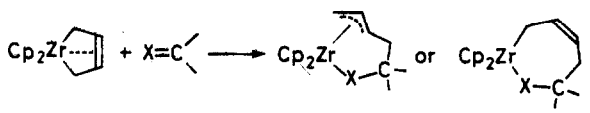
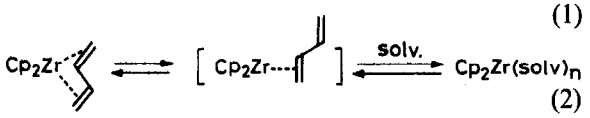
(*Received* 6 *July* 1990; *accepted* 17 *July* 1990)

Abstract—A series of 3,4-dialkylcyclopentanones was synthesized by template reactions on the "Cp_2Zr" moiety generated from Cp_2Zr(2,4-hexadiene) or Cp_2Zr(olefin) complexes by ligand exchange reactions. The addition of a 1-olefin or 1,7-octadiene to the Cp_2Zr species followed by CO insertion and acid hydrolysis gave a *cis*- or *trans*-disubstituted cyclopentanone in high yield.

Conjugated diene complexes of zirconium of the type Cp_2Zr(diene) are unique in their mode of coordination for the diene. For example, when prepared from Cp_2ZrCl_2 and butenediylmagnesium at low temperature, the simplest member exists in a mixture of complexes with s-*cis* and s-*trans* butadiene ligands.[1,2] Our subsequent study has indicated a remarkable difference in the nature of the bonding of these metal–diene complexes. The s-*cis* isomer has a metallacyclopentene structure in which the reactive metal–carbon σ-bonds readily react with organic homo- and hetero-unsaturated species [eq. (1)].[3,4] In the s-*trans* isomers, η^4-diene coordination is found and thus the diene is prone to dissociate partially to a η^2-diene species (monoene coordination) or completely to a solvent-coordinated metallocene species in solution [eq. (2)].

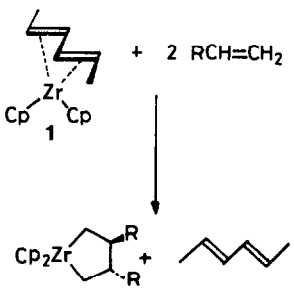


(1)



(2)

We have found that alkyl or aryl substitution at the terminal positions of the diene enhances the stability of the s-*trans* coordination.[1a,5] Thus, (*E*,*E*)-2,4-hexadiene in the zirconium complex, $Cp_2Zr(C_6H_8)$, exists exclusively in the s-*trans* form. In the reaction with 1-olefin, the s-*cis* complexes give metallacycles by olefin insertion into the Zr—C bond of the diene. In contrast, the s-*trans* complexes, especially complex **1**, release the diene and give metallacyclopentanes by oxidative coupling of two olefin molecules [eq. (3)]. Thus, the s-*trans*-2,4-hexadiene complex can serve as an equivalent of coordinatively unsaturated "Cp_2Zr".



(3)

This latter reaction seems remarkable since η^4-coordination of a diene is generally known to be more stable than the η^2-coordination of olefins.

Factors influencing regio- and stereochemistry of the metallacyclization step are important for the selective synthesis of disubstituted cyclopentanones utilizing metallacyclopentanes.[6] Regioselectivity in the formation of metallacyclopentanes has been

theoretically investigated by Lauher and Hoffmann and McKinney, and the importance of overlap between the antibonding olefin orbitals has been pointed out.[7] The validity of this prediction may be tested in the present example.

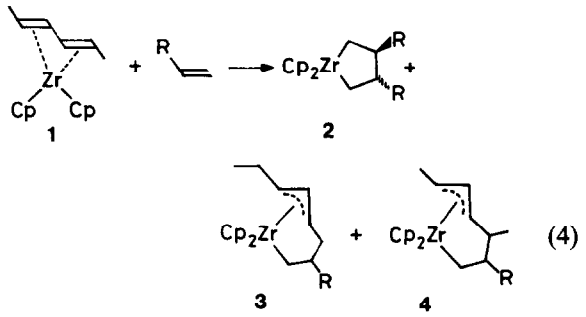
Carbonylation of alkyl–zirconium species has been extensively investigated and mechanisms involving η^2-acyl or oxycarbene ligands have been proposed.[8] The bicyclic structure of zirconahydrindane may offer a unique opportunity for investigation of this type of carbonylation. The stereochemical fate of the bicyclic ring fusion upon carbonylation and the influence of the bicycle on the carbonylation mechanism are also of interest.

In this report, we describe a template synthesis of metallacyclopentanes from a labile s-*trans* hexadiene or an olefin complex, and the formation of substituted cyclopentanones by subsequent reaction with CO followed by acid hydrolysis.

RESULTS AND DISCUSSION

Reaction of Cp_2Zr(*hexadiene*) *with* 1-*olefin*

The addition of one equiv. of 1-olefin to Cp_2Zr(2,4-hexadiene) (**1**) was found to provide a zirconacyclopentane (**2**) together with the 1 : 1 insertion product (**3**) and a trace amount (< 5%) of its isomer (**4**) [eq. (4)].



(4)

In the initial stage of this reaction (for example, at room temperature for 2–4 h), the formation of zirconacyclopentane species (**2**) was predominant as a result of ligand exchange and subsequent metallacyclization. Progress of the reaction was monitored by GLC after acidic hydrolysis of the resulting products; the results of reactions (30°C for 3 h) are summarized in Table 1.

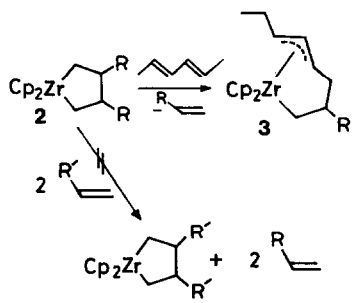
Terminal olefins readily give rise to the formation of **2** in more than 80% yield. The product from 1-pentene prefers the *trans*-configuration in sharp contrast to the *cis*-form for the 1,7-octadiene derivatives (*vide infra*). Butadiene was also converted into a metallacycle by C—C coupling at the terminal position of two butadiene molecules, liberating the ligated 2,4-hexadiene in quantitative yield, to give a zirconacyclo-3,7-nonadiene derivative (**11**) in 93% yield. Reaction with styrene, however, gave different products (the structure of the major product is unknown because of the polymeric nature). Although the 2,4-hexadiene ligand was expelled completely, the formation of a styrene dimer was not detected from the hydrolyzate. Only a small amount of ethylbenzene, presumably derived from Cp_2Zr(styrene), was detected upon hydrolysis. Inner olefins such as 2-pentene and 3-hexene were found to be completely inert to **1** under conditions employed here. By contrast, 2-butyne rapidly reacts with **1** to afford 2,3,4,5-tetramethylzirconacyclopentadiene (**12**) in high yield.

Table 1. Mode of reaction between Cp_2Zr(2,4-hexadiene) and olefins[a]

Olefins	Distribution of products (%) 2(*trans*/*cis*)	3	Others	Total yield (%)
1-Pentene	86(95/5)	14	0	96
1-Heptene	78(95/5)	22	0	94
1,7-Octadiene	89(12/88)	11	0	92
Styrene	0	0	80	20
Butadiene			95	95
2-Heptene	0	0	0	0

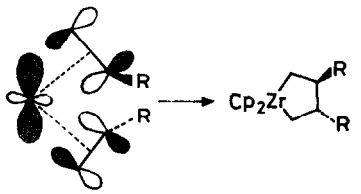
[a] Result of the reaction after stirring at 30°C for 2 h.

The zirconacyclopentanes (**2**) thus formed from 1-pentene and 1-heptene in the initial stage of the reaction were gradually transformed to diene adducts (**3**) on standing the mixture at room temperature for 4 days or heating them at 60°C for 6 h. However, when the liberated 2,4-hexadiene was removed in the initial stage of the reaction by flash distillation, compound **2** could be isolated as a dark brown oily product. Thus, the 2,4-hexadiene ligand once liberated from the metal again participates in coupling with the 1-olefin to give **3** [eq. (5)]. This type of reaction has not been observed previously when 1-olefins rather than 2,4-hexadiene were added to **2**.



Consequently, reductive cyclization occurs competitively on the metal sphere of **1** to predominantly

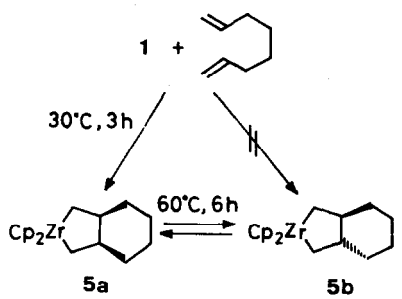
produce the *trans*-3,4-dialkylzirconacyclopentane under thermodynamic equilibrium. Two C_2 fragments may be arranged so as to facilitate the C—C bond formation between carbon atoms bearing the biggest olefinic π^* lobes, as shown below. Steric repulsion between Cp and alkyl groups of coordinating olefins should hamper the formation of 2,4- and 2,5-dialkylzirconacyclopentanes.



(6)

Reaction of $Cp_2Zr(C_6H_8)$ *with* 1,7-*octadiene*

Metallabicyclization occurs more readily by using a chelating linear diolefin, 1,7-octadiene. A high yield of the *cis*-isomer of zirconahydrindane (**5a**) starting from **1** indicates that the favourable orientation of the two olefinic units towards Cp_2Zr species is the *cis*-arrangement. However, prolonged heating of the *cis*-zirconahydrindane (**5a**) at 60°C for 6 h was found to result in quantitative conversion to the *trans*-isomer, **5b** [eq. (7)]. The configurational change may occur through an η^2,η^2-bis(olefin)metal intermediate **6a** → **6b** shown in Scheme 1.



(7)

Both of the present bicyclic complexes, **5a** and **5b**, are thermally more stable than 3,4-dialkylated zirconacyclopentanes which decompose at 60–70°C. Thus, the *cis*-isomer **5a** is concluded to be a kinetic product and the *trans*-isomer **5b** a thermodynamic product.

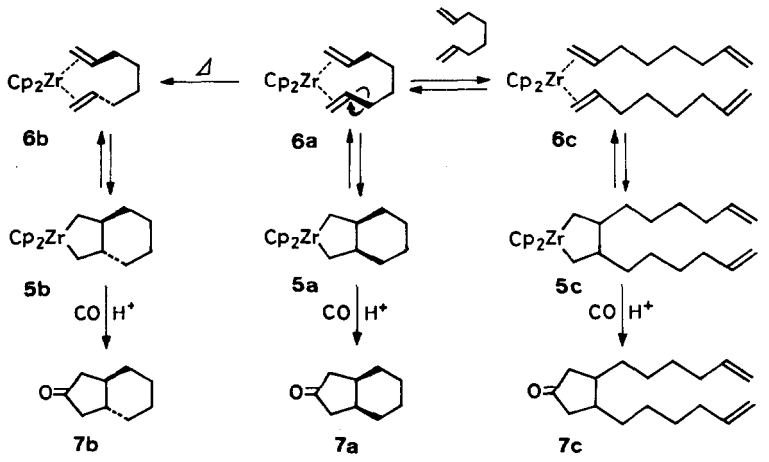
On the other hand, Gell and Schwartz reported that the addition of 1,7-octadiene to a zirconocene–phosphine complex produced a 1 : 1 mixture of **5a** and **5b** [eq. (8)].[9]

	5a	5b
$M=(PPh_3)_2Ni$	0	100
Cp_2Ti	24	76

(8)

Similar behaviour was also observed for other metallahydrindanes as reported by Grubbs and Miyashita, who prepared the corresponding titanium compounds by a ligand exchange reaction using parent monocyclic complexes.[10] Ready conversion of a nickelacycle from the *cis*-form to the *trans*-isomer, which is prepared from $(Ph_3P)_2NiCl_2$ and *cis*-1,2-di(lithiomethyl)cyclohexane, clearly confirms that the *trans*-isomer is the thermodynamic product. The formation of a mixture of *cis*- and *trans*-isomers (*ca* 1 : 1) was also found in the synthesis of a bicyclic tantalacycle, as reported by McLain and Schrock.[11]

Preference for the *cis*- or *trans*-configuration should largely depend on the strength of ligand coordination to the metal. The complexes with strongly coordinated ligands, such as phosphines, ethylene and even terminal olefins, bring about the



Scheme 1.

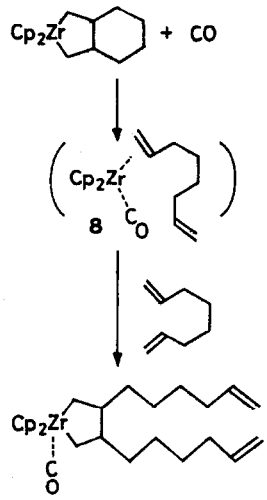
2-Heptene	0

[a] Reaction conditions for carbonylation with CO, 30°C for 6 h in benzene.

interconversion between *cis*- and *trans*-isomers and finally produce the stable *trans*-isomer. By contrast, highly hindered 2,4-hexadiene was readily liberated irreversibly from Cp_2Zr(2,4-hexadiene) and the analytically pure *cis*-zirconahydrindane could be obtained by utilizing this unique ligand exchange reaction. Thus, we can control the stereochemistry in the formation of substituted metallacyclopentanes by choosing appropriate ligands in Cp_2ML_2 or $(R_3P)ML_2$.

Carbonylation of 3,4-disubstituted zirconacyclopentanes

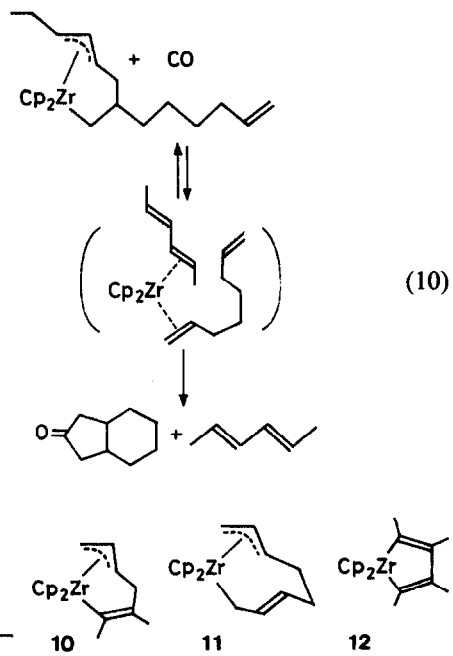
(a) *Reaction route using* Cp_2Zr(*diene*). Bicyclic zirconium complexes, **5a** and **5b**, synthesized from **1**, demonstrated an interesting series of carbonylation reactions, as shown in Scheme 1. The addition of CO to isolated **5a** and **5b**, in benzene under atmospheric pressure, afforded *cis*-hydrindanone (**7a**) and *trans*-hydrindanone (**7b**) in high yield (> 85%), respectively. The reaction occurs with retention of configuration as confirmed by the ^{13}C NMR studies. However, the corresponding reaction of **5a** in the presence of 3 equiv. of 1,7-octadiene led to the formation of a 1 : 2 adduct, 3,4-di(5-hexenyl)cyclopentanone (**7c**), in 85% yield. A reaction pathway through $Cp_2Zr(\eta^2$-1,7-octadiene$)_2$ (**6c**) seems most likely for this coupling. Although complexes **5a** and **5b** could be trapped by hydrolysis as a form of *cis*- and *trans*-1,2-dimethylcyclohexane, respectively, the expected 7,8-dimethyl-1,13-tetradacadiene was not detected from the reaction mixture obtained from **1** and excess 1,7-octadiene (4 equiv.) in the presence or absence of CO. This result indicates that the initially formed complexes, **5a** and **5b**, become labile under a CO atmosphere due to the ligation of CO and generate an intermediate **8**, a zirconocene (olefin)(carbonyl) complex [eq. (9)].



(9)

The subsequent reductive coupling of 1,7-octadiene followed by CO insertion occurs very rapidly.

On the other hand, the isolated complex **3** also could be converted into *trans*-hydrindanone in 67% yield by the addition of CO at room temperature for 3 h. However, complexes **9**, **10** and **12**, prepared from Cp_2Zr(butadiene) with 1-butene, 2-butyne or butadiene, were completely inert to CO under the usual conditions. Compound **11** is also inert to CO even at high temperature. On the basis of these results, we attribute the ease of liberation of coordinated 2,4-hexadiene to its great steric hindrance. Thus an equilibrium shown in eq. (10) is proposed, where the zirconocene species contains a σ,π-diene unit.

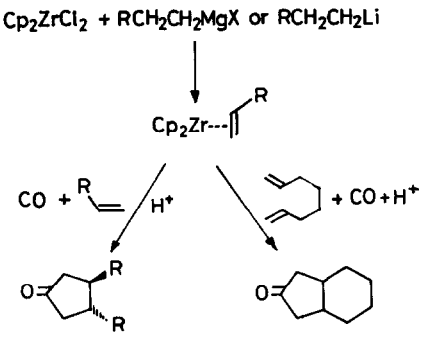


(10)

The inertness of **9–12** along with **3** (direct insertion of CO into **3** was not observed) suggests that the 18-electronic zirconium does not accept the initial coordination of CO.

The reaction of **1** with a 1-olefin (1 : 3) followed by carbonylation and protonolysis gave a simple product in high yield as shown in Table 2. The exception is the low yield (15%) observed for the zirconacyclopentane system derived from styrene. Although the formation of 3,4-diphenylzirconacyclopentane was not detected upon hydrolysis of the reaction mixture before carbonylation (only ethylbenzene was formed), the *in situ* reaction afforded 3,4-diphenylcyclopentanone. This reaction should proceed in essentially the same way as described for the formation of 3,4-di(5-hexenyl) cyclopentanone.

(b) *Reaction route using* Cp_2Zr(*olefin*) *complexes.* Recently the isolation of zirconocene–olefin complexes has been attained by Alt *et al.* and Takahashi *et al.* either by reaction of a zirconocene–phosphine complex with olefin[12] or by the 1 : 2 reaction of zirconocene dichloride with RCH_2Li or RCH_2MgX.[13] Since the Zr–olefin bond is presumed to be rather weak, these olefin complexes are expected to act as an equivalent of Cp_2Zr(2,4-hexadiene) or the coordinatively unsaturated "Cp_2Zr". Actually, a convenient one-pot synthesis of dialkylcyclopentanones has been realized by using these olefin complexes generated *in situ* [eq. (11)].[14]



(11)

The addition of excess 1-olefin to Cp_2Zr(ethylene) or Cp_2Zr(butene), followed by the reaction with CO, gave the desired cyclopentanone derivatives in high yield (Table 3). The use of EtLi or n-BuLi is favourable for obtaining high yields of the product. The use of Grignard reagents was found to be less favourable, presumably due to the stabilization of the resulting zirconacyclopentanes by coordination with ether, a donor solvent. Actually, the addition of ether, THF, triethylamine or pyridine to n-BuLi (4 : 1 ratio) resulted in a significant decrease in the product yield (< 5%). When 1,7-nonadiene or 1,9-decadiene was used in similar reaction conditions,

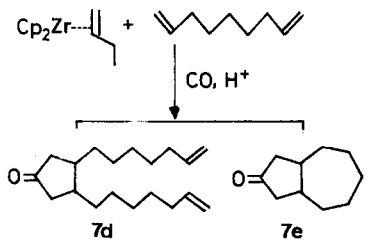
[e] Reaction conditions for carbonylation with CO.

the formation of 3,4-dialkenylcyclopentanones (for example, **7d**) was predominant due to preference of the intermolecular cyclization [eq. (12)]. Although the reaction with 1,8-nonadiene provided a bicyclic cyclopentanone derivative (**7e**) as a minor product, the corresponding reaction was not observed with 1,9-decadiene.

Analogous metallabicyclization reactions starting from enynes[15] and diynes[16] have also been reported recently, and the carbonylation leading to cyclopentenone derivatives was successful only in the former case.

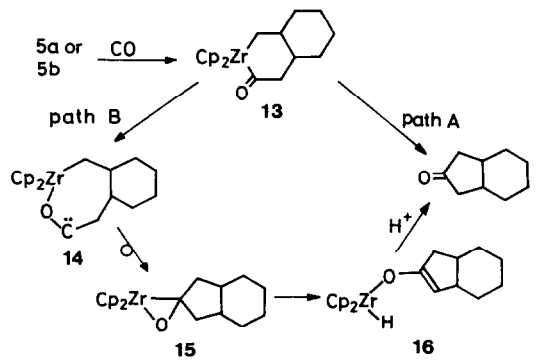


(12)

Reaction mechanism for formation of cyclopentanone

Two reaction sequences (shown in Scheme 2) are to be considered for the carbonylation of alkylzirconium complexes. Path A illustrates a reductive elimination from the alkylacyl intermediate (**13**) which is generated by CO insertion into zirconacyclopentanes (**5**). On the other hand, path B pursues migratory insertion of a transient oxycarbene intermediate (**14**) into the Zr—C bond affording zirconaoxiran (**15**), which subsequently rearranges to a hydridoenolato complex (**16**).

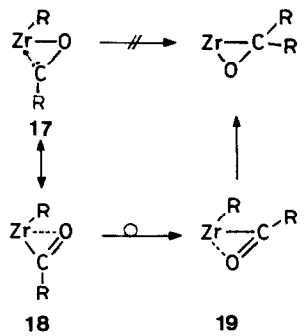
The reaction pathway has been analysed based on ^{13}C NMR studies. Four absorptions assignable to **5a** promptly disappeared upon the addition of CO and a set of seven signals emerged. This spectral change clearly confirms an unsymmetrical structure, i.e. hydrido-enolate, for the intermediate.



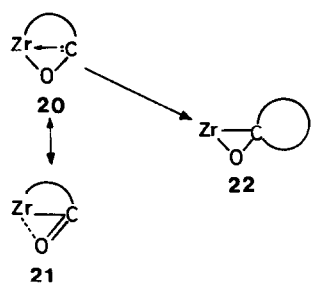
Scheme 2.

Actually, signals assignable to quarternary carbon and olefinic carbon are observed at 165.5 and 111.3 ppm, respectively. If **13** is the intermediate, the signal should be observed at around 300 ppm as found for $Cp_2Zr(Ar)(COAr)$.[17] Thus the carbonylation in the present work most likely proceeds through the migratory insertion mechanism.

The preference of the *cis*- or *trans*-configuration of the cyclopentanones may be largely effected by the mode of coordination of the acyl ligand. It is well established, based on MO calculations, that geometry **18** shown in eq. (13) is far more stable than its geometrical isomer **19**. However, the presence of a metallacyclic skeleton in **21** [eq. (14)] should prevent the rearrangement to the other isomer corresponding to **18** and hence the formation of η^2-hydrindanone **21** becomes favourable.



(13)



(14)

On the other hand, the species like **18** will not cause a migratory insertion via **17** because high energy is required for the geometrical inversion.

Concluding remarks

A series of 3,4-disubstituted cyclopentanones has been successfully synthesized by the carbonylation of dialkyl-substituted zirconacyclopentanes generated by the reaction of zirconocene-2,4-hexadiene or zirconocene–olefin complexes with two equiv. of 1-olefin or one equiv. of α,ω-unconjugated dienes. This type of reaction should have a broad application in the synthesis of cyclopentanones with a variety of substituents.

EXPERIMENTAL

Materials

Cp_2Zr(2,4-hexadiene) was prepared from $Cp_2Zr(H)Cl$ and hexadienylpotassium.[5] The 1:1 adducts of Cp_2Zr(butadiene) with 1-butene and 2-butyne were prepared as reported previously.[18]

Olefins were obtained commercially and CO was used without further purification.

Formation and carbonylation of zirconacyclopentanes from **1**

To a stirred benzene solution (10 cm^3) of Cp_2Zr(2,4-hexadiene) (**3**) (3 mmol), the 1-olefin (10 mmol) was added dropwise under argon. The mixture was stirred at room temperature for 2 h and the extent of the reaction was monitored by GLC after hydrolysis of the product. The solvent was then removed under reduced pressure. The amount of liberated (*E,E*)-2,4-hexadiene was determined by GLC analysis of the distillate. Benzene (10 cm^3) was added to the residue and the solution was cooled to −78°C. After the reaction mixture was purged with CO, reaction with CO was carried out at room temperature for 6 h. The solution was evaporated to dryness and the product was extracted with ether (20 cm^3). On addition of acetic acid (1 cm^3) the dark brown solution turned to pale yellow. Following work-up, analytically pure 3,4-dialkylcyclopentanones were obtained. Separation of the *cis*- and *trans*-isomers was carried out by preparative GLC.

Formation and carbonylation of zirconacyclopentanes from olefin complexes

A typical example of the one-pot synthesis of 3,4-dialkylcyclopentanones is shown below. Cp_2ZrCl_2 (0.5 mmol) and 1-olefin (5 mmol) were dissolved in oxygen-free, dried benzene (6 cm^3). To the stirred solution was added n-BuLi (0.63 cm^3, 1.6 M) at 0°C. The colour of the solution turned yellow–orange and finally brown by continuing the stirring for 4 h at 30°C. The reaction mixture was then cooled to −78°C and purged with CO gas using a rubber balloon. The resulting solution was stirred for 6 h at 30°C and treated with acetic acid (0.2 cm^3). On the addition of acetic acid, the colour changed to pale yellow. After the usual work-up, the sample was distilled to obtain analytically pure 3,4-dialkylcyclopentanone.

The reduction of Cp_2ZrCl_2 with RMgX in the presence of 1-olefin or 1,7-octadiene was carried out in essentially the same way as described above.

Structure determination of the products

The stereochemistry of the products was determined by ^{13}C NMR spectra with reference to the literature: *cis*- and *trans*-1,2-dimethylcyclohexane,[19] (*RS*)-6,7-dimethyldodecane,[20] *cis*-hydrindanone,[21] *trans*-3,4-diphenylcyclopentanone, cyclopentanol[22] and dimethylcyclopentanones.[23]

(*Received* 27 *February* 1990; *accepted* 1 *August* 1990)

Abstract—Complex compounds between [^{211}At] astatine(I) and chelating ligands were characterized by electromigration in free electrolytes. O, S and N served as donor atoms in the ligands. Complexes of the type (AtXL) ($X^- = Cl^-$ and Br^-) are formed in ligand exchange reactions, and their stability constants were assessed for X^- being Br^-. In the case of astatine(I) the stability depends on the kind and number of donor atoms, as well as on substituents at the nitrogen and on the basicity of the ligand. The behaviour of astatine(I) is typical for a strongly polarizable acceptor. The experiments were carried out at 298 K in anhydrous ethanolic solutions at constant ionic strength adjusted to 0.05 ± 0.01 M with $Na(H)ClO_4$.

The characterization of complex compounds between [^{211}At] astatine(I) and thiourea (tu), selenourea (su), as well as their derivatives,[1,2] provided some information about the influence of the donor atoms O, S and Se and the substituents at N on the stability of complexes of the types $[AtL_2]^+$ and [AtXL] ($X^- = Cl^-$, Br^-, I^-; L = tu, su). The aim of this work was to extend these investigations on representatives of classes of chelating ligands and aliphatic sulphides (Table 1). Studies on extraction equilibria with copper(II) and silver(I) already exist for some of these compounds.[3,4] The ligands contain aliphatic substituents which provide them with higher basicity in comparison with aromatic substituents.[5]

The method of horizontal zone electromigration in free electrolyte solution[6,7] was chosen for the characterization of complex formation equilibria. Thus, redox reactions, which could occur during extraction of astatine(I) or multivalent metals,[8,9] can be avoided provided redox-stable ligands are used. Ethanol (EtOH) was used as solvent because other astatine(I) complex compounds have already been characterized in this medium[10,11] and the solubility of the ligands was sufficient. In order to prevent the hydrolysis of astatine(I) in neutral solutions, $HClO_4$ was added (see Experimental). Some of the ligands contain nitrogen, which is completely protonated in acidic solutions, as is shown from basicity constants of similar compounds[12–16] and from titration measurements.

Numerous coordinative properties of sulphur-containing chelating ligands are known.[17–19] The complex formation behaviour of the astatine(I) cation can be compared with polarizable cations, for example silver(I).[20] The following order (Scheme 1) of decreasing affinity of ligands can be derived from stability data for the complexes of some compounds with silver(I) {log K_1 for $[AgL]^+$, $T = 293$–303 K, the ligand number according to ref. 13 in parentheses}.

The donor effect decreases in the order S > N > O. However, the analogous macroheterocycles hint at the order N > S > O in silver(I)

complexes.[21] On comparing the stability of silver(I) complexes with the ligands, in which one of the nitrogen atoms is protonated, differences between the donor strength of S and N are hard to find. However, the donor strength decreases considerably, which can be concluded from the log K values in Scheme 1 {log K for $Ag^+ + HL^+ = [AgHL]^{2+}$}. The order N > S > O can be determined for complexes between chelating ligands and copper(II) as a somewhat less polarizable cation.[22–24] Furthermore, the stability of these complexes decreases with shorter chain length of the alkyl groups at N.

EXPERIMENTAL

Production of ^{211}At

The ^{211}At isotope was obtained via irradiation of bismuth with 28 MeV alpha particles on the U-120 cyclotron at the Central Institute for Nuclear Research in Rossendorf. After which, a two-step gasthermochromatographical separation of astatine was carried out.[25] This aqueous solution of carrier-free astatine is represented by "$At^0 \times H_2O$".

Chemicals and apparatus

"$At^0 \times H_2O$" was diluted with a ten-fold volume of a 0.5 M solution of $NaClO_4$ or $LiClO_4$ in EtOH and was mixed with a surplus of ligand-containing electrolyte solution. As was shown in preparatory experiments, the oxidation state +1 was stabilized by the presence of ligands in solution without adding an oxidizing agent as described in ref. 1.

For the measurement of cationic complexes the ethanolic solutions contained 0.001–0.005 M of the ligand, 0.05 M $NaClO_4$ and $HClO_4$. For the characterization of ligand exchange equilibria the solutions consisted of ligands with a constant concentration per measurement series in the range 0.0001–0.004 M, 0.05 M LiCl or 0.05 M (NaBr + $NaClO_4$), as well as $HClO_4$. The ionic strength, μ, was adjusted to 0.05 ± 0.01 M using $Na(H)ClO_4$. $HClO_4$ was added to the solutions in order to prevent hydrolysis of astatine(I) by the following method: each solution containing the organic ligand and the salts mentioned above was titrated potentiometrically with concentrated $HClO_4$ from a microburette. A glass electrode (stored in EtOH, type GA 60 N from Forschungsinstitut Meinsberg) and a calomel electrode connected via a current key with the solutions serving as electrodes were used. The titrations were stopped at a measured pH* of 3 ± 0.3, when the nitrogen-containing ligands are completely protonated. Because EtOH is a protic solvent, the measured pH* and the calculated pH for aqueous solutions of the same composition are qualitatively comparable.

The chemicals used were of p.a. grade. Ethanol was dried over CaO and molecular sieves and distilled under flowing nitrogen. The solutions contained less than 0.3% water and were freshly prepared. The apparatus described in ref. 7 was used for the experiments, allowing measurement of the mediate ion mobility, u_m, which represents the sum of all individual ion mobilities multiplied by their partial molar fraction in the investigated solution. The temperature, T, was found to be 298 ± 0.5 K.

Synthesis of ligands

For the synthesis of compound D1 (Table 1) bis-(2-mercaptoethyl)sulphide was converted using ethylene oxide.[26] The other ligands in groups A, C and D were accessible by reaction of the corresponding thiols and α,ω-dichloro or dibromo compounds according to the usual method of nucleophilic substitution.[3,27,28] The melting points of the new D2, D4 and D5 tetrathioalkanes are given in Table 1. The B type compounds resulted from the reaction of sodium sulphide with the corresponding 1-halogenide compounds. Sulphide D8 and disulphide D3 were produced by following the methods given in refs 29 and 30.

RESULTS AND DISCUSSION

Cationic complexes

In solutions containing $NaClO_4$, $HClO_4$, 0.005 M ligand and astatine(I), cationic complexes were formed with the ligands shown in Table 2. As shown in Table 2, only type A and B ligands form cationic

Table 2. Cationic complexes of ligands with astatine(I) and their ion mobility, u_m, in EtOH (μ = 0.05 M, T = 298 K, pH* = 3)

Ligand	Concentration of ligand (M)	$u_m \pm$ error ($cm^2 V^{-1} s^{-1}$)
A1	0.005	(2.2 ± 0.4) E-05
A2	0.005	(3.4 ± 0.4) E-05
A3	0.0025	(2.9 ± 0.5) E-05
A4	0.0015	(1.7 ± 0.5) E-05
A4	0.004	(2.4 ± 0.5) E-05
B1	0.004	(4.1 ± 0.2) E-05
B2	0.004	(4.1 ± 0.3) E-05
B3	0.0025	(1.7 ± 0.5) E-05

species. At a pH* value less than four the ion mobility, u_m, was independent of the $HClO_4$ concentration but dependent on the ligand concentration. An equilibrium corresponding to eq. (1), with $X^- = ClO_4^-$ and L being the organic ligand, probably dominates in solution:

$$[AtX] + L = [AtXL]. \quad (1)$$

Complexes of this stoichiometry but with Ag^+ and Cu^{2+} as cations and partly other anions are known.[9,17,36] A positive charge on L, resulting from protonation and partial association with ClO_4^-, would be responsible for the formation of cations with type A and B ligands. Type C ligands, which are almost completely associated in these solutions, thus existing neutrally, in addition to type D ligands form neutral complexes.

Ligand exchange reactions with chloride

The u_m values were measured in ethanolic solutions containing astatine(I), 0.05 M LiCl, $HClO_4$ (pH* = 3) and 0.0025 M ligand. The data are summarized in Fig. 1. The astatine(I) ion mobility in solution under analogous conditions but without an organic ligand is $u_m = -2.06$ E-04 $cm^2\ V^{-1}\ s^{-1}$ (standard). From Fig. 1, initial conclusions on the graduation of complex stabilities can be drawn. For these purposes the following equilibria for the characterization of the ligand exchange reactions are assumed ($X^- = Cl^-$):

$$[AtX] + X^- = [AtX_2]^- \quad K_2 \quad (2)$$

$$[AtX] + L = [AtXL] \quad K. \quad (3)$$

The smaller the measured u_m value, the larger the concentration of [AtXL] in solution. Due to the high chloride concentration in solution and possible association reactions, comparison of the ligands would be useful only within the groups.

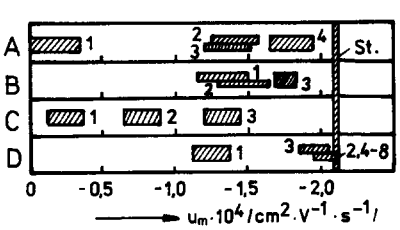

Fig. 1. Ion mobility, u_m, of astatine(I) in chloride-containing ethanolic solutions of the ligands A1–D8 at 298 K. [0.0025 M ligand, 0.05 M LiCl, $HClO_4$ (pH* = 3), EtOH, st = standard 0.05 M LiCl without second ligand].

Ligand exchange reactions with bromide

In ethanolic solutions containing astatine(I), NaBr, $NaClO_4$, $HClO_4$ and a chelating ligand, u_m was measured at different bromide concentrations and constant organic ligand concentration per measurement series ($T = 298$ K, pH* = 3, $\mu = 0.05$). Eleven chelating ligands were chosen for this purpose. Figure 2 shows the average data for u_m measured per concentration of bromide, as well as the electromigrational curve for equilibrium (2) with $X^- = Br^-$ (standard).

The electromigrational equation (4)[32] for the ligand exchange equilibria was derived from eqs (2) and (3) by modelling the measuring points:

$$u_m = \frac{u(AtBr_2^-)}{1. + \frac{1.}{K_2 \cdot [Br]} + \frac{K \cdot [L]}{K_2 \cdot [Br]}} \quad (4)$$

For two parameters, previously calculated data can be used:[10] $\log K_2 = 3.42$ and $u(AtBr_2^-) = -2.54$ E-04 $cm^2\ V^{-1}\ s^{-1}$. Thus, modelling concentrates on the calculation of K. Only anions have been measured in the investigated concentration range in the ligand exchange reactions, therefore the [AtXL] charge can be set to zero and the protonation and association of ligands do not have to be considered. This fact allows the use of the same equilibrium model for all the ligands.

The equilibrium concentration of bromide was calculated according to the method used by Schwabe,[33] taking into consideration the association with Na^+ in EtOH. For that purpose the thermodynamical association constants for NaBr ($\log K_A = 1.73$) and $NaClO_4$ ($\log K_A = 1.91$) had to be assessed from conductivity data.[34] The medium activity coefficient was evaluated according to the Debye–Hückel theory.

The parameter K in the electromigrational equation (4) was optimized with the MINUIT program[35] in such a way that the chi-square sum became minimal. Table 3 provides the $\log K$ data, and the electromigrational curves (2–14) calculated on the basis of these data are plotted in Fig. 2.

Comparison with the $\log K_2$ value of 3.42 for $[AtBr_2]^-$ shows that all type A and C, as well as ligands B1 and D1, are more likely to coordinate with AtBr than Br^-. The order of stability constants corresponds to that which can be derived from Fig. 1.

In comparing the measurements with protonated amines and diamines free of heteroatoms, *no* complexes of these compounds with astatine(I) could be proved. This is an indication that under the measurement conditions (pH* being 3) no bonding of astatine(I) to nitrogen is established.

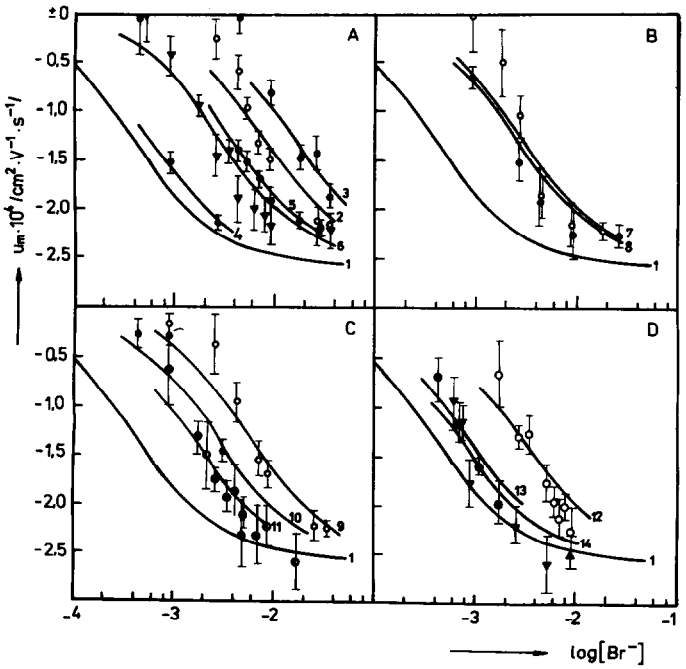

Fig. 2. Ion mobility, u_m, of astatine(I) in bromide-containing ethanolic solutions of 11 ligands at 298 K [0.05 M ($NaBr+NaClO_4$), $HClO_4$ (pH* = 3)]: 1, without organic ligand; 2, A1 0.002 M; 3, A1 0.004 M; 4, A2 0.00011 M; 5, A3 0.002 M; 6, A4 0.002 M; 7, B1 0.002 M; 8, B2 0.002 M; 9, C1 0.002 M; 10, C1 0.0008 M; 11, C2 0.00052 M; 12, D1 0.002 M; 13, D2 0.002 M; 14, D7 0.004 M.

The A1 ligand shows the strongest donor effect for astatine(I). The similarly constructed ligand D6 which is free of nitrogen is clearly less apt to complex formation. By comparing the log K values it can be stated, in general, that nitrogen-containing ligands form more stable [AtXL] complexes than nitrogen-free ligands. The undissociated [AtX] complex is probably coordinated by the chelating ligand. An interaction between the protonated nitrogen and the X^- halogenide in [AtXL] could cause the increase in stability.

Table 3. Stability constants, log K, for AtBrL {[AtBr]+L = [AtBrL]; $\mu = 0.05$ M, $T = 298$ K, pH* = 3, EtOH}

Ligand	Log K Error	n
A1	3.99±0.02	17
A3	3.64±0.02	7
A2	3.60±0.04	16
A4	3.59±0.03	23
B1	3.63±0.04	7
B2	3.42±0.04	8
C1	3.83±0.02	26
C2	3.71±0.03	15
D1	3.49±0.02	21
D2	2.75±0.04	7
D7	2.24±0.04	15

The D1 ligand with a relatively high stability constant is an exception among the type D ligands. A similar effect of increased stability was reported for alkali ion complexes in which chelating ligands with OH-groups at the chain ends are involved.[17] In the case of astatine(I), an interaction between two OH-groups at the chain ends or their lower steric hindrance in comparison with alkyl groups (D2) may be decisive.[36]

The C1, C2 and C3 ligands differ in donor effect which correlates with the length of the alkyl group at nitrogen. The A1, A2 and A4 ligands differ in the number of oxygen atoms among the sulphur atoms which influences the complex stability. A similar effect was noticed in the complex formation of silver(I) with open-chain ligands[4] and with macrocycles.[37] Thereby, the $—S(CH_2)_2O(CH_2)_2S$ group showed a stronger donor affinity than $—S(CH_2)_2S—$; this was explained due to less steric hindrance occurring in chelate formation between the metal and sulphur. The number of oxygen atoms in sulphur-containing chelating ligands influences the complex stability and extraction behaviour in the case of copper(II) also.[3]

The slight difference between A3 and A4 can be based on steric effects of the CH_2 groups. The ligands B1 (secondary amine) and B2 (tertiary amine) differ in the basicity of the nitrogen atom and in the required space of the end groups. The complex stability decreases with growing substitution at nitrogen and decreasing basicity. There is only a slight difference in affinity between B2 and B3. This effect is also found in the case of copper(II) complexes with similar ligands.[12]

The exchange of oxygen (D7) for nitrogen, as well as the exchange of nitrogen (B2) for S(C2), leads to an increase in the complex stability of the [AtXL] type of complexes. It would be of interest to study the stability of astatine complexes with cyclic analogues of the investigated ligands or with cyclic sulphides[38–40] such as (14)-ane-S_4, (18)-ane-S_6 and (28)-ane-S_8. Considering the size of the astatine(I) cation (r = 122 pm[41]), sulphur-containing analogues of 16-crown-5[42] could be suitable for that purpose.

Acknowledgements—We wish to thank Professor Dr sc. G.-J. Beyer and his team at the ZfK Rossendorf cyclotron for their cooperation. Furthermore, thanks are due to Dr Beckert (Friedrich-Schiller University, Jena) for the synthesis of D3 and D8 compounds, as well as to Mrs C. Reizenstein for drawing the figures.

(*Received* 9 *May* 1990; *accepted* 6 *August* 1990)

Abstract—Complexes of the nine-membered macrocyclic ligand 1-thia-4,7-diazacyclononane (L^1) with platinum(IV), gold(III) and silver(I) have been prepared and the X-ray crystal structures of $[Pt^{IV}(L^1)Br_3]Br_{0.5}Cl_{0.5}\cdot 2H_2O$ (**1a**), $[Au^{III}(L^1)Cl_2][AuCl_4]$ (**2a**) and $[Ag_4(L^1)_4](CF_3SO_3)_4$ (**3a**) determined. In the octahedral cation of **1a** the ligand is bound facially. Complex **2a** contains a planar $AuCl_2N_2$ unit and the thioether group is weakly donating [Au—S = 2.973(3) Å] to an axial site. In **3a**, four AgL^1 units are bridged by thioether groups to a centrosymmetrical $[Ag_4(L^1)_4]^{4+}$ tetramer. The exodentate Ag—S [2.403(2) and 2.415(2) Å] bonds are rather short.

The nine-membered macrocyclic ligands 1,4,7-triazacyclononane (L^2) and 1,4,7-trithiacyclononane (L^3) have been shown to bind to a range of transition metal ions whose coordinative properties are not fully compatible with facial binding of these ligands, e.g. Pd^{II},[1,2] Pt^{II},[1] Ag^I,[3] and Au^I and Au^{III}.[4] This has led to a number of complexes with unusual stereochemical and redox properties. We have been investigating this aspect recently using the mixed N_2S donor set macrocyclic ligand 1-thia-4,7-diazacyclononane (L^1).[5] We have shown that in $[Pd(L^1)_2]^{2+}$ the central ion is octahedrally coordinated and in addition to the square-planar PdN_4 group the S-donor atoms are weakly donating towards the axial positions. In $[Pt(L^1)_2]^{2+}$, however, the S-donor atoms are bent away from the central ion, which then is in a square-planar N_4 environment only. The electrochemical properties of both complexes are also different.[5,6] The platinum(II) complex is easily oxidized to a platinum(IV) species, even by atmospheric oxygen. The structure of this species, $[Pt^{IV}(L^1)Br_3]Br_{0.5}Cl_{0.5}\cdot 2H_2O$ (**1a**), is described in this paper.

Gold(III) is isoelectronic with palladium(II) and platinum(II). We have, therefore, prepared gold (III) complexes of L^1 in order to compare their structures with the aforementioned palladium(II) and platinum(II) complexes, especially with respect to the binding of the thioether group. Complexes of silver(I) exhibit a preference for linear two-coordination, and occasionally, tetrahedral four-coordination. Polydentate macrocyclic ligands enforce higher coordination numbers and irregular geometries.[7,8] L^3 forms monomeric trigonal-antiprismatic silver(I) complexes, $[Ag(L^3)]^+$, tetrahedral, $[Ag(L^3)Cl]$, and trimeric, $[Ag_3(L^3)_3]^{3+}$, complexes.[3] Silver(I) complexes of L^2 are unknown so far. Therefore, it seemed interesting to investigate the binding properties of 1-thia-4,7-diazacyclononane with silver(I) as well. A monomeric complex of the related hexadentate bis-coronand L^4 has been characterized very recently.[9]

EXPERIMENTAL

Preparation of 1-*thia*-4,7-*diazacyclononane* (L^1)

$L^1\cdot 2HBr$ was prepared as described previously.[10] To obtain the free ligand, NaOH (1 g) was added to an aqueous solution (10 cm^3) of

* Author to whom correspondence should be addressed.

$L^1 \cdot 2HBr$ (0.34 g, 1.1 mmol), which was extracted several times with $CHCl_3$. The solutions were combined and dried over Na_2SO_4. The solvent was distilled off, and the resultant yellow oil dissolved in a suitable solvent.

Preparation of $[Pt(L^1)Br_3]Br_{0.5}Cl_{0.5} \cdot 2H_2O$ (**1a**) *and* $[Pt(L^1)Br_3]Br_{0.5}Cl_{0.5} \cdot H_2O$ (**1b**)

To an aqueous solution of K_2PtCl_6 (0.2 g, 0.4 mmol) a solution of $L^1 \cdot 2HBr$ was added. After several days yellow prismatic crystals of **1a** and orange crystals of **1b** (as thick needles) precipitated in approximately equal amounts. Yield 0.16 g (60%). They were separated mechanically (**1a**: Found: C, 11.2; H, 2.8; N, 4.5. Calc. for $[Pt(L^1)Br_3]Br_{0.5}Cl_{0.5} \cdot 2H_2O$: C, 10.7; H, 2.7; N, 4.1%. **1b**: Found: C, 11.1; H, 2.3; N, 4.6. Calc. for $[Pt(L^1)Br_3]Br_{0.5}Cl_{0.5} \cdot H_2O$: C, 11.0; H, 2.5; N, 4.3%.) Probably the bulk material of **1a** had a higher bromine content than the crystals used for X-ray diffraction (see below).

Preparation of $[Au(L^1)Cl_2][AuCl_4]$ (**2a**)

A small amount of well-formed dark red crystals was obtained in a U-shaped tube by slow interdiffusion of solutions of $HAuCl_4$ (0.68 g, 2 mmol) and of L^1 (0.3 g, 2 mmol) in methanol (5 cm^3) through a porous glass membrane. (Found: C, 9.3; H, 1.8; N, 3.6. Calc. for $[Au(L^1)Cl_2][AuCl_4]$: C, 9.6; H, 1.9; N, 3.7%.)

Preparation of $[Au(L^1)Cl_2]Cl$ (**2b**)

L^1 (0.15 g, 1 mmol) dissolved in methanol (10 cm^3) was added to a solution of $HAuCl_4$ (0.34 g, 1 mmol) also in methanol (20 cm^3). After a few minutes, orange–red needles appeared from the solution. Yield 0.11 g (50%). (Found: C, 16.2; H, 3.1; N, 6.4. Calc. for $[Au(L^1)Cl_2]Cl$: C, 16.0; H, 3.1; N, 6.2%.)

Preparation of $[Ag_4(L^1)_4](CF_3SO_3)_4$ (**3a**)

$Ag(CF_3SO_3)$ (0.3 g, 1.2 mmol) was added to a solution of L^1 (1.1 mmol) in CH_3CN (10 cm^3) under nitrogen. After some minutes the complex precipitated as a white powder. Yield 0.13 g (30%). Crystals of X-ray quality were obtained by recrystallization from CH_3CN. (Found: C, 20.8; H, 3.5; N, 7.0. Calc. for $[Ag_4(L^1)_4](CF_3SO_3)_4$; C, 20.8; H, 3.5; N, 6.9%.)

Preparation of $[Ag_4(L^1)_4](PF_6)_4$ (**3b**)

A solution of $AgNO_3$ (0.17 g, 1 mmol) and $NaPF_6$ (0.5 g) in CH_3CN (10 cm^3) was added to a solution of L^1 (1.1 mmol) in CH_3CN (10 cm^3). The complex precipitated immediately. Yield 0.31 g (70%). Large octahedral crystals of X-ray quality were obtained by recrystallization from CH_3CN. The crystals were slightly sensitive to light. (Found: C, 18.1; H, 3.5; N, 7.0. Calc. for $[Ag_4(L^1)_4](PF_6)_4$: C, 17.8; H, 3.3; N, 7.0%.)

Preparation of $[Ag(L^1)][ClO_4)$ (**3c**)

L^1 (0.15 g, 1 mmol) dissolved in CH_3OH (40 cm^3) was dropped slowly into a solution of $AgClO_4$ (0.21 g, 1 mmol) in CH_3OH (10 cm^3). During the addition a white compound precipitated. Yield 0.23 g (65%). Recrystallization from water yielded colourless thin needles. (Found: C, 20.7; H, 3.9; N, 7.7. Calc. for $[Ag(L^1)][ClO_4)$: C, 20.4; H, 4.0; N, 7.9%.)

X-ray crystallography

Details of the crystal structure determinations are summarized in Table 1. Suitable crystals were sealed in Lindemann capillaries, and the unit cells and space groups obtained using Weissenberg photography. Diffraction studies were performed on CAD4 or Syntex $P2_1$ automated diffractometers. Graphite monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) was used. Unit cells and orientation matrices were determined by least-squares treatment of 20–25 machine-centred reflections having $2\theta > 20°$. Two or three check reflections were measured periodically to monitor crystal decay. Data were corrected for Lorentz and polarization effects. Empirical absorption corrections were applied to all data. The structures were solved by Patterson or direct methods and refined by full-matrix least-squares methods by using the SHELXTL-PLUS[11] program. Anisotropic thermal parameters were refined for all non-hydrogen atoms. Hydrogen atoms were included in calculated positions with isotropic thermal parameters fixed ($U_H = 0.008$ Å) or tied to the bonded carbon atom ($U_H = 1.2U_C$). The weighting scheme $w^{-1} = \sigma(F)^2 + gF_o^2$ (for g see Table 1) was used. Individual features of the structures are outlined below.

$[Pt(L^1)Br_3]Br_{0.5}Cl_{0.5} \cdot 2H_2O$ (**1a**). Due to the preparative routine the single crystal studied contained both Br^- and Cl^- as non-complexing anions. The halide ions occupy statistically the same crystallographic site. Refinement of the site occupation

factors resulted in the composition $Br_{0.51(2)}$ and $Cl_{0.49(2)}$.

$[Ag_4(L^1)_4](CF_3SO_3)_4$ (**3a**). During data acquisition the intensities of the check reflections dropped to approximately 56%. A correction for decay was therefore applied to the data.

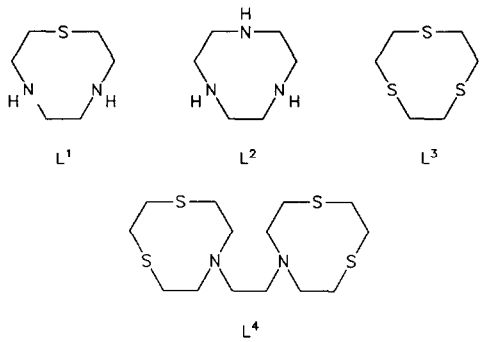
$[Pt(L^1)Br_3]Br_{0.5}Cl_{0.5}\cdot H_2O$ (**1b**). Crystal data: orthorhombic, space group *Pnma*, $a = 14.515(5)$, $b = 36.593(7)$, $c = 12.822(3)$ Å, $V = 6810.4$ Å^3, $Z = 20$. This structure was also solved (5869 reflections, $R = 0.0601$). The unit cell contains three independent $[Pt(L^1)Br_3]^+$ ions with the same bonding parameters as the cation of **1a**. The structure is not therefore further discussed.

$[Ag_4(L^1)_4](PF_6)_4$ (**3b**). Crystal data: tetragonal, $a = 12.918(7)$, $c = 14.864(9)$ Å, $V = 2476.7$ Å^3, $Z = 2$. Using a twinned crystal the structure of **3b** was refined to $R = 0.22$. Like **3a** the structure contains tetrameric, S-bridged $[AgL^1]_4^{4+}$ ions. No further efforts were made, therefore, to determine the twinning law and the true space group of **3b**.

RESULTS AND DISCUSSION

(a) *Platinum*(IV) *compounds*

Compounds **1a** and **1b** were prepared from K_2PtCl_6. In reactions of K_2PtCl_4 with L^1, which were performed in air, considerable amounts of **1a** or **1b** were also detected.[6] Obviously, platinum(II) is easily oxidized to platinum(IV) in the presence of L^1. The loss of the d_{z^2} electrons is considerably favoured, because the thioether donor atoms of L^1 closely approach the axial sites of the square planar platinum(II) coordination sphere. After oxidation a strong Pt^{IV}—S bond is formed. Both **1a** and **1b** contain $[PtL^1Br_3]^+$ cations and statistically distributed over the same crystallographic site, Cl^- or Br^- anions. In the cation, platinum(IV) is octahedrally coordinated (see Fig. 1) with L^1 in a facial position. The bond angles between all donor atoms are close to 90 or 180°. The Pt—Br, Pt—N and Pt—S bond distances are in the expected range,



Scheme 1.

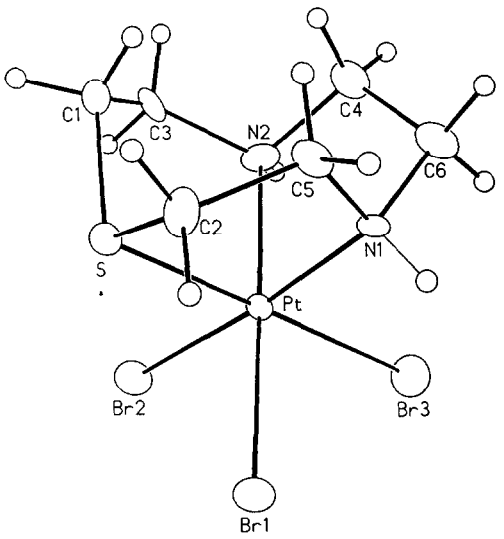


Fig. 1. Structure of the $[Pt(L^1)Br_3]^+$ ion in **1a**.

close to the sums of the respective covalent radii (see Table 2). The Pt—S bond shows a distinct *trans* effect; the Pt—Br bond opposite to the Pt—S bond is significantly ($\geqslant 10\sigma$) larger than the Pt—Br bonds in the adjacent positions.

Strong hydrogen bonds connect the non-complexed Cl^- and Br^- anions with N(1) and the water molecule O(2). Further hydrogen bonds exist between N(2) and O(2), and O(1) and O(2).

(b) *Gold compounds*

The gold(III) complexes **2a** and **2b** were easily prepared from stoichiometric solutions of L^1 and $HAuCl_4$. Only the structure of **2a** has been determined so far. According to the IR spectra **2b** contains, very probably, the same type of cation as well. In **2a** the metal centre of the $[Au(L^1)Cl_2]^+$ ion is bound in a planar fashion by two Cl atoms (mean Au—Cl = 2.27 Å) and by the two N-donors of L^1 (see Fig. 2). The mean Au—N distance (2.07 Å) is slightly shorter than in $[Au(dmp)Cl_3]$[12] or $[Au(en)(SO_3)_2]^-$,[13] where the distances 2.09 and 2.12 Å, respectively, have been found. The S-donor participates in a long-range apical coordination with the metal centre [Au—S = 2.973(3) Å]. Gold is lying 0.07 Å out of the Cl_2N_2 plane towards the S-donor. The Au—S vector is inclined 82.8° to this plane. Thus, the binding of the ligand is very similar to $[Au(L^3)_2]^{3+}$, where four Au—S bonds define a square (mean Au—S = 2.35 Å), while the remaining two donors are weakly interacting apically (Au—S = 2.929 Å). Apical interactions of the third donor atom of the nine-membered macrocyclic ligands, L^1, L^2 and L^3, have been observed so far in $[Pd(L^1)_2]^{2+}$,[5] $[Pd(L^3)_2]^{2+}$ and $[Pt(L^3)_2]^{2+}$,[1] but not in $[Pt(L^1)_2]^{2+}$,[5] $[Pt(L^2)_2]^{2+}$ [1] and $[Pd(L^2)_2]^{2+}$.[14] Obviously the affinity to the S-donor of L^1 increases from platinum(II) to gold(III). The structure of **2a** is completed by two $[AuCl_4]^{2-}$ anions, positioned in inversion centres of the unit cell; the mean Au—Cl distance is 2.27 Å, as in the cationic part of the structure.

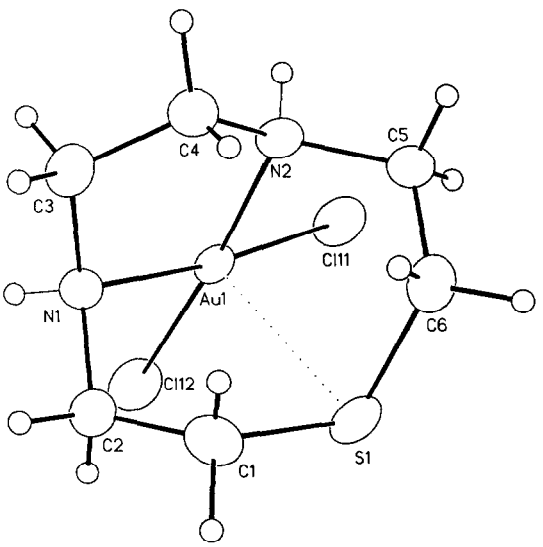

Fig. 2. Structure of the $[Au(L^1)Cl_2]^+$ ion in **2a**.

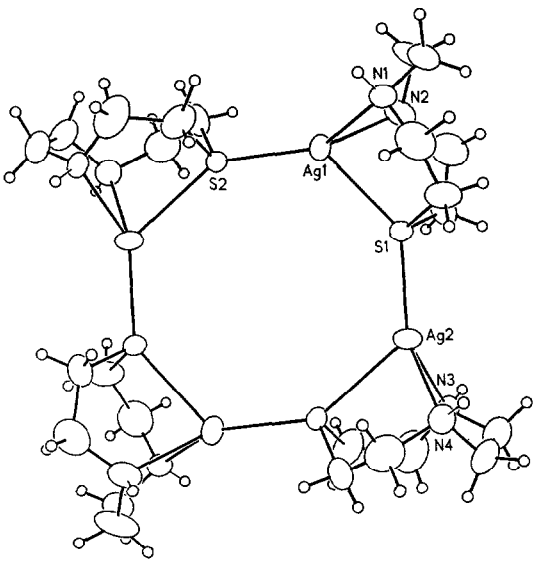

Fig. 3. Structure of the tetrameric $[Ag_4(L^1)_4]^{4+}$ ion in **3a**.

The $[AuCl_4]^-$ ions form hydrogen bridge bonds via Cl(32) and Cl(22) to N(1) [3.22(1) Å] and N(2) [3.295(1) Å], respectively. Further intermolecular contacts exist between Cl(21) and Au(1) (3.524 Å), in the direction of the empty apical site and, similarly, between Au(3) and Cl(11) (3.982 Å).

(c) *Silver compounds*

Using the non-complexing counterions $CF_3SO_3^-$ and PF_6^- and the metal : ligand ratio of 1 : 1, silver(I) forms cyclic tetranuclear complexes, $[Ag_4(L^1)_4]^{4+}$, with L^1, as shown by structure determination of **3a** and **3b**. The fully refined structure of **3a** contains the cyclic tetranuclear $[Ag_4L_4]^{4+}$ ion (see Fig. 3). Silver(I) is coordinated four-fold by two nitrogen and two sulphur atoms. Each sulphur atom in turn coordinates to two separate silver(I) ions to yield the cyclic tetramer, surrounding an inversion centre of the space group. The AgN_2S_2-tetrahedra are severely distorted; three X—Ag—X angles (X = nitrogen or sulphur within one macrocycle) are less than 80°, three X—Ag—S angles, with sulphur in the neighbouring ligand, are 127–140°. The coordination polyhedra of Ag(1) and Ag(2) differ slightly (see Table 4). The exodentate Ag—S distances [2.403(2) and 2.415(2) Å] are to our knowledge the shortest Ag—S bonds in thioether macrocyclic complexes observed so far. In the related thioether bridged trimer, $[Ag_3(L^3)_3]^{3+}$, the shortest exodentate Ag—S distance is 2.480(2) Å.[3] Ag—S distances in octahedrally coordinated sil-

ver(I) complexes with mixed N,S-donor and pure S-donor macrocycles are usually in the range 2.6–2.8 Å.[3,7–9] The endodentate Ag—S distances of **3a** [2.635(2) and 2.705(2) Å] also belong to this range.

The Ag—N distances in **3a** fall into the small range, 2.308(8)–2.369(9) Å, with the mean, 2.337 Å. There are no reports of other complexes of mixed N,S-donor macrocycles, where the central ion is coordinated tetrahedrally. In complexes with higher coordination numbers the Ag—N distances are larger and range from 2.368(7) for Ag—N (pyridine) to 2.589(10) for Ag—N (amide).[7–9]

In three dimensions, the tetrameric cations are positioned at the origin of the pseudo-tetragonal unit cell. In the cell centre and along the *c*-axis pairs of triflate ions are located. All N—H bonds of L^1 are engaged in weak hydrogen bridge bonds to oxygen atoms of the CF_3SO_3 anion. Besides **3a** and **3b**, $[AgL^1]ClO_4$ (**3c**) very probably forms a tetrameric complex cation as well.

(d) *Conformation of* L^1

According to an analysis of the torsional angles, L^1 shows in **1a** and **3a** the common [333] conformation, which is also typical for L^2 and L^3. The chelate rings have either $\lambda\lambda\lambda$ or $\delta\delta\delta$ conformation. In the gold complex **2a** the ligand adopts the [234] conformation which is usually observed in complexes of L^1, when the difference between the lengths of the M—N and M—S bonds exceeds approximately 0.3 Å, as with $[Cu(L^1)_2]$.[16] In this case the chelate rings show the $\lambda\lambda\delta$ or $\delta\delta\lambda$ conformation. According to Parker *et al.* the [333] and [234] conformations differ only slightly in energy.[4]

SYNTHESIS AND THERMAL STABILITY OF MIXED-LIGAND LANTHANIDE ORGANOMETALLICS INVOLVING BOTH CYCLOPENTADIENYL AND *o*-NITROPHENOLATO OR α-NITROSO-β-NAPHTHOLATO LIGANDS

ZHONGZHI WU* and ZHONGWEN YE

(*Received* 18 *January* 1990; *accepted* 13 *August* 1990)

Abstract—By reaction of Cp_3Nd or Cp_3Yb ($Cp = C_5H_5$) with *o*-nitrophenol (HNP) or α-nitroso-β-naphthol (HNN), eight new mixed-ligand lanthanide organometallics of the general formula $Cp_nLn(NP)_{3-n}$ and $Cp_nLn(NN)_{3-n}$ ($n = 1, 2$; NP = *o*-nitrophenolato ligand; NN = α-nitroso-β-naphtholato ligand; Ln = Nd, Yb) have been synthesized. All the complexes were characterized by elemental analyses, and IR and MS spectra, showing that they are chelates with NP and NN as bidentate chelate ligands. Their thermal stability has been studied and discussed.

Many inorganic and organometallic complexes are extremely susceptible to heat, and some of them may disproportionate at low temperatures.[1–3] Recently, we reported studies on the thermal stability of lanthanide complexes $Cp_2Sm(L)$ ($L = OCOCH_3$, Cl, Br, I)[4] and $Cp_nLn(L)_{3-n}$ ($n = 1, 2$; L = β-diketonato, 8-quinolinolato, *o*-aminophenolato, *o*-aldehydophenolato, furfuralcoholato ligand; Ln = Nd, Yb)[2,5–7] and found that they are thermally unstable and tend to disproportionate at moderately high temperatures. In continuation of our previous studies, we have now carried out the synthesis and the study of the thermal stability of eight new mixed-ligand (Nd, Yb) organometallic complexes containing both cyclopentadienyl (Cp) and *o*-nitrophenolato (NP) or α-nitroso-β-naphtholato (NN) ligands, and the results are reported in this paper.

RESULTS AND DISCUSSION

By adopting the very versatile method of liberating cyclopentadiene from a Cp_3Ln moiety by the action of protonic acids stronger than C_5H_6, we have synthesized the mixed-ligand lanthanide organometallic complexes by reaction of Cp_3Nd or Cp_3Yb with *o*-nitrophenol (HNP) or α-nitroso-β-naphthol (HNN) in tetrahydrofuran (THF) at room temperature. They are:

1 : 1 mole ratio of reactants	1 : 2 mole ratio of reactants
$Cp_2Nd(NP)$ (**1**)	$CpNd(NP)_2$ (**5**)
$Cp_2Nd(NN)$ (**2**)	$CpNd(NN)_2$ (**6**)
$Cp_2Yb(NP)$ (**3**)	$CpYb(NP)_2$ (**7**)
$Cp_2Yb(NN)$ (**4**)	$CpYb(NN)_2$ (**8**)

All these complexes were characterized by elemental analyses (Table 1), and IR (Table 2) and MS (Table 3) spectra.

The elemental analyses for all the complexes are in compliance with the general formula $Cp_nLn(L)_{3-n}$. They are soluble in THF and insoluble in pentane, n-hexane and other alkane solvents, but sparingly soluble in benzene and toluene. None of the complexes have melting points; decomposition is observed in a sealed capillary in the range 90–200°C.

The IR spectra of all the complexes show absorptions at approx. 250, 780, 1010, 1440 and 3080 cm^{-1}, characteristic of the η^5-Cp group.[8] All the complexes exhibit two bands in the IR spectra in the regions 1115 and 470 cm^{-1}. We attribute the first band to a Ln—O—C vibration mode and the second band to the ν(Ln—O) stretching.[9,10] Complexes **1**, **3**, **5** and **7** exhibit two absorptions at *ca* 1325 and 1510 cm^{-1}, attributable to the symmetric

and antisymmetric stretching vibrations of the NO_2 group, respectively. In the spectrum of the sodium salt of the ligand HNP, $\nu(NO_2)$ appears at 1334 and 1546 cm^{-1}. Therefore, the shift of the stretching vibrations of the NO_2 group to lower frequencies in these complexes may indicate the coordination of the NO_2 group.[10] The IR spectra of complexes **2**, **4**, **6** and **8** reveal that the ν(NO) in the sodium salt of the ligand HNN located at 1530 cm^{-1} is shifted to lower frequency on complexation to approx. 1476 cm^{-1}, suggesting coordination of the NO group.[11] In addition, the strong band of the phenolic-OH stretching vibration for the free ligand HNP or HNN at *ca* 3000 cm^{-1} does not appear in the IR spectra of any of the complexes. This also proves the presence of the Ln—O—C bond in each complex.

In the mass spectra of these complexes, the molecular ion peaks and main resulting fragments all appear. All the molecular ion intensities are low.

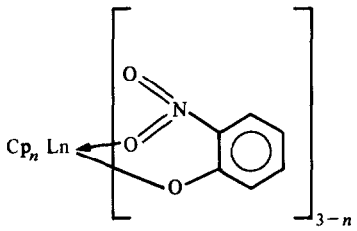
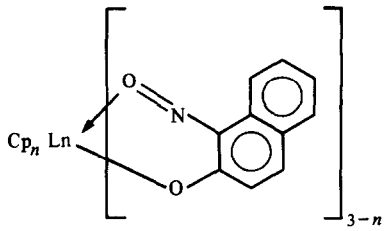
[a] MS data are given for the isotopes ^{142}Nd, ^{174}Yb, ^{14}N and ^{16}O, the peak patterns correspond to theoretical values based on the natural abundance of the isotopes.

They are characterized by ready loss of the Cp group with the $(M-Cp)^+$ ion as the base peak in the mass spectra. The ion peaks of $(M-L)^+$ (L = NP, NN) formed by direct loss of the NP or NN ligand of the molecular ion are very low. This is consistent with the results that Cp groups form η^5-bonds with metals, whereas NP and NN ligands chelate with the metal atom to form a chelating ring. Thus, the Ln—Cp bond is weaker than the Ln—L bond, and the former breaks easily under electron impact. However, it was observed that in the mass spectra, the loss of NO_2 or NO fragments occurs during cleavage. This feature can be attributed to the existence of the electron-withdrawing group NO_2 or NO weakening the C—NO_2 or C—NO bond strength, thus leading to easy fragmentation of the molecular ion.

From the above elemental and spectral analyses, it may be assumed that all the complexes are chelates with NP or NN as bidentate chelate ligands. This is in agreement with the fact that the greatest tendency to form chelate complexes is found with polyfunctional ligands whose donor atoms are separated by two or three carbon atoms, the chelating ring produced by chelate formation will be five- or six-membered. Therefore, the following structure for the eight new mixed-ligand complexes may be proposed (**1**, **2**).



(1)



(2)

In order to study the thermal stability of these complexes, their mass spectra were recorded at different evaporation temperatures. It is interesting to note that when the evaporation temperature of a sample of CpLnL-type complexes reaches a certain value, not only are the molecular ions $CpLnL_2^+$ observed in the spectra, but the peaks corresponding to Cp_2LnL^+ and their fragments are observed also. Furthermore, by increasing the evaporation temperature, the molecular ion peaks of $CpLnL_2^+$ gradually disappear and the peaks of Cp_2LnL^+ and its fragments are enhanced. In addition, we interestingly found that when the evaporation temperature reaches a moderately high value, the ion peaks of Cp_2NdL^+ completely disappear and the strong peaks corresponding to Cp_3Nd^+ and its fragments are observed instead. However, no Cp_3Yb^+ ion peak is observed in the mass spectra of complexes of $CpYbL_2$ or Cp_2YbL. Thus, based on the above results, we predict that the complexes may undergo the following disproportionation reactions during the course of raising the temperature:

$$2CpLnL_2 \rightarrow Cp_2LnL + LnL_3 \quad (1)$$

$$3Cp_2LnL \rightarrow 2Cp_3Ln + LnL_3. \quad (2)$$

This feature is consistent with the results reported in our previous studies.[6,7] The ion peaks of disproportionation products LnL_3 do not appear in the mass spectra.

In view of the mass spectra, we also found that complexes of ytterbium, either of the Cp_2LnL- or $CpLnL_2$-type, are thermally more stable than the analogues of neodymium. Above 160°C, the disproportionations of four neodymium complexes are apparently complete. But even at 300°C, the Cp_2YbL-type complexes still remain unchanged. We assume that the greater thermal stability of the ytterbium complexes compared with their neodymium analogues is due to the lanthanide contraction. As the radius of Yb^{3+} is smaller than Nd^{3+}, the attraction of the Yb—ligand bond formed by Yb^{3+} and an anionic ligand will be stronger than the Nd—ligand bond. Another reason for the superior thermal stability of ytterbium complexes may be due to the greater steric saturation present around the smaller metal centre.[12,13]

Probably due to the large radii and coordinative unsaturation of light lanthanides, their organometallic complexes involving both Cp and Cl groups, such as unsolvated Cp_2LnCl and $CpLnCl_2$ (Ln = La, Ce, Pr and Nd), have not yet been synthesized at room temperature.[3,14] The reported facile preparation of the unsolvated and room-temperature stable complexes $Cp_nNd(L)_{3-n}$ (n = 1, 2; L = NP, NN) is obviously due to stabilization of the species by the chelation effect. This also revealed that the steric bulky ligands are favourable for the stabilization of the Ln—C bond.

EXPERIMENTAL

Materials

All operations were carried out in an atmosphere of dry oxygen-free argon using standard Schlenk techniques or in a glove box. All solvents were dried over sodium, refluxed over sodium benzophenone or finely divided $LiAlH_4$, and distilled immediately before use. HNP and HNN were of chemically pure grade, and were dried *in vacuo* before use. Cp_3Nd and Cp_3Yb were prepared and purified by the literature method.[15]

Physical measurements and elemental analyses

IR spectra were recorded on a Perkin–Elmer 983G IR spectrophotometer as Nujol and Fluorolube mulls between CsI plates (200–4000 cm^{-1}). All the mass spectrometric measurements were performed on a MAT 312 mass spectrometer operating in the EI mode at a resolving power of 1000 (electron energy, 70 eV; emission current, 1 mA; ion acceleration, 3 kV). The samples were introduced by direct inlet techniques with a source temperature of 130°C and a sample evaporation temperature in the range 20–300°C.

Metal analyses for lanthanides were accomplished using the literature method.[16] Elemental analyses for carbon, hydrogen and nitrogen

were carried out on a Yanaco MT2 CHN analyser. Decomposition points were determined in a sealed capillary filled with argon and are uncorrected.

Preparation of complexes $Cp_2Ln(NP)$ *and* $CpLn(NP)_2$

A THF solution (20 cm^3) of HNP (1.5 mmol or 3.0 mmol) was added dropwise to a THF solution 30 cm^3) of Cp_3Nd or Cp_3Yb (1.5 mmol) at room temperature. After stirring for 24 h at room temperature, the resulting solution was concentrated via vacuum to *ca* 15 cm^3. On the addition of 40 cm^3 of n-hexane, a solid precipitated out, which was recrystallized twice from THF–n-hexane, washed with n-hexane and dried *in vacuo* to afford the product. Yields and elemental analyses are given in Table 1.

Preparation of complexes $Cp_2Ln(NN)$ *and* $CpLn(NN)_2$

A THF solution (20 cm^3) of HNN (1.5 or 3.0 mmol) was added dropwise to a THF solution (30 cm^3) of Cp_3Nd or Cp_3Yb (1.5 mmol) at room temperature. The reaction solution was allowed to stir for 24 h at room temperature. A solid gradually precipitated, which was separated out by centrifugation, washed twice with n-hexane and dried *in vacuo* to afford the product. Yields and elemental analyses are listed in Table 1.

ACCEPTOR BEHAVIOUR OF A $Mo^{VI}O_2$(ONO) COMPLEX WITH IMIDAZOLE LIGANDS

R. N. MOHANTY, V. CHAKRAVORTTY and K. C. DASH*

Department of Chemistry, Utkal University, Vani Vihar, Bhubaneswar-751004, India

(*Received* 3 *May* 1990; *accepted* 13 *August* 1990)

Abstract—A molybdenum(VI) complex of the type MoO_2(ONO) (ONO is a dibasic tridentate Schiff base ligand H_2SAE), reacts with imidazole or its derivatives (L) to yield [MoO_2(ONO)(L)] complexes that are yellow, diamagnetic, non-electrolytic octahedral complexes. The IR spectra have three characteristic bands in the region 890–940 cm^{-1}, attributable to the *cis*-MoO_2 stretching vibrations in addition to the vibrations of the Schiff base ligand and the imidazole ligand. The ^{1}H NMR spectra reveal the coordination of the ligands to the MoO_2^{2+} core. Cyclic voltammetric measurements provide the cathodic reduction potentials (E_{pc}) for the irreversible reduction of the molybdenum(VI) complexes and in all cases this value spans the range from −1.1 to −1.2 V vs Ag/AgCl.

Molybdenum is an important trace metal in enzymes.[1–3] It has a range of stable and accessible oxidation states in which coordination numbers can vary from four to eight.[4] The one- and two-electron transfer capability associated with molybdenum and its ability to couple ion (e.g. O^{2-}) transfer with electron transfer may be crucial to the chemical role played by molybdenum in enzymes. Many simple molybdenum(VI) complexes contain the *cis*-MoO_2^{2+} ion, which has been shown to be present in certain enzymes[5,6] on the basis of EXAFS studies.

This paper reports some dioxomolybdenum(VI) complexes, where the *cis*-MoO_2^{2+} group is attached to a planar tridentate ligand spanning three coordination positions and leaving the fourth position to be bonded by a substrate like imidazole or its derivatives; significantly important molecules from a biological point of view. Similar complexes involving other tridentate ligands have been reported by us[7] and others.[8,9]

EXPERIMENTAL

Materials

Salicylaldehyde (BDH) and 2-amino-1-ethanol (Sisco-Chem, India) were used as available commercially. Although the tridentate dibasic Schiff base ligand, N-(hydroxyethyl) salicylideneimine (H_2SAE), has been reported[10] to have been obtained as an amber oil, no attempt was made to isolate it. This ligand could be conveniently generated in solution phase by mixing the components in EtOH (*in situ*) and was then available for reaction with the metal component.

$MoO_2(acac)_2$ is a very convenient source of the MoO_2^{2+} ion and could be prepared either from Na_2MoO_4[11] or from $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$[8] and acetylacetone by adjusting the pH.

Synthesis of complexes

MoO_2(SAE)(Im) (Im = *imidazole*). Salicylaldehyde (0.12 cm^3, 1 mmol) and 2-amino-1-ethanol (0.06 cm^3, 1 mmol) were dissolved in 5 cm^3 of EtOH and refluxed for about 30 min to give a yellow solution containing the H_2SAE ligand *in situ*. To this ligand solution was added imidazole (0.136 g, 2 mmol) in EtOH (2 cm^3) and the mixture was magnetically stirred for 10–15 min before $MoO_2(acac)_2$ (0.33 g, 1 mmol) dissolved in EtOH (10 cm^3) was added slowly. The entire mixture was held under reflux for 60 min with continued stirring, after which the volume of the solvent was reduced to almost half. On cooling the mixture and storing in a refrigerator overnight the yellow solid separated out and was collected on a glass frit, washed

* Author to whom correspondence should be addressed.

several times with EtOH followed by ether and dried *in vacuo* over P_4O_{10}. Yield 0.2 g, 55%.

All other complexes involving the substituted imidazoles were prepared in a similar manner.

Physical measurements and analyses

The FT–IR spectra in KBr phase, FT–NMR spectra in $(CD_3)_2CO$ medium, electrical conductivities in $MeNO_2$ and the determinations of Mo, C, H and N were carried out as reported earlier.[12] Cyclic voltammetric measurements were made using PAR equipment comprising a three-electrode system of glassy carbon, platinum wire and Ag/AgCl (satd LiCl) electrodes as the working, auxillary and reference electrodes, respectively, using $(Bu_4N)(PF_6)$ (0.1 M) as the supporting electrolyte. All potential measurements were standardized by comparing with a ferrocenium/ferrocene couple.[13]

RESULTS AND DISCUSSION

The biological activity of molybdenum mostly involves the molybdenum(VI) state,[3] the chemistry of which is largely centred around the oxomolybdenum compounds, MoO_2^{2+}, with the two oxygens mutually *cis*. Five-coordinated molybdenum(VI) complexes with the *cis*-MoO_2^{2+} core are rare and the dioxomolybdenum(VI) complexes are mostly octahedrally coordinated.[4,14] The reaction of a dibasic, tridentate ligand with MoO_2^{2+} renders the sixth coordination site vacant in the electrically neutral molybdenum(VI) complex[9,15–17] and this may be envisaged as providing a suitable bonding site for substrates during a catalytic cycle. The tridentate ligand which was made to react with MoO_2^{2+} in the presence of imidazole base was obtained[10] by condensation of 2-amino-1-ethanol with salicylaldehyde and is abbreviated as H_2SAE. The source of the MoO_2^{2+} core was $MoO_2(acac)_2$ which could be easily prepared[8] in pure form and partial or total exchange of acac groups by other ligands takes place readily.[12,18] The displacement of both the acac groups from $MoO_2(acac)_2$ to form compounds of the type $MoO_2(SAE)(Im)$ has been confirmed by the isolation of $Cu(acac)_2$ quantitatively from the filtrate after the reaction of $MoO_2(acac)_2$ with H_2SAE and imidazole ligands. Further confirmation of the formation of these compounds, reported in Table 1, has been obtained from IR and ^1H NMR spectra. All compounds are yellow, diamagnetic and non-electrolytic. The ligand H_2SAE has an intense band at 1638 cm^{-1} assigned to coupled ν(C=N) vibrations,[10] which is shifted to lower frequencies and appears as a split band in the region close to 1600 cm^{-1}, suggesting coordination as an anionic ligand through the O and N atoms.[19,20] The aromatic ν(C—O) and the aliphatic ν(C—O) vibrations occur at 1550 and 1040 cm^{-1}, respectively. The broad hydrogen-bonded

[a] Abbreviations: H_2SAE = N-(hydroxyethyl)salicylideneimine, Im = imidazole; Et = ethyl; Bu = butyl; Vi = vinyl; Al = allyl; Me = methyl; BzIm = benzimidazole.

[b] All measurements in $MeNO_2$.

[c] Volts vs Ag/AgCl.

—OH stretch near 2700 cm^{-1} of the free ligand is absent in the complexes, suggesting coordination of the ligand as a deprotonated, dianionic ligand. The IR bands due to the imidazole derivatives occur in almost identical positions and can be easily assigned.[21] The formation of Mo—O bonds with the Schiff base results in the appearance of few medium to strong bands in the 550–650 cm^{-1} region,[22] and formation of Mo—N bonds with the Schiff base and imidazole results in the appearance of additional bands in the 520–600 cm^{-1} region.[23] All the complexes exhibit three IR bands in the region 890–938 cm^{-1} due to the *cis*-MoO_2^{2+} group.[8] The *trans*-MoO_2^{2+} configuration would have resulted in a single ν(Mo=O) band.

The ^{1}H NMR spectra of complexes in $(CD_3)_2CO$ reveal the coordination of the ligands to the MoO_2^{2+} core. The aldiminic proton (—N=CH—) appears as one proton singlet at 8.19 ppm in the ligand,[10] shifting somewhat down field to 8.67 ppm for the complexes. The aromatic protons are observed as a multiplet centred around 7.5 ppm. The methylene signals of the ligand backbone are seen as two sets of triplets at 3.89 and 4.51 ppm in the complexes. The imidazole protons in the complexes appear[24] at 7.84, 7.08 and 7.07 ppm for H-2, H-4 and H-5, respectively, and the proton signals for the substituents in the imidazole ring are appropriately assigned. The proton signals at 2.4 ppm for the 2-Me; at 1.3 and 4.0 ppm for the CH_3 and CH_2 of 1-Et; at 5.14, 5.46 and 6.95 ppm for 1-Vi and at 4.05, 4.95 and 5.30 ppm for 1-allyl substituents in the imidazole ring are observed.

The cyclic voltammetric measurements provide the values for cathodic reduction potentials. The complexes do not show any observable oxidation wave after the reverse anodic scan in the cyclic voltammogram indicating irreversible redox behaviour.[25,26] The reductions observed are irreversible and the cathodic reduction potentials (E_{pc}) in CH_3CN medium are all obtained in the narrow range of -1.1 to -1.2 V vs Ag/AgCl.

Abstract—A nickel(II) complex with S-methyl-β-N-(pyridine N-oxide-2-ylmethylidene) dithiocarbazate (LH) and pyridine (Py) as ligands with the formula $[NiLPy]ClO_4$ has been synthesized. The crystal structure has been determined by X-ray diffraction analysis. Sulphur, nitrogen and oxygen atoms of the tridentate ligand, as well as a nitrogen atom of one additive pyridine, adopt a planar conformation to produce the square planar geometry at each nickel atom. Magnetic susceptibility and IR spectra are interpreted in accordance with the proposed stereochemistry.

Transition metal complexes with Schiff base ligands containing sulphur and nitrogen atoms have been widely studied for their unique anti-tumour and anti-bacterial activities in recent years.[1–4] Although many papers focused on the characteristic and spectroscopic properties of these complexes, X-ray structure determinations are few. Recently, we reported two new tridentate Schiff base ligands derived from S-alkyldithiocarbazate with 2-pyridinecarboxaldehyde N-oxide and their four-coordinate copper(II) complexes.[5] To further explore the relationship between structure and activity of such complexes, the crystal structure of [NiL Py]ClO_4 has been studied and is reported in this paper.

EXPERIMENTAL

Preparation of the complex

A solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (1 mmol) and LH[5] (1 mmol) in ethanol (60 cm^3) was refluxed for 5 min, then pyridine (2 mmol) dissolved in ethanol (10 cm^3) was added. After refluxing for 10 min, the mixture was filtered while hot. The filtrate was left at room temperature, brown–red crystals were obtained with a yield of 80%. Found: C, 33.7; H, 2.8; N, 11.7. Calc. for $NiC_{13}H_{13}ClN_4O_2S_2$: C, 33.6; H, 2.8; N, 12.1%.

Crystallographic analysis

Crystal data are given in Table 1. A suitable crystal (0.25 × 0.32 × 0.60 mm) obtained from slow diffusion of ether (20 cm^3) into an acetonitrile solution (5 cm^3) of the complex was mounted on a glass fibre in random orientation. Unit cell and intensity data were obtained using a R3M/E four-circle diffractometer and graphite-monochromatized Mo-K_α radiation in a ω–2θ scan mode with a range of $2° < 2\theta < 45°$. The structure was solved by the direct method, Lorentz and polarization corrections but no absorption corrections were made. Hydrogen atoms were located on the difference Fourier map. The coordinate parameters of all the atoms, anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters

for hydrogen atoms, were refined by the full-matrix least-squares method.

Atomic scattering factors and anomalous dispersion corrections for all non-hydrogen atoms were taken from *International Tables for X-Ray Crystallography*.[6] Final atomic coordinates and thermal parameters and lists of F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request.

Measurements

Magnetic susceptibility was measured in the solid state at room temperature (283 K) using a Gouy balance with $[Ni(en)_3]S_2O_3$ as calibrant. IR absorption spectra from 4000 to 400 cm^{-1} were obtained on a 170SX FT–IR instrument with samples prepared as solid KBr pellets.

RESULTS AND DISCUSSION

Crystal structure

The X-ray crystal structure of $[NiLPy]ClO_4$ is shown in Fig. 1 with the atomic numbering scheme. Figure 2 is a view of the packing and selected bond lengths and angles are listed in Table 2.

The geometry of the tetra-coordinated nickel atom is square planar. S(1), N(3) and O(1) atoms of the tridentate ligand, and the N(1) atom of the additive pyridine form a least-squares plane, deviations (Å) of atoms from their least-squares plane are S(1), −0.0399; N(3), 0.0429; O(1), −0.0461; and N(1), 0.0430 Å. The nickel atom is located in the centre of that plane, with a deviation < 0.01 Å. Ni—N, Ni—O, Ni—S distances are standard for low-spin nickel(II) compounds. Bond angles of S(1)—Ni—N(3), N(3)—Ni—O(1), O(1)—Ni—N(1) and N(1)—Ni—S(1) are 87.6, 94.6, 85.9 and 92.0°, respectively. X-ray data show that the ligand is uninegative in the complex, but the hybridization of C(12) is still sp^2. Bond lengths of O(1)—N(2), C(10)—C(11), C(11)—N(3), N(3)—N(4), N(4)—C(12) and C(12)—S(1), which are between values of corresponding normal single bonds and double bonds, indicate a large degree of electronic delocalization of these atoms.

The least-squares plane composed of O(1), N(2), C(6), C(7), C(8), C(9), C(10) and C(11), with maximum deviation not greater than 0.026 Å, is nearly parallel to that of O(1), S(1), N(3) and N(1); the dihedral angle between them is only 8.2°. The additive pyridine is co-planar, deviations of ring

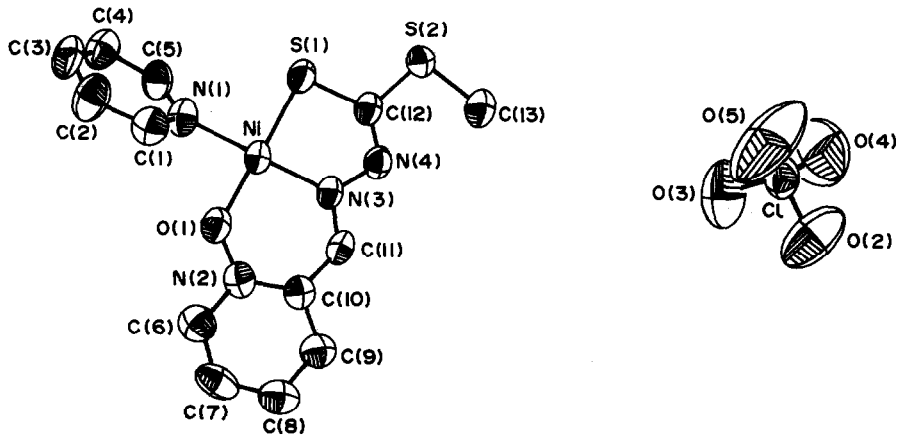

Fig. 1. Molecular structure of $[NiLPy]ClO_4$.

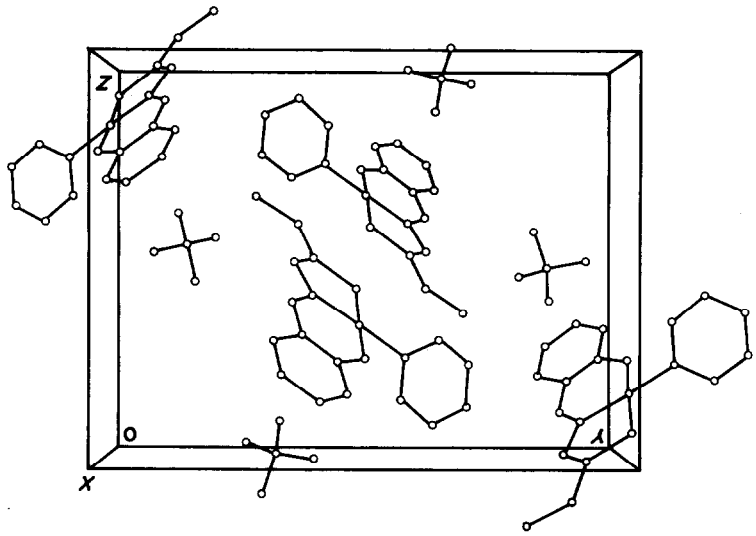

Fig. 2. The view of molecular packing.

atoms are C(1), 0.035; C(2), −0.054; C(3), 0.003; C(4), 0.0069; C(5), −0.0092; and N(1), 0.040 Å. The pyridine ring plane and the coordination plane around the nickel(II) atom have a dihedral angle of 50.8°.

The molecule is in a low symmetry. In the crystal (Fig. 2), two molecules of the complex, separated by a longer distance which results from the existence of the larger additive pyridine moiety, are situated in the opposite direction to decrease steric hindrance.

Magnetic properties and IR spectra

The magnetic susceptibility of solid samples at 283 K indicates that the complex is diamagnetic, confirming the square planar structure of the nickel(II) atom, and compatible with the proposed stereochemistry.

The IR spectra contain a very strong band at 1439 cm^{-1} assigned to ν(C=N) of the ligand. The stretching vibration of the N—O bond is observed at 1205 cm^{-1}, which is consistent with values

S(2)—C(12)—N(4)	121.3(4)		

reported in the literature.[7–13] Both ν(C=N) and ν(N—O) frequencies decrease by *ca* 41 and 16 cm^{-1} upon complex formation, respectively. The ν(C—S) frequency is at 1045 cm^{-1} with a weak band, whereas ν(C=S) and ν(N—H) frequencies are not observed. This confirms that the ligand coordinates the nickel(II) ion in the form of thiolate and is uninegative in the complex.[14–16] A strong broad band at 1088 cm^{-1} corresponds to the vibrations of Cl—O bonds.

(*Received* 21 *June* 1990; *accepted* 13 *August* 1990)

Abstract—The colourless crystalline compound $Na_2Hg_3S_4(H_2O)_2$ obtained from the heterogeneous reaction of HgS and Na_2S in DMF containing residual water, contains mercury sulphide chains $\{[Hg_2S_3]^{2-}\}_\infty$ in which tetrahedral HgS_4 units [D_2 site symmetry, Hg—S = 2.558(2) Å] are linked along the chain by pairs of digonal mercury atoms [C_2 site symmetry, Hg—S = 2.362(2) Å, S—Hg—S = 166.2(1)°]. These chains are separated by $\{[Na_2(OH_2)_2]^{2+}\}_\infty$ chains, and connected to them by O–H—S hydrogen bonds [3.261(7) Å] and Na—S contacts [2.946(5), 2.974(5) Å]. The structure embodies and mimics the coordination in both of the HgS minerals, cinnabar and metacinnabar.

We have been using the reactions of metal sulphides, MS (M = Cd, Hg), with Na_2S and S_8 in aprotic solvents such as DMF to prepare solutions of cadmium and mercury polysulphide complexes, which are characterized by metal NMR in solution and by diffraction methods after crystallization.[1,2] As part of this programme we carried out the control reaction of HgS plus Na_2S to determine whether $[Hg(S)_n]^{2-2n}$ complexes might form in DMF, as they do in water.[3,4] We observed heterogeneous reaction of black HgS and Na_2S to form almost colourless crystalline products, and here report on these reactions and on the non-molecular crystal structure of one product, $Na_2Hg_3S_4(H_2O)_2$.

RESULTS

Preparations

Although black HgS dissolves with reaction in concentrated aqueous Na_2S solution, it is not appreciably co-soluble with dehydrated Na_2S in DMF. There is, however, a heterogeneous reaction, as evinced by the colour change from black to white solids. The reaction that yielded $Na_2Hg_3S_4(H_2O)_2$ used $Na_2S \cdot 9H_2O$ that had been incompletely dehydrated, with a molar ratio of $3Na_2S$ per HgS, in deoxygenated DMF. The mixture was ultrasonicated at room temperature, converting the solid mixture from grey through yellow to white. When the mixture was heated briefly to 110°C there was no evidence that the white solids were soluble or would crystallize.† The sealed reaction mixture was ignored, and after several months it was discovered that large prismatic crystals with a very pale yellow colour had grown into the solution. On removal from the mother liquor these crystals appeared to attract atmospheric moisture within minutes and to undergo a slight morphological change leading to crystals which were less hygroscopic. Longer exposure to the atmosphere caused these crystals to revert to black HgS, but a covering of vaseline prevented this decomposition during the period of X-ray diffraction analysis.

Repetition of this preparation is difficult, and despite numerous attempts it has not yet been achieved. Heating similar mixtures at *ca* 100°C accelerates the heterogeneous conversions and colourless crystalline products appear within hours. All of these are very hygroscopic, but the X-ray diffraction patterns of the crystalline phases generated during the hydration provide no evidence for the formation of $Na_2Hg_3S_4(H_2O)_2$. Variations of the Na_2S–HgS ratio and of the water content in the reaction mixture also did not yield $Na_2Hg_3S_4(H_2O)_2$. It appears that there are at least two crystalline hydrates in this Na–Hg–S system: all are hygroscopic, and with

* Author to whom correspondence should be addressed.

† Temperature dependent blue/green colours characteristic of the $(S_6)^{2-} \rightleftharpoons 2(S_3)^-$ equilibrium in DMF were apparent.

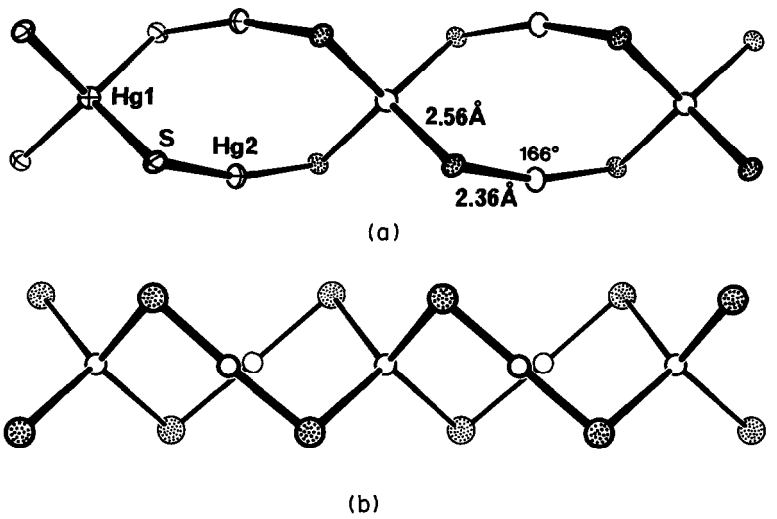

Fig. 1. Part of the $\{[Hg_2S_3]^{2-}\}_\infty$ chain in $Na_2Hg_3S_4(H_2O)_2$. (a) The three atoms, Hg(1) (tetrahedral), Hg(2) (digonal) and S, of the asymmetric unit are labelled and drawn with 50% probability ellipsoids. There is a crystallographic two-fold axis along the length of the chain, and transverse crystallographic two-fold axes through the Hg(1) and Hg(2) atoms. (b) The same chain viewed from the side, almost parallel to the transverse two-fold axes.

sufficient water undergo dissociative reversion to black HgS.

Crystal structure

The crystal structure is non-molecular. It is composed of two types of chain, one containing the Hg and S atoms and formulated $\{[Hg_2S_3]^{2-}\}_\infty$, the other the Na ions and water molecules, $\{[Na_2(OH_2)_2]^{2+}\}_\infty$. There is strong bonding within the chains and weaker bonding between chains of different types.

Appreciation of the structure is facilitated by examining first the $\{[Hg_2S_3]^{2-}\}_\infty$ chain, which is shown in Fig. 1. There are tetrahedral HgS_4 units [Hg(1)] with D_2 (222) site symmetry, linked along the chain by pairs of digonal Hg atoms [Hg(2)] with C_2 site symmetry. At the tetrahedral Hg the Hg—S distance is 2.558(2) Å, and the S—Hg—S angles are 108.2(1), 108.8(1) and 111.4(1)°. At the digonal Hg the Hg—S distance is 2.362(2) Å, and the S—Hg—S angle is 166.2(1)°. It is evident from Fig. 1 that within the chain two digonal S—Hg—S segments are directly opposed, with two Hg(2) atoms lying on the same two-fold axis: this Hg(2)—Hg(2) distance is 3.452(1) Å. The non-linearity of the digonal S—Hg—S segments is in the sense that increases the separation of the opposing Hg(2) atoms: if the S—Hg(2)—S angles were 180° the Hg(2)—Hg(2) separation would be reduced to 2.885 Å, which is at least 0.2 Å less than the sum of the normally accepted van der Waals' radius of Hg atoms (1.55 Å[5]). Thus, the observed outward bending of the opposed digonal segments along the chain is interpreted to be a consequence of repulsive Hg—Hg interactions. The Hg(1)—S—Hg(2) angle is 98.0(1)°: in many other systems with $M(\mu\text{-}S)_2M$ moieties[6] smaller values of M—S—M angles are well known, and therefore angular strain at S is not considered to be the reason for the outward bending of the digonal Hg atoms.

Each digonal Hg atom has two long contacts at 3.119(3) Å with S atoms in the adjacent $\{[Hg_2S_3]^{2-}\}_\infty$ chain: the two S atoms involved both belong to one HgS_4 tetrahedron.

The Na^+ ions and water molecules form zigzag —Na—OH_2—Na—OH_2— chains also parallel to the crystallographic *a* axis, with the Na and O atoms lying on crystallographic mirror planes. As shown in Fig. 2, each $\{[Na_2(OH_2)_2]^{2+}\}_\infty$ chain lies between four $\{[Hg_2S_3]^{2-}\}_\infty$ chains, and is connected to them by O–H—S hydrogen bonds and Na—S contacts. Along the —Na—OH_2—Na—OH_2— chain the Na—O distances alternate as 2.339(11) and 2.372(11) Å, the O—Na—O angle is 174.7(5)°, and the Na—O—Na angle is 88.7(3)°. Each Na^+ ion makes contact with four S atoms, two at 2.946(5) Å and two at 2.974(5) Å, and in the $Na(S)_4(OH_2)_2$ octahedral coordination the angles are all within 5° of 90°. Note that each S atom contacts two contiguous Na^+ ions along the $\{[Na_2(OH_2)_2]^{2+}\}_\infty$ chain. While the Na^+ ions link to the closest S

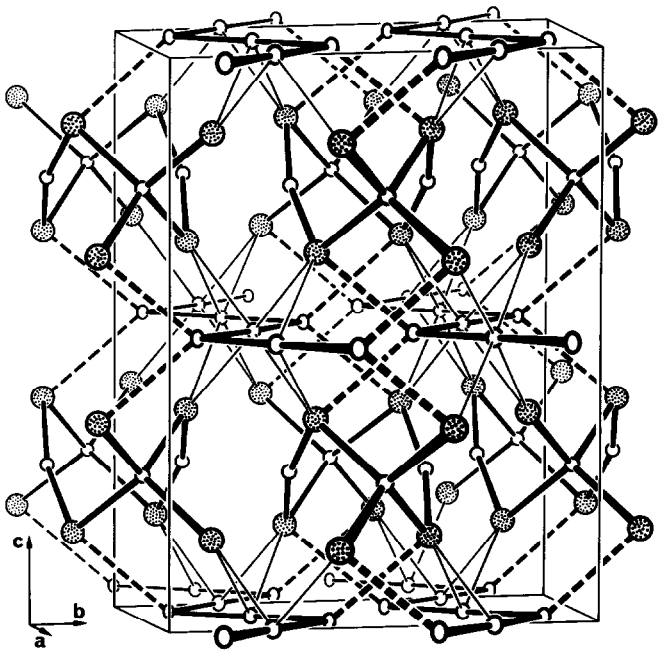

Fig. 2. The crystal lattice of $Na_2Hg_3S_4(H_2O)_2$. The dotted circles are S atoms, the small circles at $z = 0.25, 0.75$ are Hg atoms, the zigzag chains on the mirror planes at $z = 0, 0.5$ contain the Na ions (almost linear, with thin line connections to S) and O atoms of the water molecules (for which the hydrogen bonds to S are marked with thick broken lines).

atoms of the four surrounding $\{[Hg_2S_3]^{2-}\}_\infty$ chains, the O–H—S hydrogen bonds are to the more distant S atoms of the same four chains (see Fig. 2). The S—O distance is 3.261(7) Å, and the S—O—S angle 80.0(2)°. Although the hydrogen atoms were not located, it is clear that they would be slightly displaced from the O—S lines to allow H—O—H angles close to 100°. It is significant that, along *a*, the S---S separations are commensurate with the water---water separations and therefore the two chemically different chains fit together remarkably well.

DISCUSSION

HgS is dimorphic. The black form usually obtained by precipitation from aqueous solution is the same as the cubic mineral metacinnabar, with the zinc blende structure type. Metacinnabar reverts to the red stable trigonal form, cinnabar, below 344°C, while there is a first-order transformation of cinnabar to metacinnabar above 344°C.[7,8] In metacinnabar there is tetrahedral HgS_4 coordination, with Hg—S = 2.534 Å.[9] In cinnabar, helical S—Hg—S—Hg chains are present: the primary digonal HgS_2 coordination has Hg—S = 2.368 Å, S—Hg—S of 172°, while Hg—S—Hg is 105°.[10,11] Thus it is evident that the $\{[Hg_2S_3]^{2-}\}_\infty$ chains in $Na_2Hg_3S_4(H_2O)_2$ embody the structural features of both HgS minerals. The correspondence extends to the metrical details, with digonal Hg—S distances and angles of 2.362 Å, 166° and 2.368 Å, 172° in $Na_2Hg_3S_4(H_2O)_2$ and cinnabar, respectively, and tetrahedral Hg—S distances of 2.558 and 2.534 Å in $Na_2Hg_3S_4(H_2O)_2$ and metacinnabar, respectively. The significant helicity of cinnabar is not maintained in crystalline $Na_2Hg_3S_4(H_2O)_2$. The absence of visible charge-transfer absorption in $Na_2Hg_3S_4(H_2O)_2$ differentiates it from both HgS minerals, and is evidence that more extensive non-molecular interactions, rather than the primary Hg coordination, are responsible for the charge-transfer absorption of the minerals.

The motif of opposed linear digonal coordination segments occurs in many silver thiolate compounds.[12] Other relevant related compounds are the molecular ions $[HgE_2]^{2-}$, E = S, Se, Te,[3,13] the anion $[S_2W(S—Au—S)_2WS_2]^{2-}$ which contains the tetrahedral and linear components connected with the same topology,[14] and many partially hydrated alkali salts of thiometallate anions, with O–H—S hydrogen bonds.[6]

Investigations of the formation reaction for $Na_2Hg_3S_4(H_2O)_2$ and of the alternative product phases are continuing.

EXPERIMENTAL

Synthesis

$Na_2S \cdot 9H_2O$ (0.72 g, 3.0 mmol) was partially dehydrated in a stream of N_2 at 80°C, and black HgS (0.23 g, 1.0 mmol) was added. Deoxygenated and dried DMF (5 cm^3) was introduced, the vessel sealed under dinitrogen, and the mixture subjected to low power ultrasonication at room temperature. After 24 h the solid was yellow and the solution pale green: after 40 h the solid was white, and after 52 h the volume of the white solid had grown to about 4 cm^3. When the mixture was heated briefly to 110°C the pale yellow mother liquor changed to green, and returned to pale yellow on cooling, but there was no evidence that the polycrystalline solid was soluble or would crystallize. On standing at room temperature for several months large buff-coloured prismatic crystals grew in the solution. The mother liquor was removed and the crystals dried in a stream of dinitrogen. The crystals were hygroscopic and on brief exposure to the atmosphere, while mounting for X-ray diffraction, appeared to undergo a morphological change without losing single crystallinity. The sample used for collection of the X-ray diffraction data was coated with a thin layer of vaseline.

X-ray diffraction

The diffraction data were collected using a CAD4 diffractometer, at 21°C. The essential crystallographic data are as follows: crystal system orthorhombic, space group *Ibam*, $a = 6.5823(6)$, $b = 10.922(1)$, $c = 14.379(2)$ Å, $V = 1033.7(2)$ $Å^3$, $Z = 4 \times Na_2Hg_3S_4(H_2O)_2$, $D_{calc} = 5.22$ gm cm^{-3}, Mo-K_α radiation ($\lambda = 0.7107$ Å), $\mu = 452$ cm^{-1}, crystal dimensions $0.25 \times 0.08 \times 0.08$ mm^3, absorption corrections calculated and applied, max/min values of transmission coefficient = 0.028/0.092, 476 reflections measured in octant $+h$, $+k$, $+l$ to $2\theta = 50°$, 346 observed reflections [$I/\sigma(I) \geqslant 3$], 31 refined parameters, $R = 0.031$, $R_w = 0.048$.

Structure solution and refinement

There are two different Hg atoms in the structure, both located on two-fold axes: one labelled Hg(1) is on the four-fold special positions *b* of the space group *Ibam*, the other Hg(2) on the eight-fold special positions *g*. The one type of S atom is on the

general 16-fold position *k*, the Na^+ ion and the water oxygen atom (labelled O) are located on the mirror planes at $z = 0$, 1/2 (the eight-fold special position *j*). The hydrogen atoms were not directly located, and were not included in the refined model. Scattering factors for neutral atoms were taken from *International Tables for X-ray Crystallography*.[15] The least-squares refinement involved anisotropic thermal parameters for all atoms and an isotropic extinction coefficient. On completion of refinement, $R = \Sigma^m|\Delta F|/\Sigma^m|F_o| = 0.031$ and $R_w = [\Sigma^m w|\Delta F|^2/\Sigma^m w|F_o|^2]^{1/2} = 0.048$.

Important distances and angles are given in Table 1.

COMPLEXATION AND THERMODYNAMICS OF THE URANYL ION WITH PHOSPHATE

J. N. MATHUR

Radiochemistry Division, Bhabha Atomic Research Centre,
Trombay, Bombay 400 085, India

(*Received* 4 *July* 1990; *accepted* 15 *August* 1990)

Abstract—Complexation of UO_2^{2+} with the $H_2PO_4^-$ anion at various ionic strengths (0.1–1.0 M $NaClO_4$) has been studied using the solvent extraction technique. The equilibrium constants (β_1 and β_2) for the formation of the species $UO_2H_2PO_4^+$ and $UO_2(H_2PO_4)_2$ were fit to the following extended Debye–Hückel expressions:

$$\log \beta_1(I) = 3.47 - \frac{2.044\, I^{1/2}}{1+1.6\, I^{1/2}} + 0.273\, I$$

and

$$\log \beta_2(I) = 5.77 - \frac{3.066\, I^{1/2}}{1+1.6\, I^{1/2}} + 0.364\, I.$$

The thermodynamic parameters for these systems have been computed using the temperature coefficient method. The reactions are favoured by entropy and opposed by enthalpy. The complexes are predominantly the "inner sphere" type.

Complexing of UO_2^{2+} with various phosphate moieties has been a subject of interest for over four decades. Apart from the interest in the basic nature of the complexes formed, the acquired data are of great relevance in the recovery of uranium from phosphate solutions. In earlier studies, the concentrations of the UO_2^{2+} ion used were in the macro range and the methods employed were solubility,[1–4] spectrophotometry and solvent extraction[5] and anion exchange.[6] In a few recent publications,[7,8] di-2-ethylhexyl phosphoric acid has been used as an extractant for the study of uranyl–phosphoric acid complexes at very high phosphoric acid concentrations. Formation of various species like $UO_2(H_2PO_4)H_6P_2O_8^+$, $UO_2(H_5P_2O_8)\cdot H_3PO_4$, etc., has been reported. Recent interest in the environmental aspects of natural and waste waters and migration of radionuclides has re-emphasized the importance of phosphate complexation of actinide and lanthanide ions.[9,10]

The present work deals with the complexing of UO_2^{2+} with the $H_2PO_4^-$ anion at pH 2.50 and different ionic strengths. With the use of a ^{233}U tracer (concentration $\sim 10^{-6}$ M) the problems due to precipitation have been avoided. Also, as the studies were carried out at low phosphoric acid concentrations (< 0.02 M), the formation of species such as $UO_2H_3PO_4^{2+}$, $UO_2(H_2PO_4)_2\cdot H_3PO_4$, etc., as reported in earlier publications,[3–8] is also ruled out. This is the first systematic study at such low UO_2^{2+} ion concentrations where a direct complexation between UO_2^{2+} and $H_2PO_4^-$ ions is being reported. The thermodynamic parameters for the formation of the species $UO_2H_2PO_4^+$ and $UO_2(H_2PO_4)_2$ are also reported for the first time.

EXPERIMENTAL

The ^{233}U tracer was purified by the usual methods and its radiochemical purity was checked by alpha spectrometry. The stock solution was kept at pH 2.0 ($HClO_4$). A benzene solution of dinonylnaphthalene sulphonic acid (HD) from Vanderbilt Inc., U.S.A. was converted to its sodium salt (NaD) by shaking the solution thrice with 4 M NaCl solution. *o*-Phosphoric acid (A.R.) was obtained from Glaxo Laboratories, India. All other chemicals used were of A.R. grade.

For the present studies a solution of ^{233}U in 0.0016 F NaD/benzene was prepared by extracting an appropriate quantity of this tracer from the aqueous phase at pH 2.50 and was used for all the extraction experiments.

Variation of phosphoric acid concentrations at various ionic strengths

2 cm^3 of the aqueous phase containing $[H_3PO_4]_t$, in the range 0.0–0.02 M at pH 2.50 and ionic strengths 0.1, 0.3, 0.5, 0.7 and 1.0 M, were equilibrated with an equal volume of the NaD/benzene phase containing the ^{233}U tracer for 1 h by slow rotation in a thermostated bath at 25±0.1°C. In an earlier experiment this time was found to be sufficient to attain the equilibrium. The solutions were allowed to settle for 30 min, centrifuged and aliquots of the two phases taken for radioassay. The activities were measured with a liquid scintillation counter using a toluene–HDEHP scintillator cocktail. In a few test cases 5 cm^3 of the aqueous and organic phases were employed, and after equilibration the pH of the aqueous phases was checked, which was found to remain constant at 2.50±0.01.

Variation of phosphoric acid concentrations at 1.0 *M* $NaClO_4$ *and various temperatures*

2 cm^3 of the aqueous solutions containing $[H_3PO_4]_t$ (as mentioned above), at 1.0 M $NaClO_4$, were shaken with the same volume of organic solutions (NaD/benzene containing ^{233}U tracer) for 1 h at 10, 25, 40 and 50±0.1°C. After settling and centrifuging the activities in the two phases were measured as detailed above.

pH-*titration of phosphoric acid at various ionic strengths*

To determine the p*K*a values of phosphoric acid at different ionic strengths (0.1, 0.3, 0.5, 0.7 and 1.0 M $NaClO_4$), 45 cm^3 of an appropriate concentration of phosphoric acid at a fixed ionic strength was titrated with NaOH solution (keeping the ionic strength constant). The water used for this work was distilled and deionized and was boiled to remove dissolved CO_2. During the course of the titrations, care was taken to avoid any adsorption of CO_2 by the solutions.

Calculation of stability constants

The uptake of UO_2^{2+} into the NaD/benzene phase from the aqueous phase can be written as:

$$UO_{2(a)}^{2+} + (NAD)_{m(o)} \rightleftharpoons UO_2(Na_{m-2}D_m)_{(o)} + 2Na_{(a)}^{+}, \quad (1)$$

where (a) and (o) represent the aqueous and organic phases. The validity of this mechanism has been confirmed from the plot of log D (D = distribution ratio), at different $[Na^+]$ concentrations, vs log a_{Na^+} (activity of sodium ion), where the straight line had a slope of 1.7 (Fig. 1). The distribution ratio under such conditions is given by

$$D_o = \frac{[UO_2(Na_{m-2}D_m)]_{(o)}}{[UO_2^{2+}]_{(a)}}. \quad (2)$$

In the presence of a complex anion, $H_2PO_4^-$, the extraction of UO_2^{2+} is affected by the complexes formed in the aqueous phase. The complex formation equilibria can be written as:

$$UO_2^{2+} + H_2PO_4^- \overset{\beta_1}{\rightleftharpoons} UO_2H_2PO_4^+ \quad (3)$$

and

$$UO_2^{2+} + 2H_2PO_4^- \overset{\beta_2}{\rightleftharpoons} UO_2(H_2PO_4)_2. \quad (4)$$

Now D will become

$$D = \frac{[UO_2(Na_{m-2}D_m)]_{(o)}}{[UO_2^{2+}]_{(a)} + [UO_2H_2PO_4^+]_{(a)} + [UO_2(H_2PO_4)_2]_{(a)}} \quad (5)$$

$$= \frac{[UO_2(Na_{m-2}D_m)]_{(o)}}{[UO_2^{2+}]_{(a)}\{1 + \beta_1[H_2PO_4^-] + \beta_2[H_2PO_4^-]^2\}}. \quad (6)$$

By combining eqs (2) and (6) and simplifying, we can write

$$\frac{1}{D} = \frac{1}{D_0} + \frac{\beta_1}{D_0}[H_2PO_4^-] + \frac{\beta_2}{D_0}[H_2PO_4^-]^2. \quad (7)$$

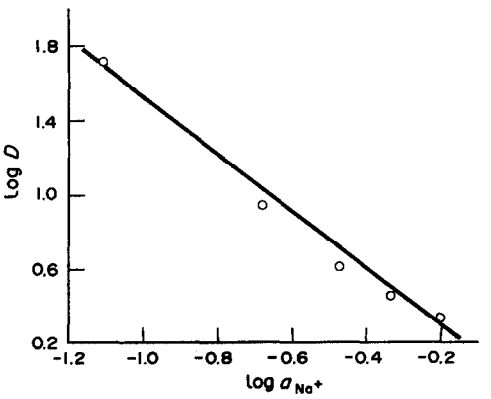

Fig. 1. Plot of log D vs log a_{Na^+} at fixed NaD concentration in the absence of phosphate ions.

At very low $H_2PO_4^-$ concentrations, where only the first complex is formed, β_1 values were evaluated using a linear least-square program (LLSP) fitting $1/D$ and $[H_2PO_4^-]$ data. The β_2 values were computed fitting $(D_0/D-1)/[H_2PO_4^-]$ and $[H_2PO_4^-]$ data at higher $[H_2PO_4^-]$ concentrations using the same program.

Calculation of thermodynamic parameters

Values of ΔG for the UO_2^{2+}–$H_2PO_4^-$ complexes were calculated from the stability constants at 25°C. Values of ΔH with their standard deviations were computed by LLSP fitting the log (stability constant) and $1/T$ (in Kelvin) data using the Van't Hoff equation. Values of ΔS were evaluated form the ΔG and ΔH values using the Gibbs–Helmholtz equation.

RESULTS AND DISCUSSION

Stability constants

For the calculation of the stability constants of UO_2^{2+}–$H_2PO_4^-$ complexes at pH 2.50, the $H_2PO_4^-$ concentrations at this pH had to be evaluated. For this purpose, the pKa_1 values at different ionic strengths were determined using the pH titration technique. The pKa_1 values thus obtained, along with the activity coefficients of $NaClO_4$ at different ionic strengths (from ref. 11), are given in Table 1. In all the calculations in this work $[H^+]$, the hydrogen ion concentration and not the hydrogen ion activity (as given by pH-meter), has been used. The molar concentrations of H_3PO_4, $H_2PO_4^-$, HPO_4^{2-} and PO_4^{3-}, at pH 2.50, 1.0 M $NaClO_4$ and $[H_3PO_4]_t = 0.02$ M were calculated by using protonation constant values from ref. 12 (log $K_1 = 1.70 \pm 0.02$, log $K_2 = 6.30 \pm 0.02$ and log $K_3 = 10.99 \pm 0.03$) and are given in Table 2. It is evident from this table that the concentrations of

Table 1. pKa_1 of phosphoric acid and activity coefficients of $NaClO_4$ at different ionic strengths

Ionic strength	pKa_1	Activity coefficient[a]
0.1	2.09 ± 0.02	0.775
0.3	2.01 ± 0.02	0.701
0.5	1.95 ± 0.03	0.668
0.7	1.86 ± 0.02	0.648
1.0	1.70 ± 0.02	0.629

[a] From ref. 11.

Table 2. Molarities of H_3PO_4, $H_2PO_4^-$, HPO_4^{2-} and PO_4^{3-} at pH 2.50, $I = 1.0$ and total phosphate = 0.02 M

Species	Molarities
H_3PO_4	4.01×10^{-3}
$H_2PO_4^-$	1.599×10^{-2}
HPO_4^{2-}	1.583×10^{-6}
PO_4^{3-}	3.226×10^{-15}

HPO_4^{2-} and PO_4^{3-} are negligibly small even at the highest $[H_3PO_4]_t$ concentration and hence the probabilities for the participation of any anions other than $H_2PO_4^-$ under these experimental conditions have been ruled out.

Figure 2 gives the plots of $1/D$ vs $[H_2PO_4^-]$ at pH 2.50 and various ionic strengths (I). It is clear from these curves that under the present experimental conditions more than one complex species is formed. However, due to the good fit of the $(D_0/D-1)/[H_2PO_4^-]$ vs $[H_2PO_4^-]$ data into a straight line it was concluded that complex species higher than $UO_2(H_2PO_4)_2$ are not formed. Table 3 gives the values of β_1 and β_2 [eqs (3) and (4)] at different values of I. Due to the uncertainty about the quality of experimental conditions such as ionic strength, high concentrations of H^+ ion, very high concentrations of phosphoric acid, uncertainty in pKa_1 values or the mixed nature of equilibrium

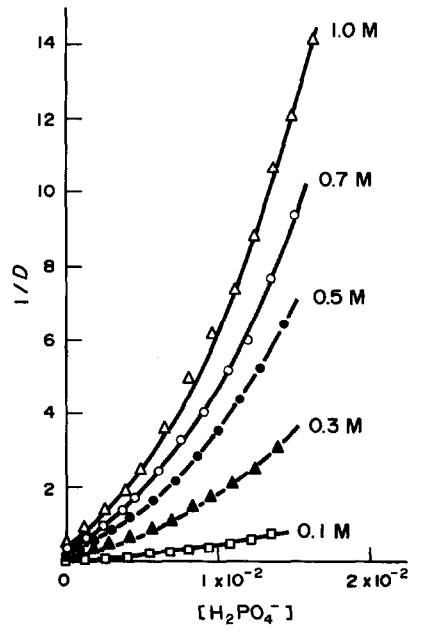

Fig. 2. Dependence of $1/D$ on $[H_2PO_4^-]$ at pH 2.50 and different ionic strengths.

Ionic strength	$\log \beta_1$	$\log \beta_2$
0.0[a]	3.47±0.02	5.77±0.02
0.1	3.04±0.03	5.15±0.02
0.3	2.97±0.01	4.97±0.03
0.5	2.95±0.02	4.96±0.02
0.7	2.94±0.02	4.94±0.03
1.0	2.94±0.02	4.93±0.02

[a] Calculated using the extended Debye–Hückel expression.

constants, it is not correct to compare the equilibrium constant values reported in refs 3, 5 and 6 with the values obtained in the present work. However, the only equilibrium constant values for the UO_2^{2+}–phosphate systems quoted in the recent critical stability constant book[12] are those given in ref. 4. These $\log \beta_1^*$ and β_2^* values correspond to the reactions

$$UO_2^{2+} + H_3PO_4 \rightleftharpoons UO_2(H_2PO_4)^+ + H^+ \quad (8)$$

and

$$UO_2^{2+} + 2H_3PO_4 \rightleftharpoons UO_2(H_2PO_4)_2 + 2H^+ \quad (9)$$

and are given at $I = 0.0$. This study has been carried out by equilibrating the solid uranyl phosphate compound with aqueous solutions, and estimating the uranyl, phosphate and hydrogen ion concentrations in the equilibrated solutions. After applying a correction for the dissociation of H_3PO_4 at $I = 0.0$ ($pKa_1 = 2.148$[13]), the values of $\log \beta_1$ and $\log \beta_2$ equivalent to our systems were calculated. These values are 3.65 and 5.60, which agree well with the values computed from the extended Debye–Hückel expression at $I = 0.0$ (Table 3). In recent work[14] on the complexing of NpO_2^{2+} with $H_2PO_4^-$ at pH 2.50, 1.0 M $NaClO_4$ and 25°C, $\log \beta_1$ for the formation of the $NpO_2H_2PO_4^+$ species was reported to be 2.52±0.07. This value is smaller than the one obtained for the similar uranyl complex (2.94) in the present work. A similar order, i.e. the NpO_2^{2+} complex stability constant being smaller than that of UO_2^{2+}, has also been reported for the first fluoride complexes.[15] Such an order could arise due to the order of effective cationic charge on the metal atoms in the dioxoactinyl ions, UO_2^{2+} (+3.2±0.1) and NpO_2^{2+} (+3.0±0.1).[15]

The stability constant values at different ionic strengths were fitted to the extended Debye–Hückel expression:

$$\log \beta(I) = \log \beta(0) + \frac{A\Delta Z^2 I^{1/2}}{1 + BI^{1/2}} + CI + DI^2, \quad (10)$$

where $\log \beta(I)$ is the equilibrium constant at a particular ionic strength I, $\log \beta(0)$ that at $I = 0.0$, $\Delta Z^2 = \Sigma Z^2(\text{products}) - \Sigma Z^2(\text{reactants})$ and $A = 0.511$. A fixed value of $B = 1.6$ was taken for our calculations, since this value has been proposed for general use in hydrolytic systems[16] and substantiated to be so from the uranyl diglycolate complex studies.[17] The value of D was set at 0.0 as has normally been done at such ionic strengths. With these values the non-linear expression (10) was fitted for two unknowns, the $\log \beta(0)$ and C. The following expressions gave the best fit with a minimum of error:

$$\log \beta_1(I) = 3.47 - \frac{2.044 I^{1/2}}{1 + 1.6 I^{1/2}} + 0.273 I \quad (11)$$

and

$$\log \beta_2(I) = 5.77 - \frac{3.066 I^{1/2}}{1 + 1.6 I^{1/2}} + 0.364 I. \quad (12)$$

The error in $\log \beta(0)$ values was computed as ±0.02. The $\log \beta(0)$ values so obtained agree well with the modified values at $I = 0.0$ reported in ref. 4.

Figure 3 gives a plot of $\log \beta_1$ and $\log \beta_2$ values of uranyl complexes with SCN^-, HSO_4^-, $H_2PO_4^-$ and F^- anions vs the pKa of these anions at 25°C and 1.0 M $NaClO_4$. The data for SCN^-, HSO_4^- and F^- complexes have been taken from ref. 13. Good fitting of these data into straight lines (separate for β_1 and β_2) suggests that the stability constant values of UO_2^{2+} complexes increase with

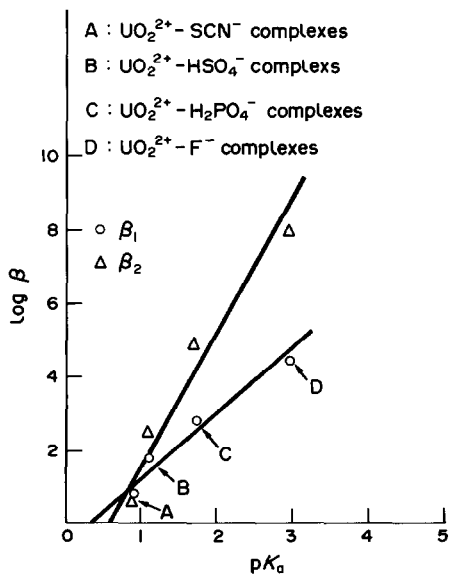

Fig. 3. Plots of pKa of HSCN, HSO_4^-, H_3PO_4 and HF vs the stability constants of these anions with UO_2^{2+} at 25°C and 1.0 M $NaClO_4$.

increasing pKa of the inorganic ligands. Such a correlation could be of help in assessing the stability constants of uranyl complexes with other inorganic ligands.

Thermodynamic data

Figure 4 gives the plots of $1/D$ vs $[H_2PO_4^-]$ at 10, 25, 40 and 50 ± 0.1°C and a fixed ionic strength of 1.0 M $NaClO_4$. For the calculation of $[H_2PO_4^-]$ concentrations at 10, 40 and 50°C, the pKa_1 values at such temperatures and 1.0 M $NaClO_4$ are not known. However, from the knowledge of pKa_1 values at these temperatures and 0.0 ionic strength we have assessed these values as 1.64, 1.77 and 1.83 at 10, 40 and 50°C and 1.0 M $NaClO_4$ and used them for our calculations. Values of log β_1 and log β_2 (Table 4) at these temperatures were evaluated as discussed earlier. The plot of log β vs $1/T$ (in Kelvin) (Fig. 5) gave straight lines. The ΔH and ΔS values were calculated as discussed earlier and are given in Table 5. Also included in this table are the thermodynamic parameters for the uranyl complexes of SCN^-, F^- and HSO_4^- at 1.0 M $NaClO_4$ and 25°C from ref. 13. The positive enthalpy and positive entropy changes associated with the formation of both the species $UO_2H_2PO_4^+$ and $UO_2(H_2PO_4)_2$ are similar to those observed for the F^- and HSO_4^- complexes. In the case of SCN^- complexes, small exothermic ΔH and very small entropy changes have been reported. The large positive entropy changes associated with the formation of uranyl–$H_2PO_4^-$ complexes suggest the inner-sphere nature of these complexes. The positive enthalpy values observed are due to a cumulative effect of the following factors: (1) heat energy needed to break uranyl–water bonds, (2) heat energy needed to break $H_2PO_4^-$–water bonds and (3) the heat energy liberated during the formation of UO_2^{2+}–$H_2PO_4^-$ bonds. The positive ΔH values encountered in the present systems suggest that in these aqueous phase reactions the heat energy needed by factors (1) and (2) together is much more than that evolved by factor (3).

For the formation of UO_2A^+ and $UO_2(A)_2$, where $A^- = F^-$, $H_2PO_4^-$ or HSO_4^-, the ΔS values are nearly the same, while the endothermic ΔH follows the order $F^- < H_2PO_4^- < HSO_4^-$. Of the three factors mentioned above, for a cumulative effect on the ΔH values, factor (1) will be the same for all the three systems. Hence the difference in ΔH

Table 4. Stability constants of UO_2^{2+} complexes with the $H_2PO_4^-$ anion at various temperatures and 1.0 M $NaClO_4$

[b] Present work.

values could arise due to factor (2) and/or factor (3). It may be noted that since the F^- ion is smaller than the $H_2PO_4^-$ or HSO_4^- ions, the affinity for water will be higher for the F^- ion rather than for the other two. If the contribution due to factor (2) was predominant, one would expect a higher positive ΔH for the fluoride complexes rather than the sulphate or phosphate complexes. Hence it could be concluded that for these complexes contributions due to factor (3) are more predominant for the changes in ΔH values. The order of ΔH observed for these systems is an indication of the bonding strength of UO_2^{2+} with these anions, which follows the order $F^- > H_2PO_4^- > HSO_4^-$.

Speciation

For the UO_2^{2+}–$H_2PO_4^-$ system, the total uranyl concentration can be written as:

$$[UO_2^{2+}]_t = [UO_2^{2+}]+[UO_2H_2PO_4^+] +[UO_2(H_2PO_4)_2]. \quad (13)$$

This could be simplified to

$$[UO_2^{2+}]_t = [UO_2^{2+}]+[UO_2^{2+}]\beta_1[H_2PO_4^-] +[UO_2^{2+}]\beta_2[H_2PO_4^-]^2. \quad (14)$$

Normalizing to $[UO_2^{2+}]_t = 1$ and rearranging, eq. (14) becomes

$$[UO_2^{2+}] = \frac{1}{1+\beta_1[H_2PO_4^-]+\beta_2[H_2PO_4^-]^2}, \quad (15)$$

by knowing values of β_1 and β_2 one could easily

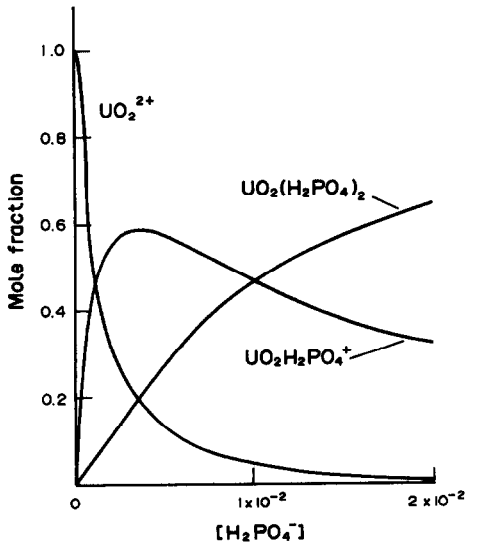

Fig. 6. Mole fraction of UO_2^{2+} species as a function of $H_2PO_4^-$ concentration at $I = 1.0$ M, pH = 2.50 and 25°C.

evaluate the value of $[UO_2^{2+}]$ at different $[H_2PO_4^-]$ concentrations. The fraction of each complexed species can be given by:

$$[UO_2H_2PO_4^+] = [UO_2^+][H_2PO_4^-]\cdot\beta_1 \quad (16)$$

and

$$[UO_2(H_2PO_4)_2] = [UO_2^{2+}][H_2P_4^-]^2\cdot\beta_2. \quad (17)$$

Figure 6 gives a plot of mole fractions of $[UO_2^{2+}]$, $[UO_2H_2PO_4^+]$ and $[UO_2(H_2PO_4)_2]$ vs $[H_2PO_4^-]$ concentration at pH 2.50.[18] It can be seen from the figure that at very low $[H_2PO_4^-]$ concentration only the first complex is predominant. With increasing $H_2PO_4^-$ concentration the formation of the $UO_2(H_2PO_4)_2$ complex increases and at a $\sim 1\times10^{-2}$ M concentration of $H_2PO_4^-$ anion both the complex species are present in almost equal quantities. At still higher $H_2PO_4^-$ concentrations the $UO_2(H_2PO_4)_2$ species predominates.

THE CHEMISTRY OF SIMPLE CERAMIC GLAZES—III. A MASNMR STUDY OF SIMULATED FELDSPARS AND THEIR REACTIONS WITH CaO, SrO, BaO OR Li_2O ON HEATING TO 1300°C

ARVIND-PAL S. MANDAIR and WILLIAM R. McWHINNIE*

Department of Chemical Engineering and Applied Chemistry, Aston University, Aston Triangle, Birmingham B4 7ET, U.K.

(*Received* 9 *July* 1990; *accepted* 13 *August* 1990)

Abstract—The influence of additions of CaO, SrO, BaO or Li_2O to a synthetic albite feldspar glass was investigated by ^{29}Si, ^{27}Al and ^{23}Na MASNMR spectroscopy. All oxides induce more ordering of the "SiO_4", "AlO_4" tetrahedra in the glass when present in greater (CaO > 60 mol % relative to SiO_2) or lesser (Li_2O > 30 mol %) proportions. Larger additions of CaO (80, 100 mol %) induced crystallization of calcium silicate phases but similar additions of SrO or BaO stabilized the glass phase. ^{27}Al MASNMR data suggested that large additions of CaO caused the separation of an aluminate phase; the data also revealed the presence of octahedral Al^{3+} sites for all additions of MO (M = Ca, Sr, Ba), however, no octahedral aluminium was seen in the presence of LiO_2. The apparent ^{23}Na chemical shift generally moved to lower field as the proportion of "AlO_4" in the glass increased.

In previous papers the use of the non-invasive, resonance spectroscopies to probe the thermolysis of the clay minerals illite and montmorillonite[1] (^{57}Fe Mössbauer), and laponite together with hectorite[2] (MASNMR), has been demonstrated. Subsequently, ^{57}Fe Mössbauer spectroscopy was used to probe the fate of iron compounds in a feldspathic ceramic glaze,[3] and MASNMR (^{29}Si, ^{27}Ai, ^{23}Na) followed the modifications produced to the pattern of thermolysis of laponite by additions of oxides such as Na_2O, CaO or Al_2O_3.[4]

X-ray powder diffraction (XRD) supplied extra, though sometimes incomplete and ambiguous, information in the above studies.[1–4] In this paper ^{29}Si, ^{23}Na and ^{27}Al MASNMR spectroscopies are used alone to explore the influence of added oxides (CaO, SrO, BaO or Li_2O) to a simulated sodium feldspar, albite ($NaAlSi_3O_8$). Albite and anorthite ($CaAl_2Si_2O_8$) are regarded as end members of a complete series of solid solutions which constitute the plagioclase feldspars.[5] The natural minerals usually contain paramagnetic impurities, often iron, which may lead to some loss of resolution in the ^{29}Si MASNMR spectrum, although reports have been published on studies of these natural minerals;[6–9] however, it was decided to simulate albite as $(Na_2O)(Al_2O_3)(SiO_2)_6$ using pure sources of oxides. Since the identification of reaction products obtained at 1300°C was the objective of the work, the use of a simulated feldspar, which provided the constituent oxides in the correct stoichiometric ratio, was deemed satisfactory.

EXPERIMENTAL

The basic simulated albite was constituted from silica, alumina and sodium carbonate of the highest available purity to give the oxide ratios $(Na_2O)(Al_2O_3)(SiO_2)_6$. To this basic mixture was added the carbonates of either calcium, strontium, barium or lithium to give the following composition ranges (based on oxides):

$(CaO)_x(Na_2O)(Al_2O_3)(SiO_2)_6$

x = 1.2, 2.4, 3.6, 4.8, 6.0

* Author to whom correspondence should be addressed.

$(SrO)_x(Na_2O)(Al_2O_3)(SiO_2)_6$

$x = 0.6, 1.2, 2.4, 4.0, 6.0$

$(BaO)_x(Na_2O)(Al_2O_3)(SiO_2)_6$

$x = 0.6, 1.2, 2.4, 3.0, 6.0$

$(Li_2O)_x(Na_2O)(Al_2O_3)(SiO_2)_6$

$x = 0.3, 0.6, 1.2, 1.8, 2.4, 3.0.$

Each individual batch was placed in a new, porcelain crucible and fired to 1300°C (monitored with a Pt/Rh thermocouple) for 4 h in a carbolite furnace. After cooling, the crucible was broken and care taken to use only a sample obtained from the centre of the melt to ensure no contamination with the material of the crucible. The sample was ground to a fine powder using an agate mortar and pestle.

Physical measurements

MASNMR spectra were obtained with a Bruker AC(E) 300 MHz spectrometer. The "magic angle" was set with KBr, and Delrin rotors were spun at approximately 5000 Hz. Frequencies were 59.580 MHz (^{29}Si), 78.206 MHz (^{27}Al) and 79.392 MHz (^{23}Na).

RESULTS

The now well accepted "Q" notation is used to classify the ^{29}Si MASNMR data in Tables 1 and 2. Thus Q^2 signifies a SiO_4 tetrahedron sharing two vertices with similar tetrahedra, whereas Q^4 (3Al), for example, indicates that the SiO_4 tetrahedron shares *all* vertices, in this case with one other SiO_4 and three AlO_4 tetrahedra.

Table 1 details the changes that occur when the simulated albite is fired in the presence of varying amounts of alkaline earth oxides. The spectrum of the simulated albite consists of a broad ($\Gamma_{1/2} = 1300$ Hz) resonance with a maximum placed in the Q^4 (2Al) range; the breadth of the signal probably reflects both a range of Q^4 (nAl) sites as well as variable OSiO angles within the glassy matrix. Small additions of CaO did not influence the breadth of the peak but shifted the maximum to high field, suggesting that Q^4 (2Al) was the dominant environment. Larger additions of CaO, e.g. 40 mol % (w.r.t. SiO_2), induced the appearance of sharp resonances (−83.6 ppm vs TMS) attributable to crystalline phases. Although the broad resonance remained discernable at 60% CaO addition, by 100% essentially only resonances from crystalline

[c] vs NaBr(aq).
[d] $\Gamma_{1/2}$ = width at half height (Hz).

phases are noted. The influence of added SrO and BaO was similar, but different in some respects to that of CaO. Thus smaller additions of these oxides are noted to be effective in changing the spectrum, and the line widths are less than for the calcium oxide case ($\Gamma_{1/2}$ = 920 Hz). The differences in the spectra for 100 mol % additions of CaO, SrO or BaO are illustrated in Fig. 1.

Table 3 combines ^{27}Al and ^{23}Na MASNMR data for the CaO, SrO and BaO modified feldspathic glazes. Both sets of spectra showed many spinning side bands, but these were readily distinguished from the true resonances by changing the rotor spinning rate. For simulated albite, both the ^{27}Al and ^{23}Na spectra consist of a broad resonance, characteristic of tetrahedral aluminium in the ^{27}Al case. Additions of the oxides certainly induced change. An octahedral signal appeared and large additions of CaO shifted the tetrahedral resonance to lower field, an effect much less marked on addition of SrO or BaO. Addition of the oxides produced an apparent deshielding of the sodium ion; in the case of BaO, the effect of small additions was quite dramatic, but the resonance underwent a high field shift on larger additions. In some cases, e.g. 60 mol % CaO, 30 mol % BaO, exceptionally broad resonances were noted.

Table 2 reports the ^{29}Si, ^{27}Al and ^{23}Na MASNMR data for simulated albite modified by additions of Li_2O, and fired to 1300°C. Even small additions (5 mol %) are effective in shifting the "albite" resonance and narrowing the resonant line width, although in an absolute sense $\Gamma_{1/2}$ remains large at 900–1100 Hz. It was only at 50 mol % addition that a weak resonance of −69.7 ppm vs TMS was perceived, which could possibly be assigned to a crystalline phase. Only a tetrahedral

site was observed in the ^{27}Al spectra, whilst the sodium resonance maximum shifted to lower field as the amount of Li_2O increased.

DISCUSSION

An earlier study of iron in air-fired feldspathic glaze modified by addition of CaO, SrO or BaO revealed, via the ^{57}Fe Mössbauer parameters, that the influence of the heavier alkaline earth oxides as glaze modifiers was in a subtle way distinct from that of CaO. This investigation was initiated, in part, to pursue this matter further. Also, an opportunity was provided to evaluate the sole use of multinuclear MASNMR to monitor the chemical changes occurring in relatively intractable systems such as ceramic glazes.

The structure of crystalline feldspars is based on a vertex-linked framework of SiO_4 and AlO_4 tetrahedra; the ratio of aluminium to silicon may range from 1:3 to 1:1. Taylor and Brown[10] concluded that albite and anorthite glasses had essentially different structures. Thus, X-ray radial distribution analysis data were consistent with a glass structure based on rings comprising six vertex-linked MO_4 (M = Si, Al) tetrahedra (trydymite type) for an albite glass, whereas anorthite glasses gave data consistent with the presence of rings based on a feldspar crystalline structure, i.e. formulated from four vertex-sharing MO_4 tetrahedra. Kirkpatrick *et al.*[9] reported a ^{29}Si resonance at −98 ppm for an albite glass constituted from the component oxides, which may be compared with the value of −93.3 ppm in Table 1. The fact that in both studies a broad, featureless peak was observed probably implies that no great significance should be attached to the different δ_{max} values since a range of $Q^4(n\text{Al})$ environments will be present, which will also depend on the rate of cooling. What can be said, is that both investigations were in agreement that the dominant silicon site was $Q^4(2\text{Al})$. The ^{27}Al spectrum (Table 3) gives a single broad resonance at 52.9 ppm relative to $[Al(H_2O)_6]^{3+}$, characteristic of a tetrahedral environment and consistent with a model in which all the aluminium is present in an AlO_4 environment. Kirkpatrick *et al.* saw a quadrupole split ^{23}Na resonance (second-order quadrupole effects are not averaged to zero by spinning at the magic angle) with maxima at −13.1 and −21.9 ppm for crystalline albite, but for albite glass a broad symmetric band centred at −18.3 ppm (vs aqueous NaCl) was observed. The ^{23}Na resonance observed in this work was broad, but relatively symmetrical, with the maximum [w.r.t. NaBr(aq)] at −21.5 ppm.

The effect of added CaO at a 20 mol % level was unspectacular. Although the maximum of the ^{29}Si resonance underwent a high field shift, the dominant environment did remain $Q^4(2\text{Al})$. However, the ^{27}Al MASNMR spectrum showed the presence of octahedral as well as tetrahedral aluminium. It was only at 40 mol % additions of CaO that significant changes in the ^{29}Si spectra occurred. The broad peak shifted to −89.9 ppm, just within the $Q^4(3\text{Al})$ range, indicating further ordering of the aluminosilicate network. In addition, a sharp resonance indicative of a new crystalline phase was seen. Crystalline synthetic anorthite was reported to give ^{29}Si resonances at −82.9, −84.8 and −89.6 ppm. It is possible that anorthite has been formed,

the higher field resonances being hidden under the major broad peak. A 60 mol % addition of CaO gives a spectrum in which the maximum of a very broad resonance arising from a glassy phase is virtually coincident with that of the same sharp resonance (−89.9 ppm) seen at 40% addition. The resonance arising from the glass has been assigned as $Q^4(4Al)$ implying a glass structure of almost perfect ordering of SiO_4 and AlO_4 tetrahedra; this glass co-exists with the same crystalline phase described above. Further additions of CaO produce dramatic spectral changes. At 80 mol %, the sharp resonance at −83.8 ppm is now very weak and a new strong, sharp band at −71.5 ppm dominates. At 100 mol % CaO the spectrum is dominated by two sharp resonances at −71.5 and −73.8 ppm. These resonances are assigned to β- and γ-Ca_2SiO_4.[11] Thus large additions of CaO encourage the formation of crystalline phases and depolymerization.

The ^{27}Al and ^{23}Na MASNMR spectral data are given in Table 3. Although arguments based on changes of shielding of these quadrupolar nuclei must be advanced with caution (MAS does not average second-order quadrupole effects to zero), there were some significant changes in the observed peak maxima for the tetrahedral ^{27}Al resonance and the ^{23}Na resonance. This is best illustrated graphically in Fig. 2 where it can be noted that the

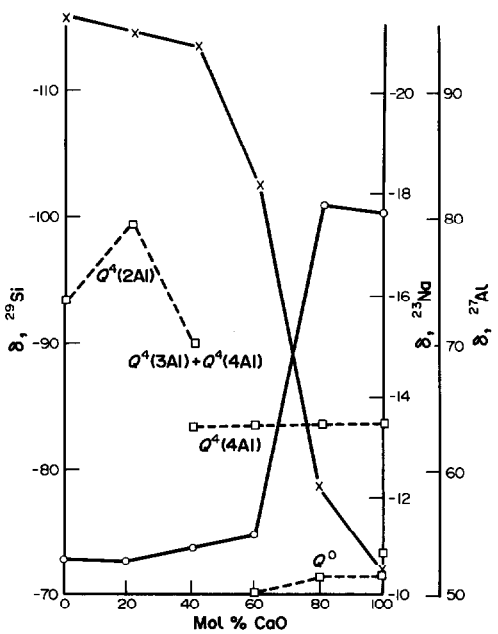

Fig. 2. Plots of chemical shift (δ) for ^{23}Na, ^{27}Al and ^{29}Si for a synthetic albite glass to which has been added the indicated mol % of CaO (—×—, ^{23}Na; —○—, ^{27}Al; --□-- ^{29}Si).

maximum change in the apparent chemical shift of both nuclei occurs between 60 and 80 mol % addition of CaO. In particular, the tetrahedral aluminium resonance undergoes a significant downfield shift to 80.4 ppm on 100% CaO addition, a region which has been correlated with aluminate (as opposed to aluminosilicate) phases.[12] A reasonable interpretation is that addition of CaO in large (>80 mol %) proportions encourages the crystallization of calcium silicate phases with the concurrent formation of, essentially, sodium aluminate phases. The ^{27}Al MASNMR data also reveal that even low additions of CaO cause one aluminium to occupy an "AlO_6" environment.

The effect of SrO and BaO was different in two respects. Firstly, their influence was felt at lower concentration (e.g. 10 mol %—see Table 1); secondly, at 100% mol % additions a *broad* resonance centred at −80.6 ppm (SrO) or −81.5 ppm (BaO) was dominant with lower field resonances characteristic of crystalline phases as weak spectral features. An earlier study using ^{57}Fe Mössbauer spectroscopy to track the fate of iron in feldspathic glazes noted differences produced by the use of different alkaline earth oxides; it was contemplated that either SrO and BaO modified the glass structure or encouraged the precipitation of "ferrate" phases. It would appear that the presence of Sr^{2+} or Ba^{2+} stabilizes the glass and discourages the precipitation of crystalline materials. Further evidence for this hypothesis comes from the ^{27}Al MASNMR data which do not give evidence of separate "aluminate" phases at high SrO, BaO additions. The ^{23}Na data are less informative; although the resonance maximum undergoes a low field shift with increasing mol % addition of MO (M = Sr, Ba), particularly for BaO, this occurs in an erratic fashion. As for CaO, some aluminium is located in an octahedral "AlO_6" site.

Lithium oxide is a strong flux. Since earlier investigations had considered the thermochemistry of laponite,[1] and how the thermal decomposition was modified by additions of oxides,[4] it was of interest to consider the influence of additions of Li_2O (up to 50 mol %) on the synthetic feldspar. The data in Table 2 reveal that lithium, in quite small additions, creates more ordering in the glass phase. The major resonance was, in all cases, broad but at 50% addition a weak resonance, possibly characteristic of a crystalline phase, was noted at −69.7 ppm. Also of interest is the fact that no aluminium was discernible in octahedral coordination. All firings were carried out under identical conditions; it is possible that the rate of reaction of alumina was slower in the presence of MO (M = Ca, Sr, Ba) than when the strong flux Li_2O was present. Alternatively, the octahedral site occupied by Al^{3+} in the

presence of M^{2+} may be preferentially occupied by Li^+. The ^{23}Na resonance shows a monotonic shift to lower field as the degree of ordering in the glass phase increases, i.e. a general conclusion from this work is that the incorporation of more aluminium in the glass leads to an apparent deshielding of the sodium ion.

HYDROXYCARBOXYLATO OXO-OSMIUM(VI) COMPLEXES

CATHERINE F. EDWARDS and WILLIAM P. GRIFFITH*

Inorganic Chemistry Research Laboratories, Imperial College of Science, Technology and Medicine, London SW7 2AY, U.K.

(*Received* 9 *July* 1990; *accepted* 13 *August* 1990)

Abstract—The new complexes OsO_2py_2L (L = oxalate, lactate, atrolactate, citrate, quinate), OsO_2pic_2L (L = oxalate, oxoisobutyrate; pic = 3-methylpyridine), $(OsO_2py_2)_2$(tartrate), $K_2[OsO_2L_2]$ (L = glycolate, quinate) and $K_4[(OsO_2)_2(tartrate)_3]$ are reported. On the basis of IR, Raman and ^{13}C NMR studies we believe them to contain *trans* OsO_2 osmyl linkages. X-ray photoelectronic and mass spectral data are also reported for some of them.

In connection with work which we have recently started on complexes of osmium with glycols and carbohydrates we have been studying oxo-osmium(VI) complexes of α-hydroxycarboxylic acids since these are good models for glycols and the aldonic acid forms of sugars. Few osmium complexes of such ligands are known; salts of $[OsO_2L_2]^{2-}$ (L = salicylate,[1] oxalate and malonate[2]) and of OsO_2py_2L' (L' = glycolate, oxoisobutyrate, mandelate and salicylate)[3] have been reported and the X-ray crystal structure of OsO_2py_2L' (L' = glycolate,[4] salicylate[5]) shows the O═Os═O, "osmyl", linkage to be essentially *trans* in these species.

RESULTS AND DISCUSSION

(a) OsO_2py_2L *and* OsO_2pic_2L

By using hydrophobic co-ligands such as pyridine (py) or 3-picoline (pic) we were able to precipitate complexes of this type. Hinckley's procedure[3] for obtaining OsO_2py_2L (L = glycolate, oxoisobutyrate, mandelate, salicylate) was semi-heterogeneous and worked with few acids: a suspension of *trans*-$K_2[OsO_2(OCH_3)_4]$ was reacted with pyridine to give a suspension, to which was added the acid. In our method we react OsO_4 with the acid in ethanolic solution in the presence of excess pyridine; it is likely that $Os_2O_6py_4$ is formed *in situ* with the ethanol having reduced osmium(VII) to osmium(VI). A similar procedure is successful for 3-picoline, but we were unable to obtain tractable products using 2,2′-bipyridyl or 1,10-phenanthroline. Complexes were obtained with a wide variety of acids, though we were unable to isolate the products with malic, tartronic or gluconic acids.

The complexes were characterized by elemental analysis, IR and Raman spectroscopy (see Table 1), and in some cases by ^{13}C NMR, mass spectral and X-ray photoelectronic spectroscopic techniques. The vibrational spectra are discussed below (Section c).

The citrato and tartrato complexes are of particular interest because citrate and tartrate can function as terminal or bridge ligands. The analysis of the citrato complex is close to that for a monomer, OsO_2py_2(citrate), and the ^{13}C NMR spectrum [Section c(i)] is consistent with this. Unfortunately the tartrato complex is not sufficiently soluble for ^{13}C NMR studies, but its IR spectrum (see below) suggests that the tartrate has a bridging role; elemental analyses and the FAB^+ mass spectrum are in agreement with its formulation as $(OsO_2py_2)_2$(tartrate).

(b) $K_2[OsO_2L_2]$

Species of this type are not easy to isolate. Methods used in the literature include reaction of *trans*-$K_2[OsO_2(OH)_4]$,[2] OsO_4 with alkali[6,7] or $K_4[Os_2O_6(NO_2)_4]$[6,7] with the acid; the species so produced were $[OsO_2ox_2]^{2-}$,[2,6,7] $[OsO_2(salicylate)_2]^{2-}$[1] and $[OsO_2(malonate)_2]^{2-}$.[2] We

[b] Raman band.

find that a better method is to use a solution of *trans*-$K_2[OsO_2(OMe)_4]$ in methanol with the acid; in this way we have prepared the known salt $K_2[OsO_2ox_2]$ as well as the new salts listed in Table 1. These salts are not very stable and tend to decompose even in the solid state after a few days, while in solution they rapidly decompose to give OsO_2. Analyses of the compounds obtained with citric and tartaric acids do not fit the general formula $K_2[OsO_2L_2]$. These ligands (and also malic and tartronic acids which give complexes of variable composition) would have free hydroxyl and carboxylate groups in an $[OsO_2L_2]^{2-}$ structure and hence a propensity to oligomerization. Such a problem is lessened in the $[OsO_2py_2L]$ type of complexes since pyridine occupies two of the coordination sites on the metal and so decreases the possibilities of oligomerization.

(c) *Spectroscopic data and structures*

None of the new complexes gave crystals suitable for X-ray examination. However, on the basis of vibrational and, in some cases, ^{13}C NMR and X-ray photoelectronic spectroscopic evidence we believe them all to contain the linear *trans* $O{=}Os^{VI}{=}O$, "osmyl", unit, and in the case of the hydroxycarboxylic acids, that coordination occurs from the deprotonated hydroxy and carboxylate groups forming a five-membered ring. Thus the coordination around the osmium in both types of complex is likely to be as shown in Fig. 1.

(i) ^{13}C NMR. We were able to measure the ^{13}C NMR spectra of OsO_2py_2(glycolate) and OsO_2py_2(lactate) in C^2HCl_3 and of OsO_2py_2(citrate) in ^2H_2O; the other complexes (apart from OsO_2py_2ox for which ^{13}C data would not be useful) were either too unstable in solution or were insufficiently soluble.

The spectrum of OsO_2py_2(glycolate) shows two resonances assignable to the glycolato ligand, at δ 188.5 and at 76.1 [all δ in ppm vs $Si(CH_3)_4$]. The former we assign as arising from the carboxylate carbon atom and the latter to the hydroxy-bearing carbon atom. The large downfield shift of the latter resonance relative to its position in free glycolic acid (δ 62.0)[8] is consistent with the alcoholic OH group coordinating, with the loss of a proton. Comparable shifts and assignments have been made for solutions of $K_2[MoO(O_2)_2$(glycolate)$]\cdot 2H_2O$, in which X-ray data showed the hydroxy group to be deprotonated,[9] and in other molybdenum, tungsten[8] and uranyl[10] glycolato complexes. For OsO_2py_2(lactate), shifts at δ 189.5, 82.1 and 20.1 are assigned to the carboxylate, deprotonated hydroxy-bearing and methyl carbon centres, respectively (observed at δ 180.4, 67.4 and 19.6 in the free ligand);[11] highly comparable shifts have been reported for lactato complexes of molybdenum(VI),[8,11] tungsten(VI)[8] and of the uranyl entity.[10] The ^{13}C NMR spectrum of OsO_2py_2(citrate) shows four resonances at δ 192.7, 176.9, 88.8 and 46.4. If a five-membered ring is formed of $(citrate)^{2-}$ involving the deprotonated hydroxy group and the central carboxylate group both bound to the central metal atom, as we have demonstrated by X-ray work to be the case in $K_2[MoO(O_2)_2$(citrate)$]\cdot 1/2H_2O_2\cdot 3H_2O$,[12] the four resonances will be as follows. That at δ 46.4 arises from the methylene carbon atoms, the tertiary deprotonated hydroxy-bearing carbon is at δ 88.8, the non-coordinating carboxylate carbon atoms at δ 176.9, while the lowest field resonance at δ 192.7 would arise from the carbon atom of the unique central coordinating carboxyl group. Similar assignments have been made for gallium[13] and aluminium[14] citrato complexes.

(ii) *Raman and IR data.* All the complexes show very strong, sharp IR bands near 840 cm^{-1} and rather weaker, broader bands near 570 cm^{-1}. The former we assign to $\nu^{as}(OsO_2)$, the asymmetric stretch of the osmyl unit as in other complexes of this type,[2,15] while the 570 cm^{-1} band, or bands in that region, are likely to arise from Os—O stretches for the coordinated ligands {in $(Bu^n{}_4N)_2[OsO_2ox_2]$ these modes were identified near 570 cm^{-1}}.[3] For those complexes whose colours do not preclude the measurement of Raman spectra strong, sharp bands are observed near 890 cm^{-1}, assigned to the symmetric stretch $\nu^s(OsO_2)$ of the osmyl unit; as expected for these centrosymmetric or quasi-centrosymmetric moieties $\nu^s(OsO_2)$ is not observed in the IR and $\nu^{as}(OsO_2)$ is not observed in the Raman. In the cases of OsO_2py_2(citrato) and OsO_2py_2(glycolate), where solubilities are sufficient to allow recording of the Raman spectra of solutions, the 890 cm^{-1} bands are found to be polarized as expected for $\nu^s(OsO_2)$ vibrations.

The bands likely to be due to C—O stretches are complex and our assignments are necessarily tentative, following those of others on analogous

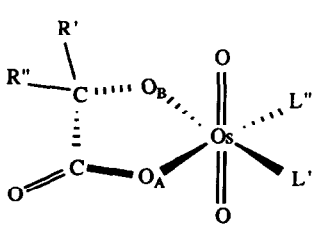

Fig. 1.

complexes. In the table we give assignments of ν(C=O), ν(C—O_A) and ν(C—O_B) where O is the *exo* carbonyl oxygen atom, O_A is the deprotonated carboxylate hydroxyl group and O_B is the deprotonated hydroxyl adjacent to the carboxyl group (see Fig. 1). Generally it is observed that there was a shift of both ν(C=O) and ν(C—O_A) towards lower frequency upon complexation, as expected.[16,17] For OsO_2py_2ox, OsO_2pic_2ox and the known *trans*-$K_2[OsO_2ox_2]$ we follow the assignments of Preetz and Schultz,[2] assigning IR bands near 1718 and 1702 cm^{-1} to ν^{as}(C=O) and ν^{s}(C=O), respectively, and at 1340 and 1205 cm^{-1} to ν^{as}(C—O) and ν^{s}(C—O), respectively. Likewise in the complexes OsO_2py_2(glycolate) and $K_2[OsO_2(glycolate)_2]$ bands near 1650 cm^{-1} are assigned to ν(C=O_A) and near 1388 cm^{-1} to ν(C—O_B), as in other glycolato complexes.[10,18] In the lactato complex, $[OsO_2py_2(lactate)]$, bands are similarly assigned by comparison with the literature for lactato complexes.[10]

The citrato and tartrato complexes are of interest here because these ligands can function as terminal or bridging ligands. The analysis of OsO_2py_2(citrate) fits well for this formula with terminal bidentate citrate, and the IR spectrum is similar to that observed for $K_2[MoO(O_2)_2(citrate)]\cdot 1/2H_2O_2\cdot 3H_2O$[12] and for $Na_2[\{VO(citrate)\}_2O]\cdot 12H_2O$.[19] As well as the band at 1595 cm^{-1} due to the complexed carboxylate group, another at 1727 cm^{-1} is seen which may be assigned to the asymmetric stretch of free carboxylic groups. A salt approximating in composition to $K_4[(OsO_2)_2(citrate)_3]$ was obtained from $K_2[OsO_2(OMe)_4]$ and citric acid; IR bands due to citrate were complicated and could arise from both terminal and bridging citrate groups. The IR spectrum of $(OsO_2py_2)_2$(tartrate), in which it is likely that the tartrate ligand bridges two osmium atoms as in the case of $K_4[Mo_2O_2(O_2)_4(tartrate)]\cdot 4H_2O$,[9] shows bands similar to those in the latter but different from those in a uranyl complex[8] in which tartrate behaves as a terminal ligand only. As would be expected for a bridging tartrate, the osmium complex shows no band assignable to a free carboxylate group.

The complex formulated by Wintrebert as $K_2[OsO_3ox]$[20] has been reformulated as $K_2[OsO_2(OH)_2ox]$ on the basis of IR data,[21] but we now reformulate it as a dimer, $K_4[Os_2O_6ox_2]\cdot 2H_2O$ (Fig. 2). This is consistent with the reformulation of "$K_2[OsO_3(NO_2)_2]$"[20] as $K_4[OsO_2O_6(NO_2)_4]$, proven by X-ray crystallography[22] to have an analogous structure. An IR band at 651 cm^{-1} and the weak Raman band at 519 cm^{-1} are likely to arise from the Os_2O_2 bridge.[23]

(iii) *X-ray photoelectron spectroscopy*. We also list in the table X-ray photoelectron spectroscopy (XPS) $4f_{7/2}$ binding energies for four of the complexes, since it is known[24,25] that such data are indicative of the oxidation state of the osmium. The values are relative to a C_{1s} binding energy of 285 eV; by comparison with $4f_{7/2}$ binding energies for standard compounds {$K_2[Os^{VI}O_2(OH)_4]$ 54.5 eV, $K_2[Os^{IV}Cl_6]$ 53.0 eV, $Os^{III}Cl_2(acac)(PPh_3)_2$ 51.9 eV} it is clear that they are likely to contain osmium in the hexavalent oxidation state. For these compounds minor peaks near 53 or 52 eV were also seen, suggesting that some decomposition had occurred under the conditions of the experiment.

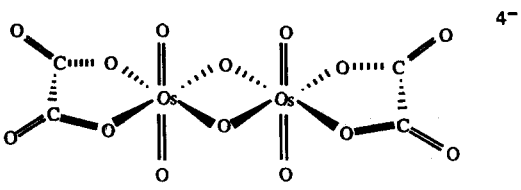

Fig. 2.

(d) *Mass spectroscopy*

We have determined the mass spectra of most of our neutral complexes using positive fast atom bombardment (FAB^+) conditions. For each of the complexes OsO_2py_2L (L = ox, lactate, atrolactate) which were run in a matrix of *meta*-nitrobenzylalcohol (MNBA) the molecular ions $[OsO_2py_2LH]^+$ are observed, as well as peaks corresponding to step-wise ligand loss giving $[OsO_2pyLH]^+$, $[OsO_2py_2]^+$, $[OsO_2py]^+$ and pyH^+; the ion $[OsO_2LH]^+$ is not seen. Similar results were obtained for the complexes OsO_2pic_2L' (L' = ox, oxoisobutyrate). For OsO_2py_2(citrate) however, which was run in glycerol $[OsO_2(citrateH)]^+$ is seen, but not $[OsO_2py_2]^+$ or $[OsO_2py]^+$. The parent ion for $(OsO_2py_2)_2$(tartrate) is seen at m/z = 909, which confirms its dimeric, tartrate-bridged structure. The spectra of all complexes studied contained peaks suggesting fragmentation of the coordinated hydroxycarboxylic acid and each osmium containing fragment gave a characteristic set of signals for which isotopic simulation gave a very similar pattern.

EXPERIMENTAL

OsO_2py_2L (L = *hydroxycarboxylate*)

OsO_4 (0.05 g, 0.19 mmol) was dissolved in ethanol (2 cm^3). The hydroxycarboxylic acid (0.19

mmol) was added, followed by pyridine (1 cm^3) (or 3-picoline in the case of two of the complexes). The reaction mixture was then placed in a freezer and left until the product precipitated. This was filtered off, washed with diethyl ether and vacuum dried. The complexes are various shades of brown in colour and slowly decompose in solution.

$K_2[OsO_2L_2]$ (L = *hydroxycarboxylate*)

$K_2[OsO_2(OMe)_4]$ (0.05 g, 0.12 mmol) prepared by the method of Criegee *et al.*,[26] was dissolved in methanol (5 cm^3). The hydroxycarboxylic acid (0.24 mmol) (or in the case of tartaric acid, 0.18 mmol), dissolved in minimum methanol, was added while stirring, whereby a colour change to green occurred. The volume of solution was reduced until the product began to precipitate. The product was centrifuged off, washed with methanol, then diethyl ether and stored under vacuum. All the complexes were dark green and decomposed readily, particularly in aqueous solution, depositing OsO_2.

$K_4[Os_2O_6ox_4]$ was prepared according to the literature for $K_2[OsO_3ox]$,[20] with the addition of a few drops of ethanol to accelerate the reaction.

IR spectra were measured on a Perkin–Elmer 1720 Infrared Fourier Transform spectrometer with samples as KBr discs. Raman spectra were measured on a Spex Ramalog 5 instrument with a Datamate data acquisition unit as spinning discs on a KBr matrix, using the red 6471 Å line of a Coherent Radiation Innova-90 krypton ion laser. XPS measurements were recorded of powdered samples mounted on a sample stub using chlorine-free, double-sided adhesive tape and analysed using Mg-K_α radiation at 15 kV and 10 mA using 6 mm slits on a Kratos XSAM 800 instrument. ^{13}C NMR spectra were measured in C^2HCl_3 or ^2H_2O on a Bruker WM 250 Fourier Transform spectrometer. Mass spectra were recorded by Mr G. Tucker and Mr J. Bilton on a VG-Micromass 7070E-HS spectrometer.

Microanalyses were provided by the Microanalytical Department of Imperial College.

Acknowledgements—We thank the SERC and Johnson Matthey PLC for a CASE award to one of us (C.F.E.), and Johnson Matthey for loan of osmium tetraoxide. We also thank Dr J. A. Busby for measurement and interpretation of the XPS data, Sue Johnson for running the NMR spectra and Dr P. D. Savage for helpful discussions.

THE CHEMICAL STRUCTURE AND THERMAL PROPERTIES OF ALKALI ULTRAPHOSPHATES

MAKOTO WATANABE* and KAZUHIRO NAKAMURA

Department of Industrial Chemistry, Chubu University, Kasugai, Aichi 487, Japan

(*Received* 16 *March* 1990; *accepted* 22 *August* 1990)

Abstract—Amorphous sodium and lithium ultraphosphates with M_2O/P_2O_5 (M = Na or Li) ratios of 1.0–0.3 have been prepared by mixing 85% phosphoric acid and sodium carbonate or lithium carbonate and then heating the mixture at 400–700°C, in air and in dry nitrogen. The ultraphosphates contained combined water and the amount of the water increased with a decrease in the M_2O/P_2O_5 ratio. When the ultraphosphates were heated in air, branching points in the ultraphosphates were hydrolysed to produce polyphosphates with shorter chain lengths.

Polyphosphates have been used in chemical fertilizers, detergents, food additives, chemical manufacture, ceramics, etc.,[1] and use of the compounds has recently expanded to other fields, for example, electrical manufacture and biomaterials.[2,3] The group of polyphosphates which are called ultraphosphates have a M_2O/P_2O_5 ratio smaller than unity and larger than zero, where M stands for a univalent cation or radical. Structurally, the ultraphosphates have branching points which are chemically active making them unstable materials. Studies on ultraphosphates lag behind in comparison with the studies on chain and ring polyphosphates. This paper describes the synthesis of alkali ultraphosphates by a heating process in air and in dry nitrogen, and the effect of the heating process on the chemical structure of the ultraphosphates. Thermal analysis of the ultraphosphates was also carried out to investigate the thermal properties of their branching points.

EXPERIMENTAL

Preparation

Sodium and lithium ultraphosphates with M_2O/P_2O_5 (M = Na or Li) ratios of 1.0–0.3 were prepared by mixing 85% phosphoric acid and sodium carbonate or lithium carbonate in a platinum crucible, carefully heating the mixture at 100–200°C for 1–2 h and then at 400–700°C (depending on the M_2O/P_2O_5 ratio) for 1 h, and finally, rapidly cooling the resulting melt in a desiccator containing silica-gel. The heating was carried out in air and in dry nitrogen.

Measurement of the mean degree of polymerization

The ultraphosphates made by the above process were dissolved in CO_2-free water. The mean degree of polymerization in an aqueous solution was measured by the end group titration method.[4,5]

Paper chromatography and colorimetry

One-dimensional paper chromatographic separation and colorimetric determination were employed for the measurement of the distribution of the phosphate species in a sample.[6]

Differential thermal analysis (DTA)

A sample was heated at a rate of 5°C min^{-1} in air and in dry nitrogen by means of a Rigaku DTA instrument.

X-ray diffractometry (XRD)

An X-ray diffraction diagram of a powder sample was taken with nickel-filtered Cu-K_α radiation by using a Rigaku X-ray diffractometer, RAD-1B.

RESULTS

Sodium ultraphosphates

The phosphate composition of the prepared sodium ultraphosphates with Na_2O/P_2O_5 ratios of 1.0–0.3 are shown in Table 1. DTA curves of the ultraphosphates prepared in air are given in Fig. 1. The phosphate composition of the thermal products, as numbered in Fig. 1, are also listed in Table 1 together with the thermal equation given in the next section. It was not possible to obtain XRD data of thermal products 9 and 12 because the samples were too soft to be powdered. The sodium ultraphosphates prepared in dry nitrogen showed the same thermal properties as those ultraphosphates prepared in air.

Lithium ultraphosphates

Phosphate composition of the prepared lithium ultraphosphates with Li_2O/P_2O_5 ratios of 1.0–0.3 are indicated in Table 2. DTA curves of the ultraphosphates are given in Fig. 2. The phosphate composition of the thermal products numbered in Fig. 2 are also listed in Table 2. The thermal products 18, 19 and 20 were too soft to be powdered and XRD data could not be obtained.

DISCUSSION

Sodium ultraphosphates

The relation between M_2O/P_2O_5 ratio (R) and mean degree of polymerization (n) of chain poly-

phosphates can be expressed by the following equation:

$$R = (n+2)/n \quad (1)$$

Ultraphosphates have branching points and these points must be considered as the factor which affects their chain length. Equation (1) can be modified as follows:

$$R+f = (n+2)/n, \quad (2)$$

where f stands for the number of branching points per atom of phosphorus. If there are no factors other than sodium and branching point which affect the lowering of the degree of polymerization, $R+f$ and n are unity and infinity, respectively. As Table 3 shows, n for the sodium ultraphosphates was a relatively small, finite number. Accordingly, it was concluded that there were some other factors which affect the degree of polymerization of the ultraphosphates. The most likely factor is the presence of combined water which exists as P—OH. If the number of hydrogens per atom of phosphorus is f', eq. (2) can be rewritten as the following:

$$R+f+f' = (n+2)/n. \quad (3)$$

One can calculate f' using the equation and the calculated values are listed in Table 3. The f' value

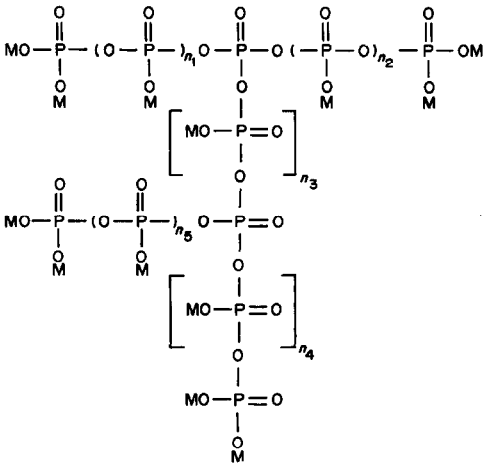
0.3	0.7	11.8	0.17	13.6	0.15

increased with a decrease in R and this means that the amount of combined water increases with a decrease in R. The measured mean degree of polymerization and the calculated f' values of the sodium ultraphosphates which were prepared in dry nitrogen are also listed in Table 3. Since the f' values of the ultraphosphates prepared in dry nitrogen are smaller than those of the ultraphosphates prepared in air, the dry atmosphere reduces the amount of combined water in the ultraphosphates, although it seemed impossible to remove all of it. It should be noted that f does not always indicate the number of branching points. Part of the f value can be responsible for the number of hydrogens which exist as combined water in the phosphates. Accordingly, f' expresses the minimum number of hydrogens per atom of phosphorus. From the above discussion, the following general chemical structure can be given for the ultraphosphates:



where M stands for sodium and/or hydrogen.

As the results of XRD and PC in Table 1 show, the amorphous polyphosphate with an Na_2O/P_2O_5 ratio of 1.0 was transformed to crystalline $NaPO_3I$, known as sodium cyclotriphosphate, through the exotherm at about 320°C.

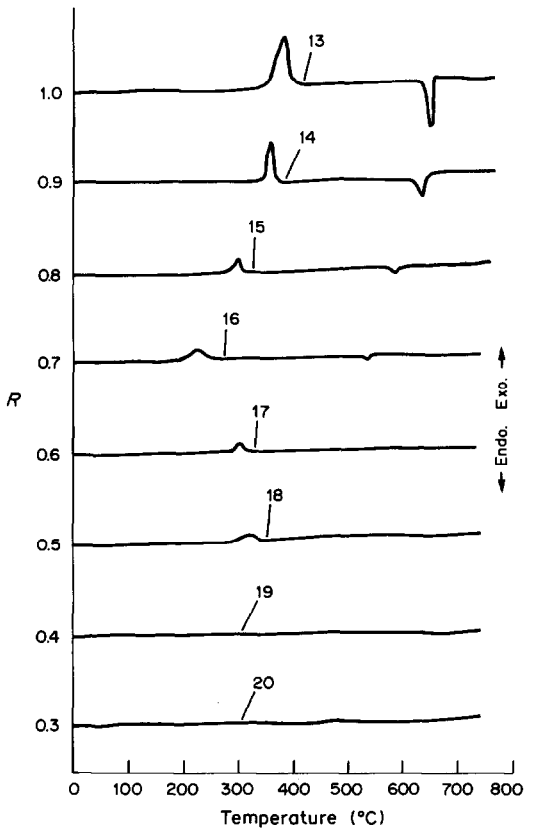


Fig. 2. DTA curves of the lithium ultraphosphates.

$$(NaPO_3)_n \longrightarrow n/3(NaPO_3)_3. \quad (4)$$

The endothermic peak at about 650°C was due to melting of the cyclotriphosphate. These results agree well with those which are given in the literature. Sodium ultraphosphate with an Na_2O/P_2O_5 ratio of 0.9 showed an exothermic peak at about 300°C. According to the XRD and PC data of thermal product 2 in Table 1, the exotherm seemed to be caused by reaction (4). Thermal product 3 showed the X-ray diffraction pattern of $NaPO_3I$, but, in comparison with the data of thermal product 2, the cyclotriphosphate content of thermal product 3 had decreased and the long chain polyphosphate content, increased. Therefore, the endothermic peak at about 400°C may be due to the transformation of part of the cyclotriphosphate to polyphosphates with longer chain lengths:

$$(NaPO_3)_3 \longrightarrow 3/n(NaPO_3)_n. \quad (5)$$

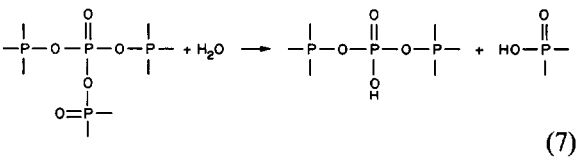
The phosphates melted through the small endotherm at about 630°C. Thermal product 4 showed the X-ray diffraction diagram of $Na_2H(PO_3)_3$ and

its cyclotriphosphate content was 91.5%. Accordingly, the ultraphosphate with an Na_2O/P_2O_5 ratio of 0.8 was changed to the cyclotriphosphate through the exotherm at about 280°C:

Sodium ultraphosphate ($R = 0.8$)

$$\xrightarrow{280°C} Na_2H(PO_3)_3. \quad (6)$$

The ultraphosphate contained 0.14 atoms of hydrogen per atom of phosphorus and therefore the hydrogen content of this ultraphosphate is less than that of $Na_2H(PO_3)_3$. It was concluded that the following hydrolysis of a branching point to an end group and/or a middle group took place during heating to 300°C:



(7)

The water in the above equation can come from the moisture in air. After the next small endothermic reaction at about 370°C, the thermal product showed weak X-ray diffraction peaks of Maddrell's salt and most of the thermal product was long chain polyphosphates. Cyclophosphates seem to be transformed to polyphosphates with longer chain lengths by condensation and reorganization:

$$n Na_2H(PO_3)_3 \longrightarrow Na_{2n}H_n(PO_3)_{3n}. \quad (8)$$

The phosphates melted after the last large endothermic peak at about 500°C. Ultraphosphates with an Na_2O/P_2O_5 ratio of 0.7 showed similar thermal changes to ultraphosphates with a ratio of 0.8; because thermal products 6 and 7 had similar X-ray diffraction patterns and phosphate contents to thermal products 4 and 5. After the first exothermic peak of the ultraphosphate with an Na_2O/P_2O_5 ratio of 0.6 at about 300°C, thermal product 8 exhibited an unknown X-ray diffraction pattern. The phosphate content indicated that considerable amounts of long chain polyphosphates were transformed to cyclotri-, cyclotetra-, and other phosphates with shorter chain lengths. This result indicates that the hydrolysis of branching points proceeds according to reaction (7) during heating. The thermal product melted partly through the endotherm at about 370°C and the phosphates with short chain lengths were reorganized to phosphates with longer chain lengths. After the last small endothermic peak, the sample melted completely. The ultraphosphates with Na_2O/P_2O_5 ratios of 0.5 and 0.4 showed similar thermal changes to each other. After the exotherm at about 250–300°C, thermal products 10 and 11 gave an X-ray diffraction pattern of $Na_2H_2(PO_3)_4$. The phosphate content of these thermal products supported the above result because they contained fairly large amounts of cyclotetraphosphate. The thermal reaction can be given for the process:

Sodium ultraphosphates ($R = 0.5$ and 0.4)

$$\xrightarrow{250\text{–}300°C} Na_2H_2(PO_3)_4. \quad (9)$$

The reaction may progress by the hydrolysis shown in reaction (7) and the resulting reorganization of phosphates. Through the first exothermic peak at about 250–320°C, the ultraphosphates with Na_2O/P_2O_5 ratios of 1.0–0.7 were reorganized to cyclotriphosphate, and the ultraphosphates with Na_2O/P_2O_5 ratios of 0.5 and 0.4 were transformed to cyclotetraphosphate. The ultraphosphate with an Na_2O/P_2O_5 ratio of 0.6 formed both of the cyclophosphates. Accordingly, it can be said that the formation of six-membered and eight-membered ring phosphates from sodium ultraphosphates by a thermal process depends on the sodium content. Thermal products 10 and 11 melted completely through the last large endothermic peaks at about 380–400°C. The ultraphosphate with an Na_2O/P_2O_5 ratio of 0.3 was hygroscopic and thermal product 12 contained only a small amount of cyclotetraphosphate. The reorganization of the ultraphosphate to cyclotri- and cyclotetraphosphates may be difficult because the sodium content of the ultraphosphate is too low.

Lithium ultraphosphates

The mean degree of polymerization of the ultraphosphates with Li_2O/P_2O_5 ratios of 1.0–0.3, prepared in air and in dry nitrogen, was measured and the results are shown in Table 4 together with the f' values calculated using eq. (3). The f' value of the ultraphosphates prepared in air and in dry nitrogen increased with a decrease in R and therefore the combined water content in the ultraphosphates also increases. The f' value of the ultraphosphates prepared in air was larger than that of the ultraphosphates prepared in dry nitrogen. Accordingly, a dry atmosphere can help to reduce the combined water content of the ultraphosphates. Since these results for lithium ultraphosphates are the same as those for sodium ultraphosphates, the same chemical structure can be used to describe them.

Some of the thermal products in Table 2 contained a water-insoluble substance (crystalline

Table 4. f, n and f' values of the lithium ultraphosphates

		In air		In dry nitrogen	
R	f	n	f'	n	f'
1.0	0.0	29.0	0.07	68.1	0.03
0.9	0.1	28.5	0.07	31.7	0.06
0.8	0.2	20.7	0.10	23.7	0.08
0.7	0.3	18.9	0.12	19.6	0.10
0.6	0.4	13.3	0.15	17.0	0.12
0.5	0.5	11.5	0.17	15.2	0.13
0.4	0.6	10.4	0.19	14.3	0.14
0.3	0.7	8.1	0.25	14.0	0.14

$LiPO_3$). The phosphate contents in parentheses indicate soluble components of the thermal products. The lithium ultraphosphates with Li_2O/P_2O_5 ratios of 1.0–0.6 were reorganized to crystalline long chain polyphosphates, $LiPO_3$, through the first exothermic peaks at about 230–400°C. The formation of ring oligophosphates, which was observed in the thermal reactions of the sodium ultraphosphates, was not detected in the thermal processes of the lithium compounds. The small exotherm of the ultraphosphate with a Li_2O/P_2O_5 ratio of 0.6 at about 300°C seemed to be due to the formation of crystalline lithium metaphosphate, but thermal product 18 was so soft that it precluded the recording of XRD data. The ultraphosphates with Li_2O/P_2O_5 ratios of 0.4 and 0.3 did not show any detectable thermal change. Thermal products 19 and 20 which were taken out of a furnace at about 300°C showed that the ultraphosphates had degraded to phosphates with shorter chain lengths. This means that branching points in the ultraphosphates were hydrolysed according to reaction (7) during heating. After the endotherm at about 550–650°C, the ultraphosphates with Li_2O/P_2O_5 ratios of 1.0–0.7 melted completely. The ultraphosphates with R smaller than 0.7 did not show a clear thermal change on melting and were fused gradually by heating up to 500°C.

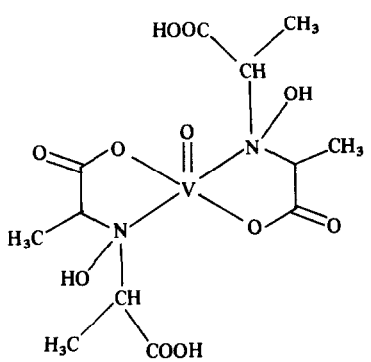
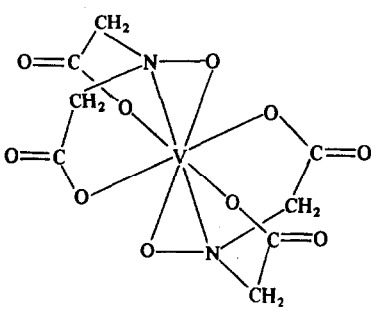
(*Received* 1 *June* 1990; *accepted* 22 *August* 1990)

Abstract—The structure of N,N′-bipyridyl, N-methoxy iminodiacetate oxovanadium(IV) has been determined by X-ray diffraction. The complex shows a distorted octahedral geometry with the vanadium atom coordinating to the oxo oxygen, two carboxyl oxygen atoms and an imino nitrogen of the N-methoxy iminodiacetate ligand, and two nitrogen atoms of the bipyridyl ligand. The V—O and V—N equatorial distances are 1.970(4), 1.982(4), 2.088(4) and 2.094(4) Å, respectively, while the axial V=O and V—N distances are 1.602(4) and 2.379(4) Å.

Some species of *Amanita* toadstools have relatively high contents of a rather simple iminodicarboxylic acid, namely, N-hydroxyimino-α,α′-dipropionic acid HIDPA.[1] For some years, the molecular structure of its oxovanadium complex was thought to be as **1** below, *i.e.* a penta-coordinated 1 : 2 complex of the vanadyl ion VO^{2+} with the above mentioned ligand. Recently, we demonstrated that with an analogue of HIDPA, namely N-hydroxyiminodiacetate acid (HIDA), an octa-coordinated vanadium(IV) bis-complex of the totally ionized ligand (including the N-hydroxyl group) is formed, as **2**, in which the oxo group of the vanadyl ion has been removed.[2]



1



2

This was the first example of an octa-coordinated vanadium(IV) complex having only nitrogen and oxygen atoms as donors. Given the close similarity of chemical properties, EPR and IR spectra, and the analogous unusually high values of the stability constants of their vanadium complexes, it seems likely that the natural HIDPA vanadium complex, named "amavadin" by the researchers who first isolated it,[1] has a structure identical to that depicted as **2** above.

The ionization of the N-hydroxyl group of the ligand seems to be a prerequisite for coordination to the metal, to enable an octa-coordinated V^{4+} bis-complex to be formed. The very high stability of this species ($\log \beta_2$ *ca* 22–23) allows the removal of the oxo group of the vanadyl ion, which is commonly considered to be the most stable oxo-ion in aqueous solution.

To confirm this idea, we have prepared another

* Present address: Centro de Tecnologia Química e Biológica, R. da Quinta Grande 6, 2780 Oeiras, Portugal.
† Author to whom correspondence should be addressed.

analogue of HIDPA in which the N-hydroxyl group cannot ionize, namely, N-methoxyiminodiacetic acid (METIDA), and studied its complexion reactions with vanadium. Several differences emerged in the first studies in aqueous solution: first METIDA behaved as other common aminopolycarboxylic ligands and a predominant 1:1 complex was formed, which hydrolysed at neutral and basic pH; secondly, its EPR spectrum showed the presence of tetravalent vanadium, but the calculated g and A parameters are typical of vanadyl aminopolycarboxylate complexes, not of a vanadium(IV) complex.[3]

In these conditions, and since the $VO^{2+} \cdot L^{2-}$ species is neutral, its isolation as a crystalline form should not be too difficult, particularly if the two free coordination positions could be occupied by a rather bulky ligand. We were able to obtain good crystals of N,N′-bipyridyl,N-methoxy iminodiacetate oxovanadium(IV), and the X-ray diffraction study of the crystal and molecular structures is now described.

EXPERIMENTAL

Preparation

Bromoacetic acid (20.8 g, 0.15 mol) was added to 4.2 g of methoxylamine hydrochloride (0.05 mol) in 100 cm^3 H_2O; 140 cm^3 of 10% NaOH were added dropwise for a period of 36 h, keeping the pH always below 7. After that, the pH was lowered to about 4 with 2 N HCl, 12.8 g (0.05 mol) of barium acetate in 50 cm^3 H_2O were added. The solution was allowed to stand and 10.4 g of a white precipitate of barium N-methoxy iminodiacetate was formed which was filtered and dried *in vacuo* (yield 66%). Found: C, 19.1; H, 2.5; N, 4.3. Calc. for $C_5H_9NO_6Ba$: C, 19.0; H, 2.8; N, 4.4%.

$VOSO_4 \cdot 5H_2O$ (63.3 mg, 0.25 mmol) was added to 158 mg (0.5 mmol) of this salt in 10 cm^3 H_2O. The solution was left to stand overnight and the deposited material was filtered; 39 mg of N,N′-bipyridyl (0.25 mmol) in 5 cm^3 ethanol were added and the mixture was stirred and slowly evaporated *in vacuo*, whereupon brownish-violet crystals were obtained. No recrystallization was attempted. Found: C, 41.2; H, 4.8; N, 9.6. Calc. for $C_{15}H_{21}N_3O_9V$: C, 41.1; H, 4.8; N, 9.6%.

X-ray data

Intensity data were collected on an Enraf Nonius CAD 4 diffractometer using graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å). The $\omega/2\theta$ scan mode was used for measuring the 4718 reflections with $1.5 \leqslant \theta \leqslant 25.0°$ in the reflection quadrant h −15–15, k 0–14, l 0–25. Three standard reflections were monitored but no decay was detected.

The crystal is monoclinic, space group $P2_1/c$, with $a = 10.954(2)$, $b = 9.944(2)$, $c = 17.822(6)$ Å and $\beta = 97.06(2)°$, $V = 1926.6(8)$ Å^3, $Z = 4$, $D_x = 1.45$ g cm^{-3}, μ(Mo-K_α) = 5.45 cm^{-1}, $F(000) = 1192$, $M = 421.9$ for $C_{15}H_{21}N_3O_9V$.

Data were corrected for Lorentz and polarization effects, an empirical absorption correction[4] was applied yielding the values of 0.9518 and 0.9996, respectively, for the minimum and maximum transmission factors.

SOLUTION AND REFINEMENT

3502 unique reflections with $|F_o| \geqslant 3\sigma|F_o|$ were used for solution and refinement with SHELX86[5] and SHELX76,[6] respectively.

The heavy atom position was located from a Patterson synthesis and all the remaining non-hydrogen atoms, including three oxygens of water molecules, were obtained from successive difference Fourier syntheses. The isotropic refinement gave $R = 0.108$ which lowered to 0.063 when anisotropic parameters were admitted.

Hydrogen atoms were introduced in positions obtained in the difference density map and were refined isotropically with no restrictions.

Final $R(F)$* = 0.043 and $R_w(F)$† = 0.048 were obtained for 337 refined parameters, using a weighting scheme $w = 1.0/[\sigma^2(F_o) + |g|F_o^2]$ with $g = 0.0007$. The highest peak on the final difference Fourier map was 0.3 e/Å^{-3}.

Atomic scattering factors were taken from International Tables.[7] All calculations were carried out on a VAX 11/780 computer at Instituto Superior Tecnico.

Fractional atomic coordinates and anisotropic temperature factors for non-hydrogen atoms, hydrogen fractional atomic coordinates and isotropic temperature factors can be obtained from the Cambridge Crystallographic Database. Tables of best least-squares planes in the ligands and lists of observed and calculated structure factors have been submitted as supplementary material.

RESULTS AND DISCUSSION

A molecular diagram presenting the numbering scheme is shown in Fig. 1, and bond lengths and bond angles are listed in Tables 1 and 2, respectively.

* $R(F) = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$.
† $R_w(F) = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.

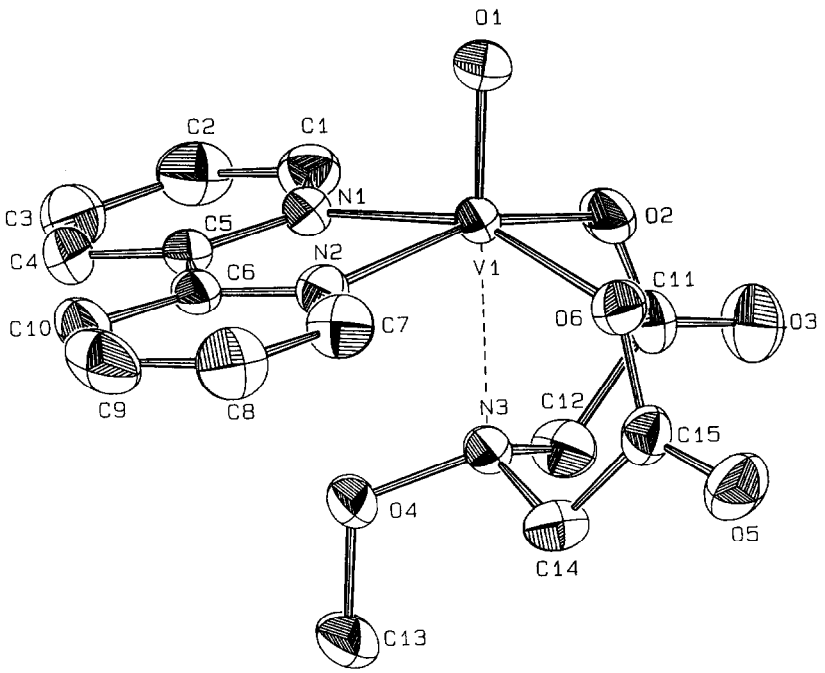


Fig. 1. Molecular diagram (ORTEP II)[8] of the complex.

The complex exhibits essentially an octahedral geometry, formed in the equatorial plane by the two nitrogen atoms of the bipyridyl ligand and the two oxygens from the N-methoxy iminodiacetate ligand; the six-fold coordination around the metal is completed by the oxo oxygen and by a weak interaction to the nitrogen atom of the imino group.

Atoms N(1) N(2) O(2) O(6) are almost coplanar with a slightly tetrahedral distortion. The vanadium atom is 0.373(1) Å away from that plane and towards the vanadyl oxygen. In other vanadyl hexa and penta-coordinated complexes with a quadrangular equatorial plane, the vanadium atom is normally out of that plane by a similar distance.[9,10]

The coordination about the vanadium atom can also be described by the angles formed between planes defined by atoms O(1) O(6) N(3) N(1) and O(1) O(2) N(3) N(2) and the equatorial plane. In our complex that angle is 94.62(5)°, and both planes are almost orthogonal to the equatorial plane. Table 3 lists the parameters of these least-squares planes, deviations of atoms and angles between the planes.

The vanadyl complex 2,2′-bipyridyl(iminodiacetate)oxovanadium(IV)[11] in which the aminopolycarboxylate ligand instead of a methoxyl group has one hydrogen atom attached to the nitrogen atom [N(3)] of the imino group, has the same type of coordination and geometry as that found in the title complex. Thus a close comparison will be made between the two complexes.

In the complex studied the V=O group is slightly tilted relative to the normal to the equatorial plane, making an angle of 1.64(9)° with this line. The corresponding angle of tilt in the other complex[11] is 1.8(2)°.

Holloway and Melnick made a survey[10] on vanadyl complexes, and found a correlation between the vanadyl V=O distance and the coordination geometry on the metal atom. Tetra and hexa-coordinated complexes have similar V=O distances,

with mean values of 1.612 and 1.615 Å, respectively, while penta-coordinated complexes normally have shorter distances, with a mean value of 1.518 Å. In ours and the iminodiacetate complexes, these distances are 1.602(4) and 1.596(2) Å, close to the hexa-coordinate mean value but on the short side of this range. This is not surprising since the six-fold coordination is indeed achieved via a weak interaction to the N(3) atom (see Fig. 1).

The V—O and V—N equatorial distances are within the normal range observed in vanadium(IV) complexes,[9,10,12,13] whilst the V—N axial distance 2.379(4) Å is longer than expected for a vanadium to nitrogen single bond. The corresponding V···N

Planes 1 and 3	87.20(6)
Planes 2 and 3	94.62(5)

interaction in the iminodiacetate complex is 2.328(3) Å.

In the N-methoxy iminodiacetate ligand the two rings formed due to its tri-coordinative behaviour, V(1) O(6) C(15) C(14) N(3) and V(1) O(2) C(11) C(12) N(3), respectively, are almost planar with maximum deviations from the mean-squares planes of ±0.258(3) and ±0.197(3) Å, and are perpendicular to each other with an angle of 85.55(6)°. Bond distances and angles within the ligand are typical of the iminodiacetate molecule.[11,14,15]

The geometry found for bipyridyl is usual in this ligand. Steric repulsions between hydrogens at C(4) and C(10), which are 2.16(4) Å away in this complex, are believed[11,16,17] to be the cause of a common distortion observed, trying to alleviate this short intramolecular contact. This is achieved with a twist of 5.3(1)° in the two benzene rings and a dihedral angle of 9.0(1)° between the axes through C(2)—C(5) and C(6)—C(8). In the analogous complex these values compare with ours as: 6.6(3)° and 10.1(3)°, respectively. The angles at C(5) and C(6) are also different from normal benzenic angles. The smaller values inside the five membered ring, N(1)—C(5)—C(6) 114.5(3)° and N(2)—C(6)—C(5) 115.2(3)°, and larger values on the other side, C(4)—C(5)—C(6) 124.1(3)° and C(5)—C(6)—C(10) 124.0(3)°, are comparable to the mean values of 115° and 124°, respectively, in the iminodiacetate complex.[11] However, the aromatic character is still present in the rings, as can be observed by their planarity and C—C and C—N bond distances.

There are some hydrogen bonds between the solvent water molecules and the complex molecules. The stronger interactions are between the water hydrogen atoms and the exocyclic oxygens O(3) and O(5) [2.855(8) and 2.740(8) Å, respectively].

CONCLUSION

The results obtained show that ionization of a N-hydroxyl group is necessary to form a complex of vanadium(IV), whose high thermodynamical stability (octa-coordination of a 4-charged metal ion) is more than enough to compensate for the energy required to remove the oxo-group from the complex anion. The substitution of a N-hydroxyl by a N-methoxyl group forbids that possibility, and a normal aminopolycarboxylate complex with the vanadyl ion VO^{2+} is formed in which not even the oxygen atom of the methoxy group interacts with the metal ion.

(*Received* 31 *May* 1990; *accepted* 28 *August* 1990)

Abstract—The reactions of *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ (dppm = $Ph_2PCH_2PPh_2$) with the nitriles RCN (R = CH_3 or C_2H_5) in the presence of $HBF_4 \cdot Et_2O$ or HPF_6 (aq.) afford salts of the *cis*-$[Re_2Cl_2(dppm)_2(NCR)_4]^{2+}$ cations. Studies on the reactivity of *cis*-$[Re_2Cl_2(dppm)_2(NCC_2H_5)_4](PF_6)_2$ with CO in acetone show that the mixed carbonyl–nitrile complexes $[Re_2Cl_3(dppm)_2(CO)_2(NCC_2H_5)]PF_6$ and $Re_2Cl_3(dppm)_2(CO)_2(NCC_2H_5)$ are the major products; these reactions involve the displacement of nitrile by CO and the uptake of Cl^- through the sacrifice of a portion of the starting dirhenium complex. Attempts to grow crystals of *cis*-$[Re_2Cl_2(dppm)_2(NCC_2H_5)_4](PF_6)_2$ led to its conversion to $[Re_2Cl_3(dppm)_2(NCC_2H_5)_2]PF_6$. The related complex $[Re_2Cl_3(dppm)_2(1,2\text{-}C_6H_4(CN)_2)_2]PF_6$ has been prepared by the reaction of $Re_2Cl_4(dppm)_2$ with $1,2\text{-}C_6H_4(CN)_2$ and KPF_6 in acetone, and its structure established by X-ray crystallography. The crystallographic data are as follows: orthorhombic space group $P2_12_12_1$, $a = 18.242(6)$, $b = 19.197(6)$, $c = 19.789(6)$ Å, $V = 6929(7)$ Å^3 and $Z = 4$. The structure was refined to $R = 0.081$ ($R_w = 0.098$) for 3511 data with $I > 3.0\sigma(I)$. The structure, which can be represented as $[Cl_2Re(\mu\text{-dppm})_2ReCl(1,2\text{-}C_6H_4(CN)_2)_2]PF_6$, contains monodentate $1,2\text{-}C_6H_4(CN)_2$ ligands and possesses a staggered rotational geometry. The Re—Re bond length is 2.265(1) Å. The reaction of *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ with $NaBH_3CN$ in THF gives *cis*-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2$, in which the structure of the parent complex is retained but with N-bound cyanotrihydroborato ligands in place of the axially bound chlorides. The crystallographic data for *cis*-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2 \cdot CH_2Cl_2$ are as follows: orthorhombic space group *Pbca*, $a = 18.072(2)$, $b = 19.982(2)$, $c = 31.795(6)$ Å, $V = 11481(5)$ Å^3 and $Z = 8$. The structure was refined to $R = 0.035$ ($R_w = 0.045$) for 4613 data with $I > 3.0\sigma(I)$. The Re—Re bond distance in this complex is 2.2938(7) Å.

The development of the chemistry of the *cis* and *trans* isomeric forms of the triply-bonded dirhenium(II) complexes $Re_2(\mu\text{-}O_2CR)_2X_2(\mu\text{-LL})_2$ (R = CH_3, C_2H_5, C_6H_5 or $4\text{-}C_5H_5N$; X = Cl or Br; LL = $Ph_2PCH_2PPh_2$, $Ph_2PNHPPh_2$ or $Ph_2AsCH_2AsPh_2$) has been a focus of recent studies in our laboratory.[1–3] Among the characteristics of these systems is their ease of oxidation to the corresponding paramagnetic monocations with retention of stereochemistry.[1,2] In the present study we set out to examine the lability of the bridging carboxylate and axial halide ligands to substitution by other nucleophiles, especially nitrile-containing ligands. We now describe the results of these investigations as they relate to the complexes *cis*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ (R = CH_3 or C_2H_5; dppm = $Ph_2PCH_2PPh_2$), and we include in this report the details of the full structural characterizations of the new complexes $[Re_2Cl_3(\mu\text{-dppm})_2(1,2\text{-}C_6H_4(CN)_2)_2]PF_6$ and *cis*-$Re_2(\mu\text{-}O_2CCH_3)_2(NCBH_3)_2(\mu\text{-dppm})_2$.

EXPERIMENTAL

Starting materials

The compounds $Re_2Cl_4(dppm)_2$,[1] *cis*-$Re_2(O_2CR)_2Cl_2(dppm)_2$ (R = CH_3 or C_2H_5)[1,3] and $[(Ph_3P)_2N]O_2CCH_3$[3,4] were prepared as described previously. The $HBF_4 \cdot Et_2O$ and HPF_6 (60% aq. solution) reagents were purchased from Aldrich Chemical Co., while carbon monoxide (99.9%) was obtained from Matheson Gas Products. These reagents were used without further purification. Solvents used in the preparation of the complexes were of commercial grade and were thoroughly deoxygenated prior to use.

Reaction procedures

Syntheses were performed in an atmosphere of dry nitrogen under the pressure provided by passing the outlet nitrogen through a mineral oil bubbler. All solvents were freshly distilled prior to use.

A. *Reactions of* cis-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ *with* $HBF_4 \cdot Et_2O$ *or* HPF_6(aq.) *in the presence of nitriles*

(i) CH_3CN. A small volume of $HBF_4 \cdot Et_2O$ (*ca* 0.1 cm^3) was added to a mixture of *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ (0.140 g, 0.103 mmol), acetone (5 cm^3) and acetonitrile (1 cm^3). The green solution thereby produced was stirred at room temperature for 15 min. The product was obtained as a pale green powder upon the slow addition of diethyl ether (*ca* 25 cm^3) to this solution. This solid was filtered off, washed with diethyl ether and dried *in vacuo*; yield 0.144 g (88%). Found: C, 42.5; H, 3.6; Cl, 4.8. Calc. for $C_{58}H_{62}B_2Cl_2F_8N_4O_3P_4Re_2$ {i.e. for $[Re_2Cl_2(dppm)_2(NCCH_3)_4](BF_4)_2 \cdot 3H_2O$}: C, 43.4; H, 3.9; Cl, 4.4%. This complex showed absorptions at 3538 (m–s,br) and 1630 (m–w,br) cm^{-1} in its IR spectrum (Nujol mull) assignable to ν(O—H) and δ(O—H) modes, respectively. The source of the water of crystallization is presumably the small quantity of water that is present in the $HBF_4 \cdot Et_2O$ reagent.

A related procedure was used to react a mixture of *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ (0.20 g, 0.147 mmol), dichloromethane (6 cm^3) and acetonitrile (0.6 cm^3) with HPF_6(aq.) (0.05 cm^3). The colour of the reaction mixture changed from orange–brown to dark green within *ca* 2 min at room temperature. The solution was stirred for an additional 20 min and the product was obtained as a pale green powder upon the addition of a large excess of diethyl ether (*ca* 50 cm^3). The product was filtered off, washed with diethyl ether and dried *in vacuo*; yield 0.19 g (74%). Found: C, 40.2; H, 3.2. Calc. for $C_{59}H_{58}Cl_4F_{12}N_4P_6Re_2$ {i.e. for $[Re_2Cl_2(dppm)_2(NCCH_3)_4](PF_6)_2 \cdot CH_2Cl_2$}: C, 40.5; H, 3.3%. The presence of lattice CH_2Cl_2 was confirmed by ^1H NMR spectroscopy.

(ii) C_2H_5CN. Procedures similar to those described in section A(i) were used to obtain green products that we formulate as the propionitrile derivatives $[Re_2Cl_2(dppm)_2(NCC_2H_5)_4]X_2$ (X = BF_4^- or PF_6^-) on the basis of the similarities of their spectroscopic and electrochemical properties to those of the acetonitrile complexes. The propionitrile complex was also obtained from $[Re_2Cl_2(dppm)_2(NCCH_3)_4](BF_4)_2 \cdot 3H_2O$ by a nitrile exchange reaction. A quantity of the acetonitrile complex (0.23 g) was treated with an excess of propionitrile and the mixture stirred at room temperature for a few minutes. A small volume (2 cm^3) of acetone was added to the solution, followed by the slow addition of diethyl ether to initiate precipitation of the green propionitrile product, which was filtered off, washed with diethyl ether and dried *in vacuo*.

During attempts to grow single crystals of $[Re_2Cl_2(dppm)_2(NCC_2H_5)_4](PF_6)_2$ from dichloromethane–diethyl ether, this complex converted to the much more stable bis(propionitrile) derivative, $[Re_2Cl_3(dppm)_2(NCC_2H_5)_2]PF_6$. The crystals that were obtained proved to be of composition $[Re_2Cl_3(dppm)_2(NCC_2H_5)_2]PF_6 \cdot 2CH_2Cl_2$.[5]

B. *Synthesis of* $[Re_2Cl_3(dppm)_2(1,2\text{-}C_6H_4(CN)_2)]PF_6$

A mixture of $Re_2Cl_4(dppm)_2$ (0.10 g, 0.08 mmol), 1,2-dicyanobenzene (0.15 g, 1.17 mmol) and KPF_6 (0.10 g, 0.54 mmol) was treated with 6 cm^3 of acetone and stirred for 1 h at room temperature. An excess of diethyl ether was added to precipitate a red solid, which was filtered off, extracted into dichloromethane (15 cm^3) and reprecipitated upon the addition of excess diethyl ether; yield 0.11 g (83%). Found: C, 47.8; H, 3.5. Calc. for $C_{66}H_{52}Cl_3F_6N_4P_5Re_2$: C, 48.1; H, 3.9%. The identity of this product was confirmed by a single crystal X-ray structure analysis.

C. *Reactions of* $[Re_2Cl_2(dppm)_2(NCR)_4]X_2$ (X = BF_4^- *or* PF_6^-)

(i) $[(Ph_3P)_2N]O_2CCH_3$. Acetonitrile (10 cm^3) was added to a mixture of $[Re_2Cl_2(dppm)_2(NCCH_3)_4](BF_4)_2 \cdot 3H_2O$ (0.036 g, 0.002 mmol) and $[(Ph_3P)_2N]O_2CCH_3$ (0.055 g, 0.092 mmol). This reaction mixture was stirred at room temperature for 30

min. The orange product was filtered off, washed with ethanol and diethyl ether and dried; yield 0.015 g. It was identified as *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ on the basis of its cyclic voltammetric properties as measured on 0.1 M TBAH–CH_2Cl_2 solutions. These data are in excellent agreement with the literature values of $E_{1/2}(ox) = +0.28$ V and $E_{1/2}(ox) = +1.34$ V vs Ag/AgCl.[1]

(ii) *Carbon monoxide.* A quantity of $[Re_2Cl_2(dppm)_2(NCC_2H_5)_4](PF_6)_2 \cdot CH_2Cl_2$ (0.10 g, 0.055 mmol) was dissolved in 10 cm^3 of deoxygenated acetone and a slow stream of carbon monoxide bubbled through the solution for 10 min. The green–brown solution was then stirred for 2 h, evaporated to dryness and the residue extracted with 10 cm^3 of dichloromethane. The resulting extract was added to 30 cm^3 of diethyl ether to precipitate a yellow–green product, which was washed with diethyl ether and dried *in vacuo*; yield 0.051 g (62%). Its identity as $[Re_2Cl_3(dppm)_2(CO)_2(NCC_2H_5)]PF_6$ was established by a comparison of its cyclic voltammetric properties and ^1H NMR and IR (Nujol mull) spectra with those reported in the literature for an authentic sample of this complex.[6]

In an alternative work-up of this reaction product, the initial green–brown reaction solution was subjected to chromatography on an Al_2O_3 column (80–200 mesh, 20 cm, CH_2Cl_2 as eluent) and a blue band collected. This was evaporated to low volume and treated with an excess of pentane to precipitate a blue solid; yield 0.02 g. Found: C, 48.3; H, 4.0. Calc. for $C_{55}H_{49}Cl_3NO_2P_4Re_2$ [i.e. for $Re_2Cl_3(dppm)_2(CO)_2(NCC_2H_5)$]: C, 48.6; H, 3.6%. The cyclic voltammetric properties and IR (Nujol mull) and X-band ESR spectral properties of this product were also in agreement with literature data.[6]

D. *Reactions of* cis-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ *with carbon monoxide*

A quantity of the title complex (0.14 g, 0.10 mmol) was dissolved in 8 cm^3 of dichloromethane, a slow stream of carbon monoxide bubbled through the solution for 5 min, and a small volume (0.10 cm^3) of HPF_6(aq.) added. The resulting mixture was stirred at room temperature for a further 20 min under an atmosphere of carbon monoxide, and a large excess of diethyl ether added to precipitate a brown solid that was filtered off and recrystallized from dichloromethane–pentane; yield 0.09 g (61%). The identity of this product as $[Re_2Cl_3(dppm)_2(CO)_3]PF_6$ was established by the similarity of its cyclic voltammetric properties and IR (Nujol mull) spectrum to those of an authentic sample.[7] Further confirmation came from its ready reduction to the blue paramagnetic neutral species, $Re_2Cl_3(dppm)_2(CO)_3$.[7]

When $HBF_4 \cdot Et_2O$ was used in place of HPF_6(aq.) in the above procedure, the analogous BF_4^- salt was obtained, viz. $[Re_2Cl_3(dppm)_2(CO)_3]BF_4$. Found: C, 44.9; H, 3.3. Calc. for $C_{53}H_{44}BCl_3F_4O_3P_4Re_2$: C, 44.9; H, 3.1%. Its cyclic voltammogram (recorded on a 0.1 M TBAH–CH_2Cl_2 solution) showed reversible redox processes at $E_{1/2}(ox) = +0.33$ V and $E_{1/2}(red) = -0.70$ V vs Ag/AgCl. Its IR spectrum (Nujol mull) had characteristic ν(CO) modes at 2045 s and 2010 s cm^{-1} (terminal C—O stretches), and 1976 m cm^{-1} (bridging C—O stretch). These data are in excellent agreement with those reported for the PF_6^- salt.[7]

E. *Reaction of* cis-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ *with* $NaBH_3CN$

A suspension of *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ (0.20 g, 0.15 mmol) and $NaBH_3CN$ (0.05 g, 0.80 mmol) in 10 cm^3 of THF was stirred at room temperature for several hours until a rust coloured precipitate deposited. This product was filtered off and extracted into dichloromethane (*ca* 25 cm^3). The extract was evaporated to half volume and then treated with a large excess of pentane to precipitate *cis*-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2$; yield 0.11 g (54%). Found: C, 50.1; H, 4.5. Calc. for $C_{56}H_{56}B_2N_2O_4P_4Re_2$: C, 50.2; H, 4.2%.

Preparation of single crystals for structure determination

Red crystals of $[Re_2Cl_3(dppm)_2(1,2\text{-}C_6H_4(CN)_2)_2]PF_6$ (**1**) were grown by the diffusion of diethyl ether into a dichloromethane solution of the complex, while crystals of composition *cis*-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2 \cdot CH_2Cl_2$ (**2**) were obtained as red cubes from a dichloromethane–pentane mixture.

X-ray crystallography

The structures were determined by the use of standard procedures. A summary of the crystallographic data for both structures is given in Table 1. The cell constants are based on 25 reflections with $7 < \theta < 13°$ for **1** and $16 < \theta < 20°$ for **2**. Three standard reflections were measured after 5000 s of beam time during data collection. There were no systematic variations in intensity. Calculations were performed on a microVAX II com-

puter using the Enraf–Nonius structure determination package.

The crystals selected for the structure determinations belong to the orthorhombic space groups $P2_12_12_1$ (No. 19) with $Z = 4$ for **1** and *Pbca* (No. 61) with $Z = 8$ for **2**. Lorentz and polarization corrections were applied to the data. The structures were solved by the use of the Patterson heavy-atom method, which revealed the positions of the rhenium atoms in the asymmetric units. The remaining atoms were located in succeeding difference Fourier synthesis. The positions for the hydrogen atoms of the ligand molecules were calculated by assuming idealized geometry and a C—H bond distance of 0.95 Å. For the methyl groups of the acetate ligands and BH_3 groups of the $NCBH_3$ ligands, one hydrogen was located in a difference Fourier map, its position idealized, and the remaining positions calculated. We assumed that the value of B(H), i.e. the isotopic equivalent thermal parameter for the hydrogen atoms, was equal to $1.3[B_{eqv}(C)]$ at the time of the inclusion of this parameter in the refinement procedure. While these hydrogen atoms were used in the calculation of F_{calc} their positions

were not refined. An empirical absorption correction was used,[8] the linear absorption coefficients being 38.24 cm^{-1} for **1** and 45.20 cm^{-1} for **2**. No corrections for extinction were applied. The structures were refined in full-matrix least-squares, where the function minimized was $\Sigma w(|F_o|-|F_c|)^2$, with the weighting factor w defined as $w = 1/\sigma^2(F_o)$. For **1**, the Re, Cl, P and F atoms were refined anisotropically. All non-hydrogen atoms for complex **2** were refined anisotropically, including the C and Cl atoms of the crystallographically unique lattice CH_2Cl_2 molecule which is located about a general position (eight symmetry related sites per unit cell). Corrections for anomalous scattering were applied to all atoms that were refined anisotropically.[9]

The refinement of the PF_6^- anion in the structure of **1** was not entirely satisfactory; the thermal parameters for the F atoms were rather large, implying high thermal motion, and the P—F distances covered a fairly large range [1.37(3)–1.68(4) Å]. Nonetheless, our modelling of the PF_6^- makes sense based upon our knowledge of the stoichiometry and spectroscopic properties of the complex. The highest peaks in the final difference Fourier maps of **1** and **2** were 2.49 and 0.77 e Å^3, respectively. Since these were not at any bonding distance to the atoms of the dirhenium molecules they were not considered to be of any chemical significance.

Further details concerning the data sets and structure solutions and refinements may be obtained from Dr P. E. Fanwick. Tables 2 and 3 list important bond distances and angles for these structures.*

Physical measurements

Perkin–Elmer 1420 and 1800 spectrophotometers were used to record the IR spectra of compounds as mineral oil (Nujol) mulls supported on KBr plates in the region 4000–400 cm^{-1}. Electrochemical measurements were carried out on dichloromethane solutions that contained 0.1 M tetra-*n*-butylammonium hexafluorophosphate (TBAH) as the supporting electrolyte. $E_{1/2}$ values, determined as $(E_{p,a}+E_{p,c})/2$, were referenced to the silver/silver chloride (Ag/AgCl) electrode at room temperature and are uncorrected for junction potentials. Under our experimental conditions, $E_{1/2} = +0.47$ V vs Ag/AgCl for the ferro-

* Atomic positional and thermal parameters and full listings of bond lengths and angles have been deposited with the Editor and with the Director, Cambridge Crystallographic Data Centre.

cenium/ferrocene couple. Voltammetric experiments were performed with a Bioanalytical Systems Inc. Model CV-1A instrument in conjunction with a Hewlett–Packard Model 7035 B *x–y* recorder. Conductivity measurements were performed on 1×10^{-3} M acetone solutions of the complexes on an Industrial Instruments Inc. Model RC-16B2 conductivity bridge. $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian XL-200 spectrometer operated at 80.98 MHz with the use of an internal deuterium lock and 85% H_3PO_4 as an external standard. ^1H NMR spectra were obtained on Varian XL-200 and GE QE-300 spectrometers. Resonances were referenced internally to the residual protons in the incompletely deuteriated solvents. ^{11}B NMR spectra were recorded on a Varian FT-80 spectrometer with the use of $BF_3 \cdot OEt_2$ as an external standard.

Analytical procedures

Elemental microanalyses were performed by Dr H. D. Lee of the Purdue University Microanalytical Laboratory.

RESULTS AND DISCUSSION

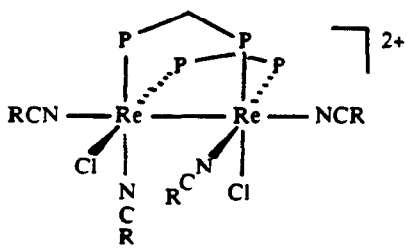
A. *Synthesis of and characterization of* cis-$[Re_2Cl_2(dppm)_2(NCR)_4]^{2+}$

Our initial objective in preparing salts of these cations was accomplished in the case of R = CH_3 and C_2H_5 through the reactions of the complex *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ with the appropriate nitrile, admixed with a suitable reaction solvent, in the presence of the strong acid $HBF_4 \cdot Et_2O$ or HPF_6(aq.). While the spectroscopic properties of the products showed the absence of propionate ligands and the presence of the appropriate nitrile, microanalytical data (supported by IR and NMR spectroscopy) indicated that lattice water, and/or solvent, was also present in the products. These are doubtless quite strongly hydrogen-bonded to the BF_4^- and PF_6^- anions. Since our attempts to free the complexes from these molecules were not successful, all subsequent studies were carried out on products that we formulate as *cis*-$[Re_2Cl_2(dppm)_2(NCR)_4](BF_4)_4 \cdot 3H_2O$ (the actual amount of water present seemed to vary somewhat from

run to run) and *cis*-$[Re_2Cl_2(dppm)_2(NCR)_4](PF_6)_2 \cdot CH_2Cl_2$.

In all instances, these salts had IR spectra (Nujol mulls) that showed the presence of coordinated nitrile ligands [ν(C≡N) at *ca* 2290 (w) cm^{-1}] and the anions $[BF_4]^-$ [ν(B—F) at *ca* 1060 (s) cm^{-1}] or $[PF_6]^-$ [ν(P—F) at *ca* 840 (s) cm^{-1}]. Further evidence as to the identity of these complexes came from conductivity measurements which showed that solutions of $[Re_2Cl_2(dppm)_2(NCR)_4](PF_6)_2 \cdot CH_2Cl_2$ in acetone ($c_m \simeq 1.0 \times 10^{-3}$ M) have conductivities characteristic of 1 : 2 electrolytes, viz 162 Ω^{-1} cm^2 mol^{-1} for R = CH_3 and 159 Ω^{-1} cm^2 mol^{-1} for R = C_2H_5. Furthermore, the reconversion of *cis*-$[Re_2Cl_2(dppm)_2(NCCH_3)_4](BF_4)_2 \cdot 3H_2O$ to *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ upon its reaction with $[(Ph_3P)_2N]O_2CCH_3$ in acetonitrile implies that the structural integrity of the dirhenium core has been retained throughout these reactions.

