the calculated and experimental isobestic points are in harmony in the case of four complexes (Table 2), we postulate the presence of CuX^+, CuX_2, CuX_3^- and CuX_4^{2-} in propan-2-ol.

With the help of the overall stability constants already determined, we calculated the individual electronic spectra of all species present in the solution. This is represented in Figs 3 and 4 and the principal absorption bands are summarized in Table 3.

Both the tetracoordinated complexes have their *d–d* transitions at about 1100 nm, a position which is commonly admitted to be due to a flattened tetrahedron and assigned to D_{2d} symmetry.[13,14]

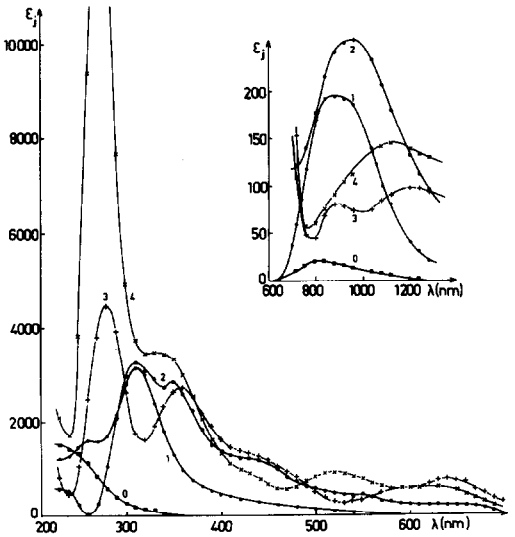

Fig. 4. Calculated electronic spectra of copper(II) bromocomplexes in anhydrous isopropanol solutions: $[Cu(^{i}PrOH)_4^{2+}$ [0]; $CuBr^+$ [1]; $CuBr_2$ [2]; $CuBr_3^-$ [3]; $CuBr_4^{2-}$ [4].

		620 sh
	1080 (135)	1120 (140)

The distribution curves of the copper(II) complexes are very similar in the chloride and bromide systems: the degree of formation of the chlorocomplexes confirms the superposition of equilibria for both systems: whatever the ligand concentration there is a simultaneous presence of at least two complexes.

For a comprehensive comparison in alcohols of stabilities and electronic spectra more than three

$CuBr_2$	5.6	7.8	8.4
$CuBr_3^-$	6.3	9.2	10.2
$CuBr_4^{2-}$	6.3	10.3	10.7

solvents are necessary, therefore a similar study in butanol is desirable and has already been undertaken in our laboratory. This may permit us to establish a few empirical laws in R-OH type solvents. Nevertheless, a tentative comparison of thermodynamic stabilities in the three alcohols, *viz* methanol, ethanol and propan-2-ol is given in Table 4.

A study of the relative stabilities of the chlorides and bromides in the three alcohols brings into prominence two major aspects: (1) in a given solvent the bromides are generally more stable than the chlorides; and (2) the stability of any specific complex increases from methanol to propanol, i.e. the stability of these complexes is directly proportional to the number of carbon atoms in the alcohol.

If this empirical rule is confirmed by the results of our study of these complexes in butanol it can be presumed that an approximate value of the stability constants of the copper(II) halogenocomplexes in the R-OH type solvents can be predicted theoretically.

Acknowledgement—We thank Arno Wedel, Graduate Student at the University of Bonn (Germany) for his contribution to the experimental part of this work performed in our laboratory and sponsored by the European Exchange Program of the I.A.E.S.T.E. and the Franco-German Youth Office.

TRIMETHYLSTANNANE DERIVATIVES OF COBALT(I); SYNTHESIS AND NMR SPECTROSCOPY. THE CRYSTAL STRUCTURES OF $[Co(Me_3Sn)(CO)_3L]$ ($L = PPh_3$, $AsPh_3$)

CHRISTA LOUBSER, JAN L. M. DILLEN and SIMON LOTZ*

Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

(*Received* 21 *January* 1991; *accepted* 22 *July* 1991)

Abstract—The Na/Hg reductive cleavage of the cobalt—cobalt bond in $Co_2(CO)_6L_2$ ($L = PPh_3$, $P(OPh)_3$, $AsPh_3$) and subsequent reaction with Me_3SnCl, afforded the five-coordinate complexes $Co(Me_3Sn)(CO)_3L$ ($L = PPh_3$, $P(OPh)_3$, $AsPh_3$). The intermediate sodium salts $Na[Co(CO)_3L]$ are unstable and were not isolated. The ^{31}P, ^{119}Sn, ^{13}C and ^{1}H NMR spectra were recorded and are discussed. Crystal structure analyses of $[Co(Me_3Sn)(CO)_3L]$ ($L = PPh_3$, $AsPh_3$) revealed, in both cases, a trigonal bipyramidal geometry with the trimethyl tin and the triphenyl phosphine/arsine in the two axial positions.

While preparing new Co^{I} compounds, we investigated the possibility of using complexes of the type $[Co(Me_3Sn)(CO)_3L]$ as useful starting materials. Compounds with Co—Sn bonds have been the subject of much interest,[1] particularly with respect to the nature of the metal—metal bond.

In $[Co(Me_3Sn)(CO)_3L]$, R and L were usually limited to triphenyl phosphine,[2,3] mainly because of the ease with which the $[Co(R_3Sn)(CO)_3PPh_3]^-$ anion is generated and handled. We found that the analogous triphenyl phosphite and triphenyl arsine anions could be prepared similarly, i.e. by cleaving the respective dimer $[Co(CO)_3L]_2$ ($L = P(OPh)_3$, $AsPh_3$), followed by stabilization with Me_3SnCl.

Here, a facile synthetic method for the preparation of $Co(Me_3Sn)(CO)_3L$ [$L = PPh_3$ (**1**), $P(OPh)_3$ (**2**), $AsPh_3$ (**3**)] in good yield and high purity is outlined, and the X-ray crystal structures of **1** and **3** discussed.

EXPERIMENTAL

Synthesis

Compounds **1**, **2** and **3** were prepared by cleaving the respective dimer $[Co(CO)_3L]_2$ [$L = PPh_3$, $P(OPh)_3$, $AsPh_3$] with a sodium amalgam according to eq. (1),

$$[Co(CO)_3L]_2 \xrightarrow[THF]{Na/Hg} 2Na[Co(CO)_3L], \quad (1)$$

whereupon the anions were treated with Me_3SnCl to form the desired products:

$$Na[Co(CO)_3L] + Me_3SnCl \longrightarrow Co(Me_3Sn)(CO)_3L. \quad (2)$$

Products were confirmed with the aid of elemental analyses and IR spectra, the results of which, together with the detailed synthetic procedures, are to be published elsewhere.[4]

NMR spectroscopy

NMR spectra were recorded on a Bruker AC300 instrument at 30°C. Deuterated solvents were degassed before use and samples prepared under N_2. Spectra were obtained at 300 (^{1}H), 75.5 (^{13}C), 121.5 (^{31}P) and 111.9 (^{119}Sn) MHz, respectively.

Crystal data: collection and analysis

$C_{24}H_{24}CoO_3PSn$ (**1**), $M = 568.96$, $a = 9.849(3)$, $b = 9.955(3)$, $c = 13.610(4)$ Å, $\alpha = 98.64(2)$, $\beta = 107.43(3)$, $\gamma = 95.620(3)°$, $U = 1244.2$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.52$ g cm^{-3}. Colourless paralleleopipeds, $\mu(Mo\text{-}K_\alpha) = 17.6$ cm^{-1}, $F(000) = 566$.

$C_{24}H_{24}CoO_3AsSn$ (**3**), $M = 612.91$, $a = 9.840(2)$, $b = 10.025(3)$, $c = 13.758(1)$ Å, $\alpha = 99.606(2)$,

* Author to whom correspondence should be addressed.

$\beta = 107.814(1)$, $\gamma = 94.8(2)°$, $U = 1260.8$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.62$ g cm^{-3}. Colourless pyramids, μ(Mo-K_α) = 28.3 cm^{-1}, $F(000) = 604$.

Diffraction data were collected at ambient temperature with an Enraf–Nonius CAD4 diffractometer using graphite monochromated Mo-K_α radiation. Unit cell dimensions were obtained from a least squares fit of 25 centred reflections. Data were measured using a variable scan speed, with a maximum of 3.30° min^{-1} (5.49 in the case of **3**) and a minimum corresponding to a 60 s measuring time per reflection. A $\omega:2\theta$-scan was employed. The horizontal aperture was fixed at 1.3 mm and the vertical slit at 4 mm. The ω-scan angle changed as $0.51 + 0.34 \tan\theta(°)$ ($0.42 + 0.34 \tan\theta$ for **3**). Intensity checks were carried out every hour and orientation control every 200 reflections. Data were corrected for Lorentz and polarization effects, and for absorption using an empirical method involving ψ-scans.

The crystal structure was solved by Patterson and subsequent Fourier methods and refined anisotropically with a full matrix method using $1/\sigma^2(F)$ weights. Hydrogen atoms were placed on calculated positions ($r_{CH} = 1.08$ Å, $\angle$**HCH** = 109.5°) and refined riding on their associated carbon atom with a common isotropic temperature factor $U = 0.11(1)$ Å^2 ($U = 0.121(4)$ Å^2 for **3**). Final residuals were $R = 0.084$ and $R_W = 0.051$ for 3028 reflections and 281 variables ($R = 0.042$ and $R_W = 0.026$ for 5046 reflections and 281 variables in the case of **3**). Computations were carried out using the SHELXTL program system.[5] The maximum residual electron densities in the final ΔF maps were 1.5 and 0.47 eÅ^{-3}.

RESULTS AND DISCUSSION

Synthesis

Although cleavage of $[Co(CO)_3PPh_3]_2$ was only accomplished after 16 h, $[Co(CO)_3L]_2$ [L = $P(OPh)_3$, $AsPh_3$] only required 20 min to be cleaved completely. This difference is merely thought to be a consequence of the low solubility of $[Co(CO)_3PPh_3]_2$.

Interestingly, although the triphenyltin analogues of **1** and **2** [i.e. $Co(Ph_3Sn)(CO)_3L$, L = PPh_3, $P(OPh)_3$] were previously prepared,[2,6] no triphenyl arsine analogue existed. In fact, a search of the literature did not reveal any compounds of the type $[Co(R_3M)(CO)_3AsR'_3]$ (R = Me, Ph; M = Si, Ge, Sn; R′ = Me, Ph).

A literature search revealed that, contrary to our results, Hieber and Lindner[7] had reported that their attempts to cleave the dimer $[Co(CO)_3AsPh_3]_2$ merely led to decomposition and the recovery of $AsPh_3$ amongst other products. We found that the successful preparation of the unstable salt Na[Co $(CO)_3AsPh_3$] crucially depended on the rigorous exclusion of air and moisture, its swift manipulation, and finally the rapid addition of Me_3SnCl.

NMR spectroscopy

^{1}H NMR data for **1**, **2** and **3** appear in Table 1, while ^{13}C, ^{31}P and ^{119}Sn NMR data are shown in Table 2. ^{1}H and ^{13}C NMR resonances could be assigned unambiguously by way of inspection. The methyl protons of **1**, **2** and **3** are observed as sharp singlets, with that of the triphenylphosphite deriva-

tive occurring 0.3 ppm downfield from those of **1** and **3**.

The slight upfield shift of the methyl carbons relative to the carbons of Me_3SnCl [$\delta(^{13}C) = 5.4$ ppm] on the ^{13}C spectrum, is indicative of the absence of a major movement of electron density across the Co—Sn bond. This supports the suggestion that this bond is of a covalent and not a donor/acceptor nature.[8] Observed $^1J(SnC)$ coupling constants fall in the range 265–280 Hz (average values are given as resolution does not always permit distinction between ^{117}Sn and ^{119}Sn). Earlier NMR studies unfortunately often lack coupling constant details,[9,10] but more recently values ranging from 280 to 320 Hz were reported for $[Co(Ph_3Sn)(CO)_3L]$ (L = carbene).[11,12] The carbonyl carbons in **1**, **2** and **3** occur in the vicinity of 200 ppm (Table 2) and were difficult to detect, presumably due to broadening caused by ^{59}Co.

The $^{31}P\{^1H\}$ spectra of **1** and **2** each consist of a singlet with $\Delta\nu_{\frac{1}{2}} = 50$ Hz (**1**) and 160 Hz (**2**). The spectrum of **1** (Fig. 1) displays the $^{117}Sn/^{119}Sn$-satellites as broad shoulders on either side of the ^{31}P resonance. An accurate value for $^2J(PSn)$ was however, obtained from the well resolved doublet on the $^{119}Sn\{^1H\}$ spectrum.

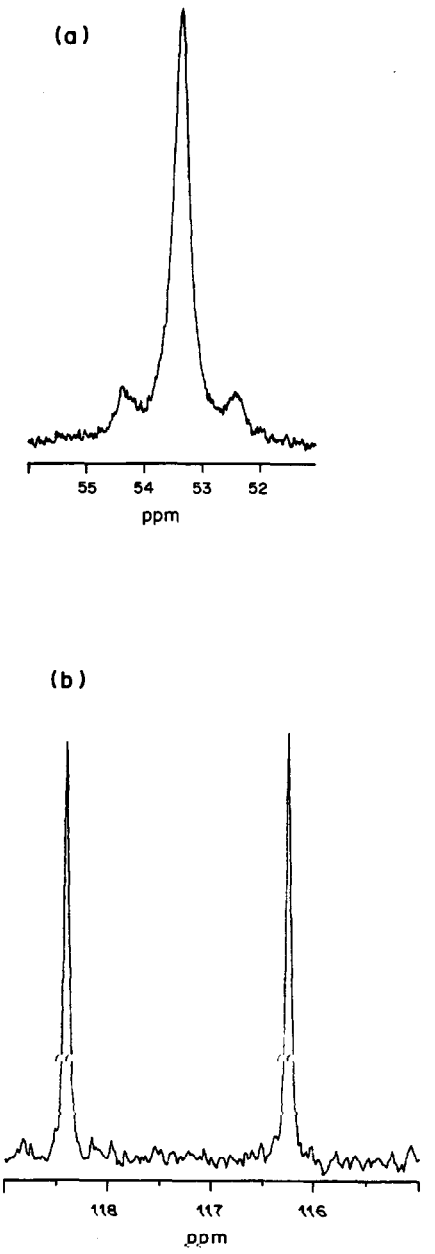

Fig. 1. (a) $^{31}P\{^1H\}$ NMR spectrum of **1** showing the Sn-satellites; (b) $^{119}Sn\{^1H\}$ NMR spectrum of **1** as a result of coupling with ^{31}P.

^{119}Sn spectra were well-resolved. The Sn nucleus seemingly uninfluenced by the neighbouring ^{59}Co nucleus. The sensitivity of the Sn nucleus towards the group occupying the *trans* position (L), is obvious from the decrease in ^{119}Sn chemical shift as electron density is moved away from L and the metal centre towards the three carbonyl groups (for the unsubstituted $Co(Me_3Sn)(CO)_3L$ (L = CO), $\delta(^{119}Sn) = 151$ ppm). The ^{119}Sn chemical shift therefore is a useful measure of the nucleophilicity of the $[Co(CO)_3L]^-$ anion.

Table 3. $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ and $^{119}Sn\{^1H\}$ NMR data[a] for **1**, **2** and **3**

[f] Coupling constants obtained from $^{119}Sn\{^1H\}$ spectra.

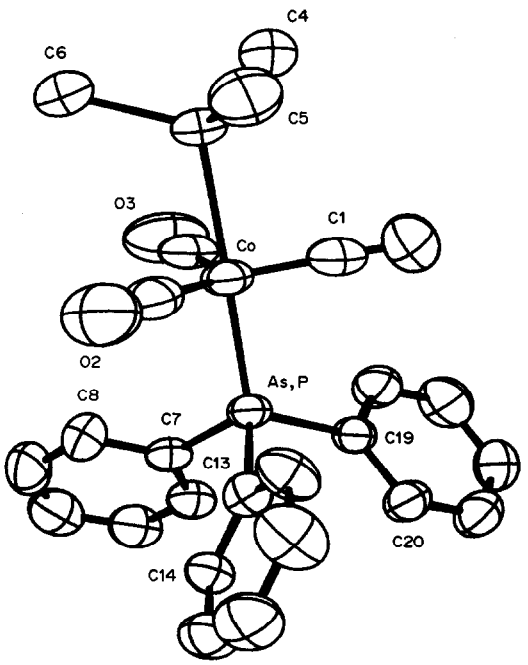

Fig. 2. The X-ray structure of **1** and **3**, showing the numbering of the atoms.

Structural determinations

The X-ray structures of **1** and **3** are shown in Fig. 2, with selected bond lengths and angles in Table 3. In both cases the Co atom forms the centre of a near-perfect trigonal bipyramid with the three carbonyl groups occupying the three equatorial sites. The three phenyl rings and the three methyl groups are eclipsed and are staggered with respect to the three CO groups. The Co atom and the three CO groups are not coplanar; the Co lies at a distance of 0.146(2) Å (**1**) and 0.162(1) Å (**3**), respectively, below the plane. This observed "bending" of the carbonyl ligands towards the $SnMe_3$ moiety has been observed for various compounds containing a transition metal–tin bond—the degree of bending is commonly thought to increase with decreasing bulkiness of the groups on Sn.[8]

In support of the covalent nature of the Co—Sn bond, the Co—Sn distance has been found to decrease on replacement of the organic substituents on Sn by halogens or oxygen.[8] Expectedly therefore, the length of this bond remains uninfluenced by the *trans* ligand, and a Co—Sn bond length of 2.574(2) Å and 2.565(1) Å was respectively measured for **1** and **3**. These values fall well within the limits obtained from a statistical calculation using the CSDS[14] which reveals a mean Co—Sn bond length of 2.58(5) Å for 34 different bonds. A comparison with the structure of the analogous $Co(Ph_3Sn)(CO)_3PPh_3$[15] will also become possible once a more detailed structural analysis is completed.

CONCLUSION

The stability of the compounds $[Co(X)(CO)_3L]$ decreases in the order $X = Ph_3Sn > Me_3Sn$ and $L = PPh_3 > AsPh_3 > P(OPh)_3$. The greater reactivity of the less bulky trimethyltin derivatives (as a result of the weaker (Co—Sn bond) could provide an entry into the synthesis of new compounds with carbonyls in the equatorial plane which, for the purpose of modification, are more accessible.

SPECTROSCOPIC AND MAGNETIC PROPERTIES OF HIGH SPIN CHROMIUM(II) AND COPPER(II) COMPLEXES WITH BIDENTATE α,α′-DIIMINE LIGANDS: 2,2′-PYRIDYLBENZIMIDAZOLE; 2,2′-PYRIDYLIMIDAZOLE AND 2,2′-PYRIDYLIMIDAZOLINE

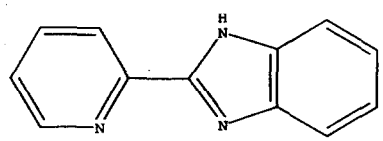
(*Received* 22 *February* 1991; *accepted* 11 *July* 1991)

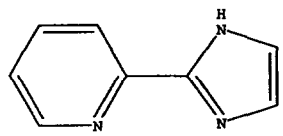
Abstract—Synthesis and physical properties of chromium(II) and copper(II) complexes of general formula $[M(L\text{-}L')Cl_2]$ are reported, where L-L′ is one of the bidentate α,α′-diimine ligands: 2,2′-pyridylbenzimidazole; 2,2′-pyridylimidazole; 2,2′-pyridylimidazoline. The chromium(II) complexes are high spin and spectroscopic data suggest a polymeric hexacoordinate distorted chloride bridged structure; the IR active bands in the region 350–250 cm^{-1} have been assigned to Cr—N and Cr—Cl stretching vibrations. The spectroscopic, EPR and magnetic data for the copper(II) compounds suggest that they are structurally similar to the chromium(II) compounds.

The complexes formed by α,α′-diimine ligands, such as 2,2′-bipyridine (bipy), 1,10-phenanthroline (phen) and related ligands with bivalent transition metals ions have been extensively investigated and several examples of mono-, bis- and tris-diimine complexes have been thoroughly characterized.[1] For chromium(II), most of the known complexes with these ligands have two or three diimines bound to the metal,[2,3] and the few examples of mono-diimine compounds occur with halides or pseudo-halides and possess polymeric hexacoordinate distorted coordination geometries.[3,4]

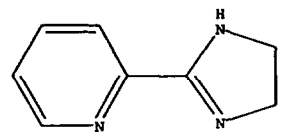
As part of a more general investigation on the coordination chemistry of chromium(II)[5] we report the synthesis and characterizaton of chromium(II) complexes of the type $[Cr(L\text{-}L')Cl_2]$, where L-L′ is one of the following bidentate α,α′-diimine ligands: 2,2′-pyridylbenzimidazole (pyb); 2,2′-pyridylimidazole (pyi) and 2,2′-pyridylimidazoline (pyim).



pyb



pyi



pyim

It is also generally observed that most high-spin chromium(II) complexes are structurally similar to the analogous copper(II) compounds as revealed by X-ray powder diffraction data,[6–8] an observation that has been attributed to the occurrence of Jahn–Teller distortions for both metal ions. This fact prompted us to prepare copper(II) complexes with the same ligands and stoichiometry, $[Cu(L\text{-}L')Cl_2]$, that are more amenable to be studied than the extremely air-sensitive chromium(II) compounds,

and to obtain indirect indications on the coordination geometry of the chromium complexes.

EXPERIMENTAL

Materials

Metallic chromium (electrolytic grade) was from Fluka Balzers and copper chloride dihydrate from Merck; all other reagents were from Aldrich and used without further purification, except for ethylenediamine (Merck) that was freshly distilled prior to use. The solvents (Merck; *pro analysi*) were dried over molecular sieves (Merck) and thoroughly degassed before use.

Preparation of compounds

(a) *Ligands.* The ligands 2,2′-pyridylbenzimidazole (pyb), 2,2′-pyridylimidazole (pyi) and 2,2′-pyridylimidazoline (pyim) were prepared and purified by literature methods.[9,10] The ligands were characterized by their ^{1}H NMR spectra and melting points. (Observed and literature values for the melting points—for pyi: 133–135 and 134–135°C;[9] for pyb: 218–220 and 216–219°C;[10] and for pyim: 95–97 and 96–98°C.[10])

(b) *Dichloro(α′-diimine)chromium* (II) *complexes.* All manipulations involving chromium(II) compounds were carried out under dry nitrogen using standard Schlenk techniques. Hydrated chromium(II) chloride was prepared by dissolving chromium metal in dilute hydrochloric acid.[11] All complexes were prepared by treating hot ethanolic solutions of $CrCl_2$ with ethanolic solutions of the ligands in a stoichiometric amount. For the complex $[Cr(pyi)Cl_2]$, 1.2 g of $CrCl_2 \cdot H_2O$ in 20 cm^3 of hot ethanol were reacted with a solution of 1.0 g of pyi in 20 cm^3 of hot ethanol and the resulting solution was then cooled in an ice bath. The microcrystalline solids that formed immediately were collected by filtration, washed with cold diethyl ether and dried by continuous pumping for several hours. Yields of purified complexes ranged from 50 to 70%. These brown compounds are air- and moisture-sensitive, and change colour to green in a few hours when exposed to air, but are stable for several weeks when kept in sealed tubes under dry nitrogen.

(c) *Dichloro(α′-diimine)copper*(II) *complexes.* These complexes were prepared similarly by treating hot solutions of $CuCl_2 \cdot 2H_2O$ (1 g) in ethanol (20 cm^3) with ethanolic solutions of the ligands in a stoichiometric amount. The resulting bright green complexes, collected and dried as described above for the chromium(II) compounds with a yield of 70–90%, are moisture sensitive.

Physical measurements

Analysis. Elemental analysis (C, H, N) were performed at the Microanalytical Laboratory, University of Manchester. Copper and chromium were determined by adding an excess of EDTA (Merck; Titrisol) and back titrating the excess of EDTA with standard calcium solutions (Merck; Titrisol) using a Ca^{2+} selective electrode. Chloride was titrated potentiometrically with silver nitrate using a Cl^- selective electrode. The analytical data are summarized in Table 1.

Visible–IR spectra. Visible and NIR spectra (solution and Nujol mulls) of the copper(II) and chromium(II) complexes were recorded at room temperature on a Cary 17 DX spectrophotometer.

IR spectra. IR spectra were recorded in a Philiphs PU-1800 FTIR spectrophotometer. In the region from 4000 to 300 cm^{-1} the spectra were obtained using KBr pellets or Nujol mulls between KBr plates. For the region 600–200 cm^{-1} CsI pellets of Nujol mulls between polyethylene plates were used.

Conductivity measurements. Conductivity measurements for solutions of the Cu^{II} complexes were carried out with a Metrohm E-518 conductivity meter at 25°C for 10^{-3} M solutions in dimethylformamide (dmf) and methanol (MeOH).

Magnetic measurements. Magnetic susceptibility measurements on powdered solids in sealed tubes were carried out by the Gouy method, from room to liquid nitrogen temperature. The apparatus, calibrated with $Hg[Co(NCS)_4]$, was supplied by Newport Instruments. The magnetic moments were corrected for diamagnetism by using Pascal's constants and for temperature independent paramagnetism, TIP = 0.75 mm^3 mol^{-1} for copper(II).[12]

EPR spectra. EPR spectra were obtained with an X-band Varian E109 spectrometer (9 GHz) equipped with a variable-temperature accessory. The spectra were calibrated with diphenylpicrylhydrazyl (dpph; $g = 2.0037$); the magnetic field was calibrated by use of Mn^{2+} in MgO. The spectra were recorded at −140°C using sealed quartz tubes.

RESULTS AND DISCUSSION

The chromium compounds are soluble or partially soluble in the majority of coordinating solvents (water, dimethyl sulphoxide, *N*,*N*′-dimethylformamide, methanol) but their solutions are dark green, except in dmf where the solutions remain brown. The copper complexes are not soluble in most solvents, being partially soluble in methanol, dmf, $(CH_3)_2SO$ and water.

[c] Calculated values are given in parentheses.

Compounds of $[Cr(L\text{-}L)Cl_2]$

Magnetic data. The observed room temperature magnetic moments are somewhat below the spin-only values expected for systems with four unpaired electrons ($\mu \approx 4.83$ BM) and their values for $[Cr(pyi)Cl_2]$ and $[Cr(pyim)Cl_2]$ decrease with decreasing temperature. The Curie–Weiss law is obeyed for all complexes down to 97 K, although for $[Cr(pyb)Cl_2]$ the value of $\theta \cong 0$ (Table 1).

The magnetic moments for monomeric, tetrahedral high-spin chromium complexes are assumed to be greater than the spin only value and to show a marked temperature dependence,[13] as expected from a T_2 ground state. Our data do not fit this pattern, as the room temperature magnetic moments are smaller than the spin-only value and thus rule out tetrahedral coordination for the chromium complexes reported in this work.

The observed magnetic behaviour is similar to those found in other high-spin chromium(II) complexes of general formula $[Cr(L\text{-}L')X_2]$, where L-L′ is a bidentate ligand and X a halide,[3,4,14] for which a polymeric species with a hexacoordinate sphere around the chromium was asserted. Assuming that a similar structure applies to our complexes, the magnetic moment dependence with temperature can be attributed to antiferromagnetic interaction between chromium atoms. A superexchange mechanism involving chlorine bridges between the metal ions can account for partial spin coupling and is consistent with the proposed polymeric structure. Although for $[Cr(pyb)Cl_2]$ the value of $\theta \cong 0$, a polymeric structure is also assumed, due to the similarity of the spectroscopic data with those of the other two chromium(II) complexes (*vide infra*).

Electronic spectra. The band maxima are presented in Table 2; the electronic spectra of the complexes in Nujol (Fig. 1A) show two bands in the region 450–600 nm (22,200–16,700 cm^{-1}) and a weaker one at ≈750 nm (13,300 cm^{-1}). This behaviour is typical of distorted high-spin six-coordinate chromium(II) complexes,[3,4,6,8,14,15] where the low energy (distortion) band is associated with transitions between the components of the ^5E ground state ($^5B_1 \rightarrow {}^5A_1$), and the higher energy (main) bands is assigned to superimposed $^5B_1 \rightarrow (^5B_2, {}^5E)$ transitions. The main bands, although affected by stereochemical distortions of the complex, are mainly determined by the ligand field strength, and their values are similar to those of polymeric hexacoordinate species with monoamine bidentate ligands and chloride.[3,4]

The complexes prepared, dissolve readily in water, methanol and other hydroxylic solvents, but the resulting solutions are dark green. The electronic spectra of the complexes in these solutions (Fig. 1B) show new high intensity bands in the region from 1250 to 400 nm (25,000–8000 cm^{-1}). These spectra show identical bands to those observed in Nujol mulls and in solution for the low-spin complexes $[Cr(L\text{-}L')_3]Cl_2$, with the same ligands (L-L′) used in our study.[5] This observation implies the existence of low-spin complexes in

[a] The molar extinction coefficients for the solution spectra are not reported as the high reactivity of these species prevents their determination.

[b] These absorption bands were obtained by spectral deconvolution.

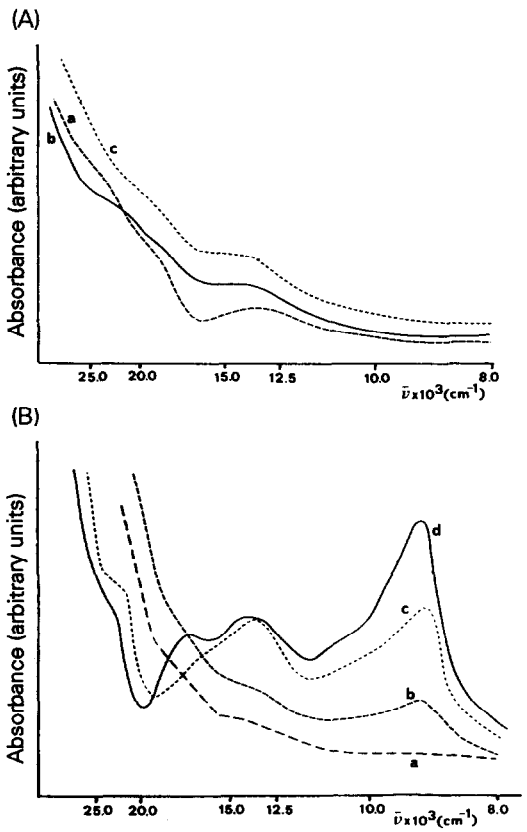

Fig. 1. Electronic specta of $Cr(L\text{-}L')Cl_2$ complexes. (A) Nujol spectra: (a) $Cr(pyi)Cl_2$; (b) $Cr(pyim)Cl_2$; (c) $Cr(pyb)Cl_2$. (B) Solution spectra of $Cr(pyi)Cl_2$ in: (a) dmf; (b) $(CH_3)_2SO$; (c) H_2O and (d) MeOH. The molar extinction coefficients are not reported as the high reactivity of the chromium(II) species prevents their determination.

hydroxylic solvents and provides spectral evidence for the disproportion of monoamine complexes in solution.

$$3/n[Cr(L\text{-}L')Cl_2]_n \rightleftharpoons [Cr(L\text{-}L')_3]Cl_2 + [CrCl_2].$$

The dissolution of these complexes in hydroxylic solvents breaks the halogen bridges and the polymeric structure is destroyed. Similar behaviour has been observed for the analogous complexes with *o*-phenanthroline, where no bands from $CrCl_2$ are observed in the spectra, since the absorption coefficients of $CrCl_2$ are negligible relative to that of the low spin complex.

The observation that solution spectra in $(CH_3)_2SO$ keep some of the features of the Nujol spectra but also exhibit new intense bands, suggests the existence in solution of some of the original species, thus implying only a partial breakdown of the solid structure. Also, as the spectra in dimethylformamide are similar to that obtained in Nujol, it is also conceivable that the solid structure must be retained to a large extent in solution.

IR spectra. Information on metal–ligand stretching vibrations for high-spin chromium(II) complexes is very scarce[16–19] and no data for complexes with bidentate α,α'-diimines and halogens were found in the literature. Larkworthy *et al.* reported IR data for several high-spin chromium(II) chlorocomplexes with pyridine derivatives and assigned the strong band at $\approx$320–330 cm^{-1} to the stretching vibration Cr—Cl, and the less intense band at 270–290 cm^{-1} to the stretching

vibration Cr—N. In these complexes the halogens are bridging the chromium atoms and one ν(Cr—N) vibration and two IR active ν(Cr—Cl) vibrations are expected for these polymeric compounds. The other ν(Cr—Cl) band was assumed to occur at *ca* 160 cm^{-1}, but in the spectra[17] of $[Cr(4\text{-mepy})_2X_2]$, a band at 280 cm^{-1} observed for the chloro-complex was shifted to 251 cm^{-1} when the chlorine was replaced by bromine. It is conceivable that this latter band is also ν(Cr—Cl). For octahedral monomeric complexes with the same ligands (L) and axial terminal halogen atoms $[CrL_4X_2]$, the stretching vibrations Cr—Cl are observed at a much lower frequency ($\approx$150 cm^{-1}), but the stretching Cr—N showed little or no variation. This result is observed for metal ions with Jahn–Teller effect, where long axial bond lengths are expected, thus shifting ν(Cr—Cl) to lower frequencies.[20–22]

To assign the IR spectra of our complexes, the spectra were compared with those of analogous compounds with bromide.[23] The observed stretching frequencies for the chloro and bromo complexes in the region 400–200 cm^{-1} are listed in Table 3, and typical IR spectra are shown in Fig. 2A.

For $[Cr(pyb)Cl_2]$ and $[Cr(pyi)Cl_2]$ the spectra show one strong anion dependent band at $\approx$330 cm^{-1}, that is shifted by *ca* 50 and 30 cm^{-1}, respectively, when the halogen is replaced by bromide (Table 3). Halogen replacement also shifts the band at 305 cm^{-1} of $[Cr(pyb)Cl_2]$ to 249 cm^{-1}; and for $[Cr(pyi)Cl_2]$ the band at 295 cm^{-1} is shifted to 260 cm^{-1}, thus allowing an unambiguous assignment of these two bands to ν(Cr—Cl). The bands at 322 and 305 cm^{-1} for $[Cr(pyb)Cl_2]$ and for $[Cr(pyi)Cl_2]$, respectively, are anion independent and are assigned to ν(Cr—N).

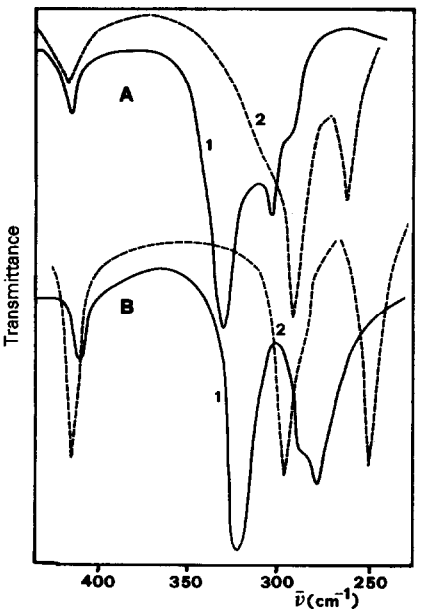

Fig. 2. IR spectra of $M(pyi)X_2$ complexes. (A) (1) $Cr(pyi)Cl_2$; (2) $Cr(pyi)Br_2$. (B) (1) $Cu(pyi)Cl_2$; (2) $Cu(pyi)Br_2$.

As the complex $[Cr(pyim)Br_2]$ could not be prepared, ν(Cr—X) was not assigned by halogen substitution, but as ν(Cr—N) are not strongly ligand dependent, the bands at 336 cm^{-1} and at 305 cm^{-1} are assigned to ν(Cr—Cl), and the one at 278 cm^{-1} is then assigned to ν(Cr—N).

The similarity of high energy band ν(Cr—Cl) in our complexes with those of other chromium(II)[17] complexes with polymeric structure also provides evidence for the postulated structure of our complexes, where asymmetric halogen bridges take place with two short and two long bonds.

[a] From ref. 33.

[b] The complex could not be prepared.

Compounds of $[Cu(L\text{-}L')Cl_2]$

Contrasting with chromium complexes, the known stereochemistries for copper complexes of general formula $[Cu(L\text{-}L')X_2]$ or $[CuL_2X_2]$ are much more diverse, and the choice of the correct one can hardly be accomplished without X-ray data from single crystals.[1,24] However, combination of spectroscopic and magnetic data, allows for some insight into the stereochemistry of the copper complexes studied.

EPR data. Powdered samples of the pure complexes exhibit at low temperature, EPR spectra that are all different (Fig. 3A and Table 4). For $[Cu(pyi)Cl_2]$ the spectrum is of the rhombic type with three g values; for $[Cu(pyb)Cl_2]$ only two g values are obtained (axial type); and for $[Cu(pyim)Cl_2]$ a pseudo-isotropic spectrum is obtained. No hyperfine splitting with copper or with the ligand nuclei (^{14}N or $^{35,37}Cl$) are observed, probably due to dipole–dipole or exchange interaction. As no signal at half field ($\Delta M_s = \pm 2$) is observed for any spectra, the existence of dimeric structures bridged either by the α,α′-diimine ligand or by the halogen, can be ruled out. However several structures are still possible, monomeric (pseudo-tetrahedral) and polymeric; the latter situation may include doubly halogen-bridged hexacoordinate structure, and singly halogen-bridged five-coordinate complexes. Polycrystalline EPR data do not allow for a clear-cut distinction between monomeric (pseudo-tetrahedral) and polymeric geometries.

Better resolution was achieved in copper-doped (α,α-diimine) cadmium dichloride compounds, for which axial type EPR spectra with coupling to copper in the low field region ($I = 3/2$; four bands) are observed (Fig. 3B). For $[Cu(pyb)Cl_2]$ a hyperfine structure is also observed in the high field region. The structures of these (α,α′-diimine) cadmium dichlorides are not known, but those of [Cd(mpyb)Cl_2], where mpyb is 2-(4′-methyl-2′-pyridyl)benzimidazole, and of other compounds of general formula $[Cd(L\text{-}L')Cl_2]$ with bidentate diimine ligands, are polymeric distorted hexacoordinate with bridging halogens.[25] This coordination geometry must be imposed on the dopant copper complexes and the values of $G = (g_\parallel - 2)/(g_\perp - 2) = 4$ are indicative of a $d_{x^2-y^2}$ ground state for these pseudo-octahedral complexes.[26] For the doped complexes, the g values are invariant within experimental error, suggesting similar electronic properties. However there is a difference between the $A_\parallel$ values of the $[Cu(pyb)Cl_2]$ and the other two complexes; this may be interpreted as resulting from stronger stereochemical distortions imposed for the complex with the bulkier ligand. Indeed, $g_\parallel$ and

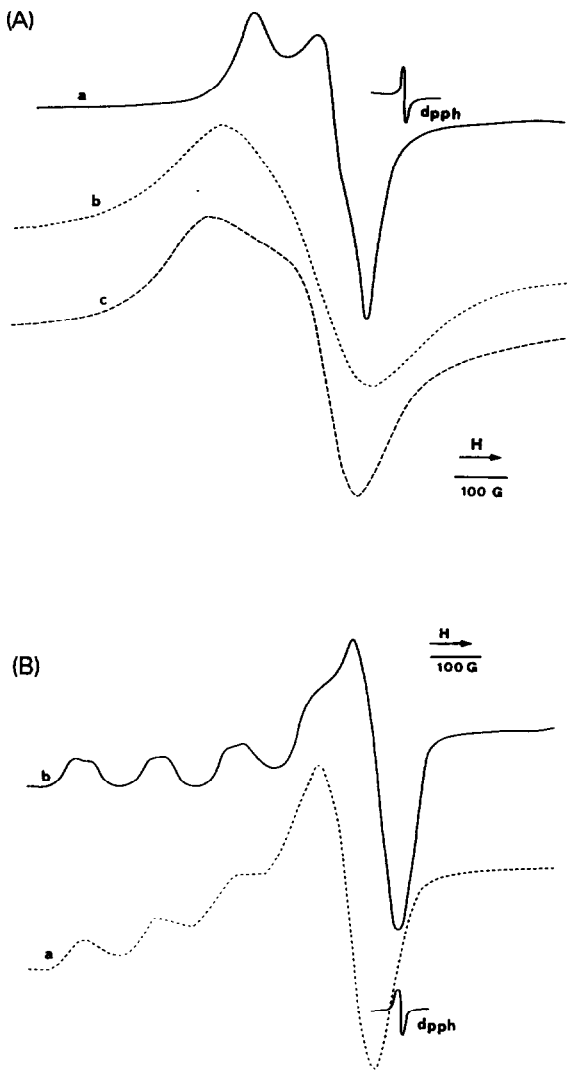

Fig. 3. EPR spectra of $Cu(L\text{-}L')Cl_2$ complexes. (A) Powder spectra: (a) $Cu(pyi)Cl_2$; (b) $Cu(pyim)Cl_2$; (c) $Cu(pyb)Cl_2$. (B) (a) Cu/doped $Cd(pyi)Cl_2$; (b) $Cu(pyi)Cl_2$ in dmf.

$A_\parallel$ values seem relatively insensitive to strong axial perturbations, but rather sensitive to in-plane distortions for hexacoordinate species.[1]

Frozen solution EPR spectra of the pure complexes in dmf (Fig. 3B) and methanol show two sets of bands that must be due to the existence of at least two different species in solution, indicating the compounds to have undergone some structural changes when in the solvents (see below electronic spectra and conductivity data). All spectra show coupling to copper in the low field region and to the nitrogen atoms in the high field region.

IR spectra. To assign the IR spectra of our complexes, the analogous bromo complexes were also prepared. The observed stretching frequencies for the chloro and bromo complexes in the region

[a] In methanol and in the doped cadmium complex, $g_\parallel$ is $g_\parallel$ and g_2 is $g_\perp$, except for $Cu(pyim)Cl_2$ whose powder spectrum is pseudo-isotropic.

[b] Calculated as $G = (g_\parallel - 2)/(g_\perp - 2)$.[25]

[c] Cu/Cd refer to EPR data for copper doped (α,α'-diimine) cadmium dichloride compounds.

[d] EPR data show that there are more than one complex in solution, see Fig. 3B.

400–200 cm^{-1} are listed in Table 3, and typical IR spectra are shown in Fig. 2B.

For $[Cu(pyb)X_2]$ and $[Cu(pyim)X_2]$ three bands are observed for both halo complexes. One of them (at 322 and 258, respectively for the pyb and pyim complexes) is invariant with halogen substitution and is attributable to ν(Cu—N). The other two are anion dependent and have been assigned to ν(Cu—X). The complexes $[Cu(pyi)X_2]$ show also two well-resolved bands that are anion dependent and assigned to ν(Cu—X), and partially superimposed on these bands the anion independent on assigned to ν(Cu—N) can also be observed. Absorptions assignable to ν(Cu—N) fall in the region 320–250 cm^{-1}, typical of copper(II) complexes with aromatic nitrogen ligands, and increase with the aromatic character of the diimine ligand.

The ν(Cu—Cl) bands lie in the frequency range indicative of terminally bound chlorides in pseudo-tetrahedral compounds (320–280 cm^{-1}),[27] although for polymeric hexacoordinate copper complexes with two nitrogen donor atoms the values observed for bridging chlorides lie in the same region, well above the expected values for bridging chlorides in other late first transition divalent metal complexes, that appear below 250 cm^{-1}. This anomalous behaviour has been attributed to asymmetric M—X—M bonds caused by the Jahn–Teller effect in d^9 systems, and as copper–halogen stretching frequencies are highly dependent on bond lengths, values ranging from 400 to 240 cm^{-1} have been observed for distorted polymeric hexacoordinate compounds.[22]

The spectra of $[Cu(bipy)X_2]$ and of $[Cu(phen)X_2]$, whose structure is known to be polymeric hexacoordinate, show three sets of strong or medium intensity bands in the region 320–220 cm^{-1} that have been assigned to ν(Cu—N) and to ν(Cu—X) (two bands).[28] The similarity of our ligands to bipy and phen, and of the IR spectra of our copper complexes with those of bipy and phen, lend some support to propose a polymeric distorted hexacoordinate structure for the complexes reported. Nevertheless, a polymeric tetragonally distorted five-coordinate structure could not be excluded for all the complexes, as two different types of Cu—Cl bonds (one short and one long) are also expected for this geometry.[29]

Magnetic data. The Curie–Weiss law is obeyed in the temperature range studied for all compounds with very small and positive Weiss constants, with room temperature magnetic moments (Table 1) lying in the range 1.8–1.9 BM, higher than the spin-only value.[13] Both results provide no evidence for significant magnetic interaction between copper atoms, in the temperature range used, despite the postulated polymeric (hexacoordinate) structure. The g values calculated from the magnetic data show reasonable agreement with those of g_{av} obtained by EPR.

Electronic spectra. The visible/NIR spectra in Nujol (Table 5) show the usual *d–d* type unsymmetrical band, with maxima at *ca* 12,500–14,500 cm^{-1} tailing into the near IR,[14] and with energies

Table 5. Nujol, solution electronic spectra and conductivity data of $Cu(L\text{-}L')Cl_2$ complexes

Complex	Electronic spectra, ν (cm^{-1})					Conductivities, Λ_M ($S\ cm^2\ mol^{-1}$)	
	Nujol	dmf	$(CH_3)_2SO$	CH_3OH	H_2O	dmf	CH_3OH
$Cu(pyb)Cl_2$	12,820	12,820	12,820	13,510	13,890	15.9	73.6
$Cu(pyi)Cl_2$	14,700	13,510	13,340	13,890	14,090	22.2	73.9
$Cu(pyim)Cl_2$	13,340	13,700	13,340	14,090	14,290	25.0	84.4

The values of Λ_M ($S\ cm^2\ mol^{-1}$) in methanol are: 80–115 for 1:1 electrolytes and 160–220 for 1:2 electrolytes, respectively; in dmf the values for 1:1 electrolytes are 60–90, and for 1:2 electrolytes 130–170.[30]

comparable to that of $[Cu(phen)Cl_2]$.[30] This broad band is likely due to several overlapping transitions that are not well resolved, although a deconvolution into two broad bands seems obvious, and assuming D_{4h} symmetry, the unsymmetrical band are assigned to $^2B_{1g} \rightarrow (^2B_2, {}^2E)$ transitions.

Solution electronic spectra show marked variation in band maxima and spectral width, suggesting that the postulated bridges are partially broken in solution, corroborating the EPR data that more than one species are present in solution. As the possible structures in solution are not known, no attempts to deconvolute the unsymmetrical band were made, since possible overlap of bands from different species are possible. Nevertheless, the band maximum show a red shift for dmf and $(CH_3)_2SO$, and a hypsochromic shift for the hydroxylic solvents (water and methanol). The latter shifts are indicative of appreciable chloride substitution by the solvent molecules yielding a stronger ligand field. The red shift can be explained by noting that dmf and $(CH_3)_2SO$ are less effective in disrupting the halogen bridges, and that the resulting species could then involve weaker axial coordination to the solvent molecules, thus rendering the total ligand field weaker than in the polymeric structures.

Conductivity data. The molar conductivity values (Table 5) for dmf solutions of the compounds (*ca* 10^{-3} M) are indicative of non-electrolyte behaviour, but as EPR and electronic spectroscopy data show, the complexes undergo structural changes in solutions through incorporation of solvent molecules in the coordinating sphere of the metal.

The conductivity data for methanol solutions are in the lower limit for 1:1 electrolyte type behaviour,[31] and suggests partial release of chloride ions into solution and an extensive disruption of the polymeric structure. As the EPR spectra also indicate the presence of at least two species in solution, in this solvent it is possible that some chloride ligands are replaced by solvent molecules, also supported by the large changes induced in their electronic spectra.

CONCLUDING REMARKS

The structural characterization of the chromium(II) compounds posed no ambiguities and hexacoordinate polymeric structures with Jahn–Teller distortions were proposed based on magnetic and spectroscopic data.

For copper a bewildering range of structural types is known for complexes of the general formulation $Cu(L\text{-}L')X_2$ or CuL_2X_2,[24,32,33] and it has proved difficult to predict even gross structural features in these complexes in the absence of crystallographic data. In the lack of relationships between structural characteristics and spectroscopic and magnetic properties for these types of copper(II) complexes, the non-availability of X-ray data raises severe difficulties in obtaining structural information for our complexes. Nevertheless, by comparing the data for our complexes with those of other copper(II) complexes with similar ligands and with known structures, we were able to suggest for the complexes reported a hexacoordinated polymeric skeleton, similar to that observed for the analogous chromium(II) complexes.

ELECTRON PARAMAGNETIC RESONANCE STUDY ON RADIATION REDUCTION OF DIRHODIUM(II) $[Rh_2(O_2CR)_4]$ AND $[Rh_2Cl_2(O_2CR)_2(N—N)_2]$ COMPLEXES

F. PRUCHNIK,* A. JEZIERSKI and E. KALECIŃSKA

Institute of Chemistry, University of Wrocław, 50-383 Wrocław, Poland

(*Received* 10 *April* 1991; *accepted* 9 *July* 1991)

Abstract—Rhodium(II) complexes $[Rh_2(O_2CR)_4L_2]$ and $[Rh_2Cl_2(O_2CR)_2(N—N)_2]$ (R = H, Me, (*S*)-PhCHOH, (N—N) = 2,2′-bipyridine, 1,10-phenanthroline, L = solvent) in various solvents were reduced using ^{60}Co γ-rays. The resulting unstable species were detected and characterized by EPR spectroscopy. The main products of reduction were axially symmetric complexes containing the Rh_2^{3+} core: $[Rh_2(O_2CR)_4L_2]^-$ and $[Rh_2Cl(O_2CR)_2(N—N)_2L]$.

The chemistry of dirhodium(II) complexes continues to attract considerable attention. The studies on these compounds have developed due to the interest in the theory of the electronic structure of clusters with the single metal–metal bond, their spectroscopic properties, reactivity and their practical application.[1–4] Binuclear rhodium(II) complexes are effective catalysts in reduction of olefins and ketones and in the oxidation of alkenes and alkylaromatic hydrocarbons. They are catalysts for silylation, for cyclopropanation of olefins with diazo compounds, for photocatalytic decomposition of water, etc.

The majority of the rhodium(II) complexes contain bridging ligands: $[Rh_2(\mu\text{-}X)_4L_2]$ (L = Lewis base, X = $RCOO^-$, R′NC(R)O, R′(NC(R)NR′, 2-C_5H_4NNR, RNNNR, 2-C_5H_4NO, etc.) (Fig. 1). The compounds containing either a lower number of bridges, *e.g.* $[Rh_2(\mu\text{-}X)_3L_4]^+$,[5] $[Rh_2X_2(\mu\text{-}OOCR)_2(N—N)_2]$[4,6–11] or containing no bridging ligands, *e.g.* $[Rh_2(dmgH)_4]$, $[Rh_2L_{10}]^{4+}$[3,12] are also known. Dimeric complexes containing the $[Rh_2]^{4+}$ core undergo one-electron transfer reactions giving compounds with $[Rh_2]^{3+}$[13–17] or $[Rh_2]^{5+}$ cores.[2,3,18–21] The dirhodium(II,III) species with the oxygen-containing ligands are easily formed and may be reduced to the parent dirhodium(II) compounds using electrochemical methods,[2,3,18,19] while the singly reduced $Rh_2^{II,I}$ are irreversible and unstable.[13,14] Relatively stable dirhodium(II,I) complexes containing nitrogen ligands: $[Rh_2(R'NCRNR')_4]^-$,[15] $[Rh_2(\mu\text{-}R'NCRNR')_2(CO)_3L]^+$,[16] $[Rh_2(\mu\text{-}RNNNR)_2(CO)_2L_2]^+$,[16] $[Rh_2(\mu\text{-}RNNNR)_2(CO)L(bpy)]^+$[16] and $[Rh_2(\mu\text{-}pz)_2(cod)_2]^+$[17] have been prepared and investigated. Spectroscopic studies suggest the delocalized bonding in the mixed valence complexes containing the $[Rh_2]^{3+}$ core.[13–17]

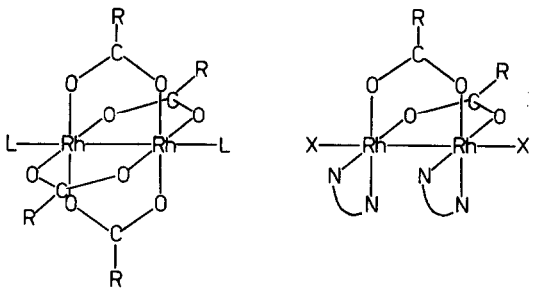

Fig. 1. Scheme of the investigated complexes.

Eastland and Symons have found that $[Rh_2(O_2CCH_3)_4]$ and $[Rh_2(O_2CCF_3)_4]$ complexes may be reduced by radiolysis in CD_3OD using ^{60}Co γ-rays.[13] We have used this method for the reduction of $[Rh_2(O_2CH)_4]$ and $[Rh_2(O_2CCHOHC_6H_5)_4]$.[14]

In this paper we detail the reduction of the $[Rh_2(O_2CR)_4]$ (R = H, $CHOHC_6H_5$) and $[Rh_2Cl_2(O_2CR)_2(N—N)_2]$ complexes (R = H, CH_3, $CHOHC_6H_5$; N—N = 2,2′-bypiridine (bpy), 1,10-phenanthroline (phen)).

Eastland and Symons have found[13] that the initial reduction product was $[Rh_2(O_2CCH_3)_4(solv)_2]^-$, an axially symmetric anion with the electron located in an antibonding $\sigma^*(d_{z^2})$ orbital. Annealing above 77 K gave the other substances; the proposed reactions and assignments of compounds are as follows:[13]

* Author to whom correspondence should be addressed.

$$[Rh_2(\mu\text{-}O_2CCH_3)_4(CD_3OD)_2] \xrightarrow[CD_3OD]{^{60}Co\ \gamma\text{-rays}} [Rh_2(\mu\text{-}O_2CCH_3)_4(CD_3OD)_2]^- \quad \mathbf{I}, g_\perp = 2.24$$

$$\longrightarrow [Rh_2(\mu\text{-}O_2CCH_3)_2(O_2CCH_3)_2(CD_3OD)_2]^- \longrightarrow \mathbf{II}, g_x = 2.248, g_y = 2.240, A_\perp = 0.35\ \text{mT}$$

$$\longrightarrow [(CD_3OD)(CH_3COO)Rh(\mu\text{-}O_2CCH_3)Rh(O_2CCH_3)_2(CD_3OD)]^- \longrightarrow \mathbf{III}, g_x = 2.32, g_y = 2.25, g_z = 2.006$$

$$\longrightarrow [Rh(O_2CCH_3)_2(CD_3OD)_n] + [Rh(O_2CCH_3)_2(CD_3OD)_m]^- \quad \mathbf{IV}, g_x = 2.57$$

In this work we have used similar assignments (I–IV) for the reaction products of our above-mentioned complexes.

EXPERIMENTAL

The complexes

$[Rh_2(O_2CCHOHC_6H_5)_4(H_2O)_2]$,[7] $[Rh_2(O_2CCH_3)_4(H_2O)_2]$,[22] $[Rh_2Cl_2(O_2CH)_2(bpy)_2]\cdot 4H_2O$,[6,8] $[Rh_2Cl_2(O_2CH)_2(phen)_2]$,[6,8] $[Rh_2Cl_2(O_2CCHOHC_6H_5)_2(bpy)_2]\cdot 2H_2O$,[7] $[Rh_2Cl_2(O_2CCH_3)_2(bpy)_2]$[6], $[Rh_2Cl_2(O_2CCH_3)_2(phen)_2]\cdot(H_2O)$[6,23] and $Na_4[Rh_2(CO_3)_4]\cdot 2.5H_2O$[12] were prepared by published procedures.

Synthesis of $[Rh_2(O_2CH)_4(H_2O)_2]$

A mixture, containing $Na_4[Rh_2(CO_3)_4]\cdot 2.5H_2O$ (1 mmol, 0.583 g) and 8.5 cm^3 6% HCOOH was heated at 100°C for 30 min. The product precipitated as a green solid was filtered off, washed with water, then with methanol and dried *in vacuo*; yield 0.27 g (65%).

Radiation reduction of the complexes

The solution of complexes were prepared in methanol, deuterated methanol and deuterated acetone in an argon atmosphere and frozen in liquid nitrogen. The samples were irradiated at 77 K in a ^{60}Co source with doses of 7–11 kGy.

EPR spectra were obtained in JES-ME (Jeol) and SE (Radiopan) X-band spectrometers. The nuclear magnetometer MJ (Radiopan) and EPR standards were used. After measurement at 77 K the samples were annealed to various temperatures and then re-cooled to 77 K for further measurements. The spectra were analysed by the method described earlier.[24]

RESULTS

Radiation reduction of $[Rh_2(O_2CCHOHC_6H_5)_4(H_2O)_2]$ was carried out in CH_3OH, CD_3OD, C_2D_5OD and CD_3COCD_3 solutions. The best results were obtained for CD_3OD solution because of the solubility of the complex and relatively simple EPR spectrum of γ-irradiated CD_3OD. In the EPR spectra of γ-irradiated samples the following paramagnetic species were detected: solvated electrons, organic free radicals, D (or H) atoms and rhodium complexes (Figs 2–4).

A single narrow line characteristic of solvated electrons strongly decreases with temperature increase, and decreases with increase of microwave power. Characteristic lines for radicals: $^{\bullet}CD_2OD$, $^{\bullet}CDO$ and $^{\bullet}CD_3$ (in CD_3OD, and analogous ones in other solvents) were also found.

The paramagnetic rhodium complexes detected in sample containing tetraformatodirhodium and tetramandelatodirhodium were attributable to electron capture species $[Rh_2(O_2CR)_4L_2]^-$ (L = solvent molecule). The initial species observed after irradiation at 77 K had a strong EPR signal with $g_\perp = 2.230$ and $g_\perp = 2.241$ for the formato and mandelato complexes, respectively. The line shape indicated that the signal is a perpendicular feature. The associated parallel feature expected at *ca* $g = 2.00$ was never observed being covered by intense free radicals and solvated electrons signals in that region (Figs 2 and 3). All attempts to detect the parallel line for the rhodium complexes have failed because of the lower stability of the complexes in comparison with that of the organic free radicals in the γ-irradiated solutions. Apart from the $[Rh_2(O_2CR)_4L_2]^-$ complexes, the monomeric complexes $[Rh(O_2CH)_2L]$ ($g_1 = 2.532$, $g_2 = 2.064$, $g_3 = 2.00$) and $[Rh(O_2CCHOHC_6H_5)_2L]$ ($g_1 = 2.512$, $g_2 = 2.046$, $g_3 = 2.00$) were formed (Figs 2 and 3).

Reduction of the $[Rh_2Cl_2(O_2CR)_2(N{-}N)_2]$ complexes gave paramagnetic compounds with $g_\perp$ values at *ca* 2.190–2.195 ($g_\parallel$ is hidden beneath the intense solvent radical lines) (Fig. 4). In the EPR spectrum of $[Rh_2Cl_{2-n}(O_2CCHOHC_6H_5)_2(bpy)_2(CD_3OD)_n]^{(n-1)+}$ the perpendicular feature at $g_\perp = 2.190$ showed a poorly resolved triplet ($A_\perp = 0.7$ mT). After annealing of the samples

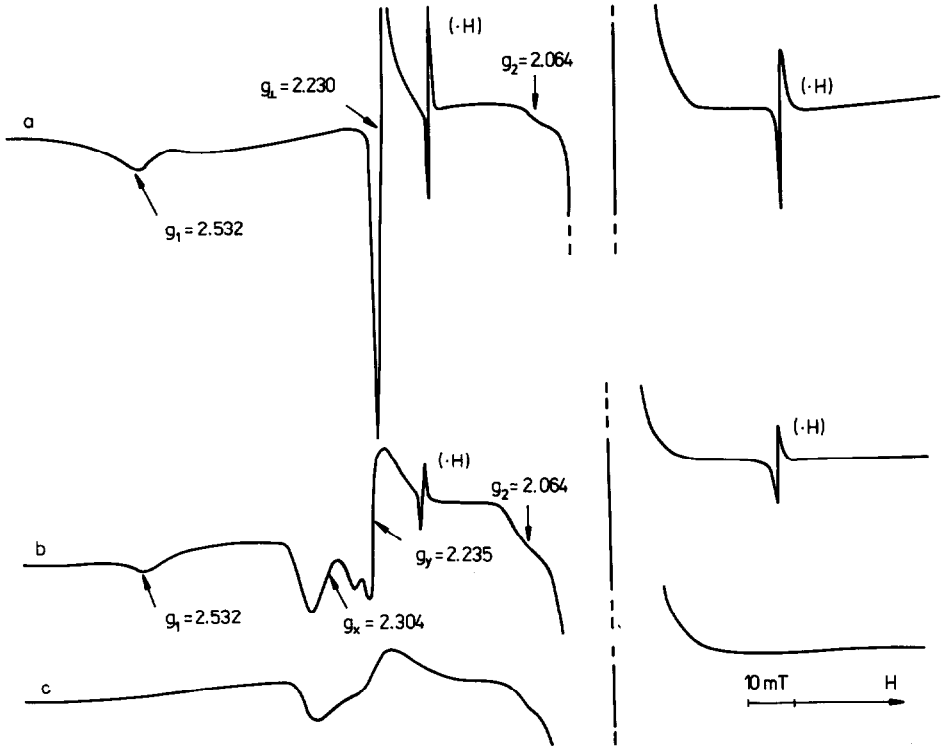

Fig. 2. EPR spectra of γ-irradiated $[Rh_2(O_2CH)_4]$ in CD_3OD. Initial concentration of the rhodium complex 2×10^{-3} M. Dose 7.7 kGy. Microwave frequency 9.112 GHz. (a) At 77 K, gain 2×10^2; (b) at 77 K after annealing at 130 K, gain 1.6×10^3; (c) at 150 K, gain 1.6×10^4.

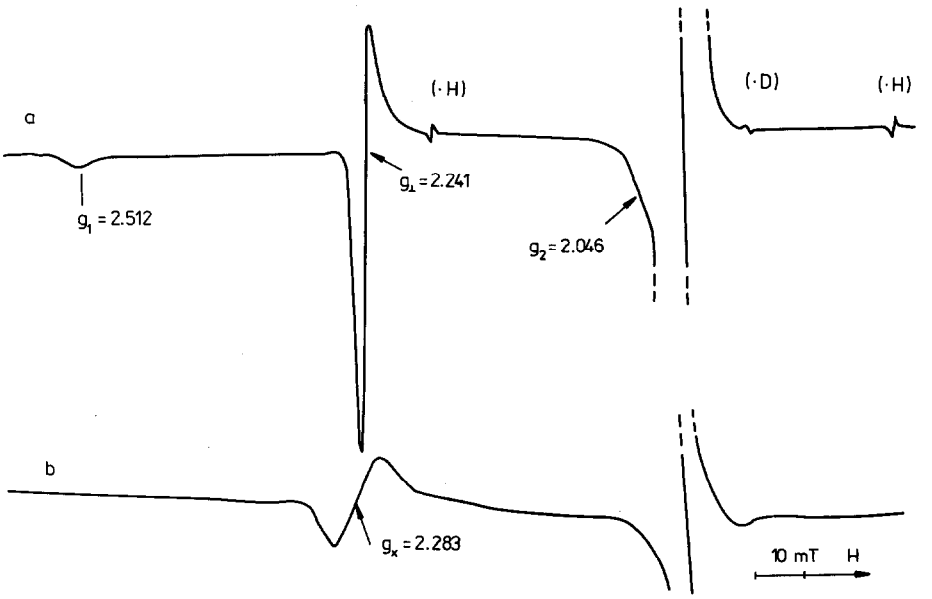

Fig. 3. EPR spectra of γ-irradiated $[Rh_2(O_2CCHOHC_6H_5)_4]$ in C_2D_5OD. Initial concentration of the rhodium complex 1×10^{-2} M. Dose 11.3 kGy. Microwave frequency 9.110 GHz. (a) At 77 K, gain 1×10^2; (b) at 77 K after annealing at 130 K, gain 1.25×10^4.

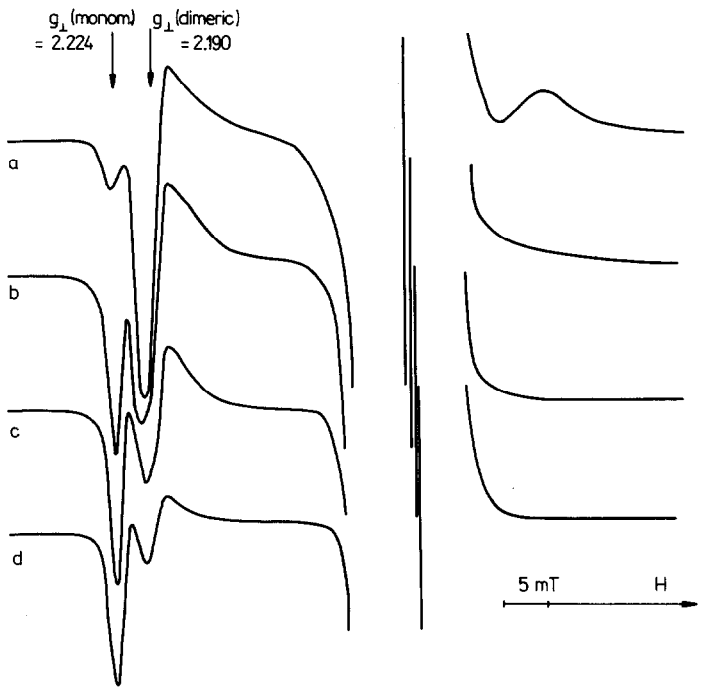

Fig. 4. Temperature dependence of the EPR spectra of the γ-irradiated $[Rh_2Cl_2(O_2C\text{-}CHOHC_6H_5)_2(bpy)_2]$ in CD_3OD. Initial concentration of the rhodium complex 10^{-3} M. Dose 11.5 kGy. Microwave frequency 9.188 GHz, gain 2×10^3. (a) At 77 K; (b) at 112 K, (c) at 125 K, (d) at 145 K.

new signals with g in the region 2.22–2.23 were detected. These signals gained intensity on annealing at the expense of the features at $g_\perp = 2.19$ (Figs 4 and 5). Weak signals at $g = 1.92$, 1.97, 2.18 and 2.28 were also detected. Their intensity is 30–40 times lower as compared with the signals with $g_\perp = 2.190$–2.195. After annealing above the melting point of CD_3OD, the samples containing $[Rh_2Cl_2(O_2CR)_2(N\text{—}N)_2]$ complexes show a relatively intense signal at 2.003, line width 0.6 mT.

The γ-irradiated solid samples of $[Rh_2Cl_2(O_2OCCHOHC_6H_5)_2(bpy)_2]\cdot 2H_2O$ and $[Rh_2Cl_2(O_2CH)_2(bpy)_2]\cdot 4H_2O$ (at room temperature, dose 560 kGy) show at room temperature the stable signals at $g = 2.200$ and $g = 2.220$, respectively.

DISCUSSION

The tetracarboxylato complexes

The signals with $g_\perp$ at *ca* 2.23–2.24 observed for solutions of $[Rh_2(O_2CH)_4(solv)_2]$ and $[Rh_2(O_2CCHOHC_6H_5)_4(solv)_2]$ γ-irradiated at 77 K in anion forming solvents (Figs 2 and 3) are assigned to axially symmetric radical anions, $[Rh_2(O_2CR)_4(solv)_2]^-$. The $g_\perp$ values are very close to that obtained for $[Rh_2(O_2CCH_3)_4(solv)_2]^-$.[13]

In the samples of the mandelato and formato complexes the paramagnetic monomeric rhodium(II) complexes with $g_1 \approx 2.5$ are present (Figs 2 and 3) at 77 K. Annealing of the samples yields the new signal at about $g = 2.3$ analogous to the form III described in ref. 13 (Figs 2 and 3).

These data indicate that the formato- and mandelatodirhodium complexes, contrary to the acetatodirhodium complex[13] during the reduction give both axially symmetric anions $[Rh_2(\mu\text{-}O_2CR)_4(CD_3OD)_2]^-$ and monomers $[Rh(O_2CR)_2(CD_3OD)_n]$. Therefore in the case of these complexes the γ-rays cause not only the reduction of $[Rh_2]^{4+}$ core to the $[Rh_2]^{3+}$ core but also splitting of the Rh—Rh bond.

On the basis of the EPR spectra the following mechanisms of radiation of the $[Rh_2(O_2CR)_4L_2]$ complexes could be proposed as in Scheme 1.

The observed differences between the formato and mandelato complexes described in Schemes 1 and 2, and the acetato complex (described in ref. 13) could be explained on the basis of different redox properties of these complexes. The oxidation potentials $E_{1/2}$ for $[Rh_2(O_2CCH_3)_4(DMF)_2]$, $[Rh_2(O_2CCHOHC_6H_5)_4(DMF)_2]$ and $[Rh_2(O_2CH)_4(DMF)_2]$ are 0.990, 1.170 and 1.215, respectively.[10] The stability of the $[Rh_2(O_2CR)_4L_2]$ complexes depends on the dissociation con-

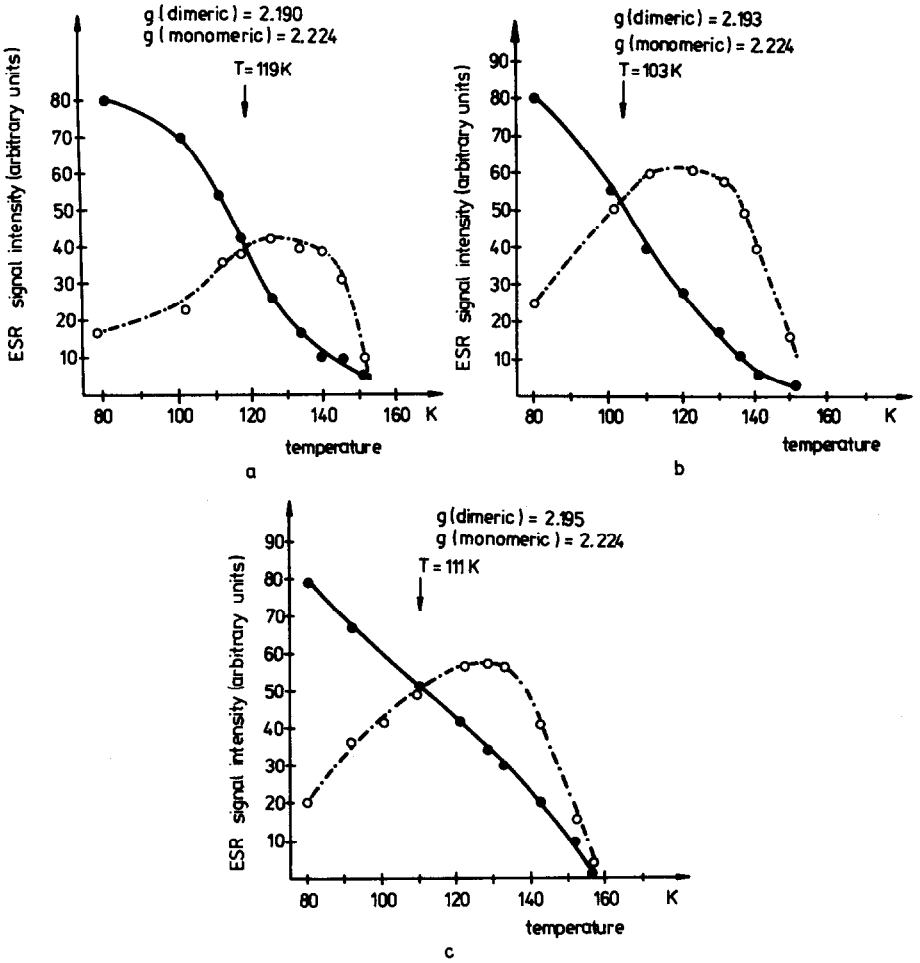

Fig. 5. Temperature dependence of "monomeric" ($g = 2.224$) and "dimeric" ($g = 2.19$) EPR lines for $[Rh_2Cl_2(O_2CR)_2(bpy)_2]$ complexes. Solvent: CD_3OD. Microwave frequency 9.2 GHz. Other comments: see text. Filled circles (solid lines)—the "dimeric" lines ($g = 2.19$); open circle (dashed lines)—the "monomeric" lines ($g = 2.224$). (a) $[Rh_2Cl_2(O_2CCHOHC_6H_5)_2(bpy)_2]$, initial concentration of the rhodium complex 10^{-3} M. (b) $[Rh_2Cl_2(O_2CCH_3)_2(bpy)_2]$, initial concentration of the rhodium complex 10^{-4} M. (c) $[Rh_2Cl_2(O_2C)_2(bpy)_2]$, initial concentration of the rhodium complex 5×10^{-4} M.

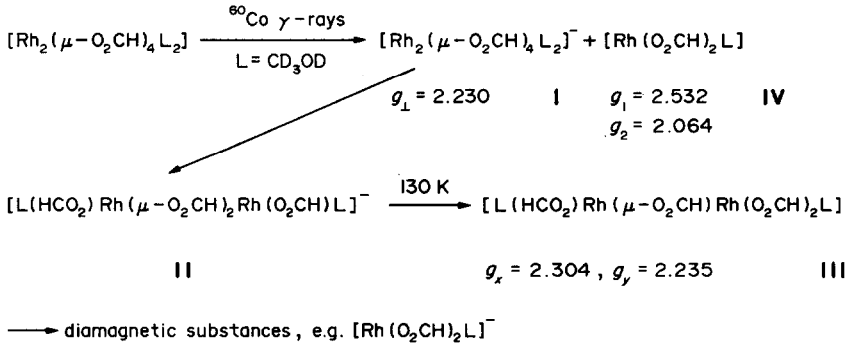
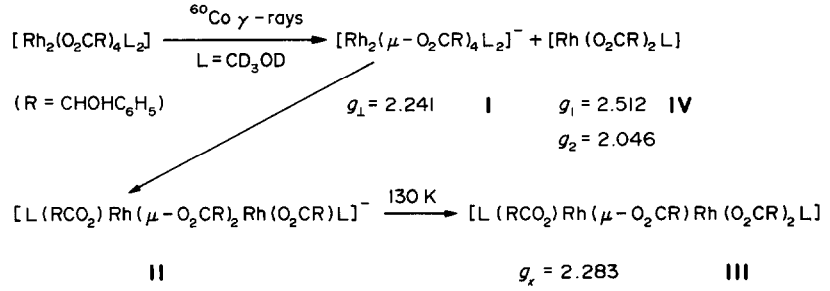
stants of the RCOOH acids. This is evidenced by the linear relationship of the half-wave potentials and dissociation constants K_{RCOOH}. The reduction potentials $E_{p,c}$ for $[Rh_2(O_2CR)_4L_2]$ complexes also increase in the same order: $O_2CCH_3 < O_2CCHOHC_6H_5 < O_2CH$. In the case of $Rh_2(O_2CCF_3)_4$ the reduction is favoured by about 0.5 V compared to the acetato complexes.[25] These



Scheme 1.



Scheme 2.

relationships indicate that electron-withdrawing substituents help to stabilize the higher oxidation state of the metal. Therefore, the formato and mandelato $[Rh_2^{I,II}(O_2CR)_4L_2]^-$ complex anions probably undergo disproportionation giving mononuclear rhodium(II) and rhodium(I) compounds opposed to the acetato complex. The strength of the Rh—Rh bond in these complexes is almost the same, since Rh—Rh distances for $[Rh_2(O_2CCH_3)_4(H_2O)_2]$, $[Rh_2(O_2CCHOHC_6H_5)_4(C_2H_5OH)_2]$ and $[Rh_2(O_2CH)_4(H_2O)_2]$ differ only slightly (these are 238.56, 238.6 and 238 pm, respectively.[1-4,26]

The complexes containing nitrogen ligands, $[Rh_2Cl_2(O_2CR)_2(N—N)_2]$

In these complexes chloro ligands are coordinated along the Rh—Rh axis (Fig. 1). The Rh—Cl bond is weak because of the long Rh—Cl distance, *ca* 251 pm. In solutions of these complexes the Cl ligands may be replaced by solvent molecules (Lewis bases), *e.g.* $[Rh_2Cl(O_2CR)_2(N—N)_2(solv)]^+$. This was proved by conductivity measurements of these complexes in water and alcohol solutions.[7]

The $[Rh_2Cl_{2-n}(O_2CR)_2(N—N)_2(solv)_n]^{n+}$ complexes are reduced with ^{60}Co γ-rays in solvents giving radicals (mainly $^{\cdot}CD_2OD$). The products are two types of paramagnetic compounds with g values in the range 2.190–2.195 and 2.22–2.23. The EPR data indicate that the $[Rh_2]^{4+}$ core is reduced to $[Rh_2]^{3+}$. In the case of the mandelato complex with 2,2′-bipyridine the dominant product is most likely $[Rh_2Cl_{2-n}(O_2CCHOHC_6H_5)_2(bpy)_2(CD_3OD)_n]^{(n-1)+}$ with $g = 2.190$. This line is a perpendicular feature with poorly resolved splitting with A about 0.7 mT due to two ^{103}Rh nuclei. The similar g values are observed for analogous $[Rh_2Cl_{2-n}(O_2CR)_2(N—N)_2(CD_3OD)_n]^{(n-1)+}$ complexes (N—N = 2,2′-bipyridine, 1,10-phenanthroline, R = H, CH_3).

Annealing of the samples in the temperature range 77–145 K leads to a decrease of the signal at $g = 2.19$ and an increase of the signal at $g = 2.22$ (Fig. 5). The complexes with $g = 2.22$ are probably monomeric rhodium(II) compounds and they arise from dimers. Stability of the dimeric complexes with $[Rh_2]^{3+}$ core decreases in the series: $O_2CCH_3 > O_2CCHOHC_6H_5 > O_2CH$, *i.e.* with the increase of the dissociation constants of the parent carboxylic acids RCOOH (1.85×10^{-5}, 1.4×10^{-4} and 1.77×10^{-4}, respectively). The oxidation potentials $E_{p,a}$ for the $[Rh_2Cl_{2-n}(O_2CR)(bpy)_2(DMF)_n]^{n+}$ complexes increase in the same order: 1.15, 1.145 and 1.160 V for R = CH_3, $CHOHC_6H_5$ and H, respectively.[27] Therefore, the rate of disproportionation reaction of $[Rh_2]^{3+}$ core with formation of Rh^{II} and Rh^{I} mononuclear complexes should decrease in the order: $O_2CH > O_2CCHOHC_6H_5 > O_2CCH_3$. According to this order the highest concentration of $[RhCl_x(O_2CR)(bpy)(CD_3OD)_y]^{y+}$ $(x+y=1)$ were found at *ca* 110–120 K for acetato, *ca* 125–130 K for mandelato and 125–135 K for formato complex (Fig. 5).

On the basis of the experimental data the following scheme of reaction proceeding during the γ-radiolysis of solutions of $[Rh_2Cl_2(O_2CR)_2(N—N)_2]$ complexes can be proposed:

$$[Rh_2Cl_2(\mu\text{-}O_2CR)_2(N—N)_2] \xrightarrow[L = CD_3OD]{^{60}Co\ \gamma\text{-rays}} [Rh_2Cl_{2-n}(\mu\text{-}O_2CR)_2(N—N)_2L_n]^{n+}$$

$$\longrightarrow [Rh_2Cl_{2-n}(\mu\text{-}O_2CR)_2(N—N)_2L_n]^{(n-1)+} + \text{small amount of monomer IV}$$

$$g_\perp = 2.190\text{–}2.195 \quad \mathbf{I}$$

(annealing 77–145 K)

$$\longrightarrow [RhCl_x(O_2CR)(N—N)L_y]^{y+} \quad (x+y=1)$$

$$g = 2.22 \quad \mathbf{IV}$$

The EPR spectra showed that in the primary products of γ-radiolysis small quantities of unidentified paramagnetic substances with g parameters 1.92, 1.97, 2.18 and 2.28 are present.

Among them monomeric rhodium(II) five- or six-coordinate complexes and dimeric complexes with the $[Rh_2]^{3+}$ core without bridging carboxylato ligands may be postulated. In the samples containing products of γ-radiolysis of the $[Rh_2Cl_2(O_2CR)_2(N{-}N)_2]$ complexes annealed to the melting point of the solvent (CD_3OD), a relatively strong signal at $g = 2.003$ and line width 0.6 mT has been observed. These signals should be assigned to rhodium(0) complexes, $[RhCl_x(O_2CR)_y(N{-}N)L]^-$ $(x+y=1)$ with the unpaired electron in the π^* orbital of 2,2′-bipyridine or 1,10-phenanthroline molecules. Similar signals were observed for [M(chel)(N—N)] and $[M(N{-}N)_2]$ (chel = 1,5-cyclooctadiene, 2,5-norboranadiene, (N—N) = bpy, phen, 4,7-Ph_2-phen, 2,2′-bipyrazine) with an electron located in the π^* orbital.[28,29]

It is noteworthy that all results obtained for the $[Rh_2Cl_2(O_2CR)_2(N{-}N)_2]$, (N—N) = 1,10-phenanthroline, are practically the same as those obtained for (N—N) = bpy; g parameters for both types of complexes are the same within the limits of experimental error.

(*Received* 18 *March* 1991; *accepted* 9 *July* 1991)

Abstract—The synthesis and characterization of stable ruthenium(III) Schiff base chloro and carbonyl complexes with the axial ligands chloro (Cl), imidazole (Im) and 2-methylimidazole (2-MeIm) are reported. The Schiff bases were synthesized by the interaction of naphthaldehyde with amines such as *o*-phenylenediamine, ethylenediamine, propylenediamine and diethylenetriamine. The geometry around ruthenium in these complexes is psuedooctahedral. The complexes are low-spin $4d^5$ (S = 1/2) and display characteristic EPR spectra in the powder samples and in frozen solutions at 298 and 77 K. The EPR data and EHMO calculations on model complexes indicate that the d_{xy} orbital lies above d_{xz} and d_{yz} orbitals.

Studies on carbonyl complexes of ruthenium are confined so far to the low-valent oxidation state of ruthenium with only a few reports available on Ru^{III} carbonyl complexes.[1,2] Several ruthenium complexes are known as homogeneous catalysts in carbonylation, hydroformylation and oxo reactions.[3–7] With the intention of synthesizing high valent stable ruthenium complexes and to study their catalytic activity, we initiated work on some Ru^{III} Schiff base chloro and carbonyl complexes derived from aldehydes, namely salicylaldehyde and picolinaldehyde and several amines.[8,9] Some of these complexes were found to be good homogeneous catalysts in the reductive carbonylation of nitrobenzene to phenylurethane by a phosgene-free route[10] and in the oxidation reaction of cyclohexene to its epoxide.[11]

In continuation of our earlier work,[8–11] we now report the synthesis and characterization of a new class of Ru^{III} Schiff base chloro (**1a–10a**) and carbonyl (**1b–10b**) complexes of the type $[RuLX(Cl)]^m$ and $[RuLX(CO)]^n$, respectively, where L = Schiff base, namely bis(naphthaldehyde)-*o*-phenylenediimine (naphoph), bis(naphthaldehyde)ethylenediimine (naphen), bis(naphthaldehyde)propylenediimine (naphprop) and bis(naphthaldehyde)diethylenetriimine (naphdien); $m = -1$ and $n = 0$ for $X = Cl^-$; $m = 0$ and $n = 1$ for X = Im and 2-MeIm (Structure 1). The geometry around ruthenium in these complexes is distorted octahedral with naphoph, naphen and naphprop coordinating as tetradentate ligands and naphdien as a pentadentate ligand.

The complexes were characterized by analytical data and spectroscopic (UV–visible, IR and EPR), magnetic susceptibility and differential pulse polarographic (DPP) techniques. The EPR spectroscopy is used as a probe to study the molecular distortions caused by the substituents on the Schiff bases and on axial ligands (X) and the catalytic activity of the complexes. Extended Hückel Molecular Orbital (EHMO) calculations were performed on model chloro and carbonyl complexes to estimate the electronic ground state wave function and MO energy level scheme.

EXPERIMENTAL

Preparation of the complexes

Ruthenium(III) Schiff base chloro complexes, $K[Ru(naphoph)Cl_2]$ (**1a**), [Ru(naphoph)(Im)Cl] (**2a**), [Ru(naphoph)(2-MeIm)Cl] (**3a**), $K[Ru(naphen)Cl_2]$ (**4a**), [Ru(naphen)(Im)Cl] (**5a**), [Ru(na-

phen)(2-MeIm)Cl] (**6a**), K[Ru(naphprop)Cl_2] (**7a**), [Ru(naphprop)(Im)Cl] (**8a**), [Ru(naphprop)(2-MeIm)Cl] (**9a**) and [Ru(naphdien)Cl] (**10a**) were prepared according to the reported procedure.[12]

The carbonyl complexes, [Ru(naphoph)(Cl)(CO)] (**1b**), [Ru(naphoph)(Im)(CO)]Cl (**2b**), [Ru(naphoph)(2-MeIm)(CO)]Cl (**3b**), [Ru(naphen)(Cl)(CO)] (**4b**), [Ru(naphen)(Im)(CO)]Cl (**5b**), [Ru(naphen)(2-MeIm)(CO)]Cl (**6b**), [Ru(naphprop)(Cl)(CO)] (**7b**), [Ru(naphprop)(Im)(CO)]Cl (**8b**), [Ru(naphprop)(2-MeIm)(CO)]Cl (**9b**) and [Ru(naphdien)(CO)]Cl (**10b**) were synthesized from their respective parent chloro complexes **1a**–**10a**.

Carbon monoxide was bubbled through the methanolic solutions of the parent complexes (2 mM) for about 10 h under constant stirring. Except complexes **1b**, **4b** and **7b**, for the rest of the carbonyl complexes the above reaction mixture was concentrated and precipitated by the addition of dry diethyl ether. The complexes were recrystallized from dry diethyl ether and ethyl acetate. The carbonyl complexes thus obtained were dried *in vacuo* over $CaCl_2$.

In the cases of complexes **1b**, **4b** and **7b**, KCl was filtered off, the filtrates were concentrated and the complexes were precipitated and recrystallized in the same way as discussed above. Naphoph complexes **1b**–**3b** were dark brown while the rest of the carbonyl complexes were dark green in colour (yield: 60–70%). All the chemicals and solvents used were of AR grade and purified further prior to use.

Physical measurements

Microanalyses (C, H, N) of the complexes were done by a Carlo Erba 1106 elemental analyser. Solution electrical conductivity was measured at

298 K by using a Digisun Electronics Conductivity bridge. IR spectra were obtained at 298 K on a Nicolet 200 SXV FT-IR instrument as Nujol mulls/KBr pellets. Electronic spectra were recorded in DMF solutions on a Shimadzu Model UV-160 spectrophotometer. DPP data were recorded at 298 K on a Princeton Applied Research Model 174 electrochemical system.

Magnetic moment of the solid complexes were measured by a PAR model 155 vibrating sample magnetometer. The complex $Hg[Co(SCN)_4]$ was used as a calibrant and the experimental magnetic moments were corrected for diamagnetism. EPR spectra were recorded on a Bruker X-band spectrometer using 100 kHz field modulation. The organic free radical DPPH was used as a field marker ($g = 2.0036$). Experiments were conducted in powder samples as well as in solutions at 298 and 77 K.

Molecular orbital calculations

MO calculations were performed by using the EHMO method described by Hoffmann.[13] The off-diagonal elements were calculated by a weighted Wolfberg–Helmholz formula,[14] with the Hückel constant of 1.65. The input parameters such as Coulomb integrals and orbital exponents for Ru, Cl, O, N and H were taken from ref. 15.

In the present Schiff base complexes such as complex **1a** one has to deal with a basis set containing 173 AOs to evaluate the MOs and their energies. As the program cannot handle such large molecules, calculations were performed on model chloro and carbonyl complexes in which the bridging group between N and O (Structure 1) was replaced by =CH—CH=CH— and that between N atoms was replaced by a NH group. As the crystal structures of the complexes are not known average Ru^{III}-ligand distances were assumed (Ru—Cl = 2.36, Ru—O = 2.03, Ru—N = 2.11, N—H = 1.0, C—H = 1.09 Å, N—Ru—O = 96° and N_1—Ru—N_2 = 84°). The Schiff base ligand was assumed to be in the *xy* plane and the *z*-axis coincides with the Cl—Ru—X axis. The Ru—C≡O bond was assumed linear with Ru—C = 1.84 Å and C≡O = 1.13 Å.

RESULTS AND DISCUSSION

The analytical data for the solid Ru^{III} Schiff base carbonyl complexes **1b–10b** are listed in Table 1. The freshly prepared DMF solutions of complexes **2b**, **3b**, **5b**, **6b**, **8b** and **9b** (1 mM) are 1:1 electrolytes while the rest of the carbonyl complexes are non-electrolytes.

In the IR spectra of the complexes a band at 1625–1635 cm^{-1} due to the azomethine group of the ligands undergoes shift to lower frequency (1590–1610 cm^{-1}) after complexation indicating the coordination of imine nitrogen to ruthenium.[16,17] The ν(Ru—Cl) band is more intense than ν(Ru—N) band and occurs around 320 cm^{-1} in all the complexes. Imidazole and 2-methylimidazole complexes show additional bands near 620 and 1000 cm^{-1} for the coordinated Im and 2-MeIm groups, respectively. The IR spectra of solid carbonyl complexes are characterized by an intense ν(C≡O) band in the range 1940–1980 cm^{-1} (Table 1) which was completely absent in the parent chloro complexes.[12] This band for free CO occurs at 2155 cm^{-1}. The shift in ν(C≡O) on coordination is consistent with those reported earlier.[9]

The electronic absorption spectra for complexes **1b–10b** are almost similar to those for the parent chloro complexes **1a–10a** except for some changes in peak intensities and positions.[12] Intense bands around 270, 305 and 345 nm in the UV region (Table 1) are assigned to the π–π^* and n–π^* transitions of the Schiff base ligand. The latter band undergoes a hypsochromic shift in all the complexes due to coordination of the Schiff base ligand to ruthenium. Three resolved and moderately intense CT bands appear in the range 420–760 nm. Some of the *d–d* bands are masked by the CT bands in this region.

The DPP of complexes **1b–10b** under dropping mercury electrode consists of a single Ru^{III}/Ru^{II} reduction couple. The equatorial and axial ligands have a significant effect on the $E_{1/2}$ values (Table 1). The $-E_{1/2}$ values for complexes **1b–10b** vary with the Schiff bases in the order naphoph > naphprop > naphen > naphdien and with the axial ligands in the order Im > 2-MeIm > Cl^-. A similar trend in $E_{1/2}$ values with the axial ligands was also observed with the other Ru^{III} Schiff base complexes reported earlier.[9] Though 2-MeIm is more basic than Im, large negative $E_{1/2}$ values for Im complexes compared to that for 2-MeIm complexes could be due to the intermolecular H-bonding in the former case than in the latter.

The magnetic moment (μ_{eff}) for all the chloro and carbonyl complexes as powder samples at 298 K falls in the range 1.97–2.08 μ_B corresponding to a single unpaired electron.

The EPR spectra for complexes **1a–10a** and **1b–10b**, as powders at 298 K consist of three partially resolved *g* features characteristic of the +3 oxidation state for ruthenium with the unpaired electron in one of the t_2 orbitals and a low-symmetry crystal field around ruthenium. The EPR lines at 298 K are broad probably due to short spin–lattice relaxation time and intermolecular spin exchange

interaction. Cooling the samples to 77 K narrowed the lines. No hyperfine coupling due to ruthenium could be observed. The absence of ruthenium hyperfine features was observed also by several investigators.[18,19] The g-values at 77 K listed in Table 2 are slightly different from those at 298 K indicating the depopulation of paramagnetic excited J states which have become thermally inaccessible at low temperatures.

The EPR spectra of the carbonyl complexes as frozen DMF solutions are similar to those for their powder samples at 77 K. However, the spectra for the chloro complexes at 77 K vary considerably with the solvent indicating that Ru^{III} chloro complexes are unstable in solution while the carbonyl complexes are quite stable. The instability of the chloro complexes could be attributed to the lability of the Ru—Cl bond that dissociates in solution to form solvated species. As the chloro complexes are not stable in solution, we had restricted our study only to solid complexes in the latter part of the section. Representative EPR spectra of the complexes are shown in Fig. 1.

The EPR data on powder samples, at 77 K, were analysed using the approach developed by Hill[20] and successfully applied to a number of low-spin d^5 systems by several investigators.[9,18,19] The details of the calculation were discussed elsewhere.[9] In the presence of low-symmetry (tetragonal, Δ and rhombic, V) distortions and spin–orbit coupling, the six T_2 orbitals of a low-spin d^5 configuration split into three Kramers' doublets. The ground state doublet is composed of t_2 functions, $|+1\rangle = -(d_{xz}+id_{yz})/\sqrt{2}$, $|\xi\rangle = id_{xy}$ and $|-1\rangle = (d_{xz}-id_{yz})/\sqrt{2}$, with admixture coefficients a, b and c, respectively.

For a particular g values set two solutions, (1) $g_z < g_x$ and g_y; g_x, g_y and g_z are positive and (2) $g_z < g_x$ and g_y; g_x and g_y are positive while g_z is negative, were found to be physically reasonable. The covalency parameter, k for solution 1 was less then 1.0 while it was greater than 1 for solution 2. The distortion parameters (Δ and V) and excitation

[a] Estimated error in g_1, g_2, g_3 is ± 0.008.

[b] Isotropic spectrum was observed and k was calculated by using the expression $g_{av} = 2/3(2k+1)$.

energies from the ground Kramers' doublet to excited doublets (ΔE_1 and ΔE_2) were larger for solution 1 than for solution 2. However, a molecular model for the complexes (Structure 1) and extended π-delocalization of the Schiff base ligand indicate that the covalency parameter must be less than 1 and distortions and excitation energies must be large. It is therefore concluded that solution 1 gives the correct ground state wave function. The MO admixture coefficients, covalency, distortion parameters and excitation energies corresponding to solution 1 for all the complexes are listed in Table 2. EHMO calculations on chloro and carbonyl complexes (vide infra) support these results.

It is clear from Table 2 that the tetragonal splitting, Δ, is larger than the rhombic splitting, V and further both these parameters are larger than the spin–orbit coupling constant (λ).* The positive value for Δ/λ for all the complexes and the larger MO coefficient for d_{xy} orbital, b, than 'a' and 'c' indicate that in the absence of spin–orbit coupling d_{xy} lies above ($d_{xz} + id_{yz}$) orbitals resulting in the ground state electronic configuration $d_{xz}^2 d_{yz}^2 d_{xy}^1$. The value for Δ is in general larger for carbonyl complexes than for chloro complexes. It is pertinent to note that Ru^{III} chloro complexes derived from salicylaldehyde have a d_{xz}/d_{yz} ground state while their carbonyl analogues have a d_{xy} ground state.[9] However, in the present case the stabilization of d_{xz}/d_{yz} orbitals for both chloro and carbonyl complexes could be because of the additional π-interaction in the naphthaldehyde group.

The parameters k, Δ/λ and $\Delta E_i/\lambda$ ($i = 1$ and 2) change with the basicity of the axial ligands in the order 2-MeIm > Im > Cl^-. The value of k is smaller for carbonyl complexes than for chloro complexes indicating that the Ru—CO bond is more covalent than Ru—Cl bond. This is because of the difference in the nature of binding of Cl^- and CO (Cl^- is a σ-donor whereas CO is a π-acceptor). As the $d\pi$ orbitals (assuming z-axis coincides with Ru—Cl or Ru—CO bond) are filled in these complexes they can donate electron density to the $p\pi$ orbitals of CO whereas the $p\pi$ orbitals of Cl^- cannot donate electron density to the metal $d\pi$ orbitals leading to a labile Ru—Cl bond. The value of k

* The spin–orbit coupling constant (λ) for the Ru^{III} ion is 1150 cm^{-1}. In complexes it is assumed to be 1000 cm^{-1}.

[a] The HOMOs for chloro and carbonyl complexes are 39th and 40th MOs respectively. The symmetry at the site of ruthenium is as low as C_{2v}.

[b] Atoms O1 and O2 belong to Schiff base; C and O belong to carbonyl group.

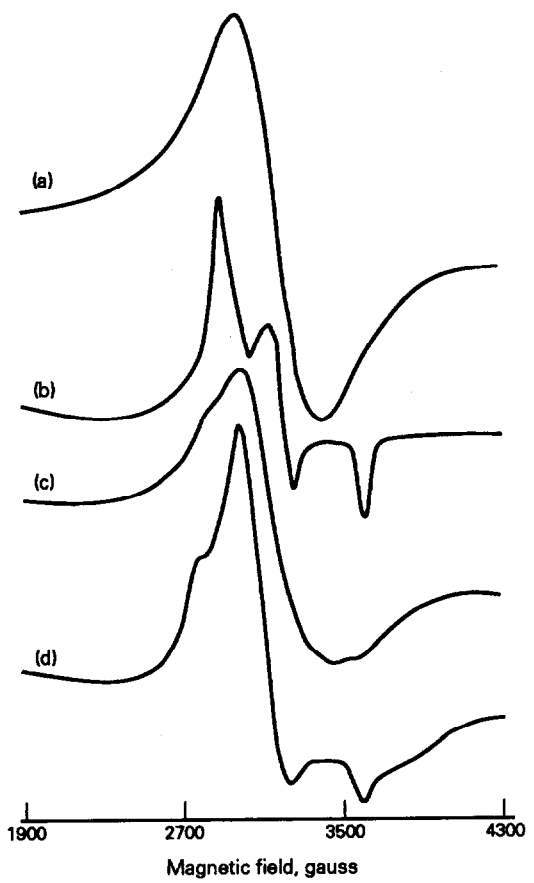

Fig. 1. X-band EPR spectra of K[Ru(naphprop)Cl_2] **7a** and [Ru(naphprop)(Cl)(CO)] **7b** complexes at 77 K. (a) **7a** as powder sample, (b) frozen acetone solution of **7a**, (c) **7b** as powder sample, and (d) frozen DMF solution of **7b**.

varies with the Schiff bases in the order salicylaldehyde > picolinaldehyde > naphthaldehyde. This suggests that the naphthaldehyde Schiff base complexes reported in this investigation are more stable than salicylaldehyde and picolinaldehyde complexes reported elsewhere.[9] Because of the higher stability of the naphthaldehyde Schiff base complexes they are less active catalytically than salicylaldehyde and picolinaldehyde complexes.[10]

EHMO calculations

The HOMO in both chloro and carbonyl complexes is predominantly a $d_{x^2-y^2}$ orbital.* The wave functions for a few MOs above and below the HOMO along with their energies are listed in Table 3. It is obvious from Table 3 that replacement of Cl^- by CO has lowered the energy of d_{xz} and d_{yz} orbitals while that of $d_{x^2-y^2}$ is unaltered. The d_{z^2} and d_{xy} orbitals are more destabilized in the case of carbonyl complexes. Ruthenium d_{xz} and d_{yz} orbitals involve an antibonding interaction with $p\pi$ orbitals of Cl^- and CO. The $d\pi$–$p\pi$ interaction is more in the case of carbonyl complexes than in chloro complexes (the coefficients for $d\pi$ orbitals are smaller in the case of carbonyl complexes than in the chloro complexes) leading to more stabilized d_{xz} and d_{yz}

* The $d_{x^2-y^2}$ orbital in EHMO calculation is the same as the d_{xy} orbital discussed in the EPR provided the coordinate system used in EHMO calculation is rotated by 45° about z-axis.

orbitals in carbonyl complexes. It is therefore expected that the replacement of Cl^- by CO group increases the axial and crystal field splittings. EPR results on chloro and carbonyl complexes are consistent with this observation (the value for the axial distortion Δ is more for carbonyl complexes than for chloro complexes). A similar behaviour in the energy level ordering was observed for the chloro and carbonyl complexes of ferrous porphyrins.[21]

SYNTHESIS AND CHARACTERIZATION OF THORIUM(IV) AND DIOXOURANIUM(VI) COMPLEXES OF PENTAMETHYLENE SULPHOXIDE

R. K. AGARWAL* and JAI PRAKASH

Postgraduate Department of Chemistry, Lajpat Rai Postgraduate College, Meerut University, Sahibabad-201 005, Ghaziabad, India

(*Received* 20 *February* 1991; *accepted* 9 *July* 1991)

Abstract—Some thorium(IV) and dioxouranium(VI) complexes with pentamethylene sulphoxide (PMSO) of the general composition $[ThX_4(PMSO)_n]$ (X = Cl, Br, NO_3 or NCS, $n = 2$; X = I, $n = 4$; X = ClO_4, $n = 6$) and $[UO_2X_2(PMSO)_n]$ (X = Cl, Br, I, NO_3, NCS or CH_3COO, $n = 2$; X = ClO_4, $n = 4$) were synthesized and characterized by IR, conductivity, molecular weight and analytical techniques. In all the complexes the PMSO is coordinated to the metal ion via its oxygen donor atom. The thermal properties of the complexes are also reported.

We have previously synthesized some actinide complexes of several sulphoxides, namely tetramethylene sulphoxide,[1–3] dibenzyl sulphoxide[4,5] and methyl phenyl sulphoxide.[6] In this paper we report our results on thorium(IV) and dioxouranium(VI) complexes of pentamethylene sulphoxide $(CH_2)_5SO$.

EXPERIMENTAL

Materials

Thorium(IV) nitrate and uranyl(VI) nitrate were obtained from B.D.H. Crystalline thorium(IV) perchlorate[7] and ThX_4 (X = Cl, Br, I or NCS)[8] were prepared by known methods. Other uranyl(VI) salts were prepared as reported earlier.[9] The ligand PMSO was obtained from Aldrich Chemical Co. and was used as received. All the solvents were of AnalaR grade.

Synthesis of the complexes

All the thorium(IV) and uranyl(VI) complexes of PMSO were prepared by the following methods.

(i) An acetone solution of the metal salt was added slowly to the constantly stirred PMSO solution in acetone at *ca* 8–10°C. After stirring the reaction mixture for 30 min, the complex separated almost quantitatively and was washed by decanting with acetone to free it from adhering ligand, filtered and dried *in vacuo* over P_4O_{10}.

(ii) A methanolic solution of the respective metal salt was treated with the calculated amount of PMSO (in the same solvent) with constant stirring at 10°C. After stirring the reaction mixture for 30 min, an excess of anhydrous diethyl ether was added to the mixture giving a precipitate which was filtered, washed with methanol and finally with diethyl ether and dried *in vacuo* over fused $CaCl_2$.

(iii) An isopropanol solution of the metal salt was treated with a solution of PMSO in ethyl acetate. The reaction mixture was cooled to *ca* 10°C and on stirring for *ca* 30 min, the solid product was obtained which was filtered, washed with ethyl acetate and isopropyl alcohol mixture. Finally it was washed with petroleum ether and dried as above.

All the analyses and physical measurements were performed as reported previously.[9]

RESULTS AND DISCUSSION

The interaction of various thorium(IV) and dioxouranium(VI) salts with pentamethylene sulphoxide (PMSO) resulted in the formation of the type $[ThI_4(PMSO)_n]$ (X = Cl, Br, NO_3 or NCS, $n = 2$; X = I, $n = 4$; X = ClO_4, $N = 6$) and $[UO_2X_2$

$(PMSO)_n]$ (X = Cl, Br, I, NO_3, NCS or CH_3COO, $n = 2$; X = ClO_4, $n = 4$). The elemental analyses of these complexes are presented in Tables 1 and 2.

In order to understand the nature of the complexes in solutions, their electrical conductivities were determined in nitrobenzene. The results are presented in Tables 1 and 2. In the case of the thorium(IV) complexes, the molar conductances of the perchlorate and iodide complexes show the presence of 1:4 and 1:2 electrolytes respectively. Thus in the perchlorate complex all four perchlorate groups are present outside the coordination sphere whilst in the case of the iodide complex only two of the four iodide groups may be ionic in nature. The molar conductances of all the uranyl(VI) complexes (except the perchlorate complex) of PMSO fall in the range 3.2–5.1 Ω^{-1} cm^2 mol^{-1} indicate that the complexes are non-electrolytes. In the case of the perchlorate complex the value corresponds to 52.5 indicating the 1:2 electrolytic nature of this complex. Data on the molecular weight of the complexes in freezing nitrobenzene are given in Tables 1 and 2 along with the formula weight. The thorium(IV) and uranyl(VI) complexes are either

diamagnetic or weakly paramagnetic depending upon the diamagnetism of the other ions and the surrounding ligand field.[10]

Infrared spectra and the nature of coordination

In the spectra of PMSO, two absorptions associated with S=O and C—S stretching modes undergo significant shift on coordination.[11] S=O stretching frequency in free PMSO appears as a strong absorption at 1022 cm^{-1},[12] which disappears on complex formation and a new band of enhanced intensity appears in the 980–950 cm^{-1} region (Table 3) showing coordination of PMSO to the metal ion through its oxygen atom.[12] The other important absorption in the spectra of sulphoxide is the C—S stretching vibration which has been identified in free PMSO at 660 cm^{-1}.[12] This absorption undergoes a slight positive shift on complexation (Table 3). A negative shift of the S=O stretching frequency and shift of the C—S stretching frequency towards higher wave number are indicative of the decrease in the double bond character of the S=O bond. ν(M—O) stretching vibrations occur at *ca* 400 cm^{-1}[5,6] and the CSO deformation modes appear in the 380–340 cm^{-1} region. A distinct difference between δ' symmetric and δ'' antisymmetric CSO absorption is an indication of electron donation from the oxygen atom of the sulphoxide molecule.

The ν(M—Cl) (M = Th or U) vibration has been assigned in 270–255 cm^{-1} region in thorium(IV) and uranyl(VI) chloride complexes of PMSO.[13] In the spectra of $[Th(PMSO)_6](ClO_4)_4$ and $[UO_2(PMSO)_4](ClO_4)_2$ the very strong ν_3 and ν_4 infrared bands appear at *ca* 1080 and *ca* 620 cm^{-1} respectively for perchlorate ions, indicating that tetrahedral symmetry is maintained and the perchlorate ions are not bonded to the thorium(IV) or uranyl(VI) ions.[14] In the complex $[Th(NO_3)_4(PMSO)_2]$ the absence of the ν_3 band of ionic nitrate (D_{3h}) around 1360 cm^{-1} and the occurrence of two strong bands at *ca* 1525 and 1300 cm^{-1} suggest the strong covalent nature of the NO_3^- ion.[15] The bidentate nature of the nitrato groups in the complex has been established by comparing the spectral bands of the complex with those of $Th(NO_3)_4 \cdot 5H_2O$.[16] In $[Th(PMSO)_4(NO_3)_4]$, the NO_3^- vibrations occur at 1525 (ν_1), 1300 (ν_4), 1040 (ν_2), 815 (ν_6) and 750 cm^{-1} (ν_3/ν_5) while in $Th(NO_3)_4 \cdot 5H_2O$ the corresponding bands occur at 1520, 1290, 1030, 808, 745 and 715 cm^{-1} respectively. The nitrate groups in $[UO_2(PMSO)_2(NO_3)_2]$ complex appears to be bidentate since the IR bands due to this group occur almost in the same region as in case of reported bidentate complexes.[17] The C—N stretching frequency in $[Th(PMSO)_2(NCS)_4]$ and $[UO_2(PMSO)_2(NCS)_2]$ appears in 2060–2050 cm^{-1} region, which lies on the border line for distinguishing between sulphur and nitrogen bonding in the thiocyanate,[18] although the high relative intensity of the band in all cases suggests that the thiocyanate groups are nitrogen bonded.[19] The ν(C—S) frequency observed at *ca* 780 and δ(NCS) at *ca* 480 cm^{-1} further confirm the N-bonding to

Table 3. Important IR bands (cm^{-1}) of Th(IV) and UO_2(VI) complexes of PMSO

the metal atom.[20] The IR spectrum of $UO_2(CH_3COO)_2 \cdot 2PMSO$ shows bands at *ca* 1540, 1420 and 665 cm^{-1} which are assigned to νOCO asymmetric, νOCO symmetric and δOCO modes, respectively, due to coordinated acetato group.[21] On the basis of previous reports, it is concluded that the acetate groups coordinate in a bidentate chelating fashion with the uranyl acetate.[22]

The other notable feature in the stretching frequency of U=O bond in uranyl(VI) compounds before and after complexation. The stretching frequency (*ca* 950 cm^{-1}) falls about 20–25 cm^{-1} after complexing with the ligand due to lowering of d_π–p_π interaction in the U=O bond which is supported by the observations of McGlynn and coworkers.[23]

Thermal studies

The TG and DT curves of the Th(IV) complexes of PMSO do not show the presence of water. In the DT curve of $[Th(PMSO)_6](ClO_4)_4$, one sharp exothermic peak at *ca* 202°C is obtained. At this temperature the compound **decomposes violently due to the oxygen content of the perchlorate group.**[24]—**Caution.** TG analysis of that complex shows that it is stable up to 195°C, beyond which the decomposition starts and is completed at *ca* 510°C. At this temperature the residual mass corresponds to ThO_2. In the halo complexes, *i.e.* chloro, bromo and thiocyanato complexes the decomposition process is completed in two steps. In the first step, the complexes lose both the ligand molecules as shown by the break in the TG curve and the endo peak in the DT curve. The final product is oxohalide in these cases. In the nitrato complex the two coordinated ligands are lost between 210 and 280°C and finally at *ca* 505°C, metal oxide is obtained as an end product.

The thermograms of the uranyl(VI) complexes indicate virtually no change in weight up to 175°C. At 175–240°C, a loss of 27–31% is observed which corresponds to a loss of 1.5 mol of ligand, PMSO, followed by a further loss of 37–41° at 265–340°C showing the complete loss of PMSO molecules leaving a residue of UO_3. The oxide U_3O_8 was finally formed at *ca* 610°C. Above this temperature there is no observable change in weight.[25]

Stereochemistry of the complexes

(a) *Thorium*(IV) *complexes.* The conductance and molecular weight data concluded that chloro, bromo and thiocyanato complexes are non-electrolytes and hence all the anionic ligands are present in the coordination sphere, but in the iodo complex, the two iodine atoms and in the perchlorate complex, all the four perchlorate groups are present outside the coordination sphere. Hence the coordination number six has been suggested in these complexes. In the $[Th(NO_3)_4(PMSO)_2]$ complex the presence of four bidentate nitrate groups and the additional two unidentate PMSO molecules produces a coordination number of ten for the thorium(IV) atoms.[26]

(b) *Uranyl*(VI) *complexes.* The complex $[UO_2(NO_3)_2(PMSO)_n]$ may be considered to have an eight-coordinated uranium atom with six-ligand atoms (two oxygens from the two ligand molecules and four oxygens from two bidentate nitrate groups) in a plane perpendicular to the linear OUO group.[27] In $[UO_2(CH_3COO)_2(PMSO)_2]$ the monodentate nature of PMSO and bidentate chelating acetato groups, an eight-coordinated (all oxygen atoms) structure with six oxygens (four from two bidentate chelating acetato ligands and two from monodentate organic ligand PMSO) around the linear uranyl group is assigned. In uranyl(VI) halo and thiocyanato complexes, the coordination number six has been suggested. In the perchlorato complex, the conductance and molecular weight data suggested the ionic nature of perchlorate ions and thus both the perchlorate ions are present outside the coordination sphere. In this complex, the uranium(VI) atom is surrounded by six oxygen atoms.

(*Received* 5 *June* 1991; *accepted* 5 *July* 1991)

Abstract—$Mo_2(O_2CMe)_4$ (**1**) reacts with the neat bidentate diamines $Me(H)NCH_2CH_2N(H)Me$ (*N,N'*-dmed), $H_2NCH_2CH_2CH_2NH_2$ (pda), $H_2NCH_2CH_2NMe_2$ (*N,N*-dmed), and $H_2NCH_2CH_2N(H)Me$ (*N*-med) to form the compounds $^1_\infty[Mo_2(O_2CMe)_4(N,N'\text{-dmed})]$ (**4**), $^1_\infty[Mo_2(O_2CMe)_4(pda)]$ (**5**), $\{[Mo_2(O_2CMe)_3(N,N\text{-dmed})_2]^+[(O_2CMe)]^-\}_2$ (**6**), and $\{[Mo_2(O_2CMe)_3(N\text{-med})_2]^+[(O_2CMe)]^-\}_2 \cdot N\text{-med}$ (**7**), respectively. Compounds **4**–**7** possess Mo—Mo quadruple bonds (Mo—Mo = 2.11(2) Å, ave) and weak axial Mo—N bonds (Mo—N_{ax} = 2.7(1) Å, ave). Compound **4** exhibits a kinked, one-dimensional chain structure comprising $Mo_2(O_2CMe)_4$ units linked by *N,N'*-dmed ligands. The amine hydrogens are weakly hydrogen-bonded to adjacent O_2CMe oxygens (N···O = 3.09(9) Å). Compound **5** crystallizes in a linear one-dimensional chain structure with a four-fold disorder in the pda chain. Conversely, compounds **6** and **7** display structures resulting from acetate displacement from the Mo_2 centre. Each Mo atom possesses a chelating diamine with the —NH_2 group bound in the equatorial position previously occupied by the displaced acetate moiety. Two $[Mo_2(O_2CMe)_3(diamine)_2]^+$ units are linked together via hydrogen bonding between the equatorial —NH_2 diamine hydrogens and the oxygens of the displaced acetate groups. The polar monoamines $MeNH_2$ and NH_3 do not affect acetate displacement presumably due to their inability to overcome entropic effects of the bidentate acetate ligands. Compounds **4**–**7** expel the diamine ligands in the solid state and reform crystalline **1** (XRD). The temperatures of amine expulsions occur at or below the boiling points of the pure diamine liquids. Crystal data for **4** at 20°C: triclinic, $P\bar{1}$, a = 8.784(3); b = 12.945(6), c = 8.663(3) Å; α = 91.73(3)°, β = 97.23(3)°, γ = 101.45(4)°;

* Authors to whom correspondence should be addressed.

$V = 956.2$ Å^3, $d_{calc} = 1.79$ g cm^{-3} and $Z = 2$. For **5** at 25°C: tetragonal, $P4_2/m$, $a = 7.852(2)$ Å, $c = 14.382(2)$; $V = 886.7$ Å^3; $d_{calc} = 1.88$ g cm^{-3} and $Z = 2$. For **6** at −155°C: monoclinic, $P2_1/c$, $a = 14.367(2)$, $b = 10.011(4)$, $c = 17.246(7)$ Å; $\beta = 95.92(2)°$, $V = 2467$ Å^3, $d_{calc} = 1.627$ g cm^{-3} and $Z = 2$. For **7** at −95°C: triclinic, $P\bar{1}$, $a = 12.988(10)$, $b = 15.881(12)$, $c = 12.963(10)$ Å, $\alpha = 105.77(3)°$, $\beta = 101.83(4)°$, $\gamma = 81.95(3)°$, $V = 2508$ Å^3; $d_{calc} = 1.653$ g cm^{-3} and $Z = 2$.

The substitutional lability of carboxylate ligands in dinuclear tetracarboxylate complexes can be correlated with the M—M molecular orbital configuration and parallels the crystal field models describing ligand substitution at mononuclear centres.[1] We have recently been investigating the reactivity of $Mo_2(O_2CMe)_4$ (**1**) with pure amines in the absence of additional co-solvents to assess the factors affecting acetate displacement and the ligand/structure/reactivity relationships of the resulting complexes. Our previous studies involving reactions of **1** with ethylenediamine (en)[2] and tetramethylethylenediamine (tmed)[3] showed that two markedly different products were obtained with significantly different properties.[2–5] The non-polar tmed ligand reacts with **1** to form a weakly associated, one-dimensional polymer of formula $^1_\infty[Mo_2(O_2CMe)_4(tmed)]$ (**2**) comprising unperturbed Mo_2 units linked head-to-tail by tmed ligands as shown by structure **I**. The reaction between **1** and neat en, however, yields an unusual ion-paired complex of formula $[Mo_2(O_2CMe)_2(en)_4]^{2+}[(O_2CMe)_2]^{2-} \cdot$ en (**3**) in which two of the acetate ligands of the parent Mo_2 complex are displaced from the Mo_2 coordination sphere by two spanning en ligands. The displaced acetate ions are in turn hydrogen bonded to the amine hydrogens of the spanning en ligands. Two additional en ligands are axially coordinated as shown by structure **II** below. Both **2** and **3** thermally decompose in the solid state to reform crystalline **1** upon expulsion of the diamine ligands.[2,3] A similar thermal instability was noted for the py complex $Mo_2(O_2CMe)_4(py)_2$.[6,7]

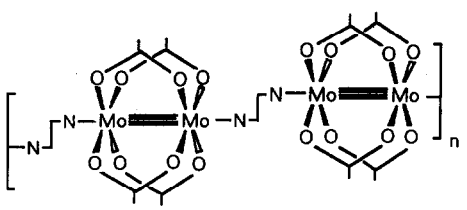
We are interested in determining what factors govern acetate displacement in these systems and how acetate displacement enhances reactivity at the Mo_2 (M≡M) centre. In this paper, we describe the reactions of **1** with bidentate diamines of polarity intermediate to those of tmed and en —namely Me(H)NCH$_2$CH$_2$N(H)Me (*N,N'*-dmed), H$_2$NCH$_2$CH$_2$CH$_2$NH$_2$ (pda), Me$_2$NCH$_2$CH$_2$NH$_2$ (*N,N*-dmed), and Me(H)NCH$_2$CH$_2$NH$_2$ (*N*-med). The latter two diamines react with **1** to form unusual coupled monocationic complexes of formula $\{[Mo_2(O_2CMe)_3(diamine)_2]^+[(O_2CMe)]^-\}_2$ whereas the former two produce one-dimensional chain structures similar to that observed for **2**. Polar monoamines NH_3 and $MeNH_2$ presumably form axial Lewis base adducts and do not affect acetate displacement.

