
Fig. 3. IR spectrum of the salt in Nujol (signals due to Nujol and tetramethylammonium are marked with asterisks).

are IR-inactive in T_d symmetry, but become active in the approximate C_{3v} symmetry of the tripod coordination. Two deformation modes, ν_3 and ν_4, are also observed in the regions 1200 and 640 cm^{-1}, respectively, with splittings.

MONONUCLEAR AND BINUCLEAR 4-CYANOPYRIDINE COMPLEXES OF BIS(2,2′-BIPYRIDINE) (PYRIDINE)RUTHENIUM(II)*

EDGARDO H. CUTIN† and NESTOR E. KATZ†‡

Instituto de Química Fisica, Facultad de Bioquímica, Química y Farmacia, Universidad Nacional de Tucumán, Ayacucho 491 (4000), San Miguel de Tucumán, República Argentina

(*Received* 17 *September* 1990; *accepted* 22 *October* 1990)

Abstract—New complexes derived from the $Ru(bpy)_2(py)^{2+}$ moiety (bpy = 2,2′-bipyridine, py = pyridine) were synthesized and characterized by spectroscopic techniques. The mononuclear complex $[Ru(bpy)_2(py)(4\text{-}CNpy)]^{2+}$ (4-CNpy = 4-cyanopyridine) seems to be the pyridine-bonded isomer of 4-CNpy, as disclosed by IR and UV–vis data ($\nu_{CN(nitrile)}$ = 2240 cm^{-1}, λ_{max} = 434 nm in CH_3CN). The binuclear complexes $[Ru(bpy)_2(py)(4\text{-}CNpy)Ru(NH_3)_5]^{4+}$ and $[Ru(bpy)_2(py)(4\text{-}CNpy)Fe(CN)_5]^{-}$ were also prepared; they showed new absorptions in the visible region at λ_{max} *ca* 450 nm ascribable to MLCT (metal-to-ligand charge-transfer) transition from d_π orbitals of ruthenium or iron to π^* orbitals of 4-CNpy. The former dimer was obtained as a PF_6^- salt, which presented $\nu_{CN(nitrile)}$ = 2178 cm^{-1}, as expected from an ammineruthenium(II) moiety bonded to 4-CNpy through the nitrile group. Oxidation of this species with cerium(IV) yielded the mixed-valence complex $[Ru^{II}(bpy)_2(py)(4\text{-}CNpy)Ru^{III}(NH_3)_5]^{5+}$, with concomitant disappearance of the MLCT band of lowest energy.

4-Cyanopyridine (4-CNpy) is an ambidentate ligand which can coordinate to transition metals through its pyridine nitrogen or its nitrile nitrogen, giving rise to stable isomeric forms of mononuclear and binuclear complexes. We are particularly interested in the properties of 4-CNpy as an effective electronic conductor,[1,2] and thus we report in this work the preparation and spectroscopic properties of new complexes derived from the $Ru(bpy)_2(py)^{2+}$ moiety (bpy = 2,2′-bipyridine, py = pyridine) which can have 4-CNpy as a bridging ligand. The $Ru^{II}(bpy)_2$ group is a well-known photosensitizer,[3] while bridged binuclear complexes are systems under intense scrutiny due to their importance in electron (or energy) transfer reactions that may eventually lead to conversion of light energy into chemical energy.[4,5]

EXPERIMENTAL

Syntheses

Analytical reagent compounds were used for all experiments reported in this work. Doubly distilled water was redistilled from alkaline permanganate in all-glass apparatus.

$[Ru(bpy)_2(py)(4\text{-}CNpy)](PF_6)_2 \cdot 8H_2O$ (A)

A mixture of $[Ru(bpy)_2(py)Cl]Cl$ (0.3 g, 0.5 mmol, prepared as in ref. 6) and 4-cyanopyridine (2 g, 19 mmol) was refluxed for 1 h in a solution of water (10 cm^3) and methanol (5 cm^3). The resulting dark red solution was filtered, evaporated to a volume of 5 cm^3 and precipitated with an aqueous saturated solution of NH_4PF_6. The solid was collected on a sintered-glass filter, washed with cold water and recrystallized from hot methanol by the addition of ether. It was dried in a vacuum desiccator over KOH. Yield: 0.27 g, 52% (Found: C, 36.1; H, 4.2; N, 10.9. Calc.: C, 36.1; H, 4.0; N, 9.5%).

$[Ru(bpy)_2(py)(4\text{-}CNpy)Ru(NH_3)_5](PF_6)_4 \cdot 8H_2O$ (**B**)

$[Ru(bpy)_2(py)(4\text{-}CNpy)](PF_6)_2 \cdot 8H_2O$ (100 mg, 0.097 mmol) and $[Ru(NH_3)_5(H_2O)](PF_6)_2$ (51 mg, 0.1 mmol, prepared as in ref. 7) were dissolved in distilled acetone (8 cm^3) under argon and the mixture was stirred for 5 h with continuous argon bubbling. Ether was added and after 1 h at 0°C, the solid was collected and washed with dichloromethane. It was then dissolved in acetone, reprecipitated with ether, filtrated and dried *in vacuo* over KOH (Found: C, 24.6; H, 3.2; N, 10.1. Calc.: C, 24.7; H, 3.7; N, 11.1%.)

$[Ru(bpy)_2(py)(4\text{-}CNpy)Fe(CN)_5]^-$ (**C**)

Compound **A** (0.5 g) was dissolved in 10 cm^3 of argon-deoxygenated water and mixed with a slight excess of $Na_3[Fe(CN)_5(NH_3)] \cdot 3H_2O$, obtained as in ref. 8. The mixture was stirred under argon for 30 min, and then visible spectra were recorded.

Instrumentation and techniques

IR spectra were obtained as KBr pellets on a Perkin-Elmer Model 983G spectrophotometer. Electronic spectra were recorded on a Perkin–Elmer Coleman 124 spectrophotometer. C, H and N microanalyses were performed at UMYMFOR, Universidad de Buenos Aires, Argentina. Oxidation experiments were carried out on the binuclear ruthenium complex (**B**) by adding stoichiometric amounts of cerium(IV) to a solution of **B** in CH_3CN (with a few added drops of HNO_3) and then recording the visible spectra.

RESULTS AND DISCUSSION

IR spectra

The wavenumbers of the IR absorptions, together with their relative intensities and description of the modes, are presented in Table 1 for complexes **A** and **B**. Assignments are tentative and made by comparison with the spectra of the free ligands py,[9] bpy[10] and 4-CNpy[11] and with those of similar complexes derived from ruthenium ammines[1,12] and polypyridines.[2,13] For the mononuclear complex **A**, the stretching frequency of the nitrile group (2240 cm^{-1}) is nearly equal to the value for the free ligand (2243 cm^{-1}),[14] suggesting coordination to the pyridine nitrogen. In the dimer **B**, the value of this frequency (2178 cm^{-1}) is shifted 65 cm^{-1} below the free ligand value, a lowering already observed in similar complexes,[1,14,15] and which can be attributed to the π-backbonding ability of the $Ru(NH_3)_5^{2+}$ moiety. The vibration corresponding to the ammonia symmetric deformation appears at 1301 cm^{-1} in the spectrum of **B** and is characteristic of ruthenium(II) ammines.[16] The IR data thus indicate that 4-CNpy bonds through its pyridine nitrogen to the polypyridine ruthenium and through its nitrile nitrogen to the ammine ruthenium. This result is in contrast to that found in ref. 2, which

Table 1. IR spectra of $[Ru(bpy)_2(py)(4\text{-}CNpy)](PF_6)_2 \cdot 8H_2O$ (**A**) and $[Ru(bpy)_2(py)(4\text{-}CNpy)Ru(NH_3)_5](PF_6)_4 \cdot 8H_2O$ (**B**) (as KBr pellets). Wavenumbers are in cm^{-1}

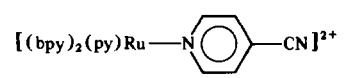
UV–vis spectra

Figure 1 shows the UV–vis spectrum of a 2×10^{-5} mol dm^{-3} solution of complex **A** in CH_3CN at room temperature. Values of λ_{max} and ε_{max}, together with the corresponding assignments (done by comparison with similar complexes),[2] are shown in Table 2. When comparing the spectrum of $[Ru(bpy)_2(py)(4\text{-}CNpy)]^{2+}$ ($\lambda_{max} = 434$ nm in CH_3CN) to that of $[Ru(bpy)_2(py)_2]^{2+}$ ($\lambda_{max} = 460$ nm in methanol),[17] a shift of the MLCT transition $d_\pi(Ru) \rightarrow \pi^*(bpy)$ to higher energy occurs, in agreement with the higher π-acceptor ability of 4-CNpy with respect to pyridine. In addition, the band at 382 nm, attributed to a $d_\pi(Ru) \rightarrow \pi^*(4\text{-}CNpy)$MLCT, is shifted to lower energies when compared with the corresponding band in $[Ru(bpy)_2(4\text{-}CNpy)_2]^{2+}$ ($\lambda_{max} \sim 360$ nm),[2] as expected for a pyridine-bonded isomer of 4-CNpy. Indeed, λ_{max} for these MLCT visible bands are unchanged in 0.1 M HCl and 1 M HCl for complex **A**, indicating the following structure:



in agreement with the IR results. The nitrile-bonded isomer must have a spectrum sensitive to pH.[2]

Figure 2 shows the obtained visible spectra for complexes **B** and **C** in CH_3CN and water, respectively, at room temperature. Both species present new absorption bands at λ_{max} *ca* 450 nm (454 nm for **B** and 452 nm for **C**) which can be assigned to MLCT transitions from d_π orbitals of ruthenium or iron [of the $Ru^{II}(NH_3)_5$ or $Fe^{II}(CN)_5$ groups] to π^* orbitals of 4-CNpy. Actually, these bands seem to be composed of superimposed polypyridine Ru → bpy and ammine Ru (or Fe) → 4-CNpy MLCT bands (cf. ref. 2). Complex **B** also has greater absorption at higher wavelengths than complex **C**; this result agrees with the higher π-backbonding capability of the $Ru(NH_3)_5^{2+}$ moiety compared with the $Fe(CN)_5^{3-}$ moiety.[18] When analysing data of visible absorption maxima of $[(CN)_5Fe^{II}L]$ complexes, as shown in Table 3, or of $[(NH_3)_5Ru^{II}L]$ derivatives, as shown in Table 4, where L = nitrile bonded 4-CNpy (with its free nitrogen coordinated to different moieties), complexes **B** and **C** fall within the correlation of λ_{max} (of the Ru or Fe → 4-CNpy MLCT band) with the inductive effect of the pyridine-bonded centres. Thus, the following structures

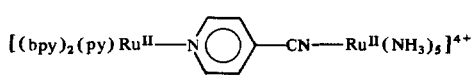
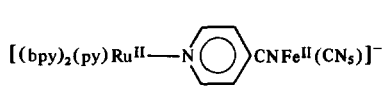
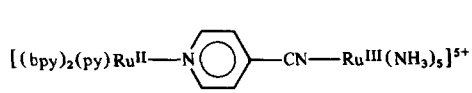
are disclosed:





Oxidation of complex **B** with cerium(IV) in CH_3CN (with added HNO_3) causes the disappearance of the MLCT band at 454 nm. The obtained mixed valence complex,



has an absorption band with $\lambda_{max} = 424$ nm, attributed to $d_\pi(Ru^{II}) \rightarrow \pi^*$(bpy)MLCT. No MMCT (metal-to-metal charge-transfer) transitions were detected up to 800 nm.

CONCLUSIONS

4-CNpy can effectively bridge the $Ru(bpy)_2(py)^{2+}$ moiety with $Ru(NH_3)_5^{2+/3+}$ or $Fe(CN)_5^{3-}$ groups. In the binuclear complex, 4-CNpy coordinates through its pyridine nitrogen to polypyridineruthenium(II) and through its nitrile nitrogen to ammineruthenium(II) and (III) or cyanoferrate(II) moieties, as deduced from spectroscopic measurements, both in the solid state and in solution. These systems may be used as models for the study of intramolecular electron (or energy) transfer processes.

^{31}P NMR AND RAMAN SPECTROSCOPIC STUDIES ON BINDING ISOMERISM AND ISOMERIZATION EQUILIBRIUM OF ALUMINIUM COMPLEXES OF MONOMERIC PHOSPHORUS OXOANIONS IN SOLUTION

QI FENG and HIROHIKO WAKI*

Department of Chemistry, Faculty of Science, Kyushu University, Higashiku, Fukuoka, Japan

(*Received* 14 *March* 1990; *accepted* 31 *October* 1990)

Abstract—The binding isomerism of Al^{3+}–phosphinate, –phosphite and –phosphate complexes was investigated by using ^{31}P NMR and Raman spectroscopies in solution. It was found that there are two types of binding mode in the complexes: a non-chelate binding mode in which the monomeric phosphorus oxoanions coordinate to the aluminium ion as monodentate ligands, and a chelate binding mode in which the monomeric phosphorus oxoanions coordinate to the aluminium ion as bidentate ligands. Furthermore, an isomerization equilibrium analysis was made on the chelate and the non-chelate isomers. The isomerization constants, $K^{chel}_{non\text{-}chel}$, for formation of the chelate isomer from the non-chelate one, were evaluated to be 2.8 for the $AlPH_2O_2^{2+}$ complex, 3.7 for the $AlPHO_3^{+}$ complex and 3.9 for the $AlPO_4$ complex.

In the coordination of a monomeric oxoanion to a metal ion in solution, non-chelate binding in which the oxoanion ligand coordinates as monodentate has been considered to be common, and there have been very few reports[1–4] on four-membered ring formation in which the ligand coordinates as bidentate. Recently we clarified the equilibrium co-existence of these two types of binding for chromium(III)–phosphinate complexes by a ^{31}P NMR study of the solution.[5] It was found that the saturated inner-sphere complex $Cr(PH_2O_2)_6^{3-}$ contained only non-chelate species, whereas the lower complexes $Cr(PH_2O_2)_5^{2-}$ and $Cr(PH_2O_2)_4^{-}$ contained both the non-chelate and chelate species. The equilibrium between these two types can also be expected for other metal–oxoanion complex systems.

In this work, a distinction between the chelate and non-chelate binding modes for more labile complexes such as aluminium–phosphinate, –phosphite and –phosphate complexes, and their isomerization equilibrium has been investigated by ^{31}P NMR and Raman spectroscopies.

EXPERIMENTAL

Reagents

Aluminium nitrate, aluminium chloride, sodium phosphinate, sodium phosphite and potassium phosphate were of commercially available reagent grade. The acidity of stock solutions of aluminium nitrate and aluminium chloride were maintained at 0.1 M with nitric acid or hydrochloric acid to avoid the formation of the hydroxo complexes.

NMR measurements

In the NMR study, the sample solutions were adjusted to pH 2 with nitric acid or sodium hydroxide. The ^{31}P NMR spectra were recorded on a JEOL spectrometer JNM-GX 400 operating at 161.86 MHz at 20°C, using a 10 mm i.d. spinning sample tube. The phosphorus chemical shift was recorded relative to an external standard of 85% H_3PO_4, a positive shift being down field. The experimental conditions were as follows: spectral width, 30,000 Hz; data points, 16 K; pulse width, 20 μs (45°); repetition time, 3.0 s. It was experimentally confirmed that quantitative data can be obtained at these conditions. The signal ratio of the complex

species to the free ligand was determined by measuring the paper weight corresponding to each signal area recorded.

Measurement of Raman spectra

In the Raman spectroscopic study, the sample solution containing aluminium chloride and the salt of the phosphorus oxoanion was adjusted to pH 2 with hydrochloric acid or sodium hydroxide. The Raman spectra were recorded at 20°C on a JASCO NR-1100 laser Raman spectrophotometer equipped with a double monochromator and a control microcomputer. The excitation beam wavelength was 514.5 nm, which was obtained from a NEC GLG 3200 argon gas laser. The spectrum for the complex was obtained by subtracting the Raman band of the free ligand from that of the corresponding sample using the datum treatment system of the Raman spectrophotometer.

RESULTS AND DISCUSSION

^{31}P NMR study of the one-to-one complexes

The ^{31}P NMR spectra of a series of solutions in which the total concentration ratio of aluminium to phosphinate was unity were measured and an example is shown in Fig. 1(a). Triplet A is from the free phosphinate and resonances B, C and D can be assigned to the complexes. The dependence of the peak area ratios of B to C and D to C on the total aluminium concentration or phosphinate are given in Fig. 2. In the lower concentration range, only triplets C and D were observed for the complexes with a nearly constant area ratio. Since under these conditions only one-to-one complexes are expected to be formed, these two peaks may have different structures to each other. We assigned them to the binding isomers in which the phosphinate ions are bound as monodentate (**I**) and bidentate (**II**), as found for the chromium–phosphinate complexes.[5] Since the interaction between the central metal ion and the ligand is stronger for chelate binding than for non-chelate binding, a larger shift from the position of the free ligand should occur for the chelate structure. Therefore, it was concluded that resonance C was due to the chelate isomer and resonance D to the non-chelate isomer. The further upfield resonance B may be due to a binuclear complex $Al_2(PH_2O_2)_2^{4+}$ (**III**). This assignment may be reasonable from its high chemical shift value and due to the fact that the intensity of peak B increased with increasing aluminium or phosphinate concentration.

In Fig. 3(a), doublets A, B, C and D may be assigned to the free phosphite ion, the binuclear complex $Al_2(PHO_3)_2^{2+}$, the chelate $AlPHO_3^+$ and the non-chelate $AlPHO_3^+$, respectively, using the above

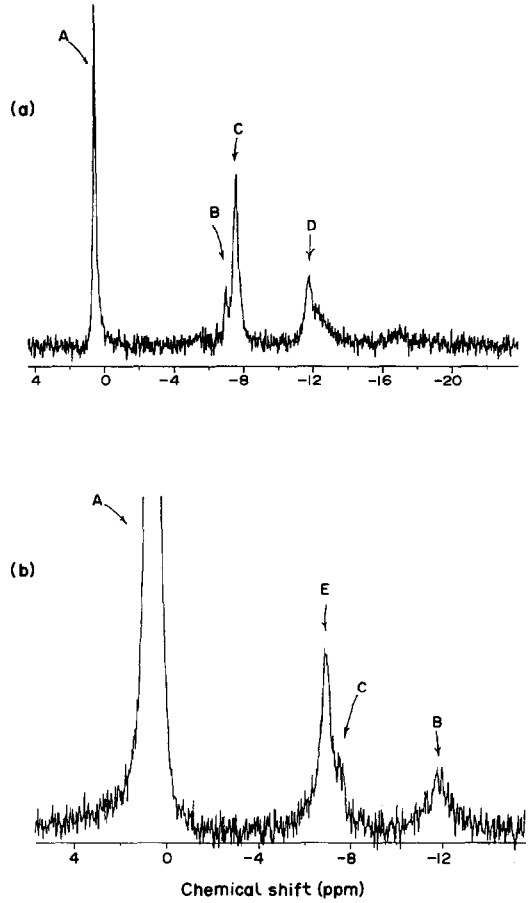

Fig. 4. ^{31}P NMR spectra of aluminium–phosphate complexes at pH 2 and 20°C. (a) 0.025 M $Al(NO_3)_3$–0.025 M KH_2PO_4 solution and (b) 0.025 M $Al(NO_3)_3$–0.25 M KH_2PO_4 solution.

reasoning. The concentration ratios of the non-chelate to the chelate isomer and of the binuclear complex to the chelate isomer are plotted against the concentration of aluminium or phosphite in Fig. 2. The concentration ratio of the non-chelate to the chelate isomer was almost unchanged, whereas that of the binuclear complex to the chelate isomer was greatly altered. The resonances observed further upfield than those of the binuclear complex are probably due to $Al_2PHO_3^{4+}$ and/or more polymeric complexes, although further studies were not carried out.

Similarly, singlets A, B, C and D in Fig. 4(a) are assigned to the free phosphate ion, the binuclear complex $Al_2(PO_4)_2$, the chelate $AlPO_4$ isomer and the non-chelate $AlPO_4$ isomer, respectively. The concentration ratio behaviour for these complexes is analogous to that of the aluminium–phosphinate and aluminium–phosphite complexes described above (Fig. 2).

^{31}P NMR study of complexes with a greater number of ligands

^{31}P NMR spectra of a series of solutions containing 0.025 M $Al(NO_3)_3$, and $NaPH_2O_2$, Na_2PHO_3 and KH_2PO_4 of differing excess concentrations were measured. Figure 1(b) shows an example of the ^{31}P NMR spectrum for aluminium–phosphinate complexes at 10 times excess ligand concentration. A signal from the one-to-one chelate complex appeared as a shoulder C, and a set of triplets E, F and G appeared with increasing ligand concentration. The E, F and G peaks may be assigned to $Al(PH_2O_2)_2^+$, $Al(PH_2O_2)_3$ and $Al(PH_2O_2)_4^-$, respectively, from the order of the chemical shifts and the increasing–decreasing behaviour with ligand concentration. Similar to the one-to-one complex, these complexes should consist of several isomers due to the chelate and non-chelate binding ligands. However, the complexes did not reveal two separate peaks in the spectrum. These chelate and non-chelate peaks are closer together than in one-to-one complexes and may overlap with peaks of complexes containing a different number of ligands. For example, peak E may be the chelate $Al(PH_2O_2)_2^+$ which overlaps the non-chelate $AlPH_2O_2^{2+}$. The sharpness of peak G may be due to the saturated tetrahedral complex with four non-chelated $PH_2O_2^-$ ligands, and the large difference in chemical shift between peaks E and F may presumably be due to the conversion of octahedral $Al(PH_2O_2)_2^+$ into tetrahedral $Al(PH_2O_2)_3$ or to a large change in the non-chelate/chelate ligand abundance in these two complexes, each peak indicating the predominance of one form.

An example of the ^{31}P NMR spectrum for the aluminium–phosphite complex system containing a large excess of phosphite is given in Fig. 3(b). Here peak C is the chelated $AlPHO_3^+$, and a broader peak F may presumably be $Al(PHO_3)_3^{3-}$, containing both chelate and non-chelate ligands or a mixture of tetrahedral and octahedral forms of the same composition. A binuclear signal B was also observed in the spectrum.

In the aluminium–phosphate complex system with a large excess of phosphate ligand [Fig. 4(b)], except for peak C (chelate $AlPO_4$), only one large peak E was revealed, which can be assigned to chelate $Al(PO_4)_2^{3-}$ overlapping with the non-chelated $AlPO_4$. A binuclear peak B was also observed under these conditions.

The chemical shift values for the aluminium–phosphinate, –phosphite and –phosphate stepwise complexes are tabulated in Table 1. It was found that the coordination ^{31}P NMR chemical shift in the corresponding aluminium complexes increases in the order $PO_4^{3-} > PHO_3^{2-} > PH_2O_2^-$, in agreement with increasing ligand charge.

Raman spectroscopic study of the aluminium–phosphinate complexes

The chelate and non-chelate binding of phosphinate ligands can also be distinguished by their Raman spectra. Figure 5 shows a Raman spectrum for a $NaPH_2O_2$ solution and for a 1 : 1 mixture of $NaPH_2O_2$ and $AlCl_3$ in the 700–1400 cm^{-1} region, where the stretching vibration band of the PO_2 group is expected to appear. In order to obtain a pure spectrum for the complexes, the free $PH_2O_2^-$ bands were eliminated by datum treatment in Fig. 5(c). In the figure, the bands at 935 and 1158 cm^{-1} are assigned to the twisting and the scissoring vibrations of the PH_2 group in the coordinated ligands, respectively. The bands at 1083, 1107 and 1191 cm^{-1} are assigned to the stretching vibration modes of the PO_2 group in the coordinated ligand. The concentration dependence of intensity ratio for the three bands at a 1 : 1 molar ratio of $AlCl_3$–$NaPH_2O_2$ is presented in Fig. 6. The intensity ratio 1191 cm^{-1}/1083 cm^{-1} was almost constant, independent of the concentration of aluminium or phosphinate, and the intensity ratio 1107 cm^{-1}/1083 cm^{-1} was constant only in the low concentration

Table 1. ^{31}P NMR chemical shift data of the complexes, relative to the corresponding fully deprotonated free ligand

	Chemical shift (ppm)					
	1 : 1					
	Chelating	Non-chelating	1 : 2	1 : 3	1 : 4 Non-chelating	2 : 2 Bridging
Al^{3+}–$PH_2O_2^-$	−3.77	−3.50	−3.48	−3.00	−2.64	−4.60
Al^{3+}–PHO_3^{2-}	−7.12	−6.43	−6.41	−5.51		−9.02
Al^{3+}–PO_4^{3-}	−13.27	−12.70	−12.66			−17.03

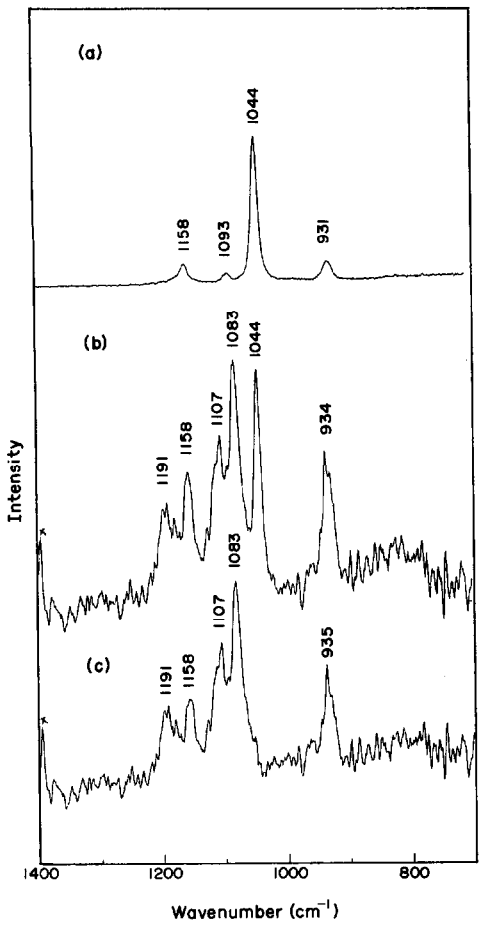

Fig. 5. Raman spectra of phosphinate and aluminium–phosphinate complexes at pH 2 and 20°C. (a) 0.2 M $NaPH_2O_2$ solution, (b) 0.075 M $AlCl_3$–0.075 M $NaPH_2O_2$ solution and (c) net complex spectrum obtained by eliminating vibration bands of the free $PH_2O_2^-$ anion from (b).

range, $C_{Al} < 0.05$ M, where binuclear complexes are negligible. The bands at 1083 and 1191 cm^{-1} may be assigned to symmetric and antisymmetric stretching vibrations of the PO_2 group of the non-chelating

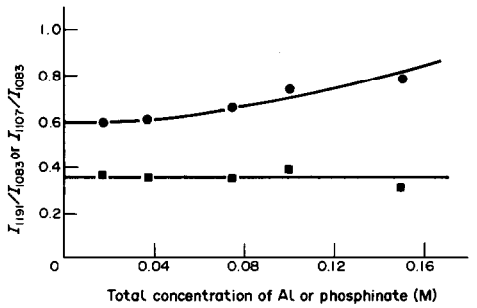

Fig. 6. The concentration dependence of vibration band intensity ratios for Al^{3+}–$PH_2O_2^-$ complex system at $C_{Al}/C_P = 1$, pH 2 and 20°C. ■: I_{1191}/I_{1083}, ●: I_{1107}/I_{1083}.

ligand, respectively, because of the constant intensity ratio. The band at 1107 cm^{-1} may be assigned to the symmetric stretching vibration of the PO_2 group of the chelating ligand. The increase in the 1107 cm^{-1}/1083 cm^{-1} ratio at high concentrations of $AlCl_3$ may be ascribed to the formation of a binuclear complex that has a PO_2 symmetric stretching vibration of the bridged $PH_2O_2^-$ ligand at 1118 cm^{-1} which overlaps with the 1107 cm^{-1} band.

The observed wave numbers of the free ligand and the complexes with their assignments are summarized in Table 2. It can be seen that all the stretching bands of the PO_2 group of the coordinated ligand shift to a higher wave number than that of the free ligand. The magnitude of the symmetric stretching band shift was 39 cm^{-1} for the non-chelating ligand, 63 cm^{-1} for the chelating ligand and 74 cm^{-1} for the bridging ligand, respectively. This behaviour agrees with the expected change in interaction between the central metal and ligand in the different types of binding.

Raman spectra of aluminium–phosphinate complexes at different ligand concentrations were also measured. The wave numbers for the complexes did

Table 2. Raman spectrum data and assignments of the free $PH_2O_2^-$ anion and Al^{3+}–$PH_2O_2^-$ complexes

Assignment	Frequency (cm^{-1})			
	Free[a]	Non-chelating	Chelating	Bridging
A_2 PH_2 twist	931	935	935	935
A_1 PO_2 symmetric stretch	1044	1083	1107	1118
B_2 PH_2 wag	1093			
A_1 PH_2 scissor	1158	1158	1158	1158
B_2 PO_2 antisymmetric stretch	1180[b]	1191		

[a] Only the assignment of the free ion is referred to in the literature.[6,7]
[b] IR spectrum datum.[6]

not appreciably change with increasing ligand concentration. This indicates that the Raman band depends only on the binding mode but is independent of the coordinated ligand number. The band intensity for the non-chelating ligand at 1083 cm^{-1} increased and that for chelating ligand at 1107 cm^{-1} decreased with increasing ligand concentration. This indicates that the abundance of chelating ligand in the complex decreases with increasing ligand number of the complex, which is in accordance with the observation in the ^{31}P NMR study.

Isomerization equilibrium of the chelating and non-chelating isomers

In the complex of composition AlL_x, where L denotes a bidentate ligand like phosphinate anion, a series of binding isomers $Al(L_{chel})_n(L_{non\text{-}chel})_{x-n}$ can, in general, be formed. In the simplest case of the one-to-one aluminium–phosphinate complex, the complexation process can be represented by the reactions

$$Al(H_2O)_6^{3+} \underset{K_{non\text{-}chel}}{\overset{-H_2O,\ +PH_2O_2^-}{\rightleftharpoons}} \underset{\text{(non-chelate complex)}}{Al(OPH_2O)(H_2O)_5^{2+}} \quad (1)$$

$$\underset{K^{chel}_{non\text{-}chel}}{\overset{-H_2O}{\rightleftharpoons}} \underset{\text{(chelate complex)}}{Al(O_2PH_2)(H_2O)_4^{2+}}. \quad (2)$$

The equilibrium constants are

$$K_{non\text{-}chel} = \frac{[Al(OPH_2O)(H_2O)_5^{2+}]}{[Al(H_2O)_6^{3+}][PH_2O_2^-]} \quad (3)$$

$$K^{chel}_{non\text{-}chel} = \frac{[Al(O_2PH_2)(H_2O)_4^{2+}]}{[Al(OPH_2O)(H_2O)_5^{2+}]}. \quad (4)$$

Since reaction (2) for the formation of the chelate from the non-chelate binding is clearly a *pseudo*-intramolecular reaction, the concentration ratio of the two isomers may be constant even at different concentrations of free Al^{3+} ion or ligand. Similar equations may be written for each step forming aluminium complexes of higher ligand number, and also for the complexes of other oxoanion ligands.

In order to provide quantitative information on the distribution of chelate and non-chelate isomers, we evaluated $K^{chel}_{non\text{-}chel}$ and $K_{non\text{-}chel}$ for the one-to-one aluminium complexes of phosphinate, phosphite and phosphate from the peak area ratios in the ^{31}P NMR spectra (Table 3). For evaluation of $K_{non\text{-}chel}$, protonation constants of the free ligands from the literature[8] were used. The conventional stability constants, K_1, were also calculated and are presented in the table for comparison. As can be seen from the table, the $K^{chel}_{non\text{-}chel}$ values occur in increasing order aluminium–phosphinate < –phosphite < –phosphate, reflecting a higher probability of oxygen binding in oxygen-rich ligands. However, this tendency did not seem very remarkable, in comparison with the difference in stability constants for these three ligands. This may be due to the fact that much more energy is required to remove water molecules from oxygen-rich ligands of higher charge coordinated to a metal ion.

Table 3. Stability constants of 1 : 1 complexes at $I = 0.1$, pH 2 and 20°C

	$K^{chel}_{non\text{-}chel}$	$K_{non\text{-}chel}$	K_1
Al^{3+}–$PH_2O_2^-$	2.8	63	2.4×10^2
Al^{3+}–PHO_3^{2-}	3.7	2.8×10^5	1.3×10^6
Al^{3+}–PO_4^{3-}	3.9	3.7×10^{16}	1.8×10^{17}

(*Received* 19 *July* 1990; *accepted* 2 *November* 1990)

Abstract—Photochemically-initiated oxidative fission of the Mo—Mo bond in $[C_5H_5Mo(CO)_3]_2$ by the ferricenium salt $[(C_5H_5)_2Fe]BF_4$ in the presence of four equivalents of L affords a good yield of $[C_5H_5Mo(CO)_2L_2]BF_4$ (L = group 15 donor ligands). ^{95}Mo NMR data are reported and discussed together with the NMR and IR data of new complexes. Decomposition of the title cations in polar solvents affords low yields of the corresponding $[C_5H_5Mo(CO)_3L]BF_4$ complexes. The X-ray crystal structure of $[C_5H_5Mo(CO)_3\{P(C_6H_5)_3\}]BF_4$ is reported. The cation has the $CpML_4$ piano-stool geometry.

In contrast to the well investigated cationic iron complexes $[C_5H_5Fe(CO)_{3-n}L_n]X$,[2] cationic molybdenum complexes of the type $[C_5H_5Mo(CO)_{4-n}L_n]X$ have attracted much less interest.[3] Known complexes of the type $[C_5H_5Mo(CO)_2L_2]X$ with L = group 15 donor ligands have been obtained by different methods: by photochemically-initiated disproportionation of $[C_5H_5Mo(CO)_3]_2$ in the presence of L ($X = [C_5H_5Mo(CO)_3]^-$) followed by anion exchange in some cases;[4] from the protonation of $C_5H_5Mo(CO)_3CH_3$ with HBF_4·ether in the presence of L = $NCCH_3$ (X = BF_4);[5] from $C_5H_5Mo(CO)_3X$ (X = halide) and two equivalents of L in refluxing non-polar solvents;[6] or from the oxidative fission of the Mo—Mo bond in $[C_5H_5Mo(CO)_3]_2$ by AgX salts (X = BF_4 or PF_6) in the presence of L.[7] All these methods have the major disadvantage that they are not normally generally applicable because of special conditions, requirements for L or the price of anhydrous AgX salts. However, during our attempts to develop new routes to cationic organometallic complexes,[8] we found a new, more general preparation of the title complexes by photochemically-initiated oxidative fission of the Mo—Mo bond in $[C_5H_5Mo(CO)_3]_2$; by ferricenium cations in the presence of L. This method makes $[C_5H_5Mo(CO)_2L_2]X$ (X = BF_4, PF_6 or SbF_6) complexes and their chemistry accessible[9] and we now report results from a ^{95}Mo NMR investigation of these complexes.

EXPERIMENTAL

Materials

$[C_5H_5Mo(CO)_3]_2$ [I (Strem)], $E(C_6H_5)_3$ [II, E = P, As, Sb (Aldrich) and E = Bi (Alfa)], PR_3

* See ref. 1.

‡ Present address: Bensberger Str. 15A, D-5064 Rösrath, F.R.G.

[**II**, R = CH_3, C_2H_5, i-C_3H_7, t-C_4H_9 (Strem), OCH_3 (Aldrich)] and $[(C_6H_5)_2PCH_2]_2$ [**II** (Aldrich)] were obtained from commercial sources and used without further purification. $[(C_5H_5)_2Fe]BF_4$ (**IV**)[10] was prepared and purified as described in the literature. All reactions were conducted in oven-dried Schlenk tubes using dried and degassed solvents under nitrogen.

Instrumentation

^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded on Varian XL-300 spectrometers as *ca* 5% solutions in dried and degassed acetone-d_6 vs internal TMS (^1H and ^{13}C) or external 85% H_3PO_4 (^{31}P) as reference. ^{95}Mo NMR spectra were obtained at room temperature on a Bruker AM-500 spectrometer equipped with a broad band tunable probe (^{95}Mo: 32.6 MHz, 90° pulse width 35 μs and using an aquisition delay of 34 μs to reduce probe ringing) in $CDCl_3$–CH_2Cl_2 solutions (*ca* 0.04 M). The external standard was 2 M Na_2MoO_4 at pH 11. IR spectra, ν(CO), were recorded in 1,2-$Cl_2C_2H_4$ solution on a Perkin–Elmer 298 IR spectrometer in 0.1 mm CaF_2 cells and were calibrated against a polystyrene standard. Microanalysis for all new complexes were carried out by Dornis und Kolbe, Mülheim (F.R.G.).

Synthesis

All $[C_5H_5Mo(CO)_2L_2]BF_4$ complexes [**VI(a)**–**VI(j)**] were obtained from the following general method. To a solution of 1.0 g (2.0 mmol) $[C_5H_5Mo(CO)_3]_2$ (**I**) in 40 cm^3 1,2-$Cl_2C_2H_4$ were added 5.0 mmol (1.25 equivalents) of **II** (for L = $[(C_6H_5)_2PCH_2]_2$ only 2.5 mmol) and 1.1 g (4.0 mmol) $[(C_5H_5)_2Fe]BF_4$ (**IV**). The resulting solution was then UV irradiated until the colour changed from red (**I**) to yellow–brown (**VI**; about 0.5 to 1.5 h). Filtration followed by concentration to 1/3 *in vacuo* and addition of excess ether precipitated the cationic complexes **VI** with yields > 90%. For further purification, the solids were washed several times with ether to remove any remaining free ligand and recrystallized from CH_2Cl_2–ether (1/2 to 1/4) at 0°C.

Spectroscopic and analytical data for all new complexes

$[C_5H_5Mo(CO)_2\{P(C_2H_5)_3\}_2]BF_4$ [**VI(b)**]. ^1H NMR: δ 5.68 [br t, C_5H_5; J(P, H) = 1.4 Hz], 2.19 [5 line m, PCH_2; J(H, H) = J(P, H) = 7.6 Hz], 1.22 [5 line m, CH_3 on PC_2H_5; J(H, H) = 7.6 Hz] ppm. $^{13}C\{^1H\}$ NMR: δ 236.13 [t, MoCO; J(P, C) = 26 Hz], 94.14 (s, C_5H_5), 23.15 [pseudo t, PCH_2; J(P, C) = 14.7 Hz], 7.08 [d, CH_3 on PC_2H_5; J(P, C) = 4.7 Hz] ppm. $^{31}P\{^1H\}$ NMR: δ 40.0 (s) ppm. IR spectrum: 1964, 1885, ν(CO), cm^{-1}. Found: C, 42.5; H, 6.6. Calc. for $C_{19}H_{35}BF_4MoO_2P_2$: C, 42.3; H, 6.5%.

$[C_5H_5Mo(CO)_2\{P(CH_3)_2C_6H_5\}_2]BF_4$ [**VI(c)**]. ^1H NMR: δ 7.74, 7.57 (m, PC_6H_5), 5.48 [t, C_5H_5; J(P, H) = 1.3 Hz], 2.16 [pseudo d, PCH_3; J(P, H) = 9.9 Hz] ppm. $^{13}C\{^1H\}$ NMR: δ 234.48 [t, MoCO; J(P, C) = 27.0 Hz], 138.4 (br m, C-1), 131.45 (s, p-C), 130.41 [t, o-C; J(P, C) = 4.5 Hz], 129.58 [t, m-C; J(P, C) = 5.2 Hz], 94.60 (s, C_5H_5), 19.58 [pseudo t, PCH_3; J(P, C) = 17.7 Hz] ppm. $^{31}P\{^1H\}$ NMR: δ 22.2 (s) ppm. $[C_5H_5Mo(CO)_2\{P(C_6H_5)_2CH_3\}_2]BF_4$ [**VI(d)**]. ^1H NMR: δ 7.61 to 7.51 (m, 10H, PC_6H_5), 5.51 [t, C_5H_5; J(P, H) = 1.3 Hz], 2.49 [pseudo d, PCH_3; J(P, H) = 8.9 Hz] ppm. $^{13}C\{^1H\}$ NMR: δ 234.16 [t, MoCO; J(P, C) = 28 Hz], 135.1 (br m, C-1), 132.35 [t, o-C; J(P, C) = 4.8 Hz], 131.85 (s, p-C), 129.57 [t, m-C; J(P, C) = 5.3 Hz], 95.41 (s, C_5H_5), 20.2 (br s, PCH_3) ppm. $^{31}P\{^1H\}$ NMR: δ 38.7 (s) ppm. IR spectrum: 1975, 1896, ν(CO) cm^{-1} Found: C, 56.7; H, 4.6. Calc. for $C_{33}H_{31}BF_4MoO_2P_2$: C, 56.4; H, 4.4%.

$[C_5H_5Mo(CO)_2\{P(OCH_3)_3\}_2]BF_4$ [**VI(i)**]. ^1H NMR: δ 5.80 (br s, C_5H_5), 3.77 (br s, 9H, $POCH_3$) ppm. $^{13}C\{^1H\}$ NMR: δ 230.66 [t, MoCO, J(P, Cl = 40.1 Hz], 93.87 (s, C_5H_5), 54.99 (br s, $POCH_3$) ppm. $^{31}P\{^1H\}$ NMR: δ 177.0 (s) ppm. IR spectrum: 1929 [br, ν(CO)] cm^{-1}. Found: C, 29.0; H, 4.4. Calc. for $C_{13}H_{23}BF_4MoO_8P_2$: C, 28.3; H, 4.2%.

$[C_5H_5Mo(CO)_2\{(C_6H_5)_2PCH_2\}_2]BF_4$ [**VI(g)**]. NMR data were remeasured in acetone-d_6; for analytical data see the literature.[9] ^1H NMR: δ 7.83 to 7.48 (m, 20H, PC_6H_5), 5.01 (s, C_5H_5), 2.42, 3.31 (each br m, 2 H, PCH_2) ppm. $^{13}C\{^1H\}$ NMR: δ 238.44 [t, MoCO; J(P, C) = 13.7 Hz], 137.29, 132.22 [both t, inequivalent C-1; J(P, C) = 24.3, 25.0 Hz], 132.23, 131.53 (both s, inequivalent p-C), 133.67, 131.02 [both t, inequivalent o-C; J(P, C) = 5.2, 5.1 Hz], 130.02, 129.52 [both t, inequivalent m-C; J(P, C) = 5.3, 4.9 Hz], 95.57 (s, C_5H_5), 29.92 [t, PCH_2; J(P, C) = 21.5 Hz] ppm. $^{31}P\{^1H\}$ NMR: δ 76.6 (s) ppm. IR spectrum (1,2-$Cl_2C_2H_4$): 1987, 1921, ν(CO), cm^{-1}.

For complete analytical and spectroscopical data for all other complexes of **VI** see the literature.[8,9]

Crystal structure determination

A brown block-like crystal of $[C_5H_5Mo(CO)_3\{P(C_6H_5)_3\}]BF_4$ (**VII**) suitable for X-ray crystallo-

graphy with the approximate dimensions $0.50 \times 0.33 \times 0.25$ mm was obtained from the repeated recrystallization of $[C_5H_5Mo(CO)_2\{P(C_6H_5)_3\}_2]BF_4$ from acetone–CH_2Cl_2–ether (see text).

Crystal data

$C_{26}H_{20}BF_4MoO_3P$, monoclinic, $a = 12.798(1)$, $b = 10.302(2)$, $c = 19.598(3)$ Å, $\beta = 96.55(1)°$, $U = 2567.1$ Å^3, space group $P2_1/c-C^5_{2h}$ (no. 14), $Z = 4$, $M = 594.17$, $D_c = 1.54$ g cm^{-3}, $\mu = 6.1$ cm^{-1}, $F(000) = 1192$.

Measurements

Refined unit cell parameters were obtained by centring 25 reflections on a Syntex $P2_1$ diffractometer. Using the θ–2θ scan measuring routine, 6287 independent reflections (up to $2\theta = 55°$) were measured with Mo-K_α radiation (graphite crystal monochromator).

Structure analysis

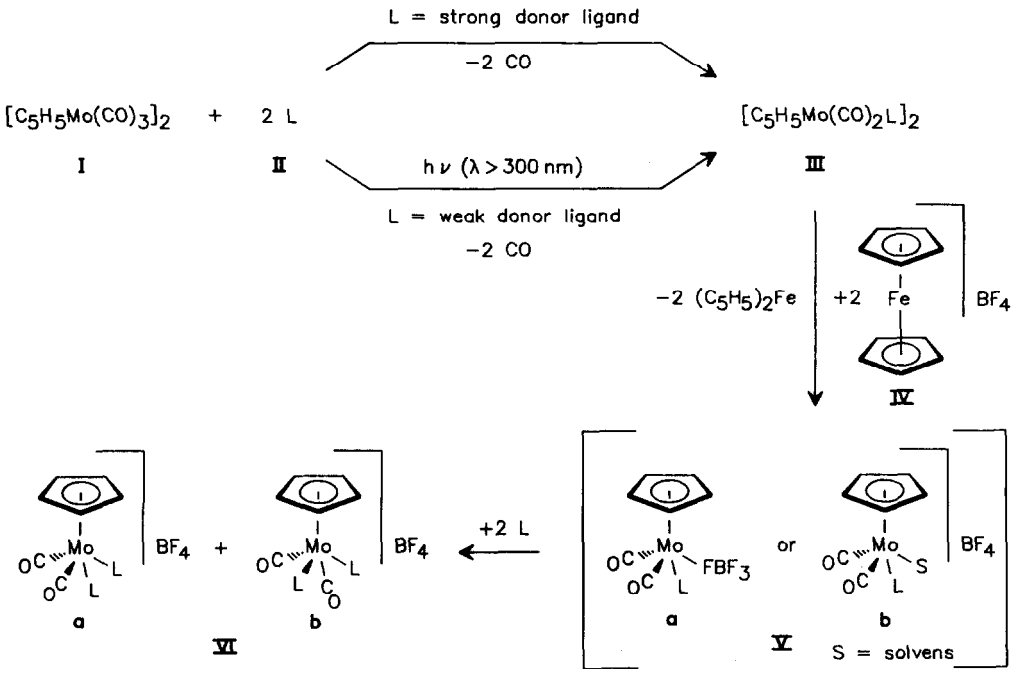
The structure was solved by the Patterson heavy-atom method which revealed the position of the molybdenum atom. The remaining atoms were located in succeeding difference Fourier syntheses. The structure was refined by full-matrix least-squares. Hydrogen atoms were included but constrained to ride on the carbon atom to which they are bonded. Only the 4044 reflections which had $F_o^1 > 3\sigma(F_o^2)$ were used in the refinements, which converged to give $R = 0.041$ and $R_w = 0.051$. Computations were carried out on a VAX computer using SDP/VAX programs.[11]

Final atomic and thermal parameters, structure factors together with F_o and F_c data have been deposited with the Editor as supplementary material. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Preparative and spectroscopic

The results show that the preparation of cationic $[C_5H_5Mo(CO)_2L_2]BF_4$ complexes with group 15 ligands (L) is readily achieved in high yields by oxidative fission of the Mo—Mo bond in $[C_5H_5Mo(CO)_3]_2$ by the ferricenium ion. As indicated in Scheme 1, the reaction clearly depends on the donor/acceptor properties of L: with strong donor ligands, **II** and **I** react directly to form the spectroscopically observed intermediate $[C_5H_5Mo(CO)_2L]_2$ (**III**)[9] while weaker donor ligands need photochemical irradiation to form **III**. Oxidation of **III** with two equivalents of $[(C_5H_5)_2Fe]^+$ (**IV**) may first afford the suggested intermediate **V**. For **V**, two different structures are possible: the unsaturated 16e complex may be stabilized either by coor-



Scheme 1.

dination of the BF_4 anion [structure **V(a)**];[12] or by coordination of a solvent molecule, S [structure **V(b)**], e.g. S = CH_2Cl_2 or acetone.[13] Both structures should be quite reactive and therefore react rapidly with the still present second equivalent of ligand to form *cis*- and/or *trans*-$[C_5H_5Mo(CO)_2L_2]^+$ [**V(a)** and **V(b)**]. The observed mixture of *cis*/*trans* isomers may arise from the intermediary of a cationic six-coordinated intermediate $[C_5H_5Mo(CO)_2L]^+$ (under the assumption that C_5H_5 occupies three coordination sites)[14] prior to the formation of seven-coordinated **V** (only the *cis* form is shown). "Small" ligands (L) such as alkyl-substituted phosphanes and phosphites afford exclusively *cis*-disubstituted complexes of **VI** while sterically more demanding ligands such as aryl-substituted ligands afford mixtures of both, with a dominance of the *cis* isomers.[15]

All complexes of **VI** were obtained in > 90% yield as yellow–brown powders which afford yellow air stable crystals after recrystallization. The complexes are very soluble in common polar solvents such as methylene chloride, acetone or nitromethane but prolonged stirring in the weak donor solvents acetone, nitromethane or dimethylsulphoxide causes decomposition with formation of the related $[C_5H_5Mo(CO)_3(L)]BF_4$ complexes in low yield. The preparation method failed for L = $P(C_3H_7\text{-i})_3$, $P(C_4H_9\text{-t})_3$ and $P[N(CH_3)_2]_3$. In all these cases, only unidentified C_5H_5- and CO-free decomposition products were obtained which can be explained by their strong donor/weak acceptor properties together with their increasing size.

The spectroscopic data obtained for all new complexes of **VI** (see Experimental) are unexceptional and in agreement with their structure. More informative are the ^{95}Mo NMR data given in Table 1 (for a general introduction to ^{95}Mo NMR spectroscopy see reference 16).

All observed ^{95}Mo NMR data are found within a relatively small range between −1687 and −1470 ppm as expected for mononuclear molybdenum(II) complexes with line widths ($H_{1/2}$) between 165 Hz [**VI(b)**] and 650 Hz [**VI(d)**, see Figs 1 and 2]. Due to the comparable small values of $^1J(^{95}Mo, ^{31}P)$ = 133–220 Hz, these couplings are only resolved in complexes **VI(b)** (*ca* 100 Hz) and **VI(i)** (170 Hz). In general, all complexes except **VI(j)** (shift *ca* 300 ppm) are shifted down field by *ca* 150 ppm with respect to the related molybdenum complexes *cis*-$Mo(CO)_4L_2$ and the coupling constants $^1J(^{95}Mo, ^{31}P)$ are of comparable size.[16] Due to the lower symmetry of complexes of **VI** with respect to *cis*-$Mo(CO)_4L_2$ and the known influence of symmetry on the line width,[16] the unresolved coupling $^1J(^{95}Mo, ^{31}P)$ for **VI** may be explained. Comparison of the chemical shift values for complexes of **VI** with data of other $C_5H_5Mo^{II}(CO)_2(L,L)$ complexes containing chelating carbon–nitrogen, dinitrogen or disulphur ligands (δ ^{95}Mo *ca* −560 to −130 ppm and $H_{1/2}$ = 70–160 Hz)[17] show that the title cations are shielded by well over 1000 ppm. This large difference may be explained at least in part by the

better acceptor properties of the ligands used in this work.

Further comparison of ^{95}Mo NMR data with other spectroscopic data which are also regarded as indicative for the bonding situation Mo—L[15] indicate no overall correlation with respect to a general application of ^{95}Mo NMR as a probe for ligand properties.

During attempts to obtain single crystals of complex **VI(e)** suitable for X-ray structure determination for comparison with the known structure of cation **VI(a)**[18] by repeated crystallization from CH_2Cl_2–acetone–ether mixtures, yellow crystals were obtained. The following structure determination identified these crystals subsequently as $[C_5H_5Mo(CO)_3\{P(C_6H_5)_3\}]BF_4$ (**VII**). The formation of **VII** may be rationalized as the result of the labile Mo—L bond in polar solvents under partial ligand replacement [possibly via a complex such as **V(b)**] followed by decomposition under CO release. Part of the released CO substitutes the coordinated solvent under formation of **VII**. Control experiments reveal the general nature of this observation; stirring of complexes **VI(c)**–**VI(i)** in acetone or acetonitrile solution for a prolonged period of time caused extensive decomposition of complexes related to **VII** to be observed.

The structure of $[C_5H_5Mo(CO)_3\{P(C_6H_5)_3\}]BF_4$ **(VII)**

As shown in Fig. 3, this cation belongs to the class of $C_5H_5MoL_4$ complexes with a four-legged piano-stool geometry around molybdenum for which a wide series of structural determinations were performed[19] and theoretical aspects discussed in detail.[20] For comparison, selected bond lengths and bond angles are given in Table 2 together with those for the related pentamethylcyclopentadienyl complex $[C_5(CH_3)_5Mo(CO)_3\{P(C_6H_5)_3\}]^+$.[21]

The data indicate a very close resemblance of both complexes in all major bond distances and angles within the standard deviation, and need no further discussion. As noted before,[21] the Mo—P

bond is slightly longer than in the comparable neutral $C_5H_5Mo(CO)_2P(C_6H_5)_3$ complexes (2.48–2.52 Å)[22] which may be attributed to the cationic nature of both complexes.

FTIR STUDY OF NOVEL PALLADIUM TRIMETHYLPHOSPHINECARBONYL CLUSTERS ENCAGED IN ZEOLITE Y

ZONGCHAO ZHANG and WOLFGANG M. H. SACHTLER*

Ipatieff Laboratory, Center for Catalysis and Surface Science, Northwestern University, Evanston, IL 60208, U.S.A.

(*Received* 24 *September* 1990; *accepted* 7 *November* 1990)

Abstract—Green palladium trimethylphosphinecarbonyl (TMPC) clusters in zeolite Y have been prepared using a "ship-in-a-bottle" method. Trimethylphosphine (TMP) ligands stabilize palladium clusters of small nuclearity; they preferentially coordinate to the corner palladium atoms. Absorption bands of triply-bonded carbonyl (1886 cm^{-1}) are observed only for samples with initially large palladium nuclearity ($n > 4$). Bands at 1960 and 1950 cm^{-1}, attributed to doubly-bonded carbonyl in a butterfly configuration, dominate the IR spectra. The palladium core in palladium TMPC clusters is electron-rich, in comparison to palladium single crystals, due to electron donation from phosphorus to the palladium. The spectra of the zeolite encaged clusters differ from those reported for Pd TAPC (A = alkyl such as ethyl and butyl) clusters in solution with nuclearity varying from 4 to 38. Zeolite encaged Pd TMPC clusters are stable at 200°C in a flow of H_2+CO. At 300°C, the TMP ligands decompose and poison the palladium particles.

Palladium carbonyl clusters are known to be unstable under normal conditions.[1] They have never been prepared from solution, but Pd_nCO and $Pd_n(CO)_2$ have been detected in molecular beams.[2] In solids, their stabilization strictly requires inert isolation matrices, such as frozen inert gases at 20 K[1] or in zeolites.[3–5] Using EXAFS and FTIR, we recently discovered that the size of the palladium carbonyl clusters is determined by the diameter of the supercage in zeolite Y, the α-cage in zeolite A, and also by the dimensions of the windows in both zeolites.[6,7] Palladium particles of nuclearity 1–6 atoms have been found for unligated clusters after mild reduction procedures. The stabilization of the extremely small palladium metal particles has been attributed to the strong metal zeolite interaction (SMZI).[6,7] However, palladium carbonyl clusters have invariably been found to have a nuclearity of at least 13 atoms in NaY, irrespective of the original particle size prior to admission of CO at room temperature. The mobility and instability of the primary palladium carbonyl clusters cause them to coalesce in the supercages of zeolite Y. Apparently, further migration of $Pd_{13}(CO)_x$ is restricted by the diameter of the supercage windows.[3–5] Thermal expansion of this window at a higher temperature leads to further particle growth, up to an average nuclearity of about 40 atoms per palladium cluster.[6,7] By selecting a zeolite of comparable cage size, but of smaller window diameter than zeolite Y, for example zeolite 5A, six-atom palladium carbonyl clusters have been stabilized by introducing CO at room temperature to pre-reduced palladium in zeolite 5A.[8]

In catalytic reactions, the large dimensions of the supercage and window diameters are desired for the passage of molecules of moderate size. Stabilization of palladium clusters with cores that are smaller than the cage windows can conceivably be achieved by introducing large and strong-bonding ligands, such as trialkylphosphines (TAP), to the primary metal particles which have been previously reduced inside the zeolite. The examination of this concept forms the main incentive for the work described in the present paper. In addition, the unique catalytic performance of rhodium triphenylphosphine (TMP) complexes in hydrogenation and hydroformylation reactions[9,10] motivates experimental work on TAP addition to reduced PdNaY, in the hope that this

*Author to whom correspondence should be addressed.

might lead to superior palladium catalysts for hydroformylation or related CO-conversion reactions.

In organic solvents, Pd_n^0 trialkylphosphinecarbonyl (TAPC) complexes of $n = 4$–38 have been prepared.[11–14] The preparation generally involves reduction of Pd^{2+} precursor compounds under a CO atmosphere and in the presence of TAP. In addition, the palladium nuclearity in the Pd TAPC complexes varies with the phosphine/carbonyl ligand ratio. In zeolites, however, palladium ionic precursors can be reduced to Pd^0 by hydrogen, prior to the admission of TAP and CO. As mentioned, unlike organic solvents, rigid zeolite cages can stabilize clusters of low nuclearity. The entrapment of Pd TAPC clusters in the zeolite framework provides a means of manufacturing a heterogeneous catalyst that avoids the need of reaction product and catalyst separation.

In the present study, faujasite type zeolite NaY is used as the stabilizing matrix. Palladium trimethylphosphinecarbonyl (TMPC) clusters are generated by the "ship-in-a-bottle" method, after prereducing the palladium ionic precursor with hydrogen.

EXPERIMENTAL

PdNaY samples (5 wt% Pd) were prepared using ion exchange techniques. A solution containing 0.01 M $Pd(NH_3)_4^{2+}$ ions [AESAR, $Pd(NH_3)_4(NO_3)_2$] was added dropwise into a slurry of NaY [200 cm^3 of doubly-distilled water (DDW) per gram of zeolite] at room temperature. Ion exchange was allowed to proceed for 24 h. The sample was filtered and washed with DDW to remove the NO_3^- ions. After drying in air, the sample was stored in a desiccator over a saturated NH_4Cl solution.

Samples were made into self-supporting wafers of 20 mg cm^{-2}. Sample wafers were supported on a quartz holder inside a pretreatment chamber. They were calcined to specified temperatures (T_c) in a flow of 200 cm^3 min^{-1} O_2 and at a heating rate of 0.5°C min^{-1}, followed by purging with Ar at T_c for 20 min. After cooling to room temperature, reduction in flowing H_2 was performed by heating at a rate of 8°C min^{-1} from room temperature to a specified temperature (T_R), followed by holding at T_R for 20 min at a flow rate of 60 cm^3 min^{-1}. Following reduction, Ar was introduced at T_R for 20 min to purge adsorbed hydrogen. The samples were then cooled to room temperature and kept under the Ar stream, unless other pretreatment conditions are specified in the text.

Specially designed glassware was used in the admission of $P(CH_3)_3$ after reduction. The Ar flow used to purge the system was switched to flow through a tube containing solid trimethylphosphine (TMP) silver iodide. The TMP silver iodide/Ar system was then slowly heated to 150–200°C to sufficiently saturate the PdNaY wafer. The tube with TMP silver iodide was then closed and the Ar gas was switched back to purge excess TMP in the reactor for 20 min at room temperature. Subsequently, a stream of CO at 1 atm was passed through the system for a specific length of time, as seen in our IR spectra. Each FTIR spectrum was collected after purging the excess CO with Ar for 10 min, using a Nicolet 60SX single-beam Fourier transform IR spectrometer (resolution: 1 cm^{-1}).

RESULTS

Samples are labelled $T_c/T_R/P$, where T_c is the calcination temperature, T_R the reduction temperature and P stands for the TMP treatment. For the samples that are further treated under a mixed flow of H_2 and CO at various reaction temperatures, T_{RXN}, the notation $T_C/T_R/P/T_{RXN}$ will be used. FTIR spectra of CO absorption were obtained by subtracting the background spectrum of the palladium zeolite sample after adsorption of TMP, followed by Ar purge from the spectra, obtained after introducing CO at various lengths of time. The FTIR spectra of sample 500/250/P after CO admission for various lengths of time on stream are shown in Fig. 1. It is evident from the spectra

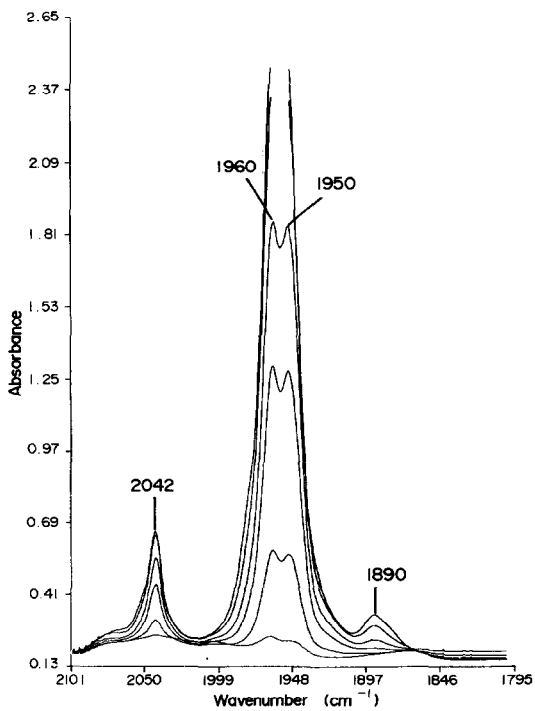

Fig. 1. CO FTIR spectra of sample 500/250/P after time on stream in CO for 1, 11, 41, 71, 131 and 191 min (from bottom to top).

that the CO absorption intensity increases with time during constant CO flow at 1 atm. The prominent peaks are the twin bands at 1960 and 1950 cm^{-1}. Two much less intense bands at 1890 and 2042 cm^{-1} are observed after extended exposure to CO. The twin bands at 1960 and 1950 cm^{-1} are off scale after 131 and 191 min, respectively, during CO exposure.

To determine the thermal stability of the Pd TMPC clusters in zeolite Y, sample 500/250/*P* was heated at 200°C for 5 min in a flow of H_2/CO (about 30 cm^3 min^{-1} each). This was followed by an Ar purge at the same temperature for an additional 5 min before cooling to room temperature under Ar. The spectrum of this sample (500/250/*P*/200) is shown in Fig. 2(A). The twin bands are off scale, but the bands at 2042 and 1890 cm^{-1} have increased slightly. The samples 500/250/*P*/250 and 500/250/*P*/300 were treated similarly to sample 500/250/*P*/200, and their FTIR spectra are shown in Fig. 2 as traces B and C, respectively. The band intensities for 500/250/*P*/250 have dropped significantly and for 500/250/*P*/300 all bands have completely disappeared. A series of colour changes were observed in the following sequence: The colour of the sample is orange after calcination to 500°C. After reduction, the catalyst turns grey. Introduction of TMP to the reduced sample does not change the colour. However, after CO admission, the colour of the sample gradually changes to green. When the sample is heated under a flow of CO and H_2 at 200°C, the same sample turns bright green, at 250°C it turns dark green, and at 300°C it turns black.

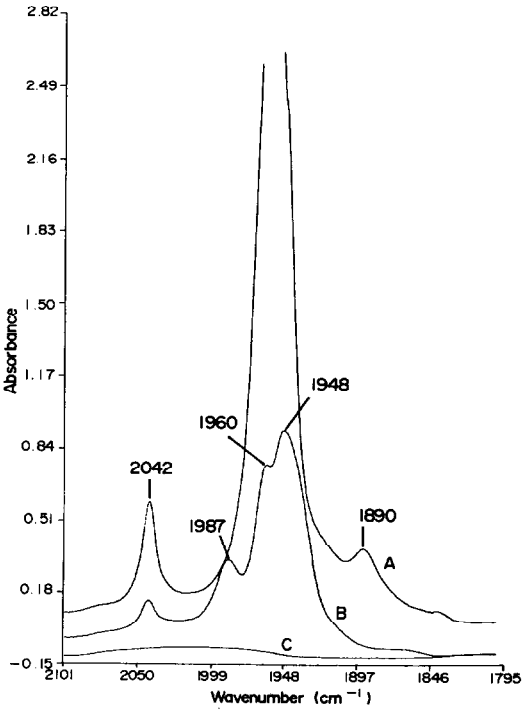

Fig. 2. CO FTIR spectra of samples 500/250/*P*/200 (A), 500/250/*P*/250 (B) and 500/250/*P*/300 (C).

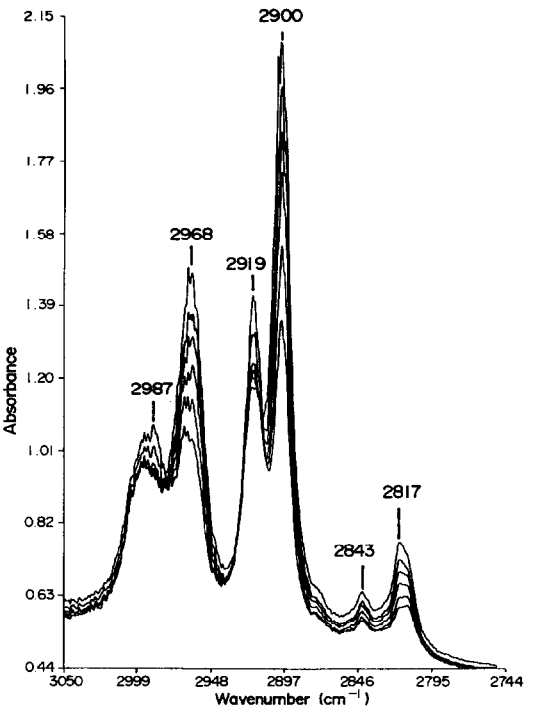

Fig. 3. CH FTIR spectra of sample 500/250/*P* after time on stream in CO for 1, 11, 41, 71, 131 and 191 min.

Figure 3 shows the absorption bands for the C—H vibration of $P(CH_3)_3$ in sample 500/250/*P*. There are six major bands at 2987, 2968, 2919, 2900, 2843 and 2817 cm^{-1}. With increasing time on stream in CO at room temperature, the bands at 2900, 2968, 2843 and 2817 cm^{-1} decrease, while the bands at 2919 and 2987 cm^{-1} increase.

The spectrum in Fig. 4(A) was recorded for sample 500/250/*P* after 191 min on stream in CO at room temperature. Figure 4(B), (C) and (D) are the spectra of 500/250/*P*/200, 500/250/*P*/250 and 500/250/*P*/300, respectively. The bands at 2900 and 2968 cm^{-1} decrease rapidly and shift to higher wavenumbers (2905 and 2973 cm^{-1}) as the reaction temperature increases. By 300°C, the C—H absorption bands disappeared altogether, concomitant with the disappearance of the CO absorption bands as shown in Fig. 2. The spectra of the C—H vibration for samples at a variety of T_c and T_R values are very similar to those displayed in Figs 3 and 4; therefore they are not included.

The CO absorption spectra for the sample 250/250/*P* are shown in Fig. 5. Again, the twin bands appear at 1960 and 1951 cm^{-1} and their intensities increase with time on stream in CO. A linear band appears at 2042 cm^{-1}. In addition, one

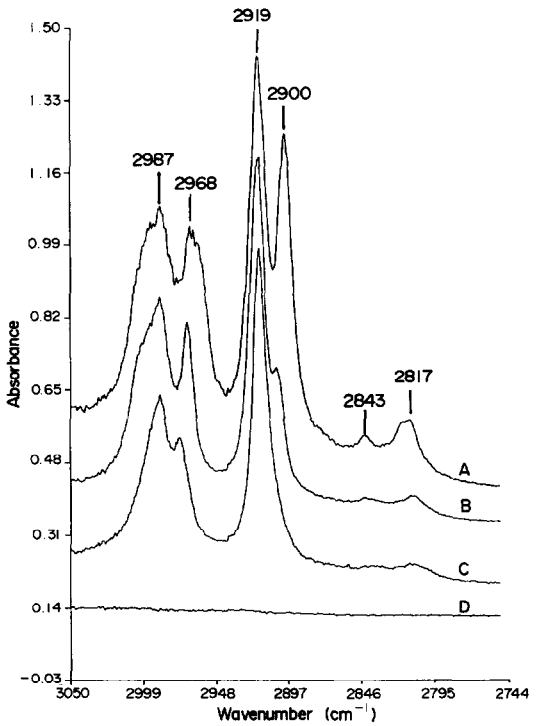

Fig. 4. CH FTIR spectra of samples 500/250/*P* (A), 500/250/*P*/200 (B), 500/250/*P*/250 (C) and 500/250/*P*/300 (D).

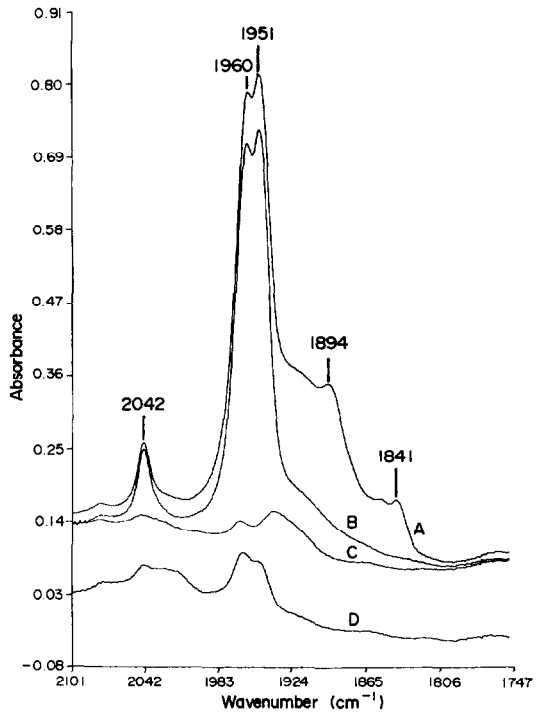

Fig. 6. CO FTIR spectra of sample 250/250/*P*/200 (i) in H_2 and CO (A), (ii) in H_2 only after i (C), and (iii) in H_2 and CO after ii (B); and CO FTIR of 250/250/*P*/250.

band due to linearly-bonded CO and one very broad band, due to triply-bonded CO, were observed as soon as CO was introduced. At 200°C under H_2 and CO flow, the intensities of the twin bands reached a maximum value [Fig. 6(A)], but all the bands could be removed at 200°C by H_2 alone, as shown in Fig. 6(C). The linear and the twin CO bands were restored by introducing CO at 200°C [Fig. 6(B)]. However, the intensity of the bands (1894 and 1841 cm^{-1}) at the triply-bonded region decreased tremendously. The CO band intensities had decreased remarkably at 250°C under CO and H_2 flow. This was also observed for the sample 500/250/*P*.

The difference spectra displayed in Figs 7 and 8 for sample 250/250/*P* were obtained by subtracting the background of the reduced palladium zeolite sample before admission of TMP from those obtained at various lengths of time on stream in CO. A band at 2481 cm^{-1} appears after adsorption of $P(CH_3)_3$. This band remains even after extended time on stream (191 min) during CO purge at room temperature [Fig. 7(A)]. FIgure 8 is the difference spectra due to O—H vibration after admission of TMP. The negative peak in Fig. 8 shows that the O—H band at 3650 cm^{-1} immediately decreased after $P(CH_3)_3$ admission. In fact, before background subtraction, the strong O—H band before

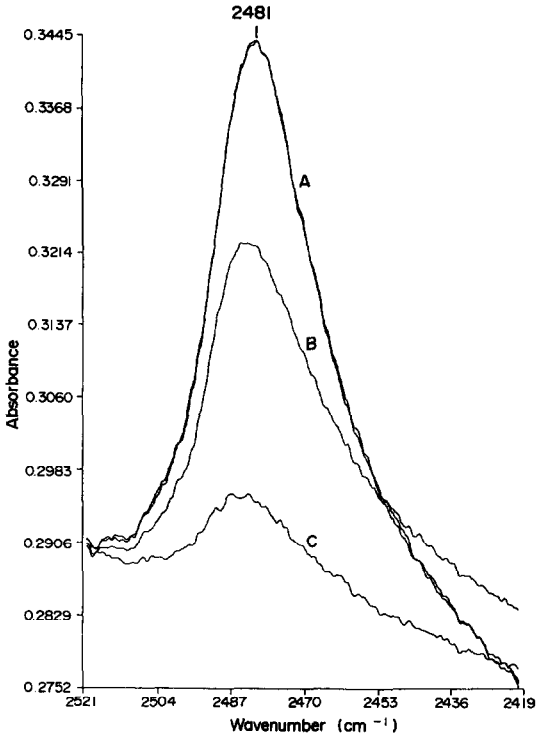

Fig. 7. PH FTIR spectra of 250/250/*P* (A), 250/250/*P*/200 (also A), 250/250/*P*/250 (B) and 250/250/*P*/300 (C).

admission of TMP completely disappeared as soon as TMP was introduced to the system. This indicates total neutralization of the protons in the sample by TMP molecules. Further treatment at both 200 and 250°C under CO and H_2 flow led to a decrease of the P—H band at 2481 cm^{-1}. However, the intensity of the negative band in Fig. 8 did not change. Similar absorption behaviour was observed for all other samples (not shown) except that the intensities differ. For example, samples that were reduced at 500°C have much lower band intensities at 2481 and 3650 cm^{-1}.

Figure 9 shows the IR absorption of the CO ligands in sample 500/500/*P*. The linear CO band at 2042 cm^{-1} and the twin bands at 1960 and 1949 cm^{-1} follow the same trends as those bands observed for samples 500/250/*P* and 250/250/*P*. In sample 500/500/*P*, a broad band is observed near the triply-bonded CO region (1848 cm^{-1}) immediately after the admission of TMP. With time on stream in CO flow, a band (at 1885 cm^{-1}) appears on top of the broad band. The reaction temperature effect is shown in Fig. 10. The intensities of the linear CO band and the doubly-bridged CO twin bands again reached a maximum at 200°C, and then decreased at 250°C, remaining consistent with all other samples previously run. The two low frequency bands after treatment at 200°C are located

at 1878 and 1837 cm^{-1} but at 250°C the bands are observed at 1853 and 1837 cm^{-1}, respectively.

The CO absorption spectra of 250/500/*P* are shown in Fig. 11. Again, they are similar to those spectra of 500/500/*P*. After high temperature reaction, spectra are similar to the ones presented above and are, therefore, not shown.

An unreduced sample was exposed to TMP after calcination and Ar purge at 500°C. This sample is referred to as 500/*P*. The spectra of CO absorption recorded at various times on stream are shown in Fig. 12. The sample mainly shows the doubly-bridged CO twin peaks with very weak linear and triply-bound CO absorption. The reaction products of CO and H_2 at high temperature were not analysed in this IR study. It will be the subject of future research.

DISCUSSION

IR and NMR studies have been reported on the characterization of zeolite acidity using TMP as a probe molecule.[15-18] The IR absorption in the region between 2800 and 3000 cm^{-1} is generally attributed to the C—H vibration in $P(CH_3)_3$.[15] Even though the total absorption decreases with time on stream in CO, the fact that the bands at 2968 and 2900 cm^{-1} decrease concomitant with the increase of the bands at 2987 and 2918 cm^{-1} (Fig

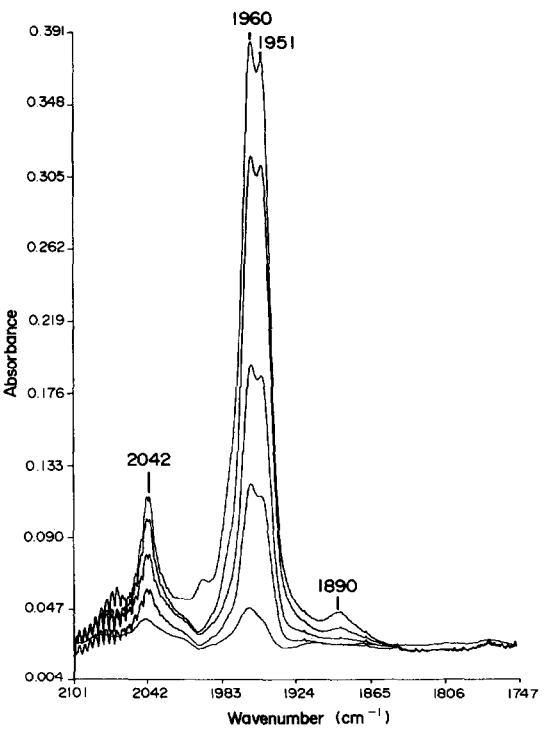

Fig. 12. CO FTIR spectra of 500/*P* after time on stream in CO for 10, 40, 70, 130 and 190 min (from bottom to top).

3 and 4) suggests that there are two main types of C—H bond. The monotonically decreasing bands at 2843 and 2817 cm^{-1} may correspond to another minor portion of $P(CH_3)_3$, which interacts with the zeolite differently from the other two.

The studies by Lunsford and co-workers[16–18] and Schoonheydt *et al.*[15] have revealed the existence of several TMP adducts: phosphonium ions, such as $[(CH_3)_3PH]^+$, $[(CH_3)_3PNa]^+$ and (Si—)(Al—)O—$P(CH_3)_3$, along with TMP oxide, $(CH_3)_3PO$. In the present study, the Pd—$P(CH_3)_3$ interaction also exists. Unfortunately, the present data do not allow for a clear assignment of the C—H absorption associated with the Pd—$P(CH_3)_3$ adducts. We will pursue this issue in our future study using ^{31}P NMR. From the spectra shown in Figs 7 and 8, we conclude that the zeolitic protons are completely consumed in the formation of the trimethylphosphonium ions. The phosphonium ions with a characteristic P—H absorption band at 2481 cm^{-1} are stable at room temperature in CO flow for an extended period. If these catalysts are heated above 250°C, the trimethylphosphonium ions are partially destroyed, but the zeolitic protons are not restored.

Previous characterization studies of palladium exchanged faujasite zeolites with X-ray diffraction;[19–21] temperature programmed oxidation, reduction and desorption;[22,23] UV–vis diffuse reflectance and EXAFS;[24–26] and FTIR[3–5] have shown that the location and size of the palladium particles are determined by the pretreatment conditions. Palladium ionic precursors are located in the supercages after calcination at temperatures below 250°C. At calcination temperatures (T_c) above 300°C, they migrate swiftly into the sodalite cages. For samples calcined at 250°C and reduced at low temperature, the palladium particles are located in the supercages. For the sample reduced at $T_R = 200$°C, the coordination number determined by EXAFS was 2.4, corresponding to Pd_3 and Pd_4 particles. When the reduction temperature is increased to $T_R = 500$°C, larger palladium particles are generated for samples calcined either at $T_c = 250$ or 500°C. On the other hand, reduced monometallic palladium located in the sodalite cages can be obtained by calcination at $T_c = 500$°C, followed by reduction at $T_R = 200$°C. Above $T_R = 350$°C, the palladium atoms will migrate out of the sodalite cages and coalesce in the supercages. A very interesting phenomenon recently observed is that the admission of CO at room temperature to reduced palladium zeolite samples induces the migration and coalescence of the primary palladium particles to an average of 13 atoms, within wide limits, independent of the sample preparation history.[6,7] The FTIR spectra after CO adsorption on all the above prereduced samples, therefore, results in identical spectra.[3–5]

In the present study, sample 500/250 is expected to have predominantly isolated palladium atoms inside the sodalite cages. The results indicate that, after introduction of TMP, palladium atoms migrate to the supercages, where they become strongly coordinated to the TMP ligands. A migration of palladium atoms from the sodalite cages at room temperature after CO admission has been previously observed.[7] The bond between palladium and phosphorus in Pd—$P(CH_3)_3$ is much stronger than the Pd—CO bond. This follows from the slow replacement of TMP by CO at room temperature under CO flow, as shown in the CO spectra (e.g. Fig. 1). Conversely, when CO was introduced to prereduced samples first, the replacement of CO by subsequently introduced TMP was found to be instantaneous. The large molecular size of the TMP ligand, in combination with the strong Pd—P bond, impede the migration of the primary Pd TMP clusters out of the supercages. Sample 500/250/*P* is, therefore, expected to contain clusters of small palladium nuclearity. In fact, the absence of triply-bonded CO bands in Fig. 1 suggests that the palladium nuclearity is, indeed, extremely small. On the basis of the absence of the linear CO bands in all CO absorption IR spectra, it is evident that TMP preferentially occupies corner positions in the clusters. However, TMP ligands do not limit the adsorption of CO on the Pd(111) sites when large palladium particles are present before the introduction of TMP. This can be rationalized on the basis of the large molecular size of TMP in comparison to CO molecules. In samples 500/500/*P* and 250/500/*P* (Figs 9 and 11), large palladium particles prevail after reduction. After introduction of TMP, the corner palladium atoms are bonded to phosphorus. However, intense CO absorption bands in the triply-bonded region are immediately observed after admission of CO to these samples. For sample 250/250, the nuclearity of palladium is estimated to be close to a tetrahedron on the basis of our previous EXAFS evaluation.[6,7] A triply-bonded CO band is also observed for sample 250/250/*P* (Fig. 5). The increase in intensity for the doubly-bridged CO twin bands with extended CO purge is likely due to purging off some of the physisorbed TMP molecules, which block the cage window, as well as purging off some of the TMP molecules on the palladium cluster. In comparison to the Pd_{13} carbonyl clusters, it is remarkable that the Pd TMPC clusters in zeolite indeed reflect the history of sample preparation.

At 200°C, the maximum intensity of CO absorption and the maintenance of the C—H bands at 2987 and 2918 cm^{-1} (Fig. 4) suggest that the Pd TMPC clusters remain stable at this reaction temperature. At $T_{RXN} = 250°C$, the decrease of the CO absorption bands' intensity and the C—H stretch clearly show the clusters degrading. At 300°C, the total disappearance of the C—H (Fig. 4) and CO absorption bands [Fig. 2(C)] clearly indicates that TMP decomposes and the palladium particles are completely poisoned by the P and CH_x fragments. A colour change was observed which can be directly related to the change of the ligand structure. Pd TMPC clusters in zeolites are green, but the poisoned samples, after destruction of TMP at elevated temperature, are black in colour. It is noted that most reported Pd TAPC clusters in organic solvents show a red colour.[11-14] It has been reported for some $Pd_4(CO)_5(PR_3)_4$ (R = alkyl group) and $Pd_4(CO)_3(PPhMe_2)_4$ in organic solvents that CO ligands are coordinated in butterfly configuration.[11,27] Based on our CO absorption spectra, the butterfly configuration prevails in the present zeolite encaged Pd TMPC clusters. Since there are no other Pd TAPC clusters known to which the present cluster can be compared, the wavenumber (cm^{-1}) of the absorption bands of CO in the closest comparable phosphine system, $Pd_4(CO)_5(PEt_3)_4$, are listed as follows:[28] 2018 v.w., 1889 m, 1874 w, 1844 s, and 1797 sh. This reported cluster has completely different IR identity from our cluster shown in Fig. 1. Only a weak band at 1890 cm^{-1} in Fig. 1 is reminiscent of the 1889 cm^{-1} band of $Pd_4(CO)_5(PEt_3)_4$; while strong triply-bonded bands appear only when the palladium nuclearity is quite large. These striking differences in IR spectra could be due to differences of the environment (organic liquid vs solid zeolite) or of the alkyl groups (Et vs Me). Furthermore, in our sample, the size of the palladium clusters is presumably smaller than those prepared in organic solvents, due to the limited dimension of the zeolite cage structure. The cluster size of our zeolite encaged Pd TMPC will be determined in our future study with EXAFS.

Our previous FTIR studies in palladium zeolite systems have shown that the linear CO absorption on electron-deficient palladium carbonyl clusters is shifted to higher wavenumbers with respect to the CO absorption band on palladium single crystals.[5,29] The terminal CO absorption on palladium single crystals has been reported to vary between 2090 and 2112 cm^{-1}, depending on the type of crystal face.[30,31] The position of the weak linear CO absorption band at 2042 cm^{-1} in the Pd TMPC clusters shows that palladium has become electron-rich in comparison to palladium single crystals. We attribute this to electron donation from phosphorus to palladium. In addition, chemical bonding of palladium clusters with zeolite protons is destroyed by the interaction of acid protons with TMP molecules acting as Lewis bases.

In the preparation of the Pd^0 TAPC clusters in organic solvents, the general strategy involves reduction of Pd^{2+} in various solvents with PR_3 under a CO atmosphere.[11-14] Figure 12 shows that Pd^0 carbonyl TMP clusters in a zeolite can also be prepared using a similar strategy. The spectra shown in Fig. 12 are essentially the same as those in Fig. 1, except the intensity is lower. It is very likely that the coalescence of the palladium cluster via this route is also limited. However, reduction with phosphine may result in undesirable destruction byproducts of phosphines, which may poison the palladium cluster. This may be the cause of the significantly lower intensity in Fig. 12 in comparison to Fig. 1.

Conclusion

Novel Pd TMPC clusters in zeolite Y are prepared using the ship-in-bottle method. TMP molecules stabilize palladium cores of small nuclearity. The FTIR spectra of the clusters, therefore, reflect the sample preparation history. TMP ligands preferentially coordinate to the corner palladium atoms. The absorption bands of triply-bonded CO are observed only for samples with initially large nuclearity ($n > 4$). Butterfly configurations of double-bonded CO prevail for all the CO absorption spectra in IR region. The Pd TMPC clusters are stable at 200°C in a flow of H_2 and CO mixture. At 300°C, the TMP ligands decompose and completely poison the palladium particles.

THE TEMPLATE SYNTHESIS AND CHARACTERIZATION OF NEW HEXADENTATE N_4O_2 ACYCLIC SCHIFF BASE COMPLEXES OF LANTHANUM, PRASEODYMIUM AND NEODYMIUM NITRATES

WANDA RADECKA-PARYZEK* and VIOLETTA PATRONIAK

Faculty of Chemistry, Adam Mickiewicz University, 60-780 Poznań, Poland

(*Received* 4 *July* 1990; *accepted* 26 *November* 1990)

Abstract—The partial Schiff base condensation reactions between 2,6-diacetylpyridine and 1,8-diaminonaphthalene in the presence of lanthanum(III), praseodymium(III) and neodymium(III) nitrates produced the new hexadentate N_4O_2-open chain complexes, which were characterized by IR, UV–vis, ^1H NMR and MS data, in addition to elemental and thermogravimetric analyses.

Interest in exploring the metal ion complexes with Schiff base ligands has continually increased, since it has been recognized that many of these complexes may serve as models for biologically important, naturally occurring ionophores. These synthetic model complexes are divided into macrocyclic (coronates and cryptates) and acyclic (podates) ionophores. The investigations concerning lanthanide complexes with Schiff bases have been devoted to their synthesis and structural studies and biological application of metal–enzyme or protein bindings.[1–6]

As part of our studies on the effectiveness of the metal ions of varying radius and electron configuration in the synthesis of Schiff base ligands, we have found that different experimental conditions (the type of metal, counterion, ratio of starting material) lead to the isolation of the macrocyclic (coronate) or ring-opened (podate) complexes.[7–9] The present paper is concerned with the preparation and characterization of Schiff base complexes of the podate type, formed in the reaction of early lanthanide nitrates with 2,6-diacetylpyridine and 1,8-diaminonaphthalene.

EXPERIMENTAL

The hydrated lanthanum, praseodymium and neodymium nitrates were prepared by dissolving the appropriate 99.99% oxide in nitric acid. The solutions were evaporated and precipitates recrystallized from methanol. 2,6-Diacetylpyridine was purchased from Aldrich Chemical Company and 1,8-diaminonaphthalene from Merck, and were used without further purification.

Preparation of the complexes. General procedure

To a solution of appropriate metal nitrate (0.1 mmol) in methanol (5 cm^3), 2,6-diacetylpyridine (0.33 g, 0.2 mmol) in methanol (10 cm^3) and 1,8-diaminonaphthalene (0.16 or 0.32 g, 0.1 or 0.2 mmol) in methanol (15 cm^3) were added dropwise with stirring. The reaction was continued for 8 h. The solution volume was then reduced to 10 cm^3 by roto-evaporation, and a dark violet precipitate formed on addition of a small amount of anhydrous diethyl ether. This was filtered off, washed with ether and dried *in vacuo*. Yields: 73–79%. The results of elemental analysis of the complexes are listed in Table 1.

Measurements

IR spectra were recorded using CsI pellets in the range 4000–200 cm^{-1} on a Perkin–Elmer 580 spectrophotometer. Electronic absorption spectra were measured on a Beckman 25 spectrophotometer. ^1H NMR spectra were run on a Varian EM-360 60 MHz spectrometer for DMSO-d_6 solutions using TMS as internal standard. Mass spectra were obtained on a Jeol–JMS mass spectrometer. Thermogravimetric measurements were

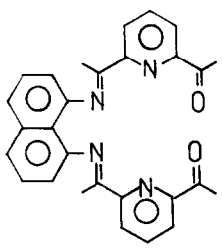
performed using the Derivatograph OD-102, MOM.

RESULTS AND DISCUSSION

The reaction of 2,6-diacetylpyridine with 1,8-diaminonaphthalene with the use of lanthanum, praseodymium and neodymium nitrates as template agents gave the new complexes of stoichiometry $[LaL(NO_3)_3]\cdot 2H_2O$, $[PrL(H_2O)_2](NO_3)_3$ and $[NdL(H_2O)_2](NO_3)_3\cdot 2H_2O$, where L is the acyclic product of a Schiff base condensation of two molecules of diketone with one molecule of diamine.



L

The complexes appear to be dark violet, air-stable solids, soluble in common polar solvents. The formulations of these complexes follow from spectral and thermal analyses, as discussed below, and elemental analysis.

The IR spectra of these three complexes are all very similar except for the anion and water vibrational modes. The most diagnostic band is the C=N stretching mode at 1625 cm^{-1} which indicates the Schiff base condensation. There is no absorption at 3050 and 3350 cm^{-1}, which would occur if residual amine groups were present. The appearance of the band at 1680 cm^{-1}, assigned to the C=O stretching vibration, indicates the formation of the open-chain product containing terminal acetylpyridyl groups. The shift of this band from 1705 cm^{-1} in uncomplexed diacetylpyridine is evidence that the carbonyl groups are coordinated to the metal. The profile of the pyridine ring vibrations observed in the 1600–1400 cm^{-1} region and the band at *ca* 1000 cm^{-1} are typical for metal bonding at the pyridine nitrogen atom.[10] The hexadentate nature of the ligand is further confirmed by the appearance of weak bands around 470–480 and 330–360 cm^{-1}, which can be assigned to ν(M—N) and ν(M—O) vibrations, respectively.[11]

The IR spectrum of the lanthanum complex demonstrates the presence of coordinated nitrates. The two bands associated with the asymmetric stretch appear near 1320 and 1470 cm^{-1}. The magnitude of the separation in addition to the appearance of the band at 1040 and 820 cm^{-1} are indicative of the interaction of the nitrate oxygen atoms with the metal ion, and provide evidence for chelating bidentate behaviour of the nitrate groups in this complex.[12,13]

In the IR spectra of praseodymium and neodymium nitrate complexes, a strong absorption band at 1380 cm^{-1} and medium band at 825 cm^{-1} occur which are typical for uncoordinated nitrate ions.

The broad, diffuse band centred at 3400 cm^{-1} is observed for all three complexes and is assigned to the symmetric and antisymmetric O—H stretching modes for water. Furthermore, the IR spectra of praseodymium and neodymium complexes exhibit weak bands at 840–870 cm^{-1} attributable to the coordinated water molecules. The presence of water bound in different ways is supported by the results of the thermogravimetric analysis. In the case of the lanthanum complex, the loss of two water molecules is observed below 100°C, whereas the praseodymium complex loses two water molecules at 150–170°C. The complex of neodymium indicates the loss of two water molecules per mol of metal ion in the temperature range 160–180°C, and the loss of two molecules at 50–70°C.

The electronic spectra of all the complexes recorded in methanol show similar features, containing three intense and medium bands with maxima at 228, 292–293 and 331–333 nm, which may be assigned to the transition of the $\pi \rightarrow \pi^*$ type located on the C=N groups and to the $n \rightarrow \pi^*$ transition of the carbonyl groups, respectively.[14]

The ^1H NMR spectrum of the diamagnetic complex of lanthanum obtained in DMSO-d_6 solution

shows the presence of pyridine (6H) and naphthalene protons (6H) at δ 8.6–8.2 and 7.2–6.4, respectively. The methyl protons of the two CH_3CO and two CH_3CN groups are observed at δ 2.98 and 2.28. The integrated intensities for all the protons are in the ratio 1 : 1 : 1 : 1, consistent with the proposed formulation of this complex. A downfield shift of the CH_3CO methyl proton resonances from δ 2.72 in the free 2,6-diacetylpyridine is assumed to be a consequence of coordination of the carbonyl oxygen atoms to the metal ion.

The mass spectrum of this complex provides strong evidence for the formation of an open-chain compound, showing the highest fragment at m/z 449 corresponding to the uncoordinated ligand.

On the basis of available evidence it can be concluded that the lanthanum, praseodymium and neodymium ions are effective templates for the synthesis of Schiff base complexes of the podate type, in which the podand acts as the hexadentate N_4O_2 ligand.

In the lanthanum complex, the metal ion is presumably coordinated to the four nitrogen atoms and to the two oxygen atoms of the open-chain ligand and to the six oxygen atoms of the bidentate chelating nitrate groups.

In the complexes of the slightly smaller praseodymium and neodymium ions, the bidentate nitrate groups are replaced by the less hindering water molecules and the coordination sphere is filled by one molecule of the N_4O_2 ligand and two water molecules.

Abstract—The electrosynthesis, X-ray crystal structure and EPR study of the 1 : 1 adduct between tetraphenyldithiapyranylidene and bis-(1,3-dithia-2-thione-4,5-dithiolato)-nickelate, (DIPSΦ$_4$)[Ni(dmit)$_2$], are reported. The triclinic unit cell contains one Ni(dmit)$_2$ and one DIPSΦ$_4$ entity, the molecular centre of each lying on a crystallographic centre of symmetry. The structure is characterized by a loose stacking (> 10 Å) of Ni(dmit)$_2$ units along [001], with no strong intermolecular interaction, consistent with the low electrical conductivity. Single-crystal EPR spectra show a single, broad line for any orientation. The angular dependences of the line width and of the *g*-factors have been determined, as well as the principal *g*-values and directions. The temperature-dependences of the susceptibility, the line width and the *g*-factor have been measured in the range 4–300 K. Analysis of these results indicates that dipolar spin–spin interaction takes place in this highly electron-correlated semiconducting system with complete charge transfer between the donor DIPSΦ$_4$ and the acceptor Ni(dmit)$_2$.

π Donor–acceptor compounds derived from [M(dmit)$_2$]$^{n-}$ complexes (M = Ni, Pd, Pt; dmit^{2-} = 1,3-dithia-2-thione-4,5-dithiolato; Fig. 1) exhibit interesting structural and electrical properties.[1–5] For example, TTF[Ni(dmit)$_2$]$_2$ (TTF = 1,4,5,8-tetrathiafulvalene) undergoes a superconducting transition under pressure.[2]

On the other hand, the heterocyclic π donor tetraphenyldithiapyranylidene (DIPSΦ$_4$ = 4-H-thiopyran, 4(2,6-diphenyl,4H-thiopyran-4-ylidene)-2,6-diphenyl; Fig. 1) is a useful precursor of organic one-dimensional conductors.[6–11] A charge-transfer complex of DIPSΦ$_4$ with TCNQ (TCNQ =

7,7,8,8-tetracyano-*p*-quinodimethane) exhibits a high conductivity (250 S cm^{-1} at room temperature).[6,7] Mixed-valence radical cation salts have been obtained by oxidation with iodine. The composition of these salts depends on the ratio of the initial reagents. Particular attention has been devoted to the highly conducting tri-iodide salt $(DIPS\Phi_4)0.76(I_3^-)$.[8-10] The oxidation of $DIPS\Phi_4$ (in CH_2Cl_2 or CH_3CN) proceeds in two well-defined electron waves[10b] corresponding to the successive formation of the radical cation and dication:

$$DIPS\Phi_4 - e^- \rightleftharpoons (DIPS\Phi_4)^+ - e^- \rightleftharpoons (DIPS\Phi_4)^{2+}.$$

It was thus tempting to explore the use of the donor $DIPS\Phi_4$ molecule and the acceptor $[M(dmit)_2]^{n-}$ complexes for preparing new donor–acceptor compounds which would possibly exhibit novel solid-state properties. We report here the synthesis and electrocrystallization, the X-ray structure determination and the EPR study of $(DIPS\Phi_4)[Ni(dmit)_2]$. The presence of a nickel complex in this system introduces a strong contribution to spin orbit coupling of the unpaired electron. This gives an opportunity to study the local environment of the charge transferred.

EXPERIMENTAL

Synthesis and electrocrystallization

The starting materials, $(n\text{-}Bu_4N)[Ni(dmit)_2]$ and $DIPS\Phi_4$, have been prepared following the procedures described by Steimecke *et al.*[12] and Fabre *et al.*,[13] respectively.

Crystals of $(DIPS\Phi_4)[Ni(dmit)_2]$ have been obtained by galvanostatic electrolysis of a $CHCl_3$ solution containing $(n\text{-}Bu_4N)[Ni(dmit)_2]$ (10^{-3} M) and $DIPS\Phi_4$ (2×10^{-3} M). This solution was placed in the anodic compartment of a nitrogen flushed U-type cell where the anode and the cathode (platinum wires) are separated by a medium-porosity glass frit. The cathodic compartment contained a $CHCl_3$ solution of $(n\text{-}Bu_4N)[Ni(dmit)_2]$ (10^{-3} M) as supporting electrolyte. The cell was thermostated (20°C) and the current ($I = 1.5$ μA; current density = 1×10^{-5} A cm^2) was held constant for periods as long as 1 month. A mixture of different crystals, formed on the anode, was collected on a glass frit by filtration, washed with ethanol and vacuum dried. This mixture contained two kinds of crystals: green needles which were characterized by IR spectroscopy as unreacted $DIPS\Phi_4$, and blue parallelepipedic crystals (typically $0.8 \times 0.4 \times 0.2$ mm^3) which were characterized by single-crystal X-ray diffraction studies as the 1:1 adduct $(DIPS\Phi_4)[Ni(dmit)_2]$.

Electrochemical measurements

Half-wave redox potentials were measured as described in refs 14 and 15 by linear and cyclic voltammetry. Deaerated CH_2Cl_2 (Merck) was used as a solvent and $(n\text{-}Bu_4N)PF_6$ (0.1 M) as supporting electrolyte. Potentials were referred vs an Ag/AgCl (0.1 M KCl) electrode.

The radical cation salts $(DIPS\Phi_4)X$ ($X = ClO_4^-$, BF_4^-, SCN^-, PF_6^-, ...) are more soluble than the starting $DIPS\Phi_4$ donor. Consequently, we were not able to isolate these salts. $(DIPS\Phi_4)^+$ species were generated in a $CH_2Cl_2/(n\text{-}Bu_4N)PF_6$ (0.1 M) solution of $DIPS\Phi_4$ (2×10^{-3} M) by controlled potential electrolyses and coulometric determination. Electrolyses were carried out at 0.25 V on a platinum gauze electrode. The resulting solution was frozen at 100 K and used for EPR measurements.

X-ray structure determination

Crystal data are reported in Table 1, together with relevant details of the intensity data collection. Data collection and reduction were conducted following standard procedures previously described.[16] The structure was determined by direct methods and refined using usual full-matrix least-squares procedure and Fourier synthesis, as previously described.[16] The centrosymmetric space group $P\bar{1}$ was assumed on the basis of $N(Z)$ statistics. Phenyl

rings were treated as idealized rigid groups, with individual isotropic temperature factors for each carbon atom and fixed arbitrary temperature factors (U = 0.07 Å^2) for hydrogen atoms. All other atoms were given anisotropic thermal parameters. Final agreement factor values are given in Table 1. Atoms are labelled according to Fig. 1; bond lengths and angles are listed in Table 2.*

EPR measurements

The X-band EPR spectrum of a CH_2Cl_2 frozen (100 K) solution of $(DIPS\Phi_4)^+$ species generated by electrolysis (see above) was obtained on a Brucker 200 TT spectrometer equipped as previously described.[17]

The single-crystal EPR experiments have been carried out using a Bruker ESP 300 X-band spectrometer provided with a NMR gaussmeter, a frequency meter and a HP900-330 computer for data handling facilities. A one-axis goniometer has been used for the rotating experiments. A single crystal was fixed on a cubic sample holder in order to perform rotations in orthogonal planes chosen in view of the crystal morphology (Fig. 2).

* Supplementary material. Positional parameters and equivalent isotropic temperature factors for non-hydrogen atoms, components of the anisotropic temperature factors, hydrogen atom positional parameters, and observed and calculated structure factor amplitudes have been deposited with the Editor.

RESULTS AND DISCUSSION

π Donor–acceptor compounds, such as the typical TTF·TCNQ, have aroused a strong interest because of their unusual solid-state properties, and

especially their high conductivity. In such compounds, partial charge transfer between separately stacked donor and acceptor molecules leads to one-dimensionally delocalized systems. Among the many criteria suggested for the formation of these partial charge-transfer compounds, the relationship $E_{1/2}(D \rightarrow D^+ + e^-) - E_{1/2}(A + e^- \rightarrow A^-) = 0.1$–$0.4$ V between the half-wave redox potentials of the donor and the acceptor has been used for the selection of appropriate donor–acceptor pairs.[18–20]

On the basis of the redox potentials [$E_{1/2}$ ($DIPS\Phi_4 \rightarrow DIPS\Phi_4^+ + e^-$) ~ 0.20 (0.28 V[10b]) and $E_{1/2}(Ni(dmit)_2 + e^- \rightarrow [Ni(dmit)_2]^-)$ ~ 0.21 V, vs Ag/AgCl], the charge transfer between the $DIPS\Phi_4$ and $Ni(dmit)_2$ moieties in $(DIPS\Phi_4)[Ni(dmit)_2]$ should be close to one, leading to $(DIPS\Phi_4)^+$ and $[Ni(dmit)_2]^-$ ionic species. This result would be consistent with the low compaction-powder conductivity (lower than 10^{-5} S cm^{-1} at room temperature) of this compound and its 1 : 1 stoichiometry.

The 1 : 1 stoichiometry of $(DIPS\Phi_4)[Ni(dmit)_2]$ has been estimated by elemental analysis, and confirmed by the X-ray structural determination.

The unit cell contains one $Ni(dmit)_2$ and one $DIPS\Phi_4$, the molecular centre of each lying on a crystallographic centre of symmetry (Fig. 3); the proposed 1 : 1 stoichiometry is thus confirmed. As usual, the $Ni(dmit)_2$ unit is fairly close to planarity. However, in the dmit ligand the outermost atoms, C(3) and S(5), deviate significantly from the plane of the inner atoms (Table 3). The planes of the inner atoms of the two dmit moieties of a $Ni(dmit)_2$ unit

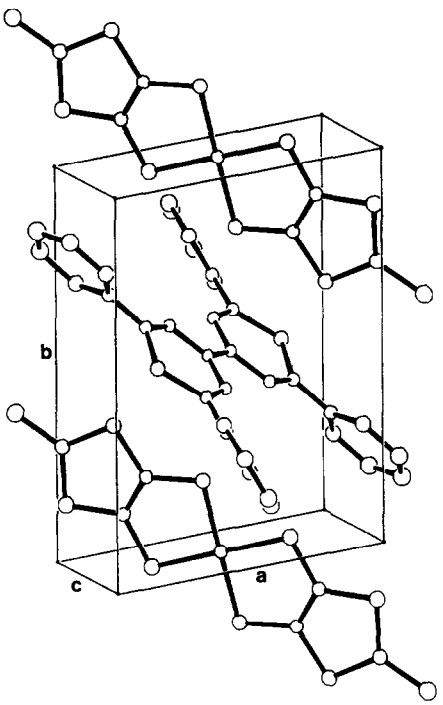

Fig. 3. Perspective view of the unit cell content.

are parallel by symmetry but apart by 0.04 Å; when a plane is fitted to all the atoms of a $Ni(dmit)_2$ unit the maximum deviation is 0.05 Å for S(5). A similar analysis of planarity can be made for the heterocyclic ring of $DIPS\Phi_4$. In each ring, the S(6) atom is well off the plane of the carbon atoms (Table 3); the ring can be considered as folded by 5° about a line between S(6) and C(4). Planes fitted to the rings are parallel by symmetry but apart by 0.15 Å; when a plane is fitted to all the atoms of the heterocyclic ring the maximum deviation is 0.07 Å for C(7). The deviation from planarity is similar, though less important, to that observed for the neutral $DIPS\Phi_4$.[21] In the polyiodides $(DIPS\Phi_4)I_x$ the two thiapyranylidene rings are not parallel but twisted by ~ 20° relative to each other.[10a,11]

Starred atoms have been used to define the plane.

Luss and Smith[21] have compared the bond lengths in the dithiapyranylidene double ring for the neutral and oxidized $DIPS\Phi_4$ species. It is worthy to extend this comparison to $(DIPS\Phi_4)[Ni(dmit)_2]$ since it has been shown that, in some cases, bond lengths in radical ions can be related to the amount of charge transfer.[22] From Table 4, it seems that the central C(4)—C(4)′ bond is the most sensitive to charge transfer as in the case of TTF.[23] Whatever the case, Table 4 clearly shows that bond lengths in $(DIPS\Phi_4)[Ni(dmit)_2]$ are close to those observed in the more oxidized species and consistent with the high charge transfer previously suggested. It would have been useful to ascertain this observation using bond lengths in the $Ni(dmit)_2$ unit. Unfortunately, as pointed out before,[1] the poor accuracy and dispersion of available results prevent drawing reliable conclusions from such a comparison.

The crystal structure can be described as being composed of stacks of $Ni(dmit)_2$ units along [001]. These stacks are arranged in layers parallel to (010) alternating with layers of $DIPS\Phi_4$. However, the stacking of the $Ni(dmit)_2$ units is very loose since the repeat parameters are more than 10 Å in both the [001] and [100] directions. This is reflected in the low density of the material (1.58 g cm^{-3}). As a result, there is no strong intermolecular interaction between the $Ni(dmit)_2$ units: the shortest intermolecular S···S distance is 3.69 Å. As a matter of fact, the "stacking" of the $Ni(dmit)_2$ units is governed by the spatial arrangement of the large $DIPS\Phi_4$ units. The central plane of the $DIPS\Phi_4$ units is perpendicular to the molecular plane of the $Ni(dmit)_2$ units (Table 3), so that they can be considered arranged side by side with almost no overlap in-between. The shortest S(6)···S distance is 4.11 Å, and thus no significant intermolecular interaction is observed between the $DIPS\Phi_4$ and the $Ni(dmit)_2$ units.

Although donor and acceptor molecules are arranged in segregated layers, the looseness of stacking of $Ni(dmit)_2$, the side by side arrangement of $DIPS\Phi_4$ and the absence of intermolecular interaction are consistent with the electrical behaviour of this material.

Since the $(DIPS\Phi_4)^+$ and $[Ni(dmit)_2]^-$ species should each carry a single unpaired electron, two single unpaired spins should be observed in the EPR spectrum of $(DIPS\Phi_4)[Ni(dmit)_2]$. In apparent contradiction with the small intermolecular inter-

action expected, only one signal was observed in the entire range of temperature investigated (300–4 K). It is noteworthy that the average g-value of this signal, 2.028 (determined on a single crystal; see below and Table 5) is intermediate between that of $(DIPS\Phi_4)^+$ species generated in solution by electrolysis, 2.007 (determined on a CH_2Cl_2 frozen solution) and that of a $[Ni(dmit)_2]^-$ salt, 2.049 (determined on a single crystal of $(n\text{-}Bu_4N)[Ni(dmit)_2]$[24]). This observation alone suggests some kind of spin-exchange coupling between both the $(DIPS\Phi_4)^+$ and $[Ni(dmit)_2]^-$ moieties in $(DIPS\Phi_4)[Ni(dmit)_2]$.

At room temperature, the single-crystal EPR spectra of $(DIPS\Phi_4)[Ni(dmit)_2]$ show a single broad line for any orientation. The g-factor differs from that of the free electron, indicating a strong spin–orbit coupling. Such a high value ($g \sim 2.03$) is in favour of a contribution of the nickel atom to the spin–orbit coupling, the two heteroatoms involved in $DIPS\Phi_4$ could not alone assume this coupling. This point has already been reported for similar complexes.[25,26] The broad line width (of the order of 25 G) confirms the role of the magnetic moment of the metal on the properties of this complex. The anisotropy of the g-factor is strong (Fig. 4; Table 5). One of the principal axis is in the xOz plane. The lowest eigenvalue corresponding to nearly the free

Fig. 4. Fig. 5. Angular variation of the half width at half power, $\Delta H_{1/2}$, of a single crystal of $(DIPS\Phi_4)[Ni(dmit)_2]$ in three orthogonal planes. See Fig. 4 for orientation conventions.

electron g-factor ($g_{xx} = 2.0033$) is related to the lowest spin–orbit coupling which is mainly due to the $[Ni(dmit)_2]$ complex moiety. The associated direction should be then nearly perpendicular to the plane of this molecule. Projection in the (010) plane of both the lowest g-factor direction and the perpendicular to the plane of the $[Ni(dmit)_2]$ complex show an angle with the z or c axis of 33 and 19°, respectively.

The angular variation of the EPR line width of this system (Fig. 5) is driven by the dipolar electronic spin–spin interaction; its anisotropy, when rotating the crystal in the applied magnetic field, shows a $(1+\cos^2\theta)$ dependence, characteristic of a three-dimensional spin diffusion.[27] The directions of the extremal values of the line width are not indentified to the principal axes of the g-tensor. The important dipolar coupling (broad line) confirms the partial molecular delocalization of the π electrons' spin nearby the nickel atoms. Both types of molecule are clearly implied in the magnetic properties; the single line indicates interstack spin exchange.

The variation of the susceptibility as a function of the temperature has been measured on one single crystal in the range 4–300 K (Fig. 6). A Curie–Weiss law is observed for temperatures higher than 30 K with a Curie–Weiss constant of $\theta_{cw} \sim 30$–50 K, confirming the antiferromagnetic spin exchange. In the same temperature range, and for a particular orientation, the line width continuously decreases (from 17 G down to 5 G; Fig. 7), whereas the g-factor increases (Fig. 8). When the temperature is lowered, the susceptibility deviates from the linear fit; the line width goes through a minimum and increases, while the g-factor strongly increases from the room temperature value, 2.036, up to 2.063 at liquid helium temperature.

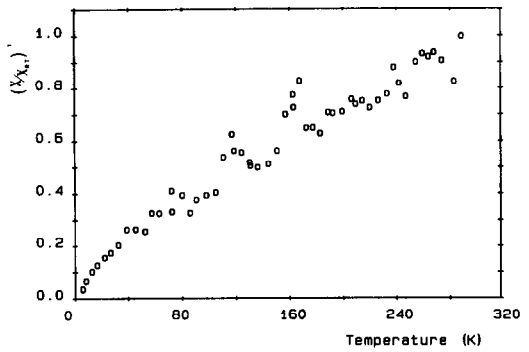

Fig. 6. Inverse of the normalized susceptibility as a function of the temperature of a single crystal of $(DIPS\Phi_4)[Ni(dmit)_2]$. The noisy signal linked to the small size of the crystal explains the spread-over of the points of the susceptibility obtained by double integration of the EPR spectra.

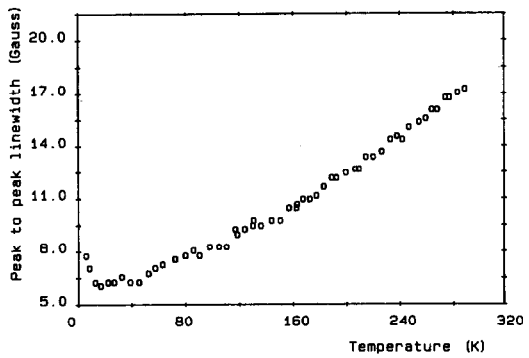

Fig. 7. Temperature dependence of the peak-to-peak line width of a single crystal of $(DIPS\Phi_4)[Ni(dmit)_2]$ for a peculiar orientation (indicated by an arrow in Fig. 4).

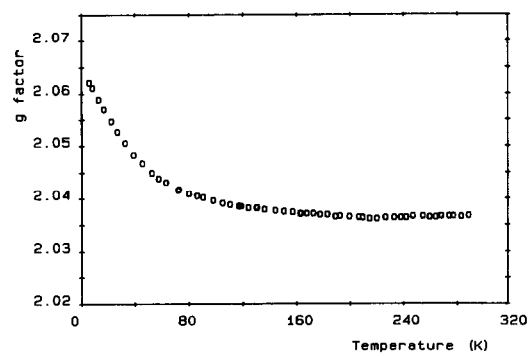

Fig. 8. Temperature dependence of the g-factor of a single crystal of $(DIPS\Phi_4)[Ni(dmit)_2]$ in the same orientation as in Fig. 7.

The decrease of the line width with decreasing temperature is very similar to that observed in the family of organic conductors, $(TMTSeF)_2X$, for example.[28] The simultaneous increase of the g-factor is also similar to that observed in these latter systems, but the susceptibility behaviour of both systems is very different. For $(DIPS\Phi_4)[Ni(dmit)_2]$, this temperature-dependence of the susceptibility, associated with the low value of the conductivity observed on a compressed powder and with the absence of any Dysonian EPR line shape, discarded a metallic behaviour; this system is likely to be a semiconductor. As no low-dimensional spin diffusion occurs in this system, and in view of the crystal structure, the gap should not be related to a Peierls distortion; this complex probably is, as previously inferred from the redox potential values, a highly electron-correlated system with a complete charge transfer from the donor to the acceptor.

In a situation of three-dimensional exchange narrowing limit, the line width is described by the model of Anderson and Weiss,[29] in which the line width is governed by the ratio $\omega_e/\omega_p{}^2$, where ω_e is the spin exchange frequency and ω_p is the characteristic frequency of the dipolar couplings. When the temperature is lowered, both interactions vary. The g-factor and the dipolar coupling increases are due to the nickel atoms (EPR silent), whereas the decrease of the line width reflects the stronger exchange between both π systems. The two phenomena may be simply related to lattice contraction which affect more efficiently the spin–spin exchange than the long range dipolar interactions.

(*Received* 16 *July* 1990; *accepted* 26 *November* 1990)

Abstract—The hydrolysis rates and activation energies of cyclopenta- and cycloheptaphosphate, which were isolated by the use of a QAE-Sephadex A-25 column, have been measured in both acidic and alkaline solutions. The rate data for the linear pentamer and heptamer have also been determined. The reaction mechanism of the hydrolysis of these condensed phosphates is discussed by comparing the rate data with those for other polyphosphates.

Condensed phosphates are useful materials as inorganic polyvalent electrolytes.[1] We have studied various chemical properties of cyclopolyphosphates with a polymerization degree smaller than eight.[2–5] Research into the hydrolysis reactions of cyclopoly- and linear polyphosphates with polymerization degrees 3, 4, 6 and 8 in aqueous solutions has recently been undertaken using the automated liquid chromatographic system.[6] Cyclopolyphosphates with polymerization degrees 3, 4, 6 and 8 can be relatively easily prepared,[7,8] as can linear tri- and tetraphosphate.[9] Sample solutions containing sufficient quantities of linear hexa- or octaphosphate for the hydrolysis study were prepared by partial hydrolysis of cyclohexa- or cyclooctaphosphate, respectively. However, preparation of cyclopenta- and cycloheptaphosphate in sufficient quantities is difficult and therefore their chemical properties have not been investigated. These two cyclopolyphosphates are known to be minor components of Graham's salt and their isolation from the salt was first achieved by Kura and Ohashi[2] using a QAE-Sephadex A-25 column.

In this study, the hydrolysis rates and activation energies of cyclopenta- and cycloheptaphosphate, isolated from the column, in 0.1 M HCl and 0.5 M NaOH were determined by automated liquid chromatography. The data thus obtained were compared with those for other cyclopolyphosphates. Hydrolysis reactions of linear penta- and heptaphosphate were similarly investigated and analysed.

In the figures and tables in this paper, cyclopolyphosphates and linear polyphosphates are abbreviated as P_{nm} and P_n, respectivly, where n is the polymerization degree.

EXPERIMENTAL

Graham's salt, $(NaPO_3)_n$, was synthesized by heating monosodium dihydrogen orthophosphate at 1000°C for approx. 2 h and rapidly cooling on an aluminium plate. A cyclopolyphosphate mixture was obtained from Graham's salt by acetone fractionation.[2] Cyclopenta- and cycloheptaphosphate were isolated from the mixture using a QAE-Sephadex A-25 column (85 cm in length and 1.5 cm in diameter).[2] As an eluting reagent, 0.3 M potassium chloride was used. Details of the hydrolysis procedure and the analytical system have been described in my previous paper.[6]

The mixture of cyclopolyphosphates contained in Graham's salt was concentrated by acetone fractionation[10] and cyclopenta- and cycloheptaphosphate in the mixture were isolated by the use of a QAE-Sephadex A-25 column. On partial hydrolysis of cyclopenta- and cycloheptaphosphate in 0.5 M LiOH for about 8 h at 40°C, the sample solutions containing the respective linear penta- and heptaphosphate to be hydrolysed were obtained. Using these samples, the hydrolysis rates of cyclic and linear phosphates with polymerization degrees 5 and 7 were determined in 0.1 M HCl and 0.5 M NaOH.

RESULTS AND DISCUSSION

The concentration of cyclopoly- and linear phosphates with the same polymerization degree at time t are denoted as x and y, and the first-order hydrolysis rate constants are defined as k_m and k_n, respectively. The following rate equations can be derived:

$$-dx/dt = k_m x \quad (1)$$

$$-dy/dt = -k_m x + k_n y. \quad (2)$$

The concentrations of cyclopolyphosphates at time t, which were experimentally determined, were substituted in a modified version of eq. (1) and k_m values were determined. The chromatograms of the hydrolysis samples of cyclopenta- and cycloheptaphosphate in 0.1 M HCl are shown as examples in Fig. 1(a) and (b). The cyclotriphosphate peak is observed in the chromatograms. The phosphate is known to be formed during the hydrolysis reactions of linear polyphosphates. The reaction rates of cyclopenta- and cycloheptaphosphate at various temperatures are shown in Fig. 2(a) and (b). The phosphate concentration at time 0 and t are defined as $[P]_0$ and $[P]_t$, respectively, and the good linear relationship between $\log([P]_t/[P]_0)$ vs t [as shown in Fig. 2(a) and (b)] reveals that the hydrolysis reaction of both phosphates is strictly first-order.

Employing k_m calculated from the slope of the straight lines in Fig. 2 and using eq. (2), the rate constants for linear penta- and heptaphosphate, k_n, were determined simultaneously from the data obtained by the analysis of the same chromatograms. Thus the obtained values k_m and k_n reproduce the experimental data. Figure 3(a) and (b) show the time dependence of the concentration of penta- and heptaphosphate during the course of hydrolysis, where the full lines represent the calculation of substituting k_m and k_n into eq. (2) and the circles indicate the experimental points. In a similar manner, the hydrolysis rates of the cyclic and linear pentamer and heptamer in 0.5 M NaOH were determined. Since these phosphates are comparatively stable in alkaline solution, taking into account the experimental error, the rates at higher temperatures, 70, 80 and 90°C, were measured. Hydrolysis rates of cyclopenta- and cycloheptaphosphate are shown in Fig. 4(a) and (b), and those of linear penta- and heptaphosphate are schematically shown in Fig. 5(a) and (b). The Arrhenius activation energies of the four phosphates in 0.1 M HCl and 0.5 M NaOH were obtained from the temperature dependence of log k_m or log k_n. The Arrhenius plots are shown in Figs 6 and 7. The hydrolysis rate constants in 0.1 M HCl and 0.5 M NaOH at various temperatures are shown in Tables 1 and 2. The rate constants in 0.5 M NaOH at 50°C are predicted values obtained by the extrapolation of the Arrhenius plots. The activation energies, E_a, are presented in Tables 1 and 2, along with the rate

constants. Four of the phosphates are hydrolysed faster in acidic solution than in alkaline solution. Linear oligophosphates contain terminal PO^- groups which are very strong Brønsted bases and combine with the H^+ ions in acidic solution. These bond formations accelerate the P—O—P bond cleavage by nucleophilic attack of H_2O on the P atoms. For the cyclopolyphosphates, as the polymerization degree becomes higher, 5 or 7, the binding to a proton becomes stronger.[3] The fast cleavage of the cyclic oligomer in acidic solution may be interpreted in the same manner as for the linear phosphates. For both pentamer and heptamer, the hydrolysis rates of the linear oligomers in acidic solution are faster. This fact is attributable to the basic strength of the terminal PO^- group in the linear oligomers.

In alkaline solution at 50°C, the rate of cleavage of the cyclic pentamer is faster than that of the linear pentamer, and on the contrary, for the heptamer the linear phosphate is hydrolysed faster.

There are no large differences between the activation energies of both linear and cyclic oligomers in acidic solution, whereas in alkaline solution, the activation energies of the linear pentamer and heptamer are higher by about 4–8 kcal mol^{-1}. The nucleophilic attack of OH^- on the P atoms in alkaline solution occurs more easily in the hydrolysis of the cyclic oligomers. The electrostatic repulsion of OH^- and PO^- groups in the linear oligomers is predicted to be stronger.

For comparison sake, the rate data for the pentamers and heptamers in 0.1 M HCl and 0.5 M NaOH are illustrated in Figs 8 and 9, along with the data for the cyclic and linear oligomers with

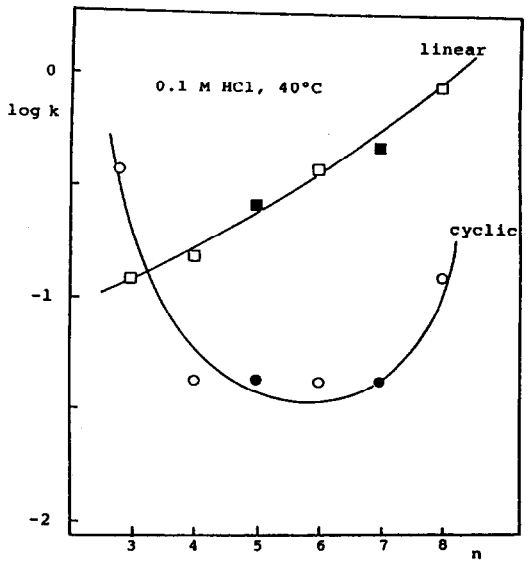

Fig. 8. Rate constants for cyclic and linear oligophosphates in 0.1 M HCl at 40°C.

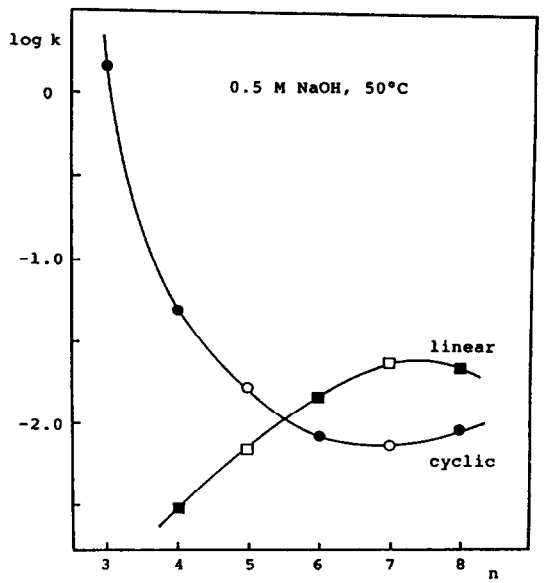

Fig. 9. Rate constants for cyclic and linear oligophosphates in 0.5 M NaOH at 50°C.

polymerization degrees 3, 4, 6 and 8.[11,12] In acidic solution, linear oligomers are hydrolysed faster than cyclic oligomers, except for cyclotriphosphate. For the linear phosphates, the rate gradually increases with increasing degree of polymerization. For the cyclic oligomers, the hydrolysis rate of the octamer becomes faster, which has been explained by greater interactions with the hydrogen ions due to the increased flexibility of the anion structure.[3] In alkaline solution, large differences are observed between the rates for cyclic and linear oligomers. However, with increasing polymerization degree the differences become smaller. For higher linear and cyclic oligomers, structural resemblance in the aqueous state is supposed. The faster rates for the lower cyclopolyphosphates are speculated to be ascribed to the ease of nucleophilic attack of OH^- on the P atoms on their strongly bending cyclic structures. During this research, the hydrolysis features in 0.1 M HCl and 0.5 M NaOH for all cyclic and linear oligomers with polymerization degrees of 3–8 have been elucidated.

(*Received* 1 *October* 1990; *accepted* 4 *December* 1990)

Abstract—The kinetics of dissociation of several iron(II) diimine complexes by aqueous hydroxide ions have been studied spectrophotometrically at atmospheric pressure and elevated pressures, at 298.2 K. Values of ΔV^* are between +10 and +16 $cm^3\ mol^{-1}$, and are interpreted as arising from a significant loss of electrostricted water from the hydroxide ion as it reacts with the iron(II) complex associatively. Dissociation of the $[Fe(5NO_2phen)_3]^{2+}$ and $[Fe(5Brphen)_3]^{2+}$ complexes in the presence of aqueous EDTA is reported. For both, ΔV^* is +22 $cm^3\ mol^{-1}$. These values can be understood by considering the reaction as a process comparable to aquation in acidic medium, a dissociative process. Activation enthalpy data support this idea.

Markedly positive activation volumes (ΔV^*) have been found for hydroxide and/or cyanide attack at low-spin iron(II) tris-diimine cations, $[Fe(bpy)_3]^{2+}$ (bpy = 2.2′-bipyridyl), $[Fe(phen)_3]^{2+}$ (phen = 1,10-phenanthroline)[1] and $[Fe(4Mephen)_3]^{2+}$ [2] in aqueous solutions. For a bimolecular reaction a value of about −10 $cm^3\ mol^{-1}$ is expected for ΔV^*.[3] For the former two ions, Stranks and co-workers,[1] although recognizing the possibility of a dominant role for desolvation of the attacking ion on forming the transition state, argued that the values of +19 to +22 $cm^3\ mol^{-1}$ pointed to a dissociative mode of activation. This interpretation was also proposed for cyanide ion displacement of ligand from $[Fe(CN)_5L]^{3-}$,[4,5] where L is 3,5-dimethylpyridine, imidazole or pyrazine, and was based upon a combination of analysis of atmospheric pressure kinetics results, and volume of activation data (ΔV^* is $\cong$ +20 $cm^3\ mol^{-1}$ and independent of departing ligand). The dissociative mechanism has been reiterated recently for base hydrolysis of several iron(II) complexes.[6] However, various features of some of these reactions are not yet resolved unambiguously and require further study and discussion.

On the basis of thorough kinetic studies of nucleophilic dissociation of $[Fe(phen)_3]^{2+}$, Margerum and Morgenthaler[7] concluded that the mechanism was associative. Except at very high nucleophile concentrations the rate law reduces to a two-term expression; one is for the aquation step and the second contains a first-order term in, for example, hydroxide ion concentration. Under typical reaction conditions, using a large excess of hydroxide ion over metal complex ion, the rate is dominated by the latter term, and thus the rate-determining step is second-order, and considered to be bimolecular and the mechanism associative. Dissociation of the complex ion can also occur in the presence of an acid or other reagents, for example, EDTA.[8,9] In these cases the reaction rate is independent of the concentration of the dissociating agent, and a ligand

molecule which has begun to separate from the ion is prevented from resuming coordination by being scavenged rapidly by a proton, in the presence of acid, or when EDTA is present the iron is scavenged. Dissociation by aquation is considered to be a dissociative mechanism.

Because of our interest in these reactions we have also proceeded to study the kinetics in selected cases, over a range of pressure, with the objective of gaining additional insight into reaction mechanism. Aquation in the presence of sulphuric acid of $[Fe(phen)_3]^{2+}$ and the 5-nitro and 4,7-dimethyl analogues yielded, at 308.2 K, ΔV^* values of +15.4, +17.9 and +11.6 $cm^3\ mol^{-1}$, respectively.[10] These results were rationalized in terms of a dissociative activation mode which consists of a two-ended partial dissociation of a phen bidentate ring, with different degrees of bond extension explaining the variation in ΔV^* values. The D mechanism for cyanide replacement of ligand in $[Fe(CN)_5L]^{3-}$ is predicated on the virtually constant degree of stretching of the Fe—N bond which gives rise to an invariant ΔV^*.[5] The hydrophilic cyanide ion has an unchanged state of solvation in the rate-determining step and the intrinsic component of ΔV^* completely dominates.

In considering bimolecular nucleophilic dissociation, the contribution of solvation effects to ΔV^* must be included and this will be especially significant for charged nucleophiles. This was illuminated by high pressure studies[11] on the reactions between $[Fe(ppsa)_3]^{4-}$ and OH^- (ppsa = **1**), and between $[Mo(CO)_4(bpy)]$ and CN^-,[3] the latter in dimethylsulphoxide. For the former case, ΔV^* is approximately zero, and ΔV^* is $-9\ cm^3\ mol^{-1}$ for the reaction of the molybdenum complex. The latter value was explained as a consequence of an associative process in which there is little or no desolvation contribution because the cyanide ion is very poorly solvated in DMSO. The reaction of the tris-iron(II) complex of **1**, which has a minus four charge, with OH^- is characterized overall, by a modest degree of desolvation as the transition state is reached, since the intrinsic volume change for the associative process is negative. Dissociation of $[Fe(4Mephen)_3]^{2+}$ by aqueous cyanide ions yields a ΔV^* value of $+10\ cm^3\ mol^{-1}$. These early examples indicate desolvation contributions ranging from zero to about $+20\ cm^3\ mol^{-1}$.

We also measured ΔV^* for attack by hydroxide ion for several closely related iron(II) complex cations, $[Fe(gmi)_3]^{2+}$,[12] $[Fe(Me_2bsb)_3]^{2+}$[13] and $[Fe(hxsb)]^{2+}$[13] (gmi = **2**, Me_2bsb = **3**, hxsb = **4**). The values of ΔV^* were +16, +11 and +13 $cm^3\ mol^{-1}$, respectively, decidedly positive, but lower than those determined for nucleophilic dissociation earlier. Because of this we measured activation volumes for hydroxide attack at two closely related Schiff base complexes, the iron(II) complexes of 3Mebsb (**5**) and 4MeObsb (**6**). Again values in the range +10 to +15 $cm^3\ mol^{-1}$ were obtained (*vide infra*).

A dissociative mechanism for a given complex would, in principle, have a constant ΔV^*, independent of the subsequent attack of the nucleophile. Since the rate-limiting step involves only lengthening of a ligand–metal bond, nucleophile solvation change is not relevant. For different complexes reacting with the same nucleophile, ΔV^* could vary, reflecting the difference in partial molar volume of the departing ligand and different degrees of stretching in the transition state. For a bimolecular reaction a negative value of ΔV^* is expected in the absence of solvation.[3] However, significant changes in the solvation of both the metal complex ion and the nucleophile can occur for an associatively formed activated complex. For a small anionic nucleophile, loss of electrostricted solvent is larger than for a positively-charged complex ion (of much lower charge density). Added co-solvent will, it may be predicted, change solvation of both species giving rise to changes in ΔV^* for a particular reactant pair. Such changes have been observed[13–15] and explanations sought in terms of solvation variation both of the nucleophile, and as a consequence of the hydrophobic/hydrophilic complex ion being compatible or not, with the co-solvent. The focus in this paper is on aqueous solution, but these earlier results[13–15] should be borne in mind as they provide a framework of explanation of ΔV^* variation. Aquation reactions for similar systems, *vide supra*, yielded variations in ΔV^*. Consequently, variations or constancy of ΔV^*, alone, are of no particular assistance necessarily in an attempt to assign a mechanism unambiguously.

However, because values of ΔV^* established for nucleophilic dissociation of several iron(II) diimine complexes were in the range +10 to +16 cm^3 mol^{-1}, it seemed incumbent on us to remeasure ΔV^* for hydroxide attack at $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ as one step in an attempt to clarify the situation. In addition, because of our general interest in dissociation and other properties of iron(II) diimine complexes, we have examined the kinetics of dissociation of two substituted trisphen complexes, $[Fe(5Brphen)_3]^{2+}$ and $[Fe(5NO_2phen)_3]^{2+}$, in aqueous EDTA solution at elevated pressures. Thus we can compare ΔV^* values with those obtained for aquation in acid medium.

EXPERIMENTAL

Materials

Solutions of $[Fe(bpy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$ were prepared by dissolving appropriate amounts of their perchlorate salts in water. The solutions of the $[Fe(5Brphen)_3]^{2+}$ and $[Fe(5NO_2phen)_3]^{2+}$ cations were obtained by adding a small excess of ligand to an aqueous solution of iron(II) ammonium sulphate. Concentrations of these solutions were checked spectrophotometrically via published molar extinction coefficients: $[Fe(bpy)_3]^{2+}$ has ε (522 nm) = 8700 mol^{-1} dm^3 cm^{-1},[16] $[Fe(phen)_3]^{2+}$ has ε (510 nm) = 11,000 mol^{-1} dm^3 cm^{-1},[17,18] $[Fe(5NO_2phen)_3]^{2+}$ has ε (512 nm) = 12,100 mol^{-1} dm^3 cm^{-1}[17] and $[Fe(5Brphen)_3]^{2+}$ has ε (510 nm) = 11,500 mol^{-1} dm^3 cm^{-1}.[19] Iron(II) complexes of the Schiff base ligands, 3Mebsb (**5**) and 4MeOBsb (**6**), were prepared according to published procedure[20] in the form of their chloride salts, which were subsequently dissolved in water to give solutions of appropriate concentration. Solutions of iron(II) cations were made up immediately prior to use in kinetic experiments. Sodium hydroxide, sodium chloride, potassium hydroxide, potassium chloride and Na_2EDTA were Analar materials.

Methods

The experimental techniques and apparatus used were those described in detail in earlier publications.[13,21]

RESULTS

All kinetic runs were carried out at 298.2 K in the presence of a large excess of hydroxide ion, or of EDTA, and all followed first-order kinetics for at least three half lives. The experimental results are presented in the form of logarithms of ratios of rate constants under pressure to those for an aliquot of the same reactions at atmospheric pressure in Table 1. For each complex, plots of these ratios against pressure were linear within experimental uncertainty. Examples are shown for OH^- + $[Fe(phen)_3]^{2+}$ and EDTA + $[Fe(5NO_2phen)_3]^{2+}$ in Fig. 1 and OH^- + $[Fe(bpy)_3]^{2+}$ and EDTA + [Fe

$(5Brphen)_3]^{2+}$ in Fig. 2. Activation volumes obtained from the slopes are reported in Table 2, together with published data for other iron(II) diimine complexes. The results are separately grouped for dissociation by nucleophilic attack and for aquation in acidic medium[10] or in the presence of EDTA. No correction was made for the contribution of aquation in the nucleophilic-dependent dissociation reaction as the former represents a very minor contribution to the observed rate constant. For dissociation by nucleophile most systems were studied at an ionic strength of 0.33 mol dm^{-3}. This and other conditions chosen reflect the need for data comparison in aqueous solvent mixtures (not reported in this communication) and practical considerations regarding solubility and rate ranges for accurate and convenient measurement.

DISCUSSION

Dissociation by hydroxide ion

All ΔV^* results for nucleophilic attack on iron(II) complexes, except those reported earlier,[1] are within the range +10 to +16 cm^3 mol^{-1}. Our results for the reaction of hydroxide on $[Fe(bpy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$, +13 and +14 cm^3 mol^{-1}, respectively, are in the centre of the small range. The earlier ΔV^* values obtained for both hydroxide and cyanide ion reaction with these two complexes are +19 to +22 cm^3 mol^{-1}, and clearly much higher than those reported here. The measurement temperature for the two studies differed by 5°C; this would give rise to a very small difference in ΔV^* values. There is a difference of about 0.10 mol dm^{-3} in the ionic strength of the solutions of the two sets of experiments, but again this would probably not account for the whole difference in ΔV^* values. Accordingly, since our values are within the range of +10 to +16 cm^3 mol^{-1} found for six other diimine complexes of iron(II), we conclude that the differences in ΔV^* remain unexplained and beyond experimental error. It is our position that the rate law for the reaction[7,10,11] indicates that the reaction is associative, and that ΔV^* can be attributed to the common domination of release of electrostricted solvent from hydroxide upon reaction with the complex ion in achieving the transition state. Since hydroxide desolvation predominates, the solvation changes at the complex ion may well be minor. Values of ΔV^* differ by only ±2 to 3 cm^3 mol^{-1}, which is not much greater than experimental error

and an attempt at an explanation is therefore not warranted. If the changes are not minor they are quite common to each iron(II) complex cation. This situation is dramatically different for dissociation in aqueous alcohol mixtures of complexes **2**, **3** and **4**,[12,13] illustrating therein significant ligand influence upon solvation changes. Preliminary findings for dissociation by hydroxide of $[Fe(phen)_3]^{2+}$ and $[Fe(bpy)_3]^{2+}$ in aqueous alcohol mixtures at high pressures indicate a significant participation by the hydrophobic ligands, more so for $[Fe(phen)_3]^{2+}$ than for $[Fe(bpy)_3]^{2+}$, in the solvation contribution to ΔV^*.