The 200 MHz ^1H NMR spectrum of $[Re_2Cl_2(dppm)_2(NCC_2H_5)_4](BF_4)_2$, recorded in CD_3CN, showed that the propionitrile ligands had been displaced by CD_3CN. The resonances of propionitrile were at δ +2.35 (quartet, —C*H*$_2$—, 8H) and +1.19 (triplet, —C*H*$_3$, 12H) and integrated in accordance with there being four C_2H_5CN ligands in the complex. The spectrum of this complex in CD_2Cl_2 showed multiplets at δ *ca* +2.65 and *ca* +1.35 that are assigned to the coordinated propionitrile ligands. The complexity of these patterns implies that inequivalent nitrile ligands are present. This is supported by the $^{31}P\{^1H\}$ NMR spectrum of this complex (also recorded in CD_2Cl_2) which is an AA′BB′ pattern, the main components of which are centred at δ *ca* −2.6, −3.4, −16.9 and −17.4. These properties may be in accordance with the following structure:



Unfortunately, attempts to determine the structure of the $[Re_2Cl_2(dppm)_2(NCR)_4]^{2+}$ cations by X-ray crystallography were thwarted by our failure to obtain suitable single crystals. In fact, solutions of these salts were unstable and converted to the much more stable $[Re_2Cl_3(dppm)_2(NCR)_2]^+$ cation[11] during the crystal growing procedures. This presumably occurs by a complicated reaction involving nitrile dissociation and chloride transfer between dirhenium species. In one such instance, the structure of $[Re_2Cl_3(dppm)_2(NCC_2H_5)_2]PF_6$ was determined[5] in the mistaken belief that the crystals were in fact those of $[Re_2Cl_2(dppm)_2(NCC_2H_5)_4](PF_6)_2$.

Attempts to derivatize $[Re_2Cl_2(dppm)_2(NCR)_4]X_2$ (X = BF_4^- or PF_6^-) by displacing some or all of the nitrile ligands led to products that are more conveniently prepared directly from $Re_2Cl_4(dppm)_2$. Thus, the reaction of $[Re_2Cl_2(dppm)_2(NCC_2H_5)_4](PF_6)_2$ with CO afforded $[Re_2Cl_3(dppm)_2(CO)_2(NCC_2H_5)]PF_6$ and $Re_2Cl_3(dppm)_2(CO)_2(NCC_2H_5)$, both of which have been prepared previously and are known to have edge-shared bioctahedral structures with an all-*cis* disposition of chloride ligands.[6] Once again, an additional chloride ligand, over and above the number that are present in the starting complex, becomes incorporated into the product. As an alternative strategy, the complex *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ was reacted with CO in the presence of $HBF_4 \cdot Et_2O$ or HPF_6(aq.), with dichloromethane as the reaction solvent in place of CH_3CN or C_2H_5CN. The products were $[Re_2Cl_3(dppm)_2(CO)_3]X$ (X = BF_4^- or PF_6^-) in which the $[Re_2Cl_3(dppm)_2]$ unit is again present. The PF_6^- salt had been prepared previously and structurally characterized.[7]

B. *Synthesis and crystal structure of* $[Re_2Cl_3(dppm)_2(1,2\text{-}C_6H_4(CN)_2)_2]PF_6$ (1)

In the course of the present study, we investigated the reactivity of dirhenium complexes such as $Re_2Cl_4(dppm)_2$ and *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ towards dinitrile ligands with the objective of ascertaining their ability to link dirhenium units so as to form small clusters or polymers. Our attempts to prepare salts of the $[Re_2Cl_2(dppm)_2(1,2\text{-}C_6H_4(CN)_2)_x]^{2+}$ cation (x = 2 or 4) from *cis*-$Re_2(O_2CC_2H_5)_2Cl_2(dppm)_2$ were not successful, and the best characterized product we isolated proved to be the title complex. It was obtained by the reaction of $Re_2Cl_4(dppm)_2$ with 1,2-dicyanobenzene and KPF_6 in acetone, a procedure that resembles the one used previously to prepare other complexes of the type $[Re_2Cl_3(dppm)_2(NCR)_2]PF_6$.[11] These compounds have an unsymmetrical structure that can be represented as $[Cl_2Re(\mu\text{-dppm})_2ReCl(NCR)_2]PF_6$.[5,11] The properties of the 1,2-dicyanobenzene complex are in accordance with those of other such derivatives. Most notably, its $^{31}P\{^1H\}$ NMR spectrum (recorded in CD_2Cl_2) consists of an AA′BB′ pattern (the most intense components are at δ −2.03 and −5.48), while a cyclic voltammetric measurement

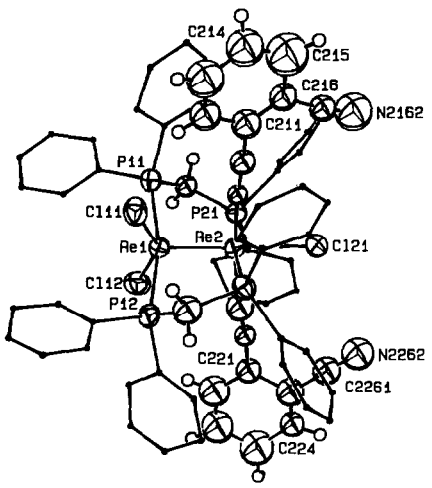


Fig. 1. ORTEP representation of the structure of the dirhenium cation in $[Re_2Cl_3(dppm)_2(1,2\text{-}C_6H_4(CN)_2)_2]PF_6$ (**1**) showing the atomic numbering scheme. The thermal ellipsoids are drawn at the 50% probability level except for the phenyl carbon atoms which are shown as circles of arbitrary radius.

on a solution of the complex in 0.1 M TBAH–CH_2Cl_2 revealed a rich redox chemistry with a reversible oxidation [$E_{1/2}(ox) = +0.75$ V vs Ag/AgCl], a reversible reduction [$E_{1/2}(red) = -1.20$ V], and an irreversible reduction at $E_{p,c} \simeq -1.8$ V. The IR spectrum (Nujol mull) of this complex has a $\nu(C{\equiv}N)$ mode at 2240 (m–w) cm^{-1}, with a shoulder at *ca* 2230 cm^{-1}, and a characteristic $\nu(P—F)$ mode for the PF_6^- anion at 842 (vs) cm^{-1}. A single crystal X-ray structure analysis, which confirmed the identity of this complex, showed that the two dinitrile ligands are bound in a monodentate fashion.

An ORTEP representation of the structure of the cation in the salt $[Re_2Cl_3(dppm)_2(1,2\text{-}C_6H_4(CN)_2)_2]PF_6$ is shown in Fig. 1. Important bond distances and angles are listed in Table 2. The dirhenium unit possesses no crystallographically-imposed symmetry. The Re—Re distance of 2.265(1) Å is essentially identical to the Re—Re distances in the analogous propionitrile[5] and benzonitrile[11] complexes, which are 2.266(1) and 2.270(1) Å, respectively. As expected, the axial Re—Cl bond [Re(2)—Cl(21)] is longer than the pair of equatorial Re—Cl bonds [2.492(6) Å vs 2.344(7) and 2.381(8) Å], a feature that is common to all three structures. All other bond lengths are normal and, with one exception, do not merit further discussion. The one exception concerns the C—N distances of the coordinated and free cyano groups of the $1,2\text{-}C_6H_4(CN)_2$ ligands. Within the significance level of 3σ, these distances are the same. The bond angles for the dirhenium cation are similar to those for the other two bis(nitrile) structures.[5,11] Thus, the Cl(11)—Re(1)—Cl(12) angle of 146.5(3)° can be compared with angles of 142.9(3) and 140.5(3)° in the propionitrile and benzonitrile complexes, respectively, while the N(210)—Re(2)—N(220) angle of 169.1(9)° compares with the values of 171.3(8) and 169.6(5)°. The conformation about the Re—Re bond is staggered as shown by values for the four torsional angles P(11)—Re(1)—Re(2)—P(21), P(12)—Re(1)—Re(2)—P(22), Cl(11)—Re(1)—Re(2)—N(210) and Cl(12)—Re(1)—Re(2)—N(220) of 33.3(4), 31.5(4), 24.5(8) and 31.2(10)°, respectively.

C. *The synthesis and characterization of* cis-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2$ (2)

A further reaction we studied was that involving an anionic nitrile ligand, namely $[BH_3CN]^-$. While we have been unable to identify the product from the reaction of $NaBH_3CN$ with $Re_2Cl_4(dppm)_2$, we found that *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ reacts with $NaBH_3CN$ in THF at room temperature to form *cis*-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2$ (**2**). Interestingly, the electrochemical properties of this complex, as measured by the cyclic voltammetric technique on a 0.1 M TBAH–CH_2Cl_2 solution of the complex, are quite different from the related behaviour of the chloride precursor complex. While *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$ has two processes with $E_{1/2}$ values of +0.28 and +1.34 V vs Ag/AgCl, which correspond to one-electron oxidations of the bulk complex,[1,3] the cyanotrihydroborate complex shows an oxidation at $E_{1/2} = +0.60$ V and two irreversible reductions at $E_{p,c} = -1.29$ and $E_{p,c} = -1.48$ V vs Ag/AgCl.

The $^{31}P\{^1H\}$ NMR spectrum of **2** (recorded in CD_2Cl_2), like the analogous chloride,[3] appears as a singlet (δ −9.48). The ^1H NMR spectrum displays resonances for the phenyl protons in the range δ +7.6 to +6.9, and multiplets for the dppm bridgehead methylene protons (—CH_AH_M—) at δ_A +6.50 and δ_M +4.89. The latter patterns resemble closely those reported previously in the spectrum of *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$. The methyl protons of the acetate ligands appear as a singlet at δ +2.45. A very broad double-humped feature spanning the range δ +0.4 to −0.4 may be due to the protons of the $[BH_3CN]^-$ ligands. The ^{11}B NMR spectrum shows a broad resonance, exhibiting some poorly-defined structure, at δ *ca* −43; this becomes a sharp singlet at δ −41.7 in the proton-decoupled mode. In the IR spectrum (Nujol mull) there are characteristic bands associated with the cyanotrihydro-

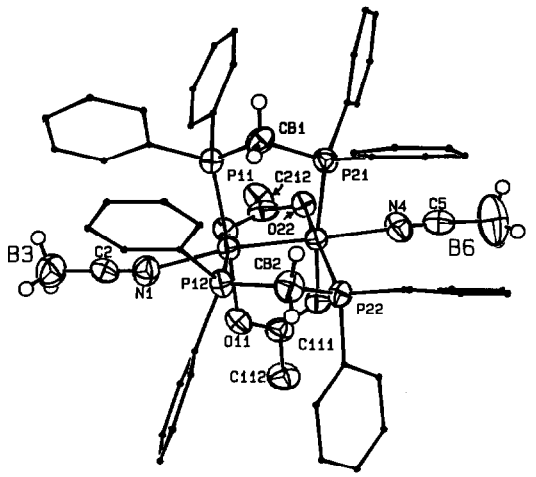

Fig. 2. ORTEP representation of the structure of the dirhenium unit in *cis*-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2 \cdot CH_2Cl_2$ (**2**) showing the atomic numbering scheme. The thermal ellipsoids are drawn at the 50% probability level except for the phenyl carbon atoms which are shown as circles of arbitrary radius.

borato ligands at 2328 (m–s,br) and 2154(s) cm^{-1} that are assigned to ν(B—H) and ν(C≡N) modes, respectively.[12–18] The C≡N stretch is unusual in being at a *lower* frequency than that of the free ligand; coordination of $[BH_3CN]^-$ to a metal ion invariably leads to an increase in this stretching frequency.[12–18] We attribute this decrease to the weakness of the Re—$NCBH_3$ interaction, a conclusion that is supported by the crystal structure data (*vide infra*).

A single crystal X-ray structure determination on this complex has confirmed its close structural relationship to *cis*-$Re_2(O_2CCH_3)_2Cl_2(dppm)_2$.[1,3] An ORTEP representation of the structure is shown in Fig. 2. The Re—Re distance in *cis*-$Re_2(O_2CCH_3)_2(NCBH_3)_2(dppm)_2$ is 2.2938(7) Å, a value that is very similar to that reported for the chloride complex [2.2763(7) Å];[3] the small difference presumably reflects the differing effects of the weakly bound axial ligands (BH_3CN^- versus Cl^-). The axial Re—N distances [2.30(1) and 2.29(1) Å] are much longer (by *ca* 0.3 Å) than the related equatorial Re—N distances in dirhenium(II) complexes that contain organic nitrile ligands,[5,11] and the Re—N distance to the $[BH_3CN]^-$ ligand in $Re(CO)_3(bpy)(NCBH_3)$.[18] The weakness of this interaction is also reflected by the IR spectral properties of this complex (*vide supra*). While the Re—N and N—C distances for the two terminal Re—$NCBH_3$ units are the same (Table 3), there is a modest difference between the associated Re—N—C angles [164(1) and 179(1)°]. These angles, as well as the related Re—Re—N angles [164.0(3) and 167.7(3)°], approach linearity. The structural parameters for the terminally bound $[BH_3CN]^-$ ligands are in satisfactory agreement with data reported in the literature for other M—$NCBH_3$ complexes.[14,17]

ISOLATION OF A TETRAKIS(μ-THIOLATO)TRIPALLADIUM COMPLEX: CRYSTAL STRUCTURE OF *TRANS*-$Pd_3(\mu\text{-}SCy)_4Cl_2(PMe_3)_2$

ESTHER M. PADILLA and CRAIG M. JENSEN*

Department of Chemistry, University of Hawaii, Honolulu, HI 96822, U.S.A.

(*Received* 7 *June* 1990; *accepted* 28 *August* 1990)

Abstract—Reaction of excess cyclohexyl mercaptan with $[PdCl(PMe_3)\mu\text{-}Cl]_2$ (**1**) in refluxing chloroform produces the unusual tetrakis(μ-thiolato)tripalladium complex, $Pd_3(\mu\text{-}SCy)_4Cl_2(PMe_3)_2$ (**2**), rather than the more common (μ-thiolato)dipalladium complexes, $Pd_2(\mu\text{-}SCy)_2Cl_2(PMe_3)_2$ (**3**) or $Pd_2(\mu\text{-}SCy)(\mu\text{-}Cl)Cl_2(PMe_3)_2$ (**4**), which are obtained, respectively, from the reactions of **1** with excess and stoichiometric amounts of the thiol under ambient conditions. The molecular structure of **2**·$CHCl_3$ has been determined by single crystal X-ray crystallography. The coordination about each of the palladium centres is essentially square planar although the bond angles are severely distorted from an idealized geometry. The complex is non-planar with a Pd(1)—Pd(2)—Pd(3) angle of 132.2(1)°. In contrast to the *cis* configuration which is generally preferred by bis(μ-alkylthiolato)dipalladium complexes, the phosphine ligands are arranged in a *trans* configuration. The cyclohexyl groups of the μ-thiolate ligands which are situated *cis* about Pd(2) are in all cases in anti conformations. Crystallographic data for **2**: orthorhombic $P2_12_12_1$, $Z = 4$; $a = 11.027(4)$; $b = 11.230(6)$; $c = 12.676(6)$ Å; $V = 4621(3)$ Å^3.

There has been recent interest in diplatinum[1,2] and dipalladium[3] μ-thiolato complexes as homogeneous catalysts. A variety of dipalladium[4–7] and diplatinum[1,2,4,5,8] μ-alkylthiolato complexes have been prepared by the reaction of thiols with $[PdCl(PR_3)\mu\text{-}Cl]_2$ at ambient conditions. We have found that the reaction of excess cyclohexyl mercaptan (CySH) with $[PdCl(PMe_3)\mu\text{-}Cl]_2$ (**1**) in refluxing chloroform does not produce a bis(μ-thiolato)dipalladium complex, but rather the tetrakis(μ-thiolato)tripalladium complex, *trans*-$Pd_3(\mu\text{-}SCy)_4(PMe_3)_2Cl_2$(**2**). Although bis($\mu$-thiolate)dipalladium complexes have been known for nearly 40 years,[4] reports of the synthesis of tetrakis(μ-thiolato)tripalladium complexes are, to our knowledge, lacking. We wish to report the synthesis and the results of the X-ray structural determination of the tripalladium complex (**2**).

EXPERIMENTAL

General details

The following were purchased from Aldrich Chemical Co. and used without further purification: cyclohexyl mercaptan, acetone (reagent-grade), chloroform (reagent-grade), chloroform-d_1 and dichloromethane-d_2. The complex $[PdCl(PMe_3)\mu\text{-}Cl]_2$ was prepared by the method of Chatt and Venanzi.[9]

The ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Nicolet NT300 spectrometer at 300 and 122 MHz, respectively. The ^1H NMR data are listed in ppm downfield from TMS at 0.00 ppm. ^{31}P NMR chemical shifts were measured relative to the deuterium resonance of the solvent by using the internal frequency lock of the spectrometer so that the resonance from a capillary of 85% H_3PO_4, centred in a 5 mm NMR tube containing the deuterated solvent, appeared at 0.0 ppm at 20°C. Microanalyses were

performed by Oneida Research Services Inc. (Whitesboro, New York).

Preparation of $Pd_3(\mu\text{-SCy})_4Cl_2(PMe_3)_2$ (**2**)

A solution of $[PdCl(PMe_3)\mu\text{-Cl}]_2$ (2.026 g, 4.00 mmol) and cyclohexyl mercaptan (1.65 cm^3, 13.49 mmol) in chloroform (150 cm^3) was refluxed for 30 min. The initial orange solution became green–yellow within 2 min. The resulting yellow crystalline product was isolated (2.124 g) by filtration from the reaction mixture. Reduction of the volume of the mother-liquor to 40 cm^3 resulted in the precipitation of an additional 0.3134 g of product (2.437 g combined yield, 91%). ^1H NMR (CD_2Cl_2): δ 3.18 m, 2.90 m, 2.36 m, 2.08 m, 1.69 m, 1.37 m, 1.18 m $S(C_6H_{11})$; 1.49 [d, J_{P-H} = 11 Hz, $P(CH_3)_3$]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ −9.7 (s).

Preparation of $Pd_2(\mu\text{-SCy})_2Cl_2(PMe_3)_2$ (**3**)

The procedure involves variations of the synthesis of $Pd_2(\mu\text{-SEt})_2(PPr_3)_2Cl_2$ reported by Chatt and Hart.[4] A solution of $[PdCl(PMe_3)\mu\text{-Cl}]_2$ (0.508 g, 1.00 mmol) in acetone (50 cm^3) was treated at 25°C with cyclohexyl mercaptan (0.41 cm^3, 3.35 mmol). The initially orange solution became green–yellow within 2 min and was stirred at room temperature for 24 h. The resulting green–yellow crystalline product was isolated (0.440 g, 66%) by filtration from the reaction mixture. ^1H NMR (CD_2Cl_2): δ 3.18 m, 2.90 m, 2.38 m, 2.07 m, 1.67 m, 1.39 m, 1.18 m $S(C_6H_{11})$; 1.49 [d, J_{P-H} = 11 Hz, $P(CH_3)_3$]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ −8.6 (s). Found: C, 32.2; H 5.6. Calc.: C, 32.4; H, 6.0%.

Preparation of $Pd_2(\mu\text{-SCy})(\mu\text{-Cl})Cl_2(PMe_3)_2$ (**4**)

The procedure involves variations of the synthesis of $Pd_2(\mu\text{-SEt})(\mu\text{-Cl})Cl_2(PPr_3)_2$ reported by Chatt and Hart.[4] A solution of $[PdCl(PMe_3)\mu\text{-Cl}]_2$ (0.414 g, 0.82 mmol) in acetone (50 cm^3) was treated at 25°C with cyclohexyl mercaptan (0.10 cm^3 0.82 mmol). The initial orange solution became yellow within 2 min and was stirred at room temperature for 24 h. The resulting green–yellow crystalline product (0.126 g) was isolated from the reaction mixture by filtration. Reduction of the volume of the mother-liquor to 5 cm^3 resulted in the precipitation of an additional 0.296 g of product (0.634 g combined yield, 87%). ^1H NMR (CD_2Cl_2): δ 3.50 m, 2.44 m, 1.78 m, 1.44 m, $S(C_6H_{11})$; 1.64 [d, J_{P-H} = 13 Hz, $P(CH_3)_3$]. $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 5.1 (s).

Crystallographic study

Crystals suitable for X-ray diffraction were obtained by slow evaporation of a chloroform solution of **2**. The crystal was mounted on a glass fibre with epoxy and centred on a Nicolet P3 automated diffractometer. The unit-cell parameters were obtained by least-square refinement of the setting angles of 20 reflections. Crystal and instrument stability were monitored with a set of three standard reflections measured every 97 reflections; no significant variations were found. Details of other crystal data and relevant information are summarized in Table 1.

The structure was solved by direct methods using SHELX PLUS computer programs (Nicolet Instrument Corp.) and refined by full-matrix least-squares procedures. All non-hydrogen atoms were refined with anisotropic coefficients. The hydrogen atoms were introduced in fixed calculated positions and the coordinates and isotropic thermal parameters for hydrogens were allowed to vary in the final cycles of full-matrix least-squares refinement. During the refinement, a group of peaks not associated with the palladium complex became apparent in the

difference Fourier maps. The peaks were refined as a chloroform solvate.

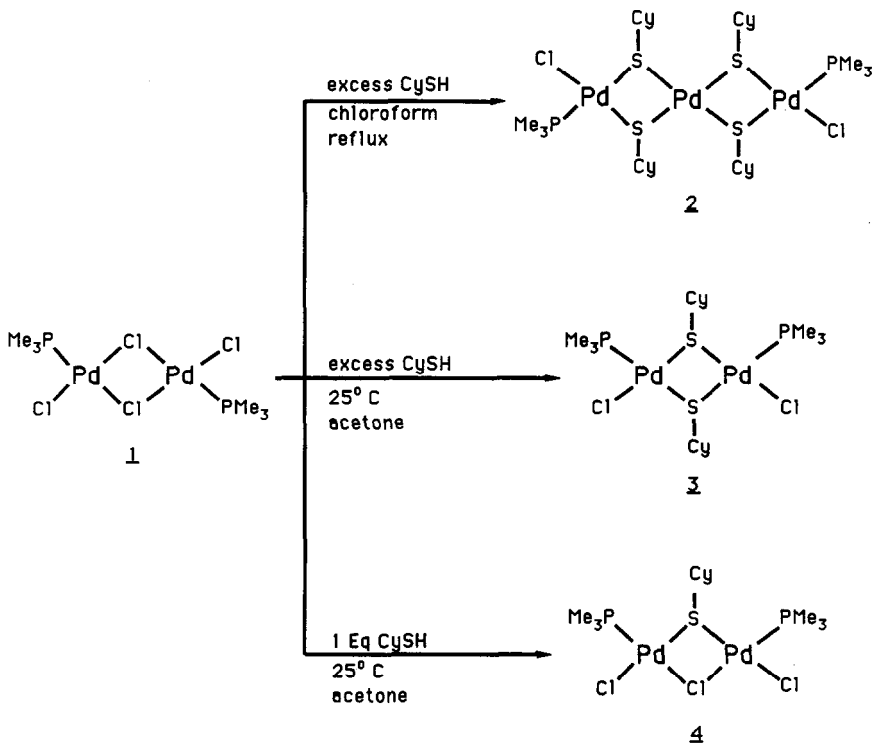
Tables of the final fractional atomic coordinates and thermal parameters, as well as full lists of bond distances and angles for $2 \cdot CHCl_3$, have been deposited as supplementary material with the Editor.

RESULTS AND DISCUSSION

At ambient conditions the reaction of $[PdCl(PMe_3)\mu\text{-}Cl]_2$ (**1**) with cyclohexyl mercaptan with excess cyclohexyl mercaptan gives the expected bis(μ-thiolato) complex, $Pd_2(\mu\text{-}SCy)_2Cl_2(PMe_3)_2$ (**3**) while reaction with stoichiometric amounts of mercaptan gives $Pd_2(\mu\text{-}SCy)(\mu\text{-}Cl)Cl_2(PMe_3)_2$ (**4**). The trimetallic complex, *trans*-$Pd_3(\mu\text{-}SCy)_4Cl_2(PMe_3)_2$ (**2**) was obtained by refluxing chloroform solutions of **1** with excess cyclohexyl mercaptan for 30 min as shown in Scheme 1. The product was isolated upon filtration of the reaction mixture and an additional amount of **2** was obtained upon concentration of the mother-liquor (91% total yield). The approximately 2 : 1 ratio of the integrated intensities of the signals for thiolate cyclohexyl and phosphine methyl protons in the ^1H NMR spectrum of the sample in CD_2Cl_2 indicated that neither **3** nor **4** had been produced in this reaction. Complex **2** can also be distinguished from the dipalladium complexes **3** and **4** by ^{31}P NMR spectroscopy. The chemical shifts observed for the coordinated phosphorous of **2** and **3** in $CDCl_3$ solution of −9.7 and −8.6 ppm, respectively, are quite similar. However, the $^{31}P\{^1H\}$ NMR spectrum of a sample containing equal amounts of authentic samples of **2** and **3** in $CDCl_3$ solution contained baseline resolved signals for both complexes. The trimetallic nature of **2** became apparent only upon X-ray structural analysis.

Structure of $Pd_3(\mu\text{-}SCy)_4Cl_2(PMe_3)_2 \cdot CHCl_3$ ($2 \cdot CHCl_3$)

An ORTEP projection of the molecular structure of **2** is seen in Fig. 1. Selected bond distances and angles are presented in Table 2. The Pd(1)—Pd(2) and Pd(2)—Pd(3) distances of 3.234(2) and 3.230(2) Å, respectively, reflect the lack of bonding interactions between the palladium atoms. The coordination about each of the palladium centres is essentially square planar, although the bond angles are severely distorted from an idealized geometry to alleviate steric congestion of the cyclohexyl groups. The complex is non-planar with a Pd(1)—Pd(2)—Pd(3) angle of 132.2(1)° and dihedral angles between the coordination plane of Pd(2) and those of Pd(1) and Pd(3) of 130 and 131°, respectively. The $M_3(\mu\text{-}SR)_4$ core is very similar to that which



Scheme 1.

has been found[10] for $[Ni_3\{o\text{-}(SCH_2)_2C_6H_4\}_4]^{2-}$. Unlike bis($\mu$-alkylthiolato)dipalladium complexes in which *cis*-phosphine configurations are preferred,[4-6] the phosphine ligands in **2** are arranged in a *trans* configuration. The cyclohexyl groups of the μ-thiolate ligands which are situated *cis* about Pd(2) are in all cases in anti conformations.

In contrast to the large number of known dipalladium complexes, tripalladium complexes are quite rare. Several triangular clusters[11] as well as the linear cluster, $[Pd_3(MeNC)_6(PPh_3)_3]$[12] have been structurally characterized. Palladium acetate has been found[13] to be trimeric, consisting of a triangular arrangement of non-bonded palladium.

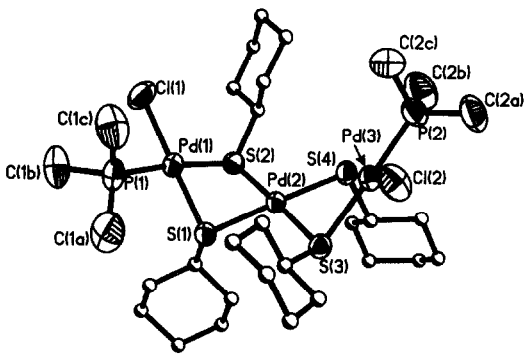

Fig. 1. ORTEP projection of $Pd_3(\mu\text{-}SCy)_4Cl_2(PMe_3)_2$ (**2**), thermal ellipsoids at 50% probability except for the cyclohexyl carbons which are shown as spheres of arbitrary radius. The hydrogen atoms have been omitted for clarity.

The structures of both $Pd_3[\eta^3\text{-}1,3\text{-di(pyvaloyl)allyl}]_2(\mu,\eta^2\text{-acetate})_4$[14] and $Pd_3[1\text{-}3\eta^3\text{-}6\text{-}(\alpha\text{-chloroethyl})\text{cyclooctenyl}]_2Cl_4$[15] have been found to be linear tripalladium complexes, which like **2** contain four bridging ligands and palladium atoms at non-bonding distances. However, $[Pd_3\{\eta^3\text{-}1,2,3\text{-tri}(p\text{-methoxyphenyl})\text{allyl}\}_2(acac)_2]$[16] and $Pd_3(\eta^3\text{-}2\text{-methylallyl})_2Cl_4$[17] are the only other examples of structurally characterized non-planar tripalladium complexes of which we are aware. In the case of the allyl complexes, it is believed[15] that the bent structures may result from crystal packing forces rather than steric interactions, as appears to be the case with **2**. Bent trimetallic structures have also been proposed for $Pd_3(\mu\text{-}PPh_2)_2(\mu\text{-}Cl)_2Cl_2(PPh_3)_2$[18] and $[NEt_4]_2[Pd_3(\mu\text{-}Cl)_4(C_6F_5)_4]$.[19]

In view of the wide variety of palladium[4-6] and platinum[1,4,5,8] $M_2(\mu\text{-}SR)_2(PR_3)_2Cl_2$ complexes which have been synthesized from the reaction of $M_2(\mu\text{-}Cl)_2(PR_3)_2Cl_2$ with thiols, it is surprising that there have been no prior reports of the isolation of $M_3(\mu\text{-}SR)_4(PR_3)_2Cl_2$ complexes. The rarity of these complexes has been somewhat clarified by our examination of the reaction of **1** with other thiols in refluxing chloroform. We have found the formation of trimetallic complexes to be surprisingly sensitive to the alkyl group of the thiol. For example, the exclusive product of the reaction of **1** with t-butyl mercaptan in refluxing chloroform is the structurally characterized[7] dimetallic complex, $Pd_2(\mu\text{-S-}t\text{-Bu})(\mu\text{-Cl})Cl_2(PMe_3)_2$.

NEUTRAL COMPLEXES OF GALLIUM DI-IODIDE CONTAINING Ga—Ga BONDS

JOHN C. BEAMISH, ALAN BOARDMAN* and IAN J. WORRALL

Department of Chemistry, The University, Lancaster LA1 4YA, U.K.

(*Received* 23 *April* 1990; *accepted* 29 *August* 1990)

Abstract—The complexes $Ga_2I_4 \cdot 2L$ (L = pyridine, 2-methylpyridine, 3-methylpyridine, 4-methylpyridine, morpholine, N-methylmorpholine, 1,4-dioxan, tetrahydrofuran, tetrahydropyran, dimethylsulphide, diethylsulphide, tetrahydrothiophene, 1,4-thioxan, 1,4-dithiane and tetramethylbiphosphine) have been prepared. Vibrational spectra indicate that the complexes adopt disubstituted ethane-like structures containing Ga—Ga bonds. We were unable to synthesize complexes of stoichiometry $Ga_2I_4 \cdot 4L$ which had previously been reported.

Brewer *et al.*[1–3] were first to isolate coordination compounds of the ionic gallium dihalides, $Ga^+GaX_4^-$ (X = Cl, Br, I). Complexes of structure $GaL_2^+GaX_4^-$ for ligands with two donor atoms, and $GaL_4^+GaX_4^-$ for monodentate ligands were proposed, mainly from analytical and electrical conductivity data. By using many of the monodentate and potentially bidentate ligands originally chosen by Brewer *et al.*, we have prepared numerous complexes of one stoichiometry only, $Ga_2X_4 \cdot 2L$ (X = Cl, Br).[4] Ga—Ga bonded, ethane-like structures were proposed from spectroscopic studies, later confirmed by crystallographic investigations of $Ga_2X_4 \cdot 2diox$[5,6] and $Ga_2X_4 \cdot 2py$.[4,7] Given the difference between Brewer's conclusions and our recent studies, a re-investigation of the chemistry of Ga_2I_4 seemed necessary.

EXPERIMENTAL

Since Ga_2I_4 and its complexes are moisture-sensitive, all reactions were carried out in a nitrogen-filled glove box, or on a vacuum line. Ga_2I_4 was prepared by shaking, in warm water, a sealed pre-evacuated tube containing benzene, gallium and iodine, until all the metal had reacted.[8] All ligands were rigorously dried and purified before use. Raman spectra (40–3500 cm^{-1}) were obtained on a Carey model 81L spectrometer, using the 4880 and 5145 Å lines. IR spectra (200–3500 cm^{-1}) were recorded using a Nicolet MX-1 machine. Reliable IR data were obtained for few complexes, since many discoloured when ground with sodium-dried Nujol. Gallium was determined by atomic absorption analysis and iodine by the Volhard method.

Attempts to repeat Brewer's work by using his experimental methods have been largely unsuccessful.[9,10] Brewer's methods involve slow addition of a benzene solution of ligand to a benzene solution of Ga_2I_4 and, for volatile ligands, prolonged attack of vapour on Ga_2I_4–benzene solutions. Such reactions were performed at ambient temperature. In this work, closely related or identical ligands were deliberately chosen in an attempt to repeat the Brewer studies. The former method gave satisfactory complexes with diox, morph and DMS, other ligands producing Ga and GaI_3 adducts. These complexes were identified as Ga—Ga bonded $Ga_2I_4 \cdot 2L$ species, by chemical and spectral analysis. The latter method resulted in decomposition of Ga_2I_4 to Ga, such reactions not proceeding further. Our successful synthetic routes require direct reaction of the ligand with frozen Ga_2I_4, or ligand replacement reactions. We were unable to isolate Ga_2I_4 adducts with acetylacetone and anisole, two ligands successfully used by Brewer *et al.*[3]

* Author to whom correspondence should be addressed. Present address: Johnson Matthey Technology Centre, Blount's Court Road, Sonning Common, Reading RG4 9NH, U.K.

Synthesis of $Ga_2I_4 \cdot 2L$ (L = *1,4-dioxane, tetrahydrofuran, tetrahydropyran, morpholine,* N*-methylmorpholine, dimethylsulphide, diethylsulphide, tetrahydrothiophene,* 1,4*-thioxan and tetramethylbiphosphine*)

Ga_2I_4 was cooled to liquid nitrogen temperature and excess dry ligand condensed on *in vacuo*. The temperature was slowly allowed to rise to the ligand's melting point and the resultant slurry rapidly stirred. A colourless solution soon formed, and the excess ligand was then slowly removed to reveal colourless, crystalline solids, which dried to chalky white powders. An exception, the tetramethylbiphosphide adduct, formed as an oil, which partially solidified with age. It was not analysed because of its inflammability.

Synthesis of $Ga_2I_4 \cdot 2L$ (L = *pyridine,* 2*-methylpyridine,* 3*-methylpyridine and* 4*-methylpyridine*)

These adducts could not be isolated in a pure form by the above method. They could be easily prepared from O- and S-donor complexes by ligand replacement reactions. Excess ligand was condensed onto liquid nirogen-cooled $Ga_2I_4 \cdot 2$diox, *in vacuo*, and the temperature allowed to rise to the melting point of the ligand. The resulting slurry was stirred until a clear solution formed. Excess solvent was removed under a vacuum, and the white powder which precipitated, dried.

Unlike chloride and bromide analogues, $Ga_2I_4 \cdot 2$diox solutions were sensitive to prolonged standing under warm conditions, or rapid warming, producing Ga and $(GaI_3 \cdot \text{diox}) \cdot 2$diox. Our unpublished crystallographic studies on $(MI_3 \cdot \text{diox}) \cdot 2$diox (M = Ga, In) show the geometry around the five coordinate metal to be trigonal bipyramidal, with bridging dioxan chairs binding the MI_3 units together in an infinite polymer. Two rows of interstitial dioxan molecules, easily removed by vacuum pumping, lie disordered between the polymer chains. Because of its rapid and easy preparation, $Ga_2I_4 \cdot 2$DMS was found to be a more suitable precursor. Its solutions were stable to rapid warming and the volatile ligand could be quickly removed. By simply dissolving uncooled $Ga_2I_4 \cdot 2$DMS in warm pyridine, or methylpyridine, large diamond-shaped crystals of $Ga_2I_4 \cdot 2L$ (L = py, 3-Mepy, 4-Mepy) were deposited on cooling, whereas $Ga_2I_4 \cdot 2$(2-Mepy) gave fine oval-shaped needles.

Crystallographic studies on these complexes were unsuccessful, due to sample deterioration. Even when stored in the absence of light, all colourless crystals slowly turned dark orange.

Synthesis of $Ga_2I_4 \cdot 2$dithiane

A dilute solution of dry dithiane in CS_2 was added dropwise to a stirred suspension of Ga_2I_4 in CS_2. The first drops caused a blood-red coloration, which slowly turned orange and then yellow. Further addition caused this colour sequence to be repeated, until all the dithiane had been added. The insoluble yellow precipitate formed was recovered, washed with CS_2, and dried to a lemon powder *in vacuo*.

DISCUSSION

Structure of complexes; chemical evidence

Our analytical data (Table 1) shows the isolation of complexes of stoichiometry $Ga_2I_4 \cdot 2L$, regardless of the donor atom involved, or the number of donor atoms on the ligand. This conflicts with Brewer's results, where the availability of donor atoms on the ligand influences the stoichiometry of the resultant complex. Thus, monodentate O-, N- and S-donors produce 1 : 4 complexes, whereas bidentate ligands chelate to give 1 : 2 complexes.

Electrical conductivity measurements, obtained by Brewer *et al.*, from solutions of Ga_2X_4 complexes, provide the main evidence for their ionic formulations. Our conclusions are largely based on solid-state spectroscopic data, and we have not studied the structure of complexes in solution.

It should be noted that complexes of 1 : 2 and 1 : 4 stoichiometry are known for closely related In_2X_4 (X = Cl, Br, I),[11,12] but that mixed species $InGaX_4$ (X = Cl, Br)[13] give only 1 : 2 complexes.

Table 1. Analytical data

Compound	Found (Calc.) (%) Ga	I
$Ga_2I_4 \cdot 2$pyridine	17.3 (17.3)	63.0 (63.1)
$Ga_2I_4 \cdot 2$(2-methylpyridine)	16.5 (16.7)	60.5 (60.9)
$Ga_2I_4 \cdot 2$(3-methylpyridine)	16.5 (16.7)	60.4 (60.9)
$Ga_2I_4 \cdot 2$(4-methylpyridine)	16.5 (16.7)	60.5 (60.9)
$Ga_2I_4 \cdot 2$morpholine	17.0 (17.0)	61.5 (61.8)
$Ga_2I_4 \cdot 2$(NMe-morpholine)	16.7 (16.4)	60.7 (59.8)
$Ga_2I_4 \cdot 2$dimethylsulphide	17.8 (18.1)	65.8 (65.8)
$Ga_2I_4 \cdot 2$diethylsulphide	16.7 (16.8)	61.7 (61.4)
$Ga_2I_4 \cdot 2$tetrahydrothiophene	17.4 (16.9)	61.0 (61.7)
$Ga_2I_4 \cdot 2$dithiane	16.1 (15.7)	57.8 (57.2)
$Ga_2I_4 \cdot 2$thioxan	16.3 (16.3)	58.9 (59.4)
$Ga_2I_4 \cdot 2$dioxan	16.9 (16.9)	61.3 (61.7)
$Ga_2I_4 \cdot 2$tetrahydrofuran	17.6 (17.6)	64.0 (64.2)
$Ga_2I_4 \cdot 2$tetrahydropyran	17.2 (17.0)	62.5 (62.0)

Vibrational spectroscopy indicates that these materials are covalent, with metal–metal bonds. Such conclusions have been crystallographically confirmed for $In_2Br_3I \cdot 2tmed$ (tmed = N,N,N^1,N^1-tetramethylethanediamine), which comprises two X_2(tmed)In units joined by an In—In bond giving favoured five-coordinate indium.[14] A similar structure is proposed for $Ga_2I_4 \cdot 2L$ complexes, with GaI_2L units linked by a Ga—Ga bond giving favoured four-coordinate gallium. This structure can be substantiated by chemical evidence, which suggests that in ligand replacement reactions the Ga—Ga bond is retained. Firstly, the reaction of $Ga_2I_4 \cdot 2diox$ with $Me_4N^+I^-$ readily proceeds giving $(Me_4N)_2Ga_2I_6$, a well-characterized Ga—Ga bonded compound.[15] Secondly, reaction of $Ga_2I_4 \cdot 2diox$ with excess pyridine, or methylpyridine, gives complexes in which the 1 : 2 stoichiometry is retained, i.e. $Ga_2I_4 \cdot 2py$. If $Ga_2I_4 \cdot 2diox$ consisted of Brewer's ionic structure $Ga(diox)_2^+GaI_4^-$, then bidentate dioxan should have been displaced by four pyridines giving $Ga(py)_4^+GaI_4^-$. Since this definitely does not occur, it leads to a rejection of the Brewer structures in the solid state.

Structure of complexes; spectral evidence

Our structural diagnosis heavily depends on Raman spectroscopy, which has previously been successful in distinguishing between gallium iodides containing GaI_4^- anions, and those with Ga—Ga bonds.[16] We have previously discussed the similar spectral pattern exhibited by $Ga_2X_4 \cdot 2L$ (X = Cl, Br) complexes and $Ga_2X_6^{2-}$ anions in terms of their mutual Ga—Ga bonded, ethane-like structure.[4] We can now confirm that this spectral likeness is extendable, to a lesser degree, to analogous iodide species. Crystallographic studies, confirming the close structural relationship, exist for $Ga_2X_4 \cdot 2L$ (X = Cl, Br; L = diox, py),[4–7] $(Me_4N)_2Ga_2Cl_6$[17] and $(n\text{-}Pr_4N)_2Ga_2Br_6$,[18] whereas $(Ph_3PH)_2Ga_2I_6$ is known to be isomorphous with its chloride counterpart.[19] Detailed spectral assignments exist for $Ga_2X_6^{2-}$ (X = Cl, Br, I),[15,20] and their spectra are very different to those of GaX_4^-.[21–23] In particular, their Raman spectra each contain an intense band, which has been assigned to a totally symmetric mode, in which the Ga—Ga bond stretches in phase with Ga—X bonds. This dominant band has been used to identify Ga—Ga bonds in new gallium compounds.[4]

In all $Ga_2I_4 \cdot 2L$ spectra, normally two Raman-active ν(Ga—I) bands could be identified, appearing in the ranges 207–239 and 294–317 cm^{-1}. They were distinguished by comparison amongst $Ga_2X_4 \cdot 2L$ (X = Cl, Br, I) spectra, and by their similar position and intensity within the di-iodide series (Table 2).

Generally, for $Ga_2I_4 \cdot 2L$ spectra, Raman bands at low values, e.g. $Ga_2I_4 \cdot 2diox$ (93m, 141vs, 226w, 239w, *302w* cm^{-1}) and $Ga_2I_4 \cdot 2THP$ (47s, 56sh, 87s, 141vs, 226m, *302w* cm^{-1}) show some resemblance to those found in $Ga^+(GaI_4)^-$ (52m, 85m, 142vs, 214vw, 235vw cm^{-1}),[16] and $H^+GaI_4^-$ (52m, 73m, 145vs, 222w cm^{-1}).[22] This suggests a possible ionic structure for the complexes, as proposed by Brewer *et al.*, i.e. $GaL_4^+GaI_4^-$ and $GaB_2^+GaI_4^-$, where L and B are monodentate and bidentate ligands, respectively.[3] However, this ionic formulation fails to account for the full distribution of bands in $Ga_2I_4 \cdot 2L$ complexes. Notable discrepancies include bands around 150–190 cm^{-1} in most N- and S-donor adducts, but more importantly, the constant appearance of a ν(Ga—I) band near 300 cm^{-1} in all complexes. This band displays close positional similarity to the highest ν(Ga—I) assignment at 285 cm^{-1} in $Ga_2I_6^{2-}$ and in the Ga—Ga bonded iodides Ga_3I_5 and Ga_4I_6, which contain this anion.[16]

Rejection of the presence of GaI_4^- and the Brewer formulation, in favour of a Ga—Ga bonded structure, requires the intense band, around 140 cm^{-1} in the complexes, to be attributed to ν(Ga—Ga). This is entirely plausible. The shift of the strong ν(Ga—Ga) mode from 118 cm^{-1} in heavy $Ga_2I_6^{2-}$ to higher values in the lighter $Ga_2I_4 \cdot 2L$ complexes is not surprising in view of Tan and Taylor's work[23] on the mixed species $Ga_2X_nY_{6-n}^{2-}$ (X and Y are different halogens: n = 0–6). In these anions the position of the strong ν(Ga—Ga) band changes appreciably with halide ion replacement. To a large extent this is associated with mass change. For the anions $Ga_2I_4Br_2^{2-}$ and $Ga_2I_4Cl_2^{2-}$, the ν(Ga—Ga) mode has been assigned at 131 and 145 cm^{-1}, respectively.[23] This compares favourably with the proposed ν(Ga—Ga) assignment in $Ga_2I_4 \cdot 2L$.

Impressive comparisons are provided by $Ga_2I_4 \cdot 2L$ (L = 2-Mepy, 3-Mepy), which display intense bands at 135 and 132 cm^{-1}, respectively, and have a similar mass to $Ga_2I_4Br_2^{2-}$. A similar situation occurs for ν(Ga—I) modes. As the total mass of anion decreases, the ν(Ga—I) bands move to higher values to give a better correlation with $Ga_2I_4 \cdot 2L$ complexes. However, slight discrepancies may be anticipated, due to differences in mixing of modes in the complexes and associated anions.

The spectra of some coordinated ligands provide further evidence untenable with the Brewer ionic structure. Ligand spectra of $Ga_2I_4 \cdot 2diox$ indicate the absence of chelating boat-form dioxan,[2] as

Table 2. Vibrational spectra of $Ga_2I_4 \cdot 2L$ in the ranges 200–400 cm^{-1} (IR) and 100–400 cm^{-1} (R)[a]

[a] R, Raman; IR, infrared; THF, tetrahydrofuran; THP, tetrahydropyran; Diox, 1,4-dioxane; Dt, 1,4-dithiane; Thiox, 1,4-thioxane; DMS, dimethylsulphide; DES, diethylsulphide; THT, tetrahydrothiophene; Py, pyridine; *n*-Mepy, *n*-methylpyridine ($n = 2, 3, 4$); Morph, morpholine; N-Memorph, N-methylmorpholine; vs, very strong; s, strong; m, medium; w, weak; vw, very weak; sh, shoulder.

required for $Ga(diox)_2^+$, and the presence of monodentately attached dioxan chairs. Bands assignable to both free and coordinated ν(C—O) modes are observed for all Ga_2X_4 dioxanates. The loss of free dioxan's centrosymmetric structure when monodentately linked[24] leads to a number of its bands becoming both IR- and Raman-active in the complexes, e.g. 616, 870 and 1256 cm^{-1}.

Other potentially bidentate or chelating ligands are also attached in a monodentate fashion. $Ga_2I_4 \cdot$ 2thiox gives sharp IR- and Raman-active bands at 826 and 1100 cm^{-1}, due to ν(C—O) bands, which remain at their free ligand values, whereas ν(C—S) bands at 648 and 685 cm^{-1} are lowered by coordination from 665 and 692 cm^{-1} in liquid thioxan.[25] Ir- and Raman-active ν(N—H) bands at 3336 and 3298 cm^{-1} in morpholine[26] are replaced by a single band at 3268 cm^{-1} in $Ga_2I_4 \cdot$ 2morph, unlike bands in the ν(C—O) region near 1100 cm^{-1} which do not shift.

Comparison of Raman data for S-donor complexes of Ga_2I_4 allows a tentative ν(Ga—L) assignment to bands in the 240–290 cm^{-1} region, but for complexes with pyridine-type ligands a ν(Ga—L) Raman assignment is restricted to shouldering near 226 cm^{-1}. This weak band is mainly concealed by the strong ν(Ga—Ga) emission, but is more discernable in other halide analogues. A strong IR

band at 227 cm^{-1}, noted only in $Ga_2I_4 \cdot 2L$ complexes, is assigned to ν(Ga—I), leaving bands at 238(py), 260(DMS) and 276(THT) cm^{-1} as ν(Ga—L) candidates. Bands arising from Ga—O bonds are expected in the range 400–550 cm^{-1} but are weak, broad and often not observed.[27,28] Since many of the ligands used have bands in this region no reliable assignment could be made. Raman bands in the 157–187 cm^{-1} range are tentatively assigned to Ga—Ga—L bends because of the small degree of positional change noticed in pyridine and methylpyridine adducts and their general dependence on the type of ligand present. Bands of similar appearance, with slightly higher values, are observed in chloride and bromide counterparts.[10] Bands below 400 cm^{-1}, arising from internal ligand modes, are observed at their free ligand values although the Raman band of methylpyridines at 210 cm^{-1} is probably masked by the stronger ν(Ga—I) emission.

Crystallographic studies have so far determined two configurations of the ethane-like $Ga_2X_4 \cdot 2L$ structure. $Ga_2X_4 \cdot 2py$ (X = Cl, Br) adopt the *trans* (C_{2h}) conformation, and $Ga_2X_4 \cdot 2diox$ (X = Cl, Br) possess a less symmetric, staggered (C_i) structure. Vibrational spectroscopy should distinguish between *trans* and lower symmetry structures, since for the former, mutual exclusion should be operative.[29] Although, we could not practically confirm this for most complexes, the simple spectral behaviour of $Ga_2I_4 \cdot 2L$ (L = py, Mepy) is indicative of the *trans* conformation, whereas $Ga_2I_4 \cdot 2L$ (L = diox, DMS) seem likely to have structures of lower symmetry, a consequence of their more complicated spectra. This has recently been confirmed by Japanese workers,[30] who have studied the NQR spectra of $Ga_2X_4 \cdot 2diox$ (X = Cl, Br, I) and have concluded the iodide complex adopts the staggered (C_i) structure at room temperature. They have also observed a temperature-dependent conformational change for $Ga_2Cl_4 \cdot 2diox$.

SYNTHESIS, CHARACTERIZATION AND MAGNETIC PROPERTIES OF SEVERAL COPPER(II)–NICKEL(II) HETERODINUCLEAR OXAMIDO COMPLEXES

JUAN RIBAS,* AUXILIADORA GARCIA and MONTSERRAT MONFORT

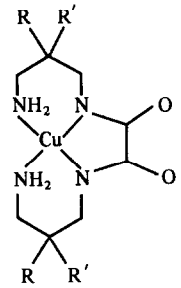
Departament de Química Inorgànica, Universitat de Barcelona, Diagonal 647, 08028-Barcelona, Spain

(*Received* 5 *April* 1990; *accepted* 29 *August* 1990)

Abstract—Seven new heterodinuclear copper(II)–nickel(II) complexes, have been synthesized from the planar monomeric fragment Cu(oxpn) (oxpn = N,N′-bis(3-aminopropyl)oxamido and its 2,2′-dimethyl derivative) and characterized. Magnetic measurements between 4 K and room temperature have been carried out to study the magnetic coupling between the two paramagnetic ions. The J values thus calculated indicate a strong antiferromagnetic coupling in all cases ($J = -104$ to -115 cm^{-1}), in accordance with the nature of the oxamido group. The average isotropic g values occur over a range of 2.09–2.25. The EPR spectra at room temperature confirm these values. All the complexes are soluble in most common organic solvents, but attempts to obtain single crystals suitable for X-ray structure determination have so far been unsuccessful.

The field of heteropolymetallic systems with two different paramagnetic centres is very important from both biological and physical aspects. The copper–iron site in cytochrome oxidase is a good example of the first type;[1] the intramolecular ferrimagnetism which can be extended in a 3D array to achieve molecular ferromagnets, is an example of the second, corresponding to the design of new magnetic materials.[2] Very recently, Kahn[3] has reviewed this kind of complex and clearly indicates that accurate magnetic data on heteropolymetallic systems is much less extensive than with homopolymetallic complexes.

The copper(II)–nickel(II) complexes with the local spins $S_{Cu} = 1/2$ and $S_{Ni} = 1$, represent one of the most comprehensive examples of heterobimetallic systems.[3–8] Very recently,[9] starting from propylene-1,3-bis(oxamato)cuprate(II) we have synthesized the first fully characterized Ni—Cu—Ni trinuclear complex, in which both terminal nickel(II) ions were blocked with bis(3-aminopropyl)amine. During the synthesis, it was possible to synthesize and characterize the corresponding Cu—Ni dinuclear complex, in which $J = -94.6$ cm^{-1}, $g_{Cu} = 2.02$ and $g_{Ni} = 2.24$. To avoid the possibility of forming trinuclear species, we decided to start from Cu(oxpn) (**I**), where oxpn is N,N′-bis(3-aminopropyl)oxamido, and its 2-hydroxy (**II**) or 2,2′-dimethyl (**III**) derivatives.



(**I**) R = R′ = H

(**II**) R = H; R′ = OH

(**III**) R = R′ = CH_3

With Cu(oxpn) Ojima and Nonoyama[10] synthesized the complex $[Cu(oxpn)Ni(bipy)_2](NO_3)_2 \cdot 2H_2O$, the magnetism and EPR spectra of which were studied by Journaux *et al.*[11] In this work, four new $[Cu(oxpn)Ni(ligand)](ClO_4)_2$ and three new $[Cu(Me_2oxpn)Ni(ligand)](ClO_4)_2$ complexes, in which the terminal nickel(II) ion is blocked with

* Author to whom correspondence should be addressed.

2,2-bipyridine (bipy), 1,10-phenanthroline (phen), 1,4,8,11-tetraazacyclotetradecane (cyclam) and 1,3-diaminopropane (tmd) have been synthesized. All attempts to start from [Cu(2-OHoxpn)] derivatives were unsuccessful, only the starting materials being obtained.

EXPERIMENTAL

Synthesis of starting mononuclear copper(II) complexes

Cu(oxpn) was obtained by the literature method.[12,13] Its dimethyl derivative [Cu(Me_2oxpn)] was obtained by the same procedure starting from 2,2′-dimethyl-1,3-diaminopropane (Fluka, without purification). The red products so formed were very soluble in water and insoluble in common organic solvents. They can be recrystallized from hot water.

Synthesis of heterodinuclear copper–nickel complexes

Hereafter we abbreviate the new complexes as [Cu(oxpn)Ni(ligand)] to indicate the hydrogen-derivatives and [Cu(Me_2oxpn)Ni(ligand)] to indicate the dimethyl-derivatives.

(a) [Cu(oxpn)Ni(cyclam)]$(ClO_4)_2$. An ice-cold solution of Cu(oxpn) (0.26 g, 1 mmol) in 20 cm^3 of water was added with constant stirring to an ice-cold solution of [Ni(cyclam)]$(ClO_4)_2$[14] (0.46 g, 1 mmol) in 30 cm^3 of water. A pink precipitate was immediately formed, which was separated by filtration and recrystallized in acetonitrile. Yield: 75%. The new compound was very soluble in acetone, acetonitrile and nitromethane; soluble in ethanol and methanol and insoluble in water. Found: C, 29.7; H, 5.3; N, 15.6; Cu, 8.8; Ni, 8.3. Calc. for $C_{18}H_{40}N_8O_2CuNi(ClO_4)_2$: C, 29.9; H, 5.5; N, 15.5; Cu, 8.8; Ni, 8.1%.

(b) [Cu(oxpn)Ni(tmd)$_2$]$(ClO_4)_2 \cdot H_2O$. An ice-cold solution of Cu(oxpn) (0.26 g, 1 mmol) in 20 cm^3 of methanol was added with constant stirring to an ice-cold solution of $Ni(ClO_4)_2$(aq) (0.36 g, 1 mmol) and 1,3-diaminopropane (0.15 g, 2 mmol) in 20 cm^3 of methanol. No precipitate was formed. Four times volume of ether was added, whereupon a red–violet precipitate was immediately formed. This was filtered and air-dried. Yield: 60%. The compound was soluble in all common solvents, including water. Found: C, 24.7; H, 5.5; N, 16.4; Cu, 9.3; Ni, 8.7. Calc. for $C_{14}H_{38}N_8O_3CuNi(ClO_4)_2$: C, 24.4; H, 5.5; N, 16.3; Cu, 9.2; Ni, 8.5%.

(c) [Cu(oxpn)Ni(bipy)$_2$]$(ClO_4)_2$. A hot solution of Cu(oxpn) (0.53 g, 2 mmol) in 25 cm^3 of methanol was added with constant stirring to a hot solution of $Ni(ClO_4)_2$(aq) (0.73 g, 1 mmol) and bipyridine (0.62 g, 4 mmol) in 25 cm^3 of methanol. After heating, a blue solution was formed, which was filtered to eliminate impurities. After several days, a microcrystalline powder was formed by slow evaporation, which was filtered and air-dried. Yield: 55%. The new complex was soluble in water, acetonitrile, nitromethane and acetone. Found: C, 41.0; H, 3.9; N, 13.5; Cu, 7.5; Ni, 7.1. Calc. for $C_{28}H_{32}N_8O_2CuNi(ClO_4)_2$: C, 40.3; H, 3.8; N, 13.4; Cu, 7.6; Ni, 7.0%.

(d) [Cu(oxpn)Ni(phen)$_2$]$(ClO_4)_2$. The product was obtained by using the same procedure as for the bipy derivative [see (c)]. Yield: 70%. It was insoluble in water and ethanol, but soluble in acetonitrile. Found: C, 43.1; H, 5.4; N, 12.5; Cu, 7.2; Ni, 6.6. Calc. for $C_{32}H_{48}N_8O_2CuNi(ClO_4)_2$: C, 42.7; H, 5.3; N, 12.5; Cu, 7.1; Ni, 6.5%.

(e) [Cu(Me_2oxpn)Ni(cyclam)]$(ClO_4)_2$. An ice-cold solution of Cu(Me_2oxpn) (0.32 g, 1 mmol) in 20 cm^3 of water was added, with constant stirring to an ice-cold solution of [Ni(cyclam)]$(ClO_4)_2$[14] (0.46 g, 1 mmol) in 25 cm^3 of water. A red solution was formed, without precipitation. After several days at room temperature, microcrystals of this compound were formed. Yield: 55%. The complex was filtered and air-dried. It was slightly soluble in ethanol and soluble in acetonitrile and nitromethane. Found: C, 34.1; H, 6.3; N, 14.6; Cu, 8.3; Ni, 7.5. Calc. for $C_{22}H_{48}N_8O_2CuNi(ClO_4)_2$: C, 33.9; H, 6.2; N, 14.4; Cu, 8.2; Ni, 7.5%.

(f) [Cu(Me_2oxpn)Ni(bipy)$_2$]$(ClO_4)_2$. The new complex was obtained by using the same procedure as for [Cu(oxpn)Ni(bipy)$_2$]$(ClO_4)_2$ [see (c)]. With Cu(Me_2oxpn) the precipitate obtained by mixing the starting complexes could be redissolved by boiling the solution. After concentration, the violet solution was allowed to stand at room temperature. Red microcrystals were formed after several days, which were filtered, washed and air-dried. Yield: 65%. The new complex is soluble in acetonitrile and nitromethane, slightly soluble in water and insoluble in ethanol. Found: C, 43.3; H, 4.5; N, 12.7; Cu, 7.3; Ni, 6.7. Calc. for $C_{32}H_{40}N_8O_2CuNi(ClO_4)_2$: C, 43.1; H, 4.5; N, 12.6; Cu, 7.1; Ni, 6.6%.

(g) [Cu(Me_2oxpn)Ni(phen)$_2$]$(ClO_4)_2$. The new product was synthesized as the bipy derivative [see (f)]. Yield: 75%. It was soluble in acetonitrile and nitromethane, but insoluble in ethanol. Found: C, 45.6; H, 5.9; N, 12.0; Cu, 6.8; Ni, 6.2. Calc. for $C_{36}H_{56}N_8O_2CuNi(ClO_4)_2$: C, 45.3; H, 5.9; N, 11.7; Cu, 6.6; Ni, 6.1%.

Physical measurements

IR spectra (4000–200 cm^{-1}) were recorded as KBr pellets with a Perkin–Elmer 1330 spec-

trophotometer. Magnetic measurements were carried out with a Faraday type magnetometer equipped with a helium continuous-flow cryostat working in the 4.2–300 K temperature range. For all the compounds the independence of the magnetic susceptibility versus the applied field was checked at each temperature. Mercury tetrakis(thiocyanato) cobaltate was used as a susceptibility standard. Diamagnetic corrections were estimated from Pascal Tables. EPR measurements were recorded with a Brucker ER-200 spectrometer working at X-band frequency.

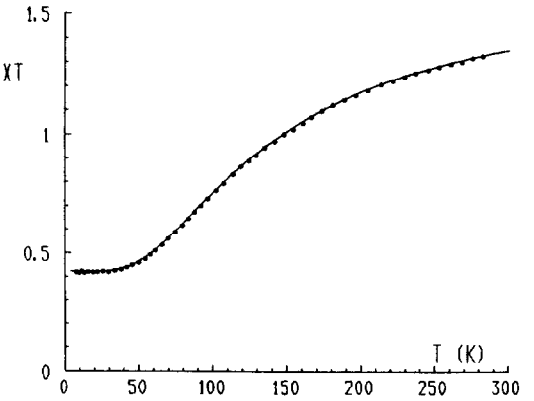


Fig. 1. XT vs T for $[Cu(oxpn)Ni(bipy)_2](ClO_4)_2$. (● experimental values; —— theoretical values). The XT curves for the other six complexes are very similar (see J and g values in Table 1).

RESULTS AND DISCUSSION

In the IR spectra all the characteristic bands attributed to the amine, oxamido and perchlorate anions are present. The most characteristic features are the very strong and wide band centred at 1600 cm^{-1} and the strong and sharp band centred at *ca* 800 cm^{-1}, due to the presence of the oxamido group. On the other hand, the two characteristic bands attributable to the perchlorate anion (non-coordinated) appear at 1100 cm^{-1} (very strong and wide) and at 620 cm^{-1} (strong and sharp). Many bands (from 3500 to 400 cm^{-1}) attributable to the bondings N—H, C—N (amine) are also present in all cases.

Magnetic measurements

Starting from the isotropic Hamiltonian $H = -J_{1,2}S_1S_2$, the interaction between copper(II) and nickel(II) leads to only two pair states (a doublet and a quartet) separated by $3J/2$.

The theoretical expression for the magnetic susceptibility, assuming that the isotropic interaction is much larger than the other terms of the spin Hamiltonian, is derived from the general Van Vleck equation as:[3,15]

$$XT = \frac{N\beta^2}{4k} \times \frac{g_{1/2}^2 + 10g_{3/2}^2 \exp(3J/2kT)}{1+2\exp(3J/2kT)}$$

where $g_{1/2} = (4g_{Ni} - g_{Cu})/3$ and $g_{3/2} = (2g_{Ni} + g_{Cu})/3$.

In this formula we have neglected the possible zero-field splitting within the excited quartet state. The magnetic properties of one of the seven new complexes, which are almost equal to those of the other six, are shown in Fig. 1. When the sample is cooled, XT decreases, then reaches a plateau with XT = 0.45 $cm^3\ mol^{-1}\ K$ corresponding to the temperature range where only the ground doublet state is thermally populated. Data for all complexes is given in Table 1. In all cases, R is less than 10^{-4}.

Such a value of J (approx. $-110\ cm^{-1}$) agrees perfectly with that reported by Journaux *et al.*[11] for $[Cu(oxpn)Ni(bipy)_2](NO_3)_2$ ($J = -110.6\ cm^{-1}$). On the other hand, this value indicates that the

Table 1. Magnetic and EPR data for the dinuclear complexes (g_{Cu} and g_{Ni} are obtained from the fitting of susceptibility data. With only one average g factor, the fitting is almost equal)

Compound	J (cm^{-1})	g_{Cu}	g_{Ni}	g(EPR)

$[Cu(Me_2oxpn)Ni(cyclam)](ClO_4)_2$	−107.3	2.15	2.25	2.22
$[Cu(Me_2oxpn)Ni(bipy)_2](ClO_4)_2$	−107.1	2.15	2.22	2.22
$[Cu(Me_2oxpn)Ni(phen)_2](ClO_4)_2$	−113.2	2.12	2.25	2.20

doublet–quartet gap ($3J/2$) is *ca* 165 $cm^{-1} \gg D$; therefore the employed equation for XT is correct. Lacking structural data we only can compare these results with those reported by Journaux *et al.*[11] for the trinuclear complex Cu—Ni—Cu with the same Cu(oxpn) as the bridging ligand ($J = -98.7\ cm^{-1}$). The slight difference may be attributed to the structural factors.

We can also compare these results with those reported by Journaux *et al.*[12] for [Cu(oxpn)Cu(bipy)]$(ClO_4)_2$ ($J = -439.7\ cm^{-1}$). The magnetic orbital in the central copper(II) ion ($d_{x^2-y^2}$) is the same in all cases. For the terminal ions, the magnetic orbitals are $d_{x^2-y^2}$ for copper(bipy) and both $d_{x^2-y^2}$ and d_{z^2} for nickel(II). Then, taking into account that the d_{z^2} orbital is not magnetically active with this kind of geometry, the overlap between the magnetic orbitals should be very similar. But, even with the correction due to the $1/n_1 \times n_2$,[16] n being the number of unpaired electrons (1×1 for CuCu and 1×2 for CuNi), the results are not comparable ($-110\ cm^{-1}$ for CuNi and $-220\ cm^{-1}$ for CuCu). Assuming a ferromagnetic contribution in CuNi which diminishes the antiferromagnetic factor is not realistic, as has been clearly indicated by Journaux.[17] Then, the only possible explanation is the less diffuse character and higher energy of the nickel(II) d orbitals: their interaction with the orbitals of the ligands is less pronounced and, consequently, the delocalization of these d orbitals into the oxamato bridge is greater in copper(II) than in nickel(II). The antiferromagnetic coupling would be more efficient in a CuCu pair than in a CuNi pair.

EPR spectra

The values of g for all complexes are collected in Table 1. There is a very wide band centred at approx. $g = 2.2$–2.3. At room temperature the complexes exhibit a smaller band centred at approx. $g = 4$, as has been also reported by Journaux *et al.*[11] for [Cu(oxpn)Ni(bipy)$_2$](NO$_3$)$_2$·2H$_2$O. The explanation would be the same as given by this author.[11] Since there is lack of structural data for this kind of complex, we hope, in the future, to obtain single crystals suitable for X-ray structural determination to examine whether the intermolecular interactions between the dimers could be the appropriate explanation.

PHOTOCHEMISTRY OF THE μ-HYDROXO-μ-PEROXO-BIS[TRIETHYLENETETRAAMINE)COBALT(III)] COMPLEX IN BASIC AQUEOUS SOLUTIONS

NOBUYOSHI SHINOHARA,* SHIGEO MATSUFUJI and WATARU OKUBO

Department of Chemistry, Yokohama City University, Seto, Kanazawa-ku, Yokohama 236, Japan

(*Received* 8 *May* 1990; *accepted* 5 *September* 1990)

Abstract—Photochemical reaction of the title complex $[(trien)Co(\mu\text{-}OH,O_2)Co(trien)]^{3+}$ (**1**) was studied in basic, aqueous solution. The photo-induced cobalt(II)–trien complexes, $[Co(trien)(H_2O)_2]^{2+}$ and $[Co(OH)(trien)(H_2O)]^{+}$, react with dioxygen in oxygenated basic, aqueous solution to give the intermediates, $[(OH)(trien)Co\text{-}O_2\text{-}Co(trien)(H_2O)]^{3+}$ and $[(OH)(trien)Co\text{-}O_2\text{-}Co(trien)(OH)]^{2+}$, which are transformed reversibly into **1**. The transient absorption spectra of the monobridged μ-peroxo complexes, which have an absorption maximum near 313 nm, were measured using a flash photolysis method. The rate constants of the reaction of cobalt(II)–trien complexes with dioxygen were measured as a function of pH. A small amount of $[Co(trien)(H_2O)_2]^{3+}$ (**2**) was detected on prolonged irradiation in both the presence and absence of dioxygen. The photochemical reaction mechanisms are discussed, and the kinetic data of the reaction of cobalt(II)–trien complexes with dioxygen are compared with those obtained by a stopped-flow method.

Of the many transition metal complexes that have the ability to absorb dioxygen, the most outstanding complexes are those of cobalt(II).[1–3] The interaction of dioxygen with cobalt(II) complexes containing ligands such as aliphatic polyamines,[4–8] salicylidenamines,[9] amino acids[10] and macrocyclic tetraamines,[11–13] has been extensively studied because of their similarity to biological oxygen carriers. The general reaction mechanism of cobalt(II)–polyamine with dioxygen involves reactions (1) and (2):[1]

$$CoL^{2+} + O_2 \rightleftharpoons CoLO_2^{2+} \quad (1)$$

$$CoLO_2^{2+} + CoL^{2+} \rightleftharpoons LCo\text{-}O_2\text{-}CoL^{4+}. \quad (2)$$

There are several reports on the photochemical reactions of μ-superoxo dicobalt(III) complexes.[14–16] However, information about the photochemical reaction of μ-peroxo cobalt(III) complexes is relatively scanty.[13,17] Kikkawa *et al.*[17] have reported that the $[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+}$ ion, undergoes deoxygenation in steady photolysis of basic, aqueous solution to give a photo-induced equilibrium (3):

$$[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+} \overset{h\nu}{\rightleftharpoons} 2[Co(en)_2(H_2O)_2]^{2+} + O_2. \quad (3)$$

Miller and Wilkins[5] have investigated the reaction of the cobalt(II)–trien complex with dioxygen using a stopped-flow method, and found that the cobalt(II)–trien complex reacts with dioxygen to give the doubly bridged species **1**.

We have studied the photolysis of **1** in oxygenated aqueous solution and obtained the transient spectra of the O_2 adduct of the photo-induced cobalt(II)–trien complex and the kinetic data of the oxygenation reaction, using a flash photolysis method. The kinetic data obtained were compared with those obtained by a stopped-flow method.[5]

EXPERIMENTAL

Materials

Methods of synthesizing $[(trien)Co(\mu\text{-}OH,O_2)Co(trien)](ClO_4)_3 \cdot H_2O$ have been reported previ-

ously.[18-20] The μ-hydroxo-μ-peroxo complex was prepared as follows.[19] $Co(ClO_4)_2 \cdot 6H_2O$ (30 g) was dissolved in a solution containing 20 cm^3 of water and 18 cm^3 of 60% $HClO_4$. Then, triethylenetetraamine (12 g) was added to the Co^{2+} solution with stirring. The solution was cooled in an ice bath and air-bubbled for 4 h. After filtering or decanting out tarry material containing small amounts of impurities, air-bubbling was continued for a further 2 h. The solution was left to stand overnight in a refrigerator and then the brown precipitate was filtered off and washed with cooled water and ethanol. Found: C, 18.2; H, 5.0; N, 14.3; Co, 15.0; ClO_4^-, 38.2. Calc. for $C_{12}H_{39}N_8O_{16}Cl_3Co_2$: C, 18.6; H, 5.1; N, 14.4; Co, 15.2; ClO_4^-, 38.5%. The spectrum in water gave λ_{max} 276 nm ($\varepsilon = 4.9 \times 10^3$ M^{-1} cm^{-1}) and λ_{max} 356 nm ($\varepsilon = 6.4 \times 10^3$ M^{-1} cm^{-1}), in good agreement with the λ_{max} 355 nm obtained by other methods.[18,20] The value of ε was larger than that found by another method.[20] When necessary, de-aeration of the solutions used for photolysis was carried out by bubbling with pure nitrogen.

Photochemical and analytical procedures

The flash photolysis apparatus was the same as that used previously.[21] Steady irradiations were carried out by using a high-pressure mercury lamp (100 W) or Xenon lamp (500 W), at room temperature. Monochromatic light was obtained by a combination of solution and glass filters. Ion-exchange chromatography on a cation resin (SP-Sephadex C-25 in sodium form) was used for the separation of products, which were determined by spectrophotometric analysis.

RESULTS AND DISCUSSION

Flash photolysis

Oscillograms obtained by the flash photolysis of **1** in basic, aqueous solution are shown in Fig. 1. The oscillogram A, obtained in an oxygen-saturated solution, showed an immediate decrease in absorbance at 310 nm after the flash, which was followed by an increase in absorbance. On the other hand,

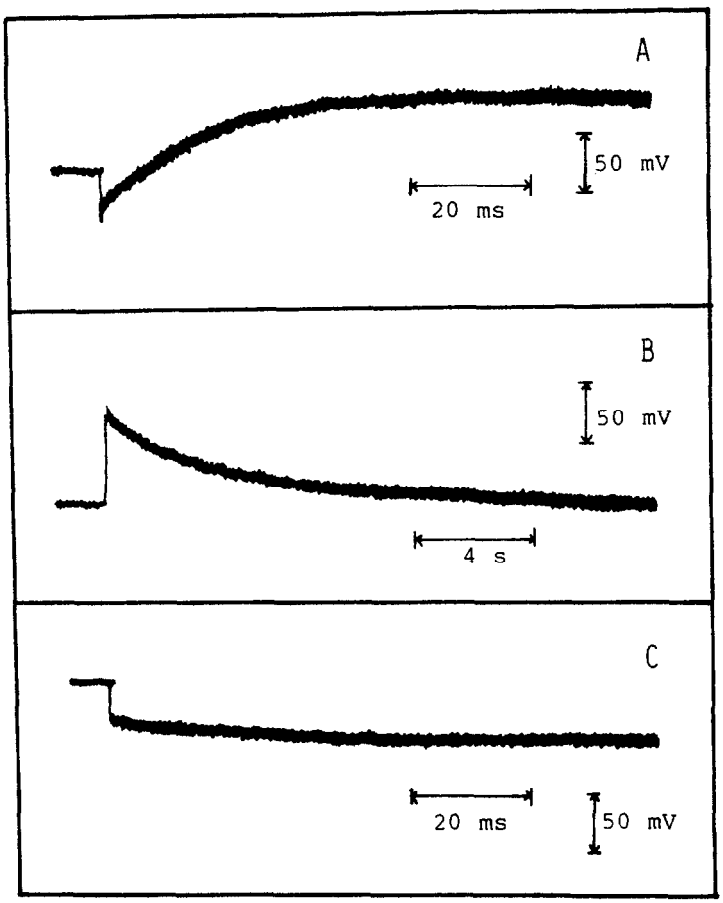

Fig. 1. Oscillograms showing changes in absorption after flashing aqueous solutions of 2.0×10^{-5} M [(trien)Co(μ-OH,O_2)Co(trien)]$^{3+}$ at pH = 10.1. The transmittance was monitored at 310 nm.

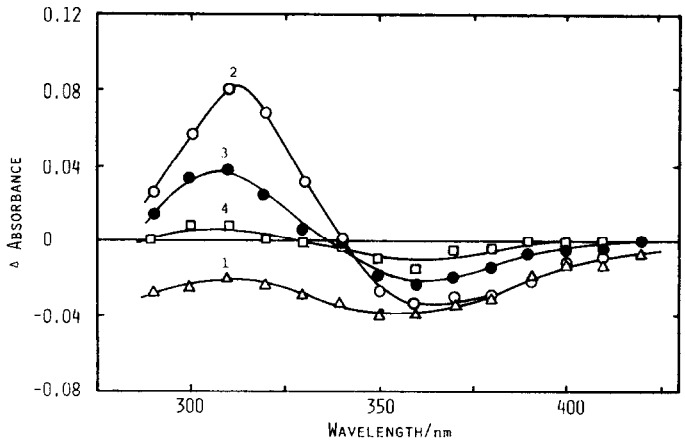

Fig. 2. Difference spectra of intermediates generated by the flash photolysis of dioxygen-saturated 2.0×10^{-5} M $[(trien)Co(\mu\text{-}OH,O_2)Co(trien)]^{3+}$ solutions at pH = 10. Spectra were obtained at the following reaction times; △ : immediately after the flash, ○ : 80 ms, ● : 1.8 s, □ : 9 s.

such an increase in absorbance was not observed in the flash photolysis of an oxygen-free solution (oscillogram C). The difference spectra obtained in the oxygen-saturated solutions are shown in Fig. 2. Spectrum 1 shows a decrease of the original two peaks at 276 and 356 nm, which is attributed to the decomposition of the bridge in the μ-peroxo dicobalt complex, similar to that suggested in the steady photolysis of $[(en)_2Co(\mu\text{-}OH,O_2)Co(en)_2]^{3+}$.[17] The absorbance in the wavelength region of < 380 nm increases progressively and reached a maximum value at about 80 ms after the flash. The spectrum of the intermediate has an absorption maximum at 313 nm (spectrum 2 in Fig. 2) and the spectrum did not change appreciably in the examined pH region.

The photochemical reaction mechanism in oxygenated, basic solution is explained in Scheme 1, where oxygenation reactions are similar to those proposed by Miller and Wilkins.[5] The first step of

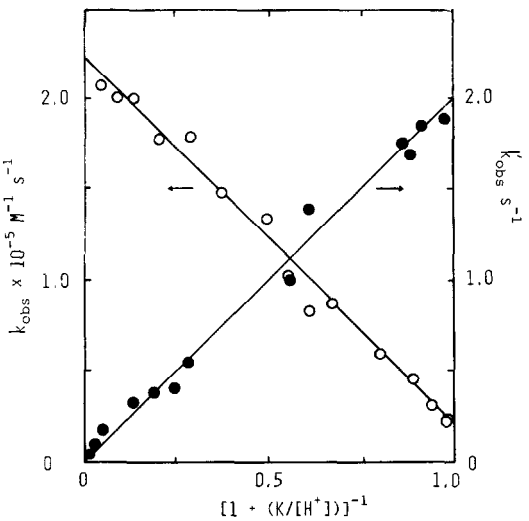

Fig. 3. Plots of k_{obs} vs $[1+(K_5/[H^+])]^{-1}$ for the first step (○) and k'_{obs} vs $[1+(K_{10}/[H^+])]^{-1}$ for the second step (●).

the oxygenation of the photo-induced cobalt(II)–trien complex **2A** or **2B** is the formation of activated dioxygen (**3A** or **3B**), followed by the rapid formation of the monobridged μ-peroxo dicobalt(III) complex **4A** or **4B**. The transient absorption spectrum 2 in Fig. 2 is attributed to the monobridged μ-peroxo dicobalt complex. The kinetics of the oxygenation of cobalt(II)–trien complexes was found to obey a pseudo-first-order rate law. The observed rate constants (k_{obs}) were independent of the initial O_2 concentration and increased with increasing pH (Table 1). Thus, k_{obs} for the first step can be given in eq. (13), where $k_a = k_7$, $k_b = k_6$ and $K_c = K_5$:

$$k_{obs} = \frac{k_a - k_b}{1+(K_c/[H^+])} + k_b. \qquad (13)$$

The plot of k_{obs} vs $[1+(K_5/[H^+])]^{-1}$ was linear (Fig. 3), the intercepts being k_6 (when the x coordinate = 0) and k_7 (when the x coordinate = 1) when the known value of $K_5 = 6.3\times10^{-12}$ M[5] was used. The rate constants, $k_7 = (2.1\pm0.1)\times10^4$ and $k_6 = (2.2\pm0.1)\times10^5\ M^{-1}s^{-1}$, estimated by a least-squares method are in good agreement with those obtained by a stopped-flow method ($k_7 = 2.5\times10^4$ and $k_6 = 2.8\times10^5\ M^{-1}s^{-1}$).[5]

An intermediate generated by the increase of absorbance at 310 nm decayed on a slow time scale (oscillogram B in Fig. 1). The absorption spectrum of the intermediate changes with an isosbestic point at 343 nm (Fig. 2). Spectrum 4, obtained at 9 s after the flash, appears to be still in the course of the change of the spectrum. We could not measure it on a longer time scale because of the limitations of the apparatus used. However, it can be expected that finally the absorbance would almost return to the original one. This observation indicates that reactions (11) and (12) really occur. The kinetics of the transformation into **1** (second step) obeyed a first-order rate law and the rate constant k'_{obs} decreased with increasing pH (Table 1) which can be given by eq. (13), where $k_a = k_{11}$, $k_b = k_{12}$ and $K_c = K_{10}$. Calculations were performed for a series of K_{10} values by using a computer, where K_{10} must be close to 10^{-11} M as can be seen from Table 1. The best plot (Fig. 3) gives $k_{11} = 2.0\pm0.1\ s^{-1}$, $k_{12} \approx 4\times10^{-2}\ s^{-1}$ and $K_{10} = (1.6\pm0.1)\times10^{-11}$ M, which are in good agreement with 2.0 s^{-1}, $\sim 1.2\times10^{-2}\ s^{-1}$ and 1.2×10^{-11} M obtained by a stopped-flow method, respectively.[5]

Steady photolysis

The spectral changes in the steady photolysis of **1** in oxygen-saturated and oxygen-free aqueous solutions are given in Fig. 4. Similar spectral changes were obtained upon irradiation with monochromatic lights, 313 and 365 nm, however, spectral changes hardly occurred upon irradiation at 436

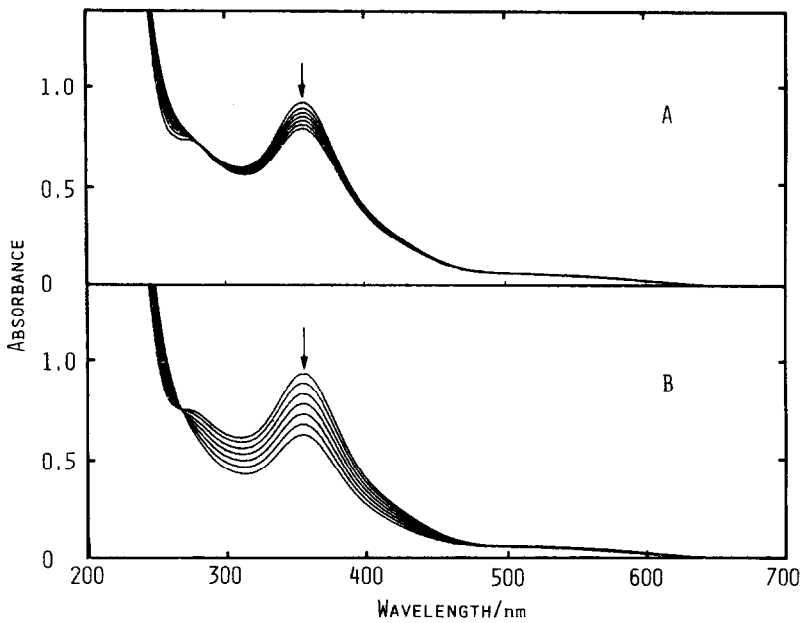

Fig. 4. Changes in the absorption spectra of 1.5×10^{-4} M $[(trien)Co(\mu\text{-}OH,O_2)Co(trien)]^{3+}$ solutions upon continuous irradiation at > 310 nm by a Xenon lamp: (A) irradiated at intervals of 5 min in the oxygen-saturated system; (B) irradiated at intervals of 2.5 min in the oxygen-free system.

nm. In the photolysis of **1** in oxygen-saturated solution, an initial small increase of absorbance in the wavelength region 240–310 nm was observed, which was followed by a slower change with an isosbestic point at 276 nm [Fig. 4(A)]. The initial and rapid equilibrium can probably be attributed to the formation of the *trans*-form of a monobridged μ-peroxo dicobalt(III) complex. The extinction coefficient of such a complex is unknown, however it can be expected to be larger than that of the μ-hydroxo-μ-peroxo dicobalt(III) complex, judging from the extinction coefficient of $[\{(H_2O)(cyclam)Co\}_2O_2]^{4+}$ ($\varepsilon > 10^4$ M^{-1} cm^{-1} at 280 nm, cyclam = 1,4,8,11-tetraazacyclotetradecane).[13,22] Whereas in the photolysis of **1** in oxygen-free solution, an initial and very small decrease was observed which can be attributed to equilibrium (14)

$$[(trien)Co(\mu\text{-}OH,O_2)Co(trien)]^{3+} \overset{h\nu}{\rightleftharpoons} 2[Co(trien)(H_2O)_2]^{2+} + O_2. \quad (14)$$

The oxygenation reaction of the photo-induced cobalt(II)–trien complexes will start to occur with the accumulation of dioxygen by reaction (4). The decomposition of the peroxo complex in the oxygen-free system takes place more rapidly than in the oxygen-saturated system, as shown in Fig. 4(B). In the oxygen-free system, the absorbance partially recovered by bubbling dioxygen through the solution after irradiation [Fig. 5(A)]. The difference spectra given in Fig. 5(B) were similar to the spectrum of **1**, which means that the photo-induced cobalt(II)–trien complexes are transformed reversibly into **1**. This fact suggests that, in the oxygen-free system, the photo-induced cobalt(II) complexes partially remain in the solution without dioxygen uptake. The final product obtained on prolonged irradiation was $[Co(trien)(H_2O)_2]^{3+}$ ($pK_1 = 5.4$ and $pK_2 = 7.3$[23]) in both systems in the presence and absence of dioxygen.

In conclusion, in the photolysis of **1** the photo-induced products were mainly cobalt(II)–trien complexes and dioxygen and the cobalt(II) complexes reacted with dioxygen, reversibly, to give μ-peroxo dinuclear complexes. The absorption spectra of the monobridged μ-peroxo complexes produced as intermediates have a maximum near 313 nm. The mononuclear cobalt(III) complex, $[Co(trien)(H_2O)_2]^{3+}$, was produced on prolonged irradiation. The kinetic data for the oxygenation of cobalt(II)–trien, obtained by the flash photolysis method, were in good agreement with those obtained by the stopped-flow method. By using the flash photolysis method with μ-peroxo cobalt complexes in oxygenated basic, aqueous solution, the oxygenation reactions of cobalt(II)–polyamine complexes can be studied easily without any interference from the oxidized reactive ligand produced by charge-transfer.

(*Received* 25 *June* 1990; *accepted* 5 *September* 1990)

Abstract—The reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ with triphenylphosphine in thf or toluene is described. In this reaction, a yellow compound of formula $Ru(O_2CCH_3)_2(PPh_3)\cdot CH_3C_6H_5$ (**1**), and a violet, diamagnetic oxo-bridged compound, formulated as $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2$ (**2**) are obtained. The compounds have been characterized by elemental analysis, magnetic susceptibility measurements and spectroscopic techniques. The structure of **2** has been determined by X-ray crystallography. Two pseudo-octahedral ruthenium(III) atoms are bridged by an oxo and two acetate ligands. The hexacoordination of each ruthenium atom is completed with a bidentate acetate and a triphenylphosphine ligand. Some spectroscopic evidence for the formation of a tetranuclear intermediate compound is also presented.

The reactions of $M_2(\mu\text{-}O_2CR)_4$ (M = Mo, W or Rh, R = alkyl or aryl) with phosphines, to give compounds of the type $M_2(\mu\text{-}O_2CR)_4(PR'_3)_2$ (R′ = alkyl or aryl) with the phosphine ligands on the axial or equatorial sites of the M—M core have been intensively studied.[1–8] However, in the case of ruthenium, similar compounds have not been isolated. For example Wilkinson and co-workers,[9] have reported the synthesis of the compound $Ru_2(\mu\text{-}O_2CCH_3)_4(PPh_3)_2$, but the crystal structure of this compound has been shown to be in fact, $Ru_3(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_6(PPh_3)_3$.[10] A yellow complex of stoichiometry $Ru_2(\mu\text{-}O_2CCH_3)_4(PPh_3)_2$ has also been described,[11] but the compound was too insoluble for molecular weight studies and no structural information was obtained.

The reactivity of PPh_3 towards $Ru_2Cl(O_2CR)_4$ (R = Me, Ph, C_6H_4-*p*-OMe) has been recently investigated.[12,13] In the reaction of $Ru_2Cl(\mu\text{-}O_2CAr)_4$ (Ar = Ph, C_6H_4-*p*-OMe) and PPh_3, in a MeCN–H_2O mixture, an asymmetric, mixed-valance diruthenium(II,III) compound of formula $Ru_2(OH_2)Cl(MeCN)(O_2CAr)_4(PPh_3)_2$ was isolated.[13] However, several unsuccessful attempts to obtain similar adducts of diruthenium(II,III) compounds, with bridging ligands other than carboxylate, have been made.

The reaction of diruthenium(II,III) amidates with triarylphosphines led to the transfer of an aryl group from the triarylphosphine onto the metal centre, giving diruthenium(III,III) compounds.[14,15] Similarly, the reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with the lithium salt of 2-aminopyridine followed by addition of PMe_2Ph gave a new diruthenium (III,III) compound of formula $Ru_2(C_5NH_4NH)_6(PMe_2Ph)_2$.[16]

The preparation of $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ has been recently described.[17] The reaction of this complex with triphenylphosphine leads to the

* Author to whom correspondence should be addressed.

formation of a violet product formulated as $[Ru(\mu\text{-}O_2CCH_3)(O_2CCH_3)(PPh_3)]_x$ ($x \geqslant 3$) and an uncharacterized yellow product.[17] In this paper we report a more detailed study of this reaction, including the crystal structure of the violet product.

RESULTS AND DISCUSSION

The reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ with triphenylphosphine carried out in thf leads to a violet solution. When this solution is pumped dry, extracted with toluene, treated with active carbon and allowed to stand at room temperature for several days, a yellow crystalline solid is formed. A violet compound is obtained from the residual solution when the solvent is removed. Similar results are achieved if the reaction is carried out in toluene.

The yellow crystals are stable in a toluene atmosphere, but in an air or nitrogen atmosphere lose solvent very quickly and the crystals are destroyed. The compound is soluble in polar organic solvents, but insoluble in diethyl ether, toluene and petroleum ether.

Magnetic susceptibility measurements indicate that the compound is diamagnetic, suggesting that the formal oxidation state for the ruthenium atom is two.

Analytical data for the yellow compound are in accordance with the stoichiometry, $Ru(O_2CCH_3)_2PPh_3 \cdot CH_3C_6H_5$ (**1**). The IR spectrum of this compound shows absorption bands due to the triphenylphosphine ligand and absorptions assigned to the symmetric and anti-symmetric vibrations of the carboxylate groups. No bands for the tetrafluoroborate anion are observed.

The ^1H NMR spectrum of this yellow complex shows a singlet at 1.26 ppm assigned to the methyl group of the acetate ligand and a singlet at 2.35 ppm assigned to the methyl group of the toluene. In the aromatic region a multiplet due to the triphenylphosphine and toluene protons is observed. The $^{13}C\{^1H\}$ NMR spectrum of this compound shows resonances due to the acetate ligands at 24.07 and 193.79 ppm, corresponding to the $—CH_3$ and $—CO_2$ groups, respectively. The signals corresponding to the aromatic carbons are observed in the region 125–135 ppm. The $^{31}P\{^1H\}$ NMR spectrum of this compound shows a singlet at 47.15 ppm, indicating the presence of only one type of phosphine. The NMR data are summarized in Table 1.

All these data are in accordance with a compound containing two bidentate acetate ligands, one phosphine ligand and a toluene molecule occupying the sixth coordination position, in accordance with the formula $Ru(O_2CCH_3)_2(PPh_3) \cdot CH_3C_6H_5$ (**1**). This compound is analogous to $Ru(O_2CCH_3)_2(PPh_3) \cdot CH_3OH$, the formation of which has been suggested by Wilkinson and co-workers[11] in the reduction of $Ru_3(\mu\text{-}O)(O_2CCH_3)_6(PPh_3)_3$.

The violet compound was initially formulated as $[Ru(\mu\text{-}O_2CCH_3)(O_2CCH_3)(PPh_3)]_x$ ($x \geqslant 3$),[17] but a more detailed study, including X-ray structural determination, has showed that it is, instead, $[Ru(\mu\text{-}O_2CCH_3)(O_2CCH_3)(PPh_3)]_2(\mu\text{-}O)$. The calculated analyses of carbon and hydrogen in these compounds are very similar, but the experimental results are in better agreement with the new formulation.

The magnetic moment for the ruthenium(III)

Table 1. NMR data for the compounds

	δ ^1H		δ $^{13}C\{^1H\}$			δ $^{31}P\{^1H\}$
Complex	CH_3COO	PPh_3	CH_3COO	CH_3COO	PPh_3	PPh_3
(**1**)	1.26(s)	6.8–7.4(m)	24.07(s)	193.79(s)	134.75(s) 132.65(d) J = 45.8 Hz 130.29(s) 127.99(s)	47.15(s)
(**2**)	174(s) 1.69(s)	7.2–7.1(m)	23.13(s) 22.29(s)	182.70(s) 181.96(s)	134.07(pt) J = 5.3 Hz 131.12(d) J = 49.9 Hz 129.65(s) 127.83(pt) J = 5.0 Hz	51.92(s)

s, singlet; d, doublet; pt, pseudo triplet; m, multiplet.

compounds must correspond to one unpaired electron per metal atom, but the magnetic susceptibility measurements at various temperatures show that the violet compound is diamagnetic. This behaviour has been observed in other oxo-bridged compounds of ruthenium(III) in which the spin-pairing occurs via the oxo groups.[10,11,18-24]

The IR spectrum of the oxo-dimer shows absorptions due to triphenylphosphine ligands and absorptions due to the presence of two types of acetate ligands.

The ^1H NMR spectrum of the oxo-dimer shows two singlets assigned to two, unequivalent acetate ligands and a multiplet due to the phenyl protons. The $^{13}C\{^1H\}$ NMR spectrum of this compound confirms the presence of two, unequivalent acetate groups. The aromatic region of this spectrum shows several resonances due to the carbons of the phenyl groups. The $^{31}P\{^1H\}$ NMR spectrum shows one singlet, which indicates the presence of only one type of phosphine (Table 1).

We have made numerous attempts to derive single crystals of the violet compound obtained from $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$. Finally, a toluene solution in air over several days gave single crystals of an unsolvated compound identified as $[Ru(\mu\text{-}O_2CCH_3)(O_2CCH_3)(PPh_3)]_2(\mu\text{-}O)$. This compound has been also obtained, as a methanol solvate, from $RuCl_3 \cdot 3H_2O$, NaO_2CCH_3 and PPh_3 in methanol, by a published procedure.[11] This method can be improved by bubbling a stream of oxygen for 30 min through the reaction mixture allowing the aforementioned compound to be obtained in shorter periods of time and in higher yield.

An ORTEP[25] drawing of the violet compound appears in Fig. 1. The distances, angles and some torsion angles are summarized in Table 2.

The molecule, $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2$ (**2**), consists of two ruthenium(III) ions bridged by an oxo and two acetate ligands. Each ruthenium atom is also bonded to one bidentate acetate group and one PPh_3 ligand. Both ruthenium(III) atoms are in a distorted octahedral environment, with the oxo and phosphine ligands in *cis* positions. The $Ru—O_{oxo}$ distances are very short, indicating considerable double bond character. This situation is similar to that seen in other structurally characterized oxodiruthenium complexes. The Ru—O—Ru angle in this compound is 121.2°. The $Ru—O_{oxo}$ distances and the Ru—O—Ru angle are similar to those described for $[L_2Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2](PF_6)_2 \cdot 0.5H_2O$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane),[20] {(tpm) $Ru(\mu\text{-}O)[\mu\text{-}O_2P(O)(OH)]_2Ru(tpm)\} \cdot 8H_2O$ [tpm = tris(1-pyrazolyl)methane][18] and $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(py)_6](ClO_4)_2 \cdot 4H_2O$,[21] and contrast with other oxoruthenium complexes in which the Ru—O—Ru angle is near 180°. The Ru—Ru distance is 3.216 Å, suggesting a weak intramolecular Ru—Ru interaction similar to that observed in other analogous oxo-dimer compounds.[18,20,21]

The bridging and bidentate acetate ligands are asymmetrically bonded to the ruthenium atoms. This asymmetrical disposition could be due to a pronounced *trans* effect of the oxo bridge and the triphenylphosphine ligands.

In order to isolate some intermediates in this reaction, it was stopped after 2 h of stirring. When

this reaction mixture was pumped dry, extracted with toluene, treated with active carbon and pumped dry again, a diamagnetic violet solid was obtained.

The IR spectrum of this solid is very similar to **2**, showing absorption bands due to the triphenylphosphine ligand and two types of acetate ligands but giving no additional information.

The NMR spectrum show the resonances due to the oxo-dimer and **1** described above (Table 1), however, new signals are also observed. Thus, in the ^1H NMR spectrum, two new singlets at 1.83 and 1.95 ppm, assigned to two inequivalent acetate groups, are observed and in the region of the phenyl groups, new signals are also present. In the $^{13}C\{^1H\}$ NMR spectrum two new signals appear at 30.30 and 29.63 ppm due to two different acetate groups and in the region of the aromatic carbons new signals appear due to coordinated phosphine. Finally, in the $^{31}P\{^1H\}$ NMR spectrum a new signal at 35.45 ppm was observed. All these data indicate the presence of a new compound containing two classes of acetate group and an equivalent phosphine ligand.

In the FAB mass spectrum of the violet solid obtained after 2 h of reaction, the base peak is observed at $m/z = 980$, corresponding to a $[Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2]^+$ ion. In addition, the spectrum shows other peaks at higher

Table 3. Mass spectral data

m/z	Ion
1911	$[Ru_4(O_2CCH_3)_8(PPh_3)_4-CH_3]^+$
1713	$[Ru_4(O_2CCH_3)_7(PPh_3)_3(PPh)]^+$
1577	$[Ru_4(O_2CCH_3)_6(PPh_3)_3(P)]^+$
1465	$[Ru_4(O_2CCH_3)_7(PPh_3)(PPh_2)(POPh_2)]^+$
1430	$[Ru_3(O_2CCH_3)_5(O_2C)(PPh_3)_3]^+$
980	$[Ru_2(O)(O_2CCH_3)_4(PPh_3)_2]^+$

m/z than this base peak. The highest observed peak is at $m/z = 1911$, in accordance with a $\{[Ru(O_2CCH_3)_2(PPh_3)]_4-CH_3\}^+$ fragment. Signals corresponding to the fragmentation of this tetramer compound at $m/z = 1465$, 1577 and 1430 are observed. In Table 3 these peaks are summarized and their possible assignments shown. Figure 2 shows the experimental and calculated isotopic distribution for some of the peaks which appear in this mass spectrum. The peak at $m/z = 1911$ seems to suggest that in this reaction a tetramer compound of formula $[Ru(O_2CCH_3)_2(PPh_3)]_4$ is formed. Accordingly with the NMR data it is possible to propose the existence of a tetranuclear intermediate with bridging and monodentate acetates and a phosphine ligand bonded to ruthenium. Without a crystal structure determination, a precise structure assignment cannot be made but it seems reasonable to assume the structure for this intermediate shown in Scheme 1. This tetramer can be formed by the coupling of two dimer units. A similar reaction in which two dimer units of molybdenum are coupled to give a planar tetranuclear compound has been described by McCarley and co-workers.[26]

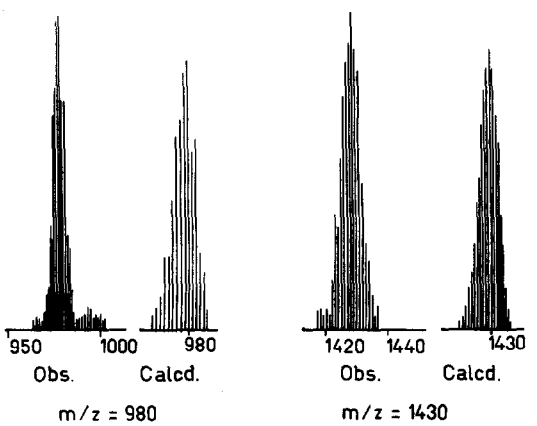

Fig. 2. Observed and calculated isotope ratios for some peaks of the mass spectrum.

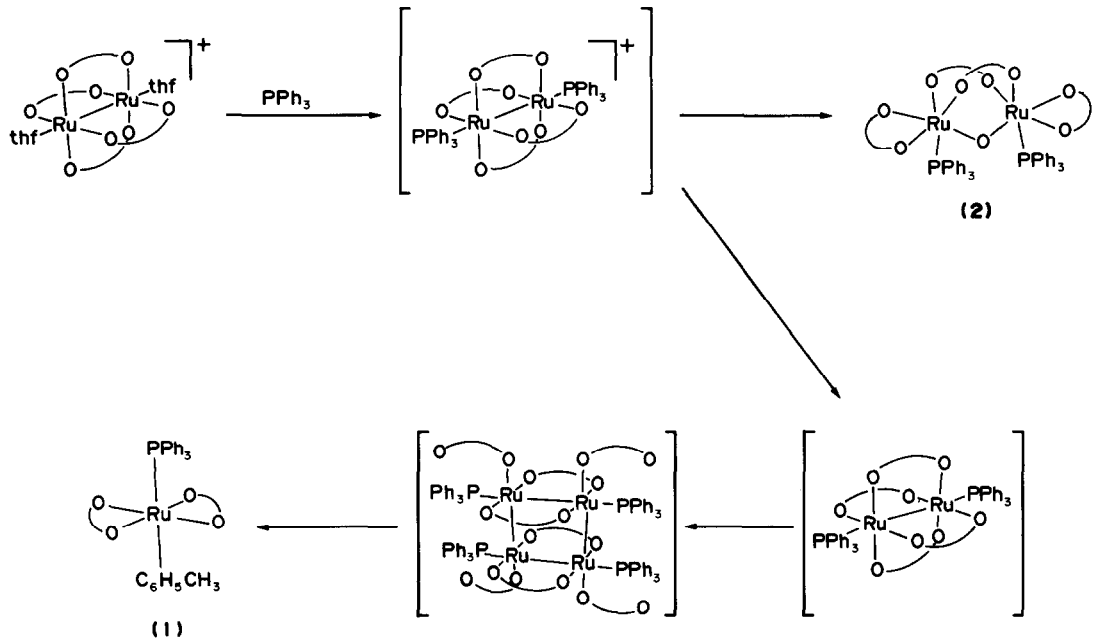
We have made numerous attempts to isolate the pure tetramer compound, but in all cases we have obtained a mixture with the oxo-dimer, which indicates very similar solubility. Nonetheless all attempts to crystallize this compound have been unsuccessful, because in solution it is transformed.

In the reaction described, the formation of a compound of ruthenium(III) and of ruthenium(II), from a diruthenium(II,III) compound, indicates a formal disproportionation process. An analogous process of dismutation has been observed by Cotton *et al.*[27] in the reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with L-mandelic acid (Hmand) to give $Ru_3(\mu\text{-}O)(mand)_6(H_2O)_3(mand)$ and $Ru_2(mand)_4(H_2O)_2$. Other disproportionations of chlorotetra-μ-acetatediruthenium(II,III) have been observed by Wilkinson and co-workers.[28,29]

The formation of an oxo-dimer instead of an oxo-trimer, as described by Cotton *et al.*,[27] could be due to the lower stability of the oxo-trimer in solution with the ligand triphenylphosphine compared with the oxo-dimer. The reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ with PPh_3 must lead initially to the substitution of the thf ligands by PPh_3, giving $[Ru_2(\mu\text{-}O_2CCH_3)_4(PPh_3)_2]BF_4$. This compound must be unstable, giving a ruthenium(III) compound, **2**, and one of ruthenium(II), $Ru_2(\mu\text{-}O_2CCH_3)_4(PPh_3)_2$. The ruthenium(II) compound undergoes a coupling reaction giving a tetramer compound of the type $[Ru(\mu\text{-}O_2CCH_3)(O_2CCH_3)(PPh_3)]_4$. This compound is slowly converted in toluene solution to **1** (Scheme 1).

The behaviour of the tetra-μ-acetatediruthenium(II,III) unit towards the triphenylphosphine ligand contrasts with the existence of other adducts of the type $[Ru_2(\mu\text{-}O_2CH_3)_4L_2]^+$.[15,30,31] On the other hand, it has been demonstrated, by electrochemical studies,[32] that the tetra-μ-acetatediruthenium(III,III) unit cannot be obtained. Although some studies have questioned the π-acceptor character of the triphenylphosphine,[33] the existence of empty orbitals of low energy in this ligand can permit the existence of a π-backbonding interaction. Thus, the triphenylphosphine ligand could produce a decrease in the electron density of the $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ unit, similar to that observed in the oxidation process of this core, leading to the rupture of the metal—metal bond.

Finally, although the oxo-dimer compound is also formed in the reaction of $Ru_2Cl(\mu\text{-}O_2CCH_3)_4$ with triphenylphosphine in alcohol,[11,13] MeCN[13] or MeCN–H_2O,[14] the mechanism of formation of this compound could be different from that observed in the reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ and triphenylphosphine in thf or toluene described above.



Scheme 1. Proposed mechanism for the formation of **1** and **2**.

EXPERIMENTAL

Ruthenium trichloride, triphenylphosphine and sodium acetate were purchased from commercial sources and used without purification. Tetrahydrofuran, toluene and diethyl ether were distilled from sodium/benzophenone. Dichloromethane was distilled from calcium hydride. Methanol was used without previous purification. The preparative method for $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ is available in a previous report.[17] All manipulations were performed under a nitrogen atmosphere using Schlenk techniques.

All ^1H, ^{13}C and ^{31}P spectra were recorded with a Varian VXR-300 spectrometer using $CDCl_3$ as solvent. ^1H and ^{13}C NMR chemical shifts are reported in ppm relative to TMS and ^{31}P NMR chemical shifts are reported in ppm relative to external 85% H_3PO_4. IR spectra were recorded on a Perkin–Elmer 1330 as KBr disks. FAB mass spectra were obtained on a Kratos MS-80 mass spectrometer. Magnetic measurements were made with a magnetometer DSM-5 in the range 85–295 K. Elemental analyses were performed on a Perkin–Elmer 240B microanalyser.

Synthesis of $Ru(O_2CCH_3)_2(PPh_3)\cdot CH_3C_6H_5$ (1)

To a solution of $[Ru_2(\mu\text{-}O_2CCH_3)_4(thf)_2]BF_4$ (0.5 g, 0.75 mmol) in thf (30 cm^3) was added PPh_3 (0.78 g, 2.99 mmol). The solution was stirred at room temperature overnight and changed from red to violet. The solvent was removed to leave a dry residue, which was extracted with toluene (3×20 cm^3). The combined extracts were treated with active carbon and filtered. The solution was allowed to stand for 4 days to obtain a yellow crystalline solid, and the crystals were isolated by filtration, washed with toluene (2×5 cm^3) and dried in a stream of nitrogen. Yield: 28%. Found: C, 50.6; H, 4.9. Calc. for $Ru(O_2CCH_3)_2(PPh_3)\cdot CH_3C_6H_5$: C, 60.7; H, 5.1%.

Synthesis of $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2$ (2)

Procedure 1. The residual solution from the preparation of **1** was pumped dry. The violet solid obtained was washed with cold diethyl ether (2×5 cm^3) and dried *in vacuo*. Yield: 32%. Found: C, 54.0; H, 4.7. Calc. for $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2$: C, 54.0; H, 4.3%.

Procedure 2. The preparation of this complex as methanol solvate was achieved by an improved method from that previously described by Wilkinson and co-workers.[11] A mixture of $RuCl_3\cdot 3H_2O$ (0.15 g, 0.57 mmol), PPh_3 (0.30 g, 1.15 mmol) and $NaO_2CCH_3\cdot 3H_2O$ (0.31 g, 2.29 mmol), in methanol (40 cm^3), was heated at reflux for 15 min, during which time the solution changed to violet. After which, a slow stream of oxygen was bubbled for 30 min through the boiling solution. On cooling to room temperature, the violet solution

was filtered and the solvent was concentrated under reduced pressure to one-third of its initial volume. On standing at −15° for 12 h, violet crystals of the product were formed. Found: C, 53.3; H, 4.6. Calc. for $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2 \cdot CH_3OH$: C, 53.5; H, 4.6%.

More violet product can be obtained from the mother liquor when this is pumped dry; the obtained solid is washed with diethyl ether and extracted with toluene. The resulting solution is evaporated to dryness to give the unsolvated violet compound. Total yield: 65%.

X-ray crystallographic procedures

A violet prismatic single crystal of $Ru_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(PPh_3)_2$ was introduced into a Lindeman capillary and mounted on a Nonius CAD-4 diffractometer. The unit cell dimensions were determined by least-squares refinement of the observed setting angles of 25 accurately centred reflections. The crystal data are summarized in Table 4. Intensities within $1 < 2\theta < 30°$ were measured at 295 K, considering as observed those with $I > 2\sigma(I)$. The data were corrected for Lorentz and polarization effects. Scattering factors for neutral atoms and anomalous dispersion corrections for ruthenium and phosphorus were taken from *International Tables for X-ray Crystallography*.[35]

The structure was solved by conventional Patterson and Fourier techniques. An empirical absorption correction,[36] applied at the end of the isotropic refinement using unit weights, led to a conventional R value of 0.085. The hydrogen atoms were fixed at the calculated positions. Final refinement with fixed atomic coordinates and isotropic temperature factors for hydrogen atoms and unit weights led to $R = 0.067$. Most of the calculations were performed with X-ray 80.[37]

Complete tables of distances and angles as well as atomic positional and anisotropic thermal parameters and structure factors have been deposited as supplementary material.

BIS(ACETATO-2,4-PENTANEDIONATO)DIZINC: REFORMULATION OF A ZINC CARBOXYLATE DIKETONATE COMPLEX

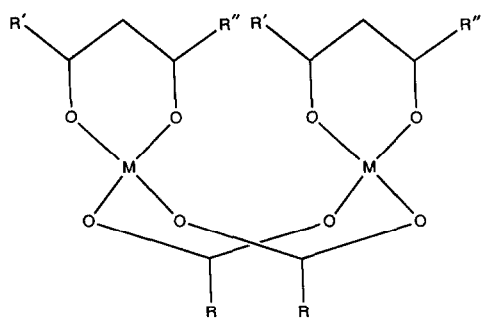
PETER G. PRITCHARD and PETER THORNTON*

Department of Chemistry, Queen Mary and Westfield College, University of London, Mile End Road, London E1 4NS, U.K.

(*Received* 10 *August* 1990; *accepted* 12 *September* 1990)

Abstract—NMR (^{1}H) spectra, supported by IR data, show that the compound previously formulated as $Zn_2(O_2CCH_3)(acac)_3$ (acac = 2,4-pentanedionate) is in fact $Zn(O_2CCH_3)$(acac), which probably has a dimeric structure with bridging acetate ligands.

Mixed carboxylate diketonate complexes of stoichiometry $[M(RCO_2)\{R'C(O)CHC(O)R''\}]$ have been recorded for a few transition elements. The most thorough investigations have been carried out on eight rhodium(II) complexes.[1] These studies involved acetate complexes of a number of diketonates, some fluorinated. The use of ^{1}H and ^{19}F NMR and IR spectra strongly indicated a structure (I) which can be considered as derived from



(I)

the familiar dimeric $[M_2(O_2CR)_4]$ structure for carboxylates,[2] well-known for rhodium(II),[3] by replacement of two of the four bridging carboxylate ligands by diketonates. These ligands are more likely to coordinate in a bidentate fashion to one Rh atom than to bridge two, giving complexes with the dimeric formulation $[Rh_2(O_2CR)_2\{R'C(O)CHC(O)R''\}_2]$. Most of the complexes contained two axial ligands (water, pyridine, etc.) along the line of the Rh—Rh bond, required by the complexes' diamagnetism.

Some cobalt(II) analogues have also been prepared using long chain carboxylates.[4] These were suggested to be trimers or tetramers but the evidence is ambiguous. The copper(II) complex $Cu(O_2CCl_3)$(acac) has also been reported.[5] For this complex the magnetic moment was given as $1.93\mu_B$ (temperature not stated) and it was suggested that the compound was monomeric. However, the IR data and green colour also fit structure **I** which avoids the constraint of a four-membered ring required by a chelating acetate, while the magnetic moment was not confirmed by measurements over a temperature range. Calcium acetate reacts with ammonium pentanedionate in water to give $[Ca(O_2CCH_3)(acac)(OH_2)_2]$, but the necessity to accommodate two water molecules on each calcium atom results in an eight-coordinate polymeric structure,[6] the only one to be confirmed crystallographically in this area.

With these results in mind we were surprised to read[7] that 2,4-pentanedione reacts with Zn $(O_2CCH_3)_2(OH_2)_2$ to give, apparently, $Zn_2(O_2CCH_3)(acac)_3$ which was formulated as the $[Zn(acac)_3]^-$ salt of the improbable cation $[Zn(O_2CCH_3)]^+$. We have reinvestigated this reaction.

We have found that the white solid reported[7] to form from this reaction is indeed produced. However, the ^{1}H NMR spectrum in $CDCl_3$ showed the methyl protons (δ2.0) to be nine times as abundant as the γ-H protons of the diketonate. This can only be

* Author to whom correspondence should be addressed.

reconciled with the formula $Zn(O_2CCH_3)(acac)$; the earlier formulation of $Zn_2(O_2CCH_3)(acac)_3$ requires a methyl to γ-proton ratio of 7:1. The acetate protons could not be distinguished from those of the diketonate. It is possible that the earlier workers were misled by erroneous elemental analyses, as we found the carbon content of our product to be appreciably higher than that required by the formula. Nevertheless, the NMR and IR spectra are very clean and there is no insoluble residue when the compound is dissolved in $CDCl_3$ or common organic solvents.

The formula $Zn(O_2CCH_3)(C_5H_7O_2)$ indicated by the NMR spectrum suggests that zinc resembles rhodium(II) in forming the dinuclear structure (**I**), which would avoid the improbabilities of three-coordination from monodentate acetate and a strained four-membered chelate ring given by bidentate acetate in monomeric formulations. The observation of CO_2 stretching frequencies at 1520 and 1400 cm^{-1} supports the dimeric formulation, but does not distinguish this from acetate chelation.[8] An interesting question, which the material's non-crystallinity prevented us answering, is whether zinc would adopt the square planar disposition of oxygens which is probably found in the rhodium compounds of structure **I**, or whether there is some distortion towards the tetrahedral geometry more usually found in zinc chemistry.

EXPERIMENTAL

Reagents were all commercially available. Spectroscopic techniques have already been described.[9]

$Zn(O_2CCH_3)(C_5H_7O_2)$

Zinc acetate dihydrate (1.00 g, 4.56 mmol) was dissolved in an excess of boiling 2,4-pentanedione (10 cm^3), and the resulting solution was concentrated by prolonged heating on a hotplate, after which it was filtered hot. On cooling, the product separated out as a white powder which was filtered off, washed with petroleum ether (60–80°C) and dried. Yield 0.77 g, 75.6%. Found: C, 40.0; H, 4.7%. $C_7H_{10}O_4Zn$ requires: C, 37.61; H, 4.52%.

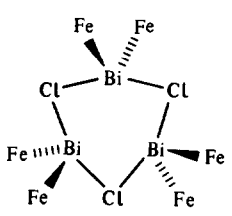
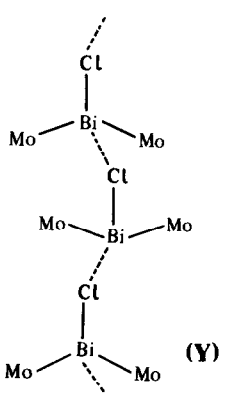
(*Received* 7 *September* 1990; *accepted* 25 *September* 1990)

Abstract—The synthesis and structures of $[PPN][BiCl_2\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_2]$ and $[PPN][BiCl_2\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (PPN = Ph_3PNPPh_3) are described; both bismuth complexes adopt structures intermediate between tetrahedral and equatorially vacant trigonal bipyramidal, possible electronic reasons for which are presented and discussed.

The syntheses of the bismuth complexes $[BiCl\{Fe(CO)_2(\eta\text{-}C_5H_4R)\}_2]$ [R = H (**1a**); R = Me (**1b**)][1] and $[BiCl\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**2**)[2] have recently been described and, in the solid state, these compounds oligomerize by way of intermolecular bismuth–chlorine interactions such that the former exists as a cyclotrimer (**X**)[1] whilst the latter forms one-dimensional infinite chains (**Y**).[2] Solution



(**X**)



(**Y**)

EXAFS data obtained for **2** in THF solution, however, show that the species present is probably $[BiCl(THF)\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**2a**).[3] These structural data, which will be discussed in more detail in a future publication,[3] indicate that the bismuth centres in **1** and **2** have appreciable Lewis acidic character, in common with many BiX_3 species, and therefore that discrete acid–base adducts of the general formula $(ML_n)_2BiCl(L)$ should be reasonable targets for chemical synthesis. Moreover, the nature of **2** in THF (i.e. **2a**) implies that such compounds might be monomeric, and thus furnish examples of four-coordinate, 10-electron bismuth species, rather than the dimeric or oligomeric structures more usually observed [e.g. $Bi_2Cl_8^{2-}$, $(BiBr_4)_n^{n-}$][4].

Accordingly, we examined the reaction between **1a**/**2** and [PPN]Cl (PPN = Ph_3PNPPh_3). Treatment of either **1a** or **2**, in THF solution, with one equivalent of solid [PPN]Cl led to no observable colour change (both **1** and **2** are dark green), but after stirring for 24 h, filtration through Celite and crystallization from THF–hexane mixtures, > 90% yields of the dark green crystalline complexes $[PPN][BiCl_2\{Fe(CO)_2(\eta\text{-}C_5H_5)\}_2]$ (**3**) and $[PPN][BiCl_2\{Mo(CO)_3(\eta\text{-}C_5H_5)\}_2]$ (**4**) were

(4)

obtained. Spectroscopic and analytical data† were consistent with the anticipated formulae and their structures were confirmed by X-ray crystallography,‡ the results of which are shown in Figs 1 and 2. Both structures contain isolated $[PPN]^+$ cations and $[BiCl_2(ML_n)_2]^-$ anions with no short interionic contacts. In the anions, a central bismuth atom is bonded to two chlorine atoms and either two $Fe(CO)_2(\eta\text{-}C_5H_5)$ fragments (**3**) or two $Mo(CO)_3(\eta\text{-}C_5H_5)$ fragments (**4**). In complex **3** the

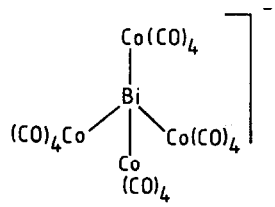
NMR ^1H (CD_2Cl_2): δ 5.49 (C_5H_5), 7.7–7.4 (m, phenyls, PPN). $C_{52}H_{40}Cl_2BiMo_2NO_6P_2$ requires: N, 1.1; C, 47.7; H, 3.1. Found: N, 1.1; C, 47.2; H, 2.9%. In the IR spectrum, the absorption at 1781 cm^{-1} is due to $[Mo(CO)_3(\eta\text{-}C_5H_5)]^-$, indicating that some dissociation takes place in this solvent. Full details on the solution-state behaviour of these complexes will be reported in a future full paper.

‡ Crystal data for **3**: $C_{50}H_{40}NO_4P_2Cl_2Fe_2Bi$, $M = 1172.4$, monoclinic, $P2_1/n$, $a = 9.009(2)$, $b = 35.049(9)$, $c = 14.796(5)$ Å, $\beta = 91.81(3)°$, $U = 4669.6$ Å^3, $Z = 4$, $D_c = 1.667$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 4.588$ mm^{-1}, $F(000) = 2312$, $T = 295$ K. The structure was determined by Patterson and difference syntheses and refined[5] to a minimum of $\Sigma w\Delta^2$ [$\Delta = |F_o| - |F_c|$, $w^{-1} = \sigma^2(F) = \sigma_c^2(F) + 2 + 792G + 9G^2 - 18S + 150S^2 - 1583GS$, $G = F_o/F_{max}$, $S = \sin\theta/\sin\theta_{max}$][6] from 3564 reflections with $2\theta < 45°$ and $F > 4\sigma_c(F)$ (σ_c from counting statistics only), measured with a Stoë–Siemens diffractometer and on-line profile fitting.[7] Anisotropic thermal parameters were refined for all non-hydrogen atoms. Hydrogen atoms were constrained. Final $R = 0.074$, $R_w = (\Sigma w\Delta^2/\Sigma wF_o^2)^{1/2} = 0.063$ for 487 parameters. For **4**: $C_{52}H_{40}NO_6P_2Cl_2Mo_2Bi$, $M = 1308.6$, monoclinic, $P2_1/c$, $a = 14.197(2)$, $b = 9.556(2)$, $c = 37.190(7)$ Å, $\beta = 92.12(2)°$, $U = 5042.05$ Å^3, $Z = 4$, $D_c = 1.724$ g cm^{-3}, $\mu = 4.166$ mm^{-1}, $F(000) = 2552$, $T = 295$ K. The structure was determined as above [$w^{-1} = \sigma^2(F) = \sigma_c^2(F) + 51 + 353G + 1060G^2 - 133S + 151S^2 - 953GS$] from 4758 reflections with $2\theta < 50°$ and $F > 4\sigma_c(F)$. Final $R = 0.058$, $R_w = 0.064$ for 520 parameters. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

angles and distances around the bismuth atom are similar to those found in **1a** [for **3**, Bi—$Cl_{av.}$ 2.795 Å, Cl(1)—Bi—Cl(2) 155.6(2)°, Fe(1)—Bi—Fe(2) 111.4(1)°; for **1a**,[1b] Bi—$Cl_{av.}$ 2.907 Å, Cl—Bi—$Cl_{av.}$ 154.2°, Fe—Bi—$Fe_{av.}$ 109.8°]. In **2** the Bi—Cl bond lengths are markedly asymmetric (see ref. 2 for details), but the angles at bismuth are similar to those in **4** [for **4**, Cl(1)—Bi—Cl(2) 138.5(1)°, Mo(1)—Bi—Mo(2) 116.4(1)°; for **2**,[2] Cl—Bi—Cl 151.6(1) and 141.6(1)°, Mo—Bi—Mo 118.3(1) and 116.4(1)° for two crystallographically-independent molecules]. The coordination geometry around bismuth for these two structures can be described as between tetrahedral and equatorially vacant trigonal bipyramidal (evtb). As judged by the latter geometry, the chlorine atoms in **3** and **4** are pseudo-axial with the angle α [defined as in Fig. 3] equal to 155.6(2) and 138.5(1)°, respectively. Ideally this angle would be either 109.5 or 180° for the aforementioned limiting geometries.

The only other anionic, 10-electron, four-coordinate bismuth complex, related to **3** and **4** is $[Bi\{Co(CO)_4\}_4]^-$ (**5**), which has been structurally characterized by Leigh and Whitmire[8] and Martinengo *et al.*,[9] and found to be tetrahedral. Clearly a range of structures are possible for $[BiX_y(ML_n)_{4-y}]^-$ complexes, ranging from tetrahedral (**5**) to almost evtb for **3**, with **4** intermediate between the two. Although steric effects cannot be



(5)

ruled out as a major contributory factor, an electronic origin involving negative hyperconjugation is a possibility.[10]

In general, the Lewis acidity of the three-coordinate $[BiCl(ML_n)_2]$ species, where ML_n is a 17-electron metal-based fragment such as $Fe(CO)_2(\eta\text{-}C_5H_5)$ (**1**) or $Mo(CO)_3(\eta\text{-}C_5H_5)$ (**2**), derives from the presence of a low-lying Bi—Cl σ^*-orbital. Moreover, the interaction of an incoming nucleophile, here Cl^-, with this orbital leads to a geometry in which the nucleophile is approximately *trans* to the pre-existing Bi—Cl bond which accounts for the observed positions of the chlorine atoms around the bismuth centres in **1**–**4**. However, the pseudo-axial Bi—Cl σ^*-orbital (**A**) of the resulting acid–base adduct will fall in energy as the Cl—Bi—Cl angle (α) decreases, as illustrated in Fig. 3,[11] due to a decrease in overlap and a corresponding reduction of antibonding character. In addition this orbital (**A**) can also play an important role in Bi—ML_n π-

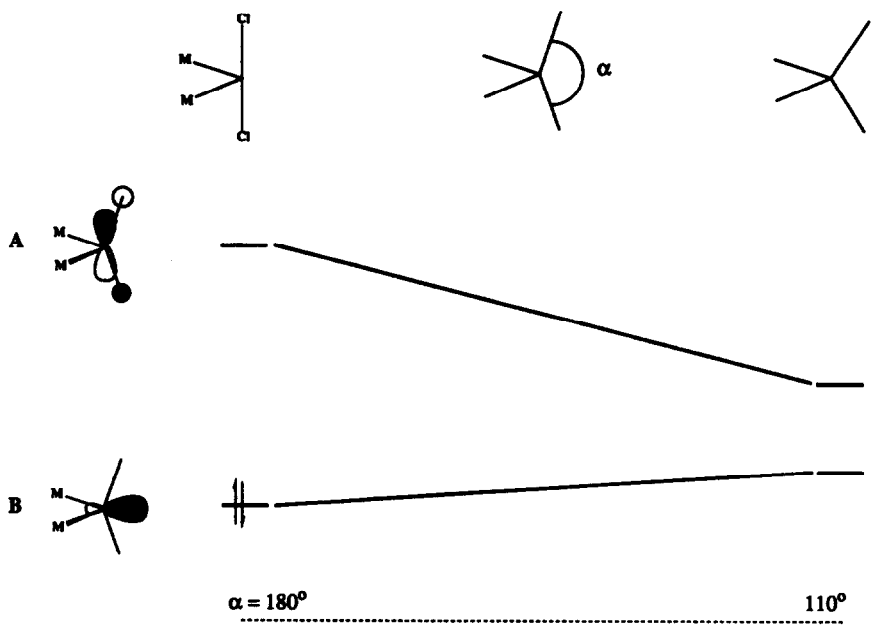


Fig. 3. Partial orbital correlation diagram[11] for the equatorially vacant trigonal bipyramidal to tetrahedral distortion of a $[BiCl_2(ML_n)_2]^-$ fragment (ML_n = 17-electron metal fragment).

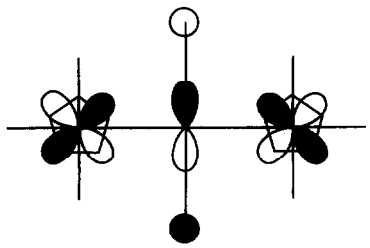

(C)

bonding as shown in **C** (see refs 10 and 12 for discussion of similar π-interactions). The effectiveness of the π-overlap will be enhanced by lowering the energy of orbital **A**, and (partial) occupancy of **A** will, therefore, promote a reduction of the angle α. Thus the presence of π-donating substituents (Z) in the pseudo-equatorial sites of a $BiCl_2Z_2$ species would be expected to lead to a distortion of the sort depicted in Fig. 3, and observed in **3** and **4**. Further evidence that metal-to-bismuth π-donation is present is provided by the observed orientations of the $Mo(CO)_3(\eta\text{-}C_5H_5)$ fragments in **4**. $(C_5H_5)ML_3$ fragments have two π-donor orbitals as described in detail in ref. 13. One of these, which lies in a plane orthogonal to the symmetry plane of the fragment, is the better disposed towards π-bonding and the orientation of both molybdenum-based fragments in **4** is such as to allow overlap of this orbital with the π-acceptor bismuth-based orbital **A**. This is shown diagrammatically in **C**.† Similar arguments can be advanced to account for the orientation of the $Fe(CO)_2(\eta\text{-}C_5H_5)$ fragments in both **1** and **3**.[3] It remains to be shown whether these distortions are indeed sterically or electronically driven, but π- to σ^*-donation, or negative hyperconjugation, is known to have pronounced effects on the angles within hypervalent main group compounds.[10] We note, also, that tetrahedral **5** is paramagnetic,[8] implying that the HOMO–LUMO gap is small or zero. As indicated in Fig. 3, this is to be expected if the "lone pair" orbital **B** is sufficiently destabilized, and the Bi—X σ^*-orbital(s) sufficiently stabilized by reduction of the X—Bi—X angles to tetrahedral values.

Further synthetic, structural and theoretical studies on these and related compounds are in progress.

Acknowledgement—We thank the SERC for financial support.

MOLECULAR HELICITY IN INORGANIC COMPLEXES: THE CRYSTAL AND MOLECULAR STRUCTURE OF 2,6-DIACETYLPYRIDINE BIS(6-CHLORO-2-PYRIDYLHYDRAZONE) SILVER(I) HEXAFLUOROPHOSPHATE DIMER

EDWIN C. CONSTABLE,* JEREMY M. HOLMES and PAUL R. RAITHBY

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

(*Received* 12 *September* 1990; *accepted* 25 *September* 1990)

Abstract—The crystal and molecular structure of the complex $[Ag_2L^1{}_2][PF_6]_2$ [L^1 = 2,6-diacetylpyridine bis(6-chloro-2-pyridylhydrazone)] have been determined. The cation is binuclear with each silver in a distorted four-coordinate environment, showing weak interactions with a fifth ligand and with a short Ag—Ag distance of 3.142 Å. The two equivalent ligands are wrapped around the binuclear core in a double-helical array. This is stabilized by π-stacking interactions between parallel pyridyl rings. The double-helical array is generated in a spontaneous self-assembly process which is dictated by the relative acceptor properties of the silver(I) ion and the donor properties of the ligand.

There has been considerable recent interest in the design of ligands which facilitate the spontaneous self-assembly of complexes[1–6] and host–guest compounds[7–9] with novel chemical, biological or topological properties. The assembly of double-helical polynuclear complexes has been studied by several groups.[10–24] We have investigated the ability of the oligopyridines to assemble flexible, but non-labile, double-helical ligand environments with a view to designing photo- and redox-active binuclear complexes.[18–24] The double-helical ligand array may be viewed as a spring which can expand or contract; in molecular terms this allows the accommodation of a wide range of metal–metal distances within the same ligand array, a feature that is not commonly observed in macrocyclic systems. In order to further probe the subtle features dictating the formation of the double-helical array, we have investigated the use of sterically demanding ligands related to the oligopyridines, and we report herein the crystal and molecular structure of the silver(I) complex of the potentially pentadentate ligand 2,6-diacetylpyridine bis(6-chloro-2-pyridylhydrazone) (L^1).

* Author to whom correspondence should be addressed.

EXPERIMENTAL

The ligand 2,6-diacetylpyridine bis(6-chloro-2-pyridylhydrazone) and its silver complex were prepared as previously reported.[25] ^{1}H NMR spectra were recorded on a Bruker WM250 spectrometer at ambient temperature.

Crystal structure determination

Pale yellow prisms of the complex were obtained by the recrystallization of $[Ag_2L^1{}_2][PF_6]_2$ from hot methanol. The crystals were stable in air, and several were mounted on glass fibres. The space group and unit cell dimensions were derived from preliminary Weissenberg photography. Pertinent crystallographic parameters are given in Table 1.

The position of the silver atom was determined from the Patterson function. Remaining non-hydrogen atoms were determined from Fourier difference maps. The structure was refined (Ag, Cl, P, F, N and C anisotropic, H isotropic in calculated positions; C—H, 1.08 Å) to $R = 0.0490$ ($R_w = 0.0554$). A final difference map showed no significant regions of electron density except for ripples of *ca* 0.75 e Å^{-3} close to the position of the

Calculations were performed using SHELX 76 on the IBM 370/165 computer at the University of Cambridge.[27] Selected dimensions within the coordination sphere are presented in Table 2. Tables of all final coordinates and thermal parameters, bond lengths, bond angles, hydrogen atom coordinates and tables of observed and calculated structure factors have been deposited with the Editor, from whom copies are available.

RESULTS AND DISCUSSION

We have previously reported the preparation and coordination chemistry of pentadentate N_5-donor macrocyclic ligands incorporating a 2,2′:6′,2″-terpyridyl functionality (L^2, R = H or Ph).[28–34] These macrocyclic ligands are relatively inflexible and possess a bonding cavity with a "hole-size" of 2.1 ± 0.5 Å. In contrast, the open-chain ligand 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (L^3) possesses considerably more flexibility. In a planar configuration, L^3 presents the five nitrogen atoms to the metal with an effective "hole-size" of 2.45 ± 0.3 Å.

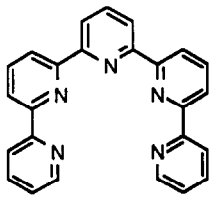
L^2



L^3

This corresponds to a pentagonal-planar geometry for metals with an ionic radius 1.0 ± 0.1 Å, and we have recently demonstrated such a geometry (with *no* axial interactions) in the complex $[AgL^3][PF_6]$.[22] The introduction of sterically demanding substituents into analogues of L^3 is

expected to increase the effective hole-size of the bonding cavity such that silver(I) is too small to be accommodated by the ligand in a planar pentadentate mode.

We have previously shown that the consequence of interaction of potentially planar pentadentate ligands with metal ions which are too small for the bonding cavity in the planar coordination mode is to introduce twisting within the ligand.[18-24] This results in the formation of double-helical binuclear coordination compounds from the interaction of first-row transition metal ions with $\mathbf{L}^3$. This process is illustrated schematically in Fig. 1, which also emphasizes that the double-helical geometry is partially dependent upon the coordination geometry of the metal ions involved. In the case of $\mathbf{L}^3$ complexes of stoichiometry $[M_2\mathbf{L}^3{}_2]^{n+}$ are formed. In these complexes the ligands have twisted around the interannular C—C bonds to adopt the helical configuration. One of the principal structural features of these complexes is the "stacking" of the planar aromatic rings, and this is responsible for the structural integrity of the double-helical array; so favourable is the $[M_2\mathbf{L}^3{}_2]^{n+}$ structural unit that it may be cycled between a range of oxidation levels ($\{Cu^I,Cu^I\}$, $\{Cu^{II},Cu^I\}$ and $\{Cu^{II},Cu^{II}\}$ for example). In fact, the double-helical array of ligands undergoes a "concertina" motion to accommodate the changes in the metal ion radius. We would anticipate that the interaction of $\mathbf{L}^1$ (which is a sterically hindered analogue of $\mathbf{L}^3$) with silver(I) might also lead to the formation of a double-helical ligand array, although the coordination properties of the silver(I) ion might preclude the formation of an octahedral centre.

The structurally developed ligand $\mathbf{L}^1$ is readily prepared by the condensation of 2,6-diacetylpyridine with 6-chloro-2-hydrazinopyridine.[25] The reaction of $\mathbf{L}^1$ with silver(I) hexafluorophosphate in methanol results in the formation of a pale yellow solution, from which pale yellow crystals of a complex of stoichiometry $[Ag\mathbf{L}^1][PF_6]$ separate on cooling.

The IR spectrum of the complex exhibits a strong absorption at 3103 cm^{-1}, which may be assigned to the hydrazino NH stretching mode. This is confirmatory evidence that the ligand has not deprotonated. A strong absorption at 1597 cm^{-1} is assigned to the C=N stretching mode.

The ^1H NMR spectrum (Fig. 2) of a solution of the complex in CD_3COCD_3 is also consistent with the presence of a complex of $\mathbf{L}^1$. The presence of a single methyl resonance centred at δ 2.88 indicates that the two methyl groups in the ligand are equivalent on the NMR time scale. The NH protons are observed as a slightly broadened resonance centred at δ 10.03. The resonances are all shifted with respect to the salt $[H\mathbf{L}^1][PF_6]$ (Table 3). The changes in chemical shift upon coordination ($\Delta\delta$) vary from +0.6 to −0.83, which is indicative of a major

change in ligand environment. We have previously demonstrated that $[HL^1][PF_6]$ adopts a configuration with the pyridyl nitrogen atoms facing *away* from the bonding cavity. If the chemical shift changes were associated simply with the rotation of these pyridyl groups about the C_{ring}—NH bond, dramatic changes are not expected at the central pyridyl ring.

In order to understand more fully the nature of the metal–ligand interactions in this complex we have determined its crystal and molecular structure. The molecular structure of the cation is presented in Fig. 3(a); selected bond parameters are listed in Table 2. The cation is dimeric and of stoichiometry $[Ag_2L^1{}_2]^{2+}$. The two silver atoms are in identical environments, in a very irregular coordination geometry. Each silver atom is bonded to *both* of the ligands, with each ligand acting as a bidentate donor to each metal. The geometry around each silver may be described as a flattened tetrahedron. Each silver is bonded to *one* terminal pyridyl ring [N(7)—Ag, 2.320(4) Å] and the associated imine nitrogen of one ligand [N(5)—Ag, 2.371(5) Å], and to the central pyridine [N(1)—Ag, 2.428(4) Å] and remaining imine nitrogen [N(2)—Ag, 2.324(5) Å]. The remaining pyridyl group of each ligand is not directly bonded to the metal, but interacts weakly with one silver atom [N(4)···Ag, 2.723(4)]. The distance between the two silver atoms is short [Ag···Ag, 3.14(1) Å], but significantly longer than that observed in silver metal (Ag···Ag, 2.899 Å). There is no direct silver–silver bond, but it seems likely that there is some degree of interaction between the two metals. However, the position of the two metals is to a great extent dictated by interligand interactions between the two ligands in the complex cation, and the question of the metal–metal interaction must remain unresolved. It is relevant that previous attempts to impose a pentadentate geometry upon silver(I) have led to complexes with short silver–silver vectors,[35–39] although this is *not* the case with L^3.[22]

The conformation of the ligands is of particular interest in this cation. The two ligands are wrapped around the binuclear silver core in a double-helical array, extremely reminiscent of that observed for the various binuclear complexes of L^3 with first-row transition metal ions. This is emphasized in Fig.

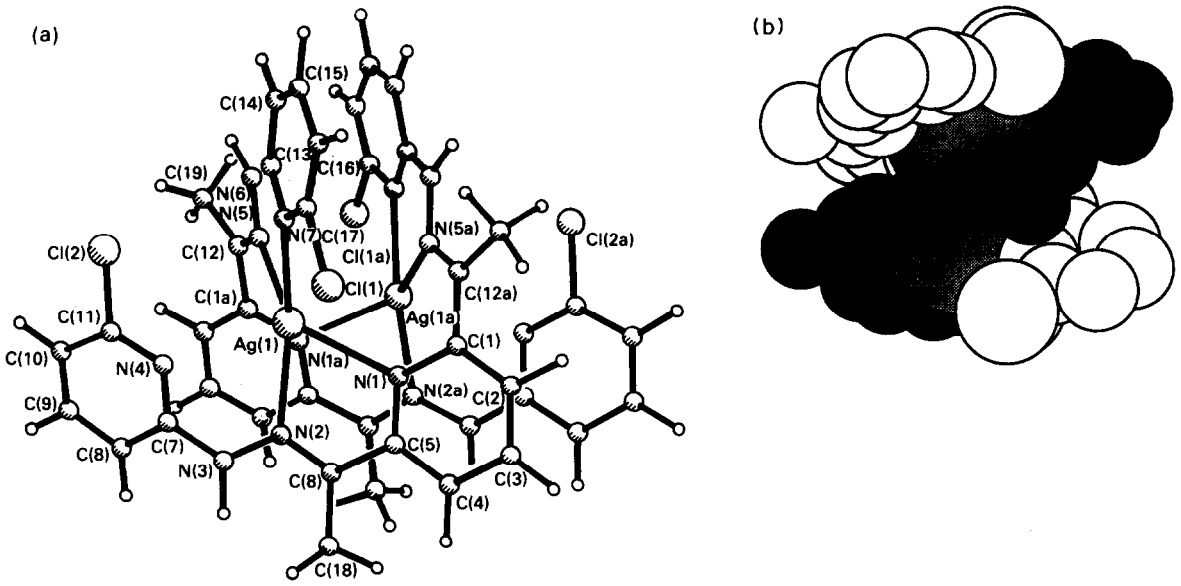

Fig. 3. (a) The molecular structure of the cation $[Ag_2L^1_2][PF_6]_2$, showing the atom numbering scheme. Hydrogen atoms have been omitted for clarity. (b) Representation of the cation $[Ag_2L^1_2]^{2+}$ showing the helical twisting of the two ligands. The two ligand molecules are represented by the different shading.

3(b), in which the two equivalent ligands are shaded to emphasize the helicity of the molecule. A further similarity with the double-helical structures of the binuclear complexes of L^3 is seen when we consider the stacking interactions of the planar aromatic rings. In the L^3 complexes, a very important component in the bonding is the stacking of parallel pyridine rings with mean interplanar separations of 3.4–4.0 Å. A very striking stacking interaction is observed between the weakly coordinated 6-chloropyridyl ring of one ligand and the central pyridine ring of the other ligand. The two rings are stacked directly one over the other, and are near parallel. The interplanar separation varies from 3.794 to 4.009 Å, indicative of a strong donor–acceptor interaction. The two coordinated 6-chloropyridyl rings are also nearly co-planar, but do not lie in a co-facial arrangement.

The helical arrangement of the ligand is achieved by a series of twists about the interannular bonds. The molecular structure of the free ligand[22] reveals it to be non-planar, with the terminal 6-chloropyridyl rings in a skewed *transoid* arrangement with the nitrogen atoms pointing away from the bonding cavity. The two terminal rings are non-equivalent, forming dihedral angles of 32.2 and 12.9°, respectively, with the central pyridine ring. In the silver complex, the helical configuration is achieved by a twist about the central 2,6-pyridyldiimine moiety, as shown in the projection in Fig. 3. The twist about the C_{ring}—C_{imine} bonds results in a dihedral angle of 45.1° between the planes of the two imine groups. This distortion from planarity is extremely unusual, and the loss of conjugation is presumably countered by the enhanced π-stacking which is possible. The twist results in dihedral angles of 37 and 11.7° between the two non-equivalent 6-chloropyridyl rings and the central pyridine ring.

We are currently further investigating the structural requirements for the spontaneous assembly of such double-helical binuclear complexes.

COMMUNICATION

REACTIVITY OF THE Mo—Sn BOND. REACTIONS OF $[MoSnPh_3(CO)_3(n\text{-}C_5H_5)]$ WITH HgX_2 (X = Cl, $OCOCF_3$)

M. CANO* and J. A. CAMPO

Departamento de Química Inorgánica, Facultad de Ciencias Químicas,
Universidad Complutense, 28040-Madrid, Spain

(*Received* 1 *June* 1990; *accepted* 2 *October* 1990)

Abstract—The cleavage of the Mo—Sn bond has been studied in the reactions of $[MoSnPh_3(CO)_3(n\text{-}C_5H_5)]$ with HgX_2 (X = Cl, $OCOCF_3$). Two new compounds were isolated, their formation depending on the reaction conditions.

The cleavage of the Mo—Sn bond in complexes of the type $[MoSnMe_3(CO)_3(n\text{-}C_5H_5)]$ by reaction with HgX_2 (X = Cl, Br, I) or RHgX (X = Cl; R = CH_3,C_6H_5) has produced the Mo—Hg—X and Mo—Hg—R species, respectively. Analogous behaviour has also been observed in the iodation reactions of the complexes $[MoSnR_3(CO)_3(n\text{-}C_5H_5)]$ (R = CH_3, C_6H_5).[1,2] The above results are summarized schematically in Table 1.

In some of the above reactions, cleavage of the Sn—C bond has been observed, giving compounds of the type $[MoSnR_2X(CO)_3(n\text{-}C_5H_5)]$.[1,2]

In a previous paper,[3] we found that the related $[MoSnPh_3(CO)_3(n\text{-}CH_3C_5H_4)]$ compound reacts with HgX_2 (X = Cl, Br, I, SCN) to give Mo—Hg—X complexes through the cleavage of the Mo—Sn bonds.

In order to obtain more information about the bonds which break (Sn—C or Mo—Sn) in the heterobimetallic compounds, we have tried to analyse the influence of different factors such as the nature of the mercury derivative, solvent and stoichiometric relations.

In this work, we describe the behaviour of the complex $[MoSnPh_3(CO)_3(n\text{-}C_5H_5)]$ with HgX_2 (X = Cl, $OCOCF_3$) in acetone and CCl_4 as solvents and at different molar ratios (1 : 1 or 1 : 5).

(1) *Reactions with* $HgCl_2$

This reaction afforded the complex $[MoHgCl(CO)_3(n\text{-}C_5H_5)]$ when a 1 : 1 molar ratio and acetone as solvent were used, but no reaction was observed in CCl_4.

(2) *Reactions with* $Hg(OCOCF_3)_2$

The reactivity of the complex with $Hg(OCOCF_3)_2$ also varied according to the reaction conditions employed and two new products, **1** and **2**, have been isolated (Scheme 1).

(a) *Reactions in acetone.* When a 1 : 1 molar ratio was used the $Hg[Mo(CO)_3(n\text{-}C_5H_5)]_2$ complex was evidently formed, as shown by the spectroscopic data.[4] However, if a 1 : 5 molar ratio was employed, a new asymmetrical complex $[Mo(HgOCOCF_3)(CO)_3(n\text{-}C_5H_5)]$ (**1**) was obtained {IR in KBr pellets: ν(CO) 2010, 1995, 1920, 1900; $\nu[CO_2(as)]$ 1678; $\nu[CO_2(sym)]$ 1422; γ(CH) 828 cm^{-1}. ^1H NMR in $CDCl_3$–TMS: 5.62 ppm}. We then proved that the asymmetrization reaction of $Hg[Mo(CO)_3(n\text{-}C_5H_5)]_2$ with $Hg(OCOCF_3)_2$, yielded the same product (**1**). This fact was consistent with our above results and suggested that in the 1 : 5 reactions the excess of $Hg(OCOCF_3)_2$ causes the asymmetrization of an intermediate, $Hg[Mo(CO)_3(n\text{-}C_5H_5)]_2$.

(b) *Reactions in* CCl_4. The reaction of $[MoSnPh_3(CO)_3(n\text{-}C_5H_5)]$ with $Hg(OCOCF_3)_2$ in CCl_4 (Scheme 1) led to a new yellow compound (**2**) in all cases. The ^1H NMR spectrum shows unexpected behaviour, no signals attributable to the phenyl and cyclopentadienyl groups appear. The IR spectrum, in KBR discs, presents carbonyl absorptions [ν(CO) 2040, 1992sh, 1945 cm^{-1}] shifted to higher frequencies than the starting

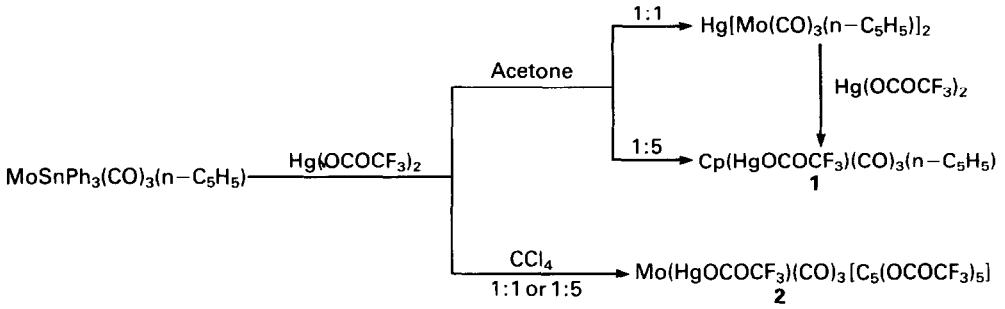
CH_3	DMSO	C_6H_5HgX	Yes	



Scheme 1.

material and the asymmetrical compound (**1**). Strong and broad bands of the carboxyl group are present $\{\nu[CO_2(as)]\ 1685;\ \nu[CO_2(sym)]\ 1420\ cm^{-1}\}$.

The above results and the analytical data suggest that formulation of the type $[Mo(HgOCOCF_3)(CO)_3\{n\text{-}C_5(OCOCF_3)_5\}]$ is appropriate for **2**. There is no evidence for the formation of the symmetrical compound, $Hg[Mo(CO)_3(n\text{-}C_5H_5)]_2$ and so we suggest a different route for the formation of this product (**2**).

On the other hand, it is remarkable to note that in this reaction we have also isolated a white product, identified as $PhHgOCOCF_3$; this fact is consistent with the breaking of Sn—C bonds. It seems likely that Mo—Sn fission is dominant and that stable species containing the Mo—Hg—$OCOCF_3$ moiety are formed, but that other competing Sn—C fissions and subsequent reactions occur.

Further studies of multinuclear NMR and other possible reactions with related compounds containing substituted cyclopentadienyl ligands are proposed in order to continue this investigation.

1. INTRODUCTION

While sigma bonded homoleptic alkyl compounds of transition metals are now well characterized and have been the focus of much study, the analogous homoleptic aryl systems have received relatively little attention. Early reports have described often poorly characterized species. The synthesis and reaction chemistry of several examples of homoleptic transition metal aryl complexes has recently been reported and X-ray structural studies provided for their conclusive identification.

* Author to whom correspondence should be addressed.

There are numerous reviews on compounds with transition metal to carbon bonds, often including homoleptic alkyls and aryls,[R1] but it seemed pertinent in view of recent work to survey only the homoleptic and some related aryl compounds.

The report consists of three sections each covering a specific type of aryl complex (neutral, anionic, and *ortho*-functionalized). For the sake of completeness special cases will be included where the aryl complex is isolable only as an adduct of solvent molecules, although strictly speaking they are not homoleptic. Sections covering the metals copper, silver and gold will include only literature from 1980 to 1990 as excellent reviews have been published for material prior to 1980.[R2] Each section contains a table listing the aryl complexes known for the respective elements.

2. NEUTRAL COMPOUNDS

2.1. *Group* 3: *Lanthanides*

The neutral homoleptic *triphenyls* of scandium and yttrium were synthesized by interaction of the metal chlorides with phenyl lithium; they were characterized on the basis of IR spectra, analyses and reactions with small molecules;[1] no structural information is available.

$Sm(C_6F_5)_3$	Decomposes in solution	2

Several fluorophenyl complexes are reported. Divalent ytterbium complexes with C_6F_5 or C_6F_4H groups are obtained on reaction of ytterbium metal and $(C_6F_5)_2Hg$.[2] The pentafluoro complex was isolated as a THF adduct but the 2,3,5,6-tetrafluorophenyl was characterized in solution, the isolation being hampered by thermal instability. The bis(2,3,4,5-tetrafluorophenyl) was even less stable than the others and this was attributed to a decomposition pathway involving abstraction of the *ortho*-hydrogen atom.[3] Interaction of $Yb(C_6F_5)_2$ with $Ph_2PC_5H_5$ gives $(\eta^5\text{-}C_5H_4PPh_2)_2Yb$.[4a]

Di- and trivalent C_6F_5 compounds of samarium were considered as initial products in the reaction of samarium and $(C_6F_5)_2Hg$, but rapid decomposition gave solutions containing, on the basis of IR and electronic spectra, the species $(C_6F_5)SmF$ and $(C_6F_5)SmF_2$.

While attempts to obtain diphenyls by interaction of lanthanide metals and $HgPh_2$ were unsuccessful,[2] the compounds $M[(C_6H_5)Cr(CO)_3]_2$ (M = Sm, Eu and Yb) were obtained from the mercury reagent and the metal (see Section 4.1).[4b]

No neutral homoleptic aryls of actinide elements are reported.

2.2. *Group* 4: *Titanium, zirconium and hafnium*

A number of syntheses and characterizations of *tetraphenyltitanium* have appeared in the early literature. Latyaeva *et al.* have reported the synthesis by reaction of PhLi and $TiCl_4$ in benzene.[5] The $TiPh_4$ thus produced was said to decompose at $-10°C$ to form diphenyltitanium and biphenyl [eq. (1)]:

$$TiCl_4+4PhLi \xrightarrow{C_6H_6} TiPh_4 \longrightarrow TiPh_2+C_{12}H_{10}. \quad (1)$$

This mode of decay is thought to take place via a radical mechanism and is a common pathway to metal–aryl bond scission. Further reaction with ammonia yielded the adduct $(Ph)_2Ti(NH_3)$.[5] Reac-

tion of $Cp_2Ti(Ph)_2$ with an excess of PhLi was also reported to give $TiPh_4$.[6] A curious series of reports by Jacot-Guillard and co-workers describes several routes to $TiPh_4$ by reaction of Grignard or diphenylmagnesium reagents with titanium(IV) alkoxides.[7–16] When prepared in the presence of 2,2′-bipyridine a product identified as $TiPh_4$ was said to be stable at elevated temperatures in the presence of a Lewis base (e.g. Et_2O). In a later paper $TiPh_4$ is reported as a complex with LiCl, $Li[Ti(Ph)_4Cl](THF)_4$.[17] It should be noted that these results should be treated with caution as in most cases the formulae are assigned on the basis of hydrolysis products, elemental analyses and by the products formed on reaction of filtered reaction mixtures with $HgCl_2$. Only very sparse spectroscopic information is provided. The *perfluoro* derivative, $(C_6F_5)_4Ti(Et_2O)_2$, was prepared via salt elimination from C_6F_5Li and $TiCl_4$ and is stable to 100°C.[18]

Tetramesityltitanium (mesityl = 2,4,6-$Me_3C_6H_2$) has been prepared via the route in eqs (2) and (3).

$$TiCl_3+4LiC_9H_{11} \xrightarrow{THF} LiTi(C_9H_{11})_4+3LiCl \quad (2)$$

$$LiTi(C_9H_{11})_4+O_2 \longrightarrow Ti(C_9H_{11})_4+\text{“lithium oxides”}. \quad (3)$$

The oxidation is best carried out in the solid state.[19] In contrast to the extreme air and water sensitivity of other titanium(IV) alkyls and aryls, $Ti(mes)_4$ is stable in dry air but is light sensitive.

Razuvaev *et al.* have prepared *tetraphenylzirconium* from $ZrCl_4$ and four equivalents of PhLi in Et_2O at −40°C.[20] The product thus obtained decomposed in a fashion similar to that of $TiPh_4$ to yield $(Ph)_2Zr(Et_2O)$ which could be recrystallized from benzene as shiny black crystals. Cryoscopic molecular weight measurements indicate a dimeric structure in solution. Reaction with ethanol gave the zirconium(IV) product $Zr(OEt)_4$, benzene and hydrogen gas [eq. (4)]:

$$(Ph)_2Zr(Et_2O)+4EtOH \xrightarrow{20°C} 2C_6H_6+Zr(OEt)_4+H_2. \quad (4)$$

2.3. *Group 5: Vanadium, niobium and tantalum*

Trimesitylvanadium was first reported by Seidel and Kreisel in 1974 with the formula $V(C_9H_{11})_3(THF)_n$.[21] The 2,6-xylyl was also prepared but the triphenyl complex could not be isolated.[22] The structure of the mesityl has confirmed the formula $V(C_9H_{11})_3(THF)$.[23] The metal atom is coordinated in a pseudo-tetrahedral fashion. The bending of the *ortho*-methyl carbon atoms out of the phenyl plane by 0.023–0.165 Å was ascribed to steric factors. The *tetramesityl*, $V(mes)_4$, was later prepared by addition of 1 equivalent of mesLi to $V(mes)_3THF$ in THF–Et_2O, and air oxidation of the intermediate formed $[V(mes)_4]Li$ [eqs (5) and (6)].[24]

$$V(mes)_3THF+mesLi \longrightarrow [V(mes)_4]Li \quad (5)$$

$$[V(mes)_4]^- + O_2 \longrightarrow V(mes)_4. \quad (6)$$

An X-ray study shows $V(mes)_4$ to have a slightly distorted tetrahedral structure.[25] Structures of $V(mes)_3THF$ and $V(mes)_4$ are shown in Figs 1 and 2, respectively. The tris-mesityl product reacts

with bulky silanols to give tris-siloxy complexes and mesitylene [eq. (7)]:[26]

$$V(mes)_3 + 3Bu^tMe_2SiOH \longrightarrow V(OSiMe_2Bu^t)_3 + 3C_9H_{12}. \quad (7)$$

Tetraphenylvanadium is obtained by reaction of VCl_4 and 4 equivalents of PhLi in diethyl ether at $-80°C$. The VPh_4 quickly decomposes at $-40°C$ to VPh_2 and biphenyl.[27] Compounds of formula $V(Ph)_2(OBu^t)_2$ could be isolated by reacting VPh_4, formed *in situ*, with Bu^tOH [eqs (8) and (9)]:[28]

$$VCl_4 + 4PhLi \longrightarrow VPh_4 \longrightarrow VPh_2 + C_{12}H_{10} \quad (8)$$

$$VPh_4 + Bu^tOH \longrightarrow V(Ph)_2(OBu^t)_2 + 2C_6H_6. \quad (9)$$

Pentafluorophenyl complexes of tri- and tetravalent vanadium have also been described. Reaction of VCl_3 and C_6F_5MgBr yields the vanadium(III) species $(C_6F_5)_3V(THF)$,[29] whereas VCl_4 and C_6F_5Li gives the tetravalent $V(C_6F_5)_4$[30] as a solvent complex with 2 moles of THF.

The neutral tantalum(V) complex, $TaPh_5$, has been postulated as a product in the reaction of $Ta(O\text{-}2,6\text{-}Me_2C_6H_2)_2Cl_3$ and excess PhLi; however no attempt at isolation was made.[31] Neutral homoleptic aryls of niobium have not been reported.

2.4. *Group 6: Chromium, molybdenum and tungsten*

The synthesis and characterization of *triphenylchromium-tris-tetrahydrofuran* in 1957 by Herwig and Zeiss represented a milestone in organometallic chemistry.[32] This complex received much attention in the time after its discovery and was found to be a key intermediate in the σ–π shift reactions investigated by Hein and co-workers in the 1920s and 1930s;[33] their "polyphenyl" chromium compounds were, of course, η^6-arene species. Many other triarylchromium complexes were synthesized soon thereafter, including the complete range of tolyls[34–37] and biphenyls.[36,37] The *trimesityl* was shown to form an adduct with only one molecule of THF,[38] while the others occurred as tris-tetrahydrofuranates. Only very recently has an X-ray structure become available for $(Ph)_3Cr(THF)_3$.[39] The chromium atom has the expected octahedral coordination geometry with the ligands lying in a *cis*(facial) configuration (Fig. 3). Each sigma-bound phenyl group lies *trans* to a coordinated THF molecule. The Cr—C bonds [$Cr—C_{av} = 2.060(10)$ Å] are much shorter than the Cr—O bonds [$Cr—O_{av} = 2.225(10)$ Å], an effect thought to be due to the stabilizing influence of $p\pi$–$d\pi$ backbonding from the metal atom to the phenyl carbon of the aryl ligand.[39]

The *tetramesityl* complexes of chromium and molybdenum have been prepared by oxidation of their parent M^{III} tetraaryl "ate" complexes.[40,41] Distorted tetrahedral structures are postulated on the basis of ESR and photoelectron spectral data.[42,43] The molybdenum complex undergoes oxidation with iodine or bromine to give molybdenum(V) salts of formula $[Mo(mes)_4][X_3]$ (X = I, Br), which also contain metal atoms in distorted tetrahedral geometries.[44] The only other Group 6 d^1

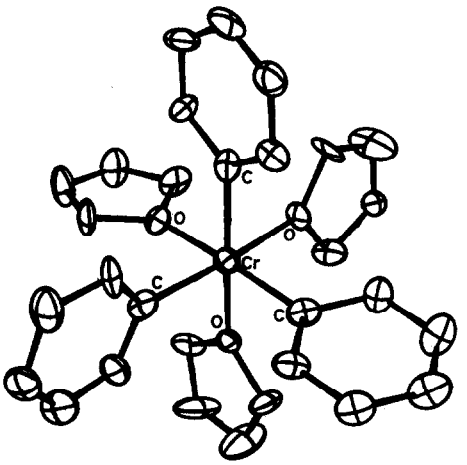

Fig. 3. Molecular structure of $(Ph)_3Cr(THF)_3$ showing the *trans* arrangement of the ligands (reprinted by permission from ref. 39).

homoleptic aryl characterized to date, the *perfluorophenyl*, $W(C_6F_5)_5$, was synthesized by thermal decomposition of $(C_6F_5)_5W(LiEt_2O)$.[45]

The *tetra*-o-*tolyl complexes* of chromium, molybdenum and tungsten are known.[46] The X-ray structure of the molybdenum derivative shows a slightly distorted tetrahedral geometry about the metal atom (Fig. 4).[47] The chromium tetratolyl is made in an oxidation reaction from $CrCl_3$ and *o*-tolLi, the molybdenum compound from $MoCl_4(THF)_2$, involving neither reduction or oxidation, and the tungsten derivative in a reduction from $W(OPh)_6$ and *o*-tolMgBr [eqs. (10)–(12)]:

$$(THF)_3CrCl_3 + 4\text{-}o\text{-tolLi} \longrightarrow Cr(o\text{-tol})_4 + 3LiCl + \text{other products} \quad (10)$$

$$MoCl_4(THF)_2 + 4\text{-}o\text{-tolLi} \longrightarrow Mo(o\text{-tol})_4 + 4LiCl \quad (11)$$

$$W(OPh)_6 + 6\text{-}o\text{-tolMgBr} \longrightarrow W(o\text{-tol})_4 + 6BrMg(OPh) + \text{bitolyl} \quad (12)$$

$$M(o\text{-tol})_4 + 2L \longrightarrow M(o\text{-tol})_2(\eta^2\text{-}2\text{-}MeC_6H_3)(L)_2 \quad (M = Mo, W;\ L = PMe_3, PMe_2Ph). \quad (13)$$

On addition of small tertiary phosphines, the molybdenum and tungsten complexes undergo facile *ortho*-hydrogen elimination to give M^{IV} aryne complexes[46] [eq. (13)], while the chromium derivative reductively eliminates bitolyl to give $[Cr(o\text{-tol})(\mu\text{-}o\text{-tol})(PMe_3)]_2$.[46] In comparison with homoleptic aryls of Groups 3–5, the Group 6 aryls are stable at room temperature as solids or in solution.

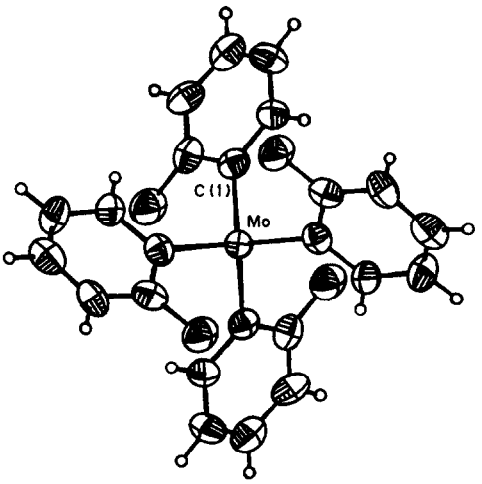

Fig. 4. Molecular structure of $Mo(o\text{-tol})_4$ (reprinted by permission from ref. 47).

While the tungsten and molybdenum aryls are extremely air- and moisture-sensitive, the chromium complex may be handled in air for short periods without decomposition.

Bis-mesityl and *bis-naphthyl* complexes of chromium(II) have been identified as products of the reaction of $CrCl_2$ and ArMgBr in THF.[48,49] It is likely these species exist only as THF adducts as dimesitylchromium has been structurally characterized only as complexes of Lewis bases.[50]

2.5. *Group 7: Manganese and rhenium*

Neutral homoleptic aryls of Group 7 are very scarce and none are known for technetium. *Bis(mesityl)manganese* has been structurally characterized and shown to exist as a trimer with the central metal atom bonded to four bridging aryls in a tetrahedral fashion (Fig. 5).[51] The terminal metal atoms have trigonal geometries with two bridging and one terminal aryl groups. Although magnetic behaviour indicates some metal–metal interaction, the metal–metal distances of 2.851(3) Å were considered too long for any significant metal–metal bonding in the solid state.[51]

*Tetra-o-tolyl*rhenium has been structurally characterized and is very similar to the tetratolyls of chromium, molybdenum and tungsten in possessing a slightly distorted tetrahedral coordination environment.[52] The synthesis involves the reaction of $ReCl_4(THF)_2$ and a deficiency of *o*-tolyl Grignard (1 : 2.4). The excess $ReCl_4$ is thought to act as an oxidant for the intermediate formed $[Re(o\text{-tol})_4]^-$ (see Section 2) to give moderate yields of the neutral compound.[47,52] As noted for the Group 6 tetra-*o*-tolyls the rhenium complex reacts with tertiary phosphines to yield benzyne species of formula $Re(2\text{-}MeC_6H_4)_2(\eta^2\text{-}2\text{-}MeC_6H_3)L_2$ ($L = PMe_3$, PMe_2Ph).[53] Air oxidation cleanly gives the rhenium(VI) *oxo-aryl* $ORe(o\text{-tol})_4$ [eq. (14)]:[52]

$$Re(o\text{-tol})_4 + 1/2O_2 \longrightarrow ORe(o\text{-tol})_4. \tag{14}$$

2.6. *Group 8 : Iron, ruthenium and osmium*

Divalent *bis(mesityl)iron* was first reported as a THF complex of formula $(mes)_2Fe(0.2THF)$;[24] however, in a later paper by the same group it is described as $Fe(mes)_2$.[54] The homoleptic aryl has a magnetic moment of 2.69 BM, indicating a low-spin electronic configuration, while the dipyridyl adduct $(mes)_2Fe(bipy)$ has a high-spin magnetic moment.[24]

[a] Synthesis also of RuR_4, R = $2,6\text{-}Me_2C_6H_3$, $2,4,6\text{-}Me_3C_6H_2$ and $4\text{-}Bu^tC_6H_4$.

Reactive iron powders prepared by the Riecke method* react with C_6F_5I in a disproportionation manner to form solvated complexes of $(C_6F_5)_2Fe$ and FeI_2 [eq. (15)].[55] Further reaction with carbon monoxide gives the known complex $Fe(C_6F_5)_2(CO)_2(THF)_2$.[55]

$$2Fe^0 + 2C_6F_5I \longrightarrow (C_6F_5)_2Fe(S)_x + FeI_2(S)_y \quad (S = \text{solvent}). \tag{15}$$

The X-ray structures, reactivity, spectroscopic and electrochemical behaviour of a series of *ruthenium and osmium tetraaryl* complexes have been described in several recent papers.[47,52,56,57] The tetra-*o*-tolyls of ruthenium and osmium are isostructural, having tetrahedral coordination environments about the metal atoms. Complexes of both metals are diamagnetic showing four equivalent *o*-tolyl groups in the ^1H NMR spectrum. Thermally very robust, the ruthenium aryl exhibits the parent ion in the mass spectrum as well as peaks due to sequential loss of *o*-tolyl groups. The ruthenium aryl was synthesized by reaction of $[Et_4N][RuCl_5(MeCN)]$ with 5 equivalents of *o*-tolMgBr or by reaction of $Ru_2(OAc)_4Cl$ and 8 equivalents of *o*-tolMgBr. The mesityl, 2,6-xylyl and $p\text{-}Bu^tC_6H_4$ complexes were also synthesized in this manner. The $Os(o\text{-tol})_4$ was obtained from OsO_4 and 8 equivalents of the aryl Grignard. The $OsPh_4$ is much less stable than $Os(o\text{-tol})_4$ and slowly decomposes in solution over a period of days to give biphenyl and an amorphous black solid. The solid-state structure of $OsPh_4$ is very similar to that of $Os(o\text{-tol})_4$ with an approximately tetrahedral coordination (Fig. 6).[56]

The reactivity of $Os(o\text{-tol})_4$ with Lewis bases was examined and proved to be quite different from that of the tetra-*o*-tolyls of molybdenum, tungsten and rhenium. Small tertiary phosphines, carbon monoxide and t-butyl isocyanide all induce reductive coupling to form species of formula $(2\text{-}MeC_6H_4)_2Os(\eta^6\text{-}C_{12}H_{10})_yL_x$ [L = CO, $x = 1$, $y = 1$; L = PMe_3, $x = 1$, $y = 1$; L = Bu^tNC, $x = 4$, $y = 0$ (Scheme 1)].[58]

The osmium complex also exhibits an interesting redox chemistry. Cyclic voltammetry studies[47] in CH_2Cl_2 and THF show reversible oxidation [+0.33 V (CH_2Cl_2), +0.41 (THF)] and reversible reduction [−1.96 V (CH_2Cl_2), −1.89 V (THF)] waves. Reaction of the neutral complex with one-electron oxidants $AgBF_4$ or AgO_3SCF_3 in CH_2Cl_2 [eq. (16)] allowed the isolation of the homoleptic osmium(V) cation, $[Os(o\text{-tol})_4]^+$, which could also be prepared via bulk electrolysis of $Os(o\text{-tol})_4$ at (+0.7 V) in CH_2Cl_2 with $[Bu^n{}_4N][PF_6]$ as supporting electrolyte.[47] An X-ray analysis again revealed an approximate tetrahedral arrangement for the OsC_4 core with only slight changes relative to the starting $Os(o\text{-tol})_4$.[57]

$$Os(o\text{-tol})_4 + AgO_3SCF_3 \longrightarrow [Os(o\text{-tol})_4]^+[O_3SCF_3]^-. \tag{16}$$

* This involves reducing suspensions of the appropriate metal halide with sodium to give fine suspensions of the metal and sodium salts.

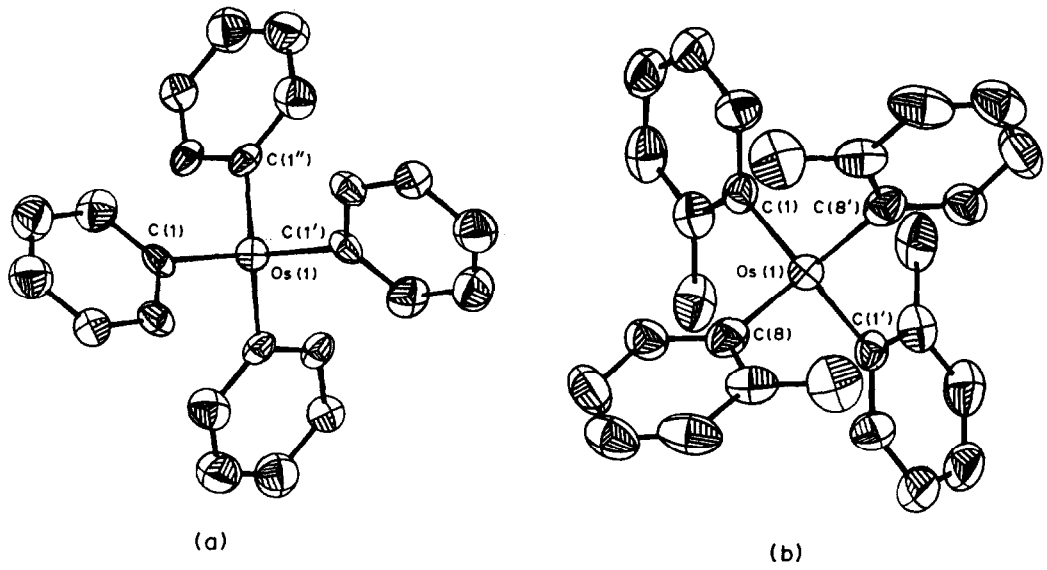

Fig. 6. Molecular structures of tetraaryl osmium complexes: (a) $OsPh_4$ and (b) $Os(o\text{-tol})_4$ (reprinted by permission from ref. 56).

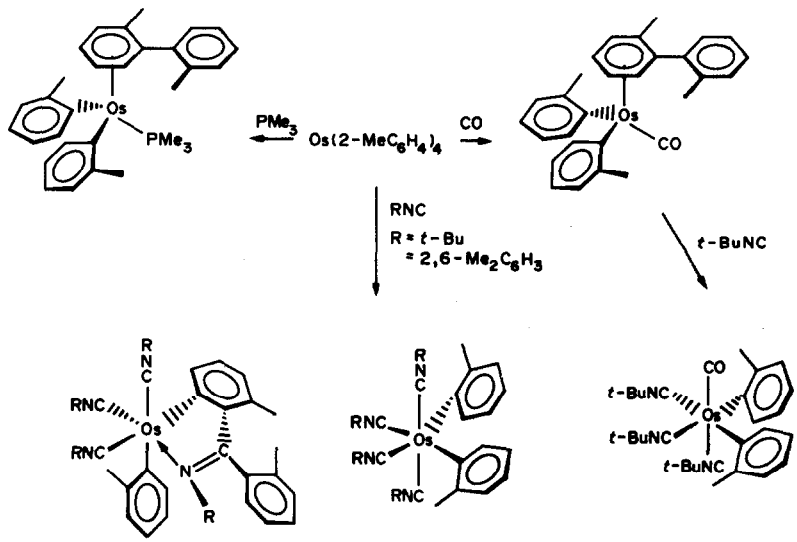

Scheme 1. Reactivity of $Os(o\text{-tol})_4$ with Lewis bases.

2.7. *Group 9: Cobalt, rhodium and iridium*

Dimesitylcobalt exists as a dimer in the solid state with the cobalt atoms lying in an almost planar coordination geometry (Fig. 7).[59] The average Co—Co distance (2.516 Å) of the two independent molecules found in the unit cell is indicative of metal–metal bonding even though the molecule exhibits a high degree of temperature-independent paramagnetism. An EHMO study supports the presence of metal–metal bonding. The *ortho*-methyls of the bridging mesityl ligands were found to have close contacts to the metal atoms, the shortest of which (2.79 Å) was within the range expected for agostic interactions.[60] Several elegant NMR experiments were undertaken to determine whether an agostic interaction was present, and on the basis of these experiments (C—H coupling, partial deuteriation isotopic effects) it was concluded that no agostic M---H—C bond was present. The

distortions noted in the solid state were ascribed to steric factors arising from contact between the *ortho*-methyl substituents of the two bridging mesityl ligands.

Other cobalt(II) homoleptic aryls include the bis(pentafluorophenyl)cobalt species generated either by reaction of cobalt(II) halides and C_6F_5MgBr in THF,[61] or by reaction of C_6F_5I and elemental cobalt generated by the Riecke method [eq. (17)].[55] In both cases the products are likely to be adducts of labile solvent molecules (DME, THF, toluene) (Table 7). An X-ray structure of $(C_6F_5)_2Co(\eta^6\text{-}C_7H_8)$ has appeared.[62]

$$2Co^0 + C_6F_5I \xrightarrow{\text{toluene}} (C_6F_5)_2Co(\eta^6\text{-}C_7H_8). \tag{17}$$

The *tris(mesityl)rhodium*(III), $Rh(mes)_3$, also has close contacts between the metal atom and the hydrogen atoms of one *ortho*-methyl group from each mesityl ligand. As is the case with $[Co(mes)_2]_2$, the absence of agostic interactions in solution was confirmed by NMR, and the aromatic rings shown to be rotating.[63]

No homoleptic aryls of iridium have been reported.

2.8. *Group* 10: *Nickel, palladium and platinum*

The aryl chemistry of nickel is much like that of its neighbour cobalt.[48] The bis(*pentafluorophenyl*) complex has been synthesized via several routes: interaction of $(C_6F_5)MgBr$ and $NiBr_2$ in THF,[64] the Riecke method using C_6F_5I and nickel^0,[55] or by direct reaction of nickel metal and C_6F_5I by metal vapour techniques [eqs (18) and (19)].[62,65,66]

$$2C_6F_5MgBr + NiBr_2 \longrightarrow (C_6F_5)_2Ni(THF)_x \tag{18}$$

The palladium and platinum analogues were synthesized by Usón and co-workers as tetrahydrothiophene (THT) complexes from the metal halides and lithium or Grignard arylating agents.[67,68]

2.9. *Group* 11: *Copper, silver and gold*

The complete series of univalent *mesityl complexes* has been prepared and characterized by X-ray crystallography. Each complex exists as a cyclic oligomer with mesityl groups bridging the metal atoms.

Both the gold[69] and copper[70] compounds are pentamers in the solid state while the silver mesityl complex crystallizes as a cyclic tetramer.[71] Addition of THT to $[Cu(mes)]_5$ leads to ring contraction and formation of the tetrameric species $[Cu(mes)]_4(THT)_2$ [eq. (20)]:[70]

$$4[Cu(mes)]_5+\text{excess THT}\longrightarrow 5[Cu(mes)]_4(THT)_2 \tag{20}$$

The molecular structure of each aryl is shown in Fig. 8.

An equilibrium between cyclic oligomeric and dimeric structures was detected in solution by ^1H NMR and cryoscopic measurements.[72] Addition of the chelate phosphine, $Ph_2PCH_2PPh_2$, to solutions of the copper and silver mesityl complexes releases mesitylene and forms new complexes of formula $M_3(Ph_2PCHPPh_2)_3$ [eq. (21)]:

$$[M(mes)]_n+Ph_2PCH_2PPh_2\longrightarrow M_3(Ph_3PCHPPh_2)_3+\text{mesitylene}. \tag{21}$$

Addition of the chelate phosphine to the gold complex gave the Lewis base adduct $Au_2(mes)_2(\mu\text{-}Ph_2PCH_2PPh_2)$.[72]

When the sterically more demanding aryl 2,4,6-*triisopropylphenyl* is used in place of mesityl, a compound with a tetrameric structure involving a distorted square plane of copper atoms is obtained. A bonding description incorporating σ-M—C and π-M—C interactions was used to explain the cluster aggregate structure (Fig. 9).[73] If an even bulkier ligand, 2,4,6-*triphenylphenyl*, is employed, monomeric structures are favoured for both copper and silver.[74] No reaction is observed between

$M(Ph_3C_6H_2)$ (M = Cu, Ag) and large Lewis bases (pyridine, t-butyl isocyanide), but smaller bases (CO, NO) give 1 : 1 adducts.[74]

The *perhaloaryl chemistry* of *silver* and *gold* has been extensively explored by Usón and co-workers.[68] The silver aryl complexes, AgAr (Ar = C_6F_5, 2,4,6-$C_6F_3H_2$, C_6Cl_5) may be reacted with gold(I) chloride compounds to give perhaloaryl gold species [eq. (22)]:[75]

$$Ag(C_6F_5)+AuCl(THT)\longrightarrow Au(C_6F_5)(THT) \quad (22)$$

$$Au(C_6F_5)+Tl(C_6F_5)_2Cl_2\longrightarrow Au(C_6F_5)_3(THT). \quad (23)$$

Further reaction of the gold(I) species with $Tl(C_6F_5)_2Cl_2$ gives the oxidation product $Au(C_6F_5)_3(THT)$, eq. (23).[76] *Mixed silver–gold perhaloaryls* are prepared from the gold(I) salt $[Bu^n{}_4N][Au(C_6Cl_5)_2]$ and silver perchlorate, as shown in eq. (24):[77]

$$[Bu^n{}_4N][Au(C_6Cl_5)_2]+AgClO_4\longrightarrow [AuAg(C_6Cl_5)_2]_n. \quad (24)$$

3. HOMOLEPTIC ANIONIC ARYL COMPLEXES

In general, the primarily lithium compounds of anionic homoleptic or "ate" complexes are more numerous and better characterized than their neutral counterparts. This is especially true for chromium for which a large variety of complexes in several oxidation states has been isolated. This disproportionate amount of work for chromium stems from Hein's discovery that stable organochromium complexes may be isolated from the reaction of $CrCl_3$ and aryl Grignards in Et_2O.[33] Anionic aryl complexes, mainly of copper, have also been receiving attention as synthons in organic chemistry.[78,R2]

3.1. *Group* 3 : *Lanthanides and actinides*

"Ate" complexes of the lanthanide metals may be isolated by reaction of the trivalent metal chloride with four equivalents of PhLi [eq. (25)]:

$$LnCl_3+4PhLi\longrightarrow [Ln(Ph)_4]Li+3LiCl \quad (Ln = Pr, Lu). \quad (25)$$

In the solid state the lutetium and ytterbium derivatives, $LiM(Ar)_4$ (Ar = 2,6-$Me_2C_6H_3$), contain the metal in an approximately tetrahedral arrangement within the aryl ligand framework (Fig. 10).[79]

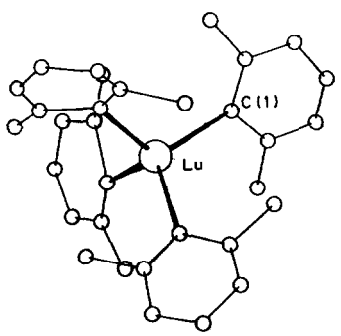

Fig. 10. Molecular structure of the anion $[Lu(xylyl)_4]^-$ (reprinted by permission from ref. 79).

The lithium counterion is surrounded by four molecules of Et_2O and does not interact strongly with the anionic portion of the molecule. Several polyphenyl and functionalized polyphenyl complexes of uranium(IV) have been isolated and found to be thermally unstable.[80]

3.2. *Groups* 4 *and* 5: *Titanium, vanadium, niobium and tantalum*

Anionic homoleptic aryl complexes of the earlier transition metals are fairly rare. The *titanium*(III) anion, $LiTi(mes)_4$, can be obtained in 20% yield from $TiCl_3$ and mesityl lithium in Et_2O–THF mixtures. A solution magnetic moment of 1.87 BM is indicative of one unpaired electron.[19]

No anionic aryl complexes have been reported for zirconium or hafnium. The *vanadium* arylate, $LiV(mes)_4$, was synthesized from the neutral $V(mes)_3$ and mesityl lithium. A distorted tetrahedral coordination environment for the vanadium atom was postulated on the basis of spectroscopic data.[81,82] Both vanadium and titanium tetramesityl anions can be converted to the neutral tetramesityl complexes by air oxidation.[24] Reaction of $V(mes)_3THF$ with other aryl lithium reagents leads to the formation of anionic mixed aryl complexes of formula $LiV(mes)_3(Ar)$ [Ar = C_6H_5, 2-MeC_6H_4 or 2,6-$(MeO)_2C_6H_3$]. The dimer $Li_2(THF)_8V_2(\mu\text{-}C_6H_4)(mes)_6$, containing a bridging C_6H_4 unit, was synthesized by reaction of $V(mes)_3$ and 1,2-$Li_2C_6H_4$ in a 2:1 stoichiometry and characterized by its magnetic, spectroscopic and thermal properties.[83]

The tris ortho-*diphenylether* complex $[Ti(C_6H_4OC_6H_4)_3](LiEt_2O)_2$ is one of a complete series of first-row anionic complexes reported by Drevs in 1975. It is diamagnetic and presumably represents a titanium(IV) species;[84] the analogous vanadium species, $[V(C_6H_4OC_6H_4)_3][Li(THF)_2]_3$, was shown to contain two unpaired electrons.

Two anionic vanadium complexes of 2,6-dimethoxyphenyl (DMOP) have been reported. The vanadium(II) species, $Li_2V(DMOP)_4$, is obtained by reaction of vanadocene with LiDMOP, and the vanadium(III) species, $LiV(DMOP)_4$, from $VBr_3(THF)_3$ and LiDMOP; both decompose to yield the well characterized $[V(DMOP)_2]_2$ [eq. (26) and (27)]:[85]

$$(C_5H_5)_2V + 4Li\text{-}2,6\text{-}(MeO)_2C_6H_3 \longrightarrow Li_2V[2,6\text{-}(MeO)_2C_6H_3]_4 \xrightarrow{\Delta} \{V[2,6\text{-}(MeO)_2C_6H_3]_2\}_2 \tag{26}$$

$$VBr_3(THF)_3 + 4Li\text{-}2,6\text{-}(MeO)_2C_6H_3 \longrightarrow LiV(2,6\text{-}(MeO)_2C_6H_3)_4. \tag{27}$$

A note has described the synthesis of $Li_4V(Ph)_6(Et_2O)_{3.5}$ from ethereal PhLi and $VCl_3(THF)_3$.[86] Characterization consisted of reaction with protic molecules and $HgCl_2$ to yield benzene and PhHgCl, respectively. If the synthesis is carried out with the Grignard in place of phenyl lithium, bis(benzene)vanadium can be isolated from the reaction mixture after hydrolysis (as is found for

chromium).[86] A recent crystallographic analysis of $Li_4V(Ph)_6(Et_2O)_{3.5}$ indicates an almost perfect octahedral geometry about vanadium, with an average V—C distance of 2.35 Å. The lithium atoms form an integral part of the molecule and each is bonded in a triply-bridging fashion to the faces of the VC_6 octahedron (C—Li_{av} = 2.225 Å) (Fig. 11).[87]

Anionic *polyphenyl complexes* of *niobium* and *tantalum* were first reported by Sarry and co-workers in the late 1960s and were originally formulated as $M(Ph)_2[Li(Ph)]_4(Et_2O)_{3.5}$ (M = Nb, Ta).[88–90] On the basis of ^7Li and ^1H NMR studies, benzyne structures were later favoured for these species.[91] The structures by X-ray diffraction show the species to be the bis-benzyne complexes $[Nb(\eta^2\text{-}C_6H_4)_2(Ph)_3(LiPh)(THF)][(LiTHF)](THF)_{0.5}(C_6H_{14})_{0.5}$ and $[Ta(\eta^2\text{-}C_6H_4)_2(Ph)_4(LiTHF)_4][Li_4Cl_2(THF)_6]$;[92] see Figs 12 and 13.

The niobium anion contains a five-coordinate metal in a roughly trigonal bipyramidal coordination geometry if the midpoint of the C—C bond of the benzyne ligands is taken to occupy one site of the coordination sphere. The equator of the bipyramid is made up of one phenyl group and two benzyne ligands. Niobium–C(phenyl) distances average 2.34 Å, while the Nb–benzyne distances are shorter in the range 2.17–2.22 Å. As was found in the structure of the polyphenyl vanadium ion described earlier, the lithium counterions are closely associated with the MC_7 core. There is one

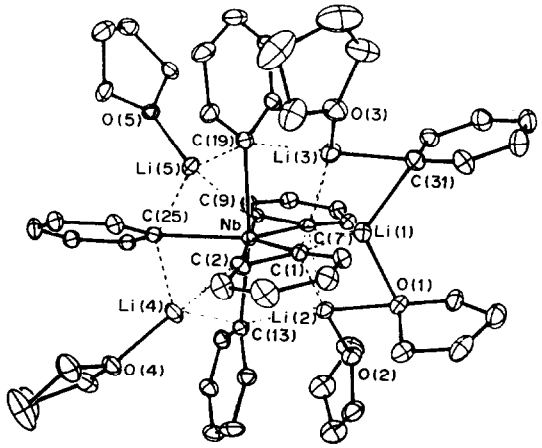

Fig. 12. Molecular structure of the benzyne niobate anion $[Nb(\eta^2\text{-}C_6H_4)_2(Ph)_3(LiPh)(THF)]^-$ (reprinted by permission from ref. 92).

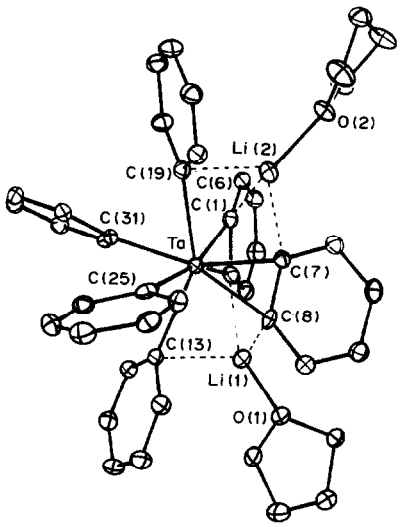

Fig. 13. Molecular structure of the polyphenyl benzyne tantalum complex $[Ta(\eta^2\text{-}C_6H_4)_2(Ph)_4(LiTHF)_2]^{2-}$ (reprinted by permission from ref. 92).

"extra" phenyl group with no bonds to niobium instead bridging two lithium atoms. The electron-rich nature of the niobium(II) complex is mirrored in the long benzyne C—C bonds relative to C—C bonds in other early transition metal benzyne complexes.[93]

The tantalum complex has a quite different structure with the metal residing in a distorted octahedron if the benzyne ligands are again assumed to occupy only one coordination site. The benzyne ligands lie *cis* to one another and are bridged by two lithium atoms which also have close contacts to two other η^1-phenyl ligands. The slight shortening of the benzyne C—C distances in the tantalum compound, relative to niobium, was ascribed to the greater electron deficiency in the former. The para-*tolyl tantalum* complex, "$LiTa(p\text{-tol})_6(Et_2O)$", has also been characterized spectroscopically as a benzyne species.[91,94]

3.3. *Group* 6: *Chromium, molybdenum and tungsten*

A brief mention of the chromium(III) p-*dimethylaminoaryl anion*, $Cr(p\text{-}Me_2NC_6H_4)_3Li$, has appeared in the literature but it is only poorly characterized.[95]

The dimeric chromium(II) phenyls $[Cr(Ph)_3Na]_2(Et_2O)_3$ and $[Cr(Ph)_3Li]_2(Et_2O)_3$ were synthesized by reaction of the compounds $M_2Cr(Ph)_5$ (M = Na, Li) with $CrCl_3$.[96] The reaction is thought to proceed via an intermediate chromium(III) complex $MCr(Ph)_4$, which disproportionates to $[MCr(Ph)_3]_2$ and biphenyl [eqs (28) and (29)]:

$$4M_2Cr(Ph)_5 + CrCl_3 \longrightarrow 5MCr(Ph)_4 + MCl \quad (M = Li, Na) \tag{28}$$

$$5MCr(Ph)_4 \longrightarrow 5MCr(Ph)_3 + 2.5(Ph)_2. \tag{29}$$

The lithium derivative could also be synthesized by reaction of $CrCl_3(THF)_3$ and PhLi in a 1:4 stoichiometry.[96] Lowered magnetic moments were thought to be due to metal–metal interaction within the molecule.[96] The monomeric high-spin chromium(II) complex $[Cr(Ph)_4Li_2](THF)_2$ was synthesized from $(PhCH_2)Cr(Ph)_2$ and two moles of PhLi in a reductive manner.[97]

More recently two *mesityl* chromium compounds have been reported, $[Cr(mes)_3][Li(dioxane)(Et_2O)]$ and $[Li(THF)_2]_2[Cr(mes)_4]$. The latter was assigned a tetrahedral structure from magnetic and spectroscopic data.[98] The synthesis involves the stepwise addition of mesLi to $Cr(mes)_2(THF)_3$ [eq. (30)]:

$$Cr(mes)_2(THF)_3 + mesLi \longrightarrow Cr(mes)_3Li + mesLi \longrightarrow [Li(THF)_2]_2[Cr(mes)_4]. \tag{30}$$

$W(C_6F_5)_5Li(Et_2O)_2$	WCl_6 + 6PhLi; decomposes to WPh_5	45

The analogous reaction of $Cr(mes)_3(THF)$ and mesLi gives the chromium(III) *tetramesityl anion* which again has a distorted tetrahedral structure.[82] Four-coordinate chromium(III) complexes of formula $MCr(Ph)_4(DME)_4$ (M = Na, Li) were formed in the presence of moisture during synthesis of chromium(II) aryl anions.[99] The ortho-*anisole* complex has also been described.[95]

An X-ray crystallographic analysis of the *pentaphenyl anion* $[Cr(Ph)_5][Na_2(Et_2O)_3(THF)]$[100] (Fig. 14) shows the distorted trigonal bipyramidal CrC_5 core.[101] The sodium ions maintain close contacts with the phenyl ligands, forming a secondary coordination sphere much like that found in the lithium polyphenyl chromates. The odd blue–green colour of the complex (other phenyl chromates are light yellow–orange) stimulated an investigation into its electronic spectrum which did not, however, prove informative because strong charge-transfer bands obscured all but one *d–d* transition.[161] Several other chromium(III) polyphenylates of formula $Cr(Ar)_6Li_3$ are known (Ar = *p*-$Me_2NC_6H_4$, biphenyl, diphenylether).[84,95] Both the tris *sodium* and tris *lithium hexaphenylchromium*(III) complexes have been reported[99,100,102] and the lithium salt structurally char-

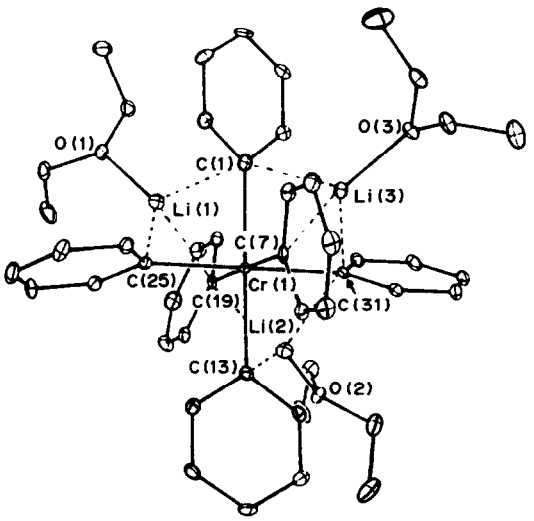

Fig. 15. Molecular structure of the Cr^{III} phenylate $Cr(Ph)_6Li_3(Et_2O)_3$ (reprinted by permission from ref. 87).

acterized.[87] This chromium complex is quite similar to the vanadium(III) complex mentioned earlier and has a central CrC_6 core in a distorted octahedron. The lithium ions cap faces of the octahedron in a triply-bridging fashion (Fig. 15).

The polyarylates of molybdenum and tungsten have also been investigated by Sarry and co-workers. As was found for the tantalum and niobium polyphenylates the original formulations, $M(Ar)_6Li_3$, were later revised to reflect the presence of aryne groups and the species reformulated as $M(\eta^2\text{-aryne})_2(Ar)_4(LiEt_2O)_4$ (M = Mo, Ar = Ph; M = W, Ar = *p*-tol, Ph) on the basis of NMR data.[106,107] No definitive conclusions were reached as to the exact nature of the coordination environments about the metal atoms. In the solid state the phenylate compounds were found to be diamagnetic with slight paramagnetism developing on dissolution. The hexatolylate of molybdenum was paramagnetic in solution (μ_{eff} = 3.9 BM) and NMR investigations were not possible.[107]

Lastly, a *perfluorophenylate* of tungsten(IV) has been synthesized in a reduction manner from PhLi and WCl_6.[45] The product was characterized by its reaction chemistry and magnetic behaviour.

3.4. *Group 7: Manganese and rhenium*

The *manganese*(II) *complexes*, $Mn(Ph)_3Li$, $Mn(p\text{-tolyl})_3Li$ and $Mn(p\text{-}MeOC_6H_4)_3Li$, reported in the early literature were prepared by the room temperature reaction of MnI_2 and the appropriate aryl lithium reagent.[108] Their characterization is questionable and formulation as monomers has been proven incorrect by Power and co-workers.[109]

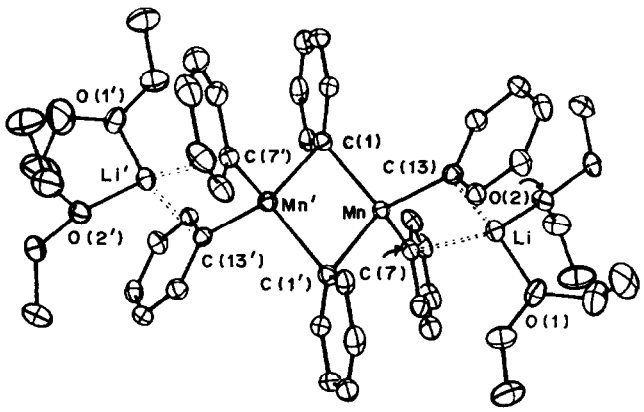

Fig. 16. Molecular structure of the dimeric manganate complex $[Mn(Ph)_3Li(Et_2O)_2]_2$ (reprinted by permission from ref. 109).

The dimer $[Mn(Ph)_3Li(Et_2O)_2]_2$ (Fig. 16) was shown to have one bridging and two terminal phenyl groups for each manganese atom. The terminal phenyl groups are closely associated with the lithium counterions and close contacts exist to the *ipso*-phenyl carbons (Li—C = 2.429 Å). If the synthesis is carried out in an Et_2O–THF mixture, crystals of $[Mn(Ph)_3]_2[Li(THF)_4]_2$ are obtained. Although there is no association between the cationic and anionic portions of the molecule, the structure (Fig. 17) is very similar to the diethyl ether analogue, although the free anion contains shorter Mn—C bonds for both bridging and terminal aryl groups [Mn—C_{av}^{free} = 2.146 (terminal), Mn—C_{av}^{free} = 2.255 Å (bridging): vs Mn—$C_{av}^{ass.}$ = 2.178 (terminal), Mn—$C_{av}^{ass.}$ = 2.285 Å (bridging)]. Distorted tetrahedral arrangements are common to metal atoms in both types of molecule.[109]

The tris-*mesityl anion*, whose preparation had been reported previously,[105] was synthesized in the same manner as the phenyl analogues and crystallized from THF–Et_2O–hexane mixtures as discrete cation–anion pairs. The molecular structure is composed of monomers containing planar MnC_3 cores (Fig. 18). This monomeric nuclearity is no doubt due to the greater steric demands of the mesityl ligands relative to the phenyl ligands. The solution magnetic moment of 5.9 BM corresponds to a high-spin complex containing five unpaired electrons. There were no distortions indicative of M---H—C interactions noted in the solid-state structures of any of these molecules.[109]

Manganese complexes of diphenyl ether have been isolated and characterized. The high-spin manganese(II) complex $Mn(C_6H_4OC_6H_4)_2Li_2(THF)_6$ is yellow–orange and the manganese(III) complex $Mn(C_6H_4OC_6H_4)_2Li(THF)_2$ is yellow–brown.[84]

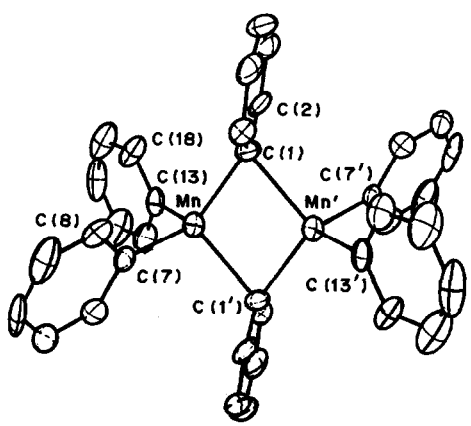

Fig. 17. Molecular structure of the anion in $[Mn(Ph)_3]_2[Li(THF)_4]_2$ (reprinted by permission from ref. 109).

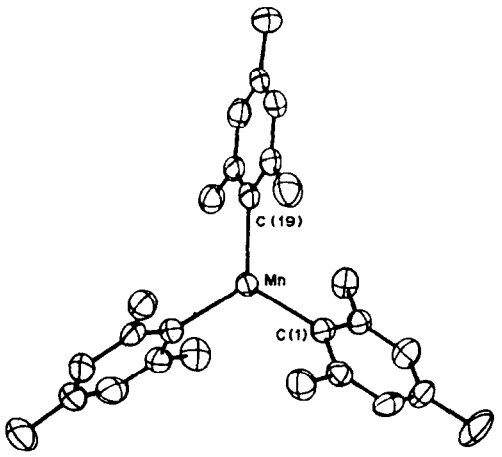

Fig. 18. Monomeric structure of the anionic portion of $[Mn(mes)_3][Li(THF)_4]$ (reprinted by permission from ref. 109).

No technetium compounds are known and the only *rhenium* compound is $[Re(o\text{-tol})_4]^-$. The presence of this anion in deep blue solutions arising from the attempted preparation of $Re(o\text{-tol})_4$ was deduced by oxidation of the solutions with CuCl to give $Re(o\text{-tol})_4$ and by reduction of $Re(o\text{-tol})_4$ with sodium amalgam to give similar deep blue solutions.[47]

3.5. *Group* 8 : *Iron*

Two aryl lithium complexes of iron(0) have been shown to have remarkable reactivity with dinitrogen. The *tetraphenyl complex*, $[Fe(Ph)_4][Li(Et_2O)_4]$, is synthesized by reaction of $FeCl_3$ and 10 equivalents of phenyl lithium in diethyl ether [eq. (31)]:[110]

$$FeCl_3 + \text{excess PhLi} \longrightarrow [Fe(Ph)_4][Li(Et_2O)_4]. \quad (31)$$

The FeC_4 core is close to being a rectangle (Fig. 19). There are close contacts between *ipso*-carbons of each pair of phenyl groups (C—C = 2.09 Å) suggesting some ligand–ligand interaction. The lithium atoms lie above and below the plane of the FeC_4 core and are coordinated to one solvent molecule and one pair of phenyl ligands.[110] The ability of the molecule to fix nitrogen was thought to be due to the ease with which a dinitrogen molecule could approach and coordinate to the metal centre and subsequently react with a nearby lithium atom to give a Fe—N=N—Li moiety. One mole of hydrazine per mole of iron is formed on acidolysis of the $Fe—N_2$ adduct with HCl.[110] A similar proposition has been put forward to explain the release of hydrazine from the acidolysis

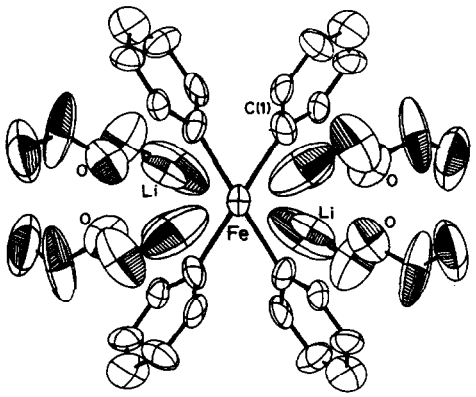

Fig. 19. Molecular structure of the ferrate complex $[Fe(Ph)_4][Li(Et_2O)]_4$ (reprinted by permission from ref. 110).

of the dinitrogen complex obtained from the iron(0) *naphthyl*, $Fe(naphthyl)_3Li_3$.[111] The black phenyl iron(0) complex, $Fe(Ph)_5Li_5$, has been reported as another product of $FeCl_3$/phenyl lithium mixtures.[112]

The tris-mesityl "ate" complexes, $Fe(mes)_3Li(dioxane)_4$ and $[Fe(mes)_3]_2Mg(THF)_{5.75}$, were synthesized in an attempt to find molecular precursors which would yield $Fe(mes)_3$ on oxidation.[54] Another iron(II) complex has been structurally characterized $Fe(naphthyl)_4(LiEt_2O)_2$.[113,114] In contrast to the rectangle found in the phenyl iron(0) complex, the naphthyl derivative has a distorted tetrahedral arrangement (Fig. 20). The lithium atoms maintain contact with the phenyl coordination sphere but no Fe—Li interaction is noted. Excess naphthyl lithium was not effective in reducing the iron to the metal(0) oxidation state. Non-bulky lithium reagents did, however, give the $[Li_3Fe(naphthyl)_3](Et_2O)_n$ complex [eq. (32)].[112,114]

$$Fe(naphthyl)_4(LiEt_2O)_2 + LiC_3H_5 \longrightarrow [Li_3Fe(naphthyl)_3](Et_2O)_n \qquad (32)$$

Drevs has reported d^6 iron(II) ferrate complexes of diphenyl ether, $Li_2Fe(C_6H_4OC_6H_4)_2(THF)_5$, and dimethoxybenzene (DMOP), $Li_2Fe(DMOP)_4(LiBr)(THF)_4$; no structural information other than magnetic moments is available.[84,115]

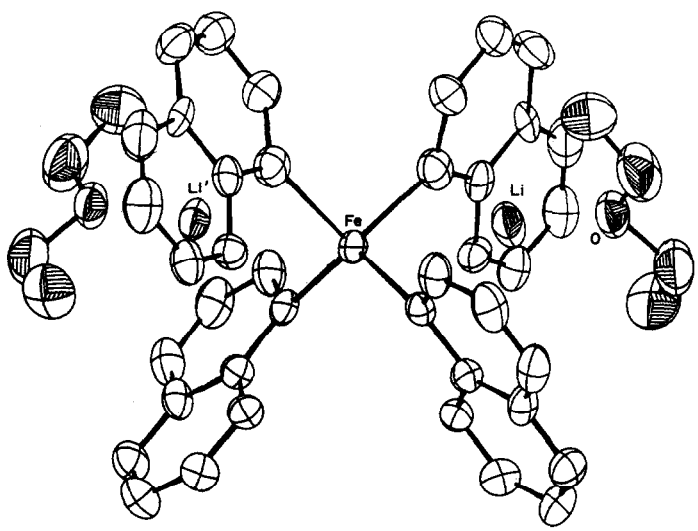

Fig. 20. Molecular structure of the iron(II) arylate complex $[Fe(naphth)_4][Li(Et_2O)]_2$ (reprinted by permission from ref. 114).

No compounds of ruthenium or osmium are known, although CV study showed reduction waves for $Os(o\text{-tol})_4$.[47]

3.6. *Group 9: Cobalt and rhodium*

The chemistry of the cobaltate $Co(Ph)_4Li_2(THF)_4$ has been examined and an interesting redox system discovered. If the compound is shaken at room temperature for 24 h biphenyl is lost and $Co_2(Ph)_4Li_4(THF)_4$ is formed [eq. (33)]:

$$2Co(Ph)_4Li_2(THF)_4 \longrightarrow Co_2(Ph)_4Li_4(THF)_4 + 2C_{12}H_{10}. \quad (33)$$

The identity of the cobalt(0) compound was determined by elemental analysis, cryoscopic molecular weight determination and reactivity with small molecules. It is believed the compound derives its stability from M–ligand π-backbonding and direct metal–lithium interaction.[116] A structure much like that of $Ni(Ph)_3Li_3(THF)_3$[117] was proposed.

Reaction of the cobalt(0) complex with four equivalents of PhLi gave the Co^{-1} species $Co(Ph)_3Li_4(THF)_5$ as a diamagnetic black–brown crystalline substance [eq. (34)]:[116]

$$Co_2(Ph)_4Li_4(THF)_4 + 4PhLi \longrightarrow 2Co(Ph)_3Li_4(THF)_5 + C_{12}H_{10}. \quad (34)$$

A monomeric structure containing two terminal phenyl ligands and an η^6-bonded phenyl lithium moiety was proposed on the basis of NMR evidence and comparison to $(C_6F_5)_2Co(\eta^6\text{-toluene})$, which has been structurally characterized.[116] As is the case for $Co_2(Ph)_4Li_4(THF)_4$, direct Co—Li interaction may be partly responsible for the stability of the molecule.

Complexes of diphenyl ether and DMOP similar to those of iron have also been characterized for cobalt. The cobalt(II) species $Co(DMOP)_4Li_2(THF)_3$ and $Co(C_6H_4OC_6H_4)_2Li_2(THF)_4$ are thermally sensitive, paramagnetic materials with magnetic moments of 3.18 and 2.79 BM, respectively.[84,115]

The cobalt(II) *mesityl* complex, $Li[Co(mes)_3(THF)]$, first reported in 1977,[105] has recently been the subject of more detailed investigation.[59] The complex shows temperature-dependent, paramagnetically-shifted ^1H NMR resonances, and the solution magnetic moment of 3.8 BM corresponds with that for a high-spin d^7 system in a trigonal environment.[59] Reaction with HBF_4 in THF gave the neutral $[Co(mes)_2]_2$ and mesitylene [eq. (35)]:[59]

$$2Li[Co(mes)_3(THF)] + HBF_4 \longrightarrow [Co(mes)_2]_2 + 2C_9H_{12}. \quad (35)$$

The *perhalophenyl* derivatives $[Bu^n{}_4N]_2[Co(C_6X_5)_4]$ (X = Cl, F) were synthesized by reaction of tetrahalocobaltate dianions with four equivalents of the appropriate lithium reagent [eq. (36)]:[118]

$$[Bu^n{}_4N]_2[CoCl_4] + 4C_6X_5Li \xrightarrow{-4LiCl} [Bu^n{}_4N]_2[Co(C_6X_5)_4]. \quad (36)$$

For *rhodium*[119] the pentacoordinate $[Rh(C_6F_5)_5]^{2-}$ dianion [eq. (37)] has been characterized crystallographically and contains a rhodium atom lying slightly above the base of a square pyramid (Fig. 21). The reaction with carbon monoxide is shown in eq. (38).

$$RhCl_3(THT)_3 + 5C_6F_5Li \longrightarrow Li_2[Rh(C_6F_5)_5] + 3LiCl \tag{37}$$

$$[Rh(C_6F_5)_5]^{2-} \xrightarrow{CO} [Rh(C_6F_5)_5(CO)]^{2-} \xrightarrow{CO} [Rh(C_6F_5)_4(CO)_2]^{-}. \tag{38}$$

3.7. *Group* 10: *Nickel, palladium and platinum*

Taube has reported both *tetraphenyl-* and *triphenylnickelate* complexes.[117,120] The tetraphenyl dianion was synthesized from the nickel(II) chelate complex Ni(dpi) [dpi = 1,3-bis(2-pyridylimino)isoindoline] and phenyl lithium [eq. (39)]:

$$Ni(dpi) + 4PhLi \longrightarrow Ni(Ph)_4Li_2. \tag{39}$$

Attempts to prepare the compound from $NiBr_2(THF)_2$ gave yields lower than 5%. It was thought the unique chelate ligand dpi had a stabilizing effect on intermediates formed during the course of the reaction.[120] The tris-phenyl complex $Ni(Ph)_3Li_2(THF)_3$, obtained either by reduction of $Ni(Ph)_4Li_2$ or from $Ni(COD)_2$ (COD = 1,5-cyclooctadiene), was thought to utilize Ni—Li π-

backbonding and Li—C contacts to stabilize the molecule,[117] and a structure like that shown in Fig. 22 was proposed.

As with cobalt and iron, divalent complexes of both DMOP and diphenyl ether are known for nickel.[84,115] The DMOP compound is stable to 240°C and may be exposed to air for prolonged periods without decomposition. Its diamagnetic nature suggested a tetragonal coordination about the metal atom with the methoxy groups lying above and below the MC_4 plane.[115]

Usón and co-workers have synthesized a comprehensive series of tetra- and tri*perhalophenyl* derivatives of nickel,[118] palladium[67] and platinum[67,68] by reaction of ammonium salts of formula $[Bu^n_4N]_2[MCl_4]$ with lithium or Grignard C_6F_5 transfer reagents. The triaryl complexes are isolated as monosolvent adducts [eqs (40)–(42)]:[67,118]

$$[Bu^n_4N]_2[NiCl_4]+4C_6F_5Li \longrightarrow [Bu^n_4N]_2[Ni(C_6F_5)_4]+4LiCl \quad (40)$$

$$[Bu^n_4N]_2[M_2(\mu\text{-}Br)_2Br_4]+4C_6F_5Li \longrightarrow [Bu^n_4N]_2[M(C_6F_5)_4] \quad (M = Pd, Pt) \quad (41)$$

$$MCl_2(THT)_2+3C_6F_5Li \longrightarrow [M(C_6F_5)_3(THT)]Li+2LiCl \quad (M = Pd, Pt). \quad (42)$$

The platinum(II) complex $[Bu^n_4N]_2[Pt(C_6Cl_5)_4]$ may be oxidized to the platinum(III) complex $[Bu^n_4N][Pt(C_6Cl_5)_4]$ by reaction with Cl_2, Br_2, I_2 and $TlCl_3$, eq. (43):

$$[Bu^n_4N]_2[Pt(C_6Cl_5)_4]+1/2Cl_2 \longrightarrow [Bu^n_4N][Pt(C_6Cl_5)_4]+[Bu^n_4N][Cl]. \quad (43)$$

The solid-state structure of the platinum(III) compound was compared to that of its platinum(II) parent and no significant differences were discovered. Metal atoms in both compounds have a virtually identical square geometry and are shown together in Fig. 23.[121,122]

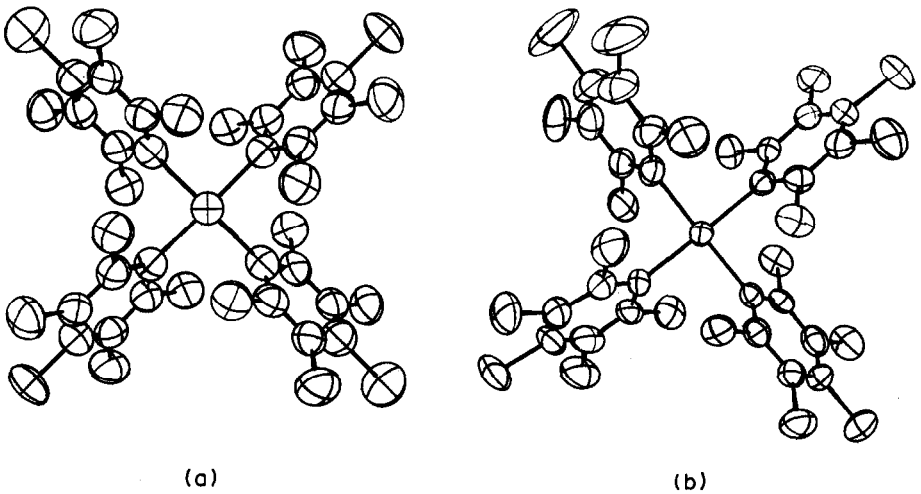

Fig. 23. Molecular structures of the platinate complexes (a) $[Pt(C_6F_5)_4]^{2-}$ and (b) $[Pt(C_6F_5)_4]^-$ (reprinted by permission from refs 121 and 122).

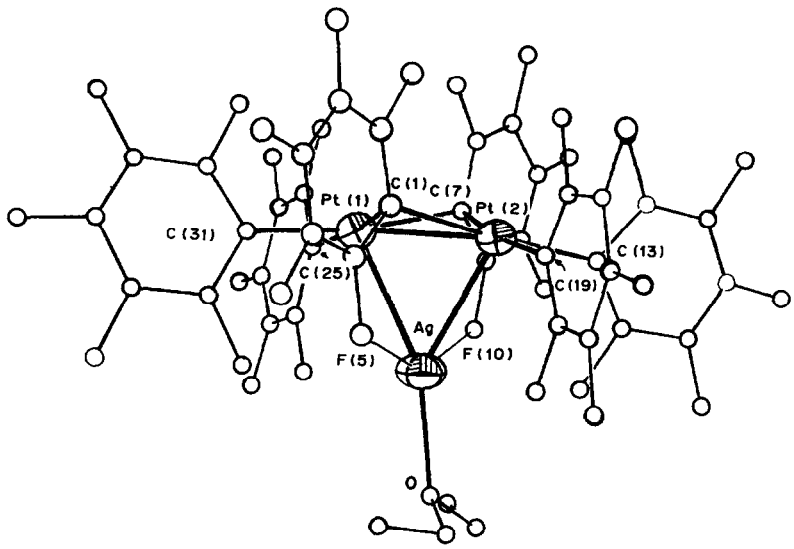

Fig. 24. Molecular structure of the mixed Pt—Ag cluster $[Pt_2Ag(C_6F_5)_6(Et_2O)]^-$ (reprinted by permission from ref. 124).

Species of formula $[M_2(\mu\text{-}X)_2(Ar)_4]^{2-}$ (M = Pd, Pt; Ar = C_6Cl_5; X = Cl, Br) are obtained when monomeric $[M(Ar)_4]^{2-}$ anions are reacted with HCl [eq. (44)]:[123]

$$[M(C_6Cl_5)_4]^{2-} + HCl \longrightarrow [M_2(\mu\text{-}Cl)_2(C_6Cl_5)_4]^{2-} + C_6Cl_5H. \quad (44)$$

The unique mixed-metal cluster $[Bu^n_4N][Pt_2Ag(C_6F_5)_6(Et_2O)](Et_2O)$ was synthesized by the route in eq. (45). An X-ray analysis revealed two closely associated $[Pt(C_6F_5)_3]^-$ units [Pt—Pt = 2.698(1) Å] bridged by two C_6F_5 ligands (Fig. 24). Weak Pt—Ag interactions are implied by short Pt—Ag distances (Pt—Ag_{av} = 2.821 Å) and the absence of bridging ligands across the Pt—Ag gaps.

$$2[Bu^n_4N]_2[PtCl(C_6F_5)_3] \xrightarrow{AgClO_4/CH_2Cl_2}$$

$$2AgCl + 3[Bu^n_4N][ClO_4] + [Bu^n_4N][Pt_2Ag(C_6F_5)_6(Et_2O)](Et_2O). \quad (45)$$

3.8. *Group* 11: *Copper, silver and gold*

Since 1980 (see Reviews for previous studies) the structural characterization of aryl cuprates has advanced dramatically. Monomeric structures are obtained for $[Cu(Ar)_2]^-$ (Ar = mes, Ph) when either a bulky aryl ligand is used[125] or the lithium counterion is complexed to a crown ether (12-C-4) to prevent it from associating closely with the anionic portion of the molecule.[126] The complexes are generated by the routes shown in eqs (46)–(47):

$$CuI \xrightarrow{PhLi} ICuPhLi \xrightarrow{PhLi} (Ph)_2CuLi(LiI) \xrightarrow{12\text{-}C\text{-}4} [(Ph)_2Cu][Li(12\text{-}C\text{-}4)] \quad (46)$$

$$2[Cu(mes)] + 2dppe \longrightarrow [Cu(mes)_2]^-[Cu(dppe)_2]^+$$

(dppe = 1,2-bis(diphenylphosphino)ethane). (47)

In the solid state both cuprate complexes have essentially linear C_{ipso}—Cu—C_{ipso} bonding.

If the diphenyl cuprate is crystallized from diethyl ether without added crown ether a dimeric species is obtained. In this case the lithium atoms play a significant role in the structural composition of the complex. An X-ray analysis shows a cyclic structure consisting of two C—Cu—C—Li units with the lithium atoms in bridging positions between two phenyl groups (Fig. 25).[127] The same C—Cu—C—Li arrangement is also found in $Cu_2Li_2(2\text{-}Me_2NCH_2C_6H_4)_4$ (see Section 4.6) where

the amino side groups are coordinated to the bridging lithium atoms (Fig. 26).[128] The same structural features are found in the gold complex $Au_2Li_2(2\text{-}Me_2NCH_2C_6H_4)_4$.[129]

Several copper phenylate clusters having solid-state structures based on distorted trigonal bipyramidal Cu_xLi_y ($x = 3$, $y = 2$; $x = 4$, $y = 1$; $x = 5$, $y = 0$) frameworks have been synthesized and characterized.[130–132] The exact composition of the molecule is dependent on slight variations in the

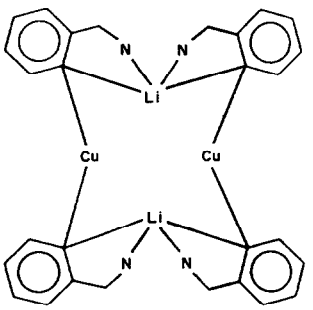

Fig. 26. Diagram of the cuprate $[Cu(2\text{-}Me_2NC_6H_4)_2Li]_2$ showing the secondary N—Li interaction (reprinted by permission from ref. 128).