EXPERIMENTAL

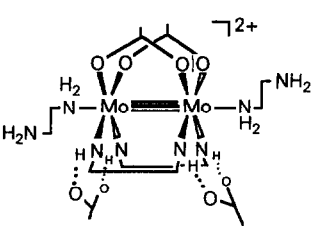
General procedures

All reactions and sample manipulations were conducted under N_2 (g) using standard Schlenk techniques and Vacuum Atmospheres Co. glovebox systems. The TGA data were obtained using a DuPont Thermal Analyst 2000 Thermogravimetric system. The samples were run under an He or Ar purge at a heating rate of 10°C min^{-1}. The powder X-ray diffraction data were collected using a Rigaku VS-DXR 3000 X-ray diffractometer. The $Mo_2(O_2CMe)_4$ residues in the TGA experiments were identified by comparisons of their X-ray diffractograms with that of an authentic sample. Elemental analyses were performed by Schwarzkopf Microanalytical Laboratories, Woodside, NY. All sample preparations for microanalysis were conducted in a glovebox.

Syntheses $Mo_2(O_2CMe)_4$ and $Mo_2(O_2CCF_3)_4$ were prepared by published methods.[8] *N,N*-Dimethylethylenediamine (*N,N*-dmed), 1,3-diaminopropane (pda), *N,N'*-Dimethylethylenediamine



I



II

(*N,N'*-dmed), and monomethylethylenediamine (*N*-med) were deoxygenated and stored over 4 Å molecular sieves under an N_2 atmosphere. NH_3 and $NMeH_2$ were distilled from Na immediately prior to use.

$^1_\infty[Mo_2(O_2CMe)_4(N,N'\text{-dmed})]$ (**4**). $Mo_2(O_2CMe)_4$ (100 mg, 0.234 mmol) and *N,N'*-dmed (2 cm^3) were combined in a Schlenk reaction vessel. The mixture was gently warmed until all the $Mo_2(O_2CMe)_4$ dissolved producing a pale yellow solution. After cooling to room temperature, the solution was filtered through a fine frit. Crystallization started immediately after filtration. The mixture was cooled to 5°C and, after 16 h, small yellow crystals of **4** separated from solution and were isolated by removing the solution and drying briefly *in vacuo* (crystalline yield: 72.7 mg, 0.141 mmol, 60%). Found: C, 27.9; H, 4.7; N, 5.4. Calc. for $Mo_2C_{12}H_{24}N_2O_8$: C, 27.9; H, 4.7; N, 5.4%.

$^1_\infty[Mo_2(O_2CMe)_4(pda)]$ (**5**). A procedure similar to that described for **4** was employed. $Mo_2(O_2CMe)_4$ (120 mg, 0.28 mmol) was dissolved in 2 cm^3 of pda and warmed to 50°C to produce a red solution. Pale yellow crystals of **5** were isolated and dried *in vacuo* (crystalline yield: 46 mg, 33%). Found: C, 26.4; H, 4.4; N, 5.4. Calc. for $Mo_2C_{11}H_{22}N_2O_8$: C, 26.3; H, 4.4; N, 5.6%.

$\{[Mo_2(O_2CMe)_3(N,N\text{-dmed})_2]^+[(O_2CMe)]^-\}_2$ (**6**). To a vial in the drybox was added $Mo_2(O_2CMe)_4$ (100 mg, 0.23 mmol) and *N,N*-dmed (2 cm^3). The solution was warmed to 50°C producing a light orange solution. The mixture was cooled to room temperature and concentrated to *ca* 1 cm^3 total volume and filtered. After 12 h, light orange crystals of **6** were separated from the solution and were isolated by filtration (crystalline yield: 86 mg, 62%). The crystals used in the X-ray study were not subjected to vacuum due to the ease of solvent loss from this complex. Found: C, 31.7; H, 6.2; N, 9.3. Calc. for $Mo_2C_{16}H_{36}N_4O_8$: C, 31.8; H, 6.0; N, 9.3%.

$\{[Mo_2(O_2CMe)_3(N\text{-med})_2]^+[(O_2CMe)]^-\}_2 \cdot$ N-med (**7**). A 20 cm^3 glass vial was charged with $Mo_2(O_2CMe)_4$ (100 mg, 0.23 mmol) and *N*-med (2 cm^3) in the drybox. The mixture was warmed to *ca* 50°C producing an orange solution. The solution was slowly cooled to room temperature and concentrated *in vacuo* to *ca* 1 cm^3 total volume. After 12 h, orange cube-shaped crystals separated from solution and were isolated by filtration (crystalline yield: 80 mg, 56%). The crystals used in the X-ray study were not subjected to vacuum due to the ease of solvent loss from this complex. Found: C, 30.3; H, 6.3; N, 11.6. Calc. for $Mo_2C_{15.5}H_{36}N_5O_8$: C, 30.4; H, 5.9; N, 11.4%.

$Mo_2(O_2CMe)_4 + NH_3$ *and* $MeNH_2$. In a typical experiment, $Mo_2(O_2CMe)_4$ (100 mg, 0.23 mmol) was placed in a 9-mm pyrex tube that was fitted with a Cajon vacuum adaptor. The tube was then attached to a vacuum line and evacuated. Gaseous NH_3 was then condensed onto Na in a 250 cm^3 three neck flask fitted with a dry ice/acetone condenser and refluxed for *ca* 30 min. The characteristic blue solution was observed. The amine (*ca* 4 cm^3) was then distilled into the pyrex tube charged with $Mo_2(O_2CMe)_4$. The tube was then frozen at −198°C, evacuated, and sealed with a torch. The mixture was warmed to room temperature *behind a shield in a hood* whereupon the solution turned pale yellow. Upon warming to 60°C, the solution turned golden yellow. After 24 h at 60°C, the mixture was cooled to −15°C for 1 week during which time chunky yellow crystals formed. Attempts to isolate the crystals by crushing the pyrex tube inside a piece of tygon tubing and allowing the NH_3 to evaporate under N_2 at 0°C were unsuccessful. The crystals decomposed to powdery yellow $Mo_2(O_2CMe)_4$ (XRD) before they could be isolated. Attempts to allow the NH_3 to evaporate in the air resulted in a brown–black residue.

$Mo_2(O_2CCF_3)_4 + NH_3$. The procedure described for $Mo_2(O_2CMe)_4 + NH_3$ was employed. Upon thawing, the $NH_3/Mo_2(O_2CCF_3)_4$ solutions turned bright red. The colour faded to orange red upon warming to room temperature. No solids were isolated from these reactions.

Crystallography

Complete listings of fractional coordinates and anisotropic thermal parameters, bond distances and angles, full crystallographic summaries and a listing of observed and calculated structure factors for **4**, **5**, **6**, and **7** have been deposited with the Editor as supplementary data.*

$^1_\infty[Mo_2(O_2CMe)_4(N,N'\text{-dmed})]$ (**4**). A pale yellow crystal was glued inside a glass capillary and sealed under N_2. Cell constants and an orientation matrix were obtained from least-squares refinement using 23 setting angles between 6° and 23° in 2θ. No systematic absences or symmetry were observed suggesting a triclinic space group. Subsequent solution and refinement of the structure in space group $P\bar{1}$ (#2) confirmed the choice.

Of the 4390 reflections collected between 5° and 54° in 2θ, 3946 were unique. Only the 2678 reflections with $I > 3\sigma(I)$ were used in the solution and

* Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre for inclusion in their Data Base. Copies are also available, on request, from the Editor at Indiana University.

refinement of the structure. Lorentz and polarization corrections were applied. The data were corrected for decay but no absorption correction was applied. The two Mo atoms were located using direct methods (MULTAN 78). The remaining atoms were located using a combination of difference Fourier syntheses and full-matrix least-squares refinements. A few of the hydrogen atoms were visible in the later difference maps and the remainder were placed at idealized positions with d(C—H) = 0.95 Å and d(N—H) = 0.92 Å. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms included as fixed atom contributors in the final cycles of refinement.

The final difference map was essentially featureless showing three peaks of approximately 1 e Å^{-3} around an acetate oxygen. No other peaks were observed above background. The final residuals were $R(F) = 0.055$ and $R_w(F) = 0.070$.

$^{1}_{\infty}$[$Mo_2(O_2CMe)_4$(pda)] (**5**). A well-formed yellow crystal of approximate dimension 0.25 × 0.25 × 0.30 mm was mounted under nitrogen inside a capillary which was then sealed with epoxy resin. The cell constants and orientation matrix for data collection were based on 25 carefully centred reflections in the range $20° < 2\theta < 30°$. Acceptable ω scans of some strong low angle reflections were obtained. ω–2θ scans over the 2θ range 4.5–65° produced 1678 unique reflections, of which 1163 ($I > 3\sigma(I)$) were used for structure refinement. The data were consistent with the tetragonal space groups $P4_2$ and $P4_2/m$. Successful solution and refinement of the structure in $P4_2/m$ (no. 84) confirmed that the centric space group was the correct choice. The structure was solved by a combination of direct methods and heavy atom Fourier techniques (Siemens SHELXTL PLUS crystallographic package). Full-matrix least-squares refinement was carried out with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atoms were placed in calculated positions. Due to positional disorder, C(3) (two-fold disordered) and C(4) (four-fold disordered) were assigned partial structure occupancies of 50 and 25%, respectively, and the C—N and C—C distances fixed at idealized values [C—C = 1.54 Å, C—N = 1.45 Å]. Refinement converged at $R = 0.0466$ and $R_w = 0.0496$. The maximum shift/ESD in the last cycle of refinement was less than 0.02 and the maximum residual electron density in the final difference Fourier map was <0.85 e Å^{-3}. No absorption correction was applied.

{[$Mo_2(O_2CMe)_3$(N,N-dmed)$_2$]$^+$[(O_2CMe)]$^-$}$_2$ (**6**). A suitable crystal was located and transferred to the goniostat using inert atmosphere handling techniques and cooled to −155°C for characterization and data collection. General operating conditions have been described elsewhere.[9]

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences uniquely determining the space group as the monoclinic $P2_1/c$. Subsequent solution and refinement of the structure confirmed this choice.

Data were collected using a continuous θ–2θ scan with fixed backgrounds. Of the 5373 total reflections collected in the range $6° < 2\theta < 45°$, 3227 were unique and the 2710 with $I > 2.33\sigma(I)$ were used in the refinement of the structure. Lorentz and polarization corrections were applied but an absorption correction was not necessary and not applied.

The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. A difference Fourier synthesis revealed the location of some, but not all, hydrogen atoms. All hydrogen atom positions were therefore calculated using idealized geometries and d(C—H) = 0.95 Å. These calculated positions were fixed for the final cycles of refinement. A final difference Fourier was featureless, with the largest peak being 0.65 e Å^{-3}. The final residuals were $R(F) = 0.064$ and $R_w(F) = 0.066$.

{[$Mo_2(O_2CMe)_3$(N-med)$_2$]$^+$[(O_2CMe)]$^-$}$_2$·N-med (**7**). A suitable crystal was located and transferred to the goniostat using inert atmosphere handling techniques and cooled to −95°C for characterization and data collection. General operating conditions have been described elsewhere.[9] Initial attempts to cool the sample to lower temperatures resulted in a catastrophic phase transition.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with no symmetry or systematic absences, indicating a triclinic space group. Subsequent solution and refinement of the structure confirmed the centrosymmetric $P\bar{1}$.

Data were collected in the usual manner using a continuous θ–2θ scan with fixed backgrounds. Data were reduced to a unique set of intensities and associated sigmas. Lorentz and polarization corrections were applied. No absorption correction was performed. A total of 10,552 reflections were collected; of which 6574 were unique. Only the 5524 unique reflections with $I > 2.33\sigma(I)$ were used in the solution and refinement of the structure.

The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. A difference Fourier synthesis revealed the location of some, but not all, hydrogen atoms. All hydrogen atoms positions were therefore calculated using idealized geometries and d(C—H) =

0.95 Å. These calculated positions were fixed for the final cycles of refinement. There were eight peaks in the latter difference maps that corresponded to the disordered *N*-med solvate molecule. These peaks were all refined as carbon atoms and included as fixed atom contributors in the final cycles of refinement. A final difference Fourier was featureless, with the largest peak being 0.45 e A^{-3}. The final residuals were $R(F) = 0.051$ and $R_w(F) = 0.055$.

RESULTS

Syntheses

$Mo_2(O_2CMe)_4$ dissolves in neat diamines *N,N'*-dmed and pda to form yellow or red–yellow solutions that, upon concentration, produce air-sensitive, pale yellow crystals of $^1_\infty[Mo_2(O_2CMe)_4(\text{diamine})]$ complexes [where diamine = *N,N'*-dmed (**4**); pda (**5**)] in 60 and 33% yields, respectively (eq. 1). Compounds **4** and **5** exhibit chain structures (Figs 1 and 2) and have been characterized by thermal gravimetric analysis (TGA), IR, elemental analysis and single-crystal X-ray diffraction.

$$Mo_2(O_2CMe)_4 + \text{heat diamine} \rightarrow {}^1_\infty[Mo_2(O_2CMe)_4(\text{diamine})] \quad (1)$$

(**4**) diamine = *N,N'*-dmed

(**5**) diamine = pda

The diamines *N,N*-dmed and *N*-med react

with $Mo_2(O_2CMe)_4$ upon gentle warming (*ca* 50°C) to form clear, pale orange solutions. Upon cooling to 30°C, air-sensitive pale orange–yellow crystals of formula $\{[Mo_2(O_2CMe)_3(diamine)_2]^+[(O_2CMe)]^-\}_2 \cdot x$ diamine precipitate from solution [where diamine = *N,N*-dmed; $x = 0$, (**6**); diamine = *N-med*, $x = 1.0$, (**7**)] in 62 and 56% yield, respectively (eq. 2).

$$Mo_2(O_2CMe)_4 + \textit{neat}\ Me(R)NCH_2CH_2NH_2 \rightarrow \{[Mo_2(O_2CMe)_3(Me(R)NCH_2CH_2NH_2)_2]^+[(O_2CMe)]^-\}_2 \cdot xMe(R)NCH_2CH_2NH_2 \quad (2)$$

(**6**) *N,N*-dmed (R = Me), $x = 0$

(**7**) *N*-med (R = H), $x = 1.0$.

Compounds **6** and **7** have similar structures comprising two Mo_2 units linked together via hydrogen bonding (Figs 3 and 4, respectively) and will be discussed in detail in the next section. Both compounds are air sensitive and decompose at room temperature even when stored under an inert atmosphere. The complexes have been characterized by TGA, IR, elemental analysis and single crystal X-ray diffraction.

$Mo_2(O_2CMe)_4$ also dissolves in liquid ammonia (*ca* 5 mg cm^{-3} at 25°C) and liquid $MeNH_2$ (*ca* 12 mg cm^{-3}) to form golden yellow solutions that yield large, air-sensitive, chunky crystals upon cooling to −15°C. When the solvent is removed (evaporated) under N_2 at 0°C, the crystals decomposed almost instantly leaving powdery $Mo_2(O_2CMe)_4$. The yel-

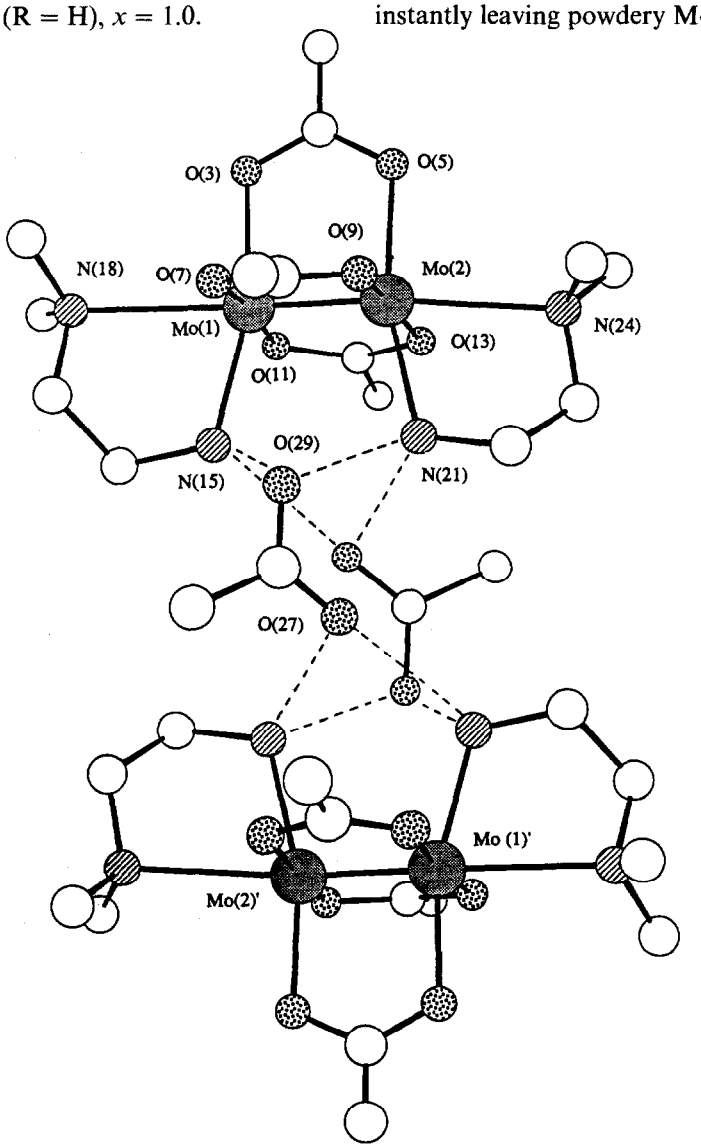

Fig. 3. Ball-and-stick representation* of the $\{[Mo_2(O_2CMe)_3(N,N\text{-dmed})_2]^+[(O_2CMe)]^-\}_2$ complex (**6**). All hydrogen atoms have been omitted for clarity. The dotted lines denote N—H···O bonding interactions.

* See footnote to p. 2577.

low crystals are presumably axial bis-amine adducts of formula $Mo_2(O_2CMe)_4L_2$ [where $L = NH_3$, $MeNH_2$] but are too unstable to isolate [cf. $Mo_2(O_2CMe)_4(py)_2$].[6,7] Heating the solutions to 60°C did not affect a colour change.

$Mo_2(O_2CCF_3)_4$ readily dissolves in liquid ammonia (*ca* 30 mg cm^{-3} at 25°C) forming bright red solutions at −77°C that fade to orange–red at room temperature. No products have been isolated from these reactions.

Solid state structures

A ball-and-stick drawing of the *N,N'*-dmed chain complex $^1_\infty[Mo_2(O_2CMe)_4(N,N'\text{-dmed})]$ (**4**) is shown in Fig. 1. A summary of the crystallographic data is given in Table 1 and selected bond distances and angles are given in Table 2.

The one-dimensional chain structure of **4** consists of $Mo_2(O_2CMe)_4$ units linked head-to-tail by axially bound *N,N'*-dmed ligands. As in the related $^1_\infty[Mo_2(O_2CMe)_4(tmed)]$ complex **2**,[3] the $Mo_2(O_2CMe)_4$ fragment of **4** is virtually unperturbed by the axial amine ligands with an Mo—Mo distance of 2.101(1) Å (ave) and Mo—O distances of 2.12(2) Å (ave). For comparison, the Mo—Mo and Mo—O distances in the parent complex **1** are 2.093(1) Å and 2.119(5) Å (ave), respectively.[10] The axial Mo—N contacts in **4** are characteristically long at 2.69 Å (ave) [Mo(1)—N(1) = 2.73(1) Å,

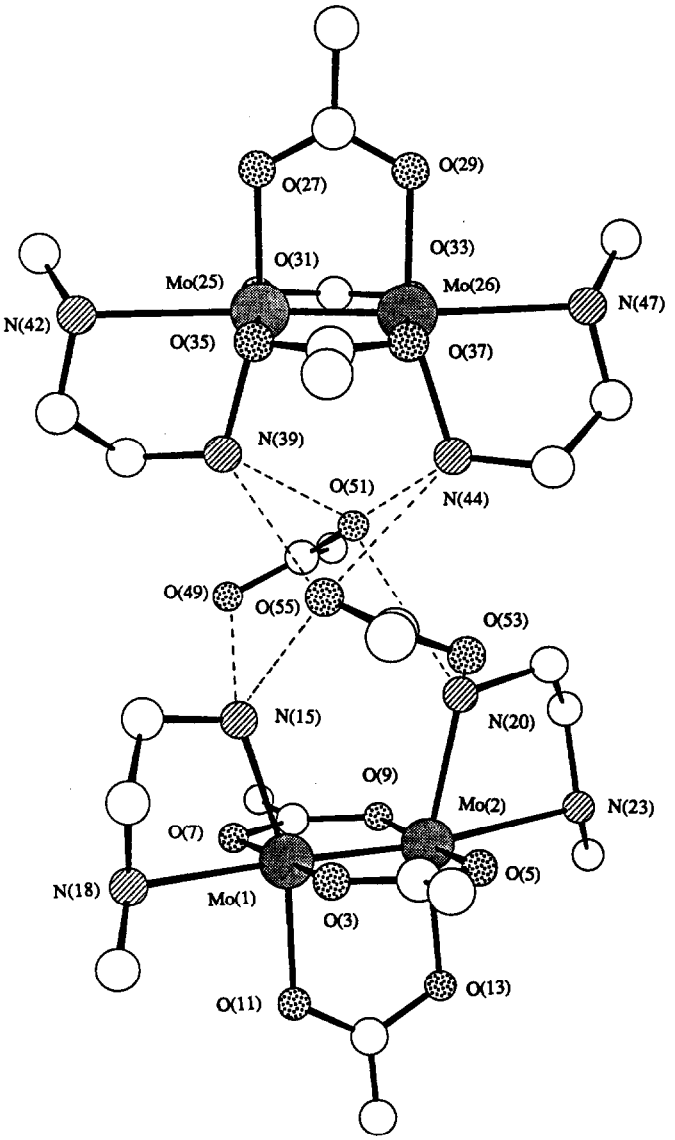

Fig. 4. Ball-and-stick representation* of the $\{[Mo_2(O_2CMe)_3(N\text{-med})_2]^+[(O_2CMe)]^-\}_2 \cdot N\text{-med}$ complex (**7**). All hydrogen atoms have been omitted for clarity. The dotted lines denote N—H···bonding interactions.

* See footnote to p. 2577.

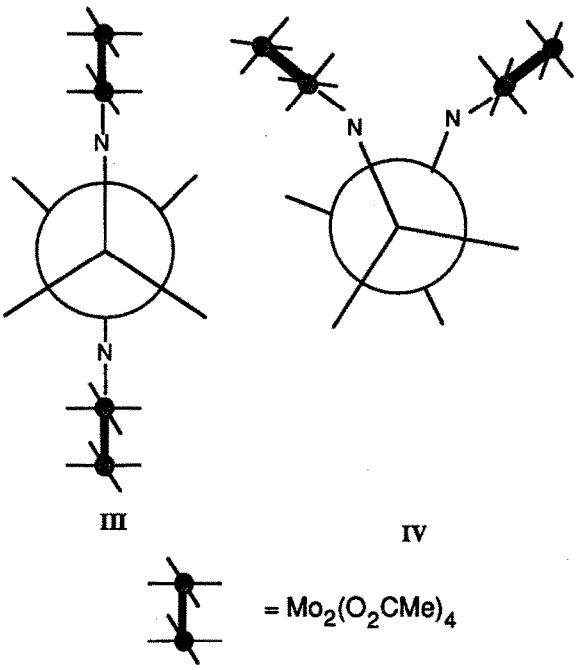
longer than normal,[12] these hydrogen bonding interactions impart a kink in chain structure that effectively doubles the unit cell relative to the tmed complex **2**. The structural differences between **2** and **4** are best illustrated by examining Newman projections of the two complexes viewed down the ethylene C—C bonds of the diamine backbones. The tmed complex **2** adopts the more stable *anti* conformation **III** which maximizes the distance between neighbouring Mo_2 units. Compound **4**, however, adopts a *gauche* conformation, **IV**, to bring the amine hydrogens and the acetate oxygens within hydrogen bonding distances. The conformational strain that results from the steric interaction of the two [NMe(H)Mo_2] groups is apparently compensated by the formation of the two hydrogen bonds—even though the interactions appear to be weak.



A ball-and-stick drawing of $^1_\infty[Mo_2(O_2CMe)_4(pda)]$ (**5**) is shown in Fig. 2 and a listing of selected bond distances and angles is given in Table 3. A summary of the crystallographic data is given in Table 1.

Compound **5** adopts a chain structure similar to that observed for the tmed complex **2**. The complex is tetragonal, space group $P4_2/m$, with Mo(1) and N(1) located in the (001) mirror plane. There is a two-fold disorder of C(3) about the mirror plane and a four-fold disorder of C(4) about the crystallographic inversion centre at 1/2, 1/2, 0 and (001) mirror plane. The rest of the complex was well behaved with typical Mo—Mo, Mo—O and O—C bonds and a characteristically long Mo—N bond length of 2.636(11) Å.

Ball-and-stick drawings of the *N,N*-dmed complex (**6**) and *N*-med complex (**7**) are shown in Figs 3 and 4, respectively. Selected bond distances and angles are given in Table 4 and 5. Summaries of the crystallographic data are presented in Table 1.

The gross structural features of compounds **6** and **7** are quite similar. Compound **6** is monoclinic, space group $P2_1/c$, with a crystallographic inversion centre that relates the two Mo_2 fragments within the Mo_4 core. Compound **7**, however, crystallizes in the triclinic space group $P\bar{1}$ and contains the entire Mo_4 complex in the asymmetric unit. With the exception of the methyl groups on the *N*-med ligands and the relative conformations of one of the chelate rings, the two Mo_2(*N*-med)$_2$ fragments are related by a pseudo centre of inversion. The lattice of the *N*-med complex **7** is also solvated with *ca* one disordered *N*-med molecule per Mo_4 formula unit.

Both **6** and **7** contain two Mo_2 subunits with Mo—Mo quadruple bonds [Mo—Mo = 2.12(1) Å (ave)] and three spanning acetate ligands with typical Mo—O distances [Mo—O = 2.12(1) Å (ave)].[13] Each metal atom possesses a chelating diamine ligand that occupies one axial [Mo—N = 2.63(3)

Å (ave)] and one equatorial [Mo—N = 2.23(1) Å (ave)] site. The axial Mo—N contacts are long relative to the equatorial Mo—N bonds and show slight deviations from linearity [Mo—Mo—N ≈ 170°] but are somewhat shorter than the axial Mo—N contacts in related compounds [cf. 2.68(4) Å in **4**, 2.7(2) Å in **3**, and 2.73(1) Å in **2**].[2,3] The equatorial Mo—N bond distances are typical for Mo—N dative bonds [cf. 2.22(2) Å in **3**] but the nitrogens are bent out of the equatorial plane. This distortion is illustrated by obtuse Mo—Mo—N_{eq} bond angles [104(2)° for **6** and 105(2)° for **7**] relative to the nearly ideal 91(1)° (ave) Mo—Mo—O angles observed for the coordinated acetates.

In **6** and **7**, the acetate ions that were displaced from the Mo_2 coordination spheres are hydrogen bonded to the NH_2 hydrogens of the diamine ligands. Four NH_2 groups and two acetate ions form a hydrogen bonding network that links the two Mo_2 subunits together. In compound **6**, the four Mo atoms are rigorously coplanar due to the crystallographic inversion centre whereas the two Mo_2 units in **7** are twisted relative to each other (dihedral Mo—Mo—Mo—Mo = 19.3°) producing a "cogging" effect. As a result, the Mo_2 moieties are closer together in **7** (Mo_2 midpoint to Mo_2 midpoint = 7.96 Å) than in **6** (Mo_2 midpoint to Mo_2 midpoint = 8.84 Å).

The hydrogen bonding networks in **6** and **7** are also somewhat dissimilar. In **6**, the displaced acetate ion O—O vectors are perpendicular to the Mo_2 vectors. This arrangement allows each oxygen atom to form two N—H···O hydrogen bonds (N···O separations less than 3.0 Å). Both N—H···O bonds to a given oxygen involve equatorial amine hydrogens on the same Mo_2 fragment. In contrast, the O—O vectors in **7** are twisted towards a parallel orientation relative to the Mo_2 fragments. This conformation allows one oxygen on each displaced acetate to form three N—H···O hydrogen bonds whereas the other oxygen only forms one. All significant N···O contacts are between 2.95 and 3.1 Å except one long contact of 3.16(2) Å involving N(39) and O(51) (see Tables 4 and 5).

Interestingly, the least Lewis basic nitrogens of the diamines, the NH_2 groups, occupy the equa-

torial positions in both **6** and **7**. Intuitively, one might expect the more Lewis basic, alkylated nitrogens (—NMeH for *N*-med, —NMe_2 for *N*,*N*-dmed) to occupy the equatorial positions where strong metal–ligand interactions occur and maximum Mo—N bonding could be realized.[1] However, if the —NH_2 groups were removed from the equatorial positions, the hydrogen-bonding network that couples the two Mo_2 fragments together would be compromised.

Thermal decomposition studies

Crystalline samples of **4**, **6** and **7** decompose thermally, in inert atmospheres, to form crystalline $Mo_2(O_2CMe)_4$ at temperatures less than 120°C. TGA studies showed diamine expulsions at temperatures at or below the boiling points of the pure diamine ligands.* In addition, diamine loss from the *N*-med complex **7** occurs in two steps, whereas the two dmed complex **4** and **6** show single step diamine losses (see Figs 5 and 6). Powder X-ray diffractograms of the brown–yellow 120°C

* Boiling points of the diamine ligands found in the **4**, **6** and **7** and the corresponding TGA expulsion temperatures (first derivative maximum) in parentheses: *N*,*N*-dmed, 104–106°C (98°C); *N*,*N*′dmed, 119°C (105°C); *N*-med, 114–116°C (110°C, ave).

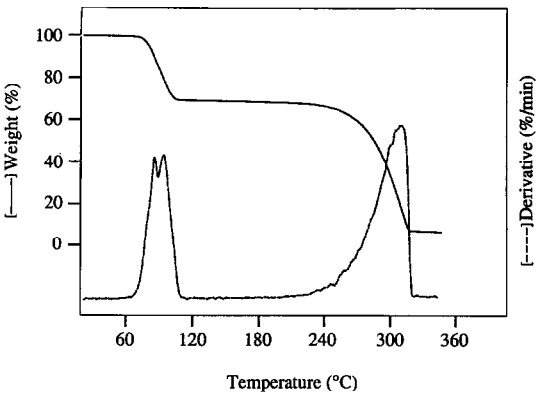

Fig. 5. TGA trace (solid line) and first derivative (dotted line) for the $\{[Mo_2(O_2CMe)_3(N\text{-med})_2]^+[(O_2CMe)]^-\}_2 \cdot N$-med complex (7) showing the two-step N-med loss.

residues from the TGA experiments showed only $Mo_2(O_2CMe)_4$. The slight discolouration [$Mo_2(O_2CMe)_4$ is pale yellow] is likely due to the partial oxidation of the air-sensitive amine complexes during TGA sample preparation, which is conducted in the air. Small amounts of an amorphous black residue (<15%) remain in the TGA pan after sublimation of the $Mo_2(O_2CMe)_4$ is complete ($T > 300$°C). As previously noted,[2] slower heating rates seem to increase the amount of final residue produced. The identity of this material is currently unknown.

The two-step N-med loss during the thermal treatment of **7** suggests that the solvate molecule and coordinated ligands are expelled separately. It is tempting to speculate that the solvate N-med molecule might be expelled before the coordinated N-med ligands, but we currently do not have quantitative data to support this hypothesis. However, a similar three-step diamine elimination was observed from the en complex **3**, which has two types of en ligands as well as an en solvate molecule.[2] The number of N-med solvate molecules in the lattice of the N-med complex **7** was determined by elemental analysis (one N-med per Mo_4), although TGA studies suggested only *ca* 0.7 N-med solvate molecules per Mo_4 unit. The lower N-med content observed in the TGA experiments probably results from partial desolvation of the complex during sample preparation.

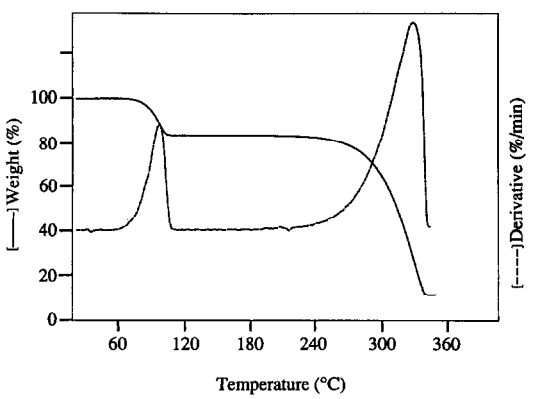

Fig. 6. TGA trace (solid line) and first derivative (dotted line) for the $^1_\infty[Mo_2(O_2CMe)_4(N,N'\text{-dmed})]$ complex (**4**) showing the simple one-step diamine elimination processes.

Table 6. Selected IR data for compounds **4**, **5**, **6** and **7**

Compound	ν_{asym}(OCO) (cm^{-1})	ν_{sym}(OCO) (cm^{-1})
4	1530	1429
5	1530	1432
6	1582, 1527	1430, 1383
7	1569, 1529	1430, 1387

It is interesting to note that the displaced acetate ions in **6** and **7** must migrate *ca* 4 Å to recoordinate to the Mo_2 centre during the amine expulsion process. A similar phenomenon occurs in the thermal decomposition of **3**.[2]

The thermal behaviour of **5** appears to follow the same decomposition pathway but was not studied in detail.

IR spectroscopic studies

The IR bands for the acetate O—C—O vibrations from solid state samples (KBr pellets) are listed in Table 6. For the coupled monocations **6** and **7**, two sets of acetate vibrations are observed which correspond to the two types of acetate moieties present in the complexes—coordinated and displaced. The chain complexes **4** and **5**, however, show only one set of acetate bands which is consistent with the presence of only bound acetate ligands.[2,3,13]

DISCUSSION

Pale yellow crystals of the weakly associated one-dimensional chain complexes $^1_\infty[Mo_2(O_2CMe)_4$(diamine)] are formed in good yield [where diamine = N,N'-dmed (**4**); pda (**5**)] from concentrated solutions of $Mo_2(O_2CMe)_4$ (**1**) dissolved in the respective pure diamine. In contrast, solutions of **1** dissolved in N,N-dmed and N-med precipitate monocationic complexes that are coupled, via hydrogen bonding, to form the tetrameric

compounds **6** and **7** of general formula $\{[Mo_2(O_2CMe)_3(diamine)_2]^+[(O_2CMe)]^-\}_2$. For each Mo_2 fragment, one acetate ligand is displaced by two diamine ligands in both of the latter complexes. Pale yellow crystals of *proposed* formula $Mo_2(O_2CMe)_4(L)_2$ [where $L = NH_3$ or $MeNH_2$] are formed from concentrated yellow solutions of $Mo_2(O_2CMe)_4$ dissolved in the neat amine [cf. $Mo_2(O_2CMe)_4(py)_2$],[6,7] however, these complexes were too unstable to fully characterize. The amines that form only axial adducts (tmed, *N,N'*-dmed, $MeNH_2$, and NH_3) form pale yellow solutions with $Mo_2(O_2CMe)_4$ whereas amines that displace acetates (en, *N*-med, *N,N*-dmed) form orange–red to red solutions. The red colour observed in the reaction of $Mo_2(O_2CMe)_4$ with pda suggests that extensive acetate displacement occurs in solution even though the resulting crystalline complex **5** has an unperturbed $Mo_2(O_2CMe)_4$ core. Similar colour changes occur in the reactions of $Mo_2(O_2CCF_3)_4$ with phosphine in which displaced carboxylates were observed.[14,15]

It is interesting to correlate the structures of compounds **2–7** with the functionalities of the diamine ligands. As the polarity and number of amine hydrogens increase in a diamine, the extent of acetate displacement increases. Of particular interest is the comparison of the *N,N'*-dmed and the *N,N*-dmed complexes **4** and **6**, respectively, in which acetate displacement is observed in the latter but not in the former. It appears that an $—NH_2$ function is necessary for acetate displacement in order to stabilize the displaced acetate ions in the solid state through hydrogen bonding. Furthermore, the $—NH_2$ functions prefer equatorial sites on the Mo_2 centre as maximum hydrogen bonding is realized in this conformation. Even though acetate displacement appears to occur in the $Mo_2(O_2CMe)_4$/pda system in solution, a suitable H-bonding network may not be available to stabilize the displaced acetates in the solid state and the axial adduct **5** is isolated instead.

A related reaction[16] between $Mo_2(O_2CCF_3)_4$ and 2,2′-bipyridyl yielded a charge-separated complex of proposed formula $[Mo_2(O_2CCF_3)_3(2,2'\text{-bipyridyl})]^+[O_2CCF_3]^-$ which would presumably have a core structure similar to those of **6** and **7** although hydrogen bonding and axial ligation would be absent in the former.

Entropic effects (ΔS_0) in the $Mo_2(O_2CMe)_4$–amine systems also appear to be important in acetate displacement in that methyl amine and liquid ammonia apparently do not affect acetate displacement even though they are as polar and would have Mo—N bond strengths similar to those found in **3**, **6** and **7**. It seems plausible that only the diamines capable of neutralizing the standard entropy effects of the bidentate, spanning acetate groups can promote acetate displacement.

PROTOLYTIC EQUILIBRIA IN AQUEOUS CONCENTRATED SOLUTIONS OF ORTHOPHOSPHATES

LIBERATO CIAVATTA,* MAURO IULIANO, RAFFAELLA PORTO and ERMANNO VASCA

Dipartimento di Chimica dell'Università, Via Mezzocannone, 4, 80134 Napoli, Italy

(*Received* 9 *November* 1990; *accepted* 4 *July* 1991)

Abstract—The protolytic equilibria, in solutions prepared to contain 3 M Na^+ ions by adding $NaClO_4$, have been studied at 25°C by potentiometric methods using glass or hydrogen half-cells. Most of the experiments (glass electrode) have been carried out in $Na(ClO_4, H_2PO_4)$ media where the phosphate molar concentration ranged from 0.1 to 3. A few experiments (hydrogen electrode) have been made in $Na(ClO_4, HPO_4)$ media at the phosphorus(V) levels of 0.3 and 1 M. The potentiometric data are consistent with the presence in solution of dimers, $H_n(PO_4)_2^{n-6}$, with n ranging from 1 to 6, as well as of the usual monomeric species. The formation constants are found to vary significantly as orthophosphates replace ClO_4^- ions of the medium. This phenomenon is ascribed to strong short-range interactions of the polar $H_2PO_4^-$ and HPO_4^{2-} ions with other species, even negatively charged ones, in evident contrast with the Brønsted principle.

For several metal orthophosphates, such as the Ca^{2+}, Mg^{2+}, Fe^{2+}, Zn^{2+} salts, which are of interest in geochemistry, oceanography, water pollution and other fields where phosphates are widely found and in large quantity, a low degree of complexation in solution is indicated by scanty and contradictory literature data.[1,2] This implies that in these systems equilibrium analysis, strictly correlated to the presence of detectable amounts of reaction products, can be reliably performed only considering concentrated reagent solutions. In this connection it is essential to establish the formation and equilibrium constants of the protolytic species that become important in phosphate solutions of concentration exceeding 0.1 M.

Though monomeric species prevail, there is some evidence by various authors, Table 1, that dimers may form in concentrated solutions. The main source of uncertainty that can be envisaged in the assessment of polynuclear complexes from the reviewed data in concentrated solutions, is the neglect of the effects of medium changes, occurring as inert ions of the medium are replaced for a large part by phosphate species. Since the polynuclear complexes are of low stability, even small medium changes may seriously influence their stoichiometry and formation constants. It was, therefore, thought worth a reinvestigation of the system by more appropriate experimental conditions and calculation procedures.

In this work the protolytic equilibria have been studied at 25°C by potentiometric titrations employing glass or hydrogen electrodes in cells without transference. All the solutions were prepared to contain 3 M Na^+ ions by adding $NaClO_4$. The measurements with the glass elecrode were carried out in $Na(ClO_4, H_2PO_4)$ media where the phosphorus(V) concentration ranged from 0.1 to 3 M. The experiments with the hydrogen half-cell were made in 0.3 and 1 M Na_2HPO_4. In order to avoid the implications connected with medium changes, data pertaining to a given phosphate level were considered separately according to the principle of the self-medium method.[11] Since glass and hydrogen electrodes cannot be calibrated in the absence of reaction products on the self-medium scale, formal standard potentials of the employed cells were adjusted simultaneously with other parameters (equilibrium constants) in the treatment of experimental data by minimizing procedures with a high-speed computer.

EXPERIMENTAL

(A) *Chemicals and analysis*

Stock solutions of *orthophosphoric acid*, prepared from a B.D.H. AnalaR product, were standardized gravimetrically, as $MgNH_4PO_4\cdot6H_2O$, by the method described by Winkler,[12] and potentiometrically by acid-base titration, using a glass electrode. Strong base was generated by constant-current coulometry. The potentiometric analyses were performed at 25°C with solutions made to contain 3 M $NaClO_4$. The presence of the inert electrolyte allowed the preliminary calibration of the apparatus in terms of concentrations. Since K_{a1} and K_{a2}, the first and second acid constant of H_3PO_4, are exactly known under the chosen experimental conditions,[13] the total phosphate concentration, C_P, could be calculated for each point of the titration from relationship (1) which was

$$C_P[1+(K_{a2}/[H^+]-[H^+]/K_{a1})/\{1+[H^+]/K_{a1}+K_{a2}/[H^+]\}] = [H^+]+C_B, \quad (1)$$

derived by assuming H_3PO_4 as monoprotic. C_B stands for concentration of strong base. It is apparent from (1) that the most accurate values of C_P can be evaluated from measurements in the vicinity of $[H^+] = (K_{a1}K_{a2})^{1/2}$, when the term in brackets approaches one and $[H^+]$ becomes sufficiently small compared with the strong base concentration. Values of C_P calculated in the $[H^+]$ range 2×10^{-3} to 10^{-5} M coincided to within 0.1% or better.

The results of analyses by the independent procedures agreed to within 0.1%.

Sodium dihydrogen phosphate, $NaH_2PO_4\cdot2H_2O$, Bakers p.a., was crystallized once from water. Stock solutions were analysed gravimetrically in two different ways: (a) as described for H_3PO_4 (b) by

drying at 120°C to constant weight. The results agreed to within 0.2%.

The level of protolytic impurities (H_3PO_4 or HPO_4^{2-}) contaminating this salt was ascertained potentiometrically with the procedure described above. An exactly known amount of $HClO_4$ was added to a 0.01 M NaH_2PO_4 solution and the excess of acid was back-titrated. The concentration of $HClO_4$ established potentiometrically coincided with that introduced to better than 0.1%. On the basis of this result we estimate the concentration of impurities introduced by NaH_2PO_4 3 molar to be less than 10^{-3} M.

Disodium hydrogen phosphate, $Na_2HPO_4 \cdot 12H_2O$, Bakers p.a., was recrystallized twice from water. The solutions were standardized gravimetrically, as described for NaH_2PO_4, and acidimetrically through potentiometric titrations to the $H_2PO_4^-$ equivalent point, using a glass electrode. The procedure illustrated for H_3PO_4 analyses was adopted to establish the end-point. The results by different methods of analysis coincided to within 0.1%.

Sodium perchlorate was obtained as described by Biedermann.[14] *Perchloric acid* solutions, prepared by dilution of a Merck p.a. product, were analysed with an accuracy of 0.1% using $KHCO_3$ and Tl_2CO_3 as standard and methyl red as visual indicator. *Sodium chloride*, Bakers p.a. and *sodium bromide*, Merck p.a., before use, were ignited at 360°C in Pt crucibles.

Nitrogen and *hydrogen* gases were taken from commercial cylinders and were passed through 1 M H_2SO_4, 1 M NaOH, 0.1 M Cr(II) chloride, water and 3 M $NaClO_4$.

(B) *Potentiometric measurements*

The experiments in $Na(ClO_4, H_2PO_4)$ media were carried out with cell (G)

$$-\text{Ag/AgCl/solution S/glass electrode}+ \quad \text{(G)}$$

where test solution S had the general composition in molar units: NaCl (0.02), $H_3PO_4(C_0)$, $NaH_2PO_4(C_1)$, $Na_2HPO_4(C_2)$, $NaClO_4(2.98-C_1-2C_2)$. The C_1 levels chosen were 0.1, 0.3, 1 and 3. In each run the total phosphate concentration, $C_P = C_o+C_1+C_2$, was kept constant, except for the highest level when the condition $C_P = 3+C_0-C_2$ was fulfilled. The quantity C_0-C_2 (the analytical concentration excess of hydrogen ions counting $H_2PO_4^-$ and H_2O as zero level) was made to vary by adding H_3PO_4 or Na_2HPO_4. To avoid large medium changes the C_0-C_2 values never exceeded the limits between 0.2 and −0.2 M.

During the measurements a vigorous stream of purified and presaturated nitrogen gas was led through S to preserve it from atmospheric contamination.

The EMF data of cell (G), E_G, as a function of C_0-C_2 are the basis of the calculations.

The measurements in $Na(ClO_4, HPO_4)$ solutions were made with cell (H)

$$-\text{Pt/H}_2\text{(g)/solution S*/AgBr/Ag}+ \quad \text{(H)}$$

where solution S* = $NaBr(C_{Br})$, $NaH_2PO_4(C_1)$, $Na_2HPO_4(C_2)$, $Na_3PO_4(C_3)$, $NaClO_4(3-C_{Br}-C_1-2C_2-3C_3)$. Owing to the limited solubility of Na_2HPO_4 the highest C_P in S* was 1. Values lower than 0.3 M were not included in the present study in consideration of little information on polynuclear species from dilute solutions.

In each titration the quantity C_1-C_3, the analytical concentration excess of hydrogen ions assuming HPO_4^{2-} and H_2O as zero level, was decreased stepwise by coulometric generation of OH^- ions. A known volume, V_o dm^3, of starting solution S_0^*: $NaBr(C_{Br}^0)$, $NaH_2PO_4(C_1^0)$, $Na_2HPO_4(C_2^0)$, $NaClO_4(3-C_{Br}^0-C_1^0-2C_2^0)$, prepared under an inert nitrogen atmosphere, formed the liquid phase of the electrolysis cell (E)

$$-\text{Pt/solution S}_0^*\text{/Ag}+ \quad \text{(E)}$$

and the acidity was decreased by connecting (E) to a constant-current supply. By assuming that only the following electrode reactions occur: $H_2O+e \rightarrow OH^- + (1/2)H_2(g)$ at the cathode and $Ag+Br^- \rightarrow AgBr+e$ at the anode, after the passage of w F, $[Br^-]$ and C_1-C_3 can be calculated as C_{Br}^0-w/V_0 and C_1^0-w/V_0, respectively. The calculations of the next section are founded on $E_H^*(C_1-C_3)$ data, where $E_H^* = E_H+0.05916\log([Br^-]p_{H_2}^{-(1/2)})$, E_H is the EMF of cell (H) and p_{H_2} is the partial pressure of hydrogen.

(C) *Apparatus*

During the EMF measurements the cell assembly was immersed in a silicone oil thermostat kept at 25.00±0.02°C. Ag–AgCl and Ag–AgBr electrodes were prepared according to Brown.[15] Glass electrodes, type EA 109 supplied by Metrohm, acquired a constant potential, within 10 min after the addition of reagents, which remained unchanged to $\pm 5\times10^{-5}$ V for several hours. Lightly platinized Pt nets served as hydrogen electrodes. They took as a rule more than 1 h to reach a steady potential which afterwards did not change by more than $\pm 5\times10^{-5}$ V for 12 h. A Pt gauze, boiled in 1:1 HNO_3, formed the cathode of cell (E).

The EMF values of (G) and (H), E_G and E_H respectively, were measured with a precision of 1×10^{-5} V by a computer controlled data acqui-

sition unit 3421 A, furnished by Hewlett–Packard. The constant-current source of the coulometric circuit was a 6186C DC, manufactured by Hewlett–Packard.

DATA AND CALCULATIONS

The experimental data $E_G((C_0-C_2), C_P)$ and $E^*_H((C_1-C_3), C_P)$, given in Tables 2 and 3, are the basis of the following treatment. First the measurements in $NaClO_4$–NaH_2PO_4 media are considered.

The EMF of cell (G) at 25°C can be written as in eq. (2)

$$E_G = E_{0G}+0.05916\log([Cl^-][H^+]y_H y_{Cl}) = E_{0G}+0.05916\log(K_{a1}[Cl^-][H_3PO_4] \times [H_2PO_4^-]^{-1}y_0 y_{Cl} y_1^{-1}), \quad (2)$$

in which E_{0G} is a constant in each run, K_{a1} is the first protolysis constant of H_3PO_4 and y stands for activity coefficient. y_0 and y_1 refer, respectively, to H_3PO_4 and $H_2PO_4^-$. The standard states are so chosen that the activity coefficients tend to unity as the composition of solution S approaches 3 M $NaClO_4$.

At a given C_P, since $(C_0-C_2)/[Na^+]$ never exceeded ± 0.07, the composition of the test solutions changed only slightly in the course of a titration. Consequently, we may regard it as a good approximation to assume the constancy of the activity coefficients. Thus, eq. (2) for any particular self-medium can be expressed as eq. (3)

$$E_G = E'_{0G}+0.05916\log[H^+] = E''_{0G}+0.05916\log([H_3PO_4]/[H_2PO_4^-]), \quad (3)$$

where E'_{0G} includes y_H, y_{Cl} and $[Cl^-] = 0.02$, whereas $E''_{oG} = E_{0G}+0.05916\log(K_{a1}[Cl^-]y_0 y_{Cl} y_1^{-1})$. The constants E'_{0G} and E''_{0G} are not directly determinable, since $[H^+]$ and $[H_3PO_4]/[H_2PO_4^-]$ are not explicitly expressible in function of analytical concentrations in a self-medium. They, however, can be estimated along with other parameters in the calculations by high-speed computer programs. It was found that E'_{0G} is strongly correlated with K_{a1} which is not known in the media in question. On the contrary, rapidly converging results could be arrived at by choosing the $[H_3PO_4]/[H_2PO_4^-]$ ratio as the independent variable.

By assuming that the reagents H_3PO_4 and $H_2PO_4^-$ form a series of complexes of general composition $(H_3PO_4)_p(H_2PO_4)_q^{q-}$, the analytical concentration excess of H^+, C_0-C_2, can be written as eq. (4), neglecting $[OH^-]$,

$$C_0-C_2 = [H^+]+\Sigma p[(H_3PO_4)_p(H_2PO_4)_q^{q-}] = [H^+]+\Sigma pK_{pq}[H_3PO_4]^p[H_2PO_4^-]^q y_0^p y_1^q y_{pq}^{-1}, \quad (4)$$

in which K_{pq} and y_{pq} stand, respectively, for the formation constant and for the activity coefficient of the (p, q) species. At a given phosphate level the activity coefficients are approximately constant and the equilibrium condition is described as well by the quotient Q_{pq} defined by (5)

$$Q_{pq} = K_{pq}y_0^p y_1^q y_{pq}^{-1}. \quad (5)$$

Introduction of $[H_3PO_4]$, expression (6) deduced from (3), into (4) yields (8)

$$[H_3PO_4] = [H_2PO_4^-]\,\text{antilog}((E_G-E''_{0G})/0.05916) = [H_2PO_4^-]\chi_0 x \quad (6)$$

$$\chi_0 = \text{antilog}(-E''_{0G}/0.05916) \quad (7)$$

$$C_0-C_2 = Q_{1,-1}\chi_0 x+\Sigma pQ_{pq}\chi_0^p x^p[H_2PO_4^-]^{(p+q)}. \quad (8)$$

Notice how H^+ in our symbolism is the $(1, -1)$ species with a formation constant $K_{1,-1}$ corresponding to the first protolysis constant of H_3PO_4.

From the stoichiometric condition one has finally

$$C_P = \Sigma(p+q)Q_{pq}\chi_0^p x^p[H_2PO_4^-]^{(p+q)}. \quad (9)$$

Values of (p, q) and of Q_{pq} for the predominating reaction products were determined by processing the experimental data with the generalized least-squares procedure Letagrop.[16] The sum (10), where

$$U = \Sigma(((C_0-C_2)-(C_0-C_2)_{calc})/(C_0-C_2))^2 \quad (10)$$

$(C_0-C_2)_{calc}$ is a value calculated with a given set of constants, was minimized. As adjustable parameters we considered the equilibrium constants as well as χ_0 for each titration. A satisfactory explanation of the data was found by assuming: H^+, HPO_4^{2-}, $H_6(PO_4)_2$, $H_5(PO_4)_2^-$, $H_4(PO_4)_2^{2-}$ and $H_3(PO_4)_2^{3-}$. Agreement factors of less than 0.5% were calculated with this scheme and gave a measure of the fit. Furthermore, the standard deviation of E''_{0G}, usually less than 10^{-4} V, matches well the reproducibility of the EMF of cell (G). On the other hand, significantly higher minima were found with other models including an equal number of species. The Q_{pq} values of Table 4a are averages from parallel runs. In the estimation of the uncertainties the accumulated errors arising from 3 times the standard deviation and from the highest deviations by the averages of Q_{pq}s found in various titrations, have all been taken into account.

Table 2. Survey of measurements in $NaClO_4$–NaH_2PO_4 media. E_G, the EMF of cell (G), in mV, as a function of the analytical concentration excess of H^+, C_0-C_2, at various C_P

(b) 537.77 (40.26); 539.89 (37.62); 542.00 (34.99); 544.20 (32.36); 546.21 (29.72); 548.48 (27.09); 551.07 (24.46); 553.86 (21.82); 556.79 (19.19); 560.10 (16.56); 563.59 (13.93); 567.41 (11.29); 571.61 (8.66); 576.19 (6.03); 580.97 (3.395); 583.81 (1.93); 586.11 (0.763); 592.56 (−2.16); 595.40 (−3.63); 600.28 (−6.26); 604.80 (−8.89); 609.01 (−11.52); 612.80 (−14.16); 616.26 (−16.79); 619.00 (−19.42); 621.82 (−22.05); 624.55 (−24.68); 627.05 (−27.32); 629.39 (−29.95); 634.00 (−35.21).

Concerning the interpretation of the $E_H^*((C_1-C_3))$ data we assumed as reagents $H_2PO_4^-$ and HPO_4^{2-} and a series of $(H_2PO_4)_q(HPO_4)_r^{(q+2r)-}$ species with equilibrium constants for their formation K'_{qr}. For a given C_P, taking as a good approximation the constancy of the activity coefficients, one has

$$E_H^* = E'_{0H} - 0.05916\log[H^+]$$
$$= E''_{0H} - 0.05916\log([H_2PO_4^-]/[HPO_4^{2-}]) \quad (11)$$

where E'_{0H} and E''_{0H} are constants. Furthermore,

0	(4.57)	(−0.2)		(1.2)	

the equilibrium condition is described also by the quotient Q'_{qr} defined in (12)

$$Q'_{qr} = K'_{qr} y_1^q y_2^r y_{qr}^{-1}, \qquad (12)$$

where y_{qr} and y_2 are the activity coefficients of the (q, r) species and HPO_4^{2-} respectively.

Values of E''_{0H} and of Q'_{qr} of the predominating complexes were sought for by minimizing the sum: $\Sigma(((C_1-C_3)-(C_1-C_3)_{calc})/(C_1-C_3))^2$, where $(C_1-C_3)_{calc}$ is a value calculated with a certain set of parameters. The results of computations, summarized in Table 4b, indicate the formation of $H_2(PO_4)_2^{4-}$ and $H(PO_4)_2^{5-}$ in addition to PO_4^{3-}, $H_4(PO_4)_2^{2-}$ and $H_3(PO_4)_2^{3-}$. The standard deviation of E''_{0H} amounted in any case to about 10^{-4} V which gives a measure of the agreement between the data and the proposed model.

In Figs 1, 2 and 3 the distributions of various species as a function of the analytical concentration excess of H^+ ions for three different C_P values are shown. Even at the lowest phosphate level investigated the dimers $H_5(PO_4)_2^-$ and $H_3(PO_4)_2^{3-}$ acquire concentrations of about 5% of C_P and are, consequently, not completely negligible.

Effect of medium changes on formation quotients

The variations of the equilibrium quotients in Table 4, as phosphate species replace ClO_4^- ions, are surprising and large according to the specific interaction theory, SIT,[17] founded on the Brønsted principle. This assumes as negligible short-range forces, and interaction coefficients between ions of the same charge sign. Consequently, since all the constants, except $Q_{1,-1}$ and Q_{20}, refer to equilibria among only anions, they should undergo no appreciable change at constant Na^+ concentrations and for the limited variations of ionic strength when $H_2PO_4^-$ is substituted by other phosphate species. This phenomenon led us to revise Brønsted's postulate. While for spherically symmetric ions, as Na^+, Ca^{2+}, Cl^-, ClO_4^-, the principle is strictly valid,

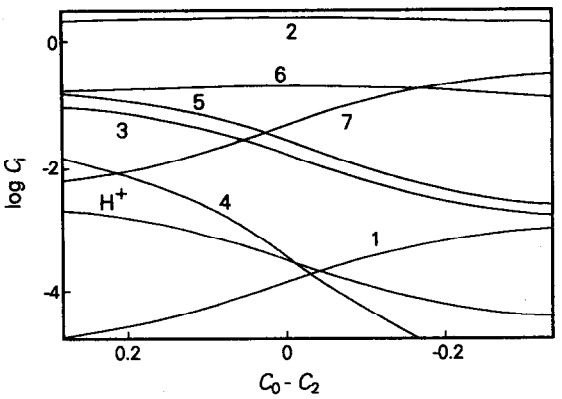

Fig. 2. Log c_i plotted as a function of the analytical concentration excess of H^+, C_0-C_2, for a 3 M $Na(H_2PO_4)$ medium with $C_P = 3+C_o-C_2$. The curves have been calculated with the quotients of the fourth row of Table 4a. Species and numbers as in Fig. 1.

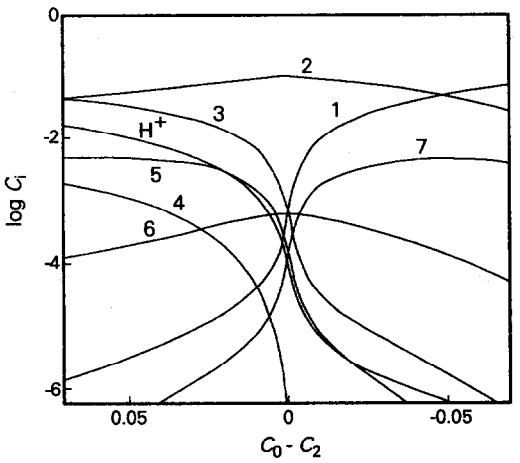

Fig. 1. Log c_i plotted as a function of the analytical concentration excess of H^+, C_0-C_2, for a 3 M $Na(ClO_4, H_2PO_4)$ medium with $C_P = 0.1$. The curves have been calculated with the quotients of the first row of Table 4a. Numbers refer to: HPO_4^{2-} (1); $H_2PO_4^-$ (2), H_3PO_4 (3); $H_6(PO_4)_2$ (4); $H_5(PO_4)_2^-$ (5); $H_4(PO_4)_2^{2-}$ (6); $H_3(PO_4)_2^{3-}$ (7).

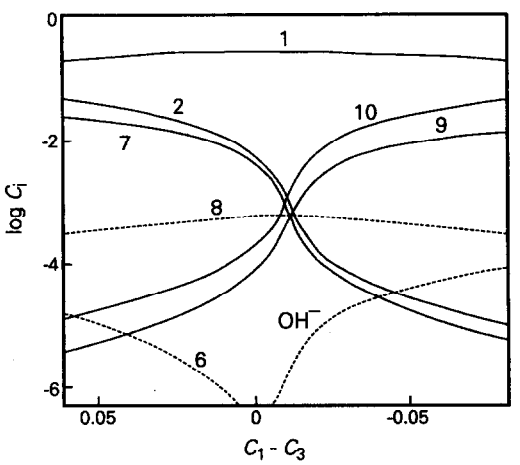

Fig. 3. Log c_i plotted as a function of the analytical concentration excess of H^+, C_1-C_3, in a 3 M $Na(ClO_4, HPO_4)$ medium with $C_P = 0.3$. The curves have been calculated with the quotients in the first row of Table 4b. Dotted curves have been traced by assuming the max values of Q'_{20} and Q'_{02}; the OH^- concentration has been estimated using $pK_w = 14.22$ and $pK_{a3}(H_3PO_4) = 10.85$ valid in 3 M $NaClO_4$. Species and numbers as in Fig. 1; in addition: $H_2(PO_4)_2^{4-}$ (8); $H(PO_4)_2^{5-}$ (9) and PO_4^{3-} (10).

it would apply not correctly for polar ions and molecules, as $H_2PO_4^-$ and HPO_4^{2-}, whose positive pole has the chance to come near a negatively charged ion. This is consistent with the tendency of $H_2PO_4^-$ to dimerize and to associate with HPO_4^{2-}. Thus short-range interactions set in to produce interaction coefficients significantly different from zero.

The remarkable effect on $Q_{-1,2}$ in $NaClO_4$–NaH_2PO_4 mixtures and on all the equilibria in Na_2HPO_4 media is an indication of a large interaction coefficient between $H_2PO_4^-$ and HPO_4^{2-}, and prompted the following estimation of its magnitude. Owing to the lack of information on several parameters necessary for a rigorous treatment, we made the approximations:

(i) pure NaH_2PO_4 solutions, though according to our findings contain a certain amount of $H_5(PO_4)_2^-$, $H_4(PO_4)_2^{2-}$ and $H_3(PO_4)_2^{3-}$, are assumed to be composed of Na^+ and $H_2PO_4^-$ ions;

(ii) ionic strength variations of $NaClO_4$–NaH_2PO_4 mixtures of constant total molarity, caused by the replacement of $H_2PO_4^-$ by phosphate ions of higher charge, are considered to be negligible.

For a "pure" 3 M NaH_2PO_4 solution, which is 3.41 molal as calculated from the density values compiled by Weast,[18] one finds, by introducing in eq. (5) of ref. 17 the osmoric coefficient, 0.691, listed by Robinson and Stokes,[19] an interaction coefficient of -0.057 molal^{-1}. This is related to interaction coefficients, b, of the constituent ions by means of (13):

$$-0.057 = b(Na^+, H_2PO_4^-) + (1/2)b(Na^+, Na^+) + (1/2)b(H_2PO_4^-, H_2PO_4^-). \quad (13)$$

If the Brønsted principle is valid $b(Na^+, Na^+) = b(H_2PO_4^-, H_2PO_4^-) = 0$. On the other hand, setting $b(Na^+, Na^+) = 0$ and $b(Na^+, H_2PO_4^-) = b(Na^+, ClO_4^-) \simeq 0$, in consideration of identical charges and comparable sizes, one gets $b(H_2PO_4^-, H_2PO_4^-) = -0.11$ molal^{-1}. The combination of this value with the dependence of the various Q_{pq} on the medium composition allows the estimation of other interaction coefficients and, consequently, of the activity coefficients.

A $NaClO_4$–NaH_2PO_4 mixture of constant total molarity has also a constant molality on account of the almost coincident densities of equimolar $NaClO_4$ and NaH_2PO_4 solutions. Thus, molal activity coefficients are practically equal to molar ones in our medium scale. Neglecting the effect of ionic strength variations, when $H_2PO_4^-$ ions are substituted by other phosphate species, one obtains from eq. (1) of ref. 17 for the activity coefficient of the i species:

$$\log y_i = (b(i, H_2PO_4^-) - b(i, ClO_4^-))1.16C_P, \quad (14)$$

where b is expressed in molal^{-1} and 1.16 is the molality/molarity ratio of the medium constituents. Setting $b(H_2PO_4^-, ClO_4^-) = 0$, $\log y_1 = -0.13C_P$. This and $b(Cl^-, H_2PO_4^-) = b(Cl^-, ClO_4^-) = 0$ allow an estimate of $\log y_0 = -0.13C_P$ from the variation of E''_{0G} with C_P. Introduction of y_1 and y_0 in the expression of $Q_{-1,2}$ yields finally $\log y_2 = 0.56\ C_P$. From the dependence of other equilibrium quotients on C_P we find: $\log y_H = -0.18C_P$; $\log y_{20} = -0.63C_P$; $\log y_{11} = -0.26C_P$; $\log y_{02} = -0.14C_P$; $\log y_{-1,3} = -0.22C_P$.

The most interesting result of the above computations is the large and positive value of $b(H_2PO_4^-, HPO_4^{2-}) = 0.48$ molal^{-1}. Evidently the ions come so near when forming $H_3(PO_4)_2^{3-}$ that appreciable repulsive short-range forces set in to yield a large interaction coefficient. On the contrary, negative coefficients for all the other interactions may suggest attractive forces prevailing over repulsive ones. Finally, the linear dependence on C_P of $\log y_i$ permits extrapolation of the various quotients to the inert 3 M $NaClO_4$. The extrapolated values are given in Table 4.

The following K_{a1} and K_{a2}/K_{a1} values ($K_{1,-1}$ and $K_{-1,2}$ in our terminology) have been determined under identical experimental conditions but with transference cells:

$-\log K_{a1}$	$-\log(K_{a2}/K_{a1})$	Authors
1.89(1)	4.38(1)	Baldwin and Sillén[13]
1.83(3)	4.41(4)	Pettersson[20]
1.88(5)	4.40(6)	Havel and Högfeldt[21]

The agreement with data of Table 4 is as good as can be expected, with the exception of K_{a1} proposed by Baldwin and Sillén. We have not been able to explain the discrepancy; probably the accuracy of this constant is overestimated.

The interpretation of data in $NaClO_4$–Na_2HPO_4 solutions is more complicated due to the variation of the ionic strength and consequently of the interaction coefficients as ClO_4^- is replaced by HPO_4^{2-}. Then extrapolation of the Q'_{qr} values to the inert 3 M $NaClO_4$ medium is more uncertain. This point is illustrated by taking into account $K'_{-1,2}$, $K'_{1,1}$ and K'_{20}, evaluated from the results in $NaClO_4$–NaH_2PO_4 media, and included in Table 4b (line corresponding to $C_P = 0$). Clearly, Q'_{qr}s go through maxima or minima so the estimation of variable interaction coefficients on the basis of two or three data points is made difficult.

In conclusion, though the data in $NaClO_4$–

Na_2HPO_4 mixtures cannot be rationalized in terms of interaction coefficients, the results are of practical importance; the presence of $H_3(PO_4)_2^{3-}$ and $H_4(PO_4)_2^{2-}$ is confirmed and the new species $H(PO_4)_2^{5-}$ is demonstrated.

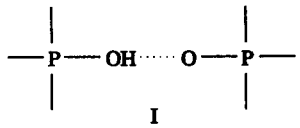
DISCUSSION

Equilibrium data give only the charge of the species and the number of phosphorus atoms but not the amount of water. So there is no way to distinguish, say, the $H_6(PO_4)_2$ species and pyrophosphoric acid $H_4P_2O_7$. A plausible proof can, however, be found by the comparison of the present results with the protolysis constants of the pyrophosphoric acid system.

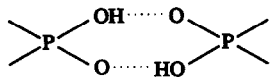
The constant for $2H_3PO_4 \leftrightarrows H_4P_2O_7 + H_2O$, as calculated from free energy values published by US NBS,[22] is about $10^{-2.79}$ at 25°C in dilute solution. If one disregards large salting effects by $NaClO_4$, the concentration of $H_4P_2O_7$ attained in our solutions less than 10^{-4} M which is the detection level of the experimental procedure. As a consequence, K_{20} of Table 4 refers to the formation of bonds which are different from the oxygen bridge between the phosphorus atoms in pyrophosphoric acid. As additional proof we may consider the acidity constants of $H_6(PO_4)_2$ and $H_4P_2O_7$, given in Table 6. The pK_a values of $H_6(PO_4)_2$ were deduced from Table 4 and their large errors are mostly due to the rather uncertain K_{02}, K_{20} and K'_{20}s. The constants for $H_4P_2O_7$ are those determined by Näsänen as quoted by Smith and Martell.[23] Clearly, the constants differ significantly; therefore, we are measuring on something of a diverse nature to the pyrophosphate system.

There is sufficient information to expect in the dimeric species hydrogen bonds which, according to Emsley's criteria,[24] may be strong as in many other bisoxo-anions such as $H(NO_3)_2^-$, $H(CO_3)_2^{3-}$, $H(RCO_2)_2^-$. Bond lengths, O···O, of about 250 ± 10 pm, found by X-ray scattering in concentrated H_3PO_4 solutions[25] as well as in solid $KH_5(PO_4)_2$,[26] KH_2PO_4[27] and $(pClC_6H_4O)_2PO_2H$,[28] are a clear indication of strong hydrogen bonding. Evidence comes also from continua in the IR spectra of H_3PO_2, H_3PO_3 and H_3PO_4 solutions[29] and from IR and NMR data of K- and NaH_2PO_2 solutions in carboxylic acids.[30] A further suggestion is the bond energy of 58 kJ mol^{-1} for the adduct $Ph_3PO \cdots HCO_2CCl_3$.[31]

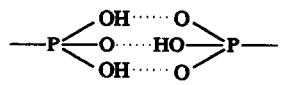
Structures I, II and III, with 1, 2 and 3 hydrogen



I



II



III

bonds, respectively, can be envisaged for the $H_n(PO_4)_2^{n-6}$ complexes. For $H(PO_4)_2^{5-}$ I is self-evident. For both $H_6(PO_4)_2$ and $H_2(PO_4)_2^{4-}$ either I or II is plausible, whilst $H_5(PO_4)_2^-$, $H_4(PO_4)_2^{2-}$ and $H_3(PO_4)_2^{3-}$ may assume each of the structures. Assignments have been attempted, Table 5, on the

Table 5. Probable structures of the dimers

[a] In these solutions $H_5(PO_4)_2^-$ prevails over H_3PO_4 and $H_6(PO_4)_2$ assuming the compositional estimates by Elmore *et al.*[4]

[b] See text.

Table 6. Comparison of pK_a values for $H_6(PO_4)_2$ and pyrophosphoric acid, $H_4P_2O_7$, at 25°C in 3 M $NaClO_4$

	$H_6(PO_4)_2$	$H_4P_2O_7$
pK_{a1}	1.35(25)	~ 0
pK_{a2}	3.45(25)	1.4
pK_{a3}	4.75(25)	5.29
pK_{a4}	~ 8.5	7.17
pK_{a5}	~ 8.7	—

basis of some literature data and of trends in dimerization constants as well as in pK_as of $H_6(PO_4)_2$.

The formation constants of $H_6(PO_4)_2$, $H_4(PO_4)_2^{2-}$ and $H_2(PO_4)_2^{4-}$ from, respectively, H_3PO_4, $H_2PO_4^-$ and HPO_4^{2-}, taking into due consideration the increasing electrostatic repulsion in the order $H_2(PO_4)_2^{4-} > H_4(PO_4)_2^{2-} > H_6(PO_4)_2$, are nearly comparable. Hence, all these species should have the same structure, *i.e.* II. Similarly, K_{11} matches well the constant for $H_2PO_4^- + HPO_2^{2-} \rightleftarrows H_3(PO_4)_2^{3-}$ so that structure III fits $H_3(PO_4)_2^{3-}$ as $H_5(PO_4)_2^-$.

The above assignments are supported by the sequence of pK_as of $H_6(PO_4)_2$. Suppose that this acid on loosing its protons does not change the configuration II. On the basis of electrostatic considerations the succession $pK_{a1} \simeq pK_{a2} \ll pK_{a3} \simeq pK_{a4}$ would result. As a matter of fact, the removal of a proton from $H_5(PO_4)_2^-$ with structure II would involve a negative charge far away to have $pK_{a1} \simeq pK_{a2}$. The third proton, on the other hand, would be given off from a tetrahedron that already has a negative charge to cause $pK_{a3} \gg pK_{a2}$. The same would apply to the fourth proton to have $pK_{a3} \simeq pK_{a4}$. The observed trend, Table 6, suggests on the contrary that $H_5(PO_4)_2^-$ and $H_3(PO_4)_2^{3-}$ have more stable structures, III, than neighbouring species with less stable configurations, as II.

(*Received* 10 *April* 1991; *accepted* 2 *July* 1991)

Abstract—X-ray diffraction analyses have been made on single crystals of [Co(picdien)(N_3)](ClO_4)$_2$, [Co(picdien)(NCS)](ClO_4)$_2$·H_2O, and [Co(picditn)(NCS)](ClO_4)$_2$·H_2O, (picdien = 1,9-bis(2′-pyridyl)-2,5,8-triazanonane; picditn = 1,11-bis(2′-pyridyl)-2,6,10-triazaundecane) in order to see if there is any structural reason for the fact that the proton acidity of the [Co(picdien)(NCS)]$^{2+}$ cation is much greater than that of the other complexes. Both NCS complexes have the *anti*-αβ configuration and the ligand is N-bonded. The *anti*-αβ configuration of the N_3 complex is also confirmed. The strain at the central meridional amine nitrogen in the picdien complex which increases the C—N—C angle to 115–116° is relieved by the larger ring size in the picditn analogues and it is suggested that this accounts for the difference in the acidity of analogous picdien and picditn complexes.

In a recent paper we examined the kinetics of the reaction, [Co(L_5)X]$^{2+}$ + OH^- → [Co(L_5)(OH)]$^{2+}$ + X^- (L_5 = picdien, picditn; X = NCS, N_3 and NO_2) and showed that, when L_5 = picdien and X = NO_2 or NCS, the rate law takes the form, $k_{obs} = ab[OH^-]/(1+b[OH^-])$ (OH^- is sufficiently more concentrated than the complex to ensure first-order kinetics; k_{obs} is the first-order rate constant) and the rate becomes almost independent of [OH^-] at concentrations greater than 0.05 mol dm^{-3}. The solvolyses of the other complexes follow the usual rate law, $k_{obs} = k_{OH}[OH^-]$.[1] In order to see whether the change in behaviour was the result of a change in stereochemistry on going from the picdien to the picditn system, the structures of the thiocyanato complexes have been determined by X-ray diffraction. The [Co(picdien)(N_3)]$^{2+}$ complex, predicted from its ^{1}H NMR spectrum to have the *anti*-αβ configuration, has also been examined in order to confirm this.

EXPERIMENTAL

Preparations

The complexes were prepared by previously reported methods.[2]

Details of the crystal structure determination

Crystals of [Co(picdien)(N_3)](ClO_4)$_2$ (**I**), were grown by dissolving the complex in dimethylformamide and diluting the solution with aqueous perchloric acid (0.1 mol dm^{-3}), those of [Co(picdien)(NCS)](ClO_4)$_2$·H_2O (**II**), and [Co(picditn)(NCS)](ClO_4)$_2$·H_2O (**III**), were obtained by

* Author to whom correspondence should be addressed.

slowly evaporating aqueous solutions of the complexes in desiccators. In all cases only one type of crystal could be observed under the microscope. Suitable single crystals were mounted on glass fibres with Araldite.

All geometric and intensity data were taken from these crystals using an automated four-circle diffractometer (Nicolet R3mV) equipped with a graphite monochromated Mo-K_α radiation (λ = 0.71073 Å) source. Important crystallographic data are collected in Table 1.

The lattice vectors were identified by application of the automatic indexing routine of the diffractometer to the positions of [30], [34], [23] reflections, respectively, for the three complexes, taken from rotation photographs and centred by the diffractometer. The ω–2θ technique was used to measure [4525], [8986], [4954] reflections for the three compounds in the range $5° < 2\theta < 50°$, of which [4018], [8243], [4431] respectively were unique. Three standard reflections, remeasured every 97 scans showed no significant loss of intensity during data collection. The data were corrected for Lorentz and polarization effects, and empirically for absorption.

(I) *anti*-$\alpha\beta$-[Co(picdien)(N_3)](ClO_4)$_2$

The 3111 unique data with $I \geqslant 1.5\sigma I$ were used in the structure solution and refinement in the space group $P2_1/n$. The structure was solved by direct methods. Alternating cycles of least-squares refinement and difference Fourier synthesis led to the complete solution of the structure. The asymmetric unit cell contains one complex cation and

two perchlorate anions, one of which is disordered between two orientations with O(5) common to both and 50% occupancy of each set of atoms {O(6), O(7) and O(8)} and {O(9), O(10) and O(11)}. With the exception of the perchlorate oxygens, which were refined isotropically, all of the non-hydrogen atoms were refined anisotropically. The hydrogens of the pyridyl groups were idealized to trigonal planar positions with C—H = 0.96 Å (U = 0.08 Å^2), while the aliphatic hydrogens and amine protons were idealized to tetrahedral positions with the same dimensions. The final least-squares cycle included 343 parameters for 3050 variables ($I \geqslant 2.5\sigma I$) and gave $R = 0.0536$ and $R_w = 0.0619$ and did not shift any parameter by more than 0.11 times its ESD. The final difference Fourier contained two peaks of 0.5 e Å^{-3} within one of the perchlorate ions but was otherwise featureless.

A selection of bond lengths and angles is listed in Table 2.

In the complex cation, Fig. 1, the cobalt is coordinated octahedrally to six nitrogens. The pentadentate ligand adopts the $\alpha\beta$ configuration and the proton on the "flat" nitrogen N(4) points towards the opposite side of the molecule to the azido ligand. The azide group is linear N(6)—N(7)—N(8) = 176.1(5)° and the bond angle Co—N(6)—N(7) = 116.7(3)°, making the azido group lie over one of the pyridine rings. The disordered perchlorate ion, $[Cl(2)O_4]^-$ is held in place by hydrogen bonding between O(5) and N(3) via H(300) and O(8) [O(10)] and N(2) vis H(200).

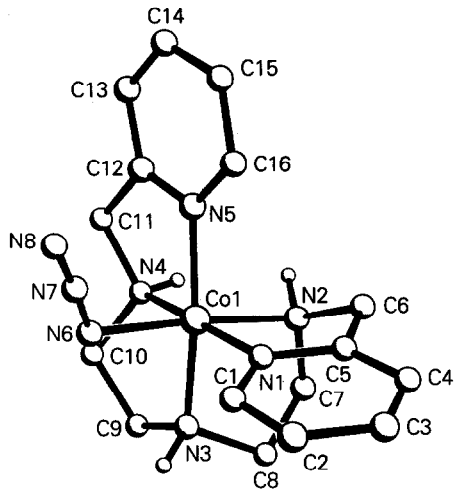

Fig. 1. A view of the *anti*-$\alpha\beta$-$[Co(picdien)(N_3)]^{2+}$ cation showing the numbering scheme. Apart from the three amine protons, all hydrogens have been omitted for clarity.

(II) $\alpha\beta$-*anti*-$[Co(picdien)(NCS)](ClO_4)_2 \cdot H_2O$

The 4360 unique data with $I \geqslant 1.5\sigma I$ were used in the structure solution and refinement in space group $P\bar{1}$. A Patterson projection showed two heavy (Co) atoms in the asymmetric unit and all the non-hydrogen atoms could be identified from the Fourier difference map after the first refinement. There was no disorder among the perchlorate oxygens.

Because of the larger number of atoms in the asymmetric unit and in order to maintain a ratio of variables to parameters of approximately 10, only the Co, Cl and N—C—S atoms were refined anisotropically. The hydrogen atoms were placed in idealized positions as before. The final least-squares cycle included 349 parameters for 3706 variables ($I \geqslant 2.5\sigma I$) and gave $R = 0.0869$, $R_w = 0.0886$ and did not shift any parameter by more than 0.004 times its ESD. Selected bond lengths and angles are given in Table 3.

S(1)—C(17)—N(6)	176.8(14)	S(2)—C(34)—N(12)	178.9(15)

The asymmetric unit consists of a pair of enantiomeric complex cations, shown in Fig. 2, together with four perchlorate ions and two water molecules. The cobalt is octahedrally coordinated to six nitrogens and the ligand adopts the *anti*-αβ configuration. The nitrogen bound thiocyanato ligand is essentially linear, N—C—S = 176.8(14)° and 178.9(15)°, but the Co—N—C angle is significantly bent, 167.1(10)° and 166.4(12)°.

The two water molecules are linked by a strong hydrogen bond O(17)···O(18) = 2.69 Å and O(18) is also bound to N(10) by hydrogen bonding

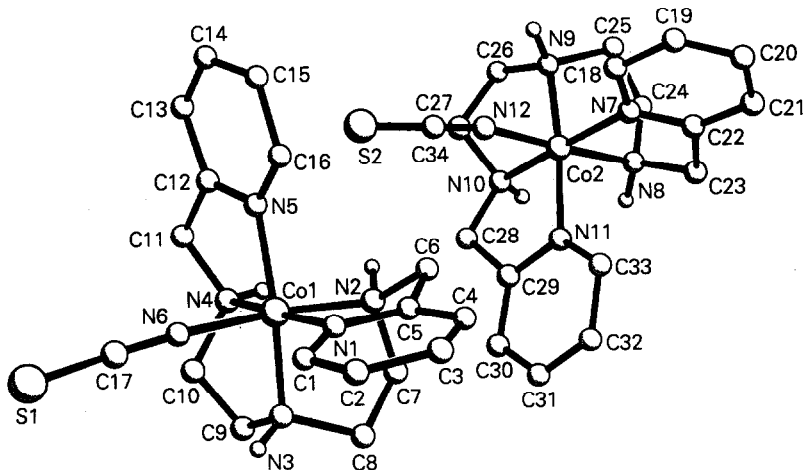

Fig. 2. A view of an enantiomeric pair of *anti*-αβ-[Co(picdien)(NCS)]$^{2+}$ cation showing the numbering scheme. Apart from the three amine protons, all hydrogens have been omitted for clarity.

through H(100) {O(18)···N(10) = 2.76 Å} and to the perchlorate oxygen, O(10) {O(18)···O(10) = 2.86 Å}. Longer interactions are to be found between N(9) and O(5) (2.97 Å), N(4) and O(14) (3.02 Å), and N(3) and O(2) (3.04 Å). These all serve to fix the perchlorate ions in rigid positions. The distinction between the enantiomeric cations lies in their relationship to these hydrogen bonding interactions. The complex cation containing Co(1) is linked to $[Cl(1)O_4]^-$ by O(2)···N(3) and $[Cl(4)O_4]^-$ by O(14)···N(4), while that containing Co(2) is bound to $[Cl(3)O_4]^-$ by O(5)···N(9) and one water of crystallization by O(18)···N(10). The other perchlorate $[Cl(2)O_4]^-$ is bound to O(18) by O(10)···O(18).

(III) $\alpha\beta$-*anti*-[Co(picditn)(NCS)]$(ClO_4)_2 \cdot H_2O$

The 3061 unique data with $I \geqslant 1.5\sigma I$ were used in the structure solution and refinement in space group $P2_1/c$. The cobalt atom was located by a Patterson projection and all the non-H atoms could be identified from the Fourier difference map after the first refinement. All non-hydrogen atoms except the oxygens of the perchlorate and the water of crystallization were refined anisotropically. There was no disorder in either of the perchlorate ions. Hydrogen atoms were idealized as described above. The final least-squares cycle included 343 parameters for 2404 variables ($I \geqslant 2.5sI$) and gave $R = 0.0636$, $R_w = 0.0679$ and did not shift any parameter by more than 0.001 times its ESD. Selected bond lengths and angles are collected in Table 4.

The asymmetric unit contains one cation, shown in Fig. 3, two perchlorate anions and one water of crystallization. The cobalt is octahedrally coordinated to six nitrogens and the ligand adopts the *anti*-$\alpha\beta$ configuration.

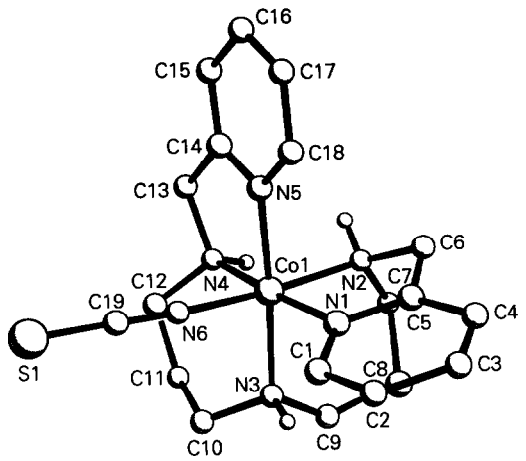

Fig. 3. A view of the *anti*-$\alpha\beta$-$[Co(picditn)(NCS)]^{2+}$ cation showing the numbering scheme. Apart from the three amine protons, all hydrogens have been omitted for clarity.

Hydrogen bonding between O(1) and N(4) {O(1)···N(4) = 2.99 Å} and O(8) and N(3) {O(8)···N(3) = 2.97 Å} anchor the perchlorate anions to the amine groups of the complex and N(2) is hydrogen bonded to the water molecule {N(2)···O(9) = 2.89 Å}.

RESULTS AND DISCUSSION

All three complexes have the same *anti*-$\alpha\beta$ configuration and so the difference in the amine acidities of the picdien and picditn NCS complexes, which both have the ligand bound to Co by N, cannot be ascribed to an isomeric difference. The Co—N—C—S sequence is closer to linearity in the picditn complex (Co—N—C = 175.8(9)°, N—C—S = 178.8(9)°) than it is in the analogous

[b] In some of the references the numbering sequence of the ligand is reversed, i.e. N(4) is labelled N(2).

picdien species, {average Co—N—C—S = 166.7°}. The M—N—C angle in *N*-bonded thiocyanate is frequently close to 180° but there are many examples where this angle lies between 160 and 170°.[3] The distortion in this case may arise from packing considerations and is unlikely to affect the acidity of the *trans* N—H group. The N—C and C—S bond lengths are within the range of those reported for other *N*-bonded thiocyanato complexes.

The effect of changing from two linked five-membered rings in picdien to two linked six-membered rings in picditn can be seen at N(4) which is the central atom in a meridional set of three donors. Two meridional five-membered rings produce noticcable strain at the linking donor which results in significant shortening of the Co—N bond and a widening of the C—N—C bond angle, Table 5. This has been found for all complexes of the type, $\alpha\beta$-[Co(picdien)X]$^{n+}$ examined, X = *anti*-Cl,[4] *syn*-[5] and *anti*-Br,[6] *syn*-NO_2,[6] *anti*-OH_2,[7] *anti*-N_3 and *anti*-NCS and also for *anti*-$\alpha\beta$-[Cr(picdien)Cl]$^{2+}$.[8] The effect of the release in strain caused by the presence of an adjacent six-membered ring in the $\alpha\beta$-[Co(picditn)X]$^{n+}$ complexes has been less thoroughly studied but in the cases where X = *anti*-Cl,[9] *anti*-ONO,[10] and *anti*-NCS, the Co—N(4) bond length is close to the average of the HN—Co bond lengths and the C—N—C bond angle is much closer to that of a regular tetrahedron (109.4°). It the N(4)—H(400) amine group was the site of the most acidic proton it might be possible to account for the differences in the acidities of the picdien and picditn complexes in terms of the stabilisation of the amido base through the release of the steric strain which is present in the picdien complex and absent in the picditn analogue. The large increase in acidity in going from the $\alpha\beta$-*anti*-[Co(picdien)(N_3)]$^{2+}$ cation to $\alpha\beta$-*anti*-[Co(picdien)(NCS)]$^{2+}$ and $\alpha\beta$-*syn*-[Co(picdien)(NO_2)$^{2+}$ is not easy to explain. We are reluctant to place any significance on the observation that the C—N(4)—C angle is smaller in the azido complex as the effect is not far enough outside experimental error to be statistically significant. Previously,[1] we argued in favour of a stabilization of the conjugate-base when X was a π-acceptor, such as, -NO_2 and -NCS through interaction between this ligand and the *trans* amido group acting as a π-donor. This would require N(2)—H(200) to be the most acidic amine group. We are therefore unable, at this time, to provide a single explanation of all the facts.

Proton exchange studies, now in progress,[10] show that the rate constants for the exchange of the most labile protons lie in the range 10^8 to 10^9 dm^3 mol^{-1} s^{-1} and there is no simple relationship between the magnitudes of these rate constants and the acidities of the complexes. Since deprotonation is approaching diffusion control, it is not unreasonable to find

that the rate constant for reprotonation becomes sensitive to the nature of the complex. These results will be reported elsewhere in due course.

Additional material consisting of lists of positional parameters, complete collection of bond lengths and angles, structure factors, thermal parameters and H-atom parameters has been deposited.

Acknowledgements—We thank the SERC for providing funds for the purchase of the diffractometer.

ELECTROSYNTHESIS OF TRANSITION METAL FLUORO COMPLEXES BY THE DISSOLUTION OF A SACRIFICIAL METAL ANODE

M. C. CHAKRAVORTI,* GAMPA. V. B. SUBRAHMANYAM and D. BANDYOPADHYAY

Department of Chemistry, Indian Institute of Technology, Kharagpur-721 302, India

(*Received* 15 *June* 1990; *accepted* 28 *June* 1991)

Abstract—A general method for the electrosynthesis of anionic fluoro complexes of transition metals has been developed by the oxidation of sacrificial metal anodes in 20% HF medium at room temperature and at an applied potential of 2–8 V. Some mixed-valent complexes, e.g. $Fe_2F_5 \cdot 2H_2O$ and $Fe_2F_5 \cdot 7H_2O$, have also been obtained by the same method. $K_2[MnF_5] \cdot H_2O$ was obtained by subsequent electrolytic oxidation of the Mn(II) fluoro complex obtained *in situ* in the first step. The method is rapid and gives a good yield with high purity.

Electrochemical synthesis in which a sacrificial metal anode is dissolved in the presence of an electrolyte containing an appropriate ligand is an established way for the electrolytic synthesis of a variety of metal complexes[1] in a single step. The process uses the metals directly, and thus contamination of the product by the anions, which is often encountered in chemical methods using the metal salts, is absent. The method is rapid and highly selective. Thiocyanato complexes of a large number of metals have been prepared by the dissolution of metal anodes in a solution containing HSCN.[2,3] The chloro complex, $[CoCl_4]^{2-}$ has been prepared[4] by using a cobalt anode in the presence of hydrochloric acid. We have also reported[5] a very convenient electrosynthesis of $K_2[MoOF_5]$ using a molybdenum anode. We have now extended our studies with various transition metals and demonstrated that the procedure can be used as a general method for the preparation of a wide variety of fluoro complexes of different metals in various oxidation states from aqueous medium. The results are presented in this communication. Some complexes in higher oxidation state, e.g. $K_2[MnF_5] \cdot H_2O$, can be prepared by a two step electrolysis—the first step resulting in the formation *in situ* of the complex in the normal oxidation state by the dissolution of the sacrificial metal anode, followed by electrolytic oxidation of the complex using inert platinum electrodes. The fluoro complexes reported in this communication are already known. Some of these are remarkable in having a variety of structures and physical properties. Many of these were prepared earlier from a non-aqueous medium or by reactions in the solid state at high temperature. The present method uses an aqueous medium at room temperature. Pure metals which are not strongly electropositive dissolve in aqueous hydrofluoric acid slowly even at higher temperature, but the application of an electrical potential increases the rate of dissolution at room temperature.

EXPERIMENTAL

The metals were in the form of rods, lumps, chips or foils and were mostly 99.8% pure. Titanium powder was pressed to make pellets. A few metals (e.g. chromium and manganese) were first deposited on a platinum foil by the electrolysis of their salt solutions and these were subsequently used as the anode. Other chemicals were of AR/GR quality from reputable manufacturers.

The electric power was supplied by a dc power supply (Aplab, India). A milliammeter was connected into the circuit in cases where the current was very feeble. The electrolytic cell was a tall form of polythene beaker (100 cm^3) fitted with a rubber

* Author to whom correspondence should be addressed.

stopper through which four holes were made. The appropriate metal rods which formed the anode were inserted through a hole. In cases where metal lumps, foils or pellets were used, these were fused onto a platinum wire which was inserted through the hole. Chromium and manganese were previously deposited onto a platinum foil sealed to a platinum wire which served as the anode. In all cases a platinum foil (about $1 \times 1 \times 0.15$ cm) connected to a platinum wire served as the cathode and was introduced through the second hole. Two polythene tubes were introduced through the other two holes. These allowed input and exit of nitrogen where it was necessary to carry out electrolysis in the absence of air.

Fluorine was analysed by titration with $Th(NO_3)_4$ after fusing the complex with sodium hydroxide, or steam distillation of fluorosilicic acid.[6] Potassium and caesium were determined by atomic absorption using a Pye Unicom instrument (SP-2900). Other metals were analysed by standard titrimetric or gravimetric methods. Reflectance spectra were recorded using a Shimadzu UV spectrophotometer (No. 3100) against barium sulphate. Infrared spectra were recorded in CsI pellets using a Perkin–Elmer instrument (No. 883). Magnetic susceptibility was measured by the Gouy method using $Hg[Co(NCS)_4]$ as calibrant. Diamagnetic corrections were taken from a standard source.[7] X-ray powder diffraction patterns were obtained with a Philip's diffractometer (PW 1729) employing nickel filtered Cu-K_α radiation.

Preparation of the complexes

$M_2[TiF_6]$, $M_2[VOF_4]$, $K_3[CrF_6]$, $K[MnF_3]$, $M_3[FeF_6]$, $M[CoF_3]$, $M[NiF_3]$, $Cs_2[NbOF_5]$ *and* $K_2[TaF_7]$ *where* M = K *or* Cs. Each electrolysis was carried out using 10 cm^3 hydrofluoric acid (20%). The details of the experimental conditions are given in Table 1. After electrolysis, the solution was filtered to free it from any disintegrated metal particles (when an iron anode was used, a yellow deposit was also obtained from which $Fe_2F_5 \cdot 7H_2O$ and $Fe_2F_5 \cdot 2H_2O$ could be prepared). The potassium and the caesium salts were precipitated by adding concentrated solutions of KF and CsF in HF (20%). The complexes were separated by fil-

[a] Total amount of iron oxidized in one experiment, out of which the yields of $K_3[FeF_6]$, $Fe_2F_5 \cdot 7H_2O$ and $Fe_2F_5 \cdot 2H_2O$ are recorded separately.

[b] The compounds were precipitated immediately on the addition of MF. In other cases the compounds were crystallized out on evaporation in a desiccator over concentrated H_2SO_4.

[c] Values in parentheses refer to the subsequent electrolytic oxidation of the initially formed M(II) complex.

tering under suction and dried by pressing between the folds of filter paper and then keeping in a desiccator over KOH. For the calculation of electrochemical efficiency (number of moles of metal dissolved per faraday of electricity passed) the anodes were weighed before and after the electrolysis.

$Fe_2F_5 \cdot 7H_2O$ *and* $Fe_2F_5 \cdot 2H_2O$. The residue which was obtained during the electrolysis using an iron anode, was digested with 10 cm^3 HF (20%) on a steam bath until it dissolved almost completely. The hot solution was quickly filtered and the filtrate was divided into two parts. One part gave a deposit of $Fe_2F_5 \cdot 7H_2O$ on cooling, while the other gave a precipitate of $Fe_2F_5 \cdot 2H_2O$ on evaporation over a steam bath until the volume was reduced to half. These were separated and dried as described above.

$K_2[MnF_5] \cdot H_2O$. After 2 h of electrolysis, the manganese anode was replaced by a platinum foil electrode and electrolysis was continued for a further 2 h. Finally, the potassium salt was obtained by the addition of a concentrated solution of KF in HF (20%).

RESULTS AND DISCUSSION

Our studies show that fluorides of many transition metals can be easily prepared from aqueous HF at room temperature. The applied voltage is low

Table 2. Physicochemical data for the complexes

[a] Values in parentheses are the intensities.

(2–8 V) and the yield is very good (about 60–85% based on the amount of metal oxidized). The main reactions taking place at the electrodes are:

$$2H^+ + 2e \longrightarrow H_2 \text{ (at cathode)}$$

$$M - ne \longrightarrow M^{+n} \text{ (at anode)}$$

which is evident from the observed electrochemical efficiency. A slight deviation of the electrochemical efficiency (Table 1) from the theoretical value of $1/n$ is ascribed to some disintegration of the metal anode and slight fluctuation of the current during electrolysis.

Anodic dissolution of the metals was also studied in a stream of nitrogen. The products however, were identical with those obtained in air using metal anodes. With titanium, a purple solution was initially obtained, which ultimately gave the same Ti(IV) compound. It appears that a Ti(III) fluoro complex is initially formed, which was subsequently oxidized during the working up.

All the compounds gave satisfactory analytical results of alkali metal, fluoride and the respective transition metals. The oxidation number of Mn in $K_2[MnF_5]\cdot H_2O$ determined iodometrically was +3.0. The observed magnetic moments of the compounds (see Table 2) were in agreement with those reported in the literature.[8–11] The X-ray powder diffraction data of many of the compounds are available in the X-ray powder diffraction file. Our data (Table 2) for these compounds were in excellent agreement with the recorded values. The band positions in the electronic spectra of the complexes are given in Table 2. These also compare well with the literature values.[8,11,12] The IR spectral data of only a few of the compounds were reported earlier.[8,13,14] The positions of the important IR spectral bands of the compounds are recorded in Table 2. The M—F stretching frequency occurs around 500 cm^{-1} for all the compounds of the type $[MF_6]^{n-}$ and also for $[TaF_7]^{2-}$, $[VOF_4]^{2-}$, $[NbOF_5]^{2-}$ and $K_2[MnF_5]\cdot H_2O$. A comparison of the vibrational spectra of these diverse types of species is very difficult. However, some characteristic features may be noted. The increase in the position of ν_3 in $[CrF_6]^{3-}$ compared to $[FeF_6]^{3-}$ is in keeping with the trend generally found among the hexafluoro complexes. The higher value of the ν_3 in $[TiF_6]^{2-}$ compared to that in $[CrF_6]^{3-}$ is again in agreeement with the expected trend. The relatively lower Ta—F band position in the spectra of $[TaF_7]^{2-}$ is attributed to an increased coordination number of the metal. The spectra of $[NiF_3]^-$ and $[CoF_3]^-$ are very similar. In these two complexes and also in $[MnF_3]^-$ the M—F vibration occurs at a lower frequency which is probably due to a —F—M—F—M—F— type of interaction in the complexes.[8,15,16] The spectrum of $K_2[MnF_5]\cdot H_2O$, which contains both bridging and terminal fluoride,[17] gives a number of bands in the region 600–250 cm^{-1}. The mixed-valent complexes $Fe_2F_5\cdot 2H_2O$ and $Fe_2F_5\cdot 7H_2O$ have been widely studied.[10,11,18,19] While the former contains fluoride bridges, the latter is represented as $[Fe(H_2O)_6][FeF_5(H_2O)]$. In keeping with these structures their spectra also give a number of bands in the above region. The spectra of the two oxo complexes $[VOF_4]^{2-}$ and $[NbOF_5]^{2-}$ give the characteristic M=O bands in the region 970–1000 cm^{-1}, in addition to M—F bands.

In recent years there has been growing interest in the synthesis of coordination compounds starting directly from metals.[20–22] Many metals are readily available in more than 99.8% purity. As stated earlier, the metals may also be previously deposited on a platinum foil by electrolysis of their salt solutions. The method, therefore serves as a general one for the electrosynthesis of fluoro complexes from aqueous medium at room temperature.

REACTIVITY OF THE COMPLEXES $Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})$ (NN = bpy, phen, dmp) WITH HgX_2 (X = Cl, Br, I, CN, SCN). FORMATION OF TRIMETALLIC Mo—Hg—Mo AND BIMETALLIC Mo—Hg COMPLEXES

Abstract—The reactions of the complexes $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ [NN = 2,2′-bipyridyl (bpy), 1,10-phenanthroline (phen), 2,9-dimethyl-1,10-phenanthroline (dmp); dppm = bis(diphenylphosphino)methane] with HgX_2 (X = Cl, Br, I, CN, SCN) led to three types of compounds $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ (NN = bpy, phen; X = Cl, Br, CN, SCN. NN = dmp; X = CN), $[Mo(CO)_3(\eta^2\text{-NN})(\mu\text{-dppm})HgI]HgI_3$ (NN = bpy, phen; X = I) and $[Mo(CO)_3(\eta^2\text{-dmp})(HgX)(X)]$ (X = Cl, Br, I, SCN), depending on the NN-ligand and the mercuric derivative employed. The formation of the trinuclear complexes $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ is favoured over the expected bimetallic derivatives, in which two metals are bridged by the dppm ligand. Bimetallic compounds are obtained when bulky ligands are present, such as dmp bonded to a molybdenum atom or I bonded to mercury, and only in the latter case is a Mo—Hg complex bridged by dppm obtained.

Heterobimetallic complexes containing a transition metal bonded to mercury are of current interest, especially because some of these have been used as intermediates in organic and organometallic synthesis. Complexes containing constraining ligands such as $Ph_2PCH_2PPh_2$ [bis(diphenylphosphino)methane, dppm] are of special interest since proximity effects involved in bridging behaviour can be used to favour formation of the metal–metal bond.[1] However, dppm bridged systems involving molybdenum and mercury have not been described and we are interested in the study of this type of compound.

On the other hand it has been established that complexes of the type $[Mo(CO)_3(\eta^2\text{-dppm})(\eta^1\text{-dppm})]$ [dppm = bis(diphenylphosphino)methane] in their reactions with transition metal derivatives are able to form dinuclear heterobimetallic complexes bridging two metals by the dppm ligand.[2,3] However, no bimetallic derivatives were obtained from the reaction of $[Mo(CO)_3(\eta^2\text{-dppm})(\eta^1\text{-dppm})]$ with HgX_2 (X = Cl, SCN) (although Mo—Hg bonded species have been suggested as intermediates) and new dicarbonyl molybdenum-complexes were formed by elimination of mercury.[4]

In a previous communication, we have reported the behaviour of the related $[Mo(CO)_3(\eta^2\text{-bpy})(\eta^1\text{-dppm})]$ complex towards some metal derivatives. Molybdenum–metal complexes were formed in all cases, and in particular a trinuclear compound $[Mo(CO)_3(\eta^2\text{-bpy})(Cl)]_2Hg$ was obtained in the reaction with $HgCl_2$.[5]

As an extension of the above results we have studied the reactions of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ [NN = 2,2′-bipyridyl (bpy), 1,10-phenanthroline (phen), 2.9-dimethyl-1,10-phenanthroline (dmp)] with HgX_2 (X = Cl, Br, I, CN, SCN), in an attempt to form new heterobimetallic Mo—Hg complexes with dppm as bridge.

RESULTS AND DISCUSSION

The spectroscopic and analytical data of the isolated compounds are summarized in Tables 1 and 2.

(a) *Reactivity of* $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (NN = bpy, phen) *with* HgX_2 (X = Cl, Br)

The $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ complex (NN = bpy, phen) reacts with mercury(II) halide, HgX_2 (X = Cl, Br), in a 1:1 or 1:2 molar ratio at room temperature and no CO evolution is observed. The solids isolated are insoluble in common solvents and they have been characterized as a mixture of $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ and $HgX_2 \cdot n$dppm.

The IR spectra of the solids show in the carbonyl region the characteristic pattern of bands of $[Mo(CO)_3(\eta^2\text{-bpy})(X)]_2Hg$ complexes;[5,6] however, absorptions attributed to coordinated dppm ligand are also observed, and suggest the presence of $HgX_2 \cdot n$dppm (NN = bpy, phen; X = Cl, Br).

In order to confirm our hypothesis we studied compounds of the type $HgX_2 \cdot n$dppm, synthesized by direct reactions between HgX_2 and dppm. New products, characterized as $HgX_2 \cdot n$dppm (X = Cl, $n = 1/3$; X = Br, $n = 1$) were isolated and all of these were insoluble in common solvents.[7]

The ^{31}P-NMR spectra of the above compounds, registered in DMSO-d_6, show a singlet (X = Cl, $\delta = 2.25$ ppm; X = Br, $\delta = 2.00$ ppm) with their corresponding mercury satellites.[7] These signals appear at the same position as those observed for the solids formed in the reactions referred to above, and confirm the suggested presence of the adducts $HgX_2 \cdot n$dppm in the products of these reactions.

On this basis we thought that a 2:1 (Mo:Hg) stoichiometry for the reaction between the molybdenum complex $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ and HgX_2 could yield the trinuclear derivative exclusively. We have carried out these 2:1 reactions and the products isolated were characterized as the expected complexes $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$. This fact indicates that the dppm ligand is always liberated from the starting molybdenum complex and that the formation of $HgX_2 \cdot n$dppm compounds occurs when an excess of HgX_2 with respect to the 2:1 molar ratio of the reaction is employed.

The above trinuclear complexes had already been obtained by reactions of $[Mo(CO)_3(\eta^2\text{-NN})(L)]$ (L = N-, P- or S-donor ligands) with HgX_2.[6,8-12] For these reactions, an insertion of $Mo(CO)_3(\eta^2\text{-NN})$ groups into Hg—X bonds had been proposed.[6]

(b) *Reactivity of* $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (NN = bpy, phen) *with* HgX_2 (X = CN, SCN)

In order to establish if the insertion of $Mo(CO)_3(\eta^2\text{-NN})$ groups into the Hg—X bonds is dependent on the X groups bonded to the mercury atom, we have studied the reactivity of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (NN = bpy, phen) with $Hg(CN)_2$ and $Hg(SCN)_2$.

The reactions have been carried out in the same conditions used with the mercury halides described above. In all cases, the isolated products have been characterized as the complexes $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ (NN = bpy, phen; X = CN, SCN). Additional $Hg(CN)_2$ molecules are present in the final compounds obtained when a 1:2 (Mo:Hg) stoichiometric ratio was employed.

The IR spectra of the compounds show a pattern of carbonyl absorptions similar to that observed in the compounds $[Mo(CO)_3(\eta^2\text{-bpy})(X)]_2Hg$,[5,6] which is characteristic of the skew configuration of the carbonyl groups round the Mo—Hg—Mo linkage.[13]

The ν_{CN} frequencies appear in the same region as those observed in complexes containing the CN and SCN groups bonded to the molybdenum atom[4,14-16] and is consistent with the analytical data. A formulation as $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ (NN = bpy, phen; X = CN, SCN) was proposed for our compounds. The low values of the ν_{CN} frequencies observed for the compounds $[Mo(CO)_3(\eta^2\text{-NN})(CN)]_2Hg$ (NN = bpy, phen) have been attributed to a pseudobridging character of the CN groups in these complexes.[17]

The elimination of the dppm ligand of the starting molybdenum complexes is revealed by spectroscopic data, and the formation of the soluble compounds $HgX_2 \cdot n$dppm (X = CN, SCN)[7] has been probed from the solution reaction when a 1:2 (Mo:Hg) molar ratio has been used.

On another occasion we have shown that $Mo(CO)_3(\eta^2\text{-NN})$ groups are formed in these reactions with elimination of the dppm ligand. These moieties with 16-electrons round the molybdenum atom are inserted into the Hg—X bonds giving the 18-electron configuration in the stable $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ (X = CN, SCN) derivatives.

(c) *Reactivity of* $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (NN = bpy, phen) *with* HgI_2

The reactions of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (NN = bpy, phen) with HgI_2 have been studied in analogous conditions that those above described in (a) and (b). No influence of the stoichiometric ratio is observed and new products formulated as $[Mo(CO)_3(\eta^2\text{-NN})(\mu\text{-dppm})HgI]HgI_3$ (NN = bpy, phen) are obtained.

The IR spectra show three carbonyl bands, shifted to higher frequencies than those of the starting complexes, consistent with an increase in the formal oxidation state of molybdenum atom. Absorptions of the NN and dppm ligands are also observed in their characteristic regions.

The new compounds are soluble in some polar solvents such as ethanol, methanol or acetone. The molar conductivity (Λ_m) measurements in acetone and dimethyl formamide solutions indicate the ionic character of these compounds. The values of Λ_m are slightly lower than those expected for 1:1 electrolytes which could be attributed to a low ionic mobility of the species present.

The ^{31}P-NMR spectra of the new complexes in acetone-d_6 at room temperature show two broad signals due to the coordinated phosphorus atoms. At −20°C, the signals appear as doublets with phosphorus–phosphorus couplings (Table 2). These results are in agreement with an inequivalence of the two phosphorus atoms of the coordinated dppm ligand. This fact eliminates the possibility of the formation of adducts of the type $HgI_2 \cdot n$dppm in these reactions.[7] No mercury satellites are observed and a tentative assingment of the signals was made, with the signal at higher field being assigned to the phosphorus atom coordinated to the molybdenum and the signal at lower field attributed to the phosphorus atom bonded to the mercury.[18]

The above results together with the analytical data suggest for these compounds a formulation of the type $[Mo(CO)_3(\eta^2\text{-NN})(\mu\text{-dppm})HgI]HgI_3$ (NN = bpy, phen). A possible structural form is shown in Fig. 1.

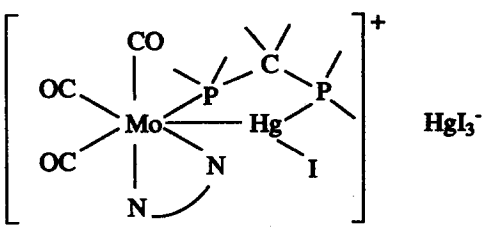

Fig. 1. Proposed structural form for $[Mo(CO)_3(\eta^2\text{-NN})(\mu\text{-dppm})HgI]HgI_3$ (NN = bpy, phen). (P—C—P = dppm.)

(d) *Reactivity of* $[Mo(CO)_3(\eta^2\text{-dmp})(\eta^1\text{-dppm})]$ *with* HgX_2 (X = Cl, Br, I, CN, SCN)

Related reactions between the complexes $[Mo(CO)_3(\eta^2\text{-dmp})(\eta^1\text{-dppm})]$ and HgX_2 (X = Cl, Br, I, CN, SCN) have been studied. In the starting molybdenum complex we have introduced dmp as the NN-ligand, which is more basic and presents more demanding steric effects than the others.

Surprisingly, compounds of the type $[Mo(CO)_3(\eta^2\text{-dmp})(HgX)(X)]$ (X = Cl, Br, I, SCN) were isolated, and only products of double insertion of the type $[Mo(CO)_3(\eta^2\text{-dmp})(CN)]_2Hg$ were obtained in the reaction with $Hg(CN)_2$. This different behaviour could be attributed to the low stability of the Mo—Hg—CN bonds.[19]

CONCLUSIONS

Formation of trinuclear complexes of the type $[(\eta^2\text{-NN})(CO)_3(X)Mo—Hg—Mo(X)(CO)_3(\eta^2\text{-NN})]$ appears to be favoured by reaction between $[Mo(CO)_3(\eta^2\text{-NN})(L)]$ and HgX_2; even when L is a PP-ligand coordinated in a monodentate form as η^1-dppm this behaviour is not modified, and the expected bimetallic complexes in which two metals are bridging by dppm ligand are not formed.

Particular results are obtained when bulky ligands are present, such as in the case of dmp bonded to molybdenum or I bonded to mercury, and bimetallic derivatives are formed in these cases. An intermediate species as in Fig. 2 is proposed to explain the formation of the final cationic compound $[Mo(CO)_3(\eta^2\text{-NN})(\mu\text{-dppm})HgI]^+$. This fact does not occur when the NN-ligand is dmp, probably due to the greater electronic and steric properties of this ligand.

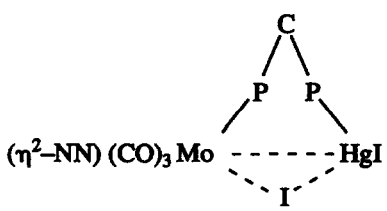

Fig. 2.

EXPERIMENTAL

(a) *General*

All reactions were carried out under oxygen-free dry nitrogen. Analytical grade solvents were used. The $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (NN = bpy, phen, dmp) complexes were prepared as previously described.[18] C, H and N analyses were carried out by Elemental Micro-Analysis Laboratories Ltd. (Devon, U.K.). IR spectra were recorded on a Perkin–Elmer 1300 spectrophotometer with KBr pellets. The NMR spectra were recorded on a Varian XL-300 spectrometer at room temperature and −20°C, operated at 299.95 MHz for ^1H and 121.42 MHz for ^{31}P, with $(CH_3)_4Si$ as internal standard for ^1H and 85% phosphoric acid as external standard for ^{31}P; the solvents used were $(CD_3)_2CO$ and $(CD_3)_2SO$. Conductance measurements were performed in dimethylformamide solutions at room temperature.

(b) *Reactions*

Preparation of $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ (NN = bpy, phen; X = Cl, Br). 0.1 mmol of HgX_2 was added to a solution of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (0.2 mmol) in dichloromethane (15 cm^3). The mixture was stirred for 1 h and the precipitate formed was filtered off, washed with dichloromethane and petroleum ether (b.p. 40–60°C) and dried *in vacuo*.

Preparation of $[Mo(CO)_3(\eta^2\text{-NN})(X)]_2Hg$ (NN = bpy, phen; X = CN, SCN). 0.12 mmol of HgX_2 was added to a solution of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (0.24 mmol) in dichloromethane (15 cm^3). The mixture was stirred for 30 min for $Hg(SCN)_2$ and 2 h for $Hg(CN)_2$. The solid formed was filtered off, washed with petroleum ether (b.p. 40–60°C) and dried *in vacuo*.

Preparation of $[Mo(CO)_3(\eta^2\text{-NN})(\mu\text{-dppm})HgI]HgI_3$ (NN = bpy, phen). 0.5 mmol of HgI_2 was added to a solution of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (0.25 mmol) in dichloromethane (15 cm^3). A colour change was observed immediately (from violet to yellow-orange) and the formation of a yellow precipitate occurred. The mixture was stirred for 15 min, and the solid was filtered off, washed with petroleum ether (b.p. 40–60°C) and dried *in vacuo*.

Preparation of $[Mo(CO)_3(\eta^2\text{-dmp})(HgX)(X)]$ (X = Cl, Br, I, SCN). 0.5 mmol of HgX_2 was added to a solution of $[Mo(CO)_3(\eta^2\text{-dmp})(\eta^1\text{-dppm})]$ (0.25 mmol) in dichloromethane (10 cm^3). A colour change was observed quickly (from violet to orange). The compounds were obtained by precipitation with petroleum ether (b.p. 40–60°C) after 5–10 min of stirring. The compound obtained with $Hg(SCN)_2$ precipitated in the reaction medium. The solids were filtered off, washed with petroleum ether (b.p. 40–60°C) and dried *in vacuo*.

(*Received* 25 *January* 1991; *accepted* 18 *June* 1991)

Abstract—Conductometric titration curves of $MO(OR)_4$ and $MO_2(OR)_2$ (M = Mo, W; R = Et, ^{i}Pr, C_2H_4OMe) by sodium (or lithium) alkoxides have ultimately proved the existence of the (1 : 1) bimetallic complexes in alcohol solutions. Upon evaporation of the solvents from the solutions, decomposition of the complexes occurs, accompanied by the elimination of ether, resulting in the precipitation of Na_2MoO_4; the molybdenum derivatives decompose more readily than the corresponding tungsten species. Under special conditions the crystals of $[NaWO(OEt)_5(EtOH)_2]_2$ (**I**) and $[NaMo_2O_4(OR)_5(ROH)]_2$ [R = ^{i}Pr (**VI**), Et (**VIII**)] complexes have been isolated. $[NaMoO_2(OC_2H_4OMe)_3]_2$ (**XI**) proved to be the only stable complex. Solubility isotherms in the systems $WO(OEt)_4$-$M(OEt)_n$-EtOH and $MoO_2(OC_2H_4OMe)_2$-$M(OC_2H_4OMe)_n$-$MeOC_2H_4OH$ (M = Na, Bi) were measured which allowed us to establish the regions of stability of the complexes. The nature of the M—O bonding in the synthesized bimetallic complexes is discussed on the basis of their crystal structures and IR spectra.

