3.5 ppm) can be assigned to non-coordinated phosphate groups. On the basis of the coordination shift and resonance area ratio, d_P and e_P of equal area can be assigned to non-coordinated and coordinated phosphate groups of complex **X**, respectively, in which the $P_6O_{18}^{6-}$ anion coordinates to the aluminium ion via three phosphate groups to form eight-membered tridentate rings. This assignment can be supported by the agreement of concentration of complex **X**, calculated from the areas of ^{31}P NMR resonances d_P or e_P, with that from the area of ^{27}Al NMR resonance d_{Al}. Resonances f_P and g_P can be assigned to the coordinated phosphate groups in the isomers containing 10-membered bidentate binding (**XI**) and six-membered bidentate binding (**XII**), respectively. Since the concentration of the single-phosphate group coordinated isomer (**XIII**) was very low [see ^{27}Al NMR resonance b_{Al} in Fig. 4(b)], the ^{31}P NMR resonance corresponding to this type of binding was not observed under these conditions. Although b_P and c_P can be assigned to the non-coordinated phosphate groups of complexes **XI**, **XII** and **III**, a further detailed assignment is difficult at present.

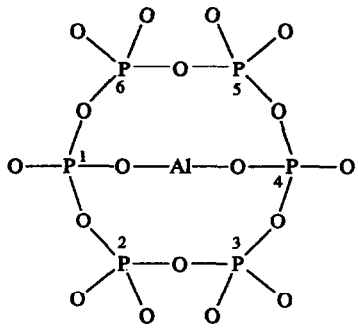
^{31}P and ^{27}Al NMR spectra of the solution containing $Na_6P_6O_{18}$ and excess $Al(NO_3)_3$ are shown in Fig. 5. The relative intensity of b_{Al} was larger and that of d_{Al} was smaller than those for the equimolar solution. This indicates the formation of 2 : 1 complexes. Using the isomerization constant values of the 1 : 1 complexes (given in Table 3) and the intensity of d_{Al} for the 1 : 1 complex **X**, it was calculated that 17% of c_{Al} is due to the 1 : 1 complexes **XI** and **XII**, and the remaining 83% to the 2 : 1 complexes. The b_{Al} resonance was due mainly to the 2 : 1 complexes.

Two resonances observed for the 2 : 1 complexes in the ^{27}Al NMR spectrum suggest that there are



$AlP_6O_{18}^{3-}$ (1–3–5)

(X)



$AlP_6O_{18}^{3-}$ (1–4)

two binding modes in the complex. In one of the modes, the aluminium ion binds to one phosphate group which has a resonance with a coordination shift of −3.5 ppm (b_{Al}), and in the other mode, the aluminium ion binds to two phosphate groups which has a resonance with a coordination shift of −6.2 ppm (c_{Al}), each value being the same as that for the 1 : 1 complex with the corresponding binding mode. On account of the repulsion between the two positively-charged aluminium ions bound to a $P_6O_{18}^{6-}$ anion, they should be located at the greatest distance from each other. Accordingly, the coordination reactions forming eight- or 10-membered rings may not be predominant. The three isomers are, therefore, possible for the 2 : 1 complexes.

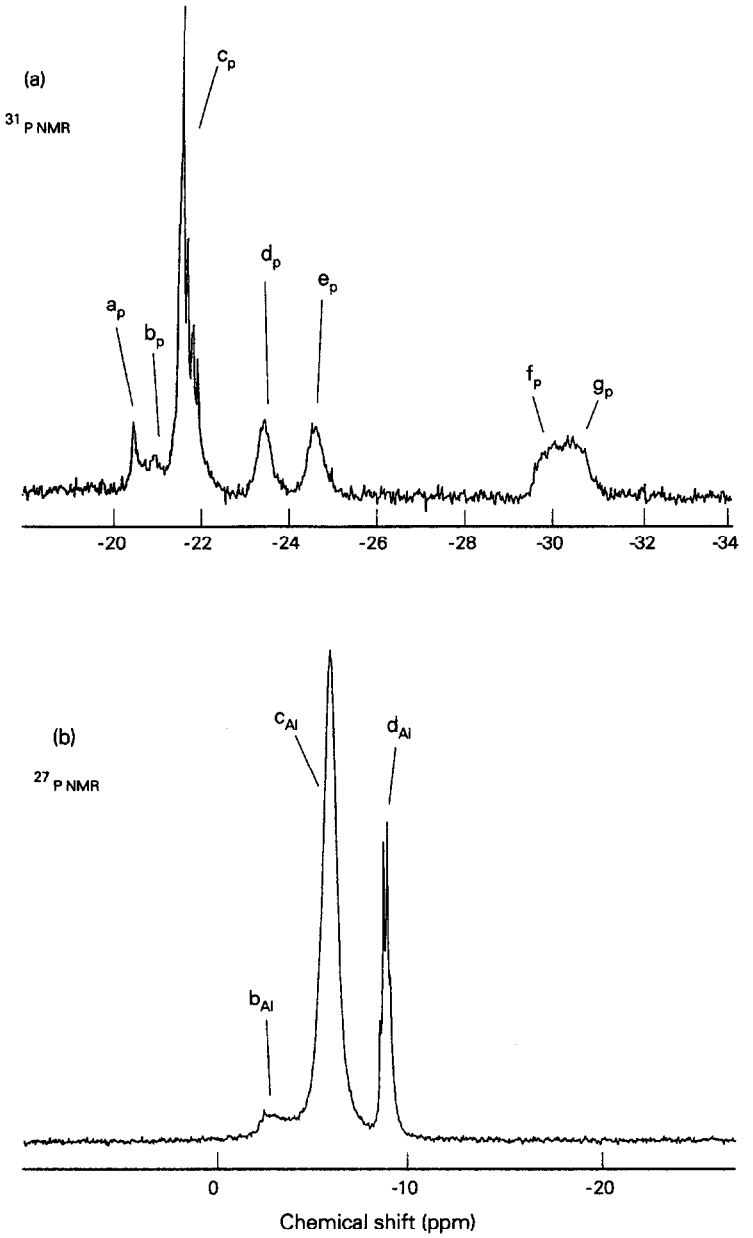

Fig. 4. ^{31}P and ^{27}Al NMR spectra of the solution containing equimolar 4×10^{-3} M $Al(NO_3)_3$ and $Na_6P_6O_{18}$ at pH 3 and 20°C.

Similar conclusions can also be drawn from the ^{31}P NMR investigation. It was observed that resonances a_P, b_P, c_P and f_P decreased, resonance g_P increased and a new resonance h_P appeared with the highest shift in the ^{31}P NMR spectrum of the solution containing excess $Al(NO_3)_3$ (Fig. 5). The h_P resonance can be assigned to P(1) and P(4) of the 2 : 1 complex **XIV** and to P(1) of complex **XVI**; g_P is an overlapping peak consisting of resonances of P(1), P(2), P(4) and P(5) of the 2 : 1 complex **XV** and P(3) and P(4) of complex **XVI** with P(1) and P(2) of the 1 : 1 complex (**XII**). The decrease of f_P due to P(1) and P(4) of complex **XI** indicates that 10-membered bidentate binding does not occur in the 2 : 1 complexes.

Trends in NMR chemical shifts of aluminium–cyclophosphate complexes

The coordination shift data of ^{27}Al and ^{31}P NMR for Al^{3+}–$P_3O_9^{3-}$, –$P_4O_{12}^{4-}$ and –$P_6O_{18}^{6-}$ com-

plexes are summarized in Tables 1 and 2. It was found that the coordination shift in ^{27}Al NMR depends almost only on the numbers of phosphate groups directly coordinating to an aluminium ion, the shift value increasing with number (Table 1). On the other hand, the coordination shift in ^{31}P NMR for the coordinating phosphate group depends not only on the number of phosphate groups coordinated directly, but also on the binding mode and the ligand structure (Table 2).

Table 1. ^{27}Al NMR coordination shifts (ppm)

	Number of coordinated phosphate groups on the aluminium ion					
	1		2			3

Isomerization constants for the aluminium–cyclophosphate complexes

In order to obtain more quantitative information on the distribution of these new binding isomers, we evaluated the isomerization constants and micro-stability constants for some of these one-to-one complexes, which are defined by the following equations:

$$K^{1}_{free} = \frac{[AlP_3O_9(1)]}{[P_3O_9^{3-}][Al^{3+}]} \quad (1)$$

$$\frac{[AlP_4O_{12}^{-}(1)]}{[P_4O_{12}^{4-}][Al^{3+}]} \quad (2)$$

$$\frac{[AlP_6O_{18}^{3-}(1)]}{[P_6O_{18}^{6-}][Al^{3+}]} \quad (3)$$

$$K^{1-2}_{1} = \frac{[AlP_4O_{12}^{-}(1\text{–}2)]}{[AlP_4O_{12}^{-}(1)]} \quad (4)$$

$$\frac{[AlP_6O_{18}^{3-}(1\text{–}2)]}{[AlP_6O_{18}^{3-}(1)]} \quad (5)$$

$$K^{1-3}_{1-2} = \frac{[AlP_4O_{12}^{-}(1\text{–}3)]}{[AlP_4O_{12}^{-}(1\text{–}2)]} \quad (6)$$

$$K^{1-4}_{1-2} = \frac{[AlP_6O_{18}^{3-}(1\text{–}4)]}{[AlP_6O_{18}^{3-}(1\text{–}2)]} \quad (7)$$

$$K^{1-3-5}_{1-4} = \frac{[AlP_6O_{18}^{3-}(1\text{–}3\text{–}5)]}{[AlP_6O_{18}^{3-}(1\text{–}4)]}. \quad (8)$$

Equations (1)–(3) represent micro-stability constants for the single-phosphate group coordinating complexes, eqs (4) and (5) give intramolecular isomerization constants between the two-phosphate groups coordinating and single-phosphate group coordinating complexes, eqs (6) and (7) give isomerization constants between different two-phosphate groups coordinating complexes, and eq. (8) represents an isomerization constant between the three- and the two-phosphate groups coordinating complexes. If these constants are all determined, the whole distribution of the isomeric complex species may become clear.

The concentrations of the complexes, free ligand and free aluminium ion were estimated from respective peak areas of ^{31}P and ^{27}Al NMR spectra under the given concentrations of each ligand and aluminium atoms. All the constants evaluated for 1 : 1 complexes are summarized in Table 3.

Since the concentration of free aluminium ion in the cyclo-hexaphosphate system was lower than its detection limit in ^{27}Al NMR, the exact K^{1}_{free} value for the cyclo-hexaphosphate complex could not be obtained, but it is predicted to be much larger than that for the cyclo-tetraphosphate complex. The stability constant K^{1}_{free} increased in the order $AlP_6O_{18}^{3-} > AlP_4O_{12}^{-} > AlP_3O_9$, in agreement with an increase in the charge and the number of donor oxygen atoms of the ligand, which is normal behaviour for the complexation reaction.[13–15] The

Table 3. Equilibrium micro-stability constants and isomerization constants of 1 : 1 complexes at $I = 0.1$ and 20°C

	K^{1}_{free}	K^{1-2}_{1}	K^{1-3}_{1-2}	K^{1-4}_{1-2}	K^{1-3-5}_{1-4}
Al^{3+}–$P_3O_9^{3-}$	1.1×10^3	0	—	—	—
Al^{3+}–$P_4O_{12}^{4-}$	3.3×10^4	0.29	6.7	—	—
Al^{3+}–$P_6O_{18}^{6-}$	Very large	8.4	—	0.91	0.62

increase of the isomerization constant K_1^{1-2} following the same order indicates that the larger the size of the ligand, the more convenient is the formation of six-membered bidentate chelate binding. The isomerization constants for the 2 : 1 complexes **XIV**, **XV** and **XVI** were not evaluated because of the difficulty in distinguishing the isomers, but the concentration ratio of total numbers of six-membered bidentate binding form to those of four-membered bidentate form was found to be 0.73. Furthermore, the tendency to form 2 : 1 complexes increased and that of 1 : 2 complexes decreased with an increase in ligand size, though this is a matter of course on considering the increase of charge and numbers of donor oxygen atoms of the ligand.

(*Received* 5 *October* 1990; *accepted* 28 *February* 1991)

Abstract—The imido complex $[ReCl_3(NPh)(PPh_3)_2]$ reacts with excess maltol to give the green complex $[Re(maltol)_2(NPh)(PPh_3)][BPh_4]$ (**1**). Under analogous conditions, $[ReCl_2(N_2COPh)(PPh_3)_2]$ gives $[ReCl(maltol)(N_2COPh)(PPh_3)_2]$ (**2**). An X-ray crystal structure of complex **1** revealed a distorted octahedral structure with *cis*-maltol ligands. Preliminary X-ray data on a poorly diffracting crystal of complex **2** has confirmed the formulation and stereochemistry. The possible structures of products from other precursors are discussed together with their redox and spectroscopic properties.

Although maltol (Fig. 1) has been known since the end of the nineteenth century, its complexes with transition metals were reported comparatively recently. Among the first to be described were the soluble, intensely-coloured species formed with iron(III).[1] Maltol has indeed found some use as a reagent for the spectrophotometric determination of iron in an acidic medium. Currently the neutral, red *tris*-chelate of maltol with iron is showing considerable promise as a clinical reagent for the control of iron *in vivo*.[2] The early studies established that maltol ligates as a chelating ligand via two oxygen atoms. However, there were few complete characterizations of the complexes and many compounds were only studied spectrophotometrically.[3–7] A relatively rare example is $[Fe(maltol)_3]$ which was very recently completely characterized by an X-ray crystal structure.[8]

Recent interest in maltol and its analogues has focused on its use as a reagent for the control of the concentrations of trivalent metals other than iron *in vivo*. Aluminium is linked with Alzheimer's disease but studies of the transport mechanism have been complicated by the facile hydrolysis of Al^{3+} in aqueous solution. However, the complex $[Al(maltol)_3]$ (maltol = monoanion of free ligand) is stable to hydrolysis in aqueous solution at physiological pH and is small enough to cross cell membranes.[9] Studies of the aluminium maltol complex

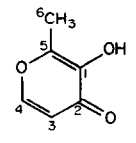

Fig. 1. Structure of maltol.

* Author to whom correspondence should be addressed.

in vivo may well shed light on the mechanism of delivery of aluminium to the brain.[10]

Maltol is established to be non-toxic and to form metal chelates with metal ions that are stable *in vivo*. As a preclude to investigating its suitability as a ligand for technetium, we here report a systematic exploration of its coordination chemistry with rhenium. The chemistry of maltol with technetium will be reported elsewhere.

(1) *Imido complexes*

The rhenium(V) complex $[ReCl_3(NPh)(PPh_3)_2]$ reacts with excess maltol in alcohol in the presence of triethylamine to give a dark green solution. $[Re(maltol)_2(NPh)(PPh_3)]^+$ (**1**) precipitated in good yield by the addition of sodium tetraphenylborate. The complex is isolated as an air-stable, green solid which is diamagnetic both in the solid state and in solution. The Nujol mull IR spectrum shows substantial shifts of *ca* 40 cm^{-1} in the bands at *ca* 1600 cm^{-1} assigned to ν(C=C) and ν(C=O) of maltol, suggesting it is functioning as a bidentate ligand. Due to interfering bands from the PPh_3 and BPh_4 groups no assignment of a band due to ν(Re=N) could be made.

The ^1H NMR spectrum of complex **1** in $CDCl_3$ showed two singlets at 2.00 and 2.60 ppm due to two, magnetically inequivalent methyl groups. There is also a doublet at 6.40 and 6.60 ppm due to one of the vinyl protons of maltol. The other doublet at about 8 ppm is presumably obscured by the phenyl protons. The integrated values are consistent with two coordinated maltol groups and these are magnetically inequivalent. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at +2.4 ppm, consistent with a single or equivalent phosphine ligands. The HPLC trace for the complex (in dichloromethane with a THF/water gradient in the presence of $[Bu_4N]Br$) showed two peaks with retention times of 4.0 and 4.6 min. This suggests the complex may have two isomers in solution.

X-ray crystal structure of $[Re(maltol)_2(NPh)(PPh_3)][BPh_4]$ (**1**). Crystals suitable for an X-ray crystal structure were grown from dichloromethane–ethanol. A selection of bond lengths and angles is presented in Table 1 and a diagram of the structure (with the atom labelling scheme) is shown in Fig. 2.

The overall geometry for rhenium is best described as distorted octahedral with *cis*-maltol ligands. The Re—O(1) and Re—O(4) bond lengths are almost identical [1.987(7) and 1.996(7) Å] as are Re—O(2) and Re—O(5) [2.122(6) and 2.111(6) Å]. Examination of the bond distances within a maltol ring (Fig. 3) shows that C(1)—C(5) and C(3)—C(4) have significant double bond character, consistent with C(2)—O(5) [1.281(10) Å] being shorter than C(1)—O(4) [1.331(10) Å]. This is also reflected in the asymmetric coordination of maltol to rhenium. The asymmetric coordination of the maltolato anion was also discussed in the structure of $[Fe(maltol)_3]$.[8] The Re=N distance of 1.709(8) Å is within the range found for other imido-rhenium

Table 1. Selected bond lengths (Å) and angles (°) for $[Re(maltol)_2(NPh)(PPh_3)]^+$ (**1**)

Bond lengths			
P—Re	2.407(4)	C(1)—O(4)	1.331(10)
O(1)—Re	1.987(7)	C(2)—O(5)	1.281(10)
O(4)—Re	1.996(7)	C(1)—C(5)	1.377(12)
O(2)—Re	2.122(6)	C(5)—O(6)	1.372(11)
O(5)—Re	2.111(6)	O(6)—C(4)	1.342(13)

O(5)—Re—P	90.2(2)	O(5)—Re—N	93.1(3)
O(5)—Re—O(1)	161.6(2)	O(5)—Re—O(2)	89.5(3)
O(5)—Re—O(4)	77.3(3)	C(13)—N—Re	165.5(5)

A complete listing of bond lengths and angles appears in the supplementary data.

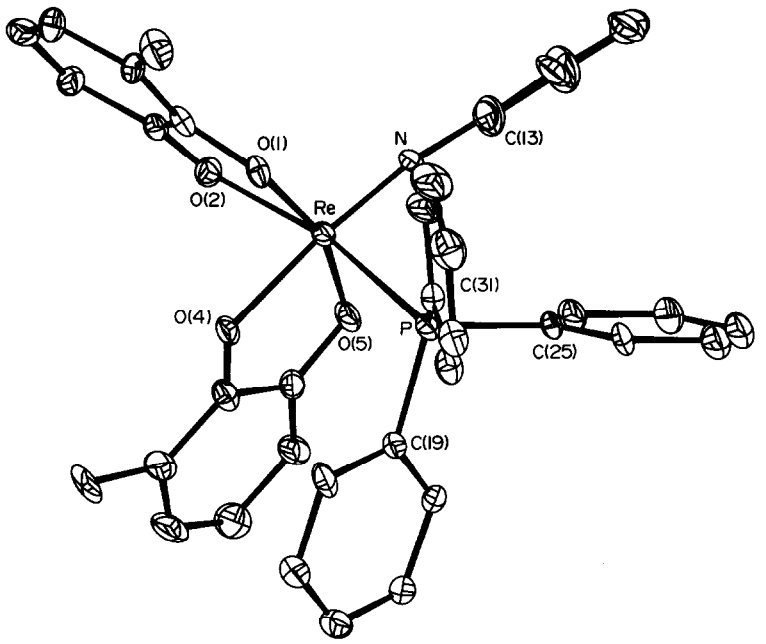

Fig. 2. The molecular structure of $[Re(maltol)_2(NPh)(PPh_3)]^+$ (**1**).

complexes.[11] The Re—N—C(13) angle of 165.5(5)° is consistent with the imido ligand functioning as a linear, four-electron donor ligand.

The O(4)—Re—O(2) angle of 81.3(3)° shows that the *cis*-maltol ligands are forced towards one another as a result of steric pressure from the bulky PPh_3 ligand. The bite angles of the maltol ligands [77.3(3) and 79.5(3)°] are similar to those found for other 1,2-disubstituted aromatic ligands. The bond lengths and angles within the BPh_4 anion are unremarkable.

Electrochemistry of complex **1**. The cyclic voltammetry of complex **1** was studied in acetonitrile solution at a platinum wire working and auxiliary electrodes, silver wire pseudo-reference electrode and 0.2 M $[Bu^n_4N][BF_4]$ as support electrolyte. An irreversible oxidation process at +1.2 V was assigned to the BPh_4 anion. A reversible reduction process is observed at $E_{1/2}$ −0.791 V (relative to SCE). The peak separation of 59.6 mV, at a scan rate of 0.2 V s^{-1}, is consistent with the process being a diffusion-controlled, reversible, one-electron reduction process. This was confirmed by convolution analysis which confirmed that the kinetics of electron transfer are rapid and that there are no accompanying homogeneous chemical processes. The reduction corresponds to the formation of a stable rhenium(IV) d^3 species $[Re(maltol)_2(NPh)(PPh_3)]$. By contrast, the precursor complex $[ReCl_3(NPh)(PPh_3)_2]$ undergoes a reversible, one-electron oxidation process at $E_{1/2}$+0.966 V[12] and two reductions at −1.05 and −1.34 V, relative to SCE, which are irreversible. The irreversibility of the reduction processes for $[ReCl_3(NPh)(PPh_3)_2]$ is almost certainly due to loss of the halide anion.

(2) *Benzoyldiazenido complex*

The chelated benzoyldiazenido(3−) complex $[ReCl_2(N_2COPh)(PPh_3)_2]$ reacts with maltol in alcohol in the presence of base to give the orange complex $[ReCl(maltol)(N_2COPh)(PPh_3)_2]$ (**2**). The IR spectrum of the product shows bands in the 1600 cm^{-1} region which are characteristic of the presence of a linear benzoyldiazenido ligand (see Scheme 1). The shift in the band of the free maltol ligand at *ca*

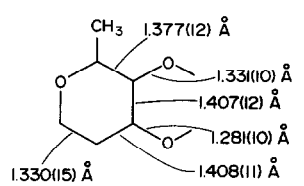

Fig. 3. Bond distances within the maltol ring.

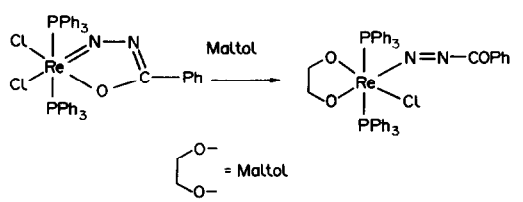

Scheme 1.

1600 cm^{-1} confirms its coordination as a bidentate ligand.

The ^1H NMR spectrum of complex **2** in $CDCl_3$ shows a doublet at 2.40 and 2.10 ppm assigned to the methyl groups of maltol. A complex multiplet at 6.4–6.8 ppm is due to one of the vinylic protons, as above. These observations are consistent with the presence of isomers due to the maltol being present in two possible orientations. The presence of two peaks in the HPLC trace at 11.6 and 13.2 min for this complex might also be in accord with the presence of isomers in solution. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at +30 ppm due to the two equivalent *trans*-phosphine ligands.

X-ray crystal structure of [ReCl(maltol)(N_2COPh)(PPh_3)$_2$] (**2**). Orange crystals of complex **2** that appeared suitable for an X-ray structure determination were obtained by slow crystallization from dichloromethane–ethanol. However, these crystals did not diffract well and although a data set was collected and the structure solved, the *R* factor remained at 13.8%. This is not appropriate for publication but did suffice to confirm the structure of the complex, a diagram of which is shown in Fig. 4. The structure is in accord with the spectroscopic data with a pseudo-octahedral geometry about rhenium with *trans*-phosphine ligands. There is no sign of disorder in the maltol ligand, so it may be that crystallization has selected single orientation for the maltol ligand shown in Fig. 4.

Electrochemistry of complex **2**. Cyclic voltammetry of **2** under analogous conditions to that above showed a reversible oxidation process at $E_{1/2}$ +0.656 V relative to SCE. The peak separation of 71 mV is suggestive of a one-electron, reversible process and the i_{pa}/i_{pc} ratio is close to unity. This process corresponds to the formation of the rhenium(IV) complex [ReCl(maltol)(N_2COPh)(PPh_3)]$^+$. A second, irreversible process occurs at +1.09 V relative to SCE which remained irreversible at the fastest scan rates. No reduction processes were observed up to potentials of −1.5 V.

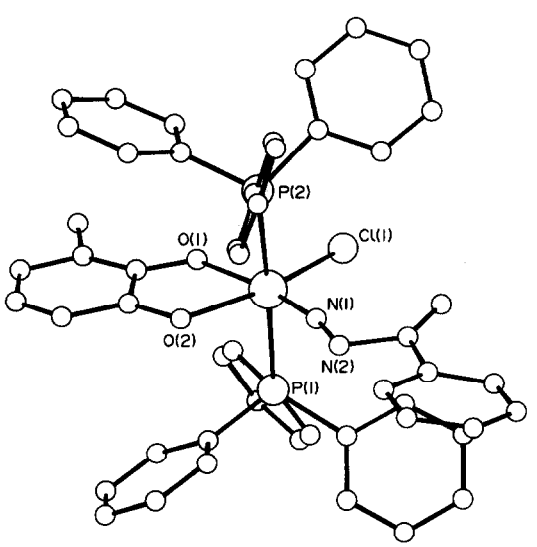

Fig. 4. Molecular structure of [ReCl(maltol)(N_2COPh)(PPh_3)$_2$] (**2**).

(3) *Other rhenium precursors*

Reaction of [$ReOCl_3(PPh_3)_2$] with maltol in ethanol under reflux in the presence of base gave a yellow–brown solution. Subsequent addition of Na[BPh_4] gave a yellow–brown solid which was recrystallized from DMF–diethyl ether. The IR spectrum confirmed the presence of chelated maltol ligands. Elemental analysis suggested the formulation [ReOCl(maltol)(PPh_3)][BPh_4], but the complex was never obtained analytically pure. Similarly, uncharacterizable complexes were obtained from [$ReNCl_2(PPh_3)_2$] and [$ReCl_3$(MeCN)(PPh_3)$_2$].

EXPERIMENTAL

Unless otherwise stated all reactions were carried out in dry solvents in conventional Schlenk glassware under an atmosphere of dinitrogen. IR spectra were recorded on a Perkin–Elmer 1350 spectrophotometer as Nujol mulls and ^1H and ^{31}P NMR spectra were measured on a Bruker WH80 spectrometer. Microanalyses were performed by the Microanalysis service of the University of Manchester. The following complexes were prepared according to the literature methods: [Re$OCl_3(PPh_3)_2$][13] and [$ReCl_2(N_2COPh)(PPh_3)_2$].[14]

Bis (maltolato) phenylimidotriphenylphosphinerhenate (V) *tetraphenylborate* (**1**)

[$ReCl_3$(NPh)(PPh_3)$_2$] (0.40 g, 4.4×10^{-4} mol), maltol (0.28 g, 2.2×10^{-3} mol) and triethylamine (0.62 ml, 4.4×10^{-3} mol) were heated under reflux in absolute ethanol (10 cm^3). Addition of Na[BPh_4] to the resulting deep green solution gave *the complex* as a dark green solid. Found: C, 64.6; H, 4.5; N, 1.2; P, 2.6. Calc. for $C_{60}H_{50}NO_6PBRe$: C, 65.0; H, 4.5; N, 1.3; P, 2.8%. ^1H NMR (ppm): 2.00 s, 2.60 s(6), maltol CH_3; 6.4 d, 6.6 d(2), vinyl protons maltol multiplet 6.8–7.5, multiplet (37), aromatic protons (integrated values in parentheses). ^{31}P NMR (ppm): 2.45.

Chloro (maltolato) benzoyldiazenidobis (triphenylphosphine)rhenium(III) (**2**)

[$ReCl_2(N_2COPh)(PPh_3)_2$] (1.0 g, 1.1×10^{-3} mol), maltol (0.74 g, 5.8×10^{-2} mol) and triethylamine

MERCURY THIOETHER CHEMISTRY: THE SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF $[Hg([15]aneS_5)](PF_6)_2$

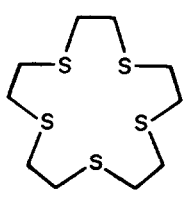
ALEXANDER J. BLAKE, ELIZABETH C. PASTEUR, GILLIAN REID and MARTIN SCHRÖDER*

Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh EH9 3JJ, Scotland, U.K.

(*Received* 9 *November* 1990; *accepted* 28 *February* 1991)

Abstract—Reaction of mercury sulphate with one molar equivalent of $[15]aneS_5$ (1,4,7,10,13-pentathiacyclopentadecane) in refluxing methanol/water for 2 h affords a colourless solution containing the complex cation $[Hg([15]aneS_5)]^{2+}$. Addition of excess NH_4PF_6 gives a white precipitate which can be recrystallized from acetonitrile/diethyl ether to give $[Hg([15]aneS_5)](PF_6)_2$ as a white solid. An X-ray crystal structure determination shows the mercury(II) ion and one thioether sulphur-donor occupying a site of *m* symmetry, with the macrocycle disordered over two equally likely conformations, neither of which possesses *m* symmetry, but which are mirror images of each other. The mercury(II) ion is bound to all five thioether donors of the macrocycle, giving a distorted square-based pyramidal stereochemistry, Hg—S = 2.491(6), 2.717(6), 2.561(8) Å.

We have been investigating the coordination chemistry of a range of thioether and mixed N_2S_4-donor macrocycles such as $[9]aneS_3$, $[15]aneS_5$, $[18]aneS_6$ and $[18]aneN_2S_4$ with transition metal ions.[1] Recently, we reported the synthesis and crystal structure of a highly unusual binuclear silver(I)



[15] ane S_5

complex $[Ag_2([15]aneS_5)_2](BPh_4)_2$.[2] The structure shows [3+1] thioether coordination to one silver(I) ion and [4+1] thioether coordination to the other, with one sulphur-donor of each macrocycle bridging asymmetrically between the two metal centres, Ag—S = 2.529(3), 2.608(4), 2.537(3), Ag···S′ = 2.907(3), Ag′—S = 2.558(4), 2.623(5), 2.716(5), 2.486(3), Ag′···S′ = 3.131(3) Å. In view of the unexpected geometry exhibited by this complex, we wondered whether similar stereochemical features would be observed upon coordination of $[15]aneS_5$ to other d^{10} metal ions. We report herein the synthesis and single crystal X-ray structure determination of $[Hg([15]aneS_5)](PF_6)_2$. Few examples of macrocyclic mercury thioether complexes have been reported. The dimeric species $[Hg_2([14]aneS_4)Cl_4]$ involves exodentate coordination of two thia-donors, with two chloride ligands completing the tetrahedral environment at each mercury(II) ion.[3] We have previously reported the synthesis and structure of $[Hg([9]aneS_3)_2]^{2+}$: this complex cation involves facial coordination of each trithia macrocycle to give a centrosymmetric, tetragonally compressed stereochemistry, Hg—S_{ap} = 2.638(3), Hg—S_{eq} = 2.728(3), 2.712(3) Å.[4] In contrast, the structure of $[Hg([18]aneN_2S_4)]^{2+}$ shows mercury(II) coordinated through all six macrocyclic donors to give a distorted octahedral geometry with the ligand in a *rac* configuration, Hg—S = 2.655(5), 2.735(4), 2.751(4), 2.639(5), Hg—N = 2.473(11), 2.472(17) Å. The small bite angle of the meridional $SCH_2CH_2NCH_2CH_2S$ linkages in $[Hg([18]aneN_2S_4)]^{2+}$ results in a large tetrahedral distortion of the four

thioether donors out of the best S_4 coordination plane.[5]

RESULTS AND DISCUSSION

Treatment of mercury sulphate with one molar equivalent of [15]aneS$_5$ in refluxing methanol/water (1 : 1 v/v) for 2 h affords a colourless solution. Addition of excess NH_4PF_6 gives a white precipitate which was recrystallized from acetonitrile/diethyl ether. The IR spectrum of this product shows peaks consistent with the presence of coordinated [15]aneS$_5$ and of PF_6^- counterion. The FAB mass spectrum exhibits molecular ion peaks at $M^+ = 647$, 521 and 501 assigned to $[^{202}Hg([15]aneS_5)PF_6]^+$, $[^{202}Hg([15]aneS_5)\cdot H_2O+H]^+$ and $[^{202}Hg([15]aneS_5)-H]^+$, respectively. The ^1H NMR spectrum measured in $(CD_3)_2CO$ at 298 K shows a single, broad resonance at δ 3.60 ppm assigned to the methylene protons of coordinated [15]aneS$_5$. Cooling this sample to 218 K results in further broadening of this resonance. The ^{13}C DEPT NMR spectrum [$(CD_3)_2CO$] measured at 298 K shows a single resonance at δ 30.83 ppm indicating that all of the macrocyclic CH_2 groups are equivalent. These data, together with elemental analysis results, indicate the formulation [Hg([15]aneS$_5$)](PF$_6$)$_2$ for the product.

Colourless needles of adequate diffraction quality were obtained by vapour diffusion of diethyl ether into a solution of [Hg([15]aneS$_5$)](PF$_6$)$_2$ in acetone. A single crystal X-ray structure determination showed (Fig. 1) the $[Hg([15]aneS_5)]^{2+}$ cation disordered across a mirror plane. This led to two alternative positions for both C(2) and C(8) and to two independent and equally likely conformations for the macrocyclic ring. Although the mercury ion and S(1) both lie on a crystallographic mirror plane, neither of the conformations determined for the ring possess *m* symmetry, but they are mirror images of each other. This model is chemically sensible since it avoids the eclipsing of macrocyclic CH_2 groups which would occur in a conformer possessing mirror symmetry. By implication, the remaining macrocyclic carbon and sulphur atoms should also have alternative sites, but these conform sufficiently well to the mirror symmetry that different sites are not identifiable. There is a mirror plane through the F—P—F axis of each PF_6^- counteranion. The atoms S(4), S(4D), S(7), S(7D) adopt a slightly distorted square-planar arrangement, S(4)···S(4D) = 3.664(9), S(4)···S(7) = 3.491(10), S(7)···S(7D) = 3.474(12) Å, with the mercury(II) ion displaced by 0.858 Å from this plane, towards the fifth thioether donor, S(1), which occupies an apical site. Thus, the metal ion is bound via all five macrocyclic donor atoms, Hg—S(1) = 2.491(6), Hg—S(4) = 2.717(6), Hg—S(7) = 2.561(8) Å, giving a distorted square-based pyramidal stereochemistry. The plane through S(1), S(4) and S(4D) is inclined at an angle of 79.87° to that through S(4), S(4D), S(7) and S(7D). Clearly, therefore, the structure adopted by [Hg([15]aneS$_5$)](PF$_6$)$_2$ is quite different to that observed for [Ag$_2$([15]aneS$_5$)$_2$](BPh$_4$)$_2$.[2] These results emphasise the coordinative flexibility of [15]aneS$_5$.

Cyclic voltammetry of [Hg([15]aneS$_5$)](PF$_6$)$_2$ measured in acetonitrile at 298 K (0.1 M ^{n}Bu$_4$NPF$_6$

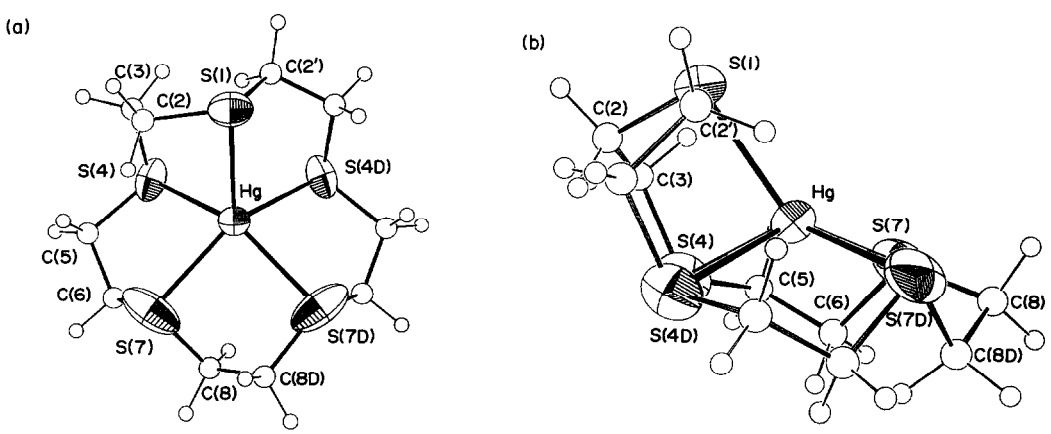

Fig. 1. (a) ORTEP plot of one conformation of $[Hg([15]aneS_5)]^{2+}$ with numbering scheme adopted. A crystallographic mirror plane passes through Hg and S(1) but C(2) and C(8) show significant deviations from this symmetry (see text). (b) Edge view.

supporting electrolyte) at platinum electrodes shows an irreversible reduction at $E_{pc} = +0.17$ V vs Fc/Fc^+ at a scan-rate of 330 mV s^{-1}. The irreversibility may be due to rapid demetallation/decomposition of the reduction product. $[Hg([9]aneS_3)_2]^{2+}$ shows a chemically reversible reduction at $E_{1/2} = -0.15$ V vs Fc/Fc^+,[4] while $[Hg([18]aneN_2S_4)]^{2+}$ shows an irreversible reduction at -1.16 V vs Fc/Fc^+.[5]

EXPERIMENTAL

IR spectra were recorded as KBr and CsI discs using a Perkin–Elmer 598 spectrometer over the range 200–4000 cm^{-1}. UV–vis spectra were measured in quartz cells using Perkin–Elmer Lambda 9 and Pye Unicam SP8-400 spectrophotometers. Microanalyses were performed by the Edinburgh University Chemistry Department Microanalytical service. Electrochemical measurements were performed on a Bruker E310 Universal Modular Polarograph. All readings were taken using a three-electrode potentiostatic system in acetonitrile containing 0.1 M $^nBu_4NPF_6$ or $^nBu_4NBF_4$ as supporting electrolyte. Cyclic voltammetric measurements were carried out using a double platinum electrode and an Ag/AgCl reference electrode. All potentials are quoted vs ferrocene/ferrocenium, Fc/Fc^+. Mass spectra were run by electron impact on a Kratos MS 902 and by fast atom bombardment on a Kratos MS 50TC spectrometer. ^1H and ^{13}C NMR spectra were obtained on Bruker WP80 and WP200 instruments.

Synthesis of $[Hg([15]aneS_5)](PF_6)_2$

Reaction of mercury sulphate (35 mg, 0.118 mmol) and [15]aneS$_5$ (35 mg, 0.116 mmol) in refluxing methanol/water (50 cm^3, 1 : 1 v/v) for 2 h under nitrogen affords a colourless solution. Cooling of the reaction mixture and addition of excess NH_4PF_6 gave a white precipitate which was recrystallized from acetonitrile/diethyl ether (Yield: 52 mg, 57%). Found: C, 15.2; H, 2.55; S, 20.3. Calc. for $[C_{10}H_{20}S_5Hg](PF_6)_2$: C, 15.2; H, 2.5; S, 20.7%. FAB mass spectrum (3-NOBA matrix): Found: $M^+ = 647$, 521 and 501. Calc. for $[^{202}Hg([15]aneS_5)PF_6]^+$: $M^+ = 647$; $[^{202}Hg([15]aneS_5)\cdot H_2O+H]^+$: $M^+ = 521$; $[^{202}Hg([15]aneS_5+H)]^+$: $M^+ = 501$. ^1H NMR spectrum [80.13 MHz, $(CD_3)_2CO$, 298 K]: δ 3.60 ppm (b, CH_2, 20H). ^{13}C DEPT NMR [50.32 MHz, $(CD_3)_2CO$, 298 K]: δ 30.83 ppm (CH_2, 10C). IR spectrum (KBr disc): 3010w, 2910m, 1420m, 1260m, 1205m, 1150w, 1120w, 840vs, 740w, 690w, 680w, 555vs cm^{-1}.

Single crystal X-ray structure determination on $[Hg([15]aneS_5)](PF_6)_2$

A colourless needle ($0.62 \times 0.05 \times 0.04$ mm) was sealed in a Lindemann glass capillary tube and mounted on a Stoë STADI-4 four circle diffractometer.

Crystal data. $[C_{10}H_{20}S_5Hg]^{2+}\cdot 2PF_6^-$, $M = 791.0$, orthorhombic, space group $Cmc2_1$, $a = 11.5487(8)$, $b = 14.4970(8)$, $c = 13.7906(8)$ Å, $V = 2308.8$ Å^3 [from 2θ values for 48 reflections measured at $\pm\omega$ ($26 < 2\theta < 28°$, $\lambda = 0.71073$ Å, $T = 298$ K)], $Z = 4$, $D_c = 2.275$ g cm^{-3}, μ(Mo-K_α) = 7.328 mm^{-1}, $F(000) = 1512$.

Data collection and processing. STADI-4 diffractometer, graphite-monochromated Mo-K_α radiation, ω–2θ scans using the learnt-profile method,[6] 880 reflections measured ($2\theta_{max} = 45°$, h 0 → 12, k 0 → 15, l 0 → 14) giving 759 with $F > 6\sigma(F)$.

Structure analysis and refinement. The mercury position was deduced from a Patterson synthesis. This was then input to DIRDIF[7] which located the positions of one phosphorus and two sulphur atoms. Subsequent iterative cycles of least-squares refinement and difference Fourier syntheses[8] located the positions of all other non-hydrogen atoms. At isotropic convergence, corrections for absorption (min. 0.755, max. 1.204) were made using DIFABS.[9] During refinement, disorder of the macrocyclic carbon atoms was identified and modelled successfully by constraining all C—C and C—S bond lengths to be 1.52 and 1.83 Å, respectively, and the angles around the carbon atoms to be tetrahedral. The two PF_6^- counteranions possess m symmetry, with one phosphorus and two fluorine atoms of each lying on a mirror plane. Anisotropic thermal parameters were refined for mercury, sulphur, phosphorus and fluorine atoms. Hydrogen atoms were included in fixed, calculated positions. The weighting scheme $w^{-1} = \sigma^2(F) + 0.0023F^2$ gave satisfactory agreement analyses. At final convergence, $R = 0.0407$, $R_w = 0.0564$, $S = 1.133$ for 130 independent parameters. At convergence the polarity of the structure was determined. This showed the R values and the uncertainties in the atomic positions to be consistently lower for the hand chosen. Excepting a peak of 1.89 e Å^{-3} close to the metal, the final difference Fourier synthesis showed no feature above 0.88 e Å^{-3}. Illustrations were prepared using ORTEPII,[10] molecular geometry calculations utilized CALC[11] and scattering factor data were inlaid[8] or taken from ref. 12. Bond lengths, angles and torsion angles are given in Table 1. Thermal parameters, fractional atomic coordinates, together with observed and calculated structure factors have been deposited with the

Abstract—The diphosphine-bridged, binuclear complexes $[\{M(CO)_3\}_2(\mu\text{-diphos})]$ (M = Mo or W; diphos = mtppm, mtppe or iptppe) have been prepared. Their binuclear structures are established by the X-ray structure of $[\{W(CO)_3\}_2(\mu\text{-mtppe})]$, in which each tungsten is ligated by three carbonyl groups in a facial arrangement with P,S,S ligation from the bridging mtppe ligand completing the octahedral geometry [average d(W—S) 2.514(9), d (W—P) 2.420(6) Å]. The bridged complexes $[\{M(CO)_4\}_2(\mu\text{-dppmpe})]$ and $[\{MBr_2(CO)_2\}_2(\mu\text{-mtppe})]$ and the mononuclear compounds $[M(CO)_4(dbtpe)]$ and $[MoBr_2(CO)_2(mtppe)]$ are also described.

The chemistry of molybdenum and tungsten with phosphine co-ligands has allowed study of the reactions of a range of small molecules such as N_2, RC≡CR′, CO, RNC, etc., bound at electron-rich centres.[1] Recently there has been great interest in the chemistry of molybdenum and related metals with sulphur-donor ligands because of the involvement of sulphur-ligated molybdenum in catalytic processes such as hydrodesulphurization and dinitrogen reduction.[2,3]

We have prepared a series of functionalized diphosphine ligands[4] which allows us to study the behaviour of metals such as low-valent molybdenum and tungsten in, *inter alia*, a phosphorus–sulphur environment.

We have briefly reported some of our work in this area with molybdenum and tungsten carbonyls[5] and here we describe this work in detail; it involves the preparation of the series of binuclear carbonyl complexes $[\{M(CO)_3\}_2(\mu\text{-diphos})]$, $[\{M(CO)_4\}_2(\mu\text{-diphos})]$ and $[\{MBr_2(CO)_2\}_2(\mu\text{-diphos})]$ and the mononuclear complexes $[M(CO)_4(diphos)]$ and $[MoBr_2(CO)_2(diphos)]$ (M = Mo or W; diphos = diphosphine as described below).

* Author to whom correspondence should be addressed.

RESULTS AND DISCUSSION

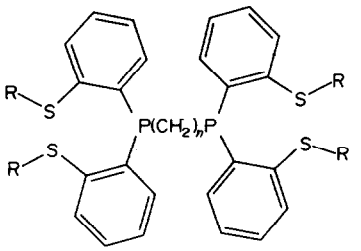
We begin by defining our nomenclature for the diphosphines mtppm **(Ia)**, mtppe **(Ib)**, iptppe **(Ic)**, dppmpe **(II)** and dptpe **(III)** as shown in Fig. 1. They were prepared by the methods already described.[4]

Binuclear complexes

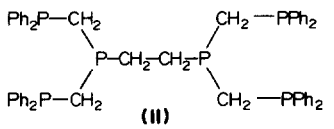
The reactions of mtppm, mtppe and iptppe with $[M(CO)_3(MeCN)_3]$ (M = Mo or W) in a 1 : 2 molar ratio in refluxing tetrahydrofuran (THF) produced yellow, crystalline bimetallic complexes of general formula $[\{M(CO)_3\}_2(\mu\text{-diphos})]$ (**1–3** and **6–8** in Table 1) [i.e. eq. (1)]

$$2[M(CO)_3(MeCN)_3] + \begin{matrix}\text{mtppm}\\ \text{mtppe}\\ \text{iptppe}\end{matrix} \xrightarrow[\text{reflux}]{\text{THF}} [\{M(CO)_3\}_2(\mu\text{-diphos})] + 6MeCN. \quad (1)$$

Analytical and spectroscopic data for these complexes are shown in Table 1; all complexes show a singlet in their $^{31}P\{H\}$ NMR spectra and CO bands in their IR spectra characteristic of tricarbonyl complexes.[6,7] They are sparingly soluble in organic solvents but can be recrystallized from hot dimethyl formamide or dimethyl sulphoxide (DMSO). They

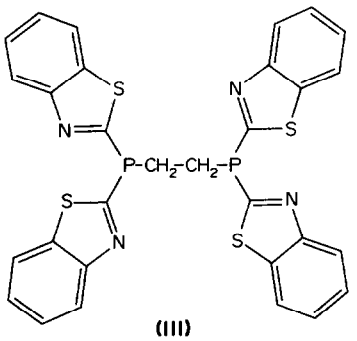


(Ia) $n = 1$, R = methyl
bis{bis(2-methylthiophenyl)phosphino}methane (mtppm)
(Ib) $n = 2$, R = methyl
1,2-bis{bis(2-methylthiophenyl)phosphino}ethane (mtppe)
(Ic) $n = 2$, R = isopropyl
1,2-bis{bis(2-isopropylthiophenyl)phosphino}ethane (iptppe)



(II)

1,1,4,4-tetrakis(diphenylphosphinomethyl)-1,4-diphosphabutane, or
1,2-bis{(diphenylphosphinomethyl)phosphino}ethane (dppmpe)



(III)

1,2-bis(dibenzothiazoylphosphino)ethane (dbtpe)

Fig. 1. Functionalized disphosphines.

are stable to air in the solid state but decompose slowly in solution. These complexes and others described later often contain solvent of crystallization, established by analysis and NMR spectroscopy.

The binuclear structure of these compounds has been established by an X-ray structure determination of $[\{W(CO)_3\}_2(\mu\text{-mtppe})]\cdot DMSO$ (7). The molecular structure of **7** is shown in Fig. 2. The unit cell consists of two molecules of the complex, each lying across a crystallographic inversion centre, with two molecules of DMSO in general positions. The single crystal was triclinic, space group $P\bar{1}$.

Each tungsten is coordinated by three facial carbonyl groups, two sulphur atoms and one phosphorus atom, the ethylene bridge of the diphosphine joins the two octahedrally-coordinated metal units. Selected bond distances and angles are given in Table 2. The W—P bond distances, av. 2.420(6) Å are close to the W—S distance [av. 2.514(9) Å]. The metal–carbonyl distances of about 1.97 Å are in the normal range for such compounds.[8] These structures are analogous to that proposed for the tricarbonyl derivative of the hexadentate diphosphine 1,2-bis{bis(diphenylphosphinoethyl)phosphino}ethane (bdpepe), $[\{Mo(CO)_3\}\mu\text{-(bdpepe)}]$.[9]

The hexaphosphine, dppmpe, reacts with two moles of $[M(CO)_3(MeCN)_3]$ to give clear yellow solutions from which complexes (**4** and **9**) have been precipitated as pale yellow solids by addition of hexane. These complexes are more soluble in organic solvents than the thiophenyldiphosphine complexes discussed above. Moreover, their IR spectra show four CO bands (2020, 1937, 1850 and 1830 cm^{-1}, M = Mo; 2017, 1930, 1885 and 1840 cm^{-1}, M = W) which differs considerably from the spectra of complexes **1–3** and **6–8** (Table 1) and of complex $[\{Mo(CO)_3\}_2(\mu\text{-bdpepe})]$, which shows only two characteristic CO bands.[9] The number and frequencies of the CO bands of **4** and **9** are in fact very similar to those observed for tetracarbonyl complexes $[M(CO)_4L_2]$.[9] The $^{31}P\{^1H\}$ NMR spectra for both complexes are more complicated than that of the free ligand,[4] which has an $AA'B_2B_2'$ spectrum,[10] but it can be seen that the chemical shift of the phosphorus giving the B pattern is moved to lower field by about 100 ppm compared with the free ligand (−165 ppm), whereas the A pattern occurs at essentially the same chemical shift as the free ligand (−170 ppm). Thus only the terminal phosphorus atoms (B) are involved in coordination to the metal and the internal phosphorus atoms (A) are uncoordinated. Therefore complexes **4** and **9**

Table 1. Data for carbonyl–polyphosphine complexes

[j] N; 5.4(5.5).

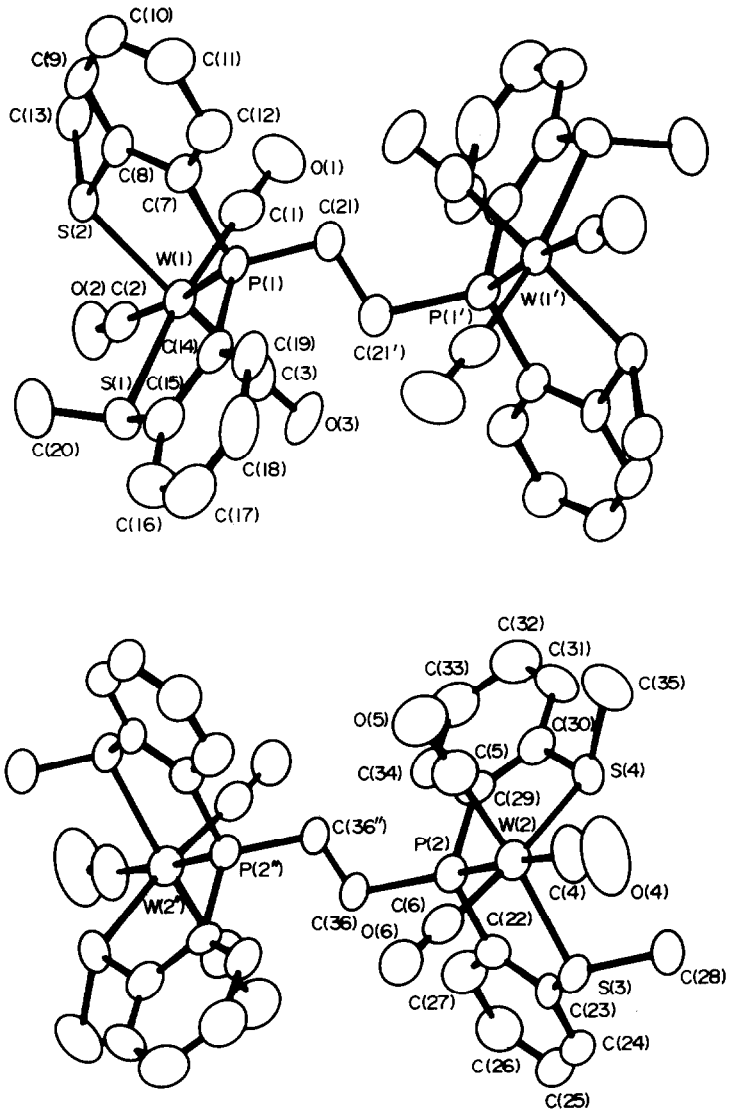

Fig. 2. Structure of $[\{W(CO)_3\}_2(\mu\text{-mtppe})]$ (**7**).

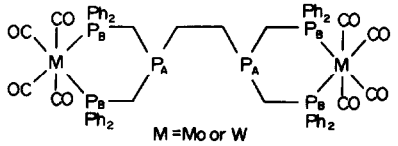
are formulated as binuclear, diphosphine-bridged tetracarbonyl complexes $[\{M(CO)_4\}_2(\mu\text{-dppmpe})]$ as shown in reaction (2):

$$[M(CO)_3(MeCN)_3] + \text{dppmpe} \xrightarrow[\text{reflux}]{\text{THF}} \quad (2)$$



The mechanism of this reaction, which involves disproportionation at some stage to generate extra carbon monoxide, has not been investigated. Presumably the tetracarbonyl species is formed to avoid the highly strained, four-membered ring, which coordination of a third phosphorus atom to each metal would produce.

Mononuclear complexes

When a 1:2 molar ratio of dbtpe and $[M(CO)_3(MeCN)_3]$ was allowed to react in refluxing THF for 20 h, a dark brown pyrophoric mixture was obtained. If, however, a 1:1 molar ratio was used, the mononuclear, olive green complexes $[M(CO)_4(\text{dbtpe})]$ (**5**) and (**10**) were obtained. Their structure [Fig. 3(a)] has been assigned on the basis of the spectroscopic and analytical data shown in Table 1. In particular, for **5**, the $\nu(CO)$ values of 2038, 1948, 1878 and 1839 cm^{-1} are very close to those of $[Mo(CO)_4(Ph_2PCH_2CH_2PPh_2)]$ (2020,

Symmetry elements: ′ $1-x, 2-y, -z$; ″ $-x, 1-y, 1-z$.

1919, 1907 and 1881 cm^{-1})[9] and the $^{31}P\{^1H\}$ NMR spectrum has a singlet resonance, i.e. **5** has equivalent phosphorus atoms. Again a disproportionation reaction has taken place to give tetracarbonyls from the tricarbonyl precursor. Compounds **5** and **10** can be prepared by direct reaction of $[M(CO)_6]$ and dbtpe in diglyme, but in low yield.

Treatment of a freshly prepared dichloromethane solution of $[\{MoBr_2(CO)_4\}_2]$ with a dichloromethane solution of mtppe at 20°C gave two products, in the form of red crystals (**11**) and yellow–orange crystals (**12**).

Compound **11** has equivalent phosphorus atoms (singlet ^{31}P NMR spectrum, Table 1) and two CO bands at 1984 and 1910 cm^{-1}, close to the values observed for complex $[\{MoBr_2(CO)_2(dppe)\}_2(\mu\text{-dppe})]$ at 1935 and 1855 cm^{-1}.[11] A likely structure for **11**, consistent with these observations and with analytical data (Table 1), is a bimetallic seven-coordinate structure [as in Fig. 3(b)]. Complex **12** has inequivalent phosphorus atoms (^{31}P NMR spectrum, Table 1) and only one CO band at 1900 cm^{-1} suggesting *trans*-carbonyl groups. A possible structure for **12** is therefore as shown in Fig. 3(c). The reaction of $[WBr_2(CO)_4]$ with tmppe did not give a clean product.

Reaction of $[\{MBr_2(CO)_4\}_2]$ with dbtpe yields salmon pink complexes (**13** and **14**) which are not soluble in common organic solvents. The two CO bands (Table 1) indicate a *cis*-$(CO)_2$ arrangement and a possible structure for **13** and **14** is as shown in Fig. 3(d). Their poor solubility has prevented further characterization.

EXPERIMENTAL

All operations were carried out under pure dinitrogen using standard Schlenk and high vacuum techniques. All solvents were dried and degassed before use. Spectroscopic measurements were made using: NMR, JeoL FX90Q, JeoL GSX270, Brucker WP80 or Brucker WM360 instruments; IR; Perkin–Elmer 598 or 883 instruments; mass spectra, Kratos MS80 RF instrument. Microanalyses were determined by Mr C. J. Macdonald of the Nitrogen

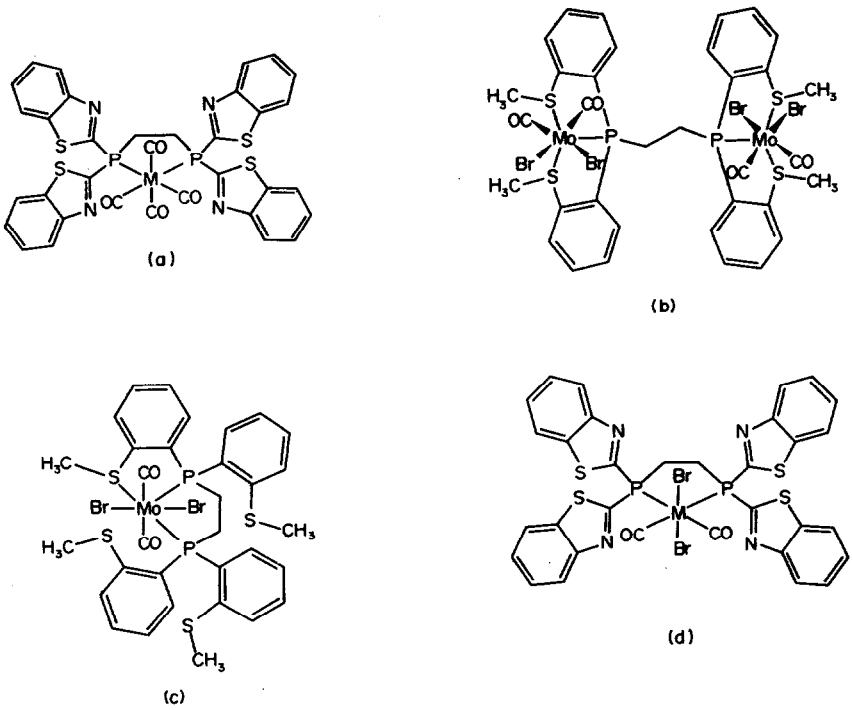

Fig. 3.

Fixation Laboratory or Ms K. Plowman of the University of Sussex. $[M(CO)_3(MeCN)_3]$[12] and $[\{MBr_2(CO)_4\}_2]$[13] were prepared by published methods.

Preparation of $[\{Mo(CO)_3\}_2(\mu\text{-mtppm})]\cdot$thf (**1**)

A mixture of $[Mo(CO)_3(MeCN)_3]$ (0.64 g, 2.1 mmol) and mtppm (0.6 g, 1.1 mmol) in thf (80 cm^3) was refluxed for 40 h, and the resulting yellow solution concentrated to *ca* 40 cm^3. The fine, yellow solid which precipitated was filtered off and dried *in vacuo*. (Yield 0.45 g, 43%.)

Preparation of $[\{Mo(CO)_3\}_2(\mu\text{-mtppe})]\cdot$thf (**2**)

A mixture of $[Mo(CO)_3(MeCN)_3]$ (0.84 g, 2.8 mmol) and mtppe (0.81 g, 1.4 mmol) in thf (100 cm^3) was refluxed under dinitrogen for 20 h, during which time a yellow, crystalline complex formed from the clear solution. This was filtered off and dried *in vacuo*. (Yield 1.0 g, 71%, m.p.: decomposed above 230°C.)

Preparation of $[\{Mo(CO)_3\}_2(\mu\text{-iptppe})]\cdot$thf (**3**)

A mixture of $[Mo(CO)_3(MeCN)_3]$ (0.7 g, 2.3 mmol), iptppe (0.8 g, 1.2 mmol) and thf (100 cm^3) was refluxed for 20 h. The yellow, crystalline solid which precipitated was filtered off, washed with thf and dried *in vacuo*. (Yield 0.85 g, 65.5%:)

Preparation of $[\{Mo(CO)_4\}_2(\mu\text{-dppmpe})]$ (**4**)

A mixture of $[Mo(CO)_3(MeCN_3]$ (1.0 g, 3.3 mmol), dppmpe (1.46 g, 1.65 mmol) and thf (100 cm^3) was refluxed for 48 h. The clear, yellow solution was cooled to room temperature and filtered from the trace of solid, then concentrated to *ca* 40 cm^3. Hexane (50 cm^3) was added to give pale, yellow material which was filtered off and dried *in vacuo*. (Yield 0.9 g, 42%.)

Preparation of $[Mo(CO)_4(dbtpe)]\cdot$thf (**5**)

A mixture of $[Mo(CO)_3(MeCN)_3]$ (0.64 g, 2.1 mmol), dbtpe (1.32 g, 2.1 mmol) and thf (100 cm^3) was refluxed for 24 h. The deep brown solution was filtered and the filtrate concentrated to *ca* 40 cm^3. Hexane (50 cm^3) was added to give an olive green solid, which was filtered off and dried *in vacuo*. (Yield 1.0 g, 52%.)

Preparation of $[\{W(CO)_3\}_2(\mu\text{-mtppm})]\cdot$thf (**6**)

A mixture of $[W(CO)_3(MeCN)_3]$ 0.65 g, 1.66 mmol), mtppm (0.47 g, 0.83 mmol) and thf (80 cm^3) was refluxed for 48 h. The yellow, crystalline solid

was filtered off washed with thf and dried *in vacuo*. (Yield 0.4 g, 41%.)

Preparation of $[\{W(CO)_3\}_2(\mu\text{-mtppe})]\cdot$thf (**7**)

A mixture of $[W(CO)_3(MeCN)_3]$ (0.8 g, 2.0 mmol), mtppe (0.6 g, 1.0 mmol) and thf (100 cm^3) was heated under reflux for 48 h, during which time all the solid material dissolved, then a yellow, crystalline solid precipitated. The mixture was cooled to room temperature and the yellow crystals filtered off, washed with thf and dried *in vacuo*. (Yield 0.6 g, 52%.)

X-ray structure analysis of $[\{W(CO)_3\}_2(\mu\text{-mtppe})]\cdot$DMSO

Crystal data: $[C_{36}H_{32}O_6P_2S_4W_2][C_2H_6OS]$, $M = 1196.7$, triclinic, space group $P\bar{1}$, $a = 11.455(2)$, $b = 11.510(1)$, $c = 17.073(2)$ Å, $\alpha = 105.22(1)$, $\beta = 97.36(1)$, $\gamma = 101.35(1)°$, $U = 2090.6$ Å^2, $Z = 2$, $D = 1.90$ g cm^{-3}, Mo-K_α radiation (graphite monochromator), $\lambda = 0.71069$ Å, $\mu = 59.8$ cm^{-1}.

Data were collected using a crystal, *ca* $0.4\times0.2\times0.1$ mm, on an Enraf–Nonius CAD4 diffractometer in the θ–2θ mode, with $\Delta\theta = (0.8+0.35\tan\theta)°$, and a maximum scan time of 1 min. A total of 5093 unique reflections were measured for $2 < \theta < 22°$ and $+h\pm k\pm l$, and 4112 reflections with $|F^2| > \sigma(F^2)$ were used in the refinement where $\sigma(F^2) = \{\sigma^2(I)+(0.04I)^2\}^{1/2}/\text{Lp}$. There was no crystal decay. An empirical absorption correction was made using DIFABS[14] with maximum and minimum corrections of 1.12 and 0.84.

The structure was solved by routine heavy atom methods and refined by full-matrix least-squares with non-hydrogen atoms anisotropic. Hydrogen atoms, except for those on the molecule of dimethyl sulphoxide solvent, were included at fixed calculated positions and B_{iso} of 6.0 Å. The weighting scheme was $w = 1/\sigma^2(F)$ and the final residuals were $R = 0.032$, $R' = 0.043$. Programs for the Enraf–Nonius SDP-plus package were run on a PDP 11/34 computer. Atomic coordinates, displacement factor coefficients, full lists of bond lengths and angles and F_o/F_c lists have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Preparation of $[\{W(CO)_3\}_2(\mu\text{-iptppe})]\cdot$thf (**8**)

A mixture of $[W(CO)_3(MeCN)_3]$ (0.53 g, 1.36 mmol), iptppe (0.47 g, 6.8 mmol) and thf (80 cm^3) was refluxed for 48 h, during which time all the solid initially dissolved and a yellow, crystalline precipitate appeared. This was filtered off, washed with thf and dried *in vacuo*. (Yield 0.45 g, 56%, m.p.: decomposed above 230°C.)

Preparation of $[\{W(CO)_4\}_2(\mu\text{-dppmpe})]$ (**9**)

A mixture of $[W(CO)_3(MeCN)_3]$ (0.71 g, 1.8 mmol), dppmpe (0.8 g, 0.9 mmol) and thf (100 cm^3) was refluxed for 48 h. The clear, yellow solution was cooled to room temperature and filtered. The filtrate was concentrated to *ca* 40 cm^3, then hexane was added to give the product as a pale yellow solid, analytically pure. (Yield 0.9 g, 67.5%.)

Preparation of $[W(CO)_4(\text{dbtpe})]\cdot$thf (**10**)

A mixture of $[W(CO)_3(MeCN)_3]$ (0.81 g, 2.0 mmol), dbtpe (1.3 g, 2.0 mmol) and thf (80 cm^3) was heated under reflux for 20 h, during which time the yellow solution changed to dark green, and most of the solid dissolved. The solution was cooled to room temperature and filtered. The filtrate was concentrated to *ca* 40 cm^3 and hexane was added to give an olive green complex, which was filtered off and dried *in vacuo*. (Yield 1.2 g, 60%.)

Reaction of $[MoBr_2(CO)_4]$ with mtppe

To a suspension of $[Mo(CO)_6]$ (1.0 g, 3.79 mmol) in dichloromethane (30 cm^3), cooled to −78°C, was added bromine (12 drops) and the mixture was left stirring at −78°C for 45 min, then at room temperature for 15 min. The resulting red solution was filtered into another flask containing a suspension of mtppe (1.2 g, 2.1 mmol) in dichloromethane (30 cm^3), and the mixture stirred for a further 4 h. The solution was concentrated *in vacuo* to 30 cm^3 and hexane added until the mixture became turbid. This was then filtered and the filtrate left in the freezer overnight to give red–orange crystals (**11**) which were filtered off and dried *in vacuo*. Hexane was added to the filtrate to give a yellow–orange complex (**12**). Complex **11** was identified as $[\{MoBr_2(CO)_2\}_2(\mu\text{-mtppe})]\cdot 2CH_2Cl_2$ and complex **12** was identified as $[MoBr_2(CO)_2(\text{mtppe})]$.

Preparation of $[MoBr_2(CO)_2(\text{dbtpe})]$ (**13**)

A solution of $[MoBr_2(CO)_2]$ [prepared as described previously from molybdenum hexacarbonyl (1.0 g, 3.78 mmol) in dichloromethane (30 cm^3) and bromine (12 drops)] was added to a suspension of dbtpe (1.8 g, 2.8 mmol) in dichloromethane (30 cm^3). The mixture was stirred at

room temperature for 20 h, then the precipitated salmon pink complex was filtered off, washed with dichloromethane and dried *in vacuo*. (Yield 2.1 g, 80%.)

Preparation of $[WBr_2(CO)_2(dbtpe)]$ (**14**)

In a similar fashion to the above, a solution of $[WBr_2(CO)_4]$ [prepared from tungsten hexacarbonyl (1.0 g, 5.4 mmol) in dichloromethane (30 cm^3) and bromine (15 drops)], was added to a suspension of dbtpe (1.6 g, 2.6 mmol) in dichloromethane (30 cm^3). The resulting mixture was stirred at room temperature for 20 h. The salmon pink complex was filtered off, washed with dichloromethane and dried *in vacuo*. (Yield 2.0 g, 76%.)

Abstract—Reaction between neodymium chips and isopropanol (Pr^i) led to the isolation of an oxoisopropoxide solvate $Nd_5(OPr^i)_{13}(Pr^iOH)_2$, which has been characterized by microanalysis and IR spectroscopy, as well as by X-ray diffraction. The molecule corresponds to a trigonal bipyramidal oxoalkoxide $Nd_5(\mu_5\text{-}O)(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_6(OR)_5(ROH)_2$ (R = Pr^i), in which all metals achieve hexacoordination. The two alcohol molecules are linked to the same neodymium centre, thus leading to distortion of the M_5O_{16} core.

Metal alkoxides are versatile precursors of oxides and are thus widely used in the sol–gel process.[1] High purity neodymium deratives are particularly attractive for their optical properties and thus find application in optical fibers or non-linear optic materials.[2] Various neodymium compounds, including alkoxides $Nd(OR)_3$ (R = Pr^i, Np)[3] associated with ethylaluminum derivatives, have also been found to be interesting for the development of Ziegler–Natta-type catalysts. The bimetallic catalyst, $[Al_3Nd_6(\mu\text{-}Cl)_6(\mu_3\text{-}Cl)_6(\mu\text{-}Et)_9Et_5(OPr^i)]_2$, obtained from the ternary system —$Nd(OPr^i)_3$–Et_3Al–Et_2AlCl—displays high activity and stereospecificity for polymerization of butadiene.[4]

Among the various routes for obtaining lanthanide alkoxides, starting from metal chlorides, nitrates or metal chips, the latter appears to be the most attractive, owing to the available purity of the metal, the absence of alkali metal residues and the high yield reported in the literature.[5] We have previously reported that the compound formulated as "$Y(OPr^i)_3$" actually corresponds to an oxoisopropoxide, $Y_5(\mu_5\text{-}O)(\mu_3\text{-}OR)_4(\mu_2\text{-}OR)_4(OR)_5$ (R = Pr^i), when isolated.[6] The precursor was shown to be a solvate, but its nature remains undetermined, since X-ray diffraction studies have so far failed to solve its structure and ^{1}H NMR data were uninformative as a result of fast exchange processes.

In the case of neodymium, it has, however, proved possible to characterize an isopropanol solvate structurally. We now wish to report the molecular structure of $Nd_5(\mu_5\text{-}O)(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_6(OR)_5(ROH)_2$ (R = Pr^i), the first example of a trigonal bipyramidal oxoalkoxide.

EXPERIMENTAL

All manipulations were routinely performed under dry argon using vacuum line or Schlenk techniques. Solvents were purified by standard methods. Isopropanol was dried by distillation over $[Al(OPr^i)_3]_4$. ^{1}H NMR and IR spectra were run on Bruker AC-200 and IR-FTS 45 spectrometers, respectively. IR spectra were obtained as Nujol

mulls. Analytical data were obtained from the Centre de Microanalyses du CNRS.

Synthesis of the neodymium isopropoxides

The neodymium derivatives were synthesized according to the procedure of Brown and Mazdiyasni.[5] Neodymium chips (Aldrich) (23 g, 0.159 mol) and activated by mercuric salts [$HgCl_2+Hg(OAc)_2$ (1:1, 15 mg) or only $[Hg(OAc)_2]$[6] in 300 cm^3 of toluene/isopropanol (1:1)] were heated under reflux over a period of 48 h. A first crop of pale blue, air-sensitive crystals, analysing as $Nd(OPr^i)_3(Pr^iOH)$[7] (**1**) (yield 46.9 g, 75.6%), was obtained after filtration of the hot reaction medium and cooling at room temperature. These are soluble in toluene, dichloromethane, THF but poorly soluble in isopropanol. Found: C, 37.4; H, 6.9. Calc. for $C_{12}H_{29}O_4Nd$: C, 37.7; H, 7.7%. IR (cm^{-1}): 3348 [ν(OH)]; 1161vs, 1132vs, [ν(C—O)]; 1049s, 993m, 959vs, 872m, 822m, 725w; 544s, 444s, 400m, 334m, 324m, 277m [ν(Nd—O)].

A second crop of crystals (**2**) with comparable solubility properties was obtained by adding isopropanol (100 cm^3) to the filtrate (250 cm_3) (yield 9.3 g, 15%). Found: C, 31.2; H, 6.1. Calc. for $C_{45}H_{107}O_{16}Nd_5$: C, 33.2; H, 6.3%. IR (cm^{-1}): 3337 [ν(O—H)]; 1161vs, 1137, 1120sh [ν(C—O)]; 1049s, 993m, 959vs, 872m, 822m, 727w; 523m, 460sh, 446m, 410, 380sh, 326m, 301m [ν(Nd—O)]. The high lability of the isopropanol molecules in **2** leads to analytical data more in agreement with the $Nd_5O(OPr^i)_{13}$ formulation. Calc. for $C_{39}H_{91}O_{14}Nd_5$: C, 31.1; H, 6.1%. IR (cm^{-1}): 1161vs, 1135vs, 1115sh [ν(C—O)]; 1045m, 995vs, 968vs, 875m, 835w, 720w; 520m, 460sh, 443m, 400sh, 330sh, 300 vs [ν(Nd—O)].

X-ray crystallography of $Nd_5O(OPr^i)_{13}(Pr^iOH)_2$

Crystals of **2** suitable for X-ray were obtained by adding 4 cm^3 of isopropanol to 10 cm^3 of the first filtrate and slow cooling to −20°C. Complex **2** crystallizes as pale blue, irregular-shaped prisms, which decompose within seconds on exposure to air. A crystal was mounted, under nitrogen, in a glass capillary, at approximately −80°C, then cooled to −150°C, and transferred immediately to a Rigaku AFC6R diffractometer. Intensities (h, k, $+l$) were measured at -150 ± 1°C, using graphite-monochromated Mo-K_α radiation from a RU200 rotating anode operating at 9 kW (50 kV, 180 mA). The w–2θ scan mode was employed for $3.5 < 2\theta < 60°$ with a scan rate of 32° min^{-1} and a scan width of $(0.89+0.3\tan\theta)°$. Weak reflections [$F < 10\sigma(F)$] were rescanned up to three times and counts accumulated to improve counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time vs background counting time was 2:1. The fact that the crystal was not subject to decay during the measurement of intensities was checked by monitoring three reflections at regular intervals (after measurement of each 150 reflections). Intensity data were corrected for Lorentz and polarization effects, and an empirical absorption correction, based on azimuthal scans for several reflections, was made (max., min. transmission factors: 1.00, 0.573). Unit-cell parameters were obtained from diffractometer setting angles for 25 reflections in the range $39 < 2\theta < 45°$. Further information on crystal data and intensity data collection is listed in Table 1.

The structure was solved by direct methods (MITHRIL)[8] and subsequent electron density calculations. One of the OPr^i ligands [O(7), C[7); C(71)] was found to be disordered with respect to

the two-fold axis through O(4), Nd(3) and O(7), such that C(7) was located and refined as a half-atom. Full-matrix least-squares refinement of positional and anisotropic thermal parameters [isotropic thermal parameter for C(7)] gave a final $R = 0.041$, $R_w = 0.048$. Atomic scattering factors and anomalous dispersion corrections were taken from ref. 9, and the F_o values were weighted according to $w = [\sigma^2(F_o)]^{-1}$ with a p factor of 0.03. A final difference map showed a max., min. residual density of 1.16 and -1.20 e Å^{-3}, respectively. All calculations were carried out with the TEXSAN program system.[10] No hydrogen atoms were included.

Tables of positional and thermal parameters, interatomic distances and angles are given as Supplementary material.

RESULTS AND DISCUSSION

The reaction between neodymium chips, activated by catalytic amounts of mercuric salts (chloride and/or acetate), and isopropanol offered several alkoxide derivatives by crystallization.[7a] The first crop of crystals analysed as a tris-isopropoxide adduct $Nd(OPr^i)_3(Pr^iOH)$ [ν(OH): 3348 cm^{-1}] (75%), and was found by X-ray diffraction to have a tetranuclear structure related to that of $[Ti(OMe)_4]_4$ with hexacoordinated neodymium atoms.[7b] Addition of isopropanol to the filtrate leads to the precipitation of another solvate [ν(OH): 3337 cm^{-1}] in lower yield ($\simeq$ 15%), which was established by X-ray diffraction to correspond to an oxo derivative, $Nd_5O(OPr^i)_{13}(Pr^iOH)_2$. Its molecular structure consists of discrete pentanuclear units, as shown in Fig. 1. Selected distances and bond lengths are reported in Table 2.

The five metals form a distorted trigonal bipyramidal cluster (Fig. 2) with a μ_5-oxo ligand, O(4). Although all metals are hexacoordinated with a distorted octahedral surrounding, they are of three different types, and there are also three types of alkoxide ligands. The trigonal pyramid is elongated along the apex, as evidenced by the Nd(2)—O(4) bond lengths of 2.719(1) Å, compared with those in the equatorial plane, Nd(1)—O(4) 2.468(8) Å and Nd(3)—O(4) 2.355(13) Å, and the non-bonding Nd---Nd distances range from 3.539(1) to 4.409(1) Å. The Nd—O distances vary over a wide range, from 2.121(9) to 2.719(1) Å, with the longest Nd—O distances implying the μ_5-O ligand. The

Symmetry code for primed atoms: $-x, -y, z$.

only neodymium alkoxide structurally characterized so far corresponds to $Nd_6(\mu_6\text{-}Cl)(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_9(OR)_6$ (R = Pr^i) and displays metal–oxygen bond lengths varying from 2.05(2) to 2.45(5) Å.[11]

Although the H(OH) of the alcohol molecules could not be located, the position of the alcohol can generally be deduced from the lengthening of the terminal metal–oxygen bonds and/or the bending of terminal ligands in the *cis* position, which allows stabilization of the solvates by hydrogen bonding.[12] By contrast with Nd(1) and Nd(2), Nd(3) bears three terminal ligands; the very different Nd—O distances [2.184(16) and 2.511(10) Å] allow the unambiguous assignment of the latter, Nd(3)—O(8) and Nd(3)—O(8′), to Nd—O(H)R bonds. This is supported by the fact that the Nd(3)—O(8)—C(8) angle is relatively small [136(1)°], while larger M—O—C angles are expected for terminal M—OR bonds. Indeed, the value of the Nd(3)—O(7)—C(7) angle is 158(1)°, and values as large as 174° (av.) are

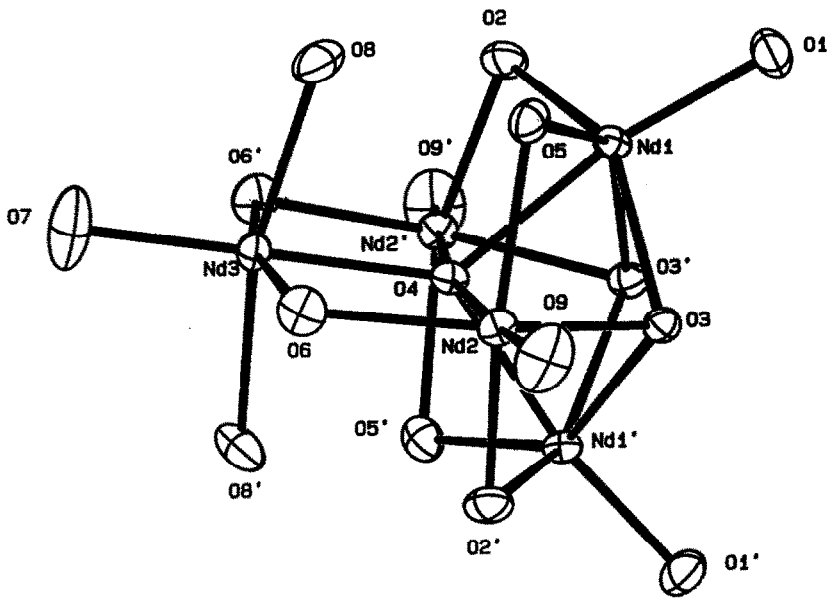

Fig. 2. View of the trigonal bipyramidal Nd_5O_{16} core.

observed for the other terminal Nd—O—C angles. The O(8)···O(5) distance of 2.737(13) Å is consistent with the presence of a hydrogen bond, which is further supported by the broad absorption at 3337 cm^{-1} in the IR spectrum. The Nd—O bond lengths vary in the order Nd—μ_5-O ≈ Nd—O(H)R > Nd—μ_3-OR > Nd—μ_2-OR > Nd—OR, the Nd—μ_5-O bond lengths displaying the largest variations.

Pentanuclear clusters remain relatively scarce, although yttrium and lanthanide oxoalkoxide derivatives such as $(\eta^5\text{-Cp})_5M_5(\mu_5\text{-O})(\mu_3\text{-OR})_4(\mu_2\text{-OR})_4(OR)_5$ (M = Y, R = Pr^i;[13] Gd, R = Bu^t[14]) or $Y_5(\mu_5\text{-O})(\mu_3\text{-OR})_4(\mu_2\text{-OR})_4(OR)_5$ (R = Pr^i[6,15]) have been shown to have a tetragonal pyramidal framework. In fact, the structure of $Nd_5(\mu_5\text{-O})(\mu_3\text{-OR})_2(\mu_2\text{-OR})_6(OR)_5(ROH)_2$ (M_5O_{16} core) can be considered as being derived from that of $Y_5O(OPr^i)_{13}$ (M_5O_{14} core) by the addition of two isopropanol molecules to the same basal metal atom, which results in the conversion of two μ_3-alkoxide groups into μ_2-alkoxide groups in order to preserve hexacoordination for all metal centres. Solvation alters the initial framework, and the resulting coordination polyhedron is a trigonal bipyramid with six doubly-bridging alkoxide groups along the edge connecting the apical and equatorial metal centres. Two μ_3-OR ligands cap the triangular faces formed by Nd(1) and Nd(1′) and one of the apical metals. The overall structure is thus different from the heterometallic lanthanide alkoxide $La_2Na_3(\mu_4\text{-OR})_3(\mu_2\text{-OR})_6(THF)_5$ (R = *p*-tolyl), for which the metal–oxygen core is also a trigonal bipyramid.[16] Distortion of the neodymium cluster is evidenced by the angles around the μ_5-oxo ligand. The presence of three terminal ligands on Nd(3) leads to a reduction of the angle between the two other Nd—O equatorial bonds [Nd(1)—O(4)—Nd(1′) 95.7(4)°] as well as of that of the apical bending [Nd(2)—O(4)—Nd(2′) 170.8(5)°]. In all previously reported examples, the μ_5-O^{2-} ligands have a square pyramidal environment, and thus the geometry observed here appears to correspond to a new coordination mode of the oxo anion, as well as to a metal polyhedron unprecedented for an oxoalkoxide. A change from a square pyramidal polyhedron into a trigonal bipyramidal one by electron donors has also been noted for metal carbonyl clusters,[17] but metal–metal bonding and the nature of the ligands led to an overall metal–carbon core which is different from the metal–oxygen core described here.

These results show that the composition of the solution resulting from reaction between isopropanol and neodymium chips is much more complex than anticipated. Neodymium is less reactive towards isopropanol than yttrium, and no reaction is observed between neodymium, and isopropanol without a catalyst. Mercuric acetate appears to be a better choice than mercuric chloride since it avoids halide contamination of the final material.* Acti-

* Even small amounts of mercuric chloride as catalyst (6.10^{-4} M per Nd) can lead to contamination by the chloroalkoxide $Nd_6Cl(OPr^i)_{17}$, which crystallizes by concentration of the mother liquor and which was identified by the crystal data.[11]

vation of neodymium can also be achieved in neat isopropanol by sonochemistry (600 W over 48 h), but the consumption of the metal and thus the total yield of the neodymium isopropoxide derivatives remains poor ($\approx$ 15%). The IR spectra of the two adducts **1** and **2** mainly contain the absorption bands of the organic ligands and thus they display only small differences in the OH and M—O stretching region. ^{1}H NMR spectra at various temperatures and in different solvents suggest magnetic, non-equivalent isopropoxo groups but the signals are broad and poorly resolved due to the paramagnetism of the compounds and/or exchange phenomena. Thus, the difference in reactivity provide better criteria for the distinction between **1** and **2**. Freshly isolated $[Nd(OPr^i)_3(Pr^iOH)]_4$ reacts with $[Al(OPr^i)_3]_4$ to give the volatile, heterometallic alkoxide $NdAl_3(OPr^i)_{12}$.[18] No reaction is observed in similar conditions between the oxoisopropoxide solvate **2** and the aluminum alkoxide. The oxoalkoxide solvate **2** is much more unstable than **1** with respect to decomplexation reactions.

Oxoisopropoxides, $M_5O(OPr^i)_{13}$, appear to display a special stability, since such compounds are obtained "even with exceptional precaution against hydrolysis"[15] by various synthetic routes and with numerous oxophilic trivalent metals (M = In, Sc, Y, Yb;[15] La[19]). Isolation of an oxoisopropoxide such as **2** directly from the reaction medium without drying provides evidence that oxo derivatives are probably also formed directly in the course of attack of the metal during the electron transfer reactions.

(*Received* 12 *December* 1990; *accepted* 20 *March* 1991)

Abstract—The mixed metal (Ca,Na) complex of benzene-1,2-dioxydiacetic acid ($BDDAH_2$), $\{[Na_2Ca(C_{10}H_8O_6)_2(H_2O)_5]\cdot 2H_2O\}_n$ has been prepared and its crystal structure determined by X-ray diffraction from data collected at 178 K. The calcium is bonded to the four "inner" oxygens of two BDDA ligands giving almost square eight-coordination [Ca—O, 2.323–2.513(3) Å]. Sodium ions link the calcium units via the "outer" carboxyl oxygens forming an infinite chain polymer. Water molecules complete four- and five-coordination about each sodium [Na—O, 2.282–2.428(4) Å].

The dicarboxylic acid, benzene-1,2-dioxydiacetic acid ($BDDAH_2$) or *o*-phenylenedioxydiacetic acid, has proved a versatile ligand for complexation of a number of metal ion types.[1] Among these are the univalent metal ions Li,[2] Na,[3] K,[4] Cs,[5] and divalent metal ions Ca, Mn, Zn, Co, Ni[6] and Mg.[3] A univalent–trivalent metal complex (Na,La) is also known.[7] With the exception of the nickel complex $\{[Ni(BDDAH)_2(H_2O)_2]\cdot H_2O\}$, where the BDDAH ligands are unidentate through the carboxylic acid group, the stereochemistry of these complexes is based on a pentagonal plane with four of the donors provided by the "inner" oxygens of the planar ligand. This is the preferred conformation of the free ligand, as seen in the ionic compound $(NH_4)_2(BDDA)$.[3] In a project to investigate the mixed metal complexes of BDDA, using the efflorescent sodium complex $[Na_2(BDDA)_2(H_2O)_8]$[2] as the starting material, small quantities of a stable, colourless crystal were obtained, with cell parameters only slightly different from the parent compound. Crystal structure determination confirmed the presence of calcium in a complex of formula $\{[Na_2Ca(BDDA)_2(H_2O)_5]\cdot 2H_2O\}_n$, reported here.

EXPERIMENTAL

The compound was prepared by the addition of a stoichiometric amount of aqueous $Ca(NO_3)_2$ to an aqueous solution of $[Na_4(BDDA)_2(H_2O)_8]_n$. The latter was prepared by the titration of $BDDAH_2$ with NaOH, as previously described.[3] A small quantity of well-formed, colourless, bipyramidal crystals formed from the solution after partial evaporation at room temperature over several weeks.

Crystal data

$C_{20}H_{30}CaNa_2O_{19}$, $M_r = 660.5$, triclinic, space group $P\bar{1}$, $a = 9.459(6)$, $b = 10.607(7)$, $c = 14.367(8)$ Å, $\alpha = 101.89(4)$, $\beta = 105.33(3)$, $\gamma = 91.55(4)°$, $V = 1355(1)$ Å^3, $Z = 2$, $D_c = 1.618$ g cm^{-3}, $D_m = 1.61$ g cm^{-3}, $T = 178$ K.

Data collection, structure solution and refinement

Data were collected from a specimen measuring $0.45 \times 0.27 \times 0.20$ mm^3 on an Enraf–Nonius CAD-4 diffractometer fitted with a low temperature (178 K) accessory. 4552 reflections were collected ($2\theta_{max} = 50°$: *hkl* range: $h = -11$ to 11 $k = -12$ to 12, $l = 0$ to 17), giving 4314 unique of which 3614 with $I > 3\sigma(I)$ were used in structure refinement. Crystal monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) was used, with empirical absorption corrections applied to the data. A total loss of *ca* 16% in the intensities of three standards monitored during the 60 h data collection period indicated significant crystal decay, which was allowed for by scaling. The structure was solved using direct methods (SHELXS 86[8]) and refined using SHELX 76.[9] Neutral atom scattering factors and f', f'' terms for anomalous dispersion were taken from ref. 10. Blocked-matrix least-squares refinement with anisotropic thermal parameters on all non-hydrogens gave $R^* = 0.048$. Unit weights were used. Hydrogen atoms were located by difference methods and included in the refinement at fixed positions with their isotropic thermal parameters set invariant at 0.05 Å^2. The maximum peak in the final difference-Fourier analysis was *ca* 0.2 e Å^{-3}.

Bond distances and angles about the coordination polyhedra are given in Table 1. Tables of atomic coordinates, anisotropic thermal parameters, intraligand bond distances and angles, hydrogen atom coordinates and observed and calculated structure factors have been deposited with the Editor as supplementary material: copies are available on request from the Editor or the Authors. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

* $R = \Sigma ||F_o| - |F_c|| / \Sigma |F_o|$.

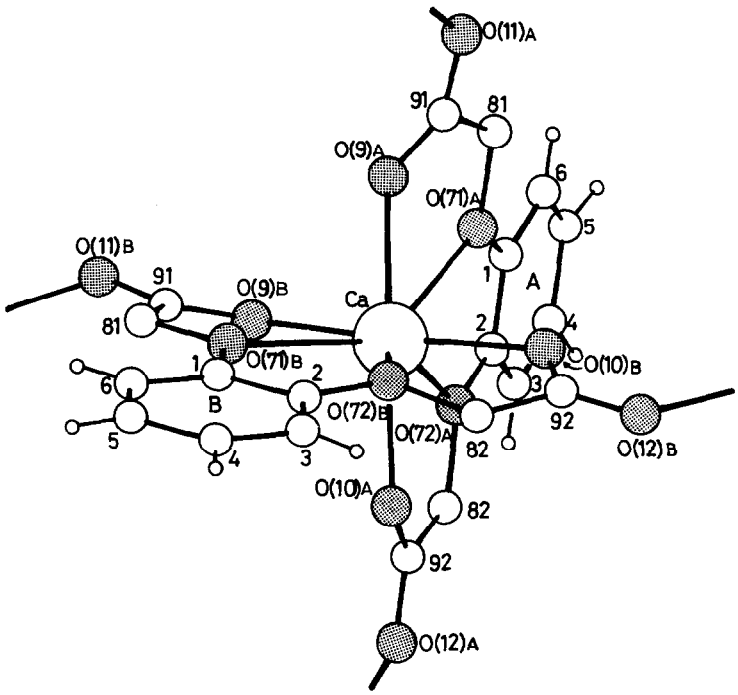

Fig. 1. Molecular configuration for the calcium complex centre. Unless otherwise indicated, atoms are carbons. Methylene hydrogens are omitted for clarity.

DISCUSSION

The structure of the complex comprises eight-coordinate calcium centres involving the four "inner" oxygens of two BDDA ligands (Fig. 1). These units are linked via the "outer" carboxylate oxygens of the ligand through $Na(H_2O)_n$ complex centres to give a cruciform chain motif which extends through the *a* direction of the unit cell (Fig. 2).

The coordination about calcium is best described as distorted square and is quite different from that observed in the 1 : 1 Ca–BDDA complex polymer, $[Ca(BDDA)(H_2O)_2]_n$,[6] in which the stereochemistry is pentagonal bipyramidal, with water molecules occupying the axial sites and an "outer" carboxylate oxygen providing the bridging link in the polymer. This oxygen lies in the fifth site of the pentagonal plane. The links to the four "inner" oxygens of the BDDA ligands are similar in both complexes: Ca—O(ether): Ca—O(carboxyl), 2.460–2.513(3) Å; 2.323–2.357(3) Å, respectively

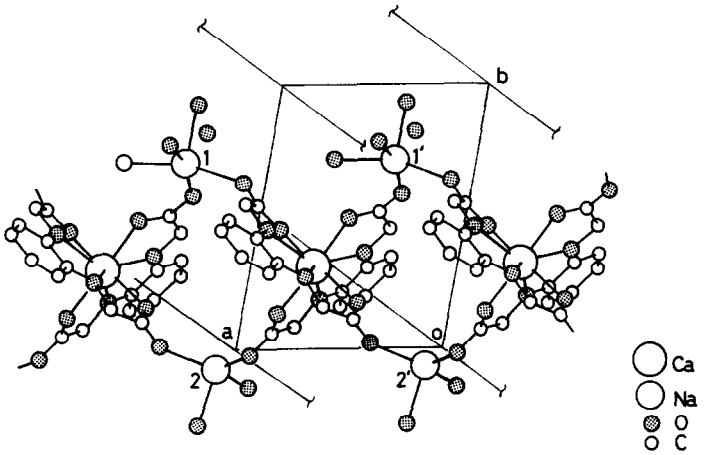

Fig. 2. Packing in the unit cell showing the bis-$Na(H_2O)_n$ bridged chains extending along the *a* cell direction.

(this example), cf. 2.516–2.521(3) Å; 2.308–2.336(3) Å, respectively (the 1 : 1 example).[6] These values are relatively inflexible for most divalent complexes of BDDA where the metal ion lies in the ligand cavity. In the univalent (Group 1A) metal ions, ionic radius is important, with lithium in $[Li_2(BDDA)(H_2O)_3]_2$ giving the best fit and almost equi-dimensional bond distances [Li—O, 2.010–2.097(5) Å].[2] With the polymeric caesium complex $[Cs_2(BDDA)(H_2O)_2]_n$ the caesium ion lies outside the ligand cavity, [Cs—O, 3.070–3.246(6) Å].[5]

Among the other 1 : 2 metal : BDDA complexes, no comparable mode of complexation is found. With $Na[La(BDDA)_2(H_2O_2)]\cdot 4H_2O$,[7] two water molecules as well as the "inner" oxygens of the two BDDA ligands complete an s-bicapped square antiprismatic coordination about La. However, the sodium ions act in a similar manner to the present example in providing $[Na(H_2O)_n]$ bridging systems via BDDA oxygens.

The BDDA ligands in the complex are essentially planar, which is the preferred conformation for this molecule in both coordinated and uncomplexed forms, e.g. $[(NH_4)_2(BDDA)]$.[3] Torsion angles for the two side-chains in the A and B ligands [C(6,3)—C(1,2)—O(7)—C(8), C(1,2)—O(7)—C(8)—C(9), O(7)—C(8)—C(9)—O(9,10)] are −3.1, +3.1, +1.2, −8.6; +170.2, +177.9, +170.1, +178.4; −8.7, +1.9, −6.0, +0.8°, respectively, for the two chains.

The four "outer" carboxylate oxygens of the two BDDA ligands are bonded to sodium atoms [O(11)A—Na(1), 2.404(4) Å; O(11)B—Na(1)′, 2.347(4) Å; O(12)A—Na(2), 2.282(4) Å; O(12)B—Na(2′), 2.315(4) Å] (primed atoms represent translation of one unit along the *a* axis in the cell, forming the chain polymer). The coordination about Na(1) and Na(2) is different, with Na(1) square pyramidal five-coordinate and Na(2) trigonal pyramidal four-coordinate. Apart from the bonds to the bridging carboxyl groups, the coordination about each sodium is completed by water molecules: Na(1)—Ow(1), 2.358(4) Å, 2.377(3) Å; Na(1)—Ow(7), 2.428(4) Å; Na(2)—Ow(4), 2.376(3) Å; Na(2)—Ow(5), 2.302(4) Å. The remaining water molecules in the structure [Ow(2),Ow(6)] are not coordinated and exist as molecules of hydration. Hydrogen bonding interactions between the alternating layers of complex $Ca(BDDA)_2$ and their associated hydrated sodium bridges with the lattice waters are also present.

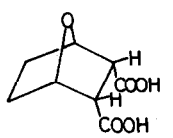
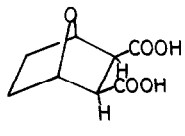
(*Received* 12 *December* 1990; *accepted* 20 *March* 1991)

Abstract—The calcium complex with the herbicide Endothall (7-oxabicyclo-[2.2.1]-heptane-2,3-dicarboxylic acid) has been synthesized and its structure determined by X-ray methods. The seven-coordination about calcium is irregular comprising four oxygens from two carboxylate groups (two bridging), an ether oxygen [Ca—O, 2.387–2.508(3) Å] and two water molecules [Ca—O, 2.389, 2.398(4) Å]. The carboxylate groups on the Endothall moiety adopt an *exo* rather than an *endo* configuration.

Endothall is the trade name for the herbicide 7-oxabicyclo-[2.2.1]-heptane-2,3-dicarboxylic acid, introduced in 1951 by Pennsalt Chemical Corporation.[1,2]



endo-



exo-

The carboxylic acid groups in Endothall were assumed to adopt an *endo* configuration relative to the 1,4-oxo-bridged cyclohexane ring.[2] However, a crystal structure determination of Endothall hydrate confirmed the *exo* configurations for the two carboxylic acid groups.[3] In the only known metal complex of this dicarboxylic acid,[4] the acid groups are also *exo* to the ring system. Furthermore, this metal complex is unusual, of the type $[Cu(H_2O)_6]^{2+}[CuL_2]^{2-}$, with each Endothall ligand tridentate (two carboxylate and one ether oxygen). The chemically stable calcium complex reported here is morphologically similar to the copper complex, although it was not expected to be similarly ionic, on the basis of common calcium carboxylate interactions.[5]

EXPERIMENTAL

Preparation

The complex was synthesized by digesting for several hours at 90°C, a 50% aqueous ethanolic solution of Endothall with excess solid calcium carbonate. Unreacted carbonate was removed by

* Author to whom correspondence should be addressed.

vacuum filtration and the solution concentrated by room temperature evaporation over a period of several weeks, giving colourless, pseudo-hexagonal, prismatic crystals suitable for structure determination. Preliminary X-ray studies, density measurement and chemical analysis indicated a formula $[Ca(L)(H_2O)_2]$. (Found: C, 34.7; H, 4.4. Required for $C_8H_{12}CaO_7$: C, 36.9; H, 4.64%.)

Crystal data

$C_8H_{12}CaO_7$, $M_r = 260.3$, triclinic, space group $P\bar{1}$, $a = 6.177(1)$, $b = 8.645(2)$, $c = 10.246(3)$ Å, $\alpha = 70.95(2)$, $\beta = 84.03(2)$, $\gamma = 74.04(2)°$, $V = 497.2(3)$ Å^3, $Z = 2$, $D_c = 1.737$, $D_m = 1.72$ g cm^{-3}, $F(000) = 272$, $\lambda = 0.71073$ Å, μ(Mo-K_α) = 6.3 cm^{-1}, $T = 293$ K.

Data collection

X-ray data were collected on a Nicolet R3m four-circle diffractometer, using graphite crystal monochromatized Mo-K_α X-radiation. A total of 1245 unique reflections were collected up to $2\theta_{max} = 45°$ from a crystal with dimensions 0.08 $\times 0.08 \times 0.14$ mm^3. Of these, 979 with $I > 2.5\sigma(I)$ were considered observed and used in structure refinement. Data were corrected for absorption. The structure was determined using the automatic Patterson procedure of SHELXS 86[6] and refined by full-matrix least-squares (SHELX 76[7]) to residuals $R = (\Sigma \|F_o| - |F_c\|/\Sigma |F_o|)$ of 0.031 and $R_w = [\Sigma w(\|F_o| - |F_c\|^2/\Sigma w \|F_o\|^2)^{1/2}]$ of 0.030. A value of $w = 1.00/(\sigma^2 F_o + 2.7 \times 10^{-4} F_o^2)$ was used. Hydrogen atoms were located in a difference-Fourier analysis and included in the refinement with both positional and thermal parameters refined. Neutral atom scattering factors were used[8] with f', f'' for anomalous dispersion from ref. 8. Bond distances and angles are listed in Table 1, while atomic coordinates, anisotropic thermal parameters, hydrogen atom coordinates and observed and calculated structure factors have been deposited with the Editor as supplementary material; copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

The structure of the title compound $[Ca(C_8H_8O_5)(H_2O)_2]_n$ involves oxygens of both carboxylate groups and the bridging ether oxygen of the Endothall ligand and two coordinated water molecules, completing an irregular seven-coordination about calcium (Fig. 1). Three of the ligand oxygens [O(111), O(211) (carboxyl) and O(36) (ether)] coordinate symmetrically to calcium [Ca—O, 2.419, 2.445, 2.508(3) Å, respectively]. This is analogous to the tridentate (but bis) mode found for the ligand in the copper(II)–Endothall anion, $[Cu(C_8H_8O_5)_2]^{2-}$.[4] The same carboxylate oxygens form bridges to other calcium ions across inversion centres in the cell [Ca—O(111)′ $(-x, -y, -z)$, 2.452(3) Å: Ca—O(211)′ $(1-x, -y, -z)$, 2.387(2) Å]. The result of this is an infinite zigzag polymer

structure which extends through the cell in the *a* direction (Fig. 2). The two water molecules [Ow(1), Ow(2)] complete the coordination sphere about calcium [Ca—O, 2.398, 2.389(4) Å, respectively]. Complex stability is enhanced by the presence of hydrogen bonds involving these water molecules and the uncoordinated carboxyl oxygens [O(110), O(210)] [O(110)···Ow(1)′ $(-x, -y, -z)$, 2.660 Å; O(110)···Ow(2)′ $(x, -1+y, z)$, 2.714 Å; O(210)···Ow(1)′ $(-x, 1-y, -z)$, 2.858 Å], as well as the coordinated oxygen [O(111)···Ow(1)′ $(-x, -y, -z)$, 2.955 Å]. The coordinated oxygens also form intermolecular hydrogen bonds [O(111)···O(111)′ $(-x, -y, -z)$, 2.735 Å; O(211)···O(211)′ $(1-x, -y, -z)$, 2.719 Å]. A polymeric mode is the one expected for calcium carboxylates,[5] although no completely analogous examples are known. The present example is a variation of the Type 3 (malonate) mode of complexation in calcium carboxylates, unique to the dicarboxylates.[9] Furthermore, Ca—O bond distances are considered normal for these compounds.

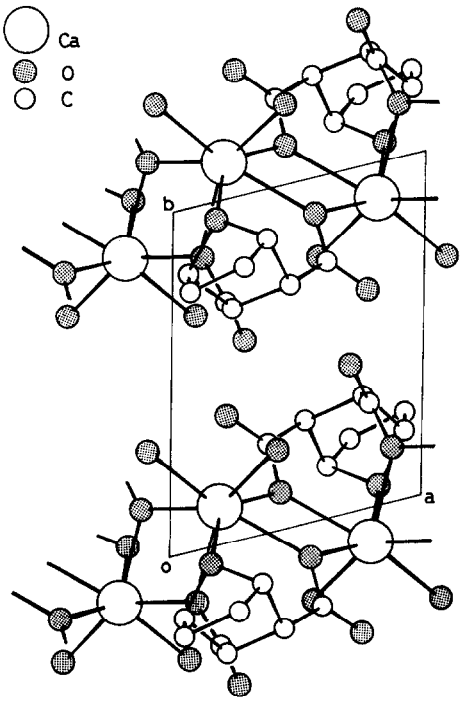

Fig. 2. Packing of the complex in the unit cell viewed down *a*.

Within the Endothall ligand, bond distances and most angles are comparable with those for the parent acid.[3] The configuration of the acid groups is *exo* rather than *endo* relative to the oxo-bridged cyclohexane ring. This is also observed for the copper(II) complex.[4] In both examples, the observed tridentate mode of complexation is possible only with the *exo* configuration. Some conformational differences in the carboxylate groups indicate slight asymmetry in the ligand relative to the metal. The torsion angles about the carboxylate groups [C(6)—C(1)—C(11)—O(111) and C(3)—C(2)—C(21)—O(211)] are −34.1, +24.1° compared with −26.2, +54.9° in the copper complex[4] and −90.5, +0.7° in the parent acid.[3]

IMINO-ETHER COMPLEXES OF PLATINUM: *cis*-$[PtCl_2(NH{=}C(OR)Me)_2]$ AND $[PtCl_4(NH{=}C(OR)Me)_2]$, WHERE R = Me, Et AND Pr^i. PREPARATION, CHARACTERIZATION AND X-RAY STRUCTURE FOR $[PtCl_2(NH{=}C(OPr^i)Me)_2]_2$

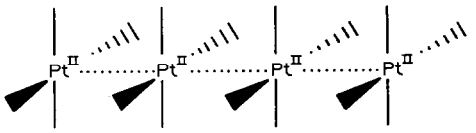
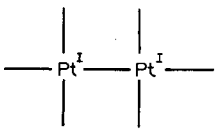
Abstract—The reaction of *cis*-$PtCl_2(NCMe)_2$ with KOH or KOPh in MeOH, EtOH or Pr^{i}OH produces the imino-ether complexes $[PtCl_2(NH{=}C(OR)Me)_2]$ which have been characterized by IR, NMR and elemental analysis. The crystal structure of $[PtCl_2(NH{=}C(OPr^i)Me)_2]_2$ was determined by X-ray diffraction. Each molecule comprises two units of $[PtCl_2(NH{=}C(OPr^i)Me)_2]$ with a Pt---Pt distance of 3.327(1) Å. The lack of any bridging ligand suggests the presence of hydrogen bonds. The N(4)—Cl(3′) and N(11)—Cl(2′) distances are within the range of van der Waals' interactions. Oxidation reactions of these compounds with $C_6H_5ICl_2$ give the corresponding platinum(IV) complexes $[PtCl_4(NH{=}C(OR)Me)_2]$.

Metal–metal bonding is well known for platinum in stacked platinum(II) complexes[1–3] of type **A**, where the filled d_{z^2}–d_{z^2} interaction is stabilized by mixing with the higher lying p_z–p_z interactions. Also Pt^{III}—Pt^{III} dimers are known,[4–11] wherein two d^7–d^7 ML_5 fragments are united such that the M—M σ bond is formed by Pt $5d_{z^2}$–Pt $5d_{z^2}$ overlap.



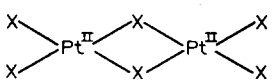
A

In addition, Pt—Pt bonding is often found in Pt^I—Pt^I dimers[12–14] of the type shown in **B**, where the M—M bond is formed from $d_{x^2-y^2}$ interactions. Basically in **B** the M—M bond occupies the fourth coordination site of an otherwise square-planar platinum(II) complex, i.e. the d^3-L_3Pt fragment is isolobal with hydrogen or methyl.



B

The bonding in edge-shared d^8–d^8 square-planar complexes of the general formula shown in **C** below was of interest to us. The principal interactions between the platinum atoms should involve the d_{xy}–d_{xy} orbitals. These are ideally suited to form M—M σ and σ^* interactions.



C

Oxidation of an edge-shared Pt^{II}–Pt^{II} dimer of type **C** to give either a mixed valence Pt^{II}—Pt^{III} or Pt^{III}—Pt^{III} dimer could result in the formation of a Pt—Pt bond of order 1/2 and 1, respectively. This has recently been seen where the bridging groups X in **C** are C_6F_5.[15] Here, presumably M—M bonding is assisted by the presence of the μ-C_6F_5 ligand

which provides both an electron-deficient bridge (3c–2e) and a naturally short Pt—Pt distance because of the relatively small Pt—C distances. For X = Cl, the Pt---Pt distance is likely to be too long to allow for significant Pt^{III} to Pt^{III} M—M bonding. We wished, therefore, to prepare alkoxy- or phenoxy-bridged Pt^{II}—Pt^{II} dimers in order to examine their redox properties and their possible ability to support Pt^{III} to Pt^{III} M—M bonds. It is, for example, known that whereas W_2Cl_{10}[16] contains no M—M bond, the compound $W_2(OMe)_{10}$[17] does, cf. W—W = 3.8 Å in W_1Cl_{10} and 2.7 Å in $W_2(OMe)_{10}$. We report here on an investigation intended to yield μ-OR-bridged platinum(II) dimers that proved unsuccessful because of the reactivity of the ancillary ligands. The work described herein provides a general route to imino-ether complexes of platinum(II) chloride.

RESULTS AND DISCUSSION

Syntheses and characterizations

The reaction of the complex *cis*-$PtCl_2(NCMe)_2$ with nucleophiles such as KOPh or KOH in several alcohols as solvents gives the imino-ether complexes $[PtCl_2(NH{=}C(OR)Me)_2]_2$ [R = Me (**1**), Et (**2**) and Pr^i (**3**)] because of the addition of alcohols to the triple C≡N bond. These reactions are base-catalysed, where the bases are not consumed in the process.

When the alcohols are EtOH or Pr^iOH, the corresponding imino-ether complexes are formed in a good yield within a few hours. When the reaction is carried out in MeOH, the solid which precipitated after 2 or 4 h shows strong ν(C=N) and ν(N—H) absorptions in its IR spectra. Its elemental analysis agrees with the stoichiometry $PtCl_2(NH{=}C(OMe)Me)_2$ but its IR spectrum in the region 290–350 cm^{-1} shows several absorptions corresponding to ν(Pt—Cl). This solid is insoluble in all common solvents and only very sparingly soluble in CH_2Cl_2, in contrast to complexes **2** and **3** which are soluble in CH_2Cl_2. If the reaction of *cis*-$PtCl_2(NCMe)_2$ with KOH in MeOH is allowed to proceed for 30 h, the solid precipitated is completely soluble in CH_2Cl_2 and shows similar IR and ^1H NMR spectra to those of complexes **2** and **3**. It is possible that the insoluble form of **1** has a polymeric hydrogen-bonded structure rather than the dimeric type observed for **3** (see later).

All the imino-ether complexes $[PtCl_2(NH{=}C(OR)Me)_2]_2$ [R = Me (**1**), Et (**2**), Pr^i (**3**)] show ν(C=N) and ν(N—H) absorptions in the regions 1630-1640 cm^{-1} and 3230–3250 cm^{-1}, respectively. Two ν(Pt—Cl) absorptions at 320–330 cm^{-1} are observed also, in agreement with their symmetry (C_{2h}) (Table 1).

^1H NMR spectral data for these complexes are collected in Table 2. Characteristic for all samples is the appearance of a N—H signal as a broadened singlet at about 7.9 ppm, a methyl group signal as a singlet at about 2.6 ppm and signals corresponding to the alkoxy group.

X-ray crystal structure of $[PtCl_2(NH{=}C(OPr^i)Me)_2]_2$ (3)

Figure 1 shows the ORTEP drawing of the molecule. In the solid state there are centrosymmetric dimers $[PtCl_2(NH{=}C(OPr^i)Me)_2]_2$ with a distance of only 3.327(1) Å between both metal centres. A summary of crystal data is given in Table 3 and selected bond distances and bond angles are given in Table 4.

Each platinum atom has a local square-planar coordination geometry as expected for platinum(II], with a *cis* disposition of the ligands. Pt—Cl bond lengths [2.309(2) and 2.317(2) Å] and Pt—N bond lengths [2.02(1) Å and 2.01(1) Å] are all longer than those in *cis*-$PtCl_2(NCMe)_2$.[18] These changes reflect the *trans*-influence order of the ligands (imino-ether > nitrile) and the hybridization at nitrogen.

The imino-ether ligands are trigonal with angles Pt(1)—N(11)—C(12), N(1)—C(12)—C(17), N(11)—C(12)—O(13) and C(17)—C(12)—O(13) close to 120° as a consequence of C(sp^2)–N(sp^2) hy-

[a] $CDCl_3$ solutions, shifts are related to external TMS.

bridization. The C—N bond length is 1.269(11) Å, in agreement with a double C=N bond.[19] The structure of the ligand indicates the *cis* addition of the alcohol to the triple C≡N bond.

The relatively short Pt(1)—Pt(2) distance in the absence of bridging ligands suggests the presence of hydrogen bonds. The observed distances in **3** for N(4)—Cl(3′) = 3.368(7) Å and N(11)—Cl(2′) = 3.322(7) Å, fall within the range expected for NH---Cl bridges, 3.25–3.45 Å.[20] Thus we propose it is hydrogen bonding that is responsible for the observed eclipsed dimer that is reminiscent of d^4–d^4 L_4M—ML_4 complexes.

The weak hydrogen-bonding interactions

responsible for the dimeric structure of these complexes in the solid state probably do not have any effect on the solution chemistry. The reactions of the complexes $[PtCl_2(NH{=}C(OR)Me)_2]_2$ (R = Et, Pr^i) with $C_6H_5ICl_2$ in equimolar amounts, do not lead to Pt^{III}—Pt^{III} dinuclear compounds with M—M bonds, but to mixtures of starting materials and platinum(IV) complexes of stoichiometry $[PtCl_4(NH{=}C(OR)Me)_2]$.

The platinum(IV) complexes can be prepared in

good yields by the reaction of $[PtCl_2[NH{=}C(OR)Me)_2]_2$ with $C_6H_5ICl_2$ in a 1:2 ratio in $CHCl_3$. Elemental analyses and ^1H NMR data for the platinum(IV) complexes are consistent with the proposed stoichiometry.

Related findings

Certain cationic platinum complexes with imino-ether ligands have been reported. These were prepared by the reactions of [PtClMe(COD)] or *trans*-$PtRXL_2$ (R = Me, X = Cl, L = PMe_2Ph, $AsMe_3$; R = CF_3, X = I, L = PMe_2Ph) with silver salts ($AgPF_6$, $AgBF_4$) and perfluoroaryl nitriles in various alcohols. The final products depend on the alcohol and in some cases on the silver salt used.[21-23]

The authors suggest a mechanism involving the initial formation of a platinum-nitrile π bond, delocalization of the positive charge from platinum onto the C≡N bond leading to activation of the C—N bond towards nucleophilic attack by the alcohol. Refluxing of the coordinated σ-bonded nitrile complexes for several hours did not lead to the imino-ether formation.

In this work, we have found that the synthesis of neutral platinum(II) imino-ether complexes from coordinated σ-bonded nitriles is promoted by a base-catalysed process. The imino-ether ligand is bound more tightly than the nitrile in the *cis*-$PtCl_2L_2$ complexes so that the complexes once formed do not enter into a catalytic cycle.

EXPERIMENTAL

IR spectra were recorded (4000–200 cm^{-1}) on a Perkin–Elmer 283 spectrophotometer, using Nujol mulls between polyethylene sheets. ^1H NMR spectra were recorded on a Varian XL300 instrument. $PtCl_2(NCMe)_2$[24] and $C_6H_5ICl_2$[25] were prepared as already reported. Reactions using KOPh were carried out under N_2.

$[PtCl_2(NH{=}C(OMe)Me)_2]$ (**1**)

To a suspension of *cis*-$PtCl_2(NCMe)_2$ (0.44 g, 1.264 mmol), in 20 cm^3 of anhydrous MeOH, was added KOH (71 mg, 1.264 mmol). The suspension was stirred for 30 h to give a white solid, which was filtered and recrystallized from CH_2Cl_2/OEt_2, 0.2811 g (yield, 54%). Found: C, 17.7; H, 3.3; N, 6.6. Calc. for $[PtCl_2(NH{=}C(OMe)Me)_2]_2$: C, 17.5; H, 3.4; N, 6.8%.

$[PtCl_2(NH{=}C(OEt)Me)_2]_2$ (**2**)

(a) To a solution of KOPh (0.2459 g, 1.86 mmol) in 20 cm^3 of absolute EtOH was added *cis*-$PtCl_2(NCMe)_2$ (0.2163 g, 0.6214 mmol). The suspension was stirred for 2 h to give a white solid, which was filtered and recrystallized from CH_2Cl_2/OEt_2, 0.16 g (yield, 63%).

(b) To a suspension of *cis*-$PtCl_2(NCMe)_2$ (0.5 g, 1.436 mmol) in 30 cm^3 of absolute EtOH was added KOH (80.6 mg, 1.436 mmol). The suspension was stirred for 4 h to give a white solid, which was filtered and recrystallized from CH_2Cl_2/OEt_2, 0.41 g (yield, 70%). Found: C, 21.8; H, 3.9; N, 6.3. Calc. for $[PtCl_2(NH{=}C(OEt)Me)_2]_2 \cdot CH_2Cl_2$: C; 21.3; H, 4.0; N, 6.2%.

$[PtCl_2(NH{=}C(OPr^i)Me)_2]_2$ (**3**)

To a solution of KOPh (0.4476 g, 3.386 mmol) in 20 cm^3 of Pr^iOH was added *cis*-$PtCl_2(NCMe)_2$ (0.3929 g, 1.129 mmol). The suspension was stirred for 2 h to give a white solid, which was filtered and recrystallized from CH_2Cl_2/OEt_2, 0.2955 g (yield, 60%). Found: C, 26.1; H, 4.6; N, 5.6. Calc. for $[PtCl_2(NH{=}C(OPr^i)Me)_2]_2 \cdot CH_2CL_2$: C, 26.3; H, 4.8; N, 5.9%.

$[PtCl_4(NH{=}C(OEt)Me)_2]$ (**4**)

To a solution of **2** (0.25 g, 0.3062 mmol) in 15 cm^3 of $CHCl_3$ was added $C_6H_5ICl_2$ (0.1683 g, 0.6124 mmol). The solution became red immediately, but changed from red to yellow within a few minutes. After 30 min the solvent was removed *in vacuo* and the oily residue was transformed to a yellow solid by adding OEt_2, 0.19 g (yield, 65%). Found: C, 19.5; H, 3.8; N, 5.1. Calc. for $[PtCl_4(NH{=}C(OEt)Me)_2]$: C, 20.1; H, 3.8; N, 5.8%.

$[PtCl_4(NH{=}C(OPr^i)Me)_2]$ (**5**)

To a solution of **3** (0.30 g, 0.34 mmol) in 15 cm^3 of $CHCl_3$ was added $C_6H_5ICl_2$ (0.19 g, 0.69 mmol). The solution became red immediately, but changed to yellow within a few minutes. After 20 min the solvent was removed *in vacuo* and the residue transformed to a yellow solid by adding OEt_2, 0.233 g (yield, 67%). Found: C, 21.8; H, 3.6; N, 5.0. Calc. for $[PtCl_4(NH{=}C(OPr^i)Me)_2] \cdot CHCl_3$: C, 21.1; H, 3.7; N, 4.5%.

X-ray analysis

A crystal of suitable size but with no well-defined faces, was obtained by cleaving a large piece of the sample in a nitrogen atmosphere glove bag. The crystal was mounted using silicone grease and was transferred to a goniostat where it was cooled to −170°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space revealed intensities with Laue symmetry and systematic absences consistent with space group $P2_1/c$, which was later proven correct by the successful solution of the structure. Following complete data collection, data processing gave a residual of 0.042 for the averaging of 193 unique intensities which had been observed more than once. Four standards measured every 300 data showed no significant trends. No correction was made for absorption.

The structure was solved using a combination of direct methods (MULTAN78) and Fourier techniques. The platinum atom position was obtained from an initial E-map. The remaining non-hydrogen atoms were obtained from subsequent iterations of least-squares refinement and difference Fourier calculations. Hydrogen atoms were included in calculated positions to improve the refinement of the non-hydrogen atoms, however the hydrogen atoms were not refined. Hydrogen atom thermal parameters were fixed at one plus the isotropic thermal parameter of the atom to which they were bonded.

In the final cycles of refinement, the non-hydrogen atoms were varied with anisotropic thermal parameters to a final $R(F) = 0.034$. The final difference Fourier had platinum residuals of 0.88–2.2 e/Å^3. All other residual peaks were less than 0.8 e/Å^3.

The centre of the molecule, e.g. the Pt—Pt midpoint, is at a crystallographic centre of symmetry. In addition, the crystal structure contains a molecule of chloroform at a general position.

Atomic coordinates have been deposited with the Director of the Cambridge Crystallographic Centre.

(*Received* 9 *January* 1991; *accepted* 21 *March* 1991)

Abstract—Four new copper(II) complexes of formula $[Cu(BQDTP)Cl_2]\cdot 2H_2O$ (**I**), $[Cu(BQDTP)Br_2]\cdot 2H_2O$ (**II**), $[Cu(BQDTP)(OH_2)_2](ClO_4)_2$ (**III**) and $[Cu(BQDTP)(NO_3)(OH_2)](NO_3)$ (**IV**), where BQDTP is 1,5-bis(quinoline-8′-yl)-1.5-dithiapentane, have been synthesized and characterized by elemental analysis, conductivity measurements, IR and ligand-field spectral studies and magnetic susceptibility measurements. The X-ray crystal structure of **IV** has been solved at 293 K by single-crystal X-ray analysis. It consists of $[Cu(BQDTP)(NO_3)(OH_2)]^+$ cations and nitrate ions, which are connected by hydrogen bonds to a water molecule. The coordination geometry about the copper atom is an elongated octahedron. The measured bond distances are: Cu—S = 2.343(3) and 2.507(3) Å, Cu—N = 1.986(7) and 1.993(7) Å, $Cu—O_{(water)}$ = 2.030(6) Å and $Cu—O_{(nitrate)}$ = 2.677(7) Å. The IR and electronic spectroscopic data, conductivity and magnetic susceptibility are in agreement with the observed structure.

Complete understanding of the mechanisms governing the physiological behaviour of metalloproteins is only possible once their structures, or at least the structure of the active metallic centre, are known. Before crystallography could be employed to determine protein structures, and hence the bonding and the function of the metal in the protein, it was practice to synthesize and analyse low molecular weight metallic complexes whose chemical and physical properties matched those of the corresponding metalloproteins. X-ray crystallography has only served to solve the structure of some proteins, although other techniques such as high-field NMR and EXAFS are proving of great use in this respect. Nonetheless, simple metallic complexes that imitate biological compounds are still very valuable in understanding the structure of the active centre and reaction mechanisms of those proteins with structures too complicated to be resolved by X-ray analysis or which cannot be crystallized.

The response to the discovery in some copper proteins of two nitrogen and two sulphur atoms coordinated to the metal[1] has been the design of several types of chelating ligands containing these atoms.[2] Of these, some of the most interesting are the quadridentate ligands of linear chain NSSN in which the nitrogen atoms belong to heterocyclic compounds such as imidazole,[3] benzimidazole,[4] pirazol[5] or pyridine,[6] and the sulphur atoms belong to thioethers.

Our work over the last few years has been along these lines.[7] This paper presents some recent results obtained using the ligand 1,5-bis(quinoline-8′-yl)-

EXPERIMENTAL

Physical measurements

Carbon, hydrogen and nitrogen were determined on a Perkin–Elmer 240B microanalyser.

IR absorption spectra (4000–200 cm^{-1}), as KBr and CsI pellets, were recorded on a Perkin–Elmer 1330 spectrophotometer. Electronic reflectance spectra were recorded on an Hitachi U-3200 spectrophotometer equipped with the standard reflectance accessory. Magnetic susceptibilities were measured in the temperature range 300–70 K by the Faraday method with a DSM-5 susceptometer and $HgCo(SCN)_4$ as the calibration standard. Corrections for the diamagnetism of the ligands were applied.

X-ray crystallographic data were obtained on an Enraf–Nonius CAD4 diffractometer. Data reduction and solution were performed on a Micro VAXII using the SHELXS86[8] and VAX/SDP[9] package of programs.

^1H NMR spectra were determined with a Bruker WM250 instrument in $CDCl_3$ using TMS as the internal standard.

Conductivity measurements were carried out on a WTW LF-3 conductivity bridge. Measurements were made for 10^{-3} M solutions in acetonitrile.

Reagents

The 8-mercaptoquinoline hydrochloride (Lancaster Synthesis Ltd), 1,3-dibromopropane (Merck) and copper(II) salts (Merck) were used without further purification. All solvents used were reagent grade and purified by conventional procedures prior to use.

Ligand synthesis

BQDTP was prepared by the method described in the literature[10] using 8-mercaptoquinoline hydrochloride (2.00 g, 10.1 mmol) in absolute ethanol (15 cm^3) and 1,3-dibromopropane (1.04 g, 5.15 mmol) (70% yield). ^1H NMR ($CDCl_3$): δ 8.95 (c, 2H, H-2q), 8.12 (c, 2H, H-4q), 7.43 (m, 8H, H-3,6,7,8q), 3.33 (t, 4H, S—CH_2—), 2.33 (q, 2H, —CH_2—).

Preparation of the complexes

A solution of BQDTP (0.15 g, 0.40 mmol) in hot ethanol (10 cm^3) was added with stirring to a solution of the copper(II) salt (0.40 mmol) in the same solvent (10 cm^3). After a few minutes the solution became green or garnet in colour. The reaction mixture was stirred at room temperature for 7 days and then filtered. The precipitate obtained was washed well with ethanol and then air-dried.

Determination of the crystal structure of $[Cu(BQDTP)(NO_3)(OH_2)](NO_3)$ (IV)

Green, prismatic crystals were obtained by slow evaporation of an ethanolic solution of the complex. A crystal, dimensions *ca* $0.60 \times 0.10 \times 0.05$ mm, was mounted on a glass fibre. Intensity measurements were performed on a CAD4 Enraf–Nonius four-circle diffractometer in ω–θ scan mode using monochromated Cu-K_α radiation. Of 4599 reflections to $\theta_{max} = 65°$, 3801 were unique ($R_{int} = 0.025$) and 1857 with $I > 3\sigma(I)$ were used in all calculations. An empirical adsorption correction was applied,[11] with correction factors of 0.704–1.600. Cell constants were refined from the θ values of 25 reflections in the range 15–36°.

The structure was solved by the heavy-atom method and subjected to full-matrix, anisotropic, least-squares refinement on *F*. Hydrogen atoms were included at the calculated positions with isotropic temperature factors of 5.0 $Å^2$ and included in the structure factor calculations, but their positional parameters were not refined. A secondary extinction correction was applied,[12] with a final coefficient, refined in the least-squares cycle, of 5.25×10^{-7}. The final *R* value was 0.058, with $R_w = 0.059$ (weighting scheme $w^{-1} = \sigma^2(F)$; 323 parameters; $S = 2.1$; maximum Δ/σ in final cycle 0.01; maximum $\Delta\rho = 0.33$ e $Å^{-3}$ near Cu). For a summary of crystal data, see Table 1.†

RESULTS AND DISCUSSION

Elemental analysis and conductance results are presented in Table 2. In general, the compounds synthesized were sparingly soluble in polar solvents and insoluble in non-polar solvents. Solutions of 10^{-3} M in acetonitrile could only be prepared with compounds **III** and **IV**. Their measured molar conductances were in agreement with values published for similar compounds.[13] The value for compound **III** shows it behaves as a 1 : 2 electrolyte in aceto-

nitrile, hence the formula $[Cu(BQDTP)(OH_2)_2](ClO_4)_2$. For compound **IV**, the conductance is in keeping with that of 1 : 1 electrolytes, which can be explained by assuming that one of the nitrate groups is coordinated to the copper(II).

IR spectra

Frequencies were assigned to BQDTP and the complexes (Table 3) bearing in mind the assignments for the quinoline molecule and derivatives,[14,15] 8-mercaptoquinoline,[16] pyridine and derivatives,[17] and those proposed for alkyl sulphides.[18]

Structural information was obtained by comparing the spectra of the complexes with that of the ligand. In the 4000–1600 cm^{-1} region a wide band appears between 3600 and 3300 cm^{-1} with a maximum around 3450 cm^{-1}, also two additional peaks appear at 3620 and 3540 cm^{-1} in compound **III**. These have been assigned to the antisymmetric and symmetric ν(OH) stretching modes. The band between 1650 and 1635 cm^{-1} is due to the δ(OH) modes.[19] The positions of these bands show the water molecules are involved in hydrogen bonds.

In the 1600-1350 cm^{-1} region, the ν_{8b} and ν_{8a} vibrations of pyridine are slightly shifted, but those assigned to the ν_{19a} and ν_{19b} modes split and move 15 and 10 cm^{-1}, respectively, to higher frequencies. The cause, as in pyridine complexes, is that the nitrogen of the heteroaromatic ring donates electrons, the C—N bond is strengthened due to an increase in the electron density of the bond, and the corresponding band appears at higher frequencies.