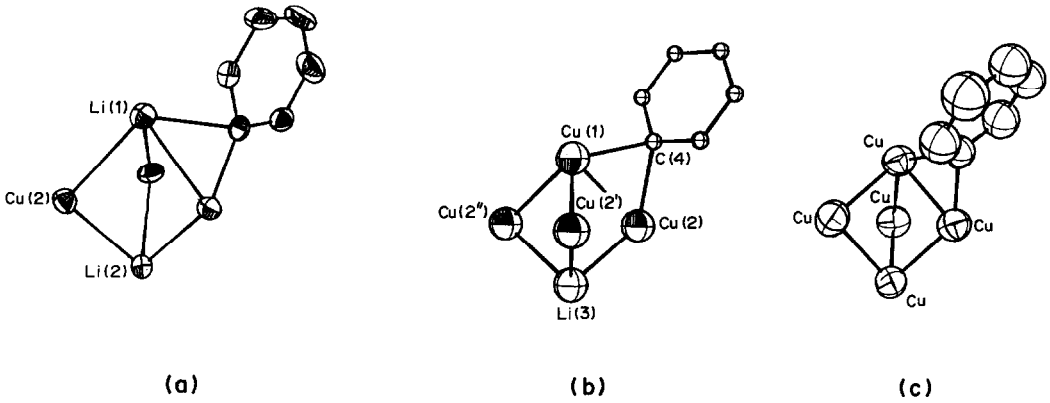

Fig. 27. Trigonal bipyramidal core structures found in the cuprate clusters (a) $[Cu_3Li_2(Ph)_6]^-$, (b) $[Cu_4Li(Ph)_6]^-$, (c) $[Cu_5(Ph)_6]^-$; only one bridging phenyl group is shown for clarity (represented by permission from refs 130, 131 and 132).

synthesis and conditions under which it was crystallized. In each case the copper atoms occupy equatorial positions with the axial positions taken by either lithium or copper atoms depending on the formula of the complex. The phenyl ligands take bridging positions across axial and equatorial sites. Any extra charge for the anion is compensated by a cation having no interaction with the Cu_xLi_y core. The structures of the Cu_xLi_y complexes are shown in Fig. 27. No significant change is noted when magnesium replaces lithium in $[Cu_4Li(Ph)_6][Li(Et_2O)_4](Et_2O)_2$ to give $Cu_4Mg(Ph)_6(Et_2O)$.[131]

A cluster compound $Cu_2Li_3(Ph)_5(SMe_2)_4$ different to those containing Cu_xLi_y trigonal bipyramidal cores and having a phenyl to copper ratio of greater than 2 : 1 may be isolated from PhLi–CuBr mixtures in Me_2S.[133] The molecular structure is shown in Fig. 28. The cluster may be viewed as two cuprate species, $[Cu(Ph)_2]^-$ and $[Cu(Ph)_3]^{2-}$, connected by bridging lithium atoms. The $[Cu(Ph)_3]^{2-}$ unit found in the molecule is the first of its kind to be structurally characterized. The bending of the copper atoms towards each other was thought to be indicative of either a weak Cu—Cu interaction or a directional influence of the phenyl groups caused by deviations in C_{ipso}—Cu planes due to the bridging lithium atoms.[133]

Both *tetraphenylaurate*(III)[134] and *tetra(perfluorophenyl)aurate*(III)[135] species have been structurally characterized and have essentially isostructural square coordination geometries with the aryl groups in a propeller configuration (Fig. 29). If the perhalo gold(I) compound $(C_6F_5)Au(THT)$ is treated with either *o*-phenylenebis(dimethylarsine) (pdma) or triphenylstibine the aurates,

$[AuL_x][Au(C_6F_5)_2]$ (L = pdma, $x = 2$; L = $SbPh_3$, $x = 4$), are obtained.[136] Crystallographic analysis shows a monomeric anion with linear C_{ipso}—Au—C_{ipso} coordination (Fig. 30).[136–138]

The syntheses [eq. (48), X = F, Cl] of the aryl silver anions $[Bu^n_4N][AgAr_2]$ (Ar = C_6Cl_5, C_6F_5) have been reported but no structural details were given:[139]

$$CF_3CO_2Ag + 2LiC_6X_5 + [CF_3CO_2][Bu^n_4N] \longrightarrow [Bu^n_4N][Ag(C_6X_5)_2]. \quad (48)$$

The argentate $[Ag_3Li_2(Ph)_6]^-$ was characterized crystallographically and has the same basic structure as its copper counterpart $[Cu_3Li_2(Ph)_6]^-$.[140]

4. FUNCTIONALIZED ARYLS

4.1. *Lanthanides*

Functionalized aryl complexes of samarium, europium and ytterbium can be obtained by reaction of $Hg[PhCr(CO)_3]_2$ and lanthanide metal filings in THF [eq. (49)].[4b]

$$Ln^0 + Hg[(CO)_3CrPh]_2 \longrightarrow Hg^0 + Ln[PhCr(CO)_3]_2(THF)_n. \quad (49)$$

Low energy ν(C—O) stretches (1600–1800 cm^{-1}) in the IR spectrum of the products were ascribed to Ln—O≡C interactions. It is not clear whether these interactions are inter- or intramolecular.[4]

The scandium chelate complex $Sc(2\text{-}Me_2NCH_2C_6H_4)_3$ is thought to owe its stability to the dative bonding of the *ortho*-amino groups.[141] This ubiquitous dimethylaminoaryl ligand has also been used in the synthesis of a number of lanthanide hydrocarbyls (Lu, Er, Yb)[142] and the solid-state structure of the lutetium derivative has been determined (Fig. 31).[143] All three ligands are bonded

Table 18. Homoleptic functionalized aryls of the lanthanide, actinide and Group 3 metals

in a chelate fashion. The variation in Lu—N bond lengths (two short and one long; $Lu—N_{av}^{short} = 2.473$ Å, $Lu—N^{long} = 2.588$ Å) was attributed to either steric forces within the molecule or packing effects which influenced the "arm" of the chelate ligand.[143]

4.2. *Groups* 4 *and* 5: *Titanium and vanadium*

The tris ortho-*pyrazolylphenyl* complex of *titanium*(III) is thought to have an octahedral coordination geometry. Stable for short periods in air, protolytic cleavage of the Ti—C bond is rapid on reaction with protic molecules.[142] The analogous *vanadium* complex $V[2\text{-}(N_2C_3H_2)C_6H_4]_3$ has also been reported.[142] A very similar compound may be obtained using the aryl group *o*-$(Ph)_2PCH_2C_6H_4$[144] where stabilization is afforded by dative P—V bonding.

A class of molecules which have received a great deal of attention, due to their relevance towards metal–metal multiple bonding, are species containing the DMOP [DMOP = 2,6-$(MeO)_2C_6H_3$] aryl group. Reduction of vanadium(III) to vanadium(II) by reaction of VCl_3 and LiDMOP produces a

Table 19. Homoleptic functionalized aryls of Groups 4 and 5

Complex	Comments	References
$M[2\text{-}(N_2C_3H_3)C_6H_4]_3$	M = Ti, V; *ortho*-chelating pyrazolyl group	142

compound which analyses for $V_2(DMOP)_4(THF)$ [eq. (50)]:

$$VCl_3 + 3Li[2,6\text{-}(MeO)_2C_6H_3] \longrightarrow \{V[2,6\text{-}(MeO)_2C_6H_3]_2\}_2(THF)_2. \quad (50)$$

The compound was originally thought to contain a vanadium–vanadium triple bond and four bridging DMOP ligands each using one available methoxy unit to bind the neighbouring atom.[145] A later crystal structure by Cotton and co-workers, one of a *series* (V, Mo, Cr) to appear involving metal complexes containing the DMOP ligand, showed two sets of unique DMOP ligands (Fig. 32). One set utilized only one methoxy oxygen atom while the other ligand set used both and contained the *ipso*-carbon in a bridging position between the vanadium atoms. A V≡V triple bond was presented as credible in comparison with other V—V bond distances.[146]

4.3. *Group* 6: *Chromium and molybdenum*

Ortho-*methoxyaryl* complexes of *chromium* are common and have been the subject of several structural investigations. The first report describing the structure of $Cr_2(DMOP)_4$ was remarkable in that the Cr—Cr distance of 1.847(1) Å was the shortest metal–metal distance known and was more than 0.6 Å shorter than the M—M separations found in the metallic element.[147] The DMOP ligands adopt a *trans*-parallel arrangement to the Cr—Cr bond forming two perpendicular planes (Fig. 33). In contrast to the vanadium derivative where one pair of DMOP ligands utilized only one

methoxy oxygen and the other DMOP ligands used both in metal–ligand bonding, the DMOP ligands in $Cr_2(DMOP)_4$ were equivalent and all four ligands used only one methoxy oxygen in secondary metal–ligand bonding. The same result was obtained for molybdenum, where a longer metal–metal bond was found [2.064(1) Å].[147] The X-ray structure of $Cr_2(DMOP)_4$ was solved to determine what effect the extra methoxy substituent would have on the metal–metal distance and no significant difference was noted.[148–149] The 5-methylanisole complex was also examined as the unsubstituted anisole derivative, which had previously been identified as a polymer,[95,150,151] proved too difficult to crystallize.[152] The gross structural features were found to be almost identical to the DMOP analogue, although some variation in metal–metal bond lengths was present: $Cr_2(5\text{-}Me\text{-}2\text{-}MeOC_6H_3)$ [Cr—Cr = 1.828(2) Å].

The 2,3- and 4-*methoxybenzene* complexes of chromium and molybdenum have also been synthesized. The 3-anisole and 4-anisole complexes do not seem to show the chelate effect displayed in the *ortho*-anisole dimers.[151,153] The *ortho*-anisole molybdenum compound, $Mo_2(2\text{-}MeOC_6H_4)_4$, has a structure very similar to the chromium analogue.[154] Chromium(III) tris(2-anisole) was the subject of thermal decomposition studies and at 100°C gave $Cr_2(2\text{-}MeOC_6H_4)_4$, 1,1,2,2-tetrakis(2-methoxyphenyl)ethane, anisole and 2,2′-(dimethoxy)biphenyl.[153]

Chromium(III) complexes with varying *ortho* "sidearm" substituents are quite abundant. The $Cr(2\text{-}Me_2NCH_2C_6H_4)_3$[141,155] compound has been structurally characterized (Fig. 34). The metal

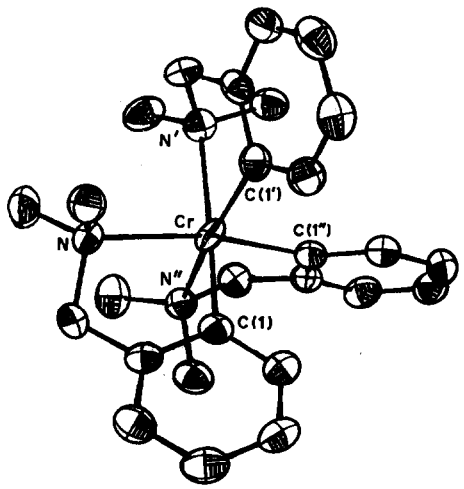

Fig. 34. Molecular structure of $Cr(2\text{-}Me_2NC_6H_4)_3$ (reprinted by permission from ref. 155).

atom resides in a distorted octahedron with a facial arrangement of ligands. Each M—C bond is *trans* to a dative M—N bond.[156] The same general features are found in the 1,3-dioxolano-substituted species, $Cr[2\text{-}(O_2C_3H_8)C_6H_4]_3$,[157] whose solid-state structure shows a chromium atom in a slightly more distorted octahedral CrC_3O_3 environment.[157] Other paramagnetic d^3 *ortho*-substituted chromium aryl complexes $Cr(2\text{-}XC_6H_4)_3$ [X = Et_2NCH_2, pyridyl, $(C_6H_5)_2PCH_2$, pyrazolyl, Me_2N] are likely to possess the same molecular geometries.[95,142,144,158,159]

4.4. *Groups* 7 *and* 8: *Manganese, rhenium and iron*

The same ligands used in the synthesis of group 6 chelate complexes have also seen application in the group 7 and 8 metal aryl complexes. The *manganese chelate* $Mn(2\text{-}Me_2NCH_2C_6H_4)_2$ is obtained from $(LiTHF)_2MnI_2(2\text{-}Me_2NCH_2C_6H_4)_2$ by removal of coordinated LiI in dioxane [eq. (51)]:

$$2Li(2\text{-}Me_2NCH_2C_6H_4) + MnI_2 \longrightarrow (LiTHF)_2MnI_2(2\text{-}Me_2NCH_2C_6H_4)_2$$

$$\xrightarrow{C_4H_8O_2} Mn(2\text{-}Me_2NCH_2C_6H_4)_2. \quad (51)$$

A dimeric structure similar to that of the benzyl chelate, $[Mn(2\text{-}Me_2NC_6H_4CH_2)_2]_2$, which was characterized crystallographically, is postulated.[155] The 2,6-dimethoxy complex of *rhenium*(III), $Re_2(2\text{-}MeOC_6H_4)_6$, has a core structure in solution (by NMR) similar to that of $Cr_2(2\text{-}MeOC_6H_4)_4$ with an additional $2\text{-}MeOC_6H_4$ ligand σ-bonded to each rhenium at the ends of the Re—Re vector.[154]

A ligand similar to 2-MeOPh was used to synthesize the *iron*(II) chelate $[Fe(2\text{-}MeOCH_2C_6H_4)_2]_n$ whose structure was thought to be polymeric.[160] Other iron chelates of ligands *o,o*-$C_6H_4CH_2N(Me)CH_2CH_2N(Me)CH_2C_6H_4$ and *o,o*-$C_6H_4CH_2OCH_2CH_2OCH_2C_6H_4$ have been reported.[160]

$Fe(2\text{-}MeOCH_2C_6H_4)_2$		160

4.5. *Groups* 9 *and* 10: *Cobalt, nickel, palladium and platinum*

The *cobalt*(III) *chelate*, $Co(2\text{-}Me_2NCH_2C_6H_4)_3$, is obtained by *oxidation* of $CoCl_2$ with $Li(2\text{-}Me_2NCH_2C_6H_4)$ [eq. (52)].[161] The distorted octahedral facial geometry, found in chromium complexes is likely to be the favoured structure for this complex also.

$$CoCl_2 + 3Li(2\text{-}Me_2NCH_2C_6H_4) \longrightarrow Co(2\text{-}Me_2NCH_2C_6H_4)_3. \quad (52)$$

The same synthetic procedure was employed for the diamagnetic $Co[2\text{-}(pyrazolyl)C_6H_4]_3$.[142] The ortho-*pyrazolyl series* is completed with $Ni[2\text{-}(pyrazolyl)C_6H_4]_2$.[42] No mention of Ni—N bonding is made.

Many tetracoordinate bis-*chelate* complexes of the group 10 metals, having d^8 electronic configurations, are known. The $2\text{-}Me_2NCH_2C_6H_4$ ligand has been used to prepare compounds of nickel,[162] palladium[162–164] and platinum[162] via a salt elimination reaction using the lithium aryl and metal dichloride [eq. (53)]:

$$MCl_2 + 2Li(2\text{-}Me_2NCH_2C_6H_4) \longrightarrow 2LiCl + M(2\text{-}Me_2NCH_2C_6H_4)_2 \quad (M = Ni, Pd, Pt). \quad (53)$$

Different isomers are obtained depending on the metal and aminoalkyl substituent used. Table 21 contains a list of isomers identified by NMR {^{1}H and ^{31}P} and dipole moments.[162] The mixed-ligand compound Pd[2-$Me_2NCH_2C_6H_4$][2-(pyrazolyl)C_6H_4] was found to prefer a *trans* orientation.[164]

The reactivity of each complex with carbon monoxide was examined. The predominant products from the nickel and palladium aryls were $Ni(CO)_4$ and palladium metal, respectively. The *trans*-platinum isomer yielded an adduct Pt(2-$Me_2NCH_2C_6H_4)_2$(CO) while the *cis* isomer inserted one mole of CO to form Pt(2-$Me_2NCH_2C_6H_4$)(2-$Me_2NCH_2C_6H_4C$(O)) (Scheme 2).[162]

The analogous 2-$(C_6H_5)_2PCH_2C_6H_4$ complexes, where the amino group has been replaced by $(Ph)_2P$, have been reported and shown to exist as a mixture of isomers, Table 21.[165] The *cis* planar structure of Pt(2-CH_2=$CHCH_2C_6H_4)_2$ was also based on dipole and NMR data.[166]

Table 22. Homoleptic functionalized aryl complexes of Groups 9 and 10

Pd(2-$Ph_2PCH_2C_6H_4$)(4-Bu$^t_2$-$PCH_2C_6H_4$)	*cis*	165
Pd(2-$Me_2NCH_2C_6H_4$)(2-$(N_2C_3H_3)C_6H_4$)		164

4.6. *Group* 11 : *Copper, silver and gold*

Ortho-*chelated* copper, silver and gold complexes are common and have an established structural chemistry. In contrast to *ortho*-functionalized aryl complexes of the nickel triad which are monomeric and have both the σ-bound aryl carbon and *ortho*-functionality connected to the same metal atom, the Group 11 species adopt oligomeric structures in which the aryl and *ortho* moieties bond to separate metal atoms. The structures range from the simple dimer found in the oxazolinyl phenyl complex[167] and gold complexes of formula [Au(*o*-XC_6H_4)]$_2$ (X = PPh_2, PEt_2, $AsPh_2$,

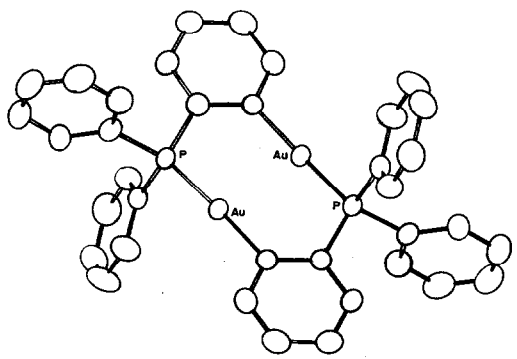

Fig. 35. Molecular structure of [Au(2-$(Ph)_2PC_6H_4$)]$_2$ (reprinted by permission from ref. 168).

PREPARATION AND X-RAY CRYSTAL STRUCTURE DETERMINATION OF AN OCTAHEDRAL POLYMERIC LUTETIUM COMPOUND WITH CILIATINE; $\{Lu(PO_3HCH_2CH_2NH_3)_3(ClO_4)_3 \cdot 3D_2O\}_n$

T. GŁOWIAK, E. HUSKOWSKA and J. LEGENDZIEWICZ*

Institute of Chemistry, University of Wrocław, Joliot-Curie 14, 50-383 Wrocław, Poland

(*Received* 30 *March* 1990; *accepted* 20 *July* 1990)

Abstract—The new octahedral compound of lutetium with ciliatine of the formula $Lu(PO_3HCH_2CH_2NH_3)_3(ClO_4)_3 \cdot 3D_2O$ was prepared in the form of single crystals from D_2O solutions and subjected to X-ray structure determination. Each lutetium ion is coordinated by six oxygen atoms from the phosphonic groups. The coordination polyhedron is an almost ideal octahedron with a mean Lu—O distance of 2.201(6) Å. The lutetium ions are bridged by two oxygen atoms from each of three phosphonic groups. In this manner the linear polymer is formed along the x axis.

Recently, great efforts have been made to understand the role of aminoalkanephosphonic acids, the analogues of amino acids. The reason for this is that several synthetic and natural phosphonic acids have rather interesting biological properties. Aminophosphonates are found in tissues as the free compounds, but their most frequent form of occurrence include complex structures, such as lipids, peptides, proteins and polysaccharides.[1–3] Since the lanthanide ions are often used as metal probes in studies of important biological systems, it seemed reasonable to study the interaction of lanthanide ions with the simplest natural aminophosphonate, ciliatine.

Recently we reported potentiometric and ^{31}P NMR investigations on Nd^{3+} and Ho^{3+} complex formation with α-aminoethanophosphonic (α-PAla) and β-aminoethanophosphonic (β-PAla) acids in solution.[4] It was found from the potentiometric studies that the forms MAH, $M(AH)_2$ and MA_2H exist in solutions of β-PAla. However, the ^{31}P NMR data at lower pH revealed the interaction of Ln^{3+} ions with the zwitterionic form of ciliatine, which means an additional form could probably exist under these conditions. To confirm this phenomenon we have attempted to obtain this form in the solid state.

In this paper we describe the X-ray studies of the compound $Ln(PO_3HCH_2CH_2NH_3)_3(ClO_4)_3 \cdot 3D_2O$ and comparison of the results with related lanthanide single crystal structural data.

EXPERIMENTAL

Sample preparation

Crystals of the lutetium compound were grown from a concentrated D_2O solution of $Lu(ClO_4)_3$ at pH < 1. The concentration of phosphonic acid was maintained well below the lanthanide concentration.

It is worth mentioning that the growth of crystals is more difficult and slower than those of its amino acid analogue. The Lu^{3+} ion concentration in the crystal was determined by EDTA titration, using Xylenol Orange as the end point indicator. The density, measured by the flotation method using a mixture of bromoform and ethylene bromide, was $d = 2.17$ g cm^{-3}.

X-ray measurements

A crystal of dimensions 0.25 mm × 0.3 mm × 0.4 mm was used for the structure determination. A Syntex $P2_1$ diffractometer and MoK_α radiation with the graphite monochromator were used for the lattice parameter and intensity measurements. The intensities of the reflections were measured by the

$S = \{\Sigma w(F_o-F_c)^2/(n-p)\}^{1/2}$	3.223

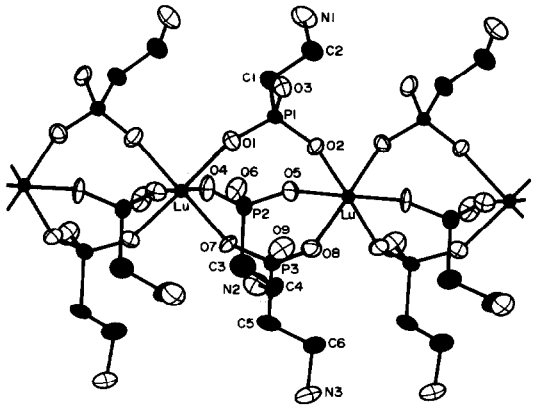

Fig. 1. An ORTEP drawing of the Lu($PO_3HCH_2CH_2NH_3$)$_3$(ClO_4)$_3$·3D_2O compound; the atoms of the crystallographic unit are labelled as in the text.

θ–2θ scan technique up to $2\theta_{max} = 55°$. The scan rate varied from 2.0 to 29.0° min^{-1}. The data were corrected for Lorentz, polarization and absorption effects. 4762 reflections, with $I > 3.0\,\sigma(I)$, were used for the structure determination. All calculations were performed using Syntex XTL programs[5] and scattering factors for neutral atoms were taken from the *International Tables for X-ray Crystallography*.[6] The structure was solved by the heavy-atom method. Full-matrix least-squares refinement was terminated at $R = 0.040$ and $R_w = 0.051$.

Crystal data are listed in Table 1. Final atomic and anisotropic thermal parameters, with estimated standard deviations, have been deposited.

CRYSTALLOGRAPHIC DESCRIPTION OF THE STRUCTURE AND DISCUSSION

Figure 1 shows the perspective view of a characteristic fraction of the title structure and the labelling of the atoms in the crystallographic unit. The geometric data for the coordination around the lutetium cation, and the covalent bond lengths and bond angles within the phosphonic acid residue, are listed in Tables 2 and 3. In the unit cell two polymeric chains are parallel to the x-axis at $y \sim 0.25$ and ~ 0.75.

The lutetium ions are six-coordinated by the oxygen atoms belonging only to the six phosphonic acids. The water molecules and perchlorate ions are not involved in coordination. The exclusion of the water molecule, while the coordination number remains so low, is very unusual for lanthanide compounds. The coordination number six is also rather rare, another example reported is cerium diethyl phosphate, Ce[$PO_2(OC_2H_5)_2$]$_3$.[7]

The coordination polyhedron is almost ideal octahedron; only some small deviations in the Ln—O distances are observed. The Ln—O distances range from 2.194(6) to 2.210(5) Å, with an average value of 2.201[6] Å. These distances are comparable with the Ln—O distances in the octahedral compound Pr($OPN_3C_6H_{18}$)$_3$$Cl_3$[8] (Pr—O = 2.35 Å) when the lanthanide contraction is considered (ER, Pr = 1.013 Å, Lu = 0.848 Å, Δr = 0.165 and ΔMe—O = 0.150), and differ significantly from the Ln—O distances found in lanthanide phosphates, where the coordination number is nine.[9] Two oxygen atoms from each of three phosphonic groups bridge the lutetium ions, so that a linear polymer along the x-axis is formed. The distance between the bridged lanthanide atoms is 5.093(1) Å. The phosphonic acid molecules exist in the structure as zwitterions. The bond distances and angles within them conform with expected values.

The P—O distance clearly indicates the coordination of two oxygen atoms of the phosphonic group to the lutetium ion. The torsion angles indicate an almost planar arrangement of the atoms. The distances of the donor groups (H_2O, NH_3^+, OH) between themselves and between the oxygen atoms of ClO_4^- groups, ranging from 2.6 to 3.0 Å, indicate the rich hydrogen bonding system formed in the structure. The crystal structure consists of parallel lutetium–phosphonic acid chains. The perchlorate anions and non-coordinating water molecules reside in the cavities between the chains and stabilize the crystal packing by forming hydrogen bonds.

The results of X-ray studies show that the coordination of the lanthanide cation in the title compound differs significantly from that in the amino acid compounds.[10–15] Although in both types of compound polymeric forms are created (by the bridges of the type M—O—P—O—M, M—O—C—

O—M and M—O—C—O—M), the coordination number of the lanthanide ions changes drastically.

The six-coordination found in the title compound is close to that observed for the calcium ion in phosphate,[16] therefore one might expect substitution of the Ca^{2+} ion by Ln^{3+} in biological systems in which phosphonic residues exist.

The structure of $\{Lu(PO_3HCH_2CH_2NH_3)_3(ClO_4)_3 \cdot 3D_2O\}_n$ also differs from the structure of α-aminomethylphosphonic analogues of transition metals (Mn^{2+}, Cu^{2+}, Zn^{2+}, Co^{2+}).[17–19] Monomers or some polymers were observed but in none of the cases were the triple phosphate bridges formed.

The crystal structure of the title compound confirms the interaction between Lu^{3+} and the AH_2 form of the ligand found by ^{31}P NMR at low pH, which was undetectable using potentiometric methods.[4]

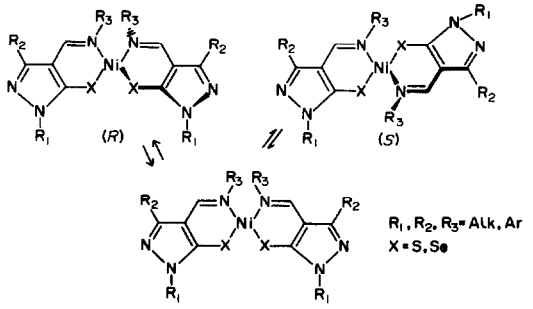
Abstract—X-ray crystallographic studies of fluxional bis[1-isopropyl-3-methyl-4-N-alkyl(aryl)aldiminopyrazole-5-thion]ato nickel(II) complexes [pyr(N-CH_3)$_2S_2$]Ni, [pyr(N-Ph)$_2S_2$]Ni and [pyr(N-t-Bu)$_2S_2$]Ni show them to possess pseudo-tetrahedral configurations with the values of dihedral angles θ between chelate planes being 81.9 and 82.4; 68.7; 96.3° respectively. The values of θ as well as those of the NNiN′ valence angles have been found to correlate with the energy barriers against intramolecular enantiomerization of tetrahedral nickel configuration R $\rightleftharpoons$ S.

In nickel(II) metal chelates possessing the coordination site of type NiN_2X_2 (X = O, S, Se), the stereoconfiguration of the central atom is strongly affected by the type of ligating atom X, ligand structure and steric volume of the substituent attached to the coordinated nitrogen atom.[1,2] Of these compounds, 1,3-substituted bis[4-N-alkyl(aryl) aldiminopyrazole-5-thion(seleno)]ato nickel(II) complexes display a significant stabilization of the tetrahedral form both in solution and in the solid state, which has been established by ^{1}H NMR spectral study, measurements of magnetic moments and by X-ray structure investigation of two of these complexes.[3–6] In solution, the above complexes undergo a rapid interconversion of their enantiomeric forms R $\rightleftharpoons$ S, with the free activation energy of the inversion process falling within the range of 40–75 kJ mol^{-1}.[4] The magnitude of the energy barrier increases when going from N-n-alkyl and aryl to N-s-alkyl and t-Bu substituents presumably owing to the steric strain developed by bulky substituents in the transition or intermediate planar structure inherent in the mode of enantiomerization.

In the present work a crystallographic study of complexes **Ia–c** containing aryl and alkyl groups at



Scheme 1.

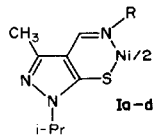
coordinated nitrogen has been carried out with the aim of clarifying whether a correlation exists between the tetrahedral-to-planar distortion of the metal bond configuration and the energy barriers to the R⇌S interconversion. The previously reported[5] structural data on the complex [pyr(N-C_6H_{11}-cyclo)$_2S_2$]Ni (**Id**) are also discussed in this connection.



Ia–d

R=CH_3(a), Ph(b), t-Bu(c), C_6H_{11}-cyclo(d)

EXPERIMENTAL

The crystal samples have been obtained by slow crystallization from toluene–octane (1 : 1) mixture.

Crystal data, details of intensity measurement and refinement for **Ia–c** are given in Table 1. The unit-cell dimensions were refined on a DRON-1 diffractometer with a monocrystal attachment. The absorption corrections were introduced for **Ib,c** by Gaussian integration[7] using Udelnov's program.[8] The structures **Ia–c** were determined by direct methods and refined by the least-squares technique, with full-matrix anisotropic (Ni, S, N and C atoms) and isotropic (H atoms) approximation using the Cruickshank weighting scheme. The hydrogen atoms in **Ib,c** were located by difference Fourier synthesis. Selected bond distances are listed in Table 2. Calculations were carried out on a BESM-6 computer using the RENTGEN-75 program package.[9] The stereoprojections (Figs 1–3) were obtained by the use of the ELLIDS program.[10]

RESULTS AND DISCUSSION

The complexes **Ia–c** possess pseudo-tetrahedral structures. The values of dihedral angles θ between the planes of chelate rings, which indicate the degree of the tetrahedral-to-planar distortion ($\theta = 90°$ for ideal tetrahedron), are equal to 81.9, 82.4 (**Ia**), 68.7 (**Ib**) and 96.3 (**Ic**). The value of θ exceeding 90° as is the case with complex **Ic** corresponds to the S···S *trans*-planar distorted structure. For the complexes **Ia,b** ($\theta < 90°$) a distortion towards the *cis*-planar geometry occurs.

The diagonal twist mechanism of the R⇌S enantiomerization includes reciprocal rotation of

chelate rings about the C(2) axis towards the achiral planar structure. Therefore, a correlation between the values of energy barriers of the tetrahedral inversion and the degree of the tetrahedral-to-planar distortion may, in principle, take place in accordance with the structure correlation concept.[11,12] The preference of *cis*-planar structures for the numerous bis-chelate complexes with the NiN_2S_2 coordination site has been revealed,[1,2] thus the gradual decrease of θ values may be associated with the decrease of the energy barriers to the enantiomerization of complexes **I**, $\Delta G^{\ddagger}$, as found from ^1H dynamic NMR spectral data.

Indeed, a comparison of θ and $G^{\ddagger}$ values (Table 3)

[a] Data from ref. 5.

for the complexes of type **I** shows that the compounds with alkyl substituents **Ia**,**c**,**d** are consistent with anticipated correlation. For the complex **Ib**, containing the phenyl substituent, the value of θ falls appreciably, and is not accompanied by a corresponding change in $\Delta G^{\ddagger}$. Moreover, the correlation of activation energies with steric constants of N-alkyl substituents, E_s,[13] has been observed.

It may be assumed that, apart from θ, some other structural parameters reflect the steric strain in **Ia**–**d**. These include the valence angles at the nickel atom. Actually, the unusually high value of the

[b] The value obtained after re-examination of ^{1}H NMR spectral patterns observed earlier.[4]

NNiN′ angle in **Ic**, 133.0°, is considerably larger than the standard tetrahedral one of 109°. It is similar to that of the bis(N-t-butylsalicylideneiminato) nickel(II) complex, 128.6°.[14] Perhaps, such a bisphenoidal torsion arises by virtue of steric repulsion of t-Bu groups. A decrease in the steric volume of R for **Ia,b,d** as compared with **Ic** leads to the decrease in the NNiN′ angle in the order as follows **Ic** > **Id** > **Ib** > **Ia**. Noteworthy is that the enhancement of the bisphenoidal distortion rigorously follows the rise of enantiomerization barriers.

According to the recent consideration by Haaland[15] based on the VSEPR theory, the increase in valence angles formed by metal–ligand bonds can be provoked by their larger covalency, manifesting itself in the shortening of the bond lengths. The examination of Ni—S and Ni—N bond lengths in **Ia–d** shows that Ni—N bonds remain practically unchanged, *ca* 1.98 Å, whilst Ni—S demonstrates a tendency towards shortening, with the decrease of the value of the angle NNiN′. The changes in the Ni—S bond lengths span the range 2.253 (**Ic**) to 2.229 Å (**Ib**). The disagreement with what might be expected in view of the above concept can be explained in that the VSEPR approach is not fully extended to transition metal complexes.

For all complexes **Ia–c** studied, the chelate rings have nearly planar conformation. The deviations from the plane common to the pyrazole and chelate ring do not exceed 4°.

The structure **Ib** contains a highly shortened intramolecular S···S contact, 3.388(2) Å, similar to the known reference value of 3.43 Å,[16] as well as shortened contacts between phenyl substituents, C(9)···C(9′) 3.241(8) Å, C(4)···C(4′) 3.346(7) Å. Phenyl rings, which are rotated by 54° along the C—N axis relative to the chelate ring, form a contact with the CH=N moiety 0.2–0.3 Å less than the conventional value.

As seen from the bond lengths in complexes **Ia–d**, the electron structure of the coordinated ligand is consistent with the delocalized iminothiolato form. It can be illustrated by the values of the bond lengths in the SC(1)C(2)C(3)N(1) portion of the chelate ring, which are intermediate between the lengths in the model aminothione moiety S=C(1)—C(2)=C(3)—N(1) for 1-isopropyl-3-methyl-4-N-cyclohexylenamine-5-pyrazolethione, and iminothiol S—C(1)=C(2)—C(3)=N(1) for 1-phenyl-3-methyl-4-cyclohexylaldimine-5-mercaptomethylpyrazole: C(1)=S 1.696, C(1)—S 1.742 Å; C(1)—C(2) 1.462, C(1)=C(2) 1.396 Å; C(2)=C(3) 1.387, C(2)—C(3) 1.425 Å; C(3)=N(1) 1.251, C(3)—N(1) 1.306 Å.[17]

Abstract—Reactions of $Rh(N\text{-}O)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$ [(N-O) = 2-C_5NH_4COO(pyC) and 2-C_9NH_6COO (quin), X = CH_3O, CH_3, F, Cl] with $Hg(R)(OOCCF_3)$ (R = Ph, $OOCCF_3$) lead to the hexacoordinate rhodium(III), $Rh(HgR)(OOCCF_3)(N\text{-}O)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$, complexes. The new compounds evolve in solution to the decarbonylated species $Rh(R)(OOCCF_3)(N\text{-}O)(H_2O)[P(4\text{-}X_6\text{-}C_6H_4)_3]$. The crystal of one of the above derivatives, $Rh(OOCCF_3)_2(quin)(H_2O)[P(4\text{-}CH_3\text{-}C_6H_4)_3]$, is reported, and a distorted octahedral coordination around the rhodium atom with the two monodentate $OOCCF_3$ ligands in *cis* positions is found.

Synthetic and structural aspects of the chemistry of complexes containing bonds between dissimilar metal atoms are of continuing interest.[1,2] In particular, the reactions of mercury(II) compounds with complexes of transition metals have been extensively studied[2] and different types of reactions have been found. Thus, when the transition metal complex is an electron-rich one, a donor–acceptor complex with mercury derivatives is usually formed.[3,4] However, when the transition metal complex is less nucelophilic and amenable to oxidation, oxidative addition products are obtained. For this reason, Vaska's complex is easily oxidized by mercury(II) halides or pseudohalides[5] but a similar reaction does not occur for analogous rhodium(I) complexes.

It is reasonable to consider that if more basic ligands, like pyridinecarboxylates, were used, facile oxidation would occur.

In previous papers[6,7] we reported the formation of oxidative addition products of the rhodium(I) complexes, $Rh(pyC)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$, by their reactions with I_2, CH_3I or HgX_2.

As an extenstion of these results, we have been studying the reactivity of new pyridinecarboxylate complexes of rhodium(I) with bulky, acidic, mercury(II) derivatives.[8]

In this paper, we describe the reaction of rhodium(I) pyridinecarboxylate complexes, $Rh(N\text{-}O)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$ [(N-O) = 2-C_5NH_4COO(pyC) and 2-C_9NH_6COO (quin), X = CH_3O, CH_3, F, Cl] with $Hg(OOCCF_3)_2$ and $Hg(Ph)(OOCCF_3)$. The new heterobimetallic Rh—Hg derivatives are stable in the solid state, but a slow evolution in solution with the formation of new decarbonylated products, $Rh(R)(OOCCF_3)(N\text{-}O)(H_2O)[P(4\text{-}X\text{-}C_6H_4)_3]$ (R = Ph, $OOCCF_3$), has been observed.

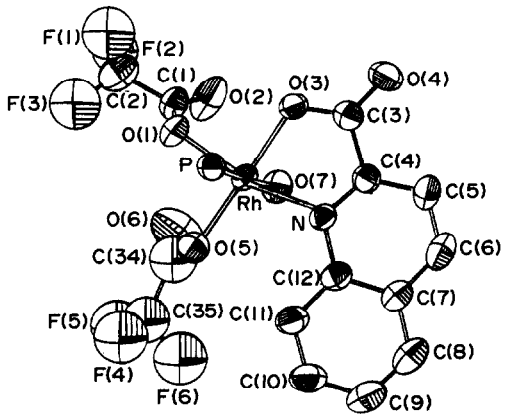

Fig. 1. Geometry of the molecule. (The phenyl groups of the triphenylphosphine have been omitted for clarity.)

The crystal structure of one these derivatives, $Rh(OOCCF_3)_2(quin)(H_2O)[P(4\text{-}CH_3\text{-}C_6H_4)_3]$, has been determined (Fig. 1).

RESULTS AND DISCUSSION

Reactions of $Rh(N\text{-}O)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$ [(N-O) = 2-pyridinecarboxylate anion (pyC) and 2-quinaldinate anion (quin), X = CH_3O, CH_3, F, Cl] with an excess of $Hg(OOCCF_3)_2$ yield oxidative addition products formulated as $Rh(HgOOCCF_3)(OOCCF_3)(N\text{-}O)[P(4\text{-}X\text{-}C_6H_4)_3]$ on the basis of their analytical and spectroscopic data.

The IR spectra of the new complexes in the solid state (Table 1) show two strong absorption bands in the carbonyl and carboxylic stretching regions.

The bands at *ca* 2060–2030 cm^{-1} attributed to $\nu(CO)$ of the carbonyl group appear at higher frequencies relative to those of the parent monocarbonyl compounds, showing a shift of 75–95 and 70–80 cm^{-1} for the pycolinate and quinaldinate complexes, respectively. This fact is consistent with an increase in the oxidation state of the rhodium atom by the addition of $Hg(OOCCF_3)_2$.

The strong absorption at *ca* 1730–1635 cm^{-1} due to $\nu_{as}(OCO)$ appears as a broad band. However, in the quinaldinate complexes this band is split into three components. The highest and the lowest could be tentatively assigned to the $\nu_{as}(OCO)$ of the CF_3COO moieties bonded to the mercury and rhodium atoms, respectively.[9] The middle band appears at the same position as for the parent $Rh(quin)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$ complexes, for which a bidentate N,O-coordination of the quinaldinate ligand is proposed.[6,10,11] However, in the absence of structural data it is not possible to unambiguously assign the different carboxylic groups present in these compounds.

Bands associated with the phosphine ligands are also observed in their characteristic regions.[12]

Thus, on the basis of the above data it appears that a pseudo-octahedral stereochemistry occurs, with $HgOOCCF_3$ and $OOCCF_3$ groups providing the fifth and sixth coordination sites.

The products are stable in the solid state, but in acetone or CH_2Cl_2 solutions evolution with Hg^0 deposition was observed and new decarbonylated products could be obtained. This evolution, which is faster for the pycolinate than the quinaldinate derivatives, sometimes prevents further studies. However, the quinaldinate derivative containing $P(4\text{-}CH_3O\text{-}C_6H_4)_3$ is more stable in $CDCl_3$ solution and we have been able to achieve good NMR spectra.

For this complex, $Rh(HgOOCCF_3)(OOCCF_3)(quin)(CO)[P(4\text{-}CH_3O\text{-}C_6H_4)_3]$, both ^1H NMR and ^{31}P NMR spectra (Table 2) show two groups of signals. In the former case, these appear as two singlets at δ 3.8 and 3.7 ppm, assigned to the protons of the CH_3O group of the phosphine ligand. In the second case, two doublets at δ 31.8 and 29.5 ppm [^1J(Rh—P) 124.0 and 120.9 Hz, respectively] were observed. A similar spectrum is obtained for the $Rh(HgOOCCF_3)(OOCCF_3)(pyC)(CO)[P(4\text{-}CH_3\text{-}C_6H_4)_3]$ complex. The presence in solution of a mixture of rhodium(III) isomers[7] could therefore be suggested.

The decarbonylated products obtained from the above compounds in acetone solution can be formulated as $Rh(OOCCF_3)_2(N\text{-}O)(H_2O)[P(4\text{-}X\text{-}C_6H_4)_3]$ on the basis of the analytical and spectroscopic data.

The IR spectra of these compounds in KBr pellets (Table 1) do not exhibit a CO stretching frequency. An absorption at *ca* 3300 cm^{-1} was assigned to $\nu(OH)$ of the coordinated water. A complicated group of bands appears in the region 1750–1620 cm^{-1}. Due to the presence of different carboxylate groups and coordinated water in the complex, the assignment of these bands is very difficult.

The complex $RH(OOCCF_3)_2(quin)(H_2O)[P(4\text{-}CH_3O\text{-}C_6H_4)_3]$ exhibits two singlets at δ 3.9 and 3.8 ppm in its ^1H NMR spectrum (Table 2), suggesting that two isomer species could be present in the decarbonylated derivatives. This fact is also confirmed by the ^{31}P NMR spectrum, and the presence of two doublets at δ 29.7 ppm, ^1J(Rh—P) 119.6 Hz and δ 27.9 ppm, ^1J(Rh—P) 116.6 Hz were observed, the first more intense than the second.

In order to characterize unambiguously these carboxylate rhodium(III) species, the crystal structure of one of these complexes, $Rh(OOCCF_3)_2(quin)(H_2O)[P(4\text{-}CH_3\text{-}C_6H_4)_3]$, has been determined. Bond lengths and angles are shown in Table

Table 2. ^{1}H NMR and ^{31}P NMR spectral data [δ (ppm), J(Hz)]

3. The geometry of the molecule is shown in Fig. 1.[13]

The coordination around the rhodium is a distorted octahedral with the equatorial positions occupied by the bidentate quinaldinate ligand and two O-monodentate $OOCCF_3$ ligands. One apical position is occupied by the $P(4\text{-}CH_3\text{-}C_6H_4)_3$ ligand and the other one is occupied by a molecule of water.

The oxygen atom [O(7)] of the water molecule is linked with one oxygen atom [O(4)] of the quinaldinate ligand of the nearest neighbouring molecule through an intermolecular hydrogen bond. It is also linked with two oxygen atoms [O(2), O(6)] of the two trifluoroacetate ligands through an assymetrically, bifurcated, intramolecular hydrogen bond. The geometrical features of the hydrogen bonds' network are shown in Fig. 2.

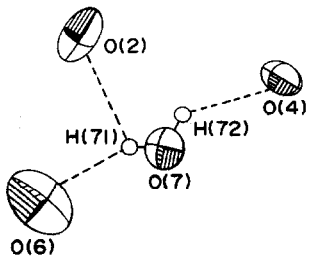

Fig. 2. The geometrical features of the hydrogen bonds. Bond distances (Å) and angles (°): O(7)—H(71), 0.707(123); O(7)—H(72), 0.747(120); O(2)—H(71), 2.413(118); O(6)—H(71), 2.081(135); O(4)—H(72), 2.134(216). H(71)—O(7)—H(72), 116.1(13.5).

So, it appears that in the evolution of the initial Rh—Hg compounds the ligands linked to mercury migrate to the rhodium atom in the decarbonylated complex.

As an extension of the above results we have studied the reactivity of the Rh(N-O)(CO)[P(4-X-$C_6H_4)_3$] complexes towards $Hg(Ph)(OOCCF_3)$. We have then obtained new σ-Rh—Ph organometallic compounds. The crystal structure of one of these complexes has been recently published.[8]

The reactions of Rh(quin)(CO)[P(4-X-$C_6H_4)_3$] with $Hg(Ph)(OOCCF_3)$ lead to the compounds formulated as $Rh(HgPh)(OOCCF_3)$(quin)(CO) [P(4-X-$C_6H_4)_3$] on the basis of analytical and spectroscopic data.

When the starting compounds were Rh(pyC)(CO) [P(4-X-$C_6H_4)_3$], we have not been able to obtain pure reaction products. In a 1 : 1 molar ratio, Rh : Hg, at low temperature and very short reactions times, mixtures of the parent compound and oxidative addition product were obtained. An increase in the molar ratio and/or the reaction time led to decomposition products. This difference in behaviour between 2-pycolinate and 2-quinaldinate starting compounds can be explained by the higher electron density of the rhodium atom in the 2-quinaldinate, than in the 2-pycolinate derivatives.

The IR spectra in the solid state (Table 1) of the new compounds $Rh(HgPh)(OOCCF_3)$(quin)(CO)[P(4-X-$C_6H_4)_3$] show the characteristic absorptions of the present ligands. The values of the ν(CO) relative to the parent compounds are consistent with the formation of oxidative addition

products. A strong absorption at 1658–1655 cm^{-1} with a shoulder at 1640–1633 cm^{-1} was assigned to the ν_{as}(OCO) of the carboxylate groups of the $OOCCCF_3$ and quinaldinate ligands. In contrast to the IR spectra of the above $Hg(OOCCF_3)_2$ derivatives, no bands attributed to the $OOCCF_3$ group bonded to the mercury atom appear in these spectra. This suggests that in the derivatives with $Hg(Ph)(OOCCF_3)$ the $OOCCF_3$ group is directly bonded to the rhodium atom.

The ^1H NMR spectrum of $Rh(HgPh)(OOCF_3)$(quin)(CO)[P(4-CH_3O-$C_6H_4)_3$] (Table 2) shows two singlets, one which is very intense at δ 3.75 ppm and the other weaker at δ 3.7 ppm. The ^{31}P NMR spectrum (Table 2) exhibits an intense signal centred at δ 31.8 ppm, split by coupling with the rhodium atom [^1J(Rh—P) 124.0 Hz], and a weak doublet centred at δ 31.9 ppm with ^1J(Rh—P) 123.0 Hz. The above data seem to confirm again the presence, in solution, of two isomeric forms of the new

rhodium(III) complexes, one of them more abundant than the other.

The addition of the (HgPh) and ($OOCCF_3$) groups to the rhodium atom of the square-planar parent compounds agrees with the related reactions with HgPhCl.[4,7]

The ^{13}C NMR spectrum of Rh(HgPh)($OOCCF_3$)(quin)(CO)[P(4-CH_3O-C_6H_4)$_3$] (Table 4) confirms this behaviour by the appearance of ^{199}Hg satellites on the signals of the carbon atoms of the phenyl ligand. The J(Hg—C) values are lower than in the free Hg(Ph)($OOCCF_3$), and they appear intermediate between those of $Hg(Ph)_2$ and HgPhCl.[14] The above results agree with the bonding of the phenyl group to the mercury atom in the oxidative addition products.

The aromatic carbons show two signals of different intensity in almost all of these cases. This fact agrees with the presence of the isomer mixture suggested above. It has not been possible to detect the carbonyl signal after 2 h, and it was not possible to use a longer time period because of the evolution of the compound in solution.

This evolution of the carbonylated rhodium(III) compounds leads to the formation of the crystalline complexes Rh(Ph)($OOCCF_3$)(quin)(H_2O)[P(4-X-C_6H_4)$_3$]. The crystal structure of one of these derivatives (X = F) has been described[8] and shows that new σ-organometallic compounds can be obtained in this way.

The ^1H NMR and ^{31}P NMR spectra of Rh(Ph)($OOCCF_3$)(quin)(H_2O)[P(4-CH_3O-C_6H_4)$_3$] (Table 2) show the same pattern that we have observed in all of the compounds studied above.

In the ^{13}C NMR spectrum of this complex (Table 4), the signals assigned to the carbon atoms of the phenyl group appear at lower δ values than in the mercuric starting compound. The spectrum shows the signals of the α- and β-carbons in the phenyl as doublets by coupling with the rhodium atom. As in the mercuric starting compound, two signals of different intensity for most of the carbon atoms of the phenyl and phosphine ligands are observed due to the presence of isomers in solution. The signals from the CF_3 group and quinaldinate ligand are weak and their assignment is not straightforward.

The ^{13}C NMR spectra of Hg(Ph)($OOCCF_3$) and Rh(quin)(CO)[P(4-CH_3O-C_6H_4)$_3$] have also been recorded for comparison (Table 4).

EXPERIMENTAL

IR spectra were recorded on a 1300 Perkin–Elmer spectrophotometer (over the 4000–200 cm^{-1} range) with KBr pellets. Analyses (C, H, N) were carried out by Elemental Microanalyses Laboratories Ltd., Devon, U.K. ^1H, ^{31}P and ^{13}C NMR spectra were recorded on a Varian XR-300 spectrometer at room temperatures, using TMS and 85% H_3PO_4 as standards. The reactions were carried out at room temperature, under oxygen-free nitrogen. Complexes Rh(N-O)(CO)[P(4-X-C_6H_4)$_3$] were prepared by our published methods.[6,10] Commercial $Hg(OOCCF_3)_2$ was used. Hg(Ph)($OOCCF_3$) was prepared by the method of Abbate and Ulrich.[16]

Solution and refinement of the crystal structure

A summary of the fundamental crystal data for the Rh($OOCCF_3$)$_2$(quin)(H_2O)[P(4-CH_3-C_6H_4)$_3$] is given in Table 5.

The heavy atom was located from the three dimensional Patterson map. The remaining non-hydrogen atoms were located in a Fourier synthesis.

An empirical absorption correction[17] was applied at the end of the isotropic refinement. Mixed full-matrix refinement with unit weights led to $R = 0.076$. The fluorine atoms of the trifluoroacetate ligands were refined isotropically because of some unsolved disorder from thermal motion. A difference synthesis calculated with reflections having $\sin\theta/\lambda < 0.5$ A^{-1} showed all hydrogen atoms as the highest peaks of the map. Final refinement with isotropic temperature factors and coordinate for the hydrogen atoms, except the hydrogen atom of the coordinated water molecule, produced $R = 0.073$.

Most of the calculations were carried out with the X-Ray 80 system.[18] Final atomic positional and thermal parameters, bond lengths and angles, and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

Preparation of the complexes

Rh(HgO$OCCF_3$)($OOCCF_3$)(pyC)(CO)[P(4 - X - C_6H_4)$_3$] (X = CH_3O, CH_3, F, Cl). To a suspension of Rh(pyC)(CO)[P(4-X-C_6H_4)$_3$] (0.1 mmol) in acetone, a 1 : 3 molar excess of $Hg(OOCCF_3)_2$ was added in the dark. After 30 min of stirring Hg^0 appeared and the solution was filtered through Kiesselghur. The solvent was partially removed and the yellow product was precipitated by addition of diethyl ether and n-hexane, filtered off, washed with Et_2O/hexane and dried *in vacuo*. Yield: 60–75%.

Rh(HgO$OCCF_3$)($OOCCF_3$)(quin)(CO)[P(4 - X - C_6H_4)$_3$] (X = CH_3O, CH_3, F, Cl). The procedure was similar to the above synthesis except the reac-

tion time was 2 h and the molar ratio was 1:2 Rh:Hg. Yield: 65–80%.

$Rh(OOCCF_3)_2(pyC)(H_2O)[P(4\text{-}X\text{-}C_6H_4)_3]$ (X = CH_3O, CH_3, F, Cl). These complexes were obtained as above with more prolonged reaction times, *ca* 3 h. Yield: 50–55%.

$Rh(OOCCF_3)_2(quin)(H_2O)[P(4\text{-}X\text{-}C_6H_4)_3]$ (X = CH_3O, CH_3, F, Cl). Solutions of $Rh(HgOOCCF_3)(OOCCF_3)(quin)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$ in acetone/Et_2O/hexane yielded after 3 days under N_2, yellow crystals of $Rh(OOCCF_3)_2(quin)(H_2O)[P(4\text{-}X\text{-}C_6H_4)_3]$ and the deposition of mercury. The crystals were filtered, washed with hexane and dried *in vacuo*. Yield: 25–30%.

$Rh(HgPh)(OOCCF_3)(quin)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$ (X = CH_3O, CH_3, F, Cl). An excess of $Hg(Ph)(OOCCF_3)$ (X = CH_3O, 50%; X = CH_3, 10%; X = F, 75%; X = Cl, 100% of excess) was added to a suspension of $Rh(quin)(CO)[P(4\text{-}X\text{-}C_6H_4)_3]$ (0.1 mmol) in acetone. The light yellow solutions were stirred (X = CH_3O, 55 min; X = CH_3, 30 min; X = F, 70 min; X = Cl, 85 min) and filtered through Kiesselghur to eliminate the Hg^0 that had appeared. The solutions were concentrated under reduced pressure and the yellow solids were precipitated by addition of cold Et_2O/hexane, filtered off, washed with hexane and dried *in vacuo*. Yield: 75–85%.

$Rh(Ph)(OOCCF_3)(quin)(H_2O)[P(4\text{ - }X\text{ - }C_6H_4)_3]$ (X = CH_3O, CH_3, F, Cl). These compounds were obtained by evolution of the above compounds in acetone/Et_2O/hexane solution under N_2. After 2 days, the yellow crystals were filtered, washed with hexane and dried *in vacuo*. Yield: 30–35%.

ELECTROCHEMICAL SYNTHESIS OF PYRIDINE-2-THIONATO COMPLEXES OF ZINC(II) AND CADMIUM(II): THE CRYSTAL STRUCTURE OF 1,10-PHENANTHROLINE-BIS(PYRIDINE-2-THIONATO)ZINC(II)

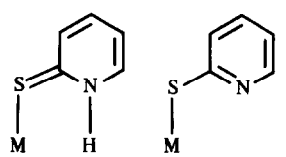
M. L. DURAN, J. ROMERO, J. A. GARCIA-VAZQUEZ, R. CASTRO, A. CASTIÑEIRAS and A. SOUSA*

Departamento de Química Inorgánica, Universidad de Santiago, Santiago de Compostela, Spain

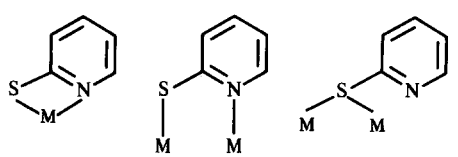
(*Received* 16 *February* 1990; *accepted* 30 *August* 1990)

Abstract—Zinc and cadmium pyridine-2-thionato complexes, $M(pyt)_2$, were prepared by direct electrochemical oxidation of the metal into a solution of pyridine-2-thione (pytH) in acetonitrile. Adducts of type $[M(pyt)_2L]$ (L = 2,2′-bipyridine or 1,10-phenanthroline) were obtained by addition of the ligand to the electrolyte phase. X-ray structure determination of $[Zn(pyt)_2phen]$ shows the molecule to have a distorted octahedral *trans*-ZnS_2N_4 core, with average bond distances of 2.182 Å for Zn—N(phen), 2.061 Å for Zn—N(pyt) and 2.586 Å for Zn—S. The vibrational, ^1H and ^{13}C NMR spectra of the compounds are discussed.

The coordination chemistry of heterocyclic thione donors is an area of great interest, especially due to their wide ranging applications.[1] Particular attention has been focussed on metal-containing compounds of pyridine-2-thione (pytH) because of their useful biological activity (see for example,[1] the use of zinc and platinum pyridine-2-thione complexes as antibacterial and anti-tumour agents, respectively) and also due to their important biological role; pytH can be considered as a model of a thiolated nucleoside such as 6-thioguanosine.[2] Moreover, the importance of zinc–sulphur compounds in biochemical processes has been known for the last few years, since they are present, from cysteine, in a number of DNA and RNA binding proteins.[3] Consequently, there is much current interest in preparing complexes of ligands bearing sulphur atoms to act as models for zinc–cysteine centres in metalloproteins.[4–6] Among sulphur ligands, pyridine-2-thione is one of the most versatile and unique, since it can behave in two ways: (i) as a neutral ligand (pytH) through the sulphur atom (**1**),[7–9] (ii) as an anionic ligand (pyt), acting in this case as a monodentate (**2**)[9,10] bidentate (**3**)[9–11] or bridging (**4**,[8,12] **5**)[13] ligand.



(1) (2)



(3) (4) (5)

This paper reports the electrochemical synthesis and properties of some thionato complexes of zinc and cadmium. Although the compound $[Zn(pyt)_2]$ has been prepared before by another method, and has been attributed a dimeric structure on the basis of mass spectral data and osmometric molecular weight determination,[14] the other compounds reported in this article have not, as far as we know,

* Author to whom correspondence should be addressed.

been synthesized before. The X-ray structure of 1,10 - phenanthroline - bis(pyridine - 2 - thionate) zinc(II) is also described. This compound, to our knowledge, represents the first example of an octahedral complex of zinc(II) with thiolate ligands, which contrasts with the tetrahedral geometry commonly observed in other zinc thiolate complexes.[15-18]

EXPERIMENTAL

Acetonitrile, pyridine-2-thione (pytH), 1,10-phenanthroline (phen) and 2,2'-bipyridine (bipy) were all commercial products and were used without further purification. Zinc and cadmium (Ega Chemie) were used as plates (*ca* 2 × 2 cm).

Preparation of complexes

The electrochemical procedure followed was similar to that described in an earlier paper.[19] A solution of pytH in acetonitrile together with a few milligrams of tetramethylammonium perchlorate, added as a supporting electrolyte, were placed into the electrochemical cell containing a platinum wire cathode and an anode derived from zinc or cadmium foil, suspended from a platinum wire. During electrolysis hydrogen was evolved at the cathode and a precipitate of the complex, $M(pyt)_2$, appeared within a few hours. The introduction of phen or bipy into the cell led to the isolation of the corresponding adducts $[M(pyt)_2L]$ (L = phen or bipy).

The cells used can be summarized as:

$$Pt(-)/CH_3CN + pytH/M(+)$$

$$Pt(-)/CH_3CN + pytH + L/M(+)$$

L = phen or bipy.

At the end of electrolysis the products to be isolated were collected, washed with acetonitrile and dried *in vacuo*. The solution composition and electrochemical conditions are given in Table 1.

Physical measurements

The C, N and H contents of the complexes were determined on a Perkin–Elmer 240B microanalyser. The analytical data are given in Table 2. IR spectra were recorded as KBr mulls on a Perkin–Elmer 180 spectrophotometer. ^1H and ^{13}C NMR were recorded on a Bruker WM 250 MHz using $CDCl_3$ or DMSO-d_6 as solvent. The chemical shifts were determined against TMS as an internal standard.

Crystal structure determination

Crystal data for $[Zn(pyt)_2(phen)]$: $C_{22}H_{16}N_4S_2Zn$, $M = 465.90$, monoclinic, space group $P2_1/c$, $a = 15.116(2)$, $b = 9.918(2)$, $c = 14.181(3)$ Å, $\beta = 108.20(3)°$, $U = 2019.7$ Å^3, $Z = 4$, $D_c = 1.532$ g cm^{-3}, $F(000) = 952$, $\lambda(Mo\text{-}K_\alpha) = 0.71073$ Å, $\mu = 14.585$ cm^{-1}.

A prismatic crystal (dimensions 0.80 × 0.12 × 0.20 mm) was used for the data collection on a CAD4 automated four-circle diffractometer at room temperature, by the ω–θ scan technique with graphite-monochromated Mo-K_α radiation. 3912 intensities registered to θ_{max} 25, 3536 unique (R_{int} 0.030) of which 1176 with $I > 3\sigma(I)$ were used in refinement. They were corrected for Lorentz–polarization factors; an empirical absorption correction[20] was applied (minimum and maximum values 0.599–1.095). The structure was solved by direct methods. Positional and anisotropic thermal parameters for Zn, S and N atoms and isotropic thermal parameters for remaining non-hydrogen atoms were refined by full-matrix least-squares. Hydrogen atoms were not located. Weighting scheme $W^{-1} = \sigma^2(F)$. The agreement factor converged to $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.065$,

Table 1. Experimental conditions for the electrochemical synthesis

Compound	Amount of pytH (g)[a]	Amount of ligand (g)	Initial voltage (V)[b]	Time (h)	Metal dissolved (mg)	E_f (mol F^{-1})
$Zn(pyt)_2$	0.300	—	25	2	50.7	0.52
$[Zn(pyt)_2bipy]$	0.165	0.300	20	2	45.0	0.46
$[Zn(pyt)_2phen]$	0.400	0.300	25	2	52.0	0.53
$Cd(pyt)_2$	0.150	—	20	1.5	65.0	0.52
$[Cd(pyt)_2phen]$	0.400	0.300	15	2	83.0	0.49

[a] Plus $[NEt_4]ClO_4$ (*ca* 10 mg).
[b] Voltage to produce a current of 20 mA.

Table 2. Analytical data for the complexes

Compound	Found (calc.) (%)		
	C	N	H
$Zn(pyt)_2$	42.4(42.1)	9.2(9.8)	3.0(2.8)
$[Zn(pyt)_2bipy]$	54.3(54.4)	12.7(12.7)	3.5(3.6)

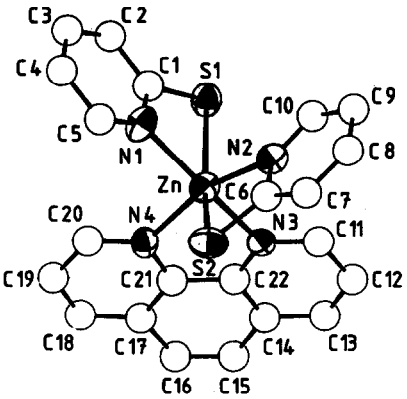

Fig. 1. The molecular structure of $[Zn(pyt)_2phen]$.

$R' = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2]^{1/2} = 0.070$, 153 parameters; S 3.408; maximum Δ/σ 0.001; maximum $\Delta\rho$ 0.488 eA^{-3}. Neutral scattering factors were used.[21] Computations were performed on a DEC MicroVAXII computer using SHELXS[22] and SPD/VAX.[23] The atomic positions, full lists of bond lengths and angles and other crystallographic data have been deposited as Supplementary Material.

RESULTS AND DISCUSSION

The electrochemical oxidation of zinc or cadmium in non-aqueous solutions of pyridine-2-thione is an efficient and simple route to the appropriate $M(pyt)_2$ compounds, and a slight modification, such as the introduction of the neutral bidentate donors 2,2'-bipyridine or 1,10-phenanthroline into the electrochemical cell, serves to provide $[M(pyt)_2L]$ adducts.

The electrochemical efficiency, defined as the amount of metal dissolved per Faraday of charge, is close to 0.5 mol F^{-1} for the synthesis of both $M(pyt)_2$ and $[M(pyt)_2L]$ compounds, showing clearly that adduct formation takes place via a process occurring after the anodic formation of $M(pyt)_2$. This E_F value, together with the evolution of hydrogen gas at the cathode, is compatible with the following reaction scheme:

$$\text{Cathode} \quad 2pytH + 2e^- \longrightarrow H_2(g) + 2pyt^-$$

$$\text{Anode} \quad 2pyt^- + M \longrightarrow [M(pyt)_2] + 2e^-$$

$$2pyt^- + M + L \longrightarrow [M(pyt)_2L] + 2e^-$$

M = Zn or Cd; L = phen or bipy.

The compounds obtained were characterized by IR and ^1H and ^{13}C NMR spectroscopy, and in the case of 1,10-phenanthroline-bis(pyridine-2-thionato)zinc(II) by X-ray diffraction.

Structure of $[Zn(pyt)_2phen]$. The molecular structure of $[Zn(pyt)_2phen]$ (Fig. 1) is based on ZnN_4S_2 octahedral geometry, necessarily distorted as the result of the bidentate character of the ligands. The coordination at zinc involves one bidentate 1,10-phenanthroline molecule and two bidentate pyridine-2-thionato ligands. The arrangement of the pyridine-2-thionato ligands is such that the sulphur atoms are *trans* to each other. The basal plane is formed by the 1,10-phenanthroline nitrogen atoms and two nitrogen atoms from the pyridine-2-thiolato ligands and the inner coordination sphere is completed by two sulphur atoms at greater distances from the zinc atom. The four "in plane" atoms N(1), N(2), N(3) and N(4) are not coplanar; N(2) and N(4), which are *trans* to each other, lie −0.2541 and −0.3153 Å, respectively, below the least-squares plane through the four atoms, while N(1) and N(3) are +0.2553 and +0.3141 Å, respectively, above this plane; the zinc atom lies nearly in the plane, sitting 0.06 Å above it. This non-planarity gives rise to N(1)—Zn—N(3) and N(2)—Zn—N(4) angles of 156.2(2) and 162.9(2)°, respectively, instead of the anticipated 180°.

Further distortion is caused by the small bite of the 1,10-phenanthroline and the pyridine-2-thionato ligands, whose N(3)—Zn—N(4) and S—Zn—N chelate angles are *ca* 76 and 66°, respectively. The S(1)—Zn—S(2) angle is also distorted from 180 to 160.32(9)°. These values are hardly different from those reported for other bidentate 1,10-phenanthroline[24,25] or pyridine-2-thionato[9,26,27] metal complexes.

The phenanthroline ligand is essentially planar, with no atom deviating from the least-squares plane by more than 0.02 Å. The bond lengths and angles within the ligand are similar to those found in other phenanthroline complexes.[25,28] The pyridine portion of the pyridine-2-thionate ligands is also planar, while the associated sulphur atoms are above the plane [0.106 Å for S(1) and 0.129 Å for S(2)] of the pyridine ring to which they are bound. The average N—C (1.338 Å), S—C (1.716 Å) and

C—C (1.41 Å) bond distances in the pyridine-2-thionato ligand are close to those observed in other bidentate pyridine-2-thionato metal complexes, in which this ligand is bound in its thionate form.[9,26,27]

As can be seen in Table 3, the Zn—N(phen) bond distances (average value 2.182 Å) do not differ significantly from those found for the octahedral $[Zn(O_2C_6H_4)(phen)_2]$ (2.189 Å),[24] but they are slightly greater than those in the tetrahedral $[phenZnCl_2]$ [2.072(7), 2.050(7) Å],[29] corresponding to the change in coordination number from four to six. The Zn—N(pyt) bond lengths (average value 2.106 Å) are considerably larger than those reported for several tetrahedral pyridine complexes of zinc(II), which have Zn—N distances in the range 2.040–2.060 Å[30] and are even slightly greater than those found in the octahedral dinitritobis (pyridine)zinc(II), 2.063, 2.068 Å and dinitritobis(2-methylpyridine)zinc(II), 2.071 Å.[31] It is clear that Zn—N bond distances in $[Zn(pyt)_2phen]$ are somewhat longer than those generally observed in analogous complexes. This is probably due to the steric strain produced by the four-membered chelate rings. The Zn—S bond lengths, 2.627(2) and 2.546(3) Å, are significantly larger than those reported for several distorted tetrahedral thiolate complexes, which have Zn—S distances in the range 2.25–2.36 Å.[6,15,32] At present, no Zn—S(thiolate) bond distance estimation in octahedral complexes is available for comparison with the Zn—S bond length in $[Zn(pyt)_2phen]$.

Vibrational spectra. The IR spectra of the complexes show no bands which are assignable to ν(N—H) (3160 cm^{-1} in the free ligand) and the shifts exhibited by the ring stretching, C—H in-plane deformation and ring breathing bands are essentially identical in all complexes, suggesting that the cordination of the pyt ligand must be similar in these compounds. In addition, the mixed complexes show IR absorptions typical of coordinated 1,10-phenanthroline and 2,2′-bipyridine.[33]

NMR spectra. The ^1H NMR spectra show that

the NH broad singlet of the free pyridine-2-thione at about 13.43 ppm is absent in the metal complexes, indicating that deprotonation of this group has occurred and, therefore, that this ligand is coordinated in the thionato form. Moreover, the complexes exhibit four distinct and widely separated signals of equal intensity, assignable to the four non-equivalent hydrogens of pyt$^-$ ligands. The lowest field signals attributable to H(6) appear as doublets, which is consistent with the chelating character of pyt$^-$ ligands.[9]

In the case of the mixed complexes, $[M(pyt)_2phen]$, the signals attributable to 2,9- and 3,8-protons undergo a small down-field shift with respect to the free ligand. This shift has been taken as proof of coordination of 1,10-phenanthroline,[34,35] in agreement with the X-ray diffraction structure for the corresponding zinc complex (*vide supra*). In the case of $[Zn(pyt)_2bipy]$, the coordination of 2,2′-bipyridine is inferred by the down-field shift of the signal attributed to the 3,3′- and the up-field shift of the signal of the 6,6′-protons.[36] This behaviour can be taken as proof that the coordination number of the zinc and cadmium atoms in these mixed complexes is six.

The ^{13}C NMR spectra of free ligand (pytH), phen and those complexes which are sufficiently soluble are shown in Table 4. Significant changes occur in the position of the signals of carbons of the pytH ligand[37] whereas smaller shifts are observed in the spectrum of 1,10-phen upon coordination. The most important feature of the spectrum is the C(2) signal, which is shifted towards high field with respect to the free ligand (pytH). This behaviour has been interpreted in terms of a reduction of the C=S bond order,[38] which is consistent with the ligand (pyt$^-$) having a higher contribution of the thionato form (*vide supra*) in the complex than in the free pyridine-2-thione.

Abstract—The ground state electronic properties of the mixed-valence clusters $Fe_7S_6(PEt_3)_4Cl_3$ (**1**), $Fe_6S_6(PEt_3)_4L_2$ [L = Cl^- (**2**), Br^- (**4**), I^- (**5**) and PhS^- (**6**)], $Fe_6Se_6(PEt_3)_4Cl_2$ (**3**) and $[Fe_6S_6(PEt)_6]^{1-}$ (**9**), have been investigated by magnetic susceptibility, magnetization and Mössbauer spectroscopic measurements. Cluster **1** has a (idealized C_{3v}) monocapped prismane structure and clusters **2–6** and **9** adopt the C_{2v} "basket" configuration based on the $[Fe_6(\mu_2\text{-}S)(\mu_3\text{-}S)_4(\mu_4\text{-}S)]^{2+,1+}$ core unit. From magnetic properties, the ground states $S = 1/2$ (**1**, **9**) and $S = 1$ (**2–5**) were established. Unlike the other clusters, **6** did not show a Curie region of susceptibility; its ground state was not directly determined but is probably $S = 1$. Mössbauer spectra were successfully analysed in terms of a 1 : 1 : 1 iron site population. Isomer shifts and quadrupole splittings were assigned to each site. Magnetically perturbed spectra obtained in applied fields of 60–80 kOe were analysed to give the magnetic hyperfine parameters and magnetic hyperfine fields in clusters **1–5** and **9**. The magnetic spectra demonstrate antiferromagnetic spin coupling which affords the indicated ground states.

Nearly all iron–sulphur clusters are characterized by core structures that are built up entirely by vertex-sharing and/or edge fusion of Fe_2S_2 rhombs.[1,2] The prototype single planar rhomb is found in the binuclear species $[Fe_2S_2L_4]^{2-}$. Clusters proceed in complexity from this type to those with nuclearities 3, 4, 6, 7, 8 and 18.[2,3] Excluding organometallics and with the exception of $[Fe_6S_8(PEt_3)_6]^{2+,1+}$ [4,5] in the preceding set, these clusters have as terminal ligands, halide, RS^- or RO^-. The electronic properties of many of these materials have been probed by application of Mössbauer spectroscopy and by magnetization and magnetic susceptibility measurements. For example, the ground spin states and associated matters of the electronic structures of cubane-type $[Fe_4S_4(SR)_4]^{3-,2-,1-}$ clusters have been eluciated in some detail by these methods.[6–8] All of these clusters have the common property of molecular antiferromagnetism.

As part of our work on higher-nuclearity Fe—S clusters, we have recently prepared and described the structures and certain reactivity aspects of a new series of hexa- and heptanuclear clusters.[3,9–12] These differ from the above in having a mixed ligand set that includes tertiary phosphines and core structures not yet found in the absence of phosphine. With reference to Fig. 1, the core geometry of $Fe_7S_6(PEt_3)_4Cl_3$[9] (**1**) approaches that of a monocapped hexagonal prism, while that of $Fe_6S_6(PR_3)_4L_2$, L = halide[10,11] (**2–5**, **7**) and thiolate[3] (**6**, **8**), and $[Fe_6S_6(PEt_3)_6]^{1+}$ [12] (**9**) resembles a basket, with the lower Fe—S—Fe fragment, which

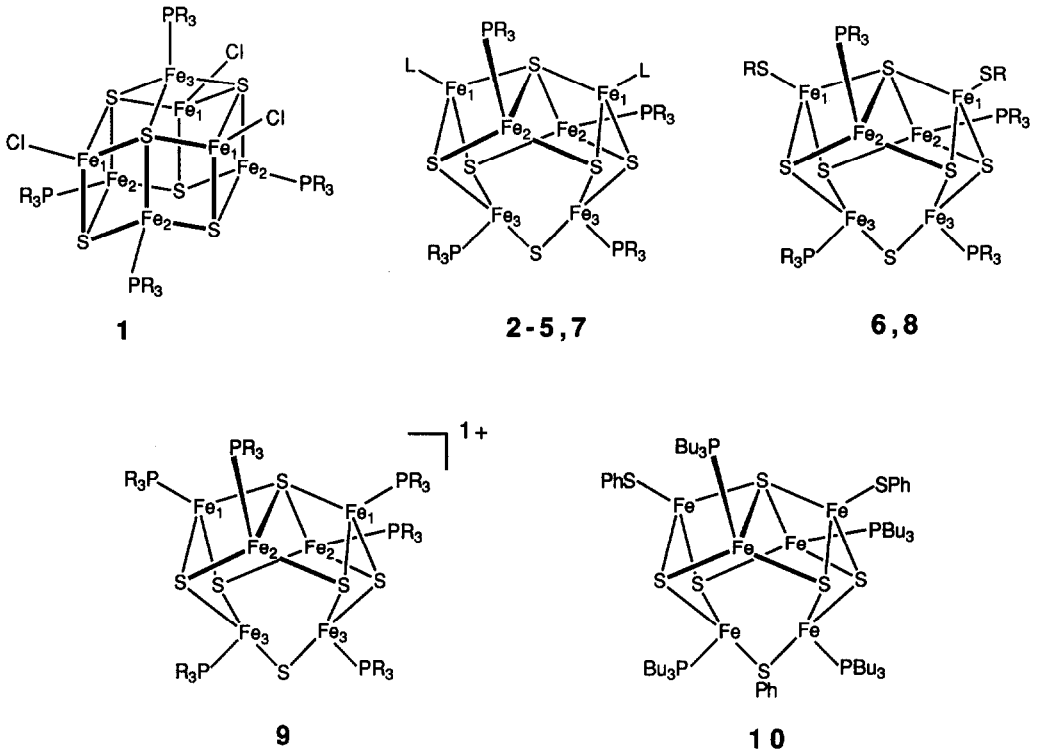

Fig. 1. Schematic structures of clusters **1–10** illustrating the monocapped prismane (**1**) and basket (**2–10**) topologies. Iron atoms are labelled so as to correspond to the site assignments in Table 2.

is not part of the aforementioned rhomb, serving as the handle. We designate these as "basket" clusters, as a means of distinguishing their $[Fe_6S_6]$ core topology from the idealized hexagonal prisms present in the "prismane" clusters, $[Fe_6S_6L_6]^{2-,3-}$.[13–16] The structures of $Fe_6S_6(PBu_3)_4Cl_2$,[11] $Fe_6S_6(PEt_3)_4(S\text{-}p\text{-}C_6H_4Br)_2$[3] and $[Fe_6S_6(PEt)_6]^{1+}$[12] define the basket topology, which is manifested in virtually isometric $[Fe(\mu_2\text{-}S)(\mu_3\text{-}S)_4(\mu_4\text{-}S)]^{2+,1+}$ core units. This unique topology is supported, in part, by the unusual coordination at the FeS_3P sites. Whereas FeS_3L sites in these and numerous other clusters have a distorted tetrahedral configuration, the phosphine-ligated sites exhibit a roughly trigonal pyramidal geometry, with the Fe atom closely approaching the S_3 plane. These species are also among the most reduced Fe—S clusters, with Fe mean oxidation states of +2.14 in $Fe_7S_6(PEt_3)_4Cl_3$, +2.17 in $[Fe_6S_6(PEt_3)_6]^{1+}$ and +2.33 in $Fe_6S_6(PEt_3)_4L_2$. As a result of their high nuclearities, unusual ligand sets and previously unencountered core structures, these molecules are of current interest as the newest additions to the extensive family of Fe—S clusters, which now encompasses seven nuclearities and 10 core structural types.[1–3] Most of these clusters exist in two or more oxidation levels, some of which have been isolated.

Their unique core structure suggests that the basket clusters may have unusual electronic features. Ground state properties, previously uninvestigated, have been examined by magnetic and Mössbauer techniques, and the leading results are reported here.

EXPERIMENTAL

Preparation of compounds

The compounds $Fe_7S_6(PEt_3)_4Cl_3$ (**1**),[9] $Fe_6S_6(PEt_3)_4Cl_2$ (**2**),[11] $Fe_6Se_6(PEt_3)_4Cl_2$ (**3**),[11] $Fe_6S_6(PEt_3)_4Br_2$ (**4**),[11] $Fe_6S_6(PEt_3)_4I_2$ (**5**),[11] $Fe_6S_6(PEt_3)_4(SPh)_2$ (**6**),[3] $Fe_6S_6(PEt_3)_4(S\text{-}p\text{-}C_6H_4Br)_2$ (**8**)[3] and $[Fe_6S_6(PEt_3)_6](BF_4)$ (**9**)[12] were prepared as previously described.

Physical measurements

All measurements were performed under strict anaerobic conditions. Magnetic susceptibility and magnetization measurements at applied fields of 10 kOe and up to 50 kOe, respectively, were carried out on a SHE 905 SQUID magnetometer operating between 1.8 and 300 K. Solid state measurements were made on finely ground polycrystalline samples (15–35 mg) loaded into precalibrated containers and

sealed with epoxy resin under a dinitrogen–helium atmosphere. Diamagnetic susceptibility corrections[17] were applied. Mössbauer spectra were determined with a constant-acceleration spectrometer equipped with a ^{57}Co source in a Rh matrix. Zero-field measurements were made between 4.2 and 300 K, with the spectrometer operating in the time mode and the source maintained at room temperature. Magnetically perturbed spectra were obtained in longitudinally applied fields up to 80 kOe, with the source and absorber at 4.2 K. Polycrystalline samples were dispersed in boron nitride powder and sealed with epoxy resin in plastic sample holders. Isomer shifts are reported relative to Fe metal at 4.2 K. EPR spectra were recorded at X-band frequencies at *ca* 19 K on a Varian E-109 spectrometer. Solution susceptibilities were determined by a NMR method.[18] Solvent susceptibilities were taken from the literature[19] and corrections for solution density changes with temperature were applied.

RESULTS AND DISCUSSION

The following clusters, **1–9**, are of primary interest in this investigation. The monocapped prismane structure of **1** has been crystallographically established.[9] The basket configurations are assigned to **2–6** on the basis of the crystal structures of **7** and **8**, and the correspondence of spectroscopic properties to those of the structurally defined clusters. All clusters are mixed-valence but individual Fe^{II} or Fe^{III} sites, if present, cannot be recognized unambiguously from crystallographic data. As will be seen, ^1H NMR spectra are consistent with retention of the basket structure of halide clusters in solution. $Fe_7S_6(PEt_3)_4Cl_3$ (**1**); $Fe_6S_6(PEt_3)_4Cl_2$ (**2**); $Fe_6Se_6(PEt_3)_4Cl_2$ (**3**); $Fe_6S_6(PEt_3)_4Br_2$ (**4**); $Fe_6S_6(PEt_3)_4I_2$ (**5**); $Fe_6S_6(PEt_3)_4(SPh)_2$ (**6**); $Fe_6S_6(PBu_3)_4Cl_2$ (**7**); $Fe_6S_6(PEt_3)_4(S\text{-}p\text{-}C_6H_4Br)_2$ (**8**); $[Fe_6S_6(PEt_3)_6]^{1+}$ (**9**).

Electronic properties

Ground spin states, other magnetic aspects and electronic distributions in clusters **1–7** have been examined using the methods of magnetic susceptibility, magnetization and ^{57}Fe Mössbauer spectroscopy. Related results for cluster **9** have been reported[12] and certain data are included here for comparison purposes. Before each measurement, the purity of a given compound was established from its distinctive, isotropically shifted ^1H NMR spectrum (*vide infra*) previously recorded on an analytical sample.[3,11,12] Magnetic and Mössbauer results are contained in Tables 1 and 2 respectively, and selected data are displayed in Figs 2–7. The numerical designation of Fe sites in Table 2 and Fig. 1 correspond. The Curie constant in the Curie–Weiss law, $\chi^M = C/(T-\theta)$, has the values $C = 0.375$, 1.000 and 1.875 emu K mol^{-1} for pure $S = 1/2$, $S = 1$ and $S = 3/2$ states, respectively, when $g_e = 2$.

(1) $Fe_7S_6(PEt_3)_4Cl_3$

(a) *Magnetism.* This odd-electron cluster formally contains $6Fe^{II} + Fe^{III}$. As shown in Fig. 2, cluster **1** obeys the Curie–Weiss law at 6–45 K, with $C = 0.581$ emu K mol^{-1}. The magnetization was found to be field-independent and to follow a $S = 1/2$ Brillouin function with saturation asymptotically approaching $g_e S\mu_B = 1\mu_B$. The EPR spectrum in frozen THF solution at 20 K (not shown) reveals a nearly isotropic signal at $g_e = 2.02$, consistent with a doublet state. Also present are weaker resonances at $g_e = 5.2$ and 5.5, which may be indicative of a small amount of the $S = 3/2$ state.[8] Physical mixtures of these spin states have been observed with Fe_4S_4 cubane-type clusters.[8] This situation could account (in part) for the positive deviation of the Curie constant from the $S = 1/2$ value and the small shift of magnetization data in the lower H/T region from the best fit for that state. The collective results support an $S = 1/2$ ground state. The negative deviation of the susceptibility from the Curie–Weiss law above 45 K indicates the population of excited levels with $S > 1/2$. At 298 K, the essentially equal solution and solid state magnetic moments of *ca* $4\mu_B$ show that the antiferromagnetic coupling (*vide infra*) is a molecular property.

(b) *Mössbauer spectra.* The monocapped prismane structure of **1** under idealized C_{3v} symmetry contains three Fe sites: Fe(1)(μ_3-S)(μ_4-S_2)$_2$Cl, Fe(2)(μ_3-S)$_2$(μ_4-S)P and Fe(3)(μ_4-S)$_3$P. The Fe(2,3) sites have approximate trigonal pyramidal geometry while the Fe(1) site is more nearly tetrahedral. The Mössbauer spectrum in zero field, shown in Fig. 3, was fit with a constrained site

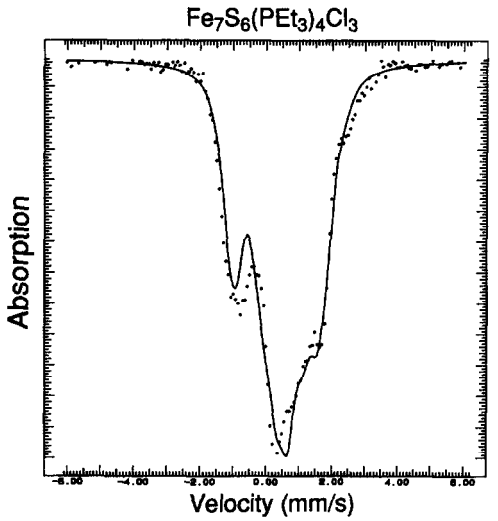

Fig. 4. Mössbauer spectrum of cluster **1** in an applied field of 60 kOe. The solid line is a theoretical fit to the data using the parameters in Table 2 with $S = 1/2$.

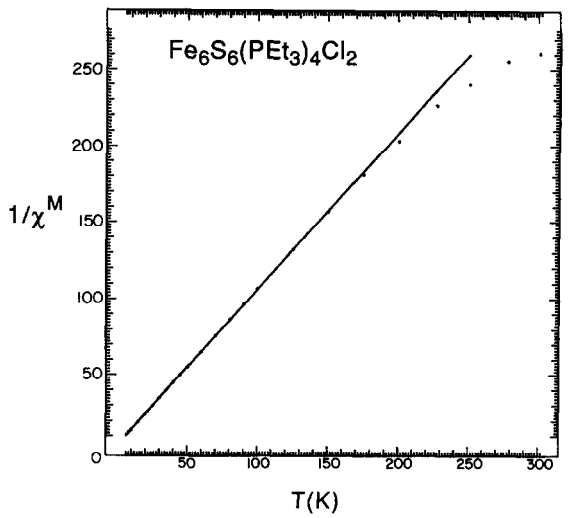

Fig. 5. Temperature dependence of the reciprocal molar susceptibility of cluster **2**. The solid line is a Curie–Weiss fit to the data using the parameters in Table 1.

population of 3:3:1. This allowed immediate identification of the Fe(3) site as that with isomer shift $\delta = 0.36$ mm s^{-1} and the (unusually) small quadrupole splitting $\Delta E_Q = 0.28$ mm s^{-1}. The Fe(2) site is common to **1** and to basket clusters **2–8**, where it also approaches trigonal pyramidal stereochemistry. On the basis of this commonality, the Fe(2) site is assigned the doublet with the same isomer shift as Fe(3), but a larger quadrupole splitting. This leaves the Fe(1) site, at which chloride is bound, as that with the largest isomer shift (0.67 mm s^{-1}). This assignment is consistent with data for the pairs $(Me_4N)_2[FeCl_4]^{20}/Fe(PEt_3)_2Cl_2$ (≈ 0.1 mm s^{-1}) and $(Me_4N)[FeCl_4]^{20}/Fe(PPh_3)Cl_3$[21] ($\approx 0.05$ mm s^{-1}), for which the indicated isomer shift differences correspond to a decrease in δ upon replacing chloride with phosphine.*

Magnetic Mössbauer spectra (not shown) exhibited movement of inner and outer features in opposite directions as the applied field was increased from 60 to 80 kOe, consistent with antiparallel spin coupling. The spectrum at 60 kOe is shown in Fig. 4, together with a theoretical fit obtained using the method described below for the basket clusters and the parameters in Table 2. In this way, the $S = 1/2$ ground state assignment was corroborated.

* Note, however, that the structure of $Fe(PPh_3)Cl_3$ has not been established.

(2) $Fe_6S_6(PEt_3)_4X_2$ (X = Cl^-, Br^-, I^-, PhS^-) *and* $Fe_6Se_6(PEt_3)_4Cl_2$

(a) *Magnetism.* This set consists of the even-electron basket clusters **2–6** which formally contain $4Fe^{II}+2Fe^{III}$. As will be evident, certain electronic aspects of these clusters are unusual and cannot be satisfactorily interpreted. Clusters **2–5** display Curie behaviour of magnetic susceptibilities over appreciable temperature intervals but in several cases with large Weiss constants (Table 1). Curie constants are fairly close to the value for a $S = 1$ state. The results for cluster **2**, which are fairly typical for compounds in this set, are shown in Fig. 5. Deviations from Curie behaviour are such as to indicate the population of higher spin states or a small TIP contribution.

Magnetization data for clusters **2–5** obtained at 1.8–100 K and at three applied fields are presented in Fig. 6. All show nested curves corresponding to different values of the applied field and indicating that the zero-field splitting parameter $D \neq 0$. The data were analysed under the simple spin Hamiltonian (1)

$$H = D[S_z^2 - S(S+1)/3] + E(S_x^2 - S_y^2) + g_e\mu_B\mathbf{H}\cdot\mathbf{S}, \quad (1)$$

with $S = 1$ by calculating the spin projection along the magnetic field direction; E is the rhombic splitting parameter and the other symbols have their usual meanings. The experimental data were simulated from the Curie to the saturation region by

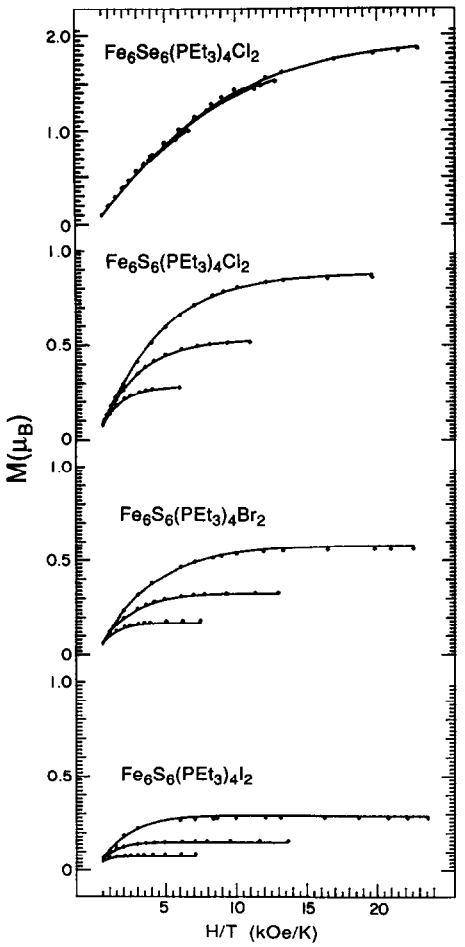

Fig. 6. Magnetization behaviour of clusters **3**, **2**, **4** and **5** (top to bottom). For each cluster, curves in ascending order refer to applied fields of 12.5, 25 and 50 kOe. The solid lines are theoretical fits to the data using the parameters in Table 1.

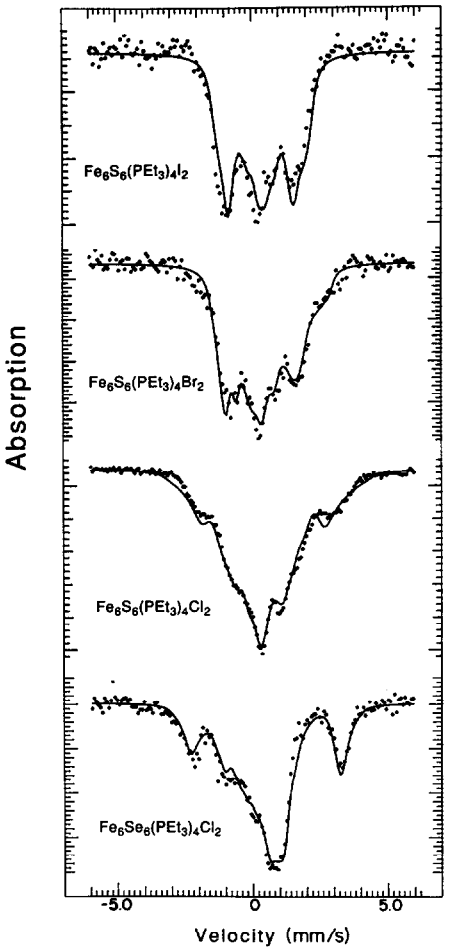

Fig. 7. Mössbauer spectra of clusters **5**, **4**, **2** and **3** (top to bottom) at 4.2 K in an applied field of 80 kOe. The solid lines are fits to the data using the parameters in Table 2 with $S = 1$.

least-squares fits, using a simplex algorithm and the parameters in Table 1. In order to obtain satisfactory fits, it was necessary to use $D < 0$ and $E/D > 0$ with inclusion of $g_e \neq 2$. The algorithm allowed for simultaneous fits of the data at the three applied fields.

The behaviour of cluster **3** is the simplest, in that the saturation magnetization of $2\mu_B$ is nearly reached and the data are well fit with unexceptional parameters for a spin-triplet, including a zero-field splitting (ZFS) of -2.27 cm^{-1}. However, the saturation magnetization of the remaining clusters (**2**, **4**, **5**) becomes increasingly and markedly suppressed in the order X = $Cl^- > Br^- > I^-$, reaching a minimum with cluster **5** ($0.29\mu_B$ at 50 kOe). Fits required increasing large negative D values, which are consistent with the respective Weiss constants. The suppression effect is intramolecular in origin because a magnetization measurement of a 41 mM solution of **4** in dichloromethane yielded essentially the same result as the polycrystalline sample.

While the foregoing treatment of magnetization is obviously phenomenological, it is presented as a means of comparing and contrasting the behaviours of clusters **2**–**5**. The large ZFS are not without precedent and are seemingly within physical reason for **2**–**4**. While no meaningful comparison can be made with other systems, owing to the uniqueness of the basket cluster topology, we note that apparent ZFS values of up to *ca* 20 cm^{-1} have been observed for certain $S = 5/2$ Fe^{III} porphyrins,[22,23] and that for two $S = 1$ planar Fe^{II} complexes values near 70 cm^{-1} have been obtained.[24,25] All of these are obviously *apparent* values, dependent on the theoretical formalism. (For a discussion of this point, cf. ref. 22.) In the present case, we are applying a spin

Hamiltonian formalism to a general case where it has not been otherwise tested; viz. to polynuclear spin-coupled systems with incompletely quenched orbital angular momentum and probable spin–orbit interactions at local metal sites.

Thiolate cluster **6** is the most anomalous member of the set. In the solid state it does not exhibit a Curie region (nor any indication of a Curie paramagnetic impurity), is very weakly paramagnetic at 6 K and shows nesting of magnetization curves with a nearly zero saturation magnetization ($0.1\mu_B$ at 50 kOe; data not shown). It is conceivable that this species represents an extension of the behaviour of **2–5**, but from the information available we are unable to demonstrate the ground state spin. Moreover, in toluene solution, $\mu_{eff} = 2.72\mu_B$, essentially the same as the solution moment for **2**, for which a triplet ground state has been established. On this limited evidence, the $S = 1$ ground state designation has been entered in Table 1. In the solid state the core structures of **8**, the magnetic properties of which are quite similar to those of **6**, and also of **7**, which bears a similar relationship to **2**, are virtually congruent.[3,11] It is unlikely, in either the solid or solution states, that the magnetic differences between **6** and other basket clusters arise from large core structural differences.

(b) *Solution properties.* In dichloromethane solutions at 190–302 K, magnetic moments of clusters **2** and **3** show a near-Curie dependence of magnetic susceptibilities with values consistent with an $S = 1$ ground state. Ranges in magnetic moments over the temperature range are given in Table 1. The larger magnetic moments of selenide cluster **3** vs sulphide cluster **2** in solution and in the solid state (Table 1) are consistent with an earlier observation of smaller antiferromagnetic coupling in Fe_4Se_4 than in Fe_4S_4 clusters.[26] The variable-temperature ^1H NMR spectra of clusters **2** and **3** are presented in Figs 8 and 9, respectively. The occurrence of two equally intense methylene and methyl resonances for **2**, from the inequivalent sites Fe(2,3), over the 190–300 K range, demonstrates retention of the solid state structure in solution. The spectra of **3** are similar but the methyl resonances are not well resolved. Line broadening at the lower temperatures is ascribed to the effect of increasing cluster paramagnetism rather than any dynamic process. The isotropic shifts of **3** are considerably larger than those of **2**, the difference being 32% at 300 K. The effect is qualitatively consistent with the magnetic susceptibilities and suggests that the isotropic shifts have a significant contact component. Other evidence for a contact contribution is the alternating phenyl proton shifts of cluster **6**.[3] However, the shifts of **2** and **3** do not scale linearly with the susceptibilities, as would be the case for pure contact shifts. This indicates the presence of dipolar

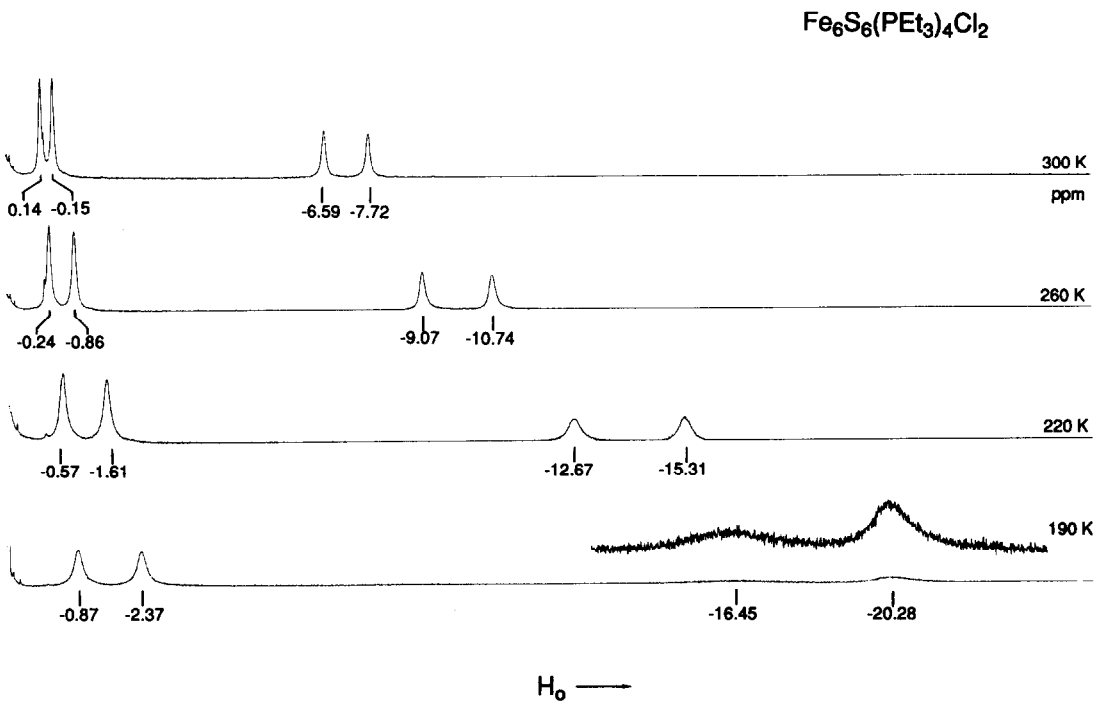

Fig. 8. Temperature dependence of the ^1H NMR spectra of cluster **2** in CD_2Cl_2 solution; chemical shifts are indicated.

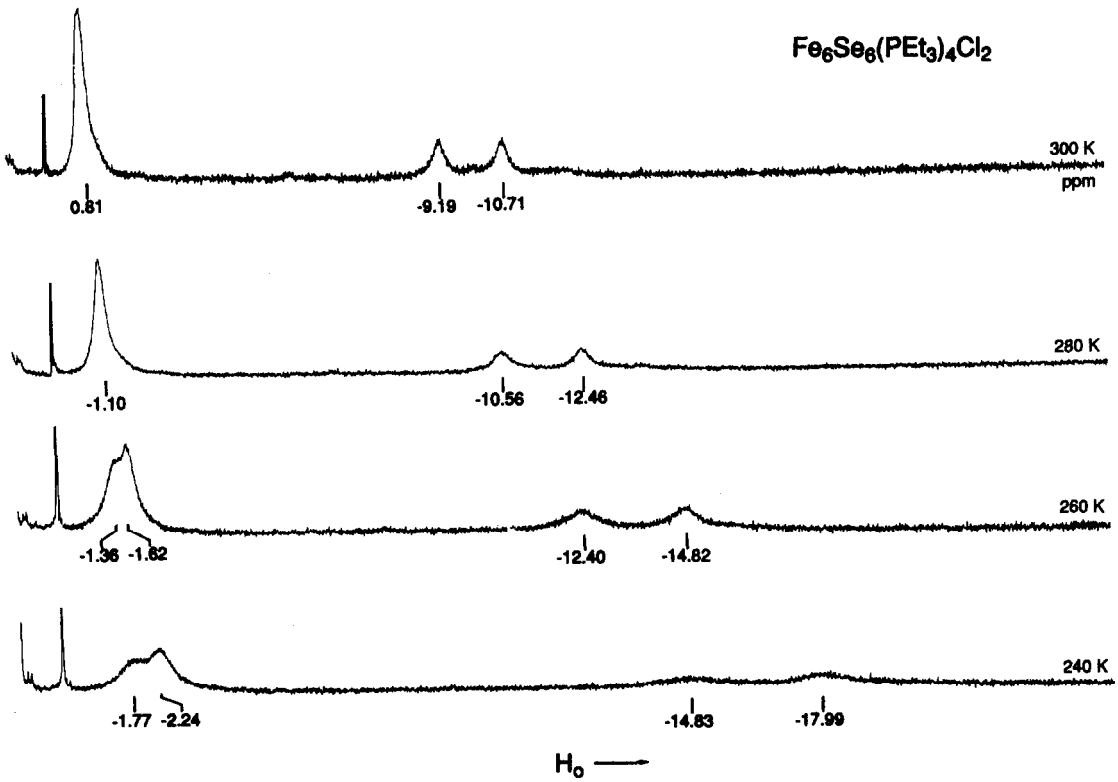

Fig. 9. Temperature dependence of the ^1H NMR spectra of cluster **3** in CD_2Cl_2 solution; chemical shifts are indicated.

shifts, a feature not unexpected in molecules with significant ZFS and magnetic anisotropies.

(c) *Mössbauer spectra.* Basket clusters contain three types of Fe sites (Fig. 1): Fe(1)(μ_3-S)$_2$(μ_4-S)L, Fe(2)(μ_3-S)$_2$(μ_4-S)P and Fe(3)(μ_2-S)(μ_3-S)$_2$P. The first of these is roughly tetrahedral, while the other two have distorted trigonal pyramidal geometry. The zero-field Mössbauer spectra of clusters **2** and **6** are displayed in Fig. 3; the spectrum of **2** closely resembles those of **3**–**5** (not shown), in containing three resolved features. All spectra were analysed with a 1:1:1 Fe site population. The assignment of the Fe(2) site has been discussed; that of the Fe(3) site in **6** is based on correlation of the largest quadrupole splitting (1.15 mm s^{-1}) with those in **2**–**5** (0.95–1.29 mm s^{-1}). This leaves the Fe(1) sites in **2**–**5** and in **6** as those with $\delta = 0.60$–0.64 and 0.43 mm s^{-1}, respectively. The relatively large isomer shift change (0.20 mm s^{-1}) upon replacing chloride (**2**) with thiolate (**6**), while the isomer shifts of the other sites change by no more than 0.05 mm s^{-1}, is another indication that the Fe(1) sites contain halide. Also, the small variation in isomer shift with halide is consistent with previous behaviour of FeS_3X sites in prismane clusters.[13–16] While we cannot insist on these site assignments, they are internally consistent within the cluster set **1**–**6** and we proceed on that basis.

Substitution of thiolate for chloride in tetrahedral FeS_3X units of prismane and cubane-type clusters has been found to cause a decrease of *ca* 0.05–0.11 mm s^{-1} in isomer shift.[13,27,28] In the basket clusters this results in the much larger change of 0.20 mm s^{-1}, as just noted. The smaller change in isomer shift in the cubane-type clusters has been previously considered in terms of a decrease in covalency of the Fe—L bond. In the case of the present clusters, however, the much larger change in δ values suggests that there is a detectable change in core charge delocalization upon ligand substitution. Earlier, it had been shown that in clusters containing well-defined Fe (mean) oxidation states, *s*, isomer shifts of tetrahedral FeS_4 sites follow the empirical linear relationship of eq. (2):[29]

$$\delta = 1.44\text{–}0.43s. \qquad (2)$$

Its application to **6** yields an oxidation state of 2.35+ at the Fe(1) sites, very close to the cluster mean oxidation state of 2.33+ and, therefore, consistent with a highly delocalized cluster. Based on structural results for $[Fe_4S_4(SR)_4]^{1-,2-,3-}$[1,7,8,30] the mean Fe—S terminal bond length of 2.255 Å in

8 is somewhat more consistent with 2.50+ than 2.33+, but not with 2.67+. No such δ/s relationship has been established for tetrahedral FeS_3Cl sites. We surmise that the chloride-bound sites Fe(1), on charge neutralization grounds, are biased toward iron(III) character, in which case the large isomer shifts result from the removal of electron density from orbitals with 4*s* character rather than an increase in the 3*d*-type orbitals. The isomer shift change of 0.05 mm s^{-1} at the Fe(2,3) sites is consistent with a marginal increase in iron(II) character, in apparent response to the effect of chloride at Fe(1). The mean Fe—Cl distance in **7** (2.193 Å), when compared with the value in $[Fe_4S_4Cl_4]^{2-}$ [2.216(2) Å],[31] is compatible with a mean oxidation state > 2.50+. In this argument, the site with the most ferric character has the largest, rather than the smallest, isomer shift. Whatever the merits of this interpretation it is certainly the case that, on the basis of structural[2,8–10] and spectroscopic evidence, clusters **1–6**, as all other mixed-valence synthetic and biological Fe—S clusters with a nuclearity of 3 or larger, are, electronically, largely delocalized systems. Note that for cluster **9**, which formally contains $5Fe^{II}+Fe^{III}$ and has only phosphine terminal ligands, isomer shifts are essentially identical.

Magnetically perturbed Mössbauer spectra of clusters **2–5** are presented in Fig. 7. For **2** and **3**, where the effect is the clearest, an increase in the applied field from 60 to 80 kOe caused features in the wings and in the central portions of the spectra to move in opposite directions, signifying antiferromagnetic coupling, which produces a $S = 1$ ground state. Solid lines are theoretical fits using the Hamiltonian (3) and a fitting program which is a modified version of the Lang–Dale minimizer.[32]

$$H = G_e\mu_B\mathbf{H}\cdot\mathbf{S}+\Sigma[A(i)\cdot\mathbf{I}_i\cdot\mathbf{S}-g_n\mu_n\mathbf{H}\cdot\mathbf{I}_i+H_Q(i)] \quad (3)$$

$$H_Q = (eQV_{zz}/12)[3I_z^2-15/4+\eta(I_x^2+I_y^2)] \quad (4)$$

Fits were performed in the fast relaxation regime with an imposed 1 : 1 : 1 site ratio, assumed random crystallite orientation, and otherwise as described for $[Fe_4S_4(SR)_4]^{3-}$ clusters.[7,8] The parameters for each site are the magnetic hyperfine coupling constants A_x, A_y and A_z, the EFG asymmetry parameter η, and the sign of the principal component of the EFG (V_{zz}). Values used in the spectral fits are listed in Table 2. Deviations of the theoretical fits from experimental points may arise from intermediate relaxation phenomena, as observed in related clusters,[6] and from the presence of crystallites. Theoretical fits of the magnetic spectra required progressively smaller values of hyperfine coupling constants along the halide series as the spectral width narrows, paralleling the monotonic decrease in the saturation magnetization for **2–5**. Inasmuch as these clusters all appear to have $S = 1$ ground states, they would be expected to have about the same A_i values at a given type of Fe site. That they do not, reflects differences in orbital states of the individual Fe sites. The spectrum of **6** (not shown) evidenced a small perturbation in an 80 kOe applied field (*ca* 2.8 mm s^{-1} spectral width) and resembled somewhat that of **5**. Owing to the uncertainty in the ground state, the spectrum was not analysed.

In the basket clusters **2–5**, phosphine-ligated sites Fe(2,3) show positive hyperfine coupling constants and correspondingly negative hyperfine fields. Site Fe(1), thought to be more ferric-like, has oppositely signed parameters while the sites Fe(1–3), in the all-phosphine basket cluster **9** have positive A_i and negative H_i parameters. These results are consistent with the same sign of the isotropic shifts of **2–5** and **9**,[12] so long as these are mainly contact in origin, as appears to be the case from other evidence. The spectra in Figs 8 and 9 show positive (upfield) shifts, when referred to Et_3P [δ 1.02 (CH_3), 1.36 (CH_2), CD_2Cl_2] as the diamagnetic reference.

All known basket clusters are schematically depicted in Fig. 1. A recent addition to this set is $Fe_6S_5(PBu_3)_4(SPh)_3$[33] (**10**), whose core structure is nearly identical to those of **7** and **8**. This molecule differs from clusters **2–9** in the handle of the basket is thiolate- rather than sulphide-bridged; it is isoelectronic with **9** and, therefore, has a probable $S = 1/2$ ground state. Cai *et al.*[33] consider that the atoms Fe(2,4) are more reduced in **10** than in **6** because of Fe—S distances in the handle which are 0.07 Å longer than in the latter cluster. As yet, no Mössbauer or other spectroscopic and magnetic data have been reported that would permit a comparison of electronic features with those of clusters **2–9**.

SYNTHESIS OF ALKYLIDYNE TUNGSTEN COMPLEXES WITH HYDROTRIS(PYRAZOL-1-YL)BORATE LIGANDS

JOHN C. JEFFERY, F. GORDON A. STONE* and GEOFFREY K. WILLIAMS

Department of Inorganic Chemistry, The University of Bristol, Bristol BS8 1TS, U.K.

(*Received* 10 *August* 1990; *accepted* 12 *September* 1990)

Abstract—Treatment of the tungsten compounds $[W(\equiv CR)Br(CO)_4]$ (R = C_6H_4Me-4, C_6H_4OMe-2, or $C_6H_3Me_2$-2,6) in tetrahydrofuran with the salts $K[HB(3,5\text{-}Me_2pz)_3]$[$HB(3,5\text{-}Me_2pz)_3$ = hydrotris(3,5-dimethylpyrazol-1-yl)borate], $K[HB(3\text{-}Phpz)_3]$ [$HB(3\text{-}Phpz)_3$ = hydrotris(3-phenylpyrazol-1-yl)borate] and $K[HB(pz)_3]$ [$HB(pz)_3$ = hydrotris(pyrazol-1-yl) borate], affords, respectively, the complexes $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2\{HB(3,5\text{-}Me_2pz)_3\}]$, $[W(\equiv C_6H_4Me\text{-}4)(CO)_2\{HB(3\text{-}Phpz)_3\}]$ and $[W(\equiv CR)(CO)_2\{HB(pz)_3\}]$ (R = $C_6H_3Me_2$-2,6 or C_6H_4OMe-2). Protonation of the compound $[W(\equiv CC_6H_4OMe\text{-}2)(CO)_2\{HB(pz)_3\}]$ with $HBF_4 \cdot Et_2O$ gives the salt $[W\{=C(H)C_6H_4OMe\text{-}2\}(CO)_2\{HB(pz)_3\}][BF_4]$. The NMR data for the new complexes are reported and discussed.

The ligating properties of the poly(pyrazol-1-yl)borato anions are well established, and these species have become important both in classical coordination chemistry and in organometallic chemistry.[1] In the latter area of study, metal complexes containing poly(pyrazol-1-yl)borate groups and alkylidyne ligands are rapidly increasing in number.[2–4] Our interest in this area stems from using the compound $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2\{HB(pz)_3\}]$ (**1**)[4a] and related species as a reagent for preparing polynuclear metal complexes containing bonds between tungsten and other transition elements.[4] As part of our continuing studies, we describe herein the synthesis of some new mononuclear alkylidyne–tungsten reagents containing the anionic ligands $HB(pz)_3^-$ [hydrotris(pyrazol-1-yl)borato], $HB(3,5\text{-}Me_2pz)_3^-$ [hydrotris(3,5-dimethylpyrazol-1-yl)borato] and $HB(3\text{-}Phpz)_3^-$ [hydrotris(3-phenylpyrazol-1-yl)borato].

RESULTS AND DISCUSSION

Treatment of a THF (tetrahydrofuran) solution of the complex $[W(\equiv CC_6H_4Me\text{-}4)Br(CO)_4]$, prepared *in situ* from the alkylidene tungsten species $[W\{=C(OMe)C_6H_4Me\text{-}4\}(CO)_5]$, with the salt $K[HB(3,5\text{-}Me_2pz)_3]$ afforded the brown crystalline compound $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2\{HB(3,5\text{-}Me_2pz)_3\}]$ (**2**). The complex $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2\{HB(3\text{-}Phpz)_3\}]$ (**3**) was similarly obtained using the salt $K[HB(3\text{-}Phpz)_3]$. Data characterizing the species **2** and **3** are given in Tables 1 and 2. In the IR spectrum two CO bands are observed, at 1974 and 1888 cm^{-1} for **2** and at 1982 and 1897 cm^{-1} for **3**. These pairs of peaks are at somewhat lower frequencies than those observed in the spectrum of **1** (1986 and 1903 cm^{-1}).[4a] This might be expected since the donor ability of the hydrotris(pyrazol-1-yl)borato ligands should increase in the order $HB(pz)_3 < HB(3\text{-}Phpz)_3 < HB(3,5\text{-}Me_2pz)_3$.

The ^1H and $^{13}C\text{-}\{^1H\}$ NMR spectra of compounds **2** and **3** are informative and in agreement with static structures of the type shown. Both

species display characteristic resonances for the ligated carbon atoms of the *p*-tolylmethylidyne groups at δ 279.6 (**2**) and 282.3 ppm (**3**). The signal for the $C{\equiv}W$ nucleus in the $^{13}C\text{-}\{^1H\}$ NMR spectrum of **1** is seen at δ 284.8 ppm.[4a]

The coordination environment of the tungsten atom in complexes **2** and **3** is essentially octahedral with the hydrotris(pyrazol-1-yl)borate group occupying three facial sites. Consequently one of the ligated nitrogen atoms is transoid to the CC_6H_4 Me-4 moiety, while the other two nitrogen atoms are transoid to CO groups. This arrangement generates a plane of symmetry through the tungsten atom, the alkylidyne-carbon and the pyrazol ring, which is transoid to the latter. The two CO groups and the remaining two pyrazol rings are, respectively, symmetrically related to each other on either side of the symmetry plane. Hence, the number of ^1H and $^{13}C\text{-}\{^1H\}$ resonances seen in the spectra is reduced from the number which would be anticipated if all three C_3N_2 rings and the two CO ligands were non-equivalent. Consequently, it was possible to make the peak assignments listed in Table 2 on the basis of the observed relative intensities of the various signals.

The two compounds $[W(\equiv CR)(CO)_2\{HB(pz)_3\}]$ (**4**, R = $C_6H_3Me_2$-2,6; **5**, R = C_6H_4 OMe-2) were prepared by treating the species $[W(\equiv CR)Br(CO)_4]$ in THF with $K[HB(pz)_3]$. Complexes **4** and **5** are closely related to the previously reported compound **1**,[4a] and some of the spectroscopic properties are very similar. Thus all three compounds display two CO stretching bands in their IR spectra as well as a diagnostic resonance for the carbon nuclei of the ligated alkylidyne groups in their $^{13}C\text{-}\{^1H\}$ NMR spectra. For **1** the signal occurs at 284.8 ppm, as mentioned above, while for **4** and **5** the peaks are at δ 288.6 and 280.5 ppm, respectively (Table 2). However, the ^1H and $^{13}C\text{-}\{^1H\}$ NMR data for **1**[4a] indicate that all three pyrazol rings are equivalent, as would be expected if the $HB(pz)_3$ group rotated on the NMR time scale. In contrast, the NMR data for **4** and **5** reveal a pattern of peaks corresponding to two equivalent and one non-equivalent pyrazol rings. This implies that the $HB(pz)_3$ ligand does not undergo dynamic behaviour, presumably because site exchange of the ligated nitrogen atoms is prevented by the presence of the *ortho* substituents on the phenyl rings of the alkylidyne groups which interact with the sterically demanding $HB(pz)_3$ moiety (see below).

We have previously shown that protonation of the compound $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$ with $HBF_4 \cdot Et_2O$ affords the ditungsten salt $[W_2(\mu\text{-}H)\{\mu\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_4(\eta\text{-}C_5H_5)_2][BF_4]$.[5] Moreover, there is evidence that the latter is formed

via the intermediacy of a transient mononuclear alkylidene tungsten species $[W\{{=}C(H)C_6H_4Me\text{-}4\}(CO)_2(\eta\text{-}C_5H_5)][BF_4]$, in which the tungsten atom with 16 electrons in its valence shell is electronically unsaturated, and therefore reacts further.[5,6] It was, therefore, of interest to protonate the species **1–5** which are isolobal with $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$. In practice, only complex **5** on treatment with $HBF_4 \cdot Et_2O$ yielded a stable product, which was identified as the alkylidene tungsten salt $[W\{{=}C(H)C_6H_4OMe\text{-}2\}(CO)_2\{HB(pz)_3\}][BF_4]$ (**6**), data for which are given in Tables 1 and 2. Protonation of compound **1** or **2** with $HBF_4 \cdot Et_2O$ afforded salts similar to **6** based on IR and ^1H NMR measurements, but attempts to purify these products by crystallization from Et_2O or by column chromatography were unsuccessful, resulting in deprotonation and formation of the precursor **1** or **2**.

Although suitable crystals of complex **6** could not be grown for an X-ray diffraction study, the structure is well established by microanalysis and by the spectroscopic data. As expected, in the IR spectrum of **6** the two CO stretching bands at 2032 and 1954 cm^{-1} occur at appreciably higher frequency than the corresponding bands (1976 and 1886 cm^{-1}) in the spectrum of the neutral complex **5**. In the ^1H NMR spectrum of **6** there is a diagnostic resonance for the proton attached to the alkylidene-carbon at δ 12.69 and this signal displays ^{183}W satellite peaks [J(WH) 27 Hz]. In the $^{13}C\text{-}\{^1H\}$ NMR spectrum of the salt **6** the resonance for the ligated carbon of the alkylidene group $C(H)C_6H_4OMe\text{-}2$ is seen at δ 239.4 ppm. These ^1H and $^{13}C\text{-}\{^1H\}$ NMR chemical shifts are comparable with those previously reported for the compound $[W\{{=}C(H)C_6H_4Me\text{-}4\}I(CO)_2(\eta\text{-}C_5H_5)]$ [^1H, δ 13.08 for $C(H)C_6H_4Me\text{-}4$; $^{13}C\text{-}\{^1H\}$, δ 267.4 ppm for $C(H)C_6H_4Me\text{-}4$], the structure of which was established by X-ray diffraction.[5]

Our success in isolating a stable alkylidene tungsten complex by protonating compound **5** and our failure to obtain stable products by protonating the species **1–4** is probably related to the nature of the substituent groups attached to the alkylidyne-carbon atoms. In the alkylidene tungsten species produced by protonation, the metal atom has a 16 valence electron shell, a situation not conducive to stability. However, the presence of the OMe-2 group on the phenyl ring in **6**, with a lone pair of electrons on the oxygen atom, may exert a stabilizing influence. All the products of protonating compounds **1–5** would have six coordinate metal atoms. Nevertheless, tungsten can increase its coordination number beyond six. Hence, there is the possibility that the lone pair on the OMe-2 group in complex **6** interacts with the tungsten atom so as to give the latter a filled 18-electron valence shell. This could inhibit decomposition observed with the other species obtained by protonating **1–4**.

It is interesting to contrast the protonation of compounds **1–5** with $HBF_4 \cdot Et_2O$ with the formation of the ditungsten salt $[W_2(\mu\text{-}H)\{\mu\text{-}C_2(C_6H_4Me\text{-}4)_2\}(CO)_4(\eta\text{-}C_5H_5)_2][BF_4]$ on protonating $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$, mentioned above. Formation of the ditungsten species requires a combination of an initially formed alkylidene complex $[W\{{=}C(H)C_6H_4Me\text{-}4\}(CO)_2(\eta\text{-}C_5H_5)]^+$ with a second molecule of $[W(\equiv CC_6H_4Me\text{-}4)(CO)_2(\eta\text{-}C_5H_5)]$, followed by C—C bond formation and migration of a hydrogen atom.[5] In the case of compounds **1–5** the presence of the hydrotris(pyrazol-1-yl)borate ligands would inhibit further reaction of an initially formed alkylidene species because of their steric bulk. The cone angles for the groups $HB\{3,5\text{-}Me_2(pz)_3\}$, $HB(pz)_3$ and $\eta\text{-}C_5H_5$ are 225, 180 and 100°, respectively.[1,7]

EXPERIMENTAL

All experiments were carried out under nitrogen using Schlenk tube techniques. Solvents were rigorously dried before use. The salts $K[HB(pz)_3]$, $K[HB(3,5\text{-}Me_2pz)_3]$ and $K[HB(3\text{-}Phpz)_3]$[7,8] and the compounds $[W(\equiv CR)Br(CO)_4]$ (R = C_6H_4Me-4, C_6H_4OMe-2 and $C_6H_3Me_2$-2,6)[9] were prepared by methods described previously. The reagent $HBF_4 \cdot Et_2O$ consisted of a 54% solution of HBF_4 in Et_2O. The NMR spectra were recorded with JEOL JNM GX270 and GX400 spectrometers, and the IR spectra were measured with a Perkin–Elmer FT1600 spectrophotometer. Analytical and physical data for the new compounds are given in Table 1.

Preparation of the alkylidyne tungsten compounds

(i) The complex $[W(\equiv CC_6H_4Me\text{-}4)Br(CO)_4]$ was first prepared by treating a hexane (80 cm^3) solution of $[W\{{=}C(OMe)C_6H_4Me\text{-}4\}(CO)_5]$ (3.03 g, 6.61 mmol) at −20°C with BBr_3 until an IR spectrum showed that none of the alkylidene tungsten reagent remained. The mixture was cooled to −30°C,

solvent was removed with a syringe, and the residue was washed with cold (*ca* −78°C) hexane (3 × 50 cm^3) to obtain [W(≡CC_6H_4Me-4)Br$(CO)_4$] (3.16 g, 6.61 mmol). The latter was dissolved in THF (100 cm^3) at −20°C and treated with the salt K[HB(3,5-Me_2pz)$_3$] (2.34 g, 6.96 mmol). Following this procedure, the mixture was stirred at *ca* −10°C for 24 h. Filtration through a Celite pad (*ca* 1 cm) at −20°C, followed by removal of solvent *in vacuo* gave brown *microcrystals* of [W(≡CC_6H_4Me-4)$(CO)_2${HB(3,5-Me_2pz)$_3$}] (**2**) (3.56 g) after crystallization from CH_2Cl_2–Et_2O (1 : 4).

(ii) The complex [W(≡CC_6H_4Me-4)$(CO)_2${HB(3-Phpz)$_3$}] (**3**) was similarly obtained, by stirring a mixture of [W(≡CC_6H_4Me-4)Br$(CO)_4$] (prepared *in situ* from [W{=C(OMe)C_6H_4Me-4}$(CO)_5$] (0.47 g, 1.02 mmol) and BBr_3) and K[HB(3-Phpz)$_3$] (0.48 g, 1.00 mmol) in THF for 4 days at *ca* −20°C. The mixture was filtered through a Celite pad (*ca* 1 cm) and solvent was removed *in vacuo*. The residue was dissolved in CH_2Cl_2–hexane (10 cm^3, 1 : 4) and chromatographed on silica gel (2 × 10 cm). Elution with the same solvent mixture, removal of solvent *in vacuo*, and recrystallization of the residue from CH_2Cl_2–Et_2O (1 : 5) gave brown *microcrystals* of compound **3** (0.13 g).

(iii) The alkylidene tungsten complex [W{=C(OMe)$C_6H_3Me_2$-2,6}$(CO)_5$] (3.10 g, 6.57 mmol) in hexane–CH_2Cl_2 (100 cm^3, 1 : 2) was converted to [W(≡$CC_6H_3Me_2$-2,6)Br$(CO)_4$] using BBr_3. After removal of solvent with a syringe, the residue was washed with cold (*ca* −50°C) hexane (3 × 50 cm^3) and dried *in vacuo*. The [W(≡$CC_6H_3Me_2$-2,6)Br$(CO)_4$] obtained in this manner was dissolved in THF (100 cm^3) and treated with K[HB$(pz)_3$] (1.71 g, 6.79 mmol). After stirring the mixture for 24 h at room temperature, it was filtered through a Celite pad (*ca* 1 cm). Solvent was removed *in vacuo*, and the residue was crystallized from CH_2Cl_2–Et_2O (1 : 5) to afford brown *microcrystals* of [W(≡$CC_6H_3Me_2$-2,6)$(CO)_2${HB$(pz)_3$}] (**4**) (2.60 g).

(iv) The complex [W(≡CC_6H_4OMe-2)$(CO)_2${HB$(pz)_3$}] (**5**) was obtained by converting [W{=C(OMe)C_6H_4OMe-2}$(CO)_5$] (3.01 g, 6.35 mmol) to [W(≡CC_6H_4OMe-2)Br$(CO)_4$] and treating the latter with K[HB$(pz)_3$] (1.71 g, 6.79 mmol) in THF (80 cm^3). The crude product was dried *in vacuo*, and then dissolved in CH_2Cl_2–hexane (10 cm^3, 1 : 2) and chromatographed at −10°C on alumina (Brockman activity III, 2 × 10 cm column), eluting with CH_2Cl_2–hexane (1. 2). After removal of solvent *in vacuo* from a pink fraction, complex **5** was obtained as dark pink *microcrystals* (0.45 g) after crystallization from CH_2Cl_2–hexane (1 : 4) at −78°C.

Protonation studies

A CH_2Cl_2 (20 cm^3) solution of complex **5** (0.10 g, 0.17 mmol) was treated with drops of $HBF_4 \cdot Et_2O$ solution (*ca* 0.1 cm^3), until the IR spectrum of the mixture showed that all of the starting compound had been consumed. Solvent was removed *in vacuo*, and the resulting residue was crystallized from CH_2Cl_2–Et_2O (1 : 3) to give deep red *crystals* of [W{=C(H)C_6H_4OMe-2}$(CO)_2${HB$(pz)_3$}][BF_4] (**6**) (0.094 g).

COMPLEX FORMATION OF RUBIDIUM AND CAESIUM CATIONS WITH CROWN ETHERS IN ACETONITRILE: A ^{133}Cs COMPETITIVE NMR STUDY

ROBERT T. STREEPER* and SADEGH KHAZAELI†

Department of Chemistry, Southern Illinois University, Edwardsville, IL 62026, U.S.A.

(*Received* 16 *May* 1990; *accepted* 17 *September* 1990)

Abstract—Caesium-133 NMR measurements were used to study the complexation of rubidium and caesium cations by 13 different crown ethers in acetonitrile. The ^{133}Cs chemical shift data indicated that the caesium cation forms both 1:1 and 2:1 (crown ether/Cs^+) complexes with 18C6, DC21C7 and DC24C8 ligands. All other complexes were of the 1:1 stoichiometry. In general, Rb^+ complexes are more stable than the corresponding Cs^+ complexes. Formation constants of the 18C6 ligand series show the following trends. For Rb^+: 1,4DT18C6 < 1,10DT18C6 ≈ 1,10DA18C6 < DB18C6 < B18C6 < DC18C6 < 18C6. For Cs^+: 1,4DT18C6 < 1,10DT18C6 < B18C6 < DB18C6 < 1,10DA18C6 < DC18C6 < 18C6.

Nuclear magnetic resonances of ^{7}Li, ^{23}Na, ^{39}K and ^{133}Cs nuclei have been used rather extensively for the study of the thermodynamics of complexation of alkali cations with macrocyclic crown ethers in aqueous and non-aqueous solvents.[1] In contradiction, we have shown that ^{85}Rb or ^{87}Rb chemical shift measurements cannot be used for such studies.[2] The ^{87}Rb natural line-width of aqueous solutions of the rubidium cation is more than 100 Hz, due to the large Steinheimer antishielding factor of this nucleus.[3] Additions of macrocyclic ligands to Rb^+ aqueous solutions result in further broadening of the resonance lines. For example, at the (18-crown-6)/(Rb^+) molar ratios of 0.50, 0.98 and 1.20 the line-widths are in the order of 1800, 3600 and 3000 Hz, respectively.[2] The broadening of the resonance line is so large that the variation in the resonance frequency as a function of the mole ratio cannot be measured with reasonable precision. The situation is even worse in non-aqueous solvents.[2]

Cox *et al.*[4–7] have developed a competitive potentiometric technique for the determination of large formation constants of macrocyclic compounds. using a silver/silver ion electrode. This technique is useful for solvents in which the silver/silver ion electrode behaves reversibly. Zink and co-workers[8] reported the use of ^{205}Tl competitive NMR for the measurement of the formation constants of alkali cations with crown ethers. This method is limited to systems where the ligand : metal cation molar ratio is such that the ligand is predominantly in the complexed form, and where only complexes with 1:1 stoichiometry are formed.

Recently Boss and Popov[9] developed a competitive NMR technique for the determination of formation constants of metal ion complexes. Their technique allows the measurement of the formation constants of metal cations whose nuclear properties are not normally favourable for NMR measurements, and also allows the determination of formation constants that are too large to be measured by the conventional non-competitive metal NMR techniques.

It was of our interest to study the complexation of rubidium, magnesium and calcium ions with crown ethers in non-aqueous solvents using this NMR competitive method. Here we report the formation constants of rubidium cation complexes with various crown ethers in acetonitrile.

EXPERIMENTAL

Reagents

Caesium chloride, rubidium chloride (Alfa) and sodium tetraphenylborate (Aldrich) were dried at 110°C. Caesium tetraphenylborate ($CsBPh_4$) was prepared by reacting equimolar amounts of sodium tetraphenylborate and caesium chloride in tetrahydrofuran.[10] The mixture was heated to promote metathesis and then was allowed to cool. The product was precipitated by adding water (Baker, HPLC grade). Rubidium tetraphenylborate ($RbBPh_4$) was synthesized in a similar manner using rubidium chloride and sodium tetraphenylborate. The tetraphenylborate salts were thoroughly washed with water and dried at 150°C. The sodium content of these salts was measured by atomic emission (Varian–SpectrA A-10) and was found to be less than 0.005%.

Acetonitrile (Aldrich) was refluxed over calcium hydride and fractionally distilled onto freshly activated 3 Å molecular sieves (Aldrich). Samples were prepared in a dry box under nitrogen atmosphere. Water contents, determined by Karl Fischer titration, were found to be less than 100 ppm.

18-Crown-6 (18C6, Aldrich) was precipitated as the acetonitrile complex and vacuum dried at room temperature to remove the acetonitrile.[11] The following macrocyclic ligands were vacuum dried for 24 h but otherwise used as received: 15-crown-5 (15C5, Aldrich), benzo-18-crown-6 (B18C6, Parish), 1,4-dithia-18-crown-6 (1,4DT18C6, Parish), 1,10-dithia-18-crown-6 (1,10DT18C6, Parish), 1,10-diaza-18-crown-6 (1,10DA18C6, Matheson Coleman Bell), 21-crown-7 (21C7, Parish), 1,10-dicyclohexano-21-crown-7 (DC21C7, Parish) and 1,13-dicyclohexano-24-crown-8 (DC24C8, Aldrich). The ligands benzo-15-crown-5 (B15C5, Aldrich), dibenzo-18-crown-6 (DB18C6, Aldrich), dicyclohexano-18-crown-6 (DC18C6, Aldrich) and 1,13-dibenzo-24-crown-8 (DB24C8, Aldrich) were recrystallized from *n*-heptane (Fisher) and vacuum dried.

NMR measurements

Caesium-133 chemical shift measurements were carried out on a JEOL FX90Q multinuclear Fourier transform NMR instrument operating at a field strength of 21.14 kG. Caesium-133 resonates at 11.70 MHz at this field strength. The instrument was locked on an externally generated deuterium signal. Caesium-133 spectra were accumulated using a 100 Hz sweep width and 8 K data points. Signal to noise ratios were always greater than 10 and the uncertainties of the peak maxima were less than 0.02 ppm. Experiments were run in 10 mm O.D. NMR tubes (Wilmad) and at the probe temperature of 25 ± 1°C.

Caesium-133 chemical shifts were initially referred to an aqueous 0.7 M solution of caesium bromide. The chemical shifts were then corrected to refer to the aqueous solution at infinite dilution and were also corrected for the diamagnetic susceptibility of the solvent.[12] Changes in the diamagnetic susceptibilities of the solutions were assumed to be insignificant because of the low concentrations used. Downfield (paramagnetic) shifts are reported as positive.

Method

Complexation formation constants of the caesium cation with crown ethers were obtained by the conventional ^{133}Cs NMR method.[13] The formation constants of the 1 : 1 (crown ether/Cs^+) complexes were calculated by fitting the ^{133}Cs chemical shifts (δ_{obs}), at various (crown ether)/(Cs^+) mole ratios at the fixed concentration of the caesium salt (0.0050 M), to the following expression:

$$\delta_{obs} = \{\delta_0 + \delta_1[L]K_1\}/\{1 + K_1[L]\}. \quad (1)$$

Where δ_0 and δ_1 are the chemical shifts of the free solvated caesium cation and the limiting chemical shift of the 1 : 1 complex, respectively. K_1 is the formation constant of the 1 : 1 complex and [L] is the free ligand concentration. The value for [L] was obtained iteratively using the non-linear least-squares program KINFIT4,[14] according to the equation:

$$K_1[L]^2 + [K_1(C_L - C_{Cs}) + 1][L] - C_L = 0. \quad (2)$$

C_{Cs} and C_L are the analytical concentrations of the salt and the ligand, respectively.

In cases where both 1 : 1 and 2 : 1 caesium cation complexes were formed the corresponding equations are:[15]

$$K_1K_2[L]^3 + \{K_1K_2(2C_{Cs} - C_L) + K_1\}[L]^2 + \{K_1(C_{Cs} - C_L) + 1\}[L] - C_L = 0 \quad (3)$$

$$\delta_{obs} = \{\delta_0 + \delta_1K_1[L] + \delta_2K_1K_2[L]^2\}/\{1 + K_1[L] + K_1K_2[L]^2\}. \quad (4)$$

Where δ_1 and δ_2 are the limiting chemical shifts of the 1 : 1 and 2 : 1 complexes, respectively, and K_1 and K_2 are the formation constants of the 1 : 1 and 2 : 1 complexes, respectively.

The competitive complexation equilibria, where only 1 : 1 complexes are formed, are:

$$Cs^+ + L \rightleftarrows CsL^+ \quad K_{Cs} = [CsL^+]/[Cs^+][L] \quad (5)$$

$$Rb^+ + L \rightleftarrows RbL^+ \quad K_{Rb} = [RbL^+]/[Rb^+][L]. \quad (6)$$

The free ligand concentration is obtained from the following equation:

$$K_{Cs}K_{Rb}[L]^3 - \{K_{Cs}K_{Rb}(C_L - C_{Cs} - C_{Rb}) - K_{Cs} - K_{Rb}\}[L]^2 - \{K_{Cs}(C_L - C_{Cs}) + K_{Rb}(C_L - C_{Rb}) - 1\}[L] - C_L = 0. \quad (7)$$

The chemical shift data are fit to eq. (1).

In the case where Cs^+ ions form both 1:1 and 2:1 complexes the following equilibrium was considered along with equilibria (5) and (6):

$$CsL^+ + L \rightleftarrows CsL_2^+ \quad K_{Cs2} = [CsL_2^+]/[CsL^+][L]. \quad (8)$$

The free ligand concentration is then obtained from eq. (9) and the chemical shift data are fit to eq. (4).

$$K_{Cs}K_{Cs2}K_{Rb}(L)^4 + \{K_{Cs}K_{Cs2}K_{Rb}(2C_{Cs} + C_{Rb} - C_L) + K_{Cs}K_{Cs2} + K_{Cs}K_{Rb}\}[L]^3 + \{K_{Cs}K_{Cs2}(2C_{Cs} - C_L) + K_{Cs}K_{Rb}(C_{Cs} + C_{Rb} - C_L) + K_{Cs} + K_{Rb}\}[L]^2 + \{K_{Cs}(C_{Cs} - C_L) + K_{Rb}(C_{Rb} - C_L) + 1\}[L] - C_L = 0. \quad (9)$$

RESULTS AND DISCUSSION

In this study the ^{133}Cs nucleus was used as the probe nucleus. This nucleus was chosen because of its narrow resonance line, large chemical shift range and relatively high receptivity.

The use of the ^{133}Cs competitive NMR method for the evaluation of the complexation formation constants of the rubidium cation with crown ethers, K_{Rb}, requires that the formation constants of Cs^+ crown ether complexes, K_{Cs}, be known under similar experimental conditions.

Caesium cation complexes

We used the ^{133}Cs conventional NMR method to determine K_{Cs} values in acetonitrile, since in some cases such data were not available or since the literature values were obtained at significantly different experimental conditions.

Figures 1 and 2 show the variation of ^{133}Cs chemical shift as a function of the C_L/C_{Cs} molar ratio for the complexation of $CsBPh_4$ with crown ethers in acetonitrile. In all cases, except for 18C6, DC21C7 and DC24C8, only 1:1 (ligand/Cs^+) complexes were formed. The 1:1 complex formation constants, K_{Cs}, obtained from the fit of data to eqs (1) and (2) are given in Table 1 along with the corresponding literature values. The data for 18C6, DC21C7 and DC24C8 were fit to eqs (3) and (4). For these ligands the strong 1:1 complex formation is following by the formation of a weaker 2:1 complex as indicated by the change in the slope and/or the change in the direction of the chemical shift above mole ratio one.

complexes are reported in many solvents.[1] The crystal ionic diameter of the Cs^+ cation is 3.38 Å[23] and the cavity diameter of 18C6 is about 2.70 Å.[24] This makes the formation of the 2 : 1 complexes possible. The cavity diameters of DC21C7 and DC24C8 are about 3.8 and 4.6 Å, respectively.[24] Since the ratio of the cavity diameter to the cationic diameter is greater than one in these cases, the formation of the 2 : 1 complexes should be unlikely. The formation of the 2 : 1 complexes of Cs^+ cation with dicyclohexano-substituted ligands might be due to the high degree of flexibility of both the large crown ether skeleton and the cyclohexano-groups. This high degree of flexibility makes the crown ether conformational changes easier. In the 2 : 1 "sandwich" complexes the cyclohexano-groups should stay far from each other. Then, in the 2 : 1 complex, the two crown ether molecules might bend outward to accommodate the cation. This situation decreases the effective cavity size as well as the degree of interaction between the cation and the oxygen donor atoms. Recently, Soong *et al.*[25] have

reported the formation of the 2:1 complexes of DC21C7 and DC24C8 with the caesium cation in amide solvents. Further studies are in progress in our laboratory to investigate the formation of the 2:1 complexes of large diameter crown ethers with alkali cations.

Even though the ratio of the cavity diameter of 15C5 to the cationic diameter is less than one, the fit of the chemical shift data was better with the 1:1 complexation equilibrium than with the simultaneous 1:1 and 2:1 equilibria. The simultaneous equilibria provided a 2:1 formation constant equal to zero, within the standard deviation estimate. At the same time, the standard deviation in K_1 increased by a factor of two. As can be seen in Table 1, the 1:1 complex is already rather unstable and the formation constant of the 2:1 complex is probably too small to be determined by our method.

The formation constants of caesium cation complexes in acetonitrile are in agreement with the criteria for selective complexation of alkali cations by macrocyclic crown ethers. The attachment of the benzo-group(s) to 15C5 or 18C6 causes a significant decrease in the formation constant. The value of log K_{Cs} falls about 0.8 units as a result of the attachment of the benzo-group to 15C5. The substitution of one or two benzo-groups to 18C6 results in the decrease of the formation constants by more than two orders of magnitude due to the electron-withdrawing nature of the substituents. The effect of the substitution of cyclohexano-groups is not as drastic as they are not as electron withdrawing as the benzo-groups. In addition, the higher rigidity of the benzo-groups compared with cyclohexano-groups inhibits the conformational changes of the crown ether molecules which are required for complex formation. A similar effect is observed for dibenzo- and dicyclohexano-substituted 24C8.

In the groups of 18C6 analogues studied, the 1:1 complex formation constants show the trend:

$$1,4DT18C6 < 1,10DT18C6 < B18C6 < DB18C6 < 1,10DA18C6 < DC18C6 < 18C6.$$

The complex formation constant of the Cs^+ cation with 1,10DA18C6 is smaller than those of 18C6 and DC18C6. This is expected since (1) the electron-donating ability of the nitrogen atoms is less than the electron-donating ability of the oxygen atoms; (2) the covalent diameter of nitrogen atom is smaller than that of the oxygen atom, which causes the 1,10DT18C6 ligand cavity to be smaller than that of 18C6 or DC18C6; and (3) the weak interaction between the relatively "hard" caesium cation and the relatively "soft" nitrogen atom.[26] Frensdorff[27] has shown that in methanol solution the complex formation constant of the K^+ ion with 1,10DA18C6 is four orders of magnitude smaller than with 18C6.

The sulphur substituted ligands, 1,4DT18C6 and 1,10DT18C6, have the smallest formation constants of all the 18-member crown ethers studied. This observation may result from at least two factors: (1) the smaller diameter of the ligand cavity due to the bulky sulphur atoms; and (2) the weak interaction between the relatively "hard" caesium cation and the relatively "soft" sulphur atoms.[26] Rounaghi and Popov[21] have determined the complex formation constant of caesium thiocyanate with 1,10DT18C6 in acetonitrile of log $K = 0.97 \pm 0.27$, compared with our result of 1.75 ± 0.08. The discrepancy probably arises from differences in the nature of the counter ion. The thiocyanate anion has a higher ion pair formation ability with the cation and/or the complexed cation as compared with the tetraphenylborate anion.[28] Since the ion pair formation competes with the complex formation, one would expect a less stable complex with the thiocyanate salt. The complex formation constant of Cs^+ is smaller with 1,4DT18C6 than with 1,10DT18C6. In 1,4DT18C6 the bulky sulphur atoms are close to each other and probably would exclude a portion of the cavity for the accommodation of the cation. Differences in the conformational mobilities of the 1,4- and 1,10-dithia-substituted ligands might also be responsible for the difference in the stability of their complexes.

Rubidium cation complexes

The similarity of the crystallographic diameters of the caesium cation (3.38 Å) and the rubidium cation (2.96 Å)[23] suggests the use of ^{133}Cs NMR to probe the complexation of the rubidium cation with crown ethers. Figures 3 and 4 depict the variation of the ^{133}Cs chemical shift as a function of C_L/C_{Cs} molar ratio ($C_{Cs} = 0.0050$ M) in the presence of rubidium tetraphenylborate ($C_{Rb} = 0.0050$ M) in acetonitrile. The data indicated the formation of only 1:1 rubidium complexes. The observed chemical shifts would fit to eqs (1) and (7) (where only 1:1 caesium complexes formed) or to eqs (4) and (9) (where both 1:1 and 2:1 caesium complexes formed). The formation constants of rubidium crown ether complexes are given in Table 1.

The chemical shift of the free solvated cation in the presence of rubidium salt is about 4 ppm downfield compared to the chemical shift in the absence of the rubidium cation, due to the difference in the ionic strengths of these solutions. For 18C6, DC21C7 and DC24C8, where K_{Cs} values are not known ($K_{Cs} > 10^4$), only the lower limits of K_{Rb} are reported.

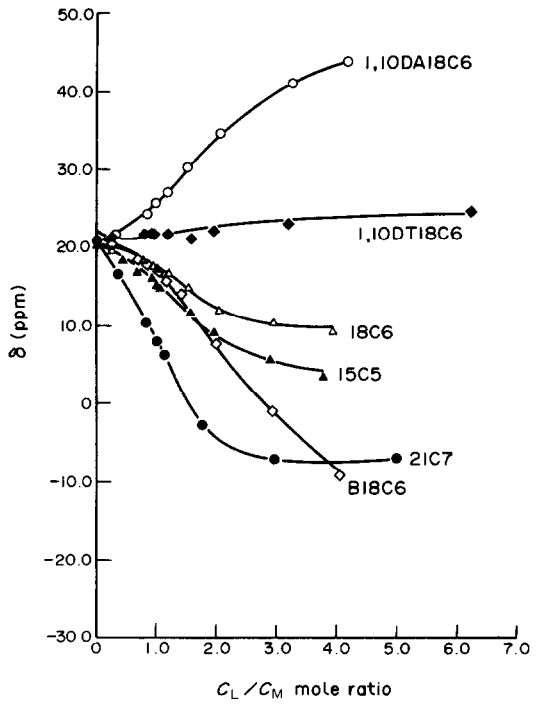

Fig. 3. Caesium-133 chemical shift vs crown ether/Cs^+ mole ratio for solutions containing 0.0050 M $CsBPh_4$ and 0.0050 M $RbBPh_4$ in acetonitrile, at 25°C. Solid lines are calculated curves.

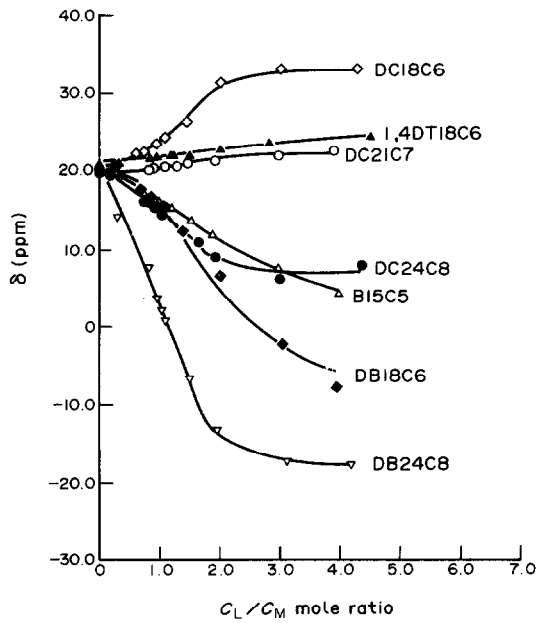

Fig. 4. Caesium-133 chemical shift vs crown ether/Cs^+ mole ratio for solutions containing 0.0050 M $CsBPh_4$ and 0.0050 M $RbBPh_4$ in acetonitrile, at 25°C. Solid lines are calculated curves.

In all cases rubidium complexes are more stable than the corresponding caesium complexes. The difference between the stability of the caesium and rubidium complexes are more pronounced with the smaller crown ethers than with the larger ligands. For smaller ligands the relative sizes of the macrocyclic cavity and the cation probably play the most important role with regard to the stability of the complexes. However, for larger crown ethers, other factors such as the flexibility of the ligand molecules can become more important.

The complex formation constants with the benzo-substituted crown ethers are smaller than with the corresponding non-substituted ligands, as expected from the electron-withdrawing ability of the benzene ring. The stability of the rubidium complexes with the benzo-substituted crown ethers increases in the order: B15C5 < DB18C6 ≈ B18C6 < DB24C8. This trend clearly shows the effect of the flexibility of the larger crown ethers on the stability of their complexes. Even though the rubidium cation is too small and its fit into the DB24C8 cavity ($d \approx 4.5$ Å) should be "loose", the crown ether molecules can wrap themselves around the cations as a result of their ability for conformational changes.

Rubidium cations form stronger complexes with the non-substituted crown ethers than with either the cyclohexano- or benzo-substituted crown ethers. This effect is similar to the caesium complexation discussed previously.

The substitution of two oxygen atoms by either two nitrogen or two sulphur atoms in the 18C6 ring decreases the stability of the rubidium complexes. This result should be interpreted with regard to the change in the crown cavity size and the interactions between relatively "hard acids" and "soft bases", as was discussed earlier. It should be mentioned that the error associated with the K_{Rb} of the $Rb^+ \cdot$ 1,10DT18C6 complex is very large due to the small chemical shift range. A more precise K_{Rb} value for this complex should be obtained before we can accurately compare this value with the other formation constants.

The above results show that the competitive ^{133}Cs NMR method can be successfully used to probe the thermodynamics of complexation of rubidium salts with macrocyclic crown ethers in non-aqueous solvents. The stability of the complexes depends not only on the relative sizes of the cation and the ligand cavity, but on other factors such as the nature of the substituents on the crown ether ring and the conformational changes of the macrocyclic ligand. Significantly, we have observed that large crown ethers may form 2 : 1 complexes with Cs^+ cation in addition to the more commonly known 1 : 1 complexes.

TRENDS IN $\delta \rightarrow \delta^*$ ENERGIES AND INTENSITIES IN BIS(ARYLIMINO)ISOINDOLINE COMPLEXES OF DIMOLYBDENUM

D. M. BAIRD† and K. Y. SHIH

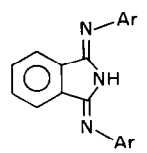
Department of Chemistry, Florida Atlantic University, Boca Raton, FL 33431, U.S.A.

(*Received* 25 *June* 1990; *accepted* 17 *September* 1990)

Abstract—It has been found that the $\delta \rightarrow \delta^*$ band in the electronic absorption spectra of a series of bis(arylimino)isoindoline dimolybdenum complexes, $Mo_2(BAII)(OAc)_3$, follows three trends. First, as the energy of the band decreases across the series its intensity increases. Second, as electron-releasing groups are added to the aryl portion of the ligand the energy of the band increases, while addition of electron-releasing groups decreases its energy. Third, as the parent aryl group becomes a better π-acceptor the band's energy decreases. These three trends are taken to indicate that the energy of the $\delta \rightarrow \delta^*$ band in this series of compounds is determined by mixing of a ligand-to-metal charge-transfer transition with the original $\delta \rightarrow \delta^*$ transition.

The understanding of both the structural and reaction chemistry of multiple metal–metal bonds has matured greatly over the past 10 years or so. In particular, investigations concerning quadruply bonded dimolybdenum compounds have been numerous.[1] Only a few homologous series of dimolybdenum compounds have been studied, however, and these form the basis for our understanding of the physical and electronic properties of dimolybdenum species. The most extensive series of well studied and well understood dimolybdenum compounds are those with the general formulae $Mo_2X_4(PR_3)_4$ and $Mo_2X_4(PP)_2$, where X = halogen, NCS^-, NCO^-, etc., and PR_3 and PP refer to monodentate and bidentate phosphine ligands, respectively. Studies of these compounds have led to a greater understanding of the structural effects on the reactivities and properties of dimolybdenum compounds in general. In particular, a greater understanding of the relationship between the electronic absorption spectra and electronic structures of these compounds has recently been realized. The relationship between the energies and intensities of the so called "$\delta \rightarrow \delta^*$" band and the energies of ligand-to-metal charge-transfer transitions has, especially, been the topic of much discussion.[2–7] It is not clear whether the reasoning developed for the $Mo_2X_4(PR_3)_4$ series can be applied to other series of structurally related dimolybdenum compounds. In fact, there has been no other extensive series of structurally related compounds available which can be investigated in terms of their electronic structures.

We have recently synthesized[8] and studied a series of 11 dimolybdenum complexes which contain bis(arylimino)isoindoline (BAII) ligands which have the general structure shown below:



In the above structure aryl is substituted or unsubstituted pyridine, pyrazine, thiazole or pyrimidine. The complexes, $Mo_2(BAII)(OAc)_3$, have been shown by NMR spectroscopy to have structures analogous to the bis(pyridylimino)isoindoline derivative whose structure has been elucidated using X-ray crystallography.[9] These compounds contain the molybdenum–molybdenum quadruple bond bridged by three acetate groups. In addition, the BAII ligand, which is planar tridentate in mononuclear complexes, has been altered by rotation about one of the imino bonds prior to binding to the dimolybdenum unit (Scheme 1). Thus the BAII

† Author to whom correspondence should be addressed.

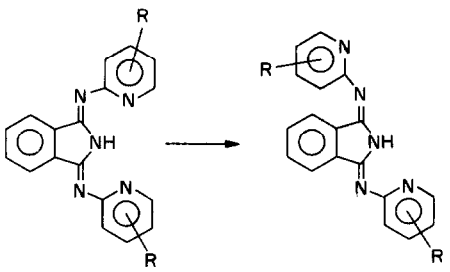

Scheme 1.

bridges the two molybdenum atoms by binding one metal with the isoindoline nitrogen and the other metal with the imino nitrogen about which rotation has occurred. This rotation places one pyridine in a position away from the dimetal unit. The other pyridine is bonded to one of the molybdenum atoms in a position co-axial with the metal–metal bond.

Since the compounds synthesized represented a large series of structurally similar dimolybdenum compounds, it was decided to subject them to a spectroscopic study. The results of this study are presented below.

EXPERIMENTAL

Materials and methods

All synthetic procedures were performed under an atmosphere of argon using standard Schlenk techniques or a glove box. Methylene chloride was dried by refluxing with calcium hydride or phosphorus pentoxide. Tetrahydrofuran was refluxed with Na–benzophenone, and methanol was refluxed with calcium sulphate. All solvents were distilled under argon just prior to use. Molybdenum acetate was prepared from $Mo(CO)_6$ using the method of Wilkinson and Dori.[10] The BAII ligands were prepared by the method of Siegl,[11] in which the appropriate aromatic amine was reacted with 1,2-dicyanobenzene in refluxing butanol in the presence of a small amount of anhydrous calcium chloride. The 2-aminoheterocyclic amines, except 5-iodopyridine, were purchased from Aldrich and used as received. 5-Iodopyridine was synthesized by the method of Caldwell *et al.*[12]

Spectroscopic samples were prepared as CH_2Cl_2 solutions in a glove box using cells equipped with a screw-on cap.

Spectra were obtained from 900 to 180 nm using a Shimadzu 2100 spectrophotometer.

Preparation of bis(pyrimidinylimino)isoindoline

It has been reported by other workers that the reaction between 1,2-dicyanobenzene and 2-aminopyrimidine does not occur.[11] We have successfully prepared this BAII derivative by the following procedure.

The reactants were heated in butanol at reflux temperature for 7 days. During this period the solution turned deep blue in colour while yellow and blue precipitates formed. After the mixture was cooled the solids were filtered and treated with $CHCl_3$. The undissolved blue–purple material was then filtered out. Addition of an equal volume of *n*-heptane to the filtrate and refrigeration produced the pale yellow bis(pyrimidinylimino)isoindoline as a precipitate (m.p. 222–224°C). This was filtered and dried *in vacuo*.

Syntheses of BAII *complexes of dimolybdenum,* $Mo_2(BAII)(OAC)_3$

$Mo_2(BAII)(OAc)_3$ (BAII = *bis(pyridylimino)isoindoline*).[9] $Mo_2(OAc)_4$ (1 g) was added as one portion to a solution of bis(pyridylimino)isoindoline in 35 cm^3 of dry, degassed methanol. The resulting yellow mixture slowly turned emerald green. After stirring overnight a green precipitate formed, which was filtered, washed with hexane and then dried *in vacuo*. This procedure resulted in about 75% yield after recrystallization from benzene–hexane.

Other BAII *complexes.* The same procedure was used for all other BAII complexes using *ca* 1 g of $Mo_2(OAc)_4$ with yields of 80% or above. In the case of the pyridine and 4-methylpyridine derivatives the yellow mixture slowly turned emerald green after stirring overnight.

The 4,6-dimethylpyridine derivative was stirred with $Mo_2(OAc)_4$ for 7 days before complete reaction was achieved. The reactions of the 5-halopyridines, the thiazole derivatives and the pyrazine

derivative were carried out overnight at reflux temperature.

RESULTS AND DISCUSSION

The $\delta \rightarrow \delta^*$ transition energies and intensities for the BAII dimolybdenum complexes are listed in Table 1 and typical spectra are shown in Fig. 1. Upon inspection of this data three trends become obvious. First, it is found that as the energy of this band decreases its intensity increases. Second, within a series of complexes derived from the same aromatic amine heterocycle the $\delta \rightarrow \delta^*$ band shifts to lower energy when electron-withdrawing substituents are added to the heterocyclic ring, and to higher energy upon addition of electron-releasing groups. Third, a large effect is observed for changes in the parent amine heterocycle. Each of these trends will be discussed below in detail.

Background

The majority of dimolybdenum complexes possess an eclipsed structure in which the donor atoms attached to one molybdenum eclipse the donor atoms on the other molybdenum when viewed along the metal–metal bond. This configuration maximizes the δ-overlap. In early reports it was thought that the energy of the $\delta \rightarrow \delta^*$ band may be a reflection of the extent of δ-overlap between the two metals.[3] Presumably then, a twist about the metal–metal bond would result in decreased δ-overlap and a lower energy $\delta \rightarrow \delta^*$ band due to a decrease in the separation of the δ and δ^* orbitals.

A series of diphosphine bridged dimolybdenum complexes, $Mo_2X_4(PP)_2$, have been reported by Cotton *et al.*,[13] in which a twist about the metal–metal bond exists due to ligand constraints imposed by the methylenes in its backbone. This work has shown that as the twist angle increases and δ-overlap decreases the energy of the $\delta \rightarrow \delta^*$ transition decreases. As would be expected, the intensity of the $\delta \rightarrow \delta^*$ band decreases as its energy decreases due to smaller δ-overlap. These results seem to confirm the notion that the energy of the $\delta \rightarrow \delta^*$ transition is related to the δ-overlap.

However, when the compounds in a series of complexes which all possess an eclipsed (twist angle = 0°) geometry are compared, it is found that the $\delta \rightarrow \delta^*$ band still varies over a fairly large range. For example, in the series $Mo_2Cl_4(PMe_3)_4$, $Mo_2Br_4(PMe_3)_4$, $Mo_2I_4(PMe_3)_4$ the $\delta \rightarrow \delta^*$ band, where δ-overlap has been theoretically estimated to change from 0.17 to 0.23,[5] red shifts by 1400 cm^{-1}. On the other hand, in the series $Mo_2X_4(PP)_2$, in which the halogen remains constant and the twist angle increases, a change of twist angle from 0 to 45° results in a red shift of the $\delta \rightarrow \delta^*$ band by 4640 cm^{-1}. It seems clear that the shift in the $\delta \rightarrow \delta^*$ band in the eclipsed series cannot be accounted for by change in δ-overlap since it is shifted more than one third that found in the twisted series, where the change in overlap should be about five times less in the most twisted case than in the eclipsed case.[6] In addition, the decrease in energy of the $\delta \rightarrow \delta^*$ transition in the eclipsed case is accompanied by an

increase in intensity. This is the opposite of the intensity trend observed for the twisted series where it is known that the δ-overlap decreases.

In order to explain the large energy shift and intensity increase across the eclipsed $Mo_2X_4(PR_3)_4$ series, Gray and co-workers have proposed that the original $\delta \rightarrow \delta^*$ transition mixes with a low energy ligand-to-metal charge-transfer (LMCT) transition.[7] The results of such mixing would be that the energy of the $\delta \rightarrow \delta^*$ transition would be lowered upon lowering of the LMCT transition. In addition, the band's intensity would be increased, rather than decreased, due to intensity borrowing.

Trends in the BAII *series*

Intensity trends. Inspection of the energies of the $\delta \rightarrow \delta^*$ band for the Mo_2(BAII)$(OAc)_3$ series reveals that the intensity increases as the energy decreases. In fact a plot of energy vs intensity yields a straight line (Fig. 2). The correlation coefficient for the line in Fig. 2 is 0.999. The halopyridine

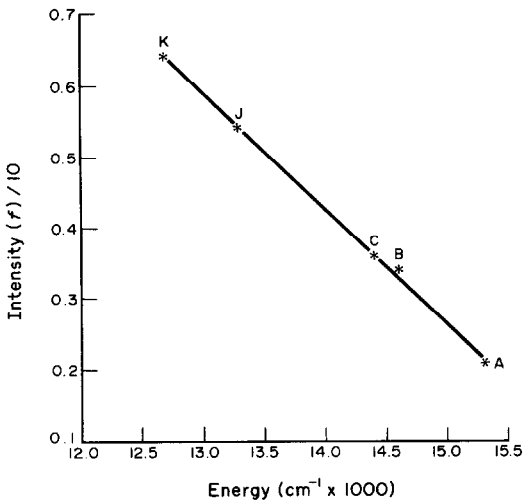

Fig. 2. Plot of energies vs intensities for the $\delta \rightarrow \delta^*$ band of Mo_2(BAII)$(OAc)_3$ complexes.

derivatives deviate slightly from the line but even when they are included the correlation is still 0.96. This would seem to suggest, based on the discussion above, that this band does not simply reflect the extent of δ-overlap between the two metal d_{xy} orbitals. This notion is further supported by the fact that the energy of this transition varies over a range of 2300 cm^{-1}. This would represent a rather large change in δ-overlap when compared with the twisted $Mo_2X_4(PP)_2$ series, where overlap is known to decrease by a factor of about five times and the band red shifts 4640 cm^{-1}. The trend of increasing intensity with decreasing energy seems to indicate that a low energy charge-transfer band may be mixing with the $\delta \rightarrow \delta^*$ band in a fashion analogous to that found in the $Mo_2X_4(PMe_3)_2$ series.

Effects of aryl substituents. The addition of electron-withdrawing substituents such as halogens to the aryl portion of the BAII ligand causes a red shift of the band relative to the unsubstituted aryl group derivative, while the addition of electron-releasing alkyl groups tends to cause a blue shift in this band. For example, inspection of the series made up of compounds derived from 3,5-dichloropyridine, 5-chloropyridine, pyridine, 4-methylpyridine and 4,6-dimethylpyridine demonstrates the trend clearly. A similar trend is observed for the thiazole and methylthiazole derivatives. This type of trend can also be observed in the compounds reported by Ewing and Shupack[14] which have the formula $Mo_2X_4(Py)_4$, where X is chloride or bromide and Py is pyridine, picoline or lutidine. If the series in which all complexes contain chlorine is examined it is discovered that addition of electron-releasing methyl groups tends to lower the energy of the $\delta \rightarrow \delta^*$ band. For example, for the series pyridine, 4-methylpyridine and 3,5-dimethylpyridine, the $\delta \rightarrow \delta^*$ band is reported at 16,667, 16,807 and 17,986 cm^{-1}, respectively. In the bromine series, the 3-methylpyridine derivative is reported to have a $\delta \rightarrow \delta^*$ band at 15,198 cm^{-1}, while the 3,4-dimethylpyridine derivative has this band at 17,904 cm^{-1}. This trend, however, is just the opposite of that expected for the mixing of a LMCT transition with the $\delta \rightarrow \delta^*$ transition such as has been observed in the $Mo_2X_4(PR_3)_4$ series. For example, an electron-releasing methyl would be expected to lower the energy of a LMCT transition. Thus after mixing, a lower energy $\delta \rightarrow \delta^*$ band would result. In the BAII series, addition of a methyl group causes a higher energy $\delta \rightarrow \delta^*$ band compared with the unsubstituted pyridine case. This apparent contradiction can be explained if the charge-transfer transition mixing with the $\delta \rightarrow \delta^*$ transition in the BAII series was a metal-to-ligand charge-transfer (MLCT) transition. In this case substitution of an electron-withdrawing chlorine onto the aryl group would result in a lowering of a MLCT transition which would then lower the energy of the $\delta \rightarrow \delta^*$ band through mixing. This is exactly what is observed in the BAII series. The idea that a MLCT transition of reasonably low energy is present in these complexes is consistent with the known π-accepting ability of aromatic nitrogen heterocycles such as the ones upon which the BAII ligands are based. In addition, the linearity of the energy vs intensity plot referred to earlier suggests that the changes in both the energy and the intensity of the $\delta \rightarrow \delta^*$ band are affected by the same phenomenon. That is, if the MLCT which is mixing with the $\delta \rightarrow \delta^*$ transition were a $\delta \rightarrow \pi^*$ transition, then lowering the ligand π^*-orbital energy would lower the MLCT transition. As a result lowering the energy of the $\delta \rightarrow \delta^*$ band. Simultaneously, the intensity of the band would increase due to more efficient intensity borrowing.

Effect of varying the parent heterocycle. If, in fact, the energy of the $\delta \rightarrow \delta^*$ band is related to the energy of a π^*-orbital on the ligand and, therefore, related to the π-accepting ability of the ligand, we would expect to find a trend which results from substituting the parent amine heterocycle portion of the BAII ligand. It can be seen that as the known π-accepting ability of the heterocycle increases (pyrazine > thiazole > pyridine) the energy of the $\delta \rightarrow \delta^*$ band decreases (pyrazine < thiazole < pyridine).

Unfortunately the role of the aryl group in these compounds is undoubtedly complex since the only

direct bond to the dimolybdenum unit from any aryl group is to the axial position at one end of the Mo—Mo bond. It seems reasonable at the outset to attribute changes in the energy of the $\delta \rightarrow \delta^*$ band to changes in the extent of axial bonding. Particularly in the case of the 4,6-dimethylpyridine derivative where steric interaction of the 6-methyl group may weaken axial bonding and shift the band towards that of the "bare" dimer. To answer this question it should be pointed out that the 3,5-dichloropyridine derivative, reported in Table 1, is shifted to an even greater extent (referenced to the unsubstituted pyridine case) than is the 4,6-dimethylpyridine case. Since there is no steric problem in the dichloropyridine case the Mo—N axial bond should be present. If axial bonding of the N-heterocycle had a significant effect on the energy of the $\delta \rightarrow \delta^*$ band it might be expected that the Mo—N axial bond in the dichloropyridine case should be weaker than in the unsubstituted pyridine case due to the electron-withdrawing groups. In this case then, the dichloro derivative should be closer to the "bare" dimer and would be expected to have a higher energy $\delta \rightarrow \delta^*$ band than the unsubstituted pyridine case. In fact, the energy in the dichloropyridine case is considerably lower than in the pyridine case. Based on this argument it must be concluded that the axial bond does not have a significant effect on the energy of the band in question. This is not unreasonable based on the long Mo—N axial bond distance in the crystal structure of the pyridine derivative. Small changes in the bond strength of the already weak bond upon addition of substituents should not have much impact. NMR spectra of the 4,6-dimethylpyridine-derived complex show that, at the very least, it has the same "inside–outside" arrangement of pyridine rings as the unsubstituted pyridine case. While it cannot be ruled out that steric interactions preclude axial Mo—N binding in this derivative, it is believed that, based on the above arguments, such bonding does not have a great impact on the energy of the $\delta \rightarrow \delta^*$ band.

Some further insight might be gained from consideration of the pyrimidine complex. In this case it is believed that, unlike the other BAII complexes, the aryl ring not bound to molybdenum is co-planar with the rest of the BAII ligand. Evidence for this notion has been gained from comparison of the ^{1}H NMR spectrum of the pyridimidine derivative with the spectra of the other BAII complexes. The spectra of the majority of BAII dimolybdenum complexes are characterized by an upfield shift of the α-proton resonance of the benzo portion of the isoindoline system closest to the non-co-planar aryl ring. This shift is apparently due to the proximity of this proton to the inside of the aryl group ring current. In the pyrimidine derivative both pyrimidine rings are co-planar with the isoindoline portion of the BAII system and the α-proton resonance is shifted downfield since it is on the outside of the ring current. The co-planarity of the second pyrimidine ring is apparently due to the fact that a nitrogen atom is in the 6-position of this ring. Since there is no hydrogen attached to this nitrogen the ring may remain co-planar without interacting with the α-proton of the benzo portion of the isoindoline group. In this case the $\delta \rightarrow \delta^*$ band is red shifted much more than would be expected based on the π-accepting ability of pyrimidine compared with the other heterocycles used in this study. Thus, it appears that the aryl rings simply act as electron-withdrawing or -releasing groups for the isoindoline portion of the ligand. In the pyrimidine case both rings may be conjugated with the isoindoline group resulting in a larger red shift of the band since the energy of the π-system of the isoindoline moiety would be lowered through increased conjugation.

CONCLUSION

In conclusion, the trend of increasing $\delta \rightarrow \delta^*$ intensity with decreasing energy indicates that this band is not simply a reflection of the extent of δ-overlap in these compounds and that there is mixing of a charge-transfer transition with the $\delta \rightarrow \delta^*$ transition. The substituent effects suggest that the charge-transfer involved is a MLCT transition, probably a $\delta \rightarrow \pi^*$ transition. The trend with respect to different heterocycles seems to confirm this idea. The possibility that the shift in the $\delta \rightarrow \delta^*$ band may be due to differences in base strength of the ligand seems to be ruled out by the range over which this band occurs in this series. Therefore, in dimolybdenum complexes of aromatic amine heterocycles the π-accepting ability of the ligand plays a role in determining the energy of the $\delta \rightarrow \delta^*$ band.

(*Received* 18 *April* 1990; *accepted* 26 *September* 1990)

Abstract—The polymerization of acrylamide photo-induced by a bicationic system was investigated. From the results of kinetic measurements, the couple chromium–copper was proved to be a suitable system to initiate and terminate the process of polymerization. $HCrO_4^-$ is the photo-initiator and $Cu(H_2O)_6^{2+}$, transparent at the excitation wavelength, only acts as a termination agent. At room temperature, the quantum yield remained unchanged when the concentration of copper(II) was varied from 5×10^{-5} to 5×10^{-3} mol dm^{-3}, whereas the rate of polymerization was strongly affected by the presence of copper(II) in the solution. By ESR spectroscopy measurements at low temperature, it was possible to assess that copper(II) was also involved in a reaction with chromium(V). Copper(II) is able to react with the two species, chromium(V) and R·, arising from the redox process between excited $HCrO_4^-$ and acrylamide.

The polymerization of a vinyl monomer, photo-initiated by coordination complexes, has received paticular interest. Iron(III) salts,[1,2] cobalt(III) salts[3–5] and manganese carbonyl complexes[6] have been proved to be efficient photo-initiators of the polymerization. Natarajan and Santappa[7] reported the photoredox phenomenon involved in acrylamide and acrylonitrile polymerization photo-initiated by diacidobis(ethylenediamine)cobalt(III) complexes. Delzenne[8] described the mechanism of acrylamide polymerization photo-initiated by penta-aminecobalt(III) complexes. Takemura and co-workers[9] more recently reported the acrylamide polymerization photo-initiated by $Ru(bipy)_3^{2+}$, excited with visible light in the presence of an electron donor.

In the series of previous papers, we reported the polymerization of vinyl monomers photo-initiated by chromium complexes in aqueous solution.[10–14] Chromium(VI) as $HCrO_4^-$ and/or chromium(III) as $Cr(H_2O)_6^{3+}$ appeared to be efficient photo-initiators of the polymerization of vinyl monomers. The initiation step, in any cases, is the redox process that takes place between the complex in the excited state and the monomer in the ground state, the final photoproducts being the polymer and chromium(III) (whatever the valence of the starting chromium complex). In the particular case of acrylamide (AA) polymerization photo-initiated by chromium(VI), two different domains were detected depending on the $[HCrO_4^-]$ concentration.[12] At low concentration, R_p (the rate of polymerization) increases with chromium concentration. A termination process of the polymerization occurring mainly by mutual annihilation of the macroradicals accounts for the experimental dependence of the polymerization rate. R_p was found to be proportional to $[AA]^{3/2}$ and $I_a^{1/2}$ (I_a being the absorbed light intensity). At higher concentrations of $HCrO_4^-$, R_p decreases with increasing chromium concentration. A process of oxidative termination of the radicals by chromium(VI) is involved, which corresponds to a different dependence of R_p; R_p appeared to be proportional to $[AA]^2$ and I_a. In this latter domain, $HCrO_4^-$ plays two roles: in the excited state, it reacts with acrylamide giving rise

* Author to whom correspondence should be addressed.

to chromium(V) and to a radical initiator of the polymerization ($HCrO_4^-$ acts as a photo-initiator). In the ground state, $HCrO_4^-$ reacts with the macroradicals yielding chromium(III) and the polymer ($HCrO_4^-$ also acts as a termination agent). Accordingly, we decided to separate these two roles: chromium(VI) as $HCrO_4^-$ would remain as the initiator agent and copper(II) as $Cu(H_2O)_6^{2+}$ would be the termination agent.

This paper deals with the primary process of the photopolymerization, a further paper will describe the kinetic parameters of the polymerization.

EXPERIMENTAL

Materials

$(NH_4)_2Cr_2O_7$ was of commercial origin (Fluka analytical grade) and used without further purification along with acrylamide (Fluka puriss product) and $CuCl_2$ (Fluka). The solutions were prepared with doubly-distilled water and deaerated by bubbling with argon for 30 min. Ionic strength was not controlled; the pH was adjusted with HCl or $HClO_4$ and was controlled to ± 0.02 pH unit.

Irradiation set-up

The monochromatic irradiations at 365 nm were performed with a high-pressure mercury lamp (Osram HBO 200 W), equipped with a grating monochromator (Bausch and Lomb). The beam was parallel and the reactor was a quartz cylindrical cell of 1 or 2 cm path length. The second set-up used was a cylinder made of stainless steel, built upon an elliptical basis. A high-pressure mercury lamp (Philips HPW type 125W), the emission of which at 365 nm was selected by an inner filter, was located at a focal axis of the elliptical cylinder, and the reactor, a water-jacketed Pyrex tube (diameter = 2.8 cm), was centred at the other focal axis. The reaction medium was stirred well. The incident light intensity was determined by ferri-oxalate actinometry. The averaged values were measured as:

$$I_o \approx 2.5 \times 10^{15} \text{ photons cm}^{-2}\text{s}^{-1}$$

$$I_o \approx 4 \times 10^{15} \text{ photons cm}^{-2}\text{s}^{-1}$$

for irradiation with the monochromator and in the elliptical system, respectively. To study the effect of the absorbed light intensity on the polymerization rate, the water surrounding the reactor in the elliptical system was replaced by a solution of CrO_4^{2-} (photostable species) used as a filter.

The UV–vis spectra were recorded on a double beam spectrophotometer (CARY 118 C). The percentage of acrylamide converted into polymer was calculated from the UV spectra based on the monomer absorption.[12] The polymer was also precipitated by pouring the irradiated solution into methanol and was then weighed. The values of monomer conversion obtained by the two methods were in good agreement. R_p, the rate of polymerization, was taken as the slope in the linear part of the curve giving the percentage of monomer conversion vs time.

ESR spectra were recorded on a Brucker ER-200D spectrometer at 9.30 GHz with a modulation field of 100 KHz. A xenon-mercury Hanovia lamp was used for irradiation in the ESR spectrometer cavity.

RESULTS

Chromium(VI) exists in three different forms, $HCrO_4^-$ and $Cr_2O_7^{2-}$ in acidic medium and CrO_4^{2-} in basic medium.[15] At pH = 3 and for the domain of concentration used, $HCrO_4^-$ was established to be the only absorbing species.[11] Under similar experimental conditions, $CuCl_2$ exists in solution as $Cu(H_2O)_6^{2+}$. The UV–vis spectra of both species are represented in Fig. 1. It appears that $Cu(H_2O)_6^{2+}$ does not absorb in the region where $HCrO_4^-$ is excited (365 or 436 nm). $Cu(H_2O)_6^{2+}$ is completely transparent over a wide range of wavelength, even at high concentration. When allowed to stand for a few days in the dark, a solution of chromium(VI), copper(II) and acrylamide was slightly unstable, therefore, the experiments were always performed with freshly prepared mixtures. In the presence of copper(II), the pH domain in which the study was performed was from 1.5 to 5. At pH values higher than 5, a precipitate

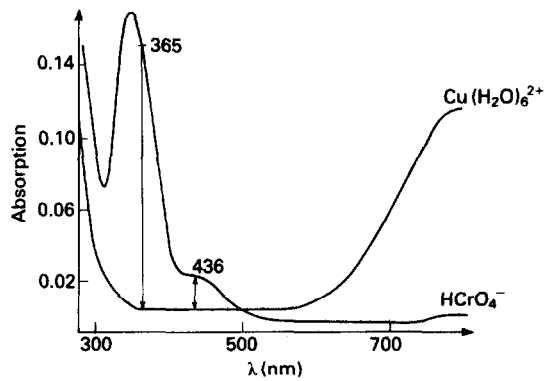

Fig. 1. UV–vis spectrum of aqueous solutions of $HCrO_4^-$ (10^{-4} mol dm^{-3}; pH = 2.5) and $Cu(H_2O)_6^{2+}$ (10^{-2} mol dm^{-3}; pH = 2.5).

was observed. We duplicated any experiment in the two domains of chromium(VI) concentration: when chromium(VI) acts only as a photo-initiator ($c < 7 \times 10^{-5}$ mol dm^{-3}) and when it plays two roles, as a photo-initiator and as a termination agent of polymerization ($c > 2 \times 10^{-4}$ mol dm^{-3}).

Photoredox phenomenon in the chromium(VI), *copper*(II)*–acrylamide system*

As shown in Fig. 2, upon irradiation at 365 nm, the absorbance at 350 and 440 nm characteristic of $HCrO_4^-$ decreased, the original yellow colour disappeared and for prolonged irradiations, the solution turned light blue. The absorbance at 700 nm due to $Cu(H_2O)_6^{2+}$ remains approximately constant and a very weak absorption at 575 nm ($\varepsilon \approx 15$ mol^{-1} dm^3 cm^{-1}) appeared together with an isosbestic point at 520 nm. The initial quantum yields of chromium(VI) to chromium(III) reduction were determined from the absorbance decrease at 350 nm vs irradiation time, neither the starting copper complex nor the final photoproducts absorb at that wavelength. We did not use any buffer to avoid the eventual complexation with the metallic cations. The quantum yields were measured with a 5% conversion at various values of pH. The ϕ values were only slightly affected by the presence of copper(II), a concentration of 10^{-2} mol dm^{-3} in copper(II) was necessary to induce a 20% decrease of the quantum yield:

$\phi = 1.6 \times 10^{-2}$ with $[CuCl_2] = 10^{-2}$ mol dm^{-3}

$\phi = 2.0 \times 10^{-2}$ in the absence of $CuCl_2$

pH = 3.

We determined that this result was not due to the change in ionic strength because the quantum yield of chromium(VI) reduction was constant in the presence or in the absence of a 1.5×10^{-2} mol dm^{-3} concentration of $NaClO_4$.

ESR spectroscopy upon irradiation ($\lambda > 335$ nm)

For a deaerated solution of $[HCrO_4^-]$, $[Cu(H_2O)_6^{2+}]$ and [AA] at room temperature ($\theta \approx 22$°C), two signals can be detected, the strong signal of copper(II) which decreased upon irradiation, and after long irradiations, the weak and broad signal of chromium(III). In a frozen solution ($\theta = -40$°C), an additional signal could be observed whose intensity increased, reached a maximum, then decreased (Fig. 3). As already described in our previous papers, the signal was assigned to chromium(V). For a given concentration of chromium(VI), the intensity of the chromium(V) signal was dependent on the copper(II) concentration; the higher the concentration, the lower the maximum intensity of the signal. The intensity maximum of the chromium(V) signal was divided by five when a 10^{-3} mol dm^{-3} concentration of copper(II) was added to the solution. This was true for both domains of chromium(VI) concentration but, at high concentrations of chromium(VI) a linear relationship occurred between the chromium(V) and copper(II) concentrations, which did not hold at lower concentration (Fig. 4).

The thermal decay of chromium(V) generated upon irradiation was, in the absence of copper(II), of first order at $[HCrO_4^-] = 5 \times 10^{-5}$ mol dm^{-3} and of second order at $[HCrO_4^-] = 5 \times 10^{-4}$ mol dm^{-3}. In the presence of increasing concentrations

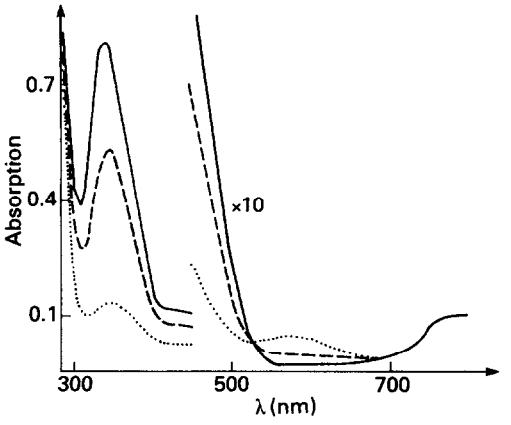

Fig. 2. Evolution of the UV–vis spectrum of a solution of $[HCrO_4^-] = 5 \times 10^{-4}$ mol dm^{-3}, $[Cu(H_2O)_6^{2+}] = 10^{-3}$ mol dm^{-3}, [AA] = 1 mol dm^{-3} and pH = 2.5, upon irradiation at 365 nm: (——) $t = 0$; (– – – –) $t =$ 1 h 40 min; (· · · ·) $t = 4$ h.

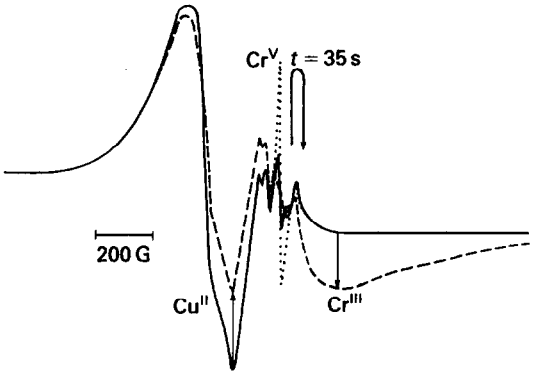

Fig. 3. ESR spectra of a frozen solution ($\theta = -40$°C) of $[HCrO_4^-] = 5 \times 10^{-4}$ mol dm^{-3}; $[Cu(H_2O)_6^{2+}] = 2 \times 10^{-4}$ mol dm^{-3}; [AA] = 2 mol dm^{-3} and pH = 2.5 upon polychromatic irradiation ($\lambda > 335$ nm); (——) $t = 0$; (· · · ·) $t = 35$ s; (– – – –) $t = 40$ min.

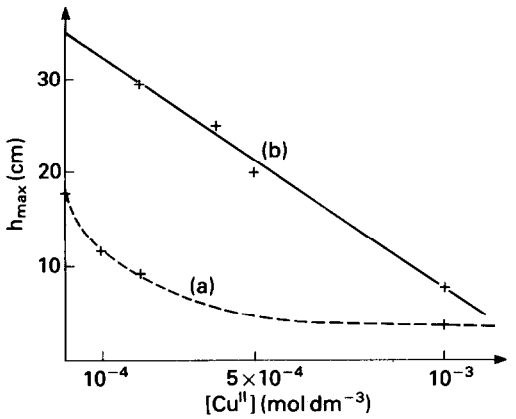

Fig. 4. Maximum intensity of the chromium(V) signal as a function of copper(II) concentration: (a) $[HCrO_4^-] = 5\times10^{-5}$ mol dm^{-3}; (b) $[HCrO_4^-] = 5\times10^{-4}$ mol dm^{-3}.

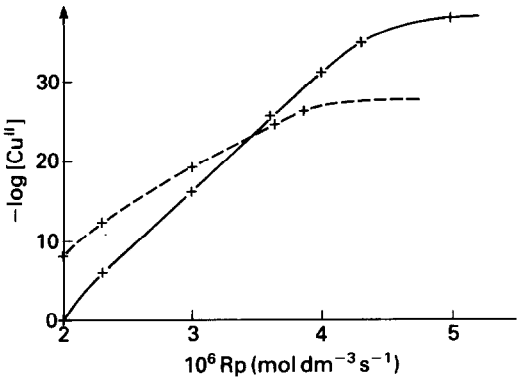

Fig. 5. R_p, the rate of polymerization, as a function of copper(II) concentration: (——) $[HCrO_4^-] = 5\times10^{-5}$ mol dm^{-3}; (– – –) $[HCrO_4^-] = 3\times10^{-4}$ mol dm^{-3}.

of copper(II), there was no more simple decay of the chromium(V) signal.

H^+ *consumption*

The photoreduction of chromium(VI) in the presence of a reductant consumes H^+ ions.[11,12] The pH measurements were performed during the photoredox process. The number of H^+ ions consumed by the redox reaction obviously depends on the number of chromium(VI) atoms reduced, therefore experiments were carried out with the same degree of conversion of chromium(VI) into chromium(III) using different concentrations of copper(II). We calculated, as a representative value, the ratio:

$$R = \frac{\text{Number of } H^+ \text{ consumed}}{\text{Number of } Cr^{VI} \text{ atoms reduced}}.$$

The values are summarized in Table 1. The effect of increasing concentration of copper(II) depends on the concentration of the photo-initiator. At low concentration of $HCrO_4^-$, where $HCrO_4^-$ played the role of initiator only, R decreased when the $CuCl_2$ concentration was increased. At higher concentrations of $HCrO_4^-$, chromium(VI) played two roles and R remained approximately constant whatever the concentration of copper(II).

Effect of copper(II) *on the polymerization rate of acrylamide*

The effect of copper(II) on R_p, the rate of polymerization, was studied at $[HCrO_4^-] = 5\times10^{-5}$ mol dm^{-3} and $[HCrO_4^-] = 3\times10^{-4}$ mol dm^{-3}. For both concentrations, the rate of polymerization decreased in the presence of copper(II) (Fig. 5).

When chromium(VI) did not interfere in the termination process ($c = 5\times10^{-5}$ mol dm^{-3}) and at $[Cu(H_2O)_6^{2+}] > 5\times10^{-4}$ M, the relationship between R_p, the monomer concentration [M] and I_a appeared to be $R_p \propto [M]^2$ and $R_p \propto [I_a]$. A 10^{-2} mol dm^{-3} concentration of copper(II) completely inhibited the polymerization.

At higher concentration of photo-initiator, in the absence or in the presence of copper(II), the rate of polymerization was proportional to I_a and to the square of the monomer concentration.

Table 1. H^+ uptake during the photoreduction of chromium(VI), pH = 3.6, λ = 365 nm

DISCUSSION

There is no complexation in the ground state between chromium(VI), copper(II) and acrylamide. Chromium(VI) as $HCrO_4^-$ is the only absorbing species. According to the general scheme we already described for acrylamide polymerization photo-initiated by $HCrO_4^-$,[12] the primary step is the formation of chromium(V) together with a radical initiator of polymerization ($AA^\cdot$) arising from acrylamide.

In a rigid matrix (the solution frozen at $-40°C$), the lifetime of chromium(V), the unstable species generated upon excitation of $HCrO_4^-$ in the presence of acrylamide, is long enough to enable its detection by ESR spectroscopy. Under these conditions and in the absence of copper(II), the first-order decay of the chromium(V) signal observed at low concentration of $HCrO_4^-$, reflects the reaction of chromium(V) with excess acrylamide present in the solution. At higher concentrations of $[HCrO_4^-]$, the second-order decay, already reported in the photoreaction between polyvinyl alcohol and dichromate,[16] is assigned to the disproportionation reaction

$$2\,Cr^{V} \longrightarrow Cr^{VI} + Cr^{IV}.$$

The decrease in chromium(V) concentration when copper(II) is added, reflects the reaction of copper(II) with chromium(V). The following equation can be written as

$$Cr^{V} + Cu^{II} \longrightarrow Cu^{I} + Cr^{VI}$$

which accounts for the experimental results.

At room temperature, when chromium(V) is short-lived, this reaction does not occur unless the concentration of copper(II) is very high. On the contrary, the rate of polymerization is very sensitive to the presence of copper(II): at low concentration of photo-initiator (pH = 3) and with a 10^{-2} mol dm^{-3} concentration of $Cu(H_2O)_6^{2+}$, the polymerization is totally inhibited, whereas the quantum yield of chromium(VI) reduction is only slightly affected. The kinetic expressions for the rate of polymerization photo-initiated by $HCrO_4^-$ were established as the following.[12]

If the termination occurs by mutual annihilation of two macroradicals, $[HCrO_4^-] < 7 \times 10^{-5}$ mol dm^{-3}:

$$M_n^\cdot + M_M^\cdot \longrightarrow \text{polymer}$$

$$R_p = k_p[AA]^{3/2} I_a^{1/2} \left[\frac{k_q}{2k_t k_d}\right]^{1/2}.$$

If the termination occurs by oxidative reaction with chromium(VI), $[HCrO_4^-] > 2 \times 10^{-4}$ mol dm^{-3}:

$$HCrO_4^- + M_n^\cdot \longrightarrow Cr^{III} + \text{polymer}$$

$$R_p = k_p[AA]^2 I_a \left[\frac{k_q}{k_{ot} k_d}\right] \frac{1}{[Cr^{VI}]}.$$

A process of oxidative termination by copper(II) would lead to the following expression:

$$R_p = k_p[AA]^2 I_a \left[\frac{k_q}{k'_{ot} k_d}\right] \frac{1}{[Cu^{II}]}.$$

The constants are defined in the general scheme.

The experimental dependence of R_p on I_a, M^2 and $1/[Cu^{II}]$, when chromium(VI) plays the role of initiator only, is in full agreement with this expression.

As far as the hydrogen consumption is concerned, the reduction of chromium(VI) into chromium(III) requires H^+ ions. For the same degree of chromium(VI) reduction, the number of H^+ ions consumed decreases with increasing concentration of copper(II) (Table 1), implying that the H^+ ions are supplied by an additional reaction. Simultaneously, the increasing copper(II) induces a decrease of the polymerization rate, which, therefore, means that the reaction between copper(II) and the macroradicals is more and more important. The following reaction accounts for the experimental observations:

$$Cu^{II} + M_n^\cdot + H_2O \longrightarrow Cu^{I} + M_nOH + H^+$$

and is assumed to be the source of H^+ ions necessary for the reduction of chromium(VI).

At high concentrations of chromium(VI), where the termination process always occurs by oxidative reaction with chromium(VI) and/or with copper(II), the ratio H^+/Cr^{VI} is lower and approximately constant, whatever the concentration of copper(II).

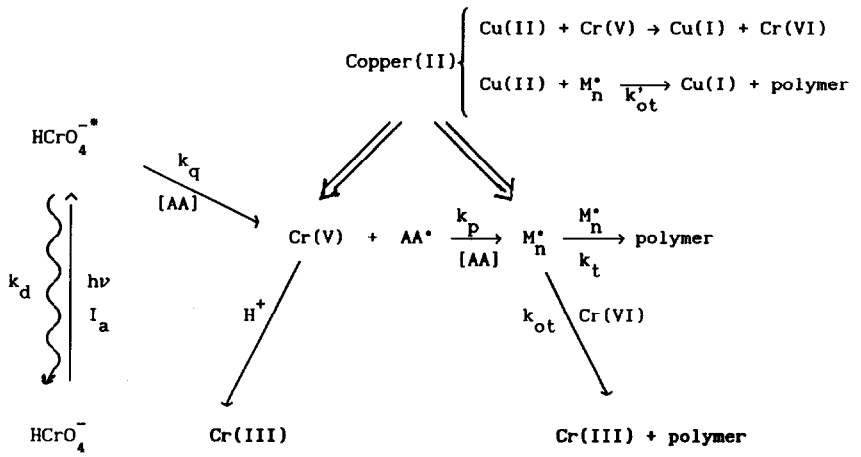
In conclusion, copper(II) as $Cu(H_2O)_6^{2+}$ is able to react with the two species generated upon irradiation of $HCrO_4^-$ in the presence of acrylamide according to the reactions:

$$Cu^{II} + M_n^\cdot \longrightarrow Cu^{I} + M_nOH + H^+ \qquad (1)$$

$$Cu^{II} + Cr^{V} \longrightarrow Cu^{I} + Cr^{VI}. \qquad (2)$$

At room temperature, chromium(V) is very short-lived which does not allow reaction with copper(II) to take place unless the concentration of copper(II) is very high. According to reaction (2), chromium(VI) is regenerated, resulting in a decrease of the quantum yield.

At low temperatures and in a rigid matrix chromium(V) is long-lived enough to react with copper(II), even at low concentrations of copper(II).



Scheme 1. General scheme of acrylamide polymerization photosensitized by $HCrO_4^-$, in the presence of copper(II).

Therefore, at room temperature, copper(II) mainly affects the polymerization rate. Copper(II) only acts as a termination agent of the polymerization, controlling the termination rate without interfering in the initiation process.

COMPLEXES OF RHENIUM(V) WITH TRIDENTATE LIGANDS HAVING O, N AND P DONOR ATOMS. THE X-RAY CRYSTAL STRUCTURES OF $ReOCl_2[OC_6H_4\text{-}2\text{-}CH{=}N(CH_2)_3PPh_2]$ AND ITS REDUCED COUNTERPART $ReOCl_2[OC_6H_4\text{-}2\text{-}CH_2NH(CH_2)_3PPh_2]$

(*Received* 30 *May* 1990; *accepted* 27 *September* 1990)

Abstract—The tridentate ligand $HOC_6H_4\text{-}2\text{-}CH_2NH(CH_2)_3PPh_2$, which contains both "hard" and "soft" potential donor atoms, has been synthesized along with its rhenium(V) complex $ReOCl_2[OC_6H_4\text{-}2\text{-}CH_2NH(CH_2)_3PPh_2]$. Single crystal X-ray diffraction studies show that this molecule has a qualitatively similar structure to its Schiff base counterpart $ReOCl_2[OC_6H_4\text{-}2\text{-}CH{=}N(CH_2)_3PPh_2]$, despite the change in bonding at the central ligating nitrogen atom from sp^3 to sp^2. At a more detailed level, significant differences in structural parameters are found to occur. In both cases the coordination site *trans* to the Re=O oxygen [Re=O = 1.680(7) and 1.695(9) Å, respectively] is occupied by the phenolic oxygen [Re—O = 1.943(7) and 1.953(9) Å, respectively] and the rhenium atom has a distorted octahedral coordination environment. The Re—N distance lengthens on reduction of the ligand [Re—N(H)— = 2.224(8) Å, Re—N= = 2.111(11) Å] while the Re—N=C(sp^2) bond angle decreases by 12.7° on reduction.

In order to investigate the ways in which facultative polydentate ligands containing both "hard" and "soft" donor atoms might bind to the $\{ReO\}^{3+}$ moiety, we have been studying the reactions of $[ReOCl_4]^-$ with polydentate ligands which contain sulphur or phosphorus as "soft" donor atoms, in combination with aryloxo and amine or imine nitrogen as "hard" ligating sites. The potentially pentadentate ligand $(HOC_6H_4\text{-}2\text{-}CH{=}NCH_2CH_2)_2S$ has been found[1] to function as a tetradentate ligand in the complex $[ReO(OEt)\{OC_6H_4\text{-}2\text{-}CH{=}NCH_2CH_2\}_2S]$, the sulphur atom remaining uncoordinated as shown schematically in Fig. 1(a). Reduction of the —CH=N— moieties in this ligand results in the formation of a bimetallic complex in which all five ligand donor atoms are bound to rhenium, but not all to the same metal centre, as illustrated in Fig. 1(b). Thus it can be seen that a modest increase in the saturation of the ligand

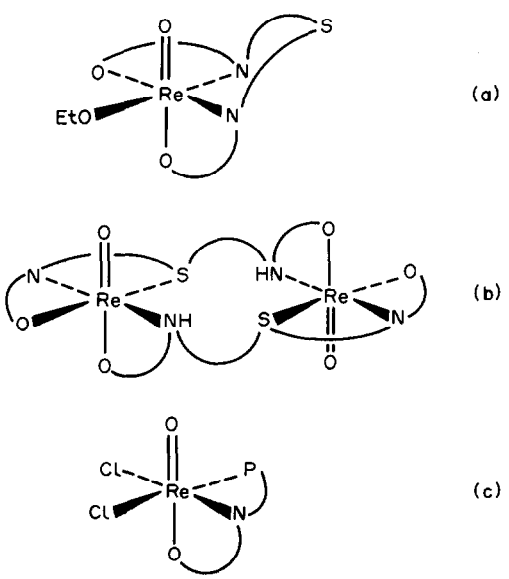

Fig. 1. Structural arrangements in some rhenium(V) complexes: (a) $[ReO(OEt)\{OC_6H_4\text{-}2\text{-}CH{=}NCH_2CH_2\}_2S]$;[1] (b) $[ReO\{(OC_6H_4\text{-}2\text{-}CH{=}NCH_2CH_2)_2S\}_2ReO]$;[1] (c) $ReOCl_2$(salimp).[2]

results in a profound structural change in the complex which is obtained.

The monobasic tridentate ligand, HOC_6H_4-2-$CH{=}N(CH_2)_3PPh_2$ (salimpH) coordinates to the $\{ReO\}^{3+}$ core through all three donor atoms in a mutually *fac* arrangement.[2] Octahedral coordination about rhenium is completed by two chloride ligands as shown in Fig. 1(c). In view of the large changes which followed reduction of the pentadentate ligand, we have now investigated the structural effect of reducing the tridentate ligand (salimpH) to HOC_6H_4-2-$[CH_2NH(CH_2)_3PPh_2]$ (salampH$_2$) to convert the sp^2 central ligating nitrogen atom to sp^3. The new complex, $ReOCl_2[OC_6H_4$-2-$CH_2NH(CH_2)_3PPh_2]$, was prepared and studied by X-ray diffraction methods. In order to provide a direct structural comparison the unsolvated complex, $ReOCl_2[OC_6H_4$-2-$CH{=}N(CH_2)_3PPh_2]$, was also prepared and studied by X-ray methods.

EXPERIMENTAL

Synthetic studies

Commercial reagents were used as supplied; HOC_6H_4-2-$CH{=}N(CH_2)_3PPh_2$[2] and $Bu^n{}_4N[ReOCl_4(H_2O)]$[3] were prepared according to previously described procedures. $ReOCl_2[OC_6H_4$-2-$CH{=}N(CH_2)_3PPh_2]\cdot CH_2Cl_2$ was prepared according to the previously described[2] method and recrystallized from Me_2SO to give the solvent-free complex, $ReOCl_2[OC_6H_4$-2-$CH{=}N(CH_2)_3PPh_2]$. Methanol and ethanol were dried over magnesium and redistilled before use, but other solvents were used as received without further purification.

IR spectra were recorded using a PE 297 instrument. ^{1}H NMR spectra were obtained using a Jeol GX 270 (270 MHz) instrument. Elemental analyses were performed by the Microanalytical Service of The School of Chemistry, University of Birmingham.

HOC_6H_4-2-$CH_2NH(CH_2)_3PPh_2$

To a solution of SalimpH (0.05 g, 1.43 mmol) in dry methanol (40 cm^3) was added $NaBH_4$ (0.31 g, 8.6 mmol). The mixture was stirred at room temperature for 1 h, after which time the solvent was removed to afford a colourless oil. The oil was triturated with n-pentane (2×15 cm^3). On standing at room temperature the pentane extract afforded the product as a white, crystalline solid. More product could be obtained by dissolving the trituration residues in dichloromethane, adding n-pentane and allowing the solution to stand at 0°C for 16 h to precipitate colourless needles of the product (total yield 0.18 g, 36%). Found: C, 75.4; H, 7.0; N, 3.7. Calc. for $C_{22}H_{24}NOP$: C, 75.6; H, 6.9; N, 4.0%.

$ReOCl_2[OC_6H_4$-2-$CH_2NH(CH_2)_3PPh_2]$

$Bu_4N[ReOCl_4(H_2O)]$ (0.25 g, 0.41 mmol) was added to a solution of SalampH$_2$ (0.15 g, 0.43 mmol) in dry methanol (10 cm^3) and the mixture stirred at room temperature for 2 h, then heated under reflux for 0.5 h. The green–brown solution which formed was allowed to cool and stand at 0°C for 16 h, during which time a green solid was deposited. This material was recrystallized from 1 : 1 dichloromethane–methanol to give bright green needles (26 mg, 10%). Found: C, 42.5; H, 3.7; N, 2.3. Calc. for $C_{22}H_{23}NO_2Cl_2PRe$: C, 43.0; H, 3.8; N, 2.4%.

Structural studies—X-ray analysis of $ReOCl_2[OC_6H_4$-2-$CH_2NH(CH_2)_3PPh_2]$ [$ReOCl_2$(salampH)] *and* $ReOCl_2[OC_6H_4$-2-$CH{=}N(CH_2)_3PPh_2]$ [$ReOCl_2$(salimp)]

Diffraction data were measured on an Enraf–Nonius CAD4 diffractometer operating in the ω–2θ mode with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) up to $\theta = 25°$ from crystals of size $0.2\times 0.3\times 0.3$ mm [$ReOCl_2$(salampH)] and $0.3\times 0.3\times 0.3$ mm [$ReOCl_2$(salimp)]. Three standard reflections were monitored periodically to check the stability of the system. 3882 unique reflections [$ReOCl_2$(salampH)] and 2498 reflections [$ReOCl_2$(salimp)] were scanned and 3254 and 1921, respectively, with $F > 5\sigma(F)$ were considered observed and used in the analyses.

Crystal data

$ReOCl_2$(salampH): $C_{22}H_{23}Cl_2NO_2PRe$, $M_r = 621.5$, monoclinic, $P2_1/c$, $a = 15.06(2)$, $b = 10.673(14)$, $c = 14.85(4)$ Å, $\beta = 111.5(2)°$, $V = 2201$ Å^3, $Z = 4$, $D_c = 1.859$ g cm^{-3}, μ(Mo-K_α) = 5.87 mm^{-1}.

$ReOCl_2$(salimp): $C_{22}H_{21}Cl_2NO_2PRe$, $M_r = 619.5$, orthorhombic $P2_12_12_1$, $a = 8.959(3)$, $b = 14.036(2)$, $c = 17.611(4)$ Å, $V = 2215$ Å^3, $Z = 4$, $D_c = 1.858$ g cm^{-3}, μ(Mo-K_α) = 5.89 mm^{-1}.

The structures were solved[4] using Patterson and Fourier methods and refined[5] by least-squares using weights, $w = 1/[\sigma^2(F)] + 0.0002F^2]$, for $ReOCl_2$(salampH) and unit weights for $ReOCl_2$(salimp), which resulted in satisfactory weighting analyses. Non-hydrogen atoms were allowed to vibrate anisotropically. Hydrogen atoms were included in calculated positions, riding on their respective

bonded atoms. Refinement was terminated when all shift/ESD ratios were < 0.1 and R, $Rw = 0.051$, 0.067 [$ReOCl_2$(salampH)] and $R = 0.034$ [$ReOCl_2$(salimp)] for 3254 and 1921 reflections, respectively. An empirical absorption correction[6] was applied to both data sets. Computations were carried out on the University of Birmingham's IBM 3090 computer. Additional material available from the Cambridge Crystallographic Data Centre comprises hydrogen atom coordinates, thermal parameters, and bond lengths and angles.

DISCUSSION

Synthetic studies

The ligand $SalampH_2$ may be prepared by the borohydride reduction of the Schiff base SalimpH. The IR spectrum of the white, crystalline solid obtained contains bands attributable to the presence of the phenyl and propyl groups, in addition to ν_{NH} at 3290 cm^{-1}. The ^1H NMR spectrum of the ligand contains two complex multiplets of total relative area 11 in the region δ_{TMS} 7.31–7.44 ppm, attributable to the phosphinophenyl protons and one of the salicylaldimine aryl protons. The remaining salicylaldimine aryl protons appear as two doublets at δ_{TMS} 6.95 ($^3J_{HH}$ 6 Hz) and 6.74 ppm ($^3J_{HH}$ 8 Hz) and a triplet at δ_{TMS} 7.11 ppm ($^3J_{HH}$ 7 Hz); each of relative area one. The protons of the 1,3-disubstituted-propyl and aryl-CH_2—N moieties appear as four signals each of relative area two at δ_{TMS} 3.91 (singlet), 2.73 (triplet, $^3J_{HH}$ 7 Hz), 2.05 (doublet of doublets, $^3J_{HH}$ 8 Hz, $^3J_{PH}$ *ca* 10 Hz) and 1.65 ppm (quintet, $^3J_{HH}$ *ca* 8 Hz).

The reaction between $Bu^n{}_4N[ReOCl_4(H_2O)]$ and $SalampH_2$ proceeded smoothly in methanol in the absence of air to produce a green complex. The IR spectrum of this material contains bands consistent with the presence of the ligand and includes ν_{NH} at 3150 cm^{-1} in addition to $\nu_{Re=O}$ at 978 cm^{-1}. The formulation of this complex as $ReOCl_2[OC_6H_4\text{-}2\text{-}CH_2NH(CH_2)_3PPh_2]$ was confirmed by the X-ray study described below.

Structural studies

The structures of the complexes $ReOCl_2$(salampH) and $ReOCl_2$(salimp) are shown in Figs 2 and 3,[7] respectively, and selected bond lengths and angles are compared in Table 1.* The X-ray analyses confirm that both complexes are neutral, monomeric compounds in which all three potential donor atoms of the ligand are coordinated to rhenium. The rhenium atom is in an approximately octahedral coordination environment with the binding of the ligands qualitatively the same in both complexes. It is note-worthy that the phenolic oxygen atom lies

[a] Mean of values for two independent molecules.

trans to the oxo group, in accord with the well established tendency of oxygen donor atoms in polydentate ligands to coordinate at this site.[1,2,8–10]

There are, however, some significant differences in the structural parameters. Thus deviation from ideal octahedral coordination is greater in the reduced complex; $ReOCl_2$(salampH) maximum angular deviation 14.6°, mean deviation 5.2°; $ReOCl_2$(salimp) maximum angular deviation 8.3°, mean deviation 4.4°. This may well be a steric effect, the hydrogen atom linked to the nitrogen atom of the reduced ligand causing some additional distortion from ideal octahedral geometry, otherwise it might have been expected that the greater flexibility of the reduced form would allow a *closer* approach to octahedral geometry. That this is a systematic effect due to the difference in the nature of the N(1)—C(7) bond may be seen from a comparison of the rhenium coordination geometries in the present structures with that of rhenium in $ReOCl_2$(salimp) in crystals of the dichloromethane solvate.[2] Comparing equivalent angles at rhenium, the differences between the salimp and salampH complexes range from 0.7 to 9.6° with a mean difference of 4.0°, whereas the differences between the two salimp complexes are much smaller, 0.2–

2.6°, mean 1.1° [see Table 1, where pertinent parameters for $ReOCl_2(salimp)\cdot 0.25CH_2Cl_2$ are also listed]. With regard to bond lengths, the rhenium–sp^3-hybridized nitrogen distance is greater by 0.1 Å than the Re—N(sp^2) distances in the $ReOCl_2$(salimp) structures. As expected, significant differences occur also in the N(1)—C(7) bond length and in the valence angles at N(1) and C(7), clearly distinguishing between the different bonding states of these two atoms in the salampH and salimp complexes. The net effect of these differences may be gauged by comparing Figs 2 and 3 which show identical views of $ReOCl_2$(salampH) and $ReOCl_2$(salimp). The Re, N(1), C(7), C(6), C(1), O(1) chelate ring is planar to within ±0.12 Å in $ReOCl_2$(salimp), but is considerably more buckled in the reduced complex, atomic deviations from the mean plane ranging from 0.25 to −0.35 Å.

The phosphorus atom occupies a site *trans* to a chlorine and *cis* to the rhenyl oxo ligand in both complexes. The bond angles at phosphorus are essentially tetrahedral. As noted previously,[2] the Re—P—C(sp^3) angles are significantly smaller than those of type Re—P—C(sp^2). This was attributed[2] to an electronic effect. The P—C lengths, however, reflect the different hybridization states of the carbon atoms bonded to phosphorus only to a small extent. The orientations of the phenyl rings are somewhat different in the two complexes. Thus in $ReOCl_2$(salampH) the angles which the C(11)—C(16) and C(17)—C(22) phenyl rings make with the Re, C(11), C(17) plane, taken as the reference plane, are 36.5 and 85.2°, respectively, and the angle between the phenyl rings is 70.5°. The corresponding inter-planar angles in $ReOCl_2$(salimp) are 25.0, 65.8 and 81.8°. In the dichloromethane solvate of $ReOCl_2$(salimp) the angle between the phenyl rings is similar; 88.6 and 83.9° in the two independent molecules.[2]

In contrast to the finding that reduction of the imine linkage in the pentadentate ligand $[HOC_6H_4\text{-}2\text{-}CH{=}N(CH_2)_2]_2S$ leads to gross changes in its mode of coordination to the $\{ReO\}^{3+}$ moiety, the reduction of the imine linkage in salimpH does not produce gross geometric changes in the ligand binding arrangement. This occurs in spite of significant changes in more detailed aspects of the geometry of the coordinated ligand.

(*Received* 25 *June* 1990; *accepted* 27 *September* 1990)

Abstract—The dimerization and deprotonation of HVO_4^{2-} have been investigated in 1 M Na(Cl) medium at 25°C. Spectrophotometric and calorimetric measurements were made at $[OH^-] \geqslant 0.05$ M, where all other vanadate(V) hydrolysis equilibria could be neglected. Equilibrium constants and other thermodynamic quantities have been determined: for the dimerization of HVO_4^{2-} $\log K_d = 0.83$, $\Delta H^0 = -28$ kJ mol^{-1} and $T\Delta S^0 = -24$ kJ mol^{-1}, and for the ionization $\log K = -13.29$, $\Delta H^0 = 24$ kJ mol^{-1} and $T\Delta S^0 = -52$ kJ mol^{-1}.

The hydrolysis of vanadate(V) leads to the formation of various mono- and polynuclear species, occurring in successive overlapping equilibria extending over the entire pH range.[1,2] Despite the complexity of the system, which comprises slow reactions in the pH range 4.5–7.5, great progress has been made in characterizing these equilibria, especially by potentiometric and NMR techniques.[3–7] Values for equilibrium constants have been reported for different ionic media, but the thermodynamic quantities ΔH^0 and ΔS^0 have not been determined for these equilibria. Only a non-specific value for the enthalpy of polymerization,[8] $\Delta H^0 = -21$ kJ mol^{-1} $H_2VO_4^-$, and another for the formation enthalpy of the polyanion, $HV_{10}O_{28}^{5-}$, have been reported,[9] which is not surprising in view of the speciation characteristics of the system.

The aim of the present investigation was to determine by spectrophotometric and calorimetric measurements the enthalpy and entropy changes for the first two hydrolysis reactions of VO_4^{3-}, i.e. for the formation of HVO_4^{2-} and $V_2O_7^{4-}$. These reactions take place in alkaline solution and by limiting the measurements to pH > 12.3, all other hydrolysis equilibria could be neglected, which brought about a considerable simplification in the interpretation and manipulation of the data. Because the interpretation of calorimetric data depends heavily on the values used for the equilibrium constants, a renewed attempt was made to obtain the best possible value for the dimerization equilibrium constant. The dimeric ion, $V_2O_7^{4-}$, attains its maximum concentration at pH ~ 12. Depending on the accuracy required, the useful range of a glass electrode in potentiometric investigations is limited to pH values less than 10 or 11. At these pH values, where several species co-exist and the percentage concentration of $V_2O_7^{4-}$ is rather small, very accurate determination of the dimerization constant is not possible. The value of the constant might also depend on the reaction model selected in the treatment of the data. Evaluation of this constant by some other method which is not based on direct pH measurements is therefore of interest, in addition to the need for an accurate value in calculating thermodynamic quantities. In the present investigation a flow-through cuvette of variable path length was used to measure the whole UV spectrum of solutions at various vanadium concentrations, from which a value for the dimerization constant was calculated. As a by-product the spectrum of $V_2O_7^{4-}$ was obtained for the first time.

EXPERIMENTAL

Reagents and solutions

Analytical grade reagents (Merck p.a. or BDH Analar) were used, and solutions were prepared

* Author to whom correspondence should be addressed.

with deionized water obtained from a Millipore Milli-Q system. A vanadate stock solution was prepared by dissolving $NaVO_3$ in hot water. The cooled solution was filtered through a porosity four sintered glass filter. Its concentration was determined by titrating a suitably diluted sample with ammonium ferrous sulphate that had been standardized by titration with potassium dichromate. Carbonate-free sodium hydroxide was standardized by titration with potassium hydrogen phthalate. The solution was kept in a polythene bottle and protected against carbon dioxide contamination with a soda lime guard tube. All vanadate solutions were prepared from the stock solution by appropriate dilution, with the addition of sodium hydroxide as required, and the further addition of sodium chloride such as to obtain a constant sodium ion concentration of 1.0 M. Solutions were left to stand for about 24 h to allow time for complete depolymerization of decavanadate ions present in the stock solution.

Spectrophotometric measurements

The measurements were made with a Varian Cary 210 spectrophotometer, and absorbance data collected by means of an Apple IIe computer. The dimerization equilibrium was studied by a titration procedure. A 0.05 M NaOH solution [1.0 M Na(Cl) medium] was titrated stepwise with a solution of 0.20 M $NaVO_3$ [0.25 M in NaOH and 1.00 M in Na(Cl)], to obtain in the titration cell the following series of vanadate(V) concentrations: 0.001980, 0.002956, 0.004305, 0.005825, 0.007692, 0.01025, 0.01343, 0.01818, 0.02456, 0.03333, 0.04375, 0.05507, 0.06667, 0.07805, 0.08889, 0.09474 M. The solution in the titration cell, which was set up in a thermostatted water bath, was circulated by means of a peristaltic pump to a variable path length flow-through cuvette. Purified and medium-conditioned nitrogen was bubbled through the solution throughout the experiment. Spectra were recorded vs air in the range 218–320 nm. The path length at each setting, which was obtained by calibration as described before,[10] was varied in this experiment from 0.1021 to 0.00386 cm. Blank absorbances were obtained by recording the spectrum of 0.0500 M NaOH [1.0 M in Na(Cl)] vs air at the corresponding path length settings.

The variation with temperature of the hydrolysis constant (K_h) of VO_4^{3-}, was studied by measuring the change in absorption of a solution of 2.002×10^{-4} M vanadate(V) [0.38 M in NaOH and 1.00 M in Na(Cl)]. After degassing with pure N_2, spectra of this solution were recorded from 240 to 320 nm, using a 0.50 cm cuvette against a degassed 0.38 M NaOH [1 M Na(Cl) medium] blank solution. By utilizing thermostatted cuvette holders, spectra were obtained at six different temperatures, viz. 11.1, 16.4, 20.1, 24.9, 29.3 and 34.75°C.

Calorimetric measurements

An isothermal titration calorimeter, Tronac model 550, described elsewhere[11,12] was used for the measurements. Vanadate solutions at three different concentrations, viz. 0.0800, 0.1144 and 0.1500 M, were titrated. Each solution was made up at least 24 h before the calorimetric titration was carried out with an accurately known concentration of NaOH, approximately equal to the vanadate(V) concentration and 1.0 M in Na(Cl). The solution (20 cm^3) was then titrated with 1.0 M NaOH from a Gilmont precision microburette at a constant speed (typically 0.05 $cm^3\ min^{-1}$) and the average number of heat pulses supplied by the control heater at fixed intervals (e.g. 100 s) recorded digitally. A blank titration of 1.0 M NaCl with 1.0 M NaOH was carried out to correct for the endothermic heat of dilution.

RESULTS AND DISCUSSION

Spectrophotometry

The dimerization equilibrium (1) has been investigated at a hydroxide ion concentration of 0.05 M, i.e. $pH_c = 12.40$ (where $pH_c = 13.70 - \log [OH^-]$ at 1 M NaCl[13])

$$2HVO_4^{2-} \overset{K_d}{\rightleftharpoons} V_2O_7^{4-} + H_2O. \quad (1)$$

At this pH_c all other protonation and condensation equilibria can be neglected. The bivanadate ion, HVO_4^{2-}, is the predominant mononuclear species; only about 10% is deprotonated to vanadate:[13]

$$HVO_4^{2-} + OH^- \overset{K_h^{-1}}{\rightleftharpoons} VO_4^{3-} + H_2O. \quad (2)$$

The vanadium concentration was varied from 0.002 to ~0.10 M and the absorption spectra measured in the wavelength range 218–320 nm. Very little dimerization takes place at concentrations < 0.002 M, whereas 0.10 M is about the upper limit which can be measured without having to forfeit accuracy because of the extremely short path length that would be required.

The computer program SPECFIT[14] was used to treat the absorbance data, taking into account equilibrium (2) and its effect on the free hydroxide ion concentration when dimerization increases. The spectra of HVO_4^{2-} and VO_4^{3-} as well as the equilibrium constant for reaction (2), pertaining to 1.0

M NaCl medium, are known with sufficient accuracy from previous work to be supplied to the program.[13] The dimerization constant, K_d, and the spectrum of $V_2O_7^{4-}$ were, therefore, the only unknown parameters to be calculated from the data. However, as a check on the consistency of the two sets of data the spectrum of HVO_4^{2-} was regarded as unknown and calculated together with K_d and the spectrum of $V_2O_7^{4-}$.

The dimerization constant, log $K_d = 0.83$, was computed with excellent agreement between experimental and calculated absorbances at all wavelengths. It is assumed that this value is more accurate than our previously reported value for 1.0 M Na(Cl) medium, i.e. log $K_d = 1.07$, which was determined from potentiometric[15] data in the pH range 7–10. In this pH range $V_2O_7^{4-}$ is one of several minor species which occur together in simultaneously overlapping equilibria and which might affect accurate characterization adversely. When the values determined for the dimerization constant in different ionic media are compared, namely log $K_d = 0.67$ (0.6 M NaCl),[4,15] log $K_d = 0.83$ (1.0 M NaCl), log $K_d = 1.24$ and 1.39 (2.0 M NaCl[7] and 2.0 M LiCl[3]) and log $K_d = 1.44$ and 1.69 (3.0 M $NaClO_4$),[6,16] and allowance is made for deviations, a rather strong dependence on ionic strength is indicated. A general stabilizing effect of high ionic medium on highly charged vanadate polyanions has also been reported by Pettersson *et al.*[6]

The spectrum now calculated for HVO_4^{2-} (Fig. 1) is practically identical to that previously obtained[13] in the determination of K_h from a series of measurements in the pH_c range 12–13.7. Also shown in Fig. 1 is the complete UV spectrum of $V_2O_7^{4-}$ which has been obtained for the first time. The spectrum of this ion, which has two strong absorption bands at 230 and 282 nm, is very similar to that of the tetrahedral[4] orthovanadate ion, VO_4^{3-}, which has absorption peaks at 226 and 270 nm. This similarity can be taken as strong evidence that the structure of $V_2O_7^{4-}$ in solution consists of two VO_4 tetrahedra sharing a vertex as is the case in the solid state.[17,18] Replacement of an oxygen atom of VO_4^{3-} by another orthovanadate group, to give $V_2O_7^{4-}$, causes a reversal in the intensity of the two charge-transfer bands and a slight shift of these bands to longer wavelengths. Similar changes in the spectra take place[19,20] when CrO_4^{2-} is protonated and dimerizes to form $Cr_2O_7^{2-}$, the only difference being that the absorption bands of $Cr_2O_7^{2-}$ appear at slightly shorter wavelengths than those of CrO_4^{2-}.

The enthalpy and entropy changes for reaction (2) were determined indirectly from the variation of the equilibrium constant with temperature. Because

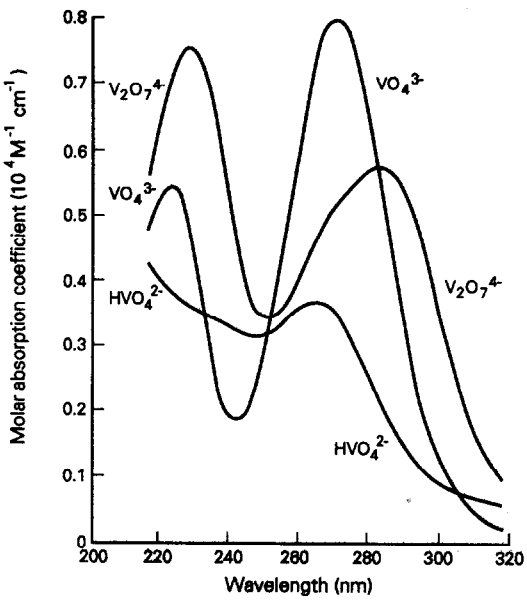

Fig. 1. Absorption spectra of VO_4^{3-}, HVO_4^{2-} and $V_2O_7^{4-}$. Molar absorption coefficients of $V_2O_7^{4-}$ have been divided by two in order to present comparable spectra.

of the great difference between the spectra of VO_4^{3-} and HVO_4^{2-} and the strong absorption bands of the latter species, the equilibrium constant can be determined quite accurately by spectrophotometry. The ΔH^0 and ΔS^0 values deduced from the straight line plot of log K_h vs $1/T$ (Fig. 2) by application of the relationship

$$-2.303RT \log K_h = \Delta G^0 = \Delta H^0 - T\Delta S^0$$

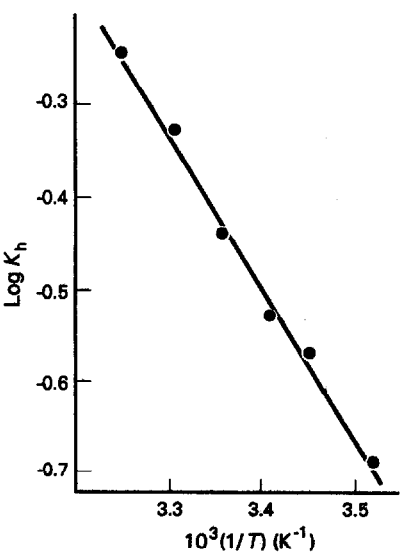

Fig. 2. Variation of logarithm of hydrolysis constant [equilibrium (2)] with reciprocal Kelvin temperature.