Activation parameters from temperature dependence studies provide support for different mechanisms for the aquation and nucleophilic attack routes of dissociation of $[Fe(phen)_3]^{2+}$. Aquation, discussed in more detail below, in the presence of 1.0 mol dm^{-3} H_2SO_4 is characterized[10] by a ΔH^* value of 122.4±0.8 kJ mol^{-1}, while dissociation by 0.1 mol dm^{-3} OH^- has a ΔH^* value of 96.3±0.5 kJ mol^{-1}. The values of ΔS^* are 88±3 and 18±3 J mol^{-1} K^{-1} for aquation and dissociation by OH^-, respectively. In the present work, we have measured the temperature dependence of the dissociation of $[Fe(5Brphen)_3]^{2+}$ in the presence of 0.10 mol dm^{-3} HCl and 0.010 mol dm^{-3} EDTA at five temperatures and find ΔH^* values of 115.6 and 119.0 kJ mol^{-1}, and ΔS^* values of 74.7 and 86.4 J mol^{-1} K^{-1}, in the two media. (Table 3 and references therein.) In contrast, the dissociation in the presence of OH^- yields $\Delta H^* = 84.2$ kJ mol^{-1} and $\Delta S^* = 37.8$ J mol^{-1} K^{-1}. Such results argue against a common mode of dissociative release of diimine ligand.

In summary, the interpretation of a dissociative process based only on ΔV^* values of ref. 2 is not unreasonable; however, the nature of the rate law, and other considerations outlined above, yield a preponderance of support for an associative process for nucleophilic attack.

Aquation

During aquation of $[Fe(phen)_3]^{2+}$ one ligand becomes extended to a certain distance from the central ion thus permitting protons to prevent reattachment of a phen ligand and causing the subsequent complete complex dissociation. It has been shown previously,[8] and in this study, that EDTA can perform an equivalent function to H^+ in the aquation process. Both can prevent the partly dissociated phen ligand reattaching itself completely to the central iron; EDTA can react with the cation, and the acid can protonate a phenanthroline nitrogen. The rate constants at atmospheric pressure for

aquation in the presence of acid and EDTA are the same and virtually independent of concentration. The associated enthalpies of activation for these two reactions are the same,[9] as discussed earlier, confirming the idea of a scavenging function. Aquation occurs through a dissociative mode of activation giving rise to similar ΔV^* values for similar ligands. The differences found[10] for $[Fe(5NO_2phen)_3]^{2+}$, $[Fe(4,7diMephen)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$, +17.9, +11.6 and +15.4 cm^3 mol^{-1}, respectively, can be rationalized in terms of a spin-state change of the iron(II),[10,22] but also with differing degrees of bond lengthening (Fe—N bonds) in the transition state. The value of ΔV^* for aquation of $[Fe(5Brphen)_3]^{2+}$, $+22.3 \pm 1.0$ cm^3 mol^{-1} (Table 2) is consistent with the variation in ΔV^*, caused by ligand substituent, that was found earlier[10] (Table 2). However, practical reasons ruled out study of the aquation kinetics at high pressure in the directly comparable acidic medium (1.0 mol dm^{-3} H_2SO_4). Where a parallel study was possible, we report ΔV^* values of $+21.7 \pm 1.0$ cm^3 mol^{-1} in the presence of EDTA at 298.2 K, and 17.9 ± 0.3 cm^3 mol^{-1} [10] for aquation of $[Fe(5NO_2phen)_3]^{2+}$ in 1.0 mol dm^{-3} H_2SO_4 at 308.2 K. This difference is larger than could be explained by experimental uncertainty or the different temperature of measurement. At present we are unable to examine the generality (or not) of this result. However, it would appear that in addition to differences in bond extension within complexes containing similar ligands, solvation effects by virtue of reaction in very different media may yield a significant difference in ΔV^* for aquation with the same ligand;[23-25] the ionic strength is 3.0 mol dm^{-3} in the acid aquation study, much higher than in the presence of 0.010 mol dm^{-3} EDTA. This gives rise to different structural characteristics of water in general and in the vicinity of the activated complex in the two reactions. Exactly how this gives rise to the particular solvation difference, and whether ionic strength effects are as significant as in redox reactions[23-25] remain to be explained. The complicated dependence upon $[H^+]$ for dissociation of $[Fe(bpy)_3]^{2+}$ [26-28] precludes a parallel proton/EDTA aquation investigation.

Dissociation of $[Fe(phen)_3]^{2+}$ in the presence of 0.1 M CF_3SO_3H in anhydrous methanol yields[22c] an activation volume of +14.1 cm^3 mol^{-1}, close to the value for aquation in aqueous acid solution (+15.4 cm^3 mol^{-1}). But both are well below the reported values for dissociation in the presence of the nucleophiles, OH^- ($\Delta V^* = +19.7$ cm^3 mol^{-1}) and CN^- ($\Delta V^* = +19.8$ cm^3 mol^{-1}). The closeness of the two ΔV^* values for the aquation is perhaps surprising in view of the pronounced differences in the reaction media, and bearing in mind the possibility that ionic strength variation may cause different volume changes upon achieving the transition state. However, it has been suggested[10,22] that ΔV^* for a dissociative reaction of this type is dominated by the spin-change preequilibrium and is only modestly sensitive to aromatic substitution, and therefore perhaps also to medium changes. It is almost ironical that ΔV^* for dissociation of $[Fe(phen)_3]^{2+}$ by OH^- according to the new results reported here and for aquation are numerically the same, although we have argued that the mechanisms are different. Therefore, based upon the interpretation presented here, the agreement is fortuitous.

(*Received* 23 *August* 1990; *accepted* 5 *December* 1990)

Abstract—Reactions of the complex $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ with one equivalent of L (L = imidazole, 2-methylimidazole or 4-methylimidazole) in the presence of excess but-2-yne at room temperature in CH_2Cl_2 affords good yields of the bis(but-2-yne) complexes $[W(CO)L(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (**1–3**). Whereas, reaction of $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ with two equivalents of L (L = imidazole, 2-methylimidazole or 4-methylimidazole) affords high yields of the new mono(but-2-yne) complexes $[W(CO)L_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4]$ (**4–6**). ^{13}C NMR spectroscopy indicates that the but-2-yne ligands in **1** are donating a total of six electrons to the tungsten, whereas in **4–6** the but-2-yne is donating four electrons to the tungsten. Variable-temperature ^1H NMR studies have been carried out on **4–6** in order to calculate the barrier to but-2-yne rotation.

In recent years considerable attention has been paid to cationic alkyne complexes of molybdenum(II) and tungsten(II). The cationic cyclopentadienyl- or indenyl-containing bis(alkyne) complexes of the type $[Mo(CO)(\eta^2\text{-}RC_2R')_2(\eta^5\text{-}C_5H_5$ or $C_9H_7)][BF_4]$[1] have been shown to be useful precursors for a diverse range of chemistry.[2–8] Templeton and co-workers[9] have reported the preparation of the cationic mono(alkyne) complex $[W(CO)(S_2CNEt_2)(dppe)(\eta^2\text{-}HOC_2CH_2Ph)][BF_4]$; more recently, we reported the synthesis of the cationic bis(but-2-yne) complex $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$[10] and described its reactions with monodentate phosphines.[11] To date, however, there have been no reports of cationic bis(alkyne) dithiocarbamate complexes of tungsten(II) containing coordinated imidazole or substituted imidazole ligands. In this paper we report on the reaction of the bis(but-2-yne) complex $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ with one and two equivalents of imidazole and substituted imidazoles.

EXPERIMENTAL

The complex $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ was prepared according to the published method.[10] All other chemicals were purchased from commercial sources.

Elemental analyses for carbon, hydrogen and nitrogen were determined using a Carlo Erba Elemental Analyser MOD 1106 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 1430 ratio recording IR spectrophotometer as thin films in $CHCl_3$ between NaCl plates. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC 250 CP/MAS NMR spectrometer and calibrated against tetramethylsilane.

$[W(CO)(N_2C_3H_4)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]\cdot 0.5CH_2Cl_2$ (1)

To $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (0.4 g, 0.484 mmol) dissolved in CH_2Cl_2 (15 cm^3) containing but-2-yne (0.2 cm^3), with continuous stirring under a stream of dry N_2, was

[a] Calculated values in parentheses.

added $N_2C_3H_4$ (imidazole) (0.033 g, 0.484 mmol). After stirring for 20 h the solution was filtered and the solvent volume reduced to 1 cm^3 *in vacuo*. Dropwise addition of diethyl ether precipitated the yellow cationic complex $[W(CO)(N_2C_3H_4)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]\cdot 0.5CH_2Cl_2$ (**1**), which on recrystallization from CH_2Cl_2/Et_2O afforded 0.33 g, 75% of pure product.

Similar reactions of $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ with one equivalent of $N_2C_3H_3$-2Me and $N_2C_3H_3$-4Me in CH_2Cl_2 afforded the analogous cationic bis(but-2-yne) complexes $[W(CO)L(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (**2** and **3**) (see Table 1 for physical and analytical data).

$[W(CO)(N_2C_3H_4)_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4]\cdot 0.5CH_2Cl_2$ (**4**)

To $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (0.4 g, 0.484 mmol) dissolved in CH_2Cl_2 (15 cm^3), with continuous stirring under a stream of dry N_2, was added $N_2C_3H_4$ (0.066 g, 0.968 mmol). After stirring for 3 days the solution was filtered and the solvent reduced to 0.5 cm^3 *in vacuo*. Dropwise addition of diethyl ether precipitated the purple cationic complex $[W(CO)(N_2C_3H_4)_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4]\cdot 0.5CH_2Cl_2$ (**4**) which on recrystallization from CH_2Cl_2/Et_2O yielded 0.31 g, 74% of pure product.

Similar reactions of $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ with two equivalents of $N_2C_3H_3$-2Me and $N_2C_3H_3$-4Me in CH_2Cl_2 afforded the analogous cationic compounds $[W(CO)L_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4]$ (**5** and **6**) (see Table 1 for physical and analytical data).

RESULTS AND DISCUSSION

Equimolar quantities of the complex $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ and L (L = imidazole, 2-methylimidazole or 4-methylimidazole) react in the presence of but-2-yne in CH_2Cl_2 at room temperature to afford a high yield of the cationic bis(but-2-yne) complexes $[W(CO)L(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ (**1–3**). Reactions of $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ with two equivalents of L (L = imidazole, 2-methylimidazole or 4-methylimidazole) afford high yields of the mono(but-2-yne) complexes $[W(CO)L_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4]$ (**4–6**). Complexes **1–6** are stable when stored under nitrogen for prolonged periods, however, they slowly decompose when exposed to air in solution. Compounds **1–6** are all soluble in CH_2Cl_2, $CHCl_3$, $OC(CH_3)_2$ and NCMe, but are totally insoluble in Et_2O and hydrocarbon solvents. All of the compounds have been fully characterized by elemental analysis (C, H and N, Table 1), IR (Table 2), ^1H and selected cases ^{13}C NMR spectroscopy (Tables 3 and 4). Compounds **1**, **2** and **4** have been confirmed as $0.5CH_2Cl_2$ solvates by repeated elemental analysis and ^1H NMR spectroscopy.

When the complex $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ is reacted with one equivalent of $N_2C_3H_4$, $N_2C_3H_3$-2Me or $N_2C_3H_3$-4Me

Table 2. IR data[a] for the compounds [W(CO)L($S_2CNC_4H_8$)(η^2-MeC_2Me)$_2$][BPh_4] and [W(CO)L_2($S_2CNC_4H_8$)(η^2-MeC_2Me)][BPh_4]

Compound	ν(NH) cm^{-1}	ν(C≡O) cm^{-1}	ν(C≡C) cm^{-1}
1	3320m 3150m	2050s	1850w

5	3300m 3220m	1905s	[b]
6	3330m 3220m	1900s	[b]

[a] Spectra recorded as thin films in $CHCl_3$ between NaCl plates: m = medium, s = strong, w = weak.
[b] ν(C≡C) was not observed for these complexes.

in CH_2Cl_2, IR spectroscopy shows the formation of the expected bis(alkyne) complexes [W(CO)L($S_2CNC_4H_8$)(η^2-MeC_2Me)$_2$][BPh_4]; however, there is also evidence for the formation of the 2:1 adducts [W(CO)L_2($S_2CNC_4H_8$)(η^2-MeC_2Me)][BPh_4] [see eq. (1)]:

$$[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4] + L \longrightarrow [W(CO)L(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4] \underset{MeC_2Me}{\overset{L}{\rightleftharpoons}} [W(CO)L_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4] \quad (1)$$

The addition of the second imidazole or substituted imidazole can be suppressed by the addition of free but-2-yne to the reaction mixture thus, allowing isolation of the bis(but-2-yne) complexes (**1–3**) without contamination from the bis-substituted mono-(but-2-yne) compounds.

The formation of the compounds [W(CO)L_2($S_2CNC_4H_8$)(η^2-MeC_2Me)][BPh_4] (**4–6**) takes approximately 3 days, even when an excess of imidazole or substituted imidazoles was added. The most likely reason for this slow alkyne substitution is due to the ability of free but-2-yne generated preventing the second substitution taking place.

The IR spectra of compounds **1–3** all show an intense carbonyl stretching band around 2055 cm^{-1}, whereas compounds **4–6** show a single intense carbonyl band around 1900 cm^{-1}. The lower value for complexes **4–6** is due to the loss of a strong π-accepting but-2-yne ligand which allows more electron density to be back donated into the π^*

Table 3. ^{1}H NMR data[a] for the compounds [W(CO)L($S_2CNC_4H_8$)(η^2-MeC_2Me)$_2$][BPh_4] and [W(CO)L_2($S_2CNC_4H_8$)(η^2-MeC_2Me)][BPh_4]

[a] Spectra recorded in $CDCl_3$ (+25°C) referenced to $SiMe_4$; s = singlet, q = quarter, b = broad.

antibonding molecular orbitals of the coordinated carbon monoxide. A weak band around 1850 cm^{-1} has been assigned to the alkyne $\nu(C{\equiv}C)$ in compounds **1–3**, this band was not observed in complexes **4–6**.

The ^1H NMR spectra of compounds **1–3** all show four but-2-yne methyl resonances which is indicative of an asymmetric isomer present in solution, Fig. 1. Considering the solid-state geometry of $[W(CO)(NCMe)(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)_2][BPh_4]$ determined by Drew and co-workers,[10] as displayed in Fig. 2, and the fluctional properties of these molecules the rearrangement in geometry can be explained in terms of a trigonal twist rearrangement, as shown in Scheme 1. The room temperature ^1H NMR spectra of compounds **4–6** display one coordinated but-2-yne methyl resonance, which is indicative of the ligated but-2-yne undergoing rapid propeller-like rotation. In order to show that the fluxional process is intramolecular and not intermolecular for $[W(CO)(N_2C_3H_3\text{-}2Me)_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BF_4]$ (**5**), the ^1H NMR spectrum of this complex was obtained in $CDCl_3$ solution above its coalescence temperature in the presence of an equimolar quantity of but-2-yne. This spectrum clearly showed two singlets at chemical shifts corresponding to those of free but-2-yne (δ 1.8 ppm) and of complex **5** (δ 3.28 ppm) rather than one signal at an averaged chemical shift. This indicates that the fluxional process observed for this complex is intramolecular. The ^1H NMR spectra for the but-2-yne methyl protons of $[W(CO)(N_2C_3H_4)_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4]\cdot 0.5CH_2Cl_2$ (**4**) are shown in Fig. 3. The barriers to but-2-yne rotation in complexes **4–6** have been calculated using the Gutowsky–

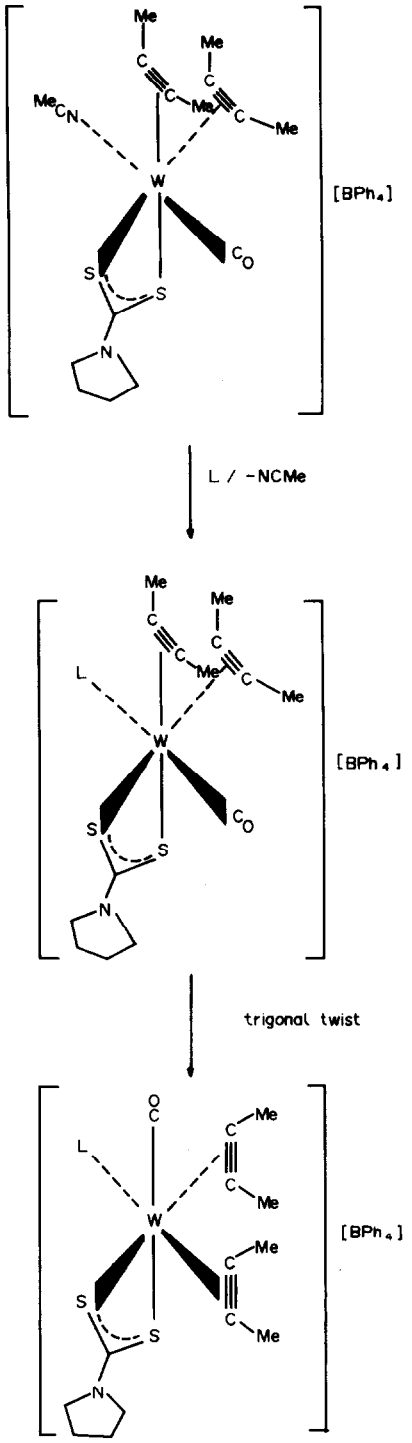

Scheme 1. Trigonal twist rearrangement to explain the solution state geometry of [W(CO)L(S$_2$CNC$_4$H$_8$)(η^2-MeC$_2$Me)$_2$][BPh$_4$].

Holm equation[13,14] [$\Delta G^{\ddagger} = -RT_c \ln(\pi\Delta\nu h/\sqrt{2}K_B T_c)$], see Table 5 for coalescence temperatures and barriers for but-2-yne rotation. All three complexes have the same value for but-2-yne rotation, within the experimental errors of the method, $\Delta G^{\ddagger} \sim 56$ kJ mol^{-1}.

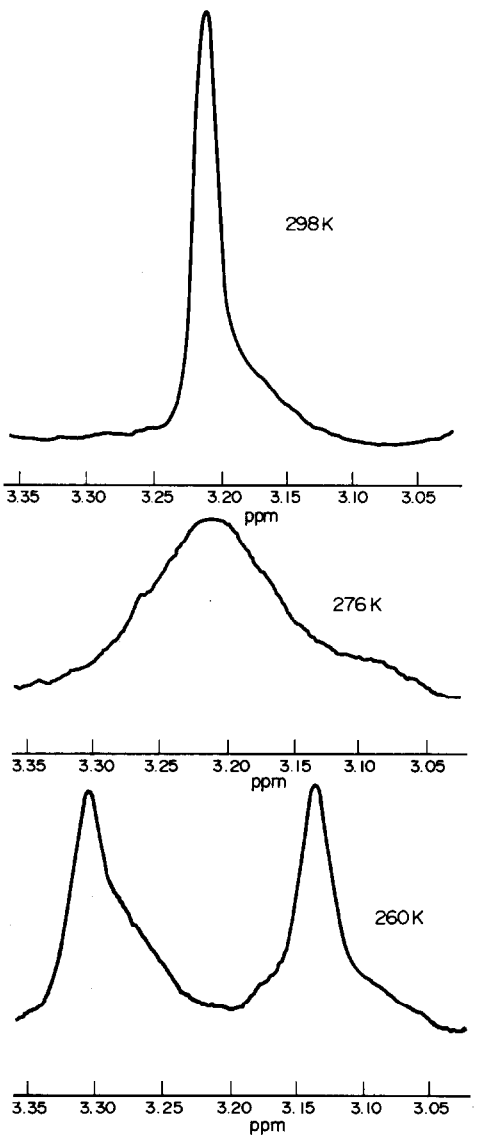

Fig. 3. ^{1}H NMR spectra of the but-2-yne methyl protons of [W(CO)(N$_2$C$_3$H$_4$)$_2$(S$_2$CNC$_4$H$_8$)(η^2-MeC$_2$Me)][BPh$_4$]·0.5CH$_2$Cl$_2$ (**4**) at three different temperatures.

The addition of the methyl groups in the 2 or 4 position seems to have little effect on the barrier to but-2-yne rotation. The other resonances in the ^{1}H NMR spectra are indicative of the coordinated imi-

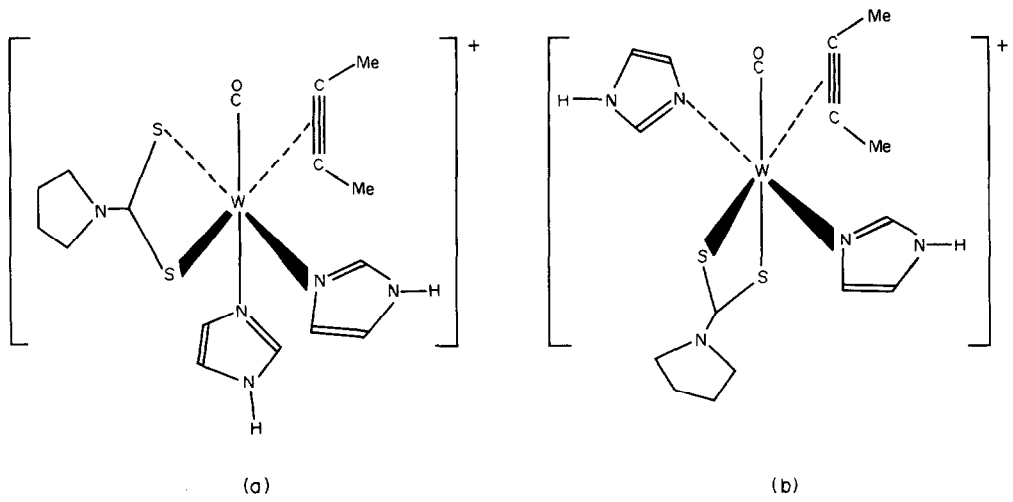
Compound	T_c (K)	$\Delta\nu$ (Hz)	$\Delta G^{\ddagger}$ (kJ mol^{-1})
4	276	42.92	56
5	270	45.78	56
6	275	64.14	56



(a) (b)

Fig. 4. Possible coordination geometries for complexes **4–6**.

dazoles being *cis* within the coordination sphere, Fig. 4(a). However, on careful consideration there is a possibility of the imidazoles being coordinated *trans*, Fig. 4(b). If the two imidazoles are not undergoing rapid rotation about the (W—N) bond they may take different orientations which would explain the observation of two resonances for each imidazole proton. The *trans* orientation of monodentate ligands within this system has been observed before in the bis(phosphine) complexes $[W(CO)L_2(S_2CNC_4H_8)(\eta^2\text{-}MeC_2Me)][BPh_4]$.[11] It is, therefore, difficult to distinguish between these two possible isomers.

The ^{13}C NMR spectrum of compound **1** shows alkyne contact carbon resonances between 188.05 and 174.0 ppm, which is indicative[14] of the but-2-yne ligands donating a total of six electrons to the tungsten. Whereas, for compounds **4–6** the alkyne contact carbon resonances are above 200 ppm which suggests[14] the coordinated but-2-yne is using both sets of $p\pi$ orbitals in bonding with the tungsten, thus behaving as a four-electron donor. The quartet around 165 ppm is indicative of the $[BPh_4]^-$ counteranion and confirms the cationic nature of these complexes.

THE SYNTHESIS AND REACTIVITY OF SOME μ-PHTHALOYL AND μ-PHENYLENE COMPLEXES

SELWYN F. MAPOLIE and JOHN R. MOSS†

Department of Chemistry, University of Cape Town, Rondebosch 7700, South Africa

(*Received* 24 *September* 1990; *accepted* 5 *December* 1990)

Abstract—The binuclear μ-phthaloyl compounds 1,4-$C_6H_4(COM)_2$, where M = $Re(CO)_5$, $Mn(CO)_5$, η^5-$C_5H_5Fe(CO)_2$, η^5-$C_5H_5Mo(CO)_3$, $Rh(PPh_3)_2Cl_2$ or $Co(CO)_3(PPh_3)$, have been prepared and converted to the μ-phenylene compounds 1,4-$C_6H_4M_2$, where M = $Re(CO)_5$, $Mn(CO)_5$ or η^5-$C_5H_5Fe(CO)_2$. The reactions of the μ-phthaloyl compounds with halogens, reducing agents and PPh_3 are reported, as are the reactions of the μ-phenylene complexes with CO, synthesis gas, SO_2, halogens and tertiary phosphines.

Mononuclear aryl complexes L_nM-Ar are well known. These complexes can be models for metal aryl species in catalytic reactions which give monofunctional aryl products, ArX.[1] Difunctional aryl compounds such as the phthalic acids $C_6H_4(COOH)_2$ are of great commercial importance.[2] Potential precursors of 1,4-$C_6H_4X_2$ compounds in a catalytic cycle would be the binuclear μ-phenylene or μ-phthaloyl complexes 1,4-$C_6H_4(ML_n)_2$ or 1,4-$C_6H_4(COML_n)_2$. When we started our investigations, very few binuclear compounds of these types were known. The compounds where ML_n = $Mn(CO)_5$ or $Re(CO)_5$ had been briefly mentioned,[3] as had 1,4-$C_6H_4(Cp^*_2Lu)_2$ (Cp^* = η^5-C_5Me_5).[4] The compound 1,4-$C_6H_4[Ni(PPh_3)_2Br]_2$ is known[5] and 1,4-C_6H_4[Fe(porphyrin)]$_2$ has recently been reported.[6] While our work was in progress, Hunter and co-workers reported some μ-phthaloyl and μ-phenylene complexes[7–10] which we had independently prepared. We now report some examples of these complexes, some new data on previously prepared compounds, as well as the results of some reactivity studies on these compounds.

EXPERIMENTAL

All reactions were performed under an atmosphere of high purity nitrogen using standard Schlenk tube techniques. Solvents were purified by standard procedures. The compounds $Mn_2(CO)_{10}$, $Re_2(CO)_{10}$, $[CpFe(CO)_2]_2$, $[CpMo(CO)_3]_2$ and $Co_2(CO)_8$ were purchased from Strem; K-Selectride (potassium tri-*sec*-butylborohydride) was purchased from Aldrich. These and other reagents were used as received. The compounds $RhCl(PPh_3)_3$[11] and $[Co(CO)_3(PPh_3)]_2$[12] were prepared by standard procedures. IR spectra were recorded on a Perkin–Elmer 983 spectrophotometer and NMR spectra on either a Varian XL 100 or VXR 200 or a Bruker WH 90 instrument. Tetramethylsilane was used as an internal standard (δ 0.00 ppm) for NMR spectra. Mass spectra were recorded on a V.G. Micromass 16 F spectrometer operating at 70 eV and using an accelerating voltage of 4 kV. Melting points were determined on a Reichert Thermovar hotstage microscope. Microanalyses were performed in the microanalytical laboratory at the University of Cape Town. Photochemical reactions were carried out in a Hanovia photochemical reactor (125 W) and high pressure reactions in a 250 cm^3 Berghoff autoclave.

μ-Phthaloyl complexes

Preparation of 1,4-$C_6H_4[COCpMo(CO)_3]_2$ (**1**)

A solution of $Na[CpMo(CO)_3]$ (2.04 mmol) was added to a solution of 1,4-$C_6H_4(COCl)_2$ (0.21 g, 1.02 mmol) in THF (2 cm^3) at −78°C. The reaction mixture was then stirred at −78°C for 30 min and then allowed to warm up to room temperature over 30 min. The solvent was removed to give a brown residue which was extracted with CH_2Cl_2

† Author to whom correspondence should be addressed.

($50\ cm^3$) and filtered. The filtrate was evaporated, resulting in an orange–red residue which was dissolved in benzene and chromatographed on an alumina column. A red band was eluted with benzene which gave $[CpMo(CO)_3]_2$ (78%). An orange band was eluted with 20% CH_2Cl_2/benzene which produced an orange–yellow solid on evaporation. The solid was recrystallized from CH_2Cl_2/hexane to yield the required product. The yield, m.p., elemental analysis and spectral data for this and other new complexes are given in Table 1. The compounds 1,4-$C_6H_4(COM)_2$ [where M = $Mn(CO)_5$ (**2**) or $CpFe(CO)_2$ (**3**)] were prepared in a similar way, as has been described by Hunter and Szigety.[9]

Preparation of 1,4-$C_6H_4[CORe(CO)_5]_2$ (**4**)

A solution of the sodium salt $Na[Re(CO)_5]$ (2 mmol) in THF ($30\ cm^3$) was added dropwise to a solution of 1,4-terephthaloyl dichloride (1 mmol) in THF ($5\ cm^3$) with rapid stirring. The reaction mixture was stirred for 3 h after which the solvent was removed and the residue triturated with water ($4 \times 30\ cm^3$). The solid product was filtered off, washed with diethyl ether ($5 \times 30\ cm^3$) and dried *in vacuo*.

Preparation of 1,4-$C_6H_4[COCo(CO)_3(PPh_3)]_2$ (**5**)

The compound $[Co(CO)_3(PPh_3)]_2$ (0.50 g, 0.62 mmol) as a suspension in THF ($20\ cm^3$) was stirred

Table 1. Data for μ-phthaloyl and μ-phenylene compounds

[c] $CDCl_3$ solution unless otherwise stated.
[d] Nujol mull.
[e] Not recorded due to insolubility of sample.
[f] CD_2Cl_2.

with a sodium amalgam (0.1 g Na in 2 cm^3 Hg) for 18 h. The resulting green solution of $Na[Co(CO)_3(PPh_3)]$ (1.24 mmol) was added to a solution of 1,4-$C_6H_4(COCl)_2$ (0.13 g, 0.62 mmol) in THF (2 cm^3) and the mixture stirred for 18 h at room temperature. The solvent was removed leaving a green residue which was extracted with CH_2Cl_2 (60 cm^3) and filtered. The volume of the filtrate was reduced to *ca* 10 cm^3 and chromatographed on a Florisil column. A pale yellow band containing 1,4-$C_6H_4(COCl)_2$ and 1,4-$C_6H_4(COOH)_2$ was eluted initially using CH_2Cl_2. A bright yellow band was then eluted with CH_2Cl_2/ethanol (1 : 1) which gave a solid on evaporation. This was recrystallized from CH_2Cl_2/hexane to give microcrystals of the product. The same compound is obtained, in lower yield, from the reaction of $Na[Co(CO)_4]$ with 1,4-$C_6H_4(COCl)_2$ followed by the addition of PPh_3 to the reaction mixture.

Preparation of 1,4-$C_6H_4[CORhCl_2(PPh_3)_2]_2$ (**6**)

To a solution of $RhCl(PPh_3)_3$ (0.50 g, 0.54 mmol) in CH_2Cl_2 (10 cm^3) was added a solution of 1,4-$C_6H_4(COCl)_2$ (0.055 g, 0.27 mmol) in CH_2Cl_2 (2 cm^3) and the reaction mixture was stirred for 6.5 h at room temperature. During this time, the solution changed colour from red to yellow and a fine precipitate formed. Hexane (100 cm^3) was added and the resulting precipitate was filtered and washed with CH_2Cl_2 (4 × 10 cm^3) to give the product as yellow microcrystals. IR (Nujol): ν(RhCl) 356 and 324 cm^{-1}.

μ-Phenylene complexes

Preparation of 1,4-$C_6H_4[Re(CO)_5]_2$ (**7**)

The compound **3** (0.050 g, 0.064 mmol), as a suspension in methyl isobutyl ketone (5 cm^3), was refluxed for 35 min then filtered hot. The solvent was reduced and the resulting mixture cooled to −15°C to give the product as white microcrystals.

The compound 1,4-$C_6H_4[Mn(CO)_5]_2$ (**8**) was prepared in 74% yield by refluxing the corresponding μ-phthaloyl compound in toluene and 1,4-$C_6H_4[CpFe(CO)_2]_2$ (**9**) was obtained in 26% yield on UV irradiation of a toluene solution of the μ-phthaloyl compound **4**; the data obtained for the manganese and iron compounds agreed well with that reported by Hunter and Szigety.[9]

Reactions of the μ-phthaloyl compounds

(a) *With halogens*

1,4-$C_6H_4[COMnCO)_5]_2$ (**2**) *with* Br_2 *or* I_2. A suspension of **2** (0.19 mmol) in THF (7 cm^3) was stirred at room temperature for *ca* 70 h with the halogen (0.76 mmol). Unreacted starting material (48%) was filtered off and 1,4-$C_6H_4(COOH)_2$ (48%) and $Mn(CO)_5X$ [where X = Br (44%), I (32%)] were isolated from the filtrate and identified by their IR spectra.

1,4-$C_6H_4[COCpFe(CO)_2]_2$ (**3**) *with* Br_2 *or* I_2. In a similar way, **4** (0.21 mmol) was reacted with the halogen (0.42 mmol) in THF (7 cm^3) for 20 min to give 1,4-$C_6H_4(COOH)_2$ (94%) and $CpFe(CO)_2X$ [where X = Br (85%), I (77%)], the latter compounds were identified by IR and ^1H NMR.

1,4-$C_6H_4[CORe(CO)_5]_2$ (**4**) *with* Br_2 *or* I_2. In a similar way, **3** (0.13 mmol) was reacted with the halogen (0.26 mmol) in THF (7 cm^3) for 2 h to give 1,4-$C_6H_4(COOH)_2$ (83%) and $Re(CO)_5X$ [where X = Br (74%), I (69%)].

(b) *With tertiary phosphines*

1,4-$C_6H_4[COCpFe(CO)_2]_2$ (**3**) *with* PPh_3. A mixture of **4** (0.41 mmol) and PPh_3 (0.82 mmol) in toluene (200 cm^3) was irradiated in a photochemical reactor for 4 h. The solvent was removed and a benzene solution of the residue was chromatographed on an alumina column. An orange band was eluted with benzene which, after evaporation and recrystallization gave 1,4-$C_6H_4[CpFe(CO)(PPh_3)]_2$ (**15**) as orange microcrystals. Elution with CH_2Cl_2/benzene (1 : 9) gave **9** (6%).

(c) *With reducing agents*

1,4-$C_6H_4[COMn(CO)_5]_2$ (**2**) *with* K–*Selectride*. K–Selectride (0.76 cm^3 of a 1 M THF) solution was added to a suspension of **2** (0.38 mmol) in THF (5 cm^3) at −78°C. The reaction mixture immediately changed colour from yellow to orange and the IR showed new bands at 1886 and 1557 cm^{-1} which are assigned to $Mn(CO)_5^-$ and an unstable formyl complex. The only product isolated after work-up of the reaction mixture was $Mn_2(CO)_{10}$ (61%).

1,4-$C_6H_4[COCpFe(CO)_2]_2$ (**3**) *with* K–*Selectride or* $LiAlH_4$. Similarly, the reaction of **4** with K–Selectride gave $[CpFe(CO)_2]_2$ (65%), whereas the corresponding reaction with $LiAlH_4$ gave $[CpFe(CO)_2]_2$ (67%) and starting material (29%).

1,4-$C_6H_4[COMn(CO)_5]_2$ (**2**) *with* $LiBEt_3H$. The reaction was carried out in THF at room temperature and monitored by IR. New bands were observed at 1880 and 1560 cm^{-1} but the only product isolated was $Mn_2(CO)_{10}$ (54%).

1,4-$C_6H_4(COM)_2$ [M = $Mn(CO)_5$ $CpFe(CO)_2$ *or* $Re(CO)_5$] *with* BH_3·THF. No reaction of these μ-phthaloyl compounds was observed with BH_3·THF at room temperature in THF.

Reactions of μ-phenylene compounds

(a) *With* CO

1,4-$C_6H_4[Mn(CO)_5]_2$ (**8**) *with* CO. The autoclave was charged with **8** (0.11 mmol), THF (10 cm^3) and CO (30 atm). The mixture was then stirred at room temperature for 22 h, after which time the autoclave was vented and the solvent removed under reduced pressure from the reaction solution to give a white solid. The solid was washed with ether and identified as **2** (84%).

1,4-$C_6H_4M_2$ *with* CO. Similarly, reaction of 1,4-$C_6H_4[Re(CO)_5]_2$ (**7**) with CO (30 atm) on stirring at room temperature for 48 h gave **3** (20%) and unreacted starting material. Compound **9** showed no reaction with CO under these conditions.

(b) *With synthesis gas*

1,4-$C_6H_4[Mn(CO)_5]_2$ (**8**) *with* CO/H_2 (1 : 1). The autoclave was charged with **8** (0.21 mmol), THF (10 cm^3) and CO/H_2 (1 : 1) (40 atm) and the mixture heated at 70°C for 3.5 h. The autoclave was cooled and the gases vented. The resulting yellow solution was filtered and the solvent removed under reduced pressure. Addition of hexane gave a white solid which was filtered off and identified as 1,4-$C_6H_4(CH_2OH)_2$ (69%) by ^1H NMR, IR and mass spectra. The solvent was removed from the yellow filtrate to give $Mn_2(CO)_{10}$ (71%).

1,4-$C_6H_4M_2$ *with* CO/H_2 (1 : 1), *where* M = $Re(CO)_5$ *or* $CpFe(CO)_2$. Under similar conditions to the above, **7** gave a mixture of products containing unreacted starting material, **3**, 1,4-$C_6H_4(CH_2OH)_2$ and an unidentified aldehyde species, which could not be separated. Similarly, **9**, after 8 h, gave unreacted starting material (58%) and $[CpFe(CO)_2]_2$ (37%).

(c) *With* SO_2

1,4-$C_6H_4[Re(CO)_5]_2$ (**7**) *with* SO_2. A Carius tube was charged with **7** (0.07 mmol) and liquid SO_2 (10 cm^3) was condensed onto the solid and the tube was sealed with its Teflon tap. The tube was then treated at 80°C for 48 h. The SO_2 was evaporated to give a cream coloured residue which was extracted with CH_2Cl_2, filtered and the solvent removed. The resulting solid was recrystallized from hot $CHCl_3$/hexane to give 1,4-$C_6H_4[SO_2Re(CO)_5]_2$ (**11**) as a white microcrystalline solid; IR (Nujol): ν(SO) 1186s, 1048s cm^{-1}.

1,4-$C_6H_4[Mn(CO)_5]_2$ (**8**) *with* SO_2. Similarly, this reaction was carried out with **8** (0.21 mmol) and SO_2 (10 cm^3) at 80°C for 60 h, after which time the SO_2 was allowed to evaporate. The pale yellow residue was extracted with ethanol (3 × 20 cm^3), filtered and the solvent removed. The resulting solid was washed with CH_2Cl_2 (4 × 10 cm^3) to give 1,4-$C_6H_4[SO_2Mn(CO)_5]_2$ (**10**) as a yellow microcrystalline solid; IR (Nujol): ν(SO) 1190s, 1030m cm^{-1}.

1,4-$C_6H_4[CpFe(CO)_2]_2$ (**9**) *with* SO_2. Similarly, a Carius tube was charged with **9** (0.07 mmol) and liquid SO_2 (10 cm^3). The mixture was then stirred at room temperature for 38 h. The excess SO_2 was evaporated and the resulting residue recrystallized from CH_2Cl_2/hexane to give 1,4-$C_6H_4[SO_2CpFe(CO)_2]_2$ (**12**) as a yellow solid; IR (Nujol): ν(SO) 1193m, 1045m cm^{-1}.

(d) *With halogens*

1,4-$C_6H_4[CpFe(CO)_2]_2$ (**9**) *with* Br_2 *or* I_2. A solution of **9** (0.23 mmol) in THF (12 cm^3) was treated with Br_2 (0.46 mmol) and the brown mixture stirred for 30 min at room temperature. The solvent was removed leaving a red–brown residue. This was taken up in CH_2Cl_2 and chromatographed on an alumina column. Elution with CH_2Cl_2/hexane (1 : 9) resulted in 1,4-$C_6H_4Br_2$ (84%). Elution with CH_2Cl_2/hexane (1 : 1) gave $CpFe(CO)_2Br$ (82%).

Similarly, the reaction of **9** with I_2 gave 1,4-$C_6H_4I_2$ (60%) and $CpFe(CO)_2I$ (62%).

1,4-$C_6H_4[Re(CO)_5]_2$ (**7**) *with* Br_2. A similar reaction with **7** (0.28 mmol) in THF (12 cm^3) gave 1,4-$C_6H_4Br_2$ (76%) and $Re(CO)_5Br$ (81%).

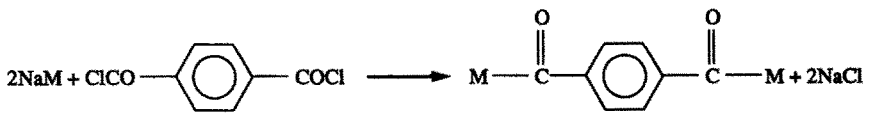
(e) *With tertiary phosphines*

1,4-$C_6H_4[Mn(CO)_5]_2$ (**8**) *with* $PMePh_2$. A solution of **8** (0.13 mmol) and $PMePh_2$ (0.26 mmol) in CH_2Cl_2 (10 cm^3) was treated with $Me_3NO \cdot 2H_2O$ (0.26 mmol) and the solution stirred at room temperature until no starting material remained, as judged by the IR spectrum. The solution was concentrated and chromatographed on an alumina column. Elution with CH_2Cl_2/hexane (1 : 1) gave a yellow solid from which 1,4-$C_6H_4[Mn(CO)_4(PMePh_2)]_2$ (**13**) was isolated. A similar reaction of **7** with PPh_3 gave 1,4-$C_6H_4[Mn(CO)_4(PPh_3)]_2$ (**14**) (76%).

1,4-$C_6H_4[CpFe(CO)_2]_2$ (**9**) *with* PPh_3. Compound **9** (0.23 mmol) and PPh_3 (0.46 mmol) in benzene (150 cm^3) was irradiated for 2 h. The solution was concentrated, chromatographed on an alumina column and eluted with benzene to give 1,4-$C_6H_4[CpFe(CO)(PPh_3)]_2$ (**15**) (11%).

DISCUSSION

The μ-phthaloyl compounds of molybdenum, manganese, rhenium, iron and cobalt were prepared by the following route

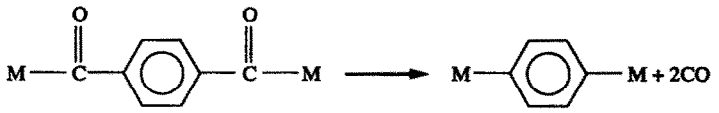


(1)

1 M = $CpMo(CO)_3$
2 M = $Mn(CO)_5$
3 M = $CpFe(CO)_2$
4 M = $Re(CO)_5$
5 M = $Co(CO)_3(PPh_3)$

The rhodium complex, $1,4\text{-}C_6H_4[CORhCl_2(PPh_3)_2]_2$ (**6**), was prepared by the oxidative addition reaction of $RhCl(PPh_3)_3$ to $1,4\text{-}C_6H_4(COCl)_2$. Characterization data for the new μ-phthaloyl compounds are given in Table 1. Data for compounds **2** and **3** have recently been reported by Hunter and Szigety.[9] Like the manganese and iron compounds (**2** and **3**) the rhenium and rhodium compounds (**4** and **6**) are air-stable in contrast to the molybdenum and cobalt compounds (**1** and **5**). With the exception of the cobalt compound, all the μ-phthaloyl compounds are rather insoluble. The ν(CO) bands in the IR spectra for **1**, **2** and **4** are in similar positions to those reported for the respective mononuclear analogues $CpMo(CO)_3(COPh)$[13] and $M(CO)_5(COPh)$ (where M = Mn or Re).[14] The IR spectrum of **6** is similar to that reported for $RhCl_2(PPh_3)_2(COR)$,[15] suggesting that the PPh_3 groups in both compounds may be *trans* to each other.

The μ-phenylene compounds of manganese, rhenium and iron were prepared by decarbonylation of the μ-phthaloyl precursors:



(2)

1 M = $Re(CO)_5$
2 M = $Mn(CO)_5$
3 M = $CpFe(CO)_2$

We obtained the rhenium and manganese compounds (**7** and **8**) by refluxing the appropriate μ-phthaloyl compounds in toluene or methyl isobutyl ketone. For compound **9**, decarbonylation was effected by either UV irradiation or chemical decarbonylation using $RhCl(PPh_3)_3$. The characterization data obtained for compounds **8** and **9** agreed well with that reported by Hunter and Szigety.[9] An attempt to synthesize **9** from $Na[CpFe(CO)_2]$ and $1,4\text{-}C_6H_4I_2$ in refluxing THF gave $1,4\text{-}C_6H_4I[CpFe(CO)_2]$ in 4% yield. We were not able to efficiently decarbonylate compounds **1**, **5** and **6** to give μ-phenylene products.

Mass spectra of the μ-phthaloyl compounds **2**–**4** did not show parent ions and the highest mass peaks we observed correspond to $[M-2CO]^+$; in fact, the spectra are identical to those of the corresponding μ-phenylene complexes **7**–**9**.

As reported by Hunter and Szigety,[9] we observe parent ions in the mass spectra for compounds **7**–**9**. We have also identified the main fragmentation pathways for these compounds which can be summarized as follows:

For compound **8**:
(1) Loss of 10 CO's from parent to give $M_2(C_6H_4)$
(2) Loss of $M(CO)_5$ from parent then 5 CO's

For compound **7**:
(1) and (2) above but also
(3) Loss of C_6H_4 from parent followed by 10 CO's

For compound **9**:
(1) Loss of 4 CO's from parent to give $Cp_2Fe_2(C_6H_4)$
(2) Loss of $CpFe(CO)_2$ from parent then 2 CO's.

Reactivity of the μ-phthaloyl complexes

Most of the reactions outlined below were carried out on the μ-phthaloyl compounds (**2–4**).

(a) *Reactivity of the μ-phthaloyl complexes* **2–4** *with halogens*

Although there are many reports of electrophilic cleavage of transition metal–carbon bonds of alkyl compounds, there are few reports of similar reactions of metal aroyl compounds and none that we are aware of on binuclear μ-phthaloyl compounds.[1] We have investigated the reactions of the μ-phthaloyl compounds of manganese, rhenium and iron with Br_2 and I_2 in THF at room temperature. In each case the metal halide and terephthalic acid were produced

$$1,4\text{-}C_6H_4(COM)_2 + 2X_2 \longrightarrow 2M\text{-}X$$

$$+ [1,4\text{-}C_6H_4(COX)_2] \longrightarrow 1,4\text{-}C_6H_4(COOH)_2$$
Not observed

[where M = $Mn(CO)_5$, $Re(CO)_5$ or $CpFe(CO)_2$; X = Br or I]; the terephthalic acid may result from hydrolysis of aroyl halide intermediates.

Even though the same type of products were obtained for the three complexes $1,4\text{-}C_6H_4(COM)_2$, the rates of the reactions were significantly different and followed the order $CpFe(CO)_2 > Re(CO)_5 > Mn(CO)_5$. This may be explained on the basis that metal–carbon bond cleavage is an electrophilic process. This is borne out by the reactivity order following decreasing electron density on the metal and that the reactions with iodine appear slower than those with bromine.

(b) *The reaction of* $1,4\text{-}C_6H_4[COCpFe(CO)_2]_2$ *with* PPh_3

Substitution of CO by PPh_3 is difficult in this complex since no reaction of compound **3** with PPh_3 occurred after refluxing in xylene for 3 days. UV irradiation in toluene for 4 h produced a 9% yield of the substituted phenylene complex, viz. $1,4\text{-}C_6H_4[CpFe(CO)(PPh_3)]_2$ (**15**).

(c) *Reactions of μ-phthaloyl complexes with reducing agents*

Attempts to reduce the aroyl CO groups in compounds **2** and **3** were made using K–Selectride, $LiAlH_4$, $LiBEt_3H$ or $BH_3 \cdot THF$ as reducing agents. Compounds **2** and **3** reacted with K–Selectride to give anionic intermediates, however, no new products could be isolated. Reaction of **3** with $LiAlH_4$ was slow and $[CpFe(CO)_2]_2$ was the only product identified, whereas $[Mn(CO)_5]^-$ was the only product identified from the reaction of **2** with $LiBEt_3H$. No reactions of **2–4** with $BH_3 \cdot THF$ were observed.

Reactivity of the μ-phenylene complexes

(a) *With* CO

Compound **8** gave 85% conversion to the μ-phthaloyl compound **2** after 22 h with CO (30 atm) in THF. There was no reaction of **8** with CO (1 atm) after 48 h. Compound **8** undergoes CO insertion much less readily than its mononuclear analogue $Mn(CO)_5Ph$.[16] The rhenium compound is less readily carbonylated than the manganese complex and only 20% of the μ-phthaloyl compound **4** was isolated after 48 h reaction time with CO (30 atm) at room temperature. The iron complex **9** showed no CO insertion under similar conditions.

(b) *With synthesis gas* (CO/H_2, 1 : 1)

The reaction of $1,4\text{-}C_6H_4[Mn(CO)_5]_2$ (**8**) gave $1,4\text{-}C_6H_4(CH_2OH)_2$ as the only isolable organic product and $Mn_2(CO)_{10}$. The reaction appears to be similar to that reported for $(CO)_5Mn(CH_2)_4Mn(CO)_5$ with synthesis gas.[17] In both these cases, the reaction with synthesis gas leads, via initial CO insertion, to a diol. No evidence for any further carbon chain growth is observed. This may be a general result in catalytic reactions, also that CO insertion leads to termination, with alcohol and aldehyde formation but not to carbon chain growth.

Compounds **7** and **9** were found to be less reactive towards synthesis gas.

(c) *With* SO_2

Since some mononuclear aryl complexes are known to react with SO_2 to form the corresponding S-sulphinates,[18,19] we were interested to investigate similar reactions with μ-phenylene complexes. Thus, we find that compounds **7–9** react with liquid SO_2 according to the following equation

$$1,4\text{-}C_6H_4M_2 + 2SO_2 \longrightarrow 1,4\text{-}C_6H_4(SO_2M)_2 \qquad (3)$$

10 M = $Mn(CO)_5$
11 M = $Re(CO)_5$
12 M = $CpFe(CO)_2$.

Data for compounds **1–12** are given in Table 1. In general, the reactions of the binuclear μ-phenylene complexes with SO_2 are significantly slower than analogous reactions with mononuclear phenyl compounds.

(d) *With halogens*

Compared to the corresponding μ-phthaloyl compounds, the μ-phenylene compounds **7–9** react more readily with the halogens Br_2 or I_2 in THF to yield the corresponding metal carbonyl halides and 1,4-dihalobenzenes [eq. (4)]:

$$1,4\text{-}C_6H_4M_2 + 2X_2 \longrightarrow 1,4\text{-}C_6H_4X_2 + 2MX \quad (4)$$

[M = $Mn(CO)_5$, $Re(CO)_5$ or $CpFe(CO)_2$; X = Br or I].

Similar results have been found for the reactions of the manganese and iron compounds.[9] We find the rate of metal–carbon cleavage by halogen in $1,4\text{-}C_6H_4M_2$ to be $CpFe(CO)_2$ > $Re(CO)_5$ > $Mn(CO)_5$; exactly the same order as we found for the μ-phthaloyl compounds.

(e) *With tertiary phosphines*

The reactions of **8** and **9** with PPh_3 or $PMePh_2$ were carried out under various conditions and gave substitution products according to eq. (5):

$$1,4\text{-}C_6H_4[M(CO)]_2 + 2PR_3 \longrightarrow 1,4\text{-}C_6H_4[M(PR_3)]_2 + 2CO \quad (5)$$

13 M = $Mn(CO)_4$, PR_3 = $PMePh_2$

14 M = $Mn(CO)_4$, PR_3 = PPh_3

15 M = CpFe(CO), PR_3 = PPh_3.

This CO substitution reaction is analogous to that reported for $Mn(CO)_5Ph$ with PPh_3, although the rate of reaction of the μ-phenylene complex **8** with PPh_3 is slower than that for $Mn(CO)_5Ph$.[20] Products resulting from aryl migration were not observed. Our results agree well with those reported by others for the reaction of **8** with PPh_3.[9] In the presence of Me_3NO, the reactions to give **13** and **14** in eq. (5) proceded much faster. Similar rate enhancement has been found for the substitution of CO by PPh_3 in $Mn(CO)_5Ph$.[21] On the basis of IR spectra in the ν(CO) region, compounds **13** and **14** adopt a *cis*-configuration at manganese.

CONCLUSIONS

The reactivity of the μ-phthaloyl and μ-phenylene complexes of several metals give similar products to analogous reactions of mononuclear compounds, although the rates of some of the reactions are different. We are at present obtaining quantitative data on these rate differences. These findings may have significance in catalytic reactions that yield difunctional aryl products.

(*Received* 27 *July* 1990; *accepted* 5 *December* 1990)

Abstract—The reaction of $(\eta^5\text{-Cp}')\text{Co(CO)}_2$ (Cp′ = C_5H_5, C_5H_4COMe) with bis(1,3-dimethylimidazolin-2-ylidene) gives the monosubstituted products $(\eta^5\text{-Cp}')\text{Co(CO)}[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]$. The reaction proceeds by first order in metal complex and first order in olefin. The rate of replacement of CO by the carbene fragment for $(\eta^5\text{-}C_5H_4COMe)Co(CO)_2$ in toluene at 95°C is 15 times faster than for the reaction of $(\eta^5\text{-}C_5H_5)Co(CO)_2$. The reasons for this difference are discussed in mechanistic terms.

Since the discovery of the first transition metal carbene complex, $(CO)_5W[C(OCH_3)CH_3]$, by Fischer and Maasböl,[1] there has been an ever increasing interest in the preparation, structure and reactivity of new transition metal carbene complexes.[2]

Carbene complexes derived from electron-rich olefins have been obtained by Lappert and coworkers,[3–5] exhibiting the nucleophilic character of the carbene fragment. The first mononuclear cobalt carbene complex derived from $(\eta^5\text{-}C_5H_5)Co(CO)_2$ has been reported recently[6] and the carbene fragment in $(\eta^5\text{-}C_5H_5)Co(CO)[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]$ is an extremely strong σ-donor ligand.

Substitution reactions of cyclopentadienyl metal compounds have been of special interest ever since Schuster-Woldan and Basolo[7] studied the reactions of $(\eta^5\text{-}C_5H_5)Rh(CO)_2$ and proposed that the cyclopentadienyl ligand promoted an associative pathway for carbonyl substitution reactions, due to the ability of the cyclopentadienyl ligand to accept an electron pair from the metal, thus creating a vacant orbital susceptible to nucleophilic attack.

If this mechanism is valid, then a complex with an electron-withdrawing group on the cyclopentadienyl ring should react faster than the parent complex. This is shown by the rate of replacement of C_2H_4 in the series $(\eta^5\text{-}C_5H_4CN)Rh(C_2H_4)_2$ > $(\eta^5\text{-}C_5H_5)Rh(C_2H_4)_2$ > $(\eta^5\text{-}C_5Me_5)Rh(C_2H_4)_2$,[8] and in the rate of replacement of CO in $(\eta^5\text{-}C_5H_4CO_2Me)Co(CO)_2$ > $(\eta^5\text{-}C_5Me_5)Co(CO)_2$ with phosphines and phosphites.[9,10]

Due to the relevance of carbene complexes in catalytic reactions, an understanding of how coordinatively saturated organometallic compounds react by associative mechanisms is significant for these catalytic transformations.

We now report a kinetic and mechanistic study of the formation of the transition metal carbene complexes from an electron-rich olefin. The reaction of $(\eta^5\text{-}C_5H_4COMe)Co(CO)[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]$ with TCNE is reported. This olefin can act as a π-acceptor ligand or as a σ-donor ligand bonding to the metal through a nitrile nitrogen. Examples of the latter are the previously reported complexes $(\eta^5\text{-}C_5H_4Me)Co(CO)L$ [L = CO, PPh_3, $P(OMe)_3$, py][11] in which TCNE acts as an oxidizing agent and coordinates to the metal through a nitrogen atom.

RESULTS AND DISCUSSION

Table 1 lists the carbonyl stretching frequencies of $Cp'Co(CO)_2$ and $Cp'Co(CO)[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]$ (Cp′ = C_5H_5, C_5H_4COMe).

Evidently the addition of the electron-withdrawing acetyl group to the cyclopentadienyl ring

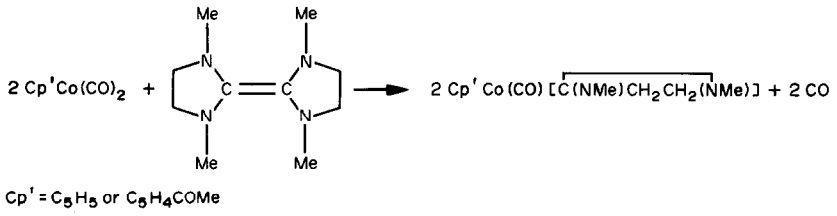
* Author to whom correspondence should be addressed.

Table 1. Carbonyl stretching frequencies in toluene solution

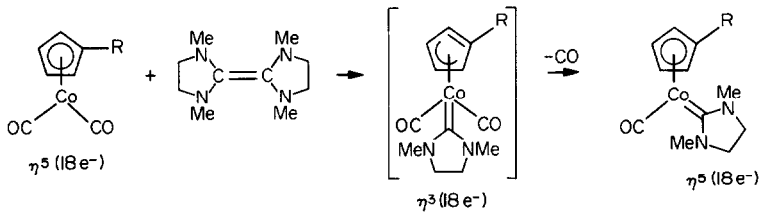
Complex	ν(CO) (cm^{-1})
$C_5H_5Co(CO)_2$	2023.2, 1959.8
$(C_5H_4COMe)Co(CO)_2$	2033.0, 1973.4
$C_5H_5Co(CO)[\overline{C(NMe)CH_2CH_2(NMe)}]$	1902.1
$(C_5H_4COMe)Co(CO)[\overline{C(NMe_4)CH_2CH_2(NMe)}]$	1916.8

results in a shift of ν(CO) to higher frequency, relative to $(\eta^5\text{-}C_5H_5)Co(CO)_2$. This is attributed to the reduced amount of backbonding between cobalt and carbon, making the CO bond closer to the triple bond in free CO, and indicates that the cobalt is less electron-rich in the acetylcyclopentadienyl complex.

Thus, substitution reaction (1) was expected to proceed faster for the acetylcyclopentadienyl compound than for the corresponding cyclopentadienyl compound.



(1)



(2)

This was observed experimentally; Table 2 contains the rate constant for reaction (1), $(\eta^5\text{-}C_5H_4COMe)Co(CO)_2$ reacts approximately 15 times faster than $(\eta^5\text{-}C_5H_5)Co(CO)_2$ in toluene at 95°C.

The rate of reaction (1) is directly proportional to the concentration of the incoming ligand. Figure 1 shows that for $(\eta^5\text{-}C_5H_4COMe)Co(CO)_2$, a straight line with a zero intercept is obtained indicating no detectable contribution from a ligand-independent (first-order) process under these experimental conditions.

Small enthalpies and especially large negative entropies of activation (Table 2) provide further evidence for an associative mechanism (S_N2). All of these results are consistent with a S_N2 mechanism similar to the mechanism first proposed for $(\eta^5\text{-}C_5H_5)Rh(CO)_2$ with PPh_3.[7]

The mechanism can be represented by eq. (2) involving a transition state in which a rearrangement of the ring from a delocalized structure to an allyl-ene structure occurs, the cobalt being bound only to the allyl portion. Several reports[8,12,13] have established a good deal of support for the η^5-to-η^3 slippage mechanism for associative substitution reactions of cyclopentadienyl compounds. An η^3-cyclopentadienyl ring has been observed during the

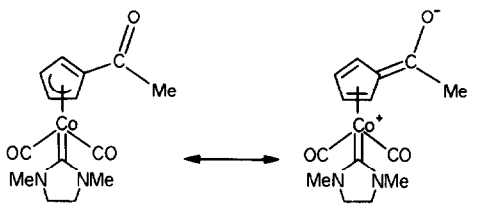
matrix photolysis of $(\eta^5\text{-}C_5H_5)Fe(CO)_2CH_3$[14] and Hüttner and co-workers[15] have isolated an η^3-cyclopentadienyl compound $(\eta^5\text{-}C_5H_5)W(\eta^3\text{-}C_5H_5)(CO)_2$. The increase in the rate constant observed for the acetylcyclopentadienyl complex is in accord with this mechanism and may be ascribed to a resonance stabilization of the transition state owing to the presence of the electron-withdrawing acetyl group on the ring, relative to the parent cyclopentadienyl compound, eq. (3).



(3)

Addition under nitrogen of a toluene solution of TCNE to a solution of $(\eta^5\text{-}C_5H_4COMe)Co(CO)[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]$ in the same solvent results in loss of CO and precipitation of a brown–black solid with the stoichiometry $(\eta^5\text{-}C_5H_4COMe)Co(TCNE)[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]$. Their IR spectra were obtained from Nujol mulls and tetrahydrofuran (THF) and dimethylsulphoxide (DMSO) solutions. The $\nu(C{\equiv}N)$ frequencies are listed in Table 3. In Nujol mulls these spectra show three bands. The one at lower frequency is broad but is resolved in solution, the resolution becoming better as the polarity of the solvent is increased (Fig. 2). The $\nu(C{\equiv}N)$ value is lowered with respect to that in free TCNE (2260, 2225 cm^{-1}). The multiplicity of $\nu(C{\equiv}N)$ bands is consistent with low (local) symmetry of the coordinated TCNE, indicating that TCNE is σ-bonded to cobalt through a nitrogen nitrile[16,17] atom.

The ^{13}C NMR spectrum shows two doublets at 91.05 and 116.94 ppm assigned to CN and C=C, respectively; this is also in accordance with coordination to cobalt through a nitrile nitrogen atom.

The electronic spectra were obtained in these same solvents. A broad band was observed at λ_{max} *ca* 550 nm. In the 360–490 nm region hyperfine structure (363, 388, 407, 423, 437, 456, 486 nm) characteristic of the TCNE anion radical is observed.[18]

The ESR spectra was obtained at room temperature in acetone, DMF and DMSO solutions. The spectra in the first two solvents show a broad signal; however, in DMSO solution the ESR spectra display a strong signal characteristic of the TCNE anion radical (nine lines, a_N 1.60 G, g = 1.998).[19] All the data obtained for the complex $(\eta^5\text{-}C_5H_4COMe)Co(TCNE)[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]$ indicate that TCNE is reduced to $TCNE^-$ and coordinates to cobalt through one of the nitrile nitrogen atoms. Thus the complex can be regarded formally as $(\eta^5\text{-}C_5H_4COMe)Co[\dot{C}(NMe)CH_2CH_2(\dot{N}Me)]^+ \cdot TCNE^-$, in which the cation has accepted σ-electron density from a nitrile nitrogen atom of $TCNE^-$.

These results are similar to those obtained for analogous complexes[11] containing phosphorus-donor ligands such as $(\eta^5\text{-}C_5H_4Me)Co(TCNE)(L)$ [L = PPh_3, $P(OMe)_3$].

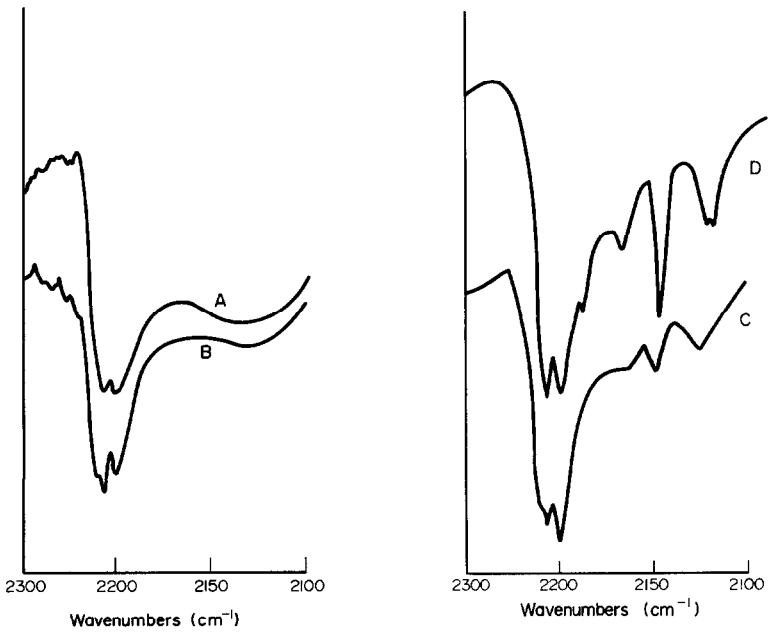

Fig. 2. $\nu(C{\equiv}N)$ stretching frequencies for the complex (η^5-C_5H_4COMe)Co(TCNE)[$\overline{C(NMe)CH_2CH_2(NMe)}$] in (A) Nujol mulls, (B) THF, (C) acetone and (D) DMSO solution.

EXPERIMENTAL

All manipulations were carried out by using standard Schlenk techniques under an atmosphere of oxygen-free nitrogen. Toluene, hexane and THF were dried over and distilled from sodium benzophenone ketyl under a nitrogen atmosphere, then bubbled with nitrogen for 1 h and stored under nitrogen. DMSO was dried over and distilled from BaO.

The reagent TCNE was obtained from Fluka and was used without further purification. Bis (1,3-dimethylimidazolin-2-ylidene)[20] was prepared according to a literature method and distilled in a stream of nitrogen at reduced pressure immediately prior to use. The compounds (η^5-C_5H_5)$Co(CO)_2$,[21] (η^5-C_5H_4COMe)$Co(CO)_2$[22] and (η^5-C_5H_5)Co(CO)[$\overline{C(NMe)CH_2CH_2(NMe)}$][6] were prepared by methods described in the literature and characterized by their IR and NMR spectra.

The microanalyses were performed by the Microanalytical Laboratory of this Department. The cobalt was determined by titration of the cobalt–EDTA complex in the presence of NET as indicator.

Instruments

The IR spectra were recorded in the range 4000–200 cm^{-1} on a Nicolet 5DX FT–IR spectrometer using Nujol and hexachlorobutadiene mulls between CsI windows or in THF and DMSO solution. $^1H^{13}C$ NMR spectra were obtained on a Bruker WH-200-SY instrument, chemical shifts are relative to TMS. The electronic spectrum was recorded on a Pye Unicam SP8-100 spectrophotometer. The ESR spectra were recorded at a microwave frequency of 9 GHz (*X*-band) on a Varian E-12 spectrometer equipped with a HP 5342 A frequency-meter and a Bruker NMR Gaussmeter.

Kinetic studies

Solutions of both the ligand and the compound (η^5-Cp′)$Co(CO)_2$ (Cp′ = C_5H_5, C_5H_4COMe) were placed under nitrogen in an aluminium foil-wrapped Schlenk flask and thermostatted in a constant temperature bath (±0.2°C). At zero time the solution of olefin was added via syringe to the cobalt compound to give exactly 8 cm^3 of reaction mixture. Aliquots were subsequently withdrawn through a rubber septum with the use of a syringe at intervals to obtain 5–10 readings during 2–3 half-lives of reaction and transferred to a 0.5 mm NaCl cell. The IR cell was flushed with nitrogen and sealed with a rubber septum before use.

Reactions were followed by monitoring the disappearance of the highest frequency carbonyl

stretching band of the complexes (η^5-Cp′)Co(CO)$_2$ (Cp′ = C_5H_5 or C_5H_4COMe) with a Nicolet 5DX FT-IR spectrophotometer, using the absorbance mode.

Approximately 8.5×10^{-3} M solutions of complex were used, and all kinetic experiments were carried out under pseudo-first-order conditions with at least a ten-fold excess of ligand. All reactions went to completion to give the corresponding monocarbonyl product (η^5-Cp′)Co(CO)[$\overline{C(NMe)CH_2CH_2(NMe)}$] (Cp′ = C_5H_5, C_5H_4COMe).

The plot of log A (absorbance, of the highest carbonyl band of the complexes) vs time were linear for more than three half-lives and k_{obs} was determined from the slope of this line by the least-squares methods. The correlation of the least-squares line ($R^2 > 0.996$) was very good.

Preparation of (η^5-C_5H_4COMe)Co(CO)[$\overline{C(NMe)CH_2CH_2(NMe)}$]

To a solution of (η^5-C_5H_4COMe)Co(CO)$_2$ (2 g, 9.01 mmol) in toluene (30 cm^3) in a nitrogen-filled 100 cm^3 Schlenck flask was slowly added, by ampoule transfer, a solution of bis(1,3-dimethylimidazolin-2-ylidene) (0.88 g, 4.51 mmol). The mixture was refluxed for 22 h, then the solution was allowed to cool to 25°C, filtered, and the solvent removed *in vacuo*. The product was recrystallized from toluene–hexane in a 1 : 1 ratio to give a brown–red powder. The yield was 1.87 g (71%) (Found: C, 53.3; H, 5.9; N, 9.5; Co, 20.1. Calc. for $C_{13}H_{17}N_2O_2Co$: C, 53.4; H, 5.8; N, 9.6; Co, 20.0%). ^{1}H NMR ($CDCl_3$): δ 2.33 (s, 3H, CH_3); 2.71 (s, 4H, CH_2); 3.29 (s, 6H, CH_3); 5.05 [s, br, 2H, H(3,4)]; 5.22 [s, br, 2H, H(2,5)].

Preparation of (η^5-C_5H_4COMe)Co(TCNE)[$\overline{C(NMe)CH_2CH_2(NMe)}$]

A solution of TCNE (0.44 g, 3.42 mmol) in toluene (30 cm^3) was slowly added, with stirring at room temperature, to a solution of (η^5-C_5H_4COMe)Co(CO)[$\overline{C(NMe)CH_2CH_2(NMe)}$] (1 g, 3.42 mmol) in toluene (15 cm^3). A brown–black solid immediately appeared and evolution of carbon monoxide was observed. The product was filtered, washed with hexane–toluene (1 : 1) and dried *in vacuo*. The yield was quantitative (Found: C, 55.0; H, 4.3; N, 21.3; Co, 15.0. Calc. for $C_{18}H_{17}N_6OCo$: C, 55.1; H; 4.3; N, 21.4; Co, 15.0%). ^{1}H NMR ($CDCl_3$): 2.34 (s, 3H, CH_3); 2.55 (s, 4H, CH_2); 3.47 (s, 6H, CH_3); 5.14 [t, 2H, H(3,4)], 5.29 [t, 2H, H(2,5)]. ^{13}C NMR ($CDCl_3$): 39.37, 38.64, 52.47, 91.05 (d, J = 66.7 Hz), 116.94 (d, J = 74.96 Hz), 128.21 m, 158.75, 175.00.

CATALYTIC AND MAGNETIC PROPERTIES OF A NEW SERIES OF BINUCLEAR COPPER(II) COMPLEXES

B. SRINIVAS, N. ARULSAMY and P. S. ZACHARIAS*

School of Chemistry, University of Hyderabad, Hyderabad 500 134, India

(*Received* 3 *May* 1990; *accepted* 5 *December* 1990)

Abstract—Binuclear copper(II) complexes of ligands derived from condensation of 2,6-diformyl-4-methylphenol with various aromatic mono- and diamines have been synthesized. Complexes derived from monoamines have the Cu_2LCl_3 composition and those from diamines have the $Cu_2L'Cl_2$ composition, where L and L′ represent the ligands. Analytical data, conductance and spectral studies support these formulations. Cu_2LCl_3 complexes are chloro-bridged, as evidenced by two intense IR bands centred around 300 and 320 cm^{-1}. Magnetic susceptibility measurements show that Cu_2LCl_3 complexes have low μ_{eff} values indicating magnetically interacting copper(II) centres and $Cu_2L'Cl_2$ complexes have non-interacting copper(II) centres. Cu_2LCl_3 complexes undergo single-step quasi-reversible reduction at −0.62 V vs SCE. Catalysis of Cu_2LCl_3 complexes for the oxidation of 3,5-di-t-butylcatechol (3,5-DTBC) and ascorbic acid by dioxygen is studied.

Investigations on binuclear complexes of transition metals are of contemporary relevance due to their interesting magnetic, catalytic and electron-transfer properties and as models of bioinorganic chemistry.[1–7] They belong to two major classes: (i) where the metal centres are close enough to have metal–metal interaction either directly or through a bridge system,[8–10] and (ii) where the metal centres are isolated and have no significant interaction.[11–13] A number of magnetically interacting binuclear copper(II) complexes are shown to be catalytically active in the oxidation of substrates like 3,5-di-t-butylcatechol (3,5-DTBC)[4,14] or N,N,N′,N′-tetramethyl-*p*-phenylenediamine (TMPD)[15,16] by oxygen. While planar mononuclear copper(II) complexes have little or no catalytic activity, binuclear copper(II) complexes are catalytically efficient. In addition, many of the binuclear copper(II) complexes undergo facile reduction to copper(I) in the presence of two-electron donors such as ascorbic acid, etc.[14] To investigate the interdependence of magnetic interaction, reduction potentials and catalytic properties, a number of new binuclear copper(II) complexes have been synthesized from ligands obtained from the condensation of 2,6-diformyl-4-methylphenol and aromatic mono- and diamines.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

All amines were either distilled or recrystallized prior to use. The ligands L and L′ were synthesized by the condensation of 2,6-diformyl-4-methylphenol[17] with the appropriate aromatic monoamines (aniline, *o*-anisidine, *o*-toluidine, 2-chloroaniline, 2-aminopyridine) and aromatic diamines (*o*-dianisidine, *o*-tolidine, 4,4′-diaminodiphenylmethane and 4,4′-diaminodiphenylethane), respectively. In a typical condensation reaction, 2,6-diformyl-4-methylphenol (10 mM) was refluxed with the respective monoamine (25 mM) in methanol for 4 h. Reducing the volume of the reaction mixture and cooling yielded red crystalline Schiff bases (L), which were recrystallized from methanol. The macrocyclic ligands, L′, were obtained using a 1:1 stoichiometric ratio of 2,6-diformyl-4-methylphenol and diamine. The crude product was recrystallized from chloroform.

Cu_2LCl_3 *complexes*

To a methanolic solution (20 cm^3) of ligand L (1 mM) was added a drop of ammonia solution and cupric chloride dihydrate (0.425 g, 2.5 mM) in methanol (20 cm^3). The resultant green microcrystalline product was recrystallized from either acetone or a dichloromethane–hexane (1:1) mixture.

$Cu_2L'Cl_2$ complexes

To a solution of the ligand (1 mM) in chloroform (100 cm^3) was added cupric chloride dihydrate (0.425 g, 2.5 mM) in methanol (20 cm^3). The resultant brown coloured product was filtered, washed thoroughly with chloroform and diethyl ether and dried *in vacuo* at 80°C for 12 h.

Physical measurements

The C, H and N analyses were carried out on a Perkin–Elmer 240C elemental analyser. Metal estimations were done on an inductively coupled plasma spectrometer (Labtem, Australia). Molecular weight measurements were carried out on a Dumfdruck Knauer osmometer in chloroform solvent using benzil as standard. Conductivity measurements were carried out on an Elico Model CM-82T conductivity meter at 25°C in dichloromethane. Melting points were recorded on a Buchi 510 melting point apparatus and are uncorrected. IR spectra were recorded on a Perkin–Elmer 283 model in the range 4000–200 cm^{-1}. Electronic spectra (Nujol mull) were recorded on a Cary 17D spectrophotometer in the range 1600–200 nm and in chloroform solution (10^{-5} M) on a Shimadzu UV 200S double beam spectrophotometer. ESR spectra were recorded on a JEOL JES FE-3X spectrometer. The room temperature magnetic susceptibility measurements were carried out on a Bruker BM-6 magnetic susceptibility set-up consisting of a Sartorius digital balance. Other measurements (77–298 K) used a Princeton Applied Research magnetometer Model-155 calibrated using a standard nickel pellet and cross checked against $[HgCo(CNS)_4]$. The resultant susceptibilities were corrected for diamagnetism and temperature independent paramagnetism (TIP). Cyclic voltammetric (CV) and differential pulse voltammetric (DPV) experiments were carried out using a three-electrode cell assembly with a PAR 175 universal programmer and PAR RE 0074 XY recorder. The cell consisted of an E410 hanging mercury drop electrode (HMDE) as the working electrode and a platinum wire auxiliary electrode. Tetraethylammonium perchlorate (TEAP) in 0.1 M concentration was used as the supporting electrolyte. All the potentials reported here are referred to the saturated calomel electrode (SCE) and are uncorrected for liquid junction potentials.

Catalysis experiments were carried out on a Shimadzu UV-200S double beam spectrophotometer using methanol as solvent. A methanol solution of 3,5-DTBC (0.3 mmol dm^{-3}) and copper(II) complex (0.003 mmol dm^{-3}) in a 25 cm^3 standard flask was kept under nitrogen. 3,5-DTBQ has a characteristic absorbance at 400 nm which was taken as a measure of the quinone formation [ε (mol^{-1} dm^3 cm^{-1}) = 1900 in methanol].[18] Absorbance was measured at intervals of 10 min immediately after exposing the solution to air. A similar procedure was used for the ascorbic acid oxidations by using 1 : 5 and 1 : 1 stoichiometric ratios of the complex and ascorbic acid.

RESULTS AND DISCUSSION

All the ligands have been characterized by analytical, IR and spectral methods. The binuclear complexes obtained from the ligands, L, can have either a 1 : 1 or 1 : 2 ligand-to-metal ratio, as shown in structures **1** and **2** (Fig. 1), respectively. Structure **2** has been identified to be correct on the basis of the following experimental observations. (i) For structure **1** the average molecular weight is *ca* 850 while for **2** it is *ca* 500. Molecular weight determinations in chloroform solution give values in the range 450–600 (Table 1), therefore excluding the structure **1**. (ii) Conductivity values of the complexes in dichloromethane are low indicating that

the complexes are non-electrolytes. (iii) The presence of a chloro bridge is evident from the observation of two IR peaks at 320 and 300 cm^{-1}, which is characteristic of chloro-bridged binuclear copper(II) complexes.[19] (iv) The analytical data (C, H, N) presented in Table 1 conclusively support structure **2**.

Structure **3**, formulated for the complexes of L′, is supported by analytical and other experimental data. The mode of coordination shown in structures **2** and **3** are further supported by IR data. The broad band at *ca* 3000 cm^{-1}, due to the free —OH group of the ligand, disappears on complex formation indicating oxygen–metal bond formation. C=N stretching vibrations of the ligands are found at 1635–1650 cm^{-1}. The band at 1550–1570 cm^{-1} is indicative of a binuclear structure bridged by phenolic oxygen.

Spectral and magnetic data

Electronic spectra of the Cu_2LCl_3 complexes in dichloromethane exhibit the *d–d* band around 720 nm. The exact positions of this band for various complexes are given in Table 2. The two prominent bands observed in the UV region at *ca* 390 and 270 nm are of ligand origin. It is known that binuclear copper(II) complexes with chloro bridges produce a *d–d* transition around 725 nm[20,21] and are of planar geometry. Hence, a similar geometry is suggested for the Cu_2LCl_3 complexes. Solution electronic spectra for $Cu_2L'Cl_2$ complexes could not be recorded due to their insolubility in various solvents. Solid spectra did not provide any resolved bands.

Powder ESR spectra of the Cu_2LCl_3 complexes show a broad band centred at *ca* 3300 gauss. For $Cu_2L^1Cl_3$ and $Cu_2L^2Cl_3$ complexes, another signal at 1600 gauss was also observed resulting from the $\Delta M_s = 2$ transition. In general, chloro-bridged binuclear copper(II) complexes give broad ESR signals[22] and is taken as further evidence for chloro-bridged structures. The $Cu_2L'Cl_2$ complexes in the solid phase give a single line ESR absorption band centred at *ca* 3200 gauss. Such spectra are characteristic of non-interacting copper(II) centres; since the two copper centres are separated by at least ~10 Å no Cu—Cu interaction is expected.

Room temperature magnetic moment values for the Cu_2LCl_3 complexes are in the range 0.8–1.2 BM. At *ca* 200 K, the μ_{eff} values are in the range 0.4–0.5 BM. At temperatures lower than 200 K these complexes showed diamagnetic behaviour resulting from a high degree of demagnetization by spin pairing. The μ_{eff} values for various complexes are given in Table 1. The spin exchange interaction is caused by the super-exchange mechanism rather than direct overlapping of the metal *d* orbitals. The $Cu_2L'Cl_2$ complexes have μ_{eff} values in the range 1.8–2.0 BM per copper centre indicating the absence of antiferromagnetic interactions. Such interactions are not expected since the two copper centres are separated by a large distance and interaction through the bridging ligands is not expected to be substantial.

Relative catalytic activity of the copper(II) complexes is partly attributable to their reduction potentials.[15] The more positive the reduction potential is, the higher the catalytic activity becomes. Binuclear complexes can undergo two-electron

reduction involving both copper centres at the same potential or have two successive one-electron reduction steps.[17,23] To identify the pattern of reduction steps and to correlate the reduction potential with the catalytic activity of the complexes, reduction characteristics of the Cu_2LCl_3 complexes are examined by cyclic voltammetric methods in dimethylformamide. They show single quasi-reversible redox peaks with an E_p value of *ca* 150 mV. The reduction peak occurs at *ca* −0.65 V and the oxidation peak at *ca* −0.50 V. CV data are collected in Table 2. The influence of reduction potential on catalytic activity is discussed in the next section. The $Cu_2L'Cl_2$ complexes could not be investigated by cyclic voltammetric methods due to their poor solubility.

Catalysis

Binuclear planar copper(II) complexes show catalytic activity for oxidation of 3,5-DTBC to quinone by dioxygen, while square-planar mononuclear complexes have little or no catalytic activity.[14] In binuclear copper(II) complexes, larger magnetic exchange interaction is observed when the planarity of the metal centre increases.[22] Binuclear systems with larger magnetic interaction (lower μ_{eff} values) should therefore exhibit greater catalytic activity. This has been found to be true in the case of some binuclear complexes of 1,3,5-triketones.[4] Catalytic activity of the Cu_2LCl_3 binuclear copper(II) complexes was examined for the oxidation of 3,5-DTBC to quinone by dioxygen. The activity for the methanolic solution of a 1 : 100 complex-to-DTBC ratio, was discovered by measuring the absorbance of the 400 nm band which is characteristic of 3,5-DTBQ. The conversion of 3,5-DTBC to 3,5-DTBQ was complete in about 90 min in the presence of various binuclear copper(II) complexes investigated here. Figure 2 shows the time-dependent growth of 3,5-DTBQ in the presence of $Cu_2L^1Cl_3$, and also the absorption profile of 3,5-DTBC with a binuclear complex under nitrogen atmosphere. In this case, the absorption at 400 nm is totally absent confirming the influence of dioxygen. The catalytic efficiency of the binuclear complexes under similar conditions is compared in Fig. 3. To a general approximation, it becomes apparent that

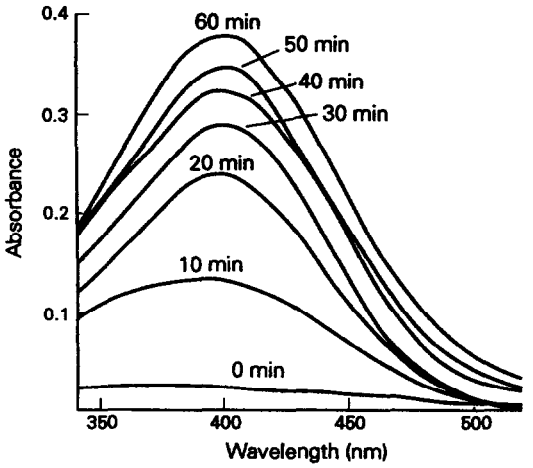

Fig. 2. Oxidation of 3,5-DTBC by a binuclear copper(II) complex ($Cu_2L^1Cl_3$).

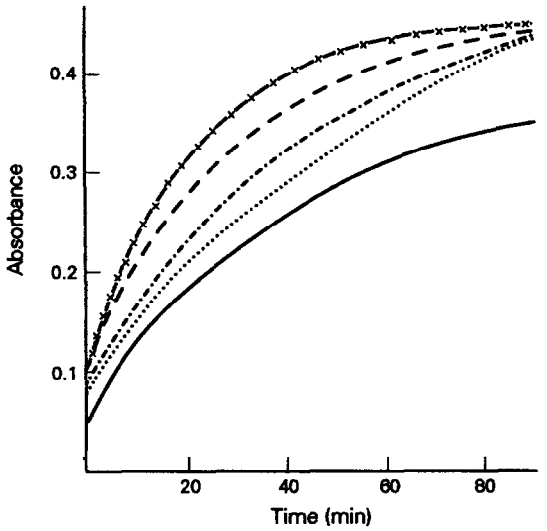

Fig. 3. Time-dependent formation of 3,5-DTBQ in the presence of $Cu_2L^1Cl_3$ (——), $Cu_2L^2Cl_3$ (---), $Cu_2L^3Cl_3$ (— · —), $Cu_2L^4Cl_3$ (— × —) and $Cu_2L^5Cl_3$ (· · · ·).

the catalytic efficiency is greater for the binuclear system which has a lower magnetic moment. The influence of the reduction potential on the catalytic efficiency of binuclear complexes is not well understood. The electron-transfer reaction between two-electron donors like ascorbic acid and the binuclear copper(II) complexes was also investigated by the same method in methanol, the *d–d* band of the complex at *ca* 14,000 cm^{-1} (720 nm) being monitored during the experiment. This *d–d* band disappears upon addition of ascorbic acid under nitrogen atmosphere and reappears when the solution is exposed to air, as shown in Fig. 4 for a representative complex $Cu_2L^1Cl_3$. These experiments clearly show that copper(II) is easily reduced to copper(I) by ascorbic acid. The proposed pathway for the electron-transfer reaction between ascorbic acid and a binuclear copper(II) complex involves a "steric match" between a donor and an acceptor.[14] A similar intermediate between the complexes and ascorbic acid is envisaged in the present case also. The $Cu_2L'Cl_2$ complexes are not expected to show any catalytic activity because of the lack of donor–acceptor interactions due to the large internuclear distance.

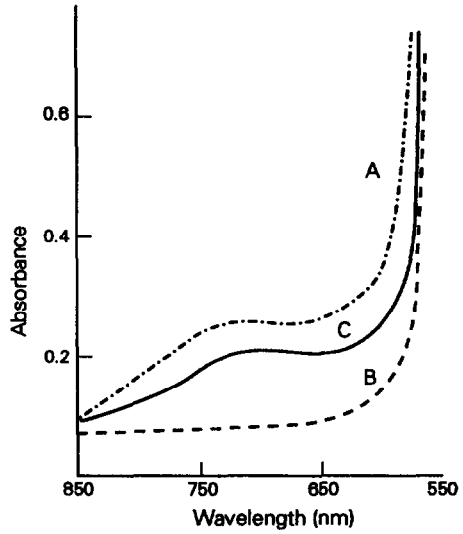

Fig. 4. Absorption spectra of $Cu_2L^1Cl_3$ (in methanol at 25°C) in presence of ascorbic acid. (A) $Cu_2L^1Cl_3$ alone, (B) $Cu_2L^1Cl_3$+ascorbic acid (under nitrogen) and (C) solution (B) in air.

Abstract—The interaction of silver trifluoromethanesulphonate and 1,2-bis(dimethylphosphino)ethane (DMPE) in acetonitrile in the presence of sodium tetraphenylborate gives the dimeric complex $[Ag_2(DMPE)_4](BPh_4)_2$. In the cation, each silver atom is four-coordinate with one chelating diphosphine and two phosphorus atoms from the two bridging DMPE ligands. The Ag—P distances are 2.465–2.557(6) Å and the AgP_4 unit has distorted tetrahedral geometry.

There are a number of monomeric, dimeric and tetrameric phosphine complexes of silver(I);[1,2] most of the diphosphine (P⌒P) compounds are of the type $[XAg(\mu\text{-P⌒P})]_2$. We now describe a new type with 1,2-bis(dimethylphosphino)ethane as ligand.

RESULTS AND DISCUSSION

The interaction of AgO_3SCF_3 with two equivalents of DMPE and of sodium tetraphenylborate in acetonitrile allows isolation of the colourless crystalline complex $[Ag_2(DMPE)_4](BPh_4)_2$. The crystal structure contains dimeric $[Ag(DMPE)_2]_2^{2+}$ cations and BPh_4^- anions. A diagram of the cation which lies on a centre of symmetry is shown in Fig. 1, whilst selected bond lengths and angles are given in Table 1.

In the dication, each silver ion is coordinated by two phosphorus atoms from a chelating DMPE ligand and then by one phosphorus from each of two bridging DMPE ligands. The AgP_4 geometry is distorted tetrahedral, the largest distortion arising from the restricted bite of the chelating DMPE [P—Ag—P = 83.5(2)°]. The Ag—P distances vary considerably, over a range of almost 0.1°, with those in the chelate ring the larger. Distances in other four-coordinate silver phosphine complexes vary from 2.42 to 2.50 Å.[3]

The ^1H and ^{31}P NMR spectra are consistent for the structure. Attempts to oxidize the cation to a silver(II) species, chemically or electrochemically, were unsuccessful; cyclic voltammetry in MeCN showed no oxidation wave.

extracted into CH_2Cl_2 (3×30 cm^3). Reduction in volume and cooling (−20°C) gave 0.45 g of a white powder. Further crops of the compound may be obtained from the supernatant. Combined yield, 0.87 g (77%); m.p. 205–207°C. Crystals for X-ray structure determination were obtained by slow evaporation of an acetonitrile solution. (Found: C, 59.6; H, 7.3. $C_{72}H_{104}Ag_2B_2P_8$ requires: C, 59.9; H, 7.2%.) The compound is readily soluble in MeCN but sparingly soluble in CH_2Cl_2 and THF. The conductivity in MeCN gives $\Lambda_M = 175\ \Omega^{-1}$ cm^2 mol^{-1}. NMR (δ ppm in CD_3CN): ^{1}H: 7.2–6.9 (m, B*Ph*$_4$); 1.7 (s, CH_2); 1.2 (s, CH_3). ^{31}P-{^{1}H}: −19.5, −26.3 both s.

Crystallography

A crystal of dimensions $0.375 \times 0.45 \times 0.53$ mm^3 was sealed in a thin-walled glass capillary and used for all X-ray measurements. Following preliminary photography, unit cell dimensions and intensity data were obtained following standard procedures using a CAD4 diffractometer and graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) operating in the ω–2θ scan mode. The structure was solved via the heavy-atom method and refined by full-matrix least-squares. Non-hydrogen atoms were refined with anisotropic displacement factor coefficients; hydrogens were included in idealized positions with group U_{iso} values for the phenyl groups on the BPh_4 anion which were themselves treated as idealised rigid bodies. Experimental details are as follows.

Crystal data. $[C_{24}H_{64}P_8Ag_2][C_{24}H_{20}B]_2$ $M_r = 1454.77$, monoclinic, $a = 11.173(3)$, $b = 21.819(4)$, $c = 16.565(5)$ Å, $\beta = 103.85(3)°$, $V = 3920.9$ Å^3, space group $P2_1/n$, $Z = 4$, $D_c = 1.32$ g cm^{-3}, μ(Mo-K_α) = 6.21 cm^{-1}, $F(000) = 1356$.

Data collection. $1.5 \leqslant \theta \leqslant 25°$, $-13 \leqslant h \leqslant 13$, $0 \leqslant k \leqslant 26$, $0 \leqslant l \leqslant 19$; 7456 reflections measured, 7368 unique, 3809 observed [$F_o > 6\sigma(F_o)$]. Lp and empirical absorption correction based on psi-scans.

Refinement. Two blocks [half cation (158 parameters) and anion (182 parameters)]. Final R, $R_w = 0.056$, 0.062, respectively, weights = $1.9/[\sigma^2(F_o) + 0.0020F_o^2]$. All calculations were made using SHELX-80 installed on a T800 transputer hosted by an IBM/AT clone.

Abstract—Electrochemical reduction of the cluster chloride Re_3Cl_9 (**1**) containing the Re_3^{9+} core, in aqueous hydrochloric acid, gives a purple, oxygen-sensitive but thermally stable solution, from which the singly reduced Re_3^{8+} anion, $[Re_3Cl_{12-n}]^{(4-n)-}$ (**4**), has been isolated and structurally characterized as the capped triply-bridging sulphato derivative $Cs_3[Re_3(\mu\text{-}Cl)_3Cl_6(\mu_3\text{-}SO_4)]$ (**5**).

The rhenium(III) cluster chloride Re_3Cl_9 (**1**) contains Re≡Re double bonds and is of interest both for historic and fundamental reasons.[1] Addition of many Lewis bases along the vacant sites of the $[Re_3(\mu\text{-}Cl)_3]^{6+}$ plane gives an extensive class of coordination compounds, for example the adducts $Re_3Cl_9(L)_n$ ($n = 1$, 2 or 3) or the salts $[Re_3Cl_{12-n}(H_2O)_n]^{(3-n)-}$ ($n = 1$, 2 or 3), depending on the conditions and the nature of the cation present.[1]

In contrast, pyridine and various aromatic amines of different basicity induce one-, two- or three-electron reduction[2] producing the complexes $[Re_3Cl_{9-n}(L)_n]_x$ ($n = 1$, 2 or 3), which while still derivatives of the $Re_3^{(9-n)+}$ ($n = 1$, 2 or 3) core are of special interest because they are the only known binary chloroanions having the rhenium atom(s) formally in an oxidation state of two.

Their structure, despite the efforts, has not been determined, but on the basis of ESCA and electronic spectra, magnetic and conductivity studies and the facile conversion to the rhenium(III) salts (amine $H)_2Re_3Cl_{11}$ on treatment with methanolic HCl, are believed to possess a halogen bridge "polymer of trimer structure"[2] except in the case of acridine where the salt $(AcrH)_2Re_3Cl_8$ is formed[3] rather than the adduct $[Re_3Cl_6(Acr)_3]$. The stepwise three-electron reduction of the Re_3^{9+} cluster unit to give Re_3^{6+} is in accordance with current ideas[4] concerning the electronic structure of these species.

The chloride **1**, in its complexed form[5] as the anion $[Re_3Cl_{12}]^{3-}$ (**2**), has been reduced electrochemically in aqueous hydrochloric acid at a DME[6] and in a eutectic, basic chloroaluminate melt ($AlCl_3$-MeEtimCl) at a glassy-carbon electrode.[7] In both media, purple species having the same electronic spectra are formed, but there is ambiguity concerning their spectroelectrochemically assigned identity. In aqueous hydrochloric acid, a single six-electron reduction wave is observed, and it has been proposed that one chloride ion is lost from the axial position on each rhenium atom during the reaction

process to give **3** [eq. (1)],

$$\underset{(2)}{[ReCl_{12}]^{3-}} + 6e^- \rightleftharpoons \underset{(3)}{[Re_3Cl_9]^{6-}} + 3Cl^-, \quad (1)$$

whereas in the melt, a reversible one-electron reaction occurs attributable to the formation of species **4** [eq. (2)] for which n may be 1:

$$\underset{(2)}{[Re_3Cl_{12}]^{3-}} + e^- \rightleftharpoons \underset{(4)}{[Re_3Cl_{12-n}]^{(4-n)-}} + nCl^-. \quad (2)$$

Here, we report the isolation of the above-mentioned purple compound and the structure determination of the product from its reaction with sulphuric acid.

EXPERIMENTAL

Re_3Cl_9 has been prepared from rhenium metal according to the literature procedures[8,9] and $Cs_3Re_3Cl_{12}$ by dissolution of the trichloride in aqueous hydrochloric acid (6 M) containing caesium chloride.[1,5] All reagents were of analytical grade, thoroughly purified and carefully deoxygenated. Demineralized by ion exchange and doubly distilled water was used. Sulphuric acid was also doubly distilled. All reactions including the electroreduction in an appropriate[10] modified cell were carried out under strictly anaerobic conditions (Argon). Microanalyses were performed in this Laboratory. Electronic spectra were recorded with a Hitachi U-2000.

Crystal structure solution

$Cs_3[Re_3Cl_9SO_4]$, space group *Pmcn* (No. 62), absences $hk0$, $h+k=2n$ and $h0l$, $l=2n$, $a = 11.665(1)$, $b = 12.339(1)$, $c = 14.265(2)$ Å, $V = 2053.3(3)$ Å^3, $Z = 4$, $d_c = 4.44$ g cm^{-3}. Unit cell dimensions were derived from a least-squares refinement of the setting angles of 32 automatically centred reflections in the range $11 < 2\theta < 23°$ on a Syntex P_{21} diffractometer controlled by the Crystal Logic software and using niobium-filtered Mo-K_α radiation. The crystal was mounted in a capillary under argon. Lorentz and Ψ-scan absorption corrections were applied to the data. Three standard reflections measured every 100 reflections showed < 3.5% intensity fluctuations. The data set consisted of 2086 reflections of which 1218 with $I_o > 3\sigma(I_o)$ were used during the refinement. The structure was solved using SIR[11] and refined with SHELX76,[12] using the full-matrix least-squares method and a weighting scheme of $1/w = \sigma^2(F_o) + 0.001(F_o)$.[12] All atoms were refined anisotropically and the number of refined parameters was 103. Final $R = 0.037$ and $\Delta\rho_{max}/\Delta\rho_{min} = 1.6/-1.4$ e Å^{-3}, with all the large peaks in the final difference Fourier map being around the rhenium positions.

Electrolytic reduction of the nonachloro-tri-μ-chloro-triangulo-trirhenium(III,III,III) *trianion and reaction with sulphuric acid*

A solution of Re_3Cl_9 (0.0412 g, 0.0469 mmol) in aqueous 6 M HCl (50 cm^3) was exhaustively electrolysed using a mercury cathode and platinum wire anode with 15 cm^3 of 0.5 M HCl as anode solution, at a steady potential of −0.400 V (relative to SCE). The dark red solution of Re_3Cl_9 slowly changed to deep purple.

To a portion of the above solution (9 cm^3) was added H_2SO_4 (1 cm^3) and the mixture was heated at 80°C for *ca* 1 h. Caesium chloride was subsequently added (0.1 g) and the solution was kept at −10°C for a week. Black crystals were precipitated which were filtered, washed with small portions of iced ethanol, and dried *in vacuo* to give 0.0547 g of a compound identified by elemental analysis and crystallography to be $Cs_3Re_3Cl_9SO_4$; yield 85% based on Re_3Cl_9. Found: Re, 40.5; Cs, 28.7; Cl, 23.4; S, 2.2. Calc.: Re, 40.7; Cs, 29.0; Cl, 23.2; S, 2.3%.

RESULTS AND DISCUSSION

The dark red coloration of an aqueous HCl (6 M) solution of **1** changes slowly to deep purple upon exhaustive reduction at −0.400 V at room temperature. The reaction can be followed by visible spectroscopy and the spectrum of the final product is shown in Fig. 1. The characteristic peaks of **2**[5,13] at 763 and 513 nm slowly diminish and absorptions at 1072, 883 and 554 nm appear which are similar to those reported.[6,7]

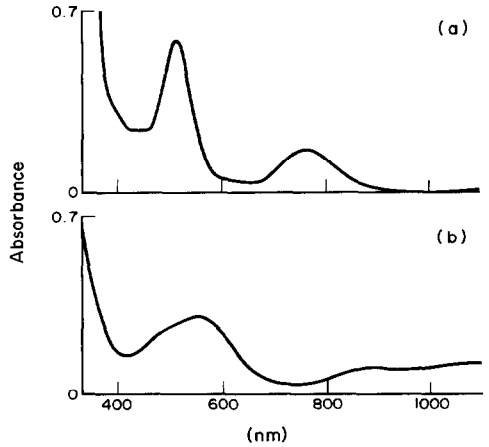

Fig. 1. Absorption spectra of: (i) a solution of Re_3Cl_9 (3.4×10^{-4} M) in aqueous HCl (6 M); (ii) after exhaustive electrolysis at room temperature.

The purple solution obtained is susceptible to oxidation by traces of oxygen, but is stable for longer periods at room temperature. By using different cations and mixtures of solvents, red–black solids precipitate upon cooling the solutions, but analytical results were not reproducible. This is due both to contamination by the co-crystallizing salt(s) of the countercation(s) and the presence of other species as indicated from examination of the electronic absorption spectra.

However, addition of sulphuric acid to the initially obtained purple solution followed by heating, causes precipitation of an oxygen-sensitive black solid, which when redissolved in HCl (6 M) gives the anion **2**.

Analytical data are consistent with its formulation as $Cs_3[Re_3Cl_9(SO_4)]$ **5** and X-ray crystallography showed that the sulphate oxyanion has displaced three labile chlorides$_{to}$[14] and functions as a tridentate triply bridging ligand capping the trirhenium unit in the same fashion as in the analogous Re_3^{9+} derivative $[N(CH_3)_4]_2[Re_3Cl_9(SO_4)]$ (**6**).[15] Such trimetal clusters, containing tridentate capping μ_3-$O_3S{=}O$ ligands, are rare[14–16] and of importance because they are considered as models for the interaction of metal clusters and oxide supports[17] or are related to oxyanion species identified when absorbed on platinum electrodes.[18] The possibility that the reduction is a multielectron process and **5** is the end oxidation product of more highly reduced species by the sulphuric acid can not be excluded. Also, the stability of **3** or **4** in HCl (6 M) and of **5** in a hot mixture of HCl/H_2SO_4 is intriguing when compared with the facile oxidation to the Re_3^{9+} cluster of the corresponding rhenium(II) derivatives, $[Re_3Cl_6 \cdot Ln]_x$ (n = 1, 2 or 3; L = aromatic amine) and makes it challenging to establish the exact nature of the latter species. The characterization of the reduction product(s) and their reactivity is under investigation.

Crystal structure

The anion structure and packing arrangement of **5** is shown in Figs 2 and 3; bond lengths and angles are given in Table 1. The triangle of the rhenium

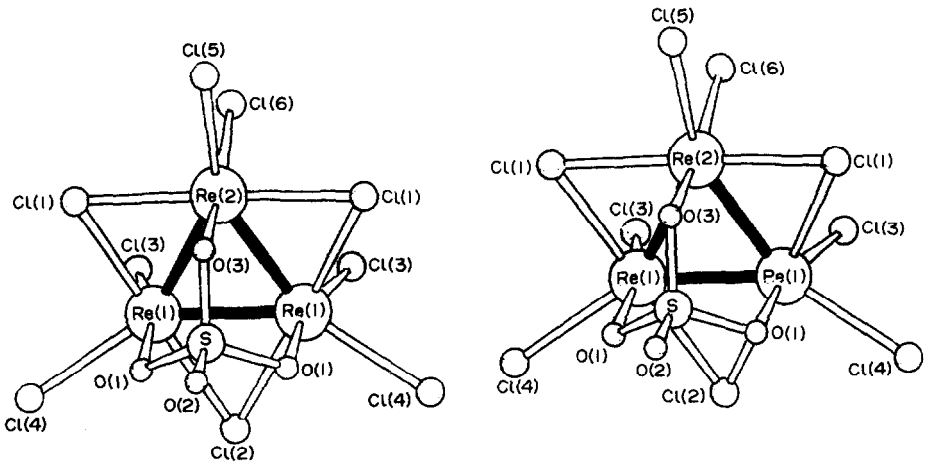

Fig. 2. The structure of $[Re_3Cl_9(SO_4)]^{3-}$.

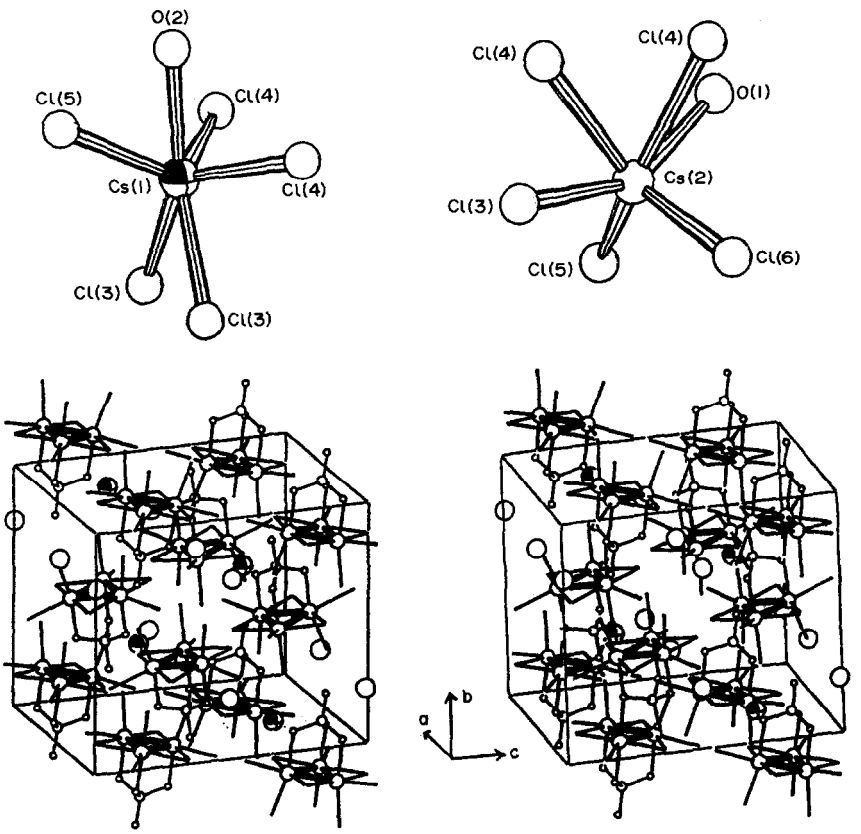

Fig. 3. ORTEP packing diagram and contact spheres of the caesium ions; Cs(1) which occupies a special position is shaded.

atoms remains equilateral [2.466(1) Å av.] with the sulphato ligand capping the trimetal unit (O—O distances are 2.43 Å av.). The three Re—O_c bonds are equidistant [2.10(1) Å av.], almost vertical to the Re_3 plane (mean Re—Re—O_c angle = 89.6° av.). Structural changes occur in the sulphato moiety relative to the free tetrahedral ion (S—O distance 1.49 Å).[19] The S—O_c distances are longer [1.51(1) Å av.] than the S—O_t distance [1.43(2) Å] and the interior O_c—S—O_c angles average 107.0°, whereas the exterior O_c—S—O_t angles average 111°. The one-electron reduction does not cause any significant changes and the structure of **5** overall is very similar to its unreduced counterpart **6**.[15]

In the crystal structure the anions are arranged in layers with the sulphate ligands pointing in opposite directions in consecutive layers. One caesium ion (the one in a special position) lies on the layers, the other one lies between the layers. The anion is situated on a crystallographic mirror plane which goes through the atoms Re(2), Cl(2), Cl(5), Cl(6), S, O(2) and O(3). Both caesium ions form six close contacts, five with chlorine and one with oxygen atoms. Cs(1) is held tightly and Cs(2) more loosely. The range in which the five Cs···Cl contacts lie is 3.310–3.398(4) Å for Cs(1) and 3.482–3.651(5) Å for Cs(2), while the Cs···O contacts are 3.04(2) Å for Cs(1) and 3.21(1) Å for Cs(2).

ORGANOAMIDOMETALLICS—IV.* SYNTHESES OF N,N′-BIS(POLYFLUOROPHENYL)ETHANE-1,2-DIAMINATO(2−)PLATINUM(II) COMPLEXES WITH TWO DIFFERENT FLUOROCARBON GROUPS

D. P. BUXTON and G. B. DEACON†

Chemistry Department, Monash University, Clayton, Victoria 3168, Australia

(*Received* 9 *November* 1990; *accepted* 11 *December* 1990)

Abstract—The N,N′-bis(polyfluorophenyl)ethane-1,2-diaminato(2−)platinum(II) complexes [Pt(N(*p*-HC_6F_4)CH_2CH_2NR)$(py)_2$] (R = *p*-HC_6F_4, *p*-BrC_6F_4, C_6F_5 or *p*-MeC_6F_4; py = pyridine) have been prepared by decarboxylation reactions between [PtI_2(*p*-$HC_6F_4NHCH_2CH_2NH_2$)], thallium(I) 2,3,5,6-tetrafluorobenzoate and a suitable polyfluorobenzene, RF, in hot dry pyridine. When R ≠ *p*-HC_6F_4, the two different polyfluorophenyl groups can be distinguished by different F3,5 resonances in the ^{19}F NMR spectra. The reactant and analogous complexes [PtX_2($RNHCH_2CH_2NH_2$)](R = *p*-HC_6F_4, X = I or Cl; R = C_6F_5, X = I) were prepared by treatment of K_2PtX_4 (X = I or Cl) with the appropriate N-polyfluorophenylethane-1,2-diamine.

Novel N,N-bis(polyfluorophenyl)ethane-1,2-diaminato-(2−)platinum(II) complexes, [$Pt(NRCH_2)_2(py)_2$] (py = pyridine), have been prepared by decarboxylation reactions between $PtCl_2$(en) (en = ethane-1,2-diamine) and thallium(I) pentafluorobenzoate or thallium(I) 2,3,5,6-tetrafluorobenzoate and a suitable reactive polyfluorobenzene in hot pyridine.[2,3] The synthetic path is completely new in organoamidometallic chemistry.[4–6] The products are moisture-stable, by contrast with simple platinum(II) organoamides, e.g. [$Pt(NRCH_2)_2$(bpy)] (R = H or Me, bpy = 2,2′-bipyridyl),[7,8] and have appreciable antitumour activity.[9] Of necessity, the decarboxylation syntheses result in substitution of the same polyfluorophenyl group on each nitrogen of the ethane-1,2-diaminate ligand. We now report a preparative route to analogous complexes with two different polyfluorophenyl groups.

RESULTS AND DISCUSSION

The synthetic strategy required the initial preparation of platinum(II) halide complexes of N-polyfluorophenylethane-1,2-diamines. The ligands $RNHCH_2CH_2NH_2$ [R = *p*-HC_6F_4 (**1a**) or C_6F_5 (**1b**)] were obtained by nucleophilic substitution reactions between ethane-1,2-diamine and the appropriate polyfluorobenzene with (R = *p*-HC_6F_4) or without (R = C_6F_5) an added base. Compound **1b** has previously been prepared in higher yield in a pyridine medium,[10] with characterization by F, N analyses and ^{19}F NMR spectroscopy.[10,11] Although the melting point of **1b** was well below the reported value,[10] identification was unequivocal on the basis of microanalyses (C, H, F, N), ^1H and ^{19}F NMR spectra and the mass spectrum. Reaction of **1a** and **1b** with the appropriate potassium tetrahalogenoplatinate(II) complex gave [PtX_2($RNHCH_2CH_2NH_2$)] [R = *p*-HC_6F_4, X = I (**2a**) or Cl (**2b**); R = C_6F_5, X = I (**2c**)]. Considerable variation in yield was observed, depending on the solvent system used (see Experimental).

Syntheses of N,N′-bis(polyfluorophenyl)ethane-1,2-diaminato(2−)platinum(II) complexes, [Pt(N(*p*-HC_6F_4)CH_2CH_2NR)$(py)_2$] (**3**), were effected by heating **2a** with thallium(I) 2,3,5,6-tetrafluorobenzoate and a polyfluoroaromatic compound, RF, in hot pyridine. Details of the reactions are given in Table 1. The method was initially validated by synthesis of the known[2,3] symmetrical organoamide **3a** before application to complexes

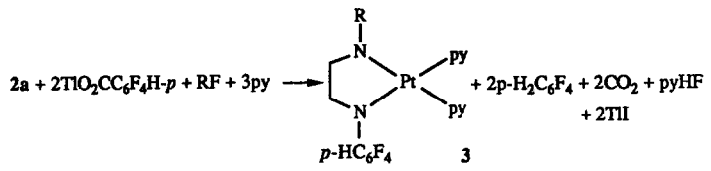
with two different polyfluorophenyl groups, **3b–3d**.



(1)

3a R=*p*-HC_6F_4
3b R=*p*-BrC_6F_4
3c R=C_6F_5
3d R=*p*-MeC_6F_4

On the basis of the reaction path to the symmetrical complexes $[Pt(NRCH_2)_2(py)_2]$,[3] reaction (1) can be envisaged as occurring by deprotonation to give the nucleophilic species, $[Pt(N(p\text{-}HC_6F_4)CH_2CH_2NH)(py)_2]$, which attacks the polyfluoroarene, RF, giving **3**. Deprotonation is effected by highly carbanionic *p*-HC_6F_4 groups, generated by decarboxylation, and the resulting 1,2,4,5-tetrafluorobenzene is relatively unreactive to nucleophilic substitution.[12]

Yields of pure complexes were low, despite near quantitative decarboxylation, owing to formation of dark coloured impurities which could be difficult to remove. Two complexes, **3b** and **3c**, were isolated as ether solvates, the composition being indicated by both duplicate microanalyses and ^1H NMR integrations. Parent ions were observed in the spectra of the unsymmetrical complexes **3b–3d**. However, only a single CH_2N resonance and a single set of pyridine resonances were observed, despite the presence of two different polyfluorophenyl groups. The (average) ^3J[PtH(py)] and ^3J[PtH(CH_2)] coupling constants (Table 2) are of similar magnitude to those of the symmetrical complexes, $[Pt(NRCH_2)_2(py)_2]$,[3] e.g. **3a** (Table 2). Clear differentiation between the two different polyfluorophenyl groups was observed in the F3,5 resonances (Table 2). The F3,5 chemical shifts of the individual polyfluorophenyl groups of **3b–3d** are in close agreement with those of the corresponding symmetrical complexes (Table 2). On the other hand, little differentiation was observed in the F2,6 resonances, since the dominant influence on the chemical shift is the amido nitrogen, which is *ortho* to F2,6 in each case.

The synthesis method, reaction (1), developed for organoamides **3b–3d** with two different polyfluorophenyl groups could presumably be extended to other similar complexes, for example, by use of **2c** as a reactant, or by preparation and use of other reactants **2** incorporating different fluorocarbon groups.

EXPERIMENTAL

General

Microanalyses were by the Australian Microanalytical Service, Melbourne. Carbon dioxide was determined gravimetrically as barium carbonate. Decarboxylation was monitored using a small volume barium hydroxide trap additional to the main trap and reactions were terminated when carbon dioxide evolution ceased. Spectroscopic methods are as for Part I.[3] Listed IR bands of compounds examined as Nujol and hexachlorobutadiene mulls are restricted to those of medium or greater intensity, except for N—H and Pt—halogen stretching frequencies. Proton chemical shifts are in ppm downfield from internal Me_4Si and fluorine chemical shifts in ppm from internal $CFCl_3$. For platinum-containing ions in the mass spectra, only the most intense peak [containing ^{195}Pt or ^{275}(PtBr)] of

the cluster is given. For bromine-containing ions without platinum, the listed peak is for the ^{79}Br ion. Visible spectra are for solutions in 95% ethanol in the range 350–700 nm.

Solvents and reagents

Petrol refers to the fraction b.p. 60–85°C unless indicated otherwise. Pentafluorobenzene and hexafluorobenzene (Bristol Organics) and ethane-1,2-diamine were dried over molecular sieves (Grade 4A) before use. Triethylamine was refluxed over and distilled from acetic anhydride under nitrogen. Purification of other solvents and sources or preparations of other reagents have been given in earlier papers.[3,13]

Synthesis of N-(polyfluorophenyl)ethane-1,2-diamines

N-(2,3,5,6-Tetrafluorophenyl)ethane-1,2-diamine (**1a**). Pentafluorobenzene (170 mmol) and ethane-1,2-diamine (84 mmol) were refluxed over anhydrous K_2CO_3 for 7 h under nitrogen. Evaporating the mixture to dryness under high vacuum gave a solid which was partitioned between ether and water. Repeated ether extraction and evaporation of the ether *in vacuo* gave a light yellow oil which crystallized upon cooling. The solid was twice recrystallized from ether–petrol giving colourless crystals (yield, 32%), m.p. 44–45°C (Found: C, 45.7; H, 3.7; F, 36.3; N, 13.8. $C_8H_8F_4N_2$ requires: C, 46.2; H, 3.9; F, 36.5; N, 13.5%). ^{19}F NMR ($CDCl_3$): −142.1, m, 2F, F3,5; −160.7, m, 2F, F2,6. ^1H NMR ($CDCl_3$): 1.15, s, 2H, NH_2; 2.91, t, ^3J(HH) 6 Hz, 2H, CH_2NH_2; 3.37, qt, ^3J[HH(CH_2)] 6 Hz, ^3J[HH(NH)] 6 Hz, ^5J(HF) 1 Hz, 2H, $CH_2N(H)C_6F_4H$; 4.40, br, 1H, N(**H**)C_6F_4H; 6.36, tt, ^3J(HF) 10 Hz, ^4J(HF) 7 Hz, 1H, HC_6F_4. IR: 3474w, 3381w and 3285(br) ν(NH), 2943m, 1650s, 1526vs, 1509vs, 1470s, 1358m, 1156s, 1142s, 924m cm^{-1}. Mass spectrum: *m/z* 208 [17%, M^+], 179 [78, $C_7H_5F_4N^+$], 178 [100, HC_6F_4NH CH_2^+]. Similarly, reaction of pentafluorobenzene (79 mmol) and ethane-1,2-diamine (26 mmol) in refluxing triethylamine (9 cm^3, 65 mmol) for 19 h under anhydrous conditions gave **1a** (21%) (IR identification).

Hydrochloride derivative. Hydrogen chloride and nitrogen were bubbled through a stirred ether solution of **1a** (9.6 mmol). The precipitated white solid (**1a**·HCl) was refluxed in acetone–petrol for a few minutes, collected and dried (yield, 70%), m.p. 275–280°C (dec.) (Found: C, 39.4; H, 3.6; N, 11.2. $C_8H_9ClF_4N_2$ requires: C, 39.3; H, 3.7; N, 11.5%). ^{19}F NMR [$(CD_3)_2SO$]: −141.2, m, 2F, F3,5; −158.8, m, 2F, F2,6. ^1H NMR [$(CD_3)_2SO$]: 3.00, t, ^3J(HH) 6 Hz, 2H, $CH_2NH_3^+$; 3.59, m, 2H, $CH_2N(H)C_6F_4H$; 6.20, m(br), 1H, N(**H**)C_6F_4H; 7.00, tt, ^3J(HF) 11 Hz, ^4J(HF) 7 Hz, 1H, HC_6F_4; 8.29, s(br), 3H, NH_3^+. IR: 3318s and 3058s(br) ν(NH), 2909m, 1651m, 1602m, 1544s(br), 1513s(br), 1471s, 1457s, 1448s, 1365s, 1282m, 1157s(br), 1110s, 1037s, 1028s, 958m, 925s, 862m, 829s, 801s, 710s, 692m, 550m(br) cm^{-1}.

N-(Pentafluorophenyl)ethane-1,2-diamine (**1b**). Stirring hexafluorobenzene (170 mmol) and ethane-1,2-diamine (170 mmol) under nitrogen with gentle heating promoted a vigorous exothermic reaction. After 10 min, the near solid mixture was dissolved in ethanol (50 cm^3) which was refluxed for 2 h. Filtration and evaporation of the solution to dryness *in vacuo* gave a dark brown solid. Recrystallization from ether–petrol at 0°C gave colourless crystals (yield, 30%), m.p. 46°C, ref. 10 m.p. 70–71°C (Found: C, 42.8; H, 3.0; F, 41.7; N,12.7. Calc. for $C_8H_7F_5N_2$: C, 42.5; H, 3.1; F, 42.0; N, 12.4%). ^{19}F NMR ($CDCl_3$): −160.2, m, 2F, F2,6; −165.2, m, 2F, F3,5; −172.7, m, 1F, F4, in satisfactory agreement with values[10,11] using CCl_4 as

solvent. ^{1}H NMR ($CDCl_3$): 1.16, s, 2H, NH_2; 2.91, m, ^3J(HH) 6 Hz, 2H, CH_2NH_2; 3.31, qt, ^3J[HH(CH_2)] 6 Hz, ^3J[HH(NH)] 6 Hz, ^5J(HF) 1 Hz, 2H, $CH_2N(H)C_6F_5$; 4.17, br, 1H, N(H) C_6F_5. IR: 3473w, 3392w, 3326w and 3212w ν(NH), 2945m, 2867m, 1518vs, 1488vs, 1470s, 1356m, 1021m, 990m, 976m, 954m cm^{-1}. Mass spectrum: *m/z* 226 [22%, M^+], 197 [68, $C_7H_4F_5N^+$], 196 [100, $C_6F_5NHCH_2^+$].

Synthesis of N-(polyfluorophenyl)ethane-1,2-diamineplatinum(II) complexes

Bis - iodo[N - (2,3,5,6 - *tetrafluorophenyl)ethane-1,2-diamine*]*platinum*(II) (**2a**). K_2PtCl_4 (1.2 mmol) and KI (5.3 mmol) were stirred in water (50 cm^3) with gentle heating for 0.5 h. Addition of a solution of **1a** (1.3 mmol) in ethanol (10 cm^3) and stirring overnight gave an orange precipitate, which was washed with a minimum of ethanol and then ether, recrystallized twice from acetone–petrol (b.p. 80–100°C), and refluxed in ether for 2 h giving an orange solid (yield, 16%), m.p. 188–189°C (Found: C; 14.3; H; 1.5; F, 11.3; N, 4.3. $C_8H_8F_4I_2N_2Pt$ requires: C, 14.6; H, 1.2; F, 11.6; N, 4.3%). UV–vis spectrum [λ_{max} (ε)]: 321 (750), 379 (820) nm. IR: 3249m and 3189s ν(NH), 3128m, 3103m, 3070m, 1562m, 1526vs, 1500m, 1473s, 1460m, 1445m, 1429m, 1257m, 1208m, 1175s, 1150m, 1062m, 1038m, 1011m, 930s, 845s, 711m, 687m, 650m, 541m, 193w and 178w ν(Pt—I) cm^{-1}. Mass spectrum: *m/z* 254 [43%, I_2^+], 208 [12, $C_8H_8F_4N_2^+$], 179 [81, $C_7H_5F_4N^+$], 178 [100, $HC_6F_4NHCH_2^+$]. A similarly prepared solution of K_2PtI_4 (0.60 mmol) in water (50 cm^3) was treated with **1a** (0.63 mmol) in acetone (10 cm^3) giving a brown oil that dissolved upon addition of more acetone (60 cm^3). After stirring for 0.5 h, the solution was evaporated to dryness *in vacuo* leaving an orange solid. The solid was extracted with acetone, the solution was filtered and again evaporated to dryness. Dissolution in ethanol and precipitation by petrol gave an orange precipitate of **2a** (yield, 73%) (IR identification). An analogous preparation in aqueous t-butanol gave crude **2a** in 86% yield (IR identification).

Dichloro[*N* - (2,3,5,6 - *tetrafluorophenyl)ethane-1,2-diamine*]*platinum*(II) (**2b**). A solution of K_2PtCl_4 (1.2 mmol) in water (15 cm^3) was stirred for 2 days with **1a** (1.5 mmol) in t-butanol (15 cm^3) giving a cream precipitate which was collected, washed with water then petrol, and dried (yield, 88%), m.p. > 250°C (dec.) (Found: C, 20.6; H, 1.5; N, 6.2. $C_8H_8Cl_2F_4N_2Pt$ requires: C, 20.3; H, 1.7; N, 5.9%). UV–vis spectrum [λ_{max} (ε)]: 313 (380), 378 (87) nm. IR: 3277m and 3202s ν(NH), 3125m, 3076m, 1648m, 1566m, 1531 and 1527vs, 1505m, 1477m, 1352m, 1288m, 1261m, 1220m, 1178s, 1170s, 1062m, 1038m, 1029m, 932vs, 846s, 713m, 690m, 658m, 337m and 331m ν(Pt—Cl) cm^{-1}. Mass spectrum: *m/z* 208 [12%, $C_8H_8F_4N_2^+$], 188 [11, $C_8H_7F_3N_2^+$], 178 [100, $HC_6F_4NHCH_2^+$].

Bis - iodo[*N* - (*pentafluorophenyl)ethane* - 1,2-*diamine*]*platinum*(II) (**2c**). K_2PtCl_4 (1.2 mmol) and KI (5.1 mmol) in water (50 cm^3) were stirred for 0.5 h and then **1b** (1.3 mmol) in acetone (25 cm^3) was added. After stirring overnight, the mixture was evaporated to dryness *in vacuo*. The solid was recrystallized from ethanol–petrol (b.p. < 40°C) to give the title compound (yield, 20%), m.p. 183–184°C (dec.) (Found: C, 14.7; H, 1.0; F, 14.3; N, 4.3. $C_8H_7F_5I_2N_2Pt$ requires: C, 14.2; H, 1.0; F, 14.1; N, 4.2%). UV–vis spectrum [λ_{max} (ε)]: 321 (880) 380 (960) nm. IR: 3246m ν(NH), 3182m, 3127m, 3110m, 1530s, 1523vs, 1456s, 1352m, 1206m, 1138m, 1131m, 1051m, 1012m, 996s, 982s, 669m, 190w and 172w ν(Pt—I) cm^{-1}. Mass spectrum: *m/z* 254 [11%, I_2^+], 226 [26, $C_8H_7F_5N_2^+$], 206 [13, $C_8HF_5N^+$], 197 [94, $C_7H_4F_5N^+$], 196 [100, $C_6F_5NHCH_2^+$].

Synthesis of N,N'-bis(polyfluorophenyl)ethane-1,2-diaminato(2−)platinum(II) *complexes*

Amounts of reagents, reaction conditions and yields of products are given in Table 1. In each case bis-iodo[N-(2,3,5,6-tetrafluorophenyl)ethane-1,2-diamine]platinum(II), thallium(I) 2,3,5,6-tetrafluorobenzoate, dry pyridine (10 cm^3) and the appropriate polyfluorobenzene were heated with stirring under purified nitrogen. After reaction, the mixture was evaporated to dryness *in vacuo* and the residue washed with petrol (2 × 20 cm^3) and extracted with ether or acetone. The resulting solution was filtered, evaporated to dryness and the residue was washed with a minimum of ethanol (2 × 2 cm^3) on a glass sinter, and recrystallized as indicated below. ^3J(PtH) values are given in Table 2.

[*N,N' -bis*(2,3,5,6 -*tetrafluorophenyl)ethane* - 1,2-*diaminato*(2−)]*dipyridineplatinum*(II) (**3a**). Extraction with acetone and recrystallization from ether–petrol gave the yellow title compound, m.p. 188–190°C (dec.), ref. 3 m.p. 173°C (dec.). ^{1}H and ^{19}F NMR, IR and mass spectra of the solid were identical with those of the authentic compound.

[*N* - (4 - *bromo* - 2,3,5,6 - *tetrafluorophenyl*) - *N'*-(2,3,5,6 - *tetrafluorophenyl)ethane* - 1,2 - *diaminato*(2−)]*dipyridineplatinum*(II)–*ether* (1:0.5) (**3b**·$0.5Et_2O$). Extraction with acetone and recrystallization from ether–petrol gave the title compound, m.p. 178–182°C (dec.) (Found: C, 38.1; 37.8; H, 2.2, 2.3; N, 6.7, 7.0. $C_{24}H_{15}BrF_8N_4Pt$·$0.5C_4H_{10}O$ requires: C, 37.9; H, 2.5; N, 6.8%).

Abstract—The interaction of thiols (RSH; R = n-butyl, t-butyl, *p*-bromophenyl, *p*-nitrophenyl and phenyl) with dichromate in dimethylformamide (DMF) has been studied and found to involve the formation of chromium(VI) thioester anions ($[RSCrO_3]^-$) followed by much slower redox reactions resulting in the formation of chromium(III) and disulphide species. The chromium(VI) thioesters can be precipitated from DMF/ether solutions as tetraphenylarsonium or bis(triphenylphosphine)iminium salts. They show characteristic visible absorptions around 420 nm (extinction coefficients *ca* 2000 mol^{-1} dm^3 cm^{-1}) and IR absorptions at *ca* 945 cm^{-1} [$\nu(Cr—O)_{asym}$] and 890 cm^{-1} [$\nu(Cr—O)_{sym}$]. The initial interaction between thiols and dichromate in DMF is an acid-catalysed hydrolysis of dichromate followed by the substitution of protonated chromate by the thiol. Arylthiols catalyse the hydrolysis more effectively, and substitute chromate more rapidly, than alkylthiols. Chromium(VI) arylthioesters decompose more rapidly than the alkyl thiol derivatives with chromium(V) intermediates being involved in the process.

The reduction of dichromate anions by thiols has been studied almost exclusively in aqueous solution, in part influenced by the interest in understanding the carcinogenic and mutagenic properties of chromium(VI).[1,2] The presence of chromium(VI) thioesters as transient intermediates in such redox processes has been suggested by UV–vis spectroscopy and other intermediates involving chromium(V) and chromium(IV) have been proposed from an analysis of kinetic data.[1,2] Recent work on the aqueous chromate/glutathione system indeed indicates a relatively stable chromium(V) intermediate.[3] The observed kinetic profile and relative stabilities of the intermediates vary with pH and nature of buffers used.[1,2]

Reactions in organic solvents have been little studied but the understanding of the use of dichromate as a "curing" agent for polysulphide prepolymers, used as sealants, requires knowledge of the redox reaction in non-aqueous media.[4] One such study by Averko-Antonovich *et al.*[5] used polarography to examine the reaction of a polysulphide oligomer with $Na_2[Cr_2O_7]$ in alcoholic KOH and DMF. It showed that thiol groups were oxidized to disulphides and chromium(VI) reduced to chromium(III). A mechanism was proposed which, as in aqueous solution, involved the initial formation of a chromium(VI) thioester followed by successive reductions to chromium(III). No study of the intermediate steps was reported.

This paper reports studies of the kinetics of reactions between dichromate anions and various aryl and alkyl thiols using spectroscopic techniques together with the isolation of further examples of chromium(VI) thioester intermediates. The structural characterization of one such compound, $[Ph_4As][p\text{-}BrPhSCrO_3]$, by a single crystal X-ray diffraction study has been reported separately.[6]

The overall reduction of dichromates by thiols results in the formation of water [eq. (1)]

$$[Cr_2O_7]^{2-} + 2RSH \rightleftharpoons 2[RSCrO_3]^- + H_2O \quad (1)$$

and hence such reactions cannot be carried out under completely anhydrous conditions. This means that $[Cr_2O_7]^{2-}$ anions can undergo hydrolysis as water is formed and an examination of the kinetics of hydrolysis of the dichromate anion in DMF has been made.

RESULTS AND DISCUSSION

The conversion of dichromate into the chromium(VI) thioesters involves an intermediate species as evident from the absence of isosbestic points in the plots of visible spectra of reacting solutions with time (Fig. 1). This results from the accompanying hydrolysis of dichromate to give the protonated chromate anion, $[HOCrO_3]^-$ (Fig. 2; Table 1). An examination of the hydrolysis of dichromate in DMF was therefore undertaken to aid the interpretation of the chromium(VI) thioester formation results.

Hydrolysis of dichromate

The hydrolysis of dichromate in aqueous solution has been the subject of several investigations.[11–15] The reaction is catalysed by acids[12] and bases,[11,13,14] as well as being affected by a number of "inert"

[c] This work, solutions prepared from $[Ph_4As][p\text{-}BrPhSCrO_3]$ or $[PPN][p\text{-}BrPhSCrO_3]$; similarly $\lambda_{max} = 410$ nm and $\varepsilon = 2170$ mol^{-1} dm^3 cm^{-1} in THF.

salts.[14,15] Nucleophiles can substitute directly onto dichromate forming reactive intermediates [eqs (2)–(4)],

$$B + [Cr_2O_7]^{2-} \xrightarrow{\text{slow}, k_B} [BCrO_3] + [CrO_4]^{2-} \quad (2)$$

$$[BCrO_3] + H_2O \xrightarrow{\text{rapid}} [HOCrO_3]^- + BH^+ \quad (3)$$

$$[HOCrO_3]^- + B \xrightarrow{\text{rapid}} [CrO_4]^{2-} + BH^+ \quad (4)$$

whereas acid catalysis most likely results from protonation of the μ-oxo bond of dichromate with subsequent heterolytic fission [eqs. (5)–(7)]:

$$HA + [Cr_2O_7]^{2-} \xrightarrow{\text{slow}, k_A} [HOCrO_3]^- + CrO_3 + A^- \quad (5)$$

$$CrO_3 + H_2O \xrightarrow{\text{rapid}} [HOCrO_3]^- + H^+ \quad (6)$$

$$H^+ + A \xrightarrow{\text{rapid}} HA. \quad (7)$$

The reaction of $[Cr_2O_7]^{2-}$ (*ca* 10^{-4} mol dm^{-3}) with excess thiol results in the formation of H_2O (*ca* 10^{-4} mol dm^{-3}) [eq. (1)]. The HPLC-grade DMF employed in this study contained < 0.03% H_2O (i.e. $< 10^{-2}$ mol dm^{-3} H_2O). Drying the DMF and/or deliberately adding up to 5% H_2O (3.1 mol dm^{-3}) had little effect on the rates or degree of chromium(VI) thioester formation. We measured the effect of both acids and bases on the rate of hydrolysis of dichromate in DMF solution containing 3.1 mol dm^{-3} H_2O ($\approx$ 5% by volume). In the absence of any catalyst the dichromate anion slowly hydrolysed ($t_{1/2} \approx 4$ h at 43°C) with $[HOCrO_3]^-$ being the final product (Fig. 2).

Catalysis by acids and bases

The addition of 3,5-lutidine resulted in an increased rate of hydrolysis which was found to vary linearly with the concentration of 3,5-lutidine (Fig. 3). Surprisingly the final product was still $[HOCrO_3]^-$ indicating that 3,5-lutidine was not a strong enough base to deprotonate this species in DMF solution thus reflecting a significant change in the relative pK_a's of these species from H_2O to DMF (cf. pK_a ($[CrO_4]^{2-}$) = 5.74[16] and pK_a (3,5-lutidine) = 6.15[17] in H_2O at 25°C).

The addition of aqueous NaOH to DMF solutions of dichromate (such that the final water content was 5%) resulted in the rapid hydrolysis to $[CrO_4]^{2-}$ (Fig. 2). The first-order rate constants observed varied linearly with $[OH^-]$ and the calculated second-order rate constant is given in Table 2. Et_3N (0.02 mol dm^{-3}) had no measurable effect on the rate of hydrolysis of dichromate in DMF.

Thus nucleophilic substitution on dichromate anion in DMF appears to be similar, albeit somewhat slower than, such reactions in aqueous solution. The relative abilities of bases to catalyse the hydrolysis of dichromate also appear to be similar (OH^- > 3,5-lutidine > H_2O > Et_3N). The poor catalytic ability of Et_3N is presumably a consequence of steric hindrance.

NH_4^+ effectively catalyses the hydrolysis of dichromate to give $[HOCrO_3]^-$ in DMF at 43°C. The variation in rate of hydrolysis with the concentration of NH_4^+ was not linear (Fig. 3) and is consistent with the catalytic species being NH_3. A half-order dependence of the first-order rate constant, k_{obs}, on the concentration of NH_4^+ is consistent with an initial dissociation into NH_3. The slope of this plot gives $k_B(K_a)^{1/2} = 0.022(2)$ mol$^{-1/2}$ dm$^{3/2}$ s^{-1}. Owing to difficulties in arranging solutions containing known concentrations of H^+ and/or NH_3 without adding competing catalysts, it was not possible to determine separate values of k_B and K_a.

Formic acid also proved to be an effective catalyst for the hydrolysis of dichromate, again resulting in the formation of $[HOCrO_3]^-$. The observed first-order rate constant varied linearly with the concentration of HCOOH over the range studied (2×10^{-4}–10^{-3} mol dm^{-3}). The mode of catalysis may again be via dissociation of the acid to give an active base ($HCOO^-$) but in view of the results, obtained for the effect of acetic acid[12] in aqueous solution, acid catalysis is most likely. HCOOH or H^+ may be the reactive species depending on the degree of dissociation in DMF ($pK_a = 3.75$[17] in H_2O at 20°C but a higher value would be expected in DMF). In Table 2, k_A represents the value obtained on dividing the observed first-order rate constants by the concentration of HCOOH.

Kinetics of chromium(VI) *thioester formation*

The observed visible absorption changes accompanying chromium(VI) thioester formation could be accurately simulated using eqs (8) and (9). For the conditions of a large excess of thiol, the scheme represents coupled pseudo first-order reactions:

$$H_2O + [Cr_2O_7]^{2-} \xrightarrow{k_A, \text{"RSH"}} 2[HOCrO_3]^- \quad (8)$$

$$RSH + [HOCrO_3]^- \xrightarrow{k_4} [RSCrO_3]^- + H_2O \quad (9)$$

* The rate equations derived from eqs (8) and (9) [where eq. (8) represents the thiol-catalysed hydrolysis of $[Cr_2O_7]^{2-}$, i.e. eqs (5)–(7)] were solved numerically by third-order Taylor expansion. Initial estimates of k_A and k_4 were used to generate concentrations of $[Cr_2O_7]^{2-}$, $[HOCrO_3]^-$ and $[RSCrO_3]^-$. Absorbance as a function of time could then be calculated from these concentrations and the known extinction coefficients for the species. The estimates of k_A and k_4 were varied and the calculated absorbance vs time data compared to the experimental data.

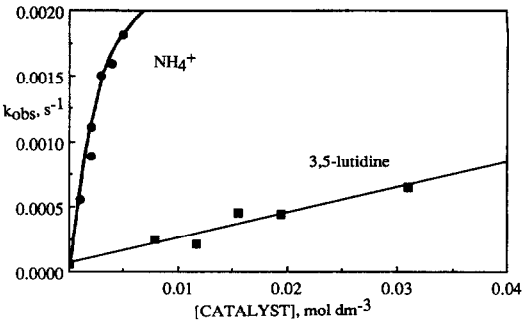

Fig. 3. Variation in first-order rate constants for dichromate hydrolysis in DMF as a function of catalyst concentration (1 mol dm^{-3} $NaNO_3$, 43°C).

$$[RSCrO_3]^- \xrightarrow{\text{"RSH"}} \text{final products.} \quad (10)$$

The calculated* visible spectrum for the intermediate substitution species {$[HOCrO_3]^-$, eq. (8)} is very similar to that of the final product of the hydrolysis of dichromate in DMF, $[HOCrO_3]^-$ (Fig. 2).