The intensive study of the chemistry of the double metal alkoxides during the last 20 years has practically left untouched the derivatives of the elements of Group VI.[1] Alkoxotungstates(V), $M^IW(OR)_6$ (R = Et, Ph), are known;[2,3] partially methylated isopolymolybdates, e.g. $Na_4[Mo_8O_{24}(OMe)_4]\cdot 8MeOH$, $[MePh_3P]_2[Mo_4O_{10}(OMe)_6]$, $[Mg(MeOH)_6]^{2+}$ $[Mg_2Mo_8O_{22}(MeO)_6(MeOH)_4]^{2-}\cdot 6MeOH$ are presently being studied.[4–6]

This paper reports the study of the bimetallic alkoxide derivatives of the two series of molybdenum and tungsten alkoxides $MO(OR)_4$ and $MO_2(OR)_2$ (R = Et, ^{i}Pr, C_2H_4OMe). The properties and structures of these complexes as well as the data on the solubility diagrams in the systems $MO_n(OR)_{6-2n}$-$M'(OR)_m$-ROH (M = Mo, W; M′ = Na, Bi) are of practical importance insofar as they may be used in oxide materials preparation; it is worth noting that they are readily available and far more stable than the derivatives of molybdenum and tungsten in the lower oxidation states.[7–9]

EXPERIMENTAL

All experiments were performed under a dry argon flow. The solvents were dried using conventional techniques. The initial molybdenum and tungsten alkoxides—$MoO(OR)_4$, $MoO_2(OR)_2$, $W(OR)_6$, $WO(OR)_4$ and $WO_2(OR)_2$—were synthesized from the corresponding chlorides and oxychlorides[10–12] or by anodic oxidation of the metals in absolute alcohol in the presence of conductive additives.[13]

Molybdenum and tungsten contents were determined gravimetrically in the form of MO_3. The hydroxides were precipitated from the solutions by hot HNO_3 (1 : 1) and washed on the filters with water and calcined at 400°C. Sodium content was calculated from the difference between the mass of the incombustible residue (in the course of organic microanalysis) and the MO_3 content in the sample, as determined gravimetrically. Solubility in the three-component systems has been studied by analytical methods. The solid phases were identified analytically as well as by means of X-ray powder analysis. Equilibrium was achieved after isothermal

saturation of the solutions by the solid phase in no more than 2 h.

IR spectra were measured with a Perkin–Elmer 580 IR spectrometer. ^{95}Mo NMR spectra were registered with a CXP-300 Bruker instrument, using a frequency of 1956 MHz.

Interaction of molybdenum (tungsten) alkoxides with M^IOR

Solid $WO(OEt)_4$ (1.64 g, 4.31 mmol) was introduced into a concentrated solution of Na (0.1 g, 4.34 mmol) in 5.4 cm^3 of EtOH (Na : W = 1.05 : 1.0) at 50–60°C. Slowly cooling the solution precipitated transparent, colourless crystals of **I** which readily release alcohol to form **II**. In an analogous manner **III** was obtained by evaporating the solutions containing $WO_2(OEt)_2$ and NaOEt. **XI** was obtained from solutions of $MoO_2(OC_2H_4OMe)_2$ and $NaOC_2H_4OMe$ in methoxyethanol. While **IV** precipitated from the freshly prepared solutions containing $WO(OEt)_4$ and LiOEt, **V** crystallized from solutions stored for 7 days. In order to obtain **VI**, sodium (0.11 g, 4.93 mmol) was dissolved in 100 cm^3 of a hexane/^{i}PrOH (1 : 1 by volume) mixture and after cooling and vigorous stirring $MoO(OPr^i)_4$ paste (3.54 g, 10.18 mmol) was introduced into the solution. The light-yellow solution thus obtained was stored for 1 day (in order to ensure that decomposition with the elimination of R_2O was completed). The solvent was then evaporated off *in vacuo* and the residue was recrystallized from 20 cm^3 of ^{i}PrOH; yield = 4.71 g (~73%).

Compound **VIII** was synthesized in the same manner as **VI** from sodium and molybdenum ethoxides. In the synthesis of **IX**, LiOEt and $MoO(OEt)_4$ or $MoO_2(OEt)_2$ were used. A colourless solution containing 7.2 mmol of each component in 30 cm^3 of EtOH was concentrated to a volume of 4 cm^3 and cooled to 0°C. The precipitated residue was isolated by centrifugation and dried *in vacuo*. Complex **IX** (0.82 g), poorly soluble in alcohol, was obtained (yield ~42%).

Reactions of alcohol interchange

Heating compound **VI** in EtOH solution at 50°C for 1 h (the operation was repeated twice, each time the solvent was evaporated) resulted in the formation of **VIII** with a quantitative yield. Liquid $MoO(OC_2H_4OMe)_4$ was synthesized from the alcohol interchange of $MoO(OEt)_4$ with an excess of methoxyethanol; EtOH and the excess of $MeOC_2H_4OH$ were evaporated *in vacuo*. Storage for 1–2 days resulted in crystallization of the liquid in accordance with the following scheme:

$$MoO(OC_2H_4OMe)_4 \longrightarrow MoO_2(OC_2H_4OMe)_2(\mathbf{X}) + (MeOC_2H_4)_2O.$$

The synthesis of **XII**—$Bi(OEt)_3$ (2 g, 5.8 mmol, which was obtained from the exchange of $BiCl_3$ with NaOEt[14]) was dissolved in $MeOC_2H_4OH$ (50 cm^3). The solvent was subsequently evaporated *in vacuo* (10^{-2} mm Hg) at 60–70°C. Analytical data for all the synthesized compounds as well as the IR spectral data for the range of M—O stretching vibrations are summarized in Table 1.

RESULTS AND DISCUSSION

Conductometry titration in alcohol solutions was used in order to determine the composition of the complexes formed between molybdenum and tungsten alkoxides and alkaline metal alkoxides. Interaction between $MoO(OR)_4$ (R = Et, ^{i}Pr) or $MoO_2(OR)_2$ (R = Et, C_2H_4OMe) and M^IOR (M^I = Li, Na) gave a break on the conductivity curve at the molar ratio M^I : Mo = 1 : 1 [Fig. 1(a)]. Titration of $W(OEt)_6$ with NaOEt solution gave a monotonous increase in conductivity, indicating the absence of interactions between the alkoxides in solution and is in good agreement with the coordination saturation of the metal atom in the octahedral $W(OR)_6$ molecule. Titration of $WO(OEt)_4$ and $WO_2(OEt)_2$ by sodium and lithium ethoxides gave breaks at the ratio of M^I : W = 1 : 1, which indicates the formation of complexes with the same composition as in the case of the molybdenum derivatives. It is worth noting that the interaction between NaOEt and $WO_2(OEt)_2$ occurs with time [Fig. 1(b), curves 2a and c]. When measurements were taken every 15 min (curve 2c) after the addition of NaOEt solution, the maximum of the curve smooths off and the character of the curve does not differ from that of the $WO(OEt)_4$ titration curve (curve 3). Presumably, the formation of quite stable associates from $WO_2(OEt)_2$ molecules[12] hinders the quick interaction with sodium alkoxides to form bimetallic complexes.

Upon evaporation of the alcohol from the solutions of the freshly prepared complexes with the composition W : M^I = 1 : 1 transparent crystals of $[NaWO(OEt)_5(EtOH)_2]_2$ (**I**) (readily losing the solvating alcohol), glasses of $NaWO_2(OEt)_3$ (**III**) and $LiWO_2(OEt)_3$ (**V**) and the amorphous powder $LiWO(OEt)_5$ (**IV**) were isolated.

Attempts to isolate the analogous bimetallic molybdenum ethoxides on evaporation of the solvent from the alcohol solutions containing $MoO(OEt)_4$ or $MoO_2(OEt)_2$ and M^IOEt in the ratio of 1 : 1 failed: Li_2MoO_4 and Na_2MoO_4 (high-tem-

[a] The X-ray powder diffraction pattern cannot be indexed in unit cell parameters obtained in the course of the X-ray single crystal study of I and differs from the patterns of the initial compounds $WO(OEt)_4$ and NaOEt, d(Å): 9.94(10), 9.12(55), 8.67(50), 8.35(100), 6.15(30), 5.37(25), 5.13(20), 4.82(15), 4.75(15), 4.62(15), 4.21(35), 3.74(10), 3.30(10), 3.16(10), 3.08(10).

[b] In the mass spectrum of III the fragmentation products of $W(OR)_6$ and $WO(OR)_4$ are registered. The latter are likely to be formed due to disproportionation of $WO_2(OEt)_2$.

[c] X-ray powder diffraction pattern of IX, d(Å): 9.06(20), 8.43(100), 6.56(50), 6.33(40), 4.04(20), 3.77(10), 3.71(20)— differs from that of LiOEt and $MoO_2(OEt)_2$.[10]

perature hexagonal and cubic phases, respectively) precipitated from the solutions. Their formation is due to the following reactions:

$$MoO(OEt)_4 + 2M^IOEt \longrightarrow M^I_2MoO_4 \downarrow + 3Et_2O$$

$$MoO_2(OEt)_2 + 2M^IOEt \longrightarrow M^I_2MoO_4 \downarrow + 2Et_2O.$$

The elimination of diethyl ether was detected by gas–liquid chromatography. The quantitative precipitation of $M^I_2MoO_4$ occurred in accordance with the stoichiometry provided the composition of the reacting solutions was $M^I : Mo = 2 : 1$.

Decomposition with the elimination of ether is to a certain extent characteristic of the simple molybdenum alkoxides as well. Thus, $MoO(OR)_4$ (R = Et, ^{i}Pr), especially in its "young" (the least associated) forms, completely transfers into $MoO_2(OR)_2$ for several days. The process occurs equally in pure $MoO(OR)_4$, in solution or in the gas phase.[10] Among tungsten alkoxides, decomposition

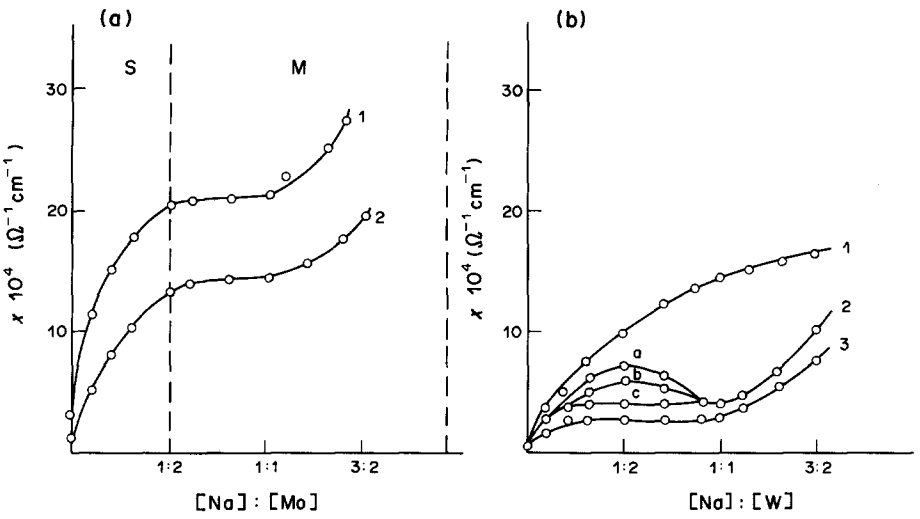

Fig. 1. Conductometric titration curves in alcohols: 0.05 M solutions of $MoO(OR)_4$ [R = Et(1), ^{i}Pr(2)] by 0.1 M solutions of NaOR (S—region of stability of solutions, M—region of slow decomposition with precipitation of Na_2MoO_4) (a); 0.02 M solutions of $W(OEt)_6$ (1), $WO_2(OEt)_2$ (2) and $WO(OEt)_4$ (3) by 0.02 M solution of NaOEt (b).

of this type was only described for $W(OBu\text{-}t)_6$ on its formation.[11] Among the bimetallic derivatives such a reaction has also been registered for $Cs[Nb(OEt)_nF_{6-n}]$.[15]

Stability of solutions containing both molybdenum and alkaline metal alkoxides depends considerably on the ratio of the components. Thus, if Li : Mo $\leqslant$ 2 : 1, precipitation of Li_2MoO_4 occurs only on refluxing the solutions. Partial evaporation of the solvent from solutions containing $MoO(OEt)_4$ or $MoO_2(OEt)_2$ and LiOEt in the ratio of Li : Mo = 1 : 1 isolated the complex with the composition $LiMoO_2(OEt)_3$. Solutions containing NaOR and $MoO(OR)_4$, with its composition within the S area [Fig. 1(a)] where Na : Mo $\leqslant$ 1 : 2, are quite stable. In the interval of the Na : Mo ratio (1 : 2)–(2 : 1) (M region) the rate of Na_2MoO_4 precipitation is low; however, further increase of the NaOR content accelerates the precipitation drastically. Careful partial evaporation of solutions with Na : Mo $\leqslant$ 1 : 2 with cooling results in crystallization of $NaMo_2O_4(OR)_5 \cdot ROH$ [R = ^{i}Pr (**VI**), Et (**VIII**)]. They are formally bimetallic derivatives of the alkoxides of the $MoO_2(OR)_2$ series [while $MoO(OR)_4$ alkoxides were introduced], but they cannot be obtained by direct synthesis: $MoO_2(OPr^i)_2$ does not exist in the individual state; interaction of $MoO_2(OEt)_2$ with NaOEt results in precipitation of Na_2MoO_4 even if the molybdenum derivative is in a considerable excess. The methoxyethoxide derivative $NaMoO_2(OC_2H_4OMe)_3$ (**XI**) is the only stable bimetallic complex of the series.

Decomposition with the elimination of ether has also been registered in the case of alkoxytungstates, but it occurs under severe conditions. Thus, after evaporation of alcohol from the $LiWO(OEt)_5$ solutions stored for 7 days, transparent glass-like $LiWO_2(OEt)_3$ (**V**) was left. The prolonged refluxing of solutions with Li : W $\leqslant$ 2 : 1 results in precipitation of hexagonal Li_2WO_4. In excess LiOEt (>2 : 1), Li_2WO_4 precipitates from solutions already at ambient temperature; a further increase of LiOEt content up to the value of 4 : 1 results in crystallization of the cubic Li_4WO_5.

On dissolution in alcohol **I** decomposes slowly with the elimination of ether and crystallization of cubic Na_2WO_4. In the 5% solution the reaction was complete in 12 h [the analogous solution of "$NaMoO(OEt)_5$" decomposes with the precipitation of Na_2MoO_4 in 1 h]. The yield of Na_2WO_4 precipitating from the 30% solution does not exceed 20% for 6 months. These facts suggest analogous decomposition in the course of the electrochemical synthesis of tungsten alkoxides, where bimetallic alkoxides are formed as a result of the interaction of alkoxides with the conductive additive. Refluxing the 5% solution of $WO(OEt)_4$ containing the conductive additive $[R_4N]X$ (under the conditions simulating electrolysis[13]) for 48 h yields a mixture of the initial alkoxide (40%) and $WO_2(OEt)_2$ (60%). Thus, formation of $WO(OR)_4$, $WO_2(OR)_2$ and ultimately oxotungstates (e.g. $[R_4N]_2W_6O_{19}$) is associated with decomposition of $W(OR)_6$—the first products of anodic oxidation of

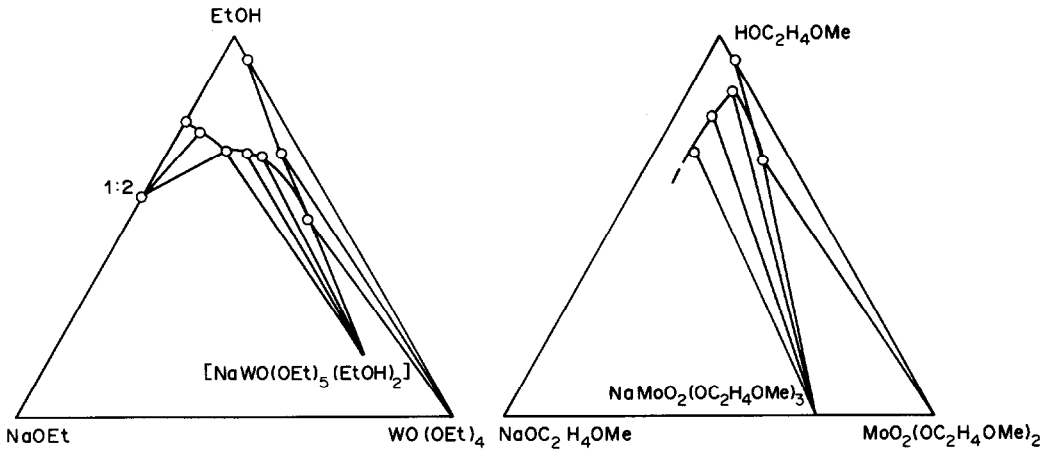

Fig. 2. Solubility diagrams for the systems NaOEt-$WO(OEt)_4$-EtOH and $NaOC_2H_4OMe$-$MoO_2(OC_2H_4OMe)_2$-$MeOC_2H_4OH$ at 25°C.

the metal. It is interesting that solutions containing both $WO(OPr^i)_4$ and $NaOPr^i$ are already stable up to the ratio of Na : W ⩽ 4 : 1 (afterwards Na_2WO_4 crystallizes), which makes them promising for application in oxide preparations.

Conditions of formation of bimetallic complexes have also been studied in the course of the investigation into solubility isotherms in the systems NaOEt-$WO(OEt)_4$-EtOH and $NaOC_2H_4OMe$-$MoO_2(OC_2H_4OMe)_2$-$MeOC_2H_4OH$ at 25°C (Fig. 2). In both systems solid complexes of the composition 1 : 1 exist, which is in good agreement with the data of the conductometric titrations. In the solubility diagrams the wide crystallization regions of the complexes are symmetrical relative to the section ROH-complex; they are located on one side of this section. Equilibrium in the first system is in fact metastable: it may be realized only in the case of a high concentration of the components (⩽ 30%) in solution, i.e. under the conditions where decomposition with precipitation of Na_2WO_4 occurs very slowly. At the same time $NaMoO_2(OC_2H_4OMe)_3$, in contrast to all other alkoxomolybdates, is quite stable even in the presence of a considerable excess of the alkaline alkoxide (which is indefinitely soluble in methoxyethanol).

Preparation of solutions containing both alkoxides of molybdenum or tungsten and bismuth is of special interest in oxide applications as far as a series of oxide materials with useful properties are known in the systems Bi_2O_3-WO_3 and Bi_2O_3-MoO_3. It proved possible to plot the branches corresponding to the crystallization of the components in the system $Bi(OEt)_3$-$WO(OEt)_4$-EtOH (Fig. 3); however, their location along the sections corresponding to Bi:W ratios of 3:2 and 1:1 suggest formation

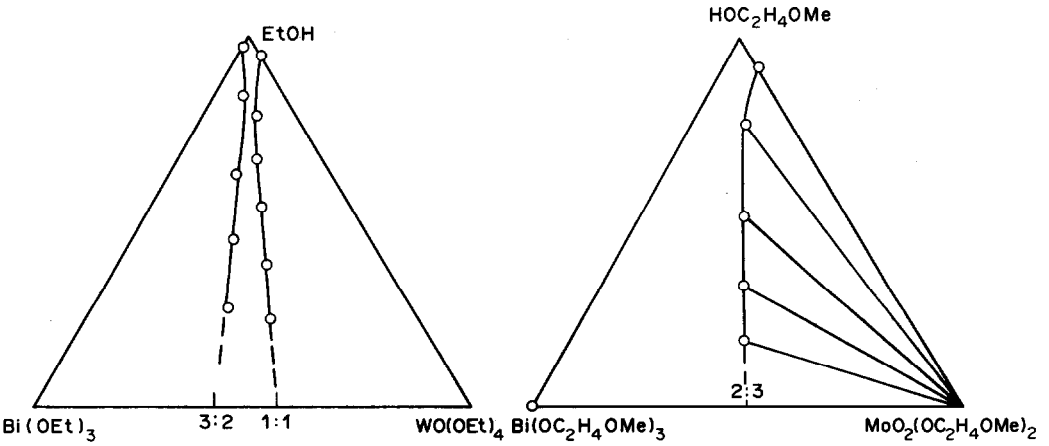

Fig. 3. Solubility diagrams for the systems $Bi(OEt)_3$-$WO(OEt)_4$-EtOH and $Bi(OC_2H_4OMe)_3$-$MoO_2(OC_2H_4OMe)_2$-$MeOC_2H_4OH$ at 25°C.

of the complexes of such compositions in solutions.[16] Diagrams of this kind are well-known in cases where bimetallic complexes exist in solution but cannot be isolated as solids [e.g. in systems $M(OR)_n$-$Fe(OR)_3$].[17] Interaction of $Bi(OEt)_3$ with $MoO(OEt)_4$ or $MoO_2(OEt)_2$ in EtOH at any reagent ratio results in the precipitation of $Bi_2O_3 \cdot nMoO_3$, although all of them have pseudo cubic structures with $a \sim 5.6$ Å (that is why they could not be identified by X-ray), and the composition of the precipitates differs in a wide range. The methoxyethoxide solutions containing bismuth and molybdenum proved to be stable. There was only one solid phase found in the $MoO_2(OC_2H_4OMe)_2$-$Bi(OC_2H_4OMe)_3$-HOC_2H_4OMe molybdenum methoxyethoxide system; its crystallization branch is located along the section with a Bi : Mo ratio of 2 : 3 (which suggests the formation of a complex with this composition in solution). $Bi(OC_2H_4OMe)_3$ is soluble indefinitely. It is clear from Fig. 3 that concentrated solutions with Mo : Bi ratios 3 : (2-∞) are stable, and diluted solutions (concentration up to ~15%) at any Mo : Bi ratio.

Among the isolated complexes the most interesting are crystalline sodium alkoxomolybdates and tungstates. $NaMo_2O_4(OR)_5 \cdot ROH$ [R = ^{i}Pr (**VI**), Et (**VIII**)] are golden-yellow crystals. They readily eliminate alcohol in dry atmosphere and are especially sensitive to moisture, soluble in benzene and poorly soluble in hexane. Compound **VIII** is extremely unstable: on dissolution in alcohol it decomposes with the precipitation of Na_2MoO_4. At the same time, **VI** is absolutely stable towards alcohol. The equilibrium values of solubility may be achieved by different means of saturation, which suggest that its molecular composition is constant either in the solid state or in solution (quite unusual for simple and complex metal alkoxides).[18,19] The solubility enthalpy ~3.5 kcal mol^{-1} (0–50°C) has been calculated by the Shrëder technique. The solubility polytherm in ^{i}PrOH (Fig. 4) is interrupted at ~80°C (due to the decomposition of the complex, accompanied by dark-red colouring of the solution).

The high stability of **VI** is noteworthy: refluxing a solution of **XI** with excess EtOH results only in the substitution of the solvating alcohol molecule with the formation of $NaMo_2O_4(OPr^i)_5 \cdot EtOH$ (**VII**). However, addition of $NaOPr^i$ to the alcohol solution of **VI** immediately results in the precipitation of Na_2MoO_4 in accordance with the following scheme:

$$NaMo_2O_4(OPr^i)_5 \cdot {}^i PrOH + 3NaOPr^i \longrightarrow 2Na_2MoO_4 + 4{}^i Pr_2O + {}^i PrOH.$$

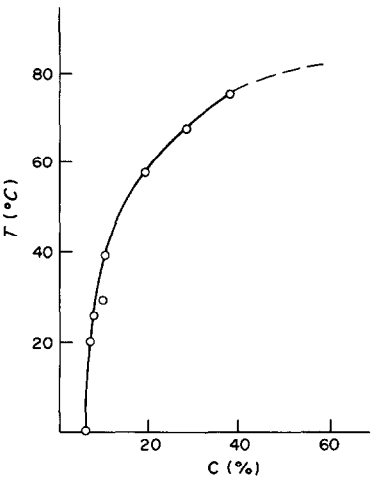

Fig. 4. Solubility polytherm of $[NaMo_2O_4(OPr^i)_5 (^iPrOH)]_2$ (**VI**) in ^{i}PrOH.

The unstable $NaMoO_2(OPr^i)_3$ is presumably formed as an intermediate in the course of this transformation (cf. Fig. 1A).

The X-ray structural study of **VI** has shown that its crystals are formed from centrosymmetric dimeric molecules of $[NaMo_2O_4(OPr^i)_5(^iPrOH)]_2$ (Fig. 5).[20] In each of the two monomeric fragments, one may distinguish a pair of molybdenum atoms [Mo(1) and Mo(2)] which are linked via three RO-bridges: one which is bidentate [RO(3)], bonded only to molybdenum atoms and two which are tridentate [RO(1) and RO(2)], bonded to the sodium atom as well. Along with two μ_3-O alkoxide groups the sodium atom is also coordinated by one μ_2-bridging O(4) atom belonging to the ^{i}PrO-group, bonded only to the Mo(1) atom. The fourth and fifth coordination sites of the sodium atom environment are occupied by the O(10) atom, belonging to the monodentate molecule of the solvating ^{i}PrOH, and the "molybdenyl" oxygen atom O(9′) which is bonded to the Mo(2) atom of the second part of the dimeric molecule.

The $[Mo_2O_4(OPr^i)_5]$ fragment is analogous in its structure to the widely spread group of the type $[M_2X_9]$, which consists of two octahedra with a common face. Fragments of such type are characteristic of clusters in low oxidation states (e.g. in numerous molybdenum and tungsten alkoxides[21]), or in bimetallic complexes of molybdenum(VI) derivatives of the polyatomic aliphatic alcohol mannitol—$Na[Mo_2O_5(\mu_3\text{-}O)_3(OH)C_6H_8(OH)_2]$[22] —and the diatomic phenolpyrocatechin—$(NH_4)_2[Mo_2O_5(C_6H_4O_2)_2] \cdot 2H_2O$.[23] The Mo—Mo bond lengths in these fragments are 3.140 and 3.135 Å, respectively. The peculiarity of the structure of the derivative we studied with a considerably elongated

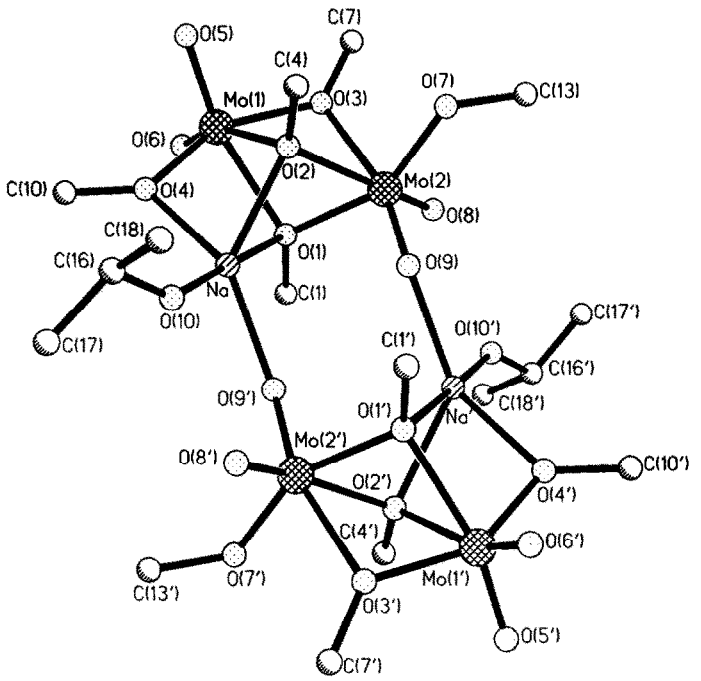

Fig. 5. Molecular structure of $[NaMo_2O_4(OPr^i)_5(^iPrOH)]_2$ (**VI**).

Mo—Mo distance [3.245(1) Å] is that the OR groups which are the residues of the monoatomic alcohol act as bridges. It is interesting to compare the structure of the dimeric fragment in **VI** with the structure of $[W(OBu^t)_2(=NPh)]_2(\mu\text{-}O)(\mu\text{-}OBu^t)_2$. In the latter molecule the two metal atoms are kept together not only by the two μ-OR groups but by oxo-bridges as well.[24] The metal–metal distance is considerably shorter (3.059 Å) and bond angles at the bridging oxygen atoms are much smaller than in **VI** [$\sim 89°$ in comparison with 93.6(1), 96.8(1), 99.6(1)°], presumably due to the presence of the bridging oxo-ligand.

Both molybdenum atoms in the molecule have considerably distorted octahedral surrounding. The different functions of the oxygen atoms in the structure ("molybdenyl", alkoxide terminal, μ_2- and μ_3-bridging) correspond to a considerable difference in the Mo—O values [from 1.690(3) to 2.279(2) Å]. However, in all cases the sums of the bond lengths located in *trans*-positions towards each other in fact coincide (3.90–3.97 Å) (which is usual for the structures of molybdenum compounds[25]). The coordination polyhedron of the sodium atom may be described as a tetrahedron [NaO(2)O(4)O(9)O(10)] (Na—O 2.197–2.999 Å), with one additional and more remote O(1) atom [2.487(3) Å] located over one of its faces. Alternatively, this polyhedron may be treated as a distorted trigonal bipyramid [O(10)NaO(1) 178.8(1)°] with considerably unequal axial distances.

The "active" hydrogen atom on the O(10) atom in **VI** participates in intramolecular hydrogen-bonding, O(10)—H···O(8′) [O(10)—H 0.68(5), H···O(8′) 2.19(5) Å, O(10)—H···O(8′) angle is 166(3)°], which results in the formation of the six nuclear chelate cycle HO(10)NaO(9)Mo(2′)O(8′). Complex **VI** presumably preserves its structure in benzene solution. In the ^{95}Mo NMR spectra there are two lines of approximately equal intensities, +74 and +3 ppm (relative to MoO_4^{2-}), which suggest the existence of molybdenum atoms of two types in the ratio of 1 : 1.

Crystal **I** is built up of dimeric centrosymmetric molecules $[NaWO(OEt)_5(EtOH)_2]_2$ (Fig. 6).[26] Two pairs of atoms, tungsten and sodium, are connected via two μ_3- and four μ_2-bridging alkoxide groups. Such structures formed by four octahedra with common edges (metal atoms belong to one plane) are known for a series of simple as well as double metal alkoxides, e.g. $[Ti(OR)_4]_4$ (R = Me, Et),[27] $[W(OEt)_4]_4$,[28] $[LiNb(OEt)_5(OH)]_2$[29] and $[Mo_4O_{10}(OMe)_6]^{2-}$.[5] While in $[Ti_4(OR)_{16}]$ or $[LiNb(OEt)_5(OH)]_2$ the increase in coordination number of the OR-group results in subsequent elongation of M—O bonds and a decrease in the values of MOC bond angles,[29] in **I** all the bond lengths and bond angles are of approximately the same order.

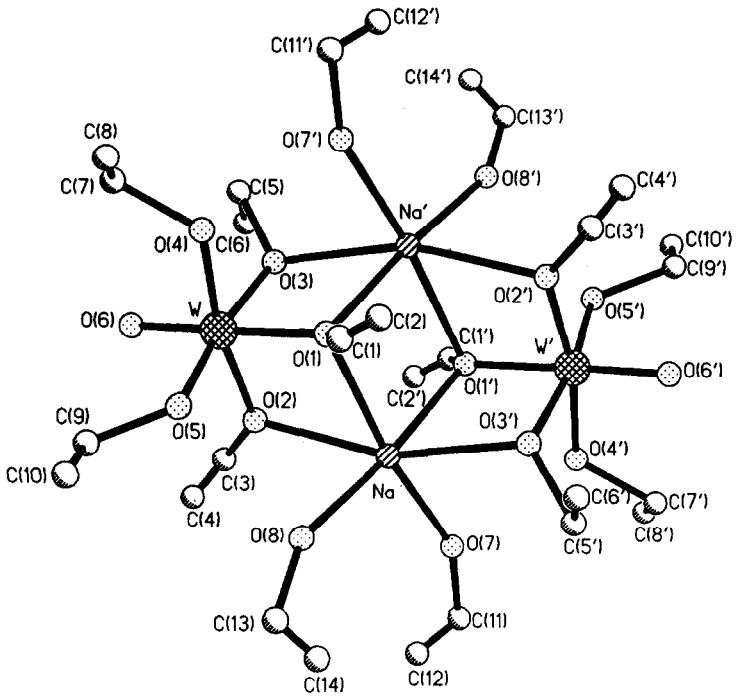

Fig. 6. Molecular structure of $[NaWO(OEt)_5(EtOH)_2]_2$ (I).

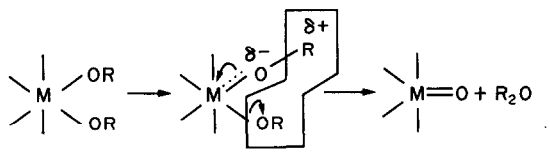
Indeed, the distances between tungsten and the μ_2-bridging alkoxide O atoms [W—O(2) 1.94(2) and W—O(3) 1.99(2) Å] in fact coincide with the distances between W and O atoms of the terminal groups [W—O(4) 1.97(2) and W—O(5) 1.98(2) Å]. Small elongation of the distance between tungsten and the μ_3-bridging oxygen atom to the value of W—O(1) 2.03(2) Å in comparison with the above-mentioned bond lengths does not substantially exceed the experimental error. The mean value of bond angles is 126°. This situation may be easily explained by the ionic character of the bonds between the sodium atom and the $[WO(OR)_5]$ fragment. In this case all OR groups at the tungsten atom are essentially terminal. Indeed the values for the Na—OR bond lengths in this complex (2.47–2.52 Å) indicate its ionic character, and thus complex **I** (in contrast to **VI**) should be regarded as an ionic salt: $[Na(EtOH)_2]_2^+[WO(OEt)_5]_2^-$. Cations and anions are combined into a quite strong ionic pair, not only by the Na···O interaction but also [as far as it can be be anticipated from the O(7)···O(4) 2.71(2) and O(8)···O(5) 2.90(2) Å distances] by hydrogen bonds [O(7')—H···O(4) and O(8)—H···O(5)].

Compound **I** is the second example after $WO(OBu\text{-}t)_4 \cdot THF$[30] among the known structures of the alkoxide derivatives of tungsten(VI) with a terminal oxo-group: usually tungsten alkoxides have the W=O···W chains in their structures.[31] Stability of the "tungstyl" in **I** is probably ensured by the coordination saturation of the tungsten atom in the $[WO(OEt)_5]^-$ anion.

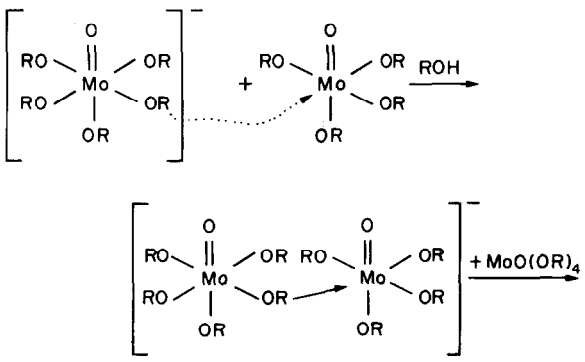
The discussed structure of **I** allows us to make certain suggestions concerning the extreme instability of the bimetallic complexes of molybdenum with the Na : Mo ratio 1 : 1. Assuming the analogy between the structures of **I** and of $NaMoO(OR)_5$. which are unknown in the solid state, it may be anticipated that the coordination sphere of the molybdenum atom contains five terminal OR groups. In accordance with the mechanism of decomposition of alkoxides occurring with the elimination of ether,[32] this complex must be extremely unstable:



Indeed, attempts to isolate this in the solid state have resulted in the precipitation of Na_2MoO_4.

$MoO(OR)_4$ are oligomers with bridging OR groups, which allow them to exist in the free state for a certain, although not long, period of time. These compounds may be stabilized by polymerization (by the introduction of small amounts of NaOR). It may be suggested that the anion $[MoO(OR)_5]^-$ formed on the introduction of

NaOR (alkoxide groups of the latter possess high electron-donor properties) attacks the neutral $MoO(OR)_4$ molecules causing the chain growth, and thus leading to the polymolybdate anions of the following type:



This mechanism is analogous to that described earlier[18] for polymerization of the oligomeric Al, Fe, Ti alkoxides with alcohols [the electron-donor properties of the latter proved, however, insufficient to cause "ageing" of $MoO(OR)_4$]. Stability of molecule **VI** towards decomposition with the elimination of ether is presumably ensured by the existence in the structure of the minimal number of terminal OR groups (only two) per four molybdenum atoms.

Overall, the process occurring in the interaction of $MoO(OR)_4$ with NaOR may be expressed by the scheme represented in Fig. 7.

The structures of complexes **I** and **VI** are of interest in connection with the widely discussed problem

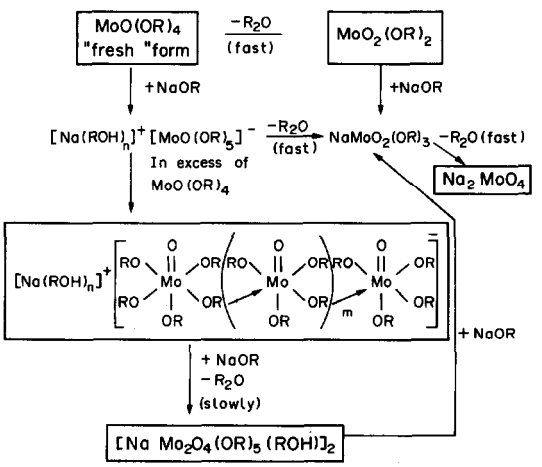


Fig. 7. Scheme of transformations occurring in the interaction of $MoO(OR)_4$ with NaOR (R = Et, ^{i}Pr). Compounds isolated as individual species are enclosed in boxes.

concerning the nature of double metal alkoxides ("Meerwein salts"). The properties of most of the complexes in this class as well as the data on their crystal structures,[1] e.g. $Li[Cr\{OCH(OBu^t)_2\}_4]\cdot THF$, $Li[Fe\{OCH(OBu^t)_2\}_4]\cdot {}^tBu_2CHOH$ and $[LiNb(OEt)_5(OH)]_2$, indicate their molecular nature.[29,33,34] On the other hand $Na[B(OMe)_4]\cdot MeOH\cdot 1.5\ H_2O$,[35] $[R_4N][W(OPh)_6]$[3] and $Na_2[Mo_6(OMe)_6(\mu_3\text{-}X)_8](MeOH)_{10}$, where X = Cl, OMe,[36] as well as the above mentioned methylated molybdates[4-6] contained in their structures, can isolate cations and anions of alkoxometallates in agreement with the ideas developed by Meerwein.[37] Structures **I** and **VI** allow us to return to the discussion of this problem. Comparison of the three shortest Na—O distances (2.20–2.30 Å) in molecule **VI** with those known for the alkoxides NaOMe, $NaOBu^t$ (2.24–2.32 Å)[38,39] and ionic structures (NaOH, Na_2O, Na_2SO_4, $Na[B(OMe)_4]\cdot MeOH\cdot 1.5\ H_2O$, Na···O 2.39–2.47 Å[35,40]) suggests that the short bonds in **VI** are at least partially covalent. Distortion of the planar surroundings of the oxygen atom which is coordinated by sodium may also be regarded as an indirect argument supporting this suggestion. Thus, the sum of the bond angles at the O(3) atom [μ_2-bridge between Mo(1) and Mo(2)] is 358.8°, whereas at the O(1) and O(2) atoms [μ_3-bridges between Mo(1), Mo(2) and Na] the MoOC angles are 348.4 and 339.9°, respectively. Thus, both oxygen atoms, especially O(2), which form a shorter bond with sodium than O(1) [2.299(3) and 2.487(3) Å] are displaced from the plane. The O(4) atom, which forms only three bonds [with Na, Mo(1) and C(10)], and O(3) have almost planar surroundings: the sum of the bond angles is 358.8°.

The manner in which the alkaline metal atom is adjusted to the dimeric fragment of the $[Mo_2(OR)_9]$ type in molecule **VI** is analogous to that known, for instance, for $KU_2(OBu^t)_9$, in which potassium coordinates two oxygen atoms of μ-OR groups and one oxygen atom of the terminal OR groups belonging to different uranium atoms.[41] However, the K—O bonds, judging by the bond lengths (~2.93–2.97 Å), are ionic. The oxygen atoms are located in the base of the tetragonal pyramid with the potassium atom at its apex.

The bimetallic methoxyethoxide derivative $NaMoO_2(OC_2H_4OMe)_3$ (**XI**) is built up of dimeric centrosymmetric molecules (Fig. 8),[42] analogous in structure to **I**. However, the positions of the sodium atoms in molecule **XI** are occupied by the tungsten atoms in **I** and alternatively, Mo in **XI** is equivalent to sodium in **I**. In contrast to **I**, $Ti_4(OR)_{16}$ and other structural analogues, molecules of **XI** are linked into infinite chains by pairs of asymmetric

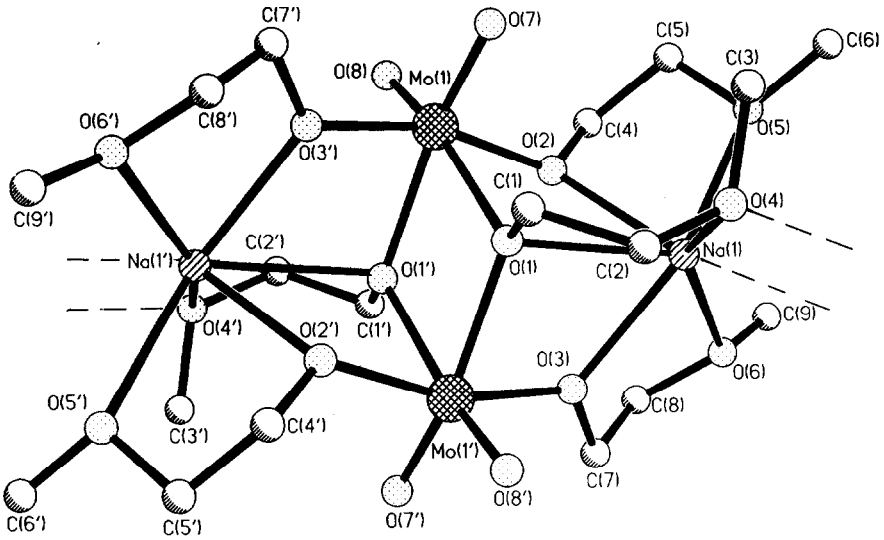

Fig. 8. Molecular structure of $[NaMoO_2(OC_2H_4OMe)_3]_2$ (**XI**).

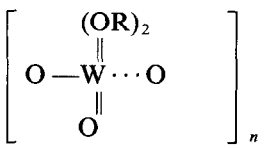
bridges which are formed by the ether oxygen atoms O(4) and O(4′) of one of the three methoxyethoxide groups. In general, the skeleton of the tetranuclear fragment $[Na_2Mo_2O_4(OC_2H_4OMe)_6]$ is similar in its structure to the cation $[Mg_4(OC_2H_4OMe)_6(MeOC_2H_4OMe)_2]^{2+}$:[43] the alkoxide oxygen atoms form bridges (μ_2 and μ_3) and the ether oxygen atoms form monodentate bridges [with the exception of O(4)]. These are part of the coordination sphere of sodium atoms thus forming chelate cycles round them. The molybdenum atoms are also attached due to the enhanced coordination number of the alkoxide oxygen atoms. The tridentate O(1) and O(1′) are located at distances of 2.255(3) and 2.162(3) Å from molybdenum, respectively, while the bidentate O(2) and O(3) are at the distances of 1.964(3) and 1.975(3) Å. Two terminal oxo-groups complete the molybdenum octahedron (Mo=O ~ 1.705 Å). The lengths of the Mo—O bonds located in the *trans* position are 3.86–3.96 Å.

A highly distorted seven-vertex polyhedron surrounding the sodium atom consists of three alkoxide oxygens [tridentate O(1), two bidentate oxygens O(2) and O(3) at the distances of 2.689(3), 2.341(4) and 2.308(4) Å, respectively] and three ether oxygens—O(4), O(5) and O(6) (with bond lengths 2.493–2.529 Å). The seventh place is occupied by the ether oxygen atom O(4′) of the neighbouring four-nuclear molecule at a distance of 2.881(4) Å, which, however, exceeds the length of the chemical bond Na—O. The Na—O (alkoxide) bond lengths in **XI** are close to those values in **VI** and NaOR; this fact together with the dependence of the Mo—O bond lengths on the coordination of oxygen indicates the molecular character of the bimetallic methoxyethoxide derivative (**XI**). The absence of the terminal OR groups and the formation of chelate cycles presumably ensure high stability of the complex towards decomposition with the elimination of ether.

The structure of **XI** differs from the structures of the known methoxyethoxides of bismuth and yttrium[44–46] by the absence of the terminal OR groups and should be close to that of $Ba_2Cu_2(\mu_3\text{-}OC_2H_4OMe)_4(acac)\cdot 2MeOC_2H_4OH$,[47] which is presumably due to the tendency of sodium and barium to chelate to polyoxoligands.

The structural data discussed above are in a good agreement with the IR spectra of bimetallic complexes. Thus, the IR spectra of **VI** contains bands corresponding to the vibrations of the two terminal (620 cm^{-1}), four bidentate (of two types) and four tridentate alkoxide groups (525, 530, 565 cm^{-1}); *cis*-MoO_2 (~930, 980 cm^{-1}); free (~910 cm^{-1}) and sodium-bonded (~885 cm^{-1}) "molybdenyls" Mo=O, and the band (OH) of the solvating alcohol (3440 cm^{-1}). The spectrum of **I** could not be registered due to quick desolvation with the formation of $NaWO(OEt)_5$ (**II**), which appears to be a result of condensation with the formation of new Na···O···W or Na—OR—W bridges (analogous to Na···O—Mo and Na—OR—Mo in structure **VI**). The spectra of **II** contain the only band (895 cm^{-1}) in the region corresponding to vibrations of W=O bonds and two bands corresponding to bridging and terminal OR groups (620 and 585 cm^{-1}). Thus, the formation of bridges by the terminal W=O seems the most probable variant. The

only W—OR band (600 cm^{-1}) in the spectra of $WO(OEt)_4$ and $WO_2(OEt)_2$ splits into two (620 and 585 cm^{-1}) in the spectra of **II** and $NaWO_2(OEt)_3$ (**III**), probably due to the existence of bridging along side the terminal alkoxides. The absorption bands corresponding to vibrations in the units of W=O···W chains in the crystal structure of $WO(OEt)_4$-*trans* $[WO_2(OEt)_4]_\infty$ (795 cm^{-1}) or



(880 cm^{-1}) shift in the amorphous $WO_2(OEt)_2$ in the direction of high-frequencies (~900–930 cm^{-1}) as a result of complex formation occurring with the rupture of asymmetric bridges and building of structures with presumably molecular character. On the other hand, in the IR spectra of $MoO_2(OR)_2$ (**X**), the associates of which contain bridges of both types —Mo···O···Mo and Mo—OR—Mo, no drastic changes were seen in the character of the IR spectra when formation of complexes with NaOR occurs. The crystalline $MoO_2(OC_2H_4OMe)_2$ is the only exception. All its oxogroups are terminal (945, 910 cm^{-1}) and $MeOC_2H_4O$ groups take part in the formation of the chelate cycles (565 cm^{-1}).[42] In $NaMoO_2(OC_2H_4OMe)_2$, ν(Mo=O) only slightly shifts in the low-frequency direction and ν(Mo—OR) splits into 605, 520 and 480 cm^{-1}.

Acknowledgement—The authors would like to express their gratitude to the student A. V. Korolev for his experimental assistance, Dr M. A. Fedotov (Institute of Catalysis of the Siberian branch of the Academy of Sciences of the U.S.S.R.) for the measurements of the ^{95}Mo NMR spectra and Dr A. I. Belokon' (State Institute of Chemical Technology of the Organometallic Compounds) for the measurements of the mass spectra of the alkoxides studied.

THE CHARACTERIZATION OF $[HSe]^-$ AND $[Se_x]^{2-}$ IONS BY ^{77}Se NMR

JOHN CUSICK and IAN DANCE*

School of Chemistry, University of New South Wales, PO Box 1, Kensington, NSW 2033, Australia

(*Received* 26 *March* 1991; *accepted* 20 *May* 1991)

Abstract—Preparative reactions for the ions Se^{2-}, HSe^- and $[Se_x]^{2-}$ in protic and aprotic solvent systems are established, and these ions in solution have been characterized by the most informative probe, ^{77}Se NMR. Fully reduced solutions in DMF contain HSe^- for which δ_{Se} ranges between -530 and -390 ppm (vs Me_2Se) depending strongly on solvent and temperature: $^1J(Se—H) = 26$ Hz. Although HSe^- and Se^{2-} are in fast equilibrium, there is no *direct* NMR evidence for the conjugate strong base Se^{2-} in any of these solutions, and it is predicted that $\delta_{Se}(Se^{2-}) < -650$ ppm. There is no NMR evidence for $[Se_2]^{2-}$, which is believed to disproportionate to HSe^- plus $[Se_x]^{2-}$ ($x > 2$) or $Se_{(s)}$. The polyselenide ions $[Se_x]^{2-}$, $x = 3$–6, all exist in DMF, and the resonances for all selenium atoms in each of these ions have been observed and assigned. Using α, β, γ to signify selenium positions relative to the equivalent ends of the chain, the $\delta_{Se}(\alpha)$, $\delta_{Se}(\beta)$, $\delta_{Se}(\gamma)$ data [in DMF plus 38% (vol) EtOH, 230°K] are: $[Se_3]^{2-}$, 193, 214, -; $[Se_4]^{2-}$, 256, 581, -; $[Se_5]^{2-}$, 354, 570, 868; $[Se_6]^{2-}$, 404, 636, 807. The chemical shifts of the Se(α) in these ions are very responsive to the solvent proticity, becoming more negative in the range DMF → ethanol, while the Se(β) atoms respond much less, and the effect at the Se(γ) atoms is small and can be in the other direction. Protic solvents retard the selenium exchange reactions of polyselenide ions. Comparative analysis is made of the δ_{Se} values for related compounds of type XSe^- or with chains of selenium atoms. There is no NMR evidence for ions with $x > 6$. The spirocyclic ion $[Se(Se_5)_2]^{2-}$ is formed from $[Se_x]^{2-}$ with many oxidants, including NO_3^- in DMF, and possesses only one exchanging ^{77}Se resonance at 720 ppm.

Although monoselenide (Se^{2-} and HSe^-) and polyselenide (Se_x^{2-}) salts with alkali and some transition metals have been known as solid compounds for some time, it is only recently that non-aqueous solvents have been used to expand the range of equilibria and compounds accessible.[1–22] This has paralleled more extensive development of polysulphide and metal polysulphide chemistry in non-aqueous media.[23]

The characterized crystalline salts of polyselenide ions (not containing transition and post-transition metals) are listed in Table 1, together with the preparative reactions and the characterization data. Despite this large amount of information about isolated compounds, uncertainty surrounds knowledge of the species and their interconversions in solution. This occurs because electronic and vibrational spectra are not unambiguously definitive. The electronic spectra of polyselenide ions in liquid ammonia contain multiple overlapping absorptions.[24] We have used ^{77}Se NMR to investigate $[Se_x]^{2-}$ ions and their metal complexes, because this technique can probe individual selenium atoms. The advantages of ^{77}Se NMR are the wide chemical shift range of *ca* 3000 ppm, the consequent dynamic range of 10^{-2}–10^{-5} s for access to interconversion reactions, and the ability to make measurements over a substantial temperature range. It has been claimed[2] that ^{77}Se NMR signals cannot be observed for $[Se_x]^{2-}$ ions in DMF solution because paramagnetic monoanions $[Se_x]^-$ are present, but we do observe the ^{77}Se NMR of $[Se_x]^{2-}$ in DMF, and report our results here. We also report new results on the preparation and redox interconversions of polyselenide ions.

Table 1. Crystalline salts of polyselenide ions (compounds containing transition metals and post-transition metals are excluded)

Polyselenide ion Cation	Preparative reactions	Crystallization solvent	Characterization data	Reference
$[Se_2]^{2-}$ Na^+	Se + Na, in NH_3	NH_3	Crystal structure	25
$[Se_3]^{2-}$ $[CH_3(CH_2)_{15}NMe_3]^+$	Na_2Se_2 + 10Se, in ethanol	Ethanol	CHN analysis	26
$[Se_4]^{2-}$ $Ph_3PNPPh_3^+$	Cs_3TaSe_4	CH_3CN	Crystal structure	27
$[Se_4]^{2-}$ $[Ba(en)_4]^{2+}$ en	Ba + Se, in ethylenediamine	Ethylenediamine	Crystal structure	28
$[Se_4]^{2-}$ $[Ba(2,2,2\text{-crypt})]^{2+}$	$BaBiSe_3$ + 2,2,2-crypt	Ethylenediamine	Crystal structure	29
$[Se_5]^{2-}$ Ph_4P^+	Side product from $Na_2Se_x + PtCl_2 + Ph_4PCl$	DMF	Crystal structure	16
	Unplanned product from Zr + $Zr(OEt)_4$ + Se + Ph_4PCl + $(OctMe_2Si)_2Se$	DMF/ether	Crystal structure, IR	30
$[Se_5]^{2-}$ $[Cs(18\text{-crown-}6)_2]^+$	Cs_3TaSe_4	CH_3CN	Crystal structure	27
$[Se_5]^{2-}$ Cs^+	Cs + Se, in NH_3	NH_3	Crystal structure	31a
$[Se_5]^{2-}$ Rb^+	Se + Na, in NH_3	NH_3	Crystal structure	31b
$[Se_5]^{2-}$ $[CH_3(CH_2)_{15}NMe_3]^+$	Na_2Se_2 + 10Se, in ethanol	Ethanol	CHN analysis	26
$[Se_6]^{2-}$ Bu_4N^+	Na_2Se_6, in H_2O	Water	Crystal structure, vibrational spectra, electronic spectra	32
$[Se_6]^{2-}$ Et_4N^+	Na_2Se + 10Se, in ethanol	Ethanol	CHN analysis	26
$[Se_6]^{2-}$ $[CH_3(CH_2)_{13}NMe_3]^+$	Na_2Se + 10Se, in ethanol	Ethanol	Crystal structure	26
$[Se_7]^{2-}$ $[CH_3(CH_2)_{15}NMe_3]^+$	Na_2Se + Se, in ethanol	Ethanol	CHN analysis	26
$[Se_8]^{2-}$ $[CH_3(CH_2)_{13}NMe_3]^+$	Na_2Se + Se, in ethanol	Ethanol	CHN analysis	26
$[Se_9]^{2-}$ $[CH_3(CH_2)_{13}NMe_3]^+$	Na_2Se + Se, in ethanol	Ethanol	CHN analysis	26
$[Se_{11}]^{2-}$ Ph_4P^+	$Na_2Se_5 + I_2$, in DMF, $Na_2Se_5 + AuCl_3$, in DMF	DMF	Crystal structure, two crystal forms, spirocyclic $[Se(Se_5)_2]^{2-}$	13
$[Se_{11}]^{2-}$ Ph_4P^+			Crystal structure	33
$[Se_{10}]^{2-}$	Li + Se in DMF	DMF	Crystal structure	34
$[Se_{16}]^{4-}$ Cs^+	Cs_2CO_3 + Se, in MeOH at 160°C	MeOH	Crystal structure, Se_6 cycle with two Se_5 chains connected to one square planar selenium	22

EXPERIMENTAL

Materials, solvents and general methods

All preparations were performed under N_2(g). DMF was purified by treatment with 4A molecular sieves for several days, followed by vacuum distillation. Solvents were deoxygenated before use. The selenium used was the black powder.

Preparation of solid compounds

NaHSe, *eq.* (1).[35] Selenium powder (1.0 g, 13 mmol) was stirred with absolute ethanol (20 cm^3) cooled with ice. Solid $NaBH_4$ (1.0 g, 26 mmol) was added gradually with stirring, causing the vigorous and exothermic evolution of hydrogen. The mixture became brown and then colourless. On completion the ethanol was distilled out leaving a white solid. $B(OC_2H_5)_3$ was not separated from NaHSe.

$$NaBH_4 + Se + 3C_2H_5OH \longrightarrow NaHSe + B(OC_2H_5)_3 + 3H_2. \quad (1)$$

$(Bu_4N)_2[Se_6]$. A flask fitted with a low temperature condenser was charged with selenium powder (2.0 g, 25 mmol) and liquid NH_3 (30 cm^3). Sodium (0.20 g, 8.7 mmol) was added and the mixture stirred until all sodium had dissolved to form a dark green solution. After removal of the NH_3, water (20 cm^3) was added to form a dark green solution, which was cooled to 0°C and treated with a cooled solution of Bu_4NBr (2.73 g, 8.5 mmol) in water (10 cm^3). The dark green needles that formed at 0°C were filtered, washed with cold water, and dried *in vacuo*. Yield 3.3 g (81%). The solid, which is oxidized to selenium after several hours exposure to air, was identified by its powder diffraction. This reaction has been successfully scaled up tenfold.

$(Ph_4P)_2[Se_5]$. The procedure of the previous reaction was followed, using selenium powder (5.0 g, 63 mmol), NH_3 (40 cm^3 liquid) and Na (0.58 g, 25 mmol), generating a dark green solution after stirring for 40 min. After removal of the NH_3 to leave a red–brown solid, water (100 cm^3) was added to form a dark red solution, which was cooled to 0°C and treated with a cooled solution of Ph_4PBr (10.6 g, 25 mmol) in ethanol (50 cm^3). The black–brown needles that formed at 0°C were filtered, washed with cold water, and dried *in vacuo*. Yield 8.2 g (88%). The compound was characterized by single crystal diffraction analysis.[36]

$(Ph_4P)_2[Se(Se_5)_2]$. To a flask fitted with a low temperature condenser was added selenium powder (5.0 g, 63 mmol) and liquid NH_3 (40 cm^3). Sodium (0.58 g, 25 mmol) was added and the mixture stirred for 40 min, generating a dark green solution. After removal of the NH_3 to leave a red–brown solid, DMF (80 cm^3) was added and the mixture stirred to complete dissolution. $NaNO_3$ (1.08 g, 13 mmol) and Ph_4PBr (5.3 g, 13 mmol) were added, and the stirring was continued for 30 min to generate an olive green solution. After filtration, THF (80 cm^3) was layered onto the solution which was stored at *ca* 0°C. After 2 days black crystals had formed. They were collected, washed with THF, and vacuum dried. Yield 1.06 g. The product was identified by powder X-ray diffraction, and by complete crystal structure determination.[37]

Preparations of solutions for NMR

NaHSe *in aqueous solution.*[35] $NaBH_4$ (1.0 g, 26 mmol) in water (10 cm^3) was stirred into a suspension of selenium (1.0 g, 13 mmol) in water (10 cm^3), at room temperature. After 10 min the H_2 evolution had ceased and the selenium had dissolved completely to yield a pale grey solution.

NaHSe *in ethanol solution.* Following Klayman and Griffin[35] eq. (1), excess $NaBH_4$ was used in this reaction. Cold absolute ethanol (20 cm^3) was added with stirring to a mixture of selenium (1.0 g, 13 mmol) and $NaBH_4$ (0.58 g, 15 mmol), and the mixture cooled during the vigorous evolution of hydrogen. A colourless solution resulted.

NaHSe *in DMF solution.* The ethanol was distilled from the previous solution, yielding a white solid which was dissolved in DMF (20 cm^3) to generate a colourless solution.

"Na_2Se_2" *in aqueous solution.* Following Klayman and Griffin[35] $NaBH_4$ (1.0 g, 26 mmol) in water (10 cm^3) was added with stirring to selenium (1.0 g, 13 mmol) suspended in water (10 cm^3) at room temperature. After the initial vigorous reaction had subsided, a further portion of selenium (1.0 g, 13 mmol) was added, the mixture stirred for 15 min, and then briefly heated to complete the reactive dissolution of the selenium, yielding a dark red–brown solution. After storage at 0°C for 16 h a black precipitate formed, but the solution was still strongly coloured.

"Na_2Se_2" *in ethanol solution, eq.* (2).[35] Absolute ethanol (100 cm^3) was added with stirring to selenium (3.0 g, 38 mmol) and $NaBH_4$ (1.0 g, 26 mmol) cooled with ice. After the initial reaction had subsided the mixture was heated at reflux for 1.5 h, while the N_2 flush gas containing H_2Se was passed through aqueous lead acetate, yielding PbSe (1.15 g, 4.0 mmol). The dark red–brown reaction solution formed a small amount of black precipitate on storage at 0°C.

$$2NaBH_4 + 3Se + 6C_2H_5OH \longrightarrow Na_2Se_2 + H_2Se + 2B(OC_2H_5)_3 + 6H_2. \quad (2)$$

"Na_2Se_x" *in DMF solution*, $x = 3$–6. The general procedure is the same for all compounds, so the description of Na_2Se_4 only is presented in detail. A two-necked flask was charged with selenium powder (1.0 g, 13 mmol), fitted with a low temperature condenser, and NH_3 (30 cm^3 liquid) was condensed into the flask. Sodium (0.15 g, 6.3 mmol) was then added against a N_2 stream, and the reaction mixture was stirred at $< -60°C$ for about 1 h until the dissolution of sodium was complete. The solution colour changed from initial blue though various colours to dark brown. The NH_3 was evaporated, leaving a dark coloured solid which was dried *in vacuo* for a further 1.2 h. The solid was then dissolved in freshly distilled and degassed DMF (15 cm^3) at room temprature, generating a dark brown coloured solution.

Preparative data for other solutions are presented as: nominal composition "Na_2Se_x"; amount of sodium; amount of selenium; volume (cm^3) of NH_3 and colour; volume (cm^3) of DMF and colour. "Na_2Se_3"; 0.21 g (9.1 mmol); 1.0 g (12.7 mmol); 30, green; 15, brown–red. "Na_2Se_4", 0.15 g (6.5 mmol); 1.0 g (12.7 mmol); 30, brown; 15, brown. "Na_2Se_5", 0.12 g (5.2 mmol); 1.0 g (12.7 mmol); 30, green; 15, green. "Na_2Se_6", 0.097 g (4.2 mmol); 1.0 g (12.7 mmol); 30, green; 15, green. "Na_2Se_7", 0.17 g (7.4 mmol); 2.0 g (25 mmol); 50, green; 20, green. "Na_2Se_8", 0.15 g (6.5 mmol); 2.0 g (25 mmol); 50, green; 20, green. "Na_2Se_9", 0.13 g (5.6 mmol); 2.0 g (25 mmol); 50, green; 20, green. "Na_2Se_{10}", 0.12 g (5.2 mmol); 2.0 g (25 mmol); 50, green; 20, green. "Na_2Se_{11}", 0.11 g (4.4 mmol); 2.0 g (25 mmol); 50, green; 20, green. Very small amounts of unreacted selenium were removed.

Attempts to use this procedure to generate a solution of Na_2Se_2 in DMF generated white solids that would not dissolve in DMF, and were abandoned.

NMR

The ^{77}Se spectra were measured at 57.2 MHz with a Bruker CXP300 spectrometer, using a 10 mm broadband probe. The spectra were recorded at temperatures in the range *ca* $-60°C$–$27°C$.[38] A 40° pulse (20 μs) was used, with a pulse delay of 1 s. Natural line widths at half height range from 13–90 Hz. Chemical shifts, positive with high frequency, are relative to Me_2Se. A saturated solution of Na_2SeO_3 in H_2O was used as the secondary chemical shift reference, set as 1253 ppm (at 300 K) relative to the primary standard of neat Me_2Se = 0 ppm.[39,40]

RESULTS

HSe^- *and* Se^{2-}

We have used ^{77}Se NMR to characterize this pair of ions, the shortest members of the $[Se_x]^{2-}$ series. The spectra of several solutions are shown in Fig. 1, and all chemical shift data are presented in Table 2. The spectrum of the aqueous solution obtained

Table 2. ^{77}Se NMR data for solutions containing Se_1 species

Solution	Temperature (°K)	Chemical shift (ppm)[a]	Resonance characteristics
NaHSe in water (0.63 M)	300	−529	Doublet, $^1J(^{77}Se—^1H)$ = 26 Hz
NaHSe in ethanol (0.63 M)	300	−518	Singlet, 30 Hz (fwhh[b])
NaHSe in DMF (0.63 M)	300	−447	Singlet, 55 Hz fwhh
	260	−404

	ca 235	−509	25 Hz doublet well resolved

[a] Reference $SeMe_2$.
[b] fwhh = full width at half height.

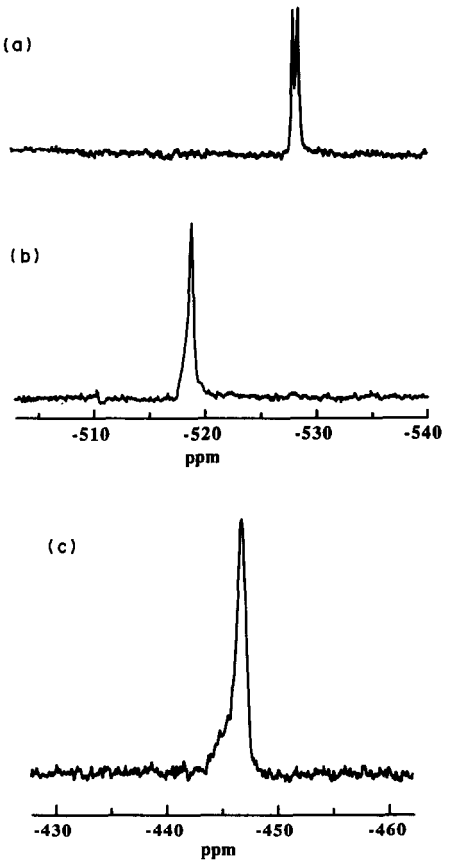

Fig. 1. ^{77}Se NMR spectra of solutions of NaHSe (*ca* 0.63 M) in (a) H_2O, (b) ethanol, and (c) DMF, at 300°K.

by BH_4^- reduction of selenium is a doublet, at $\delta_{Se} = -528$ ppm (300°K). The splitting of *ca* 26 Hz is presumed to be ^1J(Se—H) coupling because it is comparable with the value of 60.8 ± 0.1 Hz for H_2Se[41] and values of 38–61 Hz for RSeH.[42] Addition of NaOH, in attempt to deprotonate the HSe^-, causes instead the crystallization of a solid believed to be Na_2Se:[43,44] addition of Et_3N did remove the splitting, but moved the resonance to −519 ppm. However this experiment is not decisive, because the amount of Et_3N required to be equivalent to the high concentration of HSe^- is not miscible with the aqueous phase: the high proportion of Et_3N probably causes a medium effect in the chemical shift, as discussed below. Further, the K_a data for H_2Se in water[45] indicate that Et_3N would not be sufficiently basic to deprotonate HSe^- in water. Because K_a (HSe^-) is expected to be even smaller in aprotic solvents than the value of 10^{-15} in water, it is most probable that in all of our solutions the principal species is HSe^-. The resonances for solutions of HSe^-/Se^{2-} formed by other means and in other solvents are all at least 20 Hz wide at half height, and the ^1J(Se—H) coupling is generally poorly resolved, if at all. We recognise that some of the line broadening (up to 60 Hz) may be caused by minor amounts of Se^{2-} in fast exchange with HSe^-. However, the spectra are reproduceable, indicating that adventitious base in these unbuffered solutions is not influential. In the absence of definite evidence to the contrary, we presume that the species present in all of our fully reduced (colourless) solutions is HSe^-, despite the limited observation of the ^1J(Se—H) coupling.

Solutions of HSe^- prepared by borohydride reduction in ethanol showed only a sharp singlet at $\delta_{Se} = -519$ ppm (300°C), while in DMF the resonance is shifted substantially to −447 ppm. This is a medium influence on the chemical shift, which is similar in magnitude to the medium influences observed for Br^- and other halide ions,[46,47] and correlates with the thermodynamic activation of small anions in aprotic media.[48–50] Chemical shifts for *uncharged* organoselenium compounds are solvent dependent by up to 50 ppm[51] and it is known that other properties of anions are affected more by solvent proticity than are uncharged analogs. The δ_{Se} data for HSe^- in DMF/ethanol and DMF/water mixtures are intermediate between the extremes, confirming that these variations in chemical shifts are due to anion solvation.

The temperature dependence of δ_{Se} for HSe^- in DMF is large, *ca* −1 ppm per degree.

$[Se_2]^{2-}$

This ion has not been well characterized in solution. The reaction of selenium and equimolar sodium in NH_3 yielded a bright red solution and a white solid, but not a homogeneous product.[52] Literature procedures for generation of $[Se_2]^{2-}$ in solution, including reduction of selenium by BH_4^- in water (eq. 3) or ethanol (eq. 2),[35] or by reduction with sodium in DMF,[53] were assessed only through further reactions of the solutions, which were consistent with substantial yields of $[Se_2]^{2-}$ in the reduction stage. Therefore we have measured the ^{77}Se NMR of the solutions formed in ethanol or water by BH_4^- reduction, and found that in both cases there is a single resonance at the same δ_{Se} as the HSe^- solutions described above.[54] This result is consistent with our observations (see Experimental) that the amount of H_2Se formed is less (*ca* 1/3) than predicted for reaction (2), and the fact that the solutions deposited some elemental selenium on standing, indicating disproportionation. The resonance from the ethanol solution at −518 ppm is a doublet with the same 26 Hz splitting as observed for NaHSe in water. Thus we have no NMR evidence for $[Se_2]^{2-}$ in aqueous or ethanolic solution.

$$4NaBH_4 + 2Se + 2H_2O \longrightarrow 2NaHSe + Na_2B_4O_7 + 14H_2 \quad (3a)$$

$$Na_2B_4O_7 + 2NaHSe + 2Se + 5H_2O \longrightarrow 2Na_2Se_2 + 4H_3BO_3. \quad (3b)$$

When equimolar sodium and selenium were reacted in DMF at 90°C a dark red solution was obtained, which showed two equal intensity selenium resonances at 598 and 347 ppm (*ca* 220 K). This is consistent with the presence of $[Se_4]^{2-}$ (see below), and thus it appears that there is disproportionation of $[Se_2]^{2-}$ to $[Se_4]^{2-}$ and probably $[HSe]^-$. When the "Na_2Se_2" formed by reaction of the elements in NH_3(l) is treated with DMF there is not complete dissolution but instead formation of white and black solids which we interpret as disproportionation to Na_2Se and Se.

Na_2Se_x *in solution*

Solutions with nominal compositions Na_2Se_x, $x = 3$–11, and concentrations of approximately 0.3 M were prepared by reaction of sodium and selenium in NH_3(l) followed by removal of solvent and redissolution in DMF. The "Na_2Se_4" solution was brown, "Na_2Se_3" was green in NH_3 but brown in DMF, while the other "Na_2Se_x" solutions were green. All solutions were highly susceptible to oxidation by O_2, precipitating selenium on exposure to air of less than 5 s. Therefore rigorous techniques were used throughout.

None of these solutions showed ^{77}Se resonances at 300°K, and it was necessary to reduce the temperatures to *ca* 240°K in order to obtain satisfactory spectra. This temperature effect is illustrated in Fig. 2 with the spectra from the solution "Na_2Se_5" at different temperatures. There is a collection of resonances which appear for solutions "Na_2Se_3", "Na_2Se_4", "Na_2Se_5" and "Na_2Se_6", but we have not been able to detect any resonances for the solutions "Na_2Se_x", $x > 6$. We have scanned the chemical shift range 2100 to −500 ppm, at room temperature and low temperatures, with no evidence of additional resonances. Although all of the solutions are in the slow exchange regime, the slow exchange limit for polyselenide interconversions is below the accessable measurement temperatures.

The resonances for "Na_2Se_3", "Na_2Se_4", "Na_2Se_5" and "Na_2Se_6" are shown diagrammatically in Fig. 3. Clearly there exists more than one $[Se_x]^{2-}$ ion in some of these solutions, but the resonances belonging to each of the species $[Se_3]^{2-}$, $[Se_4]^{2-}$, $[Se_5]^{2-}$ and $[Se_6]^{2-}$ can be assigned unequivocally. Referring to Fig. 3, the resonances at 251 and 192 ppm (intensity ratio 2:1) are due to $[Se_3]^{2-}$; the equal intensity lines at 591 and 301 ppm are due to $[Se_4]^{2-}$, those at 860, 603 and 448 ppm (relative intensities 1:2:2) are due to $[Se_5]^{2-}$, while the equal intensity resonances at 798, 681 and 497 ppm are due to $[Se_6]^{2-}$.[55]

We have not been able to detect ^nJ(Se—Se) coupling satellites that would assist with the assignment of the resonances: the intensities of the satellites at

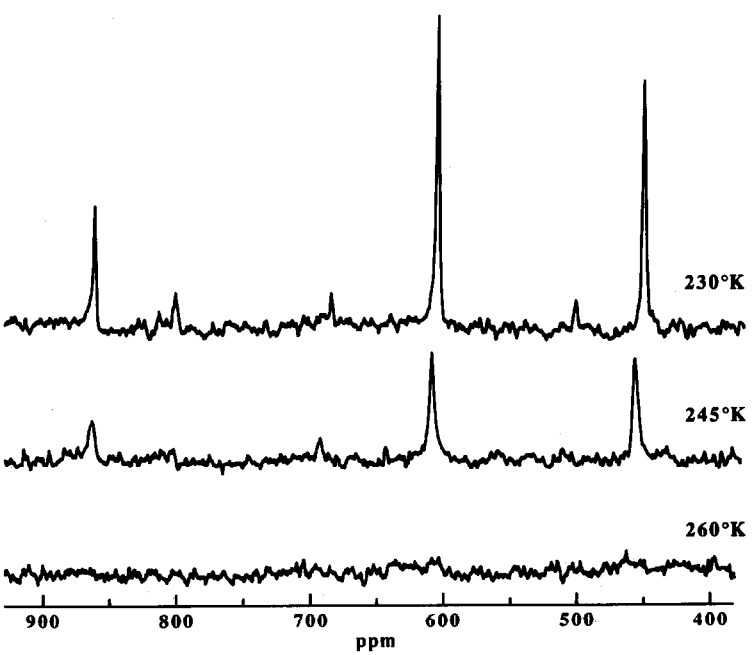

Fig. 2. ^{77}Se NMR spectra of "Na_2Se_5" in DMF at the temperatures marked.

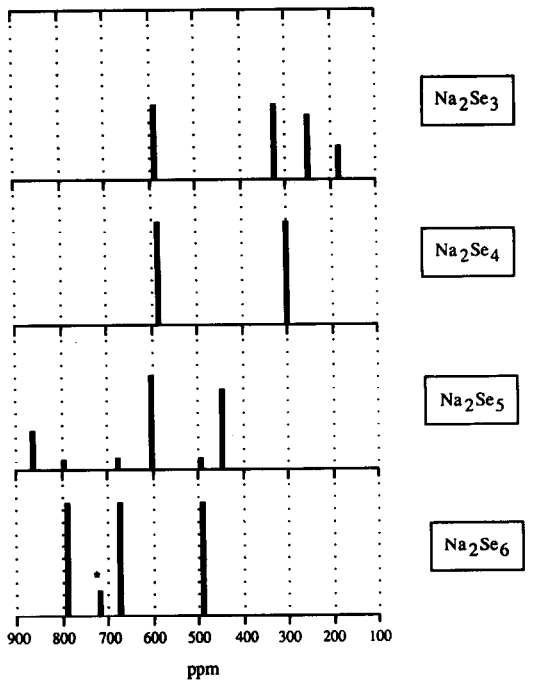

Fig. 3. Diagram of the ^{77}Se NMR resonance positions and intensities for solutions of nominal compositions Na_2Se_x in DMF at 230 K.

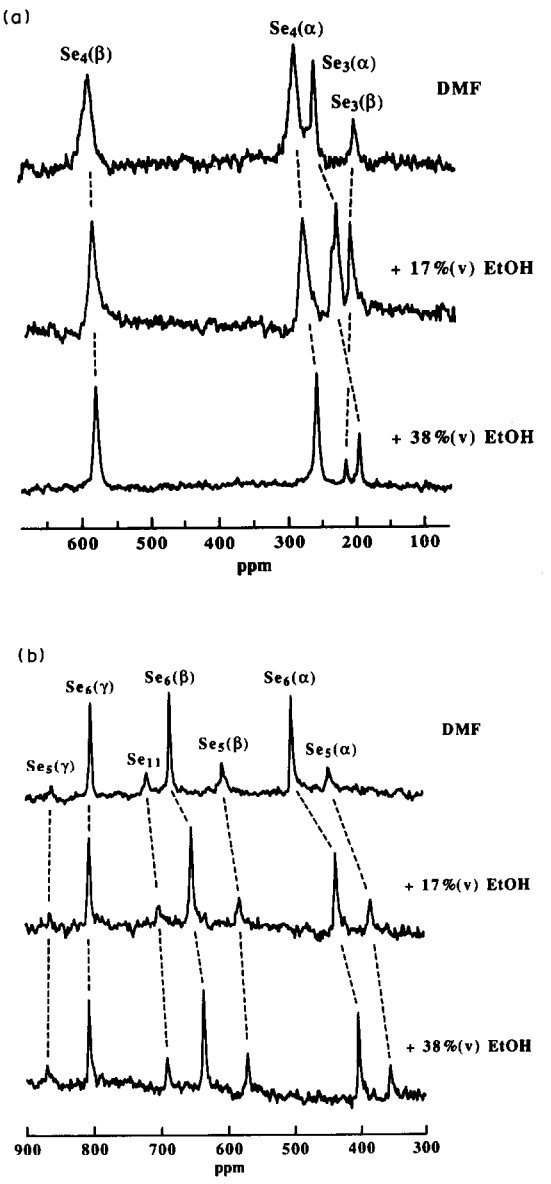

Fig. 4. Diagram of the ^{77}Se resonance positions (at 230 K) for (a) solutions containing a mixture of $[Se_3]^{2-}$ and $[Se_4]^{2-}$ and (b) solutions containing a mixture of $[Se_5]^{2-}$ and $[Se_6]^{2-}$, in DMF/ethanol in the proportions marked.

natural abundance are low (*ca* 5%), and the expected coupling magnitudes of 20–120 Hz[56,57] are less than the line-widths of our resonances.

Only for $[Se_3]^{2-}$ will the relative intensity data allow unambiguous assignment of resonances to the individual selenium atoms in the $[Se_x]^{2-}$ ions. In order to obtain experimental information on the assignments of the resonances in the other $[Se_x]^{2-}$ ions we have deployed solvent influences. As already described, the chemical shifts of ^{77}Se in HSe^- anions are strongly dependent on solvent proticity. Like all instances of solvent proticity on anion activity,[48–50] this effect is proportional to the negative charge density on the affected atoms. Therefore the solvent influences on chemical shifts in $[Se_x]^{2-}$ ions indicate the charge densities at the various selenium atoms. The chemical shifts of the resonances in a solution containing $[Se_3]^{2-}$ and $[Se_4]^{2-}$ [Fig. 4(a)] and a solution containing $[Se_5]^{2-}$ and $[Se_6]^{2-}$ [Fig. 4(b)] vary in different ways as the proportion of ethanol in DMF is increased.

We use the notation α, β, γ, to signify positions of selenium atoms relative to the chain ends in $[Se_x]^{2-}$, and quote data for solutions in DMF and 50% DMF/ethanol. In $[Se_3]^{2-}$ the 257 ppm resonance (α) in DMF shifts to 193 ppm with increasing solvent proticity, while the 194 ppm resonance (β) moves slightly in the other direction to 214 ppm: the effect is greatest on first addition of ethanol to DMF. This is entirely consistent with the assignments based on resonance intensities, and with the assumption that the negative charge density on $[Se_3]^{2-}$ is greater at the terminal α selenium atoms. This validates the assignment principle that can be applied to other $[Se_x]^{2-}$ ions, namely that as the negative charge density on selenium diminishes with distance from the terminal selenium atoms the chemical shifts (at least in protic media) become less negative. For $[Se_4]^{2-}$ the high chemical shift decreases by only 8 ppm with addition of ethanol, while the other δ_{Se} decreases by 29 ppm, thereby

Table 3. Chemical shifts for $[Se_x]^{2-}$ ions in DMF plus 38% (vol) EtOH

$[Se_x]^{2-}$ ion	$\delta_{Se}(\alpha)$ ppm	$\delta_{Se}(\beta)$ ppm	$\delta_{Se}(\gamma)$ ppm
$[Se_3]^{2-}$	193	214	—
$[Se_4]^{2-}$	256	581	—
$[Se_5]^{2-}$	354	570	868
$[Se_6]^{2-}$	404	636	807

identifying the equal intensity lines as β and α, respectively. For $[Se_5]^{2-}$ the highest δ_{Se} line increases by 7 ppm, the intermediate line decreases by 34 ppm, and the lower δ_{Se} decreases by 89 ppm, indicating the assignments Se(γ), Se(β), Se(α), respectively, for these lines. In the case of $[Se_6]^{2-}$ the solvent effects are similarly impressive, and allow similar assignments: the highest δ_{Se} line increases by 5 ppm and is assigned Se(γ), the intermediate δ_{Se} line decreases by 47 ppm and is assigned Se(β), while the lowest δ_{Se} line decreases by 95 ppm and is assigned Se(α). Note that the relationship $\delta_{Se}(\gamma) > \delta_{Se}(\beta) > \delta_{Se}(\alpha)$ applies for all $[Se_x]^{2-}$ ions, but is valid for $[Se_3]^{2-}$ only when the chemical shifts are those of protic solvents. Chemical shift assignments standardized to the solution in DMF containing 38% EtOH are presented in Table 3.

In general the line-widths of the $[Se_x]^{2-}$ resonances decrease as ethanol is added and the solvent proticity increases. This is interpreted as indicating retardation of polyselenide exchange reactions on addition of ethanol, consistent with the normal lowering of the kinetic activity of anions with increased solvent proticity.

$(Ph_4P)_2[Se_5]$ *and* $(Bu_4N)_2[Se_6]$

There have been two reports of the crystal structure of $(Ph_4P)_2[Se_5]$, from crystals obtained accidentally from an irrational reaction[30] or as a side product.[16] We provide here a direct preparation of this compound. We determined the crystal structure of our preparation before the publication of the results of others,[19,30] but report only the essential results here. There are some distinctive differences between the unit cell dimensions obtained in the three independent measurements, listed for ref. 30, ref. 16 and this work, respectively: a = 9.573, 9.615, 9.617; b = 16.945, 17.122, 17.092; c = 13.563, 13.788, 13.724 Å, β = 105.29, 105.18, 105.18°. The residual R is substantially lower for our structure than for the other two. It is interesting to compare the Se—Se distances in $[Se_5]^{2-}$ as obtained in the three independent determinations: the four Se—Se distances along the chain, listed for ref. 30, ref. 16 and this work, are 2.316, 2.355, 2.366, 2.314; 2.326, 2.345, 2.321; 2.308, 2.360, 2.354, 2.310 Å. Thus two of the determinations are in agreeement with the chemical notion that the Se(α)—Se(β) bonds are slightly (*ca* 0.04 Å) shorter than the Se(β)—Se(γ) bonds. The ^{77}Se NMR spectrum of $(Ph_4P)_2[Se_5]$ dissolved in DMF contains the resonances of $[Se_5]^{2-}$ and $[Se_6]^{2-}$, indicative of some disproportionation. Low solubility at low temperature restricted our measurement of the ^{77}Se NMR spectrum of $(Bu_4N)_2[Se_6]$.

$[Se(Se_5)_2]^{2-}$

We first observed the crystallization of the Ph_4P^+ salt of this unusual polyselenide anion during attempts to prepare polyselenide complexes of oxidising metal ions, including gold(III) and bismuth (III), and with some non-oxidising metal salts such as $Cr(NO_3)_3$. Subsequently $(Ph_4P)_2[Se(Se_5)_2]$ was characterized crystallographically by Krebs *et al.*[33] During preparation and characterization of metal polysulphide complexes in aprotic media we observed that nitrate salts in DMF caused elongation of the polysulphide chain, an oxidative process.[58] Therefore we tested $NaNO_3$ as an oxidant for polyselenides in DMF, and found that it converted $[Se_5]^{2-}$ to $[Se(Se_5)_2]^{2-}$ and can be used as a convenient oxidant in the preparation of $(Ph_4P)_2[Se(Se_5)_2]$. The use of gold(III) or I_2 for oxidation of $[Se_5]^{2-}$ to $[Se(Se_5)_2]^{2-}$ has been reported by Kanatzidis and Huang.[13] In the preparations of metal polyselenide complexes in DMF and other aprotic solvents it is important to recognise that $[Se_x]^{2-}$ can be readily oxidised by both cations and oxidising counter anions present.

Solutions containing the $[Se(Se_5)_2]^{2-}$ ion do not display an informative ^{77}Se NMR spectrum. At low temperature (*ca* 235 K) in DMF there is a broad (1000 Hz) resonance at 720 ppm. This resonance appears also in solutions of other $[Se_x]^{2-}$ ions that have undergone partial oxidation. Four NMR distinct selenium sites are expected, but despite extensive searches (2100 to −500 ppm) only the one broad resonance has been located. The one resonance observed does move to lower frequency and sharpen slightly on addition of ethanol. The magnitude of the solvent dependence of the chemical shift is similar to that of the Se(β) atoms in the noncyclic $[Se_x]^{2-}$ ions.

DISCUSSION

Although Se^{2-} and HSe^- are the simplest selenide species, their δ_{Se} characteristics had not pre-

viously been well established. Odom *et al.* observed a resonance at −511 ppm for a solution of H_2Se plus excess NH_3 in D_2O[44] which was interpreted without supporting evidence as being Se^{2-} in equilibrium with a minor amount of HSe^-. Lyons and Young[59] measured a single resonance at −670 ppm for a 3 M solution of K_2Se in 0.1 M KOH. We discuss our δ_{Se} data in the context of that collected in Table 4 for other species in the general classes XSe^- and XSeH.

In general δ_{Se} becomes more negative with the negative charge on selenium.[39,40,42] By extrapolation of $\Delta\delta_{Se}$ for deprotonation of RSeH, from R = Pr^i, Et, Me, a value of δ_{Se} for aqueous HSe^- would be estimated (from δ_{Se} for aqueous H_2Se) at $-288 - ca\ 200) = ca\ -490$ ppm. This approximate estimate is entirely consistent with the observations in Table 4, and with our interpretation of the sample of $(NH_4)_2Se$ in D_2O[44] as containing $NH_4^+ + HSe^- + NH_3$. The question remains open about the chemical shift for Se^{2-}, which is likely to exist as such only in aprotic basic media. The solution of K_2Se in aqueous 0.1 M KOH listed in Table 4 would be expected to contain the $HSe^- \rightleftharpoons Se^{2-}$ equilibrium, with HSe^- dominant since pK_2 for $H_2Se = 15$.[45] By general extrapolation using the H_2Se, HSe^-, $MeSe^-$ data in Table 4, $\delta_{Se}(Se^{2-})$ might be expected to be at least as negative as −700 ppm, and probably closer to −800 ppm. The most negative δ_{Se} recorded is the value −736 for $H_3SiSe^-Li^+$.[63]

We have established unambiguously that the four polyselenide ions $[Se_3]^{2-}$, $[Se_4]^{2-}$, $[Se_5]^{2-}$ and $[Se_6]^{2-}$ exist in solution (thus dispelling earlier claims[24] of the non-existence of $[Se_5]^{2-}$), and in equilibrium, but we have no evidence for the existence of $[Se_2]^{2-}$ in DMF solution. Kanatzidis[2] has claimed that polyselenide ions dissociate to paramagnetic polyselenide radicals, eq. (4), in solution. However the assignment[2] of the 610 nm absorption in solutions of polyselenide ions to polyselenide radicals is incorrect: such electronic absorptions had previously been attributed to the polyselenide ions.[24] Although the poor NMR spectroscopic state of the polyselenide solutions at ambient temperatures could be due to paramagnetic broadening, there is no evidence of concomitant paramagnetic shifting, and we consider that the dissociation (4) in solution occurs to a very small extent that does not interfere with the recording of ^{77}Se NMR.

$$[Se_x]^{2-} \rightleftharpoons [Se_y]^- + [Se_{x-y}]^- . \qquad (4)$$

As expected, polyselenide ions are reponsive to solvent proticity in various ways, including the selenium exchange dynamics and the selenium chemical shifts. The magnitude of the effect is dependent on the location of the selenium atom in the polyselenide chain, and its negative charge density. We have no evidence that the solvent dependence involves dissociation into radicals.

In Fig. 5 are charted δ_{Se} values for selenium atoms in four types of polyselenium chains, (a) $[Se_x]^{2-}$ and (b) Oct^n—Se_x—Oct^n which are acyclic,[64] (c) selected (d^{10}) M(Se_4) chelate rings,[19,65] and (d) cyclic $S_{8-x}Se_x$.[66] Our δ_{Se} values for selenium atoms in the

$H_3SiSe^-Li^+$		−736	63, this species is involved in an unspecified fast exchange

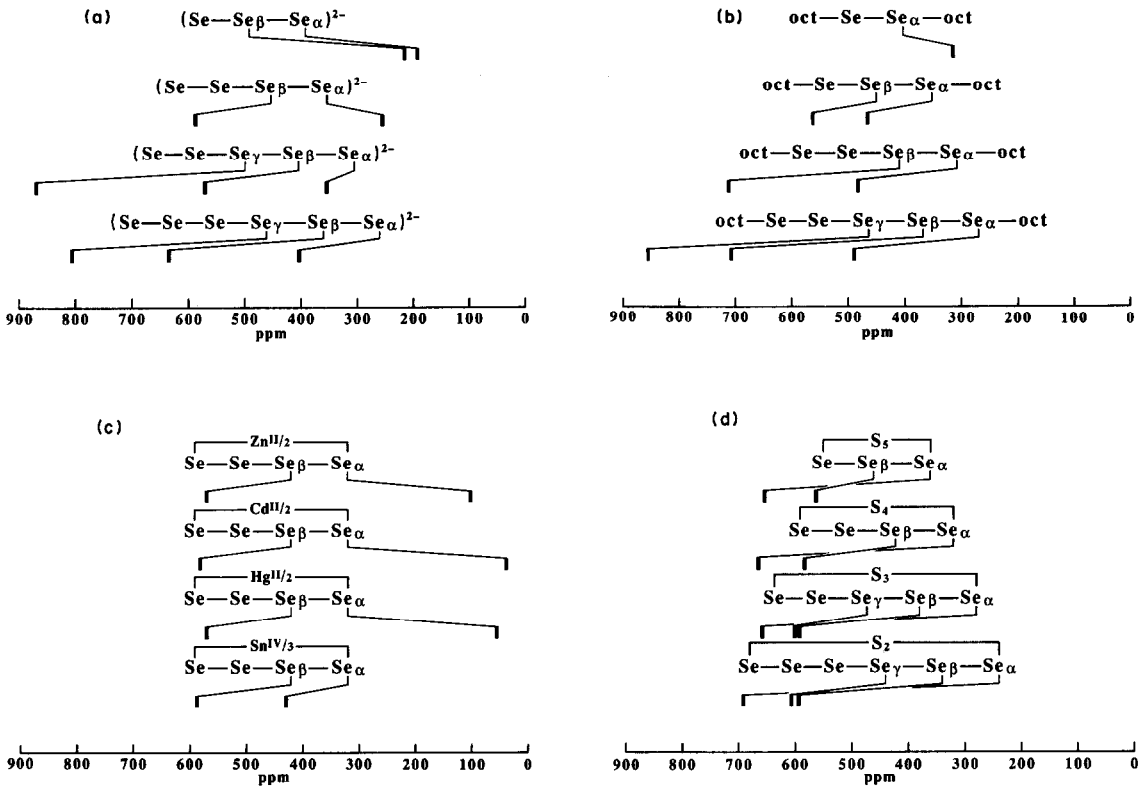

Fig. 5. Comparative chart of the ^{77}Se chemical shifts in four classes of polyselenium chains: (a) $[Se_x]^{2-}$; (b) $Oct^n—Se_x—Oct^n$; (c) $M(Se_4)$; and (d) $S_{8-x}Se_x$. The thick lines mark the chemical shift values.

polyselenide chains $[Se_x]^{2-}$ of various lengths provide the best reference for comparable δ_{Se} data from polyselenium chains R—Se_x—R with various terminating groups R. Discussing the $[Se_x]^{2-}$ data first, it can be seen that the weighted average chemical shift moves non-linearly to higher frequency as the length of the chain increases, consistent with decreased average negative charge per selenium atom. The changes in $\delta_{Se}(\alpha)$ with x in the $[Se_x]^{2-}$ series are more regular than the changes in $\delta_{Se}(\beta)$. The $\delta_{Se}(\alpha)$ values and the $\delta_{Se}(XSe^-)$ values (Table 4) are entirely consistent with the general notion that the negative charge on the terminal selenium atoms of $[Se_x]^{2-}$ is about 0.5. It is not clear why $\delta_{Se}(\gamma)$ in $[Se_5]^{2-}$ is more negative than $\delta_{Se}(\gamma)$ in $[Se_6]^{2-}$, although different torsional angles at the centre of the longer chain may be responsible. It should be remembered that these selenium chemical shift tensors are very probably quite anisotropic, and that an average chemical shift only is accessible here. Further, the influence of solvent environment is sufficient to interchange the two average chemical shifts in $[Se_3]^{2-}$. In the series $Oct^n—Se_x—Oct^n$ it is the internal selenium atoms that move more than $\delta_{Se}(\alpha)$ to larger chemical shift as x increases. We note that the δ_{Se} patterns for comparable chains $[Se_x]^{2-}$ and $Oct^n—Se_x—Oct^n$ are similar, with the δ_{Se} for $[Se_x]^{2-}$ less positive, and with the differences more pronounced for the shorter chains.

Finally we analyse the data (Fig. 5) for the cyclic polyselenide chains, closed by sulphur atoms or d^{10} metal atoms.[67] In the four MSe_4 ($M = Zn^{II}$, Cd^{II}, Hg^{II}, Sn^{IV}) chelate rings the $\delta_{Se}(\beta)$ are virtually the same (*ca* 580 ppm) as that in $[Se_4]^{2-}$, and the $\delta_{Se}(\alpha)$ are metal dependent. In the polyselenium compounds where the eight-membered cycle is completed by sulphur atoms there is little polarity and limited disperson of the selenium chemical shifts. The $\delta_{Se}(\beta)$ (and $\delta_{Se}(\gamma)$) are also close to 580 ppm as they are in the metal–chelate rings, but the $\delta_{Se}(\alpha)$ are anomalously larger. This could be due to the reversed polarity of the Se(α)—S bonds compared with Se(α)—C or Se(α)—M.

SUMMARY

The principal results from this investigation are:

(1) Fully reduced solutions of selenium in DMF contain HSe^- for which δ_{Se} ranges between −530 and −390 ppm (vs Me_2Se) depending strongly on solvent and temperature;

(2) Solutions of $[Se_x]^{2-}$ can be prepared by partial

reduction, and, for $x = 3$–6, confirmed and characterized by ^{77}Se NMR;

(3) There is no NMR evidence for the occurrence of $[Se_2]^{2-}$, which is believed to disproportionate in these solutions;

(4) δ_{Se} values for selenium atoms in $[Se_x]^{2-}$ ions are proportional to distance from the end of the chain $[\delta_{Se}(\gamma) > \delta_{Se}(\beta) > \delta_{Se}(\alpha)]$, and inversely proportional to negative charge density;

(5) δ_{Se} values for selenium atoms in $[Se_x]^{2-}$ ions are influenced by solvation with more protic solvents giving less positive δ_{Se}: the solvation dependence magnitudes are $\delta_{Se}(\alpha) > \delta_{Se}(\beta) > \delta_{Se}(\gamma)$, in proportion to negative charge density at selenium.

(6) Atom exchange in $[Se_x]^{2-}$ is relatively fast at room temperature, and is retarded by protic solvents.

(7) $[Se(Se_5)_2]^{2-}$, a common oxidation product of $[Se_x]^{2-}$, can be identified by ^{77}Se NMR, but not fully characterized because the ion appears to be undergoing exchange which is NMR-fast.

THE X-RAY CRYSTAL STRUCTURE OF $Na_2[Ph_2PSe_2]_2 \cdot THF \cdot 5H_2O$—A POLYMER CONTAINING SIX-MEMBERED SODIUM–WATER RINGS AND SODIUM COORDINATED BY SELENIUM

MARK J. PILKINGTON, ALEXANDRA M. Z. SLAWIN, DAVID J. WILLIAMS and J. DEREK WOOLLINS*

Department of Chemistry, Imperial College, London SW7 2AY, U.K.

(*Received* 9 *July* 1991; *accepted* 21 *August* 1991)

Abstract—Na_xSe_y, prepared by the reaction of sodium and selenium in liquid ammonia, has been reacted with Ph_2PCl in THF/ethanol to give a mixture of Ph_2PSeH, $Ph_2P(Se)OP(Se)Ph_2$ and the title compound (**5**) which was characterized by X-ray crystallography. Compound **5** consists of a central polymeric core built up of $Na(H_2O)_6$ and $Na(H_2O)_3(thf)(Se)$ units with additional hydrogen-bonded $Ph_2PSe_2^-$ anions.

We have recently reported[1,2] on the syntheses of four- and five-membered P–Se rings such as $(PhPSe)_2Se_2$ (**1**), $(PhP)_3Se_2$ (**2**), $(PhP)_4Se$ (**3**) and $(PMe)_4Se_3$ (**4**). Compound **1** undergoes reaction[3] with $PtCl_2(PR_3)_2$ to give complexes containing the bidentate $[PhPSe_3]^{2-}$ ligand. This observation prompted us to investigate the synthesis of Ph_2PSe_2H and its deprotonated anion $Ph_2PSe_2^-$ as a preliminary to studying its coordination chemistry. To our knowledge, although the coordination chemistry of phosphates and thiophosphates is well-developed there have been no reports on the analogous selenium chemistry. Here, we report on the X-ray crystal structure of $Na_2[Ph_2PSe_2]_2 \cdot THF \cdot 5H_2O$ (**5**).

A number of workers have described[4–6] the use of liquid ammonia solutions for the preparation of Na_xE_y (E = S, Se, Te). We have investigated the usefulness of these solutions for the preparation of P—Se heterocycles. Thus, for example, dissolution of sodium (10 mmol) in liquid ammonia (10 cm^3) at −78°C followed by addition of grey selenium (5 mmol) gives an intensely coloured solution. If this solution is allowed to warm to room temperature and the ammonia evaporated off the remaining solid may be suspended in THF and reacted with $PhPCl_2$ at reflux to give **2**. However, this reaction is not particularly reproducible, in part at least, because of the first stage giving a mixture of products together with unreacted sodium metal. Furthermore, varying the molar ratio of sodium to selenium does not improve the efficiency or the utility of the reaction with $PhPCl_2$.

We have also attempted the reaction of Na_xSe_y with Ph_2PCl in THF and here again the reactions are not readily reproducible. Some improvement in the reproducibility is obtained if the second stage of the reaction is performed in a mixture of THF and ethanol since the ethanol destroys any residual sodium. Thus, sodium (35 mmol) and selenium (50 mmol) were combined in liquid (10 cm^3) ammonia at −78°C and stirred together for 1 h before the reaction was warmed to room temperature and the ammonia evaporated off. A mixture of THF (15 cm^3) and ethanol (10 cm^3) was added followed by Ph_2PCl (35 mmol) and the reaction was stirred at room temperature overnight. ^{31}P NMR analysis of the reaction mixture revealed the presence of $Ph_2P(Se)H$ (δ = 6.4 ppm, comparable with the reported value[7]) and $Ph_2P(Se)OP(Se)Ph_2$ (δ = 84.5 ppm) together with a number of other species.

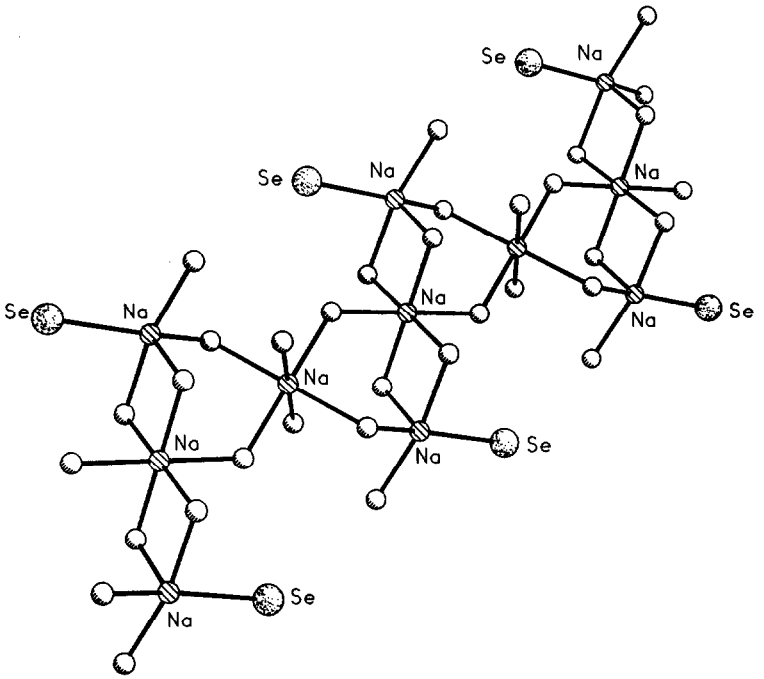

Fig. 1. The X-ray structure of the central polymeric core in **5** showing the octahedral and distorted trigonal bipyramidal sodium environments.

Addition of hexane enabled the isolation of crystals of (5) suitable for X-ray analysis.*

The X-ray analysis reveals a polymeric structure consisting of a central core of fused and spiro Na_3O_3 rings (Fig. 1). The sodium atoms are linked by water molecules; two of the sodium atoms, which are octahedrally coordinated by six water molecules, lie on independent crystallographic centres of symmetry, the third is in a general position and has distorted trigonal bipyramidal coodination. This latter sodium atom has three *facial* water molecules, the other two sites being occupied by a THF and a selenium atom from one of the $Ph_2PSe_2^-$ anions. The other $Ph_2PSe_2^-$ anion is linked (Fig. 2) to the central polymeric core via pairs of O—H···Se hydrogen bonds [Se(1)···O(2) 3.42, Se(2)···O(3) 3.38, Se(1)···H—O(2) 172°, Se(2)···H—O(3) 173°]. Within the asymmetric unit (Fig. 3) the Na—OH_2 distances are in the range 2.347(4)–2.497(4) Å (Table 1) with the Na—O(THF) distance [2.388(4) Å] also being within this range. The Na—Se distance is, as expected, significantly longer [2.984(2) Å]. The P—Se bond lengths in the hydrogen-bonded anion are equivalent [2.156(1), 2.152(1) Å] and intermediate to the two distances in the other anion which are significantly different from each other [P(2)—Se(3) 2.142(1), P(2)—Se(4) 2.161(1) Å]. Surprisingly, the shortest P—Se bond is for the sodium-bound selenium atom; the non-coordinate selenium atom Se(4) only having a long range contact to a water oxygen atom O(3′) of 3.55 Å. The closest contact of a proton of O(3′) to Se(4) is 2.61 Å, cf. H···Se distances of 2.46 and 2.43 Å for Se(1) and Se(2), respectively.

The observation of six-membered $Na_3(H_2O)_3$ rings is not especially surprising and we believe that these rings could be readily built up into extended 2-D and 3-D arrays. Perhaps the most surprising feature in the structure of **5** is the formation of an Na—Se bond with shortening of the P—Se bond

*Crystal data (**5**), $C_{28}H_{38}O_6P_2Se_4Na_2$, $M = 894.4$, triclinic, $a = 8.709(2)$, $b = 15.158(5)$, $c = 15.676(3)$ Å, $\alpha = 68.37(2)$, $\beta = 74.12(2)$, $\gamma = 77.06(2)°$, $U = 1833$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.62$ g cm^{-3}, μ(Cu-K_α) = 63.2 cm^{-1}, $F(000) = 884$. Crystal dimensions 0.13 × 0.40 × 0.60 mm. Data were measured on a Nicolet R3m diffractometer with graphite monochromated Cu-K_α radiation using ω-scans. The structure was solved by direct methods and refined anisotropically using absorption corrected data (maximum and minimum transmission factors 0.438 and 0.098, respectively) to give $R = 0.046$, $R_w = 0.051$ for 4526 independent observed reflections [$|F_o| > 3\sigma(|F_o|)$, $2\theta \leqslant 116°$]. The atomic coordinates are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Rd, Cambridge CB2 1EW. Any request should be accompanied by a full literature citation for this communication.

SYNTHESIS AND X-RAY CRYSTAL STRUCTURE OF $Re_4(NBu^t)_8(\mu\text{-}O)_2(\mu_3\text{-}O)_2(OSO_2CF_3)_4$

HON-WAH LAM, GEOFFREY WILKINSON* and DAVID J. WILLIAMS*

Johnson Matthey and Chemical Crystallography Laboratories, Chemistry Department, Imperial College, London SW7 2AY, U.K.

(*Received* 22 *July* 1991; *accepted* 21 *August* 1991)

Abstract—Interaction of $Re(NBu^t)_3(NHBu^t)$ and CF_3SO_3H in Et_2O leads to the known $[Re(NBu^t)_3(NH_2Bu^t)]O_3SCF_3$ but also to a low yield, presumably via a competitive reaction, of a red compound, $Re_4(NBu^t)_8(\mu\text{-}O)_2(\mu_3\text{-}O)_2(OSO_2CF_3)_4$, whose X-ray crystal structure has been determined.

The structure has a Re_4O_4 core comprising oxo-bridged, five- and six-coordinate rhenium centres. The six-coordinate rhenium centres have *cis* oriented oxo, NBu^t and $\eta^1\text{-}O_3SCF_3$ ligands; the five-coordinate centres have pairs of NBu^t and μ_3-O ligands and a μ-O ligand.

In previous papers we have described the synthesis and X-ray crystal structures of binuclear oxo-bridged rhenium compounds, e.g. $[Re(NBu^t)_2(OSiMe_3)]_2(\mu\text{-}O)(\mu\text{-}OSiMe_3)(\mu\text{-}O_2CCF_3)$.[1] We now report the synthesis of a tetrameric neutral species $Re_4(NBu^t)_8(\mu\text{-}O)_2(\mu_3\text{-}O)_2(OSO_2CF_3)_4$ (**1**).

In the synthesis[1b] of $[Re(NBu^t)_3(NHBu^t)]O_3SCF_3$ by interaction of CF_3SO_3H with $Re(NBu^t)_3(NHBu^t)$ in diethylether it was noted that after removal of the yellow precipitate of the triflate, the filtrate had an orange colour and gave an orange oil after the removal of volatiles. Extraction of the oil with diethylether and work-up led to red crystals of **1** whose crystal structure has been determined (see below). It is not clear whether a competitive reaction, which involves not only loss of one NBu^t group from the rhenium atom but also the formation of μ-O groups is associated with adventitious water or comes from cleavage of diethylether. The materials used were all thoroughly dried and reactions carried out under dry nitrogen or *in vacuo*. Thus, the oxo groups could arise by the well known acid cleavage of ethers,[2] *viz*

$$Et_2O + HSO_3CH_3 \longrightarrow EtSO_3CF_3 + EtOH,$$

followed by the reaction at the metal centre:

$$L_nRe + EtOH \longrightarrow L_nRe + C_2H_4 + H_2O,$$

and hydrolysis of the imido rhenium species by water.

The structure has crystallographic C_i symmetry with an approximately planar (maximum deviation 0.2 Å) Re_4O_4 core comprising oxo-bridged five- and six-coordinate rhenium centres (Fig. 1; Table 1 gives main bond lengths and angles). Re(1) has distorted octahedral symmetry with pairs of *cis*-oriented oxo, NBu^t and O_3SCF_3 ligands. The angles at Re(1) are in the ranges 74–105° and 156–164°, the enlargements from 90° being due to accommodating the bulky NBu^t and O_3SCF_3 groups. The two Re—NBu^t bonds are of the same length, 1.718(7) Å to N(1) and 1.711(7) Å to N(2). However, the angles at nitrogen differ significantly, with that *trans* to O_3SCF_3 appreciably bent [157.6(7)°], whilst that *trans* to one of the oxo bridges, N(2), is almost linear [172.0(7)°]. There is also a marked difference in the two Re—O_3SCF_3 bond lengths; that *trans* to μ-O is significantly shorter [2.084(6) Å] than that *trans* to NBu^t [2.272(7) Å].

The geometry at Re(2) can be considered as either distorted trigonal bipyramidal with the oxygens O(1) and O(2) of the oxo bridges as the apical atoms and the two NBu^t ligands and the symmetry related bridging oxo oxygen O(2′) as the equatorial components; Re(2), N(4), N(3) and O(2′) are co-planar to within 0.03 Å. Alternatively, the arrangement may be visualized as distorted square pyramidal

with O(2), O(2′), O(1), N(3) and Re(2) forming the base and N(4) the apex (Fig. 2). In this configuration Re(2) lies 0.5 Å above the basal plane towards N(4). The two Re—NBu^t bonds differ significantly, with that "*trans*" to μ_3-O to N(3) 1.684(7) Å, noticeably shorter than that to the apical N atom N(4), 1.724(7) Å. Furthermore, the angle at N(3), 171.8(6)° is very much closer to linear than that to N(4), 143.9(6)°. There are marked asymmetries in the Re—O—Re bridges with Re—O distances rang-

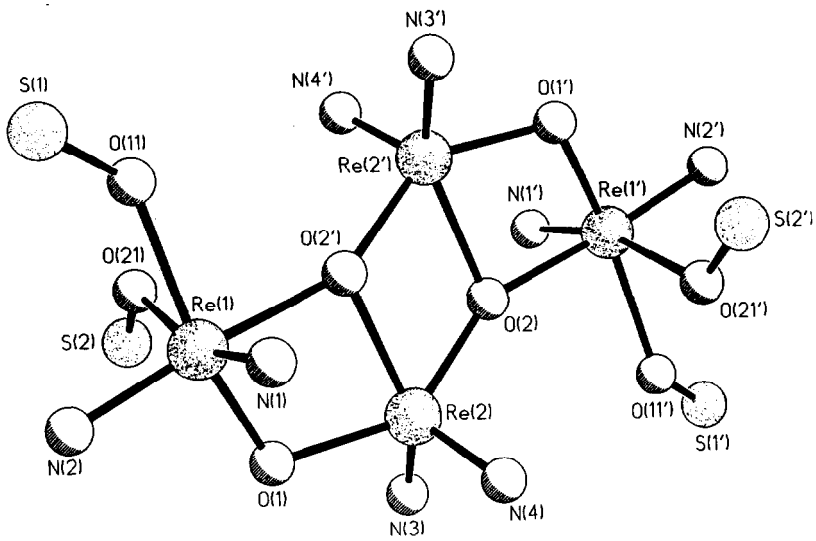

Fig. 2. Core structure of **1** showing geometries about rhenium.

ing between 1.911(5) Å for Re(1)—O(1) to 2.156(6) Å for Re(1)—O(2). There is no obvious rationale to this though overall the μ-O distances are shorter than the μ_3-O distances. The central Re_2O_2 ring is planar with transannular Re—Re and O—O distances of 3.24 and 2.41 Å, respectively, whereas the outer Re_2O_2 rings are slightly folded with fold angles of 12° about the O(1)—O(2′) axis and 17° about Re(1)—Re(2). In the latter the transannular Re—Re and O—O distances are 3.19 and 2.44 Å.

There are no important non-bonded intermolecular interactions.

The NMR and IR spectra of **1** are not particularly instructive other than bands for NBu^t and CF_3SO_3 and some bands below 1000 cm^{-1} that could be oxo stretches. Unidentate trifluoromethane sulphonate compounds have been characterized.[3]

EXPERIMENTAL

The general procedures and instruments were as previously.[1b] Solvents were dried by standard methods and all operations were carried out under purified nitrogen or argon.

The procedure[1b] for synthesis of $[Re(NBu^t)_3(NH_2Bu^t)]O_3SCF_3$ was followed using $Re(NBu^t)_3(NHBu^t)$ (0.5 g, 1.06 mmol) in Et_2O (20 cm^3) and CF_3SO_3H (3.0 cm^3 of 0.35 M solution in Et_2O, 1.06 mmol) at −78°C. After stirring (1 h) and warming to room temperature with stirring for a further 12 h, the yellow precipitate of the triflate was collected and the mother liquor evaporated in vacuum to leave an orange oil. This was extracted with Et_2O (10 cm^3) which was filtered, concentrated and cooled (−20°C) to yield red crystals. Yield: *ca* 10%; m.p. 159–160°. NMR, ^1H ($CDCl_3$); δ 1.68s, NBu^t. IR: (Nujol mull): 1260 (Re=NBu^t), 1189 (CF_3SO_3) cm^{-1}.

X-ray crystallography

Crystal data: $C_{36}H_{72}F_{12}N_8O_{16}Re_4S_4$, $M = 1974.1$, monoclinic, $a = 12.530(4)$, $b = 16.264(5)$, $c = 15.990(8)$ Å, $\beta = 94.91(3)°$, $V = 3247$ $Å^3$, space group $P2_1/n$, $Z = 2$ (the molecule is disposed about a centre of symmetry), $D_c = 2.02$ g cm^{-3}, copper radiation, $\lambda = 1.54178$ Å, μ(Cu-K_α) = 163 cm^{-1}, $F(000) = 1888$. Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans. A crystal of dimensions $0.17 \times 0.23 \times 0.41$ mm sealed under argon in a Lindemann glass capillary was used. 4386 independent reflections ($2\theta \leqslant 116°$) were measured, of which 3799 had $|F_o| > 3\sigma(|F_o|)$, and were considered to be observed. The data were corrected for Lorentz and polarization factors; a numerical absorption correction (face-indexed crystal) was applied; maximum and minimum transmission factors 0.192 and 0.047. The structure was solved by the heavy atom method. The non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbon atoms. The methyl groups were refined as rigid bodies. Refinement was by blocked full-matrix least-squares to $R = 0.036$, $R_w = 0.035$ [$w^{-1} = \sigma^2(F) + 0.00050F^2$]. The maximum and minimum

residual electron densities in the final ΔF map were 1.37 and -1.29 e $Å^{-3}$, respectively. The mean and maximum shift/error in the final refinement were 0.004 and 0.027, respectively. Computations were carried out on an IBM PS/2 model 70 PC using the SHELXTL PC program system. Full supplementary material has been deposited.

(*Received* 19 *July* 1991; *accepted* 27 *August* 1991)

Abstract—The complexes $M(mpo)_n$ (M = Mn, Ni, $n = 2$; M = Fe, Co, $n = 3$) (Hmpo = 2-mercaptopyridine N-oxide) were prepared by reacting the appropriate metal chloride with either Nampo or dtpo [2,2-dithiobis(pyridine N-oxide)] in the presence of sodium methoxide. The structure of the complex $Ni(mpo)_2$ was determined by X-ray diffraction. The nickel atom is in a square planar environment of two mpo^- ligands in the *cis* configuration. The four complexes were investigated by physicochemical methods especially by ^1H NMR spectroscopy and cyclic voltammetry.

Transition-metal thiolato complexes have been of interest for the simulation of many metallo-enzymes where the thiolato group mimics the ligation of cysteinyl residues in proteins. Recently we have studied a series of transition metal complexes with 1,2-bidentate sulphur-containing ligands such as 2-mercaptophenol (H_2mp)[1–5] and 2-mercapto-3-pyridinol (H_2mpp),[6] of which H_2mp has been found to be a multifunctional ligand in its ligation to transition metal atoms with versatile coordination modes.[5] It would be interesting to learn if other bidentate ligands with simultaneous oxido and sulphido donor atoms may exhibit similar but not identical coordination behaviour with respect to their varied aromatic rings. The coordination chemistry of metal complexes with the ligand 2-mercaptopyridine N-oxide (Hmpo) has scarcely been studied[7–8] in spite of their potential biological activities,[9] whereas those with amine N-oxide have been described and reviewed extensively.[10–11] The syntheses and physicochemical characterizations of complexes $M(mpo)_n$ (M = Mn, Ni, $n = 2$; M = Fe, Co, $n = 3$) and crystal structure of $Ni(mpo)_2$ are described in this paper following the report of the crystal structure of $Co(mpo)_3 \cdot CH_3CN$.[12]

EXPERIMENTAL

Materials and methods

All solvents were reagent grade and dried with molecular sieves. Sodium 2-mercaptopyridine N-oxide (Nampo), 2,2′-dithiobis(pyridine N-oxide) (dtpo) and metal chlorides were all commercially available and used without further purification.