Table 1. Values for equilibrium constants and thermodynamic quantities for the reactions at 298.15 K in 1 M Na(Cl) medium

Reaction	log $K \pm 3\sigma$	ΔH^0 (kJ mol^{-1})	$T\Delta S^0$ (kJ mol^{-1})
$2HVO_4^{2-} \rightleftharpoons V_2O_7^{4-} + H_2O$	0.83 ± 0.02	-28	-24
$HVO_4^{2-} + OH^- \rightleftharpoons VO_4^{3-} + H_2O$	0.431 ± 0.014[13]	-32	-29
$HVO_4^{2-} \rightleftharpoons VO_4^{3-} + H^+$	-13.27 ± 0.02	$+24$	-52
$HPO_4^{2-} \rightleftharpoons PO_4^{3-} + H^+$	-12.35	$+15$	-56 ($I = 0$)[22]
$HAsO_4^{2-} \rightleftharpoons AsO_4^{3-} + H^+$	-11.5	$+18$	-47 ($I = 0$)[22]

are given in Table 1. By using the values $pK_w = 13.70$ and $\Delta H^0 = 56.1$ kJ mol^{-1} for the ionization of water in 1.0 M NaCl medium,[13,21] the corresponding thermodynamic quantities for the ionization of HVO_4^{2-} were calculated. It is seen that these values are comparable to those of similar ionization reactions[22] of the main group V species HPO_4^{2-} and $HAsO_4^{2-}$.

Calorimetry

The enthalpy change for the dimerization was determined directly from calorimetric measurements. Vanadate solutions were titrated with 1.0 M NaOH covering the pH_c range 12.3–13.0. A pH_c of 12.3 is the lower limit if one wishes to exclude all hydrolysis equilibria except the two in question and a pH_c of 13 is about the highest that can be reached when titrations are carried out with 1.0 M NaOH. Because of the great overlap between the two equilibria in this pH_c range and the comparatively small change in the concentrations of VO_4^{3-} and $V_2O_7^{4-}$, the calculation of ΔH^0 values for both reactions from these data is not justified. The spectrophotometrically determined values, $\Delta H_h^0 = -32$ kJ mol^{-1} was therefore used in the following equation to calculate a value for the enthalpy change for the dimerization from the measured heat (corrected for dilution effects):

$$Q = n_d \Delta H_d^0 + n_h \Delta H_h^0.$$

The values n_d and n_h are the number of moles formed, while ΔH_d^0 and ΔH_h^0 are the molar enthalpy changes for the formation of $V_2O_7^{4-}$ and VO_4^{3-}, respectively, at 25°C in 1.0 M Na(Cl) medium.

The enthalpy change obtained for the dimerization of HVO_4^{2-}, i.e. $\Delta H_d^0 = -28$ kJ mol^{-1}, can be compared with that reported for the dimerization of $HCrO_4^-$ at zero ionic strength (-20 kJ mol^{-1}).[22] The entropy change for dimerization of HVO_4^{2-} ($T\Delta S^0 = -24$ kJ mol^{-1}) is also comparable to that for $HCrO_4^-$ ($T\Delta S^0 = -11$ kJ mol^{-1}).

CONCLUSION

Values for the enthalpy and entropy changes for the ionization of VO_4^{2-}, as well as those for the formation of $V_2O_7^{4-}$, have been determined for the first time. A complete UV spectrum (220–320 nm) for $V_2O_7^{4-}$, which exhibits two strong absorption bands with maxima at wavelengths 230 and 282 nm, has been calculated from the spectrophotometric data. This spectrum should prove to be particularly useful in further spectrophotometric studies of vanadate equilibria at $pH_c < 12$, where $V_2O_7^{4-}$ overlaps with several other species, some of which have not yet been characterized unambiguously.

PALLADA- AND PLATINACYCLES—III.* SYNTHESIS OF 3,4-DIALKYLIDENE-PLATINACYCLOPENTANES AND THEIR METALLO-ENE TYPE REACTION WITH DIOXYGEN. X-RAY STRUCTURE OF A 2,3-DIOXA-PLATINACYCLOHEPTANE (dad)Pt—O—O—CMe_2—C(=CH_2)—C(=CMe_2)CH_2

H. TOM DIECK,† G. FENDESAK and C. MUNZ

Institute of Inorganic and Applied Chemistry, The University of Hamburg, Martin-Luther-King-Platz 6, D-2000 Hamburg 13, F.R.G.

(*Received* 9 *July* 1990; *accepted* 27 *September* 1990)

Abstract—The reaction of bis(dibenzylideneacetone)platinum with a diazadiene (dad = 2,6-Me_2-Ph-dad, 2,6-$^iPr_2$-Ph-dad) and 1,1-dimethylallene gives the 3,4-bis(isopropylidene)platinacyclopentanes (dad)Pt—CH_2—C(=CMe_2)—C(=CMe_2)CH_2 (**6**) and (**7**). The metallacyclopentane rings are non-planar and rigid. Under air or oxygen the violet complexes **6** and **7** are slowly and quantitatively converted to green complexes **8** and **9**, respectively. The dioxygen does not insert directly into the Pt—C bond but, instead, reacts in a metallo-ene type manner to give the dioxaplatinacycloheptanes (dad)Pt—O—O—CMe_2—C(=CH_2)—C(=CMe_2)—CH_2, as revealed by NMR and X-ray diffraction studies. In complex **8** the platinum atom shows square-planar coordination. The seven-membered ring (with an almost planar C_α—Pt—O—O fragment) is folded in such a way that the two *exo*-alkylidene groups are not in conjugation. The conformation is also rigid in solution. The disposition of the methyl groups proves the unexpected allylic inversion which occurs with the incorporation of dioxygen.

Bis(dibenzylideneacetone)palladium and -platinum[2] are good starting materials for numerous other complexes of these metals used in stoichiometric or catalytic reactions. In the presence of diazadienes (dad = R—N=CH—CH=N—R) and dialkyl acetylene dicarboxylate (E—C≡C—E) stable metallacyclopentadienes **1** and **2** are obtained, which can be used for further catalytic reactions.[1,3–5] The platinacycle **1** reacts slowly with some olefins to give insertion products. This reaction is much faster with the very reactive 1,1-dimethylallene (**3**) to yield the insertion product **4**, a platinacycloheptadiene.[6] We were interested to see whether the (dad)Pt^0 system would also interact with the allene in the absence of any ester (ECCE). The dimerization of allene via the central carbon atom to afford mononuclear or dinuclear complexes is known for numerous metals.[7] In the case of nickel[8] as well as platinum[9] 3,4-methylidene-metallacyclopentanes (**5**) are well characterized. With a (dad)Ni system similar to the one used in this work, allene has been reported to give an unexpected dinuclear nickel(II) complex.[10] We report here on rigid *exo*-dialkylidene platinacycles and their reaction with dioxygen as "ene" in a metallo-ene type reaction.[11,12]

EXPERIMENTAL

In contrast to other reactions of (dad)Pt^0 complexes the following synthesis of **6** and **7** must be performed under an atmosphere of dry nitrogen and with deaerated solvents. The silica gel column must also be prepared under nitrogen. NMR spectra were recorded with a Bruker AM 360 spectrometer. For ^1H and ^{13}C assignments H,H-COSY, C,H-COSY and APT experiments were performed. When broad ^1H(Pt) satellites result as a consequence of chemical shift anisotropy, additional 1D spectra at 80 MHz were recorded.

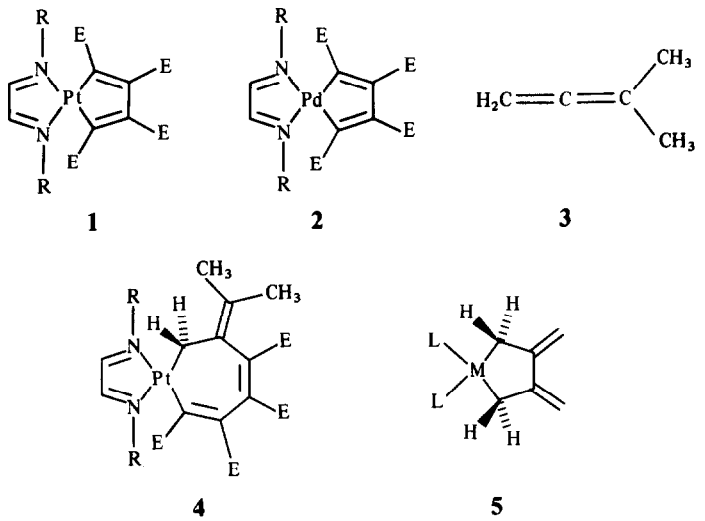

Scheme 1.

Glyoxalbis(2,6 - *dimethylphenylimine*) - 2,3 - *bis*(*isopropylidene*)*butane*-1,4-*diyl-platinum* (**6**)

Bis(dibenzylideneacetone)platinum [$Pt(dba)_2$:[2] 330 mg, 0.5 mmol] was stirred with glyoxalbis(2,6-dimethylphenylimine) (130 mg, 0.5 mmol) in 20 cm^3 of toluene. At ambient temperature a slight excess of 1,1-dimethylallene (130 mg, 1.9 mmol) was slowly added. The reaction was followed by thin-layer chromatography. After 10 h the $Pt(dba)_2$ was consumed and the new violet complex formed. After evaporating the toluene the residue was purified by column chromatography (on silica gel 60, eluent ether–hexane 1 : 1). The product **6** was a dark violet material, which unlike its solutions, is quite stable in air. Yield: 180 mg (55%). High quality crystals for an X-ray structure investigation could not be obtained.

^{1}H NMR (360 MHz, acetone-d_6): δ (ppm), J (Hz); 9.40 [s, HC=N, ^3J(PtH) = 36]; 7.17 (m, 6 H, CH_{arom}); 4.30 [d, H(1), ^2J(HH) = 12.4, ^2J(PtH) = 144, ^5J(HH) = 3]; 3.42 [d, H(1)′, ^2J(PtH) = 60]; 2.35, 2.26 (2 s, CH_{3arom}); 1.47, 1.28 (2 s, CH_3).

Glyoxalbis(2,6-*diisopropylphenylimine*)-2,3-*bis*(*isopropylidene*)*butane*-1,4-*diyl-platinum* (**7**)

In a procedure analogous to the one described for **6** with the corresponding dad, glyoxalbis(2,6-diisopropylphenylimine), a yield of 200 mg (52%) of **7** was obtained after purification.

^{1}H NMR (360 MHz; C_6D_6): δ (ppm), J (Hz); 8.79 [s, HC=N, ^3J(PtH) = 36]; 7.4 (m, CH_{arom}); 5.34 [d, H(1), ^2J(HH) = 12.4, ^5J(HH) = 3, ^2J(PtH) 155]; 4.33 [d, H(1)′, ^2J(PtH) = 90], 3.80, 3.55 (2 sept, CH_{ipr}); 2.09 (s, CH_3), 1.92 (br. s, CH_3); 1.68, 1.35 (double intensity); 1.23 (3d, CH_{3ipr}). ^{13}C NMR (90.5 MHz; $CDCl_3$): δ (ppm), J (Hz); 162.2 (CHN); 146.6 [C(2)]; 144.9 (C_{ipso}); 139.5, 139.2 (C_{ortho}); 127.0 (C_{para}); 123.0, 122.8 (C_{meta}); 113.4 [C(3); ^3J(PtC) = 72]; 27.5, 27.4 (CH_{ipr}); 25.1, 24.8, 23.2, 22.8 (CH_{3ipr}); 22.5, 19.7 (CH_{3ortho}); 14.5 [Cl, ^1J(PtC) = 745].

(*dad*)*platina*-3-*isopropylidene*-4-*methylene*-5,5-*dimethyl*-6,7-*dioxa*-*cycloheptanes* (**8** *and* **9**)

The (dad)platinacyclopentanes **6** or **7** were stirred for a few hours in toluene under an atmosphere of dioxygen. The colour changed from violet to green. The yield was quantitative. After evaporation of the toluene a green solid material was obtained, which crystallized from ether in the form of green needles.

8 (from **6**). Yield: 95%. ^{1}H NMR (360 MHz, $CDCl_3$): 9.77 [s, NCH, ^3J(PtH) = 84]; 8.69 [s, NCH, ^3J(PtH) = 42]; 7.2 (m, H_{arom}); 4.80 [d, H(8), ^2J(HH) = 2.4]; 4.65 [d, H(8)′]; 3.48 [d, H_α, ^2J(PtH) = 144]; 2.94 [d, $H_{\alpha'}$, ^2J(HH) 11.5, ^2J(PtH) = 60]; 2.36, 2.30, 2.21, 2.18 (4s, CH_{3ortho}), 1.54, 1.25, 1.17, 0.85 (4s, CH_3).

9 (from **7**). Yield: 98%. ^{1}H NMR (360 MHz, C_6D_6): 9.32 [s, NCH, ^3J(PtH) = 79], 7.99 [s, NCH, ^3J(PtH) = 40]; 7.4 (m, H_{arom}); 5.31, 5.18 [2 d, C=CH_2, ^2J(HH) = 2.5]; 4.50 [d, H_α, ^2J(HH) = 11.5, ^2J(PtH) = 144], 3.73 (m, $H_{\alpha'}$, and 2 CH_{ipr}); 3.57, 3.48 (2 sept. CH_{ipr}); 2.06, 1.75, 1.62, 1.38 (4s, C=CMe_2 and O—CMe_2); 1.76, 1.66, 1.55, 1.50, 1.31 (double intensity), 1.26, 1.22 (8d, CH_{3ipr}). ^{1}H NMR (360 Mhz, $CDCl_3$): 9.79 [s, ^3J(PtH) = 79], 8.64 [s, ^3J(PtH) = 35]; 7.35 (m, H_{arom});

4.83, 4.67 [2d, C=CH_2, ^2J(HH) = 2.3]; 3.73, 3.23 (2 sept, CH_{ipr}); 3.58 [d, H_α, ^2J(HH) = 11.5, ^2J(PtH) = 146]; 3.13 (m, $H_{\alpha'}$ and 2 CH_{ipr}); 1.50 [d, one CH_3-*exo*, $J(HH_\alpha)$ = 2 Hz]; 1.42 (double intensity), 1.31, 1.26, 1.20, 1.11, 1.04, 1.01 (8 d, CH_{3ipr}); 1.28, 1.06 (s, CH_3). ^{13}C NMR (90.5 MHz, $CDCl_3$): 164.4, 158.4 (HCN); 155.0 (C_β), 146.9, 146.5 (C_{ipso}); 140.8, 139.8, 139.1, 138.5 (C_{ortho}); 140.4 (C=CH_2); 127.9, 126.3 (C_{para}); 123.5, 123.4, 123.2, 122.7. (C_{meta}); 120.7 (C=CMe_2); 112.1 (CCH_2); 83.1 ($OCMe_2$); 28.0, 27.3 (CH_{iso}); 27.1, 25.1, 23.7, 19.5 (CH_3); 24.5, 24.0, 23.1, 22.9, 22.8, 22.6 (CH_{3iso}); 20.2 (C_α). UV–vis (CH_2Cl_2): max = 590, 388 nm.

X-ray diffraction study of **8**

Crystals were obtained from ethereal solutions, then transferred to a Lindemann tube and mounted on a Syntex $P2_1$ four-circle diffractometer. The crystals are orthorhombic, the space group is *Pcab* (No. 61),[13] the lattice constants were determined as a = 13.683(3), b = 14.058(5), c = 27.64(1) Å and V = 5316(4) Å^3. With Z = 8 and a molecular mass of 627.7 for the molecule $C_{28}H_{36}N_2O_2Pt$ the calculated density is 1.563 g cm^{-3}. The study was performed with Mo-K_α radiation (graphite monochromator, λ = 0.71069 Å). Of 5244 measured reflections and 4706 symmetry-independent reflections thereof, 2768 with $(F_o) > 3\sigma(F_o)$ were used. The number of refined parameters is 262. Linear absorption coefficient μ = 53.6 cm^{-1}. The 2θ range was 4.5–50°. The h, k, l range was 0–16; 0–16; 0–32. The position of the platinum atom was determined by a Patterson synthesis. In following difference Fourier maps the non-hydrogen atoms were located, the hydrogen atoms calculated in ideal positions.[14] All non-hydrogen atoms were refined anisotropically, the hydrogen atoms isotropically.[15] The R values converged to R = 0.0631 and R_w = 0.0764 (weight, w = 0.0005).

Further details on the crystal structure determination can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-75. Eggenstein-Leopoldshafen, on quoting the depository number CSD-54905, the authors, and the journal citation. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis and spectra

When $Pt(dba)_2$ is stirred in toluene at ambient temperature with an equimolar amount of dad [R′ = H, R = 2,6-Me_2-C_6H_3 or 2,6-$(ipr)_2$-C_6H_3] and an excess of dimethylallene, the 3,4-bis(isopropylidene)platinacyclopentanes **6** and **7** are obtained as the only reaction products. Both complexes are fully characterized by ^{1}H and/or ^{13}C NMR. The ^{195}Pt satellites are helpful in determining the structure and the conformation.[5,16] The unsubstituted double bonds of two allene molecules combine to form the ring, the methylene group being directly bonded to the platinum. The α-CH_2 hydrogen atoms are diastereotopic and thus each appears as a doublet showing quite different Pt—H coupling constants (**6**: 144 and 60, **7**: 155 and 90 Hz). The lower field signal in both complexes is further structured by the coupling to one of the exocyclic isopropylidene methyl groups. This methyl signal has a larger width and a reduced height compared with the other. The spectra agree with the proposed C_2 structure. The steric demand of the isopropylidene groups makes the molecule very rigid and, of course, non-planar. The corresponding platinacyclopentane obtained by Green and coworkers from allene itself[9] does not show diastereotopic α-hydrogen atoms in the NMR. In **7** the ^{195}Pt–^{13}C coupling is easily detected for the α-carbon (^1J = 745 Hz) and the exocyclic sp^2-carbon (^3J = 72 Hz), but not for the β-carbon.

During the first preparation of **6** and **7** a second, green complex was observed when the reaction was followed by thin-layer chromatography. From the number of signals in the NMR an isomer with reduced symmetry appears to form. Repetition of the experiment with strict exclusion of oxygen did not show any such by-product. However, stirring solutions of pure **6** and **7** under an atmosphere of oxygen for some hours gave a virtually quantitative yield of the new green complexes **8** and **9**.

The ^{1}H NMR spectra, which are rather solvent dependent, give some information about the structure. The four methyl groups of the alkylidene substituents of the former **6**, **7** are now inequivalent. One α-CH_2 group seems to persist, while the other CH_2 group gives signals in the olefinic region with the typical small geminal coupling of a C=CH_2 fragment. The number of dad signals (**9**: eight methyl doublets, four CH_{iso} septets and two HC=N singlets; **8**: four methyl singlets, two imine proton signals) clearly shows a C_1 symmetry. A substantial rearrangement must have occurred in going from **6** and **7** to **8** and **9**. Therefore a crystal structure determination was performed for **8**.

Crystal structure of **8**

Suitable crystals were obtained from ethereal solutions. Selected bond lengths and angles are

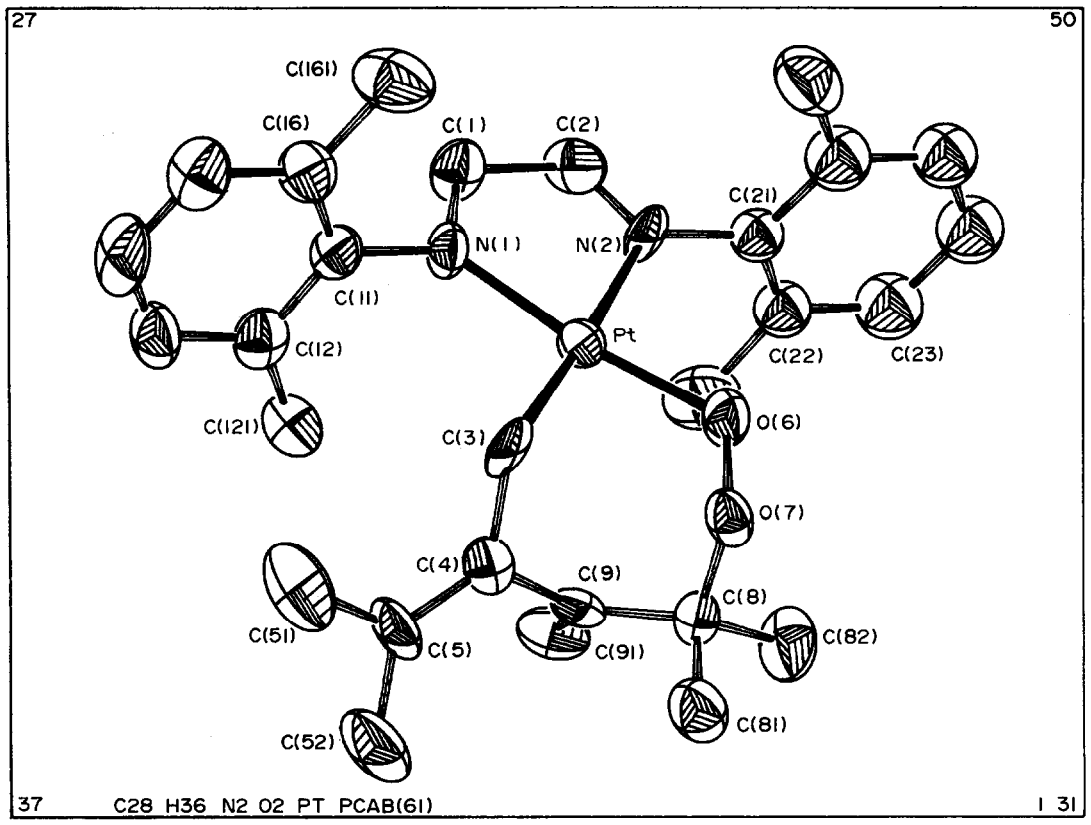

Fig. 1.

listed in Table 1 and Fig. 1 shows the molecule and the atomic numbering scheme

The molecule is a spiro compound with the platinum atom in the centre of a five-membered and a seven-membered ring. The coordination around platinum is square-planar, as expected. The dad system shows typical distances for a complex with the metal in a normal oxidation state, i.e. where backbonding does not play an important role. The standard deviations do not allow a detailed discussion, but it is obvious that the Pt—N(1) bond *trans* to oxygen is much shorter than the Pt—N(2) bond, reflecting the much stronger *trans* effect of a carbon ligand. Similar results are encountered for (dad)Ni and other (dad)Pt chelate complexes with carbon and halogen ligands.[17-19]

The interesting feature in the molecular structure is the incorporation of a dioxygen molecule. The disposition of the methyl groups, however, shows clearly that this does not occur via an insertion into the Pt—C_α bond of **6**. A metallo-ene type reaction,[11,12] as discussed below, can account for the regiochemistry.

The dihedral angle of the Pt—O—O—C fragment is 84(1)° and thus displays the typical orthogonal arrangement of hydrogen peroxide and its derivatives.[20] The *exo*-isopropylidene and the *exo*-methylene groups are not in conjugation, the dihedral angle C(5)—C(4)—C(9)—C(91) is 59(2)°. The Pt—C distance is in the expected region and slightly shorter than in the metallacycles with stronger *trans*-directing ligands than the sp^2-nitrogen.[21] As shown above, the molecule is rigid in solution. The conformation of the seven-membered ring is such that one of the α-hydrogen atoms [on C(3)] is equatorial, the other axial with respect to the plane defined by the platinum lignds. The platinum *s*-orbital is mainly engaged in the four σ-bonds, and therefore the coupling of the ^{195}Pt nuclear spin to the equatorial hydrogen is stronger (144 Hz) than to the axial one (60 Hz). Such values could give indications of the conformations of other compounds such as **6** and **7**. The equatorial hydrogen atoms on C_α in these compounds are coupled to one of the isopropylidene methyl groups and are deshielded with respect to the axial ones; structural models show that they are almost co-planar with the alkylidene substituent.

The reaction of the bis(alkylidene)platinacyclopentanes **6** and **7** with oxygen provided more information than anticipated. The structures of **8** and **9** show a direct link between oxygen and the former-

ly terminal carbon atom of one of the alkylidene groups, while the carbon atom, originally bonded to the metal, is now the terminal atom of an *exo*-methylene group. Such a reorientation is not unprecedented; there are many examples of the insertion of olefins into magnesium or zinc σ-allyl systems, with a concomitant inversion of the allyl group.[11] This work was extended to transition metals,[12] but in all cases C=C double bonds were inserted. Oppholzer called this a metallo-ene reaction,[11] and the stereochemistry of such processes invokes a six-membered cyclic transition state in a concerted process. Here, we have to consider a similar process with dioxygen as the "ene". The methyl substituents of the alkylidene groups in **6** and **7** are responsible for the strong deviation of the platinacyclopentane from planarity. This might facilitate the conformational change to the transition state. Catalytic reactions of this type are under investigation.

THE PREPARATION AND X-RAY CRYSTAL STRUCTURE OF $(PMe)_4Se_3$

STEPHEN W. HALL, MARK J. PILKINGTON, ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College of Science, Technology and Medicine, South Kensington, London SW7 2AY, U.K.

(*Received* 18 *July* 1990; *accepted* 27 *September* 1990)

Abstract—The reaction of $(PMe)_5$ with grey selenium in refluxing toluene has been studied with a range of P : Se ratios. With excess selenium, P : Se = 1 : 2, $(PMeSe_2)_2$ is obtained, whereas when the reaction is performed with P : Se ratios of between 4 : 1 and 1 : 1, complex mixtures are obtained. $(PMe)_4Se_3$ (**1**) has been isolated and crystallographically characterized, it has a folded five-membered P_4Se ring with the four phosphorus atoms coplanar. There are significant intermolecular non-bonded interactions between the exocyclic selenium atoms and the "vacant" tetrahedral site of the phosphorus(III) atoms.

Although phosphorus–sulphur rings are well known, there are only a few examples of P—Se heterocycles.[1] These compounds are potentially useful as selenating agents by analogy with the well known Lawessons reagent.[2,3] We have recently shown that reaction of $(PPh)_5$ with grey selenium gives four- and five-membered binary P—Se rings.[4–6] Here, we report on the reaction of $(PMe)_5$ with selenium, together with the X-ray crystal structure of $(PMe)_4Se_3$ (**1**).

EXPERIMENTAL

All manipulations were carried out under an atmosphere of argon or nitrogen; thf, ethoxyethane and diethyl ether were distilled from sodium–benzophenone and toluene was dried over sodium. $(PMe)_5$ was prepared by the literature method.[7] $^{31}P\{^1H\}$ NMR spectra were recorded at 101.4 and 202.8 MHz on Bruker-WM250 and AM500 instruments, respectively. IR spectra were obtained using a PE 1720X instrument. Mass spectra were obtained on a VG 2020 instrument operating in the electron impact mode.

Preparation of $(PMe)_xSe_y$

In a typical reaction grey selenium (1.33 g, 16.8 mmol) was added to 15 cm^3 of deoxygenated toluene. A solution of $(PMe)_5$ in hexane (7.8 cm^3, 0.653 M, 5.1 mmol) was added dropwise with stirring under a stream of oxygen-free nitrogen. The mixture was heated to reflux for 2.5 h. After cooling, the solvent was removed *in vacuo* to give a fine yellow powder. The solid was washed with 2×20 cm^3 cold, dry ethoxyethane and dried *in vacuo*. Yield: 1.7 g. NMR (toluene solution): see Fig. 1. IR (cm^{-1}): 2955 (m, br), 2386(w br), 1652(w br), 1405(m br), 1305(s), 1178(m br), 881(w), 849(w br), 734(m), 677(w), 491(s), 422(w), 361(w). Found: C, 11.8; H, 3.3. Calc. for $(PMe)_3Se_2$: C, 12.2; H, 3.1%. Mass spectrum: *m/z* 456 $(PMe)_3Se_4$, 424 $(PMe)_4Se_3$, 376 $(PMe)_3Se_3$, 330 $(PMe)_2Se_3$, 298 $(PMe)_3Se_2$, 252 $(PMe)_2Se_2$, 172 $(PMe)_2Se$, 126 PMeSe, 46 PMe.

Varying the phosphorus to selenium ratio of the starting materials (4P : 1Se and 1P : 1Se) gave products showing comparable NMR and IR spectra and identical mass spectra. Slow diffusion of hexane into toluene solutions of both the 1P : 1Se and 3P : 2Se reaction products gave rather poorly formed, slightly opaque crystals of $(PMe)_4Se_3$ which were just adequate for X-ray analysis.

A 1P : 2Se ratio resulted in a rust–orange powder insoluble in common solvents. Yield: 1.25 g, 66%. Found: C, 6.0; H, 2.1. Calc. for $(PMeSe_2)_2$: C, 5.9; H, 1.5%. IR (cm^{-1}): 2965(w), 2358(w), 1634(w br), 1385(w br), 844(vs), 725(m), 480(vs br), 418(w), 346(w), 303(w). Mass spectrum: *m/z* 492 $(PMe)_2Se_5$, 410 $(PMe)_2Se_4$, 330 $(PMe)_2Se_3$, 206 $PMeSe_2$, 126 PMeSe, 46 PMe.

Crystal data for $C_4H_{12}P_4Se_3$ (**1**). $M = 420.9$,

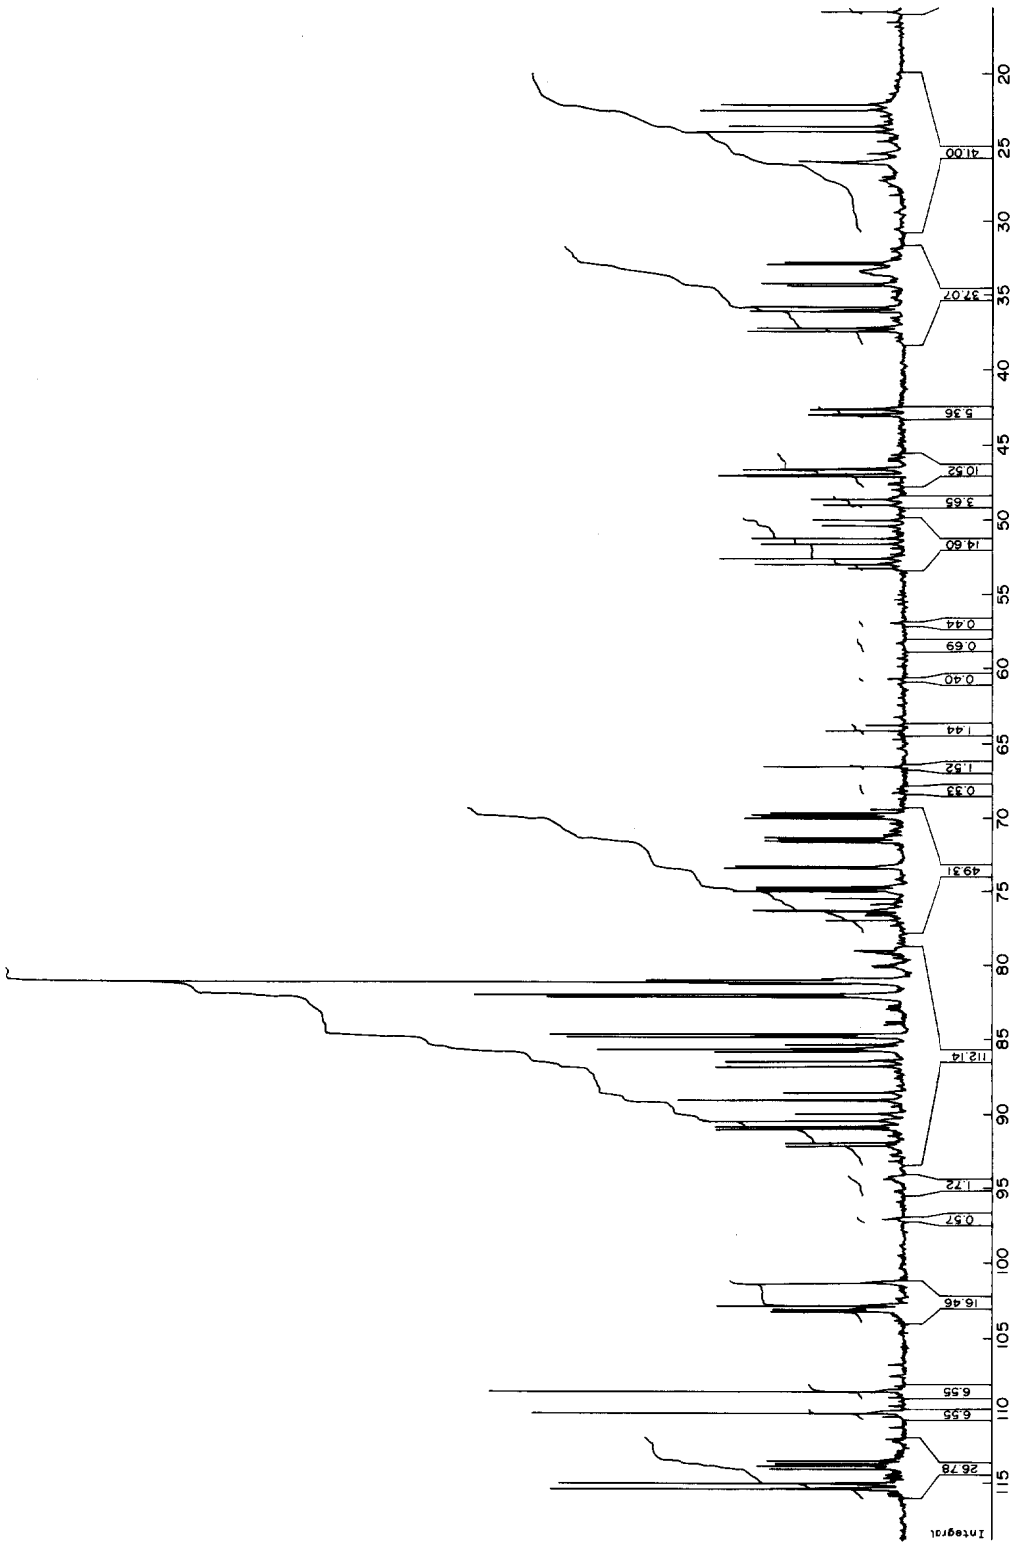

Fig. 1. $^{31}P\{^{1}H\}$ NMR (202.8 MHz) of the reaction between 3/5(PMe)$_5$ and 2Se.

monoclinic, $a = 13.225(41)$, $b = 10.586(26)$, $c = 18.493(22)$ Å, $\beta = 92.83(19)°$, $U = 2586$ Å^3, space group $I2/a$ (body-centred cell chosen because C face-centred cell had $\beta = 144°$), $Z = 8$, $D_c = 2.16$ g cm^{-3}. Crystal dimensions $0.67 \times 0.67 \times 0.40$ mm, μ(Cu-K_α) = 151 cm^{-1}, $\bar{\lambda} = 1.54178$ Å, $F(000) = 1584$. Due to the air sensitivity and instability of the compound the crystal was mounted in a Lindemann tube under liquid paraffin.

Data collection and processing. Nicolet R3m diffractometer, ω-scan method ($\theta \leqslant 58°$), graphite monochromated Cu-K_α radiation; 1427 independent measured reflections, 1298 observed [$|F_o| > 3\sigma(|F_o|)$], corrected for Lorentz and polarization factors; empirical absorption correction (ellipsoidal) based upon 312 azimuthal scans. Maximum and minimum transmission factors 0.068 and 0.008, respectively.

Structure analysis and refinement. The structure was solved by direct methods and all the non-hydrogen atoms refined anisotropically. The hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters $U(H) = 1.2U\text{eq}(C)$ and allowed to ride on their parent carbons. The methyl groups were refined as rigid bodies. Refinement was by block-cascade, full-matrix least-squares to $R = 0.065$, $[R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|]$, $R_w = 0.077$ [$w^{-1} = \sigma^2(F) + 0.00085F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 0.96 and -0.79 e Å^{-3} and the mean and maximum shifts/error in the final refinement cycle were 0.000 and 0.001, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[8]

RESULTS AND DISCUSSION

We have previously reported[5,6] that reaction of $(PPh)_5$ with grey selenium gives, depending on the ratio of reactants, $(PhPSe_2)_2$ (**2**), $(PhP)_3Se_2$ (**3**), $(PhP)_4Se$ (**4**) and $(PhP)_3Se_3$ (**5**). These compounds were characterized by multi-element NMR, mass spectrometry, microanalyses and in the case of **4**, X-ray crystallography. Compound **4** consists of a puckered five-membered ring with all four phenyl substituents axial (average P—P and P—Se bond lengths are 2.194 and 2.271 Å, respectively). Karaghiosoff and Jochem have reported the structure of **5**.[9]

We have now studied the reaction of grey selenium with $(PMe)_5$ so as to probe the degree of steric control that the cyclophosphane substituents provide. Thus, refluxing $(PMe)_5$ with grey selenium using a variety of P : Se ratios was studied. During the course of the reaction the bulk of the selenium is consumed to give yellow solutions. The ^{31}P NMR (202.8 MHz) of a typical reaction is shown in Fig. 1. As can be seen, more than one compound is formed. Varying the P : Se ratio from 4 : 1 through to 1 : 1 had little effect on the spectrum [in contrast to the $(PPh)_5$ reactions]. Simple evaporation of solvent at this stage gave a solid containing a mixture of PSe rings. Attempts to separate this many component system by HPLC (silica gel and gel permeation) have been unsuccessful. However, addition of hexane to the crude reaction mixtures from the 1 : 1 and 3 : 2 ratio reactions gave crystalline **1**, the structure of which is discussed below. Redissolution of **1** into organic solvents resulted in complex NMR spectra similar to that in Fig. 1, suggesting that the system undergoes a number of rapid equilibria. It is not surprising that the methyl substituted compounds are more labile and air sensitive than their previously reported phenyl analogues.

Using increased amounts of selenium(1P : 2Se) gave a rust–orange solid (**6**) which is insoluble in most organic solvents [eq. (1)] and analyses correctly for $(PMeSe_2)_2$. Compound **6** has similar properties to **2**; both are red–orange insoluble solids, whereas all of the other (five-membered) rings that have been described are yellow, organic soluble solids. In **6** we assign the band at 480 cm^{-1} to ν(P=Se), cf. 508 cm^{-1} in **2**. We assume that both **2** and **6** have four-membered ring structures analogous to Lawessons reagent.

$$2/5(PMe)_5 + 4Se \longrightarrow (PMeSe_2)_2 \qquad (1)$$

The X-ray structure of **1** is shown in Fig. 2 with bond lengths and angles in Table 1. The molecule consists of a five-membered P_4Se ring with all of the phosphorus atoms having methyl substituents and two phosphorus atoms having P=Se groups, both of which lie on the same side of the ring. The phosphorus(V) and phosphorus(III) centres alter-

nate around the ring. This is the first example of a five-membered P—Se ring containing two phosphorus(V) atoms. The four phosphorus atoms in **1** are co-planar to within 0.01 Å. The ring is folded about the P(1)···P(4) direction with a dihedral angle of 47° between the P(1)—P(2)—P(3)—P(4) and P(1)—Se—P(4) planes. The ring selenium lies 1.83 Å from the plane of the phosphorus atoms, on the opposite side of the plane to the exocyclic selenium atoms. The bond lengths in **1** do not differ significantly from those in the related $(PhP)_4Se$ (**4**). However, although both methyl substituents on the phosphorus(III) atoms adopt axial geometries which are very similar to those of the phenyl substituents in **4**, the angles at these centres and at the ring selenium are significantly reduced in **1**, reflecting the oxidation of the P(1) and P(3) centres here. Furthermore, the puckering of the ring in **1**

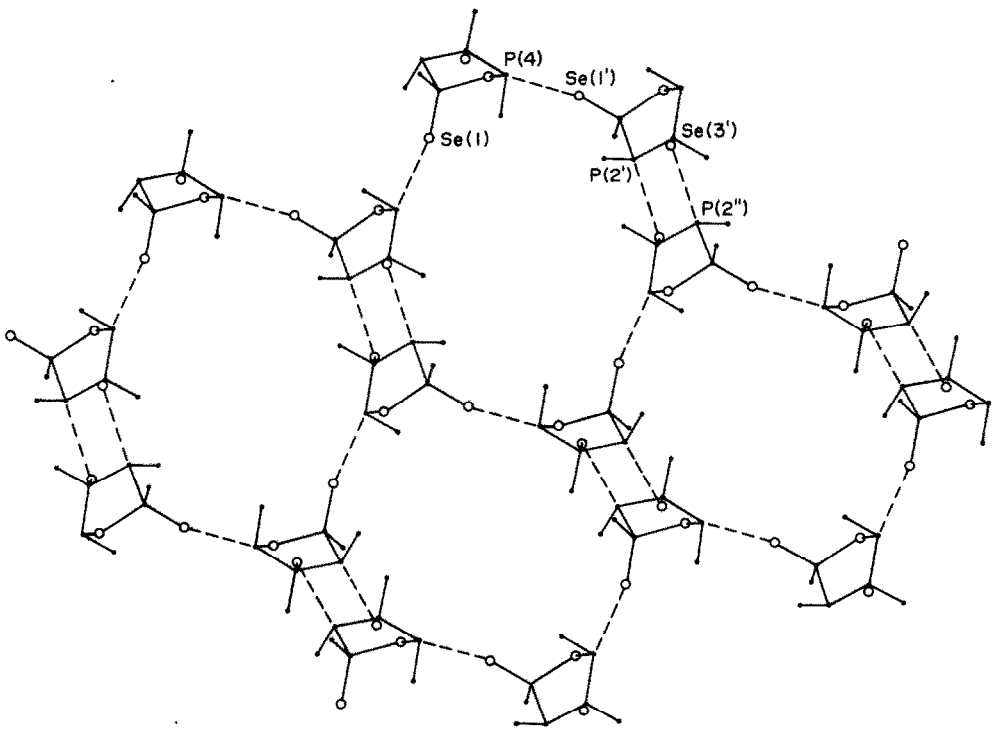

Fig. 3. Part of the contiguous hexagonal array of **1** in the crystal.

differs appreciably from that in **4** where the phosphorus atoms are significantly non-co-planar. The P=Se distances are similar to those reported for P=Se groups in organo-phosphorus–selenium compounds.[4] A study of the packing of **1** in the crystal (see Fig. 3) reveals important short, non-bonded intermolecular Se···P approaches between the exocyclic selenium atoms, Se(1),Se(3) and the phosphorus(III) atoms, P(2),P(4). There is a near tetrahedral approach of these exocyclic selenium atoms to the ring phosphorus atoms with P(4)···Se(1″) 3.43 Å (P—Se···P 165°) and P(2)···Se(3′) 3.77 Å (and vice versa about a crystallographic centre of symmetry, P—Se···P angle 116°). The combination of these interactions results in a contiguous network of loosely linked hexagonal arrays of molecules. These interactions, in particular the former, suggest possible reaction pathways for selenium transfer in these molecules. These interactions presumably involve overlap of sp^3 lone pairs on phosphorus and selenium with low-lying *d*-orbitals of the selenium and phosphorus, respectively.

Abstract—Reaction of $[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)]^+$ (M = Mo or W) with one equivalent of $CNBu^t$ affords $[M(CO)_2(CNBu^t)(\eta^7\text{-}C_7H_7)]^+$ (**1**, M = Mo; **2**, M = W), which react with further $CNBu^t$ to give the ring slipped products $[M(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)]^+$ (**3**, M = Mo; **4**, M = W). At 20°C, **3** slowly converts to a mixture of $[Mo(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**5**) (the formal substitution product of **1** with $CNBu^t$) and $[Mo(CO)(CNBu^t)_4(\eta^3\text{-}C_7H_7)]^+$ (**7**). On heating to 50°C, **7** yields **5** and $[Mo(CNBu^t)_3(\eta^7\text{-}C_7H_7)]^+$ (**8**). Reflux of $[W(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)]^+$ (**4**) in 2-butanone affords $[W(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**6**) as the major reaction product.

Much recent attention has been given to the ring slippage chemistry of transition metal cyclopentadienyl and indenyl complexes and the facilitation of substitution at the metal centre via ring slipped intermediates.[1] The cycloheptatrienyl ligand, C_7H_7, exhibits a wide range of hapticities (η^7, η^5, η^3 or σ)[2–5] in bonding to transition metals, so encouraging complementary studies on its ring slippage chemistry; our interest in this area centres on $\eta^7\text{-}C_7H_7 \rightarrow \eta^3\text{-}C_7H_7$ ring slip in complexes with molybdenum and tungsten.[6–8] Reports on $\eta^3\text{-}C_7H_7$ complexes of molybdenum and tungsten are quite scarce (see ref. 7 and refs therein) and moreover, with very few exceptions, synthesis involves addition of appropriate ligands to the metal centre of a very limited range of $\eta^7\text{-}C_7H_7$ precursors, $[MX(CO)_2(\eta^7\text{-}C_7H_7)]^{z+}$ (M = Mo or W; $z = 0$, X = halide; $z = +1$, X = NCMe). In general, $\eta^3\text{-}C_7H_7$ complexes of molybdenum and tungsten are sufficiently stable such that their intermediacy in ligand substitution processes at the metal centre, which proceed via ring slippage of the cycloheptatrienyl ligand, should be readily confirmed. However, prior to the current work only one established example of this substitution mechanism has been described,[9] namely the conversion of $[MoI(CO)_2(\eta^7\text{-}C_7H_7)]$ to $[MoI(dppe)(\eta^7\text{-}C_7H_7)]$ (dppe = $Ph_2PCH_2CH_2PPh_2$) which in fact proceeds via two successive intermediates, $[MoI(CO)_2(dppe)(\eta^3\text{-}C_7H_7)]$ and $[Mo(CO)(dppe)(\eta^7\text{-}C_7H_7)]I$.

We have previously reported the first example of $\eta^7 \rightarrow \eta^3$ ring slippage in cationic cycloheptatrienyl complexes:[8]

$$[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)]^+ + 2NCMe \rightarrow$$
$$[M(CO)_2(NCMe)_3(\eta^3\text{-}C_7H_7)]^+ \text{ (M = Mo or W).}$$

This system does not lend itself to an investigation of substitution of CO by NCMe since NCMe is generally displaced from $[M(CO)_2(NCMe)_3(\eta^3\text{-}C_7H_7)]^+$ in preference to CO, resulting in reversion to $[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)]^+$. However, we now describe the synthesis and reaction chemistry of some analogous cationic carbonylisonitrile complexes which provide a well defined example of ligand substitution at the metal centre proceeding via an isolated $\eta^3\text{-}C_7H_7$ intermediate.

RESULTS AND DISCUSSION

The application of the acetonitrile complexes $[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)]^+$ (M = Mo or W) in the high yield synthesis of $[M(CO)_2L(\eta^7\text{-}C_7H_7)]^+$ (L = P-donor ligand) has been described in an earlier paper[8] and in the current work this method

* Author to whom correspondence should be addressed.

provided a convenient entry to the synthesis of a series of cationic isonitrile complexes. Treatment of a CH_2Cl_2 solution of $[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)][BF_4]$ with one equivalent of $CNBu^t$ promoted a rapid colour change from green to red with the formation of $[M(CO)_2(CNBu^t)(\eta^7\text{-}C_7H_7)][BF_4]$ (**1**, M = Mo; **2**, M = W) (Scheme 1). Details of characterization by microanalysis, IR and FAB mass spectroscopy, ^1H and ^{13}C NMR spectroscopy are given in Tables 1–3.

The analogy between **1**, **2** and the nitrile complexes $[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)]^+$ (M = Mo or W) prompted an examination of the susceptibility of **1** and **2** to undergo ring slip on addition of ligands (L) to give $[M(CO)_2(CNBu^t)L_2(\eta^3\text{-}C_7H_7)]^+$ (L = $CNBu^t$; L_2 = dppe, etc.). Reaction of **1** or **2** with $CNBu^t$ in an approximate 1:2 ratio, or alternatively, direct reaction of $[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)][BF_4]$ with three equivalents of $CNBu^t$ in CH_2Cl_2 afforded red solutions of the trihaptocycloheptatrienyl complexes $[M(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)][BF_4]$ (**3**, M = Mo; **4**, M = W) which were isolated as brown–red solids. The operation of $\eta^7\text{-}C_7H_7 \rightarrow \eta^3\text{-}C_7H_7$ ring slippage in the formation of **3** from **1** and of **4** from **2** is indicated by a characteristic shift to lower wavenumber of the IR active carbonyl stretching frequencies and, in the ^{13}C NMR spectra, by a shift of the C_7H_7 carbon signal to low field by *ca* 10 ppm. In both ^1H and ^{13}C NMR spectra of **3** and **4** the $\eta^3\text{-}C_7H_7$ ligand exhibits only a sharp singlet signal; this may be attributed to a low energy 1,2 shift process[10] which renders all the ring positions equivalent. In favourable cases,[7,10,11] limiting low temperature spectra have been obtained for complexes in which C_7H_7 is bonded trihapto to molybdenum or tungsten thus providing additional confirmation of the η^3 coordination mode of the ring. However, whilst the ^1H NMR spectra of **3** and **4** in CD_2Cl_2 exhibited some line broadening of the C_7H_7 singlet signal on cooling, the coalescence temperature was not approached, even at −90°C, and we conclude that **3** and **4** represent unfavourable subjects for the acquisition of limiting low temperature spectra. Assuming a pseudo octahedral geometry for **3** and **4**, three isomeric structures may be proposed; that shown in Scheme 1 with *cis* carbonyl ligands and a facial arrangement of $CNBu^t$ groups {analogous to the structure proposed for $[W(CO)_2(NCMe)_3(\eta^3\text{-}C_7H_7)][BF_4]$} is preferred on the basis of the observation of a single carbonyl carbon signal in the ^{13}C NMR spectrum and, in the IR spectrum, relative intensities of the two carbonyl bands typical of *cis* carbonyls. Also of note is the successful application of FAB mass spectroscopy in the characterization of **3** and **4**; our previous attempts to characterize

any η^3-C_7H_7 complexes of molybdenum and tungsten by electron impact mass spectroscopy were unproductive.

Although **3** and **4** are close analogues of the acetonitrile complexes $[M(CO)_2(NCMe)_3(\eta^3\text{-}C_7H_7)]^+$ (M = Mo or W), $CNBu^t$ bonds more effectively to the metal centre than NCMe and therefore reversion of the C_7H_7 ring in **3** and **4** to η^7-hapticity resulted in loss of at least one carbonyl ligand and the formation of new substituted products. At

ambient temperature the tungsten derivative **4** proved to be very stable but $[Mo(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)][BF_4]$ (**3**) underwent slow conversion to new products; indeed the synthesis of **3** was best carried out at 0°C. The thermal decomposition of **3** was monitored spectroscopically at 30°C; in the ^1H NMR spectrum a decrease in the intensity of the C_7H_7 ring signal due to **3** at δ 5.72 ($CDCl_3$) was accompanied by the growth of two new signals in the C_7H_7 region of the spectrum at δ 5.51 and 5.30 and after 10 h, only these new signals remained with a respective integral ratio of 1.7 : 1. IR spectroscopy revealed two new carbonyl bands [ν(CO)(CH_2Cl_2) 1988, 1918 cm^{-1}] in addition to changes in the ν(CN) region of the spectrum. A preparative scale reaction starting with **3** led to the separation and isolation of two reaction products which were characterized by microanalysis, IR and FAB mass spectroscopy and by ^1H NMR spectroscopy.

The major reaction product was identified as $[Mo(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**5**), an authentic sample of which may be prepared more conveniently and in high yield via treatment of $[MoBr(CO)_2(\eta^7\text{-}C_7H_7)]$ with two equivalents of $CNBu^t$ and one equivalent of $NH_4[PF_6]$ in refluxing acetone; this latter reaction proceeds via the intermediate $[MoBr(CO)_2(CNBu^t)_2(\eta^3\text{-}C_7H_7)]$ which will be described in a subsequent report.

The reaction sequence **1** → **3** → **5**, demonstrates the formal substitution of CO by $CNBu^t$ via a ring slipped intermediate; it is very unlikely that **5** is formed directly from $[Mo(CO)_2(CNBu^t)(\eta^7\text{-}C_7H_7)]^+$ (**1**) since treatment of **1** with less than two equivalents of $CNBu^t$ initially leads to mixtures of **1** and **3**, moreover, monitoring by ^1H NMR spectroscopy provided no evidence for reversion of **3** to **1**. The formation of **5** from **3** is not however entirely straightforward. The minor product isolated from the thermal decomposition of $[Mo(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)]^+$ (**3**) was identified as $[Mo(CO)(CNBu^t)_4(\eta^3\text{-}C_7H_7)]^+$ (**7**) and ^1H NMR experiments revealed that **7** can (in part) also be converted to $[Mo(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**5**). However, this reaction was very slow at 30°C and it seem improbable that **7** is a primary intermediate in the formation of **5** from **3**.

Complex **7** may be surmised to originate from a direct substitution of CO by $CNBu^t$ in **3** or alternatively via reaction of $[Mo(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**5**) with free $CNBu^t$ released in the conversion of **3** to **5**. To examine this latter possibility, the reaction of $[Mo(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)][PF_6]$ with $CNBu^t$ was investigated. Prolonged reaction times and the use of a large excess of $CNBu^t$ led to the isolation of high yields of the $[PF_6]$ salt of **7**; note that the conversion of **5** to **7** is accompanied by changes in ν(CO) in the IR spectrum and δC_7H_7 in the ^{13}C NMR spectrum, characteristic of $\eta^7\text{-}C_7H_7 \rightarrow \eta^3\text{-}C_7H_7$ ring slip. On the basis of ^{13}C NMR data, **7** is assigned a structure in which $CNBu^t$ rather than CO lies *trans* to the C_7H_7 ring. The relatively strong, low field $CNBu^t$ donor carbon signal at 160.2 ppm in the ^{13}C NMR spectrum is tentatively assigned to the *trans* $CNBu^t$ ligands; in general, isocyanide donor carbons *trans* to isocyanides are deshielded with respect to isocyanide donor carbons *trans* to CO.[12] Variable temperature ^1H NMR studies on **7** in CD_2Cl_2 revealed some line broadening of the C_7H_7 signal on cooling to −90°C but, as with **3** and **4**, a limiting low temperature spectrum was not obtained.

Although the formation of **7** from **5** has been demonstrated and in fact provides the first example of ring slippage in a $\eta^7\text{-}C_7H_7$ complex not of the formulation $[MX(CO)_2(\eta^7\text{-}C_7H_7)]^{z+}$ (M = Mo or W; $z = 0$, X = halide; $z = +1$, X = NCMe), the direct formation of **7** from $[Mo(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)]^+$ (**3**), excluding $[Mo(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**5**) as an intermediate, should not be discounted. Indeed the relatively large quantity of **7** formed from **3** after a few hours at 30°C, as determined by ^1H NMR, seems inconsistent with the

long reaction time and large excess of $CNBu^t$ required to effect conversion of **5** to **7**.

In principle, further substitution of CO by $CNBu^t$ in $[Mo(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**5**) might proceed via $[Mo(CO)(CNBu^t)_4(\eta^3\text{-}C_7H_7)]^+$ (**7**) to give $[Mo(CNBu^t)_3(\eta^7\text{-}C_7H_7)]^+$ (**8**) in an analogous manner to the reaction sequence **1** → **3** → **5**. Complex **8** has been reported previously[13] but, in view of the very limited characterization data given, was independently synthesized in the current work via reaction of $[Mo(\eta^6\text{-toluene})(\eta^7\text{-}C_7H_7)][PF_6]$ with three equivalents of $CNBu^t$ in refluxing acetone. Examination of ^1H NMR data reveals that an increase in the ratio of $CNBu^t$ to CO ligands along the sequence of complexes **1**, **3**, **5**, **7**, **8** produces a steady shift to high field of δ C_7H_7 in the ^1H NMR spectra. The proposed conversion of **7** to **8** was investigated by ^1H NMR spectroscopy in $CDCl_3$ at 50°C. After 6 h the major product of thermal decomposition of **7** was **5**, but a second minor product with δ C_7H_7 ($CDCl_3$) 5.14 was also observed and identified as **8**. At this point the approximate ratio of integrals for **5**:**7**:**8** was 3:1.5:1 but this was modified to 1:0.3:1 after a total reaction time of 6 days. A preparative scale reaction involving reflux of **5** with one equivalent of $CNBu^t$ in acetone was also attempted; the formation of **8** was confirmed by ^1H NMR spectroscopy and IR spectroscopy provided evidence for the presence of small quantities of **7**. However the reaction was very slow and neither complete conversion of **5** to **8** nor separation of the reaction mixture could be achieved. In conclusion, there is good evidence to support the feasibility of the reaction sequence **5** → **7** → **8** but it is not clear that **7** is an essential intermediate. The major problem is that reversion of **7** to products with a heptahapto-bonded C_7H_7 ring can involve either loss of one $CNBu^t$ and one CO ligand or alternatively two $CNBu^t$ groups; this is in contrast to the corresponding transformation of $[Mo(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)]^+$ (**3**) which proceeds almost exclusively via loss of one $CNBu^t$ and one CO ligand.

The high thermal stability of $[W(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)]^+$ (**4**) with respect to its molybdenum analogue **3** has already been noted. However, reflux of **4** for 5 h in 2-butanone resulted in complete conversion to new products with ν(CO)(CH_2Cl_2) at 1972 and 1910 cm^{-1}. Work-up of the reaction mixture afforded moderate yields of $[W(CO)(CNBu^t)_2(\eta^7\text{-}C_7H_7)]^+$ (**6**) which was fully characterized (Tables 1, 2 and 3), but attempts to isolate the minor reaction product [ν(CO)(CH_2Cl_2) 1910 cm^{-1}], suspected to be $[W(CO)(CNBu^t)_4(\eta^3\text{-}C_7H_7)]^+$, were unsuccessful.

The monoisonitrile complexes $[Mo(CO)_2(CNBu^t)(\eta^7\text{-}C_7H_7)]^+$ (M = Mo or W) also react with dppe to give ring slipped products formulated as $[M(CO)_2(CNBu^t)(dppe)(\eta^3\text{-}C_7H_7)]^+$. However definitive characterization of these species is not straightforward due either to facile chelate ring opening or the formation of isomeric mixtures.

EXPERIMENTAL

The preparation, purification and reactions of the complexes described were carried out under dry nitrogen. All solvents were dried by standard methods, distilled and deoxygenated before use. The complexes $[M(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)][BF_4]$ (M = Mo or W)[8] and $[Mo(\eta^6\text{-}C_6H_5Me)(\eta^7\text{-}C_7H_7)][PF_6]$[13] were prepared by published procedures; Aldrich Chemical Co. supplied $CNBu^t$ and $NH_4[PF_6]$. ^1H NMR spectra were recorded on Brucker AC 300 E or AC 80 E instruments and ^{13}C NMR spectra at 75 MHz on a Varian Associates XL 300 spectrometer. IR spectra were obtained on a Perkin–Elmer FT 1710 spectrometer and FAB mass spectra using a Kratos Concept 1S instrument. Microanalyses were by the staff of the Microanalytical Service of the Department of Chemistry, University of Manchester.

Preparation of $[Mo(CO)_2(CNBu^t)(\eta^7\text{-}C_7H_7)][BF_4]$ (1)

Addition of $CNBu^t$ (0.513 g, 6.181 mmol) to a green, stirred solution of $[Mo(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)][BF_4]$ (2.291 g, 6.175 mmol) in CH_2Cl_2 (50 cm^3) rapidly produced a red solution. After 20 min the solvent volume was reduced to *ca* 10 cm^3 and the product precipitated by addition of diethyl ether. Recrystallization from CH_2Cl_2–diethyl ether gave **1** as a red solid; yield 2.403 g (94%). An identical procedure was employed to prepare $[W(CO)_2(CNBu^t)(\eta^7\text{-}C_7H_7)][BF_4]$ (**2**) as a red solid in 32% yield from $[W(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)][BF_4]$ (0.22 g, 0.48 mmol) and $CNBu^t$ (0.039 g, 0.47 mmol).

Preparation of $[Mo(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)][BF_4]$ (3)

Method A. A solution of $[Mo(CO)_2(NCMe)(\eta^7\text{-}C_7H_7)][BF_4]$ (0.297 g, 0.80 mmol) in CH_2Cl_2 (60 cm^3) was cooled to 0°C and treated with $CNBu^t$ (0.20 g, 2.41 mmol). The solution was stirred and maintained at 0°C for 12 h, after which time solvent was removed and the residue recrystallized from CH_2Cl_2–diethyl ether to give **3** as a red–brown solid; yield 0.25 g (54%). The red–brown tungsten analogue $[W(CO)_2(CNBu^t)_3(\eta^3\text{-}C_7H_7)][BF_4]$ (**4**) was prepared in 75% yield from $[W(CO)_2(NCMe)$

(η^7-C_7H_7)][BF_4] (0.291 g, 0.63 mmol) and $CNBu^t$ (0.178 g, 2.14 mmol) by a similar procedure to **3**, except that reaction was complete after 4 h at 20°C.

Method B. A solution of [$Mo(CO)_2(CNBu^t)$(η^7-C_7H_7)][BF_4] (0.510 g, 1.24 mmol) in CH_2Cl_2 (30 cm^3) was cooled to 0°C, treated with $CNBu^t$ (0.227 g, 2.73 mmol), then stirred at 0°C for 12 h. A work-up procedure identical to method A gave **3**; yield 0.252 g (35%). Similarly, **4** was prepared in 39% yield from **2** (0.244 g, 0.487 mmol) and $CNBu^t$ (0.100 g, 1.20 mmol) in CH_2Cl_2 stirred at 20°C for 4 h.

Thermal decomposition of [$Mo(CO)_2(CNBu^t)_3$(η^3-C_7H_7)][BF_4] (**3**)

A solution of **3** (0.252 g, 0.435 mmol) in CH_2Cl_2 (30 cm^3) was stirred at 20°C for 24 h when IR spectroscopy indicated completion of the reaction. The solution was filtered, reduced in volume and diethyl ether added in small portions with constant stirring. The first precipitate so obtained was isolated and recrystallized from CH_2Cl_2–diethyl ether to give [$Mo(CO)(CNBu^t)_2$(η^7-C_7H_7)][BF_4] as an orange solid; yield 0.081 g (40%). Found: C, 46.5; H, 5.4; N, 6.1. Calc. for $C_{18}H_{25}N_2OMoBF_4$: C, 46.2; H, 5.3; N, 6.0%. Addition of further diethyl ether to the reaction solution afforded a deep red solid which was also isolated and recrystallized from CH_2Cl_2–diethyl ether to give [$Mo(CO)(CNBu^t)_4$(η^3-C_7H_7)][BF_4]; yield 0.045 g (16%). Found: C, 53.1; H, 6.8; N, 8.7. Calc. for $C_{28}H_{43}N_4OMoBF_4$: C, 53.0; H, 6.8; N, 8.8%.

Preparation of [$Mo(CO)(CNBu^t)_2$(η^7-C_7H_7)][PF_6] (**5**) *from* [$MoBr(CO)_2$(η^7-C_7H_7)]

A mixture of [$MoBr(CO)_2$(η^7-C_7H_7)] (0.317 g, 0.98 mmol), $CNBu^t$ (0.163 g, 1.96 mmol) and NH_4[PF_6] (0.161 g, 0.99 mmol) was dissolved in AR acetone (40 cm^3) and the solution refluxed for 3 h. Removal of acetone and recrystallization of the residue from CH_2Cl_2–diethyl ether gave [$Mo(CO)(CNBu^t)_2$(η^7-C_7H_7)][PF_6] as an orange solid; yield 0.36 g (70%).

Preparation of [$Mo(CO)(CNBu^t)_4$(η^3-C_7H_7)][PF_6] (**7**)

A solution of [$Mo(CO)(CNBu^t)_2$(η^7-C_7H_7)][PF_6] (0.49 g, 0.93 mmol) in CH_2Cl_2 (40 cm^3)was treated with $CNBu^t$ (0.405 g, 4.88 mmol) and stirred for 24 h. Solvent was removed and the residue recrystallized from CH_2Cl_2–diethyl ether, then acetone–diethyl ether to give **7** as a deep red solid; yield 0.542 g (84%).

Preparation of [$Mo(CNBu^t)_3$(η^7-C_7H_7)][PF_6] (**8**)

A solution of [$Mo(\eta^6$-$C_6H_5Me)$(η^7-C_7H_7)][PF_6] (0.30 g, 0.71 mmol) in AR acetone (50 cm^3) was refluxed for 0.5 h to give a red solution to which $CNBu^t$ (0.176 g, 2.12 mmol) was added. After continuing the reflux for a further 1 h, solvent was removed and the residue recrystallized from CH_2Cl_2–diethyl ether, then thf–diethyl ether to give **8** as a red pink solid; yield 0.168 g (41%).

Preparation of [$W(CO)(CNBu^t)_2$(η^7-C_7H_7)][BF_4] (**6**)

A solution of [$W(CO)_2(CNBu^t)_3$(η^3-C_7H_7)][BF_4] (**4**) (0.364 g, 0.55 mmol) in 2-butanone (70 cm^3) was refluxed with stirring for 5 h, after which time IR spectroscopy indicated complete conversion to products. Solvent was removed and the residue dissolved in CH_2Cl_2, filtered and treated with diethyl ether in small aliquots. The first precipitate thus obtained was isolated and recrystallized from CH_2Cl_2–diethyl ether to give **6** as a red–brown solid; yield 0.114 g (38%).

METAL–BETAINE INTERACTIONS—VI. CRYSTAL AND MOLECULAR STRUCTURE OF TETRAKIS(BETAINE)COPPER(II) NITRATE, $[Cu(Me_3NCH_2COO)_4](NO_3)_2$

XIAO-MING CHEN and THOMAS C. W. MAK*

Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong

(*Received* 27 *September* 1990; *accepted* 22 *October* 1990)

Abstract—The crystal and molecular structure of $[Cu(BET)_4]\cdot(NO_3)_2$ (BET = $Me_3N^+CH_2COO^-$) has been established by X-ray crystallography. The complex consists of discrete $[Cu(BET)_4]^{2+}$ and nitrate anions, with the copper(II) atom eight-coordinated by four short Cu—O(carboxy) bonds [1.948(3) Å] and four long Cu—O(carboxy) bonds [2.833(4) Å] in a distorted dodecahedral $\bar{4}2m$ (D_{2d}) environment.

Coordination numbers of seven and higher for copper in its carboxylates are rare even considering Cu—L distances up to 2.9 Å.[1] To our knowledge, hitherto only three examples of structurally characterized eight-coordinate complexes of copper(II) carboxylates have been reported, which are all double salts possessing polymeric structures in the solid state. The first example, $Ca[Cu(acetato)_4]\cdot 6H_2O$, was initially characterized by Langs and Hare[2] and later refined by Klop *et al.*[3] A study of the polarized single-crystal electronic spectrum and electron spin resonance spectrum of this double salt suggests that the long Cu—O contact of 2.788(2) Å reflects a significant, though weak, metal–ligand bonding.[4] The other two examples are $Rb_2[Cu(o\text{-phthalato})_2]\cdot 2H_2O$ (phthalato group abbreviated hereafter as pht) and $Li[Cu(pht)_2]\cdot 4H_2O$,[5] in which the long Cu—O contacts are *ca* 3.05 Å.

In the course of our systematic investigation on metal complexes of betaine ligands,[6] we have prepared and characterized the title copper(II) complex, namely tetrakis(betaine)copper(II) nitrate, $[Cu(BET)_4](NO_3)_2$ (BET = betaine, $Me_3N^+CH_2COO^-$; IUPAC name: 1-carboxy-N,N,N-trimethylmethanaminium hydroxide inner salt). Its structure has now been established by means of single-crystal X-ray diffraction.

EXPERIMENTAL

Preparation and IR spectra

The complex was simply prepared by dissolving $Cu(NO_3)_2\cdot 3H_2O$ (0.242 g, 1.0 mmol) and betaine monohydrate (0.540 g, 4.0 mmol; Sigma) in hot water (3 cm^3, *ca* 60°C). After slow evaporation at room temperature for 2 days, violet–blue, cubic-like crystals suitable for X-ray work were obtained.

IR spectra (KBr pellets) were recorded on a Nicolet 20SXC FT–IR spectrometer in the range 4000–400 cm^{-1}. The complex exhibits the following IR carboxy absorption bands (v = very, s = strong, m = medium; cm^{-1}): ν(COO) at 1642vs, 1654vs and 1387vs, and δ(COO) at 727m. The average separation (Δ) between ν_{asym}(COO) and ν_{sym}(COO) is 267 cm^{-1}, which is significantly larger than that in anhydrous betaine [ν(COO) = 1624, 1388 cm^{-1}; Δ = 236 cm^{-1}],[7] hence indicative of the unidentate mode of carboxylato coordination in the present complex.[8]

X-ray crystallography

$Cu(Me_3NCH_2COO)_4 \cdot (NO_3)_2$, mol. wt 656.15, tetragonal, space group $I\bar{4}2m$ (No. 121), $a = 11.443(2)$, $b = 11.443(2)$, $c = 11.672$ (2) Å, $V = 1528.4(5)$ Å^3, $Z = 2$, $D_{exptl} = 1.427$ g cm^{-3} (flotation in CCl_4/*n*-hexane), $D_{calc} = 1.426$ g cm^{-3}, $F(000) = 694$, Mo-K_α radiation ($\lambda = 0.71073$ Å), $\mu = 0.78$ mm^{-1}.

Diffraction intensities (crystal size $0.26 \times 0.34 \times 0.40$ mm; $2\theta_{max} = 65°$, 832 unique data) were collected at 21°C on a Nicolet R3m/V diffractometer using the ω-scan (3.22–15.63°min^{-1}) mode.[9] Data processing, absorption corrections ($\mu r = 0.127$, transmission factors 0.514–0.533), structure solution and full-matrix least-squares refinement were performed with the SHELXTL-PLUS program package[10,11] on a DEC MicroVAX-II computer. The non-hydrogen atoms were refined anisotropically except the oxygen atoms of orientationally disordered nitrate groups, which were subjected to interatomic-distance constraints and assigned appropriate site occupancy factors in the refinement. Analytic expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[12] The final residuals were $R_F = 0.052$ and $R_w = 0.065$ for 758 observed data with $I \geqslant 3\sigma(I)$.

Supplementary materials including non-hydrogen and hydrogen atomic coordinates and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre, and observed and calculated structure factors are available upon request from the corresponding author.

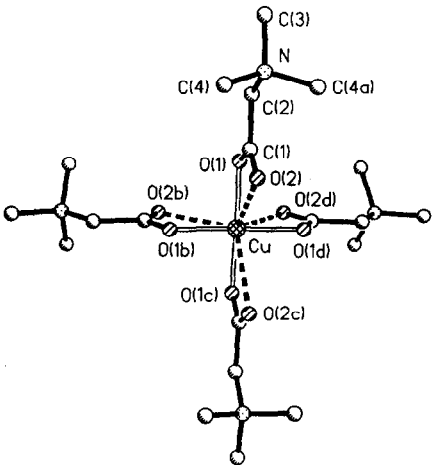

Fig. 1. Perspective view showing the molecular structure of the $[Cu(BET)_4]^{2+}$ cation and the atom numbering scheme. The short and long Cu—O(carboxy) bonds are represented by open and broken lines, respectively. Symmetry codes are given in Table 1.

RESULTS AND DISCUSSION

The crystal structure consists of a packing of discrete $[Cu(BET)_4]^{2+}$ cations and nitrate anions (Fig. 1). The copper(II) atom, occupying Wyckoff position 2(*a*) of site symmetry $\bar{4}2m$ (D_{2d}), is coordinated by four BET ligands with four short Cu—O(carboxy) bonds [Cu(1)—O(1) = 1.948(3) Å] in an approximately square-planar fashion, the most distorted angle being O(1)—Cu(1)—O(2c) at 173.2(4)° (Table 1). The coordination sphere of the

copper(II) atom is completed by the remaining four ligand O(2) atoms at much longer contacts of Cu(1)—O(2) = 2.833(4) Å. The BET ligands, as located at Wyckoff positions 8(*i*) of symmetry *m*, coordinate the copper(II) atom in an alternately up/down fashion, so that the cation may be considered to possess a (4+4*) distorted dodecahedral stereochemistry about the copper(II) atom.

Similar stereochemistry has been found in Ca[Cu(acetato)$_4$]·6H$_2$O,[2,3] in which the coordination geometry about the copper(II) atom has exact $\bar{4}$ (S_4) symmetry with four short and four long Cu—O(carboxy) bonds of lengths 1.969(1) and 2.788(2) Å, respectively. The enhanced extent of asymmetric chelation of the BET ligand to the copper(II) centre, as compared with the acetate ion, may be correlated with the fact that the O—C—O angle of the BET ligand is significantly larger in the present cation [125.6(5)°] than that of the acetato group in the calcium double salt [122.0(2)°]. The previous spectral study of the calcium double salt[4] has suggested that one of the filled sp^2 orbitals of the long-bonded carboxy oxygen weakly overlaps the d_{z^2} orbital of the copper(II) atom, and the p_z orbital of the long-bonded oxygen atom may also be involved in weak π-bonding to the metal d_{xz} and d_{yz} orbitals. The same type of metal–ligand interaction is expected to exist in the present cation. The main difference between the structures of the present complex and the calcium double salt is that the long-bonded carboxy oxygen in the latter also coordinates to the calcium(II) atom, thereby bridging the copper(II) and calcium(II) atoms into a one-dimensional polymeric structure.

As a neutral ligand, BET can form tetrakis-chelated carboxylate-like copper(II) complexes without the presence of other metal ions, thus eliminating their perturbation on the idealized geometry of the eight-coordinate copper(II) structure. The relevant structural parameters for some eight-coordinate tetrakis(carboxylato)copper(II) complexes are listed in Table 2. The calcium(II) ion has little influence on the structure of the tetrakis(carboxylato)copper(II) anion in the double salt,[2,3] which may be attributed to the fact that it has an appropriate ionic radius to coordinate the two long-bonded oxygen atoms of the upwards/downwards carboxy groups. In contrast, the geometries of the tetrakis(carboxylato)copper(II) anions in both $Rb_2[Cu(pht)_2]\cdot 2H_2O$ and $[Li_2Cu(pht)_2]\cdot 4H_2O$[5] are significantly distorted by the rubidium(I) and lithium(I) ions, which are either too large or too small, thus resulting in lowering of the symmetry of the copper(II) centres from S_4 to C_2 and C_i for the rubidium and lithium double salts, respectively, together with significantly greater differences (by more than 0.26 Å) between the pair of independent long-bonded Cu—O(carboxy) distances.

1. INTRODUCTION

The chemistry of triosmium clusters with nitrogen-donor ligands has been reviewed in some detail.[1,2] By comparison, relatively few derivatives of $Ru_3(CO)_{12}$ containing *N*-donor ligands had been described until recently. In most cases, this was the result of the use of harsh reaction conditions which leads to rapid break-up of the first-formed cluster complexes. The much greater tendency of triruthenium clusters, as opposed to triosmium clusters, to undergo cluster fragmentation is due to a greater M—M bond strength for the heavier metal; the M—M bond enthalpies of $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ are 78 and 94 kJ mol^{-1}, respectively.[3] Although $Ru_3(CO)_{12}$ has been described as "more difficult to control"[2] than $Os_3(CO)_{12}$, its very reactivity leads not only to product types analogous to those obtained with its heavier transition metal congener, but also to novel modes of reactivity not observed with $Os_3(CO)_{12}$.

This literature survey of ruthenium cluster carbonyls containing *N*-donor ligands and their chemistry is classified according to the functional groups in the ligand, and extends the last such review[4] by incorporating results published between 1981 and mid-1990, although reference is made to earlier work if necessary. The fact that almost one half of the references are from 1986 or later testifies to the current strong interest in this field.

2. STRUCTURAL TYPES

Trinuclear ruthenium carbonyl clusters have been described containing *N*-donor ligands which may be attached to one, two or three metal atoms, and which may donate from two to eight electrons to the cluster. The main types of ligand are represented schematically in Fig. 1 and relevant bond parameters of structurally characterized examples of some of these types are collected in Table 1.

2e *Donors*

Complexes containing 2e donors (**A**) are known, but most readily undergo further intramolecular reactions which produce bridging (μ_2) or capping (μ_3) ligands. Examples include organic nitriles and pyridine. Simple anionic ligands containing nitrogen (CN^-, NCO^-) may bridge Ru—Ru bonds (**B**).

3e *Donors*

Several derivatives containing NO ligands have been described (Section 9). While clusters of other metals containing terminal NO groups are known, all the ruthenium complexes reported so far have this ligand bridging a Ru—Ru bond (**C**). The isoelectronic aryldiazo ligand forms similar derivatives (**D**).

Most complexes containing 3e donor ligands (including nitrosyls) also contain a second odd-electron ligand. In many cases, these ligands result from internal oxidative addition reactions across a Ru—Ru bond, the precursors often not being isolated. Examples include (a) H and NR_2 groups (**E**) and (b) H and N-C systems, such as 2-pyridyl (**F**).

4e *Donors*

Bidentate *N*-donor ligands may chelate one metal atom, such as found with 2,2′-bipyridyl (**G**), or bridge a Ru—Ru bond, such as 1,2-diazene (**H**). By contrast, the diazo (N=N) group acts as a 6e donor when it caps a triangular face (**I**); these complexes readily undergo N=N bond cleavage to give derivatives containing alkyl- or aryl-imido ligands (μ_3-NR) (**J**). Much chemistry has centred on these complexes which are also obtained from several other organo-nitrogen compounds.

In many cases, when one side of the Ru_3 cluster is capped by an NR group, a similar μ_3-ligand caps the opposite side; examples include μ_3-CO, μ_3-S. Where two μ_3-NR groups are present, one Ru—Ru bond is broken (**K**).

Other 4e ligands containing nitrogen include the metallated amido (**L**) and aryldiazo groups (**M**).

Fig. 1. (continued)

5e *Donors*

In the nitrido clusters (Section 10), the nitrogen atom acts as a 5e donor. Other 5e ligands include aldimines, μ_3-RC=NR (**N**) and those which contain a 3e bridging group and 2e donor atom in the same molecule, such as found in derivatives of 2-(diphenylphosphino)pyridine and thiazoles (**O**); mono-deprotonated arene-1,2-diamines also act as 5e donors, having both chelating and bridging functions (**P**).

6e *and* 8e *Donors*

Attachment of diazabutadiene ligands to Ru_3 clusters by both nitrogen atoms and the unsaturated system results in these ligands donating either 6e (**Q**) or 8e (**R**) to the cluster, although, interestingly, only two metal atoms are involved.

3. ANIONIC LIGANDS

The reaction between $Ru_3(CO)_{12}$ and [ppn][CN] proceeded by way of an intermediate formulated as $[Ru_3(CN)(CO)_{11}]^-$, which dimerized with loss of CO to give the hexanuclear dianion $[Ru_6(\mu\text{-}CN)_2(CO)_{20}]^{2-}$ (**1**), containing two parallel ruthenium triangles linked by two axial CN bridges.[5] Recently, Vahrenkamp has described the CN-bridged derivative **2** (R = C_5H_5), obtained from $[Mn(CN)(CO)_2(\eta\text{-}C_5H_5)]^-$;[6] use of $[Mn(CN)(CO)_2(\eta\text{-}C_5H_4Me)]^-$ afforded **3**, together with **2** (R = C_5H_4Me).[7]

Complexes containing isocyanate ligands have been obtained from the reaction between $Ru_3(CO)_{12}$ and [ppn][N_3], which initially afforded $[Ru_3(\mu\text{-}CO)_2(CO)_9(NCO)]^-$ (**4**); this lost CO to give $[Ru_3(\mu\text{-}NCO)(CO)_{10}]^-$ (**5**). Over several days, **5** was slowly converted to $[Ru_4(\mu\text{-}NCO)(\mu\text{-}$

$CO)(CO)_{12}]^-$ (**6**).[8] The postulated structures for **4**, **5** and **6** were assigned on the basis of IR arguments.

Irradiation of a mixture of $Ru_3(CO)_{12}$ and $Au(N_3)(PPh_3)$ gave purple $AuRu_3(\mu\text{-NCO})(CO)_{10}(PPh_3)$ (**7**).[9] The $\overline{CN{=}N}$ ring in pentamethylenediazirine was cleaved during the reaction with $Ru_3(CO)_{12}$; the yellow product, **8**, contains μ-NCO and μ-ketenimine ligands.[10]

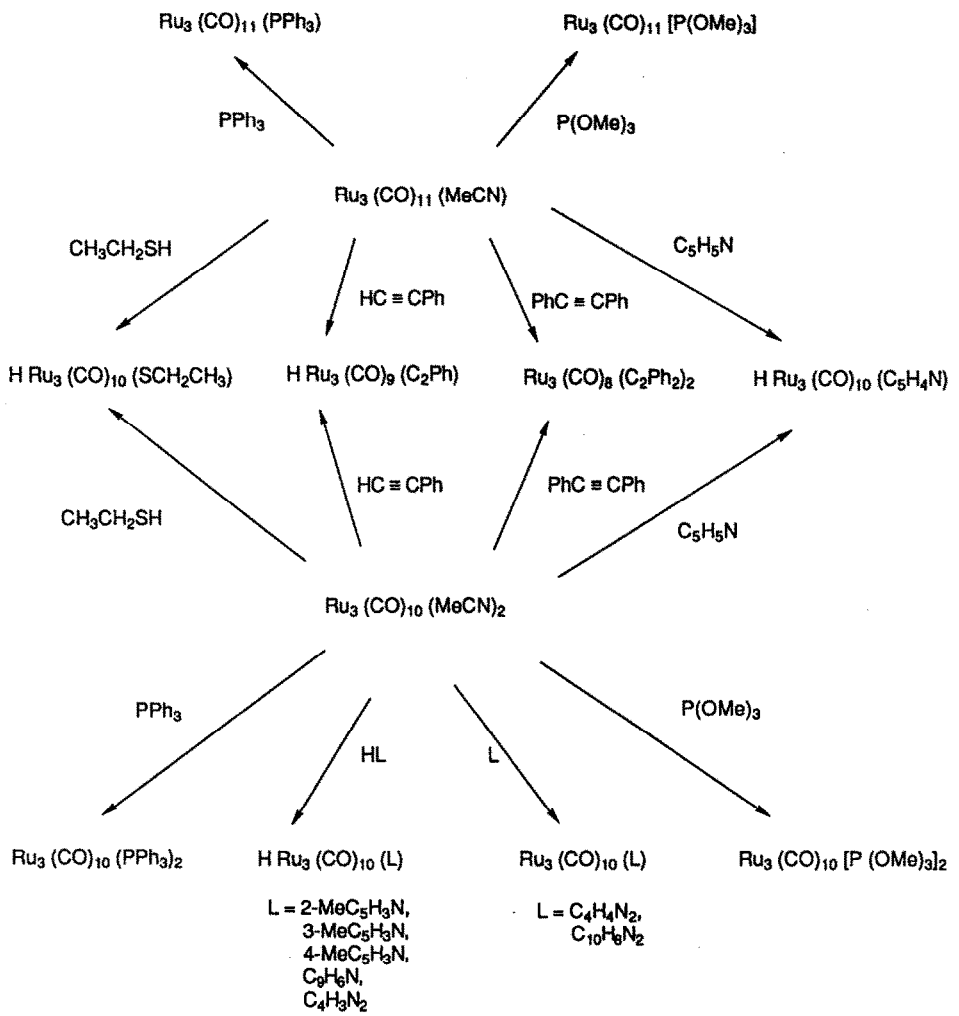
4. ORGANONITRILE DERIVATIVES

Triruthenium clusters with acetonitrile ligands have been made by the action of Me_3NO on $Ru_3(CO)_{12}$ in acetonitrile–dichloromethane mixtures: $Ru_3(CO)_{12-n}(NCMe)_n$ ($n = 1, 2$) (**9** and **10**) are formed.[11–13] The structures of these two complexes, featuring axial nitrile ligands, were assigned by comparison of their IR spectra with those of the analogous osmium complexes.[14,15] The acetonitrile ligands can be easily displaced by 2e donors (*vide infra*, Scheme 1), and these readily accessible



Scheme 1. Reactivity of $Ru_3(CO)_{12-n}(NCMe)_n$ ($n = 1, 2$).

precursors have been used to synthesize other triruthenium clusters incorporating *N*-donor ligands which are not obtained by a thermal route.

Other nitriles, such as benzonitrile, appear to form the capped clusters $Ru_3(\mu_3\text{-}NCR)(CO)_9$, which rapidly undergo further reaction. Early studies described reactions between $Ru_3(CO)_{12}$ and benzonitrile only in the presence of acetic acid or molecular hydrogen.[16] In the former case, the reaction afforded $Ru_4(\mu\text{-}H)_4(CO)_{12}$, $Ru_3(\mu\text{-}H)(\mu\text{-}N{=}CHPh)(CO)_{10}$ (**11**) and $Ru_3(\mu\text{-}H)(\mu\text{-}NHR)(CO)_{10}$ (**12**; R = CH_2Ph), the latter two containing ligands formed by reduction of a coordinated benzonitrile ligand.[17] Further work with substituted benzonitriles bearing electron-donating (OMe) or electron-withdrawing (NO_2) groups in the *para* position indicated that the formation of **12** was significantly enhanced by an electron-donating substituent; with an electron-withdrawing group, only decomposition occurred.[18] Recently, replacement of acetic acid by lauric acid has been shown to result in a higher yield of **12** (R = CH_2Ph, $CH_2C_6H_4NO_2$-4); the use of acetic acid gave higher conversion to **12** (R = $CH_2C_6H_4OCH_3$-4).[19] These results are consistent with a two-fold effect of the acid; activation of the substrate and proton donation. Reaction of $Ru_3(CO)_{12}$ with benzonitrile under 110 atm of H_2 gave mainly **12** (R = CH_2Ph), together with benzylamine, whereas reaction under H_2 at atmospheric pressure gave only **11**. Hydrogenation of **11** afforded $Ru_3(\mu\text{-}H)_2(\mu_3\text{-}NCH_2Ph)(CO)_9$ (**13**);[20] the imide–amide–nitrene transformations **11** ↔ **12** ↔ **13** have been shown to be reversible.[21,22]

The pentanuclear carbido cluster $Ru_5C(CO)_{15}$ reversibly takes up MeCN with an accompanying structural change from square pyramidal to distorted trigonal bipyramidal to afford **14**.[23,24]

5. REACTIONS WITH AMINES

Aliphatic amines do not give complexes containing *N*-bonded ligands, reacting with $Ru_3(CO)_{12}$ by nucleophilic attack at a carbonyl group to give products incorporating the carbamoyl ligand. Thus, dimethylamine reacted with $Ru_3(CO)_{12}$ at $-30°C$ to afford $Ru_3(\mu\text{-H})\{\mu\text{-O=C(NMe}_2)\}(CO)_{10}$ (**15**; L = CO).[25-27] Reaction of $Ru_3(CO)_{12}$ with $C(NMe_2)_4$ gave the $[C(NMe_2)_3]^+$ salt of $[Ru_3\{\mu\text{-O=C(NMe}_2)\}(CO)_{10}]^-$, believed to contain bridging carbonyl groups.[28] Acidification and phosphite substitution afforded [**15**; L = $P(OR)_3$, R = Me, Et, Ph].[29] Addition of base to refluxing thf solution of **15** (L = CO) gave $[Ru_6H\{\mu\text{-O=C(NMe}_2)\}_2(\mu\text{-CO})_4(CO)_{14}]^-$ (**16**), which was isolated as its $[AsPh_4]^+$ salt.[30] Reaction of **15** (L = CO) with acetylenes has also been investigated; with dimethylacetylene, a mixture of **17**, **18** and **19** was obtained,[31,32] whereas reaction with arylacetylenes gave only dinuclear products.[33]

Recently, Süss-Fink *et al.* have synthesized chiral analogues of **15**, by reaction of $Ru_3(CO)_{12}$ with *S*-proline and *S*- and *R*-methoxymethylpyrrolidine; in the latter case, the μ_3-η^2-imino cluster, **20**, was formed as a byproduct.[34]

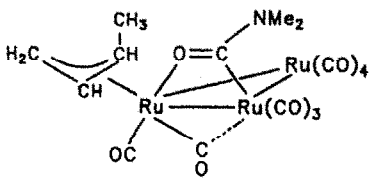
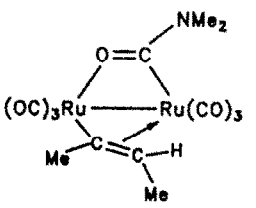
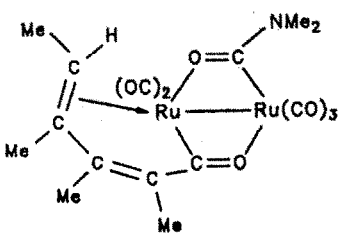
(16)



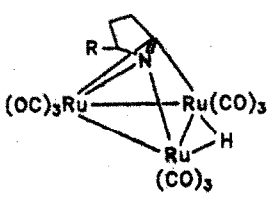
(17)



(18)

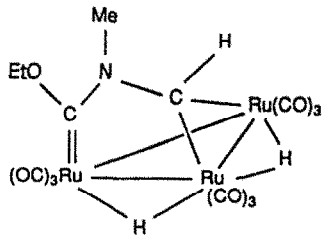


(19)

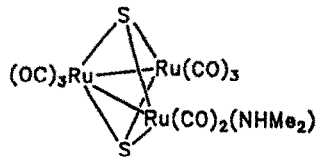


(20) R = CH_2OCH_3

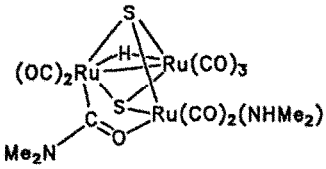
Reaction of $Ru_3(\mu\text{-}H)(\mu\text{-}O{=}CMe)(CO)_{10}$ with $HNMe_2$, followed by alkylation with $EtSO_3CF_3$ gave $Ru_3(\mu\text{-}H)_2\{\mu_3\text{-}C(OEt)NMeCH\}(CO)_9$ (**21**).[35,36] The reaction of $Ru_3(\mu_3\text{-}S)_2(CO)_9$ with dimethylamine was followed spectroscopically and found to proceed by way of the substitution product **22** to the carbamoyl-bridged complex **23** and thence to the bis(carbamoyl)-bridged complex **24**.[37]



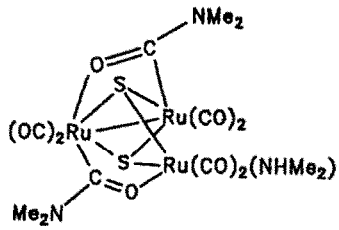
(21)



(22)



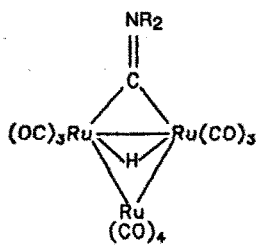
(23)



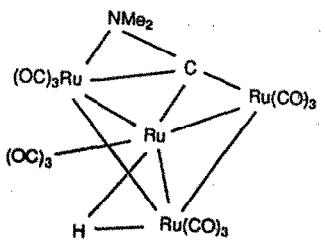
(24)

The halomethylidyne cluster $Ru_3(\mu\text{-}H)_3(\mu_3\text{-}CBr)(CO)_9$ reacted with diethylamine to give exclusively $Ru_3(\mu\text{-}H)(\mu\text{-}CNR_2)(CO)_{10}$ (**25**; R = Et), either in the presence or absence of carbon monoxide, by nucleophilic substitution at the methylidyne carbon and intermolecular CO transfer. It proved impossible to hydrogenate **25** (R = Et) to $Ru_3(\mu\text{-}H)_3(\mu_3\text{-}CNEt_2)(CO)_9$.[38] Pyridine- (R = Me) and triphenylphosphine- ($R = CH_2Ph$) substituted **25**, formed from acetonitrile-substituted **25**, have been structurally characterized;[39,40] in the former case, the pyridine occupies a "semiaxial" site on one of the dibridged ruthenium atoms and, in the latter case, the triphenylphosphine occupies an equatorial site on the non-bridged ruthenium atom.

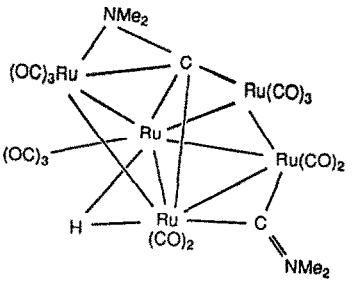
Pyrolysis of **25** (R = Me) afforded three higher nuclearity clusters **26**, **27** and **28** in low yield; **26** could also be formed in high yield on reaction of **25** (R = Me) with $Ru(CO)_5$.[41] Further reaction



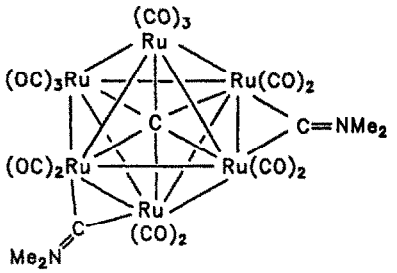
(25) R = Me, Et, CH_2Ph



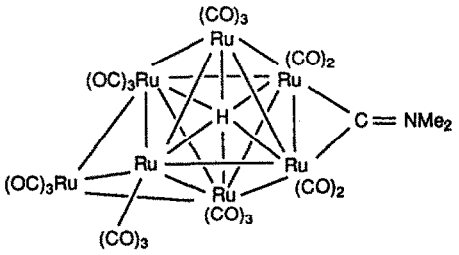
(26)



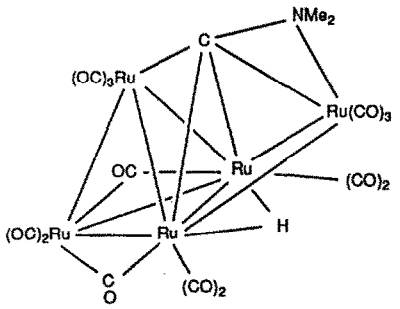
(27)



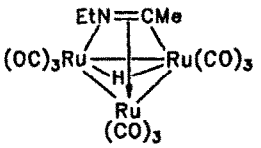
(28)



(29)



(30)



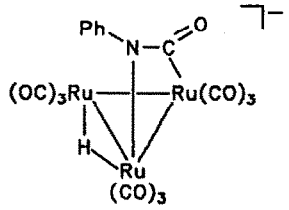
(31)

of **26** with $Ru(CO)_5$ afforded heptanuclear **29** and pentanuclear **30** in good yield, the former containing an interstitial hydride.[42]

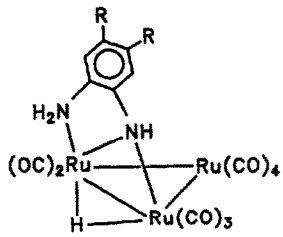
In contrast with the above reactions, the $\{Fe(\mu\text{-SEt})(CO)_2(PPh_3)\}_2$-catalysed reaction between $Ru_3(CO)_{12}$ and NEt_3 in hexane gave $Ru_3(\mu\text{-H})(\mu_3\text{-EtN=CMe})(CO)_9$ (**31**) as the major product.[43]

The first product from the reaction between $Ru_3(CO)_{12}$ and aniline was $Ru_3(\mu\text{-H})(\mu\text{-NHPh})(CO)_{10}$ (**12**; R = Ph), formed by oxidative addition of the N—H bond across a Ru—Ru bond;[44] subsequent deprotonation with KOH afforded $[Ru_3(\mu\text{-H})\{\mu_3\text{-NPh(CO)}\}(CO)_9]^-$ (**32**) by intramolecular nucleophilic attack on CO.[45] Complex **32** lost CO irreversibly in solution at room temperature to give $[Ru_3(\mu\text{-H})(\mu_3\text{-NPh})(CO)_9]^-$.

1,2-Arenediamines reacted with $Ru_3(CO)_{12}$ under a CO atmosphere to give **33**, in which the deprotonated diamine chelates and bridges atoms on the cluster. In contrast, 1,8-diaminonaphthalene gave the binuclear complex $Ru_2\{\mu\text{-}(NH)_2C_{10}H_6\}(CO)_6$.[46]



(32)



(33) R = H, Me

6. ALKYL- AND ARYL-IMIDO COMPLEXES

The metal carbonyl-catalysed reduction and, in some cases, carbonylation of nitrobenzenes to *N,N'*-disubstituted ureas,[47,48] anilines,[49–51] Schiff bases (in the presence of aldehydes),[51] carbamates (in alcohols)[52–54] and isocyanates[55] has prompted many studies on stoichiometric reactions involving these compounds. For example, nitrobenzene reacted with $Ru_3(CO)_{12}$ at elevated temperatures to afford $Ru_3(\mu_3\text{-NPh})(\mu_3\text{-CO})(CO)_9$ (**34**; R = Ph) and $Ru_3(\mu_3\text{-NPh})_2(CO)_9$ (**35**; R = R^1 = Ph).[44,56,57] Nitrene-containing species have been proposed as intermediates in the catalytic reduction of nitrobenzene to aniline[58] and isolation of polynuclear complexes with phenylnitrene groups such as **34** (R = Ph) can be taken as indirect evidence for the involvement of such species in the catalytic reaction. In the presence of $Co_2(CO)_8$, the same reaction gave **35** (R = R^1 = Ph) and $Ru_3(\mu_3\text{-NPh})(\mu_3\text{-CO})(CO)_6(\eta\text{-}C_6H_6)$ (**36**), but not **34** (R = Ph); small quantities of $Co_4(CO)_9(\eta\text{-}C_6H_6)$ were also isolated from the reaction system, and reaction of this complex with **34** (R = Ph) produced small amounts of **36**.[59]

The reductive carbonylation of nitrobenzene by $Ru_3(CO)_{12}$ with MeO^- as promoter and 2-methoxyethanol as solvent preferentially affords formanilide.[60] The carbonylation of **32** slowly formed $[Ru_3(\mu\text{-PhNCHO})(\mu\text{-CO})_3(CO)_7]^-$ (**37**) over a period of days. Furthermore, hydro-

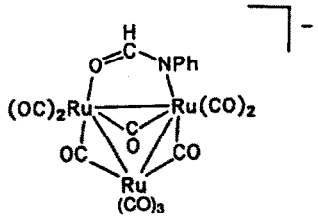
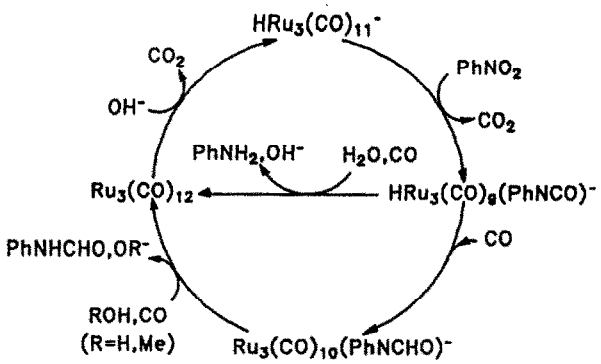
(36)



(37)



Scheme 2.

lysis of **32** and **37** gave aniline and formanilide, respectively, together with $Ru_3(CO)_{12}$, and reaction between $[Ru_3(\mu\text{-H})(CO)_{11}]^-$ and $PhNO_2$ afforded a small amount of **32**, lending support to the catalytic cycle shown in Scheme 2.[61]

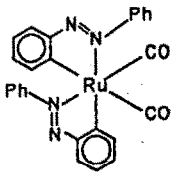
Halide catalysis of the carbonylation of nitroarenes in the presence of alcohols has afforded carbamates with high selectivity;[62] this reaction has been modelled by the stoichiometric reaction between **34** (R = Ph) and $[Ru_3(\mu\text{-X})(CO)_{10}]^-$.[63,64] The presence of chelating ligands (dppm, dppe, dppp, bipy) also increases significantly the activity of $Ru_3(CO)_{12}$ in this reaction.[65]

Arylimido complexes have been obtained from several other precursors. For example, reactions of $Ru_3(CO)_{12}$ with *para*-substituted nitrosoarenes gave analogues of **34** (R = Ph) and **35** (R = R^1 = Ph); *p*-$ClC_6H_4NO_2$ reacted with **34** (R = Ph) to afford $Ru_3(\mu_3\text{-NPh})(\mu_3\text{-NC}_6H_4Cl\text{-4})(CO)_9$ (**35**; R = Ph, $R^1 = C_6H_4Cl$-4).[63] Significant promotion of this reaction by halide has been reported.[66] Reaction of $Ru_3(CO)_{12}$ with 2*H*-hexafluoropropyl azide afforded $Ru_3(\mu_3\text{-NCF}_2CHFCF_3)_2(CO)_9$ (**35**; R = R^1 = CF_2CHFCF_3);[67] the corresponding reaction with trimethylsilyl azide gave $Ru_3(\mu_3\text{-NSiMe}_3)(\mu_3\text{-CO})(CO)_9$ (**34**; R = $SiMe_3$).[68]

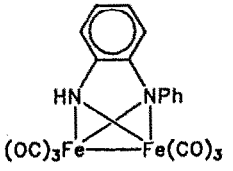
In 1971, Stone and co-workers reported that the reaction between $Ru_3(CO)_{12}$ and azobenzene afforded three complexes;[69] re-examination of this reaction recently showed that the products were **35** (R = R^1 = Ph), the mononuclear cyclometallated complex **38** (see below), and an as-yet unidentified black powder.[70] Azotoluene afforded **35** (R = R^1 = C_6H_4Me-4) and an analogue of **38**, while reactions of the asymmetric azoarenes PhN=NAr (Ar = C_6H_4F-3 and -4, $C_6H_4CF_3$-3, C_6F_5) gave the mixed complexes $Ru_3(\mu_3\text{-NPh})(\mu_3\text{-NAr})(CO)_9$, with no evidence for the formation of any cross product.

This result can be understood in terms of the formation of an intermediate $\mu_3\text{-}N_2Ar_2$ complex followed by an intramolecular cleavage of the N=N double and one Ru—Ru bond. Thermolysis of the iron–azoalkane complexes $Fe_3(\mu_3\text{-}N_2R_2)(CO)_9$ (R = Et, Pr) has given $Fe_3(\mu_3\text{-NR})_2(CO)_9$ in a reaction which is inhibited under CO.[6,71] The *o*-semidine derivative **39** was isolated from the reaction between iron carbonyl and azobenzene.[72,73]

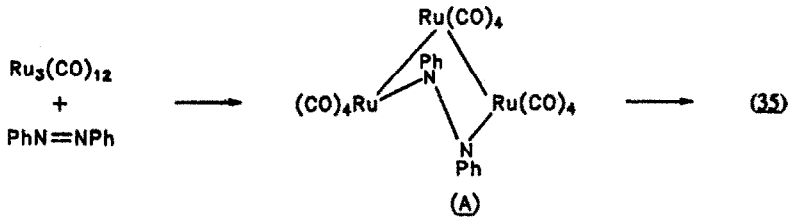
The intermediacy of **A** in Scheme 3 has not been established in the ruthenium system, but in an



(38)



(39)

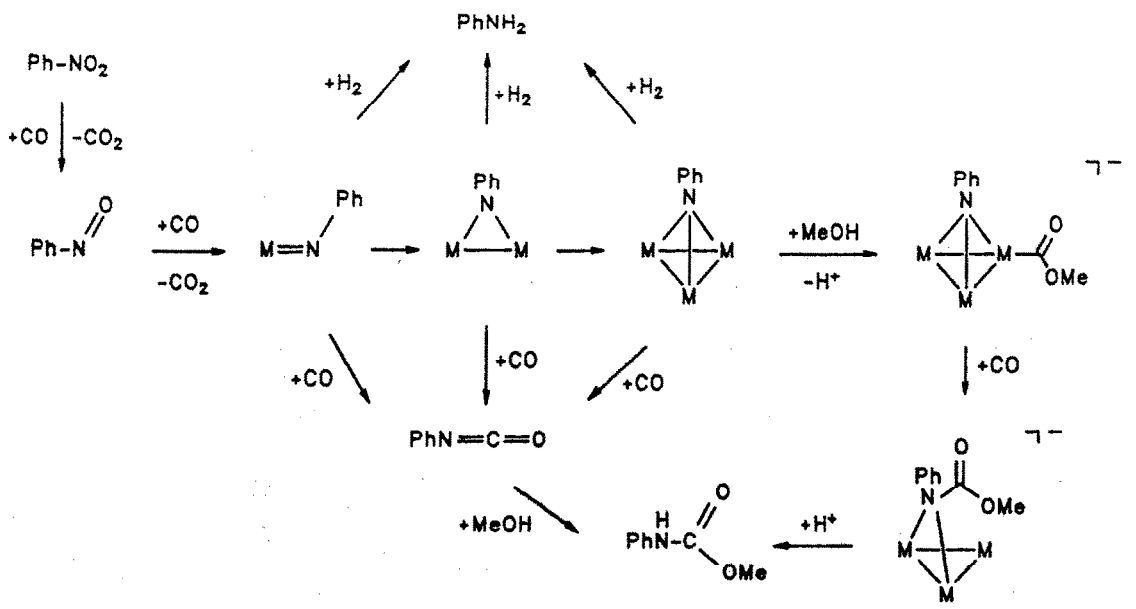


Scheme 3.

analogous reaction, $Os_3(CO)_{12-n}(MeCN)_n$ ($n = 1$ or 2) reacted with dimethyl azodicarboxylate to give $Os_3\{\mu\text{-}N(CO_2Me)NC(O)OMe\}(CO)_{11}$, which when heated in benzene afforded $Os_3\{\mu\text{-}N_2(C(O)OMe)_2\}(CO)_{10}$.[74,75] Stabilization of this intermediate is aided by coordination of the ester carbonyl oxygen atoms.

The catalysis of the carbonylation of nitrobenzene in MeOH to methyl *N*-phenylcarbamate, $PhNHCO_2Me$, is promoted by halide. Much work has been done on this reaction which is accelerated by halide ion. Scheme 4 summarizes many of the results obtained. Geoffroy's group has provided evidence for many of these postulated reactions and has clarified the role of the added halide. This chemistry has been reported in a seminal paper describing some reactions of cluster-bound imido ligands.[76]

Thus, halide does not promote deoxygenation of $PhNO_2$ to PhNO or PhN, but reactions between PhNO and $[Ru_3(\mu\text{-}X)(CO)_{10}]^-$ (X = Cl, Br, I) or $[Ru_3(CN)(CO)_{11}]^-$ rapidly gave quantitative yields of $[Ru_3(\mu_3\text{-}NPh)(\mu_3\text{-}CO)(X)(CO)_8]^-$ (X = Cl, Br, I, CN), with concomitant formation of CO_2; similarly, $[Ru_3(\mu\text{-}H)(CO)_{11}]^-$ gave $[Ru_3(\mu_3\text{-}H)(\mu_3\text{-}NPh)(CO)_9]^-$. The rates and yields of these reactions are significantly increased over those found for $Ru_3(CO)_{12}$; Cl^- and Br^- are the best promoters. A mechanism involving initial labilization of CO by halide to open up a binding site for PhNO was supported by the rapid high-yield formation of **34** (R = Ph) from PhNO and $Ru_3(CO)_{11}(NCMe)$. However, no evidence for the proposed PhNO complex was obtained, suggesting that once formed, rapid deoxygenation by CO occurred. Halides reacted with **35** ($R = R^1 = Ph$) to form $[Ru_3(\mu_3\text{-}NPh)_2(X)(CO)_8]^-$ quantitatively; addition of CO (1 atm, 22°C) reformed **35** ($R = R^1 = Ph$).[76]



Scheme 4. Formation of methyl *N*-phenylcarbamate from nitrobenzene.

Introduction of a second NR group can be achieved by way of the complex $Ru_3(\mu_3\text{-NPh})(CO)_9(NCMe)$, obtained from **34** (R = Ph) and Me_3NO in acetonitrile; reactions with PhNO or Bu^tNO gave **35** (R = Ph, R^1 = Ph, Bu^t, respectively).[76]

Attempted carbonylation of **35** (R = R^1 = Ph) (120 atm, 150°C, 22 h) gave 69% recovery of starting material;[76] complex **34** (R = Ph) gave PhNO only after 6.5 h at 120°C under 170 atm. CO.[77] In contrast, the halide clusters $[Ru_3(\mu_3\text{-NPh})(X)(CO)_9]^-$ (X = Cl, Br) reacted with CO (1 atm., 22°C, 0.5–3 h) to give PhNCO (45% $PhNHCO_2Me$ isolated after addition of MeOH).[76]

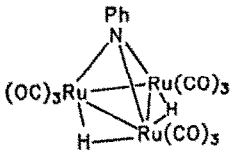
Addition of $[Co(CO)_4]^-$ to **34** (R = Ph) resulted in metal exchange to give $[CoRu_2(\mu_3\text{-NPh})(CO)_9]^-$, which was protonated ($HBF_4$) to give $CoRu_2(\mu\text{-H})(\mu_3\text{-NPh})(CO)_9$; deprotonation with [ppn]Cl afforded pure $[ppn][CoRu_2(\mu_3\text{-NPh})(CO)_9]$. Carbonylation (6 atm., 100°C, 8 h) gave $Ru_3(CO)_{12}$, $[Co(CO)_4]^-$ and the phenyl isocyanate dimer, PhNC(O)NPhC(O).[76]

The acyl clusters $[Ru_3(\mu_3\text{-NPh})(\mu_3\text{-CO})\{C(O)R\}(CO)_8]^-$ (R = Me, Ph) were formed from **34** (R = Ph) and LiR; coupling of the acyl and imido ligands occurs under CO to give $[Ru_3\{\mu\text{-NPhC(O)R}\}(\mu\text{-CO})(CO)_7]^-$, which was readily protonated (HBF_4) to give $Ru_3(\mu\text{-H})\{\mu\text{-NPhC(O)R}\}(CO)_7$. The latter (R = Me) gave PhNHCOMe when treated with CO.[76]

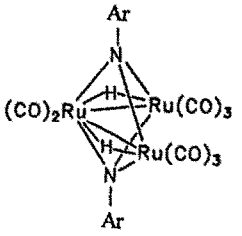
The formation of isocyanate by coupling of NR and CO ligands probably proceeds according to Scheme 4. As mentioned above (Section 5), deprotonation of $Ru_3(\mu\text{-H})(\mu\text{-NHPh})(CO)_{10}$ gave the related μ_3-PhNCO complex, **32**.[45] Presumably, halide promotes the reaction by opening the μ_3-NR cap. Similar coupling of acyl and imido ligands occurred to give the anilido ligand.

Reactivity of **34** (R = Ph) *and* **35** (R^1 = R = Ph)

Hydrogenation of **34** (R = Ph) gave $Ru_3(\mu\text{-H})_2(\mu_3\text{-NPh})(CO)_9$ (**40**),[44,78] whereas the bis (arylimido) clusters afforded $Ru_3(\mu\text{-H})_2(\mu_3\text{-NAr})_2(CO)_8$ (**41**).[79] Substitution of CO by dppm has been studied; the product $Ru_3(\mu_3\text{-NPh})(CO)_8(dppm)$ could be carbonylated with great difficulty (60 atm. CO, 170°C, most of the starting material unreacted) to afford phenyl isocyanate and $Ru_3(CO)_{10}(dppm)$.[80]



(40)

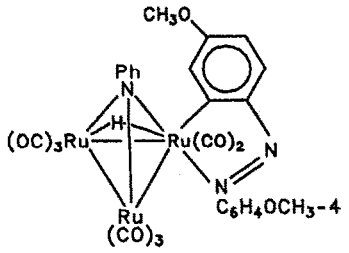


(41)

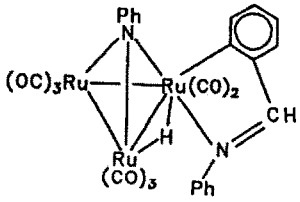
In **35** (R = R^1 = Ph), isocyanides substituted CO axially and tertiary phosphines equatorially, both on a terminal ruthenium atom, and bidentate tertiary phosphines span the non-bonded Ru···Ru vector. Carbonylation of **34** (R = Ph) or **35** (R = R^1 = Ph) in acetonitrile (20 atm., 140°C) gave quantitative yields of $Ru_3(CO)_{12}$.[81] Phenyl isocyanate is the sole organic product formed in these reactions.

Azoarenes reacted with **34** (R = Ph) and related aryl-substituted clusters under CO to give $Ru_3(\mu_3\text{-NAr})(\mu_3\text{-NAr}')(CO)_9$.[79]

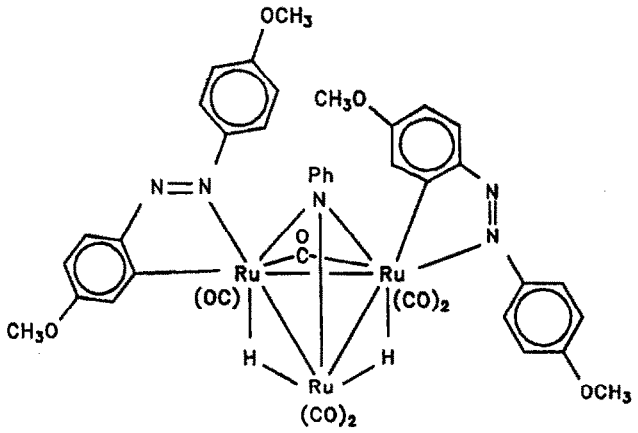
The reaction of **35** (R = R^1 = Ph) with 4,4′-dimethoxyazobenzene afforded $Ru_3(\mu_3\text{-NPh})(\mu_3\text{-NC}_6H_4OMe\text{-}4)(CO)_9$ (**35**; R = Ph, $R^1 = C_6H_4OMe\text{-}4$) and $Ru_3(\mu\text{-H})(\mu_3\text{-NPh})(MeOC_6H_3N{=}NC_6H_4OMe)(CO)_8$ (**42**), with the latter incorporating a cyclometallated azoarene.[77] Pyrolysis of **42** under CO gave **35** (R = Ph, $R^1 = C_6H_4OMe\text{-}4$) and 4-$MeOC_6H_4NCO$. Reaction of **42** with excess 4,4′-dimethoxyazobenzene afforded **35** (R = Ph, $R^1 = C_6H_4OMe\text{-}4$) and **43**. The formation of a cyclometallated cluster was found to be dependent on the electronic character of the



(42)



(44)

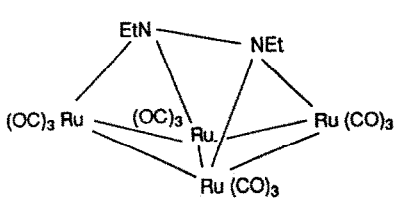


(43)

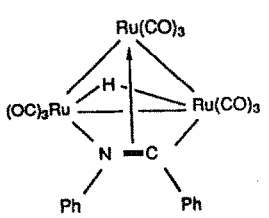
azoarene: with electron-poor aromatic rings (e.g. 4,4′-dinitroazobenzene), cyclometallation was never observed, while with electron-rich aromatic rings, N—N bond cleavage was preferred over cyclometallation only in the presence of CO. *N*-phenylbenzaldimine was cyclometallated by **35** (R = Ph) under CO to give **44**.[77]

The cyclic azoalkane 3,4-diazatricyclo[4.2.1.$0^{2,5}$]non-3-ene was found to react with $Ru_3(CO)_{12}$ to give a cluster containing an intact N_2R_2 ligand.[82,83] This compound is unstable, decomposing above room temperature in solution. The first simple azoalkane complexes were prepared recently from N_2R_2 (R = Et, Pr); further photochemical reaction with $Ru(CO)_5$ resulted in cluster expansion to give $Ru_4(\mu_4\text{-}N_2Et_2)(CO)_{12}$ (**45**) (65%), containing a Ru_4 butterfly bonded to a skewed N_2Et_2 moiety.[84]

The complex $Ru_3(\mu_3\text{-}H)(\mu_3\text{-}PhNCPh)(CO)_9$ (**46**) was isolated (45% yield) from $Ru_3(CO)_{12}$ and PhN=CHPh in Pr^iOH (as a H donor); the cyclometallated complex $Ru(C_6H_4CH{=}NPh)_2(CO)_2$ (**141**; R = Ph) was also formed in 30% yield.[85] The cluster complex is the only catalytically active species in transfer hydrogenation of ArCH=NPh to $ArCH_2NHPh$. With CO, **46** formed the decacarbonyl, which spontaneously decarbonylated on attempted isolation.

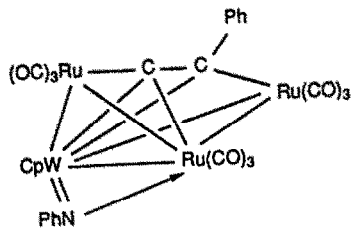


(45)

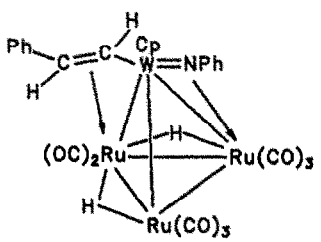


(46)

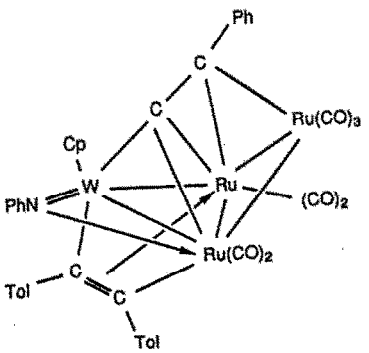
The reactions of **34** (R = Ph) with $W(C_2Ph)(CO)_3(\eta\text{-}C_5H_5)$ gave the dark red Ru_3W butterfly cluster, **47**, in which the NPh ligand asymmetrically bridges the hinge Ru—W bond, best described as a W=N(Ph) → Ru interaction; the acetylide ligand adopts a μ_4,η^2 bonding mode.[86] Hydrogenation of **47** gave $Ru_3W(\mu\text{-}H)_2(\mu\text{-}NPh)(\mu\text{-}CH{=}CHPh)(CO)_8(\eta\text{-}C_5H_5)$ (**48**), in which there is a tetrahedral metal core. Excess $C_2(tol)_2$ reacted with **47** to afford **49**, in which the alkyne takes up a μ_3,η^2-(‖) bonding mode to the WRu_2 face, while $C_2(CF_3)_2$ afforded **50**. In the latter, coupling of $C_2(CF_3)_2$ and C_2Ph moieties gave the $CPh{=}CC(CF_3){=}C(CF_3)$ ligand bridging an open Ru_2W system. In all reactions of **47**, the phenylimido ligand remains unchanged.



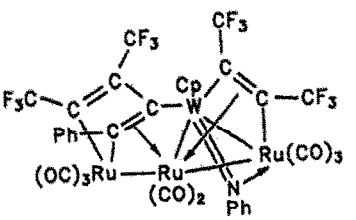
(47)



(48)



(49)



(50)

Thermolysis of **34** (R = Ph) gave the hexaruthenium cluster Ru_6 $(\mu_4\text{-}NPh)_2(CO)_{15}$ (**51**) in high yield;[87] the same complex was prepared from **35** (R = R^1 = Ph) and $Ru_3(CO)_{12}$. In the latter case, the heptaruthenium cluster $Ru_7(\mu_4\text{-}NPh)_2(CO)_{16}$ (**52**) was formed as a minor product.

Complex **34** (R = Ph) reacted with diphenylacetylene to give **53** (R = Ph), **54** and **55**, and with 1-phenylpropyne to give **53** (R = Me) by coupling of CO and the alkynes with the μ_3-nitrene. Complex **53** (R = Ph) reacted further with C_2Ph_2 and CO to form pentaphenylpyridone and 1,3,4-triphenylmaleimide, respectively.[88,89] $Ru_3(\mu_3\text{-}NPh)(dppm)(CO)_8$ (see above) reacted with phenylacetylene and diphenylacetylene to afford binuclear metallapyrrollidone complexes analogous to **53**.[90] Attempts to isolate the presumed trinuclear nitrene-alkyne intermediates were unsuccessful.

Reactions between **34** (R = Ph) or **35** (R = R^1 = Ph) and the trigoldoxonium cation $[O\{Au(PPh_3)_3\}]^+$ in the presence of $[Co(CO)_4]^-$ have given dark red $Au_2Ru_3(\mu_3\text{-}NPh)(CO)_9(PPh_3)_2$ (**56**) and orange–red $Au_2Ru_3(\mu_3\text{-}NPh)_2(CO)_8(PPh_3)_2$, respectively.[91] In **56**, the Au—Au bond is preserved, and the complex may model the approach of H_2 to **34** (R = Ph), which afforded Ru_3 $(\mu\text{-}H)_2(\mu_3\text{-}NPh)(\mu_3\text{-}CO)(CO)_8$ (**40**) as described above.

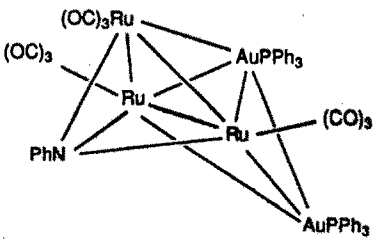
(55)

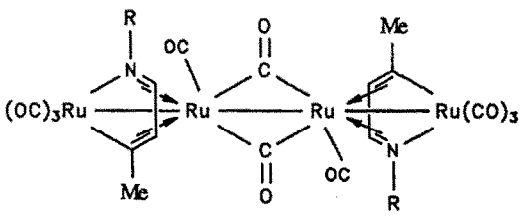


(56)

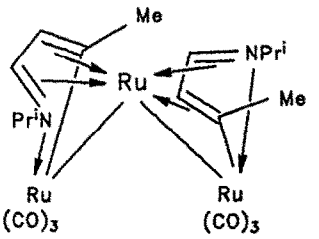
7. ENIMINES AND α,α′-DIIMINES (AZA- AND 1,4-DIAZABUTA-1,3-DIENES)

The work of the Dutch groups led by Vrieze and van Koten on the reactions of enimines and diazabutadienes with ruthenium carbonyls has recently been reviewed,[92–95] so this topic will not be surveyed exhaustively here.

Recently, attention has been focused on the reactivity of $Ru_3(CO)_{12}$ with monoazadienes. The enimines (*E*)-MeC(H)=C(H)C(H)=NR (R = Bu^t, Pr^i, cyclohexyl) reacted with $Ru_3(CO)_{12}$ to give mixtures of the linear tetraruthenium compounds $Ru_4(CO)_{10}\{MeC{=}CHCH{=}NR\}_2$ (**57**; R = Pr^i, cyclohexyl),[96] trinuclear $Ru_3(CO)_6(MeC{=}CHCH{=}NPr^i)_2$ (**58**),[97] and binuclear $Ru_2(CO)_6$ (μ-$CH_2CCHCH{=}NBu^t$) and $Ru_2(CO)_6(\mu$-EtCCHNBu^t).[98]

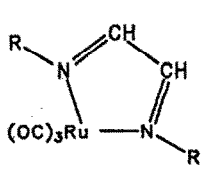


(57) R = Pr^i, cyclohexyl

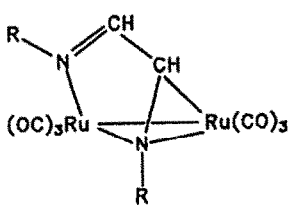


(58)

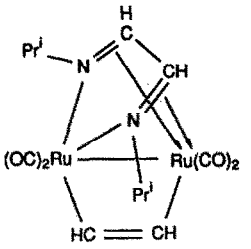
The diazadienes generally react with $Ru_3(CO)_{12}$ to give mono- or binuclear products, for which an extensive chemistry has been developed. Thus, reactions between $Ru_3(CO)_{12}$ and RN=CH CH=NR (R-dab) afforded $Ru(CO)_3$(R-dab) [**59**; R = 2,6-di(isopropyl)mesityl, mesityl and 2,6-xylyl].[92] For other R groups, the $Ru(CO)_3$(R-dab) intermediate reacted further with $Ru_3(CO)_{12}$ to give $Ru_2(CO)_6$(R-dab) (**60**; R = Pr^i, Bu^t, cyclohexyl).[99,100] Reversed phase HPLC was used to show that formation of an intermediate, postulated to be $Ru_3(CO)_{10}$(dab), is the rate-determining step in the former reaction, which is first order in $Ru_3(CO)_{12}$ and dab.[101] Reaction of **60** (R = Pr^i) with acetylenes has been examined in some detail.[102–106] Complex **61** was obtained from the reaction with acetylene.[102,103] By contrast, the reaction with HC_2CO_2Me was more complex. The first-formed product at room temperature was **62** after C—C coupling and Ru—Ru bond rupture. This subsequently lost CO to give **63** (R = H) with reformation of the Ru—Ru bond and the migration of a terminal CO ligand to adopt a bridging position. Reaction with $C_2(CO_2Me)_2$ proceeded likewise, but in this case **63** (R = CO_2Me) added a second equivalent of alkyne to give a mixture of **64** and $Ru_2(CO)_4\{Pr^iN{=}CHCH(NPr^i)C(CO_2Me){=}C(CO_2Me)\}$. Reaction with HC_2Ph afforded an inseparable mixture of two isomers of $Ru_2(CO)_4$(Pr^i-dab)(μ-PhC_2H);[104] the corresponding reaction with the internal acetylene MeC_2NEt_2 afforded **65** in the first reaction of this type with no C—C bond formation.[105]



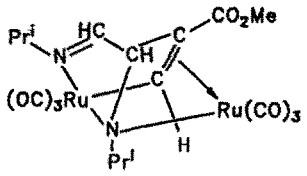
(59) R = 2,6-diisopropylmesityl, mesityl, 2,6-xylyl



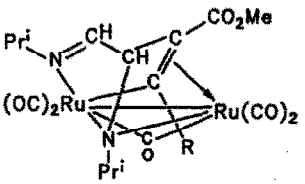
(60) R = Pr^i, Bu^t, cyclohexyl



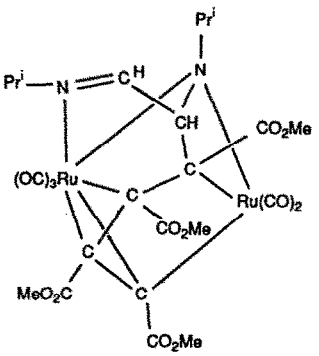
(61)



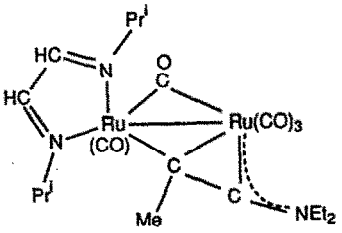
(62)



(63) R = H, CO_2Me

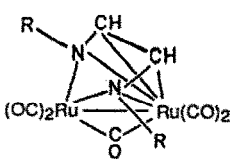


(64)

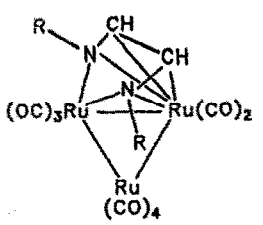


(65)

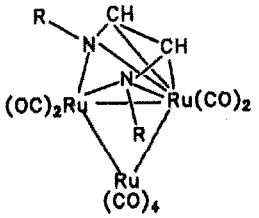
Reaction of **62** (R = Pr^i or cyclohexyl) with Me_3NO or reaction between $Ru_3(CO)_{12}$ and R-dab (R = CH_2Bu^t) afforded $Ru_2(CO)_5$(R-dab) (**66**; R = Pr^i, cyclohexyl, CH_2Bu^t).[107] Theoretical calculations indicate that there is no metal–metal bond in this complex, in contrast to the expectation from the metal–metal distance in **66** and qualitative electron counting methods.[108] When **67** (R = CH_2Bu^t, Bu^i, cyclohexyl) was heated with $Ru_3(CO)_{12}$, **67** and **68** were obtained.[109] In a "traffic light-like colour change", bright green **68** reversibly added CO to give bright red **67** and reacted with CH_2N_2 to afford **69** (R = CH_2Bu^t, Bu^i).[110] Treatment of **68** (R = CH_2Bu^t) with H_2 afforded **70**.[111]



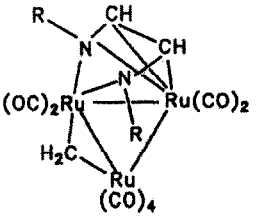
(66) R = neopentyl, Pr^i, cyclohexyl



(67) R = neopentyl, Bu^i, cyclohexyl



(68) R = neopentyl, Bu^i, cyclohexyl



(69) R = neopentyl, Bu^i

The pyridine-2-carbaldehyde-imines, R^1-py-2-C(R^2)=NR (R-pyca) (R = Bu^t, Pr^i, cyclohexyl), reacted with $Ru_3(CO)_{12}$ to give $Ru_2(CO)_6$(R-pyca) (**71**); further reaction with R-pyca afforded $Ru_2(CO)_5$(R-ape) [R-ape = 1,2-bis(μ-alkylamido)-1,2-bis(2-pyridyl)ethane] (**72**) in which R-ape consists of the two C—C coupled R-pyca ligands.[112] Thermolysis of the latter gave $Ru_2(CO)_4$(R-ape) (**73**; R^1 = Me) or $Ru_2(CO)_4$(R-pyca)$_2$ (**74**; R^1 = H) after CO loss. Interestingly, CO addition to the products regenerated $Ru_2(CO)_5$(R-ape) (R = Pr^i) for both R^1 = H and Me, implying CO addition is concomitant with the formation of a C—C bond between the two imine carbons of two pyca ligands in $Ru_2(CO)_4$(Pr^i-pyca)$_2$.[113] The reactivity of **71** (R = Bu^t, Pr^i) toward alkynes is summarized in Scheme 5.[114] Some of this chemistry is analogous to the $Ru_2(CO)_6$(R-dab)/alkyne chemistry in that C—C coupling reactions of the alkyne with the coordinated diimine ligand are observed; more importantly, however, the C—C bond formed here seems to be significantly less stable leading to further reactions.

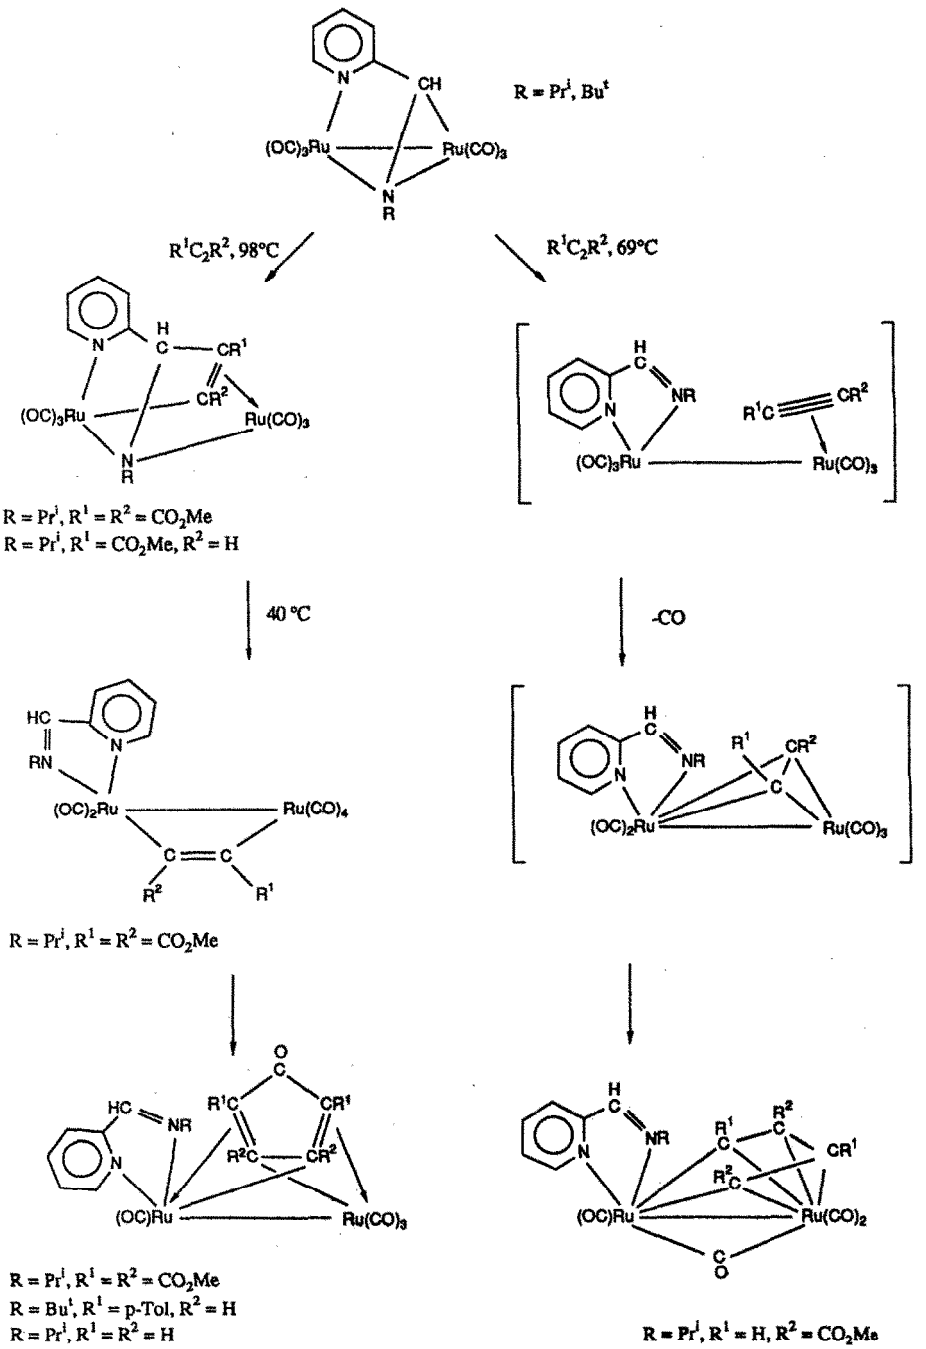


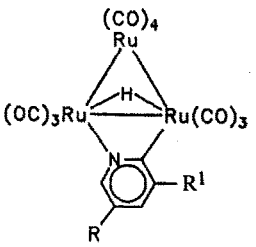
Scheme 5. Reactivity of $Ru_2(CO)_6$(R-pyca) towards alkynes.

8. *N*-HETEROCYCLES

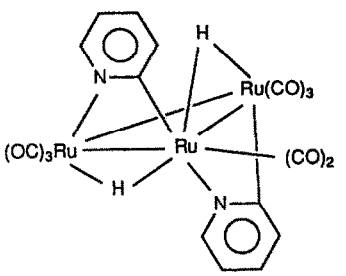
The cyclometallated complex $Ru_3(\mu\text{-}H)(\mu\text{-}C_5H_4N)(CO)_{10}$ (**75**; R = R^1 = H) was obtained from pyridine and $Ru_3(CO)_{12}$;[115] the reaction is believed to occur by way of $Ru_3(CO)_{11}(py)$, but this intermediate was not detected either here or in the reactions of pyridine with $Ru_3(CO)_{12-n}(NCMe)_n$ (n = 1 or 2).[11] Reaction with excess pyridine afforded $Ru_3(\mu\text{-}H)_2(\mu\text{-}C_5H_4N)_2(CO)_8$ (**76**).[115,116] The 2-, 3- and 4-methyl-substituted pyridines reacted with the bis(acetonitrile) cluster complex to give analogous complexes, including two isomers of the product from 3-methylpyridine (**75**; R = Me, R′ = H; R = H, R′ = Me).[12]

An equimolar mixture of two isomers of $HRu_5C(CO)_{14}(C_5H_4N)$, **77** and **78**, differing only in the orientation of a bridging ligand, was obtained from reaction of $Ru_5C(CO)_{15}$ in excess pyridine. A third product, $HRu_5C(CO)_{13}(C_5H_4N)(C_5H_5N)$, was also obtained. Complexes **77** and **78** both underwent clean decarbonylation to give the same $HRu_5C(CO)_{13}(C_5H_4N)$, which could be re-carbonylated to a mixture of equal amounts of **77** and **78**.[117]

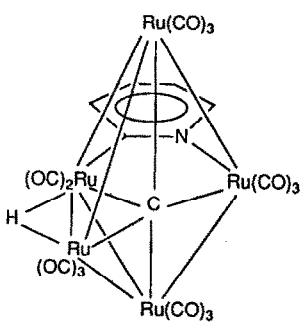
A $Ru_3(CO)_{12}$/2,2′-bipyridyl mixture has been reported to be a precursor for a highly active, low temperature catalyst for the water gas shift reaction.[118] The reaction between $Ru_3(CO)_{12}$ or $Ru_3(CO)_{10}(NCMe)_2$ and 2,2′-bipyridyl afforded a purple complex containing bridging CO groups, $Ru_3(bipy)(\mu\text{-}CO)_2(CO)_8$ (**79**);[12,115,119] this was shown to have a $Fe_3(CO)_{12}$-type structure with the bipy chelating one of the CO-bridged ruthenium atoms. Pyrolysis of **79** in refluxing toluene afforded



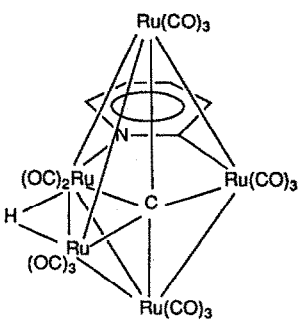
(**75**) R = R^1 = H
R = Me, R^1 = H
R = H, R^1 = Me



(**76**)

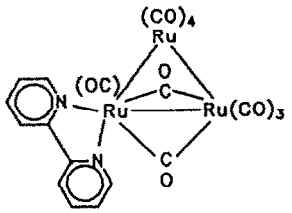


(**77**)

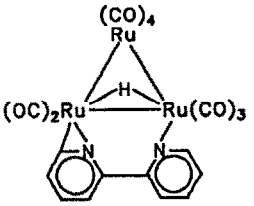


(**78**)

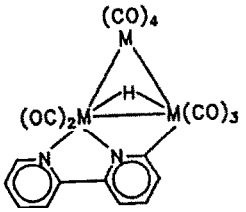
a cyclometallated complex for which structure **80** was postulated.[12] However, the structure of the pyrolysis product from the reaction between $Os_3(CO)_{12}$ and 2,2′-bipyridyl has been determined to be **81** (M = Os),[120] and structure **81** (M = Ru) seems more likely for the pyrolysis product from **79**.



(79)

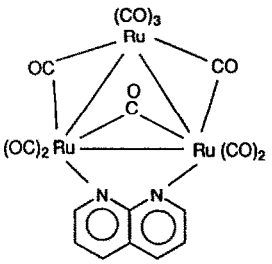


(80)

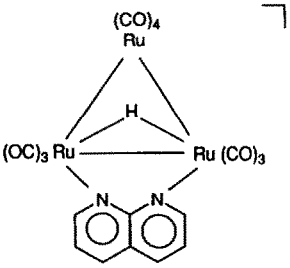


(81) M = Os, Ru

Reactions with 1,10-phenanthroline, 2,2′-biquinoline or 2,2′-bipyrimidine each gave $Ru_3(L\text{-}L)(\mu\text{-}CO)_2(CO)_8$ (L-L = phen, biquin or bipym, respectively), having the $Ru_3(bipy)(CO)_{10}$ structure.[121] 1,8-Naphthyridine reacted with $Ru_3(CO)_{12}$ to give the CO-bridged cluster $Ru_3(\mu\text{-napy})(\mu\text{-}CO)_3(CO)_7$ (**82**), which could be reversibly protonated to give $[Ru_3(\mu\text{-}H)(\mu\text{-napy})(CO)_{10}][BF_4]$ (**83**) containing only terminal carbonyls.

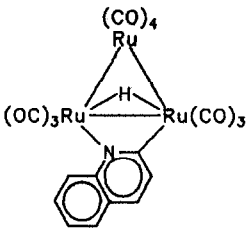


(82)

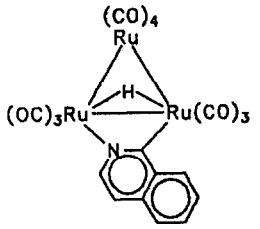


(83)

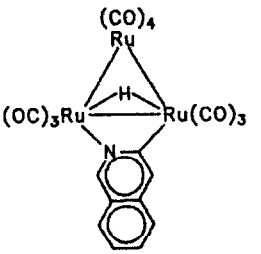
The considerably more reactive cluster $Ru_3(CO)_{10}(NCMe)_2$ cyclometallated quinoline to afford the trinuclear complex **84**; the corresponding reaction with isoquinoline afforded the two isomers **85** and **86**.[12] Reaction of quinoline with $Ru_3(CO)_{12}$ also afforded **84**;[117,122] in the presence of excess ligand, the bis(quinoline) product was obtained. Complex **84** afforded quinoline and Ru_4



(84)



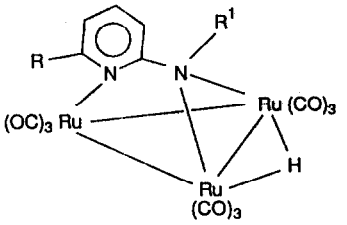
(85)



(86)

$(\mu\text{-H})_4(CO)_{12}$ on hydrogenation, but no reaction was observed with the hydridic reagents $Li[AlH_4]$ or $Li[BHEt_3]$.[122] As the carbon–nitrogen double bond is not reduced in the complex, but readily reduced in the free ligand, it seems the nitrogen ligand is not the site of reaction with H_2 or hydride reagents. Other heteroaromatic nitrogen compounds (1,2,3,4-tetrahydroquinoline, phenanthridine and 9,10-dihydrophenanthridine) also afforded oxidative addition products when reacted with $Ru_3(CO)_{12}$; the saturated nitrogen rings were dehydrogenated at the same time.

2-Aminopyridine reacted with $Ru_3(CO)_{12}$ to give orange–red $Ru_3(\mu\text{-H})(\mu\text{-NHpy})(CO)_9$ (**87**; R = R^1 = H); several substituted derivatives gave similar complexes, providing that there was at least one amino hydrogen atom present.[123] Substitution of equatorial CO groups *cis* to the μ-hydrogen and μ-amido fragments occurred in reactions of $Ru_3(\mu\text{-H})(\mu\text{-anpy})(CO)_9$ (**87**; R = Me, R^1 = H) (Hanpy = 2-amino-6-methylpyridine) with PPh_3 or dppm. The parent complex was readily protonated ($HBF_4 \cdot OEt_2$) to give $[Ru_3(\mu\text{-H})_2\{\mu_3\text{-NH}(C_5H_4N)\}(CO)_9]^+$; substitution of only those equatorial groups on the ruthenium bonded to one hydride occurred in similar reactions with tertiary phosphines.[124] The X-ray structure of the 2-anilinopyridyl complex **87** (R = H, R^1 = Ph) was determined, and is related to that of the 1*H*-pyrrolo[2,3-*b*]pyridine derivative.[121]

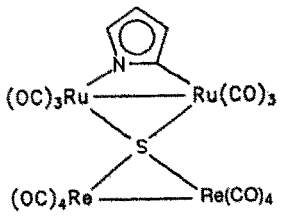


(87) R = R^1 = H
R = Me, R^1 = H
R = H, R^1 = Ph

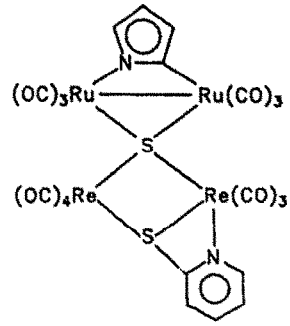
In contrast, 2-dimethylaminopyridine gave black $Ru_3\{\mu\text{-Me}_2N(C_5H_4N)\}(\mu\text{-CO})_3(CO)_7$, whose structure resembles that of the naphthyridine complex (**82**).[121]

$Ru_3(CO)_{12}$ reacted with pyridine-2-thiol to afford $Ru_3(\mu\text{-H})(\mu_3\text{-pyS})(CO)_9$; this latter complex was successively converted into polymeric $[\{Ru(\mu_3\text{-pyS})(CO)_2\}_n]$ and $Ru(pyS)_2(CO)_2$. The cluster has the same structure as the analogous 2-anilinopyridyl (*vide supra*) and pyrrolo[2,3-*b*]pyridinate complexes, and reacted with *P*-donors PPh_3 and dppm by CO substitution; the capping μ_3-pyS group proved resilient to metal–element bond cleavage.[125] Heteronuclear clusters **88**–**91** were obtained on reaction of $Re_2(pyS)_2(CO)_6$ (py = pyridine-2-thionato) with $Ru_3(CO)_{12}$;[126] in related work, $Ru(pyS)_2(CO)_2$ reacted with $Ru_3(CO)_{12}$ to afford pentanuclear $Ru_5(\mu_4\text{-S})_2(\mu\text{-}C_5H_4N)_2(CO)_{11}$, containing a Ru_5S_2 pentagonal bipyramid.[127]

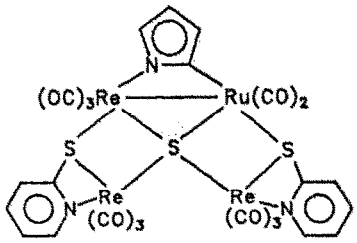
8-Quinolinol reacted with $Ru_3(CO)_{12}$ to give **92** and **93**, *O*-metallation being preferred over *C*-metallation.[128]



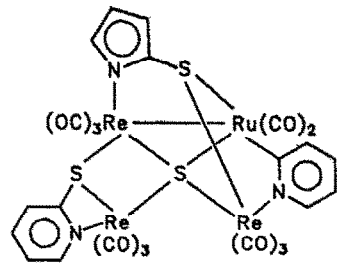
(88)



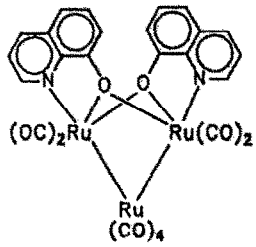
(89)



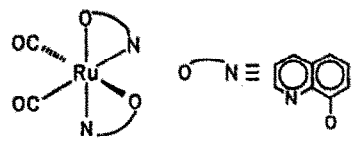
(90)



(91)



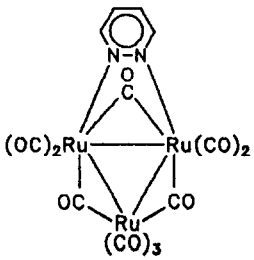
(92)



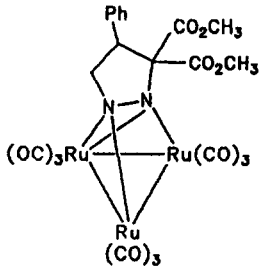
(93)

The reaction of 1,2-diazine with $Ru_3(CO)_{12}$ gave **94**;[129,130] the analogous reactions of two other 1,2-diazines afforded **95** and **96**.[131] Complex **94** can be considered to be derived from the supposed μ-CO intermediate for scrambling CO groups on $Ru_3(CO)_{12}$. The NMR spectrum at -156°C is in agreement with the solid-state structure. Between -156 and -86°C, the bridging and equatorial CO groups interchange by an exceptionally facile process ($E_a = 25.5$ kJ mol^{-1}). Between -117 and -86°C, the two axial CO groups on the unique ruthenium enter into the scrambling process, and all CO groups are equilibrated at ~ 75°C ($E_a = 58.1$ kJ mol^{-1}).

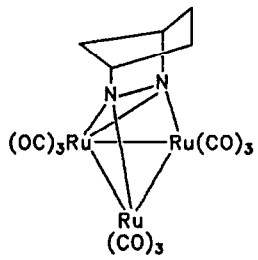
The complex $Ru_3(CO)_{10}(NCMe)_2$ reacted with 1,2-, 1,3- and 1,4-diazine to give **97**, isomeric **98** and **99**, and **100**, respectively;[12] as with pyridine, when *N*,*N*′-coordination is not possible, cyclometallation occurs.



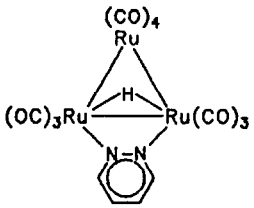
(94)



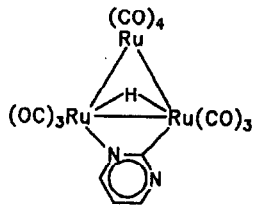
(95)



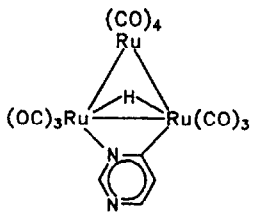
(96)



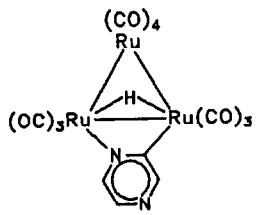
(97)



(98)



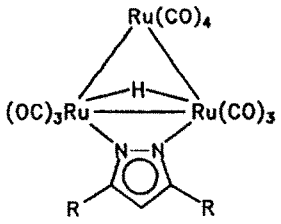
(99)



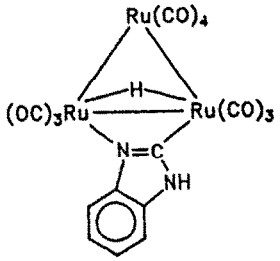
(100)

The 1 : 1 reaction between $Ru_3(CO)_{12}$ and pyrazoles in refluxing cyclohexane gave $Ru_3(\mu\text{-H})(\mu\text{-}N_2C_3HR_2)(CO)_{10}$ (**101**; R = H, Me or CF_3) by oxidative addition across a Ru—Ru bond.[115]

Thermal reactions between $Ru_3(CO)_{12}$ and the benzimidazole or benzotriazole gave $Ru_3(\mu\text{-H})(\mu\text{-bzim})(CO)_{10}$ (**103**) and $Ru_2(\mu\text{-bztz})_2(CO)_6$, respectively.[121] Reaction of **102** with PPh_3 gave a mixture of three isomers of $Ru_3(\mu\text{-H})(\mu\text{-bzim})(CO)_9(PPh_3)$ in the ratio 2.5 : 9 : 1 **103**:**104**:**105**.[132] The reaction between $Ru_3(CO)_{12}$ and 1*H*-pyrrolo-[2,3-*b*]pyridine afforded $Ru_3(\mu\text{-H})(\mu_3\text{-ppy})(CO)_9$ (**106**), the first example of a μ_3-pyrrolopyridine; the pyrrolic nitrogen is sp^3-hybridized, disrupting the ligand aromaticity.[121]



(101) R = H, Me, CF_3



(102)

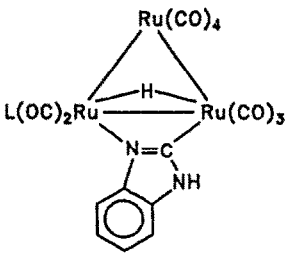
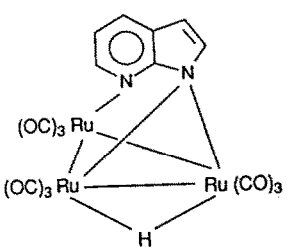
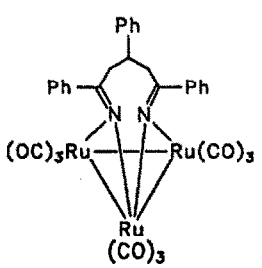
(104) L = PPh_3



(105) L = PPh_3



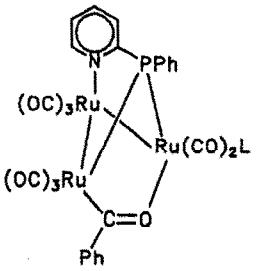
(106)



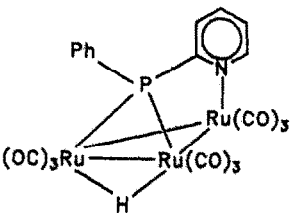
(107)

Even under very mild reaction conditions, $Ru_3(CO)_{12}$ and diazepines afforded mononuclear tricarbonyl complexes;[133,134] however, a small amount of **107** was isolated from the reaction with 4,5,6-trihydro-3,5,7-triphenyl-1,2-diazepine.[134]

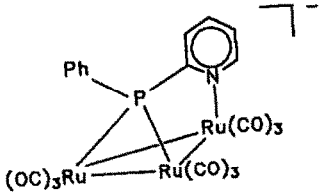
The thermal reaction between $Ru_3(CO)_{12}$ and diphenyl(2-pyridyl)phosphine afforded $Ru_3(CO)_9\{PPh_2(py)\}_3$ and monomeric species.[135] The phosphine reacted with $Ru_3(CO)_{12}$ under catalytic substitution conditions {[ppn][OAc]} to give $Ru_3(CO)_{11}\{PPh_2(py)\}$; this was metastable at room temperature, yielding $Ru_3\{\mu_3\text{-}PPh(C_5H_4N)\}\{\mu\text{-}C(O)Ph\}(CO)_9$ (**108**; L = CO).[136] This complex undergoes carbonyl substitution stereospecifically at a site *cis* to the oxygen of the acyl group to afford $Ru_3\{\mu_3\text{-}PPh(C_5H_4N)\}\{\mu\text{-}C(O)Ph\}(CO)_8(L)$ (**108**; L = PPh_3, PPh_2H, PCy_2H).[137] The PhCO functionality in **108** (L = CO) was the site of further reaction; treatment with H_2 afforded **109** by loss of CO and benzene, and with [ppn][BH_4] gave **110** after loss of benzaldehyde.[138] Interconvertion of **109** and **110** was achieved using [ppn][BH_4] as base and CF_3CO_2H as acid. Mild thermolysis of **108** (L = PPh_2H, PCy_2H) gave **111** after benzaldehyde loss; its reactivity toward



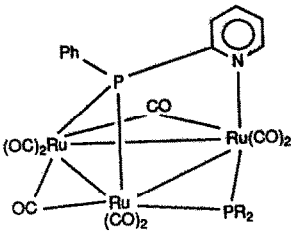
(108) L = CO, PPh_2H, PCy_2H



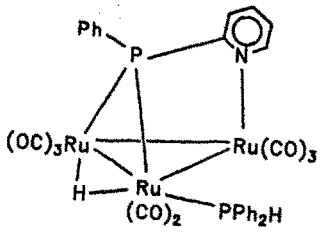
(109)



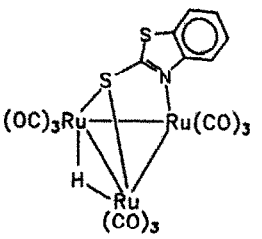
(110)



(111) R = Ph, cyclohexyl



(112)



(113)

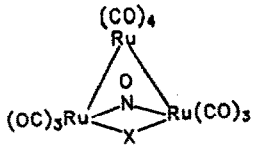
CO, PR_3 and H_2 was investigated. CO addition is reversible, and phosphines substitute at the non-phosphido-bridged ruthenium; hydrogenation afforded **112** as major product.

Coordination of the heterocyclic *N* atom was favoured over that of the *S* atom in the reaction between $Ru_3(CO)_{12}$ and the mercaptobenzothiazole (mbtH); oxidative addition of the thiol across a Ru—Ru bond gave **113**.[139] Addition of pyridine to the cluster afforded $\{Ru(\mu\text{-mbt})(CO)_2(py)\}_2$ and $Ru(mbt)_2(CO)_2(py)_2$.[140]

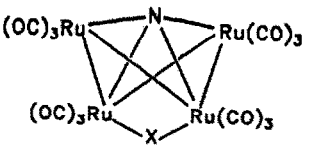
Reactions of many other *N*-heterocycles with $Ru_3(CO)_{12}$ have been studied and lead to mono- and binuclear products (Section 12).

9. NITROSYL COMPLEXES

Derivatives containing NO ligands have been obtained from reactions involving NO, NO^+ or NO_2^-. Direct reaction between $Ru_3(CO)_{12}$ and NO gave $Ru_3(\mu\text{-}NO)_2(CO)_{10}$ (**114**; X = NO), in which only two Ru—Ru bonds are present. Further reaction with NO gave a brown, insoluble, polymeric material,[141,142] while CO reacted with **114** (X = NO) to give a mixture of $Ru_3(CO)_{12}$, $Ru_3(\mu\text{-}NCO)(\mu\text{-}NO)(CO)_{10}$ (**114**; X = NCO) and $Ru_4(\mu_4\text{-}N)(\mu\text{-}X)(CO)_{12}$ (**115**; X = NO, NCO).[143] In the presence of triphenylphosphine, **114** (X = NO) underwent disubstitution to afford $Ru_3(\mu\text{-}NO)_2(CO)_8(PPh_3)_2$.[144]

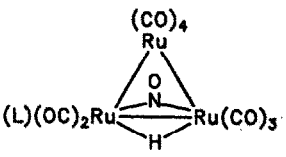


(114) X = NO, NCO

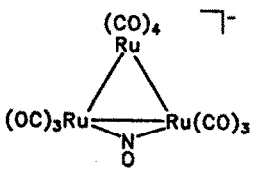


(115) X = NO, NCO

The cluster anion $[Ru_3(\mu\text{-}H)(CO)_{11}]^-$ reacted with $[NO][PF_6]$ to give $Ru_3(\mu\text{-}H)(\mu\text{-}NO)(CO)_{10}$ (**116**; L = CO); carbonyl substitution of this complex with $P(OMe)_3$ afforded **116** [L = $P(OMe)_3$].[145] The reaction between $Ru_3(CO)_{12}$ and $[ppn][NO_2]$ gave $[ppn][Ru_3(\mu\text{-}NO)(CO)_{10}]$ (**117**), which afforded **116** (L = CO) upon protonation with CF_3CO_2H.[146,147]

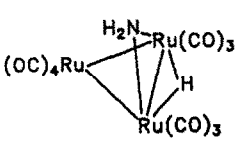


(116) L = CO, P(OMe)3

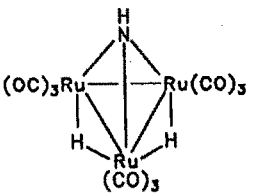


(117)

Hydrogenation of **116** gave $Ru_3(\mu\text{-}H)(\mu\text{-}NH_2)(CO)_{10}$ (**118**), $Ru_3(\mu\text{-}H)_2(\mu_3\text{-}NH)(CO)_9$ (**119**) and $Ru_4(\mu\text{-}H)_4(CO)_{12}$;[148] trace amounts of tetranuclear $Ru_4(\mu\text{-}H)_3(\mu\text{-}NH_2)(CO)_{12}$ (**120**) were also found.[149]

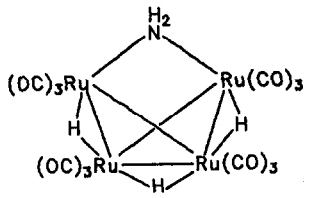


(118)

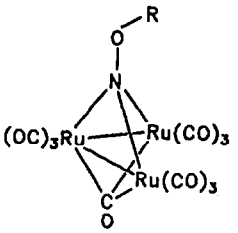


(119)

Protonation of **117** with CF_3SO_3H afforded **121** (R = H);[150] addition of the proton to the nitrosyl oxygen and subsequent capping by the face bridging NOH and CO is in contrast to the addition across a metal–metal bond found when CF_3CO_2H is used.[146] Photolysis of **121** (R = H)



(120)

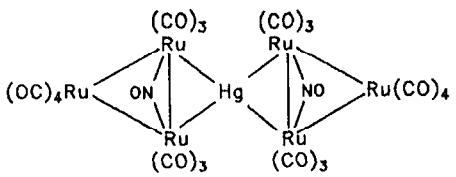


(121) R = H, Me

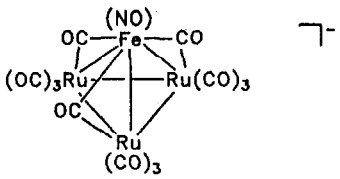
under CO generated $[Ru_3(NCO)(\mu\text{-}CO)_2(CO)_9]^-$ (**4**) quantitatively.[151] Methylation of **117** with CF_3SO_3Me gave **121** (R = Me), while reaction with [ppn][NO_2] under CO gave $[Ru(CO)_3(NO)]^-$.

The reaction of **117** with $HgCl_2$ afforded **122**, with the mercury atom bridging the same Ru—Ru bond in each Ru_3 triangular unit as the nitrosyl ligands.[152] The heteronuclear nitrosylcarbonyl cluster $[FeRu_3(CO)_{12}(NO)]^-$ (**123**) was obtained in good yield from the reaction between $Ru_3(CO)_{12}$ and $[Fe(CO)_3(NO)]^-$.[153]

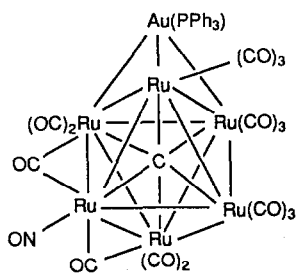
Johnson, Lewis and co-workers synthesized hexaruthenium cluster nitrosyls by auration [AuCl(PPh_3)] (**124**), protonation (**125**) or nitrosylation {$[NO]^+$} (**126**) of $[Ru_6C(CO)_{15}(NO)]^-$, generated upon reaction of $Ru_6C(CO)_{17}$ with [ppn][NO_2].[154,155]



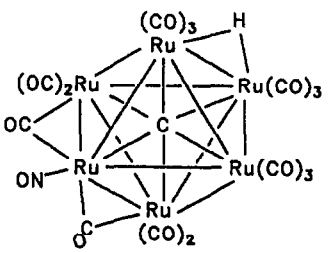
(122)



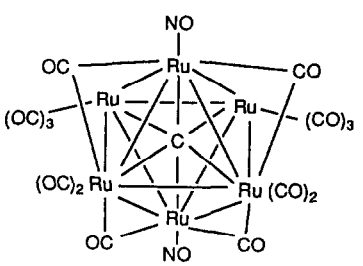
(123)



(124)



(125)



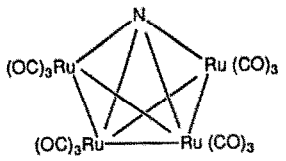
(126)

10. NITRIDO CLUSTERS

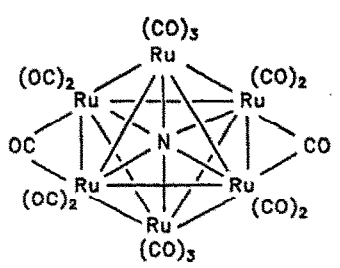
Gladfelter has surveyed the field of organometallic clusters containing nitrosyl or nitrido ligands,[156] and has summarized his earlier results in these areas with ruthenium clusters.[157]

Thermolysis of the μ-NCO complex **6** gave $[Ru_4(\mu_4\text{-}N)(CO)_{12}]^-$ (**127**) in high yield,[158] which on protonation with CF_3SO_3H gave a mixture containing $Ru_3(\mu_3\text{-}NH)(\mu_3\text{-}CO)(CO)_9$.[159] Reaction of either **4** or **9** with $Ru_3(CO)_{12}$ afforded the hexanuclear nitrido cluster $[Ru_6(\mu_6\text{-}N)(CO)_{16}]^-$ (**128**), which reacted rapidly with CO at room temperature to give $[Ru_5(\mu_5\text{-}N)(CO)_{14}]^-$ (**129**);[158] the pentanuclear complex was also obtained in low yield by thermolysis of **121** (R = H).[151]

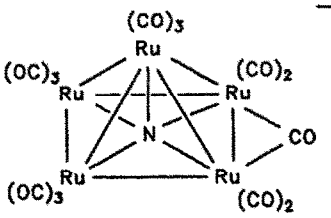
Refluxing a mixture of $Ru_3(CO)_{12}$ and [ppn][N_3] in thf overnight gave **127** in addition to **6**;[160] formation of **127** involves the cleavage of a coordinated isocyanate into a coordinated nitrogen atom and carbon monoxide.



(127)



(128)



(129)

The anions $[M_4(\mu_4\text{-}N)(CO)_{12}]^-$ (M = Fe, Ru, Os) are isostructural; the *N* atom is approximately octahedral, with two *cis* coordination sites vacant. Its bonds to the hinge atoms are 0.13–0.16 Å longer than those to the wing-tip atoms.[161]

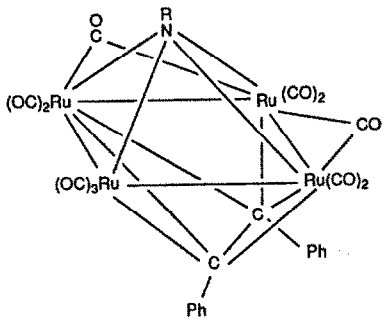
Fenske–Hall MO calculations of the electronic structures of $[M_4(\mu_4\text{-}N)(CO)_{12}]^-$ ($M_4 = Fe_4$, $FeRu_3$, Ru_4) have shown that the metal-based orbitals cover a wider energy range in the Ru_4 complex compared with Fe_4; metal–metal bonding is stronger in the former, with the bond between the hinge atoms being considerably stronger than those between the hinge and wing-tip atoms.[161] There is no significant difference in the M—N bond strengths. The metal–nitride stretching vibrations in $Ru_4(\mu\text{-}H)(\mu_4\text{-}N)(CO)_{12}$ have been assigned; however, no comparison could be made with similarly-bound nitrogen on a metal surface.[162]

The mixed-metal cluster exists as the two isomers (a) and (b), which interconvert in solution, in which the iron atom is in wing-tip or hinge positions. The metal–metal bonding is perturbed more in isomer (b). Protonation gives exclusively the hydride derived from (a), in which the hydrogen atom bridges the hinge bond, interacting with a localized hinge bonding MO found in (a) but not in (b). Auration using $AuCl(PPh_3)$ afforded an analogous product, with the $AuPPh_3$ fragment bridging the hinge and the iron atom exclusively in a wing-tip position.[163]

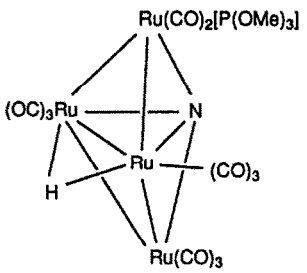
The mixed-metal nitrido cluster $CoRu_3(\mu_4\text{-}N)(CO)_{12}$, which is isoelectronic with the $[M_4(\mu_4\text{-}N)(CO)_{12}]^-$ anions discussed above, was isolated in low yield from the reaction between $[CoRu_3(CO)_{13}]^-$ and $[NO]^+$; the location of the cobalt atom was not determined.[164]

Protonation of both the Fe_4 and Ru_4 complexes appears to proceed by way of a μ-NH intermediate, which undergoes hydrogen migration to bridge the hinge atoms. In the Ru_4 system, the NH intermediate has been trapped by addition of diphenylacetylene, affording **130**;[165] an isostructural phenylnitrene has recently been prepared.[166]

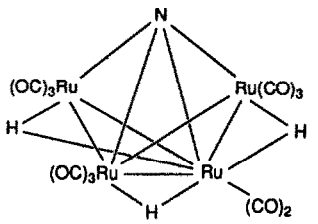
Reaction of $[H_3Ru_4(CO)_{12}]^-$ with $[NO]^+$ afforded the nitrido cluster $Ru_4(\mu\text{-}H)(\mu_4\text{-}N)(CO)_{12}$, whose $P(OMe)_3$ derivative, **131**, was structurally characterized,[167] and **132**, amongst other products.[167,168]



(130) R = H, Ph



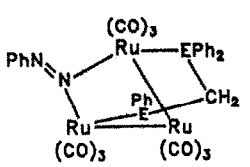
(131)



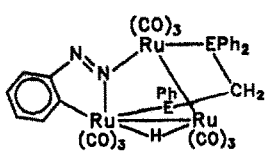
(132)

11. CLUSTERS CONTAINING OTHER *N*-DONOR LIGANDS

Given the large number of anionic Ru_3 clusters known, it is surprising that reactions with aryldiazonium cations have been little exploited in the synthesis of cluster carbonyl derivatives. One such reaction, between $[PhN_2][PF_6]$ and $[Ru_3(\mu_3\text{-}PhECH_2EPh_2)(CO)_9]^-$ (E = P, As), gave **133**, which on heating in cyclohexane underwent cyclometallation to give **134**.[169]

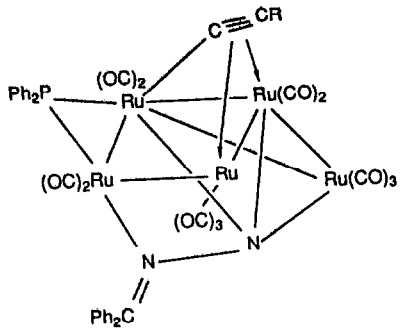


(133) E = P, As

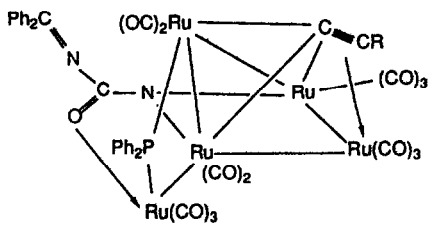


(134) E = P, As

Diphenyldiazomethane reacted with $Ru_5(CO)_{13}(\mu_4\text{-}\eta^2\text{-}C_2R)(\mu\text{-}PPh_2)$ (R = Ph, Pr^i) to afford **135**, which contains an intact μ_4-coordinated N_2CPh_2; CO inserted into the N—N bond of **135** to afford **136**.[170]



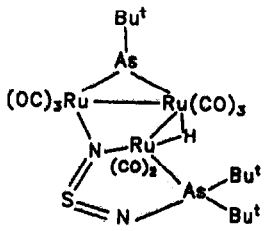
(135)



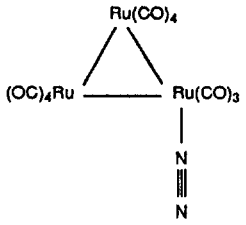
(136)

The reaction between $Ru_3(CO)_{12}$ and $S(NAsBu^t_2)_2$ afforded $Ru_3(\mu\text{-}H)(\mu_3\text{-}AsBu^t)(\mu\text{-}NSNAsBu^t_2)(CO)_8$ (**137**).[171]

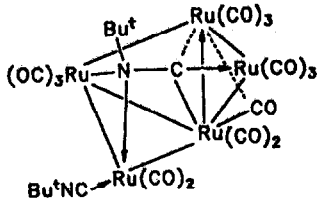
Photogenerated $Ru_3(CO)_{11}$ reacted with N_2 at 110 K to yield axially substituted $Ru_3(N_2)(CO)_{11}$ (**138**); warming the matrix to 195 K led to quantitative regeneration of $Ru_3(CO)_{12}$.[172]



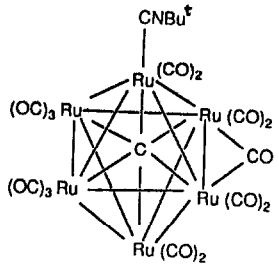
(137)



(138)



(139)



(140)

Moderate heating converted $Ru_3(CO)_{11}(CNBu^t)$ into $Ru_5(CO)_{14}(CNBu^t)_2$ (**139**), with an isocyanide ligand acting as a 6e donor bonded to all five metal atoms.[173] Pyrolysis of **139** in refluxing nonane afforded $Ru_6(\mu_6\text{-}C)(\mu\text{-}CO)(CO)_{15}(CNBu^t)$ (**140**); the carbide was shown by selective isotopic labelling to have been derived from the isonitrile ligand.[174]

12. REACTIONS OF ORGANO-NITROGEN COMPOUNDS GIVING MONO- OR BINUCLEAR PRODUCTS

(a) *Azoarenes*

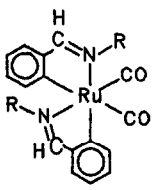
One of the three complexes isolated from reactions between azobenzene and $Ru_3(CO)_{12}$ was characterized as $Ru(azb)_2(CO)_2$ (**38**), containing the cyclometallated 2-(phenylazo)phenyl ligand.[70,87] There are three possible isomers for $Ru(CO)_2(C\text{-}N)_2$, where (C-N) is a chelating ligand with *C* and *N* donors; a different isomer is found in the product obtained from $Ru_3(CO)_{12}$ and benzo[*h*]quinoline (*vide infra*).

(b) *Enimines and α,α′-diimines*

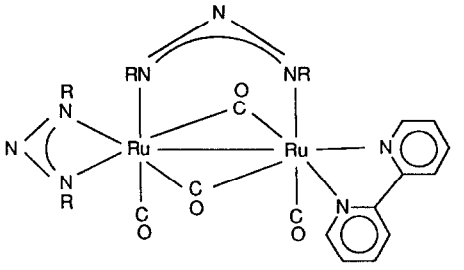
As described in Section 7, the usual products from reactions of compounds containing the N=C functionality are mono- or binuclear complexes. The reaction of $Ru_3(CO)_{12}$ with *N*-phenylsalicylidenimine afforded bis(*N*-phenylsalicylideniminato)dicarbonylruthenium(II); the corresponding reaction with *N,N′*-ethylenebis(salicylidenimine), $salenH_2$, gave a complex which analysed as Ru(CO)(salen) and was assigned a dimeric structure.[175] When this product was heated in pyridine, the monomer Ru(CO)(py)(salen) was obtained.[176] The reactions of other Schiff bases, PhCH=NR (R = Ph, Me), with $Ru_3(CO)_{12}$ also gave the yellow crystalline mononuclear complexes $Ru(C_6H_4CH{=}NR)_2(CO)_2$ (**141**; R = Ph, Me).[85,177]

(c) *Triazenes*

The ruthenium(I) triazenido complexes $\{Ru(ArNNNAr)(CO)_3\}_2$ (Ar = *p*-C_6H_4Me, *p*-C_6H_4Cl) were prepared by heating $Ru_3(CO)_{12}$ with free triazenes.[178] The bis(tolyl)triazenido complex reacted with bipy to afford the substitution product **142**.[179]



(141) R = Ph, Me

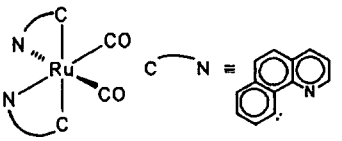


(142) R = C_6H_4Me-4

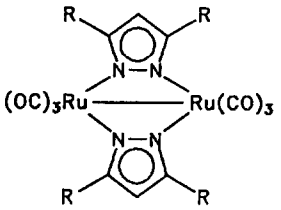
(d) N-*Heterocycles*

Reactions between $Ru_3(CO)_{12}$ and benzo[*h*]quinoline (bqH) gave the mononuclear complex $Ru(bq)_2(CO)_2$ (**143**),[180,181] together with $Ru_4(\mu\text{-}H)_4(CO)_{12}$.

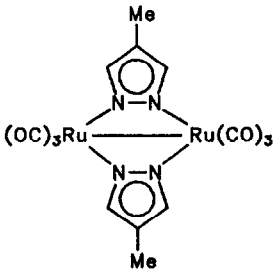
The carbonyl reacted with three equivalents of pyrazoles to give the corresponding binuclear complexes **144** (R = H, Me) and **145**.[182–184] The indazole analogue was prepared similarly as a mixture of isomers. Complex **144** (R = H or Me) reacted with iodine to afford $[Ru_2(\mu\text{-}I)(\mu\text{-pyrazolyl})_2(CO)_6]I_3$ or $Ru_2I_2(\mu\text{-pyrazolyl})_2(CO)_6$, depending on the Ru : I ratio, and **144** (R = Me) reacted with excess of pyridine, acetonitrile, PPh_3, $P(C_6H_{11})_3$ or dppm at room temperature to afford monosubstituted $Ru_2(\mu\text{-dimethylpyrazolyl})(CO)_5(L)$; the pyridine product has C_s symmetry,



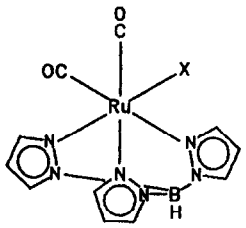
(143)



(144) R = H, Me



(145)

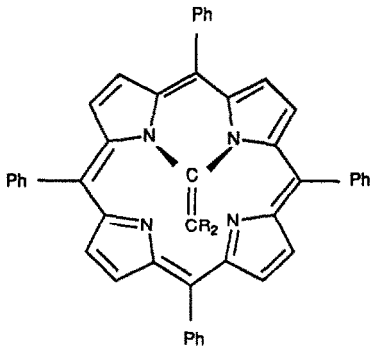


(146) X = Cl, Br, I

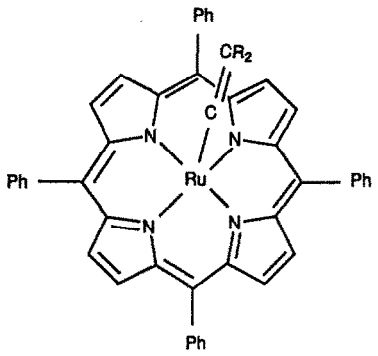
with the pyridine *trans* to the metal–metal bond, unlike all the others (C_1).[183] In refluxing thf, **144** (R = Me) could be disubstituted with dppm, to afford $Ru_2(CO)_4(\mu_2\text{-}\eta^2\text{-}Me_2pz)_2(\eta^1\text{-}dppm)_2$.[185] Complex **144** (R = H) reacted with dppe and (1*S*,2*S*)-(+)-1,2-bis(diphenylphosphinomethyl) cyclohexane (CYCLOP) to afford diphosphine-bridged $Ru_2(CO)_4(\mu_2\text{-}\eta^2\text{-}pz)(\mu_2\text{-}\eta^2\text{-}L_2)$ (L_2 = dppe, CYCLOP). In contrast, **144** (R = Me) reacted with dppe and CYCLOP by *ortho*-metallation of a phenyl group to afford $(\mu\text{-}H)Ru_2(CO)_3(\mu_2\text{-}\eta^2\text{-}3,5\text{-}Me_2pz)_2\{\eta^2\text{-}PPh_2XPPh_2(C_6H_4)\}$ (X = CH_2CH_2, $CH_2(C_6H_{10})CH_2$).[185] Complexes **144** (R = H or Me) reacted with carboxylic acids to give carboxylato-bridged dinuclear species, with displacement of the pyrazolato bridge to a monodenate position and concomitant protonation of the free nitrogen.[184] The reaction between $Ru_3(CO)_{12}$ and potassium tris(pyrazolyl)borate, K[HB(pz)$_3$], gave a deep red solution from which the compounds $RuX(CO)_2\{HB(pz)_3\}$ (**146**; X = Cl, Br, I) were obtained on treatment with the appropriate halogen.[186]

2-Pyridone reacted with $Ru_3(CO)_{12}$ to give the yellow polymeric $\{Ru_2(\mu\text{-}Opy)_2(CO)_4\}_n$, which reacted with ligands [L = CO, MeCN, $P(OPh)_3$, 2-pyridone] to give binuclear $Ru_2(\mu\text{-}Opy)_2(CO)_2(L)_2$. The cluster hydride $Ru_4(\mu\text{-}H)_4(CO)_{12}$ reacted with both 2-pyridone and $Ru_2(\mu\text{-}Opy)_2(CO)_2(L)_2$ to give the polymer.[123]

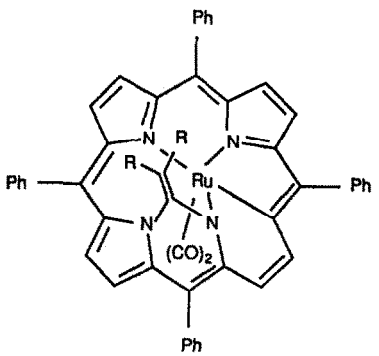
Porphyrins or phthalocyanines usually form mononuclear macrocyclic ligand complexes when reacted with $Ru_3(CO)_{12}$. The product of the reaction between $Ru_3(CO)_{12}$ and tetraphenylporphyrin (tpp) when recrystallized from chloroform–ethanol was eventually shown to be Ru(CO)(EtOH)(tpp),[187] after an earlier X-ray study had erroneously formulated it as the dicarbonyl, $Ru(CO)_2(tpp)$;[188] the unidentate ligands occupy axial sites. The *N*,*N*′-bridged tetraphenylporphyrin **147** afforded **148** and **149** from reaction with $Ru_3(CO)_{12}$, the former by insertion of the metal into the N—C(vinyl) bonds, the latter by insertion of the metal into a N—C(pyrrole) bond;[189,190] a small amount of the olefin-hydrogenated form of **149** was obtained also.[191] Heating a chlorobenzene solution of **149** cleanly afforded **148**.



(147) R = C_6H_4Cl-4



(148) R = C_6H_4Cl-4



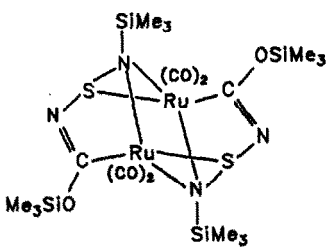
(149) R = C_6H_4Cl-4

Phthalocyanine (pcH_2) reacted with $Ru_3(CO)_{12}$ in refluxing benzonitrile to give a dark blue solid, probably Ru(CO)(pc); Soxhlet extraction with pyridine afforded $Ru(py)_2(pc)$.[192] The related complex Ru(CO)(py)(pc) was obtained from the reaction between $Ru_3(CO)_{12}$ and phthalonitrile when followed by pyridine work-up.[193]

High yields of binuclear compounds were obtained from reactions between $Ru_3(CO)_9(PPh_3)_3$ and *N*-donor ligands such as pyrazole, 2-pyridone, *N*-methyl-2-mercaptoimidazole and 1,8-diaminonaphthalene.[194]

(e) *Inorganic nitrogen ligands*

The binuclear complex $Ru_2(\mu\text{-}Me_3SiNSNCOSiMe_3)_2(CO)_4$ (**150**) was formed from the reaction of $Ru_3(CO)_{12}$ with $S(NSiMe_3)_2$.[195]



(150)

13. REACTIONS OF ORGANO-NITROGEN COMPOUNDS CATALYSED BY RUTHENIUM CLUSTERS

$Ru_3(CO)_{12}$ has been used as a catalyst for the carbonylation of amines to formamides;[196-198] carbomoyl complexes were proposed as intermediates.[198] Recently, Süss-Fink and co-workers have shown that $Ru_3(CO)_{12}$ and $Na[Ru_3(\mu\text{-}H)(CO)_{11}]$ catalyse the carbonylation of cyclic amines (piperidine, 3-methylpiperidine, pyrrolidine, heptamethylenimine and morpholine); in the case of $Ru_3(CO)_{12}$, carbamoyl clusters analogous to **15** were isolated.[199] The *ortho* positions of pyridines were acylated using olefins and carbon monoxide in the presence of $Ru_3(CO)_{12}$; the reaction is first order in pyridine and zero order in olefin and carbon monoxide, and most likely proceeds through a pyridyl hydrido intermediate such as **75**.[200]

Catalytic homogeneous double bond isomerization of 1,2-bis(ethoxycarbonyl)-1,2,3,6-tetrahydropyridazine with $Ru_4(\mu\text{-}H)_4(CO)_{12}$, but not with $Ru_4(\mu\text{-}H)_4(CO)_8(PBu_3)_4$,[201] conversion of dialkylcarbodiimides to trialkylguanidines under H_2 with several ruthenium-containing clusters,[202] and the hydro-coupling of alkyl isocyanates to carbamylformamides by $[Ru_4(\mu\text{-}H)_3(CO)_{12}]^-$[203] have been described; in the latter reaction, an intermediate containing a μ-NRCHO ligand was proposed.

$Ru_3(CO)_{12}$ has also been investigated as a catalyst for the reductive carbonylation of aromatic nitro compounds to give carbamates[52,54] and diphenylurea;[48] stoichiometric reactions aimed at elucidating the mechanism are discussed in Section 6.

$Ru_3(CO)_{12}$ catalysed the addition of *N*-substituted formamides to both terminal and internal olefins under carbon monoxide pressure,[204] and has been shown to catalyse the *N*-alkylation of amides, imides and lactams by alcohols.[205] It has also been shown to be an efficient catalyst for the transalkylation of amines.[206]

14. CONCLUSION

The chemistry of triruthenium clusters with *N*-donor ligands has expanded considerably since the former survey, due in some part to the use of milder reaction conditions involving activated triruthenium precursors. It is apparent that preferred reactivity patterns and modes of coordination of *N*-donor ligands with $Ru_3(CO)_{12}$ are becoming predictable; thus reaction types normally observed include oxidative addition across a Ru—Ru bond (benzonitriles, aromatic amines, *N*-heterocycles), reaction at a carbonyl ligand (aliphatic amines) and ligand fragmentation to give a μ_3-nitrene group (nitro-, nitroso- and azo-arenes, azides). The extensive chemistry developed with the diimines and enimines by the Vrieze–van Koten groups testifies to the potential richness of ruthenium carbonyl *N*-donor ligand chemistry and lends support to the suggestion that far from being "difficult to control", the reactivity of $Ru_3(CO)_{12}$ compared with its osmium analogue promises more chemical possibilities. The nitrosyl and nitrido chemistry, developed principally by Gladfelter and co-workers, is rather more fundamental in nature, and may model rearrangements involving nitrogen atoms occurring on metal surfaces.

Acknowledgements—We thank Dr J. A. Cabeza for sending us preprints. This review was written in Würzburg, F.R.G. and in Urbana, Illinois, and M.G.H. thanks Professors G. Erker and J. R. Shapley, respectively, for their hospitality; the Alexander von Humboldt-Stiftung is thanked for a Fellowship (M.G.H.).

MOLYBDENUM(III) COMPLEXES WITH SOME IMIDAZOLES

K. M. PRASAD,* A. N. TRIPATHY and N. M. THAKUR

Department of Chemistry, H. D. Jain College, Arrah—802301, India

(*Received* 22 *August* 1989; *accepted after revision* 1 *August* 1990)

Abstract—The synthesis and characterization of complexes of stoichiometry $[MoL_3X_3]$ (L = imidazole, 2-methylimidazole, benzimidazole or 2-methylbenzimidazole and X = Cl^-, Br^- or NCS^-) are described. The effective magnetic moments (3.68–3.78 BM) are characteristic of octahedral molybdenum(III). The C=N stretching frequency of the ligands shift to higher frequency in the complexes, suggesting that tertiary nitrogen is the active site of coordination of the ligand (L). The ν(CN) and ν(CS) bands of thiocyanate complexes are diagnostic of N-bonded thiocyanate.

As part of a systematic investigation of the synthetic, structural and biological aspects of molybdenum(III) complexes,[1–4] we report here on the complexes of molybdenum(III) with imidazole and its substituted derivatives, as these ligands are common components of several biologically important molecules such as vitamin B_{12} and iron haem. The imidazole moiety plays an extremely crucial role in the structure and functioning of these molecules, generally by virtue of being coordinated to the metal ions. To discover whether the secondary (N_2H) nitrogen or the tertiary (N_3) nitrogen binds metal ions such as molybdenum(III), we investigated the molybdenum(III) complexes with imidazole (IzH), 2-methylimidazole (2-MeIzH), benzimidazole (BzH) and 2-methylbenzimidazole (2-MeBzH) by elemental analyses, conductance, magnetic moment, electronic and IR spectral measurement.

EXPERIMENTAL

Ammonium pentachloroaquomolybdate(III), pentabromoaquomolybdate(III) and ammonium hexaisothiocyanatomolybdate(III) were prepared by the electrolysis of ammonium molybdate in (8 N) HCl, 48% HBr and dil. H_2SO_4, respectively.[5–7] All the preparative work was carried out in a purified dry nitrogen atmosphere. Physicochemical measurements were made as reported in an earlier communication.[3]

Preparation of the complexes

$[Mo(IzH)_3Cl_3]$. $(NH_4)_2[MoCl_5H_2O]$ (approx. 1.0 g) was dissolved in a mixture of water (20 cm^3), HCl (10 cm^3) and methanol (10 cm^3), to which imidazole (0.63 g) dissolved in acetone was added. The pH of the mixture was adjusted to ~ 6 by adding ammonium acetate and the resulting brownish yellow solution was shaken with benzene and an oily layer separated. With the help of a separating funnel, the oily layer was placed in a conical flask, dissolved in methanol and then treated with excess acetone. After filtering, the filtrate was diluted with a large volume of air-free water and $[Mo(IzH)_3Cl_3]$ separated as a yellow compound. This was filtered, washed with 95% ethanol and dried *in vacuo* over KOH–$CaCl_2$.

The other tris-ligated chloro- and bromo-complexes were prepared by an analogous procedure. The complexes $[MoL_3(NCS)_3]$ (L = IzH, 2MeIzH, BzH or 2MeBzH) were prepared by the interaction of an ethanolic solution of the ligands (L) with an ethanolic solution of $(NH_4)_3[Mo(NCS)_6]$ in a 3:1 molar ratio under nitrogen. Analytical data are presented in Table 1.

RESULTS AND DISCUSSION

All the complexes $[MoL_3X_3]$ are stable in air and their methanolic solutions were almost non-

[a] The band positions within parentheses are in chloroform.

conducting, indicating their non-ionic nature. The effective magnetic moment values of the complexes at room temperature are in the range 3.68–3.78 BM (Table 1), as expected for the spin-only value for a t^3_{2g} configuration,[8,9] suggesting an octahedral arrangement of the ligands around the molybdenum(III) ion. While the pentachloroaquomolybdate(III) and pentabromoaquomolybdate(III) exhibit three *d–d* transitions,[1] $[MoL_3X_3]$ complexes exhibit only one absorption band near 24,000–26,000 cm^{-1}. This has been attributed to the charge-transfer transition which masks the *d–d* transitions of molybdenum(III) in these complexes, as commonly observed with heterocyclic N-donor ligands.[2]

The IR spectra of ammonium hexaisothiocyanatomolybdate(III) has been reported in an earlier communication.[4] The $[MoL_3(NCS)_3]$ complexes exhibit only one strong C=N stretching band in the range 2070–2080 cm^{-1} and a weak CS stretching band near 810–815 cm^{-1}, which are diagnostic of N-bonded thiocyanate.[4,9] The C=N stretching band of IzH (~ 1580 cm^{-1}) and BzH (~ 1600 cm^{-1}) shift to higher frequency by 30 ± 15 suggesting that tertiary nitrogen is the bonding site of the ligands.[10–14]

Mile End Road, London E1 4NS, U.K.

(*Received* 18 *July* 1990; *accepted* 5 *September* 1990)

Abstract—The synthesis and characterization of a number of cadmium complexes with sulphur-containing ligands including: 2-mercaptopyridine, 2-mercaptobenzothiazole, 2-mercaptothiazoline, 1,4,8,11-tetrathiaundecane, 5-mercapto-1-methyltetrazole and dithiocarbamates are reported. ^{113}Cd solid-state NMR spectroscopy has been used to characterize several of the compounds and many of the complexes decompose to cadmium sulphide.

In this paper we report further studies of some thiolates of cadmium, work which is related to our recently published X-ray crystal structures[1] of the bis(mercaptobenzothioazole) and bis(2-mercaptopyridinato) complexes of cadmium. There is considerable current interest in thiolate complexes of cadmium[2–4] and other group 12 metals, which is in part due to the ability of thiolates, in combination with these metals, to form extended zeolitic and/or low-dimensional structures.[2–5] All of the complexes described in the present paper decompose to cadmium sulphide, which may make them of interest in the design of precursors for deposition of cadmium sulphide.

RESULTS AND DISCUSSION

Bis(2-mercaptopyridinato)cadmium(II)

There has been considerable interest in 2-mercaptopyridine (pySH) as a ligand.[6,7] The ligand exists in two tautomeric forms; the thione tautomer (**1**), which is thought to predominate when the ligand is dissolved in methanol or acetone,[8] and the thiol (**2**) tautomer in dilute cyclohexane solutions.[9] In the solid state the ligand exists as a hydrogen-bonded dimer.[10] The zinc complex of pyS^- has been synthesized but has not been fully characterized,[11] and a structure for the mercury complex was reported recently.[5] The cadmium complex $Cd(pyS)_2$ is a white, powdery solid which sublimes at 170°C/10^{-2} torr and is insoluble in most organic solvents, but does dissolve in pyridine and can be recrystallized. The crystal structure shows that coordination at each cadmium is close to octahedral (N_2S_4) with two different ligand coordination modes; one approximately parallel and the other perpendicular to the polymer chain, a packing diagram (not previously published) is shown in Fig. 1.

The compound is a genuine one-dimensional inorganic polymer, with the shorter Cd—S distances forming the chain as detailed in ref. 1. The mercury complex[5] shows a similar polymeric network, but

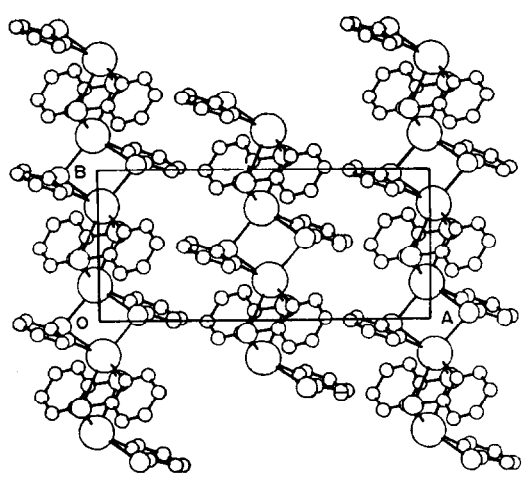

Fig. 1. The packing of the polymeric chains in the pyridine thiolate complex (viewed down *c*).

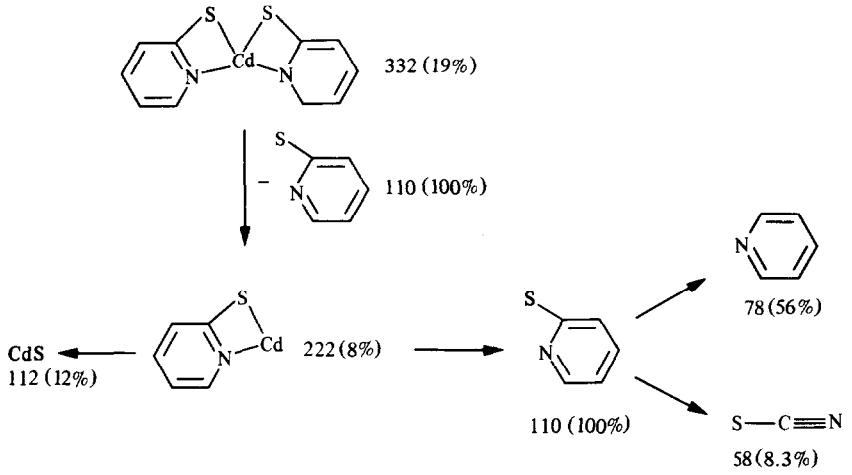

Scheme 1. Partial fragmentation pattern for bis(2-mercaptopyridinato)cadmium(II).

the nitrogen atoms are not coordinated to the metal; the mercury complex is able to coordinate metal ions and we are investigating such reactions of the cadmium complex.

Thermogravimetric analysis, in a stream of air, showed the compound to decompose cleanly to cadmium sulphide at a temperature of 230–500°C (theoretical, 43%; found, 42%). From the X-ray powder diffraction patterns, the cadmium sulphide was found to contain both cubic and hexagonal forms. The mass spectrum of bis(2-mercaptopyridinato)cadmium(II) included the fragmentation pattern shown in Scheme 1. Attempts to obtain a ^{133}Cd solid-state NMR spectrum of $Cd(pyS)_2$ were unsuccessful. This is probably due to the fact that the compound has a long proton relaxation time of *ca* 31 s.

Bis(2-mercaptobenzothiazolato)cadmium(II)

The crystal structure of $[^nBu_4N][Cd(C_7H_4NS_2)_3]$ has been described by McCleverty *et al.*[12] The cadmium atom is six-coordinate, with each $C_7H_4NS_2^-$ (MBZ^-) ligand (**3**) bonded through the exocyclic sulphur atom and the nitrogen atom. The bite angle of the ligand is 62°; the complex has strict C_3 symmetry distorted from trigonal prismatic towards octahedral.

Ligands used in this study

(1) 2-Mercaptopyridine (pySH) thione tautomer
(2) 2-Mercaptopyridine (pySH) thiol tautomer
(3) 2-Mercaptobenzothiazole (MBT)
(4) 2-Mercaptothiazoline (MTZ)
(5) 2-Mercaptothiazolidine (TDZ)
(6) 1,4,8,11-tetrathiaundecanato (TTU)
(7) 5-Mercapto-1-methyltetrazole (MTTZ)

The bis-complex of **3** has been investigated using IR spectroscopy by Khullar and Argarwalla[13] and was assumed to be polymeric. It was postulated that the ligand was bound via the exo-sulphur and the endo-nitrogen, and that the endo-sulphur was not involved in coordination to the metal. The coordination at cadmium was thought to be tetrahedral (CdN_2S_2) with bridging ligands. The bis-complex is readily prepared from ethanolic solutions as described in the Experimental and is soluble only in polar solvents such as dimethylformamide.

The structure of the crystalline mercaptothiopyrazole complex[1] is similar to that of the mercaptopyridine complex, with short ligand-to-metal contacts (Cd—N and Cd—S) to different cadmium atoms. Again a genuine one-dimensional polymeric structure is developed, but in this case the ligands take up a helical pattern.[1] The two chelating Cd—S contacts are unusually long, and the cadmium atoms are separated by 3.77 Å, well outside the sum of the van der Waals' radii (3.2 Å). The mode of ligation is very different from the chelate mode shown in the anionic tris-complex.

The above results can be used to interpret spectroscopic studies of this complex and also to comment on the results of an earlier study. The IR spectra of the crystals and the powder are very similar. The strong band at 749 cm^{-1} (which has been assigned to the C=S stretch[13]) has a shoulder for the powder sample, as observed by Khullar and Argarwalla.[13] However, the IR spectrum of the crystalline sample contains a single peak. This small difference is the only change in the IR spectrum (4000–400 cm^{-1}) on recrystallization. The powder obtained on the initial precipitation of $Cd(MBZ)_2$ is microcrystalline and the X-ray powder diffraction pattern of the crude complex and recrystallized compound showed that the former contains many lines not observed for the latter.

The solid-state ^{113}Cd NMR spectrum of $Cd(MBZ)_2$ powder is shown in Fig. 2. The spectrum shows that there are two cadmium sites with chemical shifts of δ 340 and 329 from $Cd(ClO_4)_2$, presumably due to two phases being present in the sample, which is in agreement with the X-ray powder diffraction results (Table 1). The spinning sideband pattern is slightly different for each cadmium atom and the results are summarized in Table 2 and Fig. 3. The solid-state ^{113}Cd NMR spectrum of recrystallized $Cd(MBTZ)_2$ was obtained and is also shown in Fig. 2. A single ^{113}Cd resonance is observed with a chemical shift of δ 325. This is very close to the value of δ 329 obtained for Phase II of the powder. No complexes containing cadmium

with the N_2S_4 coordination sphere have previously been studied by ^{113}Cd solid-state NMR spectroscopy.

The mass spectrum of $[Cd(MBZ)_2]_n$ (fw = 444 for monomer) consisted of many peaks, the M^+ peak observed had a mass greater than the parent ion mass. The following fragments were observed: $Cd(MBTZ)_2$, 444 (0.3%); Cd(MBTZ), 228 (0.2%); MBTZ, 116 (29%); C_6H_5NCS, 134 (14%); C_6H_5S, 109 (31%); CdS, 144 (1.9%); Cd, 112 (2.4%); CS_2, 76 (17%); SCN, 58 (24%). Thermogravimetric analysis of the complex in a stream of air showed the compound to decompose cleanly to give cadmium sulphide (theoretical yield: 32.4%; observed yield: 31.2%) at 250–500°C. X-ray powder diffraction of the cadmium sulphide obtained showed the presence of both hexagonal and cubic phases.

Bis(2-*mercaptothiazolinato*)*cadmium*(II)

The cadmium complex of 2-mercaptothiazoline (MTZ, **4**) has not been previously prepared. However, the cadmium complex of a related ligand, 2-mercaptothiazolidine (TDZ, **5**), has been synthesized and investigated by IR spectroscopy.[14] $Cd(MTZ)_2$ is a powdery white solid which is insoluble in common organic solvents; properties which are similar to those reported for $Cd(TDZ)_2$. Inspection of the IR spectrum of $Cd(MTZ)_2$ shows that shifts in the positions of the bands due to the thioamide group from those in the spectrum of the ligand are similar to the shifts reported for $Cd(TDZ)_2$. In particular, the band at 995 cm^{-1} [assigned to $\nu(C{=}N)+\nu(C{=}N)$] in the ligand appears at 976 cm^{-1}, probably indicating bonding through nitrogen and the exo-sulphur. The sulphur atom in the ring does not apparently take part in coordination. The band due to $\nu(C{-}S)$ appears at 650 cm^{-1} in the ligand and is shifted to a higher value of 677 cm^{-1} in the complex. This was also

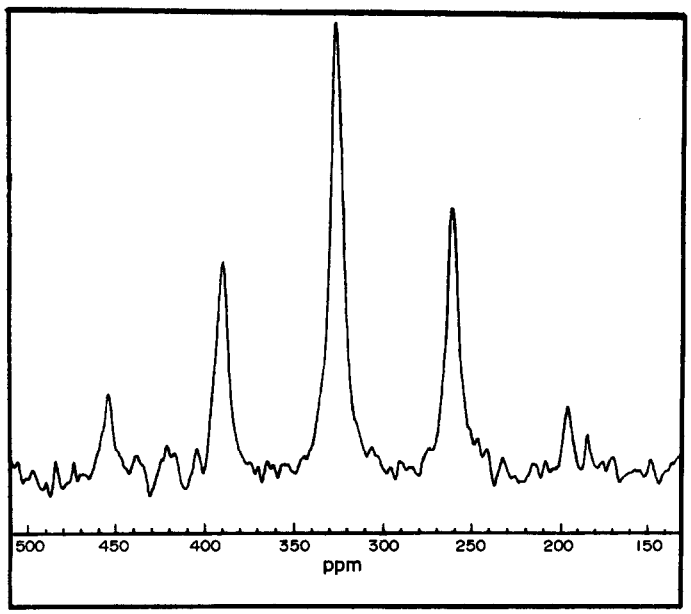

Fig. 3. High resolution solid-state ^{113}Cd NMR spectrum of recrystallized bis(mercaptobenzothiazolato)cadmium(II).

found to be the case with $Cd(TDZ)_2$.[14] The mass spectrum of $Cd(TDZ)_2$ gave a M^+ peak at 266 (3%) which is less than the mass of the parent molecule (fw = 348). The following fragments were also observed: TDZ, 118 (4%); CdS, 144 (19%); Cd, 112 (1%); CH_2CH_2SCN, 86 (23%); CS_2, 76 (24%); CH_3SCN, 73 (11%) 4.9.

1,4,8,11-*tetrathiaundecanatocadmium*(II)

The ligand 1,4,8,11-tetrathiaundecanato (TTU, **6**) was synthesized by following published procedures,[15] the complex CdTTU was prepared by the addition of $CdCl_2$ to a solution of Na_2TTU in ethanol. The elemental analysis showed that the ratio of Cd : TTU was 1 : 1, see Experimental. The cadmium complex is an involatile, white solid which decomposes at temperatures above *ca* 168°C and is insoluble in most common organic solvents. Thermogravimetric analysis showed the complex to decompose to cadmium sulphide and foul smelling products at *ca* 180°C.

The complex has not previously been synthesized. However, the reaction of zinc acetate with TTU in acetone has been reported by Roundhill[16] and yielded $Zn_3(TTU)_2(OAc)_2$.

Bis(5-*mercapto*-1-*methyltetrazolato*)*cadmium*(II)

The reaction, in aqueous solution, of cadmium chloride with the sodium salt of 5-mercapto-1-methyltetrazole (MTTZ, **7**) yields a white, powdery solid which is insoluble in most common organic solvents. Decomposition of the compound at 250–500°C in air yielded gaseous products (**CAUTION** this decomposition can be quite violent!) and a bright yellow solid which was found from X-ray powder diffraction to be a mixture of hexagonal and cubic cadmium sulphide. The ^{113}Cd solid-state NMR spectrum of $Cd(MTTZ)_2$ is detailed in Table 2 and shows a single chemical shift, δ 274 from $Cd(ClO_4)_2$, with spinning side bands; the spectrum is axial ($\sigma_{11} = \sigma_{22} = \sigma_\perp$ and $\sigma_{33} = \sigma_\parallel$) and the anisotropy is $\sigma = 235.5$, results are summarized in Table 2 and Fig. 4. This together with the chemical shift suggests coordination involving distorted S_4 tetrahedral geometry.

Cadmium dithiocarbamates

These are well known compounds and the solid-state ^{113}Cd NMR of bis(diethyldithiocarbamato) cadmium(II) (CdDTC) has been previously reported[17] (from a spectrometer with a 1.4 T magnet equivalent to 60 MHz proton frequency). A chemical shift of δ 377 was observed for the cadmium resonance, which is in good agreement with δ 357 obtained in this study. However, in an earlier paper the chemical shift principal components were not computed and, therefore, their relationship with the coordination at cadmium was not commented on. The structure of CdDTC is dimeric[18] with cadmium bonded to five sulphur atoms in a distorted trigonal bipyramid. The spectrum obtained in this study is shown in Fig. 5 and consists of a central band at δ 357 and a series of spinning side bands that are separated by the spinning frequency of 4.6 kHz. The chemical shift

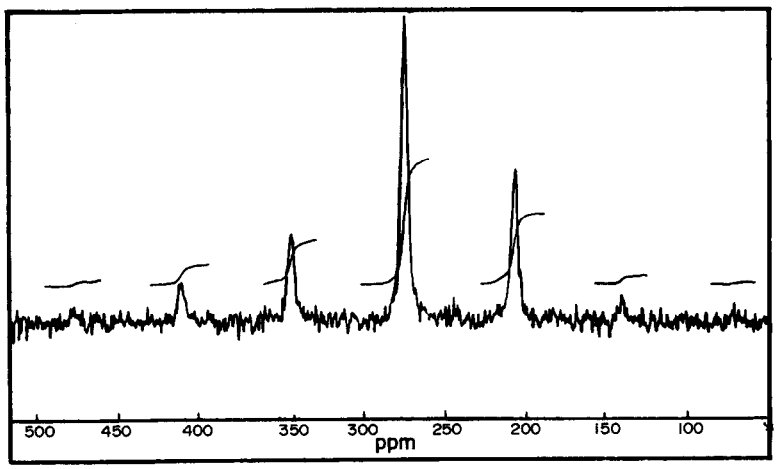

Fig. 4. High resolution solid-state ^{113}Cd NMR spectrum of bis(5-mercapto-1-methyltetrazolato) cadmium(II).

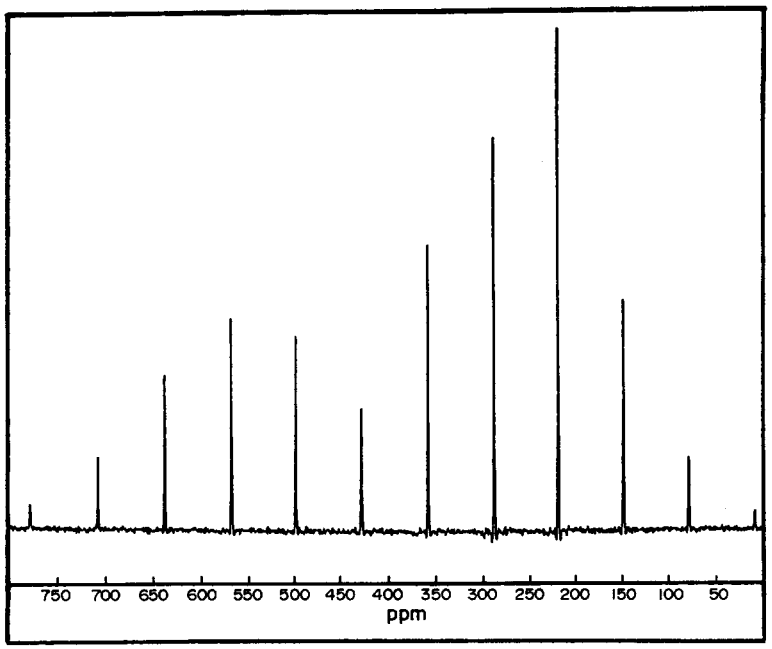

Fig. 5. High resolution solid-state ^{113}Cd NMR spectrum of bis(diethyldithiocarbamato)cadmium(II).

principal components were estimated and are given in Table 2, together with values computed from the line shapes of the spectrum given by Maciel and co-workers.[17] The signal-to-noise ratio in the earlier work was poor, our spectrum has an accuracy of *ca* 110 ppm for each value of the chemical shift component, and considering this there is good agreement between the two spectra.

The solid-state ^{113}Cd NMR spectrum of bis(pyrrolidinedithiocarbamato)cadmium(II), $Cd(PDTC)_2$, is very different from that of $Cd(DTC)_2$. The spectrum, which was obtained at a slower speed of 4.5 kHz, consists of a single peak at δ 280 and a very small peak (probably due to an impurity) at δ 211 (Table 2). The line shape indicates that the coordination around cadmium is highly symmetrical and is probably tetrahedral (S_4) since a trigonal bipyramid (S_5) geometry would lead to an axially symmetric line pattern.

Conclusions

A number of novel complexes of cadmium with sulphur-containing ligands have been prepared, and these complexes decompose to sulphide. ^{113}Cd solid-state NMR has been shown to be a sensitive

and powerful technique for characterizing such compounds.

EXPERIMENTAL

IR spectra in the region 400–200 cm^{-1} were measured using a Mattson Polaris Fourier transform IR spectrometer. Samples were prepared as mulls in Nujol (sodium dried), or as KBr or CsI discs. The following abbreviations are used in the assignment of IR bands: weak, w; medium, m; strong, s; broad, b; shoulder, sh. ^1H NMR spectra were obtained on a Bruker WP80 spectrometer. High resolution solid-state ^{113}Cd NMR were obtained on a Bruker MSL-300 NMR spectrometer with a 7.05 T magnet (equivalent to 300 MHz proton resonance frequency). Magic angle spinning (MAS), cross polarization (CP) and proton decoupling were used for signal enhancement and high resolution. ^{113}Cd chemical shifts were referenced to an external $Cd(ClO_4)_2$ reference. Mass spectra were recorded on an AEI MS902 mass spectrometer equipped with a MSS data system, and operating with an accelerating voltage of 70 eV. Thermogravimetric analysis was carried out with a Stanton Redcroft TG750 at 10°C min^{-1}, in an atmosphere of static air.

Preparation of the complexes

Bis(2-*mercaptopyridinato*)*cadmium*(II)

A solution of cadmium acetate (1 g, 0.037 mol) in water (15 cm^3) was added to a vigorously stirred solution of 2-mercaptopyridine (1.2 g, 0.0075 mol) in ethanol (40 cm^3). A white precipitate formed immediately on addition and was collected by filtration, washed with water and then ethanol, and finally air-dried. Yield obtained: 86%; dec. 324°C. Crystals were obtained by dissolving the complex in hot pyridine and slow evaporation of the hot solvent near its boiling point (*ca* 100°C). Found (Required for $C_{10}H_8N_2S_2Cd$): C, 36.0 (36.1); H, 2.3 (2.4); N, 8.4 (8.4); S, 19.2 (19.2)%. Major IR bands for the powder (Nujol mull) were as follows (cm^{-1}): 2950s, 2920s, 2850s, 1585s, 1542m, 1442s, 1415s, 1375w, 1260w, 1155w, 1135s, 1130s, 1080w, 1040w, 1000m, 770m, 750m, 750s, 720m.

Bis(2-*mercaptobenzothiazolato*)*cadmium*(II)

A solution of cadmium acetate (1 g, 0.037 mol) in water (15 cm^3) was added to a vigorously stirred solution of 2-mercaptobenzothiazole (1.2 g, 0.0075 mol) in ethanol (40 cm^3). A white precipitate formed immediately on addition and was filtered off, washed first with water and then with ethanol, and finally dried. X-ray quality crystals of the compound were obtained by dissolving the complex in hot dimethylformamide, and slow evaporation (*ca* 2 days) of the solvent near its boiling point (*ca* 140°C). Found (Required for $C_{14}H_8N_2S_4Cd$): C, 38.3 (37.8); H, 2.0 (1.8); N, 6.2 (6.3); S, 28.6 (28.8)%. Major IR bands (for the powder, Nujol mull) were as follows (cm^{-1}): 2953; 2924s, 2854s, 1560w, 1455s, 1385, 1312w, 1278w, 1247m, 1082m, 1026s, 1012s, 749s, 725m, 694m. These are in good agreement with those reported in the literature.

Bis(2-*mercaptothiazolinato*)*cadmium*(II)

A solution of cadmium acetate (1 g, 0.037 mol) in water (15 cm^3) was added to a vigorously stirred solution of 2-mercaptothiazoline (0.89 g, 0.0075 mol) in ethanol (40 cm^3). A white precipitate formed which was immediately filtered off. Yields were low, *ca* 23%; dec. 203°C. Found (Required for $C_6H_8N_2S_4Cd$): C, 20.7 (20.7); H, 2.5 (2.3); N, 8.2 (8.0); S, 37.3 (36.8)%. Major IR bands (Nujol mull) were as follows (cm^{-1}): 3139b, 3126b, 2953s, 2925s, 2854s, 1527s, 1502s, 1463s, 1444m, 1377m, 1303s, 1263w, 1198w, 1041s, 1023s, 976m, 936m, 677w.

1,4,8,11-*Tetrathiaundecanatocadmium*(II)

The ligand 1,4,8,11-tetrathiaundecane was prepared following published procedures.[5] Sodium (0.7 g, 0.03 mol) was dissolved in ethanol (150 cm^3) under nitrogen and 1,4,8,11-tetrathiaundecane (3.5 g, 0.0153 mol) was slowly added. The solution was stirred for 1 h and then added to a suspension of cadmium chloride (2.7 g, 0.0153 mol) in ethanol (150 cm^3), and the mixture stirred overnight. A white precipitate formed and was filtered, washed with water to remove any NaCl and then dried. Yield: 82%; dec. *ca* 168°C. Found (Required for $C_7H_{14}S_4Cd$): C, 26.5 (24.7); H, 4.4 (4.1); S, 38.08 (37.6)%. Major IR bands (Nujol mull) were as follows (cm^{-1}): 32,756, 32,106, 2954s, 2854s, 2825s, 1460s, 1377s, 1341m, 1298m, 1253s, 1197s, 1119m, 1050m, 721m, 694m.

Bis(5-*mercapto*-1-*methyltetrazolato*)*cadmium*(II)

A solution of cadmium chloride (1.6 g, 0.0087 mol) in water (100 km^3) was added to a stirred solution of sodium 5-mercapto-1-methyltetrazole (3 g, 0.017 mol) in water (100 cm^3). A white precipitate formed immediately and was filtered off, washed

with water, then with methanol and finally dried. Yield: 62%. Found (Required for $C_4H_6N_8S_2Cd$): C, 13.8 (14.0); H, 2.0 (1.8); N, 32.0 (32.7); S, 18.1 (18.7)%. The main IR bands (KBr disc) were (cm^{-1}): 3293br, 2959w, 1540w, 1522w, 1507w, 1466s, 1455s, 1414s, 1381s, 1281s, 1234w, 1175s, 1091m, 985s, 723s, 711s, 690s.

Bis(dithiocarbamato)cadmium(II)

A solution of cadmium chloride (1.2 g, 0.0066 mol) in water (80 cm^3) was added to a stirred solution of sodium diethyldithiocarbamate (3 g, 0.013 mol) in water. A white precipitate formed, which was filtered off and then dried. The compound was recrystallized from chloroform as large transparent crystals,[18] m.p. 248–250°C. Bis(pyrrolidinedithiocarbamato)cadmium(II) was prepared in an analogous manner.

Acknowledgements—We thank the SERC and Polaron equipment Ltd for a CASE award to O.F.Z.K., and Dr. C. J. Groombridge of the ULIRS solid-state NMR service at Royal Holloway and Bedford New College for ^{113}Cd NMR spectra.

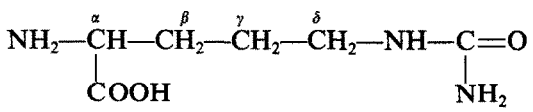
(*Received* 14 *May* 1990; *accepted* 26 *September* 1990)

Abstract—The palladium(II)–L-citrulline system has been studied in aqueous solution by potentiometric and ^1H and ^{13}C NMR spectroscopic methods. Evidence is given for the formation of a PdL_2 complex. A bonding scheme through the carboxylic and amine groups in the *trans* configuration is proposed, on the basis of NMR and IR spectra.

Metal ions play an important role in biological systems, often through coordination to proteins.[1] In order to obtain some insight into the behaviour of metal ions with L-citrulline,



an amino acid involved in the urea cycle and of great biochemical interest, we have undertaken the present investigation on the palladium(II)–L-citrulline interaction. L-Citrulline contains, in addition to amino acid functions, a —NH—CO—NH_2 group in the side chain which can offer different coordination possibilities. Palladium was chosen to represent the behaviour of bivalent metal ions, which give square planar complexes, implied in biological systems;[3] in fact its exchange kinetics are sufficiently slow on the NMR time scale to allow the separate observation of free and complexed ligand molecules.[4]

This work is part of a study on complex formation between biological ligands and metal ions in aqueous solution.[5–8]

EXPERIMENTAL

NMR studies

^{13}C NMR spectra were obtained in D_2O solution with a CFT-20 Varian spectrometer at a probe temperature of 37°C. Chemical shifts are expressed in ppm relative to external TMS. Typical Fourier transform conditions, under which the ^{13}C results were obtained, were the following: spectral width 6000 Hz, data points 8 K, pulse repetition times 0.8–4.0 s, number of accumulated transients 10,000–40,000. The ^{13}C spectra of L-citrulline and of the PdL_2 complex were obtained in the completely ^1H decoupled mode using 8 mm tubes.