The initial step in the biphasic formation of chromium(VI) thioesters in DMF is the thiol-catalysed hydrolysis of dichromate to yield $[HOCrO_3]^-$ and estimates for k_A are given in Table 2. The thiol-catalysed hydrolysis of dichromate presumably does not involve the interaction of the sulphur atom with chromium since this would essentially give us the final product, the chromium(VI) thioester. Acid-catalysed hydrolysis may be a more precise description of this initial step. Neither thiol would be expected to dissociate to a significant amount in DMF at concentrations $> 10^{-3}$ mol dm^{-3} (aque-

ous solution; pK_a (n-BuSH) = 10.65,[18] pK_a (*p*-BrPhSH) = 6.02[19]).

The results for the acid-catalysed hydrolysis of dichromate in DMF by the three acids studied (HCOOH, *p*-BrPhSH, n-BuSH) appear consistent with the conclusions drawn for reaction in aqueous solution,[12] i.e. that acid catalysis is general rather than specific with the catalytic constant increasing with increasing acid strength.

Chromium(VI) thioester formation results from thiol substitution onto $[HOCrO_3]^-$ [eq. (4)] and estimates for k_4 place *p*-BrPhSH ($k_4 \approx 4$ mol^{-1} dm^3 s^{-1}) as more reactive than n-BuSH ($k_4 \approx 0.2$ mol^{-1} dm^3 s^{-1}). There was no evidence for the direct attack on $[Cr_2O_7]^{2-}$, hence this process must be much slower than substitution on $[HOCrO_3]^-$.

Catalysis of chromium(VI) *thioester formation*

The addition of HCOOH, a possible contaminant in DMF, catalysed the formation of the thioester. HCOOH catalyses the hydrolysis of dichromate in DMF (*vide infra*). The addition of n-BuSH to solutions of $[HOCrO_3]^-$ generated by HCOOH catalysed hydrolysis of $[Cr_2O_7]^{2-}$ resulted in the rapid formation of the chromium(VI) thioester which increased non-linearly with the concentration of HCOOH and appeared independent of n-BuSH at a given HCOOH concentration.

Ammonium cations were found to catalyse the reaction relative to Na^+. The rate of formation of thioesters in the presence of NH_4^+ depended on how the experiment was performed. The addition of a small aliquot of concentrated n-BuSH solution to a solution of $[NH_4]_2[Cr_2O_7]$ in 1 mol dm^{-3} NH_4NO_3 held at 35°C, resulted in variable rates of reaction, with rates faster for "older" $[Cr_2O_7]^{2-}$/NH_4^+ solutions (Fig. 4). The addition of fresh $[NH_4]_2[Cr_2O_7]$ solution to solutions of n-BuSH/1 mol dm^{-3} NH_4NO_3 (at 35°C), however, resulted in a reproducible formation of thioester at rates independent of the concentration of n-BuSH (Fig. 4). The formation kinetics in both cases appeared first-order with no sign of the intermediate observed for the reaction in the presence of Na^+. The second-order rate constant for the apparent thiol-dependent reaction in the presence of 1 mol dm^{-3} NH_4^+ is approximately 100 times that in the presence of Na^+.

The catalysis of chromium(VI) thioester formation by HCOOH or NH_4^+ appears to result from the formation of $[HOCrO_3]^-$ which is more susceptible to substitution by thiols than $[Cr_2O_7]^{2-}$. The presence of ammine or formate complexes may also provide catalytic pathways to chromium(VI) thioester formation.

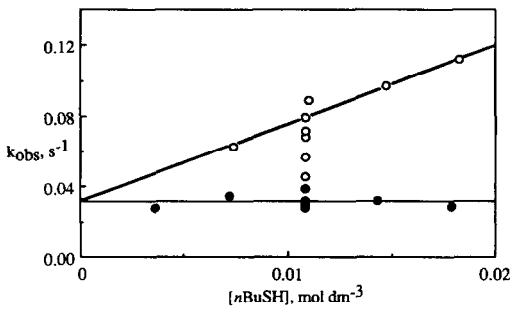

Fig. 4. Change in first-order rate constant, k_{obs}, with concentration of n-BuSH for thioester formation in DMF at 35°C in the presence of 1 mol dm^{-3} NH_4NO_3: ● $[Cr_2O_7]^{2-}$ added to n-BuSH in NH_4NO_3 solution; ○ n-BuSH added to $[Cr_2O_7]^{2-}$ in NH_4NO_3 solution.

Et_3N greatly retards the formation of the chromium(VI) n-BuS-thioester. The addition of *p*-BrPhSH to $Et_3N/[Cr_2O_7]^{2-}$ solutions results in deprotonation of *p*-BrPhSH (as evident from the immediate increase in absorbance around 360 nm) followed by chromium(VI) *p*-BrPhS-thioester formation. The rate of formation is slower than in the absence of Et_3N and does not reach completion before redox processes begin to consume chromium(VI) (as evident from the decrease in absorbance over the range 350–550 nm). The effect of Et_3N could then be explained as due to a reduction in active H^+ in the systems. Et_3N, itself, is a poor catalyst for dichromate hydrolysis.

Characterization of chromium(VI) *thioester salts*

Bis(triphenylphosphine)iminium and tetraphenylphosphonium salts of chromium(VI) thioesters can be isolated from DMF/ether solutions and Table 3 lists microanalytical data obtained for a range of such salts. The substituted thiophenol derivatives were prepared at 0°C so as to limit contamination of the products by paramagnetic material generated by redox decomposition of the chromium(VI) thioesters. The butylthiol derivatives were prepared at room temperature with much longer reaction times owing to the slow substitution onto chromium(VI). Redox reactions involving the butylthiol derivatives are also much slower than for the arylthiol species. The tetraphenylarsonium salt of the chromium(VI) *p*-bromophenylthioester, $[Ph_4As][p\text{-}BrPhSCrO_3]$, has been the subject of an X-ray structural study.[6]

The chromium thioester salts dissolve readily in most polar organic solvents. Visible absorption spectra were similar for DMF, THF and $CHCl_3$ solutions. The thioesters were sensitive to acid impurities in $CHCl_3$ but otherwise showed similar stabilities in the three solvents, slowly undergoing

Table 3. Microanalytical and IR data for chromium(VI) thioester salts

Thioester salts	Analysis [Found % (Calc. %)] C	H	N	S	P	Br	ν(Cr—O)[a] (cm^{-1}) asym.	sym.

[a] Samples prepared as Nujol mulls.

hydrolysis and/or redox decomposition over the course of many hours at room temperature.

^1H and ^{13}C NMR spectra were recorded for [PPN][n-BuSCrO$_3$] in $CDCl_3$ (atom positions as in $^{\delta}CH_3{}^{\gamma}CH_2{}^{\beta}CH_2{}^{\alpha}CH_2S$). The ^1H NMR spectrum consisted of a multiplet at 7.500 ppm, relative to internal TMS, due to the aromatic protons of the PPN^+ cation and multiplets at; 0.823 ppm ($^{\delta}H$), 1.354 ppm ($^{\gamma}H$), 1.653 ppm ($^{\beta}H$) and 3.006 ppm ($^{\alpha}H$). Integration of the peaks supported the assignments. Some broadening of the resonances due to paramagnetic decomposition products prevented complete resolution of the multiplets. Reported[20] values for n-BuSH in $CDCl_3$ are 0.92 ppm ($^{\delta}H$), 1.53 ppm ($^{\gamma}H$ and $^{\beta}H$), and 2.52 ppm ($^{\alpha}H$).

Similarly, the broad band decoupled ^{13}C NMR spectrum consisted of peaks due to the aromatic carbons of PPN^+ (nine peaks, includes ^{31}P coupling, *ca* 130 ppm relative to internal TMS) and the n-butylthio group: 13.831 ppm ($^{\delta}C$), 22.201 ppm ($^{\gamma}C$), 35.149 ppm ($^{\alpha}C$) and 35.983 ppm ($^{\beta}C$). Assignment was based on the reported[21] values for ^{13}C NMR spectra ($CDCl_3$, TMS internal standard) for n-BuSH ($^{\delta}C$, 13.5; $^{\gamma}C$, 21.5; $^{\alpha}C$, 24.3; $^{\beta}C$, 36.2) and the thioester, n-BuS-C(O)CH_3 ($^{\delta}C$, 13.6; $^{\gamma}C$, 22.1; $^{\alpha}C$, 28.9; $^{\beta}C$, 31.8).

IR spectral absorptions arising from the cations (PPN^+ bands at *ca* 695, 725, 745 and 998 cm^{-1}) and thiols (*p*-BrPhS bands at *ca* 815 and 1008 cm^{-1}; *p*-NO_2PhS bands at *ca* 845 and 852 cm^{-1}) can be identified. The chromium(VI) thioesters are characterized by two strong bands at *ca* 945 and 890 cm^{-1}, with the band at 945 cm^{-1} often having added structure (Table 3). $[ClCrO_3]^-$ also gives rise to similar bands at 954 and 907 cm^{-1} which have been assigned to $\nu(Cr—O)_{asym}$ and $\nu(Cr—O)_{sym}$ stretches, respectively.[22] A notable difference from the IR spectra of dichromates is the loss of a band at *ca* 780 cm^{-1} which has been assigned to asymmetric vibrations of the Cr—O—Cr feature.[23]

The IR spectra of DMF solutions of $Na_2[Cr_2O_7]$ with and without added *p*-BrPhSH clearly demonstrates the loss of the μ-oxo bond on thioester formation (Fig. 5). The Cr—O bands of the chromium(VI) thioester anion generated by mixing $Na_2[Cr_2O_7]$ and *p*-BrPhSH in DMF are in the same position as those observed in the IR spectrum of DMF solutions of the isolated salts, viz. 949 and 892 cm^{-1}. Nujol mulls of the solids show slight shifts in the positions of these bands (Table 3). Coupled with a similar coincidence of the visible spectra of chromium(VI) thioester anions prepared *in situ* by reaction of dichromate and thiol and on dissolution of the isolated salts (Table 1), the data strongly suggests the same structure exists in solution as in the solid state.

Thermodynamics of chromium(VI) *thioester formation*

The addition of H_2O (up to 3.1 mol dm^{-3}; $\approx$5.5% v/v) had no apparent effect on chromium(VI) thioester formation. There was no evidence for dissociation of the chromium(VI) thioester in the presence of excess thiol ($> 5\times10^{-4}$ mol dm^{-3}) even under the conditions where 3.1 mol dm^{-3} H_2O was present. $[Ph_4As][p\text{-}BrPhSCrO_3]$ (10^{-4} mol dm^{-3}) dissolved in DMF at 43°C in the presence of 3.1 mol dm^{-3} H_2O and 1 mol dm^{-3} $NaNO_3$ slowly hydrolysed into $[HOCrO_3]^-$. The process followed first-order kinetics with a half-life of 3.6 h.

The reaction corresponds to the reverse step of eq. (9), and assuming overall second-order kinetics, the implied chromium(VI) thioester hydrolysis rate constant is $k_{-4} \approx 2\times10^{-5}$ mol^{-1} dm^3 s^{-1}. The equilibrium constant for chromium(VI) thioester formation in DMF (43°C, 1 mol dm^{-3} $NaNO_3$) can then be calculated from the estimated formation and hydrolysis rate constants as $K = k_4/k_{-4} = 2\times10^4$. This value is consistent with the observa-

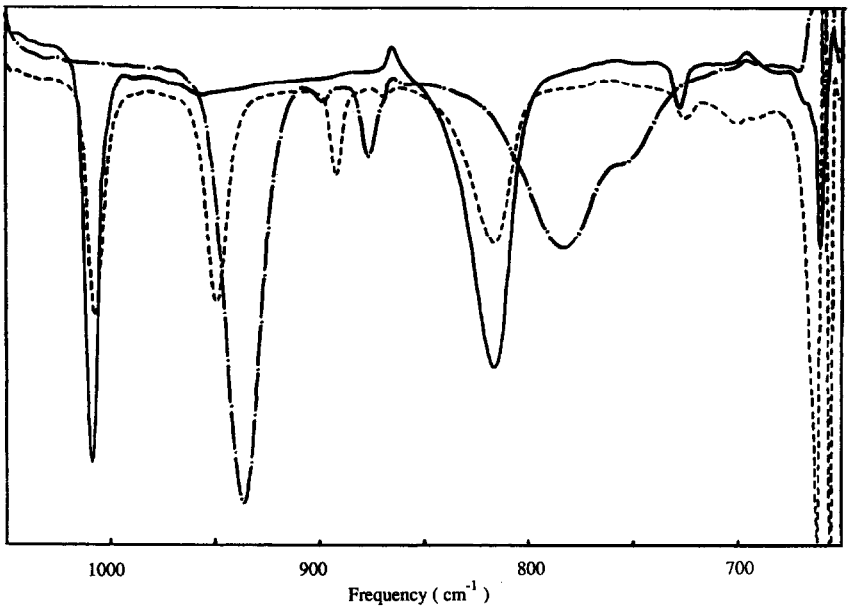

Fig. 5. IR spectra of 10^{-2} mol dm^{-3} $Na_2[Cr_2O_7]$ (– · – –), 0.25 mol dm^{-3} *p*-BrPhSH (——) in DMF and a 15 min old 50 : 50 mixture of the two solutions (– – – –).

tions of essentially complete formation of the chromium(VI) thioester in the presence of excess *p*-BrPhSH and the substantial hydrolysis in the absence of any added *p*-BrPhSH.

[PPN][n-BuSCrO$_3$] (10^{-4} mol dm^{-3}) hydrolysed in DMF in the presence of 3.1 mol dm^{-3} H_2O (43°C, 1 mol dm^{-3} $NaNO_3$) at a much slower rate ($t_{1/2} \approx 40$ h, $k_{-4} \approx 2 \times 10^{-6}$ mol^{-1} dm^3 s^{-1}). The chromium(VI) n-BuS-thioester formation equilibrium constant, $K = k_4/k_{-4} \approx 10^5$, is similar to that calculated for the *p*-BrPhSH derivative.

In aqueous solution,[1,2] chromium(VI) thioester formation constants have been found to be of the order of 1000 mol^{-1} dm^3. Inclusion of the water concentration term to establish the same constants described above, results in $K \approx 5 \times 10^4$.

Decomposition of chromium(VI) *thioesters*

Hydrolysis of the chromium(VI) thioesters has been discussed above. The chromium(VI) thioesters were also found to react with excess thiol resulting in the eventual formation of chromium(III) and disulphide. EPR spectroscopic studies have indicated the presence of chromium(V) intermediate species.[3,24–27] Thiophenol added to $K_2[Cr_2O_7]$ in DMF is reported to result in the appearance of two signals with g values at 1.996 and 1.982.[24] Likewise the reaction of chromates with glutathione in aqueous solution generates chromium(V) complexes characterized by EPR signals at $g = 1.996$ and $g = 1.985$,[3,25–27] with the $g = 1.996$ peak dominating at high concentrations of glutathione. The species with $g = 1.996$ has been isolated although not structurally characterized as yet.[26] The generation of glutathione radicals has also been indicated from EPR experiments.[27] Thus the decomposition of [*p*-BrPhSCrO$_3$]$^-$ in the presence of excess *p*-BrPhSH showed evidence for such an intermediate step.

In the presence of larger excesses of *p*-BrPhSH, $Na_2[Cr_2O_7]$ reacts to form unstable solutions of the chromium(VI) thioester anion. A general increase in absorbance over the range 550–350 nm and the development of a new band at 750 nm, was observed for several minutes after mixing the reagents, followed by a general decrease in absorption over the entire spectral range. This was consistent with conversion to chromium(III) species. The latter process followed first-order kinetics ($t_{1/2} \approx 1$ h; 0.016 mol dm^{-3} *p*-BrPhSH, 10^{-4} mol dm^{-3} $Na_2[Cr_2O_7]$, DMF, 43°C, 1 mol dm^{-3} $NaNO_3$).

EPR experiments indicated that on mixing [Ph_4As][*p*-BrPhSCrO$_3$] (10^{-3} mol dm^{-3}) in DMF with a five-fold excess of *p*-BrPhSH at room temperature, two signals ($g = 1.997$ and $g = 1.983$) appeared and increased in intensity over $\approx 1/2$ h. The relative proportion of the two species changed with time with the $g = 1.983$ peak dominating as time progressed.

Solution IR studies showed little change in the position of the Cr—O bands on reaction of [Ph_4As][*p*-BrPhSCrO$_3$] in the presence of excess *p*-BrPhSH, possibly indicating that the intermediate

species evident from the UV–vis and EPR spectral changes represent a small percentage of the total chromium.

During attempts to isolate the chromium(VI) thioesters, longer reaction times led to the formation of paramagnetic materials. The products ranged from apparently polymeric chromium(III) species (as judged by their low solubility, magnetic moments and visible absorption spectra) of uncertain constitution to a paramagnetic black solid which analysed as the chromium(V) salt, $[Ph_4As][p\text{-}BrPhSCr(O)_2(OH)]$.

The magnetic moment for this latter sample was found to be $\mu_{eff} = 1.78$ BM, consistent with the chromium(V) assignment. The product dissolved in DMF to give a UV–vis spectrum similar to that of the chromium(VI) thioester but was quite unstable, decomposing back to a mixture of $[(HO)CrO_3]^-$ and $[p\text{-}BrPhSCrO_3]^-$. The IR spectrum of a Nujol mull of the product was very similar to that of the chromium(VI) thioester, $[Ph_4As][p\text{-}BrPhSCrO_3]$, with absorptions corresponding to the cation and p-$BrPhS^-$ anion. Absorptions due to Cr—O bonds were present at 948 and 891 cm^{-1}, as well as a new absorption band at 985 cm^{-1}. A band at 3300 cm^{-1} indicated the presence of an OH group. The solid decomposed with time as evident by its change in solubility, eventually becoming insoluble in all common solvents.

Further attempts at improving the preparation of the compound have proven unsuccessful. Dark olive-green plates have been collected in samples containing chromium(VI) thioester and precipitated salts, but it has not proved possible to collect pure samples of the material.

The half-life for the disappearance of the chromium(VI) thioester generated from the reaction between n-BuSH (0.018 mol dm^{-3}) and $[Cr_2O_7]^{2-}$ (2×10^{-4} mol dm^{-3}), in DMF at 43°C in the presence of $NaNO_3$ (1 mol dm^{-3}), is approximately 2 days (cf. $t_{1/2}$ for substitution of *ca* 15 min). The spectrum of the final product is typical of an octahedral chromium(III) species (Fig. 2). Di-n-butyldisulphide could be extracted from the final solution. No intermediate chromium(V) species were apparent in the decomposition process. Much lower concentrations of chromium(V) species may result from a less favourable one-electron oxidation of the alkylthiol by chromium(VI) [eq. (10)]

$$[RSCrO_3]^- + RSH \rightleftharpoons [RSCr(O)_2(OH)]^- + RS^{\bullet} \quad (10)$$

as a result of the higher redox potential for the alkylthiol/alkylthio radical couple relative to that of the arylthiol.[28] This is the same step as proposed for the generation of the chromium(V) glutathione complex.[27]

EXPERIMENTAL

Visible spectra were recorded on a Varian Super Scan 3 spectrophotometer fitted with cell holders connected to a constant temperature bath (Haake D8 immersion circulator and Haake EK12 immersion cooler). IR spectra were recorded on a Perkin–Elmer Model 1600 FT-IR spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC-200 spectrometer with alkali-washed $CDCl_3$ as solvent and TMS as an internal reference. EPR spectra were recorded on a Varian E-line EPR spectrometer (X-band) using a flat solution cell. Magnetic moments were determined by the Faraday technique. Microanalyses were carried out by the Australian Microanalytical Service.

HPLC grade DMF (Aldrich) and AR grade anhydrous diethyl ether (Univar) were used as received. Thiophenol (PhSH; Aldrich), n-butylthiol (n-BuSH; Koch-Light Lab.) and t-butylthiol (t-BuSH; Aldrich) were dried over molecular sieves (4A; BDH) and then distilled under reduced pressure and stored under nitrogen. [PPN]Cl (PPN^+ = bis[triphenylphosphine]iminium cation; Aldrich), p-bromothiophenol (p-BrPhSH; Aldrich) and p-nitrothiophenol (p-NO_2PhSH; Aldrich) were used as received. Sodium dichromate dihydrate (May & Baker Pty. Ltd.) was dehydrated by heating at 110°C for 48 h and was stored in a desiccator. Other high purity reagents were used as received.

Solutions were freshly prepared by standard volumetric techniques. Solutions of dichromate in DMF deteriorate rapidly (noticeable colour change within hours, orange–brown powder deposited over several days) if exposed to the light, but are much more stable if kept in the dark. Reactions were generally initiated by adding small aliquots of one reagent via microlitre syringe (SGE) to much larger volumes of solutions of the second reagent in the spectrophotometric cells fitted with *Suba seal* septa and held at constant temperature in the compartment of the spectrophotometer which automatically recorded spectra at set time intervals. Much slower reactions were followed by sampling techniques whereby the reaction solutions were kept at the desired temperature in the water bath with aliquots being systematically removed for spectrophotometric examination.

Preparation of chromium(VI) *thioester salts*

Bis(triphenylphosphine)iminium thiophenolatochromate(VI), [PPN][$PhSCrO_3$]. $Na_2[Cr_2O_7]$ (0.2 g,

0.8 mmol) was stirred with thiophenol (0.34 g, 3.2 mmol) in DMF (20 cm^3) at 0°C for 15 min. Bis [triphenylphosphine]iminium chloride ([PPN]Cl, 0.9 g, 1.6 mmol) in DMF (10 cm^3) was added and the solution stirred at 0°C for a further 2 h. The addition of ether (150 cm^3) precipitated an orange powder (0.6 g). The product was dissolved in cold DMF (15 cm^3), ether (20 cm^3) added and the solution filtered. Further ether (150 cm^3) was layered onto the filtrate and after standing overnight at −5°C, orange needles (*ca* 0.4 g) of [PPN][$PhSCrO_3$] were collected and washed with ether.

Similar methods of preparation were used to obtain the PPN^+ salts of the *p*-bromothiophenol, *p*-nitrothiophenol t-butylthiol and n-butylthiol derivatives. For the butylthiol derivatives the reactions were carried out at room temperature and generally left overnight. The products were more soluble and could be separated from unreacted chromates by recrystallization as described above.

Tetraphenylarsonium and tetraphenylphosphonium salts could also be obtained (microanalytical data are given in Table 3), whereas Na^+, NH_4^+, $[n\text{-}Bu_4N]^+$ and $[MePh_3P]^+$ salts could not be isolated from DMF/ether solutions.

Isolation of a chromium(V) *thioester salt*

Tetraphenylarsonium(p - *bromothiophenolato)hydrogenchromate*(V), [Ph_4As][*p*-$BrPhSCr(O)_2(OH)$]. Although the method of preparation was essentially the same in each attempt at isolation, the composition of the products obtained was variable from one experiment to another. The reasons for this irreproducibility are not clear. A typical experimental procedure was as follows:

$Na_2[Cr_2O_7]$ (0.4 g, 1.6 mmol) in DMF (5 cm^3) was added to *p*-bromothiophenol (1.2 g, 6.4 mmol) in DMF (5 cm^3) at room temperature and the resulting dark solution was stirred for 15 min. The solution was cooled to 0°C and [Ph_4As]Br (0.75 g, 1.6 mmol) in DMF (5 cm^3) was added. After 2 h at 0°C, ether (200 cm^3) was added and an oil separated. The bulk of the solution was separated from the oil and left to stand overnight at 0°C, after which time a dark solid precipitated (yield ≈ 0.1 g).

Microprobe analysis was consistent with the sample being a homogeneous product containing equimolar amounts of As, Br, Cr and S. Microanalysis was consistent with the formulation [Ph_4As][*p*-$BrPhSCr(O)_2(OH)$]. Found: C, 53.8; H, 3.9; Br, 12.1; S, 5.2; Cr, 8.1. $C_{30}H_{25}AsBrCrO_3S$ requires: C, 53.6; H, 3.7; Br, 11.9; S, 4.8; Cr, 7.7%.

The chromium content was determined spectrophotometrically after dissolution of the complex in HCl and conversion of any chromium to $[CrO_4]^{2-}$ by H_2O_2/NaOH treatment. It was noted that di(*p*-bromophenyl)disulphide was precipitated in the acid dissolution step.

Other attempts at synthesizing the complex tended to produce small amounts contaminated with chromium(VI) thioester or other $[Ph_4As]^+$ salts. Varying the ratios of precipitating cation to chromate, the ratios of thiol to chromate, the thiol, temperature control and solvent composition did not establish reproducible conditions for obtaining pure samples of the chromium(V) species.

(*Received* 23 *August* 1989; *accepted* 13 *December* 1990)

Abstract—A new complex of iron(II) with the N_6-macrocyclic ligand hexacyclen (N-analogue of 18-Crown-6) has been synthesized. Using Mössbauer, EPR and magnetochemical measurements, a thermally controlled intramolecular reverse electron transfer was proved for the complex

Intermediate-spin iron(II) (IS) ($S = 1$) $\rightleftharpoons$ High-spin iron(III) (HS) ($S = 5/2$).

Recently we have studied the coordination and extraction ability of the N_6-macrocyclic ligand hexacyclen (Hex) (N-analogue of 18-Crown-6)[1,2] and the structure of its complexes with cobalt(II), nickel(II) and copper(II).[3–5] It was found that complexes with different structures are formed: the structure of Co(Hex)·2TPB is of the "phthalocyanine" type, e.g. planar,[3] while for Cu(Hex)·2TPB and Ni(Hex)·2TPB temperature-dependent structures were proved,[4,5] due most probably to the flexibility of the hexacyclen molecule (TBP = tetraphenylborate).

Taking into account the ability of polydentate N-containing ligands to stabilize iron(II) and, on the other hand, the ability of hexacyclen to form complexes with different structures, we have studied the magnetic properties of the iron(II) hexacyclen complex using magnetochemical, ^{57}Fe Mössbauer, EPR and IR spectroscopic methods in the temperature range 70–300 K.

EXPERIMENTAL

Apparatus

The electronic and IR spectra (KBr discs) were obtained on Specord UV–vis and Perkin-Elmer 580 spectrometers, respectively.

* Author to whom correspondence should be addressed.

The ^{57}Fe Mössbauer spectra were recorded in transmission geometry using a ^{57}Co[Pd] source (activity ~40 mC; kept at room temperature) on a Hungarian conventional spectrometer operating in the constant-acceleration mode. All isomer shifts are referred to the ^{57}Co[Pd] source as zero shift. The samples were pressed with polyvinyl alcohol (PVA) (the iron surface density being 5 mg cm^{-2}) and mounted in a nitrogen bath cryostat equipped with a calibration thermodiode and temperature controller (±0.5 K). The temperature changes were performed with a velocity of 3 K min^{-1}. The spectra were recorded in the range 77–298 K and fitted to Lorentzian lines by means of a least-squares fitting program.

Magnetic susceptibility measurements were performed over the temperature range 130–300 K in argon atmosphere according to the Faraday method and the EPR spectra were obtained on an *X*-band EPR spectrometer ERS-220 (F.R.G.) in the range 90–420 K as already described.[3,4] The *g*-values were determined according to the relation $g_1 = g_2(H_2/H_1)$, DPPH being used as the *g*-marker.

Procedures and materials

Fe(Hex)·2TPB was obtained as described elsewhere,[1] using Hex·3H_2SO_4 (Aldrich) as starting material. All other reagents used were of AR grade.

RESULTS AND DISCUSSION

The iron(II)–hexacyclen complexation is associated with an intense red coloration of the solution (λ_{max} ~ 500 nm) most probably due to a charge-transfer band. In the IR spectrum of Fe(Hex)·2TPB two ν(NH) bands are observed (3210 and 3270 cm^{-1}) similar to the Cu(Hex)·2TPB spectrum.[4]

The magnetochemical data obtained for Fe(Hex)·2TPB in the range 130–300 K (Fig. 1) show that on the μ_{eff}/T curve a knee is observed as in the corresponding Cu(Hex)·2TPB dependence.[4] These data indicate the presence of different structures at different temperatures.

The value of μ_{eff} (~5 BM) observed at ambient temperature may be ascribed either to d^6 high-spin ($S = 2$) or to d^5 high-spin ($S = 5/2$) octahedral structures.[6] On the other hand, the magnetic moment was found to be temperature dependent (Fig. 1), while the μ_{eff} values for high-spin iron(II) and iron(III) octahedral complexes should be temperature independent.[6] Hence, the data obtained indicate that at low temperatures (below 200 K) a further paramagnetic structure exists, thus ruling out the possibility of realizing a low-spin ($S = 0$) iron(II) species.

In order to obtain additional information concerning the complex, Mössbauer and EPR investigations were performed.

The ^{57}Fe Mössbauer spectra of Fe(Hex)·2TPB were recorded in the range 77–298 K. The data obtained showed that all the observed spectra are superpositions of two quadrupole doublets. The Mössbauer spectra at 77 and 298 K are represented in Fig. 2.

It is evident that in the temperature range studied two iron complexes with different spin-states are present simultaneously. One of them ($\delta = 0.18 \pm 0.03$ mm s^{-1}; $\Delta = 0.75 \pm 0.03$ mm s^{-1}

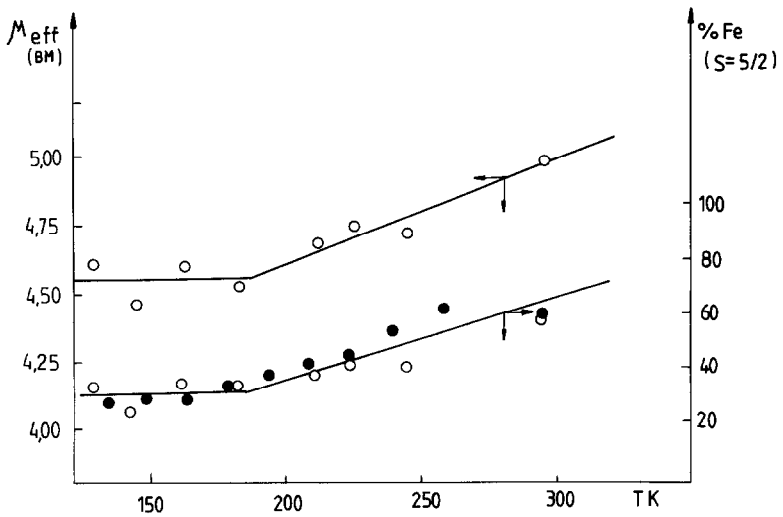

Fig. 1. Temperature dependence of μ_{eff} of Fe(Hex)·2TPB and of the molar fraction of HS ($S = 5/2$) species; ● molar fractions obtained from Mössbauer spectra and ○ molar fractions obtained from magnetochemical data.

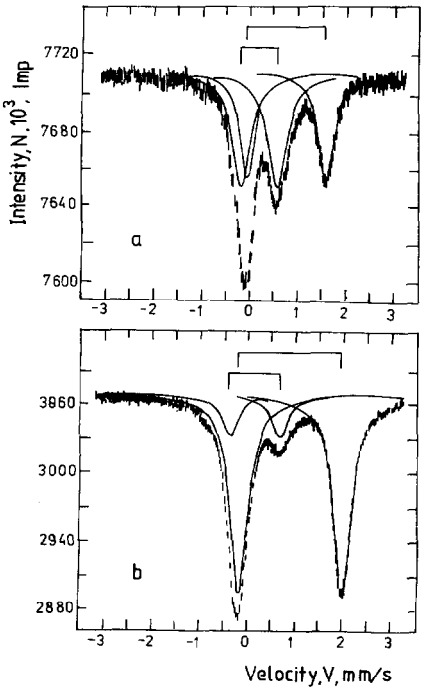

Fig. 2. Mössbauer spectra of Fe(Hex)·2TPB at different temperatures: (a) 298 K and (b) 77 K.

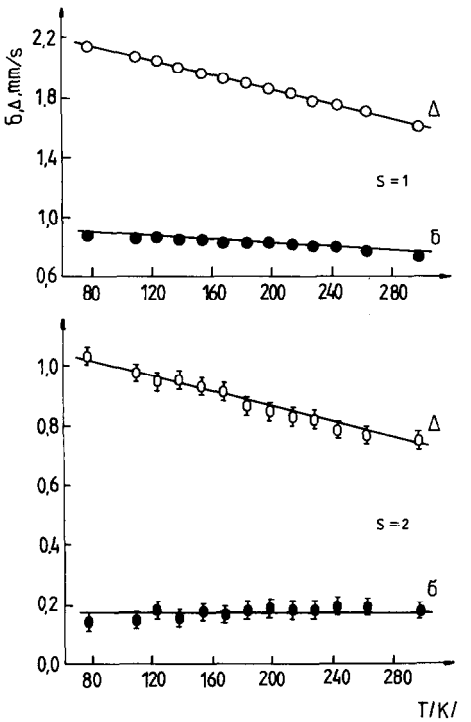

Fig. 3. Temperature dependence of isomer shifts (δ) and quadrupole splittings (Δ) of both Mössbauer doublets.

at 298 K) might be ascribed to a high-spin (HS) ($S = 5/2$) iron(III) species.[7-9] The other species ($\delta = 0.74 \pm 0.01$ mm s^{-1}; $\Delta = 1.61 \pm 0.01$ mm s^{-1} at 298 K) is likely to be due to the intermediate (IS) ($S = 1$) spin-state, typical for four-coordinated iron(II) porphyrins.[10,11]

The temperature dependence of Mössbauer parameters of both species are shown in Fig. 3. It should be noted that the Δ values of both spin-states are strongly temperature dependent and no hysteresis effects are observed in the course of Mössbauer and magnetochemical studies.

Table 1. Molar fractions (± 0.04) of IS and HS Fe(Hex)·2TPB at different temperatures

Temperature (K)	IS ($S = 1$)	HS ($S = 5/2$)
77	0.85	0.15
108	0.77	0.23
122	0.72	0.28
138	0.72	0.28
154	0.72	0.28
168	0.72	0.28
184	0.64	0.35
198	0.62	0.37
212	0.58	0.42
228	0.54	0.46
242	0.45	0.54
262	0.37	0.63
298	0.40	0.58

The molar fractions of IS iron(II) and HS iron(III) at different temperatures were calculated and the data obtained are represented in Table 1.

The Mössbauer data thus obtained are in agreement with the magnetochemical measurements. Taking into account that for the iron(II) phthalocyanine complex ($S = 1$) the μ_{eff} value was found to be 3.96 BM at 293 K,[6] it might be assumed that the IS Fe(Hex)·2TPB exhibits a similar effective magnetic moment (3.9 BM). According to the literature, μ_{eff} values for the HS iron(III) complexes in the range 5.2–5.9 BM would be expected[6] thus allowing an approximation to 5.5 BM. On the basis of these suppositions, the increase in the HS molar fraction with temperature explains the increase in the magnetic moment of the system above 200 K, while in the range 130–200 K the magnetic moment is constant as the molar fractions of both spin-states also remain constant (Fig. 1 and Table 1).

Therefore, a reversible intramolecular electron transfer with temperature might be assumed to take place in Fe(Hex)·2TPB. The latter should be connected with a free radical formation:

$$\underset{\text{IS}\ (S=1)}{[\text{Fe}^{\text{II}}\text{—L}]} \rightleftharpoons \underset{\text{HS}\ (S=5/2),}{[\text{Fe}^{\text{III}}\text{—L}^{\cdot}]}$$

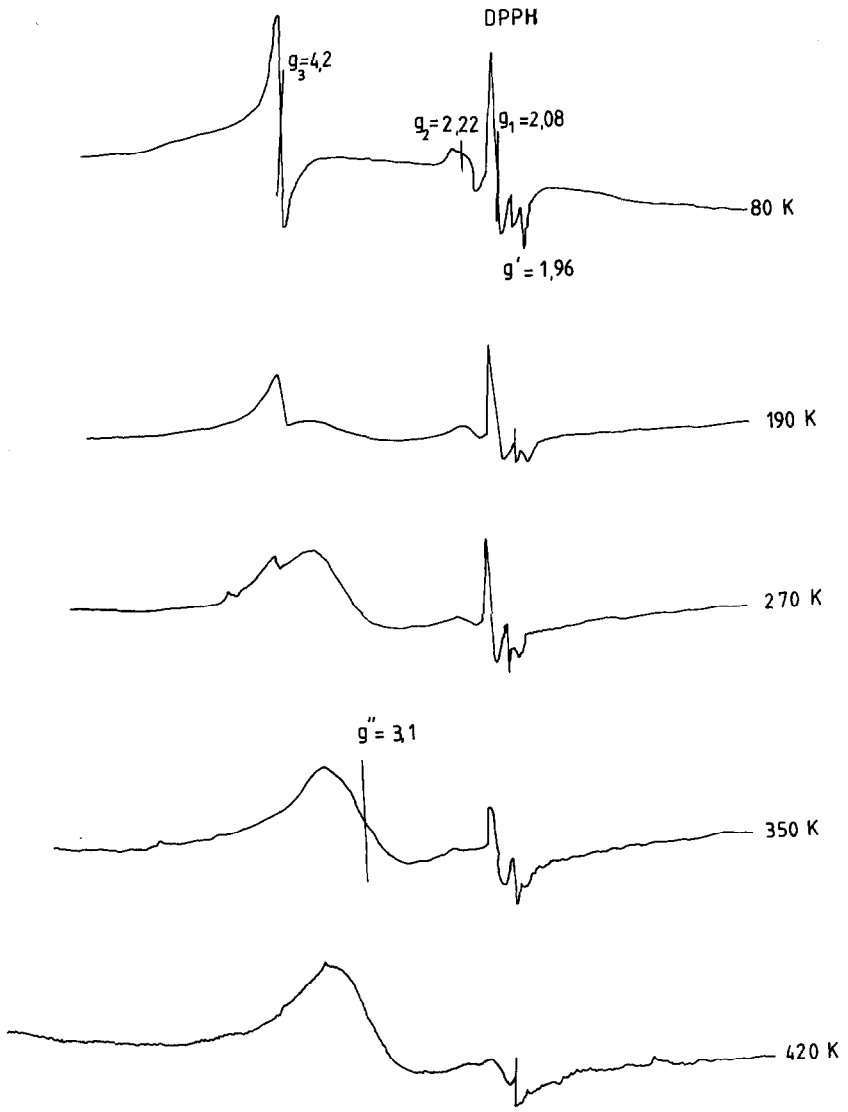

Fig. 4. EPR spectra of Fe(Hex)·2TPB at different temperatures.

where L = hexacyclen and L˙ = the free radical obtained from it. It should be noted that a reversible electron transfer with temperature was observed for Ni(Hex)·2TPB also.[5]

Using the above mentioned μ_{eff} values for both spin-states the percentage of HS iron(III) species was calculated and was found to be in a good agreement with the Mössbauer data (Fig. 1).

The existence of two different iron complex species is supported also by the presence of two bands assigned to ν(NH) in the IR spectrum of Fe(Hex)·2TPB.

Additional information was obtained by studying their EPR spectra at different temperatures; the data obtained are represented in Fig. 4. At low temperatures four different EPR signals are observed (80–200 K); a doublet with $g' \sim 2.00$ and three other EPR signals with $g_1 = 2.08$, $g_2 = 2.22$ and $g_3 = 4.2$. The intensities of g_1, g_2 and g_3 decrease with increasing temperature and therefore they might be ascribed to IS iron(II) species. The presence of more than one signal in the g-range 2.0–2.2 might be explained by dimer formation, and it seems likely that the signal with $g_3 = 4.2$ is due to the $M = 2$ dimer absorption.[12]

It might be expected that the existence of iron(II) dimers at low temperature would lead with a temperature increase to the formation of iron(III) couples also. For the latter, symmetrical Mössbauer doublets are typical and in our case also a symmetrical doublet was observed (Fig. 2). The antiferromagnetic coupling, however, evidently is not

strong, so that the resulting effective magnetic moment of the system is increasing with the temperature.

On the other hand, with increasing temperature, in addition to g', a further EPR signal with $g'' \sim 3.1$ appears with increasing intensity, and at high temperature (above 350 K) only g_1 of low intensity and g' and g'' are observed. The latter may be ascribed to the HS [Fe^{III}—L] species.

By taking into account all the available experimental data it may be assumed that iron(II) hexacyclen complex formation is accompanied by thermally controlled intramolecular electron transfer.

COMMUNICATION

THE SYNTHESIS OF BIS(HEXAMETHYLDISILYLAMIDO)BARIUM(II)

J. M. BONCELLA,* C. J. COSTON and J. K. CAMMACK

Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

(*Received* 30 *November* 1990; *accepted* 7 *January* 1991)

Abstract—Bis(hexamethyldisilylamido)barium(II) (**1**) was synthesized in the reaction between $BaCl_2$ and 2 equivalents of $NaN(SiMe_3)_2$. Compound **1** forms adducts with a variety of Lewis bases and can be used as a precursor to $YBa_2Cu_3O_{7-x}$.

The discovery of the $YBa_2Cu_3O_{7-x}$ family of superconductive ceramics in 1987[1,2] has led to a considerable research effort directed toward the use of soluble or volatile precursor compounds that can be used in sol–gel or chemical vapour deposition methods for the synthesis of this material.

In searching for novel precursors for the $YBa_2Cu_3O_{7-x}$ family of superconductors our attention was focused on the possible use of hexamethyldisilylamido complexes of the constituent metals. Such compounds are pontential precursors since they readily hydrolyse giving hexamethyldisilazane and the metal hydroxide (or oxide).[3b] Moreover, the hexamethyldisilazane is susceptible to further hydrolysis to give ammonia and hexamethyldisiloxane as products, as shown in eq. (1):

$$M[N(SiMe_3)_2]_x + xH_2O \longrightarrow M(OH)_x + xHN(SiMe_3)_2$$
$$HN(SiMe_3)_2 + H_2O \longrightarrow NH_3 + (Me_3Si)_2O. \quad (1)$$

The compounds $\{Cu[N(SiMe_3)_2]\}_4$ and $Y[N(SiMe_3)_2]_3$ have been previously reported.[3,4] However, it appears as though $Ba[N(SiMe_3)_2]_2$ has not been prepared until now. What follows is a brief account of the synthesis of this compound and some of its base adducts.

When anhydrous $BaCl_2$ was allowed to react with 2 equivalents of $NaN(SiMe_3)_2$ at room temperature in diethyl ether, the $BaCl_2$ slowly dissolved and a fine precipitate of NaCl formed over 24 h [eq. (2)]:

$$BaCl_2 + 2NaN(SiMe_3)_2 \longrightarrow \{Ba[N(SiMe_3)_2]_2\}_x \quad (2)$$
(1)

Filtration and removal of the ether under reduced pressure followed by crystallization from toluene at −20°C gives an 80% yield of $Ba[N(SiMe_3)_2]_2$ (**1**) as white crystals which become opaque when exposed to a vacuum or upon standing under an argon atmosphere at room temperature. Both the ^1H and ^{13}C NMR spectra† of **1** in toluene-d_8 show only one line down to −60°C, suggesting a highly fluxional associated structure or a monomeric structure. We assume that the former possibility is more likely since the manganese and ytterbium compounds have been shown to exist as dimers in the solid state.[5,6] Furthermore, even though **1** readily reacts with a variety of Lewis bases, there is no evidence of coordinated diethyl ether in the NMR spectra of **1** or its hydrolysis products, suggesting that diethyl ether is so weakly bound that it is removed during the isolation procedure.

Compound **1** is soluble in toluene and ether and only sparingly soluble in aliphatic hydrocarbons. It is extremely sensitive to hydrolysis in both the solid state and solution. It readily undergoes reaction with a variety of Lewis bases to give white, crys-

† Compound **1**: ^1H NMR (300 MHz, C_6D_6, 22°C) δ 0.108 (S); $^{13}C\{^1H\}$NMR (74.4 MHz, C_6D_6, 22°C) δ 6.92.

talline adducts as shown in eq. (3):

$$\{Ba[N(SiMe_3)_2]_2\}_x + 2L \longrightarrow [(Me_3Si)_2N]_2BaL_2 \quad (2)$$

2a: L= 1/2  **2b**: L= 
2c: L=  (3)

Compounds **2a–c** are all sparingly soluble in aliphatic hydrocarbons and soluble in aromatic hydrocarbons. Additionally, they may be recrystallized from THF without displacement of the amine bases from the compound. These compounds were characterized using ^{1}H NMR spectroscopy as well as by elemental analysis.* Attempts to grow single crystals suitable for an X-ray diffraction study have been frustrated by the fact that **1** and **2a–c** lose crystallinity and crumble when dried under vacuum or a stream of inert gas.

When THF solutions containing **1**, $Y[N(SiMe_3)_2]_3$ and $\{Cu[N(SiMe_3)_2)]\}_4$ in the correct stoichiometry are hydrolysed by the dropwise addition of water, an orange precipitate forms which may be processed by heating, grinding and annealing to give powders which have been shown to contain up to 80% of the superconducting phase, $YBa_2Cu_3O_{7-x}$, via X-ray diffraction techniques.[7] We are continuing to test the suitability of these compounds as precursors to superconducting ceramics.

STEREODYNAMICAL INTERCONVERSION OF BIS(N-ARYL-α-ISOPROPYL-β-AMINOVINYLTHIONATO)ZINC(II) AND -CADMIUM(II)

L. E. KONSTANTINOVSKII, R. YA. OLEKHNOVITCH, M. S. KOROBOV, L. E. NIVOROZHKIN and V. I. MINKIN*

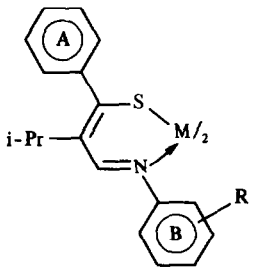
(*Received* 3 *January* 1990; *accepted* 13 *August* 1990)

Abstract—Bis N-aryl(α-isopropyl-β-aminovinylthionato)zinc(II) and -cadmium(II) complexes [**I(a,b)**] have been prepared in order to investigate their stereochemical non-rigidity and conformational interconversion. For the zinc(II) complexes [**I(a,b)**], two types of energy barrier were observed by the use of dynamic ^1H and ^{13}C NMR spectroscopy. The lower barrier ($\Delta G^{\ddagger}_{298} \sim 60$ kJ mol^{-1}) measured by averaging anisochronous *o,o'*-carbons (C-aryl ring A) is assigned to the hindered rotation of the β-phenyl ring. The higher energy barrier ($\Delta G^{\ddagger}_{298} = 77$–$78$ kJ mol^{-1}) was calculated for the interchange of the diastereotopic methyls of the α-isopropyl group for complexes **I(a,b)** and the anisochronous methyls of the N-aryl ring B in complexes **I(a)** during the $(R) \rightleftharpoons (S)$ inversion. Whereas, the tetrahedral $(R) \rightleftharpoons (S)$ inversion in the cadmium(II) complexes, **I(a,b)**, is faster ($\Delta G^{\ddagger}_{298} = 51$–$53$ kJ mol^{-1}) compared with the zinc(II) complexes. In this case, the *o,o'*-carbons in the C-aryl ring manifest the $(R) \rightleftharpoons (S)$ inversion process ($\Delta G^{\ddagger}_{298} = 47.5$–$49$ kJ mol^{-1}). The anisochronous *o,o'*-methyls of the N-aryl ring B may thus be used for studying the tetrahedral inversion at the metal centre along with the diastereotopic methyl groups in the type **I** complexes. The energy barrier for the intermolecular ligand degenerate exchange reaction ($\Delta G^{\ddagger}_{298} = 64.4$ kJ mol^{-1}) is higher than for the intramolecular $(R) \rightleftharpoons (S)$ inversion at the metal centre.

The stereochemical non-rigidity of tetrahedral bis-N-alkyl,aryl(α-isopropyl-β-aminovinylthionato) zinc(II) and -cadmium(II) (**I**) has been extensively investigated in recent years by means of the total line-shape analysis of variable-temperature NMR spectroscopic data.[1–4]



M = Zn, Cd

I

* Author to whom correspondence should be addressed.

These studies have been focused on the investigation of the inversion of the tetrahedral configuration $(R) \rightleftharpoons (S)$ (**1**) at the metal centre of the complexes

(1)

R *S*

The basic condition for the successful recording of the interconversion of enantiomers (*R*) and (*S*) (**1**), occurring on the NMR time scale, without their prior separation, was the presence of a prochiral α-isopropyl group within the dissymmetric system (**I**). By varying the substituent R, attached to the ligating atom N, it was found that the energy barriers to the enantiomerization of N-aryl,alkyl substituted complexes of type **I** essentially depend on the nature

of the metal centre atom being higher for the zinc(II) complexes than for those of cadmium(II).[1-4]

While studying the stereochemical non-rigidity of complexes **1** we have investigated their spectral behaviour caused by rotation of the two rings (A and B) about the C—N and the C—C bond, respectively. Kinetic data on the $(R) \rightleftharpoons (S)$ inversion and rotation of aryl rings have also been obtained in order to estimate the barriers of these processes. It was of particular interest to compare the data, calculated by using two independent indicator groups (i-Pr and Mes).

RESULTS AND DISCUSSION

Zinc(II) *complexes*

In the ^{1}H DNMR spectra of zinc(II) complexes **I(a)** below +50°C, anisochronous 2,6-methyls of the B-ring (doublet) are observed along with anisochronous methyls of the C-isopropyl group (a pair of overlapping doublets), Fig. 1. This anisochronicity stems from a coplanarity of the B-ring with respect to the chelate ring.

As the temperature of the solution is raised, the signals of the methyl groups of the isopropyl are substantially broadened and coalesce to a six-proton singlet. Such a dynamic picture can be produced both by inversion of configuration $(R) \rightleftharpoons (S)$ at the central atom and by increasing the velocity of the N-mesityl ring rotation about the C—N bond (Scheme 1).

It has been found that kinetic parameters for the averaging of signals of anisochronous *o,o'*-methyls in the N-aryl ring and methyls of the prochiral i-Pr group do in fact coincide within experimental accuracy (Table 1). This suggests that the inversion at

the metal centre rather than a hindered rotation of the N-mesityl group makes a predominant contribution to the kinetics of the averaging process, which is recorded by the temperature evolution of *o,o'*-CH_3 (B-ring) signals.

The variable-temperature ^{13}C NMR spectra of complex **I(a)** have also indicated the anisochronicity of *o,o'*-carbons of the C-aryl ring (δ 125.6 and 129.3 ppm) below $-20°C$. They have collapsed and transformed to a singlet peak upon raising the temperature to $+60°C$. Such a dynamic ^{13}C NMR pattern should be interpreted as a result of the rotational process (Scheme 1), since the energy barrier of such a process is lower than that for the $(R) \rightleftharpoons (S)$ inversion (Table 1). The energy barrier thus found agrees with the known data[5] on C-aryl rotations. For complex **I(b)** the inversion barrier is also higher than the rotational barrier in the case of the C-aryl ring, and its magnitude is comparable with that of **I(a)** (Table 1).

Cadmium(II) *complexes*

In the temperature-dependent ^1H NMR spectra of complexes **I(a,b)** (M = Cd) the dynamic process manifesting itself in the averaging of the signals of the diastereotopic CH_3 groups (α-i-Pr) and the anisochronous *o,o'*-CH_3 groups (B-ring) occurs at a lower temperature ($-60°$ to $-10°C$) than in the case of the zinc(II) analogues. This indicates rapid $(R) \rightleftharpoons (S)$ inversion at cadmium. Calculated barriers (Table 1) have typical values for this kind of bischelate complex[3] and are 30–40 kJ mol^{-1} lower than those for analogous zinc(II) complexes.

The methyl region of the ^{13}C NMR spectrum of **I(a)** (M = Cd) is illustrated in Fig. 2. The energy barrier calculated from line-shape changes of anisochronous methyls (i-Pr and Mes) at $-47°C$ and above this temperature, associated with the $(R) \rightleftharpoons (S)$ inversion, agrees well with the magnitude obtained from the ^1H DNMR spectrum (Table 1).

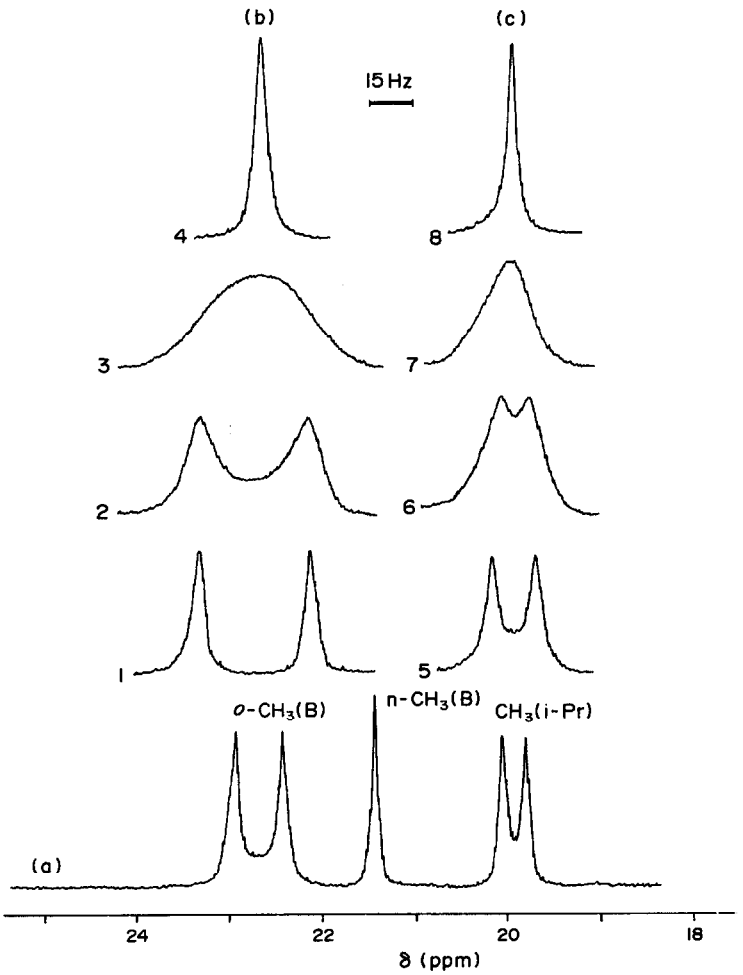

Fig. 2. 3100.58-MHz ^{13}C NMR spectrum (methyl region) of complex **I(a)** (M = Cd) at $-88°C$ in $CDCl_3$ (a); variable-temperature NMR spectra of the *o,o'*-CH_3 (B-ring) (b) and the CH_3 (i-Pr) (c) groups corresponding to: (1,5) $-47°$, 19.3 and 14.3 s^{-1}; (2,6) $-42°$, 31.3 and 21.1 s^{-1}; (3,7) $-36°$, 69 and 46.4 s^{-1}; (4,8) $-15°$, 380 and 223 s^{-1}.

Thus, the study of the $(R) \rightleftharpoons (S)$ inversion of the tetrahedral bis-chelate complexes **I(a)** (M = Cd) and **I(a)** (M = Zn), based on the temperature-dependent spectral behaviour of two different indicator groups (α-i-Pr and N-Mes), has given similar magnitudes for the energy barriers. This provides a basis for the utilization of *o,o'*-CH_3 in the N-aryl ring B as a diastereotopic probe in the ^1H and ^{13}C NMR spectra of bis-chelate complexes of type **I**.

In the ^{13}C NMR spectra of **I(a,b)** (M = Cd) (Fig. 3) at −68°C, as well as for their zinc analogues, anisochronous *o,o'*-carbons of the C-aryl ring A (δ 125.13 and 127.47 ppm) were also observed. The increase in the barrier of the hindered rotation linked to the chelate ring makes it possible to observe the process of rotation about the C—C bond on the NMR time scale.

Because the averaging of the signals of all various anisochronous groups including methyls (i-Pr), *o,o'*-methyls (Mes), *o,o*-carbons (A) and *m,m*-carbons (B) proceeded with barriers which were very close in value (Table 1), it can be inferred that the $(R) \rightleftharpoons (S)$ inversion barrier in cadmium(II) complexes is lower than the rotational one, or their values coincide accidentally.

It may be, therefore, concluded that the processes of $(R) \rightleftharpoons (S)$ inversion and of hindered rotation of phenyl rings in zinc(II) and cadmium(II) complexes [**I(a,b)**] proceed in accordance with Scheme 1, where four interconverting forms are shown. For zinc(II) complexes the lower energy barrier ($\Delta G^{\ddagger}_{rot}$) is associated with the C-aryl ring (A) rotation process, $R(r,s) \rightleftharpoons R(s,r)$ or $S(r,s) \rightleftharpoons S(s,r)$, observed in ^1H and ^{13}C DNMR spectra at lower temperatures, and the higher energy barrier ($\Delta G^{\ddagger}_{inv}$) is associated with the $R(r,s) \rightleftharpoons S(s,r)$ or $R(s,r) \rightleftharpoons S(r,s)$ interconversion at higher temperatures. Whereas for cadmium(II) complexes the energy barrier for the inversion process is lower than that of the C-aryl ring rotation. Therefore, both processes in temperature-variable NMR spectra are observed simultaneously.

To provide some information on the mechanism of these reactions, the dependence of energy barriers on the concentration of solutions was studied. The 10-fold dilution of the solutions of complexes **I(a)** (M = Zn, Cd) does not lead to any detectable changes in the activation energies (within the usual experimental accuracy). This corroborates the intramolecular character of the inversion process.

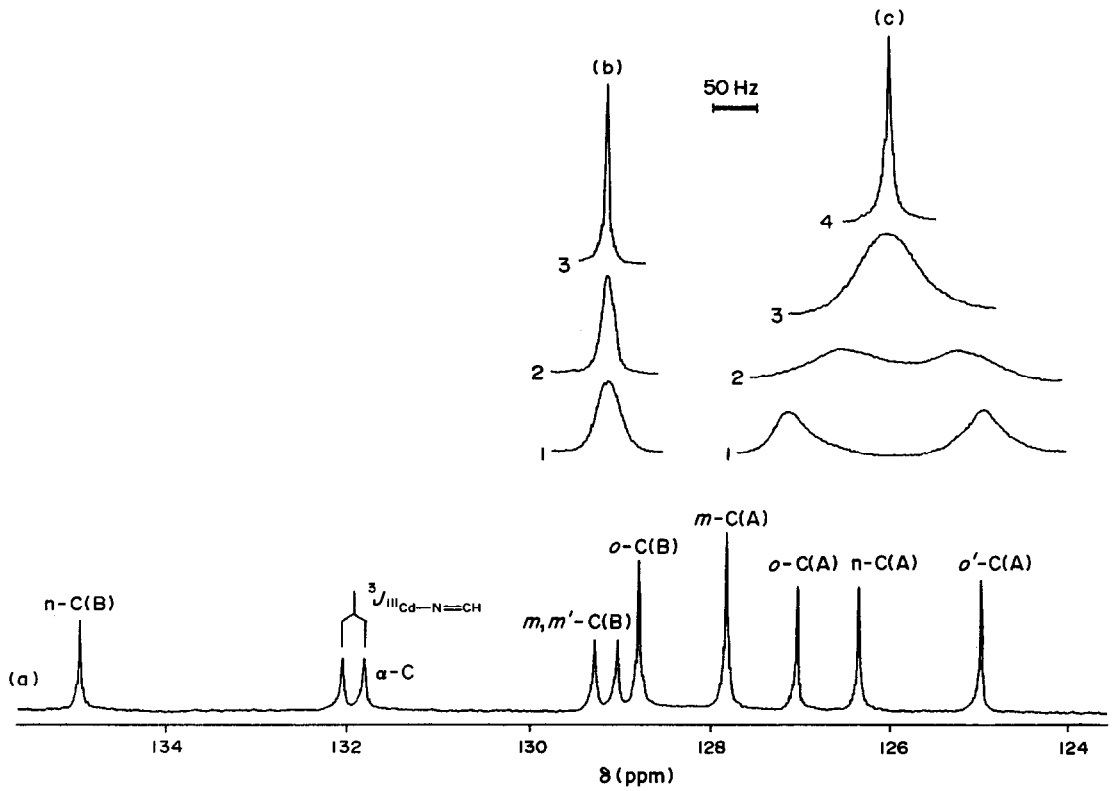

Fig. 3. 400-MHz ^{13}C NMR spectrum (aryl region) of complex **I(a)** (M = ^{111}Cd) at −68°C in $CDCl_3$ (a); variable temperature NMR spectra of the *m,m*-carbons (B-ring) (b): (1) 55°, 60 s^{-1}; (2) −45°; (3) −20°; and the *o,o'*-C groups (A-ring) (c): (1) −58°, 94 s^{-1}; (2) −33°, 370 s^{-1}; (3) −29°, 997 s^{-1}; (4) −6°, 4800 s^{-1}.

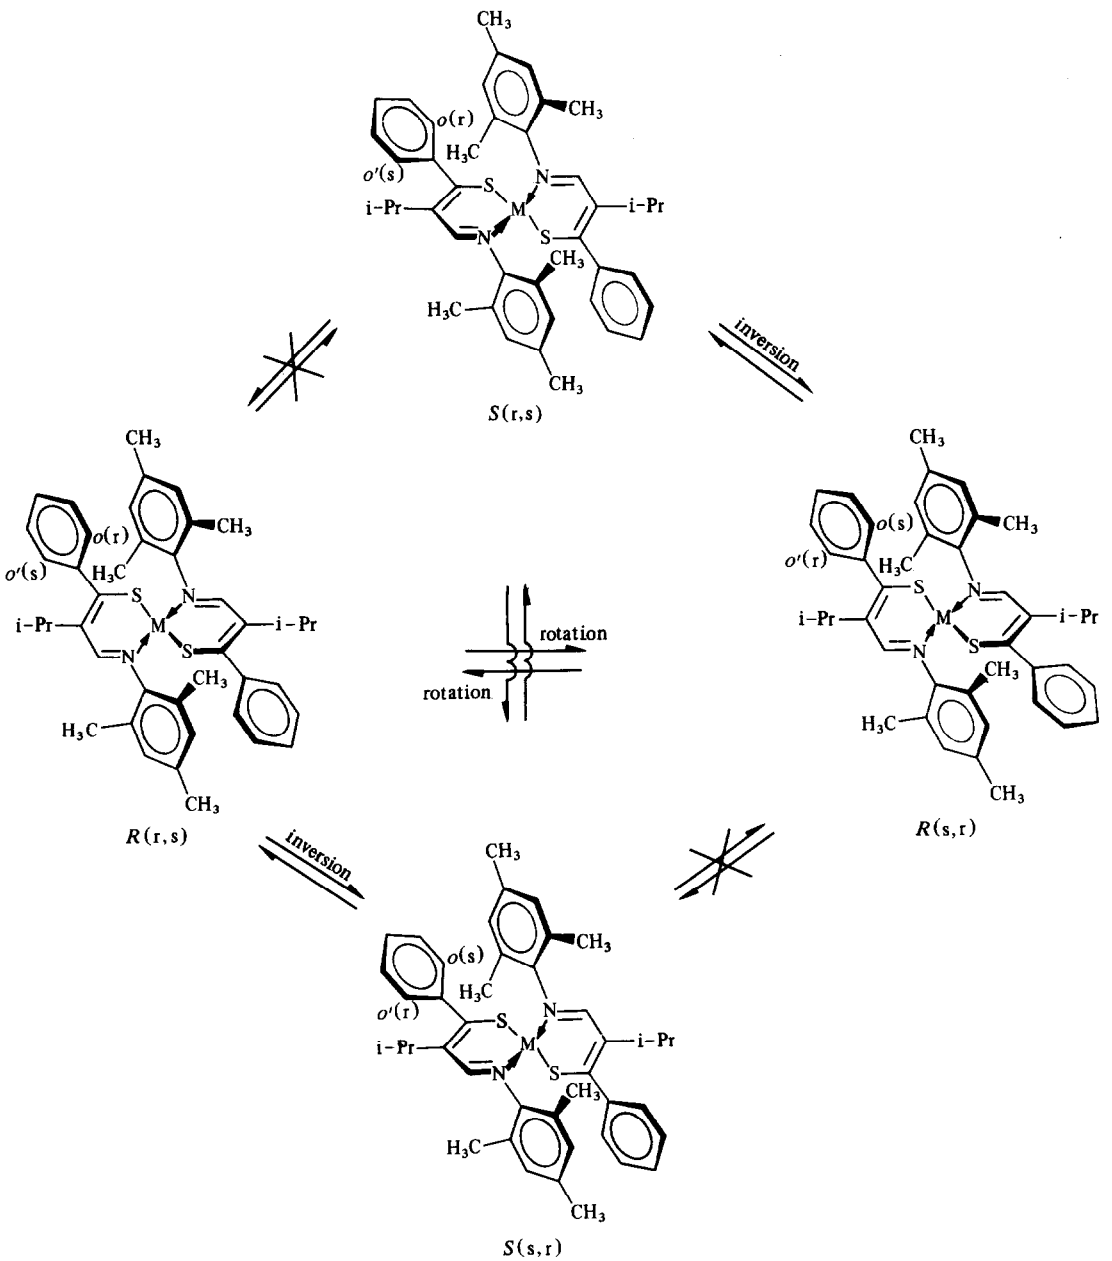
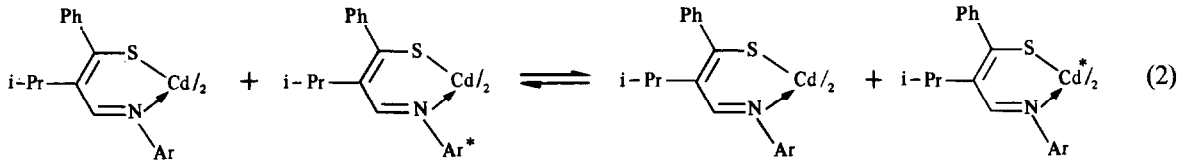


Scheme 1. General scheme of the stereodynamics of complexes **I(a,b)**. For the zinc complexes, $\Delta G^{\ddagger}_{inv} > \Delta G^{\ddagger}_{rot}$. The processes of inversion and rotation may be, therefore, independently observed. For the cadmium complexes, $G^{\ddagger}_{inv} \leqslant G^{\ddagger}_{rot}$; simultaneous averaging of all the diastereotopic groups is observed.

The intermolecular degenerate ligand exchange process was found to take place in solutions of bis-chelate cadmium(II) complexes with energy barriers 10–15 kJ mol^{-1} higher than those for the intramolecular inversion.[1]



(2)

The reaction, second-order in kinetics, is conveniently monitored by studying the temperature dependence of the $^3J(^{111}Cd—N=CH)$ spin–spin coupling. For complexes **I(a,b)** (M = Cd), 95% enriched in ^{111}Cd, the energy barrier of the ligand exchange reaction ($\Delta G^{\ddagger}_{298} = 64.4$ kJ mol^{-1}) thus obtained is higher than those of the inversion and C-alkyl ring rotation. This value agreed well with the data obtained earlier[1,3] for intermolecular ligand exchanges in solutions of N-aryl(α-isopropyl-β-aminovinylthionato)^{111}cadmium(II). The earlier suggested mechanism[1] for the ligand exchange reaction includes an intermediate dimer with trigonal bipyramidal coordinated cadmium. The rates of reaction (2), as well as of the intramolecular inversion (1), are not affected by the addition of equimolar amounts of free ligands.

EXPERIMENTAL

NMR spectroscopy

^1H and ^{13}C DNMR spectra were recorded using Tesla BS 567A (100 MHz) and Varian VXR (400 MHz) NMR spectrometers, equipped with a variable-temperature probe. The temperature of the samples was controlled with an accuracy of ±1 K. ^1H and ^{13}C chemical shifts were measured with respect to hexamethyldisiloxane as internal standard. Computer simulated spectra were calculated using the total line-shape analysis technique as described in ref. 6. The spectral parameters of indicator groups, for example δ—chemical shift, Δν—limit expansion and $\Delta\nu_0^{1/2}$—line width at half height, necessary for kinetic analysis, are given in Table 2. Activation parameters were obtained from least-square Eyring plots [$\ln(kT)$ vs $1/T$], where $k = 1/\tau$ (τ—life-time of a site). For kinetic studies, the commercially available solvents CD_2Cl_2 and

$CDCl_3$, exposed for 24 h over 4 Å molecular sieves, were used.

Synthesis

The ligands for type **I** complexes were synthesized in 70–80% yields by reflushing equimolar amounts of amine and ether solutions of α-isopropyl-β-thiocinnamic aldehyde in ethanol solutions. The following compounds were synthesized from α-isopropyl-β-chlorcinnamic aldehyde and Na_2S in DMSO according to an earlier described procedure.[2] Complexes **I** were prepared by coupling ligands and the respective metal acetate in absolute methanol (heating: 10 min; yields: 80%).[7] After crystallization from benzene, melting points were: **I(a)** (Zn), 240–242°C; **I(a)** (Cd), 259–260°C. Elemental analyses for all the complexes were satisfactory.

(*Received* 15 *January* 1990; *accepted* 22 *October* 1990)

Abstract—Reactions of disalicylaldehyde adipoyldihydrazone with uranyl acetate dihydrate and uranyl nitrate hexahydrate in aqueous and ethanolic media under different experimental conditions were studied and the resulting complexes with the compositions $[UO_2(H_2L_2)(H_2O)]_n$, $[UO_2(H_2L_2)]_n3nH_2O$, $[UO_2(H_3L_2)(CH_3COO)]_n3nH_2O$, $[UO_2Zn(L_2)(H_2O)_2]_n2nH_2O$, $[(UO_2)_2(H_2L_2)(C_2O_4)]_n2nH_2O$ and $[(UO_2)_2(L_2)(py)_2(H_2O)_4]$ were characterized on the basis of elemental analyses, EDAX and thermoanalytical data. The structural assessment of the complexes was carried out by using molar conductance, magnetic moment and ESR data and IR, electronic and ^1H NMR spectroscopy. In the complexes, the ligand functions as a bridging monobasic tetradentate, dibasic hexadentate and tetrabasic hexadentate ligand, and exhibits keto–enol tautomerism. The acetate and oxalate groups act as chelating bidentate and bridging tetradentate ligands. The complexes are considered to involve seven, eight, nine and ten coordinated uranium atoms with ligand atoms arranged in the equatorial plane around the linear uranyl group and in the heterobimetallic complex $[UO_2Zn(L_2)(H_2O)_2]_n2nH_2O$ the zinc atom is considered to have tetrahedral stereochemistry.

Due to the diverse properties of acyl- and pyridoylhydrazones and their application in many fields (pharmacological, analytical, technological, etc.) the literature indicates an increased interest in the study of their complexing affinities towards different transition metal ions.[1,2] The dihydrazones derived from condensation of *o*-hydroxyaromatic aldehydes and ketones, and acyl- and pyridoyldihydrazines, are similar to monoacyl-, aroyl-, pyridoylhydrazones in all respects except that they possess two hydrazone groupings (which are separated from each other by methylene chains of varying length or by phenyl or pyridyl groups) and two —OH groups. Therefore, depending upon the preferred stereochemical disposition of the metal valencies and nature of the bonds formed in the coordination process, these complexes may offer several alternate modes of bonding and are capable of giving rise to condensed systems, i.e. bi- and polynuclear complexes involving ligand and phenolic oxygen bridging. Disalicylaldehyde adipoyldihydrazone is an example of a novel ligand capable of exhibiting multidentate behaviour by virtue of having a greater number of donor atoms and more flexibility in three-dimensional space. This is in contrast to aroyl- and pyridoyldihydrazones in which the phenyl or pyridyl rings between the two hydrazone groupings impose planarity on them. Disalicylaldehyde adipoyldihydrazone is capable of binding two or more similar or different metal atoms in close proximity to one another and the synthesis and study of such complexes have been the subjects of active research over the past few years because the redox properties of such homometallic and heterodimetallic transition metal complexes may be related to the multinuclear metal sites in metalloenzymes.[3,4] The present paper reports the results of an investigation into the reactions of uranyl salts with disalicylaldehyde adipoyldihydrazone, capable of existing in the keto (**I**), keto–enol (**II**) and enol (**III**) forms under different

experimental conditions. Characterization and structural assessment of the resulting monometallic, homodimetallic and heterobimetallic complexes containing uranium and zinc were made by using molar conductance, magnetic moment and ESR data, and IR, electronic and ^{1}H NMR spectroscopy.

RESULTS AND DISCUSSION

Disalicylaldehyde adipoyldihydrazone (H_4L_2) is an octadentate ligand which may function as a mono- and dibasic ligand in the keto form and tri- and tetrabasic ligand in the enol form under suitable experimental and preparation conditions. However, simultaneous involvement of all the donor atoms in coordination is an unlikely possibility. In the present study, the reaction of uranyl acetate dihydrate with H_4L_2 in a 1 : 1 molar ratio in ethanol medium results in the precipitation of the complex $[UO_2(H_3L_2)(CH_3COO)]_n3nH_2O$; this signifies the loss of only one proton from the phenolic —OH group of half of the ligand. The reaction of the product of uranyl acetate dihydrate with ligand in a 3 : 1 molar ratio in 95% ethanol medium with excess of pyridine yields a complex of the composition $[(UO_2)_2(L_2)(py)_2(H_2O)_4]$, signifying a loss of four protons. When the ligand is allowed to react with uranyl nitrate hexahydrate in aqueous medium in a 1 : 3 molar ratio (ligand = uranyl nitrate hexahydrate), a complex of composition $[UO_2(H_2L_2)]_n3nH_2O$ is obtained in which the ligand functions as a dibasic species. The reaction of uranyl nitrate hexahydrate with ligand in a 2 : 1 molar ratio and subsequent reaction of the reaction mixture with oxalic acid in a molar ratio of 2 : 1 : 2 yields a complex of composition $[(UO_2)_2(H_2L_2)(C_2O_4)]_n2nH_2O$, which again shows that the ligand behaves as a dibasic ligand. This indicates that the nature of the reaction medium and metal salt plays an important role in the determination of the composition of the complexes, and basicity of the ligand. In order to synthesize the heterobimetallic complexes, the complex $[UO_2(H_3L_2)(CH_3COO)]_n3nH_2O$ was allowed to react with zinc acetate dihydrate in aqueous medium and with copper nitrate tetrahydrate, in slight excess of the 1 : 1 molar ratio. This led to the successful precipitation of the zinc complex $[UO_2Zn(L_2)(H_2O)_2]_n2nH_2O$, while the reaction with copper nitrate tetrahydrate led to complete displacement of the uranyl ion from the resultant precipitate (evident from its green colour). This was further confirmed by the IR spectrum of the compound which showed the absence of a strong absorption band in the region 950–890 cm^{-1}, characteristic of the uranyl ion due to its asymmetric stretching frequency. The initial reaction between uranyl acetate dihydrate and adipoyldihydrazine in a 1 : 1 molar ratio yielded the complex $[UO_2(CH_2CH_2C(O)NNH_2)_2]2H_2O$. This compound, on reaction with excess salicylaldehyde, precipitated a complex of composition $[UO_2(H_2L_2)(H_2O)]_n$ in which H_2L_2 refers to the loss of a proton from the enolized carbonyl oxygen.

The complexes isolated in the present study together with their colour, analyses, decomposition point and molar conductivity data are summarized in Table 1. The results of elemental analyses are consistent with the suggested formulation of the complexes. The study of the heterobimetallic complex (**4**) by EDAX[34] has shown that uranium and zinc are in the ratio of 1 : 1 and thus confirmed its formulation based on the elemental analysis. This ruled out the possibility of formation of mixed species in this case. All complexes are amorphous powders and are either dark red, orange, dark orange or brownish-orange. All complexes are insoluble in common organic solvents and dissolve in coordinating solvents like DMF and DMSO except for complex **4** which does not even dissolve in DMF and gives a suspension in DMSO. Due to their insolubility in common organic solvents, the complexes could not be recrystallized. The DMSO solutions of the compounds are coloured without showing any sign of colour change on dissolution, ruling out the possibility of displacement of the ligands in the coordination sphere by solvent molecules. All complexes decompose without melting above 300°C. The DMSO solutions of all the complexes (except that of the heterobimetallic complex **4** whose insolubility in DMSO excluded the possibility of its study by TLC) show a uniform spot on a TLC plate covered with silica gel and developed using a mixture of petroleum ether, ether and methanol in the ratio 2:2:1. The water contents were determined by heating the compounds at ~ 110 and ~ 180°C, respectively, for 4 h in an electric oven and passing the vapours through a trap containing anhydrous copper sulphate which turned blue. Complex **3** showed weight loss corresponding to three water molecules at ~110°C, while in complexes **2**, **4** and **5**, the weight loss corresponded to two water molecules only. The water molecules lost at ~ 110°C indicate that they are present in the lattice structure of the complexes. Complexes **1** and **2** showed weight loss corresponding to one water molecule while in **6** the weight loss corresponded to four water molecules at ~ 180°C. The water molecules lost at ~ 180°C in these complexes suggest that they are present in the coordination sphere around the metal centre. The IR spectra of **4** and **6** show a new band at 650 and 630 cm^{-1}, characteristic of coordinated water molecules[5,6] while that of complex **2** does not show any such band. This suggests that lone water lost at ~ 180°C in complex **2** is, most probably, embedded in the lattice structure of the complex in the strongly hydrogen-bonded form. The high decomposition temperature of the complexes suggest that they are polymeric materials in the solid state. The molar conductances of all the complexes except that of the heterobimetallic complex **4** lie in the range 20.5–0.5 Ω^{-1} cm^2 mol^{-1} in DMSO, indicating that these complexes are non-electrolytes in this solvent.[33]

Thermal analyses of the complex $[UO_2(H_2L_2)]_n$ $3nH_2O$ have been carried out as a representative sample up to 600°C. The final product of decomposition is U_3O_8. The decomposition of the complex occurs in three prominent steps, i.e. 80–120, 200–220 and 300–460°C. The complex loses

mass in the temperature range 80–120°C and the mass loss corresponds to two water molecules, indicating that they are part of the lattice. Beyond 120°C, the complex is stable up to 200°C as the average mass loss is about 0.25% per 20°C interval. The complex shows mass loss corresponding to one water molecule in the temperature range 200–200°C. Although the loss of one water molecule at such high temperatures may indicate its presence in the coordination sphere around the uranium centre,[5] the IR spectrum of the complex does not show any new band around $\sim 630\ cm^{-1}$ characteristic of the coordination of water.[6] This suggests that the third water molecule in this complex is also present in the structural unit of the complex in the strongly hydrogen-bonded form with the coordinated anion.[7] The most significant decomposition of the complex occurs in the temperature range 300–460°C, the average mass loss being 8.7% per 20°C interval. The mass loss in this temperature range corresponds to two phenyl groups, two hydrazine groupings and one —C—$(CH_2)_4$—C— group. The loss of ligand starts at 300°C, occurs simultaneously in a single step, and is complete at 420°C. Beyond this temperature the complex shows negligible mass loss and the weight becomes constant at a temperature > 460°C, corresponding to U_3O_8. Such thermal behaviour of the complex indicates the symmetrical attachment of the ligand to the uranyl ion.

IR spectral data are given in Table 2. The essential features are medium–strong, broad bands in the IR spectrum of the uncoordinated ligand in the regions 3500–3250 and 3200–3000 cm^{-1}, having multiplet structure with maximum absorption at 3423 and 3186 cm^{-1} attributed to the composite nature due to ν(OH) and ν(NH) stretching vibrations of the ligand, which are altered on complex formation. The IR spectra of complexes **1**, **4** and **6** show a single, strong, broad band in the region 3650–3100 cm^{-1} with maximum absorption in the region 3438–3420 cm^{-1}. This band arises from ν(OH) of the phenolic —OH group of the ligand or ν(OH) of the lattice or coordinaed water molecules (**4**, **6**). The bands present in the regions 3500–3250 and 3200–3000 cm^{-1} in the IR spectrum of the uncoordinated ligand undergo splitting in the IR spectra of **2**, **3** and **5** and show maximum absorptions in the regions 3580–3537, 3420–3352 and 3200–3186 cm^{-1}. The bands in the region 3580–3557 cm^{-1} are due to the ν(OH) of either the uncoordinated phenolic —OH group or of the lattice water molecules, while the band in the region 3200–3186 cm^{-1} is due to the ν(NH) of the secondary amine group of the ligand. The band in the region 3420–3352 cm^{-1} may have a composite nature due to ν(OH) and ν(NH) stretching vibrations. The band present in the region 3200–3186 cm^{-1} in the IR spectra of the complexes, which is either at the same or higher position compared with the position of ν(NH) (3186 cm^{-1}) of the —CONH— group of the uncoordinated dihydrazone, rules out the possibility of coordination of the ligand through the secondary amine nitrogen atom. The essential features of the IR spectra of **1**, **4** and **6** in the region 3650–3100 cm^{-1} compared to those in the IR spectra of **2**, **3** and **5** suggest that the ligand coordinates to the uranyl ion in the enol form in the former complexes and in the keto form in the latter.

The band present at 1666 cm^{-1}, due to ν(C=O) in the IR spectrum of the uncoordinated ligand, disappears in the IR spectra of **1**, **4** and **6** suggesting the enolization of the ligand in these complexes and its subsequent coordination to the uranyl ion through the enolized carbonyl oxygen atom. The IR spectra of **2**, **3** and **5** show single, medium to strong bands in the region 1659–1639 cm^{-1} except in the case of complex **3** in which ν(C=O) splits into two bands which appear at 1675 and 1650 cm^{-1}. The appearance of only one band in the IR spectra of **2** and **5** suggests the coordination of the ligand to the uranyl ion through both of the carbonyl oxygen atoms, and that the two uranium–oxygen bonds are of equal strength. The splitting of the ν(C=O) band in the IR spectrum of complex **3** and its appearance at higher as well as lower positions compared to the position of the ν(C=O) band in the IR spectrum of the uncoordinated ligand, suggests the coordination of the ligand through only one $>C=O$ group while the other $>C=O$ group remains unbonded. When **3** is allowed to react with zinc acetate dihydrate in a 1 : 1 molar ratio in aqueous medium, the IR spectrum of the resulting compound $[UO_2Zn(L_2)(H_2O)_2]_n 2nH_2O$ does not show any band characteristic of a $>C=O$ group suggesting the enolization of the ligand in the complex.[8]

The band at 1555 cm^{-1} attributed to amide II and the ν(C—O) (phenolic) group of the uncoordinated ligand appears at 1542 cm^{-1} in the IR spectrum of complex **1**, indicating non-involvement of the phenolic oxygen atom in bonding. The band at 1542 cm^{-1} may be due to the ν(NCO) vibration of the newly created NCO group, produced as a result of enolization of the ligand. In the remaining complexes (**2** and **6**) this band undergoes splitting into two bands. The bands present in the region 1575–1564 cm^{-1} in the IR spectra of the complexes indicate the involvement of the phenolic —OH group in bonding. Such a high shift of the ν(C—O) stretching vibration indicates the involvement of the phenolic

oxygen atom in the bridge formation.[9,10] The band present in the region 1547–1510 cm^{-1} indicated the coordination of the carbonyl oxygen atom to the uranyl ion in **2**, **3** and **5**. The band at 1545 cm^{-1} in complexes **4** and **6** is due to the newly created NCO group as a result of enolization,[11] while ν(C—O) (phenolic) appears at 1550 cm^{-1} in complex **6**. The position of ν(C—O) (phenolic) in this complex rules out the possibility of the existence of oxo-bridging. In complex **3** the IR spectrum contains a band at 1555 cm^{-1} indicating that only one $\rangle C{=}O$ group takes part in coordination while the other $\rangle C{=}O$ group remains unbonded.[12]

The IR spectrum of the ligand shows absorption bands at 1623 and 1612 cm^{-1} which are assigned to a ν(C=N) stretching vibration. These bands lose their doublet character on complexation and are considerably lower in energy, appearing in the region 1615–1603 cm^{-1} in the IR spectra of the complexes. This suggests the involvement of the azomethine nitrogen atoms in bonding.[13,14] The loss of the doublet character of bands due to $\rangle C{=}N$ groups in the IR spectra of the complexes suggests that the two azomethine nitrogen atoms are coordinated to the uranium centre and the two uranium–nitrogen bonds are of equal strength. On examining the spectra of the ligand and its uranyl complexes in the low frequency IR spectral region, the new bands appearing in the ranges 603–510, 495–383 and 396–313 cm^{-1} are tentatively assigned to ν(U—O) (phenolic),[15] ν(U—O) (carbonyl)[16] and ν(U—N),[17] respectively. Complex **6** shows a strong absorption band at 270 cm^{-1} in the low frequency IR spectral region which is observed neither in the ligand nor in the remaining complexes. This band is tentatively assigned as an IR active uranium–nitrogen stretching mode due to the coordinated pyridine group.[18]

Complex **3** shows additional bands at 1510 and 1410 cm^{-1} in its IR spectrum, which are observed neither in the IR spectrum of the uncoordinated ligand nor in those of the other complexes. Hence, these bands are identified as ν_{as}(CO) and ν_s(CO) of the coordinated acetate groups. The IR frequencies associated with ν_{as}(CO) and ν_s(CO) stretching vibrations of the coordinated acetate groups in these complexes are in the same region in which the bidentate chelating acetate group has been established to absorb by X-ray[19] and IR spectroscopy.[20] The oxalato complex (**5**) shows bands at 1659, 1394 and 1329 cm^{-1}. The band at 1659 cm^{-1} has a composite nature due to the amide I band of the coordinated ligand and ν_{as}(C=O) of the coordinated oxalate group. In view of the absence of isotopic substitution studies it is difficult, at present, to assign unambiguously the bands due to ν_{as}(CO) of the coordinated oxalate group and ν(C=O) of the coordinated ligand. The absence of any band at 1750–1680 cm^{-1} which is regarded as typical of chelated and bridging bidentate oxalato groups is consistent with the bridging tetradentate nature of the oxalato group in the complex.[21]

The IR spectra of all the uranyl complexes studied here show strong absorption in the 911–890 cm^{-1} region, masking weak ligand bands occurring in this region. This band is assigned to a ν_3 asymmetric stretching vibration of the uranyl group. ν_1 Symmetric stretching vibration of the linear uranyl group is IR forbidden. The IR spectra of the complexes do not show any band around 860 cm^{-1} except for complex **1** in which a medium intensity band is observed at 861 cm^{-1}. This band appears to have its origin due to a weak intensity band at 864 cm^{-1} in the IR spectrum of the uncoordinated ligand which appears to be activated on complex formation. This double degenerate bending mode is observed as a medium to strong band in the 264–239 cm^{-1} region.

The ligand H_4L_2 shows absorption bands at 245, 290, 300 and 344 nm due to $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions[22,23] within the ligand molecule. The absorption spectra of the complexes $[(UO_2)_2(L_2)(py)_2(H_2O)_4]$ and $[UO_2Zn(L_2)(H_2O)_2]_n 2nH_2O$ were recorded in the solid state in the region 300–800 nm as representative samples which show rather strong and easily detectable absorption bands at 370, 415, 500 and 375, 500 nm, respectively. The ligand band at 344 nm shifts to longer wavelength and appears at 370 and 375 nm in the electronic spectra of the complexes. This longer shift of the 344 nm absorption band on complexation shows that uranium–ligand interaction is strong in these complexes. The absorption band at 415 nm in the complex $[(UO_2)_2(L_2)(py)(H_2O)_4]$ may arise by strong absorption, corresponding to the charge-transfer from equatorial ligands to the uranium atom. The band at 500 nm arises from the electronic transitions from apical oxygen to *f* orbitals of the uranyl moiety.[24] Although the electronic spectrum of **4** does not exhibit any additional band in the region 375–500 nm, due to the transfer of charge from the completely filled 3*d* orbital of zinc to the completely vacant 5*f* orbital of the uranium atom, the possibility of the existence of a $3d^{10} \rightarrow 5f^0$ transition in these complexes cannot be eliminated. This band is either merged with the strong band around 375 nm or with the absorption band at around 500 nm due to the electronic transition from apical oxygen to the *f* orbital of the uranyl moiety. Thus the possibility of the existence of a metal–metal

Table 3. ^{1}H NMR spectral data for disalicylaldehyde adipoyldihydrazone and some of its dioxouranium(VI) complexes

interaction in this complex cannot be ruled out.[25]

^{1}H NMR spectral data are given in Table 3. In complexes **2**, **5** and **6** the signal due to phenolic-OH protons appearing at 11.57 ppm in the ^{1}H NMR spectrum of uncoordinated dihydrazone disappears, indicating deprotonation of the phenolic-OH group on complex formation. However, this signal is observed at 10.49 ppm in the ^{1}H NMR spectrum of $[UO_2(H_2L_2)(H_2O)]$, indicating the presence of the phenolic-OH group in the complex. The presence of phenolic-OH at the higher field suggests that the phenolic-OH group is free from strong intramolecular hydrogen-bonding, but the possibility of the existence of weak intramolecular hydrogen-bonding cannot be dismissed. This, alternatively, suggests the bonding of the ligand to the uranyl ion through the enolized carbonyl oxygen atom. The signal due to the azomethine proton appears as a singlet in the region 9.07–9.27 ppm in the ^{1}H NMR spectra of these complexes. The azomethine protons appear as a doublet resonance (8.34, 8.42 ppm) in the ^{1}H NMR spectrum of the uncoordinated dihydrazone. This downfield shift is due to the deshielding caused by the coordination of azomethine nitrogen to the uranyl ion.[26,27] The signal due to —NH protons in free ligands at 11.17 ppm disappears in **1** and **6** and appears at 11.28 and 11.31 ppm in **2** and **5**. The disappearance of the —NH signal in **1** and **6** indicates that the ligand is present in the complex in the enolic form while in **2** and **5** the downfield shift of —NH signals on complexation in ^{1}H NMR spectra is due to deshielding caused by the drainage of electrons of carbonyl oxygen to the uranyl group as a result of coordination. The multiplet resonances due to the phenyl ring protons of the ligand are altered in position on complexation and appear as multiplets in the ^{1}H NMR spectra of the complexes, indicating involvement of the ligand in coordination to the uranyl ion. The signals due to pyridine are merged with the signals of phenyl protons in the ^{1}H NMR spectrum of complex **6**. The methylene proton signals in the ligand are shifted downfield on complexation, indicating coordination of the ligand through the >C=O group either in the keto or enol form. The signals due to methylene protons of the free ligand at 1.65 and 2.28 ppm appear in the region 1.92–2.72 ppm in the ^{1}H NMR spectra of the complexes.

Based on the physico-chemical evidence presented and discussed above, complexes **5** and **6** may be suggested to involve eight-coordinated uranium[28] while **1–3** may be suggested to involve seven-,[28] nine-[29] and ten-[30]coordinated uranium, respectively. The position of $\nu_3(UO_2^{2+})$ in the IR spectrum of **4**, compared with its position in the IR spectra of the remaining complexes, and the equatorial coordination number of the uranium atom may indicate that the equatorial coordination number of uranium in this complex should be between five and eight. This therefore demands the coordination of water molecules to the uranium centre in the complex. The coordination of two water molecules to the uranium centre raises the equatorial coordination number of the complex to six. The phenolic-oxygen atom, enolized carbonyl-oxygen atom, azomethine-nitrogen atom and oxo-bridged oxygen atom occupy the vertices of a tetrahedron around the zinc atom.

EXPERIMENTAL

Materials and measurements

Uranyl acetate dihydrate, uranyl nitrate hexahydrate, diethyl adipate, hydrazine hydrate and salicylaldehyde were of BDH, AR or equivalent grade. Adipoyldihydrazine was prepared by reacting the diethyladipate (1 mol) with hydrazine hydrate (2 mol). The disalicylaldehyde adipoyldihydrazone was prepared by reacting a warm dilute ethanol solution of adipoyldihydrazine (1 mol) with salicylaldehyde (2 mol) and was suction filtered, washed with water and ethanol and dried at 70°C in an electric oven; it was characterized as described elsewhere.[31]

Uranium and zinc in the complexes were determined by the standard literature procedure.[32] Carbon, hydrogen and nitrogen were determined by microanalyses. The EDAX spectrum was recorded using the Energy Dispersive X-ray spectrometer (AN 10000, Link-Analytical). The sample was coated with carbon in a JEOL vacuum evaporator and placed into the specimen chamber of the microscope column (scanning electron microscope, JSM-3SCF) operating at 20 kV. Water molecules were determined by heating the sample in an electric oven at 110 and 180°C, respectively, and passing the vapours through a trap containing copper sulphate, which turned blue, and estimating the weight loss. IR spectra were recorded on a Perkin–Elmer 983 spectrophotometer using KBr pellets in the 4000–180 cm^{-1} region. The molar conductance of the complexes at 10^{-3} M dilution in DMSO was measured using an Elico-conductivity bridge, model CM-82T, with a dip-type conductivity cell. Electronic spectra of the complexes were recorded on a Cary-14 model in the region 300–800 nm. Magnetic measurements were made on powders using a Gouy balance with MTTCC as calibrant. The ESR spectra were recorded on a Varian spectrometer in the solid state using DPPH as reference. The ^1H NMR spectra were run on a EM-390 90 MHz spectrometer using DMSO-d_6 solutions.

Preparation of the complexes

The complexes were prepared by the following procedures.

$[UO_2(H_2L_2)(H_2O)]_n$ (**1**). An aqueous solution of adipoyldihydrazine (0.1 M, 50 cm^3) was added to the uranyl acetate dihydrate (0.11 M, 50 cm^3) solution and stirred for about 10 min, which produced a turbid mixture. The reaction mixture was refluxed for 2 h and yielded a coloured compound. This was removed by filtration, washed with water containing a drop of acetic acid, water, ethanol and ether and dried before suspending in ethanol (20 cm^2), followed by addition of salicylaldehyde (100 cm^3). The resulting mixture was refluxed for 2 h giving a dark coloured solution, which on cooling yielded a precipitate. This was removed by filtration, washed with ethanol and dried over anhydrous calcium chloride.

$[UO_2(H_2L_2)]_n3nH_2O$ (**2**). H_4L_2 (1.0 g), powdered using an agate mortar, was placed in a beaker containing 60 cm^3 of water and stirred well to give a homogeneous slurry. Uranyl nitrate hexahydrate (0.1 M) in water was added to the ligand slurry with gentle stirring, maintaining the molar ratio at 3 : 1. The complex precipitated on refluxing the reaction mixture for 3 h and was again refluxed for 15 min in benzene. It was then filtered by suction, washed twice with hot benzene and twice with water containing a drop of acetic acid, three times with hot alcohol and finally with ether and was collected as above.

$[UO_2(H_3L_2)(CH_3COO)]_n3nH_2O$ (**3**). Uranyl acetate dihydrate (1.8 g) was dissolved in warm ethanol (100 cm^3) containing a drop of acetic acid by gentle stirring. To this solution salicylaldehyde (47 cm^3, 0.1 M) in ethanol was added, accompanied by stirring, and refluxed for 15 min. Adipoyldihydrazine (42.5 cm^3, 0.1 M) in hot ethanol was added with vigorous stirring and the resulting solution was refluxed for 2 h. The complex which precipitated was filtered while hot and again refluxed for an additional 30 min in benzene and hot filtered. The complex was washed with hot benzene, ethanol and ether, and collected as above.

$[UO_2Zn(L_2)(H_2O)_2]_n2nH_2O$ (**4**). The complex $[UO_2(H_3L_2)(CH_3COO)]_n3nH_2O$ (1.0 g) was suspended in water (50 cm^3). To this suspension, zinc acetate dihydrate (0.05 M, 35 cm^3) was added and the resulting reaction mixture was refluxed for 3 h. The compound was filtered by suction, and washed three times with ethanol containing a drop of acetic acid, pure ethanol, benzene and ether, and collected as above.

$[(UO_2)_2(H_2L_2)(C_2O_4)]_n2nH_2O$ (**5**). Method 1: H_4L_2, powdered using an agate mortar, was placed in a beaker containing ethanol and stirred well to give a homogeneous slurry (0.05 M, 50 cm^3). An ethanolic solution of uranyl nitrate hexahydrate (0.05 M, 150 cm^3) was added to the ligand slurry with gentle stirring. The resulting mixture was refluxed for 3 h and produced a clear solution. Any undissolved impurities at this stage were removed by filtration. The solution, on concentration (70 cm^3) followed by addition of ether, precipitated a semi-solid. This was extracted with benzene, stirred well for about 1 h, and kept overnight. The precipitate so obtained was washed with an ethanol–benzene mixture, suspended in ethanol (100 cm^3) and heated again to give a solution. To this solution, oxalic acid solution (0.05 M, 150 cm^3) was added, maintaining the molar ratio of uranyl nitrate hexahydrate : H_4L_2 : oxalic acid at 3 : 1 : 3. The reaction mixture was refluxed for an additional 30 min which precipitated the complex. The complex was filtered while hot, washed several times with ethanol, benzene and ether, and collected as above.

Method 2: H_4L_2, powdered using an agate mortar, was placed in a beaker containing ethanol and stirred well to give a homogeneous slurry (0.05 M, 50 cm^3). Uranyl nitrate hexahydrate in ethanol was added to the ligand slurry with continuous stirring, maintaining the molar ratio at 2 : 1, and the resulting mixture was refluxed for 2 h. To this

reaction mixture, oxalic acid was added in slight excess of the required 2 : 1 : 1 molar ratio of uranyl nitrate hexahydrate : H_4L_2 : oxalic acid. The reaction mixture was refluxed for an additional 30 min followed by concentration, washing with ethanol and benzene and finally with ether, and collected as above.

$[(UO_2)_2(L_2)(py)_2(H_2O)_4]$ (**6**). Uranyl acetate dihydrate was dissolved in water solution. A slurry of the ligand (1.0 g) was prepared in the usual way in a 50 cm^3 water–ethanol mixture (4 : 1). Uranyl acetate solution was added to this slurry maintaining the uranyl acetate dihydrate : H_4L_2 ratio at 3 : 1. This reaction mixture was refluxed for 1 h and the precipitated complex was filtered, washed with a water–ethanol mixture and then suspended in excess pyridine (50 cm^3) and refluxed for 2 h. The precipitate dissolved completely, resulting in a clear solution. The solution was concentrated to 30 cm^3 by evaporation and cooled to room temperature. To this solution, benzene (150 cm^3) was added which precipitated the complex. The reaction mixture was stirred for 10 min and the precipitated complex was removed by filtration, washed with benzene, ethanol and ether, and collected in the usual manner.

Acknowledgements—The authors are thankful to Professor M. K. Chaudhuri for helpful discussion. Furthermore, they thank Dr D. T. Khathing, Head, Regional Sophisticated Instrumentation Centre, Shillong, for recording IR, NMR and EDAX spectra of the complexes.

SYNTHESIS AND CHARACTERIZATION OF ARYLOXY DERIVATIVES OF TRIORGANOARSENIC(V)

NEERAJ SHARMA,* B. S. GOLEN, R. K. MAHAJAN and S. C. CHAUDHRY

Department of Chemistry, Himachal Pradesh University,
Summer Hill, Shimla-171005, India

(*Received* 20 *June* 1990; *accepted* 16 *November* 1990)

Abstract—Triorganoarsenic(V) aryloxides of composition $Ph_3AsCl_{2-n}(OAr)_n$ (where Ar = *p*-ClC_6H_4, *p*-$(CH_3)_3CC_6H_4$, *p*-$NO_2C_6H_4$, *p*-$CH_3OC_6H_4$) have been obtained by the reaction of triphenylarsenic dichloride with the respective phenols in appropriate molar ratios in tetrahydrofuran in the presence of triethylamine. They have been characterized on the basis of elemental analysis, conductance, IR and NMR spectral studies.

A survey of the literature reveals that the role of pentacoordination of main group elements in reaction mechanisms[1–5] is potentially one of the best methods to explore the possibility of conformations extended from the ideal trigonal bipyramid to the square or rectangular pyramid. The compounds of pentacoordinated phosphorus,[6,7] arsenic and antimony[8] are probably the most interesting. Compared with pentacoordinated phosphorus and antimony compounds containing P—O and Sb—O bonds, only a limited number of analogous arsenic compounds are known. A few acyclic compounds of the type $As(OR)_5$ (R = Me, Et), $R_2As(OMe)_3$ (R = Me, Ph) and $R_3As(OMe)_2$ (R = Ph) have been reported[9,10] to be formed by the reaction of the corresponding halides of trivalent arsenic with bromine and sodium methoxide in bromine solution. In an effort to extend this chemistry, we have synthesized aryloxy derivatives of triorganoarsenic(V) by a facile and high yield synthetic route.

EXPERIMENTAL

Triphenylarsenic dichloride was prepared by the reported method, employing the reaction of triphenylarsine oxide with 2 mol of acetyl chloride. Phenols used were purified by recrystallization from carbon tetrachloride, and all the reactions were carried out under strictly anhydrous conditions. The arsenic content in isolated compounds was determined as silver arsenate. The IR spectra in the 4000–200 cm^{-1} region were scanned using KBr pellets with Perkin–Elmer 337 and 621 spectrophotometers. ^1H NMR spectra were recorded on a JEOL JNM-DMX60 spectrometer in $CDCl_3$ solutions using TMS as internal standard.

Preparation of $Ph_3AsCl(OAr)$ *and* $Ph_3As(OAr)_2$

Compounds of composition $Ph_3AsCl(OAr)$ and $Ph_3As(OAr)_2$ were prepared by reacting Ph_3AsCl_2 with the corresponding phenols in 1:1 and 1:2 molar ratios in THF in the presence of triethylamine at 0°C. The reaction mixture was slowly brought to room temperature and stirred for 3 h. Triethylamine hydrogen chloride which formed as a white solid was removed by filtration. The excess solvent from the filtrate was removed under reduced pressure at 30°C. The remaining solution was concentrated *in vacuo* to give a colourless liquid.

^1H NMR and IR spectra of the liquid compounds were recorded immediately. Brief exposure to moisture or work-up of the liquid compounds to obtain their solid analogues gave a hydrolysed product, triphenylarsenic hydroxy chloride or triphenylarsenic oxide, confirmed from the melting points reported in the literature.

RESULTS AND DISCUSSION

The compounds isolated in the present study are listed in Table 1 and can be considered to be formed as follows:

* Author to whom correspondence should be addressed.

Table 1. Physicochemical data of phenoxides of triorganoarsenic(V)

Compounds	Boiling point (°C)	Elemental analysis: % Arsenic found (calc)	Elemental analysis: % Chlorine found (calc)	Molar conductance in nitrobenzene ($\Omega^{-1}cm^2mol^{-1}$)	IR: C—O	IR: As—O	IR: As—Cl	^{1}H NMR phenoxy protons as As—OC_6H_4: H_o	H_m	—$C(CH_3)_3$	—OCH_3

$Ph_3AsCl(OC_6H_4NO_2$-*p*)	148	16.0 (15.9)	7.4 (7.4)	18.7	1234	782	372	7.1–7.15	7.9–8.0	—	—
$Ph_3AsCl(OC_6H_4OCH_3$-*p*)	138–140	16.2 (16.1)	7.6 (7.6)	17.9	1188	778	370	6.8–6.9	6.6–6.7	—	3.67
$Ph_3AsCl(OC_6H_4Cl$-*p*)	169	16.0 (15.9)	14.9 (15.1)	16.9	1210	780	375	6.7–6.9	7.15–7.25	—	—
$Ph_3As[OC_6H_4C(CH_3)_3$-*p*]$_2$	105	12.1 (12.2)	—	15.2	1192	770	—	6.8–6.9	7.1–7.2	1.25	—
$Ph_3As(OC_6H_4NO_2$-*p*)$_2$	129	12.8 (12.8)	—	16.6	1240	786	—	7.15–7.2	8.05–8.15	—	—
$Ph_3As(OC_6H_4OCH_3$-*p*)$_2$	112	13.5 (13.5)	—	16.0	1195	782	—	6.9–6.95	6.75	—	3.60
$Ph_3As(OC_6H_4Cl$-*p*)$_2$	132	13.3 (13.3)	—	15.5	1212	784	—	6.8–6.85	7.2	—	—

$$Ph_3AsCl_2 + ArOH \xrightarrow[THF]{Et_3N} Ph_3AsCl(OAr) + Et_3NHCl$$

$$Ph_3AsCl_2 + 2ArOH \xrightarrow[THF]{Et_3N} Ph_3As(OAr)_2 + 2Et_3NHCl.$$

The elemental analyses of the compounds revealed that their stoichiometric composition was $Ph_3AsCl(OAr)$ and $Ph_3As(OAr)_2$. The magnitude of molar conductance values of the compounds in nitrobenzene, acetonitrile and acetone suggest they are weak electrolytes.

The formation of triorganoarsenic(V) aryloxides is clearly indicated by the absence of phenolic OH protons in the ^1H NMR and the disappearance of bands in the region 3500–3200 cm^{-1} in the IR spectra. A significant lowering of the ν(C—O) band by 30–40 cm^{-1} and the appearance of new bands in the region 760–780 cm^{-1} attributed to ν(As—O) was observed, together with bands in the region 390–360 cm^{-1} in some of the above compounds which may be assigned to ν(As—Cl).

The aromatic protons of As—Ph appear at δ 7.6–7.7, and the positions of the protons *ortho* and *meta* to the aryloxy oxygen and those of *para* substituents also support the formation of the above compounds. All the important bands in the IR and NMR spectra are presented in Table 1. The data available do not conflict with the proposition of a trigonal bipyramidal structure for the new compounds.

(*Received* 3 *May* 1990; *accepted* 10 *December* 1990)

Abstract—Equilibrium constants (K) for the reaction:

$$[Cu(OAc)_2 \cdot L]_2 + 2L \rightleftharpoons 2[Cu(OAc)_2 \cdot L_2],$$

where OAc is the acetate anion and L = pyridine (py), β-picoline (β-pic) or γ-picoline (γ-pic), were determined from spectrophotometric and variable-temperature magnetic measurements in chloroform solutions. Good agreement was found between the two methods. The small K values (0.01–0.45) found for the equilibria are consistent with the observed instability of the monomers in chloroform, and increase in the order: py < β-pic < γ-pic. The position of the β-picoline system, for which no crystalline monomer could be isolated, and the anomalous behaviour of α-picoline within this series are discussed in terms of crystal-packing requirements arising from the steric properties of these ligands. Thermodynamic parameters for the equilibria were obtained from the temperature dependence of K. The values of $\Delta H^{\ominus}$ and $\Delta S^{\ominus}$ are in close agreement with those found for adduct formation of related copper(II) chelates with these ligands, and are discussed in terms of contributions from electronics and structural reorganization, bond formation and solvation effects.

Copper(II) carboxylate adducts with a large variety of ligands have been extensively investigated, and the results have been summarized in several reports.[1–4] Attention has been directed primarily at understanding the structural basis for the special magnetic and spectral properties of the dimeric mono-adducts. Some copper(II) carboxylates, on the other hand, tend to form monomeric bis- and tetrakis-adducts with these ligands.[5–9] There have been many studies to investigate the factors which influence dimer formation over monomer formation in copper(II) carboxylate solvate complexes.[3,6–8] It has been found, generally, that increasing acidity of the carboxylate groups and/or the basicity of the ligands increases the tendency towards formation of a monomeric adduct which is related to the electronic effects of the carboxylate groups and of the ligands.[6–8]

Previously,[9] we reported the preparation and characterization of some monomeric bis-adducts as well as the dimeric mono-adducts of copper(II) acetate with pyridine and picolines. Although the four dimeric adducts are converted to the monomeric complexes in solutions of their respective ligands, only in the cases of pyridine and α-picoline were crystalline monomeric bis-adducts isolated. In an effort to shed some light on the role of the addend in stabilizing either of the two structural types, we report herein the results of equilibrium measurements for the monomer–dimer interconversion.

* For Part I, see ref. 9.

† Author to whom correspondence should be addressed.

Because the two adducts have distinctly different spectral and magnetic properties and as a result of the relative instability of the monomers in most solvents, these systems are well suited for detailed examination by electronic and NMR spectral method. The utility of NMR spectroscopy to measure temperature-dependent magnetic properties and solution equilibria, where structural changes with concomitant changes in magnetic moments occur, has been amply demonstrated for several types of equilibria exhibited in solutions of transition metal complexes.[10-13] Solution magnetic studies of structural equilibria have the advantage of providing reliable thermodynamic parameters which are free from unpredictable lattice effects. The availability of a variable-temperature NMR probe permits the equilibrium constant to be determined over a wide range of temperatures and the thermodynamic parameters to be ascertained.

EXPERIMENTAL

Apparatus and measurements

Preparation of the complexes and characteristics of their solutions have been described previously.[9] Solution mixtures for equilibrium constant determination were prepared by the addition of varying amounts of the ligand to portions of a known fixed concentration of the dimer in chloroform solution. For NMR measurements, the latter solution contained 6% (v/v) cyclohexane as internal reference and 4% TMS for signal-locking. The ^{1}H NMR spectral measurements were recorded at 90 MHz on a Perkin–Elmer R-32 spectrometer in Wilmad co-axial tubes with movable glass spacers. The temperature calibration was monitored by methanol or ethylene glycol samples. The signal separation of the reference at each temperature was the average of at least four consecutive recordings which were further checked by comparison with the separation of chloroform signals averaged in the same manner. All other measurements and apparatus were as described previously.[9]

Procedure

According to the NMR technique proposed by Evans,[14] the corrected molar magnetic susceptibility, χ'_m, is related to the shift of the reference signal, $\delta\nu$, by the equation:

$$\chi'_m = \frac{3\delta\nu}{2\pi\nu C}, \qquad (1)$$

where ν is the oscillator frequency and C is the concentration of the paramagnetic material in mol cm^{-3}. For a solution containing an equilibrium mixture of monomer (M) and dimer (D), the observed molar susceptibility per copper is the weighted average of contributions from the monomer and dimer magnetic susceptibility.[10]

It can be shown that the observed shift for a solution mixture is given by:

$$\delta\nu = [M]\Delta\nu_{(M)} + 2[D]\Delta\nu_{(D)}, \qquad (2)$$

where $\Delta\nu$ is the "molar shift" ($\delta\nu/c$) for pure monomer or pure dimer and can be determined separately from their respective solutions at various temperatures. The concentration of the monomer and dimer for each solution can then be determined from eq. (2) and also the known total copper concentration for each mixture.

RESULTS

Spectrophotometric measurements

Representative electronic spectra of equilibrium mixtures in chloroform of copper(II) acetate-γ-picoline complexes are presented in Fig. 1. Spectra of the mixtures show two isosbestic points, consistent with an equilibrium which involves two

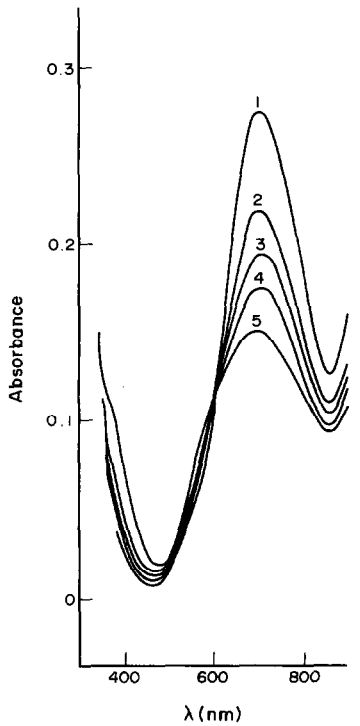

Fig. 1. Visible spectra of equilibrium mixtures in chloroform of copper(II) acetate-γ-picoline complexes, $[Cu^{2+}] = 1.916 \times 10^{-3}$ M, and γ-pic/Cu^{2+} = 25 (1), 50 (2), 76 (3), 101 (4), 239 (5), where the number in parentheses refers to the absorption curve in the figure.

absorbing species. The constant for the equilibrium:

$$[Cu(OAc)_2 \cdot L]_2 + 2L \rightleftharpoons 2[Cu(OAc)_2 \cdot 2L] \quad (3)$$
$$(D) \qquad\qquad (M)$$

was evaluated from absorptivities at the two wavelengths[9] (at the pure dimer maximum around 700 nm and at the pure monomer maximum around 650 nm), by common procedures[15] with the aid of a computer program. To further assess the degree of ligand participation in the equilibrium, the data were analysed graphically in terms of the equilibrium: $D + nL \rightleftharpoons 2M$, for which the equilibrium constant is given by:

$$K = \frac{[M]^2}{[D][L]^n}. \quad (4)$$

This can be rearranged in the form:

$$\log [M]^2/[D] = n \log [L] + \log K. \quad (5)$$

Plots of $\log [M]^2/[D]$ vs $\log [L]$ produced straight lines which are shown in Fig. 2. The value of n can be obtained from the slope, and was found to be two in all cases. The equilibrium constant values were found to be: $(1.2 \pm 0.2) \times 10^{-2}$, $(7.0 \pm 0.3) \times 10^{-2}$ and $(39 \pm 3) \times 10^{-2}$ for pyridine, β-picoline and γ-picoline, respectively. It should be pointed out that measurements of the β-picoline system were carried out at about 20°C to ensure complete conversion to the monomer in the neat ligand solutions, whereas data for the other two systems were obtained conveniently at room temperature (30°C). For comparison, the K value for the pyridine system at 20°C was found to be 3.0×10^{-2}. It was not possible to evaluate an analogous equilibrium constant for the α-picoline system since traces of dimer persist even in its solutions in the neat ligand cooled to 0°C.[9] In addition, the electronic spectra of equilibrium mixtures of the α-picoline complexes show an anomalous shift to lower energies as the ligand concentration is increased. This is in contrast to the behaviour observed in the other systems, and makes evaluation of equilibrium constants from such data questionable.

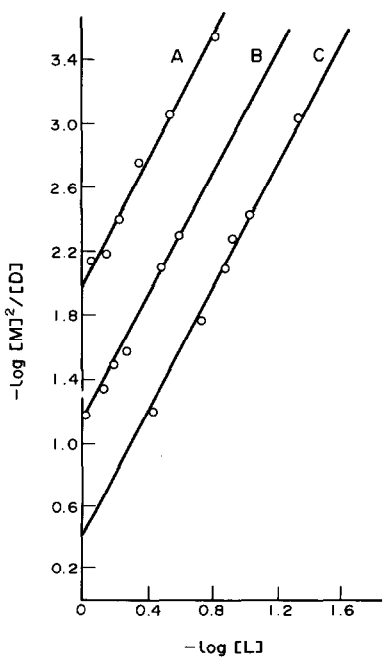

Fig. 2. Graphic determination of K and n from eq. (5): (A) py, (B) β-pic and (C) γ-pic.

NMR measurements

The effect of incremental addition of pyridine upon the NMR shift of the reference in chloroform solutions of the dimer at various temperatures is shown in Fig. 3. Similar behaviour was found at other concentrations and for the other systems. The plots demonstrate the exothermic nature of reaction (3) and the effect of the ligand on the equilibrium position. The equilibrium constant at each temperature was evaluated by solution of eq. (2). The temperature dependence of the equilibrium constants for the three systems is shown in Fig. 4. Analysis of the data by the least-squares method yielded the thermodynamic parameters for the equilibrium, which are summarized in Table 1.

DISCUSSION

The results of this study are interesting in many respects. Equilibrium constant values, at room

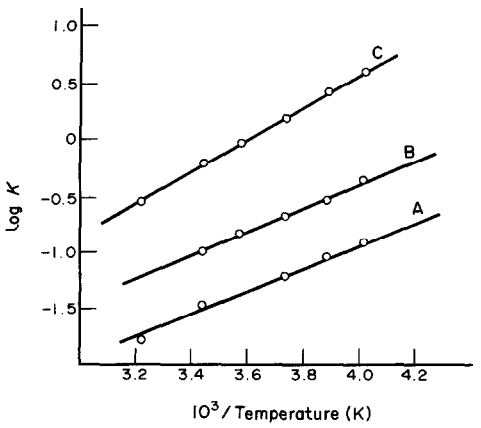

Fig. 4. Temperature dependence of the equilibrium constants: (A) py, (B) β-pic and (C) γ-pic.

temperature, measured by the NMR method agree reasonably well with those obtained spectrophotometrically, despite the inherent differences and experimental uncertainties associated with the two techniques. This confirms the validity of the equilibrium stoichiometry and the reliability of the NMR method for studying structural equilibria in solution. The small K values for the dimer–monomer conversion are consistent with the observed instability of the monomers in chloroform solutions.[9] The most obvious result, however, is that the relative formation constants of the monomeric complexes with these bases increase in the order: py < β-pic < γ-pic. This is the order of increased base strength and the order observed for the formation constants of their complexes with a large variety of Lewis acids.[16-19]

This study, on the other hand, demonstrates that the pyridine bis-adduct shows exceptional stability in spite of the smaller value of its formation constant in solution, whereas the β-picoline bis-adduct, with a higher formation constant in solution, could not be isolated as a crystalline solid. The apparent contradiction can be reconciled if one recognized that the thermal stability of the solid may have little relationship with the solution formation constants. Factors related to crystal packing requirements which stem from symmetry properties of the ligand may account for the thermal instability of the β-picoline bis-adduct. This is further demonstrated in the case of α-picoline which has the same base strength as γ-picoline but fails to form a monomeric bis-adduct either in the crystalline state or in solution. The tendency to attain six-coordination with this ligand is suppressed by crowding around the central metal ion.[9,19] Steric interactions undoubtedly play a significant role in destabilizing the monomeric complex in the case of the α- and β-picolines.

Table 1. Thermodynamic values at 298 K for the equilibrium:

$$\text{Dimer} + 2\text{L} \rightleftharpoons 2 \text{ monomer}$$

L	$K \times 10^{2a}$	$-\Delta H^{\ominus} \pm 0.5$ (kJ mol^{-1})	$-\Delta S^{\ominus} \pm 1$ (J mol^{-1} K^{-1})
Pyridine	2.5 ± 0.2 (1.2)	20.8	100
β-Picoline	8.4 ± 0.3 (7.0)	20.5	89
γ-Picoline	45 ± 2 (39)	27.6	98

[a] Values in parentheses are from spectrophotometric measurements at ~30°C.

The enthalpy and entropy values obtained for the equilibrium are not significantly different for the three systems, and are in close agreement with those found for adduct formation of related copper(II) chelates with these ligands.[16-19] The $\Delta H^{\ominus}$ values are in the range expected for copper–nitrogen bond formation[19] and increase in the order: py ≃ β-pic < γ-pic. Negative $\Delta S^{\ominus}$ values of the observed order of magnitude are to be expected in a system in which there is a net loss of translational freedom of two reactant species.

The observed thermodynamic values represent changes occurring in the total energy of the system upon monomer formation, and can be interpreted as the net result of contributions from electronic and structural reorganization, metal–ligand bond formation and solvation energy effects. However, the absence of thermochemical data for these systems does not allow a quantitative analysis of the various terms, but the significance of these contributions can be qualitatively assessed. Contribution from electronic rearrangement which accompanies monomer formation is evidenced by the fairly significant shift to higher energy in the electronic spectra (from around 700 nm in the dimer to around 650 nm in the monomer).[9] Structural reorganization within the dimer, whereby the four bridging acetate groups act as an essentially monodentate or asymmetric chelating ligand in the monomer, is expected to be extensive. The energy contribution of this term is expected to inhibit monomer formation by making a positive contribution to the enthalpy. However, the contribution of this term should be constant, or nearly so, in the three systems and is balanced by the negative contribution to the enthalpy as a result of formation of comparable copper–oxygen bonds in the monomer.

Formation of the additional copper–nitrogen bond should make a negative contribution to the enthalpy. In the absence of any steric effects, the

contribution due to bond formation depends on the availability of the electron pair on the nitrogen atom and, within a related series of ligands, is reflected by the relative order of their dipole moments, ionization energies and pK_a values.[17] On this basis the sequence of donor ability is well established to be: py < β-pic < α-pic < γ-pic.

That contribution to the observed thermodynamic parameters from solvation effects must be significant is clearly manifested in the instability of the monomer in chloroform solution where it is quantitatively converted to the dimer. Whether the dimers are solvated to any extent in these solutions is not clear, but no large variations in the degree of solvation are expected among the four complexes. On the other hand, pyridine bases are known to interact strongly with chloroform, presumably via hydrogen bonding.[17,19,20] This interaction contributes a large exothermic ΔH(soln) term, which increases in the order: py < β-pic < α-pic < γ-pic. Variations in the actual values of $\Delta H^{\ominus}$ and $\Delta S^{\ominus}$ are affected, no doubt, by differences in the solvation effects which may account for the lower than expected values found for the β-picoline system.

The thermodynamic parameters found for these systems are, in general, in accord with this analysis. While the electronic properties of the carboxylate group may be significant in affecting the stabilization of a particular structural type,[1] the steric and electronic properties of the addend also play an important role in this respect.[6–8] This view is supported by the structural results of the copper(II) acetate bis-adduct with collidine[6] in which, despite prohibitive steric crowding resulting from the two α-methyl groups, the superior donor ability of this ligand allows copper–nitrogen bond formation at the expense of disrupting the copper–acetate bonding. In addition, the importance of electronic properties of the addend are also demonstrated when basic ligands such as ammonia and imidazoles react with copper(II) acetate in which only monomeric adducts are formed.[5,21]

Abstract—Using ^{195}Pt NMR spectroscopy, several products formed in the 1 : 1 reaction at pH = 6–7 of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with creatinine ($C_4H_7N_3O$) have been identified at pH 4 in aqueous solution. The following products have been found: the head-to-head and head-to-tail creatinine-bridged dimers $[Pt_2(NH_3)_4(C_4H_7N_3O)_2]^{2+}$, assigned at −1341 ppm, −2452 ppm and −1908 ppm, respectively; the known hydroxo-bridged dimer $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2]^{2+}$ at −1153 ppm; the creatinine monomer *cis*-$[Pt(NH_3)_2(N_d$-creatinine)] at −2222 ppm. They are closely related to the products that are obtained in analogous reactions of free and substituted pyrimidines. ^{13}C NMR spectra of the complexes indicate large shifts for the C(3) and C(4) nuclei relative to the free ligand, indicating that the NH moiety within the creatinine ring, rather than the exocyclic one, is directly coordinated to the metal ion.

The field of aqueous platinum(II) chemistry is currently of great interest mainly due to the discovery and exploration of the antitumour properties of *cis*-diamminedichloroplatinum(II) (*cis*-DDP or cisplatin) which led to its widespread success in the clinical treatment of human cancer.[1] The reactions of the drug with nucleic acids and their constituents have been thoroughly studied[2–9] in an attempt to understand the inhibition of cellular replication induced by the interaction of *cis*-DDP with DNA.[10]

The reaction of *cis*-DDP or the aquated form of the complex, *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$, with free or substituted pyrimidine bases, leads to a variety of products[11–25] containing different numbers of platinum atoms. A variety of simple mononuclear and dinuclear platinum complexes of free and substituted pyrimidine bases have been isolated and studied by ^1H NMR.[12–25] In these compounds the platinum binding sites were clearly identified. In mononuclear complexes they are one of the heterocyclic nitrogens [N(1) or N(3)] of the pyrimidine base, whereas in pyrimidine-bridged dinuclear complexes they are a combination of N(1) or N(3) and one of the exocyclic atoms [O(2), O(4) or N(4)]. However, polynuclear species produced in many of the reactions of platinum with pyrimidines have been far more difficult to characterize.[11–22] This is due to the multiplicity and interconversion of the binding sites of both reactants, ligand exchange reactions which interconvert the various products, and valence instability, which may lead to the formation of partially oxidized materials collectively known as the "platinum pyrimidine blues".

In recent years, great interest has been shown in platinum blues, especially on their potential antitumour activity and low nephrotoxicity compared with the anticancer drug cisplatin. We are working on the synthesis and characterization of new crystalline platinum creatinine complexes, particularly

their coloured derivatives. 2-Imino-1-methyl-4-imidazolidinone, commonly known as creatinine [H_3C-N-C(NH)-NH-CO-CH_2, see Fig. 1 for structure and numbering], has been chosen as a ligand because as the final catabolic product of the important metabolite creatine its level in serum and urine is a very sensitive index of renal function (Creatinine Clearance Test). It has been suggested that the study of the metal–creatinine complexes can lead to an understanding of some biological aspects of creatinine metabolism.[26] Creatinine is also similar to 2-pyrrolidone, which forms a structurally well characterized family of compounds known as platinum tans, and has been chosen as a ligand because of its importance in clinical chemistry and its similarity to 2-pyrrolidone, which is structurally characterized in platinum tans.[27] Although creatinine is quite similar to the nucleotide bases in relation to its metal ion coordination potentialities,[28] so far only the crystal structures of creatininium tetrachlorocuprate(II),[29] bis(creatinine)silver(I) perchlorate and bis(creatinine)diiodoplatinum(II) trihydrate [binding at N(3)][30] have been determined.

In this paper we describe a ^{195}Pt and ^{13}C NMR characterization of the reaction products of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with creatinine (pH = 4.0) in aqueous solution. These results are compared with previous ^{195}Pt NMR studies of the hydrolysis reactions of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$.[31–36]

EXPERIMENTAL

Preparation of the platinum creatinine blues

The standard procedure for the preparation of blue complexes which was followed in this work arises from previous work on the reaction between the aquated products of cisplatin ligands such as uracil, thymine, uridine or other related pyrimidines. A second preparation procedure, involving the reaction between the tetrachloroplatinate(II) anion and primary amides, orotic acid or creatinine, has also been described.[37]

A 0.15 M solution of the *cis*-diamminediaquaplatinum(II) hydrolysis products was prepared by mixing 0.3 g of *cis*-$[(NH_3)_2PtCl_2]$ (prepared according to a published method[38]) and 0.34 g of $AgNO_3$ (from Merck) in approximately 7 cm^3 of water. After stirring in the dark at room temperature overnight, the solution was centrifuged twice to remove the AgCl precipitate. One equivalent of creatinine (from Merck), dissolved in a minimum amount of water and adjusted to pH 10 with 0.1 M NaOH, was then added to the *cis*-diamminediaquaplatinum(II) solution and the reaction mixture was adjusted to neutral pH (pH = 6–7) with 0.1 M NaOH. The solution was then kept in the dark at 37–40°C for approx. 24 h, until a deep blue–green colour appeared. Following incubation, a few drops of concentrated nitric acid and 0.75 g of sodium nitrate were added to the blue–green solution, pH = 1. This solution immediately turned very dark blue in colour and was allowed to stand for 12 h at 0°C. Dark blue crystalline needles, unsuitable for X-ray analysis, were collected.

Spectral measurements

NMR spectra of solutions of creatinine and of the products obtained from the reaction of equivalent amounts (1 : 1) of *cis*-DDP hydrolysis products and creatinine, were obtained at room temperature in D_2O (99.8% isotopic purity, from Sigma Chemical Co.). The pH was adjusted using 0.1 M solutions of DCl and NaOD (obtained from Sigma). pH values were measured on a Metrohm E250 pH meter, equipped with an Ingold 405-M3A glass electrode.

Broad-band ^1H decoupled ^{13}C NMR spectra were recorded on a Bruker WP-80 spectrometer. All ^{13}C chemical shifts were measured relative to TSP as external reference and were referenced to TMS. Natural abundance ^{195}Pt NMR spectra were obtained at 64.5 MHz on a Varian XL-200 spectrometer with a broad-band (10 mm) probe. Spectral data were typically acquired with a 26-μs pulse (90° flip angle), 160-ms acquisition time and a spectral width of either 83 or 100 kHz. ^{195}Pt shifts were measured relative to 0.2 M K_2PtCl_4 (in 0.4 M KCl/D_2O) used as external reference, with a shift of −1631 ppm relative to K_2PtCl_6.[39]

RESULTS AND DISCUSSION

The reaction of the *cis*-DDP hydrolysis products with one equivalent of creatinine in aqueous solution at pH = 6–7 were examined using natural abundance ^{195}Pt NMR spectroscopy at pH 4. This technique proved to be a feasible method to monitor the formation of reaction products, as in our instrumentation good quality spectra could be obtained within 18–20 h on samples that were 0.1 M in platinum. The large ^{195}Pt chemical shift range (15,000

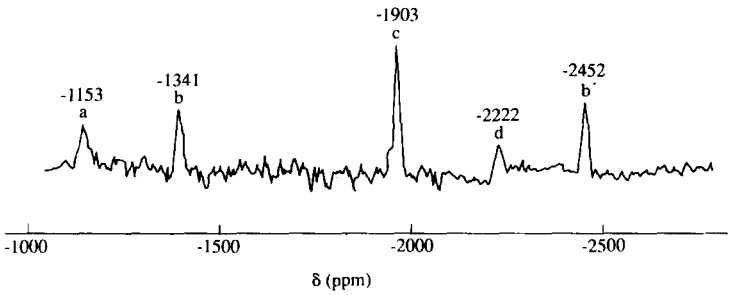

Fig. 2. ^{195}Pt NMR spectrum of the products obtained from the reaction of a 0.15 M solution of *cis*-DDP hydrolysis products with 1 equiv. of creatinine after 24 h. The chemical shifts are referenced to K_2PtCl_6 with negative values indicating a low frequency position relative to the reference. The pH of the solution was kept at 4.0, and the number of transients 50,000. The spectral assignments are described in the text.

ppm) and the predictable dependence of the shifts upon ligand substitution[39] provide an excellent means of product identification in the aqueous solution reactions of *cis*-diammineplatinum(II) complexes.[31] For example, the ^{195}Pt chemical shifts of the complexes of the form *cis*-$[Pt(NH_3)_2L_2]^{n+}$, where L is either a neutral or anionic nitrogen donor (N_d) or oxygen donor (O_d), covering a range of over 1300 ppm, are correlated in a nearly linear fashion with the electronegativity of the donor ligands L, and are found to increase in the order, *cis*-$Pt(NH_3)_2(N_d)_2$ < *cis*-$Pt(NH_3)_2(N_d)(O_d)$ < *cis*-$Pt(NH_3)_2(O_d)_2$. While other important factors also influence the ^{195}Pt chemical shifts,[39] this order holds for the complexes that are relevant to the present investigation.

The ^{195}Pt NMR spectrum of the reaction mixture of an aqueous solution of *cis*-DDP with one equivalent of creatinine, taken after 24 h of reaction at pH 6.0 and 40°C, and with the pH adjusted afterwards to 4.0, is shown in Fig. 2. At this stage in the reaction the major spectral components are peak c (at −1908 ppm) and the two peaks of equal intensity, b and b′ (at −1341 and −2452 ppm, respectively). Two other signals, of smaller but nearly equivalent intensities, are also present. These are peaks a at −1153 and d at −2222 ppm.

Assignment of the ^{195}Pt signals provides the identification of the reaction products. Some of these assignments are based on previous ^{195}Pt NMR studies of the pH dependent chemical behaviour of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ in aqueous media,[32] especially its condensation reactions following removal of acidic protons of the coordinated water molecules at pH values above 2.[31,40] Among others, the hydroxide-bridged dimer $[(NH_3)_2Pt(OH)_2Pt(NH_3)_2][(NO_3)_2]$ and a distribution of monomeric hydroxyaqua complexes *cis*-$[Pt(NH_3)_2XY]^{n+}$ (where X,Y = OH or H_2O) have been identified.[31,32] A number of these products have been isolated and fully characterized by X-ray diffraction methods.[32] Comparison of the chemical shifts of the spectral signals of Fig. 2 with the literature data[31,41] allows the assignments of peak a to the hydroxide-bridged dimer. However, the trimer, $[Pt(NH_3)_2(OH)_2]_3^{3+}$, and the monomeric hydroxyaqua complexes are not detected at this stage of the reaction, as opposed to what has been observed in a similar study with α-pyridone.[41]

The identification of the remaining signals was undertaken by comparison of their chemical shifts with the data available for the α-pyridone reaction[41] and also using the signal intensities. Thus, peak d was assigned to the mono-creatinine complex *cis*-$[Pt(NH_3)_2\{creatinine\text{-}N(3)\}(H_2O)]^{2+}$, peak c to the head-to-tail dimer and peaks b and b′ to the two signals of the head-to-head dimer. The two signals in this isomer result from the non-equivalent platinum centres: Pt(1) is bound to four nitrogen donors (peak b′), and Pt(2) is bound to two oxygen and two nitrogen donors (peak b) (Fig. 3). From the relative intensity of the signals both isomers are estimated to be present in nearly equal amounts.

The results of this experiment strongly suggest that, at the point of acidification in the preparation of the platinum creatinine blue, the head-to-head platinum(II) dimer is a major component in solution. However, when the pH of the solution is lowered from 4.0 to 1.0 with nitric acid, the solution rapidly changes colour from deep blue–green to deep blue. No ^{195}Pt NMR spectrum could be obtained from this solution, even after 50,000 transients, indicating the presence of residual paramagnetism in these samples. In fact, EPR signals of various platinum blues have been detected and interpreted in terms of partially oxidized mixed-valent complexes.[42,43] Electrochemical studies of α-pyridonate complexes[44] suggest that electron exchange reactions between the head-to-head platinum(II) and platinum(III) dimers may be involved

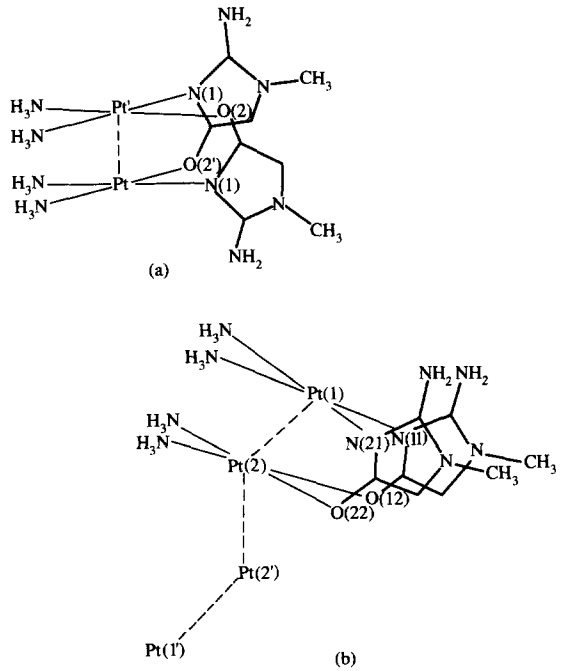

Fig. 3. Proposed structures of the creatinine-bridged complexes of *cis*-DDP: $[Pt_2(NH_3)_4(C_4H_7N_3O)_2]^{2+}$ (a) the platinum(II) dimer head-to-tail (peak c) and (b) head-to-head (peaks b and b').

in the formation of the partially oxidized tetramer.

In a similar fashion to what has been observed previously with other ligands,[41] the chemical shifts of the dinuclear creatinine complexes are shifted to high frequency relative to the corresponding mononuclear analogues. Comparing two platinum atoms with similar primary coordination sphere chemical environments, it is found that the average chemical shift difference between the head-to-tail dimer and the mononuclear creatinine complex, *cis*-$[Pt(NH_3)_2\{creatinine\text{-}N(3)\}(H_2O)]^{2+}$, is 314 ppm. This difference, too large to be attributed to charge effects, has been interpreted using a molecular orbital formulation of a metal–metal interaction in the dinuclear complexes.[45] Although the quantitative dependence of the ^{195}Pt chemical shifts upon the strength of the metal–metal interaction in binuclear platinum(II) complexes is not established, it is worth noting that the high frequency chemical shift effect observed for the head-to-tail dimer of creatinine (+314 ppm) is substantially larger than the value of +220 ppm observed for the α-pyridone complex.[41]

Creatinine is a cyclic compound containing cyclic [N(3)] and exocyclic imine [N(2'), bound to C(2)] nitrogen atoms (Fig. 1) capable, in principle, of coordinating the platinum ions. The ^{13}C complexation shifts of creatinine were, therefore, used to investigate the nitrogen coordination of creatinine. The ^{13}C NMR spectra of D_2O solutions of creatinine and of *cis*-DDP with creatinine, obtained at pH 6.0, were compared. The resonances of the C(2), C(4), C(5) and C(1') carbons of a 0.15 M solution of creatinine in D_2O occur[46] at 166.4, 184.9, 57.3 and 33.5 ppm. The products obtained from the reaction of a 0.15 M solution of *cis*-DDP hydrolysis products with one equivalent of creatinine, in D_2O at the same pH value, yield the same four intense signals at the corresponding chemical shift values of 171.7, 191.0, 58.7 and 32.5 ppm. Therefore, these ^{13}C NMR studies indicate that there are large shifts in C(2) and C(4), pointing towards coordination of creatinine occurring through the cyclic N(3) nitrogen, in agreement with the structures of the complexes proposed in Fig. 3.

This conclusion about the creatinine coordination is supported by ^1H and ^{13}C NMR data on creatinine complexation by zinc(II), cadmium(II) and mercury(II) in DMSO-d_6. The ^1H NMR spectrum of creatinine in this solvent exhibits resonances at 7.3, 3.6, 3.2 and 2.8 ppm (relative to TMS), which are due to the cyclic NH, imine NH, $—CH_2—$ and $—NCH_3$ protons, respectively.[26] The assignments were made upon comparison with the substituted guanidines.[47] Comparison of the spectra of the zinc(II), cadmium(II) and mercury(II) complexes with that of creatinine revealed that there is a large shift of the cyclic N(3)H proton (resonance at 8.4 ppm), while the positions of the other protons are unaltered.[48] ^{13}C complexation shifts, induced by those ions, of the carbonyl C(4) and imine C(2) carbons also support metal binding at N(3).[26]

CONCLUSIONS

The following platinum(II) complexes are obtained in the reactions of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with creatinine: the mono-creatinine complex *cis*-$[Pt(NH_3)_2\{creatinineN(3)\}(H_2O)]^{2+}$, as well as the head-to-head and head-to-tail isomeric dinuclear complexes of formula $[Pt_2(NH_3)_4(creatinine)_2]$ which both contain a metal–metal bond; they are closely related to the products that are obtained in analogous reactions of free and substituted pyrimidines.