Physical measurements were performed on the following instruments: IR, Perkin–Elmer 577 spectrophotometer (solids in KBr pellets); ^1H NMR, Varian FT-80A spectrometer (SIMEQ program for spectrum simulation); cyclic voltammetry, Longjin Model 8511B potentiostat (a Pt-inlay working electrode, Pt-wire auxiliary electrode and SCE reference electrode); mass spectra, Finnigan MAT 312 (or 8230) GC/MS/DS mass spectrometer (EI or FAB mode); X-ray crystallography, MSC/Rigaku diffractometer.

Preparations of complexes

$Mn(mpo)_2$ (**1**). To a solution of Nampo (0.60 g, 4.0 mmol) in 50 cm^3 of DMF/MeOH (2:1) was

* Author to whom correspondence should be addressed.

added solid $MnCl_2 \cdot 4H_2O$ (0.40 g, 2.0 mmol). The mixture was stirred for 4 h and filtered. The green filtrate was stored at 5°C for several days to give the green powder of **1** (yield: 70%), which was collected, washed with THF and dried *in vacuo*. Found: Mn, 17.5; S, 19.3. Calc. for $C_{10}H_8MnN_2O_2S_2$: Mn, 17.9; S, 20.9%. IR (KBr): 3040(w), 1585(m), 1530(m), 1450(s), 1405(s), 1265(w), 1255(w), 1230(w), 1195(s), 1180(s), 1150(m, C—S), 1140(s, C—S), 1085(s, N—O), 1025(w), 825(s), 780(m), 750(s), 705(s), 615(m), 585(s), 550(m), 435(w), 360(s), 345(w), 280(w), cm^{-1}. MS (EI): 307 (M^+).

Fe(mpo)$_3$ (**2**). Route 1: A mixture of anhydrous $FeCl_2$ (0.10 g, 0.79 mmol), dtpo (0.30 g, 1.19 mmol) and NaOMe (0.043 g, 0.80 mmol) in 20 cm^3 of MeOH was stirred for 19 h and filtered. The dark blue filtrate was stored at 5°C to give dark microcrystals of **2** (yield: 67%), which was collected and dried *in vacuo*. Found: Fe, 13.0; S, 21.8. Calc. for $C_{15}H_{12}FeN_3N_3O_3S_3$: Fe, 12.9; S, 20.1%. IR (KBr): 3040(w), 1600(m), 1540(m), 1460(s), 1420(m), 1265(w), 1230(w), 1200(m), 1160(m, C—S), 1145(m, C—S), 1090(s, N—O), 1030(w), 830(s), 765(s), 750(s), 715(s), 610(s), 560(m), 515(w), 440(w), 340(m), 260(m) cm^{-1}. MS (FAB): 434 ($M^+ + H$).

Route 2: A mixture of $FeCl_3 \cdot 6H_2O$ (0.065 g, 0.24 mmol) and Nampo (0.11 g, 0.73 mmol) in 50 cm^3 of acetone/methanol (1:2) was stirred for 1 h to give a deep blue solution with some precipitates, which was then filtered. The filtrate was stored at 5°C to give dark blue microcrystals. The precipitate was recrystallized from DMF/^{i}PrOH to give deep blue microcrystals also (total yield: 75%). Their IR spectra are identical to that obtained by route 1.

Co(mpo)$_3$ (**3**). Route 1: A mixture of $CoCl_2 \cdot 6H_2O$ (0.15 g, 0.63 mmol), dtpo (0.32 g, 1.27 mmol) and NaOMe (0.07 g, 1.3 mmol) in 40 cm^3 of MeOH/MeCN (1:1) was stirred for 18 h and filtered. The dark brown filtrate was stored at 5°C for several days to give large black block crystals of **3**·CH_3CN (yield: 63%), which were collected and dried *in vacuo*. Found: C, 43.1; H, 3.3; Co, 13.0; N, 11.2; S, 19.2. Calc. for $C_{17}H_{15}CoN_4O_3S_3$: C, 42.7; H, 3.2; Co, 12.3; N, 11.7; S, 20.1%. IR (KBr): 3040(w), 1595(m), 1535(s), 1450(s), 1400(s), 1260(m), 1230(s), 1175(s), 1150(s, C—S), 1130(s, C—S), 1085(s, N—O), 1030(w), 1020(m), 815(s), 745(s), 705(s), 610(s), 570(w), 500(w), 430(m), 380(m), 335(m) cm^{-1}. MS (FAB): 438 ($M^+ + H$).

Route 2: A mixture of anhydrous $CoCl_2$ (0.2 g, 1.54 mmol), Nampo (0.23 g, 1.53 mmol) in 30 cm^3 of THF was stirred for 21 h and filtered. The greenish brown filtrate was stored at 5°C to give microcrystals (total yield: 78%), which were collected. The IR spectrum is identical to that obtained by route 1 except for the absorptions of CH_3CN.

Ni(mpo)$_2$ (**4**). Route 1: To a suspension of dtpo (0.38 g, 1.5 mmol) in 50 cm^3 of MeOH/MeCN (1:1) was added $NiCl_2 \cdot 6H_2O$ (0.24 g, 1.0 mmol). The mixture was stirred for a while and added to NaOMe (0.10 g, 1.85 mmol). After stirring for 20 h, the solution developed a brown colour and was then filtered. The filtrate gave deep brown prism crystals of **4** (yield: 60%) on standing at 5°C, which were collected by filtration. Found: C, 38.8; H, 2.9; N, 8.6; Ni, 18.0; S, 19.9. Calc. for $C_{10}H_8N_2NiO_2S_2$: C, 38.6; H, 2.6; N, 9.0; Ni, 18.9; S, 20.6%. IR (KBr): 3040(w), 1595(m), 1545(s), 1480(w), 1455(s), 1410(m), 1270(w), 1250(s), 1180(s), 1150(sh, C—S), 1140(m, C—S), 1085(s, N—O), 1050(w), 1030(w), 825(s), 745(s), 710(s), 695(w), 665(m), 630(s), 430(m), 395(m), 335(m), 275(m) cm^{-1}. MS (EI): 310 (M^+).

Route 2: A mixture of $NiCl_2 \cdot 6H_2O$ (0.48 g, 2 mmol) and Nampo (0.60 g, 4.0 mmol) in 80 cm^3 of MeOH/MeCN (3:5) was stirred for 15 h and filtered. The precipitate was recrystallized from DMF to give brown prism crystals of **4** and the filtrate was stored at 5°C to give **4** also (total yield: 87%). The IR spectra and crystal parameters are identical to that obtained by route 1.

X-ray crystallography

Crystal data for **4**. $C_{10}H_8N_2NiO_2S_2$, Mr = 311.03, monoclinic, space group $P2_1/n$, a = 8.769(4), b = 13.627(4), c = 9.857(3) Å, β = 97.76(3)°, V = 1167.1 Å^3, Z = 4, D_c = 1.770 g cm^{-3}, μ = -22.1 cm^{-1}, $F(000)$ = 632.

A single crystal of **4** with the dimensions 0.25 × 0.3 × 0.2 mm obtained from the reaction solution of route 1 was mounted on a MSC/Rigaku diffractometer with Mo-K_α (λ = 0.71069 Å) radiation and graphite monochromator. A total of 2854 reflections were collected in the range of $2° \leqslant 2\theta \leqslant 54.1°$ in the ω–2θ scan mode and corrected for anisotropic decay, LP factors and absorptions empirically. The systemic absence ($h0l$, $h+l = 2n$; $0k0$, $k = 2n$) indicated the space group to be $P2_1/n$ exclusively. The 2133 unique reflections with $I \geqslant 3\sigma(I)$ were used for structure determination. The structure was solved by direct methods on a VAX 11/785 computer with the SDP program package and refined by full-matrix least-squares procedures with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atoms were added to the structure factor calculations but not refined. The final R value is 0.034 and the R_w value is 0.037 with w = 1.

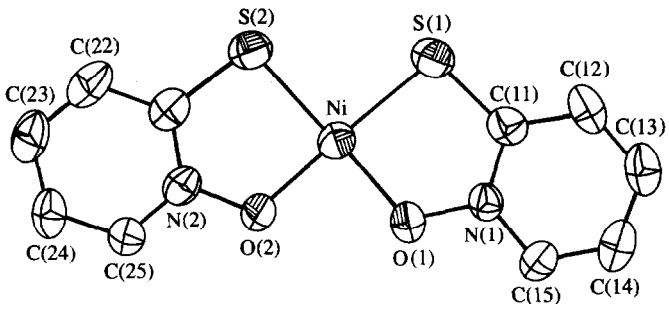

Fig. 1. ORTEP diagram of the structure of **4**.

RESULTS AND DISCUSSION

Synthetic studies

Complexes **1**–**4** were obtained by treatment of the respective metal chloride with Nampo in the appropriate organic solvent (route 2). This procedure is different from that reported by Robinson[8] which was performed in aqueous medium. All these complexes except **1**, can also be synthesized by the reaction of metal chlorides with the organic disulphide dtpo under strongly basic conditions (route 1). Considering the possibility of hetero-cleavage of the disulphide in cobalt(III) disulphide systems[13] in the presence of a strong base, we believe that route 1 might involve the cleavage of dtpo in the presence of base to form mpo^- and then the latter coordinates to the metal atoms. But, the possibility of coordination of dtpo to the metal atoms first and then by base hydrolysis to give the products is not excluded. However, the reaction of $MnCl_2 \cdot 6H_2O$ with dtpo forms only insoluble and inextractable materials which were not further studied.

It is interesting to note that these complexes can be prepared whether under a dinitrogen atmosphere or not and are stable in air. Until now, we have not been able to prepare similar complexes with the oxidation states nickel(III), manganese(III), iron(II) and cobalt(II). Unlike this, many 1,2-dithiolenes such as benzenedithiolate or toluenedithiolate[14–15] can stabilize both divalent and tervalent metal ions. This observation agrees well with the electrochemical behaviour of these complexes (*vide infra*).

Structure description

The structure of complex **4** is shown in Fig. 1 and selected bond lengths and bond angles are given in Table 1. The molecule has a nickel atom in the centre of the nearly square plane of NiS_2O_2 with the oxido and sulphido atoms from the two mpo^- ligands in *cis* configuration. The whole molecule exhibits a pseudo-C_{2v} symmetry with the C_2 axis passing through the nickel atom and the mid-points of S(1)---S(2) and O(1)---O(2). The Ni^{II}—S bond lengths of av. 2.132 Å are somewhat

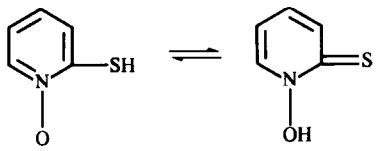
shorter than those terminal values reported for $[Ni_2(Hmp)_2(mp)_2]^{2-}$[4] (av. 2.160 Å), $[Ni_2(SCH_2CH_2S)_3]^{3-}$[16] (av. 2.185 Å), $[Ni_3(edt)_4]^{2-}$[16] (av. 2.189 Å) and $[Ni_3(SCH(CH_3)CH_2S)_4]^{2-}$[17] (av. 2.168 Å). To our knowledge, nickel complexes with the Ni—O bond in a square planar arrangement are relatively rare[4,18–22] and even the four-coordinate analogues[20] with amine N-oxide have not been investigated by X-ray diffraction analysis. The Ni—O bond of av. 1.866 Å agrees well with those in $[Ni_2(mpH)_2(mp)_2]^{2-}$[4] (av. 1.852 Å), $[Ni_3(SCH(CH_3)COO)_4]^{2-}$[18] (av. 1.875 Å) and Ni(enac)[19] (H_2enac = 4,9-dimethyl-5,8-diazadodeca-4,8-diene-2,11-dione) (av. 1.857 Å), but evidently is shorter than those in $Ni(acac)_2$[21] (acac = acetylacetonate) (av. 2.01 Å), $NiBr_2(S(CH_2CH_2OH)_2)$[22] (av. 2.046 Å) or in six-coordinate complexes with amine N-oxide such as $[Ni(pyO)_6](BrO_3)_2$[23] (pyO = pyridine N-oxide) (2.062 Å) and $[Ni(PyO)_2(2,4\text{-pentanedionate})_2]$[24] (av. 2.096 Å). The relatively short C—S distances (av. 1.712 Å) as also observed in $Co(mpo)_3$[12] (1.716 Å) show partial double bond character as they are nearly 0.1 Å shorter than the normal covalent distance (1.81 Å)[13] for a single bond. The bite distance (O---S) of av. 2.823 Å is similar to those in $Co(mpo)_3$[12] and within the range for a series of metal complexes[1–5,12] with 1,2-bidentate sulphur-containing ligands. The two bite angles O—Co—S are nearly equivalent and close to 90°, as in $Co(mpo)_3$.[12] The two five-membered rings NiS(1)O(1)N(1)C(11) and NiS(2)O(2)N(2)C(21) are nearly planar with maximum deviations of 0.0176 and 0.0285 Å, respectively. The Ni—S—C angles of av. 96.9° and Ni—O—N angles of av. 116.3° show the bonding orbitals of the sulphur atom are mainly of *p* character while those of oxygen atom sp^2 character, almost the same as those in mpH_2 ligated complexes.[3]

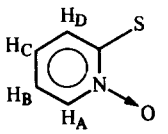
Spectroscopic studies

The IR absorptions of bonds C—S and N—O agree well with those reported in the literature.[8,25] It has been substantiated by X-ray diffraction analysis (*vide supra*) that the rather short C—S bond exhibits some double bond character. The free ligand (Hmpo) may exist in two tautomeric forms (thiol or thione) and has been established to be in the thione form predominantly.[25] When the sulphur atom is coordinated to metal atoms, it is not extraordinary that the C—S absorptions persist in the range 1160–1130 cm^{-1} as that of the free ligand (1142 cm^{-1}).[25]



thiol ⇌ thione

The ^1H NMR spectra of **1** and **2** in DMSO solution showed a paramagnetic nature with line-broadening and/or shifting of peaks to low field and only broad signals at 24 and 7.58 ppm can be assigned to the mpo^- ligands in **1** and **2**, respectively, in addition to the signals of the solvents. The ^1H NMR spectra of **3** and **4** shown in Figs 2a and 2c, respectively, are similar and showed the diamagnetic nature. The protons of mpo^- appear at 6.5–7.5



($H_B \sim H_D$) and 8.5 ppm (H_A) as a multiplet and a doublet, respectively. The simulated spectra of **3** and **4** based on the parameters listed in Table 2 are shown in Figs 2b and 2d, respectively. The consistancy of experimental spectra with simulated ones indicates the correctness of these assignments. The downfield shift of H_A is in agreement with those of the parent pyridine (8.5 ppm) or pyO (8.1 ppm).[26]

Electrochemical properties

Complexes **1–4** are all electroactive and exhibit interesting redox properties by cyclic voltammetric

Table 2. Proton chemical shifts (ppm) and coupling constants (Hz) of mpo^- in **3** and **4**

Compound	Chemical shift (ppm) A	B	C	D	Coupling constant (Hz) AB	AC	AD	BC	BD	CD
3	8.52	7.08	7.30	7.49	6.5	1.2	0.5	7.2	1.8	8.0
4	8.48	7.05	7.34	7.45	6.5	1.2	0.5	7.2	1.8	8.0

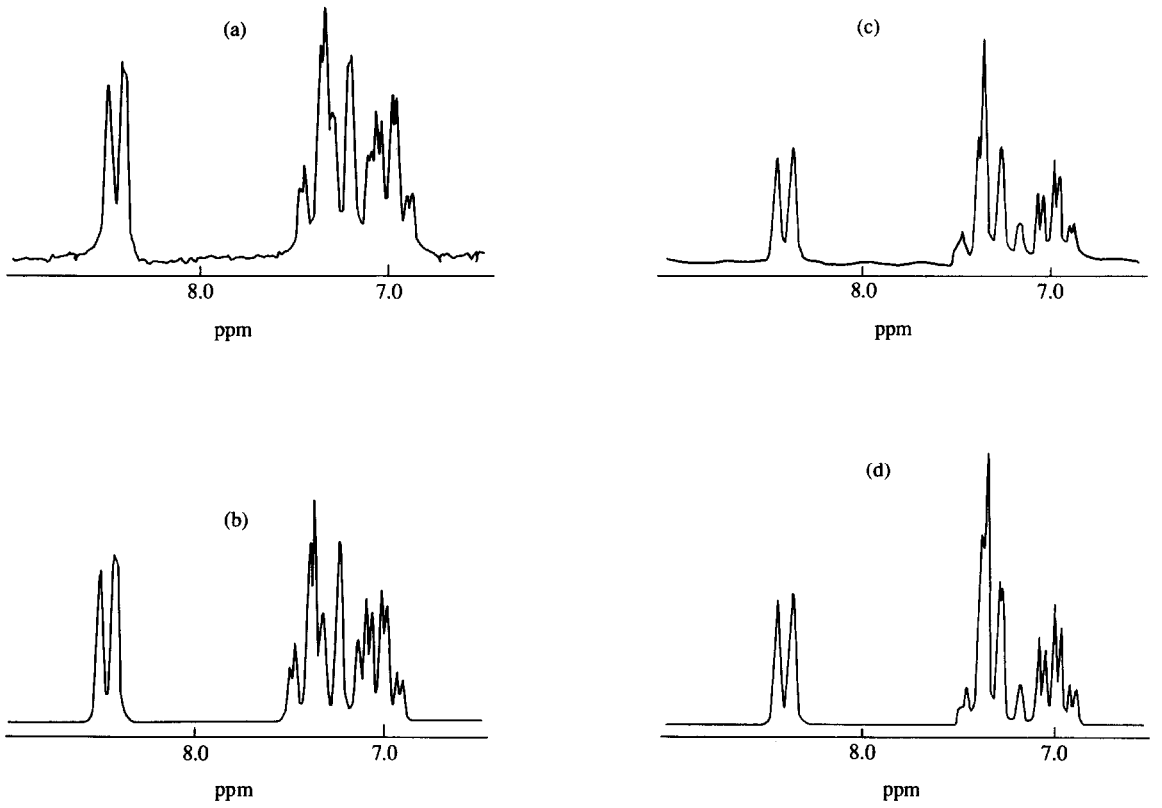


Fig. 2. ^{1}H NMR spectra. (a) Experimental spectrum of **3** in DMSO; (b) simulated spectrum of **3**; (c) experimental spectrum of **4** in DMSO; (d) simulated spectrum of **4**.

studies. As shown in Fig. 3a, the cyclic voltammogram of the DMF solution of **1** in the interval of $-0.5 \sim 1.0$ V (all potential values vs SCE) shows two reversible redox processes ($i_{pa}/i_{pc} \approx 1$) with the $E_{1/2}$ values of 0.48 and -0.04 V and the peak separations ΔE of 70 and 80 mV, respectively, which can be attributed to the following one-electron processes:

$$Mn(mpo)_2^- \underset{+e}{\overset{-e}{\rightleftharpoons}} Mn(mpo)_2 \underset{+e}{\overset{-e}{\rightleftharpoons}} Mn(mpo)_2^+.$$

This redox behaviour of **1** is quite different from manganese complexes with other 1,2-bidentate sulphur-containing ligands. For example, the redox wave at -0.67 V for $Mn(tdt)_2^-/Mn(tdt)_2^{2-}$ [15] is much more negative than the corresponding wave of **1**. Therefore, $Mn(mpo)_2$ is stable in air while $Mn(tdt)_2^{2-}$ is easily oxidized by air to $Mn(tdt)_2^-$.

The cyclic voltammogram of **2** (Fig. 3b) in DMF exhibits one quasi-reversible reduction couple for $Fe(mpo)_3/[Fe(mpo)_3]^-$ at $E_{1/2}$ of -0.53 V with ΔE of 70 mV and $i_{pa}/i_{pc} \approx 1$.

The DMF solution of **3** (Fig. 3c) shows one irreversible reduction at -0.80 V and an irreversible oxidation at -0.25 V, respectively. The former may account for the fact that the reduced species undergoes degradation and/or chemical reactions in the time-scale of CV measurements.

The reversible redox couple with $E_{1/2}$ of -1.30 V (ΔE of 100 mV, $i_{pa}/i_{pc} = 1$) in the CV diagram of **4** (Fig. 3d) corresponds to the electron-transfer process $Ni(mpo)_2/[Ni(mpo)_2]^-$. Unlike this, many nickel complexes of 1,2-dithiolene exhibit one-electron oxidation for the couple $[Ni(L)_2]^-/[Ni(L)_2]^{2-}$.

In addition to the aforementioned redox waves, all the four complexes exhibit an irreversible wave (0.88, 0.93, 1.05 and 0.85 V for **1**, **2**, **3** and **4**, respectively) for the oxidation of the bound ligand mpo^- to dtpo, which is not an electroactive species.

In summary, the coordination properties of the mpo^- ligand are shown in this unusual redox behaviour and in the high selectivity to the stabilization of oxidation states. It may be caused by the electronic nature of mpo^- in which the N-oxide bond is highly polarizable and the total charge is less negative compared to other 1,2-bidentate sulphur-containing ligands.

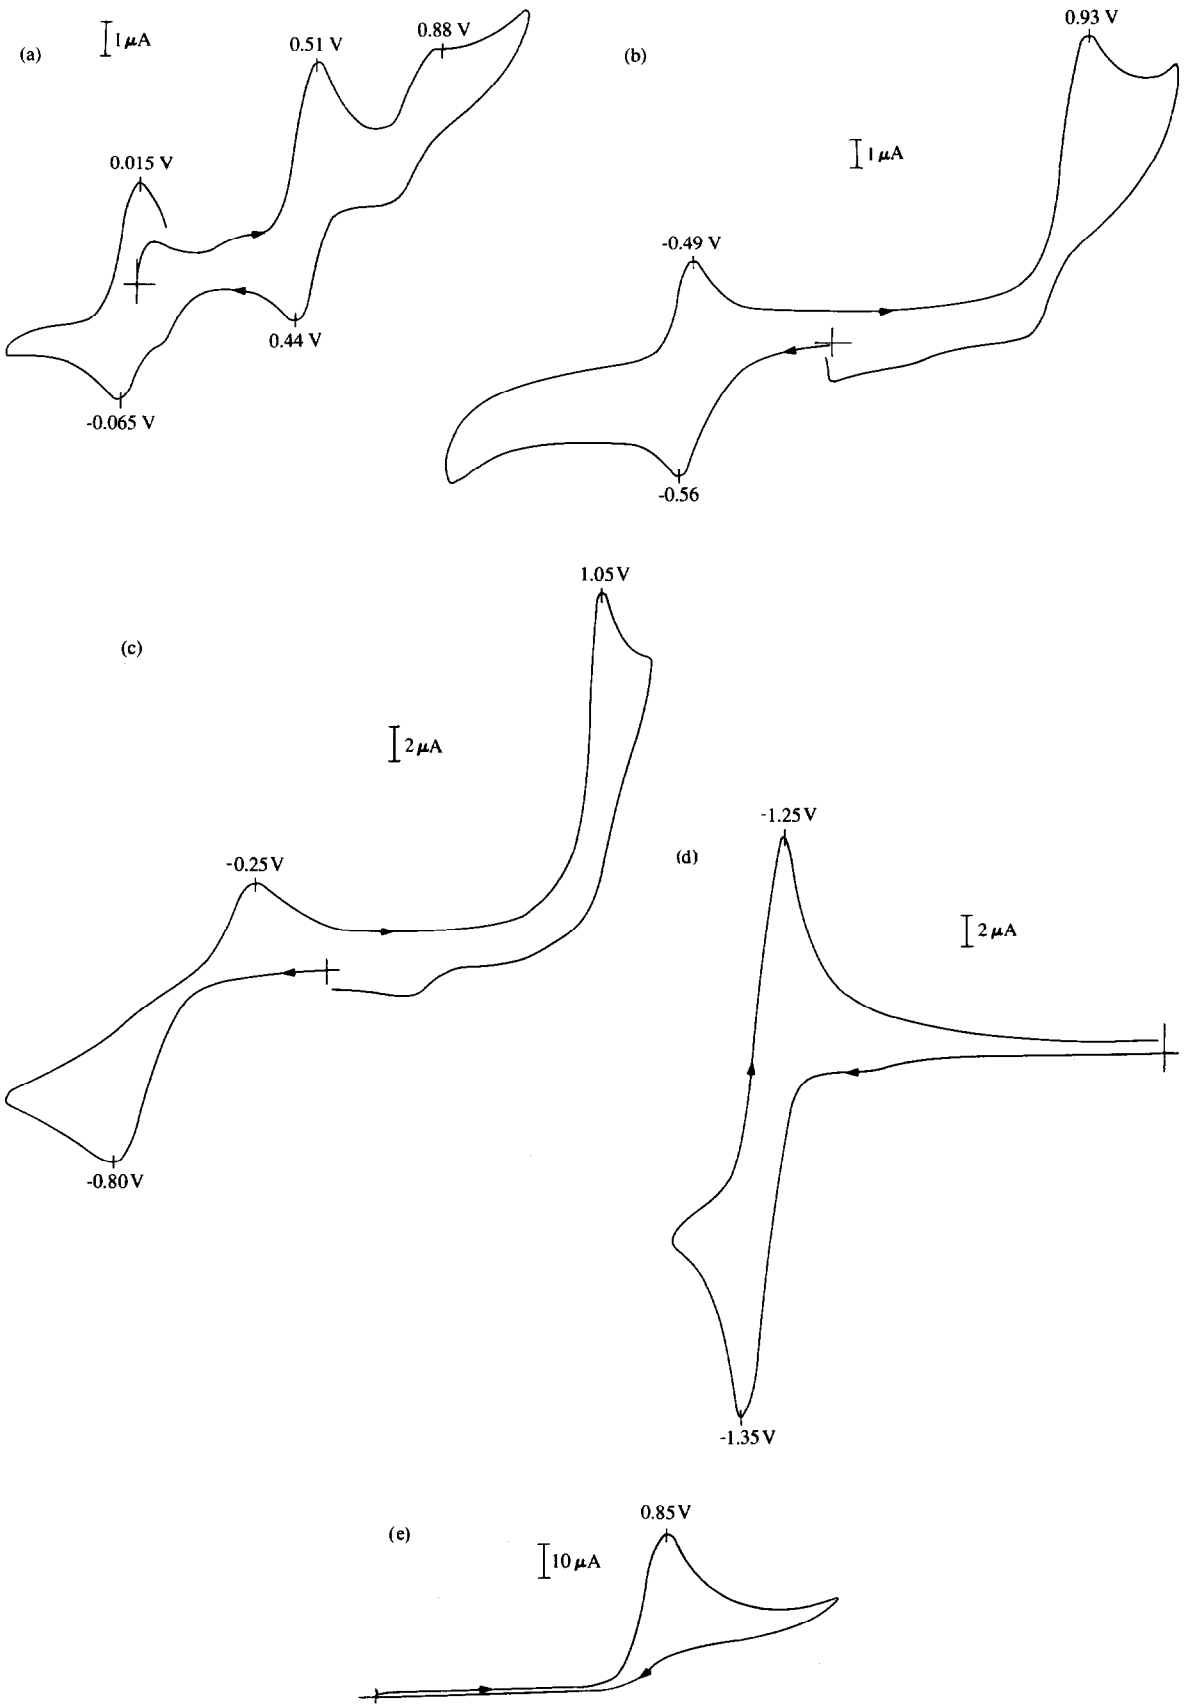

Fig. 3. Cyclic voltammograms in DMF, V vs SCE, 0.1 M of Bu_4NBF_4 as electrolyte, scan rate 100 mV s^{-1}. (a) **1**; (b) **2**; (c) **3**; (d) and (e) **4**.

(*Received* 4 *January* 1991; *accepted* 5 *August* 1991)

Abstract—A series of mononuclear nickel(II) complexes of two tridentate ligands, S-methyl- and S-benzyl-β-N-(pyridine N-oxide-2-ylmethylidene)dithiocarbazate (SMPDH and SBPDH), were prepared and their magnetic properties, electronic and IR spectra were obtained. Both square planar and octahedral configurations were defined among these complexes. The crystal structure of [Ni(SMPD)ImH]ClO_4 was determined by X-ray diffraction, and showed that the nickel atom lies in a square planar coordination environment.

We have studied copper(II) complexes of S-R-β-N-(pyridine N-oxide-2-ylmethylidene)dithiocarbazate (R = methyl, benzyl),[1,2] since these compounds may exhibit antibacterial and antitumour activities like other transition metal complexes of ligands containing sulphur and nitrogen atoms.[3,4] We report here a series of mononuclear nickel(II) complexes of the above two ligands with or without additional ligands.

EXPERIMENTAL

Preparation of the nickel(II) *complexes*

Complexes **1–4**. $Ni(ClO_4)_2 \cdot 6H_2O$ (1 mmol) dissolved in ethanol (10 cm^3) was added to a hot ethanol solution (50 cm^3) of ligand (1 mmol) (SMPDH or SBPDH). The above solution was heated under reflux for 5 min, then imidazole (2 mmol) or pyridine in ethanol (5 cm^3) was added. The mixture was kept refluxing for a further 10 min, and filtered when hot. Brown crystals were obtained when the filtrate was kept at room temperature.

Complexes **5–8**. A solution of $Ni(NO_3)_2 \cdot 6H_2O$ (1 mmol) in ethanol (10 cm^3) was added into a solution of ligand (1 mmol) (SMPDH or SBPDH) in ethanol (50 cm^3). The mixed solution was refluxed for 5 min and then NaN_3 or NaSCN in (1 mmol) of ethanol/water (10 cm^3) (1 : 1) was added. The resulting solution was kept refluxing for a further 10 min and brown crystals appeared after the solution was cooled to room temperature.

Complexes **9–10**. A solution of ligand (SMPDH or SBPDH) in hot ethanol (50 cm^3) and $NiCl_2 \cdot 6H_2O$ (1 mmol) in ethanol (10 cm^3) were mixed and refluxed; brown crystals soon appeared.

Complexes **11–12**. A solution of ligand (1 mmol) (SMPDH or SBPDH) in hot ethanol (50 cm^3) was mixed with a solution of $Ni(OAc)_2 \cdot 4H_2O$ or $Ni(NO_3)_2 \cdot 6H_2O$ (1 mmol) in 10 cm^3 ethanol. After the mixture was refluxed for 10 min, brown crystals were obtained.

Table 1 lists the data on yields and elemental analyses for all complexes.

Spectroscopic measurements

Electronic absorption spectra were recorded in acetonitrile for complexes **1–10** and in DMF for

experimental details and crystal data are as follows: $NiC_{11}H_{12}ClN_5O_5S_2$: $M_r = 452.51$, space group $P2_1/n$; $a = 9.744(2)$, $b = 10.859(2)$, $c = 16.377(6)$ Å; $\beta = 97.47(2)°$; $Z = 4$; $V = 1718.10$ Å^3; $D_c = 1.75$ g cm^{-3}; λ(Mo-K_α) = 0.71073 Å; $\mu = 15.52$ cm^{-1}; $F(000) = 892$; $T = 293$ K.

The structure was solved by direct methods (SHELXTL 4.1), and refined by least-squares techniques to an R value of 0.0398 for 1976 [$I > 3\sigma(I)$] independent reflections with 275 variables. Hydrogen atoms were refined with isotropic parameters. Scattering factors were taken from the International Tables.[5] Final atomic coordinates and equivalent isotropic temperature factors as well as lists of F_o/F_c values form the supplementary material deposited with the Editor.

RESULTS AND DISCUSSION

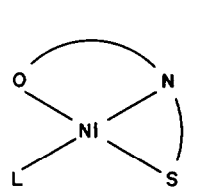
In general, *d–d* bands of nickel(II) complexes with planar structures appear in the neighbourhood of 500 nm, but these absorptions were not determined in the electronic spectra of complexes **1–10**. The reason is that the strong charge-transfer absorptions of the ligands containing sulphur atoms, appearing at lower wavenumbers,[6] have overlapped the *d–d* bands of the nickel(II) ions. Absorptions of 590 and 562 nm in complexes **11** and **12**, assigned to the $^3A_{2g} - {}^3T_{1g}$ transition of metal ions with octahedral configurations,[7] indicate that the two complexes are non-planar. The magnetic data reveal complexes **1–10** are diamagnetic, as expected for planar structures of these complexes. However, magnetic moments of complexes **11** and **12** are 3.31 and 3.86 BM respectively, suggesting that the geometry around the nickel atom is octahedral.

The IR spectra of complexes **1–10** are similar to those of reported tetracoordinated copper(II) complexes.[1] Both ν(C=N) and ν(N—O) of the ligands decrease and ν(C—S) appears upon complex formation. Complexes **1–4** have a very strong band at approx. 1090 cm^{-1}, assigned to ν(Cl—O) of ClO_4^- groups. Complexes **1** and **3** also have bands at 3278 and 3307 cm^{-1} assigned to ν(N—H) owing to the presence of imidazole rings. Sharp bands at about 2030 cm^{-1} without splitting are observed in complexes **5** and **7** due to the unsymmetric stretching vibrations of the N_3^- groups.[8] Analogously, SCN^- groups in complexes **6** and **8** show the stretching vibrations of C≡N bonds near 2100 cm^{-1}. Both ν(N≡N) and ν(C≡N) are within the normal range of wavenumbers,[9] indicating the single coordination mode of N_3^- or SCN^- groups to nickel(II) ions, consistent with literature reports.[10] Usually, the coordination of SCN^- groups to nickel(II) ions involves Ni—N bonding rather than Ni—S bonding, but this may be changed.[9] It is difficult to decide here whether an Ni—N or an Ni—S bond is preferred. ν(Ni—Cl) of complexes **9** and **10** is observed at *ca* 280 cm^{-1},[11] and ν(Ni—S) at *ca* 385 cm^{-1} in their far IR spectra.

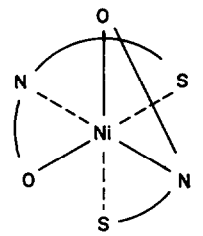
In the IR spectra of complexes **11** and **12**, neither the absorptions of the CH_3COO^- anion at 1560 and 1461 cm^{-1} [9] nor those of the NO_3^- anion in the range 800–850 cm^{-1} [12] are observed. Except the characteristic bands of the ligand, these also demonstrate the octahedral configuration among nickel ions and confirm the result derived from the magnetic data and electronic spectra. A broad absorption in the range 3000–3500 cm^{-1} is also observed in complex **11**, which is attributed to the water of crystallization.

We can conclude from above discussions that the configuration of complexes **1–10** is tetracoordinated planar and that of complexes **11** and **12** is hexacoordinated octahedral (shown as Structs I and II).

The crystal structure of [Ni(SMPD)ImH]ClO_4 has been determined by X-ray diffraction (see Fig. 1 showing the atomic numbering scheme). Figure 2 is a view of the unit cell content. Geometric data are presented in Table 3.



I



II

L = Additional ligands

This structure is isomorphous with that of the reported [Cu(SMPD)ImH]ClO_4.[1] The nickel atom is coordinated via O(1), N(3) and S(1) of the ligand as well as N(1) of the imidazole molecule, and located in the centre of the plane composed of four coordination atoms (maximum deviation: 0.0325 Å). Bond lengths of M—S, M—N and M—O in [Ni(SMPD)ImH]ClO_4 are shorter than analogous bonds in [Cu(SMPD)ImH]ClO_4, suggesting the higher stability of the nickel(II) complex with the ligand; however, they are nearly equivalent to corresponding distances in [Ni(SMPD)Py]ClO_4.[13] The maximum difference in coordination bond distances between [Ni(SMPD)ImH]ClO_4 and [Ni(SMPD)Py]ClO_4 is the Ni—N bond (arising from additional ligand) [the former is 1.888(4) Å and latter 1.912(4) Å], depending on the bulk of the additional ligands—imidazole and pyridine rings.

LIGAND FIELD ANALYSIS OF METAL–OXYGEN INTERACTIONS—I. TRIS(OXALATO)COBALTATE(III)

SNEŽANA ZARIĆ and S. R. NIKETIĆ*†

Department of Chemistry, Faculty of Science, University of Belgrade, Studentski trg 16, P.O. Box 550, YU-11001 Belgrade, Yugoslavia

(*Received* 10 *July* 1991; *accepted* 1 *August* 1991)

Abstract—Ligand field analysis of $[Co(ox)_3]^{3-}$ has been performed using the angular overlap model (AOM) approach. The metal–oxygen interactions were treated as locally anisotropic. Experimental spectra were well reproduced by the calculations in which the Trees' correction was included. The effect of geometrical distortions on the calculated energies of ligand field states has been investigated.

Our previous[1,2] study of tris(aminocarboxylato) cobalt(III) complexes revealed that the differences in the electronic structure between complexes with five-membered glycinato and six-membered β-alaninato chelate rings are a consequence of different torsional angles around M—O bonds (due to the non-planarity of β-Ala rings) rather than of different chelate (N—M—O) angles. The observation led us to propose a hypothesis about the anisotropy of the M—O interaction involving the carboxylato oxygen ligator. This model offered, therefore, the possibility to relate the conformation of a chelate ring to the electronic structure of the coordination complex.

To investigate further this relationship in structures with flexible metal chelate rings, we sought for other examples of chelate complexes containing coordinated carboxylato oxygen(s), in which the influence of chelate ring conformation is expected to be observable via the anisotropy of M—O interactions.

Tris(oxalato) complexes chosen for this study[3] do not offer wide structural variations with respect to the ring conformation. Nevertheless, as shown in this paper on $[Co(ox)_3]$ structures, and in the next paper on $[Cr(ox)_3]$ structures, small structural deformations of the $M(ox)_3$ skeleton are capable of producing significant changes in calculated energies of the ligand field states.

Another reason for our choice is that tris(oxalato) complexes offer a possibility to investigate the extent of transferability of ligand field parameters across the series of chromophores $MN_{6-3n}O_{3n}$ for $n = 0$, 1, 2. In the previous study[2] on tris(aminocarboxylato) complexes (chromophore MN_3O_3) we used the AOM parameters for nitrogen optimized on the MN_6 chromophore. Here we wanted to determine whether the AOM parameters for oxygen are transferable to the MO_6 chromophore as well.

COMPUTATIONAL METHODS

This ligand field analysis is based on the angular overlap model (AOM) approach.[4–7] Here we shall briefly examine geometry relationships for tris(oxalato) structures which are of importance for the AOM analysis. Then we shall outline some extensions of the AOM model used in this as well as in the following[8] work.

Trigonal dihedral geometry definition

The overall coordination geometry of a regular (D_3) trigonal dihedral tris(bidentate) structure is completely defined by any two of the three geometrical descriptors: chelate angle (α), tilt angle (θ) or twist angle (ω) (see e.g. Fig. 2 in Ref. 2). In the so-called trigonal orientation (i.e. z-axis coinciding with the molecular C_3 axis, and the x-axis bisecting the chelate angle, α) the geometry of the metal coordination sphere may be completely defined by, e.g.

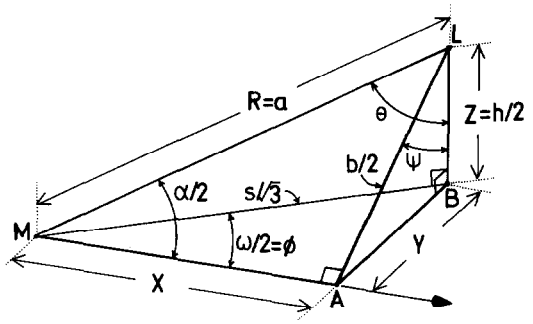

Fig. 1. Rectangular tetrahedron defined by the position of one of the ligator atoms (L) in a trigonally oriented D_3 tris(bidentate) structure showing the relationships between various geometry descriptors. Angles α, θ and ω are defined in the text. Line L-A is equal to a half of the bite distance L-L, and line L-B is a half of the octahedron height (h). M-B is likewise related to the length of the octahedron side (s) through a factor of $\sqrt{3}$. Angle ψ shown on this figure is the pitch angle (octahedral value = 35.5°) and not the ψ(AOM) (octahedral value = 45°).

the two spherical polar coordinates of one of the ligators on a sphere the radius of which corresponds to the unit M—L distance. Several workers[9-16] have commented on various relations between α, θ and ω angles or other (simple or derived) geometry descriptors and ligator (either spherical polar or Cartesian) coordinates. However, it is possible to derive all these and many other relationships between geometry descriptors of a trigonal dihedral tris(bidentate) structure by considering the trigonometry of a rectangular tetrahedron (Fig. 1) defined by the position of one of the ligator atoms in a trigonally oriented structure.

Any regular (i.e. D_3 or C_3) tris(bidentate) structure can easily be brought into a trigonal orientation and compared to other similar structures. The situation is less straightforward for the structures which lack any symmetry. Indeed, all reported crystal structures of the $M(ox)_3$ ion, except one (see below), are unsymmetrical. Therefore, any attempt to define their structural deformations must assume some kind of averaging of the geometrical descriptors. There are essentially two methods for doing this.

In cases of small deviations from C_3 symmetry, it is possible to define average values of chelate and other relevant bond angles[2,4,13] and to derive average twist angles (ω) irrespective of molecular orientation. Alternatively, it is possible to find the best trigonal orientation[10,11] of a low symmetry structure which gives an ω and a pair of θ angles ("upper" and "lower") for each chelate ring. We prefer the latter method because it retains the original structural information and, at the same time, allows for various levels of averaging if and when necessary.

Trigonal deformations in $M(ox)_3$ *structures*

Five-membered M(oxalato) chelate rings are either nearly planar or deformed in an irregular way. Accordingly, in assessing the effects of structural variations in $M(ox)_3$ structures on the results of AOM analysis, it is equally important to consider the modes of departure from the regular octahedral symmetry of the coordination polyhedron. For that reason we have analysed geometries of $M(ox)_3$ ions as reported in published crystal structure determinations.

From the CSD[17] we have extracted data on 30 crystal structure determinations of $M(ox)_3$ ions. Except in one case (PNIOCO, space group $P2_13$ allowing for C_3 symmetry of the complex anion), all the structures belong to space groups which permit at most C_1 and/or C_2 site symmetries, but $M(ox)_3$ ions in all of them were of C_1 symmetry! In order to find the values of θ and ω for these $M(ox)_3$ structures we have adopted the following procedure. Mid-points between ligator atoms belonging to the same chelate rings (three points) and those between ligators on the opposite trigonal faces on adjacent chelate rings (another three points) were located. Eulerian rotations were then applied iteratively, keeping the metal atom in the origo, so that the sum of squares of the displacements of all the six points from the xy-plane is minimized. In this orientation the axis perpendicular to the xy-plane and passing through the atom (i.e. z-axis) is taken as the best C_3 molecular axis. Angles θ and ω for each chelate ring were calculated with respect to this C_3 axis. Subsequent smoothing of the structure may be performed in two steps: by averaging the ω angles to get C_3 symmetry, and by averaging the θ angles to get D_3 symmetry. This method may be regarded as an elaboration of the twist angle definition ϕ[6] of Flandera and Lingafelter.[11] It is numerically stable and yields the smallest variation in ω and θ angles among the chelate rings.

Among many possible bivariate relationships of the geometrical descriptors of tris(bidentate) structures we have found that a plot of ω vs θ yields the most illustrative overview of the $M(ox)_3$ deformations (Fig. 2). It shows that most of the structures follow the relationship $\cos(\omega/2) = \cos(\alpha/2)\sin(\theta)$. Furthermore, metal ions of similar ionic radii have approximately similar α angles. Therefore, the points in the θ–ω plot belonging to the same metal atom or those with similar ionic radii, follow the

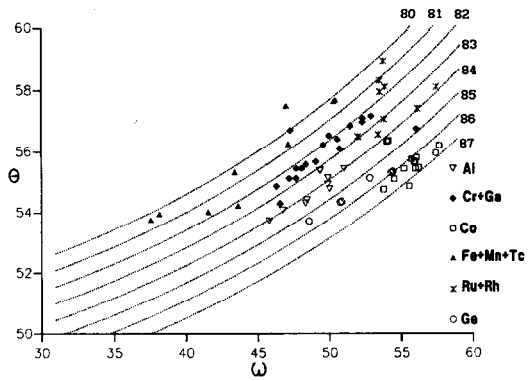

Fig. 2. X-ray structures of $[M(ox)_3]^{3-}$ ions on the θ–ω plot showing that most of the structures approximately follow the relationship $\cos(\omega/2) = \cos(\alpha/2)/\sin(\theta)$, and that metal ions of similar ionic radii have approximately similar α angles. The dotted lines correspond to constant values of α, indicated in the upper right corner of the graph. All data extracted from CSD[17] are shown.[18]

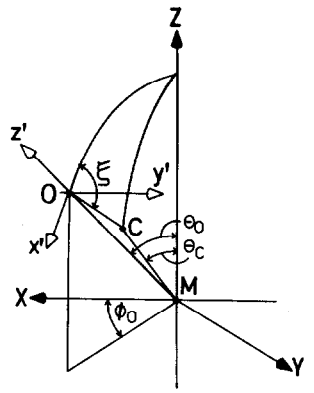

Fig. 3. The spherical trigonometry relationships of the triangle defined by projecting the positions of the oxygen ligator, O, and the neighbouring carbonyl carbon, C, onto the unit sphere around the metal atom. Spherical angle ξ is subtended by the O—C line and the x-axis of the local coordinate system on the oxygen ligator. Therefore, $\psi(\text{AOM}) = \text{abs}(\pi/2 - \xi)$.

α = const. lines (shown as dotted lines in the background on Fig. 2). A full account of the analysis of all 30 $M(ox)_3$ structures is available elsewhere.[18] Here we give only a summary of the structures of five $[Co(ox)_3]$ complexes (Table 1).

Definition and specification of ψ angles

The AOM model which takes into account the anisotropy of an M—L bond requires the specification of the ψ angle[5] in addition to the spherical polar angles which define the position of L on a unit sphere. The angle ψ is related to the torsional angle at the M—L bond. However, while the torsional angle is invariant with respect to molecular orientations, the ψ angle depends also on the spherical polar coordinates of the ligator L.

One way to evaluate the angle ψ is to locate the coordinates of a ligand atom directly connected to the ligator. In the present case it is the carbonyl carbon, C_k. Atoms M, O and C_k define a nodal plane for the π-type orbital on the oxygen ligator. The angle between this plane and the xz-plane of the local coordinate system on O, ξ, can be defined on the basis of spherical trigonometry relationships of the triangle defined by projecting the positions of O and C_k onto the unit sphere around the metal atom (see Fig. 3):

$$\cos(\psi(\text{AOM})) = \cos(\theta) \times \sqrt{\{[\cos 2(\theta) + \cos 2(\alpha/2) \times \tan 2(\omega/2)][1 + \tan 2(\omega/2)]\}}.$$

The angle ψ(AOM) has a value of 45° for the O_h symmetry. It should be distinguished from the pitch

(or tilt) angle, ψ[19,20] (O_h value = 35.5°), which is related to the angles θ and α (or ω) in the trigonal orientation of an idealized (D_3) tris(bidentate) geometry (as shown in Fig. 1):

$$\psi = \pi/2 - \arccos[\cos(\theta)/\sin(\alpha/2)]$$
$$= \pi/2 - \arctan[\tan(\theta) \times \sin(\omega/2)].$$

The latter expression or variants thereof have been sometimes imprecisely cited in connection with the definition of ψ(AOM).[14]

Computational model for the AOM analysis

The basic computational method for AOM analysis used in this work has been described.[2] In addition, for the purpose of the present study, we have adopted two extensions to the AOM procedure. They are related to the Trees' correction, and to the explicit treatment of the second coordination sphere. The former is applied both for cobalt(III) and chromium(III) complexes, and the latter only in the case of $[Cr(ox)_3]^{3-}$ in a crystal environment.

It has been repeatedly demonstrated[21-24] that the so-called Trees' correction[25-28] affects the calculated energies both for the free and for coordinated transition metal ions, so that the agreement between calculated and experimental energies becomes improved.

Trees' correction is introduced in the following form:

$$\langle \alpha SLJM|H(Trees)|\alpha'S'L'J'M'\rangle$$
$$= \delta(S,S')\delta(L,L')\delta(J,J')\delta(M,M')$$
$$\times \{[L(L+1) - 6n]\alpha + \beta Q\};$$

where α and β are the empirical parameters and Q the total seniority operator.[28] For transition metals treated in this study the contribution involving parameter β is negligible. α is treated as an empirically adjustable parameter[23,29,30] with a value ranging from 20 to 110 cm^{-1}.

The other extension of the AOM analysis is related to the inclusion of atoms of the second coordination sphere. Careful inspection of crystal structures of different $M(ox)_3$ ions shows that some counter-ions or polar molecules may influence the crystal field around the central transition metal atom. This influence may be two-fold. Counter-ions may interact with ligand atoms causing small steric and/or electronic deformations which are reflected onto M—L interactions. Furthermore, in some $M(ox)_3$ structures, there are counter-ions which are located close to the C_3 (or pseudo-C_3) molecular axis at short distances from the atom M, and thus may have a direct effect on it.

We have treated selected counter-ions from the outer coordination sphere in the same way as ligator atoms. Their positions (in spherical polar coordinates with respect to the global coordinate system of M) were determined from the crystallographic data. Their influence on M is small, therefore, only e_σ parameters are retained. Their magnitudes are roughly estimated on the basis of the well-known relationships between AOM and crystal-field parameters.[31-33]

RESULTS AND DISCUSSION

Best-fit ligand field parameters

The basis for the ligand field analysis of tris (oxalato)cobaltate(III) ion was the structural data on five complexes retrieved from the Cambridge Structural Database[17] (Table 1) and optical spectra. The latter are room temperature solution spectra which provide positions of the low-lying singlet bands[34-36] and, in one case,[37] of the first triplet transition. Single crystal spectra[38] correspond to $[Co(ox)_3]$ doped in $NaMg[Al(ox)_3]\cdot 9H_2O$, the crystal structure of which is not known.

For the optimization of crystal field parameters the recent spectral data[39] for singlet transitions, and reported[37] triplet transitions, were used. The geometrical model was, therefore, the C_3 average structure derived from four out of five crystal structure geometries. The average values of descriptors were: $\alpha = 86.5$, $\theta = 55.52$ and $\omega = 55.83$ degrees. The structure of $K[Ni(o\text{-phen})_3][Co(ox)_3]\cdot 2H_2O$[40] was omitted since it deviated from all the other structures for more than 3(σ) in most of the structural parameters relevant to this study.

The scarcity of spectroscopic data for $[Co(ox)_3]^{3-}$ limits the number of parameters that could be optimized simultaneously in an AOM calculation. Since our intention was to investigate the transferability of AOM parameters for oxygen, we chose to fix e_σ and e_π parameters for the carboxylate oxygen at the values optimized previously[2] on tris(aminocarboxylato)cobalt(III) complexes. The spin-orbit coupling constant was likewise taken over from the previous[2] study as an upper limit for cobalt(III) suggested by Wilson and Solomon.[41] Inter-electron repulsion parameters F_2 and F_4 were optimized to fit the singlet and triplet spectra in the following way. The baricentre of the A_2 and E_a trigonal components was fitted to the position of the first singlet "*d–d*" band, and the E_b component alone to the second singlet "*d–d*" band. However, it was not possible to reproduce the experimentally

Table 2. Results of ligand field analysis on $[Co(ox)_3]^{3-}$

observed $^3T_{1g}$ transition. Substantial improvement was achieved by inclusion of the Trees' parameter α in the optimization simultaneously with F_2 and F_4. The best parameter set is shown in Table 2.

The resultant Trees' parameter is rather small compared to the value reported[42] for the free cobalt(III) ion (70 cm^{-1}) although it is expected to be reduced.[22]

Effects of structural deformations

With the optimized parameters we have next studied deformations of the $M(ox)_3$ structures. There are essentially two sources for structural variations. First, they are trigonal deformations of the coordination polyhedron, characterized by deviations of global geometry descriptors (α, θ and ω) from their regular trigonal dihedral (D_3) values, both with and without retention of the C_3 axis. Second, deformations may be due to various departures from planarity of the five-membered oxalato metal chelate rings.

Deformations of the coordination polyhedron

Trigonal elongations or compressions are characteristic deformations of tris(bidentate) structures. Since α, θ and ω angles are not independent, changes in, e.g. α are accompanied by simultaneous changes in either θ or ω angles.

Simulation of deformations of α on a model structure can, therefore, be effected either at θ = const. or at ω = const. In both cases an inversion in the order of trigonal components (A and E) of the $^1T_{1g}$ and $^1T_{2g}$ states takes place at $\alpha = 90°$. However, the order is opposite in the cases of θ = const. and ω = const. These results are shown in Fig. 4.

The order of trigonal components calculated for the average crystal structure of C_3 symmetry is $A_2 < E_a < E_b < A_1$. Since the value for θ in this structure is close to octahedral [$\theta(O_h) = 54.7°$], the order of trigonal components of $^1T_{1g}$ is $A_2 < E_a$, as predicted by the model structure with θ = const.

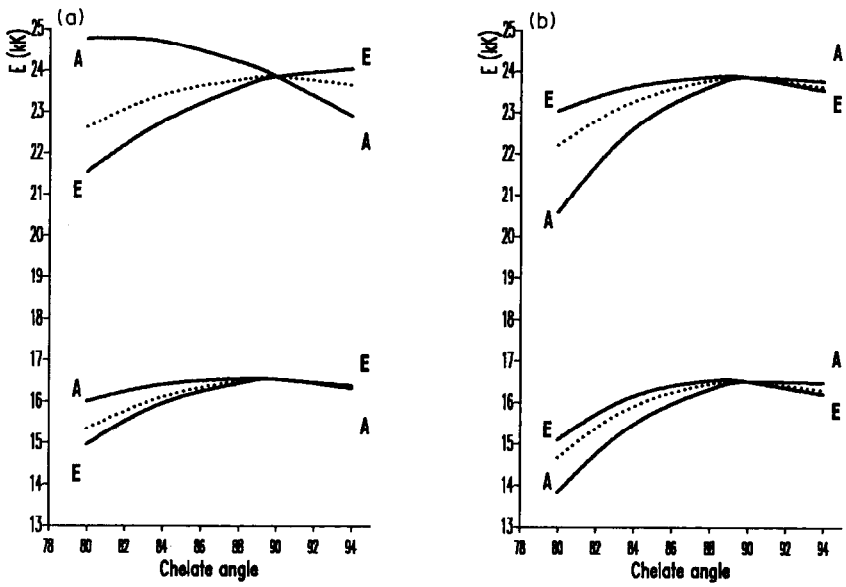

Fig. 4. The influence of trigonal deformations on the positions and splittings of singlets transitions. (a) Simultaneous change of α and θ at $\omega = 60°$. (b) Simultaneous change of α and ω at $\theta = 54.74°$. Baricentres are shown as dotted lines. For both diagrams the best-fit parameter set was used: $F_2 = 1123\ cm^{-1}$, $F_4 = 108\ cm^{-1}$, $\zeta = 600\ cm^{-1}$, $\alpha(\text{Trees}) = 11\ cm^{-1}$, $e(\sigma) = 7400\ cm^{-1}$ and $e(\pi c) = 1700\ cm^{-1}$.

[c] Average of all crystal structures (except PNIOCO) with imposed C_3 symmetry axis.
[d] Baricentre (large mixing of A and E states).

The order of trigonal components for $^1T_{2g}$ is more susceptible to the changes of the angle θ, and is difficult to predict when both ω and θ are distorted.

The results of calculations on the individual crystal structures are presented in Table 3. All structures, except PNIOCO, are unsymmetrically distorted. For PNIOCO the order of trigonal components is the same as reported[38] for the NaMg salt, but different from that calculated for the average crystal structure with C_3 symmetry.

In certain cases the reduction of symmetry affects the calculations so that the expected degeneracies of the energy levels are removed and the eigenvectors appear to be composed of mixtures of functions transforming as A and E. Notwithstanding this uncertainty, it is evident that the order of trigonal components is sensitive to small structural deformations of the coordination octahedron in $[Co(ox)_3]$ complexes. In order to circumvent the problem of symmetry assignment of the calculated eigenvectors, we have fitted each crystal structure to a model of C_3 symmetry. The results (Table 4) again show that the order of trigonal components is sensitive to the structural variations which remain after C_3 averaging. Furthermore, comparison of the results in the cases of structures DAZVUV and QQQCMA, shows that the results are sensitive to lowering of symmetry as well.

The structure PNIOCO is different from the other four not only with respect to the symmetry but also with respect to the shape of the chelate rings. The angle α in PNIOCO is the smallest [84.3° as compared to 86.50(33)° for the other four structures] and the chelate ring puckering is the highest (the torsional angle O—C—C—O is 24.0° as compared to 8.8° in average for DAZWEG, and 1.2° in average for the other structures).

Qualitatively different results are obtained for PNIOCO if the chelate rings in this structure are made planar. Therefore, we argue that the chelate ring puckering (in addition to the overall deformations of the coordination octahedron) are affecting the calculated energy levels. In order to estimate the effect of chelate ring puckering we have studied two idealized modes of ring deformations: envelope and skew-boat puckering (see Fig. 5).

In the envelope puckering, torsional angles around M—O bonds become different from zero

Table 4. Results of ligand field analysis[a] on $[Co(ox)_3]$ complexes derived from crystal structures[b] by imposing C_3 symmetry

[c] Chelate rings forced to planar conformation.
[d] Accidental degeneracy.

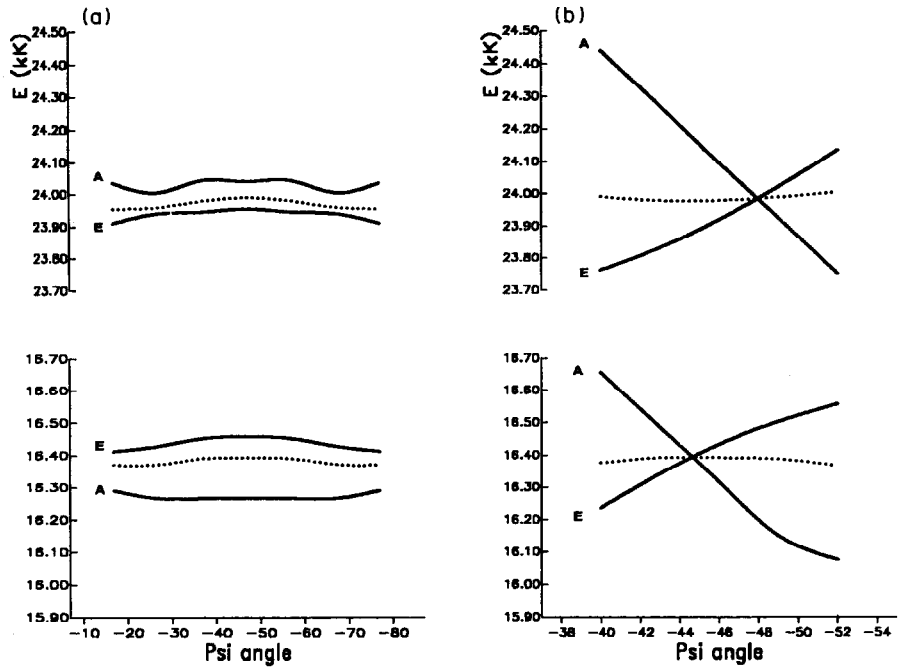

Fig. 5. The influence of the chelate ring conformation on the positions and splittings of singlets transitions. (a) Envelope type of ring puckering with ψ angles of the opposite sign. (b) Skew-boat type of ring puckering with ψ angles of the same sign. Baricentres are shown as dotted lines. For both diagrams the best-fit parameter set was used: $F_2 = 1123\ cm^{-1}$, $F_4 = 108\ cm^{-1}$, $\zeta = 600\ cm^{-1}$, $\alpha(\text{Trees}) = 11\ cm^{-1}$, $e(\sigma) = 7400\ cm^{-1}$ and $e(\pi c) = 1700\ cm^{-1}$.

and opposite in sign, whereas the value for the O—C—C—O torsion remains close to zero. This puckering mode does not change the order of trigonal components and has a very small influence on the calculated energies (Fig. 5). On the other hand, the skew-boat puckering, characterized by substantial departure from planarity in the O—C—C—O fragment and small torsional angles around M—O bonds of the same sign, greatly influences the trigonal splitting and the order of trigonal components (Fig. 5). The skew-boat mode of puckering, present in PNIOCO, explains therefore, the difference between the results obtained with the strict crystal structure and the one corresponding to the planar rings. Furthermore, in the latter case, the results are qualitatively similar to those for the other crystal structures. Angle θ is closest to its octahedral value in one of the structures of QQQCMA (column 3 in Table 4). There the order of trigonal components of the "second" band is $A_1 < E_b$ as expected from Fig. 4 for the case $\alpha < 90°$. In all other crystal structures the variation in θ is more pronounced and the opposite order, $E_b < A_1$, is obtained. The other of the two structures of QQQCMA (column 2 in Table 4) shows deformations both in θ and in ω in such a way that their effect is compensated and practically no splitting of $^1T_{2g}$ is obtained.

CONCLUSIONS

The results of AOM analysis on idealized (D_3) geometries are shown to differ appreciably from those obtained on the basis of the real geometries. This raises the question of necessity to use real geometries in AOM calculations, or at least to consider the effects of possible structural deformations when analysing spectral data for systems which are not fully characterized in terms of their structures.

Furthermore, it was shown that chelate ring conformation is an important structural feature in ligand field studies. In $[Co(ox)_3]$ structures, it is manifested in terms of deviations of oxalato metal chelate rings from planarity. They influence AOM results through the changes in α, θ and ω angles, as well as in the torsional angles around metal–ligand bonds.

Finally, it was shown that the AOM parameter may be treated as transferable across the series of chromophores $CoN_{6-3n}O_{3n}$, $n = 0, 1, 2$. The $e_{\varsigma\lambda}$ parameters for nitrogen were successfully taken over from $[Co(NH_3)_6]^{3+}$ to $[Co(Gly/\beta\text{-}Ala)_3]$, and those for oxygen from $[Co(Gly/\beta\text{-}Ala)_3]$ to $[Co(ox)_3]^{3-}$. The electron repulsion parameters optimized with such a choice for $e_{\varsigma\lambda}$ parameters yielded reasonable numerical values, which were within the limits for CoN_6 and CoO_6 chromo-

phores. However, they do not fit the interpolated values, i.e. the "rule of average environment" is not applicable to electron repulsion parameters.

LIGAND FIELD ANALYSIS OF METAL–OXYGEN INTERACTIONS—II. TRIS(OXALATO)CHROMATE(III)

SNEŽANA ZARIĆ and S. R. NIKETIĆ*†

Department of Chemistry, Faculty of Science, University of Belgrade, Studentski trg 16, P.O. Box 550, YU-11001 Belgrade, Yugoslavia

(*Received* 10 *July* 1991; *accepted* 1 *August* 1991)

Abstract—Ligand field analysis of $[Cr(ox)_3]^{3-}$ has been performed using the angular overlap model (AOM) approach. The metal–oxygen interactions were treated as locally anisotropic. The Trees' correction and the explicit treatment of the second coordination sphere were included. A set of parameters was derived which reproduces both the quartet bands and sharp doublet lines. Relationships between structural and spectral data were investigated.

In the previous paper of this series[1(a)] we have reported our studies on the tris(oxalato) cobaltate(III) ion in an attempt to examine the nature of metal–oxygen interactions, and to determine the extent of transferability of ligand-field parameters across the series of chromophores $MO_{6-3n}N_{3n}$, $n = 0, 1, 2$.

Already in the initial stages of that work we turned our attention also to chemically analogous chromium(III) complexes. In addition to offering the possibility to extend the range of systems on which we intended to investigate the above-mentioned hypotheses, $[Cr(ox)_3]^{3-}$ presents a textbook example for ligand field studies.[2,3] The latter is due to its rich and characteristic electronic absorption features.

It is therefore not surprising that $[Cr(ox)_3]^{3-}$ has been widely investigated both experimentally and theoretically. Thus, while our work was in progress (parts are described in Ref. 1(b)) Schmidtke *et al.* have published an analysis of the quartet spectra[4] and the doublet spectra[5] of $[Cr(ox)_3]^{3-}$. Also, among several examples in a review on sharp line spectra, Hoggard[6] commented on the results of an AOM analysis of $[Cr(ox)_3]^{3-}$. The paper[4] attempted to explain the observed large trigonal splitting of tris(oxalato) and tris(acetylacetonato) chromate(III) ions (the latter being of almost regular octahedral coordination) using the non-additive AOM approach due to the phase-coupling in the π-conjugated chelate rings. However, it was shown[4] that such an approach is not required for the analysis of oxalato chelates.

METHODS

Computational procedures employed in this work are based on the AOM formalism[7–10] and complete matrix diagonalization methods.[11,12] They have been fully described previously.[13] Extensions to the AOM treatment used in the study of $[Cr(ox)_3]^{3-}$ were outlined in the preceeding paper.[1(a)]

RESULTS AND DISCUSSION

In the ligand field analysis of $[Cr(ox)_3]^{3-}$ we have first optimized the parameters on quartet spectra. Then we have proceeded to fit the doublets spectra starting with those parameters. At this stage, we refined the parameters and introduced necessary extensions to the model in order to reproduce the spin-forbidden transitions and their splittings. This, eventually, led us to formulate the best parameter set and the conditions required to fit the whole optical spectrum of $[Cr(ox)_3]^{3-}$.

Quartet spectrum of $[Cr(ox)_3]^{3-}$

Development of parameters. As in the case of Co^{III},[1(a)] the basis for the ligand field analysis of $[Cr(ox)_3]^{3-}$ was X-ray structural data[14] on the following five complexes: $(NH_4)_3[Cr(ox)_3]\cdot 2H_2O$,[15] $K_3[Cr(ox)_3]\cdot 3H_2O$,[16] $(Me_4N)_3[Cr(ox)_3]\cdot$

H_2O,[17] $Na_3[Cr(ox)_3]\cdot 5H_2O$,[18] and $(NH_4)_3[Cr(ox)_3]\cdot 3H_2O$,[19] (Table 1), as well as the spectral data on $[Cr(ox)_3]^{3-}$.[20-23]

Commonly observed quartet spectra consist of two broad maxima at around 17.5 kK ($^4T_{2g}$) and 24.5 kK ($^4T_{1g}$). Trigonal splitting of the first spin-allowed band is observed[20,21,23] as $^4A_1 < {}^4E_a$ in the monocrystal polarized spectra of Cr^{III} doped in $NaMg[Al(ox)_3]\cdot 9H_2O$. Qualitatively similar splitting was inferred from the analysis of CD spectra.[24,25] The symmetry-forbidden $^4A_2$ component of the second ($^4T_{1g}$) band has been observed,[4,21] due to vibronic coupling, as a weak band in polarized spectra.

Due to the fact that the crystal structure of $NaMg[Al(ox)_3]\cdot 9H_2O$, the host lattice for all published solid-state electronic spectra of $[Cr(ox)_3]^{3-}$, is not known, we have chosen an idealized average geometry of $[Cr(ox)_3]^{3-}$ as a starting point for ligand-field analysis. The trigonal model structure was obtained by averaging over 12 oxalato rings from the four crystal structure determinations, and imposing the C_3 symmetry. This average structure is characterized by: $\alpha = 82.315°$, $\theta = 56.22°$, $\omega = 50.06°$, and $\psi = 50.01°$.

Preliminary calculations with different crystal structure geometries and idealized trigonal geometries showed that the positions and the order of trigonal components, as well as the extent of trigonal splitting, is dependent on small structural variations and on the presence or absence of a C_3 axis.

Therefore, we have set the following weighting criteria for parameter optimization. Highest relative weight was ascribed to the order of trigonal components of the "first" quartet band, taken as $^4A_1 < {}^4E_a$, as found both in the solid-state optical spectra[20,21,23] and in the solution CD spectra.[24,25] In the same way we have treated the position of the baricentre and the ^4E_b component of $^4T_{1g}(O_h)$. The magnitude of trigonal splitting, the order of the components of the "second" quartet band, and the position of the $^4A_2$ component of $^4T_{1g}(O_h)$ were given lower weight in the fitting procedure.

During the optimization the values of F_2, F_4, e_σ and e_π were allowed to vary. It was found that the results are quite insensitive with respect to the variation of the spin-orbit parameter. Therefore, its value was fixed at 115 cm^{-1} in agreement with previous studies.[4] The position of the $^4T_{2g}$ baricentre is sensitive to e_σ and e_π parameters, and the order of trigonal components depends upon e_π. Second quartet band is dependent on F_2 and F_4 as well. The best parameter set for quartet spectra (Table 2) yielded for cubic crystal-field parameter,

Table 2. Comparison of experimental and calculated quartets spectra of $[Cr(ox)_3]^{3-}$complexes (in cm^{-1})

Level	Exptl		Calc.[a]
$^4A_1$	17630[b]	17608[c]	17710

10 Dq, 18410 cm^{-1}, and for Racah electrostatic parameters: $C = 3290\ cm^{-1}$ and $B = 565\ cm^{-1}$.

Effects of structural deformations. Three characteristic modes[1] of trigonal deformations (θ = const., ω = const., and α = const.) were simulated on the idealized model of $[Cr(ox)_3]^{3-}$. Their effect is shown on Fig. 1.

The average of 12 ox chelate rings from four crystal structures of $[Cr(ox)_3]^{3-}$ with imposed C_3-axis can be classified as belonging to the θ = const.

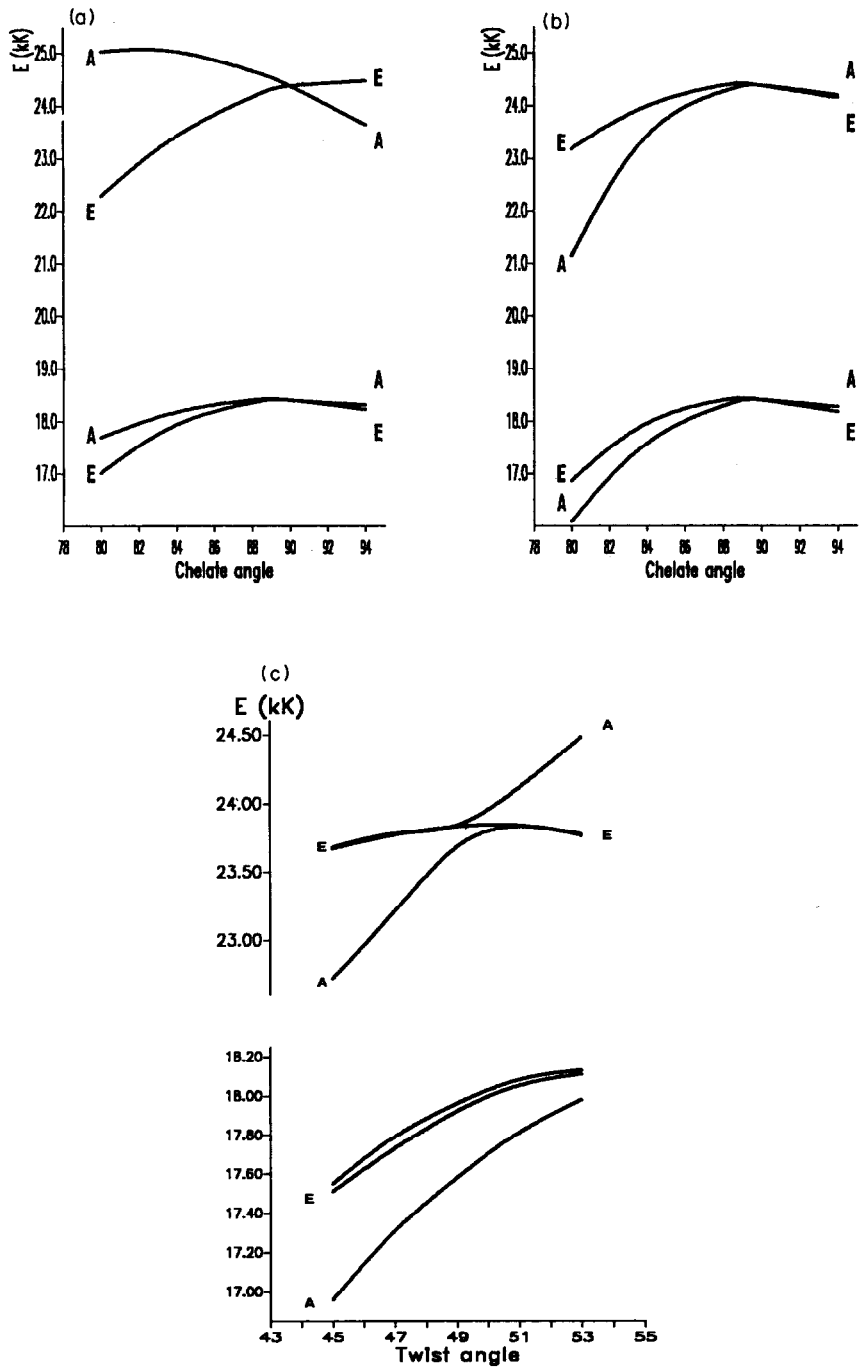

Fig. 1. The influence of characteristic modes of trigonal deformations on the calculated positions of trigonal components of the quartet bands. (a) Simultaneous change of α and θ at $\omega = 60°$. (b) Simultaneous change of α and ω at $\theta = 54.74°$. (c) Simultaneous change of θ and ω at $\alpha = 82.31°$. For all diagrams the best-fit parameter set for quartets spectra was used: $F_2 = 1035\ cm^{-1}$, $F_4 = 94\ cm^{-1}$, $\zeta = 115\ cm^{-1}$, $e(\sigma) = 6570\ cm^{-1}$, and $e(\pi c) = 650\ cm^{-1}$.

type of deformation. For that structure, analysis from Fig. 1 predicts the order $^4A_1 < {}^4E_a$, which is actually observed both in polarized crystal spectra[20,21,4] and in solution CD spectra.[24,25]

Another class of structural deformations is the one in which the trigonal symmetry is removed. In order to study the low symmetry deformations as found in actual crystal structures, we performed calculations on exact crystal structure geometries, on the same geometries with imposed C_3-symmetry, and with both the C_3-symmetry and with chelate rings constrained into planar conformations. The results (Table 3) indicate that both the baricentre positions and the order of trigonal components are indeed highly sensitive to these deformations.

Unfortunately, AOM results on actual crystal structure geometries are difficult to interpret because of extensive mixing of A and E components in both quartet bands ($^4T_{2g}$ and $^4T_{1g}$). If we assign symmetries to the trigonal components on the basis of clustering of the energy levels, we see that the experimentally established order ($A_1 < E_a < E_b < A_2$) is not the same for all structures. The question as to whether these differences are due to trigonal deformations of $[Cr(ox)_3]$ framework or to the lowering of symmetry (to C_1), or perhaps, to chelate ring puckering, is difficult to answer due to the impossibility to decouple different types of structural deformations which often show opposite effects on the energies of ligand-field states.

The order of trigonal components of the second quartet band ($^4T_{1g}$) appears to be most sensitive upon all kinds of structural deformations. In addition, this order for both quartet bands can be influenced by the changes in chelate ring conformation as shown in Fig. 2 for the skew-boat type[1(a)] of ring puckering.

Idealized structures derived from X-ray structures (by imposing C_3 symmetry and chelate-ring planarity) generally show the "correct" order of LF

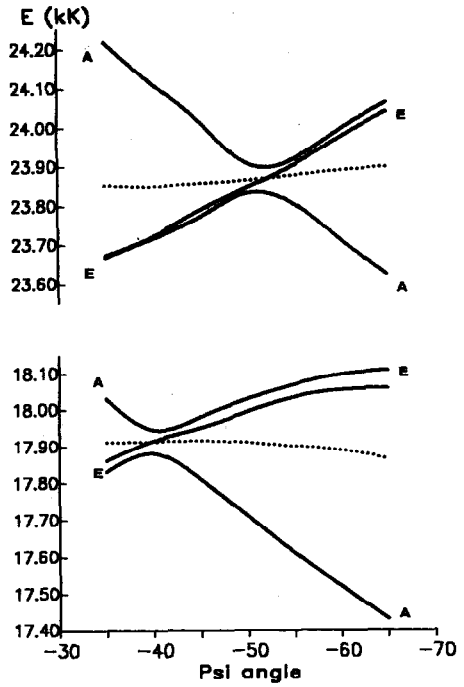

Fig. 2. The influence of the skew-boat type[1(a)] of puckering of all three chelate rings in $[Cr(ox)_3]^{3-}$ structure on the positions and splittings of quartets transitions. The best-fit parameter set for the whole spectrum was used: $F_2 = 1118.5$ cm^{-1}, $F_4 = 71.7$ cm^{-1}, $\zeta = 115$ cm^{-1}, α(Trees) = 230 cm^{-1}, $e(\sigma) = 6540$ cm^{-1}, and $e(\pi c) = 600$ cm^{-1}.

levels ($A_1 < E_a < E_b < A_2$). An exception is CROXKH[16] where it is reversed for $^4T_{1g}$. This is interpreted as being due to high relative degree of trigonal elongation of this structure (the lowest values of ω and θ; Table 1). On the other hand, idealized structures of DITFER[17] and AMOXCR,[15] which are trigonally compressed—or, at least, less elongated than CROXKH (see Table 1) show the "correct" order of ligand-field levels.

The comparison of the present results with the calculations of Schmidtke *et al.*[4] is interesting. These authors[4] have analysed $[Cr(ox)_3]^{3-}$ on the basis of their electronic spectrum [17.3, 17.5, 24.3 and 24.6 kK assigned to $^4A_1$, ^4E_a, ^4E_b and $^4A_2$, respectively] which is characterized by substantially smaller trigonal splittings compared to the previously reported spectra.[20–23] Using their parametrization, with isotropic treatment of Cr–O interactions, we obtained a good fit to the experimental spectrum when the actual X-ray geometry of CROXKH[16] was used in the calculation. However, neither the anisotropic model nor the smoothing of the CROXKH structure into the C_3 geometry, could account for the above spectral data.[4] On the other hand our parametrization based on the anisotropic AOM model, is able to reproduce well the experimental data on the solid state spectra,[21,23] on the average geometry of all crystal structures, as well as on the smoothed geometries of most of the crystal structures except for the trigonally elongated CROXKH.

Therefore the proposition[4] that $[Cr(ox)_3]$ is subjected to a trigonal compression in the host lattice of $K_3[Al(ox)_3]$ is in agreement with our results—but only if other sources of structural deformations are disregarded (as is clearly evident from the α = const. diagram of Fig. 1). However, we argue that other types of deformations, such as symmetry lowering, and chelate-ring puckering, (the latter clearly evident from Fig. 2) are equally important, and that without further structural data on [Cr/Al $(ox)_3$] systems it is not possible to extract unequivocal conclusions from the AOM results.

Doublet spectrum of $[Cr(ox)_3]^{3-}$

Development of parameters. The lowest energy spin-forbidden transitions in $[Cr(ox)_3]^{3-}$ can be detected even in aqueous solution spectra.[2,26] However, only the low-temperature spectra of monocrystals,[20,21] luminescent spectra,[22] and recent excitation spectra[23] provide accurate experimental details to identify components of ^2E, $^2T_{1g}$, and $^2T_{2g}$ that arise from the lowering of symmetry of the chromophore and from spin-orbit coupling.

For the optimization of LF parameters we have, therefore, used the data from low-temperature luminescent[22] and excitation[23] spectra of doublet transitions measured for 1% $[Cr(ox)_3]$ in $K_3[Al(ox)_3]\cdot 9H_2O$ host lattice, and the geometry corresponding to the crystal structure of $K_3[Cr(ox)_3]$. The inconsistency of such an approach may be due to the possible deformations of $[Cr(ox)_3]$ moiety in the host lattice and to the temperature effects (room temperature X-ray study vs low temperature spectral study). However, Coleman[23] assumed that differences between solid state spectra of pure Cr^{III} salts and their 1% solid solutions in isomorphous Al^{III} salts are not significant.

The LF and AOM parameters optimized on quartets spectra do not reproduce the positions of doublets at all. But it has been shown before[27] that it is impossible to fit spin-forbidden and spin-allowed transitions with the same interelectron repulsion parameters. Therefore, we first attempted to optimize F_2 and F_4 on doublets spectra keeping $e_{\zeta\lambda}$ parameters at their previously obtained (best-fit) values. This attempt failed also. Doublets spectra were indeed excellently reproduced (e.g. as in Table 4) only if all parameters were subjected to optimization. However, the parameter set that emerged

from such a refinement (see Table 4) proved to be unacceptable for quartets spectra. The improved parameter set which could simultaneously account for quartet and doublet transitions was eventually obtained after introduction of the Trees' correction, as will be discussed below.

^2E splitting. In spin-forbidden spectra of $[Cr(ox)_3]^{3-}$ below 15 kK a ^2E transition is identified[21] with ^2E splitting varying over two orders of magnitude[22] in different $[Cr(ox)_3]^{3-}$ salts (see Table 5). This splitting is ascribed[22,23] to spin-orbit coupling and its relative magnitude to lattice effects.

A number of recent examples from the literature[5,28-31] point to the difficulties in interpreting ^2E splitting in Cr^{III} complexes and to various attempts to reproduce it in LF analyses with the help of, e.g. Trees' correction,[31] second coordination sphere,[31] differential orbital expansion,[27] symmetry limited π-orbital expansion,[29] etc. but with limited success.

Using arbitrarily assumed values for electron repulsion parameters Hoggard[6] postulated that the ^2E splitting has to be much larger than experimentally deduced[22] and that the supposed ^2E splitting reported by Coleman[22] is in fact due to the existence of non-equivalent sites or to vibronic coupling. In contrast, our study showed that it is possible to account for the observed[22] splitting of ^2E within the present AOM approach.

The splitting of ^2E is very sensitive to the changes in the $e(\pi c)$ parameter. It is not at all sensitive to F_2 and F_4 which determine the difference between ^2E and the other doublet states. Therefore it appears not to be necessary to fit $\Delta E(^2E - {}^2T_{1g})$ difference with $e(\pi s)$ parameter as was done by Hoggard.[6] The spin-orbit parameter does not have much influence on the ^2E splitting, so it was not optimized in this study. Trees' parameter, α, which was introduced in order to correct the calculated position of $^2T_{2g}$, increases slightly the splitting of ^2E. Last, the skew-boat type[1] of chelate-ring puckering (but not the envelope type) also increases ^2E splitting.

Calculated ^2E splittings in the cases for which the X-ray crystal structures were available, are given in Table 5. These results show that both the magnitude and the trend within the series of $[Cr(ox)_3]^{3-}$ salts has been well reproduced. Lower calculated values for ^2E splitting than the experimental ones[22,23] are justifiable on the grounds that the present AOM treatment includes only the static contributions to splittings.

Markedly smaller ^2E splitting obtained for the mean idealized structure (with D_3 symmetry) indicates that this spectral detail is particularly sensitive to symmetry lowering deformations such as those found in crystal structures of tris(oxalato) chromates(III). Another geometrical factor that presumably influences the ^2E splitting is the trigonal compression. In the series of investigated $[Cr(ox)_3]^{3-}$ structures the potassium salt CROXKH shows the highest trigonal elongation and the largest ^2E splitting. It is smaller in the case of trigonally less-elongated SOXCRP and AMOXCR. In fact, the splitting is a result of various simultaneous structural deformations (including also the chelate-ring conformation) and is difficult to rationalize on the basis of individual contributions

taken in turn. A good example is DITFER, which shows highest trigonal compression (Table 1) and yet it yields ^2E splitting comparable to AMOXCR or SOXCRP. The explanation for such a result may be sought in different chelate-ring conformations between DITFER and AMOXCR or SOXCRP, as well as in different "degree of departure from C_3 symmetry" in addition to trigonal deformations.

$^2T_1$ and $^2T_2$ states. Spin-forbidden transitions to the components of $^2T_{1g}$ and $^2T_{2g}$ were described by several authors[20,21,23,26] who disagree in detailed assignments.

Our calculations show that F_2 and F_4 do influence the baricentres of $^2T_1$ and $^2T_2$, but that variations in $e_{\zeta\lambda}$ are particularly insignificant. Good fits to both ^2T states are possible only with Trees' correction (as shown below). Splittings of ^2T states are well-reproduced with the parameter set optimized on all doublets. Splittings are influenced by trigonal deformations (see Fig. 3), but again the trigonal elongation and chelate-ring puckering appear to be counteracting effects which cannot be disparted one from the other.

The splitting of $^2T_1$ is insensitive towards both the changes in chelate-ring conformations and the lowering of the overall symmetry of $[Cr(ox)_3]$. These deformations, however, influence the splitting of $^2T_2$. Hoggard[6] predicted a $^2T_2$ splitting of about 1000 cm^{-1}, as opposed to the value estimated[23] from the analysis of experimental spectra, which is about 120 cm^{-1} for the potassium salt. We were not able to obtain $^2T_2$ splittings greater than 580 cm^{-1} with any sensible set of parameters (see below). Moreover, our lower limit to this value was about 180 cm^{-1} which is comparable to Coleman's findings.[23]

Complete spectrum of $[Cr(ox)_3]^{3-}$

The failure of conventional AOM to account, with a unique set of parameters, both for the doublets and the quartets transitions in the optical spectra of Cr^{III} complexes is well known: a number of suggestions on how to cope with this problem have appeared in the literature.[6,31]

Another problem, which did not receive such attention, stems from the necessity to simultaneously fit data of different experimental accuracies: sharp doublet lines (which are sometimes not unambiguously assigned) and broad quartet bands (which are sometimes insufficiently resolved).

A single modification of AOM that significantly improved the overall fit was the introduction of Trees' correction in the form as described in the preceeding paper.[1(a)] Trees' parameter α causes an

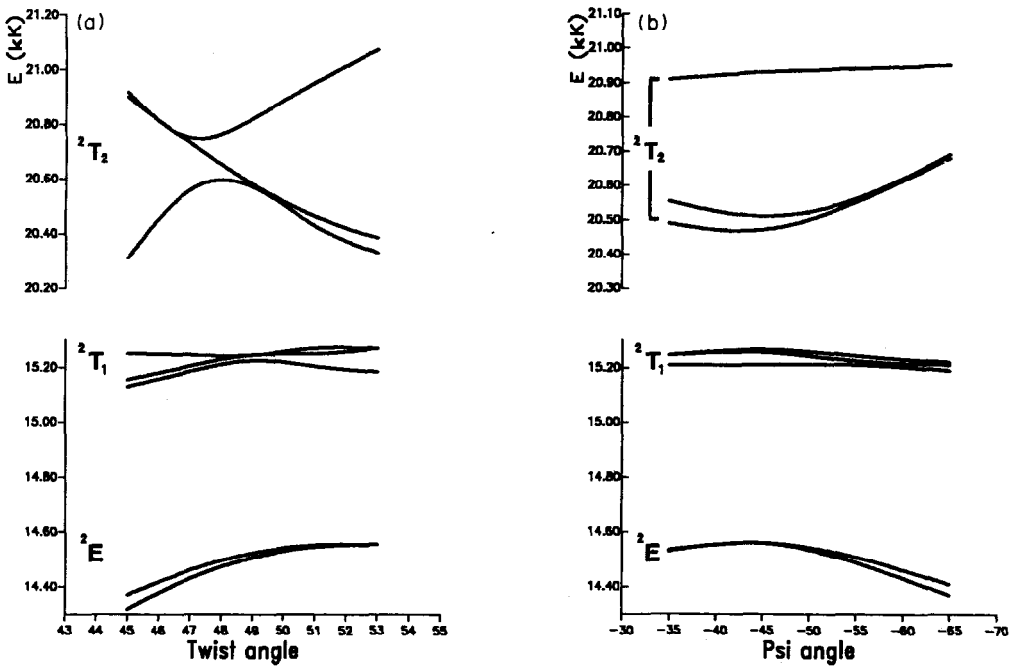

Fig. 3. The influence of trigonal deformations and chelate-ring conformation on the positions and splittings of doublets transitions. Left: Simultaneous change of θ and ω at $\alpha = 82.31°$. Right: The effect of skew-boat puckering of all three chelate rings in $[Cr(ox)_3]^{3-}$ structure. For both diagrams the best-fit parameter set for the whole spectrum was used. $F_2 = 1118.5$ cm^{-1}, $F_4 = 71.7$ cm^{-1}, $\zeta = 115$ cm^{-1}, α(Trees) $= 230$ cm^{-1}, $e(\sigma) = 6540$ cm^{-1}, and $e(\pi c) = 600$ cm^{-1}.

increase in energies of low-lying doublet states, it does not influence the position of the first quartet ($^4T_{2g}$) but it reduces the energy of the second quartet state ($^4T_{1g}$). It also increases slightly the splitting of ^2E and $^2T_{1g}$ and, most importantly, it decreases the difference $\Delta E(^2E - {}^2T_{2g})$. Introduction of parameter α, of course, requires the reoptimization of the other parameters. Thus, it calls for modification of electron repulsion parameters (F_2 and F_4), and a slight decrease in $e(\pi c)$ in order to reproduce ^2E splitting, the change of $e(\sigma)$ in order to reproduce the baricentre of $^4T_{1g}$, and readjustment of other parameters in order to improve the overall fit to the quartet transitions.

The optimized value for α (about 230 cm^{-1}) is larger than the one used[32,33] for the analysis of free Cr^{III} ion spectra. However, similarly large values of Trees' parameter were suggested before[6,31,34] in the case of Cr^{III} complexes.

[b] Geometry of the CROXKH.[16]

[c] $F_2 = 1118.5\ cm^{-1}$, $F_4 = 72\ cm^{-1}$, $e(\sigma) = 6490\ cm^{-1}$, $e(\pi c) = 600\ cm^{-1}$, $e(\pi s) = 0$, $\zeta = 115\ cm^{-1}$, α(Trees) $= 227\ cm^{-1}$.

[d] $F_2 = 1118.5\ cm^{-1}$, $F_4 = 71.7\ cm^{-1}$, $e(\sigma) = 6540\ cm^{-1}$, $e(\pi c) = 600\ cm^{-1}$, $e(\pi s) = 0$, $\zeta = 115\ cm^{-1}$, α(Trees) $= 230\ cm^{-1}$, together with 17 nearest neighbour atoms (5 potassium and 12 water oxygens) from the crystal lattice.

[e] Quartets were calculated with mean idealized geometry of all crystal structures. Agreement with experimental values is better than with crystal structure CROXKH [cf. note [f] below].

[f] Results obtained on CROXKH with parameter set [c] given in order to enable comparison with the parameter set [d] in which the counterion interactions are included.

The final results are presented in Table 6. A somewhat eclectic nature of the data (Table 6) stemmed from the fact that it was necessary to combine spectral and structural information from various sources in a consistent way. Thus, the calculation with the best-fit parameter set (data column 2 of Table 6) was done on the crystal structure CROXKH for doublets and on the mean idealized geometry for quartets since the exact geometry corresponding to the quartets spectra is not known. Furthermore, the parameter set which included the counterion contributions, was applied onto CROXKH structure both for doublets and for quartets (data column 4 of Table 6). So, for the sake of comparison of the two parameter sets, calculated quartets spectra for CROXKH are also given (data column 3 of Table 6).

An attempt to include contributions to AOM from the outersphere. Following Coleman's[22] suggestion that the second coordination sphere should be considered when analysing the shifts and splittings of sharp doublet lines, we made an attempt to extend the present AOM treatment by including contributions from the counterions and oxygens from water molecules from crystal lattices of $[Cr(ox)_3]^{3-}$ salts.

The smallest interatomic distance between the Cr^{III} centre and a counterion or H_2O in any of known crystal structures is greater than 4 Å. Therefore, interactions were treated as isotropic with $e(\pi c) = e(\pi s) = 0$.

The value of the parameter $e(\sigma)$ for a counterion or water oxygen was taken to be inversely proportional to a power of the interatomic distance. R^{-3} and R^{-5} dependence was proposed by Hoggard,[34] but R^{-7} and R^{-9} were also used.[35,36] Our calculations were performed assuming R^{-5} law. For the nearest water oxygen (approx. 4.2 Å) it gives $e(\sigma)$ of approx. 200 cm^{-1}. For the positive potassium ion, in CROXKH[16] we used $e(\sigma)$ parameters of similar magnitude and opposite sign, in line with general relations between AOM and point charge crystal-field parameters.[37-39]

These corrections increase splittings of all doublet states (^2E, $^2T_{1g}$, and $^2T_{2g}$) as well as the trigonal splitting of $^4T_{2g}$, and lower the energies of all ligand-field states. Unfortunately, for certain combinations of additional parameters, inversions in the order of trigonal components of $^4T_{1g}$ states are observed. By and large, this increase in parameter space demonstrated the necessity for reoptimization of the entire set of parameters, reasserting that for such an endeavour one needs self-consistent sets of accurate structural and spectral data, which are not available at present.

Abstract—The reaction of 1-[3′-methoxyphenylimino)methyl]-2-naphthol with dimethyltin(IV) dichloride yields an addition compound having 2:1 stoichiometry (ligand: organotin). The complex formed has been characterized by elemental analysis, ^{1}H and ^{13}C NMR spectroscopy, IR spectroscopy and X-ray analysis. Coordination of the Schiff base to the metal occurs via the phenolic oxygen atom. This preferred mode of bonding is associated with the shift of the phenolic proton towards the azomethine atom resulting in a zwitterionic configuration for the ligand.

Over the last two decades, studies on the coordination of Schiff bases to inorganic and organometallic tin compounds have received considerable attention.[1–7] Both aliphatic[3,5] and aromatic Schiff bases[4–9] in their neutral and deprotonated forms have been used to react with organotin as well as inorganic tin(II) and tin(IV) halides and pseudohalides. The complexes that are formed exhibit variable stoichiometry in the ligand to metal ratio and different modes of coordination which have been explained on the basis of inductive and steric effects of the substituents on the aromatic ring. However, studies on the structural effects of the *meta*-substituents on the atomatic ring have not been carried out. Structural correlation studies on some of the tin complexes of aldehydes and ketones have contributed to the understanding of the preferred geometry of the tin atom and the conformation of the ligands bonded to the metal.[10] In order to provide more information on the effect of substituents on the nature of the complex formed, we carried out the reaction of the *meta*-substituted 2-hydroxynaphthalideneimine Schiff base 1-[(3′-methoxyphenylimino)-methyl]-2-naphthol with dimethyl tin(IV) dichloride.

EXPERIMENTAL

Synthesis of ligand 1-[(3′-*methoxyphenylimino*) *methyl*]-2-*naphthol*

2-Hydroxy-1-naphthaldehyde (50 mmol) was dissolved in a 50 cm^3 mixture (2:1) of CH_2Cl_2 and 95% ethanol. It was then filtered and added to an ethanolic solution of *m*-anisidine (50 mmol). The mixture was stirred for 20 min, whereupon the yellow precipitate which formed was recrystallized from ethanol. M.p. 94–96°C.

Synthesis of the complex $[(CH_3)_2SnCl_2 \cdot 2HOC_{10}H_6CH:NC_6H_4OCH_3]$

A solution of the ligand (6 mmol) dissolved in CH_2Cl_2 (40 cm^3) was added to dimethyltin(IV) dichloride in 10 cm^3 of the same solvent. The mixture was stirred and on standing at room temperature orange crystals were formed. M.p. 146–148°C. Found: C, 59.0; H, 4.7; N, 3.6. Calc. for $C_{38}H_{36}N_2O_4Cl_2Sn$: C, 58.9; H, 4.7; N, 3.6%.

Physical measurements

IR absorption spectra of the compounds were recorded using a Beckman IR 20A IR spectrophotometer in the frequency range 4000–250 cm^{-1}. Samples were prepared as KBr discs. The ^1H and ^{13}C NMR spectra were obtained with a Bruker 300 MHz AC-P NMR spectrometer. Microanalysis was carried out at the School of Chemical Sciences, Universiti Sains Malaysia, Penang, Malaysia.

Crystal structure determination of $[(CH_3)_2SnCl_2 \cdot 2HOC_{10}H_6CH : NC_6H_4OCH_3]$

Intensity data for a crystal with dimensions $0.6 \times 0.4 \times 0.3$ mm were measured at room temperature on a Huber diffractometer fitted with graphite monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å. The θ–2θ scan was employed to measure a total of 4955 reflections such that $\theta_{max} \leqslant 30°$. No significant decomposition occurred during the data collection. Corrections were applied for Lorentz and polarization effects but not for absorption. There were 4955 unique data of which 4778 satisfied the $F \geqslant 2.5\sigma(F)$ criterion of observability and were used in the subsequent analysis. Crystal data are listed in Table 1.

The structure was solved by using SHELXS86[11] and refined by a full-matrix least-squares procedure based on F using SHELX76.[12] The tin atom coincides with a crystallographic centre of symmetry, so that there is only one molecule in the unit cell. All non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were included in their idealized positions (C—H = 0.96 Å) and refined isotropically. A weighting scheme of the form $w = k/[\sigma^2(F)+gF^2]$ was used and the refinement continued to final $R = 0.030$, $R_w = 0.033$ for $k = 1.94$ and $g = 0.0008$. The analysis of variance showed no special features and the maximum residual electron density peak in the final difference map was 0.89 e $Å^{-3}$ (near the tin atom). The scattering factors for all the atoms were used as incorporated in SHELX76.

Lists of atomic coordinates, thermal parameters and observed and calculated structure factors have been deposited as supplementary material with the Editor from whom copies are available on request.

RESULTS AND DISCUSSION

The ν(C=N) frequency which is found at 1615 cm^{-1} in the IR spectrum of the complex appears at almost the same position in the spectrum of the ligand. This observation indicates that the nitrogen atom is not involved in coordination to the tin atom. The band found at 1270 cm^{-1} in the spectrum of the ligand owing to the phenolic C—O stretching vibration[13,14] is shifted towards a higher frequency (1290 cm^{-1}) upon complex formation, consistent with the coordination of the phenolic oxygen atom to the tin atom. Two additional bands which appear in the spectrum of the complex at 450 and 340 cm^{-1},

respectively, may be attributed to the Sn—O and Sn—Cl vibrations, respectively.

Selected spectral assignments for the ^{1}H and ^{13}C NMR spectra[15] of the ligand and complex are shown in Table 2. The chemical shift corresponding to the carbon from the imine group remains the same for the complex as in the ligand. However, the shifting of the δ(C—O) value of the ligand downfield by 1.8 ppm upon complex formation is again characteristic of the coordination of the phenolic oxygen atom to the tin. A notable feature of the ^{1}H NMR spectrum of the complex is the broadening of the phenolic proton peak due to the weakening of the O—H bond and a strengthening of the C=N—H hydrogen bond.[1]

The structure of the complex and the atom labelling scheme is shown in Fig. 1. The bond lengths and angles are listed in Table 3. The geometry about the tin atom is all *trans*-octahedral with the two methyl groups and the two chlorine atoms occupying the equatorial positions. Coordination of the two ligands to the tin atom occurs via the phenolic oxygen atoms which are located at the axial positions. The bond lengths and angles between the tin and the donor atoms are comparable to those found for similar complexes.[16,17] The phenolic hydrogen of the ligand was found to have shifted to the imine nitrogen atom. This phenomenon of migration of the hydrogen atom has been well substantiated by Bullock *et al.*[18]

(*Received* 8 *May* 1991; *accepted* 1 *August* 1991)

Abstract—Two silver(I) complexes of triethyl betaine ($Et_3N^+CH_2COO^-$, Et_3BET) have been prepared and characterized by X-ray crystallography. Both complexes, $[Ag_2(Et_3BET)_2(NO_3)_2]$ (**1**) and $[Ag_2(Et_3BET)_2]_n(ClO_4)_{2n}$ (**2**), contain centrosymmetric bis-carboxylato-bridged Ag_2(carboxylato-O,O′)$_2$ dimers (Ag—O = 2.16–2.23 Å). The dimeric unit in **1** is bound to a chelating nitrato group [Ag—O = 2.524(3), 2.619(3) Å] at each axial site, resulting in a discrete molecule. In **2** the dimers are extended into a stair-like cationic chain via the coordination of each metal centre by a carboxylato oxygen atom [Ag—O = 2.565(5) Å] from an adjacent unit. The intra-dimer Ag···Ag distance is 2.928(1) Å for **1** and 2.856(2) Å for **2**.

The paucity of crystallographic data for silver(I) carboxylates has been ascribed to the poor solubility and light-sensitive nature of such compounds.[2] The known crystal structures have been classified into four types depending on the coordination motif:[3] type A consists of discrete Ag_2(carboxylato-O,O′)$_2$ dimers without any axial ligand; types B and C have similar dimeric structures with the axial site(s) occupied by one and two ligands, respectively, and they are commonly polymeric species; type D comprises dimeric subunits that are extended into a step polymer through the linkage of each metal centre to a carboxylato oxygen of an adjacent dimer, while modified type D has an additional axial ligand attached to each metal atom.[4] Two unusual polymeric structures that are not based on dimeric units have been classified as the fifth type, type E.[5]

As structural analogues of the corresponding carboxylate anions, the zwitterionic betaine ligands can be used to prepare carboxylate-like silver(I) complexes that have very good solubility in water and even in ethanol, and are quite stable under exposure to X-ray radiation. In previous studies we have determined the crystal structures of three silver(I) betaine complexes, namely $[Ag_2(BET)_2(H_2O)_2(NO_3)_2]_n$ (**3**), $[Ag_2(pyBET)_2(ClO_4)_2]_n$ (**4**) and $[Ag(pyBET)(NO_3)]_n$ (**5**) (BET = betaine, $Me_3N^+CH_2COO^-$; pyBET = pyridine betaine, $C_5H_5N^+CH_2COO^-$).[4,5] Both complexes (**3**) and (**4**) adopt modified type D dimeric structures,[4] whereas complex (**5**) has the type E polymeric structure.[5] The study has now been extended to include the preparation and single-crystal X-ray analysis of two silver(I) complexes of a new betaine derivative, triethyl betaine ($Et_3N^+CH_2COO^-$, Et_3BET; IUPAC name: triethylammonioacetate), namely bis(triethyl betaine)bis(nitrato)disilver(I), $[Ag_2(Et_3BET)_2(NO_3)_2]$ (**1**) and *catena*-bis(triethyl betaine)

disilver(I) diperchlorate, $[Ag_2(Et_3BET)_2]_n(ClO_4)_{2n}$ (**2**).

EXPERIMENTAL

Preparation

Triethyl betaine was synthesized according to a method reported previously.[6] A mixture of 2-bromoacetic acid (13.9 g, 0.10 mol), triethylamine (22.0 g, 0.22 mol) and distilled water (100 cm^3) was stirred at 50–60°C for 4 h. After removal of the excess triethylamine under reduced pressure, the solution was passed through an anion-exchange resin (OH^- form) column (3 × 35 cm) and eluted with distilled water (400 cm^3). The eluate was evaporated to dryness under reduced pressure with a water bath below 80°C to give a pure product (15.6 g, 98% yield) which is very hydroscopic. MS data, m/z: 160 (M + 1), 159 (M); ^1H NMR data (δ, ppm; in D_2O): 1.20 (9H, t, $3CH_3$), 3.47 (6H, q, $3CH_2N$), 3.68 (2H, s, CH_2CO).

Complex **1** was prepared by dissolving $AgNO_3$ (0.170 g, 1.0 mmol) and triethyl betaine (0.159 g, 1.0 mmol) in 90% ethanol solution (4 cm^3) with stirring at 60°C. After cooling to room temperature, colourless prismatic crystals were afforded by slow evaporation in a desiccator charged with silica gel for several days.

Complex **2** was prepared by mixing $AgClO_4$ (0.207 g, 1.0 mmol) and triethyl betaine (0.159 g, 1.5 mmol) in a water–ethanol solution (3 cm^3, v/v 1:1) with stirring at about 60°C to give a clear solution. Evaporation of the solution in air at room temperature for a week yielded colourless grain-like crystals.

Crystallography

Densities of the crystals were measured by flotation in 1,2-dibromoethane/CCl_4. Diffraction intensities for both complexes (**1**) and (**2**) were collected at 21°C on a Nicolet R3m/V diffractometer using the ω-scan (2.9–14.6° min^{-1}) mode.[7] Data processing, absorption corrections, structure solution, and full-matrix least-squares refinement were performed with the SHELXTL-PLUS program package[8,9] (detailed parameters given in Table 1) on a DEC MicroVAX-II computer. The non-hydrogen atoms were refined anisotropically, except the oxygen atoms of the two-fold orientationally disordered perchlorate group in complex (**2**) which were subjected to inter-atomic distance constraints of Cl—O = 1.40 ± 0.01 Å and O···O = 2.26 ± 0.01 Å, assigned site occupancy factors of 0.5, and refined isotropically. All the hydrogen atoms were generated geometrically (C—H = 0.96 Å), assigned isotropic temperature factors and included in the structure-factor calculations. Analytic expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated.[10] The final discrepancy indices and other parameters at the conclusion of refinement are given in Table 1, and selected inter-atomic distances and bond angles in Table 2.

Supplementary materials including non-hydrogen and hydrogen atomic coordinates and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre, and observed and calculated structure factors are available upon request from the corresponding author.

RESULTS AND DISCUSSION

$[Ag_2(Et_3BET)_2(NO_3)_2]$ (**1**)

As illustrated in Fig. 1, the crystal structure of complex (**1**) consists of discrete bis(carboxylato-O,O′)-bridged centrosymmetric $Ag_2(Et_3BET)_2$ dimers, with the carboxylato group acting in the symmetric *syn–syn* bridging mode [C—O = 1.239(5), 1.235(5) Å, O—C—O = 126.2(4)°]. The Ag···Ag separation [2.929(1) Å] in the dimer is significantly larger than that [2.89 Å] in metallic silver, thus indicating a weak or negligible metal–metal interaction. The intra-dimer Ag—O distances and O—Ag—O angle are 2.162(3), 2.207(3) Å and 160.9(1)°, respectively, which are comparable to those found in the dimeric structures of known silver(I) carboxylates. The coordination sphere is completed by an unsymmetrical chelating nitrato group at each axial site of the dimer with Ag—O(nitrato) = 2.524(3) and 2.619(3) Å, which are significantly longer than those [Ag—O(nitrato) = 2.248(2) and 2.41(1) Å] of the

$[Ag(NO_3)_2]^-$ anion found in the double metal salt $[Rh(py)_4Cl_2][Ag(NO_3)_2]$, where the nitrato groups act in the unsymmetrical chelating mode.[11] The longer Ag—O(nitrato) bonds may be attributed to the fact that the axial Ag—O bonds are significantly longer (>2.50 Å in general) than the other Ag—O bonds in the dimeric structure of silver(I) carboxylates. The presence of chelating nitrato ligands in complex (**1**) makes it unique among the $AgNO_3$ complexes containing carboxylate ligands that are presently known, although the directly-bound nitrato ligand is not without precedent in this series. For example, the nitrate groups act as unidentate ligands in complex (**5**) (type E),[5] and as bidentate bridging ligands extending type C dimers into a polymeric structure in alanine silver(I) nitrate.[12] Furthermore, complex (**1**) is the first example of a non-polymeric structure among silver(I) complexes of betaine ligands.

$[Ag_2(Et_3BET)_2]_n(ClO_4)_{2n}$ (2)

Complex (**2**) is a polymer based on bis(carboxylato-O,O′)-bridged centrosymmetric $Ag_2(Et_3BET)_2$ dimers (Fig. 2), with the carboxylato group of Et_3BET serving in the symmetric *syn–syn* bridging mode [C—O = 1.242(8), 1.243(8) Å, O—C—O = 127.5(6)°] as found in complex **1**. The Ag···Ag separation [2.856(2) Å] is smaller than that [2.89 Å] in metallic silver, suggesting a comparable extent of metal–metal interaction. The intra-dimer Ag—O distances and O—Ag—O angle are 2.222(4), 2.232(4) Å and 163.6(1)°, respectively, which are comparable to those found in complex **1** and the other dimeric structures of several known silver(I) carboxylates.[4] The present structure is extended into a stair-like cationic polymer running parallel to the a-axis via metal–carboxylate linkages [Ag(1)—O(2e) = 2.565(5) Å] between adjacent dimers, generating centrosymmetric rhombic Ag_2O_2 units as found in type D and the modified type D structures, e.g. in both complexes **3** and **4**.[4] The perchlorate group has no association shorter

than 2.70 Å with the silver(I) atom, so that complex **2** belongs to the type D dimeric structure. In contrast, perchlorate groups have been found to be unidentate axial ligands in complex **4** (type D),[4] and in di-μ-[(2-chlorophenoxy)ethanoato]disilver(I)-silver(I) perchlorate (type B).[13] This difference may arise from the fact that the greater steric bulk of the triethylamino groups may only allow the axial site to be approached by smaller ligands such as the planar nitrato group in complex (**1**). Another type D dimeric structure has been found in a silver(I) complex of an amino acid, glycine silver(I) nitrate,[14] where the nitrate group is bound to the amino group via hydrogen bonds and has no direct association with the silver(I) atom.

PREPARATIVE AND SPECTRAL INVESTIGATIONS ON *ORTHO*-TELLURATED PHENOLS AND THEIR MERCURY(III), PALLADIUM(II) AND PLATINUM(II) PHENOXIDES CHELATED THROUGH TELLURIUM

A. K. SINGH,* S. THOMAS and B. L. KHANDELWAL*

Department of Chemistry, Indian Institute of Technology, New Delhi 110 016, India

(*Received* 27 *March* 1991; *accepted* 1 *August* 1991)

Abstract—Bis(2-hydroxy-5-methylphenyl)telluride (**1**) and (2-hydroxy-5-methylphenyl) aryltelluride (**2**) have been synthesized from *p*-cresol by direct reaction with $TeCl_4$ followed by reduction of the Ar_2TeCl_2 type compound and *ortho*-mercuration followed by *trans*-metallation and reduction, respectively. The ligation behaviour of **1** and **2** has been explored. Compound **1** forms a polymeric mercury(II) complex which on reaction with PPh_3 gives [(PPh_3)HgCl(**1**-H)]. Compound **2** forms with mercury(II), palladium(II) and platinum(II) chelated phenoxides of stoichiometry $[MCl(\mathbf{2}\text{-H})]_2$, which have been found to be dimeric containing chloro bridges. ^1H and ^{13}C NMR and IR spectra of **1** and **2** are characteristic. The electronic spectra support square planar geometry around palladium(II)/platinum(II). IR and ^1H NMR spectra of the metal complexes indicate that **1** acts as a uni-negative bidentate ligand in [(PPh_3)HgCl(**1**-H)] coordinating through oxygen and tellurium. Similar behaviour was found for **2** in all its metal complexes.

Tellurium ligands favour strongly those metals which are designated as Class B in the Arhland, Chatt, Davies classification.[1] The extension of the ligand chemistry of tellurium should be possible if such ligands containing another donor atom, which is hard in the Pearson classification,[2] are synthesized and investigated for their complexation reactions. We have been working on the development of (Te, N)[3,4] and (Te, O)[5] donors for the last 4–5 years. At least five other tellurides[6] are already known which may behave as a (Te, O) donor but only the metal complexes of 2-(4-ethoxyphenyltelluro)benzoate[6] have been isolated and investigated in some detail. As part of our research programme of the development of hybrid organotellurium ligands, we have synthesized the *ortho* tellurated phenols, i.e. (Te, O) ligands **1** and **2** and investigated their ligand chemistry. The synthesis of **1** and **2**, reactions of **1** with $HgCl_2$, and mercury(II), palladium(II) and platinum(II) complexes of **2** are the subject of the present paper.

EXPERIMENTAL

Published methods were used to synthesize bis (2-hydroxy-5-methylphenyl)tellurium(IV) chloride,[7] aryltellurium(IV)chloride[8] (aryl = C_6H_5, 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$) and 1-(chloromercury)-2-hydroxy-5-methylbenzene.[9] The chlorine and tellurium were estimated by standard methods.[10] The carbon, hydrogen and nitrogen analyses were carried out with a Perkin–Elmer 240C elemental analyser. The ^1H and $^{13}C\{^1H\}$ NMR spectra in $CDCl_3$ and DMSO-d_6 were recorded at 25°C on a

* Authors to whom correspondence should be addressed.

JEOL FX-100 FT-NMR spectrometer at 99.55 and 25 MHz, respectively. IR spectra (of Nujol mulls between CsI windows or CsI/KBr discs) in the range 200–4000 cm^{-1} were recorded on a Nicolet 5DX FT-IR spectrometer. Electronic spectra were recorded on a Hitachi UV–vis spectrophotometer model 350. Far IR spectra (up to 50 cm^{-1}) in polyethylene were recorded on a Perkin Elmer far IR spectrometer model 1700X.

Synthesis of bis(2-hydroxy-5-methylphenyl)telluride (**1**)

A suspension of bis(2-hydroxy-5-methylphenyl) tellurium(IV) chloride (4.12 g, 10 mmol), prepared by the published method, in a 50% ethanol–water mixture (25–30 cm^3) was treated with hydrazine hydrate (1.5 g, 3 mmol) dissolved in 10–15 cm^3 ethanol. The resulting mixture was stirred for 10 min and poured into water. The pale yellow telluride was extracted with diethyl ether. The ether extract was washed with water, dried over Na_2SO_4 and concentrated to dryness. Yield, 65%. After recrystallization from methanol the m.p. of the pale yellow telluride was 90°C. Found: C, 47.6; H, 4.1; Te, 38.1. Calc. for $C_{14}H_{14}O_2Te$: C, 47.1; H, 4.1; Te, 37.6%. NMR: ^1H, $CDCl_3$, 25°C: δ, 2.20(s, 6H, CH_3), 6.85(bs, OH), 6.97–7.36(m, 6H, phenyl). $^{13}C\{^1H\}$, $CDCl_3$, 25°C: δ, 20.0(CH_3), 102.1(C_1), 114.0(C_3), 131.3(C_4), 131.8(C_5), 139.9(C_6), 154.0(C_2).

Synthesis of $[HgCl_2 \cdot \mathbf{1}]_n$ *and* $(PPh_3)HgCl_2 \cdot \mathbf{1}$

Mercury(II) chloride (0.27 g, 1 mmol) was refluxed with **1** (0.34 g, 1 mmol) in methanol with stirring for 2–3 h. The yellow precipitate separated out was filtered, washed with methanol and dried *in vacuo*. Yield 80%.

The suspension of $HgCl_2 \cdot \mathbf{1}$ (0.5 mmol) in 10 cm^3 methanol was mixed with triphenylphosphine (1 mmol) dissolved in methanol (10 cm^3). The reaction mixture was refluxed with stirring for 2–3 h. The suspended mercury-complex dissolved. The solution was filtered and the filtrate concentrated to 5–

[a] In $CDCl_3$ for $(Ph_3P)(HgCl_2 \cdot \mathbf{1})$ and DMSO-d_6 for others.

7 cm^3. The solid was separated, washed with hexane and recrystallized from chloroform. Yield, 75%. Elemental analysis and ^1H NMR data are given in Table 1.