In the 1350–800 cm^{-1} region, the ν_3 band, assigned to the C—H antisymmetric bending modes in the plane, increases in frequency by 6–11 cm^{-1}. This may be explained as the main effect of donation of the free pair on the nitrogen, which is passed around the ring. The ν_1 band, due to the totally symmetric vibrations of the ring, is also shifted to higher frequencies. This has been related to the strength of the donor–acceptor bond,[20] for which the order **I** ≈ **II** < **III** < **IV** can be established in these complexes, even though the magnitude of the displacement is not very large.

Lastly, in the region 800–400 cm^{-1}, the ν_{6a} and ν_{16b} bands, due to deformations of the ring in and out of the plane, undergo shifts of between +20 and +30 cm^{-1} for the first and +17 and +32 cm^{-1} for the second. This is also good indication of coordination of the pyridinic nitrogen to the copper. Also in this region we have assigned the ν(CS) modes. The small shifts of these bands to higher frequencies indicates, though not very rigorously, that the thioether sulphur atoms of BQDTP are coordinated to the metal.

The spectrum of complex **III** contains a wide,

intense band between 1160 and 1020 cm^{-1} and another strong band at 623 cm^{-1} which have been assigned, respectively, to the $\nu_a(ClO_2)$ antisymmetric stretching mode and to the $\delta(ClO_2)$ bending mode of the perchlorate ion.[21] This is in keeping with the molar conductance value found for this complex.

The spectrum of complex **IV** shows four bands together in the range 1400–1000 cm^{-1}: a strong one at 1385 cm^{-1} and a weak one at 1040 cm^{-1}, which corresponds to the antisymmetrical and symmetrical $\nu(NO_2)$ modes, respectively, of the free nitrate ion,[21] and one of medium intensity at 1290 cm^{-1} and one weak band at 1015 cm^{-1} which represent, respectively, the $\nu_s(NO_2)$ and ν(NO) symmetrical stretching modes of a nitrate group coordinated across an oxygen atom.[22]

In the far-IR region, a medium intensity band at 304 cm^{-1} was found which, since it was not seen in the other complexes, was assigned to the ν(CuCl) modes. The corresponding ν(CuBr) vibration cannot be detected in the spectrum of **II** due to the low resolution of the equipment between 250 and 200 cm^{-1}.

The spectra of compounds **III** and **IV** show weak bands at 318 and 320 cm^{-1}, respectively, which were not seen in the other complexes, and thus suggests they should be assigned to the ν(CuO) modes.[23] In the spectra of all four complexes, a weak band at 400 cm^{-1} and a shoulder at 280 cm^{-1} can be observed, which have been assigned to the ν(CuN) and ν(CuS) modes, respectively.[24]

Electronic spectra

The diffuse reflectance spectra of the complexes (Table 4) contain two classes of bands. One, in the 21,900–22,900 cm^{-1} region, is due to charge-transfer transitions from BQDTP to copper. Additionally, in complexes **I** and **II** there is also a shoulder at 20,390 cm^{-1} and a band at 18,142 cm^{-1}, respectively, which have been attributed to transitions from the halogen to copper.[25]

The solid complexes also exhibit an adsorption

Table 4. Diffuse reflectance spectral data (cm^{-1}) and magnetic moments (BM) for copper(II) complexes[a]

Complex	α	β	θ	μ_{eff}	*d–d*	
I	−48.37	2.66	18.21	1.74	13,558	20,399, 21,949
II	−88.46	3.00	29.45	1.63	13,543	18,142, 22,242
III	−49.50	2.82	17.55	1.68	15,060	22,831
IV	−19.40	2.13	9.10	1.94	14,890	22,742

[a] $1/X = \alpha + \beta T$; θ = Curie–Weiss constant.

band between 13,500–15,500 cm^{-1}. The asymmetric nature of this band is due to an unresolved shoulder at lower frequencies. Although the connection between copper(II) stereochemistry and solid-state electronic spectra is not always straightforward,[26,27] the position of the *d–d* band in all complexes is consistent with a distorted octahedral copper(II) geometry.[28,29]

Magnetic susceptibilities

The solid-state magnetic moments, between 1.60 and 1.95 BM (Table 4) are consistent with an $S = 1/2$ ground state configuration for the d^9 metal ion. Between 70–300 K, all complexes give linear plots of the reciprocal of the molar magnetic susceptibility corrected for temperature; and positive values of 9–30 K for the Curie–Weiss constant (Table 4).

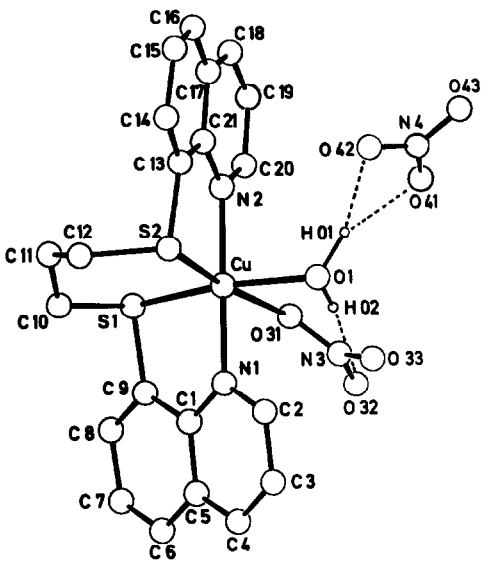

Fig. 1. Perspective view of complex **IV**.

Description of the crystal structure of **IV**

The asymmetric unit of compound **IV** contains a nitrate ion and a monovalent cation formed by a copper atom bound to a molecule of BQDTP, to a nitrate group across one of its oxygen atoms and to the oxygen of a water molecule. The geometry around the copper atom is a tetragonally distorted pseudo-octahedron. The conformation of the complex is shown in Fig. 1. Interatomic bond lengths and angles are shown in Table 5.

In the large number of copper(II) complexes with thioethers that have been characterized structurally,[30] the metal generally sits in a distorted octahedron or is pentacoordinated, with Cu—S bonds lengths in the range 2.297–2.488 Å for equatorial thioether ligands and in the range 2.560–2.919 Å for the axial ligands. The Cu—S bond lengths of 2.343(3) and 2.507(3) Å observed in complex **IV** are typical of thioethers coordinated equatorially and axially, respectively. In keeping with this orientation, the other axial site is filled by an oxygen atom from a nitrate group, with a Cu—O(3) bond length of 2.677(7) Å. This appears to be very large when compared with the bond length of 2.00 Å in copper(II) nitrate in the vapour phase,[31] or with 1.97 Å in other copper(II) complexes where the nitrate group behaves like a monodentate ligand.[32]

In the equatorial plane, two other coordination sites are occupied by the two nitrogen atoms of the quinoline groups, with a mean Cu—N bond length of 1.989(7) Å, in agreement with those observed in copper(II) complexes with a mixture of ligands containing nitrogen heterocycles and oxygen donating ligands.[33] The water molecule occupies the fourth coordination site, the Cu—O(1) bond length being typical of copper(II) complexes with similar coordination.[34] Apart from the excessively large axial bond lengths, departure from octahedral coordination is indicated by the bond angles around the copper atom, in which the greatest differences occur in the angle S(1)—Cu—S(2) [103.5(2)°] and S(1)—Cu—O(1) of [160.3(2)°].

Table 5. Selected bond lengths and angles for the [Cu(BQDTP)(ONO_2)(OH_2)](NO_3) molecule with estimated standard deviations in parentheses

Bond distances (Å)

In BQDTP, the bond lengths and angles of the thioether and quinoline groups are in close agreement with those found in similar ligands.[3–7,35]

With regard to the nitrate groups, the N—O bond lengths in the uncoordinated group are somewhat shorter than the usual distances observed in the coordinated group, but this is of no real significance given the high degree of disorder shown. Both groups participate in hydrogen bonds with the water molecule coordinated to copper(II).

THE PERMUTATIONAL ISOMERISM OF JAHN–TELLER WHEELS

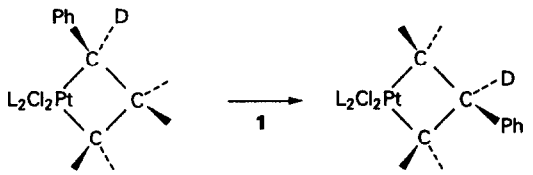
ARNOUT CEULEMANS

Department of Chemistry, Katholieke Universiteit Leuven, Celestijnenlaan 200F, B-3001 Heverlee, Belgium

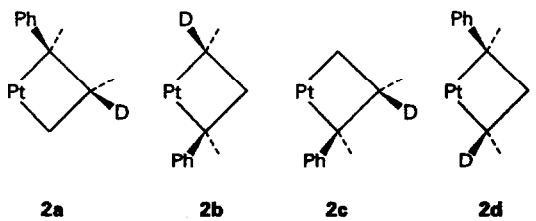
(*Received* 29 *January* 1991; *accepted* 21 *March* 1991)

Abstract—Molecular rearrangements based on a Jahn–Teller mechanism are characterized by a specific permutational isomerism. This is illustrated for the metallacyclobutane rearrangement, proposed by Wilker and Hoffmann, and for the butterfly isomerisation of $Fe(CO)_4$. It is shown that in both cases a full experimental conformation of the proposed Jahn–Teller mechanisms requires the resolution of enantiomeric reaction cycles.

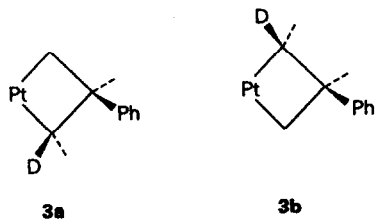
Platinacyclobutanes undergo highly stereospecific skeletal rearrangements of potential catalytic interest. Puddephatt, Tipper and their co-workers[1] first discovered that a carbon atom in the α position, adjacent to the metal, exchanges with the carbon atom in the β position, opposite to the metal. The simultaneous migration of both phenyl and deuterium substituents in **1** clearly establishes the permutational nature of this rearrangement.



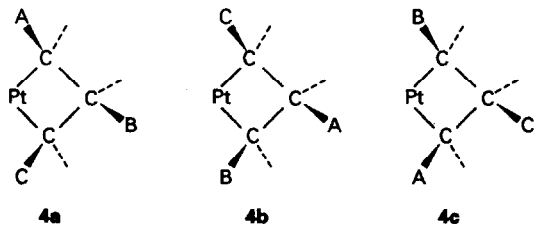
Subsequent experiments by Casey *et al.*[2] demonstrated the high stereospecificity of the Puddephatt reaction. One particularly informative experiment involved the use of platinacyclobutanes with one phenyl and one deuterium on the same side of the metallacycle. There are four such isomers with the phenyl in the α position, as shown in **2**.



Upon heating a mixture of these isomers the phenyl groups can migrate to the β position, in accordance with reaction **1**. The only two β-phenyl isomers that could be obtained are shown in **3**. In both isomers deuterium and phenyl are still on the same side. This proves that the stereochemistry of the metallacycle is retained.



Wilker and Hoffmann[3] have suggested that the Puddephatt rearrangement might be explained by an itinerary around the periphery of a Jahn–Teller wheel. Figure 1 offers a schematic drawing of this mechanism. The structure in the centre has approximate C_{3v} symmetry and is Jahn–Teller unstable. It is surrounded by a Jahn–Teller wheel with three equivalent minima, corresponding to three metallacycle isomers. These isomers have been redrawn below (**4**) in the standard orientation.



Polytopal rearrangements which interconvert these isomers are characterized by two remarkable geo-

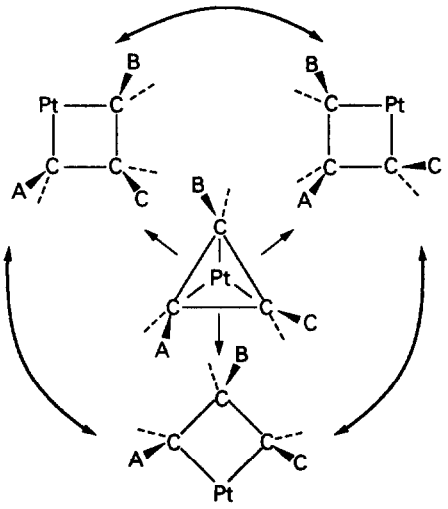


Fig. 1. Metallacyclobutane rearrangement mechanism, according to Wilker and Hoffmann.[3] The structure in the centre is a C_{3v} isomer, which sits atop a Jahn–Teller hill. Distortion of this structure may give rise to three metallacyclobutane isomers. Interconversions of these isomers proceed through a circular potential energy trough, surrounding the Jahn–Teller origin. This trough is the so-called Jahn–Teller wheel.

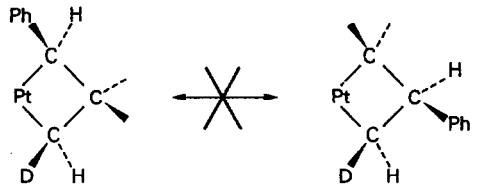
metric constraints: (i) retention of the orientation of the CH_2 groups with respect to the plane of the three carbon atoms, and (ii) retention of the handedness of the tricarbon structure. The first requirement implies that substituents will retain their relative positions with respect to the plane of the metallacycle. This point is the one that was verified by the labelling experiments of Casey *et al.*[2] The second constraint implies that the permutations associated with the rearrangement must be of an even nature. In fact it is easily verified that the permutations which interconvert the three isomers in **4** are the cyclic permutations of the symmetric group S_3. In combination with the unit element, these permutations form the alternating group A_3 of even permutations on three elements:

$$\mathbf{4a} \xrightarrow{(ABC)} \mathbf{4b}$$

$$\mathbf{4a} \xrightarrow{(ACB)} \mathbf{4c}.$$

Odd permutations, such as the one shown in **5**, are not allowed. This point seems to have been overlooked in the previous treatment.[3] It means that the reaction mixture in the Casey experiment should consist of two enantiomeric cycles, {**2a**,**2b**,**3a**} and {**2c**,**2d**,**3b**}, which are completely separated. Clearly, for an experimental verification of this prediction, we must await experiments with chiral reagents belonging to one of those cycles. Such experiments are certainly within reach, given the current synthetic expertise.[4] If the rearrangement of such a chiral metallacycle is found to induce loss of optical activity, a Jahn–Teller wheel mechanism must be ruled out.



5

The specific permutational isomerism of the Jahn–Teller wheel in Fig. 1 is not an isolated case. An interesting example of a Jahn–Teller "sphere" with the same kind of permutational isomerism as the wheel of Wilker and Hoffmann is offered by the tetrahedral $Tx(e+t_2)$ problem with stable minima of C_{2v} epikernel symmetry.[5] The C_{2v} distortion of a tetrahedron can be viewed as an opening of one of the edges to yield a butterfly-type structure. This type of distortion is encountered in the $Fe(CO)_4$ fragment,[5,6] and in many tetranuclear clusters containing 62 valence electrons.[7] Since a tetrahedron has six edges, six equivalent C_{2v} structures are attainable. These are situated on a Jahn–Teller sphere, as shown in Fig. 2. Rearrangements between these minima correspond to specific permutations of the

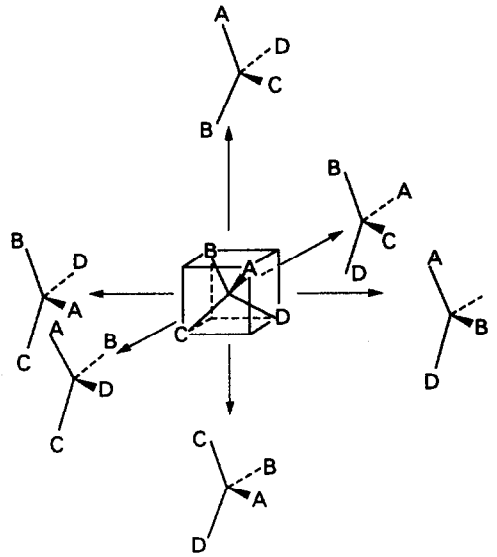


Fig. 2. The rearrangement mechanism for $Fe(CO)_4$, as proposed by Poliakoff and Ceulemans.[6] The structure in the centre has T_d symmetry and is Jahn–Teller unstable. It has six equivalent C_{2v} distortions. All butterfly isomers have been drawn with the same orientation, to make identification easier: the elongated edge between the wingtips of the butterfly is always vertical, while the hinge edge is horizontal.

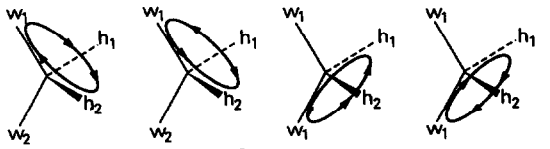
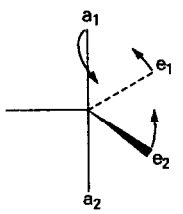
four ligands (or cluster atoms). The interconversion between two adjacent C_{2v} structures in Fig. 2 is easily identified as a cyclic permutation of one wingtip (w) with the two hinges (h) of the butterfly, while leaving the other wingtip invariant.[8] This permutation can be performed in four different ways, thus connecting a given C_{2v} structure to four adjacent minima, **6**.



6

Interestingly, the permutational isomerism of this Jahn–Teller process is entirely analogous to a rearrangement mode for a trigonal bipyramid, proposed by Muetterties.[9] The Muetterties mechanism corresponds to a cyclic exchange of one axial (a) with two equatorial (e) ligands, leaving the third equatorial ligand fixed, **7**. The topology of the Jahn–Teller sphere is seen to be a subspace of the rearrangement in **7**, in which one of the ligands is permanently blocked in the equatorial position.



7

This type of permutational isomerism has two important geometrical characteristics: (i) a simultaneous exchange of both axial sites with the equatorial ones, the so-called Berry exchange, requires a minimum number of two elementary processes, and (ii) the mechanism consists of two disjoint enantiomeric cycles.

The first characteristic implies that the open edge of the butterfly cage cannot be transferred to the antipodal site in a single step. For the case of $Fe(CO)_4$, this has indeed been confirmed experimentally in the elegant IR laser study by Poliakoff and co-workers.[10] The second characteristic indicates that the Muetterties mechanism does not invert the stereochemistry. Again experimental verification of this point must await the use of chiral reagents. It seems that butterfly clusters should offer the best chance to reach this goal.

In conclusion, rearrangement[11] mechanisms based on Jahn–Teller wheels[12] are seen to exhibit a specific permutational isomerism. This may explain the remarkable stereochemistries of reactions such as the Puddephatt rearrangement and the Muetterties process. However, for a full experimental confirmation of such proposals, the resolution of enantiomeric reaction cycles seems imperative.

COMMUNICATION

THE STABILITY OF COMPLEXES OF ALKALI AND ALKALINE EARTH IONS WITH CROWN ETHER CARBOXYLIC ACIDS

HEINZ BUKOWSKY and ERHARD UHLEMANN*

Brandenburgische Landeshochschule, Fachbereich Chemie, O-1571 Potsdam, F.R.G.

and

KARSTEN GLOE and PETER MÜHL

Institut für Festkörperphysik und Werkstofforschung, O-8027 Dresden, F.R.G.

(*Received* 11 *January* 1991; *accepted* 15 *April* 1991)

Abstract—The stability constants of sodium, potassium and calcium complexes with different dibenzo crown ether carboxylic acids were evaluated from the pH dependence of the extraction. There are only small differences between sodium and potassium, but the calcium compound is distinctly more stable.

The extraction of alkali and alkaline earth ions with crown ether carboxylic acids yields a similar curve in the plot of $\log D$/pH as is typical for chelate extraction. In this case, deprotonation of the ligand and complex formation are combined and hence it is possible to determine the stability constant of the extracted complex from the pH dependence of the extraction. Using this model, the stability constants of the sodium, potassium and calcium complexes with 2-(sym-dibenzo-14-crown-4-oxy)hexanoic acid (**1**), 4-(sym-dibenzo-14-crown-4-oxy)butanoic acid (**2**) and 2-(sym-dibenzo-16-crown-5-oxy)hexanoic acid (**3**) were calculated for the chloroform/water system (Table 1).

	X	R	n
1	$-CH_2-CH_2-CH_2-$	$-(CH_2)_3-CH_3$	0
2	$-CH_2-CH_2-CH_2-$	H	2
3	$-(CH_2)_2-O-(CH_2)_2-$	$-(CH_2)_3-CH_3$	0

Because of the influence of solvent the evaluated data are distinctly smaller than those which were determined for complexes of (sym-dibenzo-16-crown-5-oxy)acetic acid in methanol/water (Na $\log\beta_1 = 4.02$, 3.27, respectively; K $\log\beta_1 = 3.71$, 3.11, respectively) by potentiometric[1] and calorimetric measurements.[2,3] Furthermore, there is a remarkable difference in stability between the calcium complex and the complexes of alkali ions, which is also reflected in the extraction behaviour.[4,5] Regarding the alkali ions, neither the crown ether cavity nor the length of the carboxylic group have a significant influence on the complex stability. But the potassium complex is somewhat more stable than the sodium compound. For the calcium compound a "sandwich" structure is proposed, but it was not possible to isolate crystals suitable for crystal structure analysis.

* Author to whom correspondence should be addressed.

Table 1. Stability constants of sodium, potassium and calcium complexes with crown ether carboxylic acids

	Ligand 1	2	3
$\log \frac{K_V(HL)}{K_s(HL)}$	7.21	7.33	7.67
$Na^+ \log \beta_1$	1.61	1.58	1.72
$K^+ \log \beta_1$	1.97		2.05
$Ca^{2+} \log \beta_1$	0.79		0.79
$\log \beta_2$	4.23		4.16

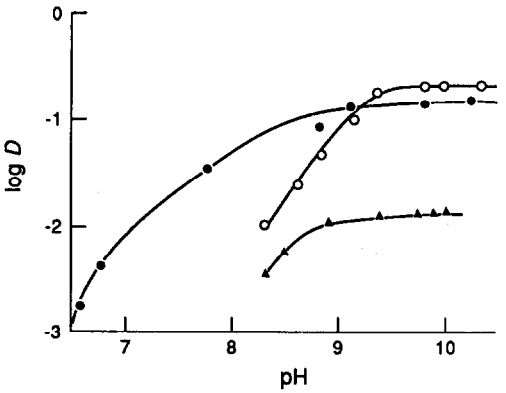

Fig. 1. Plots of log D/pH for the sodium extraction with crown ether carboxylic acids **1** (●), **2** (▲) and **3** (○).

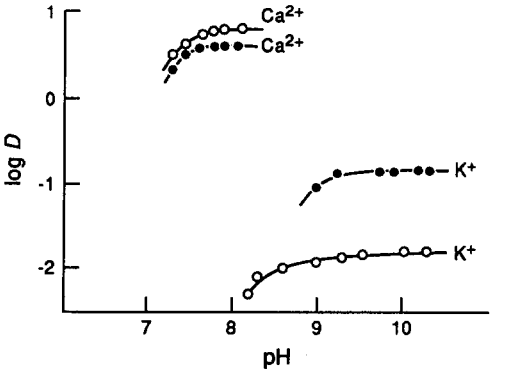

Fig. 2. Plots of log D/pH for the potassium and calcium extraction with crown ether carboxylic acids: **1** (●) and **3** (○).

The syntheses of the crown ether carboxylic acids were reported elsewhere.[4,6,7] The determination of the distribution ratios (Figs 1 and 2) was accomplished radiometrically for sodium and potassium and by flame photometry for calcium. The calculations were made using the program MIQUA[8] following the equations

$$\frac{1}{D} = \frac{1+\beta_1 c_L}{K_V(ML)\beta_1 c_L^-}$$

$$\frac{1}{D} = \frac{1+\beta_1 c_L^- + \beta_2 c_L^{2-}}{K_V(ML_2)\beta_2 c_L^{2-}},$$

respectively, where

$$c_L^- = \frac{c_{HL}(tot)}{c_{H_3O^+}} \frac{K_s(HL)}{K_V(HL)}.$$

The values of $K_s(HL)/K_V(HL)$ were determined from the pH dependence of the two-phase distribution of the crown ether carboxylic acid

$$\log D = \log \frac{K_V}{K_s} - pH$$

$$pH = \log \frac{K_V}{K_s} \quad (\text{for } \log D = 0)$$

using graphical methods.[9]

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry (8th edn); Silicon, Supplement Volume B 4, Silicon–Nitrogen Compounds. By P. Eigen, H. Keller-Rudek, W. Kurtz, P. Merlet, H. Schäfer and F. Schröder. Springer, Berlin, 1989, £564.00.

Imagine being presented with a treasure-chest: on opening it, you find it is full of old favourites, half-forgotten pleasures and newly-discovered delights... Such was the imagery that constantly recurred as I dipped into this new volume of Gmelin. For any enthusiast of silicon–nitrogen chemistry, it is guaranteed to produce excitement, coupled with the occasional slight sense of shame on being confronted by references that you should have known about but didn't.

Compared with their silicon–oxygen analogues, silicon–nitrogen molecular compounds generally show a greater variety, but our knowledge of silicon–nitrogen oligomers and polymers is far more sketchy. Much of the polymer work carefully reported in this volume was done in the 1960s, as part of the inorganic polymer initiatives launched at that time, particularly in the U.S., U.S.S.R. and U.K. That particular bubble burst, as bubbles usually do, and we were left with intriguing but perplexing sets of results, often incomplete. Many of these systems need to be re-examined, using modern techniques; this volume may well provide the necessary enthusiasm by pin-pointing systems that could be useful as preceramic polymers. There are also tantalising references to complex thermolysis reactions of some silicon–nitrogen monomers, leading to elimination of amines, H_2, methane and other volatile products, and often catalysed by bases and salts. These have been interpreted as disproportionation, condensation, elimination and rearrangement processes. But are they truly four-centre reactions? Are free radicals involved? Again, answers to such questions could and should be provided by modern investigative methods.

Because of the way in which the Gmelin system operates, this volume contains no compounds with Si—C bonds. This means that only some members of closely-related groups of compounds are included: $HSi(NR_2)_3$ compounds are described, but $R'Si(NR_2)_3$ derivatives are not. On the other hand, exotica such as $\{Si[NCCr(CO)_5]_6\}^{2-}$ are present. The best-studied silicon–nitrogen compound, silicon nitride, Si_3N_4, is excluded, as it will be the subject of another Gmelin volume, soon to be published. A count of pages gives a rough indication of the coverage accorded to various categories of compounds:

	Number of pages
(i) Nitrogen sorbed on silicon	12
(ii) Si_xN_y compounds (except Si_3N_4) and derived gas-phase ions	34
(iii) Anionic $(Si_xN_y)^{n-}$ in solids	17
(iv) Volatile Si/N/H derivatives and derived ions	67
(v) Polymeric Si/N/H species	14
(vi) Other Si/N/X or Si/N/H/X species (X not C, volatile)	5
(vii) Molecular Si/N/C or Si/N/H/C species and their adducts	192
(viii) Si/N/C or Si/N/H/C polymers	10
(ix) Contents	10.

Some surprising entries were encountered: in category (ii), for example, it has been reported that SiN_8, with a spiro structure, is a possible precursor for the deposition of amorphous silicon; an apparently even more unlikely SiN_{12} is in fact the reasonably well-characterized tetraazide, $Si(N_3)_4$. Category (iii) includes compounds such as $LaSi_3N_5$ and Li_5SiN_3, while category (iv) not only details actual compounds such as $(SiH_3)_3N$ but also theoretical studies on unknown monomeric SiN_2H_2 (with nine possible isomers!).

The distinguished group of authors guarantee the scientific authenticity of the volume, while the firm hand of the editor, Dr F. Schröder, ensures an impressive uniformity of style. I have not detected any errors of fact (nor did I expect to). Of course there must always be differences of interpretation, but it was very seldom that I could quarrel with anything other than a nuance of meaning. Despite its very high price, this volume is an essential reference for all those working with silicon–nitrogen compounds. After all, to say that it is worth its weight (0.88 kg) in gold means that it can be bought for only some 3% of its true value.

(*Received* 30 *January* 1991; *accepted* 21 *March* 1991)

Abstract—The synthesis of the $Ir(H_nBPz_{4-n})(cod)$ ($n = 2, 0$; Pz = pyrazolyl; cod = cycloocta-1,5-diene) complexes is described. They are prepared by reaction of $[Ir(\mu\text{-Cl})(cod)]_2$ with $Tl(H_nBPz_{4-n})$. The carbonyl compounds $Ir(H_nBPz_{4-n})(CO)_2$ ($n = 2, 0$) are obtained by carbonylation of the cycloocta-1,5-diene derivatives. The preparations of the $[Ir(coe)_2\{N(CH_2Pz)_3\}]BF_4$ (coe = cyclooctene) and $[M(cod)\{N(CH_2Pz)_3\}]BF_4$ (M = Ir, Rh) compounds are also reported. They are prepared by treatment of $[Ir(\mu\text{-Cl})(coe)_2]_2$ or $[M(\mu\text{-Cl})(cod)]_2$ with $N(CH_2Pz)_3$ and $NaBF_4$. The carbonyl compound $[Rh(CO)_2\{N(CH_2Pz)_3\}]BF_4$ is obtained by carbonylation of $[Rh(cod)\{N(CH_2Pz)_3\}]BF_4$.

During the past decade, the interest in the chemistry of transition metal complexes containing poly(1-pyrazolyl)borato (H_nBPz_{4-n}) ligands has grown steadily.[1,2] Part of this interest stems from the proposed structural and electronic similarity between complexes with cyclopentadienyl (C_5H_5) [or pentamethylcyclopentadienyl (C_5Me_5)] and those with H_nBPz_{4-n}.[3,4] Recently we reported[5] the activation of a vinyl carbon–hydrogen bond in a tris(1-pyrazolyl)boratoiridium complex. As part of our studies on the chemistry of iridium complexes with the H_nBPz_{4-n} ligands, we report here the preparation of complexes of the type $Ir(H_nBPz_{4-n})L_2$ ($n = 2, 0$; L_2 = cod; L = CO). This paper also describes the synthesis of a number of new alkenyl and carbonyl iridium and rhodium compounds containing tris(1-pyrazolylmethyl)amine, $N(CH_2Pz)_3$. This ligand has a tripodal shape, similar to H_nBPz_{4-n} ($n = 0$, 1), but differs in that it contains four potential donor sites.[6]

EXPERIMENTAL

All reactions were carried out under a nitrogen atmosphere using Schlenk techniques. $[Ir(\mu\text{-Cl})(coe)_2]_2$,[7] $[Ir(\mu\text{-Cl})(cod)]_2$,[8] $[Rh(\mu\text{-Cl})(cod)]_2$,[9] $Tl(H_nBPz_{4-n})$[10] and $N(CH_2Pz)_3$[6] were prepared as previously reported. IR spectra were recorded on a Perkin–Elmer 783 spectrophotometer. Elemental analyses were carried out on a Perkin–Elmer 240B microanalyser. ^1H NMR spectra were measured in $CDCl_3$ solution at room temperature on a Varian XL 200 spectrometer.

$Ir(H_2BPz_2)(cod)$

$[Ir(\mu\text{-Cl})(cod)]_2$ (300 mg, 0.45 mmol) was added to $Tl(H_2BPz_2)$ (315 mg, 0.90 mmol) in CH_2Cl_2 (20 cm^3). The mixture was stirred for 15 min, then filtered through Kieselguhr. The resulting yellow solution was concentrated under reduced pressure. Addition of pentane (20 cm^3) gave a yellow precipitate which was removed by filtration, washed with pentane and dried *in vacuo*; yield: 132 mg (33%). Found: C, 37.5; H, 4.7; N, 12.6. Calc. for $C_{14}H_{20}BIrN_4$: C, 37.6; H, 4.5; N, 12.5%. ^1H NMR ($CDCl_3$): δ 1.73 [m, 4H, CH_2(cod)]; 2.35 [br, 4H, CH_2(cod)]; 4.00 [br, 4H, =CH(cod)]; 6.20 (t, 2H, Pz); 7.48 (d, 2H, Pz); 7.52 (d, 2H, Pz).

$Ir(BPz_4)(cod)$

The complex was prepared using the procedure described for $Ir(H_2BPz_2)(cod)$, but with $[Ir(\mu\text{-Cl})(cod)]_2$ (253 mg, 0.38 mmol) and $Tl(BPz_4)$ (364 mg, 0.75 mmol). The yellow complex was obtained

* Author to whom correspondence should be addressed.

in 67% yield (292 mg). Found: C, 41.3; H, 4.2; N, 18.7. Calc. for $C_{20}H_{24}BIrN_8$: C, 41.4; H, 4.1; N, 19.3%. ^1H NMR ($CDCl_3$): δ 1.56 [m, 4H, CH_2(cod)]; 2.07 [br, 4H, CH_2(cod)]; 3.71 [br, 4H, =CH(cod)]; 6.32 (br, 4H, Pz); 7.11 (br, 4H, Pz); 7.71 (br, 4H, Pz).

$Ir(H_2BPz_2)(CO)_2$

Carbon monoxide was bubbled through a solution of $Ir(H_2BPz_2)$(cod) (264 mg, 0.59 mmol) in CH_2Cl_2 (20 ml) for 30 min. After concentration of the solution, addition of pentane (15 cm^3) gave an orange precipitate which was filtered off, washed with pentane and dried *in vacuo*; yield: 30 mg (13%). Found: C, 24.7; H, 2.1; N, 13.5. Calc. for $C_8H_8IrN_4O_2$: C, 24.3; H, 2.0; N, 14.2%. ^1H NMR ($CDCl_3$): δ 6.30 (t, 2H, Pz); 7.58 (d, 2H, Pz); 7.69 (d, 2H, Pz). IR ν(C≡O)(CH_2Cl_2): 2070 and 2000 cm^{-1}.

$Ir(BPz_4)(CO)_2$

The complex was prepared using the procedure described for $Ir(H_2BPz_2)(CO)_2$, but with $Ir(BPz_4)$(cod) (180 mg, 0.31 mmol). The yellow compound was obtained in 65% yield (106 mg). Found: C, 31.7; H, 2.1; N, 21.0. Calc. for $C_{14}H_{12}BIrN_8O_2$: C, 31.9; H, 2.3; N, 21.3%. ^1H NMR ($CDCl_3$): δ 6.37 (t, 4H, Pz); 7.07 (d, 4H, Pz); 7.83 (d, 4H, Pz). IR ν(C≡O) (CH_2Cl_2): 2080 and 2010 cm^{-1}.

$[Ir(coe)_2\{N(CH_2Pz)_3\}]BF_4$

$[Ir(\mu\text{-Cl})(coe)_2]_2$ (100 mg, 0.11 mmol) and $NaBF_4$ (26 mg, 0.22 mmol) were added to a solution of $N(CH_2Pz)_3$ (57 mg, 0.22 mmol) in CH_2Cl_2–methanol (1:1, 20 cm^3). The mixture was allowed to react for 30 min. The solution was concentrated to dryness and then CH_2Cl_2 was added. The mixture was filtered through Kieselguhr and the resulting orange solution was concentrated under reduced pressure. Addition of diethyl ether (15 cm^3) led to an orange precipitate, which was filtered off, washed with diethyl ether and dried *in vacuo*; yield: 110 mg (65%). Found: C, 44.8; H, 6.0; N, 13.5. Calc. for $C_{28}H_{43}BF_4IrN_7$: C, 44.4; H, 5.7; N, 13.7%. ^1H NMR ($CDCl_3$): δ 0.8–2.2 [m, 24H, CH_2(coe)]; 2.80 [br, 4H, =CH(coe)]; 5.14 [s, 2H, $CH_2(N(CH_2Pz)_3)$]; 5.69, 6.32 (AB system, 4H, J_{AB} = 14.95 Hz, $CH_2(N(CH_2Pz)_3)$]; 6.30 (br, 3H, Pz); 7.38 (br, 2H, Pz); 7.44 (br, 1H, Pz); 8.01 (br, 1H, Pz); 8.30 (br, 2H, Pz).

$[Ir(cod)\{N(CH_2Pz)_3\}]BF_4$

The complex was prepared using the procedure described for $[Ir(coe)_2\{N(CH_2Pz)_3\}]BF_4$, but with $[Ir(\mu\text{-Cl})(cod)]_2$ (80 mg, 0.12 mmol), $N(CH_2Pz)_3$ (62 mg, 0.24 mmol) and $NaBF_4$ (28 mg, 0.24 mmol). The orange complex was obtained in 78% yield (120 mg). Found: C, 37.6; H, 4.1; N, 15.5. Calc. for $C_{20}H_{27}BF_4IrN_7$: C, 37.3; H, 4.2; N, 15.2%. ^1H NMR ($CDCl_3$): δ 1.80 [br, 4H, CH_2(cod)]; 2.40 [br, 4H, CH_2(cod)]; 3.90 [br, 4H, =CH(cod)]; 5.21 [s, 2H, $CH_2(N(CH_2Pz)_3)$], 5.81, 6.15 [AB system, 4H, J_{AB} = 14.92 Hz, $CH_2(N(CH_2Pz)_3)$]; 6.27 (br, 2H, Pz); 6.34 (br, 1H, Pz); 7.44 (br, 1H, Pz); 7.53 (br, 2H, Pz); 7.94 (br, 1H, Pz); 8.28 (br, 2H, Pz).

$[Rh(cod)\{N(CH_2Pz)_3\}]BF_4$

The complex was prepared using the procedure described for $[Ir(coe)_2\{N(CH_2Pz)_3\}]BF_4$, but with $[Rh(\mu\text{-Cl})(cod)]_2$ (200 mg, 0.41 mmol), $N(CH_2Pz)_3$ (211 mg, 0.82 mmol) and $NaBF_4$ (94 mg, 0.82 mmol). The yellow compound was obtained in 77% yield (350 mg). Found: C, 43.0; H, 4.9; N, 17.9. Calc. for $C_{20}H_{27}BF_4N_7Rh$: C, 43.3; H, 4.9; N, 17.7%. ^1H NMR ($CDCl_3$): δ 2.00 [br, 4H, CH_2(cod)]; 2.60 [br, 4H, CH_2(cod)]; 4.20 [br, 4H, =CH(cod)]; 5.17 [br, 2H, $CH_2(N(CH_2Pz)_3)$], 5.20 [br, 2H, $CH_2(N(CH_2Pz)_3)$]; 6.25 (br, 3H, Pz); 6.30 [br, 2H, $CH_2(N(CH_2Pz)_3)$]; 7.50 (br, 3H, Pz); 7.91 (br, 1H, Pz); 8.10 (br, 2H, Pz).

$[Rh(CO)_2\{N(CH_2Pz)_3\}]BF_4$

Carbon monoxide was bubbled through a solution of $[Rh(cod)\{N(CH_2Pz)_3\}]BF_4$ (60 mg, 0.11 mmol) in CH_2Cl_2 (20 ml) for 30 min. After concentration of the solution, addition of diethyl ether (15 cm^3) gave a yellow precipitate which was filtered off, washed with diethyl ether and dried *in vacuo*; yield: 30 mg (55%). Found: C, 34.2; H, 3.2; N, 18.1. Calc. for $C_{14}H_{15}BF_4N_7O_2Rh$: C, 33.4; H, 3.0; N, 19.5%. ^1H NMR ($CDCl_3$): δ 5.0–6.0 [br, 6H, $CH_2(N(CH_2Pz)_3)$]; 6.3 (br, 3H, Pz); 7.5 (br, 3H, Pz); 8.0 (br, 3H, Pz). IR ν(C≡O) (CH_2Cl_2): 2120, 2105, 2060 and 2040 cm^{-1}.

RESULTS AND DISCUSSION

The synthesis of the $Ir(H_nBPz_{4-n})$(cod) (n = 0, 2) complexes involves a straightforward reaction in dichloromethane between $[Ir(\mu\text{-Cl})(cod)]_2$ and $Tl(H_nBPz_{4-n})$, according to the following equation:

$$1/2[Ir(\mu\text{-Cl})(cod)]_2 + Tl(H_nBPz_{4-n}) \longrightarrow Ir(H_nBPz_{4-n})(cod) + TlCl.$$

The complexes were isolated as yellow, air-stable powders and their purity was ascertained by microanalysis. We have tried to prepare these complexes by reaction in dichloromethane of $[Ir(\mu\text{-Cl})(cod)]_2$ with the sodium salt, $Na(H_nBPz_{4-n})$, but this method also afforded the pyrazolate-bridged complex $Ir_2(\mu\text{-Pz})_2(cod)_2$ as a side product. The yield of $Ir_2(\mu\text{-Pz})_2(cod)_2$ increases if the reaction with $Na(H_nBPz_{4-n})$ carried out in methanol, or by treatment of $[Ir(\mu\text{-OMe})(cod)]_2$ with $Na(H_nBPz_{4-n})$. These results suggest that the presence of a base in solution provides the cleavage of the B—N bond in H_nBPz_{4-n} leading to the formation of the pyrazolate complex.

The ^1H NMR spectrum of $Ir(H_2BPz_2)(cod)$ is compatible with a square-planar structure. It shows a unique resonance, centred at 4.00 ppm, for the vinyl protons of the cod ligand, and only three signals at 6.20, 7.48 and 7.52 ppm attributable to the pyrazolyl protons. The ^1H NMR spectrum of $Ir(BPz_4)(cod)$ at 25°C indicates that the complex is stereochemically non-rigid since the four pyrazolyl rings are equivalent. Thus, the pyrazolyl proton resonances appear as three signals at 6.32, 7.11 and 7.71 ppm. Furthermore, the vinyl protons of the cod ligand are also equivalent, appearing as one broad signal at 3.71 ppm. A similar ^1H NMR spectrum at room temperature has been reported for the stereochemically non-rigid $Rh(BPz_4)(cod)$ complex.[11–13]

Treatment of $Ir(H_nBPz_{4-n})(cod)$ ($n = 0$, 2) with carbon monoxide in dichloromethane gives $Ir(H_nBPz_{4-n})(CO)_2$. Formulation of the compounds was deduced by microanalysis, IR and ^1H NMR. $Ir(H_2BPz_2)(CO)_2$ has been previously prepared by reaction of $Na[Ir_2Cl_{4.8}(CO)_4]$ with $K[H_2BPz_2]$.[14] The IR spectrum of $Ir(BPz_4)(CO)_2$ in dichloromethane exhibits two carbonyl bands at 2080 and 2010 cm^{-1} characteristic of a *cis*-dicarbonyl structure. The ^1H NMR spectrum of $Ir(BPz_{z4})(CO)_2$ at 25°C shows that the compound is again stereochemically non-rigid. Similarly to $Ir(BPz_4)(cod)$, the four pyrazolyl rings are equivalent; the spectrum presents only three signals at 6.37, 7.07 and 7.83 ppm attributable to the pyrazolyl protons.

We have also prepared iridium and rhodium complexes containing the tripodal $N(CH_2Pz)_3$ ligand. The $[Ir(coe)_2\{N(CH_2Pz)_3\}]BF_4$ and $[M(cod)\{N(CH_2Pz)_3\}]BF_4$ (M = Ir, Rh) compounds have been synthesized by reaction of $[Ir(\mu\text{-Cl})(coe)_2]_2$ or $[M(\mu\text{-Cl})(cod)]_2$ with $N(CH_2Pz)_3$ and $NaBF_4$ in dichloromethane. Microanalyses of the compounds are in agreement with the proposed formulation. The ^1H NMR spectra of the complexes at 25°C are consistent with a square-planar structure. Thus, the spectra show the presence of non-equivalent pyrazolylmethylene groups. One of the methylene groups appears as a singlet. The other two methylene units are equivalent, but each of them shows inequivalent protons appearing as an AB spin system. Two of the pyrazolyl groups are equivalent; three signals attributable to these protons are observed. The other pyrazolyl group gives three signals; depending on the complex, some of these signals overlap with those of the other pyrazolyl groups. The vinyl protons of the olefinic ligands appear as a unique, broad signal. In a square-planar structure, two signals would be expected for the "upper" and "lower" protons. The presence of only one signal could be explained in terms of a rapid rotation of the cyclooctene or cycloocta-1,5-diene ligands.[15] An alternative explanation may be that the magnetic environments for the protons are accidentally equivalent.

Carbonylation of $[Rh(cod)\{N(CH_2Pz)_3\}]BF_4$ leads to the formation of $[Rh(CO)_2\{N(CH_2Pz)_3\}]BF_4$. The complex is hygroscopic and this has prevented an accurate microanalysis. The IR and ^1H NMR spectra are in agreement with the proposed formulation. The IR spectrum in dichloromethane at 25°C presents four $\nu(C{\equiv}O)$ frequencies, of similar intensity, at 2120, 2105, 2060 and 2040 cm^{-1}. The presence of four $\nu(C{\equiv}O)$ bands suggests the existence of two species in solution, probably tetra- and pentacoordinate species resulting from the coordination of two or three of the pyrazolyl groups to the rhodium atom. The ^1H NMR spectrum at 25°C suggests that these species undergo rapid exchange on the NMR time scale. Thus, this species shows a broad signal in the 5.0–6.0 ppm range for the six methylene protons and three broad signals at 6.3, 7.5 and 8.0 ppm for the nine pyrazolyl protons.

Carbonylation of $[Ir(cod)\{N(CH_2Pz)_3\}]BF_4$ in dichloromethane leads to a solution containing, most probably, $[Ir(CO)_2\{N(CH_2Pz)_3\}]BF_4$, as is deduced by the IR spectrum. It presents four $\nu(C{\equiv}O)$ bands at 2090, 2070, 2025 and 2000 cm^{-1}, similarly to that of $[Rh(CO)_2\{N(CH_2Pz)_3\}]BF_4$. The low stability of the complex has prevented further characterization.

SYNTHESIS AND CHARACTERIZATION OF ORGANOLANTHANIDE COMPLEXES WITH THREE DIFFERENT LIGANDS

YONGFEI YU, SHAOWU WANG, ZHONGWEN YE* and HUAIZHU MA

Institute of Organic Chemistry, Anhui Normal University, Wuhu, Anhui, China

(*Received* 30 *January* 1991; *accepted* 21 *March* 1991)

Abstract—New types of organolanthanide complexes with three different ligands, CpLn(Cl)[$OCOC_6H_4$(*o*-Z)] (Ln = Sm, Yb; Z = H, F, Br, I and OCH_3), were synthesized. These complexes were characterized by elemental analyses, IR, MS and XPS, showing that they are dimers containing carboxylate ions as bridging groups. It was found that the donor atoms (F, Br, I and O) in the complexes only slightly coordinate with lanthanide metal.

Since organolanthanide complexes possess unique and interesting structures and properties, organolanthanide chemistry is currently one of the most rapidly developing areas of organotransition metal chemistry. Up until now, no report on organolanthanide complexes with three different ligands occurs in the literature, though numerous organolanthanide complexes have been synthesized.[1] In view of this, we synthesized 10 new organolanthanide complexes with three different ligands.

RESULTS AND DISCUSSION

By the reaction of the dicyclopentadienyl samarium chloride or dicyclopentadienyl ytterbium chloride with one equivalent of (*o*-Z)C_6H_4COOH at room temperature in THF, 10 new complexes with three different ligands have been synthesized. They are:

CpSm(Cl)[$OCOC_6H_5$]	**(1)**
CpYb(Cl)[$OCOC_6H_5$]	**(2)**
CpSm(Cl)[$OCOC_6H_4$(*o*-F)]	**(3)**
CpYb(Cl)[$OCOC_6H_4$(*o*-F)]	**(4)**
CpSm(Cl)[$OCOC_6H_4$(*o*-Br)]	**(5)**
CpYb(Cl)[$OCOC_6H_4$(*o*-Br)]	**(6)**
CpSm(Cl)[$OCOC_6H_4$(*o*-I)]	**(7)**
CpYb(Cl)[$OCOC_6H_4$(*o*-I)]	**(8)**
CpSm(Cl)[$OCOC_6H_4$(*o*-OCH_3)]	**(9)**
CpYb(Cl)[$OCOC_6H_4$(*o*-OCH_3)]	**(10)**.

All complexes were characterized by elemental analysis, IR and MS spectroscopy. Complexes **3**–**10** were also identified by XPS. All complexes exhibit four characteristic Cp absorption peaks at *ca* 780, 1010, 1440 and 3100 cm^{-1} and an absorption peak at *ca* 250 cm^{-1} due to Ln—C of the π-bonded Cp group.[2] All the complexes are soluble in THF, but they are practically insoluble in benzene. We did not succeed in preparing single crystals for any of them.

Bridged dimeric structure

By studying the relationship between the structure and the IR data of the carboxylato complexes, Deacon[3] and Karraker[4] have pointed out that the value of $\Delta\nu$ [$\nu_{as}(COO^-) - \nu_s(COO^-)$] of the bridged dimeric structure of the complexes is much smaller than that for the corresponding free carboxylate anion. In Table 1, the $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ frequencies for the complexes of their corresponding free carboxylate anion are listed. It is evident that $\Delta\nu$ of the former is smaller than that of the latter. Thus, the 10 complexes would seem to have bridged dimeric structures. Moreover, the presence of bimolecular species, and fragments thereof in the mass spectra, further support the bridged dimeric structure for all complexes.

Chelate ring

If the substituent atom Z (F, Br, I and O) on the phenyl group in the complexes coordinates with the

[a]The data are obtained from measuring the results of the corresponding salts (*o*-Z)C_6H_4COONa, where Z = F, Br, I and OCH_3, respectively.

metal, the electron density at the donor atom will decrease and cause ν(C—Z) to shift to low frequency. The values in complexes **3–10** and those in the corresponding carboxylic salts are listed in Table 2. It is evident that ν(C—Z) in all eight complexes is smaller than that in the free anion, suggesting that the donor atom does indeed coordinate to the lanthanide in these eight complexes. Moreover, the XPS data reveal that the binding energy of the donor atom in the complexes is greater than in the salts. This is further evidence for the coordination of the donor atom to the metal in complexes **3–10** to form chelate rings.

From the above information, we suggest the structures shown in Fig. 1 for the 10 complexes.

EXPERIMENTAL

All reactions and manipulations were conducted under an atmosphere of purified argon using standard Schlenk techniques or a glove box. THF and n-hexane were predried over sodium wire and subsequently refluxed and distilled under argon from sodium benzophenone immediately before use. Benzoic acids with *ortho*-substituted groups were

dried by heating under vacuum and stored under argon until use. Cp_2LnCl (Ln = Sm, Yb) was prepared following published methods.[6]

IR spectra were obtained as Nujol and Fluorolube mulls on CsI crystal plates. The IR measurements were obtained on a Perkin–Elmer 983(G) spectrometer. The X-ray photoelectron spectra were recorded on a VG ESCALAB MK-II spectrometer. The mass spectra were obtained on a VG ZAB-HS organic mass spectrometer. Mass spectral data are given for isotopes ^{152}Sm, ^{174}Yb, ^{35}Cl and ^{79}Br. The peak patterns correspond to theoretical values based on the natural abundance of the isotopes. Carbon and hydrogen analyses were carried out on a Yanaco MT-2 analyser. Elemental analysis results for Ln (Ln = Sm, Yb) were obtained according to a published method.[2] The elemental analysis data for X (X = F, Br or I) were obtained using a combustion method. Melting points were determined in argon-filled capillaries and were uncorrected.

General method for the preparation of $CpLn(Cl)[OCOC_6H_4(o\text{-Z})]$

To a solution of Cp_2LnCl (Ln = Sm, Yb) (2 mmol) in 50 cm^3 of THF kept under argon in a 100 cm^3 Schlenk flask was added dried $(o\text{-Z})C_6H_4COOH$ (Z = H, F, Br, I and OCH_3) (2 mmol) and the reaction mixture was stirred at room temperature for 24 h. THF was then removed *in vacuo*. THF (5 cm^3) was added, followed by n-hexane (40 cm^3) and the solvent was removed by centrifugation. This procedure was repeated three times. The resulting solid was dried for 2 h *in vacuo* to afford complexes $CpLn(Cl)[OCOC_6H_4(o\text{-Z})]$ (Ln = Sm, Yb; Z = H, F, Br, I and OCH_3).

$CpSm(Cl)[OCOC_6H_5]$ (**1**)

Orange, dec.p., 166°C, yield, 83%. Found (calc.): Ln, 40.4 (40.6), C, 38.7 (38.4), H, 2.7 (2.5), Cl, 9.5 (10.3)%. Main peaks in MS (*m/z*): 746(M_2), 681(M_2-Cp), 373(M), 308(M−Cp), 242($M-C_6H_5COO$), 217($M-Cl-C_6H_5COO$), 152(Sm).

STRUCTURAL DEPENDENCIES OF PYRAMIDAL SULPHUR INVERSION IN HALOGENOTRICARBONYLRHENIUM(I) COMPLEXES OF MONO- AND BIS-(*o*-METHYLTHIO) DERIVATIVES OF TRIPHENYLPHOSPHINE

EDWARD W. ABEL, DAVID ELLIS, KEITH G. ORRELL* and VLADIMIR ŠIK

Department of Chemistry, University of Exeter, Exeter EX4 4QD, U.K.

(*Received* 31 *January* 1991; *accepted* 21 *March* 1991)

Abstract—A series of new halogenotricarbonylrhenium(I) complexes of the hybrid sulphur–phosphine ligands [*o*-(methylthio)phenyl]diphenylphosphine (SP) and bis-[*o*-(methylthio)phenyl]phenylphosphine (DSP) have been prepared and characterized. Both ligands act as sulphur/phosphorus mono-chelates, despite the potential tridenticity of DSP. No evidence of an intramolecular methylthio exchange process involving the uncoordinated and coordinated SMe groups was detected in the $[ReX(CO)_3(DSP)]$ (X = Cl, Br, I) complexes, in contrast to the analogous $[PdX_2(DSP)]$ and $[PtX_2(DSP)]$ complexes. Solution NMR studies revealed pyramidal inversion of the coordinated sulphur atoms in the $[ReX(CO)_3(SP)]$ and $[ReX(CO)_3(DSP)]$ complexes, with energy barriers $[\Delta G^{\ddagger}(298\ K)]$ in the range 51–55 kJ mol^{-1}.

Pyramidal sulphur or selenium inversion in halogenotricarbonylrhenium(I) complexes of dimethyl sulphide,[1] dimethyl selenide[1] and various chelating dichalcogenoethers[2,3] has been the subject of much previous investigation. In these earlier studies all coordinated ligand atoms were stereochemically non-rigid, whereas this present work has been aimed at investigating systems combining rigid and non-rigid coordinated atoms, namely phosphorus and sulphur atoms, respectively.

The ligand [*o*-(methylthio)phenyl]diphenylphosphine(SP) is shown to act as a sulphur/phosphorus chelate ligand towards rhenium(I) pentacarbonyl halides. The ligand bis-[*o*-(methylthio)phenyl]phenylphosphine (DSP) is potentially tridentate towards these reagents, but such a binding mode would require replacement of a carbonyl group *trans* to halogen, and the weak *trans* effect of the latter is unlikely to produce sufficient labilization of the Re—C bond for this to occur. Thus, DSP is more likely to act as a bidentate ligand and form $[ReX(CO)_3(DSP)]$ complexes. Such complexes would contain an uncoordinated methylthio group which might then be involved in an intramolecular sulphur exchange process analogous to those observed in DSP complexes of palladium(II)[4–6] and platinum(II).[5,6]

NMR studies were therefore undertaken to investigate the static and dynamic solution conformations of the two series of complexes $[ReX(CO)_3(SP)]$ (X = Cl, Br, I) and $[ReX(CO)_3(DSP)]$ (X = Cl, Br) in order to clarify their dynamic stereochemistries.

EXPERIMENTAL

Reagents

The ligands[7] and pentacarbonylhalogenorheniums(I)[8,9] were prepared according to literature methods.

Physical methods

IR spectra of the complexes were recorded on a Perkin–Elmer 881 IR spectrophotometer in the region 2200–1800 cm^{-1} as solutions in THF.

^1H NMR and $^{31}P-\{^1H\}$ NMR spectra were recorded on a Bruker AM250 FT spectrometer operating at 250.13 and 101.26 MHz, respectively. ^1H chemical shifts are quoted relative to Me_4Si as the internal standard. $^{31}P-\{^1H\}$ chemical shifts are

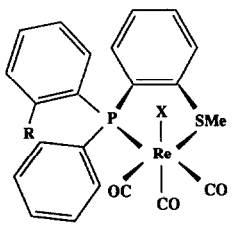
* Author to whom correspondence should be addressed.

quoted relative to H_3PO_4 as the external standard. All NMR spectra of the complexes were recorded as solutions in CD_2Cl_2.

Elemental analyses were carried out by Butterworth Laboratories Ltd, Teddington, Middlesex, London.

Melting points were recorded on a digital Gallenkamp melting point apparatus and were uncorrected.

Bandshape analyses were carried out using a modified version of the DNMR3 program of Kleier and Binsch.[10] Computer simulated spectra were fitted visually and energy parameters derived from standard Arrhenius and Eyring plots are based on least-square fittings. The errors quoted for the free energies of activation, $\Delta G^{\ddagger}$, are based on the standard deviation term, $|\sigma(\Delta H^{\ddagger}) - T\sigma(\Delta S^{\ddagger})|$, as described by Binsch and Kessler.[11]



R	X	COMPLEX
H	Cl	I
H	Br	II
H	I	III
SMe	Cl	IV
SMe	Br	V

Fig. 1. Structures of the complexes $[ReX(CO)_3(L—L')]$ (L—L') = (*o*-$MeSC_6H_4)PPh_2$, (SP); X= Cl, Br, I. (L—L') = (*o*-$MeSC_6H_4)_2PPh$, (DSP); X = Cl, Br.

Synthesis of the complexes

Methods for the preparation of all the complexes were analogous, that for the chloride being described below. The reaction time required for the iodide was considerably longer than for the chloro and bromo species.

All manipulations were carried out under nitrogen and freshly dried solvents used in all reactions. Full synthetic and analytical details of these complexes are given in Table 1. Their structures are shown in Fig. 1.

{[o - (methylthio)phenyl]diphenylphosphine}chloro - tricarbonylrhenium(I)

Chloropentacarbonylrhenium(I) (0.25 g, 0.69 mmol) and [*o*-(methylthio)phenyl]diphenylphosphine (0.41 g, 1.3 mmol) were dissolved in THF (10 cm^3) and heated under reflux for 5 h. After this time, the IR spectrum showed three new bands in the carbonyl stretching region, and the bands due to starting material were no longer observed. The solution was concentrated to dryness *in vacuo*, and the white residue washed with hexane. Recrystallization from dichloromethane/hexane gave a white crystalline product which was dried *in vacuo*. Yield: 0.25 g (59%).

RESULTS

The methods outlined above resulted in moderate yields of the complexes, those for the SP complexes being somewhat higher than their DSP analogues (Table 1). IR spectroscopy was a convenient means of monitoring these reactions, the three C—O stretching bands in the product tricarbonyl moiety ($2A' + A''$) being at very different frequencies to those of the reactant pentacarbonyl. Reasoning used elsewhere[3] implies that the three CO groups are in the *fac* configuration.

NMR studies

(i) $[ReX(CO)_3(SP)]$ *complexes*. The ^1H NMR spectra of these complexes in solution at −40°C contained two signals in the SMe region consistent with two invertomeric species. These species are described as *cis* or *trans* according to the relative positions of the ligand SMe group and the halogen with respect to the five-membered metallocycle

Table 1. Synthetic and analytical details of the complexes $[ReX(CO)_3L]$ (L = SP or DSP)

		cis	0.16	3.25	

[a] Aromatic region too complex to distinguish signals due to individual invertomers. (m) = multiplet.

(Fig. 2). Table 2 contains the relevant static NMR parameters of the solution species. It can be seen that the *trans* form is always dominant and is increasingly so as the halogen mass/size increases.

On raising the temperature above −40°C, the two signals in the SMe region broaden and coalesce such that at room temperature a broad singlet is seen which continues to sharpen on further elevation of temperature. Changes were also observed in the aromatic region but these proved too complex for detailed analysis. Addition of free ligand to the samples at temperatures above coalescence produced spectra with separate signals for free and coordinated ligands, confirming the intramolecular nature of the process being monitored.

The changes in the SMe region of the spectrum are consistent with the onset of pyramidal sulphur inversion which exchanges the *cis* and *trans* complexes. Static and dynamic spectra were simulated accurately over the temperature range −40 to 20°C. The "best-fit" rate constants used in the band-shape analysis are given in Table 3.

(ii) $[ReX(CO)_3(DSP)]$ *complexes*. The low temperature ^{1}H NMR spectra of both complexes **IV** and **V** exhibited eight signals in the SMe region. These correspond to the four static invertomers shown in Fig. 3. The additional isomerism of these complexes, compared with the SP complexes, arises from the chiral nature of the tetrahedral phosphorus atom. The four solution species are present

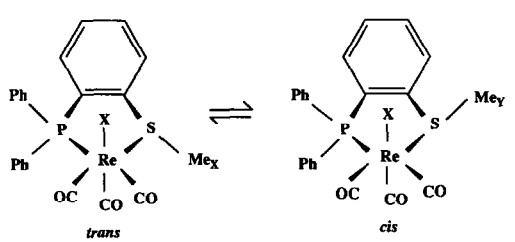

Fig. 2. The static invertomers of complexes I–III.

20	1312		

as two diastereomeric pairs, **1** and **2**, resulting from the pendent phenylthioether group being either *trans* or *cis* to the halogen. The two invertomers of each diastereomeric pair arise from the *cis* or *trans* orientation of the coordinated SMe with respect to the halogen. The description of each species refers firstly to the orientation of the pendent SMe group, and secondly to the orientation of the coordinated SMe, both with respect to halogen (Fig. 3). Each of these species exists as a DL pair, but only individual members are shown in Fig. 3 as these cannot normally be distinguished by NMR.

Assignments of signals in the SMe region arise from considerations of steric factors and comparisons with SP complexes. Coordinated SMe protons are expected to be deshielded compared with uncoordinated SMe protons and therefore the methyls A, B, E, F in Fig. 3 will resonate at highest frequencies. In addition, the species **2a** and **2b**, having a pendent phenylthioether moiety *cis* to halogen will be less abundant than the *trans* variety on steric arguments. Thus, the weakest pair of signals in the spectra of the DSP complexes is attributed to the

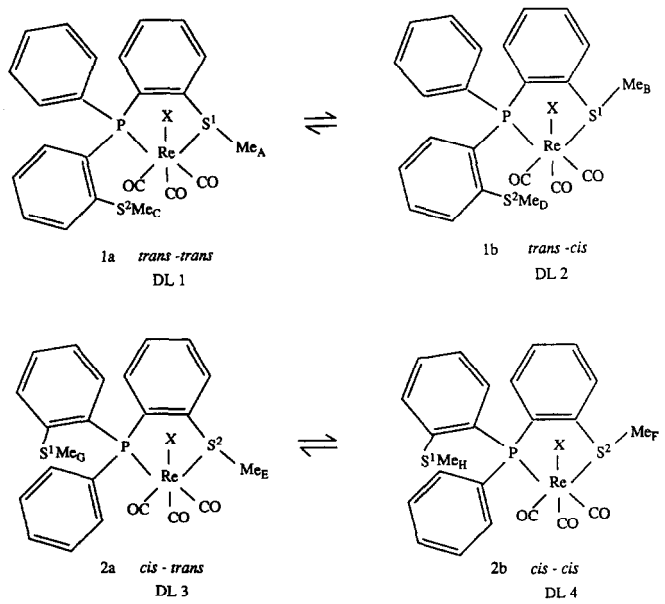

Fig. 3. The static invertomers of complexes **IV** and **V**. The labelling refers to the orientation of the pendent and coordinated SMe groups with respect to halogen, *in that order*. Only single members of the DL pairs are shown.

cis–cis invertomer, **2b**. The non-bonded interactions in this species are only slightly alleviated by placing the coordinated SMe in the *trans* position and thus the *cis–trans* invertomer, **2a**, is only slightly more favoured. The most populous invertomer will contain both SMe groups *trans* to halogen, namely **1a**, and thus the ordering of invertomer populations is expected to be *trans–trans* > *trans–cis* ≫ *cis–trans* > *cis–cis*. Each form should give rise to two SMe signals of identical intensity. However, due to signal overlap this theoretical situation is not realized (Fig. 4).

Before commencing band-shape analyses of the ^{1}H NMR spectra, reliable values of invertomer

populations were required. These were measured most accurately from low temperature $^{31}P-\{^1H\}$ NMR spectra. Population values and $^{31}P-\{^1H\}$ chemical shifts are given in Table 4. Gross band-shape changes were observed in the ^1H spectra of both the DSP complexes as the temperature was raised. The case of $[ReBr(CO)_3(DSP)]$ (**V**) is illustrated in Fig. 5. The closely spaced set of signals, labelled C, D, G, H (Fig. 4), due to the uncoordinated SMe groups broadened, coalesced around 263 K and then sharpened. The more widely dispersed set of signals, A, B, E, F (Fig. 4), due to the coordinated SMe groups experienced greater exchange broadening and coalesced around ambient temperature. Raising the temperature above ambient led to continued sharpening of all lines until four separated averaged signals, one pair for each diastereomer, were revealed.

The dynamic spin problem was formulated as:

Isomer 1 $A \rightleftharpoons B$ $C \rightleftharpoons D$
Isomer 2 $E \rightleftharpoons F$ $G \rightleftharpoons H$.

Exchanges between isomers **1** and **2** cannot occur without Re—P bond breaking and were therefore discounted from consideration. Interconversions between invertomer pairs were assumed to occur at the same rate and thus theoretical spectra were simulated for a single magnitude of rate constant at each temperature. The best-fit rate constants for **V** at each temperature are given in Fig. 5. These were converted to activation parameters in the usual way and the values are listed in Table 5.

Increasing the temperature of both complexes to *ca* 100°C resulted in further sharpening of the signals and no evidence of the onset of any other exchange process. There is, therefore, no indication of an intramolecular sulphur replacement fluxion involving fission of the Re—S bond and rotation about the Re—P bond to bring the pendent methylthio into the coordination position. Such a process has been detected in the palladium(II) and platinum(II) complexes,[4–6] where the process occurs via a five-coordinate metal transition state.

DISCUSSION

The energy barriers [$\Delta G^{\ddagger}$ (298 K)] to pyramidal sulphur inversion in these hybrid sulphur/

Table 5. Energy parameters for the pyramidal inversion in complexes **I–V**

Complex	E_a (kJ mol^{-1})	$\log_{10}(A/s^{-1})$	$\Delta H^{\ddagger}$ (kJ mol^{-1})	$\Delta S^{\ddagger}$[a] (J K^{-1} mol^{-1})	$\Delta G^{\ddagger}$ (kJ mol^{-1})
I	77.9±2.1	17.1±0.4	75.7±2.1	74.0±7.6	53.6±0.2
II	79.0±2.0	17.5±0.4	76.8±2.0	81.8±7.4	52.4±0.3
III	86.0±3.0	18.8±0.6	83.8±3.0	107.6±11.3	51.7±0.4
IV	72.1±3.5	15.8±0.7	69.9±3.5	50.7±13.0	54.7±0.4
V	84.2±1.9	18.1±0.4	81.9±1.9	93.5±7.1	54.1±0.2

[a] These values are unexpectedly large for purely intramolecular processes, but are considered to be reliable and not artefacts of poor quality band-shape fittings.[14]

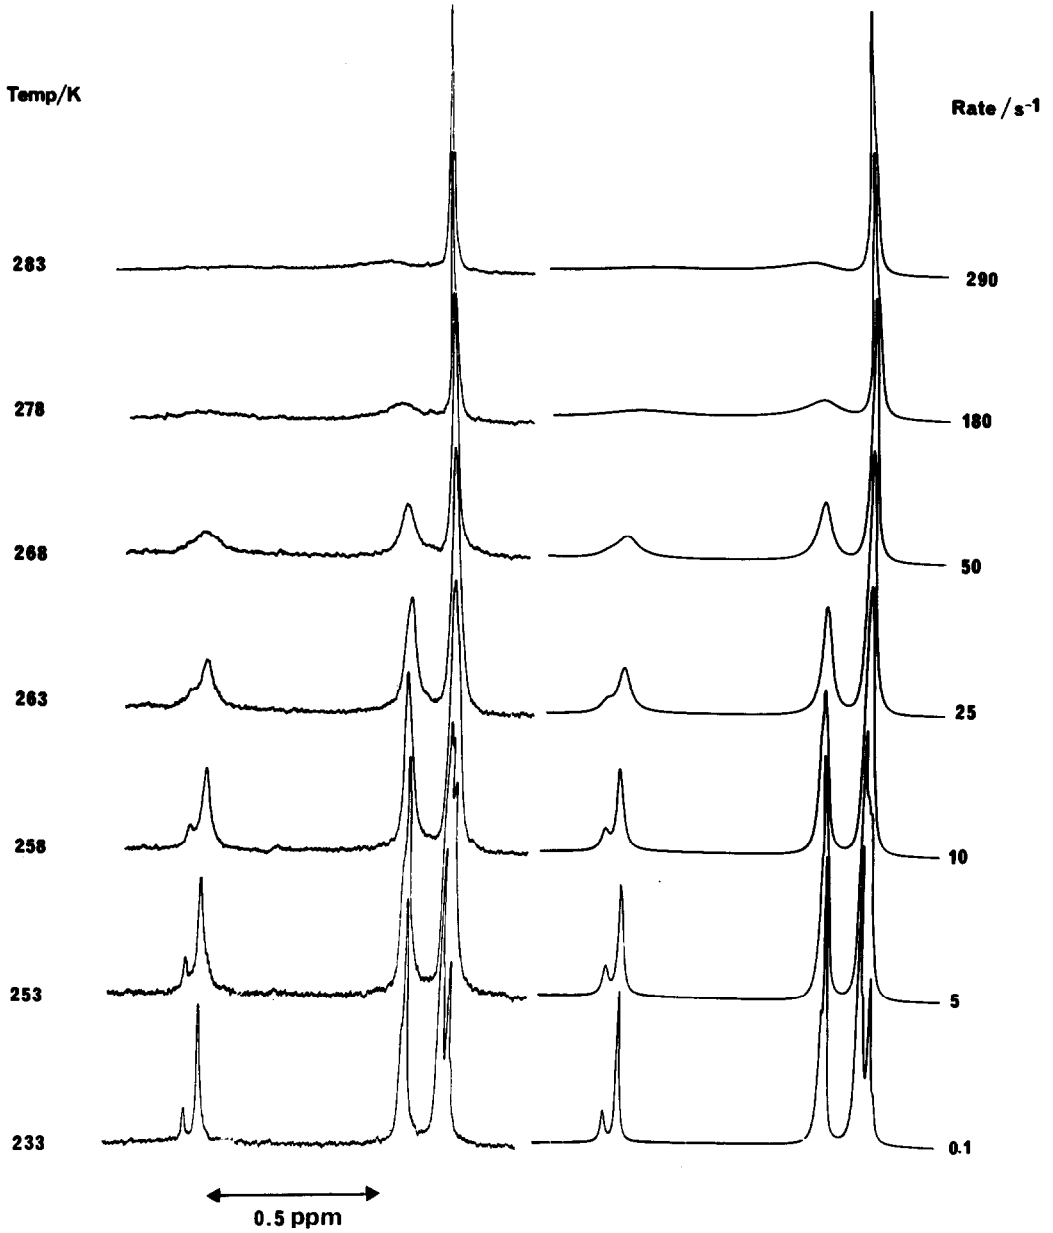

Fig. 5. Experimental and computer synthesized spectra of complex V showing the "best-fit" rate constants.

phosphorus chelate complexes lie in the range 51.7–54.7 kJ mol^{-1}. The values for SP complexes are marginally lower (1.1–1.7 kJ mol) than those for the DSP complexes, possibly the result of a slight steric effect of the uncoordinated SMe group in the latter.

There appears to be a very slight *cis*-halogen influence on the energy barrier, with $\Delta G^{\ddagger}$ values decreasing slightly with increasing halogen size. Previous studies of other $[ReX(CO)_3(L—L)]$ complexes[1–3,12] have revealed no clear halogen dependencies and so the present results should be interpreted with some caution.

The sulphur inversion barriers in these mixed sulphur/phosphorus coordinated ligand chelate complexes are somewhat lower than those in the analogous sulphur/sulphur chelate complexes, viz $[ReX(CO)_3(o\text{-}MeSC_6H_4SMe)]$ (X = Cl, Br, I),[2] where $\Delta G^{\ddagger}$ values are in the range 53.5–56.4 kJ mol^{-1}. Thus, replacement of a pyramidal sulphur atom by a tetrahedral phosphorus atom in the five-membered metallocycle increases slightly the rate

of pyramidal inversion of the coordinated sulphur atom on the other side of the five-membered ring. Whether this is due to an increase in energy of the ground state structure due to steric effects of the phenyl rings or to a stabilization of the planar transition state structure for the inversion process, is uncertain.

An aromatic ligand backbone is known to favour inversion of the heterocyclic sulphur atoms compared with the analogous aliphatic ligand backbone.[13] Thus in the complexes $[ReX(CO)_3\{MeS(CH_2)_2SMe\}]$ (X = Cl, Br, I),[2] $\Delta G^{\ddagger}$ values are *ca* 10 kJ mol^{-1} higher than in the aromatic ligand complexes. This is attributed to the effect of $(p\text{–}p)\pi$ conjugation which is more effective in the planar transition state than in the pyramidal ground-state structure. In the present complexes the conjugation effect is directed towards a single pyramidal sulphur atom rather than towards a pair as in the *o*-$MeSC_6H_4SMe$ complexes, and may be somewhat more effective for that reason. The difference in energies being discussed here, however, is very small and, indeed, the main finding of this paper is that diphenylphosphino and methylthio units appear to have very comparable electronic influences on pyramidal sulphur inversion in five-membered chelate ring complexes of $ReX(CO)_3$.

SYNTHESIS OF AN ETHER OXIME LIGAND AND ITS RHODIUM(III) COMPLEX, AND X-RAY STRUCTURE OF THE RHODIUM(III) COMPLEX: UNIQUE RHODIUM(III) BONDING TO A SIMPLE ETHER

G. ERGUN EFE and E. O. SCHLEMPER*

Department of Chemistry, University of Missouri, Columbia, MO 65211, U.S.A.

(*Received* 8 *January* 1991; *accepted* 21 *March* 1991)

Abstract—The ligand 3-methoxy-3-methyl-2-butanone oxime and its rhodium(III) complex have been synthesized, and the complex has been structurally characterized. The octahedron around the rhodium atom involves two *trans*-chlorine atoms [Rh—Cl = 2.3236(8) Å], two *cis*-oxime nitrogen atoms [av. Rh—N = 1.958(3) Å] and two *cis*-ether oxygen atoms [av. Rh—O = 2.117(3) Å]. The oxime oxygen atoms are involved in a short intramolecular hydrogen bond (O---O = 2.391 Å). Synthesis and characterization of the ligand and the rhodium(III) complex are described, and the ^{1}H NMR results are given and discussed. To our knowledge this is the first characterized ether oxime metal complex.

The development of bifunctional chelating ligands and their complexes with Rh-105 as potential radiotherapeutic agents has been under investigation in our laboratory.[1,2] The ligands used in our previous work were all of the nitrogen donor type. In this work, we have uncovered a new approach to the synthesis of 3-methoxy-3-methyl-2-butanone oxime. This compound has been known since 1903 through the work of Schmidt.[3] Additional synthetic approaches were reported in 1964[4] and 1978.[5] Here, we have discovered a rather straightforward approach which should be applicable for the synthesis of other 3-alkoxy-3-methyl-2-butanone oximes.

While many crown ether metal complexes and complexes with macrocyclic ether donors and with bonded tetrahydrofuran or dioxane are known, there are few complexes of bidentate ligands containing a single ether oxygen donor. To our knowledge this is the first reported structure of such a complex with rhodium(III).

EXPERIMENTAL

Preparation of the compounds

3-Methoxy-3-methyl-2-butanone oxime (ether oxime). This compound has been prepared and reported, most recently, by Kisan and Pritzkow,[5] who used the 3-sulphato oxime as the starting oxime. A similar procedure was applied here by using α-chloro-3-methyl-2-butanone (α-chloro oxime). α-Chloro oxime was synthesized as described by Murmann.[6] To prepare the ether oxime, absolute methanol (50 cm^3) and $NaHCO_3$ (5.04 g, 60 mmol) were placed in a round-bottomed flask and warmed up to 50–60°C while stirring. α-Chloro oxime (3.39 g, 25 mmol) was added over a 30 min period and the solution was then refluxed for 4.5 h. The flask was sealed and left at room temperature overnight. The white, inorganic precipitate was filtered out and the solvent was evaporated. The residue was extracted several times into ether and the combined ether extracts were evaporated. The product was recrystallized from hot hexanes to obtain colourless, large crystals. The yield was 30% after recrystallization, m.p. 89–91°C (lit. 92–93°C, ref. 3; 89–90°C, ref. 4). The same compound was also prepared by using triethylamine as base and by refluxing for 24 h, but the yield was lower (14%) in that case.

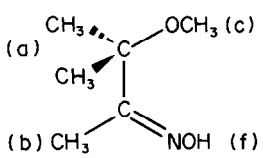
[Rh(*ether oxime*)$_2$Cl$_2$]. Ether oxime (0.295 g, 2.25 mmol) was dissolved in ethanol (15 cm^3), then $RhCl_3 \cdot 3H_2O$ (0.263 g, 1 mmol) in 5 cm^3 of water was added and the solution was refluxed for 3 h. The pH was adjusted to 7 by the addition of potassium hydroxide, and orange crystals were obtained by

* Author to whom correspondence should be addressed.

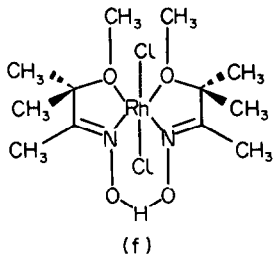
slow evaporation of the solvent. Yield: 45%. Found: C, 33.1; H, 5.7; N, 6.1; O, 15.1. Calc. for $RhCl_2O_4N_2C_{12}H_{25}$: C, 33.1; H, 5.8; N, 6.4; O, 14.7%.

^1H *NMR*

Spectra of the compounds were recorded on a JEOL FX90Q Fourier transform NMR spectrometer with TMS as an internal standard in d_6-DMSO. The chemical shifts and the integrated intensities for the designated protons are as follows: ether oxime (a) 1.23s, 6H, (b) 1.71s, 3H, (c) 2.95s, 3H, (f) 10.68s. 1H; [Rh(ether oxime)$_2$Cl$_2$] (a) 1.45s, 12H, (b) 2.21s, 6H, (c) 3.88s, 6H, (f) 18.22s, 1H. The chemical shifts for the complex are at lower fields than those of the ligand, as a result of the deshielding effect of metal and chloride ions. Deshielding due to the double bond results in the protons of the methyl carbon adjacent to the C=N group [(b) protons] resonating at a lower field strength compared with the geminal methyl protons [(a) protons]. The very low-field resonance of the hydrogen-bonded oxime proton in the rhodium complex is characteristic of α-amine oxime complexes which have short, nearly symmetrical hydrogen bonds.[1,7,8] The high symmetry of the complex indicated by the singlet peaks for the methyl protons was confirmed by the X-ray crystal structure.



Ether oxime



[Rh(ether oxime)$_2$Cl$_2$]

X-ray diffraction

Orange crystals of [Rh(ether oxime)$_2$Cl$_2$] were prepared by the slow evaporation of a solution of ethanol–water (3 : 1 ratio). A crystal of approximate dimensions $0.30 \times 0.10 \times 0.13$ mm was mounted in random orientation on an Enraf–Nonius CAD4 automated diffractometer. The crystal was optically centred. Twenty-five reflections were located by automatic search of reciprocal space and recentred. The setting angles of these reflections were used to obtain the orthorhombic cell constants which are included in Table 1 together with other crystal data and structure solution and refinement parameters.

The intensities were collected with Mo-K_α radiation (0.7107 Å) obtained from a graphite monochromator at a rate to obtain counting statistics of $\pm 3\%$ up to a maximum scan time of 90 s. To check instrument and crystal stability, the intensities of three standard reflections were recorded after every 7200 s of X-ray exposure and showed no significant decay or fluctuation. Orientation was checked after every 200 reflections with the use of the same standards and all 25 original reflections were recentred when the measured position of any scattering vector of any of these standards deviated by more than 0.06° from the calculated position. Systematic absences of $k+l$ odd for $0kl$ and h odd for $h0l$ were consistent with the space groups *Pnam* and $Pna2_1$. Statistical analysis of the intensities did not give a good agreement with the theoretical values for either the non-centrosymmetric or the centrosymmetric structure. Since the agreement in Friedel-pair intensities was good (agreement factor = 0.012), space group *Pnam* was assumed. The choice was confirmed by successful refinement in that space group. The integrated intensities were corrected for background and directly reduced to a set of relative squared structure amplitudes, $|F_o|^2$, by the application of the standard Lorentz-polarization factor (Lp). Individual estimated standard deviations ($\sigma_{counting}$) were derived based on counting statistics. Empirical (Ψ scan) absorption corrections were made with the relative transmission ranging from 0.96 to 1.00.

The structure of the complex was solved by Patterson and Fourier methods, and refinement was by the full-matrix least-squares method. The molecule is very planar, and most of the atoms of the molecule lie on the mirror plane at $z = 1/4$. The only atoms out of this plane are Cl, C(4), C(4′), all C(4) and C(4′) methyl hydrogen atoms and two hydrogen atoms on each of C(3), C(3′), C(5) and C(5′) methyl carbon atoms (see Fig. 1). The symmetry restriction imposed by the mirror plane required

fixed z-coordinates and U_{13} and U_{23} parameters for all the atoms on the mirror plane for subsequent least-squares refinements. The other positional parameters and anisotropic thermal parameters of the non-hydrogen atoms were included in the refinement. The total number of variables was 118.

The final atomic positional parameters and isotropic equivalent thermal parameters have been deposited with the Cambridge Crystallographic Data Centre. The molecular structure is shown in Fig. 1 and important bond distances and angles for non-hydrogen atoms are in Tables 2 and 3, respectively.

RESULTS AND DISCUSSION

The crystal structure consists of discrete, mononuclear, neutral and nearly octahedral rhodium(III)

molecules. The octahedron around the rhodium atom involves two *trans*-chlorine atoms, two *cis*-ether oxygen atoms and two *cis*-oxime nitrogen atoms. The molecules have very nearly C_{2v} symmetry, but only one mirror is crystallographically fixed, passing through all of the non-hydrogen atoms except Cl, C(4) and C(4′). The mirror plane relates the two chlorine atoms, as well as the two C(4) and two C(4′) methyl carbon atoms. Of special note is the trigonal planar nature of the ether oxygen atoms. Both of these have very nearly 120° angles [range 116.5(2)° for Rh—O(2)—C(2) to 124.9(2)° for Rh—O(2)—C(5)]. This apparent sp^2 hybridization is not observed in the rhodium(I) complex *trans*-[1,5-bis(diphenylphosphino)-3-oxapentane-O,P,P′]carbonylrhodium(I),[9] where the angles around the ether oxygen atom range from 112.5 to 117.5°, or in other metal monoether complexes such as chloro[1-(diphenylphosphino)-2-methoxyethane-O,P][1-(diphenylphosphino)-2-methoxyethane-P]platinum(II),[10] where the angles range from 111.5 to 120.8°.

The least-squares planes of interest are given in Table 4. The two vertical planes, each containing the rhodium, a chlorine, a coordinated ether oxygen and its *trans* oxime nitrogen, are nearly perpendicular to the chelate plane. The dihedral angle between the two vertical planes, internal to the chelate rings, is 76.45(7)°, which is much less than 90° due to chelate ring formation. The two chlorine atoms and the rhodium atom are not strictly linear, with a Cl—Rh—Cl angle of 177.39(4)°. There are no intermolecular contacts between non-hydrogen atoms less than 3.5 Å. The hydrogen bond between the oxime oxygen atoms is quite short, with an O---O distance of 2.391(4) Å. This distance is much shorter than the corresponding hydrogen bond in [Rh(AO)$_2$Cl$_2$][7] which has primary amino groups instead of ether oxygen atoms, with an O---O distance of 2.459(2) Å. Actually, the hydrogen bond distance found in [Rh(ether oxime)$_2$Cl$_2$] is the shortest among the previously studied, mononuclear rhodium(III) amine oxime complexes which have O---O distances ranging from 2.423(3) to 2.626(4) Å.[1,7,8] The dinuclear complex [Rh(BnAO)Cl$_2$]$_2$[8] has an O---O distance of 2.387(5) Å, which is the shortest found in any of the rhodium(III) amine oxime complexes.

Summary

We have prepared a bidentate ligand with an ether oxygen and an oxime nitrogen donor. The

rhodium(III) complex of this ligand was synthesized and characterized. To our knowledge this is the first reported metal complex with ligands with donor atoms of this type, and the first rhodium(III) complex with monoether coordination. The formation of this stable complex is unusual since simple ether donors do not generally form good complexes with metals. It also serves as a model for a new series of complexes containing oxygen atoms carrying appropriate functional groups that can be used to couple to protein molecules to form potential radiopharmaceuticals.

RHODIUM COMPLEXES OF TWO BIDENTATE SECONDARY AMINE OXIME LIGANDS AND APPLICATION TO THE LABELLING OF PROTEINS

G. ERGUN EFE, M. R. A. PILLAI,* E. O. SCHLEMPER† and D. E. TROUTNER

Department of Chemistry, University of Missouri, Columbia, MO 65211, U.S.A.

(*Received* 12 *December* 1990; *accepted* 21 *March* 1991)

Abstract—The syntheses of a new, bifunctional ligand, 3-[N-(4-aminobenzyl)]amino-3-methyl-2-butanone oxime, ligand **I**, and a non-bifunctional analogue 3-benzylamino-3-methyl-2-butanone oxime, ligand **II**, the former for labelling proteins with ^{105}Rh complexes for internal radiotherapy applications are reported. The rhodium complex of ligand **II** was isolated and characterized by ^{1}H NMR, IR spectroscopy and X-ray crystallography. The crystal structure consists of discrete mononuclear, neutral and slightly distorted octahedral molecules. The octahedron around rhodium consists of two *trans*-chlorine atoms and four nitrogen atoms from the two bidentate amine oxime ligands. The complex formed *in situ* with the bifunctional ligand **I** gives up to 95% yield with ^{105}Rh in pH 9 bicarbonate buffer. This complex was converted to the isothiocyanate derivative with thiophosgene and extracted into $CHCl_3$ (91%). Conjugation yields of greater than 90% could be obtained with human γ-globulin. The protein conjugation method described is suitable for the preparation of ^{105}Rh labelled antibodies with specific activities of 1.6–9.3 mCi mg^{-1}.

We have been investigating the use of ^{105}Rh as a radionuclide for use in internal radiotherapy. It is a 35.5 h moderate-energy beta-emitter whose usefulness is enhanced by the kinetic inertness and stability of the rhodium(III) complexes. Our goal is to synthesize rhodium(III) complexes of bifunctional chelates which can then be coupled to antibodies or other proteins by standard protein conjugation techniques. Our first approach to this work was to synthesize tetradentate ligands for rhodium with a pendant side arm suitable for coupling to the antibody.[1] Subsequent studies, however, showed that a simple tridentate ligand based on diethylene triamine gave rhodium complexes sufficient stability to permit preforming of the chelate followed by coupling.[2] We also showed that complexes of the simple ligand cysteine could be coupled to proteins through the pendant carboxylate group with chelation through the amine and sulphide groups.[3]

Because of this latter success we report here the design of a bidentate ligand with a pendant coupling group for rhodium. Previous work from this laboratory has shown that bis complexes of rhodium with the ligand 3-amino-3-methyl-2-butanone oxime are readily formed and are very stable.[4] For that reason we chose to modify the ligand to include a functionality for protein conjugation by substitution on the amine nitrogen. The initial modification placed a benzyl group on the amine nitrogen (Fig. 1, ligand **II**), and then we synthesized the 4-aminobenzyl analogue (ligand **I**) which is suitable for conjugation.

Rhodium-105 emits gamma radiation in significant amounts. All operations involving ^{105}Rh were performed in a laboratory approved for the handling of ^{105}Rh up to levels of 8 mCi.

EXPERIMENTAL

Materials and methods

γ-Globulins, human (G-4386) and Sephadex G 75 were purchased from Sigma Chemical Company. 4-Nitrobenzylamine hydrochloride was obtained

from Aldrich Chemicals. All other reagents or chemicals used were of reagent grade. ^{105}Rh was prepared at the Missouri University Research Reactor and supplied as aqueous $[RhCl_x \cdot (H_2O)_{6-x}]^{(x-3)-}$.

Instrumental methods. ^{1}H NMR spectra were recorded on a JEOL FX-90Q spectrometer. Solid-state IR spectra were recorded on a Nicolet 20 DXB FT–IR spectrometer using fluorolube mulls. Radioactivity was measured on a standard 5 × 5-cm NaI(Tl) well scintillation counter using 319- and 306-keV gamma rays of ^{105}Rh.

Elemental analyses were carried out by Galbraith Laboratories Inc., Knoxville, Tennessee.

Syntheses

3-[N-(4-aminobenzyl)]amino-3-methyl-2-butanone oxime, ligand **I**. 4-Nitrobenzylamine hydrochloride (2.2 g, 11.66 mmol) was dissolved in 70 cm^3 of deionized water and neutralized with 11.66 mmol of sodium hydroxide and extracted with chloroform. The chloroform extracts were combined and evaporated, and the residue was dried. 4-Nitrobenzylamine (1.38 g, 9.07 mmol) was dissolved in 50 cm^3 of absolute methanol and placed in an ice–acetone bath. 3-Chloro-3-methyl-2-butanone oxime (prepared as per ref. 5) (1.41 g, 10.44 mmol) was added to this and the solution warmed to room temperature slowly. It then was refluxed for 24 h. The solvent was evaporated, the residue was suspended in water and 5 M potassium hydroxide was added to change the pH to 8. The white precipitate was collected by filtration and recrystallized from hot ethanol. Yield: 58%.

PtO_2 catalyst (30 mg) in 1 cm^3 of ethanol was first placed in the hydrogenation apparatus and about 45 min later 340 mg of nitrobenzylamine oxime dissolved in 10 cm^3 of ethanol was added. The compound was hydrogenated with 100 cm^3 of hydrogen gas under atmospheric pressure with continuous stirring. The catalyst was removed by filtration, the ethanol was evaporated and the residue was dried. The product weighed 286 mg, yield: 95%. ^{1}H NMR (DMSO-d_6) δ(ppm): 1.17(s) methyl (6H), 1.76(s) methyl(3H), 3.2(s) CH_2 (2H), 4.85(s) NH_2 (2H), 6.46–6.93(m) aromatic (4H), 10.4(s) oxime (1H).

For elemental analysis, the dihydrohexachloroplatinate(IV) salt was prepared as follows. The ligand (0.13 mmol) was dissolved in 2.5 cm^3 of ethanol. 1 cm^3 of water was added, and the solution was acidified to pH 3 by the addition of 1.25 M hydrochloric acid. Then H_2PtCl_6 solution was gradually added and the colour of the solution became darker orange. The solution was filtered and placed in a refrigerator. Orange-coloured crystals formed over 24 h. Found: C, 21.4; H, 3.6; N, 6.1. Calc. $(C_{12}H_{21}N_{30})PtCl_6$: C, 22.8; H, 3.4; N, 6.7%. Lower observed values for carbon and nitrogen suggest that the crystals contain water molecules. For the formula $[C_{12}H_{211}H_{30}]PtCl_6 \cdot 2H_2O$, calculated percentages are as follows: C, 21.6; H, 3.2; N, 6.3%. Ligand **I** was also prepared as the chloride salt and its structure was determined by X-ray diffraction.[6]

3-Benzylamino-3-methyl-2-butanone oxime, ligand **II**. 3-Chloro-3-methyl-2-butanone oxime (2.44 g, 0.018 mol) was added to a solution of benzylamine (0.014 mol) in 25 cm^3 of absolute methanol at 0°C. The solution was stirred in an ice bath for several hours and brought to room temperature slowly. The mixture was then refluxed for 24 h. The solvent was evaporated and the residue was dissolved in water. Upon addition of base, a white precipitate formed which was collected by filtration. Yield: 64%, m.p. 68–69°C. The solid was recrystallized from a methanol–water mixture. ^{1}H NMR (DMSO-d_6) δ(ppm) 1.20(s) methyl (6H), 1.78(s) methyl (3H), 2.2(br) NH (1H), 3.4(s) CH_2 (2H), 7.28(s) aromatic (5H), 10.44(s) oxime (1H).

Rhodium complex of ligand **II**. Rhodium chloride (0.263 g, 1 mmol) was dissolved in 5 cm^3 of deionized water and to this solution, ligand **II** (0.464 g, 2.25 mmol) dissolved in 15 cm^3 of ethanol was added. Potassium hydroxide (1 mmol) was added to change the final pH to ~ 7 and the solution was heated under reflux for 7 h. The initial red colour of the solution turned to light orange, and it was filtered while hot. Orange crystals, suitable for X-ray crystallography, formed by slow evaporation of the

reaction mixture. Yield: 44%. ^{1}H NMR (DMSO-d_6) δ(ppm): 1.03(s) methyl (6H), 1.46(s) methyl (6H), 2.09(s) methyl (6H), 4.34(d) CH_2 (2H), 4.68(d of d) CH_2 (2H), 5.12(d) NH (2H), 7.37–7.44(m) aromatic 10H, 19.51(s) O—H—O (1H). Found: C, 48.9; H, 6.1; N, 9.5. Calc. $RhCl_2O_2N_4C_{24}H_{35}$: C, 49.2; H, 6.0; N, 9.6%.

Rhodium complex of ligand **I**. The procedure above was followed and initially produced an analogous orange solution. Repeated attempts to isolate the corresponding complex of ligand **I** were unsuccessful so that characterization by X-ray diffraction and NMR techniques was not possible. When the ethanol–water solutions were concentrated to attempt isolation, there were obvious additional reactions producing dark-coloured products which could not be redissolved for spectroscopic characterization. We postulate that this might be a result of a polymerization reaction involving the interaction of the dangling aromatic amines with additional rhodium atom(s). We were able to isolate the nickel(II) complex of ligand **I**, and the crystal structure confirms the expected analogous coordination of two ligands in a square plane with the dangling aromatic amines.[6] Because of the square planar preference of nickel(II), the subsequent reactions are not observed.

Collection and reduction of X-ray data

X-ray data were collected at 22(1)°C for the rhodium complex of ligand **II**, on an Enraf–Nonius CAD4 automated diffractometer controlled by a Digital PDP 11/34 computer using Mo-K_α radiation (λ = 0.7107 Å). Lattice constants were obtained by least-squares fit of 25 carefully centred reflections. To check instrument and crystal stability, the intensities of three standard reflections were recorded after every 7200 s of X-ray exposure and showed no significant decay or fluctuation. Orientation was checked after every 200 reflections with the use of the same standards and all 25 original reflections were recentred when the measured deviations of any of the three standards were significant. A summary of crystal data, data collection parameters and refinement results is given in Table 1.

Solution and refinement of the structures

The X-ray structure was solved by conventional Patterson and difference Fourier methods. The full-matrix least-squares refinements minimized the function $\Sigma w (|F_o|-|F_c|)^2$), where $w = 1/\sigma^2(F_o)$, $\sigma(F_o) = \sigma(F_o^2)/2F_o$ and $\sigma^2(F_o^2) = \sigma^2$ (counting) $+(0.04F_o^2)^2$. Atomic scattering factors were taken from the *International Tables for X-ray Crystallography*[7] and included anomalous scattering contributions. Hydrogen atoms were located by difference Fourier methods or were placed in chemically reasonable positions with B ~ 1.3 × B of atom attached. Positional parameters of hydrogen atoms were also included in the least-squares cycles. The maximum residual electron density was 0.21. The final positional parameters for the non-hydrogen atoms are included in the supplemental material.

Radiochemical studies

^{105}Rh *complexes of ligand* **I**. Bicarbonate buffer (0.5 cm^3 of 0.5 M), saline solution (1 cm^3, 0.9 %), $RhCl_3$ (2×10^{-3} mmol, 0.08 cm^3) and ^{105}Rh (0.1 cm^3, 15 MBq) were refluxed in a 10 cm^3 round-bottomed flask for 2 min. Ligand **I** (1 cm^3, 5×10^{-3} mmol) in ethanol was added to this and refluxing continued for 2 h. The final volume of the solution after refluxing was adjusted to 2 cm^3 and the rhodium concentration was 10^{-3} mmol cm^{-3}.

Estimation complex yield. The complex yield was estimated by the magnesium oxide adsorption technique.[8] Typically, a small aliquot of the complex was diluted to 0.4 cm^3 in saline. Magnesium oxide powder (50 mg) (USP, Light powder) was added to this and mixed over a vortex mixer for about 2 min. The suspension was centrifuged, and the activity associated with the supernatant was compared with the total activity to estimate the complex yield.

Preparation of the isothiocyanate derivative. For conjugation of the complex to protein the amino functional group was converted to the conjugating isothiocyanate group.[9] The complex (0.5 cm^3, 1.25×10^{-3} mmol ligand complexed to 5×10^{-4} mmol of rhodium) was mixed with 0.2 cm^3 of a chloroform solution of thiophosgene (2.7×10^{-2} mmol) for 2 min over a vortex mixer. The organic layer was separated after a 2 min centrifugation, solvent was removed under a stream of nitrogen gas and the residue was redissolved in 0.2 cm^3 of DMF.

Conjugation to γ-globulin. γ-Globulin solution (1 cm^3, 5×10^{-5} mmol) in borate buffer (pH 9) was mixed with 1×10^{-2}–5×10^{-2} cm^3 of activated complex prepared as above (2.3×10^{-5}–11×10^{-5} mmol) and incubated for 5 h at room temperature. Conjugation yields were estimated by gel filtration chromatography over a Sephadex G 75 column (30 × 1.4 cm) using 0.9% saline as eluent. Fractions (2 cm^3) were collected and their activity measured on a NaI(Tl) well scintillation counter.

Challenge studies. Labelled γ-globulin (0.8 cm^3) was mixed with 0.4 cm^3 of diethylenetriamine pentaacetic acid (10^{-2} mmol) and incubated for 24 h. The activity associated with the protein peak was estimated by gel filtration chromatography.

RESULTS

The crystal structure of the rhodium complex of ligand **II** consists of discrete, mononuclear, neutral, slightly distorted octahedral molecules (Fig. 2). The octahedron around rhodium consists of two *trans*-chlorine atoms and four nitrogen atoms from the two bidentate amine oxime ligands. The complex has two five-membered chelate rings and a six-membered ring closed by a strong hydrogen bond between the oxime oxygen atoms formed by the loss of one oxime hydrogen atom. A close examination of Fig. 2 and the torsional angles, e.g. C(2)—N(2)—C(6)—C(7): 108.3(3)°, C(2′)—N(2′)—C(6′)—C(7′): 106.1(3)°, N(2)—C(6)—C(7)—C(12): 115.7(4)°, N(2′)—C(6′)—C(7′)—C(12′): 115.2(4)°, reveals that the molecule nearly has a two-fold axis passing through rhodium and the hydrogen-bonded oxime hydrogen atom (HOO). The intramolecular bond distances and bond angles involving non-hydrogen atoms are given in Tables 2 and 3. The short intra-

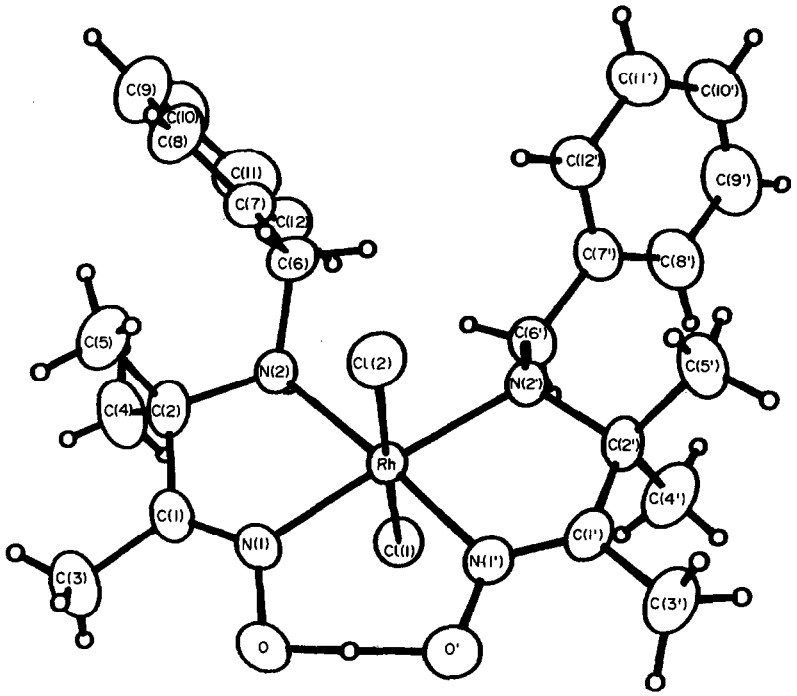

Fig. 2. Perspective view of the rhodium complex of ligand **II**.

molecular O—H—O hydrogen bond length is 2.419(4) Å. The other weaker intramolecular hydrogen bonding interactions in the molecule are between chlorine atoms and the hydrogen atoms on the amine nitrogen atoms; Cl(1)—HN(2) and Cl(2)—HN(2′) distances are 2.65 and 2.67 Å, Cl(1)—HN(2)—N(2) and Cl(2)—HN(2′)—N(2′) angles are 110 and 115°, respectively. The least-squares plane through the four nitrogen atoms and the rhodium atom is the best of the square planes around the rhodium atom and shows only a slight tetrahedral distortion. The *trans* N(1) and N(2′) atoms are slightly out of the plane towards Cl(1) and the *trans* N(1′) and N(2) atoms are slightly towards Cl(2).

The most characteristic peaks of the ^{1}H NMR spectra of the ligands are the low-field oxime proton signal around 10.5 ppm and the high field signals due to the methyl protons. The formation of the complexes is revealed by the movement of the 10.5 ppm oxime peak to *ca* 19 ppm and by splitting of the geminal methyl signal (singlet in the ligand) due to the different environment these methyl groups experience in the complex. The coupling pattern (^{1}H NMR) of the methylene proton in DMSO-d_6 suggests a similar structure in solution to that observed in the crystal structure. Only one of the non-equivalent methylene protons couples with the NH proton as a result of the angular relationship between the methylene protons and NH proton. The IR spectrum of the complex shows the characteristic broad, weak band at 1776 cm^{-1}, due to the intramolecular O—H—O hydrogen bond.

The data in Table 4 include some selected bond distances and angles around the metal atom. The corresponding data for the rhodium complex of the ligand 3-amino-3-methyl-2-butanone oxime are included for comparison.[4] A possible reason for the short distances around the oxime nitrogen atoms is the sp^2 hybridization of these atoms, whereas the amine nitrogens are sp^3 hybridized. The angles around the metal atom show significant deviations from the ideal square planar values because of the bulky phenyl substituent group on the amino nitrogens and the intramolecular O—H—O hydrogen bonding as well as the constraints of the five-membered chelate rings. As a result, the N(amine)—Rh—N(amine) angle opens up as wide as necessary for the most stable configuration. Consequently, N(amine)—Rh—N(oxime) and N(oxime)—Rh—N(oxime) angles are reduced to much smaller values. In the complex, the phenyl rings are oriented away from the rest of the molecule which is important for labelling with proteins, since the functional group on the complex would then be in a position available to react with a protein molecule. The octahedral coordination of the rhodium complexes, with two *trans*-chloride ligands prevents the phenyl rings from twisting above and below the molecular plane. We postulate a similar structure for the rhodium(III) complex of ligand **I** in the solutions discussed below. However, the exact structure

of that complex is not critical for the radiochemical results.

Radiochemical studies

Ligand I gave a clear solution after complexation with ^{105}Rh. No appreciable activity was lost as solid when the reaction mixture was centrifuged. The complex yield estimated by the MgO adsorption technique was about 95%. The conversion of the complex into the isothiocyanate derivative was nearly complete. About 91% of the activity was seen in the organic layer, consistent with formation of the expected neutral complex. The remaining 9% of the activity may be the uncomplexed rhodium and a small part of the complex which was not converted to the isothiocyanate derivative (activated complex). The high extractability of the activated

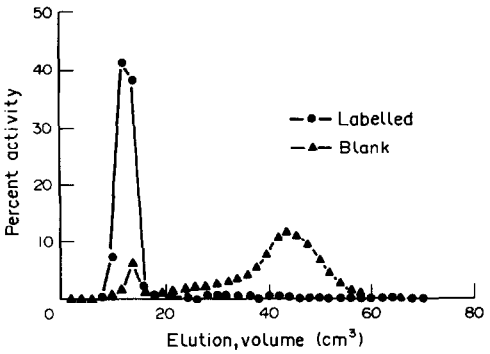

Fig. 3. Gel filtration chromatography pattern of specifically and non-specifically labelled human γ-globulin.

complex suggests a high partition coefficient for the isothiocyanate derivative compared with the original complex. Only 15% of the original complex could be extracted into chloroform under identical conditions. A back extraction of the activated complex from the organic layer was carried out and the distribution ratios of 19 and 69, respectively, were estimated. The change in distribution ratio with subsequent back extraction suggests the presence of more than one complex.

Results of the conjugation experiments are given in Table 5; yields reported are those calculated from gel filtration chromatography, and varied from 76 to 90%. At these values the number of rhodium atoms incorporated per molecule of γ-globulin varied from 0.35 to 2.0 depending on the concentration of the activated complex used for conjugation (average mol. wt of γ-globulins was taken as 15,000 for these calculations). A conjugation experiment with the unactivated complex gave only 10% of the activity in the protein fraction, indicating that the complex is not bound to γ-globulins non-specifically. Figure 3 gives the elution of labelled γ-globulins and non-specifically labelled γ-globulins in the gel filtration column.

No transfer of activity was seen from labelled γ-globulins to DTPA in challenge studies; this is indicative of the high stability of the rhodium complex in the labelled protein. Most of the activity (97%) was found in the protein fraction when the solution was chromatographed on a gel filtration column.

DISCUSSION

Rhodium-105 offers a number of advantages as a radiotherapeutic isotope. It has moderate energy β particles suitable for radioimmunotherapy. Its gamma emissions are less abundant, 306 keV (6%) and 319 keV (19%) and these gamma rays can be used for monitoring the efficacy of treatment. Rhodium forms kinetically inert and stable complexes with many ligands, and hence ^{105}Rh labelled antibodies are expected to be stable *in vivo*. Because ^{105}Rh can be produced in a nuclear reactor it offers the advantage of ready availability and low cost.

This study shows that the bidentate ligands described here form complexes with rhodium in high yields. Crystals of a quality suitable for X-ray diffraction studies were not obtained for the complex of ligand **I**, but there was no difficulty in synthesizing and isolating crystals of the complex of ligand **II**. We believe that the bifunctional ligand **I** probably forms a bis complex with rhodium similar to that with ligand **II**. Rhodium would be chelated to the four nitrogen atoms from the two ligands and the remaining two coordination sites would be satisfied by Cl^- or some other monodentate ligand. The crystal structure of the complex of ligand **II** shows both the phenyl groups to be orientated away from he rhodium atom. The coupling group, $—NH_2$, in the complex with ligand **I** is also expected to be directed away from the rest of the molecule and hence available for activation and conjugation to protein. However, the exact

[b] The complex used in this experiment was unactivated complex, for estimating the non-specific labelling of the γ-globulins by the complex.

structure of the complex(es) formed at the radiochemical level has not been established and is not critical for the labelling.

Ligand **I** formed complexes with ^{105}Rh at pH 9, HCO_3^- buffer, in yields greater than 95%. No loss of activity as inorganic rhodium during complexation was observed. The complex(es) formed is soluble at the 10^{-3} M concentration studied. Near quantitative conversion of the complex into the isothiocyanate derivative is possible, and hence it is unlikely that the functional group, $—NH_2$, is involved in metal binding. The high extraction ratio of the activated complex into chloroform aids in the isolation of the complex, leaving behind uncomplexed rhodium and most of the unactivated complex.

Depending on the initial complex to γ-globulin ratio, an average of 0.35–2 rhodium atoms could be added to each molecule of γ-globulin. Presently ^{105}Rh is available from the University of Missouri Research Reactor at specific activities greater than 700 Ci $mmol^{-1}$.[10] Using this ^{105}Rh, labelled γ-globulins with specific activities ranging from 1.6 to 9.3 mCi mg^{-1} were prepared by the method described above. It is believed that this work is extendable to label monoclonal antibodies with ^{105}Rh and that the specific activities obtained above are sufficient for radioimmunotherapy.

(*Received* 12 *December* 1990; *accepted* 21 *March* 1991)

Abstract—The thiobenzyl dithiocarbazate of 2-formylpyridine N-oxide, 2-$C_5H_4N(O)$—CH=N—NH—C(S)—$SCH_2C_6H_5$, crystallizes from ethanol as centrosymmetric dimeric units as a consequence of intermolecular N(O)···H—N bonds [O···N 2.763(4) Å]. In the centrosymmetric copper(II) complex, $\{Cu(ONO_2)[2\text{-}C_5H_4N(O)\text{—}CH\text{=}N\text{—}N\text{=}C(S)\text{—}SCH_2C_6H_5]\}_2$, the anionic ligand is coordinated via the N-oxide oxygen, the azomethine nitrogen and the thiol sulphur atoms. Including the nitrato group, the coordination geometry is primarily distorted square planar [with Cu—O(1) 1.949(1), Cu—N(9) 1.939(2), Cu—S(12) 2.254(1), Cu—O(22) 1.963(2) Å], but weak axial interactions to a second oxygen atom of the nitrato group [2.682(2) Å] and a neighbouring N-oxide oxygen atom [2.674(2) Å] complete an octahedron for the copper atoms in the dimeric units.

Thiosemicarbazones and dithiocarbazates of 2-acetylpyridine have received extensive attention due to their antimalarial, antitumour and antibacterial activity.[1] Their chelating ability with transition metal ions is found to relate to their medicinal activity.[2,3] In investigating the coordinating ability of these ligands with transition metal ions, West and co-workers recently extended their studies to thiosemicarbazones and the related S-methyldithiocarbazate of 2-acetylpyridine N-oxide.[4–6] Our current interest in sulphur–nitrogen donor ligands for copper complexation[7] led us to prepare the new potentially ONS donor ligand derived from 2-formylpyridine N-oxide and thiobenzylthiosemicarbazide, abbreviated as HONS. This paper reports the crystal structure determinations of the ligand and that of a copper(II) nitrato complex of the deprotonated ligand, $Cu(ONO_2)$(ONS); both species occur as dimeric units via bridging N-oxide atoms.

On the basis of IR, electronic and ESR spectral evidence, West and co-workers proposed that thiosemicarbazones of 2-acetylpyridine N-oxide could coordinate to copper(II) in a planar fashion, as depicted in Fig. 1. Since these earlier studies indicated that such ligands could coordinate as neutral, bidentate ligands (R = $NHCH_3$),[5] as well as in the deprotonated form utilizing ONS donor atoms [R = $N(CH_3)_2$,[6] SCH_3[6] and NC_8H_{14}[4]], the present X-ray crystal structure determinations were undertaken in initiating our complexation studies of HONS (R = $SCH_2C_6H_5$, R′ = H in Fig. 1).

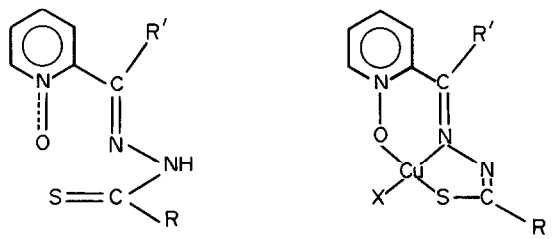

Fig. 1. General structural formula of HONS and its proposed bonding in copper(II) complexes in the deprotonated tridentate form (R′ = H, CH_3).

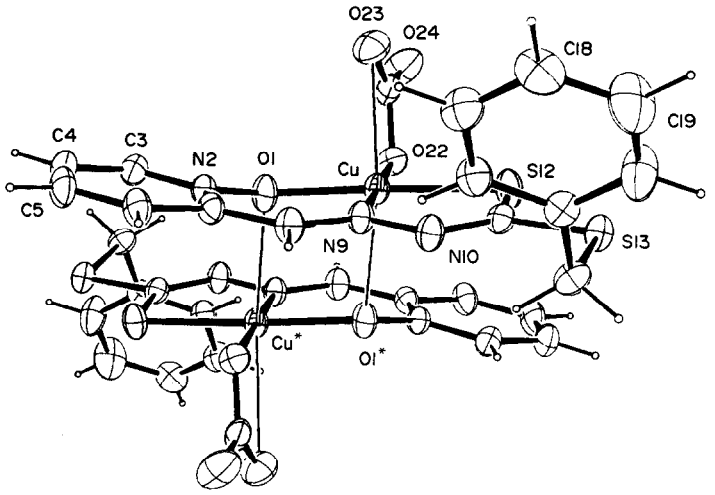

Fig. 3. A view of the dimeric $[Cu(ONO_2)(ONS)]_2$ complex with the crystallographic numbering scheme; ellipsoids are at the 50% level.

shown in Fig. 2,† displays bond lengths consistent with the representation in Fig. 1. The O(1)—N(2) distance of 1.301(4) Å is much shorter than 1.39 Å found in Me_3NO, where there can be no π-bonding,[8] and reflects significant double bond character. Similarly, the azomethine C(8)—N(9) distance [1.276(5) Å] corresponds to a double bond, as does the C(11)—S(12) bond length [1.652(4) Å, cf. 1.740(4) Å for C(11)—S(13)]. The O(1) to S(13) portion of the dithiocarbazate ligand is almost planar, with small dihedral angles between O(1)—C(8) and C(8)—C(11) (8.9°) or N(10)—S(13) (12.8°) moieties. The benzyl group, however, is twisted at right angles relative to the planes containing the potential donor atoms; for example, the dihedral angles between C(14)—C(20) and C(8)—C(11) or N(10)—S(13) planes are 87.1 and 90.8°, respectively (Table 1). An important feature of the crystal structure is the intermolecular hydrogen bond [NO···H—NO···N 2.763(4) Å] between the N-oxide oxygen atom and the amine hydrogen atom of a neighbouring molecule; the HONS ligand thus occurs as centrosymmetric dimeric units in the solid state.

Our crystallographic study of the copper complex establishes it as a centrosymmetric dimer (Fig. 3)‡ with the copper(II) geometry as primarily square planar. The copper atom is bonded to the N-oxide oxygen atom [1.949(1) Å], the azomethine nitrogen atom [1.939(2) Å] and the thiol sulphur atom [2.254(1) Å] of the deprotonated ligand; a copper–nitrato bond [Cu—O(22) = 1.963(2) Å] completes the distorted square plane. Bond length changes [e.g. longer N(2)—O(1), C(8)—N(9), C(11)—S(12) and shorter N(10)—C(11)] as com-

† Crystal data for $C_{14}H_{13}N_3OS_2$, $M_r = 303.4$, monoclinic, space group $P2_1/a$, $a = 8.873(3)$, $b = 11.635(2)$, $c = 14.193(2)$ Å, $\beta = 94.28(2)°$, $V = 1461(1)$ Å^3, $Z = 4$, $D_c = 1.38$ g cm^{-3}, $\mu = 3.5$ cm^{-1}, $F(000) = 632$, Mo-K_α radiation ($\lambda = 0.71073$ Å), $T = 21°C$. 3635 reflections were measured on a CAD4 diffractometer ($2\theta_{max} = 54°$), 3134 were unique and 1435 had $I > 3\sigma(I)$. Lorentz and polarization corrections were applied. The structure was solved using direct methods (SIMPEL). Refinement (with weights derived from the counting statistics) by full-matrix least-squares calculations (with all hydrogen atoms allowed for but not refined) converged with $R = 0.046$ and $wR = 0.057$ for the 1435 observed reflections. An extinction correction was also refined. The final cycle of refinement had 182 variables and maximum shift/error ratio of < 0.005. A final difference map had no chemically significant features. Full details of the analysis are available from the Cambridge Crystallographic Data Centre or from the authors.

The * refers to an atom at equivalent position $-x, 1-y, -z$.

pared with the uncomplexed HONS ligand are consistent with expectations, as represented in Fig. 1. However, the complex crystallizes as a dimer as a consequence of bridging N-oxide oxygen–copper interactions [Cu—O(1)* = 2.674(2) Å]. In the centrosymmetric dimer $[Cu(C_5H_5NO)_2(NO_3)_2]_2$[9] the bridging pyridine N-oxide O—Cu distance to the other copper atom is considerably shorter [2.439(6) Å], whereas the Cu—O bond lengths to the two pyridine N-oxide ligands [1.951(5), 1.968(5) Å] and the pyridine N-oxide N—O distances [1.362(7) Å] are similar to those found in the present complex (Table 2).

Pseudo-octahedral geometry for each copper(II) atom in our complex is completed by virtue of another weak axial bond to a second oxygen atom of the nitrato group [Cu—O(23) = 2.682(2) Å]. The asymmetric bidentate nature of the nitrato group, which is planar, is reflected in the disparate N—O bond distances [N(21)—O(22) 1.292(2),

N(21)—O(23) 1.232(2), N(21)—O(24) 1.217(3) Å]. Whereas the tridentate planar coordinating behaviour of similar thiosemicarbazone and dithiocarbazate ligands and the tetragonal nature of the copper(II) geometry was indicated previously by spectroscopic evidence,[4-6] the specific bonding and unique dimeric interactions are described by this first X-ray analysis of a copper(II) complex with a dithiocarbazate (or thiosemicarbazone) of a pyridine N-oxide. Complexation studies of HONS with a variety of metal ions are underway.

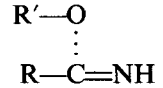
Abstract—The alcoholysis (ROH; R = Me, Et) of nitriles (RCN; R = Me, Et) in the presence of gold(III) chloride and/or hydrogen chloride was investigated. These alcoholysis reactions in the presence of gold(III) chloride occur much more rapidly than the nitrile–alcohol mixture alone. Elemental analyses and IR and NMR spectral data identified two products from the reaction. One product was the imino-ether salt, $[RC(OR')NH_2]^+[AuCl_4]^-$, while the other was the complex of the imino-ether and gold(III) chloride, $RC(OR')NH \cdot AuCl_3$ (R and R′ = Me, Et). The crystal structure of hydrogenethylpropylimidate tetrachloroaurate(III) (**3a**) was determined by X-ray diffraction techniques.

The catalysis of reactions of nitriles by metals has been of major interest for the past 20 years with considerable work focused on the metal-catalysed reactions of nitriles.[1] The coordination of the nitrile nitrogen to the metal or metal complex enhances the electrophilic nature of the nitrile carbon and typically increases the rate of reaction with nucleophiles. These reactions include the alcoholysis of nitriles to form imino-ethers[2–8] which are useful intermediates for the preparation of important acids or esters, but the slow initial reaction of the nitrile with alcohol



reduces the usefulness of these reactions. Therefore, catalysis of this step by metal complexes or other means is of interest and commercial importance.

Our interest in the alcoholysis arose for these reasons and because of the isolation of a second product in the preparation of nitrile complexes with gold(III) chloride, $RCN \cdot AuCl_3$, in chloroform solvent. The properties of the second product were very different, and analysis indicated the presence of oxygen. This paper describes the characterization and crystal structure of the product which is now known to be the imino-ether salt with the source of the oxygen being the solvent stabilizing ethyl alcohol. The complex between the imino-ether and gold(III) chloride is also described.

EXPERIMENTAL

Materials

Acetonitrile and propionitrile were dried over P_4O_{10} and distilled. All other chemicals were reagent grade. The gold(III) chloride was prepared by dissolving tetrachloroauric acid trihydrate in concentrated perchloric acid and evaporating the solution on a hot plate until crystals began to form. (**CAUTION:** Fumes from perchloric acid must be disposed of properly.) The crystals were collected and dried under vacuum at refluxing toluene temperature.

Preparation of nitrile complexes with gold(III) *chloride*

$EtCN \cdot AuCl_3$ (**1a**) and $MeCN \cdot AuCl_3$ (**1b**) were prepared as described in the literature.[9] The crystals were a very dark red colour and reacted rapidly with water in the air. The analytical results and IR spectral data are collected in Tables 1 and 2.

Preparation of imino-ether and hydrochloride salts

EtC(OEt)NH (**2a**), MeC(OMe)NH (**2b**), EtC(OMe)NH (**2c**), $[EtC(OEt)NH_2]^+[Cl]^-$ (**2d**) and $[MeC(OMe)NH_2]^+[Cl]^-$ (**2e**) were prepared as described in the literature.[10] The salts were also prepared by vacuum-line techniques. The alcohol was added to a 10-fold excess of the nitrile and degassed on a vacuum line. An amount of hydrogen chloride gas, equimolar (0.016 mol) to the alcohol, was transferred to the frozen solution. After slow warming to room temperature, a portion of the excess nitrile was removed by a vacuum until a solid began to form. The solution was placed in a refrigerator to complete crystallization, after which it was filtered, washed with diethyl ether and dried. The colourless crystals reacted slowly with water

from the air. Yields: imino-ethers, 25%; salts, > 95%. **2a**, b.p. 106°C; **2b**, b.p. 72–78°C; **2c**, b.p. 86°C; **2d**, m.p. 95–97°C; **2e**, m.p. 90–91°C. IR and NMR spectral data are collected in Tables 2 and 3.

Preparation of imino-ether tetrachloroaurate(III) *salts*

$[EtC(OEt)NH_2]^+[AuCl_4]^-$ (**3a**), $[EtC(OMe)NH_2]^+[AuCl_4]^-$ (**3b**) and $[MeC(OMe)NH_2]^+[AuCl_4]^-$ (**3c**) were prepared by dissolving gold(III) chloride (0.5 g) in a minimum of purified chloroform (40 cm^3) with equimolar amounts of the alcohol present and adding a 10-fold mole excess of the nitrile. After standing for several days, during which some solvent evaporated and trichloroethane was added, straw yellow crystals were obtained. The same product was obtained by the vacuum-line techniques described above. Equimolar amounts of the alcohol, hydrogen chloride gas, and gold(III) chloride (0.0033 mol) were dissolved in a 10-fold excess of the nitrile and treated as above with the exception that trichloroethane was added to aid precipitation. The crystals were unreactive towards air but did show visual evidence of reduction to gold metal after several weeks. Yield: > 75%. **3a**, m.p. 93–95°C, **3b**, m.p. 88–90°C. Analytical results and IR and NMR spectral data are collected in Tables 1–3.

Preparation of imino-ether complexes with gold(III) *chloride*

$EtC(OEt)NH \cdot AuCl_3$ (**4a**) and $MeC(OMe)NH \cdot AuCl_3$ (**4b**) were prepared by the direct reaction of the imino-ether in alcohol or chloroform solvents with gold(III) chloride in an inert atmosphere. However, the products were of poor quality, and the vacuum-line technique described above was used to prepare products for quantitative purposes. While reaction conditions for the production of the salt and complex were identical, some solutions would produce the salt, another would produce the complex and another would produce a mixture. The two products were identifiable because of differences in colour, melting point and IR spectra. The crystals were orange in colour and unreactive towards air but did show visual evidence of reduction to gold metal after several weeks. **4a**, m.p. 128–130°C; **4b**, m.p. 183–185°C. Analytical results and IR spectral data are collected in Tables 1 and 2.

Instrumentation

IR spectra of Nujol mulls were recorded on a Perkin–Elmer Model 283 spectrophotometer over the range 4000–200 cm^{-1}. ^1H NMR spectra were recorded on a Varian T-60A spectrometer. The spectra were obtained in deuteroacetone and deuteromethanol with TMS as the reference. ^{13}C NMR spectra were recorded on a JEOL JNM-FX60 spectrometer. The spectra were obtained in deuteroacetone with TMS as the reference. Elemental analyses were performed by Spang Microanalytical Laboratory, Eagle Harbor, Michigan and Galbraith Laboratory, Knoxville, Tennessee.

X-ray crystallography

The crystal and molecular structure of the hydrogenethylpropylimidate salt has been determined by

single crystal X-ray diffraction. Amber-coloured, rectangular plates of **3a** were grown by slow evaporation of a chloroform solution. The crystals were ground to a tear-shape by use of an air-driven crystal grinder. Crystals were then selected and mounted on glass fibres with epoxy using standard techniques. All data were collected at room temperature on a Nicolet R3 diffractometer. Precession photographs were used to evaluate the crystal quality and confirm the preliminary axial lengths and symmetry information. Corrections were made for decay, background, Lorentz and polarization using the program XTAPE.[11] Complete crystal, experimental and refinement data are given in Table 4. An empirical absorption correction was applied based on a set of appropriate psi-scans using the program XEMP.[11] The structure was solved by the use of the Patterson function to locate the gold atom, followed by successive application of difference Fourier maps and least-squares refinement to locate remaining non-hydrogen atoms.[12] Atoms C(4) and C(5) were refined with isotropic thermal parameters. All other non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions ($d_{C-H} = 0.96$ Å, riding model) and given an isotropic thermal parameter approximately equal to 1.2 times $U_{(eq)}$ for the atom to which it is bonded. Neutral atomic scattering factors were taken from the usual source[13] and were corrected for anomalous dispersion.

Important interatomic distances and angles are listed in Table 5. Additional data for the structure of **3a** and **3c** are included in the Supplementary Material. See paragraph at the end of the paper for details.

RESULTS AND DISCUSSION

While a mixture of nitrile and alcohol remains unchanged for long periods, the presence of gold(III) chloride and/or hydrogen chloride yields products in reaction times limited only by isolation times. The properties of colour and melting point support the formation of two different compounds and the elemental analyses (Table 1) give strong support to one being the imino-ether tetrachloroaurate(III) salt and the other being the complex between the imino–ether and gold(III) chloride. The IR and NMR spectral data (Tables 2 and 3) further support this conclusion and the crystal structure confirms the formation of the product. These data do indicate that the gold(III) is involved in the alcoholysis reaction. However, whether or not it is catalysing the reaction will have to await results of the kinetic study. The general observation was that it took longer to isolate the product from the gold(III) than from the hydrogen chloride reaction.

IR spectra

The major feature which indicates the formation of the imino-ether from the nitrile is the loss of the C≡N stretching frequency in the 2300 cm^{-1} region[14] and the appearance of the C=N stretching frequency in the 1600–1675 cm^{-1} region.[8] In addition, the appearance of vibrations due to the N—H group is evidence of the formation of the imino-ethers. The presence of the gold(III) and chloride is indicated by the Au—Cl stretching frequency.[15] The frequencies observed for the nitrile complexes, **1a** and **1b**, are indicative of a monosubstituted square planar complex, $AuCl_3 \cdot L$. The observation of similar frequencies for compound **4a** indicates that it is the imino-ether complex. The salts, **3b–3c**, exhibit only a single frequency which is consistent with the tetrachloroaurate(III) anion. While salt **3a** has several Au—Cl frequencies, the crystal structure shows a square planar tetrachloroaurate(III) anion. Further evidence for the formation of the complex is in the N—H frequencies. Only a single stretching frequency appears, and there are no bending or rocking frequencies. This indicates the presence of a single N—H bond.[8] A very similar system has been characterized with the $SbCl_6^-$ anion.[16]

NMR spectra

The NMR spectra (Table 3) are consistent with the presence of the imino-ether cation in solution. In the proton spectra, singlets at the appropriate chemical shift appear when methyl groups are present, and triplets and quartets at appropriate chemical shifts appear when ethyl groups are present. In the ^{13}C NMR spectra, the correct number of peaks appear at the appropriate chemical shifts. Unfortunately, neither the salt nor the complex could be identified due to the instability of the solutions. The cation undergoes further alcoholysis in methanol solution and the gold(III) is reduced in acetone solution. These results are consistent with reports of nickel(II)[1] and platinum(II)[4a] complexes. All of the salts have a broad singlet at 10.5 ppm which can be assigned to the protons on the nitrogen.