Both head-to-head and head-to-tail dinuclear species have been found from ^{195}Pt NMR studies to form in equal proportions in the reaction that leads to complex formation. ^{13}C complexation shifts indicate that platinum coordination occurs through the pyrrole-type nitrogen N(3) and the carbonyl O(4') of creatinine. Addition of nitric acid (pH = 1) to these solutions converts the head-to-

head platinum(II) complex into the platinum blue analogue while leaving the head-to-tail complex in the platinum(II) oxidation state. The importance of pH in controlling the oxidation state in the creatinine complexes of platinum has therefore, once more, been established and could possibly be used in the synthesis of related amidato-bridged complexes.

Abstract—The lithium alkoxides, $[LiOR]_n$ [R = Bu^t (**1**) and $PhMe_2C$ (**2**)], have been prepared and fully characterized in solution by IR, ^1H, ^{13}C and ^7Li NMR, and cryoscopy in benzene, which gave a value of $n = 6$. Single-crystal X-ray diffraction studies on $[LiOCMe_2Ph]_6$ (**2**) at $-169°C$ revealed that this molecule crystallizes in the monoclinic space group $P2_1/n$, with unit cell dimensions, $a = 12.555(2)$, $b = 12.010(2)$, $c = 16.405(3)$ Å; $\beta = 99.44(1)°$, $Z = 2$, $d_{calc} = 1.161$ g cm^{-3}, as a hexagonal prism. The oxygen and lithium atoms in the hexameric species are arranged into two Li_3O_3 planes.

The solution and solid-state structures of lithiated organic compounds is an area of burgeoning interest,[1] both from a purely synthetic and also a theoretical standpoint.[2] In the vast majority of these complexes, lithium is found to be in a four-coordinate environment,[3] although coordination members of five have also recently been observed in macrocyclic complexes.[4] Lower coordination numbers, e.g. two[5] and three,[6] are still comparatively rare (see Table 3), although recent examples have included lithium alkoxides and boroxides.

These materials find wide usage in organic chemistry, e.g. anionic polymerization is initiated by LiOR,[7] and it has been previously noted that organolithium (LiR) compounds are less stable in the presence of LiOR.[8] Recent studies have demonstrated that the super-base $[Bu^tLi \cdot LiOBu^t]_n$ is a tetramer of unusual structure.[9]

Previous studies have shown that $[LiOBu^t]_n$ (**1**) is in fact a hexamer in benzene (degree of aggregation, $n = 6.0$).[10] In this paper we report the synthesis of $[LiOR]_6$ (R = Bu^t and CMe_2Ph), their solution properties, and a single crystal X-ray structure of $[LiOCMe_2Ph]_6$ (**2**).

RESULTS AND DISCUSSION

Attempts to prepare single crystals of $[LiOBu^t]_6$ have been successful, but it appears that the molecule is disordered.[11] We have found similar problems, and have instead used the ligand $PhMe_2COH$. Lithiation of this molecule in tetrahydrofuran yields $[LiOCMe_2Ph]_n$ (**2**). The elucidation of the single-crystal X-ray structure was of interest in its own right, and also because the solid-state structure of **2** would be most likely related to that of **1**.

Both **1** and **2** are air-sensitive and must be handled in dry and oxygen-free atmospheres.

Solid-state and molecular structure of $[LiOCMe_2Ph]_6$ (**2**)

A ball-and-stick drawing of the molecule is given in Fig. 1 and selected bond distances and bond angles are given in Table 2. The atom numbering scheme used in Table 2 is shown in Fig. 2.

The molecule has a centre of symmetry and has a skeleton related to $[NaOBu^t]_6$,[12] with the oxygen and ligand atoms alternating at the corners of a hexagonal prism. The atoms in this hexameric species are thus arranged into two near-parallel planes. In **2** the Li—O distances are 1.91(5) Å (av.), which

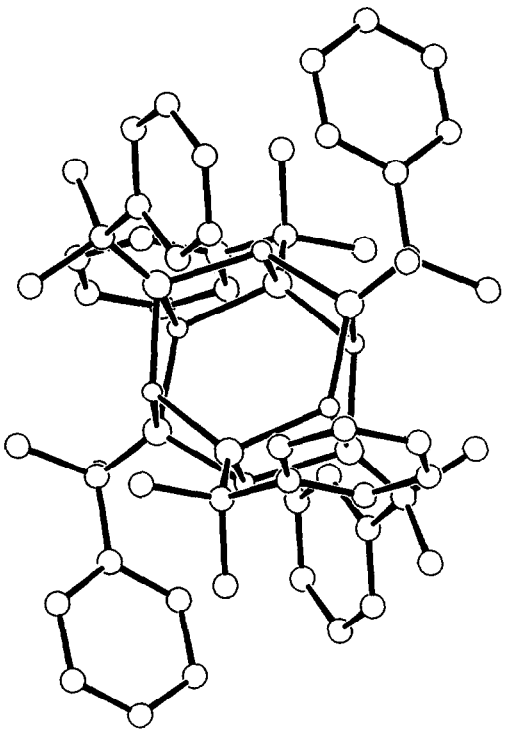

Fig. 1. Molecular structure of $[LiOCMe_2Ph]_6$ (hydrogen atoms omitted).

may be compared to those in $[NaOBu^t]_6$, 2.24(1) Å (av.),[12] the difference being accounted for by the larger ionic radii of Na^+ with respect to Li^+.

There are several features worthy of comment in this structure. The inter-lithium distances in the isosceles triangle, are 2.46 ± 0.01 Å, with the third side being longer, 2.528(14) Å (see Table 2). These features are also observed in the Li(1)—Li(3)—Li(2) angle of 77.0°. The lithium atoms in this molecule are three coordinate (see Table 3), the distances of Li(1) to O(4) and O(14) in the same plane are nearly identical, 1.88 ± 0.01 Å, while the distance between Li_3O_3 layers, Li(1)—O(24), is slightly longer, 1.92(1) Å. Similar features are also observed for Li(2) and Li(3) in relation to the Li—O distances. It may also be noted that the distances in the Li_3O_3 hexagon are not regular and span the range 1.87–1.98 Å.

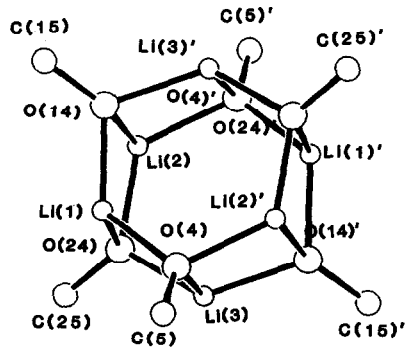

Fig. 2. A ball-and-stick drawing of the central $[LiOC]_6$ framework showing the hexagonal prismatic geometry.

Within the hexagonal prismatic structure, the O—M—O angles are found to vary over a wide range, 97.75(12)–126.277(12)°, with the most extreme being O(4)′—Li(2)—O(14) and O(4)—Li(1)—O(14). The 2-phenyl-2-propoxide ligands are essentially equivalent, being μ_3-bridging ligands.

Solution properties of **1** *and* **2**

In d_6-benzene and d_8-toluene, **1** and **2** exhibit only a single signal for the methyl groups at room temperature, as shown by ^1H and ^{13}C NMR spectroscopy. The spectra do *not* change on cooling to 220 K. As judged by the simple pattern of resonances observed for the phenyl ring (i.e. only one type of phenyl ring environment) in both ^1H and ^{13}C NMR spectra, the molecular structure is retained in solution. In solution, ^1H and ^{13}C NMR variable temperature spectroscopic studies show that the ^tBuO groups in **1** are equivalent.

In contrast, the behaviour in weak Lewis base media (e.g. THF) is more complex. The ^7Li NMR of **1** in C_7D_8 at 298 K shows only one resonance (δ −1.73), as would be expected if all the lithium environments are equivalent as observed in the solid-state structure. The behaviour of **1** in d_8-THF was markedly different, with not only a large chemical shift of 5 ppm (^7Li has a small chemical shift range), but also the observation of another peak. The two peaks are found in a ratio of 4:1 at 193 K.

Related behaviour is also observed for **2**, which exhibits a singlet at δ 4.06 in C_7D_8 at 293 K, which remains unchanged down to 253 K, and below this temperature the sample precipitates from solution. When **2** is dissolved in d_8-THF, two resonances are observed at δ 4.29 and 4.47 in a ratio of 9:1. The more sterically hindered CMe_2Ph group reducing the amount of $[LiOCMe_2Ph \cdot THF]_n$ that formed in solution, e.g.

$$[LiOR]_6 \underset{\text{toluene}}{\overset{\text{THF}}{\rightleftharpoons}} [LiOR \cdot THF]_4.$$

Removal of the d_8-THF from either **1** or **2**, and redissolution in d_8-toluene, regenerates the parent non-solvated materials. Previous studies on alkali-metal alkoxides (Li, Na and K) in a range of solvents, demonstrated that the degree of aggregation was affected by different aprotic

solvents.[10,15] It was demonstrated that solvation of lithium alkoxides could occur to a considerable extent in tetrahydrofuran, with crystalline coordination compounds, containing 1 mol of THF per mole of alkoxide being obtained. Thermoelectric molecular weight measurements showed that tetrameric aggregates are formed. One can visualize, for example, that these species would be related to the cubane alkoxides, $[MOBu^t]_4$ (M = K, Rb or Cs).[12] Hence in THF an equilibrium between hexamer and tetramer is proposed, with the coordination number of lithium remaining unchanged.

Cryoscopic molecular weight measurements for **1** and **2** in benzene are in accord with the NMR, yielding values for aggregations of six.[16] One may note that the substitution of a methyl group by phenyl in **2** increases the sublimation temperature by 60°C (at 10^{-2} torr), thereby decreasing the volatility of this species.

Electron impact mass spectrometer studies have recently been used to study the gas-phase compositions of a wide variety of lithium alkoxides (LiOR, R = Et, Pr^i, Bu^n, s-amyl, Bu^t and others).[17] The most abundant ions corresponding to tetramers, hexamers and even the observation of larger aggregates. The larger lithium clusters were stabilized by hydroxide ligands, presumably via water contamination of the materials.

Mass spectra of gas-phase lithium alkoxides share many features with those of the alkyl lithiums, yet it is clear that the higher coordination number of oxygen allows very stable and potentially larger alkoxide aggregates to form.

Mass spectroscopic results have revealed that $[LiOBu^t]_6$ (**1**) is extremely volatile, exhibiting not only a molecular ion (M^+ 480), but also the corresponding $[LiOBu^t]_n$ (n = 1–5) fragments. These mass spectral results are in accord with those of Schleyer and co-workers,[17] and Hartwell and Brown[18] who also demonstrated that **1** is a hexamer in the vapour phase. The related lithium alkyloxide $[LiOCMe_2Ph]_6$ (**2**), also yields a molecular ion in electron impact mass spectroscopy.

Concluding remarks

The lithium alkoxides $[LiOR]_n$ (R = Bu^t and CMe_2Ph) (**1**) and (**2**) have been characterized in solution, the solid-state and the vapour phase. It has been shown that the hexameric nature of these complexes remains intact in all three phases.

In deutero-benzene and toluene solutions these species show only one type of tert-butoxide environment for **1**, and one 2-phenyl-2-propoxide environment for **2** according to ^1H, ^{13}C and ^7Li NMR. The latter is in accord with the single-crystal X-ray structure, where a hexagonal prismatic geometry is observed.

Whereas in Lewis-base media more complex situations arise, in THF both **1** and **2** are solvated to a small extent (20%) to yield the corresponding $[LiOR \cdot THF]_n$ adducts, as shown by ^1H, ^{13}C and ^7Li NMR. It is highly probable that these hexameric species are in equilibrium in solution in THF with tetrameric species such as $[LiOBu^t \cdot THF]_4$.

EXPERIMENTAL

All manipulations were carried out under an atmosphere of dry (molecular sieves) argon (using standard dry-box and Schlenk techniques). All hydrocarbon and ethereal solvents were dried and distilled from sodium benzophenone ketyl. Alcohols were dried by distillation from magnesium turnings, activated by a crystal of iodine. NMR solvents were dried over 4 Å molecular sieves and stored under argon. Lithium sand was purchased from the Aldrich Chemical Company and stored in a dry-box, under an argon atmosphere. Elemental analyses were performed by Oneida Research Services. NMR data were recorded on a Bruker WM-500 NMR spectrometer, using the protio impurities of the deuterated solvents as reference for ^1H spectra and the ^{13}C resonance of the solvent as a reference for ^{13}C spectra. The ^7Li NMR data were recorded at 194.36 MHz, using a 1.0 M LiCl solution in D_2O as a reference. IR spectra were recorded on a FTIR

spectrometer. All of these experiments were carried out in either [$^2H_8$] toluene or [$^2H_8$] tetrahydrofuran solutions prepared in a glove-box under argon. All chemical shifts are positive to high frequency of the standard. At least two solutions of each compound, at a range of concentrations (0.05–0.25 M), were used.

Relative molecular mass measurements were carried out using a thermistor-type apparatus, fitted with vacuum tubing and high pressure taps to allow prior repeated evacuation/argon-filling and to allow a slow argon stream through it during the determination. The measurements were carried out with variable concentrations in benzene as solvent, typically spanning the range 50–600 mg of sample in 25 cm^3 of benzene. Each value was determined by three measurements.[16]

Mass spectroscopic studies were performed on a Kratos MS80RFQQ, operating in electron impact mode, using a direct insertion probe (to alleviate decomposition of samples), and operating over the temperature range 50–100°C.

Synthesis of [$LiOBu^t$]$_6$ (**1**)

A Schlenk flask was charged with lithium sand (0.70 g, 100.8 mmol) and suspended in toluene (45 cm^3). The Schlenk flask was then cooled to 0°C using an ice-bath and tert-butyl alcohol (8.6 cm^3, 90.8 mmol) added via syringe. After stirring for 24 h at ambient temperature, the solution was filtered to remove the excess metal, and the solvent removed *in vacuo* to yield a white solid. The product was purified by sublimation at 110–120°C (10^{-1} torr), as colourless crystals, to give 4.4 g, 54.97 mmol of [$LiOBu^t$]$_6$, a yield of 60.6% (based on Bu^tOH consumed). Found: C, 59.9; H, 11.2. Calc. for $LiOC_4H_9$: C, 60.0; H, 11.3%. Melting point: sublimes over the range 170–205°C (760 torr), > 250°C decomposes.

IR data (cm^{-1}): 1354(m), 1250(m), 1205(s), 1106(m), 962(s), 885(w), 833(m), 777(m), 754(m), 688(m).

NMR data: ^{1}H, 298 K, C_7D_8: δ 1.26 (s), spectrum remains unchanged on cooling to 220 K; ^{13}C, 298 K, C_7D_8: δ 35.67 (s, CMe_3), δ 64.96 (s, $OCMe_3$), also remains unchanged on cooling to 220 K; ^{7}Li, 233 K, C_7D_8: δ 2.83 (s), lower temperature limit; d_8-THF, 233 K: δ 3.15 (s), δ 3.67 (s) in a ratio of 4 : 1.

The molecular weights of 451 ± 46 and 468 ± 30 were measured at concentrations of 4.15×10^{-4} and 7.26×10^{-4} M, respectively. Calculated for [$LiOBu^t$]$_6$ = 480. Each value was determined by three measurements.

Mass spectroscopy shows M^+ 480 with clearly defined species, $[Li_3(OBu^t)_5]^+$ 420, $[Li_4(OBu^t)_4]^+$ 360, $[Li_3(OBu^t)_3]^+$ 300, $[Li_2(OBu^t)_2]^+$ 240 and $[LiOBu^t]^+$ 180.

Synthesis of [$LiOCMe_2Ph$]$_6$ (**2**)

A Schlenk flask was charged with lithium sand (0.14 g, 20 mmol) and 2-phenyl-2-propanol (2.73 g, 20 mmol) and tetrahydrofuran (30 cm^3). The reaction mixture was refluxed for 36 h during which time all the lithium metal was consumed. The solution was filtered to remove any unreacted metal, and the solvent removed *in vacuo* to yield a white solid. The product was then dissolved in the minimum amount of toluene (10 cm^3) and layered with n-pentane (25 cm^3), and the sample cooled to 5°C for 24 h. During this time large, regular shaped, colourless crystals of the product were deposited. The solution was subsequently filtered, and the crystals dried carefully *in vacuo* to give 2.41 g, 15.86 mmol of [$LiOCMe_2Ph$]$_6$, a yield of 79.2%. Melting point: 120–122°C, sublimes over the range 170–185°C (10^{-3} torr). Found: C, 71.2; H, 7.4. Calc. for $LiOC_9H_{11}$: C, 71.0; H, 7.2%.

IR data (cm^{-1}): 3040(m), 3020(m), 1244(s), 1161(s), 976(s), 868(s), 765(s), 592(s), 534(s).

NMR data: ^{1}H, 298 K, C_6D_6: δ 1.34 (s, Bu^t), δ 7.02 (m, Ph), δ 7.12 (m, Ph), δ 7.47 (m, Ph), spectrum remains unchanged on cooling to 220 K in C_7D_8; ^{13}C, 298 K, C_6D_6: δ 34.89 (s, CH_3), δ 70.92 (s, CMe_2), δ 124.74 (s, *para*-C), δ 126.25 (s, *meta*-C), δ 129.015 (s, *ortho*-C), δ 154.89 (s, *ipso*-C), also remains unchanged on cooling to 220 K in C_7D_8; ^{7}Li, 233 K, C_7D_8: δ 4.06 (s), lower temperature limit; d_8-THF, 233 K: δ 4.29 (s), δ 4.47 (s) in a ratio of 9 : 1.

The molecular weights of 793 ± 69 and 821 ± 44 were measured at concentrations of 3.63 ± 10^{-4} and 7.96×10^{-4} M, respectively. Calculated for [$LiOCMe_2Ph$]$_6$ = 853. Each value was determined by three measurements.

Mass spectroscopy shows M^+ 853 with clearly defined envelopes for $[Li_5(OR)_5]^+$ 710.83, $[Li_4(OR)_4]^+$ 586.67, $[Li_3(OR)_3]^+$ 426.5 and $[Li_2(OR)_2]^+$ 284.33.

X-ray diffraction studies

General operating procedures and a listing of programs have been given previously.[19] A summary of crystal data is given in Table 1. A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques employed by the Indiana University Molecular

Structure Center and cooled to −169°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/n$. Subsequent solution and refinement of the structure confirmed this choice.

Data were collected in the usual manner using a continuous θ–2θ scan with fixed backgrounds. The data were reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of direct methods (MULTAN78) and Fourier techniques. Refinement progressed smoothly, with a difference Fourier phased on the non-hydrogen atoms revealing the positions of most of the hydrogen atoms. The positions of the latter were fixed in their idealized positions for the remainder of the refinement.

In the final cycles of least-squares refinement, the non-hydrogen atoms were varied with anisotropic parameters and the hydrogen atoms were varied with isotropic thermal parameters to a final $R(F) = 0.0486$ and $Rw(F) = 0.0533$. The final difference was essentially featureless, the larger residual peak being 0.24 e/Å^3.

Selected bond distances and angles are collected in Table 2. Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Centre.

STERIC EFFECTS AND GEOMETRICAL DISTORTIONS ON A NEW SERIES OF COBALT(II) ENTWINED COMPLEXES: STABILIZATION OF LOW VALENT OXIDATION STATES, COBALT(I) AND COBALT(0) COMPLEX SPECIES

MD. ATHAR MASOOD and P. S. ZACHARIAS*

School of Chemistry, University of Hyderabad, Hyderabad-500 134, India

(*Received* 13 *August* 1990; *accepted* 10 *December* 1990)

Abstract—Cobalt(II) complexes of 2,9-disubstituted and 2-monosubstituted 1,10-phenanthrolines by phenyl moieties containing *ortho* substituents were prepared and investigated by electronic spectral and electrochemical methods. Larger *ortho* substituents are found to cause more tetrahedral distortions, while the absence of substitution at the 9-position of the phenanthroline leads to smaller distortions. The tetrahedral distortion imposed by the bulkiness of the ligands and the weakly interacting forces mediated through the *ortho* substituents of the phenyl with the central metal ion influences the electrochemical reductions and also leads to stabilized cobalt(I) and cobalt(0) complex species.

Ligands such as 1,10-phenanthroline (phen) and its substituted derivatives are known to form stable complexes with transition metal ions in their normal valencies and low valence states. The 2,9-disubstitution imposes a strain in the molecule due to steric crowding. Due to this the complexes will be constrained to form a pseudo-tetrahedral/tetrahedral geometry with a $M(N—N)_2$ chromophore environment. Recently, it has been reported that catenands derived from 2,9-di(*p*-methoxyphenyl)-1,10-phen are more suited to stabilize low oxidation states, and nearly perfect electrochemical reversibility could be achieved for the redox couples. This is attributed to the topography (two entwined units) and the topology (interlocked rings) of the ligand system. On the other hand, copper(I) complexes of 2,9-di(*p*-methoxyphenyl)-1,10-phen undergo electrochemical reduction followed by rapid dissociation to copper metal and free ligand.[1] Electrochemically these complexes are irreversible.

It was reported earlier from our laboratory that copper(I) complexes of 2,9-di(*o*-substituted phenyl)-1,10-phen show electrochemical reversibility for the Cu^{1+}/Cu^0 redox process[2] comparable with the electrochemical reversibility of the copper(I) catenate. The ligands which are soft (π-acceptors) assist in the stabilization of lower valent oxidation states, while the entwining nature of the ligands, together with the large geometrical distortions arising from the *ortho* substituents of the phenyl ring (of the ligand system), are responsible for the electrochemical reversibility of the Cu^+/Cu^0 redox couple, in which the copper(0) complex species obtained was still found to be entrapped without undergoing any dissociation into the metal atom and free ligand. Furthermore, we have also investigated the relationship between the common ligand environment and the different valence states of the copper metal and the geometrical distortions in the context of the electron transfer. Encouraged by the results on copper(I) and copper(II) complexes, it seemed appropriate to investigate the stability and electrochemical response of cobalt(II) complexes of these ligands. The results of our investigation on these complexes are presented and discussed in the following sections.

EXPERIMENTAL

Materials

All the solvents were of reagent grade and distilled either over CaH_2 or Na-wire and stored over molecular sieves prior to use. 1,10-Phenanthroline

* Author to whom correspondence should be addressed.

(E. Merck), 2-bromoanisole, 2-bromotoluene and *o*-phenetidine were obtained from Fluka and used as supplied. *o*-Phenetidine was converted to 2-bromoethoxybenzene by the usual method of diazotization followed by coupling with cuprous bromide.

Preparation of the ligands

The ligands were prepared according to a procedure described earlier.[2] These ligands are 2,9-di(*o*-tolyl)-1,10-phen (dtphen), 2,9-di(2-methoxyphenyl)-1,10-phen (dmophen), 2,9-di(2-ethoxyphenyl)-1,10-phen (deophen), 2-(2-tolyl)-1,10-phen (tphen) and 2-(2-ethoxyphenyl)-1,10-phen (eophen).

Preparation of the complexes

The $[Co(L)_2](ClO_4)_2$ and $[Co(L')_2](ClO_4)_2]$ type complexes (where L and L′ are disubstituted and monosubstituted phen ligands, respectively) were prepared by the following general procedure:

To the respective ligands (2.1 mmol) dissolved in CH_2Cl_2 (5 cm^3), an acetone solution (5 cm^3) of $Co(ClO_4)_2 \cdot 6H_2O$ (1 mmol) was added while stirring. In the case of the dtphen ligand, a violet solution with green fluorescence was obtained, and for all other ligands yellow solutions were obtained. These solutions were reduced in volume when precipitation occurred. The $[Co(dtphen)_2]^{2+}$ complex was recrystallized from hexane–benzene (4 : 1 volume ratio) and obtained as beautiful violet–green crystals. The other complexes were recrystallized from hexane–CH_2Cl_2 (4 : 1) and obtained as yellow powders. The generalized structure of these types of complexes are shown in Fig. 1.

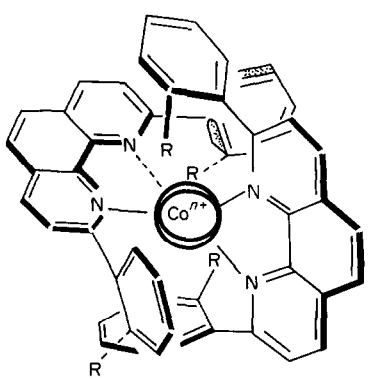

Fig. 1. Generalized structure of the bis[2,9-di(*o*-substituted phenyl)-1,10-phenanthroline] cobalt(II) complexes.

Preparation of $[CoLCl_2]$ *and* $[CoL'Cl_2]$ *complexes*

To the respective ligands (1.1 mmol) in CH_2Cl_2–EtOH (1 : 4, 5 cm^3) was added an ethanolic solution (5 cm^3) of $CoCl_2 \cdot 6H_2O$ (1 mmol) and this was stirred for 30 min. A large proportion of the solvent was allowed to evaporate at room temperature and then acetone (10 cm^3) was added and stirred vigorously, and thereby the complexes precipitated out. These were crystallized from CH_2Cl_2–hexane (1 : 4) and obtained as dark blue or dark green powder to crystalline compounds.

Physical measurements

The C, H and N analyses were carried out on a Perkin–Elmer 240C elemental analyser. Conductivity measurements were carried out on a CM 82 T Elico Model conductivity meter at 25°C in nitromethane. Vibrational spectra were recorded as KBr discs in the range 4000–200 cm^{-1} on a Perkin–Elmer 283 IR spectrophotometer. Electronic spectra were recorded with a Perkin–Elmer Lambda 3B UV–vis spectrophotometer in acetonitrile using 1×10^{-3} M solutions for the visible range and 1×10^{-5} M solutions for the UV range. Magnetic susceptibilities were measured on a Bruker BM 6 magnet with a Faraday magnetic balance. $HgCo(NCS)_4$ was used as calibrant. Cyclic voltammetric (CV) and differential pulse voltammetric (DPV) studies were carried out on a PAR electrochemistry system consisting of a 174 A polarographic analyser and a single compartment cell. Solutions of the complexes were 1×10^{-3} M in acetonitrile. In all the experiments the supporting electrolyte was 0.1 M tetraethylammonium perchlorate (TEAP) which was prepared as previously described,[3] recrystallized twice from a H_2O–MeOH mixture and dried *in vacuo* at 40°C. All experiments were carried out under dry nitrogen at 27 ± 1°C in a three-electrode configuration with a hanging mercury drop electrode (HMDE) as the working electrode, a platinum wire as the auxiliary electrode and a standard calomel electrode (SCE) as the reference electrode. All potentials are referred to vs the SCE and are uncorrected for liquid junction potential.

RESULTS AND DISCUSSION

Complexes of the types $[Co(L)_2]^{2+}$, $[Co(L')_2]^{2+}$, $[CoLCl_2]$ and $[CoL'Cl_2]$, where L = 2,9-di(*o*-substituted phenyl)-1,10-phen and L′ = 2-mono(*o*-substituted phenyl)-1,10-phen ligands, were prepared and investigated. These complexes have been characterized by elemental analyses and spectral

methods. Ligands L and L′ are abbreviated depending on the *ortho* substitution of the phenyl moiety and details are given in the Experimental. $[Co(L)_2]^{2+}$ and $[Co(L')_2]^{2+}$ type complexes show conductivity in nitromethane in the range 130–160 Ω^{-1} cm^2 mol^{-1}. These values are typical for 1 : 2 electrolyte.[4] Their IR spectra show a strong absorption band at about 1090 cm^{-1}, characteristic of an ionic perchlorate group.[5] The covalently bonded perchlorate group, on the other hand, shows two distinct IR peaks at *ca* 1030 and 1310 cm^{-1}. These bands are not observed in the complexes, therefore supporting the ionic nature of the perchlorate group. The C=N stretching band appears in the region 1490–1505 cm^{-1}. This is characteristic of the nitrogen atoms of the phen coordinating to the metal. The halide complexes of cobalt(II) do not show any electrical conductance, thus exhibiting the non-ionic nature of these complexes in conformity with their structures.

It was earlier reported that Co—$(Cl)_2$ stretches in the 300–350 cm^{-1} region for $[CoLCl_2]$ complexes.[6] All the cobalt(II) halide complexes exhibit a sharp band in that region. The analytical and spectral data are tabulated in Table 1.

The $[Co(dtphen)_2]^{2+}$ complex is found to exhibit electronic absorption bands in the visible region. In the spectra, a broad band at 590 nm with a shoulder at *ca* 575 nm and a small band at 534 nm occur, which are characteristic of distorted tetrahedral geometry with the bands decreasing in intensity in that order. Likewise, $[Co(tphen)_2]^{2+}$ exhibits bands at 543, 510 and 482 nm thus indicating less tetrahedral distortion. The absence of similar absorption bands in $[Co(dmophen)_2]^{2+}$, $[Co(deophen)_2]^{2+}$ and $[Co(eophen)]^{2+}$, which are expected to have distorted tetrahedral geometry, is due to the intramolecular charge-transfer interaction (methoxy or ethoxy phenanthrolines) to the low energy bands found in the absorption spectra.[7] Similar interactions and the consequent absence of visible absorption bands of tetrahedral geometry have been reported in the case of $[Co(dap)_2](ClO_4)_2$, where dap = 2,9-di(*p*-methoxyphenyl)-1,10-phen.

$[CoLCl_2]$ and $[CoL'Cl_2]$ complexes show absorption bands in the visible region characteristic of tetrahedral geometry. The spectra contain a broad band with two components at about 670 and 640 nm and a sharp band at 570 nm. The intensity is greater for the 670 nm band than the 570 nm band. Similar spectral features were observed for $[Co(dmp)Cl_2]$, where dmp = 2,9-dimethyl-1,10-phen, which has a tetrahedral geometry.[8] Effective magnetic moment values of cobalt(II) complexes at room temperature are in the range 4.5–5.0 μ_B,* which is as expected for complexes of tetrahedral/pseudo-tetrahedral geometry and is due to the orbital contribution to the spin-only value.

Electrochemical, CV and DPV data were obtained in acetonitrile solvent. Both positive and negative potential ranges were examined. All ligands are found to be electrochemically inactive up to −1.90 V. CV profiles at various scan rates and repeated scans were also investigated. All the cobalt(II) complexes of the type $[Co(L)_2]^{2+}$ and $[Co(L')_2]^{2+}$ show two perfectly reversible, one-electron reduction steps in the negative potential range. For the $[Co(dtphen)_2]^{2+}$ complex the successive reductions occur at −0.58 (Co^{2+}/Co^{1+}) and −1.26 V (Co^{1+}/Co^0). For the $[Co(dmophen)_2]^{2+}$ and $[Co(deophen)_2]^{2+}$ complexes the values are at more negative potentials. The ΔE_p values are *ca* 60 mV and the $-i_c/i_a$ ratio is *ca* 1 for both sets of redox peaks. Potential values do not show any shift at various scan rates. DPV technique was also used to determine the E_p values, which were in good agreement with the CV data. Similar comparisons can be drawn between $[Co(tphen)_2]^{2+}$ and $[Co(eophen)_2]^{2+}$, but the Co^{2+}/Co^{1+} couple is found at more negative potentials and the ΔE_p values are about 70–80 mV. The relevant electrochemical data is collected in Tables 2 and 3 and the CV profiles of the representative complexes are shown in Fig. 2.

Cobalt(II) catenate, obtained from interlocking catenands derived from dap units, have successive redox couples at −0.60 and −1.30 V. For $[Co(dap)_2]^{2+}$ these couples occur at −0.60 and −1.27 V. The only significant difference between catenate and its open analogue is a slightly wider potential stability range for the monovalent cobalt species. This difference is explained on the basis of the topography and the topology of the catenate. It is also a well established fact that $E_{1/2}$ moves towards more positive potentials with an increase in tetrahedral distortion for the copper(II) complexes.[9] Extending this argument, it can also be pointed out that the octahedral cobalt(II) complexes will have more negative reduction potentials than the tetrahedral complexes.[10,11] The redox potential for the Co^{2+}/Co^{1+} couples in the complex $[Co(dtphen)_2]^{2+}$ is more positive by *ca* 50 mV than that of the corresponding redox peak of the cobalt (II) catenate. This is to be expected since this complex is less distorted and not as stabilized as the catenate complex. However, for $[Co(dmophen)_2]^{2+}$ and $[Co(deophen)_2]^{2+}$ the corresponding values are more negative than the catenate complex. Thus the

* One BM signifies 9.27×10^{-24} A m^2.

[a] $n = 90.4/W_{1/2}$.

potential stability range for cobalt(I) complex species has decreased in the two complexes. These two complexes should be tetrahedrally more distorted because of the presence of bulky *ortho* substituents, and hence should show a less negative potential. The shift of the potential to more negative values thus indicates the stabilization of the cobalt(II) oxidation state, which is related to the weak interaction of the methoxy or ethoxy of the *ortho* substituent of the phenyl ring of the substituted phen with the cobalt metal ion. This weak interaction has already been explored for the iron(II) and copper(II) complexes of the above ligands. It has also been pointed out that the approach of —OMe towards the central metal ion is less hindered than that of —OEt, and that the tetrahedral distortion in the complexes involving deophen is comparable with that of catenate. Hence cobalt(II) in $[Co(dmophen)_2]^{2+}$ is more stabilized than in $[Co(deophen)_2]^{2+}$, though tetrahedrally less distorted than the latter.

Furthermore, it can be seen from the electrochemical data that the redox potential values for the Co^{1+}/Co^{0} couple have not changed in comparison with cobalt(II) catenate, still, there is a slight negative potential shift for $[Co(dmophen)_2]^{1+}$ and $[Co(deophen)_2]^{1+}$ complex species. Although the stabilization range for cobalt(I) has narrowed, the cobalt(I) species is nevertheless highly stabilized and can either revert back to cobalt(II) on oxidation at the electrode surface or can further reduce to form the cobalt(0) complex species which itself it found to be stabilized. This effect can be seen clearly in CV profiles where two perfectly reversible one-electron processes with ΔE_p values of *ca* 65 mV are observed, for any of the scan rates, and there is no decomposition of either of the species as the current cathodic and anodic peaks remain the same in multiple scans. The term "stabilized species" infers that the reduced ion or the metal species is still bound to the $(N—N)_2$ chromophore and does not dissociate into the free ligand and the metal species. Again it can be said that the —OMe at the *para* position (as in the dap ligand) will not interact with the central metal ion. Furthermore, as can be seen from the reversibility of the reduction processes, the electron transfer is not accompanied by any structural reorganization either before or after the reduction and it is reasonable to infer that all the oxidation states of cobalt, viz. (II), (I), (0), involve the tetrahedral disposition of the ligand.

Also, comparison of the electrochemical properties with the previously reported data for the cobalt bipyridyl or phen complexes[10–14] shows here, a strong stabilization of all the reduced states. Other sterically constrained polyimine cobalt compounds also lead to stabilized monovalent complexes.[15–17]

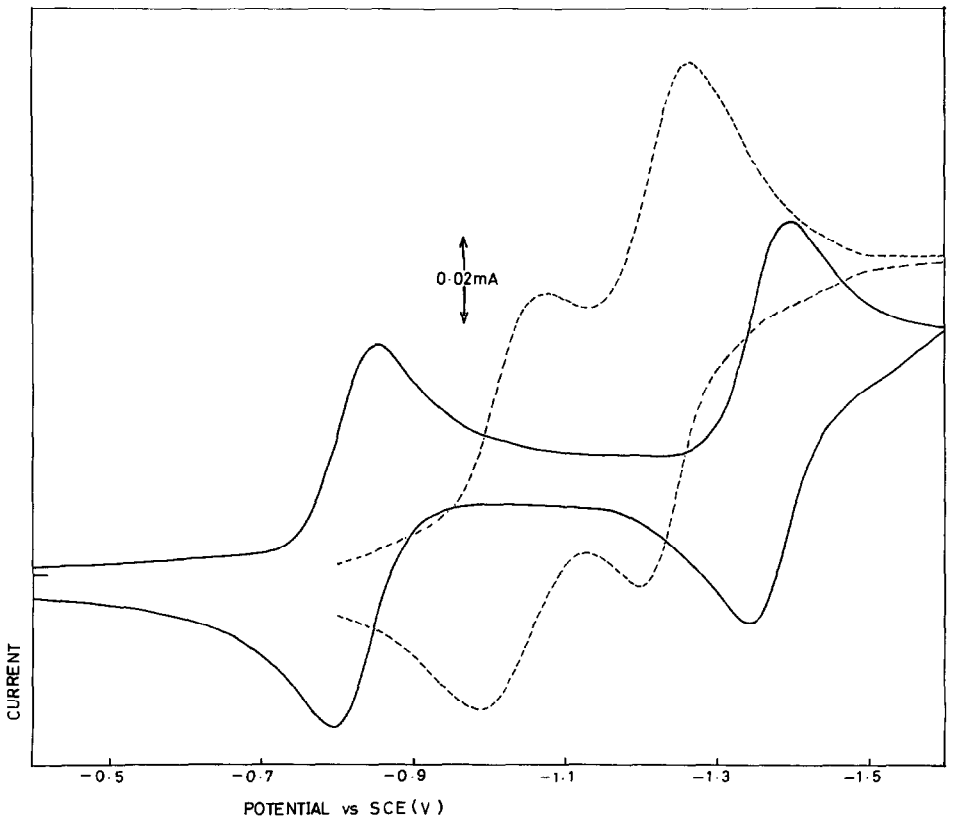

Fig. 2. Cyclic voltammetric profiles of $[Co(dmophen)_2]^{2+}$ (——) and $[Co(tphen)_2]^{2+}$ (– – – –) at a scan rate of 0.10 V s^{-1}.

For instance, the redox potential of the $Co(dmbp)_2^{2+/1+}$ couple (dmbp = 6,6′-dimethyl-2,2′-bipy) is −0.63 V, showing that in the above case of the complexes although there is no particular topography effect, stabilization is the consequence of —OMe, —OEt mediated interactions and geometrical distortions.

Remarkable also is the drastic structural effect of the ligands on the Co^{3+}/Co^{2+} redox potential, whereas bipy or phen complexes of cobalt(II) can very easily be electrochemically oxidized to octahedral cobalt(III),[18,19] the redox potential value of the Co^{3+}/Co^{2+} couple being close to 0.00 V, no oxidation peak is observed for the present complexes. The destabilization effect on this couple due to entwined ligands and *ortho* substituents, as well as due to a poor ligand field of tetrahedral geometry, is thus very large.

The monosubstituted cobalt(II) phen complexes show similarly two reversible peaks, but the peak positions for the Co^{2+}/Co^{1+} couple have moved towards higher negative potentials, *ca* −1.10 V, which, as was described earlier, is a result of less tetrahedral distortion due to the absence of substitution at the 9-position of phen. Between $[Co(eophen)_2]^{2+}$ and $[Co(tphen)_2]^{2+}$ cobalt(II) is stabilized by about 80 mV and is consistent with the interpretation of a weak intramolecular interaction of the *ortho* substituent of the phenyl of 1,10-phen with the central metal ion. Comparing this stabilization difference of 80 mV with the difference obtained between the disubstituted complexes, *ca* 270 mV, clearly demonstrates the extent of stabilization which occurs due to disubstituted ligands containing electron donor sites as *ortho* substituents in the form of alkoxy groups.

The $[CoLCl_2]$ and $[CoL'Cl_2]$ complexes are found to give either quasi-reversible or totally irreversible peaks and are thus not significant in the stabilization of the lower valent oxidation states. This also signifies that electrochemical reversibility depends on a type of chromophore environment where the central metal ion is enveloped.

Thus electrochemical reversibility, hence the stabilization of various valence states of cobalt, viz. 2, 1, 0, can invariably be accounted for as due to the π^*-nature of the ligands, the steric impositions which lead to tetrahedral disposition of the ligands around the central metal ion, the same stereochemistry in all the reduced states, and largely to

the weak interaction of the *ortho* substituents of the phenyl of 1,10-phen.

PEROXO COMPLEXES OF ZIRCONIUM(IV), THORIUM(IV), MOLYBDENUM(VI), TUNGSTEN(VI) AND URANIUM(VI) CONTAINING TWO QUADRIDENTATE ONNO SCHIFF BASES

M. T. H. TARAFDER* and A. R. KHAN

Department of Chemistry, University of Rajshahi, Rajshahi, Bangladesh

(*Received* 29 *October* 1990; *accepted* 10 *December* 1990)

Abstract—Some new peroxo complexes of molybdenum, tungsten, uranium, zirconium and thorium containing quadridentate, dinegative Schiff base ligands have been synthesized and characterized. The Schiff bases $C_{20}H_{14}N_2O_2H_2$ and $C_{14}H_{10}N_2O_2H_2$ were derived from the condensation of *o*-phenylenediamine or hydrazine hydrate with salicylaldehyde, respectively. The Schiff bases undergo deprotonation, while complexation having ONNO donor sequences producing complexes of compositions $[M(O)(O_2)(ONNO)]$ and $[M'(O_2)(ONNO)]$ [M = Mo^{VI}, W^{VI} and U^{VI}; M′ = Zr^{IV} and Th^{IV}; ONNO = $C_{20}H_{14}N_2O_2^{2-}$ and $C_{14}H_{10}N_2O_2^{2-}$]. The chelate effect of the quadridentate ligands stabilizes the metal–peroxo moiety which prevents oxygen transfer reactions to both organic and inorganic substrates. The σ-donor nature of the quadridentate ligands influences the mode of coordination of the peroxo moiety. The frequency of the ν_1 mode of the $M(O_2)$ grouping decreases with an increase in the atomic number of the metals in a particular group.

The incorporation of ancillary ligands with different donor properties into metal peroxides gives complexes which exhibit intriguing lability differences. The chemistry of the peroxo complexes has received considerable attention in recent years,[1–12] mainly because they are sources of active oxygen atoms and can be used as stoichiometric, as well as catalytic, oxidants for organic and inorganic substrates.[5–12] We have successfully employed peroxo complexes to generate glycerine from allyl alcohol which is, indeed, an industrial aspect of this project.[8] However, the metal–peroxo moiety is greatly stabilized when tridentate or quadridentate auxiliary ligands are used.[9–12] To examine this further, we have extended our study to peroxo complexes of different elements of Groups 4A and 6A containing two quadridentate, dinegative ligands. We report here the synthesis of these complexes and studies on their potential as oxygen transfer reagents. An attempt has also been made to study the effect of the size of the metal ion and the electronic nature of the quadridentate ligands on the ν_1(O—O) modes of the complexes in their IR spectra.

EXPERIMENTAL

IR spectra (as KBr discs) were recorded with a Pye–Unicam SP3-300 IR spectrophotometer. Conductivities of 10^{-3} M solutions of the complexes in dimethyl sulphoxide (DMSO) were measured at 25°C using a WPA CM35 conductivity meter and dip-type cell with platinized electrodes.

Reagents

All chemicals used were reagent grade and were used as supplied by E. Merck.

Analyses

Carbon, hydrogen and nitrogen analyses were carried out by Microanalytical Services at the University of St. Andrews, Scotland.

Preparation of ligands

Preparation of $C_{20}H_{14}N_2O_2H_2$. Salicylaldehyde (1.22 g, 0.01 mol) in absolute ethanol (30 cm^3) was added to a solution of *o*-phenylenediamine (0.54 g, 0.005 mol) in the same solvent (20 cm^3). The mixture

was boiled down to *ca* 25 cm^3 and cooled to room temperature. The orange–red crystals which separated were washed with ethanol. Melting point 142–144°C. (Found: C, 75.8; H, 4.9; N, 8.8. Calc. for $C_{20}H_{14}N_2O_2H_2$: C, 75.9; H, 5.1; N, 8.9%.)

Preparation of $C_{14}H_{10}N_2O_2H_2$. Salicylaldehyde (1.22 g, 0.01 mol) in absolute ethanol (30 cm^3) was added to a solution of hydrazine hydrate (0.25 g, 0.005 mol) in the same solvent (15 cm^3). The mixture was heated on a water bath to reduce the volume to *ca* 20 cm^3 and cooled to room temperature. The yellow crystals were separated and washed with ethanol. Melting point 209–211°C. (Found: C, 69.9; H, 4.9; N, 11.7. Calc. for $C_{14}H_{10}N_2O_2H_2$: C, 70.0; H, 5.0; N, 11.7%.)

Preparation of complexes

General method for the preparation of complexes **1**, **3** *and* **4**: $[M(O)(O_2)L]$ ($M = Mo^{VI}$ *and* W^{VI}; $L = C_{20}H_{14}N_2O_2^{2-}$ *or* $C_{14}H_{10}N_2O_2^{2-}$). A suspension of MO_3 (0.017 mol) in 30% H_2O_2 (60 cm^3) was stirred overnight at 45–50°C. This was filtered and to the clear filtrate was added a solution of L (0.017 mol) in hot ethanol (150 cm^3). The mixture was stirred whilst cooling at the same time in an ice–salt bath. A yellow precipitate appeared, which was washed successively with water and ether and dried *in vacuo* over P_4O_{10}.

Preparation of **2** *and* **5**: $[U(O)(O_2)L]$ (L = $C_{20}H_{14}N_2O_2^{2-}$ *and* $C_{14}H_{10}N_2O_2^{2-}$). To a solution of $UO_2(NO_3)_2 \cdot 6H_2O$ (0.006 mol) in ethanol (35 cm^3), a solution of L (0.006 mol) in the same solvent (100 cm^3) and then 30% H_2O_2 (35 cm^3) were added. The product was separated and stored as above.

Preparation of complexes **6** *and* **7**: $[M(O_2)(C_{20}H_{14}N_2O_2)]$ ($M = Zr^{IV}$ *and* Th^{IV}). A solution of $M(NO_3)_4 \cdot 6H_2O$ (0.005 mol) in water (40 cm^3) was added to a solution of $C_{20}H_{14}N_2O_2H_2$ (0.005 mol) in ethanol (100 cm^3), followed by the addition of 30% H_2O_2 (30 cm^3). The product was separated and stored as above.

Attempted reactions of **1** *and* **4** *with allyl alcohol and* **5–7** *with triphenylphosphine and triphenylarsine, respectively*

Refluxing of **1** with allyl alcohol in a 1 : 1 molar ratio in tetrahydrofuran (THF) medium for 48 h failed to produce any reaction; **1** was recovered unchanged.

Refluxing of **4** with allyl alcohol in the presence of a large excess of 30% H_2O_2 in dioxane medium for 48 h at 90°C also failed to produce any reaction; **2** was recovered unchanged.

Refluxing of **5–7** with equimolar quantities of triphenylphosphine and triphenylarsine, respectively in THF for 48 h also failed to produce any reaction; **5–7** were recovered unchanged.

RESULTS AND DISCUSSION

The analytical data are presented in Table 1. The molar conductance values show that all of the com-

[a] Relative band intensities are denoted by vs, s, m, w and br, representing very strong, strong, medium, weak and broad, respectively.

plexes are non-electrolytes in DMSO indicating that the chelate anions are covalently bonded in all the cases. These data are consistent with seven-fold coordination of molybdenum(VI), tungsten(VI) and uranium(VI) complexes, while the zirconium(IV) and thorium(IV) analogues are hexacoordinated.

IR spectral data are presented in Table 2. The ligands $C_{20}H_{14}N_2O_2H_2$ and $C_{14}H_{10}N_2O_2H_2$ are potentially quadridentate, coordinating via the two methine nitrogen atoms and oxo anions generated during complexation. The free Schiff bases produce ν(OH) bands (Table 2) which disappear in the complexes indicating deprotonation at the —OH end, thus providing an oxo coordination. This is also apparent from the non-electrolytic nature of the complexes. That the ligands deprotonate at the —OH end is also evident from the appearance of ν(M—O′) (O′ = oxygen in organic ligands) modes at 360–435 cm^{-1} (Table 2) in the far-IR spectra of the complexes.[4–11] The ν(C=N) bands observed at 1560 and 1570 cm^{-1} for $C_{20}H_{14}N_2O_2H_2$ and $C_{14}H_{10}N_2O_2H_2$, respectively, are shifted to lower frequencies (Table 2) upon complexation, indicating coordination by the methine nitrogen atoms. This is also apparent from the ν(M—N) modes at 260–350 cm^{-1} in the far-IR spectra of the complexes.[4–11] The ν(N—N) band[13] observed at 985 cm^{-1} for free $C_{14}H_{10}N_2O_2H_2$ is shifted to lower frequencies in **3–5**, indicating that both the azo methine nitrogen atoms are coordinated. Complexes **1–5** show diagnostic bands at 910–925 cm^{-1} attributable to ν(M=O) modes.[4,10,11] The metal–peroxo grouping (local C_{2v} symmetry) gives rise to three IR and Raman-active vibrational modes. These are predominantly O—O stretching (ν_1), the symmetric M—O stretch (ν_2) and the antisymmetric M—O stretch (ν_3). The characteristic ν_1(O—O) modes of **1–7** appear at 795–840 cm^{-1} (Table 2). In particular, the ν_1 mode decreases upon passing from molybdenum complexes (**1** and **3**) (840 and 845 cm^{-1}) to the corresponding tungsten complex (**4**) (825 cm^{-1}), which is then further decreased in the uranium peroxo complexes (**2** and **5**) (790 and 795 cm^{-1}). The ν_1 mode of the thorium peroxo complex (**7**) (805 cm^{-1}) appears at a lower frequency than the zirconium analogue (**6**) (820 cm^{-1}). The present study thus clearly reveals that for the $M(O_2)$ grouping, the ν_1(O—O) modes decrease with an increase in the atomic number of metals in a particular group. Again in the present examples, it is discernible that the ν_1 modes of molybdenum, tungsten, uranium, zirconium and thorium complexes appear at lower frequencies than the peroxo complexes of these metals containing monodentate, bidentate and tridentate auxiliary ligands.[3–11] This is presumably due to a greater charge cancellation of the metal centres by the quadridentate σ-donor ligands, thereby causing a weaker coulombic interaction in the M^{n+}—O_2^{2-} ($n = 4$ or 6) moiety in the present examples. The present peroxo complexes display ν_3 and ν_2 modes at 602–670 and 520–560 cm^{-1}, respectively (Table 2).

Reactivity

The present peroxo complexes were found to be inert towards oxidation of olefin and other substrates. Complexes **1** and **4** failed to oxidize allyl alcohol even when refluxing at 90°C was continued for 48 h. Compounds **5–7** were also unreactive towards phosphine and arsine. These negative results outline the enhanced stability of the metal–

peroxo moiety in the presence of quadridentate, dinegative chelating ligands which precludes oxygen transfer reactions. We also observed a similar stabilizing effect of the peroxo complexes containing various multidentate organic ligands.[4–6, 9–11]

SYNTHESIS AND CHARACTERIZATION OF SOME METAL COMPLEXES CONTAINING A QUADRIDENTATE NSSN AND A SEXIDENTATE ONSSNO LIGAND

M. RAHMAN, M. AKBAR ALI,* P. BHATTACHARJEE and M. NAZIMUDDIN

Department of Chemistry, Chittagong University, Bangladesh

(*Received* 16 *July* 1990, *accepted* 13 *December* 1990)

Abstract—New metal complexes of general formulae $M(NSSN)X_2 \cdot xH_2O$ (M = Ni, Cu; NSSN = quadridentate sulphur–nitrogen ligand; X = Cl, Br, NCS or I; $x = 0$ or 2) and M(ONSSNO) [M = Ni, Cu, Zn, Cd; $ONSSNO^{2-}$ = anion of sexidentate ligand formed from salicylaldehyde and α,α′-xylene-bis(N-methyldithiocarbazate)] have been prepared and characterized by conductance, magnetic and spectroscopic measurements. The nickel(II) complexes of both the ligands are high-spin and octahedral. Tetragonally distorted octahedral structures are assigned to the copper(II) complexes. In the presence of the sexidentate ligand, cobalt(II) is readily air-oxidized to form a cobalt(III) complex, Co(ONSSNO)Cl, which is spin-paired and octahedral.

There is continuing interest in the coordination chemistry of both open-chain and macrocyclic quadridentate ligands containing the N_2S_2 donor set.[1–4] Copper(II) complexes of these types of ligands have attracted considerable interest because of the occurrence of the CuN_2S_2 chromophore in blue copper proteins such as plastocyanin.[5,6] In this paper we report the synthesis and characterization of some complexes of two new multidentate sulphur–nitrogen chelating agents containing the N_2S_2 and $O_2N_2S_2$ donor sets.

EXPERIMENTAL

Physical measurements

All physical measurements and analytical procedures were similar to those described previously.[7]

Preparation of the N_2S_2 *ligand, α,α′-xylene-bis(N-methyldithiocarbazate)*

An ice-cold solution of methylhydrazine (1.84 g) in ethanol (25 cm^3) was added slowly and with constant stirring to a solution of potassium hydroxide (2.24 g) in a 9:1 mixture of ethanol and water (100 cm^3). Carbon disulphide (3.04 g) was added dropwise with vigorous stirring of the reaction mixture. The temperature of the reaction mixture was kept below 10°C during the entire period of addition of carbon disulphide. A solution of α,α′-xylene-dibromide (5.28 g) in ethanol (100 cm^3) was added with stirring over a period of 40 min, during which time a white product appeared which was filtered off, washed with water and recrystallized from ethanol. Yield, 3.5 g; m.p. 164–165°C. Found: C, 41.6; H, 5.4; N, 16.3. $C_{12}H_{18}N_4S_4$ requires: C, 41.6; H, 5.2; N, 16.2%. Mass spectrum; $m/z = 346$ (M^+); ^1H NMR ($CDCl_3$): 3.40, 3.65 (N—CH_3), 4.30, 4.52 (S—CH_2—), 5.55 (—NH_2), 7.20–7.40 (aromatic).

Preparation of the sexidentate $O_2N_2S_2$ *ligand*

A solution of α,α′-xylene-bis(N-methyldithiocarbazate) (3.46 g) in dry ethanol (250 cm^3) was added to a solution of salicylaldehyde (2.40 g) in the same solvent (50 cm^3). The mixture was heated under reflux for a period of 4 h and thereafter left to cool. The product which had formed was collected by filtration and recrystallized from acetone. Yield, 4.5 g; m.p. 217°C. Found: C, 56.3; H, 4.6; N, 10.2. $C_{26}H_{26}N_4S_4$ requires: C, 56.2; H,

4.7; N, 10.1%. ^{1}H NMR ($CDCl_3$): 10.28 (—OH), 3.64 (—NCH_3), 8.01 (—CH=N), 7.25–7.47 (aromatic), 4.41 (—SCH_2—).

General method for the preparation of $M(N_2S_2)X_2 \cdot xH_2O$ (M = Ni, Cu; X = NCS, I; $x = 0, 2$)

These were prepared by heating solutions of the appropriate metal salts with the ligand in ethanol in a 1 : 1 molar ratio and filtering out the precipitated complexes.

General method of preparation of $M(O_2N_2S_2)$ *and* $Co(O_2N_2S_2)Cl$

The ligand (1 mmol) dissolved in boiling acetone (50 cm^3) was mixed with the appropriate metal acetate (chloride in the case of cobalt) (1 mmol) in methanol (30 cm^3) and the mixture heated under reflux for *ca* 12 h. The volume of the reaction mixture was reduced to *ca* 30 cm^3, whereupon the product which had deposited was filtered off, washed several times with methanol followed by acetone.

RESULTS AND DISCUSSION

The ligand obtained by reacting α,α′-xylenedibromide with the potassium salt of N-methyldithiocarbazate can be structurally formulated as shown in Fig. 1. This formulation is supported by ^{1}H NMR, mass and IR spectroscopic data. The ligand can exhibit conformational isomerism due to hindered rotation about the partially double SC—N and SC—S bonds.[8] The ^{1}H NMR spectrum of the N_2S_2 ligand shows two signals for each —NCH_3 and —SCH_2— proton. Their 1 : 2 relative intensities suggest the presence of two conformers.

Although the signal due to the —NH_2 protons is not split, its broadness is in keeping with the presence of two isomers. The appearance of two signals for the —NCH_3— protons can tentatively be ascribed to the *cis–cis* and *trans–cis* conformers, by analogy, with similar compounds like N-methyl-S-methyldithiocarbazate,[8] thioureas[9] and thiocarbamate esters.[10]

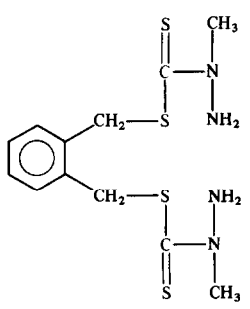

Fig. 1.

Reaction of nickel(II) salts with the ligand was found to be dependent on the nature of the anion being used. Thus, with nickel(II) nitrate, chloride and perchlorate salts the ligand failed to yield any complexes even after prolonged heating of the reaction mixture. However, reactions of nickel(II) iodide and thiocyanate with the ligand afforded stable complexes of general formula $M(N_2S_2)X_2$. This behaviour may be attributed to the symbiosis phenomenon.[11] According to the Ahrland–Chatt–Davies classification of metal complexes, the nickel(II) ion is termed as a fairly hard ion with a limited tendency to form bonds with soft thioether donors present in the ligand. However, in the presence of softer anions such as the iodide and thiocyanate, the hard nickel(II) is probably symbiotically motivated to act as a soft acceptor, thereby forming complexes with the present ligand. The hard Cl^-, ClO_4^- and NO_3^- ions cannot act in a similar manner and, therefore, no complexes are formed. With copper(II) salts, the ligand readily reacted giving complexes of formula $Cu(N_2S_2)X_2 \cdot 2H_2O$, which are non-electrolytes in DMF, indicating that the halide ions are coordinated to the copper(II) ion. The molar conductivity data of the nickel(II) complexes (Table 1) indicate that they are appreciably dissociated in DMF, but the conductance values are less than those found for 1 : 1 electrolytes. The IR spectrum of the thiocyanato complex, $Ni(N_2S_2)(NCS)_2$, shows a strong unsplit band at 2100 cm^{-1} indicating that the thiocyanate ions are coordinated to the nickel(II) ion as an N-bonded ligand.[12] The IR data in Table 2 also show that the $\nu_s(NH_2)$ and $\nu_{as}(NH_2)$ bands of the free ligand are shifted to lower frequencies in the spectra of metal complexes, indicating that the ligand is coordinated to the nickel(II) and copper(II) ions via the amino nitrogen atoms. The presence of ν(M—S) bands around 320 cm^{-1} in the spectra of the complexes suggests metal–sulphur bonding. The facts stated above indicate that the present ligand behaves as an N_2S_2 quadridentate chelating agent coordinating nickel(II) and copper(II) ions via the amino nitrogen and the two thioether sulphur atoms.

The nickel(II) complexes, $Ni(N_2S_2)X_2$ (X = NCS, I), are high-spin with room-temperature magnetic moments of 2.93 BM. Their electronic spectra (Table 2) show *d–d* bands which are typical of octa-

hedral or pseudo-octahedral nickel(II).[13] Unfortunately, the first band corresponding to the $^3A_{2g} \rightarrow {}^3T_{2g}(F)$ transition could not be measured due to the limitation of the spectrophotometer. However, the colour, magnetism and electronic spectra are consistent with their octahedral geometries.

The room-temperature magnetic moments of the copper(II) complexes, $Cu(N_2S_2)X_2 \cdot 2H_2O$ (1.81–1.87 BM), are normal for a $3d^9$ ion and their electronic spectra display a broad *d–d* band which probably contains all the transitions expected for a copper(II) ion in a tetragonal complex.

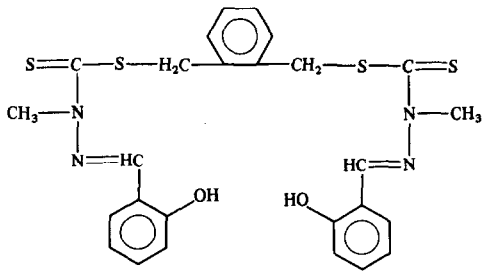

Fig. 2. $H_2ONSSNO$.

Complexes of the sexidentate ligand

The Schiff base obtained by condensation of α,α′-xylene-bis(N-methyldithiocarbazate) with salicylaldehyde may be represented by the structural formula shown in Fig. 2.

The structural formula shown in Fig. 2 is consistent with analytical and IR and ^1H NMR spectroscopic data. The electron impact mass spectrum of the compound does not display any peak due to the molecular ion, presumably due to its decomposition in the inlet tube of the spectrometer, but peaks at $m/z = 104$, 168 and 256 in the spectrum may be assigned to the $C_6H_4CH_2CH_2^{\cdot}$, $C_6H_4CH_2CH_2SS^{\cdot}$ and $C_6H_4CH_2CH_2SSCSCS^{\cdot}$ fragments, respectively, in agreement with the structure shown in Fig. 2.

Reaction of metal acetate salts with the Schiff base afforded microcrystalline compounds of empirical formula M(ONSSNO), which were found to be insoluble in most of the common non-polar solvents. They were, however, soluble in DMF, in which conductivity measurements were made. The conductivity data in Table 1 suggest that the complexes behave essentially as non-electrolytes. The Schiff base, therefore, must be coordinated to the metal ions as a dianionic ligand, which is also supported by the IR data. The IR spectrum of the free ligand shows the phenolic ν(OH) at 3420 cm^{-1} which is absent in the spectra of the complexes, supporting deprotonation of the ligand during complex formation. The ν(C=N) bands of the free ligand at 1620 cm^{-1} are lowered in the spectra of complexes indicating coordination by the azomethine nitrogen atoms.[14] The presence of ν(M—S)[15] in the range 310–320 cm^{-1} in the spectra of the complexes supports coordination by the sulphur atoms. However, since the ν(C=S) bands[16] of the free ligand at 790 cm^{-1} are not affected in the spectra of the complexes, it is assumed that the thione sulphur atoms do not participate in coordination.

The nickel(II) complex, Ni(ONSSNO), is high-spin with a room-temperature magnetic moment of 2.89 BM. Its solid-state electronic spectrum in the range 1000–200 nm shows bands at 874, 461, 429 and 300 nm. Of these, the bands at 874 and 461 nm may be assigned to the $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions, respectively, of octahedral nickel(II).[13] The copper(II) complex is brown in colour with a room-temperature magnetic moment of 1.81 BM, normal for a copper(II) ion in a magnetically dilute environment. Its electronic spectrum shows a broad *d–d* band at 600 nm which can be assigned to all the transitions expected for a tetragonal copper(II). Reaction of cobalt(II) chloride with the ligand yields a cobalt complex of composition $Co(O_2N_2S_2)Cl \cdot H_2O$, which behaves as a non-electrolyte in DMF. Its diamagnetic nature (Table 1) suggests that it is a cobalt(III) complex. The ready oxidation of cobalt(II) salts in the presence of sulphur-containing ligands to yield cobalt(III) complexes has been well documented in the literature.[17] In the cobalt complex the ligand is most probably coordinated to the cobalt(III) ion in a pentadentate fashion with the chloride ion occupying the sixth coordination position. Its solid-state electronic spectrum contains bands at 600, 492 and 300 nm. Of these three bands, the first two may be assigned to the $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions, respectively, of octahedral cobalt(III). Because of its insoluble nature in most of the common polar and non-polar organic solvents, crystals suitable for X-ray crystallographic examination could not be obtained. The zinc and cadmium complexes are yellow in colour, probably due to charge-transfer transitions of the type M → S. Their IR spectra are very similar to the nickel(II) complex indicating that they probably have octahedral geometries.

Acknowledgements—We acknowledge with thanks the assistance provided for this work by the IOCD. We also thank Professor M. S. Tempesta of the Chemistry Department, University of Missouri-Columbia, U.S.A., for the NMR and mass spectroscopic data and Professor S. Matlin of the Chemistry Department, City University of London, U.K., for the microanalytical data.

Abstract—Reductions of $Ru_2(CH_3COO)_4^+$ and $Co(C_2O_4)_3^{3-}$ by oxalato complexes of titanium(III) have been studied in $LiCF_3SO_3$ media of 1.0 mol dm^{-3} ionic strength. At 25°C and $[H^+]_f = 0.150$ mol dm^{-3}, $Ru_2(CH_3COO)_4^+$ and $Co(C_2O_4)_3^{3-}$ are reduced by $Ti(C_2O_4)_2^-$ with second-order rate constants of $(4.17 \pm 0.08) \times 10^3$ and $(3.20 \pm 0.05) \times 10^3$ dm^3 mol^{-1} s^{-1}, respectively. Both oxidants show no detectable reactivity towards $Ti(C_2O_4)^+$. Both reactions are base-catalysed. The magnitude of the rate constant for reduction of $Ru_2(CH_3COO)_4^+$ establishes an outer-sphere mechanism; the magnitude of the rate constant for $Co(C_2O_4)_3^{3-}$ indicates a substitution-limited inner-sphere mechanism.

The oxalate ion is often an efficient bridging ligand in ruthenium(III)–titanium(III)[1] and cobalt(III)–titanium(III)[2,3] electron-transfer (ET) reactions. In many of these cases the rate-determining step in the overall redox process is formation of the precursor complex.[4,5] The ET process for a dimeric ruthenium(II,III) oxidant containing an unusual orientation of the bridging oxalate ion[8] involves a more complicated mechanism.[6] Addition of the oxalate ion as a non-bridging ligand on titanium(III) accelerates Ti^{III}—Co^{III} ET reactions[3] and also Ti^{III}—Ru^{III} redox reactions.[7] The present study explores the effect of non-bridging oxalate (on both oxidant and reductant) on ET between titanium(III) and cobalt (III) and investigates the effect of non-bridging oxalate (on the reductant) on ET between a dimeric ruthenium(II,III) complex and titanium(III).

EXPERIMENTAL

Tetrakis(μ-acetato)diruthenium(II,III) chloride, $Ru_2(CH_3COO)_4Cl$, was synthesized as previously described.[8] Elemental analysis[9] and molar extinction coefficient ($\varepsilon = 695$ dm^3 mol^{-1} cm^{-1} at 425 nm) agreed with expectations.[8] Potassium tris-oxalatocobaltate(III), $K_3Co(C_2O_4)_3$, was prepared according to the method of Bailar and Jones.[10] Its molar extinction coefficients at 425 and 285 nm ($\varepsilon = 232$ and 1440 dm^3 mol^{-1} cm^{-1}, respectively) are in reasonable agreement with literature values.[11] Emerald green needles were stored in a bottle wrapped with aluminium foil.

Titanium(III) solutions were prepared under nitrogen as described.[1,12,13] The absorbance maximum of Ti^{3+} at 504 nm in CF_3SO_3H solutions ($\varepsilon = 3.87$ dm^3 mol^{-1} cm^{-1}) agrees with the literature.[12] Concentrations determined by titration of aliquot solutions with dichromate ion and those determined spectrophotometrically agreed within 5%. Standardized solutions were kept under nitrogen in a refrigerator. Oxalato complexes of titanium(III) were prepared immediately before reaction by the method of Chaudhuri and Diebler,[14] adding oxalic acid solution to aqueous solutions of titanium(III). Addition of oxalic acid to a solution of Ti^{3+} changed the colour of the solution from purple to yellowish-brown. UV–vis spectra showed peaks at

* Authors to whom correspondence should be addressed.

382 nm and 400 nm at low and high oxalate concentrations, respectively. These agree well with literature values[14] for the formation of $Ti(C_2O_4)^+$ (380 nm, $\varepsilon = 86\ dm^3\ mol^{-1}\ cm^{-1}$) and $Ti(C_2O_4)_2^-$ (400 nm, $\varepsilon = 490\ dm^3\ mol^{-1}\ cm^{-1}$).

Rate measurements were made by following absorbance changes on a computer-linked Durrum stopped-flow spectrophotometer. All reactions were monitored under pseudo first-order conditions; titanium(III) was in at least 10-fold excess over the oxidants. Kinetic measurements were made at ionic strength 1.0 mol dm^{-3} ($LiCF_3SO_3$) and at $(25.0 \pm 0.1)°C$ in a thermostated water bath. Reactions were studied in a nitrogen atmosphere to avoid air-oxidation of titanium(III).

RESULTS

The stoichiometry of each reaction was determined by spectrophotometric titration: 1.0 mole of oxidant was consumed per mole of reductant in all cases.

Pseudo first-order rate plots obtained for both systems were linear for at least three half-times. The pseudo first-order rate constants, k_s, obtained from such plots were generally reproducible within 10%. The observed second-order rate constants, k_{obs}, were obtained by dividing k_s by the total titanium(III) concentration. These rate constants, listed in Tables 1 and 2, were found to increase with increasing free oxalate ion concentration, [L].

When oxalic acid, H_2L, is added to a Ti^{3+} solution of concentration [M], several equilibria occur:

$$H_2C_2O_4 \rightleftharpoons HC_2O_4^- + H^+ \quad K_1 = \frac{[H^+][HL]}{[H_2L]} \tag{1}$$

$$HC_2O_4^- \rightleftharpoons C_2O_4^{2-} + H^+ \quad K_2 = \frac{[H^+][L]}{[HL]} \tag{2}$$

$$Ti^{3+} + C_2O_4^{2-} \rightleftharpoons TiC_2O_4^+ \quad K_3 = \frac{[ML]}{[M][L]} \tag{3}$$

$$Ti(C_2O_4)^+ + C_2O_4^{2-} \rightleftharpoons Ti(C_2O_4)_2^-$$
$$K_4 = \frac{[ML_2]}{[ML][L]} \tag{4}$$

$$Ti(C_2O_4)_2^- + C_2O_4^{2-} \rightleftharpoons Ti(C_2O_4)_3^{3-}$$
$$K_5 = \frac{[ML_3]}{[ML_2][L]} \tag{5}$$

$$Ti^{3+} + HC_2O_4^- \rightleftharpoons Ti(HC_2O_4)^{2+}$$
$$K_6 = \frac{[MHL]}{[M][HL]}. \tag{6}$$

[a] Conditions: in 1.0 mol dm^{-3} CF_3SO_3Li; $T = (25.0 \pm 0.1)$°C; $[Co^{III}]_T = 1.60 \times 10^{-4}$ mol dm^{-3}; $[Ti^{III}]_T = 1.62 \times 10^{-3}$ mol dm^{-3}.
[b] $k_{obs} = k_s/[Ti^{III}]_T$; $[Ti^{III}]_T = [Ti^{3+}]_f + [TiOH^{2+}] + [TiOx^+] + [TiOx_2^-]$, $Ox = C_2O_4^{2-}$.

Ti^{3+} undergoes hydrolysis as

$$Ti^{3+} + H_2O \rightleftharpoons TiOH^{2+} + H^+$$

$$K_A = \frac{[MOH][H^+]}{[M]}. \quad (7)$$

$TiOH^{2+}$ reacts with oxidant, Ox [Ox—$Co(C_2O_4)_3^{3-}$ or $Ru_2(CH_3COO)_4^{+}$] according to the equation

$$TiOH^{2-} + Ox \xrightarrow{k} \text{products}. \quad (8)$$

A large number of such reactions have been studied and the rate constants, k, determined.[1-7] Chaudhuri and Diebler,[14] as well as Pecsok,[15] sought, but did not find, evidence to show that $Ti(C_2O_4)_3^{3-}$ exists; the formation constant K_5 is, therefore, small. Under our conditions, contributions by $Ti(HC_2O_4)^{2+}$ and $Ti(C_2O_4)_3^{3-}$ are negligible.[16] The major species formed in the presence of added oxalate ions are $Ti(C_2O_4^{+})$ and $Ti(C_2O_4)_2^{-}$ and $TiOH^{2+}$ [eqs (3), (4) and (7)].

$$Ti(C_2O_4)^{+} + Ox \xrightarrow{k'} \text{products} \quad (9)$$

$$Ti(C_2O_4)_2^{-} + Ox \xrightarrow{k''} \text{products}. \quad (10)$$

Moorehead and Sutin[17] have determined values of K_1 and K_2 as 0.09 and 4×10^{-4} mol dm^{-3} under our conditions. Values of K_3 and K_4 have been given[16] as 8.5×10^5 and 2.5×10^5 dm^3 mol^{-1} under conditions similar to ours. Combination of eqs. (1)–(4) with (7)–(10) results in an overall equation of the form:

$$B = k' + k''K_4[C_2O_4^{2-}]_f, \quad (11)$$

where

$$B = \frac{k_{obs}\left[1 + \frac{K_A}{[H^+]_f} + K_3[C_2O_4^{2-}]_f + K_3K_4[C_2O_4^{2-}]_f^2\right] - \frac{kK_A}{[H^+]_f}}{K_3[C_2O_4^{2-}]_f} \quad (12)$$

can be calculated (see Table 3) from the known or calculated values of the parameters (k, K_A, K_3 and K_4) and calculated values of the final concentrations for each experiment in eq. (12). A plot of B vs $[C_2O_4^{2-}]_f$ should therefore be linear with an intercept of k' and a slope $k''K_4$. Such plots were linear with no detectable intercepts (within experimental error) and gave slopes of 9.63×10^7 and 1.19×10^8 dm^6 mol^{-2} s^{-1} for reductions of $Co(C_2O_4)_3^{3-}$ and $Ru_2(CH_3COO)_4^{+}$, respectively. These results indicate that k' for each of the two oxidants is less than 1.0 dm^3 mol^{-1} s^{-1}, while $k'' = 3.2 \times 10^3$ and 4.2×10^3 dm^3 mol^{-1} s^{-1} for $Co(C_2O_4)_3^{3-}$ and $Ru_2(CH_3COO)_4^{+}$, respectively.

DISCUSSION

Titanium(III) has been shown to reduce $Ru_2(CH_3COO)_4^{+}$ [12] and $Co(C_2O_4)_3^{3-}$ [2] by outer-sphere and inner-sphere mechanisms, respectively. At a constant free acid concentration, the increase in rate constant with increasing free oxalate ion concentration observed here is similar to the result obtained in earlier studies.[3,7,16] The rate constant of 4.17×10^3 dm^3 mol^{-1} s^{-1} with which $Ti(C_2O_4)_2^{-}$ reduces $Ru_2(CH_3COO)_4^{+}$ is greater than that obtained for either the Ti^{3+} or $TiOH^{2+}$ reduction of the same oxidant.[12] Also, $Ti(C_2O_4)_2^{-}$ reduces $Co(C_2O_4)_3^{3-}$ ($k = 3.21 \times 10^3$ dm^3 mol^{-1} s^{-1}) at a faster rate than does $Ti(C_2O_4)^{+}$, Ti^{3+} or $TiOH^{2+}$. The enhanced rate of reduction of $Ru_2(CH_3COO)_4^{+}$ by $Ti(C_2O_4)_2^{+}$, as compared with reduction by Ti^{3+} or $TiOH^{2+}$, may be understood to involve coulombic effects which increase the stability of the precursor complexes of outer-sphere ET reactions. However, $Co(C_2O_4)_3^{3-}$, an anionic complex, is also reduced by $Ti(C_2O_4)_2^{-}$ at a faster rate than either $Ti(C_2O_4)^{+}$ or $TiOH^{2+}$.

Olubuyide and Earley[3] based the derivation of eq. (11) on the assumption that reaction paths involving oxalatotitanium(III) complexes are base-catalysed. The results of the present study are consistent with that assumption. At constant total oxalate concentration, the rate constant increased with decreasing acidity (Tables 1 and 2).

It has been concluded[16] that the formation constants of the trinuclear intermediate involving titanium(III) and $Ru_2(CH_3COO)_2(C_2O_4)_2^{-}$ decreases as non-bridging oxalate ligands are added. We expected a similar trend with the $Ru_2(CH_3COO)_4^{+}$ oxidant, consistent with the following mechanism:

$$Ru_2(CH_3COO)_4^{+} + Ti^{3+} \rightleftharpoons Ru_2(CH_3COO)_4Ti^{4+} \quad (13)$$

$$Ru_2(CH_3COO)_4Ti^{4+} \longrightarrow \text{products} \quad (14)$$

$$Ru_2(CH_3COO)_4^{+} + Ti(C_2O_4)^{+} \rightleftharpoons Ru_2(CH_3COO)_4Ti(C_2O_4)^{2+} \quad (15)$$

$$Ru_2(CH_3COO)_4Ti(C_2O_4)^{2+} \longrightarrow \text{products} \quad (16)$$

$$Ru_2(CH_3COO)_4^{+} + Ti(C_2O_4)_2^{-} \rightleftharpoons Ru_2(CH_3COO)_4Ti(C_2O_4)_2 \quad (17)$$

$$Ru_2(CH_3COO)_4Ti(C_2O_4)_2 \longrightarrow \text{products}, \quad (18)$$

where the species produced in eqs (15) and (17) are outer-sphere complexes.

As observed from a plot of B against $[C_2O_4^{2-}]_f$

in eq. (11), the first added non-bridging oxalate does not have a significant effect on the redox rate constant, but the addition of the second non-bridging oxalate increases the rate constant for reactions involving both oxidants. Similar non-bridging ligand effects have been observed in inner-sphere titanium(III) reductions of $Co(NH_3)_4C_2O_4^+$,[3] $Ru(C_2O_4)_3^{3-}$ [7] and $Ru_2(CH_3COO)_2(C_2O_4)_2^-$.[16]

The rate constant for $Ti(C_2O_4)_2^-$ reduction of $Ru_2(CH_3COO)_4^+$ falls in the linear free energy relationship for outer-sphere Ru^{III}—Ti^{III} reactions (Fig. 1), suggesting that this diruthenium(II,III) complex is reduced by an outer-sphere mechanism of the usual kind. Even though reduction of $Ru_2(CH_3COO)_4^+$ by $Ti(C_2O_4)_2^-$ occurs at a faster rate than reduction by Ti^{3+} or $TiOH^{2+}$, all three ET reactions occur at rates that are consistent with outer-sphere mechanisms. $Ru_2(CH_3COO)_4^+$ is capable of adding one or more ligands in axial positions, replacing solvent molecules (omitted in the formulae used in this paper) that are weakly bound at those sites. Since the data give no indication that the ET reactions studied here involve any species in which oxalate occupies such a site, we may conclude that either such a species does not form or, more likely, that it forms but does not provide a sufficiently favourable pathway for ET to compete with the outer-sphere path. This in turn suggests that the attack of the reductant is roughly perpendicular to the Ru—Ru bond axis, between the acetate CH_3 groups. The rate enhancement by non-bridging oxalate can be understood to be an effect of changes in the reaction driving force.

Normally, reductions of ruthenium(III) oxidants by a given reductant are faster than reductions of the corresponding cobalt(III) oxidants by the same reductant (Table 5). The rate constant for the reaction of $Ru(C_2O_4)_3^{3-}$ with Ti^{3+} is larger than the rate constant for the reduction of $Co(C_2O_4)_3^{3-}$, but the difference is quite small. The rate constant for reduction of $Ru(C_2O_4)_3^{3-}$ by $Ti(C_2O_4)_2^-$, reported here, and also in ref. 7, is the same, within experimental error, as the rate constant for reduction of $Co(C_2O_4)_3^{3-}$ by $Ti(C_2O_4)_2^-$. The only consistent interpretations of the data are that both ruthe-

[c] o.s. = outer-sphere mechanism; i.s. = inner-sphere mechanism.

nium(III) and cobalt(III) reactions involve inner-sphere ET and that the rate-limiting feature is formation of the binuclear complex through substitution on titanium(III).

It seems likely that the reactions between $Co(C_2O_4)_3^{3-}$, $Ru(C_2O_4)_3^{3-}$ and Ti^{3+} are also substitution-controlled, or nearly so. The small difference between the two rates may be due to partial rate control by the ET step in the case of the cobalt(III) oxidant. The reason why non-bridging oxalate increases the rate of the redox reaction is that addition of the non-bridging ligand increases the rate of substitution on titanium(III) and formation of the binuclear complex.[5] Using this interpretation, the similarity between the magnitudes of the effects of the non-bridging ligand in the two cases is fortuitous.

MONONUCLEAR PYRIDINE-2-THIONATO COMPLEXES FORMED DIRECTLY FROM RUTHENIUM TRICHLORIDE

ANTONY J. DEEMING* and MANZURUL KARIM

Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ, U.K.

(*Received* 21 *August* 1990; *accepted* 4 *January* 1991)

Abstract—Reductive carbonylation of ruthenium trichloride in refluxing 2-methoxyethanol leads to a chlorocarbonyl complex of ruthenium(II) which reacts directly with pyridine-2-thione (pySH) to give high yields of $[Ru(pyS)_2(CO)_2]$, and the 6-methylpyridine-2-thionato analogue is prepared similarly but in much lower yield. Quinoline-2-thione (quinSH) gives high yields of the compound $[RuCl_2(quinSH)_2(CO)_2]$ and only low yields of the dehydrochlorination compound $[Ru(quinS)_2(CO)_2]$. The more crowded thione, 4,8-dimethylquinoline-2-thione, gives only the chloro complexes and no dehydrochlorination.

Ruthenium(II) chlorocarbonyl complexes are easily synthesized by treating ruthenium trichloride with carbon monoxide in refluxing alcoholic solvents, followed by the addition of a neutral ligand.[1] For example, tertiary phosphine complexes such as $[RuCl_2(CO)_2L_2]$ are readily synthesized in this way.[1,2] We wished to synthesize mononuclear pyridine-2-thionato complexes of ruthenium as starting materials for the synthesis of cluster and cage compounds, for example, we have synthesized the 2-pyridyl clusters $[Ru_5(S)_2(C_5H_4N)_2(CO)_{11}]$ and $[Ru_6(S)_2(C_5H_4N)_2(CO)_{18}]$ from $[Ru(pyS)_2(CO)_2]$ and $[Ru_3(CO)_{12}]$,[3] and these results will be reported later. We originally synthesized $[Ru(pyS)_2(CO)_2]$ from $[Ru_3(CO)_{12}]$ and an excess of pySH under vigorous conditions[4] but we sought a good easy route from $RuCl_3 \cdot 3H_2O$ and this method is described herein.

RESULTS AND DISCUSSION

It is well known that bubbling carbon monoxide through a refluxing solution of ruthenium trichloride in 2-methoxyethanol gives a yellow solution containing reactive ruthenium(II) chlorocarbonyl species.[1] Probably the major one present is *fac*-$[RuCl_3(CO)_3]^-$. These solutions are valuable in the synthesis of ruthenium(II) species and tertiary phosphines, arsines, amines, pyridine (L), etc., give $[RuCl_2(CO)_2L_2]$ or $[RuCl_2(CO)L_3]$ in different stereochemistries.[1,2]

Ruthenium(II) pyridine-2-thione (pySH) or thionato (pyS) complexes have been prepared previously from tertiary phosphine-containing precursors and all contain tertiary phosphines, e.g. $[Ru(pyS)_2(CO)(PPh_3)]$, $[RuH(pyS)(CO)(PPh_3)_2]$, $[Ru(pyS)_2(CO)_2(PPh_3)]$, $[RuHCl(pySH)(CO)(PPh_3)]$, or $[RuCl(pyS)(pySH)(CO)(PPh_3)_2]$.[5–7] These complexes contain pyS as a monodentate S-bonded or chelating ligand or pySH as a S-bonded neutral thione ligand.

In looking for a straightforward route to $[Ru(pyS)_2(CO)_2]$ from $RuCl_3 \cdot 3H_2O$, we found that treatment of the 2-methoxyethanol solution containing ruthenium(II) chlorocarbonyl species with pySH, followed by thermal dehydrochlorination, provides a one-pot synthesis of $[Ru(pyS)_2(CO)_2]$ in high yield (89%). Earlier we had prepared this dicarbonyl from $[Ru_3(CO)_{12}]$ with an excess of pySH.[4] Initially the reaction of pySH with $[Ru_3(CO)_{12}]$ gives the trinuclear compound $[Ru_3H(\mu\text{-pyS})(CO)_9]$, but this reacts easily with an excess of pySH to give the mononuclear compound. This is a satisfactory synthesis but more expensive than that from $RuCl_3 \cdot 3H_2O$ and is less convenient even though the yields are good in both cases.

The compound $[Ru(pyS)_2(CO)_2]$ was obtained as yellow, air-stable crystals which were simply characterized by IR and NMR spectra (Table 1). It is closely related to the corresponding osmium com-

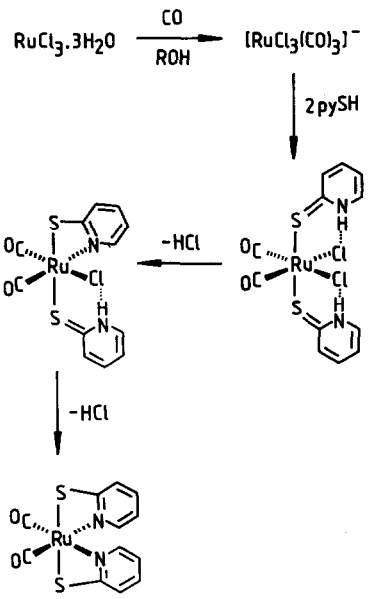
pound, which we have synthesized indirectly from $[Os_3(CO)_{12}]$.[8] The reaction of trifluoroactic acid with the dodecacarbonyl gives $[Os(CF_3CO_2)_2(CO)_4]$ and this can be converted with pySH into $[Os(pyS)_2(CO)_2]$, which has been structurally characterized by XRD. The pyS ligands are equivalent, the carbonyl *cis* and the S-atoms *trans*, and the ruthenium compound is almost certainly isostructural with it. The minor product analyses as $[Ru(pyS)_2(pySH)(CO)]$ and contains non-equivalent chelating pyS ligands and a S-bonded pySH thione ligand (^{1}H NMR evidence, Table 1). The N*H* proton in the ^{1}H NMR spectrum appears as a broad singlet at δ 13.3. We cannot be sure of the structure based on spectra but simple carbonyl substitution without rearrangement is likely since the compound would then have a structure related to those established for $[Ru(pyS)_2(CO)(PPh_3)]$[5] and $[Ru(pyS)_2(PPh_3)_2]$.[9]

Directly comparable reactions of $RuCl_3 \cdot 3H_2O$ with other thiones have been examined: 6-methylpyridine-2-thione (MepySH), quinoline-2-thione (quinSH) and 4,8-dimethylquinoline-2-thione (4,8-MequinSH). The only product from MepySH is $[Ru(MepyS)_2(CO)_2]$, which is directly analogous to the parent pyS compound but is formed in much lower yield. We have not accounted for the different yield but most of the material from the reaction does not elute on the TLC plate and we have been unable to characterize it. The other two thiones give good yields but mainly of the chloro complexes $[RuCl_2(CO)_2L_2]$ (L = quinSH or 4,8-Me_2quinSH),



Scheme 1.

which correspond to the products expected from neutral ligands. The ligand quinSH also gives a minor amount of the dehydrochlorination product $[Ru(quinS)_2(CO)_2]$. We propose the reaction route given in Scheme 1. The initial reaction leads to the adducts $[RuCl_2(CO)_2L_2]$ which are isolable for the more sterically demanding thiones and the only product for 4,8-MequinSH. Deprotonation of these thione complexes would give thionato species but it would seem that the thionato ligands, quinS and 4,8-Me_2quinS, do not easily form chelate rings with the displacement of a *cis*-chloride ligand. Certainly with 4,8-Me_2quinS there would be a serious clash of the 8-methyl group with an adjacent *cis* ligand if a chelate ring were formed. When chelate ring formation creates no such problem, it occurs readily as in the formation of $[Ru(pyS)_2(CO)_2]$ and in this case the chloro species are not observed.

EXPERIMENTAL

Reaction of $RuCl_3 \cdot 3H_2O$ *with carbon monoxide followed by pyridine-2-thione*

Carbon monoxide gas was bubbled through a refluxing dark red–brown solution of ruthenium trichloride (0.100 g, 0.38 mmol) in 2-methoxyethanol (40 cm^3) for 3 h to give a yellow solution. Pyridine-2-thione (0.106 g, 0.95 mmol) was added and the reflux without carbon monoxide gas was continued for 2 h. Water was added and the mixture extracted with dichloromethane. The dichloromethane was removed to give a yellow oil which was separated by TLC [SiO_2; light petroleum (b.p. $<40°C$)–dichloromethane (1 : 1 v/v)] to give one main yellow band yielding $[Ru(pyS)_2(CO)_2]$ as yellow crystals (0.129 g, 89%) from a dichloromethane and hexane mixture (Found: C, 38.1, H, 2.0; N, 7.25; S, 16.75. $C_{12}H_8N_2O_2RuS_2$ requires: C, 38.2; H, 2.15; N, 7.4; S, 17.0%). A minor band yielded a monocarbonyl species as an orange solid, shown by its spectra to be $[Ru(pyS)_2(pySH)(CO)]$ (0.006 g, 3%) (see alternative synthesis below).

Reaction of $[Ru_3(CO)_{12}]$ *with an excess of pyridine-2-thione*

A solution of $[Ru_3(CO)_{12}]$ (0.200 g, 0.31 mmol) and pySH (0.208 g, 1.19 mmol) in *m*-xylene was refluxed under nitrogen for 2 h. The deep yellow residue after removal of the solvent *in vacuo* was separated by TLC [SiO_2: light petroleum (b.p. $<40°C$)–dichloromethane (1 : 1 v/v)]. The major band gave $[Ru(pyS)_2(CO)_2]$ as yellow crystals (0.317 g, 89%) (Found: C, 38.1; H, 2.25; N, 7.35; S, 16.75%) and a minor band gave $[Ru(pyS)_2(pySH)(CO)]$ as orange needles (0.008 g, 2%) from a dichloromethane–hexane mixture (Found: C, 41.25; H, 2.8; N, 8.9; S, 20.85. $C_{16}H_{13}N_3ORuS_3$ requires: C, 41.7; H, 2.85; N, 9.1; S, 20.9%). Both were spectroscopically identical to the products from the previous synthesis.

Reaction of $RuCl_3 \cdot 3H_2O$ *with carbon monoxide followed by 6-methylpyridine-2-thione*

Carbon monoxide was bubbled through a refluxing solution of ruthenium trichloride (0.200 g, 0.76 mmol) in 2-methoxyethanol (40 cm^3) for 3 h. The bubbling was stopped, MepySH (0.239 g, 1.90 mmol) was added and the solution refluxed for 2 h. TLC work-up as above gave $[Ru(MepyS)_2(CO)_2]$ as yellow crystals (0.0207 g, 7%) (Found: C, 41.2; H, 2.85; N, 6.7; S, 15.1. $C_{14}H_{12}N_2O_2RuS_2$ requires: C, 41.45; H, 3.0; N, 6.9; S, 15.8%). There were other low-yield and uncharacterized products but most of the material did not elute and was not studied further.

Reaction of $RuCl_3 \cdot 3H_2O$ *with carbon monoxide followed by quinoline-2-thione*

Carbon monoxide was bubbled through a refluxing solution of ruthenium trichloride (0.300 g, 1.15 mmol) in 2-methoxyethanol (40 cm^3) for 3 h. Quinoline-2-thione (0.462 g, 2.87 mmol) was added and the solution refluxed for 15 min. Brick-red crystals,

which deposited on cooling for 1 h, were collected, washed with light petroleum (b.p. $<40°C$) and characterized as $[RuCl_2(quinSH)_2(CO)_2]$ (0.595 g, 94%) (Found: C, 43.65; H, 2.7; Cl, 12.8; N, 4.95; S, 11.25. $C_{20}H_{14}N_2O_2Cl_2RuS_2$ requires: C, 43.65; H, 2.55; Cl, 12.9; N, 5.1; S, 11.65%). Removal of the solvent from the mother liquor and TLC of the residue [SiO_2; light petroleum (b.p. $<40°C$)–methanol (19 : 1 v/v)] gave $[Ru(quinS)_2(CO)_2]$ as yellow crystals (0.010 g, 2%) from a dichloromethane–methanol mixture (Found: C, 49.45; H, 2.45; N, 5.5. $C_{20}H_{12}N_2O_2RuS_2$ requires: C, 50.3; H, 2.55; N, 5.85%).

Reaction of $RuCl_3 \cdot 3H_2O$ *with carbon monoxide followed by* 4,8-*dimethylquinoline-2-thione*

Treatment of ruthenium trichloride (0.200 g, 0.76 mmol) in 2-methoxyethanol (40 cm^3) with carbon monoxide as above, followed by treatment with the thione (0.285 g, 1.51 mmol) and further reflux for 2 h gave a solution which deposited brick-red crystals (0.272 g) on cooling for 1 h. Removal of the solvent from the mother liquor and recrystallization of the residue from a dichloromethane–methanol mixture gave more brick-red crystals (0.125 g). The total yield of $[RuCl_2(4,8\text{-}Me_2quinSH)_2(CO)_2]$ was 0.342 g (74%) (Found: C, 47.2; H, 3.65; Cl, 11.5; N, 4.6; S, 10.5. $C_{24}H_{22}Cl_2N_2O_2RuS_2$ requires: C, 47.5; H, 3.65; Cl, 11.4; N, 4.6; S, 10.5%).

Acknowledgements—We thank the Association of Commonwealth Universities for a studentship (for M.K.) and Johnson–Matthey for a loan of $RuCl_3 \cdot 3H_2O$.

(*Received* 24 *April* 1990; *accepted* 4 *January* 1991)

Abstract—Intramolecular rearrangement of $(CO)_4FeH(SiPh_3)$ (**I**), $(CO)_4FeH(SiMe_3)$ (**II**), $(CO)_4FeH(SiCl_3)$ (**III**) and $P(OPh)_3(CO)_3Fe(H)SiPh_3$ (**IV**), as studied by variable temperature ^{13}C NMR spectroscopy, yielded activation enthalpies (kcal mol^{-1}): 10.3 ± 0.1, 10.4 ± 0.4, 17.4 ± 0.1 and 10.9 ± 0.03, respectively, and activation entropies (cal deg^{-1} mol^{-1}): -1.8 ± 0.5, -2.21 ± 0.1, 0.7 ± 0.5 and -2.2 ± 0.2, respectively. Crystal structure data for **IV**: $C_{39}H_{31}FeO_6PSi$, OC-6-23-tricarbonylhydrido(triphenylphosphite)(triphenylphosphine)iron(II), triclinic, $P\bar{1}$, $a = 11.509(2)$, $b = 14.403(3)$, $c = 11.153(4)$ Å, $\alpha = 108.04(2)$, $\beta = 95.10(2)$, $\gamma = 92.55(2)°$, $Z = 2$, $V = 1746(1)$ Å^3, final R factor 0.030. The structure is a highly distorted octahedron.

Intramolecular rearrangements of organometallic compounds have been studied using variable temperature NMR spectroscopy for some time. Using ^1H and ^{31}P spectroscopy, Muetterties and co-workers studied a series of $H_2Fe(PR_3)_4$ (and analogous ruthenium) compounds. In addition to obtaining the activation parameters they proposed a tetrahedral hopping mechanism as a pathway for the rearrangement process.[1] Using ^{13}C NMR spectroscopy, Graham and co-workers studied a series of $(CO)_4M(ER_3)_2$ (M = Fe, Ru, Os; E = Si, Ge, Sn, Pb) compounds. In their studies, observation of the *trans* intermediate leads to the conclusion that the rearrangement process proceeds by a *cis–trans* equilibrium process.[2] In both of these elegant studies structural details obtained crystallographically were correlated with the proposed rearrangement mechanisms. There are other possible rearrangement mechanisms for octahedral complexes and Butler demonstrated recently that *mer*-$Cr(CO)_2(CX)[(MeO)_3P]_3$ undergoes intramolecular rearrangement by a trigonal twist mechanism.[3] A calculated study by Hansen and Marynick gives evidence that the trigonal prismatic configuration is the transition state for intramolecular rearrangement by the Bailer twist, the Ray and Dutt twist and the bicapped tetrahedral mechanism in $Cr(CO)_5PH_3$.[4] There have been several other reports on the room temperature fluxional behav-

iour of hydrido-silyl iron carbonyl compounds but they have not been studied in detail.[5] In this paper we report variable temperature ^{13}C NMR spectra of $(CO)_4Fe(H)(SiR_3)$ (R = Ph, **I**; Me, **II**; Cl, **III**) and $P(OPh)_3(CO)_3Fe(H)SiPh_3$ (**IV**).

EXPERIMENTAL

Materials

The NMR solvents, perdeuterotoluene and hexane, were dried over calcium hydride and de-aerated with argon. Compounds **I–III** were prepared by literature[6] methods and enriched by exposure to ^{13}CO in solution for 12 h or longer. Enriched samples of **IV** were prepared from enriched **I** and triphenylphosphite.[7] The crystallographic sample of **IV** was prepared photochemically from triphenylsilane and $P(OPh)_3Fe(CO)_4$;[8] X-ray quality crystals were grown from a 90 : 10 hexane–toluene solution at −15°C.

NMR experiments/simulation

NMR measurements on **I–III** were carried out using a GE QE300 spectrometer at the University of Texas; measurements on **IV** were carried out using a Varian XL300 spectrometer at the University of Kansas; measurements on deuterated **III** were carried out on a Varian VXR 300 at the Midwest Research Institute, K.C. MO. Spectrometer probe temperatures were calibrated using the chemical shift differences in methanol or ethylene glycol.[9] A mixed solvent of hexane and C_7D_8 was used in the variable temperature spectra of **I** and **II**, pure C_7D_8 was used for **III** and **IV**. Simulation was carried out using the DNMRH program obtained from QCPE. Input parameters (chemical shifts, coupling constants and line widths) were obtained from the lowest temperature spectrum. The experimental spectra in Fig. 3 were prepared by reading the raw NMR data into a VAX computer at UMKC and processing it with the FTNMR program available from Hare Research, Inc.

Structure determination

A large crystal of **IV** was cut to size and mounted on the end of a glass fibre. Cell dimensions were based upon a Delaunay reduction of a cell obtained from the centring of 25 reflections on the diffractometer (Enraf–Nonius CAD4). Intensity data were measured (298 K) with Mo-K_α radiation using a graphite monochronometer (w-2 scan, 96 steps/scan, 16 steps/side background). The intensities of three standard reflections were measured after each 7200 s exposure to the X-rays and showed a 15.2% intensity decay during the experiment. The correction factors for this decay ranged from 0.97 to 1.24. No absorption correction was needed based on scans and the low absorption coefficient. A total of 4822 reflections were measured and averaged ($R = 0.011$, on intensity) to give 4549 independent reflections. The Enraf–Nonius SDP program package was used for calculations. The structure was resolved by Patterson methods followed by successive applications of Fourier methods. Two orientations (rings 2 and 2′) for one of the phosphite phenyl groups were found with an occupancy of 80 and 20%. Occupancy values were set so that reasonable and equivalent thermal parameters for both ring orientations were obtained. The *para*-carbon [C(24)] position of the major ring orientation of an adjacent molecule overlaps with the *para*-carbon position of the minor orientation. The overlap is not exact and leads to a distorted minor ring. The peak identified as the iron hydrogen was the largest peak in the difference map. It refined correctly as hydrogen, its location in a gap between equatorial carbonyls is intuitively correct, and the Fe—C bond opposite it shows a modest *trans* influence. Phenyl hydrogen atoms were placed in calculated positions and not refined. Full matrix least-squares refinement minimizing $\Sigma w(|F_o| - |F_c|)^2$ converged to the R values given in Table 1. No extinction correction was applied. The final difference Fourier had the largest peak (0.21 e/Å^3) in the vicinity of the iron atom. The ORTEP diagram for compound **IV** is shown in Fig. 1.*

RESULTS

In Table 2 are listed the low-temperature limiting chemical shifts and coupling constants for the compounds under study, while the rate data and activation parameters for intramolecular carbonyl exchange are listed in Table 3. The line widths used in the simulation are a consequence of the ^{13}C–^{13}C coupling in the enriched samples used in the NMR studies. Figure 2 shows two high resolution spectra (0.13 Hz/data point) of an enriched sample of **III**, one at 270 K, where the compound is rigid, and the other at 298 K, where the rate constant is about 1 Hz. As the compound becomes fluxional the individual lines of the isotopomers are no longer resolved. Since this is the case, there is no advantage

* Atomic coordinates, thermal parameters, additional bond angles and bond distances, and torsional angles have been deposited with the Director, Cambridge Crystallographic Data Centre.

Table 1. Summary of crystallographic data

R	0.030
R_w	0.041

in obtaining all the data under high resolution conditions. Therefore the data were obtained using instrument settings of about 1 Hz/data point and the experimentally observed line width of 4.5 Hz was used.

Figures 3(a) and (b) show the experimental and simulated NMR spectra of **III** and **IV**, respectively. Figure 3(a) is typical of the results obtained for **I**–**III**. Using the temperatures and rate constants (Hz) in Table 3, Eyring plots yielded straight lines with correlation coefficients greater than 0.99 in each case. The spectra shown in Fig. 3 are proton decoupled. Separate room temperature measurements made with the decoupler off for **I** and **II** showed spin coupling between the iron hydrogen and the carbonyl carbon atoms, which indicates that these processes are intramolecular. The limiting fast exchange spectrum for **III** was not observed due to the high temperature required. In the case of **IV**, phosphorus–carbon spin coupling can be observed in the low temperature and high temperature regions of the spectra.

DISCUSSION

Variable temperature NMR studies yield activation parameters for the intramolecular processes which cause the fluxionality and, if the compounds

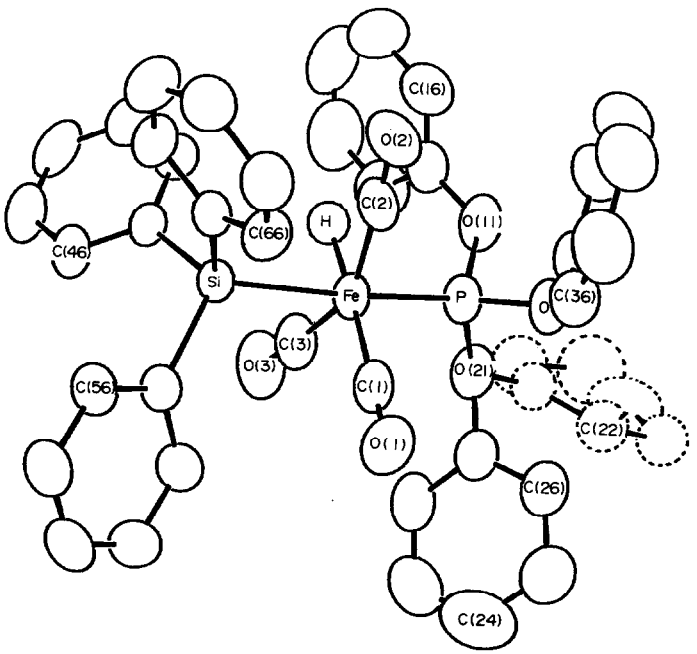

Fig. 1. ORTEP diagram of **IV**. Phenyl carbons are numbered sequentially about the ring [e.g. ring 1 : C(11), C(12), C(13), C(14), C(15), C(16)]. The dashed atoms of ring 2′ represent a second minor position for ring 2—see Experimental.

Table 2. Low temperature limiting NMR data

Compound	^{13}CO δ values Axial	Equatorial	$^2J_{C-P}$
I	206.2	206.6, 204.2	
II	207.4	206.6, 203.9	
III	201.7	200.1, 199.5	
IV	208.9	210.3	19.5, 12.7

are sufficiently asymmetric, mechanistic information about the intramolecular process. Input parameters for the simulation program include exchange vectors, which indicate which nuclei are actually exchanging. The best experimental results were obtained with **III** (Fig. 3a). Exchange vectors were chosen which best fit these data and the same exchange vectors were used for compounds **I–III**. For compound **IV** an equivalent set of exchange vectors was used except that phosphorus was substituted for carbon atom 4 and was kept in the same position throughout the exchange process. It was given a chemical shift outside the simulation range.

Figure 4 shows an idealized structure of compounds **I–IV**, and the carbonyl numbering system. The best fit of the experimental spectra was obtained by the following four exchange processes: simultaneous pairwise exchange between carbonyls 1 and 3 and 2 and 4, simultaneous pairwise exchange between 1 and 4 and 2 and 3, and pairwise exchange between 3 and 4 (counted twice). (The exchange vectors which accomplish these exchanges are 3412, 4312, 1243 and 2143, respectively.) Of course any mechanism which yields these exchange vectors is consistent with the experimental results. We have been unable to find a mechanism which yields these exchange vectors without editing. For example, the *cis–trans* mechanism proposed by Graham does not account for the 3–4 exchange being twice as fast as the other two processes. The twist mechanisms mentioned above give sets of exchange vectors which include the above four, but they also include processes which exchange carbonyls 1 and 3 (for example) faster than the data indicate.

Figure 5 shows another possible mechanism in which an incipient Si—H bond forms to produce a five-coordinate intermediate. That intermediate can rearrange to one observed product by rotation about the three-centre Fe—H—Si bond, it can also undergo a Berry pseudo-rotation which makes the other products accessible. This latter mechanism has the advantage that the activation energy pattern fits the known propensities of these compounds to eliminate the silane ligands, probably by passing through such an intermediate.[4] However, a significant deuterium isotope effect might be expected

for this mechanism and it appears from Fig. 6 that such is not the case. [The line widths in $(CO)_4FeD$ $Si(Cl)_3$ in Fig. 6 are broader due to deuterium-carbon coupling.] It has already been observed that substitution of deuterium for hydrogen in $HRh(PF_3)_4$ has very little effect on the rate of rearrangement.[10]

In Table 3(b) are listed the activation parameters for the compounds studied here, together with the literature data for similar compounds. Steric factors have surprisingly little effect on molecular rigidity. That is, replacement of one SiR_3 group by a hydrogen atom has essentially no effect on the activation energy, nor does the replacement of carbonyl by $P(OPh_3)$. This may be due to the fact that these are all highly distorted structures.

The magnitude of the observed activation free energies is dominated by the electronegativity of the silyl substituent, both in our results and in the previous study on bis-silyl iron carbonyls.[2] It is possible that the electron-withdrawing power of the silyl substituent simply makes the structure more rigid or it may be that the ground-state structure of the trichlorosilyl-containing compounds are further from the structure of the transition state. The only structural information obtained so far has been on the more rapidly exchanging compounds. The crystal structure of $(CO)_4Fe(SiMe_3)_2$ shows it to be close to a bicapped tetrahedron.[2] Table 4 lists the important bond lengths and angles for compounds **I** and **IV**. These structures are very similar to several other compounds of this type that have been reported.[12] In all cases there is significant distortion from octahedral geometry. The major distortion is the CO(2)—Fe—CO(3) bond angle which is closer to 150° than to the ideal value of 180°. On the other hand, the crystal structure of $(CO)_4Ru(GeCl_3)_2$[13] shows it to be nearly perfectly octahedral, but it is known that hexacoordinated ruthenium compounds are more nearly octahedral than hexacoordinated iron compounds.[12a]

The properties of **III** do not lend themselves to crystallographic study. Since the trichlorosilyl analogue of **IV**[14] is nearly rigid in solution at room temperature we attempted to determine its structure. We were unable to grow crystals of sufficient regularity to get a publishable crystallographic data set, although there appears to be a CO—Fe—CO bond angle of 147° in the structure. A calculational effort is underway in an attempt to explain the effect of silyl substituents on the molecular rigidity of the compounds studied here.

(*Received* 30 *March* 1989; *accepted* 4 *January* 1991)

Abstract—$[Pt_2Cl_2(\mu\text{-}X)(\mu\text{-}Y)(PR_3)_2]$ complexes [X = Cl, SPh; X = Y = SPh, Pr^i; PR_3 = PBu_3, PMe_2Ph, PPh_3, $P(p\text{-tol})_3$] have been prepared and characterized by elemental analysis, ^1H and ^{31}P NMR spectroscopy. Bridge cleavage reactions with various donor ligands have been investigated by $^{31}P\{^1H\}$ NMR. The X-ray crystal structure of $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$ is reported.

Coordination geometries of dinuclear platinum(II) complexes of the type $[Pt_2(\mu\text{-}X)(\mu\text{-}Y)Z_2L_2]$ depend on the method of preparation and on the nature of the X, Y, Z and L ligands which also influence the chemical reactivity of such complexes. The dimercapto-bridged complexes[1–10] (X = Y = SR) usually prefer a *cis* configuration when R = alkyl, but when R = aryl and L = PPr_3, only the *trans* isomer exists. The monothio-bridged complexes[1,2,9] (X = Z = Cl) adopt a *cis* configuration, however, for Z = $SnCl_3$ the *sym trans* isomer forms.[9] The *cis* and *trans* configurations can readily be identified on the basis of ^3J(Pt—P) and ^4J(P—P) values.[8–10] In continuation of our previous work, we now report the phenyl and isopropyl mercapto-bridged complexes wherein L determines the geometry of the complex, together with the X-ray structure of $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$.

RESULTS AND DISCUSSION

Treatment of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ with thiophenol in 1:2 stoichiometry, in the presence or absence of pyridine, affords the phenylthio-bridged complexes. A similar reaction, in the absence of pyridine, in 1:1 stoichiometry in dichloromethane yields the μ-chloro-μ-phenylthio complexes. These can also be obtained by reacting the tetrachloro complex with the dimercapto-bridged compound in dichloromethane. The tetrachloro complex reacts with excess isopropylmercaptan in acetone to give di-μ-isopropylthio complexes. Physical and analytical data of these complexes are given in Table 1.

The ^{31}P NMR data for $[Pt_2Cl_2(\mu\text{-}SPh)_2(PR_3)_2]$ (Table 2) suggest that these complexes adopt a *sym trans* configuration [^3J(Pt—P) = ~50 Hz and ^4J(P—P) = ~12 Hz][8,9] except tris(*p*-tolyl)phosphine which is a mixture of *cis* and *trans* isomers. The latter is in contrast to the observation of Chatt and Hart[1] that with the arylthio ligand the *trans* configuration is preferred. The existence of the *cis* isomer for $P(p\text{-tol})_3$ suggests that phosphine ligands also play a role in determining the geometry of the complex. The magnitude of ^1J(Pt—P) reflects that the chloro/mercapto-bridged complexes adopt a *sym cis* configuration in which the phosphine ligand is *trans* to the bridging chlorine.

The ^1H NMR spectra of the complex $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SPh)(PMe_2Ph)_2]$ displayed two doublets for

the methyl protons indicating non-equivalence of the methyl groups on phosphine. The corresponding di-μ-phenylthio complex exhibited only one doublet for the P—Me protons.

Structure of $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$

A single-crystal X-ray analysis of $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PPhMe_2)_2]$ has confirmed that complexes of this type have a *sym cis* configuration. An ORTEP[11] plot of the molecule, together with the numbering of non-hydrogen atoms, is shown in Fig. 1. Table 3 lists the bond lengths and bond angles in the molecule with their estimated standard deviations. The bond lengths, as shown below, are in good agreement with those reported in the literature.[3,6]

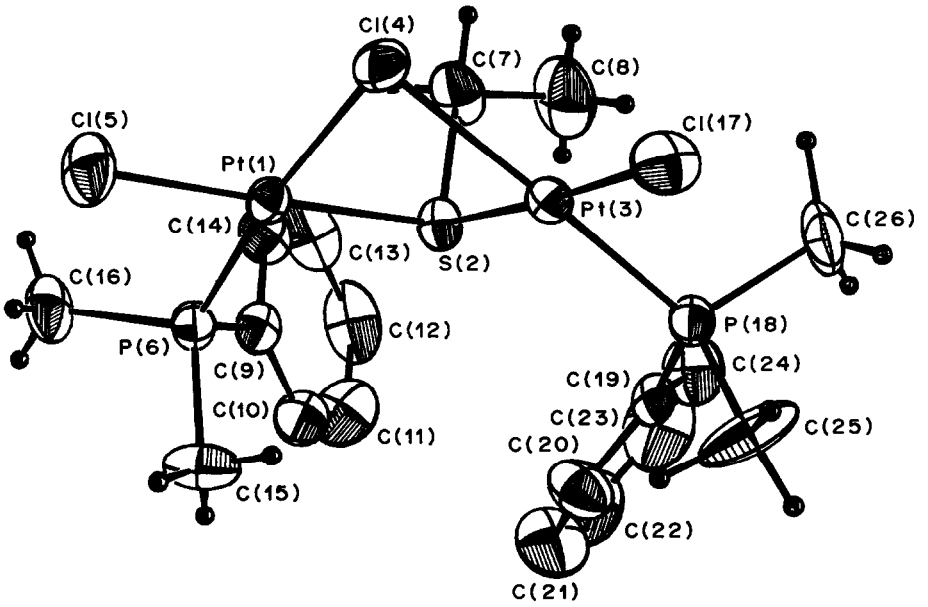

Fig. 1. ORTEP view of $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$.

Bond	*trans* group	Bond length (Å) Expected[3,6]	⟨observed⟩$_{av}$
⟨Pt—P⟩	Cl	2.23	2.222(4)
⟨Pt—S⟩	Cl	2.27	2.271(4)
⟨Pt—Cl⟩$_{terminal}$	SR	2.34	2.334(5)
⟨Pt—Cl⟩$_{bridging}$	PR_3	2.43	2.452(5)

The terminal Pt—Cl distances are shorter than the bridging distances. The Pt—P and Pt—S distances are considerably shorter than their radius sum of 2.42 and 2.36 Å, respectively. The bond lengths are thus in keeping with the usual *trans* influence order P ≫ S > Cl. The shortening of the Pt—S bond has been attributed to a strong π-bond character.[3] The possibility of forming two strong bonds at sulphur, as suggested by Hall *et al.*,[3] results in a P—Pt—S—Pt—P chain and stabilizes the *cis* configuration. The *trans* configuration would lead to weakening of one of the Pt—S bonds due to the strong *trans* influence of the phosphine ligand, thereby destabilizing the bridge framework. The Pt···Pt distance [3.299(1) Å] lies within the expected[6,12] range, 3.18–3.48 Å.

The angles around both the platinum atoms are normal and fall within the expected range. The S—Pt—P angle is larger than the ideal 90° [91.8(2) and 95.9(2)°, respectively], which results in minimization of the crowding of the alkyl and aryl groups on the sulphur and phosphorus atoms, respectively. Further, the Pt—Cl—Pt angle which lies in the range 94–96° in di-μ-chloro-bridged complexes[12–16] shows a significantly smaller value of 84.5(2)° in the present case. The angle around the bridging sulphur atom [Pt(1)—S(2)—Pt(3)] is significantly larger [93.1(2)°] than that reported for any sulphur-bridged dinuclear platinum(II) complex[6] [85.5–92.0°]. Although a wide variation in the angle at the bridging sulphur (79–98°)[17,18a] has been observed with different metal ions, the reason for this, except due to the ionic radii variation, is not clear.

The conformations of the two PMe_2Ph ligands are different. The methyl carbon [C(15)] attached to P(6) nearly lies in the plane defined by C(9), C(10), C(11), C(12), C(13), C(14) [deviation ~ 0.16(2) Å], and in the plane defined by P(6), C(9), C(10), C(11), C(12), C(13), C(14) [deviation ~ 0.11(2) Å], while deviations of −1.63(2) and −1.59(2) Å occur for C(16). The respective values for C(25) and C(26) from the planes defined by C(19), C(20), C(21), C(22), C(23), C(24), and P(18), C(19), C(20), C(21), C(22), C(23), C(24) in the other phosphine ligand are −1.31(2), −1.35(2) Å and −0.46(3), −0.50(3) Å, respectively. These deviations are also reflected in the corresponding torsion angles C(15)—P(6)—C(9)—C(10) [0.7 (2.0)°], C(15)—P(6)—C(9)—C(14) [−176.7 (1.7)°], C(16)—P(6)—C(9)—C(10) [109.6 (1.8)°], C(16)—P(6)—C(9)—C(14) [72.9 (1.8)°], C(25)—P(18)—C(19)—C(20) [53.3 (2.0)°], C(25)—P(18)—C(19)—C(24) [−127.6 (1.9)°], C(26)—

$\langle C—C \rangle_{av}$ bond length in phenyl rings 1.370(33) Å.

P(18)—C(19)—C(20) [162.8 (1.7)°] and C(26)—P(18)—C(19)—C(24) [−18.1 (2.0)°]. A similar conformation has been reported for di-μ-chlorodi(propionyl) bis (dimethylphenylphosphine)diplatinum (II).[16] These values show that the deviations of one of the methyl groups from the PPh plane are different at the two ends of the molecule, one end being distinctly more planar than the other. The two phenyl rings are inclined to each other at 129.6(9)°. The ethyl group on S(2) adopts the axial position relative to the mean plane through the Pt(1), Cl(4), S(2), Pt(3) atoms with the methylene carbon [C(7)] staggered with respect to Pt(3), as reflected by the values of the torsion angles. The Pt—S—Cl—Pt bridge is non-planar with an interplanar angle between the two platinum coordination planes of 135.6(5)°. This is in agreement with the value observed for $[Pt_2Cl_2(\mu\text{-}SEt)_2(PPr_3)_2]$ where the corresponding angle[3] is 130°. An ORTEP view of the unit cell contents is shown in Fig. 2. Most of the aforementioned results are analogous to those of the palladium derivative[18b] and the two structures appear to be isomorphous.

A few bridge cleavage reactions of phenylthio-bridged complexes have been carried out and monitored by $^{31}P\{^1H\}$ NMR spectroscopy. The products formed were identified by comparison of the observed chemical shifts and coupling constants with those reported previously.[8,9,15] The phenylthio-bridged complexes undergo bridge cleavage reactions more readily than the corresponding alkylthio complexes. Pyridine cleaves the μ-chloro-μ-phenylthio bridge readily. The $^{31}P\{^1H\}$ NMR spectra of the reactions of pyridine with $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SPh)(PR_3)_2]$ ($PR_3 = PBu_3$, PMe_2Ph) in $CDCl_3$, obtained immediately after mixing, showed resonances assignable to three molecular species, viz. $[Pt_2Cl_2(\mu\text{-}SPh)_2(PR_3)_2]$, *trans*-$[PtCl_2(py)(PR_3)]$ and $[PtCl(SPh)(py)(PR_3)]$. The concentration of *trans*-$[PtCl_2(py)(PR_3)]$ did not change with time, but the mononuclear complex $[PtCl(SPh)(py)(PR_3)]$, phosphine *trans* to pyridine [PBu_3: δ −4.6 ppm, ^1J(Pt—P) 3502 Hz; PMe_2Ph: δ −20.8 ppm, ^1J(Pt—P) 3580 Hz], established equilibrium within 10–15 h with the di-μ-phenylthio complex, since even after a week no change in their concentrations was noticed. The relative ratio of the three species from ^{31}P NMR integration was approximately 2.7 : 1.7 : 1.0 (PBu_3) and 2.5 : 1.1 : 1.2 (PMe_2Ph).

A similar bridge cleavage reaction of $[Pt_2Cl_2(\mu\text{-}SPh)_2(PBu_3)_2]$ with 2 mole equivalents of $AsPh_3$ in $CDCl_3$ gave four products, *trans*- and *cis*-$[PtCl_2(AsPh_3)(PBu_3)]$ [δ 3.4 ppm, ^1J(Pt—P) 3054 Hz; δ −3.3 ppm, ^1J(Pt—P) 3341 Hz], [PtCl(SPh)

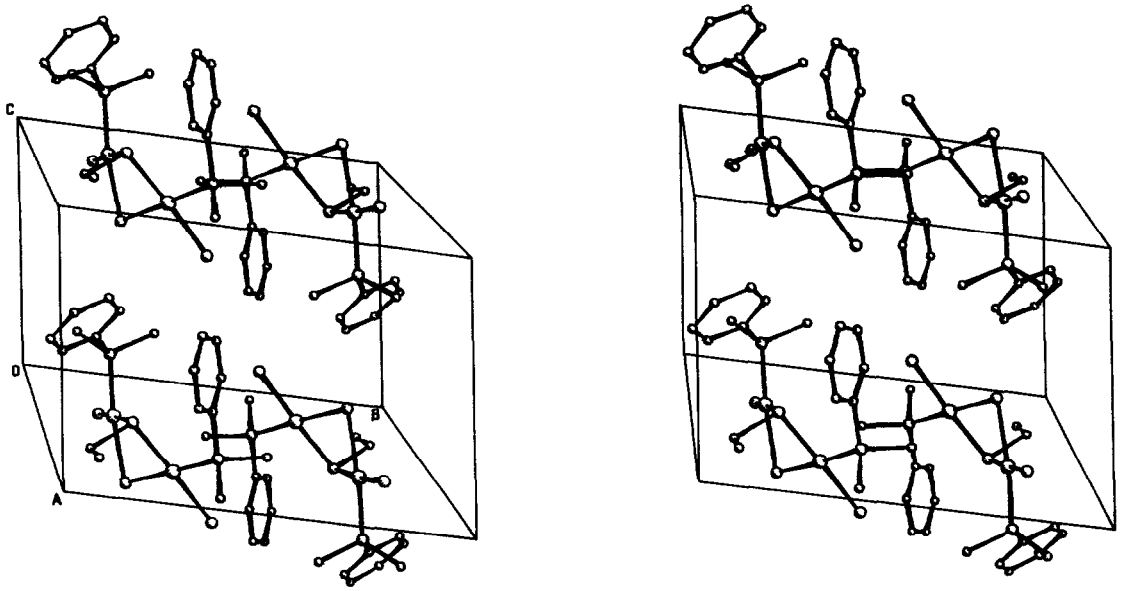

Fig. 2. ORTEP view of the unit cell contents.

$(AsPh_3)(PBu_3)]$ [δ 6.6; 0.4 ppm, ^1J(Pt—P) 3937 Hz]. After 20 h only three products, the former two and *sym trans*-$[Pt_2Cl_2(\mu\text{-}SPh)_2(PBu_3)_2]$, existed in solution and no further change was noticed even after 3 days.

A ^{31}P NMR spectrum obtained immediately after mixing an excess of pyridine with a $CDCl_3$ solution of $[Pt_2Cl_2(\mu\text{-}SPh)_2(PBu_3)_2]$ showed the formation of $[PtCl(SPh)(py)(PBu_3)]$ [δ −4.6 ppm, ^1J(Pt—P) 3504 Hz] and within a few hours (4–6) an equilibrium was established, the two being in an approximately 1:2.8 ratio, as no change was observed even after 4 days. Removal of pyridine *in vacuo* gave the parent complex quantitatively. This is in contrast to the alkylthio-bridged dinuclear platinum(II) compounds which are inert to such ligands.[1,8,9]

EXPERIMENTAL

The complexes $[Pt_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ [PR_3 = PBu_3, PMe_2Ph, PPh_3, $P(p\text{-tol})_3$] were prepared according to literature methods.[19–21] Methods and spectroscopic techniques are similar to those described previously.[9,10]

Preparation of $[Pt_2Cl_2(\mu\text{-}SPh)_2(PR_3)_2]$

(a) To a benzene solution of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PBu_3)_2]$ (406 mg, 0.43 mmol), excess pyridine (0.2 cm^3) was added and the reaction mixture was stirred at room temperature for 30 min. To this, a benzene solution (~ 5 cm^3) of benzenethiol (95 mg, 0.86 mmol) was added and the mixture was heated at ~ 60°C with stirring for 2 h. After cooling, the solvents were stripped off *in vacuo* leaving a pasty mass which was extracted from benzene, and recrystallized from benzene–hexane in 62% yield (289 mg).

(b) To a dichloromethane solution (20 cm^3) of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (142 mg, 0.17 mmol), benzenethiol (39 mg, 0.35 mmol) was added and the reactants were stirred at room temperature for 2 h. The solvent was reduced to 5 cm^3, and an equal amount of methanol was added to give pale yellow crystals (141 mg, 84%).

Similar reactions in 1:1 stoichiometry gave chloro/phenylthio-bridged complexes. The di-μ-SPr^i complexes were prepared by a method similar to the one described previously.[8,9]

Preparation of $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SPh)(PBu_3)_2]$

Benzene solutions containing $[Pt_2Cl_2(\mu\text{-}SPh)_2(PBu_3)_2]$ (120 mg, 0.11 mmol) and $[Pt_2Cl_2(\mu\text{-}Cl)_2(PBu_3)_2]$ (106 mg, 0.11 mmol) were mixed and heated under reflux for 3 h. Concentrating to 5 cm^3 under reduced pressure and addition of 10 cm^3 of hexane gave pale yellow crystals in 90% yield (205 mg). Similarly, the complex $[Pt_2Cl_2(\mu\text{-}Cl)(\mu\text{-}SEt)(PMe_2Ph)_2]$ was prepared and characterizing data are reported elsewhere.[9]

Bridge cleavage reactions

Pyridine (0.5 cm^3) or a $CDCl_3$ solution of 2 mole equivalents of $AsPh_3$ was added to a $CDCl_3$ solu-

tion of dinuclear platinum(II) complexes (90–120 mg) in an NMR tube and the progress of the reaction was monitored by $^{31}P\{^{1}H\}$ NMR spectroscopy.

Crystal data

$C_{18}H_{27}Cl_3P_2SPt_2$, Mol. wt 833.4, triclinic, space group $P\bar{1}$, $a = 10.412(1)$, $b = 13.782(1)$, $c = 9.325(1)$ Å, $\alpha = 98.00(1)$, $\beta = 112.26(2)$, $\gamma = 80.29(1)°$, $V = 1219.2$ Å^3, $Z = 2$, $D_c = 2.264$ g cm^{-3}, $D_m = 2.273$ g cm^{-3} (flotation technique, solvents: $CHBr_3$ and CH_3I), $\mu = 126.9$ cm^{-1}, $F(000) = 767.9$.

Data collection

Intensity data for 4290 reflections (crystal size: $0.3 \times 0.32 \times 0.34$ mm) were collected on an Enraf–Nonius CAD-4 diffractometer using graphite monochromatized Mo-K_α ($\lambda = 0.71068$ Å) radiation in the range $3 < 2\theta < 53°$ employing zigzag mode of data collection. Three control reflections were monitored after every 200 reflections (maximum decay = 0.70% during data collection which was corrected during data reduction). Data were corrected for Lorentz, polarization and absorption effects. The unit cell dimensions were refined using 25 arbitrarily chosen higher order reflections around θ of 15–16°.

Structure solution and refinement

A three-dimensional sharpened origin removed Patterson map yielded the positions of the platinum atoms. The least-squares method alternated with difference Fourier synthesis gave the positions of all the non-hydrogen atoms. A weighted anisotropic refinement of all the non-hydrogen atoms using BLOKLS, while keeping the hydrogen atoms in stereochemically acceptable positions, with a unit weighting scheme modified by the Dunitz–Seiler weighting scheme, gave final R and R_w values of 0.055 and 0.067, respectively. The refinement was deemed to be over when the shift-to-error ratio in scale and, positional and thermal parameters of non-hydrogen atoms reached 0.01. The final difference map has ripples of 1.68–1.00 Å around the heavy atoms. The scattering factors for platinum, phosphorus, sulphur and chlorine were taken from Vol. IV of the *International Tables for X-ray Crystallography*,[22] while those of hydrogen were taken from Stewart *et al.*[23] All the computations were carried out using the SDP package available for PDP-11/73.[24]*

PREPARATION AND CHARACTERIZATION OF A $[Ni(en)_2]^{2+}$ COMPLEX OF PERMETHYLPOLYAZINE

WILLIAM B. EULER

Department of Chemistry, University of Rhode Island, Kingston, RI 02881, U.S.A.

(*Received* 2 *November* 1990; *accepted* 4 *January* 1991)

Abstract—The bis(ethylenediamine)nickel(II) complex of permethylpolyazine is reported. The synthetic method used gives a polymer with alternate di-imine sites complexed to the metal ion. IR spectra of the monomer and polymer metal complexes are similar and demonstrate that interaction with the metal has changed the polymer geometry from all-*trans* to a mixture of *cis* and *trans* bonds. ^{1}H NMR spectra show that the ethylenediamine chelate rings attain several conformations in the monomer metal complex, but that one ring conformation dominates in the polymer. The UV–vis spectrum of the monomer metal complex shows *d–d*, π–π^* and MLCT bands, but in the polymer complex the *d–d* transitions are lost in the tails of the MLCT bands. This is consistent with band formation in the polyazine ligand.

Polyazines, $[N{=}C(R){-}C(R){=}N]_x$ (PAZ), are conjugated polymers that can be doped with iodine into highly conducting materials.[1] This is not especially surprising since polyazines are formally isoelectronic to the prototype conducting polymer, polyacetylene.[2] However, unlike polyacetylene, polyazine (with any R group) is environmentally stable.

Polyazine is amenable to a variety of chemical modifications. Like typical organic polymers, variation of the substituent groups at the carbon sites leads to polymers with different characteristics.[3–6] Long alkyl (propyl) groups can be used to give the polymer solubility in organic solvents,[4] thereby allowing films to be cast. Methyl substituents lead to polymers with the best conductivity,[1] while the completely unsubstituted polyazine is laden with saturated defects[5–7] leading to materials with low conductivity.

Use of the nitrogen atom in the polymer chain as a site of chemical modification has not been previously reported. Although the imine nitrogens are not useful as points of organic substitution, chelation of metal ions to di-imines is well known.[8] The repeat unit in polyazine is indeed a di-imine and thus should be usable as a ligand for the metal ions. However, direct reaction of a metal ion with polyazine is unsuccessful because the polymer is in the all-*trans* conformation (double bonds *E* and single bonds s-*trans*) which is unacceptable for formation of the five-membered chelate ring. Rather, a metal complex with the appropriate monomer ligand must be prepared and this is then polymerized to give the metal-containing polyazine.

The presence of the metal ion may have a number of effects on the polyazine. Certainly, the electronic structure of the conjugated π system must be perturbed which should effect the spectroscopic, oxidative and conductivity properties of the material. If a magnetic metal is used, long range interactions may lead to either antiferromagnetism or ferromagnetism (and perhaps these may be adjustable properties). Finally, a polymer-bound metal complex may be useful for catalysis purposes.

This paper reports the preparation and characterization of a bis(ethylenediamine)nickel(II) complex bound to permethylpolyazine. To achieve this polymer, the bis(ethylenediamine)mono(2,3-butanedionedihydrazone)nickel(II) complex is prepared and then this is polymerized to give the product. Dihydrazones are good ligands and are known to form bis and tris complexes with a number of metal ions.[9,10] However, a monohydrazone complex is required so that a linear, non-crosslinked polyazine can be formed. The permethyl derivative of polyazine is chosen so that a defect free linear π system will be formed. The IR, ^{1}H NMR and UV–vis spectroscopies are discussed in this paper.

EXPERIMENTAL

All starting materials were reagent grade and used as received. Hydrazine hydrate and 2,3-butanedione were obtained from Aldrich and nickel chloride hexahydrate was obtained from Allied Chemical. Elemental analyses were determined by M–H–W Laboratories, Phoenix, Arizona.

$[Ni(en)_2(BDDH)]Cl_2 \cdot 2.5H_2O$

Bis(ethylenediamine)nickel(II) chloride dihydrate[11] and 2,3-butanedionedihydrazone[1] (BDDH) were prepared by literature procedures. The nickel complex (2.00 g, 7.00 mmol) was dissolved in methanol (50 cm^3); water (1 cm^3) was added to ensure complete dissolution. To this was added freshly recrystallized BDDH (0.80 g, 7.0 mmol). The mixture was brought to the boil for *ca* 10 min, and then the solvent was removed *in vacuo* at room temperature to quantitatively give a red–brown, slightly hygroscopic, water-soluble powder. Found: C, 23.7; H, 7.2; N, 27.3; Cl, 17.1. Calc. for $NiC_8H_{26}N_8Cl_2 \cdot 2.5H_2O$: C, 23.5; H, 7.6; N, 27.4; Cl, 17.3%. Magnetic susceptibility: $\mu = 3.18$ BM at 20°C.

$[Ni(en)_2(C_8H_{12}N_4)Cl_2 \cdot 4H_2O]_x$

$[Ni(en)_2(BDDH)]Cl_2 \cdot 2.5H_2O$ (1.00 g, 2.44 mmol) was dissolved in methanol (10 cm^3) and brought to reflux. A solution of 2,3-butanedione (0.20 cm^3, 2.3 mmol) in methanol (5 cm^3) was added dropwise to the refluxing nickel solution over the course of *ca* 10 min. This caused the solution to change from purple to green and eventually to red. The reaction was heated and stirred for an additional 24 h. The solvent was removed *in vacuo* until the product was dry. The black, water-soluble powder is very hygroscopic and must be kept under desiccant. The yield is quantitative. Found: C, 30.7; H, 6.8; N, 22.8; Cl, 14.2. Calc. for $CH_3C(O)[NiC_{12}H_{26}N_8Cl_2 \cdot 4H_2O]_{6.2}C(O)CH_3$: C, 30.4; H, 7.3; N, 22.4; Cl, 14.2%. Magnetic susceptibility: $\mu = 3.10$ BM at 26°C.

Instrumentation

IR spectra were run as KBr pellets between 300 and 4000 cm^{-1} on a Perkin–Elmer 1430 Ratio Recording Infrared spectrophotometer. NMR spectra were run in D_2O at room temperature on a Bruker AM300 spectrometer at 300 MHz. Magnetic susceptibilities were measured on a home-built Gouy balance at room temperature using $HgCo(SCN)_4$ as a reference. UV–vis spectra were run between 200 and 1100 nm on a Perkin–Elmer Lambda 2 spectrophotometer.

Extended Hückel calculations

Standard parameters were used for carbon and nitrogen[12] atoms, while the values for nickel were taken from Whangbo and Stewart.[13] Bond lengths were estimated as follows:[14,15] C=N, 1.30 Å; C—C, 1.50 Å; N—N, 1.45 Å; and Ni—N, 1.84 Å. Only nearest neighbour overlaps were considered, so that the issue of *cis* and *trans* geometry is avoided. Orbitals are labelled in the C_{2v} point group as is appropriate for these complexes.

RESULTS AND DISCUSSION

Synthesis

Preparation of the nickel-containing polymer can not be accomplished using the uncomplexed polyazine as a reactant (all attempts using nickel salts with uncomplexed permethylpolyazine gave no reaction). This is because the free polymer is in the all-*trans* conformation, which is not amenable to chelation, and the complexation reaction does not provide sufficient driving energy to rotate large chain segments as would be required in this polymer. Rather, a monohydrazone metal complex is prepared that can then be condensed in the usual fashion with a diketone to form the complexed polyazine. In this manner, a nickel ion is placed at every other potential chelating position along the polyazine chain.

The monohydrazone complex is prepared by reacting one equivalent of BDDH with one equivalent of *trans*-dichlorobis(ethylenediamine) nickel(II):

$$\textit{trans}\text{-}[Ni(en)_2Cl_2] + BDDH \rightarrow [Ni(en)_2(BDDH)]Cl_2.$$

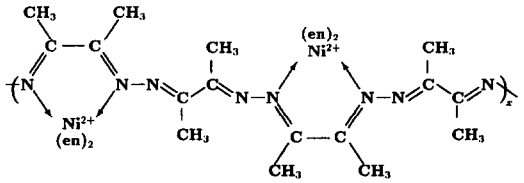
Although the nickel complex is in the *trans* conformation, the coordination sphere is sufficiently labile for the necessary ligand exchange to occur [the bis(ethylenediamine)nickel(II) chloride is prepared by ligand exchange between tris(ethylenediamine)nickel(II) and hexa-aquanickel(II)[11].] The product complex can form in a number of geometrical and optical isomers, several of which are observed in the ^1H NMR.

Polymerization of the monohydrazone nickel complex results via a condensation with 2,3-butanedione. The terminal amino groups of the dihydrazone ligand which are not involved in bonding to the metal are free to react with the diketone

similar to any other condensation that forms a polyazine:[1]

$$[Ni(en)_2(BDDH)]Cl_2 + CH_3C(O)C(O)CH_3 \rightarrow [Ni(en)_2(C_8H_{12}N_4)Cl_2]_x + H_2O.$$

This leads to a polymer with half of the N=C—C=N units acting as chelates bound to a nickel ion forcing a s-*cis* C—C bond. These nickel-bound di-imine sites alternate with free di-imine units. Elemental analysis (using an end group analysis, with carbonyl end groups indicated) suggests an average chain length of about 12.5 di-imine repeat units, shorter than the degree of polymerization (about 45 repeat units) found in the uncomplexed polymer.



The binding of a metal ion to polyazine should cause a drastic change in the geometry of the polymer chain. In the uncomplexed polymer the chain is found in the all-*trans* conformation. Upon complexation to the metal ion several of the bonds along the chain rotate to *cis* (all the double bonds are still *E* but the C—C in the chelate ring and the N—N are s-*cis* while the C—C not involved in complexation probably remains s-*trans*), as shown above. The N—N bonds at uncomplexed imine sites attain s-*cis* conformation because of repulsion between the substituent methyl group and ethylenediamine (en) ligands bound to the nickel ion (as indicated by molecular models).

IR spectroscopy

The major assigned IR bands are summarized in Table 1 for the materials reported here, as well as relevant comparison compounds. The N—H stretching region is diagnostic of the various species. The s-*trans* BDDH has two sharp bands in this region, while $[Ni(BDDH)_3]Cl_2$, which has s-*cis* BDDH ligands, has three sharp bands. In contrast, $[Ni(en)_2(BDDH)]Cl_2 \cdot 2.5H_2O$ has a broad band in this spectral area with five distinct peaks that are poorly resolved. This is a reflection of the different types of N—H bonds found in the en and BDDH ligands. Finally, the metal polymer complex only has a single, broad peak at these energies, consistent with the multiple sites expected in polymeric material.