^1H NMR spectra were recorded using D_2O solutions of 0.1 M L-citrulline and increasing palladium(II) concentration up to a [palladium(II)] : [L-citrulline] ratio of 1 : 2; above this ratio a white solid began to precipitate. The ^1H spectrum of pure L-citrulline was obtained on a VXR 300 Varian spectrometer.

Potentiometric studies

The titrations were performed on a pH-M-84 Radiometer pHmeter equipped with a Dosimat 655

Metrohm automatic titrator, at an ionic strength of 0.1 M (KNO_3) and 25°C. In all the titrations of the palladium(II)–L-citrulline solutions, the ligand concentration was 1×10^{-3} M (with added HCl, 2×10^{-3} M) and the palladium(II) concentration ranged from 0.25×10^{-3} to 2×10^{-3} M. The solutions (25 cm^3) were titrated with NaOH (0.1 M) at 25°C under a nitrogen atmosphere. The time delay between two consecutive base additions was 1200 s; 80 experimental points were collected for each titration. The standard potentials of the electrode and the slope were determined by titration of chloridic acid with NaOH, at an ionic strength of 0.1 M (KNO_3), before and after each palladium(II)–L-citrulline titration, which required about 27 h.

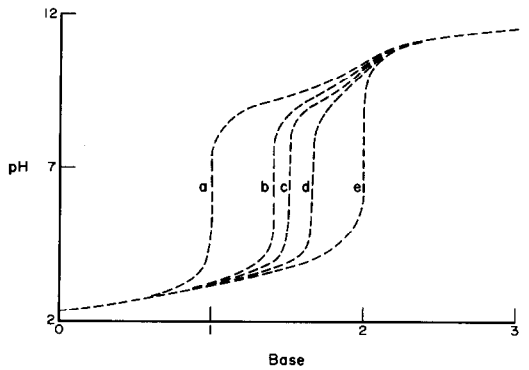

Fig. 1. The titration curves {$-\log [H^+]$ vs [titrant base]/[total L-citrulline]} of pure L-citrulline [curve (a)] and of various solutions with the same ligand concentration and increasing [palladium(II)]:[L-citrulline] ratios: (b) 1:5, (c) 1:4, (d) 1:3 and (e) 1:2.

IR spectra

Using a Perkin–Elmer 683B spectrophotometer at room temperature the IR spectra of L-citrulline and of the PdL_2 complex were obtained as KBr pellets in the range 4000–600 cm^{-1} and in Nujol on polyethylene disks in the range 600–200 cm^{-1}.

Calculations

Potentiometric data for the electrode standardization were analysed by the MAGEC program.[9] The ionization constants of L-citrulline and the formation constant of its adduct with palladium(II) were calculated by a slightly modified version of the PSEQUAD program.[11] The calculations were performed on a PS/2 50 IBM personal computer.

Materials

L-Citrulline was purchased from Sigma and used without further purification. $Na_2PdCl_4 \cdot 1/3H_2O$ was a JMC product. The complex PdL_2 (where L represents the completely deprotonated form of L-citrulline) was prepared by adding a solution of the ligand to a solution of Na_2PdCl_4, in slight excess of the ratio [palladium(II)]:[L-citrulline], 1:2. The complex was isolated as a solid by concentrating the yellow solution to a small volume *in vacuo*, at room temperature. The precipitate was washed with water and recrystallized from ethanol. Found: C, 31.6; H, 5.4; N, 18.5; Pd, 23.3. Calc. for PdL_2: C, 31.7; H, 5.3; N, 18.5; Pd, 23.4%. The value for Pd was determined by thermogravimetric analysis.

RESULTS AND DISCUSSION

The potentiometric titration of acidified L-citrulline [Fig. 1(a)] exhibits two distinct inflections; the corresponding calculated pK values are, respectively, $pK_1 = 2.275 \pm 0.005$ and $pK_2 = 9.349 \pm 0.002$, in close agreement with the pK values for carboxylic and amine groups in most amino acids. A delay of 20 min was given between the base additions in order to allow for the establishment of equilibrium; curves obtained with delay times less than 15 min were not reproducible, while no difference was noticed when 15 or 20 min delays were used. Titration curves of solutions at various [palladium(II)]:[L-citrulline] ratios are also reported in this figure. Since precipitation took place for ratios higher than 1:2, the analysis has been limited to the curves presented. They can be perfectly fitted by assuming only the formation of a PdL_2 complex with a formation constant, $\log \beta = 16.23 \pm 0.02$, which appears to be somewhat higher than those reported by Martell and Clarke[12] for 1:2 complexes of other bivalent cations with L-citrulline. The formation of PdL_2 involves the deprotonation of the amino groups of both L-citrulline molecules, which is lowered by about 6 pH units with respect to the deprotonation of free L-citrulline.

To obtain greater insight into the model of complexation we studied the palladium(II)–L-citrulline system by ^1H and ^{13}C NMR spectroscopy.

The proton 300 MHz spectra of the pure ligand shows two triplets centred at 3.65 and 3.03 ppm which can be attributed to the α-CH group and the δ-CH_2, respectively, on the basis of the signal intensities. The multiplets at 1.77 and 1.46 ppm were assigned to the β-CH_2 and γ-CH_2 groups on the basis of double resonance experiments.

^1H spectra (80 MHz) of palladium(II)–L-citrulline mixtures were collected for [palladium(II)]:[L-citrulline] ratios increasing up to 1:2, above which precipitation took place. These spectra, shown in

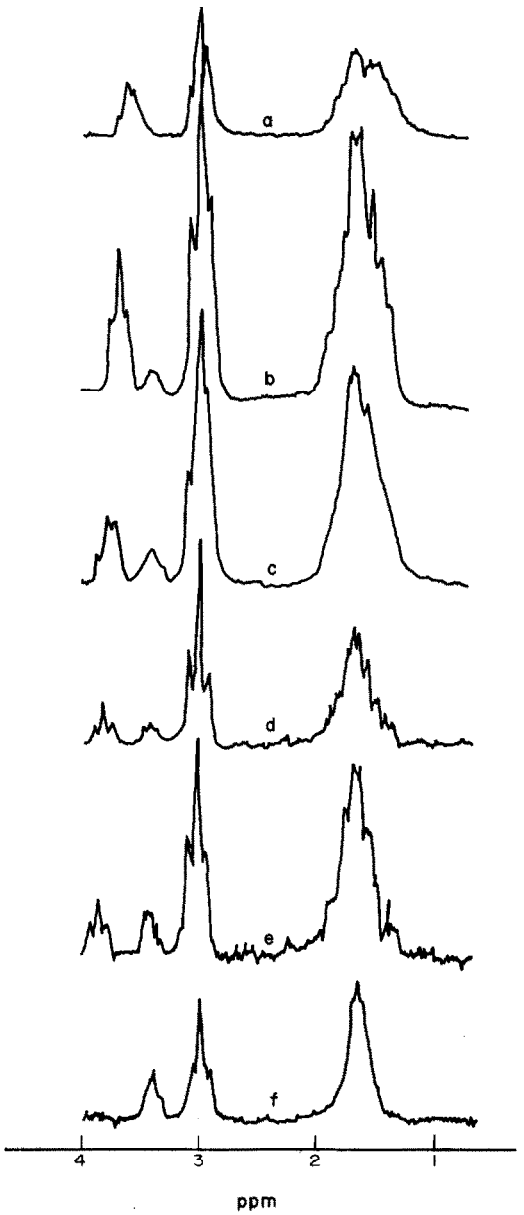

Fig. 2. ^{1}H NMR spectra (80 MHz) of pure L-citrulline (a) and various palladium(II)–L-citrulline solutions with increasing [palladium(II)]:[L-citrulline] ratios: (b) 1:10, (c) 1:8, (d) 1:6, (e) 1:4 and (f) 1:2.

Fig. 2, show some trends as a function of the added palladium(II):

(1) a small low-field shift and a decrease in intensity of the α-CH resonance, in addition to the appearance of a new signal at 3.4 ppm;

(2) the chemical shift of the δ-CH_2 triplet does not vary;

(3) the band of γ-CH_2 appears to converge towards the β-CH_2 band until at a ratio of 1:2 the two bands are superimposed;

(4) the signal from the α-CH of the free L-citrulline completely disappears for a 1:2 ratio, and a new band appears at 3.4 ppm.

A low-field shift of α-CH, also observed in solutions of pure L-citrulline when the pH is changed from neutral to acidic, can be ascribed to the deshielding of hydrogen atoms on formation of the unprotonated —COOH group. The shift in the spectra in Fig. 2 can therefore be attributed to the lowering of pH with palladium concentration, due to the release of protons when PdL_2 is formed.

The new band at 3.4 ppm (which appears as a single band in the resolution limits of the 80 MHz spectrometer used) is due to the α-CH in the PdL_2 complex undergoing slow exchange with the free L-citrulline; this band forms at the expense of the band at 3.65 ppm, which disappears when the 1:2 ratio is reached and PdL_2 is quantitatively formed. Analogous behaviour is shown by the γ-CH_2 signal, although less clearly due to overlap with the β-CH_2 signals. The signals of δ- and β-CH_2, however, seem completely unaffected by complex formation. It should be emphasized that the high-field shift of the α-CH in the complex ligand, with respect to that in the free ligand, is opposite to the behaviour of the γ-CH_2 shift.

The ^{13}C spectra of pure L-citrulline and the PdL_2 complex are reported in Fig. 3; the first spectrum exhibits six different signals, the assignments of which, reported on the same figure, were made on the basis of reports in the literature. The corresponding spectrum of the complex presents only four peaks: the resonances of the two quaternary carbons (the smallest in the spectra of pure ligand for relaxation reasons) cannot, in fact, be detected at all at the low concentration of the complex used due to its low solubility; this spectrum shows a high-field shift of the signals for the C(α) and C(β) carbon atoms.

On the basis of these observations, the involvement in complexation of the —COO^- and —NH_2 groups only can be assumed, the NH—CO—NH_2 moiety not being implicated at all. These remarks are in agreement with the results of potentiometric titration.

A planar complex such as PdL_2 can assume *cis* and *trans* configurations. In the actual situation of slow exchange between free and complexed ligand molecules, the *cis–trans* interconversion should be sufficiently slow to permit the observation of separate signals for the two isomers. The single signal exhibited by the complexed form leads to the assumption that only the *trans* isomer is present; in fact the two ligands in the *cis* configuration, being non-equivalent, should give separate signals. IR

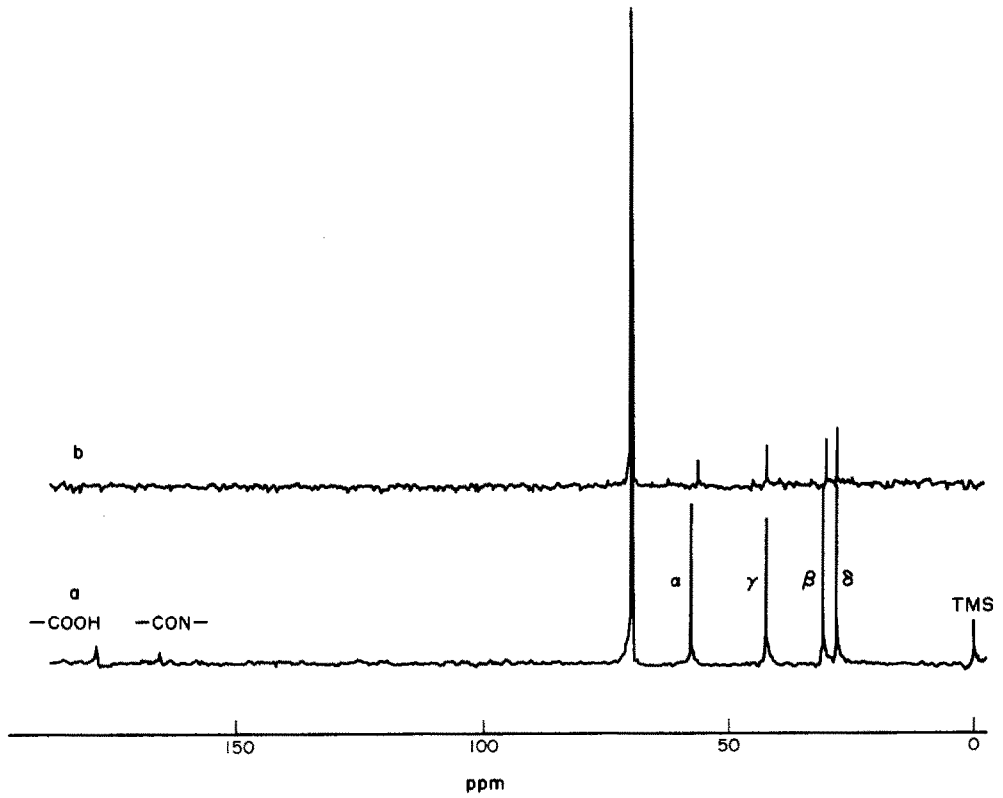

Fig. 3. ^{13}C NMR spectra of L-citrulline (a) and of PdL_2 (b) in aqueous solution.

spectra support such an assumption: in fact, while in the free ligand the NH_2 bands in the range 3450–3000 cm^{-1} are weak, due to the mixing of NH_2 and NH_3^+ signals, in the complexed form these bands are stronger due to the presence of two NH_2 groups. The shift of the ν(CO) from 1640 to 1655 cm^{-1} indicates that this group is probably involved in the binding of the metal ion; the presence of only one Pd—N band around 606 cm^{-1} moreover confirms the symmetric configuration of the complex.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURES OF THE ONE-DIMENSIONAL RIBBON CHAINS $[MOBu^t \cdot Bu^tOH]_\infty$ AND THE CUBANE SPECIES $[MOBu^t]_4$ (M = K AND Rb)

MALCOLM H. CHISHOLM,* SIMON R. DRAKE, AHMAD A. NAIINI and WILLIAM E. STREIB

Department of Chemistry and the Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 5 *July* 1990; *accepted* 27 *September* 1990)

Abstract—The series $[MOBu^t \cdot Bu^tOH]_\infty$ (M = K, Rb and Cs) have been prepared by the reaction of M with Bu^tOH in THF. Single-crystal X-ray diffraction studies revealed for M = K or Rb that $[MOBu^t \cdot Bu^tOH]_\infty$ crystallizes from tetrahydrofuran–n-pentane at −20°C in the triclinic space group $P\bar{1}$, with unit cell dimensions [K, Rb]: a = 9.862(3), 9.886(2) Å; b = 9.929(4), 9.914(2) Å; c = 6.330(2), 6.640(1) Å; β = 90.66(2), 90.46(1)° and Z = 2, as a one-dimensional chain linked by hydrogen-bonding. The strong hydrogen-bonding within the chain O(2)—O(7) (2.46, 2.44 Å) also results in a near linear O(7)—H—O(2) angle (167.4, 172.61°) with the hydrogen atom closer to O(7) (1.22, 1.18 Å), than O(2) (1.24, 1.27 Å). These alcohol adducts may be readily converted into the compounds $[MOBu^t]_4$ (M = K, Rb and Cs) by sublimation. Single-crystal X-ray diffraction studies reveal for M = K or Rb, that $[MOBu^t]_4$ crystallizes from toluene at −20°C in the cubic space group $P\bar{4}3M$; with unit cell dimensions [K, Rb]; a = 8.372(1), 8.514(1) Å, and Z = 4, as cubane structures. Within the cubane-like structures the O—M—O angles are found to deviate only slightly from 90°, with O—M—O (90.18, 89.11°) and M—O—M (89.82, 90.89°) for M = K and Rb, respectively. The alcohol adducts undergo an alkoxide ligand exchange process that is rapid on the ^1H NMR time scale at room temperature.

The chemistry of main group metal alkoxides has received renewed attention as these materials are potential precursors to metal oxides.[1,2] The sol–gel technique takes advantage of the tendency of metal alkoxides to form polymeric structures upon hydrolysis.[3] Thermolysis of the resulting materials yields amorphous oxides that may be crystallized by heating to higher temperatures.[4]

Alkali metal oxides are involved in a vast range of advanced materials, such as superconductors ($Ba_{0.6}K_{0.4}BiO_3$),[5] optical modulators ($LiNbO_3$),[6] tungsten bronzes ($KSr_2Nb_5O_{15}$)[7] and ferro-electric materials ($KTa_xNb_{1-x}O_3$).[8] These materials are normally obtained by traditional high temperature solid-state routes. Molecular precursors of alkali metal oxides remain rather limited, although they have enormous value through either sol–gel or MOCVD techniques.

In this paper we report the synthesis and single-crystal X-ray structures of $[MOBu^t \cdot Bu^tOH]$ and $[MOBu^t]_4$, where M = K and Rb. The former are highly soluble compounds and in the solid-state are one-dimensional polymers, based on the mononuclear $[MOBu^t \cdot Bu^tOH]$ subunits.

EXPERIMENTAL

All manipulations were carried out under an atmosphere of dry (molecular sieves) argon, with rigorous exclusion of air and moisture. All hydrocarbon and etheral solvents were dried and distilled from sodium benzophenone ketyl. Alcohols were dried by distillation from magnesium turnings, activated by a crystal of iodine. NMR solvents were dried over 4 Å molecular sieves and stored under argon. Potassium, rubidium and caesium metals were purchased from the Aldrich Chemical Company, and stored in a dry box under an argon atmosphere. Elemental analyses were performed

* Author to whom correspondence should be addressed.

by Oneida Research Services. NMR data were recorded on a Bruker WM-500 NMR spectrometer, using the protio impurities of the deuterated solvents as reference for ^1H and the ^{13}C chemical shifts. IR spectra were recorded on a Nicolet 510P FTIR spectrometer as Nujol mulls between KBr plates.

Synthesis of $[KOBu^t \cdot Bu^tOH]_\infty$ **(1)**

Potassium metal balls (2.6 g, 66.5 mmol) were placed in a Schlenk tube under argon in a dry box. The tube was removed from the dry box, and to this was added tert-butanol (11.8 cm^3, 126.4 mmol). The solution was then heated to 70°C for 1 h, during which time all the metal dissolved to yield a colourless solution. The resulting solution was filtered and the solvent removed *in vacuo* to yield a white solid. A minimum amount of tetrahydrofuran (10 cm^3) was added to dissolve the solid, layered with n-pentane (15 cm^3) and the sample cooled to −25°C for 24 h. During this time, small, colourless crystals were formed. The solution was subsequently filtered, and the crystals dried carefully *in vacuo* to give $[KOBu^t \cdot Bu^tOH]$ (9.9 g, 53.2 mmol, 78.8%).

IR data: Nujol mull, cm^{-1} 3503 (br, OH). M.p.: slowly sublimes at 145–160°C, decomposes at 242–244°C. ^1H NMR data (500 MHz, toluene-d_8, 20°C): δ 2.12 (s, 18H, Me_3C), δ 6.67 (s, O*H*). Variable temperature ^1H NMR data (C_7D_8): no coalescence phenomena were observed when the sample was cooled to 220 K, but the resonances were broadened at this temperature: 220 K, δ 2.14 (s, br, 18H, Me_3C), δ 4.70 (s, *OH*). ^{13}C NMR data (126 MHz, 20°C, toluene-d_8): δ 50.41 (s, Me_3C), δ 66.88 (s, Me_3C). Found: C, 51.8; H, 10.4. Calc. for $C_8H_{19}O_2K$: C, 51.6; H, 10.2%. Molecular weights of 537 ± 41 and 569 ± 34 were measured at concentrations of 2.33×10^{-3} and 4.67×10^{-3} M, respectively. Calculated for $[KOBu^t \cdot Bu^tOH]_3 = 558.3$. Each value was determined by two measurements.

Synthesis of $[KOBu^t]_4$ **(2)**

Potassium metal balls (2.6 g, 66.5 mmol) were placed in a Schlenk tube under argon in a dry box. The tube was removed from the dry box, and to this was added tert-butanol (5.9 g, 63.2 mmol) and tetrahydrofuran (60 cm^3). The solution was heated at 70°C for 67 h, during which time the majority of the metal dissolved. The resulting solution was filtered and the solvent removed *in vacuo* to yield a white solid (5.9 g, 78.8%). The solid was then sublimed at 140–150°C (10^{-3} torr) to yield crystalline $[KOBu^t]_4$ (4.3 g, 38.4 mmol, 57.4%). M.p.: slowly sublimes at 170–190°C (10^{-2} torr), decomposes at 256–258°C. ^1H NMR data (500 MHz, 20°C, toluene-d_8): δ 1.08 (s, 9H, Me_3C), remains unchanged on cooling to 200 K. ^{13}C NMR data (126 MHz, 20°C, toluene-d_8): δ 37.66 (s, Me_3C), δ 66.57 (s, Me_3C). Found: C, 43.0; H, 8.3. Calc. for $C_4H_{90}K$: C, 42.8; H, 8.1%.

Synthesis of $[RbOBu^t \cdot Bu^tOH]_\infty$ **(3)**

Rubidium metal (5 g, 58.8 mmol) was placed in a Schlenk tube under helium in a dry box. The tube was removed from the dry box and to this was added tetrahydrofuran (60 cm^3) and tert-butanol (11.8 cm^3, 126.4 mmol). The solution was then heated to 70°C for 4 h, during which time all the metal dissolved to yield a colourless solution. The resulting solution was filtered and the solvent removed *in vacuo* to yield a white solid. A minimum amount of tetrahydrofuran (10 cm^3) was added to dissolve the solid, followed by filtration. The resulting solution was layered with n-pentane (156 cm^3) and the solution cooled to −25°C for 2 days. During this time, large, regular shaped, colourless crystals formed. The solution was subsequently filtered and the crystals dried carefully *in vacuo* to give $[RbOBu^t \cdot Bu^tOH]_\infty$ (9.4 g, 40.5 mmol, 68.9%).

IR data: Nujol mull, cm^{-1} 3179 (br, OH). M.p.: sublimes 170–200°C, decomposes at 272–274°C. ^1H NMR data (500 MHz, 20°C, toluene-d_8): δ 1.14 (s, 18H, Me_3C), δ 4.83 (s, OH). Variable temperature ^1H NMR data (toluene-d_8): no coalescence phenomena were observed when the sample was cooled to 220 K, but the resonances were broadened at this temperature: 220 K δ 1.16 (s, br, 18H, Me_3C), δ 4.86 (s, br, OH). ^{13}C NMR data (126 MHz, 20°C, toluene-d_8): δ 32.18 (s, Me_3C), δ 67.63 (s, Me_3C). Found: C, 41.4; H, 8.4. Calc. for $C_8H_{19}O_2Rb$: C, 41.3; H, 8.2%.

The molecular weights of 652 ± 88, 676 ± 71 and 712 ± 43 were measured at concentrations of 1.95×10^{-3}, 3.78×10^{-3} and 5.50×10^{-3} M, respectively. Calculated for $[RbOBu^t \cdot Bu^tOH]_3 = 694.5$. Each value was determined by two measurements.

Synthesis of $[RbOBu^t]_4$ **(4)**

Rubidium metal (2.5 g, 29.9 mmol) was placed in a Schlenk tube under helium in a dry box. The tube was removed from the dry box and to this was added tetrahydrofuran (60 cm^3) and tert-butanol (5.9 cm^3, 63.2 mmol). The solution was then heated to 70°C for 24 h, during which time the majority of the metal dissolved. The resulting solution was filtered and the solvent removed *in vacuo* to yield a

white solid. This was then dissolved in the minimum amount of tetrahydrofuran (10 cm^3), layered with n-pentane (15 cm^3) and the sample cooled to 25°C for 48 h. During this time small, colourless crystals were formed. The solution was subsequently filtered and the crystals dried carefully *in vacuo* to give $[RbOBu^t]_4$ (3.6 g, 22.8 mmol, 76.2%).

Alternatively $[RbOBu^t \cdot Bu^tOH]_\infty$ (2.4 g, 10.3 mmol) was placed in a sublimation vessel and heated at 140–150°C (10^{-3} torr) for 12 h. This yielded a white crystalline solid, $[RbOBu^t]_4$ (1.25 g, 7.9 mmol, 76.8%).

M.p.: 185–200°C (10^{-2} torr) sublimed with some decomposition, decomposes at 282–284°C. ^1H NMR data (500 MHz, 20°C, toluene-d_8): δ 1.09 (s, 9H, Me_3C), remains unchanged on cooling to 220 K. ^{13}C NMR data (126 MHz, 20°C, toluene-d_8): δ 37.72 (s, Me_3C), δ 66.40 (s, Me_3C). Found: C, 30.6; H, 5.9. Calc. for C_4H_9ORb: C, 30.3; H, 5.7%.

Synthesis of $[CsOBu^t \cdot Bu^tOH]_\infty$ **(5)**

Caesium metal (5 g, 37 mmol) was placed in a Schlenk tube under helium in a dry box. The tube was removed from the dry box and to this was added tetrahydrofuran (60 cm^3) and tert-butanol (6.2 cm^3, 83.3 mmol). The solution was then heated to 70°C for 90 min, during which time all the metal dissolved to yield a colourless solution. The resulting solution was filtered and the solvent removed *in vacuo* to yield a white solid. A minimum amount of tetrahydrofuran (10 cm^3) was added to dissolve the solid, which was then layered with n-pentane (15 cm^3) and the sample cooled to −25°C for 24 h. During this time long, colourless needles formed. The solution was subsequently filtered and the crystals dried carefully *in vacuo* to give $[CsOBu^t \cdot Bu^tOH]$ (8.0 g, 28.6 mmol, 77.2%).

IR data: Nujol mull, cm^{-1} 3177 (br, OH). M.p.: 165–190°C (10^{-2} torr) sublimes with some decomposition, decomposes at 282–284°C. ^1H NMR data (500 MHz, 20°C, toluene-d_8): δ 1.13 (s, 18H, Me_3C), δ 5.01 (s, OH). No coalescence phenomena were observed when the sample was cooled to 220 K, but the resonances were broadened at this temperature: 220 K, δ 1.15 (s, br, 18H, Me_3C), δ 5.02 (s, br, OH). ^{13}C NMR data (126 MHz, 20°C, toluene-d_8): δ 33.77 (s, Me_3C), δ 67.63 (s, Me_3C). Found: C, 34.6; H, 7.0. Calc. for $C_8H_{19}O_2Cs$: C, 34.3; H, 6.8%.

The molecular weights of 765 ± 100 and 802 ± 78 were measured at concentrations of 2.44×10^{-3} and 3.60×10^{-3} M, respectively. Calculated for $[CsOBu^t \cdot Bu^tOH]_3 = 840.3$. Each value was determined by two measurements.

Synthesis of $[CsOBu^t]_4$ **(6)**

Caesium metal (2.5 g, 18.5 mmol) was placed in a Schlenk tube under helium in a dry box. The tube was removed from the dry box and to this was added tetrahydrofuran (60 cm^3) and tert-butanol (1.45 cm^3, 19 mmol). The solution was then heated for 17 h, during which time the majority of the metal dissolved. The resulting solution was filtered and the solvent removed *in vacuo* to yield a white solid (3.6 g, 94.5%). The solid was then dissolved in tetrahydrofuran (10 cm^3), layered with n-pentane (18 cm^3) and the sample cooled to −25°C for 48 h. During this time small, colourless, cubic crystals were formed. The solution was subsequently filtered and the crystals dried carefully *in vacuo* to give $[CsOBu^t]_4$ (2.6 g, 12.6 mmol, 68.2%).

M.p.: > 350°C, no observable change in colour of the sample up to this temperature. ^1H NMR data (500 MHz, 20°C, toluene-d_8): δ 1.07 (s, 9H, Me_3C), remains unchanged on cooling to 220 K. ^{13}C NMR data (126 MHz, 20°C, toluene-d_8): δ 37.58 (s, Me_3C), δ 66.64 (s, Me_3C). Found: C, 23.6; H, 4.6. Calc. for C_4H_9OCs: C, 23.3; H, 4.4%.

X-ray diffraction studies

For each of the compounds **1–4**, a suitable crystal was chosen and transferred to the goniostat using standard inert atmosphere handling techniques. Data were collected in the usual manner,[9] using a continuous θ–2θ scan with fixed backgrounds. Data were reduced to a unique set of intensities and associated sigmas, and the structures were solved by a combination of direct methods (MULTAN78) and Fourier techniques.

X-ray crystal structure of $[MOBu^t \cdot Bu^tOH]_\infty$ **(1)**

M = K. Colourless crystals of $[KOBu^t \cdot Bu^tOH]_\infty$ (**1**) suitable for X-ray structure determination were grown from tetrahydrofuran–n-pentane and mounted, under a nitrogen atmosphere glove box using silicone grease, before transferring to a goniostat, where a single crystal was cooled to −171°C, for characterization and data collection.

A summary of crystal data and collection and refinement parameters is given in Table 1. A systematic search of a limited hemisphere of reciprocal space revealed no symmetry or systematic absences. Space group $P\bar{1}$ was determined by the successful solution of the structure.

The structure was solved using a combination of direct methods (MULTAN 78) and Fourier techniques. The potassium position was obtained from an E-map. The remainder of the atoms including

most of the hydrogen atoms were found in subsequent iterations of least-squares refinement and difference Fourier calculations. Most importantly, H(19), which hydrogen-bonds O(2) to O(7), was very evident. The positions of H(1)–H(18) were initially idealized.

In the final cycles of least-squares refinement, the non-hydrogen atoms were varied with anisotropic parameters and the hydrogen atoms were varied with isotropic thermal parameters to a final $R(F) = 0.035$. The final difference map was essentially featureless, the largest residual peak being 0.23 e Å^{-3}.

Selected bond distances and angles are collected in Table 2. Additional crystallographic data are available as supplementary material.

M = Rb. Colourless crystals of $[RbOBu^t \cdot Bu^tOH]_\infty$ (3) suitable for X-ray structure determination were also grown from tetrahydrofuran–n-pentane and mounted, under a nitrogen atmosphere glove box using silicone grease, before transferring to a goniostat, where a single crystal was cooled to −155°C, for characterization and data collection.

A summary of crystal data and collection and refinement parameters is given in Table 1. A systematic search of a limited hemisphere of reciprocal space revealed no symmetry or systematic absences. Space group $P\bar{1}$ was determined by the successful solution of the structure.

The structure was solved using a combination of direct methods (MULTAN 78) and Fourier techniques. The coordinates for the potassium atom in

1 were used as a starting point for the rubidium atom in **3**. The remaining non-hydrogen atoms were obtained from subsequent iterations of least-squares refinement and difference Fourier calculations. As for **1**, H(19) hydrogen bonds O(2) to O(7). The positions of H(1)–H(18) were initially idealized.

In the final cycles of least-squares refinement, the non-hydrogen atoms were varied with anisotropic parameters and the hydrogen atoms were varied with isotropic thermal parameters to a final $R(F) = 0.031$. The final difference map was essentially featureless, with rubidium residual peaks of 0.57 to 0.64 e $Å^{-3}$ and all other residual peaks being 0.4 e $Å^{-3}$ or less. The structure of **3** is isostructural with that of **1**. Selected bond distances and angles are collected in Table 2.

X-ray crystal structure of $[MOBu^t]_4$ **(2)**

M = K. Colourless crystals of $[KOBu^t]_4$ (**2**) suitable for X-ray structure determination were grown from tetrahydrofuran–n-pentane and mounted under a nitrogen atmosphere glove box using silicone grease, before transferring to a goniostat, where a single crystal was cooled to −150°C, for characterization and data collection.

Crystal data collection and refinement parameters are given in Table 1. A systematic search of a limited hemisphere of reciprocal space revealed intensities with at least orthorhombic symmetry and possibly cubic symmetry. Following complete data collection and correction for absorption the cubic symmetry was more obvious. Space group $P\bar{4}3m$ was determined by the successful solution of the structure.

The coordinates in Weiss' powder diffraction study were used as a starting point for K(1), O(2), C(3) and C(4).[10] An initial least-squares refinement produced an unusually large thermal parameter for C(4). It was then removed, i.e. a difference Fourier was calculated, phased on the first three atoms only. This revealed that C(4) needs to be moved from a special position to a general position. The resulting structure was seen to have a well-defined disorder. Subsequent iterations of least-squares refinement and difference Fourier calculations revealed all remaining atoms including all of the hydrogen atoms. Because of this disorder, atoms C(4), H(2) and H(3) have half weight.

In the final cycles of refinement, the non-hydrogen atoms were varied with anisotropic thermal parameters and the hydrogen atoms were varied with thermal parameters to a final $R(F) = 0.016$. The final difference Fourier was featureless, the largest peak being 0.12 e $Å^{-3}$. Selected bond distances and angles are collected in Table 3.

M = Rb. Colourless plate-like crystals of $[RbOBu^t]_4$ (**4**) suitable for X-ray structure determination were grown from tetrahydrofuran–n-pentane. One crystal was mounted, under a nitrogen atmosphere glove bag using silicone grease and transferred to a goniostat, where it was cooled to −157°C, for characterization and data collection.

Table 3. Listing of pertinent bond distances and angles for $[MOBu^t]_4$ compounds

	Distances (Å)	
	M = K (2)	M = Rb (4)

M—O—M	89.82(6)	90.89(16)
M—O—C	125.39(5)	124.64(12)
O(2)—C(3)—C(4)	111.00(16)	110.7(5)

Crystal data collection and refinement parameters are given in Table 1. A systematic search of a limited hemisphere of reciprocal space revealed intensities with at least orthorhombic or possibly cubic symmetry. Following complete data collection and correction for absorption the cubic symmetry was more obvious. Space group $P\bar{4}3m$ was determined by the successful solution of the structure.

The coordinates for the potassium atom in **2** were used as a starting point for the rubidium atom in **4**. The remaining non-hydrogen atoms were obtained from subsequent iterations of least-squares refinement and difference Fourier calculation. Hydrogen atoms were included in calculated positions to improve the refinement of the non-hydrogen atoms, however the hydrogens were not refined. Hydrogen thermal parameters were fixed at one, plus the isotropic thermal parameter of the atom to which they were bonded.

In the final cycles of refinement the non-hydrogen atoms were varied with anisotropic thermal parameters to a final $R(F) = 0.027$. The final difference map was essentially featureless, all residual peaks being 0.5 e $Å^{-3}$ or less.

This structure is isostructural with **2**, including the rather well-defined disorder. Because of this disorder, atoms C(4), H(2) and H(3) have half weight. Selected bond distances and angles are collected in Table 3.

RESULTS AND DISCUSSION

Synthesis

The Group I alkoxides reported herein were prepared according to the reactions summarized in Scheme 1 below. The isolated yields were in the range 58–78%, although spectroscopic data indicate that their formation is essentially quantitative. The compounds [MOBu^t] have been prepared previously, though no synthetic details are given in the literature.[1,10]

Solid-state structures

[MOBu^t · Bu^{t}OH]$_\infty$, *where* M = K (**1**) *and* Rb (**3**). The alkali metal alkoxide alcohol adducts [MOBu^t · Bu^{t}OH]$_\infty$ (**1**) and (**3**) form a one-dimensional chain in the solid state. Figure 1 shows an ORTEP view of the central skeleton of the potassium species with the atom numbering scheme, while Fig. 2 emphasizes the coordination environment in the asymmetric unit [MOBu^t · Bu^{t}OH]$_\infty$ of **1** and **3**. (See Table 2 for selected structural data on the potassium and rubidium alkoxides.)

The asymmetric unit contains two metal atoms having a distorted tetrahedral coordination provided by two μ_3-capping t-butoxide and two μ_3-capping t-butanol ligands. The chains are constructed around a series of distorted tetrahedral metal atoms. Within the asymmetric units, one can view the geometry as staggered MOBu^t · Bu^{t}OH units. The M—O distances fall into two sets; those within a triangular MOBu^t · Bu^{t}OH unit, [K, Rb] are the shorter distances, M—O(2) (2.62, 2.77 Å) and M—O(7) (2.64, 2.79 Å), while the longer M—O contacts are between such units and involve a square M_2O_2 unit, M—O(2) (2.74, 2.87 Å) and M—O(7) (2.706, 2.83 Å). Also noteworthy is the strong hydrogen-bonding interaction O(2)—O(7) of (2.46, 2.44 Å), with the proton more likely being associated with O(7) (1.22, 1.18 Å) than with O(2) (1.24, 1.27 Å).

There are crystallographic centres of symmetry at the centres of the squares bonded by M(1)—O(2)—M(1)—O(2) and M(1)—O(7)—M(1)—O(7). The strong hydrogen-bonding within one-dimensional chains also results in a near linear O(7)—H(19)—O(2) bond angle (167.4, 172.61°).

M = Cs. Attempts to prepare single-crystals of the corresponding caesium derivative **5** have, to date, not been successful.

[MOBu^t]$_4$ *where* M = K (**2**) *and* Rb (**4**). The alkali metal t-butoxide compounds [MOBu^t]$_4$ (**2**) and (**4**) have been shown by single-crystal X-ray diffraction to have cubane-type structures. Figure 3 shows an ORTEP view of the central skeleton of the cubane structure of the potassium (**2**) species with the atom numbering scheme. Previous studies have examined samples of the above compounds **2** and **4** by X-ray powder diffraction and a cubane structure was inferred.[10]

The asymmetric unit contains four metal atoms, each in an identical environment in the cubane structure. The t-butoxide ligands are all essentially equivalent, μ_3-bridging t-butoxide ligands. The

$$M + Bu^tOH_{(excess)} \xrightarrow{\Delta} \underset{\text{K (1), Rb (3) and Cs (5)}}{[MOBu^t \cdot Bu^tOH]_\infty} \underset{Bu^tOH}{\overset{\Delta/\text{sublimation}}{\rightleftharpoons}} \underset{\text{K (2), Rb (4) and Cs (6)}}{[MOBu^t]_4}$$

(M = K, Rb, Cs)

Scheme 1.

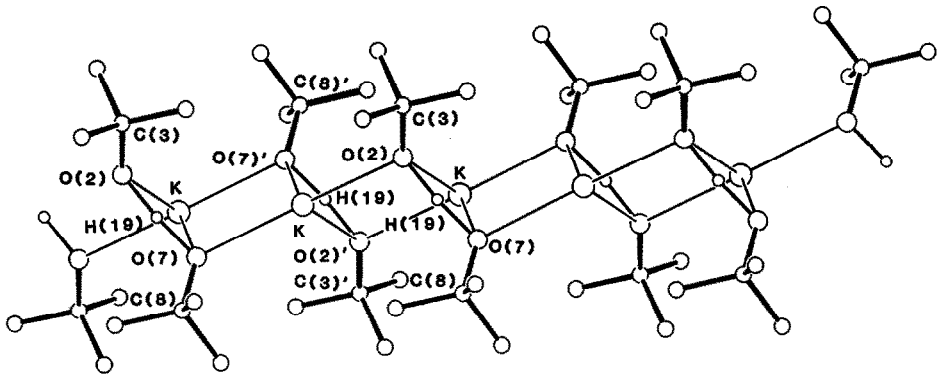

Fig. 1. A view of the $[KOBu^t]_4$ (**2**) central framework showing the cubane-like structure.

M—O distances may be compared, for **2** [2.6232(13)] and for **4** [2.757(4)]. The increase in distance expected on going from potassium to rubidium may be accounted for by the larger van der Waals' radius of rubidium. The M—O bond distances in **2** and **4** are comparable with those observed within the $MOBu^t \cdot Bu^tOH$ triangles.

Within the cubane-like structures, the O—M—O angles are found to deviate only slightly from 90°. For the angles O—M—O (90.18, 89.11°) and M—O—M (89.82, 90.89°), one may note a correlation with the ionic radii of the metal, the O—M—O angle being larger for potassium than rubidium, and likewise the M—O—M angle is larger for rubidium than potassium.

A summary of potassium and rubidium alkoxide and trialkylsiloxide structural parameters are given in Table 4. This table shows that these two metals are found in relatively low coordinative sites in these complexes, i.e. three and four.

Solution properties

In benzene-d_6 and toluene-d_8 $[MOBu^t \cdot Bu^tOH]_\infty$ compounds [M = K (**1**), Rb (**3**) and Cs (**5**)] exhibit only a single time-averaged type of t-butoxide ligand environment at room temperature, as shown by both ^1H and ^{13}C NMR spectroscopy. The ^1H NMR resonances gradually broadened upon cooling to 220 K, but the solution could not be cooled to a low enough temperature to observe coalescence. It is possible that the alcohol ligand is undergoing rapid exchange with the alkoxide ligand in solution. An intramolecular dynamic process is not surprising, given the possibility that potassium can have coordination numbers of three to eight. Likewise, ^{13}C NMR data provided no further insight, since only one type of t-butoxide ligand was observed for $[MOBu^t \cdot Bu^tOH]_\infty$, consistent with the ^1H NMR spectroscopic data. Cryoscopic molecular weight measurements for these species show

that in solution they exist as trimeric species, possibly as cyclic trimers.

The corresponding cubane species $[MOBu^t]_4$ (M = K, Rb and Cs) were also studied by both ^1H and ^{13}C NMR. In benzene and toluene solution these species exhibit a single, sharp line for the t-butoxide environment. On cooling to 220 K the lines remain sharp with no indication of broadening being observed. The ^{13}C NMR data are in accord with these observations.

Cryoscopic molecular weight measurements have been previously reported in a range of solvents, indicating that the tetramers remained intact in solution.[11] It is noteworthy that Lewis bases such as THF and Et_2O do not reduce the oligomerization or react with these species. This parallels the behaviour observed for $[Li(OCBu^t_3)(THF)]_2$ and $[Li(OCBu^t_3)]_2$.[12] Our observations on Group IIA alkoxides and aryloxides also have shown that metal geometries are strongly influenced by the type of Lewis base used.[13] This leads us to conclude that in weak donor media (Et_2O or THF), the solvent is bound more weakly than the alkoxide ligands and hence the cubane structure is retained. The interaction of an alkoxide with the solvent, and thus the degree of association of the alkoxide, is dependent not only on the composition and structure of the alkoxide, but also on the electron-donating properties and the structure of the solvent. Mass spectroscopic results on these materials have previously shown that even in the gas phase these cubane alkoxides remain tetrameric.[14] The related trimethylsilanolates $[MOSi(CH_3)_3]_4$ (M = K, Rb and Cs) have also been shown to exist in the vapour state as tetrameric units, by mass spectroscopy.[14] This surprising stability of alkali-metal alkoxides in the gas phase has allowed PES measurements on a variety of these species to be undertaken.[15] The results indicated that ionization of the alkoxides to their corresponding radical cations becomes easier as the electron density at the oxygen atom is increased.

CONCLUSIONS

The series of alkoxide–alcohol adducts $[MOBu^t \cdot Bu^tOH]_\infty$ (M = K, Rb and Cs) have been prepared from the reaction of alkali metals with tert-butanol–tetrahydrofuran and crystallized in good yields. For M = K or Rb, a one-dimensional ribbon-like chain is observed in the solid state. In benzene and toluene solution at room temperature, all of these complexes undergo a rapid dynamic exchange process on the ^1H NMR time scale, and in solution they exist as trimeric species.

The corresponding cubane alkoxides $[MOBu^t]_4$ (M = K, Rb or Cs) have been unambiguously characterized both in solution and by single-crystal X-ray studies. The interconversion of $[MOBu^t \cdot Bu^tOH]_\infty$ to $[MOBu^t]_4$ was accomplished by sublimation of the precursor in very good yield.

The excellent solubility of $[MOBu^t \cdot Bu^tOH]_\infty$ makes them very attractive for use as molecular precursors in sol–gel processes of mixed oxides. The coordinated alcohol may be an important feature of these molecules in reactions to form heterometallic

alkoxides, and further work along these lines is now in progress.

ANALYSIS OF COPPER(I) STABILITY IN THE CATIONIC $[Cu(CH_3CN)_{4-n}(Ph_3P)_n]^+$ SERIES OF COMPLEXES

ANA MARÍA LEIVA,* LEONARDO RIVERA and BÁRBARA LOEB*

Faculty of Chemistry, P. Catholic University of Chile, Casilla 6177, Santiago, Chile

(*Received* 9 *August* 1989; *accepted after revision* 5 *October* 1990)

Abstract—NMR and electrochemical studies on the stability of copper(I) complexes of the type $[Cu(CH_3CN)_{4-n}(Ph_3P)_n]^+$ ($n = 0$–4) were carried out to explore the effect of phosphine ligands on stabilization. The effect of phosphine ligands was demonstrated by cyclic voltammetry and ^{31}P NMR. A correlation between structural and electronic effects and the stability of the complexes was established.

Among the ligands known to stabilize copper(I), triphenylphosphine has been studied by several authors.[1,2] Different coordination geometries have been observed for copper(I)–triphenylphosphine complexes, but the tetrahedral geometry is dominant.[1] Triphenylphosphine complexes are expected to be more stable than those of acetonitrile for copper(I),[3,4] and CH_3CN should be displaced by PPh_3 in the equilibrium:

$$n PPh_3 + [Cu(CH_3CN)_4]^+ \rightleftharpoons [Cu(CH_3CN)_{4-n}(Ph_3P)_n]^+ + n CH_3CN. \quad (1)$$

Our work approaches the above problem by studying the electrochemical stability of the series of cationic complexes $[Cu(CH_3CN)_{4-n}(Ph_3P)_n]^+$ ($n = 0$–4). The related compound, $Cu(PPh_3)_3ClO_4$, was also studied and its behaviour compared to compounds of the above series.

EXPERIMENTAL

NMR spectra were obtained using a VARIAN XL 100 spectrometer with TMS and H_3PO_4[85% (external standard)] as references and $CDCl_3$ and $CHCl_3$ as solvents for ^1H and ^{31}P, respectively.

The voltammometric measurements were carried out with a Wenking HP72 potentiostat, a Wenking VSG72 signal generator and a Graphtex WX2300 XY recorder. For coulometric measurements a Wenking EVI80 voltage integrator was used. All electrochemical measurements were performed under Argon, purified by a Hydrox Purifier, model 8301. The working electrode was a platinum disc for cyclic voltammetry measurements, and a platinum mesh for coulometry. The counter electrode was a platinum wire and the reference a Ag/AgCl (in aqueous tetramethyl ammonium chloride) electrode, adjusted to the SCE potential.[5] All syntheses were carried out in dry solvents under nitrogen.

$[Cu(CH_3CN)_3(PPh_3)]PF_6$

PPh_3 (0.843 g, 3.21 mmol) was added to a solution of $Cu(CH_3CN)_4PF_6$[6] (1.198 g, 3.21 mmol) in dichloromethane (100 cm^3). The mixture was stirred at room temperature for 3 h and then concentrated to half its volume. The addition of diethyl ether (50 cm^3) to this mixture precipitated a white solid, which was separated by filtration under nitrogen. This product was recrystallized from a 3:1 mixture of dichloromethane–ether. Yield: 85%; ^1H NMR (TMS, $CDCl_3$): 2.16 ppm (s, 9H; CH_3), 7.37 ppm (m, 15H; C_6H_5); ^{31}P NMR (H_3PO_4 85%, $CHCl_3$): 1.23 ppm (s).

$[Cu(CH_3CN)(PPh_3)_3]ClO_4$

This product was synthesized by following a modification of the method of White and coworkers,[7b] with dichloromethane as the solvent; the solution was stirred over 3 h at room temperature.

* Authors to whom correspondence should be addressed.

$Cu(PPh_3)_3ClO_4$

Recrystallization of $[Cu(CH_3CN)(PPh_3)_3]ClO_4$ from boiling methanol gave white crystals of the product. X-ray diffraction showed[8a] the replacement of the coordinated acetonitrile by monodentate perchlorate, in agreement with literature reports.[8b]

All other complexes were synthesized following literature procedures: $Cu(CH_3CN)_4PF_6$,[6] $[Cu(CH_3CN)_2(PPh_3)_2]PF_6$[9] and $[Cu(PPh_3)_4]ClO_4$.[7a]

RESULTS AND DISCUSSION

(a) *Nuclear magnetic resonance*

The ^{31}P NMR spectra of the copper(I) complexes (Table 1) show a shift of the phosphorus atom signal toward lower field as the number of phosphine ligands in the complex increases, implying a smaller shielding of this nucleus.[10] This effect can be explained by a reduction in the π contribution to the Cu—P bond as the number of phosphine ligands increases. It is also corroborated by the Cu—P distances determined from X-ray structures of some copper complexes (Table 1),[7] which show that larger Cu—P distances occur with an increasing number of phosphine ligands in the complex.

The transformation of the $[Cu(CH_3CN)(PPh_3)_3]ClO_4$ complex into the $Cu(PPh_3)_3ClO_4$ monodentate perchlorate is shown by the displacement of the ^{31}P signal from 1.85 to 1.69 ppm, reflecting a shielding of the phosphorus nucleus due to a shortening of the Cu—P bond (from 233 to 231 ppm, as measured by X-ray diffraction[8]).

The ^1H NMR spectra of the complexes with acetonitrile ligands (Table 1) show a shift of the methyl group signal to higher field as the number of phosphine ligands in the complex increases, as expected for an increase in the electronic density around the methyl proton. This is corroborated by the X-ray data for complexes **I**, **III** and **IV** (Table 1) that indicate a lengthening of the Cu—N bond as the number of phosphine ligands increases.

(b) *Electrochemical results*

The voltammometric behaviour of triphenylphosphine has been extensively analysed and discussed;[11] in spite of some controversies,[12] it is now accepted that the phosphine undergoes an irreversible oxidation (at a potential > 1.0 V).[13] This process is ascribed to the one-electron oxidation of triphenylphosphine to the $PPh_3^{+\cdot}$ cationic radical.[14,15] The oxidation is followed by a chemical reaction in which the radical, $PPh_3^{+\cdot}$, reacts with nucleophilic components of the solution. In our system (DMF, TEAP 0.1 M, platinum disc working electrode) the oxidation of PPh_3 is observed at 1.38 V (vs SCE) and corresponds to a one-electron process (verified by coulometric measurements). The cyclic voltammograms for all the $[Cu(CH_3CN)_{4-n}(PPh_3)_n]^+$ ($n = 0$–4) compounds show an oxidation wave at potentials ranging from 0.6 to 0.92 V (Table 1), depending on the value of n. In addition, an oxidation process at the same potential (1.38 V) as free triphenylphosphine is observed for all the complexes (Fig. 1). The former wave is assigned to the oxidation of copper(I) to copper(II):

$$[Cu(CH_3CN)_{4-n}(PPh_3)_n]^+ \longrightarrow [Cu(CH_3CN)_{4-n}(PPh_3)_n]^{2+} + e. \quad (2)$$

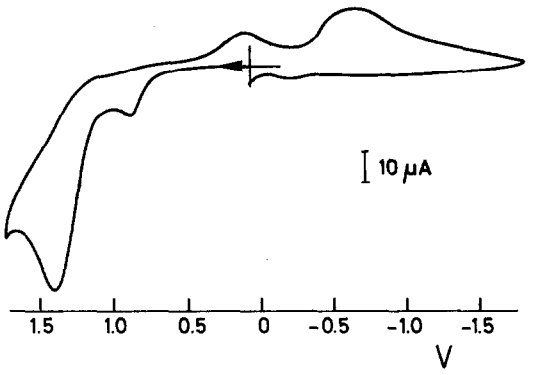

Fig. 1. Cyclic voltammetry for the $[Cu(CH_3CN)(PPh_3)_3]ClO_4$ complex (v = 200 mV s^{-1}) in DMF (TEAP 0.1 M) using a platinum disc as working electrode.

Controlled potential electrolysis corresponding to this oxidation generates, after the passage of one electron, a green coloured compound, probably a copper(II) complex. The current intensity does not manifestly decrease during the process, even after the passage of more than three electrons. The green colour quickly dissappears when the electrolysis is stopped. This behaviour suggests that the oxidation is complicated by a subsequent chemical reaction, probably the reduction of copper(II) by triphenylphosphine released during the electrochemical oxidation of the copper(I) complex [triphenylphosphine has a low affinity for copper(II)]. The ability of triphenylphosphine to reduce copper(II) is well known.[6] However, in this case, the subsequent chemical reduction is rather slow compared to the electrochemical oxidation, and therefore the copper(II) compound can be detected during the electrolysis. Similar behaviour has been shown for a series of rhenium(I) complexes of the type $[Re(CO)_2(PPh_3)_2\{(ArN)_2X\}]$ (X = N, CH; Ar = benzyl and substituted benzyl),[13] where the existence of subsequent chemical reactions was proven by several electrochemical criteria.

In the cyclic voltammetry of $Cu(PPh_3)_3ClO_4$ (**VI**) the oxidation wave appears at 0.6 V, i.e. at a considerably lower potential than the corresponding wave of $[Cu(CH_3CN)(PPh_3)_3]ClO_4$ (Table 1). Since the oxidation process for the related complex, $Cu(PPh_3)_3Cl$ (**VII**),[16] is also observed at 0.6 V, we conclude that **VI** and **VII** generate the same species in solution. An explanation for this behaviour could be the substitution of the solvent (DMF) for the perchlorate or chloride anion. The greater ease of oxidation of the solvated species reflects the greater affinity of DMF for copper(II).[17]

The electrochemical reduction of the complexes in the series was also investigated. A cathodic wave is observed for all of the complexes, the shape of it suggesting a metal deposit on the electrode. Indeed, controlled potential electrolysis for this process generated a copper deposit on the working electrode, after the passage of one electron. The voltammogram of the remaining solution corresponds to free triphenylphosphine, as would be expected for a $Cu^I \rightarrow Cu^0$ reduction.

CONCLUSIONS

The increase in the Cu—P and Cu—N bond lengths with the number of phosphine ligands in the $[Cu(CH_3CN)_{4-n}(PPh_3)_n]ClO_4$ (n = 0–4) complexes (Table 1) could be indicative of a corresponding decrease in stability. However, the greater crystal symmetry observed for the complexes with high values of n would suggest the opposite.* The actual stability tendency is clearly manifested by cyclic voltammetry, where the anodic wave related to the Cu^I/Cu^{II} oxidation moves to more positive potentials as the number of phosphine ligands in the complex increases.

In addition to the crystal symmetry effect, the enhanced stability can be ascribed to the M → L back-donation effect.[4] Since Cu^I-d^{10} is an electron-rich metal it can be regarded as a good π donor to phosphorus, which acts as a π base via its empty d orbitals. The electron density displacement is not possible with acetonitrile as the ligand since there are no energetically appropriate $d\pi$ orbitals on the nitrogen atom for this type of bond.

A comparison between the structure of the $Cu(PPh_3)_3ClO_4$ complex and that of $[Cu(CH_3CN)(PPh_3)_3]ClO_4$ reveals that the former belongs to a trigonal system,[8] while the latter belongs to an orthorhombic one.[7b] Therefore, the cyclic voltammetries should reflect the greater stability of $Cu(PPh_3)_3ClO_4$, but since the species in solution are different [due to the solvation of $Cu(PPh_3)_3ClO_4$] the oxidation of the latter complex is easier, given the greater affinity of DMF for copper(II).

It is concluded that, in this series of copper(I) complexes, a greater ordering of the structure increases the stability only if the species is not altered in solution, as seems to be the case for the $[Cu(CH_3CN)_{4-n}(PPh_3)_n]^+$ (n = 0–4) series of com-

* The $[Cu(CH_3CN)_2(PPh_3)_2]ClO_4$ complex belongs to a monoclinic system with marked distortion of the coordination polyhedra (P—Cu—P and N—Cu—N angles of 127.6 and 99.2°, respectively[7]), while the system for $Cu(PPh_3)_4ClO_4$ is rhombohedral with P—Cu—P angles of 109.6 and 109.3°.[7a]

plexes. On the other hand, the electronic effect on stability is reflected in the chemical shifts observed in the NMR spectra, as well as in the displacement of the electrochemical oxidation wave.

(*Received* 24 *May* 1990; *accepted* 5 *October* 1990)

Abstract—Mercury(II) halides react with 2,6-dimethyl-4H-pyran-4-thione (DMTP) yielding complexes of general formulae $[Hg(DMTP)_2X_2]$ and $[Hg(DMTP)X_2]_n$ (X = Cl, Br or I), in which the ligand acts as a strong sulphur donor. With 2,6-dimethyl-4H-pyran-4-one (DMP) the complexes $[Hg(DMP)X_2]_n$ and $(HgX_2)_3(DMP)_2$ (X = Cl or Br) have been isolated, which easily release the weakly bound ligand molecules in common solvents. The compounds have been characterized by IR and NMR (^1H and ^{13}C) spectroscopy and by using thermogravimetric data. The adduct geometry is discussed on the basis of IR spectra, which suggest a tetrahedral arrangement for the 1:2 DMTP adducts. A halogen-bridged dimeric structure is proposed for the 1:1 DMTP adducts, whereas the $[Hg(DMP)X_2]_n$ adducts are probably chain polymers with halide–mercury contacts. The $(HgCl_2)_3(DMP)_2$ species should contain two types of mercury atoms with different coordination environments.

Mercury(II) halides form either 1:1 or 1:2 adducts with thiocarbonyl donors, the preferred geometry generally depending on the ligand substituents. Accordingly, benzenecarbothioamide yields 1:2 complexes, the IR spectra of which support a pseudo-tetrahedral structure,[1] whereas the N,N-dialkyl analogues preferentially display a 1:1 stoichiometry.[2,3] On the basis of X-ray structural data, the complex $[Hg\{PhC(S)NEt_2\}I_2]_2$ is dimeric with asymmetric iodine bridges, the mercury atom lying in a distorted tetrahedral environment.[3] As regards imidazolidine-2-thiones, the polymeric 1:1 complexes dichloro(N,N′-diethylimidazolidine-2-thione)mercury(II) and dibromo(5,5-dimethylimidazolidine-2-thione-4-one)mercury(II) have a *catena* structure held together by halide bridges, the tetrahedral coordination sphere of mercury being distorted to a trigonal pyramid.[4,5] In dichlorobis(N-ethylimidazolidine-2-thione)mercury(II) the metal assumes the usual pseudo-tetrahedral geometry.[4] Ethylene trithiocarbonate acts as a weak donor towards mercury(II) halides, the ligand being totally removed from 1:2 and 1:1 complexes in dimethylsulphoxide.[6] Weak sulphur–mercury bonds have been observed in thiocarbamic ester complexes of the type $[Hg(EtOSCNMe_2)X_2]_n$ and $[Hg(EtOSCNHMe)_2X_2]$ (X = halide), which easily release ligands in either benzene or acetone.[7,8] In $[Hg(EtOSCNMe_2)Cl_2]_n$ the mercury atom trigonally bonds ligand-sulphur and two chlorines. At the same time it forms elongated Hg···Cl contacts in a five-coordinated environment.[7] Recently, it has been observed that 2,6-dimethyl-4H-pyran-4-

thione (DMTP) acts as a strong sulphur donor towards palladium(II) and platinum(II) halides, the related 2 : 1 adducts being unchanged in dimethyl sulphoxide, a solvent which easily removes ligand molecules from the thiocarbamic ester analogues.[9] It was therefore of interest to extend the study to the mercury halide complexes of this ligand, in which the aromatic character of the ring enhances the thiocarbonyl donor ability, and of the parent 2,6-dimethyl-4H-pyran-4-one (DMP), which accordingly should be a good carbonyl donor. Mercury halides generally form 1 : 1 adducts with monodentate oxygen donors. Thermochemical studies supported the presence of weak bonds in adducts with ureas, N,N-dimethylformamide and pyridine N-oxide.[10–14] Along with the 1 : 1 adducts, sulphoxides can give complexes with higher mercury halide to ligand ratios.[15,16] In particular, the complex $(HgCl_2)_3(Me_2SO)_2$ contains a dimeric unit in which two mercury chloride moieties are held together by two bridging Me_2SO molecules, the third mercury chloride molecule forming contacts with four chlorine atoms from adjacent dimers.[17]

EXPERIMENTAL

Materials

DMTP (C_7H_8OS, 2,6-dimethyl-4H-pyran-4-thione) was prepared by the method of Faraglia *et al.*[9] and DMP ($C_7H_8O_2$, 2,6-dimethyl-4H-pyran-4-one, Ega-Chemie) was used as supplied. Mercury halides were Merck products. Preparations of DMP complexes were carried out under nitrogen flux.

Preparation of $[Hg(DMTP)_2X_2]$

These complexes were prepared by reacting the apropriate metal salt with DMTP (molar ratio, 1 : 2.2; reaction time, *ca* 2 h) either in CH_2Cl_2 or in Me_2CO. As an example, $[Hg(DMTP)_2Cl_2]$ was prepared by adding DMTP (1.1 mmol) to a suspension of $HgCl_2$ in CH_2Cl_2 (0.5 mmol in 4 cm^3). The solid mixture gradually changed to orange and the reaction was complete within 3 h. The orange solid was filtered, washed with CH_2Cl_2 and n-pentane and dried *in vacuo* (yield, 85%). A further fraction of product separated by addition of n-pentane to the orange mother solution. The compound was also obtained by reaction of $HgCl_2$ and DMTP in Me_2CO (molar ratio 1 : 3; reaction time, 2 h). The product was washed with abundant Me_2CO and dried *in vacuo* (yield, 75%). All 1 : 2 adducts were slightly soluble in dichloromethane, acetone and methanol.

Preparation of $[Hg(DMTP)X_2]_n$

A solution of DMTP in Me_2CO (0.5 mmol in 2 cm^3) was added to a $HgCl_2$ suspension in the same solvent (0.5 mmol in 2 cm^3), with vigorous stirring. The pink solid was kept under stirring for 1 h and then was filtered, washed with abundant Me_2CO and dried *in vacuo*. The 1 : 1 chloro complex was also obtained by reaction of $HgCl_2$ and DMTP in CH_2Cl_2 (molar ratio 1 : 1; reaction time, 18 h). Bromo and iodo derivatives were prepared analogously. The complexes were generally insoluble in common solvents.

Preparation of $[Hg(DMP)X_2]_n$

The complex $[Hg(DMP)Cl_2]_n$ was prepared by dissolving $HgCl_2$ (0.5 mmol) in a solution of DMP in CH_2Cl_2 (2.1 mmol in 5 cm^3). White crystals separated out on addition of n-pentane, which were filtered, washed with C_6H_6 (1 cm^3) and n-pentane and dried *in vacuo* (yield, 80%). The same product was obtained by reaction of $HgCl_2$ and DMP in C_6H_6 (molar ratio 1 : 4; with stirring overnight). The white powder was washed with C_6H_6 and n-pentane and dried *in vacuo* (yield, 70%). If reactions were performed at lower molar ratios (1 : 3 or 1 : 2) the products were mixtures of the 1 : 1 adduct and $(HgCl_2)_3(DMP)_2$ complex. $[Hg(DMP)Br_2]_n$ was prepared in CH_2Cl_2 as for the chloro analogue (yield, 70%). Moreover, good crystals were isolated in low yield by dissolving $HgBr_2$ (1.0 mmol) and DMP (1.9 mmol) in MeOH (2 cm^3) by gentle heating. The crystals separated when the solution was left standing overnight at *ca* 4°C. They were filtered and washed with a few drops of chilled MeOH and dried *in vacuo*. Attempts to isolate the 1 : 1 iodo complexes were unsuccessful. Although HgI_2 dissolves in concentrated DMP solutions (in CH_2Cl_2 or Me_2CO) the complexes are unstable. The mercury salt is the main product when the solutions are either evaporated to dryness or treated with n-pentane.

Preparation of $(HgX_2)_3(DMP)_2$

A suspension of $HgCl_2$ (1.0 mmol) in a CH_2Cl_2 solution of DMP (1.0 mmol in 4 cm^3) was stirred overnight, obtaining a white solid which was discarded by filtration and a colourless solution which was treated with n-pentane until turbid. White needles separated slowly and were washed with n-pentane and dried *in vacuo* (yield, 50%). The bromo complex was prepared by dissolving $HgBr_2$ (1.0 mmol) and DMP (1.0 mmol) in warm Me_2CO. Addition of n-pentane until turbidity yielded white

needles which were washed with benzene and n-pentane and dried *in vacuo* (yield, 50%). The solids obtained by adding a large amount of n-pentane to the mother solution were generally mixtures of 1 : 1 and 3 : 2 species. For this reason sample homogeneity was tested by examining the crystalline products under a stereo-microscope. As for the 1 : 1 adducts, these complexes readily release DMP in common solvents.

Measurements

IR spectra were recorded by using either a Perkin–Elmer 580B spectrophotometer (4000–400 cm^{-1}) or a Bruker FT IR instrument (500–100 cm^{-1}) as Nujol mulls between KBr and polyethylene discs. In KBr pellets the spectra of the DMTP adducts were as those in Nujol whereas for the DMP adducts, partial ligand release was observed. ^1H and ^{13}C NMR spectra were obtained by a Jeol FX 90Q spectrometer. Thermogravimetric measurements were carried out on Netzsch STA 429 equipment either in air or in nitrogen (flux rate, 250 cm^3 min^{-1}; heating rate, 5°C min^{-1}; reference material, neutral Al_2O_3). Melting points (uncorrected) were determined using a Buchi apparatus.

RESULTS AND DISCUSSION

Mercury halide adducts with DMTP (Table 1) were prepared either in dichloromethane or in acetone by using reagents in stoichiometric ratios. The synthesis of the $[Hg(DMP)X_2]_n$ (X = Cl or Br) complexes required a large ligand excess (*ca* 1 : 4), otherwise mixtures of species with a lower ligand content were isolated. In particular, crystalline samples of

Table 1. Analytical data and selected IR frequencies for the mercury complexes

[a] With decomposition.
[b] $C_{14}H_{16}X_2HgO_2S_2$ (X = Cl, Br or I).
[c] $C_7H_8X_2HgOS$ (X = Cl, Br or I).
[d] $C_7H_8X_2HgO_2$ (X = Cl or Br).
[e] $C_{14}H_{16}X_6Hg_3O_4$ (X = Cl or Br).

the $(HgX_2)_3(DMP)_2$ (X = Cl or Br) species were obtained by adding n-pentane to dichloromethane or acetone solutions containing HgX_2 and ligand in a 1 : 1 molar ratio.

Thermograms of all the adducts either in air or in nitrogen indicate that total sublimation of samples takes place beyond 600°C. As shown in Fig. 1(a), degradation of $[Hg(DMP)Cl_2]_n$ in air starts at *ca* 120°C, the melting endotherm being observed at 142°C. Weight loss occurs in two close steps (endotherms at 240 and 290°C), resulting in a *ca* 6% residue at 300°C which is slowly released up to 480°C. Apart from different melting temperatures, the thermograms of $[Hg(DMP)Br_2]_n$ and $(HgX_2)_3(DMP)_2$ (X = Cl or Br), in air, follow a similar trend, with a 100% weight loss at 480°C. Thermograms in nitrogen are like those in air up to 300°C, the following process ending at *ca* 550°C. The complex $[Hg(DMTP)Cl_2]_n$ [Fig. 1(b)] melts with decomposition at 175°C, the experimental weight loss in the first step (16.2%) being close to the calculated value for evolution of half a DMTP molecule (17%) to form $(HgCl_2)_2(DMTP)$ as an intermediate. The exothermic processes which follow (297 and 470°C) end at 560°C with a total sample release. The $[Hg(DMTP)Br_2]_n$ curves do not show the initial step due to partial ligand evolution, as with the iodo derivative [Fig. 1(c)]. Near melting, $[Hg(DMTP)I_2]_n$ presents two close endotherms at 155 and 161°C, respectively, followed by the two broad exotherms at *ca* 350 and 510°C. Melting of the 1 : 2 DMTP complexes occurs at temperatures higher than those of the corresponding 1 : 1 adducts. In particular, $[Hg(DMTP)_2Cl_2]$ [Fig. 1(d)] melts at 214°C with evolution of one DMTP molecule, the experimental weight loss being 24.2% against a calculated value of 25.4%. The degradation trend that follows resembles that of the 1 : 1 complex, two broad exotherms being observed at 330 and 475°C. The thermograms of the 1 : 2 adducts support formation of the corresponding 1 : 1 species as degradation intermediates. Accordingly, $[Hg(DMTP)_2Br_2]$ loses 20.8% of the initial weight (calculated for one DMTP molecule, 21.9%) in the first decomposition step, the related value for $[Hg(DMTP)_2I_2]$ being 18.5% (versus a calculated value of 19.2%).

In the 1700–1500 cm^{-1} range the IR spectrum of DMTP contains a strong absorption at 1641 cm^{-1}, assigned to $\nu(C{=}C)$, and a medium one at 1559 cm^{-1}, due to ring vibrations.[18] The corresponding bands in DMP are observed at 1669 and 1599 cm^{-1}, respectively, the latter appearing as a shoulder of the strong $\nu(C{=}O)$ absorption at 1611 cm^{-1}. On coordination, the ring absorptions of both ligands shift slightly to low energy ($\Delta\nu$ = 10–20 cm^{-1}).[9,19] Accordingly, the $[Hg(DMTP)X_2]_n$ adducts present (Table 1) a strong $\nu(C{=}C)$ absorption at *ca* 1627 cm^{-1} which splits in the $[Hg(DMTP)_2X_2]$ complexes, suggesting a different bonding situation in

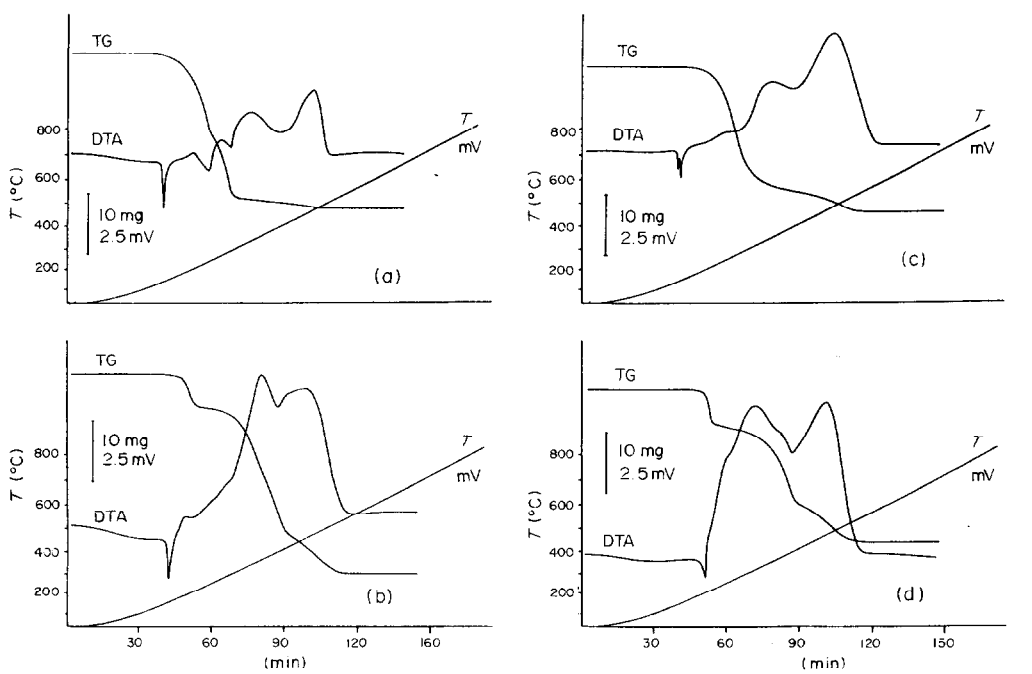

Fig. 1. Thermograms in air: (a) $[Hg(DMP)Cl_2]_n$ (25.60 mg); (b) $[Hg(DMTP)Cl_2]_n$ (32.39 mg); (c) $[Hg(DMTP)I_2]_n$ (24.11 mg); (d) $[Hg(DMTP)_2Cl_2]$ (24.56 mg).

the coordinated DMTP molecules. All DMTP adducts show the ring absorption at *ca* 1540 cm^{-1}, whereas the ν(C=S) band falls at *ca* 1105 cm^{-1} (versus 1095 cm^{-1} in free ligand). As expected, the IR spectra suggest that DMP is a weaker donor in mercury complexes than in lanthanide complexes.[19] In fact, the ring absorptions (Table 1; *ca* 1667 and 1592 cm^{-1}) are close to those of free DMP and the low energy shift of ν(C=O), of order 30 cm^{-1} for $(HgX_2)_3(DMP)_2$ (*ca* 1582 cm^{-1}) and 40 cm^{-1} for $[Hg(DMP)X_2]_n$ (1568 cm^{-1}), is smaller than in lanthanide complexes ($\Delta\nu$, 60–80 cm^{-1}).

Below 500 cm^{-1}, the IR spectra of the 1:2 DMTP adducts contain two bands assignable to mercury–halide bond vibrations (Table 2). When mercury is involved in a distorted tetrahedral arrangement with approximate C_{2v} symmetry, two mercury–halide stretching vibrations should be expected, due to symmetric and asymmetric modes. IR spectra of structurally similar 1:2 complexes sometimes show one (asymmetric) mercury–halide absorption, the symmetric vibration mode being Raman-active as for pyridine or phosphine adducts.[20,21] For a number of mercury chloride complexes there is a good correlation between the position of the high energy mercury–chloride band and the bond distance in such a way that the bond distance increases and consequently ν(Hg—Cl) decreases with the donor atom bond strength.[22] As is shown in Fig. 2, the $[Hg(DMTP)_2Cl_2]$ spectrum contains two strong ν(Hg—Cl) absorptions at 248 and 223 cm^{-1}, the strong $\delta(HgCl_2)$ absorption being observed at 94 cm^{-1}. The band at 223 cm^{-1} shows shoulders common to the iodo complex and due to ligand vibrations. In the $[Hg(DMTP)_2Br_2]$ spectrum a mercury–bromide stretching contribution to the medium band at 202 cm^{-1} can be ruled out owing to the presence of a band of similar shape and intensity in the spectra of platinum and palladium adducts. In the $[Hg(DMTP)_2I_2]$ spectrum the medium band at 123 cm^{-1} has been tentatively assigned to mercury–iodide stretching, because a smaller mercury–iodide band separation is usually observed in the spectra of 1:2 mercury iodide adducts with sulphur and phosphorus donors. The mercury–halogen bands observed in the IR spectra of 1:1 adducts are usually assigned to ν(Hg—X) modes associated with vibrations of terminal (high energy) and bridging (low energy) Hg—X bonds, the terminology used for halide-bridged dimers being extended to *catena* polymers. The separation of $\nu(Hg—X)_t$ and $\nu(Hg—X)_b$ bands is large, especially for chloro derivatives. In a series of 1:1 adducts with phosphines the $(Hg—Cl)_t$ absorptions are independent of the structure (dimeric or polymeric) and are observed in the 300–

[a] Spectra were recorded within 3 h of solution preparations.
[b] In $CDCl_3$.
[c] Almost insoluble in $CDCl_3$.

270 cm^{-1} range, whereas the position and the number of the bands arising from bridge vibrations vary with the adduct configuration.[23] The room temperature spectra of the $[Hg(DMTP)X_2]_n$ adducts (Table 2), which contain one absorption for either terminal or bridging mercury–halide bonds, could support a dimeric structure of the complexes. Conversely the coincidence of the high energy mercury–chloride absorption in $[Hg(DMTP)Cl_2]_n$ (278 cm^{-1}) with those of the polymeric $[Hg(EtOSCNMe_2)Cl_2]_n$ (280 cm^{-1}) and [Hg(N,N′-diethylimidazolidine-2-thione)$Cl_2]_n$ (280 cm^{-1}) complexes does not allow clarification of the bonding framework. Owing to the weak intereaction with oxygen donors, the mercury–halide molecules deviate slightly from linearity in complexes of the type $[Hg(L)X_2]_n$, in which L is Ph_2SO, 1,4-dioxane or tetrahydrofuran.[16,24] Consequently, the strong IR bands associated with the asymmetric ν(Hg—X) vibrations are close to those of free mercury halides[15,16,21,24] and are observed at 362 cm^{-1} for $[Hg(Ph_2SO)Cl_2]_n$, at 353 cm^{-1} for [Hg(1,4-dioxane)$Cl_2]_n$ and at 252 cm^{-1} for [Hg(tetrahydrofuran)$Br_2]_n$. Accordingly, the $[Hg(DMP)X_2]_n$ (X = Cl or Br) spectra (Table 2) show one strong ν_{as}(Hg—X) absorption (Cl, 337 cm^{-1}; Br, 240 cm^{-1}) at low energy with respect to the corresponding absorption in the above reported oxygen-bound adducts, suggesting a stronger Hg—O bond. The two strong mercury–halide bands, 20–30 cm^{-1} apart, in the $(HgX_2)_3(DMP)_2$ (X = Cl or Br) complex spectra could support a structural arrangement similar to that of $(HgCl_2)_3(Me_2SO)_2$.[17] The high energy bands (Cl, 358 cm^{-1}; Br, 256 cm^{-1}) should descend from ν_{as}(Hg—X) vibrations of the nearly linear HgX_2 molecules, whereas the low energy bands (Cl, 327 cm^{-1}; Br, 233 cm^{-1}) should be originated from the corresponding vibrations of the distorted HgX_2 molecules held by oxygen bridges to form dimeric units.

Owing to the presence of weak Hg—O bonds, the mercury halide DMP complexes readily release ligand molecules in solution. Proton NMR spectra of the complexes in deuterated chloroform and acetone contain the free DMP signals at *ca* 6.0 (ring CH) and 2.2 pm (CH_3). In contrast, the NMR spectra of the DMTP adducts (Table 3) are consistent with the coordinated ligand in either $CDCl_3$ or $(CD_3)_2SO$. On coordination both CH and CH_3 proton signals shift downfield, the effect being larger for the CH protons (0.4–0.8 ppm). Whereas $CDCl_3$ solutions of the complexes do not change over several days, $(CD_3)_2SO$ solutions begin to darken overnight. On standing for *ca* 1 week they form violet solutions and separate mixtures of unidentified violet and brown solids. For this reason the carbon spectra of Table 3 were recorded within 3 h of sample solubilization. As for the previously reported $[M(DMTP)_2X_2]$ (X = Pd or Pt) complexes, the CS carbon resonance appears upfield in the mercury complexes, with respect to free DMTP (Δppm, 4–11), whereas an opposite downfield shift is observed for the signal of the ring carbon atoms bound to oxygen (Δppm, 5–8). Carbon NMR spectra in dimethyl sulphoxide, recorded 1 day after sample solubilization, contain

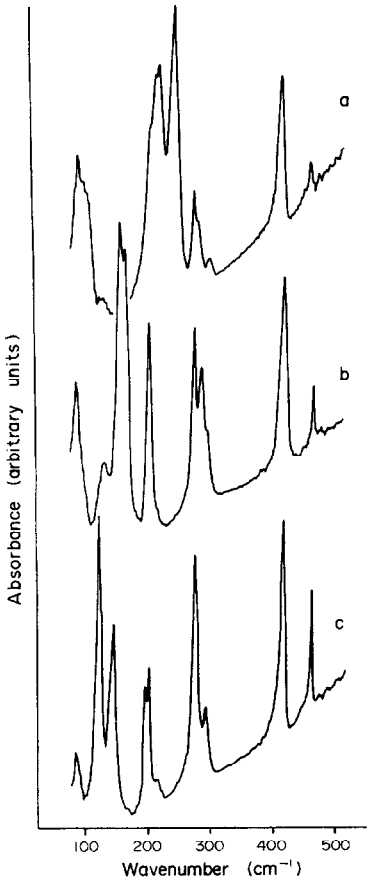

Fig. 2. IR spectra of $[Hg(DMTP)_2X_2]$: (a) X = Cl; (b) X = Br; (c) X = I.

a number of weak signals in addition to the strong resonances reported in Table 3. As an example, the $[Hg(DMTP)Br_2]_n$ spectrum displays weak signals at 185, 179 and 119 ppm, which do not coincide with free DMTP resonances.

Acknowledgements—The authors thank Mrs Franca Marzola for recording the far-IR spectra. One of us (Z.G.) thanks the Ministero degli Affari Esteri of Italy for an annual grant.

KINETICS OF THE REDOX REACTION BETWEEN $Mo_2O_4^{2+}$ AND VO_2^+ IN $HClO_4$ MEDIUM

D. O. MÁRTIRE, M. R. FÉLIZ* and A. L. CAPPARELLI†‡

Instituto de Investigaciones Fisicoquimicas Teóricas y Aplicadas (INIFTA), Facultad de Ciencias Exactas, Universidad Nacional de La Plata, Casilla de Correo 16, Sucursal 4, (1900) La Plata, Argentina

(*Received* 15 *June* 1990; *accepted* 5 *October* 1990)

Abstract—The kinetics of the oxidation of $Mo_2O_4^{2+}$ with VO_2^+ in $HClO_4$ medium at 25°C and ionic strength 2 M has been studied by the stopped-flow method. Under conditions of excess VO_2^+, the experimental rate constant is represented by the expression:

$$k_{app} = \frac{(1238[H^+]+811)}{(5.50\times10^{-4}+[H^+][VO_2^+])}[VO_2^+]^2.$$

This rate law can be interpreted by the following mechanism:

$$D \rightleftharpoons DOH + H^+ \quad \text{(I)}$$

$$D + VO_2^+ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C + H^+ \quad \text{(II)}$$

$$DOH + VO_2^+ \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} C \quad \text{(III)}$$

$$H^+ + C + VO_2^+ \xrightarrow{k_4} 2Mo^{VI} + 2V^{IV}, \quad \text{(IV)}$$

where D is $Mo_2O_4^{2+}$ and C an intermediate complex. For this mechanism, $k_2 = 1238$ $M^{-1}\,s^{-1}$, $k_3K_1 = 811\ s^{-1}$ and $k_{-3}/k_4 = 5.00\times10^{-4}\ M^2$. Limiting values for the individual constants can be estimated and the nature of the intermediate is discussed.

The kinetics of the oxidation of molybdenum(V) with different reactants has been the subject of several investigations.[1–9] The kinetics of the reaction between VO_2^+ and molybdenum(V) has already been studied by Issa *et al.*[10] in the highly complexing HCl medium via stopped-flow techniques. These authors worked in the proton concentration range 1–0.23 M HCl and ionic strength 1 M (NaCl). The pseudo first-order rate constant was found to be a function of the proton concentration but independent of the initial concentration of both reactants. They also reported very few results obtained in 1 M $HClO_4$ medium and also proposed that the effect of ClO_4^- would retard the reaction.

The present study was carried out in non-complexing perchloric medium in the concentration range 0.2–2 M ($HClO_4$) and ionic strength 2 M(Na ClO_4). Under our experimental conditions, molybdenum(V) is present as $Mo_2O_4(H_2O)_6^{2+}$. The experimental behaviour of the system and the measured rate law differ from those obtained in HCl. Therefore, the medium plays an important role in the kinetics and mechanism of this reaction.

EXPERIMENTAL

Aqueous solutions of $Mo_2O_4^{2+}$ were prepared according to Cayley and Sykes.[11] The $Mo_2O_4^{2+}$ concentration was determined at $\lambda = 384$ nm ($\varepsilon = 103\ M^{-1}\,cm^{-1}$).[12]

Reagent grade $NaClO_4\cdot H_2O$ (Merck), $HClO_4$ (Merck), $NaVO_3$ (Fluka), $VOCl_2$ (Carlo Erba) and

* Member of CICPBA.
† Member of CONICET.
‡ Author to whom correspondence should be addressed.

$Na_2MoO_4 \cdot 2H_2O$ (Merck) were used without further purification.

Absorption measurements were carried out by means of a Cary 14 spectrophotometer, while the kinetics of the reaction was followed spectrophotometrically using a Durrum-D110 stopped-flow apparatus. Most of the kinetic studies were carried out at $\lambda = 360$ nm and the ε values at this wavelength are (M^{-1} cm^{-1}) $Mo_2O_4^{2+}$, 92.5; VO_2^+, 73.5; Mo^{VI}, 14.2; and VO^{2+}, 2.0.

RESULTS AND DISCUSSION

Products and stoichiometry

The stoichiometry was determined by a spectrophotometric titration. The mole ratio of VO_2^+ to $Mo_2O_4^{2+}$ was 2.1 ± 0.1, in agreement with the oxidation of $Mo_2O_4^{2+}$ to molybdenum(VI) and the reduction of VO_2^+ to VO^{2+}. The formation of VO^{2+} was verified by comparison of the absorption spectra of the reaction mixture recorded on a Cary 14 spectrophotometer with that of a solution of $VOCl_2$ in the range 600–850 nm.

Kinetic results

The pseudo first-order rate constants (k_{app}) determined are presented in Table 1.

The experiments reported in Table 1 can be arranged into two groups:

(a) *Excess of* VO_2^+. The plots of apparent rate constants (k_{app}) against VO_2^+ initial concentrations at constant pH show a linear dependence. However, some of the straight lines obtained have negative intercepts. Therefore, a complex mechanism should be expected.

By plotting $[H^+][VO_2^+]^2/k_{app}$ against $[VO_2^+]$, a family of straight lines was found (their slopes are listed in Table 2). As shown in Fig. 1, a linear regression with proton concentration is found. In a similar way, $[VO_2^+]^2/k_{app}$ plotted against $[H^+][VO_2^+]$ appear to be linear but their slopes are reciprocal functions of $[H^+]$ (see Table 2).

An exhaustive analysis of the experimental data shows that the best fit is given by the following equation:

$$k_{app} = \frac{(1238[H^+]+811)}{(5.5\times10^{-4}+[H^+][VO_2^+])}[VO_2^+]^2. \quad (1)$$

(b) *Excess of dimer.* In an attempt to determine the reaction order with respect to the dimer, apparent rate constants were evaluated in excess dimer and are listed in Table 1. These rate constants were found to be proportional to the initial concentration of dimer.

Analysis of the intermediate spectrum

Mixtures of solutions of $Mo_2O_4^{2+}$ and VO_2^+ were followed by means of the stopped-flow technique, at different wavelengths. The time resolution of the obtained spectra employing a computational program[13] allowed us to conclude that this reaction proceeds via the formation of an intermediate with

an absorption maximum at around 330 nm. Its spectrum is shown in Fig. 2.

Efforts to detect an absorbing species different from VO^{2+} in the near-IR region (at about 750 nm), using the stopped-flow technique, were negative.

Influence of products

It was found that the addition of MoO_4^{2-} to the reaction mixtures did not affect the reaction kinetics.

The absorbances of solutions containing $Mo_2O_4^{2+}$ and VO^{2+} were measured. The mixtures of both species were found to be accompanied by changes in absorbance. However, if the only effect of VO^{2+} is the complexing of $Mo_2O_4^{2+}$, its influence on the kinetics should not be observed under conditions of excess VO_2^+. This was verified by addition of VO^{2+} to the mixtures of VO_2^+ and

$Mo_2O_4^{2+}$ in a series of stopped-flow experiments. The results are summarized in Table 3.

Mechanism

A dependence on VO_2^+ concentration similar to that represented by eq. (2) was observed for apparent rate constants in the oxidation of catechol, catechol derivatives and hydrazine[13] by VO_2^+.

To account for the observed rate law represented by eq. (1) and the linear dependence of k_{app} on dimer concentration under conditions of excess dimer, the following scheme is proposed:

$$D \overset{K_1}{\rightleftharpoons} DOH + H^+ \quad \text{(I)}$$

$$D + V \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C + H^+ \quad \text{(II)}$$

$$DOH + V \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} C \quad \text{(III)}$$

$$H^+ + C + V \xrightarrow{k_4} \text{Products} \quad \text{(IV)}. \quad (2)$$

For the sake of simplicity D is $Mo_2O_4^{2+}$ and C, a complex intermediate.

Table 3. Effect of VO^{2+} on the kinetics of the reaction between $Mo_2O_4^{2+}$ and VO_2^+, $[VO_2^+]_0 = 2$ mM, $[Mo_2O_4^{2+}]_0 = 0.25$ mM and $[HClO_4] = 2$ M

$10[VO^{2+}]_0$ (mM)	$k_{app} \pm \sigma$ (s^{-1})
1	3.03±0.16
2	3.05±0.02
3	3.13±0.19
4	3.14±0.17
5	3.29±0.16
10	3.15±0.08
15	3.43±0.20
20	3.18±0.24

The formation of transient species prior to the electron-transfer process has been postulated for other oxidations by VO_2^+ in acidic media.[14-16] In other VO_2^+ oxidations[13,17-19] there is direct evidence for the formation of an intermediate complex.

An alternative pathway could involve $HOVO^{2+}$ as oxidant. This species has been postulated in solutions of high sulphuric acid concentrations (> 2 M), however no physical evidence has been provided to support its existence under our present conditions.[20-22]

A pathway similar to (IV) was proposed in the literature for the oxidation of catechol and catechol derivatives.[13]

As a consequence of the observed first-order rate law in the dimer, no dissociative pathway for $Mo_2O_4^{2+}$ was included in the present mechanism. Furthermore, no oxidant-independent term was observed. A similar behaviour has been observed in other redox reactions where the $Mo_2O_4^{2+}$ dimer participates.[7,8] The absence of an oxidant-independent term suggests the retention of at least one oxo-bridge during the oxidation process.

The equilibrium (I) involves the presence of $Mo_2O_4(H_2O)_5OH^+$, whose reactivity has been postulated in the literature.[5,9] The equilibrium constant for the substitution of H_2O by OH— was determined for the Mo_2O_4(Hedta) complex,[23] where a value of the order of 1×10^{-3} M has been reported. The expected value for that constant in the $Mo_2O_4(H_2O)_6^{2+}$ complex is approx. 1×10^{-2} M.[4,5]

By applying the steady-state condition to C and assuming that $k_{-2}[H^+] \ll k_{-3}+k_4[VO_2^+][H^+]$, the following expression for the apparent rate constant under excess of VO_2^+ is found:

$$k_{app} = \frac{(k_2[H^+]+K_1k_3)}{(k_{-3}/k_4+[VO_2^+][H^+])}[VO_2^+]^2. \quad (3)$$

By comparison with the experimental expression (1), we obtain

$$k_2 = 1238\ M^{-1}s^{-1}$$
$$k_3K_1 = 811\ s^{-1}$$
$$k_{-3}/k_4 = 5.5 \times 10^{-4} M^2. \quad (4)$$

The molar absorptivity of the intermediate (C) can be estimated from the analysis of the initial absorbance, A_0, as measured at $\lambda = 360$ nm for a series of experiments under conditions of excess VO_2^+ in 2 M $HClO_4$. Let us define ΔA_0 as the difference between A_0 and the absorbance value corresponding to a mixture of VO_2^+ and $Mo_2O_4^{2+}$ without interaction under the same experimental conditions. The ΔA_0 values are given in Table 4.

Table 4. ΔA_0 values for a series of stopped-flow experiments in excess of dimer

$[VO_2^+]_0 \times 10^2$ (M)	$[Mo_2O_4^{2+}]_0 \times 10^3$ (M)	ΔA_0
0.5	1.00	0.473
0.5	0.50	0.235
0.5	0.37	0.256
0.5	0.25	0.160
0.5	0.12	0.053
1.0	1.00	1.486
1.0	0.50	0.591
1.0	0.37	0.579
1.0	0.25	0.387
1.0	0.12	0.201
2.0	1.00	2.502
2.0	0.50	0.934
2.0	0.37	0.438
2.0	0.25	0.683
2.0	0.12	0.330

The C concentration can be easily calculated taking into account that for the experiments reported in Table 4, $[VO_2^+]_0 \gg [Mo_2O_4^{2+}]_0$. The following expression can be derived for ΔA_0

$$\Delta A_0 = \frac{(K[VO_2^+]_0)}{(1+K[VO_2^+]_0)}(\varepsilon_C-\varepsilon_D)l[Mo_2O_4^{2+}]_0, \quad (5)$$

where $K = K_2/[H^+]$; ε_C and ε_D are the molar absorptivities of the intermediate and $Mo_2O_4^{2+}$, respectively. The plots of ΔA_0 against $[VO_2^+]_0[Mo_0O_4^{2+}]_0$ are straight lines with an intercept at zero and a slope of 1.64×10^5. These results are consistent with $K[VO_2^+]_0 \ll 1$.

From the experimental conditions given in Table 4 (with $l = 2$ cm), we can estimate $K \ll 50$ and $K_2 \ll 100$. An extinction coefficient of the intermediate, $\varepsilon_C \gg 1.64 \times 10^3\ M^{-1}\ cm^{-1}$ at $\lambda = 360$ nm, can be obtained.

This value of ε_C could mean that the intermediate, C, may be treated as a charge-transfer complex.

From the values for $K_1(\sim 1 \times 10^{-2})$ and $K_2(\ll 100)$, limit values are obtained for the individual rate constants, i.e. $k_{-2} \gg 12\ M^{-1}\ s^{-1}$, $k_3 > 8 \times 10^4\ M^{-1}\ s^{-1}$. Since $k_3 < k_4$, then $k_4 \gg 8 \times 10^4\ M^{-1}\ s^{-1}$ and $k_{-3} > 44\ s^{-1}$.

Since k_2 is lower than k_3 it is assumed that reaction (II) involves the formation of a protonated complex species (CH), whose deprotonation is the rate-determining step. In the frame of the oxidation reactions by VO_2^+, the value for k_4 is in agreement with the large redox potential couple Mo^V/Mo^{VI}.[29] At this point, some comments as to whether the reaction proceeds via an inner- or outer-sphere mechanism are pertinent.

For reaction (III), using an estimated value of 0.078 M for the outer-sphere association constant (K_{1p}), the first-order rate constant for the outer-sphere precursor complex, $k = k_3/K_{1p}$, is 1.04×10^6 s^{-1}, which can be compared with k_0 for both reactants. The water exchange rate constant (k_0) for $Mo_2O_4^{2+}$ is 2.9×10^4 s^{-1} as evaluated from the complexation of $Mo_2O_4^+$ by SCN^-.[9] For VO_2^+, k_0 is unknown,[24–26] but a lower limit of 6×10^4 s^{-1} was estimated by Kustin *et al.*[27] This value is too high for substitution of $Mo_2O_4^{2+}$. Regarding VO_2^+, the k value also seems to be higher than that estimated by Kustin *et al.* and therefore, we could be tempted to assume that the reaction proceeds via an outer-sphere mechanism. Moreover, no examples of inner-sphere activated complexes with water as a bridging ligand are known.[30,31] Although this type of electron-transfer process has been proposed for different reactions where either $Mo_2O_4^{2+}$ or VO_2^+ participate,[5,13] both ions may also behave as inner-sphere reactants.[7,8,28]

Regarding the previous study,[10] the different behaviour observed can be attributed to the nature of the reactants involved and the intermediate species. In HCl medium, different chloro complexes of molybdenum(V) can exist in equilibrium,[30] $Mo_2O_4Cl_6^{4-}$ and $Mo_2O_3Cl_8^{4-}$ being the most important species. The intermediate spectrum reported by Issa *et al.* shows a maximum at around 440 nm which seems to be coincident with that observed for $Mo_2O_3Cl_8^{4-}$.[31] Moreover, flash photolysis studies performed on $Mo_2O_4Cl_6^{4-}$ reported the formation of a monobridged intermediate whose spectrum presents a maximum at 420 nm.[32]

The intermediate detected in the present paper has an absorption maximum at around 330 nm. Some polyoxometallates of molybdenum and vanadium also absorb in this region.[33] Moreover, mixed-valence complexes of Mo^V—Mo^{VI} are characterized by strong bands at around 306 nm with ε of 4×10^3 M^{-1} cm^{-1}. Therefore complex C could be considered as a mixed-valence successor complex. An OH or/and oxo-group could bridge both reactants. This assumption is supported by the ability of VO^{2+} to complex $Mo_2O_4^{2+}$.

The rate laws obtained in this present work and in the previous study are quite different; a consequence of the nature of the molybdenum(V) and intermediate species in non-complexing and highly complexing media.

PREPARATION, CHARACTERIZATION, SPECTRAL AND THERMAL ANALYSES OF $(N_2H_5)_2MCl_4 \cdot 2H_2O$ (M = Fe, Co, Ni AND Cu); CRYSTAL STRUCTURE OF THE IRON COMPLEX

N. R. S. KUMAR, M. NETHAJI and K. C. PATIL*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-560012, India

(*Received* 16 *July* 1990; *accepted* 5 *October* 1990)

Abstract—Hydrazinium metal chlorides, $(N_2H_5)_2MCl_4 \cdot 2H_2O$ (where M = Fe, Co, Ni and Cu), have been prepared from the aqueous solutions of the respective metal chlorides and hydrazine hydrochloride ($N_2H_4 \cdot HCl$ or $N_2H_4 \cdot 2HCl$) and investigated by spectral and thermal analyses. The crystal structure of the iron complex has been determined by direct methods and refined by full-matrix least-squares to an R of 0.023 and R_w of 0.031 for 1495 independent reflections. The structure shows ferrous ion in an octahedral environment bonded by two hydrazinium cations, two chloride anions and two water molecules. In the complex cation $[Fe(N_2H_5)_2(H_2O)_2Cl_2]^{2+}$, the coordinated groups are in *trans* positions.

The coordination chemistry of hydrazine is of interest because of its ability to serve as an electron-pair donor. The presence of two, free electron pairs, as in other polybasic ligands, offers the possibility of several different types of coordination behaviour toward transition metal ions.[1–3] It can function as a monodentate[4,5] and bridging bidentate[6–10] ligand. Numerous examples of monodentate and bridging hydrazine have been demonstrated crystallographically. Monoprotonated hydrazine, the hydrazinium cation $N_2H_5^+$, still retains a basic site and is capable of coordinating to the metal. Complexes containing positively-charged hydrazinium ions are of increasing interest.[11,12]

During the course of our studies on the chemistry of hydrazine derivatives[13–24] we have prepared a number of hydrazinium metal sulphates, e.g. $N_2H_5Ln(SO_4)_2 \cdot H_2O$ (where Ln = La, Ce, Pr, Nd or Sm);[23] oxalates, e.g. $(N_2H_5)_2M(C_2O_4)_2 \cdot nH_2O$ (where M = Co, Ni or Cu);[24] $(N_2H_5)_2UO_2(C_2O_4)_2 \cdot H_2O$[21] and $(N_2H_5)_6(UO_2)_2(C_2O_4)_5 \cdot 2H_2O$.[20] The crystal structures of hydrazinium neodymium sulphate,[23] hydrazinium copper oxalate[24] and the hydrazinium uranyl oxalates[20,21] have also been solved. In continuation of these studies, we now report the preparation, characterization, spectral and thermal studies of $(N_2H_5)_2MCl_4 \cdot 2H_2O$ (where M = Fe, Co, Ni and Cu) and the crystal structure of $(N_2H_5)_2FeCl_4 \cdot 2H_2O$.

RESULTS AND DISCUSSION

The reaction between aqueous solutions of metal chlorides and $N_2H_4 \cdot HCl$ or $N_2H_4 \cdot 2HCl$ yielded complexes of the general formula $(N_2H_5)_2MCl_4 \cdot 2H_2O$ (where M = Fe, Co, Ni and Cu). The results of chemical analysis (Table 1) are in good agreement with the proposed formulae. Hydrazine and its salts are strong reducing agents in aqueous solutions[3] and reduce iron(III) to iron(II), and copper salts to copper metal. Heating of the solution is required in the case of iron for the complete reduction of iron(III) to iron(II). In the case of copper, reduction to the metal can be prevented by employing $N_2H_4 \cdot 2HCl$ which is known to dissociate in water to form $N_2H_5^+$, H_3O^+ and Cl^- ions, providing the required acidic medium. This method of preparing $(N_2H_5)_2CuCl_4 \cdot 2H_2O$ from $N_2H_4 \cdot 2HCl$ and $CuCl_2 \cdot 2H_2O$ is much simpler compared with the procedure reported earlier.[11]

*Author to whom correspondence should be addressed.

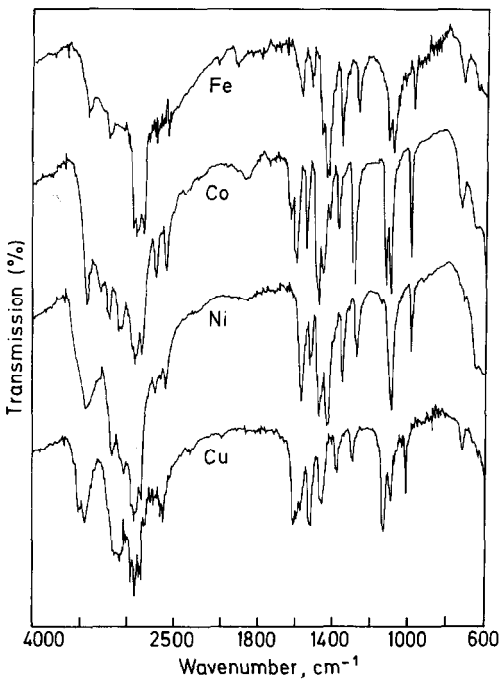

Fig. 1. IR spectra of $(N_2H_5)_2MCl_4 \cdot 2H_2O$.

IR spectra

IR spectra of all the complexes are similar (Fig. 1) and show characteristic absorption bands of $N_2H_5^+$: ~ 2650 cm^{-1} [ν(N—H) of —NH_3^+],[25] ~ 1100 cm^{-1} [ω(N—H) of —NH_3^+].[26] The N—N stretching of free $N_2H_5^+$ is known[27] to occur at 965 cm^{-1} and when it is coordinated, ν(N—N) invariably shifts to 1000 cm^{-1}. The observed ν(N—N) frequencies in the region 990–1015 cm^{-1} (Table 1) indicate the presence of coordinated $N_2H_5^+$ in all the complexes.

Electronic spectra and magnetic susceptibility measurements

The absorption bands of $(N_2H_5)_2MCl_4 \cdot 2H_2O$ in the visible region and the room temperature magnetic susceptibility values are included in Table 1. The electronic spectral data are comparable with those reported for octahedral cobalt(II), nickel(II) and copper(II).[28–31] Magnetic moment values correspond to spin-only values for cobalt(II), nickel(II) and copper(II) ions.

Thermal analysis

The results of TG–DTA studies of all hydrazinium metal chlorides are summarized in Table 2. The compositions of the intermediates proposed are those which best fit the observed weight loss. A typical TG–DTA curve of $(N_2H_5)_2CuCl_4 \cdot 2H_2O$ is shown in Fig. 2. The first step in the decomposition sequence corresponds to the loss of water molecules. The temperature range at which this decomposition occurs (60–85°C) indicates the possibility of non-coordination of water molecules to the metal. In the second step, the anhydrous compound decomposes, losing HCl and forming a hydrazine adduct. Evolution of HCl in this step has been confirmed by testing the evolved gases qualitatively. It is interesting to note that this intermediate further decomposes to form cuprous chloride, as evidenced by an endothermic DTA peak at 410°C corresponding to the melting of Cu_2Cl_2. This further decomposes to cuprous oxide at higher temperature.

The results of the other complexes show, more or less, a similar trend. They lose water in the first step followed by HCl and then form N_2H_4 adducts of different compositions. The temperature range at which the loss of water occurs (90–130°C) does not indicate conclusively whether water is bonded

to the metal or not. All the complexes decompose to their respective metal oxides via metal chlorides.

Coordination around the metal

The spectral and magnetic data coupled with thermal analysis suggest that the metal ions in iron, cobalt, nickel and copper complexes are octahedrally coordinated. IR spectra also suggest the coordination of $N_2H_5^+$ ions, but the nature of the coordination of other ligands is not clear. Furthermore, the relative positions of coordinated ligands cannot be determined from these data. For this reason, a single crystal X-ray analysis has been carried out.

Description of the structure of $(N_2H_5)_2FeCl_4 \cdot 2H_2O$

Crystal data for the complex are given in Table 3 and the bond lengths and angles are listed in Table 4. The structure of $(N_2H_5)_2FeCl_4 \cdot 2H_2O$ consists of chloride ions and the complex cation $[Fe(N_2H_5)_2(H_2O)_2Cl_2]^{2+}$. A perspective view of this complex cation showing its conformation and the atom numbering system is presented in Fig. 3.

The metal coordination site in the molecule is a distorted octahedron made up by two nitrogens (one from each $N_2H_5^+$ ion), two water oxygens and two chlorines. The cation $[Fe(N_2H_5)_2(H_2O)_2Cl_2]^{2+}$ possesses a pseudo-inversion centre as the coordinated atoms are *trans* to each other.

The observed metal–chlorine distances [2.441(1)

Z	2	Weights[a]	A, 0.002184
Crystal colour	Colourless	R	0.023
Crystal size (mm)	0.35 × 0.25 × 0.20	R_w	0.031

[a] Weighting scheme, $w = 1.0/[\sigma^2(F_o) + A|F_o|^2]$.

and 2.431(1) Å] are less than the distance of 2.526(1) Å found in the octahedral $[Fe(H_2O)_4Cl_2]$.[32,33] The metal–oxygen bonds in the present structure, with distances of 2.188(3) and 2.163(2) Å, are longer than the ones found in $[Fe(H_2O)_4Cl_2]$ [2.121(1) and 2.086(1) Å]. This indicates a relatively weaker metal–oxygen interaction which has been supported by thermal analysis.

The metal–nitrogen bond lengths [2.232(2) and 2.212(2) Å] are also larger than the estimated value of 2.15 Å for iron(II)–NH_3 complexes.[34] Comparison of metal–nitrogen bond lengths with metal–oxygen bond lengths reveal that the former are larger than the latter (Table 3). Such differences between metal–oxygen and metal–nitrogen bonds have not been observed in the complexes of neutral semicarbazide molecules, where the bonds in each of the two pairs are equal: Cu—O 1.97, Cu—N 1.99 Å; and Zn—O 2.06, Zn—N 2.07 Å.[35] The relatively longer Fe—N bonds compared with Fe—O bonds in the present structure thus indicate weaker Fe—N interaction.

The N—N distances found for the $N_2H_5^+$ ions are 1.480(4) and 1.429(2) Å. The difference in the N—N bond lengths, as well as the low temperature factors observed for these atoms, may be due to absorption effects. The average bond length of 1.452 Å is in good agreement with the value [1.457(7) Å] reported for $N_2H_5CuCl_3$.[11] The Fe—N—N′ angles in the present case are 122.5(2) and 120.2(2)°. A similar value has been reported for the copper complex [119.1(3)°].[11]

Structure of $(N_2H_5)_2CoCl_4 \cdot 2H_2O$

Preliminary studies on single crystals of the complex have been carried out. Unit cell dimensions and the space group were determined on a Weissenberg camera and were subsequently refined on a diffractometer. The systematic absences indicate the space group to be $P2_1/c$. These data are presented in Table 5.

As the space group is $P2_1/c$ and $Z = 2$, the centres of the molecules, namely the metal atoms, must lie in special positions which are inversion centres in the present case. This unequivocally shows that the coordinated atoms in the cobalt complex are also *trans* to each other as in the case of the iron complex. From these data we can infer that the most probable structure for the cobalt complex would be similar to that for the iron complex, viz. *trans*-$[Co(N_2H_5)_2(H_2O)_2Cl_2]Cl_2$.

Structure of $(N_2H_5)_2NiCl_4 \cdot 2H_2O$

Attempts to obtain single crystals of this complex were unsuccessful, but from the similarities of the spectral and thermal properties of this complex with those of the cobalt complex, it is possible to suggest that the structure of the nickel complex is similar to that of the iron and cobalt complexes.

Structure of $(N_2H_5)_2CuCl_4 \cdot 2H_2O$

From magnetic studies, Brown *et al.*[11] have assigned a *trans*-$[Cu(N_2H_5)_2Cl_4] \cdot 2H_2O$ structure to the copper complex. However, considering the similarities in spectral and thermal properties of this complex with the other complexes, it is probable that the structure would be *trans*-$[Cu(N_2H_5)_2(H_2O)_2Cl_2]Cl_2$.

EXPERIMENTAL

Preparations

The complexes were obtained from aqueous solutions of the respective metal chlorides and $N_2H_4 \cdot HCl$ or $N_2H_4 \cdot 2HCl$. Preparative methods for individual complexes vary and are described below.

$(N_2H_5)_2FeCl_4 \cdot 2H_2O$. The iron complex was prepared by refluxing an aqueous solution of $FeCl_3 \cdot 6H_2O$ (5.0 g) and $N_2H_4 \cdot HCl$ (7.6 g) in 200 cm^3 of water for 30 min. The resulting colourless solution was concentrated on a water bath and allowed to crystallize in a vacuum desiccator. Colourless plates which appeared after a week were removed from the solution, dried by pressing between filter paper and stored in an air-tight bottle.

$(N_2H_5)_2CoCl_4 \cdot 2H_2O$. The above complex was prepared by mixing aqueous saturated solutions of $CoCl_2 \cdot 6H_2O$ and $N_2H_4 \cdot HCl$ in a 1 : 2 mole ratio. The precipitate that initially formed was filtered off and the solution was left exposed to air for slow evaporation. Dark pink coloured crystals separated out from the solution, which were filtered, washed with alcohol and ether and stored in a desiccator.

Alternatively, the complex can be prepared by decomposing solid $N_2H_5Co(N_2H_3COO)_3 \cdot H_2O$[36] in dilute HCl (6 N) and keeping the solution for slow evaporation.

$(N_2H_5)_2NiCl_4 \cdot 2H_2O$. The nickel complex was prepared in a similar way, either from aqueous solu-

tions of nickel chloride and hydrazine hydrochloride or by decomposing $N_2H_5Ni(N_2H_3COO)_3 \cdot H_2O$[36] in dilute HCl. But in the present case a green crystalline product was obtained, which was found to be a hydrazine adduct, $(N_2H_5)_2NiCl_4 \cdot 2H_2O \cdot 0.5N_2H_4$. This green product was removed from the solution as and when it formed and later the hydrazinium nickel chloride complex separated out from the solution as a greenish-blue solid in small amounts.

$(N_2H_5)_2CuCl_4 \cdot 2H_2O$. The copper complex was prepared by adding a saturated solution of $CuCl_2 \cdot 4H_2O$ to a saturated solution of $N_2H_4 \cdot 2HCl$, in a 1 : 2 mole ratio, with vigorous stirring. The copper complex precipitated out as a blue crystalline mass in ~ 2 min, and was filtered off from the solution immediately and air-dried.

Physico-chemical techniques

The composition of the complexes was determined by chemical analysis.[37,38] Metal contents were estimated by titrating with EDTA, the hydrazine content by titrating with KIO_3 under Andrews conditions[3] and the chloride content by Volhard's method.

IR spectra of the complexes in the region 4000–600 cm^{-1} were recorded as Nujol mulls using a Perkin–Elmer 781 spectrophotometer. Electronic spectra in the visible region were recorded using a Hitachi U-3400 spectrophotometer. The spectra in the solid state were obtained by dispersing the samples in Nujol. Room temperature magnetic susceptibility measurements were made using a Faraday balance. Thermogravimetry (TG) and Differential Thermal Analysis (DTA) experiments were carried out using a simultaneous TG–DTG–DTA TA-1500 instrument (Ulvac Sinku Riko, Japan). All the experiments were carried out in air, using 6–8 mg of samples. Platinum cups were used as sample holders and alumina as reference. The heating rate employed was 10°C min^{-1}

X-ray work

A well-developed crystal of dimensions $0.35 \times 0.25 \times 0.20$ mm was mounted in a Lindeman capillary tube in order to prevent decomposition. Cell constants and corresponding standard deviations were obtained from a least-squares refinement of 25 reflections automatically centred on a Nonius CAD-4 diffractometer. The density of the crystal was measured by the flotation method using a chloroform–bromoform mixture.

Intensity data were collected in the usual manner.

Structure solution and refinement

The structure was solved by direct methods (SHELXS-86)[39] and refined by full-matrix least-squares procedures using the SHELX-76 system of programs.[40] Hydrogen atoms were located in the difference map and were included without refinement. Anisotropic thermal parameters were introduced for all non-hydrogen atoms. A further improvement was obtained after using weights. The final R and R_w values achieved in this way are 0.023 and 0.031, respectively.

All the details regarding the data collection and structural analysis are listed in Table 3. Major calculations were carried out on a DEC 1090 computer. The ORTEP-II program[41] was used to draw Fig. 3. Scattering factors for iron were taken from Ref. 42 and the values available in SHELX-76 were used for the other atoms.

PYROLYTIC REACTIONS OF AZIDOCHROMIUM(III) PORPHYRINS AND AZIDOIRON(III) PORPHYRINS IN THE SOLID STATE

HIROYUKI SUGAYA, JUNICHI TACHIBANA and TAIRA IMAMURA*

Department of Chemistry II, Faculty of Science, Hokkaido University, Sapporo 060, Japan

(*Received* 8 *August* 1990; *accepted* 5 *October* 1990)

Abstract—Azidochromium(III) tetraphenylporphyrin, $Cr^{III}(tpp)N_3$ (tpp = 5,10,15,20-tetraphenylporphyrinato), and azidoiron(III) tetraphenylporphyrin, $Fe^{III}(tpp)N_3$, in the solid state, were pyrolysed under 10^{-5}–10^{-6} torr at around 250°C, liberating nitrogen gas to afford $Cr^{II}(tpp)$ and $Fe^{II}(tpp)$ as final products, respectively. $Cr^{V}(tpp)N$ formed in the process of the $Cr^{III}(tpp)N_3$ pyrolysis is reduced to $Cr^{II}(tpp)$, although pure $Cr^{V}(tpp)N$ prepared independently is not pyrolysed under the same conditions. In the presence of dioxygen in the toluene solutions of these pyrolysed products, $Cr^{IV}(tpp)O$ or $[Fe(tpp)]_2O$ is formed. The mechanisms of these reactions in the solid state are discussed in comparison with those in solution.

The chemistry of azidometalloporphyrins is of great interest because these complexes undergo versatile reactions, forming either metal(II) porphyrins or nitridometal(V) porphyrins by their sensitive dependency on the conditions and the states of the reaction media. For example, both the pyrolysis of $Fe^{III}(tpp)N_3$ in xylene[1] and its photo-irradiation in THF afford the same complex; a μ-nitrido dimer of $[Fe(tpp)]_2N$.[2] However, in the presence of pyridine, the $Fe^{III}(tpp)N_3$ complex is photoreduced to form $Fe^{II}(tpp)(py)_2$,[2] suggesting that the μ-nitrido dimer of $[Fe(tpp)]_2N$ is formed by the reaction of unstable Fe(tpp)N with $Fe^{II}(tpp)$. On the other hand, the photo-irradiation of $Mn^{III}(P)N_3$ (P = porphyrinato) in organic solvents[2–4] or pyrolysis in the solid state,[5] gives the corresponding monomeric complex of $Mn^{V}(P)N$, causing cleavage of the N—N_2 bond of the axial ligand N_3. The photo-irradiation of $Mn^{III}(tpp)N_3$ in 2-methyltetrahydrofuran causes simultaneous oxidation and reduction of the central metal to produce $Mn^{V}(tpp)N$ and $Mn^{II}(tpp)$.[6] In the reaction processes of these azidometalloporphyrins, metal(II) porphyrins are indicative of playing a key role.

In the present paper, the pyrolyses of $Cr^{III}(tpp)N_3$ and $Fe^{III}(tpp)N_3$ in the solid state are reported in comparison with their reactions in solution. The study is especially focused on the mechanism of reaction in the solid state where the complexes having bulky porphyrinato ligands are supposed to be less mobile than they are in solution.

EXPERIMENTAL

Azidochromium(III) tetraphenylporphyrin† was prepared by the reaction of $Cr^{III}(tpp)Cl$ with HN_3,[8] dried at 120°C *in vacuo* and stored in the dark. Found: C, 74.3; H, 3.9; N, 13.8. Calc. for $C_{44}H_{28}N_7Cr$: C, 74.8; H, 4.0; N, 13.9%. Nitridochromium(V) tetraphenylporphyrin was prepared by the reaction of $Cr^{III}(tpp)Cl$ with NaOCl in the presence of NH_3, with reference to the reported method.[8] Found: C, 77.6; H, 4.3; N, 10.1. † In the preliminary study of the reactivity of $Cr(tpp)N_3$ we observed that this complex reacts with Mn(tpp)N in dichloromethane to produce Cr(tpp)N and $Mn(tpp)N_3$, as well as the nitrogen atom transfer reaction between Cr(tpp)Cl and Mn(tpp)N reported recently by Bottomley and Neely.[7]

with molecular sieves in the vessel on a vacuum line. Toluene must be purified, repeatedly and scrupulously, because when purification is insufficient $Cr^{III}(tpp)N_3$ changes to $Cr^{IV}(tpp)O$. The mechanism of the reaction is supposed to be that $Cr^{III}(tpp)N_3$ is first reduced by impurities such as thiophene to form $Cr^{II}(tpp)$, which is successively oxidized by dioxygen to form $Cr^{IV}(tpp)O$. Toluene was degassed rigorously by repeated freeze–thaw cycles, and vacuum-transferred into the vessel with an optical cell containing the pyrolysed products in the solid state. For preparations of the sample solutions, break–seal techniques were used to completely eliminate contamination by air. All samples in the solid state and in solution were manipulated in the dark, avoiding any photochemical reactions.

Electronic spectra were recorded on a Hitachi 808 spectrophotometer. ESR spectra were measured with a JES-FE1X spectrometer operating at 100 kHz modulation. Thermogravimetric analyses (TG) were carried out on a Cahn 2000 electrobalance. A Hitachi RMU-6 EI mass spectrometer was used to detect the gases evolved in the pyrolyses of $Cr^{III}(tpp)N_3$ and $Fe^{III}(tpp)N_3$.

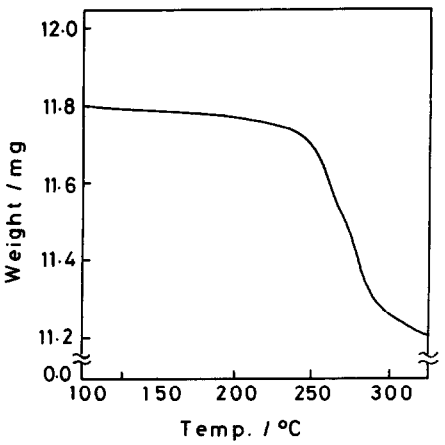

Fig. 1. Thermogravimetric analysis of $Cr^{III}(tpp)N_3$ under a 17 torr argon atmosphere.

RESULTS AND DISCUSSION

Pyrolysis of $Cr^{III}(tpp)N_3$

Our preliminary study showed that the pyrolysis of $Cr^{III}(tpp)N_3$ in the solid state yields some other complex in addition to $Cr^{V}(tpp)N$, depending on the conditions.[5] Thermogravimetric measurements showed that $Cr^{III}(tpp)N_3$ is pyrolysed at around 240°C under a 17 torr argon atmosphere (Fig. 1). The loss in weight was larger than the decrease expected by the formation of $Cr^{V}(tpp)N$. The pyrolysis was accompanied by the disappearance of the IR stretching frequency of the axial N_3 ligand observed at 2060 cm^{-1} (KBr pellet). Liberation of nitrogen gas in the pyrolysis was detected by mass spectral measurements. When the powder of the complex was pyrolysed for 30 min under 10^{-5}–10^{-6} torr at 250°C, after drying at 120°C, the products dissolved in toluene showed the spectrum with main absorption peaks at 421, 446 and 542 nm. The peak at 446 nm is due to the parent complex of $Cr^{III}(tpp)N_3$. The peaks at 421 and 542 nm almost agree with the peaks of $Cr^{V}(tpp)N$. ESR measurements of the toluene solution also confirmed that the products contained $Cr^{V}(tpp)N$, i.e. typical ESR signals ($\bar{g} = 1.98$) of ^{53}Cr ($I = 3/2$) coupled with five nitrogens with 11 lines were observed.[8,9] Usually $Cr^{V}(tpp)N$ is very resistant to pyrolysis. In practice, the $Cr^{V}(tpp)N$ complex prepared independently was not pyrolysed under the same conditions. However, the introduction of dry dioxygen or air to the above toluene solution of pyrolysed $Cr^{III}(tpp)N_3$ leads to a decrease in absorbance around 421 nm with the concomitant appearance of the absorption peak at 432 nm. The new peak is ascribed to $Cr^{IV}(tpp)O$.[10] The resulting absorption spectrum is composed of the absorption bands of $Cr^{V}(tpp)N$ (421 nm), $Cr^{IV}(tpp)O$ (432 nm) and the parent $Cr^{III}(tpp)N_3$ complex (446 nm) (Fig. 2).

The absorption spectrum of the toluene solution of the products, formed by 4 h pyrolysis of $Cr^{III}(tpp)N_3$, showed peaks at 423 and 542 nm. Introduction of dry dioxygen into the solution caused complete disappearance of these absorptions, with a simultaneous increase in the absorbances at 375, 432 and 544 nm due to the formation of $Cr^{IV}(tpp)O$ (Fig. 3). When a small amount of dioxygen was introduced into the solution prepared after pyrolysis, the μ-oxodimer of $[Cr(tpp)]_2O$ was formed. $Cr^{IV}(tpp)O$[11] and $[Cr(tpp)]_2O$[10,12] are formed by the reactions of $Cr^{II}(tpp)$ with dioxygen. These results indicate that only $Cr^{II}(tpp)$ was formed by 4 h pyrolysis, i.e. $Cr^{V}(tpp)N$ produced during the course of pyrolysis was reduced to $Cr^{II}(tpp)$ by the successive pyrolysis.* Namely, the pyrolysis of $Cr^{III}(tpp)N_3$ in the solid state affords $Cr^{II}(tpp)$ and $Cr^{V}(tpp)N$ simultaneously and the resulting $Cr^{V}(tpp)N$ is then reduced to $Cr^{II}(tpp)$.

$$2Cr(tpp)N_3 \longrightarrow 2Cr(tpp) + 3N_2. \quad (1)$$

When $Cr^{III}(tpp)N_3$ was refluxed for a few minutes

* When the pyrolysis was performed at 10^{-4}–10^{-5} torr for 4 h, relatively large amounts of $Cr^{V}(tpp)N$ were formed.

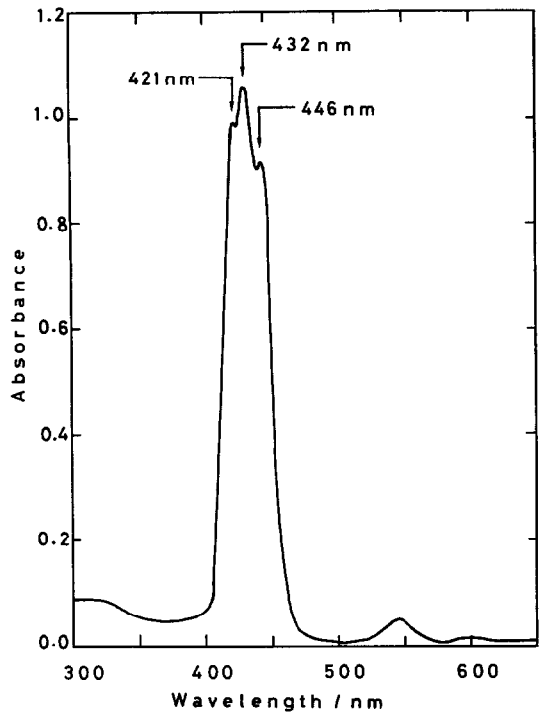

Fig. 2. Absorption spectrum, at 25°C, of the dioxygen-introduced toluene solution of the products formed by 30 min pyrolysis of $Cr^{III}(tpp)N_3$ in the solid state, at 250°C under 10^{-5}–10^{-6} torr.

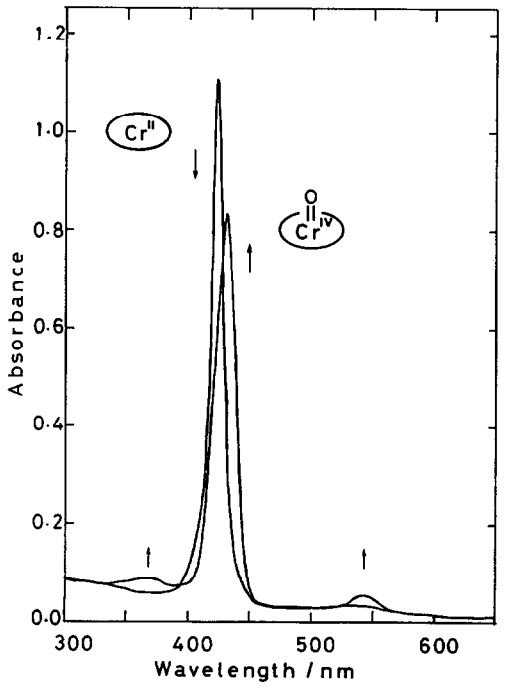

Fig. 3. Absorption spectra, at 25°C, of the toluene solution of $Cr^{II}(tpp)$ formed by 4 h pyrolysis of $Cr^{III}(tpp)N_3$ in the solid state and of $Cr^{IV}(tpp)O$ formed by the introduction of dioxygen into the solution.

in toluene or benzene in the dark, $Cr^{IV}(tpp)O$ was formed, suggesting the formation of $Cr^{II}(tpp)$ as the product in the absence of dioxygen. The formation of $Cr^{V}(tpp)N$ was not observed. The benzene solution of $Cr^{V}(tpp)N$ prepared separately was not reduced to form $Cr^{II}(tpp)$ or $Cr^{IV}(tpp)O$ in the presence of dioxygen by 3 h reflux. This suggests that the reduction path to $Cr^{II}(tpp)$ is advantageous in the pyrolytic reaction of $Cr^{III}(tpp)N_3$ in solution, compared with the pyrolytic reaction in the solid state. $Cr^{III}(tpp)Cl$ in benzene or toluene is not pyrolysed.

Pyrolysis of $Fe^{III}(tpp)N_3$

In contrast with the reported pyrolytic reaction of $Fe^{III}(tpp)N_3$ in xylene solution which afforded the μ-nitrido dimer of $[Fe(tpp)]_2N$,[1] the pyrolysis of the solid powder of $Fe^{III}(tpp)N_3$, under 10^{-5}–10^{-6} torr at 250°C for 4 h, gave $Fe^{II}(tpp)$ as the product. EI mass spectral measurements confirmed the liberation of nitrogen gas in the pyrolysis. The absorption spectrum of the product dissolved in toluene showed that no porphyrin complexes other than $Fe^{II}(tpp)$ were formed: only characteristic bands at 418, 444(sh) and 540 nm[13] were observed, as shown in Fig. 4.

$$2Fe^{III}(tpp)N_3 \longrightarrow 2Fe^{II}(tpp) + 3N_2 \qquad (2)$$

Introduction of dry dioxygen into the solution afforded $[Fe(tpp)]_2O$,[14] although $Fe^{III}(tpp)N_3$ was pyrolysed for a short time (30 min), no forma-

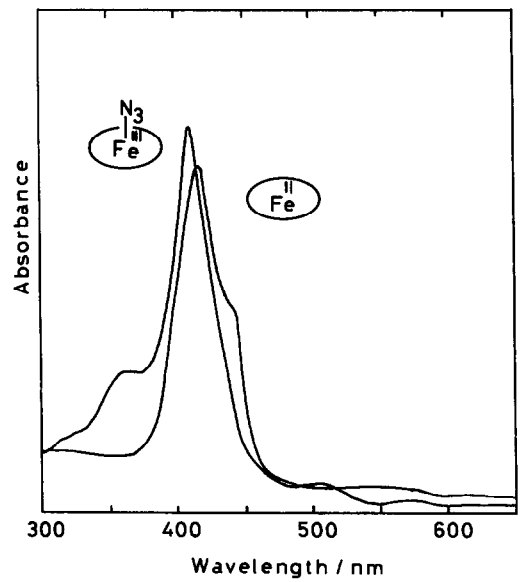

Fig. 4. Absorption spectra, at 25°C, of the toluene solutions of the parent $Fe^{III}(tpp)N_3$ and the pyrolysed product of $Fe^{II}(tpp)$.

tion of $[Fe(tpp)]_2N$ was observed. The following scheme for the pyrolysis of $Fe^{III}(tpp)N_3$ in xylene was one of those presented by Cohen and Summerville[1]:

$$Fe(tpp)N_3 \longrightarrow Fe(tpp)N + N_2 \quad (3)$$

$$Fe(tpp)N + Fe(tpp)N_3 \longrightarrow [Fe(tpp)]_2N_4 \quad (4)$$

$$[Fe(tpp)]_2N_4 \longrightarrow 2Fe(tpp)N_2 \quad (5)$$

$$2Fe(tpp)N_2 \longrightarrow Fe(tpp) + N_2 \quad (6)$$

$$Fe(tpp)N + Fe(tpp) \longrightarrow [Fe(tpp)]_2N. \quad (7)$$

The formation of $[Fe(tpp)]_2O$ in the pyrolysis with a low concentration of $Fe^{III}(tpp)N_3$ in xylene[1] suggests the presence of $Fe^{II}(tpp)$ as an intermediate in the solution pyrolysis. The photolysis of $Fe^{III}(tpp)N_3$ in THF also affords $Fe^{II}(tpp)(py)_2$ in the presence of pyridine, while in the absence of pyridine the product is $[Fe(tpp)]_2N$.[8] The formation of $Fe^{II}(tpp)(py)_2$ is not in conflict with the above steps (4)–(6) after photochemical fission of the N—N_2 bond of $Fe(tpp)N_3$. $Fe^{II}(tpp)$ formed in step (6) must be stabilized in the presence of pyridine or dioxygen by the formation of $Fe^{II}(tpp)(py)_2$ or $[Fe(tpp)]_2O$, the reaction in step (7) not occurring.

However, in the pyrolysis of the solid state, $Fe^{II}(tpp)$ only formed as the final product although there was no stabilizing ligand such as pyridine. This suggests that an intermediate complex of Fe(tpp)N is reduced by some agents to form $Fe^{II}(tpp)$, as in the $Cr^{III}(tpp)N_3$ system.

The following scheme reasonably represents the formation of metal(II) porphyrins in solid-state pyrolyses:

$$M(tpp)N_3 \longrightarrow M(tpp)N + N_2 \quad (M = Fe \text{ or } Cr) \quad (8)$$

$$M(tpp)N_3 \longrightarrow M(tpp) + {}^{\bullet}N_3 \quad (9)$$

$$M(tpp)N + {}^{\bullet}N_3 \longrightarrow M(tpp) + 2N_2 \quad (10)$$

$$2\,{}^{\bullet}N_3 \longrightarrow 3N_2. \quad (11)$$

The reactions of steps (8) and (9) proceed competitively. When the metal, M, is iron the unstable Fe(tpp)N formed by step (8) may react immediately with the ${}^{\bullet}N_3$ radical produced by the homolytic cleavage of the M—N_3 bond in step (9), affording $Fe^{II}(tpp)$ in step (10). The main difference between the two schemes for the solution system and for the solid-state system is that Fe(tpp)N dimerizes with $Fe^{II}(tpp)$ in the former system and Fe(tpp)N is reduced by ${}^{\bullet}N_3$ in the latter.* These differences may be caused by the greater mobility problems of bulky porphyrins in the solid state than in solution. The solid state may be disadvantageous to the collision between Fe(tpp)N and $Fe^{II}(tpp)$, as in step (7), but may favour the progress of step (10). This mechanism also reasonably explains the $Cr^{III}(tpp)N_3$ pyrolytic system in the solid state. In this system, $Cr^{V}(tpp)N$ was observed as an intermediate of the pyrolysis, which is unsurprising since $Cr^{V}(tpp)N$ has been stably isolated, while Fe(por)N is very unstable and was only detected recently by laser irradiation of thin films of the corresponding azido complexes at 30 K.[15] The homolytic cleavage of the Cr—N_3 bond in $Cr^{III}(tpp)N_3$ [step (9)] also seems feasible for pyrolysis in solution.

* Although the azide radical, ${}^{\bullet}N_3$, acts as an oxidizing agent for Fe(tpp)N, the metal centre of the iron atom is reduced to yield Fe(tpp).

(*Received* 26 *June* 1990; *accepted* 17 *October* 1990)

Abstract—The chemical speciation of tin(II)– and tin(IV)–pyrophosphate systems have been researched by determining formation constants through pH potentiometry. Four protonation log constants for pyrophosphate were found (8.14, 14.01, 15.78 and 16.63) and seven constants are required to describe the tin(II) system and five constants for the tin(IV) system. The solubility product for $Sn_2P_2O_7$ was measured by both precipitation and dissolution approaches.

It has long been realized that the precise chemical form in which a trace element exists, i.e. its chemical speciation, has a most profound effect upon both the toxicology and bioavailability of that element. In fluids of physiological importance, for example, milk, blood plasma and saliva, the concentrations of the component metals and ligands are generally far below the levels analysable by standard laboratory procedures and, in such cases, computer modelling can identify the most abundant complexes and can provide a measure of their bioavailability.

In modelling the speciation of tin from dietary sources, it has been necessary to evaluate all possible metal–ligand interactions and, for this reason, the solubility product and stability constants of the tin–pyrophosphate systems were measured. The complexation of tin by the pyrophosphate ligand is of particular significance for the following reasons:

(i) Tin is present in food, medicine, healthcare agents, and our environment. The speciation of this element between organic and inorganic forms and between solid and aqueous solution phases of the latter determines whether the metal is a threat or a benefit and whether it is mobile in the geosphere or bioavailable from the gastrointestinal tract.[1,2]

(ii) Phosphates are widely distributed in nature and tin(II) is likely to encounter phosphates in ship-hull antifouling paints, in food and in biofluids. Thus, a knowledge of the solubility product of tin(II)–pyrophosphate is essential for modelling speciation.

(iii) Stannous pyrophosphate itself has found application in topical dental therapies for more than 15 years.[3–6] Since it is known that both stannous fluoride and stannous chloride function as bacteriostatic agents,[7] it seems likely that the efficacy of $Sn_2P_2O_7$ as an anticaries treatment and as an efficient plaque suppressor is related to the stannous ions rather than to the ligating moiety.

(iv) Pyrophosphate is a biological anion of some importance since many biosynthetic reactions are made irreversible by the hydrolysis of inorganic pyrophosphate. It is also instrumental in the synthesis of terpenes and steroids. Although tin is not recognized as an essential

* Present address: Department of Chemistry, Faculty of Science and Engineering, Manchester Polytechnic, John Dalton Building, Manchester M1 5DG, U.K.

† Author to whom correspondence should be addressed.

trace element in man, living cytoplasm functions as an efficient cation exchanger[8] and thus tin is often present in measurable amounts in the body. It is, therefore, not difficult to imagine complexation occurring *in vivo* between the essential ligand and the non-essential contaminating metal.

This paper compares values of stannous pyrophosphate formation constants obtained in this study with previously reported figures and presents a value for the $Sn_2P_2O_7$ solubility product determined from the cells in which titrations precipitate and also from dissolving the solid. Finally, the more difficult stannic pyrophosphate system was analysed by pH potentiometry and the "best" set of formation constants derived. This quantification of the tin pyrophosphate system will, thus, permit computer simulation models of the speciation chemistry under various conditions.

EXPERIMENTAL

Theory of measurement

Precipitation of tin complexes in the titration vessel during a potentiometric titration is a relatively common phenomenon. Usually when this occurs, the titration is terminated and the electrodes removed from the solution. However, provided that the composition of precipitated tin species is known and that the kinetics of precipitation is rapid, it is possible to calculate the solubility product (K_{sp}), and solubility (S_o) of the solid species and also the solution formation constants (β_{pqr}) from experimental data within the precipitation-free pH range. The detailed procedure is described later and refers to formation of tin pyrophosphate complexes at 25°C and ionic strength 150 mmol dm^{-3} chloride.

Materials

Tetrasodium pyrophosphate (Analar, BDH Ltd) was used without further purification. Sodium hydroxide and hydrochloric acid solutions were freshly prepared from concentrated stock solution ampoules (Convol, BDH Ltd). Stannous pyrophosphate was provided by Unilever Research, U.K.

A stock solution of tin was prepared by dissolving a weighed amount of stannous chloride dihydrate (Analar, BDH Ltd) in hydrochloric acid (100 mmol dm^{-3}). Any undissolved solid was removed by vacuum filtration and the solution made up to the mark with hydrochloric acid (100 mmol dm^{-3}). The tin concentration of these freshly prepared solutions was then determined by potassium iodate redox titrations using amaranth indicator.[9] The hydrogen ion concentration was measured using strong acid–strong base titrations.[10]

All solutions were prepared using distilled degassed doubly-deionized water and maintained at an ionic strength of 150 mmol dm^{-3} chloride by the addition of sodium chloride (Analar, BDH Ltd).

Method

Pyrophosphate (Pyr^{4-}) protonation constants and tin(II)–pyrophosphate formation constants were determined by glass electrode (Russell) potentiometric titration in a vessel thermostatted at 25.0 ± 0.1°C. The electrodes were calibrated with respect to the hydrogen ion by performing strong acid–strong base titrations.[10] A stream of pure nitrogen (with a $SnCl_2$ trap for oxygen followed by ionic background traps to prevent spray) was passed through the titration solutions in order to eliminate dissolved oxygen and carbon dioxide.

Protonation curves for the ligand were obtained at a variety of different total pyrophosphate concentrations (4–25 mmol dm^{-3}). Similarly, the metal complex formation curves were obtained at different pyrophosphate–tin ratios and for different total pyrophosphate (10–50 mmol dm^{-3}) and tin (3–25 mmol dm^{-3}) concentrations. Potentiometric titrimetry was carried out using three methods, namely:

(i) with both tin and pyrophosphate in the titration vessel;
(ii) tin in the vessel and pyrophosphate in the burette; and
(iii) pyrophosphate in the vessel and tin in the burette.

Titration data analysis

A general equilibrium involving Sn^{2+} cations (M), Pyr^{4-} anions (L) and H^+ ions and its overall formation constant can be expressed thus:

$$pM + qL + rH \rightleftharpoons M_pL_qH_r;$$

$$\beta_{pqr} = \frac{[M_pL_qH_r]}{[M]^p[L]^q[H]^r}, \qquad (1)$$

where square brackets indicate concentrations and charges have been omitted for simplicity.

Protonation and metal–ligand formation curves were generated using the ESTA suite of computer programs.[11] These are represented by $\bar{Z}_H$ [the average number of protons bound per ligand—ZBAR(H)] vs $-\log[H^+]$ for the pyrophosphate protonation; and $\bar{Z}_M$ [the average number of

ligands bound per metal–ZBAR(M)] vs −log [pyrophosphate] for the tin–pyrophosphate interactions. The formation constants for the selected models of species were refined using the optimization module of ESTA with a weighted least-squares objective function.

An average value for the dissociation constant of water ($\log K_w = -13.71$) determined in our research laboratories was used. Tin hydrolysis data were included, as these species could affect complexation with pyrophosphate.[12] The values used were:

Stannous:

$\log \beta_{10-1} = -4.2$; $\log \beta_{10-2} = -8.013$;
$\log \beta_{10-3} = -17.44$; $\log \beta_{20-2} = -4.161$;
$\log \beta_{40-3} = -9.555$.

Stannic:

$\log \beta^{10-1} = -1.937$ and
$\log \beta_{10-6} = -24.108$.

RESULTS AND DISCUSSION

Pyrophosphate protonation

The four protonation constants of pyrophosphate were measured (Table 1) optimizing simultaneously for electrode intercept and initial ligand concentration. The calculated values are in good agreement with literature data[13] for background electrolyte concentrations of 100 and 200 mmol dm^{-3}. The high standard deviation of the fourth protonation constant is due to the imprecision of the glass electrode at low pH and the spread of the protonation curve below pH = 1.5.

Tin(II)–pyrophosphate interactions

The shape and non-superimposibility of the experimental formation curves (Fig. 1) for the tin(II)–pyrophosphate interactions, which show the

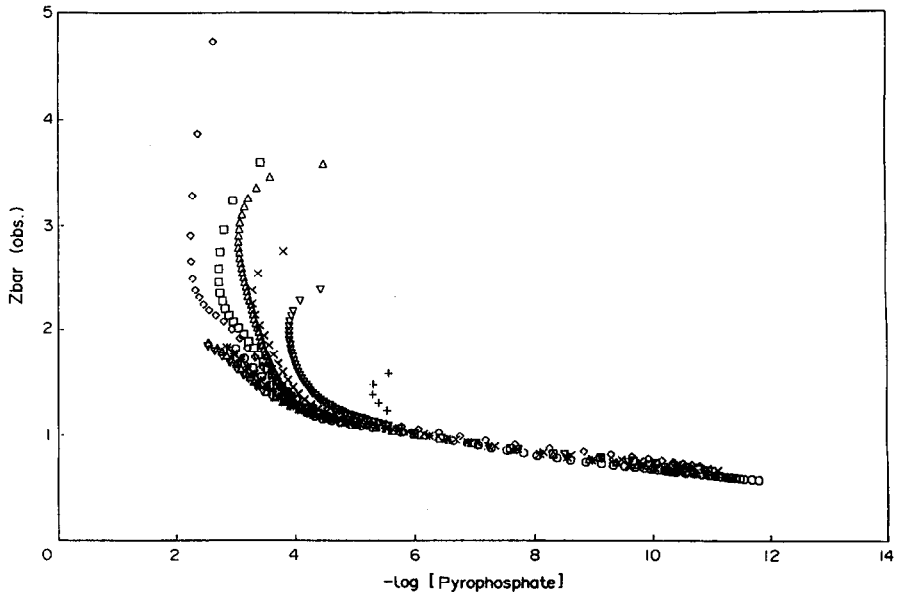

Fig. 1. Experimental metal complex formation curves for tin(II)–pyrophosphate; the different symbols indicate different titration concentrations.

results of 10 different titrations within the precipitation-free pH region from 2.2 to 11, indicate that a variety of species are present. Further, a white precipitate was observed at pH values below 2.6 when pyrophosphate was titrated with an acid solution of tin (seven titrations). Similarly, a precipitate formed on titration of an acid solution of tin(II) with pyrophosphate from pH 1.0 upwards. Initially, the composition with respect to the tin redox state of this white precipitate was uncertain as oxidation of tin(II) to tin(IV) is easily accomplished and tin(IV) salts are relatively insoluble. It was, thus, possible that the white precipitate observed in these tin(II)–pyrophosphate titrations was $SnP_2O_{7(s)}$, $Sn(OH)_{4(s)}$ or, indeed, a mixture of $SnP_2O_{7(s)}$ and $Sn_2P_2O_{7(s)}$ due to contamination of the tin(II) stock solutions with tin(IV). This perceived problem was further investigated by titrating tin(IV) solutions with pyrophosphate as described in the ensuing section(s).

The difficulties encountered in finding the "best" model to describe the experimental data are illustrated in Table 2. Most of the formation constants in model A are very close to literature values,[14–16] but this model was rejected because of poor statistical output and non-superimposibility of calculated and experimental titration curves. In model B, the overall statistics are good in comparison with the other models, but the high standard deviation of the ML_2 species (1.7028) precluded further consideration of this model. Therefore, the optimized formation constants of model C with relatively low standard deviations and objective function were considered to be the best model and were used to produce the simulated formation curves (Fig. 2). Comparison of this calculated formation curve with the experimental shows a good superimposibility.

Furthermore, comparison of the formation constants of tin(II)–pyrophosphate species with literature data revealed differences in values and species (Table 3).[14–16] This is probably due to the different experimental conditions used. Both Tur'yan *et al.*[14,15] and Orekhova *et al.*[16] worked at an ionic strength of 1 mol dm^{-3} and a lower overall concentration of tin ($\leqslant 1$ mmol dm^{-3}). For these reasons they probably did not observe precipitation at low pH values.

A knowledge of the species formed and their respective formation constants is crucial in the determination of the solubility product, K_{sp}, solubility, S_o, and formation constant, β_{pqr}, of the precipitated tin(II)–pyrophosphate species found at acid pH values.

$ML_2(OH)$	7.04±0.04		

as the titrand with tin(IV) solutions in the burette as the titrant. In this way, the point at which any precipitation of tin(IV)–pyrophosphate occurred in each titration could best be observed.

The shapes and non-superimposability of the experimental formation curves for the tin(IV)–pyrophosphate interactions, as with tin(II), indicated that a variety of species are present. It should be noted, however, that no precipitate was observed.

The difficulties encountered in finding the "best" models were similar to those for tin(II) but, by a process of elimination, the set of constants in Table 4 were preferred. Formation constants for tin(IV)–pyrophosphate species have not been previously reported in the literature.

Recently, Mathieu *et al.*[17] studied tin(IV)–pyrophosphate complexation by ^{119}Sn NMR spectroscopy and proposed a tin(IV)–pyrophosphate complex structure at a molar ratio of 1 : 1 [10 mmol dm^{-3} of tin(IV) solution and 100 mmol dm^{-3} of pyrophosphate solution] and pH 6.0 as ML_2. Figure 3 shows the tin(IV)–pyrophosphate distribution for a molar ratio of approximately 1 : 3 [15 mmol dm^{-3}

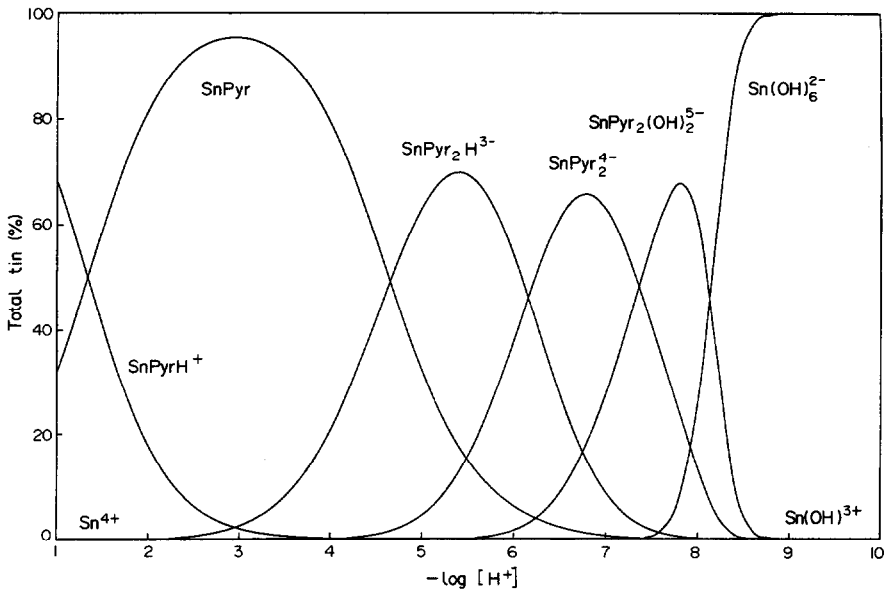

Fig. 3. The distribution of stannic pyrophosphate species calculated from the constants in Table 2 [Tin(IV) = 15 and pyrophosphate = 40 mmol dm^{-3}].

of tin(IV) solution and 40 mmol dm^{-3} of pyrophosphate solution] and the maximum of ML_2 species is at pH $\approx$ 7.0. However, one may expect a shift of the maximum to pH 6.0 and an increase of yield of the complex at a molar ratio of 1 : 10, which shows that the NMR studies support the validity of the determined formation constants.

Although the ML (stannic pyrophosphate) species predominates within the pH range 2–5 (Fig. 3), no precipitate occurred during the titrations. It follows that the precipitate of stannous pyrophosphate described next is not, therefore, contaminated with tin(IV) solids and its solubility product is not influenced by stannic pyrophosphate.

Determination of solubility product, K_{sp}, by titration

The titration of pyrophosphate with tin produced a white precipitate at pH values below 2.6. From the speciation profiles in Figs 4 and 5, it can be seen

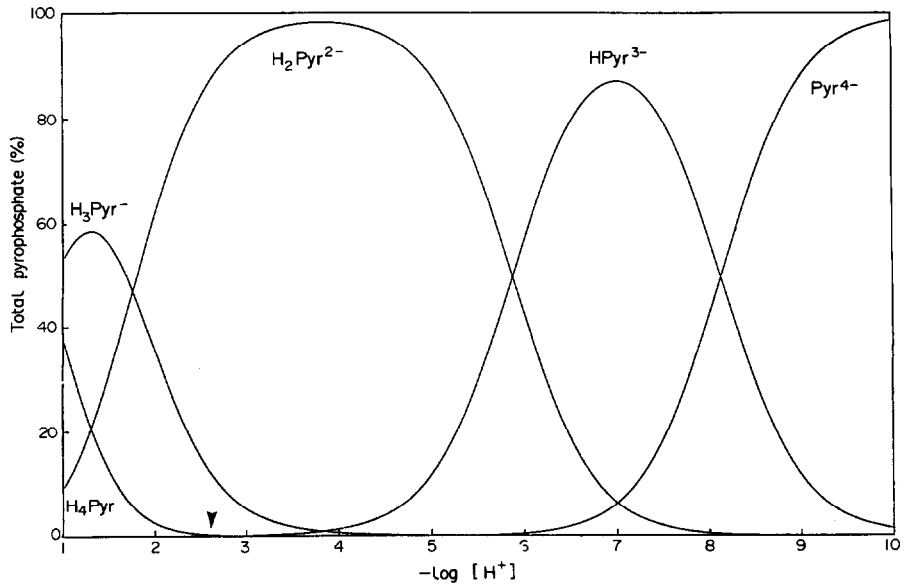

Fig. 4. Chemical species distribution plots for the proton–pyrophosphate system at $T_{Pyr^{4-}}$ = 20 mmol dm^{-3}. The arrowhead indicates pH = 2.6.

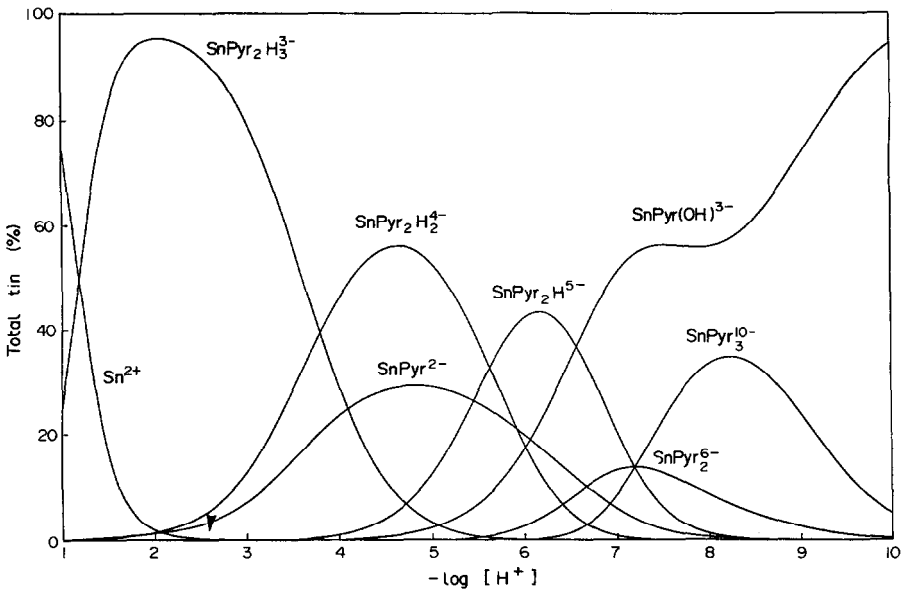

Fig. 5. Chemical species distribution plot for tin(II)–pyrophosphate. $T_{Sn^{2+}} = 5$ mmol dm^{-3}; $T_{Pyr^{4-}} = 20$ mmol dm^{-3}. The arrowhead indicates the precipitation point at pH = 2.6.

that a free metal ion and fully protonated ligand are present at approximately the same pH value. Thus, it is likely that the observed white precipitate in our experiments is stannous pyrophosphate, especially since it is known that stannous pyrophosphate can be prepared by adding tetrasodium pyrophosphate solution to a solution of stannous chloride in hydrochloric acid.[18]

The first appearance of a precipitate in the vessel indicates that saturation has been reached and the solubility product, K_{sp}, has been exceeded. This, solubility product, K_{sp}, can be expressed in the form of a general equilibrium, thus:

$$M_pL_q(s) \rightleftharpoons pM + qL; \quad K_{sp} = [M]^p[L]^q. \qquad (2)$$

The solubility product, K_{sp}, of a sparingly soluble salt can be calculated if the concentrations of free metal and ligand just before precipitation are known.

Generally, the concentrations of free metal and ligand are:

$$[M] = T_M - \sum p\beta_{pqr}[M]^p[L]^q[H]^r \qquad (3)$$

$$[L] = T_L - \sum q\beta_{pqr}[M]^p[L]^q[H]^r, \qquad (4)$$

where T_M and T_L are total concentrations of metal and ligand. Square brackets indicate free concentrations and charges have been omitted for simplicity.

Computer modelling programs permit the solution of such complex equilibria. Thus, the aqueous free ligand and free metal ion concentrations can be calculated at the point of precipitation if the ligand protonation and metal–ligand formation constants are known in addition to the free hydrogen ion concentration. Determination of the solubility product is then straightforward using eq. (2).

Table 4. Formation constants for the tin(IV)–pyrophosphate interactions at 25°C, $I = 150$ mmol dm^{-3} (four titrations, 244 points) using a stock solution of tin(IV) made from anhydrous stannic chloride

Model	Species p	q	r	$\log \beta_{pqr}$	Standard deviation	Objective function	R factor
	1	1	0	22.61	0.09		
	1	1	1	23.56	0.14		
A	1	2	0	27.08	0.03	1492	0.01352
	1	2	1	33.36	0.02		
	1	2	−1	19.84	0.04		

The solubility product can be used for the evaluation of stannous pyrophosphate solubility in water.[19] If S_o represents the solubility of stannous pyrophosphate in water (mol dm^{-3}), it follows that [Sn] = $2S_o$ and [L] = S_o, since each mole of stannous pyrophosphate that dissolves gives 2 moles of stannous ion and 1 mole of pyrophosphate ion. Hence,

$$[2S_o]^2[S_o] = K_{sp} \quad (5)$$

or

$$S_o = (K_{sp}/4)^{1/3} \quad (6)$$

or, in a negative logarithmic form,

$$pS_o = \tfrac{1}{3}pK_{sp} + 0.2. \quad (7)$$

Moreover, the same procedure can be used for calculating the formation constant, β_{210}, by substitution of eq. (5) into eq. (1). This gives eq. (6):

$$\log\beta_{210} = -\tfrac{2}{3}\log K_{sp} - 0.2 = \tfrac{2}{3}pK_{sp} - 0.2. \quad (8)$$

Solubility products calculated from the precipitation points of seven titrations are given in Table 5. The stated pH denotes the value at which precipitation was first observed. pL, pM, pK_{sp}, and pS_o are negative logarithmic values of free ligand and metal concentrations and for the solubility product, and solubility, respectively.

Variation of solubility product values may be due to (i) slower kinetics of precipitation than assumed; hence, creating an oversaturated solution in the titration vessel in spite of efficient stirring, and (ii) partial oxidation of tin(II) in the stock solution leading to the precipitate of stannous pyrophosphate becoming contaminated with stannic pyrophosphate which probably has a lower solubility product.

Literature values for the tin–pyrophosphate solubility product could not be found and, thus, the solubility product value for stannous pyrophosphate was verified as described below.

Determination of the solubility product, K_{sp}, by dissolution

The method involves dissolving to equilibrium pure samples of stannous pyrophosphate under carefully controlled pH conditions, separating solid from liquid phases, determining the total tin present in the aqueous phase and performing a speciation analysis in order to calculate the solubility product.

Tin solutions were analysed using a Varian graphite tube atomizer (GTA-95) in conjunction with a Varian atomic absorption spectrophotometer (AA 1275) and a printer (Epson LX 80). The light source was a Varian tin single-element hollow cathode lamp. The sample solutions were injected into a coated graphite tube by an automatic sampler.

The following instrumental parameters were used: lamp current 7 mA, spectral bandwidth 0.5 nm, wavelength 266.1 nm. Tin was measured from peak heights using read commands without background correction.

Standard solutions of tin (8 μg cm^{-3}) were prepared from solutions of stannous chloride (1 mg cm^{-3}) in hydrochloric acid (1 mol dm^{-3}) (Spectrosol, BDH Ltd) and by dilution with hydrochloric acid (50 mmol dm^{-3}) (Convol, BDH Ltd). These standard solutions were prepared daily. Hydrochloric acid (50 mmol dm^{-3}) and ascorbic acid (7%) were used as blanks and modifier, respectively.

Table 5. The determination of the solubility product (K_{sp}), solubility (S_o) and the formation constant (β_{210}) of stannous pyrophosphate at 25°C, I = 150 mmol dm^{-3} chloride

Titration number	pH	pA	pM	pK_{sp}	pS_o	log β_{210}
1	2.610	11.107	4.358	19.82	6.81	13.01

Average				20.48	7.03	13.45
Standard deviation				0.49	0.16	0.33

Method. Weighed amounts of stannous pyrophosphate (95.9–254.6 mg) were stirred, either with hydrochloric acid (50 cm^3) and sodium chloride (pH 1.07–3.32), or with water in a vessel thermostatted at 25.0±0.1°C, the ionic strength being maintained at 150 mmol dm^{-3} chloride. A stream of oxygen-free nitrogen was passed through the solutions in order to eliminate dissolved oxygen and carbon dioxide. The pH values of the solutions were determined after 3 h of stirring. Samples (2–3 cm^3) were taken usually at time intervals of 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6 and 7 h from the commencement of stirring. The solid and liquid phases were separated by vacuum filtration through a Sartorius membrane filter (SM RS). The filtrate was diluted 1 : 10 with hydrochloric acid (50 mmol dm^{-3}) and analysed for tin content by atomic absorption spectrometry with electrothermal atomization. An injected volume of the samples varied from 0.002 to 0.01 cm^3 for the tin concentration and was topped up with blank (50 mmol dm^{-3} hydrochloric acid) to the total volume of 0.02 cm^3. Blanks were run after the standards and after each fifth sample. A plot of absorbance of the samples at 266.1 nm vs stirring time was produced for each solution. Values taken from the plateaus of the plots were expressed as total concentration of dissolved tin by reading the calibration curve and these were used for calculating solubility of stannous pyrophosphate. Measurements were repeated at each pH value.

Free concentrations of stannous and pyrophosphate ion were calculated using the ESTA program with the protonation constant, formation constant and pH as input.[11] This permitted the solubility product of stannous pyrophosphate to be calculated for each solution.

Atomizing conditions. Atomic absorption spectrometry using electrothermal atomization was chosen for determination because of simplicity of operation and its ability to analyse the suspected presence of very low concentrations. Simple samples containing just stannous, pyrophosphate, sodium and chloride ions required ≃ 45 s of drying time. However, chemical modifications of sample was necessary when analysing tin in sodium chloride matrices.[20] A range of concentrations and volumes for literature recommended modifiers such as diammonium hydrogen citrate, trisodium citrate, EDTA, citric and tartaric acids were examined, but the best results were obtained using ascorbic acid.[21] The addition of ascorbic acid (0.01 cm^3 of 7%) to the standards and samples containing up to 100 mmol dm^{-3} sodium chloride stabilizes the tin in solution and produces a single atomization peak. The optimal ash temperature was set at 700°C, and an atomizing temperature of 2600°C was retained.[20] A temperature of 3000°C was used for cleaning the tube of the remains of ascorbic acid ash. A new coated graphite tube was used for each set of measurements (i.e. to 70 injections). The wavelength chosen was 266.1 nm.[22]

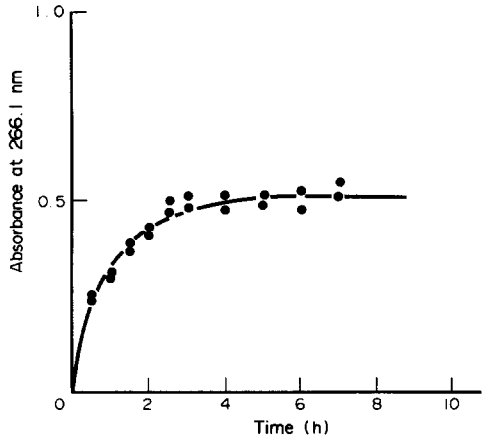

Fig. 6. Absorbance vs time for the dissolution of stannous pyrophosphate.

Dissolution. Centrifugation was replaced by vacuum filtration with a Sartorius membrane filter to separate phases. Tin concentrations in the samples were measured and a typical plot of absorbance with time of stirring is shown in Fig. 6, equilibrium being reached after 3–4 h.

Solubility of stannous pyrophosphate. The solubilities were calculated as being half of the total tin concentration on the plateau from the formula of $Sn_2P_2O_7$ (Fig. 6) and results are shown in Table 6.

Higher solubilities carry higher standard deviations because the samples are more highly diluted (see Method). Clearly, the solubility of stannous pyrophosphate decreases with increase in pH over the range 1.07–2.76. This confirms the report that stannous pyrophosphate is totally dissolved at pH 0.5.[23] Also, the solubility increased from pH 2.76

Table 6. Solubility of stannous pyrophosphate in water solutions at 25°C, I = 150 mmol dm^{-3} chloride

Composition of solutions (mmol dm^{-3})	pH	Number of points	Solubility ± SD (mmol dm^{-3})
100HCl + 50NaCl	1.07	9	2.04 ± 0.42
50HCl + 100NaCl	1.39	6	1.20 ± 0.21
10HCl + 140NaCl	1.86	10	0.51 ± 0.05
5HCl + 145NaCl	2.22	7	0.43 ± 0.04
1HCl + 149NaCl	2.76	6	0.36 ± 0.04
150NaCl	3.32	6	0.95 ± 0.07
Water	3.26	8	0.32 ± 0.03

Table 7. The solubility product (K_{sp}) for stannous pyrophosphate at 25°C, $I = 150$ mmol dm^{-3} chloride/or water

pH	Number of points	$-\log[Sn^{2+}]$	±SD	$-\log[P_2O_7^{4-}]$	±SD	pK_{sp}	SD
1.07	9	2.40	0.08	15.53	0.08	20.33	0.24
1.39	6	2.64	0.07	14.80	0.06	20.08	0.20
1.86	10	3.02	0.04	13.96	0.03	20.00	0.10
2.22	7	3.13	0.04	13.29	0.02	19.54	0.09
2.76	6	3.32	0.05	12.49	0.02	19.12	0.12
3.32	6	3.20	0.02	11.89	0.01	18.29	0.05
3.26	8	3.56	0.04	12.04	0.01	19.15	0.08

Free metal and ligand concentrations are in mol dm^{-3}. Compositions of the solutions are the same as in Table 1.

upwards and, as noted in the potentiometric data above, is totally dissolved by pH ≈ 6. Thus, minimum solubility is at pH 2.76, which matches the observations during the potentiometric study. The difference in solubilities between water and sodium chloride (150 mmol dm^{-3}) solution may be a result of interionic attraction.[24]

The solubility product of stannous pyrophosphate. The free concentrations of stannous and pyrophosphate ions were calculated by the ESTA program.[11] Input data used the total concentration of tin as determined by atomic absorption spectrometry and where the calculated total concentration of pyrophosphate was set equal to the solubility of stannous pyrophosphate. Output values of free concentrations of metal and ligand were used for calculating the solubility product of stannous pyrophosphate by eq. (9) (see Table 7).

$$K_{sp} = [Sn^{2+}]^2[P_2O_7^{4-}]. \quad (9)$$

The solubility product of stannous pyrophosphate decreases with increase in pH. The average values of $pK_{sp} = 19.65$, for ionic strength 150 mmol dm^{-3}, is not far removed from the potentiometric determined value (20.48). However, the former could be affected by kinetics of precipitation and possibly the presence of an oversaturated solution, but the agreement is quite good indicating that potentiometric titration can, indeed, be used for determining solubility products. The dissolution value was determined following equilibrium of stannous pyrophosphate dissolution and, therefore, is the best figure for speciation modelling studies.

(*Received* 2 *October* 1990; *accepted* 22 *October* 1990)

Abstract—The one-pot syntheses of $[Nb(\eta^6\text{-}C_7H_8)(PMe_3)_2Cl_2]$ and $[Nb(\eta\text{-}C_7H_7)(\eta^4\text{-}C_7H_8)(PMe_3)]$ from $[NbCl_4(thf)_2]$ (thf = tetrahydrofuran) have provided a convenient route to the virtually unexplored η-cycloheptatrienyl niobium system. The X-ray crystal structures of the subsequent derivatives $[Nb(\eta\text{-}C_7H_7)(Me_2PCH_2CH_2PMe_2)CO]$ and 17-electron $[Nb(\eta\text{-}C_7H_7)(PMe_3)_2I]$ have been determined.

The organometallic chemistry of η-C_7R_7 ligands has been relatively little developed compared with that of the ubiquitous η-C_5R_5 ligands. However, since the functional group properties of the two classes of ligands differ markedly, it seems probable that there will be an extensive chemistry of C_7-ring–metal compounds which will differ significantly from that of the C_5-ring compounds. We believe the relative paucity of η^n-C_7-ring–metal compounds, where $n = 5$–7, is due primarily to the lack of synthetic routes to suitable starting materials. Therefore, we are developing the chemistry of C_7-ring compounds of the early transition metals. The early rather than later transition metals have been chosen since they have fewer valence electrons and hence require more electrons from the ligands to achieve a filled 18-electron shell.

We and others have developed the chemistry of η-C_7H_7 derivatives of molybdenum,[1] tungsten,[2] and titanium[3] and, more recently, we described convenient synthetic routes to a rich chemistry of C_7-complexes of zero- and divalent cycloheptatriene and cycloheptatrienyl zirconium[4–6] and hafnium.[6] We now describe the convenient synthesis of a variety of C_7-ring compounds of niobium.

Cycloheptatri-ene and -enyl complexes of niobium are rare. The compounds $[Nb(\eta\text{-}C_7H_7)(\eta\text{-}C_5H_5)]$[7] and $[Nb(\eta\text{-}C_5H_5)(\eta^4\text{-}C_7H_8)(CO)_2]$[8] have been described, and we recently reported the compounds $[Nb(\eta\text{-}C_6H_5Me)(\eta^5\text{-}C_7H_9)(PMe_3)]$ and $[Nb(\eta\text{-}C_7H_7)(\eta^4\text{-}C_7H_8)(PMe_3)]$, formed as a mixture from the reaction between $[Nb(\eta\text{-}C_6H_5Me)(PMe_3)_3H]$ and cycloheptatriene.[9] This route is inconvenient since it requires the precursor $[Nb(\eta\text{-}C_6H_5Me)_2]$ which is available only via metal vapour synthesis.[10]

Reduction of $[NbCl_4(thf)_2]$ (thf = tetrahydrofuran) with 2 equivalents of sodium amalgam in thf in the presence of cycloheptatriene and trimethylphosphine gives green, air-sensitive, paramagnetic crystals of $[Nb(\eta^6\text{-}C_7H_8)(PMe_3)_2Cl_2]$ (**1**). Selected data characterizing this and all the new compounds described are summarized in the foot-

* Author to whom correspondence should be addressed.

note.* In a typical experiment, 5 g of $[NbCl_4(thf)_2]$ gave 3 g of **1**. When the above reaction was carried out with an excess of sodium amalgam, the product (in low yield) was $[Nb(\eta\text{-}C_7H_7)(\eta^4\text{-}C_7H_8)(PMe_3)]$ (**2**), previously reported as a component in a mixture.[9] It appears that **1** is an intermediate in the formation of **2**, since stirring **1** with sodium amalgam in thf in the presence of cycloheptatriene gives **2**. We assume the structure **1** is analogous to that proposed for $[Zr(\eta^6\text{-}C_7H_8)(PMe_3)_2Cl_2]$.[5] Reduction of $[NbCl_4(thf)_2]$ with magnesium, in thf in the presence of cycloheptatriene and trimethylphosphine, gives air-sensitive, lime-green crystals of **2** directly and in good yield. Typically, 10 g of $[NbCl_4(thf)_2]$ gives 3.8 g of **2**. This clean and convenient route to **2** has allowed us to explore further the chemistry of the $Nb(\eta\text{-}C_7H_7)$ moiety.

Thus, treatment of **2** with ammonium hexafluorophosphate in thf yields orange microcrystals of $[Nb(\eta\text{-}C_7H_7)(\eta^5\text{-}C_7H_9)(PMe_3)][PF_6]$ (**3**). Also, **2** reacts with a mixture of dmpe and carbon monoxide (1 atm) giving scarlet crystals of $[Nb(\eta\text{-}C_7H_7)(dmpe)CO]$ (**4**). The X-ray crystal structure of this compound has been determined† (Fig. 1). The $[Nb(\eta\text{-}C_7H_7)(dmpe)]$ fragment is clearly electron-rich since the IR spectrum of **4** shows a strong band at 1785 cm^{-1} assignable to the $\nu(C{\equiv}O)$ mode for the terminal carbonyl ligand. Treatment of **2** with

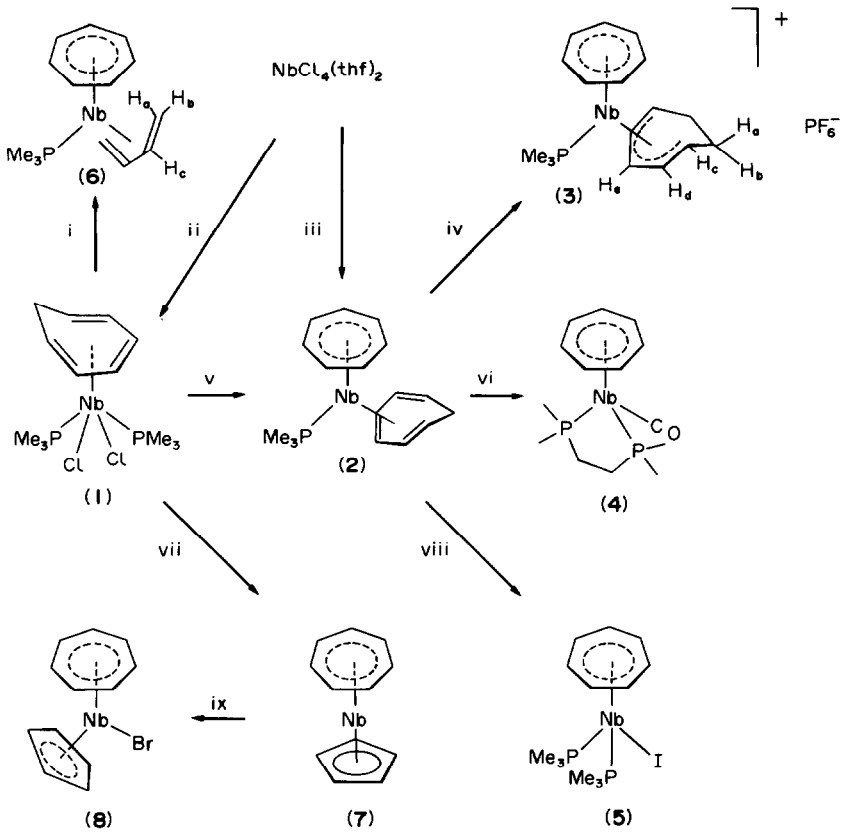
† Crystal data for **4**: $C_{14}H_{23}ONbP_2$, $M = 362.19$, monoclinic, $P2_1/n$, $a = 7.013(1)$, $b = 13.903(3)$, $c = 16.829(3)$ Å, $\beta = 94.87(2)°$, $\theta_{max} = 26°$, $V = 1635.0$ Å^3, $Z = 4$, $D_c = 1.47$ g cm^{-3}, μ(Mo-K_α) 8.86, crystal size *ca* $0.20 \times 0.30 \times 0.5$ mm, $R = 0.025$, $R_w = 0.027$ from 2681 reflections [$I > 3\sigma(I)$] and 164 independent parameters. For **5**: $C_{13}H_{25}INbP_2$, $M = 463.09$, monoclinic, Pn, $a = 7.025(10)$, $b = 13.206(3)$, $c = 9.700(3)$ Å, $\beta = 92.60(8)°$, $\theta_{max} = 25°$, $V = 898.9$ Å^3, $Z = 2$, $D_c = 1.71$ g cm^{-3}, μ(Mo-K_α) 24.99, crystal size *ca* $0.35 \times 0.35 \times 0.40$ mm, $R = 0.039$, $R_w = 0.044$ from 1554 reflections [$I > 3\sigma(I)$] and 155 independent parameters. The data for both structures were collected on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α radiation. Empirical absorptions were applied and the structures solved using heavy atom methods and difference Fourier synthesis. Hydrogen atoms were placed in calculated positions (C—H = 0.96 Å).



Scheme 1. Reagents and conditions: i, excess $[Mg(C_4H_6)\cdot 2(thf)]$ in thf at room temperature for 12 h (70%); ii, 2 Na/Hg, 2 PMe_3 and excess cycloheptatriene in thf at −80°C, warming slowly to room temperature, then stirring for 12 h (50%); iii, excess Mg, 2 PMe_3 and excess cycloheptatriene in thf at −80°C, warming slowly to room temperature then stirring for 12 h (40%); iv, NH_4PF_6 in thf at room temperature for 15 min (80%); v, excess Na/Hg and excess cycloheptatriene in thf at room temperature for 4 h (12%); vi, dmpe in toluene under CO (1 atm) at room temperature for 10 min (95%); vii, excess $Na(C_5H_5)$ in thf at room temperature for 3 h (80%); viii, MeI in toluene at −80°C warming to room temperature over 1 h (22%); ix, allyl bromide in toluene at −80°C warming to room temperature for 1 h (90%).

iodomethane in toluene gives low yields of the blue–green complex $[Nb(\eta\text{-}C_7H_7)(PMe_3)_2I]$ (**5**). A single crystal X-ray crystallographic study* (Fig. 2) on this 17-electron compound showed that it is isomorphous with the 16-electron zirconium analogue $[Zr(\eta\text{-}C_7H_7)(PMe_3)_2I]$.[5] This observation is in accord with our understanding of the bonding in $[Zr(\eta\text{-}C_7H_7)(PMe_3)_2I]$ such that the additional electron in **5** would be expected to occupy a largely non-bonding orbital and hence cause little perturbation of structural parameters.

Treatment of **1** with $[Mg(C_4H_6)\cdot 2(thf)]$[11] in thf gave lime-green crystals of $[Nb(\eta\text{-}C_7H_7)(\eta\text{-}C_4H_6)(PMe_3)]$ (**6**). Addition of an excess of sodium cyclopentadienide to **1** affords the previously reported sandwich complex $[Nb(\eta\text{-}C_7H_7)(\eta\text{-}C_5H_5)]$ (**7**) in good yield.[7] Typically, 3 g of **1** yielded 1.7 g of **7**.

We have initiated a study of the chemistry of this 17-electron compound and found that it reacts smoothly with allyl bromide to yield red crystals of the diamagnetic, bent-sandwich complex $[Nb(\eta\text{-}C_7H_7)(\eta\text{-}C_5H_5)Br]$ (**8**). This reaction is reminiscent of that between allyl bromide and $[Nb(\eta\text{-}C_6H_5Me)_2]$ giving $[Nb(\eta\text{-}C_6H_5Me)_2Br]$.[9]

The new compounds and reactions are shown in Scheme 1. We conclude that the ease of synthesis and stability of most of the compounds **1–8** shows there will be an extensive chemistry of the niobium–C_7-ring systems.

(*Received* 11 *September* 1989; *accepted after revision* 5 *October* 1990)

Abstract—The effect of non-bonded interactions (inter-ligand repulsion, ILR) on the geometry of eight-coordinate complexes was studied in the range of symmetry coordinates of the two highest symmetry structures, cube and hexagonal bipyramid (HBP). Only a few of the symmetry coordinates that convert the cube and the HBP into lower symmetry [dodecahedron (DD), square antiprism (SAP) and trigonal bicapped prism] were found to be important. ILR was demonstrated as the dominant factor in producing the lower symmetry structures for the closed-shell central atoms and it most certainly plays a very important role in helping or opposing the Jahn–Teller distortions for the orbitally degenerate complexes. The theoretical predictions were compared with a variety of structural data for ML_8. The predicted radial distortions were much larger than the experimental values and this was attributed to the electronic factors. Most of the angular distortions for ML_8 were explained in terms of a single e_u vibration.

The number of possible geometric structures sharply increases with increasing coordination number for the mononuclear ML_n complexes. Thus, for coordination number eight the following structures are possible in principle: cube, dodecahedron (DD), square prism (SP), square antiprism (SAP), bicapped (BCTP) or dishouldered (BSTP) trigonal prism, hexagonal bipyramid (HBP) and numerous intermediate structures[1–6] (see Fig. 1 for illustrations). In fact all intermediate and low symmetry structures may be obtained by symmetry descent from one of the two highest symmetry structures, namely the cube (O_h) and the hexagonal bipyramid (D_{6h}). These two structures form two distinct symmetry descent sequences that converge at C_{2v} and below.[7]

Previous studies on the shape of ML_8 complexes[1–6] have shown the predominance of two factors: (a) the electronic energy, given by electronic repulsion, central field attraction and Jahn–Teller distortion;[7] and (b) inter-ligand (non-bonded) repulsion.[3,4] These two factors can be assessed by semi-empirical methods, but the results obtained are dependent on the choice of M and L and they are not valid in general; the comparison is greatly

* Author to whom correspondence should be addressed.

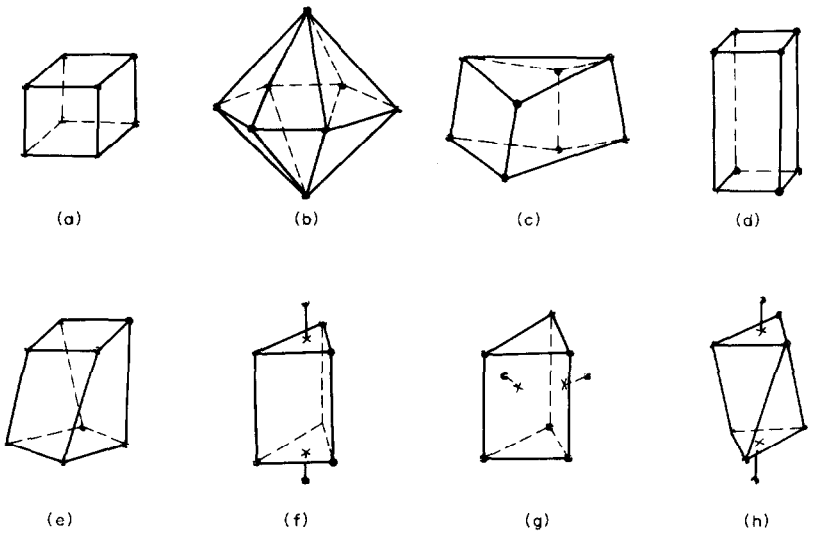

Fig. 1. Illustration of the main geometries occurring for the ML_8 complexes. Cube (a), hexagonal bipyramid (b), dodecahedron (c), square prism (d), square antiprism (e), bicapped (f), and bi-shouldered (g) trigonal prism, bicapped trigonal antiprism (h).

restricted by the initial choice. Highly sophisticated *ab initio* quantum mechanical methods can incorporate both factors (a) and (b), but for the higher coordination numbers these methods are not readily accessible even when the core potential version is used, and they give results of highly specific validity.

Studies on the shape of ML_8 complexes have shown that they form two series in order of increasing energy:[2]

$$\text{SAP} \sim \text{DD} < \text{cube} < \text{BCTP} \ll \text{BSTP} \quad \text{ILR} \quad (1)$$

$$\text{BCTP} < \text{BSTP} < \text{SAP} < \text{DD} \ll \text{cube} \sim \text{HBP} \quad \text{EH.} \quad (2)$$

The first series expresses the order in terms of the inter-ligand repulsion energy, while the second order was obtained by the Extended Huckel method[2] and involves both non-bonded repulsion and electronic factors, although the inter-electron repulsion is taken implicitly. The two structures DD and SAP are believed to be so close in ILR energy that they offer equal possibilities of forming M—L bonds; in such a case the choice of structure is governed by other factors such as the closest packing conditions in the crystal lattice.[5]

In the first paper of our series on eight-coordination we shall discuss the effect of inter-ligand repulsion on the molecular shape of ML_8. Subsequent papers will deal with the electronic factors, employing semi-empirical quantum chemical methods.

COMPUTATIONAL PROCEDURE

We shall study the inter-ligand repulsion energy as a function of the symmetry coordinates for the two highest symmetry structures, namely the cube and the hexagonal bipyramid. Thus, instead of varying one internal coordinate as previously[1,5] and missing what happens with the others, we shall separate, by symmetry, the $8 \times 3 = 24$-fold space of the L_8 cage structure, positioning M at the centre of our fixed coordinate system. Such an approach offers many advantages, the most important one being that the 24-dimensional L_8 coordinate space is reduced to:

$$a_{1g}, e_g, 2t_{2g}, a_{2u}, e_u, t_{1u}, t_{2u} \text{ for } O_h(\text{cube}) \quad (3)$$

$$2a_{1g}, b_{2g}, e_{1g}, 2e_{2g}, a_{2u}, b_{1u}, b_{2u}, 2e_{1u}, e_{2u} \text{ for } D_{6h}(\text{HBP}). \quad (4)$$

It can be readily seen that instead of groping in the 24-dimensional hyperspace we have reduced the problem to one six-dimensional ($2t_{2g}$), two three-dimensional (t_{1u} and t_{2u}), two two-dimensional (e_g and e_u) and two one-dimensional subspaces (a_{1g}, a_{2u}) for the cube. The highest dimensional subspaces for HBP are $2e_{2g}$ and $2e_{1u}$ (4), followed by e_{1g}, e_{2u} and $2a_{1g}$ (2), and the remaining b_{2g}, a_{2u}, b_{1u}, b_{2u} are one-dimensional.

Furthermore, we studied the variation of the ILR energy as a function of the symmetry coordinates listed above. These symmetry coordinates for L_8 in O_h and D_{6h} can be obtained in many ways, but in

this case were found by using projection operators.[8] The O_h symmetry coordinates were found first in D_{4h} and then by using the correlation analysis in its ascent of symmetry version they were grouped together to produce the cube's symmetry modes.[10] The final results are listed in Table 1. The projection operator technique was employed directly for D_{6h} (HBP).

Variations of the ILR energy were followed by calculating the so-called repulsion coefficient, X, as a function of the distances, d_{ij}, between each pair of non-bonded atoms, i and j, in the L_8 frame:[1]

$$X = \sum_{i<j} d_{ij}^{-6}. \qquad (5)$$

By inserting the incremental δr, $\delta\theta$ or $\delta\phi$ values in the position of atoms prescribed by the symmetry coordinates listed in Tables 1 and 2, the variation of X was found with the appropriate symmetry mode S, i.e. $X = f(S_i)$ where i numbers the symmetry species for L_8.

This simplest possible repulsion potential was widely used to explain the observed stereochemistry of many inorganic complexes,[1,4,5] and so we retain the generality of the results obtained. They would be independent of M and L and would (for the radial distortion) depend on the bond length in an explicit way.

When using eq. (5) to assess the ILR energy variations with S_i, in order to evaluate the softness or hardness of the potential energy surface near the energy minima, we have also calculated the derivatives $(\partial^2 X/\partial S_i^2)_{s_i=s_i^0}$. The numerical values thus obtained should be proportional to the Urey–Bradley force constants, reflecting the non-bonded interactions.[11,12] Our $(\partial^2 X/\partial S_i^2)_{s_i=s_i^0}$ values (Tables 3 and 4) obtained at the PES extrema could thus serve only for comparison's sake. They may be used to guess whether a certain motion over the PES is softer than another. In the same sense, the calculated changes in the repulsion coefficients, ΔX, along a certain symmetry coordinate, S_i, which convert one structure into another give a rough assessment of the barrier height of such a conversion, relative to changes in ILR energy.

In general, in order to find the pathways connecting different local minima we have used the gradients of X vs S_i.

[a] All a_1 distortions are irreducible representations.
$c_1, \ldots, c_6$ are $\sin\theta_1, \ldots, \sin\theta_6$.

The main advantage offered by the intended study of X vs S_i, which we shall call symmetry-constrained ILR energy variation, becomes evident when we begin to study the problem of mixing the electronic with the nuclear motion, i.e. when dealing with the so-called vibronic coupling.

RESULTS

Initial geometry cube

Leaving aside, for obvious reasons, the totally symmetric a_{1g} mode, we shall treat consecutively all the symmetry coordinates of L_8 with L's located at the vertices of a cube with O_h symmetry.

Symmetry coordinate a_{2u}. The variation of X with $S(a_{2u})$ is shown in Fig. 2. It can be readily seen from this figure that the cube is unstable with respect to this coordinate and that, depending on the distance to the cube centre (R in Å), the L_8 frame is easily taken into two ILR energy minima. This corresponds to two dodecahedral structures with non-equivalent A and B sites, respectively. The minima are located at

$$|\delta r| = 0.0117 + 0.1998\,R. \qquad (6)$$

This is a linear regression equation calculated from a 30 point set of local minima. $|\delta r|$ is the displacement involved in the a_{2u} symmetry coordinates at which mimum ILR energy is observed, and R is the distance to L from the cube centre in the initial octahedral geometry, both expressed in Å. Equation (6) holds for $\theta_A = \theta_B = 54.74°$. It may be used to obtain the ratio of the bond lengths for the two A and B sites in the dodecahedron, R being

the average ML bond length in a hypothetical cube:

$$R_A/R_B = (R+\delta r)/(R-\delta r) = 1.51\ \text{Å}. \quad (7)$$

This equation holds for $R = 1.5$–2.5 Å, $R_A = R+\delta r$, $R_B = R-\delta r$ and $\theta_A = 36.85°$ and $\theta_B = 69.46°$, as in the hard sphere model.[14] However, the ratios found in the literature for dodecahedral complexes exceed 1.1 Å in very few cases (see Table 5). When the condition $\theta_A = \theta_B = 54.74°$ in eq. (6) is relaxed ($\theta_A > 54.74°$, $\theta_B < 54.74°$ or vice versa), the minimum ILR energy occurs at even higher δr values, ILR being the lowest with the $\theta_A = \theta_B = 54.74°$ condition. Hence, it may be concluded that while $S(a_{2u})$ may aid the distortion of the cube to a dodecahedron, its action is strongly opposed by other factors (see Discussion).

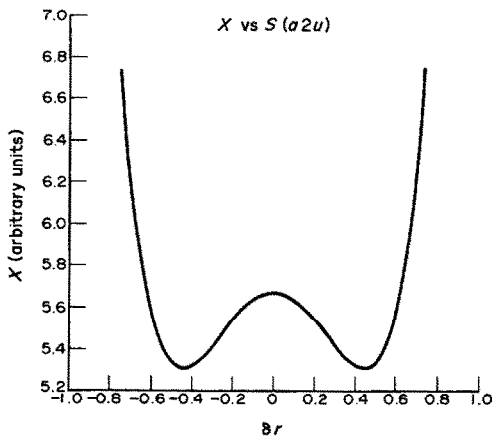

Fig. 2. The variation of the repulsion coefficient X [see eq. (5)] with the symmetry coordinate $S(a_{2u})$ in terms of δr for $R = 2.2$ Å. The distortions (δr) for minimum ILR energy as a function of R are given by eq. (6).

Table 5 contains the experimental results for the ML_8 complexes, only. No data on the chelate complexes are included since they reflect the constraints imposed by the rigid, multidentate ligands.[1]

The two differently shaped dodecahedra produced by $S(a_{2u})$ are separated by the barrier ΔX which is dependent on the distance of L to the cube centre, R, related by the equation

$$\ln(\Delta X) = 1.225 - 3.175\,R \quad (8)$$

(R is in Å). Once adopting the dodecahedron shape, the L_8 frame is very resistant (see Table 3) to possible further changes, since any attempt to take the structure out of the minima is met by a great energy loss.

Unfortunately there are no data on the interconversion of the two dodecahedra that could be compared with eq. (8).

Symmetry coordinate t_{1u}. This coordinate produces three truncated square-pyramids oriented with respect to the three coordinate axes x, y, z of the cube, each one related to the three t_{1u} components. However, the cube is the geometry of mini-

[a] Different modifications.

mum ILR energy in this subspace and the three truncated square-pyramids appear as extrema on three rotationally symmetric troughs leading to the O_h minimum.

The t_{1u} symmetry mode is not stereochemically important since there are no ML_8 complexes with the structure of a truncated square-pyramid, possibly with expected unrecorded exceptions for $M(a\text{-}b)_4$ tetrakis-(bidentate) with asymmetric bidentate ligands, where the asymmetry of the ML_8 cage may arise from the different bonding provided by the bidentate ligands. Such cases, as mentioned previously, are outside the scope of the present study.

Symmetry coordinate t_{2u}. The three t_{2u} components take the L_8 frame into a D_{2h} structure. Such a structure is attained by elongation of the distances to four L from the cube centre, the four being located at two opposite edges connected with a body-diagonal of the cube. The ILR energy minimum for each pair of t_{2u} components was found for the cube structure. This minimum, however, is not related to rotationally symmetric troughs. The troughs that lead to the O_h minimum upon distancing from the cube centre split into two branches each without producing a new minimum, so that in the entire studied δr region (± 0.8 Å) the cube is the only ILR energy minimum. It should be noted, however, that the two branches from different troughs come so near to each other that the difference in δr becomes less than 0.1 Å, and the barrier separating these branches is solely $1\text{–}2 \times 10^{-2}$ units of X.

This symmetry coordinate, with the exception of the varieties of pathways leading to the cube, is again, not interesting stereochemically.

Symmetry coordinate e_g. The two e_g components produce different geometries when the L_8 frame is taken out of its equilibrium positions: (a) a square prism (D_{4h}) elongated along the x and y axes and compressed along z, (b) a square prism elongated along y, compressed along x and unchanged along z. The angle variation in the field of the two e_g components yields only one minimum for the cube (O_h). An interesting trough system is observed, the curvature along the troughs being equal and considerably less than for the stretching symmetry

coordinates. This coordinate, giving a single maximum for the cube, is also not interesting stereochemically. However, this coordinate is Jahn–Teller active for E and $T_{1(2)}$ ground-state molecules and hence it could be ultimately, vibronically active.

Symmetry coordinate t_{2g}. The cube is the geometry with least ILR energy in this subspace. The t_{2g} mode is Jahn–Teller active for $T_{1(2)}$ ground-state molecules and may produce distortions by the vibronic mechanism.

Symmetry coordinate e_u. Stereochemically this is the most interesting symmetry coordinate. Along e_u^a it leads to a DD structure, while e_u^b produces a square antiprism. The cubic structure located at $\delta\theta = 0$; $\delta\phi = 0$ is an ILR energy maximum (Fig. 3). Two regions, located symmetrically, indicate the existence of DD minima at $\delta\phi = 0$ and $\delta\theta = \pm 17.5°$, and there are two local minima for SAP at $\delta\theta = 0$ and $\delta\phi = \pm 22.5°$. The calculated $\delta\theta$ for DD corresponds to the hard sphere $\delta\theta$ value ($\delta\theta_A = +17.9°$ and $\delta\theta_B = -14.7°$) for $R_A/R_B = 1.50$, relative to the O_h value,[14] and they match nicely the angular distortions (Table 5 and Fig. 3).

The calculated X vs $\delta\theta$, $\delta\phi$ surface is shown in Fig. 4. The locations of the three structures (cube, DD, SAP) spanned in this subspace are easily recognized. One can also discern the trough leading from one DD over the SAP minima to the other DD minimum, which is an intricate motion involving both $\delta\theta$ and $\delta\phi$ variations.

Since any small deviations from the predicted

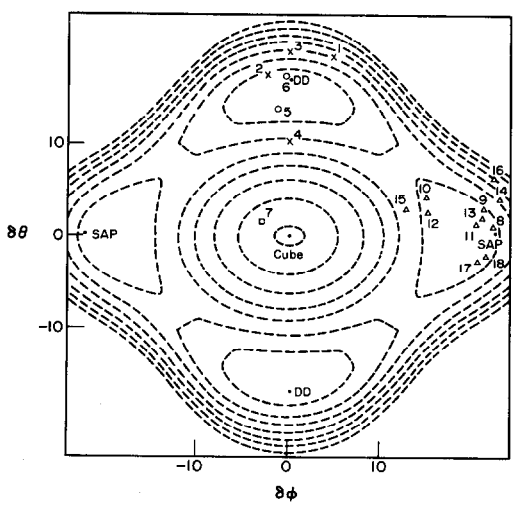

Fig. 3. The topographic surface of X vs $S(e_u^a)$ and $S(e_u^b)$. DD (dodecahedral minima), SAP (square antiprism local minima). The experimental points are: ×—regular DD; ▲—distorted DD; □—cube; ○—SAP. The lines are spaced at 0.015 units of X.

regular structures (DD, SAP, cube) could be due to either crystal packing conditions or electronic factors we shall not discuss them at this stage. They will be discussed in the subsequent papers of this series.

Symmetry coordinate t_{2u}. The only existing minimum is for the cube. The curve is less steep with respect to $\delta\phi$, then to $\delta\theta$. This coordinate is not interesting stereochemically. Each t_{2u} component produces two troughs that split upon going away from the cube centre.

Mixing between the t_{2g} *coordinates.* We also studied possible combinations of the two t_{2g} modes, one stretching and one bending. All combinations produce an ILR energy minimum for the cube and highly distorted C_2 structures obtained by elongation along two body-diagonals and shortening along two other diagonals.

Initial geometry hexagonal bipyramid

Up to this point only a few of the possible structures for L_8 have been detected, the trigonally distorted structures lacking completely from our initial geometry cube treatment. Since any combination of the degenerate symmetry coordinates is a good starting mode, by combining some of the triply degenerate modes we could obtain coordinates that produce trigonally distorted structures. Thus for example, if a combination of the t_{2g} components in O_h are taken as operative, they produce a trigonal antiprism with two additional vertices. However, since no symmetry coordinate of the cube can generate a six-fold axis, such a conversion would be symmetry forbidden.[14c] Hence, instead of seeking the combination of symmetry coordinates for the

cube that produce trigonally distorted structures that may provide unrealistic conversion pathways, it may be more profitable to start a study of another genealogical tree, generated by the highest symmetry structure with a six-fold axis, namely the hexagonal bipyramid.

Symmetry coordinate a_{2u}. This reproduces the HBP, the resulting minimum being very soft (see Table 4), indicating that L_8 with HBP symmetry can easily leave this structure and acquire a new one.

Symmetry coordinate $e_{2g}{}^{s}$. With respect to this bond stretching coordinate, HBP is a maximum and cannot exist from the point of view of ILR. Three minima exist, comparatively shallow, rotated at 120° and they correspond to D_{2h} structures elongated along one of the diagonals of the common HBP base. Since this coordinate is Jahn–Teller active for $E_{1(2)}$ ground states the ILR energy would help the vibronic factor in distorting the HBP.

Symmetry coordinate b_{1u}. This coordinate causes ring puckering of the hexagonal base that removes the C_6 axis and makes it C_3. On the plots of X vs δr, HBP is a maximum at $\delta r = 0$. Two D_{3h} structures appear at:

$$\pm\delta r = 0.079 + 0.2635\,R, \qquad (9)$$

where R is the distance of a L to the pyramid centre. The two maxima are steeper for the shorter R:

$$(\partial^2 X/\partial S_i^2)_{s_i=s_i{}^0} = 5.12 - 6.58 \ln R. \qquad (10)$$

This dependence on R proves that the minima are not those of paraboloids.

The HBP maximum that separates the two D_{3h} structures decreases with increasing R:

$$\ln[\Delta X(D_{6h} \rightarrow D_{3h})] = 2.774 - 3.185\,R. \qquad (11)$$

It should be noted that the two D_{3h} structures are of lower ILR energy than HBP but they are energetically unfavourable even with respect to the cube, as predicted elsewhere.[2]

Symmetry coordinate $e_{1u}{}^{s}$. This bond stretching coordinate is not interesting from a real symmetry point of view. It lowers the symmetry down to C_{2v} (elongated or compressed HBP along one of the C_2 axes). The ILR energy minimum lies at HBP; the second e_{1u} component is softer than the first one (see Table 4).

Symmetry coordinate b_{2g}. The HBP structure is of maximum ILR energy. There are two C_{3v} ILR energy minima on both sides of HBP at $\delta\theta = \pm 19.6°$, irrespective of the R value.

$$\ln(\Delta X) = 2.951 - 3.187\,R \qquad (12)$$

$$10^3(\partial^2 X/\partial S_i^2)_{s_i=s_i{}^0} = 6.17 - 7.33 \ln R. \qquad (13)$$

It should be noted that the coefficients in the $\ln(\Delta X)$ vs R equations, (11) and (12), are practically the same. This can only imply that when HBP is the maximum, the D_{3h} and C_{3v} minima produced by the two coordinates e_{1u} and b_{2g} are equally deep and steep.

Symmetry coordinate e_{2u}. The e_{2u} subspace reveals that the initial HBP geometry is a maximum from which, along two troughs with $\delta\theta(e_{2u}{}^{b}) = 0°$, leads to two very shallow minima being reached at $\delta\theta(e_{2u}{}^{a}) = \pm 11°$. These minima correspond to a square bipyramidal structure with two additional shoulders and C_{2v} symmetry. The $\Delta X(C_{2v} \rightarrow D_{6h} \rightarrow C_{2v})$ barrier is very low and since the two structures differ in their orientation in space (see Fig. 3) this e_{2u} coordinate may bring about a fluxional behaviour of the C_{2v} structures. Further, the different softness of two e_{2u} components should be noted.

Symmetry coordinate $e_{2g}{}^{b}$. This bending coordinate and also the subsequent coordinates that include $\delta\phi$ variations with no changes in R and θ are not interesting in themselves: they yield changes in the HBP base with an exclusive ILR energy minimum at HBP. The e_{2g} mode components are very hard and the L_8 frame cannot easily escape the HBP minimum along these pathways. The $e_{2g}{}^{b}$ coordinate is Jahn–Teller active for $E_{1(2)}$ states in D_{6h}. Hence in this case, unlike for $e_{2g}{}^{s}$, the ILR and vibronic factors will oppose each other.

Symmetry coordinate b_{2u}. Similarly to e_{2g} this coordinate is very hard with a minimum at HBP. In combination with b_{2g}, however, it can produce a BCTP structure.

Symmetry coordinate e_{1g}. The effect of this coordinate is to produce a tilt of the hexagonal base with respect to the axial bonds, and the resulting symmetry is very low (C_s). The cube has minimum ILR energy. The coordinate e_{1g} is Jahn–Teller active and JT are opposite in direction.

Symmetry coordinate $e_{1u}{}^{b}$. This is a bending mode. The situation is analogous with the two preceding coordinates, involving changes in the HBP base. It should be noted that $e_{1u}{}^{b}$ is the softest coordinate with $\delta\phi$ variations.

Mixing between the two a_{1g} *coordinates.* The unconstrained variation of the two a_{1g} modes brings about a continuous rise away from the plane of the remaining six atoms. All combinations retain the D_{6h} symmetry.

Mixing the two e_{1u} *coordinates.* All resulting changes are in the L_6 molecular plane involving δr_i and $\delta\phi_i$ variations and the regular hexagon is the structure with the lowest ILR energy.

Mixing the two e_{2g} *coordinates.* They combine δr_i and $\delta\phi_i$ variations and the hexagon is the structure with the lowest ILR energy. The pathways away

from HBP lead to highly distorted structures with high ILR energy.

DISCUSSION

This work has shown that only a few symmetry coordinate modes are important with respect to the shape of the L_8 frame, governed by ILR: for the initial geometry cube they are the a_{2u} mode, producing regular dodecahedra, and the e_u mode, producing angularly distorted dodecahedra, SAP and intermediates. The trigonally distorted L_8 shapes can be obtained by combinations of the t_{2g} mode in O_h or by the e_{2g} and b_{2g} modes in D_{6h}. The experimental results can be seen to match the energy minima obtained in our theoretical treatment: the ML_8 structures, collected in Table 5, are mostly SAP and they cluster around the ILR-produced SAP local minima in the X vs $\delta\phi$, $\delta\theta$ surface. The fewer dodecahedral structures also take positions near the ILR-predicted minima (see Figs 3 and 4).

The main conclusion from this study is, however, that ILR cannot account for the very weak radial distortions ($|\delta r| < 0.1$ Å, see Table 5) away from the two highest symmetry structures that are observed experimentally. The ILR criterion predicts very large radial distortions ($|\delta r| > 0.4$ Å) that are not matched by experiment. This conclusion is reached on the basis of Fig. 2 for the a_{2u} mode in O_h and the R_A, R_B data from Table 5.

There is no discrepancy, however, with the unrestricted ILR predictions. In fact both the trigonal dodecahedron ($X = 5.245$) and the square antiprism ($X = 5.185$) are structures with lower ILR energy than the cube ($X = 5.758$).[1] Hence, the symmetry-constrained ILR version used here correctly predicts that the cube would be distorted to DD and SAP. There are some peculiarities as to the radial distortions which have to be explained in some detail in order to avoid confusion. In the unconstrained ILR version the DD structure is reached at $\theta_A = 36.85$, $\theta_B = 110.54°$ and $r_A/r_B = 1.50$ Å (see, for example, Wells for the hard sphere model[14a]). This means that the DD is formed by exerting both radial and angular distortions of the cube ($\theta_A = 54.74$ and $\theta_B = 125.26°$, $r_A/r_B = 1.000$). Our results [see eq. (7)] agree extremely well with the hard sphere model as to the r_A/r_B ratio. The much lower experimental r_A/r_B ratios ($\lesssim 1.1$) must be attributed to the stabilizing effect of the electronic energy, which is expected to be most favourable for the highest symmetry structure.[2a] Thus, the experimental r_A/r_B ratios reflect the compromise between the high radial distortions of the cube predicted by ILR to produce the lower repulsion shapes and no radial distortion governed by the electronic energy, with the predominance of the second factor. This compromise was discussed in detail by Burdett *et al.*[2a]. We should re-iterate that there are no discrepancies or inadequacies in the symmetry-constrained ILR method proposed here and its unrestricted version used by Kepert.[1] It was also stated by Kepert that the bond lengths are influenced to a high extent by the ability of the ligands to form π-bonds (electronic factors) and thus predictions of radial distortions are in disagreement with simple ILR theory (see ref. 1, ch. 12.3).

The angular distortions, which are softer (Tables 3 and 4), are covered better by the ILR treatment (this is a well known fact[1,2]). The two main structures (DD and SAP) are nicely reproduced by the e_u mode (Figs 3 and 4). This mode is exceptional since it mirrors most of the known ML_8 shapes.

For the open-shell central ions (d^1, d^2, f^2 in Table 5), the vibronic factors may complicate the picture based on ILR. Since for d^{1-9}, the ground state in O_h (cube), both E and $T_{1(2)}$ ground states may appear, the Jahn–Teller active vibrations are e_g (for E states) and $e_g + t_{2g}$ (for $T_{1(2)}$ states).[7] For the e_g coordinate the cube is with minimum energy. Hence, ILR (retains the cube) and JT (distorts the cube) would oppose each other in the e_g space. The same holds true for the t_{2g} coordinate. Hence, it may be concluded that for the Jahn–Teller ions the ILR and vibronic factors interfere and they are compensating each other to a certain extent. The real structures reflect this compromise.

In D_{6h} the orbitally degenerate electronic states can be E_1 and E_2 (both u and g). The Jahn–Teller active modes in D_{6h} (HBP) are e_{1g} and e_{2g}.[7] It can be seen from our ILR treatment that the ILR and JT factors interfere, and the observed shapes must be a subtle compromise between these two factors.

The vibronic factors for open shell central atoms will be discussed in detail in a subsequent paper of this series.

Abstract—The title compound has been synthesized and its crystal structure determined at room temperature. The final R is 0.047 for 2216 independent observed reflections with $I \geqslant 3\sigma(I)$. The crystal structure consists of repeated $[Cu(bipy)_2(sacch)]^+$ cations, non-coordinated saccharin anions and three lattice water molecules. In the complex cation $[Cu(bipy)_2(sacch)]^+$, the Cu^{2+} is bonded to the five nitrogen atoms originating from two bipyridines and one saccharin with a distorted trigonal-bipyramidal stereochemistry. The *d–d* transition absorption and IR spectra of the title compound crystal are also reported and are explained perfectly by the scaling radial theory proposed by us.

Saccharin(*o*-sulphobenzoimide) has been used extensively as a food additive. Because of their potential effectiveness in biological systems, the structures of divalent transition metal complexes of saccharin have been determined[1,2] and the electronic spectra of these compounds have been interpreted.[3,4] The divalent transition metal ions were all found to be coordinated by the saccharin molecules and four water molecules to form an octahedral environment. In order to obtain more structural information on saccharin complexes we have used saccharin as a mixed ligand to study its complexes with transition metals. In particular, the mixed ligand copper(II) complex which has been synthesized is interesting because of its structure, which contains trigonal-bipyramidal five coordination stereochemistry.

EXPERIMENTAL

Synthesis

The title compound was obtained by a reaction between 2,2′-bipyridine and $[Cu(sacch)_2(H_2O)_4]\cdot 2H_2O$[5] in the molar ratio 2 : 1, in aqueous solution. The solution was heated in a water bath at 80–90°C with continuous stirring, and blue plate-like crystals were grown by repeated crystallization from water at room temperature. The results of elemental analysis correspond with its formula, $CuC_{32}H_{30}O_9N_6S_2$.

IR and d–d *transition spectra*

IR spectral measurements of $[Cu(sacch)(bipy)_2]\cdot(sacch)\cdot 3H_2O$ and $[Cu(sacch)_2(H_2O)_4]\cdot 2H_2O$ crystals were made as reflectance spectra, using KBr as the diluent on a FTIR instrument under standard operating conditions. The *d–d* transition spectrum was determined at room temperature in the region 4000–30,000 cm^{-1} using the absorption spectrograph for small crystals produced by the Geochemistry Institute of the Chinese Academy of Science.

Crystal structure

A crystal of approximate dimensions $0.06\times 0.60\times 0.57$ mm^3 was used. An AFC5R four-circle diffractometer with graphite-monochromatized

* Author to whom correspondence should be addressed.

Mo-K_α radiation, ω–2θ scan technique, was employed. 3774 independent reflections were collected for $\theta \leqslant 26°$ and corrected for Lorentz and polarization effects. An empirical absorption correction was also applied. 2216 independent observed reflections with intensity $I > 3\sigma(I)$ were used in the structure determination. The crystal structure was solved by direct-methods with the TEXSAN programs on a Micro VAXII computer. The structure was refined by the full-matrix least-squares method. 49 non-hydrogen atoms were refined anisotropically and the three oxygen atoms of the lattice water molecules refined isotropically. $R = 0.047$, $R_w = 0.064$. 25 hydrogen atoms (except for those of the three lattice water molecules) were located by difference Fourier synthesis and the HYDROGEN program. Hydrogen atom coordinates and isotropic temperature factors were used in the structure factor calculation but not in structure refinement. The final $R = 0.047$, $R_w = 0.054$.

Crystallographic data

$[Cu(C_{10}H_8N_2)_2(C_6H_4COSO_2N)] \cdot (C_6H_4COSO_2N) \cdot 3H_2O$, $Mr = 794.32$, orthorhombic, space group; $C222_1$, $a = 15.546(2)$, $b = 26.223(4)$, $c = 16.878(3)$ Å, $U = 6881$ Å^3, $Z = 8$, $D_{calc} = 1.535$ g cm^{-3}, $F(000) = 3272$, $R = 0.047$, $R_w = 0.054$, Mo-K_α: 0.71073 Å.

RESULTS AND DISCUSSION

The structure contains a $[Cu(bipy)_2(sacch)]^+$ complex cation, a $(sacch)^-$ anion and three lattice water molecules per asymmetric unit. In the complex cation, Cu^{2+} is bonded to five nitrogen atoms with trigonal-bipyramidal stereochemistry. The five nitrogen atoms originate from the coordinated saccharin [N(1)], the first bipyridine [N(2) and N(3)] and the second bipyridine [N(4) and N(5)]. N(1), N(2) and N(5) form a trigonal plane, the angles between these nitrogen atoms are: N(1)—N(2)—N(5), 63.5°; N(1)—N(5)—N(2), 63.2°; N(2)—N(1)—N(5), 53.3°. Cu^{2+} is 0.03 Å above the plane. N(4) and N(3), respectively, occupy the axial sites. (Bond lengths and angles are listed in Tables 1 and 2.) O(7), O(8) and O(9) are lattice water oxygen atoms, and O(4), O(5) and O(6) oxygen atoms from the other saccharin molecule are not coordinated to Cu^{2+} (see Fig. 1). The lattice water hydrogen atoms could not be located. However, since the O(7)—N(6) distance is 2.97(1) Å, the O(8)—O(4) and O(8)—O(4)′ distances are 2.64 and 2.94 Å, and the O(9)—O(6) and O(9)—O(6)′ distances are 2.82 Å and 2.89 Å, respectively, it is likely that O(7)—H···N(6), O(8)—H···O(4) and O(9)—H···O(6) hydrogen bonds exist in the crystal.

According to the above description, the structure of the title compound is roughly similar to the structure of $[Cu(C_{10}H_8N_2)_2(C_6H_5OPO_3)] \cdot (C_6H_5OPO_3) \cdot H_2O$[6] and $[Cu(bipy)_2(SCN)] \cdot (SCN)$[7] which also have distorted trigonal-bipyramidal configurations. This suggests that this type of geometry may easily arise if two bipyridine molecules coordinate with copper(II) in mixed ligand complexes.

The water molecule exhibits absorptions in the IR region 3200–3600 cm^{-1}, and the absorptions of coordinated water molecules show red transitions. As shown in Fig. 2(a), in the IR region near 3500 cm^{-1}, only one single, strong absorption exists at 3500 cm^{-1} for our compound. In Fig. 2(b) there are two strong absorptions in this IR region at 3500 and 3100 cm^{-1}. From this we can distinguish the various coordination modes of the water groups. In compound a, only uncoordinated water molecules exist, while compound b contains two types of water

molecule: coordinated and uncoordinated. This is confirmed by the X-ray crystal structure.

The X-ray crystal structure shows that one of the two saccharin groups is bonded to the copper(II) atom through one nitrogen in compound a, which is evidently different from compound b in which both saccharin groups are coordinated. The —CONH— group of saccharin absorbs in the IR region at 1550–1650 cm^{-1}. As shown in Fig. 2, compound b has two absorptions in this region with a small separation of about 25 cm^{-1}. These absorptions correspond to the crystal structure, which shows that the two coordinated saccharin groups are in slightly different environments. However, compound a has only one absorption in this region and the crystal structure shows that it con-

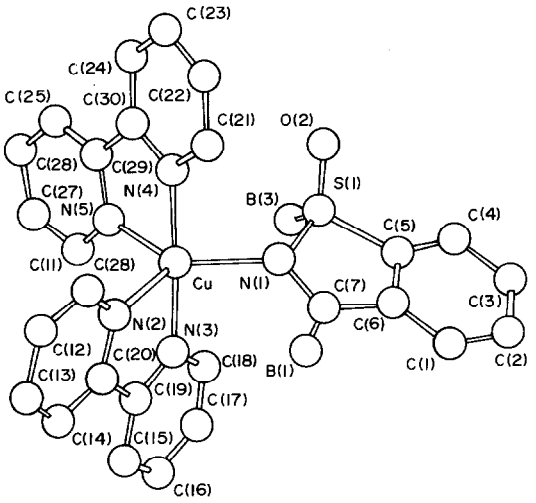

Fig. 1. Perspective view of $[Cu(C_{10}H_8N_2)_2(C_6H_4COSO_2N)]^+$.

tains an ionic saccharin group which would normally be expected to have a single absorption in this region with a small violet transition. However, in Fig. 2(a) such an absorption cannot be found in this IR region. According to the X-ray crystal structure, the ionic saccharin group is hydrated

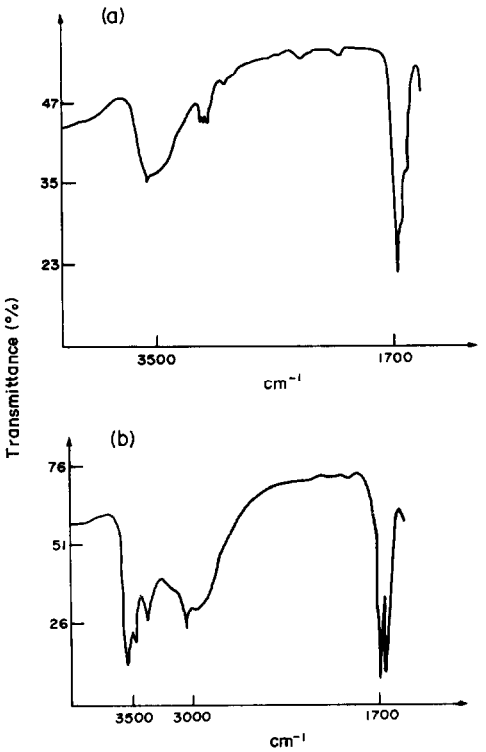

Fig. 2. IR absorptions in the 1500–3800 cm^{-1} region: (a) $[Cu(bipy)_2sacch)]\cdot(sacch)\cdot 3H_2O$ and (b) $[Cu(sacch)_2(H_2O)_4]\cdot 2H_2O$.

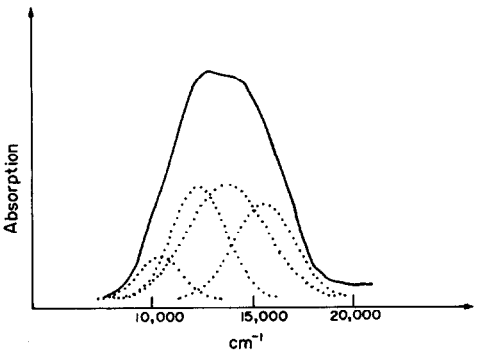

Fig. 3. The *d–d* transition spectrum of the title compound.

[O(4) and N(6) are from the ionic saccharin molecule —C(39)O(4)N(6)=] and it was suggested that extensive hydrogen bonding may be responsible,[8] explaining why the ionic saccharin group absorption is missing. In addition, Fig. 2(a) shows a multiply split, middle strong absorption in the IR region, 3000–3300 cm^{-1}, due to the vibrations of the C—H bonds of the 2,2′-bipyridine rings.

As shown in Fig. 3, the *d–d* transition spectrum of the title compound contains a strong, broad absorption band. The overlapping absorption band has been resolved using a computer program into absorption peaks at 10,474, 12,435, 13,814 and 15,627 cm^{-1}.

The wave function scaling radial theory of nonfree ions has been set up and the double-ξ radial wave functions of some transition metal ions have been proposed by our laboratory. We have discussed some coordination compounds and explained their electronic structure using this theory and results which agree perfectly with the experimental values have always been obtained.[9-11] Using the program package which calculates Ligand Field Theory (PLFT) and the crystal structure data, the crystal field parameters and the *d–d* transition energy levels of the title compound crystal were obtained and are listed in Tables 3 and 4. From the data in Table 4, the calculated results of the *d–d*

POLYAMINE COMPLEXATION—I. STABILITY CONSTANTS FOR METAL ION COMPLEXATION OF 5-(4′-AMINO-2′-AZABUTANE)-5-METHYL-3,7-DIAZANONANE-1,9-DIAMINE

GARY K. HOLLINGSHED, GEOFFREY A. LAWRANCE, MARCEL MAEDER* and MONICA ROSSIGNOLI

Department of Chemistry, The University of Newcastle, New South Wales 2308, Australia

(*Received* 13 *June* 1990; *accepted* 9 *October* 1990)

Abstract—The protonation and metal complexation of the sexidentate N_6 ligand, sen [5-(4′-amino-2′-azabutane)-5-methyl-3,7-diazanonane-1,9-diamine], has been investigated using potentiometric pH titrations. The ligand forms relatively strong complexes with the small, first-row transition metals, Mn^{2+} ($\log K = 8.6$), Fe^{2+} ($\log K = 13.4$), Co^{2+} ($\log K = 18.0$), Cu^{2+} ($\log K = 26.2$), Zn^{2+} ($\log K = 17.0$) and weaker complexes with the larger, main-group elements Cd^{2+} ($\log K = 13.4$), Pb^{2+} ($\log K = 9.2$) and In^{3+} ($\log K = 15.1$). Compared with other N_6 ligands and first-row transition metals, these values are high; this fact is ascribed to the almost ideal "cage-like" geometry of the complexes.

Multidentate N_6 ligands are able to saturate the coordination sphere of most metal ions in 1 : 1 complexes. Surprisingly few of these ligands have been synthesized and their metal complexes characterized. Examples of N_6 ligands include linear polyamines such as pentaethylenehexamine (3,6,9,12-tetraazatetradecane-1,14-diamine, L^1),[1,2] edta-type branched ligands like N,N,N′,N′-tetrakis(2-aminoethyl)ethane-1,2-diamine (L^2)[3,4] and N,N,N′,N′ - tetrakis(2 - aminoethyl)propane - 1,3 - diamine (L^3),[5] the trigonal open ligands, sen [5-(4′-amino-2′ - azabutane) - 5 - methyl - 3,7 - diazanonane - 1,9-diamine, L^4][6] and e-sen [5-(4′-amino-2′-azabutane)-5-ethyl-3,7-diazanonane-1,9-diamine, L^5],[7] macromonocyclic ligands like diammac (6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine, L^6)[8] and hexacyclen (1,4,7,10,13,16-hexaazacyclooctadecane, [18]ane N_6, L^7),[9] and the macrobicyclic cage-type ligands, sep (1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]eicosane, L^8)[10] and sar (1,3,6,10,13,19-hexaaza[6.6.6]eicosane, L^9).[11]

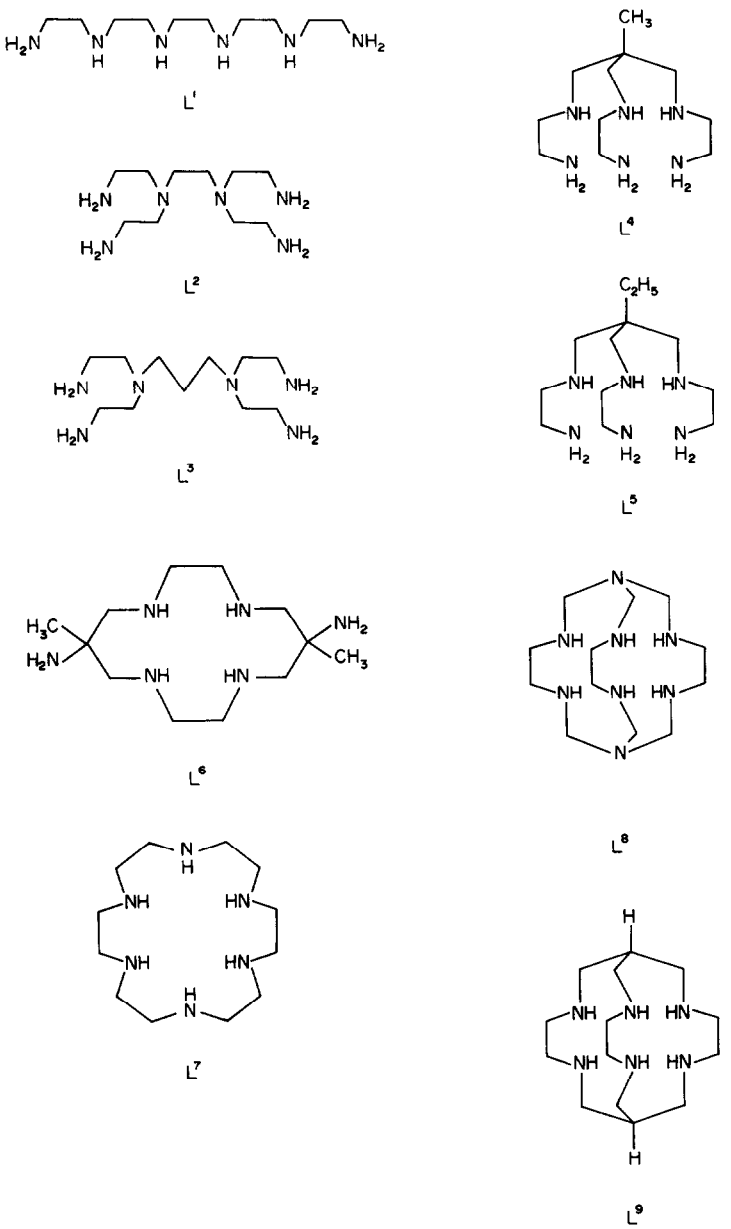
Due to their strong chelate effect these ligands are expected to form very thermodynamically stable complexes with many metal ions.[12] However, the relevant stability constants have only been determined for some of these ligands. In this contribution we report the stabilities of the complexes of sen (L^4) with the metal ions Mn^{2+}, Fe^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+} and In^{3+}, using potentiometric pH titrations. Sen has a geometry which easily accommodates smaller ions, such as the first-row transition metal ions in their 2+ oxidation state and In^{3+}, to form favourable octahedral complexes. The larger ions, Cd^{2+} and Pb^{2+}, form weaker complexes.