Crystal structure

The crystal and molecular structure of the hydrogenethylpropylimidate salt has been determined by single crystal X-ray diffraction. Salt **3a** crystallized

in the triclinic space group $P\bar{1}$ as discrete ion pairs with a $[EtC(OEt)NH_2]^+$ cation and $[AuCl_4]^-$ anion in the asymmetric unit. The gold atom forms four ionic bonds to chlorine at a mean distance of 2.285(3) Å arranged in a square planar geometry. The maximum deviation is 0.034(4) Å from the plane defined by the four chlorine and the gold atoms. The observed Au—Cl distance is in close agreement with a variety of similar compounds appearing in the Cambridge Structural Database[17] [e.g. 2.271 Å in tetraphenylarsonium tetrachloroaurate(III),[18] 2.273 Å in ammonium tetrachloroaurate(III)[19] and 2.271 Å in hydrogen bis(pyridine-N-oxide) tetrachloroaurate(III)].[20] A search of the database did not reveal an exact match for the cation. Three entries in the database did incorporate the fragment defined by the non-hydrogen atoms of the cation into larger cyclic structures without significant changes from the geometry of the cation observed in **3a**. The N—C(3) bond length of 1.28(2) Å is in the range typical of a formal N—C double bond.[21] N(1), C(2), O(1) and C(3) are co-planar within 0.01(1) Å for the plane defined by the four atoms. The cation and anion do not appear to have any appreciable interaction. The closest contact between non-hydrogen atoms is about 3.35 Å for N(1)—Cl(3). Figure 1 gives an ORTEP view of the ion pair along with the atomic numbering scheme. The structure contains the interesting feature of a near linear chain of gold atoms as illustrated in Fig. 2. The Au···Au distance of 4.264 Å lies well outside the sum of van der Waals' radii for gold of 3.40 Å.[22]

A partial structure for the hydrogenmethylethylimidate tetrachloroaurate(III) compound **3c** also has been determined, giving only the positions for the anion. The probable space group is $P2_1/a$, $Z = 2$, $a = 7.800(2)$, $b = 8.574(2)$, $c = 7.909(4)$ Å, $\beta = 102.15(3)°$, $V = 517.1(3)$ Å^3. The observed mean Au—Cl distance is 2.27(1) Å with the gold atom on an inversion centre. The closest non-bonded distance involving gold is Cl(1)···Au′ of 3.513 Å (primed atom related by $-0.5-x$, $-0.5+y$, $-z$). Experimental data and

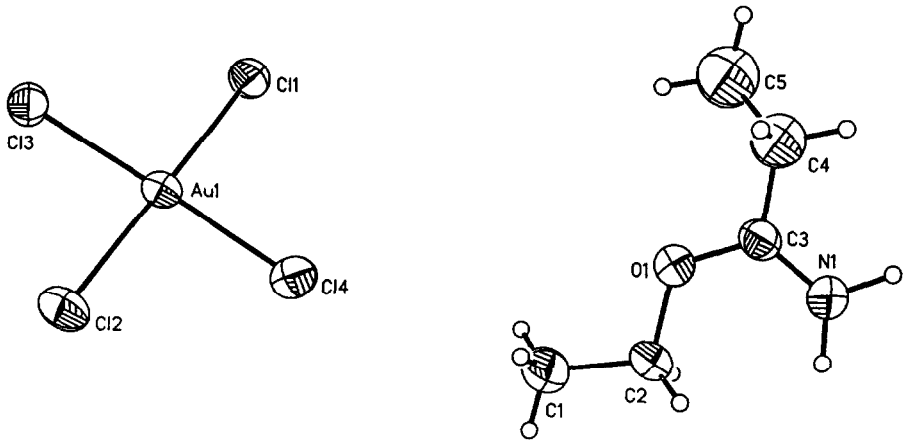

Fig. 1. An ORTEP diagram (50% thermal elipsoids) of **3a**.

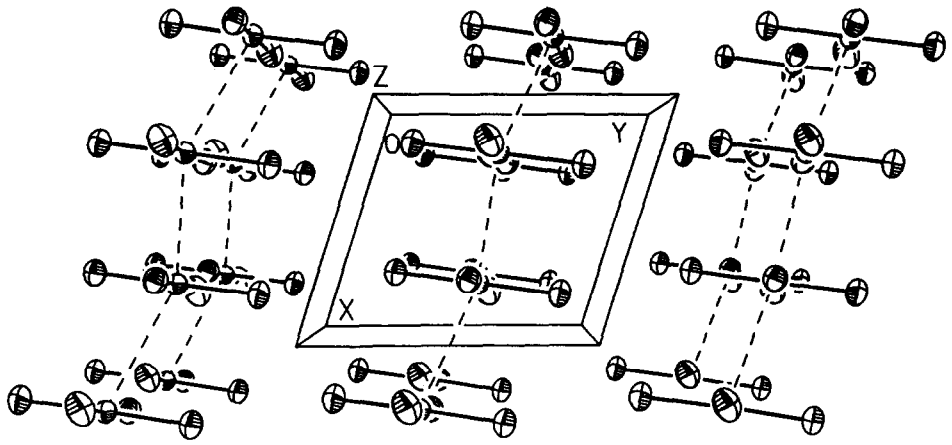

Fig. 2. A packing diagram for **3a** showing the Au—Au stacking arrangement.

positional parameters are available as Supplementary Material. Convergence of the data was achieved at $R = 0.0755$ and $R_w = 0.0921$. Unlike, **3a**, **3c** does not contain the near linear chain of gold atoms.

Supplementary material available. Atomic coordinates and thermal parameters for **3a** have been deposited with the Cambridge Crystallographic Data Centre. A summary of the crystal and data collection parameters, a description of the structure, atomic coordinates and bond lengths for **3c**, as well as observed and calculated structure factors for both compounds, are available from the authors.

(*Received* 5 *October* 1990; *accepted* 21 *March* 1991)

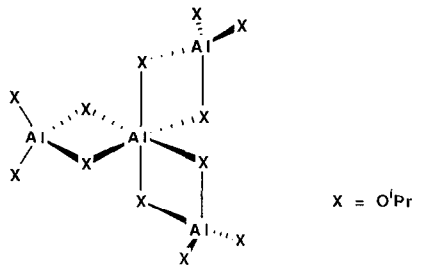
Abstract—Aluminium isopropoxide, in the form of a crystalline solid of melting point 127°C, has been shown by X-ray diffraction to be a tetrameric molecular species of formula $Al[(\mu\text{-}O^iPr)_2Al(O^iPr)_2]_3$, consistent with earlier proposals and spectroscopic data. A central aluminium achieves coordination number six via two bridging alkoxide groups from each of three $Al(O^iPr)_4^-$ groups. The resulting planar $Al(\mu_2\text{-}O)_2Al$ rings have widened ($\sim 132°$) angles at oxygen to increase the non-bonded Al—Al distance. While the terminal O^iPr groups show the shortest (1.70 Å) Al—O distances in the molecule, they are nevertheless strongly bent ($\sim 140°$) at oxygen. The ^1H NMR spectrum of $Al_4(O^iPr)_{12}$ is analysed based on the structure reported here. Characterization of aluminosiloxane derivatives $Al(O^iPr)_{3-x}(OSiMe_3)_x$ ($x = 1$–3) by ^1H and ^{27}Al NMR, mass spectrometry and IR spectroscopy is also reported. For $x = 1$ and 2, these show co-existence of several oligomers. The effect of incorporation of $OSiMe_3$ groups is to favour smaller oligomers.

The materials of empirical formula $Al(OCHMe_2)_3$ have been the focus of a variety of characterization studies and also of applications.[1] Synthetic organic applications include use as a catalyst for the Meerwein–Ponndorf–Verley hydride transfer from the ^iPrO methine carbon to ketones or for the Tishchenko reaction (conversion of aldehydes to esters). More recently, "$Al(O^iPr)_3$" has been a key component in the efforts of the group of Mehrotra to produce aluminium-containing heterometallic alkoxides. Examples include compounds of the type $M[Al(O^iPr)_4]_n$, where M^{n+} is a main group, transition metal, lanthanide or actinide element.[2] Hydrolysis of $Mg[Al(O^iPr)_4]_2$ to spinel $MgAl_2O_4$ is an example of the molecular precursor route to solid oxides.[3] Thermal condensation of $Al(O^iPr)_3$ with metal acetates offers soluble oxoheterometallic alkoxides $\{[(O^iPr)_2AlO]_2M\}_n$ (M = Fe, Co, Cr, . . .) which are catalysts for polymerization of heterocyclic compounds[4] or for oxidation reactions.[5]

The above paragraph began with "the materials . . . $Al(OCHMe_2)_3$ . . ." because this material, when synthesized from aluminium and ^iPrOH and vacuum distilled (100–150°C depending upon the pressure) is obtained as an oil or a viscous ("syrupy")[6] liquid, which is said to "age" over a period of days to give a solid.[7] Such behaviour is unusual and the viscous form has been termed a supercooled melt. Since the degree of aggregation, as measured by cryoscopy, increases with time, the ageing phenomenon is proposed to be due to a reorganization of smaller oligomers into large ones. By heating material at 200°C for 5 min, then cooling rapidly to 25°C for cryoscopy in benzene, a trimeric molecular weight was established.[6,7] The crystalline solid produced after several days (or by recrystallization of the melt from ^iPrOH), with melting

* Authors to whom correspondence should be addressed.

point 118°C, is tetrameric.[6,7] Bradley suggested structure **I** for the tetramer.[8] This represented a



I

dramatic break with the conventional wisdom of that period, which considered both the trimer and the tetramer to have cyclic structures with equivalent aluminium centres. The group of Shiner at Indiana brought ^{1}H NMR spectroscopy to bear on this problem.[6] Particularly noteworthy was their ability to use the *complex* NMR pattern of the tetramer to support the structural proposal (**I**) of Bradley. Kleinschmidt measured[9] the ^{27}Al NMR spectrum of the tetramer in toluene. Two resonances were observed, of relative intensity 3 : 1. The intensity 3 resonance was 30 times broader than the other resonance, and it fell (−59 ppm, using old sign convention) in the chemical shift region diagnostic of four-coordinate aluminium. The unit intensity resonance at −1.5 ppm was very close to the value (0.0 ppm) of six-coordinate aluminium in aluminium(acetylacetonate)$_3$. The cyclic trimer (i.e. a freshly produced melt) exhibited a different ^{27}Al NMR spectrum. These ^{27}Al NMR results have been confirmed recently by Fourier transform instrumentation.[10]

The simplicity of the system described to this point is perturbed by strong assertions[11] that a dimeric form of aluminium isopropoxide also exists.

The single-crystal X-ray determination of the solid-state structure of a sample of $[Al(O^iPr)_3]_m$ was carried out in 1979 and confirmed structure **I**.[12] However, because this determination was not cited in subsequent aluminium alkoxide articles, we remained ignorant of the work. When single crystals of one form (subsequently shown to be the *same* form as that studied earlier[12]) became available to us, we proceeded with a structure determination.

An expanded class of aluminium alkoxides, the siloxides, is also of interest. Materials based on the SiO_2–Al_2O_3 systems are well known for their refractory properties. Aluminosiloxanes $[Al(O^iPr)_{3-x}(OSiMe_3)_x]_m$ can be used as precursors of gels and ceramics. The differential hydrolysis introduced by the siloxo group (less susceptible to hydrolysis than the isopropoxo ones) prevents the precipitation of aluminium hydroxide and thus allows the formation of very homogeneous gels.[13]

We wish now to report further characterization of aluminosiloxanes, as well as our redetermination of the molecular structure of "aged" aluminium triisopropoxide.

EXPERIMENTAL

All operations were carried out under an atmosphere of dry nitrogen gas in solvents that were dried and distilled. ^{1}H and ^{27}Al NMR were registered on Bruker WH-90 and AM-200 spectrometers. ^{27}Al spectra were registered at high temperature and chemical shifts are given with respect to $Al(H_2O)_6^{3+}$ as an external reference. Synthesis of the aluminosiloxanes was achieved according to ref. 14. IR spectra were obtained as Nujol mulls on an FT IRS 45 Bruker spectrometer. Mass spectra were measured on a Ribermag R10-L10 spectrometer. Microanalyses were performed by the Centre de Microanalyses du CNRS.

The aluminium isopropoxide was prepared by a literature method,[15] distilled and allowed to crystallize from toluene at −30°C. Identity and purity of the colourless, crystalline solid (octahedral and truncated octahedral morphology) was established by comparison of the ^{1}H NMR to a literature report, and by comparison of its (sealed tube) melting point (127°C) to that measured on a commercial (Aldrich) sample (128°C), both uncorrected.[16]

X-ray diffraction study of $[Al(O^iPr)_3]_4$

Crystal data at −155°C: $C_{36}H_{84}Al_4O_{12}$, $M = 816.98$, tetragonal, $a = b = 12.317(3)$, $c = 31.724(8)$ Å, $U = 4813.19$ Å^3, $Z = 4$, $D_c = 1.13$ g cm^{-3}, $\lambda = 0.71069$ Å, $\mu = 1.42$ cm^{-1}, space group $P4_12_12$, $R = 0.0491$, $R_w = 0.0457$. This crystal was synthesized and crystallized by a method[15] identical to that used by Turova *et al.*[12] and our space group is identical to theirs.

A crystal was mounted in a nitrogen atmosphere using silicone grease and was transferred to a goniostat where it was cooled to −155°C for characterization and data collection.[17] A systematic search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited tetragonal symmetry. After intensity data collection using a narrow scan width due to the length of the *c*-axis, a more careful examination revealed systematic absences and Laue symmetry consistent with the non-centrosymmetric space group $P4_12_12$ (No. 92). A total of 4263 reflections (including stan-

dard reflections and space group extinctions) was collected, and 42 reflections which suffered from overlap were rejected. The R for the averaging was 0.066 for 1670 unique data which had been observed more than once. Four standards measured periodically showed no significant trends. No correction was made for absorption.

The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. The aluminium positions were obtained from the E-map and the remaining non-hydrogen atoms were located using difference Fourier techniques. Hydrogen atoms were located following the initial refinement. The full-matrix least-squares refinement was completed using anisotropic thermal parameters on the non-hydrogen atoms and isotropic thermal parameters on the hydrogen atoms.

The final difference map was essentially featureless, the largest peak being 0.36 e $Å^{-3}$ in the vicinity of Al(1). No attempt was made at determining the correct absolute configuration. The molecule lies on a crystallographic two-fold axis. Atoms related by the symmetry operation are indicated by ′ in Fig. 1 and Table 1. Tables of atom coordinates and thermal parameters are available from the Cambridge Crystallographic Data Centre. A list of final structure factors is available from one of the authors (K.G.C.).

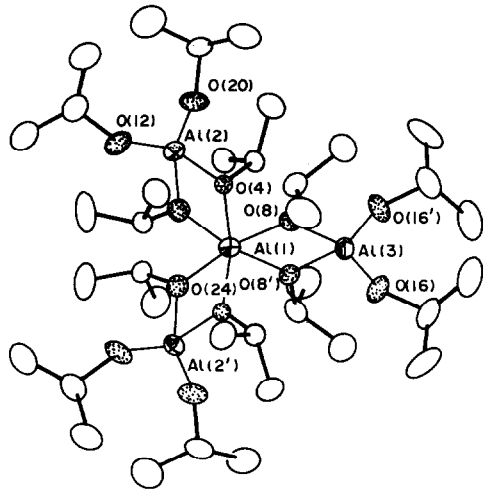


Fig. 1. Stereo ORTEP drawing of the non-hydrogen atoms of $[Al(O^iPr)_3]_4$ viewed down an idealized C_3 axis of symmetry. Selected atoms are labelled, with primed and unprimed atoms being related by a crystallographic C_2 axis passing through Al(1) and Al(3). Stippled atoms are oxygen.

$[Al(O^iPr)_2(OSiMe_3)]_m$

This was synthesized according to the literature procedure[14] from aged $Al(O^iPr)_3$ (9.86 g, 0.048 mol) and $Me_3SiO_2CCH_3$ (6.33 g, 0.048 mol) in 1.30 cm^3 of cyclohexane. Silylacetate was added over a

period of several hours during which azeotropic distillation of cyclohexane/isopropyl acetate was achieved (80°C). The solution was then concentrated and distilled (80°C/0.01 mm Hg) to give 11 g (98% yield). Found: C, 45.4; H, 10.1. Calc. for $C_9H_{23}AlO_3Si$: C, 46.1; H, 10.0%. IR (cm^{-1}): 1250 (Si—C); 1180, 1130 (C—CH_3); 1070; 950 (Si—O); 760; 640 (Al—OR). MS (m/z^+, %); M = [Al(O^{i}Pr)$_2$(OSiMe$_3$)]$_4$; M−OPr (2%); M−OSiMe$_3$ (3%); M−2OPr (6.6%); M−OSiMe$_3$−OPr (4%); $Al_2(O^iPr)_4(OSiMe_3)_2H$ (35%); $Al(OSiMe_3)_2$ (100%); AlO (90%). ^{1}H NMR ($CDCl_3$; 0.1 M, 25°C) (ppm): 4.47–4.08 (m, O*CH*Me$_2$, 2H). 1.42; 1.27; 1.47; 1.36; 1.21, 1.10; 1.06 (d, J = 6 Hz, OCHMe$_2$, 12H); 0.25, 0.22, 0.21 (s, OSiMe$_3$, 9H). We have examined six different crystals at temperatures from −150 to +5°C but found none suitable for an X-ray diffraction study.

$[Al(O^iPr)(OSiMe_3)_2]_p$

Analogous to the previous synthesis, but with a 2:1 ratio of silylacetate to aluminium (0.109 mol). Product was distilled at 105°C/0.01 mm Hg to give 24.2 g (95% yield). Found: C, 39.7; H, 9.7. Calc. for $C_9H_{25}AlO_3Si_2$: C, 40.9; H, 9.5%. IR (cm^{-1}): 1250 (Si—C); 1180, 1130 (C—CH_3); 1070, 950 (Si—O); 640 (Al—OR). MS (m/z^+, CI, NH_3): M = [Al(O^{i}Pr)$_2$(OSiMe$_3$)]$_3$; M−O^{i}Pr (1.4%); M−OSiMe$_3$ (4.6%); M−2O^{i}Pr (3.2%); M−(OSiMe$_3$+O^{i}Pr) (3.9%); M+Al(O^{i}Pr)$_2$(OSiMe$_3$) (19.4%); AlOH(OSiMe$_3$) (100%). ^{1}H NMR ($CDCl_3$; 0.1 M, 25°C) (ppm): 4.18 (m, O*CH*Me$_2$, 1H), 1.22; 1.32 (d, J = 6 Hz, OCH*Me*$_2$, 6H) 0.26; 0.04 (s, OSi*Me*$_3$, 18H).

$[Al(OSiMe_3)_3]_2$

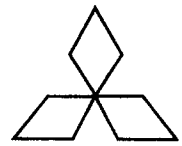
Analogous to the above synthesis, but with a 3:1 ratio of silylacetate to aluminium. The product was purified by sublimation (100°C, 10^{-2} mm Hg). Yield: 70%. Found: C, 35.2; H, 9.3. Calc. for $C_9H_{27}AlO_3Si_3$: C, 36.7; H, 9.2%. IR (cm^{-1}): 1256 (Si—C); 1067; 997, 957 (Si—O), 849, 752, 640, 598, 520, 382, 330. Mass spectrum (m/z^+ %): M (molecular ion, 61%); M−O (100%); M−HSiMe$_3$ (19%); M−OSiMe$_3$−CH$_2$ (10%); M−O(SiMe$_3$)$_2$−CH$_2$ (7%). ^{1}H NMR (d_8-toluene): 0.28, 0.22 (intensity 1:2).

RESULTS

$[Al(O^iPr)_3]_m$

The X-ray diffraction study (Fig. 1) shows the tetragonal crystals to be composed of $Al_4(O^iPr)_{12}$ molecules, each of which has crystallographic C_2 symmetry. The C_2 axis contains Al(1) and Al(3). The formula is best written as Al[(μ_2-O^{i}Pr)$_2$ Al(O^{i}Pr)$_2$]$_3$, in complete confirmation of the conclusions of earlier workers.[6,8,12] One aluminium is six-coordinate and the remaining three are four-coordinate. The overall molecular symmetry approximates D_3, with one Al^{3+} being coordinated by four $Al(O^iPr)_4^-$ units, each of which functions as a bidentate ligand. The material whose structure we report here is identical in composition of matter and space group with that studied by Turova *et al.*[12] Their study, at 25°C, shows high thermal motion and a higher R factor (0.119 for anisotropic refinement of all non-hydrogen atoms), but none of their conclusions is altered by our low-temperature study. The low-temperature study has smaller ESDs and improved agreement between Al—O distances and all bond angles which would be expected to be chemically equivalent.

The Al[(μ-O)$_2$Al]$_3$ core adopts a Mitsubishi motif (**II**). The Al—O bond lengths increase in the order



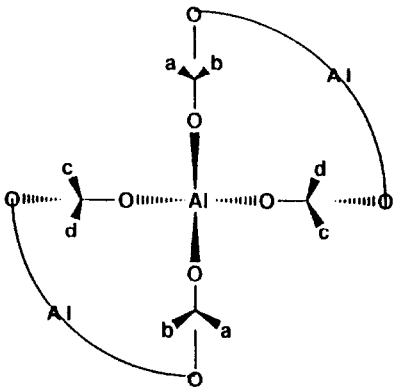
II

^{4}Al—O < ^{4}Al—(μ-O) < ^{6}Al—(μ-O), where the superscript indicates the coordination number. In each step in the above progression, the bond lengthens by 0.10–0.12 Å. In spite of the short Al—O (terminal) bond lengths (average 1.700 Å), bond angles at these oxygen atoms range from 134.5(5) to 136.9(5)°. These are relatively small. Since terminal alkoxides on early transition metals are normally within 15° of being linear at oxygen, oxygen π-donation must be greater for those metals than for aluminium.

The four-membered rings in $Al_4(O^iPr)_{12}$ are all planar. The angle ^{6}Al—O—^{4}Al is large [100.2(2)–100.8(2)°], producing non-bonded ^{6}Al—^{4}Al distances of 2.87 Å. The bridging oxygen atoms are coplanar with their attached groups, and the attached isopropyl groups bend away from the bulkier six-coordinate Al(1) towards the four-coordinate aluminium centres.

Based on the structure determined here, the ^{1}H NMR of $[Al(O^iPr)_3]_4$ warrants some discussion. The molecule has idealized D_3 symmetry, with a C_3 axis making all $Al(O^iPr)_4$ groups equivalent and three C_2 axes, each passing through one four-coordinate aluminium and the six-coordinate

aluminium. This leads to the conclusion that there is only one type of μ_2- and one type of terminal alkoxide, but that the methyl groups on each of these two ^{i}Pr groups are diastereotopic (i.e. inequivalent). One expects four methyl chemical shifts, all of equal intensity.



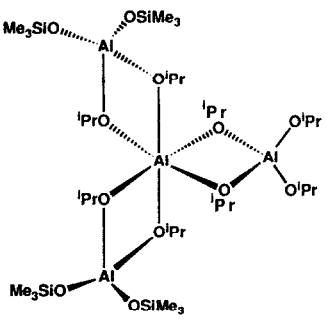
The observed ^{1}H NMR spectrum (300 MHz, 25°C, d_8-toluene) shows the expected two methine chemical shifts, but only *three* methyl resonances (doublets) of intensity 1 : 1 : 2. We assign the intensity 1 peaks to the μ_2-O^{i}Pr groups, so the *absence* of the expected inequivalences of the terminal isopropoxy methyls must be due to either (1) accidental equivalence or (2) some dynamic averaging process. We feel that an intramolecular[18] dynamic process is less likely, since such a process would almost certainly average bridge with terminal alkoxides. A Ray–Dutt twist would maintain the distinction between bridge and terminal groups, but this would cause not only the diastereotopic terminal methyls to coalesce, but also the diastereotopic bridging methyls to coalesce; two doublets are predicted.

Aluminosiloxanes

The various aluminosiloxanes $[Al(O^iPr)_{3-x}(OSiMe_3)_x]_n$ ($x = 1$–3) have been obtained by transesterification reaction in cyclohexane using Me_3SiOAc as a reactant,[14] and characterized by microanalysis, IR, ^{1}H and ^{27}Al NMR (Table 2) as well as by mass spectrometry.

$[Al(O^iPr)_2(OSiMe_3)]_m$

The mass spectrum indicates $[Al(O^iPr)_2(OSiMe_3)]_m$ contains tetrameric units. The ^{27}Al NMR spectrum of this material shows (toluene, 0.1 M, 70°C in order to narrow the signals) a sharp peak at 3.8 ppm ($\Delta_{1/2} = 40$ Hz), as well as broader signals at 40 and 60 ppm which we assign to six-coordinate and two types of four-coordinate metal centres, respectively.[19,20] We proposed structures **III** or **IV** to account for these data. These place



III

Table 2. ^{27}Al NMR data of some aluminosiloxanes

the four more bulky $OSiMe_3$ groups in the least hindered (terminal) positions of the tetramer structure. These incorporate one six-coordinate aluminium and create two distinct types of four-coordinate aluminium centres by means of the $OSiMe_3$ substituent pattern.

The C_2 symmetry of structures **III** and **IV**, interpreted rigorously, requires eight ^{i}Pr methyl chemical shifts and two $OSiMe_3$ chemical shifts. The ^{1}H NMR spectrum (0.1 M, 25°C) shows at least seven ^{i}Pr methyl and two $OSiMe_3$ resonances. This is thus consistent with either structure **III** or **IV**. Since we find the ^{1}H NMR spectrum to be concentration dependent, additional oligomers, or even a mixture of **III** and **IV** may be present under other conditions. In addition, integration of the ^{27}Al NMR spectrum shows that the tetramer comprises only about 25% of the species present at 70°C, and that species with tetracoordinate aluminium predominate. Ligand redistribution in solution [eq. (1)] can be excluded by the absence of any signal due to $[Al(O^iPr)_3]_4$:

$$2[Al(O^iPr)_2(OSiMe_3)]_m \longrightarrow m/4[Al(O^iPr)_3]_4 + [Al(O^iPr)(OSiMe_3)_2]_m. \quad (1)$$

$[Al(O^iPr)(OSiMe_3)_2]_p$

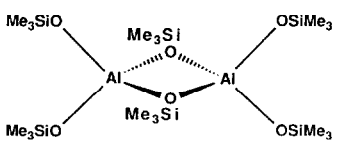
The mass spectrum of $[Al(O^iPr)(OSiMe_3)_2]_p$ shows fragments up to a trinuclear unit. The ^{27}Al NMR spectrum (toluene, 0.1 M) differs mainly from that of $[Al(O^iPr)_2(OSiMe_3)]_m$ by the absence of a sharp signal around 3 ppm, and thus establishes the absence of any six-coordinate aluminium centre. The spectrum shows very broad resonances at 40 ppm (weak) and 60 ppm (strong). We assign the former to five-coordinate and the latter to four-coordinate aluminium, and propose a small amount of structure **V** together with a cyclic trimer (**VI**) or a dimer. Structure **V** has the merit that it is the simplest structure derivable by removal of one aluminium (to give a trimer) from the structure of $[Al(O^iPr)_3]_4$, and in that way it naturally accounts for the absence of six-coordinate aluminium. The central aluminium now has a trigonal bipyramidal geometry, and structural type **V** has been firmly established for $Al_3Cl_5(O^iPr)_4$,[21] $Al_3Br_5(OSiMe_2O SiMe_2O)_2$[22] and $Al_3Cl_5(OBPh_2OBPh_2O)_2$.[23] Five-coordinate aluminium is also established in $Al_{10}(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(OEt)_{22}$.[24] While structure **V** predicts three $OSiMe_3$ resonances (two are observed) and four ^{i}Pr methyl resonances (two are observed), we feel that the rapid fluxionality common to trigonal bipyramidal structures can account for the simpler observed spectrum.

In contrast to $[Al(O^iPr)_3]_m$ and $[Al(O^iPr)_2(OSi Me_3)]_m$, which transform to solids on "ageing", $[Al(O^iPr)(OSiMe_3)_2]_m$ remains a pasty solid at 25°C. For this reason, crystals suitable for X-ray structure determination could not be obtained. Below −30°C, it is a normal, crystalline solid, but it becomes soft and waxy by 25°C, this suggests plastic phase behaviour.[25] To probe this behaviour further, we have recorded the ^{1}H NMR of neat $[Al(O^iPr)(OSiMe_3)_2]_p$ from −30 to +50°C. A signal is detectable in the solid state at −30°C ($\Delta_{1/2} = 3500$ Hz), which indicates considerable rapid reorientational motion in the solid. The peak width drops rapidly in the range +5–+15°C, and achieves a value of 100 Hz by 20°C. At 20°C, the colourless, crystalline material suddenly converts

into a translucent solid. By 50°C, the spectrum is analogous to that of a solution. This variation in line width reflects a drastic change in molecular freedom, which we assign to a plastic phase transition, above which the molecules begin to rotate or *pseudorotate*, while maintaining their centre of gravity in the solid. This interpretation is supported by differential scanning calorimetry, which shows an endothermic transformation at −27°C; upon cooling, this transition is found at −33°C. Such hysteresis is a common feature of plastic phase transitions.[25] Plastic crystals generally involve highly symmetrical, nearly spherical molecules. The behaviour observed for $[Al(O^iPr)(OSiMe_3)_2]_p$ thus supports a cyclic trimeric structure (**VI**) in the solid state.

$[Al(OSiMe_3)_3]_2$

$[Al(OSiMe_3)_3]_2$ displays a dimeric structure in solution (two types of ^1H NMR signals in a 2:1 ratio), as well as in the vapour phase. Structure **VII**



VII

is indicated,[20,26] and has been found for $Al_2Br_4(\mu\text{-}OSiMe_3)_2$.[27] The ^{27}Al NMR chemical shift is in the region characteristic of four-coordinate aluminium.

CONCLUSION

The occurrence of different oligomers of aluminium isopropoxide suggests that they may also have different reactivity. There are already indications that this is true,[18] and this general subject deserves further study.

It appears that substitution of isopropoxo by trimethylsiloxo groups stabilizes smaller oligomers in comparison to $[Al(O^iPr)_3]_4$, apparently because of the larger steric profile of $OSiMe_3$ compared with O^iPr. Higher aggregates entail higher metal coordination numbers and thus larger interligand repulsions.

Since many metal alkoxides and siloxides display *closo* structures, plastic phase behaviour may be responsible for the poor crystallizability, the poor diffraction intensity and the poorly refineable X-ray intensity data for this class of compounds.

(*Received* 12 *November* 1990; *accepted* 27 *March* 1991)

Abstract—The kinetics of ferrocene reduction of the dithiaether copper(II) complex, $[Cu(pdto)]^{2+}$ [pdto = 1,8-bis(2-pyridyl)-3,6-dithiaoctane], has been studied in the solvents acetone, acetonitrile, methanol and dimethylsulphoxide. Data have been obtained in 0.10 M n-Bu_4NPF_6 and with no added electrolyte. Formal potentials have been measured for the participating couples by cyclic voltammetry, and rate constants have been estimated for $[Cu(pdto)]^{2+}$–$[Cu(pdto)]^{+}$ self-exchange in each solvent. The effect of copper(II)–solvent interactions on the reaction mechanism and on estimated self-exchange rate constants are discussed. Stability constants for $[Cu(pdto)]^{2+}$ have also been determined in a range of dipolar solvents to assess solvent interactions.

The effect of ligand constraints on the electron-transfer self-exchange rates of copper(II)–copper(I) redox couples in coordination environments provided by nitrogen and sulphur donor ligands has been an area of much recent interest.[1] Correlation of self-exchange rate constants obtained with changes in stereochemistry and coordination number that accompany the redox change have been examined and used in some instances to provide insight into factors influencing the kinetic reactivity of blue copper protein active sites.[2–15]

We have previously reported the kinetic behaviour of the $[Cu(pdto)]^{2+}$ complex, with a $Cu^{II}N_2S_2$ coordination environment, on reduction by ruthenium(II) ammine and bipyridyl complexes in aqueous media.[8] Since the geometric change accompanying loss of an inner-sphere water molecule on reduction of the five-coordinate copper(II) reactant, $[Cu(pdto)(H_2O)]^{2+}$, to the four-coordinate copper(I) product is believed to be responsible for the relatively slow copper(I)–copper(II) self-exchange rate constant estimated for the $Cu(pdto)^{2+/+}$ couple, the kinetics of reduction of $Cu(pdto)^{2+}$ have been extended to other donor solvents, using ferrocene as reductant, to explore solvent influences on the reaction and to determine whether different solvent interactions with the copper(II) centre are reflected in the measured reaction rates, and in estimated values of copper(I)–copper(II) self-exchange rate constants. Stability constants, K_f ($Cu^{2+}{}_{(solv)}$ + pdto = $[Cu(pdto)^{2+}]$), for the complexation of Cu^{2+} by the tetradentate ligand pdto, in different solvents, have also been determined to provide information on copper(II)–solvent interactions.

EXPERIMENTAL

Materials

The ligand pdto and the complex $[Cu(pdto)](ClO_4)_2$ were prepared according to the literature method.[16] Ferrocene (Sigma) was purified by sublimation at atmospheric pressure and the electrolytes n-Bu_4NPF_6 (Aldrich) and n-Bu_4NClO_4 (G. F. Smith) were recrystallized from ethanol–water and dried *in vacuo*. Solvents were dried over molecular sieves (3–4 Å) and freshly distilled prior to use. Acetonitrile (Aldrich 99+ spectroscopic grade) was refluxed with P_2O_5 prior to distillation, with only the middle distillate fraction used.

Kinetic measurements

An Aminco stopped-flow spectrophotometer, coupled to a Nicolet 2090 digital oscilloscope and a Hewlett–Packard Vectra ES/12 computer were

* Author to whom correspondence should be addressed.
† Thomas Jefferson High School for Science and Technology, Alexandria, VA 22312, U.S.A.

used for data collection and calculation of rate constants. Reactions were carried out under pseudo-first-order conditions with ferrocene in at least 10-fold excess. First-order plots were linear to at least three half-lives. Reactions were followed at several wavelengths, usually 350 or 520 nm. Three rate determinations were usually carried out for each filling of the stopped flow.

Stability constant measurements

Determinations of $Cu(pdto)^{2+}$ stability constants, K_f, in the solvents acetone, ethylacetate, ethanol, methanol, isopropanol, acetonitrile and N,N-dimethylformamide were made spectrophotometrically using Hewlett–Packard 8452A diode array and Sequoia-Turner 340 spectrophotometers. Equilibrium solutions were thermostatted at 25.0 ± 0.1°C. Values of K_f were obtained by continuous variations and mole ratio methods,[17] with the ionic strength maintained at 0.10 M using sodium perchlorate. In the latter case, determinations were made both with $[Cu^{2+}]$ and [pdto] held constant. Mean values of at least three separate determinations of K_f in each solvent are reported. Data are summarized in Table 3. Apart from differences in intensity, the $[Cu(pdto)]^{2+}$ spectrum was essentially unchanged in all solvents reported except for DMSO. Simple one-to-one complex formation was found in all cases.

Electrochemical measurements

The standard potentials for the $Cu(pdto)^{2+/+}$ and $FeCp_2^{0/+}$ couples in the different solvents were obtained using a BAS CV-1B cyclic voltammetry unit. Potentials were obtained in deoxygenated solvents under argon with a glassy carbon working electrode, a platinum wire auxiliary electrode and a saturated calomel reference electrode (SCE). The BAS electrochemical cell was thermostatted at 25.0 ± 0.1°C. The measurements were uncorrected for liquid junction potentials, since only differences in potential between the $[Cu(pdto)]^{2+/+}$ and $FeCp_2^{0/+}$ couples in a particular solvent were being considered. The reported half-wave potentials were determined at scan rates of 20 mV s^{-1} with 0.10 M n-Bu_4NPF_6 as supporting electrolyte. Values of 0.444, 0.520 and 0.443 V for $[Cu(pdto)]^{2+/+}$, and 0.400, 0.343 and 0.453 V for $[FeCp_2]^{+/0}$, vs SCE, were obtained in acetonitrile, methanol and acetone, respectively. Anodic and cathodic peak separations of close to 0.072 V were found for $[FeCp_2]^{+/0}$, while separations between 0.10 and 0.14 V were observed for the $Cu(pdto)^{2+/+}$ couple in the three solvents. An E_f^0 value of 0.305 V was recorded for a solution of $[Cu(pdto)]^{2+}$ in DMSO, with oxidation and reduction peaks separated by 0.310 V.

RESULTS AND DISCUSSION

In the solvents acetonitrile, acetone and methanol, the reaction was found to follow a second-order rate law, rate $= k_{12}[Cu^{II}][FeCp_2]$ over the concentration ranges employed. Second-order rate constants are shown in Table 1. Similar values were obtained with no added electrolyte and in the presence of 0.10 M n-Bu_4NPF_6, as would be expected for reaction of neutral ferrocene with a dipositive cation in the absence of significant ion-pairing effects. The measured rate constants were also found to be insensitive to variations in excess ligand concentration ($[pdto]/[Cu^{II}] = 2.4$–7.8). The predominant copper(II) species in solution under the experimental conditions is a $Cu(pdto)^{2+}$ complex with a tetradentate pdto ligand and one or two coordinated solvent molecules. Tetradentate coordination by pdto is indicated by the UV–vis spectrum, characterized by an intense *d–d* band at 594 nm and a strong $S(\sigma) \rightarrow d_{x^2-y^2}$ LMCT transition at 360 nm, which appear in each solvent. The $Cu(pdto)^{2+}$ spectrum is essentially the same in acetonitrile, acetone and methanol as in aqueous solution. Similar intense ligand-field and charge-transfer bands at comparable wavelengths also characterize other dithiaether copper(II) complexes.[18,19] $[Cu(pdto)]^{2+}$ stability is expected to result largely from the strong coordinating abilities of the terminal nitrogen atoms, since thiaether coordination to copper(II) in dipolar solvents is believed to be fairly weak. No evidence for pdto complexation was found in DMSO, where the 594 and 360 nm bands characteristic of $Cu(pdto)^{2+}$ were replaced by a single maximum at 206 nm. The much slower second-order rate constant, $k_2 = 3.0 \times 10^{-4}$ M^{-1} s^{-1}, that was obtained from absorbance changes recorded in DMSO, is attributed to the $FeCp_2$ reduction of $[Cu(DMSO)_n]^{2+}$ species formed in that solvent. No anion effects were noted using hexafluorophosphate as medium. The measured rate constants were independant of [n-Bu_4NPF_6], and ion pairing interactions, if present, do not show up kinetically, Similar behaviour was noted with added n-Bu_4NClO_4, in the few experiments carried out with perchlorate salt. This is in contrast to marked anion dependencies, arising from specific anion associations with the copper complex, that were found for $[Cu(pdto)]^{2+}$–$FeCp_2$ electron-transfer rates in acetonitrile, with n-Bu_4NBF_4 and $NaCF_3CO_2$ as electrolytes.[20]

The measured rate constants, k_{12}, and the electron-transfer equilibrium constants, K_{12}, deter-

mined in each solvent are summarized in Table 2. Also shown are estimated values of the Cu $(pdto)^{2+/+}$ self-exchange rate constant, k_{22}, obtained by the Marcus relations* using known $FeCp_2^{0/+}$ self-exchange rate constants, k_{11},[21] in the different solvents. The values obtained compare to a mean k_{22} value of 0.64 M^{-1} s^{-1} previously estimated for $[Cu(pdto)]^{2+/+}$ self-exchange in 50% aqueous methanol with ruthenium(II) ammine complexes as reductants.[8] Outer-sphere electron-transfer was assumed in the previous study, and a similar mechanism is expected here with ferrocene as reductant. When corrected for driving force ($k_{12}/K_{12}^{1/2}$), the reaction rate in acetone appears more rapid than in the other solvents, which is reflected strongly in the value of the copper(I)–copper(II) self-exchange rate constant obtained (10^2– to 10^3–fold greater in acetone than in the other two solvents). For the $Cu(pdto)^{2+/+}$ system, solvent-dependent rates could arise from solvent influences on both the inner-sphere and outer-sphere components, ΔG_i and ΔG_o, of the activation free energy. Possible outer-sphere solvent influences were explored through the Marcus solvent dielectric continuum expression.[22]

* $k_{12} = (K_{12} k_{11} k_{22} f)^{1/2}$, where $\ln f = \ln (K_{12})^2/4 \ln (k_{11} k_{22}/Z^2)$; Z is the collision frequency, taken to be 10^{11} M^{-1} s^{-1}.

$\Delta G_o = (e^2/4r)[(1/D_{op})-(1/D_s)]$ by plots of $\ln k_{22}$ vs $(1/D_{op})-(1/D_s)$ and $\ln k_{12}/K_{12}^{1/2}$ vs $(1/D_{op})-(1/D_s)$, where ΔG_o, r, D_{op}, and D_s are the outer-sphere solvent reorganization component of the activation energy, the distance between the reactant centres in the transition state and the optical and static dielectric constants. Although a linear dependence was found in both cases, this would appear largely fortuitous, as the value of the slopes obtained in the plots, -169 and -84.7, respectively, correspond to separations, r, in the transition state of 0.83 and 1.7 Å, which are close to an order of magnitude smaller than expected. Failure of the reaction to follow the dielectric continuum theory points to inner-sphere reorganizational changes involving coordinated solvent molecules, rather than outer-sphere solvent effects, being responsible for the solvent-dependent reaction rates that were found. Crystal structures have established five-coordinate copper(II), $[Cu(pdto)ClO_4]ClO_4$, and four-coordinate copper(I), $[Cu(pdto)]PF_6$, structures in the solid state, and the slow self-exchange rate constant estimated for the copper(II)/(I)–pdto couple in aqueous media from k_{12} data involving ruthenium(II)ammine reductants,[6,8] has been previously attributed to the substantial inner coordination sphere reorganizations accompanying electron transfer on reduction of five-coordinate $[Cu(pdto)H_2O]^{2+}$ to the four-coordinate $[Cu(pdto)]^+$ product. With electron transfer coupled to a change in coordination number during the reaction, it is possible for rate control to be tied to either the electron-transfer step or to water loss from the copper centre. Since the reaction in aqueous media was well behaved in the Marcus sense, with $\log k_{12}$ values proportional to G^0 over a fairly wide range of driving force, an electron-transfer controlled reaction rate is indicated. This could result from a concerted one-step process or through a two-step mechanism involving a fast conformational equilibrium prior to a rate-determining electron-transfer step:

$$[Cu(pdto)H_2O]^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Cu(pdto)]^{2+} + H_2O$$

$$[Cu(pdto)]^{2+} + Ru^{II} \xrightarrow[\text{slow}]{k_2} [Cu(pdto)]^{+} + Ru^{III},$$

with $k_{-1} \gg k_2, k_1$. Of interest is the possibility that the more rapid rate constants estimated for $Cu(pdto)^{2+/+}$ self-exchange in acetone indicate a change in mechanism in that solvent, with rate control being tied to a conformational change at the copper centre. Rate controlling structural change at the copper(II) centre, with ferrocene as reductant, could result if $k_2 \gg k_{-1}, k_1$:

$$[Cu(pdto)(acetone)]^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Cu(pdto)]^{2+} + \text{acetone (slow)}$$

$$[Cu(pdto)]^{2+} + FeCp_2 \xrightarrow{k_2} [Cu(pdto)]^{+} + FeCp_2^{+}.$$

Such a change from an electron-transfer controlled reaction rate in aqueous solution ($k_{-1} \gg k_2, k_1$) to one depending on geometric change at the copper(II) centre in acetone ($k_2 \gg k_{-1}, k_1$), would be promoted by a slower rate of association of acetone with the copper(II) centre (k_{-1} step) relative to that of water, and by a more rapid rate of reduction of $[Cu(pdto)]^{2+}$ by $FeCp_2$ (k_2 step) relative to that by ruthenium(II) ammine complexes. A more rapid k_2 step is certainly expected with $FeCp_2$ as reductant on electrostatic grounds, and a *ca* 100-fold rate advantage has previously been demonstrated for the reduction of $Cu(pdto)^{2+}$ by the neutral reductant $Ru(bpy)_2Cl_2$, as compared with dipositive ruthenium(II) ammine complexes.[8] A lower rate constant for the association of acetone with $[Cu(pdto)]^{2+}$ would also be expected on steric grounds. This is also suggested by the stability constant data, where the largest K_f values for $[Cu(pdto)]^{2+}$ formation ($Cu^{2+}{}_{solv} + pdto = [Cu(pdto)(solv)]^{2+}$) have been obtained in acetone (Table 3). If variations amongst the K_f values have their origin largely in copper(II) desolvation changes, which appears likely since entropy changes are expected to be very similar for the complexation process involved, the largest K_f value is found in acetone because this has the weakest Lewis base interaction with copper(II) and is most readily replaced by the pdto ligand. The good electron pair donor solvents, DMSO, DMF and acetonitrile, afford the smallest K_f values.

Brunschwig and Sutin[24] have determined the conditions necessary for a two-step "gated" mechanism involving the intermediate formation of an

* Although rate controlling coordination changes at the copper(I) centre

$$[Cu(pdto)L]^{2+} + Red \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Cu(pdto)L]^{+} + Ox$$

$$[Cu(pdto)L]^{+} \xrightarrow[\text{slow}]{k_2} [Cu(pdto)]^{+}$$

can result in both electron-transfer ($k_1 \gg k_{-1}, k_2$) and substitution-controlled ($k_{-1} \gg k_1, k_2$) rate constants under certain conditions, provided the spectra of the two copper(I) species are the same, such a mechanism appears unlikely for copper(I), and is not considered.

Table 3. Stability constants, K_f, for $[Cu(pdto)]^{2+}$ formation in dipolar solvents at 25°C

unstable reactant to compete with a direct concerted reaction involving only the stable reactant and product. A two-step mechanism is expected to be favourable only at low driving force, and would require that the intermediate, $[Cu(pdto)]^{2+}$, is only slightly less stable than the stable reactant, $[Cu(pdto)(acetone)]^{2+}$. These conditions would appear to be met in acetone, where the solvent coordinates only weakly to the copper(II) centre, and $K_{12} = 0.68$. The data presented, however, do not in themselves confirm a change to a two-step mechanism in acetone, with rate control tied to the coordination change at the copper centre. A concerted one-step reaction involving a smaller inner-shell reorganization energy could also give rise to larger estimated k_{22} values using the Marcus theory.

Amongst other copper(I)–copper(II) self-exchange rate constants (k_{22}, $M^{-1}s^{-1}$) determined for complexes with nitrogen and sulphur donor ligands, fairly large values have been obtained with the multidentate ligands py_2DAP[10] (1.7×10^3), $(imidH)_2DAP$[13] (1.3×10^4), bidhp[12] (4×10^3) and TAAB[7] (5×10^5), where ligand constraints minimize geometric changes between oxidation states. Lower k_{22} values have been estimated with pdto and with tripodal ligands pmas (6–45) and peas[6] (0.7) in CuN_2S_2 environments, where significant structural changes in aqueous solution, particularly changes involving solvent coordination, accompany the redox step. The significantly larger $[Cu(pdto)]^{2+/+}$ self-exchange rate constant obtained in acetone, 2.6×10^3 M^{-1} s^{-1}, is comparable with the self-exchange values obtained for copper(II)–copper(I) systems, where changes in coordination are minimal. This would suggest that the more rapid self-exchange rate in acetone results from a concerted process with a relatively small reorganizational barrier resulting from the weak association of acetone with the copper(II) centre in that solvent.

Abstract—The magnetic susceptibility and electron spin resonance (ESR) spectra have been studied for copper(II) complexes with N-(aminoalkyl)salicylaldimines, tridentate Schiff bases containing O(phenol), N(imine) and N(amine) donor atoms. It has been stated that the compounds are anti-ferromagnetically coupled dimers. The ESR spectra show the depolimerization of the dimers by the polar solvents and formation of two types of adducts. On the basis of the ESR hyperfine structural parameters the structure of the adducts has been proposed.

Copper(II) complexes with low magnetic moments are of considerable interest since their magnetic behaviour may usually be attributed to spin–spin coupling within a polynuclear cluster. Often the complexes are dimeric and an exchange interaction occurs between the two copper(II) centres in the dimer. The nature of the interaction is usually interpreted as an isotropic spin–spin interaction, $-2JS_1S_2$. The magnetic properties of these compounds may be studied by electron spin resonance (ESR) and bulk susceptibility methods.

Our previous studies have considered typical binuclear copper(II) complexes with tridentate ONO chelating ligands derived from condensation products of 3-aminopropanol with 2-hydroxyaryl aldehydes (type I complexes) and *o*-aminophenol with *β*-diketones (type II complexes).[1,2]

In the present paper, the six copper(II) complexes with different tridentate ligands which were able to coordinate by the ONN donor set [i.e. O(phenol), N(imine) and N(amine)] were studied by ESR and magnetic susceptibility measurement methods. The synthesis of two of these complexes derived from salicylaldehyde and their room magnetic moments

have been reported previously.[3] The results presented here support the dimeric structure of the compounds which are revelant to type III complexes.

In continuation of our studies[2,4] on the adducts of the copper(II) complexes with tridentate Schiff bases, the formation of Cu(ONN)L adducts as the result of dissociation of the dimers in polar solvents, L, has been investigated by the ESR method.

EXPERIMENTAL

The complexes were prepared according to the high dilution reaction described by Mandal and Nag[3] and recrystallized from methanol. The elementary analysis for copper, carbon, nitrogen and hydrogen confirms the formation of copper(II) complexes with N-(aminoalkyl)salicylaldimines showing the following formulae: Cu(sal-enNH$_2$)ClO$_4$, Cu(sal-enNH$_2$)NO$_3$, Cu(sal-pnNH$_2$)ClO$_4$, Cu(sal-pnNH$_2$)NO$_3$, Cu(5-NO$_2$sal-enNH$_2$)NO$_3$·H$_2$O and Cu(5-NO$_2$sal-pnNH$_2$)NO$_3$·H$_2$O. The ligands are the condensation products of salicylaldehyde or 5-nitrosalicylaldehyde with 1,2-diaminoethane (sal-enNH$_2$), (5-NO$_2$sal-enNH$_2$) and salicylaldehyde or 5-nitrosalicylaldehyde with 1,3-diaminopropane, (sal-pnNH$_2$), (5-NO$_2$sal-pnNH$_2$), respectively. The number of water molecules was determined thermogravimetrically. The solvents were purified by the standard methods.

Variable temperature magnetic susceptibility studies between 77 and *ca* 295 K were performed on polycrystalline samples using the Gouy method. Data were corrected for diamagnetism using Pascal constants and TIP, assumed to equal 60×10^{-6} c.g.s.u. The ESR spectra were recorded on a JEOL JES-ME X-band spectrometer using a nuclear magnetometer MJ 11OR and microwave frequency meter JES-SH-30X. The IR spectra were measured on a Perkin–Elmer 180 IR spectrometer.

RESULTS AND DISCUSSION

Properties of the complexes in the solid phase

The significant feature in the IR spectra of the complexes is the presence of the bands associated with N—H (3160–3360 cm^{-1}) as well as C=N bonds (1628–1648 cm^{-1}). Another important characteristic is the appearance of a band associated with the phenolic C—O bond at *ca* 1556 cm^{-1}, which indicates[5] the presence of a bridging phenolic oxygen.

The effective magnetic moments of the compounds derived from the salicylaldehyde decrease with a decrease in temperature; from 1.0 to 1.4 BM at room temperature to near zero at 77 K, indicating antiferromagnetic interactions. The experimental data were interpreted in terms of the isotropic Heisenberg interaction model, based on the exchange Hamiltonian $H = -2JS_1S_2$. The well-known Bleaney–Bowers equation[6] was used to estimate the value of $-2J$ with g fixed at 2.12. A least-squares fitting was carried out and included a term representing a fraction of non-coupled paramagnetic copper centres, p. The results are given in Table 1, and a representative fit for Cu(sal-pnNH$_2$)NO$_3$ is shown in Fig. 1. The experimental susceptibility of the complexes obeys the Bleaney–Bowers equation well, supporting the dimeric structure.

The investigated complexes in the temperature range 77–295 K are ESR silent in the 0–7000 G range; in some cases only very weak signals of the monomeric impurities were observed. The absence of the ESR spectra of the compounds should be related to the pairwise interaction between the copper(II) ions. The complexes derived from 5-nitrosalicylaldehyde exhibit magnetic moments close to the value typical for the non-coupled copper(II) complexes in the temperature range studied. The best fit of their magnetic susceptibilities

Table 1. Magnetic properties of copper(II) complexes with N-(aminoalkyl)-salicylaldimines

Compound	μ_{eff} at 292 K (BM)	$-2J$ (cm^{-1})	p
Cu(sal-enNH$_2$)ClO$_4$	1.12	428	0.0022
Cu(sal-enNH$_2$)NO$_3$	1.40	282	0

Cu(sal-pnNH$_2$)NO$_3$	1.01	474	0.0004
Cu(5-NO$_2$sal-enNH$_2$)NO$_3$·H$_2$O	1.80	13	0
Cu(5-NO$_2$sal-pnNH$_2$)NO$_3$·H$_2$O	1.84	$\|2J\| < 4$	—

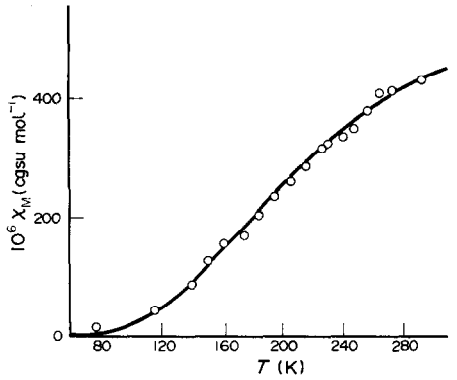

Fig. 1. Temperature dependence of the magnetic susceptibility (per copper atom mole) for $Cu(sal\text{-}pnNH_2)NO_3$.

to the dimer equation yields $-2J = 13$ cm^{-1} and $g = 2.09$ for $Cu(5\text{-}NO_2sal\text{-}enNH_2)NO_3 \cdot H_2O$ and $|2J| < 4$ cm^{-1} and $g = 2.11$ for $Cu(5\text{-}NO_2sal\text{-}pnNH_2)NO_3 \cdot H_2O$, indicating that the strength of the magnetic interactions is generally much smaller than in the corresponding compounds derived from salicylaldehyde. Although only the signals characteristic of the monomeric species are observed in the ESR spectra of these complexes, the appearance of the phenolic C—O band at 1556 cm^{-1} in the IR spectra is important, additional evidence of the binuclear structure. The considerable difference in the strength of antiferromagnetic coupling between the complexes under study may be attributed to the influence of molecular packing on the geometry of the bridging moiety.

Properties of the polymeric complexes in solution

The ESR spectra of the complexes dissolved in methanol, formamide and pyridine are typical for the monomeric species (Figs 2 and 3). They imply

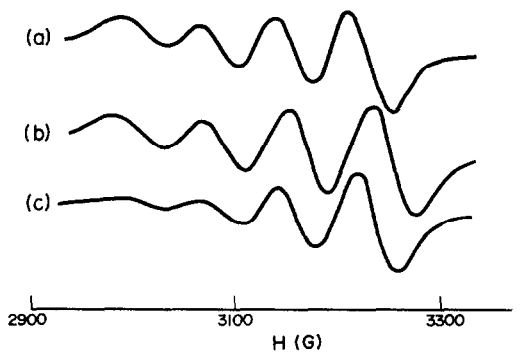

Fig. 2. ESR spectra of $Cu(sal\text{-}enNH_2)NO_3$ at 295 K: (a) in methanol (L), (b) upon addition of L_1 = pyridine to the methanol (L) solution and (c) in pyridine (L).

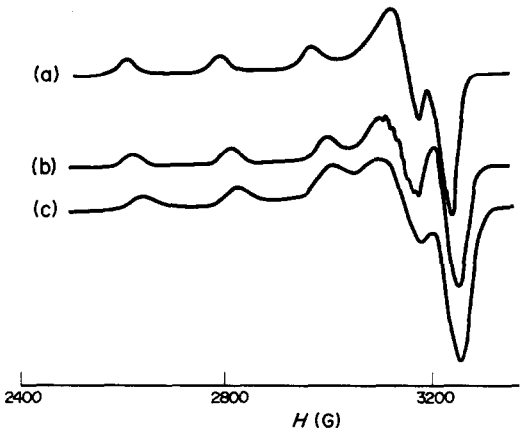

Fig. 3. ESR spectra of $Cu(sal\text{-}enNH_2)NO_3$ at 77 K: (a) in methanol (L), (b) upon addition of L_1 = pyridine to the methanol (L) solution and (c) in pyridine (L).

cleavage of the bridge bonds of dimeric molecules by polar solvents and formation of Cu(ONN)L adducts.

The important features in the interpretation of the ESR parameters (Table 2) are considerably smaller A_{iso} and $A_{\parallel}$ values and greater g_{iso} and $g_{\parallel}$ values for the compound derived from 1,3-diaminopropane compared with the parameters for the compound derived from 1,2-diaminoethane. This trend, which corresponds to the increasing degree of tetrahedral distortion[7] of coordination symmetry, can be associated with the increasing length of the methylene chain joining the nitrogen atoms. Similar chain length–tetrahedral distortion dependence has been observed[8] for tetradentate copper(II) salicylaldimine complexes.

Superhyperfine structure due to the presence of nitrogen nuclei coordinated to the copper(II) ion, which has been observed for ONO Schiff base complexes,[2,4] is not resolved at room temperature for the system under study. The lack of resolution may be explained by the greater number of nitrogen donors and their non-equivalency in our system. Although the perpendicular region of the frozen solution spectra demonstrates superhyperfine splitting due to nitrogen atoms (Fig. 3), it is not possible to determine the number of nitrogen donors on this basis.

Addition of L_1 = pyridine (the molar ratio $L_1/Cu = 6:1$) to a solution of the complexes in oxygen-coordination solvents, L, produced a characteristic change in the ESR parameters [Table 2, Fig. 2(b)]; decrease of the g_{iso} value (about 0.006) and significant increase of A_{iso} (about 10 G) as well as decrease of $g_{\parallel}$ (about 0.02). The observed spectral changes can be interpreted in terms of trans-

formation of the pseudo-tetrahedral complex of the Cu(ONN)L type into the new adduct containing the pyridine molecule. The stereochemistry of the analogous pyridine adduct has been studied previously for the ONO chelating Schiff base copper(II) complexes.[2,4] On the basis of the changes in the copper hyperfine parameters and, furthermore, analysis of the superhyperfine splitting due to the nitrogen donors, it has been found that the pseudo-tetrahedral Cu(ONO)L complex coordinates one L_1 molecule changing its geometry from pseudo-tetrahedral in Cu(ONO)L to square pyramidal in the Cu(ONO)L_1L complex. L_1 is located in the chelating ring plane, while L adopts an apical position. Although in the present system nitrogen superhyperfine splitting is not informative, the full analogy in the changes of g and A values strongly suggests the same structure in the case of Cu(ONN)pyL (py = pyridine) adducts.

SYNTHESIS, CHARACTERIZATION AND REACTIVITY OF LEAD(II) ALKOXIDES AND OXOALKOXIDES: CONDENSATION TO OXOALKOXIDES AS A GENERAL STRUCTURAL FEATURE

RENÉE PAPIERNIK, LILIANE G. HUBERT-PFALZGRAF* and MARIE C. MASSIANI

Laboratoire de Chimie Moléculaire, Associé au CNRS, Parc Valrose, 06034 Nice, France

(*Received* 6 *December* 1990; *accepted* 5 *April* 1991)

Abstract—Various routes to lead(II) alkoxides using $PbCl_2$, $Pb(OAc)_2$ and $Pb[N(SiMe_3)_2]_2$ as starting materials have been explored. The formation of homoleptic alkoxides is limited to $[Pb(OBu^t)_2]_m$, while condensation to the oxoalkoxides $Pb_4O(OR)_6$ or $Pb_6O_4(OR)_4$ (R = Et, Pr^i) seems favoured. The various products have been characterized by microanalysis, IR and NMR spectroscopy. $[Pb(OBu^t)_2]_m$ and $Pb_4O(OR)_6$ are soluble precursors of lead oxide, while the tert-butoxide derivates are also volatile. Their reactivity (alcoholysis reactions, formation of complexes) has been examined and ^{207}Pb NMR was used to follow their condensation and/or complexation.

A variety of new materials of technological value—piezoelectric ceramics, superconductors, optico-electronic devices[1]—are multicomponent oxides containing lead. Traditional access to such materials by solid-state reactions at high temperature often results in poor control of the stoichiometry and phase of the final material sought, due, in part, to the volatility of the lead(II) oxide.[2] Sol–gel technology, using molecular precursors of lead oxide, might overcome some of these problems, as lower sintering temperatures are generally required.[3]

However, alkoxides, which often are the most suitable precursors of oxides, have long been practically unknown for lead(II). Poorly characterized, insoluble, polymeric alkoxides of formula $[Pb(OR)_2]_m$ have been reported to form through disproportionation of alkylalkoxides (for R = Me), or substitution reactions from $PbCp_2$ (for R = Me, Bu^t),[4] or from PbX_2[5] (X = I, NO_3 for R = Me). The formation of $Pb(OPr^i)_2$, starting from lead(II) acetate, has been claimed on the basis of its hydrolysis product PbO, but it has not been isolated.[6] Anodic oxidation of lead in absolute isopropanol offered a hexanuclear oxoalkoxide which has been structurally characterized as $Pb_6(\mu_3\text{-}O)_4(\mu_3\text{-}OPr^i)_4$.[7] Monomeric $Pb(OAr)_2$ (Ar = 2,6-ditert-butyl-4-methylphenyl) has been obtained by the metathesis reaction of either $PbCl_2$ or $Pb[N(SiMe_3)_2]_2$.[8]

The work of the group of Buhro[9] concerning the synthesis of $Pb(OR)_2$ (R = Bu^t, Pr^i, CMe_2Et, CEt_3, C_2H_4OMe, $CHMeCH_2NMe_2$) and the crystal structure of $[Pb(\mu,\eta^1\text{-}OC_2H_4OMe)_2]_\infty$ and of $Pb_3(\mu\text{-}OBu^t)_6$ prompts us to report the synthesis of soluble lead(II) alkoxides (R = Bu^t, Pr^i), whose behaviour is dominated by their tendency to undergo condensation reactions to adamantane-like units, $Pb_4O(OR)_6$ and $Pb_6O_4(OR)_4$. ^{207}Pb NMR was used to follow these inorganic polymerization reactions. Part of our work has been published as a preliminary communication.[10]

EXPERIMENTAL

All manipulations were routinely performed under dry argon using Schlenk tubes and vacuum-line techniques. Solvents were purified by standard methods. Anhydrous lead acetate was obtained by allowing the trihydrate to react with acetic anhydride at reflux. $Pb[N(SiMe_3)_2]_2$[11] and $Bu^t{}_3COH$ (tritoxH)[12] were synthesized as reported in the

literature. IR spectra were obtained as Nujol or poly(chlorotrifluoroethylene) mulls on a Bruker IFS 45 spectrometer. ^1H and ^{207}Pb NMR spectra were registered, respectively, on Bruker WH-90 and AC-200-E spectrometers, operating in the Fourier transform mode. ^{207}Pb chemical shifts are quoted relative to $Pb(NO_3)_2$ as an external reference, and are negative for high fields. Mass spectra were measured on a Ribermag R-10 spectrometer. Molecular weight data were obtained using the Signer method.[13] Microanalyses were performed at the Centre de Microanalyses du CNRS. Analytical and spectral data are collected in Table 1.

Synthesis of $[Pb(OBu^t)_2]_m$ (**1**)

On addition of Bu^tOH (3 g, 40 mmol) in 15 cm^3 of pentane to a yellow solution of $Pb[N(SiMe_3)_2]_2$ (2.3 g, 4.34 mmol) in 25 cm^3 of pentane at −70°C, the reaction medium immediately became colourless. After 3 h, the volatiles were evaporated and the solid purified by crystallization in pentane at −20°C (2.1 g, 87%). MS (EI, 70 eV) m/z^+, %. M = $[Pb(OBu^t)_2]_2$, M − $C_4H_8O_2$ (15%), M − C_7H_{12} (10%), M/2 (10%), PbO_2 (100%), PbO (20%). Mol. wt: (C_6H_6, 25°C, 0.16 M): 648 ± 65 (calc. 353).

Synthesis of $Pb(tritox)_2(tritoxH)$

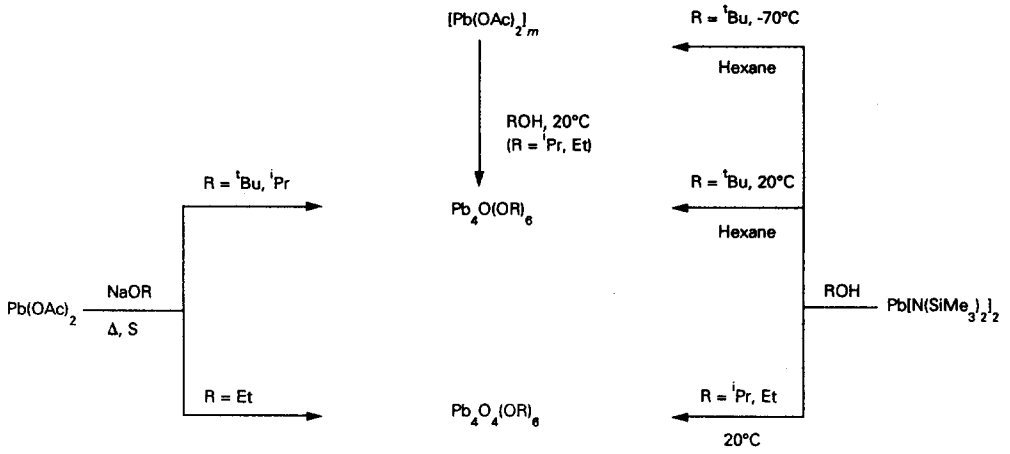
A similar procedure applied to $Pb[N(SiMe_3)_2]_2$ (1.18 g, 2.2 mmol) in pentane and tritoxH (0.9 g, 4.4 mmol) at 0°C in the dark gave, after work-up and recrystallization, 0.8 g (45%) of yellow crystals of $Pb(tritox)_2(tritoxH)$. The product is thermally and photochemically unstable, giving colloidal lead.

Synthesis of $Pb_4O(OR)_6$ (R = Bu^t, Pr^i, Et)

R = Bu^t. $Pb_4O(OBu^t)_6$ (**2**) was obtained quantitatively by adding Bu^tOH (32 mmol, 0.3 cm^3) to $Pb[N(SiMe_3)_2]_2$ (0.46 g, 0.85 mmol) in 0.5 cm^3 of hexane.

$Pb_4O(OBu^t)_6$ could also be obtained by reacting $Pb(OAc)_2$ (1.57 g, 4.83 mmol) and $NaOBu^t$ (9.7 mmol) in 100 cm^3 of THF at reflux for 24 h and sublimation of the solid obtained by evaporation to dryness at 200°C (10^{-2} mm Hg); 85%.

R = Pr^i. A suspension of $Pb(OAc)_2$ (10 g, 31.1 mmol) in 50 cm^3 of Pr^iOH was added to 100 cm^3 of 0.6 M $NaOPr^i$ in Pr^iOH. After refluxing for 15 h, the precipitate was eliminated by filtration and washed with Pr^iOH. Recrystallization of the crude product in toluene/pentane gave, as the third crop of crystals, 3 g (32%) of $Pb_4O(OPr^i)_6$ (**3**). MS



Scheme 1.

[m/z^+, M = $Pb_4O(OPr^i)_6$], M−$PbOC_3H_4$ (10%), M−$Pb(OC_3H_7)_2$ (15%), M−$Pb_2O_2C_3H_7$ (20%), $Pb_2(OC_3H_7)_2$ (30%), $PbO_2C_5H_8$ (20%), Pr_2O (100%).

Alcoholysis of either $[Pb(OBu^t)_2]_m$ or $Pb_4O(OBu^t)_6$ in hexane led to an immediate, quantitative precipitation of $Pb_4O(OR)_6$ (R = Pr^i, Et).

Synthesis of $Pb_6O_4(OR)_4$ (R = Et, Pr^i)

Addition of Pr^iOH (10 cm^3) to neat $Pb[N(SiMe_3)_2]_2$ (0.6 g, 0.96 mmol) at room temperature resulted in a slightly exothermic reaction with immediate precipitation of $Pb_6O_4(OPr^i)_4$.

$Pb_6O_4(OEt)_4$ was also obtained by refluxing $Pb(OAc)_2$ and NaOEt in EtOH for 3 days; the several recrystallizations required for a product without alkali residues led to a poor yield (10%). Cell parameters (−80°C): a = 20.024(5), b = 12.473(3), c = 17.409(3) Å and β = 95.86(4)°, monoclinic.

Synthesis of $Pb_4O(OBu^t)_3(OAc)_3$

Acetic anhydride (0.23 cm^3, 2.3 mmol) in 10 cm^3 of THF was slowly added at 0°C to $Pb(OBu^t)_2$ (0.82 g, 2.3 mmol) in 10 cm^3 of THF. Evaporation to dryness after a 1 h reaction time, left analytically pure $Pb_4O(OBu^t)_3(OAc)_3$ (0.7 g, 97%). The product is unstable in solution; further condensation with elimination of the acetato groups was observed.

The various lead(II) alkoxides are white solids; their solubility decreases with the steric demand of the alkoxo group and increasing nuclearity. The tert-butoxide derivates are highly soluble in the usual solvents, including hexane, while the ethoxides are poorly soluble; the highest solubilities are usually observed in the parent alcohol, CH_2Cl_2 or THF.

RESULTS AND DISCUSSION

(a) *Synthesis and characterization*

Various routes to lead(II) alkoxides using $PbCl_2$, $Pb(OAc)_2$ and $Pb[N(SiMe_3)_2]_2$ as starting materials were estimated (Scheme 1). Lead(II) acetate and lead(II) bis-trimethylsilylamide appear to be the most useful precursors. The novel alkoxides were characterized by microanalysis and the usual spectroscopic techniques including ^{207}Pb NMR (Table 1).

Reaction between $Pb(OAc)_2$ and NaOR (R = Bu^t, Pr^i, Et), in polar solvents (ROH or THF) at reflux for *ca* 24 h, actually led to the isolation of oxoalkoxides, $Pb_4O(OR)_6$ or $Pb_6O_4(OR)_4$. Examples of synthesis of alkoxides starting from acetates remain scarce.[14] In the case of lead, this reaction is highly dependent on the nature of the alkoxo ligand, the reaction is generally incomplete with formation of soluble acetato or oxoacetatoalkoxides [$\nu(CO_2)$ at 1541 and 1456 cm^{-1} in the IR spectra for R = Bu^t for instance].* The volatility of $Pb_4O(OBu^t)_6$ (130°C, 10^{-4} mm Hg) and the poor thermal stability of the various acetatoalkoxides allow its isolation with yields up to 85%. However, the poor selectivity of the reaction results in much lower yields when the work-up requires isolation by crystallization: 35% for R = Pr^i, even less (10%) for the lead ethoxide derivatives whose poor solubility prevented an efficient separation from the starting material. Formation of oxoalkoxides may

*Oxoacetatoalkoxides were also reported as secondary products in the anodic dissolution of lead in ethanol as a result of the reaction of the alkoxide with the supporting electrolyte.[7]

result from acetato groups acting as an oxygen donor or from condensation reactions involving $Pb(OR)_2$ species with elimination of dialkyl ether. Indeed, formation of condensed lead(II) oxoalkoxides appears to be general behaviour in the chemistry of lead(II) alkoxides, and is favoured by a low steric demand of the alkoxo ligand, kinetically fast reactions using $Pb[N(SiMe_3)_2]_2$ as starting material and subsequent recrystallization of the products. Further condensation was also reported to occur by elimination of hexaphenyldisiloxane in the recrystallization of $Pb_4(\mu_4\text{-}O)(OSiPh_3)_6$ giving $Pb_8O_5(OSiPh_3)_6$.[15]

Lead(II) bis-trismethylsilylamide offers a better route to pure lead(II) alkoxides, since the volatile bis-trimethylsilylamine is the only co-product. By contrast with the reactions using the acetate as a starting material which proceed at high temperature, homoleptic alkoxides could be obtained. Highly soluble $Pb(OBu^t)_2$ (**1**) was obtained in 80% yields, by reaction between $Pb[N(SiMe_3)_2]_2$ and the alcohol in dilute medium (pentane), while the formation of $Pb_4O(OBu^t)_6$ (**2**) was quantitative when the reaction was achieved without solvent. Compound **1** was recently established to be a trimer in the solid state, independently by two groups.[9,16] We found this compound to be dimeric in the gas phase (mass spectrometry) as well as in benzene solution at room temperature (M: exp 648 ± 65, calc. 353). Molecular weight data obtained at lower temperature (cryoscopy)[9] account for an equilibrium between dimeric and trimeric species, although we could detect only one type of alkoxo group down to $-60°C$ by ^1H NMR. ^{207}Pb NMR also shows only a single, sharp peak ($A_{1/2} = 16$ Hz).* Dimeric species have also been found for the tin and germanium analogues.[17] An increase in the steric demand of the alkoxo group by using the $OCBu^t_3$ (tritox) moiety (cone angle 125°)[18] prevents the formation of alkoxide bridges, giving a monomeric solvate $Pb(tritox)_2(tritoxH)$. However, this species is unstable and undergoes easy electron-transfer reactions, giving colloidal lead. Synthetic routes using the reactive bis-trimethylsilylamide lead derivative favour the formation of oxoalkoxides of higher nuclearity for alkoxo groups such as R = Et. $Pb_6O_4(OEt)_4$ was obtained, even at low temperature. Reactions between $PbCl_2$ and NaOR (R = Et, Pr^i) were characterized by the poor conversion of the starting material even at high temperature and thus low yields (10%).

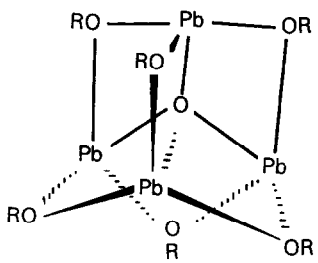
The solubility of the various species is mainly governed by the extent of condensation, and therefore, the nature of the alkoxo ligand. $[Pb(OBu^t)_2]_m$ (**1**) is the most volatile species reported here (100°C, 10^{-4} mm Hg) and by contrast with the other lead(II) alkoxides could be sublimed, but with partial conversion to the more stable oxo derivative, $Pb_4O(OBu^t)_6$ (**2**).[10] IR and ^1H NMR spectra generally offer less information, as they mainly display the pattern of the alkoxo ligand.

Characterization was therefore also achieved by using ^{207}Pb NMR. Although it has attractive properties ($I = 1/2$ and adequate natural abundance $\approx 20\%$), ^{207}Pb NMR has been relatively neglected, especially for lead(II) compounds.[19] As a general feature, in the ^{207}Pb spectra of the various lead(II) alkoxides and oxoalkoxides sharp signals were observed in the range 4100–5100 ppm (Table 1). The chemical shifts are nearly independent of the solvent, and for the $Pb_4O(OR)_6$ homologues they move to high field on substituting Bu^t for smaller and more electronegative R groups. ^{207}Pb NMR was especially useful for ascertaining the purity of **1** (4152 ppm), for instance (absence of **2** at 5032 ppm), since IR or ^1H NMR spectra were nearly identical for both compounds and thus uninformative. This method also appears attractive for analysing the composition of the complex reaction media such as $PbCl_2$ or $Pb(OAc)_2$ and $NaOBu^t$ before work-up.

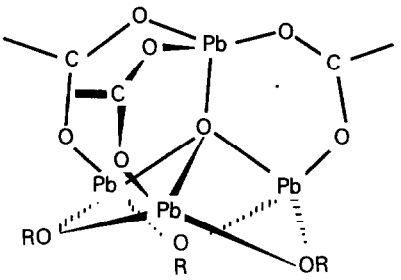
Although $Pb(OAr)_2$,[8] $Pb(OSiMe_3)_2$, $[Pb(OPr^i)_2]_m$[9] and $[Pb(OBu^t)_2]_m$ could be obtained, the stability of homoleptic lead(II) alkoxides appears poor. Condensation to oxoalkoxides of general formula $Pb_4O(OR)_6$ or $Pb_6O_4(OR)_4$ is favoured. The spectroscopic properties of compounds of formula $Pb_4O(OR)_6$ (R = Bu^t, Pr^i, Et) are in agreement with an adamantane-like structure **I**, as previously established for $Pb_4(\mu_4\text{-}O)(\mu\text{-}OSiPh_3)_6$,[15] and in which the lead atoms are in a distorted trigonal bipyramidal environment. The core of the acetatoalkoxide, $Pb_4O(OAc)_3(OBu^t)_3$, can be described accordingly. The small difference (135 cm^{-1}) between the symmetric and antisymmetric COO stretching frequencies in the IR spectra points to bidentate coordination of the acetate groups[20] and a structure of type **II**. This is also in agreement with the structure of $Be_4(\mu_4\text{-}O)(OAc)_6$ and of its derivatives $Be_4(\mu_4\text{-}O)(OAc)_{6-x}(OPr^i)_x$.[21]

Further condensation to oxoalkoxides of general formula $Pb_6O_4(OR)_4$ occurs. Compound **2** appears as the most stable oxoalkoxide towards condensation reactions, but the hexanuclear species is also obtained although in poor yields by reacting $Pb(OAc)_2$ and $NaOBu^t$ and tedious work-up by crystallization. The structure of $Pb_6O_4(OEt)_4$ is

* The line width might be affected by the solvent, the presence of residual alcohol resulted generally in line broadening.

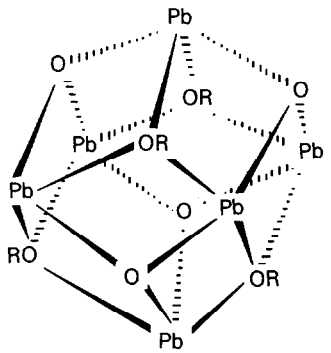


$Pb_4O(OR)_6$ (I)



$Pb_4O(OR)_3(OAc)_3$ (II)

probably based on an almost octahedral Pb(6) core (**III**), analogous to that of the isopropoxide derivative,[7] which may be considered as resulting from the condensation of two adamantane units along a common edge. This structural unit also has counterparts in tin(II) chemistry since $Sn_6O_4(OMe)_4$ and $Sn_6O_4(OH)_4$ are known.[22]



$Pb_6O_4(OR)_4$ (III)

(b) *Reactivity*

The homoleptic alkoxide $[Pb(OBu^t)_2]_m$ (**1**) is more reactive than the oxoalkoxides. Its alcoholysis offers a quantitative route to $Pb_4O(OR)_6$ (R = Et, Pr^i). A selective route to $Pb_4O(OBu)_3(OAc)_3$ can be devised by allowing **1** to react with acetic anhydride. However, the poor stability of all acetatoalkoxides (with respect to further condensation by elimination of the acetato groups, as evidenced by IR) limits the interest of this class of compounds. However, such derivatives might exist as intermediates on the routes to materials when lead acetate is used together with metal alkoxides.[23]

Since the metal atoms should bear some electronic density, complexation was estimated as a way of stabilizing the lead(II) alkoxides and limiting decomposition and/or condensation reactions. Complexes of divalent group 14 elements have been described; however, complexes of lead(II) derivatives remain scarce.[24] Complexation between $W(CO)_5L$ (L = THF or py) and **1** or **2** has been investigated by ligand exchange reactions, since most lead(II) alkoxides display poor photochemical stability. Complexation was evidenced by the rapid appearance of an orange–yellow colour, characteristic of lead–metal carbonyl complexes,[24] while new absorption bands developed in the IR spectra for the carbonyl stretching vibrations [at 1913, 1872, 1809, 1778 cm^{-1} for instance for the reaction between $W(CO)_5(THF)$ and $Pb_4O(OBu^t)_6$]. However, the W(0)—Pb(II) coordination bond is unstable and side reactions involving electron-transfer reactions with formation of colloidal lead are observed. Furthermore, when **1** is a ligand, formation of lead n-butoxide derivatives (^1H and IR evidence) resulting from THF opening[25] was observed when starting from $W(CO)_5 \cdot THF$. These reactions precluded isolation of pure complexes so far and coordination of the lead(II) centre was not further investigated.

The novel alkoxides $[Pb(OBu^t)_2]_m$ and $Pb_4O(OBu^t)_6$ have been used as precursors for the synthesis using sol–gel techniques of $PbMg_{1/3}Nb_{2/3}O_3$ (PNM), a ceramic with interesting dielectric and ferroelectric properties.[26] Since they are both volatile, they might find use in MOCVD techniques, but the higher thermal stability of the oxoalkoxide makes it a more suitable precursor. Even the poorly soluble tetra- or hexanuclear oxoalkoxides can be used as precursors to materials since they were observed to form highly soluble heterometallic alkoxides with niobium, titanium, magnesium or bismuth derivatives. The reaction between $Nb(OEt)_5$ and lead alkoxides in ethanol offered independently of the lead derivative used $[Pb(OBu^t)_2]_m$, $Pb_4O(OEt)_6$ or $Pb_6O_4(OEt)_4$, the compound $Pb_6Nb_4(\mu_4\text{-}O)_4(\mu_3\text{-}OEt)_4(\mu\text{-}OEt)_{12}(OEt)_8$ (**5**) which has been structurally characterized.[27] Compound **5** can be considered as an adduct between $Pb_6O_4(OEt)_4$ and $Nb(OEt)_5$, the lead oxoalkoxide acting as a tetradendate ligand in

which the μ_3-oxo of an electron-rich metal, lead(II), are the donor sites. ^{207}Pb NMR displays a sensitivity to coordination numbers similar to that of ^{119}Sn NMR, although much larger shifts are observed in the case of lead. Indeed, the formation of the heterometallic alkoxide **5** involves an increase in the lead coordination number from 4 to 6, which results in a drastic shift (more than 2000 ppm) to higher fields in the NMR. Large chemical shift variations are also observed for other Pb—O—M (M = Ti, Mg, Bi) systems and thus ^{207}Pb NMR gives an initial indication of the formation or not of heterometallic species and suggests a high coordination number for the lead atoms also. The study of heterometallic alkoxides involving lead and other metals is in progress.

REACTIONS OF NONABORANE ANIONS WITH SOME SEVEN-COORDINATE CARBONYL IODIDE COMPLEXES OF MOLYBDENUM(II) AND TUNGSTEN(II)

PAUL K. BAKER, MICHAEL A. BECKETT* and LISA M. SEVERS

Department of Chemistry, University of Wales, Bangor, Gwynedd, LL57 2UW, U.K.

(*Received* 28 *February* 1991; *accepted* 5 *April* 1991)

Abstract—The reactions of $[MI_2(CO)_3L_2]$ (M = Mo, W; L = PPh_3, PPh_2Me, $PPhMe_2$) with $[NMe_4][B_9H_{14}]$ and $[NMe_4][B_9H_{12}]$ in dichloromethane solution have been attempted. The new metalloborane $[6,6,6,6\text{-}(CO)_3(PPh_3)\text{-}6\text{-}W\text{-}B_9H_{13}]$ (**1**) and the previously reported $[6,6,6,6\text{-}(CO)_2(PPh_3)_2\text{-}6\text{-}Mo\text{-}B_9H_{13}]$ were isolable in low yield from the appropriate reaction mixtures. Complex **1** has been characterized by elemental analysis, IR spectroscopy and multielement (^1H, $^{11}B\text{-}\{^1H\}$ and $^{31}P\text{-}\{^1H\}$) NMR spectroscopy. In addition to **1**, moderate yields of $[NMe_4][WI_3(CO)_3(PPh_3)]$ and $[4\text{-}(PPh_3)B_9H_{13}]$ were obtained from the reaction of $[WI_2(CO)_3(PPh_3)_2]$ with $[NMe_4][B_9H_{14}]$.

Considerable interest has been shown in the preparation and reaction chemistry of metal complexes containing polyhedral boron hydride ligands and over 500 metalloboranes have been synthesized.[1] Metalloboranes containing the heavier group 6 metals are surprisingly poorly represented within this wide spectrum of compounds. Hitherto, polyhedral molybdenaborane chemistry and polyhedral wolfraborane chemistry are limited to a dozen or so reported compounds.[2–5] The readily available syntheses of seven-coordinate organophosphine-containing carbonyl iodide complexes of molybdenum(II) and tungsten(II) from $[MI_2(CO)_3(NCCH_3)_2]$ (M = Mo, W)[6] have led us to explore their reactions with the nonaborane anions $[B_9H_{12}]^-$ and $[B_9H_{14}]^-$ in attempts to synthesize new metalloborane complexes of tungsten and molybdenum.

EXPERIMENTAL

General

Reactions were carried out using standard Schlenk techniques under nitrogen, using solvents distilled under nitrogen from an appropriate drying agent. $[NMe_4][B_9H_{12}]$ and $[NMe_4][B_9H_{14}]$ were prepared by reported methods,[7,8] as were the molybdenum(II) and tungsten(II) starting materials.[9] The general procedure for the reaction of the nonaborane anions with the molybdenum(II) or tungsten(II) complexes is outlined below for the preparation of $[6,6,6,6\text{-}(CO)_3(PPh_3)\text{-}6\text{-}W\text{-}B_9H_{13}]$ (**1**).

Elemental analyses (C, H and N) were determined using a Carlo Erba elemental analyser MOD 1106 (using helium as carrier gas). IR spectra were recorded on a Perkin–Elmer F.t IR 1600 spectrophotometer. Multielement NMR spectra were recorded at room temperature in $CDCl_3$ solution on a Bruker AC 250 CP/MAS NMR spectrometer operating at 250 MHz for ^1H, 80.25 MHz for ^{11}B and $^{11}B\text{-}\{^1H\}$ and 101.2 MHz for $^{31}P\text{-}\{^1H\}$. Chemical shifts (δ) are given in ppm to high frequency (low field) of $SiMe_4$ for ^1H, 85% H_3PO_4 for ^{31}P and $BF_3\cdot OEt_2$ for ^{11}B.

Preparation of $[6,6,6,6\text{-}(CO)_3(PPh_3)\text{-}6\text{-}W\text{-}B_9H_{13}]$ (**1**)

To a stirred solution of $[WI_2(CO)_3(PPh_3)_2]$ (2.1 g, 2.00 mmol) in dry dichloromethane (15 cm^3) was added one equivalent of $[NMe_4][B_9H_{14}]$ (0.37 g, 1.98 mmol) under nitrogen. The solution was stirred for a further 24 h, during which time a yellow precipitate formed. A $^{11}B\text{-}\{^1H\}$ NMR spectrum of the reaction solution at this point showed that $[4\text{-}(PPh_3)B_9H_{13}]$ was the major boron-containing species present. The reaction mixture was filtered

* Author to whom correspondence should be addressed.

through a short column of Keiselgel and the filtrate was taken down to *ca* 3 cm^3 in volume under reduced pressure at room temperature and then applied to a series of preparative TLC plates ($20 \times 20 \times 0.1$ cm, silica, Keiselgel GF 254, made in these laboratories as required) and eluted with dichloromethane. Three coloured bands were observed on the preparative TLC plates: two very faint bands at R_f 0.7 (yellow) and R_f 0.65 (orange), and an intense, bright purple band at R_f 0.8. The purple band was removed from the silica and purified by further preparative TLC using (i) dichloromethane and then (ii) 50:50 dichloromethane/hexane as the eluants. The purple component (**1**) was recrystallized from dichloromethane/hexane to yield air-stable, purple crystals of [6,6,6,6-$(CO)_3(PPh_3)$-6-W-B_9H_{13}] (**1**) (0.204 g; 16%). IR: ν(CO) 2014(m), 1948(s), 1892 cm^{-1}; ν(BH) 2549 cm^{-1}. Found: C, 39.6; H, 4.9; N, 0.0. Calc. for $C_{21}H_{28}B_9O_3PW$: C, 39.4; H, 4.4; N, 0.0%.

Identification of the yellow solid

The yellow solid formed from the reaction of reactants as above on a 3.3 mmol scale (3.45 g of $[WI_2(CO)_3(PPh_3)_2]$ and 0.61 g of $[NMe_4][B_9H_{14}]$) was separated from the reaction mixture and washed with 2×10 cm^3 portions of dichloromethane. The mass of this yellow precipatate was 1.85 g. Extraction of this yellow solid with acetone yielded a yellow solution and a white solid (0.31 g). Elemental analysis for this white solid was consistent with it being $[NMe_4]I$; Found: C, 24.0; H, 6.5; N, 5.8. Calc. for $C_4H_{12}IN$: C, 23.9; H, 7.0; N, 6.0%. The yellow solution was evaporated to dryness to yield a yellow solid (1.52 g). Elemental analysis based upon the formula $[NMe_4][WI_3(CO)_3(PPh_3)]$; Found: C, 27.9; H, 3.0; N, 1.5. Calc. for $C_{25}H_{27}I_3NO_3PW$: C, 30.4; H, 2.7; N, 1.5%. IR: ν(CO) at 2004, 1925 and 1901 cm^{-1} comparable to data reported for the related $[N^nBu_4][WI_3(CO)_3(PPh_3)]$ complex.[12] The yellow solid was difficult to isolate free from $[NMe_4]I$.

RESULTS AND DISCUSSION

Synthetic reactions

Organophosphine complexes of the carbonyl iodides of molybdenum(II) and tungsten(II) were prepared as previously described[9] by the reaction of two equivalents of the organophosphine with the labile bis-acetonitrile complexes $[MI_2(CO)_3(NCCH_3)_2]$ (M = Mo, W), eq. (1):

$$[MI_2(CO)_3(NCCH_3)_2] + 2L \longrightarrow [MI_2(CO)_3L_2] + 2CH_3CN$$
$$(M = Mo, W;\ L = PPh_3, PPh_2Me, PPhMe_2). \quad (1)$$

These complexes were reacted separately, in dichloromethane solution, with the $[NMe_4]^+$ salts of the *nido*-$[B_9H_{12}]^-$ and the *arachno*-$[B_9H_{14}]^-$ anions. Only in two cases were metalloborane species identified as reaction products. The new, bright purple *nido*-wolfradecaborane [6,6,6,6-$(CO)_3(PPh_3)$-6-W-B_9H_{13}] (**1**) and the magenta *nido*-molybdenadecaborane [6,6,6,6-$(CO)_2(PPh_3)$-6-Mo-B_9H_{13}] (**2**) were obtained in 16 and 12% yields, respectively, from the reactions of $[MI_2(CO)_3(PPh_3)_2]$ (M = W, Mo) with the *arachno*-$[B_9H_{14}]^-$ anion, eq. (2):

$$[MI_2(CO)_3(PPh_3)_2] + [NMe_4][B_9H_{14}] \longrightarrow \mathbf{1}\ (M = W, 16\%);\ \mathbf{2}\ (M = Mo, 12\%). \quad (2)$$

The cluster geometry of **1** is shown schematically in Fig. 1. Compound **2** has been previously prepared[3] in 4% yield from the reaction of the chloro complex $[MoCl_2(CO)_3(PPh_3)_2]$ with $[N^nBu_4][B_9H_{14}]$. Unexpectedly, the previously reported[3] compound [6,6,6,6-$(CO)_3(PMe_2Ph)$-6-W-B_9H_{13}] (**3**) could not be detected in reactions of $[WI_2(CO)_3(PMe_2Ph)_2]$ with either nonaborane anion. However, the reaction of the *nido*-$[B_9H_{12}]^-$ anion with $[MI_2(CO)_3(PPh_3)_2]$ (M = Mo, W) also resulted in small yields of **1** and **2**, respectively. Compounds **1** and **2** were isolated as air-stable, microcrystalline solids and were characterized by satisfactory elemental

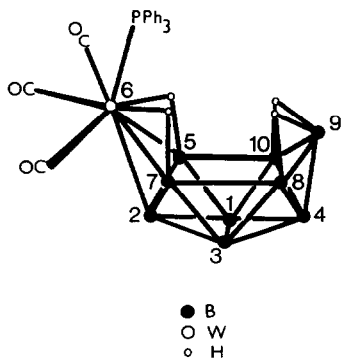

Fig. 1. Schematic representation of the cluster structure of [6,6,6,6-$(CO)_3(PPh_3)$-6-W-B_9H_{13}] (**1**) based upon that proposed for the analogous [6,6,6,6-$(CO)_3(PMe_2Ph)$-6-W-B_9H_{13}] (**3**).[3] The numbering scheme for an open 10-vertex cage is shown. Each unsubstituted boron cluster vertex has an *exo*-terminal hydrogen atom bound to it (not shown).

analysis, and by IR and multielement NMR spectroscopy.

The low yields of the metalloboranes from these reactions mixtures would suggest that they are formed as by-products of a main reaction. Indeed, non-boron-containing, yellow, insoluble materials were observed as the major products from all the reactions attempted. The composition of this yellow material was investigated for the $[WI_2(CO)_3(PPh_3)_2]$/$[NMe_4][B_9H_{14}]$ reaction, where it was found to be a mixture of two compounds which were partially separable by solvent extraction. These two materials were identified by elemental analysis and by IR spectroscopy to be $[NMe_4]I$ and $[NMe_4][WI_3(CO)_3(PPh_3)]$.[10-12] The complex $[WI_2(CO)_3(PPh_3)_2]$ and other seven-coordinate di-iodo tungsten(II) species are well known to decompose in dichloromethane solution to yield seven-coordinate tri-iodo anions.[13-16] The principal boron-containing compound produced in the reaction of $[WI_2(CO)_3(PPh_3)_2]$ with $[NMe_4][B_9H_{14}]$ in dichloromethane solution is the *arachno*-$[4\text{-}(PPh_3)B_9H_{13}]$ borane ligand complex. This was identified by its characteristic $^{11}B\text{-}\{^1H\}$ NMR spectrum.[17] This product presumably results from the reaction of $[B_9H_{14}]^-$ with free PPh_3 produced in the decomposition of the tungsten(II) species outlined above.

Characterization of boron-containing products

The identification of the *nido*-6-metalladecaboranes has been made using primarily $^{11}B\text{-}\{^1H\}$ NMR spectroscopy, augmented by $^{31}P\text{-}\{^1H\}$, ^1H NMR and IR spectroscopy and elemental analysis. The NMR parameters that we have measured for compounds **1** and **2** are given in Table 1, together with comparable NMR data for all other reported non-boron-substituted *nido*-6-metallodecaboranes of molybdenum and tungsten. The $^{11}B\text{-}\{^1H\}$ NMR data in Table 1 for compounds **1**–**4** are similar. Compound **4** is the non-carbonyl-containing species $[6,6,6,6\text{-}(PMe_2Ph)_3H_2\text{-}6\text{-}W\text{-}B_9H_{13}]$.[2] In particular the $^{11}B\text{-}\{^1H\}$ spectrum of **1** shows two high-field resonances (of equal relative intensity 1 : 1) separated from a poorly resolved set of overlapping signals (of relative intensity 7) at lower field in an overall pattern which is entirely characteristic of a *nido*-6-metallodecaborane cluster.[2,18] The $^1J(^{11}B^1H)$ coupling constants that we were able to measure for **1** are in the range 110–140 Hz and are typical for a two-centre/two-electron terminal boron hydrogen bond.[18] The ^1H NMR of compound **1** shows, in addition to a broad hump several ppm wide centred at *ca* δ 2.0 due to terminal hydrogen atoms coupled to ^{11}B, and signals due to the

aromatic protons at low field, two high-field signals of equal intensity at δ −4.30 and −6.18 ppm. These high-field signals are fully consistent with B—H—B and W—H—B bridging hydrogen atoms, respectively. The $^{31}P-\{^{1}H\}$ spectrum of compound **1** appears as a singlet at δ +44.7 ppm flanked by low intensity tungsten satellites with $^{1}J(^{183}W^{31}P)$ of 208 Hz; the magnitude of this $^{183}W-^{31}P$ coupling constant is similar to that found for compounds **3** and **4**.[2,3] Consistent with a tricarbonyl species, the IR spectrum of **1** shows three, strong, carbonyl stretches at 2014, 1948 and 1872 cm^{-1} and a further strong B—H stretch at 2549 cm^{-1}. Elemental analysis and IR data for **1** are given in the Experimental and these are fully in accord with this compound being assigned as a *nido*-6-metallodecaborane with the ligands around the metal centres, as indicated in Fig. 1.

(*Received* 7 *March* 1991; *accepted* 10 *April* 1991)

Abstract—The title compounds were obtained by reacting the corresponding $MoX_3(THF)_3$ complexes with PMe_2Ph in a 2:3 ratio in refluxing toluene. The compounds assume a face-sharing, bioctahedral structure with three bridging halide ligands, the coordination geometries being completed by one terminal halide and two phosphines for one metal centre, and by two terminal halides and one phosphine for the other one. A comparison with the known chloride analogue shows that the metal–metal separation increases in the order Cl < Br < I and, correspondingly, the paramagnetism of the molecule also increases as shown by solid-state magnetic susceptibility measurements and by the paramagnetic shifts in the solution ^1H NMR spectrum. The NMR spectrum indicates an equilibrium in solution between *anti* and *gauche* isomers. NMR monitoring of the reaction between $Mo_2Br_6(PMe_2Ph)_3$ and PMe_2Ph shows evidence for the formation of the edge-sharing bioctahedral $Mo_2Br_6(PMe_2Ph)_4$ as a short-lived intermediate, the mononuclear $MoBr_3(PMe_2Ph)_3$ being the final product.

We have recently detailed the factors that govern the interconversion between molybdenum(III) complexes of mononuclear, octahedral (MO), $MoCl_3L_3$, edge-sharing, bioctahedral (ESBO), $Mo_2Cl_6L_4$, and face-sharing, bioctahedral (FSBO), $Mo_2Cl_6L_3$ structures, where L = THF[1] or tri-substituted phosphine.[2] In particular, we found that the THF-substituted compounds have the order of relative stability MO < ESBO < FSBO, whereas the phosphine-substituted analogues have an exactly opposite trend. The ESBO compounds are unstable towards disproportionation to a mixture of MO and FSBO systems. However, the ESBO compounds could be prepared by taking advantage of the faster kinetics of the FSBO to ESBO step during the phosphine addition reaction, eq. (1):[2]

$$Mo_2Cl_6L_3 \xrightarrow{+L,\ fast} Mo_2Cl_6L_4 \xrightarrow{+L,\ slow} 2MoCl_3L_3. \quad (1)$$

Since the ESBO chloride complexes show unexpected behaviour in terms of metal–metal bond formation [e.g. the PMe_2Ph complex has a relatively strong metal–metal bond[2] with a Mo—Mo separation of 2.8036(8) Å, whereas the PEt_3 complex[3] has a non-bonded Mo—Mo distance of 3.730(1) Å], we naturally wondered how the metal–metal bonding capability would change on going to the corresponding bromide- and iodide-bridged systems.

We report here the synthesis and structure of the bromide- and iodide-bridged FSBO complexes with

† Author to whom correspondence should be addressed.

PMe_2Ph as the neutral ligand and attempt to convert them into the corresponding ESBO systems by the strategy illustrated in eq. (1).

EXPERIMENTAL

All operations were carried out under an atmosphere of dinitrogen using standard glove-box and Schlenk-line techniques. Solvents were dehydrated by conventional methods and distilled under dinitrogen prior to use. Instruments used were as follows: NMR, Bruker AF200 and WP200; UV–vis, Schimadzu UV-240; magnetic susceptibility, Johnson–Matthey magnetic balance. The elemental analyses were by Midwest Microlab, Indianapolis, Indiana. $MoBr_3(THF)_3$,[4] $MoI_3(THF)_3$[5] and $Mo_2Cl_6(PMe_2Ph)_3$[2] were prepared by literature methods, and PMe_2Ph was purchased from Strem Chemicals and used as received.

Preparation of $Mo_2Br_6(PMe_2Ph)_3$

To a suspension of $MoBr_3(THF)_3$ (1.46 g, 2.64 mmol) in 30 cm^3 of toluene was added PMe_2Ph (0.56 cm^3, 3.9 mmol). The mixture was refluxed for *ca* 7 h, resulting in the formation of a dark, crystalline precipitate and a golden yellow solution. The solid was separated by filtration, washed twice with 5 cm^3 of toluene and dried *in vacuo*. Yield: 523 mg (36.4%). The compound is only sparingly soluble in chloroform and hot toluene. It is somewhat more soluble in dichloromethane to yield intensely coloured forest green solutions. Found: C, 26.5; H, 2.9; P, 8.6. Calc. for $C_{24}H_{33}Br_6Mo_2P_3$: C, 26.5; H, 3.1; P, 8.6%. μ_{eff} (293 ± 2 K) = 0.94 μ_B per molybdenum atom (diamagnetic correction = 403.4×10^{-6} c.g.s.u. per dinuclear unit). UV–vis [CH_2Cl_2, nm (ε, M^{-1} cm^{-1})]: 244 (34,500), 340 (14,200), 418 sh (3000), 612 (2000). A single crystal for the X-ray analysis was obtained by diffusion of n-heptane into a dichloromethane solution.

Preparation of $Mo_2I_6(PMe_2Ph)_3$

This compound was prepared from $MoI_3(THF)_3$ (1.26 g, 1.82 mmol) and PMe_2Ph (0.39 cm^3, 2.7 mmol) in toluene (20 cm^3), following the general procedure described above for the corresponding bromide compound. The mixture was refluxed overnight. Yield: 1.04 g (83%). When the mixture was refluxed only for a short time (*ca* 1/2 h), a comparable amount of dark, crystalline solid was present, but ^1H NMR analysis indicated the presence of impurities. The compound is even less soluble than the bromide analogue, and its dichloromethane solutions are golden yellow. A single crystal for the X-ray analysis was obtained from CH_2Cl_2/n-heptane. Found: C, 20.9; H, 2.3. Calc. for $C_{24}H_{33}I_6Mo_2P_3$: C, 21.1; H, 2.4%. μ_{eff} (293 ± 2 K) = 1.68 μ_B per molybdenum atom (diamagnetic correction = 498.8×10^{-6} c.g.s.u. per dinuclear unit). UV–vis [CH_2Cl_2, nm (ε, M^{-1} cm^{-1})]: 231 (57,000), 318 (20,200), 406 (12,400), 450 sh (10,100), 661 (449).

Magnetism of $Mo_2Cl_6(PMe_2Ph)_3$

μ_{eff} (293 ± 2 K) = 0.23 μ_B per molybdenum atom (diamagnetic correction = 347.6×10^{-6} c.g.s.u. per dinuclear unit).

X-ray crystallography for $Mo_2X_6(PMe_2Ph)_3$ (X = Br, I)

The experimental details are given in Table 1. The cell constants and orientation matrix for data collection for both $Mo_2X_6(PMe_2Ph)_3$ (X = Br, I) compounds were based on 24 carefully centred reflections in the range $20 < 2\theta < 30°$. Acceptable ω scans were obtained. The structures were solved by a combination of direct methods and heavy atom Fourier techniques. Full-matrix least-squares refinement was carried out with anisotropic thermal parameters for all the non-hydrogen atoms. The hydrogen atoms were placed in calculated (d_{C-H} = 0.95 Å) positions. All calculations for the solution and refinement of the structures were performed using the Nicolet SHELXTL PLUS crystallographic package. Selected bond distances and angles for both compounds are listed in Table 2.†

$Mo_2Br_6(PMe_2Ph)_3$

A black, needle-shaped crystal of approximate dimensions $0.25 \times 0.20 \times 0.40$ mm was mounted on the tip of a glass fibre with epoxy resin. θ–2θ scans over the 2θ range 3.5–55.0° produced 7857 unique reflections, of which 3274 [$I > 3\sigma(I)$] were used for structure refinement. The data indicated the centrosymmetric $P\bar{1}$ space group, which was confirmed by the successful solution of the structure. Refinement converged at $R = 0.0485$ and $R_w = 0.0528$.

† Full tables of crystal data, bond lengths, bond angles, anisotropic thermal parameters, calculated hydrogen atom coordinates and F_o/F_c data for the compounds $Mo_2X_6(PMe_2Ph)_6$ (X = Br, I) have been deposited with the Editor as supplementary material. The atomic positional parameters have been deposited with the Cambridge Crystallographic Data Centre.

Temperature (°C)	23	23
Transmission factors: max., min.	0.718, 0.657	0.956, 0.799
R^a	0.0485	0.0371
$R_w{}^b$	0.0528	0.0413

[a] $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$.
[b] $R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(|F_o|)+0.002(|F_o|^2)$.

The maximum shift/ESD in the last cycle of refinement was less than 0.02 and the maximum intensity in the final difference Fourier map was < 0.5 e Å^{-3}. An absorption correction based on ψ scans was attempted, without any improvement in the agreement figures.

$Mo_2I_6(PMe_2Ph)_3$

A black, parallelepiped-shaped crystal of approximate dimensions $0.2\times0.2\times0.4$ mm was mounted on the tip of a fibre with epoxy resin. θ–2θ scans over the 2θ range 4.5–50.0° produced 6488 unique reflections, of which 4823 [$I > 3\sigma(I)$] were used for structure refinement. The space group $P\bar{1}$ was chosen and the structure solved and refined to $R = 0.0371$ and $R_w = 0.0413$. The overall geometry of the molecule is very similar to the one observed for $Mo_2Br_6(PMe_2Ph)_3$. The maximum shift/ESD in the last cycle of refinement was less than 0.01. The maximum intensity in the final difference Fourier map was < 0.8 e Å^{-3}. An absorption correction based on ψ scans was applied.

RESULTS AND DISCUSSION

The synthesis of the FSBO $Mo_2X_6(PMe_2Ph)_3$ (X = Br, I) compounds is analogous to that described before[2] for the corresponding chloride compound, eq. (2):

$$2MoX_3(THF)_3+3PMe_2Ph \longrightarrow Mo_2X_6(PMe_2Ph)_3+6THF. \quad (2)$$

Compounds of the $Mo_2X_6L_3$ class (X = halogen, L = neutral donor) are well-known for X = Cl, for instance with L = $PEtPh_2$,[6] PEt_3, PMe_2Ph,[2,7] SMe_2,[8] tetrahydrothiophene,[9] THF,[1,10] or MeCN.[11] Anionic derivatives are known also for the other halides, for instance $Mo_2X_9^{3-}$ (X = Br, I)[12] and $Mo_2X_7L_2^-$ (X = I, L = PMe_3).[13] The two compounds reported in the present paper are the first, uncharged molybdenum(III) systems of the class of FSBO complexes that contain bridging bromide or iodide ligands and, together with the $Mo_2Cl_6(PMe_2Ph)_3$ compound recently described by us, allow a comparison of the properties for the entire series of $Mo_2X_6(PMe_2Ph)_3$ compounds with X = Cl, Br and I to be made.

This comparison is analogous to but presents additional advantages with respect to others done before. It is known that, upon replacement of the chloride bridging ligands with the larger bromide and iodide ions, the metal centres are forced farther from each other and the magnetism in molybdenum(III) FSBO complexes increases. This is the case for $Cs_3Mo_2X_9$ (X = Cl, Br, I)[12a,c] and $[Mo_2X_7(PMe_3)_2]^-$ (X = Cl,[14] I[13]). However, it has recently become apparent that the energy of these systems must have a fairly shallow minimum as a

[a] In each line, geometrically equivalent parameters for the two structures are compared.

function of metal–metal distance. For instance, the metal–metal distance in two different crystalline forms of $Mo_2Cl_6(PEt_3)_3$[2,7] with identical molecular geometry varies by 0.06 Å and the distances in $[Mo_2Cl_9]^{3-}$ and $[Mo_2Br_9]^{3-}$ vary over a 0.25 and 0.54 Å range, respectively, by the mere change of the cation.[13c] Solid-state magnetic measurements may therefore reflect packing and/or counterion effects. The $Mo_2X_6(PMe_2Ph)_3$ molecules reported herein are uncharged (no counterion effects) and the presence of the phosphine protons give the opportunity to at least qualitatively assess the change of magnetic properties *in solution* (no packing effects) through an examination of the paramagnetic shifts in the ^1H NMR. In addition, the two molecules reported here are crystallographically isostructural with each other and with the chloride compound described earlier,[2] thus the packing forces in the solid state should be similar and the correlation between solid-state magnetic susceptibility and solution paramagnetic NMR shifts should be meaningful.

The ^1H NMR spectra of the three complexes show paramagnetic shifts which increase in the order Cl < Br < I, in agreement with the solid-state magnetic data (see Experimental) and with the increase in metal–metal distance on going from the chloride to the iodide derivatives (see crystallographic data below). The methyl proton resonances are shifted upfield, whereas the phenyl proton resonances are shifted downfield with respect to the characteristic regions in diamagnetic complexes. For each molecule, the paramagnetic shifts *increase* upon increasing the temperature. The methyl resonances move from the δ +1 to 0 range at 212 K to the δ −0.8 to −1.5 range at 291 K for the bromide complex, and from the δ 0.5 to −2.5 range at 226 K to the δ −1.2 to −3.4 range at 281 K for the iodide complex. This is consistent with the known electronic structure of these molecules which consists of a diamagnetic ground state ($\sigma^2\pi^4$ metal–metal bond) and low-lying paramagnetic excited states generated by promotion of electrons into the metal–metal π^* orbitals.[12c,15] A reviewer pointed out that the nature of the halogen may in itself cause a change of the phosphine proton chemical shift and thus a strict correlation of paramagnetic shift with magnetic properties is not possible. We note, however, that the position of the PMe_3 proton resonance in the homologous series of *diamagnetic* $Mo_2X_4(PMe_3)_4$ complexes shifts only by 0.29 δ on going from X = Cl to X = I.[16] This shift is very small in comparison with the corresponding shifts observed for the methyl proton resonances in $Mo_2X_6(PMe_2Ph)_3$.

The pattern of ^1H NMR resonances in the methyl region also shows, as already evidenced for the chloride complex,[2] the presence of an equilibrium mixture of *anti* and *gauche* isomers (see Fig. 1). Overlap of some of the peaks occurs in most conditions but examination of the pattern at all temperatures clearly reveals, both for the bromide and for the iodide complex, three absorptions of relative intensity 1 : 1 : 1 (*anti* isomer) and six absorptions of relative intensity 1 : 1 : 1 : 1 : 1 : 1 (*gauche* isomer). The crystalline material that we have obtained for the iodide system after a short (*ca* 1/2 h) reflux time shows more resonances in the methyl region of the ^1H NMR spectrum. These extra resonances have a temperature dependence similar to those of *anti* and *gauche* $Mo_2I_6(PMe_2Ph)$ and are due to an, as yet, unidentified impurity which disappears when the material is refluxed for a longer period.

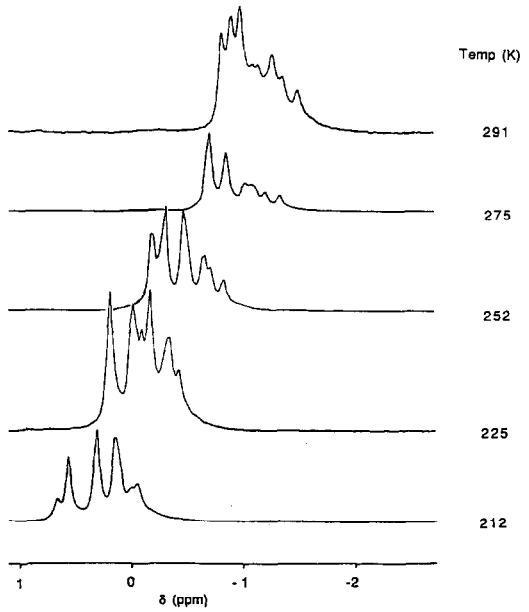

Fig. 1. Representative ^1H NMR spectra of the $Mo_2Br_6(PMe_2Ph)_3$ compound in the methyl region at various temperatures. Solvent = CD_2Cl_2.

The optical properties of the three compounds (X = Cl, Br, I) are also consistent with the known electronic structure. Upon increasing the metal–metal distance and thereby reducing the metal–metal overlap, the HOMO–LUMO gap decreases and the absorption bands experience a red shift.

The $Mo_2X_6(PMe_2Ph)_3$ (X = Br, I) compounds, like their chloride analogue, crystallize in the triclinic space group $P\bar{1}$ with similar cell dimensions. The three molecules show the same face-sharing, bioctahedral geometry with the phosphine ligand system in a relative *anti* configuration. Figure 2 shows a view of the bromide molecule. The octahedral geometry around each metal is slightly distorted, at least in part because of the compression

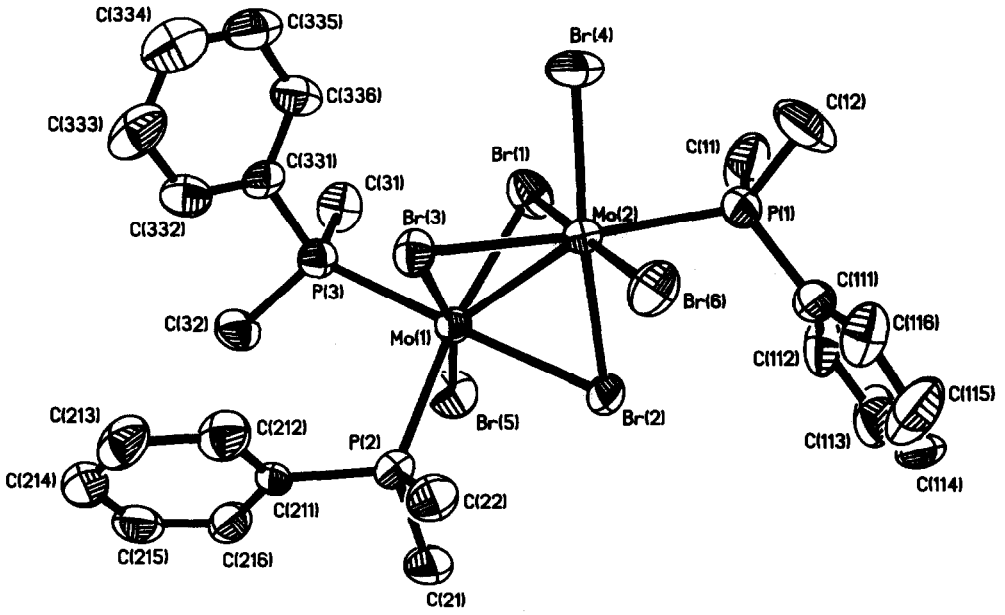

Fig. 2. ORTEP view of the $Mo_2Br_6(PMe_2Ph)_3$ molecule. The iodide analogue has an identical structure.

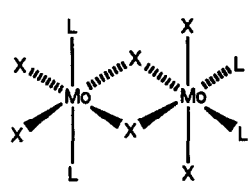
along the metal–metal axis which is caused by the metal–metal bond. For instance, the average angle between two Mo—(μ-X) vectors is higher than 90°, whereas all the Mo—(μ-X)—Mo angles are less than the value of 70.53° which is the calculated value for an undistorted FSBO structure.[17] Another indication of Mo—Mo bonding is the metal–metal separation, 2.749(2) Å for the bromide complex and 2.909(1) Å for the iodide complex, which compare with 2.6582(5) Å for the corresponding chloride complex.[2] The only other structurally characterized FSBO molybdenum(III) complexes with bridging bromides or iodides are $Cs_3Mo_2Br_9$ [Mo—Mo = 2.816(9) Å],[12] and $[Cat]^+[Mo_2I_7(PMe_3)_2]^-$ [Mo—Mo = 3.021(4) Å, Cat = $PHMe_3$; 3.022(1) Å, Cat = $AsPh_4$].[13]

As one might have anticipated, the Mo—X distances are, on average, shorter for terminal halides, and those involving bridging halide ligands reflect the higher *trans* influence of PMe_2Ph vs X. The Mo—P distances for both compounds are in the range usually found for octahedrally coordinated molybdenum(III) compounds.[4,13,18]

We now come to the original interest of our studies, that is the reaction of the FSBO bromide and iodide complexes with extra phosphine in an attempt to generate the corresponding ESBO complexes and whether the latter would or would not show a direct metal–metal interaction (see Introduction). The reaction of $Mo_2Br_6(PMe_2Ph)_3$ with three equivalents of PMe_2Ph was followed by ^1H NMR at room temperature. Figure 3 shows the salient features of this experiment. Two peaks at *ca* δ −26.5 and −39 in an approximate 1:1 ratio develop initially. These are assigned to the methyl groups of an ESBO $Mo_2Br_6(PMe_2Ph)_4$ molecule containing two phosphine ligands in the axial positions on one molybdenum centre, and the other two in the equatorial positions on the other metal, as shown in structure **I**. This is the geometry that has been found both in the solid state and in solution for the corresponding chloride system.[2,3]



I

The intensity of these resonances, however, never exceeds *ca* 1% of the total amount of the molybdenum complex and two new resonances at δ −26.5 and −40, in a 1:2 ratio, soon start to grow. These correspond to the mononuclear *mer*-$MoBr_3(PMe_2Ph)_3$.[2] Two major conclusions can be drawn from this experiment. The reaction follows the same path as that of the corresponding chloride system,[2] see eq. (2), but the relative rates of the two steps are reversed, the first step (FSBO to ESBO) being slower than the second one (ESBO

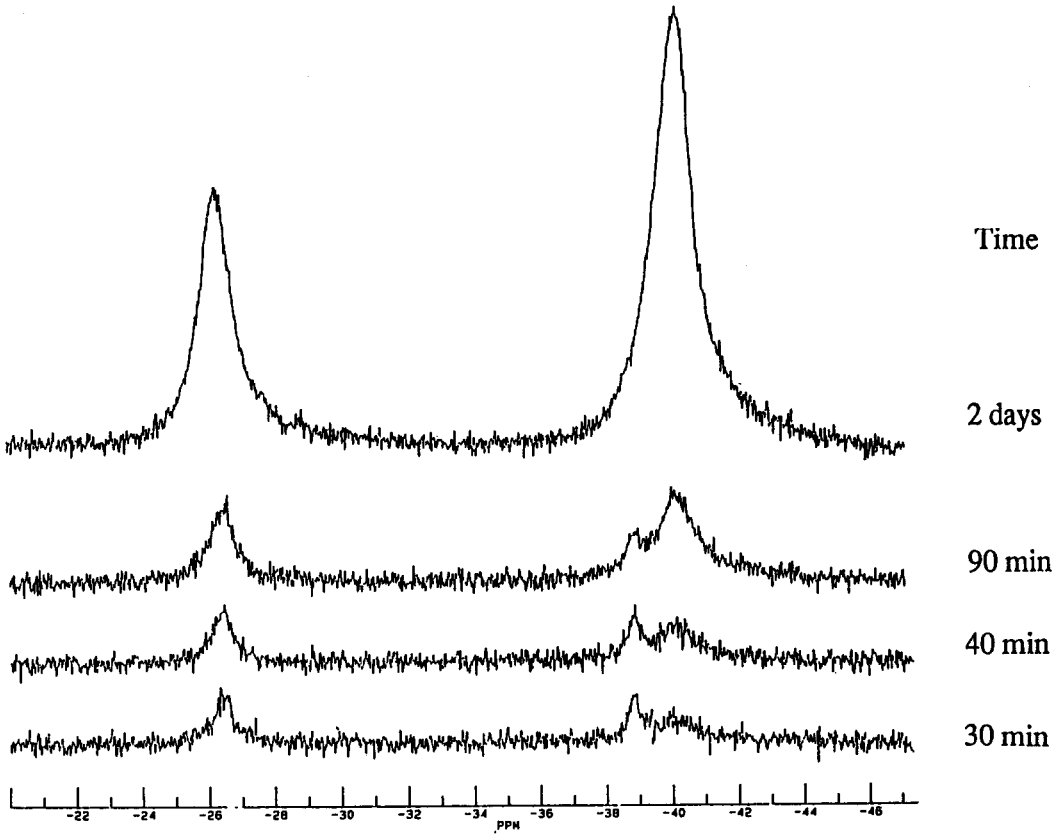


Fig. 3. ^1H NMR spectra in the phosphine methyl region during the reaction of $Mo_2Br_6(PMe_2Ph)_3$ with excess PMe_2Ph.

to MO), see eq. (3):

$$Mo_2Br_6(PMe_2Ph)_3 \xrightarrow[\text{slow}]{+PMe_2Ph} Mo_2Br_6(PMe_2Ph)_4 \xrightarrow[\text{fast}]{+PMe_2Ph} 2MoBr_3(PMe_2Ph)_3. \quad (3)$$

The second conclusion is that the ESBO $Mo_2Br_6(PMe_2Ph)_4$ molecule does not have a direct Mo—Mo bond and its magnetic properties (as indicated by the paramagnetic shifts in the ^1H NMR spectrum) are analogous to those of the mononuclear $MoBr_3(PMe_2Ph)_3$ molecule, i.e. there are three unpaired electrons per metal centre. Therefore, changing the nature of the bridging halide ligands from chloride to bromide is sufficient to change the metal–metal interaction from a situation of strong bonding[2] ($\sigma^2\pi^2\delta^{*2}$) to no bonding at all. This system differs from the corresponding $Mo_2X_6(dppe)_2$ system, in which a Mo—Mo bond exists for both X = Cl[19] and X = Br.[20] The faster second step of eq. (3), as compared with the second step of eq. (1) (L = PMe_2Ph), may be attributed to the increased kinetic barrier in the latter case due to the change of spin state on going from the ESBO to the MO system.

Based on the relative intensities and positions of the peaks in Fig. 3, and comparing the geometrical features of the ESBO $Mo_2Br_6(PMe_2Ph)_4$ with the mononuclear *mer*-$MoBr_3(PMe_2Ph)_3$, it is possible to assign, for the methyl protons of the ESBO molecule, the upfield resonance (δ −39) to the ligands that are *trans* to each other and the downfield resonance (δ −26.5) to the ligands that are *trans* to bridging bromides.

Conclusions

The investigations reported here have shown that, although FSBO systems of the type $Mo_2X_6(PMe_2Ph)_3$ maintain a direct metal–metal bonding on going from X = Cl or X = I, this interaction is lost in the corresponding ESBO $Mo_2X_6(PMe_2Ph)_4$ systems on going from X = Cl to Br. Furthermore, the FSBO to ESBO transformation becomes slower relative to the ESBO to MO transformation on going from X = Cl to X = Br. As a result, although the thermodynamically unstable (toward ligand disproportionation) ESBO chloride system could be kinetically accumulated in solution and isolated by utilizing the strategy illustrated

in eq. (1),[2] the corresponding bromide system can only be generated as a short-lived intermediate. As a corollary, ESBO compounds with monodentate phosphine ligands and bridging *iodide* ligands are not likely to be stable species either.

COPPER(II) COMPLEXES OF 1-(PYRIDINE-2-YL)-3-METHYL-3,6-DIAZAHEPTANE (PDAHP). X-RAY CRYSTAL STRUCTURE OF $Cu(PDAHP)Cl_2$

A. CASTIÑEIRAS,* R. CARBALLO and C. VÁZQUEZ

Departamento de Química Inorgánica, Universidad de Santiago de Compostela, E-15706 Santiago de Compostela, Spain

(*Received* 29 *October* 1990; *accepted* 15 *April* 1991)

Abstract—The reactions of the novel tridentate ligand 1-(pyridine-2-yl)-3-methyl-3,6-diazaheptane (PDAHP) with copper(II) salts have been investigated. The ligand and the complexes $Cu(PDAHP)Cl_2$, $Cu(PDAHP)Br_2$, $[Cu(PDAHP)(OH_2)_2](ClO_4)_2$ and $[Cu(PDAHP)(NO_3)](NO_3)$ have been characterized by elemental analyses, conductivity and magnetic susceptibility measurements, mass, IR, electronic absorption and ^1H NMR data. In addition, the X-ray crystal structure of $Cu(PDAHP)Cl_2$ is described. The structure is a distorted trigonal bipyramid in which the copper atom is coordinated by a ligand molecule that spans the two axial and one equatorial sites and by the two chlorine atoms in the remaining equatorial positions.

The preparation and study of inorganic compounds containing biologically important ligands is made easier since certain metal ions are active in many biological processes; species of low molecular weight are hence sought that reproduce, as far as possible, the structural properties and the reactivity of these ions in such processes. The fact that copper, together with magnesium, calcium, iron, zinc, chromium, vanadium and manganese, is one of the essential metallic elements (it is the third most abundant after iron and zinc[1]) and that it has great biological activity when associated with certain metal–protein complexes, participating in the transport of oxygen, electronic transfer reactions or the storage of ions,[2] has brought about enormous interest in the study of systems containing this metallic centre.[3]

Results from spectroscopic and X-ray diffraction studies have established that in many copper-based proteins the metal has either a pseudo-tetrahedral or a square-based pseudo-pyramidal configuration.[4] It may be of use, therefore, to synthesize a series of both tri- and tetradentate ligands that, in the presence of copper(II), give rise to these coordination geometries. As part of our studies of ligands like those referred to above,[5] in this paper we describe the synthesis and characterization of the new tridentate ligand 1-(pyridine-2-yl)-3-methyl-3,6-diazaheptane (PDAHP) and the complexes formed from its reactions with various copper(II) compounds. The structure of one of these complexes has been characterized by X-ray diffraction.

EXPERIMENTAL

Materials

The synthesis of the ligand PDAHP was performed using 2-vinylpyridine (Merck) and N,N′-dimethylethylendiamine (EGA). All chemicals were used without further purification.

Physical measurements

Carbon, hydrogen and nitrogen contents were carried out on a Perkin–Elmer 240B microanalyser. Positive ion FAB and electron impact (EI) mass spectra were obtained on a Kratos MS-50 mass spectrometer retrofitted with a Kratos FAB source and interfaced to a Kratos DS-90 data system. Xenon was used as the bombarding gas with atom gun energies of 8 keV. The source was operated

at 250°C. The liquid matrix used was 3-nitrobenzylalcohol.

IR absorption spectra (4000–200 cm^{-1}) using KBr and CsI pellets were recorded on a Perkin–Elmer 1330 spectrophotometer. UV–vis spectra were measured on a Hitachi U-3200 spectrophotometer using the diffuse reflectance technique with MgO as reference.

Magnetic susceptibilities were determined by the Faraday method in the temperature range 70–300 K with a DSM-5 susceptometer, operating at a fixed field strength of 15 kG. $HgCo(NCS)_4$ and $Cd_2(SO_4)_3 \cdot 8H_2O$ were used as calibrants. X-ray crystallographic data were obtained on an Enraf–Nonius CAD4 diffractometer. Data reduction and solution were performed on a MicroVAXII using the SHELXS86[6] and VAX/SDP[7] package of programs.

^1H NMR spectra were recorded on a Bruker WM250 instrument in DMSO-d_6 using TMS as internal standard. Conductivity measurements were carried out on a WTW LF-3 conductivity bridge. Measurements were made for 10^{-3} M solutions in acetonitrile.

Synthesis of the ligand

A solution of concentrated hydrochloride acid (6 cm^3) was carefully added with stirring to a solution of freshly distilled 2-vinylpyridine (8 cm^3, 74.3 mmol) in methanol (30 cm^3) over nitrogen. Stirring was continued for 20 min and an excess of N,N′-dimethylethylendiamine was then added. The mixture was heated under reflux for 1 h. Addition of sodium hydroxide then caused precipitation of sodium chloride. The solvent was removed and the resulting oil was dissolved in ether, dried with calcium sulphate and the solvent removed *in vacuo*. PDAHP was obtained upon removal of the ether solution as a yellow oil (70%).

Synthesis of the complexes

All four complexes were prepared by dissolving CuX_2 crystallized (4 mmol) (X = Cl, Br, ClO_4 or NO_3) in methanol (10 cm^3) and adding the resulting solution to PDAHP (0.77 g, 4 mmol) in methanol (10 cm^3). The mixture was stirred for 7 days after which the volume of the solution was reduced *in vacuo*, and the solids were isolated by filtration. Crystals of $Cu(PDAHP)Cl_2$ suitable for X-ray crystallographic analysis were isolated by slow evaporation of a methanolic solution of the complex.

X-ray data collection and reduction

A light green prismatic crystal of $Cu(PDAHP)Cl_2$ was mounted on a glass fibre and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range of $6 < \theta < 12°$. Data were collected at 293 K using Mo-K_α radiation ($\lambda = 0.71073$ Å) and the ω–θ scan technique. The data were corrected for Lorentz and polarization effects and empirical absorption[8] and secondary extinction corrections were applied.[9] The final coefficient, refined in the last least-squares cycle, was 2.13×10^{-7}. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

Structure solution and refinement

The structure was solved by direct methods which revealed the position of all non-hydrogen atoms, and refined on F by a full-matrix least-squares procedure using anisotropic temperature factors. Hydrogen atoms were located from geometrical considerations, added to the structure factors calculations as fixed contributions and their positional parameters were not refined. After all the shift/ESD ratios were less than 0.1, the refinement converged to the agreement factors listed in Table 1. Form factors were taken from ref. 10.*

RESULTS AND DISCUSSION

Our studies show that the reaction of the calculated quantities of copper(II) salts with PDAHP in methanolic solution give the complexes shown in Table 2, which contain a ligand molecule for each metal atom. Elemental analyses, colour and conductivity measurements for the PDAHP ligand and complexes are also listed in Table 2.

Characterization of the ligand

The free ligand was characterized by mass, IR and ^1H NMR spectroscopy.