The C—CH_3 deformation is especially useful in assessing the geometric characteristics of these materials. The C—CH_3 deformation is found at 1355 cm^{-1} for both BDDH and the uncomplexed polyazine; this shows that the local geometry about the H_3C—C—C—CH_3 bonds are the same in both compounds, i.e. s-*trans*.[1] In contrast, $[Ni(BDDH)_3]Cl_2$, which must have the C—C bond in the s-*cis* conformation, has two peaks at higher energy than the uncomplexed ligand. Finally, the polymer has bands attributable to both s-*cis* (1380 cm^{-1}) and s-*trans* conformations (1350 cm^{-1}), consistent with the conformations suggested previously.

Table 1. Major IR absorptions; values given in cm^{-1}

	NH_2 stretch	NH_2 int. deformation	C=N stretch	C—CH_3 deformation
BDDH	3185 3325	1630	1560	1355
$[Ni(BDDH)_3]Cl_2$[a]	3180 3395 3460	1655	1610	1365sh 1375
$[Ni(en)_2(BDDH)]Cl_2 \cdot 2.5H_2O$	3180 3255 3300 3350 3500	1595 1620 1650	1610	1375
$[Ni(en)_2(C_8H_{12}N_4)Cl_2 \cdot 4H_2O]_x$	3300br	1600br		1350sh 1380
$(C_4H_6N_2)_x$			1585	1355

[a] In agreement with ref. 10.
sh = shoulder, br = broad.

The assignments of the NH_2 internal deformation and the C=N stretch for $[Ni(en)_2(BDDH)]Cl_2 \cdot 2.5H_2O$ are ambiguous: complete deuteriation of the amino protons could not be achieved in this complex so that an unambiguous assignment of the C=N band is not possible. $[Ni(en)_3]Cl_2$ has a pair of bands centred around 1600 cm,$^{-1}$ so the assignments in Table 1 are tentatively given. The polymer complex has a single broad band centred at 1600 cm^{-1} that originates from both NH_2 and C=N vibrations.

Several absorptions that are characteristic of the chelated en ring can also be identified. $[Ni(en)_3]Cl_2$ has peaks at 2895, 2950 and 2970 cm^{-1} due to C—H stretches, a peak at 1465 cm^{-1} due to CH_2 scissoring, and peaks at 500 and 530 cm^{-1} due to chelate ring deformation.[16] Similar absorptions can be found in $[Ni(en)_2(BDDH)]Cl_2$ and the polymer complex also. The monomer has peaks characteristic of C—H stretches at 2900, 2960 and 2980 cm,$^{-1}$ a strong peak at 1455 cm^{-1} associated with the CH_2 scissor, and the chelate ring deformation peaks are found at 505 and 530 cm^{-1}. The polymer complex is slightly different because of the long chain nature of the material. The sharp peak at 2895 cm^{-1} is still present in the polymer but the characteristic doublet at higher energy in the monomer is found as a single broad peak centred at 2960 cm.$^{-1}$ These are the C—H stretching vibrations. The peak due to the CH_2 scissoring motion is found at 1450 cm,$^{-1}$ and has a similar line shape as the monomer. Finally, a peak at 520 cm^{-1} is accompanied by only a very weak shoulder at 500 cm^{-1}; these are attributed to the chelate ring deformation. Although some differences occur, vibrations due to chelated en are still observed in the polymer complex indicating that the polymerization condensation indeed occurred with BDDH amino groups and not with en amino groups.

^1H *NMR*

All of the compounds studied here have chemical shifts and line widths typical of paramagnetic nickel complexes.[17,18] Two well separated types of protons are found in these materials, either due to CH_3 substituents on the BDDH ligand, observed upfield of TMS, or CH_2 groups found in the en ligand, detected downfield of TMS. The amino protons from either en or BDDH are not observed, probably because of large line widths arising from a combination of exchange and paramagnetic effects. The chemical shifts are reported in Table 2. Multiple resonances are seen in some cases, reflecting the existence of different ring conformations that exist for these complexes in solution.

Table 2. Chemical shifts for ^1H NMR reported vs TMS. All spectra were run at room temperature at 300 MHz in D_2O

	CH_3	CH_2
$[Ni(en)_3]^{2+}$ [a]		78.2
		118.4

	−2.6	
	−4.7	
	−6.4	
$[Ni(en)_2(C_8H_{12}N_8)^{2+}]_x$	−8.0	95.7

[a] In agreement with ref. 18.

The model compounds, $[Ni(en)_3]Cl_2$, $[Ni(en)_2Cl_2]$ and $[Ni(BDDH)_3]Cl_2$, all have simple spectra in D_2O solution. The tris-en complex has two resonances due to CH_2 protons, interpreted as arising from two different geometrical isomers.[18] The bis-en complex (which is undoubtedly a *trans*-diaqua species in solution) has a single CH_2 resonance.[19] The tris-BDDH complex also displays a single peak, due to the CH_3 groups. The resonances from the two optical isomers are not resolved. The mixed ligand complex, $[Ni(en)_2(BDDH)]Cl_2$, has several peaks in the CH_3 region but a single peak due to CH_2 protons. The peak due to the CH_2 groups is similar to the previous examples, but the resonances from the CH_3 groups are shifted 4–9 ppm downfield relative to the tris-BDDH complex. Clearly, several conformations exist in solution and the CH_3 protons are excellent remote probes of these geometries. Finally, the polymer complex has a relatively simple NMR spectrum: a single, broad peak in both the CH_2 and CH_3 region. It is reasonable that a single conformation of the en chelate rings is found in the polymer, since interactions with the main chain backbone restrict access to the other ring conformations.

UV–vis spectroscopy

The nickel complexes all have two distinct spectral regions. Low intensity *d–d* transitions are observed in the visible and near-IR. In the UV, intense π–π^* and MLCT bands are seen. Each of these spectral regions will be discussed separately.

The visible and near-IR transitions for $[Ni(en)_2(BDDH)]^{2+}$ and $[Ni(en)_2(C_8H_{12}N_4)]_x^{2+}$ are

Table 3. *d–d* Transitions given in cm^{-1} (molar extinction coefficients are given in parentheses) using the O_h notation

	$^3T_{2g}$	$^3A_{2g}$ ^1E_g	$^3T_{1g}(F)$	*Dq*	*B*
$[Ni(en)_3]^{2+}$ [a]	11,300 (6)	12,800sh (3)	18,300 (6)	1180	790
$[Ni(BDDH)_3]^{2+}$ [b]	12,800 (9)	11,800sh (7)	20,200 (21)	1250	1070

[a] In agreement with ref. 19.
[b] In agreement with ref. 20.

summarized in Table 3. For comparison purposes, the *d–d* transitions for $[Ni(en)_3]^{2+}$[19] and $[Ni(BDDH)_3]^{2+}$[20] are also given in Table 3. The Racah *B* parameter is found using the equations of Dou.[21] The values for *Dq* are found using the procedure of Jorgensen,[19] where $10Dq$ is found from the weighted average of the two lowest energy transitions. This weighting procedure was found necessary in order to obtain a reasonable value of *B* for the $[Ni(en)_2(BDDH)]^{2+}$ complex. For the polymer complex, the lowest energy transition is seen only as a broad shoulder on the tail of the intense UV band, and therefore a rather large error is associated with the value of *Dq*.

The UV spectra of BDDH and the metal complexes $[Ni(BDDH)_3]$,$^{2+}$ $[Ni(en)_2(BDDH)]^{2+}$ and $[Ni(en)_2(C_8H_{12}N_4)]_x^{2+}$ are shown in Fig. 1. In water, the ligand has a single transition at 38,200 cm^{-1} ($\varepsilon = 14{,}000$ dm^3 mol^{-1} cm^{-1}) (similar to the spectrum in chloroform reported earlier[4]). Complexation of Ni^{2+} with three BDDH ligands to form $[Ni(BDDH)_3]^{2+}$ gives a spectrum with a strong band at about the same energy as the ligand, 38,000 cm^{-1} ($\varepsilon = 22{,}000$ dm^3 mol^{-1} cm^{-1}), and a shoulder at 33,300 cm^{-1} ($\varepsilon = 12{,}000$ dm^3 mol^{-1} cm^{-1}). $[Ni(en)_2(BDDH)]^{2+}$ shows similar features [a peak at 37,900 cm^{-1} ($\varepsilon = 8800$ dm^3 mol^{-1} cm^{-1}) and a shoulder at 33,300 cm^{-1} ($\varepsilon = 8400$ dm^3 mol^{-1} cm^{-1})], although the relative intensity of the shoulder is nearly as great as the main peak. The polymer complex, $[Ni(en)_2(C_8H_{12}N_4)]_x^{2+}$, is similar to the monomer but with extra shoulders and a much longer tail in the visible [a peak at 38,100 cm^{-1} ($\varepsilon = 8400$ dm^3 mol^{-1} cm^{-1}) and shoulders at 33,300 cm^{-1} ($\varepsilon = 7000$ dm^3 mol^{-1} cm^{-1}) and 27,800 cm^{-1} ($\varepsilon = 2400$ dm^3 mol^{-1} cm^{-1})].

The assignment of these peaks is made using the energy level diagrams shown in Fig. 2. These energy levels were found by using Extended Hückel calculations on the orbitals of π symmetry on the fragments shown in Fig. 2. The effects of the ethylene-

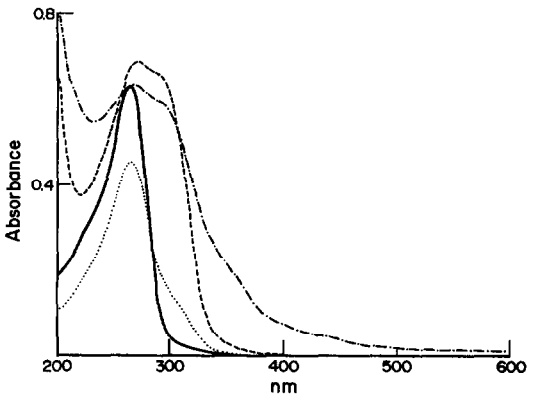

Fig. 1. UV spectra of aqueous solutions of BDDH (solid), $[Ni(BDDH)_3]^{2+}$ (dotted), $[Ni(en)_2(BDDH)]^{2+}$ (dashed) and $[Ni^{2+}(en)_2(C_8H_{12}N_4)]_x$ (dot–dash).

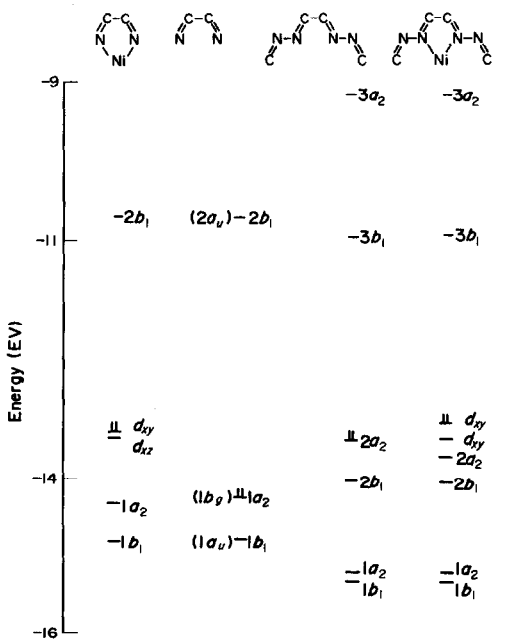

Fig. 2. Energy level diagram of the π systems for di-imine and nickel di-imine fragments.

diamine ligands and methyl groups on BDDH were ignored. The energy level diagram for the ligands is as reported previously,[14,15] while the inclusion of the metal orbitals only causes minor perturbations.

In the solid state BDDH has a s-*trans* conformation (point group C_{2h}), as determined X-ray crystallographically,[1] and the UV spectrum suggests that this geometry is retained in solution. The only allowed π–π^* transition for the C_{2h} structure is $^1A_g \rightarrow {}^1B_u$ ($1b_g^2 \rightarrow 1b_g^1 2a_u^1$), while for the s-*cis* (C_{2v}) structure both the $^1A_1 \rightarrow {}^1B_1$ ($1a_2^2 \rightarrow 1a_2^1 2b_1^1$) and $^1A_1 \rightarrow {}^1A_1$ ($1b_1^2 \rightarrow 1b_1^1 2b_1^1$) transitions are allowed. Since only a single π–π^* transition is observed, the C_{2h} structure is maintained in solution and the 38,200 cm^{-1} transition is assigned to $^1A_g \rightarrow {}^1B_u$.

Coordination of three BDDH molecules to Ni^{2+} gives the D_3 $[Ni(BDDH)_3]^{2+}$ but, as evidenced by the analysis of the *d–d* transitions, the O_h point group is an adequate approximation for this complex. In O_h, the group orbitals analogous to the highest occupied $1a_2$ transform as t_{2g}, while the lowest unoccupied π^* orbitals transform as t_{1u}. This leads to one allowed π–π^* transition, $^1A_{1g} \rightarrow {}^1T_{1u}$ ($t_{2g}^6 \rightarrow t_{2g}^5 t_{1u}^1$), which should be at nearly the same energy as the π–π^* transition in the uncomplexed molecule. A MLCT transition from the metal e_g orbitals to the empty ligand π^* orbitals is also possible. An allowed transition, $^3A_{2g} \rightarrow {}^3T_{2u}$ ($e_g^2 \rightarrow e_g^1 t_{1u}^1$), is expected at lower energy than the π–π^* transition since the metal e_g orbitals are expected to be higher in energy than the ligand π orbitals (although the relative energy of the $^3T_{2u}$ and $^1T_{1u}$ states is unknown). Thus, the peak at 38,000 cm^{-1} is assigned as a $^1A_{1g} \rightarrow {}^1T_{1u}$ ligand π–π^* transition and the shoulder at 33,300 cm^{-1} is assigned as a $^3A_{2g} \rightarrow {}^3T_{2u}$ MLCT transition.

The UV spectrum of $[Ni(en)_2(BDDH)]^{2+}$ is similar to the spectrum of $[Ni(BDDH)_3]^{2+}$, but must be interpreted in the C_{2v} point group. Thus, the peak at 37,900 cm^{-1} is assigned to the $^1A_1 \rightarrow {}^1B_2$ ($1a_2^2 \rightarrow 1a_2^1 2b_1^1$) ligand-centred π–π^* transition and the shoulder at 33,300 cm^{-1} to the $^3A_2 \rightarrow {}^3B_2$ ($d_{xy}^2 \rightarrow d_{xy}^1 2b_1^1$) MLCT transition. The π–π^* transition $1b_1^2 \rightarrow 1b_1^1 2b_1^1$ is also allowed in this complex and may be responsible for the high energy band seen at 200 nm and below in Fig. 1. The MLCT $d_{xz}^2 \rightarrow d_{xz}^1 2b_1^1$ ($^3A_2 \rightarrow {}^3A_1$) is *not* allowed for this complex.

$[Ni(en)_2(BDDH)]^{2+}$ and $[Ni(en)_2(C_8H_{12}N_4)]_x^{2+}$ have similar UV spectra, but the polymer spectrum has additional low energy shoulders and a considerably more intense tail throughout the visible region. This is consistent with band formation in the π system of the ligand. The features of the polymer at 38,100 and 33,300 cm^{-1} have the same assignments as $[Ni(en)_2(BDDH)]^{2+}$ while the visible shoulders and tail are absorptions into the delocalized band of the polymer.

CONCLUSIONS

The nickel-containing polyazine reported here indicates a different method to modify the properties of conducting polymer systems. Permethylpolyazine is a yellow, insoluble material; complexation to nickel changes this to a black, water-soluble complex. IR spectroscopy demonstrates that the desired complex has been attained, but the chain geometry is quite different from the uncomplexed polyazine. ^1H NMR spectra reveal that the monomer precursor complex has a number of conformations available, but only one of these is found with any abundance in the polymer. Presumably, this is due to steric repulsions between the en ligands on the metal ion and the bulk of the polymer chain. The dark colour of the polymer complex is due to MLCT bands that have significant tails into the visible region. The breadth of these absorptions is typical of spectral transitions associated with delocalized electronic bands.

(*Received* 12 *November* 1990; *accepted* 7 *January* 1991)

Abstract—The title compound was prepared by the oxidative addition of triphenylsilane to $Pt^0[1,4\text{-}(Cy_2P(CH_2)_4PCy_2)]$ (where Cy = cyclohexyl) generated *in situ*. The crystal structure of *cis*-$H(Ph_3Si)Pt[Cy_2P(CH_2)_4PCy_2]$ (**2**) has been determined by single-crystal X-ray diffraction techniques. The square planar geometry about the platinum atom is angularly distorted with a bite angle between the diphosphine ligands (P—Pt—P) of 102.3(1)°. Details of the structural content and selected bond lengths and angles are discussed and presented. The phenyl rings are planar and the cyclohexyl rings are in chair conformations. The enlarged tetrahedral angles at the phosphorus and silicon atoms are probably due to the steric bulk of the ligands. "Ligand profile" calculations ($\theta/2$ vs ϕ) have been performed to probe the steric interaction about the diphosphine and triphenylsilyl ligands.

The chemical significance of control over steric demands of substituents in stabilizing kinetically labile species is well known in all aspects of synthetic chemistry. In particular, the effects of the steric demands of phosphine ligands have been extensively studied in zero-valent complexes of the group 10 metals.[1,2] The steric demands of these ligands have been described by a number of different methods. Tolman characterized the steric bulk of a phosphine group by introducing the cone angle (θ) concept which was extended by Alyea *et al.*[3] and Richardson and Payne.[4] A new angle, ϕ, was defined as the angle of rotation about the metal–phosphorus bond. A plot of $\theta/2$ vs ϕ resulted in a "ligand profile". This profile, which resembles a silhouette of the orientated ligands, was improved by Smith and Oliver[5] by presenting a ligand profile defined by atomic coordinates from a structural analysis. The improved method is flexible enough to calculate ligand profiles for other stabilizing ligands such as AsR_3 and SiR_3.[6]

The reactivity of low coordination number, bulky phosphine-stabilized platinum(0) complexes towards oxidative addition has also been the subject of many studies. $Pt(PCy_3)_2$ was shown to undergo oxidative addition with polar C—H bonds,[7] but more recently, the highly reactive species $Pt^0(Cy_2P(CH_2)_2PCy_2)$, generated *in situ*, was established as the first example of activation of unactivated C—H bonds at a platinum(0) centre.[8] This is presumably the result of the small bite angle of the 1,2-$(Cy_2P(CH_2)_2PCy_2)$ ligand. We have previously reported the reactivity of similar *cis*-bis-phosphine and chelating diphosphine supported platinum(0) centres towards oxidative addition,[9–13] particularly with respect to correlation of chelate ligand backbone chain length with solution dynamic behaviour and reactivity.[11,14] Here we describe the synthesis and structural characterization of *cis*-$H(Ph_3Si)Pt[Cy_2P(CH_2)_4PCy_2]$ (**2**) together with ligand profiles for both the phosphine and silyl ligands.

EXPERIMENTAL

All manipulations were carried out under an atmosphere of dry (4 Å molecular sieves) and deoxygenated (MnO) nitrogen.[15] Hydrocarbon solvents were dried and distilled from sodium benzophenone ketyl and stored under nitrogen over 4 Å molecular sieves prior to use. Deuterated NMR solvents were dried over 4 Å molecular sieves and stored under nitrogen. NMR spectra were recorded on a Bruker AC-250 NMR spectrometer. ^{1}H NMR chemical shifts were referenced to the protio impurity in the deuterated solvent. ^{31}P NMR chemical shifts were referenced to external phosphoric acid and are quoted using the downfield positive sign convention. Temperatures were calibrated using methanol and ethylene glycol standards.

Synthesis of cis-H(Ph_3Si)Pt[$Cy_2P(CH_2)_4PCy_2$] (**2**)

To Cl_2Pt[1,4-($Cy_2P(CH_2)_4PCy_2$)] (**1**) (0.95 g, 1.33 mmol) suspended in 8 cm^3 of THF in a 50 cm^3 Schlenk flask at 0°C was added a slight excess of two equivalents of a 0.5 M solution of sodium naphthalenide in THF until the colour of the solution just remained green.[16] The reaction mixture was stirred for 3 h during which time it warmed to room temperature. The volatile components were removed *in vacuo* and the residue extracted with three 10 cm^3 portions of warm n-pentane to give a pale yellow solution believed to contain Pt^0[1,4-($Cy_2P(CH_2)_4PCy_2$)]. [The presence of the platinum(0) species was confirmed by removal of a small (0.5 cm^3) aliquot of the solution and exposure to air, which immediately resulted in the formation of a white precipitate.] To this solution was added a slight excess of Ph_3SiH (0.40 g, 1.54 mmol) which caused immediate formation of a white precipitate. The reaction mixture was stirred for 1 h, filtered and the white solid washed three times with 5 cm^3 of n-pentane to remove the excess Ph_3SiH and naphthalene. The white solid, 0.82 g (0.91 mmol) analysed correctly for **2** and was obtained in a yield of 68.1%. ^{1}H NMR data (20°C, 250 MHz, C_6D_6): −2.51 ppm, d × d, $^2J_{H-P_{cis}}$ = 19 Hz, $^2J_{H-P_{trans}}$ = 149 Hz, $^2J_{H-Pt}$ = 867 Hz, Pt—*H*; 1.0–1.3 ppm, multiplets, $Cy_2P(CH_2)_4PCy_2$; 7.20 ppm, m, Si*Ph*$_3$; 7.41 ppm, m, Si*Ph*$_3$; 8.24 ppm, m, Si*Ph*$_3$. ^{31}P NMR data (20°C, 101.2 MHz, C_6D_6): 33.9 ppm, d, J_{P-P} = 20 Hz, J_{P-Pt} = 1607 Hz, J_{P-Si} = 162 Hz, J_{P-H} = 18 Hz, P *trans* to Si; 39.4 ppm, d, J_{P-Pt} = 2471 Hz, J_{P-H} = 146 Hz, P *trans* to H. Found: C, 60.6; H, 7.3. Calc.: C, 61.0; H, 7.5%. Melting point, 172–174°C.

Crystallographic data

Crystal data. $C_{46}H_{68}P_2PtSi$, Mr = 906.16, monoclinic, space group $P2_1/n$, a = 14.142(4), b = 16.160(4), c = 20.120(6) Å, β = 109.16(2)°, V = 4343(3) Å^3, Z = 4, D_c = 1.386 Mg m^{-3}, D_m = 1.40(1) Mg m^{-3} (flotation), $F(000)$ = 1864, Mo-$K_{\bar{\alpha}}$ (λ = 0.71073 Å), μ = 3.36 mm^{-1}, T = 295 K, 6068 reflections were measured on a CAD-4F diffractometer ($2\theta_{max}$ = 45.0°); 5636 were unique and 3606 had $I > 3\sigma(I)$. Lorentz, polarization and empirical absorption corrections (transmission range, 0.9395–0.9995) were made.

Unit cell parameters were determined by employing a Debye–Scherrer cylindrical camera (114.6 mm, 295 K using Cu-$K_{\bar{\alpha}}$ radiation, λ_{mean} = 1.54184 Å). Crystals of **2** were finely ground and placed into a 0.2 mm capillary. Characterization was based on 54 lines. "Figures-of-merit" values are $F(30)$ = 46(0.005, 137)[17] and M_{20} = 20.9.[18]

Solution and refinement. The structure solution was solved by direct methods (SHELX-86)[19] and refined by block full-matrix least-squares using the SHELX-76 computer program.[20] The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where $w = (\sigma^2(F_o) + 0.0058|F_o|^2)^{-1}$. All non-hydrogen atoms were refined anisotropically. The hydrogen atom positions were computed and were not refined. The final reliability factors are R = 0.056 and R_w = 0.058 for all observed reflections.* An extinction correction was also refined. The final cycle of block refinement had 408 variables and maximum shift/error of 0.00058. In the final D-map, the highest peak density was 0.71 e$^-$ Å^{-3} and the deepest hole showed a density of −0.99 e$^-$ Å^{-3}, both in the vicinity of the platinum atom. Elsewhere, only a random fluctuating background was observed. Weights based on counting statistics were used throughout. Atomic scattering factors and anomalous dispersion correction factors were taken from the usual source.[21]

RESULTS AND DISCUSSION

The synthesis of **2** was carried out via oxidative addition of triphenylsilane to the platinum(0) species Pt^0[1,4-($Cy_2P(CH_2)_4PCy_2$)] generated *in situ* as previously reported in the literature.[14] In contrast to a number of *cis*-H[SiR_3]Pt(PR'_3)$_2$ derivatives (where R = variously substituted phenyl and

* Atomic coordinates, thermal parameters and a list of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

R′ = variously substituted phenyl and cyclohexyl), **2**, does not undergo rapid intramolecular ligand position exchange in solution.[11,14,22] This dynamic process is most easily characterized by monitoring the temperature variation of the intensity of certain resonances of the hydride ligand by ^{1}H NMR spectroscopy which are selectively broadened due to retention of spin correlation during the transition state.[23] The variable temperature ^{1}H NMR data for **2** over the range +60 to −70°C are completely temperature invariant. A close analogue of **2**, *cis*-H(SiPh$_3$)Pt[1,4-(Ph$_2$P(CH$_2$)$_4$PPh$_2$)] (**3**), which has recently been structurally characterized,[24] also does not undergo the intramolecular ligand position exchange process describd above. In order to shed more light on this observation, a single crystal X-ray diffraction study of **2** has been carried out to examine the bite angle in the 1,4-(Cy$_2$P(CH$_2$)$_4$PCy$_2$) ligand.

The title compound crystallizes in the monoclinic space group $P2_1/n$ and contains four molecules per unit cell. The platinum atom has angularly distorted square-planar geometry and is bonded to a hydrogen atom, two phosphorus atoms and a silicon atom. The molecular structure of **2** is shown in Fig. 1 and selected bond lengths and angles are given in Table 1. The atoms of the platinum first coordination sphere display only minor deviations from planarity (mean deviation of 0.035 Å) probably as a result of the minimal space requirement for the hydrogen atom compared with the more sterically demanding triphenylsilyl and diphosphine ligands. The "bite" angle of the two phosphorus atoms [P(1)—Pt—P(2) is 102.3(1)°] brought about by the bridging hydrocarbon chain, also contributes to the angular distortion. In contrast, the bite angle of *cis*-H[Ph$_3$Si(Ph$_2$P(CH$_2$)$_4$PPh$_2$)] is 103.5(1)°, which is slightly larger probably as a result of the less sterically demanding substituents on the phosphorus atoms. Due to the established higher *trans* influence of the triphenylsilyl group compared with hydride, the Pt—P(2) bond length is longer than the Pt—P(1) bond.[25] The Pt—Si distance is reasonable when compared with published values in *BIDICS*.[26] The mean P—C length of 1.864(14) Å and the mean Si—C length of 1.901(13) Å, which are bonded to the cyclohexyl and the phenyl rings, respectively, are quite normal as well as the P(1)—C(1) and

the P(2)—C(4) bond distances. Distortions are observed in the angles around the two ligating phosphorus atoms, with a maximum deviation from an ideal tetrahedral angle of 13.3°. However, the mean angles about atoms P(1) and P(2) are 109.3 and 109.2°, respectively. This type of distortion has been previously observed in tricyclohexylphosphine platinum complexes.[9–11] A similar distorted

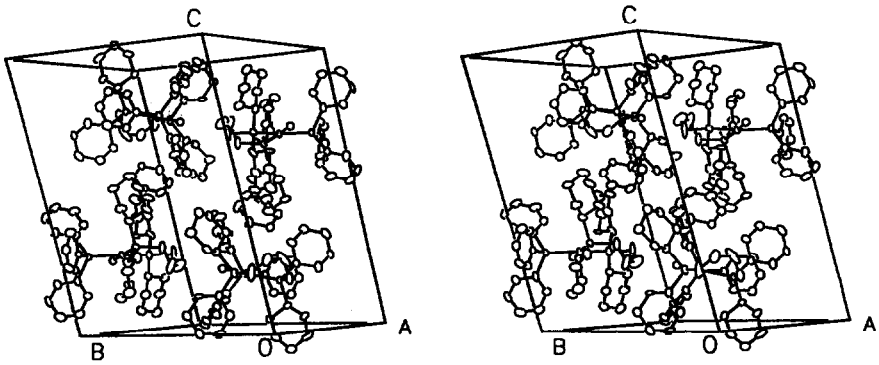

Fig. 2. Stereoscopic packing diagram of the unit cell of **2**.

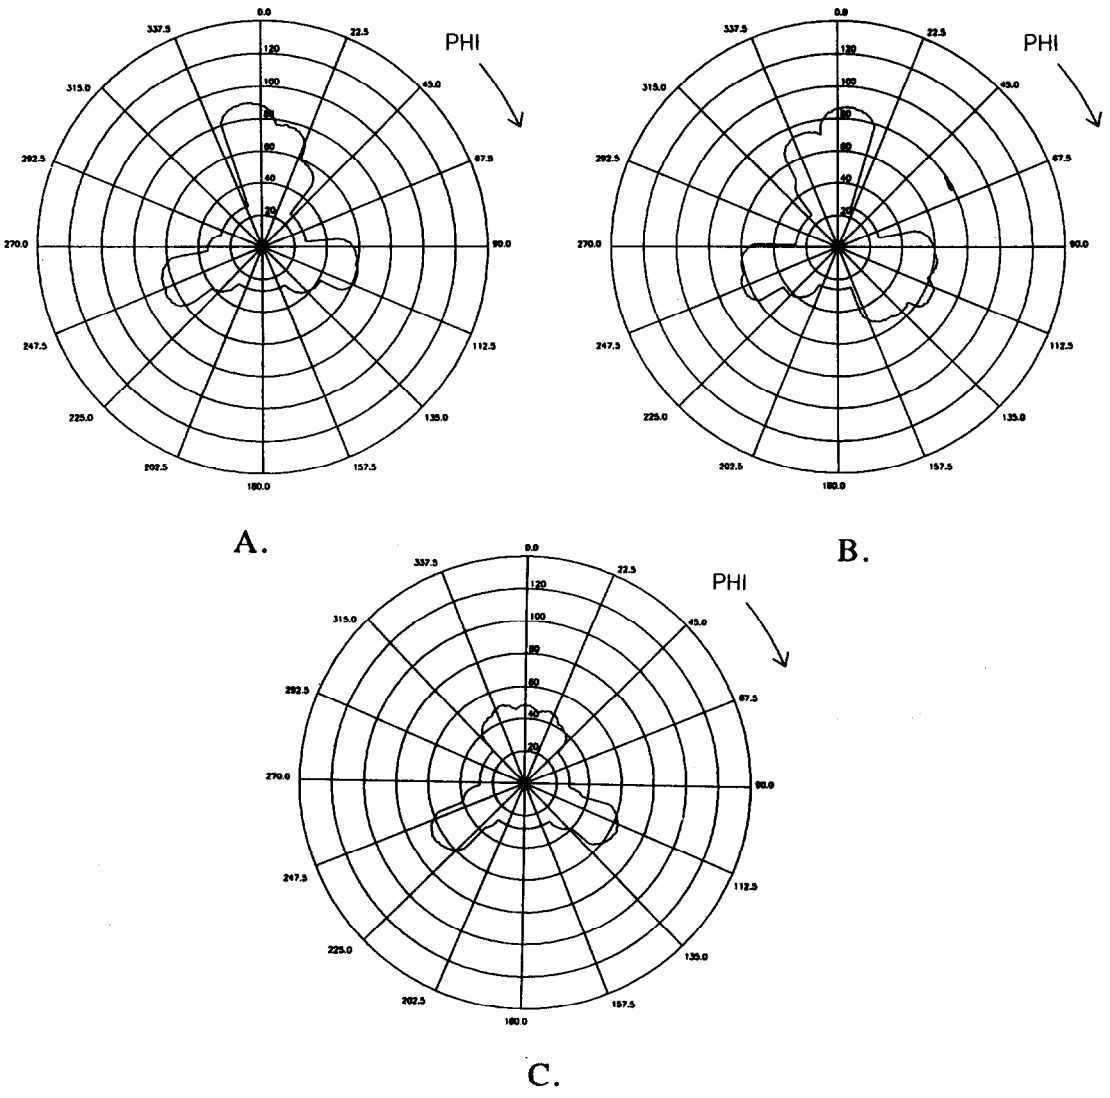

Fig. 3. Ligand profiles ($\theta/2$ vs ϕ) of **2** looking down (A) the Pt—P(1) bond, (B) the Pt—P(2) bond and (C) the Pt—Si bond.

arrangement is seen about the central silicon atom in the $SiPh_3$ ligand. The largest deviation from ideality is 12.0° (mean angle about the Si atom, 109.3°). The C—C bond distances and C—C—C bond angles within each ring system varied considerably, see Table 1. The platinum, two phosphorus and four bridging carbon atoms make up a seven-membered ring with distinct puckering. The puckering involves the virtual eclipsing of the substituents of carbons C(2) and C(3) in the seven-membered ring. This eclipsing is more severe than commonly encountered in seven-membered cycloalkane rings[27] and probably is a result of the small P(1)—Pt—P(2) angle and the planarity of these atoms. The bond lengths and angles associated with the hydrocarbon chain bridging the phosphorus atoms is further evidence of considerable ring strain.

Ligand profiles for the two phosphine ligands and the triphenylsilyl group are shown in Fig. 3. The steric bulk about the two phosphorus atoms is viewed down the platinum–phosphorus bonds: (A) for the Pt—P(1) and (B) for Pt—P(2). Note that even though both phosphorus atoms have the same type of bonded lignds and basically similar silhouettes, one of the lobes of the Pt—P(2) profile reveals more steric bulk, which further evidences the extended bond distance of Pt—P(2). This added bulk to the profile is related to the distinct ring strain puckering in the seven-membered ring, compare Pt—P(2)—C(4,61,71) angle variances to the uniformity of Pt—P(1)—C(1,41,51) angles, see Table 1. The concept of the half cone angle ($\theta/2$) and the rotational angle (ϕ)[3,4] coupled with the experimental polar ligand profile obtained from cry-

stallographic data, has also been used to evaluate steric demand in phosphine ligands. For **2**, the maximum (minimum) half-cone angle calculations about the diphosphine and triphenylsilyl ligands are: $Cy_2P(1)(CH_2)_4 = 90(61)°$, $Cy_2P(2)(CH_2)_4 = 87(62)°$ and $SiPh_3 = 66(50)°$, ESDs for each, $\pm 1.0°$. This profile is very similar to that of $H(Ph_3Si)Pt[Ph_2P(CH_2)_4PPh_2]$.[24]

Further studies of the chemical significance of sterically demanding substituents at platinum centres are in progress.

(*Received* 24 *September* 1990; *accepted* 7 *January* 1991)

Abstract—The adduct of copper(II) acetate with 2-aminopyrimidine, *catena*-[(2-aminopyrimidine-*N*,*N*′)-tetrakis-μ-(ethanoato-*O*,*O*′)-dicopper(II)], has been prepared and its structure determined using X-ray diffraction. The structure is based on a tetracarboxylate-bridged dimer unit of the copper(II) acetate hydrate type [Cu---Cu, 2.633(2) Å] but is extended into an infinite zigzag polymer via the *meta*-related nitrogen atoms of bridging 2-aminopyrimidine molecules [Cu—N, 2.218(5) Å].

Since the first tetracarboxylate-bridged copper(II) dimer structure (**1**) was reported for copper(II) acetate hydrate by van Niekerk and Schoening[1] in 1953, a number of nitrogen base and oxygen donor group adducts of copper(II) with unsubstituted acetate have been reported. These include urea,[2] α-picoline,[3] benzimidazole,[4] dimethylformamide,[5] methyl nicotinamide,[6] 2-aminopyridine,[7] isatin-3-phenylhydrazone,[8] acetic acid,[5] methanol,[9,5] N,N-diethylnicotinamide,[10] hexamethylenetetramine,[11] 1,4-diazabicyclo(2.2.2)octane,[12] pyrazine,[12] pyridine,[13] quinoline[14] and thiocyanate.[15] The majority of examples involve a discrete dimer with terminal adducted molecules (replacing water in **1**), while in only isolated cases, adducted molecules with bifunctional donor groups extend the dimers into linear polymers (**2**).[5,11,12]

With 2-aminopyrimidine (2-ampym), the *meta*-related ring nitrogen atoms have potential for the formation of an analogous but zigzag polymer chain structure, although only one such example of this has been reported, the copper(II) (2-chlorophenoxy)ethanoate-2-aminopyrimidine adduct.[16] In contrast, the adduct with copper(4-fluorophenoxy)ethanoate[17] is a discrete dimer. The chemically stable, dark green adduct formed between 2-aminopyrimidine and copper(II) acetate in ethanol gave an analysis consistent with [$Cu_2(RCO_2)_4$(2-ampym)$_1$], and suggested a polymer structure, which was confirmed in the single crystal structure determination.

EXPERIMENTAL

Preparation

The complex was prepared by dropwise addition of a 1:1 stoichiometric amount of 2-aminopyrimidine in ethanol to a stirred ethanolic solution of copper(II) acetate hydrate, maintained at 70°C. An immediate colour change was followed by rapid growth of small, dark green, prismatic crystals from the cooling solution. (Found: C, 31.0; H, 3.7; N, 8.9. Calc. for $C_{12}H_{17}Cu_2N_3O_8$: C, 31.4; H, 3.73; N, 9.2%.)

Crystal data

$C_{12}H_{17}Cu_2N_3O_8$, $M = 458.4$, monoclinic, $a = 15.126(3)$, $b = 13.709(1)$, $c = 8.659(2)$ Å, $\beta =$

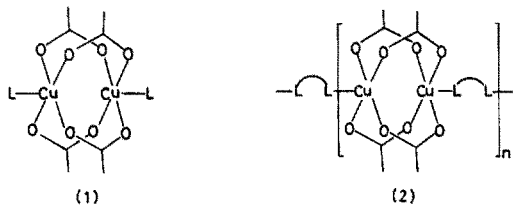
93.79(1)°, $U = 1791.7(6)$ Å^3, $D_m = 1.71$, $D_c = 1.698$ g cm^{-3}, $Z = 4$, Mo-K_α radiation, $\lambda = 0.71073$ Å, μ(Mo-K_α) = 25.1 cm^{-1}, $F(000) = 928$, space group $C2/c$, $t = 296$ K.



Data collecion, structure solution and refinement

Data were collected from a specimen measuring 0.12 × 0.05 × 0.04 mm on an Enraf–Nonius CAD-4 diffractometer. 2352 reflections were collected ($2\theta_{max} = 50°$; *hkl* range: $h = \pm 18$, $k = 0$–16, $l = 0$–10), giving 1377 unique, of which 889 with $I > 3.0\sigma(I)$ were used in structure refinement. Crystal monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) was used, with empirical absorption corrections applied to the data. A total loss of *ca* 1% in the intensities of three standards monitored during the collection period indicated negligible crystal decay. The structure was solved using the Patterson method (SHELXS 86[18]) and refined using SHELX 76.[19] Neutral atom scattering factors and f', f'' terms for anomalous dispersion were taken from ref. 20. Full-matrix least-squares refinement with anisotropic thermal parameters on all non-hydrogen atoms gave R* and R_w† of 0.042 and 0.044, respectively, with a value of $w = 0.4/(\sigma^2 F_o + 5.9 \times 10^{-3} F_o^2)$ being used. Hydrogen atoms were located by difference methods and their positional and isotropic thermal parameters refined. The maximum peak in the final difference-Fourier analysis was *ca* 0.7 eÅ^{-3}.

Bond distances and angles are given in Table 1. Atomic fractional coordinates, anisotropic thermal parameters, observed and calculated structure factors and intraligand bond distances and angles are deposited with the Editor as supplementary material, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

DISCUSSION

The structure comprises centrosymmetric tetracarboxylate-bridged dimers of the copper(II) acetate hydrate type (Fig. 1), with a Cu···Cu separation of 2.633(2) Å and a mean Cu—O (equatorial) distance of 1.966(5) Å. These values compare with 2.616(2) and 1.969(3) Å, respectively, in the re-refined copper(II) acetate hydrate structure.[21] In the axial sites of the dimers, the 2-aminopyrimidine molecules extend the structure into a zigzag chain polymer with *ca* 120° offsets through the *meta*-related hetero nitrogen atoms. The Cu—N distance [2.218(5)Å] compares with 2.243 and 2.248(9) Å in the analogous 2-aminopyrimidine adduct of copper(II) (2-chlorophenoxy)ethanoate.[16] The slight extension probably results from the greater steric imposition of the larger phenoxyalkanoate residues. The 2-aminopyrimidine molecules also lie on crystallographic two-fold rotation axes at

PHOTOCHEMISTRY OF $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ ON Si(III) SURFACES AT LOW TEMPERATURE

BENTLEY J. PALMER, ANNA BECALSKA, RAMZI HADER and ROSS H. HILL*

Department of Chemistry, Simon Fraser University, Burnaby, British Columbia, Canada, V5A 1S6

(*Received* 29 *October* 1990; *accepted* 14 *January* 1991)

Abstract—The photolysis of $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ on Si(III) surfaces at 77 K results in *cis* to *trans* isomerism. The mechanism of the photoreaction involves CO loss to generate an isomer of $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$ which, upon warming, reacts thermally with CO to generate only *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$. The first isomer of $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$ is photosensitive and converts to a second isomer which upon reaction with CO yields exclusively *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$.

We report here on the photoisomerism reactions of a film of $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ deposited on a silicon surface. Previously, we demonstrated that $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$, in low temperature glasses, underwent efficient CO loss to generate $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$.[1] This product could be generated by photolysis of either *cis*- or *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ although, upon warming, only the *trans* isomer formed in a thermal reaction with CO. This observation explained why the solution isomerism occurred only in the *cis* to *trans* direction.[2]

As part of the program underway in our group[3] to examine the different photochemistry observable in solid films we have re-examined the photochemistry of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ on a Si(III) surface. Here we report our observations concerning the photoreactivity of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ on the surface of a single crystal of silicon.

EXPERIMENTAL

The complexes, *cis*- and *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$, were prepared by literature[4] methods. The Si(III) wafers were obtained from Pacific Microelectronics Center, Canada. The wafers were *p*-type silicon with tolerances and specifications as per SEMI Standard M1.1.STD.5. The wafers were cut to the approximate dimensions of 1 cm × 1.5 cm in house.

The FTIR spectra were obtained with 4 cm^{-1} resolution using a BOMEM Michelson MB-120 FTIR spectrophotometer. The samples were held in a high conductivity copper sample mount within a CaF_2 faced vacuum Dewar.

The photolysis beam was a 100 W high pressure mercury lamp in an Oriel housing equipped with quartz condenser lenses.

Calibration of absorption of $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ *on a surface*

A stock solution of $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ was prepared in dichloromethane (1.4 mM). A drop (3.1×10^{-3} cm^3) of this solution was deposited on the surface of a silicon wafer, allowed to evaporate, and the absorbance measured. The area of the drop was found to be 0.5 cm^2. This process was repeated several times yielding the data shown in Fig. 1.

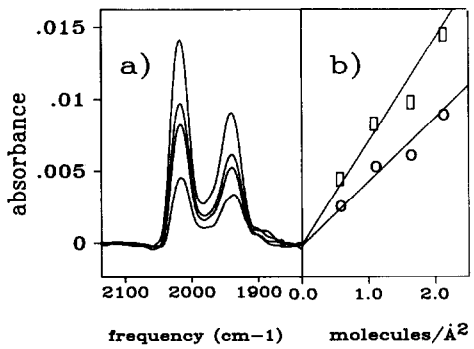

Fig. 1. (a) FTIR spectra associated with 0.5, 1.1, 1.6 and 2.2 molecules of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ per $Å^2$ on a silicon surface. (b) Plot of absorbance of the symmetric (□) and antisymmetric (○) CO stretches of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ vs coverage, data from Fig. 1(a).

* Author to whom correspondence should be addressed.

A similar experiment was conducted with the *trans* isomer yielding slopes of 0.0060 and 0.0073 molec $Å^{-2}$ for the high and low energy bands, respectively.

Photolysis of $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ *on silicon surfaces*

Five drops of a dichloromethane solution containing $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ were deposited on a silicon surface and the solvent allowed to evaporate. The silicon crystal was then mounted in the copper holder and transferred to the vacuum Dewar. This was then cooled to 77 K with liquid nitrogen and photolysed for 80 s. Spectral changes are summarized in Fig. 2.

In a similar experiment, a cut-off filter (band pass > 420 nm) and a 10 cm water filter with Pyrex optics were interposed between the light source and the sample. Spectral changes are summarized in Fig. 3.

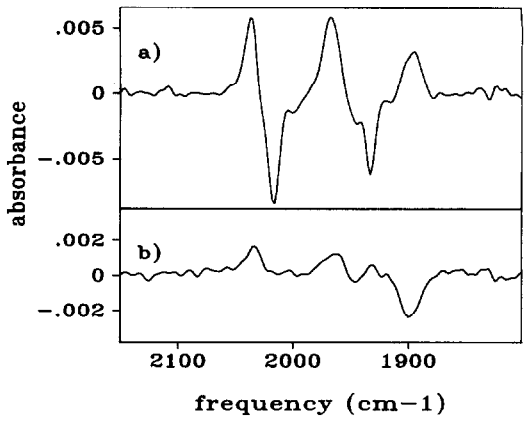

Fig. 2. FTIR spectral changes associated with (a) the photolysis of a film of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ on a silicon surface for 80 s followed by (b) the spectral changes associated with warming this sample to 150 K and recooling to 77 K.

RESULTS AND DISCUSSION

From the curve of absorbance vs coverage, Fig. 1, we can see that the surface film is composed of many monolayers of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$. The photochemistry reported here is occurring in the film and is not expected to be reflective of the silicon surface environment. For example, if we assume that the average footprint of a molecule is 100 $Å^2$ then an absorbance of 0.02 would correspond to more than 300 monolayers. The FTIR of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ on a surface consists of two absorptions in the metal carbonyl region. These are assigned as the symmetric and antisymmetric stretches at 2017 and 1938 cm^{-1}, respectively. Both the positions and relative ratio of the two CO stretching absorptions are in good agreement with the results from a low temperature glass, Table 1. Similar results are found for the deposition

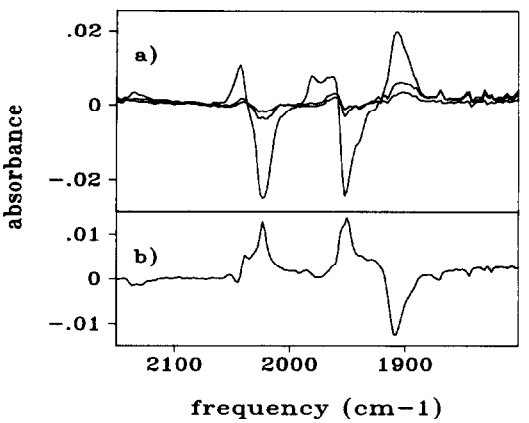

Fig. 3. FTIR spectral changes associated with (a) the photolysis of a film of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ on a silicon surface for 100 and 220 min using filtered light (band pass > 420 nm) and 5 min using unfiltered light followed by (b) the spectral changes associated with warming this sample to 150 K and recooling to 77 K.

	Glass	2028 (1.5), 1935 (1.0)
trans-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$	Si(III)	2040 (1.0), 1967 (1.2)
	Glass	2039 (1.0), 1963 (2.5)
Isomer 1 $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$	Si(III)	1900
Isomer 2	Si(III)	1909
	Glass	1910

[a] Data in glass are at 13 K in 1,2-epoxyethylbenzene, data on Si(III) are at 77 K.

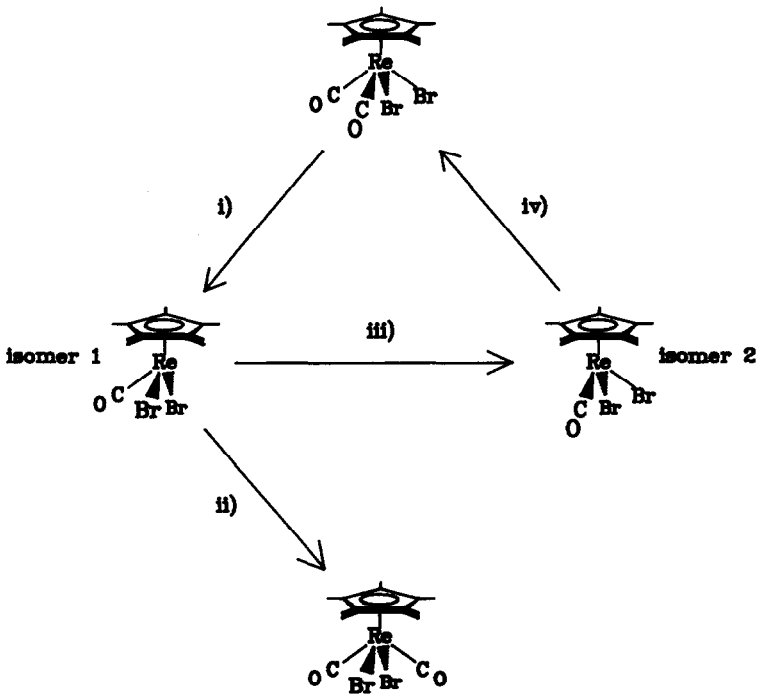
of the *trans* isomer on Si(III), although the relative intensities differ considerably. The relative intensity of the antisymmetric stretch is reduced. If we use these data to calculate the angles between the CO ligands[5] we find angles of 115° in the glass and 95° on the surface. The angle observed in the crystal structure[2] is 104°. This change may be due to an orientation effect of the surface.

Photolysis of *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$, at 77 K, into the lowest energy *d–d* absorption (band pass > 420 nm) leads to the spectral changes shown in Fig. 2(a). Loss of intensity due to the starting material at 2017 and 1938 cm^{-1} and the appearance of three new bands at 2042, 1970 and 1900 cm^{-1} is observed. The two at highest energy may be shown to be due to *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ by its independent synthesis and deposition on the surface. The latter is associated with the unsaturated complex $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$. We do not observe CO to be produced due to the low extinction coefficient. Upon warming the surface to 150 K reaction occurs consuming $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$ and presumably free CO to generate *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$, Fig. 2(b). This overall process is shown in Scheme 1, pathways (i) and (ii). This photoreaction is entirely analogous to that reported earlier in 1,2-epoxyethylbenzene glass. A similar result is found if we irradiate with higher energy photons.

The observation of $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$ and free CO establishes that CO loss is one primary photochemical event. This result explains the observed *cis* → *trans* isomerism. The unsaturated species is however photosensitive. The spectral changes are illustrated in Fig. 3(a). Initially, photolysis results in the appearance of both *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ and the unsaturated species at 1900 cm^{-1}. Continued photolysis results in the growth of an absorption at 1909 cm^{-1} which we associate with a second isomer of $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$. At these higher conversions free CO is observed in the film at 2132 cm^{-1}. This photochemical step and likely geometries for each isomer of the unsaturated species are shown in the scheme. This second isomer upon warming reacts with CO to generate only *cis*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ as indicated by the spectral changes in Fig. 3(b). This result is insensitive to irradiation wavelength.

In a 1,2-epoxyethylbenzene glass only one isomer of $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$ was observed and reaction with CO resulted in the formation of *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$. On a silicon surface we find that photolysis of this isomer leads to the photoproduction of a second isomer of $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$. The two isomers are found to react thermally with CO to yield the two different isomers of $(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$.

The probable structures of the two observed isomers are shown in Scheme 1. Each isomer is pre-



Scheme 1. (i) Photolysis in a glass at either 77 or 20 K, or photolysis in a film at 77 K; (ii) warming either a surface film or glass; (iii) photolysis in a film at 77 K; and (iv) warming photogenerated in a surface film.

sumably a result of the molecule retaining a four-legged piano stool geometry. The assignment of the structure of the two isomers is tentative. It does, however, seem most likely that the geometry of the basal ligands would be retained throughout the thermal reactions. The reaction of isomer 1 with CO results in a *trans* product. For this reason we assign isomer 1 as having CO *trans* to a vacant coordination site. Since the thermal reaction of isomer 2 with CO results in the *cis* product, we assign it as containing CO *cis* to the vacant site.

Interestingly, in glasses we have observed[6] two isomers for the unsaturated species derived from the isoelectronic molecules $(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3X$. In each case reaction of $(\eta^5\text{-}C_5H_5)Mo(CO)PR_3X$ with CO resulted in the specific generation of an isomer of $(\eta^5\text{-}C_5H_5)Mo(CO)_2PR_3X$.

Deposition and photolysis of *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ results in no change in the spectral features of this sample. This result is apparently independent of photolysis wavelength. In contrast with this is the photochemistry of *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ in a low temperature glass where CO loss was observed.[1]

We have demonstrated here that the photochemistry of *trans*-$(\eta^5\text{-}C_5Me_5)Re(CO)_2Br_2$ is altered upon the change of the medium from a low temperature glass to a surface film. Additionally, we have shown that in a film photoisomerism of $(\eta^5\text{-}C_5Me_5)Re(CO)Br_2$ is observable. The results obtained, both in a film and in a low temperature glass, are summarized in Scheme 1.

COMMUNICATION

THE EFFECT OF RING SIZE UPON THE STABILITY OF COPPER(II) COMPLEXES OF DIAMINODIAMIDO LIGANDS

GRAHAM E. JACKSON,* PETER W. LINDER and ALEXANDER VOYÉ
Department of Chemistry, University of Cape Town, Rondebosch 7700, South Africa

(*Received* 10 *December* 1990; *accepted* 5 *February* 1991)

Abstract—A novel copper(II) diaminodiamido complex is presented in which the 5,5,5-membered chelate is more stable than the 5,6,5-membered chelate analogue.

Over the years the effect of ring size upon the thermodynamic stability of copper(II) complexes has received considerable attention.[1-3] More recently, diaminodiamido ligands of the type L6–L9, shown in Fig. 1, have proved interesting.[2-4] Upon loss of the amide protons, these ligands can coordinate to a metal ion via the four nitrogen atoms, giving rise to three chelate rings. So far, copper(II) complexes of ligands which give rise to a five-, a six- and a five-(5,6,5) membered chelate system have proved more stable than their 5,5,5 chelate analogues. Although, in general, five-membered chelate rings tend to be more stable than six-membered chelate rings, the lower stability of the 5,5,5 ligands results from steric constraints of three contiguous, small rings.

Recently we have had cause to study the thermodynamic stability of copper(II) complexes of L1–L3, the results of which are given in Table 1. The results for the MLH_{-2} species show, for the first time, a system in which the 5,5,5 chelate (L1) complex is more stable than the 5,6,5 complex (L2). In order to explain this result, molecular mechanics (MM2) calculations[6] were performed on these complexes and their tetraamine analogues. The results indicate a difference of 11.3 kJ mol^{-1} in strain energy between L1 and L2 when they adopt the conformation necessary for complexation of copper(II) to all four nitrogen atoms, the 5,5,5 chelate system being more stable. On the other hand, as

expected, MM2 calculations on the tetraamine analogues showed that there was less strain in the 5,6,5 chelate than the 5,5,5 chelate. In the case of L2, it is difficult for the two amide groups to maintain their planarity and to coordinate to the metal ion. This destabilizes the central malonamide system relative to the oxamide system. At the same time the extra methylene group in the L_2 complex forces the terminal methyl groups together, further destabilizing the complex.

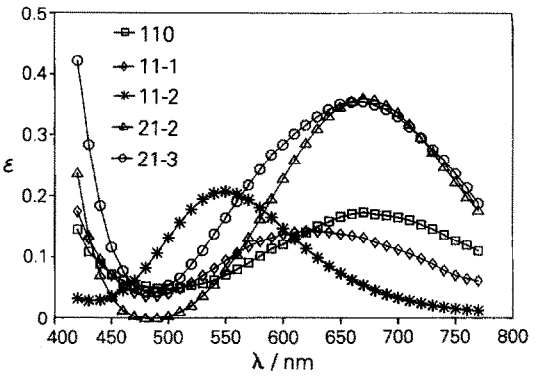

Fig. 2. Calculated electronic spectra of copper/L1 species in aqueous solution: ML (□), MLH_{-1} (◇), MLH_{-2} (*), M_2LH_{-2} (△) and M_2LH_{-3} (○).

Desseyn[7] has shown that, in the solid state, the structure of the MLH_{-2} complex (where L = L4) involves coordination of all four nitrogen atoms to the central metal ion. In order to confirm that the same structure applies to the MLH_{-2} complex of L1 and L2 in solution, the electronic spectra of these species were determined. This was achieved by calculating the individual species' contributions to the measured spectrum. The results for the Cu^{II}/L1 system are shown in Fig. 2. A λ_{max} of 540 nm for the MLH_{-2} species is consistent with coordination by two amide and two amine nitrogen atoms.[8]

In conclusion, we present evidence, for the first time, of a copper(II) chelate complex, in which a 5,5,5 chelate ligand forms more stable complexes than the 5,6,5 analogue.

Abstract—The action of sodium fluoride on chlorothallium(III) porphyrins, Tl(Por)Cl, produces the corresponding fluoroporphyrins, Tl(Por)F. These complexes were characterized by their ^{1}H-NMR, UV–vis and IR data. The crystal structures of the title compound [Tl(TPP)F] has been determined by X-ray diffraction. It crystallizes in the monoclinic space group $P2_1/n$ with $Z = 4$ and lattice dimensions $a = 10.118(3)$, $b = 16.236(5)$, $c = 21.189(6)$ Å, $\beta = 90.86(2)°$, $V = 3480(2)$ Å^3. $C_{44}H_{28}FN_4Tl$, $F_w = 836.11$ g, $\rho = 1.60$ g cm^{-3}, $\mu = 47.3$ cm^{-1}, $F(000) = 1640$, temperature 23(1)°C, $R(F) = 0.045$, $Rw(F) = 0.050$ for 2135 observed reflections. The thallium–fluorine distance is 2.441(6) Å with the thallium atom situated 0.741(1) Å above the porphyrin ring.

Much interest has been recently directed towards the synthesis and characterization of one-dimensional inorganic–organic polymeric systems in which a metallic or pseudometallic element alternates along the chain direction with a bridging element such as oxygen or fluorine.[1–6] The metallic or pseudometallic element is usually the central atom of a phthalocyanine or a porphyrin system, resulting in a rigid bridge-stacked polymeric structure. These derivatives become electrical conductors upon iodine oxidation.[7–13] We have recently initiated a search for similar low-dimensional systems in which the central atom of the porphyrin ring is a group III_B element, in which the large phthalocyanine ring is replaced by a porphyrin ligand.[14] Difference Fourier analysis of the EXAFS spectra of the hydroxo- and fluorogallium(III)-2,3,7,8,12,13,17,18-octamethylporphyrins [Ga(OMP)OH and Ga(OMP)F] has afforded some evidence for the polymeric structure of the latter complex.[14]

In this paper, the synthesis and properties of Tl(Por)F complexes are described, the metallic ion of the porphyrin centre, gallium, having been replaced by thallium. No evidence for polymer formation is found and we present a description of the crystal structure of Tl(TPP)F which is, as far as we know, the first X-ray study of a fluorothallium(III) porphyrin.

EXPERIMENTAL

Preparation of complexes

The chloro and fluoro complexes were synthesized following the general procedure described below.

* Author to whom correspondence should be addressed.

Abbreviations. Por: unspecified porphyrinate (2^-); OEP: 2,3,7,8,12,13,17,18-octaethyl porphyrinate (2^-); TPP: 5,10,15,20-tetraphenyl porphyrinate (2^-); OMP: 2,3,7,8,12,13,17,18-octamethyl porphyrinate (2^-).

Chloro-(porphyrinato)thallium(III). $Tl(CH_3COO)_3 \cdot 3/2H_2O$ (37.7 mmol) was added to a solution of porphyrin (9.35 mmol) and tetrahydrofuran (200 cm^3) and the mixture was refluxed for 4 h. Evaporation of the reaction mixture under reduced pressure and extraction of the residue with CH_2Cl_2–H_2O, followed by drying of the organic phase and evaporation *in vacuo* gave a precipitate which was chromatographed (CH_2Cl_2, Al_2O_3). Traces of the free base were eluted first, with the chloro complex as the second fraction. After evaporation of the solvent, the precipitate was recrystallized by slow diffusion of hexane or pentane into a saturated CH_2Cl_2 solution of the porphyrinic complex.

Fluoro-(porphyrinato)thallium(III). Chloro-(porphyrinato)thallium(III) (80 mmol) was dissolved in 100 cm^3 of dichloromethane. After the addition of sodium fluoride (240 mmol) and 2 cm^3 of distilled water, the mixture was stirred for 16 h. The excess of sodium fluoride was removed by washing the organic phase with water. After drying with magnesium sulphate, the solvent was removed under reduced pressure and the residual precipitate was dried at 80°C under 15 mm Hg and recrystallized as described above for the chloro complexes.

Physical measurements

^1H NMR spectra were recorded on a Varian FT-80. Spectra were measured for complex (5 mg) solutions in 0.6 cm^3 of $CDCl_3$ with tetramethylsilane as internal reference. IR spectra were recorded on a Perkin–Elmer 298 spectrophotometer. Samples were prepared as 1% dispersions in CsI pellets or Nujol mulls. Electronic absorption spectra were recorded on a Perkin–Elmer 330 spectrophotometer using 5×10^{-3} mol dm^{-3} dichloromethane solutions or a ORIEL diode-array visible spectrometer.

Crystal and molecular structure determination

A suitable crystal of Tl(TPP)F was obtained by slow diffusion of pentane into a dichloromethane solution of the compound. All data were collected on a Nicolet P3F diffractometer with Mo-K_α radiation ($\lambda = 0.71073$ Å). The crystal data and data collection parameters are summarized in Table 1.

Preliminary Weissenberg photographs along the *b* axis revealed a two-fold symmetry, and from the reflection conditions of $h0l$, $h+l = 2n$ and $0k0$, $k = 2n$ reflections and the subsequent least-squares refinement, the space group was determined to be $P2_1/n$. Experimental conditions and details of the calculations are also included in Table 1. The structure was solved using the Patterson heavy-atom method which revealed the position of the thallium atom. The remaining atoms were located in succeeding difference Fourier syntheses with the hydrogen atoms included in the refinement, but restrained to ride on the atom to which they are bonded. Full-matrix least-squares refinement minimizing $\Sigma w(|F_o| - |F_c|)^2$, with the weight w defined as $4F_o^2/\sigma(F_o^2)^2$, converged to the agreement factors shown in Table 1. The scattering factors were taken from Cromer and Waber.[15] Anomalous dispersion effects were included in F_c;[16] the values for $\Delta f'$ and $\Delta f''$ were those of Cromer.[17] Only the 2135 reflections having intensities greater than three times their standard deviations were used in the refinements. A selection of bond distances and bond angles is given in Table 2.*

RESULTS AND DISCUSSION

During the last two decades, a number of thallium(III) porphyrin complexes possessing different axial ligands have been reported.[18,19] In general, "soft" bases like Cl, I and CN tend to favour five-coordination of the thallium atom in the Tl(Por)X complexes, while a higher coordination number is achieved with hard bases like the acetate ligand.[20] Six-coordination for thallium is also known in the aquohydroxythallium(III) derivatives, Tl(Por)OH(H_2O).[19] The synthesis of metal–carbon complexes from thallium(III) porphyrins was studied first by Henrick *et al.*[21]

We have prepared the chlorothallium(III) porphyrins by the action of $Tl(CH_3COO)_3 \cdot 3/2H_2O$ on free bases in boiling tetrahydrofuran. These complexes were obtained in yields varying from 70 to 90%. Treatment of Tl(Por)Cl with sodium fluoride in dichloromethane led to Tl(Por)F derivatives, whose yields varied with the nature of the axial and equatorial ligands (57–80%).

Tl(Por)X compounds exhibit electronic absorption spectra belonging to the "normal" class[22] (Table 3). They show an intense band in the 418–436 nm region and two bands between 500 and 600 nm (α- and β-bands). One extra band [$Q(2,0)$] observed in the visible region appears blue shifted compared to the Soret band (see Fig. 1). As previously reported by Gouterman *et al.*[23,24] for tin octaethylporphyrin dihalides (with halide = F, Cl, Br, or I), the shifts in the transition energies and relative intensities of the α- and β-bands depend on

* Fractional atomic coordinates, anisotropic thermal parameters and a list of structure factors have been deposited as supplementary data with the Editor, from whom copies are available on request.

tion of the axial ligand are observed. More positively charged central metal ions reduce the electron density on the porphyrin macrocycle and thus deshield the porphyrin protons.[25] The porphyrin electron density is also dependent on the electron-withdrawing properties of the axial ligand,[26] and the *meso* proton chemical shift of Tl(OEP)X varies with the axial ligand X, as Cl < F (Fig. 2 with some ^{1}H NMR spectra). The central metal of Tl(Por)R is a heavy metal and this fact appears to be more important in influencing deshielding than the electron-donor or acceptor properties of the axial ligand. For comparison, the porphyrin proton resonances of Ga(Por)R do not depend upon the electron-donor ability of the axial ligand.[27]

As reported[28,29] in the literature, ^{1}H–^{203,205}Tl

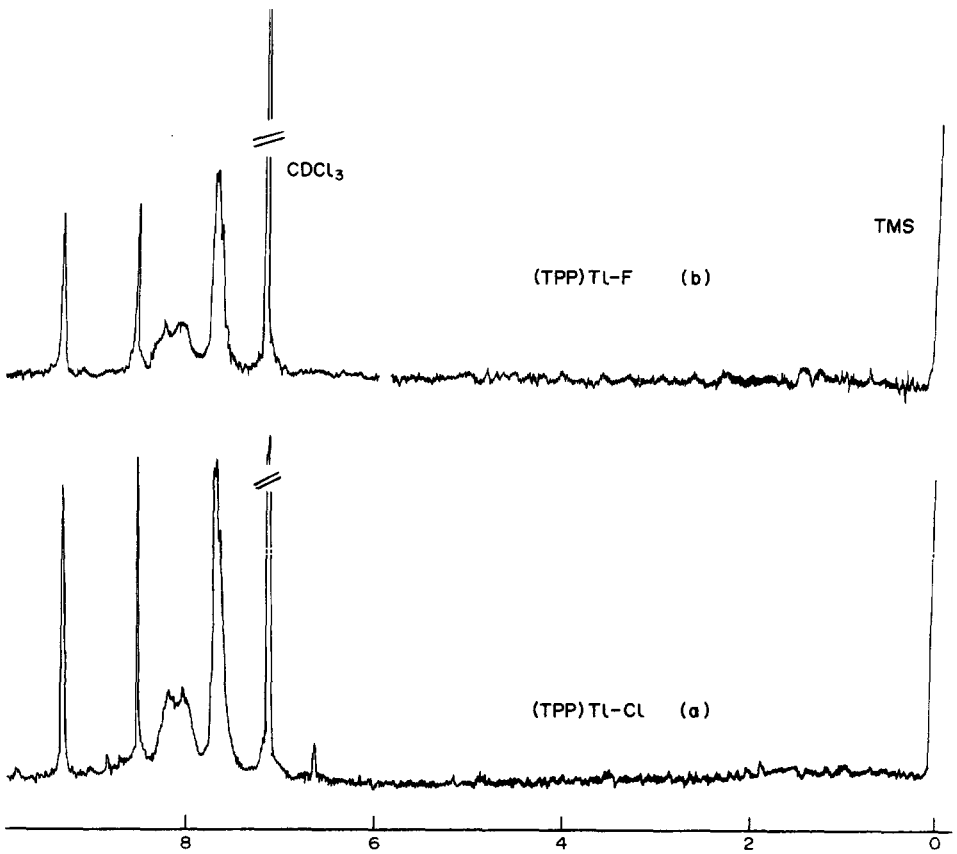

Fig. 2. ^{1}H NMR spectra of (a) Tl(TPP)Cl and (b) Tl(TPP)F complexes.

couplings are observed, but only between thallium(III) and *meso* or pyrrole protons of the porphyrin macrocycle, and the axial ligand proton. The magnitude of the coupling varies with the proton–thallium distance. The signals of octaethylporphyrin complexes show a multiplet for the methylene protons as the AB part of the ABX_3 system. This is similar to the case for complexes in the gallium or indium series and agrees with pentacoordination of the thallium(III) metal as well as an out-of-plane metal atom. The specific chemical shifts for each of Tl(OEP)X and Tl(TPP)X are given in Table 4. As seen in this table, only small and insignificant variations of the chemical shifts occur. The resonances of the methine protons or *meso* protons depend on the electron-donating ability of the axial ligands, which is a conclusion reached by comparison with other five-coordinated thallium porphyrins, where X = —CN, —SCN and $—N_3$.[30]

As no structure of a fluorothallium porphyrin has been reported before, and in order to provide a comparison with the case of gallium and indium fluoroporphyrins, the crystal structure of Tl(TPP)F has been determined (Fig. 3). The ORTEP drawing of the molecule reveals the five-coordination geometry of the thallium atom to the four nitrogen atoms (N_p) of the porphyrinato group and the fluorine atom; the coordination polyhedron is very close to a square pyramid with a Tl—F bond distance of 2.441(6) Å, and a mean Tl—N_p bond of 2.21(1) Å; the thallium atom lies 0.741(1) Å above the plane defined by the porphyrinato nitrogen atoms, resulting in a mean F—Tl—N_p bond angle of 109.6(6)°. The above values are very similar to the ones encountered in Tl(TPP)Cl and $Tl(TPP)CH_3$, where, for example, the bond distances to the axial ligands are 2.420(4) and 2.147(12) Å, respectively. From these data, the reason for the adoption of five-coordinate geometry by thallium becomes apparent: in order to minimize radial strain, the approach of a second axial ligand would require either a major distortion from planarity of the N_4 donor set, or a significant shortening of the Tl—N bonds from the average of 2.21 Å to a value of 2.01 Å. In Table 5, are collected the M—L and the average M—N_p distances for a number of metalloporphyrins of group III_B with various axial ligands. It is apparent that these distances correlate well with the increase in ionic radii from Ga^{3+} to Tl^{3+}, with the absolute values depending on the axial ligand also. Nevertheless, even though the size of the cation plays a major role in the resulting geometry of the metalloporphyrin complex, the case of the $[In(TPP)OSO_2CH_3]_n$ polymeric system clearly demonstrates that this rule is not always

(*Received* 7 *February* 1990; *accepted* 5 *December* 1990)

Abstract—N-salicylideneglycinatocopper(II) complexes of the composition Cu(salgly)(L)$(H_2O)_x$ were synthesized with L = 1-methylimidazole, 2-methylimidazole, 2-ethylimidazole, 2-ethyl-4-methylimidazole, 2-phenylimidazole, benzimidazole; and $x = 0$, 1 or 2. According to the results of ligand-field and EPR spectra, the coordination polyhedra around copper(II) exhibit geometries ranging from square-pyramidal to square-planar. The water of crystallization and the substituents on the imidazole ligand, moreover, remarkably influence cooperative ordering effects. A variety of coupling patterns between ferrodistortive and antiferrodistortive is observed. In some cases enhancement of the EPR measuring frequency from 9 to 35 GHz results in partial decoupling of the systems.

N-salicylideneglycinatocopper(II) complexes are of much interest as model compounds for the intermediates in the non-enzymatic transamination reaction.[1] Much attention has been devoted to structural and spectroscopic studies on these compounds in the solid state. As proven by X-ray structural analysis most N-salicylideneglycinatocopper(II) complexes adopt square-pyramidal copper(II) coordination with three donor atoms of the tridentate Schiff base dianion and one of the additional neutral ligands in the basal plane.[2,3] The apex of the pyramid is occupied by an oxygen atom (O′) from a neighbouring molecule or from water. For N-salicylideneglycinato(4-methylpyridine) copper(II) hexahydrate, however, square-planar copper(II) coordination has been reported recently.[4]

† Authors to whom correspondence should be addressed.

A number of N-salicylideneglycinatocopper(II) adducts (**I**) with various neutral monodentate ligands (L) involving O, N, S donor atoms has been prepared.[4-6] According to EPR and electronic spectral data most of these complexes are square-pyramidal. The substitution of the neutral ligand and variation of the number of crystal water molecules, however, remarkably influence cooperative ordering effects in the crystal structure. A variety of coupling patterns between ferrodistortive and antiferrodistortive has been observed.

In order to gain further insight into the influence of the neutral ligand on the structure of these complexes, we prepared a series of N-salicylideneglycinatocopper(II) adducts with variously substituted imidazole. Their EPR and ligand-field spectra were studied. In particular, the EPR spectroscopy is a valuable tool for investigating the coordination geometry and cooperative coupling effects in the solid state of these copper(II) complexes.

EXPERIMENTAL

Preparation of the complexes

N-salicylideneglycinato(aqua)copper(II) hemihydrate (**A**) was prepared according to ref. 7.

The N-salicylideneglycinatocopper(II) adducts with 1-methylimidazole(→ monohydrate), 2-methylimidazole(→ dihydrate), 2-ethylimidazole, 2-ethyl-4-methylimidazole, 2-phenylimidazole(→ dihydrate) and benzimidazole were synthesized in diluted ethanol (ethanol–water = 3 : 1). Each time, 1.34 g (5 mmol) of **A** was dissolved in 140 cm^3 of the solvent (in the case of 1-methylimidazole in 100 cm^3), heated to boiling and the neutral ligand was added in excess: 10 mmol were used of 1- and 2-methylimidazole (0.82 g), of 2-ethylimidazole (0.96 g) and of 2-ethyl-4-methylimidazole (1.10 g), respectively, but 7.5 mmol of 2-phenylimidazole (1.08 g) and of benzimidazole (0.90 g); the last one was in the form of a 7 cm^3 aqueous solution. The resulting solutions were heated to boiling, filtered and allowed to cool. The green or bluish-green crystals which deposited, were washed with cool solvent and dried in air.

Dehydrated N-salicylideneglycinato(2-methylimidazole)copper(II) was prepared in an analogous way using 100 cm^3 of diluted methanol (methanol–water = 3 : 1), 1.34 g of **A** and 10 mmol (0.82 g) of 2-methylimidazole.

The analytical data of the obtained complexes are given in Table 1.

Spectral measurements

The EPR spectra of powdered solids were measured at room temperature in X band (9.1 GHz) with a Varian E-4 spectrometer and in Q band (35 GHz) with a Varian E-15 device. DPPH was used as an internal standard.

The electronic spectra of finely powdered samples were recorded in the range 11,000–30,000 cm^{-1} with a Specord M-40 spectrometer (C. Zeiss, Jena) and also with a Zeiss DMR-21 spectrometer equipped with a low-temperature accessory. MgO was used as standard.

RESULTS AND DISCUSSION

The reaction of N-salicylideneglycinato(aqua)copper(II) hemihydrate with imidazole derivatives (L) led to adducts of the general formula Cu(salgly)(L)$(H_2O)_x$, where $x = 0$, 1 or 2. The preparation and spectral properties of the complexes with L = imidazole, $x = 0$, and L = 2-propylimidazole, $x = 1$, respectively, were reported in our previous paper.[5] The electronic spectra containing an asymmetric ligand-field band (maximum in the range 14,400–16,700 cm^{-1}) with a broad shoulder of about the same intensity but higher energy (Table 2) indicate square-pyramidal copper(II) coordina-

tion.[5,6,8] We tentatively assign the maximum to a superposition of the $d_{x^2-y^2} \leftarrow d_{z^2}$ and $d_{x^2-y^2} \leftarrow d_{xy}$ transitions. According to this, the shoulder may be correlated with the $d_{x^2-y^2} \leftarrow d_{xz,yz}$ transition. Apart from this, the last two examples in Table 2 deviate by a pronounced blue-shift of the absorption bands, confirmed by a low-temperature measurement in the case of [Cu(salgly)(2-MeIm)]·$2H_2O$.

The EPR spectra, however, show a great variety of patterns (Figs 1 and 2, Table 2). The g_{av} values lie, with the exception of the complexes [Cu(salgly)(2-Et-4-MeIm)] and [Cu(salgly)(2-MeIm)]·$2H_2O$, in the range 2.126–2.117. Such g factors were found for square-pyramidal N-salicylideneglycinato- or N-pyruvideneglycinatocopper(II) complexes with additional N donor ligands.[5,6,8]

The molecular g components for a system of tetragonal symmetry with the $d_{x^2-y^2}$ ground state are defined by the expressions

$$g_\parallel = 2.0023 - 8k_\parallel{}^2\lambda_0/\Delta E_{xy}$$
$$g_\perp = 2.0023 - 2k_\perp{}^2\lambda_0/\Delta E_{xz,yz} \qquad (1)$$

where $\lambda_0 = -830$ cm^{-1} is the spin–orbit coupling constant for the free Cu^{2+} ion, $k_\parallel$ and $k_\perp$ are the orbital

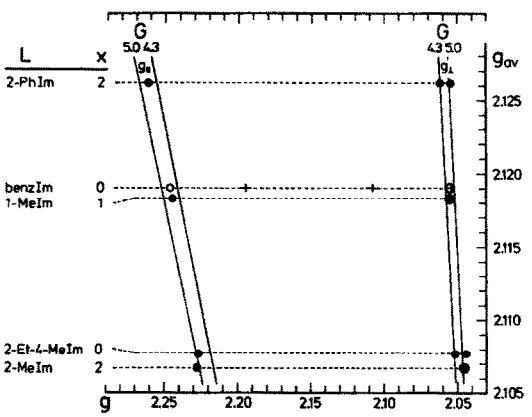

Fig. 1. Diagram showing the g values of N-salicylideneglycinatocopper(II) complexes, Cu(salgly)(L)$(H_2O)_x$: coupled components in the case of ferrodistortively ordered complex molecules, corresponding to molecular g factors. (For the benzimidazole adduct superimposed g components of a disturbed antiferrodistortive pattern are marked by crosses, see text.)

reduction factors, and ΔE the ligand-field splitting energies. Significant contribution to these energies comes from the $4\delta_1 = \Delta E(d_{x^2-y^2} \leftarrow d_{z^2})$ splitting of the cubic ^2E_g ground state of Cu^{2+} ions. This split-

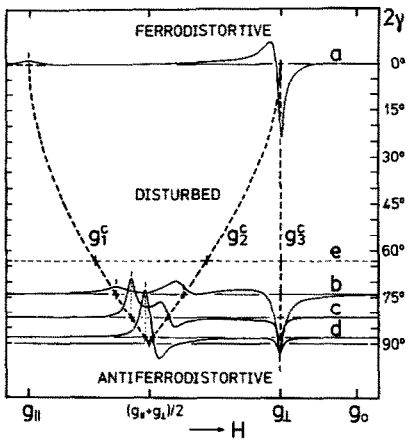

Fig. 2. EPR powder spectra of Cu(salgly)(L)$(H_2O)_x$ resulting from coupled molecular g components ($g_{\parallel}$, $g_{\perp}$) according to eq. (2); ferrodistortive pattern: L = 1-MeIm, $x = 1$ (a); disturbed antiferrodistortive patterns: L = 2-PrIm, $x = 1$ (b); L = 2-MeIm, $x = 0$ (c); L = Im, $x = 0$ (d); L = benzIm, $x = 0$ (e).

ting is proportional to the axial ligand-field component. From recently performed X-ray structural analysis of [Cu(salgly)(2-MeIm)] it is known that the highest $g_{av} = 2.126$ corresponds to an apical Cu—O′ distance of 248 pm.[9] Hence, we assume that the smaller g_{av} value of < 2.11 in both [Cu(salgly)(2-Et-4-MeIm)] and of [Cu(salgly)(2-MeIm)]·$2H_2O$ reflects a remarkably weaker axial ligand-field component in these complexes, corresponding to square-planar coordination geometry. It is in accordance with the observed blue-shift in the electronic spectra (Table 2) and identical with the g_{av} value, which was observed for the square-planar copper(II) coordination in [Cu(salgly)(4-MePy)]·$6H_2O$.[4]

The different EPR spectra give evidence for a variety of cooperative ordering effects in these solid N-salicylideneglycinatocopper(II) complexes. When the unit cell contains coordination polyhedra, the Cu^{2+} centres of which are coupled by directed sufficiently strong dipolar interactions, cooperative effects influence the EPR spectra.[10] In the case of two sets of axial complex molecules, where the g_z axes are canted by an angle 2γ ($0° \leqslant 2\gamma \leqslant 90°$), the following crystal g values are observed:[11]

$$g_1^c = \cos^2\gamma g_{\parallel} + \sin^2\gamma g_{\perp}$$
$$g_2^c = \sin^2\gamma g_{\parallel} + \cos^2\gamma g_{\perp}$$
$$g_3^c = g_{\perp}. \qquad (2)$$

If all $g_{\parallel}$ axes are aligned parallel ($2\gamma = 0°$, ferrodistortive ordering) the experimental g^c factors correspond to molecular ones. These g values, according to eq. (1), directly reflect the geometry of the coordination polyhedra. The value of the parameter $G = (g_{\parallel} - g_0)/(g_{\perp} - g_0)$ usually lies in the range 4.5–4.9 [for g tensors with small orthorhombic splitting we take $g_{\perp} = (g_x + g_y)/2$].[12] Values of the G parameter which are smaller than 4.4 indicate the presence of coupling of Cu^{2+} ions in coordination polyhedra with mutually non-parallel g_z axes. The g components are then given by both coordination geometry and cooperative ordering effects.

Four of the complexes, Cu(salgly)(L)$(H_2O)_x$, of the imidazole series with L = 2-PhIm, $x = 2$; L = 2-MeIm, $x = 2$; L = 1-MeIm, $x = 1$; and L = 2-Et-4-MeIm, $x = 0$, respectively, show molecular g values (in Fig. 1 indicated by full circles). The exchange-narrowed EPR spectral lines [see Fig. 3(a,b)] provide evidence for coupling effects between ferrodistortively ordered complex units in the structure. The g tensor of [Cu(salgly)(2-PhIm)]·$2H_2O$, where position 2 of the imidazole group adjacent to the donor nitrogen atoms is occupied by the bulky phenyl substituent, shows some orthorhombic splitting (Table 2, Fig. 1). A comparable splitting is observed for the 2-ethyl-4-methylimidazole adduct [Figs 1 and 3(a)]. The other complexes appear to be of axial symmetry. The g parameters of the compound [Cu(salgly)(2-MeIm)]·$2H_2O$ yield $G = 5.1$ (Fig. 1). High G values have been reported to arise from out-of-plane π bonding.[13] We have no reasonable explanation for this value in our complex, however.

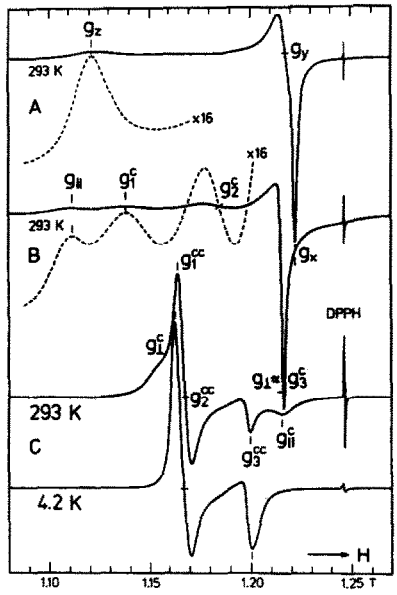

Fig. 3. A selection of EPR powder spectra (34.95 GHz) summarizing all the characteristics of local and cooperative symmetry effects in adducts of N-salicylideneglycinatocopper(II) with imidazole derivatives: (a) [Cu(salgly)(2-Et-4-MeIm)], (b) [Cu(salgly)(benzIm)] and (c) [Cu(salgly)(2-EtIm)].

When the highest experimental g component lies lower than the $g_\parallel$ area in Fig. 1, then the g tensor is influenced by coupling of the Cu^{2+} ions in crystallographically equivalent sites generated by glide-reflection planes parallel (010) to the monoclinic unit-cells, corresponding to canting angles, $20° < 2\gamma \leqslant 90°$, between the 3-ring planes of the Cu(salgly) complex molecules.* Separation of the contributions of coordination geometry and cooperative ordering effects to the experimentally determined g tensor is here of interest. From eq. (2) follows for the canting angle, 2γ:

$$\cos 2\gamma = (g_1^c - g_2^c)/(g_1^c + g_2^c - 2g^c). \qquad (3)$$

For the full interpretation, however, the complete structural data from X-ray diffraction and EPR measurements on monocrystals are necessary.[14,15]

The EPR spectra of N-salicylideneglycinatocopper(II) adducts with imidazole [Fig. 2(d)] and 2-propylimidazole [Fig. 2(b)] were interpreted in terms of two coupled copper(II) coordination polyhedra of axial symmetry canted by an angle of $2\gamma = 88°$ and 74°, respectively.[5] In the case of [Cu(salgly)(2-MeIm)] [Fig. 2(c)], from a detailed EPR investigation of a monocrystal combined with the crystallographic data from a X-ray structure analysis,[9] a canting angle of $2\gamma = 81.5°$ was deduced, resulting in an orthorhombic molecular g tensor with the components $g_z = 2.263$, $g_y = 2.063$, $g_x = 2.052$. Therefore the assumption of axial symmetry in the preceding examples was arbitrary and strictly speaking not compulsory. Changing from tetragonal to moderately orthorhombic symmetry of the estimated molecular g tensor, however, in the disturbed antiferrodistortive range, has negligible influence on the resulting canting angle, 2γ, which would become uncertain by less than 1°. Structural determinations on [Cu(salgy)(2-MeIm)] as well as on $[Cu(salgy)(OH_2)]\cdot 0.5H_2O$ gave evidence that the Cu(salgly) units are connected by carboxylate oxygen atoms from adjacent molecules to zigzag chains, where the canting angles, 2γ (82 and 58°, respectively),[2,9] are very different. As the estimated canting angles of the investigated adducts are spread over this range, we assume a comparable chain-like bridging of the complex molecules as the structural principle in this series.

Some compounds exhibit particularly interesting coupling patterns depending on the frequency of the measurement. The Q band EPR spectrum of [Cu(salgly)(benzIm)] [Fig. 3(b)] shows a superposition of two differently coupled g tensors. In addition to ferrodistortively coupled Cu^{2+} ions (Fig. 1, open circles), lines corresponding to disturbed antiferrodistortive ordering are also observed [Figs 1, crosses; 2(e)]. Using eq. (2) we calculate for the disturbed antiferrodistortively coupled complexes the molecular g values of $g_\parallel = 2.249$, $g_\perp = 2.054$, which are nearly equal to the ferrodistortive g components (Table 2). The canting angle results in $2\gamma = 63.5°$ [Fig. 2(e)]. The additional lines from the disturbed antiferrodistortive coupling of the molecular g tensors were not detected at X band frequency due to poor resolution. We assume in this compound a partly decoupled system of two disturbed antiferrodistortively ordered ferrodistortive sublattices. The compound [Cu(salgly)(2-EtIm)] shows an exchange-coupled EPR spectrum (with $g_\perp^{cc} = 2.143$ and $g_\parallel^{cc} = 2.081$) at 9 GHz. At a higher measuring frequency (35 GHz) the system is partly decoupled, and the EPR powder spectrum consists of a superposition of two differently coupled g tensors. In addition to the aforementioned coupled g^{cc} tensor ($g_1^{cc} = 2.145$, $g_2^{cc} = 2.138$, $g_3^{cc} = 2.082$), lines with $g_\perp^c \approx 2.15_5$ and $g_\parallel^c = 2.055$ are observed, which also disappear on lowering the temperature to 4.2 K [Fig. 3(c)]. Such spectral behaviour provides evidence for a coupled system, containing Cu^{2+} ions in four differently orientated coordination pyramids, which is partly decoupled at Q band frequency and higher temperatures. In this case, however, the system seems to consist of two disturbed antiferrodistortively ordered *anti*ferrodistortive sublattices. A striking angular dependence of line widths ranging between 0.5 mT and about 100 times this value was found in measurements on monocrystals.[16] This provides evidence for specific directions within the structure, where the exchange coupling becomes highly effective.[10] Further investigations in this field are in progress.

CONCLUSIONS

The spectral data provide evidence for square-pyramidal and in two cases also for square-planar coordination of the Cu^{2+} ions in the complexes under investigation. The substitutions on the imidazole ligand exhibit rather weak but distinct effects on the local environment around the Cu^{2+} ions. Some differences in axial ligand-field strength and distortions in the basal xy plane are observed. The cooperative ordering effects, however, are strongly influenced by water of crystallization and by sub-

* In the case of canting angles, 2γ, below $\approx 20°$ it is difficult to estimate whether a small orthorhombic splitting of the EPR pattern is caused by orthorhombic molecular components or by canting of axial g tensors, as can be seen from Fig. 2.

stituents on imidazole. The change from ferrodistortive to disturbed antiferrodistortive g tensors on going from N-salicylideneglycinato(2-methylimidazole)copper(II) dihydrate to the anhydrous compound is assumed to result from coupling of two disturbed antiferrodistortively ordered ferrodistortive sublattices. Analogical effects were observed in N-salicylideneglycinatocopper(II) adducts with pyridine and 4-methylpyridine.[4,6] The coupled system, at least, is confirmed in the structure of [Cu(salgly)(2-MeIm)], where the complex molecules are aligned in zigzag chains.[9] In the imidazole series, however, examples with an EPR frequency-dependent exchange coupling effect characteristic for a unit cell with four coupled Cu^{2+} ions were also detected. The substituents on the imidazole influence the hydrogen bonding system, which probably plays a considerable role in stabilizing the cooperative ordering effects in solid N-salicylideneglycinatocopper(II) complexes. Furthermore, the formation of dimers by analogy to those of [Cu(salgly)(thiouria)] noted by Pavelčik *et al.*[3] might be realized in compounds with ferrodistortively ordered square-pyramidal copper(II) coordination polyhedra.

Abstract—The electrochemical reduction of $[PtCl_2L_2]+L_2^*$ (L_2 and L_2^* = $Ph_2PCH_2CH_2PPh_2$, dppe; $Cy_2PCH_2CH_2PCy_2$, dcpe; $^nBu_2PCH_2CH_2P^nBu_2$, dbpe) systems may proceed via two different routes. Path 1 involves reduction of $[PtCl_2L_2]$ to produce $[PtL_2]$ which is trapped by L_2^* to form $[PtL_2L_2^*]$. Path 2 involves prior reaction of $[PtCl_2L_2]$ with L_2^* to form $[PtL_2L_2^*]^{2+}$ which is reduced to form $[PtL_2L_2^*]$. The extent of prior reaction of $[PtCl_2L_2]$ with L_2^* has been monitored by both cyclic voltammetry, which detects only the electroactive components in solution, and by $^{31}P\{^1H\}$ NMR spectroscopy, which allows structural assignments to be made. Bulk electrolyses have been performed at potentials sufficient to reduce both $[PtCl_2L_2]$ and $[PtL_2L_2^*]^{2+}$ and also at potentials sufficient to reduce $[PtL_2L_2^*]^{2+}$ but not to reduce $[PtCl_2L_2]$. Product analyses by $^{31}P\{^1H\}$ NMR spectroscopy show that path 1 is operative in sterically congested systems, path 2 is operative in uncongested systems, and both pathways may be operative in systems with intermediate steric congestion. Reactions via path 2 produce $[PtL_2L_2^*]$ efficiently, whereas reactions via path 1 are complicated by alternative trapping reactions of $[PtL_2]$ with the solvent/electrolyte system which compete with trapping by L_2^*.

Recently we have shown that two-coordinate platinum(0) complexes containing either triphenylphosphine or triethylphosphine as ligands may be generated by electrochemical reduction of the corresponding *cis*-$[PtCl_2L_2]$ complexes,[1–3] eq. (1):

$$cis\text{-}[PtCl_2L_2]+2e^- \longrightarrow [PtL_2]+2Cl^- . \quad (1)$$

These relatively unhindered $[PtL_2]$ compounds exhibit enhanced reactivity in comparison with their better-known, more sterically crowded analogues, such as $[Pt(PCy_3)_2]$ (Cy = cyclohexyl).[4] The electrochemical method of generation appears complementary to the previously reported photochemical[5] [e.g. eq. (2)] or thermal[4] [e.g. eq. (3)] techniques and the better-known chemical approaches[6] to the generation of $[PtL_2]$ complexes:

$$[Pt(C_2O_4)(PEt_3)_2] \xrightarrow{h\nu} [Pt(PEt_3)_2]+2CO_2 \quad (2)$$

$$trans\text{-}[PtH_2(PCy_3)_2] \xrightarrow{\Delta} [Pt(PCy_3)_2]+H_2. \quad (3)$$

Interest in the chemistry of $[PtL_2]$ complexes was recently spurred by Whitesides and co-workers' reports[7–9] that the C_{2v} intermediate $[Pt(Cy_2PCH_2CH_2PCy_2)]$, generated by thermolysis of an alkylhydride, reacts with alkanes and a variety of other organic substrates by C—H oxidative addition.[10] Here we describe an initial investigation into the utility of electrochemical reductive strategies for the generation of such non-linear $[PtL_2]$ compounds from simple $[PtCl_2L_2]$ precursors.

RESULTS AND DISCUSSION

In a preparative scale electrochemical experiment both a relatively polar solvent and a background

electrolyte are required and we felt that generation of a non-linear $[PtL_2]$ compound in such a system might lead to indiscriminate reaction with these components. An experiment involving the bulk reductive electrolysis of $[PtCl_2(dppe)]$ (dppe = $Ph_2PCH_2CH_2PPh_2$) in CH_3CN/C_6H_6 (1/1, v/v) containing tetra(n-butyl)ammonium perchlorate (TBAP, 0.08 M) at a mercury pool electrode employing a potential of −1.75 V (vs Ag/AgCl; −35 mV vs SCE) confirms this expectation. The $^{31}P\{^1H\}$ NMR spectrum of the product mixture showed that multiple products were formed, none of which could be identified by comparison of spectroscopic data with literature values. Data from this experiment are included in the Experimental for completeness. Given this situation, we felt that a trapping agent was necessary which would effectively compete for any non-linear $[PtL_2]$ intermediate that might be generated. Such a trapping agent has to survive the very negative potentials required to reduce $[PtCl_2L_2]$ complexes and bind strongly to any $[PtL_2]$ fragment generated. Accordingly we sought to use bidentate ligands as traps for potential $[PtL_2]$ fragments since the resulting $[PtL_2L_2*]$ complexes are quite robust species.[11] The choice of such a set of trapping agents is not without inherent problems since it allows two possible reaction pathways, as illustrated in Scheme 1. The first path involves reduction of $[PtCl_2L_2]$ to generate $[PtL_2]$ which is subsequently trapped by L_2* to produce $[PtL_2L_2*]$. The second path involves prior reaction of $[PtCl_2L_2]$ with L_2* to generate $[PtL_2L_2*]^{2+}$ which is subsequently reduced to produce $[PtL_2L_2*]$. Thus, the pathway of the reaction will in part be controlled by the extent to which the well-known halide displacement[12] of $[PtCl_2L_2]$ by L_2* occurs prior to electrolysis. In order to investigate this question, $^{31}P\{^1H\}$ NMR measurements (see Experimental) were made on $[PtCl_2L_2]+L_2*$ mixtures in CH_3CN/C_6D_6 which was 0.1 M in TBAP. In every case dication formation (Table 1) was detected, although it was clear that in cases where L_2 and L_2* are both sterically demanding, the reaction does not proceed to completion in the time scale of these NMR experiments (typically 1–3 h). For example, although addition of $Cy_2PCH_2CH_2PCy_2$ (dcpe) to $[PtCl_2(dcpe)]$ did indeed produce $[Pt(dcpe)_2]^{2+}$, both free dcpe and unreacted $[PtCl_2(dcpe)]$ were still present after several hours in solution. Thus, in every $[PtCl_2L_2]+L_2*$ system we have investigated, both $[PtCl_2L_2]$ and $[PtL_2L_2*]^{2+}$ could potentially participate in an electrochemical reduction and so any differentiation between the possible pathways indicated in Scheme 1 must rely heavily on differences in the electrochemical behaviour of these components. Cyclic voltammetry (CV)[13–16] gives some insight into these differences.

Figure 1(a) shows the cyclic voltammogram of $[PtCl_2(dppe)]$ in CH_3CN (0.1 M in TBAP) at a Hg/Au amalgam electrode measured at a scan rate of 200 mV s^{-1} over the potential range −0.50 to −2.20 V vs Ag/AgCl. On the basis of chemical evidence (*vide infra*) we assign peak A (−1.71 V) to the irreversible reduction of $[PtCl_2(dppe)]$, eq. (4):

$$[PtCl_2(dppe)]+2e^- \longrightarrow [Pt(dppe)]+2Cl^- \quad (4)$$

[b] For **2**, $\widehat{P_1P_{1'}}$ = dcpe, $\widehat{P_2P_{2'}}$ = dcppe; for **4**, $\widehat{P_1P_{1'}}$ = dcpe, $\widehat{P_2P_{2'}}$ = dbpe; for **5**, $\widehat{P_1P_{1'}}$ = dppe, $\widehat{P_2P_2}$ = dbpe; for **1**, **3** and **6**, $P_1 = P_{1'} = P_2 = P_{2'}$.

Addition of one equivalent of dppe to the solution of $[PtCl_2(dppe)]$ followed by immediate measurement of a cyclic voltammogram produces the result shown in Fig. 1(b). Sweeping to negative potential now generates peak B, which we assign to the reduction of the dication $[Pt(dppe)_2]^{2+}$, with peak A, due to reduction of $[PtCl_2(dppe)]$, now barely visible. This interpretation is in accord with our $^{31}P\{^1H\}$ NMR results (see Experimental) and with CV on independently prepared samples of both $[Pt(dppe)_2]Cl_2$ and $[Pt(dppe)_2]$.[17] The reverse sweep

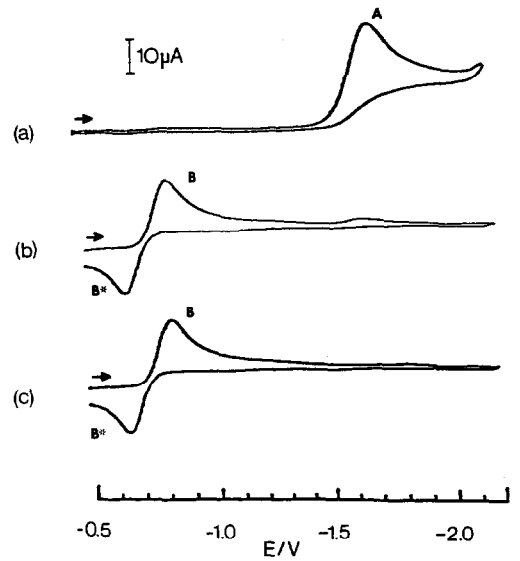

Fig. 1. Cyclic voltammograms measured in CH_3CN (10^{-1} M TBAP) at a Au/Hg amalgam working electrode (1.77 mm^2) using a scan rate of 200 mV s^{-1}. (a) 10^{-3} M solution of $[PtCl_2(dppe)]$; (b) 10^{-3} M solution of $[PtCl_2(dppe)]$ immediately after adding one equivalent of dppe; (c) 10^{-3} M solution of $[PtCl_2(dppe)]$ 1 h after adding one equivalent of dppe.

of the cyclic voltammogram shown in Fig. 1(b) produces peak B* which we assign to re-oxidation of $[Pt(dppe)_2]$. The question of reversibility of the processes generating peaks B and B* is redundant since the platinum(II)/platinum(0) interconversion is accompanied by a structural change between square-planar and tetrahedral geometries, and hence this reaction is perhaps best described as an EC process. In the absence of a structural change we would ideally anticipate a peak separation of 29.5 mV for the two-electron process. The actual separation of peaks B and B* in Fig. 1(b) is 150 mV. After standing for 1 h, the solution of $[PtCl_2(dppe)]$ + dppe produced the cyclic voltammogram shown in Fig. 1(c), i.e. no $[PtCl_2(dppe)]$ was detected and the only electroactive component found in solution was $[Pt(dppe)_2]^{2+}$.

Based on the $^{31}P\{^1H\}$ NMR and CV results, it is not surprising that controlled potential bulk reductive electrolysis of $[PtCl_2(dppe)]$ in the presence of one equivalent of dppe at a potential of −1.75 V (i.e. just negative of peak A) produces $[Pt(dppe)_2]$ efficiently. As is common in bulk electrolyses of the type described here,[1-3] separation of the products from the background electrolyte, which is present in large excess, can be exceedingly difficult. Since we are primarily interested in the solution chemistry we have not typically performed such separations. In the present case, $^{31}P\{^1H\}$ NMR spectroscopy showed $[Pt(dppe)_2]$ (83% estimated by peak heights in the spectrum) and traces of dppe, dppe oxide (dppeO) and dppe dioxide ($dppeO_2$) to be present after electrolysis. The traces of phosphine oxides were present in approximately the same amount as impurities in the original dppe added to the reaction mixture (see Experimental).

Figure 2 shows a series of cyclic voltammograms

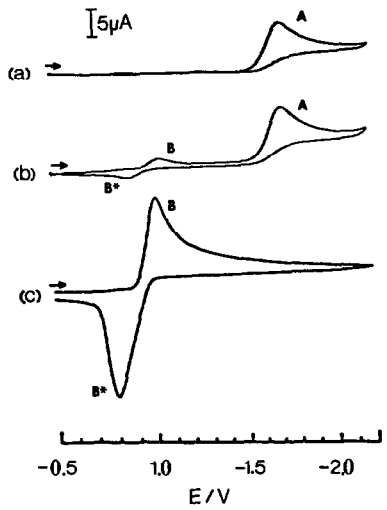

Fig. 2. Cyclic voltammograms measured in CH_3CN (10^{-1} M TBAP) at a Au/Hg amalgam working electrode (1.77 mm^2) using a scan rate of 200 mV s^{-1}. (a) 10^{-3} M solution of $[PtCl_2(dppe)]$; (b) 10^{-3} M solution of $[PtCl_2(dppe)]$ immediately after adding one equivalent of dcpe; (c) 10^{-3} M solution of $[PtCl_2(dppe)]$ 1 h after adding one equivalent of dcpe.

illustrating the effect of adding one equivalent of dcpe to $[PtCl_2(dppe)]$. Immediately after addition the sterically demanding dcpe ligand has generated only a small amount of dication and significant $[PtCl_2(dppe)]$ remains. After 1 h [Fig. 2(c)], no $[PtCl_2(dppe)]$ is detected and only the dication is observed. In the voltammogram shown in Fig. 2(c) the peak current for the reduction of $[Pt(dppe)(dcpe)]^{2+}$ is less than the peak current for the associated re-oxidation (i.e. B < B*). This effect arises since reduction of $[Pt(dppe)(dcpe)]^{2+}$ occurs at all potentials more negative than B and the reduced species, which apparently adsorbs on the electrode, is then stripped off by re-oxidation at one potential (B*) on the reverse sweep. The CV results for the $[PtCl_2(dppe)]$+dcpe system are in agreement with the $^{31}P\{^1H\}$ NMR results, where $[Pt(dppe)(dcpe)]^{2+}$ was identified as the major species in solution (Table 1). Also detected was some $[PtCl_2(dcpe)]$ formed by displacement of dppe by the stronger σ-donor dcpe, but this minor component is not detected in the cyclic voltammograms shown in Fig. 2. Given these results, the controlled potential bulk reductive electrolysis of $[PtCl_2(dppe)]$+dcpe at −1.75 V might be anticipated to produce [Pt(dppe)(dcpe)] as a major product and this is indeed the case (Table 2). In addition to this product (54% by peak heights), some $[Pt(dppe)_2]$ was also detected (8.5%), along with unreduced $[PtCl_2(dcpe)]$ (8.5%) and trace ligand impurities.

The reaction of dppe with $[PtCl_2(dcpe)]$ proceeds in a different manner to the reaction of dcpe with $[PtCl_2(dppe)]$ (*vide supra*). Thus, addition of dppe to $[PtCl_2(dcpe)]$ followed by immediate measurement of a cyclic voltammogram [Fig. 3(b)] shows some formation of a dication (peak B), but considerable $[PtCl_2(dcpe)]$ remains. Interestingly, after scanning through peak A, the reverse scan gives rise to peak B* with a larger current than peak B. We interpret this as being due to the fact that traversing peak A generates [Pt(dcpe)], some of which is trapped by dppe to produce [Pt(dcpe)(dppe)]. On the reverse scan, the oxidation of [Pt(dcpe)(dppe)] thus produces an enhanced current for peak B*. After 1 h in solution the $[PtCl_2(dcpe)]$+dppe system produces the voltammogram shown in Fig. 3(c). On the forward scan, peak B, corresponding to dication reduction, shows that significant amounts of this species are present. Peak A shows that some $[PtCl_2(dcpe)]$ remains also. On the reverse scan, no

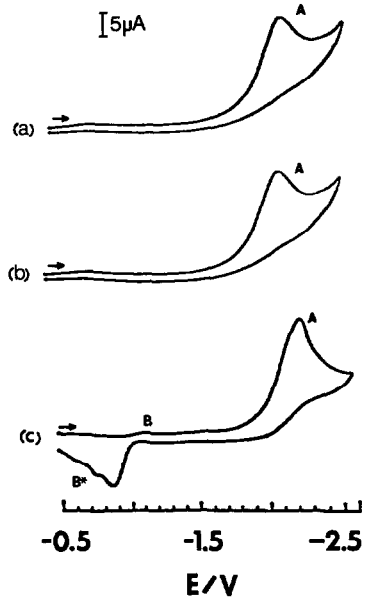

Fig. 4. Cyclic voltammograms measured in CH_3CN (10^{-1} M TBAP) at a Au/Hg amalgam working electrode (1.77 mm^2) using a scan rate of 200 mV s^{-1}. (a) 10^{-3} M solution of $[PtCl_2(dcpe)]$; (b) 10^{-3} M solution of $[PtCl_2(dcpe)]$ immediately after adding one equivalent of dcpe; (c) 10^{-3} M solution of $[PtCl_2(dcpe)]$ 1 h after adding one equivalent of dcpe.

peak for the oxidation of [Pt(dcpe)(dppe)] is seen, an occurrence for which we have no explanation. The $^{31}P\{^1H\}$ NMR results on this system show only $[Pt(dcpe)(dppe)]^{2+}$ and trace ligand impurities in solution after *ca* 1 h. Controlled potential bulk reductive electrolysis at −2.2 V (i.e. just negative of peak A) produced [Pt(dcpe)(dppe)] in 50.4% spectroscopic yield, with some $[Pt(dppe)_2]$ and trace ligand impurities also detected. The unusual CV results thus remain unexplained.

The addition of one equivalent of dcpe to $[PtCl_2(dcpe)]$ followed by immediate measurement of a cyclic voltammogram produced the result shown in Fig. 4(b). Clearly, no dication is detected. After 1 h in solution, the cyclic voltammogram shown in Fig. 4(c) is obtained. On the sweep to negative potential, peak B is barely visible with a very small current, consistent with $^{31}P\{^1H\}$ NMR measurements which show only low levels of $[Pt(dcpe)_2]^{2+}$ in solution. Square wave voltammetry unambiguously shows the presence of peak B despite its low current. Sweeping through peak A then produces peak B* in the cyclic voltammogram with a large current on the reverse sweep. Peak B* does not appear unless peak A is first traversed. This is clear evidence that traversing peak A produces [Pt(dcpe)], some of which is trapped by dcpe to generate $[Pt(dcpe)_2]$, and it is this species that is re-oxidized at peak B*. This interpretation is supported by the results of controlled potential bulk reductive electrolysis experiments. Thus, attempted electrolysis at −1.20 V (i.e. just negative of the small peak B) resulted in essentially no current flow since hardly any $[Pt(dcpe)_2]^{2+}$ was present. Electrolysis at −2.25 V (i.e. just negative of peak A), however, results in significant generation of $[Pt(dcpe)_2]$ (39% by peak heights) via initial formation of [Pt(dcpe)] and subsequent trapping by dcpe. Consistent with this interpretation is the observation of a second, unidentified product [δ = 51.6 ppm, J(Pt,P) = 3133 Hz] which we feel must originate from reaction of [Pt(dcpe)] with components of the solvent/electrolyte system. These results suggest that electrochemical reduction of the $[PtCl_2(dcpe)]$+dcpe system follows path 1 (Scheme 1) rather than path 2, which appears to dominate for the other systems described so far. It is also noteworthy that peak B* in the cyclic voltammogram shown in Fig. 4(c) may contain more than one component (*vide infra*). This may be due to the oxidation of transient platinum(0) species other than $[Pt(dcpe)_2]$. Species such as [Pt(dcpe)(solvent)$_x$] or [Pt(dcpe)(η^1-dcpe)] may be likely candidates, although, whatever the nature of this species, it is too short-lived for detection by $^{31}P\{^1H\}$ NMR methods.

Addition of dppe to $[PtCl_2(dbpe)]$ (where dbpe = $^nBu_2PCH_2CH_2P^nBu_2$) gave rise to the cyclic

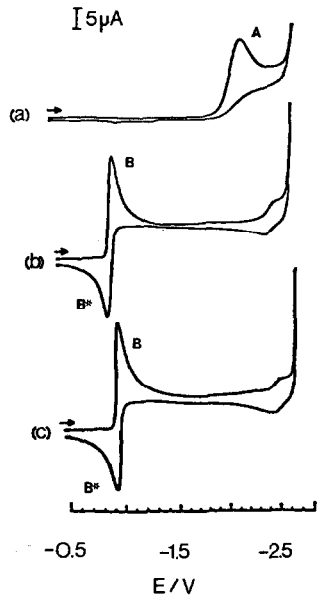

Fig. 5. Cyclic voltammograms measured in CH_3CN (10^{-1} M TBAP) at a Au/Hg amalgam working electrode (1.77 mm^2) using a scan rate of 200 mV s^{-1}. (a) 10^{-3} M solution of $[PtCl_2(dbpe)]$; (b) 10^{-3} M solution of $[PtCl_2(dbpe)]$ immediately after adding one equivalent of dppe; (c) 10^{-3} M solution of $[PtCl_2(dbpe)]$ 1 h after adding one equivalent of dbpe.

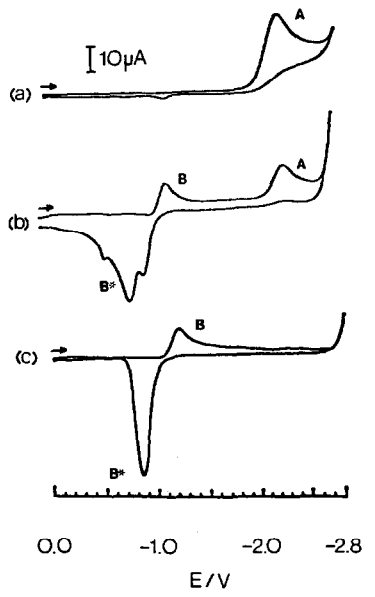

Fig. 6. Cyclic voltammograms measured in CH_3CN (10^{-1} M TBAP) at a Au/Hg amalgam working electrode (1.77 mm^2) using a scan rate of 200 mV s^{-1}. (a) 10^{-3} M solution of $[PtCl_2(dbpe)]$; (b) 10^{-3} M solution of $[PtCl_2(dbpe)]$ immediately after adding one equivalent of dcpe; (c) 10^{-3} M solution of $[PtCl_2(dbpe)]$ 1 h after adding one equivalent of dcpe.

voltammograms shown in Fig. 5. Immediately after the addition, substantial $[Pt(dbpe)(dppe)]^{2+}$ is formed while some $[PtCl_2(dbpe)]$ persists. This situation is essentially unchanged after 1 h [Fig. 5(c)]. The $^{31}P\{^1H\}$ NMR spectrum agrees with this assignment exactly (see Experimental). Controlled potential bulk reductive electrolysis at −2.40 V (i.e. just negative of peak A) produces largely [Pt(dbpe)(dppe)], as expected (63% by peak heights), but small amounts of $[Pt(dppe)_2]$ and an unidentified product [δ = 44.2 ppm, J(Pt,P) = 2245 Hz] are also formed. The latter component presumably has its origins in a reaction of [Pt(dbpe)], produced by reduction of $[PtCl_2(dbpe)]$, with components of the solvent/electrolyte system.

We find that addition of the more sterically demanding dcpe to $[PtCl_2(dbpe)]$ proceeds in a different manner to the reaction of dppe with $[PtCl_2(dbpe)]$. Thus, Fig. 6 shows the CV results for the addition of one equivalent of dcpe to $[PtCl_2(dbpe)]$. Immediately after addition, a sweep to negative potential reveals the reduction of $[Pt(dbpe)(dcpe)]^{2+}$ (peak B) followed by reduction of $[PtCl_2(dbpe)]$ (peak A). The latter process generates [Pt(dbpe)] which we might anticipate leads to the formation of additional [Pt(dbpe)(dcpe)] via possible intermediates such as $[Pt(dbpe)(solvent)_x]$ and/or $[Pt(dbpe)(\eta^1\text{-dcpe})]$. Thus, the reverse sweep reveals peak B* with a larger current than peak B and containing several components for oxidation of the different platinum(0) species present. Consistent with this interpretation, we find that after 1 h in solution [Fig. 6(c)], the reaction of $[PtCl_2(dbpe)]$ with dcpe has proceeded to completion and only $[Pt(dbpe)(dcpe)]^{2+}$ is detected on the scan to negative potential. Since reduction of the cation occurs at all potentials more negative than peak B, the reverse sweep causes stripping of adsorbed platinum(0) at the potential of peak B*, which now corresponds to the re-oxidation of just one species, [Pt(dbpe)(dcpe)]. Controlled potential bulk reductive electrolysis results support these conclusions. Thus electrolysis at −1.25 V (i.e. just negative of peak B) produces [Pt(dbpe)(dcpe)] essentially quantitatively. However, electrolysis at −2.40 V (i.e. just negative of peak A) produces not only [Pt(dbpe)(dcpe)] (49% by peak heights) but also the disproportionation products $[Pt(dbpe)_2]$ and $[Pt(dcpe)_2]$ as well as several unidentified species, formed in low yield, presumably by reaction of [Pt(dbpe)] with components of the solvent/electrolyte system. $^{31}P\{H\}$ NMR data for these unidentified minor components are listed in the Experimental for completeness.

Interestingly, we found that controlled potential electrolysis of an independently synthesized sample of $[Pt(dbpe)_2]Cl_2$, performed at a potential of −1.50 V, generated not only $[Pt(dbpe)_2]$ but also

an unidentified complex (see Experimental), suggesting that the reduction of four-coordinate dbpe complexes may involve ligand dissociation, producing reactive fragments.

CONCLUSIONS

The work described here shows that non-linear $[PtL_2]$ intermediates can be generated by electrochemical reduction of readily available $[PtCl_2L_2]$ precursors. In the absence of a specific trapping agent, [Pt(dppe)] was found to react indiscriminately with the components of the solvent/electrolyte system, but in the presence of another bidentate ligand as a trapping agent some selectivity for formation of $[PtL_2L_2^*]$ was achieved. The existence of two competing pathways (Scheme 1) caused us to investigate a series of $[PtCl_2L_2]$ precursors and L_2^* trapping agents, and this work shows how the steric and electronic effects of L_2 and L_2^* modify reactivity. Based upon these results, we are currently examining the electrochemical generation and reactivity of non-linear $[PtL_2]$ complexes containing ligands other than dppe in order to achieve more selective reactions with organic substrates.[18]

EXPERIMENTAL

General procedures

Acetonitrile (Fisher, ACS grade) was stirred with CaH_2 for 48 h, decanted and distilled from P_4O_{10}. The first 15% of the distillate was discarded as was the last 15%. The middle 70% (b.p. 83.0°C) was refluxed with CaH_2 and then fractionally distilled. Again the first and last 15% of the distillate was discarded and the middle 70% was stored under argon over Al_2O_3, activated at 110°C for 24 h. Benzene (Fisher, ACS grade) was freshly distilled from sodium wire under nitrogen prior to use. Benzene-d_6 was purchased from Aldrich and deoxygenated prior to use. Tetra(n-butyl)ammonium perchlorate (TBAP, G.F.S.) was recrystallized five times from absolute ethanol and dried *in vacuo* for 48 h at room temperature. The phosphines, bis(dicyclohexylphosphino)ethane and bis(di{n-butyl}phosphino)ethane were purchased from Strem and bis(diphenylphosphino)ethane was prepared by literature methods.[19] Commercial bis(dicyclohexylphosphino)ethane was purified by recrystallization from tetrahydrofuran prior to use, which removed several impurities although small amounts of dcpeO and $dcpeO_2$ remained. The complexes $[PtCl_2(dppe)]$ and $[PtCl_2(dcpe)]$ were prepared by displacement of 1,5-cyclooctadiene from $[PtCl_2(cod)]$[20] in methylene chloride. The complex $[PtCl_2(dbpe)]$ was synthesized by the displacement of acetonitrile from $[PtCl_2(CH_3CN)_2]$[21] in acetonitrile and was recrystallized from THF. The preparation of the dication $[Pt(dbpe)_2]Cl_2$ was accomplished by reaction of the bis-acetonitrile complex with two equivalents of phosphine.[12]

$^{31}P\{^1H\}$ (36.2 MHz) NMR spectra were measured on a Jeol FX 90Q spectrometer operating in the Fourier transform mode or were recorded on a Varian VXR 400 (161 MHz) spectrometer when second-order effects were seen at the lower field of the FX 90Q spectrometer. $^{31}P\{^1H\}$ NMR chemical shifts were measured using 85% H_3PO_4 as an external standard, with positive values of the chemical shift representing deshielding. Yields were estimated from peak heights in the $^{31}P\{^1H\}$ NMR spectra unless cited as isolated yields.

The mixed ligand platinum(II) dications gave rise to $^{31}P\{^1H\}$ NMR spectra which could be interpreted in terms of AA′BB′ or AA′XX′ spin systems (ignoring the effects of ^{195}Pt). Each spectrum was simulated using Varian's 6.2 software package to within an error of ± 5 Hz of the expected line positions, with the majority of the lines simulated to less than ± 1 Hz of the positions in the original spectra.

Cyclic voltammograms were obtained using a Bioanalytical Systems 100 control unit. Typically, 2.0×10^{-3} M solutions of the complexes in acetonitrile (10 cm^3), which was 0.08 M in TBAP, were employed. In this solvent system the ferrocene/ferrocenium couple appears at +0.760 V with a peak separation of 90 mV. The cobaltocene/cobaltocenium couple appears at −0.570 V with a peak separation of 82 mV.

A single compartment cell, thermostatted to 25 ± 1°C, equipped with a Ag/AgCl reference electrode (−35 mV vs SCE), a platinum wire auxiliary electrode and a mercury/gold amalgam working electrode was used. We have discussed CV of platinum(II) complexes using similar techniques previously.[13–16] Controlled potential bulk reductive electrolyses[1–3] were performed using a Bioanalytical Systems SP-2 synthetic potentiostat. A three-compartment cell was employed which was constructed in-house. The working electrode compartment contained the Ag/AgCl reference electrode and 18 cm^3 of mercury connected to the potentiostat by a platinum wire. The auxiliary electrode compartment contained a platinum spiral wire electrode. The compartments were separated by two medium porosity frits. The cell was equipped with

a number of fitted openings to allow inert atmosphere operation and manipulation of solutions.

$^{31}P\{^{1}H\}$ *NMR measurements*

The reactions of $[PtCl_2L_2]$ with L_2* were monitored by $^{31}P\{^{1}H\}$ NMR spectroscopy. Solutions were prepared in acetonitrile/benzene-d_6 and in acetonitrile/benzene-d_6 which was 0.1 M in TBAP. Essentially identical results were obtained for the two solvent systems.

(i) $[PtCl_2(dppe)]$ + dppe. $[Pt(dppe)_2]^{2+}$ and dppe were identified in solution. Also present were small amounts of dppeO and $dppeO_2$ which were initially present as trace impurities in the dppe employed in the reaction. No insoluble material was formed.

(ii) $[PtCl_2(dppe)]$ + dcpe. $[Pt(dppe)(dcpe)]^{2+}$ and $[PtCl_2(dcpe)]$ were identified in solution along with $dcpeO_2$, originally present as an impurity in the dcpe employed in the reaction. Some insoluble material {perhaps $[PtCl_2(dppe)]$} was also formed.

(iii) $[PtCl_2(dcpe)]$ + dppe. $[Pt(dcpe)(dppe)]^{2+}$ and dppe were identified in solution along with the ligand impurities dppeO and $dppeO_2$.

(iv) $[PtCl_2(dcpe)]$ + dcpe. $[Pt(dcpe)_2]^{2+}$, $[PtCl_2(dcpe)]$ and dcpe were identified in solution along with the ligand impurity $dcpeO_2$.

(v) $[PtCl_2(dbpe)]$ + dppe. $[Pt(dbpe)(dppe)]^{2+}$ and $[PtCl_2(dbpe)]$ were identified in solution. Trace amounts of unidentified compounds which did not appear to contain platinum were identified at very high signal-to-noise ratios. No insoluble material was formed.

(vi) $[PtCl_2(dbpe)]$ + dcpe. $[Pt(dbpe)(dcpe)]^{2+}$, $[PtCl_2(dcpe)]$ and $[Pt(dbpe)_2]^{2+}$ were identified in solution along with the trace ligand impurity $dcpeO_2$.

Controlled potential electrolyses (CPE)

Each CPE described below was repeated at least twice with consistent results.

(i) *CPE of* $[PtCl_2(dppe)]$ *in the presence of* dppe. Twenty-four hours prior to an experiment, the controlled potential electrolysis cell was charged with alumina (1.0 g) and dried at 110°C. From this point on all manipulations of the cell were done under an argon atmosphere at room temperature unless otherwise noted. At the time of the experiment, mercury (25 cm^3) was extracted with dry benzene (10 cm^3) and then the mercury (18 cm^3) and a small magnetic stirrer bar were added to the cell which was cooled under argon. A 0.1 M solution of TBAP in acetonitrile/benzene (60 cm^3, 1 : 1, v/v) was introduced into the cell under an argon stream. This was allowed to outgas for 1 h. The solution was then stirred and pre-electrolysed to approximately zero current at a potential of −1.75 V.

To the pre-electrolysed solution was added $[PtCl_2(dppe)]$ (*ca* 30 mg) and one equivalent of dppe (*ca* 18 mg) which was purged with argon for 1 h. This was then electrolysed to essentially zero current at a potential of −1.75 V. This usually required 30 min to 1 h and coulometry indicated approximately a 2-electrons/equivalent reduction, with integrations in the range of 1.9–2.1 electrons/equivalent. When the electrolysis was complete, the solution was transferred (using inert atmosphere techniques) to a Schlenk tube and evaporated. The yellowish solid was extracted with benzene (2×10 cm^3) and evaporated to give a yellow solid which was dissolved in C_6D_6 and transferred to an NMR tube. $^{31}P\{^{1}H\}$ NMR spectroscopy showed $[Pt(dppe)_2]$, $\delta_P = 29.8$ ppm, $J_{Pt-P} = 3729$ Hz (82.9%); dppe, $\delta = -13.4$ ppm (4.6%); dppeO, $\delta_{P(1)} = 26.8$ ppm, $\delta_{P(2)} = -12.5$ ppm, $J_{P-P} = 34$ Hz (5.6%); $dppeO_2$, $\delta = 28.1$ ppm (5.9%).

(ii) *CPE of* $[PtCl_2(dppe)]$ *in the presence of* dcpe. To the pre-electrolysed (−1.75 V, CH_3CN) solution was added $[PtCl_2(dppe)]$ (*ca* 30 mg) and one equivalent of dcpe (*ca* 20 mg) which was then purged with argon for 1 h and electrolysed to essentially zero current at −1.75 V. This usually required 30 min to 1 h and coulometry indicated approximately a 2-electrons/equivalent reduction, with integrations in the range of 2.0–2.1 electrons/equivalent. After work-up as previously described, $^{31}P\{^{1}H\}$ NMR spectroscopy showed [Pt(dppe)(dcpe)] (54.0%), $[Pt(dppe)_2]$ (8.5%); $[PtCl_2(dcpe)]$ (7.5%); dcpe, $\delta = 0.36$; dcpeO, $\delta_{P(1)} = 45.8$, $\delta_{P(2)} = 1.2$ ppm, $J_{P-P} = 37$ Hz; $dcpeO_2$, $\delta = 47.7$ ppm.

(iii) *CPE of* $[PtCl_2(dcpe)]$ *in the presence of* dppe. To the pre-electrolysed solution (−2.20 V, CH_3CN) was added $[PtCl_2(dcpe)]$ (*ca* 30 mg) with one equivalent of dppe (*ca* 18 mg) which was purged with argon for 1 h and electrolysed to zero current flow (1–1.5 h) with coulometry indicating a 2-electrons/equivalent reduction (range 1.9–2.1 electrons/equivalent). Collection of a yellow solid which precipitated from the acetonitrile yielded [Pt(dcppe)(dppe)] (50.4% isolated yield). A trace of $dppeO_2$ was seen by $^{31}P\{^{1}H\}$ NMR. In the solution, which was worked-up as previously described, remained $[Pt(dppe)_2]$ (17.0%); $dppeO_2$ (25.1%), dppeO (28.0%); dppe (11.4%); and $dcpeO_2$ (18.5%).

(iv) *CPE of* $[PtCl_2(dcpe)]$ *in the presence of* dcpe. (a) To the pre-electrolysed solution (−2.20 V, CH_3CN) was added $[PtCl_2(dcpe)]$ (*ca* 30 mg) and one equivalent of dcpe (*ca* 19 mg) which was purged with argon for 1 h and electrolysed to zero current flow (1.5–2.5 h) with coulometry indicating a 2-

electrons/equivalent reduction (range 1.9–2.3 electrons/equivalent). After work-up, $^{31}P\{^1H\}$ NMR (C_6D_6) showed [Pt(dcpe)$_2$] (39.2%); dcpeO$_2$ (18.2%); dcpeO (10.2%); dcpe (25.5%); and a platinum complex with the data: $\delta = 51.6$ ppm, $J_{Pt-P} = 3133$ Hz (6.9%).

(b) To a pre-electrolysed solution (−1.20 V, CH_3CN) was added [PtCl$_2$(dcpe)] (*ca* 30 mg) and one equivalent of dcpe (*ca* 19 mg) which was purged with argon for 1 h and electrolysed to near zero current flow (1–2 h). The current flow was very low and coulometry indicated that only 0.15 electrons/equivalent were consumed. After the usual work-up, $^{31}P\{^1H\}$ NMR (C_6D_6) showed [PtCl$_2$(dcpe)] (20.0%); dcpe (52.8%); dcpeO (9.1%); and dcpeO$_2$ (18.1%).

(v) *CPE of* [PtCl$_2$(dbpe)] *in the presence of* dppe. To the pre-electrolysed solution (2.40 V, CH_3CN) was added [PtCl$_2$(dbpe)] (*ca* 30 mg) with one equivalent of dppe (*ca* 20 mg) and purged with argon for 1 h. This solution was electrolysed until approximately 2 electrons/equivalent were consumed and then the electrolysis was terminated (30 min to 1 h). The formation of a precipitate occurred as the acetonitrile was concentrated and this precipitate was isolated: [Pt(dbpe)(dppe)] (52.6% isolated yield). [Pt(dbpe)(dppe)] was identified by its 161 MHz $^{31}P\{^1H\}$ NMR spectrum due to the second-order nature of the spectrum obtained at 36.2 MHz. The remaining solution contained several compounds including [Pt(dbpe)(dppe)] (66.6%); [Pt(dppe)$_2$] (10.3%) along with traces of dbpeO$_2$, dppeO$_2$ and dppeO. The only component unidentified had the data: $\delta = 44.2$ ppm, $J_{Pt-P} = 2243$ Hz.

(vi) *CPE of* [PtCl$_2$(dbpe)] *in the presence of* dcpe. (a) To the pre-electrolysed solution (−2.40 V, CH_3CN) was added [PtCl$_2$(dbpe)] (*ca* 30 mg) with one equivalent of dcpe (*ca* 22 mg). This was electrolysed until 2-electrons/equivalent were consumed (30 min to 1 h). A precipitate formed which was collected. $^{31}P\{^1H\}$ NMR data of this dark yellow solid (in C_6D_6 solution) revealed [Pt(dbpe)(dcpe)] (48.8%); [Pt(dcpe)$_2$] (11.2%); and dcpe (33.6%). In the remaining solution was seen five platinum phosphine complexes. The data for these unidentified complexes are as follows: $\delta = 46.6$ ppm, $J_{Pt-P} = 2270$ Hz (29.2%); $\delta_P = 49.8$ ppm, $J_{Pt-P} = 2020$ Hz (12.9%); $\delta_P = 39.6$ ppm, $J_{Pt-P} = 2619$ Hz (13.7%); $\delta_P = 65.0$ ppm, $J_{Pt-P} = 2430$ Hz (11.8%); $\delta_P = 68.0$ ppm, $J_{Pt-P} = 2064$ Hz (6.4%). The remaining peaks were attributed to dcpe, dbpe and the corresponding oxides.

(b) To the pre-electrolysed solution (1.50 V, CH_3CN) was added [PtCl$_2$(dbpe)] (*ca* 30 mg) with one equivalent of dcpe (*ca* 22 mg). This was electrolysed to near zero current at which point 2.2 electrons/equivalent were consumed and a white precipitate was collected. $^{31}P\{^1H\}$ NMR data of this white solid revealed [Pt(dbpe)(dcpe)] as the only phosphorus-containing product. The remaining solution contained no significant phosphorus-containing material and only traces of dcpe and dbpeO$_2$ were observed spectroscopically.

(vii) *CPE of* [Pt(dbpe)$_2$]Cl$_2$. To a pre-electrolysed solution (−1.50 V, CH_3CN/C_6H_6, 1:1 v/v) the complex [Pt(dbpe)$_2$]Cl$_2$ (*ca* 30 mg) was added and then purged with argon for 1 h. The solution was electrolysed to near zero current with coulometry indicating approximately 2-electrons/equivalent consumed (range 2.0–2.2 electrons/equivalent). After work-up as previously described the $^{31}P\{H\}$ NMR spectrum revealed three platinum complexes in addition to peaks for the free phosphine (dbpe) and its oxides. Of the three platinum complexes two were identified as [Pt(dbpe)$_2$] (48.9%) and [Pt(dbpe)$_2$]$^{2+}$ (19.2%). The remaining complex, $\delta_P = 36.7$ ppm, $J_{2Pt-P} = 3090$ Hz (11.5%) remains unidentified.

(vii) *CPE of* [PtCl$_2$(dppe)] *in the absence of a trapping agent*. To the pre-electrolysed solution (−1.75 V, CH_3CN/C_6H_6, 1:1 v/v) the complex [PtCl$_2$(dppe)] (*ca* 30 mg) was added and the solution was purged with argon for 1 h. The solution was electrolysed to near zero current with coulometry indicating consumption of 1.4 electrons/equivalent. After work-up as previously described, the $^{31}P\{^1H\}$ NMR spectrum revealed the presence of the following compounds: $\delta_P = 38.3$ ppm, $J_{Pt-P} = 1626$ Hz; $\delta_P = 40.4$ ppm, $J_{Pt-P} = 3587$ Hz; $\delta_P = 33.4$ ppm, $J_{Pt-P} = 4592$ Hz; $\delta_P = 35.2$ ppm, $J_{Pt-P} = 3592$ Hz, $J_{P-P} = 8$ Hz. The ^1H NMR spectrum of this mixture did not reveal any resonances attributable to hydrides.

C—X AND C—H CLEAVAGE BY ELECTROCHEMICALLY GENERATED NON-LINEAR [PtL_2] COMPLEXES

JULIAN A. DAVIES† and RICHARD J. STAPLES‡

Departments of Chemistry and Medicinal and Biological Chemistry,
The University of Toledo, Toledo, OH 43606, U.S.A.

(*Received* 6 *August* 1990; *accepted* 4 *January* 1991)

Abstract—The electrochemical reduction of [PtX_2L_2] (X = halide, L_2 = bidentate diphosphine: $Ph_2PCH_2CH_2PPh_2$, dppe; $Cy_2PCH_2CH_2PCy_2$, dcpe; $Cy_2P\{CH_2\}_3PCy_2$, dcpp) has been used as a method of generating non-linear [PtL_2] compounds whose reactivity with substrates Ar—X (X = Cl, Br, CN, H, C≡CPh) has been examined. Generation of [PtL_2] (L_2 = dppe or dcpe) in the presence of excess Ph—X (X = Cl, Br) produces [PtXPhL_2] efficiently. Similarly, generation of [PtL_2] (L_2 = dppe or dcpe) in the presence of PhC≡CPh results in trapping to form [PtL_2(PhC≡CPh)]. Generation of [PtL_2] (L_2 = dppe or dcpe) in the presence of PhCN or PhH results in indiscriminate reactions that do not produce tractable products. In contrast, reduction of [$PtCl_2$(dcpp)] in $CH_3CN/C_6H_6/Bu_4NClO_4$ produces [PtHPh(dcpp)] with considerable selectivity via aromatic C—H activation by [Pt(dcpp)]. At room temperature the complex [PtHPh(dcpp)] undergoes exchange with C_6D_6 to generate [PtD(C_6D_5)(dcpp)].

In a recent series of papers Whitesides and coworkers[1–3] have shown that C_{2v} [PtL_2] complexes can react with hydrocarbon substrates, including alkanes, by C—H oxidative addition. Thus, thermolysis of the alkylhydride [PtH(CH_2CMe_3)($Cy_2PCH_2CH_2PCy_2$)] (Me = methyl, Cy = cyclohexyl) was shown to result in reductive elimination of neopentane and reaction of the resulting non-linear [PtL_2] fragment with an organic substrate present in excess. We have demonstrated[4–7] that electrochemical reduction of *cis*-[$PtCl_2L_2$] complexes generates [PtL_2] equivalents and that in the case where L_2 is a bidentate tertiary phosphine ligand[7] the non-linear intermediate may be trapped by other bidentate ligands to produce [PtL_2L_2*]. Here we report on the reactions of non-linear [PtL_2] equivalents, generated by electrochemical reduction, with organic substrates including examples where C—X (X = halogen) and C—H oxidative additions are observed.

Initially we believed that the electrochemical generation of non-linear [PtL_2] equivalents by reduction of [PtX_2L_2] might prove to be problematic since the electrochemical method requires the use of a relatively polar solvent and a background electrolyte, both of which might participate in indiscriminate reactions with the C_{2v} intermediate. However, work with bidentate ligands as trapping agents[7] showed that unselective reactions with the solvent/electrolyte could largely be avoided provided a suitable trap was already present in solution as the [PtL_2] intermediate was generated. Thus, in order to probe the reactions of non-linear [PtL_2] complexes with organic substrates we sought suitable compounds to act as trapping agents. The requirements are quite stringent since the trapping agent must survive the very negative potentials required to reduce the [PtX_2L_2] precursors (typically[4–7] *ca* −1.50 to −2.40 V vs Ag/AgCl). Additionally, we sought trapping agents that would not react with the [PtX_2L_2] precursors, a problem that we had previously encountered in using bidentate ligands as trapping agents.[7] Based upon these requirements we examined compounds of the type Ph—X (where X = Cl, Br, CN, H, C≡CPh) which could either be used as solvents for electrochemical reduction or added to a solvent/electrolyte system of acetonitrile/TBAP [TBAP = tetra(n-butyl)ammonium perchlorate]. In order to probe ligand effects on the reactivity of non-linear [PtL_2] com-

pounds we have examined complexes of dppe ($PhPCH_2CH_2PPh_2$) and dcpe ($Ph_2PCH_2CH_2PPh_2$) with each trapping agent. Some experiments have also been performed with complexes of dcpp ($Cy_2P\{CH_2\}_3PCy_2$).

RESULTS AND DISCUSSION

Our initial experiments utilized PhX (X = Cl, Br, CN) as both solvent and trapping agent for the electrochemical reduction of $[PtX_2(dppe)]$ and $[PtX_2(dcpe)]$. None of these solvents is truly suitable for electroanalytical work since each has a low dielectric constant[8] (PhCl: 5.62; PhBr: 5.40; PhCN: 25.20; cf. CH_3CN: 37.50) and this is manifested in the cyclic voltammograms of $[PtI_2(dppe)]$ shown in Fig. 1. Based on these and similar measurements for other complexes we selected appropriate potentials for controlled potential bulk reductive electrolysis experiments. Each electrolysis experiment was performed utilizing the three-compartment cell, equipped with a mercury pool working electrode, a Ag/AgCl reference electrode and a platinum auxiliary electrode that we have described previously.[6] In many of the experiments described here we found that the low dielectric constant solvents led to low current flow resulting in long electrolysis times which made coulometry unreliable as a guide to determining the extent of reaction. Accordingly, many experiments were terminated at an arbitrary point where the starting material had not been fully consumed.

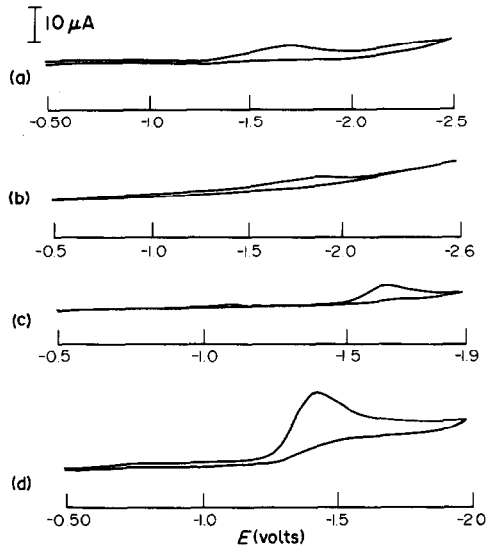

Fig. 1. Cyclic voltammograms of $[PtI_2(dppe)]$ as a 10^{-4} M solution in a solvent that is 0.08 M in TBAP, measured using a Hg/Au amalgam working electrode (1.77 mm^2) at a scan rate of 200 mV s^{-1} with a Ag/AgCl reference electrode. Solvents used were: (a) chlorobenzene, (b) bromobenzene, (c) benzonitrile and (d) acetonitrile.