EXPERIMENTAL

Synthesis of 5-(4′-*amino*-2′-*azabutane*)-5-*methyl*-3,7-*diazanonane*-1,9-*diamine hexahydrobromide* (sen·6HBr, L^4)

Sen was essentially synthesized as described.[6,7] For further purification, the perchlorate salt of the nickel complex of the crude ligand was made and recrystallized from water. (**CAUTION**: Perchlorate salts are potentially explosive, care should be taken in handling the dry salt.) Bubbling H_2S through an aqueous solution of the pure $Ni(sen)^{2+}$ complex resulted in the precipitation of NiS and the release of the free ligand which was further purified by ion exchange chromatography on a Dowex 50-WX2 (H^+ form) cation exchange column, eluting with 4 M HBr solution. Evaporation to dryness yielded

*Author to whom correspondence should be addressed.



the hexahydrobromide, which was recrystallized from aqueous ethanol acidified with HBr solution.

Potentiometric titrations and data evaluation

Potentiometric titrations were obtained using a Metrohm 605 digital pH meter, a Metrohm 665 digital burette and Metrohm combined glass electrodes. All measurements were fully automated under computer control using an IBM clone computer.[13] NBS buffers pH 4 and pH 7 were used to calibrate the electrode, thus proton activities, 10^{-pH}, were used for $[H^+]$. All measurements were performed at 25°C and an ionic strength of 0.5 M KCl under nitrogen. Solutions of sen·6HBr (50 cm^3, 0.6 mM), alone and in the presence of 0.9 and 1.4 equivalents of metal ion, were titrated with 60 increments of NaOH (0.01 cm^3, 0.4 M). In the case of the copper ion, 0.1 mM of HCl was added to the solution prior to the titration. Data reduction was performed on an IBM AT clone computer using a TURBO BASIC version of TITFIT.[14]

RESULTS AND DISCUSSION

The protonation constants of the free ligand appear in Table 1 and are compared with some other N_6 ligands. The first three to four protonation constants are reasonably similar for all the listed ligands. The higher basicity of LH_4^{4+} and LH_5^{5+} in the case of sen can be ascribed to its branched

Table 1. The logarithms of the deprotonation constants and the stability constants of metal–ligand complexes with L^4 and other related N_6 ligands

	Complex	L^{4a}	L^1	L^{2b}	L^{3b}	L^{5c}	L^{7d}

and hence potentially more open structure, allowing a better spread of the high number of positive charges compared with the other ligands. The different complexation behaviour of the ligands, therefore, has to be associated with the steric properties rather than the basicities of the ligand coordination sites.

Furthermore, the metal–ligand complexation constants of sen with a variety of metal ions are compared with the ligands L^1, L^2, L^3, L^5 and L^7 in

Table 1. Confining consideration to the first-row transition metals, sen generally forms the strongest, or almost the strongest, complexes. Although sen can be considered as an open chain ligand, as a sexidentate it adopts a "hemi-cage" geometry, similar to the ligands L^8 and L^9, enhancing binding to most of the metal ions. Apparently this cage-like structure is superior to the geometries adapted by the edta-type ligands, L^2 and L^3. The stabilities of the complexes with L^4 and the very similar L^5 are in all cases higher than those with L^2 and L^3. The results for ligands L^4 and L^5 compare very well, apart from the stability of the copper complexes, where we found a value for L^4 3.5 orders of magnitude higher than the one for L^5. This discrepancy may arise from the difficulties in determining very high stability constants. The stability of the sen complexes compares very well with the macrocycle L^7 without having the extra macrocyclic effect. The exception is copper which forms the weaker protonated complex ML^7H only.

The larger main group cations Cd^{2+} and Pb^{2+} form relatively weak complexes with sen. This probably arises because the trigonal cap linking the secondary nitrogen donors limits separation of those donors in pseudo-octahedral geometries and therefore limits the size of the effective cavity, hence introducing a preference for the smaller cations. Free-ion radii of Cd^{2+} (0.97 Å) and Pb^{2+} (1.2 Å) are substantially higher than those of the first-row metal ions studied (range, 0.72–0.80 Å), suggesting that size does play an important role. The macrocyclic ligand L^7 forms significantly stronger complexes, a fact which is assigned in that case to the macrocyclic effect.

Only very few stabilities of In^{3+} complexes have been determined. However, recent interest in indium chemistry for medical applications[15,16] prompted us to include In^{3+} in the series. In^{3+}, like all elements in the third main group, strongly prefers oxygen donors and therefore the value of 10^{15} for the stability constant of the In^{3+} sen complex is surprisingly high. However, the ionic radius of free In^{3+} (0.81 Å) is not markedly different from that of first-row metal ions, suggesting the ligand allows good coordination of the ion and supporting the view that, as a sexidentate ligand, sen has a preferred cavity like macrocycles. The formation of the hydroxo species (pK 10.4) indicates that sen itself is not able to coordinatively saturate indium. One (or more) extra water ligand(s) are coordinated to the metal ion and at least one can be deprotonated. No further deprotonation has been detected and a seven-coordinate geometry might tentatively be ascribed to the complex. Figure 1 displays the species distribution curves of the species formed during the titration.

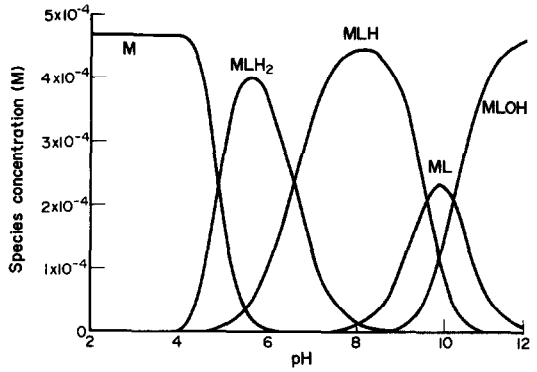

Fig. 1. Species distribution curves for the titration of L^4 (0.526 mM) with In^{3+} (0.475 mM).

Protonated complexes have been detected for all metals. The first protonation occurs at pH values between 5.9 (Co^{2+}) and 9.9 (Cu^{2+}) (see Table 1). With the exception of Mn^{2+} and Fe^{2+}, MLH_2 species have been detected at pH values between 5.6 (Co^{2+} and Cu^{2+}) and 7.5 (Pb^{2+}).

Titrations with an excess of 1.4 moles of metal with respect to ligand were performed to investigate the formation of multinuclear complexes. With the exception of copper, titrations with an excess of metal ion produced precipitates of the respective hydroxides. $Cu_2(sen)^{4+}$ has a stability of 33.5 log units, and hydroxo species $Cu_2(sen)(OH)^{3+}$ and $Cu_2(sen)(OH)_2{}^{2+}$ are formed with pK values of 7.8 and 10.7. Structural information about these multinuclear species must await spectroscopic studies.

STRUCTURES OF PALLADIUM(II) AND NICKEL(II) COMPLEXES OF THE MESOCYCLIC DIPHOSPHINE, *CIS*-1,5-DIPHENYL-1,5-DIPHOSPHACYCLOOCTANE

BRIAN W. ARBUCKLE and W. KENNETH MUSKER*

Department of Chemistry, University of California, Davis, CA 95616, U.S.A.

(*Received* 13 *August* 1990; *accepted* 10 *October* 1990)

Abstract—The preparation and X-ray crystal structures of a planar mono complex of *cis*-1,5-diphenyl-1,5-diphosphacyclooctane with palladium(II) chloride and a pentacoordinated bis complex with nickel(II) chloride are reported. Dichloro(1,5-diphenyl-1,5-diphosphacyclooctane)palladium(II) crystallizes in the monoclinic space group $C2/c$ with cell constants $a = 26.647(6)$, $b = 7.884(1)$, $c = 13{,}053(3)$ Å, $\beta = 98.15(2)°$ and $Z = 4$ at $T = 130$ K. Chloro-bis(1,5-diphenyl-1,5-diphosphacyclooctane)nickel(II) chloride crystallizes in the monoclinic space group $P2_1/n$ with $a = 18.178(7)$, $b = 10.225(2)$, $c = 20.959(7)$ Å, $\beta = 111.77(2)°$ and $Z = 4$ at $T = 130$ K.

The synthesis and coordination chemistry of a number of 1,5-disubstituted cyclooctanes have been examined in detail over the past 20 years,[1–6] but one of the last members of that series was only characterized recently[7] and no examples of its complexes are known. Both the *cis* and *trans* diastereomers of 1,5-diphenyl-1,5-diphosphacyclooctane were prepared by $LiAlH_4$ reduction of the corresponding diphosphine oxides and separated by HPLC.[7] However, only the *cis* isomer can function as a chelating agent and it can be selectively removed from the *trans* isomer by coordination. Because these ligands are bidentate dialkylphenyl phosphines, they should be expected to form complexes which have different electronic and structural properties to acyclic mono- and diphosphines and macrocyclic polyphosphines. As a first step in the development of the chemistry of these ligands, we wish to report the preparation and X-ray crystal structures of a planar mono complex of *cis*-1,5-diphenyl-1,5-diphosphacyclooctane with palladium(II) chloride and a pentacoordinated bis complex with nickel(II) chloride.

EXPERIMENTAL

Dichloro(1,5-*diphenyl*-1,5-*diphosphacyclooctane*)*palladium*(II)

$PdCl_2(PhCN)_2$ (0.13 g, 0.34 mmol) was suspended in CH_2Cl_2 (5 cm^3). A mixture of *cis* and *trans*-1,5-diphenyl-1,5-diphosphacyclooctane (0.10 g, 0.33 mmol) was dissolved in CH_2Cl_2 (2 cm^3) and added dropwise to the solution of $PdCl_2(PhCN)_2$. After the addition was complete, the solution was stirred at reflux for 20 min. The solvent was removed to give an orange–yellow solid (yield: 0.12 g, 73%). Yellow crystals suitable for structural determination were grown by slow diffusion of diethyl ether into a methylene chloride solution of the complex. The crystallographic data for dichloro(1,5-diphenyl-1,5-diphosphacyclooctane) palladium(II) are given in Table 1.

Chloro-bis(1,5-*diphenyl*-1,5-*diphosphacyclooctane*)*nickel*(II) *chloride*

$NiCl_2 \cdot 6H_2O$ (0.030 g, 0.23 mmol) was dissolved in methanol (2 cm^3). A mixture of *cis* and *trans*-1,5-diphenyl-1,5-diphosphacyclooctane (0.063 g, 0.21 mmol) was dissolved in benzene (2 cm^3). The two reagents were added dropwise into a flask containing 2 cm^3 of benzene. The solution turned a deep purple colour and the solvent was removed to give a red solid. Thin layer analysis revealed two species in the crude product which was dissolved in 5% ethanol–$CHCl_3$ and run through a column of neutral alumina. The first component from the column was a purple complex (yield: 0.10 g, 62%). The second component from the column was an uncharacterized red–orange compound which could not be recrystallized. Purple crystals suitable for structural determination were grown by slow diffusion of hexane into an ethanol solution of the

complex. The crystallographic data for chloro-bis(1,5-diphenyl-1,5-diphosphacyclooctane)nickel (II) chloride are also given in Table 1.

Structure determination and refinement

Crystals of the title complexes were coated with a hydrocarbon oil to retard decomposition, attached to a glass fibre with silicone grease and mounted in the cold stream of a Syntax $P2_1$ graphite monochromator diffractometer (Mo-K_α, $\lambda = 0.71069$) equipped with a locally modified LT-1 low temperature device ($T = 130$ K). The space groups were derived from observed extinctions. Crystals were obtained as explained in the Experimental. The 2θ range for all compounds was 0–50°. No decay in the intensity of standard reflections was observed during data collection. Solution of the structure was accomplished using the Patterson technique. All computing was carried out using the SHELXTL version 5 program installed on a Data General Eclipse computer. Atomic scattering factors and anomalous dispersion corrections were from common sources.[8] An absorption correction[9] was applied and structural refinement proceeded smoothly in the case of all compounds. All non-hydrogen atoms were assigned anisotropic thermal parameters, except in the palladium complex. Here, all non-hydrogen atoms and non-carbon atoms were assigned anisotropic thermal parameters except for three atoms in a disordered ethanol molecule, carbons C(10) and C(11) and oxygen O [O(a) and O(b)]. Oxygen (O) has partial occupancy of 50% in two positions [O(a) and O(b)]. Carbon C(2) has partial occupancy of 50% in two positions [C(2a) and C(2b)]. The hydrogen atoms were excluded from carbons C(2), C(10), C(11) and the atoms bonded to C(2) [C(1) and C(3)]. Five peaks were seen in the difference map with an electron density between 1.2 and 1.9, all due to the disordered ethanol molecule.

Hydrogen atoms were refined using a riding model in which an idealized C—H vector, 0.96 Å length, was recalculated with each cycle of refinement. Isotropic hydrogen thermal parameters were fixed at 1.2 times the equivalent isotropic thermal

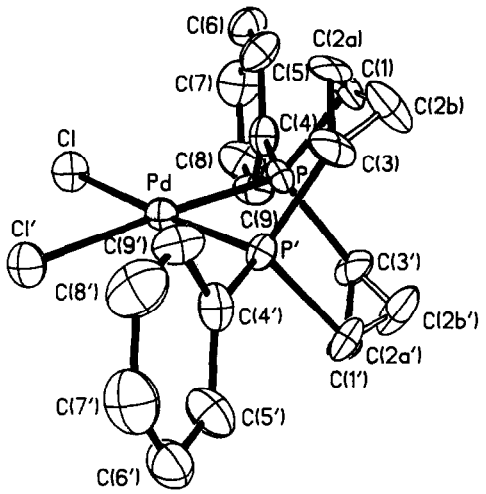

Fig. 1. Structure of dichloro(1,5-diphenyl-1,5-diphosphacyclooctane)palladium(II) showing 50% probability ellipsoids.

parameter of the bonded atom. Atomic coordinates for all compounds are given in the supplementary material.

DISCUSSION

Dichloro(1,5 - *diphenyl* - 1,5 - *diphosphacyclooctane*) *palladium*(II)

When a mixture of *cis* and *trans*-1,5-diphenyl-1,5-diphosphacyclooctane is treated with $PdCl_2(PhCN)_2$, a yellow precipitate containing yellow crystals forms. The X-ray crystal structure of the complex was carried out on a typical crystal recovered from the reaction flask. Figure 1 shows that *cis*-1,5-diphenyl-1,5-diphosphacyclooctane acts as a bidentate ligand by coordinating to the palladium atom through both phosphorus atoms. A crystallographic two-fold axis passes through the palladium and bisects the P—Pd—P angle. Selected bond lengths and bond angles are given in Tables 2 and 3. The final atomic coordinates are given in the supplementary material. The middle carbon in each methylene chain is disordered, having a partial occupancy of 50%. This shows that the ring is fluctional and the middle carbon on each trimethylene chain can either be pointing towards the palladium, C(2a), or pointing away from it, C(2b).

Table 2. Selected bond lengths (Å) for dichloro(1,5-diphenyl-1,5-diphosphacyclooctane)palladium(II)

Pd—C(1)	2.373(4)	Pd—P	2.234(4)
P—C(1)	1.840(13)	P—C(4)	1.835(13)
P—C(3a)	1.820(12)		

The four atoms, Cl, Cl(a), P, P(a), are in a planar arrangement about the palladium atom. The calculated distance from the best least-squares plane through these five atoms is as follows: Pd, 0.000; Cl, −0.017; P, 0.019; Cl(a), 0.017; P(a), −0.019 Å. The P—Pd—P bite angle of 83.3(2)° is smaller than that found in other diphosphine complexes, except when a four-membered ring is formed.[10] For example, in the following series of palladium thiocyanate complexes, $Pd(SCN)_2(Ph_2P(CH_2)_nPPh_2)$ (n = 1–3), the bite angle increases from 73.33(5) to 85.1(1) to 89.32(3)°, as n increases from 1 to 2 to 3.[10] The bite angle in the mesocycle is also much smaller than the bite angle [97.85(1)°] in the analogous acyclic bis-dialkylarylphosphine complex, *cis* - dichlorobis(dimethylphenyl)phosphinepalladium (II).[11]

The Pd—P bond length is 2.234(4) Å. This is in the lower range of the Pd—P bond lengths in the thiocyanate complexes shown above (2.24–2.28 Å)[10] and typical of complexes where the phosphine is *trans* to chloride; 2.260(2), [11] 2.232 and 2.237[12] and 2.220(4) Å.[13] The latter complex has a four-membered Pd—P—N—P ring. The Pd—Cl bond length of 2.373(4) Å is slightly longer than Pd—Cl bond lengths where the chloride is *trans* to a phosphine; typical values are 2.362(3),[11] and 2.357(2) and 2.352(1) Å.[12]

Table 3. Selected bond angles (°) for dichloro(1,5-diphenyl-1,5-diphosphacyclooctane)palladium(II)

Chloro - bis(1,5 - diphenyl - 1,5 - diphosphacyclooctane)nickel(II) chloride

When a mixture of *cis* and *trans*-1,5-diphenyl-1,5-diphosphacyclooctane is treated with $NiCl_2 \cdot 6H_2O$ a red solid is observed. Thin layer analysis reveals the solid to be a mixture of two components. After the solid was dissolved and chromatographed through a column of neutral alumina, two complexes were isolated; one is a reddish-orange colour and the other is a purple colour.

An X-ray structure determination of the purple compound revealed that it was a pentacoordinated nickel complex, Ni[Cl(*cis*-1,5-diphenyl-1,5-diphosphacyclooctane)$_2$]Cl as shown in Fig. 2. Selected bond lengths and bond angles are given in Tables 4 and 5.

The final atomic coordinates and a complete list of bond lengths and angles are given as sup-

plementary material. The molecule exhibits a distorted trigonal bipyramidal geometry with the chlorine atom occupying an equatorial position. Two phosphorus atoms [P(2) and P(4)] lie along the axis and are 179.7° apart. The Ni^{II}—P bond lengths range from 2.202(1) to 2.237(1) Å, values which are typical for trigonal bipyramidal nickel(II) complexes.[14,15] The Ni^{II}—Cl bond length is 2.410(1) Å, which is also typical.[16,17] The P—Pd—P bite angles for the chelated phosphines (83.7 and 84.1 Å) are similar to those observed in the palladium complex. The phenyl groups on the phosphorus atoms of different ligands are oriented in a near parallel fashion to each other and very similar to that observed in Pt(5-phenyl-1-thia-5-phosphacyclooctane)$_2$(BPh$_4$)$_2$.[6]

Abstract—The reaction of $[Ru(CO)Cl(RC{=}CHR')(PPh_3)_2]$ complexes with $Na[S_2CNEt_2]$ and $K[S_2CO^iPr]$ gave the complexes, $Ru(S{-}S)(CO)(RC{=}CHR')(PPh_3)_2$, where S—S = S_2CNEt_2 and S_2CO^iPr, respectively, and in which the sulphur-containing ligands are η^2-coordinated to ruthenium. The structures of the synthesized products are proposed on the basis of spectroscopic data and they contain octahedral ruthenium(II) with the S—S, CO and —RC=CHR′ ligands in an equatorial plane and the two phosphines in the *trans* position. The chemical shifts (δ) of the terminal alkenyl-containing complexes have been compared with those of the related carboxylate complexes $[Ru(O_2CR'')(CO)(HC{=}CHR')(PPh_3)_2]$.

The unsaturated complexes $[Ru(CO)Cl(RC{=}CHR')(PPh_3)_2]$[1–3] are very reactive toward carboxylate anions, giving rise to complexes $[Ru(O_2CR'')(CO)(RC{=}CHR')(PPh_3)_2]$ in which the O_2CR'' ligand is η^2-coordinated to the metal.[4,5] The substitution of the chloride by the carboxylate group leaves the alkenyl ligand unchanged. The structures of the $[Ru(O_2CR'')(CO)(HC{=}CHR')(PPh_3)_2]$ complexes were established by X-ray crystallography which demonstrate the saturation of the metal centre by the ligands and the *trans* position of phosphines. At the same time, the donor strength of the carboxylate ligands induced changes in the chemical shifts of the alkenylic hydrogens in the ^1H NMR of complexes with respect to the signals of the same protons in the $[Ru(CO)Cl(RC{=}CHR')(PPh_3)_2]$ complexes.[4,5] In order to induce some transformation in the alkenyl ligand coordinated to ruthenium, we attempted to introduce strong chelating and very strong donor ligands containing sulphur atoms, for example diethyldithiocarbamate ($S_2CNEt_2^-$) and isopropylxanthate ($S_2CO^iPr^-$). These sulphur-containing ligands should induce π-interactions different from those produced by carboxylate ligands.

The literature on dithiocarbamate and xanthate ligands is very extensive[6] but information on their coordination chemistry with ruthenium(II)[7] is scarce and their catalytic applications unknown.[8] The dithiocarbamate ligand causes interesting reactivity in some organic fragments coordinated to transition metals. For example, the substitution of a halide by $S_2CNMe_2^-$ in the $[Mo(\eta^2\text{-}COR)X(CO)_n(PMe_3)_{4-n}]$ complexes yielded an unprecedented acetyl compound $[Mo(COCH_3)(S_2CNMe_2)(CO)(PMe_3)_2]$ in which the molybdenum atom interacts with a β-C—H bond to the acetyl group.[9] Another point of interest is the coupling of two alkynes η^2-coordinated to the same metal which is promoted by the action of HBF_4 upon the $[W(S_2CNEt_2)_2(PhC{\equiv}CPh)_2]$ complex producing a η^4-C_4Ph_4H ligand.[10] In this work we attempted to increase the reactivity of the alkenyl group by the introduction

of sulphur-containing ligands, such as $S_2CNEt_2^-$ and $S_2CO^iPr^-$, into the Ru(CO)Cl(RC═CHR′)$(PPh_3)_2$ complexes. The results reflect no apparent changes in the alkenyl groups. The synthesized complexes were identified by C, H and N analyses and spectroscopic methods.

RESULTS AND DISCUSSION

When a CH_2Cl_2 solution of a [Ru(CO)Cl(RC═CHR′)$(PPh_3)_2$] complex (R = R′ = H, Me, Ph and CO_2Me; R = H and R′ = Ph, ^{t}Bu, $SiMe_3$, CO_2Me and CO_2Et) was reacted with a small excess of Na[S_2CNEt_2] or K[S_2CO^iPr], dissolved in MeOH, new yellow crystalline complexes were obtained in very good yields. The solubility and stability of these complexes were similar to those of the related carboxylate [Ru(O_2CR'')(CO)(RC═CHR′)$(PPh_3)_2$] complexes.[4] The C, N and H elemental analyses of the products were in accordance with the formulation [Ru(S—S)(CO)(RC═CHR′)$(PPh_3)_2$] (S—S = S_2CNEt_2 and S_2CO^iPr).

The IR and ^{1}H NMR data of the products are given in Tables 1 and 2. The solid IR spectra of these complexes display the characteristic bands of ligands coordinated to ruthenium. The [Ru(S_2CNEt_2)(CO)(RC═CHR′)$(PPh_3)_2$] derivatives show absorptions of the dithiocarbamate ligand at *ca* 1010 and 850 cm^{-1}, corresponding to $\nu(S_2C)$ vibrations.[11] The former is the $\nu(S_2C)_{asym}$ band which appears as a shoulder on one absorption which is also observed in [Ru(CO)Cl(RC═CHR′)$(PPh_3)_2$] complexes. The literature[11] does not assign any absorption to the dithiocarbamate ligand at *ca* 850 cm^{-1} but assuming that a medium band is observed in this position in all [Ru(S_2CNEt_2)(CO)(RC═CHR′)$(PPh_3)_2$] complexes and which is also displayed at higher energies in the IR spectrum of the sodium salt of the ligand, we assign the absorption to the $\nu(S_2C)_{sym}$ vibration. The vibration associated with ν(CN) is observed at *ca* 1548 cm^{-1}. The Ru(S_2CO^iPr)(CO)(RC═CHR′)$(PPh_3)_2$ complexes also present IR spectra with the $\nu(S_2C)$ bands at *ca* 1235 and 1049 cm^{-1} and the ν(C—O) at *ca* 1140 cm^{-1}. The strong ν(C≡O) absorptions of the sulphur derivatives[12] appear between 1909 and 1927 cm^{-1} in the dithiocarbamate complexes and at 1897–1943 cm^{-1} in the xanthate complexes. The general shift observed towards lower energies is indicative of the electron-releasing character of the ligands. The minimal ν(C≡O) values are displayed by complexes with terminal alkenyl groups containing alkyl or phenyl substituents. In complexes with an alkenyl ligand containing electron-withdrawing groups the ν(C≡O) band is observed at 1920–1943 cm^{-1}. The ν(C═C) band is often obscured by other intense absorptions but is located at *ca* 1540 cm^{-1}.

The ^{1}H NMR of two families of complexes {[Ru(S_2CNEt_2)(CO)(RC═CHR′)$(PPh_3)_2$] and [Ru(S_2CO^iPr)(CO)(RC═CHR′)$(PPh_3)_2$]} display signals due to the hydrogens of the coordinated ligands. In the complexes containing terminal alkenyl groups the signals of H_α and H_β appear as doublets with J_{H-H} = 16 Hz, indicating a *trans* disposition of the hydrogens.[4] The H_α signal is observed at 6.3–9.5 ppm and H_β at 4.5–5.5 ppm. In

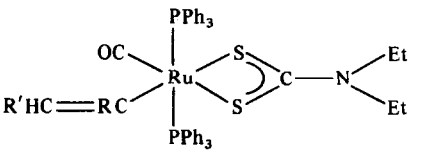
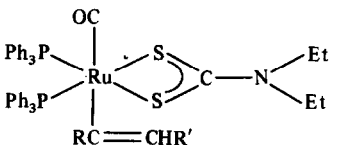
the complexes $[Ru(S—S)(CO)(HC{=}CH_2)(PPh_3)_2]$ (S—S = S_2CNEt_2 or S_2CO^iPr) the signals of the vinylic protons have values of $J_{H—H(trans)} = 16$ Hz and $J_{H—H(cis)} = 8$ Hz, whereas the geminal H—H coupling was too small to be resolved. The complexes containing a disubstituted alkenyl ligand display the alkenyl proton signals at 4.5–5.9 ppm.

As well as in related carboxylate complexes[4,5] the H_α and the H_β hydrogens are shifted in comparison with the same signals in the $Ru(CO)Cl(RC{=}CHR')(PPh_3)_2$ complexes. In Table 3 are shown the $[\Delta\delta = \delta(H_\alpha) - \delta(H_\beta)]$ values (in ppm) of some complexes synthesized by our group. It can be seen that the greater $\Delta\delta$ values are displayed by $[Ru(CO)Cl(HC{=}CHR')(PPh_3)_2]$ complexes. When L—L is a donor chelating ligand a general decrease in $\Delta\delta$ is observed which appears to be dependent on R′ and L—L. For R′ = ^{t}Bu, the greater $\Delta\delta$ values are displayed by complexes containing dithiocarbamate and xanthate ligands. The minimal $\Delta\delta$ values are displayed by the carboxylate-containing complexes. For complexes with R′ = CO_2Me, an electron-withdrawing group, the $\Delta\delta$ are higher, but carboxylate, dithiocarbamate and xanthate complexes show similar values. It appears that if R′ is an alkyl group (^{t}Bu), the σ-donor ability of the ligand induces a major approach of the H_α and H_β signals (carboxylates). If R′ is a strong electron-withdrawing group, the same effect is lower and not dependent on the donor characteristics of L—L. When L—L is CO and Cl $\{[Ru(CO)_2Cl(HC{=}CHR')(PPh_3)_2]\}$ the $\Delta\delta$ is similar to that of complexes containing dithiocarbamate and xanthate ligands. From these results it seems that CO and sulphur-containing ligands probably have similar electronic effects on the H_α and H_β hydrogens of terminal alkenyl ligands through π-interactions. Thus, the donor capabilities of the dithiocarbamate and xanthate ligands are combined with a π-acceptor character which is manifested in the ^{1}H NMR of the terminal alkenyl ligands coordinated to the same metal.

The stereochemistry of $[Ru(S_2CNEt_2)(CO)(RC{=}CHR')(PPh_3)_2]$ complexes can be deduced from ^{1}H NMR and ^{31}P NMR spectroscopies.[13] The planar configuration of the dithiocarbamate ligand and the high rotation energy[13] of the C—N bond allow us to distinguish between stereochemistries **I** and **II** with the ^{1}H NMR of complexes.



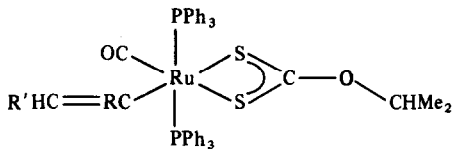
(I)



(II)

The ^{1}H NMR spectra of dithiocarbamate complexes at room temperature show different signals of the ethyl groups indicating structure **I** with the PPh_3 ligands in a *trans* position. This structure is supported by the ^{1}H-decoupled ^{31}P NMR spectra at room temperature of complexes $[Ru(S_2CNEt_2)(CO)(MeC{=}CHMe)(PPh_3)_2]$ and $[Ru(S_2CNEt_2)(CO)(HC{=}CHCO_2Me)(PPh_3)_2]$ which display signals at 34.32 and 39.77 ppm, respectively, characteristic of equivalent phosphorus atoms. The room temperature ^{1}H NMR spectra of xanthate complexes display one signal of the ^{i}Pr group revealing that the rotation around the C—O bond is fast on the NMR time-scale. The ^{1}H decoupled ^{31}P NMR spectra of $[Ru(S_2CO^iPr)(CO)(MeC{=}CHMe_2)(PPh_3)_2]$ and $[Ru(S_2CO^iPr)$

$(CO)(HC{=}CHPh)(PPh_3)_2]$, registered at room temperature, present singlets at 40.17 and 39.94 ppm, respectively, which are in accordance with an equivalence of phosphines and with a structure with the two PPh_3 in a *trans* position (**III**). Summarizing, the proposed structures for the complexes contain the two PPh_3 ligands in a *trans* position and the rest of the ligands in an equatorial plane, in accordance with the NMR data and with the structures of the related carboxylate complexes $[Ru(O_2CR'')(CO)(RC{=}CHR')(PPh_3)_2]$. The proposed structures for the dithiocarbamate and xanthate complexes are shown as **I** and **III**.



(III)

The synthesis of the complexes was performed by means of conventional Schlenk techniques. The starting materials $[Ru(CO)Cl(RC{=}CHR')(PPh_3)_2]$ were synthesized by published methods.[1-3] The compound $K[S_2CO^iPr]$ was prepared by the standard method from ^iPrOH, KOH and CS_2,[14] while $Na[S_2CNEt_2]$ was used as purchased. The IR spectra were recorded on a Perkin–Elmer 1710-FT apparatus using KBr disks. The ^1H NMR spectra were measured on a Bruker AM 400 spectrometer in $CDCl_3$ solutions and referenced to $SiMe_4$. The ^1H-decoupled ^{31}P NMR spectra were recorded on the same instrument in $CDCl_3$ solutions with aqueous 85% H_3PO_4 as external reference. The C, H and N elemental analyses were performed with a Perkin–Elmer 240-B analyser.

Synthesis of complexes

A small excess of $Na[S_2CNEt_2]$ or $K[S_2CO^iPr]$ dissolved in MeOH was added, with stirring, to a CH_2Cl_2 solution of $[Ru(CO)Cl(RC{=}CHR')(PPh_3)_2]$. The solution was stirred until the liquid turned yellow (30 min) and then the liquid was evaporated to dryness *in vacuo* and the residue extracted with CH_2Cl_2. The solution was concentrated and the products precipitated with petroleum ether. The crystalline products can be recrystallized with CH_2Cl_2–MeOH mixtures.

(*Received* 15 *August* 1990; *accepted* 10 *October* 1990)

Abstract—The binuclear, nitrosyl-bridged complex $Cs_2[Mo_2Cl_5H(NO)_2]$ was synthesized and employed in the oxygenation of nitric oxide, with insufficient oxygen. The mechanism of the oxygenation process is discussed and the "catalytic" activity of the complex in such a process described.

The goal of our work was to synthesize a molybdenum complex with nitrosyl bridges and examine the influence of such a complex on the process of nitric oxide oxygenation when oxygen is used in an insufficient amount.

The problems of treatment and utilization of nitrogen oxides as the components of exhaust gases have been known for many years[1] and there are many catalytic and non-catalytic methods involving either reduction[2] or oxygenation of NO_x.[3] The former reactions are much better known and applied more often, but the presence of oxygen, as an inseparable component of the gases, imposes serious difficulties on such processes.

Nitric oxide is hardly soluble in any alkaline solution, while the higher oxides of nitrogen are readily soluble.[4] In every case nitric oxide is present in the gases since the amount of air (oxygen) is insufficient to oxygenate it. Therefore, the methods of "extra oxygenation" of oxides of nitrogen followed by the absorption of the gases in alkaline solution have been widely applied.[1]

On the other hand, the reactivity of the nitrosyl complexes towards oxygen and nitric oxide has been indicated in the literature;[5] as a rule, these reactions are redox processes.[6] In our previous work[7] we described the possibility of such a reaction in the case of a molybdenum(II) complex with nitrosyl bridges and gaseous nitric oxide.

EXPERIMENTAL

The first stage of our work was to synthesize and characterize the nitrosyl molybdenum complex. The hydrido complex, $Cs_3[Mo_2Cl_8H]$, was prepared according to the literature[8] and the nitrosyl complex was obtained in the heterogeneous reaction with gaseous nitric oxide. Nitric oxide was formed in the reaction of $NaNO_2$ with $FeSO_4$ in H_2SO_4 solution and then purified by passing through a concentrated solution of KOH, and then over NaOH pellets. The reaction was carried out under strictly deoxygenated conditions and controlled by determination of the liberated NOCl, which was absorbed in 10% KOH, while the abstracted chlorides were determined using standard methods.[9] The solid-state mixture (complex + CsCl) was dissolved in THF and the CsCl was filtered off and dissolved in water to determine $[Cl^-]$ ions. The organic solution was evaporated and the residue was analysed using standard methods of elemental analysis. The results based on the formula $Cs_2Mo_2Cl_5HN_2O_2$ were as follows: Found: Mo,27.4; Cl, 25.8; N, 4.1 (or 3.9—from TG curve). Calc.: Mo. 27.6; Cl, 25.5; N, 4.0%. The complex was formed in the following reaction:

* Author to whom correspondence should be addressed.

$$Cs_3[Mo_2Cl_8H]+4NO \longrightarrow Cs_2[Mo_2Cl_5H(NO)_2]+CsCl+2NOCl.$$

The spectroscopic analysis of the complex was obtained with a Beckman 5240 spectrophotometer (absorption bands) and a Specord 75 IR spectrophotometer (IR measurements in KBr pellets). Magnetic susceptibility was measured using a Gouy balance and the thermogravimetric analysis was carried out with a Q-1500 D Paulik–Paulik system derivatograph.

The reactions of nitric oxide with oxygen in the presence of the complex were carried out in special tubes previously vented with argon. The mixtures of nitric oxide and oxygen (M : M = 10 : 1, 20 : 1, 30 : 1) were reacted with solid $Cs_2[Mo_2Cl_5H(NO)_2]$ several times using different amounts of the complex. In every case oxygen was added as the first component. The amounts of nitrogen oxides were determined spectrophotometrically[10] by dissolving in 2 M KOH and then determining as nitrites and nitrates. Since nitric oxide is almost insoluble in KOH (nevertheless the amounts of NO_2^- corresponding to nitric oxide were subtracted) the NO_2^- and NO_3^- formed are the products of the reaction of NO_2, N_2O_4 and N_2O_5 with KOH. The amounts of NO_2^- and NO_3^- could be easily converted into the quantities of the corresponding oxides. The reactions of similar compositions of the NO/O_2 mixtures were examined as references.

Table 1. IR vibrations of $Cs_2[Mo_2Cl_5H(NO)_2]$

Frequency (cm^{-1})	Assignment
1650(w)	ν_{as}(Mo—H—Mo)
1380(vs)	$\nu(NO_b)$

620(m)	ν(Mo—N)
550(m)	δ(Mo—O—Mo, N)
540(w)	δ(Mo—H—Mo)
310(w), 295(m)	ν(Mo—Cl_t)
280(w)	ν(Mo—Cl_b)

RESULTS AND DISCUSSION

Characterization of the $Cs_2[Mo_2Cl_5H(NO)_2]$ *complex*

IR vibrations of the complex are presented in Table 1. The vibration at 1380 cm^{-1} is typical for a bridging nitrosyl group.[7,11] Dissolution of the complex in water is accompanied by the liberation of gaseous hydrogen and this fact, together with two weak intensity vibrations at 1650 and 1250 cm^{-1}, support the presence of the bridging hydrogen in the coordination sphere of the complex. The 60 cm^{-1} shift of ν_{as}(Mo—H—Mo) in comparison with the initial complex[12] is due to the presence in the coordination sphere of nitric oxide, a ligand with strong π-acceptor ability. The presence of the two suggested nitrosyl groups is supported by the thermal analysis results (see Fig. 1).

Two well-distinguished slopes in the mass loss curve (TG) between 400 and 600 K could be attributed to the two different nitrosyl groups abstracted from the complex in the form of gaseous dinitrogen.[13] These phenomena are accompanied by two peaks in the DTG and DTA curves due to the chemical reactions taking place during heating. The absorption bands of the complexes are presented in Table 2. The decay of the band attributed to the $\delta \rightarrow \delta^*$ transition in the initial complex is due to the cleavage of the Mo—Mo multiple bond. This is a typical effect of the multiple bond complex reactions with nitric oxide.[15] The complex formed is almost diamagnetic ($\mu_{eff.} = 0.3$ BM). Electrons from d_{xz} and d_{yz} orbitals could be effectively delocalized to the π^* orbitals of nitric oxide and then transferred to the lower unoccupied orbital (LUMO) of the central atom, i.e. b_2.[16] The transfer

Table 2. Absorption bands and their characterization for $Cs_3[Mo_2Cl_8H]$ and $Cs_2[Mo_2Cl_5H(NO)_2]$ in 9 M HCl

Frequency (cm^{-1})	ε	Assignment
	$Cs_3[Mo_2Cl_8H]$[14]	
13,330	310	$e \rightarrow b_2$
28,570	2100	$e \rightarrow b_1$
32,790	12,500	$\pi \rightarrow \pi^*$
42,920	24,000	$e \rightarrow d_{x^2-y^2}$
45,450	22,000	$Cl \rightarrow b_2$
	$Cs_2[Mo_2Cl_5H(NO)_2]$	
18,690	330	$^2B_2(\pi^*_{NO}) \rightarrow \pi^*_{NO}$
23,810	1700	$^2A_1 \rightarrow {}^2B_2$
42,190	12,000	$^2A_1 \rightarrow \pi^*_{NO}$
47,600	16,500	$Cl \rightarrow {}^2B_2$

mentioned is the reason for a high activation of the bridged nitrosyl group.[17]

Reactions with oxygen and nitric oxide mixtures

It is worthy of note that the reactions of nitric oxide with oxygen in the absence of the complex have yields of about 3% (see Fig. 2). The results of similar reactions in the presence of the complex are presented in Fig. 3.

The process is not due to adsorption since the relation between the amount of oxygenated nitric oxide and the amount of the complex is curvilinear (see Fig. 4).

Consideration of the equilibrium constants of the possible reactions during the experiment[18] leads to the conclusion that the duration of the process could effect the composition of the higher nitrogen oxides formed. Since the applied method of analysis (see Experimental) enables simultaneous determination of both nitrites (as the products of the NO_2+OH^- reaction) and nitrates (N_2O_4 and $N_2O_5+OH^-$ reaction), we could estimate the amounts of NO_2 and N_2O_5 gases produced. It is clear (see Fig. 5) that the longer reaction time favours the higher contents of N_2O_5. Thus, the following reaction scheme could be proposed:

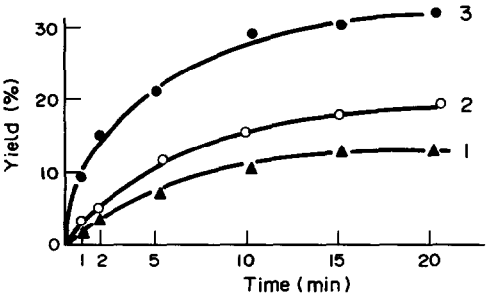

Fig. 3. Yields of the $NO+O_2$ reaction (%) vs time in the presence of $Cs_2[Mo_2Cl_5H(NO)_2]$. [Complex] = 0.5×10^{-4} M, [NO] = 4×10^{-3} M; [O_2] = 0.13×10^{-4} (1), 0.2×10^{-4} (2), 0.4×10^{-4} M (3).

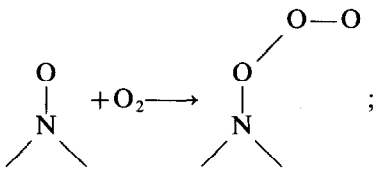
(I) coordination of oxygen into the highly activated bridging NO group:



;

(II) abstraction of the very reactive NO_3 group from the coordination sphere;

(III) reaction of NO_3 with NO supplied into the system

$$NO_3 + NO \longrightarrow 2\,NO_2,$$

with the simultaneous reconstruction of the coordination sphere of the complex;

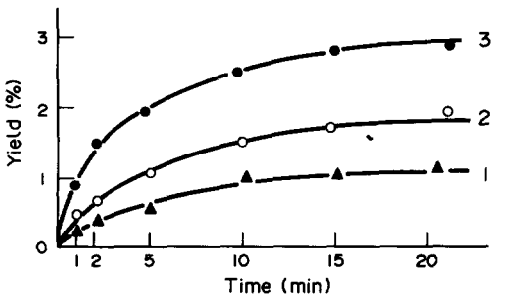


Fig. 2. Yields of the $NO+O_2$ reaction (%) vs time. [NO] = 4×10^{-3} M; [O_2] = 0.13×10^{-4} M (1), 0.2×10^{-4} M (2), 0.4×10^{-4} M (3).

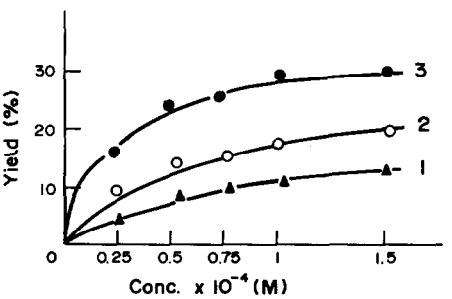

Fig. 4. Yields of the $NO+O_2$ reaction (%) vs the amount of complex, t = 15 min (Concentrations of the gases—as in Fig. 3.)

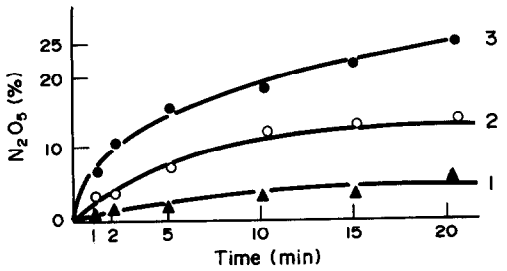

Fig. 5. The percentage of N_2O_5 in the gaseous products of the $NO+O_2$ reactions vs time. (Concentrations—as in Fig. 3.)

(IV) the slowest process,

$$NO_3 + NO_2 \longrightarrow N_2O_5.$$

The formation of the NO_3 group with the peroxo structure [reaction (I)] is a well known process,[19] while the lack of nitrite or nitro complexes on the solid surface (confirmed by recording an IR spectrum after each of the experiments) suggests the homolytic liberation of the NO_3 group[20] [reaction (II)]. The nitric oxide supplied readily reacts with NO_3, according to the corresponding rate constant,[18] while its excess reconstructs the coordination sphere of the complex [reaction (III)] and, as a consequence, the complex appears to behave as a catalyst. Kinetic factors contribute to the reaction of NO_3 with NO_2 [reaction (IV)] when sufficient time for the reaction is assured (see Fig. 5).

CONCLUSIONS

The oxygenation of nitric oxide is about 10 times more effective in the presence of the $Cs_2[Mo_2Cl_5H(NO)_2]$ complex in a system which is deficient in oxygen, due to the reactivity of the nitrosyl bridges.

SEVEN-COORDINATE ACETYLACETONATO, HEXAFLUOROACETYLACETONATO AND BENZOYLACETYLACETONATO COMPLEXES OF MOLYBDENUM(II) AND TUNGSTEN(II)

PAUL K. BAKER* and DAFYDD AP KENDRICK

Department of Chemistry, University of Wales, Bangor, Gwynedd LL57 2UW, U.K.

(*Received* 7 *September* 1990; *accepted* 11 *October* 1990)

Abstract—The complexes $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) react in CH_2Cl_2 with one or two equivalents of PPh_3 to give $[MI_2(CO)_3(NCMe)(PPh_3)]$ or $[MI_2(CO)_3(PPh_3)_2]$, which when reacted, *in situ*, with one equivalent of Na[L⌒L] [L⌒L = acetylacetonato (acac), hexafluoroacetylacetonato (hfacac) or benzoylacetylacetonato (bzacac)] give the seven-coordinate complexes $[MI(CO)_3(PPh_3)(L⌒L)]$ and $[MI(CO)_2(PPh_3)_2(L⌒L)]$, respectively. The low temperature ^{13}C NMR spectra of selected complexes are interpreted to suggest the likely structures of these compounds.

Seven-coordinate complexes of molybdenum(II) and tungsten(II) containing bidentate anionic sulphur donor ligands such as dithiocarbamates and xanthates are numerous,[1–7] whereas analogous seven-coordinate compounds containing bidentate anionic oxygen donor ligands are relatively scarce. A series of seven-coordinate mono(chloro) compounds of the type $[MCl(CO)_2L'_2(L⌒L)]$ (M = Mo or W; L′ = PEt_3 or PPh_3; L⌒L = acac or hfacac) were prepared by the reaction of $[MCl_2(CO)_3(PPh_3)_2]$ with the sodium salts of either acetylacetone or hexafluoroacetylacetone.[8] The six-coordinate, 16-electron complex $[MoBr_2(CO)_2(PPh_3)_2]$ reacts with the sodium salts of a series of anionic bidentate oxygen and sulphur ligands to give the mono(bromo) compounds $[MoBr(CO)_2(PPh_3)_2(L⌒L)]$.[9]

In this paper we describe the synthesis and properties of some new mono(iodo) seven-coordinate complexes of molybdenum(II) and tungsten(II), containing anionic oxygen donor ligands derived from acetylacetone, hexafluoroacetylacetone or benzoylacetylacetone.

EXPERIMENTAL

All reactions were carried out under nitrogen using standard Schlenk techniques. The complexes $[MI_2(CO)_3(NCMe)(PPh_3)]$ (M = Mo or W)[10] and $[MI_2(CO)_3(PPh_3)_2]$[11] were prepared by the published methods. All chemicals were purchased from commercial sources. Dichloromethane was dried over P_4O_{10} and distilled, and all solvents were purged of oxygen before use. ^1H NMR spectra were recorded on a Bruker AC 250 CP/MAS NMR spectrometer and the low temperature ^{13}C NMR spectra were recorded on a Bruker WH 400 NMR spectrometer (all spectra were calibrated against tetramethylsilane). IR spectra were recorded on a Perkin–Elmer 1430 spectrophotometer. Elemental analyses for C, H and N were obtained using a Carlo Erba Elemental Analyser MOD 1106 (with helium as a carrier gas).

$[MoI(CO)_3(PPh_3)(acac)]$ (1)

To acetylacetone (0.097 g, 0.969 mmol) was added NaH (0.0466 g, 0.967 mmol, 50% by weight) and the mixture stirred in Et_2O (5 cm^3) for 5 min, with evolution of H_2 (g). The solvent was removed *in vacuo* and the resulting sodium salt resolvated in CH_2Cl_2 (5 cm^3) and MeOH (5 cm^3). To $[MoI_2(CO)_3(NCMe)_2]$ (0.500 g, 0.969 mmol) dissolved in CH_2Cl_2 (15 cm^3), with continuous stirring under a stream of dry nitrogen was added PPh_3 (0.254 g, 0.968 mmol). After stirring for 1 min, the previously prepared solution of Na[acac] was added and the mixture stirred for a further 18 h; after

which the solvents were removed *in vacuo*. The product was resolvated in CH_2Cl_2 (15 cm^3) and filtered to remove NaI before the solvent was again removed *in vacuo* to give the dark brown crystalline complex $[MoI(CO)_3(PPh_3)(acac)]$ (**1**) (yield: 0.49 g, 76%), which was recrystallized from CH_2Cl_2.

Similar reactions of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with one equivalent of PPh_3, followed by an *in situ* reaction with one equivalent of $Na[L\frown L]$ ($L\frown L$ = acac, hfacac or bzacac) gave the new complexes $[MI(CO)_3(PPh_3)(L\frown L)]$ (**2–6**). (See Table 1 for physical and analytical data.)

$[MoI(CO)_2(PPh_3)_2(acac)]$ (**7**)

To $[MoI_2(CO)_3(NCMe)_2]$ (0.500 g, 0.969 mmol) dissolved in CH_2Cl_2 (15 cm^3), with continuous stirring under a stream of dry nitrogen was added PPh_3 (0.508 g, 1.936 mmol). After stirring for 1 min, Na[acac] (0.118 g, 0.969 mmol) was added as a CH_2Cl_2–MeOH solution. The mixture was stirred for a further 18 h, after which the solvents were removed *in vacuo*. The product was resolvated in CH_2Cl_2 (15 cm^3) and filtered to remove NaI. The solvent was again removed *in vacuo* to give the dark brown complex $[MoI(CO)_2(PPh_3)_2(acac)]$ (**7**) (yield: 0.46 g, 53%), which was recrystallized from CH_2Cl_2.

Similar reactions of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with two equivalents of PPh_3, followed by an *in situ* reaction with one equivalent of $Na[L\frown L]$ ($L\frown L$ = acac, hfacac or bzacac) gave the new complexes $[MI(CO)_2(PPh_3)_2(L\frown L)]$ (**8–12**). (See Table 1 for physical and analytical data.)

RESULTS AND DISCUSSION

The seven-coordinate complexes $[MI_2(CO)_3(NCMe)(PPh_3)]$[10] and $[MI_2(CO)_3(PPh_3)_2]$[11] react with one equivalent of the anionic bidentate oxygen donor ligands, $Na[L\frown L]$ ($L\frown L$ = acac, hfacac or bzacac), to give a series of new complexes, $[MI(CO)_3(PPh_3)(L\frown L)]$ (**1–6**) or $[MI(CO)_2(PPh_3)_2(L\frown L)]$ (**7–12**), respectively. Complexes **1–12** were characterized by elemental analyses (C, H and N) (Table 1), IR (Table 2) and ^1H NMR spectroscopy (Table 3). Compounds **8** and **12** were confirmed as CH_2Cl_2 solvates by repeated elemental

analyses and by ^{1}H NMR spectroscopy. Complexes **1–12** are soluble in polar solvents such as $CHCl_3$ and CH_2Cl_2, but only slightly soluble in Et_2O and hydrocarbon solvents. Compounds **1–12** are moderately air-sensitive in the solid state and should be stored under a nitrogen atmosphere.

The structure of these seven-coordinate complexes is likely to be capped octahedral, as most seven-coordinate compounds of molybdenum(II) and tungsten(II) have such a geometry.[12–19] From the work of Colton and Kevekordes,[20] the presence of a capping carbonyl ligand in a capped octahedral structure can be assigned from its particularly low field resonance. The low temperature ^{13}C NMR spectra (−70°C, CD_2Cl_2) of $[WI(CO)_3(PPh_3)(acac)]$, $[WI(CO)_3(PPh_3)(hfacac)]$ and $[MoI(CO)_3(PPh_3)(bzacac)]$ showed resonances at $\delta = 200.71$ and 228.24 ppm, $\delta = 200.61$ and 227.88 ppm, and $\delta = 207.79$ and 239.92 ppm, respectively, with intensity ratios of 2 : 1 (see Table 4). The spectrum in the carbonyl region of $[WI(CO)_3(PPh_3)(acac)]$ (**2**) is shown in Fig. 1. The very low field resonances at $\delta = 228.24$, 227.88 and 239.92 ppm, respectively, are likely to be due to a carbonyl in the unique capping position in these complexes,

Table 4. Low temperature ^{13}C NMR data[a] (δ, ppm) (C≡O) for selected complexes

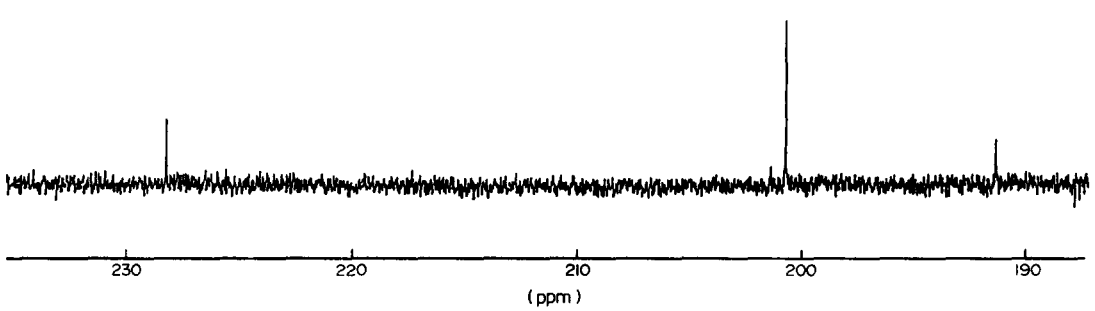

Fig. 1. Low temperature (−70°C, CD_2Cl_2) ^{13}C NMR spectrum (carbonyl region) of $[WI(CO)_3(PPh_3)(acac)]$ (**2**).

since Ganscow and Vernon[21] have suggested the low field resonances for carbonyl ligands in the capping position are due to π-back-donation, and the capping carbonyl resonance occurs at lower field compared with an octahedral carbonyl ligand. The low temperature ^{13}C NMR ($-70°C$, CD_2Cl_2) spectrum of $[MoI(CO)_2(PPh_3)_2(hfacac)]$ (**9**) shows resonances at $\delta = 207.64$ and 239.73 ppm with an intensity ratio of 2 : 1, suggesting[20,21] a capped octahedral structure with a carbonyl ligand in the capping position ($\delta = 239.73$ ppm).

Reactions of $[MI_2(CO)_3(NCMe)(PPh_3)]$ and $[MI_2(CO)_3(PPh_3)_2]$ with two equivalents of $Na[L\frown L]$ ($L\frown L$ = acac, hfacac or bzacac) were attempted. However, highly unstable reaction products and no satisfactory characterization of these products were obtained.

Acknowledgements—We wish to thank Dr O. W. Howarth for running the low temperature ^{13}C NMR spectra at the University of Warwick and the SERC for their support.

Abstract—Various routes to bismuth(III) alkoxides and β-diketonate derivatives have been investigated. Metathesis reactions of the halides and the appropriate sodium derivative offered $[Bi(O^tBu)_3]_\infty$ (**1**), $[Bi_2(OC_2H_4OMe)_6]_\infty$ (**2**), $[Bi(OSiPh_3)_3]_m$ and $Bi(dpm)_3$ (dpmH = dipivaloylmethane) in good yields. The alkoxides display different physical properties; **1** has good volatility, while **2** is highly soluble. Complex **2** and $Bi(OSiPh_3)_3(THF)_3$ (**3**) have been characterized by X-ray diffraction. Compound **2** shows a one-dimensional extended "skew" chain structure based on dimeric asymmetric $Bi_2(\mu_2,\eta^1\text{-}OC_2H_4OMe)_4(OC_2H_4OMe)_2$ units. The alkoxo functionality leads to a distorted pyramidal tetragonal surrounding, but the ether functionality of the bridging groups provides further oxygen donors, and thus coordination numbers of seven and even eight are reached. $Bi(OSiPh_3)_3(THF)_3$ is monomeric with a capped octahedron geometry around the metal. The thermal stability of the volatile precursors **1** and $Bi(dpm)_3$ is in favour of the alkoxide, while the high solubility of **2** is attractive for sol–gel purposes.

Bismuth(III) oxides are involved in various advanced materials such as superconductors,[1] photorefractive systems[2] or oxidation catalysis.[3] Molecular precursors of bismuth(III) oxides remain rather limited and most of these materials have been obtained by traditional high-temperature solid-state reactions. New precursors which could be of value for coatings, through either sol–gel or MOCVD techniques are thus desirable. Classical alkoxides $Bi(OR)_3$ (R = Me, Et, ^{i}Pr),[4] reported to form in high yield by metathesis reactions between the trichloride and alkali alkoxides, are poorly characterized, they display low solubility and are reported to sublime in low yield; although a compound of empirical formula $Bi(OEt)_3$ was used for access to Bi—Sr—Ca—Cu—O materials by MOCVD.[5] Siloxide derivatives are limited to $Me_2Bi(OSiMe_3)$.[6] β-Diketonates are often chosen as sources of oxide precursors for MOCVD applications, but surprisingly, no bismuth β-diketonate derivative has to the best of our knowledge been reported in the literature.[7]

We wish now to report the synthesis and characterization of various alkoxides, siloxides, as well as β-diketonates such as $Bi(O^tBu)_3$, $Bi(OC_2H_4OMe)_3$, $[Bi(OSiPh_3)_3]_m$, $Bi(OSiPh_3)_3(THF)_3$ and $Bi(dpm)_3$ (dpmH = dipivaloylmethane). $[Bi(O^tBu)_3]_\infty$ and

* Author to whom correspondence should be addressed.

$[Bi_2(OC_2H_4OMe)_6]_\infty$ are both polymeric solids but display different physical properties; $[Bi(O^tBu)_3]_\infty$ has good volatility, while $Bi(OC_2H_4OMe)_3$ is highly soluble; this makes them, respectively, attractive precursors for MOCVD and sol–gel processes. $Bi(OSiPh_3)_3(THF)_3$ as well as $[Bi_2(OC_2H_4OMe)_6]_\infty$ were characterized by X-ray diffraction; the characterization of the latter has been achieved and published quite independently by Buhro and his co-workers as a preliminary communication.[8]

EXPERIMENTAL

All manipulations were routinely performed under argon using Schlenk tubes and vacuum-line techniques with solvents purified by standard methods. $BiCl_3$ and $BiBr_3$ were sublimed before use, $Bi[N(SiMe_3)_2]_3$ was obtained according to the literature.[9] ^1H and ^{13}C NMR and IR spectra were run on Bruker WH-90, AC-200 and IR-FTS 45 spectrometers, respectively. IR spectra were obtained as Nujol mulls. Molecular weight measurements were obtained in benzene by using the Signer method.[10] Mass spectra were recorded on a R-10 Ribermag spectrometer by chemical ionization techniques. Analytical data were obtained from the Centre de Microanalyses du CNRS.

Synthesis of $Bi(OC_2H_4OMe)_3$

A solution of $NaOC_2H_4OMe$ (1.6 g, 0.07 mol) in 50 cm^3 of THF was added to $BiCl_3$ (7.4 g, 0.023 mol) dissolved in 50 cm^3 of THF. After 2 h, the medium was evaporated to dryness and extracted with hexane or diethyl ether. Concentration and cooling yielded 5.1 g (51%) of $Bi(OC_2H_4OMe)_3$, soluble in common organic solvents including aliphatic hydrocarbons. Found: C, 22.7; H, 4.7. Calc. for $C_{15}H_{21}O_6Bi$: C; 24.9; H, 4.5%. IR (cm^{-1}): 1273, 1236, 1194, 1123, 1070, 1010, 964, 995, 935, 740; 583, 524 [ν(Bi—O)]. ^1H NMR: ($CDCl_3$, ppm): 3.41s, 3.39s, 3.37s (CH_3); 3.50–3.54m, 3.7–3.77m (CH_2); $^{13}C\{^1H\}$ NMR (C_6D_6, 0.15 M, ppm): 58.4, 58.6 (CH_3); 62.6, 63.1, 63.5, 71.7, 71.9, 77.7 (CH_2).

The same product could also be obtained in ~ 60% yield by reaction of 2-methoxyethanol with $Bi[N(SiMe_3)_2]_3$ in hexane.

Synthesis of $Bi(O^tBu)_3$

A solution of $BiBr_3$ (4 g, 8.9 mmol) in 30 cm^3 of THF was added to a solution of NaO^tBu (26 mmol) in 50 cm^3 of THF. After 24 h, the reaction medium was evaporated to dryness, $Bi(O^tBu)_3$ was isolated by sublimation (80°C, 10^{-2} mm) (3.1 g, 80%). The compound is slightly soluble in aliphatic hydrocarbons, more soluble in aromatic hydrocarbons, dichloromethane or THF (m.p. 154°C). Found: C, 32.1; H, 5.8. Calc. for $C_{12}H_{27}O_3Bi$: C, 33.6; H, 6.3%. IR (cm^{-1}): 1232, 1182, 1022, 928, 758, 725; 572, 550, 459 (Bi—OR). ^1H NMR ($CDCl_3$, ppm): 1.39, SM: (m/z^+, IE) M = $Bi(O^tBu)_3$: M − CH_3 (24%), M − O^tBu (48%), $BiOH(O^tBu)$ (31%), BiC_4H_6 (49%), $BiOC_3H_2$ (40%), $BiOCH_3$ (29%), BiOH (15%), Bi (37%), C_4H_9 (100%).

Monocrystals were grown by sublimation in a sealed ampoule. Compound **1** crystallizes in the hexagonal 6/*mmm* system with unit cell parameters: $a = 9.955(2)$, $c = 9.887(6)$ Å, $V = 848.55$ Å^3, $D_c = 1.64$ g cm^{-3}, D_{exp}(F-decalin) ~ 1.9 g cm^{-3}, $Z = 2$. Data collection was made on a CAD-4 diffractometer with Mo-K_α radiation at room temperature. An empirical absorption correction was applied ($\mu = 98.7$ cm^{-1}). Patterson techniques were used to locate the metal atoms, which were found at 0,0,0 and 0,0,1/2. Systematic extinctions *hkl* for $l = 2n$ failed to allow a correct determination of the space group, and no atoms other than the metal atoms could be located.

Synthesis of $Bi(OEt)_3$

$Bi(OEt)_3$ was obtained quantitatively by alcoholysis of $Bi(O^tBu)_3$ in neat ethanol. It can be purified by sublimation (130°C, 10^{-2} mm Hg). It is poorly soluble in the usual organic solvents, but soluble in alcohols. Found: C, 20.8; H, 4.0. Calc. for $C_6H_{15}O_3Bi$: C, 20.9; H, 4.4%. IR (cm^{-1}): 1096, 1045, 885, 798, 729, 669, 557, 520 [ν(Bi—O)].

Synthesis of $[Bi(OSiPh_3)_3]_m$

A solution of $Bi[(N(SiMe_3)_2]_3$ (2.33 g, 3.38 mmol) in 30 cm^3 of Et_2O was added to a solution of $HOSiPh_3$ (2.86 g, 0.01 mol) in 40 cm^3 of Et_2O. Reflux was maintained for 24 h and a white precipitate formed. $Bi(OSiPh_3)_3$ was separated by filtration (2.16 g, 62%) and found to be poorly soluble. Found: C, 61.9; H, 4.3; Si, 8.3. Calc. for $C_{54}H_{45}O_3Si_3Bi$: C; 63.7; H, 4.3; Si, 8.1%. IR (cm^{-1}): 1111, 1020, 976, 916, 995, 864, 741, 708; 515, 509, 420 [ν(Bi—OR)].

Recrystallization in a mixture of THF and toluene (1:2) yielded the $Bi(OSiPh_3)_3(THF)_3$ adduct. IR (cm^{-1}): 1113, 1053, 1020, 939, 895, 741, 708; 511, 430 [ν(Bi—OR)]; 274, 215. ^1H NMR ($CDCl_3$, ppm): 7.6, 7.39 (m); 3.73(m), 1.84(m). ^{29}Si NMR (THF, ppm): −20.

Synthesis of $Bi(dpm)_3$

A solution of $BiCl_3$ (0.564 g, 1.8 mmol) in 20 cm^3 of THF was added to a solution of Nadpm (5.42 mmol) in 30 cm^3 of THF. Immediate formation of a white precipitate was observed. After 2 h, the reaction medium was evaporated to dryness. The β-diketonate derivatives were extracted by hexane or CH_2Cl_2. Separation of the unreacted Nadpm was achieved by sublimation (60°C, 4×10^{-4} mm Hg). Further sublimation (110°C, 4×10^{-4} mm Hg) gave microcrystals of $Bi(dpm)_3$ (0.55 g, 41%) (m.p. 78°C), soluble in toluene, CH_2Cl_2. Found: C, 53.0; H, 7.6. Calc. for $C_{33}H_{57}O_6Bi$: C, 52.2; H, 7.6%. IR (cm^{-1}): 1600, 1588, 1531 [ν(CO)], 1497, 1381, 1358, 1275, 1244, 1221, 1160, 1128, 1010, 951, 888, 793, 745, 735; 600, 476, 388, 274 [ν(Bi—O)]. ^1H NMR ($CDCl_3$): 1.18 (^{t}Bu), 5.74 (CH). SM: (m/z^+, %), $Bi(dpm)_2$ (100%), $Bi(dpm)(C_3H_5)$ (4%), Bi(dpm) (21%), $Bi(C_7H_{11}O_2)$ (41%), Bi (50%), $dpmH_2$ (7%), $C_7H_{11}O_2$ (50%).

Attempts to obtain monocrystals by slow sublimation (110°C) in an ampoule sealed under vacuum led to decomposition.

Crystallographic studies

The selected crystals of **2** and **3** were mounted onto an Enraf–Nonius CAD-4 automatic diffractometer. Accurate unit cell dimensions and crystal orientation matrices, together with their estimated standard deviations, were obtained from least-squares refinements of the setting angles of 25 reflections. Crystallographic data and other pertinent information are summarized in Table 1.

Corrections were made for Lorentz polarization and absorption[11] effects.

Computations were performed by using CRYSTALS[12] adapted on a Micro Vax II. Atomic form factors were taken from ref 13. Anomalous dispersion terms were used. For **2**, bismuth atoms were found using SHELXS,[14] whereas, the position of the bismuth atom in **3** was determined by Harker vector analysis of a three-dimensional Patterson map. All remaining non-hydrogen atoms were found by successive electron density map calculations. Hydrogen atoms were placed in calculated positions (H—C—H = 109°; H—C—C = 120°; C—H = 0.96 Å) and were not further refined but recalculated after each cycle. They were assigned isotropic thermal parameters 20% higher than those of the carbon atoms to which they were attached. Anisotropic temperature factors were introduced for all non-hydrogen atoms. Both structures were refined by least-squares techniques. The weighting scheme used in the last refinement cycles was $w = w'[1-(\Delta F/6\sigma(F))^2]^2$, with $w' = 1/\Sigma_{r=1,n}\mathrm{ArTr}(x)$ with n coefficients Ar for the Chebyshev polynomial $\mathrm{ArTr}(x)$ where x was $F_c/F_o(\max)$.[15] The models reached convergence with $R = \Sigma([F_o]-[F_c])/\Sigma[F_o]$ and $R_w = \{\Sigma w([F_o]-[F_c])^2/\Sigma w(F_o)^2\}^{1/2}$ having the values listed in Table 1. In complex **2**, one of the two terminal alkoxo groups is disordered. This disorder affects the oxygen atom of the ether functionality which is statistically distributed on two sites separated by 0.8 Å. The criteria for a satisfactory complete analysis were the ratios of the rms shift to standard deviation being less than 0.1 and no significant features in the final difference maps.

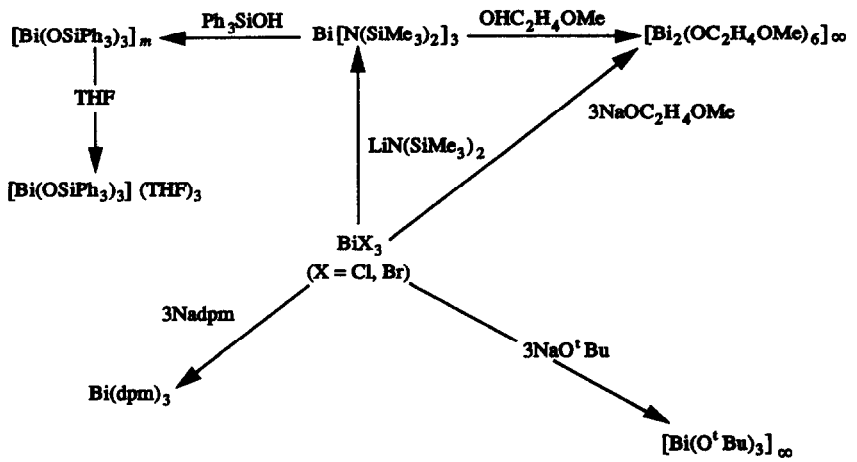
Positional parameters and equivalent isotropic thermal parameters are given as supplementary material.

RESULTS AND DISCUSSION

We have investigated various routes to bismuth(III) alkoxides and β-diketonates, including metathesis reactions of BiX_3 (X = Cl, Br), alcoholysis of $Bi[N(SiMe_3)_2]_3$ or alkoxide exchange reactions (Scheme 1). The various products were characterized by microanalysis and the usual spectroscopic methods: IR, NMR and mass spectroscopy. Complete structural characterization of $Bi(OC_2H_4OMe)_3$ and $Bi(OSiPh_3)_3(THF)_3$ was achieved by X-ray diffraction.

Synthesis and characterization

The homoleptic bismuth(III) alkoxides $Bi(O^tBu)_3$ (**1**) and $Bi(OC_2H_4OMe)_3$ (**2**) were obtained by reaction between $BiCl_3$ or $BiBr_3$ and the approximate sodium salt (ratio 1 : 3) in THF in 80% yield, while $Bi(OEt)_3$ was obtained quantitatively by alcoholysis of **1**. The good volatility of $Bi(O^tBu)_3$ allows its isolation and purification by sublimation (80–100°C, 10^{-2} mm), but although it is more soluble than the bismuth(III) alkoxides reported so far, it displays moderate solubility. The β-diketonate derivative $Bi(dpm)_3$ was isolated by sublimation as well, but is less volatile than $Bi(O^tBu)_3$. Functional alcohols are largely used as additives in the sol–gel process as a means of keeping a homogeneous medium.[16] Bismuth trismethoxyethanolate, $Bi(OC_2H_4OMe)_3$, is highly soluble (even in pentane) and was obtained by extraction of the reaction medium by diethyl ether. This alkoxide could also



Scheme 1.

be obtained by alcoholysis of $Bi[N(SiMe_3)_2]_3$. The siloxide derivative $[Bi(OSiPh_3)_3]_m$ was obtained accordingly, but its poor solubility suggests a polymeric character. Solubilization could be achieved by Lewis bases and $Bi(OSiPh_3)_3(THF)_3$ was found to be monomeric by X-ray diffraction. Comparable behaviour was observed in the case of the yttrium[16] and copper triphenylsiloxides.[17]

The IR spectra of the various derivatives display essentially the absorption bands of the ligands. The tris-dipivaloylmethanide derivative, $Bi(dpm)_3$, is characterized by C—O stretching between 1600 and 1531 cm^{-1}.

The NMR spectra of the various derivatives offer limited structural information. The ^1H NMR spectra of $Bi(OSiPh_3)_3(THF)_3$ show a single set of THF resonances and rapid exchange is observed with free additional THF. The NMR spectra of $Bi(OC_2H_4OMe)_3$ were found to be a function of the dilution, and thus account for the presence of different molecular species in solution. Equilibrium between various oligomers and/or isomers involving η^1- and η^2-coordination modes of the functional alkoxo moiety is the most likely explanation. Molecular weight data measurements (0.1 M in benzene) are in favour of the formation of dimeric $Bi_2(OC_2H_4OMe)_6$ species ($M_{exp} = 811 \pm 80$, $M_{calc} = 434$) upon dissolution of the solid-state polymer.

Solid-state structure of $[Bi(\mu_2,\eta^1\text{-}OC_2H_4OMe)_4(\eta^1\text{-}OC_2H_4OMe)_2]_\infty$

Since bismuth can adopt numerous coordination numbers and the 2-methoxyethanol various coordination modes, X-ray diffraction studies were carried out on $Bi(OC_2H_4OMe)_3$. As for $[Bi(O^tBu)_3]_\infty$, whose structure could not be completely solved, a chain structure was found. The repeat unit of this chain is a dimer, $Bi_2(\mu_2,\eta^1\text{-}OC_2H_4OMe)_4(\eta^1\text{-}OC_2H_4OMe)_2$, which is shown in Fig. 1. Relevant bond lengths and angles are collected in Table 2.

At first approximation all bismuth atoms are pentacoordinated and display a distorted tetragonal pyramidal geometry. The bismuth alkoxo bond lengths vary from 2.071(6) to 2.573(6) Å, the terminal one being the shortest, as generally observed in alkoxide chemistry. The terminal alkoxo bond length is thus comparable to the value reported recently for $Bi(OC_6H_3Me_2\text{-}2,6)_3$.[18] The lone pair is directed opposite to the terminal OR and appears stereochemically active: the O(28)—Bi—O(basal) angles (av. 83.7°) are contracted as expected for an AB_5E compound, where E stands for the lone pair. The non-bonding distances between the Bi···Bi atoms along the chain are alternate: 3.6426(4) Å within the dimeric units [Bi(1)···Bi(2)] and 3.957 Å (av.) between such units. The Bi—O—C angles

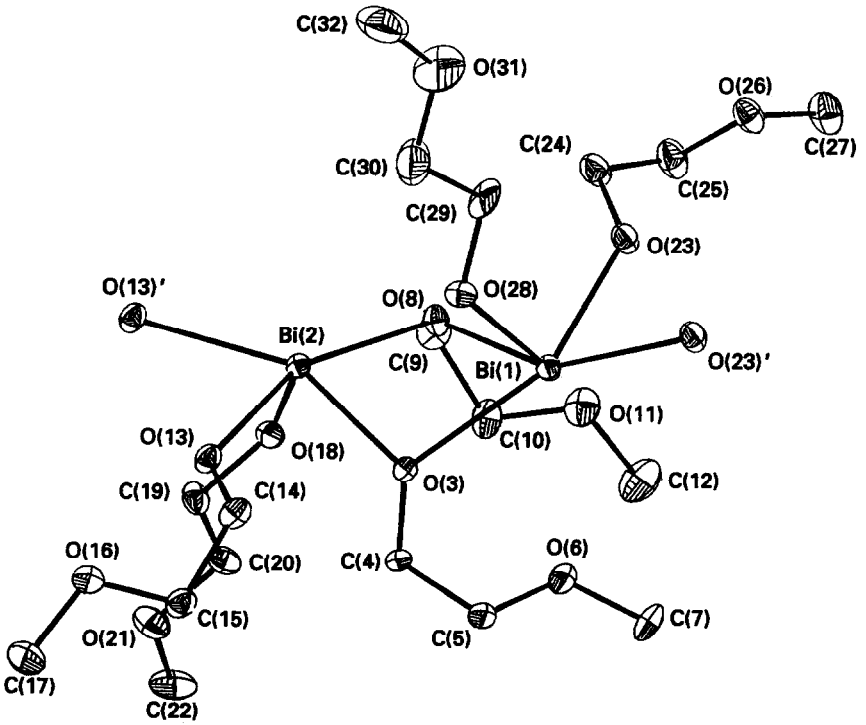


Fig. 1. ORTEP drawing of the asymmetric $[Bi_2(\mu_2,\eta^1\text{-}OC_2H_4OMe)_4(\eta^1\text{-}OC_2H_4OMe)_2]_\infty$ subunit showing the atom numbering scheme.

[a] Atoms marked with ′ are related by the inversion centre.

range from 117.0(6) to 126.1(6)°; they are quite small and thus in agreement with the rather long bismuth alkoxo bonds.

In fact, additional neighbours led finally to a different surrounding for the two metals. Bi(1) is pseudo-octacoordinated, while Bi(2) is only hepta-coordinated. The terminal alkoxo moiety linked to Bi(1) interacts with Bi(2) in a semi-bridging way [Bi—O: 2.924(6) Å]. While the ether functionality of the bridging alkoxo groups is directed towards the "open" coordination of the pyramid and thus offers further oxygen neighbours for the metals [short contacts between O(16′) and Bi(2) and between O(6), O(11), O(26′) and Bi(1)]. Although these Bi—O(Me) distances (2.90–3.10 Å) are much longer than those observed for $[Y(OC_2H_4OMe)_3]_{10}$ or $Y_3(OC_2H_4OMe)_5(acac)_4$ (2.53–2.59 Å), in which the 2-methoxyethoxo groups act as authentic η^2-bridging–chelating ligands,[19] they are significantly shorter than the sum of the van der Waals' radii (3.47 Å). Most mixed bismuth(III) oxides have five or six oxygen atoms at distances ranging from 2.1 to 2.7 Å and a variable number of additional neighbours. The coordination polyhedron of bismuth in $GeBi_{12}O_{20}$ provides an example of such behaviour, which is also observed for bismuth derivatives, such as $BiCl_3$, for instance.[20]

The chains are thus built up from dimeric asymmetric $Bi_2(\mu_2,\eta^1\text{-}OC_2H_4OMe)_4(\eta^1\text{-}OC_2H_4OMe)_2$ units (Fig. 1). These repeat units are connected to each other through bridging alkoxo oxygens, O(13) and O(23), arranged around inversion centres 0,0,0 [Bi(1)···Bi(1′)] and 0,1/2,0 [Bi(2)···Bi(2′)]. The overall structure can also be viewed as a polymerization of the $Bi(OR)_3$ units to a chain of $Bi(OR)_5$ pyramids *trans*-fused as a basal edge. This is supported by the large differences observed for the alkoxo bridges: each bismuth atom has two *cis* Bi—O of 2.53 Å (av.), and two shorter ones of 2.21 Å (av.). This assembly with the lone pairs *trans* to each other leads to a skewed chain with bismuth atoms alternatively above and below the planes containing the oxygen atoms in bridging positions. Figure 2 shows the resulting "zigzag" chains extended along the *b* axis and the packing. The bridge within the dimeric unit is folded around the O(3)···O(8) edge with a dihedral angle of 142.5°. The bridges which ensure the extended chain structure are planar and as a result the bridging oxygens are of two types: pyramidal within the repeat unit [sum of

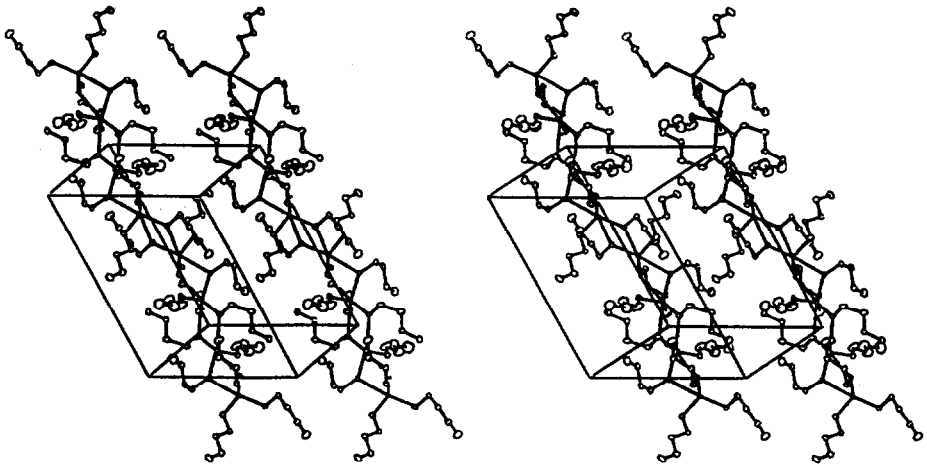

Fig. 2. Stereoview showing the extended "skew" chain structure of $[Bi_2(\mu_2,\eta^1\text{-}OC_2H_4OMe)_4(\eta^1\text{-}OC_2H_4OMe)_2]$ structure along the *b* axis. For clarity, only two chains have been represented.

the angles around O(3) and O(8), 339.4 and 344.8°, respectively], but nearly planar (Σ 359.8 and 355.5°) for O(23) and O(13) which connect the basic dimeric units. Strain in the bridge is evidenced by the reduction of the bridge angles at the metal from the ideal 90° value (72.8° in the repeat unit and 67.5° along the infinite chain). Structurally characterized polymeric alkoxides remain scarce; the overall structure of the bismuth derivative is somewhat related to that of $[VO(OMe)_3]_\infty$[21] or of $Mo_6O_{10}(O^iPr)_{12}$.[22] On the other hand, infinite "skew" chains appear as a common feature for the structures of bismuth halide derivatives such as $[BiX_4]^{n-}$ (X = Cl, Br), although the surrounding of the metal is generally octahedral.[23] The shortest contacts between two chains of $[Bi_2(OC_2H_4$

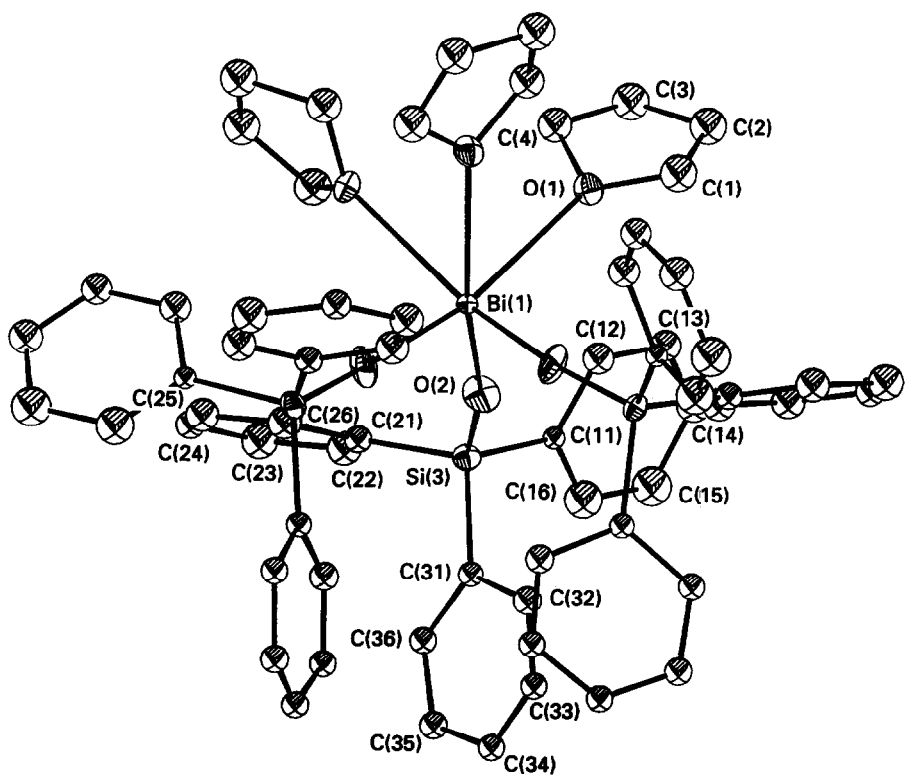

Fig. 3. ORTEP drawing of the $Bi(OSiPh_3)_3(THF)_3$ adduct indicating the atom numbering scheme.

$OMe)_6]_\infty$ are related to the carbon and oxygen atoms of the ether functionality of the terminal alkoxide (values ranging from 3.7 to 4.0 Å), the Bi···Bi distances between them being around 7.5 Å.

Structure of $Bi(OSiPh_3)_3(THF)_3$

The structure of the $Bi(OSiPh_3)_3(THF)_3$ complex is shown in Fig. 3 and selected bond distances and angles are given in Table 3. The complex is monomeric and the six oxygen-bound ligands roughly define a capped octahedron with the two sets of ligands oriented in a meridional arrangement. The overall geometry is thus greatly different from that of the lanthanide analogues $[Ln(OSiPh_3)_3(THF)_3]THF$ (Ln = Y,[16] Ce[24]) which have an octahedral facial arrangement and thus suggests a marked influence of the lone pair on the stereochemistry. The Bi—O(Si) distance is quite short [2.04(1) Å] as compared with the coordination bonds involving the THF ligands [2.95(1) Å]. These bismuth–siloxo bond distances are also quite short with respect to the values reported for other bismuth–alkoxo bonds [2.091(5) Å (av.) for $Bi(OC_6H_3Me_2\text{-}2,6)_3$] with an opening at the Bi—O—Si angles [164.8(8)°]. It appears, therefore, that although $OSiPh_3$ and $OC_6H_3Me_2$-2,6 may be interchangeable in size, the bonding mode might be different, at least in the case of bismuth. The angles involving the THF ligands, O(1)BiO(1′), are reduced to 78.9(3)°, compared with those involving the siloxo groups [∠O(2)—Bi—O(2)′ 93.0(5)°]. Distortion of the coordination polyhedron is also evidenced by the value of the angle involving THF and $OSiPh_3$ ligands *trans* to each other [168.5(4) Å].

$Bi(O^tBu)_3$, $Bi(OEt)_3$ and the β-dipivaloylmethanide derivative, $Bi(dpm)_3$, are volatile and monomeric in the vapour phase, as shown by mass spectrometry; however, by contrast with most elements, the thermal stability of the various bismuth(III) precursors is in favour of the alkoxides,[25] as shown by TGA analysis: $Bi(O^tBu)_3 > Bi(OEt)_3 > Bi(dpm)_3$.

Preliminary TGA analyses have shown a weight loss of ~ 15% for $Bi(dpm)_3$ (probably giving a polynuclear oxo species), but no further evolution between 250 and 450°C. These observations—tendency to lose some dipivaloylmethane—are in agreement with the air sensitivity of $Bi(dpm)_3$ and its poor thermal stability which precluded the obtaining of monocrystals by slow sublimation. $[Bi(O^tBu)_2(dpm)]_m$, obtained by adding one dpmH ligand to $Bi(OtBu)_3$, undergoes disproportionation reactions in the vapour phase.

Hydrolysis of $Bi(O^tBu)_3$ was performed in THF (0.2 M). Addition of small amounts of water (degree of hydrolysis, $h = 0.3$) leads to the immediate formation of a sol which transforms to a gel over a period of 12 h. Complete hydrolysis ($h = 3$) and thermal treatment at 550°C for 15 h of the amorphous powder offers cubic Bi_2O_3.[26] Hydrolysis of $Bi(OSiPh_3)_3(THF)_3$ in THF (0.06 M) with an excess of water in ethanol, and thermal treatment of the amorphous powder in air at 475°C, gives a black material corresponding to the oxohydroxocarbonate $(BiO)_4CO_3(OH)_2$.[27]

The solubility of $[Bi_2(\mu_2,\eta^1\text{-}OC_2H_4OMe)_4(\eta^1\text{-}OC_2H_4OMe)_2]_\infty$ appears attractive for obtaining Bi—Sr—Ca—Cu—O coatings via sol–gel or pyrosol techniques, and further experiments along this line are in progress.

Acknowledgements—We thank the CNRS–PIRMAT for financial support, Professor A. Gleizes (Toulouse) and D. Mercurio (Limoges) for the X-ray data of $Bi(O^tBu)_3$ and those of the hydrolysis products, respectively, and l'Air Liquide for obtaining the thermogravimetric data.

CLUSTER SYNTHESIS—XXIX. SYNTHESIS AND CHARACTERIZATION OF NEW SULPHUR-CONTAINING TUNGSTEN–RUTHENIUM CARBONYL CLUSTER COMPLEXES

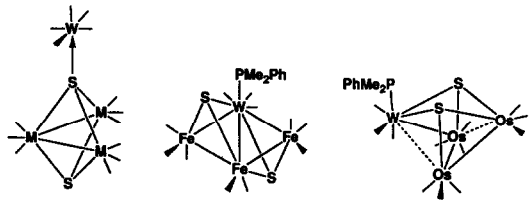
RICHARD D. ADAMS,* THOMAS A. WOLFE and WENGAN WU

Department of Chemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

(*Received* 9 *April* 1990; *accepted* 22 *October* 1990)

Abstract—The reaction of $Ru_3(CO)_9(\mu_3\text{-}S)_2$ (**4**) with $W(CO)_6$ under UV irradiation yielded the complex $Ru_3(CO)_9(\mu_3\text{-}S)(\mu_4\text{-}S)[W(CO)_5]$ (**5**) in 29% yield. Spectral data indicate that **5** has a structure similar to its osmium homologue in which a $W(CO)_5$ group is attached to one of the triply-bridging sulphido ligands in the cluster. The reaction of **4** with $W(CO)_5(PMe_2Ph)$ under UV irradiation yielded two isomeric cluster complexes, $WRu_3(CO)_{11}(PMe_2Ph)(\mu_4\text{-}S)_2$ (**6**) 16% and (**7**) 7%. Compounds **6** and **7** were characterized by single-crystal X-ray diffraction analyses. These complexes were found to contain approximately square-planar arrangements of the four metal atoms with quadruply-bridging sulphido ligands on each side of the cluster. Compound **6** contains a PMe_2Ph ligand on the tungsten atom. In compound **7** the PMe_2Ph ligand is coordinated to the ruthenium atom across the square from the tungsten atom. Crystal data for **6**: $WRu_3S_2O_{11}C_{19}H_{11}$, $M = 977.44$, orthorhombic, $P2_12_12_1$ (No. 19), $a = 13.794(2)$, $b = 16.616(2)$, $c = 11.780(2)$ Å, $V = 2700(1)$ Å^3, $D_c = 2.45$ g cm^{-3}, $Z = 4$, λ(Mo-K_α) = 0.71069 Å (graphite monochromator), $\mu = 62.1$ cm^{-1}. Methods: MITHRIL, difference Fourier, full-matrix least-squares. Refinement of 1960 reflections [$F^2 \geqslant 3\sigma(F^2)$], gave R and R_w values of 0.027 and 0.027, respectively. Crystal data for **7**: $WRu_3S_2O_{11}C_{19}H_{11}$, $M = 977.44$, monoclinic, $P2_1/n$ (No. 14), $a = 15.841(2)$, $b = 8.818(1)$, $c = 19.236(3)$ Å, $\beta = 98.04(1)°$, $V = 2660.5(6)$ Å^3, $D_c = 2.49$ g cm^{-1}, $Z = 4$, λ(Mo-K_α) = 0.17069 Å (graphite monochromator), $\mu = 63.1$ cm^{-1}. Methods: MITHRIL, difference Fourier, full-matrix least-squares. Refinement of 2880 reflections [$F^2 \geqslant 3\sigma(F^2)$], gave R and R_w values of 0.024 and 0.025, respectively.

In previous studies, we have investigated the reactions of the sulphur-containing cluster complexes $M_3(CO)_9(\mu_3\text{-}S)_3$ (M = Fe[1] and Os)[2,3] with $W(CO)_6$ and $W(CO)_5(PMe_2Ph)$ in the presence of UV irradiation. In both cases, the reactions with $W(CO)_6$ result in decarbonylation of the $W(CO)_6$ and the addition of a $W(CO)_5$ grouping to one of the sulphido ligands of the cluster to yield the adducts **1**. No metal–metal bonds were formed in the formation of **1**. Although small amounts of the phosphine-substituted adduct of **1** were obtained from the reaction of $Fe_3(CO)_9(\mu_3\text{-}S)_2$ with $W(CO)_5(PMe_2Ph)$, the principal product was the butterfly



(1) (2) (3)

M = Fe, Os

cluster complex $WFe_3(CO)_{11}(PMe_2Ph)(\mu_3\text{-}S)_2$ (**2**), in which three tungsten–iron bonds were formed with the tungsten atom located in a "hinge" position.[1] In contrast, the reaction of $Os_3(CO)_9(\mu_3\text{-}S)_2$ with $W(CO)_5(PMe_2Ph)$ yielded the butterfly cluster complex $WOs_3(CO)_{12}(PMe_2Ph)(\mu_3\text{-}S)_2$ (**3**), in which two tungsten–osmium bonds were formed

* Author to whom correspondence should be addressed.

with the tungsten atom located in a "wing-tip" position.[3]

Recently, we have been developing the chemistry of sulphido–ruthenium carbonyl cluster complexes.[4] We have now investigated the reactions of $W(CO)_6$ and $W(CO)_5(PMe_2Ph)$ with $Ru_3(CO)_9(\mu_3\text{-}S)_2$ (**4**). The reaction of **4** with $W(CO)_6$ in the presence of UV irradiation yielded the complex $Ru_3(CO)_9(\mu_3\text{-}S)(\mu_4\text{-}S)[W(CO)_5]$ (**5**), that is believed to be structurally analogous to its iron and osmium homologues, **1**. However, the reaction of **4** with $W(CO)_5(PMe_2Ph)$ yielded two isomeric products with the formula $WRu_3(CO)_{11}(PMe_2Ph)(\mu_4\text{-}S)_2$ (**6**) and (**7**), whose structures are different from both the iron complex, **2**, and the osmium complex, **3**. Both compounds have been characterized crystallographically. The results of this study are described herein.

EXPERIMENTAL

All reactions were carried out under an atmosphere of nitrogen. Reagent grade solvents were stored over 4 Å molecular sieves. UV irradiations were performed in Pyrex glassware by using an externally positioned high-pressure mercury lamp. All TLC separations were performed in air on plates (Whatman 0.25 mm silica gel, 60 Å, F_{254}). ^1H NMR spectra were recorded on a Brüker AM-300 spectrometer operating at 300 MHz. IR spectra were recorded on a Nicolet 5DXB FT–IR spectrophotometer. Mass spectra were run on a VG Model 70SQ spectrometer by using electron impact ionization. $Ru_3(CO)_9(\mu_3\text{-}S)_2$ (**4**) was prepared by the previously reported procedure.[5]

Reaction of $Ru_3(CO)_9(\mu_3\text{-}S)_2$ (**4**) *with* $W(CO)_6$

A solution of **4** (30 mg, 0.048 mmol) and $W(CO)_6$ (85 mg, 2.42 mmol) in hexane (40 cm^3) was irradiated (UV) under a purge with nitrogen at 25°C for 30 min. The colour of the solution changed from yellow to dark red and some black precipitate formed. Most of the solvent was removed *in vacuo*; the remainder was decanted. The precipitate was washed five times with hexane (5 cm^3 portions), and the final residue was redissolved in 10 cm^3 of CH_2Cl_2 to give a red–brown solution that was filtered and crystallized to yield a dark brown powder of $Ru_3(CO)_9(\mu_3\text{-}S)(\mu_4\text{-}S)[W(CO)_5]$ (**5**), 13.2 mg (29%). IR[ν(CO) in CH_2Cl_2]: 2072(vs), 2067(sh), 2028(m), 1937(s) cm^{-1}.

Reaction of **4** *with* $W(CO)_5(PMe_2Ph)$

A solution of **4** (95 mg, 0.15 mmol) and $W(CO)_5(PMe_2Ph)$ (150 mg, 0.32 mmol) in 120 cm^3 of hexane was irradiated in the presence of a continuous purge of nitrogen for 30 min. The solvent was removed *in vacuo* and the residue was chromatographed on Florisil in a column. Two bands were collected. The first (yellow) was eluted with hexane–CH_2Cl_2, 9 : 1 and the second (brown) was eluted with hexane–CH_2Cl_2, 7 : 3. These bands were subsequently purified further by TLC. The first band yielded only unreacted **4**, 10.2 mg, and unreacted $W(CO)_5(PMe_2Ph)$, 40.5 mg. The second band yielded yellow $Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}S)_2$, 4.5 mg (4%), $WRu_3(CO)_{11}(PMe_2Ph)(\mu_4\text{-}S)_2$ (**6**), 24.2 mg (16%), and its isomer **7**, 10.5 mg (7%). IR[ν(CO) in hexane] for **6**: 2074(m), 2041(vs), 2027(vs), 2010(s), 1997(m), 1971(m), 1935(w), 1885(w) 1859(w) cm^{-1}; for **7**: 2072(w), 2041(vs), 2027(m), 2014(s), 1998(m), 1971(w), 1934(m), 1874(w), 1864(w), 1831(w) cm^{-1}. ^1H NMR (δ in $CDCl_3$) for **6**: 7.47 (m, 5H), 2.24 (d, 6H, J_{P-H} = 9.6 Hz); for **7**: 7.42 (m, 5H), 1.80 (d, 6H, J_{P-H} = 10.5 Hz). Found: C, 22.8; H, 1.0. Calc. for **6**: C, 22.9; H, 1.1%. Found: C, 22.9; H, 0.98. Calc. for **7**. C, 22.9, H, 1.1%. $Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}S)_2$ was characterized further by an independent synthesis, see below.

Reaction of **6** *with carbon monoxide*

A sample of **6** (20 mg, 0.020 mmol) in 30 cm^3 of hexane was refluxed for 1 h in the presence of a slow, purge of carbon monoxide. The solvent was removed *in vacuo*, and the residue was dissolved in a minimal amount of CH_2Cl_2 and transferred to TLC plates. Elution with a (hexane–CH_2Cl_2, 8 : 2) solvent mixture separated 2.1 mg of **4**, 17%; 22 mg of $W(CO)_5(PMe_2Ph)$, 24%; 2.6 mg of $Ru_3S_2(CO)_8(PMe_2Ph)$, 17%; and 3.4 mg of **7**, 17%.

Preparation of $Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}S)_2$

Compound **4** (20 mg, 0.032 mmol) was dissolved in 10 cm^3 of hexane. PMe_2Ph (0.005 cm^3, 0.035 mmol) was added, and the solution was allowed to stir for 25 min at 25°C. The product, $Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}S)_2$, was isolated in 72% yield by TLC using a hexane–CH_2Cl_2, 3 : 1, solvent mixture. IR [ν(CO) in hexane]: 2082(m), 2049(vs), 2031(m), 2027(sh), 2015(s), 1981(m) cm^{-1}. ^1H NMR (δ in $CDCl_3$): 7.59 (m, 5H, Ph), 2.28 (d, 6H, Me, J_{P-H} = 10.9 Hz). Mass spectrum [m/z = 731 − x(28), x = 1, 3–8; $M^+ - x$(CO)].

Crystallographic analyses

Crystals of **6** and **7** suitable for diffraction analyses were grown from solutions in hexane–CH_2Cl_2,

1:9, solvent mixtures at 10°C. The data were collected on crystals mounted in thin-walled glass capillaries. Diffraction measurements were made on a Rigaku AFC6S automatic diffractometer by using graphite-monochromatized Mo-K_α radiation. The unit cells were determined from 15 randomly selected reflections obtained by using the AFC6 automatic search, centre, index and least-squares routines. Crystal data, data collection parameters and results of the analyses are listed in Table 1. All intensity measurements were made by using the standard ω-scan (moving crystal-stationary counter) technique. Background measurements were made by 1/4 additional scan at each end of the scan. All data processing was performed on a Digital Equipment Corp. MICROVAX II computer by using the TEXSAN structure solving program library (Version 2.0) obtained from the Molecular Structure Corp., The Woodlands, Texas. Neutral atom scattering factors were calculated by the standard procedures.[7a] Anomalous dispersion corrections were applied to all non-hydrogen atoms.[7b] Full-matrix least-squares refinements minimized the function: $\Sigma w(|F_{obs}| - |F_{calc}|)^2$, where $w = 1/\sigma(F)^2$, $\sigma(F) = \sigma(F_{obs}^2)/2F_{obs}$ and $\sigma(F_{obs}^2) = [\sigma(I_{raw})^2 + (0.02(F_{obs})^2)^2]^{1/2}/Lp$. Compound **6** crystallized in the orthorhombic crystal system. The space group $P2_12_12_1$ was established on the basis of the systematic absences observed during the collection of data. Compound **7** crystallized in the monoclinic crystal system. The space group $P2_1/n$ was established on the basis of the systematic absences observed during the collection of the data. Both structures were solved by a combination of direct methods (MITHRIL) and difference Fourier techniques. All non-hydrogen atoms were refined by using anisotropic thermal parameters. Hydrogen atom positions were calculated by assuming idealized geometries. Their scattering contributions were added to the structure factor calculations, but they were not refined. In the final stages of refinement of the structure of **6**, a test for enantiomorph was made by inverting the coordinates of all the atoms and refining again. This led to a significant improvement in the R-factor (0.038 vs 0.027). Thus, the second enantiomorph was deemed to be correct and is the one reported here.*

* Complete tables of bond angles, atomic coordinates, thermal parameters and observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available upon request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

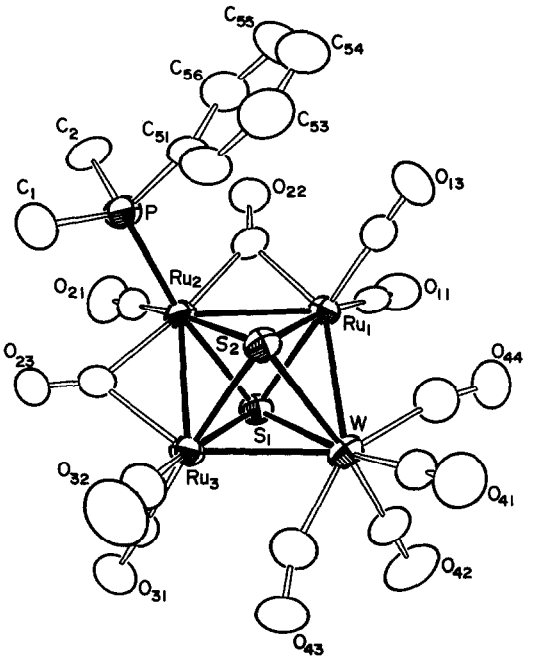

Fig. 2. An ORTEP drawing of **7** (an isomer of **6**) showing 50% probability thermal ellipsoids.

RESULTS AND DISCUSSION

From the reaction of **4** with $W(CO)_6$ in the presence of UV irradiation, the product **5** has been obtained in 29% yield. The IR spectrum of **5** is remarkably similar to those of its iron and osmium homologues. Thus, it is believed to possess an analogous structure. The osmium homologue has been characterized crystallographically.[2]

From the reaction of **4** with $W(CO)_5(PMe_2Ph)$ in the presence of UV irradiation we have isolated two new tungsten–ruthenium carbonyl complexes **6**, 16% and **7**, 7%, which have the same molecular formula, $WRu_3(CO)_{11}(PMe_2Ph)(\mu_4\text{-}S)_2$, and a small amount of the PMe_2Ph-substituted derivative of **4**, 4%. Compounds **6** and **7** are structural isomers and both have been characterized crystallographically.

ORTEP drawings of the structures of **6** and **7** are shown in Figs 1 and 2, respectively. Selected interatomic bond distances are listed in Tables 2 and 3, and selected interatomic angles are listed in Tables 4 and 5, respectively. Both molecules contain square arrangements of four metal atoms with quadruply-bridging sulphido ligands on opposite

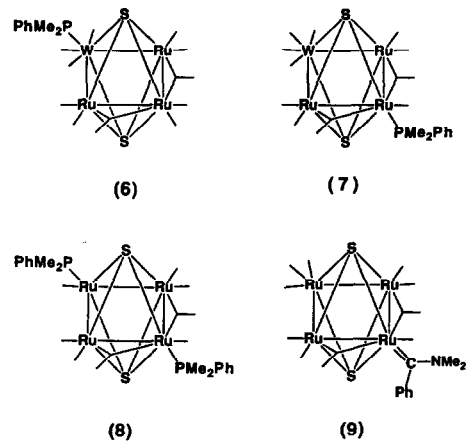
sides of the square plane. Similarly arranged $Ru_4(\mu_4\text{-}S)_2$ clusters were observed in the compounds $Ru_4(CO)_9(PMe_2Ph)_2(\mu_4\text{-}S)_2$ (**8**)[5] and $Ru_4(CO)_{10}[C(Ph)NMe_2](\mu_4\text{-}S)_2$ (**9**).[6] The principal difference between **6** and **7** is the location of the PMe_2Ph ligand. In **6** it is bonded to the tungsten atom, while in **7** it is bonded to the ruthenium atom opposite the tungsten atom, Ru(2). Both Ru—Ru bonds in **6** and **7** contain bridging carbonyl ligands. A similar arrangement was found in **8** and **9** and the Ru—Ru distances in all four molecules are very similar. The eight atoms bonded to the tungsten atom in **6** are arranged in a square antiprismatic coordination geometry. The three carbonyl ligands bonded to the tungsten atom are linear, and the Ru—W distances, 2.884(2) and 2.857(2) Å, are significantly longer than the Ru—Ru distances, 2.747(2) and 2.749(2) Å. In contrast, the eight atoms bonded to the tungsten atom in **7** are arranged in a square prismatic coordination geometry and two of the four carbonyl ligands have adopted semibridging coordinations along the Ru—W bonds, W—C(43)—O(43) = 162.1(8)° and W—C(44)—O(44) = 166.7(8)°. The Ru—W distances in **7** are similar to those in **6**, 2.8605(8) and 2.8347(7) Å. The Ru—S distances in **6**, **7**, **8** and **9** are very similar. Curiously, the W—S distances in **7** are significantly longer than those in **6**, 2.588(2) and 2.596(2) Å vs 2.522(3) and 2.524(5) Å. This may be related to the different coordination geometries about the tungsten atom in the two complexes. In **7**, a carbonyl ligand is positioned nearly opposite to each W—S bond. A structural *trans*-influence could thus be responsible for the comparative weakening of the W—S bonds in **7**.[8] In **6**, the carbonyl ligands are not positioned directly opposite to the M—S bonds.



Compounds **6** and **7** contain 62 valence electrons. This is two electrons less than the number required by the 18-electron rule for a cluster with four M—M bonds. It is, however, in accord with the requirements of the Skeletal Electron Pair theory.[9] Interestingly, structure **2**, exhibited by the iron homologue of **6**, has five M—M bonds, and each of the metal atoms in **2** obeys the 18-electron rule. The reason why **2** adopts the electron precise structure and **6** and **7** the "unsaturated" structure is not obvious to us at this time. The reaction of $Os_3(CO)_9(\mu_3\text{-}S)_2$ with $W(CO)_5(PMe_2Ph)$ yielded compound **3**, *vide supra*. Compound **3** has one more carbonyl ligand than **2**, **6** and **7** and adopts yet another "butterfly" tetrahedral structure which is believed to adhere to the Skeletal Electron Pair theory. The

most important difference between compound **5** and the phosphine-containing complexes **6** and **7** is the existence of W—Ru bonds in the latter. This was also the most important distinction between the iron compounds, **1** and **2**, and the osmium compounds, **1** and **3**. We believe that this is directly attributable to the presence of the phosphine ligand. Since M—M bond formation occurred both in **6** and **7**, it indicates that the location of the phosphine ligand in the complex is not of major importance to the stability of the cluster. Comparison of the M—M bonds lengths of a few carbonyl cluster complexes and their phosphine-substituted derivatives has shown that they are shorter and presumably stronger in the derivatives.[10] It seems likely that this is related to increases in electron density on the metal atoms caused by the more strongly electron-donating phosphine ligand.

Under an atmosphere of carbon monoxide in refluxing hexane solvent, compound **6** is partially isomerized to **7**, but there is also considerable cluster degradation to yield **4**, $W(CO)_5(PMe_2Ph)$ and some $Ru_3(CO)_8(PMe_2Ph)(\mu_3\text{-}S)_2$. The transformation of **6** to **7** almost certainly involves a dissociation of the PMe_2Ph ligand from the tungsten atom, a rearrangement of the carbonyl ligands and a readdition of a PMe_2Ph ligand at the ruthenium atom, as found in **7**.

Abstract—By using the pH-metric method it has been found that antibiotic doxycycline (H_3DTC) reacts with tungstate and molybdate ions forming 1 : 1 and 2 : 1 (H_3DTC–WO_4^{2-} or H_3DTC–MoO_4^{2-}) complex compounds. The relative stability constants of these complexes were calculated from pH-metric measurements using Job's method.

Doxycycline is a tetracycline derivative which shows a very pronounced tendency to form complexes with different metal ions. Investigations on the complexes of tetracycline antibiotics are important since they demonstrate that attention should be paid to possible complexation reactions during parallel therapy with drugs such as antacide or iron preparations.

From the analytical standpoint many coloured tetracycline complexes have been applied to the assay of tetracycline antibiotics in different pharmaceutical preparations by spectrophotometric methods.

On the basis of our reported results[1] on the complexation reactions of tetracycline with WO_4^{2-} and MoO_4^{2-} ions, methods for the determination of tetracycline antibiotics in pharmaceutical preparations were proposed.[2–4]

The results of our investigations presented in this paper comprise the determination of the compositions and the stability constants of H_3DTC–WO_4^{2-} and H_3DTC–MoO_4^{2-} complexes. The data available in the literature refer to colour-forming reactions of tetracycline antibiotics with WO_4^{2-} and MoO_4^{2-} ions at elevated temperatures and under drastic conditions using Na_2CO_3 and H_2O_2, whereby degradations of the tetracycline molecule are possible.

EXPERIMENTAL

A Iskra Model MA 5705 pH-meter and VEB Prüfgeräte thermostat, precision ±0.02°C, were used. The pH-meter was calibrated using Radiometer buffer solutions, pH = 7.02 and pH = 4.00 at 20°C.

The reagents used were H_3DTC HCl standard (Sigma), $Na_2MoO_4 \cdot 2H_2O$ (Merck) and $Na_2WO_4 \cdot 2H_2O$ (Reanal), which were all of analytical grade. Solutions of H_3DTC were prepared by dissolving appropriate amounts of the H_3DTC standard in water, whereas solutions of Na_2MoO_4 and Na_2WO_4 were standardized gravimetrically.[5] For

* Author to whom correspondence should be addressed.

the preparation of solutions, fresh doubly-distilled water was used.

RESULTS AND DISCUSSION

Complexation equilibria in the WO_4^{2-}–H_3DTC *and* MoO_4^{2-} *systems*

The composition of complexes formed between H_3DTC and WO_4^{2-} and MoO_4^{2-} ions was determined by application of Job's method,[6,7] using the results of pH-metric measurements in a series of solutions:

(a) x cm^3 of H_3DTC and x cm^3 of Na_2WO_4 or Na_2MoO_4;

(b) x cm^3 of H_3DTC and $(10-x)$ cm^3 of water; and

(c) x cm^3 of Na_2WO_4 or Na_2MoO_4 and x cm^3 of water.

The concentrations of all solutions were 5×10^{-4} M. The pH measurements were performed after thermostatting for 10 min. It was evident that the pH of the mixed solution [H_3DTC and $Na_2WO_4^{2-}$ or Na_2MoO_4 solution (a)] was higher than that of the H_3DTC solution [solution (b)]. The decrease of H^+ ion concentration, due to complex formation, takes place according to the following possible reactions:

$$2H_3DTC+Na_2WO_4 \rightleftharpoons Na_2[WO_3(H_2DTC)_2]+H_2O \quad (1)$$

$$2H_3DTC+Na_2MoO_4 \rightleftharpoons Na_2[MoO_3(H_2DTC)_2]+H_2O \quad (2)$$

$$H_3DTC+Na_2WO_4 \rightleftharpoons Na_2[WO_3HDTC]+H_2O \quad (3)$$

$$H_3DTC+Na_2MoO_4 \rightleftharpoons Na_2[MoO_3HDTC]+H_2O. \quad (4)$$

In the case when no complexation according to reactions (1)–(4) occurs, the concentration of H^+ ions in the mixed solutions of Na_2WO_4 or Na_2MoO_4 and H_3DTC would be equivalent to the sum of H^+ ion concentrations in each separate solution [solution (b) and solution (c)]. The decrease of H^+ ions concentration was calculated using the equation:

$$[H^+] = [H^+]_a - \{[H^+]_b + [H^+]_c\}, \quad (5)$$

where $[H^+]_a$ denotes H^+ ions concentrations in solution (a), and $[H^+]_b$ and $[H^+]_c$ the concentrations in solutions (b) and (c), respectively. The results of pH measurements are given in Table 1.

The dependence of $\Delta[H^+]$ on the molar fraction, n, of WO_4^{2-} or MoO_4^{2-} [n = (mol of metal salt)/(mol of metal salt + mol of H_3DTC)] is shown in Figs 1 and 2. In the calculation of $[H^+]$ from the pH value, the activity factor of the H^+ ion was taken to be equal to unity. The curve obtained had maxima at molar fractions of $n = 0.5$ and $n = 0.33$, indicating the formation of WO_4^{2-} or MoO_4^{2-} complexes of 1 : 1 and 2 : 1 molar compositions.

Data in the literature indicate the possibility of colloidal tungstic acid formation[8] under the influence of H^+ ions, according to the reaction:

$$Na_2WO_4+2H^+ \rightleftharpoons H_2WO_4+2Na^+,$$

which would lead to an increase in the pH of the solution. Due to the presence of H^+ ions, polymerization of WO_4^{2-} or MoO_4^{2-} into polyanions may also take place according to the reaction:

$$6WO_4^{2-}+7HA \rightleftharpoons [HW_6O_{21}]^{5-}+7A^-+3H_2O,$$

which would also be followed by an increase in the

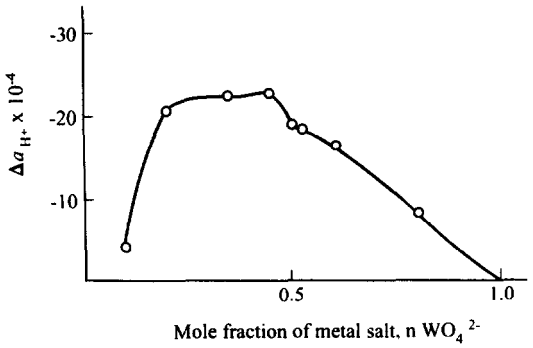

Fig. 1. Job's curve obtained by pH-metric measurements: $c_{H_3DTC} = 5 \times 10^{-4}$ M; $c_{NA_2WO_4} = 5 \times 10^{-4}$ M.

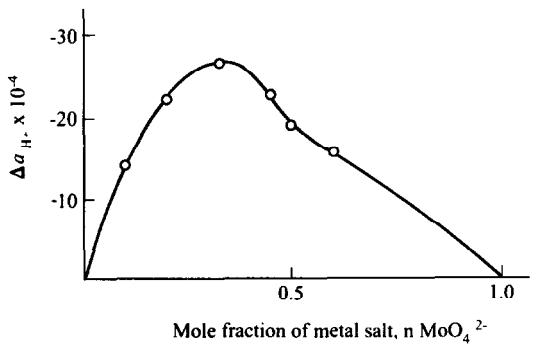

Fig. 2. Job's curve obtained by pH-metric measurements: $c_{H_3DTC} = 5 \times 10^{-4}$ M; $c_{NA_2MoO_4} = 5 \times 10^{-4}$ M.

pH of the solution.[9] However, the products of these reactions are colourless, whereas complexes formed between H_3DTC and WO_4^{2-} or MoO_4^{2-} ions are coloured.[10,11]

On the basis of the aforementioned data it may be concluded that the increase of the pH of the solution is due to the complexation reactions, not to colloidal acid formation.

Calculation of stability constants

The realtive stability constants of WO_3HDTC^{2-} and MoO_3HDTC complexes were calculated on the basis of pH-metric measurements, using the following equations:

$$[H_3DTC]^0 = [H_3DTC] + [H_2DTC^-] + [HDTC^{2-}] + [WO_3HDTC^{2-}] \quad (6)$$

$$[WO_4^{2-}]^0 = [WO_4^{2-}] + [WO_3HDTC^{2-}] \quad (7)$$

$$[H^+] = [H_2TC^-] + 2[HDTC^{2-}] \quad (8)$$

$$Kd_1 = \frac{[H^+][H_2DTC^-]}{[H_3DTC]};$$

$$Kd_2 = \frac{[H^+][HDTC^{2-}]}{[H_2DTC^-]}.$$

The relative stability constants of $WO_3(H_2DTC)_2^{2-}$ and $MoO_3(H_2DTC)_2^{2-}$ were calculated using the equations:

$$[H_3DTC]^0 = [H_3DTC] + [H_2DTC^-] + [HDTC^{2-}] + 2[WO_3(H_2DTC)_2^{2-}] \quad (9)$$

$$[WO_4^{2-}]^0 = [WO_4^{2-}] + [WO_3(H_2DTC)_2^{2-}]$$

$$\times [H^+] = [H_2DTC^-] + [HDTC^{2-}] \quad (10)$$

Kd_1 and Kd_2.

The calculations were carried out with the first and the second dissociation constants,[12] whereas the third dissociation constant was not taken into account, since the third proton dissociation takes place only in strongly basic media. The approximate concentrations of WO_4^{2-} and WO_3HDTC^{2-} were calculated from eqs (6)–(10) assuming that the activity coefficient of H^+ is equal to unity. By using the calculated approximate concentrations of these ions, the ionic strength of the solution and the activity factor were calculated. The correct H^+ ion concentration was calculated from the pH and the activity factor, and was used to calculate the concentrations of $HDTC^{2-}$, WO_4^{2-} and WO_3HDTC^{2-} ions. The relative stability constant of the complex was calculated by replacing the corresponding values into the equation:

$$K = \frac{[WO_3A]}{[WO_4^{2-}][A]}. \quad (11)$$

The results obtained are shown in Table 2.

The complexation reaction between H_3DTC and WO_4^{2-} or MoO_4^{2-} ions firstly involves the transformation of WO_4^{2-} into the oxide, which then reacts further with the ligand:

$$WO_4^{2-} + 2H^+ \rightleftharpoons WO_3 + H_2O \quad (12)$$

$$WO_3 + A \rightleftharpoons WO_3A. \quad (13)$$

Table 2. Stability constants of H_3DTC–WO_4^{2-} and H_3DTC–MoO_4^{2-} complexes

Complex	pH	I	$\log \beta_n$
WO_3HDTC^{2-}	4.98	9.03×10^{-4}	8.39
$WO_3(H_2DTC)_2^{2-}$	4.00	5.45×10^{-4}	8.26
MoO_3HDTC^{2-}	4.72	1.25×10^{-3}	7.99
$MoO_3(H_2DTC)_2^{2-}$	4.26	5.22×10^{-4}	9.21

The stability constant obtained on the basis of reaction (13) can be expressed as:

$$K = \frac{[WO_3A]}{[WO_3][A]}, \quad (14)$$

but it cannot be determined, since the equilibrium constant of reaction (12) is not known.

The stability constant calculated from eq. (11) represents a relative and specific stability constant. No data on the numerical values of the stability constants of doxycycline and WO_4^{2-} or MoO_4^{2-} complexes, determined by the pH-metric method, have so far been reported in the literature.

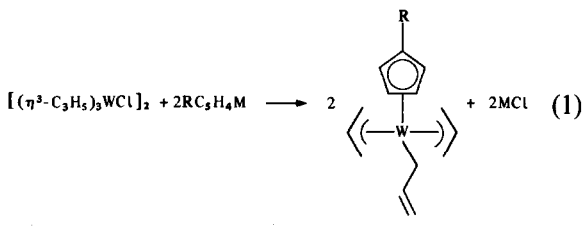
Abstract—$[(\eta^3\text{-}C_3H_5)_3WCl]_2$ reacts with substituted cyclopentadienyl alkali metal derivatives to give $(\eta^5\text{-}RC_5H_4)(\eta^3\text{-}C_3H_5)_2(\eta^1\text{-}C_3H_5)W$ (where R is H, Me or t-C_4H_9). Analogous reactions involving indenyl- or fluorenyllithium produce $(\eta^5\text{-}L)(\eta^3\text{-}C_3H_5)_2W$ species.

Preceding publications in this short series have been concerned with the preparation of $[(\eta^3\text{-}C_3H_5)_3WCl]_2$ and its further reaction with alkylmagnesium halides to give $(\eta^3\text{-}C_3H_5)_3WR$ and $(\eta^3\text{-}C_3H_5)_3W(PR_3)R$ species.[1,2] Here we discuss the reactions with cyclopentadienylsodium and related compounds.

RESULTS AND DISCUSSION

$[(\eta^3\text{-}C_3H_5)_3WCl]_2$, prepared by reacting $(\eta^3\text{-}C_3H_5)_4W$ with HCl,[1] reacts with cyclopentadienylsodium at low temperatures to give a yellow compound (**1**) whose mass spectrum suggests that an exchange of the tungsten-bonded chlorine atom and the cyclopentadienyl group has occurred. The IR and ^{1}H NMR spectra indicate that complexation of an η^5-cyclopentadienyl group to the metal is accompanied by rearrangement of one of the η^3-allyl groups into the η^1-allyl form [eq. (1)]:



(1)

1 R = H **2** R = Me **3** R = t-C_4H_9

Related compounds (**2**, **3**) have been prepared by reacting methylcyclopentadienyllithium and t-butylcyclopentadienyllithium as well as 5,6-dimethoxyindenyllithium and 3-methyl-1-carbomethoxyindenyllithium, whereby in the last two cases the compounds have not been obtained analytically pure. Reactions with 2-phenyl-isopropylcyclopentadienyllithium and pentamethylcyclopentadienyllithium were unsuccessful. The stability of compounds **1**–**3** decreases with increasing size of the substituent, with **3** decomposing in solution at −20°C.

The structure follows from the IR and NMR spectroscopic data (Table 1). The stretching frequency of the uncomplexed double bond of the η^1-allyl group is assigned to an absorption at *ca* 1600 cm^{-1}. The ^{1}H NMR spectrum of **3** is shown in Fig. 1 : 10 signals are observed for the protons of the two η^3-allyl groups, indicating that they are inequivalent and suggesting that they are twisted with respect to each other about the allyl—W axis. In addition, **3** shows fluxional behaviour involving the η^3-allyl groups but not the η^1-allyl group between −48°C and the decomposition temperature of −20°C, which is possibly the result of an oscillation of the η^3-allyl groups about the metal axis of the type discussed for $(\eta^3\text{-allyl})_4M$ (M = Mo, W).[3]

The behaviour of the tungsten compounds should be contrasted with that of the molybdenum analogues: the final products of the reaction between $[(\eta^3\text{-}C_3H_5)_3MoCl]_2$ and the RC_5H_4Li derivatives are the 17-electron compounds $(\eta^5\text{-}RC_5H_4)(\eta^3\text{-}C_3H_5)_2Mo$. However, spectroscopic evidence suggests that here initially an $(\eta^5\text{-}RC_5H_4)(\eta^3\text{-}C_3H_5)_2(\eta^1\text{-}C_3H_5)Mo$ species is formed and that this reacts further with homolytic cleavage of the Mo—η^1-

allyl bond.[4,5] This difference in behaviour of the complexes of the two metals is presumably associated with the difference in stability of the M—C bonds involved: the W—C bond is significantly stronger than the Mo—C bond.[6,7]

Attempts to prepare $(\eta^5\text{-}C_5H_5)(\eta^3\text{-}C_3H_5)_2W$ by photochemical or thermal activation of the W—C bond in **1** were unsuccessful. However, the disappearance of the absorptions due to the η^1-allyl group and a broadening of the other signals above −20°C in the ^{1}H NMR spectrum of the least stable t-butylcyclopentadienyl derivative **3** suggest that a paramagnetic $(\eta^5\text{-t-}C_4H_9C_5H_4)(\eta^3\text{-}C_3H_5)_2W$ species is formed; although the compound could not be isolated analytically pure. Paramagnetic compounds (**4**, **5**) of this type were, however, the only

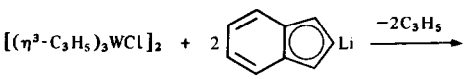
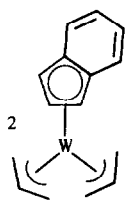
tungsten-containing products which could be isolated from the reaction between $[(\eta^3C_3H_5)_3WCl]_2$ and indenyl- or fluorenyllithium [eq. (2)]:





+ 2LiCl (2)

4

It is remarkable that the analogous reaction between fluorenyllithium and $[(\eta^3$-$C_3H_5)_3MoCl]_2$ leads to the tetrakis(η^3-allyl)molybdenum species, $(\eta^3$-$C_3H_5)_3(\eta^3$-fluorenyl)Mo.[4]

The compounds **1–3** are chemically relatively inert; protonolysis with HCl leads to cleavage of the W—C bond while no reaction is observed upon treatment with a variety of P-donor ligands.

EXPERIMENTAL

The experimental conditions and spectrometers used have been described earlier.[1] $[(\eta^3$-$C_3H_5)_3WCl]_2$ was prepared by treating $(\eta^3$-$C_3H_5)_4W$ with HCl in pentane at −78°C[1] and the substituted cyclopentadienylmetal species by reacting the appropriate cyclopentadiene compound with butyllithium or an alkali metal.[4]

$(\eta^5$-$C_5H_5)(\eta^3$-$C_3H_5)_2(\eta^1$-$C_3H_5)W$ (1)

C_5H_5Na (0.61 g, 6.90 mmol) was added to a solution of $[(\eta^3$-$C_3H_5)_3WCl]_2$ (1.45 g, 4.23 mmol) in THF (30 cm^3) at −40°C. The colour of the reaction mixture changed immediately from green to a dark salmon-pink. The reaction mixture was stirred for a further 30 min and the solvent removed under high vacuum at −40°C. Extraction of the solid residue with pentane (10 × 10 cm^3), concentration of the extract to 10 cm^3 and cooling to −70°C gave the compound as a yellow solid, which was recrystallized from pentane and dried at −40°C in a high vacuum. Yield 1.02 g (65% theory). Found: C, 45.1; H, 5.3; W, 49.2. Calc. for $C_{14}H_{20}W$: C, 45.2; H, 5.4; W, 49.4%.

IR (KBr, −40°C): ν 3040, 1465, 1021, 560 (η^3-C_3H_5); 1600 (η^1-C_3H_5); 3100, 1425, 1126, 1005, 830 (η^5-C_5H_5). MS *m/z* 372 (M^+), 342, 327, 287. ^{1}H NMR spectrum: see Table 1.

(η^5-MeC_5H_4)(η^3-C_3H_5)$_2$(η^1-C_3H_5)W (**2**)

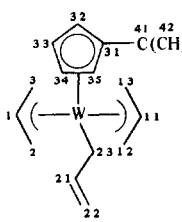
MeC_5H_4Li (0.39 g, 4.53 mmol) was added over 5 min to a suspension of [(η^3-C_3H_5)$_3$WCl]$_2$ (1.44 g, 4.20 mmol) in THF (150 cm^3) at −30°C and the resulting solution stirred for a further 12 h. The solvent was removed under high vacuum at −30°C and the residue extracted with hexane (3 × 40 cm^3). The extract was treated three times with avicel and the concentrated solution cooled to −78°C to give the compound as a yellow solid. Yield 1.12 g (69% theory). Found: C, 46.5; H, 5.8; W, 47.8. Calc. for $C_{15}H_{22}W$: C, 46.7; H, 5.7; W 47.6%.

IR (KBr, −45°C): *v* 3080–3025, 1496, 1003, 570 (η^3-C_3H_5); 1602, 908 (η^1-C_3H_5); 3098, 1035, 860, 830 (η^5-RC_5H_4); 1375. MS: *m/z* 386 (M^+), 344, 340, 300. ^{1}H NMR spectrum: see Table 1.

(η^5-t-$C_4H_9C_5H_4$)(η^3-C_3H_5)$_2$(η^1-C_3H_5)W (**3**)

Prepared as above as a yellow solid from t-butylcyclopentadienyllithium and [(η^3-C_3H_5)$_3$ WCl]$_2$. Yield 69% theory. Found: C, 50.4; H, 6.6; W, 42.9. Calc. for $C_{18}H_{28}W$: C, 50.5; H, 6.6; W, 42.9%.

IR (KBr, −45°C): *v* 3080–3025, 1496, 1003, 570 (η^3-C_3H_5); 1602, 980 (η^1-C_3H_5); 3098, 1035, 860, 830 (η^5-RC_5H_4); 1365, 1375. MS: *m/z* 428 (M^+), 386, 182. ^{1}H NMR spectrum: see Table 1 and Fig. 1. ^{13}C NMR (d_8-THF, −50°C): δ 78.8 [C-1, *J*(C,H) 159], 38.4 [C-2, *J*(C,H) 156, *J*(C,W) 16.3], 41.9 [C-3, *J*(C,H) 156, *J*(C,W) 12.2], 111.6 [C-11, *J*(C,H) 155], 72.1 [C-12, *J*(C,H) 153, *J*(C,W) 14.1], 54.7 [C-13, *J*(C,H) 156, *J*(C,W) 12.2], 146.5 [C-21, *J* (C,H) 144], 103.2 [C-22, *J*(C,H) 153], 13.8 [C-23, *J*(C,H) 131, *J*(C,W) 46.8], 113.5 (C-31), 84.0 [C-32, *J*(C,H) 182], 92.4 [C-33, *J*(C,H) 176], 67.9 [C-34, *J*(C,H) 172], 81.0 [C-35, *J*(C,H) 179], 34.6 (C-41), 31.4 [C-42, *J*(C,H) 126]—numbering scheme shown above.



(η^5-Indenyl)(η^3-C_3H_5)$_2$W (**4**)

Prepared as above as a red solid from indenyllithium and [(η^3-C_3H_5)$_3$WCl]$_2$. Yield 58% theory. Found: C, 47.1; H, 4.5; W, 48.2%. Calc. for $C_{15}H_{16}W$: C, 47.2; H, 4.2; W, 48.2%.

IR (KBr, 25°C): *v* 3080–3025; 1485, 1000, 540 (η^3-C_3H_5); 3110, 1550, 850, 820, 750 (indenyl). MS: *m/z* 381 (M^+), 339, 299.

(η^5-Fluorenyl)(η^3-C_3H_5)$_2$W (**5**)

Prepared as above as a red solid from fluorenyllithium and [(η^3-C_3H_5)$_3$WCl]$_2$ whereby the reaction was warmed to 0°C for 10 min. Yield 32% theory. Found: C, 53.2; H, 4.3; W, 42.6%. Calc. for $C_{19}H_{19}W$: C, 52.9; H, 4.4; W, 42.6%.

IR (KBr, −35°C): *v* 3080–3015, 1478, 1000, 590 (η^3-C_3H_5); 3098, 1570, 860, 820, 740 (fluorenyl). MS: *m/z* 430 (M^+), 388, 348.

UNUSUAL REACTIVITY OF ISOCYANATES WITH DIOXO- AND DIIMIDOMOLYBDENUM(VI) COMPLEXES

RICHARD LAI,* SYLVAIN MABILLE, ALAIN CROUX and SYLVIE LE BOT

ENSSPICAM, URA 1410, Université Aix-Marseille III, Marseille, France

(*Received* 4 *October* 1990; *accepted* 24 *October* 1990)

Abstract—Phenyl isocyanate reacts with dioxo- and diimidomolybdenum(VI) complexes such as $Mo(O)_2(mes)_2$ (**1**) (mes = mesityl = 2,4,6-$C_6H_2Me_3$), $Mo(mes)_2CH_2PBu_3(O)_2$ (**2**), $Mo(mes)\{CPBu_3(mes)\}(O)_2$ (**3**) and $Mo(NBu^t)_2(mes)_2$ (**4**), selectively affording phenyl mesityl amide. This reaction proceeds via insertion into the Mo—mesityl bond, leading to an unstable oxazamolydenacycle which has been identified by ^{13}C NMR. This intermediate is probably hydrolysed with generation of the amide during chromatographic work-up.

There are many reports in the literature of reactions involving heteroallenes such as isocyanates and transition metal complexes. The objectives of these studies were predominantly to better understand metal-promoted reactivity of CO_2-like molecules and also to develop reactions of synthetic utility.[1,2]

As part of our study of the synthesis and reactivity of multiple-bonded complexes,[3] it seemed appropriate to compare the reactivity of dioxodimesitylmolybdenum(VI), $Mo(O)_2(mes)_2$ (**1**) (where mes = mesityl = 2,4,6-$C_6H_2Me_3$), with the isoelectronic di(phenylimido)dimesitylmolybdenum(VI) complex. Therefore, we attempted to prepare this compound by reacting **1** with phenyl isocynate, a synthetic route which seems to have potential application to a wide variety of metals.[4] However, the reaction took an entirely different pathway and phenyl mesityl amide was found to be the sole identified product:

$$Mo(O)_2(mes)_2 + 2\,PhNCO \rightarrow \begin{cases} Mo(NPh)_2(mes)_2 + 2\,CO_2 \\ PhNHCO(mes). \end{cases}$$

We report here on the unusual reactivity of isocyanates with dioxo- and diimidomolybdenum(VI) complexes.

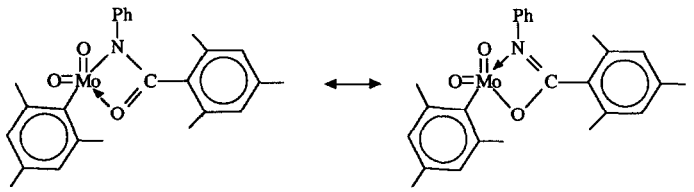
RESULTS AND DISCUSSION

When a yellow solution of $M(O)_2(mes)_2$ (**1**) in pyridine or tetrahydrofuran was treated with one equivalent of PhNCO, an instantaneous colour change occurred. After stirring for several hours, a brown solution was obtained. Analysis of the oily brown residue, obtained after vacuum evaporation of the solvent, did not reveal the presence of a diimido species, but column chromatography of the reaction mixture afforded an organic compound identified as phenyl mesityl amide by IR, NMR and mass spectrometry analysis. One equivalent of amide was obtained per mesityl group of the starting dioxo complex. Bu^tNCO reacted similarly affording $Bu^tNHCO(mes)$. However, only 0.6 equivalent of amide per mesityl group was isolated. The same behaviour was observed with the phosphorus ylide complex $Mo(mes)_2\ CH_2PBu_3(O)_2$ (**2**). However, in this case, elution of the amide from the column was only possible after on-column hydrolysis by dilute aqueous acid.

The dinitrene complex, $Mo(NBu^t)_2(mes)_2$ (**4**), obtained by an indirect method,[5] also reacted with PhNCO to give phenyl mesityl amide in good yield (92%). But in this case, the reaction was less selective since gas chromatographic analysis showed the presence of small amounts of other products. Two of them have been identified as tertiary butyl mesityl amide (1%) and a phenyl isocyanate trimer (5%). It is worth noting here that elimination of tertiary butyl mesityl amide has been observed upon treatment of $Cr(NBu^t)_2(mes)_2$ with CO.[5]

* Author to whom correspondence should be addressed.

When the dioxophosphinomethylidene complex, $Mo(mes)\{CPBu_3(mes)\}(O)_2$ (**3**), was reacted with PhNCO under the same conditions, no reaction was apparent after several hours at room temperature. Phenyl mesityl amide was detected only when the reaction was performed under more forcing conditions (70°C for 4 h) and no interaction with the Mo=C double bond was observed, in contrast with the results reported by Cramer *et al.* for $Cp_3U{=}CHPMe_2Ph$.[6]



Scheme 1.

The generation of amides (or thioamides) from isocyanates (or isothiocyanates) and Grignard or organolithium reagents has been reported.[7,8] This type of reactivity with transition metal oxo and imido complexes is unprecedented, although the formation of cyclohexyl mesityl amide by reacting $C_6H_{11}NCO$ and a vanadium complex has been mentioned recently.[9] Generally, the interaction of transition metal complexes with isocyanates leads to stable compounds resulting from insertion of RNCO into M—C,[10] M—N,[11] M=C[6] or M≡C[12] bonds. As far as oxo complexes are concerned differences in reactivity have been reported depending on the starting compound. Thus, oxo complexes either give imido species in a "classical way", or adducts.[13] An oxo-imido complex has been reported from the reaction between $Mo(O)_2Cl_2(MeCN)_2$ and Bu^tNCO.[14] In contrast, $(\eta^5\text{-}C_5H_5)_2MoO$ reacts with PhNCO to form a cyclometallacarbamate, $Mo(\eta^5\text{-}C_5H_5)_2\{OC(O)N(Ph)\}$, resulting from a formal [2+2] cycloaddition of the C=N bond to the oxo linkage.[15]

In the present case, it is obvious that the reaction leading to the imido complex is very unfavourable, if not completely inoperative. Indeed, quantitative gas chromatography analysis of the atmosphere above the reaction mixture revealed the presence of CO_2 [less than 5% with a 10-fold excess of PhNCO vs **1**] and of CO (1%). Carbon monoxide formation could arise from the decomposition of PhNCO adducts, although this type of decomposition is very rare.[16] Even with an excess of phenyl isocyanate, a single isocyanate was inserted into the Mo—mesityl bond, as observed with other systems.[1c]

We believe that the amide is formed by hydrolysis of an unstable intermediate during the chromatographic work-up. We could neither isolate nor identify such an intermediate from **2** or from **4**. However, when **1** was reacted in a sealed NMR tube with one equivalent of PhNCO in dry C_5D_5N at 20°C, we were able to obtain good ^{13}C NMR evidence for a species tentatively described as an oxazamolybenacycle, represented here as two mesomeric forms:

Two low-field signals at 187.3 and 181.3 ppm are, respectively, assigned to the carbonyl carbon atom and to the *ipso*-carbon of the η^1-mesityl ligand. At higher field, four signals are observed at 27.95, 21.8, 20.80 and 18.70 ppm. The peaks at 27.95 and 20.80 ppm are associated with the signal at 181.3 ppm. They are assigned, by analogy with the ^{13}C NMR spectrum of **1**, to the *ortho*- and *para*-methyl groups of the η^1-mesityl ligand. The two other signals at 21.8 and 18.7 ppm are assigned to the *para*- and *ortho*-methyl groups, respectively, of the mesityl group in the η^2-amide ligand. The *ortho*-methyl group is shielded as in phenyl mesityl amide due to the proximity of the carbonyl group. The assignment of the signal at 187.3 ppm to the carbonyl group is, furthermore, consistent with the spectra of other complexes with related structures.[2b,12] Formation of such a species resulting from the insertion of the isocyanate into the Mo—C σ-bond is certainly favoured by the polarization of the Mo—C structure.[1c] This insertion occurs at the N=C bond rather than at the C=O bond, reflecting the difference in bond strength between these two bonds.[17] Depending on the structure of the starting complex, this reaction would be more or less easy as shown for the dioxophosphinomethylidene complex, **3**.

EXPERIMENTAL

General

Preparations of complexes **1**,[18] **2**,[19] **3**[20] and **4**[5] have been described earlier. PhNCO and Bu^tNCO were purchased from Janssen and distilled and stored under nitrogen. All operations were conducted under oxygen-free N_2 by standard Schlenk techniques and solvents were distilled before use from sodium/benzophenone, except for pyridine which was distilled from KOH under N_2. Anhy-

drous CH_2Cl_2 was kept on molecular sieves (4 Å) and degassed prior to use.

NMR spectra were recorded on a Bruker spectrometer AM-200 and GC/MS coupling experiments were performed on a Ribernag R.10.10.c. apparatus. IR spectra were obtained using a FT–IR Nicolet MX-S spectrometer.

Gas chromatography analyses were conducted on an Intersmat 1GC 120FB apparatus and an Intersmat ICR 1B integrator, on 5m × 1/8″ columns of 5% OV 17 on Chromosorb W. Gas chromatography of gases were carried out on an Intersmat 1GC 120MB using a thermal conductivity detector on 2m × 1/8″ columns of Prorapak N (CO_2) or of molecular sieves, 3 Å (CO). Benzamide was used as an internal standard for quantitative GLC analyses.

Description of a typical experiment with isocyanates

The complex (3.2×10^{-3} mol) was dissolved in tetrahydrofuran or pyridine (20 cm^3) and after cooling at −30°C, 0.36 cm^3 (3.2×10^{-3} mol) of PhNCO was added. The solution was allowed to warm slowly to room temperature and after 5 h stirring the reaction mixture was evaporated under reduced pressure to a small volume and passed down a silica gel column (0.063–0.2 mm, Merck). Elution of the amide was obtained with CH_2Cl_2. For complex **3**, after deposition of the reaction mixture on silica gel, 10 cm^3 of H_2SO_4 (5% v/v in H_2O) was passed down the column before CH_2Cl_2 elution.

Acknowledgement—We wish to express our thanks to Professor Sir Geoffrey Wilkinson for helpful discussions.

REACTIONS OF DINITROGEN AND HYDRAZIDO(2−) COMPLEXES OF MOLYBDENUM CONTAINING A TRIDENTATE LIGAND: THE EFFECT OF ADDING REDUCING AGENTS UPON AMMONIA FORMATION*

T. ADRIAN GEORGE,† MICHAEL A. JACKSON‡ and BHARAT B. KAUL

Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304, U.S.A.

(*Received* 6 *August* 1990; *accepted* 25 *October* 1990)

Abstract—The reaction of HBr with *trans*-[$Mo(N_2)_2$(dppee)(PR_3)] (**1**), where dppee = $O(CH_2CH_2PPh_2)_2$ and PR_3 = PPh_3, PPh_2Me, in CH_2Cl_2 yields a hydrazido(2−) complex which reacts further to form ammonia and hydrazine. During this reaction an intermediate can be isolated which upon hydrolysis produces hydrazine in almost quantitative yield. Addition of $SnCl_2$ (4 mol), a two-electron reducing agent, to the reaction mixture causes a doubling of the ammonia yield and concomitant decrease in the yield of N_2. The relationship to the electrochemical two-electron reduction of two different hydrazido(2−) complexes will be discussed.

The reactivity of N_2 is remarkably influenced by the metal to which it is bonded and the co-ligands.[3] In order to study the effects of changing the ligating atoms upon the reactivity of N_2 bonded to molybdenum, a series of complexes of the type *trans*-[$Mo(N_2)_2$(tri)(PR_3)], where tri = tridentate ligand, have been synthesized[4] and their reactions with acids studied. Reactions of acids with mono- and bis(N_2) complexes of molybdenum that contain a tridentate ligand afford ammonia and hydrazine.[5,6] Short-term reactions with acid lead to the formation of complexes containing the familiar hydrazido(2−) ligand.[7,8] The two-electron electrochemical reduction of hydrazido(2−) complexes has been successfully accomplished: for example, the conversion of $[W(OTs)(NNH_2)(dppe)_2]^+$, where OTs = tosylate, dppe = $Ph_2PCH_2CH_2PPh_2$, into ammonia {together with regeneration of *trans*-$[W(N_2)_2(dppe)_2]$[9]} and $[MoBr(N\overline{NCH_2(CH_2)_3CH_2})(dppe)_2]^+$ into piperidine and $[MoBr(NH)(dppe)_2]^+$ after treatment with acid.[10] We have attempted to achieve similar results by reacting **1** and its derivatives with reducing agents. In this paper we report (i) the reactions of acids with **1**, the corresponding hydrazido(2−) complexes and an uncharacterized intermediate, from which only hydrazine is formed, and (ii) the discovery of an external reducing agent that increases the yield of ammonia.[2] The reduction of bridging N_2 to ammonia in complexes such as [MCp* $Me_3]_2(\mu$-$N_2)$, where M = Mo or W, or mixed Mo/W, and Cp* = C_5Me_5, with excess acid in the presence of excess zinc amalgam has been reported recently.[11]

RESULTS AND DISCUSSION

Formation of hydrazido(2−) complexes

Reactions of *trans*-[$Mo(N_2)_2$(dppee)(PR_3)] (**1**), where dppee = $O(CH_2CH_2PPh_2)_2$, PR_3 = PPh_3 and $PMePh_2$, with HX (X = Br, Cl) afforded high yields of the corresponding hydrazido(2−) complexes of the form [$MoX(NNH_2)$(dppee)(PR_3)]X (**2**) with no evidence for dissociation of PR_3. Exchange of the counter ion with BPh_4^- revealed sharp absorptions in the FTIR spectrum between 3100 and 3350 cm^{-1} due to ν(NH).

Reactions of **1** (PPh_3) or **2** (Br-PPh_3) with HBr in THF produced little ammonia (0.10 mol/mol of

* For part XXVI, see ref. 1.

† Author to whom correspondence should be addressed.

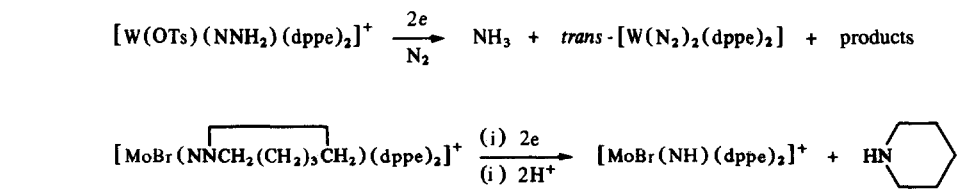

Scheme 1.

Mo), no hydrazine and 1.50 mol of N_2 for a 77% nitrogen-atom balance. On the other hand, in CH_2Cl_2, **1** (PPh_3) reacted with HBr to produce ammonia, hydrazine and N_2; 0.29, 0.44 and 1.27 mol/mol of Mo, respectively, for a 93% nitrogen-atom balance.

The hydrazido(2−) complexes formed from *trans*-[$Mo(N_2)_2$(tri)(PPh_3)], where tri = $S(CH_2CH_2CH_2PPh_2)_2$ and $PhP(CH_2CH_2CH_2PPh_2)_2$, were unstable losing PPh_3 in solution. The parent N_2 complexes displayed the same behaviour, which we attributed to steric effects associated with the propylene backbones in each tri ligand.[4]

Formation of intermediate

Reaction of [$MoBr(NNH_2)$(dppee)(PPh_3)]Br with excess HBr in CH_2Cl_2 led to the precipitation, within 1 h, of a solid **3** (*ca* 80% yield) whose colour varied from purple to purple–grey. The filtrate contained unreacted hydrazido(2−) but no free PPh_3. The latter forms the phosphonium salt under these experimental conditions. After exhaustive washing with CH_2Cl_2 and MeOH followed by drying *in vacuo*, hydrolysis of the solid with a H_2O/CH_2Cl_2 mixture produced *ca* 0.5 mol of hydrazine per mol of Mo and only a trace of ammonia. This is the first example in our work in which an intermediate produces only hydrazine. The yield of hydrazine is based upon the amount of **2** at the beginning of the reaction and results are reproducible. By the time precipitation of **3** was complete, *ca* 0.5 mol of N_2/mol of **2** had evolved. Thus beginning with **1**, *ca* 100% of the nitrogen was accounted for.

Elemental analyses of **3** were variable with Br > 40% and C:H:P ratios indicative of one dppee per Mo. The FTIR spectrum showed ν(NH) in the 2500–2800 region and ν(PH) at 2300 cm^{-1}, suggesting protonation of a pendant phosphine arm of dppee. The charge-compensating bromide ion associated with the phosphonium ion would contribute to the high per cent of bromine obtained. The solid was paramagnetic (Gouy method) and only dissolved in polar solvents such as DMF and DMSO in which is decomposed with evolution of N_2. Tests for the presence of hydrazine following decomposition were negative.

The role of external reducing agents

Dinitrogen complexes of molybdenum react with strong acids to produce ammonia or ammonia and hydrazine. The reaction involves a series of protonation and electronation steps. The initial phase entails protonation of the terminal nitrogen atom of N_2 and intramolecular electron reorganization which leads to the rapid formation of a hydrazido(2−) complex [eq. (1)]. The final phase, in THF solution, involves disproportionation[12]

$$\{Mo^0(N_2)\} + 2H^+ \longrightarrow \{Mo^{IV}(NNH_2)\}^{2+} \quad (1)$$

$$2\{Mo^{IV}(NNH_2)\}^{2+} + 4H^+ \longrightarrow 2\{Mo^{III}\} + 2NH_4^+ + N_2 \quad (2)$$

(intermolecular electron transfer) of the hydrazido(2−) complex to yield about one mol of ammonia and one-half mol of N_2 per mol of Mo, respectively [eq. (2)]. The interjection of electrons into the system would be an important step in the generation of a catalytic cycle for ammonia or hydrazine formation. This has been achieved by the two-electron electrochemical reduction of hydrazido(2−) complexes (see Introduction). We felt that the addition of a reducing agent might reduce the "purple" intermediate so that ammonia rather than hydrazine would be formed. Therefore, **1** and reducing agents were treated with HBr in CH_2Cl_2 and yields of nitrogen products determined.

Reducing agents such as cobaltocene, SmI_2 and amalgamated tin were unsuccessful, reacting with solvent or producing H_2. Tin(II) chloride, a two-electron reducing agent, provided the most satisfactory results (see Table 1). With a 1:4 ratio of **1** to $SnCl_2$, ammonia yields increased from 0.29 to 0.65 mol/mol of **1**, which corresponds almost exactly to the decrease in N_2 produced, 1.27 to 1.09. Thus, 0.18 mol of N_2 that would normally have been evolved have been converted into an extra 0.36 mol of ammonia. Hydrazine production was unaffected. The intermediate **3** was not observed in

[e] VCl_3.

these reactions. It is hard to account for this increase without proposing that $SnCl_2$ is acting as a reducing agent.[13,14] VCl_3, a Lewis acid and potential reducing agent like $SnCl_2$, caused a decrease in the overall yields of nitrogen-containing products when used in similar reactions.

Similar reactions with 10 and 20 mol of $SnCl_2$/mol of **1** resulted in decreases in the amounts of ammonia and particularly hydrazine produced (see Table 1). $SnCl_2$ is not very soluble in CH_2Cl_2 and during the reaction it took more than 12 h before it dissolved completely. Addition of $[Et_4N][SnCl_3]$ (4 mol), which is very soluble in CH_2Cl_2, caused a decrease in ammonia and hydrazine yields.

In order to investigate the mechanism of these reactions, a number of experiments were carried out in an effort to incorporate tin-containing moieties[15] into the hydrazido(2−) and other intermediate stages of ammonia formation. (i) Compound **1** was reacted with $[HPPh_3][SnBr_3]$ to try and incorporate $SnBr_3^-$ as a ligand *trans* to NNH_2; the product was $[MoBr(NNH_2)(dppee)(PPh_3)][SnBr_3]$.* (ii) The reaction of $SnCl_2$ with $[MoBr(NNH_2)(dppee)(PPh_3)]Br$ produced the analogous $SnBrCl_2^-$ salt.† (iii) Similarly, the reaction of $[Et_4N][SnCl_3]$ with $[MoBr(NNH_2)(dppee)(PPh_3)]Br$ yielded the $SnCl_3^-$ salt.‡

Further work is underway to isolate (i) intermediates that incorporate tin(II) compounds and (ii) the tin(IV) product of these interesting redox reactions.

EXPERIMENTAL

General procedures

All reactions and manipulations were carried out under dry oxygen-free N_2 or *in vacuo*. All solvents were rigorously dried by heating at reflux over an appropriate drying agent followed by distillation under N_2. Solvents were saturated with N_2 immediately before use by bubbling N_2 through the solvent (*ca* 0.5 h). Solvents used in vacuum-line experiments were degassed through four to five freeze–pump–thaw cycles. Samples were weighed out in a Vacuum Atmospheres Corp. Dribox. Specific procedures for carrying out acid reactions with **1** and quantitative determination of yields of N_2, ammonia and hydrazine have been reported elsewhere.[5b] For reactions in which $SnCl_2$, $[Et_4N][SnCl_3]$ and VCl_3 were added, the reagent was weighed out with **1**.

Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, Tennessee.

Instrumentation

IR spectra were recorded with an Analect RFX-65 FTIR spectrometer. ^{31}P and ^1H NMR spectra were obtained at room temperature in CD_2Cl_2 with a Varian VXR-200 spectrometer operating at 80,984 and 200.050 MHz, respectively. Chemical shifts are referenced to PPh_3 (−5.8 ppm vs 85% H_3PO_4 = 0 ppm) and TMS. Mass spectral data were obtained on a Kratos MS50-TA mass spectrometer.

Reagents and chemicals

Details have been given elsewhere.[4,5b] Chemicals were purchased from commercial sources and used as obtained. The following complexes were prepared by published procedures: *trans*-$[Mo(N_2)_2(dpepp)(PR_3)]$ (**1**), where PR_3 = PPh_3 and PPh_2Me,[4] and $[Et_4N][SnCl_3]$.[16] $[HPPh_3][SnBr_3]$ was synthesized[17] by reacting $SnBr_2$ and $[HPPh_3]Br$[18] in anhydrous degassed methanol. The compound was characterized by FTIR [ν(PH) 2395 (vs) cm^{-1}] and mass spectrometry; the low resolution positive ion FAB mass spectrum contained the cation $[HPPh_3]^+$

* ^{31}P NMR: δ 48.40 (t, 1, $^2J_{P_aP_x}$ = 13.5 Hz, P_x), 26.75 (d, 2, P_a). FTIR (KBr disc): ν(NH) 3345 (m), 3220 (s), 3112 (w) cm^{-1}.

† ^{31}P NMR: δ 48.0 (t, 1, $^2J_{P_aP_x}$ = 13.6 Hz, P_x), 26.38 (d, 2, P_a). FTIR (KBr disc): ν(NH) 3341 (m), 3216 (s), 3120 (w) cm^{-1}.

‡ ^{31}P NMR: δ 47.7 (t, 1, $^2J_{P_aP_x}$ = 13.6 Hz, P_x), 25.89 (d, 2, P_a). ^1H NMR: δ 8.72 (m, 35, Ph), 5.64 (s, 2, NNH_2), 4.58 (m, 4, OCH_2), 2.85 (m, 4, PCH_2). FTIR (KBr disc): ν(NH) 3338 (m), 3213 (s), 3117 (w) cm^{-1}.

(m/z = 262) as the base peak, and the negative ion FAB spectrum contained an abundant $[SnBr_3]^-$ ion (m/z = 358 for the ion with the most abundant isotopes).

$[MoBr(NNH_2)(dppee)(PPh_3)]Br$

An excess of HBr (*ca* 2.55 mmol) was condensed onto **1** (0.15 g, 0.17 mmol) at −196°C. The mixture was allowed to warm to room temperature in a closed vessel with agitation as described previously. Volatiles (N_2 and HBr) were removed and the brown–green solid dried overnight *in vacuo*. The product was dissolved in THF, the solution filtered and ether added to precipitate a khaki-green microcrystalline solid (0.13 g, 0.13 mmol, 75%). Found: C, 55.6; H, 4.6; N, 2.5. Calc. for $C_{46}H_{45}Br_2MoN_2OP_3$: C, 55.7; H, 4.6; N, 2.8%. ^{31}P NMR: δ 49.6 (t, 1, $^2J_{P_aP_x}$ = 13.4 Hz, P_x), 29.0 (d, 2, P_a).

The following complexes were prepared similarly. $[MoCl(NNH_2)(dppee)(PPh_3)]Cl$; ^{31}P NMR: δ 23.7 (t, 1, $^2J_{P_aP_x}$ = 13 Hz, P_x), 1.8 (d, 2, P_a). $[MoCl(NNH_2)(dppee)(PPh_2Me)]Cl$; ^{31}P NMR: δ 32.4 (m, 1, $^2J_{P_aP_x}$ = 13 Hz, P_x), 31.8 (d, 2, P_a); Found: C, 58.1; H, 5.2. Calc. for $C_{41}H_{43}Cl_2MoN_2OP_3$: C, 58.6; H, 5.2%.

Intermediate 3

HBr (*ca* 2.20 mmol) and CH_2Cl_2 (10 cm^3) were condensed onto *trans*-$[Mo(N_2)_2(dppee)(PPh_3)]$ (100 mg, 0.11 mmol) at −196°C. The mixture was allowed to warm to room temperature and stirred. Within 1.5–2 h a precipitate began to form. After 4 h the grey–purple solid was filtered off, washed with 4×20 cm^3 CH_2Cl_2, 4×10 cm^3 methanol and dried *in vacuo*. Yield 0.08 g. FTIR (KBr disc): ν(NH) 3301, 3260, 2800; ν(PH) 2328 cm^{-1}.

(*Received* 22 *August* 1990; *accepted* 1 *November* 1990)

Abstract—Stoichiometric reaction between Tl[9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$] and $[Ph_3PCuBr]_4$ affords the title compound in good yield. Crystallographic analysis of this species shows that the copper atom is essentially symmetrically disposed above the five-atom ligand face, thus completing a *closo* 12 vertex polyhedron. In contrast, in the formally related species 10,11-μ-H-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$ and 10,11-μ-(PPh_3Au)-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$ the hydrogen atom and {Ph_3PAu} fragment occupy bridging positions on an open face, whereas in anionic non-SMe_2-substituted analogues of the last two the hydrogen atom and {Ph_3PAu} fragment adopt *endo*-terminal sites. These differences in respect to the SMe_2-substituted compounds are traced to the form of the HOMO of the [9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$]$^-$ ligand. Inspection of the three occupied π-MOs of this ligand additionally yields a semi-quantitative understanding of patterns visible in the facial B—B, B—C and C—C distances of 3-PPh_3-4-SMe_2-3,1,2-*closo*-$CuC_2B_9H_{10}$, 10,11-μ-H-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$ and 10,11-μ-(PPh_3Au)-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$.

In a recent publication[1] we reported the synthesis and characterization of [10-*endo*-(Ph_3PAu)-7,8-*nido*-$C_2B_9H_{11}$]$^-$ ([$Ph_3PAucarb$]$^-$), the major structural feature of which is that the {Ph_3PAu} fragment is *endo*-σ-bonded to the central boron atom, B(10), of the open face of the *nido*-carbaborane ligand. This species is, therefore, structurally analogous to [7,8-*nido*-$C_2B_9H_{12}$]$^-$ ([carbH]$^-$) which has an *endo*-terminal hydrogen atom,[2] and distinct from [3-PPh_3-3,1,2-*closo*-$CuC_2B_9H_{11}$]$^-$ ([Ph_3PCucarb]$^-$) which shows an essentially closed icosahedral cage structure.[3] We rationalized observed patterns in the important molecular parameters for the series [carbH]$^-$, [$Ph_3PAucarb$]$^-$ and [Ph_3PCucarb]$^-$ in terms of differing degrees of depopulation of the occupied π-molecular orbitals (MOs) of [7,8-*nido*-$C_2B_9H_{11}$]$^{2-}$ by the fragments H^+, {Ph_3PAu}$^+$ and {Ph_3PCu},$^+$ respectively.

We are currently developing the *d*- and *f*-block metal chemistries of the monoanionic carbaborane ligand [9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$]$^-$ ([carb′]$^-$),[4] and as part of these studies we have determined the molecular structures of the ligand precursor 10,11-μ-H-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$ (carb′H, **1**)[4a] and its isolobally substituted analogue 10,11-μ-(Ph_3PAu)-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$ ($Ph_3PAucarb'$, **2**).[4b] It was, therefore, of interest to similarly study the copper analogue $Ph_3PCucarb'$ to establish:

(i) If, as with [$Ph_3PCucarb$]$^-$, a *closo* icosahedral cluster geometry is observed.
(ii) If trends are also apparent in key molecular parameters for the series carb′H, Ph_3PAucarb′ and $Ph_3PCucarb'$, and further, if their origin can be traced to electronic effects.

Accordingly, this paper describes the synthesis, and the spectroscopic and structural characterization of $Ph_3PCucarb'$, and the results of a detailed comparison of its structure with those of **1** and **2**.

EXPERIMENTAL

Synthesis and characterization

Reactions were performed under dry N_2 using standard Schlenk-line techniques, with some sub-

* Author to whom correspondence should be addressed.

sequent manipulation in air. CH_2Cl_2 and n-hexane were dried and distilled under N_2 prior to use. NMR spectra were recorded on a Brucker WP200SY spectrometer as a CD_2Cl_2 solution at 298 K. Microanalyses were performed by the departmental service. The starting materials, 10,11-μ-H-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$[5] and $[Ph_3PCuBr]_4$,[6] were prepared by literature methods.

Synthesis of Tl[9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$]

To a solution of 10,11-μ-H-9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$ (**1**) (0.3006 g, 1.545 mmol) in dmso (8 cm^3) was added, dropwise with stirring, a solution of KOH (0.5268g, 9.37 mmol) in H_2O (8 cm^3). After 30 min a solution of thallium(I) acetate (0.4702 g, 1.78 mmol) in H_2O (10 cm^3) was added, affording a thick, dull yellow precipitate of Tl[9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$] which was collected by filtration, washed with CH_2Cl_2 (5 cm^3) and Et_2O (2 × 5 cm^3), and stored in a foil-covered vessel. Yield: 0.5717 g, 93%. Found: C, 12.2; H, 3.9. Calc. for $C_4H_{16}B_9STl$: C, 12.1; H, 4.0%.

Synthesis of 3-PPh_3-4-SMe_2-3,1,2-*closo*-$CuC_2B_9H_{10}$ (**3**)

To a stirred suspension of Tl[9-SMe_2-7,8-*nido*-$C_2B_9H_{10}$] (0.4045 g, 1.12 mmol), in CH_2Cl_2 (5 cm^3) in a foil-covered reaction flask, was added a suspension of $[Ph_3PCuBr]_4$ (0.4545 g, 0.28 mmol) in CH_2Cl_2 (10 cm^3). The mixture was stirred overnight and filtered to afford a colourless filtrate, from which removal of solvent *in vacuo* gave an off-white solid. Colourless crystals of 3-PPh_3-4-SMe_2-3,1,2-*closo*-$CuC_2B_9H_{10}$ (**3**) were obtained by slow diffusion of n-hexane into a CH_2Cl_2 solution at −30°C. Yield: 0.4363 g, 75%. Found: C, 50.6; H, 6.1. Calc. for $C_{22}H_{31}B_9CuPS$: C, 50.9; H, 6.0%. NMR: ^1H δ 7.20–7.75 (multiplet, 20H, C_6H_5), 2.33 (s, 3H, CH_3), 2.24 (s, 3H, CH_3), 2.26 (br, s, 1H, $C_{cage}H$), 2.01 (br s, 1H, $C_{cage}H$) ppm; ^{11}B-{^1H} δ −15.37 (2B), −18.14 (1B), −19.54 (1B), −20.12 (1B), −21.71 (1B), −22.51 (2B), −33.66 (1B) ppm.

Crystallographic study

A single crystal (0.2 × 0.2 × 0.3 mm^3) of **3** was set on an Enraf–Nonius CAD4 diffractometer equipped with graphite-monochromated Mo-K_α X-radiation ($\bar{\lambda}$ = 0.71069 Å). The unit cell parameters and orientation matrix for data collection were determined from the least-squares refinement of the setting angles of 25 centred reflections ($10 < \theta < 11°$).

Crystal data. $C_{22}H_{31}B_9CuPS$, M = 519.36, triclinic, space group $P\bar{1}$ a = 9.100(8), b = 11.344(4), c = 14.171 Å, α = 66.85(3), β = 89.11(5), γ = 82.85(5)°, V = 1333.8 $Å^3$, Z = 2, D_c = 1.293 g cm^{-3}, μ(Mo-K_α) = 9.65 cm^{-1}, $F(000)$ = 536.

Data were collected by ω–2θ scans (ω scan width = 0.8 + 0.34 tan θ) in 96 steps for $+h$, $\pm k$, $\pm l$ and $1 \leqslant \theta \leqslant 25°$. No perceptible crystal decay or movement was noted. Of 5015 unique reflections measured, 3748 [$F \geqslant 2.0\sigma(F)$] were retained for structure solution and refinement.

The structure was solved by automatic direct methods (Cu, P, S atoms) (SHELX86[7]) and full-matrix least-squares refinement/ΔF syntheses (C, B, H_{cage}, H_{methyl}) (SHELX76[8]). Cage C atoms were identified by the usual combination of refined (as B) isotropic thermal parameters and internuclear distances. An empirical absorption correction (DIFABS[9]) was applied after isotropic convergence. Phenyl rings were modelled as regular, planar hexagons (C—C 1.395 Å, C—H 1.08 Å). All non-hydrogen atoms were allowed anisotropic thermal vibration and hydrogen atoms were refined with group isotropic thermal parameters [H_{cage}, H_{methyl} 0.062(3) $Å^2$, H_{phenyl} 0.110(4) $Å^2$ at convergence]. Weights were assigned according to $w^{-1} = [\sigma^2(F) + 0.000284F^2]$. R = 0.0410, R_w = 0.0419, S = 1.289. Maximum and minimum residues in ultimate ΔF synthesis were only 0.35 and −0.28 $eÅ^{-3}$, respectively. Atomic scattering factors for P, S, C, B and H were those inlaid in SHELX76; for Cu, values were taken from *International Tables for X-ray Crystallography*.[10]

Tables of final atomic positional and thermal parameters, a full list of interbond angles and tables of F_o/F_c values have been deposited with the Editor as supplementary material.

Theoretical study

An extended Huckel molecular orbital (EHMO) calculation was performed on [9-SMe_2-7,8-*nido*-$C_2B_9H_{10}]^-$ with charge iteration [$H_{ii} = H_{ii}^\circ$ + (sense) × (charge)]. The model was derived from the crystallographic coordinates of 3,3,3-$(CO)_3$-4-SMe_2-3,1,2-*closo*-$MnC_2B_9H_{10}$[4c] from which the {$Mn(CO)_3$} fragment was removed (note the differing numbering conventions for *closo* 12 vertex and *nido* 11 vertex polyhedra[11]). The calculation was made using the ICON8 program[12] and the weighted H_{ij} formula.[13] H_{ii}s and Slater exponents for S, C, B and H were those inlaid in ICON8.

RESULTS AND DISCUSSION

Stoichiometric reaction between suspensions of Tl[carb′] and $[Ph_3PCuBr]_4$ in CH_2Cl_2 affords the

target compound 3-PPh_3-4-SMe_2-3,1,2-*closo*-$CuC_2B_9H_{10}$ (Ph_3PCucarb′, **3**) in good yield, the crystalline product being characterized by microanalysis and by ^1H and ^{11}B NMR spectroscopy. In the ^1H NMR spectrum the methyl protons give rise to two singlets (2.33 and 2.24 ppm). This confirms the magnetic inequivalance of the two methyl groups of the SMe_2 function. The ^{11}B-{^1H} NMR spectrum diplays seven resonances of relative integral 2 : 1 : 1 : 1 : 1 : 2 : 1, consistent with a fully asymmetric carbametallaborane cage (two coincidences). On retention of proton coupling all resonances in the ^{11}B spectrum show doublet coupling (J_{BH} 120–150 ± 5 Hz) except for one of the components of the highest frequency resonance (δ −15.37 ppm), which may thus be assigned to B(4), the sulphur-bearing boron atom.

The structure of **3** was completely characterized by a single crystal X-ray diffraction study. Figure 1 presents a perspective view of a single molecule and demonstrates the atomic numbering scheme adopted.[11] Table 1 lists internuclear distances and key interbond angles determined.

Clearly, the essential structural feature of **3** is that the copper atom is η^5-bonded by the carbaborane ligand face, rendering the overall polyhedron a *closo* 12 vertex architecture. Thus the series carb′H,[4a] Ph_3PAucarb′[4b] and Ph_3PCucarb′ resembles the series [carbH]$^-$,[2] [Ph_3PAucarb]$^-$ [1] and [Ph_3PCucarb]$^-$ [3] in that the first two members are structurally similar to each other and involve a *nido* 11 vertex carbaborane supporting a non-vertex function (H and {Ph_3PAu} respectively, *endo* bonded in the carb series and bridging in the carb′ series), whereas in the final member of each series the {Ph_3PCu} fragment completes a *closo* 12 vertex (icosahedral) cluster. These findings are fully consistent with the available valence orbitals of H^+, $\{R_3PAu\}^+$ and $\{R_3PCu\}^+$,[14] and with the frontier orbitals of [carb]$^{2-}$ [1,15] and [carb′]$^-$ (see later for the last), to which more detailed reference will be subsequently made.

The carbacupraborane **3** represents an addition to the growing number of complexes of the carb′ ligand that have been structurally characterized. As in Ph_3PAucarb′,[4b] $(CO)_3$Mncarb′[4c] and carb′H itself,[4a] a preferred conformation about the B—S bond is apparent, the torsion angle* S(lone pair)—S—B(4)—C(1) being only 7.7(3)°. Moreover, S—B(4)—C(1) is considerably narrower than S—B(4)—B(8), 118.16(24) vs 128.85(4)°. These structural findings are fully consistent with an intra-

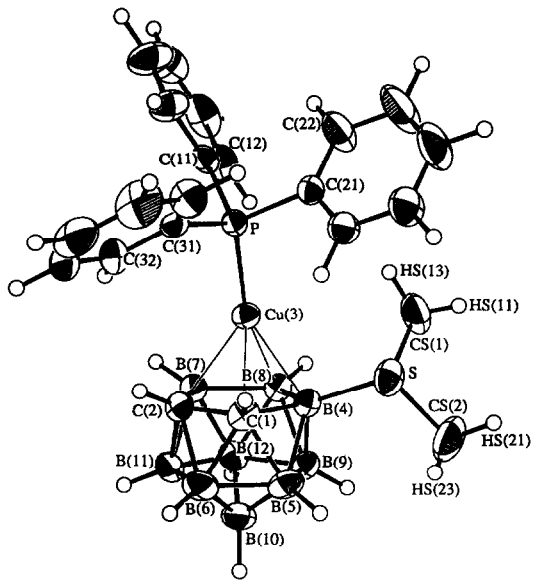

Fig. 1. Perspective view of **3**. Thermal ellipsoids are drawn at the 50% probability level, except for H atoms which have an artificial radius of 0.1 Å for clarity. Phenyl rings are numbered cyclically, C(*ij*) with i = 1–3, j = 1–6. H atoms not numbered carry the same number as the B or C to which they are attached. HS(12) and HS(22) are totally obscured by CS(1) and CS(2), respectively.

molecular electrostatic attraction between the sulphur lone pair of electrons and the (relatively protonic) H atom *exo* to C(1). It is of considerable interest that the preferred conformation about the B—S bond is retained in spite of steric crowding between the CS(1) methyl group and the C(21)—C(26) phenyl ring [HS(13)···C(21) 2.97(4) Å, HS(13)···C(26) 2.93(4)Å]. Rather than adopt an alternative B—S torsion, which would presumably relieve this crowding, it appears preferable for the SMe_2 groups to undergo a depression of *ca* 5° from its idealized 26° angle of inclination to the metallabonded C_2B_3 face. Similar intramolecular crowding was noted in the structure of Ph_3PAucarb′.[4b]

In **3** the copper atom is 1.721 Å from the C_2B_3 ligand face. The latter is measurably non-planar, being folded into an envelope conformation about the B(4)···B(7) vector, and subtending fold angles[15,16] of θ, 2.11° and ϕ, 1.15°. Moreover, the copper atom is consistently closer to the facial boron atoms than the cage carbon atoms, resulting in a slip parameter,[15,16] Δ, of +0.34 Å. As expected,[15] this slip distortion can be traced to localization of the frontier orbitals of the [carb′]$^-$ ligand onto the boron atoms of the ligand face.

The occupied π-MOs of [carb′]$^-$, as given by EHMO calculation, are sketched in Fig. 2 from a

*Calculated from the directly measurable angles CS(1)—S—B(4)—C(1) and CS(2)—S—B(4)—C(1).

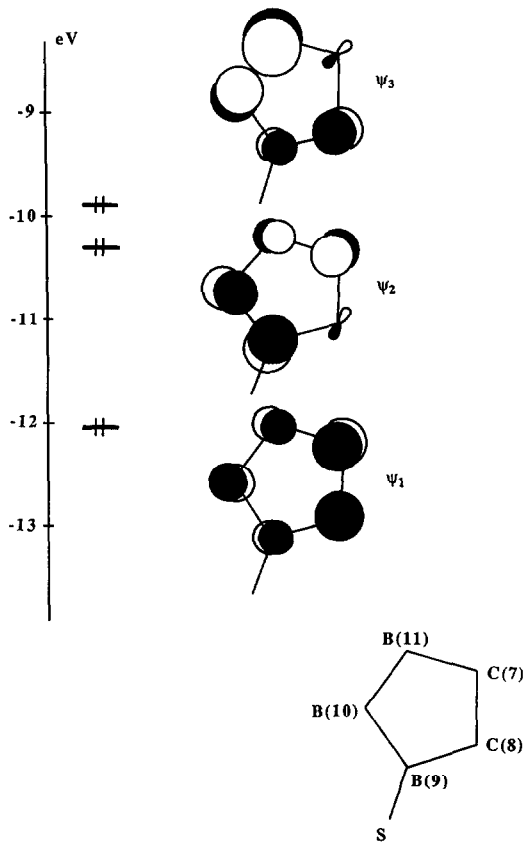

Fig. 2. The occupied π-molecular orbitals of [carb′]$^-$.

position above the centre of the C_2B_3 face. As with the series[1] [carbH]$^-$, [Ph$_3$PAucarb]$^-$ and [Ph$_3$PCucarb]$^-$, we have attempted to analyse the essential structural features of **1**, **2** and **3** by consideration of the forms of these ligand orbitals.

ψ_1 is fully analogous to the third highest occupied MO (HOMO) of [7,8-*nido*-$C_2B_9H_{11}$]$^{2-}$, being fully in phase and localized on the cage carbon atoms. ψ_2 and ψ_3 are localized on boron atoms and have near-orthogonal perpendicular nodal planes (as expected for orbitals analogous to the degenerate HOMOs of [C_5H_5]$^-$), but since [carb′]$^-$ lacks symmetry these nodal planes are not required to lie in any special direction; in fact, they appear to be rotated *ca* 36° with respect to those of [carb]$^{2-}$, the nodal plane of ψ_3, the HOMO of [carb′]$^-$, running from C(7) to the approximate mid-point of B(9)—B(10). ψ_3 is predominantly localized between B(10) and B(11), c.f. the HOMO of [carb]$^{2-}$ localized on B(10), explaining why H$^+$ and {Ph$_3$PAu}$^+$ fragments assume bridging sites in **1** and **2** but *endo*-terminal sites in [carbH]$^-$ and [Ph$_3$PAucarb]$^-$.

In Table 2 we list intrafacial distances for the carb′ ligand in **1**, **2** and **3**. Note that the accepted polyhedral numbering scheme[11] differs between *nido* **1** and **2**; and *closo* **3**, and for ready comparison the facial atoms in Table 2 are refered to the [9-SMe$_2$-7,8-*nido*-C_2B_9] framework typified by **1**.

The essential trends that are apparent in Table 2 as we more from **1** → **2** → **3** may be summarized as follows:

(i) The B—B distances, initially quite different, converge towards a common value.
(ii) Both C—B connectivities lengthen.
(iii) The C—C distance increases.

The general pattern of these trends is readily understandable by considering the depopulation of ψ_1–ψ_3 by the appropriate acceptor orbitals of H$^+$, {Ph$_3$PAu}$^+$ and {Ph$_3$PCu}$^+$, in a manner anal-

Table 2. Comparison of intrafacial distances (Å) for compounds **1**–**3**

	1[4a]	**2**[4b]	**3**
B(9)—B(10)	1.774(4)	1.772(8)	1.787(5)
B(10)—B(11)	1.847(5)	1.844(8)	1.791(5)
C(7)—B(11)	1.618(4)	1.636(8)	1.670(5)
C(8)—B(9)	1.577(5)	1.594(8)	1.643(5)
C(7)—C(8)	1.525(4)	1.558(8)	1.555(5)

ogous to our previous analysis[1] of the structures of $[carbH]^-$, $[Ph_3PAucarb]^-$ and $[Ph_3PCucarb]^-$. Briefly, as the acceptor fragment moves from bridging across B(10)—B(11) (H^+ and $\{Ph_3PAu\}^+$ fragments) to a much more central position above the five-atom face ($\{Ph_3PCu\}^+$ fragment), ψ_3 is depopulated less, and ψ_2 and ψ_1 are depopulated more. This is expected to result in the following structural changes:

(i) The changes in occupation of all three ligand orbitals will cause B(9)—B(10) to lengthen, and such lengthening is clearly apparent in **3** relative to **1** and **2**. B(10)—B(11) is expected to shorten as a consequence of the changes in occupation of ψ_3 and ψ_2, but lengthen due to the change in occupation of ψ_1. Clearly the former is the dominant effect, particularly as ψ_3 is heavily localized on these boron atoms.

(ii) C(7)—B(11) shows the anticipated lengthening as a result of increased deoccupation of both ψ_1 and ψ_2, being essentially unaffected by changes in ψ_3 since the nodal plane of the last passes close to C(7). Equally, the nodal plane of ψ_2 is close to C(8), and thus changes in the C(8)—B(9) distance are expected to reflect changes in the populations of, predominantly, ψ_1 and ψ_3. These are predicted to alter the C(8)—B(9) distance in opposite directions, but ψ_1 is much more carbon based, and thus it is quite reasonable that the change in its population, giving rise to a longer C(8)—B(9) connectivity, apparently dominates.

(iii) The length of C(7)—C(8) is influenced almost exclusively by changes in ψ_1. Increased deoccupation of this ligand orbital explains the longer C—C distance in **3** than in **1**. Less clear, however, is the cause of the apparently long C—C connectivity in **2**.

In summary, this kind of simple analysis goes a long way towards explaining structural patterns in the carb′ complexes carb′H, $Ph_3PAucarb'$ and $Ph_3PCucarb'$, and it is particularly rewarding that trends in the two independent facial B—C distances (which alter in the same direction) and two independent B—B distances (which alter in opposite directions) may be understood.

(*Received* 26 *September* 1990; *accepted* 1 *November* 1990)

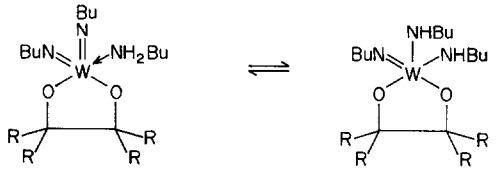
Abstract—Reactions of $[W(NBu^t)_2(NHBu^t)_2]$ (**1**) with ROH (R = Pr^i, Bu^t, CPh_3) gave $[W(NBu^t)(OPr^i)_4]$ (**2**), $[W(NBu^t)(OBu^t)_4]$ (**3**) and $[W(NBu^t)_2(OCPh_3)_2]$ (**4**). Reaction of $WOCl_4$ with $Bu^t(Me_3Si)NH$ gave $[WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)]$ (**5**) which was converted to $[WO(NBu^t)(OBu^t)_2(NH_2Bu^t)]$ (**6**) with trace amounts of $[W(NBu^t)(OBu^t)_3Cl(NH_2Bu^t)]$ (**7**) by reaction with Bu^tOH. Compound **7** was structurally characterized by single crystal X-ray crystallography. It has a distorted octahedral structure with the tertbutylimido (WN = 1.740 Å) and tertbutylamine (WN = 2.429 Å) *trans* to each other, with the three tertbutoxy (WO = 1.897, 1.864, 1.892 Å) and chloride (WCl = 2.503 Å) ligands in the equatorial plane. Compound **5** reacted with PMe_3 to give $[WO(NBu^t)_2(PMe_3)]$ (**8**).

The bis-tertbutylimido-bis-tertbutylamido tungsten(VI) compound $[W(NBu^t)_2(NHBu^t)_2]$ (**1**) was isolated by Nugent and Harlow from the reaction of WCl_6 with excess Bu^tNH_2.[1] Compound **1** was found to react with tertbutyl alcohol or triphenylsilanol to give the derivatives $W(NBu^t)_2(OR)_2$ (R = Bu^t, Ph_3Si).[1] More recently, Chan *et al.*[2] have shown that with pinacols ($HOCR_2CR_2OH$) the nature of the product of the reaction with **1** depends on group R.

$$W(NBu^t)_2(NHBu^t)_2 + HOC(CF_3)_2C(CF_3)_2OH \longrightarrow Bu^tNH_2 \longrightarrow W(NBu^t)_2\{OC(CF_3)_2C(CF_3)_2O\}(Bu^tNH_2) \quad (1)$$

$$W(NBu^t)_2(NHBu^t)_2 + HOC(Ph)_2C(Ph)_2OH \longrightarrow W(NBu^t)(NHBu^t)_2\{OC(Ph)_2C(Ph)_2O\} + 2Bu^tNH_2. \quad (2)$$

Although a single isomer was present in the crystalline state, ^1H and ^{13}C NMR studies showed that in solution a dynamic equilibrium between the isomeric forms, **I** and **II**, occurred (R = Me, CF_3, Ph).



(I) (II)

We now report some results on the reactions of **1** with Pr^iOH and Bu^tOH.

In addition, we have studied the reaction of $WOCl_4$ with $Bu^t(Me_3Si)NH$ as a means of synthesizing oxo-organoimido complexes of tungsten(VI).

RESULTS AND DISCUSSION

Reaction of **1** with four equivalents of Pr^iOH gave $[W(NBu^t)(OPr^i)_4]$ as a volatile (sublimes 50–60°C/10^{-3} torr), colourless, crystalline compound, **2**:

$$W(NBu^t)_2(NHBu^t)_2 + 4Pr^iOH \longrightarrow [W(NBu^t)(OPr^i)_4] + 3Bu^tNH_2. \quad (3)$$

The highest mass peak in the mass spectrum of **2** corresponded to the fragment ion $[W(NBu^t)(OPr^i)_3]^+$

* Authors to whom correspondence should be addressed.

and the ^{1}H NMR spectrum showed the presence of two types of isopropoxide in the ratio of 3 : 1 which suggests that it might be a mononuclear complex with a trigonal bipyramidal configuration with three isopropoxo groups equatorial and one axial. It is noteworthy that the analogous complex $[W_2(NC_6H_4Me\text{-}p)_2(\mu\text{-}OPr^i)_2(OPr^i)_6]$ has been structurally characterized as a dimer by single crystal X-ray diffraction.[3]

Reaction of **1** with four equivalents of tertbutanol gave $[W(NBu^t)(OBu^t)_4]$ (**3**) as a volatile (sublimes 70–80°C/10^{-3} torr), colourless, crystalline compound which was very soluble in hydrocarbon solvents. Its mass spectrum gave a highest mass fragment ion corresponding to $[W(NBu^t)(OBu^t)_3]^+$. The ^{1}H and ^{13}C NMR spectra showed the presence of one type of tertbutoxy ligand suggesting that **3** is monomeric in solution. Steric hindrance of the tertbutoxo groups prevents dimerization. Although a single crystal was grown from CS_2 at −30°C it was not possible to solve the structure fully due to disorder, but the presence of a four-fold axis suggests a tetragonal, pyramidal structure with the tertbutoxo groups at the base. The presence of the tertbutyl imido group in the apical position probably caused the problems in solving the structure due to its three-fold symmetry.

In contrast to $W(NBu^t)(OPr^i)_4$ which readily reacts with more Pr^iOH to form $W(OPr^i)_6$, compound **3** did not react further with excess Bu^tOH. Interestingly, it was not possible to isolate an intermediate complex, $[W(NBu^t)(NHBu^t)(OBu^t)_3]$, by the reaction of **1** with three equivalents of Bu^tOH; instead an equimolecular mixture of $W(NBu^t)_2(OBu^t)_2$ and $W(NBu^t)(OBu^t)_4$ was obtained suggesting that $W(NBu^t)(NHBu^t)(OBu^t)_3$ reacts faster with Bu^tOH than does $W(NBu^t)_2(OBu^t)_2$.

Reaction of **1** with two equivalents of triphenylcarbinol gave $[W(NBu^t)_2(OCPh_3)_2]$ (**4**) as a colourless solid.

We have explored the synthesis of tungsten oxo tertbutylimido complexes by using $WOCl_4$ as starting material. When either Bu^tNH_2 or Bu^tLiNH were used an intractable mixture of products was obtained but from the reaction of $WOCl_4$ and $Bu^t(Me_3Si)NH$ we obtained $[WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)]$ (**5**) as a pale yellow solid which was characterized by ^{1}H and ^{13}C NMR and IR spectra:

$$WOCl_4 + 3Bu^t(Me_3Si)NH \longrightarrow [WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)] + 3Me_3SiCl. \quad (4)$$

The IR spectrum of **5** gave a strong band at 970 cm^{-1} due to the terminal W=O stretching vibration and bands at 3250, 3190 and 3130 cm^{-1} due to NH_2 and NH stretching vibrations. Broad peaks in the ^{1}H NMR (C_6D_6 solution at δ 7.56 and 11.57) were assigned to NH_2 and NH protons, respectively. Although a parent molecular ion was not observed in the mass spectrum a fragment ion was observed (*m/z*, 395) corresponding to the species $(\mathbf{5}-C_4H_8)^+$. Unfortunately we were unable to grow a single crystal for X-ray crystallographic studies and the structure of **5** is a matter for conjecture.

If the oxo- and tertbutylimido ligands in **5** are both acting as four-electron donors then the tungsten(VI) attains an 18-electron configuration as a mononuclear five-coordinated complex. A trigonal pyramidal structure seems likely with the tertbutylimido and tertbutylamine ligands *trans* to one another in the axial positions and the chloro, tertbutylamido and oxo ligands in the equatorial plane. By placing the four-electron donors *cis* to one another they are able to maximize their π-bonding involving the vacant metal *d*-orbitals. A plausible alternative would place the oxo and chloro ligands *trans* to each other in the axial positions and the three bulky tertbutyl-containing ligands in the equatorial plane.

Also a matter for conjecture is the origin of the tertbutylamine which could be formed either by an intramolecular α-hydrogen transfer in an intermediate: $WO(NHBu^t)_3Cl \rightarrow [WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)]$; or by reaction of $Bu^t(Me_3Si)NH$ with HCl to give Me_3SiCl and Bu^tNH_2. Previous work[4] has shown that Bu^tNH_2 is formed in the reactions of $[W(NR)Cl_4]_2$ (R = Ph, C_6H_4Me-*p*) with $Bu^t(Me_3Si)NH$ which gave the dimeric complexes $[W(NR)(NBu^t)Cl_2(NH_2Bu^t)]_2$, which were structurally characterized by X-ray diffraction.

Compound **5** is interesting in containing tertbutylimido, tertbutylamido and tertbutylamine ligands bonded to tungsten, and may be compared with the vanadium[5] and tantalum[6] complexes, $[M(NBu^t)(NHBu^t)Cl_2(NH_2Bu^t)]_2$ (M = V, Ta).

Compound **5** was treated with one equivalent of Bu^tOH in an attempt to replace the tertbutylamido group by the tertbutoxo, but $[WO(NBu^t)(OBu^t)_2(NH_2Bu^t)]$ (**6**) was obtained in small yield instead of $[WO(NBu^t)(OBu^t)Cl(NH_2Bu^t)]$. Also, treatment of **5** with one equivalent of Bu^tLiO gave a small yield of **6** instead of the expected $[WO(NBu^t)(NHBu^t)(OBu^t)(NH_2Bu^t)]$. The best yield of **6** was obtained by treating **5** with two equivalents of Bu^tOH in the presence of tertbutylamine:

$$[WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)] + 2Bu^tOH \longrightarrow [WO(NBu^t)(OBu^t)_2(NH_2Bu^t)] + Bu^tNH_3Cl. \quad (5)$$

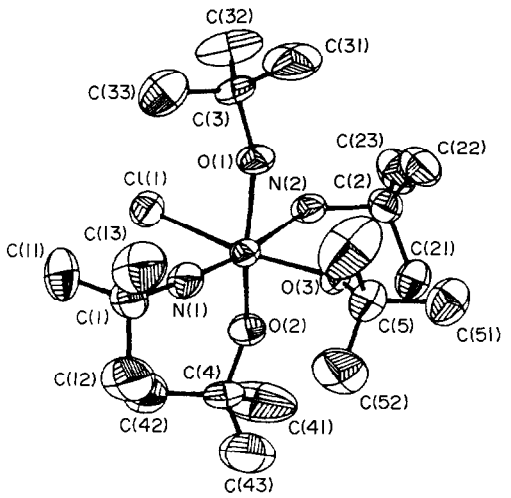


Fig. 1. ORTEP plot of $[W(NBu^t)(OBu^t)_3Cl(NH_2Bu^t)]$ (**7**): organoimido nitrogen, N(1); amine nitrogen, N(2).

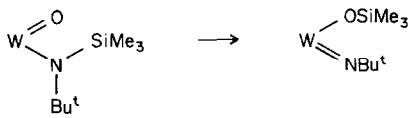
Compound **6** was crystallized from pentane at −30°C as colourless crystals and its high volatility (sublimes 45–66°C/10^{-3} torr) suggests a mononuclear complex with five-coordinated tungsten(VI). Attempts to grow single crystals from solution or by sublimation suitable for X-ray diffraction were unsuccessful. The IR spectrum showed two sharp N—H stretching vibrations (3326, 3317 cm^{-1}) and a terminal W=O stretching vibration (970 cm^{-1}). In the course of recrystallizing **6**, a single crystal was obtained which was shown by X-ray crystallography to be the complex $[W(NBu^t)(OBu^t)_3Cl(NH_2Bu^t)]$ (**7**) which contains no oxo ligand. The structure of **7** is depicted in Fig. 1 and some bond lengths and bond angles are given in Table 1. The octahedral tungsten(VI) atom has the tertbutylimido group (W ≡ N = 1.74 Å) *trans* to the tertbutylamine (W ← N = 2.429 Å), and the three tertbutoxo (W—O = 1.897, 1.892, 1.864 Å) and chloro ligands in the equatorial plane. This structure is entirely analogous to that of $[W(NPh)(OBu^t)_3Cl(NH_2Bu^t)]$ obtained from the reaction of $[W(NPh)Cl_4]_2$ with Bu^tOH and Bu^tNH_2.[7] The formation of **7** apparently as a minor product of the reaction of $[WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)]$ with Bu^tOH is puzzling especially as the reaction of either compound **5** or **6** with excess Bu^tOH gave the tungsten oxo tetratertbutoxide $WO(OBu^t)_4$ without loss of the oxo ligand. Loss of the oxo ligand might have occurred in the genesis of compound **5** from the reaction of $WOCl_4$ with $Bu^t(Me_3Si)NH$ due to attack of the Si—N bond by the W=O oxygen, viz.



(6)

Exchange of the trimethylsiloxo ligand by tertbutanol would complete the removal of the oxo ligand.

Finally, we report one other interesting reaction of compound **5**. In an attempt to replace the coordinated Bu^tNH_2 by another Lewis base, **5** was treated with PMe_3. The tungsten product isolated was $[WO(NBu^t)_2(PMe_3)]$ (**8**) after separation from tertbutylamine hydrochloride [eq. (7)]:

$$[WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)] + PMe_3 \longrightarrow Bu^tNH_3Cl + [WO(NBu^t)_2(PMe_3)]. \quad (7)$$

Compound **8** was characterized by ^1H NMR [80 MHz, C_6D_6; δ, 1.21 (PMe_3); 1.23 (NBu^t)] and IR [ν(W=O), 970 cm^{-1}; absence of NH_2 or NH stretching vibrations] spectroscopy. The PMe_3 protons gave a doublet ($^2J_{HP}$ = 10 Hz) with ^{183}W satellites ($^3J_{HW}$ = 2 Hz). Although no molecular ion was detected in the mass spectrum a number of fragment ions were observed.

EXPERIMENTAL

Preparations and manipulations were carried out under dry, oxygen-free nitrogen using standard Schlenk tube techniques. Solvents were distilled from the sodium ketyl of benzophenone and stored over molecular sieve (4 Å). $WOCl_4$ was prepared from WO_3 and $SOCl_2$ and sublimed[8] and $[W(NBu^t)_2(NHBu^t)_2]$ (**1**) was prepared from WCl_6 and Bu^tNH_2 by the literature method.[1] NMR spectra were obtained using Bruker WP-80 or WM-250 instruments and IR spectra using a Perkin–Elmer 577 spectrophotometer between 4000 and 200 cm^{-1} using Nujol mulls between CsI plates. Mass spectra were obtained by direct insertion using an AEI MS-902 spectrometer operating at 70 eV. Elemental analyses were obtained from the Microanalytical Laboratory, University College, London.

Preparation of $[W(NBu^t)_2(OCPh_3)_2]$ (**4**)

A solution of Ph_3COH (1.27 g, 4.9 mmol) in THF (30 cm^3) was added to a solution of $W(NBu^t)_2(NHBu^t)_2$ (1.15 g, 2.45 mmol) in benzene (30 cm^3) and the mixture stirred for 18 h. Solvents were evaporated off *in vacuo* and the residue crystallized from toluene–heptane (1 : 3) giving colourless needles (0.82 g) which were supplemented by another crop (0.56 g) obtained by concentrating the mother liquor, adding more heptane and cooling to −25°C. The combined batches were washed with pentane and dried *in vacuo* (1.38 g, 71% yield). Found: C, 66.2; H, 5.8; N, 3.1. $C_{38}H_{48}O_2N_2W$ requires: C, 65.5; H, 5.7; N, 3.3%. ^{1}H NMR (80 MHz, C_6D_6): δ, 1.18 (18H, s, =NBu^t), 7.05–7.60 (30H, m, aromatic CHs). ^{13}C NMR (20.1 MHz, $CDCl_3$): δ, 32.85 [NC(CH_3)$_3$], 66.19 [NC(CH$_3$)$_3$] 90.91 (OCPh$_3$), 126.99 (OCPh$_3$, *para*-C), 127.59, 128.56 (OCPh$_3$, *ortho*- and *meta*-C), 147.81 (OCPh$_3$, *ipso*-C). IR spectrum: 1595m, 1490m, 1445s, 1355m, 1295m, 1238s, 1215m, 1152m, 1086m, 1048s, 998s, 942m, 920m, 900m, 845w, 818s, 798s, 764s, 755m, 735m, 698s, 670w, 625m cm^{-1}.

Preparation of $[W(NBu^t)(OBu^t)_4]$ (**3**)

Bu^tOH (3.06 cm^3, 32.4 mmol) was added dropwise to a solution of $W(NBu^t)_2(NHBu^t)_2$ (3.82 g, 8.1 mmol) in pentane (20 cm^3) and the mixture stirred for 18 h followed by removal of solvent *in vacuo*. The colourless viscous residue was heated at 40–50°C/10^{-3} torr to remove the small amount of $W(NBu^t)_2(OBu^t)_2$ present, followed by sublimation at 70–80°C/10^{-3} torr. The sublimate was contaminated with a trace of $W(NBu^t)_2(OBu^t)_2$ which was removed by crystallization from pentane at −78°C (1.55 g, 34% yield). The low yield was caused by the very high solubility of **3** in pentane. Found: C, 41.9; H, 7.9; N, 2.6. $C_{20}H_{45}O_4NW$ requires: C, 43.9; H, 8.2; N, 2.6%. ^{1}H NMR (80 MHz, C_6D_6): δ, 1.34 (9H, s, NBu^t), 1.52 (36H, s, OBu^t). ^{13}C NMR (20.1 MHz, C_6D_6): δ, 32.17 (OBu^t, CH_3), 32.83 (NBu^t, CH_3), 69.12 (NBu^t, CMe$_3$), 80.48 (OBu^t, CMe$_3$). IR spectrum: 1469m, 1382m, 1360s, 1280m, 1235m, 1175vs, 1025w, 955vs, 782s, 550m, 520w, 480m, 368m, 282w cm^{-1}. Mass spectrum (m/z): 472 [W(NBu^t)(OBu^t)$_3$], 416 [W(NBu^t)$_2$(OH)], 360 [W(OBu^t)$_2$O$_2$], 304 [W(OBu^t)(OH)O$_2$], 288 [W(OBu^t)(OH)O], 248 [W(OH)$_2$O$_2$], 59 (C_3H_7O), 58 (C_3H_6O), 57 (C_4H_9).

Preparation of $[W(NBu^t)(OPr^i)_4]$ (**2**)

Compound **2** was obtained by adding Pr^iOH (4 mol) to $W(NBu^t)_2(NHBu^t)_2$ (1 mol) in a similar manner to the previous experiment and was obtained as colourless crystals (50% yield) after sublimation at 50–60°C/10^{-3} torr. ^{1}H NMR (250 MHz, C_6D_6): δ, 1.31 (9H, s, NBu^t), 1.36 [18H, d (^3J = 6 Hz), OCH(CH_3)$_2$], 1.52 [6H, d (^3J = 6.2 Hz), OCH (CH_3)$_2$], 4.95 [3H, sept. (^3J = 6.0 Hz), OCHMe$_2$], 5.14 [1H, sept. (^3J = 6.2 Hz), OCHMe$_2$]. IR spectrum: 1370s, 1355s, 1319s, 1275vs, 1212m, 1160s, 1110s, 970vs, 842vs, 805w, 770m, 665s, 605s, 578s, 528s, 448s, 422m, 375w, 340m, 300 cm^{-1}. Mass spectrum (m/z): 430 [W(NBu^t)(OPr^i)$_3$], 388 [W(NBu^t)(OPr^i)$_2$(OH)], 371 [W(NBu^t)(OPr^i)$_2$], 346 [W(NBu^t)(OPr^i)(OH)$_2$], 304 [W(NBu^t)(OH)$_3$], 248 [W(NH)(OH)$_3$], 59 (C_3H_7O), 58 (C_3H_6O), 57 (C_4H_9), 56 (C_4H_8).

Preparation of $[WO(NBu^t)(NHBu^t)Cl(NH_2Bu^t)]$ (**5**)

$Bu^t(Me_3Si)NH$ (2.43 cm^3, 12.5 mmol) was added dropwise to a suspension of $WOCl_4$ (1.95 g, 5.70 mmol) in benzene (50 cm^3) and the mixture, which quickly changed colour from dark red to pale orange, was stirred for 48 h. The pale yellow solution was filtered and the filtrate evaporated *in vacuo* leaving a pale yellow gum which was treated with pentane (3 × 30 cm^3) until a pale yellow powder (1.57 g, 61% yield) was obtained. Satisfactory elemental analyses were not obtained. ^{1}H NMR (80 MHz, C_6D_6): δ, 1.35 (9H, s, NH$_2$Bu^t), 1.44 (9H, s, NHBu^t), 1.56 (9H, s, =NBu^t), 7.56 (2H, broad s, $\Delta\omega_{1/2}$ = 20 Hz, NH_2Bu^t), 11.57 (1H, broad s, $\Delta\omega_{1/2}$ = 8 Hz, NHBu^t). ^{13}C NMR (20.1 MHz, C_6D_6): δ, 26.68 [NH$_2$C(CH_3)$_3$], 28.62 [NHC (CH_3)$_3$], 30.93 [=NC(CH_3)$_3$], 52.92 (NH$_2$$CMe_3$), 60.99 (NH$CMe_3$), 70.99 (=N$CMe_3$). IR spectrum. 3250m, 3190sh, 3130s, 1605m, 1582w, 1481s,

1402m, 1362s, 1345m, 1292m, 1255vs, 1215s, 1195s, 970m, 845m, 802m, 792m, 708m, 580w, 450w, 325s cm^{-1}. Mass spectrum (*m/z*): 395 (**5**−C_4H_8), 380 (**5**−C_4H_8−CH_3), 324 (**5**−$2C_4H_8$−CH_3), 58 (C_4H_{10}), 57 (C_4H_9).

Preparation of [$WO(NBu^t)(OBu^t)_2(NH_2Bu^t)$] (**6**)

Compound **5** (1.15 g, 2.55 mmol) was suspended in pentane (50 cm^3) and Bu^tOH (0.75 cm^3, 7.65 mmol) was added. The tungsten starting material dissolved and a white solid (identified as Bu^tNH_3Cl) was precipitated over a period of 8 h. After filtration, the filtrate was concentrated to *ca* 4 cm^3 and cooled to −78°C giving colourless crystals (0.42 g, 33% yield). The low yield resulted from the high solubility of **6** in pentane. The compound was sublimed at 45–60°C/10^{-3} torr with loss due to decomposition. Found: C, 39.7; H, 7.8; N, 4.7. $C_{16}H_{38}O_3N_2W$ requires: C, 39.2; H, 7.8; N, 4.9%. ^1H NMR (80 MHz, C_6D_6): δ, 1.14 (9H, s, NH_2Bu^t), 1.42 (18H, s, OBu^t), 1.56 (9H, s, NBu^t), 3.11 (2 H, broad s, $\Delta\omega_{1/2}$ = 10 Hz, NH_2Bu^t). ^{13}C NMR (20.1 MHz, C_6D_6): δ, 31.21 [$NH_2C(CH_3)_3$], 31.46 [large broad peak, overlapping $NC(CH_3)_3$ and $OC(CH_3)_3$], 52.34 (NH_2CMe_3), 71.74 ($NCMe_3$), 84.83 ($OCMe_3$). IR spectrum: 3326m, 3167m, 1560m, 1382vs, 1374sh, 1361vs, 1260vs, 1250vs, 1235, 1150vs, 1118s, 1019s, 970vs, 931vs, 911vs, 845w, 805m, 790s, 748m, 708m, 632m, 600m, 568s, 482sh, 469m, 452sh, 376m, 367m, 282vs, 255sh cm^{-1}. Mass spectrum (*m/z*): 400 (**6**−CH_3−Bu^tNH_2), 344 (**6**−Bu^tNH_2−Bu^tN), 342 (**6**−Bu^tNH_2−Bu^tO), 327 (**6**−Bu^tNH_2−Bu^tO−CH_3), 269 (**6**−$2Bu^tO$−Bu^tNH_2), 59 (C_3H_7O), 58 (C_4H_{10}), 57 (C_4H_9).

Preparation of [$WO(NBu^t)_2(PMe_3)$] (**8**)

Compound **6** (0.35 g, 0.78 mmol), dissolved in benzene (10 cm^3), was treated with PMe_3 (0.07 cm^3, 0.78 mmol) which caused a colour change from pale yellow to orange. The mixture was stirred for 18 h and the solvent evaporated off *in vacuo* and the off-white solid washed with pentane (10 cm^3). The residue contained some Bu^tNH_3Cl (IR spectrum) which was removed by dissolving the product in benzene and filtering. Evaporation of the filtrate *in vacuo* left the solid product (0.17 g, 53% yield). ^1H NMR (80 MHz, C_6D_6): δ, 1.21 [9H, *d* ($^2J_{HP}$ = 10 Hz), PMe_3], 1.23 (18H, s, NBu^t). IR spectrum: 1420m, 1376m, 1358s, 1289m, 1276s, 1261m, 1238s, 1210s, 1140m, 970s, 955sh, 805m, 760w, 750m, 680w, 583m, 499w, 320s, 282m cm^{-1}. Mass spectrum (*m/z*): 284 (**8**−C_4H_8−PMe_3), 283 (**8**−C_4H_9−PMe_3), 269 (**8**−C_4H_8−PMe_3−CH_3), 268 (**8**−C_4H_9−PMe_3−CH_3), 267 (**8**−C_4H_9−$OPMe_3$), 76 (PMe_3), 61 (PMe_2), 57 (C_4H_9).

X-ray crystallography

Structure determination of compound **7**. All X-ray measurements were made on a crystal of dimensions 0.45 × 0.40 × 0.25 mm^3 sealed under argon in a thin-walled glass capillary. Following preliminary X-ray photography, unit cell dimensions and intensities were obtained using standard procedures and a CAD4 diffractometer, operating in the ω–2θ scan mode with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å). The intensity data were corrected for absorption using psi-scan profiles. The structure was solved via the heavy atom method and refined by full-matrix least-squares. Non-hydrogen atoms were assigned anisotropic displacement factor coefficients, hydrogen atoms were included in idealized positions and refined as components of rigid groups with group N_{iso} values. Experimental details are as follows. Crystal data: $C_{20}H_{47}ClN_2O_3W$, *Mr* = 582.95, monoclinic, *a* = 17.714(2), *b* = 10.647(4), *c* = 15.328(3) Å, β = 108.13(1)°, *V* = 2747.2 $Å^3$, space group $P2_1/a$, *Z* = 4, D_c = 1.41 g cm^{-3}, μ = 44.1 cm^{-1}.

Data collection: $1.5 \leqslant \theta \leqslant 25.0°$, *T* = 265 K, total data measured 5271, total unique 4821, observed [$F_o > 3\sigma(F_o)$] 3581.

Refinement: 432 parameters, weights = $[\sigma^2(F_o)+0.0001F_o^2]^{-1}$, *R* = 0.038, R_ω = 0.034.

Scattering factor data were as included in the SHELX program or obtained from ref. 9, and calculations were made on a VAX11/750 using SHELX80[10] and associated programs.

Acknowledgements—We thank the SERC for financial support (research studentships to A.J.H. and J.D.R.). We are grateful to Mr Greg Coumbarides for obtaining the 250 MHz NMR spectra and to Mr Peter Cook for obtaining the mass spectra.

Abstract—1,1′-Diacetylferrocene reacts with neat hydrate over a period of 72 h at 20°C to give the dihydrazone $[H_2NN(Me)CC_5H_4FeC_5H_4C(Me)NNH_2]$ (**6**) in almost quantitative yield. Either prolonging the reaction time or reacting **6** with fresh hydrazine causes the iron to be stripped from the metallocene and bis(hydrazine)bis(hydrazinecarboxylato-N′,O) iron(II), $[Fe(N_2H_4)_2(OOCNHNH_2)_2]$ (**11**), crystallizes. In the presence of Ba^{2+} or Mo^{2+} ions two molecules of complex **6** react to give the cyclic diazine $[—N(Me)CC_5H_4FeC_5H_4C(Me)N—]_2$ (**7**) in high yield. Hydrazine is liberated in this reaction. Complexes **6** and **11** have been characterized crystallographically. The cyclic voltammograms of complexes **6** and **7** contain essentially non-reversible oxidation peaks.

In 1973 Gol'din *et al.*[1] found that formyl- and acetylferrocene reacted with hydrazine to give the azines **1** and **2**, respectively (Scheme 1). The same paper described the synthesis of the hydrazones **3** and **4** from formylferrocene and the respective disubstituted hydrazine. Furthermore, the authors found that a warm ethanolic solution of 1,1′-diacetylferrocene (0.02 mol) reacted with hydrazine (0.05 mol) to give the monohydrazone of the azine **5** in 26% yield (Scheme 2).[1]

We have discovered that when 1,1′-diacetylferrocene is stirred with a large excess of neat hydrazine hydrate at room temperature for *ca* 72 h (see later) the dihydrazone **6** precipitates in almost quantitative yield (Scheme 2). Similar double Schiff-base condensation reactions are known to occur when 1,1′-diacetylferrocene is treated with solutions of thiocarbonhydrazide, semicarbazide, benzoic acid hydrazide and *p*-nitrobenzoic acid hydrazide.[2]

Complex **6** reacts with an alcoholic solution of $Ba(ClO_4)_2$ {or $[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_6][BF_4]_2$}[3] to give the cyclic diazine **7** in high yield (Scheme 2). The X-ray crystal structure of complex **7** (Fig. 1 and Table 1) contains staggered ferrocene rings and therefore a slightly twisted macrocycle, in keeping with the chirality found in the solid state (space group is the non-centrosymmetric $P2_1$). The nitrogen lone pairs are directed away from the centre of the macrocycle.

The cyclization reaction leading to the formation of complex **7** possibly proceeds via the metal-ion-catalysed transamination (amine exchange) route outlined in Scheme 3. Coordination of the NH_2 groups to the Ba^{2+} ion as in species **8** makes the C=N groups more susceptible to intermolecular

nucleophilic attack by **6**, thus leading to the formation of the *gem*-diamine addition compound **9**. Elimination of one molecule of hydrazine would then give the azinedihydrazone **10**. Ring closure is effected by intramolecular nucleophilic attack on the second imine, followed by the elimination of a second hydrazine molecule. The liberated N_2H_4 was detected by adding one drop of Nessler's reagent[4] to the reaction filtrate after the removal of complex **7** (immediate formation of a black precipitate).

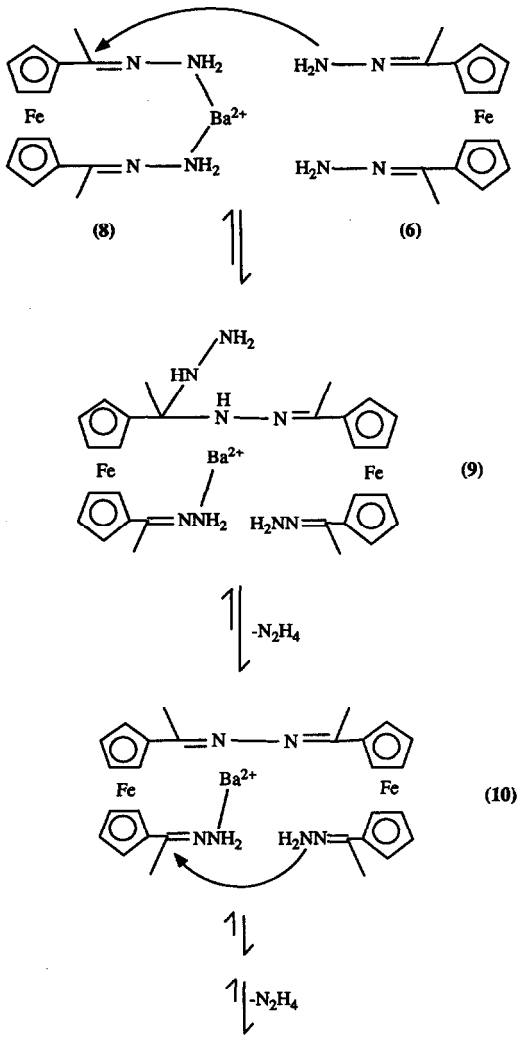

Scheme 3.

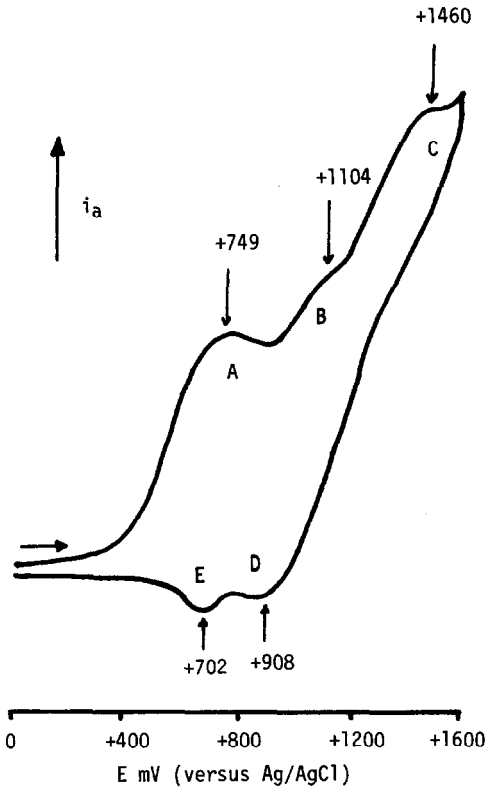

Fig. 2. Cyclic voltammogram of complex **6**. (Scan rate = 50 mV s^{-1}.)

Similar transamination reactions leading to the formation of macrocyclic Schiff-base complexes have been reported by Nelson *et al.*[5] Attempts to reduce the four imine (C=N) functions of **7** with $Na[BH_4]$ and $Li[AlH_4]$ failed, and only the unreacted diazine was recovered.

The cyclic voltammogram of complex **6** (Fig. 2) shows an irreversible oxidation peak (A) and two further quasi-reversible oxidations (BE and CD) in the region 500–1600 mV (vs Ag/AgCl). This behaviour differs markedly to that reported for other 1,1′-disubstituted ferrocenes, which are generally found to exhibit only a single, reversible, one-electron oxidation wave.[6]

The voltammogram of the diazine **7** (Fig. 3) has two irreversible oxidation peaks at 781 (F) and 1032 mV (G), and a strong reduction peak (H) at 268 mV. The electrochemical behaviour of complex **7** is very different to that reported for the closely related mono-azine **2** (Scheme 1) which showed only two, one-electron oxidations at 604 and 1002 mV (vs SCE) corresponding to the formation of $[Fe^{II}Fe^{III}]^+$ and $[Fe^{III}Fe^{III}]^{2+}$ species, respectively.[7] In addition, the large separation between the two oxidation potentials for complex **2** (ΔE = 398 mV) inferred that there was some degree of electronic interaction between the two halves of the mixed-valence complex. This difference in the redox behaviour of complexes **2** and **7** may be attributed to the presence in the molecules of one and two bridging ligands, respectively. Studies on various biferrocene complexes have, indeed, shown that both the nature and the number of bridging ligands in the molecule have a dramatic effect on its redox properties.[8,9]

When the orange dihydrazone **6** is stirred in fresh hydrazine hydrate at 40°C for *ca* 1 week the solid slowly dissolves and the solution gradually changes from orange to a pale straw colour. On cooling the solution to 4°C pale green (almost colourless) crystals of bis(hydrazine)bis(hydrazinecarboxylato-N′,O)iron(II), $[Fe(N_2H_4)_2(OOCNHNH_2)_2]$ (**11**), form in high yield (Scheme 4). Furthermore, during

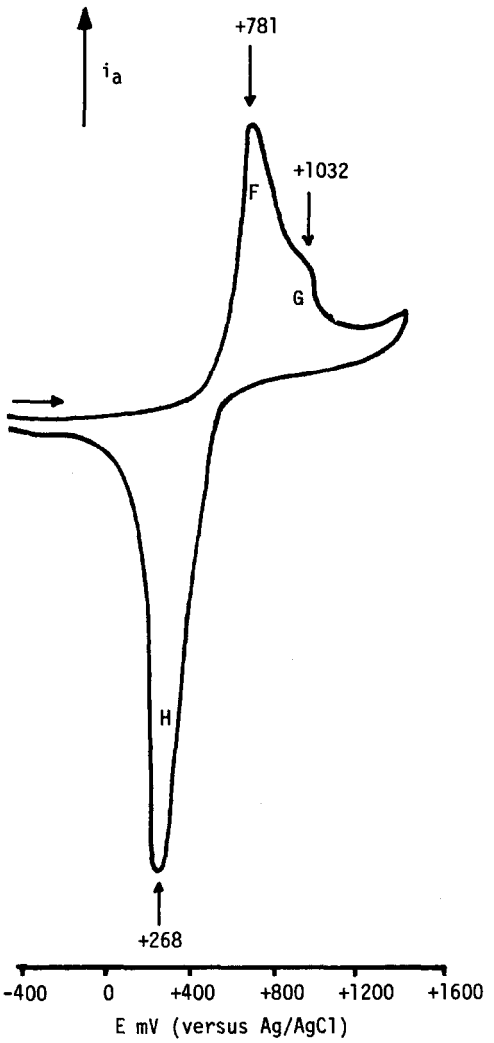

Fig. 3. Cyclic voltammogram of complex **7**. (Scan rate = 50 mV s^{-1}.)

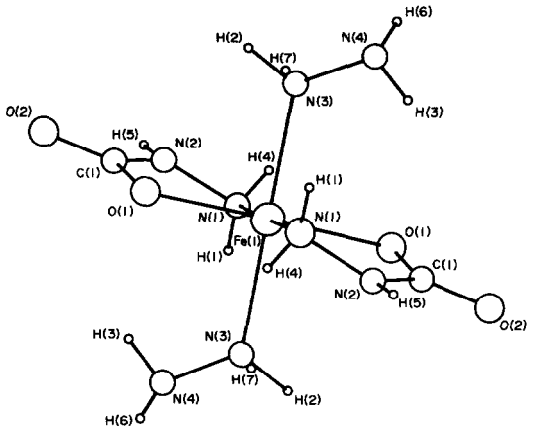

Fig. 4. Structure of complex **11**.

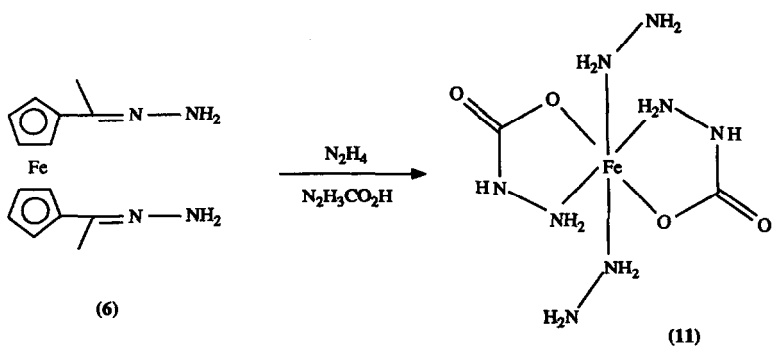
the preparation of complex **6** care must be taken not to greatly exceed the 72 h reaction period. When the reaction time is prolonged, complex **6** slowly redissolves and **11** gradually precipitates. The formation of complex **11** involves the abstraction of the Fe^{2+} ion from the metallocene **6** and its subsequent complexation with hydrazine and the hydrazinecarboxylate anion.* The conventional methods used for the preparation of complex **11** are the reactions of aqueous Fe^{2+} solutions with (i) hydrazinium hydrazinecarboxylate[11] and, (ii) a 5% solution of hydrazinecarboxylic acid in hydrazine hydrate.[12,13]

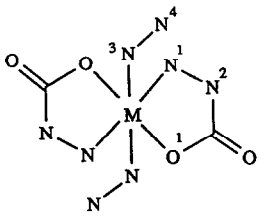
The availability of high quality crystals together with the interest in the coordination properties of the hydrazinecarboxylato ligand (which has a similar structure to the glycinato ligand[14]) prompted us to investigate the X-ray crystal structure of complex **11**. The structure of the complex is shown in Fig. 4 (see Table 2), and it is seen to be isostructural with the previously characterized zinc(II)[15] and cobalt (II)[16] complexes. The iron atom lies on a centre of symmetry; it is six-coordinate, being surrounded by two monodentate hydrazines and two bidentate

*$N_2H_4 \cdot H_2O$ absorbs atmospheric CO_2 to form hydrazinecarboxylic acid ($N_2H_3CO_2H$) metathetically,[10] and this reacts further with hydrazine to give $N_2H_5^+$ $N_2H_3CO_2^-$.