Synthesis of (2-hydroxy-5-methylphenyl)(aryl) tellurium(IV) *chlorides*

1-(Chloromercury)-2-hydroxy-5-methylbenzene (10 mmol) and an equimolar amount of aryltellurium(IV) chloride (aryl = C_6H_5, 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$) were refluxed in dry dioxane for 3–4 h under a dinitrogen atmosphere. The solution was filtered hot and the filtrate cooled to 0–5°C for 2–3 h. The $HgCl_2$·dioxane adduct separated out and was filtered off. The filtrate was concentrated to 5 cm^3 and hexane (50 cm^3) was added to the concentrate. The white precipitate resulted, which was filtered, washed with cold ethanol, dried and recrystallized from chloroform. Yield, 75–80%. M.p., elemental analyses, ^1H and $^{13}C\{^1H\}$ NMR (in $CDCl_3$ at 25°C) spectra are given below.

a(Aryl = C_6H_5): m.p. 172°C. Found: C, 41.1; H, 3.1; Te, 33.4; Cl, 18.7. Calc. for $C_{13}H_{12}OCl_2Te$: C, 40.8; H, 3.1; Te, 33.4; Cl, 18.5%. NMR (^1H): δ, 2.2(s, 3H, CH_3), 6.7–7.2, 7.4–7.8(m, 9H, ArH+OH); ($^{13}C\{^1H\}$): δ, 21.3(CH_3), 116.2(C_3), 123.3(C_1'), 128.6(C_3'), 133.1(C_5), 133.8(C_4), 134.5(C_4'), 139.1(C_2'), 141.4(C_6), 155.2(C_2). C_1 merges with the C_2' or C_6 signal.

b(Aryl = 4-$MeOC_6H_4$): m.p. 184°C. Found: C, 40.1; H, 3.4; Te, 31.6; Cl, 17.1. Calc. for $C_{14}H_{14}O_2Cl_2Te$: C, 40.7; H, 3.4; Te, 30.9; Cl, 17.2%. NMR: ^1H: δ, 2.2(s, 3H, CH_3), 3.9(s, 3H, OCH_3), 6.8–7.2, 8.1–8.2(m, 8H, ArH+OH). $^{13}C\{^1H\}$: δ, 21.8(CH_3), 55.7(OCH_3), 115.6(C_3), 124.2(C_1'), 128.2(C_3'), 133.2(C_5), 133.9(C_4), 134.4(C_4'), 139.6(C_2'), 141.5(C_6), 155.0(C_2). C_1 merges with the C_2' or C_6 signal.

c(Aryl = 4-$EtOC_6H_4$): m.p. 167°C. Found: C, 42.8; H, 3.7; Te, 30.0; Cl, 16.6. Calc. for $C_{15}H_{16}O_2Cl_2Te$: C, 42.2; H, 3.7; Te, 29.9; Cl, 16.8%. NMR: ^1H: δ, 1.4–1.5(t, 3H, CH_3 of OEt), 2.2(s, 3H, CH_3), 3.7–4.1(q, 2H, OCH_2), 6.8–7.2, 8.1–8.2(m, 8H, ArH+OH). $^{13}C\{^1H\}$: δ, 14.5(CH_3 of OEt), 21.4(CH_3), 62.1(OCH_2), aryl carbon signals are similar to that of **b**.

Synthesis of (2-hydroxy-5-methylphenyl)(aryl) telluride (**2**)

(2-Hydroxy-5-methylphenyl)tellurium(IV) chloride (**a**, **b** or **c**) (10 mmol) was suspended in water (100 cm^3) and cooled to 0–5°C. Sodium metabisulphite (10 mmol) dissolved in 50 cm^3 water or hydrazine hydrate (10 mmol) in 50 cm^3 ethanol was slowly added to the suspension with stirring. The mixture was further stirred for 2–3 h, keeping the temperature below 5°C. The yellow precipitate of the telluride thus formed was filtered, washed several times with water, dried and recrystallized from chloroform as yellow crystals. Yield, 75–78%. M.p., elemental analyses, ^1H and $^{13}C\{^1H\}$ NMR spectra (in $CDCl_3$ at 25°C) are given below.

2a: m.p. 92°C. Found: C, 50.3; H, 4.0; Te, 40.5. Calc. for $C_{13}H_{12}OTe$: C, 50.1; H, 3.8; Te, 40.9%. NMR: ^1H: δ, 2.2(s, 3H, CH_3), 6.7–7.8(m, 9H, ArH+OH). $^{13}C\{^1H\}$: δ, 20.4(CH_3), 103.1(C_1), 114.2(C_3, C_1'), 128.9(C_4'), 131.2(C_3'), 131.9(C_4), 139.8(C_5), 140.4(C_2'), 141.6(C_6), 154.6(C_2).

2b: m.p. 98°C. Found: C, 49.6; H, 4.1; Te, 38.0. Calc. for $C_{14}H_{14}O_2Te$: C, 49.2; H, 4.1; Te, 37.3%. NMR: ^1H: δ, 2.2(s, 3H, CH_3), 3.8(s, 3H, OCH_3), 6.7–6.9, 7.4–7.5(m, 7H, ArH). $^{13}C\{^1H\}$: δ, 21.0(CH_3), 55.6 (OCH_3), 102.1(C_1), 114.3(C_3, C_1'), 128.4(C_4'), 131.2(C_3'), 131.8(C_4), 139.6(C_5), 140.1(C_2'), 141.4(C_6'), 154.4(C_2).

2c: m.p. 80°C. Found: C, 50.6; H, 4.5; Te, 36.1. Calc. for $C_{16}H_{16}O_2Te$: C, 50.6; H, 4.5; Te, 35.9%. NMR: ^1H: δ, 1.3–1.4(t, 3H, CH_3 of OEt), 2.2(s, 3H, CH_3), 3.9–4.0(q, 2H, OCH_2), 6.6–7.5(m, 7H, ArH). $^{13}C\{^1H\}$: δ, 14.5(CH_3 of OEt), 20.8(CH_3), 61.8(OCH_2), aryl carbons are similar to that of **2b**.

Synthesis of mercury(II), *palladium*(II) *and platinum*(II) *complexes of* **2**

Mercuric chloride (1 mmol) dissolved in 10 cm^3 of acetone was added to a solution of **2** (**a**, **b** or **c**) (1 mmol) in acetone (10 cm^3) and the mixture was stirred at 40°C for 2 h. The resulting precipitate was filtered, washed with acetone thoroughly and dried *in vacuo*. Yield, 75–80%.

Palladium(II) complexes were synthesized by stirring **2** with $(C_6H_5CN)_2PdCl_2$ in chloroform in a manner described above. After stirring 25–30 cm^3 of petroleum ether (40–60°C) was added to this mixture and the resulting red–brown precipitate was filtered. It was washed with petroleum ether thoroughly and dried *in vacuo*. Yield, 83–85%.

To synthesize platinum(II) complexes the stirring of a metal ion–ligand mixture was carried out as described above for the mercury complexes, except **2** which was dissolved in acetone and K_2PtCl_4 in water. Thereafter, the volume of mixture was reduced to 5–7 cm^3 *in vacuo*. The reddish precipitate was filtered, washed with an acetone–water mixture (1 : 1), dried and recrystallized from chloroform. Yield, 85–90%.

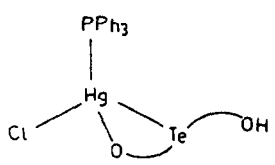
Elemental analyses, m.p. and ^1H NMR data of all the complexes of **2** are given in Table 1.

RESULTS AND DISCUSSION

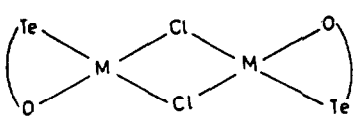
The reaction of 1-hydroxy-4-methylbenzene with tellurium tetrachloride always results in an Ar_2TeCl_2 type of compound[7] which can easily be reduced with hydrazine to **1**. The *ortho*-mercuration of 1-hydroxy-4-methyl benzene followed by *trans*-metallation with $ArTeCl_3$ results in a good yield of the precursor chloride of **2**, which can be reduced to **2** in good yield using $Na_2S_2O_5$. The OH signal in the ^1H NMR spectrum of **1** is shielded with respect to OH of their precursor chlorides by 1.1 ppm. This may be due to a decrease in the Te ← O secondary interaction and change in the inductive effect of tellurium, when the chlorides are reduced to tellurides. The OH signal of **2** and its precursor chloride could not be identified separately in the multiplet of phenyl protons with which it merges. However, its shielding on reduction of the precursor chlorides into **2** seems to be lower than that observed in the case of **1**, as it does not separate out from the multiplet.

Compound **1** reacts with $HgCl_2$ forming a complex of stoichiometry [HgCl(**1**-H)] which has defied all attempts to identify its structure, presumably due to its polymeric nature as it does not dissolve in any organic solvent. However, on refluxing its suspension in methanol with an equimolar amount of PPh_3, a complex [Ph_3PHgCl(**1**-H)] results which is soluble in polar organic solvents. The ^1H NMR spectrum of this complex exhibits an OH signal which is negligibly downfield than that of **1**. The aromatic protons of **1** on complexation with mercury undergo deshielding (0.1–0.2 ppm), indicating the involvement of tellurium in coordination. Thus, **1** behaves as a uni-negative bidentate ligand in this complex (Structure A). Most probably it also does so in the complex [HgCl(**1**-H)] and mercury completes the expected four-coordination number with the chlorine or oxygen of the OH group of the neighbouring molecule, which ultimately results in polymerization. It appears that in the absence of free OH most probably the extended polymerization is not sustained. This has been supported by the absence of a ν(Hg-Cl(terminal)) band[11] around 300 cm^{-1} in the IR spectrum of [HgCl(**1**-H)], whereas this band appears in the IR spectrum of [Ph_3 PHgCl(**1**-H)] at 315 cm^{-1} which supports Structure A for this compound. The occurrence of ν(Te—C)[12] around 250 cm^{-1} in the IR spectrum of this mixed complex further authenticates its formation. The ν(OH) was noticed in the IR spectra of all these complexes around 3300–3400 cm^{-1}, supporting the ligation of **1** in a bidentate mode.

Since of the two OH groups present in **1** only one participates in its ligation with metal ions, it was thought worthwhile to examine the ligation of **2** because the extended polymerization, complicating the structure of [HgCl(**1**-H)], due to the presence of an additional OH group would be avoided. Compound **2** reacts with mercury(II), palladium(II) and platinum(II) forming complexes of stoichiometry [MCl(**2**-H)]. In the ^1H NMR of **2** the OH signal was found merged with phenyl, as indicated by enhanced integration of these protons with respect to that of CH_3. On complexation such an enhancement was absent, indicating the loss of an OH proton on ligation. The aryl protons were deshielded (0.1–0.8 ppm) when **2** ligated with palladium(II) and platinum(II). The deshielding was small in the case of the mercury complex (<0.3 ppm). These observations after taking into account the solvent effect also suggest that in all three complexes **2** coordinates through tellurium; the Hg—Te bond is weaker than the Pd/Pt—Te bond and, therefore, the magnitude of deshielding differs. To complete the coordination number four the species having stoichiometry [MCl(**2**-H)] most probably dimerize, as depicted in Structure B. Most probably the geometry of ligands around mercury(II) is tetrahedral. The coordination number of M as four has been supported in the case of platinum/palladium(II) by the electronic spectra of their complexes in DMSO, which exhibit a band around 27 kK, characteristic of square planar geometry around the metal ion. The dimeric formulation of Struct. B has been supported by the presence of ν(M—Cl(bridging)) bands[11] around 200, 250 and 270 cm^{-1} in the IR spectra of the mercury(II), palladium(II) and platinum(II) complexes, respectively. The ν(Te—C) undergoes a red shift (~10–15 cm^{-1}) on complexation of **2** with palladium/platinum(II). This further supports the involvement of tellurium in chelation. The occurrence of only one ν(M—Cl—M) band in the IR spectra of all three complexes suggests that the



(A)



M = Hg, Pd or Pt

(B)

structures of $[Pd/PtCl(2\text{-}H)]_2$ are centrosymmetric (Struct. B).

OLIGOMERIZATION AND STRUCTURAL VARIATION OF ALKALI METAL SILYLOXIDES

MICHAEL J. McGEARY, KIRSTEN FOLTING, WILLIAM E. STREIB, JOHN C. HUFFMAN and KENNETH G. CAULTON*

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 16 *July* 1991; *accepted* 26 *July* 1991)

Abstract—Lithium and potassium silyloxide complexes $[Li(OSiPh_3)]_n$ (**1**), $[K(thf)_{0.2}(OSiPh_3)]_n$ (**3**) and $[K(OSiMe_2{}^tBu)]_n$ (**6**) were prepared by deprotonation of $HOSiPh_3$ or $HOSiMe_2{}^tBu$ with [Li("Bu)] in hexane or KH in THF, respectively. Crystalline DME adducts $[Li(\mu\text{-}OSiPh_3)(\eta^2\text{-}DME)]_2$ (**2**) and $[K_4(\mu_3\text{-}OSiPh_3)_3(\mu_3\text{-}OSiPh_2(\eta^1\text{-}Ph))(\eta^2\text{-}DME)]_2(\mu\text{-}DME)$ (**4**) were prepared by dissolving **1** or **3**, respectively, in dimethoxyethane followed by precipitation with alkane. The potassium-sequestered complexes $[K(18\text{-crown-6})(OSiPh_3)]_2$ (**5**) and $[K(18\text{-crown-6})(OSiMe_2{}^tBu)]_n$ (**7**) were prepared from **3** or **5**, respectively, and one equiv. of 18-crown-6 ether. The complexes were characterized by single-crystal X-ray diffraction: $[Li(\mu\text{-}OSiPh_3)(\eta^2\text{-}DME)]_2$ (**2**): a dimer featuring tetrahedral lithium centres linked by bridging —$OSiPh_3$ ligands. [Crystal data (−156°C): space group $P\bar{1}$, $a = 14.238(6)$, $b = 15.182(7)$, $c = 11.796(5)$ Å, $\alpha = 110.57(2)$, $\beta = 112.02(2)$, $\gamma = 63.02(1)$ Å, $V = 2055.33$ Å^3, $Z = 2$.] $[K_4(\mu_3\text{-}OSiPh_3)_3\{\mu_3\text{-}OSiPh_2(\eta^1\text{-}Ph)\}(\eta^2\text{-}DME)]_2(\mu\text{-}DME)$ (**4**): (1) two cubanes each having every potassium vertex chemically distinct; (2) one chelating DME ligand, one DME ligand bridging between two cubanes; and (3) a K-*ipso*-phenyl carbon contact. [Crystal data (−133°C): $a = 14.246(4)$, $b = 30.939(9)$, $c = 17.981(5)$ Å, $\beta = 112.33(1)°$ with $Z = 2$ in space group $P2_1/c$.] $[K(18\text{-crown-6})OSiPh_3]_2$ (**5**): A dimer with slipped face-to-face stacking of the quasi-planar $K(18\text{-crown-6})^+$ part of the two $Ph_3SiOK(18\text{-crown-6})$ molecules; these are linked by a dative bond from one ether oxygen of a given crown to potassium contained in the other crown. [Crystal data (−155°C): $a = 9.324(2)$, $b = 17.640(5)$, $c = 18.148(15)$ Å, $\beta = 91.60(1)°$ with $Z = 4$ in space group $P2_1/c$.]

Although alkali metal alkoxide chemistry has a long tradition in both organic and inorganic chemistry,[1] alkali metal silyloxide chemistry is comparatively underdeveloped.[2,3,4] We were motivated to explore the synthesis and structural features of lithium and potassium silyloxide complexes for the following reasons:

(1) The reduced basicity of the R_3SiO^- ligand in comparison to the R_3CO^- ligand was expected to diminish the capacity of R_3SiO^- to adopt bridging modes, thereby resulting in new structural types compared to the related alkoxide complexes.

(2) We are evaluating the utility of heterometallic silyloxide complexes as reagents for the preparation of mixed-metal solid-state materials.[5] One aspect of our synthetic strategy for the production of the required heterometallic silyloxide reagents centred on the condensation of a Lewis acidic metal silyloxide complex, $M(OSiR_3)_x$, with a nucleophilic-at-O silyloxide complex, $M'(OSiR_3)_y$ [eq. (1)].

$$M(OSiR_3)_x + M'(OSiR_3)_y \longrightarrow MM'(OSiR_3)_{x+y} \quad (1)$$

Because of the absence of an energetically-accessible vacant d_π manifold, we anticipated that alkali metal silyloxide complexes could serve as efficient $OSiR_3^-$ transfer agents. Indeed this expectation has been fulfilled and we have prepared a series of potassium/tin silyloxide derivatives using $KOSiR_3$ reagents.[6] Furthermore, with the availability of alkali metal/other metal heterometallic silyloxide

* Author to whom correspondence should be addressed.

complexes, synthetic routes to new heterometallic silyloxide complexes not containing the alkali metal can be envisioned based on salt elimination reactions [eq. (2)].

$$MM'(OSiR_3)_{x+y} + M''(X)L_n \longrightarrow MM''(L)_n(OSiR_3)_{x+y} + M'X; \quad (2)$$

where M, M'' = metals, M' = an alkali metal and X = a leaving group (e.g. a halide).

In this paper we report the synthesis and characterization of lithium and potassium silyloxide complexes which we have employed in our work on developing heterometallic silyloxides as molecular precursors to materials: $[Li(OSiPh_3)]_n$ (**1**), $[K(THF)_{0.2}(OSiPh_3)]$ (**3**) and $[K(OSiMe_2{}^tBu)]_n$ (**6**). These compounds were used as reagents to prepare a series of "organic soluble" ether adducts: $[Li(\mu\text{-}OSiPh_3)(\eta^2\text{-}DME)]_2$ (**2**), $[K_4(\mu_3\text{-}OSiPh_3)_3\{\mu_3\text{-}OSiPh_2(\eta^1\text{-}Ph)\}(\eta^2\text{-}DME)]_2(\mu\text{-}DME)$ (**4**), [K(18-crown-6)$(OSiPh_3)]_2$ (**5**) and [K(18-crown-6)$(OSiMe_2{}^tBu)]_n$ (**7**). X-ray structural characterization is presented for $[Li(\mu\text{-}OSiPh_3)(\eta^2\text{-}DME)]_2$, $[K_4(\mu_3\text{-}OSiPh_3)_3\{\mu_3\text{-}OSiPh_2(\eta^1Ph)\}(\eta^2\text{-}DME)]_2(\mu\text{-}DME)$ and [K(18-crown-6)$(OSiPh_3)]_2$.

EXPERIMENTAL

Materials and procedures

All manipulations were performed using standard Schlenk techniques either *in vacuo* or in an atmosphere of nitrogen or using a nitrogen-filled dry-box. Solvents were dried over appropriate desiccants (potassium, benzophenone ketyl for diethyl ether, pentane, hexane, dimethoxyethane, toluene, benzene and tetrahydrofuran; P_2O_5 for dichloromethane and chloroform; KOH for pyridine), distilled under nitrogen or *in vacuo* and subjected to freeze–evacuate–thaw cycles prior to use. The reagents Ph_3SiOH, $Me_2(^tBu)SiOH$, [Li][n-Bu] (1.6 N in hexane), KH and 18-crown-6 ether were obtained commercially (Aldrich). Potassium hydride was purified by washing repeatedly with hexane, followed by drying *in vacuo*; $Me_2(^tBu)SiOH$ was vacuum distilled prior to use; 18-crown-6 ether was sublimed prior to use. Triphenylsilanol and [Li][n-Bu] (1.6 N in hexane) were used as received.

Physical measurements

IR spectra were recorded as Nujol mulls using a Perkin–Elmer 283 spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM500 (^1H at 500.14 MHz, ^{13}C at 125.76 MHz) instrument and referenced to $SiMe_4$. NMR sample temperatures were monitored using a thermocouple. Elemental analyses were performed by Oneida Research Services, Inc. Combustion aides were used in an effort to discourage carbide formation. The results of carbon, hydrogen, nitrogen combustion analyses were sometimes variable and not always within expectations even for crystalline samples, authenticated by X-ray diffraction.

$[Li(OSiPh_3)]_n$ (1)

A 100 cm^3 Schlenk flask was charged with $HOSiPh_3$ (1.38 g, 5.00 mmol) and toluene (30 cm^3). The solution was chilled to 0°C whereupon [Li(n-Bu)] (4 cm^3, 1.6 N) was added via a pipette. A white solid precipitated immediately. The mixture was stirred for 2 h. The solid was then decanted, washed with pentane and dried *in vacuo*. IR (Nujol): no ν(OH); ν(CH) 3035, 3040; aromatic overtones; 1950, 1880, 1820, 1760; other bands 1110, 975, 705, 695 cm^{-1}. Lack of solubility in solvents with which **1** did not react (e.g. C_6D_6) precluded NMR characterization.

$[Li(\mu\text{-}OSiPh_3)(\eta^2\text{-}DME)]_2$ (2)

A 100 cm^3 Schlenk flask was charged with a small amount of $[Li(OSiPh_3)]_n$. DME (*ca* 30 cm^3) was distilled onto the lithium reagent. The mixture was stirred for 3 h, whereupon the volume of solvent was reduced *in vacuo*. Hexane was added so as to form a layer. Large, colourless crystals suitable for X-ray diffraction precipitated after standing for 24 h. IR (Nujol): no ν(OH); ν(CH) 3040; aromatic overtones: 1950, 1870, 1810; other bands: 1095, 1070, 695 cm^{-1}. ^1H NMR (C_6D_6): δ 7.98 (d, 6.4 Hz, 12H, *ortho*), 7.30–7.25 (structured m, 18H, *meta*, *para*), 3.09 (s, 8H, OCH_2), 3.03 (s, 12H, OCH_3). ^{13}C NMR (C_6D_6): δ 144.6 (*ipso*) 136.0 (*ortho*), 128.6 (*para*), 127.2 (*meta*), 71.6 (OCH_2), 58.7 (OCH_3). Found: C, 71.1; H, 6.7. Calc. for $C_{44}H_{50}Li_2O_6Si_2$: C, 70.9; H, 6.8%.

Structure determination of $[Li(\mu\text{-}OSiPh_3)(\eta^2\text{-}DME)]_2$. A crystal of suitable size was cleaved from a large piece of the sample in a nitrogen atmosphere. The crystal was mounted using silicone grease and was then transferred to a goniostat where it was cooled to −156°C for characterization (Table 1) and data collection.[7] A systematic search of a limited hemisphere of reciprocal space revealed no symmetry or systematic absences. Following intensity data collection ($6° \leqslant 2\theta \leqslant 45°$), data processing gave a residual of 0.034 for 223 unique intensities which has been measured more than once. Four standards measured every 300 data showed no significant trends. No correction was made for absorp-

tion. An initial choice of the centrosymmetric space group $P\bar{1}$ was made based on E-value statistics and was later proven correct by the successful solution of the structure.

The structure was solved by a combination of direct methods and Fourier techniques. After the non-hydrogen atoms had been located and partially refined, a difference Fourier revealed most of the hydrogen positions. In the final cycles of least-squares refinement, the non-hydrogen atoms were varied with anisotropic thermal parameters and the hydrogen atoms were varied with isotropic thermal parameters. The final difference map was essentially featureless, the largest residual peak being 0.47 e Å^{-3}. The refined C—H distances ranged from 0.89(6) to 1.08(9) Å. Selected bond lengths and bond angles are shown in Table 2 and the structure depicted in Figs 1 and 2. Additional information is available as supplementary material.

$[K(THF)_x(OSiPh_3)]$ (3)

A 200 cm^3 Schlenk flask was charged with KH (0.58 g, 14.46 mmol) and tetrahydrofuran (50 cm^3). Triphenylsilanol (2.78 g, 10.06 mmol) was added in

using inert atmosphere handling techniques. The crystal was transferred to the goniostat where it was cooled to −132°C for characterization (Table 3) and data collection. A systematic search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited monoclinic ($2/m$) symmetry. The systematic extinction of $0k0$ for $k = 2n+1$ and of $h0l$ for $l = 2n+1$ uniquely identified the space group as $P2_1/c$. A plot of the standards showed no systematic trends. No absorption correction was deemed necessary. The structure was solved by the usual combination of direct methods and Fourier techniques. The four unique potassium atoms were located in the initial E-map and the remaining non-hydrogen atoms were located in successive difference maps phased with the already located atoms. The molecule possesses a crystallographic centre of inversion. Almost all of the hydrogen atoms were evident in a difference map. They were introducted in fixed idealized positions for the final cycles of refinement during which all of the non-hydrogen atoms were refined using anisotropic thermal parameters. An overall isotropic extinction parameter was also refined. The total number of variables was 839.

The final difference map was essentially featureless, the largest peak was 0.58 e Å^{-3}. Selected bond lengths and bond angles are shown in Table 4 and the structure is depicted in Fig. 3.

Further details are available as supplementary material.

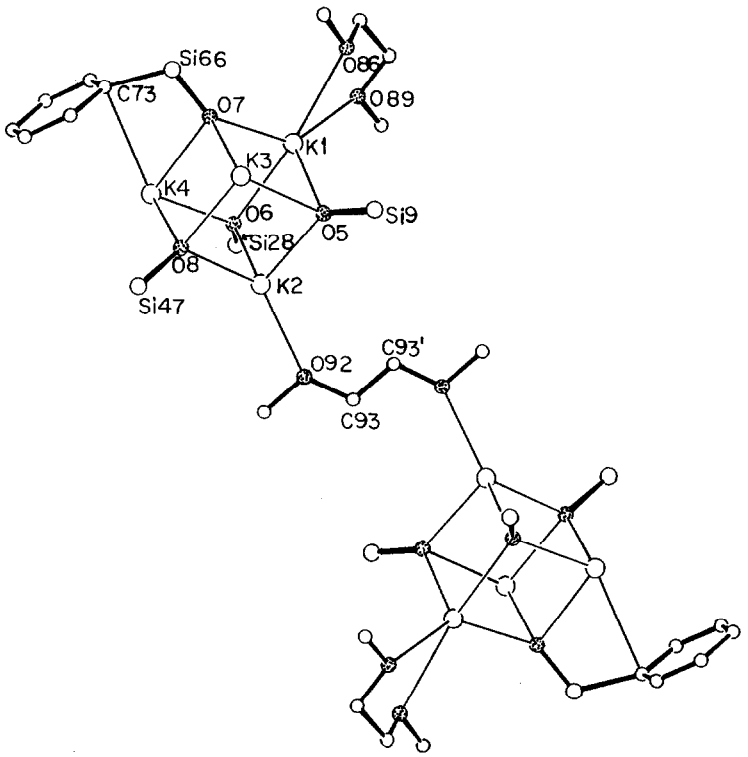

Fig. 3. ORTEP drawing of the non-hydrogen atoms of $K_8(OSiPh_3)_8(MeOC_2H_4OMe)_3$, omitting most phenyl rings for clarity. A crystallographic centre of symmetry lies between C(93) and C(93').

[K(18-crown-6)($OSiPh_3$)] (**5**)

A 100 cm^3 Schlenk flask was charged with $[K(thf)_{0.2}(OSiPh_3)]$ (0.32 g, 1.00 mmol) and 18-crown-6 ether (0.26 g, 1.00 mmol). Toluene (20 cm^3) was then added, resulting in a colourless solution. The mixture was stirred for 3 h, after which time it was concentrated *in vacuo*. Upon standing for 12 h at 0°C, large colourless crystals precipitated. These were isolated by decantation, washed with pentane and dried *in vacuo*. Yield, 90%. IR (Nujol): no ν(OH); ν(CH) 3020; aromatic overtones 1940, 1870, 1810, 1750; other bands 1290, 1270, 1245, 1235, 1100, 1030, 1010, 945, 825, 735, 690 cm^{-1}. ^1H NMR (C_6D_6): δ 8.17 (d, 6.8 Hz, 6H, *ortho*), 7.33 (t, 7.3 Hz, 3H, *para*), 3.16 (s, 24H, OCH_2). ^{13}C NMR (C_6D_6): δ 148.5 (*ipso*), 136.2 (*ortho*), 127.0 (*para*), 126.9 (*meta*), 70.0 (OCH_2). Found: C, 62.5; H, 6.6. Calc. for $C_{30}H_{39}KO_7Si$: C, 62.2; H, 6.8%.

X-ray structure determination of [K(18-crown-6)$OSiPh_3$]$_2$. A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques and cooled to −155°C for characterization and data collection (Table 5). A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/c$. Subsequent solution and refinement of the structure confirmed this choice. Data were collected ($6° < 2\theta < 45°$) in the usual manner using a continuous θ–2θ scan with fixed backgrounds.

Data were reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. All hydrogen atoms were clearly visible in a difference Fourier synthesis phased on the non-hydrogen parameters. All hydrogen atoms were refined isotropically and non-hydrogen atoms anisotropically in the final cycles. Final C—H distances ranged from 0.87(3) to 1.01(3) Å. No absorption correction was performed. A final difference Fourier was featureless, with the largest peak being 0.54 e $Å^{-3}$. Selected bond lengths and bond angles are given in Table 6 and the structure is depicted in Figs 4 and 5. Further details are available as supplementary material.

$[K(OSiMe_2{}^tBu)]_n$ (**6**)

A 100 cm^3 Schlenk flask was charged with KH (0.50 g) and THF (30 cm^3). To the resultant suspension was added $HOSiMe_2{}^tBu$ (1.0 cm^3, 6.4 mmol) via a pipette. Gas evolution occurred immediately. The mixture was stirred for 3 h, whereupon the filtration was performed to remove excess unreacted KH reagent. The solvent was evaporated *in vacuo* from the colourless solution thus obtained, leaving a white solid. The solid was dissolved in pentane. Upon standing at −20°C, colourless crystals precipitated. Yield: 60%. IR (Nujol): no ν(OH); major bands: 1235, 995, 970, 815, 740, 625 cm^{-1}. ^1H NMR (C_6D_6): δ 0.96 (s, 9H, ^{t}Bu), −0.10 (s, 6H, $SiMe_2$). ^{13}C NMR (C_6D_6): δ 27.6 [q, J(CH) 120.9 Hz, —C(CH_3)$_3$], 19.6 (s, —CMe_3), 0.17 [q, J(CH) 114.8 Hz, $SiMe_2$]. Found: C, 42.0; H, 8.9. Calc. for $C_6H_{15}KOSi$: C, 42.3; H, 8.9%.

$[K(18\text{-crown-6})(OSiMe_2{}^tBu)]_n$(**7**)

A 100 cm^3 Schlenk flask was charged with $[K(OSiMe_2{}^tBu)]_n$ (0.85 g, 5.0 mmol), 18-crown-6 ether (1.32 g, 5.00 mmol) and toluene (20 cm^3). A solution was obtained initially. Gradually, the reaction mixture grew turbid and a waxy solid precipitated. The reaction mixture was stirred for 70 h, whereupon the solvent was removed *in vacuo*. The residue was washed with hexane and dried *in vacuo*. Yield: 80%. IR (Nujol): no ν(OH), ν(CH) 2923; other bands: 1287, 1252, 1230, 1220, 1138, 1105, 1024, 962, 839, 819, 800, 770, 738, 634 cm^{-1}. ^1H NMR (C_6D_6): δ 3.26 (s, 24H, crown), 1.47 (s, 9H, ^{t}Bu), 0.49 (s, 6H, $SiMe_2$). ^{13}C NMR (C_6D_6): δ 70.1 (crown), 28.7 [—C(CH_3)$_3$], 20.8 (—CMe_3), 1.31 ($SiMe_2$). Found: C, 48.1; H, 9.1. Calc. for $C_{18}H_{39}KO_7Si$: C, 49.7; H, 9.1%.

RESULTS

Syntheses

Alkali metal silyloxide reagents $[Li(OSiPh_3)]_n$, $[K(thf)_{0.2}(OSiPh_3)]$ and $[K(OSiMe_2{}^tBu)]$ were prepared by deprotonation of Ph_3SiOH or $Me_2{}^t$BuSiOH using Li(^{n}Bu) in hexane and KH in THF, respectively. Crystalline DME adducts $[Li(\mu\text{-}OSiPh_3)(\eta^2\text{-DME})]_2$ and $[K_4(\mu_3\text{-}OSiPh_3)_3\{\mu_3\text{-}OSiPh_2(\eta^1\text{-Ph})\}(\eta^2\text{-DME})]_2(\mu\text{-DME})$ were prepared by dissolving $[Li(OSiPh_3)]_n$ or $[K(thf)_{0.2}$(OSi

Ph_3)], respectively, in dimethoxyethane followed by precipitation with alkane. Toluene-soluble [K(18-crown-6)($OSiPh_3$)]$_2$ and [(18-crown-6)(OSi$Me_2{}^tBu$)]$_n$, respectively, were prepared from [K$(thf)_{0.2}$($OSiPh_3$)] or [K($OSiMe_2{}^tBu$)]$_n$ and equivalent amounts of 18-crown-6 ether in toluene.

Spectroscopic properties

NMR spectroscopy. Both the ^1H and ^{13}C NMR spectra of the dimeric lithium complex [Li(μ-$OSiPh_3$)(η^2-DME)]$_2$ revealed a simple mono-substituted aromatic pattern along with resonances expected for the dimethoxyethane co-ligand. The base-free lithium silyloxide complex [Li($OSiPh_3$)]$_n$ was too insoluble in non-coordinating solvents to permit collection of NMR data.

The NMR spectra for the potassium triphenylsilyloxide complexes were unexpectedly simple given the solid-state structures (see below). The observation of a singlet resonance (by ^1H and ^{13}C NMR) for the 18-crown-6 ether moiety in [K(18-crown-6)($OSiPh_3$)]$_2$, (**5**) indicates that either the ethereal oxygen bridges are not maintained in solution or that a fluxional process equilibrates all 18-crown-6 atoms on the NMR time scale. Similarly, the ^1H and ^{13}C NMR measurements for [K_4(μ_3-$OSiPh_3$)$_3$(μ_3-$OSiPh_2$(η^2-Ph))(η^2-DME)]$_2$(μ-DME) (**4**) showed only one type of —$OSiPh_3$ group and one type of DME co-ligand. The implication here is that ligand reorganization processes are facile on the NMR time scale in solution.

The ^1H and ^{13}C NMR spectra for [K(OSi$Me_2{}^tBu$)]$_n$ (**6**) revealed only the expected —$OSiMe_2{}^tBu$-based signals. The absence of Lewis base co-ligands together with the solid-state characterization of [K($OSiMe_3$)]$_4$ as a cubane[4] implies a similar cubane structural formulation for **6**. The NMR results for [K(18-crown-6)($OSiMe_2{}^tBu$)]$_n$ (**7**) were analogous to those for the triphenylsilyloxide complex **5**: a singlet resonance for the 18-crown-6 ether and a single set of —$OSiMe_2{}^tBu$-based resonances.

IR spectroscopy. All triphenylsilyloxide complexes reported here shared a set of IR active absorptions, namely aromatic ν(CH) modes near 3030 cm^{-1} and mono-substituted aromatic overtone patterns between 1950 and 1780 cm^{-1}. Additionally, intense bands between 1100 and 950 cm^{-1} were detected in each spectrum and were attributed to ν(OSi) modes. Complexes bearing the —$OSiMe_2{}^tBu$ ligand revealed intense absorptions near 1240 cm^{-1}, assigned as δ_s ($SiCH_3$) modes, as well as very intense absorptions between 1050 and 950 cm^{-1}, assigned as ν(SiO) modes. No high energy ν(OH) bands were observed in any of the complexes reported in this study.

Solid-state structure of [Li(μ-$OSiPh_3$)(η^2-DME)]$_2$

The compound adopts a dimeric structure based on a symmetric (Li—O distances are equal to within 3σ) Li_2O_2 rhombus, a structural type reminiscent of lithium alkoxide chemistry.[8] (Fig. 1). This ring is obtuse at lithium [angle 97.9(4)°] and acute at the siloxide oxygen [angles 81.9(4)° and 82.2(4)°]. Bidentate coordination of one DME to each Li^+ gives this element coordination number four. The Si—O vectors do not precisely bisect the Li—O—Li angles, but the deviations are small. The two Si—O distances are equal (mean value 1.584 Å), and are identical to the values of a number of Y^{III}/$OSiPh_3$ compounds.[5] The Li—O(DME) bond distances are equal to within 3σ, and they are over 0.1 Å longer than the Li—O($SiPh_3$) distances. The DME/lithium rings are both puckered, the oxygens in these rings are distinctly pyramidal (angles at oxygen sum to 339.5–351.7°), and the ring conformation puts all terminal methyls in *trans* equatorial positions (Fig. 2). The Li—O(Si) distances (mean value 1.871 Å) are somewhat longer than those to phenoxides in [(Et_2O)Li(O-4-Me, 2,6-$^tBu_2C_6H_2$)]$_2$ [1.828(7) and 1.868(7) Å], where Li^+ is only three-coordinate.[9] Both siloxide oxygens are pyramidal (Fig. 2), but this is less dramatic at O(3) (sum of angles = 358.7°) than at O(23) (353.0°).

Solid-state structure of [K_4(μ_3-$OSiPh_3$)$_3$\{μ_2-$OSiPh_2$(η^1-Ph)\}(η^2-DME)]$_2$(μ-DME)

This molecule exists in the solid state as two K_4($OSiPh_3$)$_4$(η^2-DME) cubane units linked by a bridging DME (Fig. 3). A crystallographic centre of symmetry, located between the two methylene carbons of the bridging DME, relates the two cubane units. All Ph_3SiO^- groups are triply bridging within the cube. As a result, the four K^+ ions in the asymmetric unit have only a total of three terminal ligands: one oxygen of the DME which bridges two cubes and the two oxygens of one DME which is bidentate to a single K^+.

Potassium–oxygen bond lengths expand systematically as metal coordination number increases. This holds for K—OSi and also K—O(ether) distances. The latter are systematically longer than the former. The bridging ether binds to K^+ with a remarkably (0.20–0.27 Å) shorter distance than does the chelating ether. This may be due to a combination of chelate ring strain and the higher K^+ coordination number of the chelate/K^+ site.

There is good evidence that K4 binds to one phenyl *ipso* carbon attached to Si66. The K/C(73) distance of 3.078(4) Å is comparable to that in

potassium-intercalated graphite.[10] Moreover, the smallest of the 12 O—Si—C angles in the structure [109.51(15)°] is to C(73), although the other angles are not much larger [111.28(15)–114.69(16)°]. This K(4)/C(73) distance is only 0.1 Å longer than one of the K(1)—O(ether) distances. Atom K(3) remains only three-coordinate.

Solid state structure of $[K(18\text{-crown-6})OSiPh_3]_2$

The X-ray diffraction study reveals that K(18-crown-6)$OSiPh_3$ is an intimate ion pair in the solid state, and that it forms a dimer by bridging via ether oxygen (Figs 4 and 5). Potassium thereby achieves coordination number eight. The siloxide oxygen and the six oxygens of one crown ether furnish only seven donors. Space-filling drawings show that steric hindrance makes $OSiPh_3$ bridging impossible. Consequently, the eighth coordination site on potassium is occupied by an oxygen on the second crown ether in the dimer. This is accomplished by stacking the crown ether rings face-to-face in the dimeric structure (Fig. 5). This ether oxygen bridging is complementary (because the dimer possesses a crystallographic centre of symmetry), which leads to a "slipped" stacking of the macrocycle ring planes (Fig. 5). The bridging ether oxygen is involved in the longest (3.112 Å) and the third longest (2.918 Å) K—O distances in the structure. The K—OSi distance is the shortest (2.625 Å), and is *trans* to the bridging ether oxygen. The remaining five K—O distances range from 2.698 to 2.940 Å.

The ether oxygens are generally pyramidal, not planar, and they are "ruffled" somewhat out of their mean plane. The K—OSi vector is not perpendicular to this mean plane.

DISCUSSION

This work permits a number of conclusions about solid-state structure:

(1) The comparison of Li^+ and K^+ with $OSiPh_3^-$ and DME as ligands reveals that the larger potassium cation encourages a greater degree of aggregation. Aggregation does not follow uniquely from larger cation size, but is a consequence of ligands recruited into bridging roles, since a formulation like $K(DME)_n^+$ $OSiPh_3^-$ is, in principle, an alternative to aggregation. Indeed, we have reported $[K(\eta^2\text{-DME})_3(\eta^1\text{DME})][Y(OSiPh_3)_4(DME)]$ as an example.[5] Thus, it follows that:

(2) Ph_3SiO^- is abundantly capable of bridging between alkali metals. Not only μ_2- but also μ_3-possibilities are viable. Both bridging modes may be enabled because of minimal $O \rightarrow M^+$ π-donation when M^+ is an alkali metal (i.e. absence of empty *d* orbitals). Such a terminal siloxide remains quite nucleophilic at oxygen.

(3) The larger K^+ ion displays remarkable tolerance towards variable coordination number (and, consequently, geometry). Particularly illustrative of this point is the compound $[K_4(\mu_3\text{-}OSiPh_3)_3\{\mu_3\text{-}OSiPh_2(\eta^1\text{-Ph})\}(\eta^2\text{-DME})]_2(\mu\text{-DME})$, where coordination numbers five, four, "three-plus-one" (three oxygens and one carbon), and three co-exist. The three-coordinate potassium (K3) is also noteworthy because it is pyramidal, not the more stable planar geometry.

(4) The K—O distances show no regular variation with changing coordination number. This contrasts with the situation for transition metal siloxides. This may be a sign of predominately ionic bonding for K^+. Nevertheless, while individual K—O interactions may be largely coulombic in character, such polarity is effectively masked by the hydrocarbon periphery of these molecules and they are therefore hydrocarbon-soluble. Their utility as synthetic reagents in non-coordination solvents is thus established.

(5) The compact ligand 18-crown-6 permits the highest coordination number (eight) for K^+. The ability of an ether oxygen to bridge two metals expands the structural potential of crown ethers.

Supplementary materials available. Full crystallographic details, and atomic coordinates and anisotropic thermal parameters and observed and calculated structure factors for $[LiOSiPh_3(DME)]_2$, $K_8(OSiPh_3)_8(DME)_3$ and K(18-crown-6)$(OSiPh_3)$.

(*Received* 4 *April* 1991; *accepted* 26 *July* 1991)

Abstract—The formation of an intermediate ruthenium(III) ascorbate complex (**1**) by the interaction of L-ascorbic acid and dichlorotetraaquoruthenium(III) is reported in the temperature range 25–40°C. The kinetics and mechanism of the formation of **1** were studied as a function of $[Ru^{III}Cl_2(H_2O)_4]^+$, [ascorbic acid], pH, ionic strength and temperature. The rate of formation of **1** was found to be first order in $[Ru^{III}Cl_2(H_2O)_4]^+$ and [ascorbic acid]. The rate has an inverse dependence on hydrogen ion concentration. Ionic strength dependence indicated the formation of **1** by monoanionic and cationic species in solution. Decomposition of **1** takes place slowly and gives the products dehydroascorbic acid and $[Ru^{II}Cl_2(H_2O)_4]$. A detailed discussion of the kinetic data and a comparison of rate and equilibrium constants are presented with activation and thermodynamic parameters.

The study of the formation of an intermediate complex during a reaction is of fundamental interest in the understanding of the kinetics and mechanism of the reaction. The chemistry of ascorbic acid complexes took on new importance when a *cis*-diammine platinum ascorbate complex was synthesized[1] and found to be an efficient anti-cancer agent. Evidence of the transient appearance of the metal-ascorbate complexes has been reported in a few cases[2–5] but lacks the detailed study of complex formation. Our recent studies on ruthenium(III) chloride in aqueous solution[6–10] showed that $[Ru^{III}Cl_2(H_2O)_4]^+$ is the most stable chloro species present in solution (pH 1.0–2.5). Stoichiometric[11] and catalytic[12] oxidation of L-ascorbic acid by ruthenium(III) has been studied previously. In this paper we report an investigation of the kinetics of the formation of the ruthenium(III) ascorbate complex using fast kinetic methods and visible spectroscopy.

EXPERIMENTAL

All the solutions were prepared using freshly prepared, doubly distilled water. L-ascorbic acid was an AR grade sample and was used without further purification. A stock solution of ruthenium(III) was prepared[6] by dissolving an appropriate amount of ruthenium trichloride trihydrate $[RuCl_3 \cdot 3H_2O]$ in 1 M hydrochloric acid. AR grade potassium nitrate was used to maintain the ionic strength of the solution at 0.02–0.15 M. The desired pH (0.5–2.75) of the experimental reaction mixture was adjusted by adding either carbonate-free standard NaOH or HCl to the reaction solution. Corrections due to ionic strength were applied in calculating hydrogen ion concentration from the pH data.

pH measurements were performed with a digital pH meter (±0.01 pH) equipped with combined glass and calomel electrodes. The desired temperature (±0.1°C) was maintained in the reaction cell with a circulating water bath. A temperature-controlled Shimadzu 160 UV–vis spectrophotometer was used for all spectrophotometric experiments. Fast kinetic measurements were performed on a thermostated (±0.1°C) stopped-flow spectrophotometer Model S4-51 (HiTech) coupled with an Apple data processor as a function of [ascorbic acid], $[Ru^{III}Cl_2(H_2O)_4]^+$, pH, ionic strength and temperature. An excess of ascorbic acid was used in all cases to ensure pseudo first-order kinetic conditions and the corresponding rate constants

* Author to whom correspondence should be addressed.

were evaluated from the plots of $\log(A_\infty - A_t)$ vs time. All reported rate constants are the mean values of at least four determinations and subjected to an average error limit of $\pm 3\%$.

RESULTS AND DISCUSSION

The oxidation of L-ascorbic acid (H_2A) by $[Ru^{III}Cl_2(H_2O)_4]^+$ leads to the formation of L-dehydroascorbic acid (A) according to the overall reaction in eq. (1).

$$2[Ru^{III}Cl_2(H_2O)_4]^+ + H_2A \longrightarrow 2[Ru^{II}Cl_2(H_2O)_4] + A + 2H^+. \quad (1)$$

The stoichiometry of the reaction is similar to many other ascorbic acid oxidation reactions[13–16] by metal complexes. The reactivity of ascorbic acid depends on the actual species, H_2A, HA^- or A^{2-}, participating in the rate-determining step. In general, the reactivity increases in the order $H_2A < HA^- < A^{2-}$.[17] H_2A and HA^- are the reactive species of ascorbic acid in acidic medium.[18–22] The completely dissociated species exist only above pH 9.00.

Preliminary experiments with ascorbic acid and $[Ru^{III}Cl_2(H_2O)_4]^+$ in the pH range 0.5–2.5 indicated the rapid formation of an intermediate ascorbate complex (Fig. 1), which subsequently decomposed to the products dehydroascorbic acid and $[Ru^{II}Cl_2(H_2O)_4]$. It was possible to record the spectrum of intermediate species (ruthenium(III) ascorbate complex) during the formation and decomposition processes, from which it follows that the complex has a maximum absorption at 510 nm.

Since both the reactants $[Ru^{III}Cl_2(H_2O)_4]^+$ and HA^- in the present study are highly pH sensitive, the molar extinction coefficient of the ruthenium(III) ascorbate complex was determined by measuring the maximum absorbance reached at 510 nm as a function of pH, $[H_2A]$ and $[RuCl_2(H_2O)_4]^+$. The absorption spectrum of the complex formed between ascorbic acid (2×10^{-3} M) and $[RuCl_2(H_2O)_4]^+$ (2×10^{-4} M) in 0.1 M KNO_3 at different pH values (0.5–2.5) (Fig. 1) was obtained by performing spectrophotometric titrations from pH 0.5 to 2.5. The absorbance at 510 nm increases with pH up to 2.0. At pH > 2.0, the pH dependence on absorbance at 510 nm was found to be non-linear. It is clear from Table 1 that after pH 2.5 the absorbance starts decreasing. The dual nature of the pH dependence on complex formation, below and above pH 2.0 may be assigned to the presence of chloro and hydroxo species of ruthenium(III) in aqueous solution, because at higher pH (> 2.0) hydrolysis of the chloro complexes of ruthenium(III) takes place. Hence, at pH 2 the formation of the ruthenium(III) ascorbate complex results from the interaction of $[Ru^{III}Cl_2(H_2O)_4]^+$ and ascorbate monoanion (HA^-). In a 10-fold excess of ascorbic acid, assuming all the $[RuCl_2(H_2O)_4]^+$ in solution is involved in the formation of the ruthenium ascorbate complex, the molar extinction coefficient at 510 nm (ε_{max}^{510}) at pH 2 is 805 M^{-1} cm^{-1}.

In an attempt to measure the stoichiometry of the ruthenium(III) ascorbate complex, we have undertaken experiments in which $[Ru^{III}Cl_2(H_2O)_4]^+$, at constant concentration, was mixed with ascorbate at known but variable concentrations in the stopped-flow apparatus. The total absorbance change due to complex formation was monitored, thus giving a measure of the complex concentration as a function of ascorbate concentration. Under these conditions and at pH 2 and $\mu = 0.1$ M KNO_3, we observed a single kinetic progress curve leading to the formation of a 1 : 1 ruthenium(III) ascorbate complex at 510 nm. The method of cal-

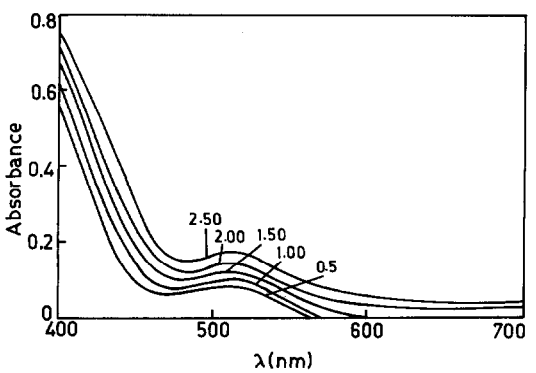

Fig. 1. Absorption spectrum of the intermediate complex formed at 510 nm at different pH values as indicated with $[Ru^{III}Cl_2(H_2O)_4]^+ = 2 \times 10^{-4}$ M, [ascorbic acid] = 2×10^{-3} M and $\mu = 0.1$ M KNO_3 at 30°C.

[a] Calculated using eq. (4).

culation for the formation constant of the complex is reported in our previous publications.[7-11]

An appropriate quantity of ruthenium(III) chloride from its stock solution (solution A) and solutions containing suitable amounts of 1 M KNO_3, 0.1 M carbonate-free sodium hydroxide and L-ascorbic acid (solution B) were made in separate containers at the required temperatues. On mixing solutions A and B a rapid increase in absorbance in the visible spectrum at 510 nm was observed, indicating rapid formation of the ruthenium(III) ascorbate complex.

The complex formation reaction was carried out by a stopped-flow apparatus as a function of pH, H_2A, μ and temperature and the kinetic data are given in Table 2. Pseudo first-order rate constants k_{obs} are independent of the concentration of $RuCl_2(H_2O)_4^+$ and increased linearly (first order) on increasing ascorbic acid concentration. The pH dependence of the reaction (Table 3) was studied in the pH range 1.50–2.50 and the rate of complex formation was found to increase with pH showing inverse dependence of $[H^+]$. This dependence is explained in terms of eqs (2) and (3).

Table 3. pH dependence for ruthenium(III) ascorbate complex formation at 35°C, μ = 0.1 M KNO_3, $[RuCl_2(H_2O)_4]^+ = 2 \times 10^{-3}$ M and $[H_2A] = 2 \times 10^{-2}$ M

pH	k_{obs} (s^{-1})	k_1 ($10^{-3} \times M^{-1} s^{-1}$)
1.50	5.4±0.1	69.1±1.2
1.75	9.6±0.2	68.9±1.2
2.00	17.0±0.3	69.2±1.5
2.25	28.6±0.5	69.9±1.8
2.50	47.6±0.8	64.0±1.6

$$H_2A \overset{K_a}{\rightleftharpoons} HA^- + H^+ \quad (2)$$

$$[Ru^{III}Cl_2(H_2O)_4]^+ + HA^- \xrightarrow{k_1} \text{complex} \quad (3)$$

The rate expression for the reaction in terms of k_{obs} is written as

$$k_{obs} = k_1 K_a [H_2A]_T (K_a + H^+); \quad (4)$$

where

$$[H_2A]_T = [H_2A] + [HA^-]. \quad (5)$$

Inversing eq. (4) we obtain

$$k_{obs}^{-1} = 1/k_1[H_2A]_T + [H^+]/k_1 K_a [H_2A]_T. \quad (6)$$

The dissociation constants K_a obtained directly by potentiometric titrations at the different temperatures reported[12] at μ = 0.1 M KNO_3 are: $K_a \times 10^5$(°C): 10.05(25), 11.22(30), 12.40(35) and 14.79M(40). Substituting K_a in the slope of the plot of k_{obs}^{-1} vs $[H^+]$ [eq. (6)], the rate constant k_1 calculated at 35°C was $69.6 \pm 0.5 \times 10^3$ $M^{-1} s^{-1}$. The rate constant k_1 computed using the dissociation constant K_a in eq. (4) is fairly constant with regards to the variation of ascorbic acid, $[RuCl_2(H_2O)_4]^+$ and hydrogen ion concentration with an average value of $k_1 = (67.8 \pm 0.2) \times 10^3$ $M^{-1} s^{-1}$, which is in excellent agreement with the rate constant calculated from eq. (6). These results indicate that there is no significant reaction of $[RuCl_2(H_2O)_4]^+$ with undissociated H_2A under the present experimental conditions. The ionic strength (0.02–0.15 M) dependence plot of $\log k_1$ vs $\mu^{1/2}/(1+\mu^{1/2})$ gave

Table 4. Thermodynamic and activation parameters for interaction of $[RuCl_2(H_2O)_4]^+$ and ascorbic acid

Thermodynamic parameters[a]	For equilibrium constants K_a	K
$\Delta H^\ominus$ (kcal mol^{-1})	6.9±0.1	4.0±0.1
$\Delta S^\ominus$ (cal K^{-1} mol^{-1})	6±1	31±3
$\Delta G^\ominus$ (kcal mol^{-1})	5.5±0.1	−5.1±0.1
Activation parameters	For rate constants k_1	k_2[a]
$\Delta H^{\ominus\,b}$ (kcal mol^{-1})	3.3±0.1	6.0±0.1
$\Delta S^{\ominus\,b}$ (cal K^{-1} mol^{-1})	−26±2	−54±3

[a] See ref. 11.
[b] Calculated at 25°C.

a slope of −1, confirming that the complex formation takes place through the interaction of a monocationic and an anionic species [eq. (3)].

Oxidation of ascorbic acid slowly takes place by the decomposition of the complex as given in eqs (7) and (8).

$$\text{Complex} \xrightarrow{k_2} [Ru^{II}Cl_2(H_2O)_4] + HA^{\cdot} \quad (7)$$

$$[Ru^{III}Cl_2(H_2O)_4]^+ + HA^{\cdot} \xrightarrow{\text{fast}} [Ru^{II}Cl_2(H_2O)_4] + H^+ + A; \quad (8)$$

where $HA^{\cdot}$ is the ascorbate radical. The detailed kinetic study of the oxidation of ascorbic acid by the present system has been reported.[11] The formation constant K given by eq. (9) directly calculated by the spectrophotometric method[23] at different temperatures is: $K \times 10^{-3}$(°C): 5.99(25), 6.91(30), 7.81(35) and 8.70 M^{-1}(40).

$$[RuCl_2(H_2O)_4]^+ + HA^- \rightleftharpoons \underset{\text{complex}}{[RuCl_2(H_2O)_2HA]} + 2H_2O \quad (9)$$

The thermodynamic parameters given in Table 4 corresponding to the dissociation constant K_a show that dissociation is highly endothermic with positive values of $\Delta H^\ominus$ and $\Delta G^\ominus$. The formation of the ascorbate complex is highly favourable with a negative value for $\Delta G^\ominus$. The enthalpy of the formation is endothermic and entropy is favourable for its decomposition. A comparison of activation parameters (Table 4) corresponding to the rate constants k_1 and k_2 indicate that the activation process is enthalpy-controlled, since enthalpy is more for slower reactions. The negative values of entropy of activation are in line with an associatively-activated process.

CONCLUSIONS

From the results of the investigation on the ruthenium(III) ascorbate reaction we conclude that intermediate **1** observed in the reaction is a dichloroascorbatodiaquoruthenium(III) complex which maximally forms near pH 2.2. The increase in absorbance at 510 nm observed in the stopped-flow apparatus corresponds to the build up of this complex. Spectrophotometric tirations of the chloro species $[RuCl_2(H_2O)_4]^+$ with ascorbate suggested that the mixed ligand complex formation reaches a maximum at a ruthenium(III) to ascorbate ratio of 1:1 and after that the addition of ascorbic acid does not much affect the complex formation.

(*Received* 30 *May* 1991; *accepted* 25 *July* 1991)

Abstract—In a direct synthesis reaction of the tris(aminocarboxylato)cobalt(III) complexes with *S*-arginine all four theoretically possible tris(*S*-arginine)cobalt(III) diastereomers were obtained as tripositive complex ions. Besides, one out of 24 theoretically possible isomers of di-μ-hydroxo-tetrakis(*S*-arginine)dicobalt(III) tetrapositive ion was obtained. Geometrical and absolute configurations of the tris(*S*-arginine)cobalt(III) isomers were determined by electronic and CD spectroscopy. The molecular structure of the $(-)_{589}$-*anti*(N)-Δ-*cis*(N),*cis*(O)-Λ-*cis*(N),*cis*(O)-di-μ-hydroxo-tetrakis(*S*-arginine)dicobalt(III) ion was solved by X-ray crystal structure analysis. The complexes obtained represent the first examples of cationic aminocarboxylato complexes of this type. For the first time the formation of the di-μ-hydroxo-tetrakis(aminocarboxylato)dicobalt(III) complex has been observed as a reaction concurrent to the formation of tris(aminocarboxylato)cobalt(III) complexes. Finally, the stereoselectivity of *S*-arginine in the tris(*S*-arginine)cobalt(III) isomers synthesis was discussed.

Arginine has a unique character among α-amino-carboxylates. It exists exclusively as a zwitter ion in the crystalline state,[1] presumably because the guanidino group is much more basic than the α-amino group. The only complex of arginine so far isolated is *cis*(NO_2),*trans*(NH_2)-bis(*S*-arginine) dinitrocobalt(III) nitrate,[2] and the arginine is indeed in the zwitter ion form.[3]

In order to investigate the structure of cobalt(III) complexes of arginine in more detail, we have undertaken the synthesis of such cobalt(III) complexes that have arginine as the exclusive ligand. It is expected that the tris(bidentate) type complex would have a tripositive charge, in contrast to neutral or anionic species formed with other α-amino-

* Author to whom correspondence should be addressed.

carboxylates.[4-6] It is also worthwhile to elucidate the stereoselectivity associated by the complex formation, with special reference to the influence of separated charges brought about by the coordination of this ligand.

EXPERIMENTAL

Synthetic procedure

To a solution of cobalt(II) nitrate (2.91 g, 10 mmol) in water (25 cm^3) a warm solution (50°C) of *S*-arginine (5.22 g, 30 mmol) in water (30 cm^3) was added. A stream of air, previously passed through a 25% solution of potassium hydroxide, was bubbled through the reaction mixture for 4.5 h. Then, 65% nitric acid (0.7 cm^3, $\rho = 1.43$ g cm^{-3}) was added to the reaction mixture, which was heated on a water bath for 2.5 h. After standing at room temperature for about 15 h, about 3 g of crystalline compound was obtained, which was filtered off by suction and washed with ethanol and ether. The crystals were dissolved in 30 cm^3 of water and the solution was poured on the cationic exchange resin "Sephadex" C-25 column (35 cm length and 3.5 cm o.d.) in potassium form. The column was washed with 50 cm^3 of water, and eluted with a 0.2 mol dm^{-3} solution of potassium nitrate. The eluate of the first zone was concentrated in a rotatory vacuum evaporator at 60°C until crystallization began, to give 2.3 g (29%) of violet crystals of meridional Λ-$(+)_{589}$-tris(*S*-arginine)cobalt(III) trinitrate dihydrate (**1**), $[\alpha]_D^{20°} = +490°$ (*ca* 0.1% in water). Found: C, 26.8; H, 5.8; N, 26.2. Calc. for $C_{18}H_{46}N_{15}O_{17}Co$: C, 26.9; H, 5.7; N, 26.1%.

Concentration of the eluate of the second zone in a rotatory vacuum evaporator at 60°C afforded blue crystals of $(-)_{589}$-*anti*(N)-Δ-*cis*(N),*cis*(O)-Λ-*cis*(N),*cis*(O)-di-μ-hydroxo-tetrakis(*S*-arginine) dicobalt(III) tetranitrate tetrahydrate (**2**) in a yield of 2.7 g (24%), $[\alpha]_D^{20°} = -216°$ (*ca* 0.1% in water). The substance for analysis was heated at 105°C for 2 h. Found: C, 26.1; H, 5.5; N, 25.3. Calc. for $C_{24}H_{58}N_{20}O_{26}Co_2$: C, 26.3; H, 5.3; N, 25.5%.

The filtrate of the reacted solution was also poured on a cationic "Sephadex" C-25 column (35 cm length and 4.5 cm o.d.). After washing with 50 cm^3 of water, the elution was carried out with a 0.1 mol dm^{-3} solution of potassium nitrate. Eluates of three small zones, containing unidentified substances, came out of the column. On elution with a 0.2 mol dm^{-3} solution of potassium nitrate three zones formed on the column. On concentrating the eluate of the first zone in a vacuum evaporator at 60°C a violet solid of meridional Δ-$(-)_{589}$-tris(*S*-arginine)cobalt(III) trinitrate trihydrate (**3**) was obtained, in a yield of 0.7 g (2%), $[\alpha]_D^{20°} = -400°$ (*ca* 0.1% in water). Found: C, 26.4; H, 5.9; N, 25.4. Calc. for $C_{18}H_{48}N_{15}O_{18}Co$: C, 26.3; H, 5.8; N, 25.6%.

The concentration of the eluate of the second zone gave a red solid of facial Λ-$(+)_{589}$-tris(*S*-arginine)cobalt(III) trinitrate dihydrate (**4**) in a yield of 0.4 g (5%), $[\alpha]_D^{20°} = +200°$ (*ca* 0.1% in water). Found: C, 26.8; H, 5.8; N, 26.2. Calc. for $C_{18}H_{46}H_{15}O_{17}Co$: C, 26.9; H, 5.7; N, 26.1%.

The third zone contained only a small amount of the product, so that the eluates from three repeated procedures were collected, to give 0.7 g of the red solid of facial Δ-$(-)_{589}$-tris(*S*-arginine)cobalt(III) trinitrate dihydrate (**5**) (the estimated yield is about 3%), $[\alpha]_D^{20°} = -325°$ (*ca* 0.1% in water). Found: C, 26.7; H, 5.6; N, 26.0. Calc. for $C_{18}H_{46}N_{15}O_{17}Co$: C, 26.9; H, 5.7; N, 26.1%.

X-ray crystal structure analysis of complex **2**

A trigonal prismatic crystal of **2** with dimensions of $0.28 \times 0.28 \times 0.18$ mm and recrystallized from water was used for data collection. It was coated with thin layers of paraffin and epoxy resin, since the crystal easily loses water of crystallization. Intensity data were collected on a Rigaku AFC-5 diffractometer at 25°C, by use of the θ–2θ scan technique and graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The intensities were corrected for Lorentz-polarization factors and the absorption effect, but not for extinction. The cell dimensions were determined by the least-squares calculation using 50 2θ values ($25° < 2\theta < 30°$), measured on the diffractometer. Crystallographic data, other data collection and refinement informations are summarized in Table 1.

The structure was solved by the conventional heavy-atom method and refined by the full-matrix least-squares program RADIEL.[7] All the non-hydrogen atoms were located from the successive Fourier syntheses and included in the refinement. The structure analysis was first performed for the space group of $P1$ and converged to $R = 0.088$ and $R_w = 0.120$. The ^{13}C NMR spectrum of **2** in dimethylsulphoxide indicated that the complex has no centre of symmetry. This coincides with the use of optically active *S*-arginine ligand. Further analysis was carried out by considering the space group $P\bar{1}$. Since the crystal structure has a pseudo-centre of symmetry, strong correlations were found between parameters of the atoms which were related by the pseudo-symmetry. Hence, the final refinement was performed on the assumption that the thermal parameters of the related atoms were equal. The final refinement with anisotropic thermal par-

ameters converged to $R = 0.063$ and $R_w = 0.076$ for 3840 independent reflections. The scattering factors and anomalous scattering corrections were taken from ref. 8. The selected bond distances and angles are shown in Table 2.

All the calculations were carried out on a HITAC M-680 computer at the Computer Centre of Institute for Molecular Science with the Universal Crystallographic Computation Program System UNICS III.[9]

Other physical measurements

^{1}H and ^{13}C NMR spectra (DMSO) were recorded on a JEOL GX-400 spectrometer operating at 400 MHz. Optical rotations, UV, vis and CD spectra were recorded on a Perkin–Elmer MC polarimeter, Varian Super Scan 3 spectrometer and JASCO J-500 A spectropolarimeter, respectively.

RESULTS AND DISCUSSION

Synthesis

As seen from the experiment, we succeeded in obtaining five stereochemically interesting substances in one chemical reaction, namely all four theoretically possible diastereomers of the tris(*S*-arginine)cobalt(III) ion (**1**, **3**–**5**), as well as one of the 24 theoretically possible isomers of the di-μ-hydroxo-tetrakis(*S*-arginine)dicobalt(III) ion, i.e. the $(-)_{589}$-*anti*(N)-Δ-*cis*(N),*cis*(O)-Λ-*cis*(N),*cis*(O)-isomer (**2**). On the basis of the yields obtained, the stoichiometry of the reaction is estimated to be:

$$4Co(NO_3)_2 + 10(S\text{-argH}) + 2HNO_3 + O_2 \longrightarrow [Co_2(OH)_2(S\text{-argH})_4](NO_3)_4 + 2[Co(S\text{-argH})_3](NO_3)_3.$$

The total yield of the reaction is very high (82%), although each isomer is obtained in relatively low yields (see Experimental). Hence, the present reaction is a very simple and efficient synthetic procedure for a simultaneous preparation of the tris(*S*-arginine)cobalt(III) complexes. They are the first examples of cationic tris(aminocarboxylato)cobalt(III) complexes. Their conversion into neutral complexes was not possible at a very high pH, since at these conditions cobalt(III) hydroxide was separated. Although di-μ-hydroxo-tetrakis(aminocarboxylato)dicobalt(III) complexes with glycine, *S*-alanine and *S*-valine have already been synthesized,[10] none of the authors, as far as we know, mentioned the formation of such complexes in a direct synthesis of the tris(aminocarboxylato)cobalt(III) complexes.

Geometrical configuration of the tris(S-arginine)cobalt(III) diastereomers

Two geometrical isomers, meridional and facial ones, are possible for a tris(aminocarboxylato)cobalt(III) complex. Each of them could be resolved into diastereomers for optically active ligands. All the four possible diastereomers of tris(*S*-arginine)cobalt(III) were successfully obtained. Their geometrical configurations were determined from their electronic spectra (Figs 1 and 2). Two red isomers **4** and **5** exhibit relatively narrow and symmetrical bands at 520 nm. On the other hand, the two violet isomers **1** and **3** display relatively wider bands with pronounced inflection in the similar wavelength region. It can be concluded that the red isomers **4** and **5** possess facial, whereas the violet ones **1** and **3** meridional configuration.[11]

Absolute configuration of the tris(S-*arginine*)*cobalt* (III) *diastereomers*

CD spectra of the isomers were recorded and shown in Figs 1 and 2. The CD spectra of the corresponding diastereomers of the tris(*S*-alaninato)cobalt(III) complex are also shown, of which the configurations had been determined by the X-ray structure analyses. The crystal structures of $(+)_{589}$-mer-[Co(S-ala)$_3$] and $(-)_{589}$-mer-[Co(S-ala)$_3$] $\cdot 3H_2O$ have been determined by Drew *et al.*[12] and Herak *et al.*,[13] respectively. They confirmed the assignments of Denning and Piper, in which the absolute configurations of these diastereomers were determined on the basis of the CD spectra of these isomers and those of Λ-*mer*-[Co(*S*-proline)$_3$].[14] Denning and Piper (l.c.) also assigned the absolute configuration of the corresponding facial diastereomers.[14] As shown in Fig. 2, the CD spectra of the two meridional isomers of the *S*-arginine complex show similar features to those of the corresponding alanine complexes with the same CoN_3O_3 chromophore. Therefore, it would be reasonable to assign the absolute configuration of the meridional isomers by comparison of their CD spectra, that the $(+)_{589}$-diastereomers possess the Λ configuration and the $(-)_{589}$-diastereomer, the Δ configuration. In an analogous manner, we also assigned the absolute configuration of the facial isomers that the $(+)_{589}$-diastereomer has Λ configuration and the $(-)_{589}$-diastereomer, Δ configuration.

^{13}C *NMR spectra of the dinuclear complex*

Owing to the asymmetric carbon atom of arginine ligand, two halves of the di-μ-hydroxo-tetrakis(*S*-arginine)dicobalt(III) complex are in a diastereomeric relationship. Therefore, a different chemical shift is expected for each carbon atom belonging to the arginine ligands. As shown in Fig. 4, ^{13}C NMR of the dinuclear complex **2** shows more than 12 signals, indicating that the observed molecular structure is essentially retained in solution. The chelate ring carbons which are close to the asymmetric centre exhibit distinctly different chemical shifts. The chemical shifts of the guanidinium moieties are, however, partially degenerate and only two signals are observable. This may be due to the fact that positively-charged moieties of the guanidinium group are separated from each other and are far apart from the asymmetric centres.

Electronic absorption and CD spectra of the dinuclear complex

The *cis*(N),*cis*(O)-configuration around each metal centre produces symmetric *d–d* absorption bands in the energy region characteristic of the CoN_2O_4 chromophore (Fig. 3). The di-μ-hydroxo bridge causes a charge-transfer band, which over-

laps partially the second *d–d* transition band (Table 3).

The CD spectra of the di-μ-hydroxo complex indicates a weak optical activity in comparison with that of the tris(*S*-arginine)cobalt(III) complexes. Because of the opposite absolute configuration of the bis(bidentate) pairs around two metal centres, only the vicinal contribution of the ligands is observed.

Structure of the dinuclear complex

No X-ray crystal structure of a dinuclear di-μ-hydroxo-tetrakis(aminocarboxylato)dicobalt(III) complex has been reported. Two crystal structures have been known for the corresponding chromium(III) complexes: *anti*(N)-Δ-*cis*(N),*cis*(O)-Λ-*cis*(N),*cis*(O)-di-μ-hydroxo-tetrakis(glycinato) dichromium(III)[15] and Δ-*trans*(N),Δ-*trans*(O)-di-μ-hydroxo-tetrakis(*S*-prolinato)chromium(III).[16] A special stability of these isomers out of 24 theoretically possible isomers was ascribed to the formation of two intramolecular NH···O hydrogen bonds, which are almost parallel to the chromium/chromium direction. Preferential formation of the geometrical isomers with *cis*(N),*cis*(O) configuration was also pointed out by Oki and Yoneda.[16] The molecular and crystal structure of **2** and its tetranitrate are shown in Figs 5 and 6, respectively.

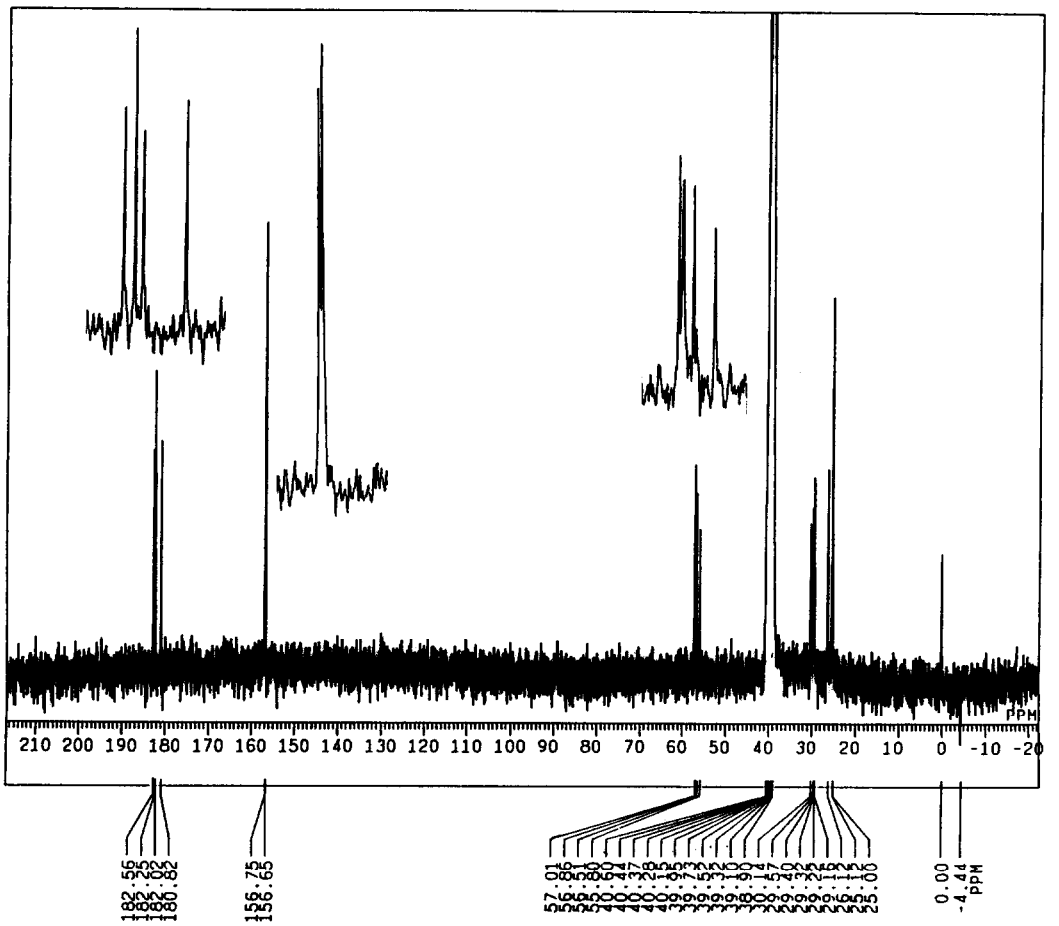

Fig. 4. ^{13}C NMR spectrum of *anti*(N),Δ-*cis*(N),*cis*(O),Λ-*cis*(N),*cis*(O)-di-μ-hydroxo-tetrakis(*S*-arginine)dicobalt(III) tetranitrate tetrahydrate (**2**), expanded in the region of the carboxylic carbon (180–183 ppm), guanidinium group carbon (156–157 ppm) and methyne group carbon (55–57 ppm).

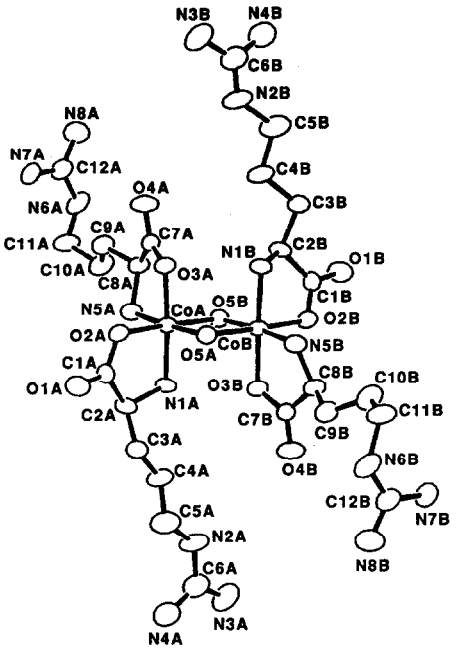

Fig. 5. Molecular structure of $(-)_{589}$-*anti*(N),Δ-*cis*(N), *cis*(O),Λ-*cis*(N),*cis*(O)-di-μ-hydroxo-tetrakis(*S*-arginine) dicobalt(III) (tetrapositive cation of complex **2**).

The present dinuclear complex also has the *cis*(N),*cis*(O)-configuration around each cobalt(III) ion. For bis- or tris-(prolinato) complexes of cobalt (III) and chromium(III), contribution of steric hindrance due to the pyrrolidine ring is very significant.[10,14] In the present complex the C_3 side-chains on the asymmetric carbon atoms extend rather straight, and no apparent steric hindrance coming from the guanidinopropyl group is seen on the chelate structure. The guanidine groups seem to be rather parallel to each other in the crystal. The counter-ions situate in the opening surrounded by the guanidinopropyl chains. It seems as if the electronic charge is compensated separately at the tris(aminocarboxylato)cobalt(III) moiety and the guanidinium nitrate ion pairs. Although the location of protons is not known from the X-ray analysis, it is clear that the arginine ligand is in a zwitter ion form in the coordinated state.

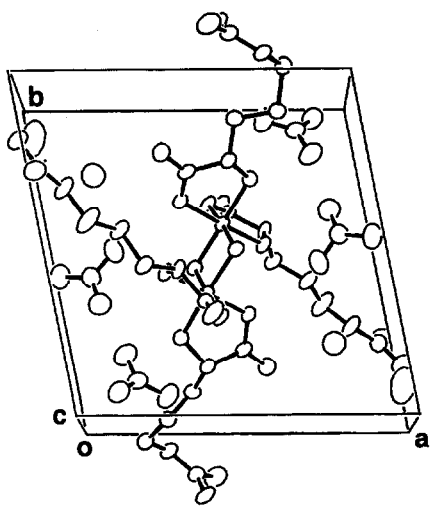

Fig. 6. Crystal structure of $(-)_{589}$-*anti*(N),Δ-*cis*(N),*cis*(O), Λ - *cis*(N),*cis*(O) - di - μ - hydroxo - tetrakis(*S* - arginine) dicobalt(III) tetranitrate tetrahydrate (**2**).

As already mentioned, Gillard[10] reported the synthesis of the di-μ-hydroxo-tetrakis(*S*-aminocarboxylato)dicobalt(III) complexes with *S*-alanine and *S*-valine. From the nature of the Cotton effect at the long wavelength *d–d* band he tentatively concluded that the Δ configuration predominates at both cobalt centres in these dinuclear complexes. We are now able to check this conclusion by comparison of the spectroscopic data of these complexes with the X-ray and spectroscopic data of our dinuclear arginine complex (Table 3). As it is seen, spectroscopic properties of all complexes are similar indicating similar geometries. Therefore, we suggest that Gillard isolated complexes with configurations on two metal centres opposite to each other, as it is in the case of the complex of arginine reported here.

Stereoselectivity

There has been a great deal of discussion about the stereoselective formation of geometrical and optical isomers of tris(aminocarboxylato) cobalt(III) complexes. It is generally understood that aminocarboxylates with short chains exhibit very different geometrical stereoselectivities in the preparation of tris(aminocarboxylato)cobalt(III) complexes. The most pronounced difference is noted when they are prepared by direct synthesis [air oxidation of a mixture of cobalt(II) salt and aminocarboxylato ligand in aqueous solution] and by ligand substitution in hexaamminecobalt(III) complex ion in water at elevated temperature.[4,14,17] On the other hand, Gillard *et al.*[10] reported that tris(*S*-lysinato)cobalt(III) is formed preferentially in the *mer* form when prepared by both methods. It was discussed that the long *S*-lysinato aminobutyl side chain in the α-carbon atom is responsible for the selectivity. Arginine is similar to lysine in the sense that both have rather long carbon chains with terminal basic functional groups. The present tris(arginine) complexes are obtained by direct synthesis more in the *mer* form than in the *fac* and our preliminary results show the same preference of the *mer* form in the reaction between *S*-arginine and

$[Co(NH_3)_6]^{3+}$. Hence, the importance of a long side-chain with a terminal basic group in an aminocarboxylato ligand for the exceptional stereoselectivity in the complex formation seems to be substantiated.

Shibata *et al.*[7] discussed the stereoselectivity involved in the formation of various bis(aminocarboxylato)diamine and tris(aminocarboxylato) cobalt(III) complexes with special reference to the hydrogen-bond formation between a ligated amino group and the free carboxyl group of *S*-aspartate. If the guanidinium moiety in the tris (arginine)cobalt(III) complex has formed hydrogen bonds with the free oxygen atom of coodinated carboxylate, appreciable stereoselectivity might be brought about. The X-ray structure of tris (arginine)cobalt(III) is not known. However, analogy to the structure of the dinuclear species suggests that the guanidinopropyl moieties on the ligands would be present in the extended form. Hence, the guanidinium group will be situated apart from the coordinated carboxylate, and there will be little possibility of forming hydrogen bonds.

We have thus demonstrated that arginine is a unique aminocarboxylato ligand, coodinated to the cobalt(III) ion in the neutral form, as a zwitter ion, to give a tripositive tris(bidentate)-type complex cation. The ligand can be reckoned as if it has the aminocarboxylate and the guanidinium moiety separately. In the crystalline state their electric charges are individually compensated by the central metal ion and the counter-ions, respectively. A similar structure must be maintained in aqueous solutions, because the electronic absorption and circular dichroism spectra are similar to those of other anionic or neutral tris(aminocarboxylato) complexes of cobalt(III).

(*Received* 6 *June* 1991; *accepted* 24 *July* 1991)

Abstract—The $[Ni(pymep)(N_3)_2]_2 \cdot 2H_2O$ and $[Ni(pymep)(NCS)_2]_2$ compounds [pymep = N-(6-methyl-2-pyridylmethylene)-2-(2-pyridyl) ethylamine] have been synthesized and magnetic susceptibility measurements (3–200 K) show the existence of ferromagnetic exchange interactions in the two complexes, with the following exchange parameters: $J = +21.4$, $D = -7.6$ cm^{-1} (N_3) and $J = +4.8$, $D = -10.4$, $z'J' = 0.3$ cm^{-1} (NCS). Both spectroscopic and magnetic results suggest for the azide complex a dimeric structure with the nickel centres being linked through one-end azide bridges, while for the thiocyanate compound bridging involves an end-to-end thiocyanate mode.

Intramolecular magnetic interactions in transition metal dimers have been extensively studied in the past in order to understand the exchange interaction phenomena.[1] In particular, nickel(II) dimers have been the focal points of several recent magnetic susceptibility studies. Antiferromagnetic exchange interactions as well as ferromagnetic interactions have been found in this kind of complex.[2–4]

N-(6-methyl-2-pyridylmethylene)-2-(2-pyridyl) ethylamine (pymep) is a tridentate ligand which forms mono-complexes with transition metals (metal : ligand ratio 1 : 1) which have been characterized as discrete or polynuclear molecules.[5–7]

The N_3 and NCS pseudohalide groups are known to coordinate metals as terminal or bridging ligands, and inside of this latter category they can act as one-end or end-to-end bridging groups, giving a wide range of magnetic behaviours in the compounds in which they are taking part.

Here we report the synthesis, IR spectroscopy, reflectance spectra, and magnetic properties of the $[Ni(pymep)(X_2)] \cdot nH_2O$ (X = N_3, NCS; $n = 2, 0$) polynuclear compounds.

EXPERIMENTAL

Synthesis of the complexes

The compound $[Ni(pymep)(N_3)_2] \cdot H_2O$ was prepared by adding an excess of a saturated NaN_3 aqueous solution to an aqueous solution containing 0.200 g (0.5 mmol) of the $Ni(pymep)Cl_2 \cdot 2H_2O$ complex, previously prepared (by mixing equimolar amounts of $NiCl_2 \cdot nH_2O$ and pymep ligand in a water/acetone solution). Within a few minutes a yellowish-green solid precipitated, which was isolated after filtration, washed with water, and dried *in vacuo* over P_2O_5 for 48 h. A similar procedure was employed to obtain the $[Ni(pymep)(NCS_2)_2]$ compound, by mixing a saturated KNCS aqueous solution with another containing 0.200 g (0.5 mmol) of the complex $Ni(pymep)Cl_2 \cdot 2H_2O$ dissolved in water. The green precipitate immediately obtained was filtered, washed with water, and dried over P_2O_5 during 48 h. Several attempts to obtain X-ray quality crystals of both compounds were unsuccessful. Found: C, 43.9; N, 32.5; H, 4.5; Ni, 15.1. Calc. for $C_{14}H_{15}N_3NiN_6H_2O$: C, 43.5; N, 32.7; H, 4.4; Ni, 15.2%. Found: C, 47.9; N, 16.8; H, 3.7; Ni, 14.6. Calc. for $C_{14}H_{15}N_3NiN_2C_2S_2$: C, 48.1;

N, 17.0; H, 3.7; Ni, 14.7%. Thermogravimetric analysis show that the water molecule in the azide compound is lost over the range 50–80°C.

Physical measurements

Water was determined thermogravimetrically using a Perkin–Elmer system 7 thermobalance. The IR spectra were recorded, with KBr pellets in the 4000–250 cm^{-1} region, using a Perkin–Elmer 1430 spectrophotometer. Reflectance spectra were recorded on a Perkin–Elmer lambda 9 UV-vis/NIR spectrophotometer. Magnetic susceptibility measurements were carried out on powdered samples in the temperature range 4.2–200 K using a DSM8 susceptometer/magnetometer, in a magnetic field of 0.1 T, a value at which the magnetization vs magnetic field curves were still linear at 4.2 K. The susceptibilities were corrected for the diamagnetism of the constituent atoms [-159.7×10^{-6} cm^3 mol^{-1} (N_3) and -215.2×10^{-6} cm^3 mol^{-1} (NCS)] and for the temperature-independent paramagnetism (TIP), estimated to be 100×10^{-6} cm^3 mol^{-1} per nickel(II) ion.

RESULTS AND DISCUSSION

The IR spectra of both compounds have been analysed paying attention to the bands due to the N_3 and NCS pseudohalide groups. The position in the bands corresponding to the $\nu_{as}(N_3)$ and ν(CN) stretching vibrations of these groups can illustrate its coordination to the metal ions, because its energy depends on the degree of symmetry of these groups. The IR spectrum of the $[Ni(pymep)(N_3)_2]\cdot H_2O$ compound exhibits two bands at 2050 and 2020 cm^{-1} due to the $\nu_{as}(N_3)$ stretching vibrations. The frequencies of these bands are similar to that exhibited by the dimeric $[Ni(terpy)(N_3)_2]_2\cdot 2H_2O$ related compound,[8] which contains two terminal azide groups and two one-end azide bridging groups. The azide symmetric stretch, $\nu_s(N_3)$, is observed at about 1300 cm^{-1} and the two signals at 620, 605 cm^{-1} correspond to the azide bending vibrations (δ). In the IR spectrum of the [Ni(pymep)$(NCS)_2$] compound the bands corresponding to the ν(CN) stretching vibrations appear at 2130 and 2100 cm^{-1}, these high frequencies of the stretching vibrations are very similar to those observed in the related [Ni(terpy)$(NCS)_2$] compound[9] which exhibits normal end-to-end NCS bridges, and quite different to those observed in the related [Cu(paphy)(NCS)(SCN)] complex[10] which exhibits unusual one-end two N-thiocyanate bridging groups. The band corresponding to the ν(CS) stretching vibration appears at 785 cm^{-1} and the δ(NCS) bending mode is observed at 465 cm^{-1}.

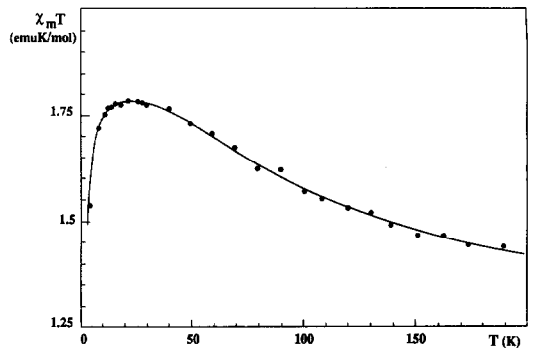

Fig. 1. Thermal evolution of the product $\chi_m T$ for the $[Ni(pymep)(N_3)_2]_2\cdot 2H_2O$ compound.

The reflectance spectra exhibit three bands at 9750, 16,000, 26,000 cm^{-1}, and 10,800, 16,850, 26,000 cm^{-1} for the N_3 and NCS compounds, respectively. These values are in agreement with those given in the literature for octahedral Ni^{II} compounds.[11,12] The bands have been ascribed to $d\rightarrow d$ transitions in a symmetry near to O_h[$^3A_{2g}\rightarrow {}^3T_{2g}$; $^3A_{2g}\rightarrow {}^3T_{1g}$(F); $^3A_{2g}\rightarrow {}^3T_{1g}$(P)]. The calculated[12] nephelauxetic parameters β are 0.81 and 0.85 for the azide and thiocyanate compounds, respectively.

Figures 1 and 2 show the magnetic susceptibility behaviour, represented as the variation of $\chi_m T$ vs T ($\chi_m T = \mu_{eff}^2/8$), for the azide and thiocyanate compounds. The product $\chi_m T$ increases, in both cases, with decreasing temperature reaching a maximum of 1.82 cm^3 K mol^{-1} at 22 K (N_3) and 1.91 cm^3 K mol^{-1} at 5.5 K (NCS), after which it rapidly decreases at lower temperatures. The positive values of the Weiss temperatures ($\theta = +19$ and $+7.7$ K for the azide and thiocyanate complexes, respectively) indicate that the main magnetic interactions are ferromagnetic.

The experimental data were fitted to the analytic

Abbreviations: terpy = 2,2′:6′,2″-terpyridine; pymep = N-(6-methyl-2-pyridylmethylene)-2-(2-pyridyl)ethylamine; en = ethylenediamine; tren = 2,2′,2″-triaminoethylamine; L = 1,5,9-triazacyclododecane. The complexes **1–3** exhibit end-on bridging modes. In the dimers **4–12** the bridges are of end-to-end type.

[b] Magnetic susceptibility data have been analysed using the simple isotropic Heisenberg dimer model assuming a zero-field parameter $D = 0$.

expression given by Ginsberg *et al.*[13] for a magnetically isotropic nickel(II) dimer. This fit allowed us to evaluate the intradimer exchange integral J, the nickel(II) single-ion zero-field splitting D, and the interdimer magnetic exchange J' for both compounds. The solid curves in the $\chi_m T$ vs T representations of Figs 1 and 2 show excellent agreement between observed and calculated values of $\chi_m T$ obtained with the following parameters:

$J = +21.4\ cm^{-1}$; $D = -7.6\ cm^{-1}$;

$Z'J' = 0.0\ cm^{-1}$; $g = 2.19$ (N_3)

$J = +4.8\ cm^{-1}$; $D = -10.4\ cm^{-1}$;

$Z'J' = 0.3\ cm^{-1}$; $g = 2.16$ (NCS).

As is usual in this type of fitting the D and $Z'J'$ parameters are approximated, because their effects are most important in the low-temperature region where the experimental uncertainties are greatest, while the calculated J values appear accurately determined. These behaviours indicate the existence of intradimeric ferromagnetic exchange interactions which increase the $\chi_m T$ values, by population of the ground state $S = 2$, with decreasing temperature in both compounds. The single-ion zero-field splittings cause a depopulation to a diamagnetic ground state and consequently the decrease of the $\chi_m T$ values at lower temperatures.

The values of the J and D parameters obtained for the azide and thiocyanate compounds have been compiled in Table 1 with those corresponding to other related complexes, some of them with known crystal structures. The results of the azide compound are in accord with those observed in the azide-terpy related complex, while those observed in the thiocyanate compound show a good accord with those corresponding to the related thiocyanate-terpy complex (see Table 1).

The above spectroscopic and magnetic results allow us to propose ferromagnetically coupled dimeric structures for both compounds; in the case of the azide complex the nickel centres being linked through one-end azide bridges, while in the thiocyanate compound the metallic centres are linked by an end-to-end thiocyanate mode.

(*Received* 25 *June* 1991; *accepted* 22 *July* 1991)

Abstract—The interaction of molecular hydrogen with $[Rh(PPh_3)_3]^+$ (**1a**) "immobilized" in the interlamellar spaces of montmorillonite resulted in the formation of a monohydrido complex, $[Rh^{II}H(PPh_3)_3]$ (**2a**), characterized by electrochemical data of the clay-loaded electrode, IR, EPR and hydrogen absorption studies. Heterogenized homogeneous catalytic hydrogenation of cyclohexene catalysed by **1a** was investigated in the temperature range 283–313 K. The order of reaction with respect to cyclohexene and hydrogen concentration is fractional and first order with respect to catalyst concentration. Thermodynamic parameters ΔH^0 and ΔS^0 corresponding to the formation of the monohydrido species were found to be 18 kcal mol^{-1} and 61 e.u., respectively. The activation enthalpy, $\Delta H^{\ddagger}$, and entropy, $\Delta S^{\ddagger}$, for the hydrogenation of cyclohexene by the Rh^{II}—H complex in clay are more negative by about 2 kcal mol^{-1} and 7 e.u. compared to Wilkinson's catalyst, $RhCl(PPh_3)_3$ (**1**), in homogeneous solution.

Heterogenized homogeneous catalysis by transition metal ions in the intracrystal matrix of naturally occurring swelling layers of lattice silicates has been the subject matter of extensive studies in recent years.[1–6] A variety of metal complex catalysts can be immobilized in smectite clays.[7] The bound or immobilized complex catalyst is often more selective and reactive than the analogous reaction of the complex in homogeneous solution. The steric requirements of the surface transition states[8] or the position of surface equilibria[9] can provide the basis for enhanced catalytic selectivity. Recently, swelling types of layered silicate clays such as montmorillonite and hectorite have been employed as alternative supports for immobilization of cationic transition metal complexes in the interlayers of clay to study solution-like reactions in the solid state.[10] The hydrogenation of olefins by the cationic rhodium complex $[Rh(COD)(PPh_3)_2]^+$ intercalated in synthetic mica[11] was studied and recently, a heterogeneous, anchored $PdCl_2$ in montmorillonite[12,13] was used for the hydrogenation of styrene and of terminal alkenes and alkynes in ambient conditions. In a previous publication we reported the synthesis and characterization of bound $RhCl(PPh_3)_3$ in montmorillonite[14] and its interaction with molecular oxygen to produce a Rh^{II}-μ-peroxo complex. The present paper describes the formation of a rhodium(II) monohydrido complex $RhH(PPh_3)_3^+$ in the interlamellar space of montmorillonite and the kinetics of the heterogenized homogeneous hydrogenation of cyclohexene by $RhCl(PPh_3)_3$ immobilized in montmorillonite. The reaction for the formation of the Rh^{II}—H complex **2a** is compared with those of the corresponding homogeneous system. Unlike the homogeneous hydrogenation reaction with $RhCl(PPh_3)_3$, where the reaction with molecular hydrogen proceeds through the formation of the well-established dihydrido rhodium(III) complex $Rh(H)_2Cl(PPh_3)_3$ (**2b**) by oxidative addition[15] of hydrogen to **1**, the reaction of **1a** with hydrogen

results in the formation of Rh^{II}—H, possibly through an intermediate Rh^{I}—μH_2—Rh^{I} species.

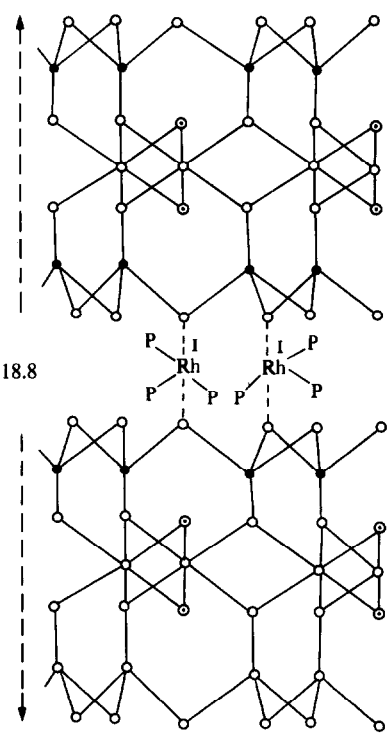
EXPERIMENTAL

Rhodium trichloride was purchased from Johnson Matthey, triphenylphosphine and montmorillonite clay were obtained from Fluka AG. The average chemical composition of the acid-washed montmorillonite, converted to the sodium form by treating with NaOH, used in the present investigation is SiO_2, 70%; Al_2O_3, 15%; Fe_2O_3, 1.5%; CaO, 2.5%; MgO, 3.0%; Na_2O, 0.59%; and K_2O, 1.5% (loss of ignition 6%). All organic solvents used were obtained from BDH and were purified by known methods[16] prior to use. Argon was used for the maintenance of an inert atmosphere and was used without purification. The montmorillonite-bound complex mont-$Rh(PPh_3)_3$ was synthesized and characterized by ^{27}Al, ^{29}Si and ^{31}P solid-state NMR according to published procedures.[14]

The IR spectrum of the clay-bound Rh^{II}-hydrido complex was measured in the form of a pellet on a Perkin–Elmer IR spectrometer. Electrochemical studies on the clay-loaded electrode were conducted with an EG&G Princeton Applied Research Model 174A polarographic analyser, a 175 Universal programmer which was employed with a three-electrode cell assembly of Model 303 SMDE/HMDE and a precision *X–Y* recorder of Model RE 0089. A hanging mercury drop (HMDE) to record sampled DC and differential pulse polarograms (DPP) was used as a working electrode. A medium sized drop of effective surface area 0.017 cm^2 was used at a flow rate 2 s per drop. A glass carbon electrode (GCE) of single surfaced area *ca* 0.012 cm^2 was used as a working electrode. A platinum wire of 0.5 mm diameter as the counter electrode and Ag/AgCl in aqueous tetraethyl ammonium chloride 1 M and SCE as the reference electrode were used. The clay-loaded electrode was prepared according to the published procedure.[17] A slurry of pure clay/mont-$Rh(PPh_3)_3$ (5–15 g dm^{-3}) and PVA (5 g dm^{-3}) in a 1 : 1 water–methanol mixture was prepared and a drop (0.01–0.05 cm^3) of the material spread over a glassy carbon electrode and dried overnight at room temperature. The EPR spectra were recorded on an X-band Bruker ESP-300 spectrometer. The magnetic field calibration was checked with TCNE for a *g* value of 2.0028. Cyclohexene was freshly prepared according to a published method.[16] The experimental details of the hydrogenation reactions are similar to those described in an earlier publication.[18] The concentration of catalyst used was in the range 1.15×10^{-5}–5.85×10^{-5} M and the hydrogen partial pressure varied over the range 0.4–1 atmos. The hydrogenation reactions were carried out in a 7 : 3 benzene–ethanol mixture in the temperature range 283–313 K. The solubility of hydrogen in a 7 : 3 benzene–ethanol mixture was calculated[19] and was considered to be constant for every run at a particular temperature. The rate of absorption of hydrogen was obtained from the tangent of the plot of the number of moles of hydrogen absorbed vs time at the desired reaction condition.

RESULTS AND DISCUSSION

The $Rh(PPh_3)_3$-intercalated clay was characterized by ^{27}Al, ^{29}Si and ^{31}P MAS NMR spectroscopy. The ^{27}Al NMR spectrum of clay gave a peak at 7.87 ppm which is shifted downfield by 1.11 ppm and the peak observed at −99.1 ppm in the ^{29}Si NMR spectrum of clay due to the $Si(O\text{-}Si)_3OAl$ site is shifted downfield by 4 ppm on intercalation. The ^{31}P NMR spectrum gave two doublets centred at 50.5 and −28 ppm for the mont-$Rh(PPh_3)_3$ due to PPh_3 *trans* to each other and PPh_3 *trans* to $Si(O\text{-}Si)_3OAl$, respectively. The complex $RhCl(PPh_3)_3$ undergoes dissociation of Cl^- and is absorbed as the cationic species $Rh(PPh_3)^{3+}$ in the intralamellar region of montmorillonite as shown in Structure I.



Structure I

The stoichiometry of hydrogen absorption was studied manometrically with a slurry of mont-$Rh(PPh_3)_3$ in benzene–ethanol (7:3) solvent at different temperatures. The absorption of hydrogen is very rapid in the beginning and levels off after 30 min. The total amount of hydrogen absorbed, about 1 mol of hydrogen per 2 mol of catalyst corresponds to the stoichiometry:

$$2[Rh(PPh_3)_3]^+ + H_2 \longrightarrow 2[Rh(PPh_3)_3H].$$
$$\textbf{1a} \qquad\qquad \textbf{2a}$$

The formation of the cationic rhodium(II) hydrido complex $[Rh^{II}(PPh_3)_3H]^+$ (**2a**), which is the actual catalytic species in the hydrogenation, was confirmed by IR and EPR spectra of the hydrido complex $[Rh^{II}(PPh_3)_3H]$ (**2a**). The IR spectrum of complex **2a** shows a single peak at 2028 cm^{-1}, confirming (Fig. 1) the formation of a monohydride. In order to ensure the monohydrido species ^2H labelling experiments were carried out for the hydrogenation of the complex using deuterium obtained by the reaction of zinc with DCl in 99.8% D_2O, supplied by Aldrich Chemicals USA. The liberated deuterium was bubbled through the bonded complex **1a** in a montmorillonite suspension in 7:3 benzene–ethanol for 30 min. The deuterated complex was characterized by IR spectroscopy. The IR spectrum clearly shows a single peak at 1480 cm^{-1} which is assigned to the monodeuterido species $RhD(PPh_3)_3^+$. These labelling results confirm the formation of a rhodium(II) monohydride species.

The formation of the monohydride **2a** by the hydrogenation of **1a** is completely different from the hydrogenation of **1** in CH_2Cl_2 which gives the dihydride $Rh(H)_2Cl(PPh_3)_3$ (**2b**). The IR spectrum of the dihydrido species **2b** gives two IR peaks of the dihydride at 2099 and 2065 cm^{-1}. The ^1H NMR of the dihydride gave peaks[20] at −26.8 and −31.25 ppm. Attempts to take the solid-state deuterium NMR of **2a** by conducting deuteration of **1a** by D_2O failed because of the paramagnetism of rhodium(II).

The bonded $[Rh(PPh_3)_3]^+$ (**1a**) complex in montmorillonite after hydrogenation becomes EPR active. At room temperature a broad signal centred at $g_{iso} = 2.3$ was observed. However, at 77 K, the compound gave a signal resolved into three components: $g_1 = 2.49$, $g_2 = 2.34$ and $g_3 = 2.20$ (Fig. 2). The absence of detectable hyperfine coupling to ^{103}Rh suggests very low values of the Rh—H coupling, *ca* 5–10 G. Recently, some of the mixed valent Rh_2^{3+} complexes such as $[Rh_2(\mu\text{-EE}')_2(^t\text{BuNC})(\mu\text{-Z})(PF_6)_2]$ (where EE′ = dppm, dapm, dpam; Z = P_2, 4mP_2, 3,5-dpp, 4-bromo, 3,5-dmp, 3,4,5-tribromo pyrazole = 3,4,5-tP) were reported.[21] The EPR spectra of these complexes showed three g values around 2.02, 2.19 and 2.22 characteristic of an orthorhombic system with hyperfine coupling of 20 G for ^{103}Rh only in the case of $Rh_2(\mu\text{-dppm})_2(^t\text{BuNC})_2(3,4,5\text{-tP})$ at −196°C. The EPR of rhodium(II) observed[21] for the rhodium(II)-μ-peroxo complex in montmorillonite gave $g_\perp = 2.03$, $g_\parallel = 1.98$ with $g_{av} = 2.01$.

Electrochemistry of the clay electrode of complex **1a**

The cyclic voltammetric responses of the clay electrode with mont-$Rh(PPh_3)_3$(**1a**-PVA) in a deaerated solution of phosphate buffer (pH 7) in the absence and presence of hydrogen were recorded. These results are shown in Fig. 3. The reproduciblity of these results was checked at least three times with freshly prepared electrodes. Figures 3(a) and (b) indicate that the pure clay-coated electrode

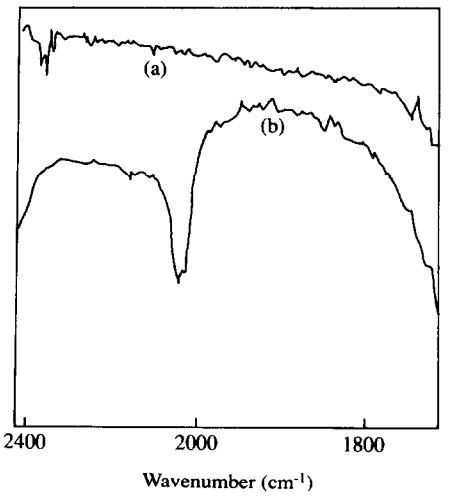


Fig. 1. IR spectrum of mont-$Rh(PPh_3)_3$ (a) before and (b) after hydrogenation.

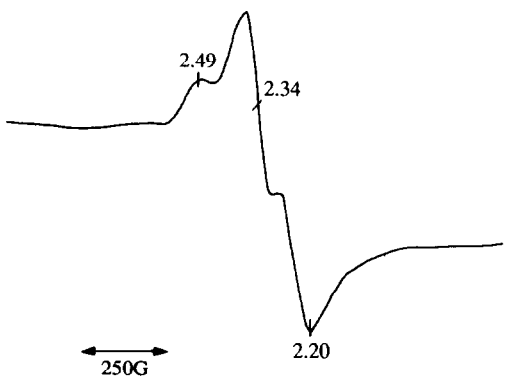

Fig. 2. EPR spectrum of the hydrogenated mont-$[Rh(PPh_3)_3]$ at 77 °K.

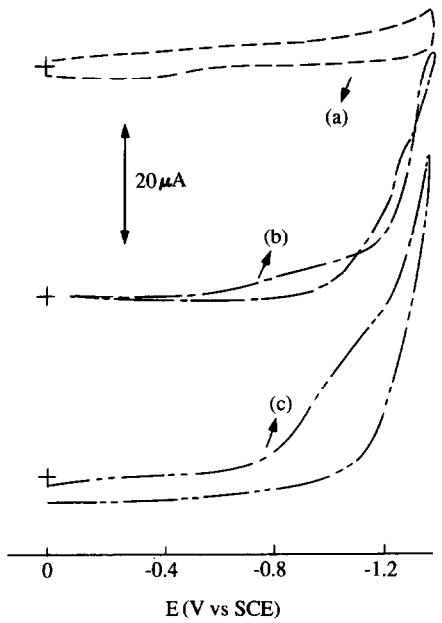

Fig. 3. Cyclic voltammogram of the glassy carbon electrode coated with a thin layer of montmorillonite, (a) and mont-[$Rh(PPh_3)_3$] under nitrogen, (b) and under hydrogen, and (c) in a phosphate buffer of pH 7.

with **1a** under an argon atmosphere did not show any reduction/oxidation step between the potentials 0.0 to −1.2 V. However, the clay-loaded electrode with **1a** under a hydrogen atmosphere showed a single cathodic reduction peak around −1.0 V (Fig. 3c) with no anodic counterpart corresponding to a Rh^{II}/Rh^{I} potential.

In order to bring out the difference in the reaction of hydrogen with **1a** and $RhCl(PPh_3)_3$ (**1**) in homogeneous solution, a solution of Wilkinson's complex (**1**) was prepared in CH_2Cl_2 containing 0.1 M TBAP (tetrabutylammonium perchlorate). The DC and DPP at dme and CV of this solution at HMDE/GCE under an argon atmosphere was recorded. The solution was then purged with hydrogen gas for about 1 h and the electrochemical responses recorded (Fig. 4) again. The solution of complex **1** under an argon atmosphere did not show any electrochemical response at DME or GCE. However, the same solution after hydrogenation showed an anodic wave at −0.1 V (dpp peak potential) and two reduction steps at −0.78 and −1.1 V (Fig. 4a) at the mercury cathode. The cyclic voltammogram (Fig. 4b) at HMDE indicates that the anodic step at −0.1 V was reversible and the reduction steps at −0.78 and −1.1 V were irreversible. This corresponds to the irreversible Rh^{III}/Rh^{II} and Rh^{II}/Rh^{I} couples at 0.78 and −1.1 V, respectively. This confirms the formation of rhodium(II) species in the hydrogenation of **1a**.

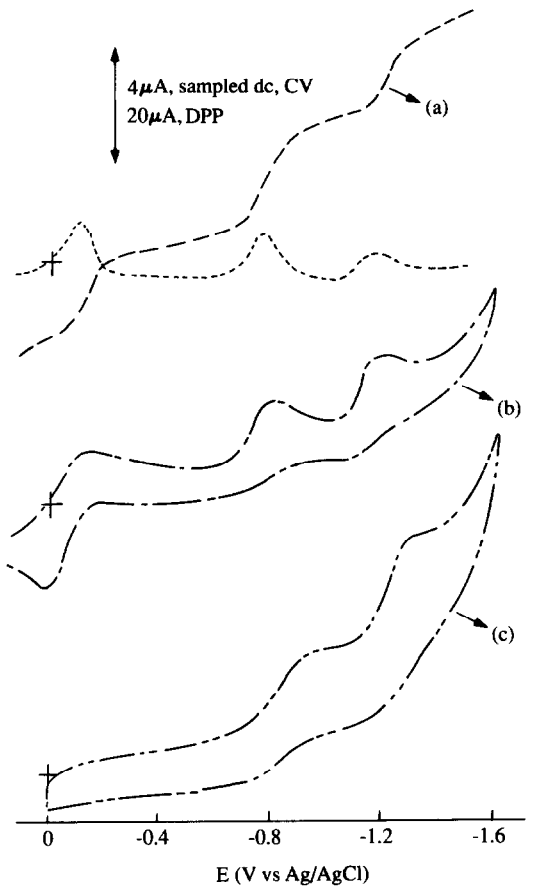

Fig. 4. Electrochemical responses of [$Rh(PPh_3)_3Cl$] (1 mmol) in CH_2Cl_2 under a hydrogen atmosphere. (a) Sampled DC, (b) CV at HMDE, and (c) CV at GCE.

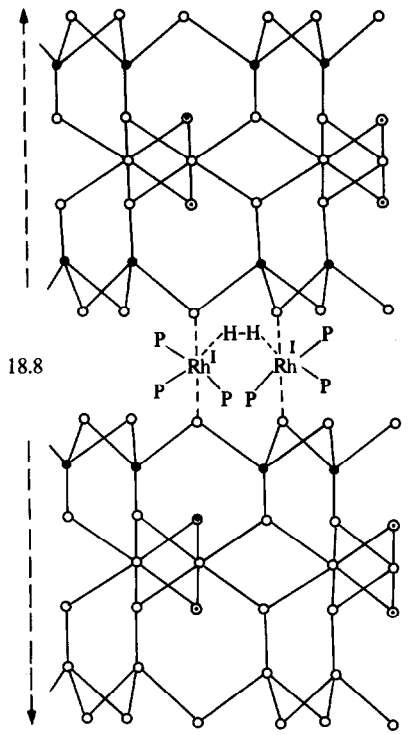
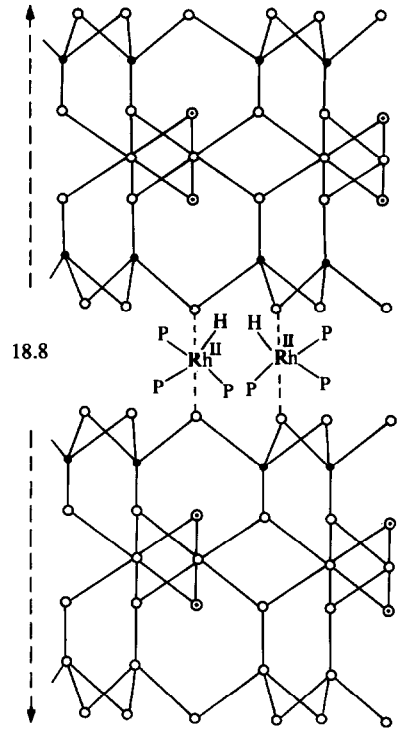
From the above electrochemical, EPR and IR data one can conclude that molecular hydrogen reacts with **1a** in the clay lattice to form the Rh^{II}—H species **2a**. One can speculate on the formation of **2a** from **1a** through the formation of an unstable μ-H_2 complex, [$Rh^{I}(\mu$-$H_2)Rh^{I}$] (Structure II), which then undergoes a cleavage of the H—H bond to give **2a** (Structure III) in a concerted manner. Recently, Collman *et al.*[22] reported this type of (μ-H_2) bonding in cofacial porphyrin ruthenium(II). The ordering of rhodium(I) centres in a clay lattice can easily promote the formation of such an unstable complex which immediately reverts to **2a**. The formation of complex **2a** is reversible. On heating a slurry of complex **2a** at 80°C, the slurry became EPR inactive losing molecular hydrogen and reverting back to the rhodium(I) complex **1a**.

Hydrogenation of cyclohexene catalysed by **1a**

(1) *Dependence of rate of hydrogenation on cyclohexene concentration.* A plot of reciprocal rate



Structure II



Structure III

vs reciprocal cyclohexene concentration at a particular catalyst concentration, temperature and hydrogen pressure is linear with a positive intercept on the ordinate. Figure 5 shows such a plot of 1/rate

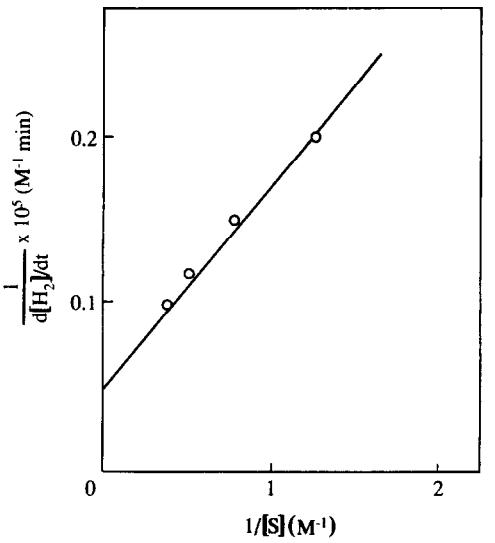


Fig. 5. A plot of $-1/d[H_2]/dt$ vs $1/[S]$.

vs 1/[cyclohexene] at 20°C and 1 atmos. of hydrogen pressure. This plot indicates that the observed rate of hydrogenation is of fractional order with respect to cyclohexane concentration and is related to the same by the following equation:

$$\frac{1}{R} = a\frac{1}{[S]} + b;$$

where R = rate, [S] is the concentration of cyclohexene a and b are the slope and intercept of the plot of 1/R vs 1/[S]. Similar types of plots were obtained at other temperatures studied: 10, 30 and 40°C.

(2) *Dependence of rate on hydrogen concentration.* Figure 6 shows the dependence of the rate of hydrogenation of cyclohexene on the concentration of

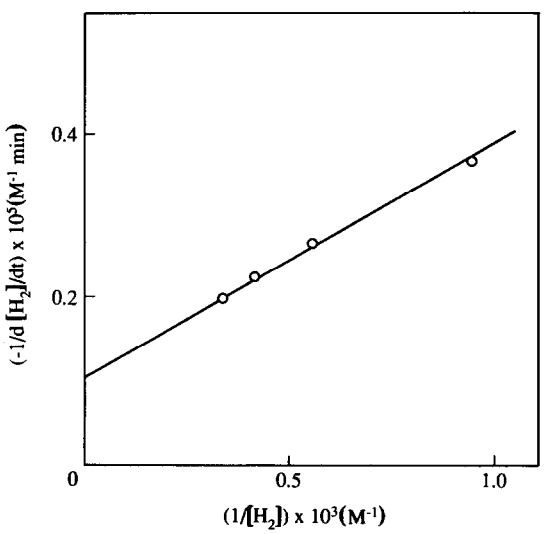

Fig. 6. A plot of $-1/d[H_2]/dt$ vs $1/[H_2]$.

molecular hydrogen in solution at 20°C. The rate was found to be of fractional order. Similar types of plots were obtained at the different temperatures studied.

(3) *Dependence of rate on catalyst concentrations.* The dependence of the rate of hydrogenation of cyclohexene on catalyst concentration was studied by adding a calculated quantity of mont-$Rh(PPh_3)_3$ (**1a**) to the reaction mixture. A first-order dependence on catalyst concentration was observed at 20°C. Similar plots were obtained at the different temperatures studied.

(4) *Dependence of rate on temperature.* The rate of hydrogenation of cyclohexene was measured in the temperature range 10–40°C at 1 atmos. of hydrogen pressure. Linear plots were obtained in all cases, the slope of which is equal to $-(E_a/2.303R)$. Based on the above rate data, stoichiometry of hydrogen absorption and EPR and electrochemical studies, the following mechanism was proposed for the catalytic hydrogenation of olefins:

$$2[Rh(PPh_3)_3]^+ + H_2 \overset{K_1}{\rightleftharpoons} 2[Rh(PPh_3)_3(H)]$$
1a **2a**

K_2 ⇕ S ; k' ↓ [2S]

$$2[Rh(PPh_3)_3(S)]^+ \xrightarrow[H_2]{k''} 2[Rh(PPh_3)_3(H)(S)]$$
4 **3**

↓ fast

$$2[Rh(PPh_3)_3]^+ + \text{Paraffin}$$
5

where S = cyclohexene. In the mechanism proposed, the complex mont-$Rh(PPh_3)_3$ (**1a**) interacts with hydrogen in a pre-equilibrium step K_1 to form the monohydrido rhodium(II) complex **2a**. The EPR and electrochemical studies support the formation of **2a**, Rh^{II}—H. The rhodium(II) hydride **2a** interacts with the substrate cyclohexene in the rate-determining step to form a mixed ligand metal–olefin–hydrido complex (**3**). The formation of **3** is also possible by the interaction of **1a** wth an olefin to form a metal–olefin complex (**4**) in another equilibrium step K_2. Species **4** reacts with molecular hydrogen in another rate-determining step k'' to form the metal–olefin hydrido species **3**. Therefore, the rate-determining step of the reaction involves the formation of the mixed ligand olefin complex **3**, which then transfers a hydrogen atom in a fast step to the coordinated olefin to form the paraffin and catalytically active species **1a**. The metal–olefin complex **4** synthesized separately was found to be inactive in the activation of molecular hydrogen. The alternative pathway k'' is therefore not operative.