Electrolysis of $[PtCl_2(dppe)]$ in chlorobenzene at −2.0 V was followed by a standard work-up (see Experimental) and examination by $^{31}P\{^1H\}$ NMR spectroscopy which showed the exclusive formation of [PtClPh(dppe)] and the presence of some residual starting material. Formation of the chlorophenyl complexes suggests electrochemical generation of the non-linear intermediate, [Pt(dppe)], followed by C—Cl oxidative addition. A similar reduction of $[PtI_2(dppe)]$ in chlorobenzene at −1.80 V was complicated by the fact that in this case generation of [Pt(dppe)] liberates iodide ions, which can engage in metathesis reactions with the starting material or product. Thus, $^{31}P\{^1H\}$ NMR spectroscopy indicates the formation of [PtIPh(dppe)], together with the presence of starting material and its metathesis products {i.e. $[PtI_2(dppe)]$, [PtICl(dppe)] and $[PtCl_2(dppe)]$}. Additionally, a trace amount of an unidentified compound (δ_P = 36.7 ppm, J_{Pt-P} = 4165 Hz) was detected. The electrochemical reduction of $[PtI_2(dcpe)]$, containing the bulky σ-donor $Cy_2PCH_2CH_2PCy_2$ ligand, in chlorobenzene at −2.0 V produced [PtClPh(dcpe)] and its metathesis product, [PtIPh(dcpe)]. Some unreacted $[PtI_2(dcpe)]$ was also detected in solution. With the dcpe ligand, no unidentified species were generated (cf. the analogous dppe reaction).

Reactions in bromobenzene were found to proceed similarly. Thus, reduction of $[PtCl_2(dppe)]$ in C_6H_5Br/CH_3CN (5:1) at −2.0 V produced [PtBrPh(dppe)] and its metathesis product, [PtClPh (dppe)]. Some residual starting material was found to be metathesized to [PtClBr(dppe)] and $[PtBr_2$ (dppe)]. The electrochemical reduction of $[PtI_2$ (dcpe)] in bromobenzene at −1.80 V produced both [PtBrPh(dcpe)] and [PtIPh(dcpe)] with some $[PtI_2(dcpe)]$ remaining.

In each of the above experiments the compounds $[PtXPhL_2]$ (X = Cl, Br, I; L_2 = dppe, dcpe), formed by Ph—X oxidative addition, and the mixed halide complexes, $[PtXYL_2]$ (X = Cl; Y = Br, I; L_2 = dppe), formed by halide metathesis, were identified by comparison of their spectroscopic data with data obtained for independently synthesized materials. Details of these syntheses are given in the Experimental and spectroscopic data, along with pertinent literature references, are collected in Tables 1 and 2.

Electrochemical reductions of both $[PtI_2(dppe)]$ and $[PtCl_2(dcpe)]$ in benzonitrile proved to be very complex. Although our earlier work[5,6] on the electrochemical reduction of *cis*-$[PtCl_2(PEt_3)_2]$ in PhCN had shown that *trans*-$[PtCN(Ph)(PEt_3)_2]$ could be effectively generated, neither of the present

[PtIBr(dcpe)]	66.3	67.5	3394	3502	5.3

[a] P_A refers to the phosphorus *trans* to the first named halide, P_B refers to the phosphorus *trans* to the second named halide. Data for independently synthesized samples (see Experimental).

systems produced tractable products. Indeed, current flow in these experiments continued past the anticipated 2 electrons/equivalent, perhaps indicating that any *cis*-phenylcyano complexes generated were unstable under the reaction conditions. In this regard it is noteworthy that our attempts to independently synthesize [PtCN(Ph)(dppe)] by treatment of [PtClPh(dppe)] with cyanide ion (see Experimental) invariably led to decomposition.

Diphenylacetylene proved to be an effective trapping agent for non-linear [PtL_2] equivalents. Thus, electrochemical reduction of [PtX_2(dppe)] in CH_3CN/C_6H_6 containing one equivalent of PhC≡CPh produced [Pt(PhC≡CPh)(dppe)] in high yield (X = Cl: 93.5%; X = Br: 94.5%; X = I: 87.0%; estimated from peak heights in the $^{31}P\{^1H\}$ NMR spectra). A similar reduction of [PtI_2(dcpe)] in the presence of PhC≡CPh generated [Pt(PhC≡CPh)(dcpe)] but here the yield was reduced to 56% with other, unidentified by-products also present. The complex [Pt(PhC≡CPh)(dppe)] was identified by comparison of its spectroscopic data with those of a sample independently synthesized by $NaBH_4$ reduction of [PtI_2(dppe)] in the presence of PhC≡CPh (see Experimental). The dcpe analogue was identified by comparison of its spectroscopic data with those extant in the literature.[1]

The results in the preceding paragraphs show that electrochemical reduction of [PtX_2L_2] precursors containing bidentate ligands produces non-linear [PtL_2] equivalents which can be trapped by Ph—X (X = Cl, Br) oxidative addition or by coordination to PhC≡CPh. As mentioned in the introductory paragraphs, we thought that reduction of

$[PtX_2L_2]$ in the absence of a trapping agent but in the presence of a relatively polar solvent (e.g. CH_3CN or CH_3CN/C_6H_6) containing a background electrolyte (e.g. TBAP) might lead to indiscriminate reaction of the non-linear $[PtL_2]$ intermediate. Indeed, reduction of $[PtCl_2(dppe)]$ (at -1.75 V) or $[PtBr_2(dppe)]$ (at -1.60 V) in CH_3CN/C_6H_6 (1 : 1, v/v, 0.1 M TBAP) produced product mixtures containing many components (see Experimental), none of which could be identified by comparison of $^{31}P\{^1H\}$ NMR data with literature values. However, reduction of $[PtI_2(dppe)]$ (at -1.40 V) in CH_3CN/C_6H_6 (1 : 2, v/v, 0.1 M TBAP) gave an indication that some meaningful chemistry might evolve from this area since the $^{31}P\{^1H\}$ NMR spectrum of the complicated product mixture contained resonances attributable to [PtIPh(dppe)], suggesting that C—H cleavage of the benzene component of the solvent mixture might have occurred, although ligand cleavage might also serve as a source of phenyl groups.

Similar indications of aromatic C—H activation were found in experiments using $[PtCl_2(dcpe)]$. Thus, although reduction in CH_3CN (0.1 M TBAP) at -2.25 V produced only unidentifiable products, reduction in CH_3CN/C_6H_6 (1 : 2, v/v, 0.1 M TBAP) at -2.25 V generated a product mixture whose ^1H NMR spectrum showed the presence of a component with a Pt—H bond and a component with a Pt—Ph bond (by the characteristic pattern[1] for the *ortho* protons). The $^{31}P\{^1H\}$ NMR spectrum of this product mixture showed that several platinum phosphine complexes were formed but no resonances attributable to the known compound [PtHPh(dcpe)][1] could be identified. Thus, it seems likely that the Pt—H and Pt—Ph groups observed in the ^1H NMR spectrum are present in different compounds. In this case ligand cleavage cannot be a source of phenyl groups and so C—H activation of benzene seems likely.

After examining several precursors, we found that electrochemical reduction of $[PtCl_2(dcpp)]$ (where dcpp = $Cy_2P\{CH_2\}_3PCy_2$) in CH_3CN/C_6H_6 (1 : 1, v/v, 0.1 M TBAP), followed by a standard work-up (see Experimental) and examination of a C_6D_6 solution by $^{31}P\{^1H\}$ NMR spectroscopy, produced the spectrum shown in Fig. 2(a). The presence of two doublets and the magnitudes of the couplings to platinum[1] suggested the compound formed was [PtHPh(dcpp)]. However,

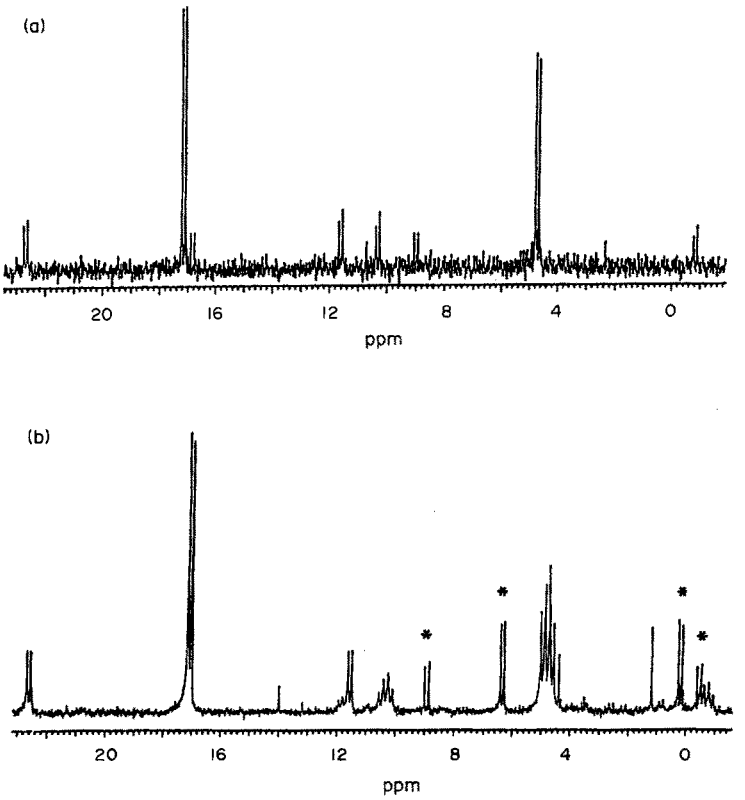

Fig. 2. $^{31}P\{^1H\}$ NMR spectra (C_6D_6 solution) of the product mixture arising from the electrochemical reduction of $[PtCl_2(dcpp)]$ in CH_3CN/C_6H_6 (1 : 1, v/v, 0.1 M TBAP): (a) immediately after work-up and (b) after 6 h in solution.

after 6 h in solution the $^{31}P\{^1H\}$ NMR spectrum had changed to that shown in Fig. 2(b). From this spectrum it is clear that both a new compound is being formed (indicated by *) and that one of the two doublets assigned to [PtHPh(dcpp)] has been transformed into a more complex multiplet while the other doublet has remained unchanged. A 2D-$^{31}P\{^1H\}$-COSY spectrum of the solution demonstrated unambiguously that the doublet at 17.1 ppm is coupled to the new multiplet at 4.7 ppm and that no other coupling to phosphorus is involved in generating this multiplet. Accompanying these changes in the $^{31}P\{^1H\}$ NMR spectrum over time are changes in the ^1H NMR spectrum. The initial ^1H NMR spectrum shows characteristic resonances for Pt—H and Pt—Ph with coupling constants entirely in accord[1] with the proposed structure, [PtHPh(dcpp)]. Six hours later, the hydride and Pt—Ph resonances are no longer present and only resonances attributable to coordinated dcpp are observed.

In order to account for these observations, we postulated that the electrochemical reduction of [PtCl$_2$(dcpp)] produces a non-linear intermediate, [Pt(dcpp)], which reacts selectively with benzene by C—H oxidative addition, despite the presence of both CH_3CN and TBAP. The complex [PtHPh(dcpp)] when dissolved in C_6D_6 undergoes two competing processes: one is decomposition to generate an unknown species [indicated by * in Fig. 2(b)] and the other is a more rapid reaction with the C_6D_6 solvent to generate [PtD(C_6D_5)(dcpp)]. In order to test this postulate, we measured the 2D $^{31}P\{^1H\}$ *J*-resolved NMR spectrum of the solution after it had stood for several hours and then generated the $^{31}P\{^1H, ^{31}P\}$ NMR spectrum. From these data we deduced that the multiplet shown at 4.7 ppm in Fig. 2(b) arose from coupling to the phosphorus observed at 17.1 ppm (*vide supra*) and coupling to a second nucleus (not ^1H or ^{31}P) which generated a 1 : 1 : 1 pattern. This pattern is entirely as expected for coupling of ^{31}P to deuterium and the magnitude of the observed coupling, $^2J(^{31}P, ^2H) = 28$ Hz, agrees well with the analogous value of $^2J(^{31}P, ^1H) = 179$ Hz for the larger of the two ^{31}P–^1H couplings observed in the ^1H NMR spectrum of [PtHPh(dcpp)]. Thus, the magnitudes of the magnetogyric ratios of ^1H and ^2H determine that a coupling of 28 ± 1 Hz involving deuterium will lead to a coupling of 182 ± 6 Hz for the analogous protio compound.

In order to confirm this exchange process, the solution which gave rise to the $^{31}P\{^1H\}$ NMR spectrum shown in Fig. 2(a), i.e. largely [PtHPh(dcpp)], was rapidly evaporated *in vacuo* and an IR spectrum of a KBr pellet of the resulting material was obtained. The spectrum showed the presence of Pt—H with ν(Pt—H) = 1995 cm^{-1}. Similar treatment of a sample giving rise to the $^{31}P\{^1H\}$ NMR spectrum shown in Fig. 2(b), i.e. largely [PtD(C_6D_6)(dcpp)], produced an IR spectrum in which the absorption at 1995 cm^{-1} was absent and a new absorption at 1419 cm^{-1} was present. This value agrees well with the calculated value of 1418 cm^{-1} for replacement of hydrogen by deuterium.

The results that we describe here show interesting similarities and differences to the results of Whitesides and co-workers.[1-3] Thus, Whitesides demonstrated that thermal generation of [Pt(dcpe)] led to selective reactions with substrates present in excess, typically as the solvent. We found that the same intermediate could be generated electrochemically by reduction of [PtX$_2$(dcpe)], but that unless specific trapping agents (e.g. PhCl, PhBr) were present, indiscriminate reaction with the C_6H_6/CH_3CN/TBAP solvent/electrolyte system occurred. Similar statements can be made for the electrochemical generation of the analogous dppe intermediate, whose thermal generation has not been described. However, use of the dcpp ligand allowed electrochemical generation of an intermediate which showed considerable selectivity in producing [PtHPh(dcpp)] via C—H oxidative addition of benzene even in the presence of reactive materials such as CH_3CN and TBAP. Whitesides and co-workers[1-3] observed that [PtHPh(dcpe)] could be induced to undergo exchange with C_6D_6 at $\geqslant 79$°C and have reported a detailed mechanistic investigation. We found that [PtHPh(dcpp)] undergoes the same exchange process at room temperature. Presumably the difference in behaviour of the dcpe and dcpp systems relates to the degree to which the non-linear [PtL$_2$] intermediate can approach linearity. Thus, in our electrochemical system we find that the presumably linear [Pt(PEt$_3$)$_2$] does not react with unactivated C—H bonds, the non-linear [Pt(dcpe)] with a dimethylene ligand backbone reacts indiscriminately, while the [Pt(dcpp)] intermediate with a trimethylene ligand backbone reacts quite selectively.[10]

EXPERIMENTAL

General procedures

The solvents, bromobenzene, chlorobenzene and benzonitrile were purified by first refluxing with anhydrous $MgSO_4$ (10 g dm^{-3}) for 24 h, followed by distillation under argon to a dry flask containing activated alumina (25 g dm^{-3}), where the first 20% of the distillate and the last 20% were discarded.

Collection temperatures were: bromobenzene 154–155°C, chlorobenzene 131–132°C and benzonitrile 190–192°C. Acetonitrile was purified as previously described.[6] Benzene (Fisher, ACS grade) was freshly distilled from sodium wire under nitrogen prior to use. Benzene-d_6 (Aldrich) and chloroform-d (Norell) were stored over molecular sieves (3 Å) and deoxygenated prior to use. Tetra(n-butyl)ammonium perchlorate (TBAP, G.F.S) was purified by recrystallization from absolute ethanol (200 g in 75 cm^3) at room temperature, followed by vacuum drying for 48 h. Diphenylacetylene (Aldrich) was vacuum dried prior to use.

The ligands dppe and dcpe were purchaed from Strem Chemicals and dcpp was prepared by a literature route.[11] The complexes [$PtCl_2$(dppe)], [$PtCl_2$(dcpe)] and [$PtCl_2$(dcpp)] were prepared by displacement of 1,5-cyclooctadiene (cod) from [$PtCl_2$(cod)]. [PtI_2(dppe)] and [PtI_2(dcpe)] were similarly prepared from [PtI_2(cod)]. [$PtBr_2$(dppe)] was prepared by NaBr metathesis of [$PtCl_2$(dppe)] in CH_2Cl_2/acetone. The complexes [PtXPhL_2] (X = Cl, Br, I; L_2 = dppe, dcpe) were prepared (X = Cl) by displacement of 1,5-cyclooctadiene from [PtClPh(cod)] and by NaX metathesis (X = Br, I) of [PtClPhL_2].

$^{31}P\{^1H\}$ (36.2 MHz) NMR spectra were measured on a JEOL FX 90Q spectrometer operating in the Fourier transform mode or were recorded on a Varian VXR 400 (162 MHz) spectrometer. $^{31}P\{^1H\}$ NMR chemical shifts were measured using 85% H_3PO_4 as an external standard with positive values of the chemical shift representing deshielding. Yields were estimated from peak heights in the $^{31}P\{^1H\}$ NMR spectra. The 2D NMR experiments were performed using the standard software on the Varian VXR 400 spectrometer. The COSY experiments were performed using the standard COSY pulse sequence with 128 × 128 fid (free induction decay) collected at 162 MHz with the 2K × 2K processed using pseudo-echo shaped weighting to give the best resolution. The homonuclear 2D *J*-resolved spectrum was recorded using a fid grid with the 1K × 1K processed using pseudo-echo shaped weighting to give the best resolution. ^1H NMR spectra were recorded on a Varian VXR 400 spectrometer and IR spectra were recorded using a Nicolet 5DX FTIR spectrometer with samples pressed as KBr pellets.

Cyclic voltammograms were obtained using a Bioanalytical Systems 100 control unit. Typically, 2.0×10^{-3} M solutions of the complexes in the appropriate solvent (10 cm^3), which was 0.08 M in TBAP, were employed. A single compartment cell, controlled to a temperature of 25 ± 1°C, equipped with a Ag/AgCl reference electrode (−35 mV vs S.C.E.), a platinum wire auxiliary electrode and a mercury/gold amalgam (Hg/Au) working electrode were used. We have discussed cyclic voltammetry of platinum(II) complexes using similar techniques previously.[12–15] Controlled potential bulk reductive electrolyses (CPRE) were performed using a Bioanalytical Systems SP-2 synthetic potentiostat. A three-compartment cell was employed which was constructed in-house. The working electrode compartment contained the Ag/AgCl reference electrode and 18 cm^3 of mercury connected to the potentiostat by a platinum wire. The auxiliary electrode compartment contained a platinum spiral wire electrode. The two compartments were separated by two medium porosity frits. The cell was equipped with a number of fitted openings to allow inert atmosphere operation and manipulation of solutions.

CPRE of [$PtCl_2$(dppe)] *in chlorobenzene*

Twenty-four hours prior to an experiment, the controlled potential electrolysis cell was charged with alumina (1.0 g) and a stir bar, and dried at 100°C. From this point on, all manipulations of the cell were performed under an argon atmosphere at room temperature unless otherwise noted. At the time of the experiment, mercury (25 cm^3) was extracted with dry chlorobenzene (10 cm^3) and then mercury (18 cm^3) was added to the cell which was cooled under argon. A 0.1 M solution of TBAP in chlorobenzene (60 cm^3) was introduced into the cell under an argon stream. This was allowed to outgas for 1 h. The solution was then stirred and pre-electrolysed for 20 min at a potential of −1.75 V.

To the pre-electrolysed solution was added [$PtCl_2$(dppe)] (*ca* 33.1 mg) which was purged with argon for 1 h. This was electrolysed for 2 h 45 min by which time the solution was yellow. The solution was then transferred to a Schlenk tube. Evaporation of the solvent (8 h) resulted in a white solid. This solid was extracted with benzene (2 × 10 cm^3), filtered and evaporated to give a white solid which was dissolved in C_6D_6 (1 cm^3) and transferred to a dry NMR tube under argon. The $^{31}P\{^1H\}$ NMR spectrum showed [PtClPh(dppe)] (88.%) $\delta_{P(1)}$ = 37.7 ppm, $J_{Pt-P(1)}$ = 1608 Hz, $\delta_{P(2)}$ = 37.6 ppm, $J_{Pt-P(2)}$ = 4092 Hz; and [$PtCl_2$(dppe)] (11.9%) δ_P = 41.2 ppm, J_{Pt-P} = 3620 Hz.

CPRE of [PtI_2(dppe)] *in chlorobenzene*

To the pre-electrolysed solution (−1.8 V, PhCl) was added [PtI_2(dppe)] (*ca* 30.0 mg) which was purged with argon for 1 h. This was electrolysed for 3 h with a low current flow (*ca* 0.6 electrons/

molecule) and worked-up as described above. The $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution showed [PtI_2(dppe)] (33.4%) $\delta_P = 45.8$ ppm, $J_{Pt-P} = 3384$ Hz; [PtIPh(dppe)] (45.3%) $\delta_{P(1)} = 39.2$ ppm, $J_{Pt-P(1)} = 1654$ Hz, $\delta_{P(2)} = 39.0$ ppm, $J_{Pt-P(2)} = 3999$ Hz; [$PtCl_2$(dppe)] (2.1%) δ_P 41.2 ppm, $J_{pt-P} = 3621$ Hz; [PtClI(dppe)] (14.9%) $\delta_{P(1)} = 42.2$ ppm, $J_{Pt-P(1)} = 3550$ Hz, $\delta_{P(2)} = 44.2$ ppm, $J_{Pt-P(2)} = 3446$ Hz; $dppeO_2$ (1.1%) $\delta_P = 30.4$ ppm; and a minor component (3.2%) $\delta_P = 36.7$ ppm, $J_{Pt-P} = 4165$ Hz.

CPRE of [PtI_2(dcpe)] *in chlorobenzene*

To the pre-electrolysed solution (−2.0 V, PhCl) was added [PtI_2(dcpe)] (*ca* 34.6 mg) which was then purged with argon for 1 h. Electrolysis resulted in a low current flow and was stopped after 3 h 10 min, after which the clear solution was evaporated (10 h 15 min) and worked-up as described above. The $^{31}P\{^1H\}$ NMR spectrum of a $CDCl_3$ solution showed [PtIPh(dcpe)] (68.9%) $\delta_{P(1)} = 59.0$ ppm, $J_{Pt-P(1)} = 1702$ Hz, $\delta_{P(2)} = 52.7$ ppm, $J_{P(1)-P(2)} = 3922$ Hz; [PtI_2(dcpe)] (16.0%) $\delta_P = 66.9$ ppm, $J_{Pt-P} = 3373$ Hz; [PtClPh(dcpe)] (15.1%) $\delta_{P(1)} = 62.0$ ppm, $J_{Pt-P(1)} = 1718$ Hz, $\delta_{P(2)} = 51.8$ ppm, $J_{Pt-P(2)} = 4062$ Hz.

CPRE of [$PtCl_2$(dppe)] *in bromobenzene/acetonitrile*

To the pre-electrolysed solution (−1.8 V, $PhBr/CH_3CN$, 5:1, v/v) was added [$PtCl_2$(dppe)] (*ca* 30.2 mg) which was then purged with argon for 1 h. Electrolysis resulted in a large current flow. A dark orange solution was produced in the oxidation compartment which began to travel to the reduction compartment. Accordingly, electrolysis was stopped after 1 h 20 min. Evaporation of the solvent required 8 h and resulted in a brown solid. The $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 extract (which leaves a white precipitate) gave the following data: [PtClBr(dppe)] (26.5%), [PtBrPh(dppe)] (20.2%), [$PtBr_2$(dppe)] (10.8%), [PtClBr(dppe)] (11.1%) and $dppeO_2$ (18.4%), with one complex undefined with data: $\delta_P = 42.3$ ppm, $J_{Pt-P} = 2310$ Hz (12.5%). A $CDCl_3$ solution of the white precipitate left from the extraction showed only [PtClPh(dppe)].

CPRE of [PtI_2(dcpe)] *in bromobenzene*

To the pre-electrolysed solution (−1.8 V, PhBr) was added [PtI_2(dcpe)] (*ca* 33.4 mg) which was then purged with argon for 1 h. Electrolysis resulted in a small current flow and was continued for 2 h 50 min. Work-up produced a light yellow solid and the $^{31}P\{^1H\}$ NMR spectrum of a $CDCl_3$ solution showed only [PtI_2(dcpe)]. This electrolysis was repeated with an electrolysis time of 6 h, with the current remaining at a low level. Evaporation of the solvent (11 h) and work-up produced a light yellow solid. The $^{31}P\{^1H\}$ NMR spectrum of a $CDCl_3$ solution showed the presence of [PtI_2(dcpe)] (50.0%), [PtIPh(dcpe)] (30.0%) and [PtIBr(dcpe)] (20%).

CPRE of [PtI_2(dppe)] *in benzonitrile*

To the pre-electrolysed solution (−1.7 V, PhCN) was added [PtI_2(dppe)] (*ca* 31.8 mg) which was then purged with argon for 1 h. Electrolysis resulted in a very large current flow and after 16 min coulometry indicated consumption of 2.25 electrons/molecule. The resulting orange solution turned yellow by the time the evaporation of the solvent *in vacuo* was complete (10 h, warm water bath). After the work-up, the $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution showed only the presence of [PtI_2(dppe)].

CPRE of [$PtCl_2$(dcpe)] *in benzonitrile*

To the pre-electrolysed solution (−1.5 V, PhCN) was added [$PtCl_2$(dcpe)] (*ca* 27.0 mg) which was then purged for 1 h with argon. Electrolysis resulted in a large current flow and was halted after 2.1 electrons/molecule had been consumed. The dark yellow solution was evaporated (20 h) and after work-up the $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution showed approximately 68 peaks including one set of resonances identifiable as a platinum complex: $\delta_P = 71.5$ ppm, $J_{Pt-P} = 3024$ Hz. ^1H NMR data: $\delta_H = -1.14$ ppm, $J_{P(1)-H} = 179.6$ Hz, $J_{P(2)-H} = 14$ Hz, J_{Pt-H} was not observed. No strong ν(C≡N) was observed in the IR spectrum.

CPRE of [$PtCl_2$(dppe)] *in the presence of* Ph—C≡C—Ph

To the pre-electrolysed solution (−1.7 V, CH_3CN/C_6H_6, 1:1, v/v) which contained Ph—C≡C—Ph (0.1804 g) was added [$PtCl_2$(dppe)] (*ca* 27.7 mg) which was purged for 1 h with argon. The electrolysis to essentially zero current was performed at −1.7 V for 1 h. Coulometry indicated 1.85 electrons/molecule were consumed. After work-up the $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution showed [Pt(Ph—C≡C—Ph)(dppe)] (93.5%) $\delta_P = 49.1$ ppm, $J_{Pt-P} = 3143$ Hz and peaks at $\delta_P = 38.9$ ppm (4.0%); $\delta_P = 40.2$ ppm (2.5%) of unknown origin.

CPRE of $[PtBr_2(dppe)]$ *in the presence of* Ph—C≡C—Ph

To the pre-electrolysed solution (−1.6 V, CH_3CN/C_6H_6, 1:1, v/v) which contained Ph—C≡C—Ph (0.1513 g) was added $[PtBr_2(dppe)]$ (28.5 mg in one experiment and 26.7 mg in a second experiment) which was purged for 1 h with argon. This was electrolysed to essentially zero current for 1 h 20 min. Coulometry indicated 1.8 electrons/molecule consumed. After work-up, the $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution showed [Pt(Ph—C≡C—Ph)(dppe)] (94.5%) $\delta_P = 49.1$ ppm, $J_{Pt-P} = 3146$ Hz and a peak at $\delta_P = 38.9$ ppm (5.5%) of unknown origin.

CPRE of $[PtI_2(dppe)]$ *in the presence of* Ph—C≡C—Ph

To the pre-electrolysed solution (−1.4 V, CH_3CN/C_6H_6, 1:1, v/v) which contained Ph—C≡C—Ph (0.1371 g) was added $[PtI_2(dppe)]$ (29.8 mg in one experiment and 28.4 mg in a second experiment) which was then degassed for 1 h with argon. Electrolysis to essentially zero current at −1.4 V took 1 h 20 min. Coulometry indicated 2.1 electrons/molecule consumed. After work-up the $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution showed [Pt(Ph—C≡C—Ph)(dppe)] (87%) $\delta_P = 49.1$ ppm, $J_{Pt-P} = 3146$ Hz and the following peaks of unknown origin: $\delta_P = 38.9$ ppm (7.7%), $\delta_P = 48.5$ ppm (1.5%), $\delta_P = 37.8$ ppm (3.8%).

CPRE of $[PtI_2(dcpe)]$ *in the presence of* Ph—C≡C—Ph

To the pre-electrolysed solution (−1.95 V, CH_3CN/C_6H_6, 1:1, v/v) which contained Ph—C≡C—Ph (0.1616 g) was added $[PtI_2(dcpe)]$ (28.1 mg in one experiment and 26.7 mg in a second experiment) which was purged for 1 h with argon. Electrolysis was performed at −1.7 V for 33 min, at which time coulometry indicated that 2.1 electrons/molecule were consumed. After work-up the $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution showed [Pt(Ph—C≡C—Ph)(dcpe)] (55.9%) $\delta_P = 66.9$ ppm, $J_{Pt-P} = 3010$ Hz; with two unknown complexes $\delta_P = 74.2$ ppm, $J_{Pt-P} = 1753$ (27.8%) and $\delta_{P(1)} = 60.7$ ppm, $J_{Pt-P(1)} = 1803$ Hz, $\delta_{P(2)} = 60.6$ ppm, $J_{Pt-P(2)} = 1750$ Hz (16.3%). ^1H NMR spectroscopy revealed a hydride signal $\delta_H = -0.34$ ppm, $J_{P-H} = 17.6$ Hz, $J_{P-H} = 189$ Hz, $J_{Pt-H} = 1230$ Hz.

CPRE of $[PtI_2(dppe)]$ *in* CH_3CN/C_6H_6/TBAP

To the pre-electrolysed solution (−1.5 V, CH_3CN/C_6H_6, 2:4 v/v) was added $[PtI_2(dppe)]$ (*ca* 32.5 mg) which was purged with argon for 1 h and electrolysed to essentially zero current at −1.4 V. This required 2 h and coulometry indicated 1.8 electrons/molecule consumed. After work-up the dark orange solution generated a brown solid. The $^{31}P\{^1H\}$ NMR spectrum of a C_6D_6 solution was obtained which gave the following data: $\delta_{P(1)} = 51.1$ ppm, $J_{Pt-P(1)} = 3700$ Hz; $\delta_{P(2)} = 50.1$ ppm, $J_{Pt-P(2)} = 2875$ Hz, $J_{P(1)-P(2)} = 60$ Hz; [PtIPh(dppe)]: $\delta_{P(1)} = 39.2$ ppm, $J_{Pt-P(1)} = 3959$ Hz; $\delta_{P(2)} = 39.3$ ppm, $J_{Pt-P(2)} = 1656$ Hz. In a similar manner to this experiment, electrolyses of $[PtCl_2(dppe)]$ (−1.75 V), $[PtBr_2(dppe)]$ (−1.60 V) and $[PtCl_2(dcpe)]$ (−2.25 V) were performed. In none of these experiments were any identifiable components present in the complex product mixtures.

CPRE of $[PtCl_2(dcpp)]$ *in acetonitrile/benzene* (1:1, v/v)

Twenty-four hours prior to an experiment, the controlled potential electrolysis cell was charged with alumina (1.0 g) and dried at 110°C. From this point on, all manipulations of the cell were carried out under an argon atmosphere at room temperature unless otherwise noted. At the time of the experiment, mercury (25 cm^3) was extracted with dry benzene (10 cm^3) and then 18 cm^3 of mercury and a small magnetic stir bar was added to the cell which was cooled under argon. A 0.1 M solution of TBAP in acetonitrile/benzene (60 cm^3, 1:1, v/v) was introduced into the cell under an argon stream. This was allowed to outgas for 1 h. The solution was then stirred and pre-electrolysed to approximately zero current at a potential of −2.10 V.

To the pre-electrolysed solution was added $[PtCl_2(dcpp)]$ (*ca* 30 mg) which was purged with argon for 1 h and then electrolysed to essentially zero current at a potential of −2.1 V. This usually required 75 min to 2 h and coulometry indicated approximately a 2 electrons/molecule reduction, with integrations in the range of 1.9–2.0 electrons/molecule. When the electrolysis was complete, the solution was transferred (using inert atmosphere techniques) to a Schlenk tube and evaporated. The brownish solid was extraced with benzene (2 × 10 cm^3) and evaporated to give a brown solid which was dissolved in C_6D_6 and transferred to an NMR tube. The $^{31}P\{^1H\}$ NMR spectrum measured immediately [Fig. 2(a)] showed [PtHPh(dcpp)] (87.4%). $^{31}P\{^1H\}$ NMR: $\delta_{P(1)} = 17.1$ ppm, $J_{Pt-P(1)} = 1793$ Hz; $\delta_{P(2)} = 4.7$ ppm, $J_{Pt-P(2)} = 1809$

Hz; $J_{P(1)-P(2)} = 21$ Hz. ^1H NMR: δ(hydride) = -1.58 ppm, $J_{P-H} = 21$ Hz, $J_{P-H} = 179$ Hz, $J_{Pt-H} = 1152$ Hz; δ(*o*-phenyl protons) = 7.86 ppm, $J_{H-H} = 13$ Hz, $J_{Pt-H} = 59$ Hz. IR (KBr pellet): ν(Pt—H) = 1995 cm^{-1}. After several hours, the spectrum began to change and when 6 h had elapsed, the $^{31}P\{^1H\}$ NMR spectrum showed [PtD(Ph-d_5)dcpp] (56.7%) and other components [Fig. 2(b)]: $\delta_P = 6.3$ ppm, $\delta_P = 0.18$ ppm, $J_{P-P} =$ 21 Hz (19.5%); $\delta_P = 8.9$ ppm, $\delta_P = -0.47$ ppm, $J_{P-P} = 24$ Hz (12.6%); $\delta_P = 47.6$ ppm (2.2%); $\delta_P = 23.7$ ppm (1.7%); $\delta_P = 4.37$ ppm (3.1%); $\delta_P = 1.18$ ppm (4.2%).

Preparation of [Pt(Ph—C≡C—Ph)(dppe)]

To a Schlenk flask containing 20 cm^3 of degassed ethanol was added [PtI_2(dppe)] (51.4 mg, 6.07×10^{-5} mol) and Ph—C≡C—Ph (10.6 mg, 5.95×10^{-5} mol). This was heated to reflux for 30 min, then allowed to cool, and $NaBH_4$ (5.1 mg, 1.42×10^{-4} mol) dissolved in H_2O (3 cm^3) was added and stirred. A precipitate appeared and the mixture was stirred for 3 h. This was then filtered quickly and vacuum dried to yield 25.1 mg (49.6%) of light yellow solid. The $^{31}P\{^1H\}$ NMR spectrum of this solid in 1 cm^3 of C_6D_6 showed [Pt(PhC≡CPh)(dppe)] exclusively: $\delta_P = 49.1$ ppm, $J_{Pt-P} = 3146$ Hz.

Generation of mixed haloplatinum(II) *complexes*

In order to obtain spectroscopic data for comparison purposes, mixed halo complexes were generated *in situ* using the following general method cited here for the specific case of [PtClL(dppe)] as an example. [$PtCl_2$(dppe)] (15.1 mg, 2.27×10^{-5} mol) and NaI (4.0 mg, 2.73×10^{-5} mol) were suspended in acetonitrile (1 cm^3) and then dichloromethane was added until all the solid was dissolved. After 10 min, the solution was evaporated *in vacuo* to a white solid and the soluble material was dissolved in 1 cm^3 of $CDCl_3$. The $^{31}P\{^1H\}$ NMR spectrum shows [PtI_2(dppe)] ($\delta_P = 46.0$ ppm, $J_{Pt-P} = 3337$ Hz), [$PtCl_2$(dppe)] ($\delta_P = 41.2$ ppm, $J_{Pt-P} = 3621$ Hz) and [PtClI(dppe)] ($\delta_{P(1)} = 42.6$ ppm, $J_{Pt-P(1)} = 3550$, $\delta_{P(2)} = 43.7$ ppm, $J_{Pt-P(2)} = 3428$ Hz, $J_{P-P} = 0.7$ Hz).

Reaction of [PtClPh(dppe)] *with* NaCN

To [PtClPh(dppe)] (15.2 mg) dissolved in CH_2Cl_2 (15 cm^3, dry, under argon) was added excess NaCN. This was stirred for 1 h then evaporated on a vacuum line to a white solid. A C_6D_6 (1 cm^3) extract produced a $^{31}P\{^1H\}$ NMR spectrum that showed only dppe ($\delta_P = -13.5$ ppm) present. Extraction with $CDCl_3$ also showed only dppe in the $^{31}P\{^1H\}$ NMR spectrum.

SOLVENT EXTRACTION OF 1-PHENYL-1,2-PROPANEDIONE-2-OXIME AND OF ITS COPPER(II) AND NICKEL(II) COMPLEXES INTO CHLOROFORM

A. IZQUIERDO,* R. COMPAÑÓ* and M. GRANADOS

Departament de Química Analítica, Universitat de Barcelona, Diagonal 647, 08028 Barcelona, Spain

(*Received* 23 *March* 1990; *accepted* 7 *January* 1991)

Abstract—The distribution equilibria of 1-phenyl-1,2-propanedione-2-oxime (PPO) and of the copper(II)–PPO and nickel(II)–PPO complexes in the water–chloroform system have been studied at 25°C. From the graphical treatment of the equilibrium data it has been deduced that PPO dimerizes in the organic phase, copper is extracted as the $CuL_2(HL)$ and $CuL_2(HL)_2$ complexes and nickel as NiL_2 and $NiL_2(HL)$. These models have been checked by treating the data with the LETAGROP-DISTR program and the following equilibrium constants have been obtained: PPO, $pK_a = 9.25 \pm 0.03$, $\log K_{DR} = 1.60 \pm 0.02$, $\log K_2 = 0.60 \pm 0.06$; copper(II)–PPO, $\log \beta_1 = 5.9 \pm 0.1$, $\log \beta_2 = 11.56 \pm 0.05$, $\log K_{DC} K_{m,1} = 2.7 \pm 0.1$, $\log K_{m,2} = 1.0 \pm 0.1$; nickel(II)–PPO, $NiL_2 \log K_{ex} = -13.57 \pm 0.05$, $NiL_2(HL)$, $\log K_{ex} = -12.6 \pm 0.1$.

α-Oxooximes act as bidentate ligands, via carbonyl and oximic nitrogen, forming chelating five-membered rings.

These compounds have been proposed as spectrophotometric reagents for the determination of iron(II), nickel(II), palladium(II), cobalt(II), iridium(III), rhodium(III) and platinum(IV).[1] Since the complexes formed are scarcely soluble in water, a previous extraction into an organic solvent is necessary, usually chloroform.

In spite of their analytical usefulness, very few studies on the formation and distribution equilibria of the metal complexes of this class of reagents have been carried out.[2–4] On the other hand, several studies on the composition and structure of the solid metal complexes of different α-oxooximes have been performed.[5–7]

In the present paper we report the study of the distribution equilibria of 1-phenyl-1,2-propanedione-2-oxime (PPO) and of its copper(II) and nickel(II) complexes in the water–chloroform system. In a previous paper[8] we reported the results of a similar study carried out with N-ethylglyoxylanilide oxime.

EXPERIMENTAL

Reagents

1-Phenyl-1,2-propanedione-2-oxime was supplied by Aldrich and used without further purification. Stock solutions of copper and nickel (1 g dm^{-3}) were prepared and standardized as described earlier.[8] The other chemicals used were all of analytical reagent grade.

Apparatus

A Beckman DU-7 spectrophotometer with 1 cm quartz cells, a Perkin–Elmer 1100B atomic absorption spectrophotometer with an air–acetylene flame and a Perkin–Elmer 4000 atomic absorption spectrophotometer with a graphite furnace (Perkin–Elmer HGA 500) and an auto-sampler (Perkin–Elmer AS-40) were used. The volumes injected into the graphite furnace were 0.02 cm^3. A Radiometer pH-meter PHM64, equipped with a Ross combination pH electrode, standardized with buffer solutions at pH 4.008 and 6.865 (25°C) prepared from Merck salts according to DIN 19266, was also used.

Procedure

The procedures followed to study the distribution of PPO and of its copper(II) and nickel(II) complexes were analogous to those used in a previous study.[8] The pH of the aqueous phase was adjusted with a potassium dihydrogen phosphate–potassium hydroxide buffer for the study of the distribution of copper(II), and with a boric acid–potassium hydroxide buffer in the case of the nickel(II) study.

In order to determine the concentration of PPO in the aqueous phase, absorbance measurements were carried out at 294 nm.

Data treatment

The experimental data were treated with graphical methods (slope analysis and curve-fitting methods) and with the LETAGROP-DISTR program.[9]

RESULTS AND DISCUSSION

Distribution of PPO *in the water–chloroform system*

The distribution ratio values obtained at pH 4.05 and 9.42 show that 5 min of shaking is enough to attain the distribution equilibrium. In subsequent experiments, an extraction time of 15 min was adopted. The influence of the reagent concentration on the distribution ratio values (Fig. 1) shows that, in the concentration range studied, molecular association in the organic phase should be taken into account. Figure 2 shows the plots of $\log D$ vs pH obtained with 10^{-1} and 10^{-2} M PPO solutions in chloroform.

Calculation of the equilibrium constants

Assuming that only the monomeric PPO is capable of distributing into the aqueous phase, and

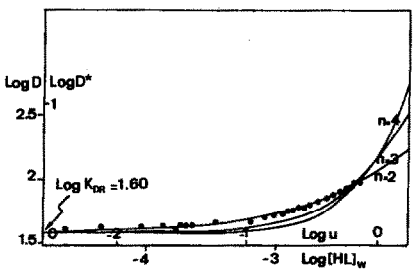

Fig. 1. Influence of reagent concentration on the distribution ratio of PPO. The full lines are the normalized curves $\log D^*$ vs $\log u$; $D^* = 1 + nu^{(n-1)}$.

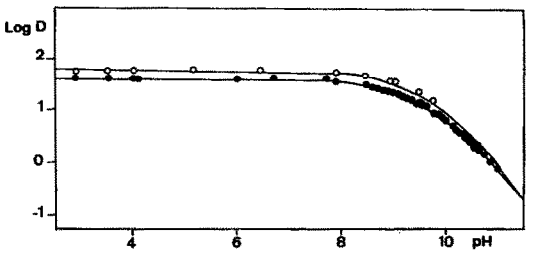

Fig. 2. Influence of pH on the distribution ratio of PPO. ○, $C_{HL} = 10^{-1}$ M; ●, $C_{HL} = 10^{-2}$ M. The full curves are calculated with the HALTAFALL program[21] using the constants given in Table 1.

that only one polymeric species exists in the organic phase, the distribution ratio of PPO is given as

$$D = \frac{[HL]_o + n[(HL)_n]_o}{[HL]_w + [L^-]} = \frac{K_{DR}[HL]_w + nK_nK_{DR}^n[HL]_w^n}{[HL]_w + K_a[H^+]^{-1}[HL]_w}, \quad (1)$$

where HL represents PPO, and K_{DR}, K_a and K_n are, respectively, the distribution, dissociation and polymerization constants of the reagent. The subscripts o and w denote the organic and the aqueous phase, respectively. When $[H^+] \gg K_a$ the following equation is obtained

$$D = K_{DR} + nK_nK_{DR}^n[HL]_w^{n-1}. \quad (2)$$

Graphical treatment

Curve-fitting methods[10,11] were applied to the experimental data in order to determine n, K_n, K_{DR} and K_a. The normalized variables and curves were defined as in a previous paper.[8] In Fig. 1 these curves are superimposed on the experimental points, $\log D$ vs $\log [HL]_w$, in the conditions of best fit. The experimental points fit the curve corresponding to $n = 2$, which means that the polymeric species is a dimer. The values obtained for $\log K_{DR}$ and $\log K_2$ are shown in Table 1.

In order to determine K_a, and because there is an increase in D due to the formation of dimers in the organic phase, corrected values of D have been calculated $\{D_{cor} = [HL]_o/([HL]_w + [L^-])\}$. In Fig. 3 the experimental curve, $\log D_{cor}$ vs pH, and the normalized curve, $\log D^*$ vs $\log u$, in the conditions of best fit are shown. The value obtained for pK_a is shown in Table 1.

Numerical treatment

The final values of the constants and their standard deviations are given in Table 1. The calculated

$\log D$ values superimposed on the experimental points are plotted in Fig. 2. The good agreement between them confirms the proposed model.

Distribution of the copper complex

In studying the distribution of the copper complex, the appearance of green precipitates at the interface was observed depending on the metal and reagent concentrations, and pH. As the metal/reagent ratio increased, the pH at which the precipitation took place was lower. Thus, in order to avoid the formation of solid phases, PPO concentrations of 8×10^{-2} M or higher were used throughout the study.

A shaking time of 15 min was adopted. The buffer concentration (potassium dihydrogenphosphate–potassium hydroxide) was 2.5×10^{-3} M and the ionic strength of the aqueous phases was adjusted to 0.1 M with potassium nitrate. For details of the influence of these parameters on the distribution ratio see Table 2.

The influence of metal concentration was studied by varying it between 3.15×10^{-5} and 3.15×10^{-4} M at PPO concentrations of 0.4 and 0.1 M. In both cases the distribution ratio is independent of the metal concentration, which suggests that only mononuclear species are extracted.

The influence of pH on the distribution ratio was studied at six different ligand concentrations ranging from 8.0×10^{-2} to 4.0×10^{-1} M. The results are shown in Fig. 4. To examine the influence of PPO concentration on the distribution ratio, at constant pH, the values of $\log D$ corresponding to each reagent concentration were calculated from the curves shown in Fig. 4 at pH 5.20, 5.30, 5.40 and 5.50. These values, plotted against $\log[HL]_o$, are shown in Fig. 5.

Finally, the influence of a second ligand on the distribution equilibrium was studied. Sometimes the addition of a second ligand increases the distribution ratio or inhibits the appearance of insoluble species via the formation of mixed complexes. Of the substances commonly used, 4-methylpyridine was chosen because in studies with similar

copper–oxime complexes[2] it was the optimum synergic agent. Six different 4-methylpyridine concentrations in the range 0.01–0.50 M were studied. The results are plotted in Fig. 6. In order to take into account the formation of copper(II)–4-methylpyridine complexes in the aqueous phase, $\log D + \log \alpha_{Cu}$ has been plotted against pH. The side reaction coefficient for copper(II) is given by

$$\alpha_{Cu} = 1+\beta_1[P]+\beta_2[P]^2+\beta_3[P]^3+\beta_4[P]^4,$$

where [P] represents the equilibrium concentration of 4-methylpyridine in the aqueous phase and the values of β_i were taken from the references.[12] The fact that the points obtained with different 4-methylpyridine concentrations fall on the same curve, shows that this substance does not participate in the distribution equilibria.

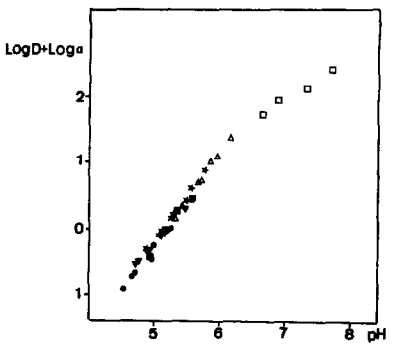

Fig. 6. Influence of 4-methylpyridine (P) concentration on the distribution ratio of copper(II). $\alpha_{Cu} = 1+\beta_1[P]+\beta_2[P]^2+\beta_3[P]^3+\beta_4[P]^4$. $C_{Cu} = 6.29\times10^{-5}$ M. $C_{PPO} = 1.4\times10^{-1}$ M. $C_{4\text{-Pic}}$: ● = 1.0×10^{-2} M; ▲ = 2.0×10^{-2} M; ★ = 3.0×10^{-2} M; ■ = 5.0×10^{-2} M; △ = 1.0×10^{-1} M; □ = 5.0×10^{-1} M.

Composition of the extracted species and calculation of the equilibrium constants

Since under the experimental conditions only mononuclear species are extracted, and complexes with nitrate, phosphate, borate and hydroxide[13] ions can be neglected in the aqueous phase, the metal distribution ratio is given by

$$D = \frac{\sum_n \sum_m [ML_n(HL)_m]_o}{[M]_w + \sum_p [ML_p]_w}, \qquad (3)$$

where M represents the metal and HL the extracting agent. The subscripts o and w denote the organic and the aqueous phase, respectively. Charges have been omitted for simplicity. If only the species $ML_n(HL)_m$ is extracted and the metal is present in the aqueous phase predominantly as the cation M^{n+}, the following equation can be obtained

$$\log D = \log K_{ex} + n\,\mathrm{pH} + (n+m)\log[HL]_o, \qquad (4)$$

where K_{ex}, the extraction constant of $ML_n(HL)_m$, is $K_m K_{DC} \beta_n K_a^n / K_{DR}^m$ (β_n, formation constant of ML_n; K_{DC}, distribution constant of ML_n; K_m, adduct formation constant in the organic phase; K_a and K_{DR}, dissociation and distribution constants of the reagent, respectively).

When species other than ML_n can be neglected in the aqueous phase, a plot of $\log D$ vs pH will give a straight line with a slope of zero; in which case the following equation is valid

$$\log D = \log(K_m K_{DC}) + m \log[HL]_o. \qquad (5)$$

Graphical treatment

The plots $\log D$ vs pH (Fig. 4) corresponding to $\log D < 1$ are straight lines with slopes 1.8–1.9. As

Table 3. Survey of the equilibrium constants for the extraction of copper(II) with PPO into chloroform

Method	$\log\beta_1$	$\log\beta_2$	$\log K_{DC}K_{m1}$	$\log K_{m2}$	$\sigma(\log D)$
Graphical	5.80	11.60	2.83		
LETAGROP-DISTR	5.9±0.1	11.56±0.05	2.7±0.1	1.0±0.1	0.043

$\log D$ increases the slope of the curve decreases progressively to zero at pH above 6.7. On the other hand, the values of $\log D$ vs $\log[HL]_o$ give straight lines with slopes 2.9–3.2. According to eqs (4) and (5) this suggests that the adduct $CuL_2(HL)$ is the extracted species.

Since under the experimental conditions the simple chelate CuL_2 is never present in the organic phase in appreciable amounts, its distribution constant could not be calculated. To calculate the product $K_{DC}K_m$, as well as the stability constants of CuL^+ and CuL_2 in the aqueous phase, Sillén's curve-fitting method was applied to the data. The normalized curves are given by $D^* = u^2/(1+pu+u^2)$, where the normalized variables and the parameter, p, are defined by $D^* = D/K_{DC}K_m[HL]_o$, $u = \beta_2^{1/2}[L^-]$ and $p = \beta_1/\beta_2^{1/2}$. The values of the constants calculated by this method are given in Table 3.

Numerical treatment

Several calculations were performed in order to ascertain the best set of complexes which would fit the experimental data. The results are given in Table 4. They show that the inclusion of the species $CuL_{2(o)}$ in the proposed model does not improve the fit with the experimental data. On the other hand, the complex $CuL_2(HL)_{2(o)}$ was tried because the slopes of the curves $\log D$ vs $\log[HL]_o$ are slightly higher than three, and its inclusion in the model considerably reduces the value of u. The values of the constants obtained with the proposed model are given in Table 3. The calculated $\log D$ values superimposed on the experimental points are plotted in Fig. 4; the good agreement between them confirms the proposed model.

Table 4. Values of u and $\sigma(\log D)$ for the different combinations of copper(II)–PPO complexes tried

Species	u	$\sigma(\log D)$

EPR absorption spectra

In order to determine the ligand atoms involved in the bonding and the structure of the extracted complexes, EPR experiments have been performed on chloroform solutions, obtained under the conditions used in the extraction study.

The EPR spectra of room temperature solutions consist of the characteristic four bands, with $g = 2.111$ and $A = 70$ G, due to coupling between the unpaired electron and copper(II) nucleus ($I = 3/2$). The high field band shows additional superhyperfine structure, consisting of five bands, with $A = 15$ G. This additional splitting is consistent with the interaction of the copper unpaired electron with two equivalent nitrogen nuclei of two PPO molecules. This assumption agrees with the proposed structures for the α-oxooximes–divalent ion complexes,[3] where these reagents act as bidentate ligands, via carbonyl and oximic nitrogen.

Besides the four main bands, at higher field values another band appears partially overlapped with the nearest one. Splitting of the fifth band is hardly observed and only three peaks can be seen, although a five peak splitting is expected. This fifth band can be attributed to the fact that two complexes, $CuL_2(HL)$ and $CuL_2(HL)_2$, are extracted, and only at higher field values, when more resolution is attained, can their respective spectra be partially resolved.

The EPR spectra of the frozen solutions at 150 K are poorly resolved. They show only two series of bands due to anisotropic electron–spin interactions ($g_\parallel \simeq 2.22$ and $g_\perp \simeq 2.01$).

All the results obtained are consistent with an octahedrically distorted geometry with a very strong in-plane interaction.

Distribution of the nickel complex

A shaking time of 15 min was adopted. The buffer concentration (boric acid–potassium hydroxide) was 5×10^{-3} M and the ionic strength of the aqueous phases was adjusted to 0.1 M with potassium nitrate. For details of the influence of these parameters on the distribution ratio, see Table 5.

At nickel concentrations below 1.0×10^{-4} M the metal concentration has no effect on the distribution. For nickel concentrations greater than 1.0×10^{-4} M the distribution ratio increases with the metal concentration, suggesting that polynuclear species are extracted under these conditions. In subsequent experiments, a nickel concentration of 6.3×10^{-5} M was used.

The influence of pH on the distribution ratio was studied for seven different ligand concentrations, ranging between 2.0×10^{-2} and 2.0×10^{-1} M. The results of these experiments are plotted in Fig. 7.

To examine the influence of PPO concentration on the distribution ratio, at constant pH, the values of $\log D$ corresponding to each reagent concentration were calculated from the curves in Fig. 7 at pH 7.6, 7.8, 8.0, 8.2 and 8.4. These values, plotted against $\log [HL]_o$ are given in Fig. 8.

Composition of the extracted species and calculation of the equilibrium constants

Graphical treatment. The curves $\log D$ vs pH (Fig. 7) are straight lines with slopes between 1.9 and 2.1. In accordance with eq. (4), this suggests that $n = 2$. The values of $\log D$ plotted vs $\log [HL]_o$ give straight lines with slopes between 2.5 and 2.9, which according to eq. (4) suggests the presence of a mixture of NiL_2 and $NiL_2(HL)$ in the organic phase, $NiL_2(HL)$ being the predominant species.

To calculate the extraction constants of the species $NiL_2(K_{1,2})$ and $NiL_2(HL)(K_{1,3})$ a curve

30	0.19	1.0×10^{-2}	0.33	2.0×10^{-1}	0.01
60	0.18			4.0×10^{-1}	0.01

[a] pH = 8.45, [PPO] = 3.0×10^{-2} M.
[b] pH = 8.50, [PPO] = 3.0×10^{-2} M.
[c] pH = 8.20, [PPO] = 5.0×10^{-2} M.

Table 6. Survey of the equilibrium constants for the extraction of nickel(II) with PPO into chloroform

Method	$\log K_{1,2}$	$\log K_{1,3}$	$\sigma(\log D)$
Graphical	-13.54	-12.58	
LETAGROP-DISTR	-13.57 ± 0.05	-12.6 ± 0.1	0.053

fitting method analogous to that used in a previous paper[8] was applied. The values obtained in the conditions of best fit are given in Table 6.

Numerical treatment. The final values of the constants are also given in Table 6. Theoretical $\log D$ values superimposed on the experimental points are plotted in Fig. 7; the good agreement between them confirms the proposed model.

The coordination between the metal ion and PPO may take place through the oximic nitrogen and carbonyl oxygen, as has been reported for nickel(II)–α-oxooximes complexes.[3,6] Usually these complexes show a square-planar geometry.

CONCLUSIONS

Despite the fact that PPO and phenylglyoxal aldoxime (PGA) have a very similar structure, the pK_a of PPO, 9.25 ± 0.03, is higher than that of PGA, which is 8.55 ± 0.08,[2] both values determined from solvent extraction data. The dissociation constants of these substances, determined by glass electrode potentiometry in a water–ethanol medium (50% v/v),[14] still show a great difference. Since both compounds are the *E* isomers, the differences between their acidities cannot be explained in terms of *E* and *Z* isomery. On the other hand, the greater acidity of aldoximes compared with that of ketoximes, although it has not been explained theoretically, has been observed in many cases.[15–17]

The pK_a values of PPO and N-ethylglyoxylanilide oxime (NEG)[8] are similar. This can be attributed to the presence of the amido group in NEG, which diminishes the acidity of its aldoxime function.

The $\log K_{DR}$ of PPO is 0.7 units higher than that of PGA.[2] Very similar increments have been observed owing to the introduction of a methyl group into other organic reagents.[18] These results agree with the increase by a factor of four observed by Dyrssen[19] in the K_{DR} values of homologous series of organic reagents when an additional carbon atom is attached to the molecule.

PPO as NEG dimerizes in the organic phase, which was not observed by Peshkova *et al.*[2] in the case of PGA. This may be due to the lower reagent concentration used in that work.

The green precipitates obtained in the extraction of copper(II) with PPO, with low PPO/copper(II) ratios, were analogous to those appearing during the potentiometric study of the copper(II)–PPO system in a water–ethanol medium (50% v/v).[20] They may consist of mixed polynuclear complexes $\{CuL(OH)\}_n$ which are very insoluble in the common solvents.[5] The high reagent concentrations used in order to avoid the formation of precipitates favour the formation of self-adduct complexes, which were not detected with other α-oxooximes studied at lower concentration ranges.[2,8]

The stoichiometry of the extracted nickel(II)–PPO complexes are analogous to those obtained with NEG,[8] although the extraction constants are lower in the case of PPO. This causes the displacement of the extraction curves by more than two pH units towards the basic region.

(*Received* 25 *April* 1990; *accepted* 7 *January* 1991)

Abstract—The reaction of Na_2X_x (X = S or Se) with $CoBr_2$ and triphenylphosphine in DMF gave rise to the clusters $Co_6X_8(PPh_3)_6$ [X = S (**I**), X = Se (**II**)] in high yields. The molecular structures of **I** and **II** have been determined by single-crystal X-ray diffraction. Both structures were solved by direct methods and refined by full-matrix least-squares techniques to converge with $R = 0.053$ for **I** and 0.048 for **II** on the basis of 5488 and 8175 reflections with $I > 3\sigma(I)$, respectively. The two clusters are isostructural with the inner core consisting of a slightly distorted Co_6 octahedron. The Co—Co distances fall in the ranges of 2.848–2.894 Å for **I** and 2.955–3.037 Å for **II**. Electrochemistry in dichloromethane shows the electron-transfer sequence for **I**:

$$Co_6S_8(PPh_3)_6 \rightleftharpoons [Co_6S_8(PPh_3)_6]^+$$

and for **II**:

$$Co_6Se_8(PPh_3)_6 \rightleftharpoons [Co_6Se_8(PPh_3)_6]^+ \rightleftharpoons [Co_6Se_8(PPh_3)_6]^{2+}.$$

Metal–sulphur cluster compounds have greatly attracted the attention of chemists because they play a prominent role as synthetic analogues of the active sites of biological function.[1] Recently polynuclear metal–chalcogen cluster compounds have become even more interesting owing to their novel structural features and potential uses as heterogeneous catalysts,[2] except as synthetic biological analogues. Structural characterization of polynuclear clusters was deemed to be exceedingly important in establishing a relevance between geometry and electronic structure. Moreover, polynuclear cluster compounds can undergo electron-transfer reaction. Therefore, it is important to understand their redox behaviours, as well as relevant structural effects.

In the studies of transition metal cluster compounds, we have successively synthesized and characterized a series of electron-rich, polynuclear metal clusters, $[M_2Cu_5S_6X_2(R_2dtc)_3]^{2-}$ (M = Mo, W; X = O, S; R = Me, Et),[3] $Co_6Se_8(PEt_3)_6$,[4] $[Au_{13}Ag_{12}(\mu\text{-}Cl)_6(PPh_3)_{10}Cl_2]^{+}$ [5] and $Ni_{15}(\mu_3\text{-}S)_6(\mu_4\text{-}S)_9(PPh_3)_6$.[6] These clusters are interesting for the following reasons. Firstly, the skeletons of these clusters may not be changed by the addition or removal of valence electrons, yet the metal–metal bonds are sensitive to the total electron count. Secondly, recognition of the polynuclear clusters suggests that they may provide a bridge for understanding the relevance of molecular compounds to infinite lattices in metal and metal sulphide, and that they may pave the way for the discovery of novel materials with unusual physical or chemical properties. Thirdly, these clusters can act as multi-electron carriers because of their ability to store unpaired electrons. Recently, several clusters with a regular octahedral Co_6 core have been characterized.[7] For a better understanding of the relevance between bonding and electron structure in Co_6X_8 (X = S, Se) clusters, we have preliminarily reported three cluster compounds, $Co_6Se_8(PEt_3)_6$,[4] $Co_6S_8(PPh_3)_6$ and $Co_6Se_8(PPh_3)_6 \cdot THF$,[8] with the

distorted octahedral Co_6 core. This paper presents the syntheses and electrochemical properties, together with the results of X-ray diffraction analysis of the two polynuclear cobalt–chalcogen clusters, $Co_6S_8(PPh_3)_6$ (**I**) and $Co_6Se_8(PPh_3)_6 \cdot THF$ (**II**).

EXPERIMENTAL

Synthesis of $Co_6S_8(PPh_3)_6$ (I)

This compound was synthesized according to our previous report,[8] but with improvements. To a stirred solution of $(Ph_3P)_2CoBr_2$, obtained from anhydrous $CoBr_2$ (1.10 g, 5 mmol) and triphenylphosphine (5.25 g, 20 mmol), in 40 cm^3 of DMF was added a solution of $Na_2S \cdot 9H_2O$ (1.60 g, 6.7 mmol) in 20 cm^3 of DMF. On mixing, the blue–green solution immediately turned dark brown and a black precipitate gradually formed. After stirring for 2 days the black solid was collected, washed with water, acetone and THF–hexane (1 : 1, v/v). The black solid which contained a small amount of binary cobalt sulphide was treated with 100 cm^3 of CH_2Cl_2 : THF (1 : 1, v/v). The resulting solution was filtered and the filtrate was covered with a layer of hexane. On standing at room temperature for several weeks, large dark brown crystals were formed which were collected, washed with THF : hexane (1 : 1, v/v) and then with dimethyl ether to give 1.26 g of **I** (69%). Found: C, 59.5; H, 4.2; Co, 16.0; P, 8.3. Calc. for $C_{108}H_{90}Co_6P_6S_8$: C, 59.4; H, 4.2; Co, 16.2; P, 8.5%.

Synthesis of $Co_6Se_8(PPh_3)_6 \cdot THF$ (II)

To a deoxygenated, stirred solution of $(Ph_3P)_2CoBr_2$, obtained from anhydrous $CoBr_2$(1.10 g, 5 mmol) and triphenylphosphine (5.25 g, 20 mmol), in 40 cm^3 of DMF was added a solution of Na_2Se_x, obtained from heating sodium (0.35 g, 15 mmol) and selenium (1.08 g, 13.5 mmol), in 20 cm^3 of DMF under nitrogen. On mixing, the blue–green solution turned immediately dark brown and microcrystals gradually precipitated. After stirring for 2 days the black solid was collected, washed with water, acetone and THF : hexane (1 : 1, v/v). The black solid which contained a small amount of binary cobalt selenide was treated with 100 cm^3 of CH_2Cl_2 : THF (1 : 1, v/v). The resulting solution was filtered and the filtrate was covered with a layer of hexane. On standing at room temperature for several weeks, large dark brown crystals formed which were collected, washed with THF : hexane (1 : 1, v/v) and then with dimethyl ether to give 1.63 g of **II** (74%). Found: C, 51.6; H, 3.8; Co, 13.5; P, 7.0. Calc. for $C_{112}H_{98}OCo_6P_6Se_8$: C, 51.1; H, 3.7; Co, 13.5; P, 7.1%.

X-ray data collection and structure determination

Diffraction data were collected at room temperature on a RIGAKU AFC5R four-circle diffractometer for **I** and an Enraf–Nonius CAD4 four-circle diffractometer for **II**. The crystal of compound **II** was mounted in a capillary with mother liquid to prevent solvent loss during the data collection. Crystal data and data collection parameters are presented in Table 1. All the calculations were performed on a VAX/VMS computer by using the SDP program package. Intensity data used in structure determination and refinement were corrected for Lorentz and polarization effects and empirically for absorption. Both structures were determined by direct methods. Several Fourier maps successively revealed all non-hydrogen atoms. Refinements were based on F_0 and weight $w = 1/\sigma^2(F_0)$. The structures were refined by full-matrix least-squares techniques with anisotropic temperature factors for all non-hydrogen atoms of the molecule and with isotropic factors for all solvent atoms. The final refinement converged at R and R_w factor values of 0.053 and 0.065 for **I** and 0.048 and 0.059 for **II**.* Final difference Fourier maps contained residual peaks ranging from 1.03 to 0.10 eA^{-3} for **I** and 0.95 to 0.13 eA^{-3} for **II**.

Physical measurements

In case the compounds in solution may be oxidized by air, all manipulation and measurement were carried out under a pure nitrogen atmosphere. Dichloromethane was dried before use. Electromeasurements were carried out with a DHZ-1 electrochemical multipurpose instrument and *X–Y* recorder. The cell was of the standard three-electrode design containing a platinum auxiliary electrode, a SCE reference electrode and a platinum working electrode. The solution contained 0.05 M Bu_4NBF_4 as supporting electrolyte and *ca* 10^{-3} M samples. Bu_4NBF_4 was dried *in vacuo* and used without further purification.

RESULTS AND DISCUSSION

Syntheses

The reaction of $(Ph_3P)_2CoBr_2$ with Na_2X_x (X = S or Se) at room temperature affords the clus-

ter compounds $Co_6X_8(PPh_3)_6$ [X = S (**I**), X = Se (**II**)]. Compound **I** can be synthesized in air, but compound **II** must be prepared with the exclusion of air in the initial stage of the reaction to prevent oxidation of Na_2Se_x. If a large excess of PPh_3 was used, the yield can be increased because precipitation of CoX_2 during the reactions can be avoided. At the end of the reactions the metal atoms in both clusters are oxidized to a mean oxidation state of +2.67 per cobalt atom. A similar oxidation was observed during the formation of the clusters $[Co_6S_8(PEt_3)_6]^{n+}$ ($n = 0, 1$),[7] with mean oxidation states of +2.67 ($n = 0$) and +2.83 ($n = 1$). If reactions were carried out under nitrogen, S_x^{2-} (or Se_x^{2-}) can be used as either oxidant or bridging ligand. However, S^{2-} must be used if the reaction was to be carried out in air. Compounds are air-stable both in the solid state and in solution. They are very soluble in polar organic solvents such as tetrahydrofuran, dichloromethane and benzene.

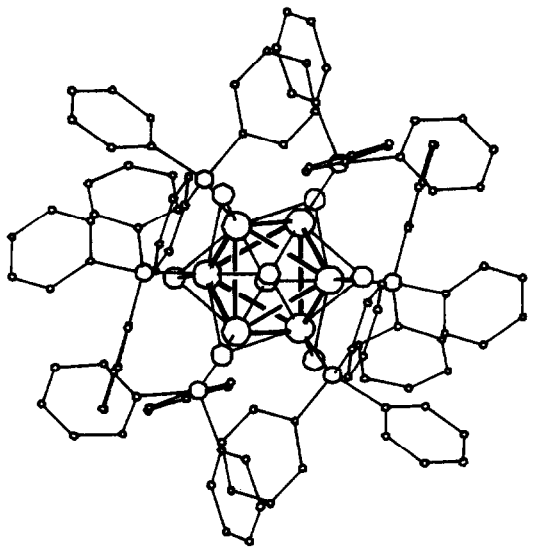

Fig. 1. Molecular structure of $Co_6S_8(PPh_3)_6$.

Description of the structures

Figure 1 shows a perspective view of the molecular structure of **I**, and Figs 2 and 3 show the inner cores of compounds **I** and **II**, respectively. Selected bond lengths and bond angles of compound **I** are presented in Tables 2 and 3, respectively. Tables 4 and 5 list selected bond lengths and bond angles of compound **II**. Compound **II** consists of two discrete cluster units (A and B), located on (1/2, 1/2, 1/2) and (0, 0, 0), with an interpenetrating molecule of tetrahydrofuran in a unit cell. The two cluster compounds, **I** and **II**, possess analogous structures. The inner Co_6 core consists of a slightly distorted octahedron of cobalt atoms. The eight Co_3 faces of the octahedral Co_6 core are each triply-bridged by one sulphur (**I**) or selenium (**II**) atom. Moreover, each cobalt atom is terminally coordinated by a triphenylphosphino ligand. Therefore, each cobalt atom is surrounded by four sulphur (selenium)

atoms and one phosphorus atom in a distorted square pyramidal environment and is linked to another four cobalt atoms.

Both clusters possess crystallographic *Ci*-$\bar{1}$ symmetry. The octahedron in **I** is slightly elongated along the three-fold axis through the Co(1)′—Co(2)—Co(3) face, while no systematic distortion is present in **II**. The Co—Co distances of compounds **I** and **II** fall in the ranges 2.848–2.894 and 2.955–3.037 Å, respectively. The distances of Co—S (or Se) and Co—P are in the ranges 2.201–2.297 Å (**I**), 2.322–2.373 Å (**II**) and 2.154–2.169 Å (**I**), 2.152–2.164 Å (**II**), respectively. The average Co—S and Co—Se bond lengths in the title clusters are 2.235 and 2.344 Å, respectively, in good agreement with those reported in other clusters with Co_6S_8 and Co_6Se_8 cores.[7] The Co—P bond lengths in the two clusters are nearly equal within experimental error, and are slightly longer than that in $[Co_6S_8(PEt_3)_6]$ (2.138 Å).[7d]

The Co—Co—Co angles of compound **I** fall within the ranges 59.1(1)–61.4(1) and 89.6(1)–91.4(1)° and are very similar to the values in cluster **II** [59.3(1)–61.3(1)° and 89.2(1)–90.8(1)°], both are very close to the values of 60.0 and 90.0° for a regular octahedron, despite the slight elongation in **I**.

Alternatively, the clusters can also be described as a slightly distorted X_8 (X = S or Se) cube, and each X_4 face is topped by a cobalt atom. The distances from metal atom to the X_4 plane in the two clusters are quite similar, ranging from 0.49 to 0.51 Å. The X—X distances are in the ranges 3.094–3.110 Å (**I**) and 3.180–3.266 Å (**II**). In comparison with X—X distances in other compounds, the S—S distances can be considered to be non-bonding, while Se—Se distances are more or less bonding. The Co—X—Co angles of 77.4(1)–81.0(1)° for **I** and 77.9(1)–81.5(1)° for **II** agree well with those in other Co_6X_8 clusters.

The clusters contain 98 valence electrons which is 14 electrons more than the 18-electron rule[9] and one electron more than in the cluster $[Co_6S_8(PEt_3)_6]^{+}$ [7e] with an almost regular Co_6 octa-

hedron. The average Co—Co bond length of 3.007 Å in compound **II** is slightly longer than that in compound **I** (2.868 Å) and is distinctly longer than any length in $[Co_6S_8(PPh_3)_6]^+$ (2.810 Å, 97e),[7b] or $[Co_6S_8(PEt_3)_6]^+$ (2.798 Å, 97e).[7e] This lengthening of the Co—Co distance indicates that metal–metal bonding does exist and that extra electrons from the selenium atoms occupy the antibonding orbitals.

Electrochemistry

The electrochemical behaviour of the two hexamers has been studied. The cyclic voltammograms of compounds **I** and **II** at a platinum electrode in CH_2Cl_2 solution are shown in Fig. 4. Compound **I** gives rise to one reversible one-electron redox wave at +0.60 V ($i_{pa}/i_{pc} = 1$), which indicates the existence of the monocationic cluster $[Co_6S_8(PPh_3)_6]^+$. In fact, this monocationic compound has already been prepared by Fenske and co-workers.[7b] However, compound **II** gives rise to two waves at +0.58 V ($i_{pa}/i_{pc} = 1$) and +1.23 V ($i_{pa}/i_{pc} < 1$). As it can be seen in Fig. 4(b), the former ($i_{pa}/i_{pc} = 1$) can be considered as a one-electron reversible charge-transfer. However, the latter ($i_{pa}/i_{pc} < 1$) is somewhat complicated, and can be considered as a one-electron reversible charge-transfer by following chemical reactions. The electrochemical data of compound **II** show the existence of three discrete species: the neutral cluster, $Co_6Se_8(PPh_3)_6$; the monocationic cluster, $[Co_6Se_8(PPh_3)_6]^+$; and the bicationic cluster, $[Co_6Se_8(PPh_3)_6]^{2+}$, of which the bicationic one is not stable for long, and the monocation has already been reported by Fenske.[7c] The electrochemistry in dichloromethane shows the electron-transfer sequence (1) for **I**:

$$Co_6S_8(PPh_3)_6 \rightleftharpoons [Co_6S_8(PPh_3)_6]^+ \quad (1)$$

and (2) for **II**:

$$[Co_6Se_8(PPh_3)_6] \rightleftharpoons [Co_6Se_8(PPh_3)_6]^+ \rightleftharpoons [Co_6Se_8(PPh_3)_6]^{2+}. \quad (2)$$

Moreover, it also indicates that the removal of one or two electrons from the antibonding orbitals of $[Co_6Se_8(PPh_3)_6]$ or the addition of one or two electrons to the antibonding orbitals of $[Co_6Se_8(PPh_3)_6]^{n+}$ ($n = 1, 2$), or the removal of one electron from the antibonding orbital of $Co_6S_8(PPh_3)_6$ or the addition of one electron to the antibonding orbital of $[Co_6S_8(PPh_3)_6]^+$ is feasible.

Acknowledgements—The authors are grateful to Professors Qianjin Wu and Shixiong Liu and co-workers for the X-ray data collections and to the National Natural Sciences Foundation of China for financial support.

SYNTHESIS AND PHOTOLYSIS OF MIXED COPPER(I) COMPLEXES WITH THIONES AND TRI-*p*-TOLYLPHOSPHINE OR TRIPHENYLPHOSPHINE; X-RAY CRYSTAL STRUCTURE OF BIS[COPPER(I)(1,3-THIAZOLIDINE-2-THIONE) (TRI-*p*-TOLYLPHOSPHINE)CHLORIDE]

(*Received* 13 *August* 1990; *accepted* 7 *January* 1991)

Abstract—Reaction of $[Cu(PR_3)Cl]_4$ [where PR_3 = tri-*p*-tolylphosphine (tptp), or triphenylphosphine(tpp)] with several heterocyclic thiones (L) yields binuclear complexes of the general formula $[Cu(PR_3)(L)Cl]_2$ [L = 1,3-thiazolidine-2-thione (tzdtH), benz-1,3-thiazoline-2-thione (bztztH), dithiouracil (dtu), purine-6-thione (pur6SH) and thiourea (tu)]. Irradition of the complexes, in chloroform, methanol and acetonitrile solutions, caused phosphine evolution while the Cu_2S_2 core remained intact. The crystal structure of $[Cu(tptp)(tzdtH)Cl]_2$ has been established by single-crystal X-ray diffraction methods. In the Cu_2S_2 core the Cu—S bond lengths are 2.386(1) and 2.470(1) Å. The Cu—P and Cu—Cl distances are 2.222(1) and 2.283(1) Å, respectively.

Copper complexes have received considerable attention since they provide suitable models for the representation of several enzyme sites[1,2] as well as active intermediates in organic synthetic reactions,[3] in particular photocatalytic isomerizations.[4,5]

Recently we have been engaged with the experimentation of a series of mixed copper(I) complexes with heterocyclic thiones and phosphines or arsines[6–8] as ligands. A study of the photoreactivity of these complexes ensued the observation of a darkening of their chloroform solution.

In an attempt to gain better understanding of the role of heterocyclic thione as well as triphenylphosphine and their derivatives as ligands, the above mentioned mixed ligand complexes have been prepared and studied.

EXPERIMENTAL

Material and instruments

Copper(I) chloride, tri-*p*-tolylphosphine (Merck) and triphenylphosphine (B.D.H.) were used as obtained, while all thiones (Merck or Aldrich) were recrystallized from hot ethanol prior to their use. The solvents used were of reagent grade and the preparations were carried out without any precautions for moisture or oxygen.

The IR spectra were obtained in KBr discs with a Perkin–Elmer 1430 spectrophotometer, while a Shimadzu UV 160 spectrophotometer was used to obtain the electronic absorption spectra. The ^1H NMR spectra were recorded in $CDCl_3$ solutions with a Brucker AW 80 spectrometer. Mass spectra were obtained on a Finigan mass spectrometer. Conductivity measurements were performed with a Wheatstone bridge Model RC 216

B2 using 10^{-3} M chloroform solutions. Melting points are uncorrected upon tube measurements. Elemental analyses for C, N and H were carried out with a Perkin–Elmer 240 elemental analyser.

For the photolyses, an Osram high pressure HBO 200 W/4 lamp was used.

Preparation of complexes

$[Cu(tptp)Cl]_4$ was prepared by refluxing equimolar quantities of CuCl and tptp in acetonitrile, for approximately 2 h,[9] while $[Cu(tpp)Cl]_4$ was prepared as described in the literature[10].

The complexes of formula $[Cu(PR_3)(L)Cl]_2$ were prepared according to the following general procedure. A solution of 0.4 mmol of the appropriate thione in 20 cm^3 of methanol was added to a solution of 0.1 mmol of $[Cu(PR_3)Cl]_4$ in 20 cm^3 of acetonitrile and the resulting solution was moderately heated. The solution was allowed to cool and the microcrystalline products were isolated. The compounds were identified by elemental analyses and by their spectral data.[9,11]

Collection and reduction of intensity data

Complete crystal data and parameters for data collection are reported in Table 1. Unit cell dimen-

[a] Nr = Number of refined parameters.

[b] $S = [\Sigma w(\Delta F)^2/(N-P)]^{1/2}$; P = number of parameters, N = number of reflections.

[c] $R = \Sigma|\Delta F||/\Sigma|F_o|$.

[d] $R_w = [\Sigma w(\Delta F)^2/\Sigma w|F_o|^2]^{1/2}$.

sions were derived from a least-squares refinement of the setting angles of 48 automatically centred reflections on a Syntex $P2_1$ diffractometer upgraded with CRYSTAL LOGIC with nickel-filtered Cu-K_α radiation. Three standard reflections measured every 97 reflections showed less than 3% intensity fluctuation. Lp and absorption corrections were applied. Scattering factors were taken from the *International Tables for X-ray Crystallography*.[12] The refinement was carried out by blocked full-matrix least-squares, in which $\Sigma w\Delta^2$ was minimized using SHELX 76.[13] The non-hydrogen atoms were refined using anisotropic temperature factors. One reflection which showed poor agreement was given zero weight during final refinement cycles.

The fractional atomic coordinates, lists of observed and calculated structure factors, anisotropic thermal parameters of the non-hydrogen atoms and thermal parameters of hydrogen atoms have been deposited.

RESULTS AND DISCUSSION

All the complexes prepared are microcrystalline solids, soluble in chloroform, acetonitrile, ethanol, methanol and acetone. Their conductivity measurements indicate their non-electrolytic nature. The most relevant physical properties of the compounds along with their analyses are reported in Table 2.

Spectroscopy

Copper(I) complexes containing heteroaromatic thiones exhibit a low-lying metal to ligand charge-transfer band (MLCT) in the near-UV spectral region.[14]

The UV–vis spectra in chloroform are dominated by two main absorptions at 250–260 and 280–310 nm, respectively. The corresponding bands in methanol or acetonitrile occur at 200–230 and 250–280 nm, respectively. The first band is ascribed to the intraligand transitions of the phosphine ligand, since the spectrum of the free phosphine reveals bands at 245, 215 and 210 nm for the chloroform, acetonitrile or methanol solutions, with log ε values similar to those observed in the complexes. Furthermore, it is readily seen[15,16] that arylphosphines do not shift their intraligand bands upon coordination to copper(I). The second band expresses a small red shift (10–20 nm) with respect to the corresponding one in the spectra of the free thiones. Therefore, it could be suggested that this band contains some MLCT character also.[16] The electronic spectra were also recorded in toluene and tetrahydrofuran; the absorption bands originating from the thione express a small blue shift (no more than 10 nm) on going to more polar solvents.

IR spectra in the region 4000–250 cm^{-1} provide information concerning the thione ligand coordination mode. The predominance of the thione form of the ligands is confirmed by the presence of ν(NH) bands at 3200–3130 cm^{-1},[17–19] the absence of ν(SH) bands in the region 2500–2600 cm^{-1}[20,21] and the occurrence of characteristic "thioamide bands"[20] as well as the ν(Cu—S) bands at 370–340 cm^{-1}.[22]

The ^1H NMR spectra of the compounds in $CDCl_3$ solution at ambient temperature display, apart from the signals expected for the phosphine and thione ligands, a single resonance at $\delta \sim 11$–14 ppm attributed to the NH protons, indicating the prevalence of the thione tautomer in solution also.

Table 2. Analytical data and relevant physical properties of the studied complexes

Complex	Melting point (°C)	Molecular weight	Elemental analysis[a] N(%)	C(%)	H(%)	Colour

Photolysis

UV irradiation of the complexes in chloroform, methanol and acetonitrile solutions at room temperature causes decomposition of the complexes within minutes, without the appearance of new bands in the UV–vis spectrum. The decomposition of the complexes, which can be summarized in the following equation, yields two photoproducts, as we can estimate following Coleman's method[23] (Fig. 2)

$$[Cu(PR_3)(L)Cl]_2 \underset{\text{heat}}{\overset{h\nu}{\rightleftharpoons}} [Cu(L)Cl]_2 + 2PR_3.$$

In every case solid products were deposited and their constitution was corroborated by elemental analyses and by their physical and spectroscopic properties. TLC of the soluble photoproducts indicates that in every case it is phosphine. To ascertain the above mechanism and to verify the reversibility, the solid photoproducts were treated with equimolar amounts of phosphine, affording the initial complexes.

Description of the crystal structure

An ORTEP[24] view of the molecule is given in Fig. 1. The complex consists of dimeric $[Cu(tptp)(L)Cl]_2$ units which are well separated from each other. The molecule is centrosymmetric. The copper(I) atoms display a distorted tetrahedral coordination surrounded by a phosphorus, a chloride and two sulphur atoms. The sulphur atoms of the thione ligands serve as bridges between two copper(I) centres.

Selected bond lengths and angles are given in Table 3. It should be pointed out that the Cu^I—P and Cu^I—S distances observed are similar to those in $[Cu(tptp)(pymtH)Cl]_2$[9] for equivalent bonds. The only significant difference is the slight shortening of the Cu^I—Cl bond in this complex, which is comparable with that in $[Cu(tptp)(pmtH)Cl]_2$ [2.283(1) and 2.300(1) Å].

The Cu^I—P and Cu^I—Cl bond lengths in the Cu/P = 1 : 1 molecule (2.22 and 2.29 Å) are comparably shorter than those found for Cu/P = 1 : 2 molecules. In contrast to this, there is no significant difference in the Cu^I—S distance of both series of complexes (2.37 Å). The copper and bridging sulphur atoms form a planar Cu_2S_2 core. The angles within the central Cu_2S_2 unit [S—Cu—S′ = 92.48(2)° and Cu—S—Cu′ = 87.52(3)°] are similar to those found in $[Cu(tptp)(pmtH)Cl]_2$ [93.24(2) and 86.72(3)°] and

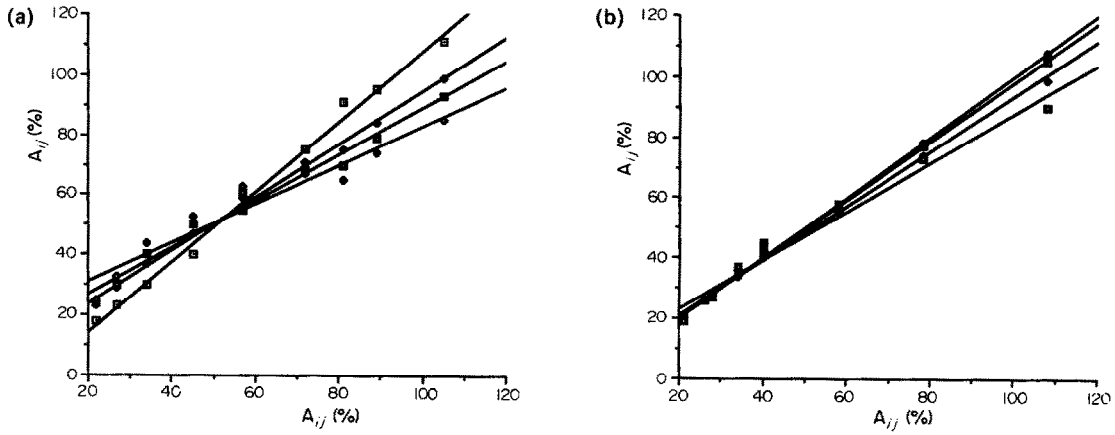

Fig. 2. Plots of the graphical matrix method test for two species in the $[Cu(tptp)(tzdtH)Cl]_2$ system during irradiation in chloroform (a) and methanol (b) solutions. A_{ij} is the absorbance of the jth (400–200 nm) wavelength after i seconds (0, 15, 30, 45, 60) of irradiation.

[a] ESDs are given in parentheses.

[Cu(purinium-6-thione)Cl]$_2$[25] [92.9° and 87.5°]. The geometric arrangement of the Cu_2S_2 core is also in agreement with the prediction made by Summerville and Hoffmann[26] for $Y_2MX_2MY_2$ dimers, as well as the observations reported by Raper *et al.*[27] in a series of centrosymmetric dimers, and is attributed to the concerted steric effects of the ligands.

The S···S distance is equal to 3.508(1) Å, while the Cu···Cu separation of 3.359(1) Å is too long to represent metal–metal interaction.[28] In analogy with similar compounds already investigated[9] the nitrogen-bonded hydrogen atom participates in an intramolecular Cl···H—N hydrogen bond, Cl···N = 3.182(3) Å, N—H = 0.92(3) Å, H(N)···Cl = 2.35(2) Å and N—H···Cl = 150(2)°.*

(*Received* 16 *August* 1990; *accepted* 7 *January* 1991)

Abstract—A new dinuclear copper(II) complex with the macrocyclic ligand (1,13-dioxa-4,7,10,16,19,22-hexaazacyclotetracosane), [24]-N_6O_2, has been prepared and its crystal structure has been determined. The two copper ions are contained inside the molecular cavity and are bound to the NNN chelating subunits situated at the two poles of the macrocycles. Each copper(II) centre displays square-pyramidal coordination. The Cu^{II}—Cu^{II} distance is 5.16 Å, and the macrocycle has an *S*-type conformation. The molecule has a symmetry centre. The temperature dependence of the magnetic susceptibility for the title complex was studied in the range 4–300 K, giving an exchange integral of $J = 19.1$ cm^{-1}. This indicates a ferromagnetic interaction between the metal ions. The ESR spectra are also discussed.

Recently attention has been directed towards cyclic polyaza complexes.[1–5] The interest in the dinuclear macrocyclic complexes is in the unusual physical properties that they may possess, in their significance as models of biological dimetallic sites,[6,7] and in their potential chemical reactivity as dinuclear catalysts.

We describe here the synthesis, the crystal structure and the magnetic properties of the dibromo dicopper(II) bromide complex with the macrocyclic ligand (1,13-dioxa-4,7,10,16,19,22-hexaazacyclotetracosane), [24]-N_6O_2.

EXPERIMENTAL

Materials

The commercially available chemicals used were of reagent grade. 2-(2-Chloroethoxy)ethanol was prepared using the literature method.[8]

Syntheses

The ligand [24]-$N_6O_2 \cdot 6HBr \cdot 4H_2O$ was synthesized using the literature method.[5]

Preparation of the title complex. [24]-$N_6O_2 \cdot 6HBr \cdot 4H_2O$ (90 mg) was dissolved in water and passed over an anion-exchange column in the hydroxide form (Dowex 50). The effluent was added to an aqueous solution of 45 mg of $CuBr_2$ and the colour of the solution changed from green to blue. After evaporation of the blue solution, blue crystals were obtained. Found: C, 21.2; H, 5.3; N, 9.3; Cu, 14.0. Calc. for $[C_{16}H_{38}N_6O_2]Cu_2Br_4 \cdot 6H_2O$: C, 21.3; H, 5.5; N, 9.3, Cu, 14.1%.

Measurements

Analyses for C, H and N were carried out on a Perkin–Elmer analyser Model 240 and metal contents were determined by EDTA titration. The electronic spectra were measured on a Perkin–Elmer Hitachi-240 spectrophotometer. Variable-temperature magnetic susceptibility was measured on a vibrating-sample magnetometer Model CF-1. Diamagnetic corrections were made using Pascal's constants[9] for all the constituent atoms, and the magnetic moments were calculated by the equation $\mu_{eff} = 2.828\ (XT)^{1/2}$.

X-ray structure determination

A single crystal of the title complex having approximate dimensions $0.3 \times 0.3 \times 0.1$ mm^3 was mounted on a glass fibre. Examination was performed with Mo-K_α radiation ($\lambda = 0.71073$ Å) on a CAD4 diffractometer equipped with a graphite monochromator. A total of 3158 independent reflections was collected by the ω–2θ scan technique in the range $2 \leqslant \theta \leqslant 25°$, in which 1424 reflections [$I > 3\sigma(I)$] were considered to be observed. Intensity data were corrected for LP factors and empirical absorption.

The locations of the copper and bromine atoms were determined by direct methods. The coordinates of the remaining non-hydrogen atoms were found in succeeding difference Fourier syntheses. The final refinement by the full-matrix least-squares method with positional and anisotropic thermal parameters for the non-hydrogen atoms was converged with the unweighted and weighted agreement factors of 0.044 and 0.051 (unit weights for all observed reflections). The highest peak in the final difference Fourier map had a height of 0.713 e/Å^3 and was 0.9 Å away from the Br(1) atom. All calculations were performed on a PDP11/44 computer.

RESULTS AND DISCUSSION

Elemental analyses have indicated that the reaction of the macrocyclic ligand [24]-N_6O_2 with $CuBr_2$ yielded the binuclear copper(II) macrocyclic complex [24]-$N_6O_2Cu_2Br_4 \cdot 6H_2O$. In the electronic absorption spectra of aqueous solutions of the complex, a strong absorption at 267 nm ($\varepsilon = 4 \times 10^3$ M^{-1} cm^{-1}) and a broad absorption at 640 nm ($\varepsilon = 2 \times 10^2$ M^{-1} cm^{-1}) were observed. The former may be attributed to the charge-transfer absorption bands and the latter to the *d*–*d* transition. Features of the optical spectra are consistent with the expected five-coordinate binuclear complex.[10] It was reported[11] that the coordination environment around the copper(II) ion can affect the frequency of the *d*–*d* transition and as the distortion from planarity increases, a lowering in the transition frequency occurs. In this complex there is no significant difference between the planarity of the copper(II) ion basal planes, hence two bands of the *d*–*d* transition may be superimposed and a broad band is observed.

The crystal structure of the complex

The complex crystallizes in the monoclinic space group $P2_1/C$, with $a = 12.702(3)$, $b = 7.885(1)$, $c = 17.316(2)$ Å, $\beta = 112.00(1)°$, $V = 1608.0$ Å^3, Mr = 895.28, $Z = 2$, $D_x = 1.848$ g cm^{-3}, $\mu = 62.936$ cm^{-1}, $F(000) = 888$.

The molecular structure of the complex is shown in Fig. 1. The macrocyclic ligand, [24]-N_6O_2, contains two sets of diethylenetriamine units which coordinate with two copper(II) ions respectively. The two copper ions are contained inside the molecular cavity bound to the NNN chelating subunits situated at the two poles of the macrocycles. The molecule has a centre symmetry. Each of the two copper atoms has a square-pyramidal coordination environment; the basal plane is defined by three nitrogen atoms and one bromide ligand. The basal planes of the two square-pyramidal CuN_3Br moieties are parallel to each other with Cu^{II}—Cu^{II} = 5.16 Å. The copper–nitrogen distances are almost equivalent [Cu—N(1) = 2.059(5) Å, Cu—N(2) = 2.044(5) Å, Cu—N(3) = 2.016(5) Å] and are shorter than the copper–bromide and

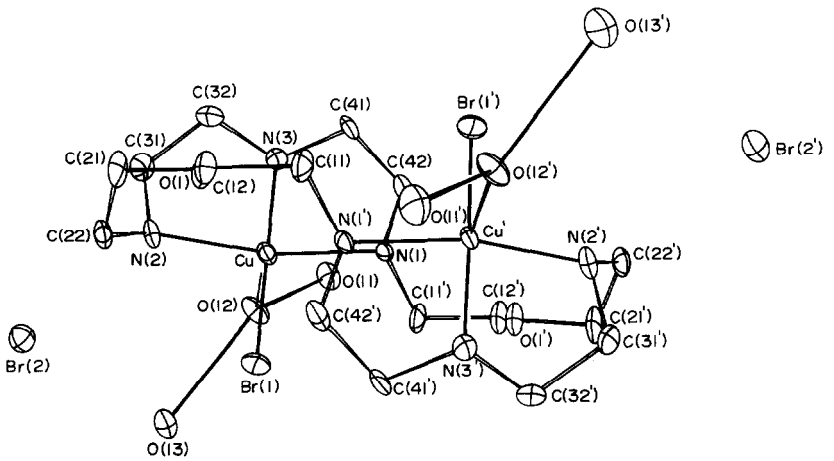

Fig. 1. A perspective view of the complex molecule.

Table 1. Main bond lengths (Å) and bond angles (°)

Cu—Br(1)	2.384(2)	N(1)—Cu—N(2)	166.5
Cu—N(1)	2.059(5)	N(3)—Cu—Br(1)	172.6(2)
Cu—N(2)	2.044(5)	O(12)—Cu—N(1)	96.1
Cu—N(3)	2.016(5)	O(12)—Cu—N(2)	90.3
Cu—O(12)	2.342	O(12)—Cu—N(3)	90.7
O(11)—O(12)	2.798	O(12)—Cu—Br(1)	96.8
O(12)—O(13)	2.776		
Cu---Cu′	5.16		
Cu---Br(2)	4.976		

copper–oxygen distances [Cu—Br(1) = 2.384(2) Å, Cu—O(12) = 2.342 Å]. Selected bond distances and angles are collected in Table 1. The coordinated water molecule acts as the apical ligand and links with two water molecules via hydrogen bonds. The axial copper–oxygen distance [Cu—O(12)] is 2.342 Å. Each copper(II) ion coordinates only one bromide ion and the other bromide ion [Br(2)] is outside the coordination sphere [Cu—Br(2) = 4.97 Å]; the Cu—Br(1)′ distance is 4.856 Å.

Compared with the molecular structure of uncomplexed [24]-N_6O_2[12] there is an obvious difference in conformation between the coordinated and uncoordinated [24]-N_6O_2. Coordinated [24]-N_6O_2 has an *S*-type conformation which may be stabilized by the formation of four pentamembered rings.

ESR spectra and magnetic properties

The X-band powder ESR spectra at room temperature for the complex are given in Fig. 2. The principal values of the g tensor are $g_1 = 2.197$, $g_2 = 2.121$ and $g_3 = 2.060$. The average g value is equal to 2.126, in agreement with the value determined from the magnetic data. No resonance is detected in the $\Delta M_s = 2$ region at 77 K, which could be due to the very weak zero-field splitting.

Fig. 2. Powder X-band ESR spectra of the complex.

Variable-temperature (4–300 K) magnetic susceptibility for the complex is shown in Fig. 3. The magnetic moment, μ_{eff}, increases slightly on cooling and appears to reach a maximum equal to 2.65 BM at *ca* 77 K, and then remains almost constant down to 47 K. This behaviour is characteristic of ferromagnetic coupling[13] between the copper(II) ions stabilizing the triplet state with respect to the singlet state. Furthermore, since the decrease in the magnetic moment below 47 K suggests that a very weak antiferromagnetic intermolecular interaction superimposes itself on the intramolecular ferromagnetic coupling, one can account for this intermolecular effect by using a θ Weiss correction. To determine J, the singlet–triplet energy gap, we may correct the Bleaney–Bowers equation based on the Heisenberg operator using the Weiss parameter, θ, as shown in eq. (1)

$$X_M = \frac{2N\beta^2 g^2}{K(T-\theta)}[3+\exp(-J/KT)]^{-1}, \qquad (1)$$

where X_M denotes the susceptibility per binuclear complex and the remaining symbols have their usual meaning. As shown in Fig. 3, good fits to the experimental data are obtained with eq. (1) by the least-squares procedure. Magnetic parameters thus determined are $J = 19.1$ cm^{-1}, $g = 2.16$ and $\theta = -5.84$ K. The agreement factor defined by $F = \Sigma_i (X_i^{obs} - X_i^{calc})^2 (X_i^{obs})^{-1}$ is equal to 3×10^{-4}. $J > 0$ indicates that there is a ferromagnetic exchange interaction between Cu^{II}—Cu^{II} and smaller $|J|$ values suggest that the interaction is weaker. Also, $\theta < 0$ and $|\theta|$ is smaller. This indicates a very weak antiferromagnetic intermolecular interaction.

Further investigation on this and similar systems is still required in order to explain the mechanism of the exchange interaction for the binuclear complexes in which there is no bridging ligand between the two metal ions.

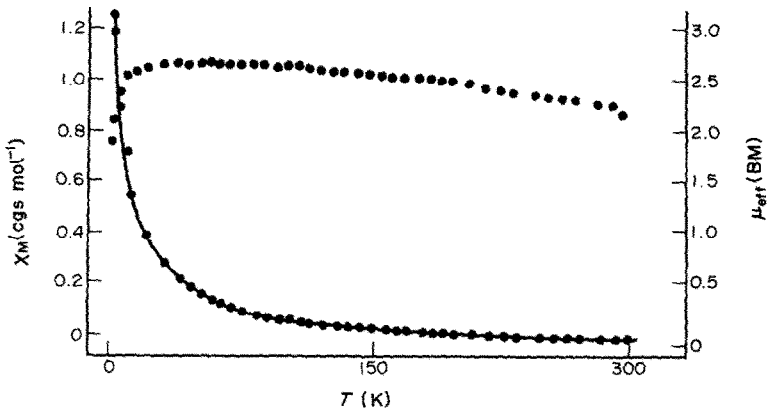

Fig. 3. Molar paramagnetic susceptibility, X_M, and effective magnetic moment per molecule, μ_{eff}, vs temperature curves for the complex. The solid lines represent the best fit of the data of the theoretical equation given in the text.

(*Received* 6 *June* 1990; *accepted* 9 *January* 1991)

Abstract—Two new cadmium complexes with the tridentate amino-ketoenamine ligands, obtained by 1 : 1 condensation of pentane-2,4-dione with 1,2-diaminoethane and 1,3-diaminopropane, respectively, exhibit an unusual coordination type, wherein the cadmium ion is coordinated by two non-deprotonated, neutral ligand molecules, in spite of the acidic properties of the enamine hydrogen atom.

An enamine hydrogen atom *f* in the mono-condensation products of pentane-2,4-dione and 1,2-diaminoethane or 1,3-diaminopropane (HL^1 and HL^2, respectively, Fig. 1) is fairly acidic and, therefore, dissociates readily upon the complexation of the metal ion.[1] All metal complexes with HL^1 and HL^2 described up to date[2–9] share a common structural feature; roughly planar ML^1 or ML^2 subunits, wherein one metal(II) ion is bound by one singly-deprotonated tridentate ligand molecule. In this paper, we report the first example of the entirely different coordination type exhibited by HL^1 and HL^2, observed in their cadmium complexes $[Cd(HL^1)_2]I_2$ and $[Cd(HL^2)_2]I_2$. In these complexes, two non-deprotonated ligand molecules are bound to one, presumably hexacoordinated cadmium ion.

RESULTS AND DISCUSSION

When HL^1 and HL^2 ligands are allowed to react with cadmium iodide at room temperature in methanol, white, microcrystalline solids separate slowly from the reaction medium. Elemental analysis shows that the products can be formulated as $[Cd(HL^1)_2]I_2$ and $[Cd(HL^2)_2]I_2$, respectively, wherein the cadmium ion is bound by two neutral tridentate amino-ketoenamine ligand molecules, forming a dipositive complex cation neutralized by two iodide counterions. FAB mass spectra of the products (Table 1) support this formulation: although the peaks of the $Cd(HL)_2I_2$ aggregate are not present, the fragments $Cd(HL)_2I$, $Cd(HL)_2$, Cd(HL)I, and Cd(HL) give rise to the most abundant fragmentation ions in the spectra of both cadmium complexes.

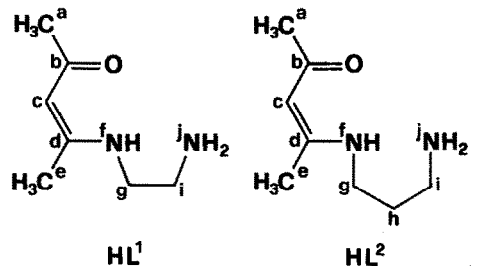

Fig. 1. Line drawings of the amino-ketoenamine ligands including the labelling scheme (indexes *a–j*) used in the discussion of the NMR spectra.

^1H NMR spectra of the cadmium complexes bear a close resemblance to the spectra of the free ligands.[1,2,5,10] Only minor shifts (up to 0.2 ppm) of proton resonances are observed upon the complexation of HL^1 and HL^2 with cadmium, except for the primary amino hydrogen atoms *j* experiencing a shift of *ca* 1 ppm. The most conspicuous similarity is the presence of a broadened resonance at 10.6 ppm in the spectra of both the free ligands and their cadmium complexes. As this resonance is attributed to the enamine proton *f* coupled to the adjacent methylene group *g* with J_{fg} *ca* 7 Hz, its presence in the spectra of cadmium compounds pro-

[e] Partially, by methyl *a* and *e* singlets.

[f] Triplet of broadened components.

[g] Partially overlapping with quartet of *g*.

[h] Entirely overlapped by the solvent multiplet. The explanation of *a–j* is the same as in Fig. 1.

vides additional evidence for the $[Cd(HL^1)_2]I_2$ and $[Cd(HL^2)_2]I_2$ formulation. A perceptible broadening of the methylene *g* and *i* resonances in the $[Cd(HL^1)_2]I_2$ spectrum implies some restriction of pseudo-rotary motion within the —CH_2—CH_2— moiety when compared with a more flexible —CH_2—CH_2—CH_2— fragment in $[Cd(HL^2)_2]I_2$, giving rise to narrower signals.

^{13}C NMR spectra of the cadmium complexes are almost identical (Table 1) and very close to the spectrum reported for the ligand HL^1 (the largest discrepancy being 1.6 ppm).[5,10] As the deprotonation of HL^1 results normally in much more substantial shifts (e.g. 17 ppm upfield for carbonyl carbon atom *b* and 9 ppm downfield for the methylene carbon atom *g* resonances[5,10]), this again indicates the unusual behaviour of HL^1 and HL^2 coordinating the cadmium(II) ion as neutral molecules.

EXPERIMENTAL

Cadmium complexes

The appropriate ligand, HL^1 or HL^2 (0.02 mol), in 150 cm^3 of methanol was added to cadmium(II) iodide (0.01 mol) dissolved in 150 cm^3 of methanol. The resulting solution was stirred for 15 min at room temperature and filtered. Cadmium complexes separated slowly from the solution in the form of white solids. These were removed by filtration, washed with methanol and dried *in vacuo* at room temperature. Bis(1-amino-3-aza-4-methyl-4-heptene-6-one)cadmium(II) diiodide, $[Cd(HL^1)_2]I_2$, was obtained in the form of small needles, yield 65%, m.p. 130°C. Found: C, 25.8; H, 4.3; I, 39.0; N, 8.6. $C_{14}CdH_{28}I_2N_4O_2$ requires: C, 25.9; H, 4.3; I, 39.0; N, 8.6%. Bis(1-amino-4-aza-5-methyl-5-octene-7-one)cadmium(II) diiodide, $[Cd(HL^2)_2]I_2$, was obtained as a white, microcrystalline powder, yield 45%, m.p. 120°C. Found: C, 28.6; H, 4.8; I, 37.5; N, 8.3. $C_{16}CdH_{32}I_2N_4O_2$ requires: C, 28.3; H, 4.8; I, 37.4; N, 8.3%.

Physical measurements

Elemental analyses were performed on a Carlo Erba MOD 1106 elemental analyser (C, H, N). Iodine content was determined by potentiometric titration of acidified solution with silver nitrate. Melting points were obtained as endothermic peaks on thermogravimetric curves recorded on a Paulik–Paulik type OD 103 derivatograph. FAB (Fast

Atom Bombardment) mass spectra of cadmium complexes in DMSO solution were recorded using a glycerol matrix on a VG 30–250 spectrometer at the probe temperature; xenon was used as the primary beam gas and the ion gun was operated at 8 kV and 100 μA. ^{1}H and ^{13}C NMR spectra were run on 300 MHz Nicolet and 100 MHz Tesla FT spectrometers.

Acknowledgements—This research was supported by Grant DS-5-530-7-016-1 from the kBN and Instrumentation Grant CHE 8102974 from NSF. The authors are grateful to Dr Edward Deutsch for his help in NMR and FAB mass studies.

SYNTHESIS AND CHARACTERIZATION OF SOME HETEROBIMETALLIC ISOPROPOXIDES OF LANTHANUM WITH ZIRCONIUM

UPENDRA M. TRIPATHI, A. SINGH and R. C. MEHROTRA*

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(*Received* 22 *October* 1990; *accepted* 9 *January* 1991)

Abstract—Seven heterobimetallic isopropoxide derivatives of lanthanum have been synthesized by the reaction of $LaCl_3 \cdot 3Pr^iOH$ with $K\{Zr_2(OPr^i)_9\}$ in different molar ratios (1 : 1, 1 : 2, 1 : 3) to yield hydrocarbon-soluble derivatives of the types $[Cl_{3-n}La\{Zr_2(OPr^i)_9\}_n]$ (n = 1, 2 or 3). The reactions of the above bimetallic chloride isopropoxides with the appropriate potassium alkoxides yield derivatives of the types $[(OR)_{3-n}La\{Zr_2(OPr^i)_9\}_n]$ (n = 1 or 2; R = Pr^i and Bu^t). All these have been characterized by elemental analyses and spectroscopic (IR and NMR) studies.

The synthesis and characterization of a large number of heterometal alkoxides[1–5] which are soluble in organic solvents and generally volatile under reduced pressure have added a new dimension to the variety of known heterometal coordination compounds. A conjecture[6] about the formation of such derivatives in a solution of a number of metal alkoxides used as precursors for ceramic materials was made in 1971 on the basis of the extraordinary homogeneity of the final products obtained by the solution–sol–gel (S–G) process. Recently, heterometal alkoxides[7–12] have attracted considerable attention as precursors for ceramics in the S–G process.

There has been of late an unprecedented upsurge in metal alkoxide chemistry[13,14] particularly for yttrium and the lanthanides.[15–19] It is interesting to note that attempts to prepare homoleptic isopropoxide of yttrium (by the reaction of the metal with isopropanol) and neodymium (by the reaction of $NdCl_3$ with $NaOPr^i$ in a 1 : 3 molar ratio) appear to result in the formation of oxide[16] or chloride alkoxides,[15] respectively. By contrast, addition of $Al(OPr^i)_3$ to the yttrium oxide–alkoxide species *in situ* results[16] in the formation of heterobimetallic isopropoxide,[1,19] $Y\{Al(OPr^i)_4\}_3$, indicating a higher stability of the heterometallic in comparison with the homoleptic alkoxides.

Despite extensive work in the field of bimetallic alkoxides of transition metals[2–5] containing different types of alkoxometallate ligands, only the tetraalkoxyaluminate(gallate) complexes of lanthanons have been described.[20,21] Observations[20,21] regarding the volatility of bimetallic isopropoxides of lanthanum with ligands like $\{Al(OPr^i)_4\}^-$ and $\{Ga(OPr^i)_4\}^-$ prompted us to synthesize new tris-bimetallic alkoxides of lanthanum with some more complex alkoxometallate ligands like $\{Zr_2(OPr^i)_9\}^-$ and extend the work to the synthesis of bimetallic chloride alkoxides of lanthanum, as such heteroleptic complexes of lanthanons do not appear to have been reported so far.

We therefore describe herein (Table 1) the synthesis and characterization of some novel heterobimetallic isopropoxide derivatives of lanthanum with zirconium of the types $[Cl_{3-n}La\{Zr_2(OPr^i)_9\}_n]$ and $[(OR)_{3-n}La\{Zr_2(OPr^i)_9\}_n]$ (where n = 1, 2 or 3).

EXPERIMENTAL

Stringent precautions were taken to exclude moisture throughout the experimental procedure. All reactions were carried out with glass apparatus which was oven-dried (130–140°C) thoroughly and cooled under a moisture-free atmosphere prior to use.

Toluene, benzene and n-hexane were dried by refluxing over sodium/benzophenone, followed by distillation. Isopropanol was dried by refluxing

over aluminium isopropoxide or calcium hydride, followed by distillation. Both benzene and isopropanol were finally dried by azeotropic distillation in the presence of dry isopropanol or benzene, respectively. Tert-butanol was fractionated over sodium tert-butoxide.

Anhydrous lanthanum trichloride was obtained by heating a mixture of hydrated lanthanum trichloride and ammonium chloride in a current of dry chlorine and hydrogen chloride gas; the temperature had to be carefully regulated in the above procedure to avoid the formation of fusible oxychloride (LaOCl).

Zirconium isopropoxide isopropanolate, $Zr(OPr^i)_4 \cdot Pr^iOH$, was prepared by the literature procedure.[22]

Zirconium was estimated as ZrO_2 after precipitation as mandelate and ignition to the oxide. Lanthanum was estimated as La_2O_3 after ignition of precipitated oxalate.

Isopropoxy contents were estimated by the oxidimetric method[23] using a N-$K_2Cr_2O_7$ solution in 12.5% H_2SO_4. Chloride was estimated by Volhard's method.

IR spectra (4000–200 cm^{-1}) were recorded as Nujol mulls on Perkin–Elmer 557 and Carl Zeiss Specord M80 spectrophotometers using CsI optics. ^1H (89.55 MHz) and ^{13}C (22.49 MHz) NMR spectra were recorded on a JEOL FX 90Q FT NMR spectrometer in $CDCl_3$ or C_6H_6, respectively. Chemical shifts were referenced internally to *protio* solvent impurities (δ 7.25, $CDCl_3$) and solvent ^{13}C references (δ 128.5, C_6H_6; δ 77.0, $CDCl_3$) and have been reported in ppm downfield of tetramethylsilane (TMS).

Preparation of $[La\{Zr_2(OPr^i)_9\}_3]$

A freshly prepared solution of $K\{Zr_2(OPr^i)_9\}$, prepared by dissolving potassium (0.236 g, 6.03 mmol) and $Zr(OPr^i)_4 \cdot Pr^iOH$ (4.673 g, 12.05 mmol) in the presence of dry isopropanol (~ 5 cm^3) and benzene (~ 25 cm^3), was added slowly to a suspension of $LaCl_3 \cdot 3Pr^iOH$ (0.855 g, 2.00 mmol) in benzene (~ 15 cm^3). The reaction mixture was refluxed for 3 h. Excess isopropanol was then distilled off and after addition of benzene (~ 60 cm^3), the reaction mixture was again refluxed for ~ 4 h. The precipitated KCl (0.441 g, 5.91 mmol) was filtered off. After removal of volatiles from the filtrate under reduced pressure, and finally drying the resulting mass at 50°C/0.8 torr for 2 h, a white, sticky, solid product of the composition $[La\{Zr_2(OPr^i)_9\}_3]$ (4.105 g, 91%) was obtained. The compound was purified by sublimation (~ 90% yield) at 217°C/0.5 torr.

Preparation of bimetallic chloride isopropoxide $[ClLa\{Zr_2(OPr^i)_9\}_2]$

Initial efforts to prepare $[ClLa\{Zr_2(OPr^i)_9\}_2]$ by the reaction of $LaCl_3 \cdot 3Pr^iOH$ and $K\{Zr_2(OPr^i)_9\}$ (1:2 molar ratio) in the presence of excess isopropanol tended to crystallize out the isopropanolate, $Zr(OPr^i)_4 \cdot Pr^iOH$. The derivative could finally be obtained by exclusion of free isopropanol in the reaction mixture.

A solution of the reagent $K\{Zr_2(OPr^i)_9\}$ in an isopropanol–benzene mixture was first prepared by the interaction of $KOPr^i$ [synthesized by dissolving 0.344 g (8.79 mmol) of potassium in a mixture of isopropanol (~ 5 cm^3) and benzene (~ 10 cm^3)] with $Zr(OPr^i)_4 \cdot Pr^iOH$ (6.820 g, 17.59 mmol) in benzene (~ 10 cm^3). This solution was evaporated to dryness and then dissolved in benzene.

A benzene solution of the reagent was added slowly to the suspension of $LaCl_3 \cdot 3Pr^iOH$ (1.878 g, 4.41 mmol) in benzene (~ 15 cm^3) with continuous stirring. The reaction mixture was stirred for 2 h with heating at ~ 65°C, followed by further stirring at room temperature for ~ 10 h. The precipitated KCl (0.621 g, 8.33 mmol) was filtered off and the volatiles were removed from the filtrate under reduced pressure (0.8 torr) at room temperature (~ 27°C) to obtain $[ClLa\{Zr_2(OPr^i)_9\}_2]$ (6.895 g, 98% yield) as a white, crystalline solid. The compound was purified by crystallization from n-hexane.

$[Cl_2La\{Zr_2(OPr^i)_9\}]$ was prepared similarly as a white, crystalline solid by the interaction of $K\{Zr_2(OPr^i)_9\}$ (4.865 g, 6.45 mmol) with $LaCl_3 \cdot 3Pr^iOH$ (2.747 g, 6.45 mmol); the product could be recrystallized from n-hexane and toluene.

Reaction of $[ClLa\{Zr_2(OPr^i)_9\}_2]$ *with* $KOPr^i$

A benzene suspension of $KOPr^i$, prepared from potassium (0.070 g, 1.79 mmol) in isopropanol (~ 2 cm^3) containing benzene (~ 20 cm^3), was added dropwise to a solution of $[ClLa\{Zr_2(OPr^i)_9\}_2]$ (2.885 g, 1.77 mmol) in benzene (~ 15 cm^3). The reaction mixture was stirred at room temperature for *ca* 8 h. The precipitated KCl (0.113 g, 1.51 mmol) was removed by filtration. After removal of the volatiles from the filtrate under reduced pressure, a white solid of the composition $[(OPr^i)La\{Zr_2(OPr^i)_9\}_2]$ (2.803 g, 96% yield) was obtained.

In a similar procedure, the reaction of $[ClLa\{Zr_2(OPr^i)_9\}_2]$ with $KOBu^t$ in an equimolar ratio afforded $[(OBu^t)La\{Zr_2(OPr^i)_9\}_2]$ in 87% yield.

Reaction of $[Cl_2La\{Zr_2(OPr^i)_9\}]$ *with* $KOPr^i$ *in a* 1 : 2 *molar ratio*

Interaction of $KOPr^i$, prepared from potassium (0.200 g, 5.11 mmol) and isopropanol (~ 5 cm^3), with a benzene solution of $[Cl_2La\{Zr_2(OPr^i)_9\}]$ (2.366 g, 2.56 mmol), followed by stirring at room temperature for a few hours resulted in the precipitation of KCl (0.373 g, 5.00 mmol), which was filtered off. The filtrate was dried under reduced pressure (0.8 torr) at room temperature to obtain the white, solid product of composition $[(OPr^i)_2La\{Zr_2(OPr^i)_9\}]$ (2.376 g, 96%).

By the same procedure, the reaction of $[Cl_2La\{Zr_2(OPr^i)_9\}]$ with $KOBu^t$ in a 1:2 molar ratio afforded a white solid, $[(OBu^t)_2La\{Zr_2(OPr^i)_9\}]$, in 96% yield.

RESULTS AND DISCUSSION

Interaction of $LaCl_3 \cdot 3Pr^iOH$ and $K\{Zr_2(OPr^i)_9\}$ in different molar ratios in benzene can be represented by the following equation:

$$LaCl_3 \cdot 3Pr^iOH + nK\{Zr_2(OPr^i)_9\} \longrightarrow [Cl_{3-n}La\{Zr_2(OPr^i)_9\}_n] + 3KCl\downarrow + 3Pr^iOH. \quad (n = 1\text{–}3)$$

Replacement of chloride in $[Cl_2La\{Zr_2(OPr^i)_9\}]$ and $[ClLa\{Zr_2(OPr^i)_9\}_2]$ with alkoxy groups produced derivatives of the types, $[(OR)_2La\{Zr_2(OPr^i)_9\}]$ and $[(OR)La\{La_2(OPr^i)_9\}_2]$:

$$[Cl_nLa\{Zr_2(OPr^i)_9\}_{3-n}] + 2KOR \longrightarrow [(OR)_nLa\{Zr_2(OPr^i)_9\}_{3-n}] + 2KCl\downarrow. \quad (R = Pr^i, Bu^t;\ n = 1, 2)$$

All these new heterobimetallic derivatives are colourless products which are highly moisture-sensitive and soluble in common, organic solvents.

The identity of the tris-product, $[La\{Zr_2(OPr^i)_9\}_3]$, has been corroborated by its sublimation in 90% yield. Similarly, the identity of the dichloride product is supported by its recrystallization from n-hexane/toluene in ~ 64% yield.

In view of $LaCl_3$ forming a stable isopropanolate, $LaCl_3 \cdot 3Pr^iOH$, an attempt was made to prepare isopropanol adducts of the chloride products by refluxing these derivatives with isopropanol. From the yields, as well as the analysis of the products, it appears that these complexes do not form any adduct(s) with isopropanol which tends to indicate that the lanthanum must be attaining a higher stable coordination state by internal chloride and isopropoxy bridges. Although final proof will emerge only after X-ray structure determination (efforts of which are in progress), non-crystallization of the zirconium tetraisopropoxide adduct, $Zr(OPr^i)_4 \cdot Pr^iOH$, tends to corroborate that these complexes are stable coordination entities which do not tend to dissociate into the component lanthanum and zirconium isopropoxide or chloride isopropoxides.

IR spectra of these newly synthesized heterobimetallic isopropoxides are being interpreted on the basis of earlier characterization of C—O and M—O stretching frequencies[1,24,25] as well as deformation and skeletal vibrations[1,26,27] due to the *gem*-dimethyl group in the spectra of metal isopropoxides.

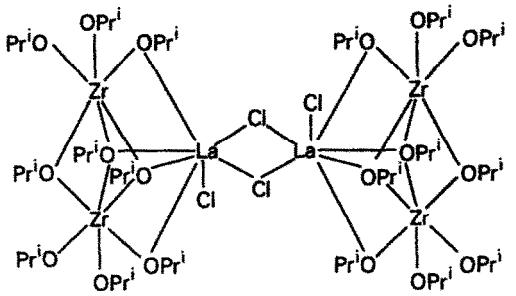
The spectra of heterobimetallic isopropoxides of lanthanum show C—H deformation stretching frequencies due to $(CH_3)_2C<$ groups in the ranges 1370–1365 and 1360–1355 cm^{-1}, while skeletal vibrations have been observed in the ranges 1160–1115 and 1120–1115 cm^{-1}. In mixed (t-butoxide) isopropoxide derivatives, the presence of the t-butoxide group is indicated by the absorption in the ranges 1382–1378 and 1260–1200 cm^{-1} due to C—H deformation and skeletal vibrations, respectively.

The ν(C—O) band which occurs at 1070 cm^{-1} in free isopropyl alcohol is observed in the ranges 1085–960 cm^{-1} (terminal) and 945–910 cm^{-1} (bridging) in these new heterometal isopropoxide derivatives.

The medium to strong broad absorptions displayed in the range 560–410 cm^{-1} may be related to ν(Zr—O) (560–535 cm^{-1}) and ν(La—O) (460–410 cm^{-1}). The heterobimetallic chloride isopropoxide derivatives exhibited absorptions in the range 294–210 cm^{-1}, which may be tentatively assigned to La—Cl stretching frequencies.[28,29]

The room temperature ^1H NMR spectrum (in $CDCl_3$) of freshly prepared $[Cl_2La\{Zr_2(OPr^i)_9\}]$ displays (i) a multiplet at δ 4.44 ppm arising from overlapping septets due to methine protons and (ii) three doublets at δ 1.67, 1.61; 1.49, 1.43; and 1.34, 1.27 ppm due to *gem*-dimethyl protons, in the approximate intensity ratio 3:2:4 which correspond to two triply (μ_3-OPr^i), three doubly (μ_2-OPr^i) bridged, and four terminal isopropoxy groups, respectively.

In view of the large size (1.15 Å), La^{3+} should generally prefer to attain a coordination higher than six in isopropoxide derivatives. Thus the ^1H NMR spectrum could, therefore, be interpreted in terms of a tentative structure **A**; this suggestion is corroborated by ^{13}C NMR data [δ 72.03, 71.14, 70.60 ppm (α-carbons); 25.25 and 24.27 ppm (β-carbons)] and the crystal structures of $KU_2(OBu^t)_9$[30] and $ClCd\{Zr_2(OPr^i)_9\}$.[31]

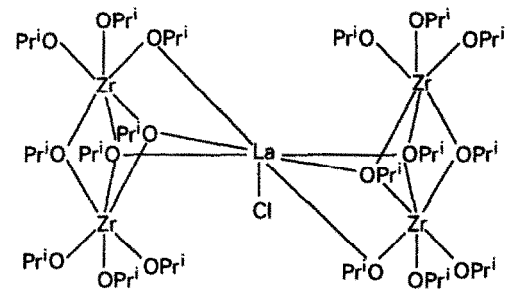


(A)

A noteworthy feature of the NMR spectrum of the complex, $[Cl_2La\{Zr_2(OPr^i)_9\}]$, is the appearance of new, minor peaks in the form of doublets on ageing the sample, which may be ascribed to structural changes from further association of the molecule.

The ^1H NMR spectra of $[X_2La\{Zr_2(OPr^i)_9\}]$ ($X = OPr^i$, OBu^t) in $CDCl_3$ at room temperature are less informative because of the broad and complex nature of observed signals due to methine and *gem*-dimethyl protons, but these could be expected to exhibit structures similar to that suggested for the parent chloro derivative, $[Cl_2La\{Zr_2(OPr^i)_9\}]$.

The derivative $[ClLa\{Zr_2(OPr^i)_9\}_2]$ exhibits an averaged septet and doublet (δ 1.29, 1.20 ppm) centred at δ 4.38 and 1.245 ppm, respectively, due to methine and *gem*-dimethyl protons, indicating fast exchange (on the NMR time scale) between bridging and terminal isopropoxy groups. The ^{13}C NMR spectrum (in benzene) for the same sample exhibits a single peak for both the α- and β-carbon atoms, respectively, at δ 69.67 and 26.49 ppm, which may be ascribed to a rapid exchange between bridging and terminal isopropoxy groups on the NMR time scale. On the basis of these observations, one can tentatively speculate structure **B** for the complex $[ClLa\{Zr_2(OPr^i)_9\}_2]$.



(B)

The ^1H NMR spectra of $[(Pr^iO)La\{Zr_2(OPr^i)_9\}_2]$ and $[(OBu^t)La\{Zr_2(OPr^i)_9\}_2]$ in $CDCl_3$ showed, as expected, an averaged septet and doublet due to α- and β-protons of the isopropoxy groups, respectively. Thus they may be expected to adopt structures similar to the one proposed for the precursor chloro complex (structure **B**).

The ^1H NMR spectrum of $[La\{Zr_2(OPr^i)_9\}_3]$ in $CDCl_3$ exhibits a broad peak centred at δ 4.37 ppm due to methine protons and two pairs of doublets centred at δ 1.34 and 1.21 ppm due to *gem*-dimethyl protons. The integration between the two sets of methyl protons appears to be an approximately 1 : 2 ratio. In the ^{13}C NMR spectrum, $[La\{Zr_2(OPr^i)_9\}_3]$ in $CDCl_3$ shows only two peaks at δ 26.63 and 70.19 ppm due to the *gem*-dimethyl (β) and methine (α) carbon atoms, respectively.

Although a definitive structure has to await X-ray studies, on the basis of spectroscopic data and known structures of similar compounds, a plausible structure (**C**) could be suggested with the possibilities of lanthanum attaining higher coordination state(s) by further bridging through suitably situated isopropoxy group(s).

Abstract—The synthesis and characterization of $Cu[C_6H_4(NH)_2]_2$ [$C_6H_4(NH)_2$ = semi-benzoquinonediiminate, abbreviated s-bqdi] are described and its relevant properties are compared with those of the known d^8 and d^6 metal bis- or tris-benzoquinonediiminate. The complex is paramagnetic in the solid state with μ_{eff} = 1.86 BM. The dominant form of Cu(s-bqdi)$_2$ in aliphatic alcohols like methanol, ethanol and n-butanol or in THF is dimeric or oligomeric, but monomeric in acetonitrile, DMSO and DMF, as proved by UV–vis and ESR spectra. The stability of Cu(s-bqdi)$_2$ to oxygen exposure in different solvents parallels the association behaviour and follows the order: ethanol ≫ DMF ≫ acetonitrile. The electrochemical (voltammetric) response of the $[Cu—N_4]^z$ system ($z = 0, \pm1, \pm2$) in acetonitrile consists of two $0 \rightleftharpoons +1$ ($E_{1/2} = -0.10$ V vs SCE) and $+1 \rightleftharpoons +2$ ($E_{1/2} = +0.98$ V vs SCE) reversible electron transfers and an irreversible process at $E_{p,c} = -1.87$ V attributed to $0 \rightarrow -1$ reduction. Iodination of an ethanolic solution of Cu(s-bqdi)$_2$ led to the isolation of polycrystalline Cu(s-bqdi)$_2$I$_5$ which is formulated as Cu(s-bqdi)$_2$(I$_3$)$_{1.66}$ on the basis of IR, Raman and thermogravimetric analysis. The new material exhibits high, room-temperature conductivity ($\sigma = 6.6 \cdot 10^{-2}$ S cm^{-1}) and semiconducting behaviour in the temperature range 70–300 K, with a sharp transition at 215 K. Static magnetic susceptibility measurements provide μ_{eff} = 1.23 BM for Cu(s-bqdi)$_2$(I$_3$)$_{1.66}$ at 295 K [calculated from $\mu_{eff} = 2.83(\chi T)^{1/2}$] which is found to obey the Curie–Weiss law between 70 and 295 K. The electrical and magnetic behaviour of Cu(s-bqdi)$_2$(I$_3$)$_{1.66}$ is interpreted as being due to strong homomolecular intra- and interstack interactions between donor molecules with radical cationic character.

Considerable efforts are still being carried out to build up new charge-transfer complexes whose stacked packing at the molecular level is the origin of peculiar, low-dimensional, cooperative phenomena. This has been recently carried out by exploring the potential of organometallic donors like decamethylferrocene, $Fe(C_5Me_5)_2$,[1] or by introducing chemical modifications on MPc[2] (Pc = phtalocyanine, M = Cu), or on classical organic donors like tetrathiofulvalene, TTF.[3]

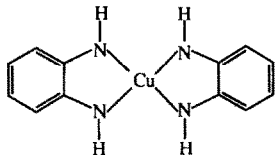
It has been seen that the coupling of new donors with a wide variety of counterions in the oxidized species leads to a fine tunability of the phenomenological properties of these materials.[4–6] In this respect, the [M—N$_4$] open systems like M(s-bqdi)$_2$ (s-bqdi = semi-benzoquinonediiminate, M = transition metals) have not been extensively investigated, due to the difficulties in growing pure crystals both of the starting compounds and of the oxidized species. In some cases, as in Cu(s-bqdi)$_2$, the practical impossibility to extend the synthetic procedure used in the d^8 analogues prevented any investigation in this direction.

Nevertheless, the recent acquisition of more suitable syntheses for the preparation of the α-diiminate

* Author to whom correspondence should be addressed.

complexes[7,8] and our discovery that suitable substitutions on the benzene ring can enhance the electrical conductivity in Ni(s-bqdi)$_2$I$_x$[9] to the values shown by NiPcI$_x$,[10] encouraged us to continue the study of this class of compounds.

The first aim was to verify the effects produced by a d^9 metallic centre in a partially oxidized bis-semi-benzoquinonediiminate context and we successfully attempted a new and reproducible synthetic approach for the title compound. Moreover, we were able to isolate its highly iodinated counterpart Cu(s-bqdi)$_2$I$_5$.



Thus we report here on these results together with the first spectroscopical and electrochemical characterization of Cu(s-bqdi)$_2$ and an overview of the interesting electrical and magnetic properties of Cu(s-bqdi)$_2$I$_5$. These are discussed with respect to the analogous behaviour of charge-transfer complexes in which donors and/or acceptors exhibit radical ionic character.

EXPERIMENTAL

Materials

All chemicals necessary for the syntheses were of reagent grade (Aldrich) and used without further purification. Absolute ethanol was purchased from BDH (Italy) and was kept over 4 Å activated molecular sieves for 24 h before use. Acetonitrile, tetrahydrofuran (THF), N,N′-dimethylformamide (DMF) and dimethylsulphoxide (DMSO) were HPLC or spectroscopic grade and were purified by standard techniques when used for voltammetric studies.

Synthesis of Cu(s-bqdi)$_2$

o-Phenylenediammine (0.50 g, 4.5 mmol) was gently refluxed in 30 cm^3 of absolute ethanol with an equimolar amount of copper acetate monohydrate (0.95 g) under argon. After 1 h, the colour of the solution turned from deep green to deep blue and a dark precipitate rapidly formed. After 3 h, the solution was cooled and filtered. The black–green solid, washed in successive steps with 20 cm^3 of water, methanol and low boiling (40–60°C) petroleum ether, respectively, and again with absolute ethanol, until a colourless washing liquid was obtained, was air-dried at 80°C. Extraction by infusion followed by accurate filtration of the black precipitate in absolute ethanol led to a deep blue–purple solution. Concentration by evaporation under a stream of nitrogen, followed by filtration, afforded green–brown, microcrystalline powders, which were vacuum-dried. Yield, calculated on *o*-phenylenediamine, 30%. Found: C, 52.4; H, 4.3; N, 20.8. Calc: C, 52.3; H, 4.4; N, 20.3%.

The most relevant spectroscopic data are: (a) UV-vis, λ in nm (log ε), ethanol as solvent, sh = shoulder, 652(4.21), 650sh(4.17), 632sh(4.07), 480sh(3.60), 460(3.47), 300sh(3.69), 285sh(3.84), 260sh(3.84), 240sh(4.30), 205sh(4.81); (b) IR, KBr pellets, vs = very strong, m = medium intensity, w = weak, 3320, 3325, 3340 cm^{-1} vs triplet of N—H stretch.; 1590, 1582 cm^{-1}, m, doublet of C=C aromatic stretch.; 1495 cm^{-1}, vs, C=N stretch.; 765 cm^{-1}, vs, out-of-plane bending of aromatic C—H; 452, 475 cm^{-1}, s, doublet of Cu—N stretch.

Synthesis of Cu(s-bqdi)$_2$I$_5$

Cu[C$_6$H$_4$(NH)$_2$]$_2$ (0.200 g) was dissolved in anhydrous ethanol; a 10^{-2} M solution of iodine in the same solvent was slowly added under magnetic stirring to the deep blue solution, until the colour turned to dark red and brilliant crystals started to form; these were collected by filtration and washed with low boiling petroleum ether. Yield, 70%. Found: C, 15.7; H, 1.3; N, 6.0. Calc: C, 15.8; H, 1.3; N, 6.2%.

The most relevant IR data are: 3276 cm^{-1}, vs, N—H stretch.; 1589, m, 1548, 1538 cm^{-1}, s, aromatic C=C stretch.; 1442 cm^{-1}, s, C=N stretch.; 868 cm^{-1}, vs, out-of-plane arom. C—H bend.; 452 cm^{-1}, s, Cu—N stretch.

Physical measurements

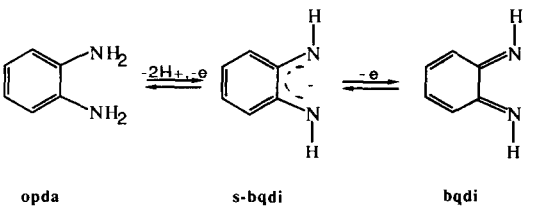
Electronic absorption and vibrational spectra were recorded on Cary 2300 and Perkin–Elmer 283B spectrophotometers, respectively. Elemental analyses were performed by H. Malissa and G. Roiter GmbH Analytische Laboratorien, Gummersbach, F.R.G. and by the Engineering Faculty of the Basilicata University. Magnetic susceptibility was determined by the Faraday method using an AZTEC-DSM5 susceptometer operating at 13.5 kG equipped with a Bruker BE15 electromagnet. Four probe dc electrical conductivity measurements at variable temperatures, thermogravimetric analysis and differential thermal analysis were performed as previously described.[9] ESR spectra were recorded with a Bruker 200D spectrometer operating at X-band. Voltammetry recorded at 200 mV s^{-1}

scan rate was performed using a standard H cell and an AMEL 5000 SYSTEM potentiostat galvanostat coupled to a microcomputer. The working electrode was a platinum disc (0.07 cm^2) and a saturated potassium chloride calomel electrode was used as reference. The solutions for spectroelectrochemistry were transferred in ESR capillaries under argon.

RESULTS AND DISCUSSION

Synthesis and spectroelectrochemical characterization of $Cu(s\text{-}bqdi)_2$

It is known that *o*-phenylenediamine (opda) can be deprotonated and oxidized to form the anionic-radical s-bqdi or the neutral diimine molecules o-benzoquinonediimine (bqdi) according to the following scheme:



Scheme 1.

The s-bqdi ligand provides square-planar, diamagnetic complexes of d^8 metal ions, with molecular orbitals well delocalized over the entire system.[11,12] These compounds, together with bqdi tris-α-diiminate complexes of d^6 metal ions have been the object of a number of investigations.[13-20] Nevertheless, since the first unambiguous spectroelectrochemical characterization of $M(s\text{-}bqdi)_2$ (M = Co, Ni, Pd, Pt),[13] the synthesis of $Cu(s\text{-}bqdi)_2$ which involves a d^9 metal ion, has been a challenge for many researchers. Yet recently Peng and Liaw[21] believed that $Cu(s\text{-}bqdi)_2$ could be an intermediate of the air oxidation of an acetonitrile solution of $Cu(opda)_2(ClO_4)_2$. To date, only one report concerning the title complex is available.[21] Here, the synthesis of $Cu(s\text{-}bqdi)_2$ is briefly described using the same procedure as used for the nickel analogue. Characterization data for the complex was not reported. Our findings, in accord with those of Balch and Holm[13] show that this method is ineffective. We used the Cu^{2+}/Cu^0 couple as an oxidizing agent for opda in place of oxygen, which is the usual oxidant in the synthesis of $M(s\text{-}bqdi)_2$ complexes. In fact, our results show that oxygen largely affects the stability of $Cu(s\text{-}bqdi)_2$. As a result, black powders of copper and acetic acid, the latter being due to the deprotonating action of the acetate ion on opda, were secondary reaction products. The high electronic affinity of the copper(II) ion has been observed in the oxidation of the cyanide ion to cyanogen[22] and is considered to be the origin of the instability of the $Cu(s\text{-}disn)_2$ complex[8] (s-disn = semi-diiminosuccinonitrile). It is noteworthy that Balch and Holm used the Co^{III}/Co^{II} electron-withdrawing couple to oxidize opda in synthesizing $Co(s\text{-}bqdi)_2$.[13] The solubility, stability and electronic spectra of $Cu(s\text{-}bqdi)_2$ are strongly dependent on the solvent and conditions. $Cu(s\text{-}bqdi)_2$ is easily dissolved in highly boiling solvents like DMSO, DMF and acetonitrile yielding deep green solutions (10^{-2} M). These slowly turn brown and decompose, although to a lesser extent in DMSO and DMF, when air-exposed. The lower solubility of the complex (10^{-3} M) in aliphatic alcohols is coupled to an appreciable stability (approximately 1 week in ethanol). After this time period, open-air evaporation of ethanolic solutions affords a grey precipitate, characterized by microanalysis as 2,3-diaminophenazine, as already found in the disproportionation of $Ni(s\text{-}bqdi)_2^+$.[7,8,14] Comparable stability is found in THF, but solubility in this solvent is scarce ($< 10^{-4}$ M). The electronic spectra of $Cu(s\text{-}bqdi)_2$ in ethanol and in acetonitrile are shown in Fig. 1 as examples of two limiting situations. $Cu(s\text{-}bqdi)_2$ in ethanol displays an intense band at 660 nm, which lies in the wavelength range characteristic of metal–semi-benzoquinonediiminate complexes. Nevertheless, the absorption exhibits shoulders of comparable intensity at 650 and 632 nm. The ethanolic solutions of $Cu(s\text{-}bqdi)_2$ being ESR silent, while the powders are paramagnetic, with $\mu_{eff} = 1.86$ BM consistent with a $S = 1/2$ ground state, may undergo dimerization or oligomerization in this solvent. Similar behaviour has been found in $Co(s\text{-}bqdi)_2$[13] and in $Ni(s\text{-}bqdi)_2$.[12] The multiple

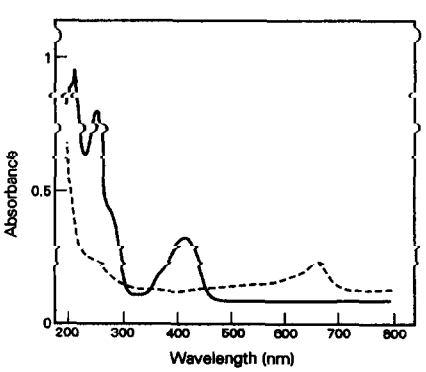


Fig. 1. Electronic absorption spectra of $Cu(s\text{-}bqdi)_2$ in acetonitrile (——) and in ethanol (– – –) at 22±1°C. *Concentrations are* 2.2×10^{-5} *M and* 2.6×10^{-5} *M*, respectively.

absorptions around 650 nm might be attributable to oligomers built with different numbers of monomers. The electronic spectrum of Cu(s-bqdi)$_2$ in acetonitrile displays an intense absorption at 420 nm whose shape appears to be reminiscent of that found at 660 nm in ethanol and is dominated in the UV region by highly intense charge-transfer bands. We note that the electronic spectrum of Cu(s-bqdi)$_2$ in its associated form looks like that of Ni(s-bqdi)$_2$ in acetone and, similarly, the region above 500 nm flattens as the complexes become monomeric, while the UV and the near-UV region is enriched by intense charge-transfer transitions.[12]

This behaviour strengthens the idea that Cu(s-bqdi)$_2$ is in a dimeric form in alcohols and THF, unlike Co(s-bqdi)$_2$ which was found to dimerize both in solution and in polycrystalline powders.[13] Room temperature X-band ESR spectra in DMF show a persistent, although not strong, signal at $g_{iso} = 2.085$. The absorption is further split by hyperfine splittings from ^{63}Cu, with $A_{iso} = 70$ G. The low value of A_{iso} compared with that of other [Cu—N$_4$] systems[23] suggests a large delocalization of the unpaired electron.