The molecular ion does not appear in the mass spectrum but fragments are seen that correspond to

* Further details of the structure determination have been deposited as Supplementary Publication No. CDS-54513. Copies may be obtained through the Fachinformationzentrum Karlsruhe, D-7514 Eggenstrin-Leopoldshafen 2, F.R.G.

[a] Ω^{-1} cm^2 mol^{-1}.

the α-splitting of the tertiary amines $[M-CH_2N(H)CH_3]^+$ ($m/z = 149$, relative abundance 90%) and $[M-C_5H_4NCH_2]^+$ ($m/z = 101$, relative abundance 10%) which can be used to deduce the relative molecular mass of the compound. Other abundant ions were $[M—C_5H_4NCH_2CH_2]^+$ ($m/z = 106$, relative abundance 100%) and $[C_5H_4N(H)CH_2]^+$ ($m/z = 93$, relative abundance 26%).

The IR spectrum showed a medium intensity band at 3320 cm^{-1} and a weak one at 1675 cm^{-1} which were assigned to the ν(NH) and δ(NH) modes of the amine group, respectively. Other strong bands at 1588, 1567, 1469 and 1431 cm^{-1} corresponding to the symmetric and asymmetric C=C and C=N vibrations of the pyridine ring. A strong band at 1120 cm^{-1} was assigned to the ν(CN) stretching modes of the amine groups, and the two medium intensity bands at 627 and 406 cm^{-1} were assigned to the deformation modes of the pyridine ring.

The ^{1}H NMR spectrum showed the following signals: 2.18 ppm (s, 3H) and 2.22 ppm (s, 3H), of the methyl groups; 2.42 ppm (m, 4H), of the ethylene group that joins the two amine nitrogen atoms; 2.63 ppm (t, 2H) and 2.82 ppm (t, 2H), of the ethylene group joined to the pyridine; 7.13 ppm (t, 1H), 7.22 ppm (d, 1H), 7.63 ppm (t, 1H) and 8.45 ppm (d, 1H), of the pyridine-1H.

Structure of $Cu(PDAHP)Cl_2$

The most important distances and angles are included in Table 3 and the molecule is represented in Fig. 1 with the atoms shown numbered, and in Fig. 2, a stereoscopic view. The asymmetric unit is formed from a copper atom coordinated by a ligand molecule across its three nitrogen atoms and by the two chlorine atoms that occupy equatorial positions in a polyhedron of distorted trigonal bipyramidal coordination.

The degree of distortion between trigonal bipyramidal and tetragonal pyramidal geometries can be estimated knowing the parameter $\tau = (\beta-\alpha)/60$,[11] where α and β are the maximum basal angles between opposite atoms, such that, ideally, $\tau = 1$ corresponds to the trigonal bipyramid and $\tau = 0$ to the tetragonal pyramid. For the compound under study, Cl(1)—Cu—N(2) = α = 141.8° and N(1)—Cu—N(3) = β = 168.7°, giving $\tau = 0.45$, indicating that there is significant distorsion from the

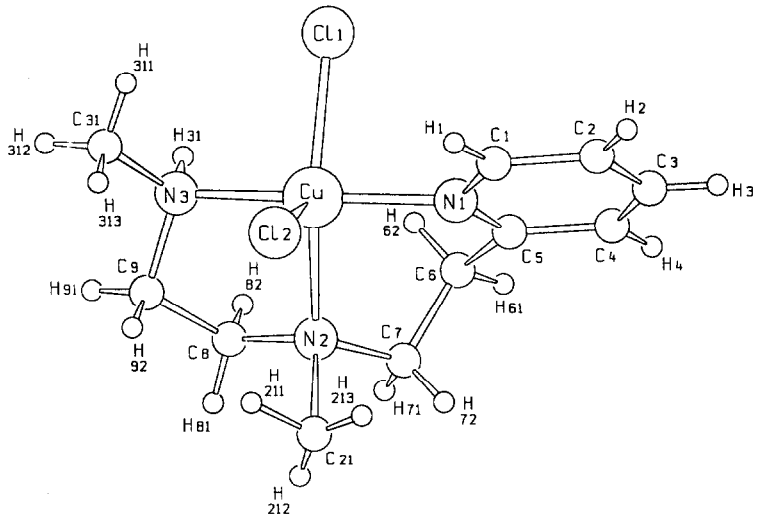

Fig. 1. Structure and numbering scheme for $[Cu(PDAHP)Cl_2]$.

trigonal bipyramid toward a tetragonal pyramidal geometry (Fig. 2). The average deviation of atoms Cl(1), N(1), N(2) and N(3) from the mean basal plane is 26.7 pm. The copper atom is located a distance of 46.16(9) pm above this plane. The distortions can be explained by bearing in mind that PDAHP is a tridentate chelate ligand that coordinates to the metal forming five- and six-membered rings; the resulting tensions cause modifications of the equatorial and axial angles.

The average bond lengths $Cu—N_{(amine)}$, 198.9(5) pm, and $Cu—N_{(pyridine)}$, 213.6(4) pm, are characteristic of copper(II)–nitrogen bonds,[12] and the Cu—Cl distances of 233.8(2) and 242.3(1) pm are slightly greater than those found in other complexes with terminal Cu—Cl bonds in a similar copper coordination.[13]

An "*envelope*" conformation can be deduced for the five-membered ring and a "*boat*" conformation for the six-membered one from the values of the dihedral angles,[14] there being an angle of 32.8(4)° between the mean planes of both rings, comparable to others found in similar systems.[15]

Mass spectra

The mass spectra of all the complexes (Table 4) show two peaks, the one of greater m/z can be assigned to the species $[Cu(PDAHP)X]^+$ and that of lower m/z, coinciding in all cases, to the species $[Cu(PDAHP)]^+$. These species are common in the mass spectra of $[ML_n]X_m$ type coordination compounds of monovalent anions with the metal in oxidation state II or III.[16]

Every spectrum also contained some peaks with higher or lower m/z values than those shown (Table 2), which may be due to oligomeric species, in the

first case, and to the fragmentation of the ligand, in the second.

Conductivity

Values of molar conductivity for 10^{-3} M solutions of the complexes in acetonitrile (Table 4), less than 30 Ω^{-1} cm^2 mol^{-1} in Cu(PDAHP)X_2 (X = Cl or Br), show that they are non-electrolytes with the halide atom coordinated to the metal.[17] The perchlorate derivative has a molar conductivity of 236.56 Ω^{-1} cm^2 mol^{-1}, in agreement with that expected for 1:2 electrolytes in acetonitrile[17] and indicates that the metal is pentacoordinated by the ligand and both water molecules. Cu(PDAHP)$(NO_3)_2$, however, has a molar conductivity of 104.89 Ω^{-1} cm^2 mol^{-1} placing it in the range of 1:1 electrolytes.[17] This is only possible if we suppose that one nitrate group is coordinated to the metal.

IR spectra

A tentative assignment of the most characteristic IR bands has been made (Table 5). The bands due to stretching vibrations in the pyridine ring, between 1590 and 1430 cm^{-1}, and those due to the deformation modes appearing near 625 and 405 cm^{-1}, are displaced to higher frequencies in the complexes. This behaviour is very indicative of the ligand being coordinated to the copper(II) across the nitrogen of the pyridine group.[18] Furthermore, the band corresponding to the ν(NH) mode is displaced between -60 and -140 cm^{-1} in the complexes, and the band assigned to ν(CN), that in the free ligand appears as a strong band at 1120 cm^{-1}, is displaced to higher frequencies by almost 20 cm^{-1} in the complex, to form a weak band. The above indicates that the nitrogen atoms of both amine groups participate in coordination, in agreement with the structural results obtained for Cu(PDAHP)Cl_2.

The spectrum of [Cu(PDAHP)$(OH_2)_2$]$(ClO_4)_2$ contains, in addition to the bands already mentioned, ν(OH) and δ(OH) modes at 3520 and 1665 cm^{-1} indicating the presence of coordinated water molecules,[19] as well as an intense band close to 1100 cm^{-1} and a strong band at *ca* 625 cm^{-1} assignable to the $\nu_3(ClO_4)$ and $\nu_4(ClO_4)$ modes, respectively, of the perchlorate ions.[20]

Table 6. Magnetic and electronic spectral data for the metal complexes[a]

Compound	α	β	θ	μ	μ(298 K)	d–d (cm^{-1})
$[Cu(PDAHP)Cl_2]$	2.359	2.316	−1.01	1.86	1.79	14,827
$[Cu(PDAHP)Br_2]$	−12.304	2.500	4.92	1.79	1.91	14,285
$[Cu(PDAHP)(H_2O)_2](ClO_4)_2$	51.892	1.080	−48.07	2.72	2.55	17,618–15,479
$[Cu(PDAHP)(NO_3)](NO_3)$	12.966	2.231	−5.81	1.89	1.89	15,271

[a] $1/\chi = \alpha + \beta T$.

In the spectrum of $[Cu(PDAHP)(NO_3)](NO_3)$, the presence of NO_3^- ions is revealed by a strong, narrow band at 1377 cm^{-1} (ν_3) and two weak bands at 815–816 and 726 cm^{-1} (ν_2 and ν_4, respectively),[21] while the bidentate nature of the nitrate ligand is shown by the presence of the bands at 1284 cm^{-1} (ν_3), 1020 cm^{-1} (ν_1) and 832 cm^{-1} (ν_2)[22a] and by the splitting of the combination band $\nu_1+\nu_4$ that appears at 1768 and 1732 cm^{-1}.[22b] The existence of ionic and bidentate nitrates explains the conductivity value found for this complex and the pentacoordination deduced from its electronic spectrum (*vide infra*).

The presence of two low frequency bands at 490–470 cm^{-1} and 380–340 cm^{-1} in the spectra of every complex lead to their assignment as ν(CuN) modes,[23] while a strong absorption at 240 cm^{-1} was identified as ν(CuCl).[24] Lastly, medium intensity bands at 284–273 cm^{-1} and 290–270 cm^{-1} in the spectra of $[Cu(PDAHP)(OH_2)_2](ClO_4)_2$ and $[Cu(PDAHP)(NO_3)](NO_3)$, respectively, which are not seen in the spectra of the other two complexes, can reasonably be assigned to the ν(CuO) modes.[19,25]

Electronic reflectance spectra

The diffuse reflectance spectra of all the complexes (Table 6), except $[Cu(PDAHP)(OH_2)_2](ClO_4)_2$, are very similar and contain a narrow, asymmetric band that is poorly resolved at high energy, with a maxima at 14,827, 14,285 and 15,271 cm^{-1} in the chloro, bromo and nitrate derivatives, respectively, suggesting distorted trigonal bipyramidal geometry,[26] which is consistent with the structural parameters found for $Cu(PDAHP)Cl_2$. The spectrum of $[Cu(PDAHP)(OH_2)_2](ClO_4)_2$, however, presents two peaks of equal intensity at 15,479 and 17.618 cm^{-1} and matches the spectra of other copper(II) complexes with distorted tetragonal pyramidal geometry.[27]

Magnetic susceptibilities

The magnetic moments of the complexes (Table 6) at room temperature have values between 1.79 and 2.55 BM, and lie in the interval expected for pentacoordinated complexes of copper(II).[28,29] Study of the variation in the reciprocal of the molar magnetic susceptibility corrected with the temperature, from 70 to 300 K, indicates that the complexes obey the Curie–Weiss law, and the magnetic moment deduced thereby (Table 6) does not differ greatly from that found at room temperature.

Acknowledgements—We thank Professor Alario Franco and Professor Sáez Puche of Complutense University (Madrid) for their collaboration in the magnetic measurements, and also thank the CICYT of Spain for financial support (Project PS88-0051).

TERNARY COMPLEXES OF URANYL BETA-DIKETONES WITH ALIPHATIC AMIDES

P. B. RUIKAR, M. S. NAGAR and M. S. SUBRAMANIAN*

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay-400 085, India

(*Received* 9 *November* 1990; *accepted* 15 *April* 1991)

Abstract—Ternary adducts of uranyl beta-diketone chelates [beta-diketones = 1-phenyl-3-methyl-4-benzoyl-pyrazolone-5 (PMBP), 1-phenyl-3-methyl-4-acetyl-pyrazolone-5 (PMAP) and thenoyltrifluoroacetone (TTA)] and dibutyl derivatives of hexanamide (DBHA), octanamide (DBOA) and decanamide (DBDA) have been isolated and characterized as UO_2(beta-diketone)$_2$·amide. The ^{1}H NMR spectra indicate the existence of restricted rotation of the C—N bond in these complexes. Evidence for the existence of the amide adducts of PMBP as an isomeric mixture has been adduced from the presence of four phenyl protons in their ^{1}H NMR spectra. Thermal investigations confirm the existence of two types of PMBP moieties as opposed to the TTA adducts.

Long chain aliphatic amides have potential applications in nuclear fuel processing as they have some specific advantages over the conventional extractant, *viz.* TBP.[1–6] A detailed investigation of several amides for the separation of uranium and plutonium is contained in some excellent review articles.[7,8] Amides can also act as synergistic donors in the extraction of actinides by beta-diketones. Recently, Yi Min and Wang Liya[9] have reported synergistic extraction of uranyl nitrate by a mixture of N,N-diisopropylbutylamide and 1-phenyl-3-methyl-4-benzoyl-pyrazolone-5 (PMBP). Recently we have also investigated the synergistic extraction of uranyl ion with thenoyltrifluroacetone (TTA) and dibutyl derivatives of hexanamide (DBHA), octanamide (DBOA) and decanamide (DBDA).[10] Several binary solid complexes of actinides with amides have also been investigated by Bagnall and co-workers.[11,12] The synthesis, thermal studies, IR and ^{1}H NMR spectra of ternary uranyl complexes with beta-diketones such as TTA, PMBP and 1-phenyl-3-methyl-4-acetyl-pyrazolone-5 (PMAP) with three amides, *viz.* the dibutyl derivatives DBHA, DBOA and DBDA are described in this paper.

EXPERIMENTAL

Preparation of the ligands

Pyrazolones and amides were synthesized by the methods of Jensen[13] and Baldwin,[14] respectively, and characterized by elemental analysis, IR and NMR spectra.

Preparation of the complexes

The complexes were prepared by solvent extraction of aqueous uranyl nitrate solution (10 cm^3, 5 mM) at pH = 2 with benzene (10 cm^3) containing 10 mM of the beta-diketone and 5 mM of the amide. The organic layer was dried with anhydrous sodium sulphate, evaporated to dryness and the crude product recrystallized from n-hexane.

Characterization of the complexes

The complexes were characterized by elemental analysis (Table 1) using standard semi-micro analytical methods.[15] Uranium was determined volumetrically, as well as gravimetrically, as reported earlier.[16,17] IR spectra of samples in Nujol mulls between CsI discs were measured using a Pu-9510 spectrophotometer in the range 4000–200 cm^{-1}.

Table 1. Analytical data of uranyl pyrazolone amide complexes[a]

^{1}H NMR spectra were obtained with a Varian FT-80A spectrophotometer using 0.05 M solutions in d-chloroform. Thermal investigations were carried out using a ULVAC (TGD-7000) differential thermal analyser in air at a heating rate of 10°C min^{-1}.

RESULTS AND DISCUSSION

IR spectra

The empirical assignments of a few typical bands in the IR spectra of the complexes are given in Table 2. The reduction in the stretching frequency of the carbonyl band of the free amide from 1640 to 1600 cm^{-1} indicates its coordination in the molecule.

^{1}H *NMR spectra*

The ^{1}H NMR spectral assignments of a few typical complexes are given in Table 3. In the complexes with TTA as the chelating agent, a broad singlet for the thienyl protons in addition to sharp singlets for the CH protons have been observed. The presence of two clear triplets for the α-CH protons of the butyl group in TTA complexes indicate their non-equivalence caused by restricted rotation of the

[c] Number of peaks.

C—N bond, the triplets arising due to the associated spin coupling by the adjacent methylene protons. Two separate signals for the N-methyl protons have also been observed in the spectra of N,N-dimethylacetamide because of their non-equivalence due to hindered rotation. Methyl protons of the butyl group are observed to be the most shielded, occuring as triplets due to coupling by the adjacent methylene protons. In the PMBP and PMAP complexes with amides, the presence of four and two separate signals, respectively, for the aromatic protons indicate their existence as a mixture of isomers. Four separate signals for the aromatic protons have also been observed in the ^{1}H NMR spectrum of $UO_2(PMBP)_2 \cdot H_2O$ in acetone. The α-methylene protons of the butyl groups in PMBP and PMAP complexes have been observed as a composite peak of six lines (only five peaks observed), involving the merger of two triplets in the PMBP and PMAP complexes, whereas they are observed as two clear triplets in the corresponding TTA complexes. From this, it is clear that the PMBP and PMAP complexes are less sterically hindered to rotation around the C—N bond compared with the TTA complexes.

Thermal investigations

The results of the thermal investigations of $UO_2(PMBP)_2$ complexes with DBHA and DBOA are given in Table 4. The DTA curves of these two complexes show a sharp dip at 125°C, presumably due to a phase change on melting. Three plateaux corresponding to weight loss due to one PMBP, amide and the second PMBP are observed, giving rise to exothermic, endothermic and strong exothermic peaks, respectively. The loss of amide and the second PMBP molecule did not give two clear plateaux and the weight loss has been computed as corresponding to the loss of both. On the other hand, the thermograms of $UO_2(TTA)_2 \cdot DBHA$ and $UO_2(TTA)_2 \cdot DBOA$ show only one plateau due to the loss of both TTA moieties, indicating that they are symmetrically bonded. This agrees with the idea that the amide complexes of pyrazolones exist as a mixture of isomers.

NEW β-DIKETON-(2-PHENYLETHYL)IMINE SCHIFF BASE CHELATES OF COPPER(II), NICKEL(II) AND COBALT(III) AND THEIR ELECTROPHILIC SUBSTITUTION PRODUCTS

S. ABDUL SAMATH, N. RAMAN, K. JEYASUBRAMANIAN and S. K. RAMALINGAM*

Department of Inorganic Chemistry, School of Chemistry, Madurai Kamaraj University, Madurai-625 021, India

(*Received* 13 *November* 1990; *accepted* 15 *April* 1991)

Abstract—New Schiff base chelates of nickel(II), copper(II) and cobalt(III) derived from acac/bzac and 2PEA (acac = 2,4-pentanedionate, bzac = 1-phenyl-1,3-butanedionate anions; 2PEA = 2-phenylethylamine) have been synthesized and characterized. The nickel(II) and copper(II) complexes are non-planar, cobalt(II) does not form any isolable complex and the cobalt(III) complex has an octahedral structure as indicated from UV–vis, IR, ^{1}H and ^{13}C NMR and analytical data. Steric factors arising from the flexible —CH_2—CH_2—Ph substituent on the nitrogen atom of 2PEA force the less hindered, non-planar, tetrahedral geometry for copper(II) and nickel(II) and the meridional octahedral geometry for cobalt(III) to predominate. Electrophilic substitution reactions of these chelates, like γ-halogenation and γ-phenylisocyanation, are also reported.

Transition metal complexes with Schiff bases as ligands have been amongst the most widely studied coordination compounds. An interesting feature of nitrogen-substituted β-ketonimine Schiff base complexes is the stereochemical problems they present.[1] For example, the stereochemistry of N-alkyl β-ketonimine complexes of many transition metals M(II) and (III) are found to be strongly dependent on the nature of the R group bonded to the nitrogen of the >C=N group (Fig. 1).[1,2]

The nickel(II) complexes (where R = CH_3, C_6H_5, *p*-$C_6H_4CH_3$) in the solid state or in solutions of non-polar solvents are planar and diamagnetic. On the other hand, when R is an α-branched alkyl group, like isopropyl or *o*-/*m*-$C_6H_4CH_3$, the complexes are known to be tetrahedral and paramagnetic.[3] In this context, it was of interest to examine the stereochemistry of some four-coordinated metal(II) and six-coordinated cobalt(III) Shiff base ketonimine chelates wherein the chosen ligand system is bulky but flexible due to free rotations around >C—N< and >C—C< bonds

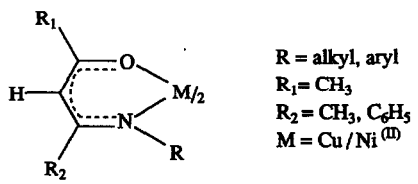

Fig. 1.

of >N—CH_2—CH_2—Ph. This paper reports the isolation and characterization of the title chelates and their γ-substituted electrophilic reaction products.

EXPERIMENTAL

The IR spectra were recorded on a Perkin–Elmer 477 spectrophotometer using KBr discs. The ^{1}H NMR measurements were carried out on a Brucker 270 MHz spectrophotometer in DMSO-d_6 with TMS as an internal standard. ^{13}C NMR spectra of the cobalt(III) Schiff base chelate were recorded on a Brucker instrument (100.62 MHz) in DMSO-d_6. The electronic spectra were recorded in solutions of DMSO and DMF on a Shimadzu UV-160 spectrophotometer.

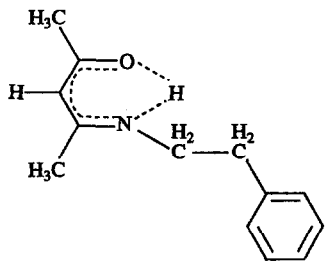

Fig. 2.

Synthesis of Schiff base complexes

The isolation of the title Schiff base ligand (Fig. 2) was not possible by the usual condensation reaction between the β-diketone and 2-phenylethylamine. Therefore, a template-type amine exchange reaction in the presence of metal salt was adopted for the successful synthesis of the title chelates.

(a) *Bis*(4*N* - (2 - *phenylethyl*) - 3 - *penten* - 2 - *ono*) *copper*(II). An ethanolic suspension (150 cm^3) of 1:2:2 stoichiometric quantities of $CuCl_2 \cdot 2H_2O$, β-ketonimine (R = H or CH_3) and 2PEA was left stirring for 2 h at room temperature. The metal salt gradually dissolved to give a clear solution, from which a green solid product separated after a time. This was filtered, washed with water, then with ethanol and dried at 110°C for 2 h.

(b) *Bis*(4*N* - (2 - *phenylethyl*) - 3 - *penten* - 2 - *ono*) *nickel*(II). This nickel(II)(Schiff base complex was prepared by the same method as described for the copper(II) complex.

(c) *Tris*(4*N* - (2 - *phenylethyl*) - 3 - *penten* - 2 - *ono*) *cobalt*(III). The cobalt(II) complex could not be precipitated out by the above method; only a clear solution resulted. But when hydrogen peroxide was added and the solution stirred vigorously, the originally pink-coloured solution turned green and eventually gave a green, solid product. This was filtered, washed with ethanol and dried in a hot air-oven at 110°C for 2 h.

(d) *Bis*/*tris*(3*N*-(2-*phenylethyl*)-1-*phenyl*-2-*buten*-1-*ono*)*metal*(II/III) *chelates*. The benzoylacetoneimine Schiff base chelates of copper(II), nickel(II) and cobalt(III) were prepared by the same methods described above.

Electrophilic substitution reactions

Bromination, chlorination and phenylisocyanation reactions at the γ-carbon of the β-biketonimine chelate ring. The presence of a facile γ-C—H proton in the above chelates offers the possibility to study the electrophilic substitution reactions like bromination, chlorination and phenylisocyanation.

To the chloroform suspension (50 cm^3) of a freshly prepared title chelate was added a stoichiometric quantity of a chloroform solution (100 cm^3) of NBS, NCS or PhNCO. The reaction mixture was heated on a water bath for 2 h with concomittant stirring. The suspension gradually yielded a clear solution, which upon cooling gave a solid, crystalline product. This was filtered, washed with warm chloroform (50 cm^3) and dried *in vacuo* over P_4O_{10}. Stirring or heating of the reaction mixture for a longer period than mentioned led to polymerization, producing dark-coloured products of indefinite composition.

RESULTS AND DISCUSSION

The Schiff base chelates of nickel(II), copper(II) and cobalt(III) and their γ-halo and γ-phenylamido products (Fig. 3) are insoluble in most solvents except DMSO and DMF. The solutions in the later solvents are non-electrolytes as inferred from their low conductivity. The thermal data suggest the presence of two water molecules, coordinated in the case of copper(II) and lattice held in nickel(II) and cobalt(III) complexes. Particulars of the compositions of the β-ketonimine chelates and their reaction products, reaction time, yield and analytical data are presented in Table 1. Important IR vibration data are given in Table 2.

The bands at *ca* 1620, 1200 and 800 cm^{-1} correspond, respectively, to ν(C=N), δ(C=N) and π(C=N) vibrations. By comparison of the IR literature data of the known β-diketonates and their γ-substituted products[4-7] with that of the present chelates the following assignments were made: ν(C=O) (1580 cm^{-1}), ν(C=C) (1550 cm^{-1}), ν(C=O+C—H) (1520 cm^{-1}), in-plane bend δ(C—H) (1190 cm^{-1}) and out-of-plane bend π(C—H) (785 cm^{-1}) vibrations. That an electrophilic substitution has taken place at the γ-carbon by replacement of the C—H proton is indicated by the disappearance of IR bands at 1190 and 785 cm^{-1} and a shift of the band at 1520 cm^{-1} to lower frequency. However, this diagnosis of the reaction product is not straightforward for ketonimines, because the stretching and bending frequencies of >C=N appear in the same diagnostic regions of 1600–1400, 1200–1100 and 750–800 cm^{-1}.

The UV–vis spectral data indicate that for the simplest bidentate Schiff base ligand with limited substituents, the arrangement of bonds in the $[MO_2N_2]$ unit is planar for copper(II) and nickel(II) and tetrahedral for cobalt(II).[1,2] Distortion from planarity of the chelate rings of the Schiff base ligands is known, depending on the nature of the

Complexes of nickel(II) and cobalt(III) were obtained in the anhydrous form by dehydration.

substituents present at the imine nitrogen of Fig. 1.[3] When the substituent is large and/or branched as in R = isopropyl, the distortion has been found to be substantial.[1,2] For the copper(II) and nickel(II) complexes, a band at *ca* 10,000 cm^{-1} (Table 3) rules out a square planar geometry.[9–11] The nickel(II) complex in DMSO solution exhibits absorption maxima at *ca* 10,000, 15,000 and 18,000 cm^{-1}, characteristic of a tetrahedral complex. The characteristic absorptions occurring at *ca* 9600 cm^{-1} (ν_1)

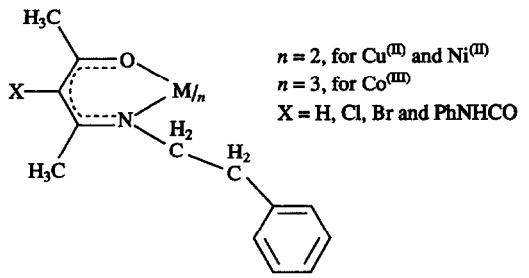

Fig. 3.

for the copper(II) and cobalt(III) ions correspond to an octahedral field around them.

The inability of the cobalt(II) ion to complex with the title Schiff base ligand can be attributed to the hydrolytic instability of cobalt(II) ketonimine complexes, in general, compared with β-diketonates. However, in the attempted preparation of the cobalt (II) complex, when the solution mixture was treated with hydrogen peroxide, the corresponding cobalt(III) complex could be isolated. The UV–vis spectral data (Table 3) coupled with the observed diamagnetism confirm an octahedral spin-paired structure for the cobalt(III) complex.

The ^1H and ^{13}C NMR spectra of the cobalt(III) chelates and their 3-bromo- and 3-phenylamido-substituted products (Tables 4 and 5) display some interesting features.

The observed three-line pattern in the NMR spectra is indicative of a less-strained meridional struc-

ture for the tris-chelate. In cobalt(III) chelate, the C—C single bond connecting the azomethine nitrogen and the phenyl group is capable of free rotation, thereby enhancing the steric repulsion between the phenyl groups of the three ligands in the tris-chelate. Furthermore, the methyl groups R_1 and R_2 on the α- and α'-carbon of the β-ketonimine chelate ring could also be expected to contribute to the overall steric influence. It has been found that when $R_1 = CH_3/C_6H_5$ and $R_2 = C_6H_5$, the complex is not formed probably due to the fact that excessive destabilization is brought about by steric crowding between the nine phenyl groups (three in R_1, three in R_2 and three in the chain attached to nitrogen) in a tris-chelated geometry.

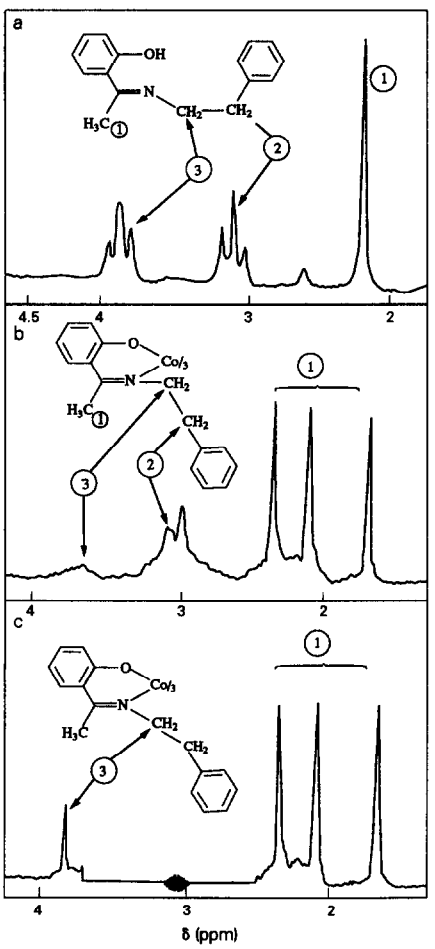

Fig. 4. NMR spectra, (a) the spin–spin splitting of the N—CH_2 and Ph—CH_2 methylene signals with near equal intensities in the isolable analogous ligand PhOH $CH_3C{=}N{-}CH_2{-}CH_2{-}Ph$ (the title ligand not isolable). (b) *Meridional* cobalt(III) complex of the ligand mentioned in (a). The methyl signal consists of 3 lines, Ph—CH_2 methylene multiplets are broad and the N—CH_2 multiplets appear insignificant. (c) Decoupling at signal 2 enhances the intensity of 3.

However, when $R_1 = CH_3$ and $R_2 = CH_3$, the distortion between the chelate rings would be less than that between the $-CH_2-CH_2-Ph$ groups of the three ligands. Still the distortion between the three [O—Co—N] planes of this $M(A—B)_3$ type chelate causes an asymmetric ligand array. Thus, the $(A—B)_3$ ligands, although chemically the same, provide different magnetic environments around the metal ion for adoption of exclusive *meridional* geometry.

Since the Schiff base ligand involved in this work is not isolable, identification of the methylene signals in the spectra of the complexes and the reaction product is carried out as follows. An analogous salicylaldimine Schiff base involving the same amine base (2-phenylethylamine) presents a ^1H NMR spectra [Fig. 4(a)] wherein the two methylene triplets are of equal intensity.[8] Whereas in the ^1H NMR spectra of its cobalt(III) tris-chelated complex [Fig. 4(b)], which exclusively exists in the meridional form, the N—CH_2 of the N—CH_2—CH_2—Ph group signals (triplet) are small in intensity and difficult to distinguish. However, when decoupling is carried out at the Ph—CH_2 resonance (*ca* at δ 3.05) [Fig. 4(c)], a N—CH_2 signal

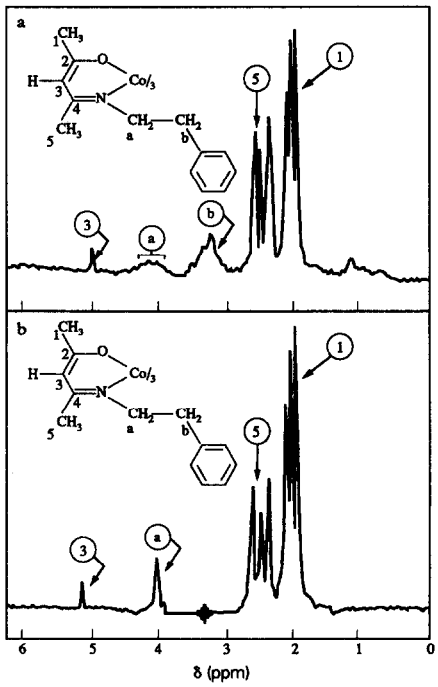

Fig. 5. NMR spectra of the title cobalt(III) Schiff base unsymmetrical tris-chelate (partly unresolved). Multiplet methylene signals appear broad in (a). In (b) decoupling at the Ph—CH_2 resonance raises the intensity of the N—CH_2 proton signal (the multiplets for the methylene signals are not as well resolved as the methyl signals).

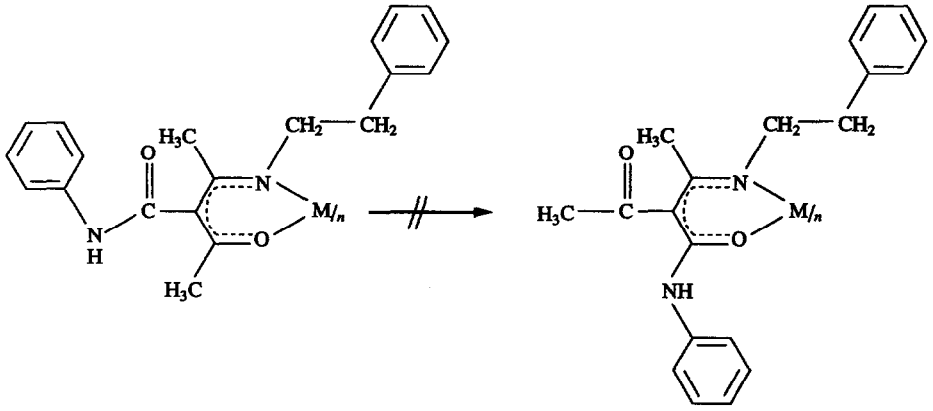

Fig. 6.

conspicuously becomes enhanced in intensity (*ca* at δ 3.90).

Examination of the ^{1}H NMR spectra of the cobalt(III) complex (*mer*) would reveal that a three-line pattern could be observed only for the methyl group resonances [Fig. 5(a)]. Identification of the spin–spin triplet for the N—CH_2 methylene proton of =N—CH_2—CH_2—Ph at *ca* δ 4.00 was difficult since the resonance was weak compared with the triplet observed around δ 3.40 for the methylene protons of Ph—CH_2—CH_2—N=. When decoupling was carried out as indicated above at δ 3.40, a strong, single-line signal appeared at δ 3.95 for the =N—CH_2—CH_2—Ph protons [Fig. 5(b)].

As expected, the ^{1}H–noise decoupled ^{13}C NMR spectra of the pure *mer*-cobalt(III) Schiff base chelate complexes are elegantly simple and most of the signals attributable to the parent Schiff base ligand (though not isolable) are resolved into a three-line pattern. Also, the 3-halo/phenylamido products, exhibit an analogous three-line pattern corresponding to a *meridional* structure without the admixture of the *facial* form. This is reasonable since the already bulky Schiff base ligands would become bulkier still after substitution by halogen or a phenylamido group and would thereby sterically enforce the *meridional* isomeric form. That the γ-substitution reactions have taken place fully is known from the conspicuous disappearance of the signal at δ 5.3 attributable to the γ-C—H proton and the absence of a signal at δ 100.16 in the ^{13}C NMR resonances of the γ-substituted products.

Confirmation by X-ray single crystal analysis was not possible since the substances were only very sparingly soluble in common organic solvents and did not yield single crystals in DMSO solution.

The IR spectra show no additional ν(C=O) (keto) band for any rearranged free acetyl group (expected at *ca* 1700 cm^{-1}), showing that no linkage isomerization has taken place (Fig. 6).

THERMODYNAMICS OF FORMATION, HYDROLYSIS AND IONIZATION OF MONOFLUOROPHOSPHOROUS ACID

JOHN W. LARSON

Department of Chemistry, Marshall University, Huntington, WV 25755-2520, U.S.A.

(*Received* 22 *October* 1990; *accepted* 19 *April* 1991)

Abstract—A NMR study of the equilibrium reaction of HF with aqueous phosphorous acid between 8 and 65°C and various hydrogen ions concentrations gave values of $\Delta G^{\ominus} = 2.2$ kJ, $\Delta H^{\ominus} = -26$ kJ and $\Delta S^{\ominus} = -94$ J K^{-1} for the acid ionization of monofluorophosphorous acid and $\Delta G^{\ominus} = -16.2$ kJ, $\Delta H^{\ominus} = -16.9$ kJ and $\Delta S^{\ominus} = -2.2$ J K^{-1} for the hydrolysis of monofluorophosphorous acid to phosphorous acid and HF.

Monofluorophosphorous acid, $H[FHPO_2]$, was first synthesized in 1968 by Centofanti and Parry[1] from the disproportionation of F_2HPO. Several additional preparative routes have subsequently been discovered.[2–5] Other names used for this acid are phosphinic fluoride, phosphonofluoridous acid and phosphonofluoridic acid.

In this work, aqueous $FHPO_2H$ is shown to be formed by a fast equilibrium reaction between aqueous HF and HPO_3H_2, e.g. (1):

$$HF(aq) + HPO_3H_2(aq) \rightleftharpoons H_2O(l) + FHPO_2H(aq). \quad (1)$$

Thermodynamic properties of monofluorophosphorous acid were obtained from the study of the temperature and hydrogen ion concentration dependence of the equilibrium quotient of this reaction.

The thermochemical properties of $FHPO_2H$ are of interest because: (i) $FHPO_2H$ contains only four heavy atoms and therefore this work may supply useful reference data in relation to theoretical calculations on important phosphorus compounds and reactions, particularly, hydrolysis reactions. (ii) This data may further our understanding of the effects of substituents that are bonded directly to second row atoms. (iii) The thermodynamics of hydrolysis of $FHPO_2H$ [reverse reaction (1)] may be related to and could be helpful in the understanding of biologically important phosphate hydrolysis reactions. No thermochemical properties of this compound are currently available.

EXPERIMENTAL

A concentration solution of phosphorous acid (5.28 mmol of H_3PO_3 per gram of solution) was made from the pure acid obtained from Aldrich. The concentration of this solution and concentrated solutions of hydrofluoric acid (19.85 mmol g^{-1}) and concentrated hydrochloric acid (10.22 mmol g^{-1}), both obtained from Fischer Scientific, were analysed by standard acidimetric titration methods. The HF was stored, dispensed and analysed using plastic labware. The sodium phosphite pentahydrate (BDH Chemicals) was analysed for water by heating *in vacuo* to 200°C. The sample solutions used in this work were prepared by weight with concentrations expressed in terms of molalities and the standard state for the solute taken as the hypothetical one molal solution.

Phosphorus magnetic resonance spectra were obtained using a Varian XL-200 spectrometer. All spectra involving HF solutions were recorded in 10 mm NMR tubes with Teflon sleeves and caps. Temperatures were controlled to within ±0.3°C and calibrated with a mercury thermometer.

The sensitivity of the NMR to low concentration phosphorus species, under the conditions of the equilibrium measurements, was investigated by making up standard solutions containing 0.5 m Na_2HPO_3 and small amounts of NaH_2PO_2. The detection limit of phosphorus as $H_2PO_2^-$ was found to be about 0.0003 m or 0.0006 mole fraction. The equilibrium fractions of phosphorus present as $FHPO_2H$ in the present work covered the range

from 0.013 to 0.007. The intrinsic error in equilibrium quotients is therefore estimated to be between 5 and 10%. This is comparable with the actual scatter in the experimental data.

CALCULATIONS AND RESULTS

When hydrofluoric acid is added to a solution of phosphorous acid, small peaks emerge immediately corresponding to the doublet of doublets of $FHPO_2H$ formed by reaction (1). For the whole temperature range between 5 and 85°C, reaction (1) appears to be fast on the time scale it takes to make the solutions and record the spectrum (20 min) and slow on the NMR time scale that would lead to line broadening (0.01 s). At high HF and H^+ concentrations and at high temperatures, the $FHPO_2H$ peaks broaden appreciably and eventually the PF splitting disappears. This is apparently due to $FHPO_2H$ exchanging F with the HF in solution. At the concentrations of the equilibrium measurements reported here, the broadening is slight and has no effect on the measurements.

Hydrogen decoupling collapses the $FHPO_2H$ spectrum to a doublet. The coupling constants and chemical shifts of the aqueous acid and its conjugate base are reported in Table 1 together with the corresponding value previously determined for liquid monofluorophosphorous acid and aqueous phosphorous acid.

The equilibrium expression for reaction (1) may be written as eq. (2):

$$K_1 = \frac{m_{FHPO_2H}}{m_{HF} m_{HPO_3H_2}}. \quad (2)$$

In this equation and all subsequent equations, the activity coefficients of the neutral species are estimated to be unity and are left out of the equilibrium expressions. The fraction of the phosphorous that is fluorinated as either $FHPO_2H$ or $FHPO_2^-$, X_{PF}, is determined directly from integration of the NMR peaks. Equation (2) may therefore be re-written as eq. (3)

$$K_1 = \frac{X_{FP}}{m_{HF}(1-X_{PF})} \frac{X_2}{X_1} = Q \frac{X_2}{X_1}, \quad (3)$$

where Q is the equilibrium quotient for the reaction and X_1 and X_2 are the respective fractions of phosphite and fluorophosphite in the acid form. Both of these fractions may be obtained via the measured P—H coupling constant of phosphite.

X_1 is calculated directly from the measured coupling constant by the method given in ref. 6, eq. (4):

$$X_1 = (J - 629.5)/56.5. \quad (4)$$

The change in the coupling constants of $FHPO_2$ when it undergoes protonation is too small and the measured values are too uncertain to apply the same procedure in calculating X_2. This fraction is instead obtained by considering the acid equilibrium reaction, eq. (5), and the equilibrium expression, eq. (6), where γ is the mean activity coefficient of H^+ and $FHPO_2^-$:

$$FHPO_2H(aq) \rightleftharpoons H^+(aq) + FHPO_2^-(aq) \quad (5)$$

$$K_5 = m_h m_{FHPO_2} \gamma^2 / m_{FHPO_2H} = H(1-X_2)/X_2. \quad (6)$$

The PH coupling constant of phosphorous acid is used a second time in an empirical method of obtaining the value of $m_H\gamma^2$, defined now as H, from the known acid ionization constant for phosphorous acid and the value of X_1, eq. (7):

$$H = m_H\gamma^2 = \{K_{a,H_3PO_3}\} X_1/(1-X_1). \quad (7)$$

Application of eq. (7) to find the value of $m_H\gamma^2$ appropriate for eq. (6) assumes that the activity coefficient of $FHPO_2^-$ is approximately equal to HPO_3H^-. Considering the similar structures of these species, this assumption is likely to be quite accurate. The fraction of $FHPO_2H$ in the acid form is then given by eq. (8):

$$X_2 = 1/(1 + K_5/H). \quad (8)$$

[c] Values are apparently effected by hydrogen-bonding to HF and are therefore known to only ±5 Hz.

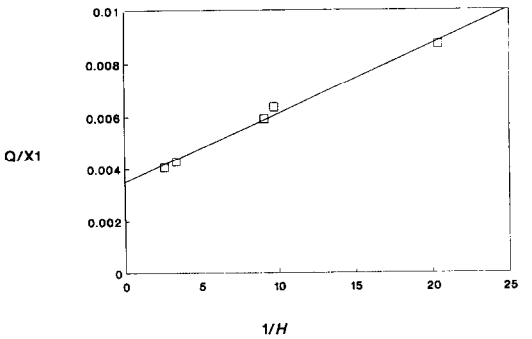

Fig. 1. Determination of K_1 and K_5 by graphing Q/X_1 vs $1/H$, eq. (9), at 65°C.

Substituting eq. (8) for X_2 in eq. (3) and rearranging results in eq. (9):

$$Q/X_1 = K_1 + K_1K_5(1/H). \quad (9)$$

Use of this equation to obtain K_1 and K_5 is demonstrated in Fig. 1. Measurements were made on five different solutions with H ranging between 0.05 and 1.5 m at temperatures of 8, 25, 45 and 65°C to obtain the values given in Table 2. The concentration ranges in these measurements were: 1.75–4.2 m for HF; 0.15–1.3 m for HPO_3H_2; 0–1.3 m for HCl; and 0–2.4 for Na_2HPO_3. None of these concentrations enter directly into the calculations of the equilibrium constants except for the concentration of HF. In the calculation of Q, the initial concentration of HF must be corrected for the amount that reacts to form F^-, $FHPO_2H$, $FHPO_2^-$ and FHF^-. Under the conditions of our measurements, calculations indicate less than 2% of the HF is present in the first three forms. At the highest pH, the concentration of FHF^- becomes appreciable, about 20%. The amount of FHF^- present was easily calculated, eq. (10):

$$m_{FHF^-} = m_{HF}^2 K_a K_d / H, \quad (10)$$

where K_a is the acid dissociation constant of HF,[7] K_d is the equilibrium constant of the reaction of F^- with HF,[7] and function H has been defined previously.

The uncertainties given in Table 2 are the total uncertainties including the uncertainty involved in the estimates of activity coefficients, the uncertainty in the reference values of K_a of phosphorous acid, and the uncertainty involved in the measurement of X_{PF}.

Thermodynamics of ionization of monofluorophosphorous acid

The van't Hoff isochore graph of the equilibrium constants is shown in Fig. 2. Standard thermodynamic analysis leads to values of $\Delta G_5^\ominus = +2.2 \pm 1.1$ kJ, $\Delta H_5^\ominus = -26.0 \pm 4.0$ kJ and $\Delta S_5^\ominus = -94 \pm 13$ J K^{-1} for the acid ionization process.

$FHPO_2H$ is a stronger acid than H_2PO_2H by 0.87 pK_a units and is the strongest known substituted phosphinic acid[8] of formula $XHPO_2H$. This fluoro-substituent effect is somewhat larger than the 0.6 units difference between the pK_{a1} values of FPO_3H_2 and HPO_3H_2 and smaller than the 1.6 units found between their pK_{a2} values. The acidity difference appears to be due entirely to the enthalpy change with the fluoro-substituted acid having a 10 kJ more exothermic heat of ionization.

Thermodynamics of hydrolysis of monofluorophosphorous acid

The value of $\Delta H_1^\ominus = 16.9 \pm 1.3$ kJ obtained from the slope of $\ln K_1$ against $1/T$ is combined with the $\Delta G_1^\ominus = 16.2 \pm 0.6$ kJ at 25°C to obtain $\Delta S_1^\ominus = 2.2 \pm 4.3$ J K^{-1}. The small entropy change is reasonable considering the symmetric nature of reaction (1) and the fact that all of the reactants and products are neutral.

Literature values[9,10] for the thermodynamics of HF(aq), H_3PO_3(aq) and H_2O(l) have been used together with the thermodynamics of reaction (1)

Table 2. Equilibrium constants for reactions (1) and (4) and the pK_a of monofluorophosphorous acid

[a] Reference values in parentheses.
[b] Reference 9.
[c] Based on $S_{H_3PO_4}$ from ref. 9 and $S_{H_3PO_4} - S_{H_3PO_3} = 8.8$ from ref. 10.

and the thermodynamics of ionization of phosphorous and monofluorophosphorous acid to calculate the thermodynamics of formation reported in Table 3.

Phosphorus appears to be at the borderline between the more electropositive elements which form fluorides that are stable in water and the more electronegative elements which form fluorides that hydrolyse completely in water. Thus SiF_6^{2-} is thermodynamically stable in aqueous solutions, while SO_3F^- is readily hydrolysed. In strong acid solutions, the enthalpy of hydrolysis of these species is calculated to be +24 and −50.1 kJ per mol of HF, respectively. The enthalpy of hydrolysis of $FHPO_2H$(aq), −16.9 kJ, is intermediate between these values.

Related values calculated from literature data[9] are:

$$PF_6^-(aq) + 4H_2O(l) \rightleftharpoons H_2PO_4^-(aq) + 6HF(aq) \quad \Delta H = -19.6\,kJ$$

$$HPO_3F^-(aq) + H_2O(l) \rightleftharpoons H_2PO_4^-(aq) + HF(aq) \quad \Delta G = +8.2\,kJ.$$

The calculated value of ΔG for this second reaction seems peculiar in light of the results of this work on $FHPO_2H$ and the tendency of fluorophosphate to undergo hydrolysis. The thermochemistry of fluorophosphoric acid is therefore currently being re-investigated along with additional substituted phosphonic and phosphinic acids.

CHROMATOGRAPHIC, SPECTROSCOPIC AND ELECTROCHEMICAL CHARACTERIZATION OF GEOMETRICAL ISOMERS OF THE DICHLOROBIS(2,6-DIMETHYLPYRAZINE)BIS(DIMETHYLSULPHOXIDE)RUTHENIUM(II) COMPLEX

HENRIQUE E. TOMA* and DENISE DE OLIVEIRA

Instituto de Química, Universidade de São Paulo, Caixa Postal 20780, São Paulo, SP, Brazil

(*Received* 7 *December* 1990; *accepted* 22 *April* 1991)

Abstract—The synthesis of the $[RuCl_2(dmso)_2(dmpz)_2]$ complex (dmso = dimethylsulphoxide, dmpz = 2,6-dimethylpyrazine) starting from $[RuCl_2(dmso)_4]$ and dmpz in excess, led to a mixture of two geometrical isomers which were characterized by HPLC, cyclic voltammetry and spectroscopic techniques. The most stable isomer was isolated in pure form, exhibiting a *cis*-Cl_2,*cis*-$(dmso)_2$,*trans*-$(dmpz)_2$ configuration. An all-*cis* configuration was suggested for the second isomer.

Ruthenium(II) sulphoxide complexes, such as $[RuCl_2(dmso)_4]$ and $[RuCl_2(dmso)_2L_2]$ (dmso- = dimethylsulphoxide), have been the subject of renewed interest, with many applications in synthesis,[1–9] oxidation catalysis[10–13] and chemotherapy.[14,17] Because of their mixed nature, the occurrence of geometrical isomers is important, particularly for the understanding of the chemical reactivity of the complexes. Surprisingly, however, this has been little investigated. In this work we studied the $[RuCl_2(dmso)_2(dmpz)_2]$ complex (dmpz = 2,6-dimethylpyrazine) obtained by reacting $[RuCl_2(dmso)_4]$ with dmpz in excess. In contrast to the imidazole analogues reported in the literature,[16,17] this complex exhibits strong charge-transfer bands and is suitable for a detailed investigation of the geometrical isomers using spectroscopic techniques.

EXPERIMENTAL

The starting complex, $[RuCl_2(dmso)_4]$, was obtained in a yellow, crystalline form according to the procedure of Bora and Singh.[18] Found: C, 19.6; H, 4.9. Calc. for $C_8H_{24}O_4S_4Cl_2Ru$: C, 19.8; H, 5.0%.

The $[RuCl_2(dmso)_2(dmpz)_2]$ complex was prepared by reacting $[RuCl_2(dmso)_4]$ with dmpz (Aldrich) in chloroform, under an argon atmosphere, using a molar ratio of 1:8 for these two reactants. The solution was refluxed for 4 h and the volume reduced using a rotary evaporator until it became turbid. At this point, an equivalent volume of diethyl ether was added. The solid was collected on a filter and washed with diethyl ether. The filtrate was kept overnight in the freezer and a second fraction of product was obtained. Found, fraction 1: C, 35.0; H, 5.3; N, 10.4; fraction 2: C, 35.0; N, 5.2; N, 10.3. Calc. for $C_{16}H_{32}N_4S_2O_2Cl_2Ru$: C, 35.3; H, 5.2; N, 10.3%.

The electronic spectra of the complexes were recorded on a Hewlett-Packard model 8451-A diode-array spectrophotometer. High-performance liquid chromatography (HPLC) measurements were carried out using a CG model 480-C instrument attached to the diode-array spectrophotometer. NMR spectra were recorded on a Brucker AC 80 spectrometer; IR spectra of the complexes were recorded on a Perkin–Elmer Model 783 spectrophotometer; and Raman spectra were obtained with a Jarrell–Ash Model 25300 instrument equipped with a krypton ion laser (λ = 647.1 nm). Electrochemical measurements were performed at 25°C, in dry acetonitrile, using a platinum working electrode vs an $Ag/AgNO_3$ (0.010 mol dm^{-3}) reference electrode, as previously reported.[19]

RESULTS AND DISCUSSION

Characterization of the geometrical isomers by HPLC

The solids obtained from the synthesis exhibited analytical results consistent with $[RuCl_2(dmso)_2(dmpz)_2]$. In order to evaluate the existence of isomers, HPLC experiments were carried out, starting from 0.3 mmol dm^{-3} solutions of the complexes, freshly prepared in the dark, followed by isocratic elution with a 60:40 methanol–water mixture at a constant flow rate of 0.010 cm^3 s^{-1}, at room temperature. A Zorbax RP C-8 (250 × 4.6 mm) column (Du Pont) was employed, leading to the typical results illustrated in Fig. 1.

According to the HPLC measurements, fraction 1 consists of a single species (**1**), exhibiting a strong absorption band at 294 nm and shoulders at *ca* 330, 380 and 430 nm. Fraction 2 consists of a mixture of species **1** with a second isomer **2**, which exhibits a strong absorption band at 294 nm and a broad composite band at 350 nm.

Attempts at isolating isomer **2** by fractional crystallization of the mixture or by carrying out chromatographic separations were unsuccessful, leading to substantial contamination with isomer **1** or with dissociation products. Photochemical products were also detected after exposing the solutions to daylight for more than 10 min.

Theoretically, the complexes of general formula $[RuCl_2(dmso)_2L_2]$ can exhibit five possible geometrical isomers, with each pair of ligands either in a *cis* or *trans* configuration, as shown in Fig. 2. In this type of complex, it has been shown that the dmso ligand binds to ruthenium(II) preferentially through the sulphur atom.[1,2] Coordination of dmso through the oxygen atom usually leads to labile and less stable complexes with ruthenium(II) ions.

IR, Raman and ^{1}H NMR spectra

Species **1** exhibited the vibrational spectra shown in Fig. 3. The dmso vibrational peaks at 1290 [$\delta_s(CH_3)$], 1095, 1078 [ν(SO)], 1025, 958, 938, 925, 875, 870 [$\rho_r(CH_3)$], 718 [ν_{as}(CSC)], 678 [ν_s(CSC)], 385 and 340 cm^{-1} [δ(CSO)] were assigned based on comparison with the pure ligand (ν, stretching; δ, deformation; ρ, rocking; s, symmetric; as, asymmetric). The ν(SO) vibration of the free dmso ligand is observed at 1040 cm^{-1}. The shift to 1095 and 1078 cm^{-1} in the IR spectra is indicative of sulphur-coordination of dmso, as in the examples reported in the literature.[1-9,20] Coordination through the oxygen atom is expected to decrease the ν(SO) frequencies to values below 1000 cm^{-1}. The dmpz vibrations can also be identified based on the assignment for the free ligand,[21] e.g. 1590, 1525, 1445 [ν(ring)], 1410, 1375 [$\delta(CH_3)$], 1310 [ν(ring)], 1170

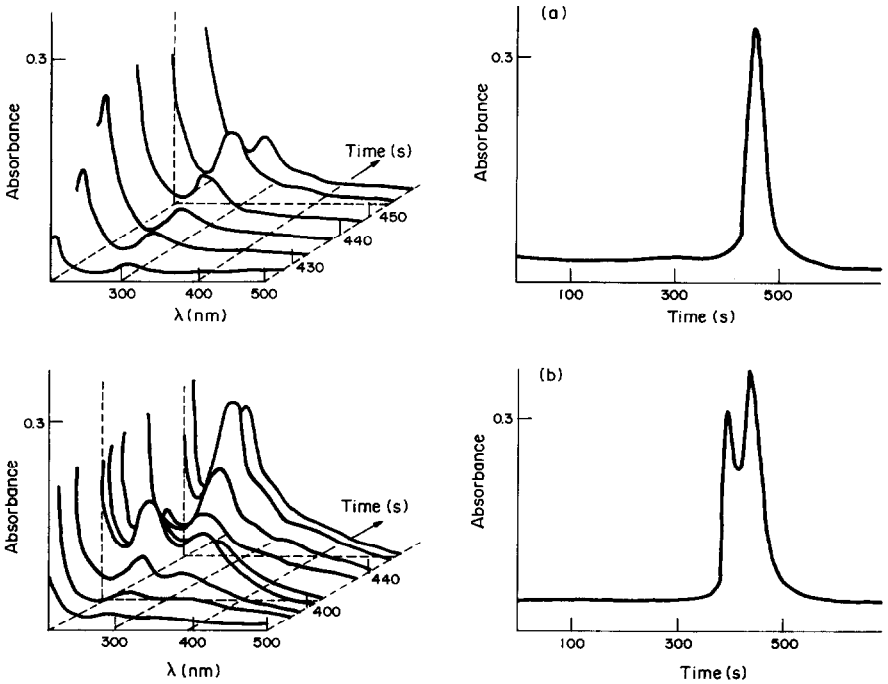

Fig. 1. Three-dimensional plots and chromatograms for the $[RuCl_2(dmso)_2(dmpz)_2]$ complex; (A) fraction **1** and (B) fraction **2**, using a Zorbax RP C-8 column, isocratic elution with 60:40 methanol–water, flow rate = 0.010 cm^3 s^{-1}, temperature = 25°C.

[ν(ring-CH_3)], 1250, 1155, 1150 [β(CH)], 1010 [β(ring)], 975 [ν(ring-CH_3)], 752 [ν(ring)], 732 [γ(CH)], 560, 515 [β(ring)], 450, 435 [γ(ring)], 295 and 268 cm^{-1} (wagging CH_3). The new bands appearing at 325 and 225 cm^{-1} in the IR and Raman spectra are very close to those previously reported[2] for Ru—Cl stretching vibrations in complexes of the type $RuCl_2X_2Y_2$, and are indicative of a *cis*-Cl_2 configuration. Whereas, the coincidence between the IR and Raman spectra, particularly in the case of the metal–ligand vibrations, is consistent with the lack of a symmetry centre in the complex. The additional peak at 420 cm^{-1} in the IR and Raman spectra can be tentatively assigned to Ru—S or Ru—N stretching vibrations.

The ^1H NMR spectra of complex **1** in D_2O solutions exhibited three singlet peaks at 2.42, 3.23 and 8.58 ppm vs TMS, with intensity ratios of 3 : 3 : 1, associated with the methyl protons of dmpz, dmso and the aromatic rings, respectively. The singlet peaks indicate equivalence for each pair of dmpz and dmso ligands.

Based on the information from the Raman, IR and NMR spectral data, complex **1** should exhibit no symmetry centre, with two chloride ligands in the *cis* configuration, and all the ligands in equivalent sites. The only structure compatible with these requirements is for case **A** in Fig. 2. In fact, isomer **A** is expected to be the most stable form, from the viewpoint of cooperative interactions in

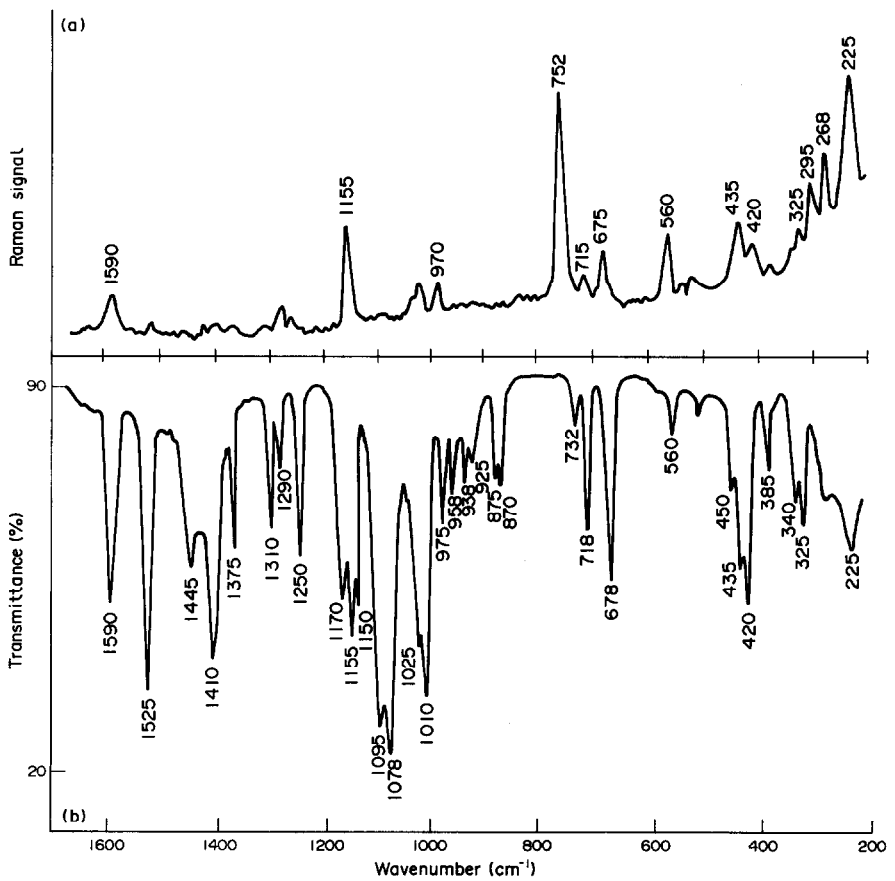

Fig. 3. (A) Raman and (B) IR spectra of the $[RuCl_2(dmso)_2(dmpz)_2]$ complex, corresponding to fraction **1**, obtained, respectively, with the solid sealed in a capillary tube or dispersed in KBr/CsI pellets.

the complex. The chloride ligand is a typical σ,π-electron donor, and dmso is a stronger π-acceptor ligand than dmpz. Therefore, the chloride and dmso ligands in the *trans* configuration can act in a cooperative manner, enhancing the donor–acceptor interactions along the Cl—Ru—S direction.

Based on similar arguments, isomers **C**, **D** and **E** are expected to be much less stable, exhibiting, in contrast to isomer **A**, *trans*-competitive interactions, particularly along the S←Ru→S bonds. It should be noticed, for example, that in the $[RuCl_2(dmso)_4]$ complex the chloride ligands are in *cis*-configuration, interacting in a cooperative manner with the dmso ligands, while the other two dmso ligands adopt a sulphur-bound and oxygen-bound *trans*-cooperative configuration.

Isomer **B**, exhibiting the all-*cis* configuration, is the only isomer which can compete, in terms of stability, with isomer **A**. In fact, this configuration has been proposed for $[RuCl_2(dmso)_2L_2]$ complexes containing substituted 2- and 4-nitroimidazoles, based on XPS, ^1H NMR and IR spectroscopy.[16,17] Therefore, isomer **B** is very likely to occur in fraction 2 from the synthesis. Unfortunately, the vibrational spectra of this material were quite similar to those of isomer **A**, providing little information about the second isomer. NMR measurements were also not conclusive, being complicated by the low solubility of the solid in D_2O and compatible solvents, and by parallel dissociation reactions.

Charge-transfer spectra

The electronic spectrum of species **1**, shown in Fig. 1(A), can be discussed in terms of the geometrical configuration **A** (Fig. 2) which has C_{2v} symmetry. By means of the Gaussian analysis, the UV–vis spectra can be deconvoluted into four bands at 294, 326, 370 and 420 nm. The absorption band around 294 nm is analogous to that observed in N-heterocyclic species, arising from internal $\pi \rightarrow \pi^*$ transitions. The remaining bands are relatively strong and consistent with ruthenium(II)-to-pyrazine, $d_\pi \rightarrow p_\pi^*$ charge-transfer transitions, as in related systems reported in the literature.[22] Analogous to the model proposed by Day and Sanders,[23] the occupied metal d_π orbitals in the C_{2v} group transform according to the symmetry representations a_1, a_2 and b_1. The lowest unoccupied π^* orbitals of the aromatic ligands in the *trans* configuration transform as $a_1(\chi)$ and $b_1(\psi)$. Based on symmetry and orbital overlap considerations,[23] the strongest bands at 326 and 370 nm can be ascribed to the $a_1(d_\pi) \rightarrow a_1(\chi)$ and $b_1(d_\pi) \rightarrow b_1(\psi)$ electronic transitions. The third band at 420 nm is less intense and may be ascribed to the $a_2(d_\pi) \rightarrow b_1(\psi)$ transition, which is symmetry allowed but involves weakly interacting orbitals decreasing the magnitude of the dipole transition moment.[23]

Isomer **B** has global C_1 symmetry. The electronic spectrum can be deconvoluted in terms of one absorption band at 294 nm, ascribed to $\pi \rightarrow \pi^*$ transitions in the aromatic ligand, and three bands at 342, 375 and 425 nm, consistent with metal-to-dmpz charge-transfer transitions. Assuming, for comparison purposes local C_{2v} symmetry for the $Ru(dmpz)_2$ chromophore with two dmpz ligands in the *cis* configuration, the intense charge-transfer bands at 342 and 375 nm could be ascribed to the $a_2(d_\pi) \rightarrow a_2(\psi)$ and $b_1(d_\pi) \rightarrow b_1(\chi)$ transitions, involving strongly interacting metal–ligand orbitals.[23] The less intense band at 425 nm could be ascribed to the $a_1(d_\pi) \rightarrow b_1(\chi)$ transition, which is symmetry allowed, but involves weakly interacting orbitals.

Kinetic aspects

In this work, dissociation reactions were always observed for the complexes in aqueous and non-aqueous solutions. For this reason, all the measurements were carried out using freshly prepared solutions.

The dissociation reactions of species **1** in aqueous solution proceeded according to first-order kinetics, leading to a decay of the charge-transfer bands with a parallel rise of the absorption band at 274 nm of the free dmpz ligand ($k_{obs} = 8.0 \times 10^{-4}$ s^{-1} at 43.8°C). Similar kinetic experiments were also monitored by HPLC, by taking aliquots and analysing their composition as a function of time. These experiments confirmed the preferential aquation of the dmpz ligand ($k_{obs} = 6.3 \times 10^{-4}$ s^{-1} at 43.7°C), in agreement with the spectrophotometrical results.

Electrochemical behaviour

Cyclic voltammograms for species **1** in acetonitrile, at several potential scan rates, are shown in Fig. 4(A). The electrochemical behaviour is consistent with a reversible monoelectronic process, involving the $Ru^{II/III}$ redox couple, with $E_{1/2} = 1.25$ V vs SHE. The pair of shoulders at *ca* 1.0 V is associated with a parallel photochemical process which proceeds to a small extent under normal conditions, leading to preferential labilization of the dmso ligand. This process is accelerated by light. Thermal dissociation can also be observed, however, it proceeds very slowly, with preferential labilization of the dmpz ligand and substitution by

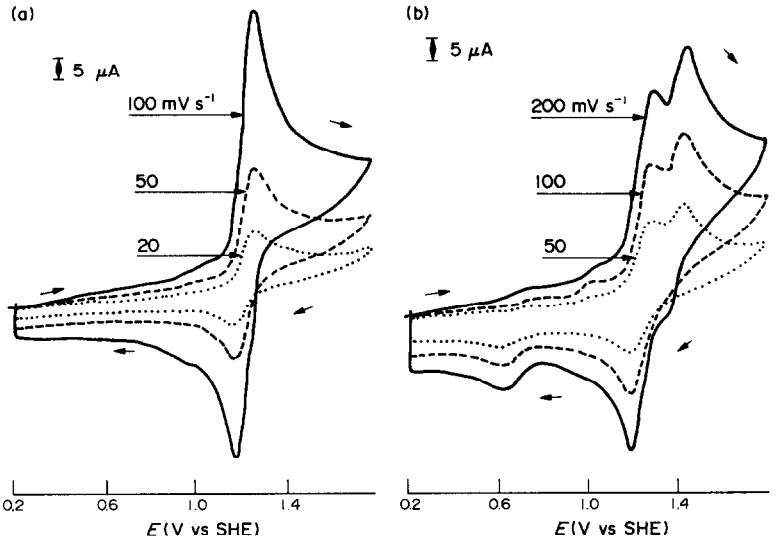

Fig. 4. Cyclic voltammograms of the $[RuCl_2(dmso)_2(dmpz)_2]$ complex (3 mmol dm^{-3}) in acetonitrile; [TEAP] = 0.10 mol dm^{-3}, 25°C; (A) fraction **1** and (B) fraction **2**.

acetonitrile yielding a new species with $E_{1/2}$ of *ca* 1.4 V.

The electrochemical behaviour shown in Fig. 4(B) for fraction 2 is consistent with a mixture of complexes, corresponding to species **1** and **2**, with $E_{1/2} = 1.25$ and 1.43 V vs SHE, respectively. The electrochemical waves of isomer **2** exhibit anodic/cathodic peak ratios smaller than unity. The oxidation of this isomer is followed by a chemical reaction, which is responsible for the rapid decay of the corresponding cathodic peak and for the increase in the cathodic peak at 0.65 V in Fig. 4(B). This species can also be detected in the starting solution after exposure to daylight. We presume that in the oxidized complex, the sulphur-bound dmso ligand is labilized as a consequence of the poor backbonding capability of the ruthenium(III) ions.

Conclusions

The occurrence of geometrical isomers in mixed ruthenium(II)–sulphoxide complexes may be a general phenomenon not readily observed using conventional spectroscopic techniques. This problem requires further investigation because of the many structural and kinetic aspects involved in the synthesis, as recently reported by Jaswal *et al.*[24] in the case of the $[RuCl_2(dmso)_4]$ complex.

THE PHOTOCHEMICAL METHYL MIGRATION IN $(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me$ [L = $P(OEt)_3$, PPh_3, PBu_3]

R. H. HILL* and JEFF D. DEBAD

The Department of Chemistry, Simon Fraser University, Burnaby, British Columbia, Canada, V5A 1S6

(*Received* 2 *January* 1991; *accepted* 3 *May* 1991)

Abstract—The photolysis of *cis*- and *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe$ [L = $P(OEt)_3$, PPh_3, PBu_3] has been studied at 12 K in 1,2-epoxyethylbenzene glass. All the *trans* species undergo CO loss upon photolysis to generate unsaturated fragments which thermally react with CO to regenerate *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe$. The *cis* species undergo different photochemistry depending on the ligand. For L = $P(OEt)_3$, CO loss is observed to generate a separate isomer of the unsaturated species, which upon thermal reaction with CO produces *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$. The photoreaction of *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe$, (L = PPh_3, PBu_3) is not CO loss but loss of L from the coordination sphere. FTIR-monitored photolysis of the acetyl derivatives, *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me$ [L = $P(OEt)_3$, PPh_3, PBu_3], leads to the stereospecific production of solely *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe$. These products arise from formal CO migration.

Herein we report an example of the migratory insertion reaction which apparently occurs via CO dis-insertion rather than methyl migration. The overall reaction studied is shown in eq. (1):

$$\textit{trans}\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me \xrightarrow{h\nu} \textit{trans}\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe + CO \quad (1)$$

[L = $P(OEt_3$, PPh_3, $PBu_3)$]

By FTIR monitoring of the photolytic reaction, we demonstrate that when this reaction is carried out under conditions where both *cis*- and *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$ are configurationally stable the reaction occurs by CO movement.

Generally, reactions such as this have been found to occur by methyl group migration rather than CO insertion.[1] This was found to be the case in the methyl migration in $(\eta^5\text{-}C_5H_5)Fe(CO)PR_3C(O)Me$[2,3] and $Mn(CO)_5C(O)Me$.[4] There have been reports in the literature concerning formal CO insertion, as opposed to methyl migration.[5–8] In the case of *cis*-$FeMeX(CO)_2(PMe_3)_2$, this result was later shown to be due to a more complicated mechanism in which only alkyl group migration occurred in any one step.[9–11] We are aware of no case in which photochemical decarbonylation leads to formal CO migration.

Previously, we have investigated the low temperature photochemistry of the complexes $(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ (L = PPh_3, PBu_3; X = Cl, Br, I).[12] In this series we found that photo-induced loss of CO from *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ (L = PPh_3, PBu_3) led to the production of an unsaturated fragment in which the site of unsaturation was *cis* to the remaining CO ligand. Similarly, loss of CO from the *trans* isomer led to the formation of a molecule in which the remaining CO was *trans* to the site of unsaturation.

The above results suggested that the unsaturated $(\eta^5\text{-}C_5H_5)Mo(CO)LX$ fragments retained the relative geometric position which was present in the precursor molecule. This result has important implications concerning the study of the reaction of $(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me$ to produce $(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe$ plus CO. If the fragments are indeed rigid we would expect that photo-induced CO loss from *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me$ (L = phosphine) would lead to different products dependent on whether the reaction is a result of methyl migration or the dis-insertion of CO.

The mechanism of alkyl group migration in

* Author to whom correspondence should be addressed.

molybdenum complexes has been studied previously[13–15] by kinetic methods. In addition, phosphine-substituted complexes have also been examined.[16] It should also be noted that the insertion reaction has been shown to involve intermediates with initial formation of *cis*-acetyl PR_3 relationships.[17]

RESULTS

FTIR studies

Near UV photolysis ($320 < \lambda < 400$ nm) of a 1,2-epoxyethylbenzene glass containing $(\eta^5\text{-}C_5H_5)Mo(CO)_3Me$ at 12 K results in the spectral changes depicted in Fig. 1. Loss of intensity of the IR absorption associated with the starting complex (relevant IR spectral data are tabulated in Table 1) is observed with concomitant growth of absorptions at 2130, 1947 and 1852 cm^{-1}. The band at 2130 cm^{-1} is associated with the production of free CO in the glass.[18] The two remaining bands are logically assigned as due to $(\eta^5\text{-}C_5H_5)Mo(CO)_2Me$.

This fragment has been observed previously in paraffin,[19] CH_4, Ar, N_2 and CO[20] matrices. The absorption bands in a paraffin matrix at 75 K are at 1967 and 1882 cm^{-1} higher energy than those found here. This shift of absorptions is due to the matrix used and not a result of coordination. For example, the FTIR absorption band associated with the coordinatively saturated species, $(\eta^5\text{-}C_5H_5)Mo(CO)_3Me$, are also at lower energy in 1,2-epoxyethylbenzene than those found in a paraffin matrix, where the absorption bands are at 2025 and 1940 cm^{-1}. From the relative intensity of the two CO stretching modes the angle between the CO oscillators (2θ) may be calculated according to the formula $\tan^2\theta = Ias/Is$.[21] The angle found in this manner for $(\eta^5\text{-}C_5H_5)Mo(CO)_2Me$ is 90°.

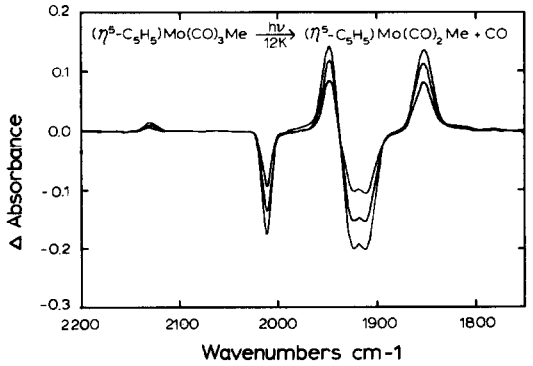

Fig. 1. The changes in the FTIR spectrum of $(\eta^5\text{-}C_5H_5)Mo(CO)_3Me$ associated with photolysis at 12 K for 5, 15 and 60 s.

Photolysis of the $P(OEt)_3$ substituted derivative, $(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$, has also been conducted. In Fig. 2(a) we show the result of near-UV irradiation of a glass containing *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$. Loss of absorption due to starting material at 1937 and 1832 cm^{-1} and the production of free CO in the glass, together with a new absorption at 1813 cm^{-1}, are observed upon photolysis. The new absorption at 1813 cm^{-1} is assigned as due to the CO loss product $(\eta^5\text{-}$

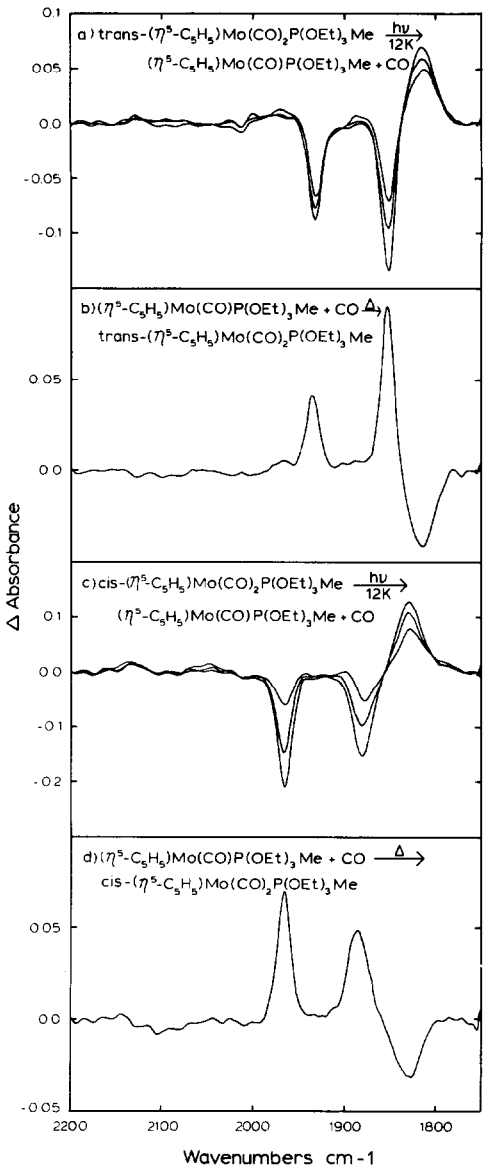

Fig. 2. The FTIR spectral changes associated with photolysis of *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$ for 4, 9 and 14 min at 12 K (a). The spectral change associated with warming this sample to 100 K and recooling to 12 K (b). The spectral changes upon photolysis of *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$ for 3, 7 and 13 min at 12 K (c). The spectral change associated with warming this sample to 30 K and recooling to 12 K (d).

$C_5H_5)Mo(CO)P(OEt)_3Me$, isomer **1**. Upon warming the glass to 100 K and recooling to 12 K the reaction is reversed [Fig. 2(b)]. It is notable that this thermal reaction is stereospecific, producing only *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$.

A similar experiment was conducted with *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$. The spectral changes are shown in Fig. 2(c). Once again CO loss occurs upon photolysis, as evidenced by the loss of absorbance due to the dicarbonyl and the production of free CO in the glass. In addition, a monocarbonyl fragment is observed, as evidenced by a single absorption band at 1830 cm^{-1}. This new fragment we assign, again, as the simple CO loss product, $(\eta^5\text{-}C_5H_5)Mo(CO)P(OEt)_3Me$, isomer **2**. The different position of the IR absorption must be due to a different stereochemistry in the unsaturated species. Further evidence for this difference is obtained from its reaction on warming.

The difference in absorption spectra found upon warming the above glass to 30 K and recooling to 12 K is shown in Fig. 2(d). Once again the photochemical reaction is reversed thermally: recombination with CO is observed. The product is solely *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$. This is easily distinguished from the *trans* isomer both by the energy and relative intensity of the two absorption bands. The reactions are given by eq. (2):

$$cis\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} (\eta^5\text{-}C_5H_5)Mo(CO)P(OEt)_3Me + CO. \quad (2)$$

Isomer **2**

Experiments similar to those above have been conducted on *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$ (R = Ph, Bu) and the results are summarized in eq. (3). The FTIR spectra are given in Table 1. In each case the result was the same as found for the $P(OEt)_3$ derivative. Photo-induced CO loss led to the production of the monocarbonyl fragments, $(\eta^5\text{-}C_5H_5)Mo(CO)PR_3Me$. In both cases, thermal back reaction with CO led to the stereospecific production of *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$.

$$trans\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} (\eta^5\text{-}C_5H_5)Mo(CO)PR_3Me + CO. \quad (3)$$

Isomer **1**

Unfortunately, the photochemistry of *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$ (R = Bu, Ph) was not so easily monitored. These isomers are not configurationally stable at room temperature, undergoing isomerism to the *trans* species.[22] In order to prepare these complexes we used our knowledge of the photochemistry of $(\eta^5\text{-}C_5H_5)Mo(CO)_3Me$. As shown earlier this species, upon photolysis, loses CO to generate the 16-electron fragment $(\eta^5\text{-}C_5H_5)Mo(CO)_2Me$. By conducting this photolysis in either PBu_3 or PPh_3 containing 1,2-epoxyethylbenzene solutions at 100 K, we were able to generate small quantities of *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$. The relevant FTIR absorptions are given in Table 1.

Photolysis of *cis*-(η^5-C_5H_5)Mo(CO)$_2$PBu$_3$Me led rapidly to loss of its absorption bands and the concomitant production of (η^5-C_5H_5)Mo(CO)$_2$Me. This product was identified by comparison of the FTIR spectrum with that observed above in the photolysis of (η^5-C_5H_5)Mo(CO)$_3$Me. Upon warming to 100 K, back reaction to yield the *cis*-phosphine-substituted complex was observed. Unfortunately, the study of *cis*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$Me was less satisfactory. We were able to produce only small amounts of *cis*-(η^5-C_5H_5)Mo(CO)$_2$PPh$_3$Me. Photolysis of this led to the production of some (η^5-C_5H_5)Mo(CO)$_2$Me giving evidence that PPh$_3$ loss is the major primary photoprocess for this molecule. The optical density of these products was, however, very low and we cannot rule out the possibility that CO loss occurs competitively. The photochemical and following thermal reactions of the PPh$_3$ and PBu$_3$ derivatives are given in eq. (4):

$$\textit{cis}\text{-}(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} (\eta^5\text{-}C_5H_5)Mo(CO)_2Me + L. \quad (4)$$

(L = PPh$_3$, PBu$_3$)

The FTIR-monitored photolysis of *trans*-(η^5-C_5H_5)Mo(CO)$_2$P(OEt)$_3$C(O)Me was also conducted at 12 K. The result of photolysis is shown in Fig. 3(a). Loss of absorbance due to the starting material and concomitant production of free CO in the glass is observed. In addition, a new absorption due to a monocarbonyl species is observed at 1813 cm^{-1} and the appearance of new absorption bands at 1937 and 1853 cm^{-1} indicates that *trans*-(η^5-C_5H_5)Mo(CO)$_2$P(OEt)$_3$Me is also formed. The 1813 cm^{-1} absorption is associated with isomer **1** of (η^5-C_5H_5)Mo(CO)P(OEt)$_3$Me. Warming the mixture upon photolysis, to 100 K, results in some reaction with CO. The product of this reaction, as identified by its FTIR, is *trans*-(η^5-C_5H_5)Mo(CO)$_2$P(OEt)$_3$Me [Fig. 3(b)]. Photolysis of this mixture, now containing *trans*-(η^5-C_5H_5)Mo(CO)$_2$P(OEt)$_3$C(O)Me and *trans*-(η^5-C_5H_5)Mo(CO)$_2$P(OEt)$_3$Me, at 12 K, results in the formation of isomer **1** of (η^5-C_5H_5)Mo(CO)P(OEt)$_3$Me. Warming this solution again results in back reaction to form *trans*-(η^5-C_5H_5)Mo(CO)$_2$P(OEt)$_3$Me.

Solutions of *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$C(O)Me (R = Bu, Ph) in 1,2-epoxyethylbenzene were also cooled to 12 K and photolysed. The FTIR spectral changes were indicative of the loss of (η^5-C_5H_5)Mo(CO)$_2$PR$_3$(CO)$_2$C(O)Me. In each case the production of free CO, *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$Me and isomer **1** of (η^5-C_5H_5)Mo(CO)PR$_3$Me were observed. These were identified by comparison of the FTIR spectra with those obtained from the corresponding authentic compounds. Warming of the samples led to back reaction with CO to produce only *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$Me.

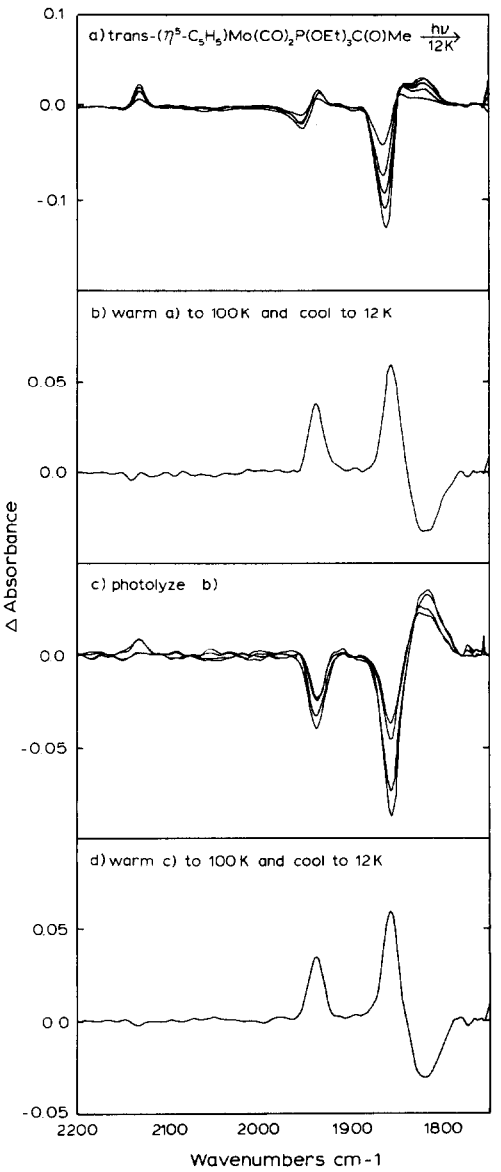

Fig. 3. The FTIR spectral changes associated with the photolysis of *trans*-(η^5-C_5H_5)Mo(CO)$_2$P(OEt)$_3$C(O)Me at 12 K for 2, 6, 9, 12 and 14 min (a). The spectral changes due to warming this solution to 100 K and recooling to 12 K (b). The FTIR changes due to further photolysis of this sample at 12 K for 4, 8, 14 and 20 min (c). The spectral change due to warming this sample to 100 K and cooling to 12 K (d).

NMR studies

In order to confirm the assignment of the molecules formed upon photolysis of the *trans*-acetyl species the following reactions were carried out. A solution containing *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3C(O)Me$ was photolysed at 77 K and the reaction monitored by ^1H NMR at room temperature. Upon photolysis, loss of intensity associated with the resonances due to *trans*-$(\eta^5C_5H_5)Mo(CO)_2P(OEt)_3C(O)Me$ was observed. The only photoproduct apparent, as monitored by ^1H NMR, was *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$.

The above experiment hence confirms our assignment of the low temperature FTIR spectra. This indicates that not only have we shown that no *cis* isomer is formed but that the sole detectable product, by either FTIR or NMR, is indeed *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$.

Similar experiments were conducted for the other phosphine complexes, *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3C(O)Me$ ($PR_3 = PPh_3$, PBu_3). In each case the sole observable photoproduct, *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$, confirmed the assignment of the FTIR experiments. In these latter cases, if *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$ had been formed, isomerism in the room temperature solutions would have led to only the *trans* isomer at room temperature. Their formation would be detectable through the production of $(\eta^5\text{-}C_5H_5)Mo(CO)_3Me$ as a result of the photolysis of the *cis* isomer at low temperature.

DISCUSSION

Previously we have shown that photolysis of $(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ ($L = PPh_3$, PBu_3; $X = Cl$, Br, I) leads to CO expulsion from the coordination sphere.[12] The product, $(\eta^5\text{-}C_5H_5)Mo(CO)LX$, was shown to be rigid since photolysis of *cis*- and *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LX$ led to the production of different unsaturated species. These species upon reaction with CO generated only the isomer corresponding to the precursor molecule. Here we have shown that this is also true for photolysis of either *cis*- or *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$ and *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$ (R = Ph, Bu), which all produce CO loss products which depend upon the stereochemistry of the precursor. Each of these CO loss products upon thermal reaction with CO generates the precursor complex in its original geometry. In each case the geometry is consistent with simple CO loss and retention of the stereochemistry associated with the the precursor molecules. The nature of these intermediates, and the possible role of solvation, has been discussed previously with regard to the halide systems and will not be repeated here. Photolysis of *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$ (R = Ph, Bu) leads to an unsaturated species but through PR_3 loss. In contrast, low temperature photolysis of *cis*- and *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2X_2$ (X = Me, Cl, Br, I) led to the production of a single CO loss product independent of the stereochemistry of the precursor.[18] In this paper we use the retention of stereochemistry in the molybdenum compounds to investigate the decarbonylation of *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me$ [$L = P(OEt)_3$, PPh_3, PBu_3].

The photolysis of the related acetyl complexes, $(\eta^5\text{-}C_5H_5)Fe(CO)_2C(O)Me$, at temperatures of $\sim$ 12 K was reported to produce the simple CO loss adduct.[23,24] The possibility of η^2-acetyl bonding in this intermediate has also been investigated.[25] We find that under our conditions we do not observe the simple CO loss adduct. We find that following the initial CO loss, rearrangement occurs to generate the saturated molecule, *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$, which is itself photolysed. Other workers have used both inert gas matrices and PVC films which are apparently considerably harder than 1,2-epoxyethylbenzene used here. It is due to this much softer environment that the migration occurs even at 12 K. In order to test this we repeated experiments with $(\eta^5\text{-}C_5H_5)Fe(CO)_2C(O)Me$ which was observed to give a simple CO loss product, $(\eta^5\text{-}C_5H_5)Fe(Co)C(O)Me$, in Ar and CH_4 matrices and in PVC films.[24] Under our conditions we are unable to stop the migration from occurring and the only product we observe is either the decarbonylated molecule or its CO loss product.

Further evidence that the environment at 12 K in 1,2-epoxyethylbenzene is less restrictive than a gas matrix comes from the observed photochemistry of *cis*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3Me$ (R = Bu, Ph). For these complexes we find light induced loss of the PR_3 in preference to CO loss. This process is only rarely observed at low temperatures.[26]

Of primary interest in this paper is the stereochemistry at the metal. In all three cases studied the result of photolysis has been an observed formal CO dis-insertion to the coordination site *cis* to the position originally occupied by the acetyl ligand. In addition, we have determined that under our conditions, temperatures of less than 100 K, the coordinatively unsaturated methyl complexes, $(\eta^5\text{-}C_5H_5)Mo(CO)PR_3Me$, are configurationally stable towards isomerism. This result indicates that the formal CO migration is not a result of the isomerism of the product complexes. In addition, due to the extremely low temperatures used in this study, whatever the mechanism is, the reaction is extremely facile at 12 K.

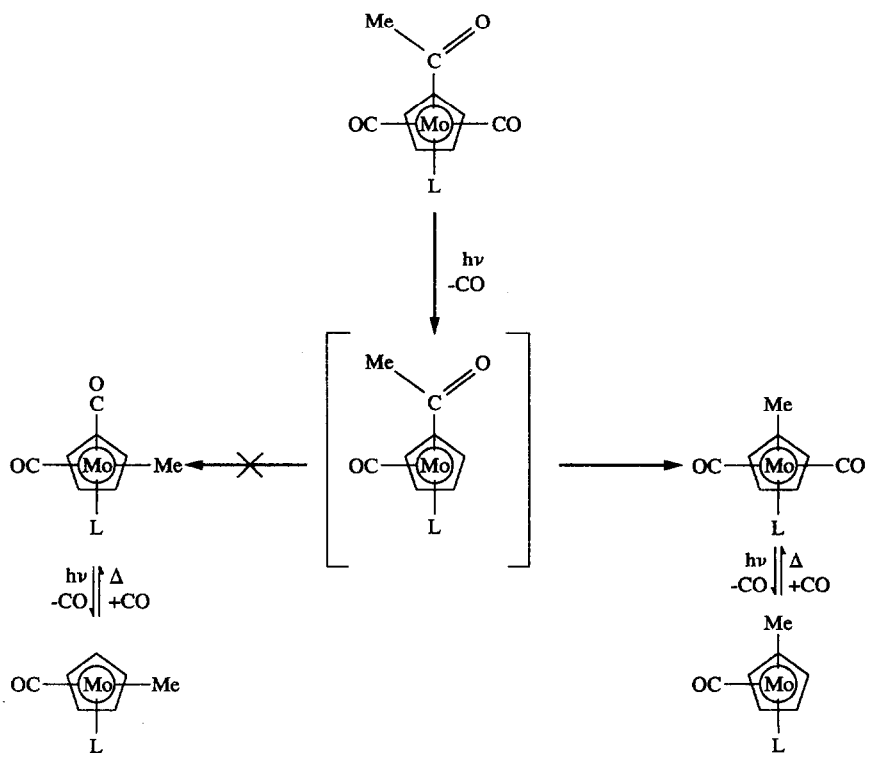
The most likely result of initial photolysis is the generation of an unsaturated species due to CO loss from *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$C(O)Me to generate (η^5-C_5H_5)Mo(CO)PR$_3$C(O)Me in which the acetyl is *trans* to the phosphine ligand. This step is then followed by simple CO migration, out of the Mo—C bond, to the vacant coordination site producing the observed product, *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$Me. This sequence of events is illustrated for the P(OEt)$_3$ derivative in Scheme 1. The finding of importance here concerns the stereochemistry of the thermal reaction following photochemical decarbonylation. This formally is a CO dis-insertion rather than a methyl migration. Under the reaction conditions the photoproduced *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$Me is irradiated, however, we have shown that the result of this secondary photochemistry is reversible [eq. (3)]. Since this secondary photolysis does not result in any observable isomerism it does not affect our conclusion.

The main assumption of this mechanism is that photoproduced (η^5-C_5H_5)Mo(CO)PR$_3$C(O)Me is configurationally stable. In order to test this hypothesis rigorously we would need to study both the *cis*- and *trans*-acetyl complexes. Unfortunately we have been unable, as of yet, to find a synthetic route to these complexes. We have, however, shown that the monocarbonyl fragments, (η^5-C_5H_5)Mo(CO)PR$_3$X, for both the methyl and halides are indeed configurationally stable.[12] It is unlikely that such a small change from methyl to acetyl would result in lowering the barrier to isomerism so significantly as to make the rearrangement facile at 12 K. It should be noted that even at 298 K the barrier for the isomerism via CO loss is significant for the halides.[12,27] In addition, the effect of temperature is not to be underestimated. The isomerism of *cis*- or *trans*-CpMo(CO)$_2$PR$_3$Me (R = Ph, Bu), which is rapid at room temperature,[22] is not observed at all at 100 K. It should be remembered that the isomerism which is observed at room temperature both via thermal[22] and photochemical[12,27] initiation is not a result of a CO loss mechanism but is a direct non-dissociative rearrangement.

An alternative explanation is that the reaction occurs through, not initial CO loss but via radical cleavage. In our case we have some compelling evidence to suggest that this is not occurring. It has been shown[28] that radicals are prone to attack the cyclopentadienyl ring. We see no evidence for products derived from reactions of a radical nature either in NMR or FTIR experiments.

EXPERIMENTAL

The complexes (η^5-C_5H_5)Mo(CO)$_3$Me, *cis*- and *trans*-(η^5-C_5H_5)Mo(CO)$_2$PR$_3$Me (R = Bu, Ph)



Scheme 1.

were prepared and purified by published methods.[16,29]

FTIR spectra were obtained with a Bruker IFS 85 spectrophotometer. Samples were cooled with a CTI-Cryogenics Model 22 cryocooler attached to a 350R compressor system. Temperatures were controlled and monitored using a Lake Shore Cryotronics silicon diode sensor (DT500 DRC) in conjunction with a Model DRC 80C temperature controller.

The solvent used in the spectroscopic studies, 1,2-epoxyethylbenzene, was obtained from Kodak and used without further purification.

Preparation of $(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3X$

The compounds, *cis*- and *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$ were prepared by analogy with the methyl complexes above[16] and separated by chromatography on Brockman neutral grade alumina, eluting initially with dichloromethane/hexane (6:1) to separate starting material, then rechromatographed eluting with benzene/hexane (1:1) to separate the isomers. The pure isomers undergo no observable isomerism if stored at 270 K. NMR ($CHCl_3$): *trans*, Cp = 5.02 ppm (d) $^3J(PH) = 1.5$ Hz; Me = 0.28 ppm (d), $^3J(PH) = 3.3$ Hz; *cis*, Cp = 5.31 ppm, Me = 0.38 ppm (d).

FTIR-monitored photolysis of $(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3X$

Several experiments were conducted in the same manner; here we describe a typical experiment. The complex, *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$, was dissolved in 1,2-epoxyethylbenzene to produce a solution of optical density 1.2 for its most intense IR absorption band in the carbonyl region at 1853 cm^{-1}. The sample was then transferred to a CaF_2 faced FTIR cell and loaded into the cold head of the cryostat. The sample chamber was evacuated and then cooled to 12 K. During the cool down FTIR spectra were obtained at different temperatures. At 12 K the sample was photolysed with the water filtered output of a 75 W high pressure mercury lamp for 4 min. The FTIR was then recorded. The above procedure was repeated until no further reaction occurred upon photolysis. At this time the sample was warmed to 100 K then cooled to 12 K. The FTIR spectrum was again recorded.

The sample was then warmed to room temperature and its FTIR spectrum recorded. In other experiments the use of both water and a Corning 7-51 filter isolated the wavelength range 320–400 nm for photolysis.

NMR-monitored photolysis of trans-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me$

A solution containing *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3C(O)Me$ (0.005 g) in d^8-toluene (1.0 cm^3) was prepared. From this solution 0.5 cm^3 was taken and degassed with three freeze–pump–thaw cycles in a 5 mm NMR tube and flame-sealed. After obtaining the ^{1}NMR spectrum the sample was photolysed (using the same lamp and filters as above) at 77 K. The changes in the ^{1}H NMR spectra were monitored as a function of photolysis times. Absorptions due to *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3C(O)Me$ [Cp = 5.02 ppm, $^3J(PH) = 1.1$ Hz; Me = 2.79 ppm] decreased in intensity with increasing photolysis times. Concomitant production of ^{1}H NMR absorptions due to *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2P(OEt)_3Me$ [Cp = 4.75 ppm, $^3J(PH) = 1.5$ Hz; Me = 0.627 ppm, $^3J(PH) = 3.3$ Hz] was observed.

Similar experiments were conducted with *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LC(O)Me$ (L = PPh_3, PBu_3). For each of these signals due to the acetyl derivative [L = PPh_3, Cp = 4.83 ppm (d), $^3J(PH) = 1.1$ Hz; Me = 2.90 ppm; L = PBu_3, Cp = 4.91 ppm (d), $^3J(PH) = 0.9$ Hz; Me = 2.86 ppm] were found to decrease with concomitant increase of absorption due to signals associated with *trans*-$(\eta^5\text{-}C_5H_5)Mo(CO)_2LMe$ [L = PPh_3, Cp = 4.50 ppm (d), $^3J(PH) = 1.5$ Hz; Me = 0.78 ppm (d), $^3J(PH) = 2.4$ Hz; L = PBu_3, Cp = 4.63 ppm (d), $^3J(PH) = 1.3$ Hz; Me = 0.66 ppm (d), $^3J(PH) = 2.4$ Hz].

CYCLOPENTADIENYL RUTHENIUM(II) AND (III) COMPLEXES WITH A CHELATING 1,2-BIS(DICYCLOHEXYLPHOSPHINO)METHANE LIGAND

FREDERICK L. JOSLIN, JOEL T. MAGUE and D. MAX ROUNDHILL*

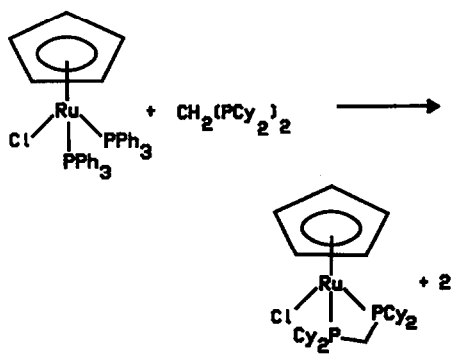
Department of Chemistry, Tulane University, New Orleans, LA 70118, U.S.A.

(*Received* 19 *March* 1991; *accepted* 17 *May* 1991)

Abstract—The reaction between η^5-cpRuCl$(PPh_3)_2$ and 1,2-bis(dicyclohexylphosphino) methane (dcpm) gives η^5-cpRuCl(dcpm). The complex is readily oxidized to η^5-cpRuCl $(dcpm)^+$. Treating η^5-cpRuCl(dcpm) with silver triflate, followed by ammonia or carbon monoxide, gives $[\eta^5$-cpRu(NH_3)(dcpm)$]CF_3SO_3$ or $[\eta^5$-cpRu(CO)(dcpm)$]CF_3SO_3$, respectively. Metathetical replacement of chloride with $LiAlH_4$ gives η^5-cpRuH(dcpm).

There has been much recent interest in the synthesis of low-valent transition metal complexes stabilized by chelating bis-phosphine ligands. In particular, chelating phosphines with electron-donating substituents have been shown to afford transition metal complexes which exhibit unusual reactivity.[1] Recently we have shown that the chelating ligand 1,2-bis(dicylohexylphosphino)ethane (dcpe) can be used to prepare η^5-cpRuCl(dcpe), which can then be converted into a series of novel neutral and cationic complexes.[2] We now report the synthesis of 1,2-bis(dicyclohexylphosphino)methane (dcpm), along with its reactivity as a chelating ligand to the η^5-cyclopentadienyl ruthenium moiety.

Reacting $CH_2(PCl_2)_2$ with 4 equivalents of cyclohexylmagnesium bromide gives the compound $CH_2(PCy_2)_2$ (dcpm) as a colourless, air-sensitive solid.† Treating η^5-cpRuCl$(PPh_3)_2$ with dcpm gives the orange chelate complex η^5-cpRuCl(dcpm) in 45–50% yield, eq. (1):



(1)

This complex shows a single $^{31}P\{^1H\}$ NMR resonance at δ 24.6, a triplet $^{13}C\{^1C\}$ NMR signal at δ 36.6 [^1J(PC) = 15.6 Hz] for the methylene carbon and multiplets in the ^1H NMR spectrum at δ 3.45 and 2.95 due to the axial and equatorial hydrogens of the methylene group. The reaction between η^5-cpRuCl(dcpm) and lithium aluminum hydride yields η^5-cpRuH(dcpm) in 90% yield, eq. (2):

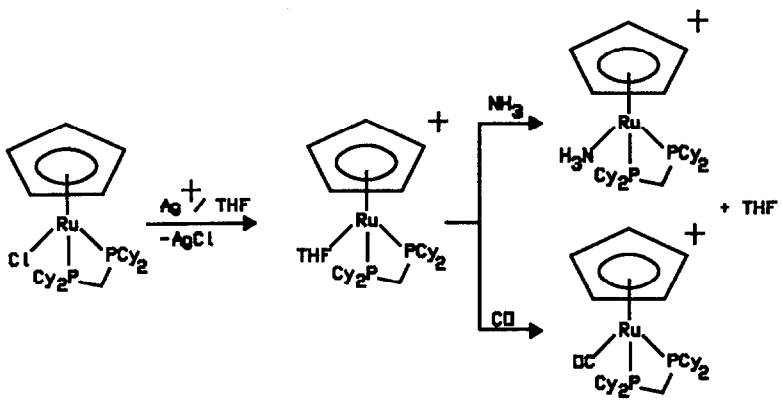
† The compound was purified by vacuum distillation and isolated in 80% yield. Exact *m/z* 408.30790. Calc. for $C_{25}H_{46}P_2$: 408.30748. $^{31}P\{^1H\}$ NMR: δ −10.1. $^{13}C\{^1H\}$ NMR: δ 13.5 t [PCH_2P, ^1J(PC) = 28 Hz], δ 34.7 t [PCH, $|^1J(PC)+{}^3J(PC)| = 5$ Hz], δ 30.6 t [$PC(2)H_2$, $|^2J(PC)+{}^4J(PC)| = 8$ Hz], δ 29.8 t [$PC(6)H_2$, $|^2J(PC)+{}^4J(PC)| = 6$ Hz], δ 26.5–28 t [$PC(3)H_2$, $PC(4)H_2$, $PC(5)H_2$]. The only other mention of $CH_2(PCy_2)_2$ appears to be in a footnote in ref. 3.

The FAB mass spectrum exhibits an envelope of peaks with m/z 572–577, having the maximum relative ion intensity at m/z 575 characteristic of cpRu(dcpm). The complex shows a band in the IR spectrum at 1930 cm^{-1} due to ν(Ru—H). The hydride resonance in the ^1H NMR spectrum is centred at δ −12.2. The double triplet pattern results from coupling to phosphorus [$^2J(PH) = 30.5$ Hz] and one methylene hydrogen [$^4J(HH) = 2.9$ Hz], as confirmed by selective decoupling.[4]

Treating η^5-cpRuCl(dcpm) in THF solution with silver triflate, followed by ammonia or carbon monoxide, gives [η^5-cpRu(NH_3)(dcpm)]CF_3SO_3 or [η^5-cpRu(CO)(dcpm)]CF_3SO_3, respectively, eq. (3):



(3)

This unstable carbonyl complex contains ν(CO) at 1933 cm^{-1}, which is lowered by 7 cm^{-1} compared with ν(CO) in the stable complex [η^5-cpRu(CO)(dcpe)]$^+$.[5] Apparently, the electron donation to the carbonyl ligand is greater for the dcpm complex compared with the dcpe analogue.

We find that η^5-cpRuCl(dcpm) undergoes one-electron oxidation to give the red chelate complex η^5-cpRuCl(dcpm)$^+$.* The molecular structure of [η^5-cpRuCl(dcpm)]CF_3SO_3 has been determined by single crystal X-ray diffraction (Fig. 1), which confirms both the monomeric nature of the complex and the chelate bonding of dcpm.† Selected bond distances and angles are collected in Table 1. The P(1)—Ru—P(2) angle within the four-membered ring is 69.57(8)°, and the Cl—Ru—P(1) and Cl—Ru—P(2) angles are slightly different at 91.09(9) and 92.01(8)°, respectively. This finding that the ruthenium(III) complex,

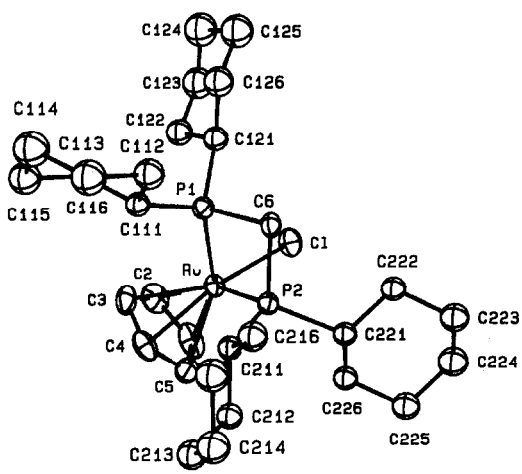


Fig. 1. A perspective view of the [η^5-cpRuCl($Cy_2PCH_2PCy_2$)]$^+$ cation. Thermal ellipsoids are drawn at the 30% probability level and hydrogen atoms are omitted for clarity.

* Possible oxidants are oxygen or silver ion. The crystals were grown from a mixed solution containing acetone and diethyl ether.

† Crystal data for [η^5-cpRuCl(dcpm)]$CF_3SO_3 \cdot 2C_6H_6$; $C_{43}H_{63}P_2O_3F_3SClRu$, mol. wt = 915.58, monoclinic, space group $P2_1/c$ (No. 14), $a = 12.720(3)$, $b = 18.337(4)$, $c = 19.446(3)$ Å, $\beta = 95.58(2)°$, $V = 4485(2)$ Å^3, $Z = 4$, ρ(calc.) = 1.36 g cm^{-3}, μ(Mo-K_α) = 5.6 cm^{-1}, $T = 296$ K, crystal dimensions $0.16 \times 0.16 \times 0.38$ mm. Intensity data were collected on an Enraf–Nonius CAD-4 diffractometer using monochromated Mo-K_α radiation (λ = 0.71073 Å) and were corrected for Lorentz and polarization effects. A total of 4755 unique reflections were collected in the range $3.0 \leqslant 2\theta \leqslant 42$, of which 2804 with $I \geqslant 3.0\sigma(I)$ were used in the structure determination. The structure was solved by Patterson methods and refined using standard difference map techniques. Many hydrogen atoms were located on the difference map. All hydrogen atoms were included as fixed contributions to the scattering with C—H = 0.95 Å, and the isotropic thermal parameters fixed as 1.2 times those of the attached carbon atom. Refinement converged to $R = 0.045$ ($R_w = 0.057$) with the largest shift/ESD in the final cycle being 0.05. The final difference map showed no significant features remaining. Atomic coordinates, bond lengths and angles and thermal parameters, along with Tables of F_o and F_c, have been deposited as supplementary material with the Editor.

Abstract—$BuSnCl_3$ reacts with $[M(CO)_3(NCR)_3]$ (M = Mo, R = Me; M = W, R = Et) to produce $[M(CO)_3(NCR)_2(SnCl_2Bu)Cl]$. These complexes react further with three molar-equivalents of $P(OR')_3$ (R' = Me, Et) at room temperature giving dicarbonyl tris-phosphite complexes $[M(CO)_2\{P(OR')_3\}_3(SnCl_2Bu)Cl]$ through displacement of the two nitrile ligands and one CO group. The molybdenum compounds can be prepared in high yields by a one-pot, two-step synthesis by heating $[M(CO)_6]$ with $BuSnCl_3$ in acetonitrile, and then adding the phosphite to the resulting solution. Similar reactions with $SnCl_2Bu_2$ and $SnCl_2Ph_2$ have been explored.

There has been a resurging interest in recent times in the chemistry of seven-coordinate complexes of molybdenum and tungsten, due mainly to their involvement in catalytic processes such as the ring-opening polymerization of norbornene[1] or the hydrostannation of alkynes.[2]

Very recently, Baker *et al.* have reported the oxidation of $[M(CO)_3(NCMe)_3]$ with $SnCl_4$ to give seven-coordinate bis-nitrile complexes $[M(CO)_3(NCMe)_2(SnCl_3)Cl]$, in which the labile acetonitrile groups can be easily replaced by other ligands.[3–5] We are now exploring the reactions of $[M(CO)_3(NCR)_3]$ with haloalkyltin derivatives, $SnCl_{4-n}R_n$, as a general route to seven-coordinate complexes of molybdenum and tungsten containing haloalkylstannate, $SnCl_{3-n}R_n$, ligands. Some preliminary results from this work suggest that the presence of at least one alkyl group bonded to the tin atom substantially modifies the substitution behaviour of the bis-nitrile complexes $[M(CO)_3(NCR)_2(SnCl_{3-n}R_n)Cl]$ when compared with that known for their analogues containing $SnCl_3$. As an example, we wish to report here a facile synthesis for seven-coordinate tris-phosphite complexes of molybdenum and tungsten containing the $SnCl_2Bu$ ligand, and the X-ray crystal structure of one of these derivatives.

$[M(CO)_3(NCR)_3]$ reacts with $BuSnCl_3$ (see Scheme 1) to give $[M(CO)_3(NCR)_2(SnCl_2Bu)Cl]$ [M = Mo, R = Me (**1a**); M = W, R = Et (**1b**)], which can be obtained in virtually quantitative yields as yellow, air-sensitive solids upon evaporation of the solvent. IR specta of **1a** and **1b** show ν(CO) and ν(CN) frequencies very close to those reported for their analogues with $SnCl_3$. Treatment

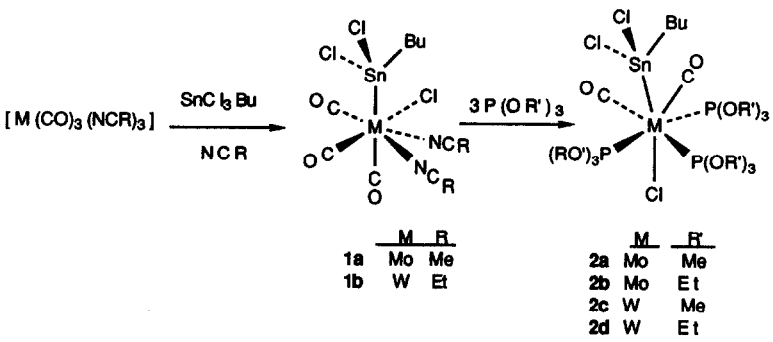

Scheme 1.

of **1a** and **1b** with three equivalents of phosphite leads to the formation, in high yield, of $[M(CO)_2\{P(OR)_3\}_3(SnCl_2Bu)Cl]$ [M = Mo, R = Me (**2a**, 92%), Et (**2b**, 90%); M = W; R = Me (**2c**, 74%), Et (**2d**, 70%)] which have been fully characterized by analytical and spectroscopic methods (see below). Since heating $[Mo(CO)_6]$ and $BuSnCl_3$ in acetonitrile gives the bis-nitrile **1a**, and the presence of excess acetonitrile does not affect the formation of the dicarbonyls **2a** and **2b**, these can be prepared in a one-pot two-step manner, without isolating the intermediate bis-nitrile complexes. In contrast, when $[W(CO)_6]$ was heated with $BuSnCl_3$ in refluxing propionitrile for a long period, IR spectra of the reaction mixture showed only the bands of tungsten carbonyl, without any significant amount of the expected bis-nitrile **1b**, or the intermediate $[W(CO)_3(NCEt)_3]$.[6]

Addition of only one or two molar-equivalents of phosphite to compounds **1a** and **1b** produces the same dicarbonyl tris-phosphite complexes **2a–d**, together with unreacted **1a** and **1b**. This suggests that the change of one chlorine for an alkyl group at the tin atom increases the lability of one of the carbonyl ligands on the molybdenum atom. This behaviour of **1a** and **1b** in substitution reactions contrasts with that reported for their $SnCl_3$ analogues which, when treated with phosphorus ligands, replace only the labile nitrile groups giving tricarbonyl complexes. Thus, it has been reported that the reaction of $[Mo(CO)_3(NCMe)_2(SnCl_3)Cl]$ with two equivalents of $Ph_2P(CH_2)_2PPh_2$ in acetone at room temperature for 24 h gave $[Mo(CO)_3(dppe)(SnCl_3)Cl]$ and unchanged $Ph_2P(CH_2)_2PPh_2$.[3]

Some attempts have been made to explore the oxidative addition of $SnCl_2R_2$ (R = Bu, Ph) to $[Mo(CO)_3(NCMe)_3]$. As expected, the reactions become more difficult as the electron density on the tin atom increases. Thus, $[Mo(CO)_3(NCMe)_3]$ does not react with SnR_2Cl_2 in acetonitrile solution, as shown by the IR monitoring of the mixture. However, when the acetonitrile is evaporated to dryness, and the mixture dissolved in dichloromethane, the oxidative addition takes place readily, and the compounds $[Mo(CO)_3(NCMe)_2(SnR_2Cl)Cl]$ [R = Bu (**1c**), Ph (**1d**)] can be identified by their IR spectra in solution. When three molar-equivalents of phosphite are added to these dichloromethane solutions of **1c** and **1d**, IR spectra of the mixtues show the formation of the dicarbonyl tris-phosphite which is analogous to **2a–d**. Unfortunately, all attempts to isolate and characterize these new compounds have been fruitless to far.

An X-ray study was carried out on a crystal of **2a** (see Fig. 1) to confirm the formulation given in Scheme 1. The molybdenum atom lies in a seven-coordinate environment which can be described as an intermediate between a distorted capped trigonal prism, CTP [with Cl(3) in the capping position], and a distorted capped octahedron, CO [with either C(1) or Sn in the capping position]. Due to the different spatial requirements of the ligands, the angles around Mo(1) deviate from the values expected for the ideal CTP and CO geometries.[7,8] A common feature of the structures reported for related complexes such as $[Mo(CO)_3(bipy)(SnCH_3Cl_2)Cl]$,[9] $[W(CO)_3\{CH_3S(CH_2)_2SCH_3\}(SnCH_3Cl_2)Cl]$[10] and $[Mo(CO)_3\{CH_3S(CH_2)_2SCH_3\}(SnCl_3)Cl]$,[11] is the presence of a chlorine atom bridging the Mo—Sn (or W—Sn) bond. In contrast, in the structure of **2a**, the chlorine atom bonded to molybdenum is at a great distance from the tin atom; Sn, Mo and Cl(3) form a nearly *trans* arrangement [angle 142.0(1)°]. Whereas, the carbon atom of one carbonyl ligand, C(1), is placed near the tin. The distance C(1)···Sn of 2.646(13) Å is too long for any significant bonding, but is short enough to be considered as a contact. Accordingly, although the linear geometry of the carbonyl ligand is not altered [angle Mo—C(1)—O(1) of

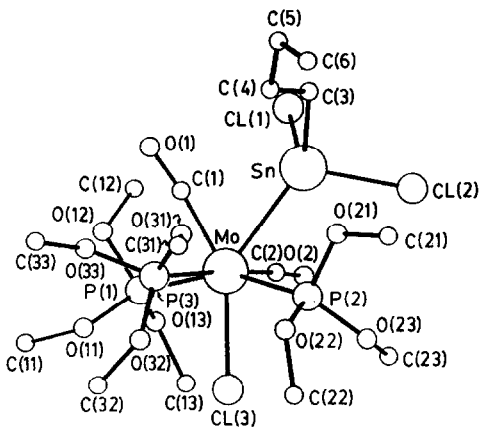

Fig. 1. Perspective view of $[Mo(CO)_2\{P(OMe)_3\}_3(SnCl_2Bu)Cl]$ (**2a**) showing the atom numbering. Selected bond distances (Å) and angles (°): Sn—Mo = 2.774(1), Sn—Cl(1) = 2.410(4), Sn—Cl(2) = 2.387(4), Sn—C(3) = 2.136(14), Mo—Cl(3) = 2.525(4), Mo—C(1) = 1.957(14), Mo—C(2) = 2.024(16), Mo—P(1) = 2.476(4), Mo—P(2) = 2.503(4), Mo—P(3) = 2.536(4); Sn—Mo—Cl(3) = 142.0(1), Sn—Mo—C(1) = 65.4(4), Cl(3)—Mo—C(2) = 90.7(4), C(1)—Mo—C(2) = 105.2(6), Sn—Mo—P(1) = 125.4(1), Cl(3)—Mo—P(1) = 82.7(1), C(1)—Mo—P(1) = 78.4(4), C(2)—Mo—P(1) = 79.7(4), Sn—Mo—P(2) = 74.9(1), Cl(3)—Mo—P(2) = 75.7(1), C(1)—Mo—P(2) = 121.0(4), C(2)—Mo—P(2) = 102.2(4), P(1)—Mo—P(2) = 158.2(1), Sn—Mo—P(3) = 112.2(1), Cl(3)—Mo—P(3) = 86.3(1), C(1)—Mo—P(3) = 75.9(4), C(2)—Mo—P(3) = 174.7(4), P(1)—Mo—P(3) = 95.5(1), P(2)—Mo—P(3) = 81.3(1), Cl(1)—Sn—Cl(2) = 93.9(2), Cl(1)—Sn—C(3) = 98.6(5), Cl(2)—Sn—C(3) = 102.0(5), Cl(1)—Sn—Mo = 109.4(1), Cl(2)—Sn—Mo = 115.6(1), C(3)—Sn—Mo = 130.3(4), Mo—C(1)—O(1) = 173.7(12), Mo—C(2)—O(2) = 176.9(13).

173.7(12)°], the tetrahedral coordination around the tin atom is somewhat distorted to accommodate the C(1) atom.

The $^{31}P\{^1H\}$ NMR spectra of **2a–d** (see below) show only one signal for the three phosphites, revealing the existence of fluxional processes in solution at room temperature. The spectra of the molybdenum compounds **2a** and **2b** exhibit one set of tin satellites (approximate relative intensities 1:10:1), the different ^{31}P–^{117}Sn and ^{31}P–^{119}Sn couplings being unresolved. For the tungsten compounds **2c** and **2d** only one set of broad satellites was observed, instead of the two sets expected (one for ^{31}P–$^{117-119}Sn$ and the other for ^{31}P–^{183}W). This suggests that the coupling constants have about the same value, the observed satellites therefore being the envelope of the two expected sets. The relative intensities measured are in agreement with this assignment. $^{31}P\{^1H\}$ NMR spectra recorded for **2a** and **2c** at −98°C in CD_2Cl_2 exhibit very complex patterns of lines (δ 140–150 ppm for **2a** and δ 120–130 ppm for **2c**), suggesting that the freezing of the dynamic process leads to the formation of more than one isomer at low temperature.

Some additional work is currently in progress to extend the study of the substitution reactions of the bis-nitrile complexes **1a–d** with other phosphorus, nitrogen and sulphur donor ligands.

Selected spectroscopic data

IR spectra (CH_2Cl_2 solution) were recorded on a Perkin–Elmer FT 1720-X spectrometer. ^1H NMR [300.1 MHz, δ(ppm) from internal $Si(Me)_4$] and $^{31}P\{^1H\}$ NMR spectra [121.5 MHz, δ(ppm) to higher frequencies from external 85% H_3PO_4] were recorded in $CDCl_3$ solutions on a Bruker AC-300. Elemental analyses were carried out on a Perkin–Elmer 240B analyser.

$[Mo(CO)_3(NCMe)_2(SnCl_2Bu)Cl]$ (**1a**). IR (cm^{-1}): ν(CO) 2014s, 1935(sh), 1916s; ν(CN) 2317w, 2290w. Satisfactory analysis could not be obtained for bis-nitrile complexes **1a–d** due to their instability.

$[W(CO)_3(NCEt)_2(SnCl_2Bu)Cl]$ (**1b**). IR (cm^{-1}): ν(CO) 2006s, 1915(sh), 1904s; ν(CN) 2320w, 2292w.

$[Mo(CO)_3(NCMe)_2(SnClBu_2)Cl]$ (**1c**). IR (cm^{-1}): ν(CO) 1990s, 1893s(br); ν(CN) 2317 w, 2288 w.

Crystal and refinement data for compound **2a**

$C_{15}H_{36}Cl_3MoO_{11}P_3Sn$, $M_r = 806.35$, monoclinic, space group $P2_1/c$, $a = 14.714(5)$, $b = 9.931(6)$, $c = 21.646(7)$ Å, $\beta = 91.12(5)°$, $V = 3162(3)$ Å^3, $D_c = 1.69$ g cm^{-3}, $Z = 4$, $F(000)$ 1608, λ(Mo-K_α) = 0.71073 Å, $\mu = 16.28$ cm^{-1}, room temperature. Pale yellow, prismatic crystal ($0.3 \times 0.1 \times 0.1$ mm) grown by slow diffusion of hexane into a concentrated solution of the compound in dichloromethane. Intensities were collected on an Enraf–Nonius CAD4 diffractometer, using the ω–2θ scan technique. 5520 reflections were measured in the range $0 \leqslant \theta \leqslant 25°$; 1951 with $I \geqslant 3\sigma(I)$ were used in the refinement. An empirical (ψ-scan based) absorption correction was applied. Molybdenum and tin atoms were located from a Patterson synthesis, and the remaining non-hydrogen atoms by DIRDIF.[12] An absorption correction was applied with DIFABS.[13] Full-matrix least-squares refinement was made with SHELX76.[14] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were geometrically positioned with a given overall isotropic temperature factor of 0.08 Å^2. Number of parameters refined, 308. Final R was 0.043 (R_w 0.038).

Abstract—The $[Rh(SnCl_3)_5]^{4-}$ complex anion, extracted into chloroform containing a quaternary ammonium type liquid anion exchanger, is readily and reversibly protonated in the chloroform phase to yield the stereochemically rigid, $[RhH(SnCl_3)_5]^{3-}$ complex.

The considerable current interest in transition metal–tin chemistry may be ascribed in part to the catalytic utility of these systems, the subject having been recently reviewed.[1] In particular, Saito and co-workers[2,3] have reported the photo-enhanced catalytic dehydrogenation of propan-2-ol using a rhodium–tin chloride system. Furthermore, the yellow solutions obtained when mixing $RhCl_3 \cdot 3H_2O$, $SnCl_2 \cdot 2H_2O$, propan-2-ol and 3 M hydrochloric acid, have been shown by means of ^{119}Sn NMR to contain the $[RhH(SnCl_3)_5]^{3-}$ anion, **1**.[4] In these studies the formation of **1** has been assumed to proceed via the catalytic dehydrogenation of propan-2-ol to yield acetone. While the photo-enhanced dehydrogenation of propan-2-ol (in the *absence* of the hydrochloric acid) doubtlessly involves a hydride complex,[3] the nature and mechanism of formation of such complexes has not been clearly elucidated.

As part of our interest in the selective extraction of the complex anions of the type $[Rh(SnCl_3)_n Cl_{6-n}]^{3-}$ (n = 1–5) by solid polyurethane foams,[5] we have used ^{119}Sn NMR to examine the distribution of these complexes between dilute hydrochloric acid and the quaternary ammonium liquid anion exchanger, tricaprylylmethylammonium chloride (AQ-336, Aldrich) in chloroform. We here report convincing ^{119}Sn NMR evidence that the yellow complex anion **1** is formed by direct protonation of the red–purple (λ_{max} = 470 nm) complex anion $Rh(SnCl_3)_5^{4-}$ (**2**).

When a suitably aged (35°C, 4 h) 0.5 M hydrochloric acid solution containing $RhCl_3 \cdot 3H_2O$ (7 mmol) and sufficient $SnCl_2 \cdot 2H_2O$ (Sn/Rh mole ratio of 10:1) is extracted with an equal volume of 10% (v/v) AQ-336 in $CDCl_3$, the red–purple rhodium–tin complex anions are quantitatively transferred into the organic phase. ^{119}Sn NMR spectroscopy at 25°C (Fig. 1) shows that the predominant species found to be extracted is **2**; this complex is also known to predominate in the aqueous phase under certain conditions.[6] Addition of a small quantity of CF_3COOH directly to the chloroform extract results in a rapid colour change from red to yellow, while the ^{119}Sn NMR spectrum that obtains, is clearly ascribable to the $[RhH(SnCl_3)_5]^{3-}$ complex [$\delta(^{119}Sn) = -14.1$ ppm(eq), +78.7 ppm(ax), $^1J(^{103}Rh–^{119}Sn) = 594$ Hz(eq), 528 Hz(ax), $^2J(^{117}Sn–^{119}Sn) = 1973$ Hz (*cis*, eq–eq), 25,334 Hz (*trans*, eq–eq), 1759 Hz (*cis*, ax–eq), $^2J(^{119}Sn–^{119}Sn) = 1844$ Hz (*cis*, ax–eq), $^2J(^1H–^{119}Sn) = 58$ (*cis*, eq), 1115 Hz (*trans*, ax)]. An identical spectrum may be obtained simply by increasing the hydrochloric acid concentration of the aqueous source phase to greater than 3 M, when the extraction is accompanied by a gradual colour change from red to yellow. The ^{119}Sn NMR spectra of extracts obtained from 5 M hydrochloric acid

* Author to whom correspondence should be addressed.

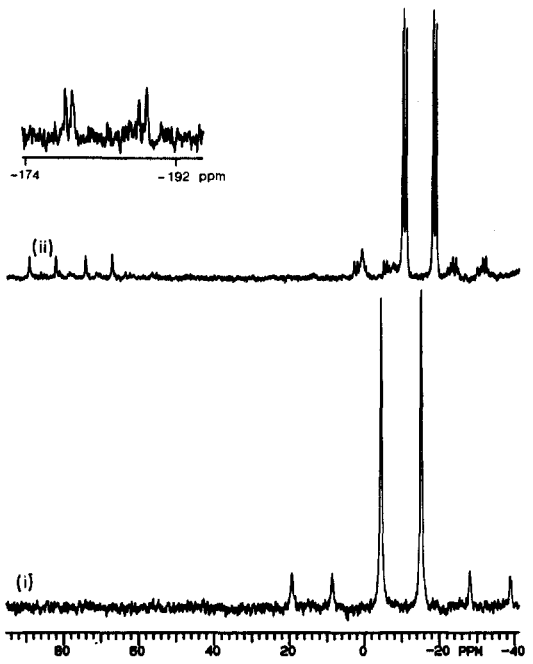

Fig. 1. ^{119}Sn NMR spectra at 74.5 MHz of: (i) a $CDCl_3$/AQ-336 extract obtained from 0.5 M hydrochloric acid containing $RhCl_3$ and $SnCl_2$ (Sn/Rh = 10) and (ii) spectrum after addition to 1 drop of CF_3COOH. [Also shown is the high-field satellite due to *trans* $^2J(^{117}Sn–^{119}Sn)$ coupling.]

solution containing tin chloride in an Sn/Rh mole ratio of 4, reveal the presence of a small amount of a second hydride complex anion assigned to be *trans*-$[RhHCl(SnCl_3)_4]^{3-}$ [$\delta(^{119}Sn) = -92.5$ ppm, $^1J(^{103}Rh–^{119}Sn) = 666$ Hz, $^2J(^{117}Sn–^{119}Sn) = 2398$ Hz, $^2J(^1H–^{119}Sn) = 105$ Hz], in addition to substantial amounts of **1**.