From the mechanism proposed for the hydrogenation of cyclohexene a rate law for the reaction can be derived as:

$$-d[H_2]/dt = \frac{k'K_1[H_2][C][S]}{(1+K_1[H_2])(1+K_2[S])}. \quad (1)$$

The above equation can be rearranged in two forms as follows:

$$\frac{1}{-d[H_2]/dt} = \frac{1+K_1[H_2]}{k'K_1[H_2][C][S]} + \frac{1+K_1[H_2]}{k'K_1[H_2][C]} \times K_2 \quad (2)$$

or

$$\frac{1}{-d[H_2]/dt} = \frac{1+K_2[S]}{k'K_2[S][C][H_2]} + \frac{1+K_2[S]}{k'K_2[S][C]} \times K_2. \quad (3)$$

Plots of reciprocal rate vs 1/[S] [eq. (2) Fig. 5] and reciprocal of rate vs $1/[H_2]$ [Fig. 6, eq. (3)] gave straight lines from which the values of K_1 and K_2 were computed, respectively. Substituting the values of K_1 and K_2 in eq. (1), the values of the rate constant k' were calculated at different temperatures. The data are presented in Table 1.

The enthalpy of formation ($\Delta H^{\ominus}$) corresponding to the equilibrium constants K_1 and K_2 were evaluated from the slopes of the plots of $\log K_1$ or K_2 vs $1/T$ and presented in Table 2. Gibb's free energy was calculated from the equation:

$$\Delta G^{\ominus} = -2.303RT \log K. \quad (4)$$

$\Delta S^{\ominus}$ was obtained from the relationship:

$$\Delta S^{\ominus} = \frac{\Delta H^{\ominus} - \Delta G^{\ominus}}{T}. \quad (5)$$

The activation parameter E_a was calculated from the slopes of the plots of $\log k'$ vs $1/T$. The par-

Table 1. Equilibrium and kinetic data for the catalytic hydrogenation of cyclohexene catalysed by mont-$Rh(PPh_3)_3$

Temperature (K)	K_1 (M^{-1})	K_2 (M^{-1})	K' ($M^{-1}\,min^{-1}$)
283	294.5	0.22	1.99
293	408.2	0.33	11.48
303	844.6	0.40	18.19
313	1412.5	0.55	26.91

ameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ were obtained from the following equations.

$$\Delta H^{\ddagger} = E_a - RT \quad (6)$$

$$2.303 \log k' = 2.303 \log \frac{RT}{Nh} + \frac{\Delta S^{\ddagger}}{R} - \frac{\Delta H^{\ddagger}}{RT}; \quad (7)$$

where N is Avagadro's number, h is Planck's constant and R is the gas constant.

The thermodynamic parameters corresponding to the formation of the hydrido species are presented in Table 2. The activation parameters corresponding to the rate constant k' are presented in Table 3. The enthalpy ($\Delta H^{\ominus}$) of the formation of the hydrido complex mont-RhH(PPh_3)$_3$ (**2a**) of 18 kcal mol^{-1} is more endothermic than that of the dihydrido[20] complex Rh(H)$_2$Cl(PPh_3)$_3$ (**2b**) (15 kcal mol^{-1}).

The free energy of the hydride complex formation ($\Delta G^{\ominus}$) also shows a decrease for the formation of the dihydrido species **2b** which is much more stable than **2a**. The monohydride is only possible in a clay matrix which is properly oriented to provide formation of a μ-hydrogen complex (Rh^{I}—H_2—Rh^{I}) and its subsequent homolytic cleavage to **2a**. As expected the entropy is highly negative for the formation of **2a** as compared to **2b**. The thermodynamic parameters for the formation of the olefin complex Rh^{I}(olefin) both for **1a** and **1** are about the same indicating no particular preference of the binding of olefins in a clay matrix.

The stable hydrido complex in solution reacts with the olefin to form the mixed ligand–olefin complex. This complex may be considered to be formed either by the reaction of the hydrido complex with the olefin (k') or the interaction of hydrogen with the olefin complex (k''). The latter route had been ruled out on the basis of kinetic evidence of a fractional-order dependence on both substrate and hydrogen concentration. The activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are given in Table 3. The difference in the reactivities of the complexes towards hydrogenation of cyclohexene in homogeneous and heterogenized homogeneous cases may be sought in the ease of formation of the mixed ligand hydrido–olefin complex in clay and subsequent fast insertion of the olefin into the M—H bond. The enthalpy of activation ($\Delta H^{\ddagger}$) is about 2 kcal mol^{-1} more negative than the homogeneous hydrogenation[20] involving **1**, indicating the ease of cleavage of the H—H bond in a 2:1 complex (Rh^{I}—H_2—Rh^{I}) rather than a 1:1 complex η^2-H_2—Rh^{I}.

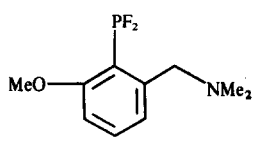
(*Received* 25 *March* 1991; *accepted* 22 *July* 1991)

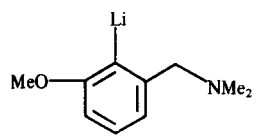
Abstract—2-Dimethylaminomethyl-6-methoxyphenyldifluorophosphine, **1** was prepared from 2-dimethylaminomethyl-6-methoxyphenyllithium and PF_2Cl. The ^{19}F and ^{31}P NMR parameters of **1** showed significant differences from those of other aryldifluorophosphines, and it is suggested that an intramolecular donor–acceptor interaction exists between the nitrogen atom of the NMe_2 group and the trivalent phosphorus atom. Strong non-bonding P–N-interactions have also been observed for a coordination compound of **1** with platinum(II), $[2\text{-}Me_2NCH_2\text{-}6\text{-}MeOC_6H_3PF_2]_2PtCl_2$, **7**, for which a single crystal X-ray diffraction study is reported.

Difluorophosphines have long been known to function as excellent donors in transition metal complexes.[1] They resemble phosphorus trifluoride and, to some extent, carbon monoxide in their donor properties towards transition metals. By contrast, the acceptor character of phosphorus trifluoride (and, presumably, of difluorophosphines, RPF_2, with R = hydrocarbon group) is much less pronounced. A donor–acceptor complex, $Me_3N \cdot PF_3$ (vapour pressure at −78.5°C, 8.0 mm), has been reported.[2] In the present paper we describe the synthesis and NMR characterization of an aromatic difluorophosphine whose phosphorus atom apparently displays both donor and acceptor properties. Furthermore, the synthesis and single crystal X-ray structure determination of a Pt^{II} complex of this difluorophosphine are reported.

The synthesis of the difluorophosphine **1**



1

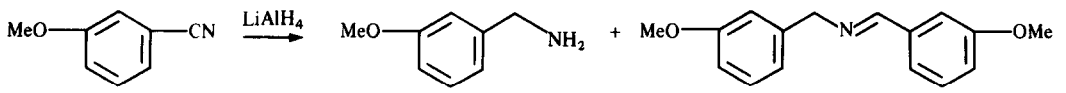


2

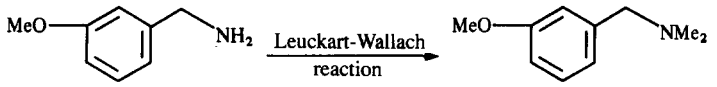
followed the previously described route.[3] The preparation of the required 1-lithio precursor compound, **2** was based on the following sequence [eqs (1) and (2)].

* Dedicated to Dr Herbert Naarmann (BASF AG, Ludwigshafen) on the occasion of his 60th birthday.

† Author to whom correspondence should be addressed.



(1)

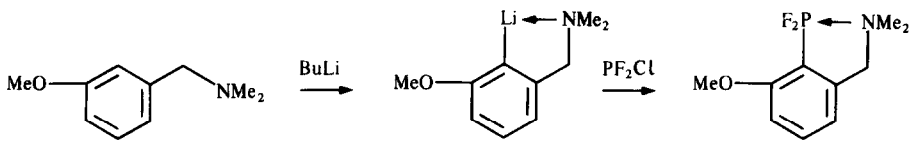


(2)

It should be noted that the $LiAlH_4$ reduction of **3** produced not only the desired amine **4** but also the Schiff base derivative **5**, originating, formally, from the reaction of **4** and 3-methoxybenzaldehyde.

4 was converted to **6** in a Leuckart–Wallach type reaction.[5]

The aromatic difluorophosphine, **1**, was synthesized by lithiation of **6**, followed by reaction of the lithio derivative **2** with PF_2Cl [eq. (3)].



(3)

The difluorophosphine **1** is a thermally unstable oil, which could not be purified by distillation. The compound was not isolated and was characterized as the crude product by ^{19}F and ^{31}P NMR spectroscopy only.

As a result of an apparent interaction between the nitrogen atom in the side chain and phosphorus, the δ_P and $^1J(PF)$ values of **1** deviate significantly [high-field shift of δ_P, decrease in $^1J(PF)$] from the values of other aryldifluorophosphines,[3]

$$\delta_P + 166 \text{ ppm}; \quad {}^1J(PF)\ 1081 \text{ Hz}.$$

These parameters usually fall in the ranges $\delta_P + 190$ to $+220$ ppm and $^1J(PF)$ 1180 ± 30 Hz.[3] The spontaneous redox disproportionation characteristic of many difluorophosphines[4] was not observed for **1**. We believe this to be associated with intramolecular, rather than intermolecular interactions, i.e. N—P instead of P—P.

The reaction of crude **1** with dichloro-(η^4-1,5-cyclooctadiene), $Cl_2Pt(COD)$platinum(II) (COD = cyclooctadiene)furnished the complex, **7** [eq. (4)],

$$Cl_2Pt(COD) + 2\ 2\text{-}Me_2NCH_2\text{-}6\text{-}MeOC_6H_3PF_2 \longrightarrow \underset{\mathbf{1}}{}$$

$$Cl_2Pt(2\text{-}Me_2NCH_2\text{-}6\text{-}MeOC_6H_3PF_2)_2 + COD. \quad (4)$$
$$\mathbf{7}$$

Because of its poor solubility in common organic solvents, the characterization of **7** by NMR spectroscopy was unsatisfactory. A single crystal X-ray structural study of **7** was therefore conducted.

The X-ray crystal structure determination of **7** indicates a strong attractive interaction between phosphorus and nitrogen in the difluorophosphine ligand. The bonding geometry around the central platinum atom is essentially planar (sum of the bond angles around platinum = 360.6°). The bond lengths of platinum to phosphorus and to chlorine are normal. As is observed in other *cis*-dichlorobis(phosphine)platinum(II) complexes, the Cl—Pt—Cl bond angle is smaller than 90° (88.4°) whereas the P—Pt—P bond angle is significantly larger (P—Pt—P 94.0°).

An analysis of the non-bonding distances reveals that there is a non-bonding interaction between phosphorus and nitrogen in the coordinated difluorophosphine (248.7 pm, as against the sum of the van der Waals radii of 335 pm[6]). This donor–acceptor interaction causes a pronounced distortion of the tetrahedral geometry around phos-

C(20)—N(18)—C(18)	111.7(13)	C(20)—N(18)—C(19)	109.6(14)

phorus in the direction of a trigonal bipyramid. This can clearly be seen by comparing bond angles that should be equivalent for tetrahedral geometry (109.5°) but are expected to be different for the trigonal bipyramid (90°, 120°);

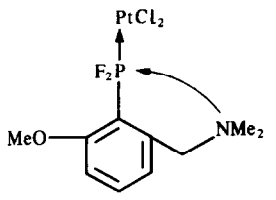
F(1)—P—Pt 117.6° F(2)—P—Pt 105.1°

F(1)—P—C(11) 107.9° F(2)—P—C(11) 97.3°.

From these values it can be seen that F(2) is located in a pseudo-axial position whereas F(1) occupies a pseudo-equatorial position at trigonal-bipyramidal phosphorus.

In addition to this attractive interaction between phosphorus and nitrogen, the phosphorus atom is forced into close contact with the two *ortho* substituent atoms (P···O(12) 296.0 ppm; P···C(18) 302.2 ppm). Bond lengths and angles for **7** are listed in Table 1.

The molecule displays crystallographic C_2 symmetry. Because of the observed pseudo-penta-coordination of the phosphorus atom of the coordinated fluorophosphine in the solid state, the resultant



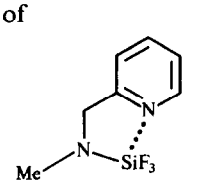
7

λ^5P^{III} moiety represents a chiral unit. The five-membered ring in **7** occupies one axial and one equatorial position at trigonal–bipyramidal phosphorus,[7] and the remaining axial position is occupied by a fluorine atom (see e.g. ref. 8). **7** is found to be present as one of three conceivable stereoisomers (at platinum), as illustrated in Fig. 2.

We believe that for steric reasons (interactions between the bulky NMe_2 groups in **C**) only enantiomers **A** and **B** (and not the diastereomer **C**) form stable crystals.

The N···P interaction in solutions of **7** is weak and it is impossible to establish it unambiguously solely by NMR spectroscopy. It must further be noted that there is a change of symmetry of the chiral compound upon breaking the N···P interaction, giving rise to different diastereomers.

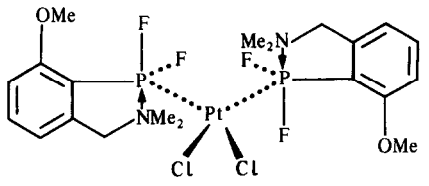
The dynamic stereochemistry of **7** should resemble that, e.g. of



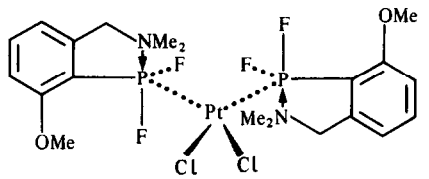
observed by Klebe,[9] and discussed more generally in a review by Corriu and Guerin.[10]

EXPERIMENTAL

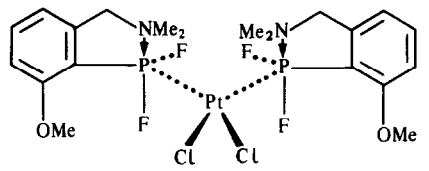
The usual precautions required in handling air- and moisture-sensitive substances were observed in



(A)



(B)



(C)

Fig. 2. Proposed diastereomers of **7**, A–C.

the course of the experimental work. Solvents were purified by standard procedures.[11] Magnetic stirring was employed throughout.

NMR spectra were recorded on the instruments BRUKER AM 200, BRUKER AM 300, and BRUKER AC 400 in $CDCl_3$ as a solvent. Shift values (positive sign for downfield shifts, negative sign for highfield shifts) are given, relative to the following reference compounds: int. TMS (^1H); $CDCl_3$ = 77.05; the multiplicity refers to proton-coupled ^{13}C NMR spectra (^{13}C); ext. CCl_3F (^{19}F); ext. 85% H_3PO_4 (^{31}P).

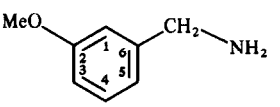
Starting materials: 3-Methoxybenzonitrile: ALDRICH CHEMICAL Co.; *n*-butyllithium: CHEMETALL GmbH; PF_2Cl;[13] $(COD)PtCl_2$.[14]

Synthesis of 3-*methoxybenzylamine*, **4** (*and of the Schiff base* **5**)

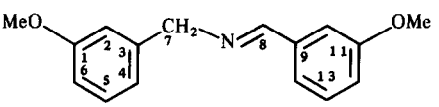
3-Methoxybenzonitrile, **3** (51.0 g; 0.38 mole) was added dropwise with stirring over 1 h to a suspension of 7.6 g (0.20 mole) of lithium aluminium hydride in 200 cm^3 of ether. Stirring was continued at room temperature for 14 h and at reflux for 1 h. About 50 cm^3 of water was cautiously added (0.5 h), followed by aluminium oxide (Woelm Grade A; 15 g). Subsequently, the reaction mixture was filtered through a sintered glass disc. The solid residue was washed with a total of 500 cm^3 of ether (in 100 cm^3 portions). The combined liquid products were concentrated *in vacuo*, and were finally distilled *in vacuo* (Vigreux column). The products, **4** (b.p. 131°C/26 mm; 27.4 g, 52%), and **5** (b.p. 231–232°C/5.5 mm; 10.6 g, 22%) were obtained as colourless liquids.

Compound **4** has previously been reported,[12] and was characterized by ^1H and ^{13}C NMR spectroscopy only:

^1H (300 MHz): δ (aromat.) 7.20 ("t", ^3J(HH) 8 Hz, 1H); δ(H1, 5) 6.86–6.82 (m, 2H); δ(H3) 6.75 ("d", ^3J(HH) 8 and 2.5 Hz, 1H); $\delta(CH_2)$ 3.76 (s, 2H); δ(MeO) 3.75 (s, 3H); $\delta(NH_2)$ 1.46 (exchangeable with D_2O). ^{13}C (75.5 MHz): δ(1) 112.3 (d); δ(2) 159.4 (s); δ(3) 111.8 (d); δ(4) 129.1 (d); δ(5) 118.9 (d); δ(6) 144.8 (s); δ(MeO) 54.7 (q); $\delta(CH_2)$ 46.1.



4



5

Compound **5**: $C_{16}H_{17}NO_2$ (255.3).
Found: C, 75.6; H, 7.3; N, 5.6.
Calc.: C, 75.3; H, 6.7; N, 5.5%.

^1H NMR (400 MHz): δ(H8) 8.27 ("s", 1H); δ(H aromat.) 7.37 ("s", 1H); 7.26 (m, 2H); 7.22 ("t", ^3J(HH) 7.5 Hz, 1H); 6.96–6.87 (m, 3H); 6.76 ("d", ^3J(HH) 7.5 Hz, 1H), $\delta(CH_2)$ 4.73 (s, 2H); δ(MeO) 3.74 (s, 3H); 3.73 (s, 3H).

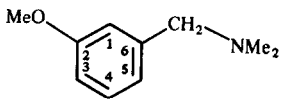
^{13}C (100 MHz): δ(C1, 11) 159.5, 159.4 (s); δ(C3) 140.6 (s); δ(C5, 13) 129.1, 129.0 (d); δ(C6, 12) 111.5, 111.9 (d); δ(C7) 64.3 (t); δ(C8) 161.3 (d); δ(C9) 137.3 (s); δ(C15.16) 54.6, 54.5 (q); δ(C2, 4, 10, 14) 121.0, 119.8, 116.8, 113.3 (d).

Leuckart–Wallach-reaction of **4**: *preparation of* **6**

A mixture of **4** (27.4 g; 0.2 mole) and formic acid (46.0 g; 1 mole) was prepared with cooling (ice bath) in a r.b. flask, fitted with a reflux condenser and a dropping funnel. Subsequently, 44 cm^3 of a 30% aqueous solution of formaldehyde (0.44 mole)

was added, and the reaction mixture was stirred with gentle heating.

A vigorous reaction ensued, accompanied by evolution of CO_2, and heating was temporarily suspended (*ca* 15 min). After a 7 h reflux period the reaction mixture was left at room temperature for 15 h. Concentrated HCl (40 cm^3) was added to the yellow reaction mixture with ice cooling. Subsequently the mixture was pumped to dryness (20 mm). The residue was dissolved in a solution of 15 g NaOH in 50 cm^3 of water, cooled with ice. This solution was extracted five times with 120 cm^3 portions of ether. The organic layer was dried over K_2CO_3, and was distilled *in vacuo*; b.p. 95–96°C/6.50 mm; yield of **6**, 31.3 g (95%).



6

$C_{10}H_{15}NO$ (165.23).
Found: C, 72.9; H, 9.1; N, 8.3.
Calc.: C, 72.7; H, 9.1; N, 8.5%.

^{1}H NMR spectrum (400 MHz): δ(4) 7.20 ("t", ^3J(HH) 8.0, 1H); δ(1, 5) 6.89–6.86 (m, 2H); δ(3) 6.78 ("dd", ^3J(HH) 8.0; ^4J(HH) 2.5, 1.0, 1H); δ(OMe) 3.78 (s, 3H); $\delta(CH_2)$ 3.38 (s, 2H); $\delta(NMe_2)$ 2.24 (s, 6H).

Synthesis of 2-dimethylaminomethyl-6-methoxyphenyl-difluorophosphine, **1**

A mixture of 40 cm^3 of ether, 5.0 g (0.03 mole) of 3-methoxy-N,N′-dimethylbenzylamine, **6**, and of 11.5 g (*ca* 0.027 mole) of *n*-butyllithium (15% in hexane) was stirred in a heavy-wall glass tube, fitted with a TEFLON® stopcock, for 20 h at room temperature. Subsequently, PF_2Cl[13] (3.6 g; 0.035 mole) was condensed onto the reaction mixture at −196°C. The reaction tube was sealed, and its contents were stirred for 12 h at room temperature. Products volatile at room temperature *in vacuo* (0.01 mm) were pumped off (0.5 h) and dichloromethane (50 cm^3) was added to the residue. Lithium chloride was removed by centrifugation, and the NMR spectra of the supernatant liquid were recorded. The yield of **1** (estimated from the CH_2 resonance in the ^{1}H NMR spectrum) was *ca* 1 g (14%).

^{19}F NMR data: δ −95.2 ppm; ^1J(PF) 1069 Hz; ^{31}P NMR data: δ +166 ppm; ^1J(PF) 1081 Hz.

Synthesis of the platinum(II) complex, **7**

The difluorophosphine, **1** (0.7 g; 3.1 mole) was added to a solution of 0.5 g (1.34 mmole) of $Cl_2Pt(COD)$[14] in 40 cm^3 of dichloromethane. The crystalline product formed after 2 days was collected by filtration, and was washed with 10 cm^3 of dichloromethane. Yield 0.42 g (42%); m.p. 194–195°C. $C_{20}H_{28}Cl_2F_4O_4P_2Pt$ (732.4). Found: C, 32.9; H, 3.8; P, 8.5. Calc.: C, 32.8; H, 3.8; P, 8.4%.

^{1}H NMR spectrum (400 MHz; CD_2Cl_2 solution): δ(aromat.) 7.45 ("q", J 8 Hz, 2H); 7.11 ("dt", J 6, 8 Hz, 2H); 6.92–6.83 (m, 2H); $\delta(CH_2)$ 4.61–4.41 (m, 4H); δ(MeO) 4.03 and 3.97 (two s, 6H); $\delta(NMe_2)$ 3.0–2.6 (m, 12H; the multiplet comprises three doublets in the ratio 3 : 2 : 1, all J 6 Hz.

X-ray crystal structure analysis of **7**

Crystals of **7**, obtained from dichloromethane, are of tetragonal symmetry; space group $P4_32_12$. The unit cell, with the parameters, a = 825.4 (6); c = 3697.3 (33) pm, contains four molecules, yielding a calculated density of 1.931 g/cm^3. The data were collected at 20°C on a SYNTEX $P2_1$ diffractometer, using graphite-monochromated Mo-K_α radiation (λ = 71.07 pm) in the $\theta-2\theta$ mode, in the range $3° < 2\theta < 50°$, at a scan speed ranging between 2.93 and 29.3°/min, depending on the intensity of the reflection.

The data were corrected for Lorentz, polarization, and absorption effects (μ = 6.337 mm^{-1}). The structure was solved by direct methods and difference Fourier syntheses. Hydrogen atom positions were calculated from those of the directly bound atoms and were refined as "riding atoms". The refinement, using 2183 out of 2765 measured independent reflections [$F > 4.0\ \delta(F)$] converged at R = 0.061 (R_w = 0.058). A final difference map displayed no electron density higher than $0.25 \cdot 10^{-6}$ e/pm^3. The program SHELX-76[15] and our own programs were used. Complex atom scattering factors[16] were employed.

Acknowledgements—We are grateful to BASF AG, BAYER AG, CHEMETALL GmbH, DEGUSSA AG, and HOECHST AG for gifts of chemicals used in this research, and to Fonds der Chemischen Industrie for financial support. Professor L. Ernst is thanked for recording NMR spectra. L.H. acknowledges a maintenance grant awarded by Land Niedersachsen.

(*Received* 18 *February* 1991; *accepted* 22 *July* 1991)

Abstract—Two novel heterometallic trinuclear incomplete cubane-like clusters $[(CH_3CH_2)_4N][\{M_2CuS_4\}(edt)_2(PPh_3)]$ (M = Mo, W) have been synthesized by reaction of $[(CH_3CH_2)_4N]_2[M_2S_4(edt)_2]$ (M = Mo, W) with $Cu(PPh_3)_2(dtp)$ [where edt is 1,2-ethanedithiolato ligand, dtp is $S_2P(OCH_2CH_3)_2^-$]. The two crystals are isomorphous in space group $P\bar{1}$ (No. 1). The unit cell contains two independent molecules, but the two discrete anions have the same orientation for the PPh_3 ligands along one axis so the space group is undoubtedly non-centrosymmetric. The discrete anion contains two edt ligands and one PPh_3 ligand attached to one incomplete cubane-like cluster core $\{M_2CuS_4\}^{3+}$ (M = Mo, W). The bond lengths of Mo—Mo[W—W] and the two Mo—Cu[W—Cu] are 2.852(2)[2.844(1)], 2.802(2)[2.765(3)], 2.760(2)[2.762(3)] Å, respectively. The $M_2S_4(edt)_2$ (M = Mo, W) moiety remains almost unchanged, except that for the compound **1** the Mo=S double bond length elongates from av. 2.10 to av. 2.165 Å. The title clusters provide a new type of unsymmetric μ_2-bridging sulphido ligand. The incomplete cubane-like cluster core $\{Mo_2CuS_4\}^{3+}$ of compound **1** is distorted because the two Cu—μ_2—S bond lengths are significantly different (2.313 Å and 2.409 Å), but the core $\{W_2CuS_4\}^{3+}$ of compound **2** has approximately C_s symmetry. The IR spectra of the two title clusters and two starting materials are assigned.

In recent years, three aspects of the synthetic and structural chemistry of transition metal clusters containing sulphido ligand(s) have developed rapidly.[1–3] (1) In bioinorganic chemistry, research on the synthetic analogue $[Fe_4S_4(SR)_4]^{2-}$ [4] of the redox sites of iron-sulphido proteins has stimulated research on other analogues of active sites of metal enzymes,[5–7] for example the Mo-containing enzymes, and on the Mo—Cu antagonism;[8] (2) research on the catalysts of hydrodesulphurization (HDS) has also prompted the development of transition metal sulphido clusters;[9–11] (3) study of superconductive materials has also attracted interest in transition metal sulphido clusters.[12]

A large number of heterometallic cubane-like clusters containing sulphido ligand(s) have been synthesized, such as $\{M_3CuS_4\}^{5+}$,[13,14] $\{Mo_3FeS_4\}^{4+}$,[15] $\{M_2Cu_2S_4\}^{4+}$,[16] $\{M_2Co_2S_4\}^{2+}$,[17] $\{MFe_3S_4\}^{n+}$,[18] $\{MCu_3S_3X\}$[19,20] (M = Mo, W; X = Cl, Br; n = 2, 3, 4, 5, 6), etc., by various methods. The research on homometallic trinuclear incomplete cubane-like clusters is extensive,[21,22] but research on heterometallic incomplete cubane-like clusters is only beginning.

We have proposed that the "unit-construction"[23] is a convenient method for the rational synthesis of transition metal clusters by the use of reactive fragments as building blocks. It was shown that the "unit", which contains sulphido ligand(s) with lone-pair electrons and unsaturated coordination, may add to another metal complex which has initial unsaturated coordination positions or easily displaceable ligand(s). To use the cluster containing active sulphido ligands with lone-pair electrons and unsaturated coordination as a starting material is a rational method. Recently, we have succeeded in employing triangular trinuclear incomplete cubane-like core clusters $[M_3S_4][S_2P(OCH_2CH_3)_2]_4 \cdot H_2O$

($M = Mo$[21f], W[24]) to obtain a series of cubane-like core $\{M_3CuS_4\}^{5+}$ ($M = Mo$[13], W[14]) clusters.

According to the idea of "unit construction", the title compounds are a successful addition by using $[M_2S_4(edt)_2]^{2-}$[25] (M = Mo, W) and $Cu(PPh_3)^+$ as building blocks. In this paper, we report in detail the synthesis and characterization of the previously communicated $[(CH_3CH_2)_4N]\{M_2CuS_4\}(S_2C_2H_4)_2(PPh_3)$[26] ($M$ = Mo, W). In the communicated paper the crystal structure of the W complex was not reported.

EXPERIMENTAL

Synthesis

The chemicals in this research were used as purchased. The dinuclear complexes $[Et_4N]_2M_2S_4(edt)_2$ (M = Mo, W) were prepared under a dinitrogen atmosphere according to the procedure of Stiefel *et al.*[25] Elemental analysis were carried out by the Elemental Analysis Laboratories of our Institute. Visible and UV electronic spectra were obtained on a Schimadzu UV-3000 spectrophotometer. IR spectra were recorded on Perkin–Elmer 577 spectrometer.

$Cu(PPh_3)_2[S_2P(OCH_2CH_3)_2]$: Triphenylphosphine (94.32 g, 0.323 mol) dissolved in 250 cm^3 CH_2Cl_2 solution was added slowly to a solution of $CuCl_2\cdot 2H_2O$ (20.4 g, 0.120 mol) in 200 cm^3 of EtOH to obtain a solution. Solid P_2S_5 (13.32 g, 0.060 mol) was dissolved in 100 cm^3 of EtOH (warmed up to increase the dissolution of the solid), the resultant solution was then added slowly to the above Cu/PPh_3 solution. The resultant solution was allowed to stand for 4 h, then filtered, and the crystals were washed with EtOH and ether and air-dried. Yield: 84.5 g (92.1%). Found: Cu, 8.7; S, 7.8; P, 12.5; C, 61.8; H, 5.1. Calc. for $CuS_2P_3OC_{40}H_{40}$: Cu, 8.2; S, 8.3; P, 12.0; C, 62.1; H, 5.2%.

$[Et_4N]\{Mo_2CuS_4\}(edt)_2(PPh_3)$ (**1**): $Cu(PPh_3)_2[S_2P(OCH_2CH_3)_2]$ (3.85 g, 5 mmol) dissolved in 50 cm^3 of CH_2Cl_2 was added to a solution of $[Et_4N]_2Mo_2S_4(edt)_2$ (3.80 g, 5 mmol) in 200 cm^3 of CH_3CN, stirred and filtered. The filtrate was allowed to evaporate in air. After standing for 1.5 h, brown–red needle-shaped crystals formed, which were isolated by filtration and washed with isopropanol and ether. Yield 3.27 g (68.9%) analytically pure crystals which were suitable for X-ray measurements. Found: Mo, 19.7; Cu, 6.9; S, 26.3; C, 38.0; N, 2.1; H, 4.8. Calc. for $Mo_2CuS_8PNC_{30}H_{43}$: Mo, 20.0; Cu, 6.6; S, 26.7; C, 37.5; N, 1.5; H, 4.8%.

$[Et_4N]\{W_2CuS_4\}(edt)_2(PPh_3)$ (**2**): $Cu(PPh_3)_2[S_2P(OCH_2CH_3)_2]$ (0.77 g, 1 mmol) dissolved in 30 cm^3 of CH_2Cl_2 was added to a solution of $[Et_4N]_2W_2S_4(edt)_2$ (0.94 g, 1 mmol) in 40 cm^3 CH_3CN. The resulting solution was filtered and the filtrate was allowed to evaporate in the air. After 1 day, some yellow precipitate was filtered off. Subsequent evaporation of the filtrate in the air for 3 days, produced 0.20 g (17.6% yield) of orange–red crystals which were filtered and washed with isopropanol and ether. The crystals were analytically pure and suitable for X-ray measurements. Additional evaporation produced more orange–red crystals. Found: W, 33.1; Cu, 5.5; S, 21.6; C, 31.7; H, 3.8; P, 2.8. Calc. for $W_2CuS_8PNC_{30}H_{43}$: W, 32.4; Cu, 5.6; S, 22.5; C, 31.7; H, 3.8; N, 1.2; P, 2.7%.

X-ray structure determination

(a) $[Et_4N]\{Mo_2CuS_4\}(edt)_2(PPh_3)$ (**1**): A crystal with dimensions $0.33\times0.13\times0.1$ mm was mounted in random orientation on a glass fibre. Some experimental conditions are reported in Table 1. Diffraction data were collected on a CAD-4 K-geometry diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Cell constants were obtained by least-squares fit to 25 diffraction maxima ($24° < 2\theta < 28°$). The intensities were corrected for Lorentz and polarization factors and for absorption by using empirical scan data and DIFABS.[27] A total 7154 reflections were collected, and 6122 reflections with $I > 3\sigma(I)$ were used in the refinement. No extinction correction was applied.

The structure was solved by direct methods using MULTAN 11/82[28] and the positions of six heavy atoms were obtained from the E map. The remaining non-hydrogen atoms were located in the succeeding difference Fourier synthesis, except for some C atoms of one disordered cation which were located geometrically in their calculated positions and allowed to refine. The refinement was based on F. The scattering factors were taken from Cromer and Waber.[29] The structure was refined by full-matrix least-squares technique with anisotropic thermal parameters for the 32 atoms of the cores and isotropic thermal parameters for the remaining non-H atoms (527 variables). $R = \Sigma\|F_o|-|F_c\|/\Sigma|F_o| = 0.056$, $Rw = (\Sigma w(|F_o|-|F_c|)^2/\Sigma wF_o^2)^{1/2} = 0.065$, $S = [\Sigma w(|F_o|-|F_c|)^2/(N_{obs}-N_{var})]^{1/2} = 1.27$, $w = 1/[\sigma(F_o)^2+(PWT\cdot F_o)^2+QWT]-F_o$ (for PWT = 0.020, QWT = 1.0),[30] the function minimized was $\Sigma w(|F_o|-|F_c|)^2$. All calculations were performed on a VAX 785 computer using the SDP program package.[31]

(b) $[Et_4N]\{W_2CuS_4\}(edt)_2(PPh_3)$: An orange–red crystal with dimensions 0.40 × 0.20 × 0.15 mm was mounted in random orientation on a glass fibre. Some experimental conditions are reported in Table 1. Data were collected using a RIGAKU AFC5R diffractometer[32] using Mo-K_α radiation at *ca* 296 K. Cell constants were obtained by least-squares analysis on 20 diffraction maxima ($20° < 2\theta < 26°$). Scan speed varied on the basis of SEARCH intensity. A total 7281 (of which 6927 were unique) reflections were collected. Three standard reflections were measured periodically, the absence of random deviations of intensity indicated crystal and electronic stability. A linear decay correction was not applied. The collected intensity was defined as $C\text{-}1/2(t_c/t_b)(b_1+b_2)$, where C = total number of counts, t_c = time spent counting peak intensity, t_b = time spent counting one side of the background, b_1 = high-angle background counts and b_2 = low-angle background counts; the intensity error was defined as $\sigma(F^2) = [C+1/4(t_c/t_b)^2(b_1+b_2)+(pI)^2]^{1/2}$, where I is the intensity and p is the factor that downweighs strong reflections, taken to be 0.05. The data were corrected for Lorentz and polarization factors and for absorption using empirical scan data and DIFABS. 6275 reflections

with $I \geqslant 3\sigma(I)$ were considered observed, and used in the refinement. An extinction correction was applied.

The structure was solved by direct methods using MITHRIL;[33] the W and Cu atoms were located in the E map. Most non-hydrogen atoms were located using the succeeding DIRDIF program;[34] some non-hydrogen atoms were located in the succeeding difference Fourier syntheses, while the positions for some C atoms in the disordered cation were calculated in geometrically reasonable positions and then refined. The structure was refined by full-matrix least-squares techniques with anisotropic thermal parameters for all W, Cu, S, P atoms, and isotropic thermal parameters for all C atoms (487 variables in all). Final $R = \Sigma||F_o|-|F_c||/\Sigma|F_o| = 0.050$, $wR = [\Sigma(|F_o|-|F_c|)^2/\Sigma wF_o^2]^{1/2} = 0.071$ and $S = [\Sigma w(|F_o|-|F_c|)^2/(N_o-N)]^{1/2} = 1.940$, $w = 1/\sigma^2(F_o)$. $(\Delta/\sigma)_{max} = 0.90$ in the final difference electron density synthesis largest and smallest heights were 1.57 and -1.95 e Å^{-3} which were in the vicinity of the W atom. All calculations were performed on a VAX 785 computer using the TEXSAN (1985) program package.[35] Non-hydrogen scattering factors were taken from Cromer and Waber.[30]

RESULTS AND DISCUSSION

Synthesis

For synthesis of the Mo-compound (**1**), we had tried some Cu/PPh_3 complexes, e.g. $Cu(PPh_3)_3Cl$[36] or $CuCl_2 \cdot 2H_2O/PPh_3$ (1:1.5) in CH_3CN/CH_2Cl_2 solution. The reaction was carried out under anaerobic condition and the products were crystallized by gaseous diffusion of ether. The resulting crystals are very stable in air, but obtaining them took much time. If the above reaction solution was under air, the yield is very low and the products are contaminated by a black precipitate. However, when we tried the $Cu(PPh_3)_2[S_2P(OCH_2CH_3)_2]$ in an open container, it was surprising to find that the reaction solution is stable in air. The yield is high in a relatively short time and the products are of analytical purity. This means that, although the ligand $S_2P(OCH_2CH_3)_2^-$ does not exist in the products, it may have some helpful functon in the synthesis in preventing the solution from being oxidized by air. Correspondingly, the halogen ligand does not have this kind of function in the solution.

The synthesis of the W-complex can also be done under air, but it takes a few days and the yield is low.

The reaction is easily followed because the colour of the solution changes quickly from orange–red to brown–red or from orange to orange–red. The reaction procedures can be outlined in Scheme 1.

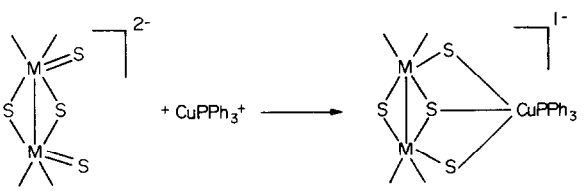
Scheme 1 implies that this procedure is a convenient one for synthesizing the incomplete cubane-like clusters from other metal complexes. If a new metal complex is used to substitute the Cu/PPh_3 complex, a novel heterometallic incomplete cubane-like clusters could be expected to be obtained.

The trimolybdenum clusters with the incomplete cubane-like cluster core $\{Mo_3S_4\}^{4+}$[21] have attracted much attention, not only because the $\{Mo_3S_4\}^{4+}$ aquo ion is especially stable,[37] but also because it may be employed as a starting material to react with many metals, e.g. Fe,[15] Cu,[13,14] Ni,[38] etc., to form cubane-like clusters, or to dimerize to form an Mo_6S_8 cluster.[12] The cores $\{Mo_2CuS_4\}^{3+}$ and $\{W_2CuS_4\}^{3+}$ of the title compounds are very similar to the cores $\{M_3S_4\}^{4+}$ (M = Mo, W). They are the first two heterometallic incomplete cubane-like cluster cores. The reactivity of the homo- and hetero-clusters of the above compounds are expected to be similar. Recently, the cubane-like core $\{M_2Cu_2S_4\}^{4+}$[16] (M = Mo, W) clusters have been synthesized, this justifies this expectation. Therefore, a procedure to design synthesis of sulphido-bridging cubane-like clusters has been outlined by the experiments, which is $[1+1] = 2$, $[2+1] = 3$, $[3+1] = 4$. Many dinuclear complexes containing the $\{M_2S_4\}^{2+}$ (M = Mo, W) core have been synthesized,[25,39] which are from the step of $[1+1] = 2$. Scheme 1 shows the second step of $[2+1] = 3$ for the incomplete cubane-like clusters. The third step of $[3+1] = 4$ for cubane-like clusters has been verified in many papers.[13–15,38]

IR spectra

The Mo=S and W=S vibration absorptions of dinuclear complexes have been identified.[25] According to the procedures of "unit-construction", the IR spectra comparison of the di-, tri-, tetra-clusters (i.e. M_2S_4, M_2CuS_4, $M_2Cu_2S_4$)[16] help us to assign all the absorptions. The results are shown in Table 2.

For the Mo-compound, the three bands at around 520, 510 and 495 cm^{-1} are obviously



Scheme 1.

Table 2. IR spectra data of four compounds (cm^{-1})

Compound	ν(M—S)	ν(Cu—P)	ν(M—μ_2-S)	ν(M—μ_3-S)	ν(M—SR)$_{edt}$
$\{Mo_2S_4\}^{2+}$	515(s)	—	465(w), 430(w) 325(m)	—	340(w), 295(w)
$\{Mo_2CuS_3\}^{3+}$	495(s)	520(s) 510(s)	465(w), 430(w) 325(w)	465(w), 430(w)	350(w), 310(w)
$\{W_2S_4\}^{2+}$	505(s)	—	465(w), 425(w) 330(s)	—	343(w), 300(w)
$\{W_2CuS_4\}^{3+}$	500(m)	520(s) 508(s)	465(w), 425(w) 330(w)	480(s), 425(w)	350(m), 310(m)

isolated. The first two are assigned to ν(Cu—P) and the other to ν(Mo—S). The first two bands also exist in the compound of $Cu(PPh_3)_2[S_2P(OCH_2CH_3)_2]$. The two bands at 460(w) and 430(w) are due to asymmetric stretching vibrations of a sulphur bridged[40] MoS_2Mo group. The vibration absorptions of Mo—μ_3—S groups are overlapping around 460 and 430 cm^{-1}. From dinuclear complex to trinuclear compound, the band at 325 cm^{-1} becomes weak (in the cubane-like $\{Mo_2Cu_2S_4\}^{4+}$ cluster the band disappeared); this band is assigned to symmetric stretching vibration of a sulphur bridged[40] MoS_2Mo group. The two bands at 340 (350) and 295 (310) cm^{-1} of dimolybdenum complex (trinuclear compound) are attributed[41] to ν(Mo—SR). The vibrational coupling of the two SR groups of the edt ligand at the Mo atom causes the absorption to separate into two bands. The assignment of the IR spectra of the W-compound is similar to that of the Mo-compound, except that the band at 480 cm^{-1} is assigned to ν(W—μ_3—S); this is because the bond length of W—μ_3—S is shorter than that of W—μ_2—S.

Electronic spectra

For comparison, the electronic spectra of the cubane-like core $\{M_2Cu_2S_4\}^{4+}$ [16] (M = Mo, W) clusters were also shown in Table 3. The right peaks

Table 3. Electronic spectra [in CH_2Cl_2 solution, $\lambda(\varepsilon)$ nm ($M^{-1}\cdot cm^{-1}$)]

Compound	Left peak	Centre peak	Right peak
$\{Mo_2S_4\}^{2+}$	228(37,000)	306(26,000)	445(24,000)
$\{Mo_2CuS_4\}^{3+}$	228(49,000)	305(23,000)	482(8600)
$\{Mo_2Cu_2S_4\}^{4+}$	230(60,000)	315(26,000)	510(8900)
$\{W_2S_4\}^{2+}$	235(24,000)	284(20,000)	362(6600)
$\{W_2CuS_4\}^{3+}$	228(44,000)	280(30,700)	405(11,000)
$\{W_2Cu_2S_4\}^{4+}$	230(37,000)	275(37,000)	428(10,600)

of these clusters are broad and rather low. With the increasing of the nuclei, the right peak shifts to a larger wavelength. The longest wavelength peak is attributed to the S_t–M charge transition. The red shift tendency of the S_t–M charge transition with the increasing of the Cu group has also been found elsewhere[42–45] in a series of Mo(W)/Cu/S complexes.

Cyclic voltammetry

The cyclic voltammography[46] has been done in the range 0.0 to −1.75 V. Compound **1** displays a pair of redox waves at −1.28 to −1.07 V while compound **2** displays no electron transfer process in this range. The two starting compounds also show no waves in this range. As reported, the $[Et_4N]_2Mo_2S_4(SCH_2CH_2S)_2$ displays[47] a reversible one-electron transfer at −1.88 V. When the positively $CuPPh_3^+$ group is added, it results in the less negative reduction potentials because of the decreasing of the electron density on the $\{Mo_2S_4\}$ moiety.

Description of the structure

The ORTEP drawings of the two independent anions of $\{Mo_2CuS_4(edt)_2(PPh_3)\}^-$ are shown in Figs 1(a) and (b). Figures 1(c) and (d) show the drawings of the two independent anions of $\{W_2CuS_4\}(edt)_2(PPh_3)^-$. The packing drawing of the unit cell for $[(CH_3CH_2)_4N][Mo_2CuS_4(edt)_2(PPh_3)]$ is shown in Fig. 2. The unit cell contains two discrete anions and two cations. The two discrete anions have the same orientation for the $CuPPh_3$ groups along one axis, so that the space group is undoubtedly noncentrosymmetric. The PPh_3 ligands of the two independent anions have some difference in conformation. One of the two cations $[(CH_3CH_2)_4N]^+$ in the unit cell is disordered. In the unit cell, the dihedral angle of the two triangular Mo_2Cu (or

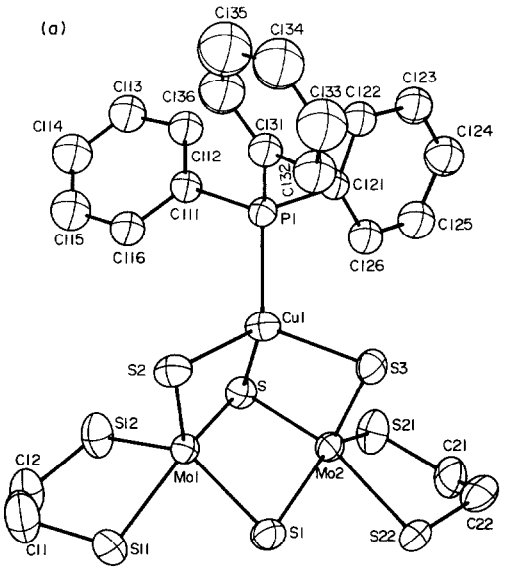


Fig. 1. (a) The ORTEP drawing of the first independent anion of $\{Mo_2CuS_4\}(edt)_2(PPh_3)^-$.

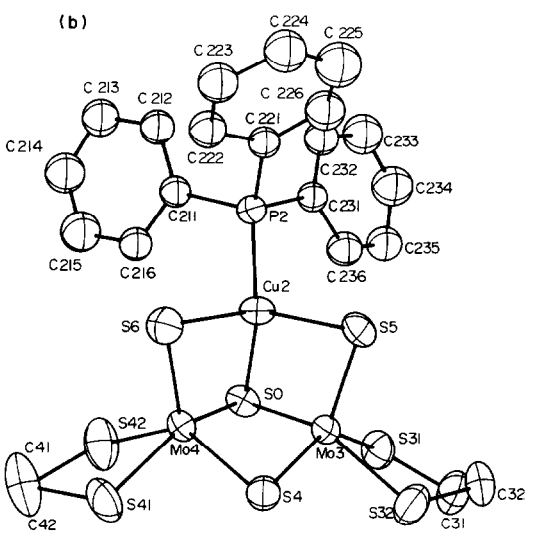

Fig. 1. (b) The ORTEP drawing of the second independent anion of $\{Mo_2CuS_4\}(edt)_2(PPh_3)^-$.

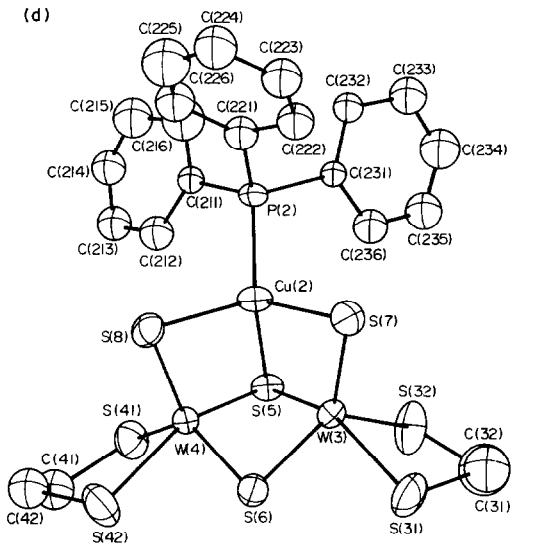

Fig. 1. (d) The ORTEP drawing of the second independent anion of $\{W_2CuS_4\}(edt)_2(PPh_3)^-$.

W_2Cu) metallic planes of the two anions is 173.5° (or 173.9°). If one anion is rotated and overlapped on the other anion, it is found that the two cores of the two anions are extremely similar in structure.

Except for the structural difference of the PPh_3 ligands of the two independent anions, the two cores of the two anions are very similar, so only one core of the anion is discussed below. Selected bond lengths appear in Table 4 and the selected bond angles in Table 5.

The idealized symmetry of the anion is C_s (exclusive of the methylene groups of the edt ligands). Each Mo(W) atom displays tetragonal–pyramidal coordination (TP) by five sulphurs; one μ_3-S atom, two μ_2-S atoms and two terminal sulphurs of the edt ligand, which is the same as in the isolated dinuclear compound.[25,48] The axial position of each TP is occupied by a μ_2-S_t (in the dinuclear complexes the S_t atom is the terminal sulphido atom and the S_b below is the bridging sulphido atom), the equatorial positions are occupied by bridging sulphido ligands (μ_3-S, μ_2-S_b) and the sulphur atoms from the edt ligand. The Mo(W) atom is mean 0.71 Å (0.74 Å) above the basal plane of TP.

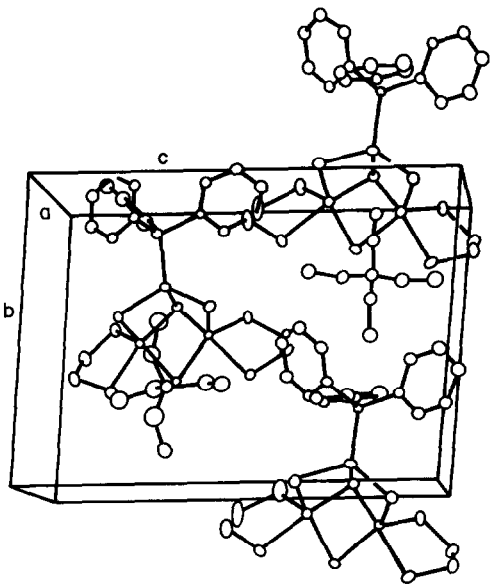

Fig. 2. The packing drawing of the unit cell of compound $[Et_4N]\{W_2CuS_4\}(edt)_2(PPh_3)$ (for clarity only one structure of the disordered cation was drawn).

The deviations from planarity of the four sulphur atoms is shown in Table 6. The large deviations from their least-squares planes show the slight distortion of each TP toward trigonal–bipyramidal coordination. The Cu atom was tetrahedrally coordinated by one μ_3-S atom, two μ_2-S atoms and one PPh_3 ligand.

For the Mo compound (**1**), the dihedral angle of the two Mo/S/S in the Mo_2S_2 ring is almost unchanged (av. 146.8° for compound **1**, 146.9° for the starting dimolybdenum complex). If the Mo_2S_2 ring is used as a frame of reference, the results of the reaction are that the μ_3-bridging sulphido atom side moves toward the two S_t atoms while S(12) and S(21) atoms side rotate away from the two S_t atoms (see Table 5). The resultant S(2)—Mo(1)—S and S(3)—Mo(2)—S angles are less than 5–8° smaller than the corresponding S(2)—Mo(1)—S(1) and S(3)—Mo(2)—S(1) angles, meanwhile the resultant S(2)—Mo(1)—S(12) and S(3)—Mo(2)—S(21) angles are more than 6–7° larger than the corresponding S(2)—Mo(1)—S(11) and S(3)—Mo(2)—S(22). Except for some slight change, the bond lengths and bond angles of the $Mo_2S_4(edt)_2$ moiety in the trinuclear cluster are almost the same as in the isolated dinuclear complex.[48] Only the Mo—S_t double bond lengths elongate from av. 2.10 to av. 2.165 Å, when the terminal S atom becomes μ_2-S atom. This result is con-

sistent with the IR spectra, which show that the vibration of the Mo—S double bond decreases from 515 to 495 cm^{-1}. The Mo—Cu bonds are av. 2.771 Å, which is in the range of effectively bonding. The Cu—μ_3-S bond length is 2.265 Å, but the two Cu—μ_2-S bond lengths are significantly different. One Cu—μ_2-S is 2.313 Å and the other 2.409 Å. This lowers the overall symmetry of the core from C_s to C_1.

Comparing the W-compound (**2**) with the starting ditungsten complex, the dihedral angle in the W_2S_2 ring changes a little from 148.9(1)° to 143.8(3)°. As pointed out for the dinuclear tungsten complex,[25] the two terminal sulphido atoms are in a *cis* position relative to the $S_2WS_2WS_2$ unit. The product atoms are in a *cis* position relative to the $S_2WS_2WS_2$ unit. The product compound also has this *cis* configuration, but the $CuPPh_3^+$ group is only attached to one side (see Table 5). At the μ_3-S side with reference to the W_2S_2 ring, the angles of S(3)—W(1)—S(12) and S(4)—W(2)—S(22) are approximately 10° larger than the corresponding angles S(3)—W(1)—S(11) and S(4)—W(2)—S(21), respectively. Unlike the Mo-compound (**1**), the W—S_t double bond does not elongate, in fact it seems to be somewhat stronger (from av. 2.144 Å to av. 2.123 Å). However, the vibrational frequency of the W—S double bond is slightly reduced from

[a] Equations were fitted to the sulphur atoms only.

504 to 498 cm^{-1}. The Cu—μ_3-S bond length is 2.304(7) Å, and the other two Cu—μ_2-S bond lengths are 2.398(7) and 2.378(7) Å, respectively. The overall symmetry of the core is approximately C_s.

DISCUSSION

The title compounds both have three metal—metal bonds. The short Mo—Mo or W—W bonds are comparable to the dinuclear complexes and can also be interpreted in terms of a metal—metal σ bond. The Mo—Cu or W—Cu bonds are much weaker but the bond lengths are somewhat shorter than Mo—Mo or W—W bonds. The M—μ_2-S_t bonds are very short and can be regarded as double bonds. Meanwhile, the Cu—μ_2-S_t bonds are relatively long, for example they are even approximately 0.1 Å longer than the Cu—μ_3-S bond. Therefore, in the $\{Mo_2CuS_4\}^{3+}$ and $\{W_2CuS_4\}^{3+}$ core there are two unsymmetrical μ_2-bridging sulphido atoms, respectively, in which the two bridging bonds are double bond and single bond. It is noted that the Cu—μ_3-S is shorter than the Cu—μ_2-S_t. This may be because the Cu—μ_3-S bond is approximately parallel to the two M—μ_2-S_t double bonds. Association with the organic olefin chemistry, the reduced short Cu—μ_3-S bond and the two M—μ_2-S_t double bonds may form a large conjugation system due to the approximately space parallel. The conjugation system is stereoscopic because of the participation of the *d* orbitals.

The two title clusters are examples which have new unsymmetrical μ_2-bridging sulphido atoms.[1,23] The M—μ_2-S_t double bonds play an important role in the structure of the $\{M_2CuS_4\}^{3+}$ cores. Very similar to the property of withdrawing electrons through the C—C double bond in organic chemistry, one positively metallic atom (Cu^+ here) may also withdraw electrons through the bridging double bond (Mo—μ_2-S_t or W—μ_2-S_t), which causes the bond of Mo—S_{edt} or W—S_{edt} to become stronger. The result of withdrawing electrons through Mo—μ_2-S_t or W—μ_2-S_t double bonds is consistent with the bond length changes (see Table 4) and the shifts of the IR vibrational bands (see Table 2) of Mo—S_{edt} or W—S_{edt}. Association with the bond lengths and IR spectra of $[M_2Cu_2S_4]^{4+}$, it makes the phenomenon more obvious (for clarity, Table 7 lists the bond changes and the IR shifts). Scheme 2 shows the flow of the electrons when the $CuPPh_3^+$ group withdraws the lone-pair electrons from the sulphido atoms to its 4*s*, 4*p* orbitals through the M—μ_2-S_t double bond to make the M—S_{edt} bond shorter.

Table 7. Bond lengths changing and IR spectra shift of $(M—SR)_{edt}$[a] bonds from dinuclear complexes to cubane-like clusters

Compound	Av. bond length of M—S_{edt}		IR bands of ν(M—SR), cm^{-1}	
$\{Mo_2S_4\}^{2+}$	2.406(3) Å		340(w), 295(w)	
$\{Mo_2CuS_4\}^{3+}$	2.380(4), 2.368(4)[b]	[c]	350(w), 310(w)	[d]
$\{Mo_2Cu_2S_4\}^{4+}$	2.360(2)		360(m), 320(w)	
$\{W_2S_4\}^{2+}$	2.404(2)		343(w), 300(w)	
$\{W_2CuS_4\}^{3+}$	2.386(7), 2.387(7)[b]	[c]	350(m), 310(m)	[d]
$\{W_2Cu_2S_4\}^{4+}$	2.346(4)		365(s), 324(m)	

[a] M = Mo, W.
[b] The two average bond lengths are from two discrete anions, respectively.
[c] The bond lengths become shorter in order.
[d] The corresponding absorption bands shift to higher frequency in order.

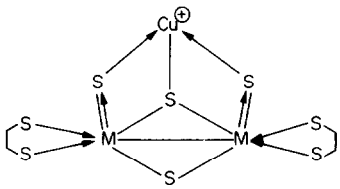
[a] The data are from ref. 49.
[b] The bond lengths and angles are averaged from those of two independent anions.
[c] The data are from ref. 21(j).



Scheme 2.

Scheme 2 shows that the function of the double bond is very similar to the C=C double bond in transmitting electron density. However, the pattern of the flow of electrons here may also be more three-dimensional because of the participation of *d* orbitals of the Mo atom or W atom.

For comparison, the major average bond distances and bond angles of the four homo- and heterometallic incomplete cubane-like clusters are listed in Table 8. In homometallic clusters with $\{M_3S_4\}^{4+}$, the six M—μ_2-S bonds are approximately identical and they are shorter than the M—μ_3-S bonds. The $M_3S_4{}^{4+}$ cores are about C_{3v} symmetry with the regular six-membered puckered M_3S_3 ring. However, in the two heterometallic clusters with the $\{M_2CuS_4\}^{3+}$ cores, the six bonds of the six-membered M_2CuS_4 puckered ring are quite different. The three separated μ_2-S atoms in the heterometallic cluster cores have distances 0.3–0.5 Å longer than those in the homometallic cluster cores. In the $W_2CuS_4{}^{3+}$ core, the bond length of W—μ_3-S_b is exceptionally shorter than that of W—μ_2-S_b. Additionally, the long bond length of the W—μ_2-S is unusual.

Based on the stability, substitution, addition and oxidation, quantum calculation, etc., the quasi-aromaticity hypothesis in the $Mo_3(\mu_2\text{-}S)_3$ structural unit of the $Mo_3S_4{}^{4+}$ core has been proposed by Huang *et al.*,[50] which has been pictured[51] by the quantum chemistry using the three-centre two-electron *d*(Mo)-*p*(S)-*d*(Mo) π bond. The detailed structure of the $M_2Cu(\mu_2\text{-}S)_3$ unit of the $M_2CuS_4{}^{3+}$ (M = Mo, W) core is different from the Mo_3S_3 unit. The main reason is that the Cu^+ has d^{10} configuration which has no vacant *d* orbital. But other bonds in the core have been strengthened.

(*Received* 4 *February* 1991; *accepted* 22 *July* 1991)

Abstract—The syntheses of trifluoromethanesulphonato (OTf) complexes of Co^{II}, Ni^{II}, Cu^{II}, Fe^{III} and Ga^{III} by the reaction of simple metal salts (Cl^-, Br^-, CO_3^{2-}, ClO_4^-) or metallic gallium with trifluoromethanesulphonic acid have been systematically investigated.

Comparison of the vibrational spectra of coordinated OTf in these complexes with that in simple ionic salts indicates the ligand to be bridging bidentate in $M(OTf)_3$, M = Ga, Fe and in $M(OTf)_2$, M = Cu and bridging tridentate in $M'(OTf)_2$, M′ = Co, Ni, Cd. EXAFS spectroscopic data can be interpreted in terms of layered structural arrangements for Co, Ni, Cd and Ga trifluoromethanesulphonato complexes, similar to that of the corresponding anhydrous metal perchlorates studied previously. In $Cu(OTf)_2$, however, the copper atom is in a square planar environment. The short metal–oxygen distances, 1.96–2.09 Å are consistent with strong interactions between the ligand and metallic centre.

Research on the coordinating ability of weakly basic ligands, such as fluorosulphonate FSO_3^-, trifluoromethanesulphonate $CF_3SO_3^-$ and perchlorate ClO_4^- ions, has been considerably developed since the 1970s.[1–6] More recently the use of these weakly coordinated complexes in cationic polymerization,[7,8b] dehydration processes,[9] oxidation,[10] and superacid chemistry[8a] has been reported. Comparison of the Hammett acidities H_0 of their conjugate acids: $FSO_3H \sim CF_3SO_3H \sim -14$[11]; $HClO_4 \sim -17$[12] suggests that development of the chemistry of the $CF_3SO_3^-$ group along lines similar to that of ClO_4^- should be possible, with the clear advantage of avoiding the risks of manipulation associated with the oxidizing and instability properties of the latter.

Many advances have been made in recent years on the synthesis of ClO_4^- complexes and in obtaining structural information on them. For the $CF_3SO_3^-$ ligand only the synthetic aspect has been relatively well developed.[5,13] Complexes $M(OTf)_n$ (OTf = CF_3SO_3) are usually prepared from anhydrous CF_3SO_3H (HOTf) or aqueous HOTf solutions, however no study has yet compared these methods with other possible synthetic routes. Furthermore, structural data on the complexes so isolated is often restricted to that deducible from vibrational and electronic spectroscopies[5] or, more infrequently, from Mössbauer spectroscopy.[14]

The crystal structures of HOTf[15] and its oxonium[16] and alkali metal[17] salts are known, as well as that of $SeO(CF_3SO_3)_2$.[18] Only limited information on coordinated metal–oxygen distances is thus available, growth of single crystals containing coordinated OTf to the exclusion of other ligands being of great difficulty. An analogous situation exists in perchlorate chemistry, where classical methods of recrystallization frequently lead to the introduction of more basic solvent molecules into the coordination sphere.[19]

The contribution of EXAFS spectroscopy, applicable to polycrystalline compounds, in obtaining not only metal–oxygen but also metal to next-nearest-neighbour interatomic distances, has been considerable and has allowed the derivation

* Author to whom correspondence should be addressed.

of three-dimensional structural arrangements in favourable cases. The technique has been applied to perchlorate complexes,[20–22] for example, with success.

In the present paper, various synthetic routes to metal trifluoromethanesulphonate complexes $M(OTf)_n$ ($M = Ni^{II}$, Co^{II}, Cd^{II}, Ga^{III} and Fe^{III}) are discussed, and vibrational and EXAFS spectroscopic results are reported. Here the choice of M was directed such as to enable a comparative study of the perchlorate and trifluoromethanesulphonate ligands.

EXPERIMENTAL

All syntheses were performed in a Pyrex vacuum line analogous to that described for the preparation of anhydrous perchlorate complexes.[3] This set-up allows purification of trifluoromethanesulphonic acid or its anhydride, elimination of gases produced by the reactions and IR analysis by *in situ* deposition in a cell described previously.[23]

Trifluoromethanesulphonic acid and the corresponding anhydride (Merck) were distilled at room temperature under dynamic vacuum (10^{-2} torr). HOTf was mixed with sulphuric acid (36N) prior to distillation, while $(CF_3SO_2)_2O$ was subsequently stored over P_2O_5. The reaction of HOTf on different anhydrous or hydrated salts were conducted as described previously.[3,24]

Synthesis

OTf complexes have often been prepared by replacement of the *m*-bromobenzoate ligand,[25] a reaction which necessitates the prior synthesis of the appropriate benzoate and by which $Co(OTf)_2$ cannot be obtained.[26] In an attempt to avoid this intermediate step, alternative readily available metal salts—such as chlorides or carbonates—were used. Furthermore, the influence of the metal and the ligand to be substituted, and the source of the OTf ligand were examined in order to identify the best synthetic routes. Initial studies have concentrated on the following groups of metals: Ni/Co/Cd; Cu; Fe/Ga and on two distinct types of reaction:

(1) $ML_n + m(HOTf \cdot xH_2O) \longrightarrow nHL + M(OTf)_n \cdot m - n[H(mxH_2O)OTf]$

M = Co, Fe	L = Cl	
M = Ga	L = Br	$x \geqslant 0$
M = Cd	$L = CO_3$	
M = Cd	$L = NO_3$	
M = Cu, Ni	$L = CO_3$, OH	
M = Co	$L = ClO_4$	$(x = 0)$.

(2) $M + m(HOTf \cdot xH_2O) \longrightarrow n/2H_2 + M(OTf)_n \cdot m - n[H(mxH_2O)OTf]$,

n being the oxidation state of the metal.

The second of these general reactions[7] was adapted, in the present study, by using anhydrous HOTf and metallic gallium.

The use of hydrated salts, or of aqueous HOTf solutions, necessitates the subsequent elimination of H_3OOTf by heating, while with nitrates removal of NO_2OTf is required. As far as possible, reactions were performed using anhydrous salts—including $FeCl_3$, $CoCl_2$, $GaBr_3$ and $Co(ClO_4)_2$—to avoid this additional step.

A summary of the experimental conditions, the formation of intermediate complexes, the obtention of trifluoromethanesulphonatometal from them and elemental analyses of the products is given in Table 1.

Chemical analyses

Elemental analyses were carried out according to the method established for perchlorate ions[3] (in order to avoid all losses, dissolutions, in water, of the complexes are performed at low temperature, 90 K). Ni, Co, Cu and Fe were determined by complexation, Ga by atomic absorption spectroscopy, OTf by the acid–base conductimetric method developed by one of us[28] and halide ions by $AgNO_3$ potentiometry.

Vibrational spectroscopy

Vibrational spectroscopic data were recorded at temperatures between 80 and 298 K depending on the $M(OTf)_n$ complex (see below). IR spectra, reproduced in Fig. 1, were recorded on powdered samples between silicon windows on a Perkin–Elmer 180 instrument. Spectral resolution was 1–5 cm^{-1} at 1400 cm^{-1} and 7 cm^{-1} at 300 cm^{-1}. Raman spectra were obtained using a Dilor spectrometer coupled to a Tracor multichannel analyser with an argon laser (5145 Å, 150 mW), (Fig. 2). The powdered compounds were held in 5 mm o.d. Pyrex tubes. Spectral resolution was 0.5–1.0 cm^{-1} over the entire spectral range.

UV–vis spectroscopy

The UV–vis reflectance spectra of Cu, Co and Ni triflato complexes were recorded on a Cary-Varian 2300 spectrophotometer. The finely powdered samples were held in a teflon cell capped with an infrasil window.[24]

ESR spectrum

The X-band ESR spectrum of $Cu(OTf)_2$ sealed in a 5 mm Pyrex tube was recorded at room temperature and at 77 K.*

EXAFS spectroscopy

X-ray absorption spectra were recorded at the Fe (7112 eV), Co (7709 eV), Ni (8333 eV) and Ga (10367 eV) K edges at 77 K on the EXAFS I spectrometer at the French synchrotron facility, DCI at LURE under typical beam conditions (1.85 GeV, 200 mA). The X-ray beam was monochromatized with a channel-cut Si (331) crystal. No additional measures were taken to eliminate harmonics. After calibration of the spectrometer using appropriate metal foils (Fe, Co, Ni), spectra were recorded in transmission mode in three energy regions: the first from 100 to 20 eV before the edge (stepsize 4 eV), the second from here to 50 eV after the edge (stepsize 1 eV) and thereafter in steps of 2 eV to at least 700 eV above the absorption edge.

Complexes $M(OTf)_n$ were prepared as thick mulls with parafilm oil stored over molecular sieves, and were pressed between the parafilm windows of stainless steel sample cells to form homogeneous thin films. Air-filled ionization chambers were used to measure the incident and transmitted X-ray flux. In each case at least three spectra were recorded to maximize the signal/noise ratio in subsequent data analysis.

All mathematical analysis was performed using the programmes developed by Michalowicz.[30] Normalization was typically performed after background subtraction using a 5th or 6th order polynomial in the $\mu_{1\,exp.} - \mu_{0\,exp.}$ formalism. The resulting spectra $\chi(k)$ vs k are reported in Fig. 3. Fourier transformation (FT) was carried out over a range typically 3–13 $Å^{-1}$ using a Hamming window and k^3 weighting, Fig. 4. Quantitative analysis using curve fitting procedures was performed on Fourier-filtered back-transformed spectra. Phase and amplitude functions were the *ab initio* values of McKale[31] (curved wave–small atom formalism).

Quantitative analysis in each case was approached by Fourier filtration of individual peaks in the FT and backtransformation to k-space. Simulation of the experimental spectra by introduction

* The spectra were recorded on a home built ESR spectrometer.[29]

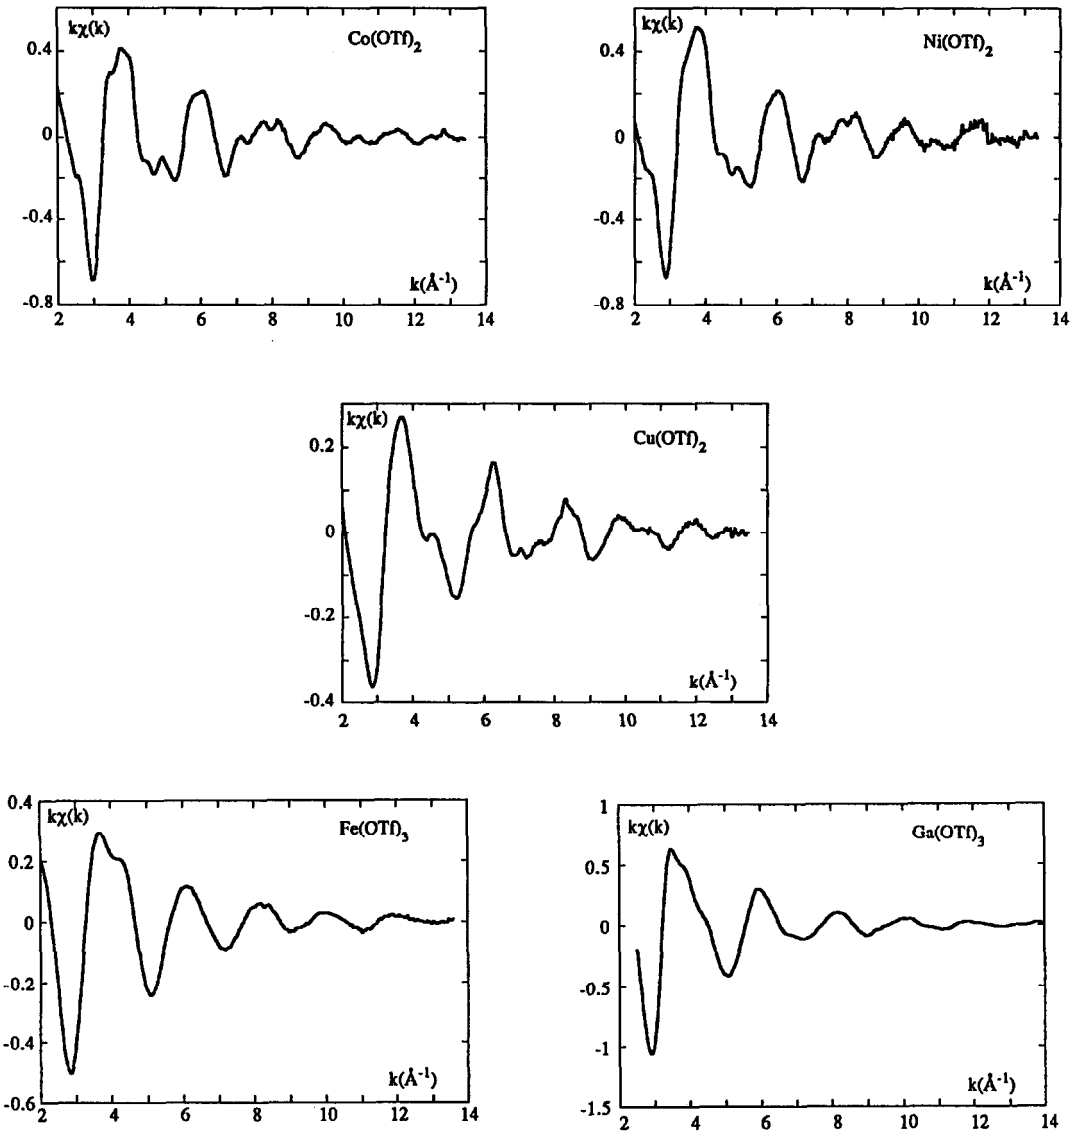

Fig. 3. EXAFS spectra of $Ni(OTf)_2$, $Co(OTf)_2$, $Cu(OTf)_2$, $Fe(OTf)_3$ and $Ga(OTf)_3$ after background substraction and normalization.

of the coordination number, N, absorber–backscatter distance, R (Å), Debye–Waller factor, σ (Å), energy offset, E_0 (eV) and phase and amplitude parameters into the EXAFS equation, was followed by curve-fitting (minimization) routines. After satisfactory convergence had been obtained for individual shells, two shell refinements were performed on the Ni, Co and Cu complexes.

RESULTS AND DISCUSSION

Syntheses

In general the syntheses (Table 1) suffer from the absence of a satisfactorily reactive source of the OTf ligand; only HOTf and the corresponding anhydride are available and neither is particularly efficient: the latter is rather inert[32,37] and HOTf only mildly reactive such that, for example, the synthesis of certain trifluoromethanesulphonato complexes from anhydrous or hydrated chlorides is not achieved. An analogous problem arises in the preparation of perchlorate complexes from chlorides,[3] where an explanation in terms of the compactness of the crystal lattices was suggested.

However the relative electronegativity of the halides must also be considered: the preparation of trifluoromethanesulphonato complexes is easier from bromides than the corresponding chlorides.[8b]

In general, the results obtained using metal chlor-

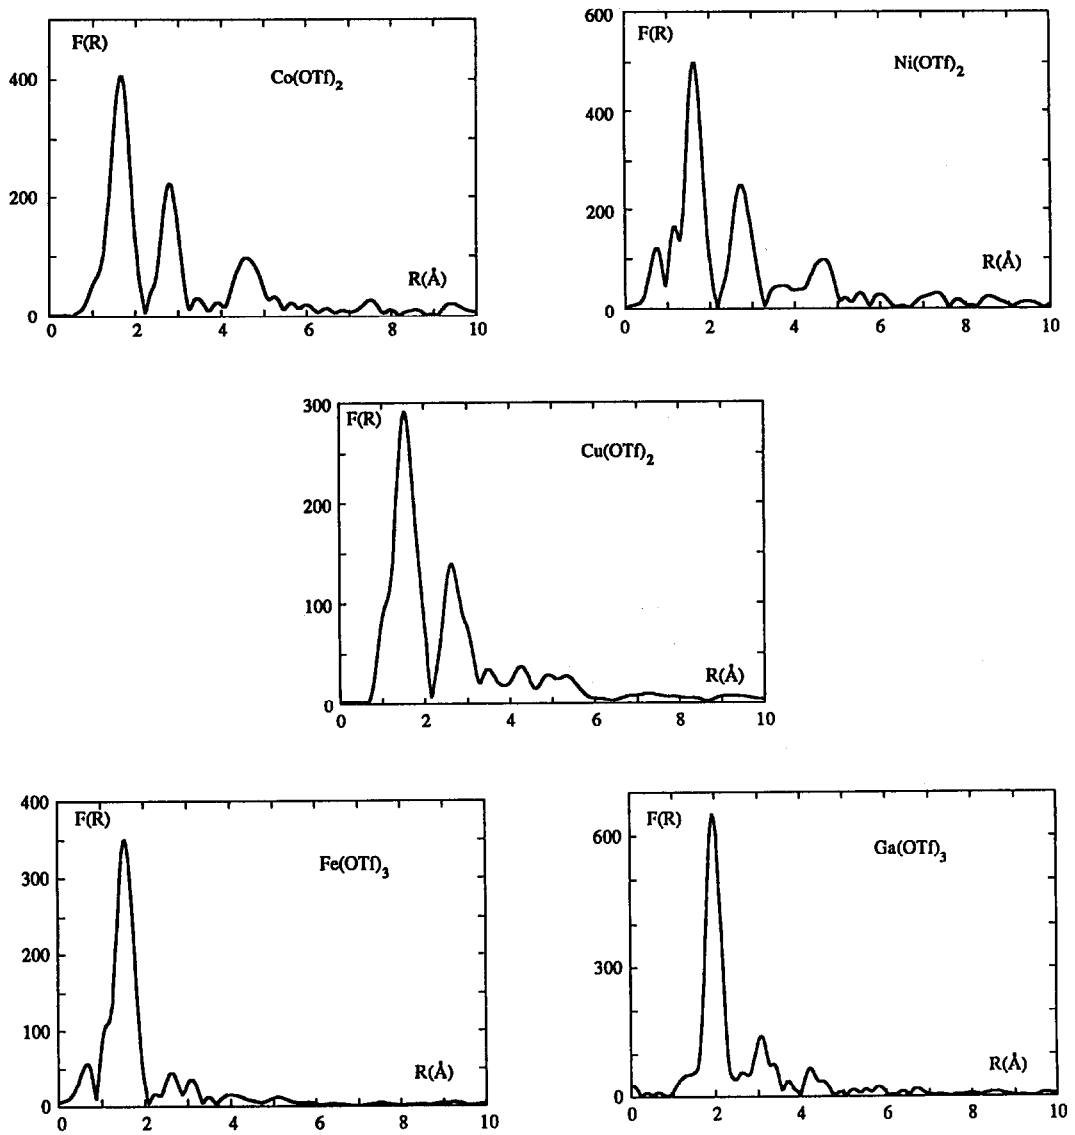

Fig. 4. Fourier transforms of the weighted EXAFS spectra.

ides, bromides and carbonates (basic or neutral) agree with those reported by other workers. The formation of $Ga(OTf)_3$ from $GaBr_3$ occurs via the partially substituted $GaBr_2OTf$. Partial replacement of this type was also observed in the synthesis of boron, gallium and germanium perchlorates from the corresponding chlorides.[4,33,34]

The preparation of OTf complexes from anhydrous perchlorates, although considered inadvisable by certain authors[13] can be succeeded without particular danger if performed in the absence of organic solvents. Progressive formation of $HClO_4$ during the reaction can be detected spectroscopically.[35] The substitution of ClO_4^- by $CF_3SO_3^-$ can be explained by their different basicities (or degrees of hardness according to Pearson).[36] ClO_4 is highly labile and very hard (or weakly basic) and is replaceable by the softer, more basic CF_3SO_3.[37] Although the nitrates are more basic still, they are easily replaced by OTf, as NO_2^+ is formed in strong acid media (see, eg. ref. 38). Thus the reaction of HOTf with $Cd(NO_3)_2 \cdot nH_2O$, $n \leqslant 4$ can lead to the nitryl salt, $(NO_2)_xCd(OTf)_{2+x}$, as demonstrated by vibrational spectroscopy.[28] This reaction is not always reproducible however and frequently leads to a mixture x NO_2OTf,$Cd(OTf)_2$ from which $Cd(OTf)_2$ is obtained by sublimation of NO_2OTf above 360 K, according to methods previously published.[24] As such, nitrates represent an excellent source of the nitrating agent NO_2OTf.

The positive and facile reaction of HOTf with metallic gallium presents the advantage of avoiding the formation of intermediate salts. It is limited, unfortunately, since closely related to the ionization potential of the metal and the redox equilibrium in the metal–acid reaction. For example, whereas HPO_2F_2 reacts with copper metal to give $Cu(PO_2F_2)_2$,[38] HOTf is inactive.[37] Furthermore, passivation phenomena due to the formation of surface oxide can slow down or completely prevent reaction by this route.

Vibrational spectroscopy

The trifluoromethanesulphonate ion has been comprehensively studied by IR and Raman.[5,6,40] Miles[41] and Burger[42] have pointed out the superposition of spectral zones in which internal vibrations of both the pyramidal groups, CF_3 and SO_3, are expected, in particular for the asymmetric CF_3 and SO_3 stretching modes $\nu_{as}CF_3$, $\nu_{as}SO_3$. The latter has been reported to occur at 1150 or at 1270 cm^{-1}, and both positions are consistent with force field calculations.[42] In similar compounds containing the SO_3 group, $\nu_{as}SO_3$ has been identified at 1200, 1254 and 1287 cm^{-1} in CH_3SO_3,[43] CCl_3SO_3[42] and FSO_3,[44] respectively. Consideration of the relative polarizing powers of CH_3, CCl_3, F and CF_3 groups allows the tentative prediction of $\nu_{as}SO_3$ in CF_3SO_3 as ~ 1260 cm^{-1}. Coupling of the A_1 modes is expected, with $\delta_s CF_3$ and νCS being particularly affected. For example potential energy calculations indicate a high contribution of νCS to a band in IR situated at 320 cm^{-1}; that at 770 cm^{-1} is dominated by δCF_3.

Vibrations of the OTf anion are sensitive also to the polarizing power of the countercation.[28] The symmetric stretch ν_sOTf is displaced by ~ 50 cm^{-1} in the series from the lithium to the caesium salts, to a position similar to that observed in the corresponding series of nitrates.[45] Indeed the weak polarizing power of caesium allows the vibrational spectrum of CsOTf to be considered as a "reference".

Coordination of OTf to a metal ion is expected to induce marked spectral changes owing to changes in geometry and symmetry, with vibrations of the SO_3 group being particularly affected.

Finally, in addition to the internal vibrations of OTf, skeletal vibrational modes of the metal—oxygen polyhedron MO_x are expected below 300 cm^{-1}.

Typical IR and Raman spectra of $M(OTf)_2$, and $M(OTf)_3$ complexes, the Raman spectrum of $GaBr_2OTf$ and the vibrational spectra of CsOTf for comparison, are reproduced in Figs 1 (IR) and 2 (Raman). If, as suggested above, CsOTf is regarded as a point of reference, close resemblence is found between its IR spectrum and those of $M(OTf)_2$ M = Ni, Co, Cd. Some significant differences are observed, however, with the spectra of $M'(OTf)_3$, M = Ga, Fe and $Cu(OTf)_2$. Here, for example, four bands occur between 900 and 1400 cm^{-1}, whilst there are only three in the spectrum of CsOTf. This loss of degeneracy strongly suggests that in the presence of Ga, Fe or Cu, OTf is bidentate, whereas retention of degeneracy in the Ni, Co and Cd salts is indicative of tridentate trifluoromethanesulphonate where the SO_3 group has essentially retained its C_{3v} symmetry. Rather similar conclusions reported previously were limited to $M(OTf)_2$ M = Cu, Co[28,46] and $M'(OTf)_3$ M′ = Fe[28,46], Ga.[8]

In the tridentate series of Ni, Co and Cd trifluoromethanesulphonates, two characteristic vibrational bands are displaced: νCS to a higher frequency ($+50$ cm^{-1}), and νSO_b—the average stretching vibration of bridging SO—to a lower frequency (-40 cm^{-1}). These shifts may be interpreted in terms of an elongation of the three SO_b bonds and concomitant shortening of the C—S bond, both modifications induced by coordination.

For the bidentate series, three frequency shifts are observed: νSO_b by -130 cm^{-1}, νSO_t—the stretching vibration of the terminal SO bond—by $+140$ cm^{-1} and νCS by $+15$ cm^{-1} implying that the induced shortening of the C—S bond is less in the bidentate than in the tridentate salts. Indeed, the sensitivity of the position of this band to the nature of metal–oxygen coordination justifies its assignment to νCS. In Fe, Ga and Cu trifluoromethanesulphonato complexes, the bands or lines around 430 cm^{-1} are assigned to the rocking mode of terminal SO_3, only present in the spectrum of bidentate CF_3SO_3, they could be useful in detecting this type of coordination. The M—O stretching vibrations, observed for trifluoromethanesulphonate salts for the first time in this study, are ~ 20 cm^{-1} lower than in the corresponding metal perchlorates.

$GaBr_2OTf$: from the similarity of the vibrational spectra of $GaBr_2OTf$ and $Ga(OTf)_3$ it may be deduced that the OTf ligand in the former compound is bidentate. In addition, vibrations occur at positions characteristic of the $GaBr_2$ group. For example, an intense line in the Raman spectrum at 204 cm^{-1} indicates a GaBrGa bridge while the line at 75 cm^{-1} is a breathing mode of the Ga_2Br_2 ring. No terminal Ga—Br_t bands are present, in accordance with the absence of absorption in UR at 348 cm^{-1}.

Vibrational frequencies for the trifluoromethanesulphonate complexes and their assignments are reported in Tables 2 and 3.

UV–vis spectra

UV–vis spectra of the Ni, Co and Cu complexes are characterized by broad bands which are located respectively at:

7142–7535, 12,195 and 24,390 cm^{-1} [$Ni(OTf)_2$]; 6945–7690, 13,890 and 18,870 cm^{-1} [$Co(OTf)_2$]; 7935 and 10,525 cm^{-1} [$Cu(OTf)_2$].

The observed frequencies are in agreement with the previous results on the triflato[25,26] and the perchlorato[3] complexes.

The absorptions are consistent with a regular octahedral surrounding of the core atoms for the Ni and Co complexes which is well supported by EXAFS spectroscopic results (see below). Assignments for the absorption bands were given previously.[24,25]

The ligand field parameter Dq (735 cm^{-1}) for $Ni(OTf)_2$ is higher than that observed for the corresponding ClO_4 complex ($\Delta\nu = +45$ cm^{-1}) since the basicity of $CF_3SO_3^-$ is stronger than that of ClO_4^-.

The interpretation of the spectra of $Cu(OTf)_2$ developed by other authors[25] describes a Cu atom closely surrounded by four oxygen atoms, this is entirely consistent with our ESR and EXAFS results.

ESR spectrum

The electron paramagnetic resonance spectrum of $Cu(OTf)_2$[28] gives a two component spectrum with sharp lines and no temperature dependence. The g values, $g_\parallel$: 2.4282, $g_\perp$: 2.0774, are consistent with the presence of copper in a square planar or in a compressed tetrahedral environment, and the value of the gyromagnetic tensor G, 5.53, indicates an axial symmetry with probably a $d_{x^2-y^2}$ ground state, where the principal tetragonal axes are parallel, excluding all possibility of exchange interaction between metal centres, as observed previously for $Cu(ClO_4)_2$.[20]

EXAFS spectroscopy

The EXAFS spectra (Fig. 3) of $Ni(OTf)_2$ and $Co(OTf)_2$ obtained after background subtraction and normalization are almost identical (and different from that of $Cu(OTf)_2$), suggesting the same mode of coordination in the two former complexes. Similarly, the frequency and amplitude of EXAFS oscillations of $M(OTf)_3$, M = Fe, Ga are highly comparable and their relative simplicity (absence of beats characteristic of the superposition of several

[a] The recording of Raman spectra of $Fe(OTf)_3$ and $Ga(OTf)_3$ presents great difficulty due to dominating fluorescence; the main lines of $Ga(OTf)_3$ could however be seen on a complimentary FT Raman spectrum recorded at Nicolet.

[b] h,c harmonic, combination.

EXAFS contributions), compared to the spectra of the M^{II} complexes, is striking.

An alternative representation of the EXAFS data is obtained by Fourier transformation, which allows visualization of the various atom shells and an estimate of their distance from the absorbing atom in direct space. The FT of all five OTf complexes are displayed in Fig. 4, where the similarities observable in the EXAFS spectra are even more apparent. The FT of $Ni(OTf)_2$ and $Co(OTf)_2$ consist of three distinct shells of atoms at 1.58 (1.66, Co), 2.71 (2.75, Co) and 4.42 (4.50, Co) Å before phase correction, corresponding to backscattering from oxygen, sulphur and metal atom shells, respectively. Only two maxima (metal–oxygen, metal–sulphur) are closely observable in the FT of $Cu(OTf)_2$

Table 4. Results of the fitting procedure for Ni^{II}, Co^{II}, Cu^{II}, Fe^{III} and Ga^{III} trifluoromethanesulphonato complexes

	N	σ (Å)	R (Å)	ΔE_0 (eV)	R (Å) $M(ClO_4)_2$[a]
$Ni(OTf)_2$

Fe—O	5	0.042	1.99	−0.3	—
$Ga(OTf)_3$					
Ga—O	6	0.041	1.96	3.1	1.95

The quality of the fit as estimated from the residual factor R ($R = \Sigma_k(\chi_{exp} - \chi_{calc})/\Sigma_k\chi^2_{exp}$) is 2.2% $Ni(OTf)_2$, 1.2% $Co(OTf)_2$, 2.7% $Cu(OTf)_2$ (1st and 2nd shells), 1.3% $Fe(OTf)_3$, 2.8% $Ga(OTf)_3$ (1st shell). Standard deviations derived from the calculations for the first and second shells of atoms are N±1; $\sigma \pm 0.005$ Å; R±0.02 Å; $E_0 \pm 2$ eV).

[a] Bond lengths obtained previously for the corresponding metal perchlorates are included for comparison (M = Ni^{II},[21] Co^{II},[21] Cu^{II},[20] Ga^{III}[22]).

and structural information in the gallium and iron complexes is essentially limited to the first shell, where the metal–oxygen contribution produces an intense first peak and the metal–sulphur only a broad, relatively very weak second peak in the FT.

The results of curve fitting to the experimental EXAFS of $Ni(OTf)_2$ and $Co(OTf)_2$ containing first and second shell contributions are reported in Table 4. In both compounds the first shell includes six oxygen atoms at a distance of 2.04 Å in the nickel complex and 2.08 Å in the cobalt analogue. The low Debye–Waller factors attest to little distribution about these mean values and regular octahedral environments may be assumed. The second shell is composed of five–six sulphur atoms, situated at 3.23 Å (Ni), 3.26 Å (Co) from the metal absorber. Although curve fitting methods were not attempted on the third shell, metal—metal distances could be obtained directly from the FT after phase correction and adjustment of the energy offset until coincidence of the maxima of the imaginary part and modulus of the FT, and the zero of the real component was obtained,[47] giving intermetallic separations of 4.88 Å (Ni) and 4.96 Å (Co). All of these values are almost identical to those observed previously in $Ni(ClO_4)_2$ and $Co(ClO_4)_2$ by EXAFS measurements (Ni—O 2.04, Ni—Cl 3.24, Ni---Ni 4.80 Å; Co—O 2.08, Co—Cl 3.26, Co---Co 4.80 Å).[21] Bond lengths and coordination numbers are compatible in both the perchlorates and trifluoromethanesulphonates with bridging tridentate ligands in an arrangement in which the ligand lies alternatively above and below a plane defined by the metal atoms.

For $Cu(OTf)_2$, quantitative analysis shows that the first peak in the FT is due to four nearest neighbour oxygen atoms at 1.96 Å with a low Debye–Waller factor, 0.014 Å, (Table 4). This Cu–O distance is identical to that observed in the majority of copper compounds[48] and indicates the presence of strongly coordinated CF_3SO_3. As for the nickel and cobalt complexes above, least squares refinements were satisfactory with the second shell containing sulphur atoms alone (4, at 3.14 Å from Cu),

although a slight improvement in overall agreement between experimental and calculated curves was obtained (Fig. 5) when a second oxygen atom shell was included (Cu—O_{long}) to account for the "4+2" environment frequently observed in oxygen-containing copper salts. Refinement of this model was performed by fixing all structural parameters of the first oxygen shell, and varying only those (S and O_{long}) in the second coordination sphere. The Cu—O distance so obtained, 3.35 Å, is too long for these oxygens to be considered as directly coordinated (compare, for example with the corresponding value of 2.68 Å obtained from EXAFS in $Cu(ClO_4)_2$,[20] or 2.62 Å in $Cu(O_2PF_2)_2$ from X-ray diffraction).[39] It is therefore concluded that in $Cu(OTf)_2$, steric hindrance by the bulky CF_3SO_3 ligand restricts the immediate oxygen environment of copper to square planar, in agreement with the result obtained from ESR measurements. The four oxygen–four sulphur atom surroundings are compatible with the presence of bridging bidentate ligands, and are consistent with conclusions from vibrational spectroscopy.

EXAFS is able to provide first shell information only in the case of $Fe(OTf)_3$ and $Ga(OTf)_3$. Indeed, the first shell filtered and backtransformed EXAFS spectrum is essentially that of the raw (non-filtered, total) EXAFS of these compounds. In both complexes the metal–oxygen distances are short: Fe–O = 1.99; Ga–O = 1.96 Å, and it may be concluded from the coordination numbers, 5–6, that the metal atoms are octahedrally surrounded by oxygen. Furthermore, consideration of the coordination number and the stoichiometry of the metal(III) complexes allows bidentate CF_3SO_3 to be assumed, which may be bridging or chelating.

The absence of longer distance information for these latter complexes may be due to a high static component to the Debye–Waller factor, either through a broad distribution of M^{III}—S distances or through, for example, orientational disorder. Such effects would cause rapid dampening of the EXAFS signal. Alternatively, an explanation in terms of destructive interference of EXAFS signals may be invoked. Calculation of the single scattering EXAFS of oxygen and sulphur at the same distance from iron, for example, clearly shows a phase difference of approximately $\pi(\phi(Fe—S)-\phi(Fe—O) = 3.16$ rad.), which would therefore drastically reduce or even cancel the overall signal. Occurrence of oxygen and sulphur atoms at identical (or almost) distances is possible in the iron or gallium trifluoromethanesulphonate complexes in view of the bidentate coordination of CF_3SO_3 to the metal centre, and consequent freedom of the third —SO_3 oxygen atom. Finally, the possibility of the destruction of the single scattering EXAFS from sulphur through interference with a multiple scattering process involving the Fe—O—S triad cannot be excluded. This has been observed in other metal salts containing tetrahedral oxyanions: $CaHPO_4$,[49] $Ca_5(PO_4)_3OH$,[49] $CaHPO_4 \cdot 2H_2O$[49] and $Zr(HPO_4)_2 \cdot H_2O$.[50]

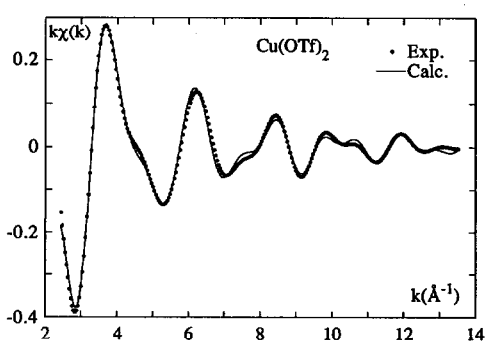

Fig. 5. K space filtered spectrum (dotted line) with the corresponding calculated curve (solid line) for $Cu(OTf)_2$.

CONCLUSION

Systematic investigation of the synthetic routes to known trifluoromethanesulphonato complexes of di- and trivalent metals (Ni^{II}, Co^{II}, Cd^{II}, Cu^{II}, Fe^{III}, Ga^{III}) has led to identification of novel routes using the reaction of trifluoromethanesulphonic acid with metal nitrates, perchlorates and, in one case only, the metal itself (Ga).

The key to the successful preparation of such coordination complexes lies in the availability of an efficient, reactive source of $CF_3SO_3^-$, and research for a reagent more energetic than CF_3SO_3H or its anhydride continues.

The simultaneous availability of spectroscopic data from IR, Raman and EXAFS measurements has facilitated their interpretation. Whilst vibrational spectroscopies have indicated the mode of coordination (bridging bidentate in $Cu(OTf)_2$, $Ga(OTf)_3$, $Fe(OTf)_3$; tridentate in $Ni(OTf)_2$ and $Co(OTf)_2$), EXAFS has provided metal–oxygen and metal–sulphur bond lengths, and corroboration of the ligand arrangement through coordination numbers of the first and second shells of atoms. $Ni(OTf)_2$ and $Co(OTf)_2$ both exhibit the same local structure as observed previously in the corresponding anhydrous perchlorates. Considerable differences however exist between the metal environments in $Cu(OTf)_2$ and $Cu(ClO_4)_2$. In certain cases, structural information is limited to the first shell only for reasons inherent to the geometry of the metal–ligand complex and to the nature of

the EXAFS process; here extension of the structural data available awaits the isolation of single crystalline products.

Acknowledgements—We are grateful to Rhône Poulenc-Péchiney for the gift of metallic gallium. We thank the CEA/CENG/CNRS for access to experimental stations at LURE, and the CNRS for financially supporting this project.

Abstract—$[Cu_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]$, $[CuCO_3 \cdot Cu(OH)_2]$, $[CoSO_4 \cdot 7H_2O]$, [Co((+)-tartrate)], and $[FeSO_4 \cdot 7H_2O]$ react with excess racemic (±)-1,1′-binaphthyl-2,2′-diyl hydrogen phosphate {(±)-PhosH} to give mononuclear Cu^{II}, Co^{II} and Fe^{II} products. The cobalt product, $[Co(CH_3OH)_4(H_2O)_2]((+)\text{-Phos})((-)\text{-Phos}) \cdot 2CH_3OH \cdot H_2O$ (**7**), has been identified by X-ray diffraction. The high-spin, octahedral Co^{II} atom is ligated by four equatorial methanol molecules and two axial water molecules. A (+)- and a (−)-$Phos^-$ ion are associated with each molecule of the complex but are not coordinated to the metal centre. For the other Co^{II}, Cu^{II} and Fe^{II} samples of similar formulation to (**7**) it is also thought that the $Phos^-$ ions are not bonded directly to the metal. When some of the Cu^{II} and Co^{II} samples are heated under high vacuum there is evidence that the $Phos^-$ ions are coordinated directly to the metals in the products.

The axially disymmetric binaphthyl skeleton (Fig. 1a) has been shown to have very good chirality recognition properties and has found increasing use in enantiomeric resolution and asymmetric synthesis.[1] Specifically, (+) and (−) enantiomers of 1,1′-binaphthyl-2,2′-diyl hydrogen phosphate (PhosH) (Fig. 1b) are known to be extremely effective for the resolution of racemic organic bases,[2] and they have also been employed as chiral shift reagents for NMR spectroscopy.[3] In addition, Mikeš and Boshart[4] have linked PhosH to silica gel and used it as the chiral stationary phase in HPLC columns for the resolution of helicenes. More recently, (R)-(−)- and (S)-(+)-PhosH have each been used effectively in the asymmetric synthesis of acids via the palladium-catalyzed hydrocarboxylation of olefins.[5] The present paper details our investigations into the potential coordination chemistry of the $Phos^-$ anion towards Cu^{II}, Co^{II} and Fe^{II} centres.

RESULTS AND DISCUSSION

Racemic mixtures of PhosH (i.e. (±)-PhosH) were used throughout this study, and the synthetic routes to the products are summarized in Scheme 1. In general, the complexes were found to be insoluble in water and other common polar solvents, The tetrapyridine complexes **3** and **9** behaved as weak electrolytes in methanol, and in cases where the complexes were soluble in chloroform they were found to be non-electrolytes in that solvent. (±)-PhosH itself was only partially ionized in methanol and remained undissociated in chloroform. Allowing for the spectral differences caused by the presence of either methanol or pyridine all of the complexes were found to have essentially identical IR spectra. As with the sodium salt, Na^+Phos^-, the ν(PO) band for the compounds was present at 1100 cm^{-1} (1110 cm^{-1} for **8** and **10**). The magnetic moments of the complexes were in the ranges expected for normal Cu^{II}, high-spin Co^{II} and high-spin Fe^{II}.[6]

A crystal of the cobalt complex **7** was examined by X-ray diffraction.* The structure is shown in Figs 2(a) and (b). The metal is octahedrally coordinated as $[Co(CH_3OH)_4(H_2O)_2]^{2+}$, and the (+)-$Phos^-$ and (−)-$Phos^-$ ions are not directly bonded to the metal (although there is a network of hydrogen bonds linking the terminal oxygens of the $Phos^-$ ions to the coordinated and uncoordinated methanol and water molecules).

When a sample of the pale-pink solid **6** was placed under high vacuum and heated (120°C) for 12 h, it changed to the dark blue solid **8**. The IR spectrum of **8** did not contain a ν(CO) (methanol) band and there was a significant decrease in the relative intensity of the ν(OH) band when compared to the spectrum of **6**. A small shift in the ν(PO) band was also noted on going from **6** to **8**. The visible spectra of **6** (in wet DMF) and **8** (in dry CH_2Cl_2) were as expected for high-spin octahedral and tetrahedral cobalt(II), respectively (see page 730 in ref. 6). Prolonged exposure of the blue solid to the atmosphere caused it to revert back to the original pink colour. These colour changes suggest that the following equilibrium is operative, and that the $Phos^-$ ions

*X-ray crystallographic data for complex **7**: $C_{46}H_{54}O_{17}CoP_2$, $Mr = 999.77$. Monoclinic, $C2/c$ (no. 15), $a = 41.93(3)$, $b = 8.683(2)$, $c = 13.21(1)$ Å; $\beta = 105.41(4)°$. $V = 4636(5)$ Å. $D_c = 1.426$ g cm $^{-3}$, $z = 4$; $F(000) = 1619.96$, $\lambda = 0.71069$, μ(Mo-K_α) = 4.51 cm^{-1}. The complex crystallized as very thin, fragile, pink plates. Data were collected to 20° on an Enraf–Nonius CAD4 diffractometer on a capillary-mounted sample. All non-hydrogen atoms could be unambiguously identified, but the structure could only be refined to R = 0.13 using 1577 unique data for which $I > \sigma(I)$. The low precision of the data is attributed to the smallness of the largest available crystals and their thinness. The data have therefore not been deposited with the Cambridge Crystallographic Data Centre.

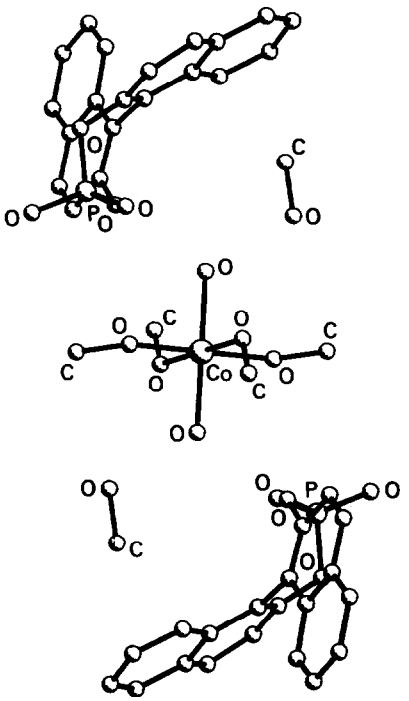

Fig. 2. X-ray structure of $[Co(CH_3OH)_4(H_2O)_2]((+)\text{-Phos})((-)\text{-Phos})\cdot 2CH_3OH\cdot H_2O$ (7) view of one asymmetric unit (excluding water molecule).

are coordinated to the metal in the blue solid **8**:

$$[Co(H_2O)_6]((+)\text{-Phos})((-)\text{-Phos}) \rightleftarrows [Co((+)\text{-Phos})((-)\text{-Phos})] + 6H_2O$$

O_h, pink — T_d, blue

Further evidence for the coordination of $Phos^-$ to the metal comes from the FAB mass spectrum of the Cu^{II} complex **2**, which contained peaks for the following ions: $[Cu(Phos)]^+$ (*m/z* 410); $[Cu_2(Phos)]^+$ (473); $[Cu(Phos)_2]^+$ (757); $[Cu_2(Phos)_2]^+$ (820); $[Cu_3(Phos)_2]^+$ (883).* Some of the possible monomeric and polymeric structures for $[M((\pm)\text{-Phos})_2]$ are illustrated in Fig. 3.

The thermogravimetric (TG) analysis curve for a sample of (±)-PhosH contained a well-defined thermal event between *ca* 200–440°C which correlated with the loss of dinaphtho[2,1-b:1′,2′-d]furan (Fig. 4).† At higher temperatures the remaining residue underwent multistage decomposition in which stable intermediates were not formed.[7] The TG curves for the tetrapyridine complexes **3** and **9** each contained two thermal events, the first of which corresponded to the loss of the four pyridine ligands in a single stage between *ca* 120–280°C. Single stage decomposition of the $Phos^-$ groups (loss of dinaphtho[2,1-b:1′,2′-d]furan) then took place at *ca* 320–480°C for the copper complex **3**, and at *ca* 400–600°C for the cobalt sample **9**.

The cyclic voltammogram of **3** in the potential range +212 to −788 mV [vs the ferrocene/ferrocenium (Fc/Fc^+) couple] showed a reversible, one-electron Cu^{2+}/Cu^+ couple (peaks AB in Fig. 5: $\Delta E = 87$ mV; $E_{1/2} = -407$ mV; $i_{P_c}/i_{P_a} = 1$), and the $E_{1/2}$ value of the couple suggested that the isolation of an air-stable Cu^I Phos compound would be thermodynamically unfavourable. Indeed, the reduction of **3** using the tetraphenylborate ion[8] did appear to give a Cu^I species. Addition of excess $Na[BPh_4]$ to a methanolic solution of **3** (under N_2) produced an immediate pale blue to light yellow colour change, and subsequent concentration of the solution caused the precipitation of a creamy-yellow solid. This solid (presumably a Cu^I species) was found to be extremely air-sensitive and turned green almost immediately on exposure to air. When the scan range of the voltammetry experiment was extended to −1388 mV (Fig. 6) two additional peaks appeared. Peak C was due to the irreversible reduction process, $Cu^+ + e \rightarrow Cu$ ($E_c = -1002$ mV), and the large peak D arose from the anodic stripping reaction, $Cu \rightarrow Cu^+ + e$ ($E_a = -451$ mV).‡

In summary, it appears that in the presence of donor solvents (methanol, water, pyridine) the $Phos^-$ ion does not coordinate directly to Cu^{II}, Co^{II} or Fe^{II} centres. However, in the case of some of the Cu^{II} and Co^{II} compounds there is evidence to suggest that when the compounds are de-solvated (by heating under high vacuum) the $Phos^-$ ions do then coordinate to the metals. Our current efforts are being directed towards the preparation of a sample of a coordinated $Phos^-$ complex for X-ray crystal structure determination in order to establish the coordination mode of the $Phos^-$ ligand.

EXPERIMENTAL

Except where specified all chemicals were reagent grade and were used without further purification. (±)-1,1′-Binaphthyl-2,2′-diyl hydrogen phosphate {(±)-PhosH} was prepared from (±)-1,1′-bi-2-naphthol[9] by using the method outlined by Cramm *et al.*[10] The sodium salt, Na^+Phos^- [ν(PO) = 1100 cm^{-1}], was made by treating a suspension of (±)-PhosH in water with an equimolar amount of NaOH. Most of the $Phos^-$ compounds which were

* The *m/z* values listed are based on the Cu^{63} isotope.

† In the mass spectrum (electron-impact) of (±)-PhosH (probe temperature = 380°C) the base peak was given by the (dinaphtho[2,1-b:1′,2′-d]furan)$^+$ ion (see Fig. 5).

‡ (±)-PhosH was electroinactive in the potential range +212 to −1388 mV (versus Fc/Fc^+).

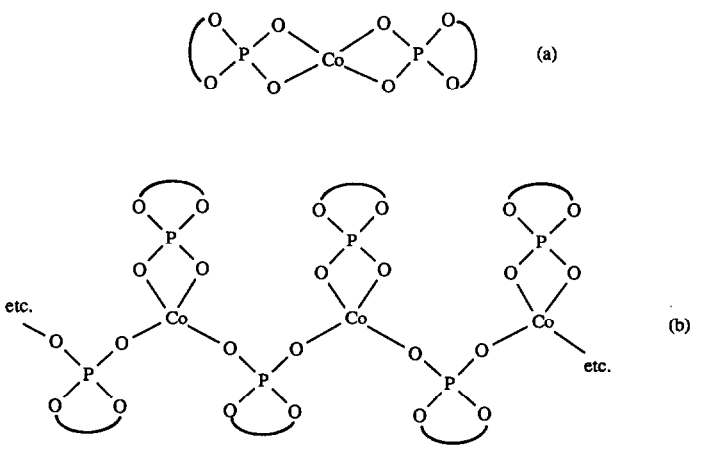

Fig. 3. Some of the possible structures of [Co((+)-Phos)((−)-Phos)] · 1.5H_2O (**8**) (tetrahedral Co^{II}): (a) monomeric, (b) polymeric. (Water molecules not shown.)

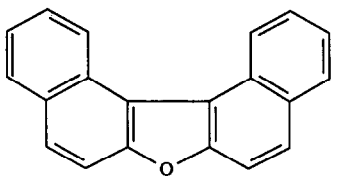

Fig. 4. Dinaphtho[2,1-b : 1′,2′-d]furan.

prepared were found to be hygroscopic. [Co(+)-tartrate] (i.e. [Co((+)-$C_4H_4O_6$)]) was prepared by reacting $CoCO_3$ with a refluxing aqueous solution of [(2*R*,3*R*)-(+)-tartaric acid]. Elemental analyses were performed by the Microanalytical Laboratory, University College Cork, Ireland. FAB mass spectra were run on a Varian MAT711 A spectrometer,

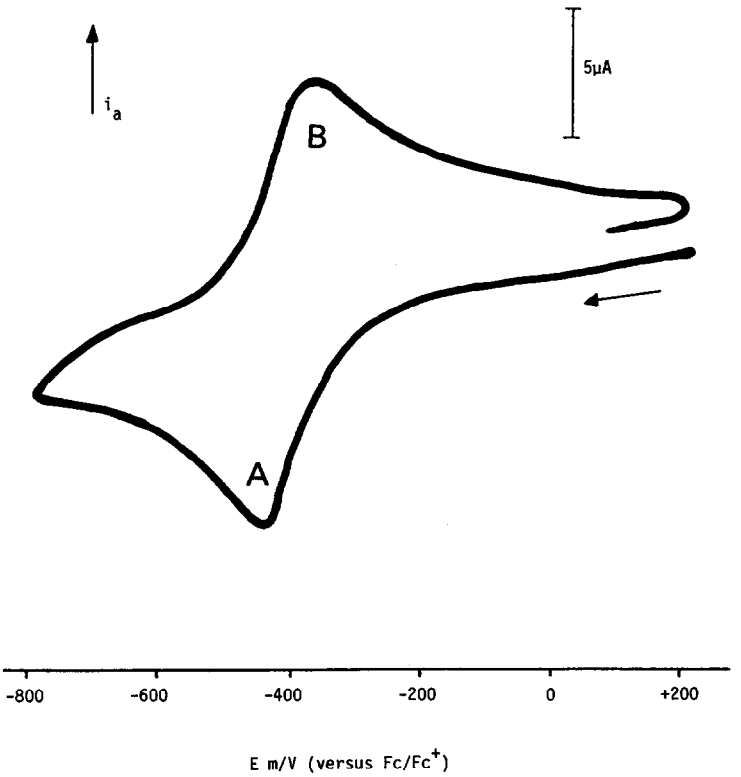

Fig. 5. Cyclic voltammogram of (3) in the potential range +212 to −788 mV (vs Fc/Fc^+). Scan rate = 50 mV s^{-1}.

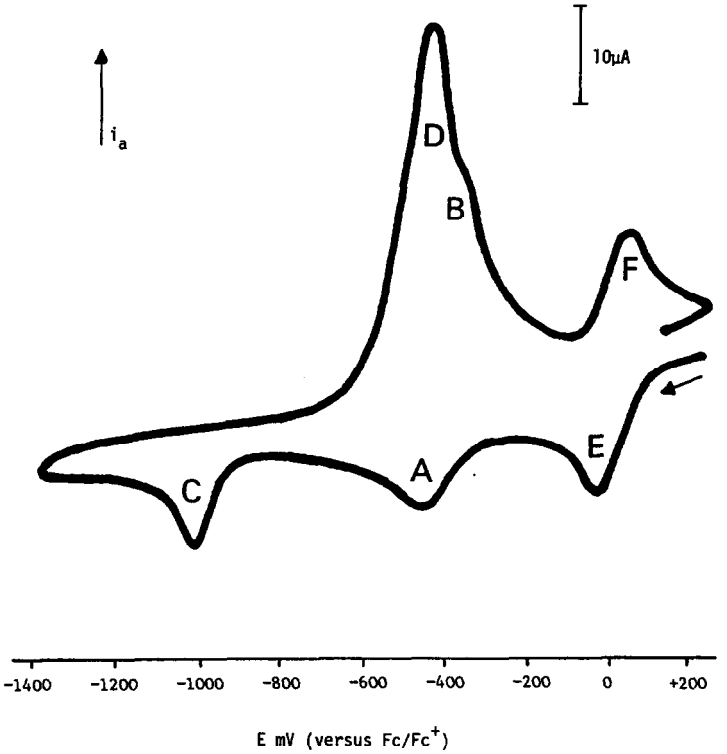

Fig. 6. Cyclic voltammogram of **3** in the potential range +212 to −1388 mV (vs Fc/Fc^+). Scan rate = 50 mV s^{-1}.

and electron-impact mass spectra were obtained using an AEI MS30 instrument equipped with an MSS data system. IR spectra (KBr disc) were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 783 grating spectrometer, and solid-state, room-temperature magnetic susceptibility measurements were made using a Johnson Matthey magnetic susceptibility balance. Cyclic voltammograms (*ca* 20°C and under N_2) were recorded using an EG&G model 264A polarographic analyser in combination with an EG&G PARC model 303 electrode assembly. A glassy carbon disc and a platinum wire were used as the working and reference electrodes, respectively. Potentials (mV) were measured with respect to an internal reference standard,[11] the ferrocene/ferrocenium(1+) (Fc/Fc^+) couple. The voltammetry data was analysed with the aid of the EG&G Condecon (TM) 300 system (software iRu compensation was used). Tetraethylammonium perchlorate in dry DMF (1.0×10^{-1} M) was used as the supporting electrolyte/solvent system, and complex **3** and ferrocene were each used at a concentration of 2.0×10^{-3} M. Conductivities (1.0×10^{-3} M in methanol or chloroform) were measured using an AGB Scientific Ltd model 10 conductivity meter. A Milton Roy Spectronic 3000 Array instrument was used for recording UV–vis spectra. Thermogravimetric analyses (under N_2) were done on a Stanton Redcroft TG750/770 instrument which was coupled to a Houston Instrument Omniscribe (series D5000) recorder. The heating rate was 10°C min^{-1}.

$[Cu(CH_3OH)_2(H_2O)_3]((+)$-*Phos*$)((-)$-*Phos*$)$ (**1**)

A mixture of $CuCO_3 \cdot Cu(OH)_2$ (0.16 g, 0.72 mmol), (±)-PhosH (2.02 g, 5.80 mmol) and methanol (40 cm^3) was refluxed for 48 h. The hot suspension was filtered, and the white solid product was then washed with methanol and allowed to air-dry. Yield: 1.11 g (88%). Found: C, 58.9; H, 4.4. Calc: C, 57.6; H, 4.4%. IR: 3600–2600 (OH), 1100 (PO), 1020 cm^{-1} (CO of CH_3OH); $\mu_{eff.}$ = 1.9 BM (17°C); non-electrolyte in $CHCl_3$.

$[Cu(H_2O)_2((+)$-*Phos*$)((-)$-*Phos*$)]$ (**2**)

Complex **1** was heated (*ca* 50°C) under high vacuum for 8 h to give the white solid **2**. Found: C, 60.4; H, 3.5. Calc: C, 60.5; H, 3.5%. IR: 3600–2600 (OH), 1100 cm^{-1} (PO), no methanol (CO) band.

$[Cu(py)_4]((+)$-*Phos*$)((-)$-Phos) (**3**)

Method (*a*). Complex **1** (0.29 g, 0.33 mmol) was refluxed in pyridine (py) (15 cm^3) for 1 h. The resulting suspension was allowed to cool to room temperature and the blue product was then removed by filtration. The solid was washed well with diethyl ether and then air-dried. Yield: 0.27 g (76%).

Method (*b*). $[Cu_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]$ (0.10 g, 0.25 mmol), (±)-PhosH (0.53 g, 1.52 mmol) and pyridine (40 cm^3) were refluxed together for 2 h. The product was then recovered from the resulting suspension as described in Method (a) above. Yield: 0.49 g (91%). Found: C, 66.1; H, 4.3; N, 4.6. Calc: C, 67.1; H, 4.1; N, 5.2%. IR: 1100 (PO), 1605 cm^{-1} (py); $\mu_{eff.}$ = 1.8 BM (26°C); Λ_M = 56 S cm^2 mol^{-1} (in MeOH): non-electrolyte in $CHCl_3$.