The voltammogram of Cu(s-bqdi)$_2$ in acetonitrile, as shown in Fig. 2, exhibits two, fully reversible and monoelectronic waves at $E_{1/2}(1) = -0.10$ V ($i_{p,a}/i_{p,c} = 0.98$, $\Delta E_p = 0.062$ V), $E_{1/2}(2) = 0.98$ V ($i_{p,a}/i_{p,c} = 0.95$, $\Delta E_p = 0.060$ V) vs SCE $\pm$ 0.01 V and a totally irreversible wave with $E_{p,c} = -1.87 \pm 0.01$ V vs SCE. The electrochemical behaviour of the complex in DMSO and DMF retain the same essential features as in acetonitrile. However, some changes, indicative of the strong interactions between the complex and solvents, are noticeable. In DMSO and DMF, the second oxidative process shows a complete loss of its cathodic counterpart, while its position is coincident with that found in acetonitrile [$E_{p,a}(2)$ is 0.94 and 0.90, respectively]. The first oxidation, while becoming quasi-reversible in DMSO and DMF ($\Delta E_p = 0.095$ V), shifts markedly towards positive potentials. The value of $E_{p,a}(1)$ is found to be 0.180 V in DMSO and 0.350 V (vs SCE) in DMF. The considerable influence of the nature of the solvent on the energetics of the first anodic process might be interpreted as due to the strong destabilization of the HOMO orbital in the complex. In this hypothesis, the high donating capability of acetonitrile could be responsible for the lowering of the potential for the removal of the first electron in Cu(s-bqdi)$_2$. The similar donating ability is probably the origin of the stabilization of the cations produced after the first and second oxidation in the voltammetric time scale used. Most likely, the easy oxidizability of the complex when exposed to oxygen in strong donor solvents and the tendency to dimerize in less powerful donors solvents have to be reconciled to the same cause.

ESR characterization of the oxidized species of Cu(s-bqdi)$_2$ was carried out after controlled potential electrolysis of a 10^{-3} M solution in 0.1 M [n-Bu$_4$N][BF$_4$] acetonitrile, 150 mV beyond $E_{1/2}(1)$ and $E_{1/2}(2)$, respectively. For the sake of completeness, we should report that ESR and UV–vis spectra of the final products of a bulk controlled potential electrolysis in DMF or in ethanol looked like that found in acetonitrile. The one-electron removal produced an ESR silent solution, while the

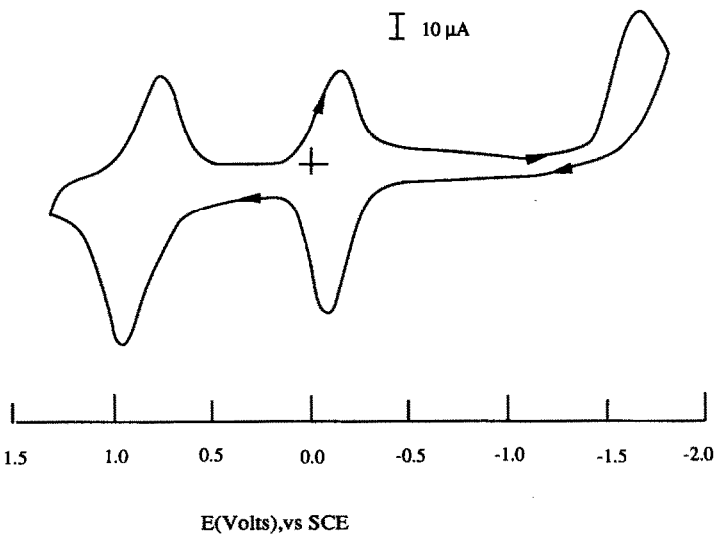

Fig. 2. DC cyclic voltammogram of a 5.0×10^{-4} M solution of Cu(s-bqdi)$_2$; $v = 200$ mV/s; 0.1 M [n-Bu$_4$N][BF$_4$]/CH$_3$CN; Pt disc, E vs SCE.

species resulting from the second oxidation showed a large absorption ($\Delta H = 180$ G) centred at $g = 2.150$. This spectroscopic evidence led us to believe that the first oxidation is essentially centred on copper, while the second one produces a complete rearrangement of the electronic structure of the molecule. As a result, the formation of $Cu(bqdi)_2(BF_4)_2$ can be taken into account. The irreversibility of the reduction at $E_{p,c} = -1.87$ V (vs SCE) can be attributed to the formation of a very reactive and geometrically distorted copper(I) species: due to the high cathodic potential of formation its characterization was impossible. Unlike found in d^8 metal ion s-bqdi complexes, Cu(s-bqdi)$_2$ does not show the complete charge-transfer $[M—N_4]^z$ series, where $z = \pm 2, \pm 1, 0$.

Synthesis, conductivity and magnetic data for Cu(s-bqdi)$_2$I$_5$

As expected, the response of Cu(s-bqdi)$_2$ to iodine was quite dependent on the solvent. Oxidation in acetonitrile, DMF or DMSO afforded red–brown microcrystals that were characterized as $Cu(bqdi)_2I_3$. This compound was found to be diamagnetic and electrically non-conducting ($\sigma_{295K} = 1.8 \times 10^{-9}$ S cm^{-1}). In anhydrous ethanol, very thin, gold, lustrous platelets with almost uniform dimensions ($0.13 \times 0.09 \times 0.005$ mm^3) were isolated. Their composition, checked by microanalysis and DTGA, was found to be $Cu(s\text{-}bqdi)_2I_5$ regardless of the preparative conditions. Polycrystalline samples diffracted very well, but single crystals were not suitable for structural, magnetic and electrical determinations. TGA and DTGA curves of $Cu(s\text{-}bqdi)_2I_5$ in the range 20–300°C are shown in Fig. 3. Two, sharp, almost equivalent iodine losses with maxima at 170 and 245°C were observed. This shaped thermogram was found in highly iodinated $NiPcI_x$,[10] in $(SiOPc)_nI_x$[24] and $Ni(s\text{-}bqdi)_2I_x$,[9] and was interpreted as due to the successive decomposition of I_5^- and I_3^- polyiodide, respectively. Raman spectra of $Cu(s\text{-}bqdi)_2I_5$ showed the intense absorption at 108 cm^{-1} and the superior harmonics of the symmetric I_3^- stretching, but did not reveal the presence of I_5^- or I_2 in the range 150–220 cm^{-1}. Therefore, the two consecutive iodine losses are due to decomposition of structurally distinguishable I_3^- species. In the mixed-valence notation, $Cu(s\text{-}bqdi)_2I_5$ can be written as $Cu(s\text{-}bqdi)_2(I_3)_{1.66}$: this evidences the incomplete oxidation of the starting complex. Surprisingly, the room temperature conductivity of $Cu(s\text{-}bqdi)_2I_5$ (6.6×10^{-2} S cm^{-1}) is 10^3–10^4 times greater than that found for $Ni(s\text{-}bqdi)_2I_x$ powders.[9,16] The conductivity is activated in the range 80–300 K and the values fit the Arrhenius-like relation $\sigma = \sigma^0 e^{-E_a/kT}$, where k = Boltzmann constant and $E_a = 0.10$ eV from 300 to ~215 K; at this temperature, as shown in Fig. 4, a transition is observed, indicating a slower diminution of the conductivity. This could be due to the creation of defects by cracking processes on crystals at lower temperatures. In fact, while the conductivity data in the range 300–215 K, obtained by cooling the sample, are reproduced on warming, the same does not occur in the range 200–70 K. On the other hand, at the same temperature we did not find similar magnetic behaviour (*vide infra*). Static magnetic susceptibility measurements on $Cu(s\text{-}bqdi)_2I_5$ gave

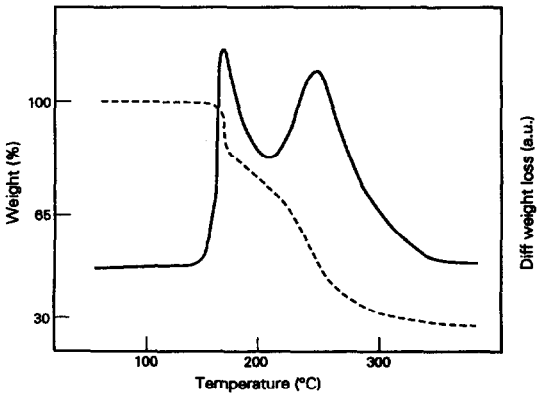

Fig. 3. TGA (– – –) and DTGA (——) of $Cu(s\text{-}bqdi)_2I_5$. Initial weight = 8.7 mg; heating rate = 20° min^{-1}.

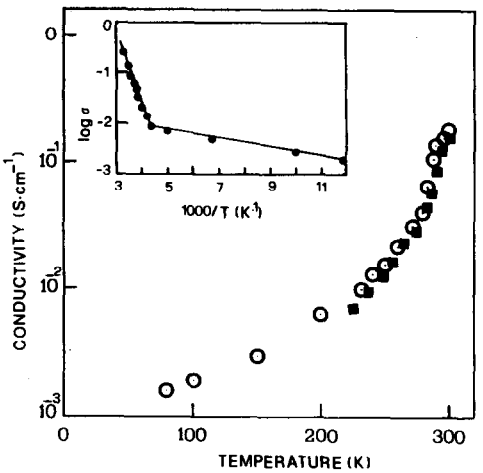

Fig. 4. Four probe DC electrical conductivity of $Cu(s\text{-}bqdi)_2I_5$ plotted vs temperature (○) obtained by cooling the sample from 300 to 70 K. The reversible values of the conductivity obtained by warming the sample in the range 200–300 K are also shown (■). Inset: log σ is reported as a function of $1000/T$.

$\mu_{eff} = 1.23$ BM at 295 K [calculated from $\mu_{eff} = 2.83(\chi T)^{1/2}$], which is consistent with 2/3 unpaired electrons per Cu(s-bqdi)$_2^{1.66+}$ molecular unit in the spin-only approximation. This value is coincident with that calculated on the basis of the ionic formula.

A similar distribution of the unpaired electrons, owing to the electrochemical behaviour of the complex, might imply the formation of alternate diamagnetic [Cu(s-bqdi)$_2$]$^+$ and radical [Cu(s-bqdi)$_2$]$^{+\cdot}$ cationic species. The radical character of [Cu(s-bqdi)$_2$]$^{+\cdot}$ implies that a formal oxidation state of +3 can be assumed for the copper centre and the ligand localization of the unpaired electron. The ESR spectrum of Cu(s-bqdi)$_2$I$_5$ shows a unique signal centred at $g = 2.064$. This value seems to suggest that there is a strong interaction between hypothetical copper(II) centres and unpaired electrons located on the α-diiminate frame. This could be achieved by an internal redox process between adjacent donor molecules. Cu(s-bqdi)$_2$I$_5$ is ferromagnetic given that, as shown in Fig. 5, χT increases as T decreases. Attempts to fit the experimental data show that the compound obeys the Curie–Weiss law between 70 and 295 K with $\theta = 28 \pm 5$ K. The value of θ is indicative of relatively strong coupling in this temperature range. Since the first elaboration of a physical model for ferromagnetism in charge-transfer complexes by McConnell in 1963,[25] only a limited number of experimental situations have been well characterized. Dominant ferromagnetic interactions have been found in tetrathiofulvalene platinum bis(*cis*-1,2-ditrifluoromethylene-1,2-dithienate) (TTF)[Pt(S$_2$C$_2$(CF$_3$)$_2$],[26] between 270 and 40 K, and more recently in decamethylferrocenium tetracyanoethenide, [(C$_5$Me$_5$)]$^+$[TCNE]$^{-\cdot}$.[1] Both these compounds have paramagnetic donors (D) and acceptors (A) stacked in a ...DADA... sequence and show strong intra- and interchain interactions.

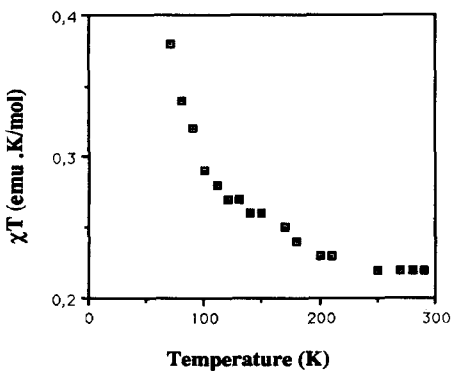

Fig. 5. Experimental values of χT plotted vs temperature for Cu(s-bqdi)$_2$I$_5$.

Owing to the diamagnetism of I_3^-, the magnetic behaviour of Cu(s-bqdi)$_2$I$_5$ is similar to that of ditetrabutylammonium copper maleonitride, [n-Bu$_4$N]$_2$[Cu(mnt)$_2$],[27] where stacks of paramagnetic, square-planar [Cu(mnt)$_2$]$^{2-}$ units are separated by [n-Bu$_4$N]$^+$ cations. However, the ferromagnetic coupling in Cu(s-bqdi)$_2$I$_5$ suggests that interactions between Cu(s-bqdi)$_2^{1.66+}$ radical cations are considerably stronger and, probably, not negligible in bidimensional directions, as supported by the strongly exchange-coupled ESR signal ($\Delta H = 70$ G) and by the partial loss of resolution of the most important IR absorptions. On the other hand, homomolecular ferromagnetic coupling due to disproportion of the donor molecules, is not excluded by McConnell, and this model has been found to rationalize ferromagnetism in [(C$_5$Me$_5$)]$^{\cdot+}$ [TCNE]$^{-\cdot}$ also.

Summarizing, the results allow us to conclude that:

(i) the first complete characterization data set on Cu(s-bqdi)$_2$ shows unambiguously that it belongs to the metal ion semi-benzoquinonediiminate complexes that, from an electrochemical point of view, are confirmed to be the counterparts of metal dithiolenes in the oxidative field; however the insertion of a d^9 metal centre into the diiminate square-planar environment enriches the properties of this class of compounds;

(ii) chemical oxidation of Cu(s-bqdi)$_2$ provides a compound with extremely promising electrical and magnetic properties.

Furthermore, electrical conductivity and magnetical data for Cu(s-bqdi)$_2$I$_5$ show that [M—N$_4$] open systems can be compared at least with [M—S$_4$] charge-transfer complexes. Nevertheless, structural order and stoichiometries, though basic requirements, are very far from their optimization. Attempts to grow crystals of Cu(s-bqdi)$_2$I$_5$ suitable for structural investigations and the characterization of similar charge-transfer complexes using paramagnetic counteranions are currently in progress in our laboratory.

Abstract—Some reactions of the μ-(α,ω)alkanediyl complexes of the type $[L(CO)_2M(CH_2)_nM(CO)_2L]$ with both nucleophiles and electrophiles have been investigated. Reaction of the di-iron compounds $[L(CO)_2Fe(CH_2)_nFe(CO)_2L]$ with neutral donor ligands (D) gives $[LD(CO)FeC(O)(CH_2)_nC(O)Fe(CO)DL]$ [where L = η^5-C_5H_4Me (Cp′), D = $PMePh_2$, PMe_2Ph or t-BuNC and n = 4 or 6; L = η^5-C_5Me_5 (Cp*), D = CO and n = 4]. Reactions of the di-iron compounds with SO_2 yield disulphinato derivatives $[L(CO)_2Fe(SO_2)(CH_2)_4(SO_2)Fe(CO)_2L]$ (L = Cp′ or Cp*). Halogens cause cleavage of the M—C bonds to give $LM(CO)_2X$ and $X(CH_2)_nX$ (M = Fe, L = Cp′ or Cp*, X = Br or I and n = 4–6; M = Ru, L = Cp, X = Br or I and n = 5). Reactions of the di-iron or diruthenium compounds with Ph_3CPF_6 yield the cationic alkene, alkyl complexes $[L(CO)_2M\{\mu$-$(C_nH_{2n-1})\}M(CO)_2L]PF_6$ (M = Fe, L = Cp or Cp* and n = 4 or 6; M = Ru, L = Cp and n = 5). The diruthenium complex $[Cp(CO)_2Ru(CH_2)_5Ru(CO)_2Cp]$ reacts with ligands (D) to give the monosubstituted monoacyl compound $[Cp(CO)_2Ru(CH_2)_5C(O)Ru(CO)DCp]$ and the disubstituted diacyl compound $[CpD(CO)RuC(O)(CH_2)_5C(O)Ru(CO)DCp]$ (D = PPh_3, $PMePh_2$ or PMe_2Ph). The reactions are compared with those found for the di-iron compounds $[Cp(CO)_2Fe(CH_2)_nFe(CO)_2Cp]$ as well as mononuclear alkyl analogues.

There is currently much interest in hydrocarbon-bridged dinuclear metal complexes.[1–4] We are particularly interested in trying to determine the factors that can affect the reactivity of complexes of the type $[L_mM(CH_2)_nML_m]$ (where L_mM is a metal with its associated ligands). A particular class of compounds of this type are the bis(cyclopentadienyl metal dicarbonyl) alkanediyl compounds $[L(CO)_2M(CH_2)_nM(CO)_2L]$. Here there is the opportunity to vary the metal (M), the cyclopentadienyl ligand (L) and the length of the polymethylene chain (n) and to see what effect changing these parameters has on the reactivity of the complexes.

We have previously reported the synthesis,[5] structure[6] and reactivity[7] of some of the complexes $[Cp(CO)_2Fe(CH_2)_nFe(CO)_2Cp]$ [where Cp = η^5-C_5H_5, η^5-C_5H_4Me (Cp′) and η^5-C_5Me_5 (Cp*)] as well as the ruthenium compounds $[Cp(CO)_2Ru(CH_2)_nRu(CO)_2Cp]$ (n = 5–10).[8] We now report results of our reactivity studies on some of these alkanediylbridged dinuclear complexes.

EXPERIMENTAL

All reactions were carried out in Schlenk tubes under an atmosphere of nitrogen. General experimental methods have been described previously.[7] IR spectra were recorded on a Perkin–Elmer 983 spectrophotometer and NMR spectra on a Brucker WH 90 or a Varian VXR 200 spectrometer using tetramethylsilane as standard (δ 0.00 ppm). The compound $[CpRu(CO)_2]_2$ was prepared by the method of Doherty and Knox.[9] $[Cp'Fe(CO)_2]_2$ and $[Cp^*Fe(CO)_2]_2$ were obtained from Strem. The alkanediyl compounds $[L(CO)_2Fe(CH_2)_n(CO)_2L]$

(L = Cp,[5] Cp′[10] or Cp*[10]) and $[Cp(CO)_2Ru(CH_2)_nRu(CO)_2Cp]$[8] were prepared as previously described. Yields and characterization data for the new compounds are given in Table 1.

Reactions with neutral donor ligands

(i) $[Cp'(CO)_2Fe(CH_2)_4Fe(CO)_2Cp']$ (**1**) *with tertiary phosphines.* A solution containing **1** (0.46 mmol) and PR_3 (0.92 mmol) in THF (15 cm^3) was heated under reflux (17 h for $PMePh_2$, 12 h for PMe_2Ph) until no further change was observed in the IR spectrum in the ν(CO) region. The solvent was removed under reduced pressure and the resulting residue extracted with hexane (30 cm^3), filtered, concentrated and cooled to give yellow–orange solids $[Cp'(CO)(PR_3)FeC(O)(CH_2)_4C(O)Fe(CO)$

[a] Calculated values in parentheses.
[b] Measured in CH_2Cl_2 unless otherwise stated.
[c] Measured in $CDCl_3$.
[d] Due to ν(CN).
[e] Measured in hexane.
[f] $H_A/H_{A'}$, $H_B/H_{B'}$ and H_C represent the geminal methylene protons of the alkyl chain.
[g] Signals occur as doublets due to ^{31}P coupling.
[h] Measured in $CHCl_3$.
[i] Measured in Nujol.
[j] Due to ν(SO)
[k] Measured in acetone-d_6.
* Data not obtained.

$(PR_3)Cp']$ (**2**) ($PR_3 = PMePh_2$) and (**3**) ($PR_3 = PMe_2Ph$).

(ii) $[Cp^*(CO)_2Fe(CH_2)_4Fe(CO)_2Cp^*]$ (**4**) *with* CO. A solution of **4** (0.05 g) in THF (6 cm^3) was placed in an autoclave which was then charged with CO (30 atm). The reaction mixture was stirred at room temperature for 23 h, after which time the gases were vented and the reaction mixture evaporated to dryness. The resulting solid was dissolved in CH_2Cl_2 and chromatographed on an alumina column. The first yellow band was identified as **4** (70%) and a second, bright yellow band gave the yellow solid diacyl compound **5**.

(iii) *Compound* **1** *with* t-BuNC. A solution containing **1** (0.10 g, 0.23 mmol) and t-BuNC (0.038 g, 0.46 mmol) in THF (10 cm^3) was heated under reflux until no further change occurred in the IR spectrum (43 h). The solvent was removed under reduced pressure and the residue extracted with hexane, filtered and the filtrate cooled to $-78°C$. A yellow–orange precipitate of **6** formed which melted to an oil below room temperature.

(iv) $[Cp'(CO)_2Fe(CH_2)_6Fe(CO)_2Cp']$ (**7**) *with* t-BuNC. In a similar way, the reaction of **7** (0.11 g, 0.24 mmol) with t-BuNC (0.04 g, 0.48 mmol) in THF (10 cm^3) gave **8** as an orange–yellow oil.

(v) $[Cp(CO)_2Fe(CH_2)_5Fe(CO)_2Cp]$ (**9**) *with* t-BuNC. In a similar way, the reaction of **9** (0.19 g, 0.45 mmol) with t-BuNC (0.074 g, 0.89 mmol) in THF (20 cm^3) (after 22 h) gave **10** as an orange–yellow oil.

Reaction of $Cp(CO)_2Ru(CH_2)_5Ru(CO)_2Cp]$ (**11**) with t-BuNC in refluxing xylene for 21 h gave $[Cp(CO)(t\text{-BuNC})Ru(CH_2)_5Ru(t\text{-BuNC})(CO)Cp]$ (20%), identified by its IR only; ν(CN) 2156 m and 2117 m, ν(CO) 1969 m cm^{-1}.

(vi) *Compound* **11** *with* PPh_3. Compound **11** (0.17, 0.33 mmol) and PPh_3 (0.17 g, 0.66 mmol) in xylene (15 cm^3) were heated under reflux for 165 h. The solvent was removed under reduced pressure and the residue taken up in CH_2Cl_2 and chromatographed on a Florisil column. Elution with CH_2Cl_2/hexane (1 : 1) gave a pale yellow band from which yellow microcrystals of $[Cp(CO)_2Ru(CH_2)_5C(O)Ru(CO)(PPh_3)Cp]$ (**12**) (0.07 g, 23%) were obtained. [Compound **12** was obtained in yields up to 46% on using shorter reaction times (17 h) with a 1 : 1 molar ratio of compound **11** : PPh_3]. Elution with CH_3OH gave a yellow band from which **13** was isolated as pale yellow crystals. Compounds **12** (31%) and **13** (14%) were obtained on refluxing **11** with PPh_3 (1 : 2) in CH_3CN for 10 days.

(vii) *Compound* **11** *with* $PMePh_2$. Similarly, from the reaction of **11** (0.25 g, 0.49 mmol) with $PMePh_2$ (0.20 g, 1.0 mmol) on refluxing in xylene (20 cm^3) for 92 h were isolated orange $[Cp(CO)_2Ru(CH_2)_5C(O)Ru(CO)(PMePh_2)Cp]$ (**14**) (0.03 g, 9%) and pale yellow microcrystals of **15**.

(viii) *Compound* **11** *with* PMe_2Ph. Similarly, the reaction of **11** (0.17 g, 0.32 mmol) with PMe_2Ph (0.10 g, 0.23 mmol) on refluxing in xylene (15 cm^3) for 21 h gave **16** as a yellow oil.

Reactions with sulphur dioxide

(i) *Compound* **1** *with* SO_2. A Carius tube was charged with **1** (0.10 g, 0.23 mmol) and liquid SO_2 (10 cm^3), sealed with its Teflon tap and the mixture stirred at room temperature for 21 h. The tube was opened and the SO_2 allowed to evaporate leaving a red–brown residue. This was extracted with $CHCl_3$, filtered and the filtrate cooled to $-15°C$ to give **17** as a yellow, microcrystalline solid.

(ii) *Compound* **4** *with* SO_2. In a similar way, reaction of **4** (0.06 g, 0.12 mmol) with liquid SO_2 (10 cm^3) gave, after 8 h at room temperature, compound **18** as yellow microcrystals.

Reactions with halogens

(i) *Compound* **1** *with* X_2 (X = Br *or* I). A solution of Br_2 (0.26 mmol) in THF (2 cm^3) was added to a solution of **1** (0.13 mmol) in THF (5 cm^3) and the red–brown reaction mixture was stirred at room temperature for 10 min. The solvent was removed under reduced pressure leaving a brown residue which was dissolved in CH_2Cl_2 and chromatographed on an alumina column made up with hexane. Elution with hexane gave a pale yellow band which resulted in an almost colourless oil on removal of the solvent. This was identified as $Br(CH_2)_4Br$ by comparison of its IR and ^1H NMR spectra with that of an authentic sample. Elution with CH_2Cl_2 gave a red band which yielded a dark red solid on removal of solvent, this solid showed identifical IR and ^1H NMR spectra to an authentic sample of $Cp'Fe(CO)_2Br$ (85%). Similar reactions of $[Cp'(CO)_2Fe(CH_2)_5Fe(CO)_2Cp']$ with X_2 yielded $X(CH_2)_5X$ and $Cp'Fe(CO)_2Br$ (76%) or $Cp'Fe(CO)_2I$ (69%), where X = Br or I, respectively.

(ii) *Compound* **4** *with* X_2 (X = Br *or* I). In a similar way, reaction of **4** with X_2 gave $X(CH_2)_4X$ and $Cp^*Fe(CO)_2Br$ (93%) and $Cp^*Fe(CO)_2I$ (80%), where X = Br or I, respectively. Similar reactions of $[Cp^*(CO)_2Fe(CH_2)_6Fe(CO)_2Cp^*]$ with X_2 gave $X(CH_2)_6X$ and $Cp^*Fe(CO)_2Br$ (73%) and $Cp^*Fe(CO)_2I$ (69%), where X = Br or I, respectively.

(iii) *Compound* **11** *with* X_2 (X = Br *or* I). In a similar way, reaction of **11** with X_2 gave $X(CH_2)_5X$ (> 90%) and $CpRu(CO)_2Br$ (91%) and $CpRu(CO)_2I$ (86%), where X = Br or I, respectively.

Reactions with trityl salt

(i) *Compound* **1** *with* Ph_3CPF_6. A solution of **1** (0.11 g, 0.24 mmol) in CH_2Cl_2 (5 cm^3) was added to a solution of Ph_3CPF_6 (0.093 g, 0.24 mmol) in dichloromethane (2 cm^3). The reaction mixture was stirred for 12 h at room temperature, the solution filtered and the filtrate concentrated. Addition of diethyl ether and cooling gave a fine, yellow solid which was filtered and washed with diethyl ether (3×5 cm^3) and dried to give $[Cp'(CO)_2Fe(CH_2CHCH_2CH_2)Fe(CO)_2Cp']^+PF_6^-$ (**19**) as yellow microcrystals.

(ii) *Compound* **7** *with* Ph_3CPF_6. Similarly, reaction of **7** (0.10 g, 0.21 mmol) with Ph_3CPF_6 (0.08 g, 0.21 mmol) in CH_2Cl_2 (7 cm^3) gave **20** as yellow microcrystals.

(iii) *Compound* **4** *with* Ph_3CPF_6. Similarly, reaction of **4** (0.07 g, 0.13 mmol) with Ph_3CPF_6 (0.05 g, 0.13 mmol) in CH_2Cl_2 (7 cm^3), after 3 h at room temperature, gave **21** as yellow microcrystals.

(iv) *Compound* **11** *with* Ph_3CPF_6. Ph_3CPF_6 (0.057 g, 0.147 mol) was added to a solution of **11** (0.05 g, 0.097 mmol) in CH_2Cl_2 (8 cm^3) and the solution stirred for 10 min at room temperature. The solvent was removed and the residue dissolved in a minimum of CH_2Cl_2. Addition of hexane to the solution gave fine, white microcrystals which were filtered, washed with hexane and dried to give $[Cp(CO)_2Ru(CH_2CHCH_2CH_2CH_2)Ru(CO)_2Cp]^+PF_6^-$ (**22**).

(v) *Compound* **9** *with* Ph_3CPF_6. Similarly, reaction of **9** (0.40 g, 0.94 mmol) with Ph_3CPF_6 (0.55 g, 1.42 mmol) in CH_2Cl_2 (10 cm^3), after 10 min at room temperature, gave **23** as yellow microcrystals. This is an improved procedure to that reported previously for this compound.[11]

RESULTS AND DISCUSSION

The reactions of the alkanediyl compounds with the neutral donor ligands (D) gave, in most cases, disubstituted diacyl compounds [eq. (1)]:

$$[L(CO)_2M(CH_2)_nM(CO)_2L] + 2D \longrightarrow \left[L(CO)DMC(=O)(CH_2)_nC(=O)MD(CO)L \right] \quad (1)$$

2 M = Fe, L = Cp′, D = $PMePh_2$, $n = 4$
3 M = Fe, L = Cp′, D = PMe_2Ph, $n = 4$
5 M = Fe, L = Cp*, D = CO, $n = 4$
6 M = Fe, L = Cp′, D = t-BuNC, $n = 4$
8 M = Fe, L = Cp′, D = t-BuNC, $n = 6$
10 M = Fe, L = Cp, D = t-BuNC, $n = 5$
13 M = Ru, L = Cp, D = PPh_3, $n = 5$
15 M = Ru, L = Cp, D = $PMePh_2$, $n = 5$
16 M = Ru, L = Cp, D = PMe_2Ph, $n = 5$.

From the reactions of $[Cp(CO)_2Ru(CH_2)_5Ru(CO)_2Cp]$ (**11**) with some ligands, the monosubstituted monoacyl compounds $[Cp(CO)_2Ru(CH_2)_5C(O)Ru(CO)DCp]$ (**12**, D = PPh_3 and **14**, D = $PMePh_2$) could also be isolated. The reaction of **11** with t-BuNC in refluxing xylene for 21 h gave a product which was partially characterized as $[Cp(CO)(t\text{-}BuNC)Ru(CH_2)_5Ru(t\text{-}BuNC)(CO)Cp]$; this disubstituted alkanediyl compound may be formed by decarbonylation of the diacyl species under the reaction conditions.

From these reactions of the alkanediyl complexes several general conclusions can be drawn:

(1) the reactions with neutral donor ligands usually lead to disubstituted, diacyl compounds;
(2) the reactions of the diruthenium compounds are much slower than their iron analogues;
(3) increasing the methyl substitution in the Cp ring decreases the reaction rate for steric and electronic reasons thus $C_5H_5 > C_5H_4Me \gg C_5Me_3$;
(4) stronger nucleophiles react faster.

From previous studies,[7] it has also been shown that the rates of similar ligand-induced migrating insertion reactions of $[Cp(CO)_2Fe(CH_2)_4Fe(CO)_2Cp]$ with PPh_3 increased with increasing polymethylene chain, presumably mainly due to the relief of steric crowding. However, this is not always the case since the reaction of $[Cp'(CO)_2Fe(CH_2)_4Fe(CO)_2Cp']$ with t-BuNC is slower for $n = 6$ than $n = 4$. It is also interesting to note that compounds $[L(CO)_2FeC(O)(CH_2)_4C(O)Fe(CO)_2L]$ (L = Cp or Cp*) are extremely reluctant to undergo decarbonylation; this may be, in part, for steric reasons since decarbonylation would place the two metals closer together. Similarly, it has previously been found that decarbonylation of $[(CO)_5MnC(O)(CH_2)_4C(O)Mn(CO)_5]$ is *slower* than for mononuclear $RMn(CO)_5$ (R = CH_3 or C_2H_5) but that reaction of $(CO)_5Mn(CH_2)_4Mn(CO)_5$ with PPh_3 is *faster* than for $RMn(CO)_5$

($R = CH_3$ or C_2H_5).[12] We also find that the rate of the reaction of $[Cp(CO)_2Ru(CH_2)_5Ru(CO)_2Cp]$ with PPh_3 is faster if the ligand concentration is higher; this may be a general result for $L_mM(CO)R$ and $[L_m(CO)M(CH_2)_nM(CO)L_m]$.

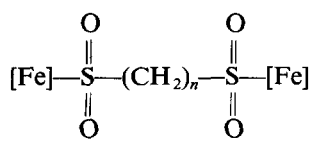
We also note that the reaction of $[Cp(CO)_2Ru(CH_2)_5Ru(CO)_2Cp]$ with PPh_3 to give CO insertion products occurs *faster* than for the mononuclear analogues $CpRu(CO)_2R$, with a five times excess of PPh_3 under similar conditions. It is interesting to note that the monosubstituted monoacyl products (e.g. **12**) have one chiral metal centre and the disubstituted diacyl products (e.g. **2**) have two. It has been shown that the chiral auxiliary $CpFe(CO)(PPh_3)$, in mononuclear complexes, is useful to effect stereospecific transformations.[13] It may be that complexes such as **2** will be useful for the synthesis of molecules with two chiral centres. The chirality of **13**, **15** and **16** is reflected in their ^1H and ^{13}C NMR spectra.

Since the insertion reaction into a metal–alkyl bond is a fundamental step in many catalytic reactions and because we have shown in the previous section that CO insertion can occur at both ends of the alkanediyl complexes, we were interested to see if SO_2 would also insert in these binuclear systems.[14] We thus investigated the reactions shown in eq. (2):

$$[L(CO)_2Fe(CH_2)_4Fe(CO)_2L] + 2SO_2 \longrightarrow [L(CO)_2Fe(SO_2)(CH_2)_4(SO_2)Fe(CO)_2L] \quad (2)$$

17 L = Cp′
18 L = Cp*.

The disulphinato products **17** and **18**, where SO_2 has inserted into both $Fe—CH_2$ bonds, were isolated as yellow, microcrystalline solids and characterized by the usual techniques (see Table 1). This reaction is similar to that reported for the complex $[Cp(CO)_2Fe(CH_2)_3Fe(CO)_2Cp]$ with SO_2.[15] All these reactions give the disulphinato complexes containing the group



(where [Fe] = metal and associated ligands). It is interesting to note that although the same *types* of products are obtained with Cp, Cp′ or Cp*, the rates of reactions with SO_2 follow the order Cp* > Cp′ > Cp, which is the same order as found for SO_2 insertion reactions of the mononuclear iron alkyl compound $[LFe(CO)_2CH_2Ph]$ (where L = Cp, Cp′ or Cp*).[16] Thus the rates of these reactions with SO_2 increase with increasing electron density on the iron.

The electrophilic cleavage reaction of metal–carbon bonds in mononuclear alkyl compounds is well-known.[17] We were interested to see how the binuclear alkanediyl compounds would react with halogens and particularly to see what effects, if any, there would be in changing the metal, the substituents on the cyclopentadienyl ring and the nature of the halogen.

The diruthenium compound $[Cp(CO)_2Ru(CH_2)_5Ru(CO)_2Cp]$ reacts with bromine or iodine according to eq. (3):

$$[L(CO)_2M(CH_2)_nM(CO)_2L] + 2X_2 \longrightarrow 2LM(CO)_2X + X(CH_2)_nX \quad (3)$$

M = Ru, L = Cp, $n = 5$, X = Br or I
M = Fe, L = Cp′, $n = 4$ or 5, X = Br or I
M = Fe, L = Cp*, $n = 4$ or 6, X = Br or I.

The diruthenium compound reacted rapidly at room temperature to give the cleavage products in high yield. No evidence was obtained for the intermediacy of any cationic intermediate as had been observed in the reactions of the similar di-iron compounds.[7]

The reactions of the Cp′ di-iron compounds similarly proceed rapidly at room temperature to give the cleavage products in high yields. These reactions appear to be independent of alkanediyl chain length. No haloalkyl intermediates were observed as was found with the Cp di-iron compounds, this may be a consequence of the Cp′ compounds reacting faster with halogens due to increased electron density on the metal. In agreement with this, the reactions of the Cp* di-iron alkanediyl compounds appear to proceed slightly faster than the Cp′ or Cp analogues.

The reactions of mononuclear $[CpFe(CO)_2R]$ with trityl salts (such as Ph_3CPF_6) are known to give cationic alkene species $[CpFe(CO)_2(alkene)]^+$[18,19] and binuclear compounds $[Cp(CO)_2Fe(CH_2)_nFe(CO)_2Cp]$ also give cationic species; $[Cp(CO)_2Fe(C_nH_{2n-1})Fe(CO)_2Cp]^+$ by hydride abstraction.[11,20,21] The di-iron alkene, alkyl cations

are thought to be good models for 1-alkene formation in the Fischer Tropsch reaction.[22] We were thus interested to see the effect of changing the metal, the substituents on the cyclopentadienyl rings, as well as the chain length.

The reactions investigated here all proceeded according to eq. (4) to give moderate to good yields of the dinuclear cationic alkene, alkyl complexes as air-stable, crystalline solids.

electrophiles follow the reverse order, thus the reactions with halogens are all fast but follow the order Cp* > Cp′ > Cp. Also, the reactions of the dinuclear ruthenium compounds with electrophiles are at least as fast, if not faster than their iron counterparts. Further experiments are underway to obtain quantitative information on these reactions.

$$[L(CO)_2M(CH_2)_nM(CO)_2L] + Ph_3CPF_6 \longrightarrow [L(CO)_2M(=CH_2)CH{-}(CH_2)_{n-2}M(CO)_2L]PF_6 \quad (4)$$

19 M = Fe, L = Cp′, $n = 4$
20 M = Fe, L = Cp′, $n = 6$.
21 M = Fe, L = Cp*, $n = 4$
22 M = Ru, L = Cp, $n = 5$
23 M = Fe, L = Cp, $n = 5$.

The di-iron complexes ***19***, ***20*** and ***23*** are pale yellow, **21** is yellow–orange and the diruthenium complex **22** is white. All these alkene, alkyl compounds show four strong ν(CO) bands in their IR spectra with the two high frequency bands corresponding to the cationic metal alkene end of the molecule and the two lower ν(CO) bands are due to the alkyl end of the complex. The reactions of the di-iron Cp* compounds appear to react faster with Ph_3CPF_6 than the Cp′ or Cp analogues.

CONCLUSIONS

From the reactions of the alkanediyl complexes that have been studied it is possible to make several generalizations:

(1) Changing the metal from iron to ruthenium and changing the ligands from Cp to Cp′ to Cp* in most cases does not change the *type* of products formed but it does significantly change the rates at which these products are formed. Similarly, the types of products are often analogous to those obtained for mononuclear alkyl compounds but again, the rates of the reactions, on a qualitative basis, are different.
(2) For the ligand induced migrating insertion reactions, the di-iron complexes react much faster than the diruthenium analogues. Also, increasing the methyl substitution of the cyclopentadienyl rings decreases the rates of these reactions with nucleophiles, thus the reactivity order is Cp > Cp′ ≫ Cp*.
(3) Reactions of the alkanediyl complexes with

Acknowledgements—We thank the University of Cape Town, FRD and Mobil for support, Johnson Matthey for a generous loan of ruthenium trichloride and SAR Knox for a kind donation of some $Ru_3(CO)_{12}$. We also thank Nazir Ahmed for synthesizing some of the $[CpRu(CO)_2]_2$.

PEROXO COMPLEXES OF ZIRCONIUM(IV), THORIUM(IV), MOLYBDENUM(VI), TUNGSTEN(VI) and URANIUM(VI) IONS CONTAINING A QUADRIDENTATE SNNS SCHIFF BASE

M. T. H. TARAFDER* and A. R. KHAN

Department of Chemistry, University of Rajshahi, Rajshahi, Bangladesh

(*Received* 14 *November* 1990; *accepted* 9 *January* 1991)

Abstract—New peroxo complexes of zirconium(IV), thorium(IV), molybdenum(VI), tungsten(VI) and uranium(VI) containing a quadridentate Schiff base, formed by the condensation of S-benzyldithiocarbazate and benzil, have been synthesized and characterized. The complexes have the general formulae $[M(O_2)(SNNS)]$ ($M = Zr^{IV}$ and Th^{IV}) and $[M^1(O)(O_2)(SNNS)]$ ($M^1 = Mo^{VI}$, W^{VI} and U^{VI}). These peroxo complexes were found to be inert towards oxidation. The size of the metals as well as the electronic effect derived from the quadridentate Schiff base influence the mode of coordination of the peroxo moiety. The frequency of the ν_1 mode of the $M(O_2)$ grouping decreases with an increase in the atomic number of the metals in a particular group and in the σ-donor electronic nature of the quadridentate Schiff base used.

Studies on peroxo complexes have received considerable attention in recent years[1–9] because many of these complexes are efficient stiochiometric or catalytic oxidants for organic and inorganic substrates. The reactivity of metal peroxides can be greatly modified by introducing metals of different sizes and ancillary ligands with different donor properties. In particular, peroxo complexes containing lighter metals, for instance, $[Zr(C_5H_5NCOO)_2(O_2)]$ were kinetically stable towards olefinic compounds,[6] whereas the analogous complex of thorium[5] was as an efficient oxidant. The coordination of nucleophilic substrates to zirconium, forming seven-coordinate intermediates prior to oxygen transfer, is not favourable, whereas six-coordinate thorium can adopt an expanded coordination shell very readily. Also, peroxo complexes containing monodentate and bidentate auxiliary ligands were found to undergo oxygen transfer reactions,[1–9] however, those containing tridentate and quadridentate ligands were inert towards oxidation reactions.[5,10,11] We are interested in extending such a study to new peroxo complexes of different elements of groups 4A and 6A containing nitrogen–sulphur donor ligands. We reported earlier a series of peroxo complexes containing a bidentate nitrogen–sulphur donor ligand.[8] No attempt appears to have been made so far to isolate peroxo complexes of transition metals containing quadridentate S,N,N,S ligands. We present here the synthesis of these complexes and their possible attempted oxygen transfer reactions. An attempt has also been made to study the influence of the size of the metal ions and the electronic effect derived from the quadridentate Schiff base on the ν_1(O—O) modes of the complexes in their IR spectra.

EXPERIMENTAL

Reagents

All chemicals used were reagent grade and were used as supplied by Merck.

Physical measurements and elemental analyses

IR spectra (as KBr pellets) were recorded on a Pye–Unicam SP3-300 IR spectrophotometer. Conductivities of 10^{-3} M solutions in dimethyl sulphoxide (DMSO) were measured at 25°C using a WPA CM35 conductivity meter and dip-type cell with platinized electrodes.

Carbon, hydrogen and nitrogen analyses were carried out by Microanalytical Services at the University of St Andrews, Scotland.

* Author to whom correspondence should be addressed.

Preparation of the Schiff base

S-benzyldithiocarbazate, $NH_2NHCSSCH_2C_6H_5$, was prepared by the literature method[12] and its purity checked by elemental analyses, m.p. 125°C.

A solution of S-benzyldithiocarbazate (11.2 g, 0.0564 mol) in absolute ethanol (300 cm^3) was added to a solution of benzil (3.9 g, 0.0188 mol) in the same solvent (100 cm^3). The mixture was refluxed for 6 h, and the yellow crystals which settled on cooling were separated out and washed with ethanol, yield 1.2 g, m.p. 168°C (Found: C, 63.2; H, 4.6; N, 9.8. $C_{30}H_{26}N_4S_4$ requires: C, 63.2; H, 4.6; N, 9.8%).

Preparation of the complexes: general method for the preparation of $[M(O_2)(SNNS)]$ [M = Zr^{IV} (**1**) and Th^{IV} (**2**); SNNS = $(C_{30}H_{24}N_4S_4)^{2-}$]

The Schiff base $C_{30}H_{26}N_4S_4$ (0.0002 mol) was added to a solution of potassium hydroxide (0.0004 mol) in 30% H_2O_2 (20 cm^3). The solution was heated for 5 min, filtered and to the filtrate was added, with stirring, a solution of $M(NO_3)_4 \cdot 4H_2O$ (0.0002 mol) in water (15 cm^3). The resulting precipitate which separated out was filtered, washed several times with water and dried *in vacuo* over P_4O_{10}.

Preparation of $[M(O)(O_2)(SNNS)]$ [M = Mo^{VI} (**3**) and W^{VI} (**4**)]

The Schiff base $C_{30}H_{26}N_4S_4$ (0.005 mol) was added to a solution of potassium hydroxide (0.01 mol) in 30% H_2O_2 (100 cm^3). The solution was heated for 5 min, filtered and to the filtrate was added, with stirring, a solution of MO_3 (M = Mo^{VI} and W^{VI}) (0.005 mol) in 30% H_2O_2 (60 cm^3). The resulting precipitate was filtered, washed successively with water and ether and stored.

Preparation of $[U(O)(O_2)(SNNS)]$ (**5**)

The Schiff base $C_{30}H_{26}N_4S_4$ (0.005 mol) was dissolved in a solution of potassium hydroxide (0.01 mol) in 30% H_2O_2 (100 cm^3). The solution was heated for 5 min, filtered and to the filtrate was added, a solution of $UO_2(NO_3)_2 \cdot 6H_2O$ (0.005 mol) in water (50 cm^3). The solution was boiled and cooled. The resulting precipitate was filtered, washed successively with water and ether and stored.

Attempted reactions of **1** *and* **2** *with allyl alcohol and* **3** *and* **5** *with triphenylphosphine and triphenylarsine, respectively*

Refluxing **1** with allyl alcohol in a 1:1 molar ratio in THF medium for 48 h failed to produce any reaction; **1** was recovered unchanged.

Refluxing **2** with allyl alcohol in the presence of a large excess of 30% H_2O_2 in dioxane medium for 48 h at 90°C also failed to produce any reaction; **2** was recovered unchanged.

Refluxing **3** and **5** with equimolar quantities of triphenylphosphine and triphenylarsine, respectively, in THF for 48 h also failed to produce any reaction; **3** and **5** were recovered unchanged.

RESULTS AND DISCUSSION

Elemental analyses and conductivity data for the complexes are presented in Table 1. The complexes are non-electrolytes in solution suggesting that the anions are covalently bonded in all the cases. The mass spectrum of the Schiff base $C_{30}H_{26}N_4S_4$ does not display the molecular ion peak but shows other diagnostic peaks at *m/z* 285, 211, 149, 105, 77, 51

(Ib)

and 28. The Schiff base **I** can exist in the thioketo form (**Ia**) or in enethiol form (**Ib**) or as a mixture of both. The IR spectrum of the Schiff base does not display ν(SH) at *ca* 2570 cm^{-1} but exhibits ν(NH), ν(C=N) and ν(C=S) modes (Table 2), indicating that in the solid state the Schiff base remains in the thioketo form (**Ia**). Its ^1H NMR spectrum in $CDCl_3$ exhibits signals at 4.36, 7.5 and 9.89 ppm corresponding to the methylene, phenyl and —NH— protons, respectively. The ^1H NMR spectrum does not display any peak attributable to a S—H proton. Therefore the Schiff base remains predominantly in the thioketo form (**Ia**) in $CDCl_3$. The Schiff base, however, forms complexes only in basic medium. Attempts to prepare complexes from a neutral medium were unsuccessful. This suggests that the nucleophilicity of the ligand is greatly enhanced in alkaline medium probably due to the creation of an anionic site *in situ*.[12-16] The thione group is relatively unstable in the monomeric form and undergoes a thione (**Ia**)⇌thiol (**Ib**) equilibrium.[17] The deprotonation and consequent formation of an anionic site *in situ* is favoured by the basicity of the medium and the ν(N—H) and ν(C=S) bands of the free ligand disappear in the spectra of the complexes suggesting that the ligand is coordinated in the deprotonated thiol form. This is also evident from the appearance of ν(C—S)[18,19] bands at 710–725 cm^{-1} and ν(M—S) bands[8,14,15,20] at 255–270 cm^{-1} (Table 2) in the IR spectra of the complexes. The ν(C=N) band of the free Schiff base is shifted to lower frequencies in the complexes (Table 2) suggesting that the azomethine nitrogen is coordinated. A molecular model shows that the α-nitrogen (imino nitrogen) is not bonded due to considerable steric strain.[12-16] The far-IR spectra of the complexes exhibit bands in the region 300–325 cm^{-1} (Table 2) which are tentatively attributed to ν(M—N) modes.[4-8,20-22] Complexes **3–5** display bands at 915–925 cm^{-1} assignable to ν(M=O) modes.[4,9,11] The metal peroxo grouping (local C_{2v} symmetry) gives rise to three IR- and Raman-active vibrational modes. These are predominantly O—O stretching (ν_1), the symmetric M—O stretch (ν_2) and the antisymmetric M—O stretch (ν_3). The characteristic ν_1(O—O) modes of **1–5** appear at 800–840 cm^{-1} (Table 2). In particular, the ν_1 mode decreases from the zirconium complex (**1**, 820 cm^{-1}) to the corresponding thorium complex (**2**, 810 cm^{-1}). This is also discernible in the cases of peroxo complexes of the elements of group 6A, there is a decrease in ν_1 upon passing from the molybdenum complex (**3**, 840 cm^{-1}) to the corresponding tungsten complex (**4**, 830 cm^{-1}), which is further decreased in the uranium peroxo complexes (**5**, 800 cm^{-1}). The present data thus clearly reveal that for the $M(O_2)$ grouping, the ν_1(O—O) modes decrease with an increase in the atomic number of the metals in a particular group. In the present examples, ν_3 and ν_2 modes appear at 620–650 and 530–550 cm^{-1}, respectively. It is noteworthy that the ν_1 mode of the present peroxo complexes of zirconium, thorium, molybdenum, tungsten and uranium appear at lower frequencies than the peroxo complexes of these metals containing monodentate, bidentate and tridentate ancillary ligands.[4-11] This is pre-

sumably due to greater charge neutralization of the metal centres by the quadridentate, dinegative σ-donor ligand, causing a weaker coulombic interaction in the M^{n+}—O_2^{2-} moiety ($n = 4$ or 6).

Reactivity

The present peroxo complexes were not found to undergo oxygen transfer reactions. Complexes **1** and **2** failed to oxidize allyl alcohol even when refluxing at 90°C was continued for 48 h. Complexes **3** and **5** were also unreactive towards phosphine and arsine. These negative results outline the enhanced stability of the metal peroxo moiety in the presence of the quadridentate chelating ligand which precludes oxygen transfer reactions. Similar results were also found for the peroxo complexes containing tridentate and quadridentate ligands.[4,6,9,10]

SYNTHESIS, CHARACTERIZATION AND STEREOCHEMICAL PREFERENCES OF COBALT(III) TERNARY AMINO ACID COMPLEXES CONTAINING *N*-((2-PYRIDYL)METHYL)-2-((2-AMINOETHYL)THIO)ACETAMIDE, A STEREOSPECIFIC LINEAR NSNN TETRADENTATE LIGAND

PAUL J. TOSCANO,* KIMBERLY A. BELSKY, TZE-CHEN HSIEH, TERRENCE NICHOLSON and JON ZUBIETA

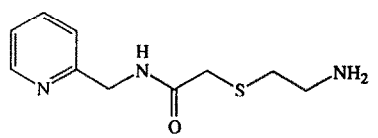
Department of Chemistry, State University of New York at Albany, Albany, NY 12222, U.S.A.

(*Received* 11 *October* 1990; *accepted* 14 *January* 1991)

Abstract—The preparation, isolation and characterization of *cis*-β-[Co(pyge)(AA)]PF_6 [pygeH = *N*-((2-pyridyl)methyl)-2-((2-aminoethyl)thio)acetamide; AA = gly, L-ala, L-ile, L-leu, sarcosine (sar), α-aminoisobutyric acid (aiba) and β-ala] are described. ^1H and ^{13}C NMR spectra of the new cobalt complexes strongly suggest that one geometrical isomer is obtained with very high stereoselectivity. β_1-[Co(pyge)(gly)]$PF_6 \cdot 2H_2O$ (**1**) crystallized in the monoclinic space group $P2_1/c$ with $a = 14.518(2)$, $b = 14.583(2)$, $c = 19.783(3)$ Å, $\beta = 98.51(1)°$ and $Z = 8$ and was refined to $R = 0.080$. In both of the two independent cations in the asymmetric unit, the gly chelate had the β_1 configuration with respect to the pyge ligand. The complex β-[Co(pyge)(Cl)(NO_2)]$\cdot H_2O$ was prepared; recrystallization of this complex provided single crystals of β-[Co(pyge)(Cl)(NO_2)]$\cdot$[Co(pyge)$(NO_2)_2$]$\cdot 2H_2O$ (**2**). Complex **2** crystallized in the triclinic space group $P\bar{1}$ with $a = 7.850(1)$, $b = 13.346(2)$, $c = 15.998(2)$ Å, $\alpha = 106.45(1)$, $\beta = 99.07(1)$, $\gamma = 104.78(1)°$ and $Z = 2$, and was refined to $R = 0.052$. The chlorine ligand was found to be *trans* to the amido donor of the pyge ligand, suggesting that the β_1 configuration found for the amino acid complexes stems from kinetically-based substitutions. The complex β-[Co(pyge)Cl_2]$\cdot H_2O$ promotes the hydrolysis of amide and ester bonds of dipeptides and amino acid esters to again give β_1-[Co(pyge)(AA)]PF_6. Finally, evidence is presented for sar and L-ala, that the diastereomeric β_1 complex that predominates at equilibrium is the isomer with the ligand methyl group hydrophobically interacting with the pyridyl moiety of the pyge ligand.

Studies involving the chelation and coordination of amino acids and related ligands to octahedral cobalt (III) centres containing a flexible, linear tetradentate ligand or two bidentate ligands have been an ongoing area of active research.[1–6] Major topics of investigation have included delineation of the factors governing stereoselectivity in the coordination of the optically active amino acids[3,7,8] and activation of the carbonyl or other functionalities of amino acid esters, amides and peptides for hydrolysis,[1,4,9,10] substitution[11] and synthetic reactions.[12]

Recently, we along with others have described the synthesis of *N*-((2-pyridyl)methyl)-2-((2-aminoethyl)thio)acetamide (pygeH).[13–15] Previous studies have demonstrated that complexes of the type



pygeH

$CoL(NO_2)_2$, where L is a flexible, linear NSNN tetradentate ligand that has internal thioether and deprotonated amido nitrogen donor atoms and that coordinates to give three five-membered chelate rings such as pyge, exist in the solid state in the

*Author to whom correspondence should be addressed.

cis-β (unsymmetrical *cis*) geometry.[13,14,16] Further evidence strongly suggests that only the *cis*-β configuration is found for $[Co(pyge)(NO_2)_2]$ in solution.[13,14] More importantly, chemical interconversions of β-$[Co(pyge)(NO_2)_2]$ that yield new complexes of composition $[Co(pyge)X_2]$, where X_2 is two monodentate ligands or one symmetrical bidentate ligand, give only one spectroscopically detectable geometrical isomer.[14] In these cases, the geometry is almost certainly *cis*-β rather than *cis*-α (symmetrical *cis*) or *trans*, since the original *cis*-β dinitrocobalt(III) complex can be recovered via appropriate reaction steps.[14] The apparent stereospecificity for adoption of the *cis*-β geometry by $[Co(pyge)X_2]$ complexes presumably stems from the preference of sulphur for pyramidal coordination when it is at the junction of two five-membered chelate rings flanked by nitrogen (or oxygen) donors at one of the other termini,[17,18] coupled with the planarity enforced about the deprotonated amido donor.[19]

In this contribution we report on our studies involving the synthesis and isolation of complexes of the type β-$[Co(pyge)(AA)]PF_6$, where AA is the anion of an amino acid, from the readily available β-$[Co(pyge)Cl_2]\cdot H_2O$.[14] Since the amino acidato chelates are unsymmetrical, two geometrical configurations are possible for these bidentate ligands which are designated as β_1 and β_2 (see Fig. 1).[20] Thus, for ligands such as gly that contain no asymmetric centres, it is possible to prepare two pairs of enantiomeric complexes that can be designated as Δ,Λ-β_1 and Δ,Λ-β_2.* On the other hand, a chiral amino acid such as L-ala can give rise to four diastereomeric complexes, namely Δ_L-β_1, Λ_L-β_1, Δ_L-β_2 and Λ_L-β_2, due to the additional asymmetric carbon atom.† An *N*-alkylated amino acid such as sarcosine (sar) can also give rise to additional stereoisomers due to the asymmetric coordinated amino group. We will present spectroscopic, as well as crystallographic, evidence that the number of isomeric complexes actually isolated is limited by the kinetic considerations involving the special nature of the tetradentate pyge ligand. We also present results concerning stereochemical preferences within some of the isolated isomeric complexes (AA = sar, L-ala) under equilibrium conditions, as well as evidence that $[Co(pyge)Cl_2]\cdot H_2O$ facilely promotes the cleavage of amide and ester bonds of α-amino carbonyl compounds.

* The cobalt centre itself is asymmetric due to the sense in which the tetradentate ligand is wrapped around the metal (see Fig. 1).

† Here we employ the subscript L to indicate the chirality of the asymmetric carbon atom of the amino acid ligand.

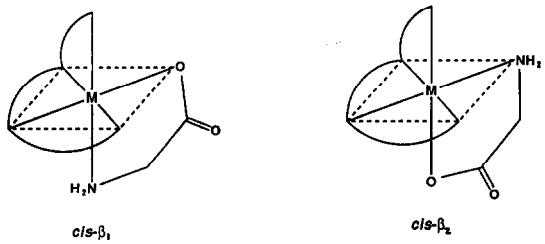


Fig. 1. The two possible geometrical configurations for a chelating gly ligand in a *cis*-β octahedral complex. Only one enantiomer (Δ) is depicted for each configuration. The mirror images would then have the Λ designation.

EXPERIMENTAL

Materials and methods

^1H and ^{13}C NMR spectra were obtained on a Varian XL-300 spectrometer at 299.943 and 75.429 MHz, respectively. Spectra obtained in D_2O solution were referenced to 3-(trimethylsilyl)propionic acid, sodium salt (^1H) or dioxane (^{13}C). Spectra obtained in Me_2SO-d_6 solution were referenced to Me_4Si. The NMR spectra for complex cations having amino acidato ligands with asymmetric centres are complicated, since these compounds are generally isolated as equal mixtures of two diastereomers (see Results and Discussion). If resonances for the same group in the ^1H NMR spectrum of the two diastereomers are sufficiently well separated, then the chemical shift values are presented as pairs next to the assignment. For overlapping or indistinguishable resonances, only one chemical shift value (or range of shift values) is provided. NMR samples for ^1H–^1H NOE experiments were degassed by three freeze–pump–thaw cycles. Visible absorption spectra of dilute aqueous or Me_2SO solutions were recorded on either Varian DMS-80 or Shimadzu UV-160 spectrophotometers at ambient temperature. Molar absorptivity coefficients are given in units of $mol^{-1}\ dm^3\ cm^{-1}$. Elemental analyses were determined by Atlantic Microlab, Inc. (Norcross, GA).

Preparation of compounds

Unless otherwise noted, all starting materials and solvents were obtained from standard sources and used without further purification.

cis-β_1-$[Co(pyge)(AA)]PF_6$ [AA = gly, L-ala, L-val, L-ile, L-leu, β-ala, sarcosine (sar), α-aminoisobutyric acid (aiba)]

A general preparation for the amino acidato complexes will be given. The complex β-$[Co(pyge)Cl_2]\cdot H_2O$[14] (0.75 g, 2.0 mmol) was dissolved in

water (10 cm^3). The free amino acid (2.2 mmol; except for sar, where 5.2 mmol was employed) was added and the pH adjusted to 7.6–7.8 by dropwise addition of NaOH solution (2.5 M). The purple reaction mixture was heated at 50–60°C until a deep red–orange colour was attained (typically 0.5–3.0 h, depending upon the particular AA). After filtration, the filtrate was cooled and NH_4PF_6 (0.49 g, 3.0 mmol) was added. (If a small amount of dull purplish maroon material precipitated at this point, the mixture was refiltered.) Upon slow evaporation, the solution deposited deep red to red–orange, microcrystalline material. Crude yields ranged between 50–70%. Recrystallization from a minimum volume of hot water gave pure compounds. Analytical and spectroscopic data for specific complexes follow.

For AA = gly, the complex was anhydrous. Found: C, 28.6; H, 3.6; N, 11.1. Calc. for $C_{12}H_{18}F_6N_4O_3PSCo$: C, 28.7; H, 3.6; N, 11.2%. Vis (H_2O): λ_{max} 499 nm (ε 420). Vis (Me_2SO): λ_{max} 508 nm (ε 460). ^1H NMR (D_2O): δ 8.36 (d, 1H, H-6 py), 8.14 (t, 1H, H-4 py), 7.70 (m, 2H, H-3 and H-5 py), 4.69 (br s, 2H, $pyCH_2$), 4.08 (d, 1H, SCH_2CO), 3.61 (d, 1H, SCH_2CO), 3.54 (d, 1H, gly—CH_2), 3.24 (d, 1H, gly—CH_2), 2.65–3.15 (complex m, 4H, SCH_2CH_2N). ^{13}C (D_2O): δ 186.47, 178.90, 167.10, 148.95, 141.89, 126.43, 124.45, 53.53, 46.88, 43.59, 39.61, 39.46. Crystals suitable for X-ray diffraction studies were grown by slow evaporation of a saturated aqueous solution of the complex.

For AA = L-ala, the complex was a dihydrate. Found: C, 28.4; H, 4.2; N, 10.0. Calc. for $C_{13}H_{20}F_6N_4O_3PSCo \cdot 2H_2O$: C, 28.3; H, 4.4; N, 10.1%. Vis (H_2O): λ_{max} 500 nm (ε 400). Vis (Me_2SO): λ_{max} 510 nm (ε 530). ^1H NMR (D_2O): δ (8.32, 8.29) (d, 1H, H-6 py), 8.14 (t, 1H, H-4 py), 7.69 (m, 2H, H-3 and H-5 py), (4.72, 4.69) (br s, 2H, $pyCH_2$), 4.08 (d, 1H, SCH_2CO), (3.76, 3.32) (q, 1H, ala—CH), (3.61, 3.59) (d, 1H, SCH_2CO), 2.65–3.15 (complex m, 4H, SCH_2CH_2N), (1.40, 1.24) (d, 3H, ala—CH_3). ^{13}C (D_2O): δ (188.29, 187.63), 179.06, 178.92), (167.23, 167.16), (148.85, 148.61), 141.86, (126.52, 126.44), (124.51, 124.43), (54.92, 53.58), 53.58 (accidental equivalence of $pyCH_2$ with L-ala—CH), (43.49, 43.35), (39.71, 39.54). (39.54, 39.49), (18.76, 18.34).

For AA = L-val, the complex had three and a half water molecules of hydration. Found: C, 29.3; H, 4.7; N, 9.3. Calc. for $C_{15}H_{24}F_6N_4O_3PSCo \cdot 3.5H_2O$: C, 29.7; H, 5.1; N, 9.2%. Vis (H_2O): λ_{max} 500 nm (ε 430). Vis (Me_2SO): λ_{max} 506 nm (ε 530). ^1H NMR (D_2O): δ (8.32, 8.25) (d, 1H, H-6 py), 8.14 (t, 1H, H-4 py), 7.68 (m, 2H, H-3 and H-5 py), (4.74, 4.72) (br s, 2H, $pyCH_2$), (4.17, 4.15) (d, 1H, SCH_2CO), (3.67, 3.17) (d, 1H, val—NCH), (3.59, 3.57) (d, 1H, SCH_2CO), 2.65–3.15 (complex m, 4H, SCH_2CH_2N), 2.23 (m, 1H, val—iPrCH), (0.97, 0.94, 0.92, 0.60) (d, 6H, val—CH_3). ^{13}C (D_2O): δ (187.23, 186.81), (179.15, 179.04), (167.60, 167.45), (148.78, 148.63), (141.93, 141.85), (126.43, 126.27), (124.62, 124.40), (64.47, 62.95), 53.72 (br), (43.44, 43.39), (39.72, 39.49), (39.49, 39.31), (30.98, 30.81), (18.60, 18.50), (16.33, 15.83).

For AA = L-ile, the complex was a dihydrate. Found: C, 32.6; H, 4.7; N, 9.2. Calc. for $C_{16}H_{26}F_6N_4O_3PSCo \cdot 2H_2O$: C, 32.3; H, 5.1; N, 9.4%. Vis (H_2O): λ_{max} 501 nm (ε 430). Vis (Me_2SO): λ_{max} 508 nm (ε 460). ^1H NMR (D_2O): δ (8.34, 8.24) (d, 1H, H-6 py), 8.14 (t, 1H, H-4 py), 7.69 (m, 2H, H-3 and H-5 py), (4.74, 4.72) (br s, 2H, $pyCH_2$), (4.16, 4.14) (d, 1H, SCH_2CO), (3.70, 3.19) (d, 1H, ile—NCH), (3.59, 3.57) (d, 1H, SCH_2CO), 2.65–3.15 (complex m, 4H, SCH_2CH_2N), 1.92 (m, 1H, ile—sBuCH), 1.33 (m, 2H, ile—$sBuCH_2$), 0.75–1.00 (overlapping d and t, 6H, ile—CH_3). ^{13}C (D_2O): δ (187.30, 186.76), (179.11, 179.01), (167.57, 167.45), (148.79, 148.56), (141.89, 141.85), (126.41, 126.24), (124.60, 124.35), (64.58, 62.89), 53.70 (br), 43.55 (br), (39.70, 39.53), (39.43, 39.35), (38.15, 38.06), (24.51, 23.93), (15.50, 15.05), (12.32, 12.06).

For AA = L-leu, the complex was a monohydrate. Found: C, 33.0; H, 4.8; N, 9.7. Calc. for $C_{16}H_{26}F_6N_4O_3PSCo \cdot H_2O$: C, 33.3; H, 4.9; N, 9.7%. Vis (H_2O): λ_{max} 501 nm (ε 500). Vis (Me_2SO): λ_{max} 508 nm (ε 500). ^1H NMR (D_2O): δ (8.31, 8.29) (d, 1H, H-6 py), 8.14 (m, 1H, H-4 py), 7.69 (m, 2H, H-3 and H-5 py), (4.73, 4.71) (br s, 2H, $pyCH_2$), (4.14, 4.13) (d, 1H, SCH_2CO), (3.65, 3.21) (d of d, 1H, leu—NCH), (3.59, 3.57) (d, 1H, SCH_2CO), 2.65–3.15 (complex m, 4H, SCH_2CH_2N), 1.25–1.85 (complex m, 3H, leu—CH_2 and leu—iPrCH), (0.90, 0.87, 0.82, 0.79) (d, 6H, leu—CH_3). ^{13}C (D_2O): δ (188.51, 187.96), (179.13, 179.01), 167.36, (148.70, 148.54), 141.82, (126.44, 126.41), (124.55, 124.46), (57.30, 56.05), 53.62, (43.39, 43.29), (43.14, 42.35), 39.40–39.60 (broadened manifold of four ill-resolved resonances), (24.62, 24.42), (23.19, 23.11), (20.85, 20.79).

For AA = β-ala, the complex was a dihydrate. Found: C, 28.0; H, 3.9; N, 10.3. Calc. for $C_{13}H_{20}F_6N_4O_3PSCo \cdot 2H_2O$: C, 28.3; H, 4.4; N, 10.1%. Vis (H_2O): λ_{max} 502 nm (ε 460). Vis (Me_2SO): λ_{max} 509 nm (ε 460). ^1H NMR (D_2O): δ 8.37 (d, 1H, H-6 py), 8.15 (t, 1H, H-4 py), 7.70 (m, 2H, H-3 and H-5 py), 4.67 (s, 2H, $pyCH_2$), 4.05 (d, 1H, SCH_2CO), 3.59 (d, 1H, SCH_2CO), 2.45–3.15 (complex m, 8H, SCH_2CH_2N and ala—CH_2). ^{13}C (D_2O): δ 182.31, 178.81, 166.93, 149.71, 141.85, 126.32, 124.48, 53.50, 43.80, 39.57, 39.33, 39.26, 34.59.

For AA = sar, the complex was a trihydrate. Found: C, 27.1; H, 4.2; N, 10.1. Calc. for $C_{13}H_{20}F_6N_4O_3PSCo \cdot 3H_2O$: C, 27.4; H, 4.6; N, 9.8%. Vis (H_2O): λ_{max} 503 nm (ε 430). Vis (Me_2SO): λ_{max} 510 nm (ε 500). The isolated complex was a mixture (14 : 86) of two diastereomers due to stereochemistry about the coordinated methylamino group of sar. ^{1}H NMR for the major isomer (D_2O): δ 8.41 (d, 1H, H-6 py), 8.21 (t, 1H, H-4 py), 7.77 (m, 2H, H-3 and H-5 py), 4.84 (br s, 2H, pyCH_2), 4.13 (d, 1H, SCH_2CO), 3.63 (d, 1H, SCH_2CO), 3.63 (d, 1H, gly—CH_2), 3.12 (d, 1H, gly—CH_2), 2.65–3.15 (complex m, 4H, SCH_2CH_2N), 1.66 (s, 3H, NCH_3). Most of the ^{1}H resonances for the minor isomer were either too weak to accurately determine the chemical shifts or overlapping those of the major isomer. However, the NCH_3 resonance was easily observed at 2.73 ppm. ^{13}C NMR of the major isomer (D_2O): δ 183.89, 178.94, 167.02, 149.13, 142.09, 126.63, 124.50, 58.46, 53.43, 43.92, 40.10, 39.22, 37.47. ^{13}C NMR of the minor isomer (D_2O): δ 184.60, 179.03, 167.15, 149.21, 142.09, 126.73, 124.87, 57.46, 53.34, 43.97, 39.50, 39.10, 38.68.

For AA = aiba, the complex was a dihydrate. Found: C, 29.8; H, 4.3; N, 9.9. Calc. for $C_{14}H_{22}F_6N_4O_3PSCo \cdot 2H_2O$: C, 29.7; H, 4.6; N, 9.9%. Vis (H_2O): λ_{max} 504 nm (ε 510). Vis (Me_2SO): λ_{max} 512 nm (ε 540). ^{1}H NMR (D_2O): δ 8.32 (d, 1H, H-6 py), 8.16 (t, 1H, H-4 py), 7.71 (m, 2H, H-3 and H-5 py), 4.72 (br s, 2H, pyCH_2), 4.12 (d, 1H, SCH_2CO), 3.60 (d, 1H, SCH_2CO), 2.65–3.15 (complex m, 4H, SCH_2CH_2N), 1.50 (s, 3H, aiba—CH_3), 1.17 (s, 3H, aiba—CH_3). ^{13}C (D_2O): δ 190.81, 179.05, 167.57, 148.54, 141.92, 126.46, 124.58, 60.62, 53.71, 43.23, 39.68, 39.54, 27.60, 26.84.

β-[Co(pyge)(Cl)(NO_2)] · H_2O

A solution of $NaNO_2$ (0.092 g, 1.33 mmol) was added to a solution of β-[Co(pyge)Cl_2] · H_2O[14] (0.50 g, 1.33 mmol) in water (8 cm^3). After stirring for 10 min, the product began to precipitate. After 1 h, the rose-coloured product (0.093 g, 18% based on the product being a monohydrate) was collected and air-dried. Found: C, 31.5; H, 3.9; N, 14.3. Calc. for $C_{10}H_{14}ClN_4O_3SCo \cdot H_2O$: C, 31.4; H, 4.2; N, 14.6%. ^{1}H NMR (Me_2SO-d_6): δ 9.17 (d, 1H, H-6 py), 8.05 (t, 1H, H-4 py), 7.64 (t, 1H, H-3 py), 7.60 (d, 1H, H-5 py), 4.51 (AB q, 2H, pyCH_2), 4.34 (br s, 1H, NH), 3.85 (br s, 1H, NH), 3.80 (d, 1H, SCH_2CO), 3.44 (d, 1H, SCH_2CO), 2.63 (complex m, 4H, SCH_2CH_2N). ^{13}C NMR (Me_2SO-d_6): δ 176.40, 166.72, 150.19, 138.70, 123.37, 121.79, 52.96, 43.33, 39.48, 36.58.

Crystallization of β-[Co(pyge)(Cl)(NO_2)] · [Co(pyge)(NO_2)$_2$] · $2H_2O$ (**2**)

β-[Co(pyge)(Cl)(NO_2)] · H_2O had limited solubility in water at room temperature; however, dissolution occurred readily in warm (60°C) water. Slow evaporation of a saturated aqueous solution gave dark maroon needles. The ^{1}H NMR spectrum of the crystals in Me_2SO-d_6 was more complex than that of the starting material; the diagnostic H-6 py (*ortho*-hydrogen of the pyridyl group of the pyge ligand) region suggested that the crystals consisted of equal parts β-[Co(pyge)(Cl)(NO_2)] (doublet at δ 9.17) and another cobalt complex, that was likely to be β-[Co(pyge)(NO_2)$_2$] (doublet at δ 8.73).[13] The ^{13}C NMR spectrum (Me_2SO-d_6) of the crystals confirmed this assignment for **2**: in addition to resonances that are attributable to β-[Co(pyge)(Cl)(NO_2)] having the same relative configuration of Cl and NO_2 ligands as in the original starting material before the recrystallization, resonances occurred at δ 175.59, 167.21, 150.38, 138.96, 123.70, 122.17, 52.74, 43.69 and 36.88, in good agreement with literature values for β-[Co(pyge)(NO_2)$_2$].[14]

Promotion of the hydrolysis of amide and ester bonds by β-[Co(pyge)Cl_2] · H_2O

The experiments involving glycine methyl ester, glycylglycine (gly–gly) and L-alanylglycine (L-ala–gly) were conducted in exactly the same fashion as for the preparation of β_1-[Co(pyge)(AA)]PF_6 reported above, except that the above three compounds were substituted for the amino acid. For the first two compounds, the isolated complex had visible, ^{1}H NMR and ^{13}C NMR spectra that were identical to those of independently prepared β_1-[Co(pyge)(gly)]PF_6, while the latter compound gave as the major (> 85%) product a 50 : 50 mixture of the two β_1-[Co(pyge)(L-ala)]PF_6 diastereomers and the minor product (< 15%) β_1-[Co(pyge)(gly)]PF_6. On the other hand, *N*-acetylglycine gave no isolable cobalt(III) amino acid complex, even under forcing conditions of prolonged heating.

Equilibration of diastereomers of β_1-[Co(pyge)(AA)]PF_6 (L = L-ala *and* sar)

The complex β_1-[Co(pyge)(L-ala)]PF_6 was isolated as a 50 : 50 mixture of diastereomers from the preparative procedure employed (*vide supra*). For reasons to be enumerated in the Discussion, we believe that the two isomers have the Δ_L-β_1 and Λ_L-β_1 configurations. If the isolated L-ala cobalt

complex is redissolved in D_2O and the pH adjusted to ~8.0–8.5 (pD ~ 7.6–8.1), the main change in the ^1H NMR spectrum of the solution is the rapid (< 15 min) $^1H/^2H$ exchange of the protons in the $SCH_2C(O)$ moiety of the pyge ligand. If the solution is heated at ~ 50°C, then further spectral changes, involving the coordinated L-ala ligand, occur in the spectrum over a period of time. The L-ala methyl and methine resonances for the two diastereomeric complexes, which are initially equal in intensity, change so that at equilibrium the ratio of major to minor isomer is 63:37. The "major" isomer has resonances at δ 3.76 and 1.24 for the methine and methyl resonances, respectively, while the "minor" isomer displays the analogous peaks at δ 3.32 and 1.40, respectively. The equilibration takes *ca* 1.5–2 days to complete; further monitoring of the solution over an 8-day period revealed no further changes in the ^1H NMR spectrum.

The complex β_1-[Co(pyge)(sar)]PF_6 is also isolated as a mixture of diastereomers due to the formation of an asymmetric centre at the *N*-methyl amino group of sar upon coordination; in this case, each isomeric complex presumably consists of enantiomeric pairs of complexes. The diastereomeric ratio of 14:86 was not affected by added base, implying that the equilibrium ratio of the diastereomers is isolated under the preparative conditions.

X-ray crystallographic studies of **1** *and* **2**

Intensity data for crystals of **1** and **2** were measured on a Nicolet R3mV four-circle diffractometer equipped with a graphite monochromator, using Mo-K_α radiation ($\lambda = 0.71073$ Å). Data were corrected for background, attenuators, Lorentz and polarization effects in the usual fashion, but not for absorption.[21] Heavy atoms were located via Patterson maps and full-matrix least-squares refinement was accomplished with the SHELXTL Plus package of programs. Hydrogen atom positions were calculated geometrically, fixed at a C—H distance of 0.96 Å, and not refined. Crystal data and details of the data collection methods and refinement procedures are given in Table 1 and in supplementary Tables S1 and S10.

The two independent PF_6 anions in **1** were highly disordered and merit some further discussion. From difference Fourier maps, the disorder appeared to be of an axial type, mostly confined to a plane containing four of the six fluorine atoms. The disorder was modelled with some difficulty by inserting six partially occupied fluorine sites for the four atoms and limited the ultimate accuracy of the structure. However, this problem was immaterial to the main purpose of determining the structure of **1**, which was to elucidate the relative configuration

Table 1. Crystallographic data for β_1-[Co(pyge)(gly)]$PF_6 \cdot 2H_2O$ (**1**) and β-[Co(pyge)(Cl)(NO_2)]·[Co(pyge)$(NO_2)_2$]$\cdot 2H_2O$ (**2**)

of the gly ligand with respect to the pyge ligand. Full listings of atomic coordinates, bond lengths and angles, isotropic and anisotropic displacement factors, and hydrogen atom parameters for complexes **1** and **2**, as well as fractional occupancies for the fluorine atoms of the PF_6 anions of **1** have been deposited as supplementary material with the Editor and the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The reaction of *cis*-β-[Co(pyge)Cl_2]·H_2O with gly, L-ala, L-val, L-ile, L-leu, β-ala, sar and aiba in aqueous solution at pH 7.7 ± 0.1 and 50–60°C gave good yields of β-[Co(pyge)(AA)]$^+$ (where AA is the corresponding amino acidato ligand). It is likely that intermediates of type β-[Co(pyge)(Cl)(H_2O)]$^+$ or β-[Co(pyge)(H_2O)$_2$]$^{2+}$ are involved in the formation of the amino acid complexes reported herein by analogy to similar known chemistry.[1] Completion of the preparative reaction appeared to be slower in cases where the side group of the amino acid is large (such as in L-val or L-ile) or where a six-membered chelate ring must form (such as for β-ala). The complex ions are readily isolated as their hexafluorophosphate salts in good yields (60–70%).

In general, dilute aqueous solutions of [Co(pyge)(AA)]PF_6 had one broad, relatively symmetrical absorption of modest intensity ($\varepsilon \sim 440 \pm 80$ mol^{-1} dm^3 cm^{-1}) at about 501 ± 3 nm with very little dependence on the identity of the amino acid. A weak shoulder was evident on the higher energy side of this main absorption for some complexes. In dilute Me_2SO solution, the visible band had comparable intensity and line shape to the absorptions in aqueous solution and was bathochromically shifted by 6–10 nm.

In the case of a tertiary *cis*-β octahedral complex with an unsymmetrical bidentate ligand, two geometrical configurations are possible; these isomers are designated as *cis*-β_1 and *cis*-β_2 (see Fig. 1) in accordance with literature convention.[20] Each of these geometrical isomers will exist as a pair of enantiomers (Δ and Λ)[21] for AA = gly, β-ala and aiba and as a pair of diastereomers (Δ_L-β_1, Λ_L-β_1 and Δ_L-β_2, Λ_L-β_2) for AA = L-ala, L-val, L-ile and L-leu due to an intrinsic asymmetric centre in the bidentate ligand. ^{1}H and ^{13}C NMR spectra for [Co(pyge)(AA)]PF_6 strongly indicate that only one of the two possible geometrical configurations (*cis*-β_1 or *cis*-β_2) is found in the isolated complexes for each amino acid ligand, since only one set of NMR resonances is observed for the achiral amino acids and two sets of closely-spaced resonances are observed for the chiral (see Experimental and Fig. 2). The ^{13}C NMR spectra are especially persuasive, since variations in ligating atoms at the two substitutable coordination sites β-[Co(pyge)X_2] result in significant changes in chemical shift for many of the carbon nuclei in the pyge ligand.[13,14,22]

The sar ligand deserves special mention. While sar has no asymmetric centre in the free amino acid, an asymmetric centre at the methylated amino group is generated upon coordination.[8,23] In this case, a mixture of two diastereomeric complexes was isolated in an approximately 14:86 ratio (by integration of the *N*-methyl resonances in the ^{1}H NMR spectrum, which are separated by 1.07 ppm). The presence of two different isomers was most clearly illustrated in the ^{13}C NMR spectrum by the occurrence of pairs of closely spaced resonances. The resonances corresponding to each isomeric complex could be distinguished easily in the ^{13}C NMR spectrum, since there was an approximately 4:1 ratio in intensities for the two resonances in each pair of peaks.

Electronic and NMR spectral results alone were not sufficient to determine the coordination mode (β_1 vs β_2) of the amino acid chelate. Ultimately, the structure of **1** was solved by diffraction methods. Two independent formula units of **1** make up the asymmetric unit of the unit cell. The description of the structure will be limited to that involving the cations, since the PF_6 anions were disordered.

The bonding parameters and ligand conformations within each independent cation are essentially the same. Selected bond distances and angles are provided in Table 2 and an ORTEP representation for "cation A" is depicted in Fig. 3. The pyge ligand adopts the expected *cis*-β configuration.[13,14] Bond lengths and angles within the pyge ligand are very similar to those previously reported for β-[Co(pyge)(NO_2)$_2$]·H_2O.[13]

The geometrical parameters in the cobalt–glycinato moiety are also within expected values.[24–26] The orientation of the gly ligand with respect to the tetradentate ligand is β_1 (with the amino and carboxylato groups of the gly ligand *trans* to the amino and amido groups of the pyge ligand, respectively; see Figs 1 and 3) in each independent cation. The solution visible, ^{1}H NMR and ^{13}C NMR spectra of the crystals of **1** are identical to those of the [Co(pyge)(gly)]PF_6 starting material, strongly suggesting that the β_1 configuration persists in the solution and solid states. Thus, the orientation of the gly ligand in **1** can be reasonably assigned to be β_1; more specifically the Δ,Λ-β_1 pair of enantiomers has been obtained.

As noted above, for [Co(pyge)(AA)]PF_6 (where AA = amino acidato ligands other than gly), NMR

spectral results indicate that the corresponding ^1H and ^{13}C NMR chemical shifts for the pyge backbone ligand are very similar to those in the gly complex and that only one geometrical configuration is isolated. Coupled with the observations that the visible spectra of these complexes are essentially the same in two different solvents as those for AA = gly and that $[Co(pyge)(gly)]^+$ has β_1 geometry, these data imply that the β_1 configuration obtains in general for β-$[Co(pyge)(AA)]^+$.

In order to probe whether the apparent preference for β_1 coordination of the amino acid ligands might be kinetic in origin, β-$[Co(pyge)Cl_2]\cdot H_2O$ was carefully reacted with one equivalent of $NaNO_2$ to give $[Co(pyge)(Cl)(NO_2)]\cdot H_2O$. The ^1H NMR spectrum of the product was typical for a single cobalt complex containing the pyge ligand [see Fig. 4(a) for the portion of the spectrum containing the diagnostic resonance for H-6 of the pyridyl ring of the pyge ligand]. In addition, the ^{13}C NMR spectrum of this material displayed only one set of ligand resonances (see Experimental). Taken together, these pieces of evidence strongly suggest that the isolated material involves the formation of only one new compound. Thus, the occurrence of equal

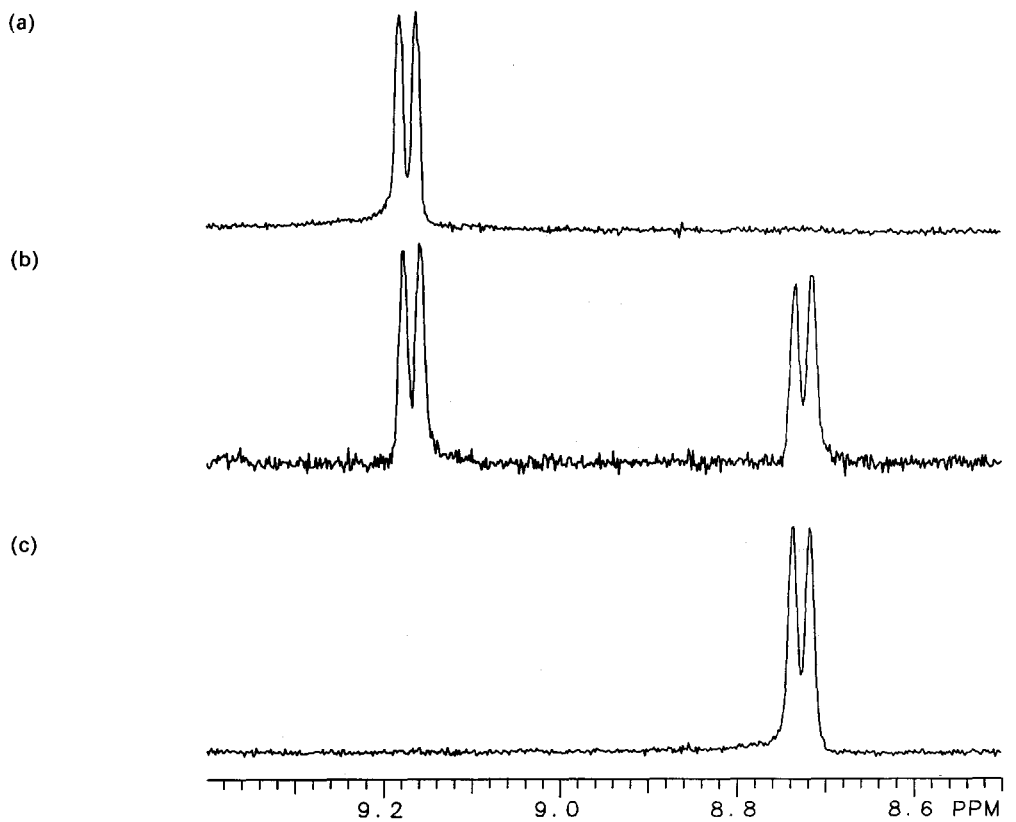

Fig. 4. ^1H NMR spectral expansion (Me_2SO-d_6) of the H-6 pyridyl proton of the pyge ligand for (a) β-$[Co(pyge)(Cl)(NO_2)]\cdot H_2O$, (b) the crystals of **2** and (c) authentic β-$[Co(pyge)(NO_2)_2]$.

mixtures of dinitro and dichloro cobalt(III) complexes was eliminated, as well as the presence of both of the two possible complexes containing one nitro and one chloro ligand. While we could conclude that only one of two possible *cis-β* isomers having one nitrogen and one chloro ligand was present, the relative positions of the two monodentate ligands in the *cis-β* cobalt(III) complex could not be discerned from the NMR spectra.

An attempted recrystallization of *β*-[Co(pyge)(Cl)(NO_2)]·H_2O from hot water led to the isolation of single crystals of the new compound, *β*-[Co(pyge)(Cl)(NO_2)]·[Co(pyge)(NO_2)$_2$]·$2H_2O$ (**2**). Complex **2** possibly arises from the redistribution equilibrium [eq. (1)]:

$$2[\text{Co(pyge)(Cl)}(NO_2)] \rightleftharpoons [\text{Co(pyge)}(NO_2)_2] + [\text{Co(pyge)Cl}_2] \quad (1)$$

The dichloro cobalt(III) complex is very soluble in aqueous solution and could lead to the serendipitous co-crystallization of *β*-[Co(pyge)(Cl)(NO_2)] and *β*-[Co(pyge)(NO_2)$_2$]. The equilibrium mixture of these two complexes could also arise via a series of aquation and anation reactions, as well, without the intervention of *β*-[Co(pyge)Cl_2]. The ^{1}H (see Fig. 4 and the Experimental) and ^{13}C NMR spectra of the crystals consist of a superposition of the resonances for *β*-[Co(pyge)(Cl)(NO_2)] and *β*-[Co(pyge)(NO_2)$_2$]. Most importantly, the NMR spectra confirm that in the crystals of complex **2**, the two monodentate ligands of the *β*-[Co(pyge)(Cl)(NO_2)] moiety have the same relative disposition with respect to one another as in the originally isolated complex, [Co(pyge)(Cl)(NO_2)]·H_2O.

The asymmetric unit of the unit cell for **2** consists of one complex molecule each of [Co(pyge)(Cl)(NO_2)] and [Co(pyge)(NO_2)$_2$] and two water molecules of hydration. Selected bond distances and angles for **2** are collected in Table 3. The pyge ligand in both complexes adopts the *cis-β* geometry that is dictated by the constraints imposed by the tetradentate ligand.[13,14] In general, bond lengths and angles in the two complex molecules are within expected values.[13] The *β*-[Co(pyge)(NO_2)$_2$] molecule is depicted in Fig. 5. The structure is virtually identical to that found for [Co(pyge)(NO_2)$_2$]·H_2O[13] with one minor difference. Although the N(15) nitro ligand is again twisted out of the major coordination plane of ligating atoms and the N(11)—Co(11)—N(15) angle of 99.9(3)° is abnormally large, the twist of this nitro ligand in the present case is in the opposite sense of that found in *β*-[Co(pyge)(NO_2)$_2$]·H_2O.[13] Presumably, the two rotational configurations are comparably stable and allow the nitro ligand to relieve unfavourable steric interactions with the hydrogen atom bonded to C(11) of the pyridyl ring.

The *β*-[Co(pyge)(Cl)(NO_2)] structure is shown in

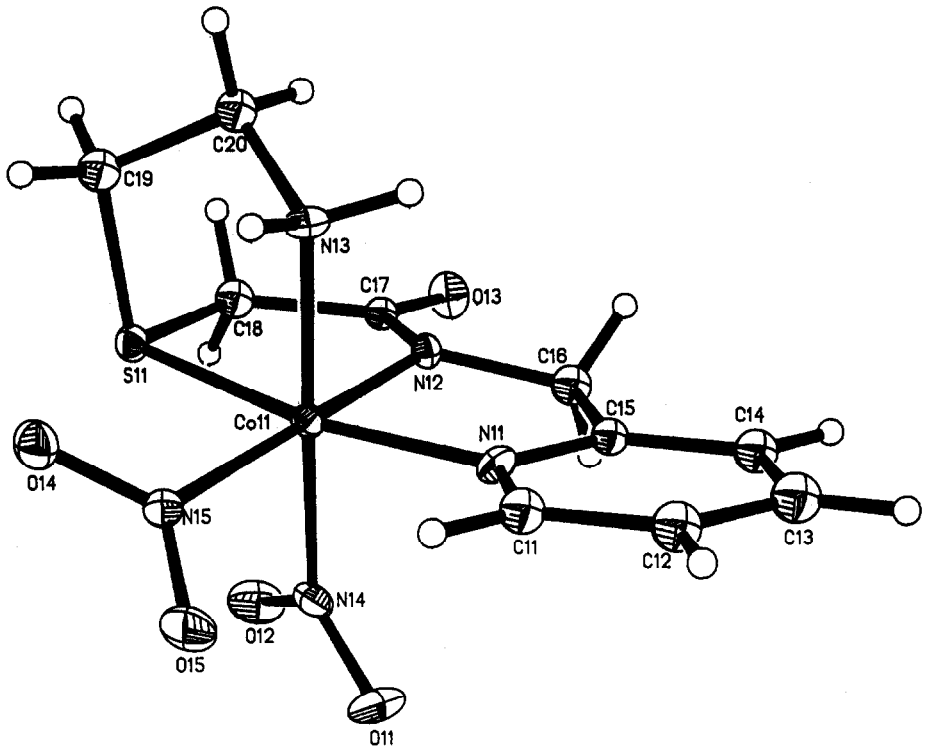

Fig. 5. Molecular structure and atom-numbering scheme for the molecule of β-[Co(pyge)$(NO_2)_2$] of **2**.

Fig. 6. The chloride and NO_2 ligands are *trans* to the amido and amino groups of the pyge ligand, respectively. Thus, coupled with the NMR data reported above, we may conclude that this same configuration of the monodentate ligands also obtains for the original compound from which the crystals of **2** were grown and that the chloride ligand (or possibly aquo ligand) *trans* to the amino donor

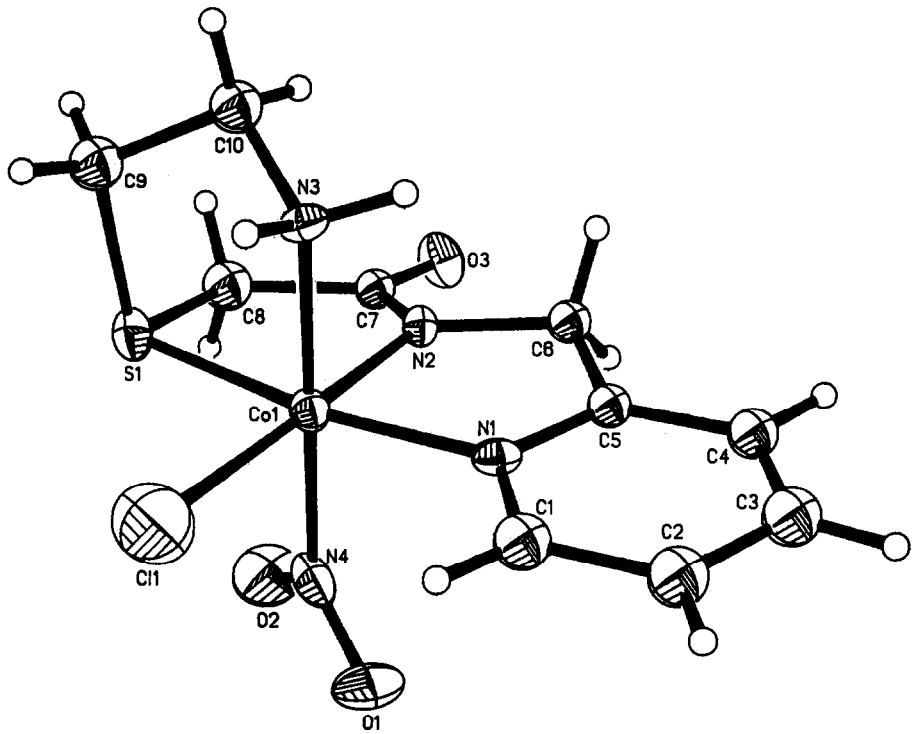

Fig. 6. Molecular structure and atom-numbering scheme for the molecule of β-[Co(pyge)(Cl)(NO_2)] of **2**.

of the pyge ligand is apparently preferentially substituted by the nitro anion in the formation of β-[Co(pyge)(Cl)(NO_2)]. The cobalt(III) centre is known to show a strong affinity for nitrogen donor ligands.[27] We then infer that the β_1 configuration fo the amino acid complexes arises as a result of initial coordination of the amino group of the amino acid ligand to the cobalt ion at the position *trans* to the amino group of the pyge ligand, followed by the chelate ring closure. The isoelectric points (pI) for the amino acids in this study are all near 6.0, so an appreciable fraction of the amino groups of the amino acid ligands should be available for binding under the reaction conditions (pH 7.6–7.8).

The preference for substitution *trans* to the amino donor of the pyge ligand in β-[Co(pyge)Cl_2] could be steric in origin. However, we believe that the steric differences between the two relatively labile coordination sites on cobalt should be too small to account for the extremely high stereoselectivity observed for nitro substitution in the preparation of β-[Co(pyge)(Cl)(NO_2)] and formation of the β_1 amino acid complexes that occurs in the present instance.

We feel that a more likely explanation is that the substitution of the position *trans* to the amino group of the pyge ligand is kinetically favoured; that is, the chloride (or aquo) ligand *trans* to the amino group of pyge is labilized relative to the other chloride (or possibly aquo) ligand *trans* to the amido nitrogen. We would then conclude that the amino group is a better *trans*-labilizer than the deprotonated amido group. Whether this is just intrinsically so, or may be due to the ability of the amino group to readily deprotonate under the slightly basic (pH 7.6–7.8) conditions of the substitution reactions (à la a D-CB type mechanism), is a matter of speculation. We note that in all cases at neutral to basic pH values, the amino protons readily exchange with deuterons from the bulk D_2O solvent by ^1H NMR spectroscopy in support of the above hypothesis. In any event, the geometrical configuration of the amino acid chelate (β_1) would then be established by this kinetically-controlled substitution pattern, combined with the preference of cobalt(III) ions for nitrogen donor ligands.

Examination of the filtrates of preparations of β-[Co(pyge)(AA)]$^+$ revealed little evidence for the formation of significant amounts of complexes with β_2 configuration; essentially only β_1 isomers could be detected within the limits of the NMR techniques. This last result contrasts sharply with elegant studies involving [Co(trien)(gly)]$^{2+}$, where *cis*-α, *cis*-β_1 and *cis*-β_2 isomers could be obtained.[24–26] In the trien case, additional isomerism involving stereochemistry about the coordinated secondary nitrogen donor atoms of the trien ligand must also be considered;[24–26] no such problem occurs in the pyge case of the present investigation. In the case of the chiral AA ligands, we exclude the possibility that Δ_D-β_1 and Λ_D-β_1 isomers might also be present in significant amounts also. In order for these complexes to be formed, either racemization of the asymmetric centre on the amino acid would have to occur before coordination, or epimerization might occur after coordination to the cobalt centre. We feel that the former is unlikely given the mild conditions employed in the synthesis of the amino acid complexes. The latter is more problematic, since epimerization of amino acids chelated to cobalt(III) and other metal ion centres is a well-known phenomenon.[28] However, no evidence for $^1H/^2H$ exchange was found for the methine proton of coordinated L-ala under pH conditions entirely analogous to those employed in the synthesis of the complexes (*vide infra*). Thus, the assignment of the Δ_L-β_1 and Λ_L-β_1 configurations appears to be secure for the asymmetric amino acids.

The equilibration of diastereomeric cobalt(III) amino acid complexes under basic conditions (pH ~ 8.0) was studied for AA = sar and L-ala. For AA = sar, the asymmetry arises as a result of the chiral coordinated *N*—CH_3 group. Two β_1 isomers are isolated (presumably as a mixture of two pairs of enantiomers) in a ratio of 14 : 86, which does not change over a period of time at basic pH values; the only change in the ^1H NMR spectrum involved the $SCH_2C(O)$ protons which were rapidly exchanged for deuterons. The isolation of an equilibrium mixture of isomers is understandable by consideration of the facile $^1H/^2H$ exchange for the protons at coordinated amino groups of the ligands at neutral to basic pH values (*vide supra*).

The *N*—CH_3 resonance for the sar ligand occurs in the ^1H NMR spectrum at δ 1.66 for the major isomer and δ 2.73 for the minor isomer [for free sar, δ(*N*—CH_3) is 2.77 ppm]. The large upfield shift of this resonance for the predominant complex suggests that it is the isomer with the *N*—CH_3 group situated under the pyridyl ring of the pyge ligand and thus, in the shielding region of the aromatic ring. Using tables of computed shieldings due to aromatic ring currents,[29] combined with structural parameters estimated from the molecular structure of **1**,* we can calculate a ring-current shielding of

* The required structural parameters for the sar complex with the *N*—CH_3 moiety under the pyridyl ring are $z = 2.2$ Å and $p = 1.8$ Å, while for the isomer with the opposite configuration at nitrogen, $z = 2.2$ Å and $p = 5.2$ Å. See ref. 29 for definitions of z and p.

−1.07 ppm for the sar complex with the *N*—CH_3 group under the ring and a ring-current contribution of +0.08 ppm for the other isomer with the opposite configuration at nitrogen. The predicted difference in chemical shifts of 1.15 ppm, based solely on ring current effects,[29,*] is very close to the observed difference of 1.07 ppm. Furthermore, irradiation of the *N*—CH_3 ^{1}H NMR resonance at δ 1.66 under NOE conditions resulted in a 10±2% increase in intensity in the H-6 pyridyl proton resonance of the pyge ligand. We estimate that these groups should be *ca* 3.0 Å apart from the structural determination of **1**. Literature results suggest that *ca* 15% enhancement can be expected for ^{1}H–^{1}H NOE for these types of groups separated by this distance.[30]

In terms of the above interpretation, the observed preference in [Co(pyge)(sar)]$^+$ for the β_1 diastereomer with the *N*—CH_3 moiety under the pyridyl group may be explained in terms of electronic, and possibly, steric origins. Stability might be gained via hydrophobic and/or attractive van der Waals' interactions between the methyl and pyridyl groups by having the *N*—CH_3 functionality under the electron-deficient pyridyl ring. In addition, this configuration could allow more favourable solvation of the amino proton of the sar ligand. Such types of interactions are well-documented and depend upon a number of factors, including the nature of the groups involved and solvent polarity.[31–33] We note that unfavourable steric interactions might also come about in the minor diastereomer from van der Waals' interactions between the *N*—CH_3 moiety and one of the hydrogen atoms on C(8), as well as the lone pair of electrons on S(7) of the pyge ligand.

On the other hand, for AA = L-ala, the two β_1 diastereomers (Δ_L-β_1 and Λ_L-β_1) are isolated in essentially equal amounts, but can be equilibrated to a 37 : 63 ratio under basic conditions (pH ~ 8.0) over a period of 2 days (see Fig. 7). If we again presume that the further upfield shift of the L-ala methyl group for the preferred diastereomer arises from its proximity to the shielding region of the pyridyl ring, then similar arguments to that for AA = sar (*vide supra*) obtain in this case in order to explain the observed results. Further support for this hypothesis may be derived from the fact that the L-ala methine resonance for the minor isomer is observed upfield from that of the major isomer (Fig. 7). This reversal in chemical shift order (compared with that of the methyl resonances) is reasonable since the methine proton for the minor isomer should now be the group closest to the shielding region of the pyridyl ring.

However, there is a less marked discrimination of one isomer (Λ_L-β_1) over the other (Δ_L-β_1) at equilibrium in the L-ala vs the sar case. This can be understood from the viewpoint of a less efficient hydrophobic interaction of the methyl group of L-ala with the pyridyl ring of the pyge ligand due to distance constraints, which is in accord with the smaller difference in the chemical shifts for the pertinent methyl group of the two diastereomers in the L-ala case as compared with that for sar. It is also likely that any steric interactions involving C(8) and S(7) (*vide supra*) are lessened with the methyl group attached to the α-carbon atom in L-ala, as opposed to the amino group in sar.

In the case of the base-catalysed equilibration of the β_1-[Co(pyge)(L-ala)]$^+$ diastereomers, another interesting development occurs. Up until this point in the discussion, we have largely presumed that the stereochemistry about the asymmetric centre on the chelated L-ala ligand is preserved during equilibration. The equilibration could occur via carbanionic epimerization of the asymmetric centre at the α-carbon atom of the L-ala ligand as has been previously observed for [Co(en)$_2$(AA)]$^{2+}$ (en = 1,2-diaminoethane).[28] However, essentially *no* deuterium exchange is observed for that methine proton in the ^{1}H NMR spectra during the equilibration of the β_1-[Co(pyge)(L-ala)]$^+$ isomers (see Fig. 7). This consequence means that either the carbanion intermediate is preferentially reprotonated instead of deuterated or that a different mechanism is operational in the instance at hand. Since the equilibration of the β_1-[Co(pyge)(L-ala)]$^+$ complexes was performed at pH ~ 8.0 (at higher pH values, significant decomposition occurs, possibly involving the pyge ligand) vs pH > 11 for the en complexes, and since the reprotonation should be highly unlikely, we favour the latter explanation.

One possible isomerization mechanism to explain the present results is somewhat reminiscent of that proposed for epimerization of *cis*-β-[Co(7,7′-Me_2salen)(AA)] [7,7′-Me_2salen = bis(2′-hydroxyacetophenone)ethylenediimine] and related complexes in which metal–ligand bond-breaking is invoked.[34] In this scenario, the two β_1-[Co(pyge)(L-ala)]$^+$ diastereomers can be equilibrated via exchange of coordination positions by the amino group of the pyge ligand with that of the amino donor of the L-ala ligand under base catalysis, with all other donor atoms remaining in their original coordination sites. One of the amino groups could be deprotonated, thereby labilizing the amino ligand at the *trans* position; the deprotonation of coordinated amino donors in β_1-[Co(pyge)(AA)]$^+$ is

* See footnote on previous page.

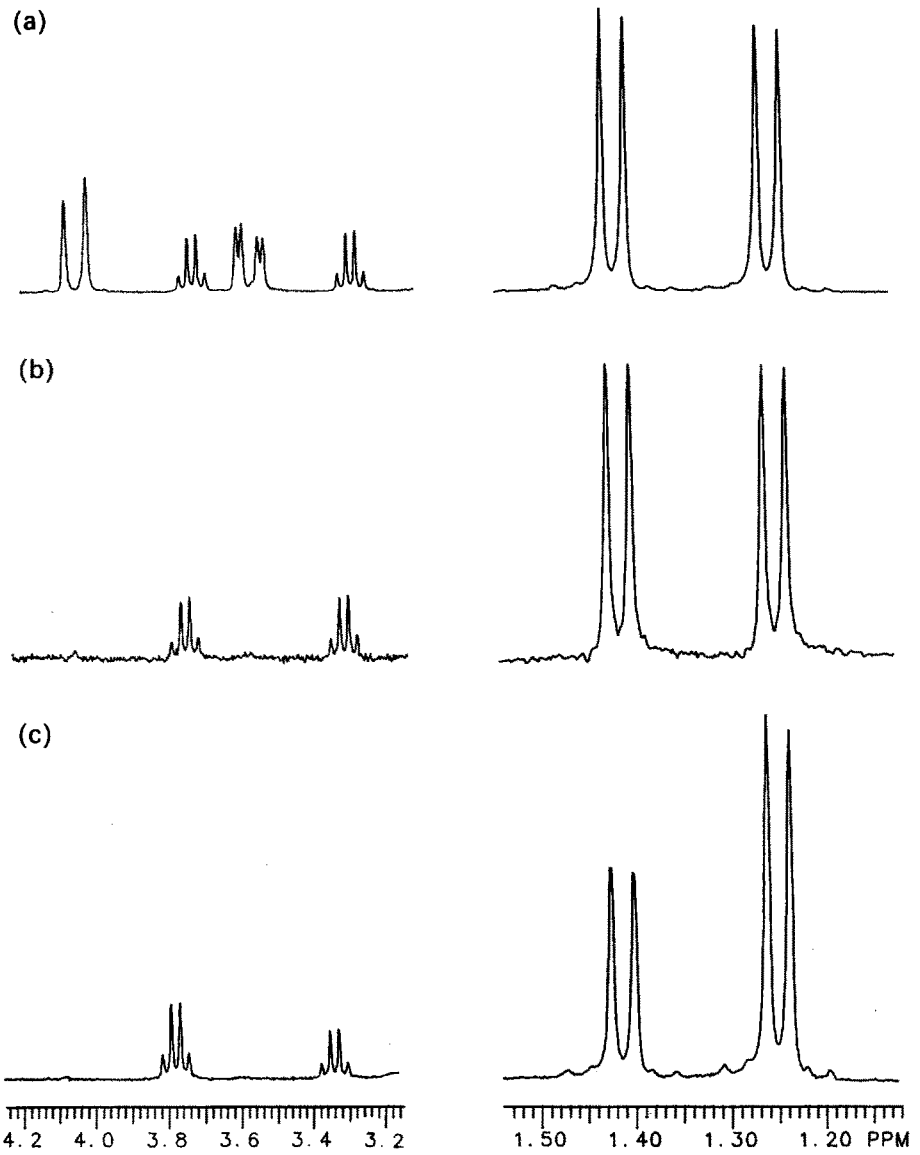

Fig. 7. ^{1}H NMR spectral expansions (D_2O) for the methine and methyl resonances of the L-ala ligand of β_1-[Co(pyge)(L-ala)]PF_6: (a) neutral D_2O, (b) 15 min after addition of NaOD (pH ~ 8.0) and (c) at equilibrium (45 h after addition of NaOD).

feasible as demonstrated above by the facile exchange of amino protons in neutral to basic D_2O solution. We would then require that the dangling amino group swing around to substitute at the position of the other amino ligand, which would then eventually occupy the other, recently vacated site. Considerable reorganization, including an inversion at the sulphur centre, would be required, and may explain the relatively slow approach to equilibrium. Other mechanisms, including intermolecular ones, may be put forth; however, the above speculative mechanism is consistent with the lack of deuterium exchange observed at the α-carbon atom with the L-ala ligand.

The complex β-[Co(pyge)Cl_2]·H_2O (or its corresponding hydrolysis products) is also quite effective in the promotion of the hydrolysis of peptide and amino acid ester bonds under mild conditions (50–60°C, pH 7.6–7.8, 0.5–1.0 h) in much the same manner as $[CoN_4(OH)(H_2O)]^{2+}$ (where N_4 is one tetradentate ligand or two bidentate ligands with four nitrogen donor atoms) and related complexes.[1,4,7,10] Thus, the reaction of the dichloro cobalt complex with either gly–gly or gly methyl ester gives β_1-[Co(pyge)(gly)]$^+$, with no detectable intermediate. The spectroscopic (visible, ^{1}H and ^{13}C NMR) analysis of the isolated complexes indicates that they have the same β_1 configuration as the complex prepared from gly.

With the unsymmetrical dipeptide L-ala–gly, the

major isolated product (> 85–90%) is the mixture of β_1 diastereomers of [Co(pyge)(L-ala)]$^+$. The remainder of the isolated material is mostly β_1-[Co(pyge)(gly)]$^+$. The formation of the gly cobalt complex could occur via a small amount of *O*-terminal cleavage or by competition of gly formed in the N-terminal hydrolysis of L-ala–gly with unreacted L-ala–gly for cobalt reactive sites. In order to determine which of the two possibilities might be operating in this case, the dichloro cobalt complex was treated with *N*-acetylglycine. Essentially no hydrolysis occurred, even after long reaction times. Thus, it appears that the promotion of the cleavage of the dipeptides and amino acid esters proceeds via prior coordination of the *N*-terminal end, followed by chelation with and activation of the carbonyl oxygen of the functionality to be hydrolysed, much as has been elegantly demonstrated for similar cobalt complexes.[1,4,7] The stereoselective control of the configuration (again β_1) of the isolated amino acidato complexes in the hydrolyses would then be the result of the same kinetic factors enumerated above in the direct syntheses of β_1-[Co(pyge)(AA)]$^+$.

Conclusions

The β-[Co(pyge)X_2] complexes have proved to be a versatile system for the study of the stereochemical coordination preferences of amino acid anionic ligands. The tetradentate ligand, pyge, enforces the strict formation of pseudo-octahedral complexes having the *cis*-β geometry. At first glance, this would appear to be a hindrance with regard to unsymmetrical bidentate chelates, since such ligands could potentially coordinate in two different geometrical configurations, β_1 and β_2. However, the unsymmetrical nature of the pyge ligand apparently leads to the kinetically-controlled isolation of only the β_1 isomer. The complex β-[Co(pyge)Cl_2] promotes the hydrolysis of amide and ester bonds of α-amino carbonyl compounds from the *N*-terminal end under mild conditions, again giving only β_1-cobalt(III) amino acid complexes.

In cases where an asymmetric centre is formed upon chelation to the cobalt(III) centre (sar) or is contained in the amino acid ligand (L-ala), diastereomeric β_1-complexes are isolated. In the former case, the diastereomers are isolated in their equilibrium ratio (14 : 86). On the other hand, in the latter case a 50 : 50 mixture of the two diastereomers are isolated, which can be slowly equilibrated under basic conditions to a 37 : 63 proportion, without the involvement of a carbanionic intermediate. In both instances, evidence was presented and arguments put forth that the favoured diastereomer was the β_1-complex with the methyl group of the amino acid chelate in position to interact with the pyridyl moiety of the pyge ligand. Such types of interactions have been proposed to be important with regard to substrate binding to metalloenzymes, including carboxypeptidase A.[31] In view of the peptidase type activity demonstrated by β-[Co(pyge)Cl_2] and the hydrophobic stereochemical preferences shown by sar and L-ala reported herein, work is in progress towards the end of extending these studies to other optically active amino acids and related unsymmetrical bidentate ligands.

POLYKETONES VIA OXIDATION OF POLYBUTADIENES CATALYSED BY COMPLEXES OF PLATINUM(II)

AHMED IRAQI and DAVID J. COLE-HAMILTON*

Chemistry Department, University of St Andrews, St Andrews, Fife, KY16 9ST, Scotland, U.K.

(*Received* 23 *January* 1991; *accepted* 5 *February* 1991)

Abstract—Polybutadienes containing different ratios of 1,4- and 1,2-polymerized units are converted to polyketones by oxidation with ^{t}BuOOH in the presence of catalytic quantities of $[Pt(diphoe)CF_3(CH_2Cl_2)]^+$ (diphoe = $Ph_2PCH{=}CHPPh_2$); reactivity ratios for the different double bonds are determined as pendant/*trans*/*cis*, 6 : 5 : 3.

Polyketones are known to be good precursors for the synthesis of many other polymers,[1] but they also have considerable potential uses in their own right since they are photodegradable.[2] Polyketones can be synthesized by (i) polymerization of unsaturated ketones using metal alkyl catalysts[3] or free radical initiators;[4] (ii) co-polymerization of unsaturated ketones with other unsaturated monomers such as 2-chloro-1,3-butadiene[5] or vinyl acetate;[6] and (iii) co-polymerization of carbon monoxide with ethene catalysed by palladium(II) complexes.[7]

We have been investigating the synthesis of new polymers via the modification of polybutadiene using homogeneous catalysis. In a previous communication[8] we reported that polybutadiene containing 55% of its double bonds in the backbone of the polymer and 45% pendant from the double bond could be selectively epoxidized only on the backbone double bonds using ^{t}BuOOH as oxidant and a molybdenum-based catalyst that we have developed. In order to attempt to prepare polyketones with different structures using homogeneous catalysis, we have studied reactions of polybutadienes with ^{t}BuOOH in the presence of $[Pt(diphoe)CF_3(CH_2Cl_2)]^+$ (diphoe = $Ph_2PCH{=}CHPPh_2$). This catalyst system has been extensively studied by Strukul *et al.* and has been shown to be selective for the formation of methylketones from terminal alkenes. Very few other catalysts allow oxidation of alkenes to methyl ketones and none is as active and selective as $[Pt(diphoe)CF_3(CH_2Cl_2)]^+$.

Polybutadienes having a variety of different structures were reacted with ^{t}BuOOH in dichloromethane containing the catalyst at 80°C in sealed tubes under nitrogen.† The resulting polymers were isolated and analysed using IR, ^{1}H and ^{13}C NMR spectroscopy. The starting materials were selected so as to have various proportions of *cis* and *trans* backbone or terminal pendant double bonds (see Table 1).

All of the products show strong absorption in their IR spectra at *ca* 1720 cm^{-1} and resonances in the ^{13}C NMR spectra near δ 212 (this is generally a weak resonance and is not observed for the product from *cis*-polybutadiene, where only low conversion is obtained) confirming that ketones are formed. The carbon atoms α to the ketones give resonances at δ 26.5 and 26.6 and resonances from protons on the ketones appear near δ 1.25. From integration of the ^{1}H NMR spectra it is possible to determine the extent of oxidation as well as the pendant/backbone

* Author to whom correspondence should be addressed.

† In the absence of added catalyst, a low conversion (~5%) to alcoholic type products [^{13}C NMR: δ 82 (pendant double bonds) and 86 (backbone double bonds)] is observed. These are not peroxides of the polymer since they are not removed by shaking with acidified ferrous ammonium sulphate, but are obtained as a side product (> 5%) in the catalytic reaction.

Table 1. Composition of polymers (%) formed by oxidation of polybutadienes; figures in parentheses represent per cent conversion of the particular type of double bond

						Overall conversion (%)
cis-Polybutadiene, 100% *cis*-1,4	—	—	88 (12)	12	—	12
Polybutadiene, 21% vinyl, 19% *cis*-1,4 and 60% *trans*-1,4	9 (57)	34 (43)	13 (31)	32	12	44
Polybutadiene, 47% vinyl, 17% *cis*-1,4 and 36% *trans*-1,4	18 (61)	17 (52)	12 (29)	24	29	53
Polybutadiene, 83% vinyl, 17% *trans*-1,4	34 (59)	9 (47)	—	8	49	57

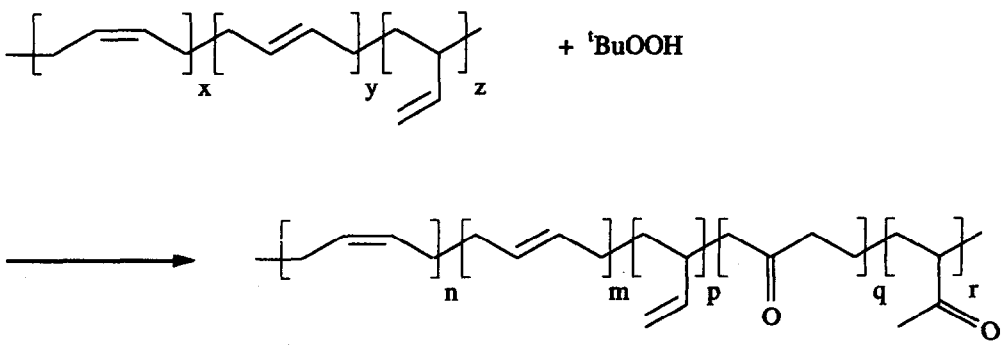
selectively, whilst integration of resonances at δ 27.5 and 32.8 gives the relative amounts of *cis* and *trans* backbone double bonds remaining in the polymer.[10] Integration of these resonances relative to the resonances at δ 26.5 and 26.6 gives an internal check on the calculations.

The results of these analyses are shown in Table 1 and indicate that in all cases partial oxidation to ketones occurs. Unlike simple alkenes, in which high selectivities to oxidation of terminal double bonds are observed,[9] both internal and terminal double bonds in the polymers are oxidized and it is therefore possible to calculate reactivity ratios of terminal/internal of *ca* 4:3 for a polymer with approximately equal amounts of pendant and backbone double bonds. The relatively high reactivity of the internal double bonds is somewhat surprising in view of the results obtained with simple alkenes.[9]

The overall conversion of double bonds to ketonic functions increases as the proportion of pendant double bonds in the polymer increases, although not simply as a result of the higher reactivity of the pendant double bonds. Thus, if only *cis* double bonds are present in the polymer, 12% of these are oxidized, whereas in other cases the conversion of backbone double bonds under similar conditions can be as high as 47%.

Analysis of Table 1 shows that this arises because of a higher reactivity of the *trans* than of the *cis* backbone double bonds. From a comparison of the data in Table 1, it appears that a reactivity ratio of 6:5:3 for pendant/*trans*/*cis* double bonds is operating. All *cis*-1,4-polybutadiene appears to be less reactive, however, than expected on this basis.

Since the ratio of the different kinds of double bonds in the polymer can readily be controlled, the oxidation reaction that we report and which is illustrated in Scheme 1 provides a versatile route to polymers containing ketone groups pendant from the main chain and/or in the backbone, with ready



Scheme 1. Oxidation of polybutadiene to polyketones catalysed by $[Pt(diphoe)CF_3(CH_2Cl_2)]^+$.

control of the two types of ketone group. It also provides a simple method for functionalizing at the internal carbon atom of pendant double bonds in polybutadienes. Other reactions that we have studied either functionalize the backbone double bonds (epoxidation)[8] or the terminal atom of the pendant double bonds (hydroformylation, hydrosilation[11]).

Acknowledgements—We thank the SERC for support (A.I.), Johnson Matthey plc for generous loans of platinum metal salts, and the Japanese Soda Company for generous gifts of samples of polybutadienes.

(*Received* 25 *July* 1990; *accepted* 9 *October* 1990)

Abstract—Alkylammonium salts, $W_2{}^{34}S_4X_4{}^{2-}$ (X = Cl, Br), $M_2{}^{34}S_4Br_8{}^{2-}$ (M = Mo, W) and $Mo_2{}^{34}S_6O_2{}^{2-}$, have been obtained from $^{34}S_8$. IR and Raman spectra of these compounds have been studied and the normal vibrations calculated. A number of vibrations involving sulphur atoms [for example ν(M=S), ν(S—S)] are characteristic, which allows vibrational spectroscopy to be used to study the changes occurring in the metal–sulphur containing fragments. The interaction of $W_2(\mu_2\text{-}S)(\mu_2\text{-}S_2)Br_8{}^{2-}$ with $^{34}S_8$ was shown to produce $W_2(\mu_2\text{-}S_2)_2Br_8{}^{2-}$. The reaction of $Mo_2(\mu_2\text{-}{}^{34}S_2)_2Cl_4Cl_{4/2}$ with $S_x{}^{2-}$ results in the replacement of ^{34}S by ^{32}S to produce the $Mo_2(\mu_2\text{-}S_2)_2(S_2)_4{}^{2-}$ complex.

As a result of studies in the last 10–15 years a large new area of specifically built polynuclear thio complexes of transition metals has been revealed. The greatest number of synthetic results in the study of homometallic complexes have been obtained for molybdenum and tungsten.[1–3] These complexes may undergo complex rearrangements, accompanied by substantial changes in their metal–sulphur containing fragments.[3–5] Important information on the structural changes in these clusters upon their transformations can be obtained by using X-ray structural analysis and vibrational spectroscopy methods.[6–9] In the literature there have been practically no reports on the calculations of normal vibrations, which appears to be due to the difficulty of obtaining isotopomeric thio complexes. Earlier we reported calculations of the vibrational spectra for some triangular thio, thiohalogenide and thioselenohalogenide complexes of molybdenum: $Mo_3S_{13}{}^{2-}$,[7] $Mo_3S_7Cl_6{}^{2-}$[8] and $Mo_3S_4Se_3Cl_6{}^{2-}$.[9] In the present study we discuss the synthesis of thio complexes of molybdenum and tungsten with the ^{34}S isotope and present calculations of the normal vibrations in these complexes. Vibrational spectroscopy has been shown to be the most informative method in the study of the reactions of thio complexes, accompanied by changes in their metal–sulphur containing fragments. Examples are discussed.

EXPERIMENTAL

The syntheses were carried out using standard Schlenk techniques. The compounds with isotopes prepared from elemental sulphur contained 99.95% of the ^{34}S isotope.

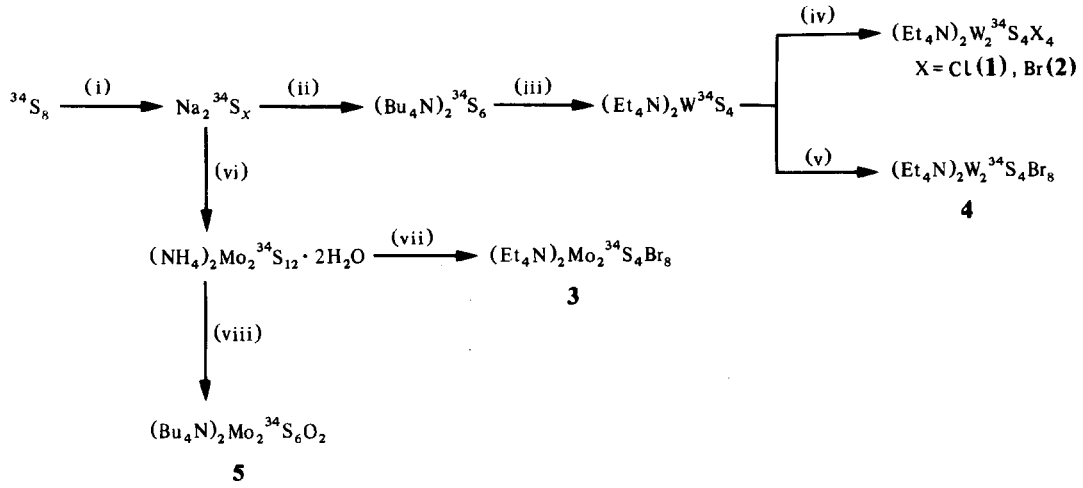
The IR spectra were obtained on a IFS-113 (Brüker) Fourier spectrometer, and the Raman spectra on a DFS-24 spectrometer using the 632.8 nm line of a He–Ne laser for excitation.

The synthesis of binuclear complexes of molybdenum and tungsten with the ^{34}S isotopes, proceeding from ^{34}S elemental sulphur, is shown in Scheme 1.

Preparation of $(Bu_4N)_2{}^{34}S_6$

To a solution of $Na_2{}^{34}S_x$ prepared from $NaBH_4$ (1.00 g) and $^{34}S_8$ (0.71 g) in H_2O (20 cm^3),[7] n-Bu_4NBr (3.0 g) was added. The precipitated solid was filtered off, washed with ether and dried *in vacuo*. Obtained: 2.11 g (n-$Bu_4N)_2{}^{34}S_6$. Yield 88%.

* Author to whom correspondence should be addressed.



Scheme 1. Preparation of binuclear ^{34}S-thio complexes of molybdenum and tungsten: (i) $NaBH_4$ in H_2O;[7] (ii) Bu_4NBr in H_2O; (iii) $W(CO)_6$ and Et_4NBr in CH_3CN; (iv) HX (X = Cl, Br) in CH_2Cl_2;[10] (v) HBr in CH_2Cl_2;[10] (vi) $K_4Mo_2Cl_8$ and NH_4Br in H_2O;[11] (vii) Br_2 and Et_4NBr in CH_3CN;[13] (viii) NH_4OH and Bu_4NBr.[12]

Preparation of $(Et_4N)_2W^{34}S_4$

$W(CO)_6$ (0.40 g) and $(Bu_4N)_2{}^{34}S_6$ (0.52 g) were boiled in CH_3CN (30 cm^3) for 1 h. The complex, Et_4NBr (1.50 g), was added and the solution cooled to $-5°C$. The precipitated solid was filtered off, washed with alcohol and ether and dried *in vacuo*. Obtained: 0.34 g $(Et_4N)_2W^{34}S_4$. Yield 54%.

RESULTS AND DISCUSSION

Preparation of molybdenum and tungsten binuclear complexes with the ^{34}S *isotope*

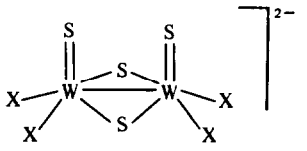
Scheme 1 shows the routes by which complexes **1–5** were synthesized, proceeding from $^{34}S_8$. The main difficulty to overcome in the synthesis of these compounds is the preparation of $(Et_4N)_2W^{34}S_4$. The traditional method for the preparation of WS_4^{2-} which consists of passing H_2S through a solution of WO_4^{2-} in ammonia for an extended period of time, turned out to be unsuitable for these purposes. We found that tetrathiotungstate can be obtained in good yield by interacting $W(CO)_6$ with $(Bu_4N)_2{}^{34}S_6$. Upon boiling, the colour of the solution in acetonitrile changes from dark green (S_3^-) to yellow (WS_4^{2-}). After addition of Et_4NBr and cooling, the yellow $(Et_4N)_2W^{34}S_4$ crystallizes in good yield. Again, adding Bu_4NBr to an aqueous solution of $Na_2{}^{34}S_x$ produces $(Bu_4N)_2{}^{34}S_6$ in practically quantitative yield. All other syntheses shown by the reaction schemes were carried out under the conditions described earlier. Thus, the reactions shown in Scheme 1 allow the binuclear thio complexes of molybdenum and tungsten to be synthesized with minimal losses of the ^{34}S isotope.

Vibrational spectra

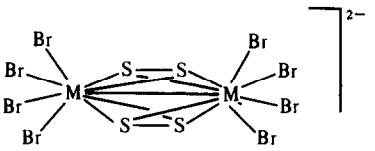
The structures of $W_2S_4X_4^{2-}$, $M_2S_4Br_8^{2-}$ and $Mo_2S_6O_2^{2-}$ are shown in Fig. 1. The X-ray structures of $W_2S_4Br_8^{2-}$, $Mo_2S_4Br_8^{2-}$ and $Mo_2S_6O_2^{2-}$ are known from the literature.[16–18] The structure of the $W_2S_4X_4^{2-}$ salts has not been determined by X-ray structural analysis and therefore in order to calculate the normal vibrations, use was made of the X-ray structural data for the $W_2S_4Br_2(PPh_3)_2$[19] and $W_2S_2O_2Cl_4^{2-}$[20] complexes. Using probable structural parameters in the absence of experimental ones does not significantly affect the final results within the adopted method of calculation—the approximation of the valence forces[21] (the vibrational frequencies in this method being given by the force constants, quantitites that are independent of interatomic distances). More serious consequences may result from incorrectly chosen bond angles, since in this case there will be considerable changes in the kinematic coefficients. However, deviations within several degrees are quite acceptable. The calculated force constants of the complexes are listed in Table 1.

$W_2S_4X_4^{2-}$ (X = Cl, Br)

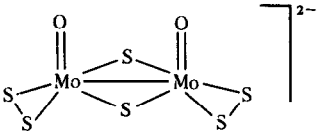
The IR and Raman spectra of $W_2S_4Cl_4^{2-}$ and $W_2S_4Br_4^{2-}$ complexes (Fig. 2) are very simple and do not present difficulties in assigning the



$W_2S_4Cl_4^{2-}$ (1) and $W_2S_4Br_4^{2-}$ (2)



$Mo_2S_4Br_8^{2-}$ (3) and $W_2S_4Br_8^{2-}$ (4)



$Mo_2S_6O_2^{2-}$ (5)

Fig. 1. Schematic drawing of the structure of binuclear thio complexes of molybdenum and tungsten.

vibrations, which hardly mix with each other mainly due to substantial differences in force constants between the individual bonds of the molecule. The lines at 530–515 cm^{-1} belong to the W=S vibrations and those at 460–440 cm^{-1}, to the W—S—W fragment.[14,15] This follows both from the isotope shift of these frequencies on going from the ^{32}S to ^{34}S complexes and their almost complete invariance with change of the halogen. A practically zero isotope shift and large variations on going from Cl to Br obviously allow assignment of the 350–280 cm^{-1} vibrations to the valence vibrations of the W—Cl bonds, and those at 280–210 cm^{-1} to W—Br. These conclusions are supported by calculations of the frequencies and shapes of the vibrational modes for the studied complexes. The results are shown in Tables 2 and 3 which list the observed and calculated frequencies, isotope shifts and potential energy distribution among the groups of equivalent vibrational coordinates. The force constants in complexes **1** and **2** (Table 1) practically coincide. It should be noted that the W—W bond constant is the least defined due to the W—W frequency appearing at *ca* 100 cm^{-1}, in the region where both deformational internal and external (translational and librational) vibrations that are strongly mixed with each other appear. Division of the spectrum into a high-frequency region of the internal valence vibrations and a low-frequency region (below 200 cm^{-1}) follows from the differences in the behaviour of these frequencies with the change in the crystal temperature, and holds for all of the complexes. Therefore, the remark concerning the metal–metal bond force constant refers to all of the complexes discussed in the present work.

$M_2S_4Br_8^{2-}$

The spectra of these compounds are also easy to interpret. The most remarkable aspect is the

appearance of an IR- and Raman-active line at $\sim 600\ cm^{-1}$. This vibration is noted for its characteristic nature. It is sufficient to say that upon $^{92}Mo \rightarrow {}^{100}Mo$ substitution its frequency changes within 1 cm^{-1} both in bi- and trinuclear complexes,[6-8] and on going from the ^{32}S to ^{34}S complexes the shift may become as large as 17 cm^{-1} and may serve as a reliable indication of the presence of the S_2^{n-} fragment in the complexes. Although the frequency of the S—S vibration may vary from 610 to 530 cm^{-1},[22] depending on the type of complex, it is not its kinematic relation with other

vibrations which is responsible for the variation, but the charge state of the pair itself. The M—S vibrations appear as intense lines at 350–300 cm^{-1} in the Raman spectra and together with the S_2^{n-} vibrations ($\sim$ 600 cm^{-1}) provide spectral proof of the presence of a bridging μ_2-S_2 group in the complex.

It should be noted that upon replacement of the bromine ligands by the chlorine ligands the M—X vibration mixes with the vibrations of the M—S bonds, which results in the shift of the latter to 380–330 cm^{-1}.[6] The M—Br vibrations appear as a series of very intense IR bands at 260–180 cm^{-1}. According to the X-ray structural analysis[16,17] there are two types of bromine in these complexes; the equatorial atoms which lie in the plane defined by the metals

and the middle points of the S—S bonds, and the axial atoms which are all the other bromines. There is a difference of 0.1 Å between the M—Br bond lengths for the axial and equatorial bromines. Values of the force constants reflect these differences. Thus, the force constant of the M—Br_e bond exceeds that of the M—Br_a bond. Tables 4 and 5 show the experimental and calculated parameters for the thiobromide complexes.

and its experimental and calculated characteristics are given in Table 6. The Mo=O vibration is readily recognizable in the spectrum by the high-frequency line at 940 cm^{-1}. Most important from the chemical point of view was the establishment of the vibrational frequencies for the terminal fragment S_2^{n-} and the comparison of its spectral behaviour with that of the bridging ligand S_2^{n-}. The frequency of the terminal S_2^{n-} fragment vibration, 520 cm^{-1} (as follows from the isotope shift values), was found to be below that of its bridging counterpart in each of the studied complexes (bi- and trinuclear complexes).[6-8]

Reactions of binuclear thio complexes of molybdenum and tungsten

The study of the vibrational spectra of binuclear thio complexes of molybdenum and tungsten revealed some characteristic vibrations which are useful in identifying individual fragments of the structure. Thus, in addition to the Mo—O and M—Br (M = Mo, W) vibrations, those of W=S (~ 530 cm^{-1}), S—S of the μ_2-S_2 bridging ligand (~ 600 cm^{-1}) and of S—S of the terminal S_2 ligand (~ 520 cm^{-1}) are also highly characteristic. The high characteristic nature of these bands may help solve chemical problems of establishing the mechanisms or routes by which the reactions of polynuclear thio complexes proceed.

In the present work we present two examples of the use of the vibrational spectroscopy to study the reactions of binuclear thio complexes of molybdenum and tungsten.

Example 1. Earlier we found that the thiobromide

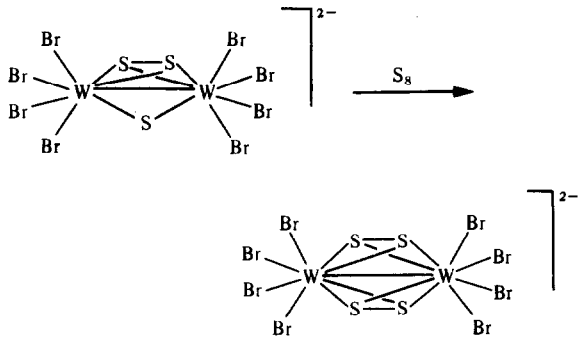
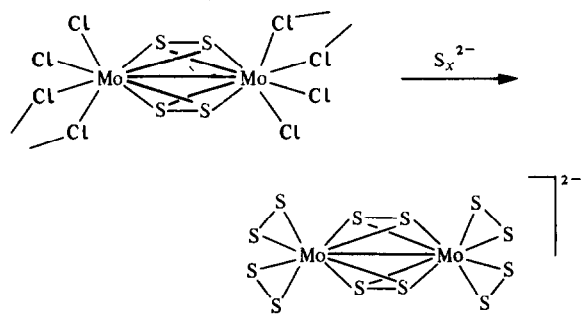


Scheme 2.

complex of tungsten, $W_2S_3Br_8^{2-}$, interacts with S_8 in CH_3CN to form $W_2S_4Br_8^{2-}$.[10]

We have studied the interaction of $W_2S_3Br_8^{2-}$ with ^{34}S under analogous conditions. It is clear that if the reaction proceeds by addition of ^{34}S to the μ_2-S ligand to form μ_2-$^{32}S^{34}S$, in the IR and Raman spectra there must appear an extra band with $\Delta\nu = 8$ cm^{-1} relative to ν(S—S) in $W_2S_4Br_8^{2-}$. According to the vibrational spectroscopy data the interaction of $W_2S_3Br_8^{2-}$ with ^{34}S only produces complex **3** which does not contain ^{34}S. Thus, the interaction of $W_2S_3Br_8^{2-}$ with sulphur in CH_3CN takes a complex route with several directions. This is indicated by the fact that $(Et_4N)_2W_2S_4Br_8$ was obtained in only 20% yield.[10] The other products of this reaction could not be isolated in an analytically pure form.