The partial reversibility of the proposed protonation

$$[Rh(SnCl_3)_5]^{4-} + H(org)^+ \rightleftharpoons [RhH(SnCl_3)_5]^{3-}$$

in the AQ-336/$CDCl_3$ phase may be conveniently ascertained by means of a photometric titration. Addition of an appropriate amount of strong acid, e.g. CF_3COOH, to a chloroform extract containing **2**, results in a progressive decrease of the absorbance at 470 nm with a concomitant increase in the absorbance below 350 nm. This trend may be reversed by the subsequent addition of the relatively basic N,N-dimethylformamide.

It is thus clear that the formation of **1** in solutions of propan-2-ol containing dilute hydrochloric acid results from the simple protonation of the pentacoordinate species **2** in the organic phase, and need not involve the deprotonation of propan-2-ol as has been tacitly assumed.[3,4] Further support for this contention is obtained from the observation that the yellow complex anion **1** predominates in 4-methylpentan-2-one (MIBK) extracts obtained from aqueous source phases under a variety of acid concentrations and Sn/Rh ratios. All attempts to detect **2** in the MIBK phase proved fruitless. This observation can now be understood in view of the well established tendency for solvents such as MIBK to co-extract substantial amounts of hydrochloric acid,[7] which results in the rapid protonation of **2** on transfer into the MIBK phase. While the catalytic photo-enhanced dehydrogenation of propan-2-ol most probably involves complex rhodium–chlorotin hydrido species, it is clear that the coordinatively saturated anion **1** is easily formed by facile protonation of **2** in organic solvents, even in the absence of alcohols such as propan-2-ol.

METAL–BETAINE INTERACTIONS—VIII. CRYSTAL STRUCTURE OF *CATENA*-(PYRIDINE BETAINE)(NITRATO)SILVER(I), $[Ag(C_5H_5NCH_2COO)(NO_3)]_n$

XIAO-MING CHEN and THOMAS C. W. MAK*

Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

(*Received* 17 *January* 1991; *accepted* 23 *May* 1991)

Abstract—The crystal structure of $[Ag(pyBET)(NO_3)]_n$ (pyBET = $C_5H_5N^+CH_2COO^-$) has been characterized by X-ray crystallography. The complex comprises (carboxylato-*O*,*O*′)-bridged one-dimensional polymeric chains with the Ag(I) atom forming two Ag—O(carboxylato) bonds [2.289(1) and 2.334(1) Å to different pyBET ligands] and one Ag—O(nitrato) bond [2.434(2) Å] in a distorted trigonal-planar configuration.

Among the characterized crystal structures of silver(I) carboxylates, most are composed of either discrete dimers or polymeric system constructed by the linkage of dimeric subunits, which have been classified into four principal types [Fig. 1(a)–(d)].[1] Exceptions are extremely rare. The only example to our knowledge is a one-dimensional polymeric arrangement of linear O—Ag—O bonds found in silver(I)(4-chloro-2-methylphenoxy)acetate,[2] where the bridging carboxylato group acts in the *syn–anti* mode [Fig. 1(f)].

Betaines are structurally analogous to the corresponding carboxylate anions, and advantage can be taken of their overall charge neutrality to provide synthetic access to new varieties of metal complexes related to the well-known carboxylates.[3] Recent studies include the preparation and crystal structures of two silver(I) complexes,[4] $[Ag_2(BET)_2(H_2O)_2(NO_3)_2]_n$ (**1**) and $[Ag_2(pyBET)_2(ClO_4)_2]_n$ (**2**) (BET = betaine, $Me_3N^+CH_2COO^-$; pyBET = pyridine betaine, $C_5H_5N^+CH_2COO^-$).† We now report the preparation and single-crystal X-ray analysis of a new betaine silver(I) complex, *catena*-(pyridine betaine)(nitrato)silver(I), $[Ag(pyBET)(NO_3)]_n$ (**3**), which has been found to be the first example of a *syn–syn* (carboxylato-*O*,*O*′)-bridged one-dimensional polymeric structure that is not based on dimeric subunits.

EXPERIMENTAL

Preparation and IR spectra

Pyridine betaine was prepared as described previously.[5] Complex (**3**) was prepared by dissolving $AgNO_3$ (0.250 g, 1.5 mmol) and pyridine betaine (0.411 g, 3.0 mmol) in hot water (3 cm^3, 60°C). After filtration, the solution was evaporated at room temperature in the dark for a week to obtain colourless plate-like crystals.

IR spectra (KBr pellets) were recorded on a Nicolet 20SXC FT-IR spectrometer in the range of 4000–400 cm^{-1}. The complex exhibits the following IR carboxy absorption bands (v = very, s = strong, m = medium; cm^{-1}): ν(COO) at 1633vs, 1384s and δ at 694m. The separation (Δ) between ν_{asym}(COO) and ν_{sym}(COO), 249 cm^{-1}, is smaller than that in uncomplexed pyridine betaine [ν(COO) = 1635, 1377, δ(COO) = 706 cm^{-1}; Δ = 258 cm^{-1}][5] and hence indicative of the bridging mode of carboxylato coordination in the present complex.[6]

X-ray crystallography

$Ag(C_5H_5NCH_2COO)(NO_3)$ (**3**), Mol. wt 307.01, monoclinic, space group $P2_1/c$ (no. 14), $Z = 4$, $a = 12.849(2)$, $b = 4.9992(3)$, $c = 15.047(3)$ Å, $\beta = 113.91(1)°$, $U = 883.6(3)$ Å^3, $D_{calc} = 2.308$ g cm^{-3}, $F(000) = 600$, Mo-K_α radiation ($\lambda = 0.71073$ Å), $\mu = 2.26$ mm^{-1}.

Diffraction intensities (crystal size $0.12 \times 0.28 \times 0.30$ mm; $2\theta_{max} = 55°$, 2024 unique data) were collected at 21°C on a Nicolet R3m/V diffractometer using the ω-scan (2.91–14.63° min^{-1}) mode.[7] Data processing, absorption corrections ($\mu r = 0.27$, transmission factors 0.577–0.795), structure solution, and full-matrix least-squares refinement were performed with the SHELXTL-PLUS program package[8,9] on a DEC MicroVAX-II computer. The non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were generated geometrically (C—H = 0.96 Å), assigned isotropic temperature factors, and included in the structure–factor calculations. Analytic expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[10] The final residuals were $R_F = 0.026$ and $R_{wF^2} = 0.028$ for 1706 observed data with $I \geqslant 3\sigma(I)$.

Supplementary materials including non-hydrogen and hydrogen atomic coordinates, bond lengths and angles, and thermal parameters have been

deposited at the Cambridge Crystallographic Data Centre, and observed and calculated structure factors are available upon request from the corresponding author.

RESULTS AND DISCUSSION

As illustrated in Fig. 2, the silver(I) atom in complex (**3**) is coordinated by three oxygen atoms in a nearly planar and distorted trigonal environment. The two metal–ligand bonds involving different carboxylato groups of pyBET ligands [Ag(1)—O(1) = 2.334(3), Ag(1)—O(2a) = 2.289(3) Å] are slightly longer than those [Ag—O(carboxy) = 2.211(6), 2.220(6) Å] found in $[Ag_2(pyBET)_2(ClO_4)_2]_n$ (**2**),[4] and the third linked to a nitrate group [Ag(1)—O(3) = 2.434(3) Å] is shorter than those of axially bonded nitrate groups in the dimeric structure of alanine silver(I) nitrate [2.58(3) Å].[11] There is no other Ag—O contact less than 2.75 Å in the crystal structure. Each pair of adjacent silver(I) atoms are bridged in the *syn–syn* mode by the carboxylato group of a *single* pyBET ligand, resulting in a zigzag polymeric chain running parallel to the 2_1 axis. The metal–metal separation of 3.011(1) Å is significantly larger than the average value (*ca* 2.9 Å) found in dimeric silver(I) carboxylates.[4]

It is worthy of note that the present structure (**3**) is distinct from those of two related silver(I) betaine complexes, $[Ag_2(BET)_2(H_2O)_2(NO_3)_2]_n$ (**1**) and $[Ag_2(pyBET)_2(ClO_4)_2]_n$ (**2**), both of which adopt the modified Type D structure[4] [Fig. 1(e)]. Furthermore, complex (**3**) is different from all the other known silver(I) complexes containing related ligands such as the zwitterionic amino acids; for example, alanine silver(I) nitrate[11] and glycine silver(I) nitrate[12] both have dimeric structures of Type B and D, respectively.

The coordination motif in complex (**3**) is also different from that in the zigzag chain occurring in silver(I) (4-chloro-2-methylphenoxy)acetate,[2] where the silver(I) atom is linearly coordinated by

THE REACTIONS OF $[Ru(\eta^6\text{-arene})Cl_2]_2$ COMPOUNDS WITH A SERIES OF AMINOPYRIDINE LIGANDS: X-RAY CRYSTAL STRUCTURES OF $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ AND $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$

REES ARONSON, MARK R. J. ELSEGOOD, JONATHAN W. STEED and DEREK A. TOCHER*

Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ, U.K.

(*Received* 3 *January* 1991; *accepted* 21 *March* 1991)

Abstract—The reactions of the dimers $[Ru(\eta^6\text{-arene})Cl_2]_2$ (arene = C_6H_6, 1,4-$MeC_6H_4CHMe_2$, [2.2](1,4)$C_{16}H_{16}$) with a range of aminopyridine ligands have been investigated. These ligands can potentially coordinate to a single metal centre in a monodentate fashion through either pyridyl or amino nitrogen atoms, can chelate a single metal centre, or can bridge across two metal ions. Spectroscopic data collected on 12 compounds is exclusively consistent with monodentate coordination via the pyridyl nitrogen atoms. This mode of coordination has been conclusively established by X-ray structure determinations of the compounds $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ and $Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$.

Recently we reported the results of our investigations into the reactions of $[Ru(\eta^6\text{-}C_6H_6)Cl_2]_2$ and $[Ru(\eta^6\text{-}C_6H_6)Cl(O_2CCF_3)]$ with α-pyridone and related ligands.[1] Coordination of this series of ligands was almost exclusively of the bidentate type to a single metal centre. In only one instance was monodentate coordination, via the pyridone oxygen atom, observed. Other workers[2] have observed bidentate coordination of the hydroxypyridinate anion in the compound $[Ru(\eta^6\text{-}MeC_6H_4CHMe_2)Cl(NC_5H_4O)]$. In an extension to that earlier work we have examined the reactions of 2-aminopyridine and several variously substituted derivatives with several $[Ru(\eta^6\text{-arene})Cl_2]_2$ compounds, including the paracyclophane compound $[Ru(\eta^6\text{-}[2_2](1,4)C_{16}H_{16})Cl_2]_2$, whose chemistry we are currently studying intensively.[3–5]

EXPERIMENTAL

Microanalyses were carried out by the Chemistry Department of University College London. NMR spectra were obtained on Varian XL-200 and VXR-400 spectrometers (chemical shifts quoted in ppm with positive values to high frequency of $SiMe_4$). IR spectra were recorded in the range 4000–200 cm^{-1} on a Perkin–Elmer 983 spectrophotometer using Nujol mulls on CsI plates.

Materials

The compounds $[Ru(\eta^6\text{-arene})Cl_2]_2$ (arene = C_6H_6, 1,4-$MeC_6H_4CHMe_2$, [2.2](1,4)$C_{16}H_{16}$) were prepared by published literature methods.[6–8] All other reagents were obtained from normal commercial suppliers. All reactions were carried out in degassed solvents under a nitrogen atmosphere.

$[Ru(\eta^6\text{-}C_6H_6)Cl_2(NC_5H_4NH_2)]$

A solution of 2-aminopyridine (0.11 g, 2.2 mmol) in toluene (5 cm^3) was added to a suspension of $[Ru(\eta^6\text{-}C_6H_6)Cl_2]_2$ (0.1 g, 0.2 mmol) in toluene (15 cm^3) and the mixture stirred for 12 h at room temperature. The red–orange product was filtered off, washed with diethyl ether and methanol, and then dried *in vacuo* for 4 h. Yield 36%. IR spectrum ν(N—H) 3287, 3179 cm^{-1}, ν(Ru—Cl) 278 cm^{-1}.

Yield 65%. IR spectrum ν(N—H) 3195 cm^{-1}, ν(Ru—Cl) 297 cm^{-1}.

$[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NHCH_2C_6H_5)]$

Yield 44%. IR spectrum ν(N—H) 3290 cm^{-1}, ν(Ru—Cl) 288 cm^{-1}.

Tables 1 and 2 contain microanalytical and ^1H NMR data for the 12 new compounds.

X-ray studies

The structures of $[Ru(\eta^6\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ and $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$ were determined using general procedures which have been described previously.[9,10] The structures were solved routinely by direct methods and refined, with all non-hydrogen atoms anisotropic, by full-matrix least-squares. Hydrogen atoms were not included in the refinement. In the latter cycles of the refinement of the structure of $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$, a methanol of crystallization was located on the four-fold axis at $\frac{1}{4}, \frac{1}{4}, y$ and subsequently included in the refinement. Pertinent crystallographic data are

included in Table 3. Tables 4 and 5 contain selected bond lengths and bond angles for $[Ru(\eta^6\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ and $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$, respectively. Crystallographic calculations used the SHELXTL PLUS program package.[11]

Final atomic coordinates, full listings of bond lengths and angles, thermal parameters and structure factor tables have been deposited with the Editor, and with the Cambridge Crystallographic Data Centre, as supplementary material.

RESULTS AND DISCUSSION

Orange or red, microcrystalline compounds of general formula $[Ru(\eta^6\text{-arene})Cl_2(Hap)]$ (arene = C_6H_6, 1,4-$MeC_6H_4CHMe_2$, $C_{16}H_{16}$; Hap = 2-aminopyridine, 2-amino-3-picoline, 2-benzylaminopyridine, 2-anilinopyridine) have been prepared by the reaction of the dinuclear compounds $[Ru(\eta^6\text{-arene})Cl_2]_2$ with an excess of the appropriate ligand in toluene. Non-polar solvents have frequently been employed in the past to give a wide range of $[Ru(\eta^6\text{-arene})Cl_2L]$ (L = pyridine, tertiary phosphines, etc.) compounds.[12,13] However, when polar solvents have been employed, cationic products, $[Ru(\eta^6\text{-arene})ClL_2]^+$, have usually been formed. Alternatively, if the incoming ligand can be deprotonated, e.g. a carboxylic acid, then a neutral compound such as $[Ru(\eta^6\text{-}C_6H_6)Cl(O_2CCF_3)]$[14] is often formed. Surprisingly the products which were isolated when we reacted $[Ru(\eta^6\text{-arene})Cl_2]_2$ compounds with this series of Hap ligands in methanol were almost invariably identical to those obtained from the non-polar solvent, although admittedly the isolated yield was often smaller. This was particularly surprising given that previously we have been able to prepare a range of neutral compounds of the type $[Ru(\eta^6\text{-arene})Cl(hp)]$[1,15] (Hhp = 2-hydroxypyridine, 6-methyl-2-hydroxypidine, 6-chloro-2-hydroxypyridine) by using precisely these reaction conditions. The differences in reactivity can most likely be explained by invoking the appreciably lower acidity of the amino protons in these ligands, when compared with the hydroxyl protons on the

various hydroxypyridine ligands used in our earlier study. Given that each of the aminopyridine ligands employed in this study only coordinates unidentately to a ruthenium(II) centre, then there are two potential ligand donor atoms, namely the amino and pyridyl nitrogen atoms. Although it is known[16,17] that ammonia will bind to a "Ru(η^6-arene)" fragment, there are few examples of other coordinated amines in this area of chemistry. In contrast, there are numerous examples of co-ordinated pyridines or pyridyl ligands. Comparison of the H NMR signals from free and coordinated Hap ligands strongly suggested that coordination to the metal was via the pyridyl nitrogen atoms.

This was conclusively established by single crystal X-ray diffraction experiments on $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ and $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$.

X-ray crystal structures of $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ *and* $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$

The molecular structures of $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ and $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$ are shown in Figs 1 and 2, respectively. Important bond lengths and bond angles are presented in Tables 4 and 5. The geometry about each ruthenium ion is that of a distorted octahedron with the η-arene ring and the other ligands adopting a "piano stool" configuration. Both the complexes have an overall geometry similar to that of several $[Ru(\eta^6\text{-arene})Cl_2L]$ and $[Ru(\eta^6\text{-arene})ClL_2]^+$ species[1-3,17,18] described previously. The two Ru—N distances are closely similar, however there are significant variations in the Ru—Cl distances. In particular, the two Ru—Cl distances, 2.409(2) and 2.421(2) Å, in the compound $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ are statistically different. Both chloride ligands are involved in hydrogen bonding to amino nitrogen atoms. The ligand Cl(1) is involved in an intermolecular hydrogen bond of 3.23 Å, while Cl(2) forms an intramolecular hydrogen bond, of 3.24 Å, to N(2). In contrast, only Cl(2) is involved in intramolecular hydrogen bonding, to N(2), 3.16 Å, in $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$, and the two Ru—Cl bond distances in this molecule are indistinguishable.

In $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ the Ru—C distances lie in the range 2.16–2.22 Å, and the ring centroid is 1.67 Å from the ruthenium ion. Similar distances are observed in the ruthenium(II) *p*-cymene complexes $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl(hp)]^2$, $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl(pyz)_2][PF_6]$[14] and $[Ru_2(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)_2(\mu\text{-}Cl)_3][BPh_4]$.[19] The C—C bond length alternation which has been observed in several other studies on η^6-arenes coordinated to transition metal ions[18,20] is not readily apparent in this

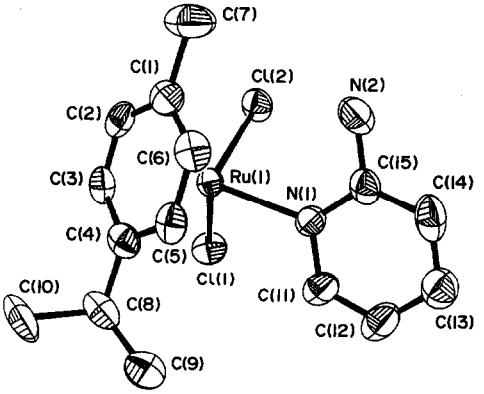

Fig. 1. Thermal ellipsoid plot of the $[Ru(\eta^6\text{-}1,4\text{-}MeC_6H_4CHMe_2)Cl_2(NC_5H_4NH_2)]$ molecule. Atoms are represented by thermal vibration ellipsoids at the 50% confidence level, and the atom-labelling scheme is defined.

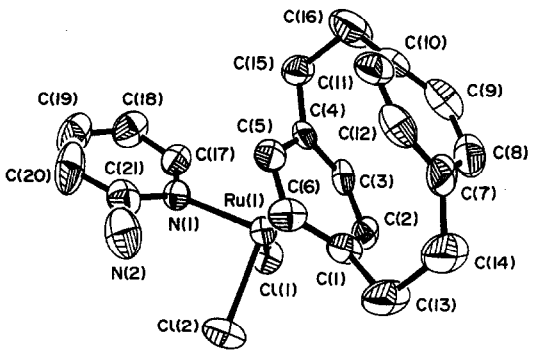

Fig. 2. Thermal ellipsoid plot of the $[Ru(\eta^6\text{-}C_{16}H_{16})Cl_2(NC_5H_4NH_2)]$ molecule. Atoms are represented by thermal vibration ellipsoids at the 50% confidence level, and the atom-labelling scheme is defined.

study. The methyl and isopropyl groups are bent towards the ruthenium ion by 2.3 and 3.4°, respectively. The isopropyl group is not symmetrically placed with respect to the C_6 ring but forms a torsion angle, C(5)—C(4)—C(8)—C(9) = 14.7°, with the mean plane.

In [Ru(η^6-$C_{16}H_{16}$)Cl_2($NC_5H_4NH_2$)] the Ru—C distances fall into two sets; there are four short bonds, to C(2), C(3), C(5) and C(6), 2.13–2.22 Å, and two long bonds to the bridgehead carbons C(1) and C(4), 2.337(9) and 2.260(8) Å, respectively. This variation in metal–carbon bond length is attributed to the presence of the two ethylenic bridges between the aromatic decks of the cyclophane and has been commented on in several previous reports.[3–5,21,22] Indeed, it is a feature of the free ligand, as well as its metal complexes, that the aromatic rings are non-planar. The two bridgehead carbon atoms of the coordinated deck lie, on average, 0.18 Å above the mean plane of the other four coordinated carbon atoms, while the two bridgehead carbons of the non-coordinated deck lie *ca* 0.15 Å below the plane defined by the remaining four carbon atoms of the second deck. It is also noteworthy that the two Ru—C bonds *trans* to the pyridyl nitrogen atom are significantly lengthened with respect to the remaining four Ru—C bonds. Similar observations have been made on the Ru—C bonds *trans* to the tertiary phosphine ligands in the compounds [Ru(η^6-arene)Cl_2(PMe_2Ph)].[18] The two decks are not precisely eclipsed with respect to each other. There is an average torsion angle in the ethylenic bridges of 4.4°. This compares with an estimated value of *ca* 3.2° in the disordered structure of the free ligand.[23] The shallow boat conformation of the free ligand has been ascribed to electronic interactions between the stacked decks. On coordination to a metal ion these unfavourable interactions are reduced and the separation between decks is decreased from 3.09 Å, in the non-coordinated ligand, to 2.99 Å for this compound.

The molecular parameters of the coordinated 2-aminopyridine ligands in the two structures are not significantly different from each other.

Acknowledgements—We thank Johnson–Matthey plc for generous loans of ruthenium trichloride and the SERC for financial support (M.R.J.E.) and for provision of the X-ray diffractometer.

SYNTHETIC, SPECTROSCOPIC AND MAGNETIC STUDIES OF HETEROMETAL ALKOXIDES OF COBALT(II), NICKEL(II) AND COPPER(II) CONTAINING THE STERICALLY CROWDED TETRAALKOXOALUMINATE LIGAND

G. GARG, R. K. DUBEY, A. SINGH and R. C. MEHROTRA*

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 15 *October* 1990; *accepted* 5 *April* 1991)

Abstract—Heterobimetallic alkoxides of the types $[ClM\{Al(OBu^t)_4\}]$ **(I)** and $[M\{Al(OBu^t)_4\}_2]$ **(II)** ($M = Co^{II}$, Ni^{II} and Cu^{II}) have been prepared by the interactions of MCl_2 with $K\{Al(OBu^t)_4\}$ in 1:1 and 1:2 molar ratios, respectively. These chloro(tetra-t-butoxoaluminato) complexes proved to be useful precursors for the synthesis of a variety of bimetallic alkoxo derivatives such as: $[(OBu^t)M\{Al(OBu^t)_4\}]$, $[\{Al(OEt)_4\}M\{Al(OBu^t)_4\}]$ and $[\{Al(OPr^i)_4\}M\{Al(OBu^t)_4\}]$. All these derivatives are highly moisture-sensitive, coloured solids or viscous liquids. Most of these are volatile except the mixed derivatives like $[ClM\{Al(OBu^t)_4\}]$ and $[(OBu^t)M\{Al(OBu^t)_4\}]$ which tend to disproportionate on heating. These heterometal alkoxides have been characterized by elemental analyses, spectroscopic (IR and visible) and magnetic studies, as well as molecular weight determinations.

Examples of heterometal alkoxides containing the isopropoxoaluminate ligand now include many of the possible combinations of metals[1–4] from group 3 to group 13. Earlier attempts to prepare bis(tetra-t-butoxoaluminato)cobalt,[5] -nickel[6] and -copper[7] by alcoholysis of analogous tetraisopropoxo derivatives $[M\{Al(OPr^i)_4\}_2]$ resulted in the replacement of only three of the four isopropoxide groups in the $\{Al(OPr^i)_4\}^-$ ligands with the formation of $[M\{Al(OPr^i)(OBu^t)_3\}_2]$. Additionally, our earlier findings have also shown that the corresponding alkoxoaluminate derivatives tend to show variation in their coordination state with the nature of the alkyl group. For example, the coordination number in $[Ni\{Al(OR)_4\}_2]$ tends to change from six to four as the R group is changed from methyl in $[\{Ni(\mu\text{-}OMe)_3Al(OMe)\}_2]$ to comparatively more sterically demanding isopropyl groups[6] in $[Ni\{(\mu\text{-}OPr^i)_2Al(OPr^i)_2\}_2]$.

We are, therefore, currently involved in the exploration of the possibility of synthesizing heterobimetallic alkoxides of the types $MCl_{n-x}\{Al(OBu^t)_4\}_x$ and $M\{Al(OBu^t)_4\}_n$ and in examining the effect of the $\{Al(OBu^t)_4\}^-$ group(s) on the stereochemistry of the metal in complexes formed by varied possible combinations with other alkoxo or alkoxometallate group(s). This paper, therefore, is concerned with the synthesis and characterization of heterometal alkoxides of cobalt(II), nickel(II) and copper(II) containing $\{Al(OBu^t)_4\}^-$ group(s).

EXPERIMENTAL

Stringent precautions were taken to exclude moisture throughout all the experimental procedures. Oven-dried (130–140°C) glass apparatus was used throughout all the experimental manipulations. Anhydrous metal chlorides were prepared in a current of dry HCl gas and analysed as reported earlier.[8,9]

Aluminium t-butoxide was prepared by the literature procedure.[10] The metal contents in the derivatives have been analysed as mixed oxides. Copper(II) in the complex was analysed volumetrically. Chloride was estimated by Volhard's method[11] and alcohols (ethanol and isopropanol) were estimated by an oxidimetric method.[12]

IR (4000–200 cm^{-1}) spectra were recorded on Perkin–Elmer and Carl Zeiss Specord M80 spectrophotometers. Electronic spectra were recorded on a Pye–Unicam Model 557/SP 8-100 spectrometer. Magnetic susceptibility measurements were made at room temperature (23.5°C) by the Gouy method. The magnetic moments, μ_{eff}, listed in Table 1 have been corrected for the diamagnetic susceptibilities of the ligands and the central metal ion using standard values.[13] Molecular weights were measured ebullioscopically (Gallenkamp apparatus) in benzene.

Synthetic procedure

As preparative procedures are similar in most cases, only details of typical examples of each type are given below, for the sake of brevity.

Preparation of $[ClCo\{Al(OBu^t)_4\}]$ **(Ia)**

A benzene (*ca* 25 cm^3) suspension of $K\{Al(OBu^t)_4\}$ [prepared by dissolving potassium (0.34 g, 8.69 mmol) and $Al(OBu^t)_3$ (2.16 g, 8.76 mmol) in Bu^tOH (*ca* 20 cm^3) and benzene (*ca* 15 cm^3)] was added to a suspension of $CoCl_2$ (1.13 g, 8.71 mmol) in Bu^tOH (*ca* 40 cm^3) and the reaction mixture was stirred for ~12 h at room temperature, during which the colour of the solution changed from light blue to dark blue. The precipitated KCl (1.14 g, 15.31 mmol) was removed by filtration. Removal of volatiles from the filtrate under reduced pressure afforded a dark blue solid (3.10 g, 85%) which was further recrystallized from a benzene/n-hexane mixture.

A similar procedure was used to obtain $[ClNi\{Al(OBu^t)_4\}]$ **(Ib)**.

Preparation of $[Co\{Al(OBu^t)_4\}_2]$ **(IIa)**

To a suspension of $CoCl_2$ (0.82 g, 6.32 mmol) in Bu^tOH (*ca* 30 cm^3) was added a solution of $K\{Al(OBu^t)_4\}$ [prepared by dissolving potassium (0.49 g, 12.5 mmol) and $Al(OBu^t)_3$ (3.16 g, 12.8 mmol) in Bu^tOH (*ca* 20 cm^3) and benzene (*ca* 15 cm^3)]. The reaction mixture was allowed to reflux for about 15 h, during which the colour of the solution changed from blue to purple–red. The precipitated KCl (0.94 g, 12.62 mmol) was removed by filtration. The solvent was removed from the filtrate under reduced pressure to afford a purple solid (4.0 g, 90%).

A similar procedure was used to isolate the coloured solid and viscous liquid products, respectively, $[Ni\{Al(OBu^t)_4\}_2]$ **(IIb)** and $[Cu\{Al(OBu^t)_4\}_2]$ **(IIc)**. Details are given in Table 2.

Reactions of $[ClM\{Al(OBu^t)_4\}]$ $(M = Co^{II})$ *and* Ni^{II}

Reaction of **Ia** *with* $K(OBu^t)$. A benzene suspension of $K(OBu^t)$ [prepared from potassium (0.12 g, 3.00 mmol) and Bu^tOH (*ca* 20 cm^3)] was added to a solution of $[ClCo\{Al(OBu^t)_4\}]$ (1.30 g, 3.00 mmol) in benzene (*ca* 20 cm^3). The resulting reaction mixture was stirred for about 6 h, followed by refluxing for 2 h. Precipitated KCl (0.21 g, 2.82 mmol) was filtered and volatiles were removed under reduced pressure from the filtrate to afford a dirty brown–violet solid $[(OBu^t)Co\{Al(OBu^t)_4\}]$ **(IIIa)** (1.33 g, 94%). The product was purified by recrystallization from a benzene/n-hexane mixture.

A similar procedure was used for the preparation of $[(OBu^t)Ni\{Al(OBu^t)_4\}]$ **(IIIb)**.

Reaction of **Ia** *with* $K\{Al(OR)_4\}$ (R = Et, Pr^i). A benzene (*ca* 20 cm^3) suspension of $K\{Al(OPr^i)_4\}$ [freshly prepared by the interaction of potassium (0.10 g, 2.55 mmol) and $Al(OPr^i)_3$ (0.53 g, 2.59 mmol) in Pr^iOH (*ca* 10 cm^3), followed by removal of the volatiles] was added to a benzene (*ca* 20 cm^3) solution of $[ClCo\{Al(OBu^t)_4\}]$ (1.07 g, 2.58 mmol). The reaction mixture was allowed to reflux for about 6 h, during which the colour changed from blue to violet. Precipitated KCl (0.50 g, 6.71 mmol) was removed by filtration and volatiles were removed under reduced pressure to yield a violet, solid product $[\{Al(OPr^i)_4\}Co\{Al(OBu^t)_4\}]$ **(Va)** (1.30 g, 80%). The product was purified either by distillation under reduced pressure or by recrystallization from n-hexane.

A similar procedure was used for the preparation of $[\{Al(OEt)_4\}M\{Al(OBu^t)_4\}]$ **(IVa** and **IVb)** (M = Co, Ni). Details are given in Table 2.

RESULTS AND DISCUSSION

The new heterobimetallic derivatives of cobalt(II), nickel(II) and copper(II) have been synthesized by the reaction of MCl_2 (anhydrous) with $K\{Al(OBu^t)_4\}$ in 1:1 and 1:2 molar ratios, respectively, in a mixture of benzene and Bu^tOH:

$$MCl_2 + K\{Al(OBu^t)_4\} \xrightarrow[C_6H_6,\ stir]{Bu^tOH} \tfrac{1}{2}[ClM\{Al(OBu^t)_4\}]_2 + KCl\downarrow \quad \textbf{(I)}$$

Ia; $M = Co^{II}$

Ib; $M = Ni^{II}$

Table 2. Preparative, analytical and some physical data of heterobimetallic alkoxide derivatives of Co^{II}, Ni^{II} and Cu^{II}

Reactants (in g)	Product; Nature; Percent yield	Sublimation/ distillation; Percent yield	Analysis: Found (Calc.) (%)

$[ClCo\{Al(OBu^t)_4\}] + K\{Al(OPr^i)_4\}$ (1.07) (0.77)	$[\{Al(OPr^i)_4\}Co\{Al(OBu^t)_4\}]$ **(Va)**; violet, sticky solid; 70%	Distilled at 150°C/0.05 mm Hg; 80	8.7 (9.1)	—	8.7 (8.4)	—	36.7 (36.8)
$[ClNi\{Al(OBu^t)_4\}] + K\{Al(OPr^i)_4\}$ (1.25) (0.92)	$[\{(Al(OPr^i)_4\}Ni\{Al(OBu^t)_4\}]$ **(Vb)**; purple, sticky solid; 75%	Distilled at 144°C/0.05 mm Hg; 60	8.9 (9.1)	—	8.6 (8.4)	—	36.5 (36.8)
$CuCl_2 + 2K\{Al(OBu^t)_4\}$ (0.51) (2.48)	$[Cu\{Al(OBu^t)_4\}_2]$ **(IIc)**; green, sticky solid; 80%	Distilled at 162°C/0.05 mm Hg; 80	8.9 (9.0)	—	7.6 (7.7)	—	—

$$MCl_2 + 2K\{Al(OBu^t)_4\} \xrightarrow[\text{Reflux}]{C_6H_6,\ Bu^tOH} [M\{Al(OBu^t)_4\}_2] + 2KCl\downarrow$$

(II)

IIa; M = Co^{II}

IIb; M = Ni^{II}

IIc; M = Cu^{II}.

Complexes **IIa**–**IIc** could also be prepared by the equimolar interaction of **Ia**, **Ib** or $[ClCu\{Al(OBu^t)_4\}]$, respectively, with $K\{Al(OBu^t)_4\}$ in benzene.

All these derivatives are moisture-sensitive, coloured [cobalt (purple), nickel (purple) and copper (green)] solids or viscous liquids, soluble in organic solvents (e.g. n-hexane, benzene, toluene). Derivatives **Ia** and **Ib** are dimeric in boiling benzene, whereas complexes **IIa** and **IIb** are monomeric. Derivatives **IIa**–**IIc** are thermally stable and could be sublimed/distilled unchanged under reduced pressure. By contrast, derivatives **Ia** and **Ib** decomposed on heating even under reduced pressure at 150°C/0.05 mmHg.

Derivatives **Ia** and **Ib** proved to be of great synthetic utility for the synthesis of interesting varieties of new heterometal alkoxide derivatives by the reactions shown below:

$$[ClM\{Al(OBu^t)_4\}] + K(OBu^t) \xrightarrow{C_6H_6} [(OBu^t)M\{Al(OBu^t)_4\}] + KCl\downarrow$$

(III)

IIIa; M = Co

IIIb; M = Ni

$$[ClM\{Al(OBu^t)_4\}] + K\{Al(OR)_4\} \xrightarrow{C_6H_6} [\{Al(OR)_4\}M\{Al(OBu^t)_4\}] + KCl\downarrow$$

(IV and V)

IVa; R = Et, M = Co

IVb; R = Et, M = Ni

Va; R = Pr^i, M = Co

Vb; R = Pr^i, M = Ni.

Derivatives **IIIa** and **IIIb**, **IVa** and **IVb** and **Va** and **Vb** are coloured solids, soluble in common organic solvents. Most of these are monomeric (ebullioscopically) in benzene, whereas **IIIa** and **IIIb** depict a dimeric nature.

The reaction of $K\{Al(OBu^t)_4\}$ with $NiCl_2$ was extremely slow, but it could be facilitated by the use of the adduct $NiCl_2 \cdot x Pr^iOH$, in the presence of a few drops of pyridine.

IR spectral studies

Complexes $[ClM\{Al(OBu^t)_4\}]$, $[(OBu^t)M\{Al(OBu^t)_4\}]$ and $[M\{Al(OBu^t)_4\}_2]$ showed structurally useful IR absorptions[14,15] in the regions 1250–1205, 910–905, 800–720 (OBu^t skeleton vibrations); 1080, 1050 ν(C—O), 760–600 ν(Al—O) and 499–400 cm^{-1} ν(M—O) (M = Co, Ni and Cu).

The metal chloride stretching frequency in **Ia** and **Ib** is observed in the range 384–248 cm^{-1}, as expected for bridged chloride[16–18] systems with a coordination environment lower than six.

In the derivatives $[\{Al(OEt)_4\}M\{Al(OBu^t)_4\}]$ and $[\{Al(OPr^i)_4\}M\{Al(OBu^t)_4\}]$, bands were observed in the range 1080, 1060 ν(C—O); 910–905 (due to OBu^t skeleton vibrations); 690, 660, 665 ν(Al—O) and 395–470 cm^{-1} ν(M—O). In the former derivatives, characteristic bands due to OEt skeleton vibrations are observed at 1180 (M = Co), 1160 (M = Ni) cm^{-1}, while in latter complex, bands observed at 1130 (M = Co), 1150 (M = Ni) cm^{-1} are characteristic of OPr^i skeleton vibrations.

Electronic spectral and magnetic studies

The electronic spectrum of $[Ni\{Al(OBu^t)_4\}_2]$ (**IIb**) is characteristic of a tetrahedral environment[19–21] around nickel and the same is corroborated by its magnetic moment (3.91 BM). The electronic spectra of other nickel derivatives show a small equilibrium contribution of octahedral species, increasing from **IIIb** to **Ib** to **Vb**, which is corroborated from their magnetic moments[22,23] (3.88–3.95 BM). These conclusions receive additional support from the spectra (Table 1) observed in different solvents, showing the relative concentration of the octahedral species increasing with the donor capability of the ligand in general: benzene < tetrahydrofuran < pyridine (2,6-dimethylpyridine); in spite of a higher donating capacity expected for 2,6-dimethylpyridine compared with pyridine, the steric effects appear to reduce the donor property of the former ligand.

The spectra of cobalt derivatives[19] **Ia**–**Va** (Table 1) indicate qualitatively an octahedral environment with an increasing component in equilibrium of the tetrahedral form in the sequence **IVa** < **Va** < **IIa** < **Ia** < **IIIa**; however, an alternative possibility of a pentacoordinated species can also not be ruled out. Magnetic moments[22,23] (4.81–4.90 BM) for **Ia**–**Va** are consistent with the above conclusions.

The spectrum of $[Cu\{Al(OBu^t)_4\}_2]$ (Table 1) in benzene shows a medium to weak intensity, very broad absorption band around 14,040 cm^{-1} arising from either a highly distorted tetragonal or a trigonal field. When the spectra were recorded in

different solvents (e.g. tetrahydrofuran, pyridine, lutidine), there was a noticeable blue shift in the position of the band in the following order: tetrahydrofuran < pyridine < lutidine. These observations do indicate, as expected, that as the basicity (or donor strength) of the solvent increases, copper(II) tends to attain an octahedral geometry. The observed magnetic moment, 1.96 BM, for the derivative $[Cu\{Al(OBu^t)_4\}_2]$ also corresponds to the d^9 configuration of copper(II).[22,23]

Although the above limited data do indicate the possibilities of several structural patterns involving fluxional bi- or tridentate bonding of the alkoxometallate ligands in solution, with variations consistent in general with their steric requirements, definite conclusions regarding the structures of these fascinating heterometal alkoxides in the solid state would be possible only after X-ray crystallographic studies, which have not been successful so far.

(*Received* 21 *January* 1991; *accepted* 8 *April* 1991)

Abstract—Cyclic voltammograms, electronic and Mössbauer spectra were recorded for a series of sterically hindered ferrocenes bearing trimethylsilyl and tert-butyl groups Fe[η^5-$C_5H_3(EMe_3)_2$-1,3]$_2$, Fe[η^5-$C_5H_2(EMe_3)$-4-$(SiMe_3)_2$-1,2]$_2$ (E = C, Si), and Fe[η^5-$C_5H_2(SiMe_3)_3$-1,2,4](η^5-C_5R_5) (R = H, CH_3). The redox potential of Fe[η^5-$C_5H_2(SiMe_3)_3$-1,2,4]$_2$ is more negative than is expected for the trimethylsilyl group's electron-withdrawing property, which is confirmed by the value of the lowest wavenumber electronic absorption and of the quadrupole splitting. Oxidation of Fe[η^5-$C_5H_2(SiMe_3)_3$-1,2,4]$_2$ with $AgBF_4$ gives [Fe{η^5-$C_5H_2(SiMe_3)_3$-1,2,4}$_2$]BF_4. A single crystal X-ray structural analysis shows that the cation adopts a conformation with a pair of trimethylsilyl groups eclipsed. The compound crystallizes in the monoclinic space group $P2_1/n$, with $a = 10.597(1)$, $b = 20.739(4)$, $c = 18.450(3)$ Å, $\beta = 105.49(1)°$ and $V = 3907$ Å^3.

1,1′,3,3′-Tetra(tert-butyl)ferrocene[1] represents the first metallocene which has a rotational barrier of the cyclopentadienyl ligand which is high enough to be determined by conventional solution NMR spectroscopy.[2] Recently, we have shown that in addition to the 1,3-di(tert-butyl)cyclopentadienyl (Bu_2Cp) ligand, multiply trimethylsilyl-substituted ligands such as 1,3-bis(trimethylsilyl)cyclopentadienyl (Si_2Cp),[3] 1,2,4-tris(trimethylsilyl)cyclopentadienyl (Si_3Cp)[4] and 4-tert-butyl-1,2-bis(trimethylsilyl)cyclopentadienyl ($BuSi_2Cp$)[5] also form ferrocenes that show similar values of barriers to ring rotation about the metal–ligand axis.[6] The conformational rigidity of these metallocenes has been ascribed to consequences of purely steric effects, viz. to pronounced interligand repulsions.[3,4,6] In order to detect further manifestation of steric influences on the iron centre, we have studied a series of ferrocenes bearing the above mentioned ligands by cyclic voltammetry as well as by electronic and Mössbauer spectroscopy. In this context, we have also performed the preparative oxidation of multiply trimethylsilyl-substituted ferrocenes $Fe(Si_nCp)_2$ ($n = 2$, 3) and an X-ray structural determination of $[Fe(Si_3Cp)_2]BF_4$.

RESULTS AND DISCUSSION

Cyclic voltammograms of the previously synthesized ferrocenes $Fe(Bu_2Cp)_2$,[1] $Fe(Si_2Cp)_2$,[3,7] $Fe(Si_3Cp)_2$,[4,8] $Fe(BuSi_2Cp)_2$,[5] $Fe(Si_3Cp)Cp$[4] and $Fe(Si_3Cp)Cp^*$[4] ($Cp = \eta^5$-C_5H_5; $Cp^* = \eta^5$-C_5Me_5) were obtained at room temperature in dichloro-

methane solution. All compounds exhibit reversible one-electron oxidations. The redox potentials, $\Delta E_{1/2}$, compiled in Table 1 were internally referenced to ferrocene. For the sake of comparison we have also added $\Delta E_{1/2}$ values of FeCp* Cp[9] and FeCp*$_2$.[10] In Fig. 1 the redox potentials are plotted against the sum of resonance parameters $\Sigma\sigma_R$ (σ_R for Me, 0.11; CMe_3, 0.16; and $SiMe_3$, 0.12[11]). In accordance with literature reports,[10,12] each alkyl group such as methyl or tert-butyl at the ring periphery cathodically shifts the oxidation potential of the substituted ferrocene by *ca* 50 mV relative to the parent compound. Thus, a fairly good linear correlation of $\Delta E_{1/2}$ values with substituent constants is obtained for the alkylated ferrocenes FeCp*$_2$, FeCp*Cp and Fe(Bu$_2$Cp)$_2$. This reflects the steady increase of electron density at the iron centre by successive ring substitution

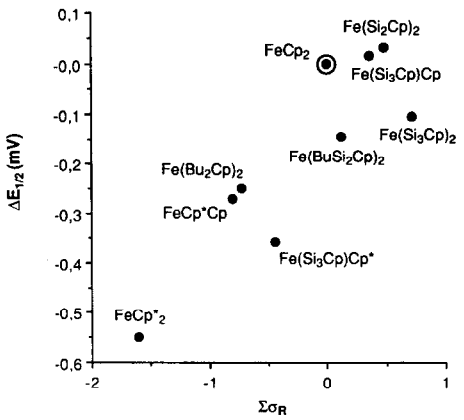

Fig. 1. Plot of redox potentials, $\Delta E_{1/2}$ (V vs internal ferrocene), against the sum of resonance parameters, $\Sigma\sigma_R$, for substituted ferrocenes.

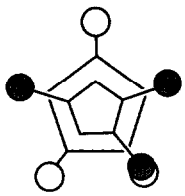
with electron-donating alkyl groups, facilitating the removal of one electron from the bonding orbital ($1e_{2g}$). On the other hand, ferrocenes with trimethylsilyl groups should be more difficult to oxidize, since the electronic effect of this silicon substituent can be summarized as the π-accepting or $-M$ effect prevailing over the weak σ-donating or $+I$ effect.[13] There is indeed an increase of the redox potential within the series $FeCp_2$, $Fe(Si_3Cp)Cp$, $Fe(Si_2Cp)_2$ in keeping with what is expected of the overall electron-withdrawing nature of the trimethylsilyl group. However, the $E_{1/2}$ value of the hexakis-substituted derivative $Fe(Si_3Cp)_2$ is unexpectedly low and is almost comparable with that of 1,1′-dimethylferrocene ($\Delta E_{1/2} = 0.12$ V).[12] The same trend is observed for $Fe(BuSi_2Cp)_2$ and $Fe(Si_3Cp)Cp^*$ when compared with $Fe(BuCp)_2$ and FeCp*Cp, respectively. We believe that this cathodic shift of the redox potential with successive substitution by trimethylsilyl groups is caused by some steric factors. Presumably there is some relief from steric constraint upon oxidation of a sterically-hindered ferrocene to give the corresponding ferrocenium ion which is less hindered due to a longer metal–ligand bond distance. A related sterically-induced shift of redox potential in distorted ferrocenes such as bridged derivatives was reported in the literature,[14] whereas in a number of studies, linear free energy relationships for redox potentials of substituted ferrocenes have been determined.[12,15]

In order to verify that oxidation is also chemically feasible we treated $Fe(Si_2Cp)_2$ and $Fe(Si_3Cp)_2$ with $AgBF_4$ in dichloromethane and isolated the corresponding ferrocenium ion, $[Fe(Si_2Cp)_2]BF_4$ and $[Fe(Si_3Cp)_2]BF_4$, as thermally stable, dark blue crystals in virtually quantitative yield according to eq. (1):

$$Fe(Si_nCp)_2 + AgBF_4 \longrightarrow [Fe(Si_nCp)_2]BF_4 + Ag. \quad n = 2, 3 \qquad (1)$$

Analytical, IR, UV–vis and Mössbauer spectroscopic data clearly indicate the structure of a cationic sandwich complex. Furthermore, we carried out an X-ray structure determination of the hexakis-substituted derivative $[Fe(Si_3Cp)_2]BF_4$. Analogous to the neutral $Fe(Si_3Cp)_2$, for which we performed a detailed conformational analysis,[4] the conformation adopted by $[Fe(Si_3Cp)_2]^+$ is derived from a nearly ideally eclipsed arrangement of the five-membered rings with one pair of trimethylsilyl groups eclipsed (conformation "e_1" of C_2 symmetry[4]). The mean ring carbon–iron distance of 2.137 Å and the ring centroid–iron distance of 1.751



Å are increased by 0.055 and 0.065 Å, respectively, compared with the ferrocene precursor $Fe(Si_3Cp)_2$. This finding clearly indicates a less sterically constrained coordination sphere in the cation. Consequently, the deviation of the two ring ligands from parallel is small, the tilt angle observed is only 4.5°. Also reduced is the degree of the substituents' bending away from the metal centre. Other structural features are comparable with those in analogous sandwich complexes of the type $E(Si_3Cp)_2$ (E = Fe,[4] Mg,[16] Ge,[17] Sn[18]). Figure 2 depicts the molecular structure of the cation, and Table 2 contains selected bond lengths and angles.

The electronic spectra of ferrocene was thoroughly analysed by Gray and co-workers[19] and complete assignment of both charge-transfer and ligand-field absorption bands was undertaken. For the substituted ferrocenes under consideration here the same pattern of one intense metal–ligand charge-transfer band and two d–d absorption bands is observed. The ligand-field absorption at the lowest wavenumber ($^1A_{1g} - {}^1E_{1g}$) is bathochromically shifted as the number of trimethylsilyl substituents at the ring periphery increases. This can qualitatively be ascribed to the electron-withdrawing effect of the trimethylsilyl substituents. However, only poor correlation ($r^2 = 0.52$) between λ_{max} values and substituent parameters such as σ_R (Fig. 3) or redox potentials, $E_{1/2}$, is observed. A good

correlation between $E_{1/2}$ and the frequencies of the *d–d* transition bands was found for a series of ferrocenes with electron-withdrawing substituents and this was rationalized in terms of the molecular

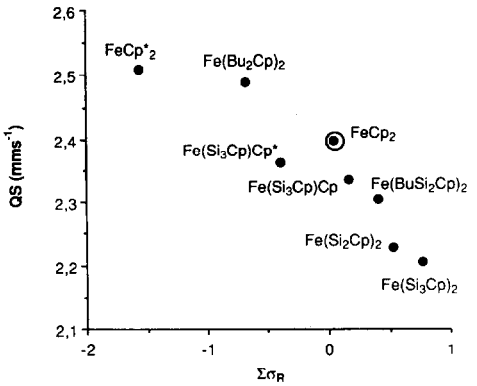

Fig. 4. Plot of quadrupole splittings, QS (mm s^{-1}), against the sum of resonance parameters, $\Sigma\sigma_R$, for substituted ferrocenes.

orbital description for ferrocene.[20] The strong charge-transfer band ($1e_{1u}-2e_{1g}$) was also used to estimate the electron-donating property of a ring ligand,[21] but this relation was not applicable here.

As was noted previously, the isomer shift, δ, in the Mössbauer spectrum of substituted ferrocenes does not significantly reflect the electronic influence of the ring substituents.[22] This is also the case for the sterically-hindered ferrocenes. However, the value of quadrupole splitting, QS, shows a dependence on the groups attached to the five-membered ring and this parameter was also successfully used to probe distortions from the parallel arrangement of the ligands in substituted ferrocenes.[23] When the QS values are plotted against the resonance parameters, $\Sigma\sigma_R$, a fair correlation ($r^2 = 0.84$) results (Fig. 4). In keeping with a reduced electric field gradient caused by introducing electron-withdrawing ring substituents,[24] the QS values for the trimethylsilyl-substituted ferrocenes are significantly decreased. Likewise, electron-donating groups tend to increase the quadrupole splitting, as has been reported recently for a series of dinuclear complexes of the type $[Fe(Bu_nCp)(CO)_2]_2$ ($n = 0$–2).[25] Thus, the QS data for the trimethylsilyl-substituted ferrocenes seem to reflect mainly the electronic effects of the substituents on the iron centre. At this point it remains questionable whether this dependence of the QS values also originates from some steric influence.

Conclusion

On examining the redox potential by cyclic voltammetry, a cathodically-shifted $E_{1/2}$ value for the hexakis-substituted ferrocene, $Fe(Si_3Cp)_2$, has been detected and interpreted as evidence for a sterically-hindered coordination sphere caused by the trimethylsilyl groups. As the solid-state structure of the $[Fe(Si_3Cp)_2]^+$ cation suggests, oxidation of $Fe(Si_3Cp)_2$ clearly leads to a less congested situation around the iron centre. Both UV–vis and Mössbauer spectroscopic data are consistent with the slightly electron-withdrawing property of the trimethylsilyl substituent. This effect, however, is less pronounced than an alkyl group such as methyl or tert-butyl which is electron-donating. Accordingly, a trimethylsilyl group represents a ring substituent that allows the study of the steric effects on ring-substituted cyclopentadienyl metal complexes without inducing a strong electronic perturbation of the metal–ligand bonding.

EXPERIMENTAL

General consideration

All experiments were carried out under nitrogen using standard Schlenk techniques. Solvents were purified, dried and distilled under nitrogen. 1,1′,3,3′-tetra(tert-butyl)ferrocene $[Fe(Bu_2Cp)_2]$,[1] 1,1′,3,3′-tetrakis(trimethylsilyl)ferrocene $[Fe(Si_2Cp)_2]$,[3,7] 1,2,4-tris(trimethylsilyl)ferrocene $[Fe(Si_3Cp)Cp]$,[4] (1,2,3,4,5-pentamethyl)[1′,2′,4′-tris(trimethylsilyl)]ferrocene $[Fe(Si_3Cp)Cp^*]$,[4] 1,1′,2,2′,4,4′-hexakis(trimethylsilyl)ferrocene $[Fe(Si_3Cp)_2]$[4,8] and 4,4′-di(tert-butyl)-1,1′,2,2′-tetrakis(trimethylsilyl)ferrocene $[Fe(BuSi_2Cp)_2]$[5] were prepared as described in the literature.

IR spectra were recorded as KBr pellets with a Nicolet FT–5DX instrument. UV–vis spectra were obtained using dichloromethane solutions with a Perkin–Elmer Lambda 2 spectrophotometer. ^{57}Fe Mössbauer spectroscopic measurements were obtained with a $^{57}Co(Rh)$ source moving in a sinusoidal velocity mode at room temperature. Isomer shifts, δ, and quadrupole splittings, QS, were recorded relative to metallic iron foil. Cyclic voltammograms were recorded with a computer-controlled PAR Model 173 potentiostat. A conventional three-electrode configuration (platinum auxiliary electrode, an Ag/AgCl reference electrode and a glassy carbon working electrode) was employed. Tetra-n-butylammonium hexafluorophosphate was used as supporting electrolyte. Redox potentials were calculated by using the formula $E_{1/2} = 1/2(E_p^{ox} + E_p^{red})$, where E_p^{ox} and E_p^{red} are peak potentials. Elemental analyses were performed by the Microanalytical Laboratory of the Anorganisch-chemisches Institut.

$[Fe(Si_2Cp)_2]BF_4$

To a mixture of $Fe(Si_2Cp)_2$ (0.35 g, 0.74 mmol) and $AgBF_4$ (0.14 g, 0.74 mmol) was added 15 cm^3 of dichloromethane. Immediately, the colour of the

mixture darkened and the mixture was left stirring for 2 h to give a dark green solution. The silver metal was filtered off and the filtrate concentrated to a few cm^3. Ether was layered on top of the solution and after standing overnight at room temperature, dark blue, lustrous platelets were isolated: yield 0.32 g (78%); m.p. 195°C. IR (cm^{-1}): 3098 w, 2954 mw, 2898 w, 1410 m, 1254 s, 1191 m, 1054 s, 891 s, 841 br vs, 754 s, 691 m, 629 m. UV–vis (CH_2Cl_2, ε): λ_{max} 645.5 nm (560), 506 (280), 398 (560), 306.5 (11,740), 269 (14,360), 227 (91.50). Mössbauer: δ 0.441(7) mm s^{-1}. Found: C, 47.0; H, 7.5; Fe, 10.0. Calc. for $C_{22}H_{42}BF_4FeSi_4$: C, 47.0; H, 7.5; Fe, 9.9%.

$[Fe(Si_3Cp)_2]BF_4$

The compound was prepared in a manner analogous to that used to prepare $[Fe(Si_2Cp)_2BF_4$ and was isolated as lustrous, black cubes in 88% yield; dec. > 250°C. IR (cm^{-1}): 2959 m, 2902 w, 1414 w, 1248 s, 1095 ms, 1060 s, 1048 s, 924 mw, 902 w, 842 br s, 757 ms, 694 mw, 633 mw. UV–vis (CH_2Cl_2, ε): λ_{max} 662 nm (460), 548 (370), 420.5 (840), 323 (10,320), 288 (9910), 227 (11,450). Mössbauer: δ 0.518(1) mm s^{-1}. Found: C, 47.5; H, 8.1; Fe, 8.0. Calc. for $C_{28}H_{58}BF_4FeSi_6$: C, 47.6; H, 8.3; Fe, 7.9%.

Crystal structure determination

Crystal data and details of the X-ray diffraction experiments were reported in Table 3. The compound, obtained as black cubes by layering ether on top of a dichloromethane solution, crystallizes in the monoclinic space group $P2_1/n$ (No. 14). Cell constants were obtained from least-squares refinement by using a set of 44 reflections in the range $34.2° \leqslant 2\theta \leqslant 44.7°$. The iron atom was determined from the Patterson function. All remaining non-hydrogen atoms were located by successive structure factor calculations and difference Fourier maps. Not all hydrogen atoms were found; their ideal positions were added to the calculations but not refined. The tetrafluoroborate ion is partially disordered. A second orientation is obtained from the first by a C_3 rotation about the B(1)—F(1) axis. Occupancies refined to 50% for each of the orientations. Maximum residual electron density of +0.88 e $Å^{-3}$ near the fluorine atoms indicates that the disorder model is imperfect. The refinements converged with unweighted and weighted agreement factors, $R = 0.058$ and $R_w = 0.047$, respectively. All crystallographic calculations were performed on VAX11/730 and VAX8200 computers using SDP[26] and STRUX II[27] systems. Atomic coordinates and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre.

QUALITATIVE MODELS FOR THE NMR CHEMICAL SHIFTS OF INTERSTITIAL ATOMS IN CLUSTERS

MELINDA J. DUER and DAVID J. WALES*

University Chemical Laboratories, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 27 *November* 1990; *accepted* 15 *April* 1991)

Abstract—Qualitative models for the NMR chemical shifts of interstitial atoms in clusters are presented which draw heavily upon our present understanding of cluster bonding. The deshielding of interstitial hydrogen atoms can be understood in terms of secondary paramagnetic fields arising on the transition metal centres, whilst that of interstitial carbon and nitrogen atoms is thought to arise from more local sources. In these models, Stone's Tensor Surface Harmonic theory is used to describe the interaction between the interstitial atoms and the metal cluster framework. Model calculations of the susceptibility tensor for $[Ru_6H(CO)_{18}]^-$ and the electronic structures of $[Rh_6C(CO)_{15}]^{2-}$ and $[Rh_6N(CO)_{15}]^-$ support the proposals.

The NMR shielding in a molecule, and hence the chemical shift, depends upon the induced current in the presence of an external magnetic field. To predict the effect of such a field upon the molecular electron density is generally not a simple matter, but much progress has been made, for example, in organic molecules where the bonding is well understood.[1] Successful models have also been developed for the chemical shifts of the central metal atom in octahedral transition metal complexes[2] and for hydride ligands in mononuclear transition metal complexes.[3] However, the bonding in all these systems is relatively simple compared with that in a transition metal cluster. Drawing from the great advances made in understanding the bonding in the latter molecules in recent years, and Stone's Tensor Surface Harmonic (TSH) theory in particular,[4,5] we propose a simple, qualitative model for the chemical shifts of interstitial atoms in a cluster. Estimates of the susceptibility tensor for $[Ru_6H(CO)_{18}]^-$ and electronic structure calculations for $[Rh_6C(CO)_{15}]^{2-}$ and $[Rh_6N(CO)_{15}]^-$ using the Fenske–Hall approximate molecular orbital treatment support this model.

TSH theory has proved to be a highly versatile tool for the discussion of the bonding in cluster compounds.[6] In particular, the method has been used to provide a firmer theoretical foundation for empirical rules of cluster electron counting such as the *Debor Principle*[7] and the *Polyhedral Skeletal Electron Pair Theory*.[8] TSH theory is based upon an approximate descent in symmetry from the full rotation group. Basis functions are classified as σ, π and δ according to the number of nodal planes they possess which contain the radius vector from the centre of the cluster to the atom. Cluster orbitals are formed from σ-type basis functions (with no nodal planes containing the radius vector) using the values of spherical harmonics evaluated at the cluster vertices as expansion coefficients. A helpful comparison may be made with the Hückel wavefunctions for cyclic and linear polyenes: the appropriate linear combinations can be obtained from the wavefunctions for a free electron on-a-ring or in-a-box, respectively. For an approximately spherical cluster we use the eigenfunctions for a free electron on-a-sphere in a similar manner to construct and classify cluster wavefunctions. For example, a σ cluster orbital, $\psi^{\sigma}_{L,M}$ is given by

$$\psi^{\sigma}_{L,M} = \sum_i Y_{L,M}(\theta_i, \phi_i)\sigma(i), \qquad (1)$$

where θ_i and ϕ_i are the angular spherical polar coordinates of vertex i.

To treat π- and δ-type basis functions (which have one and two nodal planes containing the radius vector, respectively) we proceed in a similar manner but use the values of tensor spherical harmonics as expansion coefficients. For further details

the reader is referred elsewhere.[5] Recently the method has been extended to consider detailed cluster structure,[9] cluster rearrangements[10] and the relationship between shape and electronic structure.[11]

For $\psi^{\lambda}_{L,M}$ ($\lambda = \sigma, \pi, \delta$) the L and M subscripts reflect the parentage of the orbital under spherical symmetry, where they are good quantum numbers. In a finite point group we find that functions with different L or M do not mix with each other strongly, and hence that L and M are very useful symmetry labels. Furthermore, the cluster orbitals transform under rotations of the point group in the same way as the parent spherical harmonic upon which the expansion coefficients are based. Under reflections, inversions and other "improper" symmetry operations they may transform in the same way or with a change of sign.[9]

NMR SHIELDING—THE RAMSEY THEORY

In this section we summarize the theory of the NMR chemical shift and so introduce the problem to be addressed, bearing in mind that this material may be relatively unfamiliar to cluster chemists. The shielding tensor, σ_{ij}, is defined by

$$\mathbf{B}' = \mathbf{B} - \sigma\mathbf{B}, \tag{2}$$

where $\mathbf{B}$ is the applied field and $\mathbf{B}'$ is the resulting field at the nucleus. Using perturbation theory to express the ground state wavefunction correct to first order in the applied magnetic field and taking the expectation value for the classical expression for $\mathbf{B}'$ gives[12]

$$\sigma_{zz} = \frac{e^2\mu_0}{8\pi m_e}\langle 0|(x^2+y^2)/r^3|0\rangle - \frac{e^2\mu_0}{4\pi m_e^2}\sum_{n>0}\frac{\langle 0|L_z|n\rangle\langle n|L_z/r^3|0\rangle + c.c.}{E_n^0 - E_0^0}, \tag{3}$$

where E_n^0 is the unperturbed energy of state $\psi_n \equiv |n\rangle$, L_z is the z component of the angular momentum operator, $\mathbf{L}$, and *c.c.* denotes the complex conjugate of the previous term in the numerator. This expression, and the analogous terms for the other components of σ, was first given by Ramsey.[13]

The first term depends only upon the ground-state wavefunction and corresponds to the precession of the molecular electron density about the direction of the magnetic field. It is known as the diamagnetic contribution. The second term involves the induced mixing of the ground state with excited states, and is known as the paramagnetic term. It is by reference to the matrix elements of this term that we later rationalize the chemical shift trends in transition metal cluster molecules.

The large, negative values of δ for hydrogen bound to a transition metal complex have been explained by Buckingham and Stephens[3] in terms of a large (anisotropic) paramagnetic shielding contribution (i.e. positive σ) from the metal atom. Essentially, a paramagnetic current centred on the transition metal atom/ion creates a magnetic field which supports the applied field at the transition metal nucleus, but may oppose the applied field at a hydride ligand bound to the transition metal ion. This is illustrated in Fig. 1.

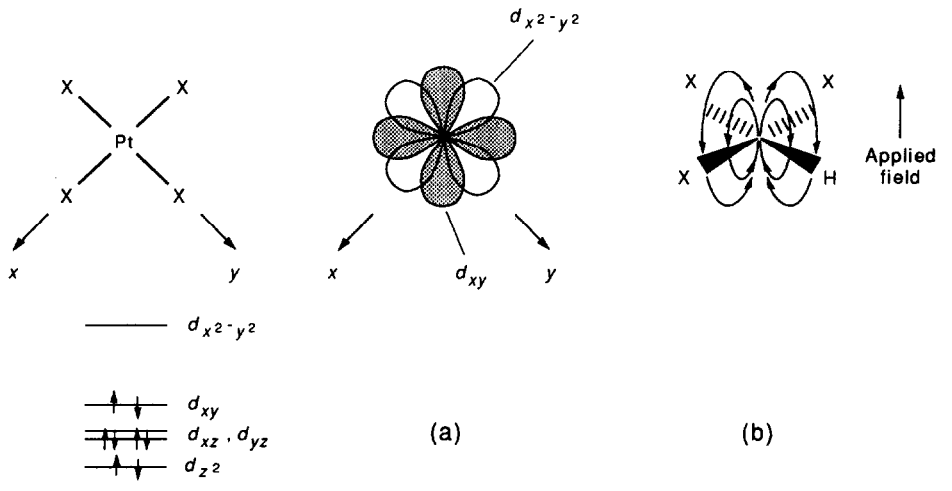

Fig. 1. An induced paramagnetic field arises when a d^8 transition metal ion with square planar coordination is placed in a magnetic field. (a) Electrons from the d_{xy} orbital, for instance, are "rotated" about the z axis into the higher energy $d_{x^2-y^2}$ orbital. This creates the field shown in (b) which supports the applied field at the transition metal centre.

The paramagnetic current arises from the admixture of excited "paramagnetic" mostly *d* electron states into the ground state, through the perturbation provided by the magnetic field. This admixture of excited states may be thought of in one-electron terms as the "rotation" of *d* electrons from a filled or partially filled *d* orbital into higher energy, vacant (or half-filled) *d* orbitals. This "rotation" of charge then gives rise to the magnetic field supporting the applied field at the transition metal nucleus. The precise location of the hydride ligand then determines whether the induced magnetic field has a shielding or a deshielding effect at this nucleus.

In contrast to terminally bound hydride ligands, interstitial hydrogen atoms in clusters are generally only weakly shielded or are deshielded relative to atomic hydrogen. Clearly, the much more complicated electronic structures of cluster molecules do not lend themselves to an analysis as simple as that for single-centre, transition metal complexes. Nevertheless, it is one of the aims of this paper to show how paramagnetic currents on the transition metal atoms, which induce secondary magnetic fields centred on the transition metal atom, may cause the very large chemical shifts of interstitial hydride ligands. Our other aim is to explain the range of chemical shifts observed for clusters with interstitial carbon and nitrogen atoms. A consistent framework must account for the following features:

(i) The chemical shifts of interstitial protons in both symmetrical and unsymmetrical cluster environments.
(ii) Differences between the chemical shifts of interstitial carbon and nitrogen atoms relative to hydrogen.
(iii) Differences between the chemical shifts observed for interstitial carbon and nitrogen atoms in geometrically similar clusters.
(iv) The variation of chemical shifts between octahedral and trigonal prismatic clusters for carbon and nitrogen interstitial atoms.
(v) Variations of chemical shift in analogous clusters with different metal atoms.

We draw heavily upon the TSH description of cluster bonding in the course of rationalizing these trends, even for interstitial hydrogen atoms where a neighbouring group approximation is employed.

CHEMICAL SHIFTS OF INTERSTITIAL PROTONS

We first consider a proton in a symmetrical environment at the centre of a cluster. It is well known that the chemical shifts of protons in the vicinity of aromatic rings can be explained by considering the "ring current" induced by an applied field. In the case of an octahedral cluster, such as $[Ru_6H(CO)_{18}]^-$ or $[Co_6H(CO)_{15}]^-$, the skeletal bonding is essentially delocalized in three dimensions. Hence, on the application of a magnetic field we might expect to observe effects due to a "cylindrical current" arising from a set of current loops. The induced precession of the molecular electron density can be discussed in terms of Larmor Precession or Lenz's Law: the magnetic field of the induced current opposes the change of flux through the electronic orbits (assumed globally delocalized over the cluster skeleton). This term is clearly shielding at the centre of the cluster (Fig. 2).

The above argument considers the diamagnetic contribution to the shielding which correspond to the first term in eq. (3). For a cluster compound with many electrons, the picture of circulating, delocalized currents implies that σ^d is much larger than for the free hydrogen atom; an estimate could be obtained from the Flygare–Goodisman formula.[14] However, there is still the paramagnetic term to consider and this is expected to cancel out much of the diamagnetic effect. In fact, the interstitial protons in both $[Ru_6H(CO)_{18}]^-$ and $[Co_6H(CO)_{15}]^-$ are deshielded with respect to the hydrogen atom and shielded with respect to the bare nucleus. Theoretically we know that the hydrogen 1*s* orbital mixes weakly with an in-pointing S^σ cluster orbital to give bonding and antibonding combinations, leaving the interstitial atom formally associated with two electrons and the energy level pattern of the parent octahedron relatively unperturbed. To calculate the approximate shielding of the hydride nucleus we employ the neighbouring group approximation,[15] where the cluster metal atoms are represented as point magnetic dipoles. The limitations of this approach have been discussed before;[3] however, we feel justified in employ-

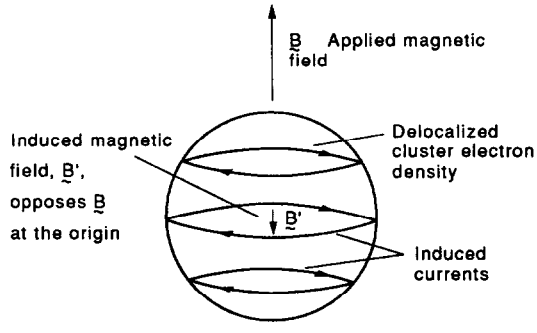

Fig. 2. The induced magnetic field will act to oppose the applied field and lead to shielding of a nucleus at the centre of a spherical cluster with delocalized skeletal bonding.

ing the method in the context of the modest aims of these calculations. The induced field arising on each transition metal atom is then calculated from the magnetic susceptibility tensor, $\chi_{\alpha\beta}$, of the atom using

$$M_\alpha = \chi_{\alpha\beta} H_\beta, \tag{4}$$

where **M** is the associated magnetization. The susceptibility tensor for a transition metal cluster may be written as a sum over the atoms in the cluster. The contribution from a given atom n, is

$$\chi_{zz} = -\frac{e^2\mu_0 N_A \rho}{8\pi m_e M_m} \sum_{i=1}^{Z_n} \langle 0|x_i^2 + y_i^2|0\rangle + \frac{e^2\mu_0 N_A \rho}{4\pi m_e^2 M_m} \sum_{k>0} \frac{\left\langle 0\left|\sum_{i=1}^{Z_n} L_z^i\right|k\right\rangle\left\langle k\left|\sum_{i=1}^{Z_n} L_z^i\right|0\right\rangle + c.c.}{E_k^0 - E_0^0}, \tag{5}$$

where N_A is Avogadro's number, ρ is the density of the sample, M_m is the molar mass, Z_n is the atomic number of nucleus n. All the coordinates are referred to an origin at the local nucleus in question. This form may be derived by explicit transformation of origins[16] or by noting that all the components of the total susceptibility tensor must be gauge-independent. At each atom the local z axis points away from the global origin, which we chose at the centre of the cluster. The shielding at the hydrogen nucleus is then calculated from the total field it experiences due to the induced fields from all the transition metal atoms n:

$$\sigma \approx \frac{M_m}{12\pi\rho N_A} \sum_n (\chi_\parallel^n - \chi_\perp^n) \frac{(1 - 3\cos^2\theta_n)}{R_n^3}, \tag{6}$$

where θ_n is the angle between the radius vector of atom n and the internuclear vector from the interstitial atom to that nucleus, R_n is the distance between the latter atoms and we have assumed local axial symmetry. The expression includes a sum of contributions from all metal atoms in the cluster. It gives an estimate of the shift relative to a hydrogen atom because the diamagnetic contribution local to the interstitial atom has been omitted.

Now we can employ the TSH theory description of the cluster bonding to study the above expressions. The skeletal bonding in an octahedral cluster is essentially delocalized, so we must consider the matrix elements of delocalized cluster orbitals and the true cluster energy levels. The lowest energy virtual excitations in an electron delocalized deltahedral cluster are from L^π to $\overline{L^\pi}$ cluster orbitals, which are linear combinations of p^π and d^π atomic orbitals that have one nodal plane containing the atomic radius vector.[5] In local axes these orbitals are characterized by an m quantum number of ± 1. Now the local angular momentum operators have the following selection rules: for L_z, $\Delta m = 0$ and for L_x and L_y, $\Delta m = \pm 1$ (recall that the latter are linear combinations of the raising and lowering operators). Hence for all the cluster vertices we will have $\chi_\parallel > \chi_\perp$, because all the ψ in question consist mainly of local p^π and d^π functions for which $|m| = 1$. This result should be independent of the precise position of the interstitial atom in the octahedral cavity. When the proton is at the centre of the cluster, $\theta_n = 0$ for all the cluster vertices and σ is negative, i.e. deshielding relative to the hydrogen atom, in agreement with the shifts of $\delta = 23.2$ and 16.4 ppm for the cobalt and ruthenium clusters mentioned above. When the proton moves away from the centre of the cluster some of the θ_n increase from zero and the deshielding due to these terms decreases. Hence we expect the deshielding to be greatest at the centre of a symmetrical cluster. The neighbouring group terms can actually be shielding for larger θ values which may arise for protons in unsymmetrical environments, such as the tetrahedral cavities associated with capping atoms on an octahedron. Furthermore, the TSH bonding description is most appropriate for roughly spherical clusters.[5]

Experimental values of interstitial hydride shifts measured to date are summarized in Table 1; most are qualitatively in accord with the foregoing theory, with positive chemical shifts. The nickel clusters, however, have negative shifts. In these clusters, the hydride ligands effectively cap an interior face of the nickel polyhedron, and are not at all near the centre of an approximately spherical cavity within the cluster. We would expect the hydride ligands in these compounds to behave more like those which cap an exterior face of a cluster. We will not attempt to explain here the precise differences in chemical shift between the deshielded hydrides, since small details of geometry and electronic structure could be significant in determining the magnitude of the deshielding.

To further investigate the validity of our approach some model calculations were performed for $[Ru_6H(CO)_{18}]^-$ as a typical cluster molecule with a deshielded interstitial hydride. All molecular orbital calculations were carried out using the Fenske–Hall method,[17] using tabulated exponential factors for the metal atom.[18] Input molecular geometry was the published structure determined by neutron diffraction[19] and is illustrated in Fig. 3(a). Calculations were also performed for a $[Ru_6H(CO)_{18}]^-$ anion, where the hydrogen atom was placed on the exterior of the metal cluster as

Table 1. Experimental chemical shifts of hydrides for which interstitial geometries have been proposed

Structure	δ (ppm)	Hydride environment
$[Co_6H(CO)_{15}]^-$	+23.2	Octahedral[24]
$[Ru_6H(CO)_{18}]^-$	+16.4	Octahedral[19]
$[Ru_8H_2(CO)_{21}]^{2-}$	+6.88[a]	Octahedral[25]
$[Ru_{10}HC(CO)_{24}]^-$	+0.2	Tetrahedral[26]
$[Ni_{12}H(CO)_{21}]^{3-}$	−24.0	Distorted octahedral,
$[Ni_{12}H_2(CO)_{21}]^{2-}$	−18.0	(3 long, 3 short Ni—H)[28]
$[Rh_{13}H_{5-n}(CO)_{24}]^{n-}$	−16.7 ($n = 3$[b])	Unknown[28]
	−14.3 ($n = 2$[b])	

[a] Note that the proton nucleus giving rise to this signal was not located in the X-ray structure, but was postulated to be interstitial.[26]

[b] The hydrides were postulated to be interstitial from the results of a solution NMR study. However, their precise environment is clearly very important in determining the chemical shift, as discussed in the text; we will not consider these compounds any further here.

shown in Fig. 3(b). These calculations are intended only to demonstrate the qualitative trends in the ^1H chemical shift with changes of the hydride position, and are not expected to give quantitative answers.

We concentrate initially on the $[Ru_6H(CO)_{18}]^-$ anion with an interstitial hydride. The molecular orbital calculation places a charge of −0.4 on the interstitial hydride ligand, confirming that it is not a partial positive charge on the hydride that causes the deshielding of the proton nucleus. In the corresponding metal cluster with an interstitial carbide ligand, the deshielding of the ^{13}C nuclear resonance is ascribed to the carbonium ion nature of the carbon atom.[20]

The paramagnetic part of χ is given in general by Van Vleck's formula:

$$\chi_{\alpha\beta} = \frac{e^2\mu_0 N_A \rho}{4m_e^2 M_m} \sum_{n>0}' \left\{ \frac{\langle 0|l_\alpha|n\rangle\langle n|l_\beta|0\rangle + c.c.}{E_n - E_0} \right\}. \quad (7)$$

Clearly, there is little we can do with this expression without a knowledge of the excited states, $|n\rangle$. Therefore, we approximate the variable energy denominator $(E_n - E_0)$ with a constant Δ, and use the closure approximation to obtain:

$$\chi_{\alpha\beta} = \frac{e^2\mu_0 N_A \rho}{2m_e^2 M_m \Delta} \langle 0|l_\alpha l_\beta|0\rangle. \quad (8)$$

If the ground state is written in terms of molecular orbitals which are themselves linear combinations

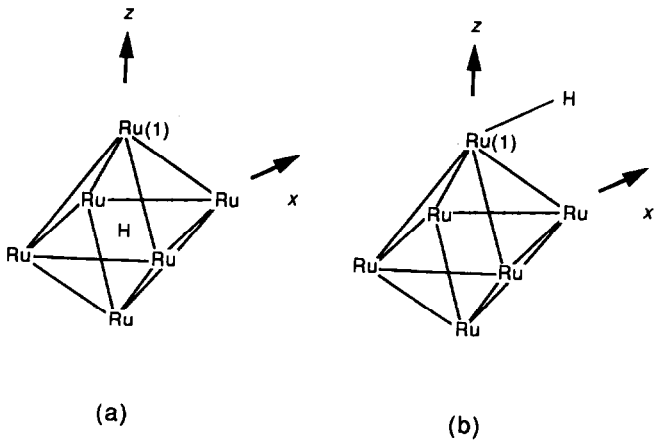

Fig. 3. (a) The structure of the $[Ru_6H(CO)_{18}]^-$ anion in the PPN salt. (b) The structure of the hypothetical $[Ru_6H(CO)_{18}]^-$ anion with an external hydride. The Ru(1)—H distance is 2.03 Å in both cases. In (b) the Ru—H vector is parallel to the x axis.

of atomic orbitals, ϕ, then the above equation becomes

$$\chi_{\alpha\beta} = \frac{e^2\mu_0 N_A \rho}{2m_e^2 M_m \Delta} \sum_j \left\{ \sum_{\nu,\mu} a^*_{\nu j} a_{\mu j} \langle \phi_\nu | l_\alpha l_\beta | \phi_\mu \rangle - \sum_{j'} \sum_{\nu,\mu} \sum_{\lambda,\rho} a^*_{\nu j} a_{\mu j} a^*_{\lambda j'} a_{\rho j'} \langle \phi_\nu | l_\alpha | \phi_\rho \rangle \langle \phi_\lambda | l_\beta | \phi_\mu \rangle \right\}. \quad (9)$$

The subscripts j and j' denote filled molecular orbitals. Equation (9) can also be written in terms of the atomic charges and bond order matrix elements. It can be used to calculate the contribution of a single transition metal atom to the total susceptibility of the molecule if we assume that all the integrals $\langle \phi_\nu | l_\alpha l_\beta | \phi_\mu \rangle$ and $\langle \phi_\nu | l_\alpha | \phi_\mu \rangle$ are negligible if ϕ_ν and ϕ_μ are atomic orbitals on different centres. The sum over atomic orbitals is then restricted to those valence d and p orbitals on the transition metal atom of interest. The resulting susceptibility tensor allows us to calculate the magnetic field arising from paramagnetic currents on that atom. Because the local site symmetry of a ruthenium atom in the octahedral cluster closely approximates C_{3v}, the susceptibility tensor should be approximately diagonal in the local axis frame where the z axis points radially outwards, as above. We estimate the diagonal components to be $\chi_{xx} = 5.71K/\Delta$, $\chi_{yy} = 5.72K/\Delta$ and $\chi_{zz} = 5.79K/\Delta$, where $K = e^2\mu_0 N_A \rho / m_m^2 M_m$ and χ is indeed approximately axial. Then using eq. (6) with $R = 3.86$ bohr, we obtain $\sigma = -0.046/\Delta$ ppm (with Δ measured in hartrees), i.e. deshielded. The HOMO–LUMO gap found in our molecular orbital calculation is 0.07 hartrees (1.7 eV), so that $\sigma = -0.8$ ppm is the contribution to the shielding from each ruthenium centre. This gives the total contribution to σ^p from all six ruthenium atoms around the ^{1}H nucleus as about -5 ppm, i.e. deshielding, which is certainly of the correct order of magnitude.

Using the molecular orbitals calculated for the $[Ru_6H(CO)_{18}]^-$ molecule shown in Fig. 3(b), with an external hydride, we find that the contribution from Ru(1) is $\sigma = 0.026/\Delta$ ppm, i.e. shielded. This is equivalent to $\sigma = 0.7$ ppm for $\Delta = 1$ eV.

The valence d and p orbital populations arising from the Fenske–Hall molecular orbital calculations for both the above molecules are given in Table 2. We note that the d orbital splittings (and indeed populations) change little with the position of the hydrogen atom, as expected.

Table 2. Valence d and p orbital populations of Ru(1) calculated for the structures shown in Fig. 3(a) and (b)

Orbital	(a)	(b)
$4d_{xz}$	0.85	0.84
$4d_{yz}$	0.90	0.95
$4d_{xy}$	1.05	1.03
$4d_{x^2-y^2}$	1.08	1.15
$4d_{z^2}$	1.36	1.33
$5p_z$	0.07	0.06
$5p_y$	0.08	0.09
$5p_x$	0.10	0.12

INTERSTITIAL CARBON AND NITROGEN ATOMS

Above we found that protons in symmetrical, interstitial positions in a cluster are deshielded relative to a hydrogen atom, due to the local field arising from the surrounding transition metal atomic centres. When carbon and nitrogen atoms occupy the centre of an octahedral cluster the deshielding is still more dramatic, even relative to the bare nucleus. A range of values for clusters of interest is given in Fig. 4.†

The presence of valence shell $2s/2p$ orbitals for carbon and nitrogen, which interact with the skeletal cluster orbitals, causes a large, paramagnetic term at the interstitial atom itself. In an octahedral cluster the $2s$ and $2p$ orbitals of these interstitial atoms interact with the inwardly hybridized S^σ and P^σ/P^π cluster orbitals which transform as A_{1g} and T_{1u}, respectively.[5] Bonding and antibonding combinations are formed, of which only the bonding sets are occupied, and the interaction is too large for the neighbouring group approximation applied above to be realistic.

If we denote the bonding and antibonding t_{1u} orbitals by t_{1u} and t^*_{1u}, respectively, then the ground electronic configuration may be denoted by $|t^6_{1u}(^1A_{1g})\rangle$, where we omit the other filled orbitals. The configuration $|t^5_{1u}t^*_{1u}(^1T_{1g})\rangle$ generates a term of symmetry $^1T_{1g}$, and since $\mathbf{L}$ transforms as T_{1g}, the integral

$$\langle t^6_{1u}(^1A_{1g})|\mathbf{L}|t^5_{1u}t^*_{1u}(^1T_{1g})\rangle \quad (10)$$

may be non-zero. Such terms produce a paramagnetic contribution to σ which is deshielding for a central interstitial atom, as *local* paramagnetic effects always are, and larger than the non-local deshielding experienced by interstitial protons. The $|t^5_{1u}t^*_{1u}(^1T_{1g})\rangle$ state is the only excited state which needs to be considered. The $2s/S^\sigma$ bonding and antibonding orbitals, a_{1g} and a^*_{1g}, cannot contribute to

† This tabulation was kindly prepared for us by Dr Joan Mason.

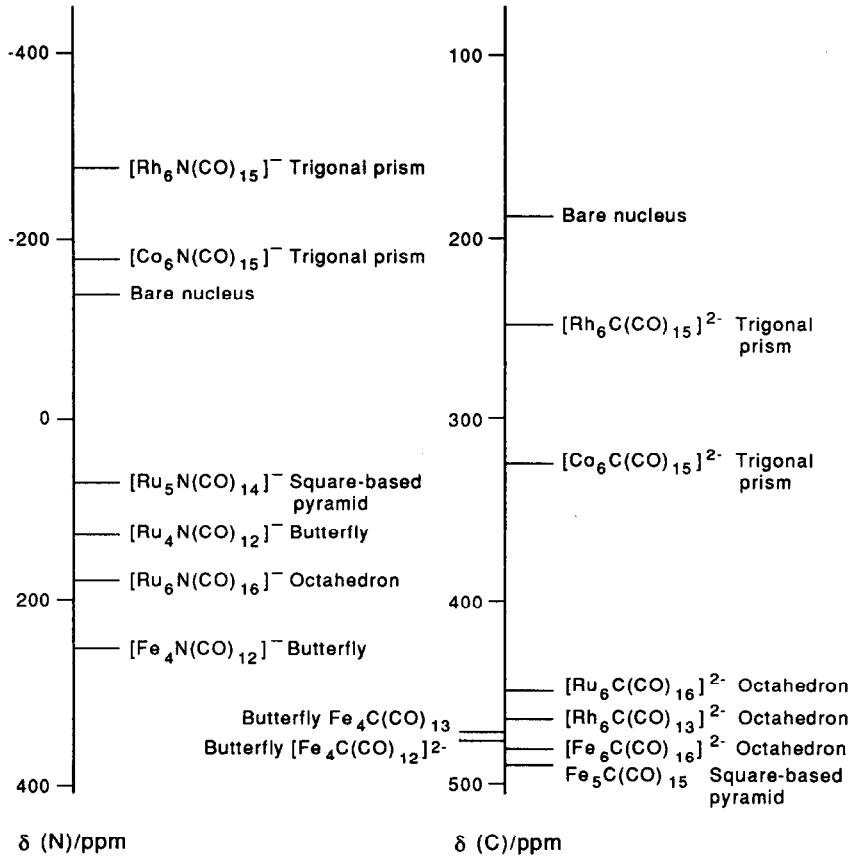

Fig. 4. NMR chemical shifts for interstitial carbon (right) and nitrogen (left) atoms. The origins are for TMS ($SiMe_4$) for carbon and nitromethane ($MeNO_2$) for nitrogen.

the paramagnetic term in this way; the same is true for the $1s/S^{\sigma}$ combinations present for interstitial hydrides. Furthermore, a $^1T_{1g}$ term formed by exciting an electron from the a_{1g} orbital (which is mostly interstitial s in character) to a t_{1g} orbital (with no interstitial s character) is likely to lie rather high in energy. Such contributions are therefore expected to be small.

Hence the shielding of an interstitial carbon or nitrogen atom is rather different from that of a proton. If the critical electronic state is relatively low-lying and the non-vanishing matrix elements have appreciable magnitude, then we expect deshielding relative to the bare nucleus. Furthermore, since the mechanism is now essentially local, the deshielding is greater than for interstitial hydrides. The Extended Hückel calculations for the idealized $[Ru_6C(CO)_{18}]^{2-}$, performed by Wijeyesekera and Hoffmann, support the above model.[21] They show that the bonding and antibonding combinations of $2p$ and P^{σ} orbitals are split by *ca* 4–5 eV in this cluster, so that the energy difference in the denominator of the expression for σ^p would not be excessive.

From Fig. 4 we note that, relative to the bare nuclei, interstitial carbon atoms in cobalt and rhodium trigonal prisms are more deshielded than interstitial nitrogen atoms. However, for the octahedra $[Ru_6C(CO)_{16}]^{2-}$ and $[Ru_6N(CO)_{16}]^{-}$ the deshielding of the interstitial atoms is quite similar, and is greater for the nitrogen atom. Equation (5) suggests that two factors will influence the magnitude of the deshielding: the matrix elements of **L** and the energy difference which appears in the denominator. The valence orbitals of the main group atoms are low-lying compared with those of the metal atoms, and if they did not mix at all then the main group atom would be formally associated with filled $2s$ and $2p$ shells. The matrix elements of the angular momentum operator between such a ground configuration and one involving promotion of a "$2p$" electron to a vacant P^{σ} orbital would be small. Hence, the stronger the metal–interstitial interaction, the greater we expect the deshielding to be. This agrees with both the larger deshielding (relative to the bare nucleus) experienced by the less electronegative interstitial carbon atom in the trigonal prismatic clusters, and with the results of

model calculations described in the next section. However, experience suggests[5] that the energy difference in the denominator will be larger for the octahedral clusters than the trigonal prisms, while the overlap of interstitial and metal valence orbitals should be more favourable, as discussed below. Clearly more data is needed to discern any patterns that may be present, as the identity of the metal must also be important.

CHEMICAL SHIFT AND CLUSTER GEOMETRY

From the data in Fig. 4, we see that interstitial carbon and nitrogen atoms are more deshielded in octahedral clusters than in trigonal prisms. In these metal clusters (with a relatively large density of electronic states) it is likely that the strength of the metal–interstitial interaction is the most variable factor, rather than the energy difference in the denominator. The skeletal bonding orbitals of the trigonal prism can be presented as edge-localized two-centre, two-electron bonds, but for the octahedron the skeletal bonding is delocalized.[6] This, and the fact that the inwardly hybridized p^{σ} orbitals of the octahedron are ideally oriented for overlap with the $2p$ orbitals of the interstitial atom, means that the critical matrix elements of $\mathbf{L}$ are larger for the octahedra. Hence σ^{p} is larger in magnitude (i.e. more negative) and there is a greater deshielding effect in the octahedron.

We would also expect the deshielding to be smaller for an interstitial proton in a trigonal prism than at the centre of an octahedron. In this case we refer back to the neighbouring group model and consider the change in the composition of the frontier orbitals and the effect this has on the local susceptibilities. From the edge-localized bonding pattern of the trigonal prism we know that the frontier orbitals may be written as linear combinations of localized σ-type edge-bonds and antibonds. We expect to find around 33% σ character in the frontier orbitals of a trigonal prism, in contrast to the electron delocalized octahedral clusters, where the frontier orbitals are well described as linear combinations of local π orbitals. To calculate the susceptibility tensors for the metal atoms of the trigonal prism, we define local axes frames (x, y, z) on each atom, rather than $\parallel$ and $\perp$, since the site symmetries are now lower than C_{3v}. The z axis points from the interstitial atom towards the metal atom in each case. Whereas a frontier orbital composed of local π orbitals gives rise to zero matrix elements with L_x and L_y, and to non-zero ones only with L_z, the frontier orbitals in the trigonal prism admit non-zero L_x, L_y matrix elements. This is simply because of the mixing between σ and π cluster orbitals. Hence, we may expect a smaller difference between χ_{xx} (or χ_{yy}) and χ_{zz} in the trigonal prism and, consequently, less deshielding.

To investigate further we performed calculations on the trigonal prismatic clusters $[Rh_6C(CO)_{15}]^{2-}$ and $[Rh_6N(CO)_{15}]$ and octahedral $Ru_6C(CO)_{17}$ using the Fenske–Hall method[17] and tabulated exponential factors for the metal atoms.[18] The geometries of the two trigonal prisms are available from X-ray crystallography, while the octahedral geometry was constructed from idealized parameters.[21]

For the two trigonal prisms (Fig. 5) the cage–

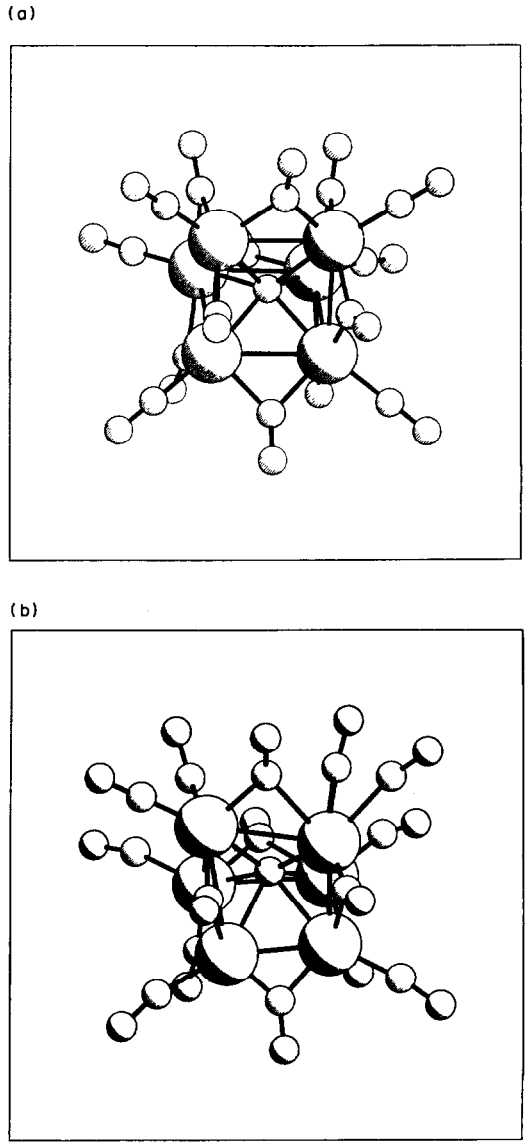

Fig. 5. The structures of (a) $[Rh_6C(CO)_{15}]^{2-}$ and (b) $[Rh_6N(CO)_{15}]^{-}$.

interstitial overlap integrals were found to be around 20% smaller for the nitrogen atom, as expected, and the most significant mixing in both cases was between 2*s* and $S^{\sigma}_{d_{z^2}}$ and 2*p* and $P^{\sigma}_{d_{z^2}}$. The corresponding overlap integrals for the trigonal prisms were found to be only about half the magnitude of those in the octahedral cluster. Both these observations are in accord with the ideas discussed above and with the bonding descriptions of the two types of cluster.

The Mulliken 2*p* atomic orbital populations[22] are also in agreement with the model, lying between 1.4 and 1.8 for the nitrogen and 1.2 and 1.3 for the carbon in the trigonal prismatic cluster, compared with 1.05–1.1 for the carbon atom in the octahedral cluster. The calculated Mulliken atomic charges were −1.7, −1.8 and −0.8 in the same order. These are around 10 times larger than those found using the Extended Hückel method for interstitial carbon atoms in hypothetical cobalt compounds with the same cluster geometries but with hydride ligands instead of carbonyls and large positive charges.[23] The large difference in overall charge between the two sets of clusters probably explains much of the discrepancy. Furthermore, although the Mulliken atomic charges on the interstitial atom vary, it seems unlikely that this would cause σ^d to change sufficiently to explain the wide range of chemical shifts observed.

The other trends in the data of Fig. 4 are also consisent with our qualitative analysis. For example, we know that the energy level patterns in series of *closo*, *nido* and *arachno* clusters are very similar.[5] Hence the interstitial atom chemical shifts in the octahedron, square-based pyramid, butterfly series should be similar, so long as the delocalized bonding pattern is maintained. Considering how large the structural perturbation of losing one or more vertices is, the agreement of the experimental values is quite remarkable.

We can also provide rationalizations and predictions for the changes in chemical shift of a given interstitial atom in cluster cavities of differing size, or for a given polyhedron with different metal atoms. Consider first a change from an octahedron to a tetrahedron. For an interstitial hydride the decrease in the number of neighbouring groups will probably outweigh the somewhat smaller cavity size, and the deshielding should decrease. As for variations in metal atom for otherwise isostructural systems, we predict that the deshielding will be greater for metals with smaller metallic radii. For interstitial hydrogen atoms this effect is largely due to the shorter metal–interstitial distance: for carbon and nitrogen the shorter distance is expected to increase the mixing between the metal and interstitial orbitals. Hence the greatest deshielding is predicted to occur in clusters of late first-row transition metals (smallest metallic radii) and the smallest deshielding for early second- and third-row metals. This is in agreement with the observed shifts of $[Ru_6H(CO)_{18}]^-$ and $[Co_6H(CO)_{15}]^-$, since cobalt has the smaller metallic radius.

CONCLUSIONS

We have proposed qualitative models for rationalizing the chemical shifts of interstitial atoms in clusters. For interstitial hydrogen, it seems reasonable to represent the shielding using the neighbouring group approximation for the skeletal metal atoms. By exploiting our current understanding of cluster bonding in terms of approximate forms for the cluster orbitals, we can explain the chemical shifts of interstitial protons in both symmetrical and unsymmetrical environments.

Interstitial carbon and nitrogen atoms are different from hydrogen, because the interaction of the 2*p* valence orbitals and the $P^{\sigma}_{d_{z^2}}$ cluster orbitals admits significant and large *local* deshielding paramagnetic terms. The magnitude of the deshielding term depends upon the strength of the metal framework–interstitial interaction—greater mixing means more deshielding. The trends observed for the variation of the chemical shift with the electronegativity of the intersitial atom and the geometry (and bonding) in the cluster cage can be rationalized on this basis, and are in accord with our present understanding of the bonding in these clusters.

Current bonding models also suggest that the energy level patterns are largely retained in a *closo*, *nido*, *arachno* series, in agreement with the similar shifts observed for related octahedra, square-based pyramids and butterfly clusters. Finally, we have tried to rationalize and predict the qualitative variation of the chemical shifts of interstitial atoms in isostructural clusters as the identity of the metal atom changes.

(*Received* 2 *July* 1990; *accepted* 22 *April* 1991)

Abstract—The electronic spectra of tetragonal nickel(II) complexes of the type $Ni(Py)_4L_2$ (where Py = pyridine and L = NCS, Cl, Br or I), have been measured in methanol solutions at room temperature. The experimental curves were resolved by Gaussian analysis. The various ligand-field parameters are discussed in terms of their chemical utility and their relation to ligand-field strengths. The ligand-field parameters were examined by two minimization algorithms: the Davidon–Fletcher–Powell method (gradient estimation) and the Powell method (non-gradient). The standard deviations of the parameters were obtained from the former. It was found that the stereochemistry of the complexes in methanol solution differed from that in chloroform solution or in the solid state.

The previous paper[1] presented the theoretical interpretation of the electronic spectra of tetragonal *trans*-$[Ni(Py)_4L_2]$ type complexes in a 10% solution of pyridine in chloroform. The values of the parameters presented for the solutions were comparable with those published before for the solid state.[2–6] These studies are intended to show the effect of methanol on the tetragonal distortion compared to chloroform (as well as the solid state).

EXPERIMENTAL

All the complexes were prepared according to the method of Nelson and Shepherd.[7] Carbon, hydrogen, nitrogen and nickel analyses were performed as before.[1] The measurement conditions for the electronic absorption spectra were the same as reported earlier.[1] The solutions were prepared by dissolving a weighed amount of the complex in methanol. All of the complexes are easily soluble in methanol and are electrolytes in these solutions.

The composition of the complex species in methanol solution has been confirmed by conductance measurements. The molar conductances were measured using the conductivity meter OK-102/1 and electrode OK-902 (Radelkis). The $Ni(Py)_4L_2$ (L = NCS, Cl, Br, I) complexes in methanol solution have the molar conductivity values 20, 72, 102 and 120 Ω^{-1} mol^{-1} cm^2, respectively. The value observed for the dithiocyanatotetrakis(pyridine) nickel(II) is well below the typical range of 1:1 electrolytes, indicating that the coordinated thiocyanate ion is not appreciably removed by the solvent. The molar conductivity of $Ni(Py)_4I_2$ corresponds to that of 1:2 electrolytes.[8] The molar conductivity values of dichloro and dibromo complexes are as expected[8] for 1:1 electrolytes.† More-

† For 5×10^{-2} M solutions of $Ni(Py)_4X_2$ (X = Cl, Br, I) and 2.5×10^{-2} M solutions of $Ni(Py)_4(NCS)_2$ at 25°C, i.e. conditions for spectroscopy measurements. The molar conductivity values, measured under the same conditions are: NaCl, 87; NaBr, 101; NaSCN, 76; and KI 112 Ω^{-1} mol^{-1} cm^2, for 1:1 electrolytes.

over, the concentration of chloride ions in the methanol solution of $Ni(Py)_4Cl_2$, measured using the chloride ion sensitive electrode, confirms that the complex studied is a 1 : 1 electrolyte in methanol.

Methods

Spectra were resolved using the procedures described in detail in other work[1,9,10] (and references therein). There is also a description of the procedure used to make band assignments and calculate ligand-field parameters. For CFM calculations the full energy matrices reported by Perumareddi[11] were used. For AOM calculations the matrix elements of the excited states given by Hitchman[4] were used and the one-electron orbital energies given by Hitchman[12] were adopted. In order to apply them to the interpretation presented here (which does allow anisotropy of nitrogen atoms), the elements were zeroed with the $e_{\pi\parallel}$ parameter for a pyridine ligand. Because of the cylindrical symmetry of metal ligand interactions in the axial donor ligands, only one parameter $e_\pi(L)$ (L = NCS, Cl, Br, I) for the complexes was taken into account. The orbital energies for the complexes with different axial ligands are given elsewhere.[4,10,12] Since the orbital energies for the complexes are rather expressed as a function of the sum of the corresponding axial parameters, the AOM parameters were calculated fixing e_σ and e_π of one of the axial ligands.[10]

RESULTS AND DISCUSSION

General

The molar conductivity values of the $Ni(Py)_2Cl_2$ and $Ni(Py)_2Br_2$ complexes in methanol are as expected for 1 : 1 electrolytes, suggesting the formation of $[Ni(Py)_4L]L$ or $[Ni(Py)_4L(solv.)]L$ species (where L = Cl, Br, and solv. refers to solvent). On account of the strong preference of the high-spin nickel(II) ion for the octahedral surrounding, the creation of the first complex is not possible under the conditions of the experiment. Moreover, the calculations show that the parameters of σ-antibonding ability of the halogen ligands ($\sim$7 kK) are much greater than that for pyridine ($\sim$4 kK) for the supposed five-coordinate systems. The relation between these parameters is not in agreement with the data obtained before[1] for the bipyramidal site. Therefore, the formation of the six-coordinate mixed ion seems to be more probable and this one (i.e. $[Ni(Py)_4L(solv.)]L$ structure) was assumed. For the $[Ni(Py)_4(NCS)_2]$ complex in methanol solution we assumed the tetragonal symmetry with *trans*-thiocyanate ions. On account of the conductivity measurements for $Ni(Py)_4I_2$ which corresponded to 1 : 2 electrolytes, we treated that complex as $[Ni(Py)_4(solv.)_2]I_2$ species. The observed solution spectra (see Fig. 1) for all these compounds display only three absorption bands and they do not exhibit any spin-forbidden bands, except for $[Ni(Py)_4(NCS)_2]$. This last compound contains a shoulder related to a triplet–singlet transition at 13350 cm^{-1}.

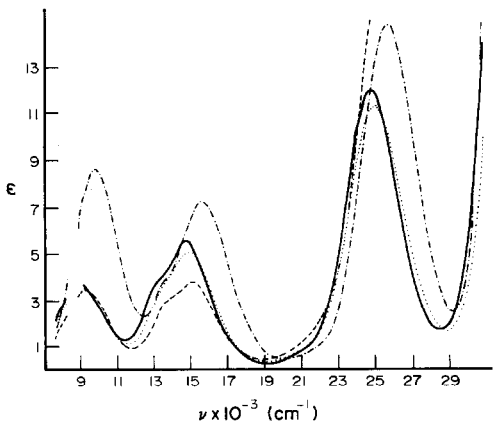

Fig. 1. Electronic absorption spectra of methanol solutions at room temperature of complexes: $[Ni(Py)_4Cl(MeOH)]Cl$, solid line; $[Ni(Py)_4Br(MeOH)]Br$, dot; $[Ni(Py)_4(MeOH)_2]I_2$, dash; $[Ni(Py)_4NCS_2]$, dash–dot.

The theoretical energy level diagram for nickel(II) ions indicates that as many as six triplet–triplet transitions may be observed in the electronic spectra of complexes with C_{4v} and D_{4h} symmetry. This results from tetragonal splittings that are small compared to their band-widths. The *d–d* spectrum may also be further complicated by the overlap of more intense charge-transfer or intramolecular (ligand) spectral bands [for instance in $Ni(Py)_4I_2$]. In general, the solution spectra at room temperature do not provide sufficient resolution to require consideration of the lower symmetry. The presented method assumes that spin–orbital coupling has an effect on the band-widths only in solution at room temperature. The site symmetry was assumed to be $D_{4h}(C_{4v})$ and the electronic spectra fitted this model. The spectra in methanol solution presented in this study differ significantly from those previously reported.[1] From the spectra in chloroform it was immediately evident that except for $[Ni(Py)_4(NCS)_2]$, tetragonal splittings Δ^1_{tetr} and Δ^2_{tetr} of $^3T_{2g}(t_{2g}^5e_g^3)$ and $^3T_{1g}(t_{2g}^5e_g^3)$, respectively, were observed.

The absorption spectrum of $Ni(Py)_4I_2$ in methanol solution consists of two spin-allowed bands at 9260 cm^{-1} and 15120 cm^{-1} (Fig. 2). The observed triplet tetragonal components are related to parent

[a] For D_{4h} term assignments (first column) the "g" subscript is needed.

octahedral transitions $^3T_{2g}$ and $^3T_{1g}(F)$. The other components related to the parent octahedral transition $^3T_{1g}(P)$ are overlapped by a strong band in the near UV region, but allowed a weak shoulder at about 25,000–27,000 cm^{-1}. Figures 2–5 show the experimental spectra of all the studied complexes along with Gaussian components.

Table 1 shows a comparison of the experimental (Gaussian analysis) and theoretical energy levels together with their assignments for all the investigated complexes. The band assignment is based on fitting the resolved band maxima (Gaussian analysis) with the calculated transition energies (eigenvectors) using d^8 quadrate energy levels with full configuration interactions and without spin–orbit coupling. The extension of our calculations to include spin–orbit coupling would be desirable, but since no fine structure was detected the results would have little meaning.

The values of the crystal field, angular overlap and electron correlation parameters for all the investigated complexes are shown in Tables 2 and 3. The transition energies corresponding to these parameters are shown in Table 1.

Analysis of the parameters

In the previous paper, the AOM parameters without anisotropy of pyridine were presented [i.e. averaging e_π(Py) values]. If the anisotropy of pyridine is taken into account, the AOM parameters are as given in Table 4. The e_σ and $e_{\pi\perp}$(Py) parameters for all these complexes in chloroform solution are slightly smaller (e_σ about 200 cm^{-1}) than those without anisotropy but e_π(L) is somewhat greater. This gives rise to a change in the ordering of the π-bonding series. Somewhat less π-antibonding ability of pyridine than of chloride is in agreement with Perumareddi's data.[13]

The bonding parameter values of the studied complexes in methanol solution suggest that, as

expected, the σ-antibonding effects of the halide ions are considerably less than those of pyridine. The estimation of the e_σ parameters seems to be reasonable and quite similar to those reported for two mixed ligand complexes.[1] Both the dichloro and dibromo complexes in methanol are [Ni(Py)$_4$L (solv.)]L species (three mixed ligand complexes). As mentioned above for the complexes with different axial ligands, the AOM parameters were calculated by fixing the parameters for one ligand. These fixed values for the oxygen-donor of methanol (e_σ(O) = 3145, e_π(O) = 1500 cm^{-1}) were taken from the results obtained for [Ni(Py)$_4$(MeOH)$_2$]I$_2$ (see the last column in Table 3). The series for σ-bonding ability of the studied complexes is similar to that for the solid state and in chloroform solution. The σ-antibonding parameter for pyridine is dependent on the axial ligands. The e_σ(Py) in [Ni(Py)$_4$Cl(MeOH)]Cl is approximate to that of [Ni(Py)$_4$Br(MeOH)]Br, but is sightly different for [Ni(Py)$_4$(NCS)$_2$] and [Ni(Py)$_4$(MeOH)$_2$]I$_2$. Values of $e_{\pi\perp}$(Py) for the chloro and bromo complexes are very close (within the error limits), whilst they are somewhat greater for the other complex. It was deduced that the ligand-field strengths of the coordinated solvent are greater than those of the chloro and bromo ligands. That the σ-antibonding parameter is greater for the thiocyanate ion than for the oxygen-donor ligator (methanol) is in agreement with the low molar conductivity value which suggests that the thiocyanate ion is not appreciably substituted by the solvent molecules. Comparison of the results for both of the solutions (i.e. chloroform and methanol) shows a similar relation for the σ- and π-antibonding parameters.

The crystal field parameters of these complexes suggest that, in agreement with the crystal structures, the perturbation of the octahedral environment of the nickel(II) is an elongation along the z-axis. The reduction of the symmetry from O_h to C_{4v} corresponds to a weaker ligand field along the z-axis, i.e. $Dq_z < Dq_{xy}$. The splitting of all the parent cubic levels by the additional ligand field (in-plane) for all the complexes is shown in Fig. 6. This energy term diagram corresponds to tetragonally elongated octahedral systems.

The values of parameters calculated in this work are different from those presented by Kurzak and Bartecki.[1] The Racah B parameters (Tables 2 and 3) of halogen–pyridine systems are slightly less than those obtained from chloroform solution spectra and the C parameters are considerably greater. However, the B and C parameters are due to the free-ion values which are 1042 and 4060 cm^{-1}, respectively for nickel(II). An interesting fact is that the B and C parameters for the dithiocyanato complex are the same as for the chloro and bromo complexes ($C/B = 4.2$), although in chloroform these values were considerably different ($C/B = 4.2$ and 3.8, respectively). The Dq_N values are almost constant at about 1050 cm^{-1}, and they are somewhat less than those given by Kurzak and Bartecki[1] for chloroform solution spectra. No other definite trends for these parameters could be inferred for these tetragonal complexes.

(*Received* 16 *January* 1991; *accepted* 22 *April* 1991)

Abstract—New monomeric and dimeric copper(II) complexes with creatinine were synthesized in organic media. Formation of different complex species depending on the reaction medium was proved. Using spectroscopic (EPR and IR) and magnetochemical methods, the structure of the complexes obtained was studied.

In our earlier study on the complexation between copper(II) and creatinine (**I**) in aqueous solution, the formation of a monomeric copper(II) complex with a 1 : 2 metal-to-ligand ratio was proved.[1]

By studying the complex formation of creatinine with different metal ions, however, we have found that different complex species are formed depending on the reaction conditions.[2–11] In some cases oligomeric species were obtained,[2,6,8,11] thus proving the ability of creatinine to serve as a bridging ligand, similar to the nucleobases.[12] On the other hand, it has already been shown that in organic solvents dimeric copper(II) complexes with bridging ligands are formed in some cases.[13,14] For that reason the aim of the present study was to obtain dimeric complexes of copper(II) from the copper(II)–creatinine reaction in organic media (methanol and acetonitrile).

EXPERIMENTAL

Synthetic and analytical procedures

$Cu(creat)_4(OCH_3)_2$ (**1**) (creat = *creatinine*, *bright green*, $\lambda_{Max} = 430$, 670 nm). $Cu(NO_3)_2 \cdot 3H_2O$ (0.1208 g, 0.5 mmol) and creatinine (0.3394, 3.0 mmol) in a 1 : 6 molar ratio were dissolved in 20 cm^3 of methanol. The mixture was refluxed (50–60°C) under constant stirring for 15 min, resulting in the formation of a bright green residue. The latter was filtered off, washed repeatedly with acetone and dried over P_4O_{10} for 2–3 days. Found: C, 37.0; H, 6.0; N, 29.5; Cu, 10.6. Calc.: C, 37.4; H, 5.9; N, 29.1; Cu, 11.0%.

$Cu_2(creat)_6$ (**2**) (*blue–green*, $\lambda_{max} = 438$, 680 nm). $Cu(NO_3)_2 \cdot H_2O$ (0.1208 g, 0.5 mmol) and creatinine (0.4525 g, 4.0 mmol) were dissolved in 20 cm^3 of acetonitrile. The mixture was refluxed (50–60°C) under constant stirring for 1 h, resulting in the formation of a blue–green residue. The latter was filtered off, washed repeatedly with acetone and dried over P_4O_{10} for 2–3 days. Found: C, 35.5; H, 5.0; N, 31.5; Cu, 16.0. Calc. C, 35.8; H, 4.7; N, 31.5; Cu, 15.8%.

$Cu_2(creat)_4$ (**3**) (*reddish-brown*, $\lambda_{max} = 450$ nm). $Cu(NO_3)_2 \cdot 3H_2O$ (0.1208 g, 0.5 mmol) and creatinine (0.4525 g, 4.0 mmol) was dissolved in ace-

tonitrile and refluxed (50–60°C) under constant stirring for 6–7 h, resulting in the formation of a reddish-brown precipitate. The latter was filtered off, washed repeatedly with acetone and dried over P_4O_{10} for 2–3 days. Found: C, 33.3; H, 4.7; N, 29.8; Cu, 21.4. Calc.: C, 33.4; H, 4.2; N, 29.2; Cu, 22.1%.

The compositions of the complexes were determined by elemental analysis, the copper content being determined complexometrically.

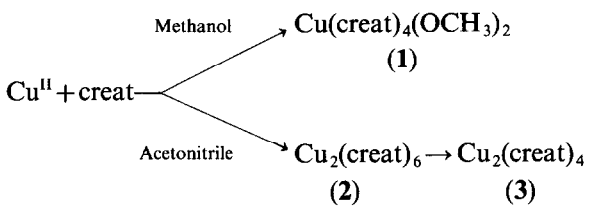
Materials and apparatus

The electronic, IR and EPR spectra were recorded on a Specord UV–vis (Carl–Zeiss, Jena), a Perkin–Elmer 983 spectrometer (CsI discs, spectral range 4000–200 cm^{-1}) and an X-band EPR Bruker B-ER 420 spectrometer (g-marker DPPH, temperature range 130–300 K), respectively. The magnetic susceptibility was determined in argon atmosphere by the Faraday method in the range 150–350 K. TG and DTA measurements were carried out with Panton Red Croft 781, appart STA.

All reagents used were of AR grade and the solvents (methanol, deuteriated methanol and acetonitrile) were of spectroscopic grade (Uvasol, Merck).

RESULTS AND DISCUSSION

The first reaction products obtained in different solvents (**1** and **2**) differ significantly in content and structure. Products **2** and **3** were obtained consequently in the course of the copper(II)–creatinine interaction in acetonitrile.



In the protic solvent methanol, the copper(II)–creatinine interaction resulted in the formation of monomeric species and their inner coordination sphere deprotonated solvent molecules were also included. [The autoprotolytic constant of methanol is rather high ($pK_a = 16.9$)[15] and creatinine itself contains the $—NH_2$ group.] The coordination of deprotonated solvent molecules was proved by means of the kinetic isotopic effect. For this purpose the copper(II)–creatinine reaction was carried out in deuterated methanol (CD_3OD) under the same conditions as described for compound **1** in the Experimental. It was found that over 2 h no precipitate was formed thus indicating the coordination of deprotonated methanol.

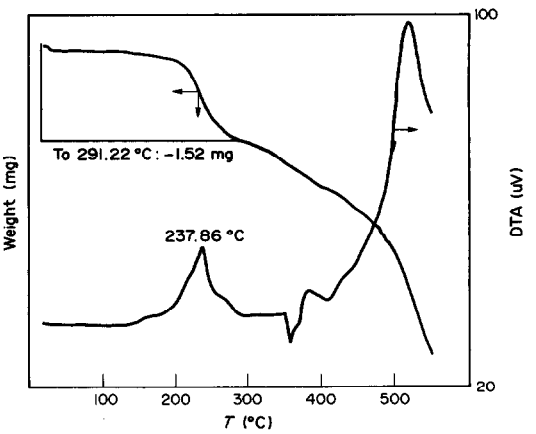


Fig. 1. TG and DTA curves for $Cu(creat)_4(OCH_3)_2$ (**1**).

In order to check this supposition, TG and DTA measurements on **1** were also performed; the data obtained are shown in Fig. 1. It is evident that above 200°C a small mass of the compound was abstracted. This is most likely due to abstraction of two CH_3O^- groups, as the metal alkoxides proved to be rather stable.[16]

In contrast to methanol, in the aprotic solvent acetonitrile, the first reaction product (**2**) was found to be a dimeric copper(II) species. This fact should most probably be connected with the poorer coordination properties of acetonitrile, thus allowing creatinine to act as a bridging ligand.

The reaction in acetonitrile resulted in the formation of another dimeric copper(II) complex (**3**), thus proving the formation of dimeric complexes of copper(II) with the bridging ligand creatinine in organic solvents.

Structure of the complexes

In order to obtain information concerning the structure and coordination mode of the ligand, magnetochemical and spectroscopic (IR and EPR) studies were performed.

The magnetochemical data obtained are represented in Fig. 2. The μ_{eff} values obtained confirm the supposition of the monomeric structure for **1** and the dimeric structure for **2** and **3** (2.0, 1.5 and 1.6 BM, respectively). On the other hand, the temperature dependence of the corresponding μ_{eff} values show a significant difference in the copper(II) stereochemistry.

It is evident that μ_{eff} of **1** is temperature independent, indicating an octahedral structure for the

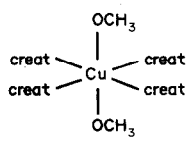
complex.[17] The EPR data obtained (Table 1) are in agreement with these results. The anisotropic g values obtained ($g_\parallel \gg g_\perp > 2.0$) for **1** correspond to an elongated octahedral structure with a $d_{x^2-y^2}$ ground state.[18] The polycrystalline EPR parameters were found to be temperature independent. A four-component $^{63,65}Cu$ ($I = 3/2$) hyperfine splitting is readily observed in the $g_\parallel$ component allowing evaluation of $A_\parallel$. It should be mentioned that in frozen DMF solution, a poorly resolved nine-component shfs due to four ^{15}N ($I = 1$) atoms ($A_n \sim 13$ G) is also observed, thus indicating coordination via the nitrogen atom of the ligand.

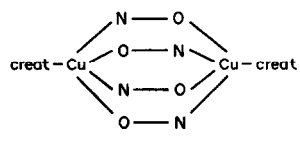
Additional information concerning the coordination mode of the ligand was obtained by studying the IR spectra of the ligand and the complexes (Table 2). It is evident that >C=O and the NH_2-stretching vibrations of complex **1** are observed at higher frequencies than those of the free ligand.* These data indicate coordination via the endocyclic nitrogen atom, as already proved by X-ray diffraction, for platinum(III)–creatinine complexes.[3,4,10]

A band at 1050 cm^{-1} is also observed (absent in the spectra of complexes **2** and **3** and the free ligand) which might be ascribed to the C—O vibration.

On summarizing all the data obtained for the complex, it might be suggested that as a result of a copper(II)–creatinine interaction in methanol, a monomeric copper(II) complex is formed with an elongated octahedral structure (**II**), four creatinine molecules being present in the xy plane and two CH_3O groups occupying the fifth and sixth coordination sites.



(II)



(III)

In contrast to methanol, when acetonitrile was used as solvent the first step of the copper(II)–creatinine interaction resulted in the formation of the

*Most probably due to hydrogen bond interactions between the creatinine molecules.

dimeric copper(II) creatinine complex (**2**) ($\mu_{eff} \sim 1.5$ BM (Fig. 2). In its EPR spectrum a signal with very low intensity and $g = 2.94$ is observed (Table 1), typical for a half-field transition in a copper(II) dimeric species.[14] It may be suggested that in acetonitrile (solvent with weaker coordination properties) the creatinine molecules act as bridging ligands resulting in the formation of the dimeric complex (**III**).

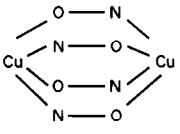
The IR data obtained are in agreement with this supposition. In contrast to the monomeric complex, in the IR spectrum of **2**, two pairs of bands ascribed to ν(C=O) and ν(C=N) are observed (Table 2) due to two types of coordination modes existing. Evidently the ν(C=O) band at 1690 cm^{-1} should be ascribed to the vibration of the bridging ligands and the other band present at higher frequency (1705 cm^{-1}) to the creatinine molecules coordinated as monodentate ligands via the endocyclic nitrogen atom.

As no counterions were found in complex molecules, it may be expected that the positive charge of both copper(II) ions is balanced by four deprotonated creatinine molecules, e.g. four amido anions. In accordance with this supposition, in the IR spectrum of complex **2**, in addition to the two bands ascribed to ν_{as} and ν_s, a new band at $\sim$ 3220 cm^{-1} is also observed. The latter is due most probably to a NH-stretching vibration.

Summarizing the experimental data obtained, a dimeric structure (**III**) is proposed, the latter being consistent with the analytical, magnetochemical and EPR data. As is well documented,[17] the strong temperature dependence of μ_{eff} and the coordination number of five indicate a structure differing significantly from octahedral or square-planar, and most likely a square-pyramidal structure should be expected.

As was mentioned above, in the last step of the reaction in acetonitrile a brown-coloured, almost insoluble,* dimeric copper(II) complex (coordination number four) is obtained. [In this case no signal due to the half-field transition of dimeric copper(II) species was observed, most probably because of the significant broadness of the main EPR signal.] The spectroscopic data (anisotropic EPR signal and the presence of only one band at 450 nm in the visible spectrum) and the strong temperature dependence of μ_{eff} (Fig. 2) again indicate a different stereochemistry. In agreement with a coordination number of four and the IR data obtained (Table 2), structure **IV** may be proposed. In this case the four ligands (as amido anions) act as bridging ligands and therefore only one ν(C=O) (with rather low frequency) and one ν(C=N) band are present in the IR spectrum. As is indicated in Table 2, in this case no bands due to $\nu_{as}(NH_2)$ and $\nu_s(NH_2)$ are observed and only the band at $\sim$ 3220 cm^{-1}, ascribed to the ν(NH) of the amide anion, is present.

In order to obtain some information concerning the structure of the complexes in solution their EPR spectra in different solvents were recorded (Table 3).



(IV)

It is evident that the EPR parameters obtained for the monomeric complex **1** are different from the corresponding values of the polycrystalline sample, and the $g_\parallel$ and $A_\parallel$ are solvent dependent. This fact may be explained by the $Cu(creat)_4(OCH_3)_2$–solvent interaction.

Rather surprisingly, the EPR parameters obtained for the frozen solutions of the dimeric complex **2** are the same as those for the monomeric complex **1** (Table 3). These data indicate that the

* Showing only low solubility in high-polar solvents (formamide, water).

dissolution of both **1** and **2** results in the formation of one and the same copper(II) complex in the corresponding solvent. Taking into account that in all cases $g_{\parallel} > g_{\perp} > 2.0$, it may be supposed that the monomeric complex $Cu(creat)_4S_2$ (S = solvent molecule) with an elongated octahedral structure is formed, that is to say for **1**, the dissolution is connected with substitution of $^{-}OCH_3$ by solvent molecules and for **2**, with destruction of the dimeric structure. The fact that in a frozen solution of DMF a partially resolved signal due to four ^{15}N ($I = 1$) is observed supports the supposition for the presence of four creatinine molecules in the xy plane (coordination via nitrogen atom).

The dimeric complex **3** proved to be only partially soluble in formamide and water. The EPR data obtained are different from those observed for solutions of **1** and **2** and are also solvent dependent. It might be supposed, therefore, that solvent interaction of the dimeric $Cu_2(creat)_4$ complex also occurs.

(*Received* 22 *January* 1991; *accepted* 22 *April* 1991)

Abstract—The 1:2 adducts of bis(3-nitro-2,4-pentanedionato)copper(II) with ethylenediamine, 1,3-diaminopropane and 1,4-diaminobutane have been isolated and characterized. These adducts have been considered to be intermediates in the formation of the corresponding tetraaza macrocyclic complexes and a template reaction mechanism is proposed.

Reactions of coordinated ligands of metal complexes have been shown to be potentially very useful for their applications to organic syntheses and clarification of the reaction mechanisms involved in living processes. For example, metal chelates of acetylacetonates have been extensively investigated in the reaction with nucleophiles such as nitro[1] and halogen[2] groups. Recently, the metal chelates with acetylacetones having electron-withdrawing substituents on their γ-positions have been reported to exhibit much higher reactivities for amines, and thus these can be applied to the synthesis of tetraaza macrocycles by the so-called template synthesis.[3a–d] The role of metal ions in template reactions has been discussed based on their functions as Lewis acids, as reagents controlling free amine concentration or as genuine templates.[4]

Previously, we have reported that nickel(II) ions are superior to copper(II) ions as template metal ions in the reaction between [dibenzoyl-bis(β-ketoiminato)]metal(II) and ethylenediamine.[5] However, we have also shown that a copper(II) ion can function as a template ion when it is coordinated with acetylacetones having strong electron-withdrawing substituents such as nitro groups.[6]

In this paper we describe the template reactions between a copper(II) complex, bis(3-nitro-2,4-pentanedionato)copper(II), and α,ω-diaminoalkanes such as ethylenediamine, 1,3-diaminopropane and 1,4-diaminobutane in N,N-dimethylformamide (DMF). In addition, the reaction mechanism for the template reaction will be discussed.

EXPERIMENTAL

Materials

All reagents were of reagent grade. DMF was distilled over CaH_2 under reduced pressure before use. Other solvents were purified by the usual manner.

Measurements

UV and visible absorption spectra were recorded on a Hitachi 340 recording spectrophotometer. IR

spectra of dimethyl sulphoxide solutions were recorded on a Hitachi 215 grating spectrophotometer by the use of TlI cells with a lead spacer (0.3 mm).

Preparation of bis(3-nitro-2,4-pentanedionato)-copper(II), $Cu(3\text{-}NO_2acac)_2$

This complex was prepared according to the literature.[1]

Preparation of ethylenediamine adduct of $Cu(3\text{-}NO_2acac)_2$, $Cu(3\text{-}NO_2acac)_2 \cdot en_2$

To a suspension of $Cu(3\text{-}NO_2acac)_2$ (5.0 g, 1.4×10^{-2} mol) in ethanol (200 cm^3) was added a slight excess of ethylenediamine (2.0 g, 3.3×10^{-2} mol). The green colour of the complex turned grey immediately. The mixture was stirred at room temperature for 3 h and cooled in an ice–water bath. The resulting grey precipitates were collected on a glass filter, washed with cold ethanol, and dried *in vacuo*. Found: C, 35.7; H, 6.0; N, 17.7. Calc. for $CuC_{14}H_{28}N_6O_8$: C, 35.6; H, 6.0; N, 17.8%.

Other diamine adducts, $Cu(3\text{-}NO_2acac)_2 \cdot pn_2$ and $Cu(3\text{-}NO_2acac)_2 \cdot bn_2$, were obtained by a similar method to that described above, where pn and bn denote 1,3-diaminopropane and 1,4-diaminobutane. In the case of the latter 1:2 adduct, the diamine (4.5 g, 5.6×10^{-2} mol) was required in order to isolate it.

RESULTS AND DISCUSSION

The 1:2 diamine adducts of $Cu(3\text{-}NO_2acac)_2$ and $Cu(3\text{-}NO_2acac)_2 \cdot L_2$, could be isolated by the reaction of $Cu(3\text{-}NO_2acac)_2$ with a diamine (L) in absolute ethanol, where L is ethylenediamine, 1,3-diaminopropane or 1,4-diaminobutane. These adducts were characterized by IR spectra, visible absorption spectra and elemental analyses. The absorption spectral changes of the adducts in hot DMF solution indicate that they may be considered as intermediates in the formation of tetraaza macrocyclic complexes.

IR spectra

The diamine adducts of $Cu(3\text{-}NO_2acac)_2$ were examined by measuring their IR spectra in both solid and solution states. Since these adducts are almost insoluble in non-coordinating solvents such as dichloromethane and chloroform, dimethyl sulphoxide (DMSO) was employed. The DMSO solution spectra are almost the same as those observed in the solid state.[7] The DMSO solution IR spectral data for the diamine, the parent complex and the diamine adducts are shown in Table 1. The IR spectra of the three diamine adducts in the 4000 to 650 cm^{-1} region are quite similar to each other and exhibit characteristic absorption bands around 3400, 3250, 1640, 1580 and 765 cm^{-1}. The bands

[a] Weak absorption band.

at 3400 and 3250 cm^{-1} can be assigned to N—H stretching vibrations due to coordinating diamines; those at 1640, 1580, and 765 cm^{-1} to N—H bending, C=O stretching and a combination of N—H and C—H deformation vibrations, respectively.

It should be noticed that no absorption band around 1700 cm^{-1} is observed due to uncoordinated, free carbonyl moieties of 3-nitro-2,4-pentanedionato groups. These results indicate that the configurations of the diamine adducts in DMSO are maintained in the solid state: the 3-nitro-2,4-pentanedionato groups act as bidentate ligands and the diamine groups coordinate with copper(II) as unidentate ligands. That is, the central copper(II) ions in the diamine adducts are surrounded by donor sets of N_2O_4.

Electronic spectra of copper(II) complexes

Figure 1 shows the electronic spectra of the DMF solutions of the parent complex, $Cu(3\text{-}NO_2acac)_2$, its ethylenediamine adduct, $Cu(3\text{-}NO_2acac)_2 \cdot en_2$, and the macrocyclic compound, $Cu(NO_2\text{-}N_4[14])$, which was obtained in the template reaction of $Cu(3\text{-}NO_2acac)_2$ with ethylenediamine.