$[Cu(H_2O)_5]((+)$-*Phos*$)((-)$-*Phos*$)\cdot(\pm)$-*Phos*H (**4**)

$[Cu_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]$ (0.45 g, 1.13 mmol), (±)-PhosH (2.53 g, 7.26 mmol) and THF (30 cm^3) were refluxed together for 3 h. The resulting suspension was allowed to cool to room temperature and the white product was removed by filtration. The solid was washed with THF and then allowed to air-dry. Yield: 1.95 g (72%). Found: C, 60.0; H, 4.1. Calc: C, 60.2; H, 4.0%. IR: 3600–2600 (OH), 1100 cm^{-1} (PO); $\mu_{eff.}$ = 2.0 BM (17°C).

$[Cu(H_2O)_2(DMF)_2]((+)$-*Phos*$)((-)$-*Phos*) (**5**)

Complex **4** (1.52 g, 1.27 mmol) was dissolved in hot dimethylformamide (DMF) (250 cm^3). The resulting brown solution was reduced in volume to *ca* 120 cm^3 by vacuum distillation, and on cooling the white product precipitated. The solid was filtered off, washed with diethyl ether and then allowed to air-dry. Yield: 0.46 g (39%). Found: C, 58.8; H, 4.5; N, 3.2. Calc: C, 58.8; H, 4.5; N, 3.0%. IR: 3600–2600 (OH), 1100 (PO), 1705 cm^{-1} (CO of DMF); $\mu_{eff.}$ = 1.8 BM (17°C).

$[CO(H_2O)_6]((+)$-*Phos*$)((-)$-*Phos*$)\cdot CH_3OH$ (**6**) *and* $[Co(CH_3OH)_4(H_2O)_2]((+)$-*Phos*$)((-)$-*Phos*$)\cdot 2CH_3OH\cdot H_2O$ (**7**)

A mixture comprising [Co(+)-tartrate)] (0.10 g, 0.48 mmol), (±)-PhosH (0.67 g, 1.92 mmol) and methanol (25 cm^3) were refluxed together for 15 min, and the mixture was then allowed to stir overnight at room temperature. The suspension was filtered, and the pale pink product **6** was washed with methanol and then air-dried. Yield: 0.35 g (81%). Found: C, 55.0; H, 4.2. Calc: C, 55.1; H, 4.5%. IR: 3600–2600 (OH), 1100 (PO), 1020 cm^{-1} (CO of CH_3OH); $\mu_{eff.}$ = 4.6 BM (22°C); non-electrolyte in $CHCl_3$. A crystal suitable for X-ray analysis (i.e. **7**) was obtained by allowing the above reaction filtrate to concentrate by slow evaporation in the fume cupboard.

$[Co((+)$-*Phos*$)((-)$-*Phos*$)]\cdot 1.5H_2O$ (**8**)

A sample of the pale pink solid **6** was heated (120°C) under high vacuum for 12 h to give the dark blue solid **8**. Found: C, 61.5; H, 3.3. Calc: C, 61.5; H, 3.5%. IR: 3600–3100 (OH), 1110 cm^{-1} (PO); $\mu_{eff.}$ = 4.8 BM (15°C). Complex **8** slowly turns pink again when it is exposed to the atmosphere. When **8** is reacted with concentrated HCl white, crystalline (±)-PhosH is recovered.

$[Co(py)_4((+)$-*Phos*$)((-)$-*Phos*$)]$ (**9**)

Complex (**6**) (0.60 g, 0.67 mmol) was refluxed in pyridine (15 cm^3) for 1 h and the resulting suspension was then allowed to cool to room temperature. The pink solid was filtered off, washed with diethyl ether and then dried under high vacuum (without heat). Yield: 0.22 g (31%). Found: C, 67.3; H, 3.9; N, 5.2. Calc: C, 67.4; H, 4.1; N, 5.2%. IR: 1100 (PO), 1608 cm^{-1} (py); $\mu_{eff.}$ = 4.7 BM (18°C); Λ_M = 59 S cm^2 mol^{-1} (in MeOH); non-electrolyte in $CHCl_3$.

$[Fe(CH_3OH)_2(H_2O)_4]((+)$-*Phos*$)((-)$-*Phos*) (**10**)

$FeSO_4\cdot 7H_2O$ (0.26 g, 0.94 mmol), (±)-PhosH (1.50 g, 4.31 mmol) and methanol (50 cm^3) were refluxed together for 1.5 h. The resulting suspension was filtered, and the white product was washed with methanol and dried under vacuum (without heating). Yield: 0.76 g (91%). Found: C, 57.9; H, 4.6. Calc: C, 56.9; H. 4.5%. IR: 3500–2600 (OH), 1100 (PO), 1020 cm^{-1} (CO of CH_3OH); $\mu_{eff.}$ = 4.6 BM (16°C); non-electrolyte in $CHCl_3$.

BUTYRYLHYDRAZINE CHELATES OF LANTHANIDE DODECAHYDRODODECABORATES

XIN-LAN CHEN and LUN ZHANG*

Department of Chemistry, Wuhan University, Wuhan 430072, China

(*Received* 2 *January* 1991; *accepted* 22 *July* 1991)

Abstract—The butyrylhydrazine[buhy, $CH_3CH_2CH_2C(O)NHNH_2$] chelates of lanthanide dodecahydrododecaborates were synthesized by the reaction of butyrylhydrazine with lanthanide dodecahydrododecaborates. They have the formula $[Ln(buhy)_4]_2(B_{12}H_{12})_3nH_2O$. When Ln = La, Sm, Gd, $n = 5$; and when Ln = Ho, Er, Tm, Yb, $n = 4$. The IR, UV, ^1H NMR spectra and TG-DTA graphs of these chelates were recorded and are discussed.

Recently, we have described the benzoyl- and butyrylhydrazine complexes of first-row transition metal and IIB group metal hydroborates,[1] and the benzoylhydrazine complexes of lanthanide dodecahydrododecaborates.[2] The metal complexes have the formulae $[M(bh)_3]B_nH_n$ and $[M(buhy)_3]B_nH_n$, respectively; where bh is benzoylhydrazine and buhy is butyrylhydrazine; M = Mn, Fe, Co, Ni, Cu, Zn, Cd, and Hg; and $n = 10$ and 12. The formula of the lanthanide complexes is $[Ln(bh)_4]_2B_{12}H_{12}$ and Ln = La, Pr, Nd, Sm, Eu, Gd, Tb, Ho, Er, Tm and Yb. Some of these complexes exhibit biological activity and are able to inhibit the growth of cancer cells.[3]

As a continuation of our previous work, we report here the synthesis of butyrylhydrazine chelates of lanthanide dodecahydrododecaborates, and their spectral and thermal properties.

EXPERIMENTAL

Materials

Synthesis of butyrylhydrazine. An aqueous solution of hydrazine monohydrate (300 mmol, 17 cm^3) was mixed with ethyl butyrate (250 mmol, 34 cm^3) and stirred at room temperature until the reaction mixture became homogeneous. Then the mixture was heated to about 120°C to distill off the by-products and unreacted materials. The residue was cooled to −5°C and crystallized. Recrystallization from ethanol gave needle crystals (yield 80%, 200 mmol). Its m.p. (43–44°C) and IR spectra (see Table 2) are in accordance with the literature data.[4]

Preparation of dodecahydrododecaboric acid. A solution of bis(tetramethylammonium) dodecahydrododecaborate (3.50 mmol) in 50 cm^3 of cold water was passed through a column containing H-form cation exchange resin (100–200 mesh, 50 × 2 cm) and the effused dodecahydrododecaboric acid aqueous solution was collected and used for the preparation of $Ln_2(B_{12}H_{12})_3xH_2O$.

The ethyl butyrate (98%, $d = 0.878$) and hydrazine monohydrate (85%, $d = 1.032$) of reagent grade were used. The lanthanide oxides, all of 99.9% purity, were obtained from Yun Long Chemical Plant (Shanghai). Bis(tetramethylammonium) dodecahydrododecaborate was prepared by a known method.[5]

Physical measurements

IR spectra were obtained on a Shimadzu IR-450 spectrophotometer using KBr discs. UV spectra were recorded in H_2O with a Shimadzu UV-300 spectrophotometer. ^1H NMR spectra were recorded in CD_3CN with a JEOL JNM-90Q spectrometer using tetramethylsilane as internal standard. TG-DTA graphs were recorded on a Beijing LCT-1 TG-DTA instrument at a heating rate of 10°C min^{-1} in dynamic nitrogen of 60 cm^3 min^{-1} over a temperature range from 25°C to about 500°C.

* Author to whom correspondence should be addressed.

Synthesis of the chelates

All the chelates were synthesized using a general procedure that is illustrated below by the synthesis of $[La(buhy)_4]_2(B_{12}H_{12})_3 5H_2O$.

La_2O_3 (0.31 mmol) was dissolved in 16 cm^3 of about 0.07 M dodecahydrododecaboric acid solution. $La_2(B_{12}H_{12})_3 xH_2O$ solid was obtained after concentration of the solution to dryness under reduced pressure at 70°C. The solid $La_2(B_{12}H_{12})_3 xH_2O$ obtained from 0.31 mmol La_2O_3 was dissolved in 10 cm^3 of methanol and to this solution the butyrylhydrazine (7.40 mmol) was added with stirring. After 6 h, the reaction mixture was slowly heated to remove methanol under reduced pressure. The viscose residue was obtained and recrystallized from methanol—ether. The product was filtered, washed twice with small quantities of ether and dried *in vacuo*. A complete list of the chelates, yields and microanalyses are given in Table 1.

$$Ln_2O_3 + 3H_2B_{12}H_{12} \xrightarrow[60^\circ C]{H_2O} Ln_2(B_{12}H_{12})_3 \cdot xH_2O$$

$$[Ln(buhy)_4]_2(B_{12}H_{12})_3 \cdot nH_2O \xleftarrow[\text{Room temperature}]{CH_3OH} \text{buhy}$$

Ln = La, Sm, Gd. $n = 5$; Ln = Ho, Er, Tm, Yb, $n = 4$

Scheme 1.

RESULTS AND DISCUSSION

Syntheses and properties

The synthesis of the butyrylhydrazine chelates of lanthanide dodecahydrododecaborates is outlined in Scheme 1.

Microanalytical data for the chelates (Table 1) show that all the chelates have a 4:1 ratio of buhy to Ln^{3+}, which is independent of the ratio of reactants.

All these chelates are white hygroscopic solids, which are soluble in water, methanol and acetonitrile, and insoluble in ether and acetone.

IR spectra. Since these chelates have similar IR spectra, only the spectral data of buhy, lanthanum dodecahydrododecaborate hydrates, and lanthanum chelate chosen as a representative are listed in Table 2. The detailed vibrational frequencies (4000–400 cm^{-1}) with possible assignments are given.

The important changes observed after chelation are: (1) the splitting and shift of amide I and II frequencies from 1660 to 1610 cm^{-1} in the parent ligand to 1646 cm^{-1} (Amide I) and 1600 cm^{-1} (Amide II); (2) the shifts of the $\nu(N—N)$ vibrations from 995 and 920 cm^{-1} in the ligand to 948 and 905 cm^{-1}, respectively; (3) two bands around 645 and 475 cm^{-1} being found for all chelates, which may be attributed to $\nu(N \rightarrow Ln)$ and $\nu(O \rightarrow Ln)$ vibrations, respectively. These important changes suggest that buhy is coordinated with the lanthanide ions through its carbonyl oxygen and nitrogen atoms, forming five-membered chelate rings.

In comparison with $La_2(B_{12}H_{12})_3 xH_2O$, no change for the characteristic vibration bands of $B_{12}H_{12}^{2-}$ in all chelates were observed. It shows that all *closo*-$B_{12}H_{12}^{2-}$ are outer sphere anions.

UV spectra. The UV spectral data of buhy and its lanthanide chelates are given in Table 3. No absorption was observed in the visible region (900–400 nm) for the ligand and any of its chelates. The spectra of the chelates are similar to the spectrum of the ligand and all of them exhibit only one band due to C=O and $—NH_2$ groups. The absorption maximum (λ_{max}) of the ligand undergoes red shifts of 1–6 nm in the chelates. However, the values of the molar extinction coefficient (ε) of the chelates measured at identical wavelength show significant

Table 3. UV spectral data of buhy and chelates

Ligand or chelates	λ_{max} (nm)	ε
buhy	206	1919
La	209	14756
Sm	211	14288
Gd	212	12134
Ho	207	18122
Er	207	17777
Tm	211	13250
Yb	209	15127

increments when compared with the value of the ligand. It also suggests that the carbonyl oxygen and amine nitrogen atoms are coordinated to the lanthanide ions.

^1H NMR spectra. The proton signals of ligand (buhy) and lanthanide chelates (Ln = La, Sm, Gd, Ho, Er, Tm and Yb) were recorded (Table 4). Among the lanthanide ions mentioned above, La^{3+} is diamagnetic, while the others containing unpaired $4f$ electrons are all paramagnetic. In the lanthanum ($4f^0$) chelate all the proton signals suffer upfield shifts when compared with that of the free ligand. With the samarium ($4f^5$) chelate the proton signals of the butyryl group suffer downfield shifts. With the gadolinium ($4f^7$) chelate no signal was observed at all, which is similar to that of methylene bis(diphenylphosphine oxide) complex of gadolinium dodecahydrododecaborate.[5] With the holmium ($4f^{10}$) and erbium ($4f^{11}$) chelates all the proton signals suffer downfield shifts and broadening compared with that of the lanthanum chelate. Both the thulium ($4f^{12}$) and ytterbium ($4f^{13}$) chelates display two broad signals, the former centred at 1.50 and 3.92, and the latter at 1.26 and 3.90 ppm, respectively. These spectra with broadened signals may be due to a spin–spin relaxation process arising from the paramagnetic lanthanide ions. Gd^{3+} has the maximum number of unpaired electrons and is strongly paramagnetic, making the signals extremely broad.

Table 4. ^{1}H NMR spectral data of ligand (buhy) and chelates

Er	1.04br,t	2.12m	3.32br,s	—[d]	4.31br,s

[a] Scanned covering a range of 0–50 ppm at 25°C.
[b] sh, sharp; br, broad; s, singlet; t, triplet; m, multiplet.
[c] Recorded in $CDCl_3$.
[d] Unobserved.

TG-DTA graphs

All the chelates show similar TG-DTA graphs as typically given in Figs 1 and 2 for the Sm- and Yb-chelate respectively.

The TG curve reveals four weight-loss stages. The first two are the dehydration of the chelates, including the loss of crystalline water and coordinated water. The observed weight-loss compares favourably with the calculated values (Table 5). The second two are the decomposition of anhydrous chelates, which are very complex and probably include the partial loss of ligands and the decompo-

MACROCYCLIC DIVALENT TRANSITION METAL COMPLEXES OF ACETYLACETONE BUCKLED WITH TWO DIFFERENT DIAMINES

K. HUSSAIN REDDY,* G. KRISHNAIAH and Y. SREENIVASULU

Department of Chemistry, Sri Krishnadevaraya University, Anantapur-515 003, India

(*Received* 14 *November* 1990; *accepted* 22 *July* 1991)

Abstract—Metal-mediated condensation of *o*-phenylenediamine with bisacetylacetone-ethylenediimine yields 14-membered tetraaza macrocyclic six-coordinate complexes of the type $[M(mac)Cl_2]$, $[M(mac)SO_4 \cdot H_2O]$ (where M = Fe^{II}, Co^{II} and Cu^{II}; mac = macrocyclic ligand formed in the template reaction). The metal ions are coordinated by four azomethine nitrogen atoms bridged by acetylacetone moieties. The electrical conductance magnetic moments, electronic and IR spectral data of all complexes are discussed.

Several transition-metal macrocyclic complexes either by template or non-template methods have been prepared using different dicarbonyl compounds and diamines. Various synthetic possibilities of the 2,4-pentanedione-1,2-diaminoethane system have been discussed[1] and different macrocyclic ligand complexes have been recently reviewed by Lindoy.[2] Truck and Holm[3] have prepared macrocyclic complexes which are completely conjugated using ethylenediamine and acetylacetone. Similarly, tetraaza macrocyclic transition-metal complexes have been prepared using *o*-phenylenediamine and acetylacetone.[4] Recently,[5] divalent metal complexes with *m*-phenylenediamine and acetylacetone have been prepared and characterized.

However, divalent transition-metal complexes with acetylacetone buckled with both aliphatic and aromatic amines are not reported so far. In continuation[6] of our efforts to derive model compounds using macrocyclic ligands, we report here the synthesis and spectral properties of six-coordinate complexes of tetradentate ligands formed *in situ* in the presence of metal ions with bisacetylacetone-ethylenediimine and *o*-phenylenediamine.

EXPERIMENTAL

All the chemicals and solvents used were of reagent grade.

Ethylenediamine (BDH) was dried over solid potassium hydroxide for 12 h and distilled, the fraction boiling over the range 116–117°C being used in this study. Acetylacetone used in the preparation of complexes was from Germed, Veb Laborchemie and used without further purification. *Ortho* phenylenediamine used in this study was from SD and recrystallized from methanol and used.

The Schiff base bisacetylacetone-ethylenediimine was prepared and purified following the literature procedure[7] (m.p. 111°C; lit. m.p. 111–111.5°C).

Preparation of complexes

To a hot reaction mixture containing *ortho* phenylenediamine (0.002 mol) dissolved in methanol (50 cm^3) and an adequate quantity (0.002 mol) of corresponding metal salt solution, was added bisacetylacetone-ethylenediimine (0.002 mol) dissolved in methanol (25 cm^3). The reaction mixture was then heated under reflux for 2 h in a hot water bath. On cooling the reaction mixture, the product was separated, collected by filtration *in vacuo*, washed with hot water and then with cold methanol and dried. The colour, yield, molar conductance and magnetic moments together with analytical data for all complexes are given in Table 1. Chloro and sulphato complexes were prepared by taking metal chlorides and sulphates, respectively.

The microanalyses of C, H and N were done at the Regional Sophisticated Instrumentation Centre, Central Drug Research Institute, Lucknow, UP, India. The metal contents were estimated using standard EDTA titrations.

Physical measurements

The IR spectra were recorded in the range 4000–180 cm^{-1} using KBr discs. Magnetic susceptibility measurements were made using a vibrating sample magnetometer (VSM) operating at a field strength of 3–8 kg at room temperature. The electronic spectra for all complexes in the UV and visible region were recorded in the range 185–1200 nm on a Carl Zeiss DMR-21 recording spectrophotometer in dimethylformamide (DMF) medium. The electrical conductivity measurements were made in DMF solvent at room temperature (31+2°C) using a Systronic 303 direct-reading conductivity bridge. A suitable quantity of solid complex was weighed and dissolved in DMF to reach a 10^{-3} M concentration. The ^1H NMR spectra were obtained on a Varian XL-300 MHz spectrometer at room temperature.

RESULTS AND DISCUSSION

The colours, analyses, molar conductance and magnetic moment values of the complexes are given in Table 1. Attempts to isolate iron(III) complexes by the procedure described for the preparation of complexes were unsuccessful and resulted in rapid reduction and formation of tetraaza macrocyclic iron(II) complexes.

All the complexes are soluble in hot methanol and DMF. The complexes are stable towards water and unstable either in mineral acids or in alkali.

The analytical data of these complexes show their formulae to be $[M(C_{18}H_{22}N_4)Cl_2]$ and $[M(C_{18}H_{22}N_4)SO_4 \cdot H_2O]$, where M = Fe^{II}, Co^{II} and Cu^{II}. Except [Ni(mac)]Cl_2 (155) and [Ni(mac)]SO_4 (110 Ω^{-1} cm^{-2} mol^{-1}), all the complexes are non-electrolytes in dimethylformamide. Molar conductivity values of nickel complexes are given in parentheses.

Magnetic moments and electronic spectra

Tetraaza macrocyclic iron(II) sulphato and chloro complexes show lower magneton values of 4.89 and 3.61 BM, which may be attributed to the quenching of orbital contribution arising from the lower symmetry.[8] Two bands are observed in the electronic spectrum of iron(II) complexes. Chloro and sulphato macrocyclic iron(II) complexes exhibit bands at 5900, 5200 and 12,800, 12,510 cm^{-1} assigned to $^5A_{1g} \leftarrow {}^5T_{2g}$ and $^5B_{1g} \leftarrow {}^5T_{2g}$ transitions,

[a] Difference in the observed and calculated value of frequencies.
[b] Ratio of the free ion and of the complex.

respectively, characteristic of six-coordinate iron(II) complexes[9] of the type FeL_4X_2. These complexes exhibit charge-transfer bands at 18,520 (chloro) and 20,830 cm^{-1} (sulphato) with iron(II) t_{2g} electrons being transferred to the empty π-antibonding orbitals of the ligand.

Magnetic moments of [Co(mac)Cl_2] and [Co(mac)$SO_4 \cdot H_2O$] are found to be 3.70 and 3.51 BM, respectively, corresponding to spin-only values for three unpaired electrons of a d^7 system. Most of the octahedral cobalt(II) derivatives are pink or reddish-brown while many of the tetrahedral cobalt (II) complexes are intense blue or green. However, these colours are infallible guides so as to decide the geometry of the complexes. In the electronic spectrum of [Co(mac)Cl_2] and [Co(mac)$SO_4 \cdot H_2O$] three bands are observed at 7300 and 7500, 15,150 and 16,600 and 18,540 and 18,520 cm^{-1}, assigned to $^4T_{2g} \leftarrow {}^4T_{1g}$, $^4A_{2g} \leftarrow {}^4T_{1g}$ and $^4T_{1g}(P) \leftarrow {}^4T_{1g}$ transitions, respectively, in an octahedral geometry.[10] The inter-electronic repulsion (B) and 10 Dq are found to be 786 and 841 and 7850 and 9100 for chloro and sulphato macrocyclic cobalt(II) complexes, respectively. The ratio of observed ν_2 to calculated ν_1 are found to be 2.07 and 2.21 for chloro and sulphato complexes, respectively, as required for an octahedral cobalt(II) complex.[11] The LFSE are calculated and found to be 22.4 and 26.0 kcal mol^{-1} for chloro and sulphato complexes, respectively.

The electronic spectral data for [Ni(mac)]Cl_2 and [Ni(mac)]SO_4 show bands at 8750 and 8820, 16,540 and 16,860 and 23,810 and 24,100 cm^{-1}, attributable to $^3T_{2g}(F) \leftarrow {}^3A_{2g}(F)$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}(F)$ and $^3T_{1g}(F) \leftarrow {}^3A_{2g}(F)$ transitions, respectively. The electronic spectral data suggest an octahedral geometry for these complexes.

The nickel(II) macrocycles are diamagnetic but in DMF the electronic spectral data correspond to octahedral geometry. DMF is known to be a coordinating solvent and presumably coordinates nickel in the axial positions to become six-coordinate. The electronic spectra of the complexes in the solid state correspond to square-planar geometry. The spectral data utilized important ligand field parameters to compute 10 Dq and B_{35}, using the ligand field theory of spin-allowed transitions in a d^8 configuration. The values of B_{35} and 10 Dq were used to calculate ν_2 and ν_3 and the results are given in Table 2.

The diamagnetic nature of the copper(II) sulphato tetraaza macrocyclic complex indicates the possible spin–spin interaction by the overlap of occupied $d_{x^2-y^2}$ orbitals of the two cupric ions to form a δ-type bond similar to that reported in copper(II) acetate monohydrate. The electronic spectrum of this complex shows one broad, strong band at 18,870 cm^{-1} with a more or less pronounced low energy shoulder (17,860 cm^{-1}). Based on the electronic spectrum, this complex seems to be tetragonally distorted.[12] For a copper(II) ion in a tetragonal environment three principal absorption bands are expected, but only in a few complexes[13–15] have these absorption bands been resolved, either by Gaussian analysis or single-crystal polarization studies, and are assigned to the transitions $^2A_{1g} \leftarrow {}^2B_{1g} \cdots (\nu_1)$, $^2B_{2g} \leftarrow {}^2B_{1g} \cdots (\nu_2)$ and $^2E_g \leftarrow {}^2B_{1g} \cdots (\nu_3)$ in order of increasing energy. The low energy shoulder in the present complex can be assigned to[14,15] the splitting of the ^2E_g term. Because of the low intensity of the $^2B_{2g} \leftarrow {}^2B_{2g}$ (which is equal to 10 Dq) band, it is not usually observed as a separate band in tetragonal copper complexes. Another band in the electronic spectrum of this complex is located at 14,600 cm^{-1}, attributable to the $^2E_g \leftarrow {}^2B_{1g}$ transition suggesting octahedral geometry for this complex.[16]

The magnetic moment of the chloro derivative

Table 3. Important IR spectral bands and their assignments

Complex	ν(C=N)+ν(C=C)	ν_{asym}(C—CH_3)	ν_{sym}(C—CH_3)	δ(CH)+ν(C—CH_3)	P_r—CH_3	Anions

[Co(mac)SO_4H_2O]	1615 1580	1410	1370	1210	1025	1118 1055 1020
[Co(mac)Cl_2]	1610 1587	1425	1365	1205	1022	300
[Ni(mac)]SO_4	1615 1580	1400	1353	1219	1030	1122 1072 1015
[Ni(mac)]Cl_2	1615 1575	1410	1355	1210	1020	—
[Cu(mac)SO_4]$_2$	1610 1585	1422	1365	1225	1025	1160 1065 1005
[Cu(mac)Cl_2]	1615 1575	1420	1360	1220	1020	283

of the tetraaza macrocyclic copper(II) complex is found to be 1.69 BM, which is very close to the spin-only value for one unpaired electron and is in the range normally observed for copper(II) complexes having an orbitally non-degenerate B_{1g} ground state. This complex shows one band in the visible region with λ_{max} at 15,380 cm^{-1}. This is characteristic of a $^2T_{2g} \leftarrow {}^2E_g$ absorption in octahedral geometry.[17]

IR spectra

The important IR spectral bands of the tetraaza macrocyclic complexes and their assignments are presented in Table 3. In the IR spectra the stretching and deformation vibrations of the NH_2 groups are absent. Strong bands appearing as doublets in the range 1610–1585 cm^{-1} are assigned[18–21] to the coordinated and conjugated $\rangle C{=}N$ group present in all the complexes. The bands characteristic of the acetylacetone moiety (Table 3) are present in all the complexes. The absence of stretching and bending vibrations of the (C—O) group (1525 and 1280 cm^{-1}) indicate the absence of this group in these complexes.[5]

The bands appearing in the spectra of the sulphato complexes, 1120, 1070 and 1020 cm^{-1}, may be assigned to unidentate sulphate groups.[22–24] In the sulphate containing complexes bands in the region 3455–3485 cm^{-1} are assigned to the presence of coordinated water molecules.

Characteristic bands in the far IR spectra of complexes are observed. The chloro complexes exhibit bands at 290, 300 and 283 cm^{-1} and these are assigned to Fe—Cl, Co—Cl and Cu—Cl vibrations, respectively. The appearance of single bands and their regions are consistent with the *trans* octahedral nature of these complexes.[25] In the spectra of all the complexes, bands are observed in the region 440–485 cm^{-1}, assigned to the ν(M—N) vibrations which substantiate the participation of the azomethine nitrogen atom in coordination.[26]

^1H NMR spectra of the nickel complexes: the ^1H NMR spectra of [Ni(mac)]Cl_2 and [Ni(mac)]SO_4 complexes are virtually identical. ^1H NMR ($CDCl_3$): 1.98 (s, 12H, methyl H), 3.23 (s, 4H, methylene H), 3.53 (s, 4H, methylene H), 6.95–7.25 (m, 4H, phenyl H).

Based on the results we have presented so far, structure **I** is assigned for these complexes.

TITRATION AND SPECTRAL STUDIES OF COMPLEXES BETWEEN FIRST-ROW TRANSITION METALS AND TRIS(2-PYRIDYL)CARBINOL AND BIS(2-PYRIDYL)PHENYLCARBINOL[1]

ROBERT K. BOGGESS,* ANNE H. LAMSON and STEVEN YORK

Department of Chemistry, Radford University, Radford, VA 24142, U.S.A.

(*Received* 1 *March* 1991; *accepted* 16 *July* 1991)

Abstract—Titrations of tris(2-pyridyl)carbinol (py_3COH) and di(2-pyridyl)phenylcarbinol (py_2phCOH) in the presence of first-row transition metals form 2:1 complexes and one —COH group per complex is made acidic. For py_3COH, coordination is via a mixed-mode method, i.e. one ligand is bound in a symmetric N,N′,N″ mode and the second, in which the —COH group is made acidic, in a non-symmetric N,N′,O mode. The cobalt(II) and nickel(II) complexes titrate as a weak acid (pK_a 6.6) and the H^+ is bound to a non-coordinated pyridyl nitrogen. The iron(II) and manganese(II) titrate as strong acids, even through a pyridyl nitrogen is not coordinated. The copper(II) and zinc(II) have both ligands coordinated in a symmetrical fashion and do not consume OH^- until considerably higher pH values. Di(2-pyridyl)phenylcarbinol binds, as it must if it is to be tridentate, exclusively in an N,N′,O fashion and all the complexes titrate as strong acids. The complexes have been characterized by spectroscopic techniques.

Tris(2-pyridyl)carbinol, py_3COH, can coordinate as a tridentate ligand in the N,N′,N″ symmetric mode, **1**, or in an N,N′,O non-symmetric mode, **2**, with first-row transition metals,[2–4] ruthenium,[5]

methylmercury(II)[6] and monomethylindium.[7] The solution ^1H NMR spectrum in methanol of $(CH_3)_2Au(py_3COH)$ has also suggested bidentate coordination through two pyridyl nitrogens[8] as a mode of coordination for this ligand. Linkage isomers of cobalt(III), with one isomer having both ligands coordinated in the N,N′,N″ symmetric mode[5] while the other has one ligand coordinated in the N,N′,N″ symmetric mode and the second in the N,N′,O non-symmetric mode (the oxygen of the —COH group is deprotonated) to give $[Co(N,N',N''\text{-}py_3COH)(N,N',O\text{-}py_3CO)]^{2+}$ [3] have been reported. The cobalt(II) complex with py_3COH has not been isolated and is unusual in that it is very sensitive to oxygen even though complexes of other py_3X ligands (X is N, P, P=O, or As[9]) are relatively inert toward oxygen and are easily prepared without the necessity of a nitrogen atmosphere and are stable indefinitely in solution. The two ruthenium(II) complexes with py_3COH each have one ligand coordinated in the symmetric mode and the other in the non-symmetric mode, the difference being that the coordinated —COH group is deprotonated in the second complex.

The non-symmetric N,N′,O mode of coor-

dination of py_3COH found in many complexes suggested that the carbinol group might be forced upon other transition metals both in the presence and absence of a competing pyridyl group. The latter point was investigated using the ligand bis(2-pyridyl)phenylcarbinol, py_2phCOH, as steric requirements for py_2phCOH and py_3COH should be similar. N,N',O-coordination has been found for py_2phCOH complexes with first-row transition metals[10] and later for monomethylindium[7] complexes. Coordination by both —COH and —CO^- have been reported. A feature of this ligand not found to date for py_3COH is the ability of the oxygen of the —CO^- to bridge two metal ions.[10,7]

Metal-promoted ionizations are important in a number of chemical systems, including many biological ones. An earlier paper attempted to use py_3COH and related ligands as model systems for the active site of carbonic anhydrase.[11] Binding constants for Zn^{2+}, Co^{2+}, Ni^{2+} and Cu^{2+} with several tridentate ligands, including py_3COH, were determined. The authors report that some H^+ were formed as a result of mixing py_3COH with these ions, especially Co^{2+}. However, the acidity was attributed more to M^{2+}-OH_2 than to loss of the proton from the —COH group. Since both py_3COH and py_2phCOH when coordinated can act as a proton donor, we have now investigated the titration curves of these ligands in both the absence and presence of transition metals and report our findings herein.

EXPERIMENTAL

Reagents

All reagents are commercially available and were used as received unless noted below. Bis(2-pyridyl)phenylcarbinol[12] and tris(2-pyridyl)carbinol[13] were prepared as previously reported.

Physical measurements

UV–vis spectra were recorded with a Perkin–Elmer Model 552 or Model 330 spectrophotometer. All titrations were done under nitrogen that had been bubbled through a vanadium(II) solution to remove trace amounts of oxygen and in a mixed ethanol–water (1 : 1 by volume) solution that was also 0.10 M in KCl. A Radiometer titration system (Model 64 pH meter, Model TTT80 automatic titrator, Model 80 autoburet and Model 80 recorder) equipped with a combination electrode was used for all titrations. Electrode calibration was by means of commercially available NBS aqueous buffer solutions (pH 4.00 and pH 7.00). To obtain a measure of the a_{H^+} referred to the standard state in the mixed solvent system, 0.15 log unit was subtracted from each pH meter reading.[14] A typical experiment consisted of adding metal(II) chloride (0.25 mmol) to the ethanol–water mixture (25 cm^3), thoroughly deaerating with nitrogen, adding ligand (0.50 mmol) and titrating with NaOH (1.00 M). Spectra were recorded at specified pH without exposure to the atmosphere. The ^{13}C NMR spectrum was obtained on a Brucker Model WP-200SY instrument at 50.327 MHz. d_3-Acetonitrile was used as the solvent and the spectrum is referenced to TMS at zero ppm.

RESULTS AND DISCUSSION

Titration of a solution containing HCl and py_3COH (3 : 1 molar ratio) or HCl and py_2phCOH (2 : 1 molar ratio) allows the calculation[15] of the pK_a of one pyridyl nitrogen (Table 1) corresponding to the reaction

$$HL^+ \longrightarrow L + H^+ \quad K_a = \frac{[L]a_{H^+}}{[HL]}.$$

The pK_a for py_3COH compares favourably with values reported previously considering that different solvents and different ionic strengths were employed. Titration curves of HCl and HCl-py_3COH (3 : 1 molar ratio) are given in Fig. 1. The complete overlap of the first portion of the titration curves and the near overlap of the middle portion suggests no interaction and only minimal interaction, respectively, of two of the three H^+ with py_3COH, i.e. two of the three pyridyl nitrogens have minimal basic properties. The third pyridyl nitrogen titrates as a typical weak acid. This point is emphasized by the isolation of only the monoprotonated ligand, $py_2(py \cdot H)COH^+$ as the perchlorate salt from a reaction of py_3COH and tetrakis (methylsulphoxide)ruthenium(II) chloride in dilute perchloric acid solution.[16] The crystal structure[17] of this salt has no exceptional features and is similar to that of py_3COH previously reported.[18] The —COH in $[py_2(py \cdot H)COH]ClO_4$ is hydrogen bonded to one pyridine ring with an estimated N—H distance of 1.92(4) Å. In the ruthenium(II) complex with py_3COH[5] (*vide infra*), such hydrogen

bonding was used to suggest why the coordinated oxygen rather than an uncoordinated nitrogen of a pyridyl ring is protonated in acid solution.

At high pH values, there is no hint of carbinol ionization in the titration curve of either py_3COH or py_2phCOH nor is any anticipated due to the high pK_a value expected.[19] However, titration curves for solutions containing both py_3COH and metal ion in a 2:1 molar ratio (Fig. 2) do show consumption of one hydroxide per metal ion for manganese(II), iron(II), cobalt(II) and nickel(II) in the pH range 3–8 while for copper(II) and zinc(II), consumption of hydroxide approaches two moles per mole of metal ion at considerably higher pH values. For manganese(II) and iron(II), the titration curves are not those of a typical weak acid and their mathematical analyses[15] confirm this. Cobalt(II) and nickel(II), however, do provide titration curves typical of a weak acid and are clearly distinct from the manganese(II) and iron(II). Except at high pH [> 10 for copper(II) and zinc(II)], no precipitates were observed in any titration. Spectral data for the complexes as a function of pH are given in Table 2.

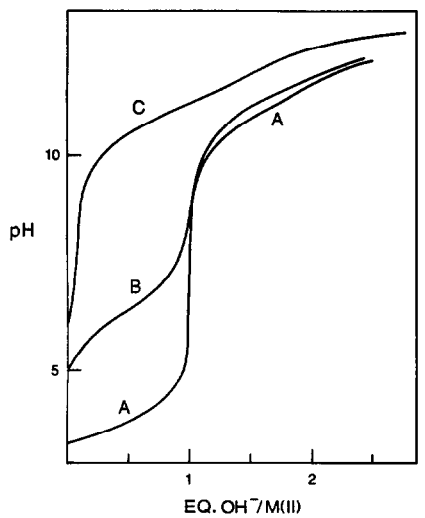

Fig. 2. Titration of py_3COH : metal(II) (2 : 1 molar ratio): Fe(II), A; Ni(II), B; Cu(II), C.

When py_3COH is added to a solution containing iron(II), a complex is formed as indicated by the decrease in pH and the change and increase in the intensity of the colour of the solution. When base is added to this solution, there is considerable darkening of the solution. The intensities of the absorptions for the iron(II) complex indicate that they are change-transfer ones and probably metal-to-ligand.[20] However, neither the band positions nor intensities are those reported previously for $[Fe(N,N',N''\text{-}py_3COH)_2]^{2+}$.[21] Mossbauer data on the solid state of this complex suggested a symmetric arrangement of the ligand and the visible spectrum in acetonitrile was similar to other $[Fe(py_3X)_2]^{2+}$ complexes.[21] The symmetric nature of this isomer in solution has now been confirmed by measuring the ^{13}C NMR spectrum, as only six resonances are observed (Fig. 3) and the bridgehead carbon has a resonance value at 81.3 ppm, almost identical to that in py_3COH and in the symmetric

$[Co(N,N',N''\text{-}py_3COH)]^{3+}$ isomer.[4] When the solid is dissolved in the mixed water–ethanol solvent system used in the titration studies, the visible spectrum is unchanged from that of the solid dissolved in acetonitrile, suggesting the symmetric isomer remains intact. However, when the complex is formed by mixing iron(II) chloride and py_3COH in the water–ethanol solvent system, the spectrum is dependent upon the pH of the system (Fig. 4) and is somewhat time-dependent. Since these spectra are different from the symmetric isomer, the species present at pH 3.0 probably has the iron(II) coordinated by two neutral ligands in the mixed-mode fashion while the species present at pH 10.2 is the same mixed-mode coordination with the non-symmetric ligand present as the anion, py_3CO^-. Spectra at intermediate pH are a composite of the pH 3.0 and 10.2 spectra. The spectra at the low and high pH values resemble those for the analogous ruthenium(II) complexes[5] except that for iron(II), the maxima are found at about 35 nm longer wavelengths and the intensity is only about one-fourth at low pH and one-half at high pH. The results indicate a strong tendency for the iron(II) to bind in the mixed-mode fashion and to cause the proton of the —COH group, presumably the one bound to the iron(II), to become a strong acid. A similar result was noted for the analogous ruthenium(II) complex. However, the symmetric isomer, once formed and precipitated as the perchlorate salt, is stable and does not readily change to the mixed-mode isomer even upon redissolving in various solvents. Although spectral data are lacking, the similarity of the titration curves of iron(II) and manganese(II) suggest a similar coordination for the manganese(II).

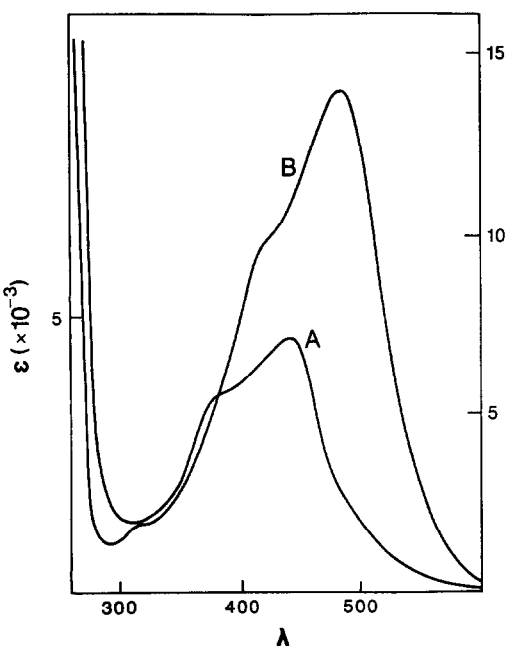

Fig. 4. Visible spectrum of $py_3COH:Fe^{II}$ (2:1 molar ratio). The scale on the left refers to curve A (pH 3.0) and the scale on the right refers to curve B (pH 10.2).

If oxygen is rigorously excluded from the reaction mixture, a cobalt(II) complex with py_3COH is formed and the complex titrates as a weak acid with a pK_a of 6.6(±0.1). The absorption spectrum of this complex does not resemble those of symmetric $[Co(py_3X)_2]^{2+}$ complexes[9] but instead has a maximum absorption at 378 nm (ε 1300) that is part of a more intense band at shorter wavelength. Upon increasing the pH to > 10, the bands between 400 and 300 nm are lost on intense bands below 300 nm. The spectral data strongly suggest that at both the low and high pH, coordination is in the mixed-mode fashion and, unlike the iron(II) and ruthenium(II) complexes, one py_3COH ligand can act as a proton donor but in a weak-acid fashion. What is not clear is whether the proton is being removed directly from a coordinated —COH group, as is claimed in the ruthenium(II) case[5] and above for iron(II), or from the nitrogen of the non-coordinated pyridyl ring. An attempt was made to answer this question by monitoring the ligand absorption bands below 300 nm. For the free ligand, the spectrum between 300 and 225 nm was studied as a function of pH (Fig. 5). At pH 2.9, the spectrum appears as a double-humped band with maximum absorptions at 261 and 267 nm. When the pH is raised, the total intensity of the band decreases with that of the 267 nm band decreasing more rapidly than the 261 nm band and a shoulder at 255 nm becomes more pronounced. A plot of pH vs $\log(\alpha/1-\alpha)$ (α is the fraction of the ligand neutralized) gives a linear plot of slope 0.87, from which a pK_a of 4.5, in reasonable agreement with the titration data of Table 1, is obtained. However, in the same spectral region of the complexes, one

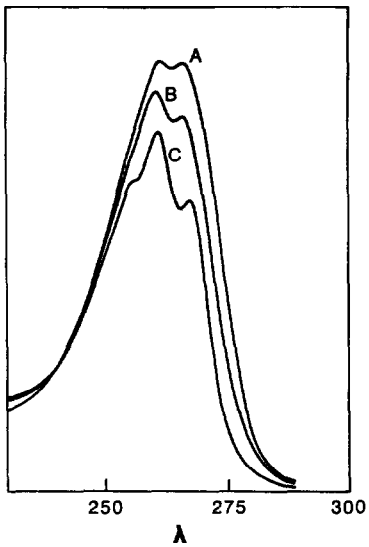

Fig. 5. UV spectra of py_3COH at various pH values: pH 2.9, A; pH 4.4, B; and pH 6.5, C.

cannot distinguish between coordinated pyridyl rings, non-coordinated pyridyl rings, and protonated pyridyl rings due to the broadness and overlap of these bands. Hence, the question of where the proton resides in the cobalt(II) complex is not resolved by these data.

Spectral results from the nickel(II) and py_3COH indicate an octahedral configuration around the metal ion. There are only minor differences in the spectra at low and high pH and the spectra are very similar to that of the symmetric complex previously reported.[2] Much of the discussion of the acid–base characteristics of the cobalt(II) complex above is applicable to the nickel(II) complex as the mixture of nickel(II) and py_3COH also titrates as a weak acid with a pK_a 6.6($\pm$0.1). It is surprising that both cobalt(II) and nickel(II) have the same pK_a and this may be important in determining the site of proton loss. Although not an entirely analogous system, amide deprotonation of a nitrogen coordinated to nickel(II) is approximately 100 times easier when compared to cobalt(II).[22] If this ease of deprotonation was maintained in the py_3COH ligand, the pK_a for nickel(II) should then be significantly lower than for cobalt(II) if the metal ion was competing directly for a basic site. That the pK_as for cobalt(II) and nickel(II) are the same within experimental error would suggest that the removal of the proton is not from a coordinated —COH group. This then leaves the pyridyl nitrogen of the non-coordinated ring as the basic site and suggests that the pK_a of the nitrogen has been increased upon coordination by py_3COH. In fact, metal ion substitution for a proton always increases the pK_a of non-coordinated basic sites elsewhere on the ligand and thus is consistent with these results. Previously mentioned was the result that an analogous situation has been reported for ruthenium(II);[5] based upon bond lengths in the two crystal structures and ^{13}C data on the bridgehead carbon, it was concluded that the basic site was indeed the coordinated —COH group and not a pyridyl nitrogen. However, the pK_a was 3.78, clearly more acidic than either the cobalt(II) or nickel(II) complexes. Thus, based upon titration and spectral evidence, we believe the basic site for the proton in the cobalt(II) and nickel(II) complexes is the pyridyl nitrogen and the coordination is in the mixed-mode fashion. As was the situation for the iron(II) complex, this is in contrast to the structure suggested for the solid state nickel(II) complex. However, a re-examination of these data still suggests the symmetric isomer in the solid state as the stoichiometry of the complex requires a neutral ligand and there is no evidence in the IR spectrum of a protonated pyridyl nitrogen. We have previously reported on complexes with protonated pyridyl nitrogens[23] and there is a very definitive py-H^+ band at 1530 cm^{-1}. No such band appears in the IR spectrum of the solid $[Ni(py_3COH)_2](ClO_4)_2$ complex.

The titration curves for copper(II) and zinc(II) do not show consumption of the hydroxide ion in the acid to neutral pH range but only at pH > 10. The solution spectrum of the copper(II) complex below pH 7 is identical to that of the solid reported earlier.[2] Since no evidence for coordination by the —COH group was observed in the solid and there is no tendency to titrate a proton in the present study, coordination must be by the symmetric mode for the copper(II) and zinc(II) complexes both in the solid and in solution. The ^1H NMR spectrum of $[Zn(py_3COH)_2](ClO_4)_2$ dissolved in d_3-acetonitrile[2] and the complex formed in aqueous solution from Zn^{2+} and py_3COH[11] also suggested a nearly symmetrical mode of coordination. Support for similar coordination here is provided by the titration of solutions containing HCl : py_3COH : copper(II) or zinc(II) in a molar ratio of 6 : 2 : 1. The acid titrates strictly as a strong acid with no evidence for titration of protonated pyridyl rings, whether coordinated or free. With regard to the strong tendency of copper(II) to form complexes with both nitrogen and oxygen ligating atoms,[24] this is especially surprising. Solids isolated at high pH do contain py_3COH but are probably mixed copper(II)—py_3COH—OH^- complexes. No further attempts to characterize these products have been made.

All mixtures of bis(2-pyridyl)phenylcarbinol and metal(II) ions yield an acidic proton (Fig. 6), with most titration curves resembling a strong acid.

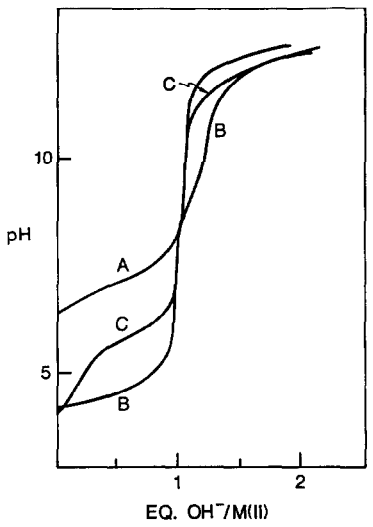

Fig. 6. Titration curves of py_2phCOH : metal(II) (2 : 1 molar ratio): Mn(II), A; Fe(II), B; Ni(II), C.

When n moles of HCl are added to the titration mixture, $n+1$ equivalents of OH^- are consumed in the pH range 3–8; several mixtures consume additional OH^- at higher pH and yield precipitates. Spectral data as a function of pH were recorded (Table 2); generally, the spectra do not show the pH dependence of the py_3COH complexes and most were time-dependent. The results suggest that the —COH of the ligand is coordinated at low pH and that this group titrates in the manner of a strong acid, though not as a completely free proton, as indicated by the different range of pH values for the titration curves.

A 2 : 1 mixture of py_2phCOH : manganese(II) consumed one equivalent of OH^- per manganese(II), beginning about pH 6 and complete by pH 9. Titrations were also carried out using a variety of HCl : py_2phCOH : manganese(II) ratios. For the ratio 4 : 2 : 1, a total of five equivalents of OH^- were consumed, the first two by HCl, the next two by protonated but non-complexed ligand (pK_a 4.0), and the last one by the complex. For the ratio 12 : 4 : 1, a total of 13 equivalents of OH^- were consumed, the first eight by HCl, the next four by protonated but non-complexed ligand (pK_a 4.0), and the last by the complex. The results demonstrate that only one pyridyl nitrogen of non-complexed ligand is protonated and that any interaction between manganese(II) and the ligand is weak although a complex is formed or the $n+1$ OH^- would not be consumed. The solutions are air-sensitive at higher pH and the complex formed is probably a mixture of manganese(II), py_2phCOH, and OH^-. No manganese(II) complex was isolated in the previous study[10] as should be when the weak interaction indicated by the titration data is considered.

The titration curves of py_2phCOH with iron(II), cobalt(II) and zinc(II) in a 2 : 1 molar ratio are nearly identical to each other and are similar to that for manganese(II), the major difference being that the initial pH of the solutions is near 4 and the titrations are complete by pH 6. One equivalent of OH^- is consumed per metal ion.

The py_2phCOH : iron(II) mixture gave spectral results noticeably different than for py_3COH, both in the position and intensity of the bands. Both features are consistent with loss of coordination of a pyridyl nitrogen. For the zinc(II) titrations, the perchlorate salt rather than the chloride was used and upon addition of the ligand, immediate precipitation of $[Zn(py_2phCOH)(py_2phCO)]ClO_4$ occurred. For cobalt(II) chloride, precipitation occurs only at higher pH. There is little difference in the spectrum of the cobalt(II) complex regardless of pH, consistent with the titration data implying that the complex is fully formed at low pH. Spectra at pH 3.7 and 9.0 are typical of octahedral cobalt(II) and closely match that of $[Co(py_2phCOH)(py_2phCO)]ClO_4$[10] and symmetrical octahedral $[Co(py_3X)_2]^{2+}$[9] complexes, the most noticable difference being the partial splitting of the band near 500 nm and the longer wavelength of the absorption bands. These features are consistent with the replacement of two nitrogen atoms of py_3X with two oxygen atoms of py_2phCOH as donor atoms. The cobalt(II) complex with py_2phCOH, unlike that of py_3COH, is relatively inert to oxygen; there is little evidence for oxidation even when a solution at pH 12 is exposed to the atmosphere overnight. The N_5O donor set of the py_3COH complex appears to be the key requirement for oxidation of cobalt(II) as the symmetrical py_3X complexes and the py_2phCOH complex, with N_6 and N_4O_2 donor sets, respectively, are not readily oxidized. Cobalt(II) and zinc(II) complexes previously isolated gave only the stoichiometry $[M(py_2ph(COH)(py_2phCO)]ClO_4$;[10] considering the acidity of the proton, this is reasonable. What is surprising is the inability of zinc(II) to promote ionization in the py_3COH ligand but to promote similar ionization in py_2phCOH to the extent that only the deprotonated complex can be isolated. This in turn argues for the nearly exclusive formation of the symmetrical isomer in $[Zn(py_3COH)_2]^{2+}$.

Titration and spectral results for the py_2phCOH : nickel(II) mixture provide results again consistent with the previous work in which two complexes, $[Ni(py_2phCOH)_2]^{2+}$ and $[Ni(py_2phCOH)(py_2phCO)]^+$, were isolated.[10] The spectra

at pH 4.1 and 9.0 closely match those of the two isolated nickel(II) complexes. The ability of the nickel(II) to promote ionization of the ligand is less than that of either cobalt(II) or zinc(II) and thus both stoichiometries were obtained. In view of this result, the similarity of the cobalt(II) and nickel(II) results with py_3COH (*vide supra*) is even more striking.

Two distinct copper(II) compounds were previously obtained[10] with py_2phCOH, dependent upon the pH and ligand : metal ratio. When mixed in a 1 : 1 molar ratio, a deep blue solution results (λ_{max} 682 nm, ε 67) and one proton is titrated as a strong acid by pH 6.0 to produce a solution of a slightly different blue (λ_{max} 708 nm, ε 130). Some additional consumption of base occurs above pH 9.0 and a light blue precipitate formed about pH 10.0. When acid was added to the final mixture and the pH returned to 3.0, the original spectrum returned. The compound formed by pH 6.0 is probably similar to that isolated,[10] $[Cu(py_2phCO)]ClO_4$, in which bridging oxygen atoms were postulated. If the ligand : metal ratio is 2 : 1 or larger, a purple compound forms after the initial titration of the one proton. This compound is not very soluble in most solvents. Further attempts to ascertain its structure are in progress.

CONCLUSIONS

The ligands py_3COH and py_2phCOH readily coordinate with first-row transition metals. Py_3COH has several possible modes of coordination and the one obtained is dependent upon the method of preparation and/or the pH. In the case of iron(II), three different complexes have been identified. These include one with both ligands coordinated in a symmetric (N,N′,N″) fashion, a second with one ligand bound in a symmetric fashion and the other in a non-symmetric (N,N′,O) protonated fashion, and a third coordinated as the second but with loss of a proton from one ligand. Nickel(II) and cobalt(II) give complexes in which the coordination is by the mixed-mode fashion, i.e. one ligand in the symmetric (N,N′,N″) and the second in the non-symmetric (N,N′,O) mode, with the proton residing on the non-coordinated pyridine and titrating as a weak acid. Copper(II) and zinc(II) form only the symmetric complex with py_3COH and do not promote any ionization of the ligand. Py_2phCOH lacks the third pyridine ring and is forced to coordinate in the N,N′,O mode and complexes with protonated, —COH groups are initially formed. However, the —COH group then titrates as a relatively strong acid, but whose pH range is influenced by the metal of the complex.

LOCALIZED MOLECULAR ORBITALS AND THE PROBLEM OF QUASI-AROMATICITY IN TRINUCLEAR MOLYBDENUM CLUSTER COMPOUNDS WITH CORES OF THE TYPE $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{n+}$ (X, Y = O, S, $n = 4$; X = O, Y = Cl, $n = 5$)

(*Received* 7 *March* 1991; *accepted* 11 *July* 1991)

Abstract—Calculations of localized molecular orbitals (LMO) and their energy levels for the cluster cores $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[Mo_3OS_3]^{4+}$, $[Mo_3S_4]^{4+}$ and $[Mo_3OCl_3]^{5+}$ have been made by the use of energy-localized CNDO/2-LMO. The results of these LMO calculations show that the six-membered closed and continuous π-conjugated systems around the $[Mo_3Y_3]$ rings, each of which is formed from three synergically connected three-centred two-electron (Mo, Mo, Y) π bonds, is the most significant feature of the electronic structure for the quasi-aromatic clusters $[Mo_3(\mu_3\text{-}Y)(\mu\text{-}X)_3]^{4+}$ (X, Y = O, S), and the size and electronegativity of the bridging Y atoms exhibit significant effects on the degree of quasi-aromaticity of these cluster compounds. For the non-aromatic reference cluster $[Mo_3OCl_3]^{5+}$, the results of our calculations also show a bonding scheme with only one isolated (Mo, Mo, Y) π bond, thus leading to the loss of quasi-aromaticity; and meanwhile, there is a pair of extra electrons localized on the apical molybdenum atom of the Mo_3 triangle, thus with three Mo—Mo single bonds.

During the past decade a number of trinuclear cluster compounds with molybdenum atoms in higher oxidation states with the geometrical configuration of a discrete equilateral triangle have been reported,[1] and a few comprehensive reviews have appeared.[2] Cotton further classified these trinuclear molybdenum cluster compounds into the following two structural types: trigonal pyramidal and trigonal bipyramidal. During the past few years systematic crystal structure analyses and chemical reactivity studies for a series of typical trigonal pyramidal cluster compounds have been carried out in our Institute and Research Laboratory. Thus Huang[3] established on a very sound basis a new concept of quasi-aromaticity, i.e. the puckered six-membered ring $[Mo_3(\mu\text{-}S)_3]^{6+}$ in $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3(\chi\text{-}dtp)_3(\mu\text{-}dtp)(OH_2)]$ (I) [where dtp and χ denote $\{S_2P(OEt)_2\}^{-1}$ and chelating dtp ligands, respectively; cf. Fig. 1] exhibits benzene-like behaviour. Structurally, the six Mo—(μ-S) bonds have an average length of (2.281+0.017) Å, intermediate between the Mo—S single-bond length of 2.44 Å and the Mo=S double-bond 2.08 Å; whereas the six bond angles fall into two sets of (96.6+0.7)° for ∠(μ-S)—Mo—(μ-S) and (74.3+0.8)° for ∠Mo—(μ-S)—Mo. With regard to its chemical reactivity, the reactivity sequence for ligand substitution reactions is H_2O > μ-dtp > χ-dtp ≫ (μ_3-S) ≫ (μ-S), with the $[Mo_3S_3]$ ring kept intact and practically invariant in the course of these reactions. There are two types of addition reactions: simultaneous addition of three sulphur atoms with the formation of three μ-S_2; addition of one metal atom alone to form, for instance, a cubane-like $[(Mo_3S_4)Cu]^{5+}$ or a sandwich-type $[(Mo_3S_4)_2Mo]^{8+}$, with the entire $[Mo_3S_4]^{4+}$ core entering into these reactions as a whole. On the

other hand, oxidation of one of the three (μ-S) atoms is at once accompanied by the rupture of two adjoining Mo—(μ-S) bonds and the formation of two new Mo=O bonds. The resemblances to C_6H_6 in all these respects are indeed rather striking. In a series of previous papers[4] we have made comparative studies on the electronic structures of benzene and other aromatic molecules on one hand and the cluster compound **I** on the other hand by the use of the energy-localized CNDO/2 molecular orbital method, it is shown that from a localized bonding point of view, for the well-known aromatic planar six-membered ring C_6H_6, each of the three π-electron pairs is localized on three adjoining carbon atom triads, thus forming three adjoining three-centred two-electron (*p–p–p*) π-bonds. Upon comparing aromatic and quasi-aromatic C_6H_6, $C_3N_3H_3$, $B_3N_3H_6$, and $(B_3O_6)^{3-}$ with the non-aromatic reference molecule $P_3N_3Cl_6$, it is found that a sufficiently large interaction energy between the three (*p–p–p*) or (*d–p–d*) π-bonds is necessary for the formation of a closed continuous π-conjugated system around the ring. Furthermore, it is found that for the $[Mo_3S_3]$ ring in compound **I** there are three three-centred two-electron

π-bonds, with each μ-S atom contributing one pair of electrons from the lone pair occupying the p_z AO perpendicular to the Mo(μ-S)Mo plane and the two adjoining molybdenum atoms contributing one vacant *d* AO each, thus forming a three-centred two-electron (*d–p–d*) π-bond with rather large interaction energy between these π-bonds. This non-planar puckered $[Mo_3S_3]$ ring thus forms a rather interesting three-dimensional closed continuous π-conjugated system. It is obvious that the π-electronic structure of the $[Mo_3S_3]$ ring in compound **I** is quite similar to that of benzene insofar as in either the benzene molecule or the $[Mo_3S_3]$ ring there exists a six-membered closed continuous π-conjugated system formed from three synergically connected three-centred two-electron π bonds around the rings. Huang's[3] further studies have also shown that quasi-aromaticity exists in cluster compounds containing the cores $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S) (cf. Fig. 1). It is interesting to note that Shibahara[5] has recently reported the presence of extra diamagnetic susceptibilities in two molybdenum cluster compounds with the cores $[Mo_3(\mu_3\text{-}S)(\mu\text{-}O)_3]^{4+}$ and $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3]^{4+}$ at very low temperatures.

In the present paper we report the results of our calculations made on $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[Mo_3OS_3]^{4+}$ and $[Mo_3S_4]^{4+}$ by the use of the energy-localized CNDO/2 molecular orbital method. It is interesting to note that replacement of the three bridging oxygen atoms in the $[Mo_3O_4]^{4+}$ cluster by chlorine or bromine atoms to form the $[Mo_3(\mu_3\text{-}O)(\mu\text{-}Y)_3]^{5+}$ (Y = Cl, Br) cluster cores results in loss of such quasi-aromaticity. Thus in the prototype molecule[3,6] $(Me_4N)[Mo_3(\mu_3\text{-}O)(\mu\text{-}Cl)_3(\mu\text{-}O_2CH)_3(Cl_t)_3]$ (t for terminal) the Mo—(μ-Cl)

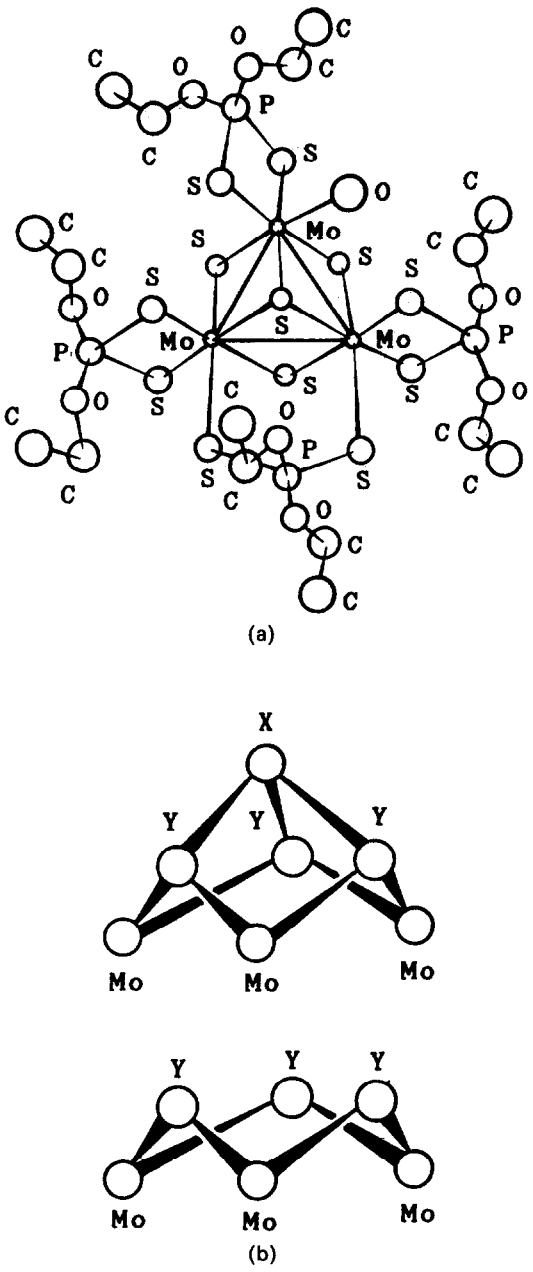

Fig. 1. (a) Configuration of the cluster molecule $[Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3(\chi\text{-dtp})_3(\mu\text{-dtp})(OH_2)]$; (b) configurations of the cluster cores $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{n+}$ (X, Y = O, S, $n = 4$; X = O, Y = Cl, $n = 5$) and the six-membered puckered ring $[Mo_3Y_3]$.

2.467 Å) is much longer compared Mo—Cl_t internuclear distance (2.084 Å), longer obeys the rule for the quasi-aromatic $Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S), in which the Mo—(μ-Y) bond distance lies in between the Mo—Y single and the Mo=Y double bond length. In our calculations this molecule can only be regarded as a non-aromatic reference molecule in order to give a deeper insight into the nature of quasi-aromaticity. In other words, we have attempted to focus our discussion in this paper on the effect of the three bridging Y atoms upon aromaticity, and thus consider only the $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{n+}$ cores instead of the entire cluster molecules. As discussed in [2] and the previous papers,[4] the core fragment analysis is indeed a good and reasonable approximation in studying the effect of these capping and bridging ligands upon the electronic structures of trinuclear molybdenum cluster compounds.

METHOD OF CALCULATION

The procedure adopted in our calculation is to use the spin unrestricted CNDO/2 method, followed by transformation of the occupied canonical MOs into LMOs by the Edmiston–Ruedenberg energy localized technique, which has been described in [7]. For atoms of non-metal elements n*s* and n*p* AOs are taken as the basis functions; while a complete set of 5*s*, 5*p* and 4*d* valence AOs is taken for each of the molybdenum atoms. The CNDO/2 parameters: orbital exponent ζ, electronegativity χ, bonding parameter β° are listed in Table 1. The geometrical configurations for the cluster cores $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[Mo_3OS_3]^{4+}$, $[Mo_3S_4]^{4+}$ and $[Mo_3OCl_3]^{5+}$ are idealized to C_{3v} symmetry by using bond lengths (cf. Table 3) and angles from the crystal structures of $Cs_2[Mo_3O_4(C_2O_4)_3(H_2O)_3]\cdot 4H_2O\cdot 1/2\,H_2C_2O_4$,[8] $Ba[Mo_3SO_3(Hnta)_3]\cdot 10H_2O$,[9] $[Mo_3OS_3\{S_2P(OEt)_2\}_4]C_3H_3N_2$,[10] $[Mo_3S_4\{\mu\text{—}S_2P(OEt)_2\}\{S_2P(OEt)_2\}_3(H_2O)]$[11] and $(Me_4N)[Mo_3OCl_3(\mu\text{—}O_2CH)_3Cl_3]$,[6] respectively. The atomic contributions for each of the LMOs are obtained by means of Mulliken population analysis, and the non-diagonal elements F_{ij} of the F^{LMO} matrix are regarded as the interaction energies between the *i*th and *j*th LMOs, where

$$F^{LMO} = U^+ F^{CMO} U.$$

F^{CMO} denotes the Fock matrix of the canonical MOs, and U denotes the transformation unitary matrix. All the calculations are carried out on a VAX-11/785 computer.

RESULTS AND DISCUSSION

The cluster cores with closed-shell electron configurations have each pair of α- and β-spin occupied LMOs very close to each other. Thus only the α-spin occupied LMOs are listed in Table 2, which gives relative energy levels, main atomic contributions and chemical bond assignments of the LMOs. From our results it is obvious that all the LMOs are localized in two-centred or three-centred σ- and π-bonds or lone electron pairs, thus allowing us to establish one-to-one correspondences between the LMOs and the chemical bonds in the valence bond theory. Figure 2 shows the energy level diagrams of the LMOs for these cluster cores and a diagrammatic representation of the LMOs of the cluster core $[Mo_3S_4]^{4+}$.

$[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[Mo_3OS_3]^{4+}$ *and* $[Mo_3S_4]^{4+}$

These four cluster cores have different bridging and capping atoms, although they have quite similar electronic structures in the core frameworks. Of the 19 occupied LMOs, the LMOs for the four lower levels correspond to the four lone pairs of electrons on the bridging and capping atoms. The LMOs of the next nine higher levels correspond obviously to the three σ(Mo—X) and the six σ(Mo—Y), nine polar bonds altogether as viewed from the angle of atomic orbital population. It is important that for all these cores there exist three three-centred two-electron (Mo Mo / Y) π bonds, as described in [4] with each bridging Y atom contributing one pair of electrons from the lone pair occupying the p_z AO perpendicular to the Mo Mo / Y plane and each of the two molyb-

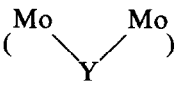
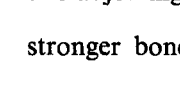
denum atoms contributing its unique vacant 4*d* AO, thus forming a (*d*–*p*–*d*) π-bond (cf. Fig. 2). It is seen that the delocalization of the lone pair electrons of the bridging atom onto the two adjoining molybdenum atoms depends mainly on the size and electronegativity of the bridging atom itself. The populations of the bridging atoms in Table 2 show that the degree of delocalization for a bridging sulphur atom is larger than that for a bridging oxygen atom due to the larger atomic volume and smaller electronegativity of the sulphur atom. For the three highest levels, the LMOs correspond obviously to the three two-centred two-electron σ(Mo—Mo) bonds.

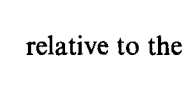
Meanwhile, Fig. 2 shows clearly how the energy levels of these cluster cores change with the different bridging and capping atoms. In general, the LMO energy levels for these four cluster cores are raised to some extent as the number of sulphur atoms is increased. In particular, the LMO energy for the σ(Mo—Mo) bonds are only rather inappreciably raised as bridging oxygen atoms are replaced by the sulphur atom. On the other hand, the increasing trends for the LMO energies corresponding to the



π bonds and the σ(Mo—Y) bonds are much more apparent, arising essentially from the difference in electronegativities between the valence orbitals of the constituent oxygen and sulphur atoms. The Mulliken bond order, in general, decreases as the bond length increases. However, as shown in Tables 3 and 4, for the Mo—Y atom pairs in $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[Mo_3OS_3]^{4+}$ and $[Mo_3S_4]^{4+}$, the Mulliken bond orders are 0.447, 0.449, 0.573 and 0.565 (in unit e), respectively, while their bond lengths are 1.921, 1.917, 2.282 and 2.283 (in unit Å) in the order. It may be seen that though the bond lengths of Mo—(μ-S) in $[Mo_3OS_3]^{4+}$ and $[Mo_3S_4]^{4+}$ are quite larger than of Mo—(μ-O) in $[Mo_3O_4]^{4+}$ and $[Mo_3SO_3]^{4+}$, the Mulliken bond orders of Mo—(μ-S) are unusually large compared to those of Mo—(μ-O). This change of the Mulliken bond orders following the replacement of the bridging oxygen atoms arises indeed from the large delocalization of the lone pair electrons of the bridging sulphur atoms into the vacant 4*d* AO in each of the two adjoining molybdenum atoms, resulting in the stronger bonding in the



π bonds relative to the



π bonds.

$[Mo_3OCl_3]^{5+}$

In our calculation, the idealized C_{3v} symmetry for the trinuclear molybdenum cluster core is lowered to C_s symmetry with the geometrical configuration of an isosceles triangle for this $[Mo_3OCl_3]^{5+}$ cluster core. From the net charges on the molybdenum atoms (+1.503, +1.503, and +1.542 in unit e) in Table 5, this is not so much a Jahn–Teller distortion with Mulliken bond orders of 0.318 e for the base and 0.370 e for the two other sides. Of the 20 α-spin occupied LMOs, the 13 LMOs of the lower energy levels, similar to the case of the four cluster cores studied above, correspond obviously to the four lone pairs of electrons on the bridging chlorine atoms and capping oxygen atom, the three polar σ(Mo—O) bonds and the six polar σ(Mo—Cl) bonds. It is very interesting to note that the LMOs of the next three energy levels

Table 4. Mulliken bond order in $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[Mo_3OS_3]^{4+}$, $[Mo_3S_4]^{4+}$ and $[Mo_3OCl_3]^{5+}$ (e)

Table 5. Charges of atoms in $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[MoOS_3]^{4+}$, $[Mo_3S_4]^{4+}$ and $[Mo_3OCl_3]^{5+}$ (e)

	$[Mo_3O_4]^{4+}$	$[Mo_3SO_3]^{4+}$	$[Mo_3OS_3]^{4+}$	$[Mo_3S_4]^{4+}$	$[Mo_3OCl_3]^{5+}$
Mo	1.794	1.674	1.327	1.192	1.542, 1.503(2x)
μ_3-X	−0.473	−0.133	−0.391	−0.020	−0.359
μ-Y	−0.303	−0.297	0.137	0.148	0.300, 0.255(2x)

correspond, respectively, to the (Mo, Mo, Y) (d–p–d) π-bond, and the two lone pairs of π-electrons localized mostly on each of the other two chlorine atoms, with only a little delocalized onto the basal molybdenum atom, instead of the three synergically connected (Mo, Mo, Y) (d–p–d) π-bonds in the cluster cores of the type $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S). The LMOs of the four higher energy levels correspond clearly to the lone pair of electrons localized on the 4d AO of the apical molybdenum atom, and the three σ(Mo—Mo) bonds forming the Mo_3 triangular skeleton. Thus there will be some interaction between this lone pair of the electrons on the apical molybdenum atom and each of the two lone pairs of the π-electron on the adjacent bridging chlorine atoms. This interaction lowers its energy down somewhat below that of the σ(Mo—Mo) bonds. On the other hand, it is seen from Table 2 that the bonding electrons forming the two σ(Mo—Mo) bonds involved in the apical molybdenum atom differ from those of the other σ(Mo—Mo) bonds in the fact that these electrons forming these two polar metal–metal bonds are distinctly inclined to the basal atoms of the Mo_3 triangle. A simple electron-counting scheme gives a total of eight for the valence electrons of the Mo_3 skeleton in the $[Mo_3OCl_3]^{5+}$ cluster core, two more than are found in the core $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S). It is apparent that these two extra electrons must primarily occupy the lone electron pair on the apical molybdenum atom from the LMO point of view, resulting in only single bonds for all the Mo—Mo bonds in the $[Mo_3OCl_3]^{5+}$ cluster core. It is these two extra electrons that lower the idealized C_{3v} symmetry of the $[Mo_3OCl_3]^{5+}$ geometry.

Bridging atom and the degree of quasi-aromaticity

The two types of bonding schemes for the cluster cores $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{n+}$ (X = O, S; Y = O, S, Cl; n = 4, 5) are represented in Fig. 3, without showing here the lone pair electrons except the lone pair π-electrons.

It has been shown in [4] that for $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S) each of the bridging oxygen and sulphur atoms depopulate the lone pair π-electrons onto each of the two adjacent molybdenum atoms, which contribute their vacant 4d AO to accept electrons from this bridging atom in the mode of bonding [cf. Fig. 3(a)]. However, replace-

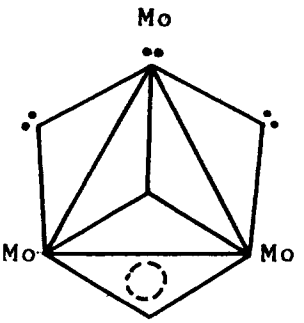
(a)



$[Mo_3(\mu_3\text{-}O)(\mu\text{-}Y)_3]^{5+}$ (Y = Cl, Br)

(b)

Fig. 3. Bonding schemes for the cluster cores $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{n+}$ (n = 4, 5). (a) $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S); (b) $[Mo_3(\mu_3\text{-}O)(\mu\text{-}Y)_3]^{5+}$ (Y = Cl, Br).

Table 6. Inter-(*d–p–d*) π-bond interaction energy and atomic population corresponding to these π bonds in $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[MoOS_3]^{4+}$ and $[M$

Cluster core	$[Mo_3O_4]^{4+}$	$[Mo_3SO_3]^{4+}$	$[Mo_3OS_3]^{4+}$	$[Mo_3S_4]$
Interaction energy (a.u.)	0.045	0.045	0.048	0.050
Mo (%)	8.35	8.41	10.68	10.50
(μ-Y) (%)	82.85	82.72	77.81	78.00

In the previous paper[4] the inter-(*d–p–d*) π-bond interaction energy 0.092 a.u. in $[Mo_3S_4]^{4+}$ is reported for the calculation in which 3*s*, 3*p* and 3*d* AOs are taken as basis functions of the sulphur atom. From the results of *ab initio* calculation followed by Boys localization performed by us, the parameter of the 3*d* AO of the sulphur atom results in an overestimate of the inter-(*d–p–d*) π-bonds interaction energy.

ment of the bridging oxygen and sulphur atoms by the bridging chlorine atom changes the electron count. On the one hand, the six valence electrons for each of the bridging oxygen and sulphur atoms are involved in one lone electron pair, two σ(Mo—O) or σ(Mo—S) bonds, and one three-centred two-electron π-bond; on the other hand, the seven valence electrons for each of the two bridging chlorine between the apical and basal molybdenum atoms are involved in two lone electron pairs and two σ(Mo—Cl) bonds; for the bridging chlorine between the two basal molybdenum atoms one lone electron pair, two σ(Mo—Cl) bonds, and one three-centred two-electron π-bond. Considering the difference of the ionic charges of the cluster cores ($n = 4, 5$), there are still two extra electrons of the Mo_3 skeleton in the $[Mo_3OCl_3]^{5+}$ cluster core, arising from replacement of the chlorine atoms. The two extra electrons enable the $[Mo_3(\mu_3\text{-}O)(\mu\text{-}Cl)_3]^{5+}$ core to adopt another bonding scheme [cf. Fig. 3(b)], in which only one (Mo Cl Mo) π bond is formed between the basal molybdenum atoms of the Mo_3 triangle and the bridging chlorine atom, but the two lone pairs of π-electrons of the two other bridging chlorine atoms remain essentially unchanged in their position without any significant depopulation to the adjacent molybdenum atoms. Thus these two types of bonding schemes would lead the cluster cores in question to exhibit different behaviours. For the case discussed in [4], on one hand, the three three-centred two-electron (Mo Y Mo) π bonds in the $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S) core cooperate actually with each other through each of the common molybdenum atoms, forming a large six-membered closed continuous π-conjugated system around the $[Mo_3Y_3]$ ring. On the other hand, for the other bonding scheme in $[Mo_3(\mu_3\text{-}O)(\mu\text{-}Cl)_3]^{5+}$ only one isolated three-centred two-electron π bond is formed. In the absence of two adjacent (Mo Cl Mo) π bonds, it is impossible to form a large closed continuous π-conjugated system in the $[Mo_3Cl_3]$ ring. Such a cluster core cannot exhibit any quasi-aromaticity at all.

Even though some cluster cores, $[Mo_3O_4]^{4+}$, $[Mo_3SO_3]^{4+}$, $[Mo_3OS_3]^{4+}$ and $[Mo_3S_4]^{4+}$, all have identical bonding schemes, different bridging atoms make these cluster cores exhibit, more or less, different degrees of quasi-aromaticity. The large delocalizability of the lone pair π-electrons in a bridging sulphur atom gives rise to a greater stability of the local delocalized (Mo Y Mo) π bond; but, on the other hand, enhances inter-LMO interaction for the three (Mo Y Mo) π bonds. In Table 6, the inter-bond interaction energy for the (Mo Y Mo) π bonds, and the atomic population for the bridging Y atom and each of the two adjoining molybdenum atoms are also listed. Both the interaction energy and the depopulation of the bridging atom show consistently that the three π bonds with bridging sulphur atoms form a more stabilized π-conjugated system around the $[Mo_3S_3]$ ring than in the case of bridging oxygen atoms. Furthermore, the more labile π-electrons around the $[Mo_3S_3]$ ring give rise to a larger diamagnetic susceptibility than in the $[Mo_3O_3]$ ring. This conclusion is in good agreement with Shibahara's experimental measurements made for $Ba[Mo_3SO_3(Hnta)_3]\cdot 10H_2O$ and $Ca_{1.5}[Mo_3S_4(Hnta)_2(nta)]\cdot 12H_2O$. It is quite apparent that the size and electronegativity of the bridging atoms, which is the decisive factor for the delocalizability of the lone

pair π-electrons in the bridging atom, enable the $[Mo_3Y_3]$ ring (Y = O, S) to exhibit different degrees of quasi-aromaticity in the cluster compounds containing the cores $[Mo_3(\mu_3\text{-}X)(\mu\text{-}Y)_3]^{4+}$ (X, Y = O, S).

SOME COORDINATION POLYMERS OF THORIUM(IV) WITH 4,4′-BIPYRIDYL-*N*,*N*′-DIOXIDE AND 4-ETHOXYCARBONYLAMINOPYRIDINE-*N*-OXIDE*

R. K. AGARWAL† and JAI PRAKASH

Postgraduate Department of Chemistry, Lajpat Rai Postgraduate College, Sahibabad-201 005, Ghaziabad, India

(*Received* 20 *February* 1991; *accepted* 9 *July* 1991)

Abstract—The synthesis and characterization of some coordination polymers of thorium(IV) salts with 4,4′-bipyridyl-*N*,*N*′-dioxide (4,4′-BipyO_2) and 4-ethoxycarbonylaminopyridine *N*-oxide (4-ECAPO) is described. Both ligands form 1:2 (metal:ligand) complexes with thorium(IV) chloride, bromide and thiocyanate but a 1:1 complex with thorium(IV) nitrate. Infrared spectra of these complexes indicate that both ligands are O,O-donors and bridged between two thorium ions to form a polymer chain. The nitrate groups in the nitrato complexes are bidentate chelating. These polymeric chain compounds contain either eight or ten coordinated thorium(IV) depending on the nature of anions.

In recent years a number of coordination polymers have been synthesized from organic ligands and various metal ions.[1] But there is no formal report on thorium(IV) coordination polymers of aromatic amine *N*-oxides.[2,3] In this paper we report our results on some coordination polymers of thorium(IV) with 4,4′-bipyridyl-*N*,*N*′-dioxide (4,4′-BipyO_2) (**I**) and 4-ethoxycarbonylaminopyridine *N*-oxide (4-ECAPO) (**II**).

EXPERIMENTAL

$Th(NO_3)_4 \cdot 5H_2O$ (B.D.H., AnalaR) was used as received. Thorium(IV) perchlorate, halo and thiocyanato salts were prepared as reported.[4,5] The ligand 4,4′-bipyridyl-*N*,*N*′-dioxide was prepared by oxidation of 4,4′-bipyridyl (Koch-Light) by the method of Ochiai.[6] The ligand 4-ethoxycarbonylaminopyridine *N*-oxide was prepared from 4-amino pyridine by the method of Katritzky.[7]

Synthesis of coordination polymers

All the complexes were isolated by one of the following methods:

(i) To a solution of the metal salt in ethyl acetate an excess of the ligand in methanol was added and a solid compound was immediately precipitated. It was filtered, washed with ethyl acetate and methanol and finally with solvent ether and dried *in vacuo* over fused $CaCl_2$.

(ii) A solution of Lewis acid in absolute ethanol was treated with an excess of the Lewis base in the same solvent. The mixture was refluxed for *ca* 2 h on the water bath and the excess solvent was removed by distillation. The residual mass on treatment with anhydrous diethyl ether yielded a crystalline solid which was filtered, washed with diethyl ether and dried *in vacuo* over P_4O_{10}.

(iii) A solution of the Lewis acid in ethanol was treated with an excess of the Lewis base on the same solvent. The mixture was refluxed for *ca* 2 h. After cooling the solid mass which settled was filtered, washed with ethanol and solvent ether and dried as above.

All the physicochemical analyses were carried out as reported earlier.[8]

RESULTS AND DISCUSSION

The interaction of 4,4′-$BipyO_2$ and 4-ECAPO with thorium(IV) salts results in the formation of $[ThX_4L_n]$ ($n = 2$; X = Cl, Br or NCS; $n = 1$; X = NO_3 and L = 4,4′-$BipyO_2$ or 4-ECAPO). The analytical data were recorded in Table 1. No absorption bands were observed which could be attributed to water or ethanol thus establishing these complexes to be anhydrous and free from coordinated or lattice water of ethanol. This view was further supported by thermal data. Because of the insolubility of the thorium(IV) complexes studied herein, in suitable organic solvents and in molten camphor, molecular weight determinations could not be carried out.

IR spectra and the nature of coordination

(a) 4,4′-*Bipyridyl* N,N′-*dioxide complexes*. Some IR data for the Th^{IV} complexes of 4,4′-$BipyO_2$ are given in Table 2. IR spectral data indicate that both the donor atoms of 4,4′-$BipyO_2$ are bonded to metal ions and this ligand is bridged between two thorium ions. The steric position of the donor atoms in this ligand precludes chelation but favours coordination to different metal ions thus leading to polymer chain formation. The NO stretching vibration appears as a strong doublet at *ca* 1250 and 1235 cm^{-1} in free 4,4′-$BipyO_2$ shifts to lower frequency region in the complexes indicating a decrease in the π-bond character of the NO bond as a result of oxygen to metal coordination.[1-3] The NO bending vibration appearing as a strong absorption at *ca* 850 and 835 cm^{-1} in the uncoordinated 4,4′-$BipyO_2$ is observed with similar intensity but shifted slightly to the lower frequencies in the IR spectra of the thorium(IV) complexes. Several absorptions associated with C—H out-of-plane deformation modes depending on the number of adjacent hydrogen atoms in the aromatic ring. These absorptions undergo slight positive shifts on complexation due to the decrease of electron density on the aromatic ring. Some new medium or weak bands are also observed in the 410–350 cm^{-1} region due to ν(Th—O).[9,10] These bands further support that oxygens are the only donating centres in 4,4′-$BipyO_2$.

(b) 4-*Ethoxycarbonylaminopyridine* N-*oxide complexes*. This ligand is a potentially multidentate (O, N, O) ligand. Framework molecular models show that it is more likely to bond to different metal ions and thus may act as a bridging rather than a chelating ligand. Some IR data for the 4-ECAPO

complexes of Th^{IV} are given in Table 3. The split bands at 1245 and 1230 cm^{-1} have been assigned to ν(N—O) modes of vibration in free 4-ECAPO which undergo a significant negative shift on complexation. This decrease in frequency is attributed to coordination on the oxygen atom of the base to the metal causing a decrease in π-character of N—O bonding.[9,10] The N—O bending vibration is assigned to *ca* 830 cm^{-1} in free 4-ECAPO.[11,12] The data summarized in Table 3 shows that there is only a slight shift of this vibration in some cases while in others it is unaffected.[13] The absorptions associated with C—H out-of-plane deformation modes depending on the number of adjacent hydrogen atoms in the aromatic ring undergo slight positive shifts on complexation due to decrease of electron density on the aromatic ring. The amide–I band in free 4-ECAPO, appears at 1735 cm^{-1}, which causes a considerable negative shift on complexation suggested coordination through the carbonyl oxygen atom of the free base. The NH stretching absorption in the free ligand occurs at 3200 and 3120 cm^{-1} which remains unaffected after complexation.[14,15] This precludes the possibility of coordination through the imine nitrogen atom.

The steric position of the donor atoms (O, O) in this ligand precludes the possibility of chelation but favours coordination to different metal ions leading

to polymer chain formation. The insolubility and higher decomposition temperature also support this view. The overall IR spectral evidence suggest that 4-ECAPO acts as a bidentate bridging ligand and coordinates through *N*-oxygen and carbonyl oxygen atoms. The bands observed in the 420–380 cm^{-1} region are assigned as ν(Th—O).[9-10]

The spectral bands due to NO_3^- groups in $[Th(NO_3)_4(4,4'\text{-BipyO}_2)]$ and $[Th(NO_3)_4$(4-ECAPO)] complexes which occur at *ca* 1525, 1300, 1040, 820, 750 and 720 cm^{-1} region were compared with the known bands of $Th(NO_3)_4 \cdot 5H_2O$,[16] i.e. 1520 (ν_4), 1290 (ν_1), 1030 (ν_2), 808 (ν_6), 745 (ν_3) and 715 cm^{-1} (ν_5) in which the bidentate character of the nitrato groups has been established by X-ray and neutron diffraction studies.[17] In both the thiocyanato complexes, the three fundamental absorptions C—N stretch (ν_1), C—S stretch (ν_3) and N—C—S bending (ν_2) are identified at *ca* 2050, 830–805 and 460 cm^{-1} respectively. These frequencies are associated with the terminal *N*-bonded isothiocyanate ions.[18]

Thermal studies

The TG and DT curves of these complexes do not show the presence of water molecules. All the complexes decompose endothermically. Thermogravimetric analyses show the following decomposition scheme:

$$[ThX_4L_3] \longrightarrow ThX_4L \longrightarrow ThX_4 \longrightarrow ThOX_2$$

(X = Cl, Br or NCS;
L = 4,4′-$BipyO_2$ or 4-ECAPO)

$$[Th(NO_3)_4L] \longrightarrow [Th(NO_3)_4L_{0.5}] \longrightarrow Th(NO_3)_4 \longrightarrow ThO_2$$

(L = 4,4′-$BipyO_2$ or 4-ECAPO).

On the basis of TG decomposition temperature the order of thermal stability of the complexes is

$$NO_3 > Cl > Br \approx NCS.$$

Structure of the coordination polymers

Thorium(IV) halide (chloride, bromide and thiocyanate) gave 1 : 2 complexes with 4,4′-$BipyO_2$ and 4-ECAPO and the ligands bands indicating the bidentate bridging character of the organic ligands. Thiocyanate (NCS) is *N*-bonded in this complex. On this basis the halide complexes are assigned polymeric chain structures involving eight-coordinated thorium(IV) with eight ligand atoms—four oxygens of the bidentate 4-ECAPO or 4,4′-$BipyO_2$ molecules and 4-chlorine, bromine or nitrogens of the *N*-bonded NCS groups. In nitrato complexes, the bidentate chelating nature of the nitrato ligands and bridging bidentate nature of organic ligands, the 1 : 1 thorium(IV) nitrate complexes are tentatively assigned as polymeric chain structures involving 10-coordinated thorium(IV) with 10 oxygen atoms—two from bidentate bridging 4-ECAPO or 4,4′-$BipyO_2$ molecules and eight from four bidentate chelating nitrate groups.

THE PREPARATION OF DIMOLYBDENUM(V,V) COMPLEXES FROM MOLYBDENUM QUADRUPLY BONDED METAL–METAL DIMERS

JOEL I. DULEBOHN, THEODORE C. STAMATAKOS, DONALD L. WARD, and DANIEL G. NOCERA*

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 24 *June* 1991; *accepted* 5 *July* 1991)

Abstract—Oxidation of quadruply bonded metal–metal dimers in the presence of good π-accepting ligands results in the formation of Mo^{V}—Mo^{V} compounds of the type $[Mo_2(\mu\text{-}X)_2(Y)(Y')]^{2+}$ (X = O or S; Y,Y′ = O,O; S,S; O,S). Reaction of $Mo_2(O_2CCH_3)_4$ with oxygen in the presence of Na_2mnt (mnt = 1,2-dicyanoethylene-2,2-dithiolate) gives $[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]^{2-}$ (**1**). The compound crystallizes in the monoclinic space group $P2_1/c$, with cell dimensions $a = 19.547(4)$, $b = 15.210(4)$, $c = 18.754(6)$ Å, $\beta = 101.69(2)°$, $V = 5460(2)$ Å^3, and $Z = 4$. Similarly, oxidation of *o*-dichlorobenzene solutions of $Mo_2Cl_4(CH_3CN)_4$ and 4,4′-dimethyl-2,2′-dipyridyl (dmpby) or, more directly, the reaction of $Mo_2Cl_4(dmbpy)_2$ with oxygen leads to the formation of a red solid, which was characterized by X-ray crystallography to be $Mo_2(\mu\text{-}O)_2(O)_2(Cl)_2(dmbpy)_2$ (**2**). Red diamond crystals, prepared by slow evaporation of CH_3CN solutions of **2**, are trigonal and in the space group $P3_121$ with cell dimensions $a = 16.135(4)$, $b = 16.135(4)$, $c = 10.709(3)$ Å, $V = 2414.4(13)$ Å^3 and $Z = 3$. In both structures, the geometry about each of the molybdenum atoms is a distorted square pyramid with terminal oxygen or sulphur atoms at the apices and in a *syn* conformation. The molybdenum–molybdenum bond distances of 2.858(1) Å and 2.562(2) Å in structures of **1** and **2**, respectively, are typical of other Mo^{V}—Mo^{V} dimers and indicative of a single Mo—Mo bond.

Quadruply bonded metal–metal complexes are convenient starting materials for binuclear complexes containing oxidized metal cores. A prevalent reaction is the thermal,[1–3] electrochemical[4] or photochemical[5,6] removal of an electron from each metal centre to yield species with a formally reduced bond order. A recurrent theme in M≡M chemistry is that the one-electron oxidation of individual metal atoms is typically accompanied by rearrangement of the ligating sphere to the octahedral coordination geometry[1,2,7] of confacial[8–11] or edge-sharing bioctahedral species.[12–14]

In contrast, multielectron changes in the formal oxidation states of one or both of the metals of M≡M cores is typically accompanied by fragmentation to monomeric species. Nevertheless, the retention of a binuclear core has been observed for some multielectron transformations. For instance Cotton, Walton and co-workers have discovered that quadruply bonded $Re_2^{(III,III)}$ cores disproportionate to yield $Re_2^{(II,IV)}$ mixed-valence species.[15] Four-electron disproportionations of M≡M cores have been observed by Chisholm and co-workers[16] in their pioneering work on $Mo_2^{(II,II)}$ tetraalkoxides to give a $Mo_2^{(0,IV)}$ structure, and most recently by Walton and co-workers who have isolated an $Re_2^{(II,VI)}$ compound from $Re_2^{(III,III)}$ parent complexes.[17]

We now report the conversion of quadruply bonded $Mo_2^{(II,II)}$ complexes to highly oxidized $Mo_2^{(V,V)}$ species of the type $[Mo_2(\mu\text{-}X)_2(Y)(Y')]^{2+}$ (X = O or S; Y,Y′ = O,O; S,S; O,S). This conversion in which the binuclear core is retained may be general when the first coordination sphere of quadruply bonded metal cores are substituted with ligands possessing good π-accepting properties; and indeed this method provides a convenient route to the preparation of this important class[18–20] of binuclear molybdenum compounds.

EXPERIMENTAL

Starting materials

The starting compounds $(NH_4)_5Mo_2Cl_9 \cdot H_2O$, disodium 1,2-dicyanoethylene-2,2-dithiolate (Na_2mnt), and $Mo_2(O_2CCH_3)_4$ were prepared by literature methods.[21–23] $(C_4H_9)_4NBr$ and 4,4′-dimethyl-2,2′-dipyridyl (dmpby) were purchased from Aldrich and used as received.

Synthesis of dimolybdenum complexes

$[(C_4H_9)_4(N)]_2[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]$, **1**. A suspension of $Mo_2(O_2CCH_3)_4$ (0.604 g, 1.41 mmol) in 50 cm^3 of dry methanol was charged with 1.06 g of $Na_2[S_2C_2(CN)_2]$ (5.67 mmol) prompting the yellow suspension to turn dark green. After 5 h of stirring, the mixture was filtered and the volume of the filtrate was reduced to 35 cm^3 by rotary evaporation. To this solution, 1.81 g (5.62 mmol) of $(C_4H_9)_4NBr$ was added and the flask was cooled for 12 h in a dry ice–acetone bath. A solid formed, which was collected by filtration in air and washed with methanol. Addition of this solid to refluxing methanol produced a green solution with a red precipitate remaining undissolved. The red precipitate was filtered and recrystallized from hot methanol and acetone. Yield: 0.278 g (0.264 mmol, 19%). X-ray quality crystals of **1** were grown from a solution of CH_2Cl_2 layered with hexane. Crystals grown from the green filtrate were identified by IR and absorption spectra to be the known $[(C_4H_9)_4N]_2Mo(mnt)_3$. Yield: 0.500 g (0.494 mmol, 35%).

$Mo_2(\mu\text{-}O)_2(O)_2(Cl)_2(dmbpy)_2$, **2**. The synthesis of the $Mo_2^{(V,V)}$ compound was achieved from the quadruple bond complex $Mo_2Cl_4(dmbpy)_2$, which was obtained from the modification of the procedure used for the preparation of $Mo_2Cl_4(bpy)_2$.[24] Subsequent addition of 0.500 g of $(NH_4)_5Mo_2Cl_9 \cdot H_2O$ (0.826 mmol) to 2.00 g (10.9 mmol) of dmbpy in 30 cm^3 of methanol with stirring over 90 min yielded a solid. The product was filtered, washed with 10 cm^3 of water, methanol, and three 10 cm^3 portions of ether. The solid was dried *in vacuo*. Yield: 0.406 g (0.578 mmol, 70%).

A suspension of 0.384 g (0.547 mmol) of $Mo_2Cl_4(dmbpy)_2$ in 50 cm^3 of *o*-dichlorobenzene was heated to reflux for 5 h under air. The suspension was cooled to room temperature, and filtered. Hexane was added to the red filtrate and a red precipitate formed, which was filtered, washed with ether, and dried under vacuum. The precipitate was recrystallized from CH_2Cl_2 and hexane. Yield: 0.080 g (0.115 mmol, 21%). X-ray quality crystals of **2** were grown from the slow evaporation of CH_3CN from a solution of the compound.

Instruments

IR spectra were obtained as KBr pellets on a Perkin–Elmer 599 and a Nicolet 740 FT IR spectrophotometer. The diffraction data for the dimolybdenum complexes were collected on a Nicolet P3F diffractometer using graphite-monochromated Mo-K_α ($\lambda = 0.71073$ Å) radiation. All calculations were performed on a VAX 11/750 computer using SDP/VAX.[25]

X-ray crystallographic studies

The intensity data were collected by using θ–2θ scans at a rate of 2° min^{-1} (in 2θ) for **1** and a rate of 4° min^{-1} for **2**. Table 1 lists crystal parameters and details of intensity collection and refinement. Complete tables of positional parameters, bond distances, bond angles, anisotropic thermal parameters, hydrogen atom parameters and structure factors for **1** and **2** are available as Supplementary Material.

A red crystal platelet of **1** (dimensions 0.11 × 0.30 × 0.50 mm) was mounted on a glass fibre in a random orientation. The cell parameters and orientation matrix were obtained from least-square refinement of 21 reflections in the range $15 < 2\theta < 20°$. The space group was determined to be $P2_1/c$. A total of 7767 reflections were collected, of which 7168 were unique and not systematically absent. Three standard reflections were measured every 93 reflections and indicated a decrease of intensity of 0.6%; a linear decay correction was applied. The structure was solved using the direct methods. The two molybdenum atoms were located from an E-map; the remaining atoms were located in succeeding difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in the refinement but restrained to ride on the atom to which they are bonded. Anisotropic refinement was used to give $R = 0.044$ and $R_w = 0.046$. The largest shift-to-error was 0.01 σ, and the largest peak in the final difference map was 0.45(7) e Å^{-3}.

A clear red diamond shape crystal of **2** (dimensions 0.10 × 0.15 × 0.20 mm) was mounted on a fibre in a random orientation. The cell constants and orientation matrix were obtained from least-square refinement of 12 reflections in the range $15 < 2\theta < 20°$. From systematic absences and from refinement, the space group was determined to be

[a] $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$.
[b] $R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $w = 1/\sigma^2(|F_o|)$.
[c] Goodness of fit $= [\Sigma w(|F_o|-|F_c|)^2/(N_{obsd}-N_{parameters})]^{1/2}$.

$P3_121$. A total of 9353 reflections were collected, of which 2109 were unique and not systematically absent. Three standard reflections were measured every 93 reflections and indicated an increase of intensity of 16.5%; an anisotropic decay correction was applied. The structure was solved by using the Patterson heavy-atom method, which revealed the positions of the molybdenum atoms. The remaining atoms were located in succeeding difference Fourier syntheses. The hydrogen atoms were included in the refinement to ride on the atom to which they are bonded. Complex **2** possesses a crystallographic two-fold axis that passes between the Mo(1), Mo(1)′ atoms; only half of the atoms are crystallographically unique. Anisotropic refinement was used to give $R = 0.042$ and $R_w = 0.051$. The largest shift-to-error was 0.01 σ, and the largest peak in the final difference map was 1.13(12) e Å^{-3}. The refinement performed in the enantiomorphic space group $P3_221$ is slightly inferior with $R = 0.043$, $R_w = 0.052$, and a largest shift-to-error of 0.02 σ. For these reasons we report the results of the refinement for the $P3_121$ enantiomorphic space group.

RESULTS AND DISCUSSION

A common precursor in the preparation of substituted molybdenum quadruple bonded metal–metal dimers is $Mo_2(O_2CCH_3)_4$. Successful synthetic methodologies using this compound have involved the use of Me_3SiCl to remove the acetate ligands.[26–28] However the reaction of Na_2mnt (disodium 1,2-dicyanoethylene-2,2-dithiolate) with $Mo_2(O_2CCH_3)_4$ in the presence of Me_3SiCl yields yet unidentified decomposition products. In the absence of Me_3SiCl, green and orange precipitates form. Elemental analysis and electronic absorption spectra of the green precipitate are identical to that of $[(C_4H_9)_4N]_2Mo(mnt)_3$.[29] The likely alternative product $[(C_4H_9)_4N]_2MoO(mnt)_3$ is not obtained as indicated by the absence of an Mo—O stretch at 930

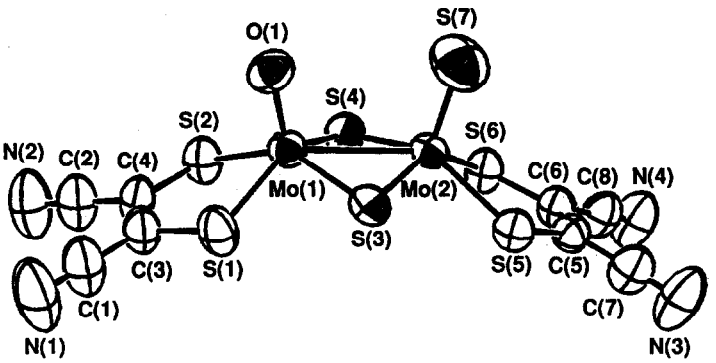

Fig. 1. ORTEP drawing and labelling scheme of $[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]^{2-}$ anion with 50% probability thermal ellipsoids.

cm^{-1}. Spectroscopic analysis of the orange precipitate clearly shows that a binuclear core is retained.

The IR spectrum supports a complex with a $[Mo_2(\mu\text{-}S)_2(O)(S)]^{2+}$ core. Absorptions at 955 and 530 cm^{-1} are characteristic of terminal Mo=O and Mo=S stretching vibrations, respectively.[30-32] A weak band at 340 cm^{-1} and a band at 470 cm^{-1} are assigned to the stretching vibration of di-μ-sulphido bridge, which typically appear with medium intensity in the ~350 and 450 cm^{-1} spectral region.[30] The presence of the mnt^{2-} ligand at the binuclear core is in evidence from the intense C≡N stretch at 2200 cm^{-1}.

The precise nature of the binuclear core ligation sphere was unequivocally determined by solving the X-ray crystal structure. Consistent with spectroscopic data, the molecular structure of **1**, represented by the ORTEP diagram shown in Fig. 1, is determined to be $[(C_4H_9)_4N]_2[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]$. The structure of the dianion displays features that are a composite of those reported by Gelder and Enemark for the symmetric $[Mo_2(\mu\text{-}S)_2(O)_2(i\text{-}mnt)_2]^2$ ion[33] and those observed for the more unusual asymmetric $[Mo_2(\mu\text{-}S)_2(O)(S)]^{2+}$ species.[32,34] The geometry about each of the molybdenum atoms in the $[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]^{2-}$ ion is best described as a distorted square pyramid formed by a terminal oxygen or sulphur atom at the apex and two bridging sulphur atoms and the two sulphur atoms from the mnt^{2-} ligands constituting the basal plane. The bases of the edge-sharing square pyramids are not coplanar but canted towards each other. The axial groups are *cis* to the two bridging ligands and assume a *syn* conformation.

Inspection of selected bond distances and angles listed in Table 2 reveals structural trends that parallel other *syn*-$[Mo_2(\mu\text{-}S)_2(X)(Y)]^{2+}$ (X, Y = O, S) structues. As shown by Tables 3, an $Mo^V\cdots Mo^V$ separation of 2.858(1) Å in **1** is typical of other $Mo^V\cdots Mo^V$ dimers and indicative of a single Mo—Mo bond. The formation of the single Mo—Mo bond in these cores is attributed to the interaction of the single electron occupancy of the d_{xy} orbitals on each molybdenum centre.[20,35] An average Mo—S_b—Mo (S_b = bridging sulphur) bond angle of 76.0°, a Mo—S_b bond distance of 2.321 Å, and a dihedral angle of 148.4° for the Mo_2S_2 unit are characteristic of $[Mo_2(\mu\text{-}S)_2(X)(Y)]^{2+}$ compounds (Table 4), as is the displacement of the Mo atoms 0.706 Å above the basal plane of the square pyramid.[18,32-34,36-39] Despite these similarities, it is noteworthy that the observed apical Mo=O_t = 1.757(5) Å and Mo=S_t = 1.948(3) Å distances are shorter than average Mo—O and Mo—S bond distances but consistent with those cores featuring electron withdrawing ancillary ligands. The good π-accepting properties of the mnt^{2-} ligand will reduce the electron density at the metal thereby enhancing the Mo—O and M—S π-donating interaction. This synergistic effect between the π-accepting and terminal π-donor ligands may well explain the short terminal bond distances.

The origins of the bridging sulphur and terminal sulphur and oxygen atoms have not been resolved. An unidentified intermediate could be oxidized with molecular oxygen to form the terminal oxygen bond. Yet when the reaction was performed under rigorously air-free conditions, $[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]^{2-}$ still formed, albeit in small yield. These results suggest that the oxygen may be delivered from the acetate ligand of the starting complex upon oxidation. Similarly, the bridging and terminal sulphur must come from the oxidation of the Na_2mnt ligand, as this is the only source of sulphur in the reaction. Solutions of $Mo(mnt)_3^{2-}$ and $[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]^{2-}$ do not interconvert under a variety of oxidizing and reducing conditions

Table 2. Selected bond distances (Å) and bond angles (°) for $[Mo_2(\mu\text{-}S)_2(O)(S)(mnt)_2]^{2-}$ anion. Numbers in parentheses are estimated standard deviations in the least significant digits

S(1)—Mo(1)—S(3)	78.81(7)	S(6)—Mo(2)—S(7)	104.7(1)

and, therefore, it is unlikely that they are produced along a concerted reaction pathway.

The susceptibility of the $Mo_2^{(II,II)}$ core towards oxidation when coordinated by good π-accepting cores is further in evidence from the chemistry of $Mo_2Cl_4(dmbpy)_2$, which exhibits greater solubility than its previously prepared bipyridine counterpart. Refluxing *o*-dichlorobenzene solutions of $Mo_2Cl_4(dmbpy)_2$ yields $Mo_2(\mu\text{-}O)_2(O)_2(Cl)_2(dmbpy)_2$, as determined by X-ray crystallography. The ORTEP diagram of **2**, shown in Fig. 2, closely parallels that of $Mo_2(\mu\text{-}O)_2(O)_2(Cl)_2(bpy)_2$,[40] which was prepared from $MoCl_4(bpy)$ monomers. These compounds exhibit

an $[Mo_2(\mu\text{-}O)_2(O)_2(Cl)_2]$ core with a bipyridyl ligand chelating each molybdenum centre. The bond lengths and bond angles for **2** listed in Table 5 compare favourably to those reported for $Mo_2(\mu\text{-}O)_2(O)_2(Cl)_2(bpy)_2$ and the related compound $Mo_2(\mu\text{-}O)_2(O)_2(OPH_2O)_2(bpy)_2$.[41] The strong interaction of the Mo atoms with the terminal oxo ligands is manifested in a pronounced *trans* influence with the Mo—N distances *cis* to the Mo=O_t functionality 0.031 Å shorter than of the *trans* Mo—N distance. The Mo=O_t stretching vibration for **2** appears at 965 cm^{-1} in the IR, and the antisymmetric and symmetric stretching vibrations of the $Mo_2(\mu\text{-}O)_2$ unit are observed at 760 and 440 cm^{-1}, respectively.[42,43] The Mo—Mo bond distances in these compounds are short [d(Mo—Mo) = 2.562(2) Å in **2**, d(Mo—Mo) = 2.565(1) in $Mo_2(\mu\text{-}O)_2(O)_2(Cl)_2(bpy)_2$, and d(Mo—Mo) = 2.554(3) in $Mo_2(\mu\text{-}O)_2(O)_2(OPH_2O)_2(bpy)_2$] and, as is the case for **1**, they are indicative of a Mo—Mo single bond resulting from a d^1—d^1 interaction.[20,35]

There has been significant interest in the role of monomeric and dimeric Mo^V centres coordinated to oxygen and sulphur at the redox-active sites of enzymes.[19,44] The $[Mo_2(\mu\text{-}X)_2(Y)(Y')]^{2+}$ (X = O or S; Y,Y′ = O,O; S,S; O,S) dimeric compounds have frequently been observed as products of reactions directed towards the synthesis of Mo^V model compounds of oxomolybdenum enzymes. Most synthetic strategies involved with the preparation of these compounds have relied on assembling molybdenum monomers in oxidizing environments. Such an approach can be problematic in view of the preponderance of different side reactions competing with dimer formation. In this respect a synthetic design using molybdenum quadruple bond dimers as starting reagents is useful because the bimetallic core acts as a template for the conversion to $[Mo_2(\mu\text{-}X)_2(Y)(Y')]^{2+}$ cores.

A NOVEL ROUTE FOR THE SYNTHESIS OF DITHIOCARBAMATE AND XANTHATE NICKEL(II) COMPLEXES STARTING FROM THE DI-μ-HYDROXO-BIS[BIS(PENTAFLUOROPHENYL)NICKELATE(II)] ION

G. LÓPEZ,* G. SÁNCHEZ, G. GARCÍA, J. GARCÍA, A. SANMARTÍN and M. D. SANTANA

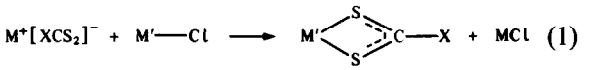
(*Received* 21 *May* 1991; *accepted* 2 *July* 1991)

Abstract—In dichloromethane, $[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]$ reacts with amines [$EtNH_2$, $PrNH_2$, Me_2NH, Et_2NH, pirrolidine (C_4H_8NH), piperidine ($C_5H_{10}NH$) and morpholine (C_4H_8ONH)] or alcohols (MeOH and EtOH) in the presence of carbon disulphide to give the corresponding dithiocarbamate or xanthate complexes $[NBu_4][(C_6F_5)_2Ni(S_2C\text{-}X)]$ [X = NHEt (**1**), NHPr (**2**), NMe_2 (**3**), NEt_2 (**4**), NC_4H_8 (**5**), NC_5H_{10} (**6**), NC_4H_8O (**7**), OMe (**8**) or OEt (**9**)]. In the same solvent, the reaction of the hydroxo-nickel complex with carbon disulphide and $[NBu_4]OH$ leads to the formation of the dithiocarbonate complex $[NBu_4]_2[(C_6F_5)_2Ni(S_2CO)]$ (**10**). The new complexes are air-stable, orange solids which have been studied by conductance measurements and spectroscopic (IR, V–UV, ^1H- and ^{19}F-NMR) methods.

Transition-metal complexes in which a 1,1-dithio ligand forms a four-membered ring with the metal ion have been extensively studied and thoroughly reviewed.[1–4] The general synthetic method for the preparation of these complexes involves the reaction of a transition-metal halocomplex with the alkali metal salt of the corresponding thioacid (eq. 1),



(1)

and the alkali salt is available from the reaction between the amine or alcohol and carbon disulphide in the presence of alkali hydroxide (eq. 2):

$$CS_2 + HX + MOH \longrightarrow M^+[XCS_2]^- + H_2O. \quad (2)$$

On the other hand, the synthesis of the binuclear anionic complexes $[\{M(C_6F_5)_2(\mu\text{-}OH)\}_2]^{2-}$ (M = Ni, Pd or Pt)[5] have been reported recently. These hydroxo complexes react with weak, protic electrophiles H(LL) to give $[\{MR_2(\mu\text{-}LL)\}_2]^{2-}$ or $[MR_2(LL)]^-$ complexes depending on the nature of the $(LL)^-$ ligand (pyrazolate- or beta-diketonate-type ligand respectively).[6] Following our investigations on these hydroxo complexes, we have now found that organometallic dithiocarbamate- and xanthate-nickel(II) complexes can be prepared by reaction of the hydroxo complex $[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]^{2-}$ with amines or alcohols, respectively, in the presence of carbon disulphide.

EXPERIMENTAL

Physical measurements and materials

C, H and N analyses were carried out with a Perkin–Elmer 240 C microanalyser. Melting points were determined on a Reichert microscope. Molar conductivities were measured in acetone solution (conc. $\approx 5 \times 10^{-4}$ M) with a Crison 525 conductimeter. The spectroscopic instruments used were Perkin–Elmer 1430 for IR spectra (Nujol mulls), Hitachi 2000U for UV–vis spectra and Bruker AC 200E (^1H) or Varian FT 80A (^{19}F) for NMR spectra. $SiMe_4$ and $CFCl_3$ were used as internal standards, respectively.

The precursor $[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]$ was prepared as described elsewhere.[5] Solvents were dried by standard methods before use.

Synthesis

Dithiocarbamate complexes (**1–7**). In separate experiments, the stoichiometric amount (0.23 mmol) of the corresponding amine was added to a solution of $[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.15 g, 0.115 mmol) in dichloromethane (10 cm^3) and carbon disulphide (0.14 cm^3, 0.23 mmol). The solution was stirred at room temperature for 30 min, then concentrated under reduced pressure to half the original volume. Addition of diethyl ether resulted in the precipitation of the expected organo complex as an orange solid which was filtered off, washed with diethyl ether and dried in the air. The compounds were recrystallized from dichloromethane–diethyl ether.

Xanthate complexes (**8**, **9**). Carbon disulphide (1 cm^3) was added to an alcohol (MeOH or EtOH) solution (5 cm^3) containing $[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.15 g, 0.115 mmol). The mixture was stirred at room temperature for 1 h, and the solvent was removed *in vacuo*. The residue was extracted with alcohol (MeOH or EtOH) and the addition of water caused the precipitation of an orange–brown solid, which was filtered off, washed with water and dried *in vacuo*.

$[NBu_4]_2[Ni(C_6F_5)_2(S_2CO)]$ (**10**). Carbon disulphide (0.14 cm^3, 0.23 mmol) was added to a mixture of $[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.15 g, 0.115 mmol) and $[NBu_4]OH$ (0.30 cm^3 of 20% aqueous solution, 0.23 mmol) in dichloromethane (10 cm^3). The mixture was stirred at room temperature for 1 h, and the solvent was removed *in vacuo*. The resulting solid was treated with 5 cm^3 of dichloromethane and the addition of diethyl ether led to precipitation of an orange solid, which was filtered off, washed with diethyl ether and dried *in vacuo*.

The analytical data and individual yields of the complexes are presented in Table 1.

RESULTS AND DISCUSSION

Previous use[5,7] of the nickel complex $[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]^{2-}$ as a precursor in synthetic work was based on the considerable nucleophilicity of the OH bridges, which is consistent with the high-field proton resonance observed at δ −5.7. In dichloromethane, $[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2]$ reacts with amines in the presence of carbon disulphide to give the respective dithiocarbamate complexes **1–7**, according to eq. (3).

$$[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2] + 2HX + 2CS_2 \longrightarrow 2[NBu_4]\left[\begin{array}{c} C_6F_5 \\ Ni \\ C_6F_5 \end{array}\right.\!\!\begin{array}{c} S \\ \diagup\!\diagdown \\ S \end{array}\!\!\left.\begin{array}{c} \\ C\!-\!X \\ \end{array}\right] + 2H_2O \quad (3)$$

[X = NHEt (**1**), NHPr (**2**), NMe_2 (**3**), NEt_2 (**4**), NC_4H_8 (**5**), NC_5H_{10} (**6**) or NC_4H_8O (**7**)]

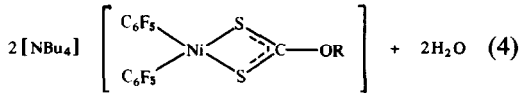
[a] $Ohm^{-1}\,cm^2\,mol^{-1}$ (in acetone solution, conc. $\approx 5\times10^{-4}$ M).

Formally, the hydroxo-nickel complex acts here as the proton acceptor initiating the formation of the dithiocarbamate ion and providing the metal substrate (the $Ni(C_6F_5)_2$ moiety) which is trapped by the 1,1-dithio ligand to form the dithiocarbamate nickel complex.

Similarly, the reaction of the hydroxo-nickel complex with alcohols and carbon disulphide proceeds with the formation of the corresponding xanthate complexes, as represented by eq. (4).

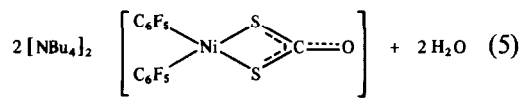
$$[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2] + 2ROH + 2CS_2 \longrightarrow$$



[X = Me (**8**) or Et (**9**)]

However, the reaction of the hydroxo complex with carbon disulphide in the presence of $[NBu_4]OH$ affords a dithiocarbonate complex (eq. 5).

$$[NBu_4]_2[\{Ni(C_6F_5)_2(\mu\text{-}OH)\}_2] + 2CS_2 + 2[NBu_4]OH \longrightarrow$$



The new pentafluorophenyl–nickel derivatives are air-stable, orange solids and their acetone solutions exhibit conductance values (Table 1) corresponding to 1:1 (dithiocarbamate and xanthate complexes) or 2:1 (dithiocarbonate complex) electrolytes.[8] The IR spectra show the absorptions attributed to the C_6F_5 group[9] at *ca* 1630 m, 1490 vs, 1050 s and 950 vs cm^{-1}, as well as a broad or split band at 780 cm^{-1} for the so-called X-sensitive mode of C_6F_5 which is characteristic of the *cis*-$M(C_6F_5)_2$ fragment.[10]

The most relevant absorption bands in the IR spectra of the dithiocarbamate complexes and their tentative assignments[11–15] are presented in Table 2. The thioureide band near 1500 cm^{-1} indicates considerable double-bond character in the C⋯N bond; this behaviour may be attributed to the electron-releasing ability of the amines, which forces high electron density towards the sulphur atoms, via the π system, thus producing greater double-bond character in the carbon–nitrogen bond, and shifting ν(C⋯N) to higher energy [ν(C=N) = 1690–1640 cm^{-1}; ν(C—N) = 1350–1250 cm^{-1}].[16] This effect should be favoured by the high electronegativity of the C_6F_5 ligands. The band in the 995–970 cm^{-1} region is attributed to the stretching vibration of the C⋯S bonds. The presence of only one band in this region supports the bidentate coordination of the dithio ligand,[17,18] as represented by structure I.