Scheme 4.

Table 3. Main interatomic bond distances (Å) for structurally characterized $[M(N_2H_4)_2(OOCNHNH_2)_2]$ complexes (M = Fe, Co,[16] Zn[15])



Metal	M—O^1	M—N^1	M—N^3	N^1—N^2	N^3—N^4
Fe	2.069	2.241	2.224	1.408	1.453
Co	2.064	2.198	2.178	1.425	1.454
Zn	2.05	2.25	2.17	1.39	1.46

hydrazinecarboxylato(N′,O) ligands. Table 3 shows that the main interatomic distances in the iron, cobalt and zinc complexes are very similar.

EXPERIMENTAL

All chemicals were reagent grade and were used without further purification. $[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_6][BF_4]_2$ was prepared using the literature method.[3] Elemental analyses were performed by the Microanalytical Laboratory, University College Cork, Ireland. ^{1}H NMR spectra were run on a Bruker AC 80 spectrometer, and mass spectra were obtained using an AEI MS30 instrument equipped with a MSS Data System. IR spectra (KBr disc) were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 783 grating spectrometer, and UV–vis spectra were run on a Milton Roy Spectronic 3000 Array. Cyclic voltammograms (*ca* 20°C and under N_2) were recorded using an EG&G Model 264A polarographic analyser in combination with an EG&G PARC Model 303 electrode assembly. A glassy carbon disc and a platinum wire were used as the working counter electrodes, respectively. Potentials (mV) were recorded with respect to a silver–silver chloride reference electrode (*i*Ru compensation not used). Tetrabutylammonium perchlorate in dry THF (0.2 M) was used as the supporting electrolyte/solvent system.

$[H_2NN(Me)CC_5H_4FeC_5H_4C(Me)NNH_2]$ (**6**)

A red suspension of 1,1′-diacetylferrocene (1.0 g, 3.7 mmol) in hydrazine hydrate (20 cm^3) was stirred for *ca* 72 h at 20°C under N_2. The orange product which formed was removed by filtration, washed with ice-cold ethanol and then dried *in vacuo*. Yield: 1.04 g (94%). Found: C, 56.4; H, 6.1; N, 18.2. Calc: C, 56.4; H, 6.1; N, 18.8%; m.p. 182–185°C; MS: *m/z* 298 (M^+); IR: 3340, 3205 (—NH_2), 1590 cm^{-1} (—C=N); UV–vis (EtOH): $\lambda_{max.}$ 452 nm, $\varepsilon_{max.}$ 574 dm^3 mol^{-1} cm^{-1}; ^{1}H NMR (ppm):* 1.20 (s, 6H, CH_3), 4.27 (t, 4H, Fc ring), 4.54 (t, 4H, Fc ring), 5.10 (br-s, 4H, NH_2).

$[—N(Me)CC_5H_4FeC_5H_4C(Me)N—]_2$ (**7**)

Method (a). **6** (0.40 g, 1.34 mmol) and anhydrous barium perchlorate (0.45 g, 1.34 mmol) were refluxed together in ethanol (50 cm^3) for 15 h. When the red–orange solution was reduced to *ca* 5 cm^3 the red product precipitated. The solid was washed with ice-cold ethanol and then dried *in vacuo*. The product was recrystallized from chloroform. Yield: 0.31 g (87%).

Method (b). Complex **7** was also prepared by reacting a methanolic solution of $[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_6][BF_4]_2$ with **6** in a 1:3 molar ratio at 20°C under N_2. Found: C, 63.5; H, 5.2; N, 10.95. Calc.: C, 63.2; H, 5.3; N, 10.5%; m.p. 250°C (dec); MS: *m/z* 532 (M^+); IR: 1597 cm^{-1} (—C=N); UV–vis ($CHCl_3$): $\lambda_{max.}$ 475 nm, $\varepsilon_{max.}$ 2252 dm^3 mol^{-1} cm^{-1}; ^{1}H NMR (ppm):* 2.51 (s, 12H, CH_3), 4.25 (sx, 4H, Fc ring), 4.57 (sx, 4H, Fc ring), 4.73 (q, 4H, Fc ring), 5.13 (q, 4H, Fc ring).

$[Fe(N_2H_4)_2(OOCNHNH_2)_2]$ (**11**)

A mixture comprising complex **6** (0.20 g, 0.67 mmol) and hydrazine hydrate (10 cm^3) was shaken at 40°C under N_2 for 1 week. The solution gradually changed from red to a pale straw colour. On standing for 2 weeks at 4°C the product formed as light green (almost colourless) crystals. After centrifugation the solid was washed with several portions of cold ethanol and then dried *in vacuo*. Yield: 0.14 g (77%). The solid is somewhat air-sensitive and the crystals take on a light brown coloration after a few days. Found: C, 9.0; H, 5.3; N, 40.7. Calc: C, 8.9; H, 5.2; N, 41.5%; IR:[11,17] 3260, 3160 (—NH_2), 1470 (sym. —OCO), 990 (—N—N of $N_2H_3CO_2$), 950 (—N—N of N_2H_4), 418 cm^{-1} (—Fe—N).

* br = broad, s = singlet, t = triplet (dd), q = quintet (ddd), sx = sextet (ddd), dd = doublet of doublets, ddd = doublet of doublets of doublets.

Crystallography

For complex **7** a red, needle-shaped crystal of approximate size $0.5 \times 0.5 \times 0.1$ mm^3 was used, and for complex **11** a colourless, rhombic crystal of approximate size $0.1 \times 0.1 \times 0.3$ mm^3 was used. X-ray reflections were measured using an Enraf–Nonius CAD4 diffractometer, and the intensities of the reflections in the range $1 < \theta < 20°$ were measured using Mo-K_α radiation with a graphite monochromator. For complex **7** the data were corrected for decay and absorption, and reduced to give 2215 reflections (merging $R = 1.3\%$) of which 2052 had $|F_{obs}| > 4\sigma(F_{obs})$ and were used in structure solution and refinement. For complex **11** the data were corrected for decay and absorption, and reduced to give 660 reflections (merging $R = 1.4\%$) of which 637 had $|F_{obs}| > 4\sigma(F_{obs})$ and were used in structure solution and refinement. The structures were solved by the direct method (SHELXS) and refined by full-matrix least-squares to a conventional R-factor of 6.2% for **7** (2.97% for **11**). Unit weights were used with hydrogen atoms in calculated positions. Heavy atoms were given anisotropic temperature factors. The programs SHELXS and SHELX-76 were used by kind permission of Professor G. F. Sheldrick (University of Gottingen). The data have been deposited with the Cambridge Crystallographic Data Centre. Crystal data for complex **7**: $C_{28}H_{28}Fe_2N_4$, $M_r = 532.250$, monoclinic, space group $P2_1$, $a = 9.747(1)$, $b = 10.219(1)$, $c = 12.228(2)$ Å; $\beta = 102.95(1)$, $U = 1186.93$ Å^3. $D_c = 1.49$ g cm^{-3}, $Z = 2$; $F(000) = 551.96$, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 11.78 cm^{-1}. Crystal data for complex **11**: $C_2H_{14}FeN_8O_4$, $M_r = 270.032$, monoclinic, space group $P2_1/n$, $a = 8.144(5)$, $b = 7.378(2)$, $c = 8.651(5)$ Å; $\beta = 110.51(3)$, $U = 486.86(42)$ Å^3. $D_c = 1.842$ g cm^{-3}, $Z = 2$; $F(000) = 280$, $\lambda = 0.71069$ Å, μ(Mo-K_α) = 14.90 cm^{-1}.

Acknowledgements—We wish to thank Dr D. G. Gilheany for assistance with NMR interpretations, and also EOLAS for a postgraduate grant (to P.G.).

THE FIRST STRUCTURALLY CHARACTERIZED DIRUTHENIUM(II,III) COMPLEX WITH FOUR BRIDGING ARYLCARBOXYLATO LIGANDS

BIRINCHI K. DAS and AKHIL R. CHAKRAVARTY*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 4 *July* 1990; *accepted* 2 *November* 1990)

Abstract—The diruthenium(II,III) compound $[Ru_2Cl(O_2CC_6H_4\text{-}p\text{-}OMe)_4](H_2O)_{0.25}$ (**1**) has been prepared and its crystal structure determined by X-ray studies. The crystals belong to the triclinic space group, $P\bar{1}$, and the asymmetric unit consists of one full dimer and two half dimers. The $\{Ru_2(O_2CC_6H_4\text{-}p\text{-}OMe)_4^+\}$ units are bridged by chloride ions into an infinite zigzag chain, with an average Ru—Cl distance and Ru—Cl—Ru angle of 2.567(2) Å and 121.0(1)°, respectively. The average Ru—Ru distance of 2.286(1) Å in **1** is comparable with that in analogous tetra-alkylcarboxylates, $Ru_2Cl(O_2CR)_4$ and tetra-amidates, $Ru_2Cl(ArCONH)_4$.

An interesting feature[1] in the chemistry of diruthenium compounds with four three-atom bridging ligands and a Ru—Ru multiple bond is the unusual stability of the Ru_2^{5+} mixed-valance state. The tetra-alkylcarboxylates, $Ru_2Cl(O_2CR)_4$, which constitute an important class of compounds in this chemistry were the first to be discovered,[2] structurally characterized[3–7] and subjected to various physico-chemical studies.[8–16] The chemistry of analogous tetra-arylcarboxylato compounds has, however, remained virtually unexplored.[17–19]

Recent work from our laboratory has shown[18,20,21] that $Ru_2Cl(O_2CAr)_4$ could be a better precursor for studying the reactivity of the diruthenium(II,III) core towards phosphine- and nitrogen-donor bases. While our earlier attempts[18] to crystallize the sparingly soluble tetra-alkylcarboxylates were unsuccessful, we have now succeeded in isolating $[Ru_2Cl(O_2CC_6H_4\text{-}p\text{-}OMe)_4](H_2O)_{0.25}$ (**1**) in crystalline form. The results of the X-ray study carried out on **1** are presented here. The structural data are of importance in developing the chemistry of the hitherto unknown series of tetra-arylcarboxylatodiruthenium(II,III) complexes.

EXPERIMENTAL

Compound **1** was isolated as a homogeneous crystalline mass by using a diffusion technique in which a methanolic solution of *p*-methoxybenzoic acid was layered carefully on a saturated methanolic solution of $Ru_2Cl(O_2CMe)_4$. The crystals obtained from this reaction were found to be suitable for X-ray studies.

Crystal data for **1**

$[Ru_2Cl(O_2CC_6H_4\text{-}p\text{-}OMe)_4](H_2O)_{0.25}$, M = 842.12, triclinic, $P\bar{1}$, a = 12.765(2), b = 12.879(4), c = 23.855(4) Å, α = 80.55(2), β = 98.61(1), γ = 116.58(2)°, V = 3447 Å^3, Z = 4, d_c = 1.631 g cm^{-3}, λ = 0.7107 Å, μ(Mo-K_α) = 8.26 cm^{-1}.

Structure solution and refinement[21]

12,094 unique data were collected on an Enraf–Nonius range CAD-4 diffractometer using the ω–2θ scan method in the range $4° \leqslant 2\theta \leqslant 50°$, out of which 9478 reflections had $I \geqslant 2.5\sigma(I)$. Lorentz and polarization corrections were made on the data but no absorption correction was made. No decay of the crystal was noticed during data collection. The

structure was solved by the direct method part of SHELX-86 and refined by SHELX-76.[22] Atoms in the coordination sphere along with the carbon atoms in the carboxylate groups were refined anisotropically leaving out the remaining atoms at the isotropic stage. Residuals: $R = 0.0653$ ($R_w = 0.0738$ for $w = k/[\sigma^2(F_o)+gF_o^2]$), $g = 0.000000$; overall scale factor 1.39; lowest shift/ESD = 0.10; highest peak in the final difference Fourier map = 1.94 e/Å^3 situated 0.96 Å away from the Ru(4) atom; number of parameters in the final stage of least-squares refinement was 531.

The probable source of water as solvent of crystallization in **1** could be methanol which was used as a reaction medium. The water molecule which refined with a site occupancy factor of 0.5 for oxygen does not have any interaction with the atoms of the metal complex. Complete tables of structure factors, anisotropic thermal parameters and complete lists of bond distances and angles (59 pages) have been deposited with the Editor at Queen Mary and Westfield College. Positional parameters and isotropic thermal parameters have been forwarded to the Director, Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The structure of **1**, obtained by X-ray crystallography,[22] is shown in Fig. 1. The asymmetric unit of the unit cell consists of one full dimer and two half dimers. The presence of three different dimeric units in the unit cell could be due to packing effects in the presence of bulky aryl groups. The dimeric $\{Ru_2(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4^+\}$ cores are linked by chloride bridges in a zigzag fashion forming an infinite chain. A similar sort of bridging is known to occur in tetra-alkylcarboxylates[3-7] and in tetra-amidates[23,24] with two exceptions[4] in which the Ru—Cl—Ru bridge is linear.

The essential bond distances and angles in **1** are presented in Table 1. A comparison of the Ru—Ru and Ru—Cl distances in **1** and in other related complexes is given in Table 2. In **1**, the average Ru—Ru distance is 2.286(1) Å, the geometry of each ruthenium centre is near octahedral and the Ru—Ru—Cl angles are essentially linear. The presence of a relatively weak Ru—Cl bond in **1** is observed from the structural data, which is also consistent for a Ru—Ru bond order of 2.5 with a $\sigma^2\pi^4\delta^2(\delta^*\pi^*)^3$ ground electronic configuration. From the data in Table 2, we infer that while linear and/or zigzag Ru—Cl—Ru bridges are observed in the tetra-alkylcarboxylato compounds containing small alkyl groups like methyl or ethyl, the presence of a bulky alkyl or an aryl group in the carboxylato or amidato ligands, bonded to the diruthenium(II,III) core, makes the Ru—Cl—Ru bridge non-linear with an angle of *ca* 120° in forming an infinite zigzag chain.

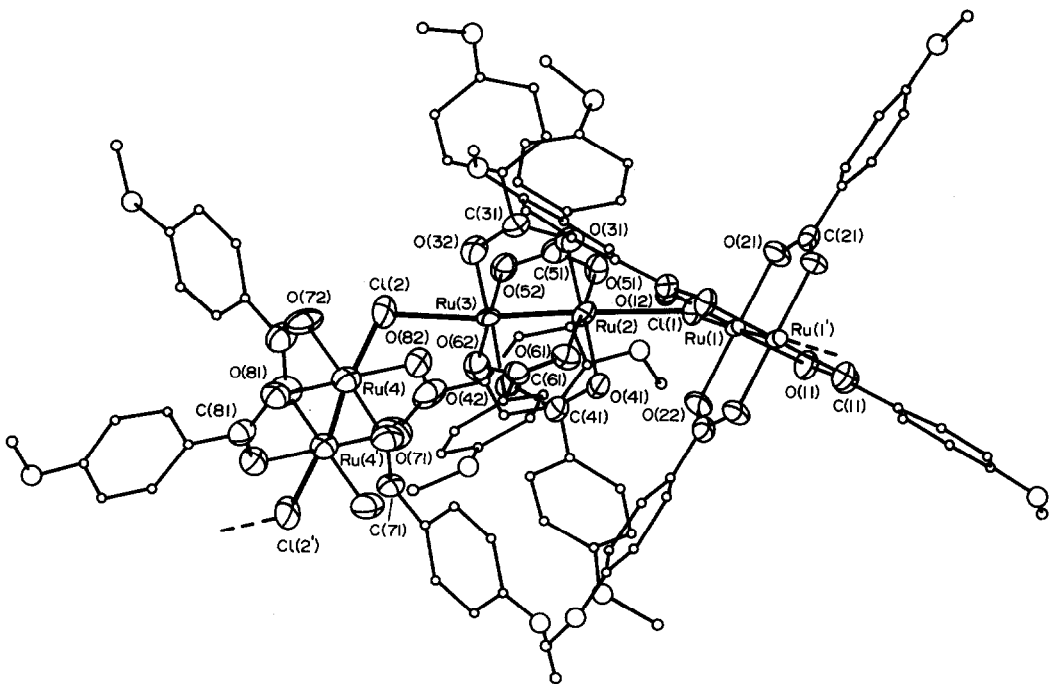

Fig. 1. An ORTEP drawing of the complex $Ru_2Cl(O_2CC_6H_4\text{-}p\text{-}OMe)_4$ with the atom-labelling scheme of the coordination sphere. The sizes of the atoms in the aryl groups are reduced for clarity.

(*Received* 19 *July* 1990; *accepted* 2 *November* 1990)

Abstract—A novel complex of copper(II) with the tridentate ligand N-[2′-(6-methyl)pyridyl]methylene-2-(2′-pyridyl)ethylamine (pymep), of formula [Cu(pymep)Cl(H_2O)](PF_6), has been synthesized and its X-ray crystal structure determined. The structure consists of [Cu(pymep)Cl(H_2O)]$^+$ cations and hexafluorophosphate anions. The copper complex is stacked to make a chain arrangement orientated in the |010| direction. The geometry of the coordination polyhedron around the copper(II) ion is close to tetrahedrally distorted square pyramidal (SP_{th}). One broad, unresolved band centred at 13,800 cm^{-1} is observed in the diffuse reflectance spectrum. The X-band ESR powder spectrum shows an orthorhombic signal with $g_1 = 2.219$, $g_2 = 2.210$ and $g_3 = 2.047$.

Continual study is devoted to low dimensional systems, by both physicists and chemists, because of their interesting properties (magnetic, optic, electric, . . .).[1–3] In this context, we have reported the synthesis and magnetic characterization of a wide set of one-dimensional pentacoordinated copper(II) compounds containing the entity [$CuL_{III}X$], where L_{III} is a tridentate rigid "quasi-planar" ligand, such as terpy (2,2′ : 6′,2″-terpyridine), paphy (pyridine-2-carboxaldehyde 2-pyridylhydrazone), and X is a halide or pseudohalide anion.[4–7] The precursors of these condensed systems are the monomeric [$CuL_{III}X_2$] complexes.[8–11] When an X ligand is extruded from the monomer, the planarity of the tridentate ligands favours the stacking of the resulting planar [$CuL_{III}X$] moieties to give dimers[4,12–14] or more extended systems (linear or ladder-like chains).[6,15]

The rigidity of the tridentate ligands plays an important role in determining the final arrangement of the copper(II) ions. Binuclear species have been obtained with the rigid ligand, terpy,[4–5] whereas dimers and linear and ladder-like chains were obtained with the less rigid tridentate ligand, paphy.[6–7] In order to improve our knowledge of the rigidity effects, we have studied a series of compounds with the Schiff base N-[2′-(6-methyl) pyridyl]methylene-2-(2′-pyridyl)ethylamine (hereafter called pymep), a tridentate ligand with less rigidity than those mentioned above.

In this work, the crystal structure and spectroscopic properties of the [Cu(pymep)Cl(H_2O)](PF_6) complex are reported. Unlike the related [Cu(paphy)Cl](PF_6)(H_2O) (linear chain)[6] and [Cu(terpy)Cl]$_2$(PF_6)$_2$ (dimer)[4] compounds, the title compound exhibits a chain arrangement via hydrogen bonds.

EXPERIMENTAL

Synthesis

Analytical grade copper(II) chloride, N-[2′-(6-methyl)pyridyl]methylene-2-(2′-pyridyl)ethylamine, and potassium hexafluorophosphate were employed to prepare samples of [Cu(pymep)Cl(H_2O)](PF_6). An excess of a saturated KPF_6 aqueous solution was added to a warm aqueous solution containing the simple Cu(pymep)Cl_2 complex previously prepared.[16] The resulting solution was evaporated to obtain microcrystalline

† Author to whom correspondence should be addressed.

powder. Crystallization from a saturated aqueous solution of the latter precipitate gave blue prismatic crystals of relatively good quality. Found: Cu, 13.2; C, 34.3; H, 3.4; N, 8.6. Calc. for $CuC_{14}H_{17}N_2ClOPF_6$: Cu, 13.0; C, 34.5; H, 3.5; N, 8.6%.

X-ray and structure determination

Preliminary cell dimensions and space group symmetry were determined from Weissenberg and oscillation photographs. A prismatic crystal ($0.25 \times 0.20 \times 0.05$ mm) was selected and mounted on an Enraf–Nonius CAD-4 diffractometer with its long dimension roughly parallel to the ϕ axis of the goniometer. Accurate cell parameters and orientation matrix were obtained by a least-squares refinement of the setting angles of 25 reflections with $10 \leqslant 2\theta \leqslant 34°$, recorded using graphite-monochromatized Mo-K_{α_1} radiation.

Crystal data. $[Cu(C_{14}H_{15}N_6)Cl(H_2O)](PF_6)$, $M = 487.3$ g mol^{-1}, orthorhombic system, space group *Pbca*, $a = 7.9222(4)$, $b = 15.7633(5)$, $c = 29.623(1)$ Å; $V = 3699.3(3)$ Å^3; $Z = 8$; $D_x = 1.75$ g cm^{-3}; λ(Mo-K_{α_1}) = 0.7107 Å, μ(Mo-K_{α_1}) = 14.73 cm^{-1}, $F(000) = 1944$, $T = 292$ K. Density was measured by flotation in a bromoform–ethanol solution [$D_m = 1.75(6)$ g cm^{-3}].

A total of 5368 reflections were recorded in the range $2 \leqslant 2\theta \leqslant 60°$, with h: $0 \rightarrow 11$, k: $0 \rightarrow 22$, l: $0 \rightarrow 41$, ω–2θ scan technique. Orientation (every 150 reflections) and intensity control (every 3600 s) by means of three standard reflections showed no significant changes during the data collection. The intensity data were corrected for Lorentz polarization factors; absorption effects were neglected. 1763 reflections with $I \geqslant 3\sigma(I)$ were taken into account to solve the structure via direct methods (MULTAN 84 system),[17] and for refinement by successive least-squares and Fourier synthesis cycles (SHELX 76 program).[18] The function minimized was $\Sigma w[|F_o| - |F_c|]$, were $w = [\sigma^2(F_o) + 0.0024(F_o)]^{-1}$. Anisotropic thermal parameters were introduced for all atoms except hydrogen atoms whose thermal parameters were isotropic. The hydrogen positions could be derived from a difference Fourier map. Final difference maps revealed no significant regions of electron density with max. 0.65 and min. -0.32 eÅ^{-3}. The final value of the discrepancy indice is $R = 4.31$ ($R_w = 4.78$).

Scattering factors were taken from the *International Tables for X-Ray Crystallography*.[19] All calculations were carried out on a MicroVAX computer at the computer centre of the Basque University. The geometric calculations were performed with XANADU[20] and molecular illustrations were drawn with SCHAKAL 88.[21] Further details are presented as Supplementary Data, together with final atomic coordinates, thermal parameters, bond lengths and angles, mean average planes and structure factors.

Physical measurements

Water was determined thermogravimetrically using a Perkin–Elmer TSG-1 thermobalance. IR spectra were obtained with KBr pellets in the 4000–250 cm^{-1} region, using a Perkin–Elmer 1430 spectrophotometer. Visible reflectance spectra on solid powdered samples were recorded at room temperature using a Perkin–Elmer Lamba-9 UV-vis/NIR spectrophotometer. A Bruker 200 tt spectrometer equipped with a standard low-temperature device, operating at X-band calibrated by a NMR probe for the magnetic field and a HP 5342A frequency counter for the microwave frequency, was used to record the ESR powder spectra of the complex at different temperatures.

RESULTS AND DISCUSSION

The structure of the title compound consists of cationic $[Cu(pymep)Cl(H_2O)]^+$ units and hexafluorophosphate anions. The copper complex, presented with labelling in Fig. 1, is stacked to make a chain arrangement orientated in the |010| direction.

The main interatomic distances and angles of this compound are listed in Table 1.

The coordination sphere of the copper(II) ion can be described as a distorted square pyramid. The basal positions are occupied by the three nitrogen atoms of the tridentate ligand [Cu—N(1), N(2), N(3); 2.010(6), 1.964(5), 2.046(6) Å, respectively] and the chlorine atom [Cu—Cl, 2.240(2) Å]. The fifth coordination site (at the apical position) is occupied by the oxygen atom from the water molecule [Cu—O_w, 2.439(7) Å].

The $[Cu(pymep)Cl(H_2O)]^+$ units are linked by hydrogen bonds between the water molecules and the $(PF_6)^-$ ions (see Fig. 2). The $O_w \cdots F(4)$ and $F(5) \cdots O_w^i$ [$i = -x+3/2, y+1/2, z$] distances are 3.091(10) and 3.190(10) Å, respectively. An helicoidal binary axis serves to propagate the chain along the b axis. The chains are isolated with the shorter interchain distance Cu—Cu^{ii} being 7.922(1) Å [$ii = x+1, y, z$].

The hexafluorophosphate anion exhibits a geometry close to regular octahedron. The average P—F distance is 1.55(3) Å, while the average *cis*- and *trans*-F—P—F angles are 90(2) and 178(2)°, respectively.

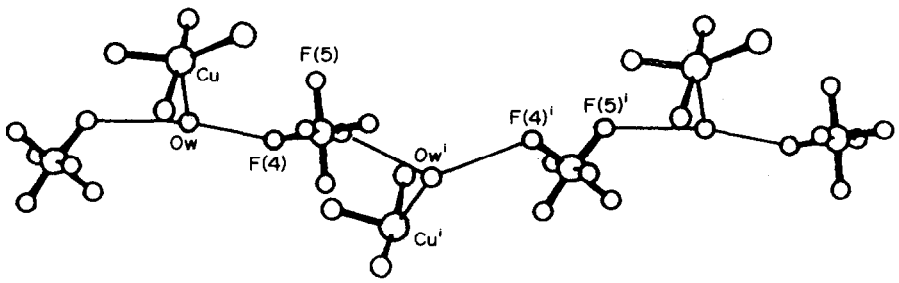

Fig. 2. Perspective view of the catenation of the [Cu(pymep)Cl(H_2O)](PF_6) complex in the |010| direction.

The coordination polyhedron around the copper atom in this type of compound has been described as "distorted square pyramidal" or "distorted trigonal bipyramidal". However, these geometries are better described as "regular square pyramidal" (SP_r) and "tetrahedral or trigonal distorted square pyramidal" (SP_{th} and SP_{tr}, respectively) as Hathaway[22] has pointed out. We have quantified the distortion of the coordination polyhedron of the title compound using the Muetterties and Guggenberger[23] description and by considering the regular square pyramid (SP_r) and the ideal trigonal bipyramid (TBP) as the limiting geometries. The dihedral angles and the deviation (Δ) from TBP for the ideal geometries and the title compound are given in Table 2. The value obtained for this compound ($\Delta = 0.24$) shows a topology close to the tetrahedral distorted square pyramidal (SP_{th}).

In the IR spectrum, the characteristic vibrations of the H_2O and PF_6 groups can be observed. For the water molecule, the stretching and bending vibrations appear at 3660–3580 and 1665 cm^{-1}, respectively. The rotation modes are masked by the pymep ligand bands and cannot be observed. The F_{1u} active modes of the PF_6 group are observed at 545 and 840 cm^{-1}. The band at 840 cm^{-1} appears slightly split due to the hydrogen bonds between the F(4) [F(5)] and O_w [O_w'] atoms.

The X-band room temperature spectrum of a powdered sample of the title compound is given in Fig. 3. The spectrum exhibits the characteristics of an orthorhombic g tensor [$g_1 = 2.219$, $g_2 = 2.120$, $g_3 = 2.047$] and remains unchanged over the temperature range 4.2–298 K. On the other hand, the diffuse reflectance spectrum of the [Cu(pymep)Cl(H_2O)](PF_6) complex, recorded at room tem-

Δ is calculated using the following formula:

$$\Delta = \Sigma\left|\frac{(\delta a_1+\delta a_3+\delta a_4+\delta a_6)-406.0}{182.7}\right| + \left|\frac{(\delta a_2+\delta a_5)-203.0}{248.4}\right| + \left|\frac{(\delta e_1+\delta e_2)-106.2}{187.2}\right| + \left|\frac{(\delta e_3)-53.1}{477.9}\right|.$$

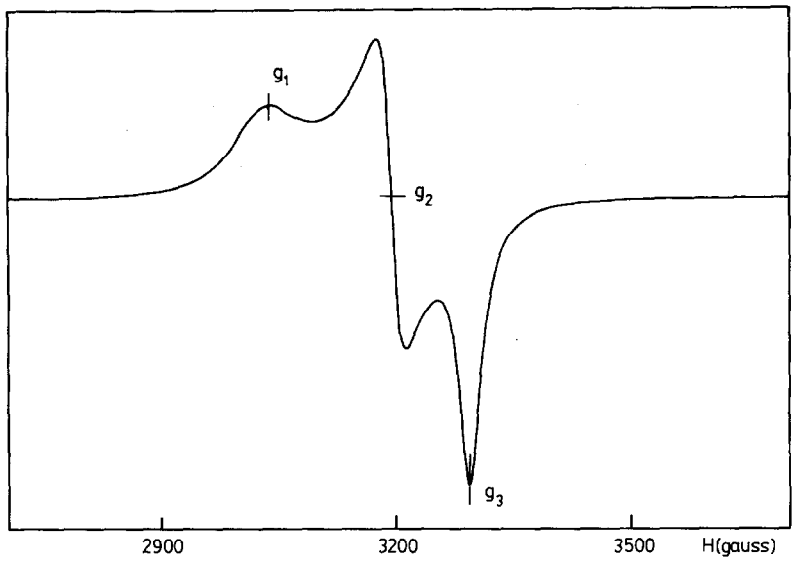

Fig. 3. X-band ESR spectrum of a powdered sample of the $[Cu(pymep)Cl(H_2O)](PF_6)$ complex, recorded at room temperature.

perature, shows one broad, unresolved band centred at about 13,800 cm^{-1}. These results are in good agreement with a geometry near to SP_{th} for the $[CuN_3ClO]$ chromophore.[24-26]

In the $[Cu(pymep)Cl(H_2O)](PF_6)$ compound, magnetic interactions could be propagated by a super-exchange path through the water molecules and PF_6^- ions connected by hydrogen bonds (see Fig. 2). Considering the Cu—Cu^i distance through that extended bridging network [14.2 Å] and the experimentally determined function for long-range magnetic super-exchange proposed by Coffman and Buettner,[27] the expected $|J|$ value is less than 10^{-3} cm^{-1}. Likewise, a dipolar magnetic interaction cannot be assumed negligible in this compound ($D_d = 2 \times 10^{-3}$ cm^{-1} from the Cu—Cu^{ii} shorter interchains distances). Thus, magnetic measurements at temperatures lower than 1 K should be performed to detect these magnetic interactions.

METAL COMPLEXES OF FUNCTIONALIZED PHOSPHINES—I. SYNTHESIS AND CHARACTERIZATION OF 2-DIPHENYLPHOSPHINOETHYLAMINES AND SOME OF THEIR COMPLEXES WITH PLATINUM. X-RAY STRUCTURE OF $[Pt(Ph_2PCH_2CH_2NHBu^t)(Ph_2PCH_2CH_2NHBu^t \cdot HCl)Cl]Cl \cdot H_2O$

MANDY BASSETT, DAVID L. DAVIES,* JULIE NEILD, LESLEY J. S. PROUSE and DAVID R. RUSSELL

Department of Chemistry, University of Leicester, Leicester LE1 7RH, U.K.

(*Received* 15 *August* 1990; *accepted* 5 *November* 1990)

Abstract—The new bidentate ligands $Ph_2PCH_2CH_2NHR$ [R = Bu^t, CH_2Ph, CH(Me)Ph] and $Ph_2PCH_2CH_2N(CH_2Ph)_2$ and their corresponding hydrochloride salts have been synthesized and were characterized by ^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectroscopy. The ligand $Ph_2PCH_2CH_2NHBu^t$ reacts with K_2PtCl_4 or $(COD)PtCl_2$ to form $[Pt(Ph_2PCH_2CH_2NHBu^t)(Ph_2PCH_2CH_2NHBu^t \cdot HCl)Cl]Cl$, whose structure has been determined by X-ray diffraction. Treatment of this complex with HCl gas gives $[Pt(Ph_2PCH_2CH_2NHBu^t \cdot HCl)_2Cl_2]$ which can also be synthesized from $Ph_2PCH_2CH_2NHBu^t \cdot HCl$ and K_2PtCl_4.

Recently we have studied a range of amino-alkyl and hydroxy-alkyl substituted phosphines. In this paper we report the synthesis of a number of diphenylphosphinoethylamines and some of their complexes with platinum metals.

Bidentate ligands with one hard nitrogen donor and one soft phosphorus donor have been the subject of many recent reports.[1–9] These ligands can act as chelating ligands or as bridging ligands, and the enhanced stability provided by chelation has been used to examine platinum metal amides and N—H activation by these metals. Though early transition metal amides are well known, such complexes of the platinum metals are still quite rare.[10,11] However, such species have been implicated in many catalytic processes such as the rhodium catalysed synthesis of β-lactams by carbonylation of aziridines.[12] Platinum metal amides have also been proposed as key intermediates in a possible route to the catalytic amination of alkenes.[13–15] To date, most of the studies have used phosphines having a phenyl backbone connecting the phosphorus and the nitrogen centres, we are examining ligands with an alkyl backbone which should be more flexible. During the course of this work some related work using the ligand diphenylphosphinoethyl-benzylamine has been published.[16] We have synthesized this phosphine by a different route and have found some differences to the published data which were discussed below.

RESULTS AND DISCUSSION

Base-catalysed addition of amines to vinyldiphenylphosphine has been reported, using methyl lithium as the base catalyst.[17] Using primary amines the products were usually bis(diphenylphosphinoethyl)amines, though it was stated that the intermediate diphenylphosphinoethyl secondary amine could be isolated in certain cases. We have found that sodium amide is a convenient catalyst for this reaction, its low solubility in THF means that it is only present in small concentrations. Thus, refluxing vinyldiphenylphosphine with an excess of amine in THF with sodium amide as catalyst gives diphenylphosphinoethylamines $Ph_2PCH_2CH_2NHR$ [R = Bu^t, CH_2Ph, CH(Me)Ph] (**1a–c**) in good yields. The ligand **1a** is isolated as a crystalline solid, however **1b** and **1c** are oils. An excess of

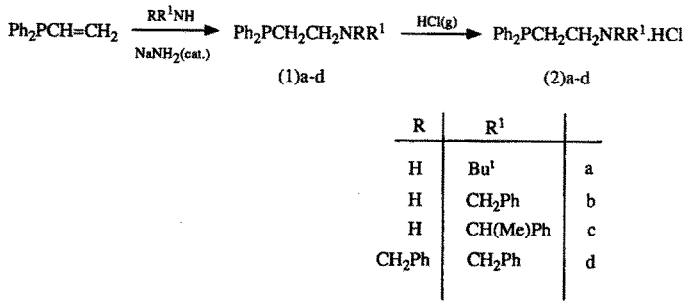

Scheme 1.

amine is used to minimize the formation of bis(diphenylphosphinoethyl)amines. If the secondary amine dibenzylamine is used instead of a primary amine, then the product is $Ph_2PCH_2CH_2N(CH_2Ph)_2$ (**1d**) (see Scheme 1).

The ligands have been characterized by their ^1H, ^{13}C-$\{^1H\}$ and ^{31}P-$\{^1H\}$ NMR spectra (Table 1). All the ligands show a single resonance in the ^{31}P-$\{^1H\}$ NMR spectrum at around δ −20. The ^{13}C-$\{^1H\}$ NMR spectra each show two doublets between δ 29 and 46 due to the C_2H_4 backbone, as well as signals due to the phenyl groups and the R substituent on the nitrogen. There is some confusion in the literature about the assignment of these signals

[a] Chemical shifts (δ) in ppm, coupling constants in Hz. Measurements at room temperature in $CDCl_3$.
[b] Chemical shifts are positive to high frequency of 85% H_3PO_4 (external) (0.0 ppm).
[c] The carbon atoms of the ethyl backbone of the ligands are numbered as follows $Ph_2PC_1C_2NRR^1$.

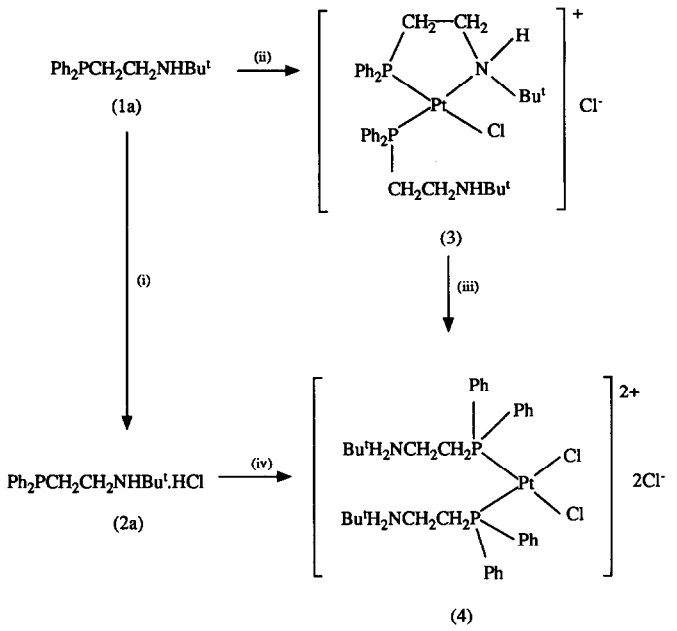
which has been based on the relative magnitudes of ^1J(PC) and ^2J(PC).[9,16] Since we have made a series of these ligands which vary only in the nature of the groups attached to nitrogen we have been able to base our assignments on chemical shift arguments as well as on coupling constants. The signal at δ 29 does not vary by more than 1 ppm for each different R group, whereas the other doublet at around δ 40 varies by about 7 ppm depending on the nature of R thus, we assign the signals at approx. δ 29 to the CH_2 next to the phosphorus atom and those at approx. δ 40 to the CH_2 next to the nitrogen. The greater electronegativity of nitrogen compared to phosphorus leads to the signal being more down field. With these assignments we find that ^2J(PC) is bigger than ^1J(PC) for all these phosphines, as was suggested for $Ph_2PCH_2CH_2NMe_2$.[9] A previous study of tertiary phosphines concluded that ^1J(PC) and ^2J(PC) for alkyl side chains are approximately equal in magnitude.[18] This contrasts with the assignment made recently for the ligand $Ph_2PCH_2CH_2NHR \cdot HCl$ (R = CH_2Ph) where the assignments were made on the basis that ^1J(PC) is larger than ^2J(PC).[16] The ^{1}H NMR spectra show two multiplets in the region δ 2–3 due to the CH_2CH_2 backbone, as well as signals due to the phenyl groups and the R substituent attached to nitrogen. We assume the multiplet to lower field is due to the CH_2 next to nitrogen, with that to higher field being the one next to phosphorus as suggested for the $^{13}C\{^1H\}$ spectra.

Reaction of the ligands **1a–d**, as a solution in diethyl ether, with HCl gas readily yields the hydrochloride salts, **2a–d**, which may be recrystallized from methanol, in certain cases with incorporation of methanol into the crystal. It is this presence of methanol of crystallization which we feel confused previous workers in their reported isolation of $Ph_2PCH_2CH_2NHCH_2Ph \cdot HCl$ (**2b**). The ^{1}H NMR spectrum of this salt (Table 1) shows two multiplets at δ 2.6 and 2.85 assigned to the PCH_2CH_2N backbone, as well as a singlet δ 3.95 due to the CH_2 of the benzyl. This contrasts with the reported values of multiplets at δ 4.2 and 2.7 assigned to the PCH_2CH_2N backbone, and a singlet at δ 3.5 due to the CH_2 of the benzyl. We believe that the ligand previously formulated as $Ph_2PCH_2CH_2NHCH_2Ph \cdot HCl$[16] (**2b**) is in fact $Ph_2PCH_2CH_2N(CH_2Ph)_2 \cdot HCl \cdot (MeOH)$ (**2d**), which we have prepared independently from vinyldiphenylphosphine and dibenzylamine followed by treatment with gaseous HCl as described above. On examining the ^{1}H NMR spectrum of $Ph_2PCH_2CH_2N(CH_2Ph)_2 \cdot HCl \cdot (MeOH)$ (**2d**) at high field (300 MHz) (Table 1), the signal at δ 2.7 can be seen to consist of two multiplets at δ 2.65 and 2.95 which we assign to the PCH_2CH_2N backbone, while the multiplet at δ 4.2 is actually two doublets of doublets at δ 4.3 and 4.15 which we now assign to the CH_2 of the benzyl groups, each CH_2 consisting of two diastereotopic protons which couple to each other and to the hydrogen on the nitrogen. The singlet at δ 3.5 is due to methanol of crystallization and can be observed in the $^{13}C\{^1H\}$ NMR spectrum at δ 50.

We have attempted to repeat the synthesis of $Ph_2PCH_2CH_2NHCH_2Ph$ as reported by Khan and Reddy[16] starting from 2-aminoethanol and benzyl chloride. However, we find that this gives dibenzylaminoethanol as the major product even when only one equivalent of benzyl chloride is used. This could explain their isolation of $Ph_2PCH_2CH_2N(CH_2Ph)_2$ which, as explained above, we believe to be their final product.

The ligand **1a** (R = Bu^t) reacts with K_2PtCl_4 or with $(COD)PtCl_2$ to give the salt **3** (Scheme 2) in which one ligand coordinates through just the phosphorus atom while the other forms a five-membered ring coordinating through both the phosphorus and nitrogen atoms. This is easily seen in the $^{31}P\{^1H\}$ NMR spectrum which shows two inequivalent phosphorus atoms at δ +32.67 and −2.22, respectively. The signal to lower field being the phosphorus in the five-membered ring.[19] The P—Pt coupling constants are 3765 and 3203 Hz as expected for phosphorus *trans* to chloride and amine, respectively. Similar complexes have been obtained from $Ph_2PCH_2CH_2NMe_2$[9] and $Ph_2PCH_2CH_2NHR$ (R = CH_2Ph),[16] though as discussed above the latter actually contains $Ph_2PCH_2CH_2N(CH_2Ph)_2$. Using the related hydroxyalkylphosphine, $Ph_2PCH_2CH_2OH$, Pringle *et al.* showed that the species formed was solvent dependent.[20] We observe some broadness in the $^{31}P\{^1H\}$ NMR spectrum of **3** in $CDCl_3$ which may be indicative of an exchange process, but do not observe the species with both chlorides coordinated and the ligands coordinated only through the phosphorus. This is consistent with an amine being a better donor than an alcohol and thus competing more effectively with chloride for one coordination site.

We have carried out an X-ray crystal structure determination of complex **3** which actually crystallized as the hydrochloride salt, i.e. the uncoordinated nitrogen had been protonated by traces of acid possibly from the dichloromethane solvent, and with a molecule of water of crystallization. The structure of the cation and the principal bond lengths and angles are shown in Fig. 1. The structure clearly shows the presence of one monodentate phosphine and one bidentate ligand. The chelating ligand spans an angle of 85.9(3)° and has Pt—P and



Scheme 2. (i) HCl(g); (ii) K_2PtCl_4 or $(COD)PtCl_2$; (iii) HCl(g); (iv) K_2PtCl_4.

Pt—N bond lengths of 2.226(3) and 2.139(8) Å, respectively, which are similar to those of 86.4°, 2.245 and 2.12 Å, respectively, found for the *o*-diphenylphosphinoaniline ligand in the dication *cis*-$[Pt(o\text{-}Ph_2PC_6H_4NH_2)_2]^{2+}$.[4b]

Treatment of complex **3** with HCl gas gives complex **4** (Scheme 2) in which both the ligands are coordinated through the phosphorus atom only, the amine substituents having been protonated to the hydrochloride salts. This complex may be prepared independently from the ligand hydrochloride salt and K_2PtCl_4. Complex **4** shows the expected $^{31}P\{^1H\}$ NMR spectrum (δ +3.63) with platinum satellites [J(Pt—P) = 3623 Hz] consistent with phosphorus coordinated *trans* to chloride.

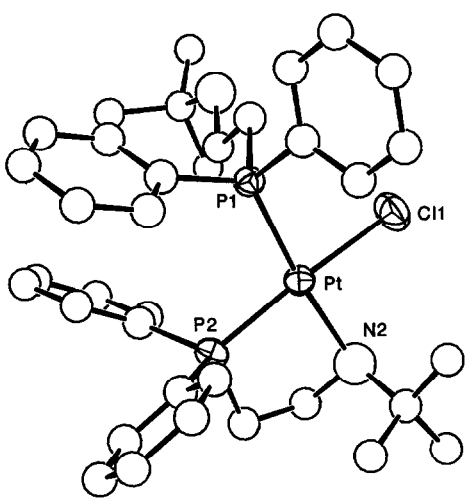


Fig. 1. Molecular structures of the cation $[Pt(Ph_2PCH_2CH_2NHBu^t)(Ph_2PCH_2CH_2NH_2Bu^t)Cl]^{2+}$. Selected bond lengths (Å) and bond angles (°): P(1)—Pt 2.260(2), Pt—Cl(1) 2.367(3), P(2)—Pt 2.226(3), N(2)—Pt 2.139(8); P(2)—Pt—P(1) 100.4(1), P(2)—Pt—N(2) 85.9(3), P(1)—Pt—Cl(1) 87.0(1), N(2)—Pt—Cl(1) 86.6(3).

In conclusion, we have shown that sodium amide-catalysed addition of amines to vinyldiphenylphosphine can be used to produce a series of ligands $Ph_2PCH_2CH_2NHR$. Our evidence suggests that a previous report[16] of $Ph_2PCH_2CH_2NH(CH_2Ph)$ and some of its complexes is wrong, and that they should be reformulated as containing $Ph_2PCH_2CH_2N(CH_2Ph)_2$. The ligand $Ph_2PCH_2CH_2NHBu^t$ reacts with K_2PtCl_4 or $(COD)PtCl_2$ to form a complex in which one ligand is chelated and the other is bound only through phosphorus. Further studies to examine the reactivity of this complex and the effect of changing the Bu^t group are in progress.

EXPERIMENTAL

Petroleum ether, diethyl ether, toluene and THF were all dried by refluxing over purple sodium/benzophenone in a nitrogen atmosphere. Dichloromethane was purified by refluxing over calcium hydride. The compounds vinyldiphenylphosphine[21] and $(COD)PtCl_2$[22] were prepared by the literature methods. Chlorodiphenylphosphine and L-(−)-1-phenylethylamine (Lancaster Synthesis), t-butylamine, benzylamine and sodium amide suspension in toluene (Aldrich) were all used as

supplied. The syntheses of phosphorus-containing compounds were carried out in deoxygenated solvents under a nitrogen atmosphere. Once isolated as pure solids, all new phosphine compounds are relatively air-stable and precautions for their storage are unnecessary.

^1H and ^{13}C-$\{^1H\}$ NMR spectra were recorded on a Bruker AM300 spectrometer as $CDCl_3$ solutions with internal $SiMe_4$ as reference. ^{31}P-$\{^1H\}$ NMR spectra were recorded on a Jeol FX60 instrument at 24.15 MHz in $CDCl_3$ solution and were referenced to external 85% H_3PO_4 with shifts to high frequency being positive. Microanalyses were performed by Butterworth Laboratories Ltd, Middlesex.

Preparation of $Ph_2PCH_2CH_2NHBu^t$ (**1a**)

An excess of t-butylamine (3.38 g, 46.12 mmol) and sodium amide (two spatulas full from a suspension in toluene) were added to a solution of vinyldiphenylphosphine (2.46 g, 11.53 mmol) in THF (30 cm^3). The solution was refluxed under a nitrogen atmosphere for 1.5 h. The sodium amide was destroyed by addition of aqueous ammonium chloride solution (15 cm^3 of a 10% solution). The phosphine was extracted from the aqueous layer with dichloromethane and dried with anhydrous magnesium sulphate. The dichloromethane was removed under reduced pressure and the product was dissolved in petroleum ether and filtered to remove any insoluble impurities. Recrystallization from petroleum ether gave $Ph_2PCH_2CH_2NHBu^t$ as a cream solid (2.80 g, 85%). Found: C, 75.2; H, 8.3; N, 4.3. $C_{18}H_{24}NP$ requires: C, 75.8; H, 8.5; N, 4.9%.

Preparation of $Ph_2PCH_2CH_2NHCH_2Ph$ (**1b**)

This was prepared in a similar manner to $Ph_2PCH_2CH_2NBu^t$ above from vinyldiphenylphosphine (5.34 g, 25.2 mmol), though after refluxing for 1.5 h the solution had become purple. Excess benzylamine was removed from the product by heating at 60°C *in vacuo*. The product, $Ph_2PCH_2CH_2NHCH_2Ph$ (5.84 g, 73%), was isolated as a yellow oil.

Preparation of $Ph_2PCH_2CH_2NHCH(Me)Ph$ (**1c**)

$Ph_2PCH_2CH_2NHCH(Me)Ph$ was prepared as above, and was isolated as a colourless oil in 84% yield.

Preparation of $Ph_2PCH_2CH_2N(CH_2Ph)_2$ (**1d**)

This was prepared in a similar way except that only a slight excess of dibenzylamine was used (1.1 equiv.). Excess amine was removed by heating at 150°C *in vacuo* and $Ph_2PCH_2CH_2N(CH_2Ph)_2$ was isolated as a pale yellow oil in 79% yield.

Preparation of $Ph_2PCH_2CH_2NHBu^t \cdot HCl$ (**2a**)

Hydrogen chloride gas was bubbled through a solution of $Ph_2PCH_2CH_2NHBu^t$ (3.0 g, 10.51 mmol) in diethyl ether (50 cm^3). After a few seconds a white solid precipitated, the diethyl ether was removed *in vacuo* and the product was recrystallized from methanol giving $Ph_2PCH_2CH_2NHBu^t \cdot HCl$ (2.78 g, 82%) as white crystals. Found: C, 66.0; H, 7.4; N, 4.4. $C_{18}H_{25}ClNP$ requires: C, 67.2; H; 7.8; N, 4.3%.

The other hydrochloride salts were prepared in the same way; $Ph_2PCH_2CH_2NH(CH_2Ph) \cdot HCl$ (**2b**) (80%); Found: C, 69.6; H, 6.7; N, 4.0. $C_{21}H_{23}ClNP$ requires: C, 70.9; H, 6.5; N, 3.9%. $Ph_2PCH_2CH_2NHCH(Me)Ph \cdot HCl$ (**2c**) (75%); Found: C, 70.1; H, 7.0; N, 3.9. $C_{22}H_{25}ClNP$ requires: C, 71.4; H, 6.8; N, 3.8%. $Ph_2PCH_2CH_2N(CH_2Ph)_2 \cdot HCl \cdot (MeOH)$ (**2d**) (64%); Found: C, 72.6; H, 6.9; N, 3.1. $C_{29}H_{33}ClNOP$ requires: C, 72.9; H, 7.0; N, 2.9%.

Reaction of K_2PtCl_4 *with* $Ph_2PCH_2CH_2NHBu^t$

A solution of $Ph_2PCH_2CH_2NHBu^t$ (700 mg, 2.45 mmol) in acetone (25 cm^3) was added to a solution of K_2PtCl_4 (500 mg, 1.2 mmol) in water (8 cm^3). The solution changed from red to yellow on addition of the phosphine and was stirred for 0.5 h at room temperature. The solvent was removed *in vacuo* and the residue was dissolved in dichloromethane and filtered to remove potassium chloride. Evaporation of the dichloromethane gave $[\overline{Pt(Ph_2PCH_2CH_2NHBu^t)}(Ph_2PCH_2CH_2NHBu^t)Cl]Cl$ (**3**) as a yellow solid (915 mg, 91%). Recrystallization gave the hydrochloride salt with one molecule of water of crystallization. Found: C, 47.9; H, 5.9; N, 2.6. $C_{36}H_{51}Cl_3N_2OP_2Pt$ requires: C, 48.5; H, 5.8; N, 3.1%. ^1H NMR: δ 1.35 (s, 9H, Bu^t), 1.45 (s, 9H, Bu^t), 2.6–3.5 (br m, 8H, CH_2), 7.5 (m, 20H, Ph). ^{31}P-$\{^1H\}$ NMR: δ −2.2 [d, J(PP) 20, J(PtP) 3203 Hz], +32.7 [d, J(PP) 20, J(PtP) 3765 Hz].

Reaction of $(COD)PtCl_2$ *with* $Ph_2PCH_2CH_2NHBu^t$

A solution of $(COD)PtCl_2$ (300 mg, 0.80 mmol) and $Ph_2PCH_2CH_2NHBu^t$ (480 mg, 1.68 mmol) in dichloromethane (50 cm^3) was stirred for 30 min,

the solution was reduced in volume and petroleum ether was added to precipitate [Pt($Ph_2PCH_2CH_2NHBu^t$)($Ph_2PCH_2CH_2NHBu^t$)Cl]Cl (**3**) (506 mg, 75%) as a yellow solid.

Reaction of K_2PtCl_4 *with* $Ph_2PCH_2CH_2NHBu^t \cdot HCl$

A solution of $Ph_2PCH_2CH_2NHBu^t \cdot HCl$ (404 mg, 1.26 mmol) in methanol (30 cm^3) was added to a solution of K_2PtCl_4 (260 mg, 0.63 mmol) in water (5 cm^3). The solution was stirred for 2 h after which time the solvent was removed and the residue was dissolved in dichloromethane and filtered. Evaporation of the dichloromethane gave [Pt($Ph_2PCH_2CH_2NHBu^t \cdot HCl)_2Cl_2$] (**4**) as a white solid (360 mg, 68%). Found: C; 46.9; H, 6.0; N, 2.8. $C_{36}H_{50}Cl_4N_2P_2Pt$ requires: C, 47.5; H, 5.5; N, 3.1%. ^1H NMR: δ 1.40 (s, 18H, Bu^t), 3.40 (br, 8H, CH_2), 7.30 (br m, 20H, Ph), 9.50 (br, 4H, NH_2). ^{31}P-{^1H} NMR: δ 3.63 [J(PtP) 3623 Hz].

Reaction of [Pt($Ph_2PCH_2CH_2NHBu^t$)($Ph_2PCH_2CH_2NHBu^t$)Cl]Cl (**3**) *with* HCl

Hydrogen chloride gas was bubbled through a solution of [Pt($Ph_2PCH_2CH_2NHBu^t$)($Ph_2PCH_2CH_2NHBu^t$)Cl]Cl in methanol for 5 min, after which time the ^{31}P-{^1H} NMR spectrum showed complete conversion to [Pt($Ph_2PCH_2CH_2NHBu^t \cdot HCl)_2Cl_2$] (**4**).

Crystal structure determination

Crystals of complex **3** were obtained from methanol–dichloromethane. The unit cell parameters were determined by least squares refinement of ω-measurements of different layers.[23] Data were collected on a Stoë STADI-2 diffractometer with an ω-scan technique in the range $7 < 2\theta < 50°$. The intensities of 8135 reflections were measured and these data were corrected for Lorentz and polarization effects to give 4958 unique reflections with $I > 3\sigma(I)$. Subsequent calculations were carried out with the computer program SHELX-76.[24]

Crystal data for [$C_{36}H_{51}Cl_3N_2OP_2Pt$] (**3**): M = 891.16, monoclinic, a = 11.430(14), b = 14.726(9), c = 24.129(6) Å, β = 104.46(4)°, U = 3932.69 $Å^3$, Z = 4, D_c = 1.50 g cm^{-3}, $F(000)$ = 1792. Space group $P2_1/c$, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 36.41 cm^{-1}.

The molecular structure was solved by conventional Patterson and Fourier difference techniques. Scattering factors were taken from ref. 25. An absorption correction[23] was applied to the data with the maximum and minimum transmission factors of 0.712 and 0.604, respectively. Phenyl rings were included as rigid groups with D_{6h} symmetry and C—C distances of 1.395 Å. The hydrogen atoms of the phenyl and the CH_2 groups were included in calculated positions (C—H = 1.08 Å). All non-hydrogen atoms were refined anisotropically. Final cycles of refinement employed a weighting factor w calculated from $w = k/(\sigma^2F + gF^2)$, where k = 1.6096 and g = 0.000826, and gave final values of R = 0.0534 and R_w = 0.0535.

Abstract—A series of five complexes of tin(IV) with 5,10,15,20-tetraphenylporphyrin (H_2tpp) of the type [SnX_2(tpp)] has been prepared and characterized using NMR and single crystal X-ray diffraction techniques. The complexes are [$Sn(OH)_2$(tpp)] (**1**), [$Sn(OH_2)_2$(tpp)] $(CF_3SO_3)_2$ (**2**), [$Sn(C_6H_5CO_2)_2$(tpp)] (**3**), [$Sn(2\text{-}OH\text{-}C_6H_4CO_2)_2$(tpp)] (**4**) and [$Sn(2\text{-}OCOCH_3\text{-}C_6H_4CO_2)_2$(tpp)] (**5**). All complexes are monomeric with little structural variation within the Sn(tpp) framework. All axial substituents act as unidentate ligands with the Sn—O bond lengths varying from 2.017(4) Å (X = OH) (**1**) through 2.055(5) Å (**3**), 2.06(3) Å (mean) (**5**), 2.09(1) Å (**4**) (the substituted benzoates) to 2.16(1) Å (mean) ($X = OH_2$) (**2**).

The octahedral tin(IV) complexes of porphyrins and related ligands have attracted interest in recent years in a variety of fields. Tin(IV) proto- and meso-porphyrin show promise as therapeutic agents for neonatal jaundice, as they are potent inhibitors of haem oxygenases.[2] Morgan *et al.* have reported studies of photodynamic cancer treatment using the tin complexes of the porphyrin-derived purpurins and verdins.[3] Water-soluble complexes such as tetrakis(N-methyl-4-pyridyl)porphyrinatotin(IV) have been used as photosensitizers for energy transfer to water and other molecules for hydrogen generation.[4] Most recently, Meyerhoff and co-workers[5] reported the use of dichloro-5,10,15,20-tetraphenylporphyrinatotin(IV) {[$SnCl_2$(tpp)]} in polymer membrane anion-selective electrodes. These electrodes displayed surprising selectivity for salicylate over benzoate, and excellent selectivity for salicylate over chloride. It was proposed that the order of anion selectivities reflects strength of binding of anions to a cationic tin porphyrin centre in the membrane.[5]

One of us has studied a wide range of Sn(tpp) complexes by NMR and visible absorption spectroscopy. The favourable chemical and NMR properties of these complexes have enabled the gen-

† Author to whom correspondence should be addressed.

eration of spectroscopic *cis*- and *trans*-influence series for oxygen-bound axial ligands of widely differing base strengths, and for various other ligands.[1,6] Others have investigated the electrochemical behaviour of some tetra(aryl)porphyrin tin(IV) complexes,[7] although some of their spectroscopic data are in conflict with an earlier communication.[6b] It therefore appeared worthwhile to study the solid-state structures of some Sn(tpp) complexes with various axial ligands, to see if salicylate displayed any unusual coordination behaviour, and to complement the spectroscopic studies.

Tin(IV) porphyrins have not been extensively studied by crystallography. The dichloro complexes $[SnCl_2(tpp)]$[8] and $[SnCl_2(oep)]$ (H_2oep = 2,3,7,8, 12,13,17,18-octaethylporphyrin),[9] and a partially disordered example of the dihydroxo complex $[Sn(OH)_2(tpp)]$ [as a bis(chloroform), bis(carbon tetrachloride) solvate][10] are the only published structures containing simple electronegative axial ligands. As the dihydroxo species is the normal starting material for most tin(IV) tpp bis(acido) complexes, we felt it was important to determine its structure more precisely, for comparison with other complexes. We report herein the structures of five Sn(tpp) complexes which are relevant to several of the above-mentioned studies, namely $[SnX_2(tpp)]$ (X = hydroxide, water, benzoate, salicylate and acetylsalicylate).

EXPERIMENTAL

General

IR spectra were recorded in KBr discs on a Perkin–Elmer 881 spectrometer, and visible spectra in $CHCl_3$ solutions (unless otherwise stated) on a Varian DMS100 spectrometer. NMR spectra were recorded in $CDCl_3$ on the Bruker CXP300 instrument at the Brisbane NMR Centre, Griffith University. Spectra were accumulated with 16K data points and zero filled to 32K, using spectral widths of 3500–5500 Hz. The individual satellites due to coupling of β-pyrrole protons with ^{117}Sn and ^{119}Sn were not resolved. Coupling constants are therefore averaged values determined from the top of the peak as assigned by the spectrometer computer, so are $\pm$*ca* 0.5 Hz at the digital resolution obtainable. Microanalyses were carried out by the Microanalytical Service, University of Queensland. Chloroform was distilled from anhydrous potassium carbonate and tetrahydrofuran (THF) from sodium under nitrogen. All other solvents were Ajax A.R. grade. Organic acids were Merck "zur Synthese" grade. Silver trifluoromethanesulphonate (triflate) was obtained from Aldrich.

Preparation of complexes

(a) $[Sn(OH)_2(tpp)]$ (**1**). This complex was prepared as previously reported,[6c] and crystals were grown by diffusion of pentane vapour into a $CHCl_3$ solution.

(b) $[Sn(CF_3SO_3)_2(tpp)]$ *or* $[Sn(OH_2)_2(tpp)](CF_3SO_3)_2$ (**2**). Silver triflate (160 mg, 0.63 mmol) was placed in a Schlenk flask and dried *in vacuo*. Nitrogen was admitted, then THF (*ca* 15 cm^3) was distilled from sodium into the flask. Solid $[SnCl_2(tpp)]$ (250 mg, 0.31 mmol) was added, and the mixture was stirred under nitrogen for 20 min. The solution was removed from the silver chloride by decantation through a cannula with attached filter paper, and concentrated *in vacuo* to a volume of *ca* 5 cm^3. Hexane (30 cm^3) was slowly added with stirring, to yield a fine, dark red powder. Recrystallization from THF–pentane gave maroon microcrystals (233 mg, 73%). Crystals for X-ray analysis were grown by layering pentane over a concentrated THF solution, and leaving in a refrigerator for several weeks. Elemental analysis and the crystal structure showed these to be the diaqua complex. We have subsequently prepared **2** by reaction of triflic acid with $[Sn(OH)_2(tpp)]$ in CH_2Cl_2 solution[1] (Found: C, 52.0; H, 3.0; N, 5.2. $C_{46}H_{32}F_6N_4O_8S_2Sn$ requires: C, 51.8; H, 3.0; N, 5.25%); ν_{max} (Nujol) 1295s and 1022s (SO_3), 1225vs and 1180m cm^{-1} (CF_3); δ_H *ca* 7.8 (m, 3′, 4′ and 5′), *ca* 8.3 (m, 2′ and 6′) and 9.36 [s, ^4J(SnH) 20 Hz] (see text for discussion); λ_{max} (THF) 512, 550 and 590 nm (log ε 3.49, 4.32 and 3.83), ($CHCl_3$) 420, 511, 549 and 588 nm (log ε 5.75, 3.48, 4.37 and 3.85).

(c) $[Sn(C_6H_5CO_2)_2(tpp)]$ (**3**). Solid benzoic acid (30 mg, 0.25 mmol) was added to a solution of $[Sn(OH)_2(tpp)]$ (77 mg, 0.1 mmol) in $CHCl_3$ (5 cm^3), and the mixture was stirred at room temperature for 30 min. The solution was filtered through anhydrous sodium sulphate and evaporated to dryness *in vacuo*. The residue was recrystallized from chloroform–hexane to yield violet prisms (83 mg, 86%). Crystals for X-ray analysis were grown by diffusion of pentane vapour into a CH_2Cl_2 solution (Found: C, 71.8; H, 3.9; N, 5.75. $C_{58}H_{38}N_4O_4Sn$ requires: C, 71.55; H, 3.9; N, 5.75%); ν_{max} 1649, 1314 and 1298 cm^{-1} (carboxylate); δ_H 4.90 (4H, dd, 2″ and 6″), 6.32 (4H, dt, 3″ and 5″), 6.65 (2H, dt, 4″), *ca* 7.8 (12H, m, 3′, 4′ and 5′), *ca* 8.2 (8H, m, 2′ and 6′) and 9.18 [8H, s, ^4J(SnH) 15 Hz, β-pyrrole]; λ_{max} 423, 517, 556 and 596 nm (log ε 5.78, 3.53, 4.33 and 3.98).

(d) $[Sn(2\text{-}OH\text{-}C_6H_4CO_2)_2(tpp)]$ (**4**). This complex

(94 mg, 94%) was prepared and purified as for **3** above, using salicylic acid (30 mg, 0.22 mmol) and [Sn(OH)$_2$(tpp)] (77 mg, 0.1 mmol) (Found: C, 69.2; H, 3.7; N, 5.6. $C_{58}H_{38}N_4O_6Sn$ requires: C, 69.3; H, 3.8; N, 5.6%); ν_{max} 1667, 1634 and 1307 (carboxylate) and 1363 cm^{-1} (phenol C—O); δ_H 3.96 (2H; br d, 6″), 5.67 (2H, dt, 5″), 5.97 (2H, dd, 3″), 6.57 (2H, dt, 4″), *ca* 7.8 (12H, m, 3′, 4′ and 5′), *ca* 8.2 (8H, m, 2′ and 6′), 9.21 [8H, s, ^4J(SnH) 16 Hz, β-pyrrole] and 9.3 (2H, br s, OH); λ_{max} 423, 517, 556 and 595 nm (log ε 5.76, 3.53, 4.34 and 3.98).

(e) [Sn(2-OCOCH$_3$-C$_6$H$_4$CO$_2$)$_2$(tpp)] (**5**). This complex (97 mg, 89%) was prepared as for **3** above, using acetylsalicylic acid (42 mg, 0.23 mmol) and [Sn(OH)$_2$(tpp)] (77 mg, 0.1 mmol). Crystals were grown by diffusion of pentane vapour into a $CHCl_3$ solution (Found: C, 68.0; H, 3.9; N, 5.0. $C_{62}H_{42}N_4O_8Sn$ requires: C, 68.3; H, 3.9; N, 5.1%); ν_{max} 1766, 1750 and 1363 (acetate), 1654 and 1313 cm^{-1} (carboxylate); δ_H 1.19 (6H, s, CH_3), 4.18 (2H, dd, 6″), 6.01 (2H, dd, 3″), 6.08 (2H, dt, 5″), 6.61 (2H, dt, 4″), *ca* 7.8 (12H, m, 3′, 4′ and 5′), *ca* 8.3 (8H, m, 2′ and 6′), and 9.15 [8H, s, ^4J(SnH) 15 Hz, β-pyrrole]; λ_{max} 424, 518, 557 and 596 nm (log ε 5.77, 3.53, 4.32 and 3.95).

X-ray data collection, structure solution and refinement

Data for complexes **1**–**5** were collected on Nicolet R3m diffractometers, **3**, **4** and **5** at normal temperature (293 K), **1** and **2** at low temperature (163 K). Data were corrected for absorption. Structures were solved using SHELXS 86[11] and refined using SHELX 76.[12] Disorder problems were resolved using partial site occupancies for atoms in structures **2** (in the $CF_3SO_3^-$ groups) and **5** (the peripheral phenyl rings and acetylsalicylate groups). This accounts for the rather high refinement residuals for these structures. Anisotropic thermal parameters were used for all non-hydrogen atoms in structures **1**, **3** and **4**, while for **2** and **5** isotropic factors were used. Hydrogens were incorporated only in the structures showing no disorder. These were located by difference methods and were included with refinement of both positional and thermal parameters. Neutral atom scattering factors were used,[13] while the heavy atoms were corrected for the effects of anomalous dispersion.[13]

Atomic coordinates, thermal parameters, and observed and calculated structure factors have been

deposited with the Editor as supplementary material; copies are available on request. Table 1 lists crystal data for the five compounds. Bond distances and angles for the coordination polyhedra are given in Table 2. Intraligand bond distances and angles and hydrogen atom coordinates are available from the authors.

RESULTS AND DISCUSSION

The complexes **1** and **3–5** were prepared and purified by standard methods.[1,6] The diaqua complex **2** was isolated as a result of attempts to extend the previously studied *cis*-influence series[6a] to complexes of weakly basic anions. The complex was prepared either by abstraction of chloride from $[SnCl_2(tpp)]$ with silver triflate in THF or by protonation of $[Sn(OH)_2(tpp)]$ with anhydrous triflic acid in dichloromethane. It is very insoluble in $CDCl_3$, in contrast to all other known members of the family of $[SnX_2(tpp)]$ complexes, with the exception of $X = ClO_4$. Moreover, solutions of **2** in $CDCl_3$ which initially show one major β-pyrrole signal [δ 9.36, ^4J(SnH) 20 Hz] and a minor, broader one at slightly higher field, slowly deposit solid, with diminution of the former signal. This behaviour is similar to that reported for $[Sn(ClO_4)_2(tpp)]$,[6a] and is explicable in terms of equilibria involving the covalent bis(triflate), and mono- and bis(solvento) ionic forms. Kadish *et al.*[7] recently reported similar findings for $[Sn(ClO_4)_2L]$ complexes [H_2L = tetrakis(*m*- and *p*-tolyl)porphyrin]. The earlier conclusion of a possible intermolecular aggregation[6a] is probably erroneous. In any case, the species which crystallized from THF/pentane was shown by elemental and crystal structure analyses to be the diaqua complex **2**.

The structures of the five tpp complexes have been determined with varying degrees of precision. Complex **1** (Fig. 1) has crystallographically imposed 4/*m* symmetry and exhibits none of the disorder evident in the other complexes. Because of the fourfold rotational symmetry, the hydroxyl protons are delocalized over four quarter sites and are therefore not located in the determination. The complex is isomorphous with the dichloro analogue.[8] Its ease of crystallization free from solvent molecules contrasts with the previously reported and considerably disordered structure for $[Sn(OH)_2(tpp)]$.[10] Importantly, for comparison with complexes of less basic

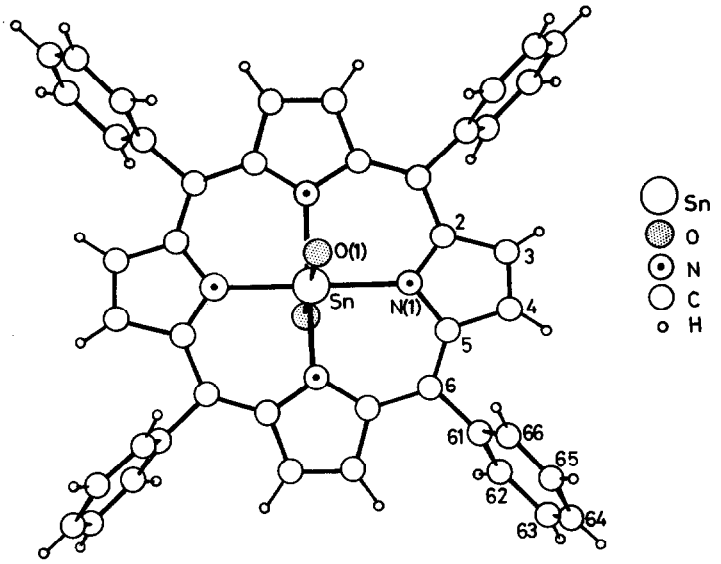

Fig. 1. Molecular configuration and atom naming scheme for **1**. The molecule has four-fold rotational symmetry down the O(1)—Sn—O(1)′ bond, while primed atoms are generated by mirror symmetry. Unless otherwise indicated, atoms are carbons.

axial ligands, the Sn—N and Sn—O bond distances [2.106(3) and 2.017(4) Å, respectively] have been determined to a higher precision than before [averages 2.09(5) and 2.02(4) Å].[10]

In crystals of compounds **2**–**5**, approximate or exact inversion symmetry is found for the [SnX_2(tpp)] species. With **2** (Fig. 2), only pseudo-inversion symmetry is present, while **3**, **4** and **5** have crystallographic inversion centres. In the case of **5**, the two independent molecules (A and B) are located about inversion centres at (0,0,0) and $(0,\frac{1}{2},\frac{1}{2})$, respectively. With these examples (**2**–**5**), various degrees of disorder were found in the peripheral substituents. However, bond distances and angles within the coordination polyhedra are considered precise enough to allow a meaningful comparison for the series. The tin(IV) ion is amongst the largest which can be accommodated within a planar tpp moiety. The Sn—N bond distances in complexes **1**–**5**, and in [$SnCl_2$(tpp)], vary only slightly, as expected for such a situation. While the core size is constrained, variation is certainly evident in the axial Sn—O distances. These increase in the order hydroxide < benzoate ≈ acetylsalicylate < salicylate < water, and so broadly follow the trend expected for mutually *trans* ligands of decreasing basicity. To complement our spectroscopic studies of the *cis*- and *trans*-influences in [Sn(tpp)] complexes, it would be interesting to determine the structures of some unsymmetrical derivatives [SnXY(tpp)]. Such studies would most likely be frustrated by redistribution equilibria, which prevent crystallization of pure complexes.[1]

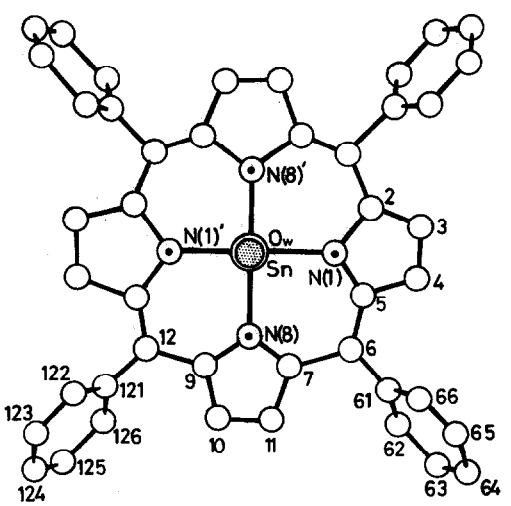

Fig. 2. Molecular configuration and atom naming scheme for **2**. Primed atoms are generated by pseudo-inversion symmetry.

The benzoate and salicylate structures are very similar (Figs 3 and 4). This is apparent not only from cell data (Table 1), but also from structural features, e.g. the conformations of the phenyl rings and the disposition of the axial ligands. The comparative C(5)—C(6)—C(61)—C(62) and C(9)—C(12)—C(121)—C(122) torsion angles for the phenyl rings are +79, −74° (**3**) and −82, +75°

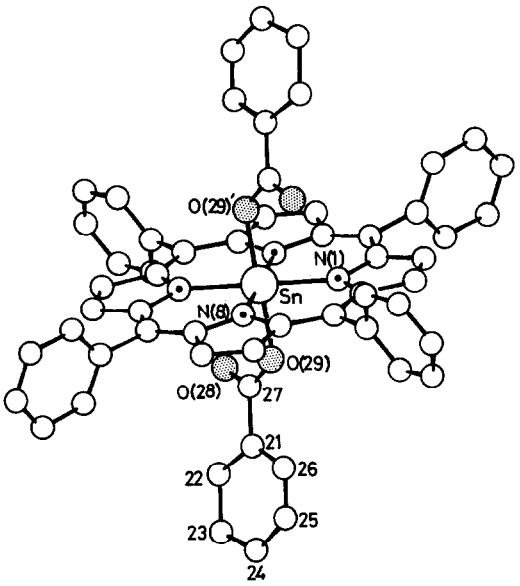

Fig. 3. Molecular configuration and atom naming scheme for **3**. Primed atoms are generated by inversion symmetry. For the tpp moiety, naming follows the convention used in **2**.

(**4**), which compare with 90° in **1**, which has mirror symmetry. The maximum deviation from 90° is found in **2** (−61°). In all carboxylate examples, the interaction with the metal is purely unidentate, the second carboxylate oxygen being 3.356(5) Å (**3**), 3.44(1) Å (**4**) and 3.28, 3.36(3) Å (**5**) from the tin atom. This further confirms the IR spectroscopic method of assigning bonding type in metalloporphyrin carboxylates,[14] since the present series shows frequency differences for the two carboxylate bands of *ca* 330 cm^{-1}. Ionic/bidentate carboxylates exhibit frequency differences of $\leqslant 150$ cm^{-1}. Furthermore, the *ortho*-hydroxy group in **3** does not interact in any way with either the tin or any atoms from adjacent molecules. However, it is clearly instrumental in maintaining the planar conformation of the whole axial ligand via intramolecular hydrogen-bonding, leading to an O—O distance of 2.50(2) Å to the non-coordinated carboxylate oxygen. In this respect it is similar to the parent salicylic acid[15] (O—O, 2.62 Å). The comparative torsion angles [C(22)—C(21)—C(27)—O(29)] for **3**, **4** and salicylic acid are +166, +174 and 180°, respectively. For the acetylsalicylate derivative **5** (Fig. 5), the complex molecule not showing disorder in the axial substituent (Molecule B), is also found to be conformationally similar to the parent acid.[16] The carboxylate group is approximately co-planar with the phenyl ring [C(22)—C(21)—C(27)—O(29), +172°] while the acetyl group is synclinally related to the ring [C(21)—C(22)—O(22)—C(30), +73°]. These compare with +178 and −85°, respectively, for acetylsalicylic acid. The packing of all complexes in their respective unit cells involves few intermolecular associations. This may be seen in Fig. 6 for **1**. The aquated porphyrin cation in **2** shows O—O contacts with the disordered triflate anions $O_w(2)$—O(3)A (2.64 Å) and $O_w(2)$—O(5)A (2.86 Å) (Fig. 7).

Finally, do these structures indicate any specific structural reasons for the salicylate selectivity of the [Sn(tpp)] based membrane electrode?[5] With the obvious caveat regarding comparisons of solution and solid-state structures, there appear to be no such special factors in operation. Likewise, the NMR data for **3**, **4** and **5** are unexceptional, although in this series only *cis*-influences can be studied. Even in the complexes $[Sn(HCO_2)(X)(tpp)]$, where *trans*-influences are observable, the ligands benzoate and salicylate are well-behaved within a series of oxygen-bound ligands.[1] The ion-selectivity displayed by the electrodes appears to have its origin in factors other than simply relative binding strengths of anions.

(*Received* 18 *May* 1990; *accepted* 26 *November* 1990)

Abstract—The system formed by dimethylthallium(III), 2-thiobarbiturate (TBA) and hydrogen ions in aqueous solution at 20°C and $I = 100$ mmol dm^{-3} (nitrate) has been characterized by means of glass-electrode potentiometry. Protonation constants for 2-thiobarbiturate and the formation constant for the complex $[(Me_2Tl)(TBA)]^-$ were found to be $\log \beta_{LH} = 10.531$, $\log \beta_{LH_2} = 12.634$ and $\log \beta_{ML} = 2.343$, respectively.

Concern about the environmental and toxicological effects of the biomethylation of heavy metals[1] has led to increasing research on the coordination chemistry of methylated metal species. Like mercury and lead, inorganic thallium can be biomethylated by anaerobic organisms in sediments.[2] But, unlike other organometallic compounds generated by biological systems, e.g. methylmercury(II), dimethylthallium(III) appears to be less toxic than other chemical forms of the metal.[3] The observed behaviour of dimethylthallium(III), probably related to its binding properties, has prompted us to study its coordination chemistry in solution with ligands offering a variety of forms of bonding.

A literature search regarding the solution chemistry of dimethylthallium(III) shows that this field is largely unexplored. Only one reference concerning equilibria with β-diketones[4] could be found in the literature. Our first study[5] on the complexation of dimethylthallium(III) by some sulphur-containing amino acids revealed that dimethylthallium(III) weakly binds with amino and thiol groups, their logarithmic stability constants being 1.2 and 2.6, respectively. The presence of both groups in the same chelating ring did not exhibit any additional effect.

Since a deeper understanding of the coordinating behaviour of dimethylthallium(III) *vis-à-vis* ligands containing nitrogen, sulphur and oxygen appeared to be desirable, the study of its complexation by 2-thiobarbiturate was chosen as a model system for studying its complexation properties. 2-Thiobarbiturate contains thioenolic, enolic and imine groups in a benzenoid heterocyclic ring (Fig. 1) and therefore can act as a multidentate ligand. A number of solid metal complexes of 2-thiobarbiturate have been characterized[6–13] and formation constants for some metal complexes in solution have been reported.[14–18] Because of its complexing properties, 2-thiobarbiturate has been used as an analytical reagent for the determination of metal ions.[19–28]

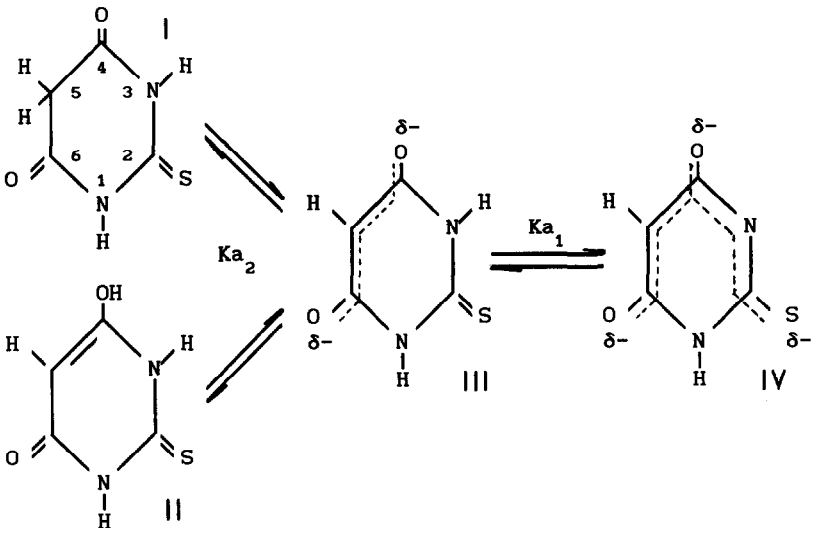

Fig. 1. Acid–base equilibria of 2-thiobarbiturate.

EXPERIMENTAL

Analytical grade reagents were used throughout. All solutions were prepared using demineralized water (Millipore system), boiled and cooled under nitrogen.

2-Thiobarbituric acid was supplied by Ega-Chemie as a biochemical grade product. Its purity was tested potentiometrically and was found to be sufficiently pure and therefore did not need further purification. Freshly prepared solutions were used for each titration and were thoroughly flushed with nitrogen before use. The poor water solubility of the ligand limited the range of ligand concentrations that could be used, i.e. 2-thiobarbiturate solutions having concentrations greater than 5 mmol dm^{-3} could not be prepared.

Stock solutions of dimethylthallium(III) nitrate, obtained as described previously,[5] were slightly acidified by adding nitric acid to prevent hydrolysis and absorption of carbon dioxide. Its mineral acid concentration was determined by titrating it with standard alkali (Gran plots).

Potassium hydroxide solutions and nitric acid solutions were prepared and standardized as previously described.[29] The ionic strength of the solution was maintained at 100 mmol dm^{-3} by the addition of potassium nitrate.

Formation constants were determined by performing potentiometric titrations at 20°C. The equipment and procedures used have already been described in detail.[29] The electrode system was calibrated in terms of hydrogen ion concentration by performing strong acid versus strong base titrations.[30] The logarithmic product of water under the same experimental conditions was found to be −13.88. The data used for the calculation of the formation constants are summarized in Table 1.

Protonation constants of 2-thiobarbiturate and formation constants of the complexes formed with dimethylthallium(III) were calculated using the latest version of the computer program library ESTA.[31–34] The approach followed in the selection of the possible species formed is discussed in detail in ref. 35. The ESTA objective function can be minimized with respect to either EMF or total ion concentration. The objective functions quoted in Table 2 are based on unweighted total ion concentration residuals (OBJT) and on weighted EMF residuals (OBJE). The weighting scheme proposed by May and Murray[33] was applied throughout the OBJE calculations. The weight at each titration point was based on errors of 0.2% in analytical concentrations, 0.01 cm^3 in titre and 0.1 mV in EMF.

Computations were done on a VAX 8700 computer and on a COMPAQ DESKPRO 386/20e microcomputer.

RESULTS AND DISCUSSION

The TBA–H^+ *system**

TBA protonation curves obtained for five protonation titrations carried out with ligand concentrations in the range 2.5–5 mmol dm^{-3} (and the conditions given in Table 1) revealed two separate buffer zones from which two protonation constants

* TBA = L^{2-} = deprotonated 2-thiobarbituric acid.

Table 1. Summary of titration data used in formation constant calculations. Number of titration points, initial total concentrations of dimethylthallium(III) (C_M), 2-thiobarbiturate (C_L) and nitric acid (C_H), and $-\log$ [H] range investigated. All concentrations are expressed in mmol dm^{-3}

System	Titration	Number of points	C_M	C_L	C_H	$-\log$[H] range
TBA–H$^+$	1	27		2.500	5.025	2.46–11.07
	2	29		5.000	5.025	2.11–11.08
	3	29		5.000	10.050	2.05–11.52
	4	42		5.000	10.050	1.91–11.85
	5	36		5.000	20.100	1.67–11.39
Me_2Tl^+–TBA–H$^+$	1	27	2.000	4.970	10.050	3.04–11.39
	2	31	2.000	4.890	10.060	3.10–10.95
	3	28	2.500	4.975	10.050	3.01–11.34
	4	29	2.500	4.975	10.060	3.04–11.09
	5	25	5.000	2.500	5.025	3.06–11.38
	6	21	5.000	5.000	10.050	3.07–10.64
	7	25	10.000	5.000	10.050	3.07–11.07
	8	28	10.000	5.050	10.050	2.84–11.34
	9	27	12.500	5.000	10.050	3.09–11.44
	10	21	15.000	5.000	10.050	2.94–10.67

were calculated. Values found are presented in Table 2. A satisfactory fit between the calculated parameters and the experimental data is indicated by reasonable values obtained for the ESTA objective functions (Table 2). Nevertheless, it should be mentioned that the experimental data do not cover all the jump corresponding to the second protonation constant (the highest $\bar{Z}_H$ values varied between 1.26 in titration 1 and 1.73 in titration 5) because of the acidic value (2.10) of the constant. This experimental limitation is reflected by the higher standard deviation associated with the corresponding calculated value.

The protonation constants found in this study are in reasonable agreement with those previously reported under similar conditions (2.10, 10.55 at 18°C in 100 mmol dm^{-3} $NaClO_4$)[16] (1.97, 10.54 at 25°C in 100 mmol dm^{-3} KCl).[36] Unfortunately, most of the data published[15,37–43] could not be considered for comparison purpose due either to the non-specification of the experimental conditions used or to the use of aqueous ethanolic mixtures to dissolve the ligand.

Assignment of the macroscopic, calculated protonation constants to the functional groups present in the molecule has been extensively discussed but

Table 2. Formation constants determined in this study at 20°C and I = 100 mmol dm^{-3} NO_3^-. ($\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r$)

inconclusive results have been obtained up until now. In fact, this problem is directly linked to the problem of determining the predominant tautomeric forms present in aqueous solution. The answer to this still remains open with regard to thiobarbiturate derivatives.

The second stepwise protonation constant (2.10) has been associated either with the ionization of the methylene hydrogen at the 5-position[37,41,42] in the tautomeric dioxothione form I or with the ionization of the phenolic group in the hydroxy-oxothione form II[38,42] (Fig. 1). Probably, both equilibria co-exist at a certain degree in solution since aqueous solutions of 2-thiobarbituric acid have been found to contain both tautomeric forms,[42,44] although the hydroxy-oxo-thione II and its zwitterion seem to predominate over the dioxothione I when the dielectric constant of the solvent increases.[44] The tentative assignment of the second protonation constant to the protonation of a nitrogen by some authors[40] seems highly improbable. A more general consensus seems to exist on the assignment of the first protonation constant (10.53) to the ionization of the HNCS group[37,41,42] (Fig. 1).

The possibility of a hydrolytic process taking place instead of the HNCS deprotonation has been carefully considered in the present work; but, although the alkaline hydrolysis of barbitals is well-documented[45] and the alkali-catalysed opening of the 1–6 bond of the pyrimidine ring has been reported in the case of 2-thiobarbituric acid,[46] no indication of ligand hydrolysis could be obtained under the experimental conditions used: all the protonation titration curves obtained at different initial ligand concentrations are fully superimposable.

The dimethylthallium(III)–TBA–H^+ *system*

The system Me_2Tl^+–TBA–H^+ was studied by performing 10 titrations with initial metal concentrations of 2.0–15.0 mmol dm^{-3}. As mentioned earlier, the upper concentrations used were limited by the poor solubility of the ligand in water. The individual metal complexation curves yielded overlapping formation curves, the maximum $\bar{Z}_M$ values found depended on the metal–ligand ratio. These maximum values never exceeded one. Thus, the experimental formation curves suggest that mononuclear binary complexes with a maximum metal–ligand ratio of one predominate. This working hypothesis was fully confirmed by applying our usual data reduction approach:[35] as expected, polynuclear (i.e. M_2L, M_2L_2), hydroxo (i.e. MLOH, $ML(OH)_2$) and high ratio ligand–metal species were systematically rejected by the computer program.

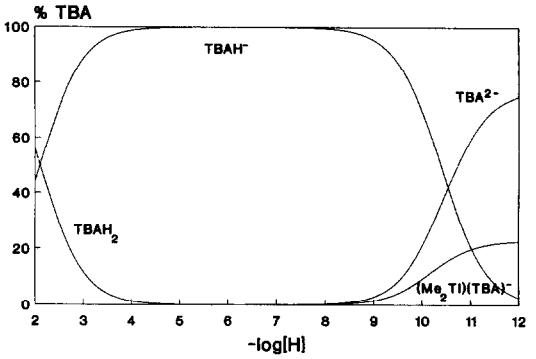

Fig. 2. Simulated species distribution of TBA: free, protonated and dimethylthallium(III)-complexed species as a function of $-\log[H]$, for TBA concentration = 5 mmol dm^{-3} and dimethylthallium(III) concentration = 2.5 mmol dm^{-3}.

A value for the MLH formation constant (12.0) was calculated by the program, but this species was discarded because the estimated error in its formation constant was unacceptable, the percentage of the complex formation negligible and its inclusion did not improve the goodness of the fit. Finally in the model chosen, only the ML complex was included and the results found for the numerical and graphical fitting (Table 2) were satisfactory.

Figure 2 shows the species distribution for this system, computed from the constants reported in Table 2, for total concentration of TBA equal to 5.0 mmol dm^{-3} and total concentration of dimethylthallium(III) equal to 2.5 mmol dm^{-3}. It can be seen that ML formation begins at $-\log[H] = 8$, when the ligand starts losing its second proton, thus implying that for coordination to occur the ionization of the NCS group is necessary. A simultaneous coordination of thallium by the N and S of the NCS group can be suggested on the basis that a similar type of coordination has been reported for the dimethyl(pyridine-2-thiolato)thallium(III) crystal structure from X-ray measurement.[47] Participation of the thiol group in the coordination is indicated by the fact that the value of the ML formation constant (2.34) is of the same order of magnitude as that of the estimated stability constant of the dimethylthallium(III) complexes formed with a deprotonated thiol group as the donor centre (2.6).[5]

The MLH species has been isolated in the solid form from an equimolar mixture of Me_2TlOH and TBA.[48] Its negligible formation in aqueous solution may be explained by its high degree of ionization, derived from the hard nature[49,50] of the coordinating atoms present in the monoanionic form of the ligand. As MLH is highly ionized in DMSO,[48] it

could be fully ionized in a solvent with a higher dielectric constant such as water.

NEW COPPER(II)–TETRAAZAANNULENE COMPLEXES. POTENTIAL BUILDING BLOCKS FOR MIXED VALENCE, CONDUCTING, MOLECULAR CRYSTALS: SYNTHESIS, EXPERIMENTAL AND THEORETICAL CHARACTERIZATION

FRANCESCO LELJ,* GIANCARLO MORELLI, GIAMPAOLO RICCIARDI and ANGELA ROSA

Dipartimento di Chimica, Università della Basilicata, Via N. Sauro 85, 85100 Potenza, Italy

(*Received* 23 *April* 1990; *accepted* 26 *September* 1990)

Abstract—Copper(II)–tetraaza[14]annulene complexes: Cu(dibenzo[b,i][1,4,8,11]tetraaza [14]annulene), Cu(dbTAA); Cu(dinaphtho[b,i][1,4,8,11]tetraaza[14]annulene), Cu(dnTAA) and Cu(diphenanthro[b,i][1,4,8,11]tetraaza[14]annulene), Cu(dpTAA) have been synthesized and studied by UV–vis spectroscopy, static magnetic susceptibility, ESR and cyclic voltammetry. UV–vis spectral evidence for Cu(dbTAA) and Cu(dnTAA) association was found in low donor ability solvents. The ground state electronic structure of Cu(dbTAA) has been investigated by very accurate SCF–LCAO calculations in the local-density approximation. According to the ESR and magnetic susceptibility data, the theoretical results indicate that the unpaired electron is shared in almost equal amounts by metal $3d_{xy}$ and ligand nitrogen orbitals. The optical transitions in the case of Cu(dbTAA) have been calculated by a ΔSCF procedure and compared with experimental spectra obtained in highly diluted solution. Cyclic voltammetry, UV–vis and theoretical calculations suggest that the dpTAA ligand both in the free state as well as in the complex strongly deviates from planarity.

Since the end of the past decade it has been known[1,2] that partial iodine oxidation of tetraazaannulene complexes of various transition metals provides an interesting class of molecular conductors. The interest in these compounds is due to the anisotropic conducting properties associated with their one-dimensionality.[3] Although the effect on their properties of the nature of the ligand and the degree of oxidation has not been systematically investigated, some studies on metal(II) (M = Ni, Cu, Co, Pd) complexes of the dianionic ligands: dibenzo [b,i][1,4,8,11]tetraaza[14]annulene^{2-} (dbTAA);[1,3–6] 5,7,12,14-tetramethyldibenzo[b,i][1,4,8,11]tetraaza [14]annulene^{2-} (dbTMTAA)[1,7–9] and other variously substituted dibenzo[b,i][1,4,8,11]tetraaza[14] annulenes^{2-},[1,3] have been undertaken. Among these, the non-substituted dbTAA ligand gave rise to the most conductive materials and showed very promising transport parameters, slightly smaller than those of "molecular metals" like (NiPc)I (Pc = phthalocyanine).[10,11]

The lack of studies on these systems is probably due to the difficulty in obtaining single crystals of the oxidized materials suitable for structural and anisotropic investigation.

In this paper we present the preparation and an experimental characterization of complexes of copper(II) with new tetraaza[14]annulene macrocyclic dianionic ligands with increasing aromatic moiety, i.e. dinaphtho[b,i][1,4,8,11]tetraaza[14] annulene^{2-} (dnTAA)$^{2-}$ and diphenanthro[b,i][1,4, 8,11]tetraaza[14]annulene^{2-} (dpTAA), as well as a detailed discussion of the influence of the ligand structure and conformation on the properties of the complexes in view of their potential

use as starting compounds for new conducting materials. Furthermore, the results concerning these compounds are compared with new data and a very accurate theoretical characterization for the analogous copper(II)dibenzo [b,i][1,4,8,11]tetraaza[14]annulene complex, Cu (dbTAA). Metal tetraazaannulene complexes have not been theoretically investigated and their chemical behaviour has been interpreted by analogy with related system metalloporphyrins and metallophthalocyanins. The little data available in the literature[1] are in agreement with our results. We compare these new compounds with substituted phthalocyanine, which has been synthesized[12] by the same philosophy suggested by us in the case of aromatic diimine ligands.[13(b)]

EXPERIMENTAL

Reagents

1,2-Diaminobenzene, 2,3-diaminenaphthalene and 9,10-diaminephenanthrene were obtained commercially (Aldrich) and purified by sublimation (10^{-2} mm Hg). Propiolaldehyde was obtained by oxidation of propargyl alcohol.[14] Crystals of I_2, 99.8% A.C.S. reagent grade, were used after resublimation. Solvents were of analytical reagent or spectrograde quality. Dimethylformamide (DMF) was dried by the standard method when used for cyclic voltammetric measurements. Elemental analyses were performed by the Analytical Laboratory, Faculty of Engineering, Potenza.

Synthesis of the compounds

The three ligands H_2dbTAA, H_2dnTAA and H_2dpTAA were obtained as previously reported for H_2dbTAA,[14] by condensation of propiolaldehyde with the appropriate diamine in a refluxing DMF–methanol (9 : 1) solution. Prolonged refluxing time, 8 h and 5 d for H_2dnTAA and H_2dpTAA, respectively, was needed.

H_2dnTAA was obtained in 60% yield as a blue–purple microcrystalline powder. Found: C, 81.3; H, 4.9; N, 14.2. Calc. for $C_{26}H_{20}N_4$: C, 80.5; H, 5.1; N, 14.5%. ^{1}H NMR signals ($CDCl_3$ solution, TMS as internal standard) at: 7.1–6.8 multiplets (aromatic protons, 12 H), 5.03 triplet (C—C*H*=C, 2 H), 7.66 multiplet (=C*H*—NH, triplet, superimposed to —C*H*=N, doublet, 4 H), 13.60 triplet (—N*H*, 2 H). UV–vis (DMF, 4×10^{-5} M): 484(3809)sh, 412(17,619), 390(20,000), 288(30,000)sh nm (mol cm^{-1}).

H_2dpTAA was obtained in 90% yield as a blue–purple microcrystalline powder. Found: C, 84.1; H, 5.3; N, 11.1%. Calc. for $C_{34}H_{28}N_4$: C, 83.0; H, 5.7; N, 11.4%. ^{1}H NMR signals ($CDCl_3$ solution, TMS as internal standard) at: 7.1–6.8 multiplets (aromatic protons, 12 H), 5.05 triplet (C—C*H*=C, 2 H), 7.69 multiplet (=C*H*—NH, triplet, superimposed to —C*H*=N, doublet, 4 H), 13.60 triplet (—N*H*, 2 H). UV–vis (acetone, 3×10^{-5} M): 412(2243)sh, 380(5128)sh, 296(23,076)sh, 276(48,076)sh nm (mol cm^{-1}).

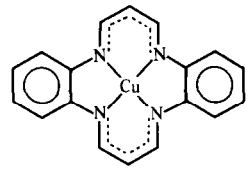
Copper complexes of the three ligands (Fig. 1) were obtained according to the procedure used for the Cu(dbTAA) complex[15] by reaction of equimolar solutions of $Cu(CH_3COO)_2 \cdot H_2O$ and of the appropriate annulene ligand in boiling DMF.

Cu(dnTAA) was obtained as dark-red crystals in 95% yield. Found: C, 69.8; H, 4.3; N, 12.6. Calc. for $C_{26}H_{18}CuN_4$: C, 69.4; H, 4.0; N, 12.4%.

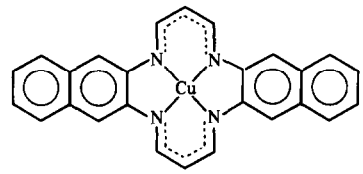
Cu(dpTAA) was obtained as yellow needle crystals in 70% yield. Found: C, 74.4; H, 4.1; N, 10.5. Calc. for $C_{34}H_{28}CuN_4$: C, 74.2; H, 4.0; N, 10.2%.

Methods

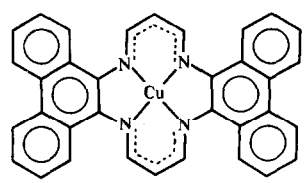
Spectroscopy and cyclic voltammetry. IR spectra were recorded on Nujol mulls with a Perkin–Elmer Model 883 spectrophotometer. Solution (DMF or CH_2Cl_2, 10 cm path length cells) UV–vis spectra



Copper(II) – dibenzo[b,i][1,4,8,11] tetraaza[14]annulene
[Cu(dbTAA)]



Copper(II) – dinaphto[b,i][1,4,8,11] tetraaza[14]annulene
[Cu(dnTAA)]



Copper(II) – diphenanthro[b,i][1,4,8,11]tetraaza[14]annulene
[Cu(dp AA)]

Fig. 1. Structures of the three complexes.

were run by using a Cary 2300 spectrophotometer. ^{1}H NMR spectra were obtained with a Bruker 300 MHz spectrometer in $CDCl_3$ solutions at room temperature. The ESR spectra were recorded with a Bruker 200D spectrometer operating at the X band and equipped with an Aspect 2000 computer for spectra accumulation and magnetic parameter calculation. Susceptibility measurements were carried out by an AZTEC-DSM5 susceptometer operating at 13,500 G equipped with a Bruker BE15 electromagnet.

D.C. cyclic voltammograms were performed by using a G&G PAR model 273 Potentiostat–Galvanostat coupled to a computerized data acquisition system. A two-compartment, three-electrode locally built cell was used. The compartment of the working electrode (Pt disk, 0.07 cm^2 of area) was separated from that of the counter electrode (Pt wire) by a very fine porosity frit glass set. As reference we used an aqueous Ag/AgCl electrode. The solutions were typically 1.5×10^{-4} M in the electroactive species and contained 0.1 M [TBA][BF_4] as supporting electrolyte in DMF. The reversible couple ferrocene–ferrocenium ion was used as an internal standard to eliminate the interference of contact potentials. Scans were run at 0.100 V s^{-1} where not stated otherwise. The scan range was 0.00 to +1.40 to 0.00 V (vs NHE) in DMF. The solutions were degassed with purified Nitrogen for 10 min before measurements and trace contamination by oxygen was avoided. All the data are reported vs NHE.

Theoretical calculations. All calculations were based on the newest vectorized version of the HFS program system[16,17] with minor modifications to allow for Becke's[18] non-local exchange correction, as well as the correlation between electrons of different spins in the formulation by Stoll *et al.*[19] based on parametrization from electron gas data, Vosko *et al.*[20] Ionization and excitation energies were obtained from the ΔSCF procedure employing the scheme for total energy differences developed by Ziegler and Rauk.[21] Relaxation effects were thus fully incorporated. The Slater type basis[22] used was of double quality for the valence shells except for the 3*d* copper orbital where a triple basis was used. A 4*p* STO polarization function for copper was added. The total molecular electron density was fitted in each SCF iteration by an auxiliary basis of *s*, *p*, *d*, *f* and *g* STOs[23] centred on the different atoms in order to represent the Coulomb and exchange potentials accurately. Use was made of the frozen core approximation.[24] In absence of experimental structural data we assumed for Cu(dbTAA) the idealized D_{2h} geometry of the planar Ni(dbTAA)[5] as standard, with the nitrogen atoms moved out from the centre to a distance of 1.90 Å, according to preliminary studies of spin-echo ESR[24] and molecular mechanics calculations.[25]

RESULTS AND DISCUSSION

UV–vis characterization

Electronic spectra of Cu(dbTAA), Cu(dnTAA) and Cu(dpTAA) were recorded using solvents with different polarity and coordination power. In Fig. 2 the spectra of the three complexes in the range 250–800 nm in DMF are reported. The absorptions for the three complexes are observed in the same spectral wavelength range as the respective free ligands (see Experimental for the absorption maxima of free ligands). The main spectroscopic behaviour of Cu(dpTAA) does not appear to be affected by the coordinating power or polarity of the solvents; conversely the electronic spectra of Cu(dbTAA) and Cu(dnTAA), when recorded in CH_2Cl_2 solutions at low concentrations (10^{-5} M), show new bands at 720 nm [Cu(dbTAA)] and 740 nm [Cu(dnTAA)]. Furthermore, an isosbestic point at 475 nm for Cu(dbTAA) and at 520 nm for Cu(dnTAA) was observed: the colour of the two solutions changes from yellow to pale green on going to lower concentration values (from 10^{-4} to 10^{-6} M). Contextually, a large deviation from the Lambert–Beer law is observed for both complexes as the concentration of Cu(dbTAA) and Cu(dnTAA) reaches 2×10^{-6} and 1.2×10^{-6} M, respectively. This behaviour can be interpreted assuming that an equilibrium exists in non-coordinating solvents, between a monomeric and a dimeric (or oligomeric) form, as previously observed for square-planar nickel(II) complexes with aromatic diimine.[13] The solubility of Cu (dpTAA) in dichloromethane was negligible.

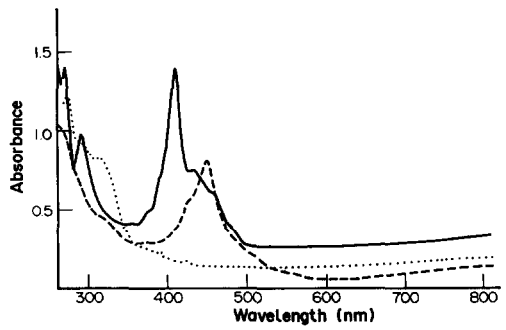


Fig. 2. UV–vis spectra of Cu(dbTAA) (solid line); Cu(dnTAA) (dashed line) and Cu(dpTAA) (dotted line) in DMF 1.8×10^{-5} M at room temperature.

Moreover, a comparative examination of the three UV–vis spectra in DMF solution (see Fig. 2) shows a bathochromic effect on going from Cu(dbTAA) to Cu(dnTAA), while Cu(dpTAA) does not follow this trend. This behaviour parallels that found for the free ligands.

In Table 1 the calculated optical transitions (*in vacuo*) are reported for Cu(dbTAA) and compared with experimental values obtained in very diluted CH_2Cl_2, since this solvent shows very low complexing ability and simulates the vacuum conditions better than DMF. There is fair agreement between the main features of the excitation spectrum; in particular, the intense absorption Soret band at 405(CH_2Cl_2), 408(DMF), 390(theoretical) can be assigned to a π–π^* transition between $4b_{2g}$ and $3a_u$ ligand-centred orbitals, whereas the α band is assigned to transitions from the $4b_{3g}$ to $3a_u$ orbital. Two further considerations suggest this assignment: (i) there is no significant shift of this band as compared with the analogous band in the free ligand spectrum; (ii) a red shift is observed in Cu(dnTAA), where the degree of delocalization increases. The pronounced shoulder of the Soret band at 385 nm is due to a charge-transfer transition from the $10b_{1g}$ HOMO orbital into the b_{1u} π ligand orbital. Moreover, transitions into the half-filled $10b_{1g}$ level span the region 486–250 nm and in the same region fall the remaining π–π^* transitions. The calculated HOMO–LUMO transition falls at too low energy (893 nm) compared with the experimental band (724 nm), so we believe that this assignment is ambiguous. In the case of complex Cu(dnTAA) a shift of 20 nm towards higher wavelengths, without an appreciable change in the shape of the spectrum, can be noted for the Soret band and its π–π^* bands. The spectrum of Cu(dpTAA) exhibits a totally different shape, being dominated by highly intense bands centred at 280, 304 and 310(sh) nm, related to the aromatic ligand moiety (as can be deduced by comparing the data of the free ligand) and probably to a charge-transfer transition. Furthermore, a band at 415 nm is observed. The spectra of all three complexes showing strong absorptions in the low wavelength region are consistent with a square-planar coordination of copper(II),[26] as also shown for Cu(dbTAA) from the theoretical results.

Table 1. Comparison of theoretical and experimental optical transitions in Cu(dbTAA)[a]

Experimental values[b]	Calculated values	Transition
724	893	$10b_{1g} \rightarrow 3a_u$
480	495	$5b_{1u} \rightarrow 5b_{2g}$
	486	$5b_{1u} \rightarrow 10b_{1g}$
	486	$4b_{3g} \rightarrow 10b_{1g}$
460	474	$4b_{3g} \rightarrow 3a_u$
427	429[c]	$4b_{3g} \rightarrow 5b_{2g}$
405[d]	390	$4b_{2g} \rightarrow 3a_u$
385	386	$10b_{1g} \rightarrow 6b_{1u}$
367	341[c]	$4b_{2g} \rightarrow 5b_{2g}$
295	309	$10b_{1g} \rightarrow 4a_u$
	295	$5b_{1u} \rightarrow 5b_{3g}$
275	264	$3b_{2g} \rightarrow 3a_u$
250	255	$2a_u \rightarrow 10b_{1g}$
	230	$12b_{3u} \rightarrow 10b_{1g}$

Cyclic voltammetry studies

The three complexes, Cu(dbTAA), Cu(dnTAA) and Cu(dpTAA), exhibit two anodic ($E_{pa,1}$; $E_{pa,2}$), totally irreversible, monoelectronic waves centred at (0.44; 0.88), (0.40; 0.70) and (0.60; 0.82) V, respectively (Fig. 3). The Cu(dbTAA) data are in good agreement with already[27,28] published data. In the case of the $E_{pa,1}$ value of Cu(dpTAA) the process becomes reversible if the sample is swept with a speed greater than 0.50 V s^{-1}. The free ligands have oxidation waves (totally irreversible) at $E_{pa,1}$ and $E_{pa,2}$ values about 0.020 V more anodic than the respective copper complexes. For all three complexes $E_{pa,2}$ shifts towards more anodic values

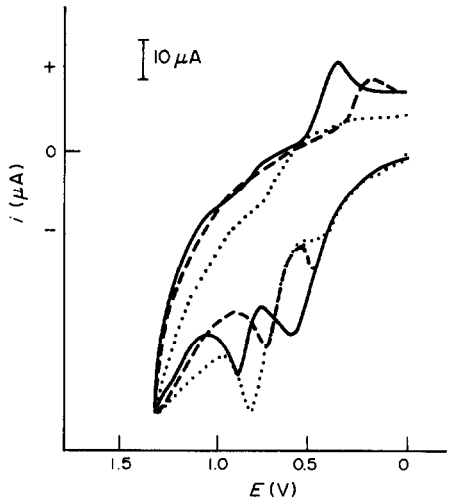

Fig. 3. Voltammograms of: Cu(dbTAA) (dotted line), Cu(dnTAA) (dashed line) and Cu(dpTAA) (solid line) in DMF solutions; scan range 0–1.300 V (potentials reported vs NHE); scan rate: 0.200 V s^{-1}; [TBA][BF4] as supporting electrolyte.

(about 0.035 V) as the scan rate is increased 10-fold on going from 0.010 to 0.200 V s^{-1}; in the same scan rate range $i_{pa}2/v^{1/2}$ is independent of v, as found for EC processes.[29] The two oxidative processes mimic the behaviour of similar tetraazaannulene complexes of various transition metals[27,28,30] and porphyrin complexes.[12] The first process generates a radical cation which undergoes further oxidation followed by homogeneous reaction. It has been noted[12] that expansion of the π system of the porphyrins by peripheral substitution of the ligand results in a lowering of the first oxidation potential of the macrocycle; this is indeed the case on going from Cu(dbTAA) to Cu(dnTAA), but the first oxidative potential of Cu(dpTAA) is higher than that found for Cu(dbTAA).

IR spectroscopy

The three complexes as well as the free ligands were investigated by IR spectroscopy in the range 200–4000 cm^{-1}. The most important features of the spectra concern the position and the intensity of the sharp and strong absorption attributable to the stretching of the C=N group bonded to the aromatic rings. We found that this band occurred for the free ligands at 1665 (H_2dbTAA), 1685 (H_2dnTAA) and 1665 cm^{-1} (H_2dpTAA), respectively; considerable shifts towards lower frequencies were observed in the copper complexes: these showed intense bands localized at 1550 (CudbTAA), 1560 (CudnTAA) and 1550 cm^{-1} (CudpTAA); the free ligands also showed a strong absorption at 3200 cm^{-1} due to N—H stretching that obviously disappeared when the complexes were formed.

Magnetic susceptibility

The static paramagnetic susceptibility (χ^S_M) of Cu(dbTAA), Cu(dnTAA) and Cu(dpTAA), measured at 290 K and corrected for the diamagnetism of the tetraazaannulene ring and the metal, at 1.32×10^{-3}, 1.33×10^{-3} and 1.28×10^{-3} emu mol^{-1}, respectively. These values correspond to 1.0 unpaired electron spin ($S = 1/2$, assuming $g = 2$) for each metallomacrocycle and are coherent with an appreciable localization of the unpaired electron on the copper atom, as shown by ESR data (*vide infra*), as well as with susceptibility data reported[31] for Cu(dbTAA).

ESR results

The ESR spectra of powders of Cu(dbTAA) (Fig. 4) exhibited a single line at $H \approx 3377$ G ($g \approx 2.065$).

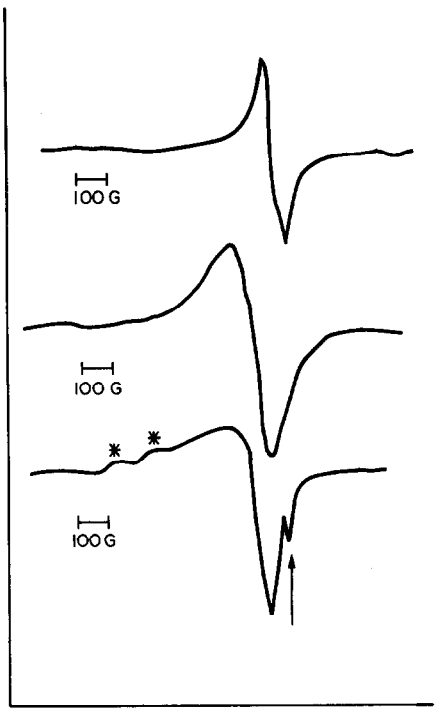

Fig. 4. Room temperature ESR powder spectra of: (a) Cu(dbTAA) (field modulation intensity: 0.25 Gpp; gain: 5.103); (b) Cu(dnTAA) (field modulation intensity: 0.25 Gpp; gain: 1.6.104); and (c) Cu(dpTAA) (field modulation intensity: 1.0 Gpp; gain: 5.104). All the spectra were recorded with a central field $H = 3200$ G and scan range 1500 G.

To our knowledge only the $A_\parallel$ 218 cm^{-1} has been determined for this complex when diluted in the metal-free ligand;[4] thus one can set this value as a lower limit for the exchange strength. The derivative absorption line shape of Cu(dnTAA) is still determined by spin–spin interactions; the signal is centred at $g \approx 2.067$, very close to the value found in the Cu(dbTAA); however the line width is $\delta H \approx 150$ G, whereas in the Cu(dbTAA) $\delta H \approx 90$ G; this indicates a lower exchange interaction. Finally the spectrum of Cu(dpTAA) can be interpreted as the superposition of two signals; the two low-field bands can be identified as slightly resolved parallel hyperfine lines with $m = 3/2, 1/2$ (asterisked in Fig. 4) due to a copper species in a relatively diluted environment; approximated evaluation of $g_\parallel$ and $g_\perp$ gives 2.30 and 2.07. The superimposed signal is a broadened line centred at $g \approx 2.08$ with a $\delta H \approx 190$ G, assignable to a copper species undergoing spin–spin exchange,[32] weakened with respect to that of Cu(dnTAA). The position ($g \approx 2.00$) and narrowness of the very low amplitude signal at $H \approx 3490$ G (arrow in Fig. 4) are similar to those

of the absorption found by other authors in systems involving phthalocyanines[33] and diamagnetic metal–phthalocyanines complexes.[34] They are attributed by Assour and Harrison[35] to a radical formed by reversible absorption of oxygen by phthalocyanines. We found that ESR spectra of our ligands showed a quite similar signal. On this basis, the partial resolution of a copper spectrum can be due to the dilution exerted by metal-free ligand molecules present as impurities.

The spectral behaviour indicates that the exchange interaction between the metallic electrons decreases by increasing the number of rings in the copper(II) complexes. This effect denotes an increased distance among the molecules in the crystal going from Cu(dbTAA) to Cu(dpTAA). In all cases the suggested arrangement of the four nitrogen atoms around the metal is planar with a little tetragonal distortion to take into account the anisotropy of the g tensor.

Ligand conformation

Both the UV–vis and cyclic voltammetry results seem to suggest that the behaviour of the dpTAA ligand does not follow the trend indicated by dpTAA and dnTAA. At present structures of the 5,7,12,14-tetramethyldibenzo[b,i][1,4,8,11]tetraaza[14]annulene (tmdbTAA) free ligand and of M(tmdbTAA) complexes (M = Ni, Co, Fe, Mn, Pd, Pt) are known[36–39] as well as the M(dbTAA) complexes (M = Ni, Pd, Cu)[3,40] [although only cell parameters and interplanar spacing have been published in the case of the mixed valence solid obtained by iodine oxidation of Cu(dbTAA)] which seem to indicate that in the case of dbTAA the free ligand in the complex is substantially planar, whereas in the case of tmdbTAA the ligand, both free and in the complex, strongly deviates from planarity. In order to check the behaviour of the whole series of our studied compounds, we have performed some molecular mechanics computations on the free ligand using the force-field of Allinger and Burkert[41] in connection with the MM2[42] program which includes the explicit treatment of π electrons by means of a Huckel–VESPR approach.[41]

Full geometry optimization (i.e. bond length, valence angles and dihedral angles) in the case of H_2(tmdbTAA) results in fairly good agreement with the X-ray experimental data of the free ligand[38] (all bond distance and valence angles within 0.02 nm and 1.1°, respectively) with the only exception being the C_{aryl}—N bond which is predicted to be 0.07 nm shorter than the X-ray data value. As regards the molecular shape, the computations indicate that the molecule also has a non-planar structure *in vacuo*. The deviation from planarity measured as the dihedral angle between both the mean phenanthrene plane and the mean pentadiiminato plane, with respect to the four nitrogen atoms, is 20.1° and 32.2°, in good agreement with the values found[38] of (25.1°, 24.1°) and (32.0°, 36.5°) for the benzene and diiminato planes, respectively. The same procedure applied in the case of H_2(dbTAA) gives a planar structure that compares well with the ligand geometry in the nickel and palladium complexes.[3]

For the H_2(dnTTA) and H_2(dpTAA) molecules the same procedure gives a different trend. In fact, while the former has the same behaviour as the H_2(dbTAA) molecule (i.e. the molecule is planar) the latter shows a fairly large deviation from planarity, as can be seen in Fig. 5. The deviation from planarity, previously defined, is 8.5° and 36.2°. The molecular distortion for tmdbTAA is due to the interaction between the methyl groups on the pentadiiminate moieties and the hydrogen atoms on the benzo moieties. On the other hand, for the dnTAA ligand the most important interaction is between the hydrogen atoms on the pentadiiminato and the phenanthrene moieties. Because the two phenanthrene moieties and pentadiiminate moieties bend out from the molecule plane, a non-negligible breaking of the molecular π conjugation results: this may well account for the different spectroscopic behaviour of the molecules and their complexes.

Electronic structure

In Fig. 6 we show the calculated ground-state level ordering of Cu(dbTAA) in terms of the copper atom and the dbTAA ligand fragment. The splitting between $10b_{1g}$ HOMO and $5b_{1u}$ SHOMO is 1.56 eV and the ground state of this complex is quite unambiguously $^2B_{1g}$.

The ground-state one-electron energies and composition of the orbitals are given in Table 2. For the Mulliken population analysis, on which the table is based, we have transformed the primitive basis set to a basis of SCF orbitals of the macrocycle and copper atom. The HOMO, shown in Fig. 7, is found to be an anti-bonding mixture (we found a Cu–dbTAA overlap population of −0.128) of almost equal amounts of Cu-$3d_{xy}$ and dbTAA-$2b_{1g}$ which, within the dbTAA ligand, is mainly localized (75.4%) on the nitrogen atoms. In fact Fig. 7(b) shows the large peaks corresponding to the Cu-d_{xy} orbital and the related N-"lone pairs" originated from the $2s$, $2p_x$ and $2p_y$ nitrogen orbitals, and the not negligible peaks due to the amplitude around the C—N—C moieties whose intensity is far larger than those of other carbon and hydrogen orbitals. Furthermore,

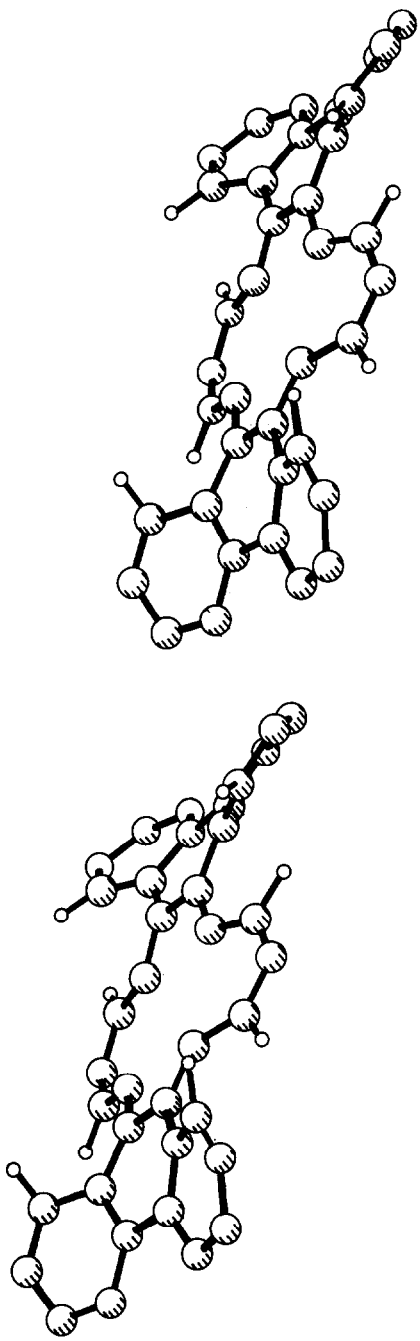

Fig. 5. Stick and ball stereo plot of the computed structure by the molecular mechanics approach to H_2dpTAA. Only strongly interacting hydrogen atoms are reported. Small ball H; medium ball C; large ball N.

as can be seen from Table 2, the HOMO is an antibonding mixture of the Cu-d_{xy} and dbTAA-$2b_{1g}$ orbitals and this is well pointed out by Fig. 7(a) which clearly shows the out-of-phase mixing of the Cu-d_{xy} and the N-"lone pairs". The bonding partner of the $10b_{1g}$ HOMO is the $9b_{1g}$ orbital which lies 5 eV below.

The σ interactions are by far the most important ones and account for the metal–macrocycle bond in the complex. The charge rearrangement due to the bond may be inferred by the Mulliken gross population given in Table 3 for each symmetry. We should note that two electrons are transferred from the copper to the B_{1u} symmetry in Cu(dbTAA), so the reference copper configuration is $3d^9 4s^0$. The $4s$ population in copper is mainly provided by the macrocycle σ-orbitals, although a small amount is due to the admixture of $4s$ into $3d_{z^2}$ orbital occurring in $15a_g$. The $4p_x$ and $4p_y$ copper orbitals are also involved to a small extent in the σ bond as it comes out from their population. From the populations given in Table 3 for B_{1g} symmetry it is immediately apparent how strong the mixing of $3d_{xy}$ is with the dbTAA-σ ($2b_{1g}$).

The large energy gap between copper-$3d$ and the ligand empty orbitals does not allow for a back-donation in the complex, as is clearly shown in the gross populations relative to B_{3g} and B_{2g} symmetry which remain substantially unchanged.

As found for metal–porphyrins,[23,43(a,b)] this complex shows a large polarity, even though the calculated copper charge (+0.75) indicates that the metal does not achieve the ionicity corresponding to its formal valence (+2). Furthermore, the charge distribution we found in the complex suggests that the delocalization in the ligand moiety only slightly involves the "1,2-diaminobenzene" five-membered chelate rings, while it is confined in benzene and to a lesser extent in diiminato rings. In particular, the calculated overlap population is 0.29 for a C—N bond in five-membered rings against the values 0.38, 0.43 and 0.43 relative to the three C—C bonds in benzene rings and 0.32 and 0.41 relative to the C—N and C—C bonds of diiminato rings, respectively. These results are in agreement with X-ray data available[5] for M(dbTAA) complexes which show a lengthening of the C_{aryl}—N bond.

CONCLUSIONS

Comparison of spectroscopic results for Cu (dbTAA), Cu(dnTAA) and Cu(dpTAA) coupled with very accurate theoretical investigations on Cu(dbTAA) allows us to consider all the compounds as complexes with the copper atom in an N_4 planar environment. Little tetragonal distortion of the metal can occur in the solid state [as also suggested by our own, and previous, ESR studies[4] on Cu(dbTAA)] to take into account the values of anisotropy for the g tensor. For Cu(dpTAA), as well as for the free ligand, appreciable deviation of the phenanthrene rings from plan-

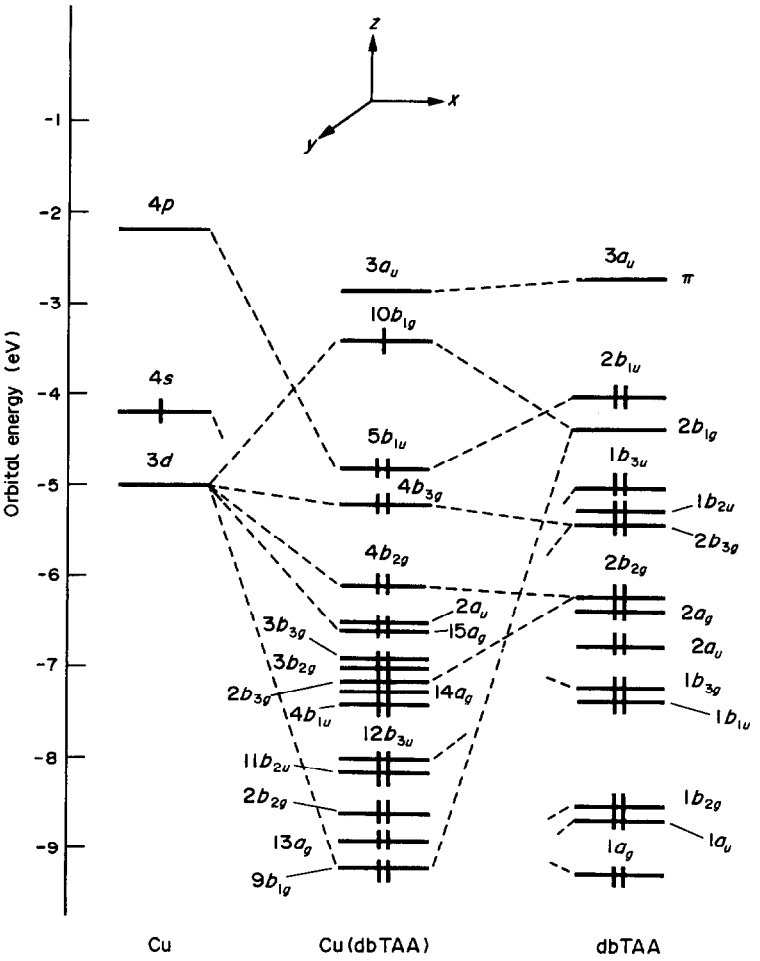

Fig. 6. Energy level diagram for Cu(dbTAA). Only some correlations are reported. The 4*p* copper atomic level does not correspond to the calculated one electron energy.

arity with respect to the macrocyclic framework can be predicted on the basis of the observed trend in the case of UV spectra. The deviation from planarity can be explained on the basis of the steric repulsion between hydrogen atoms of the diiminic carbon and the opposite hydrogen bonded to the phenanthrene ring, as supported by molecular mechanics calculations.[25] Furthermore, the distortion of the phenanthrene moiety explains well the increased distance between the copper centres in the solid state as pointed out by ESR results.

The paramagnetism of the Cu(dbTAA) complex is in agreement with the HOMO composition which indicates that the unpaired electron is shared, in almost equal amounts, by the metal-centred d_{xy} orbital and a combination of s and p orbitals of the nitrogen atoms of the ligand. Owing to the substantial structural similarity of all three complexes and on the basis of the susceptibility values and ESR measurements, it is reasonable to assume that the unpaired electron in Cu(dnTAA) and Cu(dpTAA) is similar in character to that of Cu(dbTAA).

Acknowledgements—We thank Professor E. J. Baerends for a copy of the newest version of the HFS-program system. We are indebted to Professor M. Romanelli (University of Basilicata) and Dr M. F. Ottaviani (University of Firenze) for ESR measurements and helpful discussions, Dr C. Caneschi (University of Firenze) for magnetic susceptibility measurements, Dr M. Latronico (University of Basilicata) for elemental analyses and C. Barlabà for technical support. We would like to thank Cineca of Bologna for the access to the Cray Y-MP 8/432 computer and C.I.S.I.T. of Università della Basilicata for a generous gift of computer time. SYNTHESIS, DEMETALLATION, REMETALLATION AND TRANSMETALLATION OF NEW MONO- AND BINUCLEAR SCHIFF BASE COMPLEXES

AHMED EL-TOUKHY

Department of Chemistry, Faculty of Science, University of Qatar, P.O. Box 2713, Doha, Qatar

(*Received* 23 *April* 1990; *accepted* 9 *October* 1990)

Abstract—New mono- and binuclear nickel(II) complexes [PyNi(ONS-COPh)] and [PyNi(ONS-CO)]$_2$-C_6H_4 have been prepared by a nucleophilic substitution reaction of the C—H methine-containing complex, mono-pyridine-S-methyl-N-acetylacetonehydrazinecarbodithioate nickel(II) [PyNi(HONS)], with benzoyl chloride and phthaloyl dichloride, respectively. Reaction of phenylisocyanate and *m*-xylene diisocyanate to [PyNi(HONS)] also gave new mono- and binuclear nickel(II) complexes, [PyNi(ONS-CONHPh)] and [PyNi(ONS-CONH)]$_2$-*m*-xyl, respectively. The demetallation and transmetallation of the prepared nickel(II) complexes with Na_2EDTA and copper(II) acetate monohydrate afford the corresponding mono- and binucleating ligands and mono- and binuclear copper(II) complexes, respectively. The conditions of the reliable demetallation and transmetallation reactions are described. The copper(II) complexes are also synthesized from the reaction of copper(II) acetate with the free ligands. All new compounds are characterized by various physical techniques. The mono- and binuclear nickel(II) and copper(II) complexes display magnetic and spectroscopic behaviour characteristic of square planar complexes. The ESR spectra of the mono- and binuclear copper(II) complexes are similar, indicating the absence of any magnetic coupling between the metal centres.

There has been considerable interest in the synthesis, characterization and reactivity of binuclear complexes which contain ligands capable of holding two metal ions in close proximity.[1–4] Homo- and hetero-dinuclear complexes are of interest in studies related to metalloenzymes[5,6] and bioinorganic chemistry,[7] homogeneous catalysis and the activation of small molecules (N_2, O_2, CO, CO_2, H_2),[5,8–11] multi-electron transfer processes,[12,13] redox catalysis,[14] and magnetic exchange phenomena.[15,16] Many Schiff base ligands have been synthesized which exhibit some or all of the features specified above.[1,4,17,18]

In this paper, interest has been focused upon the reactivity of the nickel(II) complex, **I**, containing a C—H methine group in a metallo-organic ring. The complex is capable, in principle, of undergoing addition–insertion reactions[4] with phenylisocyanate and *m*-xylenediisocyanate and nucleophilic substitution reactions[19–23] with benzoyl chloride and isophthaloyl dichloride according to the reaction scheme shown in Fig. 1. Demetallation of the prepared mono- and binuclear nickel(II) complexes and remetallation of the isolated ligands with copper(II) are also reported. By applying the recently discovered transmetallation procedure,[24,25] the replacement of nickel by copper (Fig. 1) is possible and the usually laborious, multistep synthesis can be avoided.

EXPERIMENTAL

Materials

All solvents used were reagent grade and were dried using standard literature procedures. The parent complex, **I**, was prepared according to the method of Iskander *et al.*[26] and recrystallized from dichloromethane. Na_2EDTA, benzoyl chloride, isophthaloyl dichloride, phenylisocyanate and *m*-xylenediisocyanate were purchased from Aldrich and used without further purification.

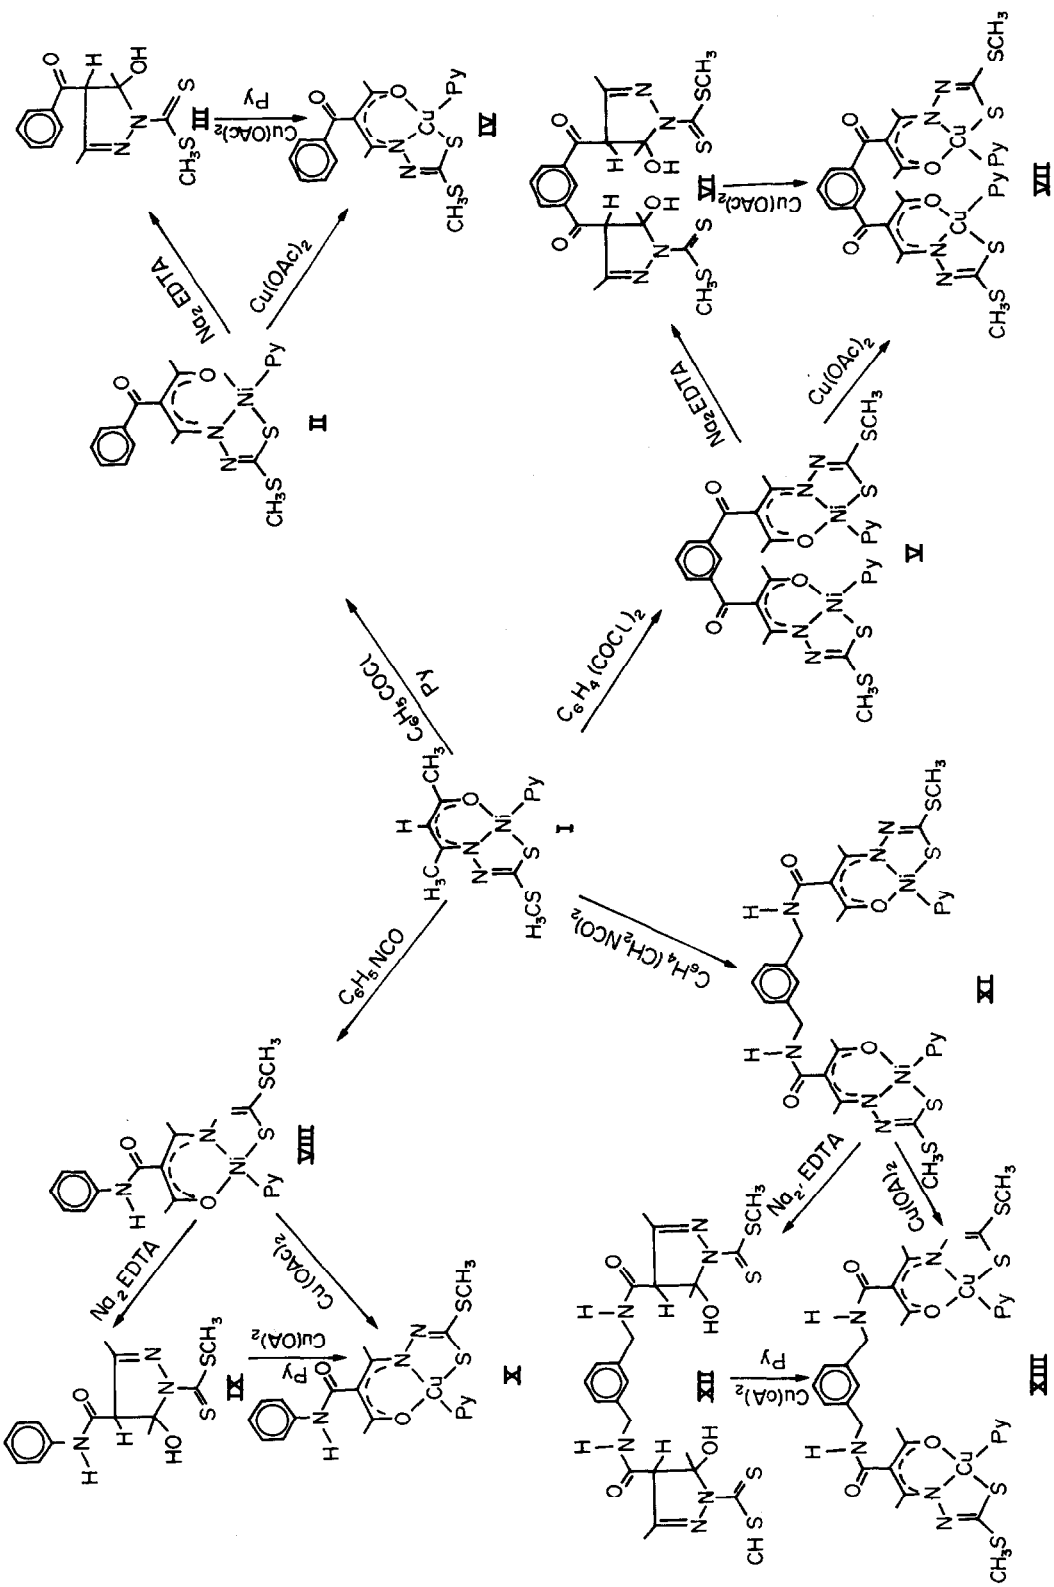

Fig. 1.

Preparation of [PyNi(ONS-COPh)] (**II**)

A clear solution of **I** (0.01 mol) in dry benzene (30 cm^3) was treated with benzoyl chloride (0.01 mol) in the presence of pyridine (0.01 mol). The reaction mixture was refluxed for 6 h with stirring, evaporated to half its volume and left to cool. A crystalline precipitate consisting of the benzoylation product and pyridine hydrochloride was filtered off, dried and treated with hot water with stirring. The brown, crystalline material was collected, washed with hot water and alcohol and recrystallized from benzene–petroleum ether (40–60°C).

Preparation of [PyNi(ONS-CO)]$_2$-*m*-xyl (**V**)

The reaction of **I** with isophthaloyl dichloride in a 2 : 1 molar ratio was performed by a procedure similar to that described above for the preparation of the title compound.

Preparation of [PyNi(ONS-CONHPh)] (**VIII**)

The title mononuclear complex was prepared by mixing a stirred solution of **I** and phenylisocyanate (1 : 1 molar ratio) in dichloromethane at room temperature for 6 h. The reaction mixture was evaporated under reduced pressure to a small volume and diluted with n-hexane. A brown solid material was collected, dried and then recrystallized from dichloromethane–hexane.

Preparation of [PyNi(ONS-CONH)]$_2$-*m*-xyl (**XI**)

This binuclear nickel(II) complex was prepared according to a method similar to that for the mononuclear nickel(II) complex, **VIII**, except that **I** and *m*-xylenedi-isocyanate were reacted in a 2 : 1 molar ratio.

Preparation of the metal free ligands: (H_2ONS-COPh) (**III**), (H_2ONS-CONHPh) (**IX**), (H_2ONS-CO)$_2$-*m*-xyl (**VI**) *and* (H_2ONS-CONH)$_2$-*m*-xyl (**XII**)

General procedure. The demetallation of the nickel(II) complexes was carried out by treating the suspended complex (0.5 g) in water (50 cm^3), with a 0.05 M Na_2EDTA solution (25 cm^3). The reaction mixture was stirred for 3 h at room temperature. The metal-free ligand was deposited as an insoluble solid, filtered off, washed with water and recrystallized from ethanol.

Preparation of copper(II) *complexes:* [PyCu(ONS-COPh)] (**IV**), [PyCu(ONS-CONHPh)] (**X**), [PyCu(ONS-CO)]$_2$-*m*-xyl (**VII**) *and* [PyCu(ONS-CONH)]$_2$-*m*-xyl (**XIII**)

(a) *Direct method.* A clear solution of the ligand, **III**, **VI**, **IX** or **XII**, in ethanol, was treated with a methanol solution of copper(II) acetate monohydrate in the appropriate molar ratio in the presence of pyridine. The reaction mixture was refluxed for 1 h, evaporated to half its volume and left to cool. The precipitated complex was filtered off, washed with ethanol and diethyl ether and dried *in vacuo*.

(b) *Transmetallation method.* A clear solution of the nickel(II) complex (0.01 mol) in methylene chloride (50 cm^3) was treated with copper(II) acetate monohydrate [0.01 mol for the mononuclear nickel(II) complexes **II** and **VIII**, and 0.02 mol for the binuclear nickel(II) complexes **V** and **XI**] in methanol (30 cm^3). The reaction mixture was stirred for 6 h at room temperature. The solvent was removed using a rotary evaporator. The copper(II) complex was extracted with methylene chloride, reprecipitated with hexane, isolated by filtration, washed with hexane and dried *in vacuo*.

Physical measurements

Nickel and copper analyses were performed on a Leeman Labs Plasma Spec inductively coupled plasma emission spectrometer. Nitrogen and sulphur analyses were performed by Mic Anal. Organic Microanalysis, Tucson, U.S.A. Cryoscopic molecular weight measurements of products were made by measuring the freezing point depression of nitrobenzene solutions containing a known amount of solute. The freezing point depression constant ($K_f = 7.00$°C mol^{-1}) for nitrobenzene was determined using benzil as a standard (see Table 1).

Solution electronic spectral measurements were made with a Perkin–Elmer 552 spectrophotometer in matched quartz cells at room temperature. The solvent, dichloromethane, was used as reference. IR spectra (KBr disks) were obtained with a Pye Unicam SP2000 spectrophotometer calibrated with the 906.5 or 3026.3 cm^{-1} absorption of polystyrene. ^{1}H NMR spectra were recorded with a Varian EM-390-90 MHz NMR spectrometer; the magnet temperature was adjusted to 38°C. A tetramethylsilane (TMS) signal ($\delta = 0$) was employed as internal standard and deutero-chloroform (Aldrich) was used as the solvent. ESR spectra were recorded at 100 kHz modulation and 10 G modulation amplitude on a Varian E-9 spectrometer. An incident power of 10 mW was used and resonance conditions were *ca* 9.75 GHz (X-band) at room temperature and *ca*

[a] Analytical methods are described in the text; calculated values are given in parentheses.
[b] In nitrobenzene: typical molar concentration, 2×10^{-2}.

9.10 GHz at 11 K. Spectra at low temperature were obtained with an Air Products LTD-3-100 Heli-Tran liquid helium transfer refrigerator; the field being calibrated with a powder sample of DPPH (g = 2.0037).[27] Magnetic susceptibilities were measured by the Gouy method using $HgCo(SCN)_4$ for calibration, and Pascal constants were used to correct all data for diamagnetism.[28]

RESULTS AND DISCUSSION

The starting mononuclear, square planar nickel (II) complex, **I**, (Fig. 1) has been prepared following the previously reported procedure.[26] The presence of a C—H methine group in the metallo-organic ring in **I** greatly assists nucleophilic substitution reactions on that centre.[19] According to the reaction procedure shown in Fig. 1, the γ-substituted mono- and binuclear nickel(II) complexes **II** and **V** were obtained by reaction of a solution of **I** in benzene with benzoyl chloride and isophthaloyl dichloride, respectively, in a 1:1 and 2:1 molar ratio in the presence of pyridine (see Experimental). Also, the mono- and binuclear nickel(II) complexes **VIII** and **XI** were obtained by reaction of **I** with phenylisocyanate and *m*-xylenediisocyanate, respectively, in a 1:1 and 2:1 molar ratio in methylene chloride at room temperature. These addition–insertion reactions were carried out almost quantitatively because the starting nickel(II) complex, **I**, and the isocyanate-containing compounds possess nucleophilic and electrophilic centres, respectively.[4]

The mononucleating (**III**, **IX**) and the binucleating (**VI**, **XII**) ligands can be obtained by the demetallation reaction of the corresponding nickel(II) complexes with aqueous Na_2EDTA,[29] (Fig. 1). These ligands can be formulated either as a cyclic pyrazoline, **XIV**, or an open chain hydrozone, **XVa**[26] (Fig. 2).

The ^1H NMR spectra of the isolated ligands in $CDCl_3$ (Table 2) show that these products exist mainly as the 5-hydroxy-2-pyrazolin-1-(S-methyl-carbodithioate), **XIV**, rather than the open chain

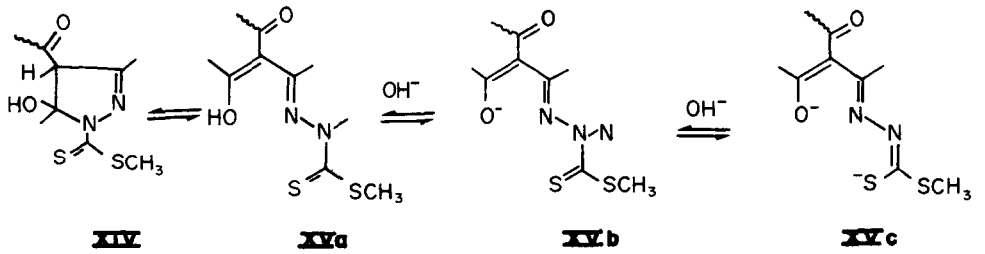

Fig. 2.

Schiff base, **XV**.[26] The electronic spectra of **III** at different values of pH provide evidence for the existence of an equilibrium between the cyclic, **XIV**, and open chain, **XV**, tautomers. By increasing the pH of the medium the equilibrium is shifted towards the formation of the dinegative anion **XVc**[26] (Fig. 2).

Remetallation of these ligands with copper(II) can be easily performed by reaction of **IV**, **IX** and **VI**, **XII** ligands with copper(II) acetate monohydrate in 1 : 1 and 1 : 2 molar ratios, respectively, in the presence of pyridine. The high affinity of such sulphur–nitrogen-containing ligands to copper, relative to nickel,[20] stimulates an interest to apply the transmetallation phenomenon[24,25] for the preparation of the mono- and binuclear copper(II) complexes **IV**, **VII**, **X** and **XIII**, to avoid the multi-step demetallation–remetallation route. The transmetallation reactions were carried out by mixing a stirred methylene chloride solution of the nickel(II) complexes with a methanolic solution of copper(II) acetate monohydrate* for 6 h at room temperature (see Experimental). The elemental analyses for the prepared ligands and complexes are given in Table 1. All the organic ligands and the nickel(II) and copper(II) complexes are quite stable at room temperature and do not show any sign of decomposition over long periods of time. All of the ligands and complexes do not possess sharp melting points but they decompose above 200°C.

Crystals suitable for X-ray crystallographic analysis have not been obtained to date. Cryoscopic measurements in nitrobenzene (Table 1) indicate that **VI** and **XII** are binucleating ligands and that **V**, **VII**, **XI** and **XIII** are all binuclear complexes.

The diffuse reflectance IR spectra of the reaction products of **I** with isocyanates, **VIII–XIII**, differ from those of the starting compounds, most notably in the absence of the intense band at 2250 cm^{-1} assignable to the ν(C=N) stretching mode of isocyanate. The IR spectra of all products, **II–XIII**, exhibit new strong broad absorptions either at *ca* 1700 cm^{-1} or *ca* 1640 cm^{-1} due to the ν(C=O) stretch of the carbonyl group in compounds **II–VII** and the amide NHCO group in compounds **VIII–**

* The metal(II) acetate is insoluble in methylene chloride which necessitated the use of methanol as the solvent in the transmetallation reaction.

Table 2. ^{1}H NMR spectra of mono- and binucleating ligands and their nickel(II) complexes in $CDCl_3$

	δ (ppm)							
Compound	SCH_3	CH_3C—O	CH_3C—N	C—H	N—H	O—H	CH_2	Aromatic H
I	2.43	2.20	1.90	5.08[a]	—	—	—	7.31–8.73
II	2.47	2.26	1.97	—	—	—	—	7.42–8.96
III	2.40	2.07	1.72	3.58	—	4.38	—	7.72–8.37
V	2.51	2.25	1.93	—	—	—	—	7.25–8.88
VI	2.38	2.11	1.78	3.52	—	4.35	—	7.64–8.52
VIII	2.54	2.28	1.94	—	9.62s	—	—	7.58–8.93
IX	2.43	2.09	1.80	3.55	9.48s	4.32	—	7.66–8.35
XI	2.53	2.27	1.96	—	9.67t[b]	—	4.30d[b]	7.39–8.86
XII	2.41	2.08	1.79	3.52	9.46t[b]	4.31	4.15d[b]	7.91–8.49

[a] Vinylic proton, s = singlet, d = doublet, t = triplet.
[b] J = 7 Hz.

XIII, respectively. The IR spectra of both **III** and **VI** ligands lack any absorption which can be attributed to N—H vibration modes. This gives further evidence for the formation of the 5-hydroxy-2-pyrazoline-1-(S-methylcarbodithioate) and excludes the possible formation of the open chain, **XV**, in the solid state. Based on the analogue of the reaction products of N,N-diacetylacetoneethylenediiminocopper(II) with isocyanates,[31] the weak sharp absorption in the IR spectra of compounds **VIII**–**XIII** at *ca* 3230 cm^{-1} can be assigned to the amide N—H stretch of the molecules. The IR spectra of metal(II) complexes show two strong but broad absorptions at *ca* 1570 and 1510 cm^{-1} which are attributed to the C⋯O and C⋯N stretching modes of the molecules. Similar spectral properties have been reported for other metal(II) Schiff base macrocycles.[2,4,32] In the far-IR region, all the metal(II) complexes show bands at *ca* 430, 390 and 280 cm^{-1} which are assigned to ν(M—O), ν(M—N) and ν(M—S) vibrations, respectively.[33,34]

The isolated nickel(II) complexes, **II**, **V**, **VIII** and **XI**, are diamagnetic in the solid state and in $CDCl_3$ solution (^{1}H NMR detectable) implying an $^1A_{1g}$ ground state.[35] The methylene chloride solution electronic spectra of these complexes (Table 1) exhibit *d–d* transitions at *ca* 400, 480 and 600 nm. No absorption was observed beyond 700 nm. Both magnetic and spectral data are consistent with a square planar arrangement of the N_2OS donor atoms around the nickel(II) ion.[26,36] The bands at *ca* 400 and 480 nm are assigned as ν_3 and ν_2, respectively.[35] The band at *ca* 600 nm is not always present in the spectra of square planar nickel(II) complexes, however, it is usually observed with complexes of sulphur ligands.[36] Indeed, the spectra of the Schiff base complexes (Table 1) are very similar to those of the nickel(II) complexes of sulphur ligands, the parent compound, **I**,[26] diethyl dithiophosphate, diethyl dithiocarbamate and ethylxanthate.[37] In fact, the spectra of the binuclear nickel(II) complexes **V** and **XI**, resemble those of the mononuclear complexes **II** and **VIII** and the parent nickel(II) complex **I**, so that the effects due to substitution and the formation of the binuclear species were not observed in the electronic spectra. The same observation was seen in the spectra of the binuclear copper(II) complexes **VII** and **XIII** and those of the mononuclear copper(II) complexes **IV** and **X** (Table 1).

The copper(II) complexes, **IV**, **VII**, **X** and **XIII**, are paramagnetic in the solid state and in solution. The room temperature effective magnetic moment of these complexes as a solid is $\simeq$ 1.85 BM/Cu centre (normal magnetic moment), which is consistent with other square planar copper(II) complexes.[38,39] The methylene chloride solution electronic spectra of these copper(II) complexes (Table 1) are typical of square planar copper(II) complexes and show a λ_{max} at *ca* 590 nm with a shoulder at *ca* 400 nm. These bands are assignable to *d–d* transitions and several bands in the UV region are assignable to L–L and charge-transfer bands. The solid-state spectra agree with the results obtained in solution, indicating that there is no change in coordination geometry as a result of solvent interactions.[40]

The ^{1}H NMR spectra of the **III**, **VI**, **IX** and **XII** ligands as well as their corresponding diamagnetic nickel(II) complexes, **II**, **V**, **VIII** and **XI**, were recorded in $CDCl_3$. Table 2 contains the ^{1}H NMR data and their respective assignments. The methine proton resonance of the acetylacetonato residue at δ 5.08 ppm appeared in the spectrum of the unsubstituted nickel(II) complexes, **I**, but disappeared in those of mononuclear **II** and **VIII** and in those of binuclear **V** and **XI** nickel(II) complexes and their demetallated products, **III**, **VI**, **IX** and **XII**, indicative of substitution. It was noted that the ^{1}H NMR spectra of all ligands and their nickel(II) complexes shows the —SCH_3 signal at δ 2.46 $\pm$ 0.08, which is essentially constant and independent of the rest of the molecule.[41,42] Two distinct singlets are observed for the free ligands, **III**, **VI**, **IX** and **XII**, and the nickel(II) complexes, **I**, **II**, **V**, **VIII** and **XI**, δ 2.07–2.28 and 1.72–1.97 ppm, which are assigned to the two inequivalent sets of methyl protons, CH_3C—O and CH_3C—N, respectively.

It is of interest to note that the chemical shifts of these methyl protons in the spectra of all nickel(II) complexes show a downfield shift compared with the corresponding organic ligands. This can be attributed to a quasi-aromatic character of the chelate ring and the resulting ring current could cause deshielding of the groups attached to the chelate ring. Similar deshielding effects were previously observed for many nickel(II) and palladium(II) chelates with sulphur-containing ligands.[41,43]

The ^{1}H NMR spectra of **XI** and **XII** show the resonance of the methylene protons of the *m*-xylene dicarbamoyl, as a bridging group, and the —SCH_3 protons at δ 4.15–4.30 ppm and δ 2.41–2.53 ppm, respectively. The ratio of the integrated intensities is 2 : 3, consistent with the formation of the binuclear species.

The N—H resonance, which disappeared on deuteration, is observed as a singlet at δ 9.62 and 9.48 ppm for **VIII** and **IX**, respectively, while in **XI** and **XII** it is observed as a triplet centred at δ 9.67 and 9.46 ppm, respectively. The chemical shifts of aromatic and pyridine protons appear as a series of multiplets at δ 6.9–8.9 ppm.

Table 3. ESR spectra of mono- and binuclear copper(II) complexes in methylene chloride

Compound	Temperature (K)	ESR parameters g_0 (A_0)[a]	$g_\parallel$ ($A_\parallel$)[a]	$g_\perp$	$\langle g \rangle$[b]	G[c]	Ground state
IV	298	2.09 (100)					
	11		2.21 (155)	2.05	2.10	4.20	$d_{x^2-y^2}$
VII	300	2.11 (95)					
	11		2.19 (140)	2.04	2.09	4.75	$d_{x^2-y^2}$
X	300	2.08 (97)					
	11		2.22 (150)	2.05	2.11	4.40	$d_{x^2-y^2}$
XIII	298	2.12 (94)					
	11		2.18 (135)	2.03	2.08	6.00	$d_{x^2-y^2}$

[a] Units are in 10^{-4} cm^{-1}.
[b] $\langle g \rangle = 1/3g_\parallel + 2/3g_\perp$.
[c] $G = (g_\parallel - 2)/(g_\perp - 2)$.

The X-band ESR spectra of mono- and binuclear copper(II) complexes, **IV**, **X**, **VII** and **XIII**, were measured in methylene chloride solution at ambient and liquid helium temperatures. The ESR spectral data are collected in Table 3. The room temperature ESR spectra of **IV**, **X**, **VII** and **XIII** are isotropic spectra with a four-line pattern ($g_0 \simeq 2.10$ and $A_0 \simeq 95 \times 10^{-4}$ cm^{-1}) observed for planar mononuclear copper(II) complexes and indicative of an electron interacting with only one copper nucleus. There are also no observable $\Delta M_s = 2$ transitions and no ligand hyperfine structure. Apparently, complexes **VII** and **XIII** exist as magnetic, noncoupled dimers in methylene chloride at room temperature. Even at 11 K the ESR spectra are consistent with a monomeric environment around each copper centre. The spectra are of axial symmetry with $g_\parallel > g_\perp$, small exchange coupling (G in the range of 4–6) and $d_{x^2-y^2}$ ground state (Table 3). This indicates square planar geometry around the copper(II) centre.[44] The rather low g values (Table 3) are typical of copper(II) chromophores containing sulphur ligands.[45] Five lines are clearly resolved on the perpendicular component, with an average spacing of 7×10^{-4} cm^{-1} indicating that the unpaired electron is interacting with two nitrogen nuclei.

CONCLUSIONS

Two new mononucleating, **III** and **IX**, and two new binucleating, **VI** and **XII**, ligands have been prepared and characterized. The four ligands form stable nickel(II) and copper(II) complexes. The spectral and magnetic properties of nickel(II) and copper(II) complexes are characteristic of a square planar ligand environment. No magnetic exchange was observed between the copper(II) centres in the solid state or in solution at room or liquid helium temperatures, indicating that the metal centres are magnetically isolated. Attempts to determine the flexibility of the binuclear system through the formation of adducts bridging both metal centres in these and other similar binuclear Schiff base complexes are in progress.

SYNTHESIS OF PHOSPHIDO-BRIDGED MULTINUCLEAR COMPLEXES VIA A MONONUCLEAR RHODIUM(I) COMPOUND: X-RAY STRUCTURES OF $Rh_3H(COD)_2(\mu\text{-}CO)_2\{\mu\text{-}P(t\text{-}Bu)_2\}_2$ AND $[Fe(CO_3)](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)\{HP(t\text{-}Bu)_2\}]$ (COD = 1,5-CYCLOOCTADIENE)

ATTA M. ARIF, DUANE E. HEATON and RICHARD A. JONES*

Department of Chemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.

(*Received* 19 *July* 1990; *accepted* 22 *October* 1990)

Abstract—The mononuclear rhodium(I) complex *trans*-$RhCl(CO)\{HP(t\text{-}Bu)_2\}_2$ (**1**) was used to form multinuclear complexes with $P(t\text{-}Bu)_2$ bridges. Reaction of **1** with n-BuLi in THF yields yellow–orange crystalline $[Rh(CO)\{HP(t\text{-}Bu)_2\}]_2(\mu\text{-}H)\{\mu\text{-}P(t\text{-}Bu)_2\}$ (**2**) (74%). Reaction of a mixture of **1** and $[Rh(COD)Cl]_2$ (COD = 1,5-cyclooctadiene) with n-BuLi in THF produces orange $[Rh(COD)](\mu\text{-}H)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)\{HP(t\text{-}Bu)_2\}]$ (**3**) (46%) and dark red $Rh_3H(COD)_2(\mu\text{-}CO)_2\{\mu\text{-}P(t\text{-}Bu)_2\}_2$ (**4**) (25%). Reaction of **1** with $Fe(CO)_5$ in refluxing toluene yields orange crystalline $[Fe(CO)_3](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)\{HP(t\text{-}Bu)_2\}]$ (**5**) (85%). The structures of **4** and **5** have been determined by X-ray crystallography. Complex **2** has been described elsewhere. The proposed structure of **3** has a planar core with a $P(t\text{-}Bu)_2$ unit and a hydride bridging a metal–metal bond. One rhodium atom is further coordinated by a COD (1,5-cyclooctadiene) ligand, while the other rhodium atom bears a CO group and an $HP(t\text{-}Bu)_2$ ligand. The molecular structure of **4** consists of a linear arrangement of three rhodium atoms with single metal–metal bonds bridged by $P(t\text{-}Bu)_2$ and CO groups. The terminal rhodium atoms are coordinated by COD ligands. The molecular structure of **5** consists of a mixed metal dinuclear complex with a single Fe—Rh bond bridged by a $P(t\text{-}Bu)_2$ unit and a CO group in a butterfly configuration. The rhodium atom is further coordinated by a CO and an $HP(t\text{-}Bu)_2$ ligand. The iron atom bears three terminal CO groups.

There has been increased interest in the synthesis of multinuclear transition metal complexes because of their potential as homogeneous catalysts, as models for heterogeneous catalysts, and as reagents for specific stoichiometric transformations.[1–3] Much attention has recently been focused on the potential of the phosphide (R_2P^-) ligand as a building block for multinuclear complexes due to its tendency to act as a bridging ligand and its ability to tolerate a wide range of metals and bonding situations.[4]

One method for preparing multinuclear complexes from mononuclear species involves deprotonation of a coordinated secondary phosphine followed by reaction with a transition metal halide.

$$L_nMPR_2H + \text{n-BuLi} \longrightarrow L_nMPR_2Li + \text{n-BuH}$$

$$L_nMPR_2Li + L_nM'X \longrightarrow L_nM(\mu\text{-}PR_2)M'L_n + LiX$$

L = ancilliary ligands; X = halide.

This approach has proven particularly useful in the synthesis of heterobimetallic complexes. For example, Geoffroy and co-workers, using $W(CO)_4(PPh_2H)_2$, have prepared a series of mixed metal complexes of the general formula $(CO)_4W(\mu\text{-}PPh_2)_2ML_x$ [$ML_x = Re(CO)_3CH_3$, $RhH(CO)(PPh_3)$, $IrH(CO)(PPh_3)$, IrH(COD), $Pt(PPh_3)$, $ZrCp_2$, $Os(CO)_3$], many of which have displayed unusual reaction chemistry.[5] Similarly, $Fe(CO)_3\{HP(t\text{-}Bu)_2\}_2$ may be used to prepare a series of novel Fe—Rh complexes of formula $[Fe(CO)_2L](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[RhL'L'']$ [$L = HP(t\text{-}Bu)_2$,

L′L″ = COD (1,5-cyclooctadiene), $(CO)_2$; L = PMe_3, L′ = PMe_3, L″ = PMe_3, CO].[6,7]

As part of a programme to investigate steric and electronic effects in transition metal phosphides (R_2P^-) we have studied multinuclear complexes containing the sterically demanding μ-P(t-Bu)$_2$ ligand. In this paper we describe studies of the mononuclear, late transition metal rhodium(I) complex *trans*-RhCl(CO){HP(t-Bu)$_2$}$_2$ (**1**)[8] (see Scheme 1). The reaction of n-BuLi with **1** produces the dirhodium complex [Rh(CO){HP(t-Bu)$_2$}]$_2$(μ-H){μ-P(t-Bu)$_2$} (**2**), which was previously synthesized via a different route.[9] A mixture of **1** and [Rh(COD)Cl]$_2$ reacts with n-BuLi to produce the asymmetric dinuclear complex [Rh(COD)](μ-H){μ-P(t-Bu)$_2$}[Rh(CO){HP(t-Bu)$_2$}] (**3**) and the unusual linear trinuclear complex $Rh_3H(COD)_2(\mu\text{-}CO)_2\{\mu\text{-}P(t\text{-}Bu)_2\}_2$ (**4**). The reaction of **1** with $Fe(CO)_5$ in boiling toluene produces the mixed metal complex [Fe(CO)$_3$](μ-CO){μ-P(t-Bu)$_2$}[Rh(CO){HP(t-Bu)$_2$}] (**5**). This paper describes the synthesis and characterization of **2**–**5**, and the X-ray crystal structures of **4** and **5**.

RESULTS AND DISCUSSION

Synthesis of [Rh(CO){HP(t-Bu)$_2$}]$_2$(μ-H){μ-P(t-Bu)$_2$} (**2**)

Reaction of *trans*-RhCl(CO){HP(t-Bu)$_2$}$_2$ (**1**) with n-BuLi in THF at 25°C produces an orange solution from which the dinuclear complex [Rh(CO){HP(t-Bu)$_2$}]$_2$(μ-H){μ-P(t-Bu)$_2$} (**2**) can be isolated following chromatography as yellow–orange solvent-dependent crystals in *ca* 71% yield. This complex has been previously described and is formed as a product of the reaction of $Rh_4(CO)_{12}$ with HP(t-Bu)$_2$ in refluxing toluene.[9] Spectroscopic data for **2** were in accord with those previously described.[9]

Although the actual mechanistic pathway by which **2** is formed is not clear, it must involve removal of chloride as well as the loss of hydrogen from a phosphine HP(t-Bu)$_2$ unit. In an effort to prepare complexes of higher nuclearity, the use of n-BuLi was investigated with a mixture of **1** and [Rh(COD)Cl]$_2$.

Synthesis of [Rh(COD)](μ-H){μ-P(t-Bu)$_2$}[Rh(CO){HP(t-Bu)$_2$}] (**3**) *and* $Rh_3H(COD)_2(\mu\text{-}CO)_2\{\mu\text{-}P(t\text{-}Bu)_2\}_2$ (**4**)

Reaction of a mixture of **1** and [Rh(COD)Cl]$_2$ (COD = 1,5-cyclooctadiene) with n-BuLi in THF at 25°C produces a deep red solution from which the dinuclear complex [Rh(COD)](μ-H){μ-P(t-Bu)$_2$}[Rh(CO){HP(t-Bu)$_2$}] (**3**) and the linear trinuclear complex $Rh_3H(COD)_2(\mu\text{-}CO)_2\{\mu\text{-}P(t\text{-}Bu)_2\}_2$ (**4**) can be isolated as orange and red crystals following chromatography. Complex **3** represents one in a series of isostructural complexes of rhodium and iridium recently characterized, with the general formula [MLL′](μ-H){μ-P(t-Bu)$_2$}[ML″L‴] (M = Rh, Ir; L,L′,L″,L‴ = two-electron donor ligand). Other complexes in this series include [Ir(CO){HP(t-Bu)$_2$}]$_2$(μ-H){μ-P(t-Bu)$_2$},[10] [Ir(CO)$_2$](μ-H){μ-P(t-Bu)$_2$}[Ir(CO){HP(t-Bu)$_2$}][10] and complex **2**. These complexes generally consist of a central metal–phosphorus core with a metal–metal bond bridged by a P(t-Bu)$_2$ ligand and a hydride; the metal atoms are further coordinated by two two-electron donor ligands producing square-planar geometry about each metal. Unfortunately, crystals of **3** were unsuitable for X-ray crystallographic studies.

The structure of **3** is assigned on the basis of spectroscopic data and the IR spectrum contains a terminal ν(CO) absorption (1944 cm^{-1}) in addition to weak ν(P—H) and ν(Rh—H) peaks at 2305 and 1891 cm^{-1}, respectively. The ^{1}H NMR spectrum contains a signal assigned to the *H*P(t-Bu)$_2$ proton [δ 4.57, ^1J(P—H) = 306 Hz] and an upfield multiplet indicative of a μ-*H* proton (δ −10.85). The $^{31}P\{^1H\}$ NMR spectrum consists of a doublet of doublets in the region expected for a coordinated phosphine [δ 56.2, ^2J(P—P) = 196 Hz, ^1J(Rh—P) = 121 Hz] and a doublet of doublets of

doublets in the region expected for a phosphido group bridging a metal–metal bond [δ 226.0, ^2J(P—P) = 196 Hz, ^1J(Rh—P) = 140 Hz, ^1J(Rh—P) = 110 Hz].[11] Both signals show coupling to each other as well as the appropriate number of rhodium atoms. Unfortunately, crystals of **3** were unsuitable for X-ray crystallographic studies.

For complex **4**, spectroscopic data are in accord with the structure as determined by X-ray crystallography and the IR spectrum exhibits bands in the regions expected for a terminal hydride (1947 cm^{-1}) and bridging carbonyl groups (1832 cm^{-1}). The ^1H NMR of **4** exhibits a multiplet shifted upfield in the region expected for a hydride (δ −8.35). The $^{31}P\{^1H\}$ NMR of **4** in C_6D_6 (ambient temperature) shows a broad multiplet shifted well down field (δ 228.2) indicative of phosphido groups bridging metal–metal bonds.[12]

X-ray structure of **4**

Molecules of **4** crystallize in the monoclinic space group $P2_1/n$ with two molecules in the unit cell. Figure 1 shows the molecular geometry and atom numbering scheme and selected bond lengths and angles are given in Tables 1 and 2, respectively. The structure of **4** was successfully solved with each molecule possessing a centre of inversion at Rh(1).

The core of **4** contains a precisely linear arrangement of three singly-bonded rhodium atoms with each bond bridged by a μ-P(t-Bu)$_2$ unit and a carbonyl ligand. Due to the centre of inversion, the μ-P(t-Bu)$_2$ groups are *trans* to each other through Rh(1), as are the μ-CO groups. The two terminal rhodium atoms are each coordinated to a 1,5-cyclooctadiene ligand and the molecule thus has a planar core consisting of the three rhodium atoms, the two phosphorus atoms and the two carbonyl groups. Hydrogen atoms were not located in the structure and so the location of the single hydride ligand cannot be determined unequivocally. A model involving crystals of **4** which contain equal amounts of the hydride bridging Rh(1)—Rh(2) as well as Rh(1)—Rh(2)′ would be consistent with the crystallographically imposed symmetry of the molecule. Although simple electron counting procedures are often misleading, if one arbitrarily assigns the single Rh—H to Rh(1) then each rhodium atom is formally rhodium(I); the terminal rhodium atoms, Rh(2) and Rh(2)′, would then have electron counts of 16, while Rh(1) would have 18 electrons. The two Rh—Rh bond distances

[2.818(2) Å] are within normal limits for a Rh—Rh single bond. The Rh—P distances [2.296(5) and 2.275(5) Å] and the Rh—C(1) distances [2.19(5) and 1.94(5) Å] are also typical of those for phosphido and carbonyl groups bridging a Rh—Rh bond, and all other structural parameters for the molecule fall within reasonable limits.

There are few structurally characterized examples of open phosphido-bridged trinuclear complexes and, to the best of our knowledge, **4** represents the first with an accurately linear metal core. Some other examples of such compounds and the angle between the three metal atoms are as follows: $[Rh\{Fe(\mu\text{-}PPh_2)(\mu\text{-}CO)_2(\eta^5\text{-}C_5H_4Me)\}_2]^+$ [145.03(5)°],[13] $Fe_3(\mu\text{-}PMe_2)_3(CO)_4(NO)_3$ [160.1(3)°],[11] $Fe_2Co(\mu\text{-}PMe_2)_3(CO)_5(NO)_2$ [161.1(2)°][11] and $PtMn_2(\mu\text{-}PPh_2)_2(CO)_9$ [159.56(4)°].[14]

Synthesis of $[Fe(CO)_3](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)\{HP(t\text{-}Bu)_2\}]$ (**5**)

Reaction of **1** with $Fe(CO)_5$ in boiling toluene produces a red–black solution from which the mixed metal dinuclear complex $[Fe(CO)_3](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)\{HP(t\text{-}Bu)_2\}]$ (**5**) can be isolated as red–orange crystals following chromatography in *ca* 85% yield. Spectroscopic data for **5** are in accord with the structure as determined by X-ray crystallography, and the IR spectrum exhibits bands in the regions expected for terminal carbonyl groups, a bridging carbonyl group (1843 cm^{-1}) and a P—H unit (2310 cm^{-1}). The ^1H NMR of **5** exhibits a signal corresponding to the proton on the coordinated phosphine [δ 4.398, $^1J(P—H) = 312$ Hz]. The $^{31}P\{^1H\}$ NMR of **5** shows two doublets of doublets one of which is shifted well down field (δ 220.9) indicative of a phosphido group bridging a metal–metal bond.[12] The other multiplet (δ 62.6) is in the region expected for a coordinated phosphine ligand.

This complex represents one in a series of μ-P(t-Bu)$_2$ bridged Fe—Rh dinuclear complexes which include $[Fe(CO)_2(HP(t\text{-}Bu)_2)](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(COD)]$ (COD = η^4-1,5-cyclooctadiene),[6] $[Fe(CO)_2\{HP(t\text{-}Bu)_2\}](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)_2]$,[7] $[Fe(CO)_2(PMe_3)](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(PMe_3)_2]$[7] and $[Fe(CO)_2(PMe_3)](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)(PMe_3)]$[7] and these compounds appear to be isostructural with **5**.

X-ray structure of **5**

Molecules of **5** crystallize in the monoclinic space group $P2_1/a$ with four molecules in the unit cell. Figure 2 shows the molecular geometry and atom numbering scheme of complex **5**, and selected bond lengths and angles are given in Tables 3 and 4, respectively. The overall molecular geometry contains a single Fe—Rh bond [Fe—Rh = 2.670(1) Å] which is bridged by a μ-P(t-Bu)$_2$ group and a semibridging CO ligand [C(4)—O(4)] in a butterfly configuration. The Fe(1)—C(4)—O(4) angle of 157.5(8)° and the Fe(1)—C(4) distance of 1.840(9) Å indicate only a slight degree of bonding to the rhodium atom. Thus, the Rh(1)—C(4) distance is relatively long [2.268(9) Å] and the Rh(1)—C(4)—O(4) angle relatively acute [121.5(7)°]. The

coordination geometry about iron, ignoring the Fe—Rh bond, is roughly trigonal bipyramidal and the μ-P(t-Bu)$_2$ group occupies an axial position *trans* to a terminal carbonyl ligand [C(1)—O(1); P(1)—Fe(1)—C(1) = 175.3(3)°]. The two remaining terminal carbonyl groups and the semi-bridging CO ligand are virtually co-planar and occupy the equatorial positions around the iron atom with the sum of the angles subtended about iron = 359.7°. The rhodium atom of **5** has a roughly square-planar coordination geometry with the μ-P(t-Bu)$_2$ group and the HP(t-Bu)$_2$ ligand *trans* to each other [P(1)—Rh(1)—P(2) = 164.32(8)°]. The Fe(1)—Rh(1) distance as well as the Fe(1)—P(1) and Rh(1)—P(1) distances are normal [Fe(1)—P(1) = 2.301(3) Å, Rh(1)—P(1) = 2.262(2) Å] and can be compared along with all other structural parameters to those found in similar complexes.[6,7]

EXPERIMENTAL

All reactions were performed under oxygen-free nitrogen or *in vacuo*. Hexane, THF and toluene

were dried over sodium and distilled from sodium–benzophenone under nitrogen before use. Instruments: IR, Perkin–Elmer 1330, Digilab FTS-40; NMR, Varian EM-390 (^{1}H 90 MHz), Nicolet NT 360 (^{1}H), FT-80 (^{31}P, 32.384 MHz), GE QE-300 (^{1}H, ^{31}P). IR spectra were run as Nujol mulls by using NaCl disks or in solution (matched KBr cells). NMR spectra were recorded in C_6D_6 at ambient temperature unless otherwise stated and are in ppm referenced to Me_4Si (δ 0.0, ^{1}H) and 85% H_3PO_4(aq.) (δ 0.0, ^{31}P). Melting points were obtained in sealed capillaries under nitrogen (1 atm) and are uncorrected. Complex **1**[8] and $[Rh(COD)Cl]_2$[15] were prepared as previously described.

Synthesis of $[Rh(CO)\{HP(t\text{-}Bu)_2\}]_2(\mu\text{-}H)\{\mu\text{-}P(t\text{-}Bu)_2\}$ **(2)**

To a solution of *trans*-$RhCl(CO)\{HP(t\text{-}Bu)_2\}_2$ **(1)** (0.23 g, 0.50 mmol) in THF (40 cm^3) at room temperature was added n-BuLi (0.42 cm^3 of a 2.4 M hexane solution, 1.0 mmol) dropwise with a syringe. The solution darkened immediately and was left to stir for 1 h. Volatile materials were removed *in vacuo* and the residue was extracted with hexane (2×15 cm^3). The filtered combined extracts were concentrated *in vacuo* (*ca* 15 cm^3) and passed down a column of alumina (4 cm × 3 cm) using hexane as the eluent, giving a yellow–orange band which was collected. The solution was concentrated *in vacuo* (*ca* 10 cm^3) and cooled (−40°C), producing yellow–orange, solvent-dependent crystals of **2** which were collected and dried *in vacuo*. Yield 0.13 g, 74.0%, based on rhodium.

Synthesis of $[Rh(COD)](\mu\text{-}H)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)\{HP(t\text{-}Bu)_2\}]$ **(3)** *and* $Rh_3H(COD)_2(\mu\text{-}CO)_2\{\mu\text{-}P(t\text{-}Bu)_2\}_2$ **(4)**

To a mixture of *trans*-$RhCl(CO)\{HP(t\text{-}Bu)_2\}_2$ **(1)** (0.19 g, 0.41 mmol) and $[Rh(COD)Cl]_2$ (0.30 g, 0.61 mmol) in THF (40 cm^3) at room temperature was added n-BuLi (0.49 cm^3 of a 3.3 M hexane solution, 1.63 mmol) dropwise with a syringe. The solution immediately darkened to deep red and was left to stir for 1 h. Volatile materials were removed *in vacuo* and the residue was extracted with hexane (2×25 cm^3). The filtered combined extracts were concentrated *in vacuo* (*ca* 15 cm^3) and passed down a column of alumina (15 cm × 3 cm) using hexane as the eluent. This resulted in three fractions (orange, purple and red) which were collected. The first and third fractions were concentrated *in vacuo* (*ca* 10 and 5 cm^3, respectively) and cooled (−40°C) producing orange crystals of **3** and red crystals of **4**, respectively, which were collected and dried *in vacuo*. The second fraction is still under investigation. For **3**: Yield 0.12 g, 45.7%, based on **1**. M.p.: 163–168°C (dec.). IR (Nujol mull): 2304m, 1944s, 1891w,sh, 1510w, 1435m, 1379w, 1358m, 1331w, 1304w, 1171m, 1025m, 1017m, 848m, 810m (cm^{-1}). ^{1}H NMR (300.152 MHz): δ 5.49 (br. mult., 2H, COD), 5.10 (br. mult., 2H, COD), 4.57 [d, 1H, ^1J(P—H) = 306 Hz, *H*P(t-Bu)$_2$], 1.95 (br. mult., 8H, COD), 1.46 [d, 18H, ^3J(P—H) = 13 Hz, μ-P(t-*Bu*)$_2$], 1.20 [d, 18H, ^3J(P—H) = 15 Hz, HP(t-*Bu*)$_2$], −10.85 (mult., 1H, μ-*H*). ^{31}P{^{1}H} NMR (121.503 MHz): δ 225.7 [ddd, ^2J(P—P) = 196 Hz, ^1J(Rh—P) = 140 Hz, ^1J(Rh—P) = 110 Hz, μ-*P*(t-Bu)$_2$], 56.2 [dd, ^2J(P—P) = 196 Hz, ^1J(Rh—P) = 121 Hz, H*P*(t-Bu)$_2$]. For **4**: Yield 0.09 g, 24.9%, based on **1**. M.p.: 155–158°C (dec.). IR (Nujol mull, NaCl plates): 1947m, 1832s, 1353m, 1347m,sh, 1324w, 1298w, 1168m, 1069w, 1012m, 942w, 928w, 860w, 839w, 807m (cm^{-1}); (hexane solution, KBr cells): 1949w, 1851m (cm^{-1}). ^{1}H NMR (361.084 MHz): δ 5.62 (br. mult., 4H, COD), 5.09 (br. mult., 4H, COD), 2.06 (br. mult., 16H, COD), 1.45 [t, 36H, μ-P(t-*Bu*)$_2$], −8.35 [dtt, 1H, ^1J(Rh(1)—H) = 25 Hz, ^2J(P—H) = 13 Hz, ^2J(Rh(2)—H) = 9 Hz, Rh—*H*]. ^{31}P{^{1}H} NMR (32.384 MHz): δ 228.2 [br. mult., μ-P(t-Bu)$_2$].

Synthesis of $[Fe(CO)_3](\mu\text{-}CO)\{\mu\text{-}P(t\text{-}Bu)_2\}[Rh(CO)\{HP(t\text{-}Bu)_2\}]$ **(5)**

$Fe(CO)_5$ (1.0 cm^3) was added to a solution of **1** (0.41 g, 0.90 mmol) in toluene (40 cm^3) and the resulting mixture was refluxed (4 h) during which time the solution gradually turned black–green with the formation of considerable black precipitate. The mixture was filtered and the black residue was washed with toluene (15 cm^3). The resulting solution was passed down an alumina column (3 cm × 3 cm) giving a yellow–orange band which was collected. Volatile materials were removed *in vacuo* and the residue was dissolved in hexane (10 cm^3) and cooled (−40°C), producing orange crystals of **5** which were collected and dried *in vacuo*. Yield: 0.45 g, 85%, based on rhodium. M.p.: 138–139°C (dec.). IR (Nujol mull, NaCl plates): 2310w, 2024s, 1962s, 1950s, 1905w,sh, 1843br, 1362m, 1168s, 1023m, 930m, 887m, 825m, 803s, 624m, 605m (cm^{-1}); (hexane solution, KBr cells): 2025s, 1965s, 1952s, 1921w, 1855br (cm^{-1}). ^{1}H NMR (361.084 MHz): δ 4.40 [d, 1H, ^1J(P—H) = 312 Hz, *H*P(t-Bu)$_2$], 1.37 [d, 18H, ^3J(P—H) = 14 Hz, μ-P(t-*Bu*)$_2$], 1.17 (d, 18H, ^3J(P—H) = 14 Hz, HP(t-*Bu*)$_2$]. ^{31}P{^{1}H} NMR (32.384 MHz): δ 220.9 [dd, ^1J(Rh—P) = 97 Hz, ^2J(P—P) = 189 Hz, μ-*P*(t-Bu)$_2$], 62.6 [dd, ^1J(Rh—P) = 126 Hz, ^2J(P—P) = 189 Hz, H*P*(t-Bu)$_2$].

X-ray experimental data

Details of crystal data and a summary of intensity data collection parameters for **4** and **5** are given in Table 5. Data were collected on an Enraf–Nonius CAD-4 diffractometer at 23±2°C using graphite monochromated Mo-K_α radiation. All calculations were performed on a PDP 11/44 computer using the Enraf–Nonius software package "SDP-PLUS".[16] For each structure, the data were corrected for Lorentz and polarization effects. The structures were solved by direct methods (MULTAN)[17] and suc-

[a] $R = \Sigma|F_o| - |F_c|/\Sigma|F_o|$.

[b] $R_w = [\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega(|F_o|)^2]^{1/2}$. The function minimized in the least-squares refinement was $\Sigma\omega(|F_o| - |F_c|)^2$, $\omega = 1/\sigma^2(|F_o|)$.

cessive cycles of difference Fourier maps followed by least-squares refinement.

Complex **4**. Crystals suitable for X-ray diffraction were grown by cooling a hexane solution (−35°C). The crystals were mounted in thin walled glass capillaries and sealed under nitrogen. Unit cell parameters were obtained by centring 25 reflections having 2θ values between 20 and 26°. The monoclinic space group $P2_1/n$ was uniquely determined by the systematic absences $h01$, $h+1=2n+1$, $0k0$, $k=2n+1$ and data were collected in the $+h+k\pm l$ quadrant between 2θ values of 3 and 48°. The check reflections indicated < 1% decrease in intensity over the course of data collection, and hence no correction was applied. A ψ scan of four reflections having χ values between 80 and 90° showed that no absorption correction was necessary and none was applied. The observed structure factors of equivalent reflections were averaged. Hydrogen atoms were not located, but their contributions were included in the final refinements, while all non-hydrogen atoms except for O(1), C(1) and C(2) were refined anisotropically. Data with intensities less than $3.0\sigma(I)$, $(\sin\theta)/\lambda$ greater than 0.55 and $(\sin\theta)/\lambda$ less than 0.05 were excluded, and a non-Poisson contribution weighting scheme with an experimental instability factor of $P=0.06$ was used in the final stages of refinement.* The maximum peak in the final difference Fourier map had a height of 1.468 e/Å^3 and was located 0.657 Å from Rh(1).

Complex **5**. Crystals suitable for X-ray diffraction were grown by cooling a hexane solution (−35°C). The crystals were mounted in thin walled glass capillaries and sealed under nitrogen. Unit cell parameters were obtained by centring 25 reflections having 2θ values between 22 and 26°. The monoclinic space group $P2_1/a$ was uniquely determined by the systematic absences $h01$, $h=2n+1$, $0k0$, $k=2n+1$. Data were collected in the $+h+k\pm l$ quadrant between 2θ values of 3 and 48°. The check reflections indicated a 1.4% decrease in intensity over the course of data collection, and hence no correction was applied. A ψ scan of four reflections having χ values between 80 and 90° showed a minimum transmission of 75.3% and a maximum transmission of 99.8%. An empirical absorption correction was applied. The observed structure factors of equivalent reflections were averaged. Hydrogen atoms were not located, but their contributions were included in the final refinements. Data with intensities less than $3.0\sigma(I)$ and $(\sin\theta/\lambda)$ less than 0.10 were excluded, and a non-Poisson contribution weighting scheme with an experimental instability factor of $P=0.06$ was used in the final stages of refinement.* The maximum peak in the final difference Fourier map had a height of 1.303 e/Å^3 and was located 0.660 Å from Rh(1).

Acknowledgements—We thank the National Science Foundation (CHE-8818984) and the Robert A. Welch Foundation (F-816) for support.

* P is used in the calculation of $\sigma(I)$ to downweight intense reflections in the least square refinement. The function minimized was $\Sigma\omega(|F_o|-|F_c|)^2$, where $\omega=4(F_o)^2/[\Sigma(F_o)^2]^2$, in which $[\Sigma(F_o)^2]^2=[S^2(C+R^2B)+\{P(|F_o|)^2\}^2]/(L_p)^2$ (S is the scan rate, C is the total integrated peak count, R is the ratio of scan time to background counting time, B is the total background count and L_p is the Lorentz-polarization factor).

(*Received* 3 *April* 1990; *accepted* 31 *October* 1990)

Abstract—From reactions of $Co(dppm)_2Cl_2$ or $Co(dppm)Cl_2$ with thiolate and elemental selenium or sulphur in DMF, the following complexes were prepared in good yields: $[Co_2(dppm)(\mu\text{-}SR)_2(SR)_2]$ (R = C_6H_5, **1**; *m*-$C_6H_4CH_3$, **2**; *p*-$C_6H_4CH_3$, **3**; and *p*-C_6H_4-$^tC_4H_9$, **4**). Compound **1** crystallizes in two different isomeric crystals, **1A** and **1S**, containing three stereoisomers of molecular conformations: **1aa**, **1sa** and **1ss**. The two different crystal structures of compound **1** were confirmed by thermal analysis and IR spectra. Compound **2** crystallizes with molecules of type **ss**. Compound $[Co_2(dppe)(\mu\text{-}SPh)_3(SPh)]$ (**5**) is an asymmetric molecule with one five-coordinate cobalt atom and one four-coordinate cobalt atom. From the EPR spectra and magnetic susceptibility data, it is deduced that there is antiferromagnetic coupling between the two paramagnetic cobalt(II) atoms in compounds **1**–**5**.

Tertiary phosphine ligands have played a major role in modern coordination chemistry.[1] Ditertiary phosphine complexes of transition metals have been studied extensively recently, not only due to their variation of structures and properties, but also because of their application as homogeneous or heterogeneous catalytic functions.[2] Metal thiolato complexes are known as ubiquitous biological electron-transfer mediators,[3,4] yet complexes containing both diphosphine and thiolato ligands have received relatively little attention and only a few reports have been found in this area.[5]

We have explored the coordination chemistry and the reactivity of metal complexes combining both ditertiary phosphine and thiolate ligands. Herein we report the syntheses and stereochemistry of two types of dicobalt complexes: $[Co_2(dppm)(\mu\text{-}SR)_2(SR)_2]$ (R = Ph, **1**; *m*-tol, **2**; *p*-tol, **3**; and *p*-tbb, **4**)† and $[Co_2(dppe)(\mu\text{-}SPh)_3(SPh)]$ (**5**) with a mole ratio of 2:1 for metal–diphosphine. A preliminary account of the asymmetrical dicobalt(II) complex **5** has been communicated elsewhere.[6]

EXPERIMENTAL

All operations were carried out under a dinitrogen atmosphere. The reagent dppm was purchased from Aldrich, thiols from Merck, solvents and $CoCl_2 \cdot 6H_2O$ from the Shanghai Factory of Chemical Reagents. Solvents were dried, distilled and gassed prior to use. $Co(dppm)Cl_2$ and $Co(dppm)_2Cl_2$ were prepared according to the literature method.[7]

Preparation of $[Co_2(dppm)(\mu\text{-}SPh)_2(SPh)_2]$ (1)

(i) *From* $Co(dppm)Cl_2$ *and elemental sulphur.* A mixture of NaSPh (0.264 g, 2 mmol) and elemental sulphur (0.032 g, 1 mmol) in DMF (20 cm^3) formed an orange solution after stirring for 30 min. The

† Abbreviations: Ph, C_6H_5; tol, $C_6H_4CH_3$; tbb, tert-butylbenzyl (C_6H_4-$^tC_4H_9$); dppm, bis(diphenylphosphino)methane; dppe, 1,2-bis(diphenylphosphino) ethane; dppp, 1,3,-bis(diphenylphosphino)propane; b for bridge; t for terminal; IR, infrared; EPR, electron paramagnetic resonance.

solution turned crimson–black after addition of $Co(dppm)Cl_2$ (0.514 g, 1 mmol) and stirring for 30 min. Part of the solvent was removed under reduced pressure at 40°C to yield a sticky liquid.

(ii) *From* $Co(dppm)_2Cl_2$ *and elemental selenium.* The procedure is similar to that of (i) except 1.5 mmol of elemental selenium (0.118 g) was used and $Co(dppm)Cl_2$ was replaced by $Co(dppm)_2Cl_2$. A sticky liquid was also obtained after concentrating the solution at 40°C.

(iii) *Crystallization of* **1A**. Ethanol (10 cm^3) was added to either of the above sticky liquids from (i) or (ii) and the mixture was stirred for 15 min. After standing overnight at room temperature, the precipitate was removed by filtration. The solution was kept at 5°C for 3 weeks and the black, octahedral-shaped crystals were collected, washed with ethanol and ether, and dried *in vacuo* to afford 0.39 g (83%) of crystal **1A**. Found: C; 62.2; H, 4.5; Co, 12.4; P, 6.6; S, 13.5. Calc. for $C_{49}H_{42}Co_2P_2S_4$: C, 62.3; H, 4.5; Co, 12.6; P, 6.6; S, 13.7%. IR data and magnetic moment values are summarized in Table 1. The solution was sensitive to both air and water, but the crystal was stable in dry air for weeks.

(iv) *Crystallization of* **1S**. Ethanol (40 cm^3) was added to either of the above sticky liquids from (i) or (ii). After stirring slowly for 5 min, the precipitate was removed by filtration. The filtrate was kept at 0°C for 4 days. Black, rhombic, plate-shaped crystals were collected and washed with ethanol and ether to afford 0.35 g (74%) of **1S**. Found: C, 62.4; H, 4.7; Co, 12.5; P, 6.1; S, 13.2. Calc. for $C_{49}H_{42}Co_2P_2S_4$: C, 62.3; H, 4.5; Co, 12.6; P, 6.6; S, 13.7%. The remaining filtrate which was kept at 0°C for a month yielded a small amount of **1A**.

Preparation of $[Co_2(dppm)(\mu\text{-S-}m\text{-tol})_2(\text{S-}m\text{-tol})_2]$ (**2**)

Compound **2** was prepared from either $Co(dppm)Cl_2$ and sulphur or $Co(dppm)_2Cl_2$ and selenium following procedures similar to those for the preparation of **1**. Na(S-*m*-tol) (0.298 g, 2 mmol), elemental selenium (0.118 g, 1.5 mmol), $Co(dppm)_2Cl_2$ (0.899 g, 1 mmol) and DMF (25 cm^3) were used, and the volume of the mixture was reduced to one-fourth by low pressure evaporation. Ethanol (10 cm^3) was added and the precipitate was removed after the solution was kept overnight at room temperature. After standing at room temperature for 2 weeks, black, plate-like crystals (0.27 g, 54%) were collected and washed with ethanol and ether. Found: C, 64.6; H, 5.8; Co, 11.6; S, 13.3. Calc. for $C_{53}H_{50}Co_2P_2S_4$: C, 64.0; H; 5.1; Co, 11.9; S, 12.9%. Attempts to grow isomeric crystals similar to **1** were not successful.

Preparation of $[Co_2(dppm)(\mu\text{-S-}p\text{-tol})_2(\text{S-}p\text{-tol})_2]$ (**3**) *and* $[Co_2(dppm)\text{-}(\mu\text{-S-}p\text{-tbb})_2(\text{S-}p\text{-tbb})_2]$ (**4**)

The procedures were similar to those for the preparation of **1**. The yields were between 50 and 70%.

Preparation of $[Co_2(dppe)(\mu\text{-SPh})_3(\text{SPh})]$ (**5**)

This has been described elsewhere.[6]

X-ray structures

A suitable single crystal of **1A**, **1S** or **2** was mounted on a glass fibre and data collections were performed at ambient temperature on an Enraf–Nonius CAD4 diffractometer using graphite-monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å). The crystallographic and machine parameters are summarized in Table 2. The cell parameters were obtained from the least-squares refinement, using 25 high-angle reflections. All intensity data were corrected for standard decay, since the three standard reflections monitored periodically during data collection showed small fluctuations of intensity. The data were corrected for Lorentz and polariz-

ation effects. Absorption corrections for crystals of **1A** and **1S** were based on empirical psi-scan and DIFABS techniques, respectively. Both empirical psi-scan absorption and DIFABS were applied for the crystal of **2**.

Calculations were performed on a VAX-11/785 computer with the SDP program package.[8] The structures were solved by direct methods and subsequently by difference Fourier maps. Anisotropic thermal refinements were applied[9] to all non-hydrogen atoms, except for seven carbon atoms in crystal **1S**. In the last stage of refinement, contributions were included for hydrogen atoms with fixed "idealized" positions of C—H = 0.95 Å and a group of isotropic thermal parameters varied according to the average thermal parameters of the carbon atoms in the corresponding benzene ring. Atomic positional and thermal parameters, and listings of interatomic distances and bond angles for **1A**, **1S** and **2** are available as supplementary material from the Editor or the Authors.

Spectral measurements

IR spectra were recorded on a Digilab FTS-20E/D spectrometer. Magnetic susceptibilities were measured with a powdered sample at room temperature on a home-made Gouy–Faraday magnetic balance using the Faraday method.[4] The magnetic moment (μ_{eff}) was calculated after diamagnetic molar correction (χ_{dia}) of the ligands: $\mu_{eff}^2 = 3kT(fw\chi_g - \chi_{dia})$. EPR spectra were obtained on a Bruker ER-420 spectrometer at both 295 and 77 K. NMR spectra were recorded on a Varian FT-80A spectrometer. Elemental analyses were performed by the Analytical Chemistry Group of this Institute.

RESULTS AND DISCUSSION

Syntheses of $[Co_2(dppm)(\mu\text{-}SR)_2(SR)_2]$

The synthetic reaction of the dppe complexes consists of the formation of the by-product $dppeX_2$ (X = S or Se) as described by eq. (1):

$$[2NaSR + (2n-1)X] + Co(dppe)_nCl_2 \longrightarrow 1/2[Co_2(dppe)(SR)_4] + (n-1/2)dppeX_2 + 2NaCl \quad (n = 1 \text{ or } 2). \quad (1)$$

Equation (1) is applicable for $dppmS_2$, but not for $dppmSe_2$. ^{31}P NMR spectra revealed that selenium reacts with dppm to form the monoselenium compound dppmSe, while elemental sulphur reacts with dppm to form the disulphide compound $dppmS_2$, while elemental sulphur reacts with dppm to form the disulphide compound $dppmS_2$. Carr and Colton observed a similar result in reacting $SeCN^-$ and SCN^- with dppm.[10] Therefore, the mole ratio of the reagents is altered according to the following equation in order to prepare compound **1**:

$$[2NaSR + 3/2Se] + Co(dppm)_2Cl_2 \longrightarrow 1/2[Co_2(dppm)(SR)_4] + 3/2dppmSe + 2NaCl. \quad (2)$$

Attempts to prepare compound **1** or **2** by direct interaction of NaSR with $Co(dppm)Cl_2$ or with $CoCl_2$ and dppm in the absence of elemental sulphur or selenium did not succeed.

General structural features of $[Co_2(dppm)(SR)_4]$

The structures of the two neutral dicobalt compounds containing dppm were determined. The two cobalt atoms in compound **1** or **2** are bridged by two SR ligands and joined by a dppm ligand through the two phosphorus atoms. The core $Co_2(\mu\text{-}S)_2$ is decidedly non-planar, but slightly puckered with cobalt(II) and S_b atoms on the opposite sides of the weighted least-squares plane. The phenyl rings of the two bridging SPh and the plane of CoPCPCo are perpendicular to and on opposite sides of the above Co_2S_2 "plane", as seen in Figs 1–3.

There are three different molecular conformations of the compound $[Co_2(dppm)(\mu\text{-}SPh)_2(SPh)_2]$ in the two isomeric crystals **1A** and **1S**: **1aa**, **1sa** and **1ss** as shown in Figs 1, 2 and 3, respectively. Selected interatomic distances and bond angles of **1aa**, **1sa** and **1ss** are collected in Table 3. The corresponding atomic distances in the three conformations do not differ considerably from each other. The main difference between the three stereoisomers is the geometry of the terminal

[a] Numbers in parentheses are ESDs of SDs for several equivalent values; $s = [\text{sum}\,\chi_i^2 - n\bar{\chi}^2]^{1/2}n$, $\bar{\chi} = [\text{sum}\,\chi_i]/n$.

[b] Average values of *syn*-$[Co_2(SEt)_6]^{2-}$.

SPh ligand with respect to the central core. Relative to the "spine" S—Co—S—S—Co—S, the phenyl groups of the bridging and terminal —SPh can be arranged in the *anti* or *syn* form, and therefore the molecular conformations could be one of the three forms: *anti–anti* (**aa**), *syn–anti* (**sa**) or *syn–syn* (**ss**). The S—Co—Co—S spine is noticeably straightened in going from **1aa** to **1ss**. Different molecular

syn-syn
ss

structure arrangements also occur in other cobalt thiolate compounds, for example for $[Co_2(SEt)_6]^{2-}$ (**6**) with *anti* and *syn* bridged forms.[11] The *syn* conformation (**6s**) is closely related to compound **1** because their central Co_2S_2 cores are puckered to the butterfly form. The atomic distances Co—S_t and Co—S_b in **1** are 0.06–0.10 Å shorter than those of **6s**, and the Co—Co distance in **1** is much shorter than that of **6s**, 2.67 vs 3.02 Å. The ditertiary phosphine ligand dppm plays an important role in stabilizing the dicobalt complex **1** and locks together two metal atoms in close proximity, and consequently reduces the bridge angle Co—S_b—Co, from 79.5(2)° in **6s** to 72.3(3)° in **1** The usual order of distances between the cobalt atom and bridging or terminal ligands, Co—S_b > Co—S_t, prevails in both compounds.

There are four molecules of **1aa** in a unit cell of **1A** and four molecules each of **1as** and **1ss** in a unit cell of **1S**. In our experiment, the crystals of **1A** grow in a solution having a lower ratio of EtOH–DMF and at a lower rate than those of **1S**. The difference in structure of **1A** and **1S** is confirmed by IR spectra (presented in Table 1) and by differential thermal analyses.[12] The Co—S—Ph bond rotates freely in solution, but there are energy wells with respect to the —PPh_2 group and to the crystal lattice, and therefore it is possible to have different stereoisomers in the solid state.

Compound **2** crystallizes in the orthorhombic space group *Pbca* with eight molecules of type **ss** in a unit cell. Since the perspective view of **3** is very similar to that of **1ss** (Fig. 3), its ORTEP drawing is given in the supplementary material. Selected interatomic distances and bond angles of **2** are also listed in Table 3 for comparison.

Comparison of the molecular structures

Ditertiary phosphine reacts with cobalt(II) and thiolate to form disparate molecular structures:

dppm acts as a bridge to connect two cobalt atoms forming a symmetric dicobalt compound **1**; dppe acts as a bidentate ligand chelating to a cobalt atom forming an asymmetric dicobalt compound **5** (Fig. 4); dppp also acts as a bidentate ligand chelating to one cobalt atom forming a mono-cobalt complex, $Co(dppp)(SR)_2$.[13]

The coordination geometry of the core $P_2Co_2S_4$ in structure type **1** can be viewed as two edge-shared trigonal pyramids. Although there is no imposed symmetry for compounds **1** or **2**, inspection of the structure of **1aa** and **1ss** shown in Figs 1 and 3 and their geometric data reveals that the entire neutral molecules of **1aa**, **1ss** or **2** approach C_2 symmetry. Atoms Co(1), Co(2), P(1), P(2), S(3) and S(4) are in a plane. The bidentate phosphine ligand bridges two cobalt atoms and provides additional stability to the structure in the sense of locking two cobalt atoms together.

The role of the thiolate ligands, —SR, as a μ_2-bridge in transition-element compounds has been extensively documented by X-ray structure determination.[11] Acting as a μ_2-bridge, —SPh forms a di-bridge in compound **1** and tri-bridge in compound **5**. The structure of compound **5** is totally different from that of **1**. The molecule of **5** is asymmetric with one five-coordinate and one four-coordinate cobalt atom. The atomic distances between cobalt and the bridging sulphur atom vary moderately in structure type **1**, but dramatically in compound **5**, which range from 2.215(4) to 2.376(3) Å. The mean bond length, Co—S_t, of 2.197(22) Å in type **1** is close to the Co(2)—S(4) distance [2.215(4) Å] in structure **5** but is shorter than the mean Co—S_t bond length of 2.245(4) Å in the five-coordinate cobalt complex $Co[(C_6H_5)_2PC_2H_4]_2PC_6H_5(SPh)_2$,[13] and much shorter than that of 2.33(1) Å found in the tetrahedral complex $[Co(SPh)_4]^{2-}$.[14] The mean Co—P bond lengths ot type **1**, ranging from 2.337(1) Å in **1aa** to 2.349(9) Å in structure **1ss**, is significantly longer than that of 2.210(6) Å in structure **5**. No dramatic variation can be observed in the corresponding cobalt–ligand bond lengths among the three conformations of **1**. However, the cobalt–cobalt distances vary considerably even among the three conformations of the same complex [from 2.683 to 2.655(2) Å]. This cannot be explained by the individual cobalt–ligand coordination mode, but should take into account the whole structure. Structure **2** might benefit from both a favourable steric conformation and electronic effects of the methyl groups in phenyl-thiols acting on the cobalt atoms, which consequently enable the molecule to possess the shortest cobalt–

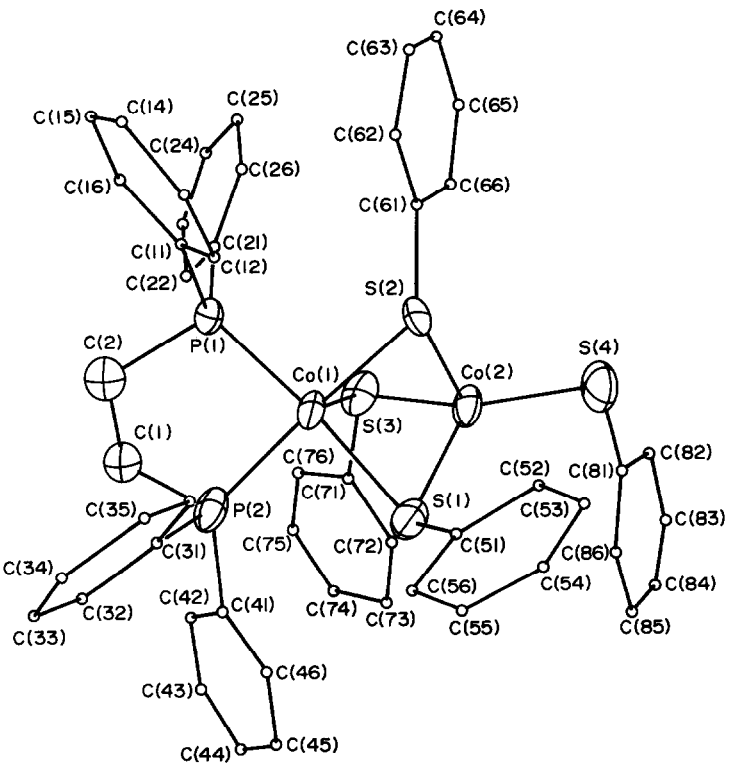

Fig. 4. Perspective view of the structure of $[Co_2(dppe)(SPh)_4]$ (**5**).

cobalt distance [2.634(1) Å] of the four structures.

Cobalt(II) (d^7) can assume either a low- ($S = 1/2$) or a high- ($S = 3/2$) spin configuration when the energy separation (ΔE) between the two highest orbitals is higher or lower than the spin-pairing energy. Five-coordinate complexes with "soft" donor atoms such as phosphorus have the low-spin configuration.[15] Making assumptions of spin-only, high-temperature approximation and no magnetic interaction between paramagnetic centres, the magnetic moment of the complex can be calculated as $\mu_{calc} = \Sigma[g_i S_i(S_i+1)]^{1/2}/N$. For the complex containing two low-spin cobalt(II), $\mu_{ll} = 2.45\ \mu_B$, and for the complex with one high-spin and one low-spin cobalt(II) atoms, $\mu_{hl} = 4.24\ \mu_B$. The observed magnetic moments of complexes with dppm (**1–4**, $1.67 \pm 0.05\ \mu_B$) and with dppe (**5**, $3.69\ \mu_B$) are slightly smaller than the calculated values of μ_{ll} and μ_{hl}, respectively. Therefore, it is sensible to assume that the former complexes (**1–4**) consist of two low-spin cobalt(II) atoms, while **5** consists of one high- and one low-spin cobalt(II) atom with antiferromagnetic coupling between the two cobalt(II) atoms within a molecule in any one of the complexes **1–5**. The EPR spectra showed coherent signals for complex **5**, but there is no EPR signal for the dppm complexes (**1–4**). The g features of **5** are similar to those of five-coordinate mono-cobalt(II) complexes in the literature.[16]

(*Received* 8 *August* 1990; *accepted* 31 *October* 1990)

Abstract—Reactions of $Na_2[PdCl_4]$ with one equivalent and two equivalents of bis(benzylthio)methane (btm) yield *trans*-$[PdCl_2(\mu\text{-btm})]_n$ (**1**) and *trans*-$[PdCl_2(\text{btm-}S)_2]$ (**2**), respectively. Treatment of **2** with $[PdCl_2(NCMe)_2]$ gives the face-to-face type palladium(II) complex, *trans*-$[Pd_2Cl_4(\mu\text{-btm})_2]$ (**3**), whereas the reaction of **2** with $[Pd(dba)_2]$ (dba = dibenzylideneacetone) produces the side-by-side type palladium(I) complex, $[Pd_2Cl_2(\mu\text{-btm})_2]$ (**4**). Treatment of **4** with dimethyl acetylenedicarboxylate gives the A-frame type complex $[Pd_2Cl_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-btm})_2]\cdot 1/2CH_2Cl_2$ (**5**). The complexes obtained in this study were characterized by elemental analysis, IR and NMR spectroscopy.

There has been interest recently in binuclear complexes containing the "short-bite" ligands such as bis(diphenylphosphino)methane[1] and 2-(diphenylphosphino)pyridine,[2] etc. In our previous papers, we have reported the synthesis of mono- and bimetallic complexes of palladium[3] and rhodium[4] containing the unsymmetrical "short-bite" ligand, (benzylthiomethyl)diphenylphosphine. Syntheses have also been reported of various metal complexes with symmetrical "short-bite" sulphur donor ligands; specifically thioether ligands, $RSCH_2SR$ (R = Me, Ph).[5–12] These dithioether ligands are mostly coordinated in unidentate or bidentate chelating modes in metal complexes. As for the bidentate bridging coordination mode of dithioether ligands, few have been reported: the platinum complexes of $[(PtXMe_3)_2(\mu\text{-MeSCH}_2\text{SMe})]$[8,9] and the rhodium complex of $[Rh_2Cl_2(\mu\text{-CO})(\mu\text{-PhSCH}_2\text{SPh})_2]$[10] are two examples.

Here, we wish to report the synthesis of palladium complexes with a dithioether ligand, bis(benzylthio)methane (btm), including the side-by-side type bimetallic complex of $[Pd_2Cl_2(\mu\text{-btm})_2]$, the face-to-face type complex of $[Pd_2Cl_4(\mu\text{-btm})_2]$ and the A-frame type complex of $[Pd_2Cl_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-btm})_2]$.

RESULTS AND DISCUSSION

The new reactions of bis(benzylthio)methane are summarized in Scheme 1. Yields, melting points and analytical data are listed in Table 1, while ^1H and ^{13}C NMR data are summarized in Table 2.

Reactions of $Na_2[PdCl_4]$ *with* btm

Treatment of btm with one or a half equivalent of $Na_2[PdCl_4]$ yielded *trans*-$[PdCl_2(\mu\text{-btm})]_n$ (**1**) and *trans*-$[PdCl_2(\text{btm-}S)_2]$ (**2**), respectively. The ^1H NMR spectrum of **1** was not obtained due to its poor solubility in common solvents. However, the far-IR spectrum showed a single band at 361 cm^{-1} assigned to ν(Pd—Cl), suggesting a *trans* con-

figuration of the chloro ligands. On the basis of these results and the elemental analysis, **1** was assigned an oligomeric structure in which btm acts as a bidentate bridging ligand, as shown in Scheme 1.

As for **2**, the elemental analysis supported the formulation of $[PdCl_2(btm\text{-}S)_2]$ and the far-IR spectrum indicated a *trans* configuration of the chloro ligands [ν(Pd—Cl) 362 cm^{-1}]. Complex **2** showed temperature-dependent ^1H NMR spectra, as shown in Fig. 1. At 50°C, two singlets appeared at δ 4.11 and 3.81 due to CH_2Ph and SCH_2S, respectively. The former singlet broadened at 25°C and then at −10°C separated into two broad resonances at δ 4.25 and 3.95. Furthermore, at −50°C the resonance at δ 4.25 became sharp (δ 4.28), whereas the signal at δ 3.95 separated into two resonances at δ 3.95 and 3.90. In contrast, the SCH_2S resonance, observed at δ 3.81 at 50°C, broadened at −10°C and then at −50°C separated into two humps at δ 3.8 and 3.6. These phenomena could be explained in terms of 1,3-intramolecular metal shifts between the four ligand sulphur atoms and the pyramidal inversions of the ligated sulphur atoms, as illustrated in Fig. 2. At 50°C, the 1,3-metal shifts and the

pyramidal inversions were supposed to take place rapidly, and these motions caused two differential sited CH_2Ph groups to resonate as one singlet at δ 4.11. At −10°C, the 1,3-metal shifts seem to be quenched, while the pyramidal inversions are still occurring. Accordingly, at this temperature two different environmental CH_2Ph groups appeared as two signals. Finally, at −50°C, when the pyramidal inversions were nearly quenched, the CH_2Ph groups directly attached to the ligated sulphur atoms further split into two signals owing to the presence of diastereomers, DL and *meso* (Fig. 2). Corresponding to this fact, at −50°C SCH_2S separated into two humps. Further measurements below −50°C were

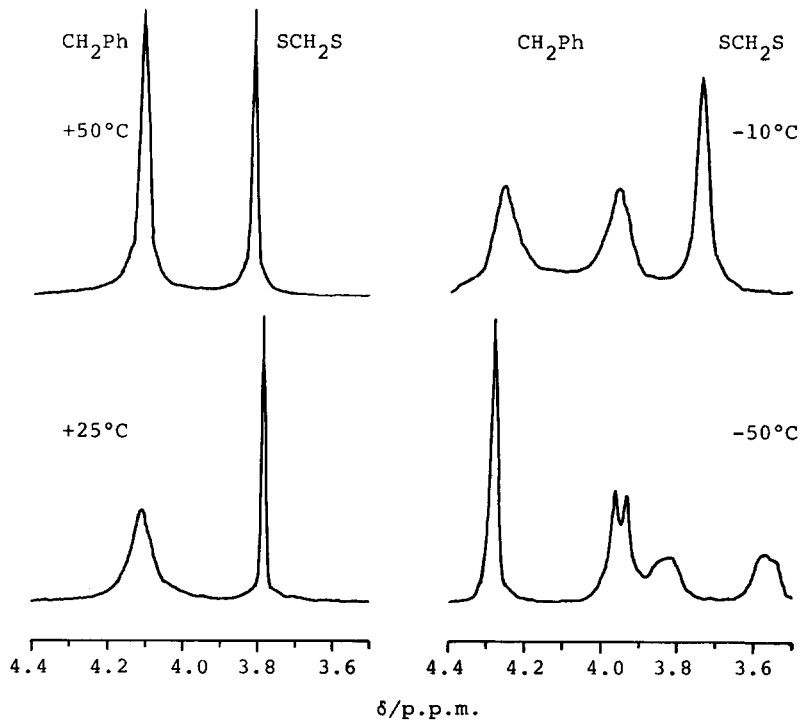

Fig. 1. Temperature-dependent ^{1}H NMR spectra of [$PdCl_2$(btm-*S*)$_2$] (**2**) in $CDCl_3$.

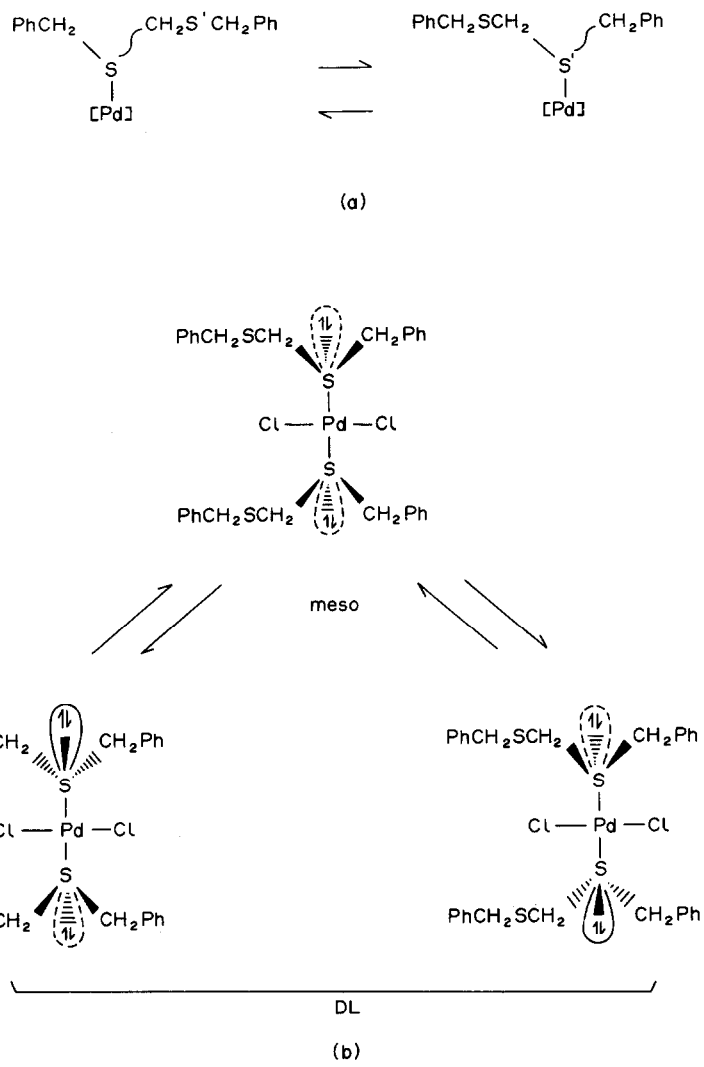

Fig. 2. (a) The 1,3-intramolecular metal shifts and (b) the pyramidal inversions of ligated sulphur atoms and invertomers of $[PdCl_2(btm\text{-}S)_2]$ (**2**).

unsuccessful due to precipitation of solids from the NMR sample solution. Precise studies on the 1,3-intramolecular metal shifts between the ligand sulphur atoms and the pyramidal inversions of the sulphur atoms have been reported by the groups of Abel[5] and Kuhn.[11] In the $^{13}C\{^1H\}$ NMR spectrum at 50°C, two methylene carbons due to CH_2Ph and SCH_2S were observed at δ 38.45 and 37.93, respectively.

On the basis of the results mentioned above, together with the molar conductance (Λ_M 2.4 S cm^2 mol^{-1} in acetone), **2** was assigned to *trans*-$[PdCl_2(btm\text{-}S)_2]$ in which two btm ligands are coordinated in a unidentate fashion. Two sulphur atoms in each btm ligand in **2** are coordinatively free, and **2** reacted to form bimetallic complexes (see below).

The face-to-face type complexes $[Pd_2Cl_4(\mu\text{-btm})_2]$ (**3**)

Treatment of **2** with one equivalent of $[PdCl_2(NCMe)_2]$ afforded **3** which had the same composition as **1** by elemental analysis. However, the molecular weight of **3** was 804.5 (determined by osmometry in benzene at 42°C; calc. for $C_{30}H_{32}Cl_4Pd_2S_4$: 875.5). In contrast with **1**, **3** is soluble in benzene, chloroform and dichloromethane, but is not as stable under conditions of prolonged standing or heating in solution due to gradual conversion back to **1**. For this reason, the ^{13}C NMR spectrum could not be measured. Temperature-dependent ^1H NMR spectra were observed for **3**. At 50°C, **3** showed a nearly high-

temperature limiting spectrum exhibiting two kinds of methylene proton due to CH_2Ph and SCH_2S moieties. These occurred as slightly broad singlets at δ 4.35 and 3.9, respectively. However, the low-temperature limiting spectra were very complicated owing to a number of conformers caused by the pyramidal inversions of the ligated sulphur atoms. Complete analysis of the temperature-dependent spectra will be reported elsewhere in due course. The ^1H NMR spectra of **4** and **5**, showed similar situations to **3**, but only high-temperature limiting spectra are described in this paper (see below).

On the basis of these results and the far-IR spectrum [ν(Pd—Cl) 357 cm^{-1}], **3** was assigned to the face-to-face type palladium(II) complex, $[Pd_2Cl_4(\mu\text{-btm})_2]$, as illustrated in Scheme 1.

The side-by-side type complex $[Pd_2Cl_2(\mu\text{-btm})_2]$ **(4)**

Treatment of **2** with one equivalent of $[Pd(bda)_2]$ (dba = dibenzylideneacetone) afforded **4** as orange–brown microcrystals. The high-temperature limiting ^1H NMR spectrum at 50°C exhibited singlets at δ 4.29 and 3.96 due to CH_2Ph and SCH_2S, respectively. The $^{13}C\{^1H\}$ NMR spectrum at 50°C exhibited two methylene carbon signals at δ 42.89 (CH_2Ph) and 38.12 (SCH_2S). On the basis of these results, elemental analysis, its deep colour and the reactivity towards dimethyl acetylenedicarboxylate (see below), **4** was assigned to the side-by-side type palladium(I) complex $[Pd_2Cl_2(\mu\text{-btm})_2]$.

The A-frame type complex $[Pd_2Cl_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-btm})_2]$ **(5)**

The reaction of **4** with dimethyl acetylenedicarboxylate yielded the A-frame type complex **5**. The IR spectrum showed a ν(C=O) band at 1700 cm^{-1} and a ν(C=C) band at 1580 cm^{-1}. The ^1H NMR spectrum was measured at 50°C, a temperature at which the pyramidal inversions occurred rapidly. Together with the OCH_3 resonance at δ 3.69, CH_2Ph and SCH_2S appeared as AB quartets at δ 4.45 (d) and 4.38 (d), and δ 3.43 (d) and 2.73 (d), respectively. As this complex is an A-frame type, the two protons of the SCH_2S moieties are originally non-equivalent and CH_2Ph are diastereotopic even when rapid pyramidal inversions of the ligated sulphur atoms occur, and they were observed as AB quartets. In the $^{13}C\{^1H\}$ NMR spectrum at 50°C, all carbons except for the olefinic carbons formed by the insertion of the acetylene were clearly detected (Table 2).