The electronic spectrum of $Cu(3\text{-}NO_2acac)_2$ exhibits an absorption band at 14,900 cm^{-1} (672 nm) in the visible region, which can be assigned to ligand field transitions. In the spectrum of its ethylenediamine adduct, the absorption peak is observed at 18,200 cm^{-1} (548 nm). This higher energy shift by 3300 cm^{-1} may be caused by the additional coordination of two molecules of ethylenediamine to the parent complex. On the other hand, in the absorption spectrum of $Cu(NO_2\text{-}N_4[14])$, the absorption band is observed at 17,200 cm^{-1} (580 nm), which can also be assigned to ligand field transitions. The lower energy shift by 1000 cm^{-1} compared to that of the adduct may be due to the transformation from the distorted octahedral $Cu(3\text{-}NO_2acac)_2 \cdot en_2$ to the square planar $Cu(NO_2\text{-}N_4[14])$.

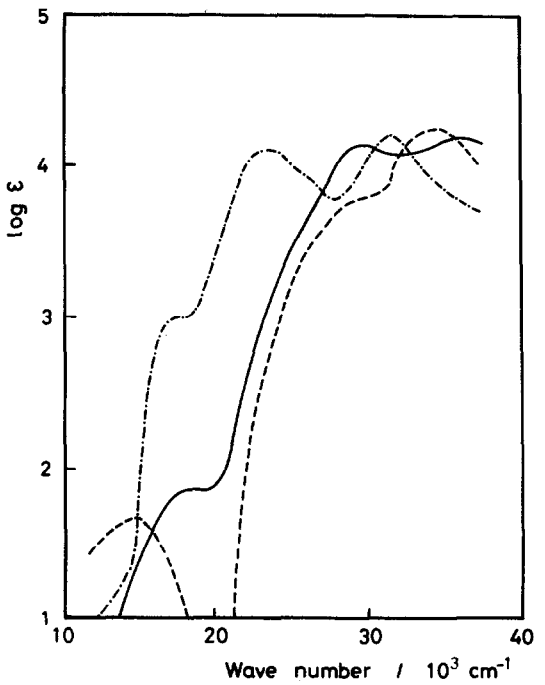

Fig. 1. Electronic spectra of copper(II) complexes in DMF. (·····): $Cu(3\text{-}NO_2acac)_2$; (———): $Cu(3\text{-}NO_2acac)_2 \cdot en_2$; and (–·–·–·–): $Cu(NO_2\text{-}N_4[14])$.

Absorption spectra of the parent complex and its diamine adducts in DMF and DMSO solutions

The absorption spectroscopic data for the parent complex and its diamine adducts in DMF and DMSO are summarized in Table 2. The spectrum of the parent complex in DMF solution has three absorption bands at 676, 337 and 285 nm. That of the ethylenediamine adduct has absorption bands at 549, 336 and 278 nm. Although the band positions in the UV region are almost the same as each other, those in the visible region are different; the absorption peak of the adduct is shifted to shorter wavelengths by approximately 130 nm compared to that of the parent complex. The absorption bands of the 1,3-diaminopropane and 1,4-diaminobutane adducts in the visible region are also shifted to shorter wavelengths by approximately 95 and 85 nm, respectively, compared to that of the parent complex. These shifts are smaller than that observed in the case of ethylenediamine and may

arise from the coordination of diamine molecules to the parent complex. Therefore, it can concluded that coordination bonds between the diamines and the copper(II) ions are stronger in the order ethylenediamine ≫ 1,3-diaminopropane > 1,4-diaminobutane.

All the absorption spectra of these copper(II) complexes in DMSO have three absorption peaks in the UV and visible regions as well as those in DMF. Moreover, the peak positions of the diamine adducts are quite similar to those in DMF. However, the spectrum of the parent complex in DMSO is significantly different from that in DMF, particularly in the visible region. The absorption peak in DMF is observed at 676 nm, which is shifted to shorter wavelengths by about 50 nm compared to that in DMSO. These results suggest that DMF molecules weakly coordinate to the copper(II) ion of $Cu(3\text{-}NO_2acac)_2$.

On the other hand, the fact that the absorption peaks of each diamine adduct are observed at the same positions in DMF and DMSO indicates that these solvent molecules cannot coordinate to the central copper(II) ion of the adducts because the coordination sites of the copper(II) ion in the adducts are already occupied with two nitrogen atoms of the diamines and four oxygen atoms of the 3-nitro-2,4-pentanedianato groups.

It has been reported that in the ethylenediamine adduct of bis(2,4-pentanedionato)copper(II), the central copper(II) ion is surrounded by a donor set of N_4O_2: two molecules of the diamine act as bidentate ligands and two 2,4-pentanedionato groups act as unidentate ligands.[8] This adduct has been found to be very labile and decomposes with elimination of the ethylenediamine. On the contrary, in the present diamine adducts of $Cu(3\text{-}NO_2acac)_2$, β-diketonato ligands act as bidentate ligands and two molecules of the diamines act as unidentate ligands. Moreover, these diamines do not dissociate even in coordinating solvents such as DMF and DMSO, as mentioned above. This is due to the strong electron-withdrawing nitro groups, which can stabilize the coordination bonds between the nitrogen atoms of the diamines and the central copper(II) ion.

Absorption spectral changes caused by the template reaction

In order to clarify a mechanism for the template reaction between $Cu(3\text{-}NO_2acac)_2$ and diamines, absorption spectral changes of their mixed DMF solutions were measured. A DMF solution of the complex $Cu(3\text{-}NO_2acac)_2$ (0.05 mol dm^{-3}) and each diamine (0.10 mol dm^{-3}) was heated to 90°C, and its absorption spectra were measured at regular time intervals. In Fig. 2, the result obtained for the reaction of $Cu(3\text{-}NO_2acac)_2$ with ethylenediamine is given as an example.

In the case of ethylenediamine, addition of the diamine caused an immediate shift of the absorption maximum from 676 nm, due to the parent complex, to 550 nm. This spectrum is almost the same as that of the isolated ethylenediamine adduct, $Cu(3\text{-}NO_2acac)_2 \cdot en_2$. Initially, the absorption maximum of the solution was gradually shifted to longer wavelengths and reached 588 nm after ca. 180 min, and then shifted in the opposite direction to shorter wavelengths with a big increase in intensity. After 360 min, it reached 580 nm with a slight increase in its intensity and shifted no further. This final absorption spectrum is quite similar to that of $Cu(NO_2\text{-}N_4$[14]).

Similar spectral changes were observed for the cases of 1,3-diaminopropane and 1,4-diaminobutane. With 1,3-diaminopropane, its addition to a DMF solution of $Cu(3\text{-}NO_2acac)_2$ caused an immediate shift of the absorption maximum by about 100 nm (from 676 to 576 nm). Initially, this absorption maximum was gradually shifted to longer wavelengths (to 588 nm after 90 min) and then oppositely to shorter wavelengths with an elapse of time. The shift value was smaller than that observed value for the ethylenediamine case but the

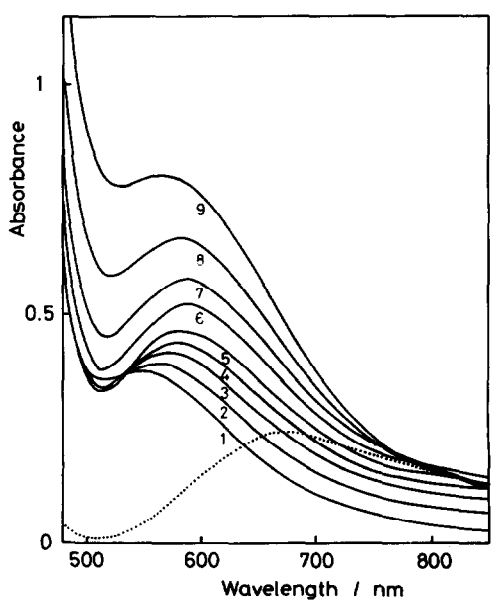

Fig. 2. Absorption spectral changes caused by reacting $Cu(3\text{-}NO_2acac)_2$ with ethylenediamine in DMF at 90°C. (·····): $Cu(3\text{-}NO_2acac)_2$; and (———): 1, 2, 3, 4, 5, 6, 7, 8 and 9, after 5, 30, 60, 90, 120, 180, 300 and 360 min, respectively.

reaction time was shorter than that for the above case; after 180 min the absorption maximum was observed at 580 nm with a high intensity. On the other hand, with 1,4-diaminobutane, the addition of the diamine to the copper(II) complex solution immediately caused a shorter wavelength shift by 60 nm with an increase in intensity. After 30 min, the absorption maximum was observed at 574 nm and its intensity was very high. These absorption spectral changes suggest that the reactivity of the diamines toward the parent complex was in the order en < pn ≪ bn.

Mechanism for the template reaction of Cu(3-NO_2acac)$_2$ *with diamines*

From the results described above, the following mechanism is proposed for the template reaction of Cu(3-NO_2acac)$_2$ with the diamines en, pn and bn. The scheme for the template reaction is shown in Fig. 3. Initially, two diamine molecules coordinate to the central copper(II) ion of Cu(3-NO_2acac)$_2$ as unidentate ligands. In the second stage, the uncoordinated, free amine groups may attack the carbonyl carbons of coordinated β-diketone groups and subsequently can afford two Schiff base bonds, being accompanied with the elimination of two water molecules. In the third stage, the Cu—N bond-fission between the copper(II) ion and the coordinated diamines may take place to leave the free amine groups. At the final stage, these free amine groups react further with the residual and coordinating carbonyl groups of the β-diketones to form the tetraaza macrocyclic Schiff base copper(III) complex, with elimination of two water molecules.

It has been reported that in the reaction of bis(2,4-pentanedionato)copper(II) with ethylenediamine, the desired tetraaza macrocyclic Schiff base copper(II) complex could not be obtained.[8] This significant difference in reactivity between Cu(acac)$_2$ and Cu(3-NO_2acac)$_2$ may be ascribed to the strong electron-withdrawing nitro groups. The electron-withdrawing groups lower the electron density on the carbon atoms of the carbonyl groups, making nucleophilic attack onto the carbon atoms by the amine groups much easier. An important role of the electron-withdrawing groups can be seen in the formation of the tetraaza macrocyclic compound by the template reaction. For example, in the case of the reactions of diamines with bis(3-benzoyl-2,4-pentanedionato)metal(II), where metal(II) is nickel(II) or copper(II), the former complex can form the corresponding tetraaza macrocyclic compound, but the latter gives only an acyclic compound.[5] The reason why the nickel(II) ion is superior to the copper(II) ion as a template ion may be considered to be due to the difference in the stabilizing effect of the metal–nitrogen bond between the metal ion and additional diamines; in the bis(β-diketonato)nickel(II) complex, diamines can coordinate to the central nickel(II) ion to form a six-coordinate complex, whereas in the corresponding copper(II) complex, coordination of two molecules of diamines to the central copper(II) ion is restricted and weakened because of the Jahn–Teller effect. The above-mentioned template reaction is a case of the following. In the reaction of the present Cu(3-NO_2acac)$_2$ with the diamines, the copper(II) ion can act efficiently as a template ion to form the corresponding tetraaza macrocyclic complexes. This is due to the strong electron-with-

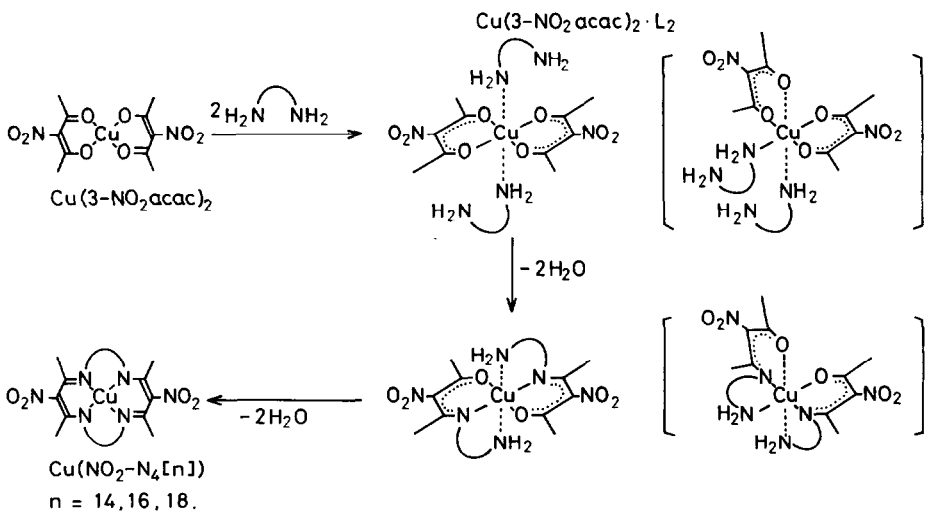

Fig. 3. Mechanistic scheme of the template reaction of Cu(3-NO_2acac)$_2$ with diamine.

drawing effect of the nitro groups on the γ-carbon atoms of acetylacetones. In fact, electrochemical study on the copper(II) complexes indicates that the reduction of $Cu(3\text{-}NO_2acac)_2$ is observed at a much more negative potential, ca. 1.0 V, than that for $Cu(acac)_2$. Both these are effects of the electron-withdrawing nitro groups; that is, to form adequately strong coordination bonds between the copper(II) ion and additional diamines and to coordinate easily by attack on the carbonyl carbon atoms of the coordinated diketones by the free amine moieties of the diamines, to form the desired tetraaza macrocyclic Schiff base complexes by the reaction of $Cu(3\text{-}NO_2acac)_2$ with the diamines.

On the other hand, it has been found that the reactivity of the diamines towards $Cu(3\text{-}NO_2acac)_2$ is very different: reaction rates forming the tetraaza macrocyclic complexes increase in the order $Cu(3\text{-}NO_2acac)_2 \cdot en_2 < Cu(3\text{-}NO_2acac)_2 \cdot pn_2 \ll Cu(3\text{-}NO_2acac)_2 \cdot bn_2$. This agrees with the order of increasing the methylene chain lengths linking the two amine groups of the diamines. These results can be explained as follows: it is necessary for the formation of the Schiff base bonds in the diamine adducts for an adequate distance between the free amine moieties of the coordinated diamines and the coordinated carbonyl groups to exist. Green *et al.* have reported that in the template reaction between 4,7-diaza-2,3:8,9-dibenzodecane-1,10-dione and diamines, a rotation around the C—C bond of ethylenediamine which superimposes the lone pair electrons on the nitrogen atom is less favorable for nucleophilic attack on the carbon atom; whereas this is sterically easy for 1,3-diaminopropane and 1,4-diaminobutane.[9]

However, when the diamines are linked with long methylene chain lengths, it might be inevitable for the formation of Schiff base bonds to take place intermolecularly and intramolecularly. In fact, in the case of the template reaction of $Cu(3\text{-}NO_2acac)_2$ with 1,3-diaminopropane or 1,4-diaminobutane, considerable amounts of by-products which were insoluble in ordinary organic solvents were obtained. These were considered to be polymeric compounds formed by intermolecular reactions, which were not further investigated.

SYNTHESIS AND CHARACTERIZATION OF COBALT(II) AND COBALT(III) COMPLEXES OF SUBSTITUTED DIBENZOTETRAAZA[14]ANNULENES

JULITA EILMES

Faculty of Chemistry, Jagiellonian University, Karasia 3, 30-060 Cracow, Poland

(*Received* 12 *February* 1990; *accepted* 25 *April* 1991)

Abstract—The macrocyclic complexes $Co^{II}L_1 \cdot 2H_2O$ and $Co^{II}L_2$ (L_1H_2 = $Bz_2Bzo_2Me_4$[14]hexaeneN$_4$, L_2H_2 = $Bz_2Bzo_2Me_2Ph_2$[14]hexaeneN$_4$) have been synthesized from free ligands and cobalt(II) acetate tetrahydrate. They reacted with dioxygen in pyridine solution to give the corresponding $[Co^{III}L(py)_2]X$ complex (where X = BF_4^-, I^-). The new compounds were characterized by elemental analysis, magnetic moments, IR, ^{1}H NMR and MS data. The steric non-equivalence of the axial sites of the coordinated macrocyclic ligands is discussed on the basis of the ^{1}H NMR spectra of the cobalt(III) complexes. The new cobalt complexes were found to be efficient catalysts for auto-oxidation of benzenethiol to diphenyl disulphide.

The development of synthetic models for naturally occuring metalloenzymes continues to be an important goal.

Synthetic biomimetic systems are of both fundamental and practical interest. They help the understanding of biochemical processes and being capable of imitating some enzymatic functions, can be employed practically as efficient and selective catalysts. Thus, biomimetic oxygenation is considered to be one of the most promising areas of catalysis.[1,2]

Among the macrocyclic systems used for the construction of model complexes, those containing the dibenzotetraaza[14]annulene framework are particularly attractive due to their synthetic accessibility and structural similarity to porphyrins (four donor atoms with substantial unsaturation and delocalization). Moreover, these macrocyclic ligands are able to accommodate a variety of substituents on the phenylene and diimine carbon atoms.

In our previous papers we showed that introduction of the peripheral substituents into the dibenzotetraaza[14]annulene system may be accomplished through a direct synthesis[3] or via substitution/addition reactions at the reactive β-methine carbon centre.[4–6] Further chemical transformations within these pendant groups were also found to be advantageous for the modification of the ligand periphery.[7,8]

Recently, we began studies on the chemistry of the cobalt complexes of previously synthesized, substituted dibenzotetraaza[14]annulenes. This paper reports the synthesis and characterization of the cobalt(II) and cobalt(III) complexes of $Bz_2Bzo_2Me_4$[14]hexaeneN$_4$ (L_1H_2) and $Bz_2Bzo_2Me_2Ph_2$[14]hexaeneN$_4$ (L_2H_2). Use of the new cobalt complexes as efficient catalysts for auto-oxidation of benzenethiol to diphenyl disulphide is also described.

RESULTS

Insertion of the cobalt into the macrocyclic ligand L_1H_2 was accomplished by the reaction with cobalt(II) acetate tetrahydrate (1 equivalent) performed under argon in refluxing acetonitrile–methanol (2:1). In the case of the ligand L_2H_2, the use of ethanol as a solvent was found to be more convenient for the precipitation of the crystalline product in a satisfactory yield. As a result of these reactions the low-spin four-coordinate complexes $Co^{II}L_1 \cdot 2H_2O$ (μ_{eff} = 2.85 BM) and $Co^{II}L_2$ (μ_{eff} = 2.65 BM) were obtained in 90 and 70% yields, respectively.

Diamagnetic cobalt(III) complexes of the L_1H_2 and L_2H_2 ligands were synthesized by the aerial oxidation of cobalt(II) complexes in excess pyridine in the presence of aqueous solutions of the appropriate inorganic salts. On the basis of analytical

and spectral data they have been formulated as six-coordinate $[Co^{III}L(py)_2]X$ complexes.

Scheme 1 outlines the reactions performed. Physical properties and magnetic and spectral data of the complexes are collected in Tables 1 and 2.

The tests of catalytic activity of the cobalt complexes for the auto-oxidation of organic compounds were performed with benzenethiol as a substrate. It was found that in an atmosphere of air, under mild conditions (temperature 20°C), the addition of 1.5 mol% of cobalt(II) and cobalt(III) complexes efficiently catalyse the oxidation of benzenethiol to diphenyl disulphide (yield 58–93%). The results are summarized in Table 3. The general procedure for the catalytic auto-oxidation is given in the Experimental.

(m)	**1**, DBMP	Air	1.0
(n)	**2**, DBMP	Air	0.8
(o)	**3**, DBMP	Air	0.5
(p)	**5**, DBMP	Air	0.5

General procedure given in the Experimental; (g) no catalyst added; (h) 1.5 mol% of $Ni^{II}L_1$; (i)–(j) slow stream of argon supplied instead of air; and (m–p) 5 mmol of 2,6-di-tert-butyl-4-methylphenol (DBMP) added.

DISCUSSION

Proof of the proposed structure of the cobalt complexes is supported by analytical and spectral data.

The IR spectra reveal the presence of the coordinated macrocyclic ligands and are fully consistent with their structure. The most diagnostic IR frequencies and their assignments are collected in Table 2.

The EI mass spectra exhibit the expected molecular peaks for all complexes synthesized (Table 1). The cobalt(III) complexes showed additional peaks of remarkable intensity at *m/z* 79, providing evidence for the presence of coordinated pyridine.

The structure of the coordinated macrocycle is confirmed by the ^{1}H NMR spectra of diamagnetic cobalt(III) complexes, showing signals for methyl, phenylene and phenyl groups (Table 2).

Two molecules of pyridine that are present in the complexes $[Co^{III}L(py)_2]X$ and supposed to be axially coordinated, give rise to separate sets of signals (Table 2). This can be explained in terms of the non-equivalence of the axial sites of the coordinated macrocycle and corresponds well with the recent findings on the non-planar conformation of the substituted dibenzotetraaza[14]annulene macrocycle.

Goedken *et al.*[9] first found crystallographically that the tetramethyl-dibenzotetraaza[14]annulene macrocycle adopts the saddle-shaped conformation in which *o*-phenylene rings and the diiminate chelate framework are tilted to opposite sides of the plane defined by four nitrogen atoms. The distortion from planarity is mainly due to steric interactions of β-substituents with the phenylene rings.

Similar pronounced saddle shapes are observed in the free ligands L_1H_2[10] and L_2H_2.[11] In these molecules one side of the non-planar macrocycle is sterically more crowded, due to the benzoyl substituents attached at the *meso* positions of the diiminate framework.

In the ^{1}H NMR spectra of the $[Co^{III}L_2(py)_2]X$ complexes, one of the two non-equivalently coordinated molecules of pyridine is represented by five distinct interpretable resonances [α(d, 1H), α'(d, 1H), γ(t, 1H), β(t, 1H), β'(t, 1H)], whereas the other molecule exhibits only three signals [α(d, 2H), γ(t, 1H), β(t, 2H] (Table 2).

The spectral set of five resonances indicates that one molecule of pyridine does not rotate freely on the NMR time scale and adopts the orientation in which α and α' protons are directed towards the non-equivalent part of the macrocycle. It seems reasonable to assume that the pyridine in question is the one coordinated in the more crowded axial site, i.e. on the non-planar macrocycle face which is equipped with the benzoyl substituents (Fig. 1,* pyridine A). Restrictions in the free rotation is presumed to be mainly due to the steric interactions with pendant benzoyl groups.

For the second molecule of coordinated pyridine, a distinction in the ^{1}H NMR spectra can only be made among the α, β and γ protons (three signals). The question then arises whether the pyridine does rotate freely on the NMR time scale or whether, due to interaction with phenylene rings, it adopts an orientation in which α and α' protons are directed towards the equivalent part of the macrocycle (Fig. 1, pyridine B). Standard ^{1}H NMR spectra cannot provide a conclusive answer to these questions and thus, the problem remains to be solved in further studies.

In the ^{1}H NMR spectra of the complexes $[Co^{III}L_1(py)_2]X$, each of the two non-equivalently coordinated molecules of pyridine gives rise to three signals attributed to the α, β and γ protons (Table 2). Here again, the point in question is whether the

* The figures used for the discussion show only essential features of the structure of free ligands. Complete crystallographic data for the free ligands will be published elsewhere.[10,11]

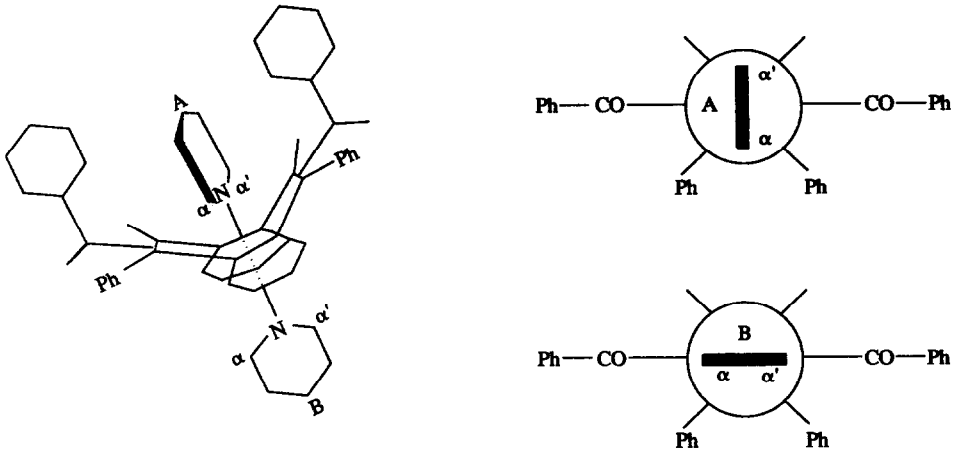

Fig. 1. Schematic representation of the orientation of axial base planes in $[Co^{III}L_2(py)_2]X$.

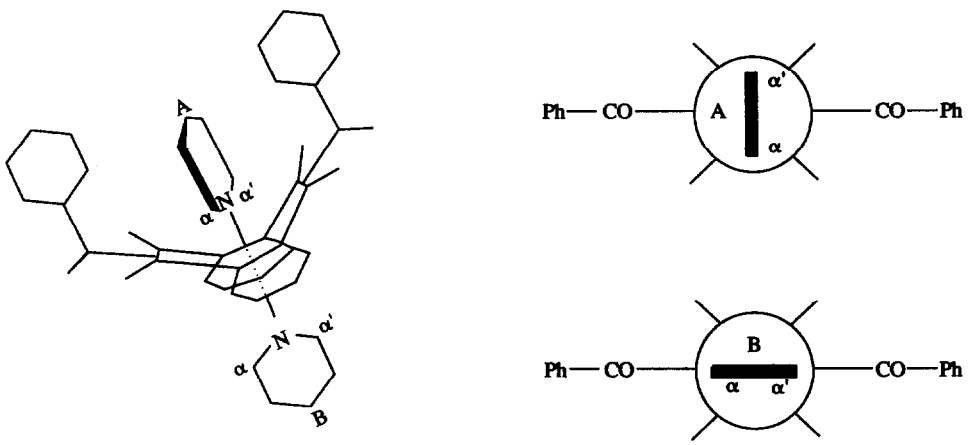

Fig. 2. Schematic representation of the orientation of axial base planes in $[Co^{III}L_1(py)_2]X$.

three resonances represent an average spectrum of freely rotating molecules of pyridine, or whether they correspond to the molecule whose freedom to rotate is restricted on the NMR time scale.

The structural similarity of ligands L_1H_2 and L_2H_2, both non-planar and equipped with pendant benzoyl substituents, strongly suggests similar structures for their complexes. It seems possible that the pyridine coordinated in the more crowded axial position of the complexes $[Co^{III}L_1(py)_2]X$ is also sterically hindered and assumes the orientation shown in Fig. 2* (pyridine A). However, the ^1H NMR spectra mentioned above, although consistent with such an orientation of pyridine A, do not provide straightforward evidence for the restriction of free rotation. It is easily noticed that due to the symmetry of the ligands L_1H_2 (see Fig. 2), ^1H NMR resonances assigned to the sterically hindered pyridine A consist of three signals and in this respect the spectrum does not differ from that which would correspond to the freely rotating molecule.

In conclusion, the ^1H NMR spectra reveal that axial coordination in the cobalt(III) complexes of substituted dibenzotetraaza[14]annulenes is remarkably influenced by the peripheral substituents and the macrocyclic ligand conformation. Two axial coordination sites appear to be sterically non-equivalent in all cobalt(III) complexes synthesized. ^1H NMR spectra of the cobalt(III) complexes derived from non-symmetrically substituted ligands, L_2H_2, allow the detection of hindered rotation of the axial pyridine.

The results show that introducing pendant substituents at the γ,γ' positions of the dibenzotetraaza[14]annulenes may control the rotational orientation of axial ligands in their complexes.

It is worth mentioning at this point that the rotational orientation of the axial base plane remarkably affects various physicochemical prop-

* See footnote on p. 1782.

erties of the complexes[12–14] and is considered to be essential for the activity of the natural haemoproteins.[15–17]

Further experiments are being undertaken in order to investigate the dynamic processes such as axial lability and internal rotation of the pyridine.

The cobalt complexes reported in this paper seem to be suitable for the study of oxygen transport. The structural similairty to the porphyrins and access to various oxidation states of the central metal atom makes them also attractive as potential catalysts.

In this paper we would like only to communicate the results of our preliminary tests of their catalytic activity in the oxidation of organic compounds with molecular oxygen.

As concluded from the results of all the experiments performed (see Table 3), the cobalt complexes **1–6** appeared to be efficient catalysts for the auto-oxidation of benzenethiol to diphenyl disulphide under mild conditions, eq. (1):

$$C_6H_5—SH \xrightarrow[CHCl_3,\ 20°C,\ 30\ min]{O_2,\ complexes\ 1–6} C_6H_5—S—S—C_6H_5. \quad (1)$$

Thus, experiments (a)–(f) showed that the reaction of benzenethiol with molecular oxygen, performed in the presence of 1.5 mol % of complexes **1–6**, led to diphenyl disulphide within 30 min, in fair yield (58–93%). Experiments (g) and (h) provided evidence that the oxidation with air practically did not occur in the absence of the cobalt complexes. Similarly, the presence of molecular oxygen was confirmed to be necessary for the reaction to occur [experiments (i)–(l)]. Furthermore, the yield of diphenyl disulphide was found to be very poor when the reaction was carried out in the presence of the free-radical reaction inhibitor 2,6-di-tert-butyl-4-methylphenol (DBMP) [experiments (m)–(p)].

Although no detailed mechanism can be proposed at this stage, the presumption that the reaction proceeds via a free-radical mechanistic pathway, involving binding and activation of dioxygen by the cobalt complexes, seems to be reasonable. It can be suggested further, that in this respect, the catalytic reaction may be considered as analogous to the auto-oxidation of organic products with the use of the cobalt porphyrins.[18–20]

Investigations of the scope and mechanisms of catalytic activity of the cobalt complexes in the oxidation of organic substrates are presently being carried out.

EXPERIMENTAL

Melting points are uncorrected. IR spectra were recorded in Nujol and hexachlorobutadiene on a Zeiss UR-10 spectrometer. ^{1}H NMR spectra were measured at 500 MHz on a Bruker AM instrument in $CDCl_3$. The spectra were referenced to δ $Me_4Si = 0$. EI mass spectra were run on a Perkin–Elmer 1000 mass spectrometer at 70 eV. The magnetic moments were measured by Evans' method[21] in $CDCl_3$ with Me_4Si at 295 K. Diamagnetic corrections for the ligands were made using Pascal's constants.[22]

All the solvents were distilled before use and degassed where indicated. Inorganic salts were reagent grade and were used without further purification. The ligands L_1H_2 and L_2H_2 were prepared by the procedure described earlier.[4]

[2,3:9,10 - *Dibenzo* - 6,13 - *dibenzoyl* - 5,7,12,14 - *tetra methyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 2,4,6,9,11, 13-*hexaenato*(2−)]*cobalt*(II) *dihydrate* (**1**)

A solution of the cobalt(II) acetate tetrahydrate (0.5 g, 2 mmol) in degassed methanol (10 cm^3) was added to the warm solution prepared by dissolving the ligand L_1H_2 (0.29 g, 0.5 mmol) in degassed acetonitrile (30 cm^3). The reaction mixture was allowed to reflux for 10 min under argon, then left aside for 1 h. The deep brown crystalline product was filtered off, washed with cold water and dried *in vacuo*. Found: C, 67.3; H. 5.0; N, 8.6. Calc. for $C_{36}H_{34}N_4O_4Co$: C, 67.0; H, 5.3; N, 8.7%.

[2,3:9,10 - *Dibenzo* - 6,13 - *dibenzoyl* - 7,12 - *dimethyl* - 5,14 - *diphenyl* - 1,4,8,11 - *tetraazacyclotetradeca* - 2, 5,7,11,13-*hexaenato*(2−)]*cobalt*(II) (**2**)

A solution of the cobalt acetate tetrahydrate (0.53 g, 2 mmol) in degassed water (5 cm^3) was added to a slurry prepared by refluxing the ligand L_2H_2 (0.35 g, 0.5 mmol) in degassed ethanol (100 cm^3). The reaction mixture was refluxed with stirring for 1 h under argon. During this time the colour of the reaction mixture changed from orange to a brown–green, and the whole amount of the ligand dissolved. Upon cooling, the brown–green precipitate was isolated by filtration, then washed with water and dried *in vacuo*. Found: 75.8; H, 4.5; N, 7.3. Calc. for $C_{46}H_{34}N_4O_2Co$: C, 75.3; H, 4.7; N, 7.6%.

Synthesis of the cobalt(III) *complexes* (*general procedure*)

Method (a). A sample of the appropriate complex $Co^{II}L$ was dissolved in warm pyridine to give a deep red solution. Upon cooling, a saturated aqueous solution of the appropriate inorganic salt NaX was added dropwise with stirring to the pyridine

solution, until abundant precipitate appeared. Stirring was continued for a further 2 h and then the reaction mixture was left overnight at room temperature. A crystalline product was filtered off, washed with water and dried *in vacuo*.

Method (b). A violet solution of the cobalt acetate tetrahydrate (0.5 mmol) in warm pyridine (5 cm^3) was added to a slurry of the appropriate ligand (0.5 mmol) in refluxing acetonitrile (10 cm^3). The reaction mixture which became intensively red was gently heated for 5 min and then cooled. A saturated aqueous solution of the appropriate salt (NaX) was added dropwise to the intensively stirred solution until the precipitation of the crystalline product was complete. The mixture was stirred for 2 h and then left overnight at room temperature. The crystalline solid was collected by filtration, washed carefully with water and dried *in vacuo*.

Purification of the cobalt(III) complexes was accomplished by dissolving in a small amount of pyridine and reprecipitating with a saturated aqueous solution of the appropriate inorganic salt NaX. Complex **3**, Found: C, 64.3; H, 4.3; N, 9.4. Calc. for $C_{46}H_{40}N_6O_2CoBF_4$: C, 64.7; H, 4.7; N, 9.8%. Complex **4**, Found: C, 61.4; H, 4.7; N, 9.8. Calc. for $C_{46}H_{40}N_6O_2CoI$: C, 61.8; H, 4.5; N, 9.4%. Complex **5**, Found: C, 68.2; H, 4.6; N, 8.8. Calc. for $C_{56}H_{44}N_6O_2CoBF_4$: C, 68.7; H, 4.5; N, 8.6%. Complex **6**, Found: C, 65.6; H, 4.5; N, 8.6. Calc. for $C_{56}H_{44}N_6O_2CoI$: C, 66.0; H, 4.4; N, 8.3%.

Yields and physical properties of cobalt(II) and cobalt(III) complexes are collected in Table 1.

Catalytic auto-oxidation of benzenethiol to diphenyl disulphide (general procedure)

A stream of air was bubbled through a solution of the catalyst (0.074 mmol) and benzenethiol (0.5 cm^3, 4.9 mmol) in chloroform (15 cm^3). After 30 min, the solvent and unchanged substrate were removed under reduced pressure at room temperature. The residue was chromatographed on neutral alumina. The first fraction eluted with benzene contained pure diphenyl disulphide.

SYNTHESIS AND MAGNETIC PROPERTIES OF BINUCLEAR COPPER(II)–COBALT(II) COMPLEXES WITH N,N′-BIS (2-AMINOPROPYL)OXAMIDOCOPPER(II)

DAI-ZHENG LIAO,* LI-CUN LI and GEN-LINE WANG

Department of Chemistry, Nankai University, Tianjin, P.R.C.

(*Received* 28 *September* 1990; *accepted* 25 *April* 1991)

Abstract—Three heterobinuclear complexes have been synthesized, namely [Cu(oxap) $Co(L)_2](ClO_4)_2$ [where L = 2,2′-bipyridyl (bpy), 1,10-phenanthroline (phen) and 5-nitro-1,10-phenanthroline (NO_2-phen)], where oxap is N,N′-bis(2-aminopropyl)oxamido. Based on IR, elemental analyses, conductivity measurements and electronic spectra, these complexes are proposed to have extended oxamido-bridged structures and to consist of copper(II) in a planar environment and cobalt(II) in an octahedral environment. The complexes have been characterized by variable temperature magnetic susceptibility (4.2–300 K) and the data were fit by least-squares to a susceptibility equation derived from the spin Hamiltonian, $\hat{H} = -2J\hat{S}\cdot\hat{S}_2 - D\hat{S}_{z1}^2$. The exchange integral, J, was found to be -15 cm^{-1} (for bpy), -24 cm^{-1} (for phen) and -26 cm^{-1} (for NO_2-phen), indicating that a weak antiferromagnetic spin-exchange interaction operates between the metal ions.

Binuclear metal complexes with extended bridged structures are of current interest due to spin-exchange and charge transfer between metal ions and in the domain of metalloenzymes and homogeneous catalysis.[1]

In view of the effective bridging function of the oxamido group, Ojima and Nonoyama[2] first utilized N,N′-bis(2-aminopropyl)oxamidocopper(II), Cu(oxap), as a bidentate mononuclear fragment to prepare the binuclear complex [Cu(oxap)Cu(bpy)] $(NO_3)_2$, but its detailed physicochemical properties have not been reported. Recently, complexes of this kind with various terminal ligands and other metal ions, such as [Cu(oxap)Zn(phen)$_2$] $(ClO_4)_2$ and [Cu(oxap)Ni(phen)$_2$]$(ClO_4)_2$, were synthesized in our laboratory and their magnetic properties and crystal structures were studied.[3] As an extension of the above investigation, this paper deals with the synthesis and the magnetic and EPR properties of three new complexes, [Cu(oxap)$Co(L)_2](ClO_4)_2$ [where L = 2,2′-bipyridyl (bpy), 1,10-phenanthroline (phen) and 5-nitro-1,10-phenanthroline (NO_2-phen)].

EXPERIMENTAL

Preparation of [Cu(oxap)$Co(bpy)_2](ClO_4)_2\cdot 1.5H_2O$

N,N′ - bis(2 - aminopropyl)oxamidocopper(II) [Cu(oxap)] was prepared by a literature method.[4] Bpy, phen and NO_2-phen were purchased from Peking Chemical Company.

To an absolute methanol solution (20 cm^3) of Cu(oxpn) (264 mg, 10^{-3} mol) were successively added an absolute methanol solution (10 cm^3) containing $Co(ClO_4)_2\cdot 6H_2O$ (366 mg, 10^{-3} mol) and bpy (312 mg, 2×10^{-3} mol) to give dark purple microcrystals which were separated, washed several times with absolute methanol and diethyl ether and dried *in vacuo*. Found: C, 39.4; H, 3.8; N, 12.6; Cu, 7.0; Co, 6.9. Calc. for $C_{28}H_{32}N_8O_{10}Cl_2CuCo\cdot 1.5H_2O$: C, 39.1; H, 4.1; N, 13.0; Cu, 7.4; Co, 6.8%.

Preparation of [Cu(oxap)$Co(phen)_2](ClO_4)_2\cdot 1.5H_2O$

This complex was obtained as purple microcrystals by the same procedure but by using phen instead of bpy. Found: C, 42.1; H, 3.5; N, 12.3; Cu, 6.9; Co, 6.7. Calc. for $C_{32}H_{32}N_8O_{10}Cl_2CuCo\cdot$

$1.5H_2O$: C, 42.3; H, 3.9; N, 12.3; Cu, 7.0; Co, 6.5%.

Preparation of $[Cu(oxap)Co(NO_2\text{-phen})_2](ClO_4)_2 \cdot 1.5H_2O$

This complex was obtained as light purple microcrystals by the same procedure but by using NO_2-phen instead of bpy. Found: C, 38.1; H, 3.0; N, 14.0; Cu, 6.2; Co, 5.9. Calc. for $C_{32}H_{30}N_{10}O_{14}Cl_2CuCo \cdot 1.5H_2O$: C, 38.5; H, 3.3; N, 14.0; Cu, 6.4; Co, 5.9%.

Measurements

Elemental analyses of carbon, hydrogen and nitrogen were carried out with a Perkin–Elmer analyser, Model 240. Metal contents were determined by EDTA titration, IR spectra were measured on a Shimadzu IR spectrophotometer, Model 408, using KBr pellets, and the electronic spectra (methanol solution) were measured on a Hitachi-240 spectrophotometer. The molar conductance was measured with a DDS-11A conductometer. Variable temperature magnetic susceptibilities were measured on a vibrating sample magnetometer, Model CF. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms, and the magnetic moments were calculated using the equation $\mu_{eff} = 2.828(XT)^{1/2}$. ESR spectra were measured with a JES-FEIXG ESR-apparatus using the X-band.

RESULTS AND DISCUSSION

General characterization

Elemental analyses indicated that the reaction of Cu(oxap) with $Co(ClO_4)_2 \cdot 6H_2O$ and bpy, phen or NO_2-phen yielded the binuclear complexes. For the three $[Cu(oxpn)Co(L)_2](ClO_4)_2$ complexes, the molar conductance values (see Table 1) fall in the expected range for 1 : 2 electrolytes,[5] indicating that the two perchlorate anions are situated outside the metal coordination sphere. The significant bands in the IR spectra of the complexes are given in Table 1. The $\rangle C{=}O$ (carbonyl) stretching vibration at 1588 cm^{-1} for Cu(oxap) and the —C=N— stretching vibration at 1450–1500 cm^{-1} for the terminal ligands (bpy, phen and NO_2-phen) were shifted to higher frequencies in their binuclear complexes. It is likely that the bond order of C=O in the binuclear complexes is higher than that in the mononuclear complexes. These shifts have often been used as definite proof for the existence of the oxamido bridge.[2] In addition, the $-NH_2$ vibration at 3175 cm^{-1} for Cu(oxap) was present for all complexes and a broad, intense band is observed at 1100 cm^{-1}, which is typical for a non-coordinated perchlorate ion. The electronic absorption spectral data for these complexes (methanol solutions) are given in Table 1. A strong absorption in the UV range and only a weak absorption in the visible range can be observed. The former may be attributed to the charge-transfer absorption bands and the latter to the *d–d* transition.[6] Based on the discussion above, these complexes are proposed to have extended oxamido-bridged structures and to contain copper(II) in a planar environment and cobalt(II) in an octahedral environment, as shown in Fig. 1.

Magnetic properties

The temperature dependence of the susceptibilities and magnetic moments for the three binuclear complexes are shown in Figs 2–4. The magnetic moments decrease steadily with decreasing temperature, implying the existence of an antiferromagnetic spin-exchange interaction within each molecule. Furthermore, the drastic decrease of magnetic moments around 70 K suggests a zero-field interaction and an intermolecular antiferromagnetic interaction.

The magnetic analyses for the complexes (d^9–d^7) were carried out using the susceptibility equation based on the Heisenberg spin operator ($\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2$). However, the data at low temperature do not satisfactorily fit this equation, because they neglect the single ion zero-field interaction of the cobalt(II) ion and the intermolecular interaction. We therefore adopted a susceptibility equation based on the modified Heisenberg operator, $\hat{H} = -J\hat{S}_1 \cdot \hat{S}_2 + D\hat{S}_{z1}^2$, where D is the axial zero-field splitting parameter for the cobalt(II) ion. The expression for the susceptibility, χ_m, is given by eq. (1):[7]

$$\chi_m = (2Ng^2\beta^2/K(T-\theta))[\exp(A) + 4\exp(C) + \exp(E)]/[2\exp(A) + \exp(B) + 2\exp(C) + \exp(D) + 2\exp(E)],$$

$$A = [4J + 5D/4 - (4J^2 - 2DJ + D^2)^{1/2}]/KT$$

$$B = (2J + D/4)/KT$$

$$C = (6J + 9D/4)/KT$$

$$D = (6J + D/4)/KT$$

$$E = [4J + 5D/4 + (4J^2 - 2DJ + D^2)^{1/2}]/KT, \quad (1)$$

where N, g, β, K and T have their usual meanings, J is the exchange integral and θ is the Curie–Weiss parameter. As shown in Figs 2–4, good least-squares fits to the experimental data were attained with eq. (1). The agreement factor F defined here as $\Sigma_i (X_i^{obs})^{-1}(X_i^{obs} - X_i^{calc})^2$ is equal to approx. 1×10^{-5} in all cases. Compared with the simple model ($H = 2J\hat{S}_1 \cdot \hat{S}_2$, $F \simeq 10^{-3}$), a much better fit was obtained with the modified Heisenberg operator. The magnetic parameters thus determined are: $J = -15$ cm^{-1}, $g = 2.31$, $D = -1.18$ cm^{-1}, $\theta = -34.9$ K (bpy); $J = -24$ cm^{-1}, $g = 2.47$, $D = -0.04$ cm^{-1}, $\theta = -37.4$ K (phen); and $J = -26$ cm^{-1}, $g = 2.33$, $D = -1.61$ cm^{-1}, $\theta = -6.5$ (NO_2-phen). These results (negative, small J values) indicate that the complexes undergo a weak antiferromagnetic spin-exchange interaction between the metal ions.

To describe the mechanism of the exchange interaction, several models have been proposed.[8–10] According to these models, strict orbital orthogonality results in ferromagnetism, otherwise an antiferromagnetic coupling should be expected. For the present complexes, if the whole molecular symmetry is considered to be C_{2v} and the reference used is shown by Fig. 1, the 3d metallic orbitals of copper(II) and cobalt(II) ions transform as $a_1(d_{z^2}$,

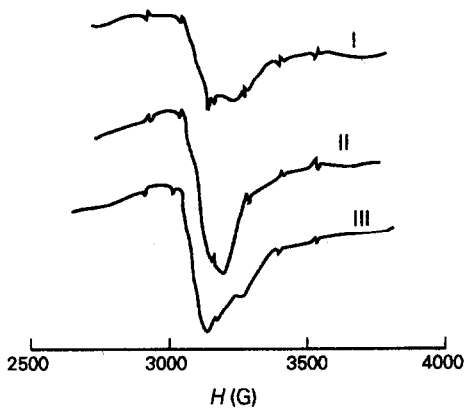

Fig. 5. X-band powder ESR spectra of the complexes at room temperature: **I**, bpy; **II**, phen; and **III**, NO_2-phen.

$d_{x^2-y^2}$), $a_2(d_{yz})$, $b_1(d_{xy})$ and $b_2(d_{zx})$. Around the copper(II) ion there is just one unpaired electron which occupies the b_1(Cu) orbital. Around the cobalt(II) ion the unpaired electron has some distribution in b_1(Co).[11] Because there is no orthogonality between the b_1 magnetic orbitals centred on the copper(II) and cobalt(II) ions, the antiferromagnetic interaction should be observed. We also investigated the magnetic behaviour of Cu^{II}–Cu^{II} and Cu^{II}–Ni^{II} binuclear complexes containing the same oxamido bridge and terminal ligands (e.g. phen) and obtained the following sequence for the magnetic interaction: [CuCu] ($J = -235\ cm^{-1}$) > [CuNi] ($J = -92\ cm^{-1}$) > [CuCo] ($J = -24\ cm-1$).[3] This result is in accordance with Kahn *et al.*'s expectation.[11]

ESR spectra

The powder ESR spectra of the three complexes at room temperature are shown in Fig. 5. They are obviously different from the mononuclear fragments; each exhibits a dissymmetric broad band of upper and lower peaks probably due to coupling of copper(II) ($S_1 = 1/2$) and cobalt(II) ($S_2 = 3/2$), although their assignments have not been made.

Abstract—We consider in this work the complexation of copper(II) by two different complexing agents [7-4(ethyl-1-methyloctyl)-8-hydroxyquinoline (C_{11}-HQ) and 6-(hexadecylamino)methyl-2-hydroxymethylpyridine (C_{16}NHMePyr)] in different kinds of micellar surfactant solutions (SDS, $C_{12}EO_6$, CTAB and mixed CTAB/butanol). Stopped-flow kinetic experiments at controlled pH have provided values of the apparent rate constants for complex formation, which are discussed with reference to literature data in homogeneous solutions. They show considerable rate decreases, especially in CTAB micellar systems.

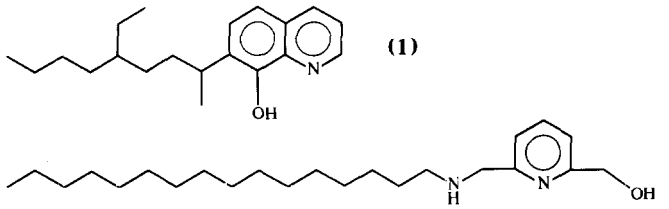
Since the pioneering work of Eigen and coworkers, it is well known that the rate of complexation of metal ions with complexing agents correlates with the characteristic rate constant for substitution of water molecules from the inner coordination sphere of metal ions.[1,2] The order of magnitude of this characteristic rate can be assigned to a given metal ion irrespective of the incoming ligand.[2] Apart from very special cases involving unusual mechanisms, this appears to be generally true in homogeneous solutions where the complexation process is always fast. The characteristic rate constants are for instance of the order 10^4, 10^5 and 10^8 s^{-1} for Ni^{2+}, Co^{2+} and Cu^{2+}, respectively. The much larger rate observed for the Cu^{2+} ion compared to the other mentioned ions has been ascribed to the operation of the Jahn–Teller effect, consisting of a distortion in the cation geometry which results in two relatively distant and weakly bonded water molecules in the primary hydration sphere.[3–5] As a consequence, kinetic investigations concerning copper(II) have been particularly difficult, requiring the use of relaxation techniques such as the temperature-jump technique. In some instances the reaction rate could be brought into the lower limit of reaction times attainable by the more classical stopped-flow technique, either by decreasing the concentration of reagents or by using a less reactive protonated form of the ligand.[4]

A class of complexing agents deserving special interest is that of lipophilic extractants which have applications for metal recovery in solvent extraction processes[6] and for functional micellar catalysis.[7,8] These extractant molecules are insoluble or extremely poorly soluble in water but they can be solubilized in an aqueous environment using micellar solutions or micro-emulsions. Such micro-heterogeneous media have been shown to mimic in some way the conditions of an extraction process taking place at an oil/water interface,[9,10] when a "kinetic regime" is established.

In this paper we report results concerning copper(II) complexation by micelle-solubilized long-chain complexing agents, which show very

* Author to whom correspondence should be addressed.

slow complexation rates in comparison to most of the available data in the literature. Such slowing down of the rate of complex formation may prove useful for separation purposes.[11] Compounds **1** and **2** were used as complexing agents:



Compound **1**, which will be abbreviated to C_{11}-HQ, had an industrial origin,[9,12] whereas compound **2** (C_{16}NHMePyr in the following) was synthesized in one of our laboratories.[13]

RESULTS AND DISCUSSION

Complexation of Cu^{2+} *with* C_{11}-HQ

Most of the preceding stopped-flow kinetic studies involving this extractant were carried out in conditions where the metal ions (up to now only Ni^{2+} and Co^{2+}) were in a large excess compared to the complexing agent.[9,10,14] The reverse situation, which is closer to that encountered in solvent extraction, is examined here: the final concentration of copper chloride was 3×10^{-4} mol dm^{-3}, whereas the concentration of C_{11}-HQ varied between 3.34×10^{-3} and 1.67×10^{-2} mol dm^{-3} (i.e. 0.1–0.5 in weight by weight per cent). The source solution of C_{11}-HQ had the following composition (values in weight per cent): CTAB (4.5)/butanol (4.5)/C_{11}-HQ (1.0)/water 0.1 mol dm^{-3} TEA/HCl buffer (90.0). Different dilution methods were investigated (see schematic drawing in Fig. 1) leading to different results. In each case, the same diluent (either a micellar solution of the same composition or an aqueous solution) was also used to solubilize the metal ions. Three different kinds of aqueous solutions were tested: (1) solution of 0.1 mol dm^{-3} TEA, pH 6.5; (2) solution of ionic strength 0.25 mol dm^{-3} KBr; and (3) solution with no buffer or salt (pH of the metal ion solution was adjusted with drops of sodium hydroxyde or hydrochloric acid).

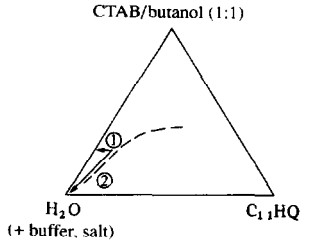


Fig. 1. Schematic phase diagram showing the two possible dilution paths: path (1): dilution with a micellar solution; path (2): dilution with water.

The kinetic curves recorded at 432 nm were generally bi-exponential, with the fastest relaxation process accounting for approximately 90% of the total absorption change. The slow relaxation process whose origin was previously discussed[9] will not be considered here. It was in fact almost undetectable when the aqueous diluent did not contain TEA [cases (2) and (3) above], but this may be due to a slight acidic shift in the final pH.

The variations of the reciprocal relaxation time of the exponential versus concentration of C_{11}-HQ have been plotted in Fig. 2 for the different ways of mixing the solutions described above. Fairly good linear plots were obtained in all cases. The slopes of the straight lines provide the values of the apparent rate constants k_f^{app} for complex formation. This is 3.2×10^3 mol^{-1} dm^3 s^{-1} when the composition of the micellar solution is kept constant during the mixing and from 2 to 2.3 times lower when diluted by an aqueous solution (1.4×10^3 with 0.25 mol dm^{-3} KBr, 1.7×10^3 with no buffer or salt and 2.1×10^3 with 0.1 mol dm^{-3} TEA).

In the case of dilution by an aqueous solution,

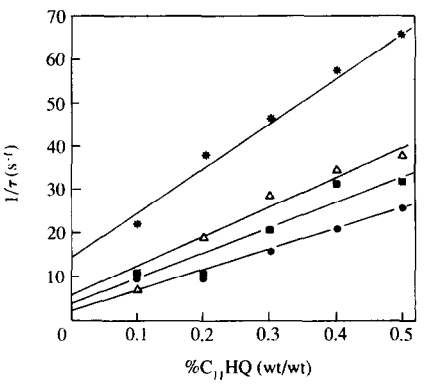

Fig. 2. Reciprocal relaxation time (or observed rate constant) versus concentration of C_{11}HQ in % (wt/wt). Copper concentration: 3×10^{-4} mol dm^{-3}, pH 6.5. Dilution by: (*) micellar solution; (△) water 0.1 mol dm^{-3} TEA; (■) water; (●) water 0.25 mol dm^{-3} KBr.

the final concentration of micelles is half that in the former case and thus the *local* concentration of micelle-solubilized extractants should be larger. Considering this local concentration instead of the overall one does not allow one to rationalize the data. The results would thus indicate that (due to electrostatic repulsions) the probability of a successful collision between Cu^{2+} and an extractant molecule is increased when these molecules are distributed over a larger number of micelles.

We have also examined the complexation of copper ions in the presence of an equivalent concentration of cobalt ions, which are expected to react much more slowly. Two well-separated relaxation processes were obtained in that case: the fastest one, due to copper complexation, remained unaffected by the presence of the second metal ion species. From the variation of the slowest one with concentration of C_{11}-HQ, an apparent rate constant of 8.6 mol^{-1} dm^3 s^{-1} was determined for cobalt complexation. The ratio between the rate constants for copper and cobalt respectively amounts to 372. This value, which is in the order of magnitude expected for the ratio of the water exchange rates in the inner coordination spheres of these metal ions,[1,2] can be taken as proof that the kinetics observed are truly related to metal ion complexation.

The time scale involved in copper complexation by C_{11}-HQ is much longer than what is generally found in homogeneous solutions, as far as neutral ligands are concerned (see Table 1). The values found for k_f^{app} are even smaller than those measured for a number of protonated species, which have been qualified as "abnormal" slow-reacting species.[4] In the present case, as the local pH at the micellar surface is expected to be more basic than the measured one (due to Br^-/OH^- ion exchange[15]), we assume that the extractant exists mainly in its neutral form. Indeed the first pK of the non-alkylated analogue of C_{11}-HQ (8-hydroxyquinoline) was around 5,[16,17] and measurements performed in methanol gave a lower pK value (decrease of about 0.8 units) for C_{11}-HQ than for 8-hydroxyquinoline.[12]

The low rate of complexation can be attributed to several effects whose contributions will have to be investigated more closely: (1) electrostatic repulsions between the metal ions and the micelles in which the extractant is solubilized; (2) hydrophobic interactions between the extractant molecules and the micelles, implying a strong partition of the extractant in favour of the micellar pseudo-phase; (3) a possible effect of reduction of dimensionality if the reaction takes place on the micellar surface;[18] and (4) steric hindrance preventing the approach to the complexing site.

Complexation of Cu^{2+} *with* C_{16}NHMePyr

The kinetics of complex formation were investigated in micellar solutions made respectively of anionic, cationic and non-ionic surfactants. The appearance of the complex in the presence of a large excess of Cu^{2+} ions (1 : 1 complex) was detected at 285 nm (SDS solutions) or at 300 nm (CTAB and $C_{12}EO_6$ solutions). Figure 3 shows that the behaviour of the curves giving the variation of absorbance versus time may be very sensitive to pH changes. In the cases of CTAB and $C_{12}EO_6$, if the solutions of metal and extractant respectively are mixed, with no special pH adjustments, a bimodal curve is obtained which can be nicely fitted with a bi-exponential

Table 1. Comparison of rate constants for Cu^{2+} complexation in homogeneous media (k_f) and in micro-heterogeneous media (k_f^{app})

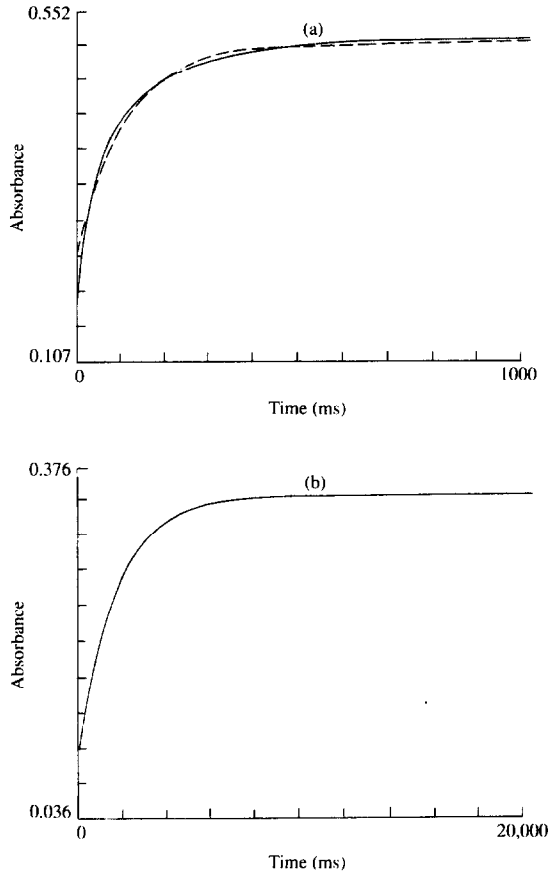

Fig. 3. Typical change of absorbance versus time during $C_{16}NHMePyr/Cu^{2+}$ complexation in CTAB at 300 nm. (a) No HCl added; --- theoretical fit with mono-exponential function; —— experimental curve and fit with biexponential function (undistinguishable). (b) HCl added; experimental curve and monoexponential fit undistinguishable.

function. On the other hand, one always obtains a strictly mono-exponential behaviour if one of the solutions is slightly acidified, so that the final pH is below 4.0. In the case of SDS, the second relaxation time was not observed.

Figures 4–6 indicate the conditions in which one or two relaxation times were obtained (the observed rate constants k_{obs} are equivalent to the reciprocal relaxation times). The pH was adjusted with a few drops of hydrochloric acid or sodium hydroxyde, avoiding the use of any buffer. An aliquot of the mixed solutions was taken out of the stopped-flow apparatus in order to measure the final equilibrium pH values which are plotted in Figs 4–6. The general shape of these curves is as expected when several protonation steps are involved in the mechanism considered.[19,20]

Taking advantage of the preceding observations we fixed the pH at 3.5 ($\pm$0.2) in order to investigate

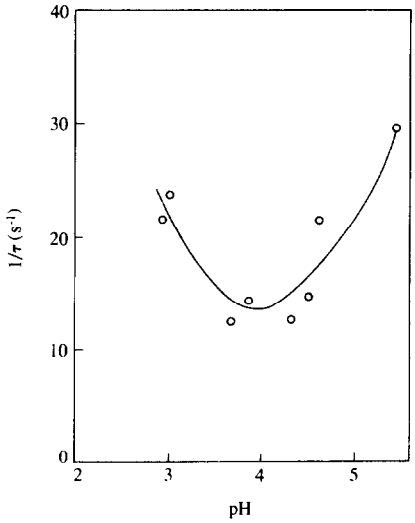

Fig. 4. Reciprocal relaxation times versus pH for $C_{16}NHMePyr/Cu^{2+}$ complexation in SDS 0.2 mol dm^{-3}; $[Cu^{2+}] = 10^{-3}$ mol dm^{-3}.

the effect of the concentration of Cu^{2+} ions on k_{obs}. The results are represented in Fig. 7 for the three micellar systems used as reaction media. A linear variation was always found, the slope of which gives the value of the apparent rate constant for complex formation: 128 mol^{-1} dm^3 s^{-1}, 237 mol^{-1} dm^3 s^{-1} and 7100 mol^{-1} dm^3 s^{-1} for CTAB, $C_{12}EO_6$ and SDS, respectively. These values are likely to be assigned to the reaction between the protonated form of the ligand $C_{16}\overset{+}{N}H_2MePyr$ and the metal ion (see below).

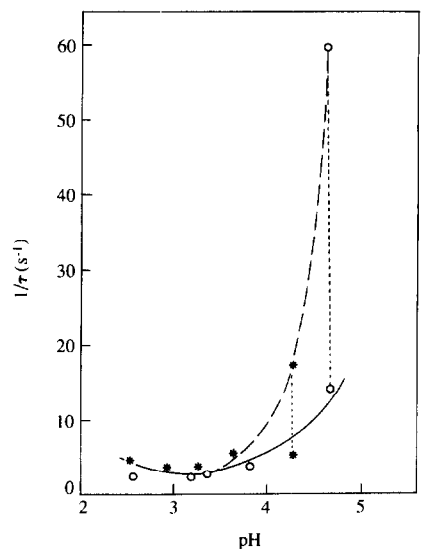

Fig. 5. Reciprocal relaxation times versus pH for $C_{16}NHMePyr/Cu^{2+}$ complexation in $C_{12}EO_6$ 0.02 mol dm^{-3} (○) and 0.2 mol dm^{-3} (*), $[Cu^{2+}] = 5 \times 10^{-3}$ mol dm^{-3}. The dashed lines refer to the second relaxation times.

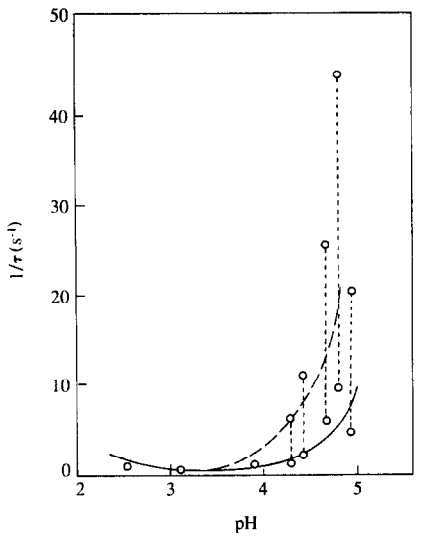

Fig. 6. Reciprocal relaxation times versus pH for $C_{16}NHMePyr/Cu^{2+}$ complexation in CTAB 2.5×10^{-2} mol dm^{-3}; $[Cu^{2+}] = 5 \times 10^{-3}$ mol dm^{-3}. The dashed lines refer to the second relaxation times.

As expected, a much larger value was obtained in SDS solutions than in solutions of the other surfactants. This is due to the high local concentration of Cu^{2+} ions in the Stern layer of the SDS micelles in which the complexing agent is solubilized. It can thus be viewed as a classical micellar "catalysis" effect. Note, however, that the measured rate constant has a value in the same order as that obtained for the protonated form of the non-alkylated ligand aminomethylpyridine ($AmpH^+$) in purely aqueous solution.[4]

The situation is completely different for the case

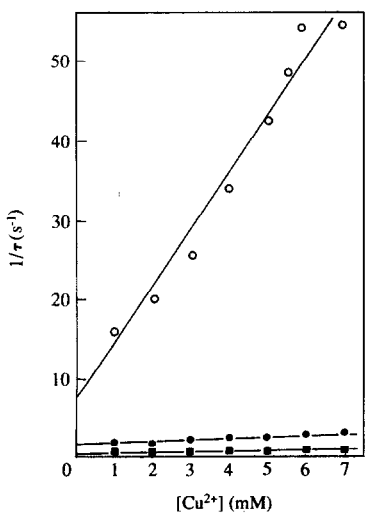

Fig. 7. Reciprocal relaxation times versus concentration of Cu^{2+} at pH 3.5 (±0.2); (○) SDS 0.2 mol dm^{-3}; (●) $C_{12}EO_6$ 0.02 mol dm^{-3}; (■) CTAB 0.025 mol dm^{-3}.

of cationic micelles in which the apparent rate constant has an unusually low value when compared to the literature data (see Table 1). The value obtained with $C_{12}EO_6$ is less than twice as large, which can be taken as an indication that the hydrophobic interactions between the ligand and the micelles play a larger part than the electrostatic repulsions between the metal ions and the surface of the micelles.

The intercepts of the lines shown in Fig. 7 are expected to give the values of the dissociation rate constants. They indicate that the release of Cu^{2+} from its complex is much easier in SDS micelles than in CTAB micelles, with an intermediary situation for $C_{12}EO_6$.

This may be attributed to the fact that in the case of SDS the surfactant ions in the vicinity of the complex can attract the metal ion and thus can destabilize the complex more easily than in the case of cationic or non-ionic micelles.

In the present paper, the micellar systems have been considered as simple reaction media and we will not attempt to define more precisely the site of the reaction of complexation. This will be done in a next step.

Concerning the origin of the two relaxation processes which depend on the pH, additional information regarding the ionization state of the ligand is required. For this reason we have performed potentiometric measurements on a C_4-analogue of $C_{16}NHMePyr$, which is sufficiently water soluble. These measurements indicate a pK of 9.05 for the free ligand [a pK of 8.61 was reported for 2-aminomethylpyridine (Amp) which has a close structure[21]], whereas it is only of 6.1 for the complex with copper(II). The concentration of ligand was 10^{-2} M and a 20% excess of Cu^{2+} ions was used in the second case. If one refers to the case of alkylamines, the pK should be almost independent of the alkyl chain length (pKs are respectively 10.7, 10.63 and 10.61 for ethylamine, $C_{12}NH_2$ and $C_{16}NH_2$).[22] However, the pKs measured in water may be different from the effective pKs in the micellar pseudo-phases.[23,24] The pK shifts are expected to go in opposite directions in SDS and CTAB micellar solutions, respectively. This may explain why the second relaxation time was not observed with SDS.

Neglecting the effect of the micro-environment, the following assumptions can be made from the preceding pK values: (1) essentially the ligand protonated on the amine function should be considered as the reacting species at the pH values used; and (2) the protonation equilibrium of the complex may be responsible for the existence of a second relaxation process.

In fact, according to Roche and Wilkins,[4] the deprotonation of the complex can be quite slow, since proton loss may even be rate-limiting in the reaction of $AmpH^+$ with Cu^{2+}. In this last case the pK shift between the free amine and its complex was estimated to be about 2 units from the comparison with literature data concerning comparable situations. It is close to 3 units in the present case.

From the preceding considerations the simplest mechanism that can be proposed to qualitatively account for our results is the following:

$$Cu^{2+} + LH_2^+ \underset{k_{-1}^{app}}{\overset{k_1^{app}}{\rightleftharpoons}} Cu-LH_2^{3+} \qquad (1)$$

$$Cu-LH_2^{3+} \underset{k_{-2}^{app}}{\overset{k_2^{app}}{\rightleftharpoons}} CuLH^{2+} + H^+. \qquad (2)$$

Protonation of the pyridinium ring has been omitted, but it would have to be taken into consideration in the very low pH range.

The preceding mechanism is characterized by two relaxation times except when the pH is sufficiently acidic that the complex remains entirely protonated. There is no longer a contribution of reaction (2) in that case, and the system is reduced to reaction (1) whose time constant is given by:[25,26]

$$k_{obs} = \frac{1}{\tau} = k_1^{app}[Cu^{2+} + LH_2^+] + k_{-1}^{app}$$

$$\sim k_1^{app}[Cu^{2+}]_0 + k_{-1}^{app}$$

in agreement with the linear behaviours reported in Fig. 7.

Following classical methods of calculations,[26] a complete treatment of the above mechanism was attempted in order to verify how the two relaxation times vary when the pH is changed. Assuming that the equilibrium constants for reaction (1) and (2) are known ($K_1 = k_1^{app}/k_{-1}^{app}$ and K_2 was given the value obtained from pK measurements in water), all the equilibrium concentrations can be calculated. The only unknown quantities for the calculation of the relaxation times are k_2^{app} and k_{-2}^{app}, which are related through K_2. Varying the value of k_2^{app} has not permitted a quantitative agreement with the data, although the same kind of variations could be obtained for the two relaxation times. From these variations the shortest relaxation time could be tentatively assigned to reaction (2) and the longest relaxation time, which was found almost independent of pH, to reaction (1).

This treatment, which considered the micellar solution as an ordinary solvent, provides an explanation for the existence of a second relaxation time but it is inadequate to interpret the data on quantitative grounds because it ignores the actual micro-heterogeneous nature of the solution. One related question is that of the possible existence of free and micellar-bound ligands and the rate controlling their exchange reaction. At pH 3.5, $C_{16}\overset{+}{N}H_2MePyr$ is assumed to behave like a surfactant due to its amphiphilic nature. The mean rate constant for the dissociation of a C_{16}-surfactant monomer from a micelle was shown to be around 10^5 s^{-1}.[27,28] This quantity has to be divided by the micellar number if one particular monomer in the micelle is considered. This would also apply for one single complexing molecule solubilized in a classical micelle made of surfactant ions bearing the same electric charge. In this case, the rate constant for dissociation can thus reasonably be estimated to be in the ms range, which is quite fast in comparison with the time scale of the present experiments. Due to this fast ligand exchange we assumed that we measured an average complexation rate, in which the micelle-solubilized long-chain complexing agent is expected to contribute in an overwhelming manner.

To prove this view to be correct we would need to vary the hydrophobic character of the complexing agent to see if this has an influence on the existence of one or two relaxation times. This should be investigated before a complete treatment, taking into account the micro-heterogeneous nature of the solution, could be attempted as for instance in the work of Miyake *et al.*[29]

Conclusion

We report in this paper unusually slow reaction rates for the complexation of copper(II) with two different complexing agents. However, unlike the case of nickel(II) for which the overall complexation time could be brought down to a time of the order 1 h,[11] the time scale involved always remained shorter than 1 min. This demonstrates that, although considerably decreased, the rate of complexation by micelle-solubilized long-chain complexing agents is still correlated with the rate of substitution of water molecules in the inner coordination sphere of the metal ion.

A direct comparison between ligands **1** and **2** is made difficult due to the existence of different chemical functions, especially the protonatable amine function in compound **2**. In addition, the signal amplitudes had a tendency to vanish when the pH was decreased with compound **1** and increased with compound **2**, preventing us from performing a comparison at the same pH.

The difference by one order of magnitude for the apparent rate constants measured in the presence of CTAB (see Table 1) can hardly be rationalized for this reason. Although a longer alkyl chain may

be responsible for a decrease in k_1^{app}, it is likely that the low value obtained with compound **2** is mainly due to the positive charge on the complexing site. Experiments with ligands having varying alkyl chain lengths appear necessary to go further in the understanding of these complex systems.

EXPERIMENTAL

Chemicals

Recrystallized 99% sodium dodecylsulphate (SDS) was obtained from Roth (Germany), hexaethyleneglycol dodecylether ($C_{12}EO_6$) from Nikko Chemicals (Japan) and cetyltrimethylammonium bromide (CTAB) from Fluka. All these products were used as received with the exception of CTAB, which was twice recrystallized in methanol/diethylether.

$CuCl_2 \cdot 2H_2O$ (normapur) was obtained from Prolabo (France). Compound **1** was obtained by purification of the industrial extractant Kelex 100 (Shering, Germany), according to a previously published procedure.[12] Compound **2** was synthesized by the Padova group.[13] The C_4 analogue was synthesized following the same procedure reported[13] for C_{16}NHMePyr, but using butylamine. The compound is a pale yellow oil. ^{1}H NMR δ ($CDCl_3$, TMS) 0.9 (t, 3H, CH_3), 1.2–1.7 (m, 4H, $2CH_2$), 2.7 (t, 2H, CH_2N), 3.2 (brs, 2H, OH and NH), 3.95 (s, 2H, NCH_2Py), 4.7 (s, 2H, OCH_2), 7.1 and 7.2 (2d, 2H, PyH_3 and H_5), 7.65 (t, 1H, PyH_4). Found: C, 67.9; H, 9.4; N, 14.3. Calc. for $C_{11}H_{18}N_2O$: C, 68.0; H, 9.3; N, 14.4%.

Triethanolamine (TEA) from Merck (pro-analysis) was used in some instances with hydrochloric acid to buffer the solutions (0.1 M concentration).

Techniques

The stopped-flow technique with optical detection was used to investigate the kinetics of complex formation at 25°C. Either a Durrum D-110 apparatus with a 2 cm optical path or a Hi-Tech (SF-3L, England) with a 2 mm optical path was used depending on the extent of light absorption by the metal complex. Both apparatus were on-line with a data acquisition system. The observed rate constants were computed from a least-squares fitting of the experimental curves with mono- or bi-exponential functions.

The stopped-flow experiments involved the rapid mixing of a micellar solution containing the lipophilic extractant with a solution containing the metal ions. This second solution was either a micellar solution having the same composition as the first one or simply an aqueous solution. pH measurements were performed with a combined glass electrode (Metrohm).

All the concentrations refer to the state of the system after rapid mixing. It is not clear whether the terms "micelle" or "micro-emulsion" should be used for the solutions with CTAB/butanol and large concentrations of C_{11}-HQ. The second one is preferable because the extractant was previously shown to play the same part as the oil in a classical microemulsion system.[11]

REACTIONS OF PRIMARY AROMATIC AMINES WITH STRONGLY ELECTROPHILIC NO COORDINATED TO A RUTHENIUM COMPLEX OF 2-(PHENYLAZO)PYRIDINE

ALOK KUMAR DEB and SREEBRATA GOSWAMI*

Department of Chemistry, North-Eastern Hill University, Shillong 793003, India

(*Received* 18 *March* 1991; *accepted* 3 *May* 1991)

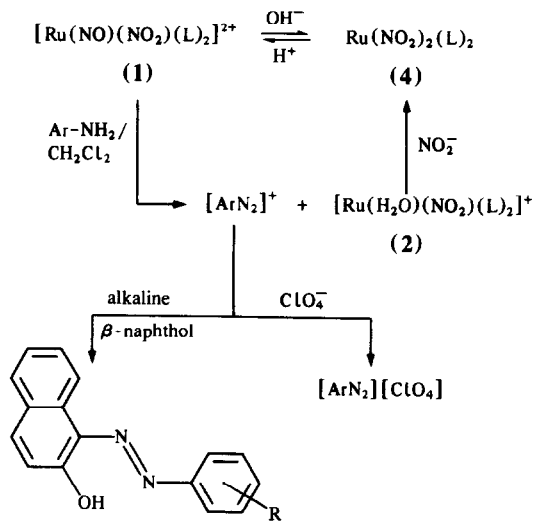
Abstract—The diazotization of primary aromatic amines with a strongly electrophilic mononitrosyl complex, $[Ru(NO)(NO_2)L_2](ClO_4)_2$ [L = 2-(phenylazo)pyridine], in acetonitrile and dichloromethane, is described. The reactions were studied by following the reaction sequence through the isolation of products at various stages of each reaction.

There has been considerable interest in the reactivities of the transition metal nitrosyls,[1,2] in general, and those of Group VIII metal ions,[3–6] in particular. Very recently, we have reported[7] the synthesis of a mononitrosyl complex of the type $[Ru(NO)(NO_2)L_2](ClO_4)_2$ (**1**) [L = 2-(phenylazo) pyridine], and it has been shown from its physicochemical data that the nitrosonium ion (NO^+) character of the coordinated nitric oxide in **1** is very high. Given the presence of a strongly electrophilic NO^+ centre in **1**, we initiated research to study the reactivities of **1** with various nucleophiles. Herein we report the diazotization reaction of aromatic primary amines using **1** as the source material of the nitrosonium cation. This reaction is one of the rare examples of its type and is important in connection with the synthesis of aryldiazonium[8–10] complexes which may be considered as a model[11,12] for dinitrogen complexes.

RESULTS AND DISCUSSION

The amines are abbreviated as $Ar\text{-}NH_2$. Reactions of the nitrosyl complex **1** with $Ar\text{-}NH_2$ were studied by following the reaction sequence through the isolation of products at various stages of the reactions. The reactions which have been studied are shown in Scheme 1. Strategically, the reactions were conducted in two solvents, viz. acetonitrile and dichloromethane, to provide a better insight into the mechanisms of the reactions.

The orange solution of **1** in acetonitrile readily reacted with $Ar\text{-}NH_2$ to produce a mixture of $[Ru(S)(NO_2)L_2]^+$ (**2**) (S = CH_3CN) and $Ar\text{-}N_2^+$. The cationic complex, **2**, has been isolated as a crystalline perchlorate salt. The aryldiazonium cation has been identified by spectral data and also by performing a chemical test with alkaline β-naphthol. Red crystals of the known[13] 1-arylazo-2-naphthol have been isolated from the reaction mixture. The metal part has been characterized by



R	Yield (%)

elemental analysis as well as by examining the spectral data (see Experimental). A strong band at 1370 cm^{-1} assignable to $\nu(NO_2)$ and a weak band at 2300 cm^{-1} assignable to $\nu(C{\equiv}N)$ are observed in the IR spectrum and an intense MLCT absorption band at 515 nm in the visible spectrum. The same reaction, when performed in the presence of very dilute aqueous perchloric acid, yielded the aryldiazonium cation in slightly improved yield together with a diacetonitrile complex of the type $[Ru(CH_3CN)_2L_2]^{2+}$ (**3**), which was isolated as a perchlorate salt. This has been formulated by elemental analysis. This compound showed two $\nu(C{\equiv}N)$ modes in the IR spectrum indicating a *cis* geometry[14] with respect to the solvent. The formation of the diacetonitrile compound **3** from the acidic medium was not unexpected since it has already been shown[7] that the dinitro complex, $Ru(NO_2)_2L_2$, is unstable in acidic media and yields disolvento species of the type $[Ru(S)_2L_2]^{2+}$ (S = solvent). The cationic complex **3** was further characterized by comparison of its spectral data with authentic $[Ru(CH_3CN)_2L_2]^{2+}$, which has been synthesized following the procedure described by Chakravorty and co-workers.[14]

The transformation of **1** to **2** requires firstly diazotization, followed by substitution of coordinated $Ar\text{-}N_2^+$ by acetonitrile. Keeping the high affinity[14] of acetonitrile for ruthenium(II) in mind, we examined the same diazotization reaction in a non-coordinating solvent, dichloromethane, hoping to isolate the coordinated aryldiazonium complex. Unfortunately, the crude reaction product obtained from the red dichloromethane solution showed a strong band at *ca* 2260 cm^{-1}, indicating the presence[9] of free $Ar\text{-}N_2^+$. It is quite significant to note that the IR spectrum of the crude product shows all the characteristic bands for both coordinated NO_2[7] and for coordinated L.[15] Analytically, the crude product was always inconsistent. Therefore, we conclude that the isolated product is a mixture of a salt of $Ar\text{-}N_2^+$ and some ruthenium complex of L. However, extraction of the crude product with water separated $[Ar\text{-}N_2]^+$ from the metal complex. The residue was soluble in dichloromethane which, on slow addition of hexane, yielded crystalline $[Ru(S)(NO_2)L_2]ClO_4 \cdot H_2O$ (**2**) (S = H_2O). Complex **2** (S = H_2O) was characterized by elemental analysis and by spectral data (see Experimental). A strong MLCT absorption band occurred at 530 nm (ε, 8500 $dm^3\ mol^{-1}\ cm^{-1}$). The cationic monoaquo complex **2** (S = H_2O) produced the monoacetonitrile complex **2** (S = CH_3CN) on treatment with acetonitrile, showing its instability in this solvent. This observation also in turn justifies the formation of the monoacetonitrile complex in the reaction when it is carried out in acetonitrile.

Free aryldiazonium ions as well as **2** and **3** are obtained in high yields. The regeneration of **1** can be performed first by treating **2** or **3** with an aqueous solution of sodium nitrite to obtain the known[7] dinitro complex $[Ru(NO_2)_2L_2]$ (**4**), which on treatment with acid produces **1** (Scheme 1). In contrast to the lone example[11,12] of a similar type of reaction, reported previously, free diazonium cations are directly obtained from the reaction of **1** and $Ar\text{-}NH_2$. The results could be interpreted by considering the high π-acidity of L. It is well documented in the literature that aryldiazonium complexes are generally stabilized[12] by π-back donation. In the present complex, L being a very strong π-acceptor[14-17] reduces the back donation to $Ar\text{-}N_2^+$ in the intermediate and thus makes it labile towards solvolysis reactions.

The results of the reactions described above are convincing, and one real advantage of such reactions is the possibility of developing a catalytic route for synthetic nitrosation reactions of organic substrates using **1** as the source of NO^+ under mildly acidic or even neutral conditions.

EXPERIMENTAL

IR spectra were recorded on a Perkin–Elmer IR-983 spectrophotometer in KBr pellets. Electronic spectra were obtained using a Hitachi 330 spectrophotometer. Solution electrical conductivity was measured using a Elico CM 82T conductivity bridge with a solution concentration of 10^{-3} mol dm^{-3}. Spectrograde acetonitrile and dichloromethane were used as the solvents in the diazotization reactions. The substituted anilines used were of reagent grade and used without further purification, aniline was distilled over potassium hydroxide before use. Elemental analyses were obtained using a Haraous CHN-O-RAPID elemental analyser.

Reaction of $[Ru(NO)(NO_2)L_2](ClO_4)_2$ *with* $Ar\text{-}NH_2$ ($Ar\text{-}NH_2$ = *aniline*, p-*anisidine*, p-*chloroaniline*, p-*toluidine*)

The reactions were performed by using a general procedure. Specific details are given for aniline.

Reaction in acetonitrile. The salt $[Ru(NO)(NO_2)L_2](ClO_4)_2$ (0.125 g, 0.17 mmol) was dissolved in acetonitrile (10 cm^3) and aniline (0.016 g, 0.17 mmol) was added. The mixture was stirred for 30 min at room temperature (295 K) and then evaporated to dryness using a vacuum pump. The crude product was then extracted with 30 cm^3 (3 × 10 cm^3) of ice-cold water and the aqueous solution was collected by filtration. To the aqueous solution, an aqueous solution of alkaline β-naphthol was added

with continuous stirring over a period of 15 min. Red crystals of 1-phenylazo-2-naphthol were separated and recrystallized from methanol (m.p. 130°C).

The dark tan residue obtained after water extraction was dried and dissolved in dichloromethane. On slow addition of hexane, light brown crystals of $[Ru(S)(NO_2)L_2]ClO_4 \cdot H_2O$ (S = CH_3CN) were obtained, which were filtered and dried *in vacuo* over P_4O_{10}; yield 60%. Found: C, 42.9; H, 3.3; N, 16.5. Calc. for $C_{24}H_{23}N_8O_7ClRu$: C, 42.9; H, 3.4; N, 16.7%. Λ_M(MeCN): 140 Ω^{-1} cm^2 mol^{-1}; ν_{max} (KBr): 1370 (NO_2), 2300 (C≡N) and 1360 cm^{-1} (N=N); λ_{max} (CH_3CN): 515, 350 and 310 (sh) nm (ε, 6475, 12,050 and 11,920 dm^3 mol^{-1} cm^{-1}).

Reaction in acetonitrile in presence of aqueous perchloric acid. This was carried out similarly except 0.1 cm^3 of 1 M aqueous perchloric acid was added together with Ar-NH_2. The metal part was crystallized from a 1 : 1 acetonitrile/water mixture and left to evaporate at room temperature overnight. The dark crystalline compound was collected by filtration and dried *in vacuo* over P_4O_{10} (compound $[Ru(CH_3CN)_2L_2](ClO_4)_2 \cdot H_2O$; yield 62%. Found: C, 41.0; H, 3.1; N, 14.3. Calc.: C, 40.7; H, 3.4; N, 14.6%. Λ_M(MeCN): 300 Ω^{-1} cm^2 mol^{-1}; ν_{max} (KBr): 2295, 2320 (C≡N) and 1365 cm^{-1} (N=N); λ_{max} (CH_3CN): 500, 470(sh), 365, 310(sh) and 280 nm (ε, 9670, 6400, 7910, 17,200 and 17,500 dm^3 mol^{-1} cm^{-1}).

Reaction in dichloromethane. $[Ru(NO)(NO_2)L_2](ClO_4)_2$ (0.125 g, 0.17 mmol) was suspended in dichloromethane (10 cm^3) and aniline (0.016 g, 0.17 mmol) was added. The mixture was then stirred for 30 min at room temperature (295 K) and the red–brown solution was then filtered. Brownish-white needles of $[C_6H_5N_2](ClO_4)$ were collected, washed with 5 cm^3 of dichloromethane and finally dried *in vacuo* over P_4O_{10}; yield 50%.

The cation $[C_6H_5N_2]^+$ could also be extracted with ice-cold water, and on addition of an aqueous alkaline solution of β-naphthol yielded red crystals of 1-phenylazo-2-naphthol, which were recrystallized from methanol (m.p. 130°C).

The red–brown dichloromethane filtrate was concentrated to 10 cm^3 under reduced pressure and slow addition of hexane yielded dark crystals of $[Ru(S)(NO_2)L_2]ClO_4 \cdot H_2O$ (S = H_2O). These were collected by filtration and dried *in vacuo* over P_4O_{10}, yield 55%. Found: C, 41.0; H, 3.5; N, 15.1. Calc. for $C_{22}H_{22}N_7O_8ClRu$: C, 40.7; H, 3.4; N, 15.1%. Λ_M(MeCN): 140 Ω^{-1} cm^2 mol^{-1}; ν_{max}(KBr): 1370 (NO_2) and 1360 cm^{-1} (N=N); λ_{max}(CH_2Cl_2): 530, 470(sh), 360(sh), 325(sh) and 312 nm (ε, 8500, 4750, 36,950, 58,550 and 67,015 dm^3 mol^{-1} cm^{-1}).

Conversion of $[Ru(S)(NO_2)L_2]ClO_4 \cdot H_2O$ (S = H_2O) *to* $[Ru(S)(NO_2)L_2]ClO_4 \cdot H_2O$ (S = CH_3CN). $[Ru(S)(NO_2)L_2]ClO_4 \cdot H_2O$ (S = H_2O) (0.100 g, 0.15 mmol) was dissolved in acetonitrile (15 cm^3) and stirred at room temperature for 30 min. To the brown solution, an equal volume of water was added and left to evaporate at room temperature overnight. Dark brown crystals of $[Ru(S)(NO_2)L_2]ClO_4 \cdot H_2O$ (S = CH_3CN) were obtained. The analytical and spectral data correspond exactly to those of the previously isolated compound **2** (S = CH_3CN).

Acknowledgements—We are thankful to Professor S. N. Bhat and RSIC for the spectral data.

FORMATION AND SPECTROSCOPIC CHARACTERIZATION OF HETEROBIMETALLIC COMPLEXES CONTAINING SIX-COORDINATE IRON(IV) OR MANGANESE(IV) COMPLEX ANION OF 1,1-DICARBOETHOXY-2,2-ETHYLENE DITHIOLATE AND OCTAHEDRALLY COORDINATED COMPLEX CATIONS OF IRON(II), COBALT(II), NICKEL(II) OR ZINC(II) WITH 1,10-PHENANTHROLINE

NANHAI SINGH,* RAGINI VERMA and N. K. SINGH

Department of Chemistry, Banaras Hindu University, Varanasi 221 005, India

(*Received* 23 *November* 1990; *accepted* 14 *May* 1991)

Abstract—Novel heterobinuclear complexes ($[M(o\text{-phen})_3][M'(DED)_3]$ [M = Fe^{II}, Co^{II}, Ni^{II} or Zn^{II}; M′ = Mn^{IV} or Fe^{IV}; *o*-phen = 1,10-phenanthroline; DED = 1,1-dicarboethoxy-2,2-ethylene dithiolate) have been prepared and characterized. The precursor complex anion $[Fe(DED)_3]^{2-}$ has been isolated as $[Bu_4N)_2[Fe(DED)_3]$. Molar conductivities of these complexes in acetonitrile indicate their 1 : 1 electrolytic behaviour. Bonding modes of the ligands, *o*-phen and DED have been inferred from characteristic IR absorptions suggesting their chelating nature. Room temperature magnetic moments have been measured. Electronic spectral bands suggest octahedral geometry around cobalt(II), nickel(II), iron(II), manganese(IV) and iron(IV) in these complexes. Features of ESR spectra and their *g* values are suggestive of manganese(IV).

The use of the ligand DED is of interest because of its strong tendency to stabilize the high formal oxidation states of certain metals, viz. manganese(IV), iron(IV) or copper(III) in their simple complexes.[1–4] The ligand DED has been characterized by a conjugated π-system.[4] The accessibility of several oxidation states of iron and manganese has evoked a great deal of interest, especially since iron(IV) complexes are important in some biological processes.[5] One of the most interesting characteristics of coordination compounds involving dithioligands is the diversity of their redox properties. The combination of a complex cation and complex anion of different metal ions has been effectively used in the synthesis of polynuclear complexes.[6–8] Our interest in these systems is because heterobimetallic complexes containing a complex cation and a complex anion are important in optical outer sphere ligand-to-metal charge-transfer,[9] and are of great importance in photochemistry[10] as well as electrically conducting materials.[8]

Polypyridine complexes of metal ions such as $Ru(bipy)_3^{2+}$ and related complexes have attracted much attention[11,12] in recent years due to the suitable combination of redox potentials, chemical inertness and excited state life-times which makes them useful as sensitizers. This direction synthesis of heterobimetallic complexes containing $[M(o\text{-phen})_3]^{2+}$ as the cation and $[M'(DED)_3]^{2-}$ as the anion may be interesting. With these points in mind and our continuing effort to explore the tendency of the dithioligands to function as binucleating/bridging ligands in the synthesis of heteronuclear complexes,[13] heterobimetallic complexes of the type $[M(o\text{-phen})_3][M'(DED)_3]$ have been synthesized and characterized. The results of these investigations are described in this paper.

EXPERIMENTAL

Materials and methods

The chemicals used for the synthesis of the complexes were BDH (AR) or equivalent grades. K_2DED was prepared as described earlier.[14] The

* Author to whom correspondence should be addressed.

solvents were freshly distilled and dried before use where necessary.

Preparation of the complexes

$(Bu_4N)_2[Fe(DED)_3]$. $K_2[Fe(DED)_3]$ was prepared[4] *in situ* by slow addition of an aqueous solution (50 cm^3) of anhydrous $FeCl_3$ (0.27 g) to an aqueous solution (200 cm^3) of K_2DED (1.8 g) in a 1 : 3 molar ratio with vigorous stirring. The complex formed immediatedly dissolved to give a dark brownish-black colour. The product was stirred for approx. 15 min and then filtered to an aqueous solution (50 cm^3) containing tetrabutyl ammonium chloride (3.0 g). A shiny black crystalline compound was immediately formed, which was filtered and washed thoroughly with water and dried in air.

Heterobimetallic complexes

$[M(o\text{-phen})_3][Fe(DED)_3]$ [M = Fe^{II}, Co^{II}, Ni^{II} *or* Zn^{II}]

To a solution of $K_2[Fe(DED)_3]$, prepared *in situ* as described above, a solution/suspension of $[Fe(o\text{-phen})_3]^{2+}$, $[Co(o\text{-phen})_3]^{2+}$, $[Ni(o\text{-phen})_3]^{2+}$ and $[Zn(o\text{-phen})_3]^{2+}$ complex ions prepared by mixing an ethanol/methanol–water [80 : 20 (v/v)] mixture solution (30 cm^3) containing $FeSO_4(NH_4)_2SO_4 \cdot 6H_2O$ (0.65 g), $CoCl_2 \cdot 6H_2O$ (0.40 g), $NiCl_2 \cdot 6H_2O$ (0.40 g) and $Zn(CH_3COO)_2 \cdot 2H_2O$ (0.36 g) to an ethanolic solution (20 cm^3) of *o*-phen (1.0 g) in a 1 : 3 molar ratio, were added gradually in a 1 : 1 molar ratio with constant stirring for approx. 30 min. The dark brownish-black microcrystalline complexes formed immediately and were suction filtered, washed thrice with a 50 : 50 ethanol–water (v/v) mixture followed by ethanol, and dried in air.

$[M(o\text{-phen})_3][Mn(DED)_3]$ (M = Fe^{II}, Ni^{II}, Co^{II} *or* Zn^{II})

$K_2[Mn(DED)_3]$ was prepared *in situ* by gradual addition of an ethanolic suspension (30 cm^3) of $Mn(CH_3COO)_3 \cdot 2H_2O$ (0.45 g) to an ethanolic suspension (50 cm^3) of K_2DED (2.0 g) in a 1 : 3 molar ratio (method described elsewhere[1]). The reaction mixture was stirred for 15 min and a dark purple coloured solution was formed. This was filtered, and a solution/suspension (30 cm^3) of $[Fe(o\text{-phen})_3]^{2+}$, $[Co(o\text{-phen})_3]^{2+}$, $[Ni(o\text{-phen})_3]^{2+}$ and $[Zn(o\text{-phen})_3]^{2+}$ complex ions, prepared in ethanol as above, was added in a 1 : 1 molar ratio. Within a short while the dark purple coloured crystalline heterobimetallic complexes were precipitated. The reaction mixture was stirred for approx. 30 min to ensure the completion of the reaction and then suction filtered and washed with dry ethanol. The complexes obtained in this way were suspended in a 90 : 10 (v/v) ethanol–water mixture (50 cm^3) and stirred thoroughly with a glass rod to dissolve the potassium acetate formed by the metathetic reactions. This was filtered and washed with the above solvent mixture and dried in air.

Analysis and physical measurements

The complexes were decomposed with hot concentrated aquaregia and then the metals were gravimetrically determined following standard literature procedures.[15] The molar conductances of the complexes were determined in acetonitrile solution (10^{-3} M). Electronic spectra in the visible and UV region were recorded on a Simadzu UV-160A, UV-vis. spectrophotometer. The experimental details for the elemental analyses, molar conductance and room temperature magnetic susceptibility measurements, and recording of IR and electronic spectra were the same as described earlier.[13] ESR spectra were recorded on a Varian E-117 X-band spectrometer using TCNE radical $g = 2.00277$ as a $\langle g \rangle$ marker. The relevant analytical results and physicochemical data are given in Table 1.

RESULTS AND DISCUSSION

The stoichiometry of the heterobimetallic complexes $[M(o\text{-phen})_3][M'(DED)_3]$ was suggested on the basis of their analytical results. These complexes are formed by the following metathetic reactions:

$$K_2[M'(DED)_3] + [M(o\text{–phen})_3]X_2 \longrightarrow [M(o\text{-phen})_3][M'(DED)_3] + 2KX;$$

where $M' = Fe^{IV}$ or Mn^{IV}; M = Fe^{II}, Co^{II}, Ni^{II} or Zn^{II}; and X = CH_3COO^-, Cl^-, $\frac{1}{2}SO_4^{2-}$.

All the complexes are stable at room temperature, fairly soluble in acetonitrile and DMF but are insoluble in water and ethanol. Their ionic conductivities (S = 80–118 $cm^2\,\Omega^{-1}\,mol^{-1}$) in acetonitrile suggest 1 : 1 electrolytic behaviour.[16] Slightly lower values of conductivities may be regarded due to the presence of two heavier complex ions.

IR spectra

The prominent IR bands of the complexes have been recorded over the range 4000–200 cm^{-1}. There is much evidence that the canonical form of the type shown in **1** plays a key role in the description of the bonding mode of the ligand DED in its

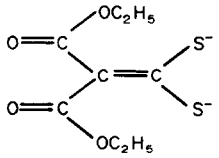
[a] Zinc and manganese have been estimated collectively.
Calculated values appear in parentheses.



complexes.[1,6,14] The four most important features of the spectra are (a) the occurrence of two absorptions in the 1680–1715 cm^{-1} region in all the complexes due to C=O stretching vibrations indicating twisting of one of the ester groups out of the plane of the ethylene carbons and the non-involvement of the carbonyl group in bonding. (b) The appearance of a sharp band at 1450–1465 cm^{-1}, invariably indicating the presence of a $\nu(C{=}CS_2)$ vibration in all the complexes. (c) The occurrence of bands at 925–1030 cm^{-1}, due to $\nu(CS_2)$ modes. (d) The occurrence of bands at *ca* 630 and 425 cm^{-1}, indicating the coordinated nature[17] of *o*-phen in these complexes. The number and position of the IR spectral bands are suggestive of dinegative bidentate behaviour of DED and bidentate behaviour of *o*-phen in these complexes.

The bands occurring below 400 cm^{-1} in all the complexes may be considered to be associated with metal–sulphur and metal–nitrogen stretching vibrations. The lower frequency bands may be related to metal–sulphur while the higher ones to the metal–nitrogen stretching modes.

Magnetic moments and electronic spectra

The metal ions in higher oxidation states have vacant *d*-orbitals and therefore their visible region spectrum is dominated by charge-transfer bands. With dithioligands this tendency seems to be more pronounced. The $[Zn(o\text{-phen})_3][Mn(DED)_3]$ complex exhibits a broad structured band giving peaks at 400, 511 and 545 nm which are close to the charge-transfer bands of the octahedral $[M(Et_2dtc)_3]BF_4$.[18,19] The magnetic moment, 3.75 BM, for this complex is slightly less than the spin only value (3.88 BM) for a high spin manganese(IV). In the case of $[Fe(o\text{-phen})_3][Mn(DED)_3]$, a broad shaped band comprising peaks at 453, 537, 588 and 800 nm is observed. These are attributed to the charge-transfer bands as well as *d–d* transition bands indicating the presence of octahedral $[Fe(o\text{-phen})_3]^{2+}$ and $[Mn^{IV}(DED)_3]^{2-}$. The tail of this band at 537–588 nm is assigned to MLCT Fe^{II} (t_{2g}^6), to the ligand (π) orbital, and the head at 800 nm to the *d–d* spin triplet.[20–22] The magnetic moment (4.29 BM) for this complex may be related to the presence of high spin manganese(IV) and low spin iron(II).[1,23] The heterobimetallic complexes $[Co(o\text{-phen})_3][Mn(DED)_3]$ and $[Ni(o\text{-phen})_3][Mn(DED)_3]$ exhibit magnetic moments of 5.48 and 4.66 BM, respectively, in which the contributions from both cationic and anionic species are included. Although magnetic data obtained at room temperature are insufficient for evaluating magnetic moments for stereochemical purposes in systems where both cationic and anionic species are paramagnetic, nevertheless, the data obtained at room temperature are comparatively lower than the average values of magnetic moments expected for both paramagnetic centres but higher than those expected for either the cation or anion. This shows the presence of some paramagnetic interactions in the solid state. The former complex shows bands at 454, 473, 520, 545 and 800 nm and the latter at 450, 512 and 545 nm. These bands show the presence of octahedral $[Co(o\text{-phen})_3]^{2+}$ and $[Ni(o\text{-phen})_3]^{2+}$ associated with octahedrally coordinated $[Mn(DED)_3]^{2-}$. The bands at 450–473 nm are mainly due to $[Mn(DED)_3]^{2-}$, while those at 512–800 nm are attributed to octahedral $[Co(o\text{-phen})_3]^{2+}$ and $[Ni(o\text{-phen})_3]^{2+}$ moieties.[22,24]

Magnetic moments (2.88–3.10 BM) for $(Bu_4N)_2[Fe(DED)_3]$, $[Zn(o\text{-phen})_3][Fe(DED)_3]$ and $[Fe(o\text{-phen})_3][Fe(DED)_3]$ are consistent with low spin iron(IV) (d^4 configuration).[1,5,25] $(Bu_4N)_2[Fe(DED)_3]$ shows absorptions at 390, 450, 480 and 530 nm, which are charge-transfer bands.[5] $[Co(o\text{-phen})_3][Fe(DED)_3]$ and $[Ni(o\text{-phen})_3][Fe(DED)_3]$[5] exhibit characteristic electronic spectral bands showing octahedrally coordinated $[M(o\text{-phen})_3]^{2+}$ ($M = Co^{II}$ or Ni^{II}) and $[Fe(DED)_3]^{2-}$ moieties. The magnetic moments 4.81 and 5.15 BM for these complexes may be related to the presence of cationic and anionic species. In all the heterometallic complexes, the bands occurring between 200–300 nm are attributed to the charge-transfer bands.

ESR spectra

The ESR spectra of the heterobimetallic complexes $[M(o\text{-phen})_3][Mn(DED)_3]$ have been recorded in DMF and as polycrystalline samples at room temperature as well as LNT. The spectra of the polycrystalline samples show a single broad, first derivative[23] band at about $g = 2.0$, which is expected for an odd, unpaired electron system showing only the central $Ms = 1/2 \leftrightarrow -\frac{1}{2}$ transition which, in first order, is independent of orientation of the crystallites. The powder ESR spectra with $g = 2.0$ do not unambiguously support the Mn^{IV}, d^3 system since the observed pattern could arise from d^5, Mn^{II} also. Except $[Fe(o\text{-phen})_3][Mn(DED)_3]$, all other heterobimetallic complexes also exhibit a typical solid state spectrum giving $g_{\|} = 4.83$–5.3, which is well in the range

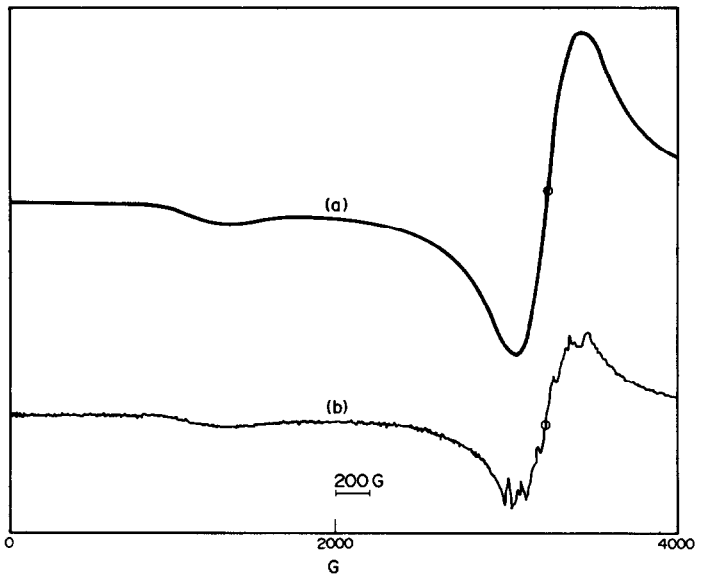


Fig. 1. ESR spectra of (a) [Co(*o*-phen)$_3$][Mn(DED)$_3$] (solid); (b) [Co(*o*-phen)$_3$][Mn(DED)$_3$] (DMF) solution at LNT.

reported[1] for [Mn^{IV}(DED)$_3$](BzPh$_3$P)$_2$. Since our starting material is manganese(III) and the ligand DED has a strong tendency to stabilize manganese(IV), we expect that this pattern arises from manganese(IV).[1]

The ESR spectrum of [Co(*o*-phen)$_3$][Mn(DED)$_3$] in DMF at LNT (Fig. 1) is characterized by isotropic g value = 2.00 and hyperfine interaction constant $\langle A \rangle$ = 92 G, which is quite comparable to the frozen $CHCl_3$ solution spectrum of Mn^{IV} ($R_2Dtc)_3ClO_4$[23] at (113 K). However, other complexes show weak, resolved hyperfine features with g values = 1.99–2.0, but the hyperfine interaction constant $\langle A \rangle$ could not be derived. All the complexes exhibit a weak broad band with g values (4.9–5.00) similar to the solid state spectra. The features of the solid and solution spectra suggest the presence of manganese(IV) in the heterobimetallic complexes. There is no remarkable change in the g values of the complexes recorded as polycrystalline samples or in DMF solution at LNT, which suggests that the structure of the heterobimetallic complexes remains unchanged and rules out the possibility of ligand-exchange reactions in solution.

On the basis of the various physicochemical studies and their close similarity to [M′(DED)$_3$](BzPh$_3$P)$_2$ (M′ = Mn^{IV} or Fe^{IV}), a plausible structure for the heterobimetallic complexes may be suggested where iron(IV) and manganese(IV) have a six coordinate M′S_6 chromophore and iron(II), cobalt(II), nickel(II) or zinc(II) are octahedrally coordinated with three *o*-phen molecules.

IRON(III) AND COPPER(II) COMPLEXES OF POLYDENTATE LIGANDS INCORPORATING BENZIMIDAZOLE AND PHENOLIC RESIDUES

JONATHAN D. CRANE and DAVID E. FENTON*

Department of Chemistry, The University, Sheffield S3 7HF, U.K.

(*Received* 23 *April* 1991; *accepted* 14 *May* 1991)

Abstract—The preparation and complexing properties towards iron(III) and copper(II) of the unsymmetric polydentate ligands 1-(2-hydroxy-phenyl)-2-aza-3,5-bis(benzimidazol-2-yl)pentane, H(**2**), and 1-(2-hydroxy-5-bromo-phenyl)-2-aza-3,5-bis(benzimidazol-2-yl) pentane, H(**3**), are discussed.

The preparation of small molecule complexes as models for dinuclear transition metal biosites may be viewed as essential in helping to gain an understanding of the structure and function of the natural systems.[1] A logical strategy for the synthesis of potential model compounds is to mimic as closely as possible the suspected coordination environment of the metals in these proteins; this can be achieved by designing and preparing synthetically accessible polydentate ligands, and investigating their coordination chemistry with the appropriate transition metal.

Ideally these ligands should contain the correct number of donor groups and these should be as chemically similar as possible to the protein-based donor atoms. Only a few amino acid residues, histidine (imidazole), tyrosine (phenolate), aspartic and glutamic acids (carboxylate) are commonly found coordinated to transition metals in metalloproteins; other residues (e.g. cysteine and methionine) are known to be involved in some cases.[2] The structure and degree of flexibility of the ligands can be used to ensure that the metals are coordinated in an appropriate geometry. Such structural constraints may also be effective in controlling inter-metal distances, therefore favouring the binding of bridging groups that are found (or are believed to be present) in the biosite, but which were not incorporable in the ligand. Finally, for the preparation of a functioning model, consideration must be given to the number, accessibility, and location of any vacant coordination sites on the metal.

To date, two major strategies for ligand based control have been developed for the preparation of dinuclear metal complexes. The first strategy is based on ligands that are large enough and contain sufficient donor atoms to coordinate both metals and any required exogenous bridging groups.[1] At the simplest level these dinucleating ligands comprise two donor sets joined by a non-coordinating linking group. In more complex ligands the linking group may also act as the source of an endogenous bridge. The second strategy is the use of facially coordinating, tridentate ligands such as 1,4,7-triazacyclononane and its tris-N-methylated derivative,[3] and the hydrotris-(1-pyrazolyl)borate anion.[4] Additional coordination of potential bridging groups (three for octahedral and two for trigonal bipyramidal or square based pyramidal geometries) can give dinuclear complexes by spontaneous self assembly. This approach has also been used successfully with the dinucleating ligand 2,2′-dipyridyl.[5–7]

Ligands incorporating benzimidazole groups are of importance for the preparation of model compounds as they contain the biologically relevant imidazole moiety found in histidine. It must be noted however, that benzimidazoles differ from imidazoles in size and chemical properties due to the fused benzene ring. Imidazoles are significantly more basic than their benzimidazole equivalents and the benzimidazole hydrogen is more acidic.[8] The main reason for preparing ligands containing benzimidazoles rather than imidazoles is the

* Author to whom correspondence should be addressed.

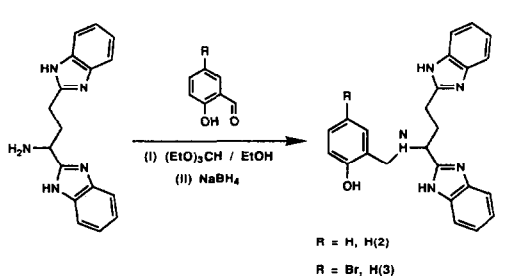
relative ease of synthesis. Condensation of 1,2-diaminobenzene with a carboxylic acid under the appropriate reaction conditions gives the corresponding benzimidazole.[9] Similarly, the reaction of polycarboxylic acids yields polybenzimidazole ligands in fair to good yields.

In dinuclear transition metal biosites the metal ions are usually found in chemically or geometrically distinct environments. Such distinctions range from a relatively insignificant difference in coordination geometries (as in haemocyanin), to major differences in donor set and/or coordination number (purple acid phosphatases and haemerythrin). Symmetric dinucleating ligands can only promote minor differences in metal environment upon complexation, and this is always due to steric constraints imposed by other ligands or the metals themselves. Therefore a necessary step towards the synthesis of better models for these metalloproteins is the preparation of unsymmetric dinucleating ligands that provide chemically distinct donor environments.

In this paper we present the synthesis and complexation properties towards copper(II) and iron(III) of unsymmetric polydentate ligands incorporating a phenolic residue and derived from the functionalization of 1,3-bis-(benzimidazol-2-yl)-1-aminopropane (**1**). The ligands contain both imidazole and phenolic functions and therefore may be viewed as appropriate for biosite modelling studies.

RESULTS AND DISCUSSION

Ligands containing phenolic residues are potentially useful for preparing model compounds for transition metal biosites which have tyrosine residues involved in the metal coordination. The primary amine function of (**1**) is readily condensed with salicylaldehyde or its derivatives to give Schiff bases, which were not isolated. The imines were reduced *in situ* to give the corresponding hydrolytically stable secondary amines H(**2**) and H(**3**) (Scheme 1).



Scheme 1.

Recrystallization from acetone/water gives H(**2**) and H(**3**) as stable 1 : 1 adducts with acetone. In the IR spectra (KBr disc) the characteristic acetone carbonyl stretch occurs at 1705 cm^{-1}. The stoichiometry of the adducts were confirmed by ^1H NMR and elemental analysis. Attempts to grow crystals of these inclusion complexes for X-ray diffraction structure determinations failed, yielding white powders only.

As expected the ^1H NMR spectra (Table 1) show the benzimidazoles to be non-equivalent, with two distinct pairs of A_2B_2 multiplets. Assignments of the benzimidazoles were made by comparison with the spectra of (**1**) and the phenolic groups were assigned by comparison with predicted chemical shifts and coupling for substituted benzenes. The hydrogens of the methylene group formed upon reduction of the Schiff base are non-equivalent and give rise to an AB system. Along with the increased complexity of the propane chain backbone signals, this implies a significant degree of intramolecular hydrogen bonding in solution, preventing rotation of the phenolic group relative to the rest of the molecule on the NMR timescale.

The—CH_2—NH— linkage formed by reduction

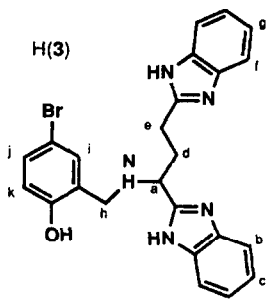

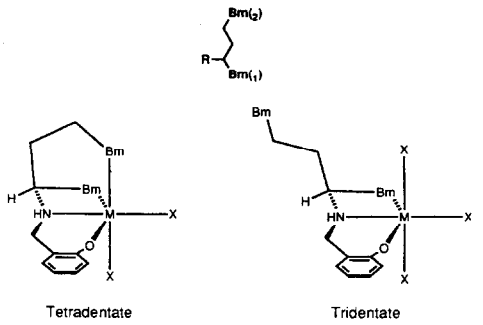

Fig. 1. Possible coordination geometries of (2).

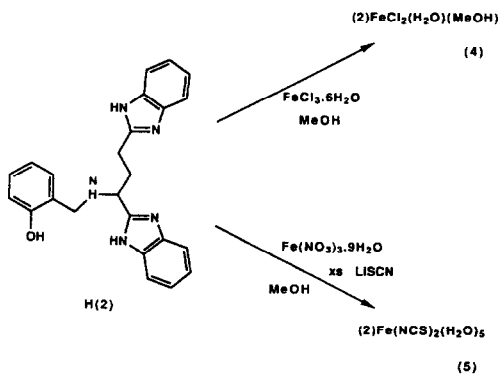
of the Schiff base is benzilic in nature. The ease of fragmentation at this bond is reflected in the c.i. mass spectra of H(2) and H(3). A MH^+ ion is only observed for H(2), at m/z 398 (2%). The dominant peak in both spectra is due to $[H(1)]^+$.

Both (2) and (3) are potentially tetradentate but will possess steric problems similar to (1). Comparison with a similar phenol-containing ligand suggests that the phenol, amine, and Bm(1) will coordinate in a meridional manner.[10] Bm(2) may possibly coordinate as a distant axial ligand (Fig. 1).

Preparation of (2)$FeCl_2(H_2O)$(MeOH) (4) *and* (2)$Fe(NCS)_2(H_2O)_5$ (5)

The phenol group deprotonates in methanolic solutions of iron(III) to give intense purple complexes of the anionic ligand (2). Reaction with iron(III) chloride hexahydrate gave a characterizable product as thin purple needles of (2) $FeCl_2(H_2O)$(MeOH) (4) (Scheme 2). The positive ion FAB mass spectrum confirms that both the ligand and at least one of the chlorides are coordinated to the metal with peaks at m/z 487 (24%), $[(2)Fe(Cl]^+$, and 452 (100%), $[(2)Fe]^+$. By analogy



Scheme 2.

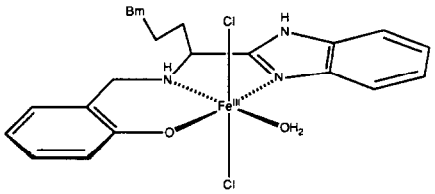


Fig. 2. Proposed structure of (4).

with the closely related benzimidazole complexes $LFeCl_3$ it is probable that both chlorides are bound to the iron in the solid state.[11]

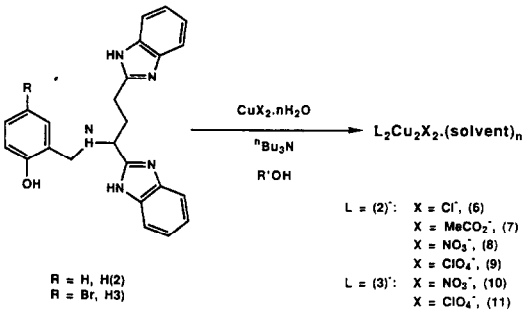
The overall molecular geometry of (4) is hard to predict, but it is likely that one of the benzimidazoles is non-coordinating and the remaining tridentate ligand fragment is bound meridionally. If the complex is octahedral the water molecule is probably the sixth ligand but it is impossible to say which of the three possible sites it occupies (Fig. 2).

The analogous reaction in the presence of excess thiocyanate instead of chloride ions gave the diisothiocyanate complex (2)$Fe(NCS)_2(H_2O)_5$ (5) (Scheme 2), presumably with only one of the water molecules coordinated to the iron to give a similar structure to (4). In the IR spectrum a single band at 2045 cm^{-1} is assignable to the ν_{CN} stretch of the isothiocyanate groups, proving that both SCN— ligands are bound to the iron and that as expected both are coordinated through nitrogen. Compound (4) was too insoluble to record a solution electronic absorption spectrum but (5) was slightly soluble in acetonitrile. Two intense charge-transfer bands are apparent: λ_{max} = 420 (5120) and 590 nm (ε = 1870 $dm^3\ cm^{-1}\ mol^{-1}$). Theoretically the reaction of (2) with iron(III) in the presence of carboxylate should give new multinuclear complexes. Unfortunately no such products could be isolated from such mixtures.

Preparation of dinuclear copper(II) *complexes of the phenol-containing ligands* H(2) *and* H(3)

Reaction of hydrated copper(II) salts with the phenol containing ligands H(2) and H(3) in alcoholic solution and in the presence of base gave complexes in which the phenols are deprotonated and coordinated to the metal. Such complexes were prepared with a range of counterions: Cl^-, $MeCO_2^-$, NO_2^- and ClO_2^- (Scheme 3).

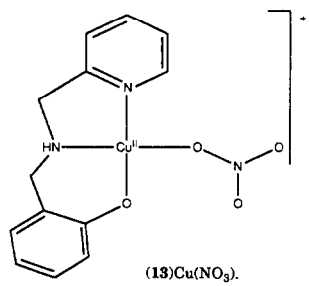
The IR spectra of all six complexes are similar. The spectrum of (6) (chloride counterion) is well resolved and free of anion bands, thus allowing the assignment of these bands in the other compounds. For the acetate complex (7) a single carboxylate symmetric stretch occurs at 1420 cm^{-1}. However there are two antisymmetric stretching bands of



Scheme 3.

approximately equal intensity at 1540 and 1560 cm^{-1}, which implies the presence of two types of acetate. The $\Delta\nu$ values of *ca* 130 cm^{-1} are less than generally found for ionic or monodentate acetates,[12] but nevertheless similar to the values found for the formally monodentate acetates in the mononuclear manganese(II) complex, [N,N-bis(benzimidazol-2-ylmethyl)-amine]bis(acetato) manganese(II) (**12**).[11] Therefore although both acetates are coordinated, it is difficult to say whether they are monodentate, bidentate, or bridging. For the complexes with nitrate [(**8**) and (**10**)] and perchlorate [(**9**) and (**11**)] counterions there is no evidence of coordination, only bands corresponding to the free anions are apparent at 1395 cm^{-1} (NO_3^-), and 1100 and 625 cm^{-1} (ClO_4^-), respectively. In addition, for (**6**) and (**8**) a single sharp band is clearly visible at 3600 cm^{-1}, assignable as the O—H stretch of coordinated water.

As discussed earlier for the coordination of (**2**) and (**3**) with iron(III) it is probable that they act only as tridentate ligands with one of the benzimidazoles, Bm(2), not being coordinated. A copper complex of the structurally similar, tridentate ligand H(**13**), prepared by reduction of the Schiff base formed by condensation of 2-aminomethylpyridine with salicylaldehyde, has been characterized as the neutral mononuclear species (**13**)Cu(NO_3).[10] In this complex the nitrate anion acts as a monodentate ligand but it has already been shown that in (**8**) and (**10**) the nitrates are not coordinated. Hence (**2**) and (**3**) give copper complexes with different metal environments to that found in (**13**)Cu(NO_3). The positive ion FAB mass spectrum of (**13**)Cu(NO_3) has not been reported so it is not known whether high mass aggregation peaks are apparent for this proven mononuclear complex. In all six complexes of (**2**) and (**3**) however, peaks corresponding to dinuclear as well as the expected mononuclear moieties are observed. The high mass peaks are assignable as $[L_2Cu_2(\text{counterion})]^+$ and $[L_2Cu_2—H]^+$ (Table 2). For the complexes of (**3**) the presence of the additional bromine atom means that the observed peak maxima occur at +2 mass units. If the mass spectra are a true reflection of the structure of these complexes in the solid state, it is likely that the phenolate groups are acting as the bridging ligands. Similar dimerizations are known to occur for other phenol containing ligands.[13] For (**8**) and (**10**) this formulation is in agreement with the observed non-coordination of the nitrates, but the reason for the preferred mononuclear nature of the related complex (**13**)Cu(NO_3) is unclear. The presence of the



(**13**)Cu(NO_3).

$[L_2Cu_2(\text{counterion})]^+$ peaks does not necessarily mean that the counterion is bound to the dinuclear

Table 2. Positive ion FAB mass spectra assignments of the copper(II) complexes of (**2**) and (**3**)

Compound	Anion (X^-)	*m/z* (% intensity) $[L_2Cu_2(X)]^+$	$[L_2Cu_2—H]^+$	$[LCu]^+$
(a) L = (**2**):				
(**6**)	Cl^-	955 (9)	919 (16)	460 (43)
(7)	$MeCO_2^-$	979 (3)	919 (8)	460 (24)
(**8**)	NO_3^-	982 (3)	919 (18)	460 (29)
(**9**)	ClO_4^-	1019 (20)	919 (15)	460 (63)
(b) L = (**3**):				
(**10**)	NO_3^-	1140 (5)	1077 (22)	540 (71)
(**11**)	ClO_4^-	1175 (10)	1077 (5)	540 (41)

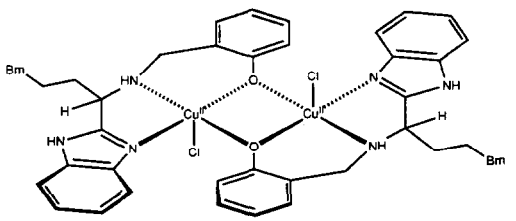


Fig. 3. Proposed structure of (**6**).

metal core, but may be due to ion pairing. However, it has been shown that in (**7**) the acetates are coordinated. There are literature precedents for both terminal and asymmetric bidentate coordination of carboxylates in such dinuclear, phenolate bridged copper complexes.[13] Similarly by comparison with known systems it is likely that the chlorides in (**6**) are coordinated as terminal ligands (Fig. 3).[14]

The room temperature magnetic moment of (**10**) is 1.03 μ_{BM}, significantly less than the theoretical spin only value for copper(II) (1.73 μ_{BM}). This indicates appreciable antiferromagnetic coupling[15] and is consistent with the proposed dinuclear, bis-phenolate bridged nature of these complexes.

EXPERIMENTAL

Elemental analyses were carried out by the Sheffield University microanalytical service. IR spectra were recorded as KBr discs using a Perkin–Elmer 297 IR spectrophotometer (4000–600 cm^{-1}) or a Perkin–Elmer 1710 IR Fourier Transform spectrophotometer (4000–400 cm^{-1}). Electronic absorption spectra were recorded using a Philips PU8720 UV–vis scanning spectrophotometer operating in the range (280–900 nm). ^1H NMR spectra were recorded at 220 MHz on a Perkin–Elmer R34 spectrometer. ^{13}C NMR spectra (62.9 MHz) were recorded using a Bruker AM-250 spectrometer. Electron impact (e.i.) and chemical impact (c.i., ammonia) spectra were recorded on a Kratos MS25 operating at low resolution and positive ion fast atom bombardment (FAB) mass spectra were recorded on a Kratos MS80 spectrometer. The matrix solvent used was 3-nitrobenzylalcohol (NOBA) unless otherwise stated.

1,3-*bis*(*benzimidazol*-2-*yl*)*propylamine* (**1**)

DL-glutamic acid (11.0 g, 75 mmol) and 1,2-diaminobenzene (18.50 g, 170 mmol) were refluxed in aqueous hydrochloric acid (120 cm^3, 5.5 M) for 15 days. The solution changed from an initial deep red colour to intense blue over the first 3 days. The reaction mixture was cooled to room temperature and vigorously stirred while carefully neutralized with excess aqueous ammonia (specific gravity 0.880). The crude product (purple solid) was filtered off and washed with water. Two recrystallizations from methanol/water gave white needles of H(**1**)·1.25(H_2O) (8.70 g, 37%). M.p. 120°C. To confirm the hydration number, a sample was recrystallized a third time for a second analysis. Found: C, 65.1, 64.9; H, 6.1, 6.1; N, 22.3, 22.1. Calc. for $C_{17}H_{19.5}N_5O_{1.25}$: C, 65.0; H, 6.3; N, 22.3%. *m/z* e.i. 291 (M^+, 12%), c.i. 292 (MH^+, 100%). δ_H (CD_3OD) 7.53 (2H, m), 7.48 (2H, m), 7.20 (2H, m), 7.17 (2H, m), 4.24 (1H, t), 2.95 (2H, t), and 2.40 (2H, m). δ_C (CD_3OD) 159.0, 155.8, 139.4, 123.5, 123.2, 115.7, 115.3, 51.1, 36.5 and 26.3.

L-glutamic acid gave white needles with identical spectroscopic properties to H(**1**). Solutions of this product at different concentrations gave no measurable rotation of polarized light, indicating that complete racemization had occurred under the reaction conditions.

1-(2-*hydroxyphenyl*)-2-*aza*-3,5-*bis*(*benzimidazol*-2-*yl*)*pentane* H(**2**)

1,3-bis(benzimidazol-2-yl)propylamine (10.0 g, 30 mmol), salicylaldehyde (3.70 g, 30 mmol), and triethylorthoformate (1 cm^3) was refluxed in ethanol (150 cm^3) for 2 h. The golden yellow solution was cooled to room temperature and sodium borohydride (2 g, 54 mmol) added carefully in small portions. The resulting pale yellow solution was refluxed for 1 h. After cooling, water (50 cm^3) was added and the solution rendered acidic by dropwise addition of concentrated hydrochloric acid. After refluxing for 15 min to hydrolyse any borate esters present, the solution was cooled and the ethanol removed under reduced pressure. The sticky residue was extracted with CH_2Cl_2 (2 × 80 cm^3), dried over $MgSO_4$, filtered, and the solvent removed. The resulting pasty yellow solid was taken up in acetone (100 cm^3) and after *ca* 5 min a thick white precipitate was deposited. This was recrystallized from acetone/water to give H(**2**)(Me_2CO) as a white powder (12.3 g, 90%). M.p. 250°C (decomp.). Found: C, 71.0; H, 6.6; N, 15.2. Calc. for $C_{27}H_{29}N_5O_2$: C, 71.2; H, 6.4; N, 15.4%. *m/z* c.i. 398 (MH^+, 2%). ν_{max} 1705 cm^{-1} (C=O).

The acetone was removed by dissolving a sample in methanol, then evaporating to dryness. This was repeated with CH_2Cl_2 to give a white powder with significantly higher solubilities in organic solvents. δ_C (CD_3OD) 157.6 (s), 156.8 (s), 155.5 (s), 139.3 (s), 130.6 (d), 129.5 (d), 125.1 (s), 123.5 (d), 123.1 (d), 120.3 (d), 116.5 (d), 115.8 (d), 115.3 (d), 57.0 (d), 49.6 (t), 34.4 (t), and 26.4 (t).

1 - (2 - hydroxy - 5 - bromophenyl) - 2 - aza - 3,5 - bis (benzimidazol-2-yl)pentane H(**3**)

This was prepared by the same method as for H(**2**) but using 5-bromosalicylaldehyde. H(**3**) (Me_2CO), white powder (85%). M.p. 240°C (decomp.). Found: C, 60.4; H, 5.3; N, 13.0; Br, 14.9. Calc. for $C_{27}H_{28}BrN_5O_2$: C, 60.7; H, 5.3; N, 13.1; Br, 14.9%. No molecular ion observed in the mass spectrum, highest observed peak: *m/z* c.i. 292 (M—C_7H_5OBr+H, 53%). ν_{max} 1705 cm^{-1} (C=O).

Preparation of (**2**)$FeCl_2(H_2O)(MeOH)$ (**4**)

Iron(III) chloride hexahydrate (0.27 g, 1 mmol) was added to a solution of H(**2**)(Me_2CO) (0.46 g, 1 mmol) and tri-*n*-butylamine (0.19 g, 1 mmol) in methanol (80 cm^3) with stirring. The intense purple solution was filtered as soon as all the iron salt had dissolved. Upon standing overnight (**4**) was deposited as very fine, purple needles (0.51 g, 89%). Found: C, 52.4; H, 4.9; N, 12.2; Cl, 12.3. Calc. for $C_{25}H_{28}Cl_2FeN_5O_3$: C, 52.4; H, 4.9; N, 12.2; Cl, 12.4%.

Preparation of (**2**)$Fe(NCS)_2(H_2O)_5$ (**5**)

Iron(III) nitrate nonahydrate (0.41 g, 1 mmol), H(**2**)(Me_2CO) (0.46 g, 1 mmol), and tri-*n*-butylamine (0.19 g, 1 mmol) were dissolved in methanol (40 cm^3) to give an intense purple solution. Lithium thiocyanate (0.2 g, 3 mmol) in methanol (40 cm^3) was added with stirring. A brown precipitate formed immediately. After 1 h this was filtered off and the filtrate allowed to stand overnight. Purple microcrystals (0.22 g, 33%). Found: C, 47.7; H, 4.7; N, 15.1; S, 9.3. Calc. for $C_{26}H_{32}FeN_7O_6S_2$: C, 47.4; H, 4.9; N, 14.9; S, 9.7%.