(10)		−110.5	−168.4	

[a] In $(CD_3)_2CO$.

[b] Additional peaks of $[NBu_4]^+$ are found at δ *ca* 3.7 (t, N—CH_2), 1.8 (m, N—CH_2—CH_2), 1.5 (m, CH_2—CH_3) and 1.0 (t, CH_3), the relative intensities being 8 : 8 : 8 : 12.

[c] Partly overlapped with the peaks of the tetrabutylammonium cation.

The mono-ethyl and -propyl dithiocarbamate derivatives give an additional band in the 3200 cm^{-1} region, due the N—H stretching mode.

The methyl and ethyl xanthate complexes exhibit three IR bands in the 1235–1080 cm^{-1} region (Table 2) which are related to the vibrations of the S_2COR group.[19–22] They are highly coupled and, according to the normal coordinate analysis of $Ni(S_2COEt)_2$,[23] the 1230 cm^{-1} band has a substantial contribution from C—O—C stretching, the band around 1150 cm^{-1} is mainly a contribution of the ν(C—O) mode, and the band around 1050 cm^{-1} is entirely ν(C=S). The ν(Ni—S) mode is assigned to a band located at 350–335 cm^{-1}.

The IR spectrum of the dithiocarbonate complex (Table 2) is consistent with the presence of the bidentate S_2CO group.[19–24] According to Burke and Fackler[24] the band at 1700 cm^{-1} is thought to be due to the first overtone of the carbon–sulphur antisymmetric stretching mode.

The ^1H- and ^{19}F-NMR data for the complexes isolated are listed in Table 3. The ^1H spectra show the expected patterns for the S_2CNHR, S_2CNR_2 or S_2COR ligands. The ^{19}F spectra exhibit the three signals (intensity ratio 4 : 2 : 4) corresponding to the *ortho-*, *para-* and *meta-*F atoms of two equivalent C_6F_5 rings, which supports the assignment of bidentate 1,1-dithio ligand. All the complexes give an absorption band in their electronic spectra (Table 2) which is assigned to the $^1A_{1g} \rightarrow {}^1A_{2g}$ transition in a square-planar ligand field.

THE CYCLIC FIXATION AND REDUCTION OF MOLECULAR NITROGEN WITH $[WH_4(Ph_2PCH_2CH_2PPh_2)_2]$ IN γ-IRRADIATED SOLUTIONS

J. O. DZIĘGIELEWSKI* and J. G. MAŁECKI

Department of Inorganic and Radiation Chemistry, Institute of Chemistry, Silesian University, 40006 Katowice, Szkolna 9, Poland

(*Received* 19 *April* 1991; *accepted* 2 *July* 1991)

Abstract—Yields of NH_3 and N_2H_4 in radiation-catalytic reduction of N_2 by means of a hydride complex of W^{IV} with dppe in thf solution and in mixtures of thf with other solvents have been estimated. A mechanism proposed earlier of reduction of coordinated N_2 has been confirmed and the role of solvent in reduction of N_2 to NH_3 and amines has been explained.

In our recent work it has been shown that the hydride complexes of W^{IV} and Mo^{IV} with $Ph_2PCH_2CH_2PPh_2$(dppe) have higher activity as catalysts in the process of radiation-catalytic reduction of molecular nitrogen when compared with the activity of $[MoOCl(dppe)_2]$ and $[M(dppe)_2]$ (M = Mo, W).[1–4]

Making a comparison between the yields of the redox factors (i.e. H, e_s^-, R) and the yields of H_4N_2 and H_3N it was pointed out that the corresponding complexes formed H^- ions as a result of attachment of H^+ ions to the central ions,[5] and the H^- ions formed could reduce the coordinated N_2.

Using $[WH_4(dppe)_2]$ as a catalyst revealed the formation of $[WH(N_2)_2(dppe)_2]^+$ ions and their reduction to H_4N_2 in a radical process (by means of H atoms from $[WH_5(dppe)_2]^+$ and then to H_3N in an ion involved process (with H^- ions and e^- from the central ion).[2]

In our previous work[2] the remarkable effect of the solvent on the yields of H_3N was shown—the more stable the W—H group the higher the yields of ammonia in the particular solvent.

It is apparent that the role of the solvent cannot be restricted to the thermodynamic aspects of the M—H groups. Especially in the radiation process features such as molecular structure, polarity and polarizability, not to mention the donor–acceptor abilities of the solvent, play a very important role parallel to the stable and unstable radiolysis products.

The influence of the solvent on the yields and the products of the chemical reduction of coordinated N_2 has been reported,[6,7] but not explained so far. Thus, the problem of the solvent choice in the process of nitrogen fixation, especially for a cyclic process in a γ-radiation field is still to be explored. Taking into account the poor solubility of the neutral and ionic complexes of W^{IV} and Mo^{IV} on the one hand and thermodynamic and kinetic properties of the complex solutions including the yields of the stable and unstable radiolysis products on the other, we decided to use tetrahydrofuran (thf) and its mixtures as the most proper solvents. Thf is a medium polarity solvent and the products of its radiolysis are similar to those of the previously applied solvents, i.e. alcohols and cyclohexane.[8] In a mixture of thf with cyclohexane the yields of H_3N are supposed to be higher, while a small addition of water as a polar component can lead to the lower yields of N_2 reduction. The latter suggestion could support the results of our earlier works.

The application of the higher doses is accompanied by a lowering of the yields of ammonia in the solutions of Mo^{IV} and W^{IV} complexes. That fact is to be explained in this paper.

EXPERIMENTAL

Ligand dppe and a complex $[WH_4(dppe)_2]$ were synthesized according to the literature.[9] Thf was

* Author to whom correspondence should be addressed.

purified by refluxing with $LiAlH_4$ and then distilled. Before making solutions, thf and its mixtures with cyclohexane were saturated with N_2+H_2 mixtures or deoxygenated nitrogen.

The complex was dissolved in thf or its mixtures with cyclohexane. The solutions of $[WH_5(dppe)_2]HSO_4$ were obtained by the dissolving of $[WH_4(dppe)_2]$ in 0.1 M or 0.01 M solutions of H_2SO_4 in thf, thf+cyclohexane or thf+H_2O. The solutions of $[WH_5(dppe)_2]HSO_4$ were irradiated in a γ-radiation ^{60}Co source (Issliedowatiel) with simultaneous saturation of the proper solution with deoxygenated nitrogen or a mixture of deoxygenated nitrogen and hydrogen (v/v = 1 : 3). Dose rate was calculated as 7.66×10^{16} eV cm^{-3} min^{-1} in conversion to thf solution on the basis of a Fricke's dosimeter. In order to keep the concentrations of the solutions constant the gases were passed through the scrubbers filled with the proper solvent.

The H_4N_2 and H_3N generated were absorbed in aqueous solutions of H_2SO_4 ($c = 5 \times 10^{-2}$ M). Hydrazine and ammonia were determined by the standard methods, according to the cited papers,[9,10] respectively. For the acidified solutions the products were estimated in the irradiated solutions and in the traps filled with sulphuric acid using the same procedure. The aliphatic amines were detected spectrophotometrically, using salicyl aldehyde.[13] IR spectra were recorded for the irradiated solutions or in KBr pellets (the latter for the substances isolated from the irradiated solutions after evaporation of the solvent). The spectra were made using a Specord 75 IR spectrophotometer. ^1H and ^{31}P NMR spectra were made using a VXR-300 Varian spectrometer. The resonance signals were measured in the irradiated solutions and for the substances isolated from the irradiated solutions. Such substances were dissolved in $CDCl_3$.

RESULTS AND DISCUSSION

The numbers of $(N_2H_6)SO_4$ ions are shown in Fig. 1 and the numbers of $(NH_4)_2SO_4$ molecules in Fig. 2 vs dose and the concentrations of $[WH_5(dppe)_2]^+$ solutions. The radiation yields of ammonia and hydrazine together with the catalytic efficiency of the N_2 reduction are presented in Table 1. The catalytic efficiency of the process equals the number of NH_4^+ ions formed during 1 h irradiation of the $[WH_5(dppe)_2]HSO_4$ solutions. The number of ions is related to 1 mol of $[WH_5(dppe)_2]^+$ ions. Since, according to our earlier work,[2] only 1/3 of the complex is engaged in fixation of N_2, the numbers in column 5 were tripled.

The curves in Fig. 1 are similar to those presented in our earlier papers[1-5] where different complexes

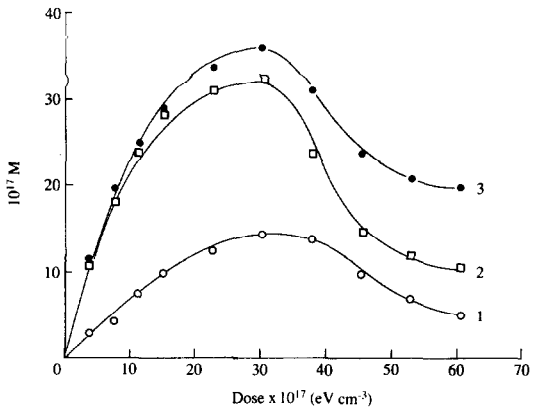

Fig. 1. The numbers of $(N_2H_6)SO_4$ molecules per 1 cm^3 (M) vs dose and concentration of a catalyst in acidified thf solution saturated with N_2+H_2 (1 : 3) mixture. Conc. $[WH_4(dppe)_2]$ = (1, ○) 5×10^{-3} mol dm^{-3}; (2, □) 1×10^{-2} mol dm^{-3}; (3, ●) 5×10^{-2} mol dm^{-3}.

and solvents were applied and the shapes of the curves were explained earlier.[4] The apparent formation of ammonia as a result of reduction of hydrazine was elaborated earlier.[1-5] It is easy to notice from Table 1 and Figs 1 and 2 that the radiation yields of ammonia and hydrazine do not depend directly on the concentrations of the complex. The relative catalytic efficiency (excluding the formation of the W—H groups, H_4N_2 and RNH_2) is increased at the lower concentrations of $[WH_4(dppe)_2]$ and the opposite effect is observed at the higher concentrations. The results presented are likely to be due to the too low dose rate applied. As a consequence, too many molecules of the catalyst

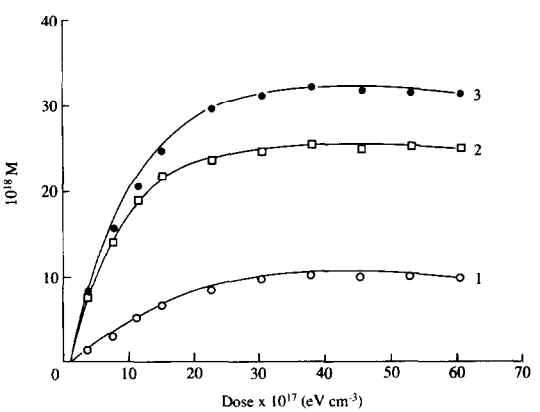

Fig. 2. The numbers of $(NH_4)_2SO_4$ molecules per 1 cm^3 (M) vs dose and concentration of a catalyst in acidified thf solution saturated with N_2+H_2 (1 : 3) mixture. Conc. $[WH_4(dppe)_2]$ = (1, ○) 5×10^{-3} mol dm^{-3}; (2, □) 1×10^{-2} mol dm^{-3}; (3, ●) 5×10^{-2} mol dm^{-3}.

Table 1. The parameters of the catalytic system ([$WH_4(dppe)_2$] dissolved in thf acidified with H_2SO_4 saturated with N_2+H_2)

Concentration of [$WH_4(dppe)_2$] (mol dm^{-3})	Number of $N_2H_6^{2+}$ ions/100 eV	Number of NH_4^+ ions/100 eV	Concentration of NH_4^+ ions after absorption of dose 45.36×10^{17} eV cm^{-3} (mol dm^{-3})	NH_4^+/[$WH_4(dppe)_2$] fixing N_2
5×10^{-3}	77	687	1.67×10^{-2}	10
1×10^{-2}	214	4174	4.24×10^{-2}	13
5×10^{-2}	317	5700	5.29×10^{-2}	3.3

do not take part in the process of fixation and reduction of N_2. The visible induction period (see Figs 2, 4 and 5) was explained earlier.[1-5] The yields of N_2 reduction in the presence of $[WH_5(dppe)_2]^+$ in thf are higher than those in cyclohexane–ethanol and cyclohexane–methanol systems.[2] Our earlier hypothesis that the higher stability of the hydride complex in a low polarity solvent can effect the yields of hydrazine and ammonia seems to be supported by that observation. However, in thf solutions the numbers of NH_4^+ are slightly decreased while increasing the dose as for methanol and methanol–cyclohexane systems.[2,3-5] The observed decrease of the NH_4^+ concentrations was explained earlier[3] as a result of their reactions with the radicals formed in the course of radiolysis of methanol. In the irradiated thf solutions the radicals formed, C_4H_7O,[8,14] can react with NH_4^+ ions and H_3N molecules. It is obvious for the reaction (1) type to go independently of the dose in the γ-radiation field, however in the initial stage of N_2 reduction its rate is much lower than that of the H_3N formation. That is why an increase of the NH_4^+ ions concentration is observed until the plateau starts (see Fig. 2).

$$H_3N+R\longrightarrow RH+NH_2 \quad \text{(ref. 3).} \qquad (1)$$

When the plateau starts, the rate of reaction (1) is greater than the rate of H_3N formation. Thus, the application of greater doses is accompanied by a decrease in the number of NH_4^+ ions. The rate of coordinated nitrogen reduction to ammonia is affected by a concentration of H^- ions.[1,2] The ions can be formed as a result either of the substitution of W—N_2 groups by W—H group or addition of H^+ ions into the central atom.

The equal tangents of the curves from Figs 3 and 4 for the acidified solutions saturated with nitrogen and the non-acidified ones saturated with nitrogen–hydrogen mixture, and, as a consequence, the equal values of $G_{NH_4^+}$ are satisfying supports for the previously proposed two ways of formation of H^- ions and their influence on the reduction of N_2. Regardless of the way H^- ions are formed, they possess the same ability to reduce H_4N_2 to H_3N, i.e. at different oxidation states of the central W ions the $G_{NH_4^+}$ values are equal in the acidified solutions saturated with nitrogen and in the non-acidified ones saturated with nitrogen–hydrogen mixture (see Fig. 4 and Table 2). The association of H^+ ions to W ions is a very rapid process when compared with the process of H^- ion formation to be a result of N_2 elimination using H_2. Therefore, the amount of hydrazine to be reduced to NH_4^+ ions is the lowest in the non-acidified solutions (see Figs 3 and 4). Insufficient concentration of the H^- ions prevents the reduction of all the hydrazine to ammonia (high placed plateau in curve 1 in Fig. 3). Thus, as a consequence, the $G_{NH_4^+}$ in non-acidified solutions is lower than that in the acidified ones and/or solutions saturated with hydrogen (Fig. 4 and Table 2). Hence, the influence of hydrazine amount on the yields of ammonia is supported and the role of H^- and H^+ ions in the process of reduction of molecular nitrogen seems to be explained sat-

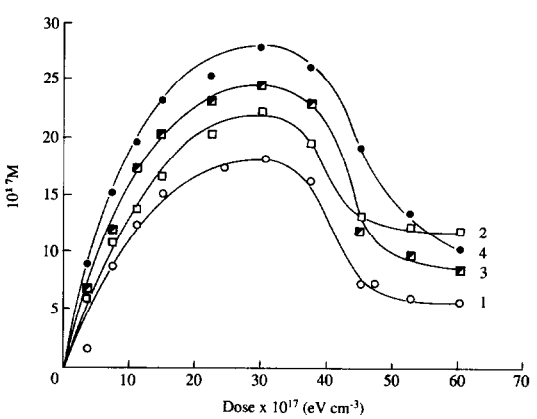

Fig. 3. The numbers of $(N_2H_6)SO_4$ molecules per 1 cm^3 (M) vs dose and concentration of H_2SO_4 (c[$WH_4(dppe)_2$] = 1×10^{-2} mol dm^{-3}) in thf solution. $c_{H_2SO_4}$ = (1) 0 mol dm^{-3} (○)—saturated with N_2+H_2 (1:3); (2) 10^{-2} mol dm^{-3} (□)—saturated with N_2; (3) 10^{-1} mol dm^{-3} (◪)—saturated with N_2; (4) 10^{-2} mol dm^{-3} (●)—saturated with N_2+H_2 (1:3).

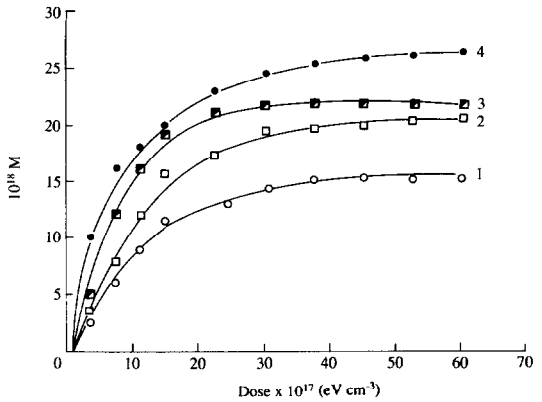

Fig. 4. The numbers of $(NH_4)_2SO_4$ molecules per 1 cm^3 (M) vs dose and concentration of H_2SO_4 ($c[WH_4(dppe)_2] = 1 \times 10^{-2}$ mol dm^{-3}) in thf solution. $c_{H_2SO_4}$ = (1) 0 mol dm^{-3} (○)—saturated with N_2+H_2 (1:3); (2) 10^{-2} mol dm^{-3} (□)—saturated with N_2; (3) 10^{-1} mol dm^{-3} (◪)—saturated with N_2; (4) 10^{-2} mol dm^{-3} (●)—saturated with N_2+H_2 (1:3).

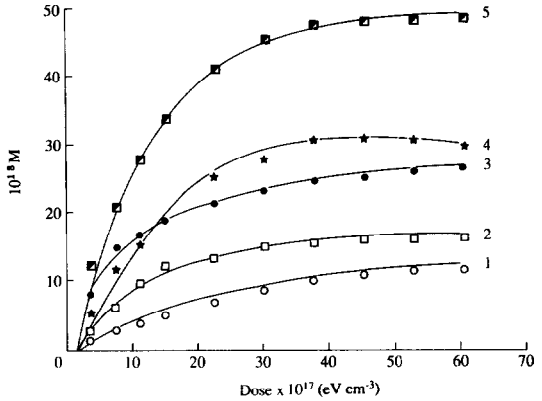

Fig. 5. The numbers of NH_4^+ ions per 1 cm^3 (M) vs dose and concentration of $[WH_4(dppe)_2]$ in different systems. (1,○) $c[WH_4(dppe_2)] = 5 \times 10^{-3}$ mol dm^{-3} in thf+dppe ($c = 5 \times 10^{-3}$ mol dm^{-3}) saturated N_2+H_2 (1:3); (2, □) $c[WH_4(dppe)_2] = 1 \times 10^{-2}$ mol dm^{-3} in thf+dppe ($c = 1 \times 10^{-2}$ mol dm^{-3}) saturated N_2+H_2 (1:3); (3, ●) $c[WH_4(dppe)_2] = 1 \times 10^{-2}$ mol dm^{-3} in thf acidified+dppe ($c = 1 \times 10^{-2}$ mol dm^{-3}) saturated N_2+H_2 (1:3); (4, ★) $c[WH_4(dppe)_2] = 1 \times 10^{-2}$ mol dm^{-3} in thf+C_6H_{12} (1:1) saturated N_2+H_2 (1:3); (5, ◪) $c[WH_4(dppe)_2] = 1 \times 10^{-2}$ mol dm^{-3} in thf acidified+C_6H_{12} (1:1)+dppe ($c = 1 \times 10^{-2}$ mol dm^{-3}) saturated N_2+H_2 (1:3).

isfactorily. Nevertheless, the H^+ ions could protonate the coordinated nitrogen and, indirectly, the other products of reduction. The influence of H^- ions on the mechanism of N_2 reduction (i.e. disproportionation of —NNH_2 group) was observed by the other authors.[15] The influence of the solvent on the coordination sphere of the catalyst is thought to be another reason for the decreasing rate of formation of H_3N when the applied dose is increased.

When free ligand dppe is present in the reaction system it affects the yields of H_4N_2; either in the acidified solutions or in the non-acidified ones the yield of hydrazine is increased about 20% while the yield of NH_4^+ ions is increased about 20% in the acidified solutions only (compare curves 1 and 2 in Fig. 5 with curve 1 in Fig. 4 and the corresponding data from Tables 1–3). The curves in Fig. 5 (excluding curve 4) have permanent tendencies to increase their values, however, at the higher doses the rate of ammonia formation is distinctly lower than at the initial stage of the process. In the non-acidified solutions the presence of dppe does not affect G_{NH_3}, however, due to the relatively high value of $G_{N_2H_4}$ the concentration of NH_3 is increased. These observations suggest that dppe is liberated from the coordination sphere in the two-step competitive pathway (2 and 3) which is as

I—numbers of $(N_2H_6)SO_4$ molecules per 100 eV.
II—numbers of $(NH_4)_2SO_4$ or RNH_2 molecules per 100 eV.
III—concentrations of NH_4^+ ions or RNH_2 molecules after absorption of 45.36×10^{17} eV cm^{-3} (mol dm^{-3}).
IV—numbers of NH_4^+ ions or RNH_2 molecules per number of $[WH_4(dppe)_2]$ moles fixing N_2.

follows:

$$[WH(N_2)_2(dppe)_2]^+ + [WH_5(dppe)_2]^+ + 2\,HSO_4^- \rightarrow [HWNNH_2(SO_4)(dppe)]^+ + N_2 + [WH_3(dppe)_2]^+ + (dppe\,H_2)SO_4 \quad (2)$$

$$[HWNNH_2(SO_4)(dppe)]^+ \xrightarrow[dppe\,H_2^{2+}]{2thf,\,2H^+} \begin{cases} \xrightarrow{a} [HW(N_2H_4)(thf)_2(dppe)]^+ + SO_4^{-2} \\ \xrightarrow{b} [HW(N_2H_4)(dppe)_2]^+ + H_2SO_4 \end{cases} \quad (3)$$

The products of reaction (2) were not isolated due to their instability and relatively low concentration. The composition of the $[HWNNH_2(SO_4)(dppe)]^+$ product was proposed as the most likely one.

The formation of the hydrazide complexes of type $[WNNH_2(HSO_4)_2L_3]$ was shown by other authors.[16] Since the central ion is protonated the HSO_4^- ion is most likely to act as a bidentate ligand (in a form of SO_4^{2-} ion).[17]

Reactions (2) and (3) are complementary to those presented earlier when $[WH_5(dppe)_2]^+$ was applied as a catalyst.[2] For a process made in thf-cyclohexane system the role of reaction 3a is slightly diminished. The effect is enlarged by the small addition of dppe into the reaction system. The latter is accompanied by the apparent increase of the yields of NH_4^+ ions. On the other hand, the addition of a polar solvent (i.e. H_2O) into thf solution results in a contradictory effect of decreasing yields of hydrazine and ammonia.

The liberation of dppe from the coordination sphere of the complex was monitored by ^{31}P NMR spectroscopy. In a solution of $[WH_4(dppe)_2]$ in thf ($c = 1 \times 10^{-2}$ M) irradiated with a dose 5.4×10^{18} eV cm^{-3} two signals at 33.44 and 27.02 ppm were observed. The former was attributed to $[WH_x(dppe)_2]$ ($x < 4$)[18] complex while the latter was assigned to phosphine oxide[19] which is formed as a result of a liberation of dppe from the coordination sphere of the complex and its oxygenation by oxygen from the air. The chemical shifts of ^{31}P signals of dppe and its oxide were determined for the non-irradiated samples as −12.13 and 27.02 ppm, respectively.[19b] Comparing the integral intensities of the ^{31}P signals one could count the amount of dppe which is effectively exchanged by thf in the coordination sphere to be 10% of the whole amount of the former. Thus, reactions 2 and 3a could not be assumed to have decreased the rate of N_2 reduction to H_3N.

That conclusion seems to be supported by the fact of a relatively high concentration of the bis-dinitrogen complex of W in the irradiated complex solution. In fact, in the IR spectrum of the complex a few characteristic bands appear, e.g. at 1960 cm^{-1} assigned as A_{2u} vibration of a $W(N_2)_2$ group, besides, the lower intensities of the bands at 1830, 1775 and 1730 cm^{-1} attributed to ν(W—H) vibrations are due to the lower concentration of W—H groups in the irradiated solution of $[WH_4(dppe)_2]$. Thus, the other direction of the process of dinitrogen reduction leading neither to hydrazine nor to ammonia could be taken into account. The reduction by the radicals with the simultaneous action of H^+ or H^- ions and H atoms seems to be the alternative explanation of the observed phenomena. As a matter of fact, at the higher doses aliphatic amines are observed (see Table 3). The amines are formed in the acidified solutions, as well. Aromatic amines are not observed. The RNH_2 type amines in the irradiated solution of $[WH_4(dppe)_2]$ saturated with N_2+H_2 were found in the IR spectrum—ν(NH) at 3500 cm^{-1} and δ(NH) at 1640 cm^{-1}.

The other support for the presence of amines is its ^1H NMR spectrum, i.e. the signals at 0.8–1.8 ppm region, in fact, partially overlapped by the signals of dppe. Thus, $[W(N_2)_2(dppe)_2]$ is believed to be reduced by the W—H groups or the radicals R:

$$[W(N_2)_2(dppe)_2] \xrightarrow[R]{H^-} \begin{cases} \xrightarrow{a} H_3N + \\ \xrightarrow{b} [(N_2)W(N_2R)(dppe)_2] \end{cases} \quad (4)$$

More detailed mechanism of the process was presented earlier.[1-5]

The complexes of $[XW(N_2R)(dppe)_2]$ (R = C_6H_{11} or ) were described in the literature.[20] Our work concerning the formation of diazenide complex and its transformation to amines is in progress. Actually, the probability of reactions 4a and 4b seems to be dependent on the concentration of W—H groups and the lower concentration of the groups the more likely reaction 4b. The yields of the radicals C_6H_{11} and C_4H_7O are lower than 6 ($G_R < 6$) in cyclohexane–thf mixture.[8] If the radicals were formed as a result of the radiation decomposition of the solvents the G_R value should have been higher than 120. Therefore, the radicals are assumed to be formed in the other way without the influence of radiation. This problem will be explained in the next paper. On the other hand, H_3N seems to be the main product of reduction, although the yields of amines are remarkable. Taking into account the entire yields of reduction, i.e. H_3N and RNH_2, the high catalytic ability of the $[WH_4(dppe)_2]$—thf—C_6H_{12}—N_2—H_2 system seems to be obvious.

(*Received* 5 *February* 1991; *accepted* 21 *June* 1991)

Abstract—The nickel(II) Schiff base complexes with isobutyl chains and benzoyl substituents have been prepared and characterized by ^1H and ^{13}C NMR spectroscopies. In the complex, the donor set of N_2O_2 has a square planar coordination, the benzoyl substituents are perpendicular to the chelate plane and the isobutyl groups move segmentally so that they may approach the benzoyl substituents.

It has been well known that not only the strong interactions such as covalent bonds, coordination bonds or ionic bonds, but also the weak interactions such as hydrogen bonds and hydrophobic interactions play an important role in most biological proceses relating to the regulation of metabolism.[1] In the case of metal complexes, such hydrophobic interactions operating between ligands may provide distinct features in the structure, stability and reactivity of complexes. Fisher and Sigel[2] reported that the interligand interaction operating between aromatic and aliphatic groups increases the stability of the mixed ligand complex with an amino acid having long alkyl chains and bipyridyl or *o*-phenanthroline. Okawa and co-workers[3] reported that the interligand, hydrophobic interactions can be applicable for selective syntheses of geometrical and optical isomers of complexes. In this paper, we report the preparation and characterization of the nickel(II) Schiff base complexes with 2-methylpropyl(isobutyl) chains and benzoyl substituents. Their structures and dynamics in chloroform solution will be discussed from the results of ^1H and ^{13}C NMR spectra, and ^{13}C relaxation-time measurements. It will be made clear that an interaction between isobutyl groups and benzoyl substituents in nickel(II) Schiff base complex is weak but validly affects the characteristic structure and dynamics of isobutyl chains in chloroform solution.

EXPERIMENTAL

Preparation of benzoyl derivatives of nickel(II) Schiff base complexes[4]

To a dry chloroform solution (500 cm^3) of nickel(II) Schiff base complex (0.05 mol) and excess trimethylamine (0.12 mol) was added excess benzoyl chloride (0.12 mol) (benzoyl chloride, *m*-nitrobenzoyl chloride or 3,5-dinitrobenzoyl chloride). The mixture was refluxed for 60 h, and evaporated under reduced pressure. The residue was recrystallized from a mixture of chloroform and methanol (1 : 10) for the derivatives of Ni(Me, Meen), or a mixture of ethanol and diethylether (1 : 1) for the derivatives of Ni(isoBu, Meen). The results of the elemental analyses, IR and electronic spectral data of all complexes indicate that they are quite pure and are consistent with their chemical structures (see Fig. 1).

Measurements

The ^1H NMR, ^{13}C NMR and ^{13}C relaxation-time (T_1) measurements were recorded using a JEOL FX-90 spectrometer at 90 MHz for ^1H and at 22.5 MHz for ^{13}C nuclei. Each sample solution was almost saturated with the respective complexes.

RESULTS AND DISCUSSION

^{1}H *NMR spectra*

The chemical shift values in the ^{1}H NMR spectra for nickel(II) Schiff base complexes in $CDCl_3$ are summarized in Table 1. For the ^{1}H NMR spectrum of Ni(Me, Meen), three singlet peaks at 1.86, 3.01 and 4.86 ppm were obtained and can be assigned to the overlap of methyl protons attached to azomethine [CH_3(N)] and keto moieties [CH_3(O)], the methylene protons of the ethylenediamine moiety [CH_2(en)], and the methine protons on the γ-positions of the chelate ring, respectively. For the spectra of benzoyl and *m*-nitrobenzoyl derivatives of Ni(Me, Meen), the singlet resonance signals due to CH_3(N) and CH_3(O) are shifted to higher fields, *ca* 0.05 ppm for the benzoyl derivative and 0.02 ppm for the *m*-nitrobenzoyl derivative compared to the parent complex. Other singlet resonance signals due to CH_2(en) are shifted to lower fields, *ca* 0.15, 0.20 and 0.25 ppm, respectively. The shifts were caused by the electron-withdrawing effects of benzoyl substituents which are of the order benzoyl < *m*-nitrobenzoyl < 3,5-dinitrobenzoyl group. However, the shifts to higher field of the signals due to CH_3(N) and CH_3(O) are consequent on the combination of the electron-withdrawing effect and the magnetic anisotropy effect[5] by benzoyl substituents; the latter is associated with higher-field shifts and the former with lower-field shifts. It is evident that the latter effect is stronger than the former in the case of benzoyl and *m*-nitrobenzoyl derivatives, but both are the same in the case of the 3,5-dinitrobenzoyl derivative.

On the other hand, for Ni(isoBu, Meen) the spectrum has a doublet resonance due to the methyl protons of 2-methylpropyl(isobutyl) groups [CH_3(O)] at 0.89 ppm, a singlet due to the methyl protons attached to azomethine moieties [CH_3(N)] at 1.85 ppm, an overlapping multiplet resonance due to the methine and methylene protons of isobutyl groups [CH_2+CH(O)] at 1.95 ppm, a singlet due to CH_2(en) at 3.01 ppm, and a singlet due to the methine protons on the γ-positions of the chelate ring at 4.86 ppm. For the benzoyl, *m*-nitrobenzoyl and 3,5-dinitrobenzoyl derivatives of Ni(isoBu, Meen), similar spectra in the high-field region were obtained (<4.0 ppm), though the signals due to CH_3(N), CH_3(O) and CH_2+CH(O) shifted to higher field and the signals due to CH_2(en) to lower field. These results were caused by exactly the same reasons as in the case for Ni(Me, Meen)s. However, the values of the higher-field shifts on the protons of even methyl and isobutyl groups for Ni(isoBu, Meen)s are larger than those of both methyl groups for Ni(Me, Meen)s, while the values of the lower-field shifts on CH_2(en) are similar for the derivatives of Ni(Me, Meen) and Ni(isoBu, Meen), respectively. This fact is important with respect to the structures of nickel(II) Schiff base complexes in solution. In addition, the ^{1}H NMR chemical shifts and signal features did not depend so much on temperature in the region from −20 to 30°C.

Table 1. ^{1}H NMR spectral data of nickel(II) complexes in $CDCl_3$

Complex	δ (ppm) CH_2(en)	CH_3(N)	CH_3(O)	CH_2+CH(O)
Ni(Me, Meen)	3.01	1.86	1.86

CH(O)	27.0	2.7	27.0	0.4
$CH_2(O)$	47.3	1.2	46.5	0.6
$CH_2(en)$	53.0	1.1	53.6	0.3

^{13}C *NMR spectra*

The ^{13}C NMR spectrum of Ni(isoBu, Meen) in $CDCl_3$ has eight sharp signals at 21.0, 22.7, 27.0, 47.3, 53.0, 99.8, 164.1 and 179.9 ppm assignable to the methyl carbons attached to azomethine moieties [$CH_3(N)$], methyl carbons of isobutyl groups [$CH_3(O)$], methine carbons of isobutyl groups [CH(O)], methylene carbons of isobutyl groups [$CH_2(O)$], methylene carbons of the ethylenediamine moiety [$CH_2(en)$], methine carbon at γ-positions of the chelate ring, azomethine carbons, and keto carbons, respectively. Similarly, the spectra of its benzoyl, *m*-nitrobenzoyl and 3,5-dinitrobenzoyl derivatives have 13 or 15 sharp signals. The higher-field peaks can be assigned to $CH_3(N)$, $CH_3(O)$, CH(O), $CH_2(O)$, $CH_2(en)$, quarternary carbons at γ-positions of the chelate ring, phenyl carbons of benzoyl substituents (four or six signals), azomethine carbons, keto carbons, and carbonyl carbons of benzoyl substituents, respectively. These results are consistent with the structures of nickel(II) Schiff base complexes shown in Fig. 1.

T_1 *measurements*

The T_1 measurements were obtained using the inversion recovery method[6] for the nickel(II) Schiff base complexes Ni(Me, Meen), Ni(Me, Meen)-*m*-NO_2B, Ni(isoBu, Meen) and Ni(isoBu, Meen)-*m*-NO_2 in $CDCl_3$. The T_1 data for the four nickel(II) complexes are listed in Table 2. It is considered that in large molecules such as the nickel(II) complexes investigated here, the dipole–dipole relaxation is dominant.[7]* It is difficult to extract intramolecular movements such as distortion, the rotation of the benzoyl group or segmental movement of the isobutyl group from the whole movements of the complex molecule. However, the relative difference in intramolecular movements between Ni(Me, Meen) and Ni(isoBu, Meen), or the parent complex and its benzoyl derivative, can be discussed qualitatively based on T_1 data. It can be said that the larger the T_1 value of the ^{13}C atom, the faster its motion. The relaxation times of the methyl, methylene and methine carbons are not the same, even if they have similar mobility. They may be correlated by the following equation:

$$3 \times T_1(\text{methyl}) \fallingdotseq 2 \times T_1(\text{methylene}) = T_1(\text{methine}).$$

All the T_1 values of ^{13}C atoms were reduced greatly owing to the insertion of *m*-nitrobenzoyl groups in the nickel(II) Schiff base complex. This is caused by the reduction of movements such as translation and rotation for the whole complex molecule due to the increase in molecular weight. This effect can be extracted directly from the T_1 value of $CH_2(en)$ because its molecular structure and intramolecular movement may be steady before and after the insertion of benzoyl groups. The T_1 values of $CH_2(en)$ in *m*-nitrobenzoyl derivatives decrease to about a fifth of those in their parent complexes by the insertion of *m*-nitrobenzoyl substituents. However, the magnitude of the decrease in T_1 values for other carbons is not similar to that for $CH_2(en)$.

For Ni(Me, Meen), the T_1 value of $CH_3(N)$ is similar to that of $CH_3(O)$. The T_1 value of $CH_2(en)$ is rather small and it indicates that the chelate plane containing the central nickel(II) ion and chelate rings is rather rigid.

For Ni(Me, Meen)-*m*-NO_2B, the decrease in T_1 values by the insertion of *m*-nitrobenzoyl sub-

* This assumption was confirmed by measuring the NOE factor (η). We have measured this for analogous complexes. The values were found to be within the 2.0 ± 0.1 range for all carbons of the complexes.

stituents is much faster for CH_2(en) than for CH_3(N) and CH_3(O). Therefore, it can be said that the activity of "intramolecular movement", such as the bending and deformation vibrations for both methyl groups, is higher in the *m*-nitrobenzoyl derivative than that in its parent complex. In addition, the T_1 value of CH_3(O) became larger than that of CH_3(N).

On the other hand, for Ni(isoBu, Meen) the T_1 values of both methyl carbons are different even without *m*-nitrobenzoyl substituents, and the T_1 value of CH_3(O) which belongs to the isobutyl chain as its terminal methyl group is much smaller than that of CH_3(N). When *m*-nitrobenzoyl groups are inserted into Ni(isoBu, Meen), the T_1 value of CH_3(N) decreases faster and becomes almost the same as that of CH_3(O). Similarly, the T_1 values for the methylene and methine carbons of the isobutyl group, CH_2(O) and CH(O), decrease by the insertion of *m*-nitrobenzoyl groups, but the degree of the decrease is different. The T_1 value of CH(O) in Ni(isoBu, Meen)-*m*-NO_2B is very small and only *ca* 15% of that in Ni(isoBu, Meen), although values for CH_2(O) and CH_2(en) are *ca* 50 and 27%, respectively. These results indicate that the segmental movement of the isobutyl group, especially the movement at the methine moiety, is restricted by the presence of the *m*-nitrobenzoyl group. Both neighbouring carbons of CH_2(O), the keto carbon in the chelate ring and CH(O) are brought to a standstill, so that like a string the intramolecular movement of CH_2(O) becomes vigorous.

The T_1 values of the phenyl carbons of *m*(3)-nitrobenzoyl substituents at the 2-, 4-, 5- and 6-positions are 0.3, 0.3, 0.2 and 0.2 s, respectively. They are rather small and similar to each other in both the cases of Ni(Me, Meen)-*m*-NO_2B and Ni(isoBu, Meen)-*m*-NO_2B, indicating that *m*-nitrobenzoyl groups are rather rigid.

Temperature dependence of T_1

In order to investigate the temperature dependence of T_1 values, Ni(Me, Meen), Ni(Me, Meen)-*m*-NO_2B, Ni(isoBu, Meen) and Ni(isoBu, Meen)-*m*-NO_2B in $CDCl_3$ solutions were measured at temperatures from −20 to 30°C. For Ni(Me, Meen) and Ni(Me, Meen)-*m*-NO_2B, all T_1 values of CH_3(N), CH_3(O) and CH_2(en) decreased continuously with decreasing temperature (Figs 2 and 3). This is in accordance with the fact that molecular movement such as the internal rotation becomes restricted at lower temperatures.

On the other hand, the result for Ni(isoBu, Meen), which has no benzoyl substituents, is similar to those for Ni(Me, Meen) and Ni(Me, Meen)-*m*-NO_2B as shown in Fig. 4. However, the result for Ni(isoBu, Meen)-*m*-NO_2B (Fig. 5) is different from those for other nickel(II) complexes. All T_1 values of ^{13}C atoms in Ni(isoBu, Meen)-*m*-NO_2B decreased continuously with a decrease in temperature. The magnitude of the decrease in T_1 for CH_3(O) is especially much larger. The T_1 value for CH_3(O) is smaller than for CH_3(N) in the region below 0°C. This result suggests that the intramolecular movement of the isobutyl group in Ni(isoBu, Meen)-*m*-NO_2B in chloroform solution is significantly different from those in the other three complexes. Although the T_1 value of CH(O)

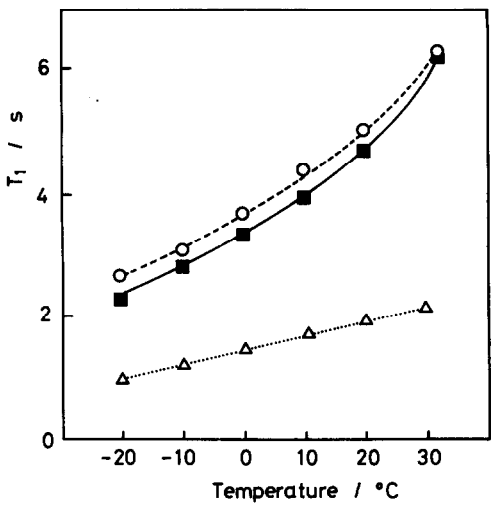

Fig. 2. Temperature dependence of T_1 for Ni(Me, Meen). (---○---): CH_3(O), (——■——): CH_3(N), (···△···): CH_2(en).

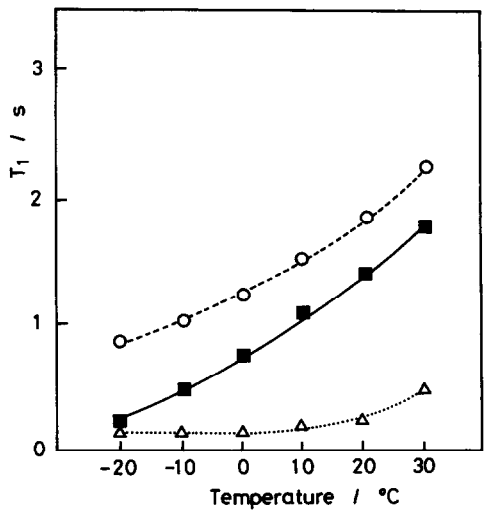

Fig. 3. Temperature dependence of T_1 for Ni(Me, Meen)-*m*-NO_2B. (---○---): CH_3(O), (——■——): CH_3(N), (···△···): CH_2(en).

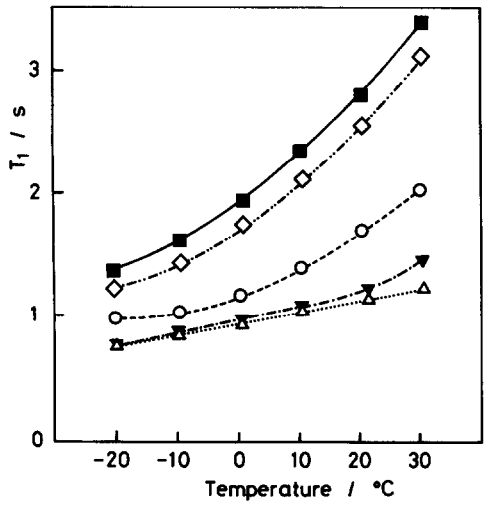

Fig. 4. Temperature dependence of T_1 for Ni(isoBu, Meen). (——■——): CH_3(N), (—··—◇—··—··): CH(O), (---○---): CH_3(O), (—·—▼—·—·—): CH_2(O), (···△···): CH_2(en).

is much larger than that of CH_2(en) in Ni(isoBu, Meen), they are almost the same in Ni(isoBu, Meen)-*m*-NO_2B, indicating that the methine carbon of the isobutyl group is fixed by the inserted *m*-nitrobenzoyl substituent so that the terminal methyl carbons [CH_3(O)] and methylene carbon [CH_2(O)] in the isobutyl group can increase the degree of movement. However, this increase in movement on the methylene and methyl carbons by the insertion of the *m*-nitrobenzoyl substituent diminishes at lower temperature, and the methyl carbons begin to fix in the neighbourhood of the benzoyl group as the methine carbon of the isobutyl group.

Structures and dynamics of nickel(II) complexes in solution

The structures and dynamics of nickel(II) Schiff base complexes in chloroform solution can be proposed from the results of the ^1H and ^{13}C NMR spectra, and ^{13}C relaxation time measurements. In all the nickel(II) complexes studied, the donor sets of N_2O_2 which belong to three chelate rings have a square-planar coordination. Their intramolecular movements are not fast but rather slow. For benzoyl derivatives, the inserted benzoyl groups are perpendicular to the chelate planes containing the nickel(II) ions. There is steric hindrance between benzoyl groups and adjacent isobutyl chains in nickel(II) complexes with both isobutyl and benzoyl groups, and the benzoyl groups are inclined to approach methyl groups attached to azomethine moieties to avoid the isobutyl chains. The isobutyl groups move segmentally so that they may approach the benzoyl groups. The movement of only the methine moiety in the isobutyl group is restricted by the benzoyl substituent but the methylene and terminal methyl moieties move much more actively in benzoyl derivatives than in their parent complexes at room temperature. The movement of the methyl groups became much slower below 0°C. The isobutyl groups may choose some conformations to approach the benzoyl substituents, so that the isobutyl groups can experience the magnetic anisotropy effect of the benzoyl groups for a certain time. The characteristic behaviour of the isobutyl groups may be affected by the so-called CH···π interaction between alkyl and phenyl groups. However, this interaction is so weak in a non-polar organic solvent that the isobutyl groups are not fixed at only one conformation. The isobutyl group is a rather short alkyl chain and its freedom of movement is not naturally high. We are now preparing the nickel(II) Schiff base complexes, with longer alkyl chains such as isopentyl and isohexyl groups, Ni(isoPe, Meen)s and Ni(isoHx, Meen)s and measuring their NMR spectra.

(*Received* 26 *March* 1991; *accepted* 18 *June* 1991)

Abstract—Reaction of $M_2(NMe_2)_6$ (M = Mo, W) with triphenylmethanol in hexane/ether produces $M_2(OCPh_3)_2(NMe_2)_4$ (**I**) as yellow crystals in high yield (92–97%). $M_2(OCPh_3)_2(NMe_2)_4$ are air-sensitive, soluble in aromatic solvents and decompose around 160°C. The ^1H NMR of **I** is temperature dependent and shows a mixture of *anti* and *gauche* rotamers. The X-ray crystal structures of **I** reveal exclusively the *gauche* isomer for tungsten and the *anti* isomer for molybdenum. The reactions between $M_2(NMe_2)_6$ and triphenylsilanol (2 equiv.) yield $M_2(OSiPh_3)_2(NMe_2)_4$ compounds (M = Mo, W) (**II**) as orange crystals. In the presence of >6 equiv. of Ph_3SiOH the $M_2(NMe_2)_6$ compounds react further to give yellow crystalline compounds, $M_2(OSiPh_3)_4(NMe_2)_2$. In compound **II**, where M = W, the $W_2O_2N_4$ skeleton adopted the *anti* conformation with W—W = 2.2954(6) Å, W—O = 1.925(4) Å, W—N = 1.935(8) Å, W—W—O = 108.1(1)°, W—W—N = 102(1)°. The addition of Ph_3SiOH (>6 equiv.) to $W_2(OBu^t)_6$ yielded the related compound $W_2(OBu^t)_2(OSiPh_3)_4$.

It is well-established that the addition of an alcohol to a metal amide leads to a metal alkoxide and the liberation of an amine and this often provides a synthetic route to metal alkoxides when other routes fail.[1] We have used this reaction extensively in the synthesis of both dinuclear and tetranuclear alkoxides of molybdenum and tungsten starting from the amido compounds $M_2(NMe_2)_6$.[2–5] Though these reactions must surely proceed in a stepwise RO-for-NMe_2 exchange at the M_2 centre with concomitant hydrogen atom transfer no intermediates have been isolated or detected in previous studies. Reasoning that the introduction of a more sterically demanding RO group (relative to NMe_2) might slow the subsequent substitution step we carried out reactions involving Ph_3COH and Ph_3SiOH. These do indeed allow for the isolation of mixed amido-alkoxide M_2-containing compounds as we describe here. These findings complement the recent report by Cotton and co-workers of the synthesis and characterization of the mixed amido perfluoroalkoxide $Mo_2(NMe_2)_2(OC(CF_3)_3)_4$.[6]

RESULTS AND DISCUSSION

Synthesis

Treatment of an ether/hydrocarbon solution of $M_2(NMe_2)_6$ with >six-fold excess of triphenylmethanol produces $M_2(OCPh_3)_2(NMe_2)_4$ (**I**) in high yield [eq. (1)].

$$M_2(NMe_2)_6 + 2HOCPh_3 \xrightarrow[(M = Mo, W)]{RT/hexane/ether} M_2(OCPh_3)_2(NMe_2)_4 + 2HNMe_2 \quad (1)$$

† Author to whom correspondence should be addressed.

When the reaction is followed by ^1H NMR spectroscopy no intermediate is detected. Only $M_2(OCPh_3)_2(NMe_2)_4$, dimethyl-amine and unreacted starting material are observed. The product $M_2(OCPH_3)_2(NMe_2)_4$ (**I**) precipitates from the reaction solution as well-formed yellow crystals. Heating the reaction or using longer reaction times does not enable further substitution and formation of $M_2(OCPh_3)_n(NMe_2)_{6-n}$ ($n \geqslant 3$) species. The reaction shown in eq. (1) is driven by the stronger acidity of triphenylmethanol compared to $HNMe_2$, the entropically-favoured loss of dimethylamine gas and enthalpically by M—O bonds being somewhat stronger than M—N bonds (M = Mo, W).

Compounds **I** are obtained as well-formed yellow crystals which precipitate from the reaction solution on standing. They are air-sensitive, both in the solid state and in solution. However, crystals of **I** are stable for *ca* 2–3 h in air before noticeable decomposition occurs. The decomposition points at 162°C (M = Mo) and 145–7°C (M = W) are comparable with related $M_2(OR)_6$ and $M_2R_2(OR)_4$ compounds.[7]

When $W_2(NMe_2)_6$ is allowed to react with Ph_3SiOH in hydrocarbon/ether solvents the compound $W_2(OSiPh_3)_2(NMe_2)_4$ is formed in a reaction closely related to that of eq. (1). The latter compound is an orange crystalline, hydrocarbon-soluble solid that does react further in the presence of an excess of Ph_3SiOH to yield $W_2(OSiPh_3)_4(NMe_2)_2$. The latter is obtained as a yellow microcrystalline sample only sparingly soluble in hexane.

The addition of $\geqslant 6$ equiv. of Ph_3SiOH to a hydrocarbon solution of $W_2(OBu^t)_6$ gives the mixed siloxide–alkoxide $W_2(OSiPh_3)_4(OBu^t)_2$. Presumably, in this reaction, as in the reaction with $W_2(NMe_2)_6$, the compounds of the formula $W_2(OSiPh_3)_4X_2$, where $X = NMe_2$ or OBu^t, are obtained because further replacement of X by $OSiPh_3$ is prevented by steric hindrance. In reactions with the $W_2(NMe_2)_6$ compound, the replacement of four NMe_2 groups by $OSiPh_3$ relative to two by $OCPh_3$ is also most likely a reflection of the steric effects of the OR ligands. The longer O—Si bonds, relative to O—C, and longer Si—C(phenyl) bonds, relative to C—C(phenyl), make the $OSiPh_3$ less sterically demanding at the metal centre than $OCPh_3$.

Solid-state and molecular structures

Ball-and-stick drawings showing the molecular structures and the atom number scheme for compound **I**, where M = Mo and W, and $W_2(OSiPh_3)_2(NMe_2)_4$ are given in Figs 1, 2 and 3, respectively. Comparisons of the bond distances and bond angles for compounds **I** are given in Table 1, while selected bond distances and angles for $W_2(OSiPh_3)_2(NMe_2)_4$ are given in Table 2. A summary of crystal data for all three compounds is given in Table 3.

The compounds adopt the now familiar staggered ethane-like ground state structures for $M_2X_2Y_4$ (M≡M) compounds.[8] The M—M distances are typical of those found in these types of compounds and most notably the Mo—Mo distance is 0.08 Å shorter than the W—W distance. The M—O and M—N distances are, however, equivalent in all three compounds when the 3σ criteria is applied. This is noteworthy since we see here both *anti* and *gauche* forms of $M_2(OCPh_3)_2(NMe_2)_4$ and the *anti* form of $W_2(OSiPh_3)_2(NMe_2)_4$. Structurally there is very little difference in the bonding in these compounds. The M—O distances are longer than those typically seen in $M_2(OR)_6$ compounds, where R = alkyl, which fall in a very narrow range 1.88(1) Å.[8] Moreover, the M—N distances observed in these compounds are all shorter than those seen in $M_2(NMe_2)_6$ compounds, where M—N = 1.98(1) Å.[9] Thus, the M—O/M—N distances are reflecting the π-bond order of the ligands $Me_2N > OCPh_3$ and $SiPh_3$. Of the M—N distances determined in this study it is also worth noting that those in $W_2(OSiPh_3)_2$

† As with PR_3 ligands this π-bonding can involve Si—C σ^* orbitals.

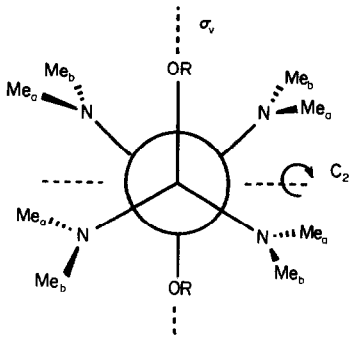
$(NMe_2)_4$ are the shortest, 1.935(8) Å (ave), which is consistent with the view that the Ph_3SiO ligand is the weakest π-donor as a result of competitive oxygen-to-silicon π-bonding.†

Solution ^{1}H *NMR studies*

As with many other compounds of the general formula 1,2-$X_2M_2(NMe_2)_4$ they exist in equilibria involving *anti* and *gauche* rotamers in solution.[8] Since the M—M π-bonding uses metal d_{xy} and d_{yz} atomic orbitals, the Me_2N ligands are required to π-donate to metal $d_{x^2-y^2}$ and d_{xy} orbitals. This requires that the NC_2 blades of the Me_2N ligands lie along the M—M axis (as found in the X-ray structures). In the low temperature limiting spectrum we observe four N*Me* resonances for the *gauche* rotamer and two for the *anti* as indicated below.

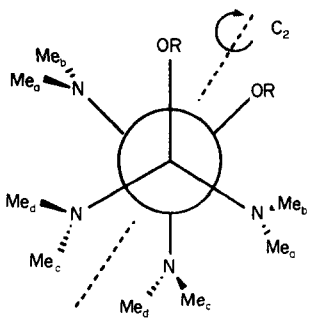
The diamagnetic anisotropy of the M≡≡M bonds[9] leads to a *ca* 2 ppm separation in distal and proximal NMe resonances. On raising the temperature proximal and distal exchange occurs by M—N bond rotation and this leads to coalescence behaviour at higher temperatures. The barriers to M—N bond rotation are influenced by both steric and electronic factors.

Data pertaining to *anti* and *gauche* equilibrium concentrations and M—N rotational barriers are summarized in Table 4. Despite the greater steric pressure at the metal centre that results from $OCPh_3$ relative to $OSiPh_3$ ligands, we see higher barriers to M—N bond rotation for the siloxide. This further



Anti configuration

At low temperature two types of dimethylamide resonances, one at high temperature.



Gauche configuration

At low temperature four resonances, two at high temperature.

[a] Calculated from

$$K_{ex} = \frac{\pi \Delta v}{2}, \quad \Delta G^{\dagger} = -\ln\left[\frac{K_{ex}h}{KT_c}\right]RT_c.$$

supports the view that Me_2N-to-M π-bonding is stronger in the siloxide derivative than in compounds **I**.

The compounds $M_2(OSiPh_3)_4(NMe_2)_2$ also exist in solution as a mixture of *anti* and *gauche* rotamers, *ca* 60:40, but each has only one NMe_2 ligand. The T_c values fall in the range 30–55°C and 100–115°C. The latter are somewhat higher than the highest value for the $W_2(OSiPh_3)_2(NMe_2)_4$, consistent with the view that replacement of a Me_2N ligand by a $OSiPh_3$ ligand enhances Me_2N-to-M π-bonding in the remaining M-NMe_2 group.

Concluding remarks

The addition of the sterically demanding Ph_3COH and Ph_3SiOH to $M_2(NMe_2)_6$ compounds leads to only partial replacement of the NMe_2 ligands. The compounds $M_2(OEPh_3)_2(NMe_2)_4$, where E = C and Si and M = Mo and W, exist in *anti* and *gauche* rotamers of the now familiar ethane-like 1,2-$M_2X_2Y_4$ compounds (M≡M). The M—N distances are shorter than those in the parent $M_2(NMe_2)_6$ compounds and the M—N rotational barriers are higher supporting the view that the π-bonding order of the ligands is $Me_2N > Ph_3CO > Ph_3SiO$.

EXPERIMENTAL

All reactions were carried out under an inert atmosphere using standard Schlenk techniques. Solvents were distilled under nitrogen prior to use from sodium/benzophenone. Proton NMR spectra were measured on a Varian 300 XL spectrometer operating at 299.66 MHz in d^6-benzene or d^8-toluene and referenced to residual protio impurity at 7.15 and 2.07 ppm, respectively. IR spectra were obtained as pressed KBr pellets on a Perkin–Elmer 283 spectrophotometer. Microanalysis were provided by Oneida Research Services, Whiteboro, New York. $M_2(NMe_2)_6$ compounds were prepared as described previously[9] from WCl_4 or $MoCl_3$ with $LiNMe_2$ and the product was sublimed prior to use. Triphenylmethanol and triphenylsilanol were purchased from Aldrich Chemical Co. and were used as supplied.

The same general procedure and reaction scale was adopted for reactions involving both molybdenum and tungsten as outlined below.

$Mo_2(OCPh_3)_2(NMe_2)_4$

To $Mo_2(NMe_2)_6$ (0.200 g, 0.44 mmol) dissolved in hexane (10 cm^3) at room temperature was added dropwise with stirring over 5 min triphenylcarbinol (0.500 g, 2.0 mmol) in THF/hexane (5/5 cm^3) to generate a green solution. The solution was allowed to stand at room temperature for 2 h then placed in the freezer at −20°C for 3 days. Large yellow crystals of $Mo_2(OCPh_3)_2(NMe_2)_4$ were collected from the solution by removal of solvent via cannula and washing with hexane (5 cm^3) and diethylether (5 cm^3). Obtained $Mo_2(OCPh_3)_2(NMe_2)_4$ (0.380 g, 42.8 mmol, 97%). Found: C, 62.8; H, 6.4; N, 6.1. Calc.: C, 62.3; H, 6.1; N, 6.3%.

IR (cm^{-1}): 3050m, 3020m, 3010m, 2960w, 2940w, 2845s, 2800s, 2760s, 1940w, 1870w, 1790w, 1690w, 1480s, 1440vs, 1420s, 1410s, 1390w, 1310w, 1275w, 1235s, 1195m, 1170m, 1140m, 1100w, 1070m, 1040vs, 1020vs, 950vs, 930vs, 910s, 895s, 840w, 780vs, 760vs, 750vs, 720w, 690vs, 650m, 625s, 550s, 525w, 500w, 480s, 350s. Dec. p. = 162°C.

^{1}H NMR (benzene, 25°C): δ = 7.82 (d, 8H), 7.45 (d, 4H), 7.10 (m, 18H), 4.08 (s, H), 3.6 (br, 8H), 2.4 (br, 8H), 1.82 (4, 4H).

$W_2(OCPh_3)_2(NMe_2)_4$ (0.300 g, 0.283 mmol, 92%). Found: C, 52.9; H, 5.3; N, 4.0. Calc. for residual W_2N: C, 52.8; H, 5.1; N, 4.0%.

^{1}H NMR (benzene, 25°C): δ = 7.85 (d, 8H), 7.56 (d, 8H), 7.10 (m, 14H), 4.15 (s, 3H), 3.65 (s, 9H), 2.5 (s, 9H), 1.84 (s, 3H).

IR (cm^{-1}): 3070m, 3050m, 3020m, 3010m, 2970m, 2950m, 2855vs, 2810vs, 2780vs, 1940w, 1805w, 1795w, 1595m, 1575w, 1492vs, 1440vs, 1420s, 1390m, 1375w, 1310w, 1275w, 1260m, 1243s, 1200m, 1180m, 1160sh, 1155sh, 1150vs, 1110w, 1085s, 1078s, 1045vs, 1025vs, 998s, 955vs, 940vs, 915s, 900s, 865m, 840w, 790vs, 760vs, 750s, 725w,

700vs, 660m, 635s, 630s, 615m, 550m, 530m, 495m, 483s, 345s, 305m, 280w.

$W_2(OSiPh_3)_2(NMe_2)_4$

To $W_2(NMe_2)_6$ (0.500 g, 0.80 mmol) dissolved in hexane (10 cm^3) at 65°C was added $HOSiPh_3$ (0.401 g, 1.45 mmol) in hexane 5 cm^3/ether (5 cm^3)/toluene (1 cm^3). The solution was allowed to cool to room temperature. Five minutes after addition yellow crystals started to form. The solution was left to stand overnight and the filtrate was removed by decanting to leave $W_2(OSiPh_3)_2(NMe_2)_4$ (0.600 g, 0.55 mmol, yield = 68%).

IR (KBr pellet) (cm^{-1}): 3040m, 3020m, 2950m, 2885m, 2840m, 1950w, 1890w, 1810w, 1584s, 1500w, 1470m, 1400m, 1370w, 1340w, 1240s, 1185m, 1140m, 1100s, 910s, 960s, 890m, 800m, 730s, 690s, 540sh, 490vs, 420m, 370w, 350m, 330s, 300m, 286w.

^1H NMR in C_6D_6 at 25°C: δ = 7.8 (m, 12H), 7.1 (m, 12H), 6.8 (m, 6H), 4.1 (s, 3H), 3.9 (s, 6H), 3.15 (s, br, 6H), 2.5 (s, 6H), 2.2 (s, 3H).

V. T. NMR in $C_6D_5CD_3$: T_c-*anti*, 60°C, Δ = 437 Hz, $\Delta G^{\dagger}$ = 62.7 kJ mol^{-1}. T_c-*gauche*, 40°C, Δ = 510 Hz, $\Delta G^{\dagger}$ = 55.5 kJ mol^{-1}. T_c-*gauche*, 95°C, Δ = 325 Hz, $\Delta G^{\dagger}$ = 69.1 kJ mol^{-1}.

$W_2(O^tBu)_2(OSiPh_3)_4$

To $W_2(O^tBu)_6$ (0.250 g, 0.31 mmol) dissolved in hexane (10 cm^3) at room temperature was added triphenylsilanol (0.520 g, 1.88 mmol) in hexane (10 cm^3)/ether (15 cm^3) to generate a dark red–brown solution. The solution was allowed to stand at room temperature for 6 h and then cooled to −20°C for 12 h to produce orange–brown crystals. The filtrate was removed and the solid washed with hexane (10 cm^3) and ether (10 cm^3) to yield $W_2(O^tBu)_2(OSiPh_3)_4$ (0.420 g, 0.269 mmol, yield = 87%). Found: C, 59.4; H, 5.2; N, 0.0. Calc.: C, 59.5; H, 4.8; N, 0.0%. Dec. p. = 132–6°C.

^1H NMR in C_6D_6 at 25°C: δ = 7.63 (d, 24H), 7.13 (t, 12H), 6.97 (t, 24H), 1.40 (s, 18H).

$M_2(OSiPh_3)_4(NMe_2)_2$ (M = Mo, W)

The same general scale and procedure was used for both the molybdenum and tungsten compounds illustrated below for molybdenum.

To $Mo_2(NMe_2)_6$ (0.250 g, 0.55 mmol) dissolved in hexane (15 cm^3) at 65°C was added triphenylsilanol (0.600 g, 2.20 mmol) in diethylether (10 cm^3)/hexane (10 cm^3)/toluene (10 cm^3). This caused an immediate darkening of the solution to a red–brown. The solution was allowed to cool to room temperature overnight, with light orange "rosette" crystals starting to precipitate after 25 min. The filtrate was removed and the crystals washed with hexane (10 cm^3) and diethylether (10 cm^3) and dried briefly *in vacuo* for 10 min. Obtained $Mo_2(OSiPh_3)_4(NMe_2)_2$ (0.724 g, 0.52 mmol, yield = 95%). Found: C, 63.9; H, 5.2; N, 2.0. Calc.: C, 64.3; H, 5.2; N, 2.1%. Dec. p. = 165°C.

IR (cm^{-1}) = 3020s, 2950s, 2900m, 2880s, 2840s, 1940w, 1880w, 1810w, 1580m, 1555w, 1545w, 1470m, 1425vs, 1370m, 1320w, 1295w, 1250s, 1175m, 1145w, 1100vs, 1015, 990s, 920vs, 820sh, 730s, 695vs, 640sh, 505vs, 445m, 410m, 300m.

^1H NMR in C_6D_6 at 25°C: δ = 7.80 (m, 24H), 7.16 (m, 12H), 7.07 (m, 24H), 4.8 (br, 3H), 4.2 (br, 3H), 2.1 (br, 3H), 1.8 (br, 3H).

For $W_2(OSiPh_3)_4(NMe_2)_2$: obtained: 0.575 g, 0.37 mmol, yield = 94% as orange rosettes. Dec. p. = 160°C.

IR (KBr disc) (cm^{-1}) = 3050w, 3020s, 2950s, 2900m, 2880s, 2840s, 1940w, 1880w, 1810w, 1760w, 1580m, 1555w, 1545w, 1476m, 1425vs, 1370m, 1320w, 1295w, 1250s, 1175m, 1145w, 1100vs, 1015s, 990s, 920vs, 820sh, 730s, 695vs, 640sh, 505vs, 435m, 410m, 300m.

^1H NMR in C_6D_6 at 24°C: δ = 7.75 (m, 24H), 6.95 (m, 12H), 6.75 (m, 24H), 3.82 (s, 4H), 2.0 (s, 4H), 1.6 (s, 4H).

Structural determinations

General procedures and a listing of programs used have been reported.[10] Crystal data are summarized in Table 3.

$W_2(OCPh_3)_2(NMe_2)_4$. A suitable small single crystal was selected from the bulk sample using inert-atmosphere handling techniques. The crystal was transferred to the goniostat where it was cooled to −169°C for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space yielded a set of reflections which exhibited orthorhombic symmetry. Unit cell dimensions were determined using 60 unique reflections having two θ values between 12 and 25°. The systematic extinctions of $0kl$ for $k = 2n+l$, of $h0l$ for $h+l = 2n+1$ and of $hk0$ for $h = 2n+1$ identified the space group as *Pbna* [an alternative setting of *Pbcn* (No. 60)]. It should be mentioned that the space group assignment was complicated by the pseudo carbon-centring of the data, all reflections having $h+k = 2n+1$ were quite weak due to the location of the heavy atoms on either side of the two-fold axis. A total of 5196 reflections (including standards and space group extinctions) were col-

lected in the given range. Following the usual data reduction and averaging of equivalent reflections a unique set of 1596 reflections was obtained. 1804 reflections were considered observed by the criterion $F > 3.0\sigma(F)$. A correction for absorption was performed. The R for the averaging was 0.03 for 1586 reflections, measured more than once. A plot of the four standard reflections measured every 400 reflections shows no systematic trends.

The structure was solved after some initial difficulty caused by the pseudo-symmetry. The heavy atom was eventually located by means of a Patterson function as well as by direct methods. The remaining non-hydrogen atoms were located in successive difference maps. Following the initial refinement almost all of the hydrogen atoms were evident in a difference map. The full-matrix least-squares refinement was completed using anisotropic thermal parameters on all non-hydrogen atoms. The hydrogen atoms were introduced in fixed idealized positions using isotropic thermal parameters of 1.0 plus the isotropic equivalent of the parent atom. The final R was 0.044 and $R_w(F)$ was 0.041, using all of the unique data. The total number of variables was 245 giving a ratio of observations to parameters of 10.97.

The final difference map was essentially featureless, the largest peak was about 2 e $Å^{-3}$, in the immediate vicinity of the tungsten atom.

$Mo_2(OCPh_3)_2(NMe_2)_4$. A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques and cooled to $-171°C$ for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/n$. Subsequent solution and refinement of the structure confirmed this choice.

Data were collected using a continuous θ–2θ scan with fixed backgrounds and data were reduced to a unique set of intensities and associated sigmas. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. A difference Fourier synthesis revealed the location of some, but not all, hydrogen atoms. All hydrogen atom positions were therefore calculated using idealized geometries and d(C—H) = 0.95 Å. These calculated positions were fixed for the final cycles of refinement.

A final difference Fourier was featureless, with the largest peak being 0.74 e Å.

$W_2(OSiPh_3)_2(NMe_2)_4$. A crystal of suitable size was mounted using silicon grease and was transferred to a goniostat where it was cooled to $-126°C$ for characterization and data collection. A systematic search of a limited hemisphere of reciprocal space revealed symmetry and systematic absences corresponding to the monoclinic space group $P2_1/n$.

The structure was solved by a usual combination of direct methods (MULTAN78) and Fourier techniques. The tungsten atom position was obtained from an initial E-Map, and the remainder of the non-hydrogen atoms were found in subsequent iterations of least-squares refinement and difference Fourier calculations. After partial refinement of the non-hydrogen atoms, a difference Fourier revealed all hydrogen atoms. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms isotropically to an R-factor equal to 2.5%.

Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

COMMUNICATION

ON THE TRIS((*R*)CYSTEINATE)COBALT(III) AND TRIS((*R*)CYSTEINESULPHINATE)COBALT(III) IONS: A FINALE

A. P. ARNOLD and W. G. JACKSON*

Contribution from the Department of Chemistry, University College (NSW), Australian Defence Force Academy, Northcott Drive, Campbell, ACT 2600, Australia

(*Received* 21 *August* 1991; *accepted* 2 *September* 1991)

Abstract—Responses are offered to a recent critical communication by R. D. Gillard (*Polyhedron* 1991, **10**, 1453) which defend our positions (A. P. Arnold and W. G. Jackson, *Inorg. Chem.* 1990, **29**, 3618) with respect to the stereospecificity in the synthesis of the title complexes.

A paper by Arnold and Jackson published in *Inorganic Chemistry* in 1990,[1] concerning the ions tris(cysteinato)- and tris(cysteinesulphinato) cobalt(III), was the subject of criticism in a communication published very recently in this journal.[2] We prefer not to comment on its tone. Those who have closely read both papers will have assessed the scientific facts for themselves. However, this note serves to clarify some confusion created about our work by Gillard's note, and is directed in particular to those who have read Gillard's communication but not ours.

Our paper[1] addressed the question of specificity in the synthesis of tris(cysteinato)- and tris(cysteinesulphinato)-cobalt(III), while Gillard's note[2] stressed the reliability of the latter complex as a resolving agent when made by a particular method (but asserting that we implied otherwise). He went on to defend earlier claims[3–6] that the tris((*R*)cysteinesulphinate-N,S)cobalt(III) ion could be synthesized by a reliable and stereospecific synthesis.

To summarize the facts: the chiral anion $[Co((R)cysSO_2\text{-}N,S)_3]^{3-}$ can be synthesized in two steps from cobalt(II) or (III) starting materials. The Δ and Λ forms of $[Co((R)cysS\text{-}N,S)_3]^{3-}$ are produced in the first step with a degree of stereoselectivity which depends upon the method of synthesis.[1] Both of these diastereomers are oxidized by H_2O_2 to $[Co((R)cysSO_2\text{-}N,S)_3]^{3-}$, and we demonstrated that this step was stereospecific,[7] as expected.[1]

We consider general points first, and there are two fundamental ones. First, if a substance exists in two isomeric forms and a particular synthesis carried out in solution gives much less than a quantitative yield of a solid complex believed to be a single isomer, it is reasonable to enquire if the other isomer is left in solution. It is not correct to claim that such a synthesis is stereospecific, even if the isolated solid were a single isomer (unless, for all of the material of that particular composition, it was isolated quantitatively). Gillard[2] has defended earlier criticism[1] by stating that he was referring to the isolated solid, but the term to describe such an isolated solid is "pure" or "isomerically pure", not as a solid obtained "stereospecifically". The terms "stereoselective" and "stereospecific", despite differences in inorganic and organic[7] parlance, refer to total product.

The second point is that one cannot know with certainty an isomer distribution, or even establish isomeric purity, if only one of the two isomers has been characterized. For a technique such as NMR spectroscopy, two sets of signals for a product may be diagnostic of composition whereas the observation of one set remains ambiguous. The degree of ambiguity of course depends upon the level of spectroscopic resolution. In summary, where one

* Author to whom correspondence should be addressed.

has characterized just the one isomer, evidence of isomeric composition can only be circumstantial.

Gillard *et al.*,[2-5] and others before them,[8-11] had reported only the one stereoisomer, although there has been recognition that both might have been obtained (by a kinetic route, for example). We, however, have isolated both as pure crystalline solids, for each of the tris(cysteine)- and tris(cysteinesulphinate)-complexes, and despite expressed or implied views to the contrary,[2] this is a significant advance.

Gillard has emphasized the reliability of his synthesis of Schubert's[8] resolving agent. We have never contested this. But there are several synthetic methods,[1,8] not just theirs,[4,5] and we showed that you can and do get isomeric mixtures, depending upon the route you choose.[1] Mindful of this fact, we tested the recrystallization process used by Gillard and others and showed that it does lead to an isomerically pure product. In this regard Gillard takes issue with our use of the word "repeated", in respect of a simple recrystallization. In reference to the $[Co((R)cysSO_2\text{-}N,S)_3]^{3-}$ anion, Gillard stated[2] he always used the Δ form, whereas we[1] used the Δ, the Λ, and a Λ/Δ isomer mixture, and therefore technically we only repeated his work when using the Δ isomer! Actually we may well have repeated his work in the strictest sense since, as already noted, his crude material could have been a mixture; this could never have been known since no one had previously reported that fractionation (or recrystallization) from water/ethanol removes the other isomer.

We feel obliged to respond to his more specific criticisms:[2]

(1) Gillard refers in three places to our "ignorance" of his "extensive reported work". But of course the fact that we did not reference all his work does not mean we were ignorant of it.

(2) In the last paragraph of his communication,[2] he again alludes to our apparent ignorance of the literature, noting our "failure ... to acknowledge relevant, prior work". In particular, he cites a structural paper of a cobalt(III) trinuclear species which contains the tris((*R*)cysteinato)cobalt(III) anion as a ligand,[12] and goes on to say that "... they too" (Okamoto *et al.*) "had gone over the question of the stereoselectivity of the formation of green Δ_{LLL}-*fac*(*S*)-$[Co(L\text{-}cys\text{-}N,S)_3]^{3-}$ but were able to agree in full with our earlier work". We believe that this is misrepresentation of their paper. Okamoto *et al.*[12] discussed the evidence for stereoselectivity of formation for each of two trinuclear species, not that for their precursor. In regard to the latter, Okamoto *et al.*[12] merely noted that the tris(cysteinate)cobalt(III) complex was prepared by the method of Schubert,[8] and stated in two places but without experimental evidence that the Δ_{LLL} isomer was formed selectively (with references to Kita *et al.*[13] and Gillard[3]!).

(3) We suggested[1] that it might be desirable to recrystallize the resolving agent and check its isomeric purity before using it. However, Gillard[2] states that "all that is required is to follow the published directions properly". He fails to accept that there are numerous others routes[1,8] to its synthesis which one might use, and we showed[1] that these can (and often do) give isomeric mixtures. We didn't use his particular method[4,5] (starting from $[Co(NH_3)_6]^{3+}$), and he acknowledged that,[2] and if there were an inference that his method might also give a mixture, it is of no consequence; Gillard *et al.* use recrystallized material,[4,5] and *we showed* (through the characterization of both isomers) that recrystallization as described[4,5] removes any of the other isomeric form.

(4) Gillard[2] singles out a host of remarks from our[1] paper, and deals with these in turn as (i)–(v) on the second page of his communication. With respect to his (i), the "sic" annotation to a quotation from our work is inappropriate. It is true that the ^{13}C NMR spectrum had not been published (prior to our[1] work), although spectral data[5,14] had appeared. Further, Gillard draws attention to a trivial typographical error in our paper, intimating that a temperature difference of 7° as regards chemical shifts might be important; it is our experience that the shift differences between our two isomers were such that temperature could have no possible bearing on the issue; in any event, the spectra of the two isomers were measured at the *same* temperature.

Gillard[2] quotes two sets of chemical shift values he published[5,14] for his complex, stating that they "agree well" with our data. They do not even agree well with each other, let alone our data. Indeed the two sets of values span the shift differences between the authentic two isomers we obtained.[1] From these data, one could even be led to believe that Gillard *et al.* inadvertently obtained the two isomers we described, although we do not think so.

(5) The comments under his (iv)[2] disguise the full truth. We are attributed to having obtained two isomers for the green tris((*R*)cysteinate-N,S) complex *in solution*; the italics are Gillard's.[2] We did,[1] but it is also very clear from our paper that we actually isolated and characterized these as pure solids, and went to some pains to prove this.

(6) Again under (iv), Gillard seems to be equating equilibrium isomer distributions in solution with the isomer or isomers one might crystallize from

solution. They may not be related. We showed[1] one can get a second-order asymmetric transformation in this system, so it is *not* "rather odd[ly]" that we should suggest checking the isolated material for isomeric purity knowing that the equilibrium strongly favours one isomer, but rather for very good reason.

(7) The next paragraph makes a number of statements out of context which convey a very imbalanced account. He suggests[2] there is complete overlap in his and our work, in stating "Jackson and Arnold have confirmed the following facts...". In the light of the present and previous[1] notes, "established" would be a better word than "confirmed". Furthermore, he dismisses the "new facts" about the green compound in a sentence, and totally ignores the new facts about the yellow tris ((*R*)cysteinesulphinate-N,S) compounds, one a new isomer.

Finally, the last paragraph of his note[2] refers to a matter totally unrelated to the cysteine problem, and is clearly directed at discrediting one of us. The readers of the papers[15,16] can make up their own minds, but Gillard's reference to "criticisms and misquotation[7] by Jackson" (ref. 7 is the present ref. 15) again misrepresents a situation. In politest terms, we are unaware of the "misquotation" to which Gillard refers;[2] if there was one,[15,16] it was not by one of us.

ISOLATION AND CHARACTERIZATION OF A NOVEL MULTIBRIDGED TETRADENTATE DIANIONIC FORM OF PYRIDOXIC ACID. CRYSTAL STRUCTURE OF TETRANUCLEAR $[Cu_4(PAA)_2(Bipyam)_4(H_2O)_2Cl_2](NO_3)_2 \cdot CH_3OH \cdot 10H_2O$*

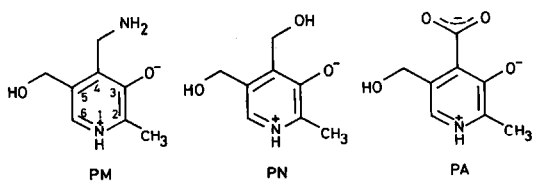
IRIMPAN I. MATHEWS and HATTIKUDUR MANOHAR†

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-560 012, India

(*Received* 19 *July* 1991; *accepted* 27 *August* 1991)

Abstract—The X-ray analysis of the tetranuclear copper(II) complex formed from pyridoxic acid and 2,2′-dipyridylamine reveals a novel metal binding mode of pyridoxic acid as a multibridged tetradentate dianion. Here the pyridoxic acid moiety uses all possible sites except the pyridine nitrogen for metal coordination.

Metal complexes of B_6 vitamins and the Schiff bases derived from them have been an interesting area of study for the bioinorganic chemist.[1] Much research has been concerned with the ligating sites in these compounds. The most common binding sites are phenolic oxygen and the 4-(aminomethyl), 4-(hydroxymethyl) or the 4(-carboxyl) groups of pyridoxamine (PM), pyridoxine (PN) and pyridoxic acid (PA), respectively (Sketch).[2–4] Binding of the metal at other sites like the pyridine nitrogen or the side chain at the 5-position is rare.[3,5] The Vitamin B_6 moiety usually functions as a bidentate and rarely as a tridentate monoanion. The various monoanionic forms, characterized crystallographically, have been discussed in detail recently.[4] Pyridoxic acid is one of the oxidation products of pyridoxal which is an active form of Vitamin B_6. A novel oxidation of pyridoxal to pyridoxic acid was reported earlier from this laboratory during attempts to prepare ternary Schiff base metal complexes with 2,2′-bipyridine as the ternary ligand.[2] The title compound was isolated during studies on the oxidation reaction in metal complexes varying the ternary ligand. The X-ray structure of the complex reveals a novel mode of binding for pyridoxic acid as a multibridged tetradentate dianion where all potential sites except the pyridine nitrogen are used for coordination.



The complex was prepared by treating pyridoxal·HCl with 0.1 N NaOH until the pH reached a value of ~4.1. An aqueous solution of $Cu(NO_3)_2 \cdot 3H_2O$ was then added and the pH raised to ~4.2. This was treated with an aqueous methanolic solution of bipyam and the solution kept aside for slow evaporation. Dark green crystals of the title compound appeared after 4 months.

* PA = pyridoxic acid, PAA = dianionic form of PA, bipyam = 2,2′-dipyridylamine.

† Author to whom correspondence should be addressed.

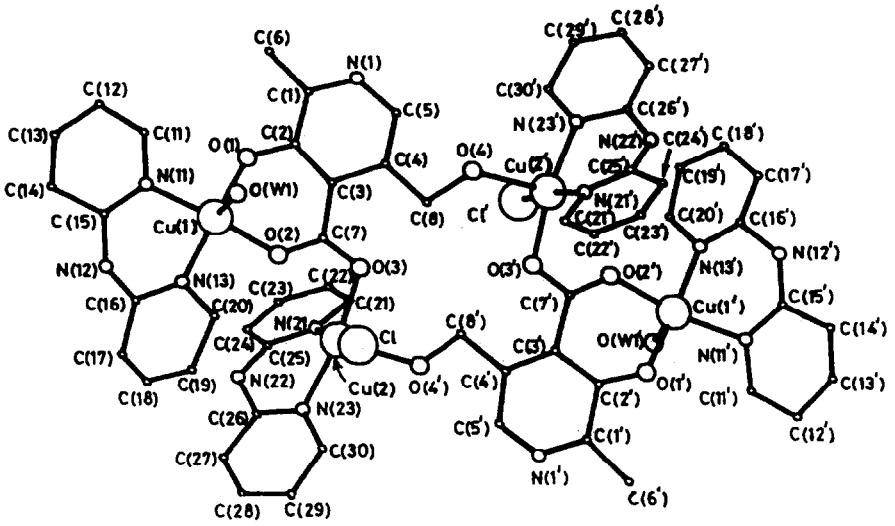


Fig. 1. Molecular structure of $[Cu_4(PAA)_2(Bipyam)_4(H_2O)_2Cl_2]$. Coordinating distances (Å): Cu—N (bipyam) 1.97(2)–2.05(2); Cu—O (carboxylate, phenolic) 1.90(2)–1.99(2); Cu—O(hydroxymethyl) 2.30(2), 2.34(2); Cu—Cl 2.26(1), 2.32(1); Cu—O(water) 2.29(2).

The X-ray structure,* Fig. 1, reveals that the compound is tetranuclear with four square pyramidally coordinated coppers, two PA moieties and four bipyam ligands. The coordinating atoms for Cu(1) and Cu(1′) and Cu(2) and Cu(2′) are similar. The basal sites for the first two are occupied by two bipyam nitrogens, one phenolic oxygen and one carboxylate oxygen. The axial position is filled by a water molecule. On the other hand, for the latter two the phenolic oxygen at the basal site is replaced by a Cl^- ion and a 5-hydroxymethyl oxygen of the pyridoxic acid occupies the axial position. The pyridoxic acid moiety bridges three coppers in both a monodentate and bidentate fashion. The 5-hydroxymethyl oxygen and phenolic oxygen are involved in monodentate coordination, whereas the carboxylate functions as a bridging bidentate. Pyridoxic acid exists as a dianion with carboxylate, phenolate and 5-hydroxymethyl groups deprotonated and the ring nitrogen protonated. The existance of Vitamin B_6 as a dianion and the deprotonation of the 5-hydroxymethyl group are unprecedented. It is interesting to note that the chelation of the metal ions by PAA moieties results in the formation of a 14-membered macrocyclic ring.

To our knowledge this is the first structural study of a tetranuclear complex involving Vitamin B_6 or its derivatives and also of a tetranuclear metal complex involving the chemically important bipyam ligand. Furthermore, this is the first structure of a Vitamin B_6 complex involving bipyam as a ternary ligand.

* *Crystal data*: $C_{57}H_{78}Cl_2N_{16}O_{27}Cu_4$, triclinic, space group $P\bar{1}$, $a = 13.825(6)$, $b = 14.034(6)$, $c = 19.231(5)$ Å, $\alpha = 92.23(3)$, $\beta = 98.89(5)$, $\gamma = 98.47(6)°$; $U = 3639$ Å^3, $Z = 2$, $M = 1743.1$, $D_c = 1.591$ g cm^{-3}, $F(000) = 1797$, μ(Mo-K_α) = 13.64 cm^{-1}, θ range 1.0–20.0° (reflections were very weak at high angles). Final R value 0.098 for 3168 out of 7212 reflections [$I > 2\sigma(I)$], collected on an Enraf–Nonius CAD4 diffractometer. The structure was solved by the heavy-atom method and refined by full-matrix least-squares procedure based on F.[6] Copper, nitrogen and oxygen atoms were refined anisotropically and the carbon atoms isotropically. Hydrogen atoms were located from the electron density maps and used without refinement. One of the nitrate groups showed disorder and was refined with constraints on bond parameters. The molecule shows a pseudo-centre of inversion, but an analysis of the Niggli matrix revealed no higher symmetry. Final atomic coordinates, thermal parameters, bond parameters and structure factor tables have been deposited with the Editor as Supplementary Material. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

BOOK REVIEW

Noble Gas and High Temperature Chemistry (Structure and Bonding 73). Edited by M. J. Clarke, J. D. Dunitz, J. B. Goodenough *et al.* Springer-Verlag, Berlin, 1990, ISBN 3-540-52124-0, 262 pp., DM 148.

The latest volume in this well-established series contains five reviews. Two of these are concerned with Noble Gas (Ng) chemistry, two with stellar elemental synthesis and the remaining one with the chemistry of inorganic vapours. Normally, on realising that the same person was involved in three of the reviews, my reaction would be of scepticism; however, since that author happens to be C. K. Jørgensen, one anticipates a certain panache, and his participation in two pieces on nuclear synthesis in the Big Bang, supernovae, etc. may well be termed a star turn.

A brief first chapter (15 pages) by C. K. Jørgensen and G. Frenking reviewing the history of the discovery of the Noble Gases and their compounds is full of interesting points; with follow-up of initial observations, the Fraunhofer lines might today remember W. H. Wollaston (who discovered palladium and rhodium). Similarly, comments "chemists can never know what may happen tomorrow" and questions—why should an element have only one electronegativity? The review of preparative Ng chemistry beginning with the complicated Xe/PtF_6 reaction "Inorganic chemistry is sometimes too complicated to be easily rationalized by beautiful, but less complicated, ideas" (Reader, what first interested *you* in Inorganic Chemistry?) continues by pointing out that ozone should oxidize xenon at pH 14–15 on thermodynamic grounds, as well as the similarity of isoelectronic Xe^{II} and I^{I}, Xe^{IV} and I^{III}, Xe^{VI} and I^{V} and Xe^{VIII} and I^{VII} couples. Other plausible species include ArO_4 and oxo anions of Kr^{VI} and ^{VIII}, as well as $Xe(CN)_2$.

The second chapter (by G. Frenking and D. Cremer) examines at more length (nearly 80 pages) the chemistry of the more noble Ngs (He, Ne and Ar) of which the authors remark that the common chemical thinking is that they "should be left to physicists and engineers to do work on superconductors and to prepare light bulbs", pointing out that gas-phase species involving these elements have a respectable pedigree (1925 in the case of HeH^+).

The article goes on to look at the role of theoretical predictions in guiding experimentalists, particularly *ab initio* calculations. Species examined include known ones like Ng_2^+ and NgH^+ and polyatomics like $ArCO^+$ (it is pointed out that argon should resemble krypton in its chemistry rather than neon); the scheme used is the donor–acceptor model. A table of predicted stable or metastable species includes neutral NgBeO molecules as well as a range of ions such as $NgCCH^+$ and Ng_2C^{2+}. (Is it not time for a book "Non-existent compounds 30 years on"?)

K. Hilpert's article "Chemistry of inorganic vapours" is a very thorough hundred page survey of the area. It looks mainly at the species present in equilibrium vapours and their dissociation or atomization energies. These results were mainly obtained by Knudsen cells linked to MS, and the methodology is reviewed. Particular developments over the last decade include the identification of complex Zintl compounds, detailed studies of some metal oxides like Li_2O, and various metal halides. It is interesting to note how these gas phase studies can complement solid-state research—i.e. results indicating essentially ionic character in RbAu and CsAu in contrast to LiAu and NaAu; similarly, gas-phase FeI_3 was identified long before the recent successful isolation of the compound in the solid state. Not the least useful feature of the article is the collection of thermodynamic data.

Jørgensen looks at the synthesis of heavy elements in peculiar A-type (A_p) stars. He points out that the vast majority of chemical elements are synthesized in the collapsing core of supernovae; A_p stars have peculiarly high abundances of certain elements, europium for example; others appear to be high in mercury. Various ideas based on neutron irradiation followed by various types of accretion or diffusion have been suggested as explanations. Some A_p stars may have originated in multiple-star systems along with a progenitor that exploded as a supernova.

In the final article, Jørgensen and G. B. Kauffman examine ideas of nuclear synthesis based on high-temperature polymerization of hydrogen (Crookes, 1887) and deviations from mass additivity (Marignac, 1860; Harkins and Wilson, 1915). We are taken through the types of elementary particles, quarks and all, not to mention Dark Matter and WIMPS, together with the possibility of fractionally charged systems. More conventionally, we are given comparative abundances of elements in the solar photosphere and in the earth's crust. We are left to speculate on the intuitive processes of a scientist like Crookes, not to mention universes made up of anti-elements, where presumably antibonding orbitals are desirable.

Thoroughly recommended, but I fear that not enough university libraries in the U.K. are able to afford a standing order to this series, relatively inexpensive though it is.

ANNOUNCEMENT

MOLECULAR ELECTROCHEMISTRY OF INORGANIC, BIOINORGANIC AND ORGANOMETALLIC COMPOUNDS

Sintra, close to Lisbon, Portugal
25–29 March 1992

Contact: Prof. A. J. L. Pombeiro,
Complexo I, Instituto Superior Técnico,
Av. Rovisco Pais, 1096 Lisbon Codex, Portugal.
Fax: 351-1-3524372. Tel: 351-1-3524303.

Organizing Committee: Profs A. J. L. Pombeiro (Director),
J. McCleverty (Director),
J.-M. Savéant and K. M. Kadish.

General Objective

Assessment of the state-of-the-art in the application of electrochemistry to the investigation of the properties (including synthesis and reactivity) of inorganic, bioinorganic and organometallic complexes, discussion of prospects and formulation of recommendations.

cobalt triphosphine triphosphorus mercury complex, 2477
cobalt(-I) carbonyl phosphine indium complex, 2533
cobalt(II) alkyl chloride diamine complexes, 931
cobalt(II) amine carboxylate water complex, 2873
cobalt(II) chloride pyridine-*N*-oxide water complex, 2315
cobalt(III) amide amine nitrite thioether complexes, 1079
cobalt(III) nitrite valinate complex, 2149
copper(I) amine bromide tripod Schiff base complex, 2463
copper(I) amine Schiff base complex, 739
copper(I) arsine nitrile phosphine thioether binuclear macrocyclic complexes, 2919
copper(I) bromide phosphine thione complex, 981
copper(I) diphosphine tetraimine binuclear complex, 2603
copper(I) iodide osmium complexes, 75
copper(I) phosphine thione complex, 2833
copper(I) thioether binuclear macrocyclic complexes, 2911
copper(I) thiolate complexes, 1155,1659
copper(II) acetate alkoxide amine pyridine binucleating complexes, 2867
copper(II) amide amine azide bromide thioether complexes, 2375
copper(II) aminoalkoxides, 611
copper(II) aminoethoxide thiocyanate, 535
copper(II) azide dipyridylamine complex, 2693
copper(II) carboxylate carboxylic acid complex, 1667
copper(II) cyanate diamine complex, 2937
copper(II) diketonate pyridine complex, 2061
copper(II) imidazole Schiff base complex, 2981
copper(II) pyridine thiocyanate complex, 1029
cycloarsane, 319
diacetylferrocene hydrazone, 2751
europium acetate hexamine macrocyclic complex, 1411
europium azole diketonate complex, 751
gallium(I),(III) arene chloride complex, 283
gallium(III) alkyl amine complexes, 343
gallium(III) alkyl cyclopentadienyl ether iodide pyridine heterobinuclear complexes, 2763
gallium(III) alkyl phosphine complexes, 335
gold dithiolate complex, 1561
gold(III) chloride complex, 2199
indium alkoxide oxide, 719
indium chloride phosphine cobalt complex, 2533
indium chloride phospholyl complex, 329
indium(III) chloride porphyrin, 1297
iridium(I) alkyne phosphine complex, 1867
iridium(I) diene phenol phenoxide complex, 969
iridium(II,III) alkenediyl carbonyl diphosphine isocyanide phenyl complex, 2635
iridium((III) alkyl cyclopentadienyl phosphine thiolate cyclometallated complexes, 1883
iron carbonyl cyclopentadienyl gallium complex, 2763
iron carbonyl vinylidene complexes, 1809
iron(-II) carbonyl germanium complex, 1127
iron(0) carbonyl chloride phosphine phosphite silyl complexes, 1337
iron(II) amine thioether macrocyclic complex, 2641
iron(II) azole thiocyanate complex, 2971
iron(II) carbonyl cyclopentadienyl germyl complexes, 773
iron(III) chloride diphosphine complex, 2139
iron(III) chloride phosphine oxide complex, 1695
magnesium chloride pyrazolylborate, 1775
magnesium ether silylamide complex, 2959
magnesium pyrazolylborate siloxide, 2655
manganese(II) acetonitrile phenoxide complex, 1311
manganese(II) dipyridylamide complex, 2699
manganese(II) ether silylamide complex, 2959

mercury amine thioether macrocyclic complex, 2931
mercury bromide telluroether complex, 2041
mercury methylhydantoin complex, 1765
molybdenum alkoxycarbene alkylidyne cycloheptatrienyl methylene tungsten complex, 2953
molybdenum carbonyl cyclopentadienyl gallium compound, 2763
molybdenum dithiolate pyrazolylborate thiocyanate complex, 2965
molybdenum(0) carbonyl diphosphine complexes, 2393
molybdenum(0) carbonyl phosphine complex, 2901
molybdenum(II) bromide pyridine complex, 1209
molybdenum(II) carbonyl cyclopentadienyl phosphido complex, 2901
molybdenum(III) alkoxide alkylamide, 1821
molybdenum(III) alkoxide selenophenoxides, 2941
molybdenum(III) carbonyl cyclopentadienyl oxo phosphido complex, 2469
molybdenum(IV) chloride hydrazide phosphine triphosphine complexes, 545
molybdenum(IV) thio water complex, 1671
molybdenum(VI) nitrilotriacetate oxo polyalkoxide triethanol-amine complexes, 1541
neodymium acetate hexamine macrocyclic complex, 1411
nickel dithiolate complex, 2053
nickel(0) diphosphine isocyanide platinum(II) complex, 2651
nickel(II) aminoethanol thiocyanate complex, 535
nickel(II) diphosphine iodide isocyanide complex, 1487
nickel(II) dithiocarbamate macrocyclic tetramine complex, 1729
nickel(II) dithiophosphinate, 2597
nickel(II) phosphine xanthate complex, 1341
niobium(III) phosphine thio thiolate complexes, 1689
niobium(V) chloride phenoxide cyclometallated complex, 1051
osmium alkylidene carbonyl hydride tungsten complex, 1491
osmium carbonyl copper(I) complexes, 75
osmium carbonyl thio complexes, 2385
osmium(0) alkyne carbonyl complex, 1867
palladium(II) aryl phosphinoe triphosphinomethanide complex, 2181
palladium(II) nitrite phosphine complex, 2591
palladium(II) phosphine thioether complex, 2579
phosphiniminocyclotrithiazenes, 1433
phosphorus(V) aryl seleno compounds, 681
platinum dithiolate phosphine complex, 1561
platinum(II) bromide phosphine complex, 1683
platinum(II) chloride isocyanide nickel(0) complex, 2651
platinum(II) diphosphine triselenophosphonate complex, 987
platinum(II) phosphine selenium - nitrogen complex, 1567
platinum(II) phosphine tellurium - sulphur - nitrogen complex, 2659
rhenium carbonyl pyridinethionate thio ruthenium complexes, 623
rhenium(II) acetate chloride diphosphine complex, 743
rhenium(II) carbonyl chloride diphosphine phosphine complex, 565
rhenium(II) chloride diphosphine complex, 573
rhenium(III) chloride phosphine complexes, 1165
rhenium(V) aryl butylimido cyclohexadienyl complex, 2081
rhenium(V) cyclopentadienyl dithiolate complex, 2211
rhenium(V) methoxide oxo Schiff base complex, 615
rhenium(V) neopentyl oxo sodium complex, 957
rhenium(VI) aryl bromide butylimide oxo cyclometallated complexes, 2081
rhenium(VII) aryl butylimide oxo complex, 2081
rhenium(VII) catecholate oxo complexes, 1323
rhenium(VII) oxo tripod phosphine oxide cobalt(0) complex, 2549
rhodium(I) carbonyl phenoxide complex, 969
rhodium acetate chloride nitrosyl phosphine complex, 1589
rhodium(II) alkenediyl carbonyl chloride phosphinopyridie complex, 2635
rhodium(III) amine thioether macrocyclic complex, 2925
rhodium(III) aryl dipyridyl pyridine cyclometallated complex, 1613
rhodium((III) carbonyl diamine methyl phosphine thioether complexes, 2071
rhodium(III) chloride pyridine complex, 2127
rhodium(IV) neopentyl oxo complex, 2071
ruthenium carbonyl pyridinethionate pyridyl thio rhenium complexes, 623
ruthenium dipyridyl pyridine

quinone complexes, 2267
ruthenium(0) alkyne carbonyl complex, 1867
ruthenum(0) phosphine tetramine macrocyclic complex, 1221
ruthenium(II) alkenyl carbonyl carboxylate phosphine complexes, 907
ruthenium(II) cyclopentadienyl phosphine phosphinothioformate complexes, 2163
ruthenium(II) cyclopentadienyl phosphite polysulphide complexes, 1893
ruthenium(II) violurate complex, 2733
silver nitrate complex, 2127
silver thiolates, 769,1429
sodium acetonitrile oxo rhenium(V) complex, 957
sodium uracil complex, 2199
spirophosphorane, 1463
tantalum(V) alkyl phenoxide cyclometallated complexes, 1051
tantalum(V) phenoxide phenyl, 963
tellurium(II),(IV) romide thione complexes, 2879
thorium chloride pyrazolylborate complex, 1645
thorium nitrate pyridone complex, 491
tin(IV) chloride phenol phenyl complexes, 653
tin(IV) tetraselenide complex, 1389
titanium(III) chloride phenoxide complex, 1617
titanium(IV) carboxylate cyclopentadienyl, 783
titanium(IV) cyclopentadienyl hydroxide ketoimine complex, 2097
titanium(IV) methyl silylamide complexes, 1423
tungsten alkoxycarbene alkylidyne carbaborane methylene molybdenum complex, 2953
tungsten alkylidene cyclopentadienyl oxo osmium complex, 1491
tungsten(0) carbonyl diimine complex, 1217
tungsten(0) carbonyl phosphine complex, 1363
tungsten(0) carbonyl phosphine thioether complex, 2579
tungsten(0) carbonyl phosphinine complex, 991
tungsten(II) carbonyl cyclopentadienyl phosphaallyl complex, 2859
tungsten(III) alkoxide chloride oxo complexes, 1829
tungsten(III) alkoxide selenophenoxides, 2941
tungsten(III) chloride cyclopentadienyl, 669
tungsten(IV) arylimide chloride dinitrogen phosphine complex, 669
tungsten(V) chloride cyclopentadienyl phosphine complex, 669
tungsten(VI) alkyl alkylidyne pyridine complexes, 1271
uranium(IV) chloride cyclopentadienyl pyrazolyl-borate complexes, 69
uranium(IV) chloride pyrazolylborate, 1645
vanadium(IV) diketonate oxo pyrazolylborate complex, 2483
ytterbium alkoxide oxide, 719
yttrium acetate diketonate water complex, 1305
zinc aminothiolate, 763
zirconium benzyl cyclopentadienyl iminoacyl phenoxide compounds, 839
zirconium methyl silylamide complexes, 1423
X - ray diffraction
aluminium niobium(V) oxide, 367
cobalt(III) complexes on clay surfaces, 2273
indium tin oxide, 361
iron(II),(III) in glasses, glazes, 999
nickel(II) complexes on clay surfaces, 2273
uranium(VI) fluoride complex, 47
X - ray fluorescence, clays, 517
Xylitol complexes
molybdenum(VI), 1225
1,1-Xylylenebis(cyclopentadienyl) complexes, lanthanides, 479
Xylyl complexes
rhenium(V),(VI),(VII), 2081

Y

Ylide complexes
lanthanides, 875
Ytterbium(II)
chloride, 1919
Ytterbium(III)
alkoxide oxo compound, 719
aminophenoxide carboxylate cyclopentadienyl hydroxyquin-olate complexes, 2143
azole diketonate compound, 751
chloride cyclopentadienyl, 1453
chloride cyclopentadienyl ether complexes, 479
crown ether thiocyanate water complexes, 2371
diketonate pyrazolylborate compounds, 697
nitrate Schiff base complexes, 2019
phenanthroline polyketonate complex, 2285
phosphotungstates, 1249
Yttrium
acetate diketonate water complex, 1305
alkoxide oxo compound, 719
carboxylate pyrazolylborates, 1119
chloride cyclopentadienyl, 1453
chloride cyclopentadienyl ether complexes, 479

diketonate pyrazolylborate compounds, 697
diketone nitrate complexes, 795
nitrate pyridine Schiff base macrocyclic complex, 475
phenanthroline polyketonate complex, 2285

SUBJECT INDEX

(Compiled by Peter Thornton)

A

Ab initio calculations
  cluster compounds, group 14, 1299
  propellanes, 1247
  silanes, 1265
Acetates and acetato complexes
  cobalt(II), 1333,1395
  copper(II), 793,873,1333,2301
  europium, 1385
  lead(II), 1657
  molybdenum(II), 229,2573
  molybdenum(III,IV), 2203
  palladium(I), 2523
  palladium(II), 2037
  rhenium(II), 79
  rhodium(I,II), 2551
  ruthenium(II), 113
  ruthenium(II,III), 829
  ruthenium(III), 113
  silicon, 1173
  thallium(III), 2069
  uranium(VI), 779,2399,2567
  zinc, 121
Acetohydroxamates
  silicon, 1131
Acetonitrile complexes
  copper(I), 347
  molybdenum(II), 433,1717,2283, 2519
  palladium(II), 1513
  rhenium(I,II),(II), 79
  rhenium(V), 2241
  ruthenium(II),(IV), 1173
  tungsten(II), 433,595
Acetophenone, enantioselective hydrosilation, 1061
Acetyls
  molybdenum(II), 1705
Acetylcyclopentadienyls
  cobalt(III), 725
Acetylferrocene-3-nitrobenzoyl-hydrazone complexes
  lanthanides, 2185
Acetylsalicylates
  tin(IV), 509
Acrylamide polymerization with Cr(VI) and Cu(II), 237
Acrylonitrile complexes
  B, Sb, Sn, Ti, 2131
Acyls
  Co(I),Fe(II),Mn(I), 717
  molybdenum(II), 717,1705
  Re(I),Rh(III), 717
  ruthenium(II), 963
Acylpyrazolonates
  uranium(VI), 1683
Adenosine complexes
  ruthenium(III), 2465
Alanine complexes
  chromium(III), 575
  cobalt(III), 977
Albite, 55
Alcohols, oxidation catalysed by Ru(III) complexes, 2137,2511
Alcohol complexes
  aluminium, 1657
  astatine(I), 11
  bismuth(III), 2617
  cadmium, 2111
  caesium, 337
  lanthanum, 1049
  molybdenum(VI), 2617
  neodymium, 1559
  niobium, 2031
  potassium, 337
  rubidium, 337
  sodium, 2617
  tantalum, 2031
  tungsten(VI), 2617
  yttrium, 1049
Alkanediyl complexes
  iron(II), ruthenium(II), 963
Alkenes
  hydrogenation catalysed by Rh(II) complex, 2729
  polymerisation catalysed by Mo(II) complexes, 2283
Alkene complexes
  iridium(I), 1595
  iron(II), ruthenium(II), 963
  zirconium, 1
Alkenediyl complexes
  palladium(II), 561
Alkenyls
  ruthenium(II), 421
Alkoxides
  aluminium, 1639,1733,1967
  barium, 2045
  bismuth, 437,2617
  caesium, 337
  chromium(III), 2255
  cobalt(II), 1733,2791
  copper(II), 1733,1767,1791,2791
  germanium, 1153
  iron(II), 1163,2791
  lanthanum, 949,1049
  lead(II), 1103,1657
  lithium, 805
  manganese(II), 2791
  mercury, 2065
  molybdenum(III), 2309,2839
  molybdenum(VI), 2617
  neodymium, 1559
  nickel(II), 1733,2791
  Pd(II), Pt(II), 2065
  potassium, rubidium, 337
  silicon, 1097,1173
  sodium, 2617

tungsten(III), 2309,2839
tungsten(VI), 477,2617
yttrium, 1049
zinc, 2791
zirconium, 949
Alkyls
gallium, 1897
germanium, 1153,1221,2347
hafnium, 1177
iron(II), 963,1177
mercury, 1465
molybdenum(II), 1705
phosphorus, 261
platinum(II), 993,1411
ruthenium(II), 963
silicon, 1097,1147,1227,1231
thallium(III), 517,1465
tin(IV), 1085,1497,1717,2683
titanium, 1177
tungsten(II), 1177
zirconium, 1177
Alkylamides
molybdenum(III), 2839
platinum(II), 747
rhenium(VII), 2241
tungsten(III), 1215,2839
tungsten(VI), 477
Alkylidene complexes
tungsten(IV), 215
Alkylidyne complexes
tungsten(IV), 215
Alkylimides
cobalt, 1423
molybdenum(VI), 463
niobium(V), 1959
rhenium, 1423,2241,2647
ruthenium, 291
tungsten(VI), 477
Alkyne complexes
chromium(0), 1427
molybdenum(II), 2519
palladium(I), 2523
platinum(0), 909
rhodium, 1995
tungsten(II), 711
Alkynyl complexes
platinum(II), 2153
Allyls
chromium(I), 1427
molybdenum(II), 605
niobium(III), 1075
tungsten(III),(IV), 459
1-Allylimidazole complexes
molybdenum(VI), 33
Allylphosphido complexes
osmium, 1955
Allyltrimethylsilane, reaction with WCl_6, 2089
Aluminium
alkoxides, aminoalkoxides, carboxylates, diketonates, review, 1967
alkoxide heterometallic complexes, 1733
alkoxide siloxides, 1639
oxide minerals, 55
phosphorus oxyanion water complexes, 659
polyphosphates, 1527
siloxide complexes, 1367
Aluminohydrides
Mo(II), W(II), 595
Amide complexes
cobalt(III), 2075
platinum(II), 1473
sodium, 1877
thorium, 2809
uranium(VI), 1683
Amidopyridine complexes
lanthanides, 2405
Amines, reaction with ruthenium complex, 1799
Amine complexes
astatine(I), 11
cadmium, 409
caesium, 221
cobalt(II), 409
cobalt(III), 977,1449,2075,2597
copper(II), 103,409,495,823,883, 941,1653,1675,1791,1809
europium, 1385
gallium, 1897
iron(II), 409
iron(III), 1809
lead(II), 409
manganese(II), 409
molybdenum(III), 2309
nickel(II), 823,2725
palladium(II), 1521
platinum(II), 799
rhenium(V), 243
rhenium(VII), 2241
rhodium(I), 1061
rhodium(III), 1617
rubidium, 221
ruthenium, 288
sexidentate, 409
silver, 19
tungsten(III), 2309
tungsten(VI), 477
zinc, 409
Aminoacid complexes
chromium(III), 575
cobalt(III), 977,2717,2847
copper(II), 273
palladium(II), 333
Aminoacid Schiff base complexes
copper(II), 2163
Aminoalkoxides
aluminium, review, 1988
barium, 2045
Aminoalkylsalicylaldimine complexes, copper(II), 1653
2-Aminoethylphosphonic acid complexes, lutetium, 175
2-Amino-3-hydroxypyridine complexes
ruthenium(III), 2137
2-Aminoisobutyrates
cobalt(III), 977
Aminophenoxides
ruthenium(III), 2137
titanium(IV), 1847
2-Aminopyrimidine complexes
copper(II), 873
ruthenium(II), 1727
4-Aminopyridine complexes
ruthenium(III), 1139
Aminothiolates
cadmium, 325
Ammonia complexes
cobalt(III), 2075,2317,2495
platinum(II), 799
ruthenium(II), 653,1139,1713
ruthenium(II,III), 653
ruthenium(III), 1139

t-Amyl alcohol, amyloxide
complexes,
lead(II), 1103
yttrium, 1049
t-Amylamine complexes
europium, 1385
Angular overlap calculations
chromium(III) oxalate complexes, 2673
cobalt(III) oxalate complexes, 2665
nickel(II) halide pyridine thiocyanate complexes, 1759
Aniline complexes
europium, 1385
gallium, 1897
Mo(III), W(III), 2309
p-Anisates
ruthenium(II,III), 491
Antimony(V)
chloride nitrile complexes, 2131
Antipyrine Schiff base complexes
thorium(IV), uranium(VI), 2399
Antitumor properties, titanium(IV)
aminophenoxide carboxylate
chloride cyclopentadienyl
thiophenoxide thiosalicylate
complexes, 1847
Arene complexes
potassium, 2353
ruthenium(II), 1091,1727
Arginine complexes
cobalt(III), 2717
Arsenic(V)
chloride phenoxide phenyl complexes, 789
fluoride, in polysilanes, 1227
Arsine complexes
cobalt(I), 2535
iron(II), 2095
molybdenum(II), 665
osmium(III), 2511
ruthenium(III), 2137
Aryls
arsenic(V), 789
germanium, 1153,2347
iridium(IV), 1457
iron(II),717
manganese(I), 717
mercury, 187,1013,1465
molybdenum(VI), 463
nickel(II), 2821
palladium(II), 1513,2037
platinum(II), 909
review, 135
rhenium(I), 717
rhodium(III), 187
silicon, 1173,1231
thallium(III), 1465
tin(IV), 1085
Arylamides
gallium, 1897
molybdenum(III), 2309
platinum(II), 747
potassium, 1839
rhenium(VII), 2241
sodium, 1839
tungsten(III), 2309
Arylimides
rhenium(VI), 1539
ruthenium, 291
Aryliminoisoindoline complexes
molybdenum(II), 229
2-Aryltelluroethoxides,
Hg, Pd(II), Pt(II), 2065
Ascorbate complexes
ruthenium(III), 2711
Ascorbic acid, oxidation catalysed by Cu(II) complexes, 731
ASED - MO calculations
copper dithiolene complexes, 2377
Astatine(I)
halide chelate complexes, 11
Atrolactate complexes
osmium(VI), 61
Azide complexes
chromium(III), 373
cobalt(III), 2597
copper(II), 2451
iron(III), 373
nickel(II), 2659,2725
palladium(II), 1513
Azole complexes
cobalt(II), 1333
copper(II), 893,1333,1767,1809
iron(III), 1809
molybdenum(III), 323
molybdenum(VI), 33
nickel(II), 1031,2659
palladium(II), 1513
platinum(II), 1443
ruthenium(III), 2559
tungsten(II), 711

B

Barium
aminoalkoxide, 2045
diimine pyridine silylamide, 769
oxide in feldspar glass, 55
Benzene complexes
potassium, 2353
ruthenium(II), 1727
Benzene-1,2-dioxydiacetates
calcium, sodium, 1565
Benzenethiolates
palladium(II), 1343
Benzil Schiff base complexes, 973
Benzimidazole complexes
copper(II), 893
molybdenum(III), 323
molybdenum(VI), 33
Benzoates
palladium(I), 2523
samarium, 1599
tin(IV), 509
titanium(IV), 1847
ytterbium, 1599
Benzo-15-crown-5 complexes
potassium, 1025
Benzohydroxamates
silicon, 1131
Benzoic hydrazide complexes
ruthenium(III), 2137
Benzoyldiazenide complexes
rhenium(V), 1539
S-Benzyldithiocarbazate Schiff base complexes, 973
Benzylfluorenyls
germanium, 1153
Betaine complexes
copper(II), 273
silver(I), 1723,2687

Biaryls, formation catalysed by
Pd(II) complex, 2037
Bicyclo[2.2.1]hept-5-ene-2-carboxylate complexes
copper(II), 2273
molybdenum(II), 2273,2283
ruthenium(II,III), 2273
N,N'-Bis(2-aminopropyl)oxamide complexes, Co(II), Cu(II), 1787
N,N'-Bis(3-aminopropyl)oxamide complexes, nickel(II), 103
Bis(arylimino)isoindoline complexes, molybdenum(II), 229
Bis(benzylthio)methane complexes
palladium(I),(II), 561
Bis[bis(2-diphenylphosphinoethyl)-amino]ethane complexes
copper(I), 1827
1,2-Bis[bis(2-methylthiophenyl)-phosphino]ethane complexes
Mo(0),W(0), 1549
1,2-Bis(di-*n*-butylphosphino)ethane complexes, Pt(0),(II), 899
1,4-Bis(dicyclohexylphosphino)butane complexes, Pt(II), 867
1,2-Bis(dicyclohexylphosphino)ethane complexes,
platinum(0),(II), 899,909
Bis(dicyclohexylphosphino)methane complexes, Ru(II),(III), 1713
1,3-Bis(dicyclohexylphosphino)propane complexes, Pt(II), 909
1,2-Bis(dimethylphosphino)ethane complexes
silver(I), 737
tungsten(II),(IV), 595
1,3-Bis(diphenylphosphinoacetyl)-benzene complexes, Pd(II), 1521
1,4-Bis(diphenylphosphino)butane complexes, Pt(II), 1411
1,2-Bis(diphenylphosphino)ethane complexes
cobalt(II), 553
molybdenum(II), 665
molybdenum(V), 1459
niobium(-I), 389
platinum(0), 899,909
platinum(II), 899,909,1411
ruthenium(II), 1019
tungsten(IV), 2827
tungsten(VI), 1311
1,2-Bis(diphenylphosphino)ethene complexes, Pt(II), 993
Bis(2-diphenylphosphinoethyl)ether complexes
molybdenum(IV), 467
Bis(2-diphenylphosphinoethyl)-phenyl)phosphine complexes
platinum(II), 2471
1,1'-Bis(diphenylphosphino)ferrocene complexes
manganese(0), 2437
platinum(II), 1411
rhenium(0), 2437
Bis(diphenylphosphino)methane complexes
cobalt(II), 553
molybdenum(0), 2611
platinum(II), 1411,2153
rhenium(I,II),(II), 79
rhodium(I), 2153
1,3-Bis(diphenylphosphino)-2-methylprop-2-ene complexes
Cr(0), Mo(0), W(0), 2381
1,3-Bis(diphenylphosphino)propane complexes, Pt(II), 1411
1,2-Bis(dipropylphosphino)ethane complexes, Cr(0), 1427
1,2-Bis(di-*o*-tolylphosphino)ethane complexes
tungsten(IV), 1007
Bis(2-hydroxy-5-methylphenyl)telluride complexes, Hg,Pd,Pt, 2693
Bis(2-methylthiophenyl)phenylphosphine complexes, Re(I), 1603
Bismuth