Conclusions

The dithioether ligand, btm, was found to coordinate to palladium complexes in a unidentate manner in **2**, and a bidentate bridging fashion in **1** to form an oligomeric compound, or in **3** and **4** to produce bimetallic complexes. Complexes **2**–**4** are fairly stable in the solid state, but gradually decomposed in solution under prolonged heating or standing in air, which precluded the growing of suitable crystals for X-ray structural analysis. The ^{13}C NMR spectra could be successfully measured at 50°C. ^1H NMR spectra were all temperature-dependent mainly owing to the pyramidal inversions of the ligated sulphur atoms, and therefore in this paper only high-temperature limiting spectra have been described.

EXPERIMENTAL

General methods were as previously described in a recent paper from our laboratory.[3] Bis(benzylthio)methane was prepared according to a literature method.[13]

Preparation of trans-$[PdCl_2(\mu\text{-btm})]_n$ **(1)**

A solution of btm (0.097 g, 0.36 mmol) in MeOH (5 cm^3) was added to a solution of $Na_2[PdCl_4]$ (0.100 g, 0.34 mmol) in MeOH (15 cm^3). A yellow precipitate was formed immediately. The resulting suspension was stirred at room temperature for 2 h and filtered to yield **1**.

Synthesis of trans-$[PdCl_2(btm\text{-}S)_2]$ **(2)**

A solution of btm (0.186 g, 0.71 mmol) in MeOH (10 cm^3) was added to a solution of $Na_2[PdCl_4]$ (0.100 g, 0.34 mmol) in MeOH (15 cm^3). A yellow precipitate which initially formed was dissolved and then a yellow precipitate reappeared. Stirring was continued for at least 1 day at room temperature, and the precipitate was collected to give **2**.

Preparation of $[Pd_2Cl_4(\mu\text{-btm})_2]$ **(3)**

Solid $[PdCl_2(NCMe)_2]$ (0.037 g, 0.14 mmol) was added to a solution of **2** (0.100 g, 0.14 mmol) in CH_2Cl_2 (10 cm^3). The resulting solution was stirred at room temperature for 2 h, and the volatile materials were removed under reduced pressure. The residue was recrystallized from CH_2Cl_2–Et_2O–hexane to afford **3** as yellow crystals.

Synthesis of $[Pd_2Cl_2(\mu\text{-btm})_2]$ (**4**)

Solid $[Pd(dba)_2]$ (0.300 g, 0.52 mmol) was added to a solution of **3** (0.363 g, 0.52 mmol) in CH_2Cl_2 (15 cm^3), and the mixture was refluxed for 30 min. After the reaction mixture was evaporated to dryness, the residue was chromatographed on a silica gel column (200 mesh, 200 × 10 mm). The red fraction eluted by CH_2Cl_2 was concentrated and diluted with hexane to give **4** as orange–brown microcrystals.

Preparation of $[Pd_2Cl_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-btm})_2]\cdot 1/2CH_2Cl_2$ (**5**).

An excess of dimethyl acetylenedicarboxylate (0.233 g, 1.57 mmol) was added to a stirred solution of **4** (0.315 g, 0.39 mmol) in CH_2Cl_2 (20 cm^3). The resulting solution was stirred for 1 day, during which time the colour changed from orange–brown to yellow–orange. After the reaction mixture was evaporated to dryness, the residue was chromatographed on a silica gel column (200 mesh, 180 × 10 mm). The yellow–orange fraction eluted by CH_2Cl_2–Et_2O (10 : 1) was collected and recrystallized from CH_2Cl_2–hexane to afford **5**.

A STUDY OF THE INTERACTION OF METHYL SALICYLATE WITH SMECTITE CLAYS

PAUL O'BRIEN* and COLIN J. WILLIAMSON

Department of Chemistry, Queen Mary and Westfield College, Mile End Road, London, E1 4NS, U.K.

(*Received* 17 *July* 1990; *accepted* 2 *November* 1990)

Abstract—The binding of methyl salicylate to smectite clays has been studied using a wide range of techniques. The work encompasses studies by classical methods (thermal analysis and adsorption isotherms) and by ^{13}C solid-state NMR, electronic and FTIR spectroscopies. Mobile and static phases have been identified within the clay matrix in MAS and CP/MAS solid-state NMR experiments. Pillaring of the clay substantially modifies the mode of interaction of methyl salicylate with the clay; NMR evidence is again particularly useful.

Smectite clays are widely used as adsorbents/absorbants in a variety of industrial applications, including waste disposal and catalysis.[1,2] Fuller's Earth, calcium montmorillonite, is a common, cheap clay widely utilized for organic/inorganic absorption. Molecules can bind to clays in many ways depending on the properties of the molecule (e.g. polarity, size, charge) and the clay (e.g. interlamellar cation, hydration state, surface charge). Accommodation of organic molecules by the clay is mainly, but not exclusively, within the interlamellar regions.

The binding of organic molecules to clays saturated with inorganic cations can occur in a variety of ways. These include: direct coordination to the interlamellar metal ion(s), coordination via water bridges, van der Waals' attraction between molecules and the clay surfaces, protonation of organic bases and hydrogen bonding to surface oxygens.[3] In the present work, the sorption of methyl salicylate by montmorillonites has been studied using solid-state ^{13}C NMR, thermogravimetric analysis (TGA), Fourier transform IR (FTIR) and diffuse reflectance electronic spectroscopy. Results from these studies complement an earlier study in which X-ray diffraction (XRD) and differential thermal analysis (DTA) were used to investigate various clay, methyl salicylate systems.[4]

In the present paper, the sorption of methyl salicylate by various cation-exchanged smectite clays, calcium montmorillonite, Westonite (a magnesium montmorillonite especially suitable for NMR work) and Westonite pillared with hydroxyaluminium ions, has been studied. Previous studies of methyl salicylate binding to smectite clays have shown that Fuller's Earth and Westonite adsorb/absorb 26% and 22% w/w methyl salicylate, respectively, before free liquid is observed by thermal methods.[4] However, ^{1}H solid-state NMR spectra provide unequivocal evidence of mobile species even at low loadings.[5] Such observations may be important for a proper understanding of the mobility of organic molecules both in soil and within clay matrices used for waste disposal.

RESULTS AND DISCUSSION

Adsorption isotherms for methyl salicylate

The uptake of methyl salicylate (MS) from hexane, by the various clay samples, was monitored by electronic spectroscopy using the absorption band of methyl salicylate centred on 307 nm (n to π^* of C=O, $\varepsilon = 33{,}980\ mol^{-1}\ cm^{-1}\ dm^3$). Hexane, being non-polar, has little or no affinity for the clay, an assumption which was tested by immersing a small quantity of the clay in hexane and leaving the sample to stand for some hours. After the removal

* Author to whom correspondence should be addressed.

of the hexane, by filtration, and air drying, the FTIR spectrum of the clay showed no evidence for sorbed hexane.

A typical set of adsorption isotherms for the methyl salicylate/calcium montmorillonite system are shown in Fig. 1. As the concentration of methyl salicylate in solution is increased the quantity absorbed by the clay increases to a limiting value. The isotherms are close to hyperbolic, and of several adsorption isotherms[6] considered, the Langmuir isotherm provided the best fit, especially at the lower temperatures. The absorption characteristics of the various clay samples, in a range of hydration states, have been investigated and these results are summarized in Figs 1 and 2 and Table 1.

The effect of temperature on the absorption of methyl salicylate is interesting. At higher temperatures the maximum amount of methyl salicylate adsorbed decreases (Fig. 1). However, consistent isosteric heats of adsorption can be calculated using the Clausius–Clapeyron equation (see Table 1). The fact that such plots give excellent straight lines and consistent values for H suggests that similar sites are responsible for absorption at each temperature. The variation in equilibrium coverage with temperature (Fig. 1) can be explained in terms of the equilibrium position of the reaction shifting in favour of desorption as temperature increases; the expected result for an exothermic process. The values obtained for the heat of adsorption by expanded clays, 3–30 kJ mol^{-1}, are in the range

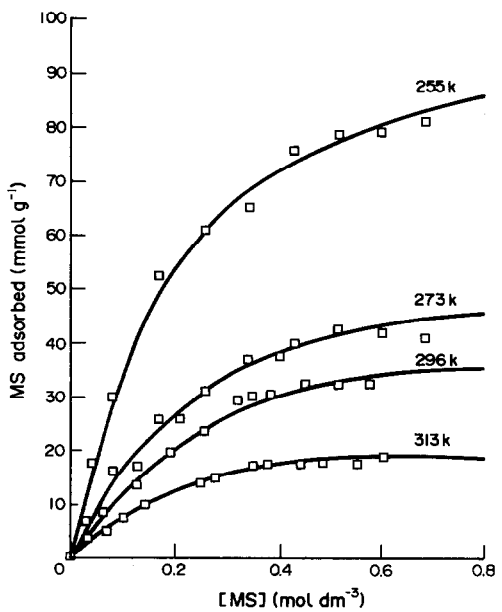

Fig. 1. Adsorption isotherms: the solid lines are fits to the experimental data using the Langmuir isotherm by the Marquard method.

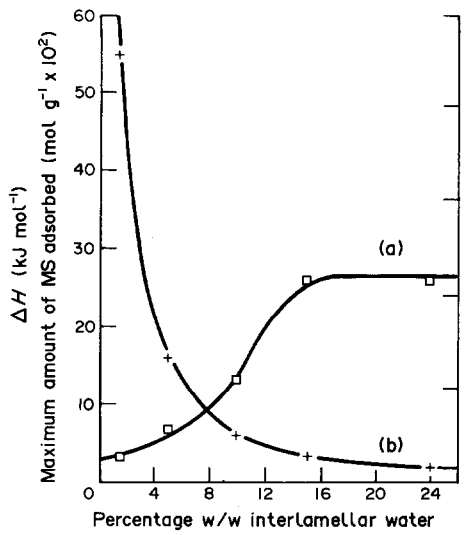

Fig. 2. Variation of maximum observed surface coverage (b) and enthalpy of absorption (a) with hydration state (at 296 K).

generally taken as being typical of the physisorption to a surface. However, in this case some other form of weak interaction, such as hydrogen bonding to interlamellar water, provides a more likely explanation *vide infra*.

The adsorption of methyl salicylate from solution in hexane is also influenced by the state of hydration of the clay. Clays with a decreased water content, in the interlamellar region, have an increased maximum affinity for methyl salicylate at room temperature, but a lower isosteric enthalpy of absorption (see Fig. 2 and Table 1). These results suggest that water has a crucial role in determining the absorption/adsorption of methyl salicylate by smectite clays.

The nearly totally dehydrated clay (1.5% w/w water) is effectively "collapsed" and failed to re-expand (confirmed by XRD) on exposure to methyl salicylate. In this case only external surfaces are available for adsorption of methyl salicylate.

The change in the interlamellar cation, Ca^{2+} to Mg^{2+} (Fuller's Earth to Westonite), causes a slight increase in the amount of methyl salicylate adsorbed, and a decrease in the enthalpy of absorption. This may be due to an effect of the greater charge density of magnesium on either, methyl salicylate directly, or on methyl salicylate via a water bridge. The latter appears to be a more likely explanation; water is not displaced from the interlamellar region on the intercalation of methyl salicylate (see IR results) at the same hydration state. The pillared clay has a much higher heat of absorption for methyl salicylate than any of the other clays studied (Table 1), an observation which may

suggest a different site of interaction for this clay. This suggestion is supported by the NMR spectroscopic studies.

Thermogravimetric analysis of clay/methyl salicylate samples

Thermogravimetric traces for the Fuller's Earth, 5% and 12% interlamellar water, and the same samples loaded with 10% w/w methyl salicylate, are shown in Fig. 3. The results for the clays show that interlamellar water desorbs from the clay and is completely removed by *ca* 80°C (10°C min^{-1}, static air).

The samples doped with methyl salicylate show two distinct steps in their decomposition. The nature of the species in the vapour phase above such samples was investigated by FTIR spectroscopy, methyl salicylate was found to be present in the vapour at all temperatures.

The "two-step" nature of the desorption of methyl salicylate suggests that there are two types of loss of it from the clay. Methyl salicylate lost concurrently with the loss of interlamellar water, and a second, subsequent loss predominantly of methyl salicylate alone. A possible explanation for these observations is as follows. At lower temperatures, methyl salicylate is coordinated to the hydrated silicate layers and hydrated metal cations, loss of methyl salicylate occurs concurrently with the loss of coordinated water molecules. However, methyl salicylate is less volatile than water (the temperatures for saturated vapour pressures of 40 torr are 126 and 34.1°C, respectively[7]) and once the interlamellar water is removed, the methyl salicylate remaining in the sample re-orientates and binds to the dehydrated layers/cations and is only removed at elevated temperatures. Lower dopings were tested (*ca* 5%) but the same pattern of traces occurred.

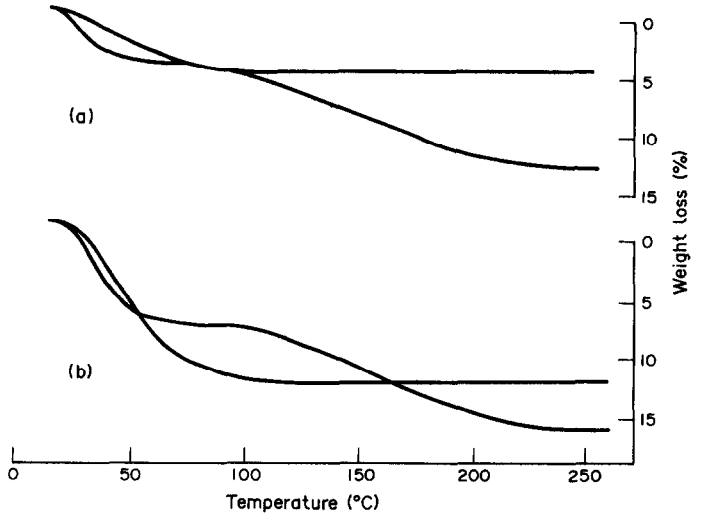

Fig. 3. Typical thermal analysis results. Traces are for clay in the presence and absence of methyl salicylate. (a) 10% methyl salicylate on Fuller's Earth (5% w/w water); (b) 10% methyl salicylate on Fuller's Earth (10% w/w/ water).

Solid-state NMR and FTIR spectra of methyl salicylate/clay samples

Westonite was chosen as a substitute for Fuller's Earth when recording solid-state NMR due to the very small quantities of paramagnetic ions, mainly iron(III) and manganese(II), within the clay. ESR and EDAX measurements were able to establish the quantity of paramagnetics and hence assess the suitability for solid-state NMR.[8] Two kinds of solid-state NMR experiments have been carried out: magic-angle spinning (MAS) decoupled spectra and cross-polarized CP/MAS spectra. The methods are detailed in the Experimental; CP/MAS spectra are only observed for immobile phases, whereas MAS spectra will occur predominantly for mobile and to a lesser extent for immobile phases. Static ^{1}H NMR spectra could not be observed for Westonite/methyl salicylate samples, presumably due to the presence of some paramagnetic material in the clay sample.

A typical ^{13}C NMR CP/MAS spectrum of methyl salicylate adsorbed on Westonite is shown in Fig. 4. The spectrum is unusual when compared with the ^{13}C solution or solid-state (frozen MS) NMR spectrum of methyl salicylate in that the resonances associated with the two carbons adjacent to the ester function (7 and 1) are absent. The signal for the carbon adjacent to the phenolic group (2) is also affected and is weakened in the CP/MAS spectrum. However, the signal due to the methyl group of the ester function (8) is still observed. Similar results are obtained for other salicylate esters. However, related systems containing a quaternary carbon atom, such as the Westonite complex of methyl-2-hydroxyisobutyric acid, have peaks for the quaternary carbon atoms in the CP/MAS spectrum.

The explanation for the disappearance of peaks in the CP/MAS spectrum of the Westonite/methyl

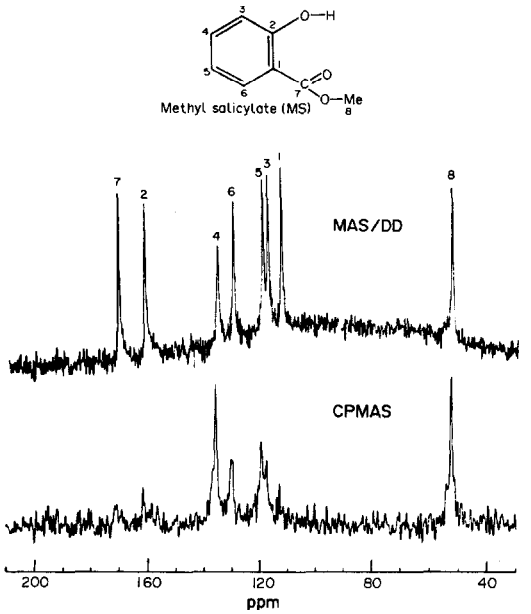

Fig. 4. Typical ^{13}C solid-state NMR spectra of Westonite/methyl salicylate samples. Spectra of methyl salicylate/Westonite (23% w/w). The ^{13}C NMR spectrum of liquid methyl salicylate is identical with the MAS/DD spectrum above and the major peaks in the CP/MAS spectrum, see Table 1.

salicylate system is probably that traces of paramagnetics in the clay relax the nuclei of the carbon atoms closest to the point of attachment too rapidly for these nuclei to be observed. The CP/MAS experiment is particularly sensitive to such effects. These observations may suggest that the protons which are not observed lie close to the clay sheets, as these contain the paramagnetic ions.

It was also possible to observe a MAS/decoupled spectrum of methyl salicylate associated with a clay sample. Such spectra were essentially identical to the high resolution spectrum of liquid or solid methyl salicylate (Fig. 4, Table 2). Solid-state ^1H MAS NMR also provides evidence for mobile species of methyl salicylate associated with the clay at low dopings; sharp peaks associated with the organic are observed.[5]

Taken together, the results suggest that methyl salicylate exists as two phases within the clay matrix, a fluid phase (giving rise to the MAS/decoupled spectrum) and an immobile phase (associated with the CP/MAS spectrum). As might be expected, the signal due to the fluid phase was relatively more intense at the higher dopings of methyl salicylate onto the clay.

It is interesting to contrast the major changes in the solid-state NMR spectrum with the relatively small shifts observed in the IR spectrum of methyl salicylate adsorbed by such clays. In the conventional IR region of the spectrum the frequency of the carbonyl peak at 1678 cm^{-1} increases by 2–4 cm^{-1} on intercalation (spectra as Nujol mulls or in KBr/CsI discs), and although a new peak associated with the —OH stretch of methyl salicylate can be observed, this is only possible after spectral subtraction. Other changes occur in the far-IR spectrum (Fig. 5, Table 3), but are more difficult to measure. The IR changes are all associated with the ester and phenolic functions, suggesting that these groups are involved in the bonding of the methyl salicylate to the clay. IR spectra of various samples of the clays with methyl salicylate show no evidence for the displacement of water from the interlamellar space of the clay, as has recently been reported for the intercalation of phosphate esters.[9] In contrast, the peaks associated with both the ester function and the carbon adjacent to the phenolic group are greatly modified in the CP/MAS spectrum, and provide clear evidence that these are influenced by sorption. The NMR spectra also provide evidence for two separate phases of methyl salicylate within the clay, fluid and immobile.

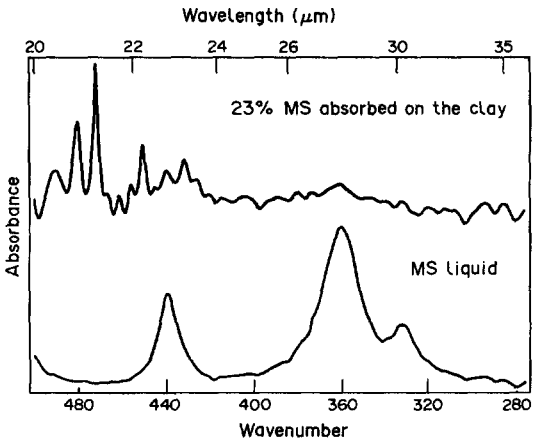

Fig. 5. Far IR spectrum (clay subtracted) of sorbed methyl salicylate compared with a thin film of methyl salicylate.

Typical CP/MAS and MAS/DD spectra of 20% w/w methyl salicylate adsorbed on the pillared Westonite clay are shown in Fig. 6. The CP/MAS spectra of methyl salicylate adsorbed on Westonite and

Table 2. Chemical shift values for the various Westonite/methyl salicylate samples

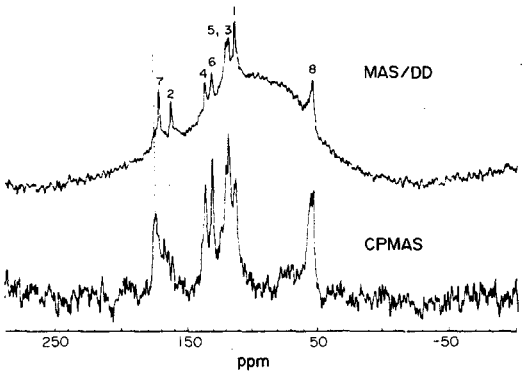

Fig. 6. Typical ^{13}C solid-state NMR spectrum of pillared Westonite/methyl salicylate samples. Spectra of methyl salicylate/Westonite (23% w/w).

the pillared Westonite are different. All eight peaks of methyl salicylate are present in the CP/MAS spectrum of pillared interlamellar Westonite compared with only five in the CP/MAS of methyl salicylate on Westonite (MS/W). The appearance of resonances 1, 2 and 7 of methyl salicylate in the spectrum of pillared interlamellar Westonite may suggest a different point of attachment of the organic molecule to the clay. One explanation for this observation is that the adsorption sites are removed from any paramagnetic impurities (in the clay matrix), which in the parent clay (Westonite) system caused relaxation of the appropriate carbons. Conversely, the fact that all the characteristic signals of methyl salicylate can be observed in the CP/MAS for the pillared interlamellar Westonite sample supports the suggestion that the point of attachment is responsible for the disappearance of these resonances in the parent system. Specifically this observation tends to rule out explanations for the non-appearance of the resonances based on their quaternary nature. The MAS/DD spectrum is identical to that of the parent system, suggesting a fluid phase within the clay.

There are other important features of the CP/MAS spectrum of the pillared interlamellar Westonite/methyl salicylate samples. Significant shifts in the carbonyl and phenolic carbon resonances (2 ppm for the latter case) occur. This observation may indicate binding to the pillar adjacent to these carbon atoms; no such shifts were found for the parent system. There is also splitting of the resonances due to carbons 1, 2, 7 and 8 in the CP/MAS spectrum, suggesting two immobile or motion-restricted phases of methyl salicylate within the pillared clay sample. The remaining four phenolic carbons may be too far away from the point of attachment to be significantly affected. There appears to be three types of methyl salicylate molecule associated with pillared interlamellar Westonite, two motion-restricted species and a mobile species.

Electronic spectroscopy

Various ion-exchanged samples of Westonite and Westonite/methyl salicylate were investigated using UV diffuse reflectance spectroscopy. The results of this work are summarized in Table 4. Varying the interlamellar cation within the clay produces little or no change in the dominant UV absorption at *ca* 257 nm. This transition is difficult to assign, but charge-transfer behaviour involving the intercalated metal ion can be ruled out on the basis of this observation.

In the presence of 10% methyl salicylate, this peak shifts to lower wavelength (higher energy) by about 15 nm— a blue, hypochromic shift. The shift appears to be independent of the cation, with the exception of NBu_4^+, for which the shift is only 7 nm. Higher dopings were assessed but no further changes were apparent. The absorption at 307 nm, due to methyl salicylate, is unaffected by the in clay/methyl salicylate samples.

Table 3. IR peaks (cm^{-1}) associated with the sorption of methyl salicylate by montmorillonites

MS	Westonite 10/20% w/w	Fuller's Earth 10–20% w/w

PILW	255	245

CONCLUSIONS

As detected by solid-state ^1H and ^{13}C NMR spectroscopy there are mobile organic species associated with the clay at a range of dopings. These species are unlike the liquid state. The Westonite/methyl salicylate samples also contain a restricted-motion species which tends to be associated with the small amount of paramagnetics within the clay.

The adsorption is probably best described as binding via "water bridges" within the clay interlamellar spacing, particularly evident in the FTIR spectrum. The isosteric enthalpy of adsorption and the maximum surface coverage is also strongly dependent upon the state of hydration of the clay.

It can be assumed that water bridge formation is the most likely type of adsorption of methyl salicylate to the clay in its normal state of hydration. This type of binding has been suggested for a variety of montmorillonite–organic clay complexes. Molecules of study have included benzonitrile,[10] benzoic acid and nitrobenzene,[11] pyridine,[12] ketones,[13] pyridine-N-oxide,[14] aniline and its derivatives,[15] nitriles[16] and phenol.[17] All such cases tend to be associated with the benzene rings coupled to an electronegative group.

EXPERIMENTAL

Materials

Fuller's Earth (calcium montmorillonite, unknown type location) was obtained from the British Drug Houses (Poole, Dorset, U.K.) and used in various hydration states. Westonite is a naturally-occurring magnesium montmorillonite, low in paramagnetic iron, and was a gift from English China Clays, St Austell, Cornwall (of unknown type location). This clay has been used as a substitute for Fuller's Earth in obtaining NMR spectra and used in its natural hydration state. Westonite has also been studied after "pillaring" with a hydroxy-aluminium ion by a literature method.[18] Each of the clays was characterized as a smectite by XRD and the water content was determined by TGA. Their properties were as follows.

Fuller's Earth (used in various states of hydration) had interlamellar water contents ranging from 2 to 24% (w/w) and corresponding $d(001)$ values from 10.2 to 18.6 Å.

Westonite had a water content of 13% w/w and a $d(001)$ value of 14.7 Å, characteristic of two layers of intercalated water. Pillared interlamellar Westonite had a water content of 9% w/w and a $d(001)$ value of 18.4 Å.

Methyl salicylate was distilled under reduced pressure and dried over molecular sieves before use. Clay samples were prepared by direct mixing of known weights of methyl salicylate and the clay followed by gentle mixing in a pestle and mortar. For the adsorption isotherms, 1 g of clay was added to 10 cm^3 of the appropriate methyl salicylate solution and allowed to equilibrate, with shaking, at the appropriate temperature, for 2 h. A small portion of the solution was extracted and the concentration of methyl salicylate remaining in the solution evaluated spectrophotometrically.

Instrumentation

Solid-state NMR spectra were recorded with a Bruker MSL-300 Instrument (equivalent proton frequency, 300 MHz). ^{13}C NMR shifts are in ppm relative to external TMS. The rotor used was a Kelrin type and the spinning frequency was in the range 4–4.5 kHz. All measurements were made at room temperature. ^{13}C NMR spectra were recorded in single pulse magic-angle spinning experiments (MAS/DD), typically: 400 scans, with a 10 s delay, 34 ms acquisition time. Cross-polarization magic-angle spinning experiments (CP/MAS) were typically: 2000 scans, with a 2 s delay, an acquisition time of 34 ms and a contact time of 1 ms. In both cases the sweep width was close to 30,000 Hz with 70 kHz proton decoupling. FTIR spectra were recorded on a Mattson Polaris Instrument in the range 50–4000 cm^{-1}, using KBr or CsI discs (typically 2 mg of sample to 200 mg of KBr/CsI), 4 cm^{-1} resolution and 32 scans. Electronic spectra were recorded on a Perkin–Elmer 330 spectrophotometer. TGA results were obtained on a Stanton Redcroft TG-750 apparatus in a static air atmosphere using a heating rate of 10° min^{-1}, sample weights were of the order of 5 mg.

Acknowledgements—We thank the Procurement Executive of the Ministry of Defence for their support of this

project and Dr C. J. Groombridge of the University of London Intercollegiate Solid-state NMR Service at Royal Holloway and Bedford New College for enthusiastic help with the solid-state NMR spectroscopy.

(*Received* 1 *November* 1990; *accepted* 10 *December* 1990)

Abstract—Pink tris(S-alaninato)chromium(III) has been prepared and characterized. The compound is found to have sufficient solubility in water for the circular dichroism to be measured, moreover the circular dichroism in water is identical to that of the complex dissolved in DMSO or in the solid state (KBr disc). These results are used to comment on the work of earlier workers and can be used to clarify the assignments of the dominant bands in the visible circular dichroism of tris-aminoacidates of chromium(III).

The tris-aminoacidates of chromium(III) have been studied on a number of occasions.[1–6] Despite the large number of studies of such complexes, there is a remarkable variation both in the nature of the chiroptic spectra reported and their assignment. In this work we report a detailed study of the pink form of the tris-chelate of S-alanine with chromium(III) and clarify this confusion.

The synthesis of a complex of chromium(III) with alanine was first reported by Ley and Winkler in 1912.[1] However, it is only more recently that detailed studies of such complexes have been reported. Such work has tended to point to the formation of a single, or very significantly dominant, isomer. The complex which forms stereospecifically is usually assigned, for the S-alanine complex, as the Λ-*fac*(+) or β-(+) isomer.[2–6] This compound has generally been considered to be insoluble in water. To our knowledge, Green and Ang[2] are the only workers to suggest slight solubility of the tris complex in water, and they only reported electronic spectra. However, they did note some instability of the complex, in aqueous solution, with time. A similar observation was later reported by Minor *et al.*,[3] but these authors suggested the presence of two different species in the solid. The first soluble in water and the second insoluble.

RESULTS AND DISCUSSION

The compound studied in the present work was prepared by a variety of methods, as reported in the earlier literature,[2–5] and in all cases each sample had the same spectroscopic properties. The solid has slight solubility in water and it was possible to dissolve a complete sample by successive extractions with separate aliquots of water, all fractions having identical circular dichroism. A typical spectrum of the complex dissolved in water is shown in Fig. 1 and detailed in Table 1. The solid complex is much more soluble in DMSO or acidic aqueous solutions. Freshly prepared acidic solutions† are pink and

* Authors to whom correspondence should be addressed.

† Slight colour changes from red–pink to purple have been noted for the reactions discussed in this paper. However the changes in the electronic spectra are very slight, very small shifts in the maxima of broad bands and changes in half-widths, results of such studies have been uninformative and for the sake of brevity are not detailed here.

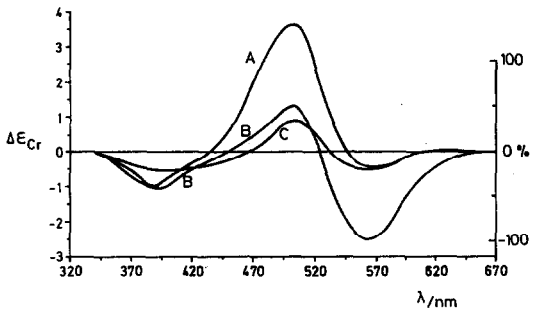

Fig. 1. The circular dichroism of tris(S-alaninato) chromium(III): (A) In water; (B) As 1% KBr pellet; (C) In DMSO.

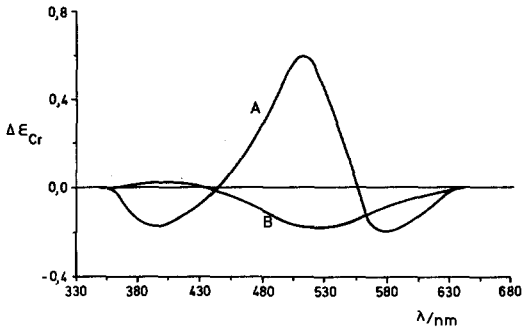

Fig. 2. The circular dichroism of tris(S-alaninato) chromium(III) in acidic solution. The compound was dissolved in 4 M perchloric acid and the spectrum recorded as soon as possible after mixing; (A) and (B) 30 min later.

have a circular dichroism spectrum which resembles that of a solution in water or DMSO. However, on standing, the spectra of acidic solutions soon change, over a period of minutes, in the way shown in Fig. 2. The instability of the complex in acidic solution does not appear to have been appreciated by earlier workers.[4] Another interesting observation is that the spectrum in acidic solution can be reversed to that of the aqueous solution by neutralization with sodium hydroxide. The fact that the reaction in acid occurs over a period of minutes suggests a genuine chemical reaction, such as ring opening, rather than the formation of an outer-sphere complex.

The solid complex dispersed in a KBr disc has the same circular dichroism sign pattern as the complex in aqueous solution, Table 1. The spectrum of the tris complex, as determined in the present study, either in the solid, aqueous or DMSO solution, shows the same sign pattern, strongly suggesting that the same complex is present in each of these situations.

There has been considerable debate concerning the assignment of the lowest energy ligand-field transitions in tris-chelates of chromium(III) (T_{2g}

parentage in O_h, the A and E terms.[7,8] The argument was eventually settled by X-ray crystallographic studies.[9] The ordering of the A and E terms is different in the tris(ethylenediamine) and tris (oxalato) complexes of chromium(III).[8] Consequently, the sign of the E component, which can be correlated with the absolute configuration of the complex[4,8] must be determined with care. However, the dominant tris(S-alanine) complexes of cobalt (III) and chromium(III) are isomorphous,[4] suggesting that they are both lambda-β isomers. Our work, in addition, allows us to observe that the circular dichroism of the chromium complex (Fig. 1) is fully consistent with the ordering of the terms A followed by E, as in the corresponding lambda-tris(oxalato)chromium(III).[8,9] The simple correlation of the spectrum of the tris complex with absolute configuration had been overlooked in earlier work because of a lack of sensitivity of circular dichroism equipment and a failure to realize the reactivity of such compounds in aqueous and acidic solutions. The lability of the chromium(III) complexes in acidic solution is perhaps surprising. The corresponding cobalt complexes have identical spectra in acidic and neutral solution. Relatively labile complexes of chromium(III) are rare[10] and the kinetics of these reactions are under further investigation.

EXPERIMENTAL

Materials and method

Chromium nitrate nonahydrate was obtained from Fluka, S-alanine, dimethylsulphoxide and perchloric acid from Merck and sodium hydroxide from Pronolab.

Circular dichroism spectra were recorded with a Jobin-Yvon Auto-Dichrographie Mk.IV at the Universidade Aveiro; essentially similar results were obtained using a JASCO C.D. instrument at the University of London Intercollegiate Service at University College. X-ray powder diffraction results were obtained from the Department of Earth Sciences at Queen Mary and Westfield College.

Preparation of the complex

The method was either, essentially as described by Minor *et al.*[3] or Gillard *et al.*[4] and involved the reaction of hot aqueous solution of S-alanine with chromium nitrate, followed by neutralization with sodium hydroxide, or by the "solid-state" method of Oki.[5,11] A pink compound with identical spectroscopic properties to those described in this paper was obtained on all occasions. The compound was isomorphous with the pink insoluble phase described by Minor *et al.*[3] and had satisfactory microanalysis (CHN) for the anhydrous tris complex.

SYNTHESIS, SPECTRAL AND STRUCTURAL STUDIES ON $(N_2H_5)_2MCl_4(H_2O)_2$ (M = Pt AND Pd); CRYSTAL STRUCTURE OF THE PLATINUM COMPLEX

N. R. SREENIVASA KUMAR, I. I. MATHEWS and K. C. PATIL*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-560012, India

(*Received* 2 *August* 1990; *accepted* 5 *November* 1990)

Abstract—Hydrazinium complexes of platinum and palladium, viz. $(N_2H_5)_2MCl_4(H_2O)_2$ (where M = Pt and Pd), have been prepared and characterized. The structure of the platinum complex has been determined by single crystal X-ray crystallography. The platinum atoms lie on inversion centres and are coordinated by two chlorines and two $N_2H_5^+$ ions through *trans* positions.

In continuation of our studies on metal complexes containing the hydrazinium cation, e.g. $N_2H_5Ln(SO_4)_2(H_2O)$ (Ln = La, Ce, Pr, Nd and Sm),[1] $(N_2H_5)_2M(C_2O_4)_2(H_2O)_n$ (M = Co, Ni and Cu),[2] $(N_2H_5)_2UO_2(C_2O_4)_2(H_2O)$,[3] $N_2H_5M(N_2H_3COO)_3(H_2O)$ (M = Fe, Co, Ni and Zn),[4] $(N_2H_5)_6(UO_2)_2(C_2O_4)_5(H_2O)_2$[5] and $(N_2H_5)_2MCl_4(H_2O)_2$ (M = Fe, CO, Ni and Cu),[6] we now report the synthesis of $(N_2H_5)_2MCl_4(H_2O)_2$ (M = Pt and Pd) and also the crystal structure of the platinum complex.

RESULTS AND DISCUSSION

The reaction between the metal chlorides of platinum and palladium [K_2PtCl_4 or $H_2PtCl_6(H_2O)_2$ Na_2PdCl_4] and hydrazinium dihydrochloride [$N_2H_4(HCl)_2$] yields $(N_2H_5)_2PtCl_4(H_2O)_2$ and $(N_2H_5)_2PdCl_4(H_2O)_2$ complexes instantaneously. It is essential to use $N_2H_4(HCl)_2$ rather than N_2H_4HCl in order to prevent the reduction of platinum and palladium salts to the metals. The compositions of the complexes have been fixed by chemical analysis (Table 1). IR spectra of the complexes show ν(N—N) of $N_2H_5^+$ at around 1000 cm^{-1} indicating coordination of $N_2H_5^+$ to the metal.[7] The observed absorptions in the visible region (24,800 and 26,400 cm^{-1}) are characteristic of $^1A_{1g} \rightarrow {}^1B_{1g}$ transitions of square-planar complexes.[8]

Hydrazine, which can be visualized as the amino derivative of ammonia, is a weaker base than ammonia because of the electronegative character of the amino group. Monoprotonated hydrazine, the hydrazinium cation, has a lone pair like in the ammine and its basicity is very much lowered due to the presence of a positive charge immediately adjacent to the donor atom.[9]

It is well known that the reaction between K_2PtCl_4 and NH_4Cl leads to the formation of *cis*-$[Pt(NH_3)_2Cl_2]$. Because of the similarities between $:NH_3$ and $:N_2H_5^+$, a similar *cis* structure was proposed for the corresponding hydrazinium complex.[10] Further, from IR studies, Stetsenko *et al.* have assigned the *cis* structure to $[Pt(N_2H_5)_2Cl_2]Cl_2(H_2O)_2$.[11] However, single crystal X-ray studies have shown that the complex has a *trans* structure.

Description of the structure

The structure of $(N_2H_5)_2PtCl_4(H_2O)_2$ consists of $[Pt(N_2H_5)_2Cl_2]^{2+}$, Cl^- ions and water molecules. The platinum atom has a square-planar coordination, bonded by two chlorine atoms and two nitrogen atoms from the $N_2H_5^+$ ions. The structure of the cation, $[Pt(N_2H_5)_2Cl_2]^{2+}$, is illustrated in Fig. 1.

The Pt—Cl distance [2.296(1) Å] is equal to the value of 2.30(2) Å found in *trans*-$[Pt(NH_3)_2Cl_2]$[12] and also in a variety of other chloroplatinum(II) complexes. The Pt—N bond length [2.044(5) Å] observed in the present structure is unusually

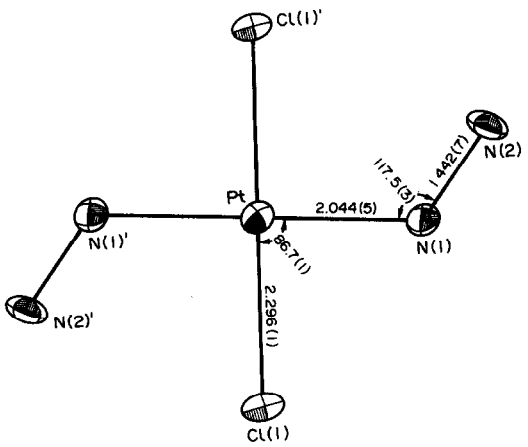

Fig. 1. ORTEP diagram of the $[Pt(N_2H_5)_2Cl_2]^{2+}$ ion with bond lengths (Å) and angles (°). Thermal ellipsoids are drawn at the 50% probability level and symmetry related atoms are shown by primes (′).

shorter than in the corresponding ammine complexes, e.g. 2.17(4) Å in *trans*-$[Pt(NH_3)_2Cl_2]$. The observed short metal–nitrogen distance in the present case is surprising as $N_2H_5^+$ is a poorer σ-donor compared to NH_3 and known to form weak metal–nitrogen bonds. The N—N bond length [1.443(7) Å] in the present structure is not significantly different from the one observed in N_2H_5Cl (1.45 Å).[13] The Pt—N(1)—N(2) angle is 117.5(3)°, larger than the value of 110° observed in $(N_2H_5)_2Zn(SO_4)_2$,[14] but comparable to 119.1(3)° found in $N_2H_5CuCl_3$.[15]

The N(2) atom is 0.476 Å away from the plane of Pt—N(1)—Cl(1). The water molecules are in the vicinity of $—NH_3^+$ of $N_2H_5^+$, bonded by N—H---O type hydrogen bonds. The distance of 2.755(1) Å observed for N(2)—O(w) indicates strong hydrogen bonding. The angle observed for N(1)—N(2)—O(w) is 104.5(1)°.

NH_3 *vs* $N_2H_5^+$

Ammines complex to platinum(II) ion by donation of an electron pair from an sp^3 hybrid on nitrogen to an empty orbital of correct symmetry on platinum. Since there are no low-energy empty orbitals on nitrogen suitable for π-back donation, the Pt—N bond can be considered to be a pure σ-bond. The $N_2H_5^+$ cation is similar to ammine in this aspect. Further, the ammine ligands are low in the *trans* effect and the *trans* influence series, low in the nephalauxetic series and high in the spectrochemical series.[16] This feature is evidenced where the singlet→singlet absorption is at 29,800 cm^{-1} in *cis*-$[Pt(NH_3)_2Cl_2]$, at 26,600 cm^{-1} in *trans*-$[Pt(NH_3)_2Cl_2]$, but at 21,000 cm^{-1} in K_2PtCl_4.[17] Surprisingly, the electronic spectrum of *trans*-$[Pt(N_2H_5)_2Cl_2]Cl_2(H_2O)_2$ (Table 1) shows the absorption at 26,400 cm^{-1}, indicating the similar bonding nature of the $N_2H_5^+$ ion with respect to NH_3, even though the basicity of the $N_2H_5^+$ ion is significantly lower than the ammine.[9] Being a poorer σ donor, formation of the *trans* isomer in the case of $N_2H_5^+$ compared with NH_3 is rather puzzling.

Although the *trans* effect is concerned only with kinetics, reference is sometimes made to a static *trans* influence which affects physical properties such as bond lengths, vibrational frequencies, etc.[18,19] Moreover, investigations on the thermal stabilities of platinum(II) ammines indicate that *trans* isomers are generally more stable than the corresponding *cis* isomers.[20] This difference in stabilities was explained on the basis that the *trans* effect of Cl^- is greater than that of NH_3, and also that the Pt—Cl bond strength is less than that of Pt—N. Thus, in the *cis* isomer, the Pt—N bond is weaker than in the *trans* form because of the greater bond-weakening effect of Cl^- compared with NH_3. For the same reason, the reverse is true for the Pt—Cl bond. Since the Pt—Cl bond strength is less than that of Pt—N, the overall stability of the complex will be affected more by changes in the Pt—N than Pt—Cl bond strengths. This explanation supports the view that the *trans* effect order $Cl^- > NH_3$ is a consequence of Pt—Cl bond weakening. In this connection it is of interest to recall that the intermediate $[Pt(NH_3)Cl_3]$ reacts to yield *cis*-

$[Pt(NH_3)_2Cl_2]$, meaning that the less stable isomer is formed as the kinetic product. Since the Pt—N bond in the hydrazinium complex is shorter than the corresponding ammine complex, the same *cis* product can be expected, though experiments show the formation of the *trans* isomer. Thus the formation of the *trans* product in the case of $N_2H_5^+$, in contrast to NH_3, can be attributed to the reduced repulsion between the two $N_2H_5^+$ cations in the resulting complex due to the larger separation in the *trans* arrangement.

Structure of $(N_2H_5)_2PdCl_4(H_2O)_2$

Since the IR and electronic spectral data for the above complex are similar to those observed for the platinum complex (Table 1), the same structure, viz. *trans*-$[Pd(N_2H_5)_2Cl_2]Cl_2(H_2O)_2$ can be assigned to the palladium complex.

EXPERIMENTAL

Preparation

$(N_2H_5)_2PtCl_4(H_2O)_2$. The platinum complex was obtained by adding K_2PtCl_4 (or H_2PtCl_6) solution (0.5 g in a minimum amount of water) to a saturated solution of $N_2H_4(HCl)_2$ (10 cm^3). Golden yellow crystals of the complex formed in a day. The crystals were filtered from the solution and air dried.

$(N_2H_5)_2PdCl_4(H_2O)_2$. The palladium complex was prepared in the same way by starting either with Na_2PdCl_4 or $PdCl_2$ (in HCl) and $N_2H_4(HCl)_2$.

Physico-chemical methods

The composition of the complexes was determined by chemical analysis:[21] hydrazine by titrating with KIO_3 under Andrews conditions, metals from TG weight loss, and chloride by Volhard's method.

IR spectra of the complexes in the region 4000–600 cm^{-1} were recorded using a Perkin–Elmer 781 spectrophotometer as Nujol mulls. Electronic spectra in the solid state were obtained using a Hitachi U-3400 spectrophotometer by dispersing the samples in Nujol.

X-ray analysis

A crystal of dimensions $0.40 \times 0.30 \times 0.15$ mm was used in the present work. The cell dimensions

and space group were determined on a Weissenberg camera and the cell constants were subsequently refined on a CAD-4 diffractometer. Intensity data were collected in the usual manner.

Structure solution and refinement

The structure was solved by conventional Patterson function and refined by full-matrix least-squares techniques using SHELX-76 system of programs.[22] Hydrogen atoms could not be located in the difference Fourier map. Further refinement of the structure was carried out by introducing anisotropic thermal parameters, followed by the sigma weighting scheme and absorption corrections. The ORTEP-II program[23] was used for the diagram. All the details regarding the data collection and structural analysis are given in Table 2.

ISOLATION OF $Cp_2Cr_2(CO)_4Se_2$ FROM THE INTERACTION OF $Cp_2Cr_2(CO)_4Se$ WITH MOLECULAR OXYGEN. ESR EVIDENCE FOR PARAMAGNETIC INTERMEDIATES

LAI YOONG GOH* and S. K. KHOO

Department of Chemistry, University of Malaya, 59100 Kuala Lumpur, Malaysia

(*Received* 27 *April* 1990; *accepted* 16 *November* 1990)

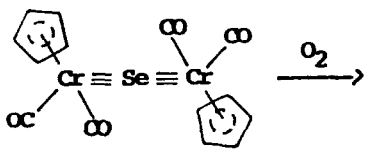
Abstract—The interaction of $Cp_2Cr_2(CO)_4Se$ with molecular oxygen at ambient temperature led to the isolation of *ca* 30% yield of $Cp_2Cr_2(CO)_4Se_2$ from a product mixture also containing $Cp_4Cr_4Se_4$ and other CpCr diamagnetic species. $CpCr(CO)_2(O_2)$ was one of the paramagnetic intermediates detected at −70°C in the ESR spectrum.

The degradation of organometallic compounds by molecular oxygen is a well-known, though little-understood phenomenon.[1] In the last two decades, the interaction of dioxygen with organic and organometallic compounds has received increasing attention because of their relevance to organic synthesis and biological processes.[2–6] Literature reports include the air-oxidation of $[CpMo(CO)_3]_2$,[7] the $CpMo(CO)_3^-$ anion,[8] and lately of $[(C_5Me_5)Mo(\mu\text{-Br})(Me)NO]_2$,[9] the photo-oxidation of $Mn_2(CO)_{10}$ and related complexes,[10] the unusual hydrogen atom abstraction by O_2 from one of the CH_3 groups of $CpFe(\eta^6\text{-}C_6Me_6)$,[11] oxygenation reactions of $[CpMn(CO)_2]_2S$,[12] $CpM(NO)R_2$ (M = Mo, W),[13] $Cp_2Cr_2(CO)_6$,[14] $Cp_2Mo_2S_4$[15] and more recently of $[CpMo(\mu\text{-S})(\mu\text{-SH})]_2$,[16] $(C_5Me_5)_2Ta(=CH_2)H$[17] and $(C_5Me_5)_2W{=}O$,[18] and alkyliron(III) porphyrins.[19] In this paper, we describe the interaction of $Cp_2Cr_2(CO)_4Se$ (**1**) with O_2. This study was prompted by the facile insertion of sulphur[20] and selenium,[21] the heavier congeners of oxygen in Group 16, into the Cr≡Se≡Cr bond of **1**.

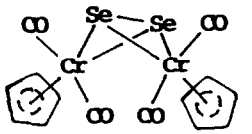
RESULTS AND DISCUSSION

Reaction with oxygen

Products. The reaction of the triply-bonded Cr≡Se≡Cr complex, $Cp_2Cr_2(CO)_4Se$ (**1**), with O_2 led to the isolation of crystalline $Cp_2Cr_2(CO)_4Se_2$ (**2**) in *ca* 30% yield, which could be increased to *ca* 50% with a controlled supply of O_2, together with impure solids of $Cp_4Cr_4Se_4$ [eq. (1)],



(1)



(2)

$$+ Cp_4Cr_4Se_4 + \cdots \quad (1)$$

and minor amounts of some unidentified CpCr species detectable in solution in the NMR spectrum. Complex **2** was characterized by its elemental analysis and the identical resemblance of its spectral features to those of the structurally determined $\mu\text{-}\eta^2\text{-}Se_2$ bonded dichromium complex.[21] On a comparative note, it may be pointed out that this complex was also the major product from the interaction of **1** with elemental sulphur[20] and selenium.[21]

Paramagnetic intermediates

A solution of **1** in toluene was ESR-inactive under an inert atmosphere. However, in the presence of a trace amount of air or O_2 at −70°C, two weak

* Author to whom correspondence should be addressed.

signals rapidly developed, viz. X ($g = 2.021$) and Y ($g = 1.996$). Signal Y was observed to be stronger and broader. As more air or O_2 was admitted, signal X was observed to sharpen and intensify, while signal Y gradually diminished and eventually disappeared. This was accompanied by the emergence of a third signal Z which was observed as a sextet ($a = 0.12$ mT) with clearly visible quartet satellites ($a = 1.72$ mT) centred at $g = 1.987$. The resulting ESR spectrum is illustrated in Fig. 1. The signal intensity of X and Z persisted for several hours at $-70°C$ but showed signs of decomposition when the temperature was raised above $-45°C$.

The sextet characteristics of Z, arising from the hyperfine interactions of the five ^1H nuclei in the Cp ring, together with its quartet satellites, assignable to coupling with the central ^{53}Cr nucleus ($I = 3/2$, 9.5% natural abundance), conform exactly to those reported for the chromium dioxygen complex **3A**.[14] The latter species has been generated from the interaction of $[CpCr(CO)_3]_2$ in toluene at $-70°C$ with O_2 or air, pressurized at 100–300 torr, or from photo-oxygenation of Hg $[CpCr(CO)_3]_2$ and $CpCr(CO)_3Cu(phen)_n$.[14]

The close proximity of the g value (2.021) of the X signal to those observed for CO-substituted derivatives, $CpCr(CO)_2L$, of the radical $CpCr(CO)_3$, e.g. $g = 2.025$ for $L = C_6H_5CN$,[22] $g = 2.030$ (broad doublet) for $L = PPh_3$,[23] and $g = 1.996$ for $L = P(OMe)_3$,[24] suggests that it is derived from an analogous radical, where L = Se, as represented by **3B**. It is conceivable that **1** interacts with O_2 to form a peroxo complex (**3**), as shown in Scheme 1. Subsequent homolytic dissociation of **3** will generate the 17-electron paramagnetic species **3A** and **3B**, which are substantiated by our ESR observations.

The proposal of an intermediate peroxo radical species (**3**) is in agreement with the observation of the transient ESR signal Y which diminishes with the growth of two signals, Z ascribed to **3A** as discussed above, and X attributed to **3B**. Initially, only signals X and Y were observed without Z. This is due to the broad character of signal Y and the close proximity of the g values of Y and Z, resulting in the weak signal Z being obscurred under the broad envelope of Y. The assignment of **3** as a peroxo radical finds precedent in similar species isolated or ESR-detected in the photo-oxidation of $Mn_2(CO)_{10}$, $[CpFe(CO)_2]_2$ and related dimeric species,[10] in the insertion of O_2 into the M—C bond of alkylcobaloximes[25] and alkyliron(III) porphyrins,[19] and in the interaction of the dirhodium(II) aquo cation $\{Rh_2(aq)^{4+}\}$ with O_2.[26] Indeed, there is ample evidence indicating that the reaction of organometallic compounds with O_2 involves primarily the initial coordination of O_2 to the central M atom, leading to the eventual formation of peroxo complexes or radicals which may be organic or organometallic in nature.[4] Hence, probable for-

EXPERIMENTAL

General procedures and physical measurements

Inert atmospheric manipulation techniques, sources and preparation of reagents and solvents were as described previously.[20,21] ^{1}H NMR spectra were measured on a JEOL FX100 100 MHz spectrometer, and chemical shifts are relative to residual C_6H_6 in C_6D_6. ESR spectra were measured on a Bruker B-R 70 spectrometer (23 cm magnet) equipped with a variable temperature accessory and the field determined with the aid of a NMR oscillator; the g value was calibrated using DPPH. IR spectra were measured on a Perkin–Elmer 1330 instrument. Elemental analyses were performed by the Analytical Unit of the Research School of Chemistry, Australian National University, except for chromium, which we analysed as CrO_4^{2-}.[27]

Reaction of $Cp_2Cr_2(CO)_4Se$ (**1**) *with* O_2

A filtered solution of **1**, prepared *in situ* from $Cp_2Cr_2(CO)_6$ (400 mg, 1.0 mmol) and Se_8 (80 mg, 1.0 mmol)[21] in toluene (*ca* 10 cm^3) was stirred under an atmosphere of dried O_2 at ambient temperature for 3 h, until the original orange–brown colour had turned to dark greenish-brown. IR monitoring of the carbonyl stretching frequency indicated that the reaction was almost complete. Filtration removed fine, dark, sparingly soluble solids (*ca* 200 mg). IR (Nujol): ν(CO) 1925 and 1855 cm^{-1}. ^{1}H NMR (C_6D_6): δ 4.08, 5.13 and 5.88 pertaining to **2**, $Cp_4Cr_4Se_4$ and an unidentified species, respectively. The dark brown filtrate possessed Cp resonances at δ 4.36 and 4.08 belonging to **1** and $Cp_2Cr_2(CO)_4Se_2$ **2**, respectively, with a relative intensity of 1 : 7. On concentration to *ca* 1 cm^3 and addition of n-hexane (*ca* 1 cm^3), followed by cooling at −30°C, dark brown needles of **2** were obtained (146 mg, 0.29 mmol, 29% yield). (Found: C, 32.45; H, 1.97; Cr, 20.57; Se, 30.70. $(C_5H_5)_2Cr_2(CO)_4Se_2$ requires: C, 33.35; H, 2.00; Cr, 20.63; Se, 31.32%.) A small amount remained in the mother liquor together with traces of other unidentified cp-containing species. The above reaction with a controlled amount of O_2 [**1**, 41 mg, 0.096 mmol, in toluene (4 cm^3) and O_2 (6 cm^3, *ca* 0.3 mmol)] for 4 h led to a 33% conversion to **2**, as indicated in the ^{1}H NMR spectrum of the resultant solution. Approx-

imately 50% conversion was achieved after a further 3 h of reaction with a fresh quantity (10 cm^3) of O_2.

ESR spectra

ESR experiments were carried out on a *ca* 0.06 mol dm^{-3} solution of **1**, prepared in toluene in a 2-mm serum-capped quartz tube under argon. Air or O_2 was admitted when required via a needle puncture in the serum cap. X-band ESR spectra were recorded at $-70°C$ and higher temperatures.

(*Received* 15 *October* 1990; *accepted* 16 *November* 1990)

Abstract—The reduction of $WCl_4(THF)_2$ by sodium naphthalenide in the presence of 1,2-bis(dimethylphosphino)ethane (DMPE) in tetrahydrofuran affords *trans*-$WCl_2(DMPE)_2$. Interaction of this complex with $NaBPh_4$ in MeCN gives $[WCl(\eta^2\text{-MeCN})(DMPE)_2]BPh_4$ and with $SbCl_5$ the tungsten(V) complex $[WCl_4(DMPE)_2]SbCl_6$. The X-ray crystal structure of the latter shows the cation to have dodecahedral geometry with equatorial chlorine atoms. Interaction of *trans*-$MCl_2(DMPE)_2$ (M = Mo and W) with $LiAlH_4$ gives the hydrido aluminohydrides, $[MH(AlH_4)(DMPE)_2]_2$, and the X-ray crystal structure of the molybdenum compound has been determined. Methanolysis of the tungsten compound gives $WH_4(DMPE)_2$.

The compounds of the Group 6 elements, *trans*-$MCl_2(DMPE)_2$ (M = Cr[1] and Mo[2]) and reactions of the chromium[3a,b] and molybdenum[4] halides with acetonitrile have been described. The proposal of a η^2-MeCN intermediate in the reactions of $[Cr(MeCN)_2(DMPE)_2]^{2+}$ and $[CrCl(MeCN)(DMPE)_2]^+$ with methanol[3b] was supported by the isolation and X-ray crystal structure determination of *trans*-$[MoCl(\eta^2\text{-MeCN})(DMPE)_2]BPh_4$.[4]

The hydridoaluminohydrido complex of chromium(II), $[(DMPE)_2HCr(\mu\text{-H})_2Al(H)(\mu\text{-H})]_2$, and for molybdenum and tungsten the similar PMe_3 complexes $[(Me_3P)_4HM(\mu\text{-H})_2Al(H)(\mu\text{-H})]_2$ were obtained.[5] The tetrahydrides $MH_4(DMPE)_2$ (M = Cr[6a] and Mo[6b]) have also been described.

We now describe the synthesis of *trans*-$WCl_2(DMPE)_2$, its oxidation by $SbCl_5$ to $[WCl_4(DMPE)_2]SbCl_6$ and the synthesis of the aluminohydrides $[MH(AlH_4)(DMPE)_2]_2$ (M = Mo and W) and of $WH_4(DMPE)_2$.

RESULTS AND DISCUSSION

The interaction of $WCl_4(THF)_2$ with two equivalents of sodium naphthalenide in THF containing excess DMPE gives *trans*-$WCl_2(DMPE)_2$ in about 35% yield. On a small scale Na/Hg can be used as reductant. The compound crystallizes from hexane as large, deep red crystals that are soluble in toluene, THF, CH_2Cl_2 and MeCN but sparingly soluble in Et_2O and hexane. In addition to DMPE bands, the IR spectrum shows a single band at 324 cm^{-1} that can be assigned as the W—Cl stretch of

* Authors to whom correspondence should be addressed.

the *trans*-ClWCl moiety. Although paramagnetic with the magnetic moment, $\mu_{eff} = 2.2$ BM, implying a low spin d^4 configuration with two unpaired electrons [cf. $MoCl_2(DMPE)_2$, $\mu_{eff} = 2.65$ BM[2]], the compound is EPR silent at both 293 and 77 K. As for the molybdenum compound,[2] NMR spectra can be obtained for this and other tungsten(II) complexes; the CH_2 and CH_3 resonances of DMPE are, however, shifted compared with diamagnetic species.

Reaction with acetonitrile

In refluxing MeCN in the presence of $NaBPh_4$ the compound reacts to give a green solution from which the monosubstituted complex $[WCl(\eta^2\text{-MeCN})(DMPE)_2]BPh_4$, similar to its molybdenum analogue,[4] can be isolated. This complex is a 1:1 electrolyte in MeCN; the IR spectrum shows no band attributable to MeCN—a phenomenon[7] not uncommon.

The ^1H NMR spectrum shows the methyl resonance of MeCN at 3.4 ppm, which is close to the values for similar η^2-MeCN species,[4] while the $^{31}P\{^1H\}$ spectrum has a singlet (14.92 ppm) showing ^{183}W satellites ($J_{W-P} = 118$ Hz).

Reaction with antimony pentachloride

Although bis-acetonitrile complexes, $[M(DMPE)_2(MeCN)_2]^{2+}$, were obtained for chromium[3] and vanadium,[4] neither the molybdenum[4] nor tungsten analogues but only the cations $[MCl(\eta^2\text{-MeCN})(DMPE)_2]^+$, were formed. In an attempt to remove the second chloride we treated $WCl_2(DMPE)_2$ with $SbCl_5$ in refluxing MeCN. This led, however, to chlorination by $SbCl_5$ and the isolation in high yield of the unusual tungsten(V) salt, $[WCl_4(DMPE)_2]SbCl_6$. It may be noted that $MoCl_2(DMPE)_2$ could be oxidized only to the molybdenum(III) cation $[MoCl_2(DMPE)_2]^+$.[2]

The magnetic moments for tungsten(V) compounds d^1, are known to be low[8-10] and no shift in MeCN solutions of the salt by Evans' NMR method were observed. In CH_2Cl_2 solution at 293 K, the X-band EPR spectrum showed a single sharp resonance with $g = 1.90$.

Cationic tungsten(V) species are not well known. Some poorly characterized complexes have been considered[8-10] to be of the type $[WX_4L_2]X$, which include the green WCl_5dppe[9] [dppe = 1,2-bis(diphenyl)phosphinoethane]. Apart from compounds containing oxo, sulphido, η^5-cyclopentadienyl, etc., groups, established tungsten(V) compounds are the halides and alkoxohalides[10] and octahedral WX_6^- and eight-coordinate $[W(CN)_8]^{3-}$ anions.[10,11] Recently, aryloxides, notably the Et_4N^+ and Li^+ salts of the octahedral $[W(OC_6H_5)_6]^-$ ion,[12] and the aryloxohalides with bulky OAr groups, $WCl_3(OC_6H_3\text{-}2,6\text{-}Ph_2)_2L$ (L = THF and PMe_2Ph),[13a] and $W(O\text{-}C_6H_3\text{-}2,6\text{-}Cl_2)_4Cl(Et_2O)$[13b] have had their X-ray structures determined.

The $[WCl_4(DMPE)_2]^+$ cation has a dodecahedral structure with the four chlorines occupying the equatorial, **B**, sites and the phosphorus atoms the **A** sites. A diagram of the crystal structure, which also contains two independent centrosymmetric $SbCl_6^-$ anions, is shown in Fig. 1(a), the cation in Fig. 1(b); bond lengths and angles are given in Table 1.

The dodecahedral geometry is analogous to that found in the chromium(IV) complex $CrH_4(DMPE)_2$,[6a] in which the anionic ligands, the hydrides, are also equatorial. Dodecahedral geometry also almost certainly occurs in the tungsten(IV) phosphine hydride and aluminohydride complexes,[14,15a] but in these structures the monodentate phosphines occupy both types of site. It is pertinent to note that the W—P bonds in the present tungsten(V) complex are longer than any of those in the tungsten(IV) complexes *and* also longer than the W—Cl bonds. This feature is a reflection of the weakness of the W—P interactions in the absence of any W—P π-back bonding.

Aluminohydride complexes

As noted above, interaction of $CrCl_2(DMPE)_2$ with $LiAlH_4$ gave a chromium(II) hydrido aluminohydride $[CrH(AlH_4)(DMPE)_2]_2$,[5] which was characterized by X-ray diffraction.

For both tungsten and molybdenum, interaction of excess $LiAlH_4$ on $MCl_2(DMPE)_2$ in Et_2O gives the metal(II) aluminohydride species, $[MH(AlH_4)(DMPE)_2]_2$, as yellow air- and moisture-sensitive crystals. Due to twinning, X-ray quality crystals of the tungsten compound could not be obtained but suitable crystals of the molybdenum compound were found.

The structure of the molybdenum complex as $[(DMPE)_2HMo(\mu\text{-}H)_2Al(H)(\mu\text{-}H)]_2$ has been confirmed by X-ray crystallography. A diagram of the dimeric molecule is shown in Fig. 2; selected bond lengths and angles are given in Table 2.

Although we were not able to reliably locate any hydrogens except for the two in the $Al(\mu\text{-}H)_2Al$ bridge, the structure is similar in most respects to those for other hydridoaluminohydride complexes.[15a] The relative position of the molybdenum

Key to symmetry operations relating designated atoms to reference atoms at (x, y, z): (B) $1.0+x$, $1.0+y$, z.

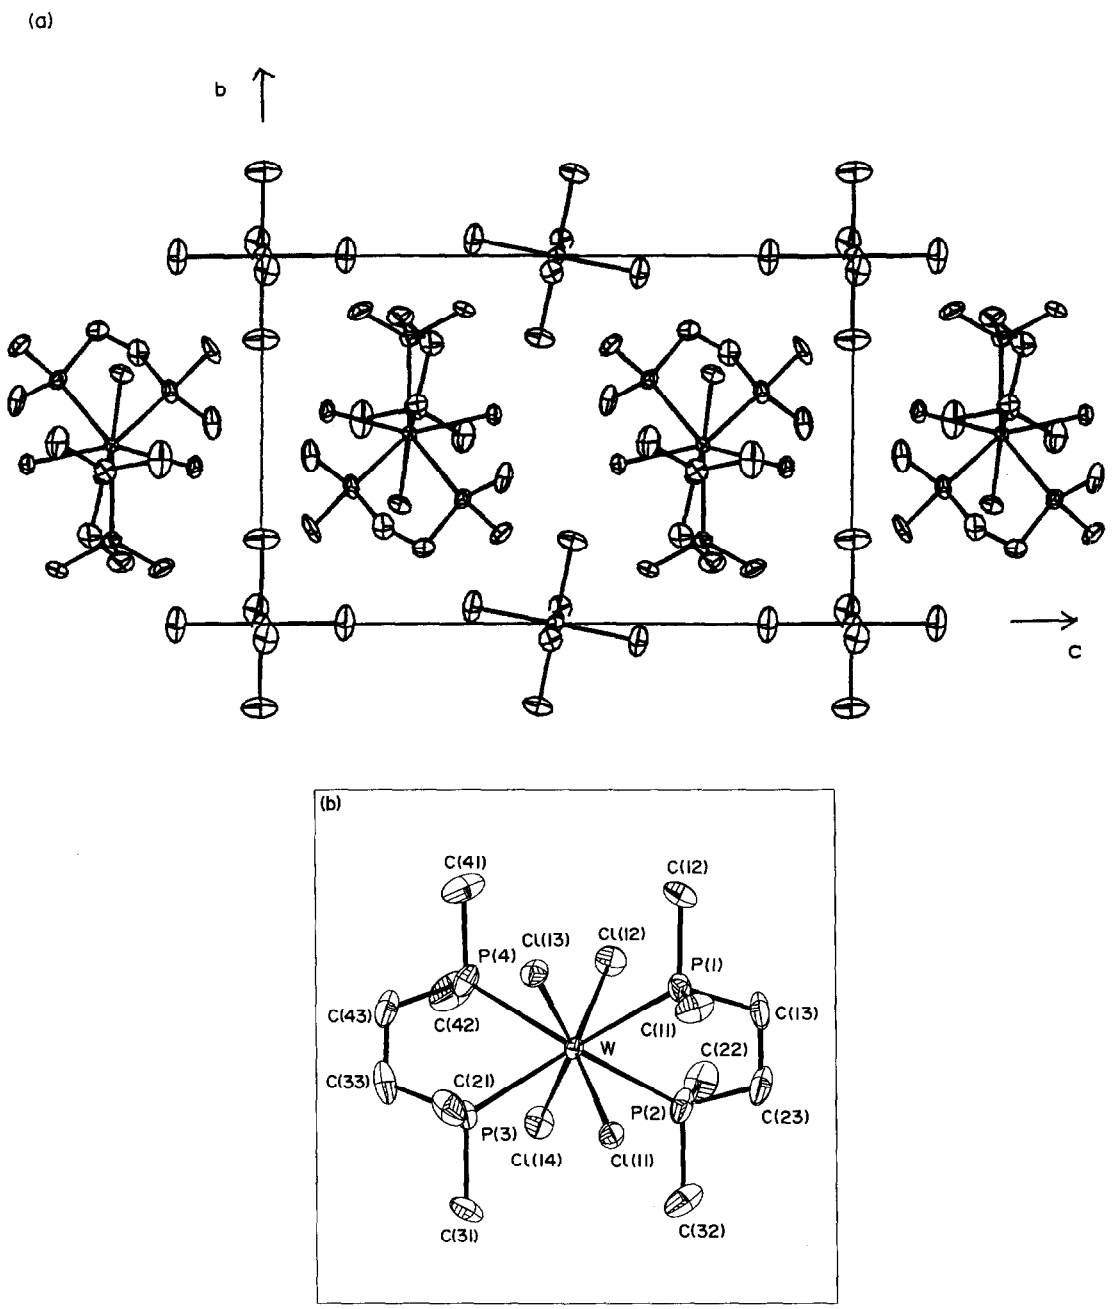

Fig. 1. (a) The crystal structure of $[WCl_4(DMPE)_2]^+[SbCl_6]^-$ and (b) the structure of the $[WCl_4(DMPE)_2]^+$ cation.

atom to the plane of the $Al(\mu\text{-}H)_2Al$ bridge strongly suggests that if, as is likely, the Mo···Al links are also via $Mo(\mu\text{-}H)_2Al$ bridges, then a terminal hydrogen is also present on the aluminium atom. That this is the case is shown by the ^{27}Al NMR spectra which fall in the region for five-coordinate aluminium.[5,15]

The four phosphorus atoms coordinate in an approximately planar manner and we presume the single hydrogen on molybdenum occupies the apparent vacant site "*trans*" to the coordination of the two bridging hydrogens. The molybdenum is thus seven-coordinate as in the similar molybdenum(II) and tungsten(II) trimethylphosphine complexes.[5] In view of the approximate planarity of the MoP_4 unit with *trans* P—Mo—P angles of 149 and 169°, a distorted mono-capped octahedral structure is a possibility. The absence of confirmed positions for the hydrides makes it difficult to have much confidence in this assignment, however.

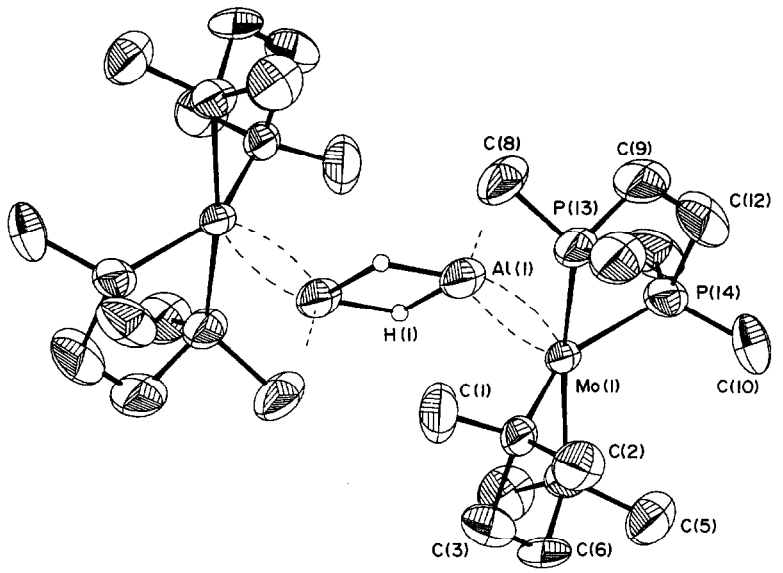

Fig. 2. The structure of one of the two indendent molecules of $[MoH(AlH_4)(DMPE)_2]_2$. Bonds to presumed hydrogen atoms are shown by dashed lines.

The ^1H NMR spectra are not very useful since the bands are broad as a result of the ^{27}Al quadrupole phosphorus couplings and the paramagnetism; also the molecules are doubtless non-rigid as in similar species.[5] The bands, though poorly resolved, are in similar positions to those in the PMe_3 compounds,[5] with terminal Al—H and $Al(\mu\text{-}H)_2Al$ bands at *ca* 4.1 ppm, the CH_2 and CH_3 resonances of DMPE around 1.58 ppm and the $Al(\mu\text{-}H)_2M$ bands around −5.5 ppm. For the tungsten compound there is a band at −8.3 ppm which is due to the terminal W—H.

Interaction of the tungsten complex with methanol allows the isolation of the *tetrahydride*, $WH_4(DMPE)_2$, as pale yellow crystals [cf. methanolysis of the PMe_3 analogues to give $MH_4(PMe_3)_4$[5]]. The molybdenum tetrahydride, $MoH_4(DMPE)_2$, which was made[6b] by sodium reduction of $MoCl_2(DMPE)_2$ under hydrogen, can also be obtained by methanolysis of the aluminohydride. The IR and NMR spectra of the tungsten tetrahydride are similar to those of the molybdenum and chromium[6a] analogues. Thus the IR spectrum has W—H bands at 1745 and 1720 cm^{-1}, while the ^1H NMR spectrum has a quintet at −5.46 ppm (333 K) with $J_{P-H} = 29.2$ Hz (cf. Cr, −6.91 ppm, $J_{P-H} = 56.1$; Mo −5.51 ppm, $J_{P-H} = 31.5$ Hz). Unlike the rigid chromium analogue, $WH_4(DMPE)_2$ is non-rigid from the fast exchange limit (333 K) down to 273 K, similar to $MH_4(PMe_3)_4$ (M = Mo and W).[16] No comment is made [6b] concerning non-rigidity of $MoH_4(DMPE)_2$, but presumably it is.

EXPERIMENTAL

The general techniques and instrumentation used have been described.[17] $WCl_4(THF)_2$ was prepared by adding excess THF to $WCl_4(SEt_2)_2$[18] and stirring for a few minutes, when the THF complex precipitates as an orange powder which was collected, washed with THF and dried. IR spectra are in Nujol mulls in cm^{-1}; NMR spectra, δ values in ppm in C_6D_6 unless otherwise stated and referenced to Me_4Si (^1H), external H_3PO_4 (^{31}P) and external $[Al(H_2O)_6]^{3+}$ (^{27}Al). All operations were carried out under nitrogen, argon or *in vacuo*.

(1) Trans-*bis*[1,2-*bis*(*dimethylphosphino*)*ethane*] *dichlorotungsten*(II)

To a suspension of $WCl(THF)_2$ (6 g, 13 mmol) in THF (100 cm^3) at 0°C was added DMPE (4.5 cm^3 27 mmol) and sodium naphthalenide (92 cm^3 of a 0.28 M solution in THF, 26 mmol). The solution was stirred at room temperature for about 18 h, filtered and evaporated to dryness. The naphthalene was removed by sublimation *in vacuo* and the residue was extracted into warm hexane (4 × 50 cm^3). The extract was filtered, concentrated to about 100 cm^3 and cooled at −20°C to give 2.1 g of dark red crystals of $WCl_2(DMPE)_2$. Further crops of crystals may be obtained from the supernatant. Combined yield: 2.5 g (35%); m.p. *ca* 310°C. (Found: C, 25.1; H, 5.8. $C_{16}H_{32}P_4W$ requires: C, 26.0; H, 5.8%.) Magnetic moment (Evans' NMR method), 2.2 BM. IR: 1418s, 1291m, 1277s, 1227s, 1227w, 1112m,

Key to symmetry operations relating designated atoms to reference atoms at (x, y, z): (a) $2.0-x, -y, 2.0-z$; (*b*) $1.0-x, 1.0-y, 1.0-z$.

1073m, 989m, 927vs, 921vs, 888s, 859s, 832s, 784s, 730s, 698s, 630s, 452m, 324s. ^{1}H NMR: 19.55 (s, PCH_2); −3.99 (s, PMe_2).

(2) Trans-(*η^2-acetonitrile*)(*chloro*)*bis*[1,2-*bis*(*dimethylphosphino*)*ethane*]*tungsten*(II) *tetraphenylborate*

To $WCl_2(DMPE)_2$ (0.31 g, 0.56 mmol) in MeCN (50 cm^3) was added an excess of $NaBPh_4$ (0.4 g, 1.17 mmol). The solution was refluxed for 24 h, cooled and the yellow–green solution filtered. After evaporation, the residue was extracted with CH_2Cl_2 (30 cm^3) and the extract evaporated to dryness; the residue was crystallized from MeCN. Yield: 0.35 g (71%); m.p. 190°C. (Found: C, 51.1; H, 6.2; N, 1.4. $WC_{38}H_{55}P_4BClN$ requires: C, 51.9; H, 6.3; N, 1.6%.) IR: 3050s, 3032s, 1945w, 1881w, 1814w, 1580m, 1428s, 1416s, 1299m, 1288m, 1267w, 1182w, 1149w, 1033w, 944s, 930s, 891m, 865w, 851w, 793w, 745s, 710s, 703s, 976m, 649m, 625w, 615m, 604s, 485w, 452w. Conductivity (MeCN): $\Lambda_M = 86\ \Omega^{-1}$ cm^2 mol^{-1}. ^{1}H NMR (CD_3CN): 7.31–6.96 (20, m, BPh_4); 3.4 (3, s, CH_3CN); 1.57–1.35 (32, m, DMPE). ^{31}P-{^{1}H} NMR: 14.92s; $J_{W-P} = 118$ Hz.

(3) Trans-*bis*[1,2-*bis*(*dimethylphosphino*)*ethane*] *tetrachlorotungsten*(V) *hexachloroantimonate*

To $WCl_2(DMPE)_2$ (0.3 g, 0.54 mmol) in MeCN (50 cm^3) was added $SbCl_5$ (1.2 cm^3 of a 1 M solution in CH_2Cl_2, 1.2 mmol). The initial red solution was refluxed for 12 h, after which the colour was green. The solution was filtered, concentrated (15 cm^3) and cooled at −20°C to give dark green crystals. Yield: 0.33 g (73%); m.p. 230°C. (Found: C, 15.3; H, 3.4; P, 12.5. $C_{12}H_{32}Cl_{10}P_4SbW$ requires: C, 15.0; H, 3.4; P, 12.9%.) IR: 1413s, 1295m, 1284s, 1247w, 1132w, 1086w, 1001w, 938vs, 901s, 853w, 794w, 749m, 717s, 659m, 643w, 433m. Conductivity (MeCN): $\Lambda_M = 90\ \Omega^{-1}$ cm^2 mol^{-1}.

(4) *Bis*[1,2-*bis*(*dimethylphosphino*)*ethane*](*tetrahydridoaluminato*)*hydridotungsten*(II) *dimer*

To $WCl_2(DMPE)_2$ (0.22 g, 0.40 mmol) in Et_2O (50 cm^3) at −78°C was added a suspension of $LiAlH_4$ (0.12 g, 3.20 mmol) in Et_2O (30 cm^3). Upon warming to room temperature the solution turned orange and gas was evolved. After stirring for 12 h; the solution was filtered, concentrated (*ca* 50 cm^3) and cooled to −20°C to give yellow crystals. Further crops of crystals may be obtained from the supernatant. Combined yield: 0.29 g (72%); m.p. 215°C (decomp). (Found: C, 28.0; H, 7.2; P, 23.8. $W_2C_{24}H_{72}P_8Al_2$ requires: C, 28.0; H, 7.0; P, 24.0%.) IR: 1618s (AlH), 1650s, [W(μ-H)$_2$Al]; other bands 1420s, 1336s, 1291m, 1275s, 1228w, 1118w, 1077w, 936vs, 922vs, 886s, 836s, 787m, 696s, 636s, 575m, 535s, 461m. ^{1}H NMR: 4.1 (m, terminal Al—H and Al—H—Al); 1.58 (m, DMPE); −5.5 (m, W—H—Al); −8.3 (m, W—H-terminal). ^{31}P-{^{1}H} NMR: 20.84, s; $J_{W-P} = 108.55$ Hz. ^{27}Al-{^{1}H} NMR: 99 ("t", $w_{1/2} = 4500$ Hz).

The *molybdenum* analogue was obtained similarly from $MoCl_2(DMPE)_2$;[2] X-ray quality crystals were grown from diethyl ether. The IR and NMR spectra closely resemble those of the tungsten compound except that the Mo—H band is probably mixed in with the Mo—H—Al resonances as in other cases.[5]

(5) *Bis*[1,2-*bis*(*dimethylphosphino*)*ethane*]*tetrahydridotungsten*(IV)

To a solution of $[WH(AlH_4)(DMPE)_2]_2$ (0.42 g, 0.41 mmol) in hexane (30 cm^3) was added MeOH dropwise until gas evolution ceased. The solution was filtered, evaporated to dryness and the residue extracted with hexane. The filtered extract was concentrated (to *ca* 10 cm^3) and cooled to −20°C to give pale yellow crystals (0.11 g). Further crops of crystals may be obtained from the supernatant. Combined yield: 0.14 g (70%); m.p. 152°C. (Found: C, 29.5; H, 7.4; P, 25.4. $WC_{12}H_{36}P_4$ requires: C, 29.5; H, 7.4; P, 25.4%.) IR: 1745m, 1720s, (W—H); other bands 1415m, 1283m, 1270s, 1230w, 1115w, 1080w, 923vs, 885s, 835s, 787s, 700s, 639s, 549w, 456m. ^{1}H NMR: 1.56–1.43 (m, 32, DMPE); −5.46 (m, 4, W—H), $J_{P-H} = 29.2$ Hz. ^{31}P-{^{1}H} NMR: 22.92 (s, DMPE), $J_{W-P} = 82$ Hz.

X-ray crystallography

Crystals of the two complexes were sealed under argon in glass capillaries. Following preliminary photography, unit cell and intensity data were obtained using an Enraf–Nonius CAD4 diffractometer and graphite monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) by following standard procedures.[19]

The structures were solved via the heavy atom method and refined by full-matrix least-squares. Non-hydrogen atoms were refined in the anisotropic approximation; hydrogen atoms on the ligands (in idealized positions) plus the two in the Al(μ-H)$_2$Al bridge were included only for the molybdenum complex and refined in the isotropic approximation. Crystallographic data are given in Table 3. Atomic coordinates, temperature factor

SELECTIVE PROTONATION OF TERMINALLY BOUND η^3-ALLYLS ON $(\eta^3$-ALLYL$)_2(\mu_2$-η^3-ALLYL$)_2$DIMOLYBDENUM(II) BY β-DIKETONES FORMING $(\mu_2$-η^3-ALLYL$)_2(\eta^2$-β-DIKETONATE$)_2$ DIMOLYBDENUM(II) COMPLEXES

(*Received* 20 *August* 1990; *accepted* 20 *November* 1990)

Abstract—The β-diketones, R(C=O)CH$_2$(C=O)R′ [where R = R′ = Me (acac); R = Me, R′ = CF$_3$ (tfac); or R = R′ = CF$_3$ (hfac)] selectively protonate the terminally bound η^3-allyls on $Mo_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$ (**A**) leaving the $Mo_2(\mu_2$-η^3-allyl$)_2$ core intact. The molybdenum(II) dimers, $Mo_2(\mu_2$-η^3-allyl$)_2(\eta^2$-L$)_2$ [where L = acac (**B**), tfac (**C**) or hfac (**D**)] are formed from this reaction. From ^{1}H, ^{13}C and ^{19}F NMR data, it is evident that the two bridging allyls in each complex, **B**–**D**, are bound in a *cis* arrangement with endo and exo conformations, respectively. Thus, a plane of symmetry bisects the Mo—Mo bond axis and the two bridging allyls in **B** and **D**, but is absent parallel to the Mo—Mo bond axis and bisecting each of the chelating β-diketonate ligands. The complex, **C**, exists primarily as the isomer in which the bulky trifluoromethyl groups on the two tfac ligands are as far apart as possible from each other. As the electron-donating ability of the terminally bound ligands in **A**–**D** decreases, allyl > acac > tfac > hfac, an upfield shift in the proton resonances of the bridging allyls is observed.

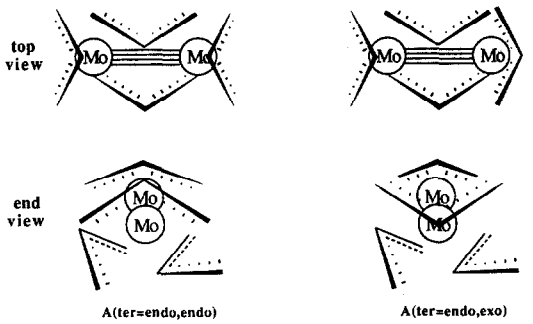
Allyl complexes of the group VI transition metals, W(η^3-allyl)$_4$, Mo(η^3-allyl)$_4$, $Mo_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$, Cr(η^3-allyl)$_3$ and $Cr_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$ were first characterized at the dawn of the modern era of organotransition metal chemistry.[1] They have been utilized extensively as precursors in the formulation of catalysts for olefin[2] and alkyne metathesis,[3] propene and ethanol oxidation,[4] olefin and thiophene hydrogenation,[5] and the polymerization of a variety of olefins including butadiene,[6] methyl methacrylate,[7] alicyclic dienes and trienes.[8] Most recently, catalysts have been prepared by chemisorption of these allyl complexes on inorganic oxide support surfaces. Many of these catalysts have been characterized stoichiometrically and spectroscopically and much is known about the structure and function of their active sites.[4,9]

Our initial interest in this area was stimulated by reports that $Mo_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$[10] forms discrete surface structures when allowed to react with hydroxyl groups on silica or alumina surfaces.[4] These surface species were found to be efficient olefin metathesis catalysts[11] as well as precursors to several other functional surface structures.[12,13] The species resulting from $Mo_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$ chemisorption on silica were assigned to be molybdenum(III) or molybdenum(IV) dimers depending on the type of silica, with two or four allylic ligands, respectively, still intact. In an effort to better understand the chemisorption process and what factors control the variability in structure and oxidation state of the surface species thus formed, we are investigating homogeneously the reactions of $Mo_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$ with a variety of proton donors. We report herein results from the reactions of a series of β-diketones with $Mo_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$.

$Mo_2(\mu_2$-η^3-allyl$)_2(\eta^3$-allyl$)_2$ (**A**) is unique in that its four allylic ligands are coordinated through two different bonding modes: two π-allyls are bridging the Mo—Mo quadruple bond in a *cis* arrangement, with each π-allyl in the remaining pair binding to a single molybdenum atom.[14] Exchange of allyls between bridging and terminal positions is not observed even at 80°C.[15] In solution, **A** is reported to exist as a mixture of two isomers differing only

* Author to whom correspondence should be addressed.

in the relative conformation of the terminal ligands:



These isomers were observed in a nine to one ratio of $Mo_2(\mu_2\text{-}\eta^3\text{-endo-allyl})(\mu_2\text{-}\eta^3\text{-exo-allyl})(\eta^3\text{-endo-allyl})_2$ **[A(ter = endo,endo)]** to $Mo_2(\mu_2\text{-}\eta^3\text{-endo-allyl})(\mu_2\text{-}\eta^3\text{-exo-allyl})(\eta^3\text{-endo-allyl})(\eta^3\text{-exo-allyl})$ **[A(ter = endo,exo)]**. Interconversion of these two isomers was detected at 80°C by way of ^{1}H NMR magnetization transfer.[15] The investigation into the reactions of proton donors and other reagents with **A** has led to a better understanding of structure/reactivity relationships as they deal with the synergy between the bridging allyls, the Mo—Mo quadruple bond and the terminally coordinated ligands in **A** and related complexes.

RESULTS AND DISCUSSION

Synthesis of $Mo_2(allyl)_2(\beta\text{-diketonate})_2$ *complexes*

The reaction of green $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-allyl})_2$ **(A)**[10] with two equiv. of acetylacetone (acacH) at 0°C in pentane yields a pink precipitate with concurrent, ^{1}H NMR verifiable evolution of propene. Similarly, violet and brown products are formed from the reaction of **A** with two equiv. of trifluoroacetylacetone (tfacH) and hexafluoroacetylacetone (hfacH), respectively. The latter two products are considerably more soluble in pentane and related solvents than the acac derivative. Empirical observations suggest that rates of product formation parallel the inherent acidity of the diketone: $k_{hfacH} > k_{tfacH} > k_{acacH}$.

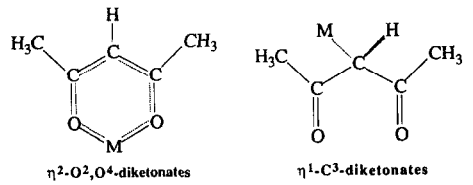
Elemental analyses of these derivatives are consistent with the empirical formula $Mo_n(allyl)_n(diketonate)_n$. Intense molecular ion peaks are observed via electron impact mass spectrometry which correspond to dimeric species, $Mo_2(allyl)_2(diketonate)_2$. Thus, protonation of two allylic ligands on **A** by β-diketones to form propene occurs concurrently with coordination of the two resulting β-diketonate anions:

$$Mo_2(C_3H_5)_4 + 2R\text{-}CO\text{-}CH_2\text{-}CO\text{-}R' \longrightarrow Mo_2(C_3H_5)_2(R\text{-}CO\text{-}CH\text{-}CO\text{-}R')_2 + 2C_3H_6.$$

Additional products form upon addition of more than two equiv. of β-diketone to **A** with further evolution of propene. In most cases, these products have not been characterized, however, $Mo(hfac)_3$ is formed in significant yields in the reaction of **A** with hfacH.

Molecular structure of $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^2\text{-diketonate})_2$ *complexes*

There are two common modes of diketonate binding to metal centres:



Sharp bands are observed in the IR spectra of $Mo_2(allyl)_2(diketonate)_2$ at 1570, 1615 and 1630 cm^{-1} for the acac, tfac and hfac derivatives, respectively. These bands are in the range normally observed for C=O stretches of complexes containing η^2-O^2,O^4-diketonates.[16] The C=O stretch for platinum(II) complexes containing η^1-C^3-diketonates is observed at higher frequency, i.e. near 1670 cm^{-1}.[17] Thus, the diketonate ligands in these dimolybdenum(II) complexes are acting as bidentate, four electron donors binding through the two carbonyl oxygens.

The NMR spectra for this series of molybdenum dimers are rich in information and were invaluable in selecting the most probable structural type. The spectral characterization of the acac and hfac derivatives will be discussed initially due to their higher symmetry.

Through various ^{1}H NMR homodecoupling techniques, it was determined that both $Mo_2(allyl)_2(acac)_2$ **(B)** and $Mo_2(allyl)_2(hfac)_2$ **(D)** contain two π-allyls unrelated by symmetry. Two allylic AMM′XX′ coupling patterns are observed for **B** whereas one AMM′XX′ pattern and a more complicated ABB′XX′ pattern are observed for **D** (see Table 1). This suggests that the two *syn* and *anti* protons in each allyl are related symmetrically. The ^{13}C NMR data are supportive of these propositions: two methine and two methylene carbons are observed in the allylic region of each spectrum.

In **B** and **D**, the β-diketonate ligands are symmetrically related because only one type of methine hydrogen is observed in the ^{1}H NMR, however, each diketonate is coordinated asymmetrically since two types of methyl or trifluoromethyl resonances are observed in their ^{1}H or ^{19}F NMR spectra, respectively.

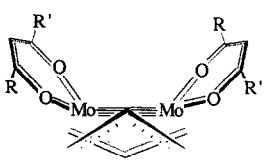
Table 1. Proton chemical shifts and coupling constants for $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2L_2$ complexes in benzene-d_6

Derivative	Exo-allyl Chemical shifts (ppm)			Exo-allyl J(H–H) (Hz)		Endo-allyl Chemical shifts (ppm)			Endo-allyl J(H–H) (Hz)	
	meso	*syn*	*anti*	(*m*–*s*)	(*m*–*a*)	*meso*	*syn*	*anti*	*J*(*m*–*s*)	*J*(*m*–*a*)
Terminal allyls in **A**[a,b]	3.99	3.49	0.70	8.3	14.4		3.87[b]	1.44[b]	8.3[b]	15.1[b]
Bridging allyls in **A**[a]	6.42	3.38	0.77	7.0	11.7	2.72	1.31	3.10	6.4	9.4
B, L = acac	4.11	3.35	0.50	6.9	12.0	2.23	3.02	2.05	6.6	11.2
C, L = tfac	4.12	3.21	0.29	7.2	12.0	2.03	2.82	1.89	6.8	11.0
D, L = hfac	4.13	3.13	0.10	7.1	11.8	1.80	2.67	1.84	3.4	12.4

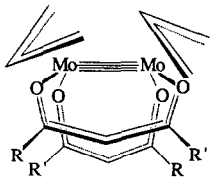
[a] Values are for $Mo_2(\mu_2\text{-}\eta^3\text{-endo-allyl})(\mu_2\text{-}\eta^3\text{-exo-allyl})(\eta^3\text{-endo-allyl})_2$ **[A(ter = endo,endo)]** in benzene-d_6 from ref. 15.

[b] The two *syn* and two *anti* protons of these terminal allyls are not related by symmetry. Thus, the second set of *syn* and *anti* chemical shifts and coupling constants are found in the second column.

Given the metal to ligand ratios, the molecular weights and the spectroscopic data for these complexes, two structures are possible. Structure **I** may be derived from both reported isomers of $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-allyl})_2$ **[A(ter = endo,endo)]** and **A(ter = endo,exo)**,[15] by replacing the two allyls bound terminally by chelating diketonate ligands. Structure **II** has two β-diketonates bridging the dimolybdenum centre. It is closely related to **A(ter = endo,exo)**, since both structures contain an endo,exo arrangement of terminal allyl ligands. Although **A(ter = endo,exo)** is found in 10% abundance relative to **A(ter = endo,endo)** in solution, interconversion is observed at 80°C which occurs via rotation of a terminal allyl about its Mo–allyl bond axis.[15] This allows a potential pathway for the formation of Structure **II** from **A(ter = endo,endo)**.

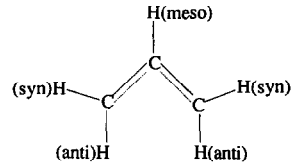


Structure I



Structure II

Literature precedence suggests that Structure **I** is most plausible for this series of complexes. For instance, the two acac ligands in the molybdenum(II) dimer, $Mo_2(\eta^2\text{-}\mu_2\text{-acetate})_2(\eta^2\text{-acac})_2$, bind preferentially at terminal positions with the two bridging acetates binding *cis* to each other.[18] Again, in the platinum(II) dimer, $Pt_2(\eta^2\text{-}Pt^1,\sigma\text{-}Pt^2\text{-allyl})(\sigma\text{-}Pt^1,\eta^2\text{-}Pt^2\text{-allyl})(\eta^2\text{-acac})_2$,[19] the acetylacetonate ligands chelate a single platinum atom whereas the allylic ligands bridge two metal atoms.[20] Bridging β-diketonates such as those in Structure **II** form seven-membered rings which are strained relative to the six-membered rings formed upon chelation of one molybdenum as in Structure **I**. Furthermore, aromatic resonance may enhance the stability of chelating versus bridging diketonates.[21]



Comparison of the proton chemical shifts (discussed below) and ^1H–^1H coupling constants of **B**, **C** and **D** with those for **A** (see Table 1) suggests that the two allylic ligands in each of the β-diketonate derivatives are in bridging positions. This is supportive of **I** as the most likely structure. The $^1H_{meso}$–$^1H_{syn}$ and $^1H_{meso}$–$^1H_{anti}$ coupling constants[22] in **A** are consistently smaller for the bridging allyls than they are for those at terminal positions. Both types of coupling constants in **B**, **C** and **D** are similar in magnitude with those observed for the bridging allyls in **A(ter = endo,endo)** (see Table 1). Thus, β-diketonates have replaced the terminal η^3-allyls structurally in **A** leaving the $Mo_2(\mu_2\text{-}\eta^3\text{-endo-allyl})(\mu_2\text{-}\eta^3\text{-exo-allyl})$ core intact.

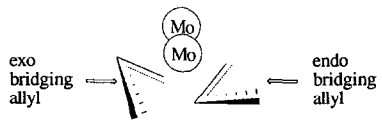
$Mo_2(\mu_2\text{-}\eta^3\text{-endo-allyl})(\mu_2\text{-}\eta^3\text{-exo-allyl})(tfac)_2$ (**C**) (R = Me, R′ = CF_3 in Structure **I**) exists predominantly as the isomer in which the bulkier CF_3 groups of the two tfac ligands are as far apart as possible. NMR spectra include a pair each of well-separated methyl and trifluoromethyl resonances. Thus, the two tfac ligands in **C** are not symmetry related as the β-diketonate ligands are in **B** and **D**. This is supported by the fact that two predominant tfac methine resonances are observed in the ^1H NMR of **C**. Also, the two methylene groups in each bridging allyl are not related symmetrically since we observe six allylic resonances in the ^{13}C NMR spectrum of $Mo_2(\mu_2\text{-}\eta^3\text{-endo-allyl})(\mu_2\text{-}\eta^3\text{-exo-allyl})(tfac)_2$ due to the central and two unique ter-

minal carbons in each allyl.[23] Because this geometric isomer lacks a plane of symmetry, it should exist as a racemic mixture of two optical isomers.

If the above-mentioned, major isomer of **C** is designated as *trans*, there will be two *cis* isomers: one with the two CF_3 groups closest to the μ_2-η^3-exo-allyl and the other with the CF_3 groups closest to the μ_2-η^3-endo-allyl. Both *cis* isomers will exhibit only one type of methyl or CF_3 resonance each and indeed, two low intensity CF_3 resonances with near equal intensity are observed in the reaction mixture resulting from the reaction of **A** with tfacH. The *trans* isomer can be isolated from the mixture of isomers by fractional crystallization.

Trends in proton chemical shifts on bridging allyls as a function of terminal ligand, L, *in* $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2L_2$

There is a general shift upfield for the μ_2-η^3-allylic ^1H NMR resonances of $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^2\text{-}\beta\text{-diketonate})_2$ as the electron donor ability of the terminal ligand decreases: acac > tfac > hfac (Table 1). The change in chemical shift over this series of complexes is greatest for the *anti* protons of the μ_2-η^3-exo-allyls and the *meso* protons of the μ_2-η^3-endo-allyls (Table 1):[24]



These particular protons are on the opposite side of the Mo—Mo quadruple bond and thus insensitive to anisotropic effects of the terminal ligands. Because of this, their electronic and steric environment is similar not only in the η^2-β-diketonate-containing series **B–D** but also in **A(ter = endo,endo)**. Thus, the trend in decreasing chemical shifts for the *anti* protons of the μ_2-η^3-exo-allyls and the *meso* protons of the μ_2-η^3-endo-allyls can be expanded in the series $Mo_2(\mu_2\text{-}\eta^3\text{-endo-allyl})(\mu_2\text{-}\eta^3\text{-exo-allyl})(L)_2$ to include L = allyl: allyl > acac > tfac > hfac. These allylic protons are not only tangential to the electron cloud of the Mo—Mo quadruple bond, but may also be affected by the π-electron cloud of the adjacent bridging allyl.

This upfield trend in chemical shifts parallels an increase in the electron-accepting ability of the corresponding terminally bound ligands: allyl ≪ acac < tfac < hfac. Supporting evidence for the latter trend comes, for example, from the highest energy CO stretching frequencies in $(CO)_4ReL$: allyl (2083 cm^{-1}), acac (2105 cm^{-1}), tfac (2110 cm^{-1}) and hfac (2120 cm^{-1}).[25,26] A similar trend is observed in $(CO)_2RhL$: allyl (2060 cm^{-1}), acac (2085 cm^{-1}), tfac (2094 cm^{-1}) and hfac (2103 cm^{-1}).[27,28] Thus, the allyl ligand may be considered a poor electron acceptor, whereas hfac resembles chlorophosphines or phosphites in their ability to accept electrons.[25] We postulate that the increased electron accepting ability of the terminal ligands increases the positive charge on the Mo_2 centre which, in turn, should promote enhanced bonding to the strongly π-electron donating μ_2-η^3-allyls. Thus, the μ_2-η^3-allylic Mo—C bonds are predicted to be shorter. This, in turn, should force the accompanying allylic protons to be closer to the Mo_2 electron cloud resulting in an increased anisotropic shift of the respective proton resonances upfield.

Reactivity of $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(L)_2$ *complexes*

The electron-withdrawing ability of the terminal ligands, L, not only effects the chemical shifts of the μ_2-η^3-allylic protons as described, but also the oxygen sensitivity for this series of molybdenum dimers: allyl ≫ acac > tfac ≈ hfac. Thus, the greater electron-withdrawing ability of the terminal tfac and hfac ligands stabilizes the $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2$ fragment towards oxidation.

Carbon monoxide does not react with complexes where L = β-diketone under ambient conditions, whereas it readily promotes cleavage of the Mo—Mo quadruple bond in $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-allyl})_2$ forming $Mo(CO)_6$ and 1,5-hexadiene as the ultimate products.[29]

$Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^2\text{-diketonate})_2$ complexes do react with allylMgX reforming $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-allyl})_2$. Similar reactions with allylMgX in which the allyl is substituted or deuterated may allow formation of $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-substituted allyl})_2$. Such complexes may be synthetically or mechanistically useful, e.g. in probing the mechanism of the carbon monoxide-induced allyl coupling from $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-allyl})_2$.[29]

The pronounced selectivity exhibited by β-diketones for protonation of the terminally bound allyls relative to their bridging counterparts in **A** suggests that a variety of complexes, $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(L)_2$, may be synthesized. The terminal ligand(s), L, may be a variety of anionic four-electron donors or a combination of two two-electron donors: one anionic and one neutral, e.g. t-BuO^- and pyridine in $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(O\text{-t-Bu})_2(py)_2$.[30] Thus, the reactivity may be fine tuned over a broad range for the organometallic fragment, $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2$, containing allylic ligands in the rare symmetrically bridging mode of bonding.[31]

A determination of the general reactivity of this series of complexes is ongoing.

EXPERIMENTAL

Physical techniques

Elemental analyses were performed by Texas Analytical Laboratories, Tallahassee, Florida. IR spectra were recorded on a Perkin–Elmer 599B spectrophotometer as Nujol mulls between NaCl plates. NMR spectra were recorded on a Nicolet NT-200WB spectrometer at 200, 50 and 188 MHz for ^{1}H, ^{13}C and ^{19}F, respectively, using C_6D_6 as the solvent. Occasional ^{13}C and ^{19}F spectra were obtained on a Bruker MSL-300 NMR spectrometer. All ^{1}H NMR chemical shifts are in ppm relative to the C_6D_5H singlet set at 7.13 ppm. The ^{13}C chemical shifts are relative to the C_6D_6 triplet at 128.0 ppm, whereas ^{19}F chemical shifts are relative to an external perfluorobenzene standard (−163.0 ppm). Difference homodecoupling spectroscopy was utilized to resolve ^{1}H–^{1}H coupling for more complicated spectra with overlapping multiplets.[32] Mass spectra were obtained on a Finnigan MAT TSQ-70 mass spectrometer in the electron-impact ionization (EI) mode. The samples were introduced quickly on a direct exposure solid probe before insertion into the source vacuum lock.

General synthetic techniques

All the reactions were carried out under a dry and oxygen-free atmosphere of nitrogen using standard Schlenk techniques. Samples were handled in a Vacuum Atmospheres Co. Dry Lab System. Pentane and hexane were refluxed over a Na–K alloy for at least 16 h before use. Diethyl ether was dried over sodium benzophenone ketyl. All solvents were collected and stored over 3-A molecular sieves. Organic reagents were procured commercially and deoxygenated by bubbling nitrogen through them for about 20 min. Molybdenum hexacarbonyl was purchased from Pressure Chemical. Tetrakis(acetato)dimolybdenum[33] and allylmagnesium chloride[34] were prepared according to literature procedures. The latter may be stored as a solid in the dry box after removal of the diethyl ether in which it was synthesized. Tetraallyldimolybdenum can be synthesized utilizing $MoCl_5$,[14] $MoCl_3$[35] or $Mo_2(OOCCH_3)_4$[9] as the molybdenum source. The latter method was found to be most suitable for this application.

Bis(μ_2-η^3-allyl)bis(acetylacetonato)dimolybdenum (**B**)

2,4-Pentanedione (0.150 cm^3, 1.46 mmol) was added by a syringe at a rate of 0.025 cm^3 every 5 min to 0.4 g (1.1 mmol) of $Mo_2(\mu_2$-η^3-allyl)$_2(\eta^3$-allyl)$_2$ dissolved in 150 cm^3 of pentane at 0°C in a 250-cm^3 round bottom flask. The colour of the solution changed from green to violet. The pink precipitate which formed was allowed to settle to the bottom of the flask over a period of 1 h at room temperature. The supernatant liquid was decanted. The pink solid was washed with two 10 cm^3 portions of pentane, dried *in vacuo* and 0.25 g (0.53 mmol) of analytically pure product were collected. The yield was 47%. Found: C, 40.4; H, 5.2. Calc.: C, 40.7; H, 5.1%. IR (cm^{-1}): 1570(s), 1525(s), 1275(s), 1090(sh), 1020(m), 860(m), 825(s), 770(m), 676(s). Mass spectrum (*m/z* for $^{100}Mo_2$): 388 [Mo_2(acac)$_2$], 430 [Mo_2(acac)$_2$(allyl)], 480 [Mo_2(acac)$_2$(allyl)$_2$]. ^{13}C NMR (ppm): $CH_3(C{=}O)CH(C{=}O)CH_3$ 189.9, 189.0; $CH_3(C{=}O)CH(C{=}O)CH_3$ 100.2; CH_2CHCH_2 91.7, 84.8; CH_2CHCH_2 57.9, 55.3; $CH_3(C{=}O)CH(C{=}O)CH_3$ 27.5, 26.7. ^{1}H NMR (ppm): $CH_3(C{=}O)CH(C{=}O)CH_3$ 5.06; for allyl resonances, see Table 1; $CH_3(C{=}O)CH(C{=}O)CH_3$ 1.84, 1.74.

Bis (μ_2 - η^3 - allyl)bis(1,1,1 - *trifluoroacetylacetonato)dimolybdenum* (**C**)

1,1,1-Trifluoro-2,4-pentanedione (0.341 cm^3, 2.8 mmol) was added by a syringe to an ether solution of 0.5 g (1.4 mmol) of $Mo_2(\mu_2$-η^3-allyl)$_2(\eta^3$-allyl)$_2$ at 0°C and stirred for 6 h. The solvent was then removed *in vacuo* and the purple–red solid was extracted with hexane. The solution was then filtered through celite and hexane was removed *in vacuo*, leaving a purple–red solid. The yield was 75–80%. Analytically pure microcrystalline solid can be obtained via crystallization from pentane. Found: C, 32.5; H, 3.6. Calc.: C, 33.1; H, 3.1%. IR (cm^{-1}): 1615(s), 1525(s), 1300(s), 1225(s), 1180(s), 1138(s), 1020(m), 880(m), 840(s), 790(s), 731(s). Mass spectrum (*m/z* for $^{100}Mo_2$): 436 [Mo_2(tfac)$_2$], 498 [Mo_2(tfac)(allyl)$_2$], 588 [Mo_2(tfac)$_2$(allyl)$_2$]. ^{13}C NMR (ppm): $CH_3(C{=}O)CH(C{=}O)CF_3$ 198.4, 198.3; $CH_3(C{=}O)CH(C{=}O)CF_3$ 169.7, 169.5; $CH_3(C{=}O)CH(C{=}O)CF_3$ 113.6, 113.6, $^1J(^{13}C$–$^{19}F)$ = 285 Hz, $^2J(^{13}C$–$^{19}F)$ = 33 Hz; $CH_3(C{=}O)CH(C{=}O)CF_3$ 95.9, 95.7; CH_2CHCH_2 91.8, 86.3; CH_2CHCH_2 59.3, 59.1, 51.7, 51.5; $CH_3(C{=}O)CH(C{=}O)CF_3$ 28.6, 27.7. ^{1}H NMR (ppm): $CH_3(C{=}O)CH(C{=}O)CF_3$ 5.52, 5.51; for allyl resonances, see Table 1; $CH_3(C{=}O)CH(C{=}O)CF_3$ 1.77, 1.67 (minor isomers: 1.61, 1.51).

^{19}F NMR (ppm): −77.9, −78.0 (minor isomers −78.1, −78.2).

Bis (μ_2 - η^3 - *allyl*)*bis*(1,1,1,5,5,5 - *hexafluoroacetylacetonato*)*dimolybdenum* (**D**)

1,1,1,5,5,5-Hexafluoro-2,4-pentanedione (0.397 cm^3, 2.8 mmol) was added by a syringe to an ether solution containing 0.5 g (1.4 mmol) of $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-allyl})_2$ at 0°C and stirred overnight. The ether was removed *in vacuo* and the brown–red solid was extracted with pentane. The solution was filtered through celite and the pentane was evaporated, leaving a brown–red solid. The yield was 65–70%. Analytically pure microcrystalline solid can be obtained via crystallization from pentane. Found: C, 27.8; H, 1.7. Calc.: C, 27.9; H, 1.8%. IR (cm^{-1}): 1630(s), 1605(s), 1560(s), 1530(m), 1259(s), 1220(s), 1145(s), 1112(m), 1020(m), 900(m), 850(s), 809(s), 740(m), 665(s). Mass spectrum (*m/z* for $^{100}Mo_2$): 438 [Mo_2(hfac)(allyl)], 604 [$Mo_2(hfac)_2$], 696 [$Mo_2(hfac)_2(allyl)_2$]. ^{13}C NMR (ppm): $CF_3(C{=}O)CH(C{=}O)CF_3$ 177.8; $CF_3(C{=}O)CH(C{=}O)CF_3$ 117.6, $^1J(^{13}C\text{–}^{19}F) = 282$ Hz, $^2J(^{13}C\text{–}^{19}F) = 21$ Hz; $CF_3(C{=}O)CH(C{=}O)CF_3$ 90.7; CH_2CHCH_2 91.3, 87.1; CH_2CHCH_2 61.2, 52.8. ^1H NMR (ppm): $CF_3(C{=}O)CH(C{=}O)CF_3$ 5.97; for allyl resonances, see Table 1. ^{19}F NMR (ppm): −73.9, −74.1.

Reaction of **B**, **C** *or* **D** *with allylmagnesium chloride*

$Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(acac)_2$, $Mo_2(\mu_2\text{-}\eta^3\text{-allyl}_2(tfac)_2$ or $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(hfac)_2$ (0.3 g) were added to an ether solution containing three equiv. of C_3H_5MgCl at 0°C and then stirred for 3 h. The ether was evaporated at room temperature and the solid was extracted with pentane. The resulting green solution was filtered through celite and pentane was removed *in vacuo*, yielding a green solid. The yield was 50–60%. The NMR spectrum of the green solid was found to be exactly identical with that of $Mo_2(\mu_2\text{-}\eta^3\text{-allyl})_2(\eta^3\text{-allyl})_2$.[15]

BORIC ACID COMPLEXES OF PHENOLIC ACIDS

COLIN F. BELL,* BERNADETTE C. GALLAGHER, KENNETH A. K. LOTT, ERIC L. SHORT and LESLEY WALTON

Department of Chemistry, Brunel University, Uxbridge UB8 3PH, U.K.

(*Received* 25 *June* 1990; *accepted* 26 *November* 1990)

Abstract—The complexation between boric acid and the three phenolic carboxylic acids, 3,4-dihydroxybenzoic, caffeic and chlorogenic acids, has been examined spectroscopically and this has established that a 1 : 1 complex is formed in each case. With the first two acids, there is also evidence of a 2 : 1 complex being formed at high acid to B ratios. Equilibrium constants have been calculated from ^{11}B NMR spectra of mixtures for the equation for the formation of the 1 : 1 complex: $B+H_2A^- = BA^{2-}+H_3O^+$. Conditions in which aerial oxidation of the organic acids occurs have been studied by ESR and UV spectroscopy. The presence of boron stabilizes the acids towards oxidation to free radicals and also retards the rate at which the radicals, when formed, are oxidized further to semiquinones.

Boron is an essential trace element in higher plants and in some algae and diatoms. It is believed to be multifunctional and to be involved in processes as diverse as growth and differentiation, the control of membrane permeability, sugar translocation, and the control of enzymes involved in the metabolism of carbohydrates, auxins, nucleic acids and polyphenols.

Boron deficiency in the plant appears to lead to an accumulation of phenolic compounds and a decrease in lignin levels. Lignin precursors such as caffeic (3,4-dihydroxycinnamic acid) and chlorogenic acids accumulate at the same time. Necrosis of tissue due to boron deficiency may be related to increased levels of caffeic acid.[1]

Caffeic and chlorogenic acids are derivatives of catechol and they should form borato complexes by reaction of the *ortho*-hydroxy groups with boric acid or borate.[2–4] With catechol, the formation of a mono and a spirocyclic complex (in which the molar ratios of acid to boron are respectively 1 : 1 and 2 : 1) has been shown.

We have studied complexation in aqueous solution between boron and 3,4-dihydroxybenzoic acid, caffeic acid and chlorogenic acid using UV, NMR and ESR spectroscopy, and evaluated formation constants for the species observed. The acids are easily oxidized in alkaline media to produce semiquinone radicals and we report on the effect of added borate or boric acid on the oxidation process.

Table 1. UV absorption spectra of aqueous solutions of phenolic acids at 25°C

3,4-Dihydroxybenzoic acid
Experimental λ_{max} (nm) and relative absorbance (in parentheses)
pH 2.0: 203.4(1.52), 217.3(1.33), 260.4(0.76), 293.4(0.39)
pH 6.5: 203.7(3.0), 227.0(1.80), 280.0(1.23), 290.0(1.40)
pH 8.5: 203.6(2.94), 226.7(1.82), 281.0(1.3), 301.2(1.49)
Theoretical λ_{max} (nm) and oscillator strength (in parentheses)
For H_2A^-: 195.6(0.72), 200.8(0.75), 205.7(0.32), 236.7(0.36)
For HA^{2-}: 197.1(0.81), 210.0(0.28), 277.2(0.61), 317.5(0.14)

Caffeic acid
pH 2.0: 193.7(1.54), 217.7(1.21), 234.8(0.96), 300.0(1.22), 321.7(1.38)
pH 6.5: 215.0(1.72), 232.0(1.23), 286.2(1.35), 309.8(1.22)
pH 8.5: 216.4(1.86), 240.0(1.15), 288.4(1.37), 315.5(1.38)
For H_2A^{2-}: 193.6(0.42), 217.6(0.18), 227.0(0.27), 286.2(0.71), 293.0(0.22)
For HA^{2-}: 191.6(0.61), 200.1(0.41), 215.5(0.23), 239.5(0.23), 325.8(0.19), 327.4(0.37), 336.8(0.59)

Chlorogenic acid
pH 2.0: 190.0(1.62), 217.1(0.88), 240.0(0.59), 299.8(0.85), 325.0(1.01)
pH 6.0: 218.5(0.85), 240.4(0.62), 200.2(0.92), 324.8(1.10)
pH 8.5: 225.2(0.59), 257.7(0.48), 310.4(0.44), 367.4(1.27)
For HA^{2-}: 194.2(0.40), 216.4(0.12), 226.0(0.16), 236.9(0.60), 286.8(0.33)

RESULTS

3,4-*Dihydroxybenzoic acids* (I)

This is tribasic ($pK_1 = 4.25$, $pK_2 = 8.64$, $pK_3 = 13.12$[5]). UV spectra of aqueous solutions of pH 2, 6.5 and 8.5 show four maxima between 190 and 310 nm (Table 1). At pH 2, the spectrum is that of the undissociated acid, H_3A; at pH 6.5, H_2A^-, formed by the loss of the carboxyl group proton predominates; and at pH 8.5, H_2A^- and HA^{2-}, formed by the deprotonation of one phenolic OH, are present in nearly equal amounts. Above pH 9.5, absorbance in the above wavelength range decreases rapidly with time as aerial oxidation occurs. Oscillator strengths and λ_{max} values for H_2A^- and HA^{2-}, calculated by the PPP Semi-empirical Theory of Electronic Spectra,[6–8] are also given in Table 1. The general agreement between experimental and calculated values confirms the ionization scheme for H_3A.

^{11}B NMR spectra of boric acid/3,4-dihydroxybenzoic acid mixtures show the presence of a mono complex (**II**) (δ 7.55–7.82 ppm over the range pH 6.0–12.0). In the pH range 7–11 the resonance peak due to uncomplexed boron moves from 18.9 to 1.56 ppm as the boric acid/borate ratio changes with pH. At pH 7.0, the extent of formation of the complex varies with acid/B molar ratio as shown in Table 2. Complexation is maximal between pH 8.0 and 10.0 and little complexation takes place at pH 12.0 even with ratios of 10 or above. However, the presence of boron evidently has a stabilizing effect on the ligand at this high pH for it to be possible to observe complexation at all. At pH 8.0 with a ratio of 16, a small second peak (δ 13.1 ppm) shows the formation of a spirocyclic complex.

Table 2. Complexation of boric acid by phenolic acids[a]

[Acid]:[B] Ratio	$\%B_{free}$	$\%BA^{2-}$	pH
3,4-Dihydroxybenzoic acid			
4.0	75.8	24.2	6.0
4.0	23.3	76.7	8.0
5.0	62.5	37.5	6.2
5.0	14.8	85.2	8.0
Caffeic acid			
0.5	87.4	12.6	8.0
1.0	71.2	28.8	8.0
1.0	76.0	24.0	8.4
2.0	53.5	46.5	8.0
4.0	19.4	80.6	8.0
5.0	15.5	84.5	8.4
Chlorogenic acid			
1.0	70.3	29.7	8.0
2.0	50.0	50.0	8.0
3.0	39.5	60.5	8.0
5.0	17.1	82.9	8.0

[a] Note that many spectra were measured but this table includes only the data used in calculating equilibrium constants.

When 3,4-dihydroxybenzoic acid is aerially oxidized in water–ethanol solutions of high nominal pH, the primary semiquinone radical is produced. The ESR spectrum has the structure expected from the splitting effect of the three non-equivalent ring protons, namely a $2\times2\times2$ pattern.[9,10] Coupling constants were measured and their values refined by simulation until the best possible match between experimental and simulated spectra was reached. Values (mT) found, $a_2 = 0.07$, $a_5 = 0.12$ and $a_6 = 0.31$, are in good agreement with those reported earlier.[9]

For 3,4-dihydroxybenzoic acid in water/ethanol (1 : 1 by vol.) radical formation is first observed at pH 10.06. At pH 11.6, the radical is stable for at least 5 min: at pH 12.5, slow decay is observed and this becomes rapid ($t_{1/2} = 2.5$ min) at pH 13.0. When boron is present, with a boron/ligand molar ratio of 3, no ESR spectrum is observed below pH 10.2. Above this, a stable radical is produced up to pH 12.6. The spectrum is very similar to that when borate is absent, although there are small decreases in coupling constants ($a_1 = 0.070$, $a_5 = 0.12$, $a_6 = 0.307$).

The first peak in the ESR spectrum is prominent and well-resolved with a constant line width as we have assumed its height to be a reliable measure of radical concentration. This is found to be less at a given pH when boron is present rather than when it is absent (Fig. 1). We may therefore conclude that boric acid stabilizes the phenolic acid at a given pH with respect to oxidation and that the radical, once formed, decays more slowly when boron is also present.

3,4-*Dihydroxycinnamic acid* (*caffeic acid*) (III)

This is tribasic ($pK_1 = 4.45$, $pK_2 = 8.66$, $pK_3 = 11.8$[11]). UV absorption spectra of aqueous solutions of caffeic acid are similar to those of 3,4-dihydroxybenzoic acid and four maxima are observed between 195 and 325 nm. Table 1 gives λ_{max} and relative absorbance values for solutions of pH 2.0, 6.5 and 8.5. As before, theoretically calculated values for H_2A^- and HA^{2-} are included. At pH 8.5, these forms are present in approximately equal amounts. Above pH 9.5, absorbance in the given wavelength range decreases with time, accompanied by a broadening of bands until only one, λ_{max} *ca* 290 nm, remains. These changes are due to oxidation. When boric acid is added to solutions of caffeic acid of pH 6 and above, λ_{max} values do not change significantly but there are small increases in relative absorbance for each band as a result of complexation.

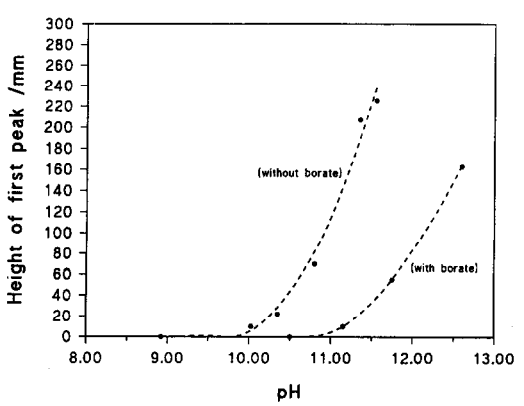

Fig. 1. 3,4-Dihydroxybenzoic acid ESR spectra; effect of pH on peak height.

From ^{11}B NMR spectroscopy, we have identified a mono complex at various acid/B ratios between pH 6 and 12 (δ 7.5 ppm). Table 2 shows how the proportion of mono complex changes with composition at pH 7. The presence of boron stabilizes caffeic acid towards oxidation at higher pHs. With large (>10) acid/B ratios, a small amount of spirocyclic complex (δ 13.3 ppm) is also observed.

ESR spectroscopy of oxidized caffeic acid in water/ethanol mixtures demonstrates primary semiquinone radical formation. Coupling constants (mT) were $a_\alpha = 0.12$, $a_\beta = 0.12$, $a_2 = 0.025$, $a_5 = 0.227$, $a_6 = 0.268$ (α and β are side-chain protons in H_2A^- and a_2, a_5 and a_6 are ring protons). Refinement by simulation proved difficult in this case because the central spectral region showed evidence of secondary radical formation, but our values are close to those reported by Ashworth.[10] At pH < 9, the acid is stable to oxidation. Above pH 9, oxidation produces the semiquinone radical which decays rapidly at pH > 11. Borate stabilizes the acid towards radical formation up to pH 10.7. From pH 11.5 to 12.1, the primary radical is formed. At pH > 12.4, this decays with increasing rate the higher the pH. The presence of boron therefore has exactly the same kind of stabilization effect as it does on 3,4-dihydroxybenzoic acid. There are slight changes in coupling constants due to the presence of boron (a_α 0.12, a_β 0.11, a_2 0.019, a_5 0.238, a_6 0.272). There is no evidence of hyperfine structure due to boron coupling.

Chlorogenic acid (IV)

This is tribasic ($pK_1 = 3.37$, $pK_2 = 8.27$, $pK_3 = 11.5$[11]). UV absorption spectra data are given in Table 1 for aqeuous solutions at three pH values. At pH 8.5, the strongest absorbance is at 367 nm and this is believed to indicate partial decomposition. The onset of this occurs at a lower pH

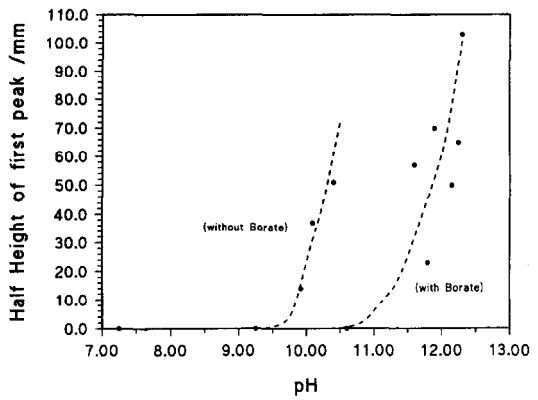

Fig. 2. Caffeic acid ESR spectra; effect of pH on peak height.

than with caffeic or 3,4-dihydroxybenzoic acids. Theoretical PPP values for λ_{max} and oscillator strength for HA^{2-} were found by making the simplifying assumption that there was no effect on the π-electron system of the cinnamic acid moiety from the attached trihydroxycyclohexane carboxylate moiety. This could be another reason for the lack of good agreement between experimental and theoretical values in addition to a discrepancy arising from acid degeneration.

A mono complex (δ 7.70 ppm) is indicated by ^{11}B NMR spectroscopy. It does not form below pH 6.5 and reaches optimum concentration between pH 8.0 and 9.0. At pH 8, a 10-fold excess of chlorogenic acid is sufficient to complex all the boron present as the mono species but there is no sign of a spirocyclic form. Table 2 shows how the composition of mixtures at pH 8 varies with molar proportions of the components. Difficulty was experienced in measuring the ESR spectra of radicals formed in solution by chlorogenic acid. Dissolution in ethanol gave solutions which immedially darkened due to decomposition. Aqueous solution study was limited because of the low solubility of the acid. Oxidation in aqueous solution was noticeably more rapid than for the other two acids studied.

Initially, the spectrum of the primary radical was produced but this decayed in a short time to a secondary species, as observed for other substituted catechols.[9] It was possible, however, to establish that the presence of boron in solution increased the stability of the primary radical and decreased the rate at which this decayed at a given pH.

DISCUSSION

Aqueous solutions of boric acid and one of the phenolic acids studied at pH < 8.0 contain $B(OH)_3$ and H_2A^- as the predominant species [as the pK_a of boric acid is 8.98, possible complexation involving $B(OH)_4^-$ need not be considered[12]]. 1 : 1 Complex formation proceeds according to:

$$B + H_2A^- = BA^{2-} + H_3O^+ \qquad (1)$$

where B is $B(OH)_3$.

At a pH of 7 or 8, a carboxylic acid with a pK_a value of ~4 will be virtually completely dissociated and it is therefore assumed that $[H_3A] \approx 0$.

(a) $B + OH^- \overset{K_b}{\rightleftharpoons} B^-$ and, hence, $[B^-] = K_b[B][OH^-]$,

where $B \equiv B(OH)_3$

(b) $[H_3A]_t = [H_2A^-] + [HA^{2-}] + [BA^{2-}]$ and $K_2 = [H^+][HA^{2-}]/[H_2A^-]$, where $BA^{2-} \equiv (OH)_2BA^{2-}$.

Therefore

$$[H_3A]_t = [H_2A^-] + \frac{K_2[H_2A^-]}{[H^+]} + [BA^{2-}]$$

$$= [H_2A^-]\left\{1 + \frac{K_2}{[H^+]}\right\} + [BA^{2-}]. \quad (i)$$

Now consider the equilibrium

$$B + H_2A^- \overset{K_1}{\rightleftharpoons} BA^{2-} + H_3O^+ :$$

therefore

$$[BA^{2-}] = K_1[B][H_2A^-]/[H^+].$$

By substituting the latter expression into (i), we obtain

$$[H_3A]_t = [H_2A^-]\left\{1 + \frac{K_2}{[H^+]} + \frac{K_1[B]}{[H^+]}\right\}.$$

Also,

$$[B]_t = [B]\left\{1 + K_b[OH^-] + \frac{K_1[H_2A^-]}{[H^+]}\right\}$$

or

$$[B] = \frac{[B]_t}{(1 + K_b[OH^-] + K_1[H_2A^-]/[H^+])}. \quad (ii)$$

By substituting (ii) into (i), we obtain

$$[H_3A]_t = [H_2A^-]\left\{1 + \frac{K_2}{[H^+]} + \frac{K_1[B]_t}{\{[H^+] + K_bK_w + K_1[H_2A^-]\}}\right\}.$$

This equation is now solved for $[H_2A^-]$.

After some manipulation, it is represented as a quadratic equation in $[H_2A^-]$:

$$A[H_2A^-]^2 + B[H_2A^-] + C = 0,$$

where

$$A = K_1 \times X \times [H_3A]_t;$$

$$B = [H_3A]_t\{X[H^+] + X \times K_bK_w - K_1\} + K_1[B]_t;$$

$$C = -[H_3A]_t\{[H^+] + K_bK_w\}$$

$$X = \{1/[H_3A]_t\} + \{K_2/([H_3A]_t[H^+])\}.$$

Once $[H_2A^-]$ has been found, the equilibrium concentrations of all the other species present can be easily calculated.

The procedure is started with a trial value of K_1 and this is subsequently modified until the sum of the squares of the differences between the calculated and experimental concentrations is minimized. K_1 values for the 1 : 1 complexes are found to be: 3,4-dihydroxybenzoic acid, 4.3×10^{-6}; caffeic acid, 7.2×10^{-7}; and chlorogenic acid, 1.06×10^{-6}.

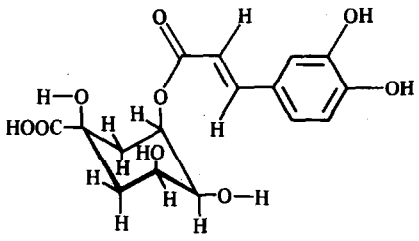
These constants are a measure of the stabilities of the respective 1 : 1 complexes; they are several orders of magnitude less than K_1 for boric acid/lactic acid complexation (1.8×10^{-3}).[13] The difference shows the much greater stability of the chelate of lactic acid (using the carboxyl and the adjacent OH group) compared with that formed by a 1,2-*cis*-diol grouping.

The significance of the K_1 values for caffeic and chlorogenic acids is that they point to maximum complexation with boric acid close to the pH levels believed to exist in plant tissues. Our results also show that only a very small amount of 2 : 1 complex is formed in the case of 3,4-dihydroxybenzoic and caffeic acids and then only with a large excess of organic acid present. We would expect K_2 to be very small because complexation of a second H_2A^- ion by BA^{2-} is most improbable on steric grounds.

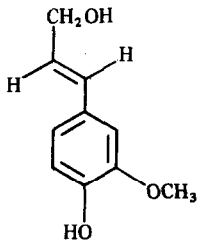
One of the most common pathways for lignin synthesis is from shikimic acid, produced by biosynthesis from D-glucose[14]. Shikimic acid is converted to either L-phenylalanine or L-tyrosine. The biosynthetic route from L-phenylalanine to coniferyl alcohol (**V**), the immediate precursor of lignin, proceeds thus:

L-phenylalanine → *trans*-cinnamic acid
→ *p*-coumaric acid → caffeic acid
→ ferulic acid → coniferyl alcohol.

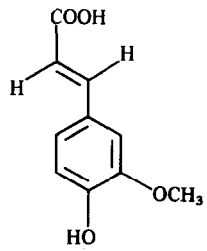
Caffeic acid is the only one of these compounds that contains the 1,2-diol grouping for boron coordination. If boric acid is present, *in vivo* complexation at physiological pHs would be expected to occur, as indicated by our NMR results. This is thus likely to influence the methylation of caffeic acid to give ferulic acid (**VI**). Phenolic acids are reported to accumulate in boron-deficient plants beyond levels found in healthy plants. It appears



IV



V



VI

therefore that the presence of boron in some way favours the synthesis of ferulic acid.

It has been shown[15] that ferulate is formed from caffeate at pH 7 by methylation with S-adenosylmethionine catalysed by catechol O-methyltransferase isolated from plant tissue. If this type of enzyme is responsible for the methylation of caffeate *in vivo*, boron complexation with the catechol component would be another factor to consider. It is intriguing to also note that S-adenosylmethionine itself has a 1,2-*cis*-diol grouping in the adenosyl moiety which could also chelate boron under appropriate conditions.

Boron evidently has a stabilizing influence on the oxidation of caffeic and chlorogenic acids to a free radical and retards the further oxidation of this to a quinone. Aluminium also stabilizes *o*-semiquinone radicals in aqueous solution and is believed to influence the manner in which these polymerize.[16]

EXPERIMENTAL

Sodium tetraborate (98%) and boric acid (99.5%) were obtained from BDH Chemicals Ltd and 3,4-dihydroxybenzoic acid (97%), 3,4-dihydroxycinnamic acid (99%) and chlorogenic acid (predominantly *trans*) were obtained from

Aldrich Chemical Co Ltd. Solutions, except where specified, were made up in deaerated, distilled water and the pH adjusted using either dilute hydrochloric acid or sodium hydroxide solutions. UV spectra were recorded at 25°C on a Cecil Series 5000 Computing Double Beam spectrometer. ^{11}B NMR spectra were recorded at 33°C on a Joel JNM FX 200 Multinuclear NMR spectrometer operating at 63.95 MHz, using $(C_2H_5)_2O \cdot BF_3$ as external reference. Solutions were prepared by mixing different molar ratios of borax to phenolic acid in aqueous solution, so that in each case the resulting solution was 0.01 mol dm^{-3} with respect to boron. Where small quantities of acid were used and the pH of the borax solution would have been high enough to cause oxidation, dilute hydrochloric acid was added to ensure the pH stayed below 9. Equilibrium in solution was rapidly attained and the spectra were measured as soon as possible after mixing to eliminate the possibility of decomposition. ESR spectra were recorded on a Varian E-3 EPR spectrometer. In the case of 3,4-dihydroxybenzoic and 3,4-dihydroxycinnamic acids, mixtures were made up of 25 cm^3 of a solution of the phenolic acid in ethanol (0.02 mol dm^{-3}) and 25 cm^3 of an aqueous solution of the required amounts of boric acid and sodium hydroxide. The phenolic acid/boron molar ratio was three in each case and the pH was adjusted with sodium hydroxide solution (0.1 mol dm^{-3}). Chlorogenic acid solutions were prepared in water because of the rapid aerial oxidation observed for this acid in ethanol solution. ESR spectra were run using a mixture of 10 cm^3 of chlorogenic acid solution and 25 cm^3 of boric acid/sodium hydroxide solution.

Abstract—The singly-bridged hydrolytic dimer $[(H_2O)_5Cr(\mu\text{-}OH)Cr(OH_2)_5]^{5+}$ (SBD), undergoes a ring closure reaction which transforms it into the doubly-bridged dimer, $[(H_2O)_4Cr(\mu\text{-}OH)_2Cr(OH_2)_4]^{4+}$ (DBD). The kinetics of this conversion have been studied over the pH range 0–4.93, temperature range 288.15–313.35 K and $I = 1.0$ M (adjusted with either $LiClO_4$ or $NaClO_4$). The pH dependence of the first-order rate constant, k_{obs}, was interpreted in terms of three distinct pathways involving ring closure within fully protonated, mono- and doubly-deprotonated SBD and two pathways accounting for acid-catalysed and uncatalysed cleavage of DBD which are important at low pH. Least-squares analysis of the data permitted the determination of rate constants for each of these pathways and the first two acid dissociation constants of the SBD. A reactivity increase of *ca* four-fold observed on monodeprotonation of SBD was suggested to reflect, at least in part, the greater nucleophilicity of coordinated OH^-, cf. coordinated H_2O. The more substantial rate enhancement of 25-fold resulting from double deprotonation of SBD was concluded to be due to an increase in the lability of the chromium(III) centre at which substitution occurs. The activation parameters for all pathways are consistent with an associative substitution mechanism, either *A* or I_a.

In the hydrolytic polymerization of metal ions in aqueous solution, *deprotonation* and *substitution*, either intermolecular or intramolecular, are two fundamental processes that are involved in the formation and rearrangement of polynuclear species. As part of our continuing work on the hydrolytic polymerization of chromium(III), several reactions which feature both of these processes have been studied: viz. the dimerization of Cr^{3+} to give the doubly-bridged dimer (DBD),[2] the dimerization of DBD to give the tetramer,[3] and the interconversion between the open and closed form of tetramer.[4]

The dimerization studies[2,3] have highlighted the importance of deprotonation in promoting the substitution processes that ultimately result in the propagation of polymerization. In both cases, pairs of conjugate bases of the reactant were found to undergo dimerization at a much faster rate than the aqua ions alone, or in combination with a conjugate base. For Cr^{3+},[2] each additional deprotonation corresponds to rate enhancement of 50–200-fold and the measured rates were much faster than H_2O

† For part V, see ref. 1.

§ Deceased 20 September 1986.

exchange on Cr^{3+}.[5] These rate accelerations were consistent with the increase in rate of H_2O exchange on $CrOH^{2+}$ compared with Cr^{3+} [5] and were attributed to increases in the lability of the chromium(III) centres on deprotonation. This facilitated substitution by H_2O from the solvent or by a nucleophile such as OH^- coordinated to chromium.[2]

Formation of the dimer from conjugate bases of Cr^{3+} is believed to involve two consecutive substitution processes, intermolecular substitution to form a singly-bridged dimer (SBD), followed by intramolecular ring closure to a doubly-bridged form, eq. (1):[2]

$$2Cr(OH)_r^{(3-r)+} \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} Cr(\mu\text{-}OH)Cr(OH)_s^{(5-s)+} \underset{k_{-c}}{\overset{k_c}{\rightleftharpoons}} Cr(\mu\text{-}OH)_2Cr(OH)_t^{(4-t)+}. \quad (1)$$

Supporting this proposal was evidence that SBD was an intermediate in the cleavage of DBD in acidic solution (pH $\leqslant$ 1).[6] This arises because the rates of interconversion between SBD and DBD (k_c and k_{-c}) are much faster than cleavage of SBD (k_{-d}).[6] Thus, an equilibrium [eq. (2)] is established between the two forms of dimer prior to slow cleavage of SBD into Cr^{3+}:

$$Cr(\mu\text{-}OH)Cr^{5+} \underset{}{\overset{K_{eq}}{\rightleftharpoons}} Cr(\mu\text{-}OH)_2Cr^{4+} + H^+. \quad (2)$$

This behaviour parallels that of related tetramine complexes of the type, $A_4M(\mu\text{-}OH)_2MA_4^{4+}$, where M = Cr, Rh or Ir and $A_4 = (en)_2$ or $(NH_3)_4$, whose properties have been reviewed recently.[7]

Early estimates of K_{eq} (1.24 M at 25°C), obtained from kinetic studies of the SBD–DBD interconversion in the pH range 0–2.3, indicated that SBD is favoured at high $[H^+]$ and DBD at low $[H^+]$. Note that this conclusion is supported by recent direct determinations of K_{eq} (1.83 M at 25°C and I = 1.0 M) which were made possible by the successful use of low temperature (0–5°C) ion-exchange chromatography to quantitatively separate SBD forms from DBD present in dimer solutions at equilibrium.[1] Combining these results with the observation that k_d was slower than either k_c or k_{-c}, intermolecular formation of SBD was concluded to be rate determining in the dimerization of Cr^{3+}.[2]

The interconversion between SBD and DBD [eq. (2)] is sufficiently slow to measure using conventional kinetic techniques and has been previously investigated at low pH ($\leqslant$ 2.3),[6] where small variations in rate were found. The present study has focussed attention on the conversion of SBD into DBD in the pH range 0–5, but in addition, information about the conversion of DBD into SBD has been obtained. The major aims of this work were:

(1) to probe the effect of deprotonation on the rate of an intramolecular hydrolytic process. The SBD is ideal for such a study since, in principle, the rate of ring closure could be measured over several deprotonations of the reactant and compared with the rate enhancements observed for intermolecular processes such as the dimerization of Cr^{3+};
(2) to determine whether dimerization of Cr^{3+} is rate determined by SBD formation throughout the accessible pH range. Previous conclusions (see above) are based on rate constants measured over different pH ranges, 3.5–5.0 for Cr^{3+} [2] dimerization and 0–2.3 for SBD–DBD interconversion.[6]

In this context, the work is not intended to duplicate existing data. However, it was necessary to measure rates over the pH range 0–5 in order to obtain a complete set of rate constants under identical experimental conditions.

RESULTS

The conversion of SBD into DBD was studied using conventional techniques in the pH range 0–4.93, temperature range 288.15–313.35 K and I = 1.0 M. Reaction mixtures were prepared by adding small volumes of standardized SBD stock solutions to thermally equilibrated solution of either $HClO_4$ or a buffer depending on the desired pH value (see Experimental) and the reaction followed using UV–vis spectrophotometry.

At low pH ($\leqslant$ 2), conversion of SBD into DBD resulted in increases in absorbance in the UV region (λ < 300 nm) which were much larger than spectral changes observed at higher λ. The reaction was followed at 250 nm where for $[SBD]_0 = 2.72 \times 10^{-3}$ M the absorbance increased by 0.25–0.5 units. Buffering of the reaction mixtures was necessary at pH > 2 because firstly, the overall reaction involves the liberation of H^+ and secondly, the two dimer forms differ in their acidity. The choice of buffers was restricted to those which do not react with or bind to either form of dimer, at least during the time scale of the reaction. However, all of the buffers which satisfied this requirement and whose pK_a was in the correct range were found to absorb strongly in the UV and the reaction could no longer be followed in this region. Fortunately, the visible spectrum of SBD changes appreciably upon deprotonation (pK_{a1} = 0.74 at 298.15 K was reported recently[1] and is similar to the value deter-

mined here) making it considerably different from that of DBD. The reaction was followed at 440 nm where absorbance decreases of between 0.2 and 0.3 units were observed for $[SBD]_0 = 6.81 \times 10^{-3}$ M.

The observed rate constants (k_{obs}) were determined by non-linear least-squares fitting of the absorbance data, taken over at least four half-lives, to expression (3).

$$A_t = (A_0 - A_\infty)\, e^{-k_{obs}t} + A_\infty. \quad (3)$$

Excellent fits were obtained for each run ($\sigma_{k_{obs}} \leqslant 0.015\, k_{obs}$) indicating that the reaction is first order with respect to SBD over the whole pH range. A table of the dependence of k_{obs} on $[H^+]$ and T is available as supplementary material. As a check for specific cation effects, duplicate measurements were made in $LiClO_4$ and $NaClO_4$. However, k_{obs} values determined with different electrolytes agreed within experimental error. For example, at pH = 0.22 and $T = 298.15$ K, $k_{obs} = 1.94(\pm 0.02) \times 10^{-4}$ s^{-1} in $LiClO_4$ and $1.97(\pm 0.02) \times 10^{-4}$ s^{-1} in $NaClO_4$.

Reaction mechanism and rate law

The pH dependence of k_{obs} (Fig. 1) shows the presence of two regions in which increases in rate are evident, one in the pH range 0.5–2 and the other at pH $\leqslant$ 3. In addition, a small decrease in rate with pH is found at the lowest pH values and temperatures. This kinetic data can be interpreted in terms of the three reaction pathways given in Scheme 1. These pathways involve fully protonated (SBD), mono-deprotonated (SBD − H) and doubly-deprotonated (SBD − 2H) singly-bridged dimer. This interpretation is in keeping with conclusions reached in previous kinetic[6] and thermodynamic[1] studies of the SBD–DBD interconversion at low pH ($\leqslant$ 2). Thompson[6] attributed variations in the rate of interconversion between SBD and DBD to the existence of pathways involving SBD and SBD − H, with both forward and back reactions being significant. This proposal is strongly supported by recent measurements of the SBD–DBD equilibrium[1] at pH < 2. These experiments have established that the relative amounts of SBD species and DBD present at equilibrium vary with $[H^+]$ in a manner consistent with the view that deprotonation of SBD occurs as pH increases, to generate SBD − H. Furthermore, the values of K_1K_{a1}, K_1 and K_{a1}, determined from this work, suggest that at pH < 2, SBD, SBD − H and DBD are present in significant concentrations at equilibrium. In contrast, very little HDBD, formed by protonation of DBD (Scheme 1), is expected at these acid concentrations since $K_{p3} \ll 0.1$ M^{-1} is predicted from information on analogous systems.[7] In summary, this information strongly supports the proposal that for the SBD and SDB − H pathways both forward and back reactions contribute to the overall rate. This is clear at the lowest pH values where decreases in k_{obs} are observed as pH increases (Fig. 1). Although the SBD and SBD − H pathways can rationalize rate variations at low pH they cannot account for the large accelerations in rate

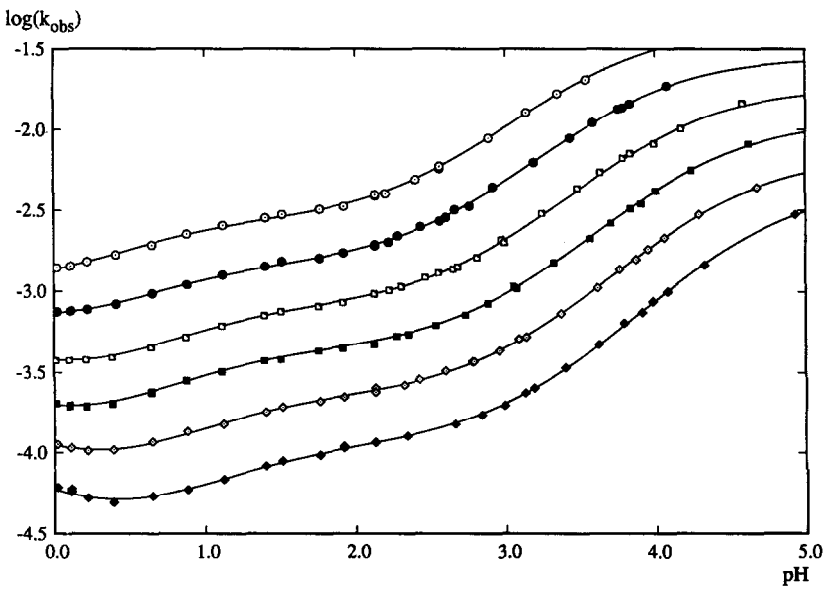

Fig. 1. pH and temperature dependence of the observed rate constant (k_{obs}) for the SBD–DBD interconversion at $I = 1.0$ M. Solid lines are the calculated values of k_{obs} obtained from eq. (6): (◆) 288.15 K; (◇) 293.35 K; (■) 298.15 K; (□) 303.05 K; (●) 308.15 K; (○) 313.35 K.

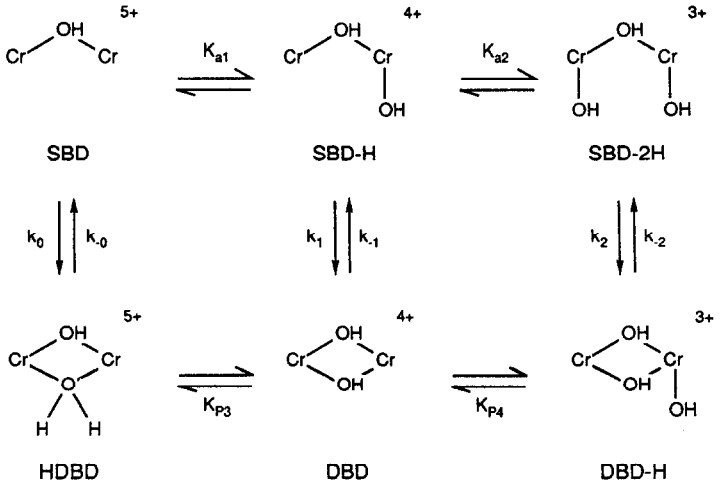

Scheme 1.

observed at pH $\geqslant$ 3. We attribute this to the formation of SBD−2H, which undergoes ring closure at a faster rate than either SBD or SBD−H. Note that in principle the reaction could be followed over several further deprotonations of SBD, but that this is precluded in practice by the precipitation of the "active" dimer hydroxide which forms from DBD at pH $\geqslant$ 5.

From the rate law for conversion of SBD into DBD [eq. (4)]

$$\frac{d[DBD]_T}{dt} = k_0[SBD]+k_1[SBD-H] + k_2[SBD-2H]-k_{-0}[HDBD]-k_{-1}(DBD] -k_{-2}[DBD-H] \quad (4)$$

and appropriate expressions for the various acid–base equilibria, the following expressions for k_{obs} may be derived:

$$k_{obs} = \left[\frac{k_0[H^+]^2+k_1K_{a1}[H^+]+k_2K_{a1}K_{a2}}{[H^+]^2+K_{a1}[H^+]+K_{a1}K_{a2}}\right] + \left[\frac{k_{-0}K_{p3}[H^+]+k_{-1}+k_{-2}/(K_{p4}[H^+])}{K_{p3}[H^+]+1+1/(K_{p4}[H^+])}\right]. \quad (5)$$

The following independent experiments show that some of the terms in eq. (5) are small and that a number of simplifications to the expression for k_{obs} are justified:

(i) Previous work on the closely related $[A_4Cr(\mu\text{-}OH)_2CrA_4]^{4+}$ systems [$A_4 = (NH_3)_4$ or $(en)_2$] has concluded that $K_{p3} \ll 0.1$ M^{-1}.[7] Consequently, at the concentrations of H^+ in our study (< 1 M), $K_{p3}[H^+]$ is small and need not be included in the denominator of the back reaction term in eq. (5).

(ii) Chromatographic analysis (procedure outlined elsewhere[1]) of dimer solutions after the interconversion reaction had reached completion at pH−4.10 and $T = 298.15$ [substantial proportions of DBD−H would be present at this pH since pK_a (DBD) = 3.68], showed that the amount of SBD present was below the limit of detection of *ca* 2–3%. This means that at this and higher pH the contribution of the back reactions (k_{-0}, k_{-1}, k_{-2} pathways), either individually or in total, is less than 3%. Since the contribution of the k_{-2} pathway (Scheme 1) is small under these conditions and it is expected to be even smaller at lower pH, where even less DBD−H is present in solution, it may be concluded that the k_{-2} pathway will make only very minor contributions to the reaction rate over the whole pH range. The inclusion of this term in the expression for k_{obs} [eq. (5)] is not warranted. The term $1/(K_{p4}[H^+])$ which appears in the denominator of the second half of eq. (5) can also be neglected since it would become important at pH > 3 ($K_{p4} = 10^{3.68}$ M^{-1},[8] where we have shown that the back reaction is not significant and in any case its effect would be to reduce the contribution of the back reaction to the overall rate.

Modification of eq. (5) to incorporate the above information and substitution of k_{-0} K_{p3} and k_{-1} by k_0/K_1K_{a1} and k_1K_{a1}/K_1K_{a1}, respectively, gives the following expression for k_{obs}:

$$k_{obs} = \left[\frac{k_0[H^+]^2+k_1K_{a1}[H^+]+k_2K_{a1}K_{a2}}{[H^+]^2+K_{a1}[H^+]+K_{a1}K_{a2}}\right] + \left[\frac{k_0[H^+]+k_1K_{a1}}{K_1K_{a1}}\right]. \quad (6)$$

[a] Calculated from $k_{-1} = k_1 K_{a1}/K_1 K_{a1}$, using K_{a1} and k_1 from this work and $K_1 K_{aa}$ from ref. 1.
[b] Calculated using $k_{-0}K_{p3} = k_0/K_1 K_{a1}$ and using k_0 from this work and $K_1 K_{a1}$ from ref. 1.
[c] $K_1 = k_1/k_{-1}$.

(Note that $K_1 K_{a1}$ corresponds to the equilibrium constant for interconversion between SBD and DBD.)[1]

In fitting the data to eq. (6), published values at $K_1 K_{a1}$ were used.[1]† These were obtained over the same range of temperature and $I = 1.00$ M.[1] The data were fitted using a weighted least-squares analysis procedure minimizing the function, $\Sigma_i w_i[k_{obs,i} - k_{calc,i}]^2$, where $w_i = 1/\sigma^2_{k_{obs,i}}$ and $k_{obs,i}$, $k_{calc,i}$, w_i and $\sigma^2_{k_{obs,i}}$ are the observed rate constants, calculated rate constants, weighting factors and standard errors in each k_{obs} value, respectively. The difference between measured and calculated k_{obs} values were always $\leqslant 5\%$ and were unsystematically scattered around the fitted curve throughout the pH range and for all temperatures studied (see also Fig. 1). This observation provides strong support for the model chosen to describe the conversion of SBD into DBD (Scheme 1). All of the parameters in the expression for k_{obs}, i.e. k_0, k_1, k_2, K_{a1} and K_{a2}, were evaluated simultaneously. Their values are listed in Table 1 together with previously published values of $K_1 K_{a1}$[1] and values of $k_{-0}K_{p3}$, k_{-1} and K_1 which were calculated from k_0, k_1, K_{a1} and $K_1 K_{a1}$ using the expressions $k_{-0}K_{p3} = k_0/K_1 K_{a1}$, $k_{-1} = k_1 K_{a1}/K_1 K_{a1}$, and $K_1 = k_1/k_{-1} = K_1 K_{a1}/K_{a1}$, respectively.

Activation parameters for k_0, k_1, k_2, k_{-1} and $k_{-0}K_{p3}$, and thermodynamic constants for K_{a1}, K_{a2} and K_1 were determined from the temperature dependence of each constant by weighted non-linear least-squares analysis. They are listed in Table 2.

† Further reduction in the number of parameters to four was possible by using values of K_1 and K_{a1} determined in the same work[1] but these values were of lower accuracy and more importantly their use in fitting the data led to systematic variations between measured and calculated k_{obs} values.

DISCUSSION

The kinetic data for the conversion of SBD into DBD can be rationalized in terms of the reaction pathways described in Scheme 1. The pH dependence of k_{obs} has been successfully fitted to an expression [eq. (6)] which allows for contributions to the overall rate from both forward (k_0, k_1 and k_2) and back (k_{-0} and k_{-1}) reactions and for the effect of K_{a1} and K_{a2} on the distribution of SBD species in solution.

The values of pK_{a1} (1.00 at 298.15 K) and related thermodynamic constants (Table 2) are in good agreement with those obtained from direct measurements on the SBD–DBD equilibrium made using ion-exchange chromatography.[1] The constants (K_1, ΔH^0 and ΔS^0; Tables 1 and 2) describing the equilibrium between SBD−H and DBD also match those from this previous work.[1] These results have been rationalized by invoking the participation of SBD−H in hydrogen-bond stabilization.[1] Hydrogen-bond stabilization is widely believed to be responsible for the high acidity of related tetraamine mono-ols.[7] Direct measurements of pK_{a2} for SBD have been precluded by the fast rate of conversion of SBD into DBD in the pH range where this deprotonation takes place. The value of pK_{a2} (4.30 at 298.15 K) determined from this kinetic study is similar to pK_{a1} for other chromium(III) hydrolytic oligomers[8] [for example, pK_{a1}(DBD) = 3.68 and pK_{a1}(Trimer) = 4.30], but smaller than pK_{a2} for the tetraammine mono-ols.[7] Double deprotonation of the tetraammine mono-ols requires disruption of the hydrogen-bonding network of the monodeprotonated form, giving rise to the high pK_{a2} values, while for SBD, double deprotonation may occur without hydrogen-bond disruption. For SBD, a comparison of the thermodynamic constants of K_{a1} and K_{a2} reveals that ΔS^0 is essentially the same and that an increase in ΔH^0 for K_{a2} of *ca* 20 kJ mol^{-1} is predominantly

Table 2. Activation parameters and thermodynamic constants for the interconversion between SBD and DBD

responsible for the difference in the values of K_{a1} and K_{a2}. For $[(H_2O)(en)_2Ir(\mu\text{-}OH)Ir(en)_2(OH_2)]^{5+}$ the difference between $\Delta H^0(K_{a2})$ and $\Delta H^0(K_{a1})$ is about 40 kJ mol^{-1} and is coupled with little change in ΔS^0. This difference has been attributed to the need for hydrogen-bond disruption prior to double deprotonation.[9]

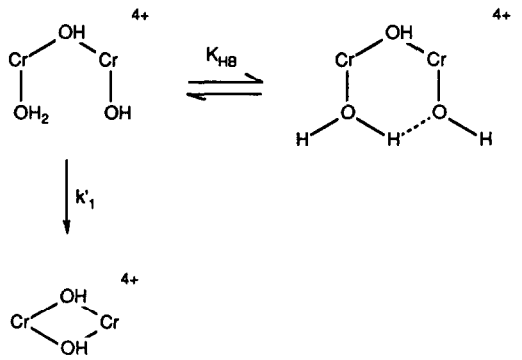
Previous work in this area has analysed the effect of deprotonation on the rate of dimerization of Cr^{3+}.[2] It has been proposed that the reaction involves intermolecular formation of SBD followed by conversion to DBD [eq. (1)]. Although intermolecular substitution was concluded to be rate determining, the rate of the two steps [eq. (1)] could not be compared in the pH range of dimerization studies because of a lack of information on the conversion of SBD into DBD. The data presented here, determined under identical experimental conditions, strongly support this earlier conclusion. Since the two processes differ in molecularity (uni- and bimolecular), overall rates rather than rate constants will be compared for $[Cr]_T = 0.02$ M (concentration used in both studies). The bimolecular rate constant for conversion of $CrOH^{2+}$ into $[Cr(\mu\text{-}OH)_2Cr]^{4+}$, $k_{11} = 2\times10^{-4}$ M^{-1} s^{-1},[2] corresponds to a rate of 8×10^{-8} M s^{-1} ($R = k_{11}[CrOH^{2+}]^2$ where $[CrOH^{2+}] = 0.02$ M) which is considerably slower than the rate of ring closure within $[Cr(\mu\text{-}OH)Cr(OH)]^{4+}$ (SBD−H) of 4.2×10^{-6} M s^{-1} ($R = k_1$[SBD−H], where [SBD−H] = 0.01 M and $k_1 = 4.2\times10^{-4}$ s^{-1}). Similarly, the bimolecular rate constant for the reaction of $CrOH^{2+}$ with $Cr(OH)_2^+$ to give $[Cr(\mu\text{-}OH)_2(Cr(OH)]^{3+}$ (DBD−H), 3.8×10^{-2} M^{-1} s^{-1},[2] converts to a rate of 3.8×10^{-6} M s^{-1} ($R = k_{21}$ $[CrOH^{2+}](Cr(OH)_2^+]$, where $[CrOH^{2+}] = [Cr(OH)_2^+] = 0.01$ M) which is once again slower than the rate of ring closure within $[(HO)Cr(\mu\text{-}OH)Cr(OH)]^{3+}$ (SBD−2H) of 1.14×10^{-4} M s^{-1} ($R = k_2$[SBD−2H], where [SBD−2H] = 0.01 M and $k_2 = 1.14\times10^{-2}$ s^{-1}). These simple comparisons indicate that an assessment of the effect of deprotonation on the rate of both intra- and intermolecular processes can be made by comparing results of the current work with those from previous dimerization studies.[2]

The *most important feature of the reaction mechanism is the pathway involving SBD−2H* which is proposed to account for large accelerations in rate

at pH $\geqslant 3$. Previous work on this system[6] concentrated on measurements at low pH ($\leqslant 2$) where this pathway makes little contribution. The mechanism for conversion of SBD into DBD at low pH is the same as reported for ring closure within a range of related mono-ols, $[A_4(H_2O)M(\mu\text{-}OH)M(OH_2)A_4]^{5+}$ [M = Cr, Rh or Ir and $A_4 = (NH_3)_4$ or $(en)_2$].[7] For these systems, kinetic studies concentrated on the pH range 0–5 where only one coordinated H_2O is deprotonated. Deprotonation of the remaining H_2O does occur at higher pH but ring closure is then expected to be more difficult (slower) since it requires substitution of OH^- rather than H_2O. Hydrolytic systems, such as SBD, are distinctly different from tetraamine complexes in that the presence of many H_2O ligands allows the reaction to proceed via the more facile substitution of H_2O even when the reactant has been deprotonated several times.

The rate constants for conversion of SBD and SBD−H into DBD ($k_0 = 1.01 \times 10^{-4}$ s^{-1} and $k_1 = 4.17 \times 10^{-4}$ s^{-1} at 298.15 K) determined in this study are in agreement with those obtained from early studies on this system[6] ($k_0 = 1.2 \times 10^{-4}$ s^{-1} and $k_1 = 8.1 \times 10^{-4}$ s^{-1} at 298.15 K and $I = 2.0$ M). The rate enhancement of about four-fold resulting from monodeprotonation reflects to some extent the greater nucleophilicity of coordinated OH^-, cf. coordinated H_2O.† Springborg and coworkers have proposed the order of nucleophilicity Cr—OH > H_2O > Cr—OH_2 from studies on the $[(H_2O)(NH_3)_4Cr(\mu\text{-}OH)Cr(NH_3)_4(OH_2)]^{5+}$ system.[7,10,11] However, the net effect of nucleophilicity is masked by hydrogen-bond stabilization of the monodeprotonated mono-ols.[7,10,11] This may also be the case for SBD−H (Scheme 2). It is important to note that in the case of the en mono-ols of iridium and rhodium, $k_0 > k_1$, that is, deprotonation leads to a slower rate of ring closure.

The much larger rate increase of *ca* 25-fold observed on double deprotonation of SBD ($k_2 = 1.14 \times 10^{-2}$ s^{-1}) is interpretable in terms of the labilization introduced at one chromium(III) centre which facilitates nucleophilic attack by an OH^- coordinated to the other chromium(III) centre. This rate enhancement is in excellent agreement with the 20-fold increase in the rate of dimerization of DBD for each additional deprotonation of DBD.[3] However, it is somewhat smaller than those observed in the dimerization of Cr^{3+}, where each additional deprotonation results in rate increases of 50–200-fold[3] and the increase in the rate of H_2O exchange on $CrOH^{2+}$ compared with Cr^{3+} (75-fold).[5] The current work demonstrates that the effect of deprotonation on the rate of hydrolytic substitution reactions is not restricted to intermolecular processes but it is also important in intramolecular processes.



Scheme 2.

ΔH^* for ring closure within SBD is in good agreement with that for the SBD−H pathways, while ΔS^* is more positive for the latter (Table 2). Assuming coordinated OH^- is a better nucleophile than coordinated H_2O, $\Delta H^*(k_1)$ would be lower than $\Delta H^*(k_0)$ for an associative mechanism and close to equal for a dissociative mechanism.[11] Thus, ring closure appears to occur via a dissociative mechanism. However, this straightforward interpretation does not take into account the effect of hydrogen-bonding within SBD−H, which is disrupted prior to diol formation and would result in artificially high values of $\Delta H^*(k_1)$ and $\Delta S^*(k_1)$. In reality, ΔH^* and ΔS^* for k'_1 (true rate constant for ring closure within SBD−H) are probably lower than $\Delta H^*(k_1)$ and $\Delta S^*(k_1)$. This means that $\Delta H^*(k'_1)$ is also lower than $\Delta H^*(k_0)$ which would suggest an associative mechanism of substitution. The parameters for k_2 (Table 2) are consistent with this interpretation. In addition, the much lower value of $\Delta H^*(k_2)$ is consistent with the proposal that the much faster rate of ring closure is due to labilization of the chromium(III) coordination sphere. The values of ΔS^* are probably all negative and in the range −20 to −60 J K^{-1} mol^{-1}, after allowance for hydrogen-bonding stabilization is made. This is also in keeping with an associative mode of substitution.

The back reactions involving acid-catalysed ($k_{-0}K_{a3}$) and uncatalysed cleavage (k_{-1}) of DBD

† We favour this interpretation because it is consistent with data from previous work.[7] An alternative interpretation can be based on the proposal that the introduction of a coordinated OH^- at one of the chromium(III) centres, by deprotonation of an H_2O ligand, labilizes its coordinated H_2O, and, as is the case for SBD, the ring closure reaction could occur by attack of coordinated H_2O at the more labile chromium(III) centre and H_2O displacement from that centre.

are another important feature of the SBD–DBD system. The values of these rate constants (Table 1), determined from k_0, k_1 and K_{a1} of this work and K_1K_{a1} from previous work on the SBD–DBD equilibrium[1] compare favourably with those determined previously[6] ($k_{-0}K_{p3} = 9.4 \times 10^{-5}$ M^{-1} s^{-1} and $k_{-1} = 1.5 \times 10^{-5}$ s^{-1}) under different reaction conditions, such as $I = 2.0$ M. At low pH in particular, these pathways represent a significant proportion of the overall rate. For example, they account for 37 and 10% of k_{obs} at pH = 0 and 1, respectively. A major proportion of the difference in activation parameters for $k_{-0}K_{p3}$ and k_{-1} (Table 2) is attributable to contributions from the K_{p3} term. Assuming as a very rough approximation that protonation of bridging and terminal OH^- are energetically similar, i.e. $\Delta H^0 = -45$ kJ mol^{-1} and $\Delta S^0 = -130$ J K^{-1} mol^{-1} for protonation of SBD−H, then it may be concluded that for the acid-catalysed cleavage of DBD, $\Delta H^*(k_{-0}) \simeq 104$ kJ mol^{-1} and $\Delta S^*(k_{-0}) \simeq 0$ J K^{-1} mol^{-1}. These estimates and the experimentally determined values for k_{-1} are very similar to those for H_2O exchange on Cr^{3+} (Table 2),[5] which has been estabished to occur via an associative mechanism (note that these reactions are similar in the sense that they all involve substitution by H_2O from the bulk solvent). Thus, it would seem reasonable to suggest that both bridge cleavage reactions occur via associative substitution. This may be less important for the acid-catalysed pathway where protonation of a bridging OH^- occurs prior to substitution.

In the preceding discussion the experimental data for the SBD–DBD system has been rationalized by invoking an associative substitution mechanism at chromium(III) for both ring closure within SBD forms and cleavage of DBD which is essentially unaffected by the degree of protonation or deprotonation of the reactants. However, recent measurements of ΔV^* for H_2O exchange on Fe^{3+} [12] and Cr^{3+} [5] suggest that deprotonation causes changes in mechanism for associative (A or I_a) to dissociative (probably I_d). ΔV^* was negative for exchange of M^{3+} and positive for exchange on MOH^{2+}. These changes in mechanism could not be ascertained from temperature dependence studies because the faster rate of H_2O exchange on MOH^{2+} originates from ΔS^* for $CrOH^{2+}$ [5] and ΔH^* for $FeOH^{2+}$.[13]

Mechanistic information concerning H_2O exchange of aqueous metal ions, M^{3+}, cannot be directly related to hydrolytic processes such as the interconversion between SBD and DBD because of several differences between these systems: (i) for ring closure within SBD, the nucleophilicity of coordinated OH^- and H_2O is probably different from that of free H_2O;[7,11] (ii) for cleavage of DBD the leaving group is either an OH^- or H_2O coordinated to chromium(III) and not H_2O alone, as is the case for H_2O exchange; (iii) bridging OH^- may introduce steric constraints which may affect the mechanism; and (iv) both SBD and DBD contain OH^- bridges which might give rise to more dissociative substitution, as is the case for H_2O exchange on $CrOH^{2+}$ [5] and $FeOH^{2+}$.[12] Thus, there is a need for detailed investigations of the pressure dependence of these ring closure and bridge cleavage reactions to assist with the assignment of mechanisms. This could be nicely complemented with mechanistic studies of H_2O exchange on SBD and DBD, and other related systems.

In conclusion, the singly-bridged hydrolytic dimer of chromium(III) may be considered as a model system which has allowed us to probe the effect of successive deprotonations on the rate of intramolecular ring closure. Our data indicate that deprotonation leads to substantial rate enhancements, in keeping with observations for the intermolecular dimerization processes of Cr^{3+} [2] and DBD,[3] and for H_2O exchange on Cr^{3+}.[5] Collectively, these investigations demonstrate that deprotonation plays a major role in the polymerization of metal ions in aqueous solution, by facilitating the substitution processes involved in the formation of polynuclear species.

EXPERIMENTAL

Materials

Solutions of $[Cr(OH_2)_6](ClO_4)_3$ and $[Cr_2(\mu\text{-}OH)_2(OH_2)_8](ClO_4)_4$ were prepared and standardized as described previously.[8] Lithium perchloriate (Fluka, puriss), sodium perchlorate (Merck, p.a.), 70% perchloric acid (Fluka, puriss), Titrisol standard solutions of NaOH and HCl (Merck), 4-sulphanilic acid (Fluka, puriss), isonicotinamide (Fluka, purum) and 2,6-dimethylpyridine 3-sulphonic acid (Merck, p.a.) were all used as received. Water was deionized and distilled prior to use.

Sodium perchlorate solutions of accurately known concentrations were prepared by neutralization of standardized NaOH solutions with perchloric acid. All solutions were filtered through Sartorius SM11307 cellulose nitrate membrane filters (0.2. μm median pore size) prior to use.

Solutions of the hydrolytic DBD, free of $NaClO_4$, were prepared by elution of the DBD from a Sephadex SP C25 cation exchange column with $HClO_4$ (0.2–0.5 M). Rapid elution (*ca* 30 min) minimized the acid hydrolysis of the resin. Evaporation of the eluted dimer solution gave concentrated solu-

tions of the SBD since this form is favoured at high $[H^+]$. Typically, 600 cm^3 of 0.02 M dimer ($[HClO_4] \sim 0.25$ M) was reduced in volume at 25°C to *ca* 25 cm^3 to give [dimer] ~ 0.45 M and $[HClO_4] \sim 6$ M. This solution was equilibrated at room temperature (20°C) for 120 min, to ensure conversion to the SBD, and then stored at −18°C until required. The preparation was complete in 4 h. This procedure minimized the acid-induced cleavage of the dimer into Cr^{3+} ($t_{1/2} \sim 7$ days in 1 M $HClO_4$ at 25°C).[8] Indeed, chromatographic analysis of the stock SBD solution showed that only small amounts of Cr^{3+} had formed (< 2%), in agreement with the cleavage information. In any case, Cr^{3+} is not expected to interfere with the study of the SBD conversion to DBD since its concentration will remain constant throughout the reaction.

Instruments

UV–vis spectra were recorded using a Uvikon 820 spectrophotometer fitted with a multiple cell compartment. This accessory allowed the simultaneous measurement of six kinetic runs. Within the cell compartment constant temperature (±0.1 K) was maintained by circulating water from a Haake N3 thermostat. Calibrated thermometers were used to accurately measure the temperatures of the reaction mixtures directly in the cell compartment.

pH measurements

The pH values of the reaction mixture were measured using a Ross glass electrode (Orion) connected to a Metroohm 605 pH meter. These measurements were made at constant temperature in a jacketed vessel connected to a Haake N3 thermostat. Since the acidity (or basicity) constants of the buffers may vary with temperature it was necessary to measure the pH of the reaction mixtures at each temperature. This involved standardization of the electrode at each temperature by titration of a 0.01 M $HClO_4$ solution with 0.1 M Titrisol, both at $I = 1.00$ M ($NaClO_4$). As a consequence of this calibration, the pH values measured for the reaction mixtures are in concentration units which is convenient for the treatment of kinetic data.

Kinetic measurements

(*a*) *Experiments at low* pH (≤ 2). Reaction mixtures for kinetic studies in the pH range 0–2 were prepared by adding 3×10^{-2} cm^3 of concentrated SBD stock ([SBD] = 0.454 M and $[H^+] = 6.48$ M) to 5 cm^3 of (Na, H)ClO_4 mixtures at thermal equilibrium in a spectrophotometer cell, 2 cm path length. This gave $[SBD] = 2.72 \times 10^{-3}$ M and $I = 1.0$ M. The reaction was followed in the region 240–300 nm where substantial increases in absorbance are observed; much greater than the corresponding changes in the visible region. In some experiments, $LiClO_4$ was substituted for $NaClO_4$ to check on whether the reaction rate was affected by the counter-cation.

(b) *Experiments at higher* pH (≥ 2). In the pH range 2–4.9, reaction mixtures were buffered to minimize changes in $[H^+]$ during the reaction. Reaction mixtures containing 4-sulphanilic acid/NaOH and 2,6-dimethylpyridine 3-sulphonic acid/NaOH were prepared by mixing 7.5×10^{-2} cm^3 of SBD stock [concentration as in (a) above] with 5 cm^3 of each buffer equilibrated at the desired temperature. This gave $[SBD] = 6.81 \times 10^{-3}$ M at the commencement of the reaction. Mixtures containing isonicotinamide were made by mixing 0.1 cm^3 of SBD stock ([SBD] = 0.404 M, $[H^+] = 5.86$ M) with 5 cm^3 of the buffers, giving $[SBD] = 7.9 \times 10^{-3}$ M. The buffer solutions contained sufficient $NaClO_4$ to give $I = 1.0$ M in the reaction mixture. Since all of these buffers absorb strongly in the UV region, it was necessary to follow the reaction in the visible region (440 nm) where the absorbance of deprotonated forms of SBD is greater than that of DBD (see Results).

At the highest pH values, the dimer has been shown to undergo polymerization (initially producing tetramer) and it was necessary to check whether the extent of this polymerization reaction was sufficient to interfere with measurements of the rate of conversion of SBD into DBD. A reaction mixture was prepared from SBD and 0.14 M 2,6-dimethylpyridine 3-sulphonic acid/NaOH (pH = 4.65) and reacted until conversion of SBD into DBD was complete. The mixture was quenched with 0.5 cm^3 of 70% $HClO_4$, after a reaction time of 25 min at 298.15 K (*ca* 18 $t_{1/2}$), diluted to *ca* 100 cm^3 and absorbed onto a Sephadex SP C25 ion exchange column. The oligomers present, eluted in turn with increasing $[NaClO_4]$, were monomer ≈ 1%; dimer 93.7%; and tetramer, 3.2%. [After $5 \times t_{1/2}$ of the SBD–DBD reaction, the amounts of monomer (≈ 1%) and tetramer (< 1%) are too small to have a significant effect on the spectra and are, therefore, unlikely to influence k_{obs}.]

Supplementary material. Table of k_{obs} values for the SBD–DBD interconversion is available from the authors (L.S.).

(*Received* 23 *July* 1990; *accepted* 28 *November* 1990)

Abstract—Lanthanide perchlorate complexes with *rac*-bis(phenylsulphinyl)ethane: $[Ln_2(L)_7(ClO_4)_2](ClO_4)_4 \cdot nH_2O$ (where Ln = La–Nd, Sm, Gd–Er, Yb; $n = 0, 4$) have been prepared by the reaction of the corresponding lanthanide perchlorate with *rac*-bis(phenylsulphinyl)ethane and characterized by elemental analysis, electrical conductance, magnetic susceptibility, IR and electronic spectra and thermal analysis.

Disulphoxide complexes with trivalent lanthanides have been reported over the last few years.[1,2] They have been shown to produce lanthanide complexes with different stoichiometries.[2,3] While there is some information about transition metal complexes with bis(phenylsulphinyl)ethane,[4,5] little is known about lanthanide complexes with this ligand.[3] We recently reported lanthanide complexes with *meso*-bis(phenylsulphinyl)ethane of the ratio 1 : 3.[6] In this paper, the synthesis and characterization of lanthanide complexes of *rac*-bis(phenylsulphinyl) ethane of the ratio 1 : 3.5 are reported.

EXPERIMENTAL

Physical and analytical measurements

IR spectra were obtained on KBr pellets using a Nicolet DX V4 spectrometer in the 400–4000 cm^{-1} region. Electronic spectra were recorded on a UV-240 spectrophotometer in the regions 340–900 nm (solid) and 190–330 nm (solution). Conductivity measurements were carried out using a 10^{-3} M solution in methanol and methyl cyanide on a DDS-11A conductometer at 25°C. Magnetic susceptibility measurements were carried out using Gouy's method. Thermal characterization studies were undertaken using a standard TG-DTA analyser and MP-500 melting point meter. Metal analyses were determined by titration with EDTA after decomposition of the sample with $HClO_4$. Carbon and hydrogen analyses were obtained on a Perkin–Elmer 240C elemental analyser, and sulphur was determined by the literature method.[7]

Materials and methods

The lanthanide perchlorates were prepared by dissolving the respective oxide (99.95%) in $HClO_4$. The ligand, *rac*-bis(phenylsulphinyl)ethane, was prepared according to the literature method.[4] The other chemicals were analytical reagent grade.

The complexes were prepared as follows. A solution of metal perchlorate (0.5 mmol) in anhydrous ethanol (5 cm^3) was added dropwise to a 10 cm^3 solution of the ligand (2 mmol) in chloroform containing 2 cm^3 of triethylorthoformate. The reaction mixture was stirred and refluxed for 6 h, to give the complex as a precipitate. The complex was filtered, washed several times with chloroform, ethanol and ether, and dried *in vacuo* over P_4O_{10} at room temperature.

RESULTS AND DISCUSSION

Elemental analyses (Table 1) show that the metal-to-ligand ratio in the complexes is 1 : 3.5. The complexes are air-stable at room temperature, soluble in DMF, DMSO and CH_3CN, slightly soluble in CH_3OH and C_2H_5OH, and insoluble in water.

The electrical conductance data in CH_3OH and CH_3CN (Table 2) indicate that they behave as 2 : 1 electrolytes in these solvents.[8] Thermal analyses of the ligand and its complexes show that decomposition occurs when they are heated above 150°C. The TGA data of Nd and Ho complexes (Table 1)

Er	171	292	9.47
Yb	169	339	4.44

show that the complex $NdL_{3.5}(ClO_4)_3 \cdot 2H_2O$ loses about 2.36% of its weight, which corresponds to the loss of two crystal water molecules (calc. for $2H_2O$, 2.48%) at 50–100°C. Similarly, $HoL_{3.5}(ClO_4)_3 \cdot 2H_2O$ loses 3.01% of its weight (calc. for $2H_2O$, 2.44%) at 50–100°C which apparently is also crystal water. Thus, based on the analytical data, electrical conductance and thermal studies, the empirical formula $[Ln_2L_7(ClO_4)_2](ClO_4)_4 \cdot nH_2O$ ($n = 0, 4$) may tentatively be assigned to the complexes.

IR spectra

The IR spectra of all the complexes (Table 3) indicate that the ligand binds the metal through the oxygen atoms of the disulphoxide moieties: the S—O bond stretching frequencies of the complexes are lower than the corresponding ones in the free ligand. Investigation of a wide variety of sulphoxide complexes strongly suggests that the IR shift of the S—O bond on coordination reflects the nature of the donor atom, i.e. sulphur or oxygen. An increase in ν(S—O) is diagnostic for sulphur coordination, and a decrease for oxygen coordination.[9] Thus the ligand acts as a neutral, bidentate ligand in the complexes, coordinating through the oxygen atoms of disulphoxide moieties forming a seven-membered chelate ring. IR data for the complexes also show the Cl—O vibrational band of ClO_4^- (*Td*) and ClO_4^- (C_{2v}) (Table 3), which suggests the existence of ClO_4^- which is coordinated bidentately.[10]

Magnetic susceptibility

The observed magnetic moments of the complexes are close to those given by Van Vleck, indi-

cating that the lanthanides in the complexes remain in the +3 oxidation state and the 4*f* electrons are little influenced by the ligand bis(phenylsulphinyl)ethane.

Electronic spectra

The electronic spectra of Pr, Nd, Ho and Er complexes have been determined in the solids in the 340–900 nm region. The nephelauxetic parameter (β) was calculated from the spectroscopic data, in comparison with the corresponding values of the aquoions.[11] The nephelauxetic parameter (β), the bonding parameter ($b^{1/2}$)[12] and Sinha's covalence parameter (δ)[13] for the complexes of Pr^{3+}, Nd^{3+}, Ho^{3+} and Er^{3+} are presented in Table 4. The parameters suggest a weak covalent nature of the M—O bonds formed between the metal ion and ligand. The values of $b^{1/2}$ and δ in the complexes are in the order Pr, Nd > Ho, Er which reveals that for the same ligand covalency in the lighter lanthanides is greater than in the heavier lanthanides.

Table 4. Covalence parameters

Complex	β	$b^{1/2}$	δ
$PrL_{3.5}(ClO_4)_3 \cdot 2H_2O$	0.9965	0.0418	0.3512
$NdL_{3.5}(ClO_4)_3 \cdot 2H_2O$	0.9930	0.0592	0.7050
$HoL_{3.5}(ClO_4)_3 \cdot 2H_2O$	0.9985	0.0274	0.1502
$ErL_{3.5}(ClO_4)_3 \cdot 2H_2O$	0.9997	0.0122	0.0300

The UV spectral data of the ligand and its complexes in methanol are shown in Table 5. It can

Er	269.2 (1727)	241.0 (9034)	217.2 (9097)
Yb	270.6 (1447)	240.0 (9846)	219.6 (12,591)

be seen that the UV spectra of the ligand and its complexes are similar, and show characteristic bands at 240 and 270 nm arising from the *K* and *B* bands (π–π^*) of the benzene ring.[14] The characteristic band at about 218 nm is attributed to an n–π^* transition of the S=O group.

Conclusion

Lanthanide perchlorates with *rac*-bis(phenylsulphinyl)ethane form complexes which may be formulated as $[Ln_2L_7(ClO_4)_2](ClO_4)_4 \cdot nH_2O$ (where Ln = La–Nd, Sm, Gd–Er, Yb; $n = 0$, 4). The ligand is bidentate in these complexes, coordinating through the oxygen atoms of the disulphoxide moieties. The coordination number is nine.

and

N. W. GREGORY*

Department of Chemistry, University of Washington, Seattle, WA 98195, U.S.A.

(*Received* 21 *May* 1990; *accepted* 4 *December* 1990)

Abstract—The UV–vis absorption spectrum of $Au_2Cl_6(g)$ is reported. Maxima are observed at 222, 244 and 460 nm. Spectral data are used to derive equilibrium and thermodynamic constants for vaporization reactions in the gold–chlorine system. In gold–chlorine–water mixtures, no evidence is found for the presence of complexes of gold(III) chloride and water in the vapour phase.

Recently, we have reported spectral evidence for the formation of iron(III) halide hydrate molecules, $Fe(H_2O)X_3$, in the vapour phase;[1,2] a similar study of other transition metal halide systems is of interest. We now report a spectrophotometric study of vapours formed by gold–chlorine and gold–chlorine–water mixtures. No previous report of the UV–vis absorption spectrum of gold(III) chloride vapour has been found. Like iron(III) chloride, gold(III) chloride is appreciably volatile[3–11] around 500 K and is known to form stable complexes with water in aqueous solutions at room temperature.[12] However, gold(III) chloride is less stable than iron(III) chloride, and thermally decomposes at relatively low temperatures to gold(I) chloride or gold and chlorine. The observed spectral data have also been used to derive enthalpy and entropy changes for the reactions

$$Au_2Cl_6(s) = Au_2Cl_6(g) \quad (1)$$

$$2Au(s)+3Cl_2(g) = Au_2Cl_6(g) \quad (2)$$

$$2AuCl(s)+2Cl_2(g) = Au_2Cl_6(g) \quad (3)$$

$$0.5Au_2Cl_6(s) = AuCl(s)+Cl_2(g). \quad (4)$$

The results are compared with those of other workers who used different methods.[3–11] The spectra provide no evidence, however, that the addition of water leads to the formation of appreciable concentrations of gold chloride hydrate molecules in the vapour phase.

EXPERIMENTAL

The procedures for preparing and isolating mixtures in quartz absorption cells, heating and measuring temperatures, and recording of spectra with a Cary 14H spectrophotometer were similar to those described in the previous iron halide studies.[1,2] The gold (Morgan, Hastings and Co., "pure" gold) was examined with an ICP atomic emission spectrometer (Model 955, Plasmo Atomcorp); no significant impurities were found. For the samples used to determine the molar absorptivity of $Au_2Cl_6(g)$ the small quantities of gold necessary were weighed on a Cahn 21 automatic electrobalance. A Mettler analytical balance was used for larger quantities. As before, chlorine was prepared by heating $CuCl_2(s)$. Cell path lengths, b, volumes, V, and initial amounts of reactants for the nine mixtures studied are listed in Table 1. Only gold and chlorine were present in samples 1–5. Water

was also introduced[1,2] in samples 6, 7 and 9; water and hydrogen chloride were introduced in sample 8.

After isolation in a cell, a given mixture was held at a selected temperature until equilibrium was reached, i.e. until the absorbance no longer changed with time. Temperatures were measured with calibrated chromel–alumel thermocouples. The temperature of the gas was taken as that of the cell body, T(g). The temperature of any solid phase, T(s), was measured at the place where the solid condensed, usually in the cell sidearm. A day, or in some cases several days, was usually required for equilibration when a solid phase was present; a few minutes were sufficient for the all vapour samples.

RESULTS AND DISCUSSION

The gold–chlorine system has been studied and reviewed by a number of investigators.[3–12] Hager and Hill[7] give a summary of work prior to 1970. At temperatures of interest in the present work, 450–650 K, only three solid phases, Au, AuCl and Au_2Cl_6 have been observed; only Cl_2 and Au_2Cl_6 have been found at significant concentrations in the vapour phase. Recent workers have used static pressure,[6] transpiration,[3,8] effusion[6,8] and mass spectrometric measurements[3,6–8] to characterize the various vaporization reactions.

The UV–vis absorption spectrum of Au_2Cl_6(g)

Chlorine gas has a temperature-dependent, vibronic, absorption spectrum between 250 and 480 nm, with λ_{max} at 330 nm.[13] The chlorine absorbances must be subtracted from the total absorbances to derive the spectrum of Au_2Cl_6(g). In an unreported study, we have derived equations for the temperature dependence of the chlorine molar absorptivity, $\varepsilon_{C,\lambda}$, at various wavelengths λ. For example, $\varepsilon_{C,330} = 82.0 - 0.0529T + 1.427 \times 10^{-5}T^2$ dm^3 mol^{-1} cm^{-1} (T in Kelvin). The concentration of chlorine, before and after reaction with the gold to form gold(III) chloride, was determined at room temperature from the measured absorbance at 330 nm and $\varepsilon_{C,330}$. The chlorine concentration, together with the appropriate molar absorptivity–temperature equation, was then used to derive the chlorine absorbances at the various wavelengths and temperatures of the equilibrium mixtures. These values were subtracted from the total observed absorbances between 250 and 480 nm to obtain the absorbances of Au_2Cl_6(g), $A_{D,\lambda}$ (subscript D designates dimer); at other wavelengths the total absorbance was attributed to Au_2Cl_6(g).

Samples 2, 3, 7 and 8 contained small enough amounts of gold and sufficient amounts of chlorine so that complete vaporization of gold, as Au_2Cl_6(g), could be achieved. Consequently, molar absorptivities of Au_2Cl_6(g), $\varepsilon_{D,\lambda}$, were determined at various wavelengths and temperatures from $A_{D,\lambda}$, using the relationship: $\varepsilon_{D,\lambda} = 2A_{D,\lambda}V/bm_{Au}$ dm^3 mol^{-1} cm^{-1}, where m_{Au} is the number of moles of gold in the cell of volume V and path length b. To derive absorptivities from absorbances measured when part of the gold was in a condensed phase, the least-squared molar absorptivity–temperature equation for $\varepsilon_{D,244}$, based on 23 observations for fully vaporized samples, see Table 2(a), was used

Table 2. Absorbance data for various equilibrium mixtures

(a) Gold completely vaporized (as Au_2Cl_6); $Q = A_{244}V/bm_{Au} = 0.5\varepsilon_{D,244}$

Sample number	T(g) (K)	A_{244}	A_{330}	P_C(atm)	Q
2	468.8	0.856	1.710	0.1070	0.1615E+05
2	469.8	0.855	1.705	0.1072	0.1613E+05

$\ln P_C = -9258(1.6\%)/T(s) + 17.760(1.7\%)$; variance = 0.0035.

to calculate the concentration of Au_2Cl_6(g), C_D: $C_D = A_{D,244}/b\varepsilon_{D,244}$. $\varepsilon_{D,\lambda}$ Values at other wavelengths were then calculated for these samples from C_D and $A_{D,\lambda}$, $\varepsilon_{D,\lambda} = A_{D,\lambda}/bC_D$. Using all data, the variation of the molar absorptivity with temperature at each wavelength was approximated by a least-squares fit to the empirical equation $\varepsilon_{D,\lambda} = A + BT$. The derived constants, A and B, and the relative standard deviations of the means are listed in Table 3. Within the experimental uncertainties, samples with and without the various condensed phases present, and with and without water, or water and hydrogen chloride, gave identical spectra. Hence we conclude that, under the conditions of our study, complexes of gold(III) chloride with water or hydrogen chloride are not present in the vapour at concentrations which can be detected by the Cary 14H spectrophotometer.

Evidence that photolysis of Au_2Cl_6(g) occurs was observed with samples 2 and 7. While light was passing through the cell, a decrease in absorbance with time and formation of condensate on the windows were detected; the absorbance returned to its initially observed value after the cell was allowed to stand in the dark for a short time. Photolytic effects were not observed with the other samples. In these other cases the concentrations of the other gases were apparently high enough to decrease the rate of diffusion and thus the photolysis products recombined before condensation occured; also no changes with time were observed when vapour concentrations were fixed by equilibrium with a solid phase. This photolytic behaviour is similar to that observed for Fe_2Cl_6(g).[14] $[AuCl_4]^-$ ions in solution are also reported to photolyse readily.[15] For samples 2 and 7 light was not passed through the vapour except for the brief period necessary to record an absorbance reading at a preset wavelength.

The Au_2Cl_6(g) spectrum is significantly different from that reported by others for the square-planar $[AuCl_4]^-$ ion in solution and that of solid gold(III) chloride in a film. For example, spectra[16] of $[(n\text{-}C_4H_9)_4N][AuCl_4]$ in different solvents at 300 and 70 K show transitions in the following ranges of wavelengths in nm (molar absorptivities in M^{-1} cm^{-1}): 226 (44,250), 322 (5020)–329 (6500), 400 (304)–380 (267) and 460 (15). The first and second transitions are distinct peaks with quite different molar absorptivities, whereas the third and fourth transitions are seen as very weak shoulders. In solid gold(III) chloride, square-planar Au_2Cl_6 molecular units are observed.[17] The spectrum[18] of solid gold(III) chloride film shows four distinct peaks at 293 K—230, 320, 358 and 438 nm—and three distinct peaks at 83 K—230, 320 and 438 nm. For the solid the molar absorptivities for the 358 and

438 nm peaks are relatively larger than those for the $[AuCl_4]^-$ ion. In contrast, $Au_2Cl_6(g)$ has three distinct peaks—222, 244 and 460 nm—see Fig. 1. The first two have similar large molar absorptivities; the third is much weaker but has a much larger molar absorptivity than the corresponding peak for the $[AuCl_4]^-$ ion. These spectral differences are being studied further.

Vaporization equilibria

Values of the total observed absorbance, A, at 244 nm, A_{244}, and 330 nm, A_{330}, the temperatures, the partial pressures of chlorine, derived using the perfect gas law, and equilibrium quotients are listed in Table 2. In cases where the concentration of chlorine could not be determined in the manner described above, due to the decomposition of gold(III) chloride, chlorine partial pressures, P_C, were derived from the expression $P_C(\text{atm}) = [A_{330} - (A_{244}\varepsilon_{D,330}/\varepsilon_{D,244})] \times 0.08205 \times T(\text{g})/b\varepsilon_{C,330}$. Values of $\varepsilon_{D,\lambda}$ were taken from the results in Table 3. Chlorine does not absorb significantly at 244 nm. Partial pressures of $Au_2Cl_6(g)$, P_D, were calculated from the equation $P_D(\text{atm}) = A_{244} \times 0.08205 \times T(\text{g})/b\varepsilon_{D,244}$.

Equilibrium constants[19] for the reaction $Cl_2(g) + H_2O(g) = 2HCl(g) + 0.5O_2(g)$ are *ca* 1.6×10^{-3} atm$^{0.5}$ in the temperature range in which samples 6, 7 and 9 were studied, 480–580 K. Hence, one expects that for these samples chlorine will react with

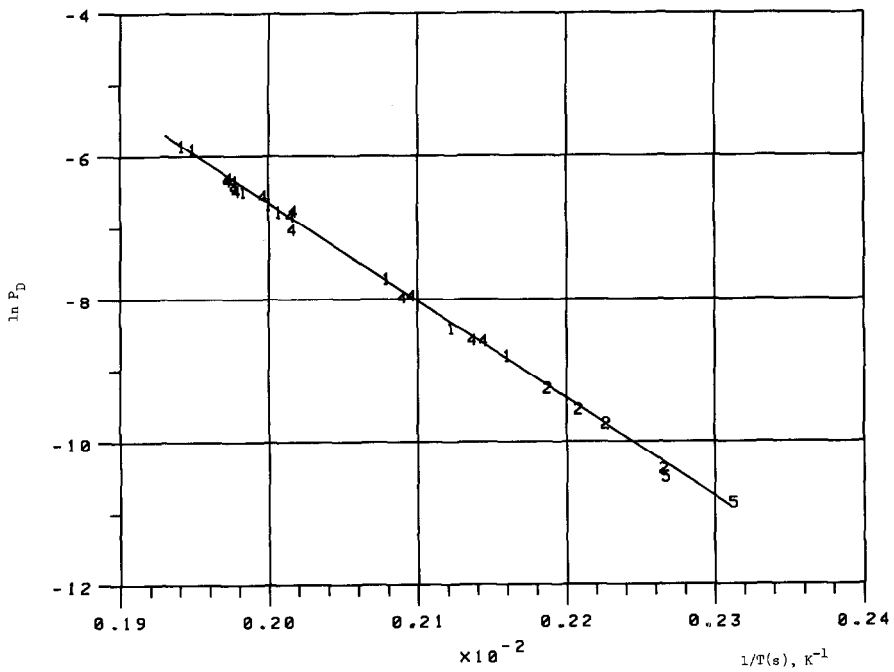

Fig. 2. ln P_D vs $1/T$(s) for equilibrium 1. Points identified by sample numbers. [See Tables 1 and 2(b).] Solid line corresponds to least-squares fit.

water to form appreciable amounts of hydrogen chloride and oxygen. We did not, however, observe the changes in the chlorine absorbance expected from this reaction and conclude, consistent with the observations of others,[20] that the chlorine–water reaction is kinetically inhibited under the conditions of our experiments.

Equilibrium 1

At 432–515 K, samples 1, 2, 4 and 5 have vapour in equilibrium with Au_2Cl_6(s). The A_{244} values correlate with T(s), the temperature of the cell sidearm tip where the solid was observed to condense. Data are listed in Table 2(b) and are shown, plotted as ln P_D vs $1/T$(s), in Fig. 2. The line drawn represents the least-squares fit of 27 observations: ln $P_D = -13744(0.93\%)/T(s)+20.835(1.3\%)$; variance 0.0050.* At low temperatures, absorbances of samples with water present were less than values expected for equilibrium with Au_2Cl_6(s) and condensed liquid solutions were visible. In such cases, absorbance values were not used.

Equilibrium 2

At higher temperatures, up to 635 K, the exact range depending on composition, vapours are in equilibrium with Au(s). Because reaction 2 is exothermic, gold crystals deposited in the section of the cell at the highest temperature. Generally this was in the sidearm close to the cell body, at a point where the sidearm passed close to the heating element of the cell body furnace. For samples 3–9 a thermocouple placed at this point was used to measure T(s).† For some of the samples with large amounts of gold, measurements were sometimes made before all the gold had been transported from the cell body to the hot spot, occasionally confirmed by visual observation; in these cases T(g) was taken as T(s). The 60 observations are tabulated in Table 2(c); a plot of ln $P_D/P_C{}^3$ vs $1/T$(s) is shown in Fig. 3. Samples with and without water show a similar behaviour. A least-squares treatment gave ln $P_D/P_C{}^3 = 12959(0.64\%)/T(s)-29.011(0.53\%)$; variance 0.010.

Equilibrium 3

In the ranges 470–560 K for sample 4 and 444–477 K for sample 5, Au_2Cl_6(s) is not present; Cl_2(g)

* The numbers in parentheses, in this and in similar equations to follow, are least-squares per cent standard deviations for slope and intercept, respectively. The variance represents the value of $[\Sigma(\ln Q(\text{obs})-\ln Q(\text{calc}))^2]/n-1$; Q is the equilibrium quotient for the particular reaction and n is the number of observations.

† T(s) was not measured for samples 1 and 2; these samples were excluded from consideration of equilibrium 2.

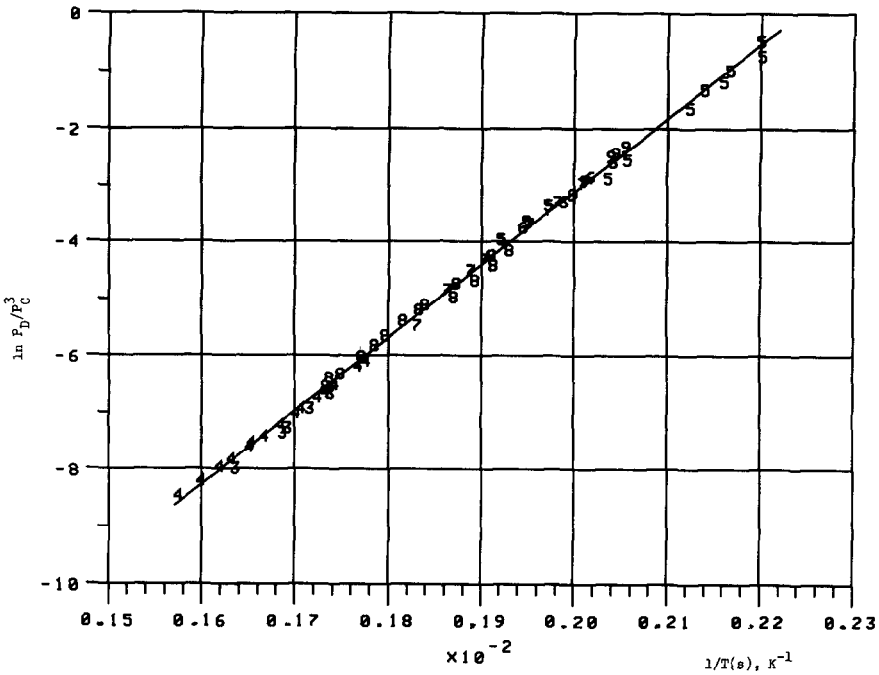

Fig. 3. ln $P_D/P_C{}^3$ vs $1/T$(s) for equilibrium 2. Points identified by sample numbers. [See Tables 1 and 2(c).] Solid line corresponds to least-squares fit.

and Au_2Cl_6(g) are in equilibrium with AuCl(s). The 41 observed absorbances are listed in Table 2(d). In some of these mixtures solid gold is also present. As observed by other workers,[3–11] the reaction between crystalline gold and chlorine is slow. Equilibration between Cl_2(g), Au_2Cl_6(g) and AuCl(s) was faster, however, and even though Cl_2(g) pressures changed very slowly as Au(s) and AuCl(s) were interconverted, the ratios $P_D/P_C{}^2$ measured during the change were found to correlate well with those measured when equilibrium had been fully established. Results are shown graphically in Fig. 4,

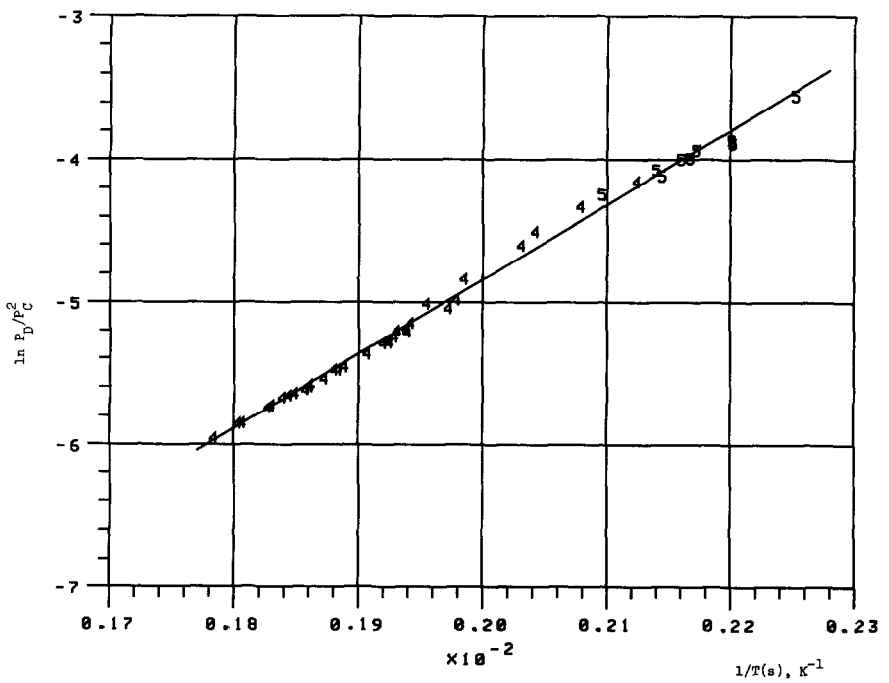

Fig. 4. ln $P_D/P_C{}^2$ vs $1/T$(s) for equilibrium 3. Points identified by sample numbers. [See Tables 1 and 2(d).] Solid line corresponds to least-squares fit.

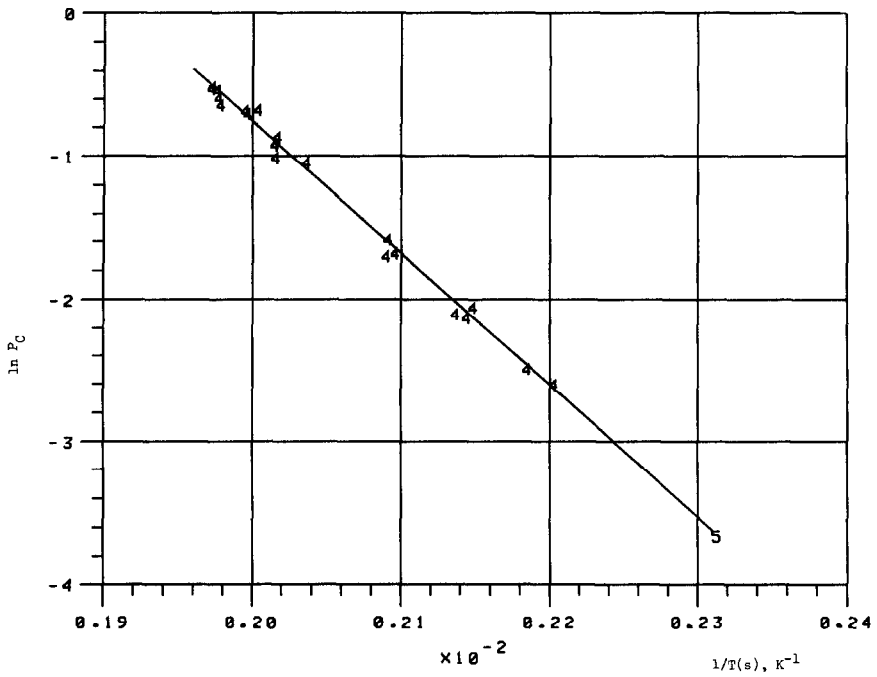

Fig. 5. ln P_C vs $1/T$(s) for equilibrium 4. Points identified by sample numbers. [See Tables 1 and 2(e).] Solid line corresponds to least-squares fit.

along with the least-squares solution line, ln $P_D/P_C^2 = 5250(1.1\%)/T(s) - 15.341(0.74\%)$; variance 0.0022.

Equilibrium 4

Equilibrium constants for reaction 4 correspond to the Cl_2(g) partial pressures when both AuCl(s) and Au_2Cl_6(s) are present. Values were observed for samples 4 and 5 in the range 432–507 K. The 20 observations, mainly from sample 4, are listed in Table 2(e) and are shown graphically in Fig. 5. The least-squares line corresponds to the equation ln $P_C = -9258(1.6\%)/T(s) + 17.760(1.7\%)$; variance 0.0035.

Only three of these four reactions are independent, and, for example, the thermodynamic constants derived for reaction 4 may be compared with

those calculated from the constants derived for reactions 1 and 3, 0.5(1–3). In Table 4 the various constants, derived from the least-squares equations presented above, are compared with those reported by other workers. The general accord supports our belief that the absorbance data have been interpreted correctly.

Several differences in the properties of iron(III) chloride and gold(III) chloride appear related to the lack of formation of detectable concentrations of a volatile hydrate in the gold chloride system. Around 500 K, the saturation vapour pressure of iron(III) chloride is *ca* 10 times larger than that of gold(III) chloride. Hence, higher vapour concentrations of iron(III) chloride can be produced at lower temperatures. And, importantly, the dissociation of $Fe_2Cl_6(g)$ to $FeCl_3(g)$ is substantial at low concentrations in the temperature ranges of interest here. In the iron system, only the vapour hydrate of the monomer was observed. In contrast, the monomer $AuCl_3(g)$ has not been detected in gold(III) chloride vapours. At higher temperatures, at which dissociation of the dimer to monomer might be expected, gold(III) chloride is unstable relative to chlorine and gold. Furthermore one would expect the gold–oxygen bond energy in a hydrate linkage to be appreciably less than the similar interaction for iron.

(*Received* 9 *July* 1990; *accepted* 9 *November* 1990)

Abstract—A series of (β-diketonate)Cu(PMe_3), where β-diketonate = acetylacetonate (acac) (**1**), trifluoroacetylacetonate (**2**) and hexafluoroacetylacetonate (**3**), compounds have been prepared by the reaction of β-diketones with (η^5-C_5H_5)CuPMe_3. A single crystal X-ray diffraction study of (tfa)CuPMe_3 reveals that it is monomeric in the solid state with a trigonal planar copper coordination environment. All three new compounds are volatile and soluble in hydrocarbon solvents.

The metal–organic chemistry of copper is currently receiving renewed interest due to new applications including Chemical Vapour Deposition (CVD) of copper metal for microelectronic applications and copper oxide for superconducting ceramics. These applications have driven the development of molecular routes to copper-containing materials. The synthesis of multi-component metal oxide phases containing copper is being investigated by using either volatile precursors to copper oxide for CVD[1] or soluble precursors for hydrolytic condensation.[2] The deposition of copper metal films by CVD also requires molecular precursors that are volatile.[3] There is, however, a distinct paucity of volatile and soluble copper(I) and copper(II) compounds, due to their tendency to oligomerize.[4] Copper(II) β-diketonates[3,5] and $[Cu(O\text{-}t\text{-}Bu)]_4$[6] have been used as precursors to copper metal films, but have low volatility (e.g. $[Cu(O\text{-}t\text{-}Bu)]_4$ sublimes slowly at 100°C and 10^{-5} torr). It has recently been demonstrated that copper(I) species, such as cyclopentadienyl copper(I) phosphine complexes, have higher volatility and are suitable precursors for deposition of copper.[7] Here we report the synthesis and characterization of a series of monomeric copper(I) β-diketonate complexes, which are both volatile and soluble in hydrocarbon solvents. Although copper(II) β-diketonates are well known, there are few reports of copper(I) β-diketonate compounds,[8] and their solubility and volatility is much lower than that of the title compounds.

The reaction of cyclopentadienyl copper(I) trimethylphosphine, (η^5-C_5H_5)CuPMe_3, with β-di-

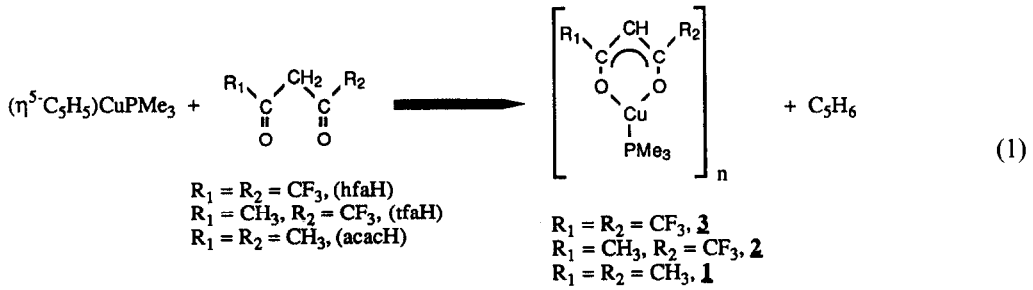
ketones results in the displacement of cyclopentadiene, according to the reaction of eq. (1) below.*



(1)

Upon work-up, **1** is isolated as a yellow liquid, while **2** and **3** are isolated as pale yellow and orange solids, respectively. All three reactions result in high yields of the respective products that can be crystallized from n-pentane at low temperatures. All three compounds can be sublimed *in vacuo* at relatively low temperatures and pressures (~35°C and 0.01 torr). However, while **2** and **3** sublime unchanged, **1** decomposes upon sublimation to yield (acac)Cu(PMe_3)$_2$ (**4**).†

The high volatility of these species is consistent with a low degree of molecular aggregation. In benzene solution, **2** and **3** are monomeric, as determined by cryoscopic molecular weight determination. However, positive ion mass spectral data (electron impact) of **1–3** exhibit ions of higher molecular mass than those expected for monomeric species.‡ For example, the highest masses observed for both **2** and **3** correspond to [(β-diketonate)$Cu_2(PMe_3)_2$]$^{+\cdot}$ with isotope distribution patterns characteristic of the presence of two copper atoms.

To unambiguously establish the degree of oligomerization in the solid state, a single crystal X-ray diffraction study of **2** was carried out.§ The molecular structure of **2** is shown in Fig. 1, together with relevant bond lengths and angles. These data show that **2** is monomeric in the solid state, with a trigonal planar copper(I) coordination environment.[9] The β-diketonate ligand is chelated to copper through oxygen ligands,[10] as expected, but distinction cannot be made between the Cu—O(1) and Cu—O(2) distances within the limits of error on the data. The Cu—P distance is slightly longer than the value we have recently observed in the structure of (η^5-C_5H_5)$CuPMe_3$.[7b] The O(1)—Cu—O(2) angle is small [91.9(2)°], as expected from the bite angle of

* Compounds **1–3** were prepared by a similar method. The preparation of **2** is described here. (η^5-C_5H_5)$CuPMe_3$ (3.40 g, 16.6 mmol) was placed in a 100 cm^3 Schlenk flask and 10 cm^3 of dry n-pentane were added. The suspension was cooled to 0°C and 4.04 cm^3 (33.2 mmol) of trifluoroacetylacetone (tfaH) were added while stirring. The (η^5-C_5H_5)$CuPMe_3$ started to dissolve to give a yellow solution. After stirring for 0.75 h, all the starting material had dissolved and the volatile components were removed *in vacuo* to give a yellow–green oily residue. The residue was sublimed at 35°C/10^{-2} torr to give 4.86 g of (tfa)$CuPMe_3$, a yield of 96.3%. This compound is soluble in n-pentane and can be crystallized from this solvent at −30°C. Compounds **1** and **3** were obtained in yields of 87.8 and 98.5%, respectively, from reactions conducted on a similar scale. Characterization data: m.p. (sealed tube, uncorrected): **1** = 27°C, **2** = 48°C, **3** = 67°C. ^{1}H NMR data (C_6D_6, 23°C, 250.13 MHz): **1**: 5.41 ppm, s, 1H; 1.98 ppm, s, 6H; 0.68 ppm, d, 6.7 Hz, 9H. **2**: 5.88 ppm, s, 1H; 1.83 ppm, s, 3H; 0.51 ppm, d, 7.4 Hz, 9H. **3**: 6.33 ppm, s, 1H; 0.38 ppm, d, 8.0 Hz, 9H. ^{31}P NMR data (C_6D_6, 23°C, 101.22 MHz): **1**: −44.1 ppm, s, br. **2**: −43.7 ppm, s, br. **3**: −42.7 ppm, s, br. Relevant bond lengths (Å): Cu—P = 2.133(2), Cu—O(2) = 1.982(4), Cu—O(1) = 1.990(4), C(1)—O(1) = 1.257(7), C(1)—C(2) = 1.362(9), C(2)—C(3) = 1.406(8), C(3)—O(2) = 1.249(7), C(1)—C(4) = 1.539(12), C(3)—C(5) = 1.496(8). Relevant bond angles (°): O(2)—Cu—O(1) = 91.9(2), P—Cu—O(1) = 132.4(1), P—Cu—O(2) = 135.6(1), Cu—O(2)—C(3) = 126.5(4), O(2)—C(3)—C(2) = 124.4(s), C(3)—C(2)—C(1) = 124.4(s), C(2)—C(1)—O(1) = 128.6(s), C(1)—O(1)—Cu = 123.1(4).

this chelating ligand, resulting in enlarged O(1)—Cu—P and O(2)—Cu—P angles. Other angles and distances within the ligands are unremarkable, and there is no evidence for intermolecular interactions.

The apparent discrepancy between the mass spectral data and the X-ray diffraction data probably results from the high volatility of these species. However, variation in the mass spectral parameters, such as reducing the ionization potential and decreasing the sample size, did not result in a significant reduction of the ions of higher mass than the monomeric molecular ion. Finally, we note that the solid state, solution phase and gas phase IR data for **2** are virtually identical, and it is likely that **2** is monomeric in the gas phase, although this remains to be established unambiguously.

In conclusion, some examples of a new family of copper(I) β-diketonate compounds have been prepared and characterized that are both volatile and soluble in hydrocarbon solvents. This family of compounds has the potential to be substituted either at the metal centre, or at the β-diketonate ligand to produce copper(I) species with a variety of physical properties.

Abstract—The title peroxotungstosulphate as the first example of a polytungstosulphate has been prepared and its structure determined. The salt crystallizes under the conditions: $[WO_4^{2-}] = 0.3$–1.0 mol dm^{-3}, $[WO_4^{2-}]/[SO_4^{2-}] = 1$–$1/4$, $[WO_4^{2-}]/[H_2O_2] = 1/2$–$1/4$ and pH < 1. The SO_4^{2-} tetrahedron shares its three vertices with two $WO_5(O_2)_2$ decahedra and one WO_6 octahedron to form a diperoxotritungstosulphate moiety; the polyanion is made of the two moieties bridged with three μ-oxo groups.

In the course of our investigations on peroxopolytungstates, the title compound was obtained from X^+–H^+–WO_4^{2-}–H_2O_2 systems, and its structure was determined by single crystal X-ray diffraction. As far as polyoxometallosulphates are concerned, three structures have been reported;[1–3] this is the first example of a structure being analysed for a polytungstosulphate.

EXPERIMENTAL

Preparation

To prepare the mother solution of this compound, two methods were available.

(1) To a solution of $Na_2WO_4 \cdot 2H_2O$ (5.0 g) in 17 cm^3 of H_2O, 3.0 cm^3 of H_2O_2 was added and the pH promptly adjusted to *ca* 0.5 with 60% nitric acid. Then tetramethylammonium hydrogensulphate (5.0 g) in 10 cm^3 of H_2O was added.

(2) WS_2 powder (5.0 g) was dissolved in 50 cm^3 of 30% H_2O_2 (Note: the reaction is very vigorous). After evaporating the solution to *ca* 12 cm^3, it was mixed with an equivolume aqueous solution of $N(CH_3)_4HSO_4$ (8.0 g).

In each case pale yellow, tabular crystals were obtained within a few days at room temperature. A single crystal for X-ray diffraction measurements was prepared by method (1).

This compound crystallizes in wide ranges of $[WO_4^{2-}]$, $[WO_4^{2-}]/[SO_4^{2-}]$ and $[WO_4^{2-}]/[H_2O_2]$ at pH < 1. Appropriate conditions are $[WO_4^{2-}] = 0.3$–1.0 mol dm^{-3}, $[WO_4^{2-}]/[SO_4^{2-}] = 1$–$1/4$ and $[WO_4^{2-}]/[H_2O_2] = 1/2$–$1/4$.

Intensity collection and structure determination

A single crystal with dimensions $0.22 \times 0.31 \times 0.45$ mm^3 was mounted on a RIGAKU AFC-5R automated four-circle diffractometer at the Department of Chemistry, Faculty of Science, The University of Tokyo, using graphite-monochromated Mo-K_α radiation (50 kV, 200 mA, $\lambda = 0.71069$ Å) at 25°C.

Crystallographic data: formula $C_{16}H_{50}N_4O_{31}S_2W_6$, FW = 1961.81, monoclinic, $C2/c$, $a = 20.87(1)$, $b = 10.611(2)$, $c = 20.077(8)$ Å, $\beta = 103.13(3)°$, $V = 4330$ Å^3, $D_m = 2.98$, $D_x = 3.01$ g cm^{-3} and $Z = 4$.

Calculations were carried out on HITAC M-680H/682H systems at the Computer Centre, The University of Tokyo, using UNICS III programs[4] including ORTEP.[5] Atomic scattering factors including real and imaginary dispersion corrections were cited from the *International Tables for X-Ray Crystallography*.[6] Positions of three independent tungsten atoms were determined from Patterson functions and the remaining non-hydrogen atoms were located by successive Fourier and difference Fourier syntheses. Tungsten, sulphur and oxygen atoms were refined anisotropically and nitrogen and carbon atoms isotropically using the block-diagonal least-squares method with the absorption correction based on psi-scans.

The final R value, 0.0655, was obtained for 3176 independent reflections with $4.0° \leqslant 2\theta \leqslant 55°$, $|F_o| > 5.5\sigma(F_o)$ and $|F_o| > 10.0$ from 5548 measured reflections.

STRUCTURE DESCRIPTION AND DISCUSSION

An ORTEP view of the polyanion together with the atomic numbering is shown in Fig. 1, and a polyhedra model in Fig. 2. Two $[H(SO_4)W_3O_8(O_2)_2]$ units related by a two-fold axis passing through O(12) are linked by three μ-oxo groups, and the anion has C_2 symmetry. The SO_4^{2-} groups behave as a tripod ligand sharing three oxygen atoms with respective independent tungsten atoms. Each of two peroxo groups in the asymmetric unit coordinates to W(2) and W(3); O(7)—O(8) to W(2) and O(9)—O(10) to W(3), respectively. Thus seven oxygen atoms ligate to these two tungsten atoms constructing decahedral (pentagonal bi-

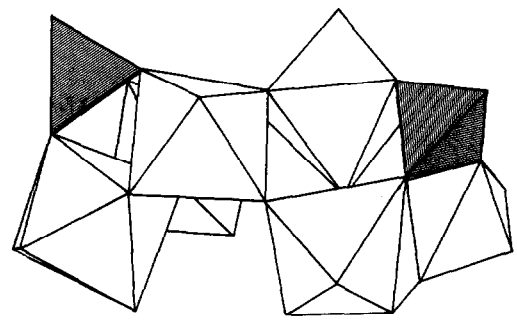

Fig. 2. The anion structure in the polyhedra model (the SO_4^{2-} groups are shaded).

pyramid) coordination spheres. W(1) has no O_2^{2-} ligand and shares two vertices of its octahedral (square bipyramid) sphere with the other half of the polyanion. A dihedral angle of *ca* 100° is found between W(1)—W(2)—W(3) and W(1')—W(2')—W(3') (the primed atoms are generated by rotation of original atoms about the two-fold axis through the polyanion) planes. Hence the shape of the polyanion looks like a twisted boomerang. The sulphate group is only slightly distorted from the regular tetrahedral structure. The tripod ligation of SO_4^{2-} makes each axis of the three tungsten polyhedra recline about 20°, and an apparently trigonal pyramid is formed with O(16) at the top and O(5)—O(6)—O(11) at the bottom. The result of bond valence calculations[7] shows that the acidity of O(2) is lower (1.46) than the other oxygen atoms, suggesting that this position is protonated.

In the IR spectrum, as shown in Fig. 3, the bands due to the S—O stretch mode (ν_1)[8] and the deformation mode (ν_2) are observed at *ca* 970 and 450 cm^{-1} with shoulders, respectively. Both mode types