Preparation of $(2)_2Cu_2Cl_2(H_2O)_4$ (**6**)

Tri-n-butylamine (0.19 g, 1 mmol) and H(**2**) (Me_2CO) (0.46 g, 1 mmol) were dissolved in methanol (40 cm^3). A solution of copper(II) chloride dihydrate (0.17 g, 1 mmol) in methanol (5 cm^3) was added in one portion with stirring, and the resulting dark green solution was filtered. Thin yellow–green needles began forming almost immediately (*ca* 1 min). After standing overnight the product was filtered off, washed with methanol, and air dried (0.41 g, 77%). Found: C, 54.1; H, 4.5; N, 13.3; Cl, 7.0. Calc. for $C_{48}H_{52}Cl_2Cu_2N_{10}O_6$: C, 54.2; H, 4.9; N, 13.2; Cl, 6.7%.

Preparation of $(2)_2Cu_2(MeCO_2)_2(H_2O)_2(MeOH)_2$ (**7**)

This was prepared as for (**6**) but using hydrated copper(II) acetate (0.20 g, 1 mmol) and more dilute conditions (100+20 cm^3). Yellow–green powder (0.47 g, 83%). Found: C, 56.8; H, 5.5; N, 12.2. Calc. for $C_{54}H_{62}Cu_2N_{10}O_{10}$: C, 57.0; H, 5.5; N, 12.3%.

Preparation of $(2)_2Cu_2(NO_3)_2(H_2O)_2$ (**8**)

This was prepared as for (**6**) but using copper(II) nitrate trihydrate (0.25 g, 1 mmol) in ethanol as solvent. Yellow–green needles (0.38 g, 70%). Found: C, 53.5; H, 4.4; N, 15.4. Calc. for $C_{48}H_{48}Cu_2N_{12}O_{10}$: C, 53.4; H, 4.5; N, 15.6%.

Preparation of $(2)_2Cu_2(ClO_4)_2(H_2O)$ (**9**)

This was prepared as for (**6**) but using copper(II) perchlorate hexahydrate (0.37 g, 1 mmol) in ethanol as solvent. Pale green needles (0.42 g, 69%). Found: C, 50.6; H, 4.4; N, 11.9; Cl, 6.1. Calc. for $C_{48}H_{46}Cl_2Cu_2N_{10}O_{11}$: C, 50.7; H, 4.1; N, 12.3; Cl, 6.2%.

Preparation of $(3)_2Cu_2(NO_3)_2(MeOH)_4$ (**10**)

This was prepared as for (**6**) but using H(**3**)·(Me_2CO) (0.54 g, 1 mmol) and copper(II) nitrate trihydrate (0.25 g, 1 mmol). Green microcrystals (0.56 g, 88%). Found: C, 46.8; H, 4.2; N, 12.8; Br, 11.9. Calc. for $C_{52}H_{58}Br_2Cu_2N_{12}O_{12}$: C, 47.0; H, 4.4; N, 12.6; Br, 12.0%.

Preparation of $(3)_2Cu_2(ClO_4)_2(MeOH)_5$ (**11**)

This was prepared as for (**10**) but using copper(II) perchlorate (0.37 g, 1 mmol). The initial green needles formed redissolved and after standing (*ca* 5 days) dark green intergrown blocks were deposited (0.62 g, 86%). Found: C, 44.3; H, 4.2; N, 9.4; Br, 11.2; Cl, 4.9. Calc. for $C_{53}H_{62}Br_2Cl_2Cu_2N_{10}O_{15}$: C, 44.3; H, 4.3; N, 9.7; Br, 11.1; Cl, 4.9%.

(*Received* 12 *March* 1991; *accepted* 16 *May* 1991)

Abstract—A new procedure for the deoxygenation of VO^{+2} complexes is described. The synthesis and properties of mononuclear vanadium complexes $VCl_2(S_2CNR_2)_2$ [R = Me, Et, and Py/2 (Me = CH_3, Et = C_2H_5, and Py = C_4H_4) (pyrrolidyl)] and $VBr_2(S_2CNEt_2)_2$ are reported. The compounds were synthesized in high yield by the general reaction of $VO(S_2CNR_2)_2$ with the appropriate acetyl halide in methylene chloride. Single crystal X-ray analysis was performed on both $VCl_2(S_2CN(C_2H_5)_2)_2$ and $VBr_2(S_2CN(C_2H_5)_2)_2$. The analogous structures consist of a mononuclear unit with distorted C_{2v} symmetry, where the halogen atoms are on the same side of the distorted plane formed by the sulphur atoms. The V—Cl distances are inequivalent at 2.260(1) and 2.247(1) Å, as are the V—Br distances at 2.414(1) and 2.401(1) Å. Two sets of V—S bond lengths are also observed for both complexes. The complexes were examined by IR, and the spectra are similar to the spectra of the vanadyl starting material except for the absence of the V=O band at approximately 1000 cm^{-1}. The ligand C—S and C—N bands are slightly higher in energy in the dihalide complexes than in the vanadyl counterpart, contrary to the effects expected from replacing the oxygen with the electron withdrawing halogen atoms. This behaviour, however is indicative of distortions out of the $d_{x^2-y^2}$ orbital bonding plane causing less π bonding and reducing delocalization of charge among the ligands and the metal centre. This is also seen structurally with the two sets of inequivalent V—S and C—S bond lengths. The UV–vis spectra show a weak maximum at around 570 nm with ε_m of approximately 2000 L mol cm^{-1}, typical of dihalogenated V^{IV} complexes.

It is becoming increasingly apparent that the chemistry of vanadium is of great importance to a wide variety of biological and industrial systems. Recent work in the field of inorganic biochemistry indicates there is a class of nitrogenase metallo-enzymes which have vanadium at the active site.[1,2] In these enzymes, vanadium appears to shuttle between V^{II} and V^{IV}, and is possibly bound to an iron–sulphur cluster. However, few models have been made of this active site. One synthetic difficulty is the problem of directly linking iron–sulphur clusters and V^{IV} compounds. This requires functionality on the vanadium atom which can be synthetically manipulated. Thus, having new V^{IV} compounds with functionality is highly desirable.

Vanadium is commercially important in the conversion of crude oils to transportation fuels.[3] Vanadium occurs naturally and can be of high con-

* Authors to whom correspondence should be addressed.

centration in heavier crude oils.[4] It impacts the industry because its necessary removal during upgrading[5] poisons heterogenous catalysts used in processing.[6] The intermediate species in this transformation of the naturally occurring VO^{2+} complexes to the vanadium sulphide on the upgrading catalyst surface are not well characterized. Some evidence suggests VO^{2+} is deoxygenated to V^{IV}.[7-10] Characterizing this transformation is critical to the understanding of catalytic poisoning due to metals.

Vanadium compounds have also been used to generate slurry-type catalysts to upgrade heavy oils and assist in coal liquefaction. These catalysts increase the conversion of petroleum and coal to lower boiling materials,[11] and desulphurize the resulting liquids.[12,13] The exact species responsible could be finely dispersed vanadium sulphides. These are often formed by *in situ* preparation from vanadyl model compounds such as $VO(acac)_2$.[14] The transformation chemistry and the active VS_x species have not been well characterized. Clearly, activation of the V=O bond is a critical part of this mechanism.

The strong V=O bond is extremely stable and generally dominates the coordination chemistry of vanadium.[15] The reactivity of this bond has not been widely studied because access to other types of vanadium compounds has been through easier synthetic routes which do not employ vanadyl reagents. This is unfortunate because many vanadyl compounds are easy to prepare as starting materials (many can be purchased commercially).

Of the limited V^{IV} non-oxo species reported in the literature, many are dihalide complexes. These have been characterized by spectroscopic methods which indicate six coordinate V and both *trans* and *cis* configurations to be possible. However, only one of these complexes, VCl_2(salen-N-Bu^t)$_2$ [salen-N-Bu^t = N-n-butyl(salicylideniminato)] has been characterized by single crystal X-ray analysis.[16] The structure shows an octahedral V centre with *trans* chlorine atoms. We have also recently synthesized and characterized by single crystal X-ray analysis, $VCl_2(acac)_2$ (acac = acetylacetonato),[17] which has a very similar *trans* structure to VCl_2(salen-N-Bu^t)$_2$.

Many methods have been employed to make these types of compounds: (1) by direct halogenation of the corresponding vanadyl complex;[16,19-23] (2) by reactions of VCl_4 and the appropriate free ligand;[18] and (3) by reaction of thiuram disulphides with V^{II} compounds.[24] Although these methods are all adequate, there are some drawbacks. Many of the reagents are difficult to handle, some react with the ligand as well as the vanadium, and some require involved ligand synthesis.

In this report, we describe a useful new method for the mild deoxygenation of VO^{2+} complexes. We present the synthesis and characterization of $VCl_2(S_2CNEt_2)_2$, $VCl_2(S_2CNMe_2)_2$, $VCl_2(S_2CNPy)_2$ and $VBr_2(S_2CNEt_2)_2$ from the reaction of the corresponding vanadyl dithiocarbamates with acetyl halides. In addition, we present the structural characterization by single crystal X-ray analysis of $VCl_2(S_2CNEt_2)_2$ and $VBr_2(S_2CNEt_2)_2$. The described procedure is a new, more facile and direct synthetic method which gives clean products. The crystal structures are the first reported for vanadium dihalodithiocarbamates, and the structures are surprising in as much as the halogen atoms are unexpectedly *cis*.

EXPERIMENTAL

All syntheses were carried out in a dry/inert atmosphere of purified dinitrogen employing standard Schlenk glassware. Air-sensitive samples for spectroscopic study were prepared in a dinitrogen glovebag or Vacuum Atmospheres glove box. IR spectra were recorded as KBr pellets with the Mattson Polaris Model 10410 spectrophotometer. Electronic spectra were recorded on CH_2Cl_2 solutions using a Varian Model 503 spectrophotometer and Spectrochem quartz anaerobic cells. Because the dihalide complexes readily convert back to the corresponding vanadyl complex upon exposure to even trace quantities of water, excess AcCl or AcBr were added to the solutions. Elemental analyses were perfomed by the Lawrence Livermore National Laboratory analytical department and Galbraith Laboratories, Inc., Knoxville, TN.

Reagents

Spectroanalytical grade methylene chloride (0.006% water) and hexanes were obtained from Burdick and Jackson Laboratories, and were dried over CaH_2 and $LiAlH_4$, respectively, under a dinotrogen atmosphere and degassed before use. Ethanol was obtained from Gold Shield Chemical company. Dimethyldithiocarbamic acid, sodium salt dihydrate; diethyldithiocarbamic acid, sodium salt trihydrate; acetyl chloride; and acetyl bromide were purchased from Aldrich. The pyrrolidinedithiocarbamate derivative was purchased from Matheson Coleman and Bell Manufacturing Chemists. The acetyl bromide was distilled before use and the acetyl chloride used as purchased.

Synthesis of complexes

The vanadyl complexes $VO(S_2CNMe_2)_2$, $VO(S_2CNEt_2)_2$ and $VO(S_2CNPy)_2$ were prepared

by the method of McCormick[25] and recrystallized from methylene chloride.

Dichlorobis(dimethyldithiocarbamato)vanadium(IV) $[VCl_2(S_2CNMe_2)_2]$ (**1**). $VO(S_2CNMe_2)_2$ (0.971 g, 0.00358 mol) was dissolved in methylene chloride (125 cm^3) to give a green–brown solution. This was degassed, and acetyl chloride (0.762 cm^3, 0.0107 mol) was added with stirring. The $VO(S_2CNMe_2)_2$ solution slowly turned black. The reaction solution was stirred at room temperature overnight, and then layered with hexanes (125 cm^3) and placed in a freezer. Storage at −10°C for 3 days led to the formation of black crystals. The crystals were filtered and dried *in vacuo*. The yield of crude product was 45% based on vanadium. Recrystallization from a CH_2Cl_2/hexanes mixture (layered) led to pure material as determined by IR, UV–vis and elemental analysis. Found: C, 19.3; H, 4.2; N, 7.4. Calc. for $C_6H_{12}N_2S_4Cl_2V$: C, 19.9; H, 3.3; N, 7.7%. Electronic absorption maxima = λ, nm (ε_m, L mol cm^{-1}); 578.1(1814), 485.9(1575), 379.9^{sh}(6060).

Dichlorobis(diethyldithiocarbamato)vanadium(IV) $[VCl_2(S_2CNEt_2)_2]$ (**2**). This black complex was prepared and purified from $VO(S_2CNEt_2)_2$ (2.06 g, 0.00567 mol) and acetyl chloride (1.21 cm^3, 0.0170 mol) by a similar procedure as above. The yield of the crude product was 56% based on vanadium. Found: C, 28.7; H, 5.6; N, 6.9. Calc. for $C_{10}H_{20}N_2S_4Cl_2V$: C, 28.7; H, 4.8; N, 6.7%. Electronic absorption maxima = λ, nm (ε_m, L mol cm^{-1}); 570.1(1258), 455.2(1459).

Dibromobis(diethyldithiocarbamato)vanadium(IV) $[VBr_2(S_2CNEt_2)_2]$ (**3**). This black complex was prepared and purified from $VO(S_2CNEt_2)_2$ (0.502 g, 0.00138 mol) and acetyl bromide (0.295 cm^3, 0.00415 mol) by similar procedures as above. The yield of the crude product was 58% based on vanadium. Found: C, 23.0; H, 4.1; N, 5.2. Calc. for $C_{10}H_{20}N_2S_4Br_2V$: C, 23.7; H, 4.0; N, 5.5%. Electronic absorption maxima = λ, nm (ε_m, L mol cm^{-1}); 571.4(2023), 484.6(2064), 357.6^{sh}(4314).

Dichlorobis(pyrrolidyldithiocarbamato)vanadium(IV) $[VCl_2(S_2CNPy)_2]$ (**4**). This black complex was prepared and purified from $VO(S_2CNPy)_2$ (1.16 g, 0.00324 mol) and acetyl chloride (0.690 cm^3, 0.00971 mol) by similar procedures as above. The yield of the crude product was 46% based on vanadium. Found: C, 26.5; H, 3.5; N, 5.6. Calc. for $C_{10}H_8N_2S_4Cl_2V(CH_2Cl_2)$: C, 26.9; H, 2.0; N, 5.7%. Electronic absorption maxima = λ, nm (ε_m, L mol cm^{-1}); 578.1(1106), 489.9(959), 417.0^{slsh} (1288).

X-ray crystallography and structure solution

Data were collected on a Picker four-circle diffractometer by using standard low-temperature facilities. Details of the diffractometry, low-temperature facilities, and computational procedures

employed by the Molecular Structure Center are available elsewhere.[26] Data collection parameters are summarized in Table 1 for $VCl_2(S_2CNEt_2)_2$ and $VBr_2(S_2CNEt_2)_2$. The structures were solved by a combination of MULTAN and Fourier techniques, and refined by full-matrix least-squares.

For both complexes, **2** and **3**, a systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with no symmetry or systematic absences indicating a triclinic space group. Subsequent solution and refinement of the structure confirmed the centrosymmetric choice $P\bar{1}$. For **2**, a total of 4825 reflections were collected. Following the usual data processing 4033 unique reflections remained. Of the 4033 reflections, 3424 were considered observed [$F > 2.33\sigma(F)$]. For **3**, a total of 2390 reflections were collected. Following the usual data processing 2366 unique reflections remained. Of the 2366 reflections, 2161 were considered observed [$F > 3\sigma(F)$]. All non-hydrogen atoms were readily located and refined anisotropically for both complexes. All hydrogen atoms were clearly visible in subsequent difference Fourier maps, and were included in the final refinement cycles with isotropic thermal parameters. The final difference maps were essentially featureless, with the largest peak being 0.45 e $Å^{-3}$ near the vanadium atom for complex **2** and 1.02 e $Å^{-3}$ in the immediate vicinity of a bromine atom for complex **3**.

RESULTS AND DISCUSSION

Synthesis

Vanadyl complexes can be deoxygenated by a variety of reagents ($SOCl_2$, $SOBr_2$, PCl_5, $SeOCl_2$, and $COCl_2$)[19,21,23,27] to yield the corresponding dihalide derivative. These reagents, however, are caustic and often react with the ligands. In addition, some dihalide complexes can be made by the direct reaction of VCl_4 (which is difficult to handle) with the ligand,[18] and by less direct methods including going through thiuram disulphide intermediates.[24] We have now discovered acetyl halides can also be used to synthesize V^{IV} dihalide complexes. The cheap and relatively easy to handle AcX reagents (X = Cl, Br) directly afford the dihalide complexes, overcoming the potential side reactions of the other reagents. As a result, we have successfully synthesized, directly from the corresponding vanadyl complexes, $VCl_2(S_2CNMe_2)_2$ (**1**), $VCl_2(S_2CNEt_2)_2$ (**2**), $VBr_2(S_2CNEt_2)_2$ (**3**), and $VCl_2(S_2CNPy)_2$ (**4**) by eq. (1). Previous attempts in the literature to synthesize such compounds using the other halogenating agents mentioned above often led to poorly characterized, impure products, probably due to the halogenating agent reacting with the ligand. The present procedure yields very clean products, and this has also made single crystal growth easy. As a result, single crystal X-ray analyses on **2** and **3** have been performed.

$$VO(S_2CNR_2)_2 + 2AcX \longrightarrow VX_2(S_2CNR_2)_2 + Ac_2O \quad (1)$$

(X = Cl, Br; R = Me, Et, Py/2).

An excess (50%) of AcX was routinely employed after observing incomplete conversion with stoichiometric amounts of reagents (probably due to hydrolysis by adventitious water). Isolation of **4** was difficult because crystals turned to powder upon vacuum drying due to loss of solvent. This was overcome by drying under N_2 purge. However, even under these conditions, the crystals would gradually turn to a powder, making analysis difficult. The inclusion of solvent was verified by elemental analyses which indicated one CH_2Cl_2 in the molecular formula.

Although we have not experimentally studied the mechanism of the reaction, it probably involves electrophilic attack at the VO^{2+}. Reaction Scheme 1 shows a possible pathway.

Description of structures

Figure 1 shows the structure of **2** with the atom numbering scheme. Selected structural parameters are collected in Table 2. The crystal is composed of discrete molecules of $VCl_2(S_2CNEt_2)_2$ with the expected six coodination at vanadium. The geometry around the metal can be described as highly distorted octahedral, with the chlorine atoms

cis to each other on the same side of the distorted plane formed by the four sulphurs of the dithiocarbamate ligands. This is contrary to the structure of VCl_2(salen-N-Bu^t)$_2$, the only reported[19] single crystal determination of a V^{IV} dihalide, which has octahedral coordination with *trans* chlorine atoms. In addition, our crystallographic determination of the structure of $VCl_2(acac)_2$ shows that the latter also exhibits a *trans* geometry.[17] Figure 2 shows the structure of **3** with the atom numbering scheme. Table 3 lists selected structural parameters. The structure is very similar to $VCl_2(S_2CNEt_2)_2$, being composed of discrete molecules of $VBr_2(S_2CNEt_2)_2$, with distorted octahedral coordination at the vanadium. As in the dichloro complex, the bromine atoms are *cis* to each other and on the same side of the plane formed by the four sulphurs of the dithiocarbamate ligands. The structures of **2** and **3** are the first reported single crystal determinations of a V^{IV} *cis* dihalide complex. This geometry was not expected and is contrary to that predicted by several EPR and IR studies.[21,24]

Table 2 shows that the V—Cl bond lengths of **2** are slightly inequivalent. Table 4 compares these bond lengths with other V—Cl bond lengths in the literature. The V—Cl lengths of **2** are slightly shorter than those for two other V^{IV} dichloro complexes. This is probably due to the differences between the *cis* and *trans* structures. The sulphur atoms of the ligands in the *cis* structure are considerably out of the equatorial bonding plane of the metal. As a result, the σ-bonding d_{xy} and π-bonding $d_{x^2-y^2}$ orbital interactions between the vanadium and the dithiocarbamate ligands in the equatorial

$VOCl_2(C_5H_{12}N_2O)_2$[42]	2.34	5
$VOCl_2(C_2H_5O)_2(H_2O)$[43]	2.39	5

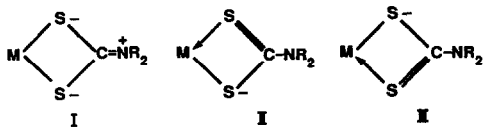
plane are not as extensive as in *trans* structures. Consequently, there is less delocalization of charge onto the ligands, resulting in a stronger V—Cl bond. This change in bonding interaction has been substantiated in EPR[21] and far IR[18] examination of *cis* and *trans* dihalide V^{IV} complexes.

The effect of the ligand type on the length of the V—Cl bond cannot be ruled out, however. V=O bond lengths in the corresponding vanadyl complexes are subject to variations due to both the first coordination sphere[28–30] and substituents on the ligands.[31]

For complex **2**, the four V—S bonds are divided into two short (average 2.382 Å) and two long (average 2.451 Å). This is reflected in the corresponding C—S bond lengths, where the two sulphur atoms with the longer V—S bond lengths have the shorter C—S bond lengths (average 1.711 Å), and the two sulphur atoms with the shorter V—S bond lengths have the longer C—S bond lengths (average 1.733 Å). This can be reasoned by considering the structural deviation from the equatorial plane of the molecule. Starting with the *trans* structure, the two dithiocarbamate ligands in a planar configuration distort to the *cis* structure by bending below this plane and also twisting in opposite directions around the C—N axis of each ligand. This removes one sulphur of each ligand from the plane of the π-bonding orbitals more than the other, therefore yielding two sets of V—S bond lengths, as well as two sets of S—V—S bond angles. Indeed, Fig. 1 shows S(6) and S(14) closer to the perpendicular to the plane formed by Cl(2), V, and Cl(3), and shows the planes formed by the S_2CNC_2 atoms in each of the ligands are also twisted with respect to each other. This behaviour is also seen in **3** (Fig. 2), where the longer V—S bond lengths average to 2.4587 Å and the shorter to 2.3804 Å. The corresponding C—S bond lengths average to 1.717 and 1.729 Å, respectively.

Several investigators have shown canonical form I to be particularly important and predominant in binding many dialkyldithiocarbamates to metals.[24,32,33] The C—N stretching frequencies in the IR support this (see below). However, canonical forms II and III cannot be ignored, particularly in light of the two sets of V—S and C—S bond lengths. When the ligands distort out of the equatorial plane, canonical form I is likely to be less important, and either II or III contribute proportionately more to the bonding. If the contribution of II or III is large enough, this would be reflected in each ligand hav-

ing one long and short C—S bond, as observed in the structures.



I II III

The single crystal X-ray structure of the vanadyl starting material, $VO(S_2CNEt_2)_2$ is available.[29] Since only the oxygen has been substituted, this allows an interesting comparison of the effects of the chlorine and bromine atom substitution on the $[V(S_2CNEt_2)_2]^{2+}$ subunit structure. The V—S distances reflect more distortion from the equatorial plane in the dihalide complexes than in the vanadyl complex (2.387–2.410 Å). In the vanadyl complex, only one of the four V—S bonds is short, which is considered to be due to crystal packing forces. However, the *average* V—S bond distance for the dichloro complex (2.41 Å), and vanadyl complex (2.40 Å) are similar. These values are slightly shorter than values seen for other vanadium complexes with the $V(S_2C)$ moiety. In these cases, inequivalences in the V—S bond lengths were also seen. $V(S_2CCH_3)_4$,[34] $V(S_2CC_6H_5)_4$,[35] $V(S_2CCH_2C_6H_5)_4$,[35] and $VO(S_2CNEt_2)_3$[36] exhibited the following V—S_{long} distances (Å), V—S_{short} distances (Å), V—S bond ratio (long to short): 2.50, 2.46, 1.02; 2.56, 2.45, 1.05; 2.53, 2.46, 1.03; 2.75, 2.55, 1.08; respectively. These compare to $VO(S_2CNEt_2)_2$, $VCl_2(S_2CNEt_2)_2$ and $VBr_2(S_2CN(Et_2)_2$ with C—S bond ratios of 1.00, 1.03 and 1.03, respectively. The π bonding in $V(S_2CC_6H_5)_4$ and $V(S_2CCH_2C_6H_5)_4$ was also considered weak. Although it is unlikely crystal packing forces would be completely responsible for the V—S bond behaviour described above, it certainly cannot be ruled out and probably accounts for at least some of the distortions in the structures cited.

$VO(S_2CNEt_2)_2$ also exhibits two sets of C—S bond lengths (1.715, 1.727; 1.721, 1.732 Å). Even though the average C—S bond lengths are approximately the same for all three complexes (1.722 Å $\pm$ 0.001 Å), the inequivalences seen in the dihalide complexes are greater than the vanadyl complex. This suggests that the canonical form II or III can have significance even when there is less equatorial distortion, as in the vanadyl complex (the vanadium is 0.7 Å above the basal plane formed by the four sulphur atoms of the dithiocarbamate ligands).

IR spectra

Table 5 lists the most important and characteristic bands of the IR spectra of **1** through **4** and compares them with the corresponding vanadyl starting material. The dihalide derivatives have spectra very similar to the corresponding VO starting material. Both have C—N and C—S bands around 1500 and 950 cm^{-1}, respectively, and a weak C—S stretching band around 850 cm^{-1}. The C—N band is at slightly higher energy than the free ligand (1490 cm^{-1}) for all the complexes.[32] The C—S band is higher for the dihalodialkyldithiocarbamates, and lower or the same for the other complexes compared to the free ligand band (970 cm^{-1}).[32] The most obvious feature of Table 5, however, is the absence of the very intense V=O band in the dihalide complexes. This diagnostic band has been our best indicator of purity during synthesis. The weak C—S absorption which does appear in this region of the dihalide spectra also appears in the vanadyl IR but is partially masked by the very strong V=O stretch.

Table 5. IR data for selected vanadyl and V^{IV} dithiocarbamate complexes (cm^{-1})

Complex	ν(C—N)	ν(C—S)	ν(V=O)
$VO(S_2CNEt_2)_2$	1514	955	988
$VCl_2(S_2CNEt_2)_2$	1521	994	
$VBr_2(S_2CNEt_2)_2$	1520	996	
$VO(S_2CNMe_2)_2$	1539	970	983
$VCl_2(S_2CNMe_2)_2$	1545	981	
$VO(S_2CNPy)_2$	1494	947	994
$VCl_2(S_2CNPy)_2$	1496	947	

In the dihalobisdialkyldithiocarbamate complexes the C—N and C—S stretches are shifted to higher frequencies or, in the case of the pyrrolidine derivative, stay relatively the same upon deoxygenation of the vanadium and addition of the halides [C—N and C—S bands for $VCl_2(S_2CNMe_2)_2$: 6 and 11 cm^{-1} higher, respectively; $VCl_2(S_2CNEt_2)_2$: 7 and 39 cm^{-1} higher, respectively, than the corresponding bands for the vanadyl complexes]. This is in contrast to the other dihalide complexes reported in the literature. Behzadi and Thompson[27] report, for V^{IV} β-diketonate complexes of the form $VX_2(dik)_2$ (X = Cl, Br; dik = acac, bzac), the dichloro derivatives have C—C and C—O bands which are lower frequencies than the same bands in the corresponding vanadyl complexes. From supporting far IR, EPR, and X-ray powder pattern data, these structures appear to have *trans* halogens. Seangprasertkij and Riechel[37] likewise report that for complexes of the type *trans*-VX_2(salen) (X = Phenyl, Cl), the C—N stretch shifts to a lower frequency on going from the vanadyl to the disubstituted derivative. Cuadrado and

Moran[24] report for $VCl_2(S_2CNMe_2)_2$, C—N and C—S bands to be 28 and 15 cm^{-1} lower, respectively, than the corresponding values for $VO(S_2CNMe_2)_2$. However, for $VCl_2(S_2CNEt_2)_2$, they report the C—N and C—S bands to be the same and 21 cm^{-1} higher than the corresponding values for $VO(S_2CNEt_2)_2$. They also conclude, based on the metal–halogen stretch in the far IR (370 cm^{-1}) that these structures have *trans* halogens.

These differences in IR behaviour with respect to the vanadyl precursor can be rationalized by considering the metal complex symmetry and electronic effects of the substituents on the ligands. Jezierski and Raynor[21] in their EPR study of several V^{IV} dihalide complexes deduce that going from the vanadyl structure (where the metal is somewhat out of the plane of the equatorial ligands) to the *trans*-type structure (where the metal is in the plane of the ligands) stabilizes the σ-bonding d_{xy} orbital slightly and stabilizes the π-bonding $d_{x^2-y^2}$ orbital greatly due to increased orbital overlap. This orbital overlap increases delocalization, effectively reducing the charge on the ligand and therefore decreasing the frequencies of the diagnostic ligand bands.

In the *cis*-type structures, the orbital overlap is reduced because the deviation from the ligand plane is increased. This localizes the charge on the ligand, therefore increasing the frequencies of the diagnostic ligand bands, as observed in complexes **1–3**. This is also consistent with the observations of Chatt *et al.*[32] who concluded from examining a large series of metal dithiocarbamate complexes, that the symmetry arrangement in order of decreasing C—N frequencies is planar > tetrahedral > octahedral > distorted octahedral and pyramidal. This is further appreciated if the binding vector of the dithiocarbamates ligand is drawn from the C (on the CS_2) to the metal centre (as opposed to bidentate through the sulphurs), then the coordination around the vanadium in the structures **2** and **3** can be viewed as distorted tetrahedral. The arguments are the same for **4**, except the localized electron density which caused an increase in the C—N and C—S frequencies for **1–3** is offset by delocalization onto the pyrrole ring in **4**. The net effect is the frequencies are almost identical in $VCl_2(S_2CNPy)_2$ and $VO(S_2CNPy)_2$.

CONCLUSIONS

A new and convenient synthesis of vanadium dihalodithiocarbamates from vanadyl starting materials has been developed. The dihalodithiocarbamates, $VCl_2(S_2CNMe_2)_2$, $VCl_2(S_2CNEt_2)_2$, $VCl_2(S_2CNPy)_2$ and $VBr_2(S_2CNEt_2)_2$ show definite physical property deviations from previously characterized dihalide derivatives of V^{IV} coordination complexes. The single crystal structures and IR properties definitely indicate a *cis* configuration of the halides which is contrary to all other structurally characterized V^{IV} dihalide complexes. This *cis* configuration can be considered to be a distortion from octahedral coordination to a tetrahedral-type complex with the dithiocarbamate ligand being smaller than acac, acting like a monodentate ligand instead of a bidentate ligand.

(*Received* 18 *March* 1991; *accepted* 20 *May* 1991)

Abstract—The synthesis and structural characterization of [α,α′-bis{bis(2-(diphenylphosphino)ethyl)amino}ethane]bis(tetrahydroborato)dicopper(I) complex is reported. Crystal structure analysis shows that each copper atom possesses a distorted tetrahedral geometry with ligation to two phosphorus atoms of the ligand and two hydrogen atoms of BH_4^-. ^1H, ^{13}C, ^{31}P and ^{11}B NMR and IR data are also presented.

Synthesis of metal complexes containing the tetrahydroborate group has gained considerable interest in research due to their catalytic activity in hydrogenation, isomerization, polymerization and oligomerization reactions.[1] A number of such complexes containing copper(I) and tertiary phosphine ligands with different bonding modes of BH_4^- have been reported.[1–4] Recently, photocatalytic behaviour of some of these complexes, viz. $Cu(PPh_3)_2(BH_4)$, Cu(diphos)(BH_4) and Cu(prophos)(BH_4), has also been reported.[5] With a view to investigating the BH_4^- bonding mode and its catalytic activity we have synthesized the title compound with a new hexadentate ligand, viz. α,α′-bis{bis(2-(diphenylphosphino) ethyl)amino}ethane.

EXPERIMENTAL

The compound was synthesized by the reaction of $[Cu(NCCH_3)_4](ClO_4)$[6] and the ligand[7] in a 2:1 mole ratio under refluxing conditions in acetone, followed by the addition of a slight excess of an ethanolic solution of $NaBH_4$ at room temperature. The white compound thus obtained was washed with water and ethanol and on recrystallization from hot DMF gave crystals suitable for single crystal X-ray study.†

* Author to whom correspondence should be addressed.

† *X-ray study.* Intensity data were collected on an Enraf–Nonius CAD4/PDP-11/73 system with graphite-monochromatized Mo-K_α ($\lambda = 0.71069$ Å) radiation in the θ range of 4–47°. After correcting for Lorentz and polarization factors, the intensities were collected for absorption using the empirical absorption correction method with three reflections near $\chi = 90°$. The structure was solved by Multan 82 (P. Main, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq and M. M. Woolfrom, Universities of York, U.K. and Louvain, Belgium), which gave the positions of the metal and phosphorus atoms unambiguously and the structure was developed by alternated least-squares refinement and difference Fourier maps. Anisotropic refinement of non-hydrogen atoms was by block diagonal matrix and hydrogen atoms were held fixed by stereochemical constraints in the positions in the difference maps with a unit weighting scheme, and the Dunitz–Seiler factor converges to $R = 0.038$ ($R_w = 0.045$).

Crystallographic data. $C_{58}H_{68}Cu_2N_2P_4B_2$, $M_r = 1064.72$, monoclinic, space group $C2/c$, $a = 30.915(3)$, $b = 15.298(2)$, $c = 11.996(1)$ Å, $\beta = 97.33(1)°$, $V = 5627(2)$ Å^3, $Z = 4$, $\mu = 9.07$ cm^{-1}, crystal size $= 0.28 \times 0.24 \times 0.26$ mm, reflections collected = 4142, reflections observed = 3058. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited with the Cambridge Crystallographic Data Centre.

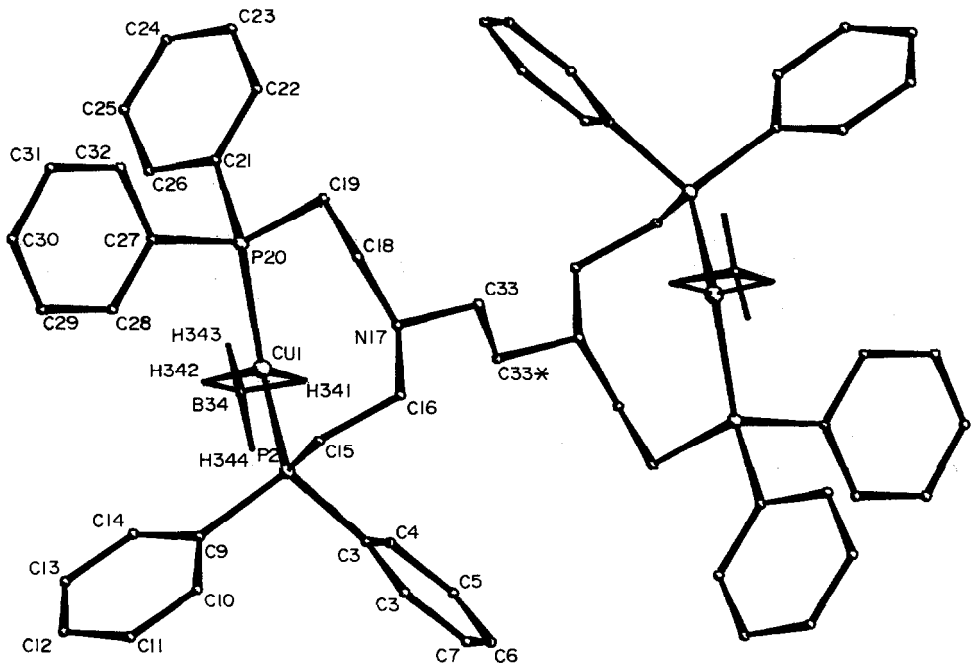

Fig. 1. Molecular structure of the title compound, showing the atom numbering scheme.

RESULTS AND DISCUSSION

The ^{1}H NMR* spectrum of the complex exhibits phenyl protons at 7.25 ppm and methylene protons at 2.16(m), 2.34(m) and 2.40(s) ppm. The first two multiplets are due to the P—CH_2—CH_2—N moiety, their multiplicity is due to coupling between two non-equivalent methylene groups followed by the ^{31}P nucleus. The singlet at 2.40 ppm is assigned to methylene protons of the N—CH_2—CH_2—N bridge. The B—H proton appeared as a broad resonance at 0.9 ppm, consistent with other reported values.[1] The ^{13}C{^{1}H} NMR spectrum contains aromatic carbons in the range 129.30–138.54 ppm, methylene carbons of the P—CH_2—CH_2—N moiety at 28.04 and 50.92 ppm, and the methylene group of the N—CH_2—CH_2—N bridge at 52.14 ppm as a singlet. ^{31}P{^{1}H} NMR exhibits a singlet at -15.68 ppm (in the free ligand this appeared at -19.01 ppm) which indicates the equivalence of phosphorus atoms coordinated to copper(I). The ^{11}B NMR spectrum shows a singlet at -52.48 ppm [relative to $B(OCH_3)_3$], significantly deshielded compared with $NaBH_4$ (-61.00 ppm).

The IR spectrum of the complex exhibits bands at 2365 (broad and strong), 2010 (strong with shoulder) and 1120 (strong and sharp) cm^{-1}, which can be assigned to ν(B—H_t), ν(B—H_b) and BH_2 deformations, respectively, for double hydrogen-bridged BH_4^-.[1,8]

The molecular structure of the complex is shown in Fig. 1. For the sake of clarity, the ORTEP view of the coordination site of one copper atom is displayed in Fig. 2. The crystal structure analysis shows that the complex contains a crystallographic centre of symmetry, which is located at the middle point of the C(33)—C(33′) bond, thus dividing the molecule into identical halves. The copper atom

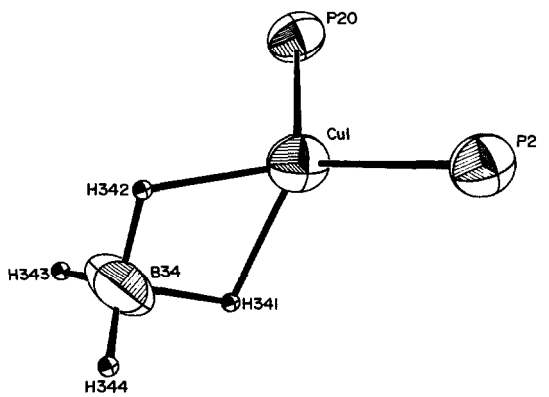

Fig. 2. ORTEP view of the surroundings of the copper(I) polyhedron.

* NMR spectra were recorded on a Jeol FX-100 FT-NMR in $CDCl_3$ (^{1}H) or $CHCl_3$, references used were tetramethylsilane for ^{1}H and ^{13}C, 85% H_3PO_4 for ^{31}P and $B(OCH_3)_3$ for ^{11}B.

Table 1. Selected bond distances (Å) and angles (°) of the title compound

Bond distances		Bond angles	
Cu(1)—P(2)	2.261(1)	P(2)—Cu(1)—P(20)	119.72(6)
Cu(1)—P(20)	2.258(1)	P(2)—Cu(1)—H(341)	113.9
Cu(1)—H(341)	1.683	P(2)—Cu(1)—H(342)	121.4
Cu(1)—H(342)	1.681	P(20)—Cu(1)—H(341)	119.3
Cu(1)—B(34)	2.247(6)	P(20)—Cu(1)—H(342)	108.8
		H(341)—Cu(1)—H(342)	59.8

shows distorted tetrahedral geometry with ligation to two phosphorus atoms of the ligand and the two hydrogen atoms of the tetrahydroborate group. Some selected bond distances and angles are shown in Table 1. The Cu—P distances are slightly shorter compared with those found in $Cu(PPh_3)_2(BH_4)$[2] which has the same coordination site. This can be attributed to the chelating effect of the ligand which results in strong Cu—P bond formation. The Cu—H distances (1.682 ± 1 Å) are also significantly shorter compared with the value of 2.02(5) Å found in $Cu(PPh_3)_2(BH_4)$,[2] which indicates strong bond formation between the copper and the hydrogen atom of BH_4^-. The bond angles found in the coordination sphere (shown in Table 1) indicate a significant distortion in the tetrahedral geometry of copper and is due to different surroundings. The smallest bond angle (59.8°), as expected, is found between two hydrogen atoms [H(341)—Cu(1)—H(342)] due to their small size.

The Cu---B distance of 2.247(6) Å is in the range found for double hydrogen-bridged tetrahydroborato complexes of the first transition metals[1,9,10] but slightly longer compared with the value of 2.184 Å found in $Cu(PPh_3)_2(BH_4)$. Such a short distance between Cu^+ and B^- (even shorter than the sum of the covalent radii of Cu^+ and B^-) indicates a significant interaction between the two atoms, as supported by the significant downfield shift of 8.5 ppm in the ^{11}B NMR spectrum of the complex.

SOLID STATE ^{31}P NUCLEAR MAGNETIC RESONANCE OF TRICYANOPHOSPHINE

M. A. H. A. AL-JUBOORI, A. FINCH, P. J. GARDNER* and C. J. GROOMBRIDGE†

Department of Chemistry, Royal Holloway and Bedford New College, Egham Hill, Egham TW20 0EX, Surrey, U.K.

(*Received* 17 *May* 1991; *accepted* 3 *June* 1991)

Abstract—The high resolution ^{31}P NMR spectrum of solid tricyanophosphine is reported. The use of magic angle sample spinning gives the chemical shift much more accurately than the earlier wideline measurement, and spinning sideband analysis gives an improved estimate of the ^{31}P chemical shift anisotropy: -96 ± 5 ppm.

The structure-determining ability of nuclear magnetic resonance spectroscopy is well known, and often depends on interpretation of the chemical shift parameter, most commonly through accumulated empirical knowledge. Considerable progress has been made in recent years in improving the theoretical computation of light element chemical shifts, especially ^{13}C and $^{14/15}$N, and this is gradually being extended to heavier species, of which ^{31}P is of most widespread interest. Chemical shifts (the term "shielding" tends to be used in the context of theoretical work, and has opposite sign) are actually second rank tensors, i.e. functions of orientation relative to the external influence, and it has been pointed out[1] that a full determination (principal components and directions) can lead to a much more complete understanding of the relationship between chemical shifts and structure.

It is clearly important to have experimental values for a range of small molecules and it has become increasingly common for high resolution solid state NMR to be used to provide this, particularly by analysis of spinning sideband patterns given by slow magic-angle sample spinning (MAS). Here we report an investigation of $P(CN)_3$, improving upon an earlier wideline ^{31}P NMR study.[2]

$P(CN)_3$ is pyramidal and crystallizes with tetragonal $I\bar{4}2d$ unit cells in which all molecules are symmetry-equivalent.[3] The bond distances and angles give almost C_{3v} symmetry, but each P—C≡N is slightly bent and weak intermolecular N···P interactions have been implicated.[3]

EXPERIMENTAL

Sample preparation

Tricyanophosphine was prepared from PCl_3 and AgCN by the method of Staats and Morgan[4] and was purified by vacuum sublimation. It was a white crystalline material subsequently handled in a dry nitrogen atmosphere.

NMR spectroscopy

All spectra were obtained on a Bruker MSL-300 spectrometer using a standard double air bearing magic-angle spinning probe. The $P(CN)_3$ sample was packed into a 7 mm zirconia rotor in a nitrogen-filled glove box. A reasonable air seal was made by the use of a small amount of vacuum grease on the rotor endcap. The sample was spun using dry compressed nitrogen gas boiled from a liquid N_2 dewar.

The ^{31}P frequency was 121.481 MHz and the sample was spun at 4433 Hz. The spectrum was recorded using single 90° pulses with a 64 s recycle. An attempt to acquire a ^{13}C spectrum gave no

* Author to whom correspondence should be addressed.
† Present address: BP Research Centre, Chertsey Road, Sunbury-on-Thames TW16 7LN, Middlesex, U.K.

signal. The ^{31}P chemical shift scale was referenced by replacement with 85% orthophosphoric acid in a sealed glass ampoule; positive shifts are to high frequency and are precise to ± 0.2 ppm. The centreband occurs at the intensity-weighted centre of the spectrum, and this was confirmed by spinning speed adjustment; its position gives the isotropic (i.e. "normal") chemical shift. An estimate of the ^{31}P relaxation time, T_1, was made using a saturation-recovery pulse sequence, and it was verified that the relative sideband intensities were not affected by incomplete relaxation.

Spinning sideband analysis was carried out using the least-squares computer program developed by Sales and co-workers,[5] which uses Herzfeld and Berger sideband ratio data.[6] Principal components were determined in the chemical shift sense, and error estimates (95% confidence intervals) were obtained from sum-of-squares derivatives.

RESULTS AND DISCUSSION

The ^{31}P MAS spectrum of $P(CN)_3$ is shown in Fig. 1. The bands were close to Gaussian shape with 164 Hz full width. The isotropic chemical shift was -140.0 ppm, close to the reported MeCN solution value,[7] -137.83 ppm, rather than -129.72 ppm found in iodopropane.[7] Self-coordination in the crystal[3] would thus appear to resemble the MeCN solvent effect. Signal recovery from saturation was found still to be incomplete at 64 s but the ^{31}P T_1 was of the order of 100 s.

Chemical shift principal components were found to be $\delta_{33} = -100(\pm 4)$, $\delta_{22} = -116(\pm 8)$, and $\delta_{11} = -204(\pm 5)$. Different definitions exist for the anisotropy, but if $\delta_\perp = 1/2(\delta_{22}+\delta_{33}) = -108$ ppm, the anisotropy can be taken as $\Delta = \delta_\parallel - \delta_\perp = -96$ ppm. Using the definition for asymmetry $\eta = (\delta_{33}-\delta_{22})/(\delta_{iso}-\delta_{11})$, this is found to differ significantly (0.24) from axial symmetry. These values are not corrected for bulk magnetic susceptibility since this is likely to be less than experimental error. Jameson *et al.*[8] have recently given the shielding on the absolute scale of the phosphoric acid reference, and this can be used to give $P(CN)_3$ *shieldings* as: $\sigma_{iso} = 468.3$ ppm, $\sigma_{11} = 428$, $\sigma_{22} = 444$, $\sigma_{33} = 532$.

Recent *ab initio* molecular calculations of substituted phosphines have suggested[9] a significant participation of phosphorus 3*d* orbitals in the bonding of $P(CN)_3$, due to partial $p\pi$–$d\pi$ overlap (3*p* and 3*d* contributions to P—CN bonding were calculated as 0.57 and 0.14). The simple semi-empirical treatment given by Lucken and Williams[2] yielded a chemical shift anisotropy of -115 ppm, but ignored 3*d* involvement and left considerable flexibility in average excitation energy and electron $\langle r^{-3} \rangle$. An attempt to improve on this would also have to incorporate the intermolecular interaction, since the solvent effect on $P(CN)_3$ shift[7] indicates that this may be of the order of 10 ppm.

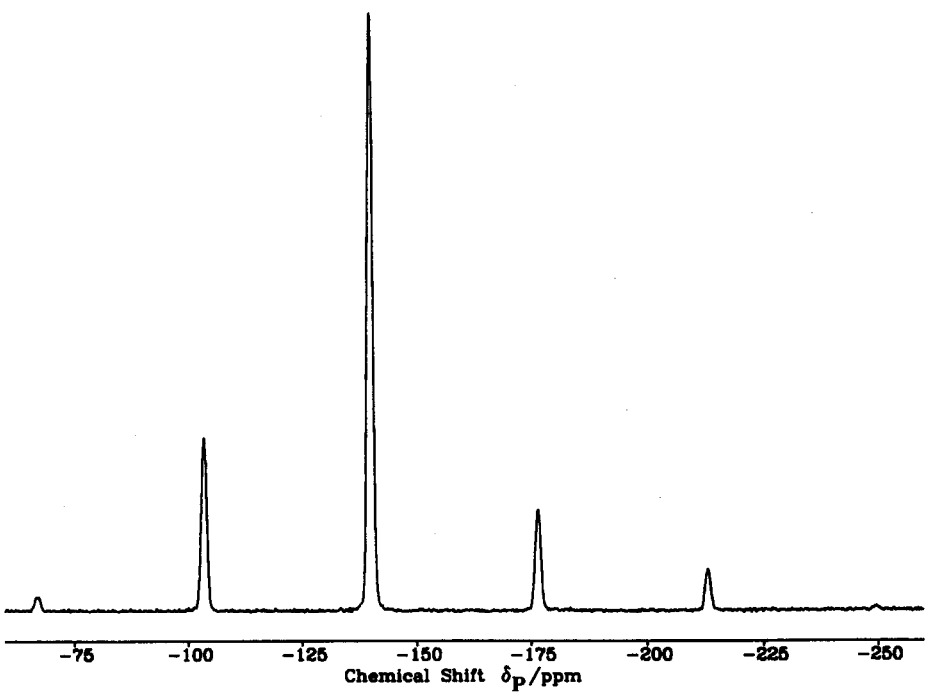

Fig. 1. ^{31}P Magic angle spinning NMR spectrum $P(CN)_3$. Spinning speed 4433 Hz, 400 scans, 64 s recycle.

Acknowledgements—All NMR spectra were obtained using the University of London Intercollegiate Research Service (ULIRS) solid state NMR facility at RHBNC, with assistance from R. T. Mathavan. Our thanks to Dr K. Sales (Queen Mary and Westfield College, London) for use of the SRCH sideband program.

(*Received* 25 *March* 1991; *accepted* 5 *June* 1991)

Abstract—Reaction of $Cu(ClO_4)_2$ with 2,3-dimethylpyrazine (2,3-dmpz) in aqueous solution yields the bright yellow, air-stable, crystalline complex $Cu_2(2,3\text{-dmpz})_3(ClO_4)_2$ (**1**) in 40% yield. The single-crystal X-ray structure reveals a two-dimensional polymeric lattice of tricoordinate copper(I) atoms bridged by 2,3-dimethylpyrazine ligands.

Motivated by our interest in magnetic interactions between metals in two-dimensional lattices, we have begun a series of studies based upon the $Cu(pz)_2(ClO_4)_2$ (pz = pyrazine) 2D-Heisenberg antiferromagnetic system.[1] In the crystalline state, this complex exists as a two-dimensional array of Cu^{2+} ions with bridging pyrazine ligands. Each copper atom is bonded to four pyrazine molecules in a pseudo-square planar array (the perchlorate ions are loosely coordinated in the axial sites). The dihedral angle, δ, between the CuN_4 plane and the plane of the pyrazine molecule is 66°. This canting of the pyrazine ligands, presumably to relieve steric crowding, provides poor overlap between the metal *d*-orbitals and the pyrazine π-system, and reduces the ligands ability to provide an exchange network between Cu^{2+} ions. We are interested in modifying that dihedral angle, either into or perpendicular to the Cu—N plane, to improve the Cu—Cu exchange. Since increasing the steric interactions between the rings would potentially increase the dihedral angle, we attempted the synthesis of $Cu(2,3\text{-dmpz})_2(ClO_4)_2$ [2,3-dmpz = 2,3-dimethylpyrazine].

RESULTS AND DISCUSSION

A deep blue–green solution of $Cu(ClO_4)_2$ and 2,3-dmpz (2:1) was allowed to stand at room temperature for several days.[2] After that time, we noted a distinct change in the colour of the solution to dark green and small yellow crystals appeared at the bottom of the beaker. After another 1–2 days the crystal formation appeared complete and the solid (**1**) was isolated. IR spectroscopy confirmed the presence of the ligand and implied the presence of the metal (via the ClO_4^- absorption at 1100 cm^{-1}). To our surprise, the complex was diamagnetic. The magnetic susceptibility exhibited no temperature dependance over the range 100–300 K. The reduction of Cu^{2+} to Cu^{1+} was confirmed by ^{63}Cu NMR in CH_3CN solution.[3] A single peak was observed at 8.7 ppm ($\nu_{1/2}$ = 40 Hz).

The product proved insoluble in most solvents, but readily dissolved in DMSO and CH_3CN. Unlike the solid material, these solutions proved unstable to air, their bright yellow colour quickly

turning to green. Recrystallization of **1** from CH_3CN under argon gave pale yellow, transparent crystals which appeared to be the solvent adduct (by IR, $\nu(C{\equiv}N) = 2290\ cm^{-1}$) and thus unsuitable for elucidating the structure of complex **1**.

Careful examination of the initial precipitate yielded a small number of crystals suitable for single crystal X-ray diffraction study.[4] An ORTEP drawing showing the coordination spheres about the copper(I) atoms is shown in Fig. 1. A stereodrawing showing the nature of the polymeric sheets is shown in Fig. 2. The structure is described as a pleated sheet. Zigzag chains of alternating copper(I) ions and coordinated 2,3-dmpz molecules run roughly parallel to the *x*-axis. The chains are cross-linked by additional 2,3-dmpz molecules to form the sheets. Adjacent chains are displaced by different amounts along the *z*-axis, providing the pleats (see Fig. 2). The methyl substituents on the pyrazine rings within a given chain are all directed in the same sense relative to the *z*-axis. The methyl substituents on the cross-linking pyrazines are all oriented in the same direction with respect to the *z*-axis.

The coordination spheres of the copper(I) ions are nearly trigonal planar. The sums of N—Cu—N bond angles about copper(1) and (2) are 359.8° and 358.9°, respectively. The coordination geometry about the copper atoms in $KCu_2(CN)_3 \cdot H_2O$ is similar.[5] The pyrazine rings themselves exhibit a

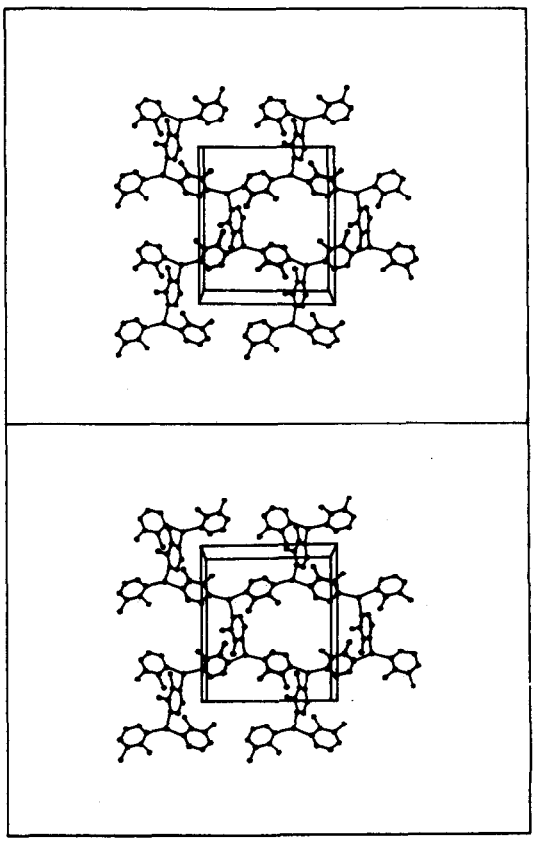

Fig. 2. Stereoview of the Cu_2(2,3-dimethylpyrazine)$_3$ pleated sheets.

wide variety of orientations with respect to the planes defined by the copper ions and their coordinated nitrogen atoms. About copper(1) the δ angles are 72° and 11° along the chain and 111° for the linking pyrazine. For copper(2), the intra-chain δ angles are 68° and 10°, and 110° to the linking pyrazine ring. The δ angles between the chains and one δ angle for each copper within the chains are all within 6° of the 66° angle found in the parent complex $[Cu(pz)_2^{2+}]_n$, but the remaining angles within the chains are substantially reduced. It is difficult to determine how much of the changes in these dihedral angles are due to the methyl substituents, because of the change from four-coordinate to three-coordinate copper centres.

Reduction of copper(II) complexes with chelating amine ligands is well established. Copper(I) complexes with 2,9-dialkylphenanthroline or 6,6′-dialkyl-2,2′-bipyridine have been prepared via chemical[6] or photochemical[7] reduction of the corresponding copper(II) compounds. Autoreduction of bis-chelated copper(II) complexes of 6,6′-dialkyl-2,2′-bipyridines[8] and 8-dimethylarsinoquinoline[9] has also been reported. In these cases, the steric bulk of the ligands is believed to force a tetrahedral geometry about the copper atom which induces a positive shift in the reduction potential. We find no examples in the literature of such a reduction with non-chelating amine ligands in the presence of non-coordinating anions. However, in the presence of halide counter-ions, reduction processes are frequently observed. This includes formation of mixed valence compounds[10] and halogenation of the organic species,[11] as well as isolation of simple copper(I) complexes.[12] The preparation of Cu^I–imidazole complexes via disproportionation of the copper(II) complexes with copper metal has also been described.[13]

We believe the most plausible course for the reaction begins with the initial formation of some Cu^{2+} species with four coordinated 2,3-dimethylpyrazines, perhaps in the manner observed in the $Cu(pz)_2(ClO_4)_2$ lattice. Crowding around the metal ion caused by the methyl groups forces a distortion of geometry to some form of distorted tetrahedron which is then reduced, perhaps by one of the ligands. The non-chelating nature of the pyrazines and the relatively electron-rich nature of the copper(I) ion then make the loss of one ligand, to relieve crowding, a facile process.

Preliminary results indicate that the conditions for reduction of copper(II) to copper(I) in this system are quite specific. Heating the initial solution causes almost immediate formation of **1**, while a solution kept at 5°C showed no evidence of reduction after 10 weeks. Cu(2-methylpyrazine)$_2(ClO_4)_2(H_2O)_2$ and Cu(2-methylpyrazine)$_4(ClO_4)_2(H_2O)$ complexes have been isolated as well and show no evidence of autoreduction.[14] In addition, reaction with 2,5-dimethylpyrazine yielded a copper(II) complex as the major isolated product. Tiny amounts of a yellow crystalline solid were also observed and are believed to be a copper(I) complex analogous to **1**. Further study of this system is in progress.

Acknowledgements—This work was supported by a grant from the National Science Foundation (DMR-9006470). The Bruker MSL-300 NMR spectrometer was purchased with the aid of NSF Grant No. CHE8720106. The X-ray diffractometer facility was established through funds provided by NSF Grant No. CHE8408407 and the Boeing Company. We also thank Professor Christopher P. Landee and Dr Fontaine C. Bradley for helpful discussions and Mr Changan Zhang for obtaining the ^{63}Cu NMR spectrum.

2. Synthesis of (**1**)—$Cu(ClO_4)_2 \cdot 6H_2O$ (3.70 g, 10 mmol) was dissolved in 5.0 cm^3 of H_2O and added to a stirred solution of 2,3-dimethylpyrazine (2.16 g, 20 mmol) in 5.0 cm^3 of H_2O. The resulting deep blue–green solution was allowed to sit at room temperature in the air for several days (7–10). Initially, a very small amount of blue–green crystalline solid was deposited in the bottom of the beaker (not yet characterized). This was followed by a change in the colour of the solution to dark green and the appearance of a yellow crystalline solid over the course of 24–48 h. The solid was collected by vacuum filtration, washed with H_2O and acetone, and then air-dried to give 2.62 g (40%). Found: C, 32.9; H, 3.5; N, 12.9. Calc. for $C_{18}H_{24}Cl_2Cu_2N_6O_8$: C, 33.2; H, 3.7; N, 13.0%. The formation of **1** can be hastened by heating the initial solution to 60°C, whereupon the previously observed colour change occurs and a bright yellow powder precipitated, 2.80 g (43%). This powder was identical to the crystalline complex according to IR and microanalysis.
3. We do not believe this spectrum represents the actual complex **1**, but rather the acetonitrile adduct. The spectrum was obtained at 79.618 MHz using a 2 μs pulse, on a Bruker MSL-300 spectrometer and referenced to $Cu(CH_3CN)_4Cl$. Attempts to obtain a solid state ^{63}Cu CPMAS spectrum were unsuccessful.
4. X-ray structure determination: Crystal dimensions 0.5 mm × 0.16 mm × 0.08 mm. Data collection was carried out on an upgraded Syntex $P2_1$ diffractometer employing Mo-K_α radiation (λ = 0.71069 Å)

and a graphite monochromator. The orientation matrix and lattice parameters were optimized from a least squares calculation on 25 centred reflections with high Bragg angles (27–30°). Two standard reflections (026, 122) were monitored every 96 reflections and showed no systematic variation. The intensities of 4623 reflections were measured by using an ω-scan (0.9° range) with speeds varying from 3 to 30° min^{-1}. Following the data reduction, 4225 unique reflections remained, with 2642 having $|F_o| \geqslant 3\sigma$. The positions of the copper and chloride atoms were found via direct methods, with the remaining molecules being found from subsequent electron difference maps. All non-hydrogen atoms were refined to final values of $R = 0.0699$ and $R_w = 0.0616$. The final refinement included 325 least squares parameters with a mean value of $|\Delta/\sigma| = 0.007$ and $g = 0.00033$. The goodness of fit was 1.552 and the final difference map showed a residual of 0.64 e $Å^{-3}$ near copper. The hydrogen atoms included were at idealized locations with the C—H distances fixed at 0.96 Å, and isotropic thermal parameters fixed at 0.08. Empirical absorption corrections were applied, resulting in a transmission range of 0.699–0.897. All data reduction, structure solution and refinement and graphics were performed by using SHELXTL 5.1 software. Full data collection information, final atomic coordinates, thermal parameters, all bond lengths and angles and observed and calculated structure factors have been deposited with the Editor. **Crystal data:** Formula: $C_{18}H_{24}Cl_2Cu_2N_6O_8$. (*Received* 12 *March* 1991; *accepted* 17 *June* 1991)

Abstract—Two alkali metal amide complexes, [Ph(2-Pyr)NK·TMEDA]$_2$ and [Me(2-Pyr)NNa·TMEDA]$_2$, synthesized from 1:1:1 mixtures of PhM (M = K or Na), the appropriate secondary amine and the Lewis base TMEDA, have been structurally identified by X-ray diffraction and shown to adopt analogous dimeric structures based on planar (N—M)$_2$ rings with additional "internal"- and "external"-donor N·M links that render the metal cations six-coordinate.

Structural information on potassium amides is particularly scarce.[1] Those which have been identified hitherto exhibit marked differences from their sodium congeners. Two sets of crystal structures illustrate this point. Unsolvated $[(Me_3Si)_2NM]_n$ is dimeric for M = K[2] and polymeric for M = Na.[3] While $\{[Bu^t_2(F)Si]N(Bu^t)M\cdot(THF)_x\}_n$ is dimeric ($n = 2$) for both metals, the larger K^{m+} cation displays additional interactions to F and to THF ($x = 2$) to attain six-coordination, in contrast to the four-coordinate Na^{m+} cations ($x = 1$).[4] Here, however, we report a K/Na pair, [Ph(2-Pyr)NK·TMEDA]$_2$ (**1**) and [Me(2-Pyr)NNa·TMEDA]$_2$ (**2**), which adopt essentially identical solid-state structures as revealed by X-ray diffraction studies (TMEDA = $Me_2NCH_2CH_2NMe_2$).

EXPERIMENTAL

Metal amides **1** and **2** were prepared by the method outlined in Scheme 1. Typically for alkali metal organic compounds, moisture and oxygen must be rigorously excluded during the preparation and subsequent storage of these pale yellow crystalline solids. Yields of first crops were 70 and 72%, m.p. is 253–254 and 95–96°C, respectively. Satisfactory analyses (C, H, N, M) were obtained. Excess tetrahydrofuran co-solvent is necessary to dissolve **1** prior to its recrystallization.

[a] This structure belongs to the same family as **1** and **2**.

respectively). This feature is beginning to dominate K/Na amide structural chemistry. Table 1 compares the key dimensions of eight four-membered rings of this type. Rings with M = K are inherently larger than those with M = Na, in keeping with periodic M^{m+} radius considerations. The R(2-Pyr) substituents in **1** and **2** occupy *transoid* positions, above and below the ring plane, enabling each pyridyl N to bridge to each pair of M^{m+} cations. Distances involved in these "internal"-donor metal linkages measure 2.841(2)/2.877(3) Å and 2.677(4)/2.709(4) Å, respectively. More unsymmetrical K-(pyridyl)N-K bridging [N—K distances, 2.779(7)/2.956(8) Å] was earlier noted in the binuclear ylide derivative $[(Ph)_2PC(H)P(Ph)_2C(H)(C_5H_4N) \cdot K \cdot (THF)_2]_2$.[10] The dihedral angles between the (amido N—M)$_2$ ring planes and the (pyridyl N—M)$_2$ ones are 120.0° for **1** and 116.9° for **2**. "External"-donor molecules (bidentate TMEDA ligands) complete the hexa-coordination of the M^{m+} cations [N—M distances: 2.825(2)/2.906(3) Å for **1**; 2.510(6)/2.511(2) Å for **2**]. The combined effect of the above structural features is the M^{m+} cations are enclosed within a distorted octahedron of nitrogen atoms. Both M^{m+} cations in each structure carry a high positive charge (greater for K, although *m* approaches one in each case), while an equal negative charge (approaching two in total) is dispersed over the eight nitrogen centres.

BOOK REVIEWS

Nomenclature of Inorganic Chemistry: Recommendations 1990. International Union of Pure and Applied Chemistry. Edited by G. J. Leigh. Blackwell Scientific Publications, Oxford, London, Cambridge, MA, 1990, xxiv+289 pp., $70.00 hardback, $27.50 paperback.

Nomenclature has been an integral part of modern chemistry since its very inception. In fact, the publication of Guyton de Morveau, Lavoisier, Berthollet and de Fourcroy's *Méthode de Nomenclature Chimique* (1787), which replaced the ambiguities of alchemical and phlogistic names with those incorporating the reforms of the "new chemistry", preceded by 2 years the publication of Lavoisier's *Traité Élémentaire de Chimie* (1789), were universally regarded as marking the birth of modern chemistry. In accord with the crucial importance of nomenclature, in 1913 the Council of the International Association of Chemical Societies appointed a commission on inorganic and organic nomenclature, but its activities were abruptly ended by World War I. In 1921, the recently formed International Union of Pure and Applied Chemistry (IUPAC) appointed commissions on inorganic, organic and biological chemistry.

The first report of the IUPAC's Commission on the Nomenclature of Inorganic Chemistry (CNIC), known as the "1940 Rules", was published in the leading journals of different countries, e.g. *Ber.* 1941, **A73**, 53; *J. Chem. Soc.* 1940, 1404; and *J. Am. Chem. Soc.* 1941, **63**, 889. These rules, revised and rewritten, were published as a small book, *Nomenclature of Inorganic Chemistry 1957*; Butterworths, London, 1959; ix+93 pp., known as the "1957 Rules" or the "Red Book" from the colour of its cover. A second revision, *Nomenclature of Inorganic Chemistry: Definitive Rules 1970*; Pergamon, Oxford, 1971; xi+110 pp., was more than twice as long as the 1957 rules because, unlike the latter, it no longer included a French version on each right-hand page. The 1970 rules were supplemented by a 36-page IUPAC booklet, *How to Name an Inorganic Substance* and by articles in various publications such as the *Journal of Chemical Education*'s bimonthly series *Notes on Nomenclature* beginning in July 1971 (W. C. Fernelius, K. Loening and R. M. Adams, *J. Chem. Educ.* 1971, **48**, 433).

Since the appearance of the 1970 rules, many new compounds have been prepared, some of which are difficult to name with these rules because they contain new types of bonding or structures. Therefore, trivial and local systems sprouted, especially for coordination and boron compounds, a situation that emphasized the need for a systematic, widely comprehensible nomenclature. Consequently, in 1978 the IUPAC CNIC decided to replace the 1970 red book. The result is "not a revision ... but a completely new version presented in a new way which it is hoped will be much more useful to the general reader". Many of the new fields of chemistry are very highly specialized and need complex types of names. Therefore, the new edition is scheduled to appear in several parts.

Part I, under review here, required a decade to produce and is almost three times as long as its predecessor. It is concerned with the basic principles of nomenclature for the fundamental areas of inorganic chemistry, and the principal authors, 13 eminent chemists from the United States, the United Kingdom, France, the Netherlands and Hungary hope that "its general principles will not be undermined, and that it should retain its currency for many years". Part II will deal with more specialized areas such as quasi-single strand inorganic polymers, organometallic and labelled compounds, and polyoxoanions; some of its contents have already been published in *Pure and Applied Chemistry*. Scheduled for publication in the near future, it will probably require more frequent revision because of its more specialized nature. Subsequent volumes are also planned.

The 1990 edition is presented in an instructional format with numerous examples, rather than as a series of numbered rules as in previous editions. After two entirely new concise chapters on the history and usages of inorganic nomenclature, the remaining nine chapters of Part I deal with elements, atoms, groups of atoms, formulae, names based on stoichiometry, solids, neutral molecular compounds, ions, substituent groups, radicals, salts, oxoacids and derived anions, coordination compounds and boron hydrides and related compounds. Each chapter was written by nominated individuals, assisted by working parties, and was repeatedly reviewed and edited by approx. 15 CNIC members. British spelling is used consistently.

Because of the conflicting use of A and B notation for groups of elements in the periodic table, the unpopular (at least among my acquaintances) 1–18 designation is presented as the preferred one, but the related controversy and other systems are discussed in an appendix, which concludes that "any ultimate recommendation ... must be responsive to the broadest possible constituency" (p. 280). Another recommendation likely to be disputed or ignored by chemists is the use of "lanthanoid" and "actinoid", although "owing to wide current use, 'lanthanide' and 'actinide' are still allowed" (p. 43), even though "the ending -ide normally indicates a negative ion". Similarly, the system recommended for naming elements of atomic numbers greater than 103 which have not yet been discovered and named by their discoverers (p. 37), resulting in such awkward names as ununquadrium (element 114), will probably not find favour with most chemists, who are likely to continue referring

to these species by atomic numbers. Other recommended changes include the avoidance of the term "radical" in anything other than the context of free radicals, the replacement of the terms "Stock number" (G. B. Kauffman and C. K. Jørgensen, *J. Chem. Educ.* 1985, **62**, 243) and "Ewens–Bassett number" (G. B. Kauffman and C. K. Jørgensen, *J. Chem. Educ.* 1985, **62**, 474) by the more readily comprehensible terms "oxidation number" and "charge number", the use of oxide names for anhydrides of fully dehydrated inorganic acids and the use of configuration indexes for *fac* and *mer* isomers "for precise nomenclature purposes".

As expected for such a thoroughly reviewed and edited volume, the errors are few and minor, e.g. Gebieten for Gebiete (p. 2), Jorisson for Jorissen, Damens for Damiens (p. 8) and entitled for titled (p. 9). A useful companion volume dealing with further types of species and providing additional examples has recently been published (B. P. Block, W. H. Powell and W. C. Fernelius, *Inorganic Chemical Nomenclature: Principles and Practice*. American Chemical Society, Washington, DC, 1990; for a review see G. B. Kauffman, *J. Chem. Educ.* 1991, **68**, A158). CNIC Chairmen Joseph Chatt, Yves Jeannin and Daryle H. Busch and their dedicated band of collaborators, including editor G. J. Leigh, deserve our profound thanks for melding "established and traditional practices and systems of nomenclature" into a reference book that should be definitive for many years to come.

Advances in Metal Carbene Chemistry. (NATO Advanced Science Institutes Series C, Vol. 269). Edited by U. Schubert. Kluwer Academic Publishers, Dortrecht, 1989, ISBN 0-7923-0156-0, xxiv+407 pp., Dfl 200; $114; £64.

Carbenes, compounds containing a $=CR_1R_2$ moiety bound to a metal, have come of age. Over the last 25 years, they have moved from being unknowns to an organometallic fact of life.

This volume is a collection of papers presented at a NATO Advanced Research Workshop in 1988 (will these workshops fall victim to the end of the Cold War?) and contains 43 contributions from many leading practitioners, including a personal history of metal carbene complexes by E. O. Fischer.

One's response to a compilation like this is essentially a personal one; this reviewer found particular interest in contributions on methylene complexes of ruthenium, osmium and iridium (W. R. Roper), carbene analogues of Wilkinson's catalyst (M. F. Lappert *et al.*) and carbenes of molybdenum(VI) (R. Lai, R. R. Schrock, J. A. Osborn and their co-workers). Carbenes are beginning to be used more widely in organic synthesis (K. H. Dötz, R. Aumann, L. S. Hegedus amongst others) and factors influencing the stability of metal–carbene complexes are better understood.

With a view to rapid publication, this volume has been compiled from camera-ready manuscripts, though this is certainly not obtrusive; it is very thoroughly indexed.

Scientists often have mixed views about the value of this type of publication. I certainly found it very worthwhile for getting an overview of the state of the art in metal–carbene complexes in a way that would not have been possible from scattered publications in the normal literature, and commend it to others similarly placed.

Gmelin Handbook of Inorganic Chemistry. Fe—Organoiron compounds, Part A9—Ferrocene 9. By M. Drössmar-Wolf, 8th edn. Springer-Verlag, Berlin, 1989, ISBN 3-540-93590-8, xiv+384 pp., DM 1742.

The previous volume (A8) of this series completed coverage of the disubstituted ferrocenes with oxygen-containing substituents; this one continues the treatment of the $(C_5H_5)Fe(C_5H_3RR')$ and $(C_5H_4R)Fe(C_5H_4R')$ systems where the substituents R and R′ contain nitrogen, sulphur, selenium, boron and silicon, allotted 197, 71, 4, 15 and 48 pages, respectively. To give an idea of the range of compounds considered, those with nitrogen-containing substituents include amines, amides, isocyanates, nitro-compounds, oximes, and those with N—N and N=N linkages.

As usual, the coverage is extremely comprehensive, with clearly set-out tabulations of data, with all relevant material for any one compound kept together with additional textual discussion. Moreover, all pages of tabulated data have the reminder as a footnote of which page contains the references to that section, an invaluable feature for rapid and accurate locating of references that could well be followed by other book-length review volumes. Another strong point of the Gmelin treatment is the ability to compare alternative synthetic routes and properties. Taking $Fe(C_5H_4CN)_2$ as an example, the relevant table contains references to nine different syntheses (with yields), six reported melting points, two NMR spectra, five IR spectra, two UV spectra and mass spectral information. These are discussed further in another section of the text, along with Mossbauer parameters, ring reactions, and oxidation to the corresponding ferrocenium cation.

Visual representations of many compounds are provided, sometimes a little compressed and distorted, presumably for reasons of spatial economy. There is a 43-page index which provides molecular and line formulae side-by-side.

Like the previous volume, published 3 years ago, this volume is the work of Marianne Drössmar-Wolf, who is to be commended for the thoroughness of her compilation (this must seem rather like the chemical equi-

to these species by atomic numbers. Other recommended changes include the avoidance of the term "radical" in anything other than the context of free radicals, the replacement of the terms "Stock number" (G. B. Kauffman and C. K. Jørgensen, *J. Chem. Educ.* 1985, **62**, 243) and "Ewens–Bassett number" (G. B. Kauffman and C. K. Jørgensen, *J. Chem. Educ.* 1985, **62**, 474) by the more readily comprehensible terms "oxidation number" and "charge number", the use of oxide names for anhydrides of fully dehydrated inorganic acids and the use of configuration indexes for *fac* and *mer* isomers "for precise nomenclature purposes".

As expected for such a thoroughly reviewed and edited volume, the errors are few and minor, e.g. Gebieten for Gebiete (p. 2), Jorisson for Jorissen, Damens for Damiens (p. 8) and entitled for titled (p. 9). A useful companion volume dealing with further types of species and providing additional examples has recently been published (B. P. Block, W. H. Powell and W. C. Fernelius, *Inorganic Chemical Nomenclature: Principles and Practice*. American Chemical Society, Washington, DC, 1990; for a review see G. B. Kauffman, *J. Chem. Educ.* 1991, **68**, A158). Visual representations of many compounds are provided, sometimes a little compressed and distorted, presumably for reasons of spatial economy. There is a 43-page index which provides molecular and line formulae side-by-side.

Like the previous volume, published 3 years ago, this volume is the work of Marianne Drössmar-Wolf, who is to be commended for the thoroughness of her compilation (this must seem rather like the chemical equi-

valent of painting the Forth Bridge at times) which makes this book a tremendous timesaver—like the rest of the series—to organometallic chemists.

Gmelin Handbook of Inorganic Chemistry. Tungsten. Supplement Volume A5a, Electrochemistry. By G. Bär, D. Gras, V. Haase and G. Hönes. Springer-Verlag, Berlin, 1990, ISBN 3-540-93605-X, DM 972.

This is the sixth volume of the tungsten supplement dealing with the synthesis, properties and reactions of the metal (in addition, a separate series, of which parts B1–6 have been published, deals with tungsten compounds). It is multi-disciplinary in that much of the content will be of interest to non-inorganic chemists. A wide range of data has been assimilated, mostly from Soviet sources.

The volume opens with a résumé of the standard potentials for tungsten electrodes in a variety of equilibria. There follows an account of the behaviour of tungsten as a cathode and an anode in both aqueous and non-aqueous media. Detailed consideration of hydrogen over-voltages shows the need for scrupulous cleanliness of apparatus to achieve reproducible and consistent results. The effects of various experimental factors—pH, temperature, solvent, anions and cations—on over-voltage are clearly set out. Unfortunately for synthetic chemists, it appears that attempts to use electrochemical oxidation of tungsten in halogen-saturated solvents have been unsuccessful as a route to solutions of tungsten halides (suitable synthetic starting materials), in contrast to uranium and molybdenum. The latter part of the book details polarographic characteristics and electrode position.

The clarity of the layout assists its intelligibility to the non-specialist. The literature is surveyed to the end of 1987, but as usual more recent data are considered.

Organometallic Radical Processes (Journal of Organometallic Chemistry Library 22). Edited by William C. Trogler. Elsevier, Amsterdam and New York (Published in conjunction with Akademie-Verlag, Berlin), 1990, vii+380 pp., ISBM 0-444-98827-0, vii+380 pp., $130.75, Dfl 255.

The 18-electron rule is one of the cornerstones of organometallic chemistry; this book celebrates many of the exceptions in discussing 17- and 19-electron systems. Increasingly sophisticated techniques have revealed them often acting as intermediates in the reactions of even-electron systems, so that this book is of particular interest to the spectroscopist, kineticist and the organometallic chemist.

This latest volume in a well-established series contains 10 self-contained chapters, of which the first (by C. Amatore) details electrochemical methods for generating these radicals. The complementary techniques of chronoamperometry and cyclic voltammetry are contrasted and the power of their combined use propounded. Particular examples studied include oxidative addition to Ni(O) and Pd(O) complexes and the mechanism of formation of Collman's reagent $Fe(CO)_4^{2-}$. Chapter 2 (M. C. Baird) looks at 17-electron metal-centred radicals, beginning with the classic example of the uniquely stable paramagnetic carbonyl, $V(CO)_6$. This chapter contains a considerable amount of comparative IR and ESR data for a very wide range of paramagnetic substituted carbonyl species of vanadium, chromium, molybdenum, tungsten, manganese and iron. In Chapter 3, T. L. Brown starts by examining the formation and reactions of organometallic radicals before getting down to the rich variety of processes involving atom transfer. This very thorough treatment includes several extensive tabulations of data and numerous correlations.

N. J. Coville focuses on ligand substitution reactions from the aspect of synthesis, pointing out the increasing number of techniques (e.g. electrochemical, phase transfer catalysts) now available in addition to the classical methods of thermal and photochemical routes. The very handy listings of catalysts could well serve as springboards for a number of research projects. The prototype 17-electron metallocene system, the ferrocenium ion, is the starting point of W. E. Geiger's chapter on redox reactions of sandwich systems. This brings together a valuable collection of redox potentials, both for cyclopentadienyls and arenes. Chapter 6 (W. Kaim and B. Olbrich-Deussner) reviews paramagnetic main-group and transition-metal complexes with unsaturated nitrogen ligands. As they point out, these are particularly amenable to study by ESR as ^{14}N h.f.s. is easily recognised. There is a comprehensive listing of systems implicated in radical formation; careful study of this chapter could lead to developing ligands calculated to stabilize unusual oxidation states in isolable compounds. J. K. Kochi reviews activation of metal carbonyls in Chapter 7, considering electrochemical, thermal and photochemical electron transfer. The non-thermal routes have been found to proceed at considerably faster rates in certain cases, raising possibilities of alternative synthetic routes and catalytic pathways. The potential of cyclic voltammetry at extremely high scan rates is considered, mainly applied here to manganese. The coupling reactions of carbonyl-containing cations and anions are examined, linked with studies of the charge-transfer salts.

P. H. Rieger's chapter on ESR studies on organometallic radicals gives a number of recorded spectra together with computer simulations. He points out that it is frequently necessary to include second-order corrections in the analysis (does anyone ever use Q-band?); and also the problems that can arise if the g- and hyperfine tensor axes are not coincident. This is an excellent chapter for the ESR spectroscopist, but probably not user-friendly enough for the average organometallic chemist. Chapter 9 (W. C. Trogler) is a review of the mechanisms for ligand substitution, insertion and disproportionation in 17-electron radicals; these mechanisms are in common with 18-electron systems, but faster by a factor of a million to a billion in the case of

valent of painting the Forth Bridge at times) which makes this book a tremendous timesaver—like the rest of the series—to organometallic chemists.

Gmelin Handbook of Inorganic Chemistry. Tungsten. Supplement Volume A5a, Electrochemistry. By G. Bär, D. Gras, V. Haase and G. Hönes. Springer-Verlag, Berlin, 1990, ISBN 3-540-93605-X, DM 972.

valent of painting the Forth Bridge at times) which makes this book a tremendous timesaver—like the rest of the series—to organometallic chemists.

Gmelin Handbook of Inorganic Chemistry. Tungsten. Supplement Volume A5a, Electrochemistry. By G. Bär, D. Gras, V. Haase and G. Hönes. Springer-Verlag, Berlin, 1990, ISBN 3-540-93605-X, DM 972.

This is the sixth volume of the tungsten supplement dealing with the synthesis, properties and reactions of the metal (in addition, a separate series, of which parts B1–6 have been published, deals with tungsten compounds). It is multi-disciplinary in that much of the content will be of interest to non-inorganic chemists. A wide range of data has been assimilated, mostly from Soviet sources.

The volume opens with a résumé of the standard potentials for tungsten electrodes in a variety of equilibria. There follows an account of the behaviour of tungsten as a cathode and an anode in both aqueous and non-aqueous media. Detailed consideration of hydrogen over-voltages shows the need for scrupulous cleanliness of apparatus to achieve reproducible and consistent results. The effects of various experimental factors—pH, temperature, solvent, anions and cations—on over-voltage are clearly set out. Unfortunately for synthetic chemists, it appears that attempts to use electrochemical oxidation of tungsten in halogen-saturated solvents have been unsuccessful as a route to solutions of tungsten halides (suitable synthetic starting materials), in contrast to uranium and molybdenum. The latter part of the book details polarographic characteristics and electrode position.

The clarity of the layout assists its intelligibility to the non-specialist. The literature is surveyed to the end of 1987, but as usual more recent data are considered.

Organometallic Radical Processes (Journal of Organometallic Chemistry Library 22). Edited by William C. Trogler. Elsevier, Amsterdam and New York (Published in conjunction with Akademie-Verlag, Berlin), 1990, vii+380 pp., ISBM 0-444-98827-0, vii+380 pp., $130.75, Dfl 255.

The 18-electron rule is one of the cornerstones of organometallic chemistry; this book celebrates many of the exceptions in discussing 17- and 19-electron systems. Increasingly sophisticated techniques have revealed them often acting as intermediates in the reactions of even-electron systems, so that this book is of particular interest to the spectroscopist, kineticist and the organometallic chemist.

This latest volume in a well-established series contains 10 self-contained chapters, of which the first (by C. Amatore) details electrochemical methods for generating these radicals. The complementary techniques of chronoamperometry and cyclic voltammetry are contrasted and the power of their combined use propounded. Particular examples studied include oxidative addition to Ni(O) and Pd(O) complexes and the mechanism of formation of Collman's reagent $Fe(CO)_4^{2-}$. Chapter 2 (M. C. Baird) looks at 17-electron metal-centred radicals, beginning with the classic example of the uniquely stable paramagnetic carbonyl, $V(CO)_6$. This chapter contains a considerable amount of comparative IR and ESR data for a very wide range of paramagnetic substituted carbonyl species of vanadium, chromium, molybdenum, tungsten, manganese and iron. In Chapter 3, T. L. Brown starts by examining the formation and reactions of organometallic radicals before getting down to the rich variety of processes involving atom transfer. This very thorough treatment includes several extensive tabulations of data and numerous correlations.

N. J. Coville focuses on ligand substitution reactions from the aspect of synthesis, pointing out the increasing number of techniques (e.g. electrochemical, phase transfer catalysts) now available in addition to the classical methods of thermal and photochemical routes. The very handy listings of catalysts could well serve as springboards for a number of research projects. The prototype 17-electron metallocene system, the ferrocenium ion, is the starting point of W. E. Geiger's chapter on redox reactions of sandwich systems. This brings together a valuable collection of redox potentials, both for cyclopentadienyls and arenes. Chapter 6 (W. Kaim and B. Olbrich-Deussner) reviews paramagnetic main-group and transition-metal complexes with unsaturated nitrogen ligands. As they point out, these are particularly amenable to study by ESR as ^{14}N h.f.s. is easily recognised. There is a comprehensive listing of systems implicated in radical formation; careful study of this chapter could lead to developing ligands calculated to stabilize unusual oxidation states in isolable compounds. J. K. Kochi reviews activation of metal carbonyls in Chapter 7, considering electrochemical, thermal and photochemical electron transfer. The non-thermal routes have been found to proceed at considerably faster rates in certain cases, raising possibilities of alternative synthetic routes and catalytic pathways. The potential of cyclic voltammetry at extremely high scan rates is considered, mainly applied here to manganese. The coupling reactions of carbonyl-containing cations and anions are examined, linked with studies of the charge-transfer salts.

P. H. Rieger's chapter on ESR studies on organometallic radicals gives a number of recorded spectra together with computer simulations. He points out that it is frequently necessary to include second-order corrections in the analysis (does anyone ever use Q-band?); and also the problems that can arise if the g- and hyperfine tensor axes are not coincident. This is an excellent chapter for the ESR spectroscopist, but probably not user-friendly enough for the average organometallic chemist. Chapter 9 (W. C. Trogler) is a review of the mechanisms for ligand substitution, insertion and disproportionation in 17-electron radicals; these mechanisms are in common with 18-electron systems, but faster by a factor of a million to a billion in the case of

the paramagnetic systems. Organometallic chemists have long been familiar with the cycles involving 16–18-electron systems; similar 17–19-electron changes seem to apply here. Reasons are advanced for the frequently observed stability of the 19-electron systems. Nineteen-electron systems themselves are the subject of D. R. Tyler's final chapter, with an emphasis on photochemically generated radicals, which have grown in importance over the last decade.

The book is well produced, with few obvious errors (e.g. pp. 175 and 202). Apart from a subject index, it very sensibly has a radical formula index.

(*Received* 4 *February* 1991; *accepted* 18 *June* 1991)

Abstract—The new complexes $Ti(\eta^5\text{-}C_5H_5)Cl(OC_6H_4NH_2\text{-}3)_2$, $Ti(\eta^5\text{-}C_5H_5)Cl(O_2CPh)_2$, $Ti(\eta^5\text{-}C_5H_5)_2(O_2C(S)C_6H_4\text{-}1,2)$, $Ti(\eta^5\text{-}C_5H_5)_2Cl(SC_6H_4OH\text{-}4)$, $Ti(\eta^5\text{-}C_5H_5)_2(OC_6H_4NH_2\text{-}3)_2$ and $Ti(\eta^5\text{-}C_5H_5)_2Cl(OC_6H_4Z)$ (Z = NO_2-2, NO_2-3, NO_2-4, NH_2-3) have been synthesized. The free amine group in $Ti(\eta^5\text{-}C_5H_5)_2Cl(OC_6H_4NH_2\text{-}3)$ reacts with RCl [R = MeCO, PhCO, $(OCCO)_{1/2}$, $Br(CH_2)_3CO$] in the presence of base to give $Ti(\eta^5\text{-}C_5H_5)_2Cl(R)$ but, in the absence of base, PhCOCl reacts to give $PhCONHC_6H_4OH$-3 and $Ti(\eta^5\text{-}C_5H_5)_2Cl_2$. The X-ray crystal structure of $Ti(\eta^5\text{-}C_5H_5)_2(OPh)_2$ has been determined and reveals a *pseudo*-tetrahedral arrangement of the two η^5-cyclopentadienyl and two phenoxide ligands around titanium. The Ti—O(Ph) distances are 1.907(3) Å and O—Ti—O is 98.1(2)°. The anti-tumour activities of $Ti(\eta^5\text{-}C_5H_5)Cl(OC_6H_4NH_2\text{-}3)_2$, $Ti(\eta^5\text{-}C_5H_5)Cl(O_2CPh)_2$ and $Ti(\eta^5\text{-}C_5H_5)_2(O_2C(S)C_6H_4\text{-}1,2)$ have been assessed *in vitro* using a panel of seven human tumour cell lines.

The anti-tumour properties of the metallocene dihalides, and in particular $TiCp_2Cl_2$ (Cp = C_5H_5), have aroused considerable interest in recent years.[1,2] A number of derivatives of this titanium compound have been synthesized in the search for a material which might be sufficiently effective for clinical use. So far work in this area has largely concentrated on bis-cyclopentadienyl complexes containing monodentate co-ligands.[1] In the work described here we report the syntheses and anti-tumour activities of two monocyclopentadienyl titanium complexes and of a bis-cyclopentadienyl complex which contains a chelating co-ligand.

In a further development of this work we are interested in incorporating, in the titanium complexes, functional groups which might exhibit interactions with DNA. This approach is based on the proposal that the titanium complexes act through interactions with intracellular DNA[1] and follows precedents set with work on derivatives of the anti-tumour drug cisplatin.[3] As an initial stage in this synthetic programme we have been examining the substitution of the halide ligands in $TiCp_2Cl_2$ with ligands containing functionalized aryl groups. Earlier reports[4] indicate that phenoxide derivatives of

$TiCp_2Cl_2$ may be obtained through the substitution of either cyclopentadienyl[5] or halide[6] ligands. Aryl carboxylate derivatives containing the $\{TiCp_2\}^{2+}$ moiety have also been reported.[4,7-9] Here we describe alternative syntheses which afford mono- or bis-phenoxide derivatives and a reaction in which a Cp^- ligand is displaced by $PhCO_2^-$. The further derivatization of the amine group in $TiCp_2Cl(O\text{-}C_6H_4NH_2\text{-}3)$ to produce amides has been investigated and the molecular structure of $TiCp_2(OPh)_2$ has been determined.

In order to overcome the limitations of murine tumour models, a panel of seven human tumour cell lines has been used to assess the anti-tumour activity of three new compounds *in vitro*. The results obtained are compared with those obtained with $TiCp_2Cl_2$ and with cisplatin.

RESULTS AND DISCUSSION

Synthetic studies

The reaction between $TiCp_2Cl_2$ and $HOC_6H_4NH_2\text{-}3$ in the presence of NEt_3 proceeds in toluene at 90°C over a period of 2 h to give the mono-phenoxide complex $TiCp_2Cl(OC_6H_4NH_2\text{-}3)$ and triethylammonium chloride. Attempts to produce the bis-phenoxide derivative by using more forcing conditions resulted in the displacement of cyclopentadienyl to give $TiCpCl(OC_6H_4NH_2\text{-}3)_2$. However, by using NaH to produce phenoxide ions during the reaction it was possible to obtain $TiCp_2(OC_6H_4NH_2\text{-}3)_2$. When present in two-fold stoichiometric excess, the *meta* and *para* mono-nitrophenols, $HOC_6H_4NO_2$, reacted with $TiCp_2Cl_2$ in the presence of NaH to give only monophenoxide derivatives. In contrast $HOC_6H_4NO_2\text{-}2$ proved more reactive and, under these conditions, afforded the known[6] bis-phenoxide complex $TiCp_2(OC_6H_4NO_2\text{-}2)_2$. The mono-phenoxide derivative $TiCp_2Cl(OC_6H_4NO_2\text{-}2)$ could also be obtained in the presence of NaH if the reactants were present in a 1:1 molar ratio. The known[6] compound $TiCp_2(OPh)_2$ could also be prepared using NaH. The reactivities of the chloride ligands in $TiCp_2Cl_2$ towards substitution by phenoxide contrast markedly with those observed[10,11] for the zirconium halides $ZrCp\{HBpz_3\}Cl_2$ and $Zr\{HB\{3,5\text{-}Me_2C_3N_2H\}_3\}Cl_3$. In the case of the titanium complex, substitution of the second halide generally requires more forcing conditions than substitution of the first and mixed chlorophenoxide complexes have been readily obtained. In the zirconium complexes, substitution of the first chloride appears to facilitate subsequent chloride substitutions so that the reaction between $Zr\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl_3$ and $HOC_6N_4NO_2\text{-}4$ in 1:1 molar ratio, for example, affords only $Zr\{HB(3,5\text{-}Me_2C_3N_2H)_3\}(OC_6H_4NO_2\text{-}4)_3$ and unreacted $Zr\{HB(3,5\text{-}Me_2C_3N_2H)_3\}Cl_3$. Mixed chloride–aryloxide or chloride–alkoxide derivatives of the zirconium complexes have only been obtained by the use of highly sterically demanding ligands.[11,12]

In a search for means of further derivatizing the titanium complexes the reactions of the free amine group in $TiCp_2Cl(OC_6H_4NH_2\text{-}3)$ were investigated. Diazotization reactions are not possible since the phenoxide ligand is displaced in the presence of acid. The formation of Schiff base derivatives in reactions with ketones or aldehydes also fails since, even under otherwise anhydrous conditions, the H_2O liberated in the condensation reaction causes hydrolysis of the titanium complex. However, in the presence of a reagent such as NaH or NEt_3 which can absorb the acid liberated, reactions with acyl chlorides can be successfully executed. Thus the complexes $TiCp_2Cl(OC_6H_4NHCOR)$ [R = Me, Ph, $(CH_2)_3Br$] can be obtained from the reactions of the aminophenoxide complexes with RCOCl. The bimetallic complex $TiCp_2Cl(OC_6H_4NHCOR)]_2$ can also be obtained from a reaction with oxalyl chloride. A particularly interesting finding was that, in the absence of base, the reaction with PhCOCl affords $PhCONHC_6H_4OH\text{-}3$ and $TiCp_2Cl_2$ through cleavage of the Ti—O bond by the HCl released during the reaction. Thus, under these conditions $TiCp_2Cl_2$ may be used as a protecting group to prevent reaction with the hydroxy function of 3-aminophenol while producing the amide by reaction with the acyl chloride. The protecting agent is then recovered after the reaction so that the overall process may be described as follows:

$$TiCp_2Cl_2 + HOC_6H_4NH_2\text{-}3 + NEt_3 \longrightarrow TiCp_2Cl(OC_6H_4NH_2\text{-}3) + Et_3NHCl$$

$$TiCp_2Cl(OC_6H_4NH_2\text{-}3) + PhCOCl \longrightarrow TiCp_2Cl(OC_6H_4NHCOPh) + HCl$$

$$TiCp_2Cl(OC_6H_4NHCOPh) + HCl \longrightarrow TiCp_2Cl_2 + HOC_6H_4NHCOPh\text{-}3$$

$$HO\text{-}C_6H_4\text{-}NH_2\text{-}3 + PhCOCl + NEt_3 \longrightarrow HO\text{-}C_6H_4\text{-}NHCOPh\text{-}3 + Et_3NHCl$$

Normally in preparing $HOC_6H_4NHCOPh$ from $HOC_6H_4NH_2$ by reaction with PhCOCl it would be necessary to protect the hydroxy group, form the amide then de-protect the hydroxy function. In this reaction the $TiCp_2Cl_2$ serves as a novel protecting group which is removed in the same reaction step as the amide formation.

The use of the $\{TiCp_2Cl\}^+$ moiety as a protecting group for the —SH functionality in HOC_6H_4SH-4 was also investigated. $TiCp_2Cl_2$ reacts with the thiolate group in HOC_6H_4SH-4, in preference to the hydroxyl group, to give $TiCp_2Cl(SC_6H_4OH$-4). However, the reactions of the free hydroxy group with RCOCl afforded complex product mixtures which we were unable to purify, suggesting that the $\{TiCp_2Cl\}^+$ may not be so useful in this role. An ether synthesis was also attempted by reacting $Me(CH_2)_5Br$ with $TiCp_2Cl(SC_6H_4OH$-4) in dichloromethane in the presence of NaH. This reaction was also unsuccessful.

The reaction of benzoic acid with $TiCp_2Cl_2$ has also been studied using refluxing toluene as the reaction medium and NaH to remove the HCl liberated. The reaction between $PhCO_2H$ and $TiCp_2Cl_2$ in 1:1 molar ratio affords the known complex $TiCp_2Cl(O_2CPh)$. However, when a 2:1 molar ratio was used to obtain the bis-carboxylate, displacement of η^5-C_5H_5 occurred to give $TiCpCl(O_2CPh)_2$. This finding contrasts with the recently reported syntheses[8] of $Ti(\eta^5$-$C_5H_4Me)_2(O_2CC_6H_4X$-2)$_2$ (X = F, Br, NO_2, Me) from $Ti(\eta^5$-$C_5H_4Me)_2Cl_2$ and NaO_2CPh in benzene at 30°C where both chloride ligands are displaced. The reaction of thiosalicylic acid with $TiCp_2Cl_2$ proceeds rapidly in refluxing toluene in the presence of NEt_3 to give the chelate complex $TiCp_2(O_2C(S)C_6H_4$-1,2). Unlike the other phenoxide or carboxylate complexes studied this compound proved to be sufficiently stable to allow purification by column chromatography on silica gel.

The new complexes have been characterized by elemental analyses and IR, ^{1}H NMR and mass spectroscopy. The IR spectra of the new phenoxide complexes contain ν_{C-O} at *ca* 1260 cm^{-1} along with bands attributable to the cyclopentadienyl ligands at 810, 1020 and 3100 cm^{-1}. The spectra of the nitrophenoxide derivatives also contain ν_{NO_2} at 1560 cm^{-1} whilst those of the aminophenoxide derivatives contain ν_{NH} at 3350 cm^{-1}. The 270 MHz ^{1}H NMR spectra of these compounds contain singlets attributable to the cyclopentadienyl ligands in the region 6.2–6.5 ppm in addition to signals in the aromatic region which are of the expected relative intensity for the formulation of mono- or bis-phenoxide complexes as appropriate. In the case of the *meta*-substituted complexes a singlet, two doublets and a triplet ($^3J_{H-H}$ *ca* 8 Hz) are observed for the aromatic protons. The chelate complex $TiCp_2\{O_2C(S)C_6H_4$-1,2} exhibits two doublets and two triplets while the *para*-substituted derivatives exhibit two doublets from the aryl protons. The IR spectra of the amide derivatives obtained from $TiCp_2Cl\{OC_6H_4NH_2$-3} and RCOCl (R = Me, Ph) exhibit $\nu_{C=O}$ at 1680 and 1650 cm^{-1} respectively and the ^{1}H NMR spectra contain additional signals attributable to the acyl substituents.

The mass spectra of the new compounds contain only weak molecular ions, the most abundant ions in the spectra of the monophenoxide complexes are those which retain the chloride substituents and involve loss of the cyclopentadienyl ligands. The electronic spectra of the new complexes generally contain two maxima with high extinction coefficients typical of charge transfer bands.

*Structural studies**

The complex $TiCp_2(OPh)_2$ afforded crystals of sufficient quality to allow an X-ray crystal structure to be determined. Bond lengths and angles are presented in Table 1 using the numbering scheme shown in Fig. 1.[13] The molecule possesses cry-

[a] O(1)′ is related to O(1) by the crystallographic two-fold axis.

stallographic two-fold symmetry, the two-fold axis passing through the titanium atom. The two symmetry related oxygen atoms, together with the centroids (Ct) of the symmetry related cyclopentadienyl rings form a considerably distorted tetrahedral coordination geometry around titanium with angles ranging from 98.1(2) to 131.4(2)° for the O—Ti—O′ and Ct—Ti—Ct′ angles, respectively (see Table 2). The four Ct—Ti—O angles fall into two categories, two angles at 103.3(2)° and two angles at 108.1(2)°. The O—Ti—O angle is just over the upper limit of the 94–97° range for the ligand–metal–ligand angle considered[14] characteristic of MCp_2L_2 compounds, where M is a d^0 metal. A very similar geometry has been found[15] in the crystal structure of $TiCp_2(OC_6H_2Cl_3)_2$ and, apart from the longer Ti—S bond, also in the crystal structure[16] of $TiCp_2(SPh)_2$. Selected parameters are compared in Table 2.

Noteworthy is the large Ti—O—C(aromatic) angle. This appears to indicate some electron $p\pi$–$d\pi$ donation from oxygen to titanium, also indicated by the slight shortening of the Ti—O bond length relative to the single bond value of *ca* 2.0 Å. This is in accord with the observations of others and with EHMO calculations.[17] However, in the sulphur analogue,[16] the angles at sulphur adopt near tetrahedral values of 112.9 and 115.4°. The Ti—S—C (aliphatic) angle in the crystal structure[18] of $TiCp_2(SMe)_2$ is slightly smaller at 109.9(1)° and that in $TiCp_2(SEt)_2$ is 110.7(6)°.[19]

Similar geometries have also been found[20] in a

[c] Ref. 16; molecule has approximate C_2 symmetry.
[d] Ct denotes the centroid of the cyclopentadienyl ring.

number of chloroaryloxo and diaryloxo titanocenes. In these compounds, the ligand–Ti–ligand and (cyclopentadienyl)centroid–Ti–(cyclopentadienyl)centroid angles are in the ranges 126–131 and 94–98° respectively, and the Ti–centroid and Ti—O distances are 2.09–2.13 and 1.86–1.93 Å. There is, however, some indication that the Ti—O length is greater in the diaryloxo compounds than in the chloroaryloxo derivatives; 1.91–1.95 Å in the former, compared with 1.86–1.88 Å in the latter.[15,20,21] This effect may be related to the competitive $p\pi$–$d\pi$ donation of the Ti—O bonds. The Ti—O—C(aromatic) angles are in the range 140–150°, in good agreement with the present work. This angle appears to be quite flexible as demonstrated by its relatively small value of 123° in the crystal structure[21] of ethylene bis(4,5,6,7-tetrahydro-(*S*)-1-indenyl)titanium-(*S*)-1′,1″-bi-2-naphtholate. Here it is apparently constrained to a small value by formation of a seven-membered chelate ring. In $TiCp_2(O_2CPh)_2$ a Ti—O—C(carboxyl) angle of 148.3(8)° is observed.[19]

The cyclopentadienyl rings in $TiCp_2(OPh)_2$ are planar to within ±0.01 Å and are inclined at an angle of 130.5(2)° to one another, in good agreement with the Ct—Ti—Ct′ angle. When viewed in a direction perpendicular to the plane bisecting the interplanar angle the cyclopentadienyl rings are close to an eclipsed orientation.

Anti-tumour testing

Primary screening for new anti-neoplatic agents has been predominantly based on transplantable murine tumours such as the P388 and L1210 leukaemias. These screening models have had limited success in identifying drugs capable of acting against solid tumours.[22] In order to overcome the limitations of murine tumour models, a panel of human tumour derived cell lines has been used as a primary *in vitro* screen for metal-containing anti-tumour drugs.[23] The cell lines (SW403, SW620, SW1116 colon carcinoma; HT1376 bladder carcinoma; HT29/219 rectal carcinoma, ZR-75-1 breast carcinoma and SK-OV-3 ovarian carcinoma) are representative of tumours of different tissue origin and clinical responsiveness. All have been shown to exhibit a differential cytotoxic response to known anti-tumour agents, an indicator of anti-tumour activity as opposed to non-selective cytotoxicity.[24]

Four titanium complexes were tested against the cell line panel. The IC_{50} values (the concentration of test compound causing 50% cell death) are shown in Table 3 and are compared with the clinically used metal-containing anti-tumour drug, cisplatin. Cisplatin is particularly active against four of the cell lines (ZR-75-1, HT 1376, HT29/219 and SK-OV-3) and has limited activity against the colon carcinomas. Titanocene dichloride, $TiCp_2Cl_2$, a candidate for phase 1 clinical trials, exhibited limited activity against the tumour panel with some indication of differential activity. This was not as marked as with cisplatin, with the lowest IC_{50} values being against the cisplatin sensitive lines.

Three other titanium cyclopentadienyl complexes were tested against the tumour panel. $TiCp_2(O_2C(S)C_6H_4)$ exhibited marginal activity against the colon carcinoma lines and the ovarian carcinoma line; the monocyclopentadienyl complexes $TiCpCl(OC_6H_4NH_2\text{-}3)_2$ and $TiCpCl(O_2CC_6H_4)_2$ exhibited little or no cytotoxicity against the cell line panel. The titanium cyclopentadienyl complexes tested do not show selective anti-tumour activity *in vitro* against the cell line panel used. The anti-tumour activity of titanocene complexes has been demonstrated in a variety of *in vivo* murine models, and it has been proposed that the limited activity observed *in vitro* may be due to rapid hydrolysis of the complex.[25] This may account for the high IC_{50} values obtained with the titanium complexes tested against the cell line panel. It would appear that the strategy of replacing the chloride ligands in $TiCp_2Cl_2$ with the chelating ligand 1,2-

Table 3. *In vitro* anti-tumour activity of titanium complexes and cisplatin

Formula	IC_{50} (μg/ml) vs cell line

$O_2C(S)C_6H_4$ in an attempt to suppress any hydrolysis reactions is ineffective in improving the antitumour activity of this class of compound.

EXPERIMENTAL

Synthetic studies

All reactions were performed under an atmosphere of dry nitrogen, but products were treated as air-stable. Solvents used for these reactions were purified by distillation from standard drying agents under dry nitrogen. Reagents were used as supplied, $TiCp_2Cl_2$ was obtained from Lancaster Synthesis Ltd. Elemental analyses were performed by the Microanalytical Laboratory of the University of Birmingham.

IR and mass spectra were recorded on PE 297 and Kratos MS 80 instruments respectively and ^1H NMR spectra were recorded using PE R12B 60 MHz and JEOL GX270 270 MHz instruments.

Preparations

$TiCp_2(OPh)_2$. In a 25 cm^3 round bottom flask $TiCp_2Cl_2$ (126 mg, 0.5 mmol) was mixed with sodium hyride (excess, 300 mg) and a solution of phenol (93 mg, 1 mmol) in toluene (10 cm^3) added. The mixture was heated under reflux for 3 h, cooled, filtered through kieselguhr and the yellow filtrate was then evaporated to dryness to give a yellow oil. This was redissolved in CH_2Cl_2 (20 cm^3) and pentane added (10 cm^3). Bright yellow crystals of the product were obtained on standing and were dried *in vacuo* (129 mg, 70%). M.p. 142°C. Found: C, 72.2; H, 5.6; M^+, 364. $C_{22}H_{20}O_2Ti$ requires C, 72.5; H, 5.5; M, 365.9. $\delta_H(CDCl_3)$ 6.28 [10H, S, η^5-C_5H_5]; 7.23, 6.80, 6.66 [4H, t; 2H, t; 4H, d, C_6H_5]; *m/z* 364 (M^+), 299 (M—Cp) and 271 (M—OC_6H_5).

$TiCp_2(OC_6H_4NO_2$-3)Cl. An excess of sodium hydride (150 mg) was added to a solution of 3-nitrophenol (420 mg, 3.0 mmol) in toluene (60 cm^3) and $TiCp_2Cl_2$ (380 mg, 1.5 mmol) added. The mixture was then stirred at 100°C for 24 h, allowed to cool, filtered and the red/orange filtrate evaporated to dryness to give a red/orange oil. The crude product was triturated with diethyl ether (30 cm^3) to remove residual $TiCp_2Cl_2$ and 3-nitrophenol. Recrystallization from CH_2Cl_2/*n*-pentane (1 : 1, 20 cm^3) afforded the product as bright orange crystals (273 mg, 51%). M.p. 140°C. Found: C, 54.6; H, 4.2; N, 3.7%; M^+, 351.5. $C_{16}H_{14}NClO_3Ti$ requires C, 54.6; H, 4.0; N, 4.0%; M, 351.4. $\delta_H(CDCl_3)$ 6.43 [10H, s, η^5-C_5H_5]; 7.65, 7.37, 7.35, 7.04 [1H, d; 1H, t; 1H, s; 1H, d, C_6H_4]; *m/z* 351 (M^+); 316 (M—Cl); 286 (M—Cp); 213 (M—$OC_6H_4NO_2$).

$TiCp_2(OC_6H_4NO_2$-2)Cl. An excess of sodium hydride (150 mg) was added to a solution of 2-nitrophenol (197 mg, 1.2 mmol) in toluene (30 cm^3). The mixture was heated under reflux for 3 h and $TiCp_2Cl_2$ (305 mg, 1.2 mmol) was then added. After heating under reflux for a further 2 h, the brown mixture that formed was cooled, filtered and the filtrate evaporated to dryness. The crude product (237 mg, 55%) was recrystallized from dichloromethane/*n*-pentane (1 : 1, 30 cm^3) to give a brownish orange solid. M.p. 131–133°C. Found: C, 54.3; H, 4.3; N, 3.9%; M^+, 352. $C_{16}H_{14}NClO_3Ti$ requires C, 54.6; H, 4.0; N, 4.0%; M, 351.5. ν_{max}: 1600, C_6H_5; 1560, N=O; 1260, Ph—O; 3100, 1020, 810, η^5-C_5H_5; 750, C_6H_4-*o* cm^{-1} (KBr); λ_{max}: 370, 350 nm; ε: 0.74, 3.0 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.46 [10H, s, η^5-C_5H_5]; 7.87, 7.45, 7.1, 6.86 [1H, d, J = 8.2 Hz; 1H, t, J = 8.4 Hz; 1H, d, J = 8.4 Hz; 1H, d, J = 8.4 Hz, C_6H_4]; *m/z* 351 (M^+); 316 (M—Cl); 286 (M—Cp); 213 (M—$OC_6H_4NO_2$).

$TiCp_2(OC_6H_4NO_2$-4)Cl. An excess of sodium hydride (150 mg) was added to a solution of 4-nitrophenol (421 mg, 3 mmol) in toluene (60 cm^3). The mixture was stirred for 0.5 h at 100°C and then $TiCp_2Cl_2$ (377 mg, 1.5 mmol) was added. After stirring the mixture at 100°C for a further 24 h, the mixture was cooled, filtered through kieselguhr and the filtrate evaporated to dryness to give a red/orange oil (254 mg, 59%). The crude product was recrystallized from dichloromethane/*n*-pentane (1 : 1, 20 cm^3) to give dark red needles. M.p. 173–175°C. Found: C, 54.6; H, 4.2; N, 3.9%; M^+, 352. $C_{16}H_{14}NClO_3Ti$ requires C, 54.6; H, 4.0; N, 4.0%; M, 352. ν_{max}: 1600, C_6H_5; 1560, N=O; 1260, Ph—O; 3100, 1020, 810, η^5-C_5H_5; 780, C_6H_4-*p* cm^{-1} (KBr); λ_{max}: 250, 355 nm; ε: 1.3, 1.7 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.44 [10H, s, η^5-C_5H_5]; 6.65, 8.14 [2H, d, J = 9.4 Hz; 2H, d, J = 9.2 Hz, C_6H_4]; *m/z* 351 (M^+); 316 (M—Cl); 286 (M—Cp); 213 (M—$C_6H_4NO_2$).

$TiCp_2(OC_6H_4NO_2$-2)$_2$. An excess of sodium hydride (300 mg) was added to a solution of 2-nitrophenol (421 mg, 3 mmol) in toluene (30 cm^3). The mixture was heated under reflux for 2 h and then $TiCp_2Cl_2$ (377 mg, 1.5 mmol) was added. After heating under reflux for a further 3 h, the mixture was cooled, filtered and the brownish filtrate evaporated to dryness to give a brownish oil (426, 62%). The crude product was recrystallized from dichloromethane/*n*-pentane (1 : 1, 10 cm^3) to give a brownish/yellow solid. M.p. 195°C. Found: C, 57.8; H, 4.2; N, 6.0%; M^+, 454. $C_{22}H_{18}N_2O_6Ti$ requires C, 58.2; H, 4.0; N, 6.2%; M, 454. ν_{max}: 1600, 1480, C_6H_4; 1560, N=O; 1260, Ph—O;

3100, 1010, 810, η^5-C_5H_5; 750, C_6H_4-*o* cm^{-1} (KBr); λ_{max}; 375, 254 nm; ε: 0.66, 3.7 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.38 [10H, s, η^5-C_5H_5]; 7.87, 7.42, 6.89, 6.85 [2H, d, $J = 8.1$ Hz; 2H, t, $J = 7.8$ Hz; 2H, t, $J = 7.9$ Hz; 2H, d, $J = 8.2$ Hz, C_6H_4]; *m/z* 454 (M^+); 389 (M—Cp); 316 (M—$OC_6H_4NO_2$).

$TiCp_2(OC_6H_4NH_2$-3)Cl. In a 100 cm^3 round bottom Schlenk flask, a solution of finely ground 3-aminophenol (56 mg, 0.5 mmol) in toluene (15 cm^3) was stirred at 90°C. Triethylamine (0.3 cm^3) and $TiCp_2Cl_2$ (127 mg, 0.5 mmol) were added and the reddish/brown mixture was stirred for 2 h at this temperature. The mixture was cooled, filtered and the filtrate evaporated to dryness, to give an orange oil. The crude product was then recrystallized from dichloromethane/*n*-pentane (1 : 2, 30 cm^3) to give a shiny orange/brown solid (104 mg, 62%). M.p. 56–58°C. Found: C, 60.0; H, 5.5; N, 4.8%; M^+, 321. $C_{16}H_{16}NClOTi$ requires C, 59.8; H; 5.0; N, 4.4%; M, 322. ν_{max}: 1600, 1480, C_6H_4; 1280, Ph—O; 1200, C—N; 3100, 1020, 810, η^5-C_5H_5 cm^{-1} (KBr); λ_{max}: 350, 248 nm; ε: 0.6, 1.9 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.37 [10H, s, η^5-C_5H_5]; 6.99, 6.0–7.0, 6.04 [1H, t, $J = 7.8$ Hz; 2H, d; 1H, s, C_6H_4]; 3.65 [2H, s, NH_2]; *m/z* 321 (M^+); 285 (M—Cl), 256 (M—Cp), 213 (M—$OC_6H_4NH_2$).

$[TiCp_2(OC_6H_4NH_2$-3)$_2$. A solution of 3-aminophenol (330 mg, 3 mmol) in toluene (60 cm^3) was stirred at 100°C with an excess of sodium hydride (400 mg). $TiCp_2Cl_2$ (377 mg, 1.5 mmol) was added and the mixture stirred for 2 days 20 h at this temperature. The mixture was cooled, filtered over kieselguhr and the filtrate evaporated to dryness to give a dark brown oil (364 mg, 61%). The crude product was recrystallized from dichloromethane/*n*-pentane (1 : 1, 30 cm^3) to give a dark brown solid. M.p. 62–64°C(d). Found: C, 67.2; H, 5.6; N, 6.8%; M^+, 394. $C_{22}H_{22}N_2O_2Ti$ requires C, 67.0; H, 5.6; N, 7.1%; M, 394. ν_{max}: 3350, NH_2; 1590, 1480, C_6H_4; 1280, Ph—O; 1190, C—N; 3100, 1010, 810, η^5-C_5H_5; 680, C_6H_4-*m* cm^{-1} (KBr); λ_{max}: 350, 240 nm; ε: 0.86, 2.7 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.27 [10H, s, η^5-C_5H_5]; 7.0, 6.2–6.6, 6.1 [2H, t, $J = 7.9$ Hz; 4H, d; 2H, s, C_6H_4]; 3.7 [4H, s, NH_2]; *m/z* 394(M^+); 329 (M—Cp).

$TiCp(OC_6H_4NH_2$-3)$_2$Cl. A solution of 3-aminophenol (131 mg, 1 mmol) and $TiCp_2Cl_2$ (300 mg, 1 mmol) in toluene (80 cm^3) was stirred at 100°C with triethylamine (0.6 cm^3) for 24 h. The mixture was cooled, filtered through kieselguhr and the red/orange filtrate evaporated to dryness (215 mg, 49%). The crude product was recrystallized from dichloromethane/*n*-pentane (1 : 1, 20 cm^3) to give a bright orange solid. M.p. 100°C(d). Found: C, 55.7; H, 4.4; N, 8.0%; M^+, 365. $C_{17}H_{17}N_2ClO_2Ti$ requires C, 56.0; H, 4.7; N, 7.7%; M, 364.5. ν_{max}: 3350, NH_2; 1600, 1460, C_6H_4; 1180, C—N; 3100, 1020, 810, η^5-C_5H_5; 690, C_6H_4-*m*, cm^{-1} (KBr); λ_{max}: 380, 320 nm; ε: 0.24, 0.52 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.29 [5H, s, η^5-C_5H_5]; 6.99; 6.94, 6.2, 6.18 [2H, t, $J = 7.9$ Hz; 2H, d, $J = 7.7$ Hz; 2H, $J = 7.9$ Hz; 2H, s, C_6H_4]; 3.7 [4H, s, NH_2]; *m/z* 364 (M^+); 329 (M—Cl); 299 (M—Cp); 256 (M—$OC_6H_4NH_2$).

$TiCp_2(O_2CPh)Cl$. An excess of sodium hydride (150 mg) was added to a solution of benzoic acid (294 mg, 2 mmol) in toluene (60 cm^3) and the mixture was heated under reflux for 3 h. $TiCp_2Cl_2$ (600 mg, 2 mmol) was added and the resulting mixture heated under reflux for a further 2 h. The mixture was then cooled, filtered and the filtrate evaporated to dryness to give a reddish/orange oil (410 mg, 51%). The crude product was recrystallized from dichloromethane/pentane (1 : 1, 20 cm^3) to give a yellow solid. M.p. 105°C(d). Found: C, 60.9; H, 4.2%; M^+, 334. $C_{17}H_{15}ClO_2Ti$ requires C, 61.0; H, 4.5%; M, 334.5. ν_{max}: 1700, C=O; 1600, 1440, C_6H_5; 3100, 1020, 800, η^5-C_5H_5, cm^{-1} (KBr); $\delta_H(CDCl_3)$ 6.43 [10H, s, η^5-C_5H_6]; 7.51, 7.9, 8.04 [1H, t, $J = 6.9$ Hz; 2H, d, $J = 7.0$ Hz; 2H, d, $J = 7.0$ Hz, C_6H_5]; *m/z* 334 (M^+); 298 (M—Cl); 269 (M—Cp); 213 (M—O_2CPh).

$TiCp(O_2CPh)_2Cl$. An excess of sodium hydride (300 mg) was added to a solution of benzoic acid (294 mg, 2 mmol) in toluene (30 cm^3) and the mixture was heated under reflux for 3 h. $TiCp_2Cl_2$ (300 mg, 1 mmol) was added and the mixture heated under reflux for a further 2 h. The mixture was cooled, filtered and the filtrate evaporated to dryness to give a bright yellow oil (334 mg, 71%). The crude product was recrystallized from dichloromethane/pentane (1 : 1; 30 cm^3) to give a yellow solid. M.p. > 300°C. Found: C, 58.5; H, 3.8%; M^+, 390. $C_{19}H_{15}ClO_4Ti$ requires C, 58.4; H, 3.8%; M, 390. ν_{max}: 1690, C=O; 1600, 1440, C_6H_5; 3100, 810, η^5-C_5H_5, cm^{-1} (KBr); λ_{max}: 360, 247 nm; ε: 0.64, 2.8 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.62 [5H, s, η^5-C_5H_5]; 8.04, 7.52, 7.43 [4H, d, $J = 7$ Hz; 4H, t, $J = 7.3$ Hz; 2H, t, $J = 7.7$ Hz, C_6H_5]; *m/z* 355 (M—Cl); 234 (M—Cl—O_2CPh).

$TiCp_2\{O_2C(S)C_6H_4$-1,2$\}$. A solution of $TiCp_2Cl_2$ (500 mg, 2 mmol), thiosalicylic acid (309 mg, 2 mmol) and triethylamine (410 mg, 3 mmol) in toluene (40 cm^3) was heated under reflux for 0.5 h. An intense green precipitate formed and the mixture was allowed to cool, then filtered and the filtrate evaporated to dryness to give a green oil. The crude product was purified using a silica gel column (14 cm × 3.5 cm) with methanol as the eluant. The major green band was collected and afforded the product as a dark green solid (440 mg, 82%). M.p. 144–146°C. Found: C, 62.0; H, 4.7%; M^+, 331.

$C_{17}H_{15}SO_2Ti$ requires C, 61.6; H, 4.5%; M, 331. ν_{max}: 1600, 1440, C_6H_4; 1620, C=O; 3100, 1020, 820, η^5-C_5H_5, cm^{-1} (KBr); λ_{max}: 320, 239 nm; ε: 1.1, 3.0 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.31 [10H, s, η^5-C_5H_5]; 8.38, 7.52, 7.38 [1H, d, $J = 7.9$ Hz; 1H, d, $J = 7.9$ Hz; 1H, t, $J = 7.9$ Hz, C_6H_4]; *m/z* 330 (M^+): 221 (M—SC_6H_4); 178 (M—$O_2C(S)C_6H_4$).

$TiCp_2(OC_6H_4NHCOCH_3$-3)Cl. A solution of 3-aminophenol (180 mg, 1.7 mmol) in toluene (40 cm^3) was stirred at 95–100°C with triethylamine (0.9 cm^3) and $TiCp_2Cl_2$ (412 mg, 1.7 mmol) for 2 h. The mixture was cooled, filtered through kieselguhr and toluene (20 cm^3), triethylamine (0.3 cm^3) and acetyl chloride (0.12 cm^3, 1.7 mmol) were then added to the filtrate and the mixture stirred at room temperature for 2.5 h. The resulting orange suspension was filtered through kieselguhr and the filtrate evaporated to dryness to give a red/orange oil (248 mg, 41%). The crude product was recrystallized from dichloromethane/*n*-pentane (1 : 1, 20 cm^3) to give a bright orange solid which was dried *in vacuo* at 50°C overnight. M.p. 80°C(d). Found: C, 59.4; H, 4.9; N, 4.3%; M^+, 363.5. $C_{18}H_{18}NClO_2Ti$ requires C, 59.4; H, 5.0; N, 3.9%; M, 364. ν_{max}: 3250, 1540, NH; 1680, C=O; 1600, 1480, C_6H_4; 1280, Ph—O; 3100, 1020, 810, η^5-C_5H_5, cm^{-1} (KBr); λ_{max}: 360, 247 nm; ε: 0.64, 2.8 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.38 [10H, s, η^5-C_5H_5]; 6.29–7.15 [4H, C_6H_4]; 7.21 [1H, s, NH]; 2.2 [3H, s, CH_3]; *m/z* 363 (M^+); 298 (M—Cp); 262 (M—Cp—Cl); 213 (M—$OC_6H_4NHCOCH_3$).

$TiCp_2(OC_6H_4NHCOPh)Cl$. A solution of $TiCp_2Cl_2$ (157 mg, 0.6 mmol) in toluene (40 cm^3) was stirred at 95–100°C with triethylamine (0.9 cm^3), finely ground 3-aminophenol (157 mg, 1.4 mmol) for 20 h. The mixture was cooled, filtered and the filtrate stirred with a mixture of toluene (20 cm^3), triethylamine (0.3 cm^3) and benzoyl chloride (0.15 cm^3, 1.5 mmol) at room temperature for $2\frac{1}{2}$ h. The mixture was cooled, filtered through kieselguhr and the filtrate evaporated to dryness, to give a shiny orange solid (48 mg, 56%). The crude product was recrystallized from dicholoromethane/*n*-pentane (1 : 1, 20 cm^3) to give an orange solid. M.p. 125°C. Found: C, 65.0; H, 5.2; N, 3.8%; M^+, 425. $C_{23}H_{20}NO_2ClTi$ requires C, 64.9; H, 4.70; N, 3.3%; M, 425.5. ν_{max}: 3300, 1540, NH; 1650, C=O; 1600, 1440, C_6H_4; 1280, Ph—O; 3100, 1020, 810, η^5-C_5H_5, cm^{-1} (KBr); λ_{max}: 350, 250 nm; ε: 0.59, 4.0 mol^{-1} dm^3 cm; $\delta_H(CDCl_3)$ 6.40 [10H, s, η^5-C_5H_5]; 6.44–7.86 [9H, C_6H_4/C_6H_5]; 7.96 [1H, s, NH]; *m/z* 426 (M^+); 360 (M—Cp); 213 (M—OP $C_6H_4NHCOPh$).

$PhCONHC_6H_4OH$-3. A solution of $TiCp_2(OPC_6H_4NH_2$-3)Cl (276 mg, 0.9 mmol) in dichloromethane (25 cm^3) was stirred at room temperature with benzoyl chloride (0.1 cm^3, 0.9 mmol). The orange precipitate that formed was stirred at this temperature for 0.5 h and at 40°C for 2 h. The mixture was then cooled, filtered through kieselguhr and the filtrate evaporated to dryness forming a pale orange solid. The crude product was recrystallized from dichloromethane/*n*-pentane (1 : 1, 20 cm^3) affording white needles. Crystals of $TiCp_2Cl_2$ were also obtained during purification (356 mg, 77%). Found: C, 73.3; H, 5.0; N, 6.6%; M^+, 213. $C_{13}H_{11}NO_2$ requires C, 73.2; H, 5.2; N, 6.6%; M, 213. ν_{max}: 3300, OH; 3200, 1580, NH; 1640, C=O; 1600, 1440, C_6H_4; *m/z* 213 (M^+); 137 (M—Ph); 105 (M—HOC_6H_4NH).

$\{TiCp_2Cl(OC_6H_4NHCO$-$)\}_2$. A solution of 3-aminophenol (255 mg, 2.3 mmol) in toluene (35 cm^3) was stirred at 95–100°C with triethylamine (0.9 cm^3) and $TiCp_2Cl_2$ (584 mg, 2.3 mmol) for 2 h. The mixture was cooled, filtered and the filtrate was then stirred with a mixture of toluene (25 cm^3), triethylamine (0.3 cm^3) and oxalyl chloride (0.1 cm^3, 1.2 mmol) at room temperature for 1 h and at 45°C for 2 h. The orange precipitate was cooled, filtered through kieselguhr and the orange filtrate evaporated to dryness to give an orange oil (490 mg, 31%). The crude product was recrystallized from dichloromethane/*n*-pentane (1 : 1, 30 cm^3) to give an orange solid. M.p. 105°C(d). Found: C, 57.3; H, 4.6; N, 3.5%; M^+, 697. $C_{34}H_{30}N_2Cl_2O_4Ti_2 \cdot 0.3CH_2Cl_2$ requires C, 57.0; H, 4.2; N, 3.9%; M, 697. ν_{max}: 3250, 1590, NH; 1680, C=O; 1595, 1480, C_6H_4; 1290, Ph—O; 3100, 1100, 810, η^5-C_5H_5, cm^{-1} (KBr); $\delta_H(CDCl_3)$ 6.41 [20H, s, η^5-C_5H_5]; 7.23; 7.1, 6.5, 6.36 [2H, t, $J = 8.2$ Hz; 2H, d; 2H, d, $J = 6.7$ Hz; 2H, d, $J = 8.44$ Hz, C_6H_4].

$TiCp_2Cl(OC_6H_4NHCOCH_2CH_2Br)$. A solution of $TiCp_2Cl(OC_6H_4NH_2$-3) (277 mg, 0.9 mmol), triethylamine (0.3 cm^3) and 4-bromobutyric chloride (0.1 ml, 0.9 mmol) was stirred at 60°C in toluene (30 cm^3) for 3 h. The mixture was cooled, filtered through kieselguhr and the red filtrate evaporated to dryness (163 mg, 41%). The crude product was recrystallized from dichloromethane/*n*-hexane (1 : 1, 20 cm^3) to give a bright orange crystalline solid. M.p. 95°C(d). Found: C, 51.4; H, 4.2; N, 3.2; M^+, 470. $C_{20}H_{21}NBrClO_2Ti$ requires C, 51.1; H, 4.5; N, 3.0; M, 470.5. ν_{max}: 3150, 1530, NH; 2900, CH_2; 1660, C=O; 1590, 1440, C_6H_4; 1280, Ph—O; 3100, 1020, 800, η_5-C_5H_5, cm^{-1} (KBr); $\delta_H(CDCl_3)$ 6.39 [10H, s, η^5-C_5H_5]; 6.4–7.2 [4H, C_6H_4]; 1.44, 2.54, 3.54 [2H, t, $J = 7.2$ Hz; 2H, m, $J = 7.2$ Hz; 2H, T, $J = 6.4$ Hz, $(CH_2)_3Br$]; *m/z* 470 (M^+), 405 (M—Cp), 213 (M—$OC_6H_4NHCO(CH_2)_3Br$).

$TiCpCl(SC_6H_4OH$-4). A solution of $TiCp_2Cl_2$ (223 mg, 0.9 mmol), 4-hydroxythiophenol (0.1 cm^3,

0.9 mmol) and triethylamine (0.12 cm^3, 0.9 mmol) was heated under reflux in toluene (30 cm^3) for 23 h. The reddish precipitate was cooled, filtered and the filtrate evaporated to dryness giving a reddish oil (242 mg, 80%). The crude product was purified using a silica gel column (12 cm × 1.5 cm) with dichloromethane as the eluent, affording a purple brown solid. Found: C, 56.3; H, 4.5%; M^+, 338. $C_{16}H_{15}SClOTi$ requires C, 56.7; H, 4.5%; M, 338.5. ν_{max}: 3400, OH; 1590, 1480, C_6H_4; 1260, Ph—O; 3100, 1020, 820, η^5-C_5H_5, cm^{-1} (KBr); $\delta_H(CDCl_3)$ 6.48 [10H, s, η^5-C_5H_5]; 7.28, 6.96 [2H, d, J = 8.7 Hz; 2H, d, J = 8.7 Hz, C_6H_4]; m/z 300 (M—C_3H_3).

Structural studies

A crystal of $TiCp_2(OPh)_2$ (0.4 × 0.4 × 0.8 mm) was mounted on an Enraf-Nonius CAD-4 diffractometer; cell dimensions and intensities were measured by ω–2θ scans with graphite-monochromated Mo-K_α radiation and scan range $(\omega) = (1.1 + 0.35 \tan\theta)°$. Scan speed varied from 1.7 to 5.0° min^{-1} depending on the intensity. 2244 reflections were scanned within $2 < \theta < 27°$. Of these 2007 were unique (merging $R_{int} = 0.038$).

Three standard reflections measured every 2 h showed no significant variation in intensity. 1069 structure amplitudes with $F > 4\sigma(F)$ were considered observed and used in the analysis. No absorption corrections were applied.

Crystal data. $C_{22}H_{20}O_2Ti$, M_r = 364.3, orthorhombic, space group *Pbcn*, a = 9.801(2), b = 10.861(4), c = 17.297(23) Å, V = 1841 $Å^3$, Z = 4, molecular symmetry 2 (C_2), D_c = 1.314 g cm^{-3}, $F(000)$ = 760, μ(Mo-K_α) = 0.469 mm^{-1}, λ = 0.71069 Å, T = 293 K.

The structure was solved by Patterson and Fourier methods[26,27] and refined by least-squares using anisotropic thermal parameters for the heavier atoms. Hydrogen atoms were placed in calculated positions riding on their respective bonded atoms. Isotropic temperature factors were refined for the hydrogen atoms. Weights $w = [\sigma^2(F) + 0.001F^2]^{-1}$ which resulted in a satisfactory weighting analysis, were used in the least-squares refinement. The refinement converged to R = 0.047, Rw = 0.060, with a maximum shift/error ratio of 0.02. The residual electron density in the final difference map was in the range ±0.35 e $Å^{-3}$.

Complex neutral-atom scattering factors were employed. Computations were carried out on the University of Birmingham IBM 3090 with the SHELXS86[26] and SHELX76[27] programs. Lists of atomic fractional coordinates and anisotropic thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

Anti-tumour testing

Maintenance of cell lines. Anti-tumour activity was assessed on an *in vitro* panel of seven human tumour cell lines. The colon carcinoma lines (SW403, SW620, SW1116) were maintained in Leibovitz L15 medium; the colorectal carcinoma line (HT29/219), the ovarian carcinoma line (SK-OV-3) and the bladder carcinoma line (HT1376) were maintained in Eagles minimal essential medium with Earles salts; the breast carcinoma line (ZR-75-1) was maintained in RPMI 1640 supplemented with 1 mM sodium pyruvate. All media were supplemented with 10% foetal bovine serum, 2 mM L-glutamine, 100 IU penicillin cm^{-3} and 100 μg streptomycin cm^{-3}. Cell cultures were grown as monolayers at 37°C in a 5% CO_2 atmosphere.

Dosing regimen. On day 1, 96-well microtitre plates were seeded with 200 μl cell suspension at 5×10^4 cells cm^{-3} (HT29/219, HT29/219, HT1376, ZR-75-1, SK-OV-3) and 10^5 cells cm^{-3} (SW403, SW620, SW1116). On day 2, the cells were treated with test compound over a concentration range of 1–200 μg cm^{-3} for 2 h. Compounds were formulated in 0.2 cm^3 1% dimethylacetamide medium, untreated control cells were exposed to 1% dimethylacetamide for 2 h. The compounds were removed after the 2 h incubation period and replaced with fresh medium. The cells were cultured for a further 72 h and total cell protein determined using sulphorhodamine B.[28]

Sulphorhodamine B assay. The medium was removed and the cells fixed in 0.1 cm^3 10% trichloroacetic acid for 30 min at 4°C. The cells were washed five times with tap water followed by staining with 100% 0.1% sulphorhodamine B in 1% acetic acid for 15 min. The cells were washed four times with 1% acetic acid and air dried. The stain was dissolved in 0.2 cm^3 10 mM unbuffered Tris. Absorbance at 540 nm, reference 690 nm, was measured using a microtitre plate reader. Results were normalized with respect to control cells and expressed as per cent survival. Dose/response curves were constructed from the normalized data. The IC_{50}, the concentration of test compound giving 50% survival with respect to controls, was calculated from the dose/response curves.

ROTATIONAL ISOMERISM IN OCTAHEDRAL d^6-IRIDIUM(III) COMPLEXES *TRANS,MER*-$[IrCl_2(PMe_3)_3L]^+$ WHERE L = PMe_3, PMe_2Ph OR $PMePh_2$; X-RAY CRYSTAL STRUCTURE OF $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4 \cdot CH_2Cl_2$

(*Received* 30 *January* 1991; *accepted* 18 *June* 1991)

Abstract—The cationic d^6-complexes $[IrCl_2(PMe_3)_3L]^+$ where L = PMe_3, PMe_2Ph or $PMePh_2$ have been synthesized and the single-crystal X-ray structure of *trans,mer*-$[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4 \cdot CH_2Cl_2$ determined; the cation is chiral because of the conformation adopted about the Ir—PMe_2Ph bond. The low-temperature $^{31}P\{^1H\}$ NMR spectrum (−75°C, CD_3COCD_3) of this salt shows a major ABCD component (95%), consistent with the chiral conformer found in the crystal, and a minor AB_2C component (5%) corresponding to a symmetrical achiral isomer. These isomers interconvert by rotation about the Ir—PMe_2Ph bond and at 45°C a sharp coalesced AB_2C spectrum is obtained. In the low-temperature ^1H NMR spectrum, the major chiral isomer shows non-equivalent *ortho*-protons, whereas the minor achiral isomer gives a single resonance for these protons. Related rotamers are observed for the $PMePh_2$ complex but we could not obtain frozen-out spectra for $[IrCl_2(PMe_3)_4]^+$. We conclude that, even for these small tertiary phosphines, it is possible to have rotamers that interconvert slowly enough for line-shape effects to be observed in NMR spectra at ambient temperatures provided that there are four phosphines in each complex. Chiral rotamers may be dominant in rotameric equilibria.

We have described the internal rotational behaviour of the tetrakis-phosphine complex *trans*-$[IrCl_2(PMe_2Ph)_4]ClO_4$, which exists in three clearly identifiable rotameric forms which interconvert slowly at −50°C whereas rotation about the Ir—P bonds is rapid above room temperature. The interpretation of the low-temperature $^{31}P\{^1H\}$ NMR spectrum in terms of overlapping ABCD, AA′BB′ and A_4 spectra was moderately straightforward but a complete analysis of the very rich ^1H NMR spectrum was not possible.[1] In this paper we have examined related complexes containing three PMe_3 ligands and only one tertiary phosphine carrying aryl substituents (PMe_2Ph or $PMePh_2$) to see if there was still restricted rotation about Ir—P bonds in these rather less-crowded systems. Furthermore, we hoped that the analysis of the NMR spectra, especially the ^1H NMR spectra in the aryl region, would be much simpler than for $[IrCl_2(PMe_2Ph)_4]ClO_4$, partly because there would be fewer accessible isomers.

RESULTS AND DISCUSSION

Syntheses

Reaction of chloroiridic acid with an excess of PMe_3 under argon in 2-methoxyethanol gave brick-red crystals of the salt $[IrCl_2(PMe_3)_4][IrCl_4(PMe_3)_2]$, which was characterized by elemental analysis, its conductivity in nitrobenzene and its ^1H NMR spectrum which contained methyl multiplets in the ratio 1:2. Extended thermolysis in the same solvent gave a redistribution of the PMe_3 ligands to give *mer*-$[IrCl_3(PMe_3)_3]$.

The chlorine ligand *trans* to PMe_3 is labile and treatment with silver perchlorate in wet acetone gave a precipitate of AgCl and a yellow solution of the aqua complex *trans,mer*-$[IrCl_2(H_2O)(PMe_3)_3]$

* Author to whom correspondence should be addressed.

ClO_4. This complex gives a ^1H NMR spectrum which is consistent with the static structure unlike that of *trans,mer*-$[IrCl_2(H_2O)(PMe_2Ph)_3]^+$ which shows coalescence behaviour involving rapid and reversible H_2O dissociation and stereochemical non-rigidity of the intermediate, $[IrCl_2(PMe_2Ph)_3]^+$, leading to phosphine exchange.[2] Presumably, the bulkier PMe_2Ph ligands lead to higher rates of H_2O dissociation and we expect that higher temperatures would be required for the PMe_3 species to show comparable behaviour, although we did not test this. Even so, the H_2O ligand in *trans,mer*-$[IrCl_2(H_2O)(PMe_3)_3]^+$ can be easily replaced in dichloromethane at room temperature by tertiary phosphines, L, to give the desired products of the type *trans,mer*-$[IrCl_2(PMe_3)_3L]ClO_4$. The compounds with L = PMe_2Ph (**1**) or $PMePh_2$ (**2**) were isolated as air-stable yellow crystalline solids. The cation with L = PMe_3 (**3**) had already been identified in the salt prepared directly from chloroiridic acid and the room-temperature ^1H and ^{31}P NMR spectra of the nitrate salt have been described.[3] The perchlorate salt with L = PPh_3 was not formed even on treatment of the aqua complex with an excess of this ligand; we believe that the equilibrium leading to the displacement of the aqua-ligand is unfavourable. This gives some indication of the extent of crowding since, in the absence of crowding, one would expect a tertiary phosphine to be more favourably coordinated than H_2O in such complexes.

Crystal structure of $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4 \cdot CH_2Cl_2$ (**1**)

The complexes *trans,mer*-$[IrCl_2(PMe_3)_2L]ClO_4$ (L = PMe_2Ph or $PMePh_2$) exhibit interconverting isomers in solution (see below) so, to establish a basis for understanding this behaviour, we determined the single-crystal X-ray structure of the dimethylphenylphosphine complex (**1**) (Fig. 1). Selected bond lengths and angles are shown in Table 1. The *trans,mer*-configuration is confirmed and, although the geometry is clearly octahedral, the four phosphorus atoms are somewhat distorted from a planar towards a tetrahedral arrangement. The P(1)IrP(2) and P(3)IrP(4) angles are 167.3(1)° and 168.9(1)°, respectively. As in other compounds of this type, such as $[IrCl_2(PMe_2Ph)_4]^+$, two substituents at each phosphorus atom are above the approximate P_4 plane and one is below with this arrangement alternating around the phosphine plane.[1] The Ph group of the PMe_2Ph shares one side of this plane with a Me group so that the molecule is asymmetric and all four phosphorus atoms are different. As an alternative, the Ph ligand might have occupied a central position with the two Me groups on the opposite side of the approximate P_4 plane and in this case there would have been a molecular plane of symmetry and the molecule would have been achiral.

Rotational isomers of $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4$ (**1**) *in solution*

Restricted rotation is normally only associated with bulky tertiary phosphine ligands such as tertiary butyl substituted ligands.[4] However, we have found that there are two rotamers of this cation in solution which give separate signals in low-temperature NMR spectra. Figure 2 shows the $^{31}P\{^1H\}$ NMR spectrum of the complex $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4$ (**1**) in CD_3COCD_3 at −75°C together with a computer simulation. This simulated spectrum requires the presence of an ABCD

pattern (δ 28.3, 26.2, 30.0, 25.5) for the major isomer (**1a**) (95%) and an AB_2C pattern (δ 21.2, 29.4, 33.4) for the minor isomer (**1b**) (5%) (labelled as $A'B_2'C'$ in Fig. 2). Good simulated spectra were obtained by fixing the *cis* coupling constants at −27 Hz and the *trans* coupling constants at 366Hz for **1a** and −30 Hz (*cis*) and 366 Hz (*trans*) for **1b**. This situation may be compared with that of *trans*-$[IrCl_2(PMe_2Ph)_4]ClO_4$ for which *cis* (−23 Hz) and *trans* (363 Hz) couplings between the ^{31}P nuclei were also of opposite sign. We believe that the predominant isomer at low temperature is that observed in the crystal, since the ABCD spectrum is as expected for this particular chiral rotamer (**1a**). The minor isomer (**1b**) with higher symmetry (AB_2C spectrum) would then correspond to a rotamer with a mirror plane and the phenyl group in the central position. The $^{31}P\{^1H\}$ NMR spectra of (**1**) start to broaden above −75°C and at 45°C, rotamers **1a** and **1b** are in fast exchange and a single coalesced AB_2C spectrum (δ 25.98, 23.56, 28.65) is observed (Fig. 3).

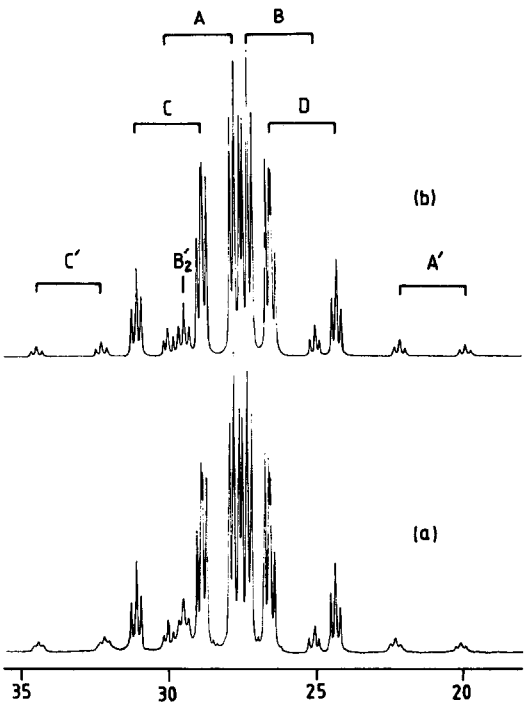

Fig. 2. (a) The $^{31}P\{^1H\}$ NMR spectrum of $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4$ (**1**) in CD_3COCD_3 at −75°C and (b) its computer simulation as the sum of an ABCD spectrum (isomer **1a**) and an AB_2C spectrum (isomer **1b**) with signals labelled A′, B_2' and C′).

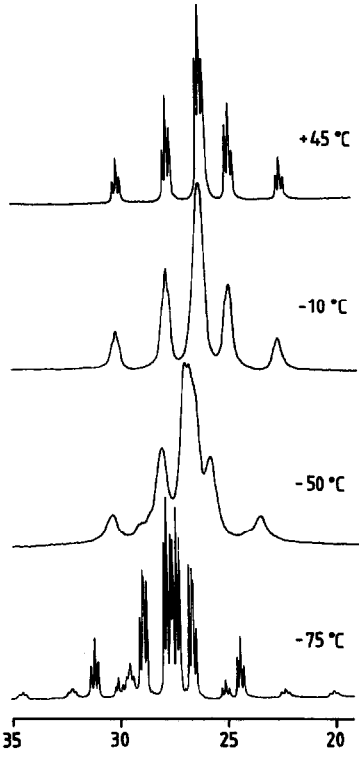

Fig. 3. $^{31}P\{^1H\}$ NMR spectra of $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4$ (**1**) in CD_3COCD_3 at the temperatures given, showing the broadening and collapse of the spectrum (ABCD + AB_2C) at −75°C to give a simple AB_2C spectrum at +45°C.

The ^{1}H NMR spectra are also consistent with this interpretation. Figures 4 and 5 contain the variable-temperature spectra in the phenyl and methyl regions, respectively. The major isomer (**1a**) has non-equivalent *ortho* protons giving separate triplet signals at δ 8.44 and 7.42 at -75°C (the latter resonance is partly obscured by the *meta* and *para* signals), whereas the minor isomer shows a single *ortho* triplet at δ 8.08. This is consistent with the different symmetries of **1a** and **1b** as shown in Scheme 1. As the temperature is raised the spectrum broadens and the three *ortho* resonances finally coalesce to the broad resonance at δ 8.04 at room temperature. At the same time the other resonances simplify (*para*, δ 7.55t and *meta*, δ 7.48t). We presume that the *ortho* resonance would resolve into a sharp triplet at higher temperatures but these spectra were not recorded.

The methyl region of the ^{1}H NMR spectrum (Fig. 5) is too complex to be analysed totally and signals for the minor isomer (**1b**) are largely obscured by those of the major isomer (**1a**). The diastereotopic Me groups of the PMe_2Ph ligand give two overlapping doublets at low tempratures which coalsesce to a single doublet at room temperature as expected. Two doublets (δ 1.04 and 1.12) are at significantly higher field than any others and are assigned to the two Me groups that lie over the face of the Ph group (see Fig. 1). This confirms that the major isomer in solution is that found in the crystal. The complexity of the Me region at low temperatures is only consistent with the restricted rotation about the Ir—PMe_3 bonds as well as about the Ir—PMe_2Ph bond. Fast rotation about Ir—PMe_3 bonds with restricted roation about the Ir—PMe_2Ph bond would give a spectrum much simpler than that in Fig. 5 at low temperature. We believe that the mechanism shown in Scheme 1 hides the fact that, as the PMe_2Ph ligand rotates, there is rotation about the other Ir—P bonds. Presumably this is a cog-wheel type process which maintains the overall arrangement of substitutents at the phosphines with two up and one down, alternately around the molecule. Thus, the PMe_2Ph ligand and the PMe_3 ligand *trans* to it are expected to maintain an eclipsed conformation as in the crystal structure. We can see in Scheme 1 that the interconversion of the enantiomeric forms of **1a**, with its associated exchange of P^1 with P^2, H^1 with H^2, and of Me^1 with Me^2, occurs via the minor isomer (**1b**). Our NMR results are in qualitative agreement with this.

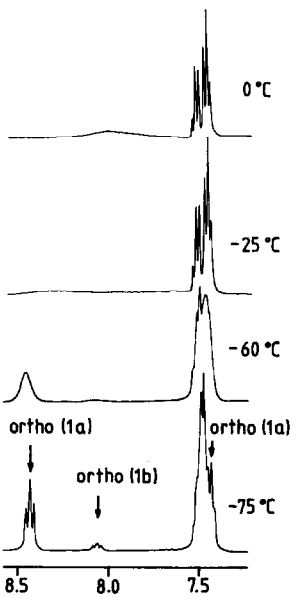

Fig. 4. ^{1}H NMR spectra of $[IrCl_2(PMe_3)_3(PMe_3Ph)]ClO_4$ (**1**) in the phenyl region at different temperatures.

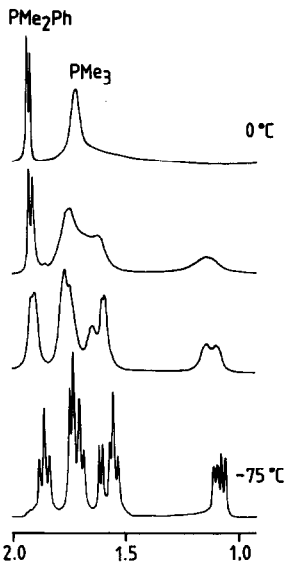

Fig. 5. ^{1}H NMR spectra of $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4$ (**1**) in the methyl region at different temperatures.

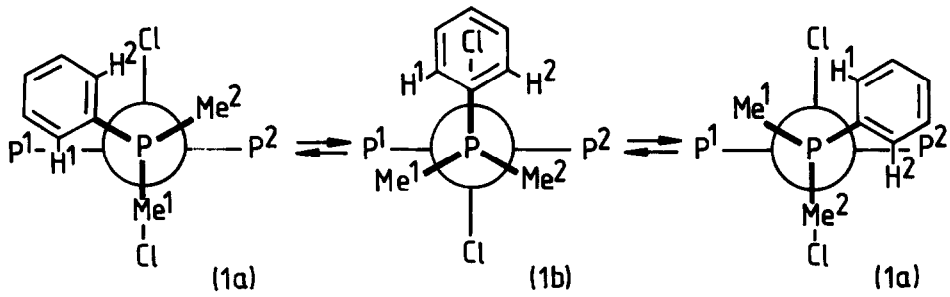
Rotational isomers of $[IrCl_2(PMe_3)_3(PMePh_2)]ClO_4$ (**2**) *in solution*

Similarly, the low-temperature $^{31}P\{^1H\}$ NMR spectrum (-75°C, CD_3COCD_3) demonstrates that there are two isomers in unequal abundance which are only slowly interconverting at this temperature. However, in contrast to the PMe_2Ph species, the spectra of both the major and the minor species can both be interpreted in terms of AB_2C patterns (see Fig. 6 for the observed and the simulated spectra); major isomer (**2a**) (δ 26.0, 16.9, 30.8) and minor isomer (**2b**) (δ 32.8, 26.0, 26.0) with *cis* and *trans*



Scheme 1.

coupling of −27 and 366 Hz for both. Above −75°C the effects of exchange are observed and at room temperature exchange is rapid enough to give a coalesced AB_2C spectrum (δ 20.50, 24.20, 29.80).

In spite of the above observations, we propose that the isomers (**2a**) and (**2b**) are unsymmetrical and symmetrical, respectively, as shown in Scheme 2. There are various possible explanations for the AB_2C spectrum for **2a**. There could be a process which is rapid even at −75°C which exchanges P^1 with P^2 of the major isomer (**2a**), without the involvement of the minor isomer (**2b**). For this to be true, the most rapid equilibria in Scheme 2 would need to be one or more of the processes across the middle rather than those on the outer circuit. We believe that this would only be possible if the $PMePh_2$ ligand rotated about the Ir—P bond while the PMe_3 ligand *trans* to it was stationary. This would allow the forms of **2a** to interconvert with each other but not with **2b**. This seems to be unlikely and we propose that the outer circuit is the favoured pathway. We can only explain the observed spectra by an accidental coincidence of chemical shifts leading to the AB_2C spectrum for **2a**.

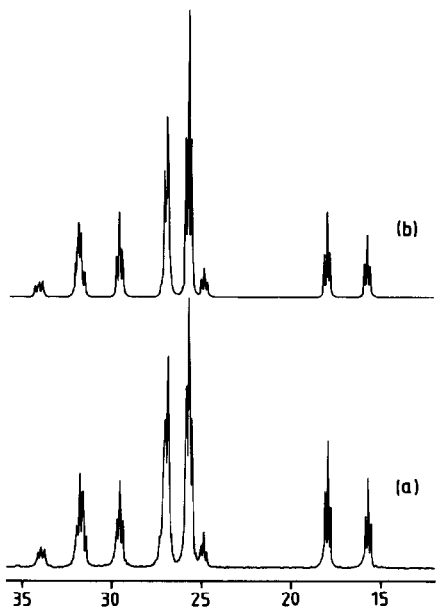


Fig. 6. (a) The $^{31}P\{^1H\}$ NMR spectrum of $[IrCl_2(PMe_3)_3(PMePh_2)]ClO_4$ (**2**) in CD_3COCD_3 at −75°C and (b) its computer simulation as the sum of two ABCD spectra for isomers **2a** and **2b**, respectively.

In principle, the low-temperature ^1H NMR spectrum of the cation $[IrCl_2(PMe_3)_4]^+$ should show separate signals for the Me groups that are up and those that are down in the ratio 1:2 if rotation about the Ir—P bonds was slowed sufficiently. At −90°C the methyl multiplet has broadened but we could not obtain spectra at temperatures lower than this that are necessary to obtain separate resonances.

We believe that the relatively high rotation barriers in the systems described in this paper are the result of having four tertiary phosphines in a plane in an octahedral complex. We have not observed rotational effects in tris-phosphine complexes, but envisage that the introduction of any relatively bulky ligand in complexes of the type *mer*-$[MCl_2L(PR_3)_3]$ should give such effects. We believe that chirality in simple complexes of the kind in this paper has not previously been stressed or even recognized as leading to distinct effects in solution.

EXPERIMENTAL

^1H and $^{31}P\{^1H\}$ NMR data are presented in Tables 2 and 3, respectively.

Synthesis of $[IrCl_2(PMe_3)_4][IrCl_4(PMe_3)_2]$

A solution of chloroiridic acid (1.55 g, 3.6 mmol) in a mixture of 2-methoxyethanol (20 cm^3) and concentrated aqueous HCl (*ca* 0.5 cm^3) was refluxed for 15 min in a Schlenk tube under argon. Trimethylphosphine (1.40 g, 18 mmol) was added and the tube was sealed and the mixture heated under reflux for 8 h, during which time the green solution

[c] At 45°C.

became orange–red. The solution stood at room temperature overnight and the brick-red crystals (1.21 g, 67%) were filtered off, washed with diethyl-ether, and dried *in vacuo*. Found: C, 20.7; H, 5.0; P, 17.7. $C_{18}H_{54}Cl_6Ir_2P_6$ requires: C, 20.5; H, 5.1; P, 17.6%. MS (EI): $m/z = 526$ for the parent ion corresponding to $[IrCl_3(PMe_3)_3]^+$, rearrangement apparently occurring in the mass spectrometer probe.

Synthesis of mer-$[IrCl_3(PMe_3)_3]$

An orange–red solution of some of the above salt (0.45 g, 0.43 mmol) in 2-methoxyethanol (50 cm^3) was heated under reflux for 60 min until it became deep yellow. The volume of the solution was reduced under reduced pressure to about 5 cm^3 and the solution stored at −20°C overnight. The yellow precipitate was collected and combined with more precipitate formed on concentrating and cooling the filtrate further. After washing and drying, the combined yield of yellow crystals of the product was 0.411 g (91%). Found: C, 20.4; H, 5.0; P, 16.1. $C_9H_{27}Cl_3IrP_3$ requires: C, 20.5; H, 5.1; P, 17.6%. MS (EI): $m/z = 526$ (parent molecular ion).

Synthesis of trans,mer-$[IrCl_2(H_2O)(PMe_3)_3]ClO_4$

Silver perchlorate (0.027 g, 0.13 mmol) was added to a suspension of *mer*-$[IrCl_3(PMe_3)_3]$ (0.0682 g, 0.13 mmol) in acetone (10 cm^3) and the mixture was shaken for 30 min. The filtered yellow solution was evaporated to dryness under reduced pressure to give a yellow oil which was crystallized from a dichloromethane/diethyl-ether mixture to give the title compound as yellow needles (0.056 g, 71%). Found: C, 17.7; H, 4.8; P, 17.4. $C_9H_{29}Cl_3IrO_5P_4$ requires: C, 17.7; H, 4.7; P, 17.2%.

Synthesis of trans,mer-$[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4$

Dimethylphenylphosphine (0.024 cm^3, 0.17 mmol) was added to a solution of the cationic aqua-complex above (0.060 g, 0.10 mmol) in dichloromethane (5 cm^3) and the mixture stirred for 60 min at room temperature. The solvent was removed to give an oil. Careful addition of diethyl-ether to a solution of the oil in dichloromethane gave the product $[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4 \cdot CH_2Cl_2$ as pale yellow crystals (0.053 g, 73%) of a quality suitable for X-ray structure determination. Found: C, 26.5; H, 4.8; P, 15.7. $C_{15}H_{40}Cl_5IrO_4P_4$ requires: C, 26.6; H, 4.9; P, 15.2%.

Synthesis of $[IrCl_2(PMe_3)_3(PMePh_2)]ClO_4$

A procedure similar to that above using the aqua-complex (0.0281, 0.053 mmol) and methyl-diphenylphosphine (0.019 cm^3, 0.053 mmol) and

crystallization as above gave the title compound in good yield (0.031 g, 86%). Found: C, 33.4; H, 5.3; P, 13.5. $C_{22}H_{40}Cl_3IrO_4P_4$ requires: C, 33.4; H, 5.1; P, 13.4%.

X-ray crystal structure determination for trans,mer-$[IrCl_2(PMe_3)_3(PMe_2Ph)]ClO_4 \cdot CH_2Cl_2$

A yellow crystal of $C_{18}H_{40}Cl_5IrO_4P_4$ with dimensions $0.22 \times 0.12 \times 0.06$ mm^3 suitable for an X-ray structure determination was obtained by layering diethyl-ether on to a dichloromethane solution of the salt and allowing slow diffusion to occur. Measurements were made at 293 K on a Nicolet R3m/v diffractometer operating with graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) in the ω–2θ mode. An orthorhombic cell, $a = 13.730(3)$, $b = 20.715(5)$, $c = 21.720(3)$ Å, $U = 6178(2)$ Å^3, was obtained by auto-indexing and least-squares fitting of 30 orientation reflections in the 2θ range 12–26°. A total of 5986 intensity data (5412 unique) in the 2θ range 5–50° were corrected for Lorentz and polarization effects and for absorption by the azimuthal scan method; μ(Mo-K_α) = 49.7 cm^{-1}. No significant decay was found by monitoring three check reflections periodically throughout the data collection.

The structure was solved by direct methods in the space group *Pcab*, $Z = 8$, $F(000) = 3216$, $D_c = 1.75$ g cm^{-3}. The model with 268 parameters was refined to $R = 0.0514$ and $R_w = 0.0549$ using 2859 data with $I_0 > 1.5\sigma(I_o)$, where $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ and $w = 1/[\sigma^2(F_o) + 0.000436(F_o)^2]$. All non-hydrogen atoms of the iridium complex cation were refined anisotropically. The disordered perchlorate anions were refined with constrained tetrahedral geometry and with Cl—O distances of 1.417 Å. The chloride atom and one oxygen atom were refined with an occupancy of 1.0 but the other six oxygen sites were given an occupancy of 0.5. Hydrogen atoms on the Me and Ph groups were included in idealized positions and allowed to ride on the carbon atoms with fixed C—H distances (0.96 Å) and thermal parameters ($U = 0.080$ Å^2). The maximum shift/ESD in the final least-squares cycle was 0.024 and the maximum peak in the final difference Fourier map was 1.86 e Å^{-3}. All calculations were carried out using a MicroVax II computer running SHELXTL-PLUS.[5] Atomic coordinates, thermal parameters, full tables of bond lengths and angles, and listings of the observed and calculated structure factors have been deposited with the Editor as supplementary material.

Acknowledgements—We thank the S.E.R.C. for research studentships (for S.D. and J.E.M.) and for funds for the purchase of a diffractometer and Johnson-Matthey for a loan of iridium.

EARLY STAGES OF THE HYDROLYSIS OF CHROMIUM(III) IN AQUEOUS SOLUTION—7. KINETICS OF CLEAVAGE OF THE HYDROLYTIC DIMER IN ACIDIC SOLUTION†

LEONE SPICCIA

Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia

(*Received* 26 *February* 1991; *accepted* 4 *June* 1991)

Abstract—The kinetics of cleavage of the hydrolytic dimer of chromium(III) have been studied in acidic solution and at elevated temperatures using spectrophotometric methods. The slightly curved dependence of k_{obs} on $[H^+]$ has been attributed to equilibration between a doubly-bridged dimer (DBD) and two singly-bridged dimer forms (fully protonated, SBD and monodeprotonated SBD-H), which are related by a protonation equilibrium that gives rise to the acid dependence of k_{obs}. Two pathways for cleavage of SBD forms into Cr^{3+} are proposed involving SBD and SBD-H and the actual bridge cleavage reactions are concluded to be acid independent. The calculated rate constants and activation parameters at 25°C were as follows: $k_{SBD\text{-}H} = 3.9(\pm 0.4) \times 10^{-7}$ s^{-1} [$\Delta H^* = 98(\pm 3)$ kJ mol^{-1} and $\Delta S^* = 20(\pm 11)$ JK^{-1} mol^{-1}]; $k_{SBD} = 2.7(\pm 0.2) \times 10^{-6}$ s^{-1} [$\Delta H^* = 112(\pm 2)$ kJ mol^{-1} and $\Delta S^* = 83(\pm 5)$ JK^{-1} mol^{-1}]. The significance of these results is discussed and a comparison with existing information on the oxo-bridged hydrolytic dimer of chromium(III) is made. The rate of the dimerization reaction between Cr^{3+} and $CrOH^{2+}$ has been estimated and found to be about 1000 times slower than the dimerization of two $CrOH^{2+}$ ions.

Hydroxy- (or oxo-) bridged binuclear complexes, dimers, are the first products of the hydrolytic polymerization of many metal ions in aqueous solution. Consequently, there is continuing interest in the properties of these complexes.[2,3] However, most work has focussed on complexes in which the metal centre is bound to several N-donor ligands[3] and in comparison very few hydrolytic dimers, in which the ligands are derived entirely from the solvent (H_2O), have been studied in detail.[2–7] Thus, comparisons of the behaviour and properties of binuclear complexes containing, for example, N-donor ligands, with those of purely hydrolytic dimers are generally lacking and there is some uncertainty as to whether the information obtained for the former is directly relevant to the hydrolytic behaviour of aqueous metal ions. The hydrolytic dimer of chromium(III) is one oligomer which has been the subject of extensive characterization studies[3,6–9] as well as comprehensive kinetic and thermodynamic investigations[1,6,9–13] and is particularly well-suited for making such an assessment.

Thompson and Connick[6] have demonstrated that the hydrolytic dimer can exist in both singly-bridged (SBD) and doubly-bridged (DBD) forms. Subsequently, the structure of DBD has been determined,[7] and its magnetic and spectroscopic properties investigated.[14] Thompson[6,9] further showed that the acid cleavage of DBD into Cr^{3+} involves two consecutive, clearly separable processes [eq. (1)]. The order of these processes is believed to be reversed in the dimerization of Cr^{3+}.[11] The overall rate of acid cleavage is much slower for SBD than for DBD which means that each of these processes can be studied with little interference from the other. As a result, measurements of the rate of interconversion[1,9] and equilibrium[13] between SBD and DBD have been possible. In addition, estimates of the overall rate of acid cleavage to give Cr^{3+} are also available but were obtained at variable ionic strength.[9]

$$DBD \rightleftharpoons SBD \rightleftharpoons Cr^{3+} \qquad (1)$$

† Part VI: Ref. 1.

We report here the result of a variable temperature and $[H^+]$ ($I = 1.0$ M) study of the cleavage of the dimer into Cr^{3+}, from which two reaction pathways have been established.

EXPERIMENTAL

Materials

Solutions of the hydrolytic dimer $[Cr_2(\mu\text{-}OH)_2(OH_2)_8](ClO_4)_4$, were prepared using a recently published method,[15] the only modification being that $HClO_4$ rather than aromatic sulphonic acids was used to oxidize chromium metal to Cr^{2+}. The resulting crude dimer solutions were purified and standardized as described previously.[10] When stored at -18°C stock dimer solutions showed no change in composition after several months.

Analytical grade reagents were used throughout. Water was deionized and doubly distilled prior to use. $NaClO_4$ and $LiClO_4$ solutions of known concentration were prepared by neutralization of standardized solutions of either NaOH or LiOH with $HClO_4$. All solutions were filtered through 0.22 μm Sartorius SM11307 cellulose nitrate membrane filters prior to use in kinetic experiments.

Instruments

The instruments and techniques used to measure the pH of the solutions and to carry out kinetic measurements have been described previously.[1]

Kinetic experiments

Reaction mixtures were prepared at the desired temperature (62.3–91.5°C) by mixing equal volumes of a dimer solution ($[Cr_2(\mu\text{-}OH)_2(OH_2)_8]^{4+} = 4.28 \times 10^{-3}$ M, $[HClO_4] = 9.3 \times 10^{-3}$ M and $[NaClO_4] = 0.122$ M, determined at room temperature, *ca* 22°C, according to published methods) with a series of solutions containing varying proportions of $HClO_4$ and $NaClO_4$ (or $LiClO_4$ in some cases) but whose ionic strength was constant (1.83 M at room temperature). The final reaction conditions were [Dimer] $= 2.14 \times 10^{-3}$ M, $[HClO_4] = 0.0271$–0.919 M and $I = 1.0$ M ($NaClO_4$ or $LiClO_4$). In the analysis of the kinetic data these acid concentrations were corrected for the temperature-dependent expansion of the solvent.

The reaction was monitored in the UV region ($\lambda < 300$ nm) where the absorbance was found to decrease as the dimer is converted into Cr^{3+}. The data were analysed at 250 nm where this decrease was between 0.5 and 0.7 units. Pseudo-first order rate constants, k_{obs}, were calculated at this wavelength from the change in absorbance, A_t, with time, t, by means of linear least-squares fitting of the data to the expression $A_t = (A_0 - A_\infty)e^{-k_{obs}t} + A_\infty$. In most cases A_0, A_∞ and k_{obs} were determined from the A_t vs t data. However, as a check on the suitability of the procedure A_∞ was measured experimentally for several runs and used in the calculation of k_{obs}. The values of k_{obs} obtained from the two treatments were within experimental error. Furthermore, experimental and fitted A_∞ values were in excellent agreement.

RESULTS

The overall rate of cleavage of the hydrolytic dimer of chromium(III) was measured in the temperature range 62.3–91.5°C and $[H^+]$ range 0.026–0.90 M, but at constant ionic strength (1.0 M). High temperatures were chosen because this gave reaction rates which could be measured using conventional spectrophotometric methods. Chromatographic analysis was used to show that Cr^{3+} is the only species present at the completion of the reaction. That is, the reaction is irreversible under the conditions used. The spectrophotometric data could be fitted accurately with a single exponential function ($0.002k_{obs} < \sigma_{k_{obs}} < 0.01k_{obs}$), which indicates that the process being followed is first order with respect to the dimer. Table 1 summarizes the $[H^+]$ and temperature dependence of the observed rate constants (k_{obs}).

The dependence of k_{obs} on $[H^+]$ is almost linear (slight curvature becomes apparent at high $[H^+]$) with a non-zero intercept at all temperatures (see Fig. 1). Thus, the cleavage of the dimer involves at

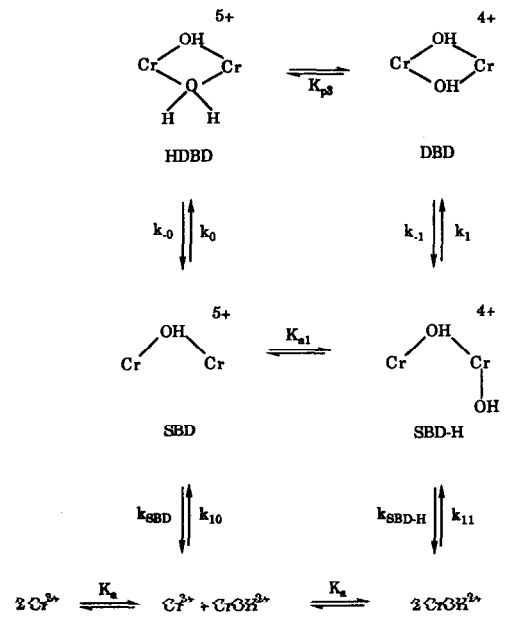
least two pathways, one of which is dependent on $[H^+]$. In contrast, Thompson[9] observed no systematic variation of k_{obs} with $[H^+]$ in the concentration range 1–8 M but in this case no attempt was made to maintain constant ionic strength.

The simplest reaction mechanism which will accommodate the almost linear dependence of k_{obs} on $[H^+]$, and existing information on the interconversion between SBD and DBD forms[1,9] is that given in Scheme I. The overall process involves several pathways which can be subdivided into two types: cleavage of DBD to give SBD forms (top half of Scheme I) followed by cleavage of SBD forms into Cr^{3+}. Thompson[9] has shown that there are substantial differences in the rates at which these processes occur, interconversion between SBD and DBD being *ca* 200 times faster than cleavage to Cr^{3+}. In fact, measurements of the equilibrium between SBD forms and DBD have been possible without interference from the cleavage of SBD forms to Cr^{3+}.[13] This suggests that the overall cleavage of the dimer is rate-determined by the cleavage of SBD forms. In Scheme I, the rate constants of importance are k_{SBD} and $k_{SBD\text{-}H}$, which represent the rate of bridge cleavage within SBD and SBD-H, respectively. Note that the actual bridge cleavage processes are proposed to be acid independent and that the acid dependence of k_{obs} arises from the protonation equilibrium between SBD-H and SBD. If the actual bridge cleavage processes were acid catalysed, a dependence of k_{obs} on $[H^+]^2$ might be expected. The rate law for the



Scheme I.

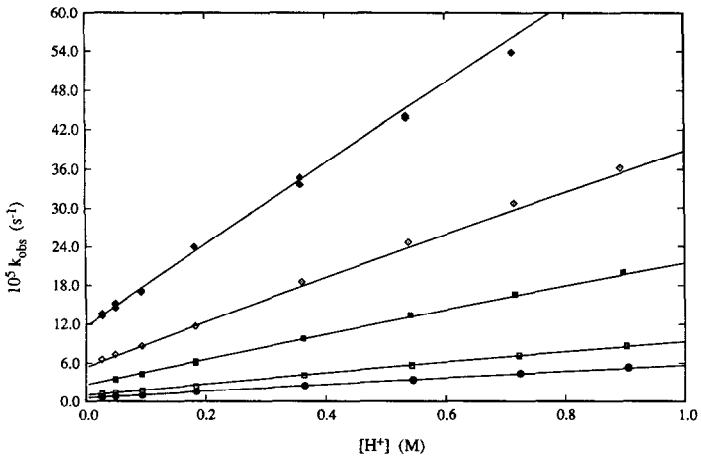


Fig. 1. Acid concentration and temperature dependence of the observed rate constant for cleavage of the hydrolytic dimer of chromium(III) at $I = 1.0$ M. Full lines represent the calculated values of k_{obs} determined from eq. (4). (●) 62.3°C; (□) 67.6°C; (■) 76.9°C; (◇) 83.5°C; (◆) 91.5°C.

cleavage of the dimer may be written as:

$$\frac{d[Cr^{3+}]}{dt} = k_{SBD\text{-}H}[SBD\text{-}H] + k_{SBD}[SBD], \quad (2)$$

where $k_{SBD\text{-}H}$ and k_{SBD} are the rate constants for cleavage of SBD-H and SBD, respectively. Use of the expressions $K_1 = [SBD\text{-}H]/[DBD]$, $K_{a1} = [SBD\text{-}H][H^+]/[SBD]$ and $[DIM]_T = \{[DBD] + [SBD\text{-}H] + [SBD]\} = \{1 + 1/K_1 + [H^+]/K_1K_{a1}\}[DBD]$ followed by simplification gives eq. (3).

$$\frac{d[Cr^{3+}]}{dt} = \left\{\frac{[k_{uc} + k_c[H^+]]}{[1 + 1/K_1 + [H^+]/K_1K_{a1}]}\right\}[DIM]_T = k_{obs}[DIM]_T \quad (3)$$

[In eq. (3), $k_{uc} = k_{SBD\text{-}H}/K_1$ and $k_c = k_{SBD}/K_1K_{a1}$.] In the case where both K_1 and K_1K_{a1} are large and the denominator in eq. (3) is *ca* 1, a linear dependence of k_{obs} on $[H^+]$ would result. Taking into account the temperature dependence of each parameter gives the following expression for k_{obs}:

$$k_{obs} = \frac{\left[\frac{kT}{h}\left\{\exp\left(\frac{\Delta H^*_{k_{uc}} - T\Delta S^*_{k_{uc}}}{RT}\right) + [H^+]\exp\left(\frac{\Delta H^*_{k_c} - T\Delta S^*_{k_c}}{RT}\right)\right\}\right]}{\left[1 + \left\{\exp\left(\frac{-\Delta H^\circ_{K_1} + T\Delta S^\circ_{K_1}}{RT}\right) + [H^+]\exp\left(\frac{-\Delta H^\circ_{K_1K_{a1}} + T\Delta S^\circ_{K_1K_{a1}}}{RT}\right)\right\}\right]}. \quad (4)$$

In analysing the data, previously determined[13] thermodynamic constants for K_1 ($\Delta H^\circ = -10.4$ (± 2.7) kJ mol^{-1} and $\Delta S^\circ = -15.0(\pm 8.9)$ JK^{-1} mol^{-1}) and K_1K_{a1} ($\Delta H^\circ = 29.5(\pm 1.1)$ kJ mol^{-1} and $\Delta S^\circ = 104.4(\pm 3.7)$ JK^{-1} mol^{-1}) were used to reduce the number of parameters in eq. (4). The activation parameters for k_{uc} and k_c (Table 2) were determined from weighted non-linear least squares fitting of the temperature and $[H^+]$ dependence of k_{obs} to eq. (4). The procedure involved minimization of $\Sigma_i W_i(k_{obs,i} - k_{calc,i})^2$ where $W_i = 1/\sigma^2_{k_{obs,i}}$ and $k_{obs,i}$, $k_{calc,i}$, W_i and $\sigma_{k_{obs,i}}$ are the observed rate constants, calculated rate constants, weighting factors and standard error in each k_{obs} value, respectively. An excellent fit of the data is indicated by the small standard errors associated with each parameter (Table 2).

The activation parameters for each cleavage process have been used to calculate k_c and k_{uc} at 25°C, which is outside the range of temperature used in this study. From these values, published values of K_1 and K_1K_{a1}, (respectively, 10.1 and 1.83 at 25°C)[13] and using the expressions $k_{SBD\text{-}H} = K_1k_{uc}$ and $k_{SBD} = k_cK_1K_{a1}$, $k_{SBD\text{-}H}$ and k_{SBD} have been estimated. Activation parameters for $k_{SBD\text{-}H}$ and k_{SBD} were determined from those of k_{uc} and k_c and the thermodynamic constants of K_1 and K_1K_{a1} given above. All of this information is listed in Table 2 and will be used in the discussion to follow.

DISCUSSION

The kinetic data for cleavage of the hydrolytic dimer of chromium(III) can be interpreted in terms of two bridge-cleavage processes (Scheme I), cleav-

Table 2. Activation parameters and calculated rate constants for cleavage of the hydrolytic dimer of chromium(III)

Parameter	$10^6 k$ (s^{-1})	ΔH^* (kJ mol^{-1})	ΔS^* (JK^{-1} mol^{-1})
k_{uc}	0.038(±0.002)[a]	108.7(±0.8)[b]	35(±2)[b]
k_c	1.46(±0.05)[a,c]	82.7(±0.6)[b]	−22(±2)[b]
$k_{SBD\text{-}H}$[d]	0.39(±0.04)	98(±3)	20(±11)
$k_{SBD\text{-}H}$[e]	2.7(±0.2)	112(±2)	83(±5)
k_{-1}[f]	22(±1)	110(±5)	35(±16)
$k_{-0}K_{p3}$[f]	52(±1)[c]	59(±2)	−130(±8)
k_{-0}	520 (est)[g]	104 (est)[h]	0 (est)[h]

[a] Rate constants at 25°C calculated from the activation parameters.

[b] Determined by fitting the data to eq. (4).

[c] Units are M^{-1} s^{-1}.

[d] Activation parameters for $k_{SBD\text{-}H}$ determined assuming $k_{SBD\text{-}H} = K_1 k_{uc}$ and using data for k_{uc} given above and published values of K_1, $\Delta H°(K_1)$ and $\Delta S°(K_1)$ (ref. 13).

[e] Activation parameters for k_{SBD} determined assuming $k_{SBD} = k_c K_1 K_{a1}$ using data for k_c given above and published values of $K_1 K_{a1}$, $\Delta H°(K_1 K_{a1})$ and $\Delta S°(K_1 K_{a1})$ (ref. 13).

[f] Data from ref. 1.

[g] Estimated from $k_{-0}K_{p3}$ assuming $K_{p3} \simeq 0.1$ M^{-1}.

[h] Activation parameters for k_{-0} estimated from parameters for $k_{-0}K_{p3}$ and assuming $\Delta H°$ $(K_{p3}) \simeq -45$ kJ mol^{-1} and $\Delta S°$ $(K_{p3}) = -130$ JK^{-1} mol^{-1}.

age of SBD-H ($k_{SBD\text{-}H}$) and SBD (k_{SBD}). The actual bridge-cleavage reactions are proposed to be acid independent and the acid dependence of k_{obs} attributed to equilibration between DBD and SBD forms. This is much faster than cleavage of SBD forms and involves a protonation equilibrium for SBD-H, which accounts for the acid dependence. Existing data on the cleavage of DBD into SBD suggests that this is not unreasonable (Table 2). In this case, acid-catalysed cleavage becomes apparent at the highest $[H^+]$,[1,9] but the rate for this pathway ($k_{-0}K_{p3}$) in 1 M H^+ at 25°C is only twice as fast as the corresponding uncatalysed process (k_{-1}). The value of K_{p3} has been estimated[3] as < 0.1 M^{-1}. Protonation of the bridging OH^- in SBD is expected to be more difficult than for DBD because of the higher overall charge while for SBD-H protonation is more likely at the terminal OH^-, giving SBD (at 298.15 K, pKa_1(SBD) determined from equilibrium studies[13] and kinetic measurements[1] were 0.74 and 1.00, respectively). It is important to note that decreases in protonation constants of 100 fold (or even higher) per unit charge increase are not uncommon for terminal OH^- groups coordinated to Cr^{3+} or chromium(III) oligomers.[10] Assuming similar variations in the case of bridging OH^- groups the protonation constant for the bridging OH^- group in SBD is likely to be $\ll 0.001$ M^{-1}. Thus, under the conditions of the current study ($[H^+] \sim 0.02$–1 M) acid-catalysed bridge cleavage of SBD forms would become apparent if the rate of cleavage of the protonated form, i.e. Cr—OH_2—Cr, is faster than the uncatalysed pathway by at least 1000 fold. To the author's knowledge there are no examples of singly-bridged binuclear complexes of chromium(III) for which such accelerations in bridge cleavage rate are found (see ref. 3 for a recent review). In the case of rhodium(III), however, acid-catalysed cleavage processes are not uncommon for both singly- and doubly-bridged complexes.[3] An excellent example highlighting this behaviour is the Δ,Λ-$[(en)_2 Rh(OH)_2 Rh(en)_2]^{4+}$ complex.[16]

Holwerda and co-workers[17] claim to have isolated an oxo-bridged aquo dimer $(H_2O)_5CrO Cr(OH_2)_5^{4+}$, as a product of the oxidation of Cr^{2+} with 1,4-benzoquinone. This species cannot be obtained by deprotonation of SBD because this occurs at the more acidic terminal H_2O groups. Indeed the kinetics of conversion of SBD into DBD have been followed over several deprotonations of SBD but no evidence for bridge deprotonation was

obtained.[1] This would be apparent in the UV-vis spectrum where the appearance of intense absorptions characteristic of oxo-bridges would occur, as is the case for $(NH_3)_5CrOHCr(NH_3)_5^{5+}$.[3,18] Furthermore, deprotonation of DBD results in the formation of the "active" dimer hydroxide $Cr_2(\mu\text{-}OH)_2(OH)_4(OH_2)_4 \cdot 2H_2O$ and not an oxo-bridged binuclear species. Cleavage of Holwerda's oxo dimer[17b] in acidic solution (1 M $HClO_4$) is much faster than cleavage of SBD forms, found in this study (difference in rate *ca* 1300 fold) and previously by Thompson.[9] This is a surprising observation given that the oxo-bridged dimer would be expected to be protonated in acidic solution [note that pKa for $(NH_3)_5CrOHCr(NH_3)_5^{5+}$ is 7.6][19] and there are no obvious steric factors which would hinder this protonation process. Thus, it would be expected that an oxo-bridged hydrolytic dimer of this type would be protonated in acidic solution and its cleavage behaviour should parallel that observed for SBD forms.

The rate of bridge cleavage in acidic solution is generally faster for DBD than for SBD forms (Table 2), i.e. k_{-1} and k_0 are larger than $k_{SBD\text{-}H}$ and k_{SBD}. This cannot be attributed to a change in nucleophile because an important feature of these bridge-cleavage reactions is that they involve attack by a common nucleophile, H_2O from the solvent. Note that this is not the case for bridge-formation reactions where coordinated OH^-, H_2O and O^{2-} (in some cases) can all act as nucleophiles. Although the commonality of nucleophiles reduces the complexity of bridge-cleavage processes, cf. bridge formation, there are nevertheless several other factors that could influence the rate of these processes. These include: (i) electrostatic attraction between the differently charged dimer forms and the incoming nucleophile; (ii) the relative lability of the chromium(III) coordination spheres which is known to be influenced by the degree of deprotonation on each chromium(III) centre;[1,11] (iii) geometrical differences between dimer forms which may influence the ease of nuclephilic attack; (iv) hydrogen-bond stabilization of deprotonated forms.[3] In the case of SBD-H, intramolecular hydrogen-bond stabilization is believed to be important[1,3,13] and is likely to influence the rate of both bridge formation and cleavage reactions. This means that $k_{SBD\text{-}H}$ is probably not a true measure of the rate of cleavage of SBD-H and furthermore, the form undergoing bridge cleavage is uncertain. From the well-established accelerations in substitution rates with degree of deprotonation of reactants[11,20] it would seem that cleavage of SBD-H should be faster than cleavage of SBD, but the opposite is true in practice (Table 2). The most likely explanation is that the hydrogen-bonded form does not participate in bridge cleavage and retards the process. Alternatively, the higher charge on SBD (5+), cf. SBD-H (4+), suggests a greater attraction of SBD for H_2O and this might be responsible for the observed faster rate of cleavage of SBD. However, previous work on the rate of H_2O exchange on Cr^{3+} and $CrOH^{2+}$ [20] and intramolecular ring closure within SBD forms[1] has shown that labilization of the coordination sphere of chromium(III), induced by deprotonation, has a much greater effect on reactivity than these electrostatic effects.

The faster rate of bridge cleavage for DBD ($k_{-1} = 2.7 \times 10^{-5}$ s^{-1}) when compared with SBD ($k_{SBD} = 2 \times 10^{-6}$ s^{-1}) is probably reflecting a higher lability of DBD (OH/Cr = 1.0) which overall has a higher degree of deprotonation than SBD (OH/Cr = 0.5). In addition, the double-bridging moiety in DBD (bridging O—Cr—O angle of 78°) introduces constraints which effectively enlarge some adjacent angles in the chromium(III) sphere and expand some of the faces of the chromium octahedron. For an associative substitution this might facilitate nucleophilic attack. The actual rate of bridge cleavage within protonated DBD, $Cr(\mu\text{—}OH)(\mu\text{—}OH_2)Cr^{5+}$ (Scheme I) has been estimated as 5×10^{-4} s^{-1} (assuming $K_{p3} = 0.1$ M^{-1}). A somewhat faster rate of cleavage of protonated DBD, cf. DBD and SBD, would not be unexpected since bridging H_2O would be held less tightly than bridging OH^-, but this difference may not be that large.

The activation enthalpies for bridge cleavage are concentrated in the range 98–112 kJ mol^{-1} while the activation entropies cover a wider range, 0–80 JK^{-1} mol^{-1} (Table 2). In the case of SBD-H, hydrogen-bond stabilization would affect ΔH^* and furthermore, it is not known whether the form undergoing cleavage is the hydrogen-bonded form or not. Apart from this, the remarkably constant values of ΔH^* for dimer bridge cleavage correspond closely with those determined for $(NH_3)_5Cr(OH)Cr(NH_3)_5^{5+}$ and *cis*- and *trans*-$[(NH_3)_5Cr(OH)Cr(NH_3)_4(OH_2)]^{5+}$ which range between 105–113 kJ mol^{-1} [13,21] and more importantly with ΔH^* for H_2O exchange on Cr^{3+} and $CrOH^{2+}$ (respectively, 109 and 111 kJ mol^{-1}).[20] On the basis of these comparisons it could be argued that these reactions all involve a similar mechanism (possibly I_a) and that there are no dramatic differences in the lability of the chromium(III) coordination sphere for each form of the hydrolytic dimer. However, the data for H_2O exchange on Cr^{3+} and $CrOH^{2+}$ has firmly established that changes in mechanism, from I_a to I_d, and lability derived solely from ΔS^* are possible.[20] Indeed, sub-

stantial variations in ΔS^* are found for the bridge-cleavage reactions but their interpretation is not straightforward.

The results of this study together with measurements of the SBD–DBD equilibrium[13] and of the equilibrium distribution of polynuclear species in partially neutralized solutions of Cr^{3+} [12] allow prediction of dimerization rates for mononuclear chromium(III) species. For example, from the reaction sequence for the formation of DBD from Cr^{3+} (Scheme I) it can be shown that k_{11}, the rate of dimerization of $CrOH^{2+}$, is given by eq. (6)

$$k_{11} = \beta_{22}k_{-1}k_{SBD\text{-}H}/k_1K_a^2 = \beta_{22}k_{uc}/K_a^2; \quad (6)$$

where β_{22} is the stability constant for the dimer [$5.6(\pm0.5)\times10^{-6}$ M^{-1} at 25°C],[12] K_a is the first acid dissociation constant of Cr^{3+} [$5.13(\pm0.4)\times10^{-5}$ M at 25°C],[10] $K_1 = (k_1/k_{-1})$ is the equilibrium constant for interconversion between SBD-H and DBD, $k_{SBD\text{-}H}$ is the rate of cleavage of SBD-H and k_{uc} is the overall rate for the uncatalysed cleavage of the dimer (Table 2). This calculation gave $k_{11} = 8(\pm2)\times10^{-5}$ M^{-1} s^{-1} which is in reasonable agreement with the directly determined value of $2.0(\pm0.4)\times10^{-4}$ M^{-1} s^{-1}.[11] Similarly for the reaction of Cr^{3+} with $CrOH^{2+}$, the rate of dimerization k_{10} is given by eq. (7)

$$k_{10} = \beta_{22}k_{-1}k_{SBD}/k_1K_{a1}K_a = \beta_{22}k_c/K_a; \quad (7)$$

where K_{a1} is the first acid dissociation constant of SBD,[13] k_{SBD} is the rate of cleavage of SBD and k_c is the overall rate of acid-catalysed cleavage of dimer (Table 2). The value of k_{10} [$1.6(\pm0.3)\times10^{-7}$ M^{-1} s^{-1}] obtained in this way is much lower than that given previously in ref. 11 where a calculation error was made. The reaction of Cr^{3+} with $CrOH^{2+}$ is *ca* 1000 times slower than dimerization of $CrOH^{2+}$, further demonstrating the dramatic effect of deprotonation on reactivity. The predicted rate of the reaction between $CrOH^{2+}$ and Cr^{3+} is only slightly faster than the rate of H_2O substitution on Cr^{3+} (4.3×10^{-8} M^{-1} s^{-1} when corrected for $[H_2O]$). This indicates that the difference in nucleophilic character between coordinated OH^- and H_2O from the solvent is small, assuming of course, that the coordinated OH^- is the attacking nucleophile in the dimerization reaction. Indirect evidence exists suggesting that this is the case.[3,22]

The constant for the $2CrOH^{2+} \rightleftarrows$ SBD-H equilibrium is $K_{11} = k_{11}/k_{SBD\text{-}H} \simeq 500$ M^{-1} and is much greater than that for the $Cr^{3+} + CrOH^{2+} \rightleftarrows$ SBD equilibrium, where $K_{10} = k_{10}/k_{SBD} \simeq 0.6$ M^{-1}. This comparison suggests that SBD forms become strongly favoured over mononuclear chromium(III) species as the overall degree of deprotonation increases.

CONCLUSION

Bridge formation and cleavage processes play important roles in the formation, cleavage and interconversion reactions of hydrolytic oligomers but the information available on these processes is limited. The current and previous[1,9–13] kinetic investigations of the hydrolytic dimer of chromium(III) have focussed attention on the factors that determine the rate of these substitution processes. The important factors, some of which also determine the behaviour of $A_4M(\mu\text{-}OH)_2MA_4^{4+}$ systems[3] include the degree of deprotonation, lability and overall charge on the dimer species undergoing reaction, the nature of the attacking nucleophile,[3] the mechanism of substitution and in the case of SBD-H, intramolecular hydrogen-bond stabilization.[3] However, it has been difficult to disentangle the relative importance of each of these factors.

In comparing the information for the hydrolytic dimer with the numerous studies on related systems of the type $A_4M(\mu\text{-}OH)_2MA_4^{4+}$, it is found that the behaviour of the hydrolytic dimer parallels closely that of these tetraammine systems at low pH ($\leqslant 2$).[1,3,9] This is true of both bridge-cleavage and formation processes. At higher pH values, such as those found in natural systems, the behaviour of the hydrolytic dimer becomes vastly different from that of the tetraammines.[1,3] In the case of the hydrolytic dimer, many coordinated H_2O ligands are present which when deprotonated allow bridge formation processes, in particular, to occur at greatly enhanced rates. For example, double deprotonation of SBD ($pK_{a2} = 4.30$)[1] has a much greater effect on the rate of ring closure than monodeprotonation ($pK_{a1} = 1.00$).[1] In addition, the dimerization of DBD to give the tetramer occurs at measurable rates at pH > 3 [pK_{a1}(DBD) = 3.68] and is followed by further polymerization.[23] This is in complete contrast to the tetraammine complexes, where once diol formation (DBD forms) is complete further reaction (except for bridge deprotonation) is prevented by the presence of four nitrogen-donor ligands.[3]

(*Received* 17 *February* 1991; *accepted* 4 *June* 1991)

Abstract—The phosphine complexes, $(\eta^5\text{-}C_5Me_5)Re(CO)_2PR_2R'$ [R = R′ = Ph (**1**); R = Me, R′ = Ph (**2**)] and the phosphite complexes, $(\eta^5\text{-}C_5Me_5)Re(CO)_2[P(OR)_3]$ [R = Et (**3**); R = Ph (**4**)] have been prepared in 38–70% yield by reaction of the THF complex $(\eta^5\text{-}C_5Me_5)Re(CO)_2(THF)$ with the corresponding phosphine or by direct irradiation of $(\eta^5\text{-}C_5Me_5)Re(CO)_3$ in the presence of the phosphite ligand. From the reaction of the neutral triphenylphosphite complex (**4**) with I_2 in hexane the cationic complex *cis*-$[(\eta^5\text{-}C_5Me_5)Re(CO)_2\{P(OPh)_3\}I]^+$ (**5**) could be isolated in almost quantitative yield. The *cis* orientation of the CO groups for the latter complex has been assigned on the basis of $^2J(CP)$ coupling constants and by the intensity ratio of the symmetric and antisymmetric stretching frequencies of the CO ligands.

Traditionally, cyclopentadienyl complexes of the type $CpM(CO)_2L$, Cp = $\eta^5\text{-}C_5H_5$, with M = Mn or Re and L = neutral two electron donor ligand, have been produced by photosubstitution of a CO ligand from the corresponding tricarbonyl complex.[1] Two experimental procedures have been used to incorporate the ligand L to a metal center. These are direct irradiation of $CpM(CO)_3$, dissolved in a non-coordinating solvent, in the presence of the entering ligand[2] or photochemical generation of an intermediate, usually with a solvent molecule as ligand, followed by thermal reaction in the presence of L. The latter method is currently the most widely used for the preparation of the $CpM(CO)_2L$ complexes. In rhenium complexes, for example, Nesmeyanov *et al.* have used the THF derivatives $CpRe(CO)_2(THF)$ for the preparation of a series of compounds with phosphorus containing ligands $CpRe(CO)_2(PR_3)$ (R = Ph, OEt and OPh).[3] It is worth noting that thermal CO substitution by PMe_3, generating the $CpRe(CO)_2(PMe_3)$ complex, has also been reported.[4] To our knowledge, of analogous pentamethylcyclopentadienyl complexes with phosphorus ligands only the PMe_3 complex, $Cp^*Re(CO)_2(PMe_3)$ ($Cp^* = \eta^5\text{-}C_5Me_5$), is known. This complex has been synthesized in a straightforward photosubstitution reaction involving $Cp^*Re(CO)_3$ and PMe_3,[5] and via the THF complex, $Cp^*Re(CO)_2(THF)$, followed by the addition of PMe_3.[6] The triphenylphosphine analog $Cp^*Re(CO)_2(PPh_3)$ was briefly mentioned with no details of either its synthesis or characterization.[7]

In the present work, we wish to report the synthesis and spectroscopic characterization of a series of pentamethylcyclopentadienylrhenium complexes containing phosphine, namely $Cp^*Re(CO)_2(PR_2R')$ [R = R′ = Ph (**1**); R = Me, R′ = Ph (**2**)], or phosphite ligands, $Cp^*Re(CO)_2[P(OR)_3]$ [R = Et (**3**); R = Ph (**4**)]. In addition, this paper also describes the reaction of the neutral triphenylphosphite complex (**4**) with I_2 leading to the first example of a cationic phosphite complex possessing a four-legged piano stool type of structure *cis*-$[Cp^*Re(CO)_2\{P(OPh)_3\}I]^+$ (**5**).

EXPERIMENTAL

All reactions were carried out under nitrogen using Schlenk apparatus connected to a double manifold providing a low vacuum or nitrogen atmosphere. Photochemical reactions were conducted in quartz tubes irradiated with a Hanovia Model 679 A36, 450 W high-pressure mercury vapor lamp. Solvents were dried by conventional methods, distilled under N_2 and used immediately. IR spectra were measured with a Bomen MB-120 FTIR. ^1H and ^{13}C NMR spectra were measured at 400 and 100 MHz respectively, on a Bruker WM-400 instrument. Coupling constants are reported in Hertz. Mass spectra were obtained on a Hewlett-Packard 5985 mass spectrometer with electron impact source. Reported masses are based on ^{187}Re. Microanalyses were performed by M. K. Yang of the SFU Microanalytical Laboratory. Rhenium was purchased as $Re_2(CO)_{10}$ (Strem Chemical Co.) and converted to $Cp^*Re(CO)_3$ according to the literature procedure.[8] The ligands, PPh_3, PMe_2Ph, $P(OEt)_3$ and $P(OPh)_3$ (Strem) were used as received.

Preparation of $Cp^*Re(CO)_2(PPh_3)$ (**1**)

This complex was prepared using a method similar to that reported[6] for $Cp^*Re(CO)_2(PMe_3)$: a solution of $Cp^*Re(CO)_3$ (200 mg, 0.49 mmol) in THF (50 cm_3) was irradiated at 20°C for 40 min. It gradually turned yellow and the IR spectrum indicated a ratio $Cp^*Re(CO)_3$: $Cp^*Re(CO)_2(THF)$ of approximately 1 : 1.5. Upon reduction of the volume of solvent under vacuum to about 10 cm^3, an excess (300 mg, 1.14 mmol) of solid PPh_3 was added. The mixture was heated for 1 h at 50°C. After cooling the IR showed the complete conversion of $Cp^*Re(CO)_2(THF)$ into (**1**), some unreacted $Cp^*Re(CO)_3$ was also present. The solvent was removed under vacuum and the brown oily solid remaining was dissolved in CH_2Cl_2 and chromatographed on a neutral alumina column. Hexane moved first the $Cp^*Re(CO)_3$ and then the product was eluted with a mixture of hexane–diethylether 1 : 1. Removal of the solvents, under vacuum, resulted in a pale yellow solid. Recrystallization from hexane at −10°C gave complex (**1**) (125 mg) as pale yellow crystals in 38% yield [based on $Cp^*Re(CO)_3$]. M.p.: 205–207°C. Elemental analysis for $C_{30}H_{30}O_2PRe$: Found: C, 56.4; H, 4.7. Calc.: C, 56.2; H, 4.7%. IR (CH_2Cl_2, cm^{-1}): ν(CO) 1912 (vs), 1842 (vs). ^1H NMR ($CDCl_3$): δ 1.80 (s, 15H, Cp*), 7.46 (m, 15H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 10.36 (s, $C_5\mathit{Me}_5$), 96.90 (s, C_5Me_5), 127.85 (d, $J = 9.9$), 129.30 (s), 133.35 (d, $J = 11.5$) and 137.80 (d, $J = 49.5$, Ph), 206.50 (d, $J = 7.8$, CO). MS: m/z 640 (M^+), 612 ($M^+ - CO$), 584 ($M^+ - 2CO$), 563 ($M^+ - Ph$).

Preparation of $Cp^*Re(CO)_2(PMe_2Ph)$ (**2**)

A procedure similar to that used in the synthesis of (**1**) gave the product in 45% yield as pale yellow crystals. M.p. 106–108°C. Elemental analysis for $C_{20}H_{26}PO_2Re$: Found: C, 46.2; H, 4.9. Calc.: C, 46.5; H, 5.0%. IR (CH_2Cl_2, cm^{-1}): ν(CO) 1906 (vs), 1833 (vs). ^1H NMR ($CDCl_3$): δ 1.87 (s, 15H, Cp*), 1.88 (d, $J = 8.8$, 6H, Me), 7.52 (m, 5H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 10.59 (s, $C_5\mathit{Me}_5$), 22.48 (d, $J = 37.2$, $P\mathit{Me}_2Ph$), 95.82 (s, C_5Me_5), 128.11 (d, $J = 9.1$), 129.18 (s), 130.12 (d, $J = 11.1$) and 139.50 (d, $J = 48.5$, PMe_2Ph), 206.63 (d, $J = 7.0$, CO). MS: m/z 516 (M^+), 501 ($M^+ - Me$), 488 ($M^+ - CO$), 460 ($M^+ - 2CO$), 445 ($M^+ - 2CO - Me$).

Preparation of $Cp^*Re(CO)_2[P(OEt)_3]$ (**3**)

This complex was prepared by following the same procedure used to prepare complex (**4**) (see below) but the photolysis was carried out in THF. It was obtained in 70% yield as slightly yellow crystals. M.p. 50–52°C. Elemental analysis for $C_{18}H_{30}PO_5Re$: Found: C, 40.0; H, 5.8. Calc.: C, 39.8; H, 5.5%. IR (CH_2Cl_2, cm^{-1}): ν(CO) 1923 (vs), 1852 (vs). ^1H NMR ($CDCl_3$): δ 1.28 (t, $J = 7.1$, 9H, $P(OCH_2CH_3)_3$) 2.07 (s, 15H, Cp*), 3.86 (q, $J = 7.1$, 6H, $P(OCH_2CH_3)_3$): $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 10.61 (s, $C_5\mathit{Me}_5$), 16.03 (s, $P(OCH_2\mathit{CH}_3)$, 60.04 (d, $J = 2.0$, $P(OCH_2Me)_3$), 96.36 (s, C_5Me_5), 204.42 (d, $J = 12.07$, CO). MS: m/z 544 (M^+), 516 ($M^+ - CO$), ($M^+ - OEt$), 471 ($M^+ - CO - OEt$).

Preparation of $Cp^*Re(CO)_2[P(OPh)_3]$ (**4**)

$Cp^*Re(CO)_3$ (300 mg, 0.74 mmol) was dissolved in 100 cm^3 of toluene. To this solution 0.5 cm^3 (1.9 mmol) of $P(OPh)_3$ was added, under stirring, and the mixture was irradiated for 45 min. Evaporation of toluene under vacuum yielded a brown oil which was dissolved in CH_2Cl_2 and chromatographed on a silica gel column. The unreacted $Cp^*Re(CO)_3$ and excess of $P(OPh)_3$ was washed from the column using hexane and compound (**4**) was eluted with diethylether. The solvent was removed with a rotary evaporator yielding a slightly yellow solid. This was crystallized from hexane to give pale yellow crystals. Yield 305 mg (60% based on starting *tricarbonyl* complex). M.p. 130–132°C. Elemental analysis for $C_{30}H_{30}O_5PRe$: Found: C, 52.5; H, 4.3. Calc.: C, 52.4; H, 4.4%. IR (CH_2Cl_2, cm^{-1}): ν(CO) 1944 (vs), 1873 (vs). ^1H NMR ($CDCl_3$): δ 1.87 (s, 15H,

Cp*), 7.35 (m, 15H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 10.34 (s, C_5Me_5), 96.90 (s, C_5Me_5), 121.46 (d, $J = 4.5$), 124.07 (s), 129.47(s), 153.00 (broad singlet, J not resolved, Ph), 202.55 (d, $J = 11.4$, CO). MS: m/z 688 (M^+), 660 ($M^+ - CO$), 595 ($M^+ - OPh$).

Preparation of cis-$[Cp^*Re(CO)_2[P(OPh)_3]I][I_3]$ (5-(I_3))

This complex was prepared using a method similar to that reported[6] for the PMe_3 analog, *cis*-$[Cp^*Re(CO)_2(PMe_3)I]^+$: a solution of complex (**4**) (100 mg, 0.14 mmol) in hexane (10 cm^3) was treated with a saturated solution of I_2 in hexane with stirring until all the rhenium complex had reacted (by IR). The dark red precipitate formed was separated, washed with diethyl ether, and dried *in vacuo*. Recrystallization from CH_2Cl_2–ether yielded 164 mg (95%) of dark red crystals. M.p. 79–81°C with decomposition. Elemental analysis for $C_{30}H_{30}O_5I_4PRe$: Found: C, 30.1; H, 2.5. Calc.: C, 30.2; H, 2.5%. IR (CH_2Cl_2, cm^{-1}): ν(CO) 2052 (vs), 2002 (s), (intensity ratio 1.3 : 1.0). ^1H NMR ($CDCl_3$): δ 2.52 (s, 15H, Cp*), 7.28 (m, 15H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 12.02 (s, C_5Me_5), 108.24 (s, C_5Me_5), 120.81 (d, $J = 4.0$), 126.76 (s), 130.31 (s), 151.27 (d, $J = 13.1$, Ph), 182.50 (d, $J = 18.3$, CO), 196.80 (d, $J = 32.0$, CO).

RESULTS AND DISCUSSION

(a) *Neutral phosphine and phosphite complexes*

The phosphine complexes $Cp^*Re(CO)_2(PR_2R')$, [R = R′ = Ph (**1**); R = Me, R′ = Ph (**2**)] were easily prepared following the method described for the synthesis of $Cp^*Re(CO)_2(PMe_3)$,[6] that is a thermal reaction of the THF complex $Cp^*Re(CO)_2(THF)$ [prepared *in situ* by irradiation of $Cp^*Re(CO)_3$ in THF] with the corresponding phosphine. A different method was used to prepare the phosphite derivatives $Cp^*Re(CO)_2[P(OR)_3]$ [R = Et (**3**); R = Ph (**4**)], which involved direct photochemical reaction of the tricarbonyl complex, dissolved in THF (**3**) or toluene (**4**), with the phosphite ligand. A possible disubstituted product $Cp^*Re(CO)[P(OR)_3]_2$ was not observed in the latter reaction even though the bisphosphine complex $Cp^*Re(CO)(PMe_3)_2$ was produced by photolysis of $Cp^*Re(CO)_3$ in the presence of PMe_3 using a 100 W medium-pressure mercury lamp and much prolonged irradiation times.[5]

Since better yields were obtained in the preparation of the phosphite compounds, the same method was also attempted to produce complexes (**1**) and (**2**). However, irradiation of $Cp^*Re(CO)_3$ in THF or toluene with an excess of phosphine produced dark yellow solutions plus some unidentified solid, which showed no ν(CO) absorptions in the IR spectra. From the solutions, only small amount of products could be isolated (10% yield).

Phosphine and phosphite complexes (**1–4**) were isolated as pale or slightly yellow crystals analytically and spectroscopically pure. They are indefinitely stable under N_2 and appear not to deteriorate when exposed to air and light over a period of days. They are soluble in most common organic solvents.

The carbonyl stretching region of the IR spectra of compounds **1–4** consists of two very strong absorption bands near 1930 and 1850 cm^{-1}. As expected these bands are shifted by about 20 cm^{-1} to lower frequencies than those reported for the corresponding Cp analogs.[3] Frequencies decrease in the order $P(OPh)_3 > P(OEt)_3 > PPh_3 > PMe_3Ph$. This is the same order found in the compounds $CpMn(CO)_2(PR_3)$[9,10] and indicates an increase of electron density on the metal as a result of the phosphorus ligands. The observed trend is consistent with that expected from relative basicity and acceptor ability of phosphorus ligands.[11,12]

The electron impact mass spectra of **1–4** clearly established the molecular ion and showed fragments corresponding to loss of CO. In none of the cases is the loss of the intact phosphorus ligand observed.

The ^1H NMR spectra of these complexes showed no unusual features, a singlet for Cp* (between δ 1.80–2.07) and the resonances attributed to the phosphorus ligand. The $^{13}C\{^1H\}$ NMR spectra, in addition to the single resonances for the Cp* and the corresponding carbons of PR_3, showed a doublet in the low field region (δ 204) for the carbonyl carbon resonance. The resonances for the phosphite complexes (**3**) and (**4**) are more shielded and have the greater $^2J_{CP}$, in agreement with the well-established better π-acceptor properties of these ligands compared with the phosphines.[11–14]

(b) *The cationic phosphite complex*, cis-$[Cp^*Re(CO)_2\{P(OPh)_3\}I]^+$ (**5**)

The reaction of the dicarbonyltriphenylphosphite complex (**4**) with I_2 in hexane resulted in an oxidative addition of the iodo ligand with almost quantitative formation of cationic complex **5**. Similar reactions have been observed for $Cp^*Re(CO)_3$[14] and $Cp^*Re(CO)_2(PMe_3)$[6] with I_2. In the IR spectrum of this dark-red, air stable crystalline compound, two ν(CO) absorptions are observed. As expected, they are shifted by more than 100 cm^{-1} to higher frequencies when compared with **4**. The

higher wavenumber band, ν_s(CO) is stronger than ν_{as}(CO), which we interpret to indicate a *cis* orientation of the CO groups by comparison with other dicarbonyl complexes possessing a four-legged piano stool type of structure.[6,14] The *cis* stereochemistry was also confirmed by ^{13}C NMR. In fact, the ^{13}C NMR spectrum of **5** in the CO region showed two doublets at δ 182.50, $J = 18.3$ and 196.80, $J = 32.0$ indicating the non-equivalence of the COs as expected for a *cis* configuration of these groups. We tentatively assign the resonance at higher δ value having the greater ^2J(CP) value to the CO group *cis* to the $P(OPh)_3$ ligand, in an analogous manner to the assignment made in the *cis*-$[Cp^*Re(CO)_2(PMe_3)I]^+$ complex.[6]

Attempts to isomerize **5** to the less hindered *trans* isomer were unsuccessful. The complex was recovered unchanged when boiled in THF for 6 h. After 2 h in refluxing toluene total decomposition was observed.

The formation of only one isomer for this iodo complex is not surprising since it has been tentatively established that the *cis* configuration is preferred to *trans* for the complexes $[Cp^*Re(CO)_2(PMe_3)X]^+$ when the halogen is changed from Cl through Br to I.[6] However, it is important to mention at this point that only the *trans* configuration has been found in the manganese cationic complexes resulting from the reaction of $(C_5H_4Me)Mn(CO)_2L$ ($L = PEt_3$, PPh_3, PMe_2Ph and $P(OPh)_3$) or $Cp^*Mn(CO)_2(PPh_3)$ with I_2.[15] Accordingly, more work has to be done to establish the factors influencing the stereochemistry in these types of complexes.

THE EFFECT OF SODIUM CATIONS ON THE MOLECULAR DYNAMICS OF N-ACETYLAZA-15-CROWN-5†

GRAHAM C. SAUNDERS

Inorganic Chemistry Laboratory, South Parks Road, Oxford OX1 3QR, U.K.

(*Received* 19 *April* 1991; *accepted* 20 *May* 1991)

Abstract—N-acetylaza-15-crown-5 exhibits restricted rotation about the amide N—C bond, with a value of the free energy of activation, ΔG^*, of 73 ± 1 kJ mol^{-1}, as determined by dynamic ^{13}C-{^1H} NMR spectroscopy. Addition of sodium cations leads to a reduction in ΔG^* which is dependent upon the amount of sodium cations added. ΔG^* falls to 54 ± 1 kJ mol^{-1} with three equivalents of Na^+. A simple mathematical model is used to explain the variation of ΔG^* with sodium cations.

Alkali metal cation binding by non-cyclic and cyclic polyethers has been investigated by a number of NMR spectroscopic techniques. Most studies have concentrated on shifts of δ in the ^{13}C and ^1H NMR spectra,[1,2] changes in the value of the spin-lattice relaxation time, T_1,[1,3] and alkali metal NMR spectroscopy.[4] Conformational changes of complexed and uncomplexed crown ethers upon cooling have also been investigated by variable temperature ^{13}C and ^1H NMR spectroscopy.[5] The study of restricted rotation about amide N—C bonds by variable temperature ^{13}C and ^1H NMR spectroscopy in some ferrocene derivatives containing crown ether groups has been reported,[6] but the effect of adding alkali metal cations on the dynamic NMR of these compounds has not. Prior to our study of the effects of alkali metal cations upon the molecular dynamics of bis(aza-15-crown-5)thiuram disulphide‡ (**1**),[7] the only reported investigation into the effects of alkali metal cations upon restricted rotation was that into the molecular dynamics of non-cyclic amides by Jagur-Grodzinski and co-workers.[8] They report an increase in the activation energy for rotation about the amide N—C bond, E_A, of 16 ± 5 kJ mol^{-1} for amide **2** upon the addition of two equivalents of lithium perchlorate in [^2H]$_3$-nitromethane. This can be attributed to an interaction between the lithium cation and the amide oxygen atoms, which through inductive and resonance effects increases the π-electron donation into the N—C bonds from the nitrogen atoms.

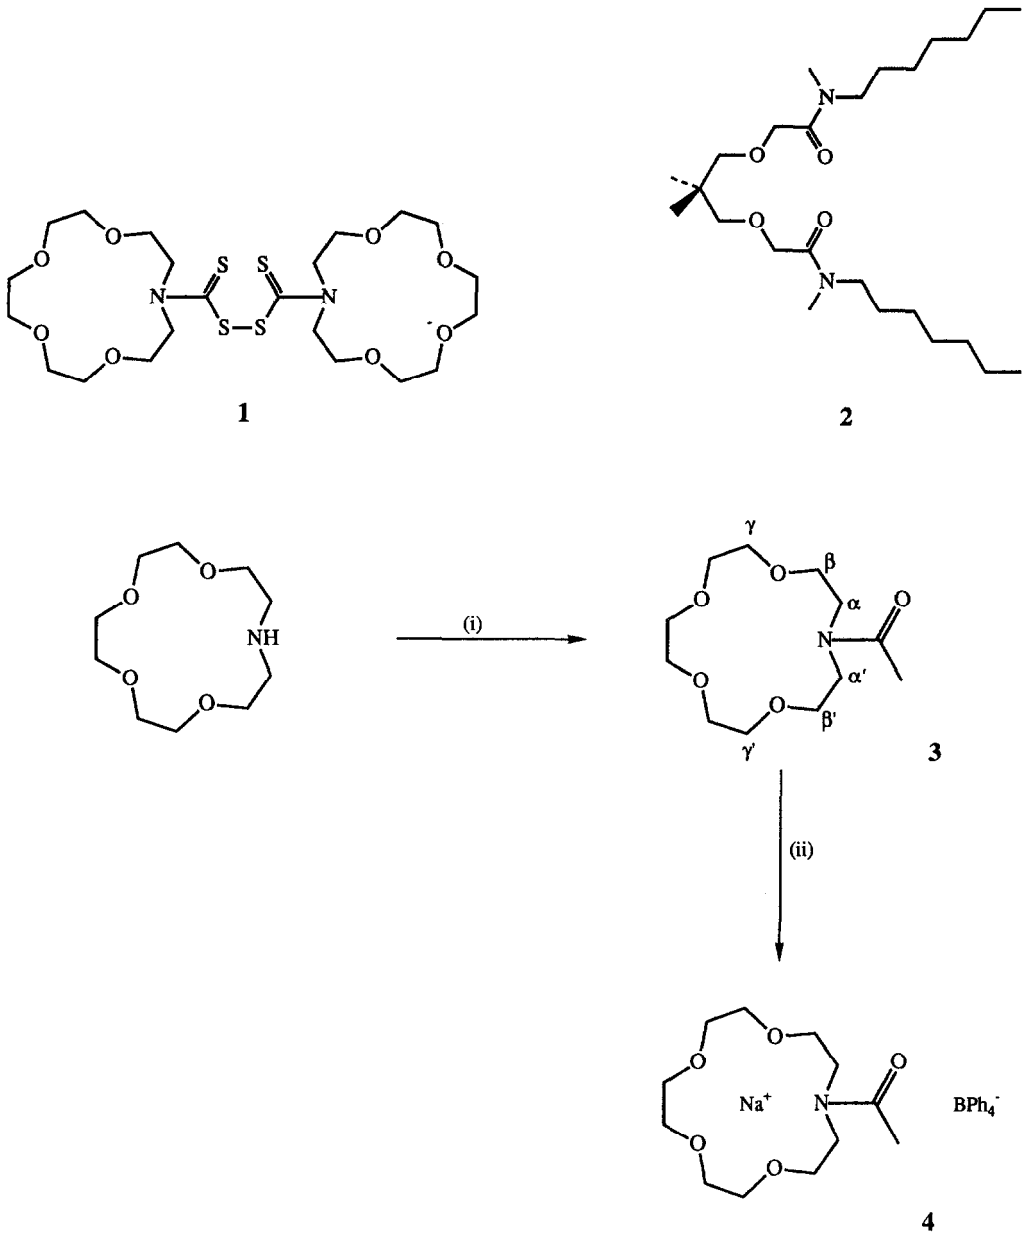
Herein is reported the effect of sodium cations upon the molecular dynamics of N-acetylaza-15-crown-5 (**3**) and a mathematical model to explain the effects of cations on the molecular dynamics of compounds **1** and **3**.

RESULTS AND DISCUSSION

Reaction of aza-15-crown-5 with excess acetyl chloride gave N-acetylaza-15-crown-5 (**3**) in *ca* 35% yield as a pale brown oil (Scheme 1), which was characterized by IR, ^1H and ^{13}C NMR spectroscopy and mass spectrometry. The 1 : 1 $NaBPh_4$ complex of **3** and **4**, was prepared by slow evaporation of a dichloromethane solution of a mixture of **3** and $NaBPh_4$. Complex **4** was obtained as a cream-coloured microcrystalline solid, which was characterized by elemental analysis, and IR and ^1H NMR spectroscopy. Both **3** and **4** showed strong bands in their IR spectra at *ca* 1630 cm^{-1}, assigned to the amide C=O stretch. The ^1H NMR spectrum of **3** recorded in [^2H]$_3$-acetonitrile showed a triplet, two multiplets and a singlet, with relative intensities 2 : 14 : 4 : 3. The first three sets of resonances are assigned to the crown-ether ring hydrogen atoms and the singlet to the methyl hydrogen atoms. The ^{13}C-{^1H} NMR spectrum recorded in [^2H]$_3$-acetonitrile at 300 K includes two singlets at 51.8 and 49.3 ppm, assigned to the α-carbon atoms, and six peaks between 69 and 72 ppm, assigned to the other crown-ether ring carbon atoms. These data indicate that, as expected, there is restricted rotation about

† 13-acetyl-1,4,7,10-tetraoxo-13-azacyclopentadecane.

‡ 13,13′ - (1,4 - dithioxo - 2,3 - dithiabutane - 1,4 - diyl) di(1,4,7,10-tetraoxo-13-azacyclopentadecane).



Scheme 1. (i) CH_3COCl, 34%; (ii) $NaBPh_4$, CH_2Cl_2.

the amide N—C bond, which at 300 K causes the inequivalence of the α, β and γ pairs of carbon atoms. At 342 K no coalescence of any of the pairs of peaks was observed.

From eq. (1)[9] the rate constant may be obtained, then from the Eyring equation [eq. (2)],[10] a value for the free energy of activation, ΔG^*, may be calculated. (Contrary to the results reported in the original Holm-Gutowsky papers the overall rate constant is twice the observed rate constant, i.e. $k = 2k_c'$.[11]) The lack of any coalescence at 342 K indicates that ΔG^* is greater than 72.5 kJ mol^{-1}.

$$k_c' = \pi \cdot \delta\nu/(2)^{1/2} \quad (1)$$

$$k = (\kappa k_B T/h)e^{-(\Delta G^*/RT)} \quad (2)$$

Variable temperature ^{13}C-{^1H} NMR spectra of (3) in $[^2H]_8$-toluene gave a value of ΔG^* of 73 ± 1 kJ mol^{-1}.

The ^1H NMR spectrum of **4** in $[^2H]_3$-acetonitrile includes a multiplet, a triplet and a singlet with relative intensities 16:4:3, which are assigned to the 16 OCH_2 crown-ether hydrogen atoms, the four NCH_2 hydrogen atoms and the methyl hydrogen atoms, respectively. Thus, the complexation of a sodium cation by **3** has a significant effect upon the ^1H NMR spectrum. In particular, the NCH_2 hydrogen atoms which are inequivalent in **3** are

equivalent in **4**, suggesting that complexation of a sodium cation has a dramatic effect upon the rotation about the N—CO bond. The IR spectra and the lack of any significant shift of δ for the methyl hydrogen resonance shows that the sodium cation has little effect upon the C=O bond.

The effect of sodium cations upon the value of ΔG^* for **3** at a concentration of 0.1 M in $[^2H]_3$-acetonitrile was investigated by variable temperature $^{13}C-\{^1H\}$ NMR spectroscopy. The spectra indicated that, as expected, intermolecular exchange of the sodium cations is fast on the NMR timescale, and thus the methylene carbon atoms of uncomplexed and complexed **3** gave rise to averaged signals. The results are shown in Fig. 1. Addition of *ca* 0.02 equivalents of $NaBPh_4$ caused a decrease in ΔG^* of *ca* 6 kJ mol^{-1}, and addition of 0.9 equivalents of $NaBPh_4$ led to a decrease in ΔG^* of *ca* 16 kJ mol^{-1}. This decrease in ΔG^* implies that sodium cations interact with the nitrogen atom so as to withdraw electron density available for π-bonding in the N—C bond, and not with the amide oxygen atom, which would have caused an increase in the value of ΔG^*, as observed for **2**. The interaction with the nitrogen atom is due to the preferential binding of the cation to the crown-ether heteroatoms over that to the amide oxygen atom. The ^{23}Na NMR spectrum of $NaBPh_4$ in the presence of excess **3** in $[^2H]_3$-acetonitrile gave a value of the width at half-height, $\Delta\nu(1/2)$, of the single peak observed of 130 Hz, compared to the value of 16 Hz for $NaBPh_4$ alone. Further, the $^{13}C-\{^1H\}$ NMR spectrum of **3** with $NaBPh_4$ added showed shifts of the resonances of the crown ether and amide NCO carbon atoms from those of **3** alone. These data together with the ^1H NMR and IR spectra of **4** confirm that the sodium cations are bound by the crown-ether rings.

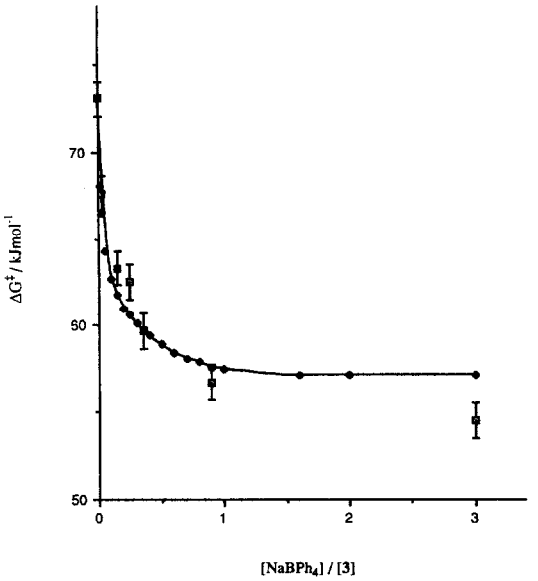


Fig. 1. Plot of ΔG^* for rotation about the amide N—C bond of **3** against equivalents of $NaBPh_4$ (experimental values are shown with error bars, the line represents the theoretical values derived from $K = 250$ mol^{-1} dm^3, $\Delta G^*_{uncomp} = 73$ kJ mol^{-1}, $\Delta G^*_{comp} = 57$ kJ mol^{-1}, at a concentration of **3** of 0.1 M).

Addition of excess $NaBPh_4$ to **3** might be expected to lead to an increase in ΔG^* from a minimum value due to the sodium cation–amide oxygen atom interaction becoming significant as the amount of uncomplexed cations available to interact with the amide oxygen atom increases. However the variable temperature $^{13}C-\{^1H\}$ NMR spectra of **3** with three equivalents of $NaBPh_4$ gave a value of ΔG^* of 54 ± 1 kJ mol^{-1}, which is significantly lower than with 0.9 equivalents of $NaBPh_4$. This indicates that the sodium cation–amide oxygen atom interaction is weak, especially in comparison to the lithium cation–amide oxygen atom interaction in amide **2**.

The shape of the plots of ΔG^* against equivalents of $NaBPh_4$ for thiuram disulphide **1** and amide **3** are similar, and a suitable model can be applied to provide an explanation. For a simple crown-ether amide such as **3**, where intermolecular cation exchange is fast on the NMR timescale, the rate constant for rotation about the amide N—C bond at temperature T, k_T, can be assumed to be the weighted average of the rate constants for the uncomplexed and complexed molecules, k_T^1 and k_T^2, respectively; given by eq. (3).

$$k_T = (1-X)k_T^1 + Xk_T^2; \quad (3)$$

where X is the proportion of complexed crown ether at any instant. An expression for X may be derived from eqs (4)–(6) [eq. (7)], which is similar to one quoted by Popov and co-workers.[12]

$$[M^+ \cdot C] = K_T[C][M^+] \quad (4)$$

$$[C]_0 = [C] + [M^+ \cdot C] \quad (5)$$

$$[M^+]_0 = [M^+] + [M^+ \cdot C]; \quad (6)$$

where $[C]_0$ and $[M^+]_0$ are the total concentrations of crown ether and cation, respectively; [C] and $[M^+]$ are the concentrations of uncomplexed crown ether and cation, respectively; and $[M^+ \cdot C]$ is the concentration of the complex.

$$X = (1/2K')\{(1 + K' + \varepsilon K') - [1 + 2K' + K'^2 + 2K'(1-K')\varepsilon + K'^2\varepsilon^2]^{1/2}\}; \quad (7)$$

where ε is the number of equivalents of cation per crown ether, $[M^+]_0/[C]_0$, and K' is related to the

binding constant of the crown ether at temperature T, K_T, by eq. (8).

$$K' = K_T[C]_0. \quad (8)$$

Thus, values of k and therefore ΔG^* may be calculated from the binding constant, K_T, the concentration of the crown ether, and the number of equivalents of $NaBPh_4$. A theoretical plot of ΔG^* against equivalents of sodium cations was calculated from eqs (2), (3), (7) and (8) using values of k^1_{293} of 0.625 s^{-1} (corresponding to a value of ΔG^* of 73 kJ mol^{-1}), k^2_{293} of 446.0 s^{-1} ($\Delta G^* = 57$ kJ mol^{-1}), and K_{293} of 250 mol^{-1} dm^3, which is a reasonable value to expect for a functionalized 15-crown-5[13] (Fig. 1). The similarity of the experimental and theoretical plots strongly suggests that the original assumption is appropriate for the system. The differences between the theoretical and experimental values of ΔG^* may be attributed to the temperature dependence of both the free energy of activation and the binding constant. The entropy for rotation about a bond is usually considered to be small, and thus the direct effect of temperature upon ΔG^* is also likely to be small. The effect upon K is likely to be large due to the large entropic change accompanying complexation by a crown ether. However, it is noted from eqs (2), (3), (7) and (8) that relatively large changes in the value of K have a small influence on ΔG^* at low equivalents ($< ca$ 0.8) of cation, and thus this technique could not be used for determining K.

This model can also be applied to explain the effects of adding sodium cations to thiuram disulphide **1**, the molecular dynamics of which has been reported previously,[7] but here the values of ΔG^* are corrected to account for the difference between the observed and overall rate constants. Making the assumption that binding of a cation by one of the crown-ether rings of **1** affects neither the binding ability nor the rotation about the N—CS_2 bond of the other crown ether ring of **1**, then eqs (4)–(7) are appropriate. K' must be multiplied by two to account for **1** possessing two crown-ether rings and ε is the number of equivalents per crown ether ring ($\varepsilon = [M^+]_0/2[\mathbf{1}]$). Values of ΔG^* calculated from eqs (2), (3), (7) and (8) for a concentration of **1** of 0.07 M (that used in the experimental study) and values of k^1_{293} of 30.9 s^{-1} ($\Delta G^* = 63.5$ kJ mol^{-1}), k^2_{293} of 320.2 s^{-1} ($\Delta G^* = 52.2$ kJ mol^{-1}), and K_{293} of 250 mol^{-1} dm^3 are shown in Fig. 2. Again the theoretical and experimental results are similar. The differences between the experimentally determined results and the theoretical values may be attributed to the temperature dependence of ΔG^* and K, and also that the assumption that binding of a cation by one crown-ether ring does not affect the other ring is not strictly true.

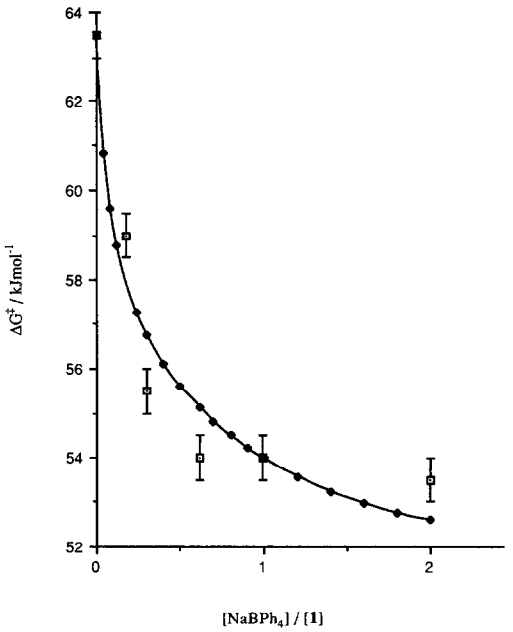

Fig. 2. Plot of ΔG^* for rotation about the N—CS_2 bonds of **1** against equivalents of $NaBPh_4$ (experimental values are shown with error bars, the line represents the theoretical values derived from $K = 250$ mol^{-1} dm^3, $\Delta G^*_{uncomp} = 63.5$ kJ mol^{-1}, $\Delta G^*_{comp} = 52.2$ kJ mol^{-1}, at a concentration of **1** of 0.07 M).

In conclusion, sodium cations cause a dramatic reduction in the free energy of activation for rotation about the amide N—C bond in N-acetyl-aza-15-crown-5, which is explained by the interaction between the cation and the nitrogen atom reducing the amount of π-electron density available for bonding in the N—C bond. A simple mathematical model relating the value of ΔG^* to the binding constant of the crown ether and the amount of cation added is shown to be applicable and theoretical values of ΔG^* for thiuram disulphide **1** and amide **3** agree well with those determined experimentally.

EXPERIMENTAL

^1H, ^{13}C and ^{23}Na NMR spectra were recorded on a Brüker AM300 spectrometer. ^1H NMR spectra were recorded at 300 MHz and referenced internally using the residual protio solvent resonance relative to tetramethylsilane ($\delta = 0$ ppm). ^{13}C NMR spectra were recorded at 75.47 MHz and referenced internally using the solvent resonance relative to tetramethysilane ($\delta = 0$ ppm). ^{23}Na NMR spectra were recorded at 79.35 MHz and

referenced externally to 3 M NaCl in $[^2H]_2$-water ($\delta = 0$ ppm). All chemical shifts are quoted in δ (ppm) and coupling constants in Hz. Abbreviations used in multiplicities are s = singlet, t = triplet and m = multiplet. The variable temperature unit of the NMR spectrometer was calibrated by use of a thermocouple immersed in toluene within an NMR tube. Temperatures were accurate to within ± 1 K.

IR spectra were recorded neat between CsI plates or as a CsI pellet on a Perkin–Elmer IR Fourier transform spectrometer. The mass spectrum was recorded on an AEI m.s. 902 mass spectrometer updated by a data handling system supplied by Mass Spectroscopy Services Ltd.

Where necessary solvents were dried over activated molecular sieves and distilled under nitrogen from over phosphorus pentoxide (dichloromethane). $[^2H]_3$-acetonitrile was dried by storage over activated molecular sieves. Chromatography was performed on columns of neutral alumina (Fluka) deactivated with 6% w/w water.

Aza-15-crown-5 was prepared as described in the literature.[14] Sodium tetraphenylborate (Aldrich) was dried by heating at 80°C *in vacuo* for several hours and stored under nitrogen.

N-Acetylaza-15-crown-5 (**3**)

Acetyl chloride (*ca* 7 cm^3, 0.1 mol) was added slowly to aza-15-crown-5 (1.22 g, 5.6 mmol) in diethyl ether (50 cm^3) and stirred for 10 min. A white precipitate was formed. Sodium hydroxide (2 g) in water (10 cm^3) was added and the diethyl ether allowed to evaporate. The pale yellow aqueous solution was extracted with dichloromethane (5×20 cm^3). The combined extracts were dried over magnesium sulphate, filtered and the solvent removed by rotary evaporation affording a brown oil. Chromatography with 1:1 petroleum ether/dichloromethane as eluant separated the product as a pale brown oil, which was dried *in vacuo*. Yield 0.50 g (34%). Mass spectrum, *m/z* (%): 261 (22), 262 (71), 263 (37) [$(M+H)^+$], 219 (100), 220 (44) [$(M—CH_3CO)^+$]. ^1H (300 MHz, $[^2H]_3$-acetonitrile): 3.69 [t, $^3J(H_\alpha H_\beta$ or $H_{\alpha'}H_{\beta'})$ 6.2 Hz, 2H, H_α or $H_{\alpha'}$], 3.57 (m, 14H, OCH_2), 3.45 (m, 4H, OCH_2), 2.02 (s, 3H, CH_3). ^{13}C-{^1H} (75.47 MHz, $[^2H]_3$-acetonitrile): 171.4 (NCO), 71.6, 71.4, 71.0, 70.8, 70.6, 69.8 (OCH_2), 51.8 and 49.3 (C_α and $C_{\alpha'}$), 22.0 (CH_3). ν (neat) 1629 cm^{-1} (NC=O).

N-Acetylaza-15-crown-5 sodium tetraphenylborate (**4**)

3 (*ca* 0.2 g, 0.8 mmol) and $NaBPh_4$ (excess) were dissolved in acetonitrile (20 cm^3). The solvent was removed under reduced pressure and the solid stirred in dichloromethane for 2 h. The solution was filtered and the solvent removed under reduced pressure to give small cream-coloured crystals of **4**. Found: C, 69.4; H, 7.05; N, 2.2. Calc. for $C_{36}H_{43}NO_5NaB(CH_2Cl_2)_{0.25}$: C, 69.7; H, 7.0; N, 2.2%. ^1H (300 MHz, $[^2H]_3$-acetonitrile): 7.29 (m, 8H, BPh_4), 7.03 [t, ^3J(HH) 7.3 Hz, 8H, BPh_4], 6.85 [t, ^3J(HH) 7.3 Hz, 4H, BPh_4], 5.46 (s, 0.5H, CH_2Cl_2), 3.58 (m, 16H, OCH_2), 3.46 [t, $^3J(H_\alpha H_\beta)$ 5.8 Hz, 4H, NCH_2], 2.03 (s, 3H, CH_3). ν (CsI) 1632 cm^{-1} (NC=O).

(*Received* 26 *November* 1990; *accepted* 20 *May* 1991)

Abstract—The complex $[Mg(terpy)_2][ClO_4]_2 \cdot H_2O$ (terpy = 2,2′:6′,2″-terpyridine) may be prepared by the direct reaction of magnesium perchlorate with 2,2′:6′,2″-terpyridine. The magnesium is in a pseudo-octahedral environment very similar to that observed in transition metal *bis*-(2,2′:6′,2″-terpyridine) complexes. Crystallographic data: space group $I4_1/a$, $a = 12.531(13)$, $c = 40.52(4)$ Å, $V = 2912$ Å^3, $Z = 8$.

2,2′:6′,2″-Terpyridine (terpy) is a ligand which has found very widespread application in coordination chemistry.[1] The ligand shows all of the versatility of its bidentate analogue 2,2′-bipyridine (bipy)[2,3] and forms complexes with representatives from most of the groups of the periodic table, although those with the transition elements have attracted by far the greatest attention. In general, 2,2′:6′,2″-terpyridine acts as a terdentate chelating ligand, although isolated examples of a bidentate bonding mode have been described.[4–7a] Although the coordination chemistry of the alkali metals and the alkaline earths is dominated by interactions with anionic or oxygen donor ligands, we and others have recently demonstrated that these metal ions form remarkably stable complexes with macrocyclic ligands[8–15] containing only sp^2-hybridized nitrogen donor atoms. Although there have been isolated reports over the years regarding the interactions of the group 1 and group 2 metal ions with open-chain oligopyridine and 1,10-phenanthroline ligands,[16–22] few such complexes have been reported for the terdentate ligand 2,2′:6′,2″-terpyridine (terpy).[22] We have been particularly interested in the interactions of magnesium ions with 2,2′:6′,2″-terpyridine in view of the previous reports of the formation of a relatively stable 1:1 complex ($K = 5.858 \pm 0.023$) in water.[23,24] The solid state species $Mg(NO_3)_2 \cdot terpy \cdot 2H_2O$ has been described, but nothing is known about the coordination environment about the metal atom.[22] This report is concerned with the preparation and structural characterization of the complex $[Mg(terpy)_2][ClO_4]_2 \cdot H_2O$.

EXPERIMENTAL

IR spectra were recorded in compressed KBr pellets on a Perkin–Elmer FT 910 spectrometer; ^{1}H NMR spectra were recorded on Brüker WM 250 or AM 400 spectrometers. Fast atom bombardment (FAB) mass spectra were recorded on a Kratos MS50 mass spectrometer. 2,2′:6′,2″-Terpyridine was prepared as described previously.[25]

Preparation

A solution of $[Mg(H_2O)_6][ClO_4]_2$ (0.165 g, 0.50 mol) in boiling MeCN (25 cm^3) was added to a solution of 2,2′:6′,2″-terpyridine (0.23 g, 0.100 mol) in warm $CHCl_3$ (10 cm^3) to yield a voluminous off-white precipitate. The resulting suspension was heated to reflux for 1 h, cooled, and the solid collected by filtration. The solid was washed with water

(3×1 cm^3) and diethyl ether (3×1 cm^3) and dried *in vacuo* to yield $[Mg(terpy)_2][ClO_4]_2$ as a pale yellow solid. Yield: 0.2 g; 58%. Found: C, 52.3; H, 3.2; N, 12.4. Calc. for $C_{30}H_{22}Cl_2MgN_6O_8$: C, 52.2; H, 3.2; N, 12.4%.

Crystal structural determination of $[Mg(terpy)_2][ClO_4]_2 \cdot H_2O$

Crystals of the monohydrated complex were obtained by the diffusion of diethyl ether vapour into a solution of $[Mg(terpy)_2][ClO_4]_2$ in reagent grade acetonitrile. A very pale pink single crystal of approximate size $0.25 \times 0.3 \times 0.3$ mm was mounted in a capillary and set up to rotate about the {*110*} direction on a Stoe Stadi2 diffractometer and data collected via variable width ω scan. Background counts were for 20 s, and a scan rate of 0.0333° s^{-1} was applied to a width of $(1.5+\sin\mu/\tan\theta)$. A total of 3149 independent reflections were measured with a 2θ(max) of 50°, of which 1260 with $I > 2\sigma(I)$ were used in subsequent refinement.

Starting coordinates for the cation were taken from those of isomorphous structures.[26-30] The perchlorate anion and one water molecule with half occupancy were located in a difference Fourier map. Unlike the anions in the other isostructural compounds, the perchlorate anion showed no sign of disorder. Hydrogen atoms of the 2,2′:6′,2″-terpyridine ligands were placed in trigonal positions with a common refineable thermal parameter (one for each ligand). The structure was given a weighting scheme in the form $\omega = 1/[\sigma_2(F)+0.003F^2]$. The final R value was 0.081 ($R_w = 0.085$). In the final cycle of refinement all shift/error ratios were $< 0.3\sigma$. The final difference Fourier map had no peaks larger than 0.3 e Å^{-3}. Calculations were carried out using SHELX 76[31] and some of our own programs on the Amdahl 5870 at the University of Reading. Pertinent crystallographic data are given in Table 1 and bond distances and bond angles within the metal coordination sphere are given in Table 2.

Table 1. Crystal data for $[Mg(terpy)_2][ClO_4]_2 \cdot H_2O$

Formula	$C_{30}Cl_2H_{24}MgN_6O_9$

[a] $R = \Sigma[|F_o|-|F_c|]/\Sigma|F_o|$.
[b] $R' = \Sigma w^{1/2}[|F_o|-|F_c|]/\Sigma w^{1/2}|F_o|$.

RESULTS AND DISCUSSION

Very little is known concerning the coordination chemistry of 2,2′:6′,2″-terpyridine with group 2 metal ions. The complexes $Mg(NO_3)_2 \cdot 2H_2O$, $Ca(SCN)_2 \cdot 2terpy \cdot H_2O$ and $Ba(SCN)_2 \cdot terpy \cdot H_2O$ have been reported, but are of unknown structure.[20] The radical anions generated by the reaction of 2,2′:6′,2″-terpyridine with group 2 metals in inert solvents have been studied, and there is ESR evidence for the formation of contact ion-pairs or coordination compounds of significant lifetime, although no further characterization has been made.[4] The only other species which has been described is a 1:1 complex with magnesium sul-

phate which has been characterized as a solution species in aqueous solutions containing the two components.[23,24]

The reaction of magnesium perchlorate with 2,2′ : 6′,2″-terpyridine in a mixed acetonitrile–chloroform solvent yields a white solid. The same product may be obtained from reaction in methanolic solution, and is not decomposed upon treatment with water. X-ray quality crystals may be obtained by the slow diffusion of ether vapour into an acetonitrile solution. The ^{1}H NMR spectrum of a solution of the crystalline compound dissolved in CD_3CN is shown in Fig. 1. This clearly demonstrates that a single 2,2′ : 6′,2″-terpyridine containing product is obtained. The ^{1}H NMR spectrum differs significantly from those of 2,2′ : 6′,2″-terpyridine or 2,2′ : 6′,2″-terpyridinium salts in CD_3CN. This is an important observation, as 2,2′ : 6′,2″-terpyridinium salts are a possible (indeed, in view of the ancitipated low stability of the magnesium salts, a likely) product from the reaction. The ^{1}H NMR spectrum of the compound exhibits a doublet of doublets (δ 7.40, 2H, H_5), a doublet (δ 7.84, 2H, H_6), a triplet of doublets (δ 8.17, 2H, H_4), a doublet (δ 8.53, 2H, H_3) and an AB_2 apparent triplet (δ 8.69, 3H, $H_{3',4',5'}$). The most notable feature is the upfield shift of H_6 with respect to 2,2′ : 6′,2″-terpyridine (δ 8.7) and the downfield shift of $H_{4'}$ (δ 8.1). The upfield shift of H_6 is a feature which is commonly observed in *pseudo*-octahedral *trias*(2,2′-bipyridine) and *bis*(2,2′ : 6′,2″-terpyridine) complexes,[1,32,33] and is usually ascribed to the shielding experienced by these protons lying above another pyridine ring. The FAB mass spectrum of the complex exhibits peaks at *m/z* 490 ({[Mg(terpy)$_2$]}$^{2+}$) and *m/z* 257 ({[Mg(terpy)]}$^+$). These results strongly suggest that a salt containing the six-coordinate $[Mg(terpy)_2]^{2+}$ cation has been formed.

The crystal and molecular structure of the cation in the complex $[Mg(terpy)_2][ClO_4]_2 \cdot H_2O$ is presented in Fig. 2. The structure consists of discrete $[Mg(terpy)_2]^{2+}$ cations with crystallographically imposed C_2 symmetry, together with perchlorate anions in general positions and a water molecule with half occupancy. This structure is startlingly reminiscent of a transition metal *bis*(2,2′ : 6′,2″-terpyridine) complex, and indeed is isomorphous with the compounds $[Co(terpy)_2][ClO_4]_2 \cdot 0.5H_2O$,[26] $[Co(terpy)_2][ClO_4]_2 \cdot 1.3H_2O$,[27] $(Co(terpy)_2][NO_3]_2 \cdot 2H_2O$,[28] and $[Cu(terpy)_2][NO_3]_2$.[29,30] In these structures the anions and water molecules lie in channels created by staggered layers of the $[Co(terpy)_2]^{2+}$ cations. In the present structure no disorder was noted in the perchlorate counter ions, although in all of the previously reported complexes the anions were disordered in some way. The dimensions and anisotropic thermal parameters of the

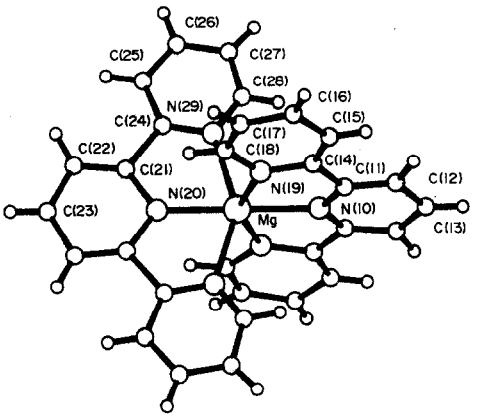

Fig. 2. Crystal and molecular structure of the cation in $[Mg(terpy)_2][ClO_4]_2 \cdot H_2O$ showing the numbering scheme adopted.

perchlorate anion are reasonable and the final difference Fourier map showed no significant areas of electron density in its vicinity. Only one position was found for the water molecule, which was refined with half-occupancy.

Considerable variations in the dimensions within $[M(terpy)_2]^{n+}$ cations have been observed, and these are commonly ascribed to crystal packing effects within the lattice.[1,27] Within a series of $[Co(terpy)_2]^{2+}$ complexes, the angle of intersection between the two terpy ligands was found to range between 84.5 and 90.0° and the N(central)—Co—N(central) angles varied from 175–180° with inter-annular twists of up to 10° between adjacent pyridyl rings of each terpy ligand.[27] It is also a feature common to all $[M(terpy)_2]^{n+}$ structures that the M—N(central) bond distance is significantly shorter than the M—N(terminal) distances.[1] The dimensions within this present structure fall within these trends with Mg—N(central) distances of 2.050(10) and 2.109(8) Å and Mg—N(terminal) distances of 2.247(6) and 2.244(7) Å. The twist angles between the central and terminal pyridine rings are only 2.6 and 3.3°, and the two ligands make an angle of 88.1(1)°.

There are very few structurally characterized compounds containing magnesium ions coordinated to six nitrogen donor ligands. The majority of these complexes are porphyrin complexes in which the two axial sites are occupied by *N*-donor ligands[34,35] but two structures containing the $[Mg(NCMe)_6]^{2+}$ cation are known.[36,37] Of these latter, one is disordered,[36] while in the other[37] the Mg—N bond lengths are in the range 2.134–2.178 Å. In the porphyrin adducts[34,35] the Mg—N(porphyrin) distances are in the range 2.04–2.09 Å, and the Mg—N(axial) distances in the range 2.29–2.42 Å. These values indicate that the dimensions found in the $[Mg(terpy)_2]^{2+}$ cation are reasonable, and the the Mg^{2+} cation is of the right size to form such a complex. The formation of such a cation with six Mg—N bonds is unusual and there are no precedents for such complexes with terpy or similar ligands.

Acknowledgements—We should like to thank the SERC for the award of a Post-Doctoral Fellowship (JH) and for funds for the diffractometer. We thank A. W. Johans for his assistance with the crystallographic investigation.

Abstract—The crystal and molecular structures of $Gd(NCS)_3(H_2O)_2L$ (L = dibenzo-30-crown-10) have been determined by single crystal X-ray diffraction. In this compound the gadolinium centre is eight-coordinate (three oxygen atoms of the crown ether, three isothiocyanate anions and two water molecules).

The coordination chemistry of the alkali, alkaline earth metals, lanthanide and transition metals has been extensively studied since the initial discovery[1,2] of the crown ethers. Complexes formed were found to depend not only on the size of the cation and crown ether cavity but also the choice of anion and solvent. Dibenzo-30-crown-10 (hereafter named L) is a larger ether. Very few solid complexes of this ligand with metal ions have been reported.[3–5] Bush and Troter[3] determined the crystal structure of the complex of potassium with dibenzo-30-crown-10 and found the ligand was wrapped round the potassium ion. Ciampolini and Nardi[5] synthesized the compounds of lanthanide perchlorates with L by using anhydrous salts and anhydrous acetonitrile. So far, to our knowledge, no report on the crystal structure of complexes between lanthanide metal ions and L has appeared. Recently, we were successful in the synthesis and structural characterization of the title complex. This complex is very different from the complex of potassium and is the subject of this report.

EXPERIMENTAL

Synthesis and crystallization of $Gd(NCS)_3(H_2O)_2L$

L (1 mmol) in acetonitrile (10 cm^3) was added to a stirred solution of $Gd(NCS)_3 \cdot 6H_2O$ (1 mmol) in the same solvent (10 cm^3). The reaction mixture was heated to 80°C for 2 h, cooled to room temperature, and stored in a desiccator containing P_4O_{10}. Crystals formed over a period of several weeks at room temperature. Found: C, 41.1; H, 4.8; N, 4.3. Calc. for $Gd(NCS)_3(H_2O)_2L$: C, 41.1; H, 4.9; N, 4.6%.

X-ray data collection, structure determination, and refinement for title compound

A transparent colourless crystal of the title compound having approximate dimensions of $0.2 \times 0.2 \times 0.3$ mm was mounted on a glass fibre in a random orientation. The determination of the unit cell and the data collection were performed with Mo-K_α radiation ($\lambda = 0.71073$ Å) on an Enraf–Nonius CAD4 diffractometer equipped with a graphite crystal monochromator. A total of 5200 independent reflections were collected in the range of $2° \leqslant \theta \leqslant 25°$ by the ω–2θ scan technique at room temperature, in which 2667 reflections with ($I \geqslant 3\sigma I$) were considered to be observed and used in the succeeding refinement. A correction for Lp effects was applied to the data.

Crystals are triclinic, space group $P\bar{1}$, with $a = 12.874(2)$, $b = 12.952(3)$, $c = 14.691(5)$ Å, $\alpha = 64.77(2)$, $\beta = 64.43(2)$, $\gamma = 77.17(2)°$; $V = 1996.77$ Å^3, $M_w = 904.07$, $Z = 2$, $D_x = 1.497$ g cm^{-3}, $\mu = 18.7$ cm^{-1}, $F(000) = 910$.

The structure was solved by the Patterson

method. All the other non-hydrogen atoms were determined from successive difference Fourier syntheses.

The final refinement by full-matrix least-squares with anisotropic thermal parameters for non-hydrogen atoms converged with agreement factors of $R = \Sigma|\Delta F|/\Sigma|F_o| = 0.070$ and $R_w = [\Sigma_w|\Delta F|^2/\Sigma_w|F_o|^2]^{1/2} = 0.085$ (unit weights for all observed

reflections). The highest peak on the final difference Fourier map had a height of 0.99 e $Å^{-3}$.

All calculations were performed on a PDP11/44 computer using SDP-PLUS program system.

Tables of final atomic positional and thermal parameters, full lists of bond lengths and angles, equations of least-squares planes have been deposited as supplementary material with the Editor.

RESULTS AND DISCUSSION

The crystal structure of the complex is shown with the crystallographic numbering of the atoms in Fig. 1. Some bond lengths, and bond angles are given in Tables 1 and 2.

In the complex, only three oxygen atoms O(7), O(8), O(9) of the cyclic ether interact with the gadolinium(III) ion with the Gd—O distances ranging from 2.460(6) to 2.516(7) Å (mean, 2.482 Å). The nitrogen atoms of the three isothiocyanate anions and two oxygen atoms of coordinated water molecules are also bonded to the gadolinium(III) ion. Two coordinated water molecules contact the cyclic ether oxygen atoms O(1), O(3), O(4) and O(6) with hydrogen bonds (Table 3). The coordination number of the gadolinium(III) ion is eight. The O(7), O(8), O(9), O(11) and gadolinium atoms lie approximately in a plane (Fig. 2). The maximum deviation from the plane is 0.0088 Å (gadolinium). The gadolinium atom simultaneously lies in the plane which consists of N(1), N(2), N(3) and O(12). The maximum deviation from the plane is 0.0246 Å (gadolinium). The dihedral angle between the two planes is 86.94°. All the eight donor atoms around gadolinium(III) ion make up a coordination dodecahedron with D_{2d} symmetry (Fig. 3). The structures of the potassium iodide complex with dibenzo-30-crown-10 and of our complex are very different. In the potassium complex, the cyclic ether is wrapped round the potassium, and all 10 oxygen atoms of the cyclic ether interact with the cation. The difference in crystal structures may be caused by: (i) the K ion has a larger radius than the gadolinium ion (1.33 and 0.93 Å for K^+ and Gd^{3+}, respectively); (ii) the water molecule and isothiocyanate anion have stronger coordination ability than cyclic ether oxygen atoms for gadolinium. The coordinated water molecules and isothiocyanate anions inhibit other oxygen atoms of the cyclic ether from coordinating to Gd.

CRYSTAL STRUCTURE OF BIS(α-METHACRYLATO)-2,2′-BIPYRIDINE-MONOHYDRATE COPPER(II)

GAO YICI,* WANG YAOYU, ZHU YING and SHI QIZHEN

Department of Chemistry, Lanzhou University, Lanzhou, Gansu, P.R.C.

(*Received* 27 *July* 1990; *accepted* 20 *May* 1991)

Abstract—The X-ray crystal structure of the title copper(II) complex has been determined and shows that the complex is mononuclear with distorted square pyramidal coordination from two monodentate carboxylates, a bidentate bipyridiyl and one aquo ligands.

There have been many studies[1,2] directed towards extending our understanding of the particularity and diversity of structures of copper(II) complexes. Numerous papers dealing with copper carboxylates have been published,[3–11] but compounds with unsaturated carboxylic acids, especially their structural information, are still very little known. Edmondson and Lever[12] and Morzinski and Heyduk[13–15] synthesized the copper(II) complexes of unsaturated acids with monodentate hetrocyclic amines in 1965 and 1983, respectively, and reported these compounds to have binuclear bridge structures, indicated by spectroscopic (UV–vis, IR, EPR) and magnetic investigations.

In an attempt to obtain more information on these complexes we recently prepared single crystals of copper(II) complexes of α-methacrylic acid and its derivatives with bidentate heterocyclic amines from the mixed solvent system methyl alcohol and ethylene glycol dimethyl ether (2:1, v/v) at room temperature. This, our first study, reports crystal data and important features of the copper(II) complex of α-methacrylate with 2,2′-bipyridine. Further studies will report the syntheses and structures for other copper unsaturated carboxylates.

EXPERIMENTAL

Synthesis

The parent complex [Cu(α-methacrylato)$_2$·H_2O] was first prepared in methyl alcohol by an improvement of the method of Edmondson and Lever.[12] The product was recrystallized from the mixed solvent described above. Found: C, 38.4; H, 4.8; Cu, 25.4. Calc. for $C_8H_{12}CuO_5$: C, 38.2; H, 4.8; Cu, 25.3%.

Methyl alcohol (15 cm^3), the parent complex (1.00 g) and 2,.2′-bipyridine (0.65 g) were mixed and the deep green–blue crystals which formed after refluxing and evaporating for several hours were filtered and dried. The crude product was recrystallized from methyl alcohol and ethylene glycol dimethyl ether (2:1 v/v) at room temperature. Found: C, 53.0; H, 4.9; N, 6.9; Cu, 15.7. Calc. for $C_{18}H_{18}CuN_2O_5$: C, 53.0; H, 4.9; N, 6.9; Cu, 15.7%.

Structure solution

Preliminary photographic examination and data collection were performed with Mo-K_α radiation ($\lambda = 0.7107$ Å) on an Enraf–Nonius CAD-4 computer-controlled K-axis diffractometer with a graphite crystal-incident beam monochromator. The sample selected for investigation, had dimensions of $0.26 \times 0.26 \times 0.19$ mm^3. Accurate unit cell parameters were obtained by least-squares refinement. 4393 independent reflections ($1° \leqslant \theta \leqslant 27°$) were collected by using the ω–2θ scan technique but only 2611 with $I \geqslant 3\sigma(I)$ were used in the refinement. All data were corrected for Lorentz and polarization effects and also for absorption. Crystal data are listed in Table 1.

The crystal structure was solved by direct methods (MULTAN-82). The copper and most non-hydrogen atoms were located from an E map. The remaining non-hydrogen atoms were located by difference Fourier synthesis. The structure was refined by full-matrix least-squares with anisotropic

thermal parameters for the copper atom and isotropic thermal parameters for other atoms. The final discrepancy factor of R is 0.031, R_w was 0.030.

RESULTS AND DISCUSSION

Bond distances and angles for the complex are listed in Tables 2 and 3. The least-squares planes and their dihedral angle are listed in Table 4. Figures 1 and 2 show the molecular structure and crystal packing.

The structure in this five-coordinated complex has the central copper atom in a distorted square pyramidal configuration with two α-methacrylate ligands, a 2,2′-bipyridine ligand and an aquo ligand.

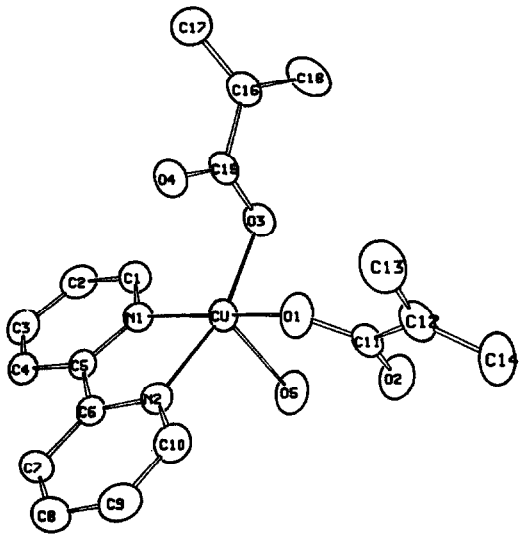

Fig. 1. Perspective view of the molecule of complex.

The heterocyclic amine is bidentate to the copper atom to form a rather stable chelate ring. It is quite interesting that each unsaturated carboxylate contributes only one carboxyl oxygen atom for coordination to copper (Fig. 1). This is the first such example for copper complexes with unsaturated carboxylates. The weakly basic and π accepting character of 2,2′-bipyridine render the copper atom fairly positive and thus increases the interaction between the copper and the negative oxygen atoms.

The observed bond lengths and angles (Tables 2 and 3) are within accepted limits for compounds of this type.[3] In the molecule the distances of Cu—O(1), Cu—O(3), Cu—O(5), Cu—N(1) and Cu—N(2) are 1.969(2), 1.926(2), 2.292(2), 2.023(3) and 2.005(3) Å. The angles of O(1)—Cu—O(5), O(3)—Cu—O(5), N(1)—Cu—O(5) and N(2)—Cu—O(5) are 100.26(9), 95.44(9), 96.3(1) and 91.81(9)°, respectively. Obviously, the distance of Cu—O(5) is much longer than others and this is one of the geometrical features for a square pyramid.

The four atoms N(1), N(2), O(1) and O(3) are nearly in a plane, and the copper atom is 0.297 Å above the pyramid base. The reason for the apparent equivalence of the two C—C bonds (C=C and C—C) is disorder [Table 2; C(16)—C(17) and C(16)—C(18)].

Abstract—Reaction of $t\text{-}Bu_2GaCl$ with LiNHPh in toluene/diethylether (4:1) at −78°C gives the dimeric primary amido complex $[t\text{-}Bu_2Ga(\mu\text{-}NHPh)]_2$ (**1**) in 60% yield. The reaction of $t\text{-}Bu_3Ga$ with NH_2Ph at −78°C in toluene gives the adduct $t\text{-}Bu_3Ga \cdot NH_2Ph$ (**2**) in 75% yield. The structures of both compounds have been determined by X-ray crystallography. The molecular geometry of **1** consists of a dinuclear unit with two bridging —NHPh groups and two terminal t-Bu groups bound to each gallium atom. The coordination geometry of both the gallium and nitrogen atoms is distorted tetrahedral. The molecular geometry of **2** involves a fairly long dative N→Ga donor bond [2.246(9) Å] and the configuration of the amine is distorted from an idealized tetrahedral geometry due to steric repulsions. Crystallographic data for both **1** and **2** suggest the presence of close interactions between the N—H hydrogen atoms and the gallium atoms (N—H···Ga).