Example 2. Earlier, the binuclear thiobromide, $Mo_2S_4Cl_6$, was shown to interact with ammonium polysulphide to form $(NH_4)_2Mo_2S_{12}\cdot 2H_2O$.



Scheme 3.

We studied this reaction using isotopomeric compounds, and it turned out that the interaction of $Mo_2{}^{34}S_4Cl_6$ with $(NH_4)_2{}^{32}S_x$ produces only $(NH_4)_2Mo_2{}^{32}S_{12}\cdot 2H_2O$.

$$Mo_2{}^{34}S_4Cl_6 \xrightarrow{{}^{32}S_x^{2-}} Mo_2{}^{32}S_{12}{}^{2-}$$

$$\xrightarrow[(2)\,Me_4NCl]{(1)\,NH_4OH} (Me_4N)_2Mo_2{}^{32}S_6O_2$$

In the IR spectra of $Mo_2S_{12}^{2-}$, in the region below 600 cm^{-1} there is only one characteristic band at 520 cm^{-1} resulting from the valence S—S vibrations. The conclusion that substitution of the ^{34}S atoms of the μ_2-S_2 ligands by the ^{32}S atoms took place is made on the basis of the following two observations: (1) there is no shift of the splitting of the 520 cm^{-1} band and (2) the interaction of the reaction product with the aqueous solution of ammonia produces $Mo_2S_6O_2^{2-}$.[12] This complex exhibits very rich IR and Raman spectra which reliably suggest that there are no essential amounts of the ^{34}S isotope.

RADIATION-CATALYTIC REDUCTION OF MOLECULAR NITROGEN WITH APPLICATION OF THE TUNGSTEN(IV) HYDRIDE COMPLEXES

J. O. DZIĘGIELEWSKI,* J. MAŁECKI and R. GRZYBEK

Institute of Chemistry, Silesian University, 9 Szkolna Street, 40006 Katowice, Poland

(*Received* 1 *June* 1990; *accepted* 13 *December* 1990)

Abstract—A radiation-catalytic experiment of the fixation and reduction of molecular nitrogen has been carried out. The $[WH_4(dtpe)_2]$ complex was applied to fix molecular nitrogen in a γ-radiation field. Plots of the dependence of either the number of molecules of ammonia or hydrazine vs dose are presented. A mechanism for the radiation-catalytic fixation and reduction of molecular nitrogen using the $[WH_4(dtpe)_2]$ complex is suggested. The unusually high radiation yields of ammonia and hydrazine are explained as due to a cyclic process.

In previous work, methanol solutions of the complex $[MoOCl(dppe)_2]Cl$[1,2] and cyclohexane solutions of the complex $[MoH_4(dtpe)_2]$[3] were used in the process of radiation-catalytic reduction of molecular nitrogen [dppe = $(C_6H_5)_2P(CH_2)_2P(C_6H_5)_2$, dtpe = $(o\text{-}CH_3C_6H_4)_2P(CH_2)_2P(o\text{-}CH_3C_6H_4)_2$]. It was determined in these papers[1–3] that in a γ-radiation field the bis-dinitrogen molybdenum(0) complex formed and the coordinated dinitrogen was gradually reduced to $—NNH_2$, then to $—N_2H_4$ and finally to NH_3. The yields obtained were, however, much higher than expected from the amounts of e_s^-, H and R which should be produced in the radiation field (agents reducing central atoms or —NH groups). In another paper[4] it was shown that during the course of irradiation of a methanol solution of $[Mo(NNH_2)(HSO_4)(dppe)_2]HSO_4$ the intermediate $[HMoN_2H_3(dppe)_2]^+$ was formed as a result of the addition of a H^+ ion to the former complex. The hydrido intermediate immediately reacted with H^+ ions and initiated cyclic production of H atoms and H_2 molecules. In order to determine the role of hydrido ligands formed in the course of attaching the H^+ ion to the central atom, the complex $[WH_4(dtpe)_2]$ was used instead of the molybdenum analogue because of its presumed higher stability. It was shown previously[3] that H^- ions participate in the reduction of coordinated dinitrogen, but important problems such as reactions between H^- ions and the negatively-polarized N atom (the terminal one) in the M—N—N group were not considered. In this paper this problem is also explained. Taking into account the higher reducing ability of the tungsten ions than the molybdenum ions and the evident influence of H^+ ions on the yields of ammonia,[1,2] we came to the conclusion that the tungsten(IV) hydrido complex should increase the yields of the reduction of molecular nitrogen.

EXPERIMENTAL

The ligands dppe and dtpe were synthesized as reported elsewhere.[5] The complexes $[WH_4(dtpe)_2]$ and $[W(dtpe)_2]$ were obtained by literature methods.[3,6] Cyclohexane solutions of the $[W(dtpe)_2]$ complex were irradiated in the γ-radiation source "Issledovatel" (stationary ^{60}Co γ-radiation source) with simultaneous saturation with deoxygenated nitrogen. Dose rate in conversion to cyclohexane and methanol was calculated as 2.3×10^{17} eV cm^{-3} min^{-1} on the basis of a Fricke dosimeter. The $[WH_4(dtpe)_2]$ complex was dissolved in cyclohexane, acidified methanol (H_2SO_4) or in a mixture of acidified ethanol and cyclohexane (1 : 1). Acidified solutions of the tungsten(IV) hydride complex were irradiated in the same manner as $[W(dtpe)_2]$ except that in these cases the solutions were saturated either with N_2 or with a mixture of N_2 and H_2 (1 : 3). In order to keep the

* Author to whom correspondence should be addressed.

concentrations of the tungsten complexes constant, the gases were passed through scrubbers filled with the appropriate solvent. The hydrazine and ammonia generated were absorbed in aqueous solutions of H_2SO_4 ($C = 5 \times 10^{-2}$ mol dm^{-3}). Hydrazine[7,8] and ammonia[9,10] were estimated by standard methods. In the case of acidified solutions, products were estimated either in irradiated solutions or in traps filled with aqueous H_2SO_4.

RESULTS AND DISCUSSION

Figure 1 presents typical curves of the dependence of the number of N_2H_4 molecules on dose, generated during the irradiation of cyclohexane solutions of $[W(dtpe)_2]$ and $[WH_4(dtpe)_2]$ complexes saturated with N_2 or with a mixture of N_2 and H_2. These curves have been discussed earlier.[1]

The presence of H^- in the tungsten(IV) complex evidently increases the number of hydrazine molecules (curves 3 and 1) similar to the molybdenum analogues.[3] The maximum on curve 3 is lower than on curve 1 and is shifted towards higher doses. The exponential shape, up to the maximum, of curve 3 suggests that in the course of irradiation of the $[W(dtpe)_2]$ complex solutions the $[WH_4(dtpe)_2]$ complex is formed which accelerates reduction of the generated $[W(N_2)_2(dtpe)_2]$ complex to hydrazine. Generation of the W—H groups in the irradiated cyclohexane solution of $[W(dtpe)_2]$ was determined on observing IR absorptions at 1830, 1796 and 1775 cm^{-1} for the separated substance (after removing solvent). The deeper slope of curve 2 shows that the coordinated dinitrogen is highly reduced, which together with increased hydrazine yield is connected to the constant supply of H_2 into the irradiated solution. This is caused by the high concentration of W—H groups. Table 1 gives yields of hydrazine molecules. These conclusions are generally confirmed by Fig. 2 and Table 2.

The radiation yield of hydrazine is about 10 times greater than in solutions of the tungsten(IV) hydrido complex of lower concentrations. An increase in the $[WH_4(dtpe)_2]$ concentration causes a decrease in the yield of hydrazine and an increase in the ammonia yield in comparison with the $[W(dtpe)_2]$ complex (Tables 1 and 2). Use of the tungsten complexes leads to higher yields of hydrazine and ammonia than in the case of molybdenum complexes (data in Tables 1 and 2 and in Figs 1 and 2, together with the data from a previous paper[3]). Increase in the yield of N_2 reduction is caused by the greater ability of tungsten(IV) complexes and their higher stability. On the basis of the difference

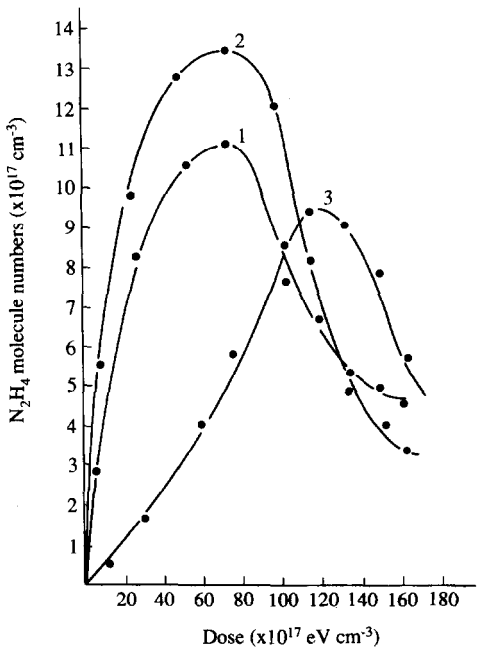

Fig. 1. Plot of the dependence of the number of N_2H_4 molecules on dose: (1) cyclohexane solution of the $[WH_4(dtpe)_2]$ complex, $C = 10^{-2}$ mol dm^{-3} saturated with N_2; (2) cyclohexane solution of the $[WH_4(dtpe)_2]$ complex, $C = 10^{-2}$ mol dm^{-3} saturated with a 1 : 3 mixture of N_2 and H_2; (3) cyclohexane solution of the $[W(dtpe)_2]$ complex, $C = 10^{-2}$ mol dm^{-3} saturated with N_2.

between the induction periods in the generation of ammonia (shorter for tungsten complexes), it was stated that the reduction ability in the process of reduction of hydrazine to ammonia is about 25% higher for tungsten complexes than for molybdenum complexes.

Consideration of the differences $G_{NH_3([MH_4(dtpe)_2])} - G_{NH_3([M(dtpe)_2])}$ for tungsten and molybdenum complexes leads to the conclusion that the tungsten(IV) hydrido complex is about 1.75 times more stable than the molybdenum(IV) hydrido complex, under the conditions of the experiment. Such a meaningful difference in the stability of these complexes allows protonation of the tungsten(IV) hydrido complex by the stoichiometric amount of H_2SO_4:

$$[WH_4(dppe)_2] + H_2SO_4 \longrightarrow [WH_5(dtpe)_2]HSO_4.$$

Figures 3 and 4 show the plots of the numbers of $N_2H_6^{2+}$ and NH_4^+ ions as functions of dose, and Table 3 presents yields of these ions.

Acidification of the solutions of the tungsten(IV) hydrido complexes causes effects opposite to those in the case of the $[MoH_4(dtpe)_2]$ complexes.[3] This shows that $[WH_5(dtpe)_2]^+$ ions were present in solution. The stability of these ions depends evidently on the nature of the solvent; they are more stable in a mixture of ethanol and cyclohexane than in pure methanol. It is noticeable (Fig. 3) that the yield of hydrazine is highly dependent on the H^- concentration and independent of the H^+ concentration, as can be seen from the plots. This means that the reduction of W—N_2 groups by W—H groups is the radical process. Therefore, H^- ions are not joined to the negatively polarized terminal N atom in the W—N—N^- group (similar to the molybdenum complexes). So, the H atom is transferred from the W—H group to the W—N_2 group, which changes the charge allocation. Transfer of the H atom from the W—H group onto other ligands was observed earlier.[11] Yields of ammonia are highly dependent on the concentration of H^+ ions, as can be seen in Fig. 4 and was also observed earlier.[1,2] This means that the coordinated hydrazine is reduced by the hydrido complex in an ionic way (e^- from atom centres and H^-). The radical mechanism of reduction of hydrazine seems to be unbelievable because the H—H bond energy is higher than the N—H bond energy (by *ca* 45 kJ mol^{-1}). It also causes the fact that H atoms could not be attached to hydrazine molecules but rather remove H atoms from hydrazine and form H_2 molecules with a constant rate of 2.4×10^4 dm^3 mol s^{-1}.[12] Formation of hydrazine in the reaction of $[Mo(N_2)_2(dtpe)_2]$ with H atoms, together with the lack

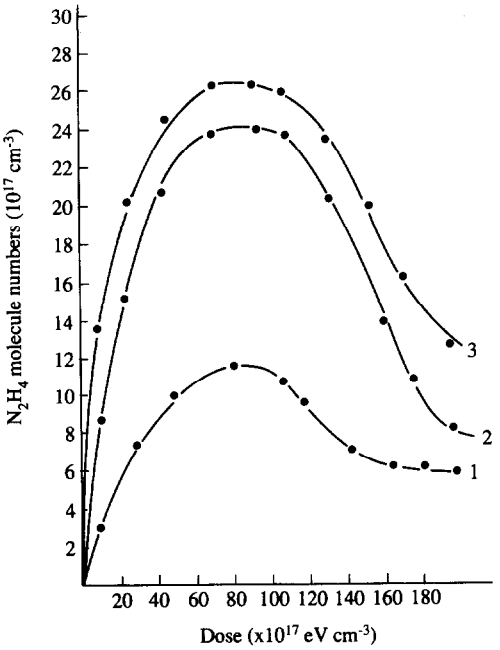

Fig. 3. Plot of the dependence of the number of N_2H_4 molecules on dose: (1) methanol solution of the $[WH_4(dtpe)_2]$ complex acidified with H_2SO_4 ($C = 10^{-2}$ mol dm^{-3}), $C = 10^{-2}$ mol dm^{-3} (the curve is the same for an acid concentration of $C = 10^{-1}$ mol dm^{-3}); (2) $[WH_4(dtpe)_2]$ solution in a mixture of C_2H_5O and C_6H_{12} (1 : 1) acidified with H_2SO_4 ($C = 10^{-2}$ mol dm^{-3}), saturated with N_2; (3) $[WH_4(dtpe)_2]$ solution in a mixture of C_2H_5OH and C_6H_{12} (1 : 1) acidified with H_2SO_4 ($C = 10^{-2}$ mol dm^{-3}), saturated with a 1 : 3 mixture of N_2 and H_2.

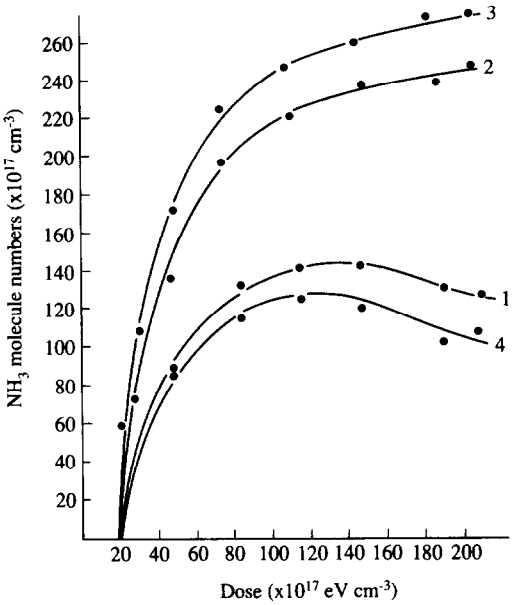

Fig. 4. Plot of the dependence of the number of NH_3 molecules on dose: (1) $[WH_4(dtpe)_2]$ complex in CH_3OH, $C = 10^{-2}$ mol dm^{-3}, acidified with H_2SO_4 ($C = 10^{-1}$ mol dm^{-3}), saturated with N_2; (2) $[WH_4(dtpe)_2]$ complex in a mixture of C_2H_5OH and C_6H_{12} (1 : 1) acidified with H_2SO_4 ($C = 10^{-2}$ mol dm^{-3}), saturated with N_2; (3) $[WH_4(dtpe)_2]$ complex in a mixture of C_2H_5OH and C_6H_{12} (1 : 1) acidified with H_2SO_4 ($C = 10^{-2}$ mol dm^{-3}), saturated with a 1 : 3 mixture of N_2 and H_2; (4) $[WH_4(dtpe)_2]$ complex in CH_3OH, $C = 10^{-2}$ mol dm^{-3}, acidified with H_2SO_4 ($C = 10^{-2}$ mol dm^{-3}), saturated with N_2.

Table 3. Radiation yields of $(N_2H_6)SO_4$ and $(NH_4)_2SO_4$ for different concentrations of the $[WH_4(dtpe)_2]$ complex dissolved in acidified methanol or in mixture of ethanol and cyclohexane (1 : 1)

Irradiated system	Number of molecules per 100 eV	
	$(N_2H_6)SO_4$	$(NH_4)_2SO_4$
CH_3OH solution saturated with N_2 $C_{H_2SO_4} = 10^{-2}$ mol dm^{-3}	46.0	444.4
CH_3OH solution saturated with N_2 $C_{H_2SO_4} = 10^{-1}$ mol dm^{-3}	46.0	500.0
Mixture of C_2H_5OH and C_6H_{12} saturated with N_2 $C_{H_2SO_4} = 10^{-2}$ mol dm^{-3}	95.0	1917.0
Mixture of C_2H_5OH and C_6H_{12} saturated with N_2+H_2 (1 : 3) $C_{H_2SO_4} = 10^{-2}$ mol dm^{-3}	110.0	2182.0

of ammonia in the products was evidenced earlier.[3]

From comparison of Figs 3 and 1 it can be seen that the stationary concentration of hydrazine (at the maximal doses—see figures) is maximal for $[WH_5(dtpe)_2]^+$ solutions saturated with a mixture of N_2 and H_2 and depends on the nature of the solvent. Its value influences the yield of ammonia. Curves 1 and 2 in Fig. 4 are permanently raised and the ammonia concentration (curve 1) at the point corresponding to a dose of 160×10^{17} eV cm^{-3} is 4×10^{-2} mol dm^{-3}. One-third of the $[WH_5(dtpe)_2]^+$ ions could effectively form the bis-dinitrogen tungsten(0) complex which then gives ammonia. The other two-thirds of the tungsten(IV) hydrido complex provide the source of H atoms or H^- ions, which are necessary to reduce coordinated dinitrogen. By considering all these facts it may be stated that the molar ratio of ammonia ($C = 4\times10^{-2}$ mol dm^{-3}) to $[WH_5(dtpe)_2]^+$ ($C = 3.3\times10^{-3}$ mol dm^{-3}) is about 12:1. Thus, the process of fixation and reduction of molecular nitrogen must be cyclic in nature. Also considering that the amount of donor H atoms in W—H groups ($C = 5\times10^{-2}$ mol dm^{-3}) was too low to generate 16×10^{-2} mol dm^{-3} H atoms in N—H groups ($C_{NH_4^+} = 4\times10^{-2}$ mol dm^{-3}), one may predict that the correct amount of $[WH(dtpe)_2(N_2)_2]^+$ converted into $[WH_5(dtpe)_2]^+$ is represented by reaction 1 in the mechanism. The exchange of N_2 for H_2 in the $[W(N_2)_2(dtpe)_2]$ complex proceeds with a lower rate because of the higher energy of the W—N_2 bond.[15] Therefore, the degree of sloping of the part of the curve in Fig. 2 corresponding to higher doses is lower than in Fig. 4. Maxima on curves 3 and 4 in Fig. 4 are connected with the decomposition of NH_4^+ ions by CH_2OH radicals, as was discussed earlier.[2]

On the basis of all the above and on data presented in previous papers[1-4] the following mechanism of the radiation-catalytic process of fixation and reduction of molecular nitrogen could be proposed:

Mechanism (a)

$$\text{solvent} \rightsquigarrow S^+, H, R, e_s^-, S^* \tag{1}$$

$$[WH_4(dtpe)_2] + 2N_2 \overset{e_s^-, S^*, H}{\rightleftharpoons} [W(N_2)_2(dtpe)_2] + 2H_2 \tag{2}$$

$$[W(N_2)_2(dtpe)_2] + [WH_4(dtpe)_2] \longrightarrow \begin{bmatrix} W(dtpe)_2 \\ | \\ N_2H_4 \end{bmatrix} + [W(dtpe)_2] + N_2 \tag{3}$$

$$\begin{bmatrix} N_2H_4 \\ | \\ W(dtpe)_2 \end{bmatrix} \xrightarrow[H^+]{S^+} \begin{bmatrix} N_2H_5^+ \\ | \\ W(dtpe)_2 \end{bmatrix} \tag{4}$$

$$\begin{bmatrix} N_2H_5^+ \\ | \\ W(dtpe)_2 \end{bmatrix} \xrightarrow[e^-, H^-]{H^+, S^+} 2NH_3 + [W(dtpe)_2] \tag{5}$$

$$[W(dtpe)_2] + 2N_2 \longrightarrow [W(N_2)_2(dtpe)_2]. \tag{6}$$

Mechanism (b)
(in acidified solutions)

$$[WH_5(dtpe)_2]^+ + 2N_2 \overset{H, S^*, R}{\rightleftharpoons} [WH(N_2)_2(dtpe)_2]^+ + 2H_2 \tag{1}$$

$$[WH(N_2)_2(dtpe)_2]^+ + [WH_5(dtpe)_2]^+ \longrightarrow \begin{bmatrix} WH(dtpe)_2 \\ | \\ N_2H_4 \end{bmatrix}^+ + [WH(dtpe)_2]^+ + N_2 \tag{2}$$

$$\begin{bmatrix} WH(dtpe)_2 \\ | \\ N_2H_4 \end{bmatrix}^+ + [WH_5(dtpe)_2]^+ \xrightarrow{2H^+} \begin{cases} \xrightarrow{(a)} 2NH_3 + [WH(dtpe)_2]^+ + [WH_3(dtpe)_2]^{3+} + H_2 \\ \xrightarrow{(b)} 2NH_3 + [WH(dtpe)_2]^+ + [WH_3(dtpe)]^+ + H_2 \end{cases} \tag{3}$$

$$[WH_3(dtpe)_2]^{3+} + H_2 \xrightarrow[R]{H} [WH_5(dtpe)_2]^+ \tag{4}$$

$$[WH(dtpe)_2]^+ + 2N_2 \longrightarrow [WH(N_2)_2(dtpe)_2]^+. \tag{5}$$

Complex $[WH(N_2)_2(dtpe)_2]^+$ [reactions (1) and (5)] is well known in the solid phase with dppe,[13–15] whereas hydrogenation reactions of olefins using molybdenum or tungsten hydrido complexes which proceed with reduction of the central atoms [like reactions (2) and (3b)] are also described.[16]

The proposed mechanism of fixation and reduction of molecular nitrogen using $[WH_4(dtpe)_2]$ is in accord with the well known fact that in the course of the reduction of N_2 by nitrogenase together with two ammonia molecules one molecule of H_2 is liberated. This could mean that metal centres in nitrogenase are protonated (H^+ ions from the environment) and then nitrogenase could be reduced as in reaction (3) (in acidified solution) or (4) (in non-acidified solution). Thus, the proposed mechanism could be treated as an alternative one for the simplified explanation of the action of nitrogenase to that proposed earlier.[18]

FORMATION OF HETEROBIMETALLIC RUTHENIUM–MERCURY NITROSYL COMPLEXES

LORETO BALLESTER-REVENTOS,* ANGEL GUTIERREZ-ALONSO and MARIA FELISA PERPIÑAN-VIELBA

Departamento de Quimica Inorganica, Facultad de Ciencias Quimicas, Universidad Complutense, 28040-Madrid, Spain

(*Received* 13 *June* 1990; *accepted* 7 *January* 1991)

Abstract—The nitrosyl ruthenium complexes $[RuCl(CO)(NO)(PPh_3)_2]$ and $[Ru(NO)_2(PR_3)_2]$ (R = Ph, CH_2CH_2CN) react with an excess of mercury salts, HgX_2, to give the first nitrosyl ruthenium complexes containing ruthenium–mercury bonds. The reactions take place with substitution of one or more ligands in the parent compound and *cis* addition of the X and HgX groups.

One of the reactions most extensively used in the synthesis of heterobimetallic transition compounds is the addition of a mercury(II) compound to an electron-rich metal complex.[1] The usual reaction implies an adduct type interaction with formation, in some cases, of the oxidative addition product.[2]

There are very few examples of bimetallic ruthenium–mercury compounds, the majority being adduct type complexes, for example $[Ru(C_5H_5)_2 \cdot HgCl_2]$[3] and $[RuCl_2(PPh_3)_3 \cdot HgCl_2]$.[4] Even more scarce are the oxidative addition complexes and only the mononuclear carbonyls $[Ru(CF_3)(HgCF_3)(CO)_2(PPh_3)_2]$[5] and $[Ru(X)(HgX)(CO)_3(PR_3)]$ are known.[6]

The unstable derivative $[RuCl_2(HgCl)(NO)(PPh_3)_2]$ has also been reported as an unisolated intermediate in the reaction between $[RuCl(CO)(NO)(PPh_3)_2]$ and $HgCl_2$.[7] The analogous osmium complex is, however, known.[8]

We report now the isolation and characterization of the first ruthenium–mercury bimetallic nitrosyls, obtained by oxidative addition of mercury salts to ruthenium nitrosyl derivatives.

RESULTS AND DISCUSSION

Reactions of $[RuCl(CO)(NO)(PPh_3)_2]$

The reaction between $[RuCl(CO)(NO)(PPh_3)_2]$ and excess HgI_2 leads to an orange–brown solid of formula $[RuCl(I)(HgI)(CO)(NO)(PPh_3)]$ (**I**). The IR spectrum of which (Table 1) shows increases of 43 and 268 cm^{-1} in the ν(CO) and ν(NO) bands, respectively, relative to the starting material and indicative of oxidation.

This oxidation is not localized over the metal, with a formal oxidation state of +2 in both cases, but over the [RuNO] system which is oxidized from $[RuNO]^8$, with a bent nitrosyl (NO^-) in the starting material,[9] to $[RuNO]^6$, with a linear nitrosyl (NO^+) in the reaction product.

Using $Hg(SCN)_2$ a similar reaction takes place and together with the addition of the mercuric salt, substitution of the halogen by thiocyanate is also observed, with formation of $[Ru(SCN)_2(HgSCN)(CO)(NO)(PPh_3)]$ (**II**). Its IR spectrum shows that the carbonyl and nitrosyl bands shift to higher frequencies due to oxidation. There are also two bands at 2100 and 2130 cm^{-1} due to the ν(CN) stretch of two different thiocyanates, which could be those bonded to mercury and ruthenium.

The ^{31}P NMR spectrum in DMSO for this compound shows one single signal at 25.4 ppm with satellites due to the ^{199}Hg–^{31}P coupling. The coupling constant of 850 Hz is higher than the values reported in the literature,[10] supporting a *trans* arrangement of the Hg(SCN) and PPh_3 groups in the molecule. As the nitrosyl and carbonyl ligands both have a high *trans* influence, it is unlikely that these groups are opposite in the molecule and so the stereochemistry for complex **II** shown in Fig. 1(a) was proposed.

The reaction between $[RuCl(CO)(NO)(PPh_3)_2]$

and $Hg(CN)_2$ leads to different compounds depending on the solvent used.

When the reaction takes place in dichloromethane–ethanol the complex $[RuCl(CN)(HgCN)(CO)(NO)(PPh_3)]$ (**III**) is obtained. As is shown in Table 1, the IR spectrum is similar to those of complexes **I** and **II**, suggesting a similar structure. There are also two $\nu(CN)$ stretches corresponding to two different cyanides. The insolubility of this complex and the ready decomposition that occurs in DMSO prevents the attainment of a good NMR spectrum, but as this complex is similar to the thiocyanate complex, a *trans* configuration Hg—Ru—P is expected. By assuming a *cis* disposition of the carbonyl and nitrosyl ligands and according to the proposed mechanism for these reactions (see below), Fig. 1(b) is suggested as the most likely stereochemistry for this complex.

If the reaction occurs in ethanol a different compound of formula $[RuCl(CO)(NO)(PPh_3)_2 \cdot Hg(CN)_2]$ (**IV**) is formed. The IR spectrum shows bands at 1935 cm^{-1}, $\nu(CO)$, and 1605 cm^{-1}, $\nu(NO)$, very close to those of the parent compound (1925 and 1592 cm^{-1}, respectively). This suggests a weak interaction between the metals, probably as an adduct complex where the oxidation state of the ruthenium is not sensibly modified, in contrast to the high shift observed in the oxidative addition complex.

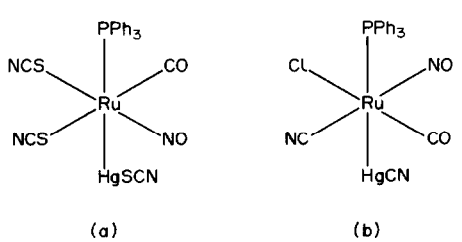

Fig. 1. Proposed structures for complexes (a)**II** and (b)**III**.

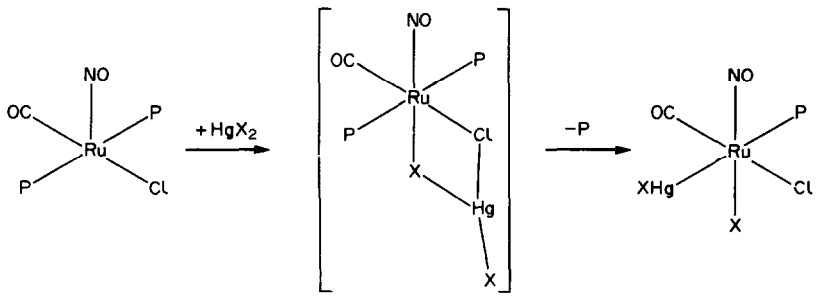
Complex **IV** undergoes conversion in solution to the oxidative addition derivative, **III**. This fact suggests that the adduct is an intermediate in the oxidative addition reaction and the proposed mechanism for this reaction is shown in Scheme 1.

The formation of a similar intermediate has been proposed in the reaction of $[RuCl_2(CO)_2(PPh_3)_2]$ with $HgPh_2$ to account for the formation of $[RuCl(Ph)(CO)_2(PPh_3)_2]$ as the final product.[11] The ruthenium–mercury interaction in complex **IV** is assumed to be via pseudohalogen and chlorine bridges due to the low value of the $\nu(Ru—Cl)$ stretch, about 40 cm^{-1} lower than a typical terminal Ru—Cl bond (for example in complex **I**, Table 1), which appears to indicate that the chlorine is acting as a bridge between ruthenium and mercury. Nevertheless, other possible links, like direct bonds between the metals or a single bridge through the cyano group, cannot be excluded, as we have not enough evidence to choose one specific coordination mode.



Scheme 1.

The tetrahedral complex $[Ru(NO)_2(PPh_3)_2]$ (**V**) reacts with excess HgX_2 with substitution of one nitrosyl and one phosphine and oxidation to formal ruthenium(II) complexes of formula $[RuX_2(HgX)(NO)(PPh_3)]$. An exception to this behaviour is the reaction with $Hg(SCN)_2$ which gives rise to the formation of $[Ru(SCN)(HgSCN)_2(NO)(PPh_3)]$ (**VII**), although this compound has several similarities with the rest of the complexes of the series.

The complex $[Ru(NO)_2(tcep)_2]$ (**VI**) was obtained from **B** by phosphine substitution. The increase in the ν(NO) band can be explained in terms of the lower basicity of tris-2-cyanoethylphosphine relative to triphenylphosphine.[12]

Complexes **VII–XIII** show an increase of *ca* 250 cm^{-1} in the ν(NO) stretch, indicative of a NO^+ group in ruthenium(II) complexes. Complex **IX** probably contains lattice $Hg(CN)_2$ and the IR spectrum shows, for the three different M—CN bonds of the compound, two bands at 2100 and 2140 $cm.^{-1}$ Since complex **X**, containing only Ru—CN and Hg—CN bonds, has only one broad band at 2100 cm^{-1} which must include both stretches, the extra band in the IR of complex **IX** may be attributable to the lattice mercury cyanide. The high value of this frequency may indicate that the cyanides of these lattice molecules act as bridges, as in free $Hg(CN)_2$ [ν(CN) = 2195 cm^{-1}].

In the reaction of **V** with $HgCl_2$, elimination of mercury and formation of $[RuCl_3(NO)(PPh_3)_2]$ occurs, whereas complex **VI** produces $[RuCl_2(HgCl)(NO)(tcep)]$ (**XI**), with ν(Ru—Cl) and ν(Hg—Cl) at 320 and 270 cm^{-1}, respectively. In a similar manner, complex **V** reacts with ClHgPh to give a mixture of $[RuCl_3(NO)(PPh_3)_2]$ and $[RuCl_2(HgPh)(NO)(PPh_3)]$ (**XII**). Reaction of **VI** and ClHgPh affords the analogous complex **XIII**, whose IR spectrum shows only one ν(Ru—Cl) band, suggesting a Cl—HgPh break in the addition reaction.

The ^{13}C NMR spectrum of **XIII** shows two signals for the cyanide (119.8 and 120.4 ppm) and for the methylene carbons (23.5 and 22.6, and 11.8 and 9.9 ppm) of the tcep, indicating different CH_2CH_2CN groups. This fact can be interpreted in terms of a restricted rotation of the phosphine. The phenyl signals appear slightly shifted to lower fields relative to free ClHgPh,[13] as expected if HgPh acts as a Lewis acid. The *ortho* and *meta* carbons of this phenyl group show coupling to ^{199}Hg of similar magnitude to that in the free ClHgPh, supporting the idea of the Cl—HgPh break and the addition of the Cl and HgPh groups to the ruthenium.

Finally the ^{31}P NMR spectrum of this compound contains a septuplet at 29.6 ppm [^2J(P—H) = 11.5 Hz] with two satellites [^2J(Hg—P) = 486 Hz], indicative of a *trans* Hg—Ru—P arrangement in the molecule. In contrast, the spectrum of **XII** contains the signal at 26.5 ppm with ^2J(Hg—P) = 101.8 Hz. This coupling appears to be smaller than those observed for *trans* dispositions and we cannot determine if mercury and phosphorus are mutually *cis* or *trans* in this compound.

EXPERIMENTAL

All reactions were carried out under oxygen-free nitrogen. $[RuCl(CO)(NO)(PPh_3)_2]$[7] and $[Ru(NO)_2(PPh_3)_2]$[14] were synthesized by the published methods. IR spectra were recorded on KBr pellets using a Perkin–Elmer 1330 spectrophotometer. NMR spectra were recorded with a Bruker WP-80-SY relative to TMS (^{13}C) and 85% $[H_3PO_4(^{31}P)$.

Preparation of $[RuCl(I)(HgI)(CO)(NO)(PPh_3)]$ (**I**)

A suspension of $[RuCl(CO)(NO)(PPh_3)_2]$ (0.36 g, 0.5 mmol) and HgI_2 (0.67 g, 1.5 mmol) in ethanol (30 cm^3) was refluxed for 2 h. The brown solution was filtered and the solvent removed *in vacuo*. The solid was extracted with dicholoromethane. Addition of diethyl ether gave a purple solid in 63% yield. Found: C, 23.9; H, 1.6; N, 1.6. Calc.: C, 25.0; H, 1.7; N, 1.5.

Preparation of [$Ru(SCN)_2(HgSCN)(CO)(NO)(PPh_3)$] (**II**)

A mixture of [$RuCl(CO)(NO)(PPh_3)_2$] (0.36 g, 0.5 mmol) in dichloromethane (20 cm^3) and $Hg(SCN)_2$ (0.47 g, 1.5 mmol) in ethanol (20 cm^3) was refluxed for 2 h. The orange–brown precipitate which formed was collected and washed with dichloromethane, ethanol and diethyl ether. Yield 87%. Found: C, 33.1; H, 1.8; N, 7.2. Calc.: C, 33.2; H, 1.9; N, 7.0.%

Preparation of [$RuCl(CN)(HgCN)(CO)(NO)(PPh_3)$] (**III**)

To a solution of [$RuCl(CO)(NO)(PPh_3)_2$] (0.36 g, 0.5 mmol) in dichloromethane (15 cm^3), a solution of $Hg(CN)_2$ (0.38 g, 1.5 mmol) in ethanol (20 cm^3) was added and the mixture was stirred for 3 h. The solution, which became orange, was concentrated to 5 cm^3 and then 20 cm^3 of diethyl ether were added affording **III** as an orange precipitate. Yield 79%. Found: C, 35.6; H, 2.4; N, 6.0. Calc.: C, 35.5; H, 2.1; N, 5.9%.

Preparation of [$RuCl(CO)(NO)(PPh_3)_2 \cdot Hg(CN)_2$] (**IV**)

A mixture of [$RuCl(CO)(NO)(PPh_3)_2$] (0.36 g, 0.5 mmol) and $Hg(CN)_2$ (0.25 g, 1.0 mmol) in ethanol was refluxed for 3 h. During this time the solid changed from green to orange–brown, then was filtered and washed with ethanol, dichloromethane and diethyl ether. Yield 60%. Found: C, 47.8; H, 3.2; N, 4.4. Calc.: C, 48.2; H, 3.1; N, 4.3%.

Preparation of [$Ru(NO)_2(tcep)_2$] (**VI**)

A solution of [$Ru(NO)_2(PPh_3)_2$] (3.45 g, 5 mmol) and tcep (2.85 g, 15 mmol) in toluene (50 cm^3) was refluxed for 2 h. The solution changed from red to orange and a dark orange precipitate appeared. After cooling to room temperature, the solid was filtered, washed with toluene, ethanol and diethyl ether. Yield 77%. Found: C, 39.6; H. 4.4; N, 20.9. Calc.: C, 39.5; H, 4.4; N, 20.4%.

Preparation of [$Ru(SCN)(HgSCN)_2(NO)(PPh_3)$] (**VII**)

A suspension of [$Ru(NO)_2(PPh_3)_2$] (0.35 g, 0.5 mmol) and $Hg(SCN)_2$ (0.48 g, 1.5 mmol) in ethanol was refluxed for 3 h. The ochre solid was collected, washed with ethanol, toluene and ethanol and dried. Yield 84%. Found: C, 26.2; H, 1.6; N, 5.8. Calc.: C, 26.0; H, 1.6; N, 5.8%.

The following complexes were prepared in a similar way using [$Ru(NO)_2(PPh_3)_2$] or [$Ru(NO)_2(tcep)_2$] and a 1 : 3 excess of the appropriate mercury salt:

[$Ru(SCN)_2(HgSCN)(NO)(tcep)$] (**VIII**): brown solid; yield 71%. Found: C, 20.4; H, 1.8; N, 14.0. Calc.: C, 20.6; H, 1.7; N, 14.0%.

[$Ru(CN)_2(HgCN)(NO)(PPh_3) \cdot Hg(CN)_2$] (**IX**): ochre solid; yield 69%. Found: C, 29.4; H, 1.7; N, 9.1. Calc.: C, 29.9; H, 1.6; N, 9.1%.

[$Ru(CN)_2(HgCN)(NO)(tcep)$] (**X**): brown solid; yield 74%. Found: C, 23.5; H, 2.1; N, 16.4. Calc.: C, 23.9; H, 2.0; N, 16.3%.

[$RuCl_2(HgCl)(NO)(tcep)$] (**XI**): yellow–orange solid; yield 58%. Found: C, 17.0; H, 2.0; N, 8.8. Calc.: C, 17.1; H, 1.9; N, 8.9%.

[$RuCl_2(HgPh)(NO)(PPh_3)$] (**XII**): orange–brown solid; yield 49%. Found: C, 38.9; H, 2.7; N, 2.2. Calc.: C, 40.4; H, 2.8; N, 2.0%.

[$RuCl_2(HgPh)(NO)(tcep)$] (**XIII**): orange–brown solid; yield 76%. Found: C, 26.5; H, 2.5; N, 8.4. Calc.: C, 26.8; H, 2.5; N, 8.4%.

REACTIONS OF CARBONYL AND NITROSYL RUTHENIUM COMPLEXES WITH UNINEGATIVE (X,S)-DONOR LIGANDS (X = S, P)

A. GUTIERREZ-ALONSO and L. BALLESTER-REVENTOS*

Departamento de Quimica Inorganica, Facultad de Ciencias Quimicas,
Universidad Complutense, 28040-Madrid, Spain

(*Received* 13 *June* 1990; *accepted* 7 *January* 1991)

Abstract—Reactions of 1,1-dithiolates ($EtOCS_2^-$ and $Et_2NCS_2^-$) and the related (P,S)-donor ligand ($Ph_2PCSNPh^-$) with halocarbonylphosphine complexes of ruthenium give halide substitution derivatives with chelation of the (S,S)- or (P,S)-donor ligand. The reaction of $[RuCl_2(CO)(CS)(PPh_3)_2]$ with dithiolates gives rise to displacement of the thiocarbonyl ligand, while with $Ph_2PCSNPh^-$ the derivative $[RuCl(Ph_2PCSNPh)(CO)(CS)(PPh_3)]$ is obtained. The carbonyl nitrosyl complex $[RuCl(CO)(NO)(PPh_3)_2]$ reacts with displacement of nitrosyl and formation of $[RuCl(X,S)(CO)(PPh_3)_2]$ complexes.

The halocarbonyl and halophosphine complexes of ruthenium react with 1,1-dithiolates with formation of hexacoordinated $Ru(S,S)_2L_2$ (L = CO, PPh_3),[1] with the (S,S)-donor ligands mutually *cis*. The neutral ligands in these complexes are not easily substituted, unlike the R_2PS_2 analogues[2] which undergo substitution of one neutral ligand, e.g. PPh_3, by carbonyl of other phosphines to give the mixed $Ru(S,S)_2LL'$ complexes. The phosphine carbonyl derivative has also been produced by reaction of $[RuCl(OOCCH_3)(CO)(PPh_3)_2]$ with the alkali dithiocarbamate.[3] To date there are no reports of the reactions of 1,1-dithiolates with thiocarbonyl or nitrosyl ruthenium derivatives.

We report in this paper the study of the reactivity of halocarbonylphosphine ruthenium complexes towards anionic (X,S)-donor ligands: Etxant ($EtOCS_2^-$), Et_2dtc ($Et_2NCS_2^-$) and $Ph_2PCSNPh^-$, the latter usually acting as a (P,S) bidentate ligand.[4,5] The observed reactions take place with substitution of at least one of the chlorine ligands and one or more of the neutral ligands by the (X,S)-donor ligand.

RESULTS AND DISCUSSION

The reaction of $RuCl_2(PPh_3)_2$ and $Ph_2PCSNPh^-$ in ethanol gives the complex $[Ru(Ph_2PCSNPh)_2(PPh_3)_2]$ (**I**), similar to those described for xanthates and dithiocarbamates.[1,3] This complex reacts with phosphines, like tcep {$P(CH_2CH_2CN)_3$} or dppe ($Ph_2PCH_2CH_2PPh_2$) in refluxing acetone to give $[Ru(Ph_2PCSNPh)_2(tcep)_2]$ (**II**) and $[Ru(Ph_2PCSNPh)_2(dppe)]$ (**III**), respectively. The IR spectra of these complexes (Table 1) show a strong band at 1525–1550 cm^{-1} attributed to the ν(C=N) stretch of the exocyclic C=NPh group, which reveals bidentate coordination to the metal[6] via phosphorus and sulphur atoms. A medium intensity band at 940 cm^{-1} is assigned to the ν(C—S) vibration.

The ^{31}P NMR spectrum of complex **I** (Table 2) shows two triplets with a coupling of 20 Hz, indicating two pairs of equivalent phosphorus mutually *cis*. This can be interpreted as being due to *cis* positioning of the PPh_3 ligands, as has been observed in the analogous dithiocarbamate complex[2] and evidenced in their substitution by dppe, and *trans* coordination of the two phosphorus atoms of the phosphinethioformamido ligands, as shown in Fig. 1(a).

The $[RuCl_2(CS)(PPh_3)_2]_2$ complex, obtained from $RuCl_2(PPh_3)_3$ and CS_2,[7] has a dimeric structure with chloro bridges, which can be cleaved by donor ligands like CO and forms $[RuCl_2(CO)(CS)(PPh_3)_2]$. These complexes react in different ways with dithiolate ligands. Thus, $[RuCl_2(CS)(PPh_3)_2]_2$ reacts with the (X,S)-donor ligands to give com-

plexes of formula $[Ru(X,S)_2(CS)(PPh_3)]$ (**IV–VI**), while the carbonyl–thiocarbonyl derivative reacts with Etxant or Et_2dtc to give the previously known $[Ru(S,S)_2(CO)(PPh_3)]$ (**VII–VIII**)[4] and with $Ph_2PCSNPh^-$ forming $[RuCl(Ph_2PCSNPh)(CO)(PPh_3)]$ (**IX**). All these complexes show characteristic IR bands of bidentate (X,S) ligands (Table 1).[1,8,9] Complexes **IV**, **V**, **VI** and **IX** also exhibit a band at 1270–1290 cm^{-1} attributed to ν(CS) of a terminal thiocarbonyl ligand.

The ^{31}P NMR spectrum of **VI** shows a triplet at 31.43 ppm for the triphenylphosphine phosphorous and a doublet at 21.90 ppm for the two equivalent phosphinothioformate ligands. The coupling constant, 22 Hz, suggests a *cis* disposition of the non-equivalent phosphorus [Fig. 1(b)]. The *cis* disposition of PPh_3 and CS is proposed in accordance with that observed in the related carbonyl complexes **VII** and **VIII**.[4]

The substitution of a thiocarbonyl group in the presence of carbonyl ligands is a very unusual reaction and has been interpreted according to the relative strengths of the M—CO and M—CS bonds.[10] Richardson *et al.*[11] suggest that substitution may occur when $\nu(CS) \geqslant 1348$ cm^{-1}, as found in $[Fe(C_5H_5)(CO)_2(CS)]^+$ where both carbonyl and thiocarbonyl can be displaced by other ligands. In our case, the complex $[RuCl_2(CO)(CS)(PPh_3)_2]$ shows ν(CS) at 1295 cm^{-1}, suggesting a stronger M—CS than M—CO bond. The observed behaviour must then be explained on the basis of nucleophilic attack on the thiocarbonyl, as has been reported in reactions with amines or alcohols.[12]

A possible mechanism for this reaction would be the substitution of one chlorine and one phosphine by the dithiolate, followed by nucleophilic attack on CS by a second dithiolate with formation of the metallacycle Ru—C(S)—S—C(X)—S. This ring has been reported in molybdenum(II) chemistry with Et_2dtc and CS ligands.[13] In our complexes the metallacyclic intermediate would not be stable, probably because of the high reaction temperature (reflux of ethanol), and would decompose with loss of CS to isolated $[Ru(S,S)_2(CO)(PPh_3)]$.

The reaction with $Ph_2PCSNPh^-$ stops after the first step and so derivative **IX** is isolated. The most probable chlorine to be substituted in this step is the one situated *trans* to CS, which corresponds to the higher *trans* effect of this ligand relative to CO.

The ^{31}P NMR spectrum of **IX** shows two doub-

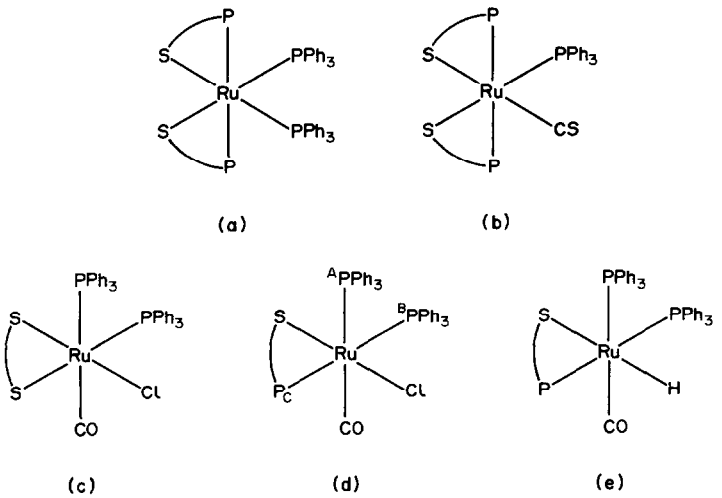

Fig. 1. Proposed structures for complexes: (a) **I**, (b) **VI**, (c) **XI**, (d) **XII** and (e) **XIII**.

lets which can be assigned to two non-equivalent phosphorus atoms. The ^2J(P—P) value of 81 Hz does not distinguish unambiguously between a *cis* or *trans* disposition of both phosphorus atoms. This coupling value is intermediate between the published values found for two *cis* (0–70 Hz) and *trans* (60–800 Hz) phosphorus atoms.[14] However, the coupling constants found in the present work for the ruthenium complexes of *ca* 20 Hz for *cis* coupling and 82 Hz (see below) for *trans* coupling suggest that complex **IX** may have a *trans* arrangement of the two phosphorus atoms.

The reaction of $[RuCl(CO)(NO)(PPh_3)_2]$ with 1,1-dithiolates takes place with substitution of the nitrosyl to give complexes of formula $[RuCl(X,S)(CO)(PPh_3)_2]$ (**X–XII**). The IR spectra show the characteristic bands of chelate (X,S) ligands together with a ν(Ru—Cl) stretch at 330 cm^{-1}, shifted to higher frequencies than the parent compound as a consequence of the loss of nitrosyl.

The ^{31}P NMR spectrum of **XI** shows two doublets for the two *cis* non-equivalent phosphorus atoms and the ^{13}C NMR shows the carbonyl signal as a doublet, $^2J(^{13}C—^{31}P) = 15$ Hz, for a carbonyl *trans* to one phosphine. Although this value is rather small and more typical of a *cis* coupling,[15] the pattern, a doublet, indicates that the carbonyl is coupled only to one phosphorus, e.g. in our case the expected J(C—P) should be nearly zero. On the other hand (see below), the analogous $[RuH(Ph_2PCSNPh)(CO)(PPh_3)_2]$ in which the only variation is the exchange of chlorine by hydride should have the carbonyl *trans* to one phosphine and thus we propose the same stereochemistry for both complexes. The only stereochemistry that fits these conditions for **XI** is shown in Fig. 1(c). The ^{31}P NMR spectrum of **XII** shows an ABC pattern

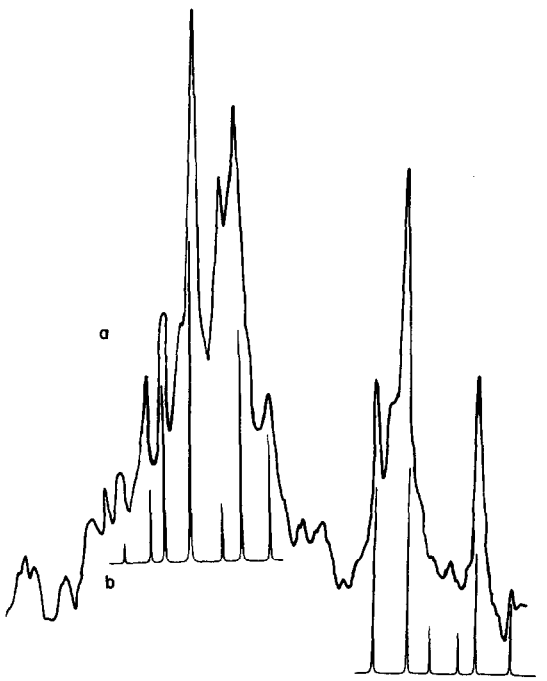

Fig. 2. (a) Observed and (b) simulated ^{31}P NMR spectra of **XII**.

interpreted by a *mer* disposition of the three phosphorus nuclei as shown in Fig. 2, where both the experimental and the simulated spectra are represented. We assign the signal at lower frequencies to the phosphinothioformamido ligand in accordance with that observed in the spectrum of **VI** (Table 2). The most likely structure has been chosen in accordance with the similarities between complexes **XI** and **XII** and is represented in Fig. 1(d).

The reaction of $[RuHCl(CO)(PPh_3)_3]$ with $Ph_2PCSNPh^-$ affords the hydride $[RuH(Ph_2$

$PCSNPh)(CO)(PPh_3)_2]$ (**XIII**), having the same formula as those of Etxant and Et_2dtc previously reported.[3] This derivative shows the ν(Ru—H) stretch as a shoulder at 1970 cm^{-1}, shifted 40 cm^{-1} to lower frequencies relative to the starting chlorohydride and attributed to the substitution of the phosphine *trans* to this hydride. The ^1H NMR spectrum shows a pseudo-quadruplet at -0.64 ppm with ^2J(P—H) = 7.1, 7.4 and 7.5 Hz for similar coupling of the three non-equivalent phosphorus atoms to the hydride. From this result and from comparison with complexes **XI** and **XII** the stereochemistry chosen for complex **XIII** is shown in Fig. 1(e).

The 1,1-dithiolates used react with *cis,cis,trans*-$[RuCl_2(CO)_2(PPh_3)_2]$ with partial substitution of chlorines, and formation of $[RuCl(S,S)(CO)_2(PPh_3)]$ (**XIV–XV**) that show bands for a bidentate dithiolate ligand and for two *cis* carbonyls, which shift to lower frequencies than in the dichloride and are related to the higher donor character of the dithiolates. On the other hand, the reaction with $Ph_2PCSNPh^-$ occurs with substitution of one carbonyl ligand instead of a phosphine. The $[RuCl(Ph_2PCSNPh)(CO)(PPh_3)_2]$ complex thus obtained shows an identical IR spectrum to **XII**, suggesting that the same isomer has been formed. This would imply reorganization of the ligands around the metal had occurred in the reaction.

EXPERIMENTAL

All reactions were carried out under oxygen-free nitrogen. $Ph_2PCSNHPh$,[16] $RuCl_2(PPh_3)_3$,[17] $[RuCl_2(CS)(PPh_3)_2]_2$,[7] $[RuCl_2(CO)(CS)(PPh_3)_2]$,[7] $[RuCl(CO)(NO)(PPh_3)_2]$,[18] $[RuHCl(CO)(PPh_3)_3]$[19] and *cis,cis,trans*-$[RuCl_2(CO)_2(PPh_3)_2]$[20] were prepared as reported. Analyses were carried out by Elemental Microanalysis Ltd (Devon); IR spectra were recorded on KBr discs using a Perkin–Elmer 1330 spectrophotometer; and NMR spectra were recorded on a Bruker WP80SY using TMS and 85% H_3PO_4 as standards.

Preparation of $[Ru(Ph_2PCSNPh)_2(PPh_3)_2]$ (**I**)

An ethanolic solution of $RuCl_2(PPh_3)_3$ (0.96 g) and $Ph_2PCSNHPh$ (0.64 g) with a few drops of NEt_3 was refluxed for 2 h. The orange solution was concentrated *in vacuo* to 10 cm^3 and filtered. Addition of 30 cm^3 of cold Et_2O produces an orange solid, which was filtered and washed with Et_2O. Yield: 86%. Found: C, 70.0; H, 4.8; N, 2.2. Calc.: C, 70.2; H, 4.8; N, 2.2%.

Preparation of $[Ru(Ph_2PCSNPh)_2(tcep)_2]$ (**II**)

A solution of **I** (0.43 g) and tcep (0.55 g) in toluene was refluxed for 3 h. The solvent was then removed *in vacuo* and the solid extracted with CH_2Cl_2 and precipitated as a yellow powder by addition of light petroleum. Yield: 48%. Found: C, 59.8; H, 4.9; N, 10.1. Calc.: C, 59.6; H, 4.8; N, 9.9%.

Preparation of $[Ru(Ph_2PCSNPh_2)(dppe)]$ (**III**)

The compound was obtained as yellow microcrystals from **I** (0.31 g) and dppe (0.15 g) as described for **II**. Yield: 74%. Found: C, 67.3; H, 4.9; N, 2.6. Calc.: C, 67.4; H, 4.8; N, 2.4%.

Preparation of $[Ru(X,S)_2(CS)(PPh_3)]$ (**IV–VI**)

A solution of $[RuCl_2(CS)(PPh_3)_2]_2$ (1 mmol) and the alkali dithiolate (2.1 mmol) (or $Ph_2PCSNHPh$ and excess of NEt_3) in 25 cm^3 of EtOH was refluxed for 2 h. The solvent was removed *in vacuo* and the solid extracted with CH_2Cl_2. Addition of hexane affords the product as an orange solid, which was washed with Et_2O. $[Ru(Etxant)_2(CS)(PPh_3)]$ (**IV**), yield: 83%. Found: C, 46.1; H, 3.8. Calc.: C, 46.2; H, 3.9%. $[Ru(Et_2dtc)_2(CS)(PPh_3)]$ (**V**), yield: 76%. Found: C, 48.7; H, 5.2; N, 4.0. Calc.: C, 49.5; H, 5.0; N, 4.0%. $[Ru(Ph_2PCSNPh)_2(CS)(PPh_3)]$ (**VI**), yield: 74%. Found: C, 65.5; H, 4.0; N, 2.7. Calc.: C, 65.3; H, 4.3; N, 2.6%.

Preparation of $[Ru(S,S)_2(CO)(PPh_3)]$ (**VII–VIII**)

A solution of $[RuCl_2(CO)(CS)(PPh_3)_2]$ (1 mmol) and the alkali dithiolate (2 mmol) in EtOH was refluxed for 2 h. The orange solution was filtered, concentrated to 5 cm^3 and cooled at 0°C for 2 days to give orange microcrystals of the product. $[Ru(Etxant)_2(CO)(PPh_3)]$ (**VII**), yield: 87%. Found: C, 47.1; H, 4.0. Calc.: C, 47.4; H, 4.0%. $[Ru(Et_2dtc)_2(CO)(PPh_3)]$ (**VIII**), yield: 83%. Found: C, 50.5; H, 5.2; N, 4.1. Calc.: C, 50.6; H, 5.1; N, 4.0%.

Preparation of $[RuCl(Ph_2PCSNPh)(CO)(CS)(PPh_3)]$ (**IX**)

A solution of $Ph_2PCSNHPh$ (0.64 g) and NEt_3 (1 cm^3) in 10 cm^3 of EtOH was added to a hot solution of $[RuCl_2(CO)(CS)(PPh_3)_2]$ (0.77 g) in EtOH (15 cm^3) and the mixture was refluxed for 30 min. The solution was then worked-up as above to give **IX** as an orange solid. Yield: 87%. Found: C, 59.0; H, 3.7; N. 2.0. Calc.: C, 59.2; H, 3.8; N, 1.8%.

Preparation of [RuCl(S,S)(CO)(PPh_3)$_2$] (**X–XI**)

A suspension of [RuCl(CO)(NO)(PPh_3)$_2$] (0.72 g) and the alkali dithiolate (2 mmol) in MeOH (25 cm^3) was refluxed for 15 min until the solution turned red–brown. The hot solution was filtered and cooled at 0°C depositing a brown solid. [RuCl(Etxant)(CO)(PPh_3)$_2$] (**X**), yield: 61%. Found: C; 59.6; H, 4.3. Calc.: C, 59.3; H, 4.3%. [RuCl(Et_2dtc)(CO)(PPh_3)$_2$] (**XI**), yield: 74%. Found: C, 61.3; H, 4.6; N, 1.7. Calc.: C, 60.2; H, 4.8; N, 1.7%. ^{13}C NMR (ppm): 201.65 d [*C*O, ^2J(P—C) = 15 Hz], 194.40 s (S_2CNEt_2), 136–126 m (Ph) 43.15 s (NCH_2CH_3), 12.61 s (NCH_2CH_3).

Preparation of [RuCl($Ph_2PCSNPh$)(CO)(PPh_3)$_2$] (**XII**)

Method (a). A solution of $Ph_2PCSNHPh$ (0.48 g) and NEt_3 (1 cm^3) in EtOH (10 cm^3) was added to a refluxing solution of [RuCl(CO)(NO)(PPh_3)$_2$] (0.72 g) in CH_2Cl_2 (20 cm^3). The solution was refluxed for 1 h, concentrated to 10 cm^3 and filtered. Addition of pentane (20 cm^3) and cooling at 0°C overnight afforded orange microcrystals in 76% yield.

Method (b). A solution of [$RuCl_2$(CO)$_2$(PPh_3)$_2$] (0.75 g), $Ph_2PCSNHPh$ (0.64 g) and NEt_3 (1 cm^3) in EtOH (25 cm^3) was refluxed for 5 h. The solution was filtered, the solvent was removed *in vacuo* and the residue extracted with 2 × 10 cm^3 of acetone. Addition of Et_2O (30 cm^3) afforded a yellow solid which was recrystallized from CH_2Cl_2–pentane. Yield: 63%. Found: C, 65.5; H, 4.6; N, 1.4. Calc.: C, 66.6; H, 4.5; N, 1.3%.

Preparation of [RuH($Ph_2PCSNPh$)(CO)(PPh_3)$_2$] (**XIII**)

A solution of [RuHCl(CO)(PPh_3)$_3$] (0.95 g, 1 mmol), $Ph_2PCSNHPh$ (0.35 g, 1.1 mmol) and NEt_3(0.5 cm^3) in acetone (30 cm^3) was refluxed for 2 h and then stirred for 1 h. The green precipitate that appeared was recrystallized from CH_2Cl_2–hexane. Yield: 83%. Found: C, 69.2; H, 4.7; N, 1.4. Calc.: C, 69.0; H, 4.7; N, 1.4%. ^{1}H NMR (ppm): 7.7–7.2 m (40H, *Ph*), 6.2–5.4 m (5H, *Ph*—N), −0.64 q [1H, *H*—Ru, J(P—H) = 7.3 Hz, average].

Preparation of [RuCl(S,S)(CO)$_2$(PPh_3)] (**XIV–XV**)

A suspension of *cis,cis,trans*-[$RuCl_2$(CO)$_2$(PPh_3)$_2$] (0.75 g, 1 mmol) and the alkali dithiolate (2.5 mmol) was refluxed for 3 h in EtOH. The solution was filtered, concentrated to 10 cm^3 and then 15 cm^3 of Et_2O were added. The ochre precipitate that appeared was collected, washed with EtOH and Et_2O, and dried. [RuCl(Etxant)(CO)$_2$(PPh_3)] (**XIV**), yield: 65%. Found: C, 47.8; H, 3.5. Calc.: C, 48.9; H, 3.5%. [RuCl(Et_2dtc)(CO)$_2$(PPh_3)] (**XV**), yield: 58%. Found: C, 49.5; H, 4.2; N, 2.5. Calc.: C, 49.8; H, 4.2; N, 2.3%.

(*Received* 5 *October* 1990; *accepted* 9 *January* 1991)

Abstract—Gold(III) can be extracted efficiently into 1,2-dichloroethane with benzo-15-crown-5 (B15C5) from an aqueous solution containing hydrochloric acid and potassium ion. It is found that a bulky ion pair is formed by association of a potassium–crown ether complex cation and complex anion $AuCl_4^-$ in the organic phase. The effects of acidity, temperature and other metal ions on the extraction have been studied. The apparent extraction equilibrium constant K_{ex} has been measured to be 2.7×10^7 at 15°C and the enthalpy change ΔH for the extraction process to be -28.4 kJ mol^{-1}. The crystalline extracted complex was characterized by elemental analysis, IR and UV–vis spectra, and its composition is found to be $K(B15C5)_2AuCl_4$.

Although benzo-15-crown-5 (B15C5) has been widely used to extract and separate alkali and alkali-earth metal ions, there are only a few reports on the extraction and separation of anions and complex anions by it. It has been found that B15C5 can be changed into the potassium–crown ether complex in the presence of potassium ion. The complex reaction may be expressed as follows:

$$n\,B15C5 + K^+ \rightleftharpoons K^+(B15C5)_n \quad n = 1\text{–}2.$$

By associating it with a univalent anion, ReO_4^-,[1] or metallic complex anions, $InBr_4^-$ and InI_4^-,[2] these ion-pair species can be easily extracted into the organic phase. In this paper, the extraction of $AuCl_4^-$ by the potassium–crown ether complex was examined and some satisfactory results were obtained.

EXPERIMENTAL

Reagents and apparatus

B15C5, m.p. 79–80.5°C, was obtained from Anyang Oil and Chemical Factory. The purity of gold is 99.99%. Analytical-grade 1,2-dichloroethane and distilled water were saturated with each other prior to use. Other reagents were of analytical grade.

Spectrophotometric measurements were carried out with Hitachi Model UV-220A (Japan) and Shimadzu IR-435 (Japan) spectrophotometers. For elemental and thermal analyses, a Carlo Erba elemental analysis apparatus Model 1106 (Italy) and a Rigaku thermofiex thermal analyser (Japan) were used.

Procedure

(i) *Extraction.* An aqueous solution containing gold(III) (100 μg cm^{-3}) and 1M hydrochloric acid and the same volume of 1,2-dichloroethane containing a certain amount of B15C5 were placed in a stoppered glass tube and shaken for 5 min at 15 ± 1°C, then centrifuged to separate the phases. The aqueous phase was used to measure the absorbance at 314 nm[3] in order to determine the gold concentration (Beer's law is followed in the concentration ranges of 0–35 μg cm^{-3} of gold) and the gold in the organic phase was determined by subtracting the concentration in the aqueous phase from the total concentration added to the tube initially.

* Author to whom correspondence should be addressed.

The distribution ratio of the gold was defined as:

$$D = [Au^{III}]_o/[Au^{III}],$$

where the subscript "o" denotes organic and the lack of a subscript refers to the aqueous phase.

(ii) *Preparation of the crystalline extracted complex.* A saturated organic phase of benzo-15-crown-5–potassium tetrachloroaurate, obtained from successive extractions of the gold(III) in the aqueous solution containing 1 M hydrochloric acid and a certain amount of potassium ion, was evaporated to almost dryness in a water bath. The residue was recrystallized twice with 1,2-dichloroethane and a red–orange, crystalline complex was obtained.

(iii) *Elemental analyses of the crystalline extracted complex.* Carbon and hydrogen were determined using a 1106 elemental analysis apparatus (Italy), and chlorine by silver nitrate titration with a K_2CrO_4 indicator after the complex was decomposed by alkali solution. The amount of gold was measured at 314 nm after the complex was broken down at 700°C and dissolved in the aqua regia.

RESULTS AND DISCUSSION

The study of the extraction mechanism

The effects of diverse metal ions on extraction of gold were tested by mixing an aqueous phase containing 100 $\mu g\ cm^{-3}$ of gold(III), 1 M hydrochloric acid and 1 M of another metal ion with the same volume of organic phase containing 1.0×10^{-3} M B15C5 according to the proposed extraction method. As can be seen in Table 1, by adding the metal ions to the aqueous solution, the extraction efficiency of gold(III) is increased with varying degrees. This is not surprising since the metal ions can coordinate with B15C5 to form complex cations and the gold(III) which should exist as a complex anion $AuCl_4^-$ in the presence of Cl^- can be extracted on forming an ion-pair species.

Although Na^+ fits well into the cavity of the B15C5 molecule, K^+ is the most effective for gold extraction. Because the radius of K^+ is larger than that of the B15C5 cavity (~1.0 Å), it can be sandwiched between two molecules and a 1:2 (K^+:B15C5) hydrophobic complex can be formed.[4,5]

However, with decreasing radii and increasing valency of the metal ions, the interaction between the metal ions and water molecules becomes stronger and the B15C5 molecule mainly forms 1:1 complexes with the metal ions[4,6,7] and for this reason, the most hydrophobic complex of $K^+(B15C5)_2$ displays the highest efficiency for the extraction of $AuCl_4^-$.

In the absence of the metal ion the extraction of $AuCl_4^-$ is very poor, because it is difficult to form the complex cation of B15C5. As can be seen from Fig. 1 and Table 1, if $[H^+]$ in the aqueous phase is $\leqslant 1$ M, the distribution ratio D is $\leqslant 0.03$. However, with increasing acidity in the aqueous phase gold(III) also can be moderately extracted by B15C5, which may be attributed to the formation of an ion-pair species of $H_3O^+(B15C5)\cdot AuCl_4^-$.

The UV–vis spectra of B15C5 and the extracted complex in 1,2-dichloroethane and $KAuCl_4$ in aqueous solution are shown in Fig. 2. The absorption maximum of B15C5 at 278 nm, caused by an electronic transition in the benzene ring, is shifted to 274 nm in the extracted complex $K(B15C5)_2AuCl_4$, indicating the formation of the complex cation $K^+(B15C5)_2$. After the extraction equilibrium, the golden yellow colour of the organic phase is the same as that of the aqueous phase, and the shapes of the UV–vis absorption spectra in the two phases are similar except for a bathochromic shift from 314 nm in the aqueous solution to 325 nm in 1,2-dichloroethane. This originates from the electronic transition from Cl^- to Au^{III} in the complex anion $AuCl_4^-$,[8] whose absorption spectrum will shift to longer wavelengths with decreasing polarity of the solvent. These results indicate that $AuCl_4^-$ has the same configuration in the organic phase as in the aqueous phase.[9]

Table 1. Effect of metal ions

	LiCl	NaCl	KCl	$MgCl_2$	$AlCl_3$	—
D	2.01	6.67	22.04	0.16	0.35	0.03
r'	0.60	0.95	1.33	0.65	0.50	—

[a] Ionic radius of metal (Å).

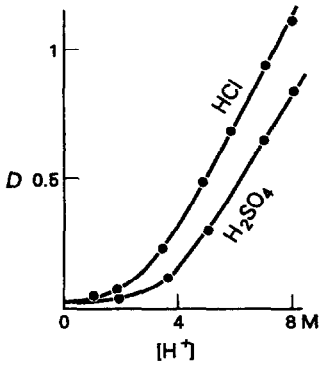

Fig. 1. Effect of acidity on D of gold(III); $[Au^{III}] = 0.50 \times 10^{-3}$ M and $[B15C5] = 1.0 \times 10^{-3}$ M.

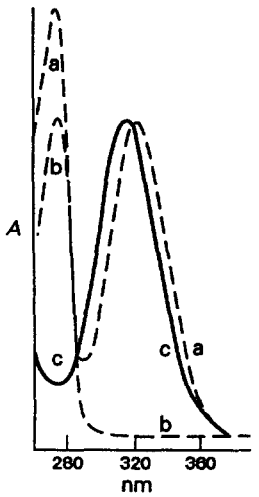

Fig. 2. UV absorption spectra of: (a) $[K(B15C5)_2AuCl_4] = 2.0 \times 10^{-5}$ M, (b) [B15C5] = 2.0×10^{-5} M and (c) $[KAuCl_4] = 2.0 \times 10^{-5}$ M.

On the basis of the above discussion and the electroneutrality principle, the extraction equilibrium may be assumed as:

$$m\,AuCl_4^- + m\,K^+ + n\,B15C5_o \rightleftharpoons [Km(B15C5)_n(AuCl_4)_m]_o \quad (1)$$

and the extraction equilibrium constant can be written as follows:

$$K_{ex} = D/[K^+]^m[B15C5]_o^n \quad (2)$$

$$\log D = m \log [K^+] + n \log [B15C5]_o + \log K_{ex}. \quad (3)$$

According to eq. (1), when two of the concentrations of the three reactants were kept constant and the third reactant concentration was changed, the extractions were carried out and the results are shown in Figs 3 and 4. From slopes

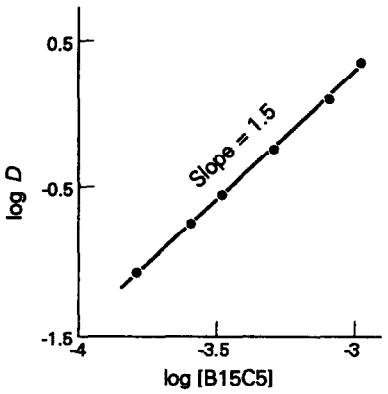

Fig. 4. Effect of log [B15C5] on log D; $[Au^{III}] = 0.50 \times 10^{-3}$ M and $[K^+] = 6.70 \times 10^{-3}$ M.

of the straight lines in the figures and eq. (3), the following conclusions can be obtained: $m = 1$ and $n = 1.5$.

Therefore, the component of the extracted complex in solution was preliminarily determined as $K(B15C5)_{1.5}AuCl_4$, and in accordance with this composition, the extraction equilibrium constant was calculated to be 2.7×10^7 at 15°C.

It should be mentioned that the slope of the straight line in Fig. 4 is 1.5 which may result from two types of extracted complexes of 1 : 1 and 1 : 2 (K^+ : B15C5) species existing simultaneously in the organic phase. A similar result has also been observed in the extraction of $InBr_4^-$ with B15C5 in the presence of K^+.[1]

As shown in Fig. 5 the values of $\ln D$ increase monotonously with a decrease in the temperature. A plot of $\ln D$ against $1/T$ shows a straight line. By using the thermodynamic relation:

$$\ln D = -\Delta H/RT + C, \quad (4)$$

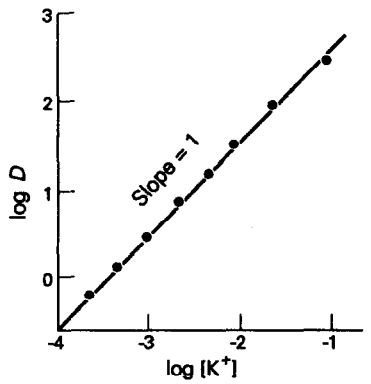

Fig. 3. Effect of $\log[K^+]$ on $\log D$; $[Au^{III}] = 0.50 \times 10^{-3}$ M and [B15C5] = 1.0×10^{-3} M.

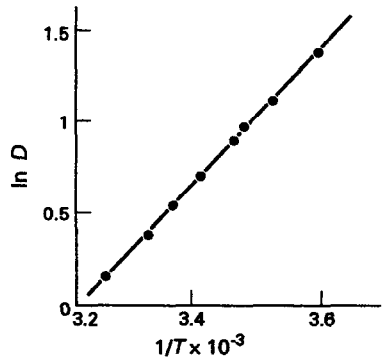

Fig. 5. Effect of T on $\ln D$ of gold(III); $[Au^{III}] = 0.50 \times 10^{-3}$ M and [B15C5] = 1.0×10^{-3} M.

Table 2. Elemental analyses

Complex	Colour		C (%)	H (%)	Cl (%)	Au (%)
$K(B15C5)_2AuCl_4$	Red–orange	Calc.	36.8	4.4	15.5	21.5
		Found	36.8	4.4	15.5	21.6

the value of the enthalpy change, ΔH, was calculated to be -28.4 kJ mol^{-1}. The result indicates that the extraction reaction is exothermic and the extraction efficiency decreases with increasing temperature.

The characterization of the extracted crystalline complex

The extracted crystalline complex is a bright red–orange single crystal, which is stable in air and not deliquescent. It is easily soluble in 1,2-dichloroethane and the solution is also stable, but it is only slightly soluble in methanol and the complex decomposes if left in the air for a long period. The complex is also slightly soluble in water but readily decomposes depositing gold.

The results of elemental analyses are listed in Table 2, which shows that the crystalline complex has the composition $K(C_{14}H_{20}O_5)_2AuCl_4$ ($C_{14}H_{20}O_5$ = B15C5). It is consistent with ref. 2 that the ratio of K^+ : B15C5 is 1 : 2 in the crystalline complex but in the extracted complex in the organic phase it is 1 : 1.5. This may be interpreted as during the process of extraction because of competitive coordination to K^+(B15C5) between free B15C5 and the water molecule the 1 : 1 and 1 : 2 extracted complexes (K^+ : B15C5) are simultaneously present in the organic phase.

Since it is impossible to record real IR spectra of B15C5 and complex $K(B15C5)_2AuCl_4$ using the KBr-pressed-disc technique,[10] their spectra were taken as Nujol mulls and are shown in Fig. 6. In the complex $K(B15C5)_2AuCl_4$, the characteristic frequency of free B15C5 at 978 cm^{-1} almost disappears and a double peak of B15C5 at 1048 and 1040 cm^{-1} becomes a single peak at 1040 cm^{-1}. These results indicate the formation of coordinate bonds in the crystalline complex.[10,11]

The results of thermal analyses of the extracted crystalline complex in nitrogen gas are shown in Fig. 7. The endothermic peak at 198°C on the DTA curve is the melting point of the extracted crystalline complex which is consistent with that measured using a Model X4 micromelting point apparatus. A high and sharp exothermic peak at 225°C on the DTA curve and a corresponding rapid and continuous weight loss in the TG curve indicate the decomposition of the complex. The process continues until the decomposition is complete and the weight is constant.

These results show that in the presence of K^+ in an aqueous solution containing 1 M hydrochloric acid, the complex anion $AuCl_4^-$ can be extracted quantitatively into an organic phase by B15C5 which can coordinate with K^+ extremely well to

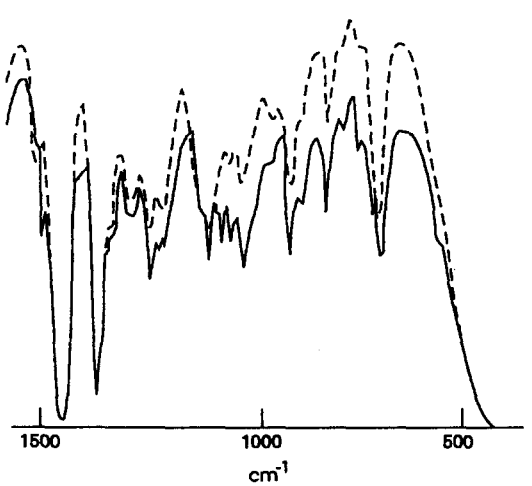

Fig. 6. IR spectra of the crystalline complex and B15C5: – – – B15C5 and —— $K(B15C5)_2AuCl_4$.

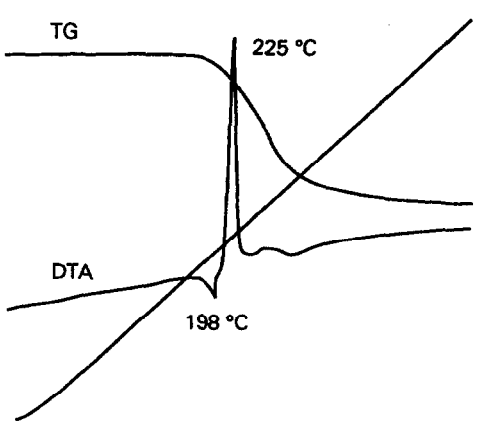

Fig. 7. DTA and TG curves of $K(B15C5)_2AuCl_4$.

form a complex cation of potassium–crown ether. It is certain that the selective coordination of B15C5 with K^+ will restrain other kinds of cations and hydrophilic anions from entering the organic phase, and therefore, it can be predicted that the extraction system proposed in this paper may be applied to the extraction and separation of gold(III) in practical production.

(*Received* 5 *October* 1990; *accepted* 9 *January* 1991)

Abstract—The crystal structure of Ni(metiamide)$_2$(NCS)$_2$ was determined by X-ray diffraction methods. Unlike cimetidine, which is a tridentate ligand, metiamide ($C_9H_{16}N_4S_2$): N-Methyl-N-[2-{(5-methylimidazol-4-yl)methylthio}ethyl]thiourea (which also possesses three potential donor sites) is bidentate, coordinated to the nickel atom through N(imidazole) and S(thioether) atoms. The S(thiourea) atom does not take part in the coordination; instead, the isothiocyanate ion is coordinated through nitrogen to the metal atom. The nickel atom lies on a centre of symmetry in an elongated octahedral environment: the nitrogen atoms occupy equatorial positions (Ni—N = 2.04 and 2.06 Å) and S(thioether) atoms occupy apical positions (Ni—S = 2.58 Å). Individual molecules are linked together by a unique S···H—N hydrogen bond involving the uncoordinated S(thiourea) atom. IR, electronic reflectance and magnetic data are consistent with the structural results.

Imidazole is a common component of some important molecules of biological interest. A current field of interest in our group is to study the complexation of such molecules with transition metals. Previous work has been devoted to metal complexes of cimetidine (CM), a histamine H_2-receptor antagonist. Cimetidine contains the imidazole ring linked to a chain containing a thioether function and a cyanoguanidine moiety which provide several potential donor sites. In the complexes $Cu(CM)_2X_2$ [$X_2 = (ClO_4^-)_2$,[1,2] $(NO_3^-)_2$[3] and SO_4^{2-}[4]] the ligand is coordinated through S(thioether), N(imidazole) and N(cyano) atoms; in all these compounds the copper(II) ion has a basically octahedral environment which displays significantly different distortion depending on the nature of the counter-anion, even though no direct interaction exists between the metal atom and the counter-anion.

We have started the study of a series of metal complexes of a new, biologically active ligand, metiamide‡ (Met, Fig. 1), related to cimetidine. Metiamide like CM is a histamine H_2-receptor antagonist[5,6] and the substitution of a thiourea group for the cyanoguanidine moiety is expected to alter the reactivity of this kind of chelate.

In this paper the synthesis, spectroscopic characterization, and X-ray crystal structure of the bis (metiamide)bis(isothiocyanato)nickel(II) complex, $Ni(Met)_2(NCS)_2$, are presented and discussed.

EXPERIMENTAL

Preparation and analyses of the complex

An aqueous solution (30 cm^3) of nickel chloride (2 mmol) was added to an ethanol solution (50 cm^3)

* Permanent address: Departament de Química Inorgánica, Facultat de Farmacia, Universitat de Valencia, Blasco Ibañez No. 13, 46010 Valencia, Spain.

† Author to whom correspondence should be addressed.

‡ Metiamide ($C_9H_{16}N_4S_2$): N-Methyl-N-[2-{(5-methylimidazol-4-yl)methylthio}ethyl]thiourea.

of the ligand (4 mmol) and potassium thiocyanate (4 mmol). The violet crystals obtained from the solution were filtered, washed with ethanol and dried at 100°C. Found: Ni, 9.0; C, 36.3; N, 21.0; S, 28.8; H, 4.8. Calc. for $NiC_{20}H_{32}N_{10}S_6$: Ni, 8.9; C, 36.2; N, 21.1; S, 29.0; H; 4.8%.

Spectroscopic measurements

IR spectra were obtained using a Perkin–Elmer Model 845 spectrophotometer with KBr discs and Nujol mulls (below 400 cm^{-1}). Solid reflectance spectra were recorded with a Perkin–Elmer Lambda 9 spectrophotometer, with a reflectance attachment fitted. Magnetic susceptibility measurements were carried out using the Faraday method with a Brucker Magnet BE-15 balance and $(Ni(en)_3)S_2O_3$ as calibrant. Diamagnetic corrections were estimated from Pascal constants.[7]

Crystal structure determination

General operating procedures have been described previously.[8] Crystal data and relevant parameters of the crystallographic study are given in Table 1. Systematic absences indicate the space group $P2_1/c$. The structure was determined by the Patterson method and refined using standard full-matrix least-squares and Fourier procedures.[9] Structure factors were corrected for anomalous dispersion; no correction was applied for absorption because of the small μ value and small-sized, block-shaped crystal. All hydrogen atoms were located on difference Fourier maps. Their contribution to the structure factors was calculated using idealized, unrefined positions and isotropic temperature factors equal to 1.3 times the B_{eq} of the atoms to which they are bonded. Final atomic positional and thermal parameters and lists of F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Crystal structure

Bond lengths and angles are listed in Table 2. Atoms are labelled according to Fig. 1. The crystal structure is made up of isolated centro-symmetric $Ni(Met)_2(NCS)_2$ complex molecules (Figs 2 and 3). The nickel atom lies on a crystallographic centre of symmetry and possesses an elongated octahedral NiN_4S_2 environment. Two metiamide molecules are coordinated to the metal atom through the imidazole N(2) and the thioether S(1) atoms. In addition, two NCS^- ions are also coordinated through their N(20) atom. The nitrogen atoms form an almost perfect NiN_4 equatorial square plane [Ni—N(2) = 2.06 Å, Ni—N(20) = 2.04 Å and N(20)—Ni—N(2) = 90.0°]. The axial sulphur atoms are located at a distance [Ni—S(1) = 2.58 Å] indicating a rather weak Ni—S interaction (Ni—S coordination distances are usually close to 2.2 Å for a square-planar geometry). It is worthwhile to compare this coordination with that of copper in

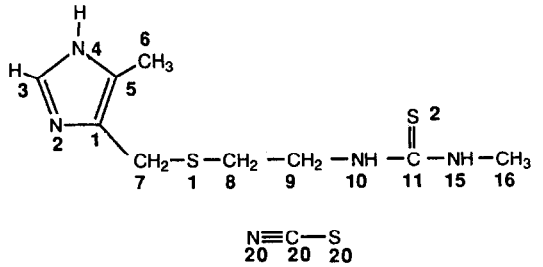

Fig. 1. The metiamide molecule. The numbering of non-hydrogen atoms used throughout the paper is indicated. To facilitate comparisons, the numbering scheme used in previous cimetidine papers[2–4] has been kept as far as possible. The numbering of atoms of the isothiocyanate ligand is also given.

the three previously reported Cu—CM complexes (Table 3). In the three Cu—CM complexes CM acts as a tridentate ligand through the imidazole N(2), the thioether S(1) and the cyano N(14) atoms. In the metiamide molecule a thiourea group replaces the cyanoguanidine moiety of the cimetidine ligand thus providing a third potential coordination site: the S(2) atom of the thiourea group. However, in the Ni—Met complex this atom is not bonded to the metal atom. The C(11)—S(2) distance (1.699 Å) is close to the C—S bond length in the free thiourea (1.707 Å),[10] which is consistent with non-coordination of the S(2) atom. The isothiocyanate group, linear as usual, shows normal bond lengths and coordinates linearly to the nickel atom.

In the metiamide ligand the imidazole ring is

planar with the methyl C(6) atom in the plane of the ring, the thiourea group is also planar although the methyl C(16) atom is located somewhat out-of-plane (Table 4). The dihedral angle between the two planes is 10.8°. The conformation of the coordinated metiamide ligand is described by the torsion angles listed in Table 5. In the absence of other X-ray data on metiamide or its complexes, a comparison could be attempted with related cimetidine and its complexes, however, such a comparison does not show any analogy between the conformation of metiamide in $Ni(Met)_2(NCS)_2$ and the A[11] or Z[12] conformations of cimetidine (or the corresponding chelated forms[4]).

The crystal packing is shown in Fig. 3. The only intermolecular interaction which can be considered as a hydrogen bond, on the basis of the criterion $d(S\cdots N) < 3.6$ Å,[13] involves the non-coordinated S(2) atom. The $S(2)\cdots N(4)^i$ distance is 3.354 Å (the superscript i refers to the transformation $-1+x$, $1/2-y$, $1/2+z$) with $S(2)\cdots H(11)^i = 2.497$ Å and $S(2)\cdots H(11)^i—N(4)^i = 148.8°$. Other intermolecular interactions are van der Waals' contacts.

Spectroscopic and magnetic properties

The IR spectrum of the complex shows two bands at 3330 and 3200 cm^{-1} assigned to the stretching vibrations of the N—H groups.[14] The bands in the 1495–1260 cm^{-1} region correspond to a combination of ν(C=N), ν(C=N—C=C), ν(N—H) and ν(N—C=S) of imidazole and thiourea groups.[15,16] Since the S(thiourea) atom is not included in the coordination sphere, the corresponding stretching frequency, ν(C=S), should be affected mainly by hydrogen bonding. The corresponding absorption band[17] is observed at 740 cm^{-1} for the complex as well as for the free ligand; this result indicates either that the hydrogen bond is rather weak or that the S(thiourea) atom also accepts a hydrogen bond in the solid state structure of the free ligand. Three bands located at 2100, 825 and 475 cm^{-1} are attributed, respectively, to the ν(CN), ν(CS) and δ(NCS) vibration modes of the thiocyanate group. The shifts, relative to the free anion, are in agreement with the presence of a nitrogen-bonded thiocyanate group.[18,19] The ν(CN) vibration appears as a sharp band as expected for a *trans* arrangement of the two thiocyanate groups.[20] The ν(Ni—S) and ν(Ni—N) stretching modes are observed in the 320–290 cm^{-1} region.[21,22]

The electronic reflectance spectrum of $Ni(Met)_2(NCS)_2$ shows bands characteristic of an octahedral geometry.[23] Table 6 lists the assignments of the observed bands. The nature and position of these bands are similar to those observed for Ni—CM complexes[24,25] which also contain a NiN_4S_2 chromophore.

The room temperature magnetic moment μ_{eff} is 3.10 BM, consistent with the octahedral geometry.[26]

CONCLUSIONS

Because of its similarity with the cimetidine molecule, the metiamide molecule is expected to be very flexible. Thus, the non-coordination of the thiourea S(2) atom cannot be attributed to geometrical constraints but rather to the coordination strength of the NCS^- ion. Since it has been shown[4] that the geometry of the coordination polyhedron of the copper atom in the Cu—CM complexes is very sensitive to the nature of the counter-anion (Table 3), it would be interesting to use NCS^- as the counter-anion of a Cu—CM complex. On the one hand, the two N(cyano) atoms of the guanidine moiety and of the thiocyanate ion would compete to enter the coordination sphere and possibly lead to unusual dicoordinated cimetidine. On the other hand, the possibility of the occurrence of sulphur-coordinated thiocyanate cannot be ruled out. In addition, the so-called "plasticity"[27] of copper(II) allows many coordination schemes ranging from severely flattened tetrahedron to strongly elongated octahedron. The $Cu(CM)_2(NCS)_2$ complex was thus prepared, however, no crystal suitable for X-ray analysis could be grown until now.

(*Received* 18 *September* 1990; *accepted* 24 *January* 1991)

Abstract—Mixing of S_2Cl_2 and Se_2Cl_2 at 21°C results in the formation of $SeSCl_2$ as shown by ^{77}Se NMR, mass, and Raman spectroscopy. The enthalpy of this reaction has been determined as +13 kJ mol^{-1} (S_2Cl_2), and the equilibrium constant $K_c = 0.066$ at 294 K. In addition, the formation of other Se—S—Cl molecules and of $SeCl_2$ is observed. An Se_2Cl_2–S_2Cl_2–$SeSCl_2$ mixture (Se:S = 1:1) reacts with titanocene pentasulphide to give mainly S_7, SeS_6 and 1,2-Se_2S_5 but small concentrations of six-, eight-, nine- and 12-membered Se—S ring molecules have also been observed. The reaction of Se_2Cl_2–S_2Cl_2 mixtures (Se:S = 1:2) with potassium iodide affords 1,2,5-Se_3S_5 as the major product followed by 1,2-Se_2S_6, 1,4-Se_2S_6 and 1,3-Se_2S_6. HPLC analysis of this reaction shows, however, that selenium sulphide ring molecules of ring sizes 6–8 are formed. Mixing of SCl_2 and Se_2Cl_2 at 21°C results in precipitation of $SeCl_4$ and formation of S_2Cl_2, which reacts with Se_2Cl_2 to give $SeSCl_2$.

The well known similarities between the chemistry of sulphur and selenium can be seen from the ever increasing number of chain- and ring-like compounds with homonuclear SS and SeSe bonds, respectively. More recently compounds with SeS bonds, cyclic selenium sulphides, have been prepared in considerable numbers.[2] From a synthetic point of view the dichlorosulphanes, S_nCl_2 ($n = 1, 2, \ldots$), are of particular importance because of their rôle in the preparation of sulphur rings, sulphanes, organic polysulphanes, etc. Milne *et al.*[3,4] have recently shown that dichloroselenanes, Se_nCl_2 ($n = 1, \ldots, 4$), exist in equilibrium in liquid Se_2Cl_2:

$$2\,Se_2Cl_2 \rightleftharpoons SeCl_2 + Se_3Cl_2, \quad K_c = 6 \times 10^{-4}\,(20°C); \tag{1}$$

$$3\,Se_2Cl_2 \rightleftharpoons 2\,SeCl_2 + Se_4Cl_2, \quad K_c = 3 \times 10^{-6}\,(20°C). \tag{2}$$

Dissolution of elemental selenium in liquid Se_2Cl_2 increases the concentrations of Se_3Cl_2 and Se_4Cl_2, as was shown by ^{77}Se NMR spectroscopy.[3,4] In a similar fashion, pure, freshly distilled S_2Cl_2 is in equilibrium with SCl_2 and S_3Cl_2, but the equilibrium constant is much smaller:[5]

$$2\,S_2Cl_2 \rightleftharpoons SCl_2 + S_3Cl_2. \tag{3}$$

While in liquid Se_2Cl_2 *ca* 5% of the liquid is present as $SeCl_2$ and Se_3Cl_2,[3,4] the self-dissociation of S_2Cl_2 amounts to only *ca* 1% at 20°C.[5] Nevertheless, mixing of Se_2Cl_2 with S_2Cl_2 should result in mixed SeS species:

* Part 137 of the Series *Sulphur Compounds*; for Part 136 see ref. 1.

† Author to whom correspondence should be addressed.

$$S_2Cl_2 + Se_2Cl_2 \rightleftharpoons 2\,SeSCl_2, \quad (4)$$

$$2\,SeSCl_2 \rightleftharpoons SeCl_2 + SeS_2Cl_2, \quad (5)$$

$$SeSCl_2 + Se_2Cl_2 \rightleftharpoons SeCl_2 + Se_2SCl_2. \quad (6)$$

The formation of $SeSCl_2$ has in fact been claimed by Volkov *et al.*[6] who had studied the Raman spectra of Se_2Cl_2–S_2Cl_2 mixtures in molar ratios of 3 : 1, 1 : 1 and 1 : 3 at 20°C, and had compared the spectra with those of the pure components. These authors observed three new lines for the mixtures and assigned them to the molecule $SeSCl_2$ as follows:[6]

410 cm^{-1}: SCl stretching,
396 cm^{-1}: SeS stretching,
164 cm^{-1}: bending (not specified).

Volkov *et al.* suggested the structure $Se{=}SCl_2$ (symmetry C_s) for the new compound which is in contrast to the well established chain-structures of both S_2Cl_2 and Se_2Cl_2 (symmetry C_2).[7] We have therefore repeated this work and studied reaction (4) by mass, ^{77}Se NMR and Raman spectroscopy hoping that we could find additional information to establish both the structure of $SeSCl_2$ and the equilibrium constant of reaction (4).

EXPERIMENTAL

Materials

Carbon disulphide (CS_2; techn. grade) was purified by distillation from phosphorus pentoxide (P_4O_{10}). Disulphur dichloride (S_2Cl_2) was distilled immediately prior to use. Diselenium dichloride (Se_2Cl_2)[8] and titanocene pentasulphide (Cp_2TiS_5; Cp = η^5-C_5H_5)[9] were prepared according to literature methods. Methanol used as an eluent for HPLC was distilled from anhydrous magnesium sulphate (to remove water and nucleophilic impurities) and degassed in a vacuum immediately prior to use. Spectra of Se_2Cl_2–S_2Cl_2 mixtures were measured in sealed glass tubes.

Procedures

^{77}Se NMR spectra were recorded with a Bruker WM 360 spectrometer equipped with Aspect 3000 computer for spectrometer control and data processing (frequency, 68.679 MHz; temperature, 21°C; sample tube diameter, 20 mm). Raman spectra were obtained with an Instruments S.A. spectrometer which is based on a Jobin Yvon U 1000 double monochromator and controlled by a MAC 80 computer. Raman scattering was excited with a Spectra Physics krypton ion laser (647.1 nm) and measured by a Hamamatsu R943-02 GaAs photomultiplier. The wavenumbers were reproducible to within ± 1 cm^{-1}. To prevent the Raman samples from thermal or photolytic decomposition during the measurements they were usually cooled to well below 0°C using a self-made cryostat in which the vapour of liquid nitrogen was used as a coolant. Evaporation of the nitrogen by an electric heater was controlled by a Pt 100 temperature sensor placed next to the sample which was contained in a glass capillary inside a glass Dewar vessel. High-performance liquid chromatography (HPLC) was performed with the following equipment: Perkin–Elmer Liquid Chromatograph (Series 2 with two pumps), Rheodyne Syringe Loading Injector (Model 7125 with a 10-μl sample loop), Millipore-Waters Radial-Pak column cartridges filled with C18 phase for reversed-phase chromatography (column length, 10 cm; inner diameter, 8 mm; particle size, 5 or 10 μm) and contained in a RCM-100 compression module, Perkin–Elmer LC75 UV spectrophotometer with autocontrol (variable wavelength detector with a deuterium lamp), Hewlett–Packard 3390A electronic integrator with an integrated recorder and printer. Mass spectra were recorded using a double-focusing sector-field spectrometer (MAT 311A) controlled by a Kratos DS 90 computer.

Chemical shifts

The NMR spectra of Se_2Cl_2–S_2Cl_2 mixtures were measured with D_2O as an external lock substance and $(CH_3Se)_2$ as an external reference, the shift of which was taken from the literature as 275.0 ppm versus $(CH_3)_2Se$.[10] Shifts therefore refer to $(CH_3)_2Se$. The same holds for the NMR spectra of selenium sulphides dissolved in CS_2 for which C_6D_6 was used as an internal lock and 1,2,3-Se_3S_5 (653.4 and 559.9 ppm[11]) as an internal standard.

Reaction of Se_2Cl_2–S_2Cl_2 *mixtures with* KI

Disulphur dichloride, (1.1 cm^3, 13.3 mmol) and 0.55 cm^3 Se_2Cl_2 (6.7 mmol) dissolved in 100 cm^3 CS_2 were reacted with 19.9 g finely powdered dry potassium iodide (0.12 mol) for 4 h with stirring at 20°C in the dark. After filtration the solution was shaken with powdered $Na_2S_2O_3 \cdot 5H_2O$ (25.3 g, 0.16 mol) to remove elemental iodine followed by filtration and drying with $MgSO_4$. Part of this solution was measured by NMR spectroscopy within 5 h after preparation. Another part was cooled to −60°C for 24 h resulting in orange needle-like crystals of m.p. 110–115°C (360 mg).

Reaction of Se_2Cl_2–S_2Cl_2 *mixtures with titanocene pentasulphide*

To 1.1 g (3.25 mmol) Cp_2TiS_5 dissolved in CS_2 at 20°C in diffuse daylight was added 0.2 cm^3 of an equimolar mixture of Se_2Cl_2 and S_2Cl_2 with stirring. After 5 min (or later) 1 cm^3 of the mixture was diluted to 50 cm^3 with CS_2 and immediately analysed by HPLC.

RESULTS AND DISCUSSION

Mass spectrum of $SeSCl_2$

The electron impact mass spectrum of an equimolar mixture of S_2Cl_2 and Se_2Cl_2 is shown in Table 1. The liquid sample was evaporated into the ion source of the spectrometer. According to the differing volatilities, the ions originating from S_2Cl_2 give rise to the strongest peaks. However, besides the molecular ions $S_2Cl_2^+$ and $Se_2Cl_2^+$ with their characteristic isotopic pattern, we also observed the ion $SeSCl_2^+$ of the mixed species. The isotopic pattern of this signal at m/z 176,..., 192 matched the calculated pattern very well with m/z 182 being the largest peak. Under high-resolution conditions the mass of this ion was determined as 181.8254 (calculated for $^{80}Se^{32}S^{35}Cl_2^+$: 181.8263). According to these results the existence of $SeSCl_2$ in equilibrium with S_2Cl_2 and Se_2Cl_2 is beyond any doubt. The spectrum also shows the presence of $SeCl_2$ since the ion $SeCl_2^+$ can hardly be a fragment ion of the chain-like Se_2Cl_2.

Table 1. Mass spectrum of an equimolar mixture of S_2Cl_2 and Se_2Cl_2 (largest peaks only); electron energy 70 eV

Peak (m/z)	Relative intensity	Assignment
230	0.24	$Se_2Cl_2^+$
195	0.20	Se_2Cl^+
182	0.57	$SeSCl_2^+$
150	4.6	$SeCl_2^+$
134	94.9	$S_2Cl_2^+$
99	100	S_2Cl^+
67	13.8	SCl^+
64	50.7	S_2^+

^{77}Se *NMR spectrum of* $SeSCl_2$

Quantitative data regarding the equilibrium concentrations of $SeSCl_2$ and Se_2Cl_2 can best be obtained using ^{77}Se NMR spectroscopy (^{77}Se: $I = 1/2$, natural abundance, 7.6%). The resonance line of neat Se_2Cl_2 has been observed before: it occurs at 1272 ppm versus dimethylselenide as external standard.[4] We have found that mixtures of S_2Cl_2 and Se_2Cl_2 in molar ratios of 1:1 and 5:1 show up to 10 lines of very different intensity which we assign as shown in Table 2. The chemical shifts slightly depend on the S_2Cl_2 content of the mixture. The assignment of the second most intense line located 13 ppm downfield from the Se_2Cl_2 line is in accord with observations that substitution of one Se by S in an Se_2 unit shifts the signal of the remaining Se atom to lower field.[12,13] The intensity ratio of the $SeSCl_2$ and Se_2Cl_2 lines at various temperatures provides a means to calculate the equilibrium constant (K_c), the reaction enthalpy ($\Delta H°$), the reaction entropy ($\Delta S°$) and the free reaction enthalpy ($\Delta G°$) of reaction (4):

$$K_c = \frac{[SeSCl_2]^2}{[S_2Cl_2][Se_2Cl_2]}. \qquad (a)$$

Table 2. ^{77}Se NMR spectra of two liquid S_2Cl_2–Se_2Cl_2 mixtures at 21°C (molar ratios S:Se = 1:1 and 5:1; b = broad). Chemical shifts relative to $(CH_3)_2Se$

	1:1		5:1		
No.	Shift (ppm)	Peak height	Shift (ppm)	Peak height	Assignment
1	1746.0	3	1753.5	18	$SeCl_2$
2	~1350	>1, b	1352.9	0.5, b	ClSe*SeSCl
3	—		1345.3	1.3	ClSeSSeCl
4	~1340	>1, b	1341.3	0.5, b	ClSeSe*SCl
5	—		1335.4	0.7	ClSeSSSCl
6	—		1327.0	0.5	ClSSeSSCl
7	1314.9	1	1308.9	1	ClSeSSCl
8	1303.0	21	1295.1	42	ClSeSCl
9	1290.2	100	1282.3	100	Se_2Cl_2
10	1284.7	1.5	1278.7	2.5	ClSSeSCl

Neglecting the dissociation of Se_2Cl_2 according to eqs (1) and (2), and of S_2Cl_2 according to eq. (3), we assume $[S_2Cl_2] = [Se_2Cl_2]$. Since the peak area A of Se_2Cl_2 represents two Se atoms it follows:

$$K_c = \frac{[SeSCl_2]^2}{[Se_2Cl_2]^2} = \frac{4A^2(SeSCl_2)}{A^2(Se_2Cl_2)}. \quad \text{(b)}$$

The thermodynamic functions have been calculated from eqs (c) and (d):

$$\frac{d \ln K_c}{dT} = \frac{-\Delta H^\circ}{RT^2}, \quad \text{(c)}$$

$$\ln K_c = -\frac{\Delta G^\circ}{RT} = -\frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R}, \quad \text{(d)}$$

using the peak areas measured at four different temperatures (see Table 3). The linear regression of the $\ln K_c$ values of Table 3 according to eq. (c) resulted in a correlation coefficient of $r = 0.997$ for the equation $\ln K_c = -(1562/T) + 2.599$, and an enthalpy of $\Delta H^\circ = 13$ kJ mol^{-1} for reaction (4). From the linear regression K_c was obtained as 0.066 for 294 K resulting in $\Delta G^\circ_{293} = 6.6$ kJ mol^{-1} and $\Delta S^\circ_{293} = 22$ J mol^{-1}. The directly measured K_c value for 294 K was 0.065 (Table 3).

The less intense lines in the NMR spectra of S_2Cl_2–Se_2Cl_2 mixtures are assigned as follows. Near 1750 ppm the well known line of $SeCl_2$[3,4] is observed, the relative intensity of which dramatically increases with increasing S_2Cl_2 content. This indicates that S_2Cl_2 oxidizes Se_2Cl_2 partly to $SeCl_2$, which must result in longer-chain sulphur chlorides, e.g. by reactions of types (4)–(8):

$$2\,S_2Cl_2 + Se_2Cl_2 \rightleftharpoons SeCl_2 + S_4Cl_2, \quad (7)$$

$$S_4Cl_2 + Se_2Cl_2 \rightleftharpoons SeSCl_2 + SeS_3Cl_2. \quad (8)$$

All species on the right sides of eqs (4)–(8) have been observed directly or indirectly in this work (see below). The NMR line near 1280 ppm on a first glance may represent Se_3Cl_2,[3,4] which in liquid Se_2Cl_2 has been observed 0.6 ppm upfield from Se_2Cl_2. However, the 1280 ppm line increases in intensity with increasing S_2Cl_2 content. It should also be noted that the relatively high $SeCl_2$ concentration in the 5:1 mixture will result in suppression of Se_3Cl_2 and Se_4Cl_2 in the equilibrium reactions (1) and (2). No Se_4Cl_2 line[3,4] has been observed in S_2Cl_2–Se_2Cl_2 mixtures, although the spectra were recorded in the range 670–1820 ppm. Therefore, the line near 1280 ppm should not be assigned to Se_3Cl_2 but rather to an S—Se—Cl species. The intensity of this line seems to be not related to the intensity of any of the other weak lines. A relationship between the $SeSCl_2$ line near 1300 ppm and the 1280 ppm line can, however, not entirely be excluded and the latter may represent an isomer of $SeSCl_2$, namely S=$SeCl_2$. More likely, however, the chain-like species ClSSeSCl seems to be responsible for this signal. Further evidence for such a molecule in the S_2Cl_2–Se_2Cl_2 mixtures will be presented below.

The other weak signals, located in the range 1305–1355 ppm, have been only tentatively assigned. The most intense lines are probably arising from trichalcogendichlorides and the weakest from the two isomeric SeS_3Cl_2 molecules. Again, evidence for all these species comes also from the HPLC analysis described below.

The two relatively broad signals near 1340 and 1350 ppm are assigned to the two non-equivalent atoms in 1,2-$Se_2S_2Cl_2$, which may undergo an exchange reaction resulting in line broadening.

In the thermodynamic calculations presented above, reactions (1)–(3) and (5)–(8) have been neglected. The data in Table 2 show that in a 1:1 mixture of S_2Cl_2 and Se_2Cl_2 at 21°C only about 4% of the Se atoms are not present in either Se_2Cl_2 or $SeSCl_2$. The approximation therefore seems to be justified.

Table 3. Quantitative analysis of the ^{77}Se NMR spectra of a S_2Cl_2–Se_2Cl_2 mixture (molar ratio 1:1) at various temperatures

Peak areas at T:	294 K	305 K	311 K	325 K
$A_1(Se_2Cl_2)$	1091.0	1447.2	1580.4	1521.3
$A_2(SeSCl_2)$	139.5	207.5	234.7	251.4
$A_2:A_1$	0.128	0.143	0.149	0.165
$(A_2:A_1)^2$	0.0163	0.0206	0.0221	0.0273
$\ln K_c$	−2.727	−2.498	−2.428	−2.214
K_c	0.065	0.082	0.088	0.109

A = peak area; T = temperature in K.

Raman spectrum of $SeSCl_2$

While the mass and NMR spectra allowed the detection and determination of $SeSCl_2$, the Raman spectrum should provide information about its structure. The three alternative structures ClSSeCl, S=$SeCl_2$ and Se=SCl_2 all result in six fundamental vibrations which are all Raman active. The first molecule is of C_1 symmetry and all its Raman lines will be polarized, while the other two are of C_s symmetry resulting in three polarized and three depolarized Raman lines. We have measured the Raman spectra of S_2Cl_2–Se_2Cl_2 mixtures with molar ratios of between 3 : 1 and 1 : 3, and at temperatures between −100 and +20°C. A krypton ion laser operating at 647.1 nm was used to minimize photodecomposition reactions of the deeply coloured reaction mixtures. The spectra obtained were compared with the spectra of the pure components S_2Cl_2 and Se_2Cl_2 which had been reported earlier,[14] and to the spectra of SCl_2–Se_2Cl_2 mixtures. Typical Raman spectra of an S_2Cl_2–Se_2Cl_2 1 : 1 mixture at 20 and −40°C are shown in Fig. 1. They show five weak features at 411, 388, 219, 185 and 164 cm^{-1} which are not present (or much weaker) in the spectra of either S_2Cl_2 or Se_2Cl_2 and which are assigned as follows.

The 411 cm^{-1} line has also been observed for pure Se_2Cl_2,[14,15] although with much lower intensity; in Se_2Cl_2 it disappears completely on cooling to −100°C. Milne *et al.*[15] assigned this signal to ν_1 (a) of $SeCl_2$ originating from reactions (1) and (2). In S_2Cl_2–Se_2Cl_2 mixtures the 411 cm^{-1} line is much stronger than in pure Se_2Cl_2 at the same temperature but it also gradually disappears on cooling and cannot be seen at −75°C anymore, while simultaneously the 388 cm^{-1} line increases in intensity suggesting a conversion of one compound into another. This behaviour is incompatible with the properties of $SeSCl_2$ which, according to its thermodynamic properties (see above), should still be present at −75°C ($K_c = 0.005$) in detectable concentrations, and should not be converted to a compound other than S_2Cl_2 and Se_2Cl_2. We therefore assign the 411 cm^{-1} line to ν_1 of $SeCl_2$ and the 388 cm^{-1} signal to ν_1 of $SeCl_4$, the strongest Raman line of which is located near 390 cm^{-1}.[16–18] Its formation from $SeCl_2$ is shown in eq. (9):[3,4]

$$3\,SeCl_2 \rightleftharpoons SeCl_4 + Se_2Cl_2. \qquad (9)$$

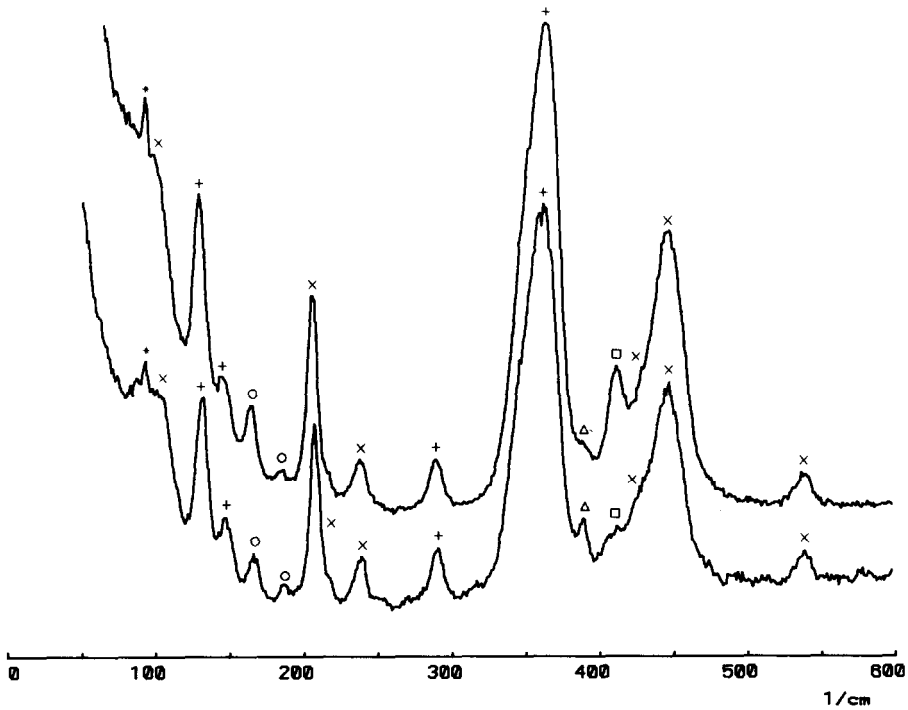

Fig. 1. Raman spectra of a S_2Cl_2–Se_2Cl_2 mixture (molar ratio 1 : 1) at 20°C (top) and −40°C (bottom) showing the lines of S_2Cl_2 (×), Se_2Cl_2 (+), $SeSCl_2$ (○), $SeCl_2$ (□), and $SeCl_4$ (△). The starred line arises from the laser. Wavenumbers (intensities in parentheses): 20°C—537 (m), 446 (s), 428 (sh), 411 (m), 388 (sh), 364 (vs), 352 (sh), 289 (m), 237 (m), 205 (s), 185 (w), 164 (w-m), 145 (w), 129 (m) cm^{-1}; −40°C—539 (w), 446 (s), 424 (sh), 412 (vw), 389 (vw), 362 (vs), 290 (m), 238 (m), 219 (sh), 207 (s), 187 (w), 167 (m), 147 (m), 132 (s) cm^{-1}.

Unfortunately, K_c and ΔH of this reaction are unknown. In addition, redox reactions of type (10),

$$2\,SeCl_2 + S_2Cl_2 \rightleftharpoons SeCl_4 + SeS_2Cl_2, \quad (10)$$

may play a rôle. The higher concentration of $SeCl_2$ in S_2Cl_2–Se_2Cl_2 mixtures has already been discussed above.

Support for the above assignment comes from the observations made with SCl_2–Se_2Cl_2 mixtures. When 3 cm^3 SCl_2 (freshly distilled) were carefully added to 2 cm^3 Se_2Cl_2 at 0°C, with exclusion of light, an exothermic reaction took place resulting in a precipitate and a brownish solution. After filtration the precipitate was washed with pentane and identified as $SeCl_4$ by Raman spectroscopy. The Raman spectrum of the solution measured at −40 and −100°C showed the presence of S_2Cl_2 by the following lines: 542, 445, 240, 209 and 112 cm^{-1}. Obviously, the following reaction had taken place:

$$6\,SCl_2 + Se_2Cl_2 \rightleftharpoons 2\,SeCl_4 + 3\,S_2Cl_2. \quad (11)$$

Since the molar ratio SCl_2–Se_2Cl_2 was only 2:1 some Se_2Cl_2 remained in the mixture, while SCl_2 was consumed completely. The S_2Cl_2 formed may then react according to eq. (4); the molar ratio S_2Cl_2–Se_2Cl_2 must have been 1:0.67. In addition to the Raman lines of S_2Cl_2 and Se_2Cl_2 the following signals were observed (intensities in parentheses):

412 cm^{-1} (sh), not observed at −100°C, probably $SeCl_2$;
392 cm^{-1} (s), probably $SeCl_4$[16–18] (which is soluble in Se_2Cl_2[19]);
303 cm^{-1} (w), observed only at −100°C, probably $SeCl_4$;[16–18]
188 cm^{-1} (vw), 170 cm^{-1} (m) } bending modes of $SeSCl_2$.

The line at 392 cm^{-1} was much stronger than in any of the S_2Cl_2–Se_2Cl_2 mixtures; it is therefore assigned to $SeCl_4$. The two weak features at 170 and 188 cm^{-1} may be identical to the 164 and 185 cm^{-1} lines observed for S_2Cl_2–Se_2Cl_2 mixtures (see above). Since their intensities were not related to the intensity of the line at 390 ± 2 cm^{-1} these lines are not assigned to $SeCl_4$ but to the bending modes of chain-like $SeSCl_2$.

It may be assumed that most of the vibrational wavenumbers of ClSeSCl can be estimated as arithmetic means of the corresponding wavenumbers of the binary chlorides. For example, ν(SS) = 540 cm^{-1} of S_2Cl_2 and ν(SeSe) = 290 cm^{-1} of Se_2Cl_2 result in ν(SSe) = 415 cm^{-1} of ClSeSCl. In a similar fashion the torsional modes of the binary chlorides give, by averaging, δ(ClSeSCl) = 104 cm^{-1}. The arithmetic mean of all bending modes of S_2Cl_2 and Se_2Cl_2 results in δ = 180 cm^{-1}, which indicates the approximate position of δ(ClSeS) and δ(ClSSe) of ClSeSCl. The two stretching modes SCl and SeCl of ClSeSCl will occur at about the same wavenumbers as the corresponding modes of the binary compounds. From the above it is obvious that, at best, four of the six ClSeSCl fundamental modes may be observed since ν(SCl) and ν(SeCl) will be obscured by the strong signals of the simultaneously present binary chlorides.

The SeS stretching mode of ClSeSCl will be of low Raman intensity (cf. S_2Cl_2) and strongly coupled with both ν(SCl) and ν(SeCl) due to the low molecular symmetry. Due to the interference by the broad SCl line of S_2Cl_2 we did not observe ν(SeS), unless one assigns the shoulder of the broad SCl line at *ca* 425 to this mode.

The two bending modes each of S_2Cl_2 and Se_2Cl_2 occur as neighbouring lines with the symmetrical one of somewhat higher intensity and lower wavenumber than the asymmetrical vibration. This pattern fits the two $SeSCl_2$ lines at 166 ± 3 and 186 ± 2 cm^{-1} which are located between the bending modes of the binary chlorides and which therefore are assigned to δ(ClSSe) and δ(ClSeS) of chain-like $SeSCl_2$. For 1:1 mixtures of S_2Cl_2 and Se_2Cl_2 the intensity of these lines decreases with decreasing temperature, as is to be expected. There is no evidence for the presence of any other isomer of $SeSCl_2$ (symmetry C_s) the SeS stretching vibration of which should show up in the range 550–650 cm^{-1}.

There remains to be addressed the question of whether the other strong lines of $SeCl_4$ can be seen in our spectra. Besides the 390 cm^{-1} line, strong to medium signals for dissolved $SeCl_4$ (in CH_3NO_2)[18] are to be expected at:

358 cm^{-1}, hidden under ν(SeCl) of Se_2Cl_2;
264 cm^{-1}, shoulder in Fig. 1;
206 cm^{-1}, shoulder in Fig. 1;
150 cm^{-1}, hidden under $\nu(Se_2Cl_2)$.

As can be seen from Fig. 1, two of the four expected signals are in fact observed (shoulders at 206 and 260 cm^{-1}) in the −40°C spectrum while the other two are obscured by strong Se_2Cl_2 lines.

Reaction of $SeSCl_2$ *with titanocene pentasulphide*

The reaction of sulphur chlorides with $(C_5H_5)_2TiS_5$ can be considered a derivatization reaction since the reaction is quantitative and irreversible and, consequently, the products obtained show what kind of chlorides and in which concentrations have been present before:[20]

$$Cp_2TiS_5 + S_nCl_2 \rightarrow Cp_2TiCl_2 + S_{n+5} \quad (Cp = \eta^5\text{-}C_5H_5). \quad (12)$$

S_2Cl_2 yields S_7 (99%), SCl_2 gives S_6 and S_{12}, and S_3Cl_2 will result in formation of S_8,[20] while with Se_2Cl_2 the analogous 1,2-Se_2S_5 is formed:[21]

$$Cp_2TiS_5 + Se_2Cl_2 \rightarrow Cp_2TiCl_2 + Se_2S_5. \quad (13)$$

If a reaction mixture contained $SeCl_2$, Se_3Cl_2 or $SeSCl_2$ the expected derivatives would be SeS_5, 1,2,3-Se_3S_5 and SeS_6, respectively. HPLC using reversed-phase columns and a UV absorbance detector may be used to separate and identify the above compounds by their retention times.[21–23] It has been shown that the retention of Se_xS_y molecules ($x = 0, 1, \ldots$; $y = 0, 1, \ldots$) of ring sizes 6–12 depends on the ring size, the number of Se atoms, and the number of heteronuclear bonds per molecule only.[23]

Since selenium sulphide molecules are light-sensitive, thermally unstable, and subject to decomposition by nucleophiles, the reactions were carried out under very clean conditions, with exclusion of daylight, and as fast as possible. Cp_2TiS_5 was used in excess to make sure that all chlorides reacted. Between mixing of the components at 20°C in CS_2, followed by dilution to 1 : 50, and injection for HPLC analysis *ca* 9 min passed; deliberately, samples were also analysed 90 min and 24 h after mixing.

Independent of the mixing ratio of S_2Cl_2 and Se_2Cl_2 (3 : 1, 1 : 1 and 1 : 3) the main products from the reaction of the mixture with Cp_2TiS_5 were qualitatively always the same: SeS_5, 1,2-Se_2S_5, SeS_6, S_7 and 1,2,3-Se_3S_5, which may have originated from $SeCl_2$, Se_2Cl_2, $SeSCl_2$, S_2Cl_2 and Se_3Cl_2, respectively. Figure 2 shows a typical chromatogram using a methanol–water mixture (95 : 5, v/v) as eluent; the retention times are listed in Table 4. In addition to the above mentioned compounds, very weak peaks have been observed which can be assigned to other seven-, eight-, nine- and 12-membered Se_xS_y rings on the basis of their retention times and retention indices (RS) as shown in Table 4.

To calculate the RS data the molecules S_6, S_8, S_9 and S_{10} have been measured under identical conditions as reference materials. From their retention data the RS values of the Se_xS_y molecules are obtained.[23] RS values are specific for a certain substance and a certain eluent composition but independent of flow rate and column length.[23] As can be seen from Table 4, most of the peaks can be definitely assigned to certain six-, seven- and eight-membered rings. RS data of nine-membered Se_xS_y molecules are scarce but the two species observed in this work seem to be identical with S_9 and SeS_8 previously observed in the chromatogram of the extract of an Se—S melt.[23] The identity of the two 12-membered rings was checked by comparison with authentic samples;[24] their extremely long retention times result in less accurate RS values and, consequently, the agreement with the literature

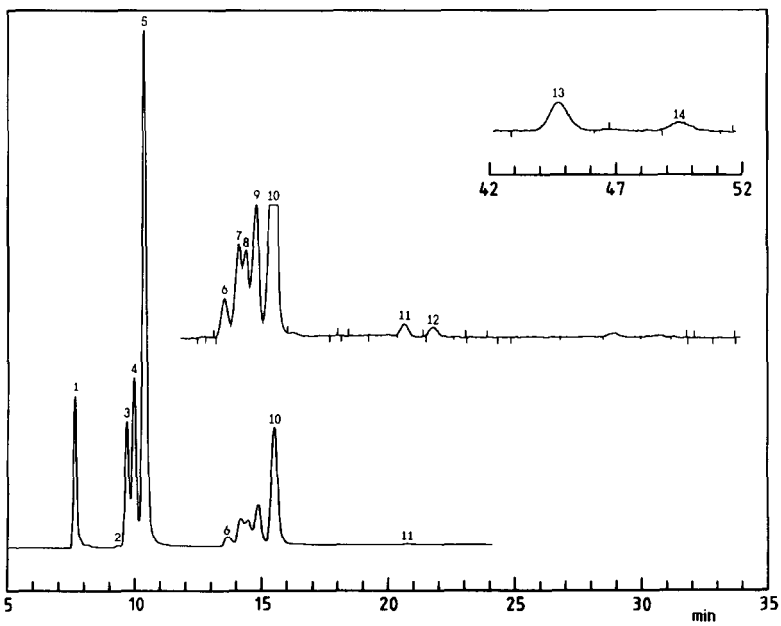

Fig. 2. HPLC analysis of the reaction products from titanocene pentasulphide with a S_2Cl_2–Se_2Cl_2 mixture (1 : 1) showing the presence of 6–12-membered Se_xS_y ring molecules (for details see Table 4).

Table 4. HPLC analysis of the products from the reaction of a S_2Cl_2–Se_2Cl_2 mixture (1 : 1) with titanocene pentasulphide

Peak	Retention time (min)	RS_{exp}	Assignment	RS_{calc}[23]	RS_{exp}[23]
1	7.66	576	SeS_5		575
2	9.30	645	$Se_2S_5{}^4$	643	
3	9.68	659	SeS_6	659	
4	9.96	668	1,2-Se_2S_5		662
5	10.37	682	S_7		681
6	13.61	767	$Se_2S_6{}^4$	761	
7	14.13	778	SeS_7		775
8	14.41	784	$Se_2S_5{}^4$	779	
9	14.80	792	$Se_2S_6{}^2$; S_8	794 ($Se_2S_6{}^2$)	793 (S_8)
10	15.44	804	$Se_3S_5{}^2$		804
11	20.64	886	SeS_8		886
12	21.78	901	S_9		902
13	44.76	1090	1,7-Se_2S_{10}		1059
14	49.46	1116	1,2-Se_2S_{10}		1092

The retention indices RS_{exp} have been calculated as explained in the text and compared with previously published data (columns 5 and 6) for peak assignment. In cases where no experimental RS data (column 6) are known, calculated RS values have been used (column 5). The exponents at some formulae indicate the number of SeS bonds in the molecule (e.g. $Se_2S_6{}^4$ = 1,3-Se_2S_6 or 1,4-Se_2S_6; $Se_2S_6{}^2$ = 1,2-Se_2S_6).

data is less satisfactory. These Se_2S_{10} species originate from a dimerization of SeS_5,[24] and part of SeS_5, and all 1,2,3-Se_3S_5 originate from a dismutation of Se_2S_5:[21]

$$2\ \text{1,2-}Se_2S_5 \rightarrow SeS_5 + \text{1,2,3-}Se_3S_5. \qquad (14)$$

The detection of 1,2,3-Se_3S_5 is therefore no evidence for the presence of Se_3Cl_2.

The other products indicate that the S_2Cl_2–Se_2Cl_2 mixture contains traces of E_nCl_2 compounds (E = S or Se) resulting in $Se_2S_6{}^4$ (from 1,3-Se_2SCl_2), SeS_7 (from SeS_2Cl_2), $Se_2S_6{}^2$ (from 1,2-Se_2SCl_2), S_8 (from S_3Cl_2), SeS_8 (from SeS_3Cl_2) and S_9 (from S_4Cl_2). In this notation the exponents give the number of SeS bonds in the molecule (1,3-Se_2S_6 and 1,4-Se_2S_6 have the same RS value and are therefore collectively denoted as $Se_2S_6{}^4$).

The fact that no S_6 was observed shows that S_2Cl_2–Se_2Cl_2 mixtures do not contain SCl_2. On the other hand, the S_3Cl_2 assumed to explain the formation of S_8 may originate from reaction (15):

$$S_2Cl_2 + S_4Cl_2 \rightleftharpoons 2\,S_3Cl_2. \qquad (15)$$

To determine the rate of reaction (4) the following experiments were carried out. 1 cm^3 each of S_2Cl_2 and Se_2Cl_2 were mixed at 20°C, and after 2, 4 and 5 min, respectively, samples were taken and immediately reacted with titanocene pentasulphide in CS_2. This reaction mixture was then rapidly analysed by HPLC (after sedimentation of Cp_2TiCl_2 and dilution of a sample). The results show that mixing of the two chlorides for 2 min is sufficient to form $SeSCl_2$, which on reaction with Cp_2TiS_5 yields SeS_6. The concentration of SeS_6 neither increased nor decreased when the reaction times were increased.

Reaction of $SeSCl_2$ *with potassium iodide*

The reaction of a S_2Cl_2–Se_2Cl_2 mixture with solid KI results in I_2, KCl and a mixture of cyclic selenium sulphides which have been separated by HPLC and characterized by their retention time, Se content, crystal shape and Raman spectra as six-, seven- and eight-membered rings;[22,25] e.g.:

$$S_2Cl_2 + 2\,KI \rightarrow S_2I_2 + 2\,KCl, \qquad (16)$$

$$Se_2Cl_2 + 2\,KI \rightarrow Se_2I_2 + 2\,KCl, \qquad (17)$$

$$2\,Se_2I_2 + 2\,S_2I_2 \rightarrow Se_4S_4 + 4\,I_2, \qquad (18)$$

$$Se_2I_2 + 3\,S_2I_2 \rightarrow Se_2S_6 + 4\,I_2. \qquad (19)$$

Because of the complex nature of the mixture not all components could initially be identified. We have therefore repeated our previous work and analysed the reaction products simultaneously by HPLC, Raman and ^{77}Se NMR spectroscopy hoping to find compounds directly derived from $SeSCl_2$. Such

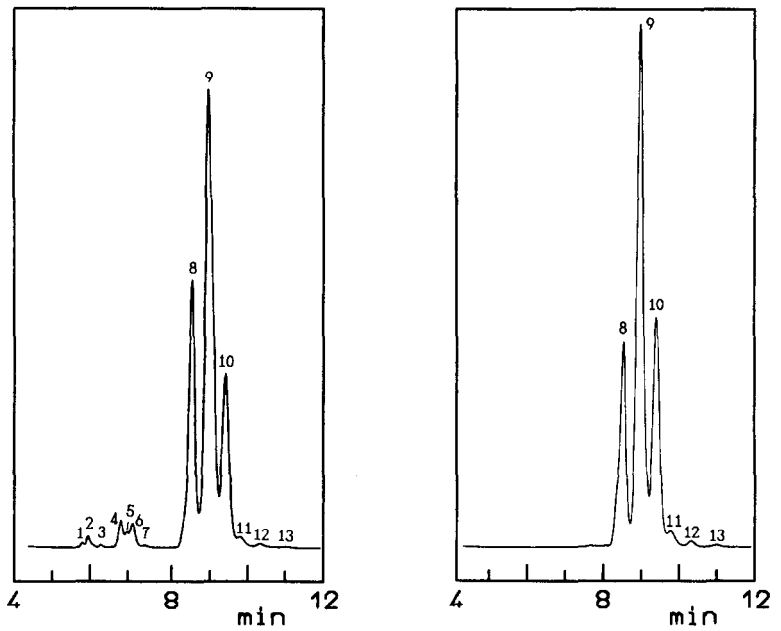

Fig. 3. HPLC analysis of the reaction mixture obtained from treating a S_2Cl_2–Se_2Cl_2 mixture (2 : 1) with potassium iodide at 20°C (left), and of the Se_xS_{8-x} crystals obtained from the reaction mixture at −60°C (right) (for details see Table 5).

molecules should contain single (isolated) Se atoms resulting from reactions of types (20) and (21):

$$ISSI + ISeSI \rightarrow ISSSeSI + I_2, \quad (20)$$

$$2\,ISSSeSI \rightarrow 1,4\text{-}Se_2S_6 \text{ or } 1,5\text{-}Se_2S_6 + 2I_2. \quad (21)$$

In order to increase the $SeSCl_2$–Se_2Cl_2 ratio we have treated a 2 : 1 molar mixture of S_2Cl_2 and Se_2Cl_2 in CS_2 with potassium iodide at 20°C with exclusion of light. After stirring for 4 h and removal of the iodine formed by thiosulphate, the solution was dried with $MgSO_4$ and immediately analysed by HPLC and NMR spectroscopy. Part of the solution was cooled to −60°C for 24 h resulting in orange needle-like crystals of m.p. 110–115°C (360 mg from 1.1 cm^3 S_2Cl_2 and 0.55 cm^3 Se_2Cl_2) which

were analysed by HPLC, ^{77}Se NMR and Raman spectroscopy.

Figure 3 shows the chromatograms of the reaction solution and of the crystals obtained from this solution on cooling; the assignment is given in Table 5. In Fig. 4 the Raman spectrum of the crystals is shown; for wavenumbers and assignment see Table 6. The Raman spectrum shows the typical signals for SS (400–500 cm^{-1}) and SeSe (250–300 cm^{-1}) bonds as well as two types of SeS bonds: those of isolated Se atoms as in S—Se—S units resulting in a strong vibrational coupling between the two neighbouring SeS bonds (340/380 cm^{-1}) and those of cumulated Se atoms as in S—Se—Se—S structural units resulting in weak coupling and lines near 360 cm^{-1} [26] for the SeS stretching vibration. Thus, the Raman spectrum is in agreement with the other analytical findings; the SSeS units are evidence for the presence of $SeSCl_2$ in the initial reaction mixture. To a first approximation, the spectrum indicates a slightly higher con-

centration of SSeS over SSe_xS ($x > 1$) units. The spectrum also shows that the sample contains more SeS than SeSe bonds.

In Table 7 the results of the NMR analysis of the freshly prepared reaction solution, of the freshly redissolved orange crystals, and of the same sample after standing at 20°C for 6 months are shown. All peaks could be assigned on the basis of literature data for the chemical shifts of selenium sulphides.[11,13]

All results show that the main products are certain eight-membered Se_xS_y rings, but the HPLC analysis demonstrates the presence of at least four six-membered and three seven-membered Se_xS_y rings in addition. These species are not present in the crystals, the composition of which seems to be less complex since the HPLC trace shows only three strong and three weak peaks, and one shoulder indicating the presence of seven species forming a solid solution. The retention times, RS values and assignment are shown in Table 5. This assignment basically rests on a comparison of RS values with literature data[23] and on the results of the NMR spectra.

The data in Table 7 show 1,2,5-Se_3S_5 as the major reaction product which is also responsible for the largest HPLC peak. This substance is unstable in solution since its concentration decreases on standing, while species with all Se atoms neighbouring increase on ageing; it is known that such species are somewhat more stable[27] which also follows from the positive enthalpy of reaction (4).

We noted that some decomposition of 1,2,5-Se_3S_5 took place already within the first 15 h after preparation of the reaction mixture. At that time 1,2-Se_2S_6 had become the major species in the CS_2 solution followed by 1,2,5-Se_3S_5 with 1,4-Se_2S_6 still being third.

Formally, 1,2,5-Se_3S_5 may be formed by reaction (22):

$$SeSCl_2 + Se_2Cl_2 + 2S_2Cl_2 \xrightarrow[-8KCl,4I_2]{+8KI} \begin{cases} \rightarrow 1,2,5\text{-}Se_3S_5 \\ \rightarrow 1,2,3\text{-}Se_3S_5 \end{cases} \quad (22)$$

When the intermediate ISeSI reacts with ISeSeI via the SeI bond, 1,2,3-Se_3S_5 is formed. In the case that ISeSeI first reacts with two ISSI and then with ISeSI, 1,2,5-Se_3S_5 is to be expected. The other expected isomer, 1,2,4-Se_3S_5, has not been observed in our work. On grounds of the initial mixing ratio of $S_2Cl_2 : Se_2Cl_2 = 2:1$, reaction (22) is more likely

than other reactions and, consequently, Se_3S_5 is the major product. (In Se_3S_5 the S : Se ratio amounts to 1.7 : 1.) Seven eight-membered Se_xS_y molecules can be seen in the NMR spectra of the freshly dissolved orange crystals; the spectrum of the reaction mixture (column 4 of Table 7) showed only five species due to the poor signal-to-noise ratio.

In general, our NMR results are in perfect agreement with the HPLC data which show only traces of selenium-rich rings in the freshly prepared reaction mixture as well as in the freshly prepared solution of the crystals. In contrast, Laitinen *et al.*[28] studying the same reaction have observed reaction products by ^{77}Se NMR spectroscopy which resemble the products in our decomposed (aged) solution. These authors had reacted S_2Cl_2–Se_2Cl_2 mixtures of different molar proportions (1 : 4 through 4 : 1) with potassium iodide in CS_2, obviously following our earlier procedure.[22] Without giving many details the reaction mixtures were analysed quantitatively by ^{77}Se NMR using the natural isotopic composition. For a 2 : 1 (S–Se) mixture the results listed in Table 7, last column, were obtained.[28] These data clearly resemble the composition of our aged solution (column 6 of Table 7) indicating that the samples of Laitinen *et al.* had decomposed prior to NMR spectroscopy. These authors did not state the time elapsed between sample preparation and recording of the NMR spectra. It should be noted that reliable results of unstable selenium sulphides can be obtained only with strict exclusion of light and nucleophilic impurities, which requires special acid treatment of glassware including NMR tubes and solvents. In addition, all solutions should be analysed as rapidly as possible.

Summarizing, we have shown that mixing Se_2Cl_2 with S_2Cl_2 rapidly yields $SeSCl_2$ and other mixed Se—S—Cl molecules together with $SeCl_2$. These species can be detected by NMR and Raman spectroscopy and react with titanocene pentasulphide as well as with potassium iodide to give a variety of cyclic selenium sulphides. SCl_2 and Se_2Cl_2 react quantitatively to give $SeCl_4$ and S_2Cl_2.

Acknowledgements—We are grateful to Dr Maria Papavassiliou for reproducing some experiments, to Ms K. Thiel for typing the manuscript, and to the Deutsche Forschungsgemeinschaft and Verband der Chemischen Industrie for support.

VOLATILE TRIS-TERTIARY-ALKOXIDES OF YTTRIUM AND LANTHANUM. THE X-RAY CRYSTAL STRUCTURE OF $[La_3(OBu^t)_9(Bu^tOH)_2]$

DONALD C. BRADLEY,* HALINA CHUDZYNSKA, MICHAEL B. HURSTHOUSE* and MAJID MOTEVALLI

Department of Chemistry, Queen Mary and Westfield College, Mile End Road, London E1 4NS, U.K.

(*Received* 19 *December* 1990; *accepted* 30 *January* 1991)

Abstract—Tertiary alkoxides of yttrium and lanthanum have been prepared by addition of excess tertiary alcohol to the metal tris-(bis-trimethylsilylamides), $M\{N(SiMe_3)_2\}_3$ (M = Y, La), and characterized by elemental analyses, NMR, IR and mass spectroscopy. With t-butanol and t-amyl alcohol the alcoholates $[Y_3(OBu^t)_9(Bu^tOH)_2]$ (**1**), $[Y_3(OAm^t)_9(Am^tOH)_2]$ (**2**) and $[La_3(OBu^t)_9(Bu^tOH)_2]$ (**3**) were isolated. With higher tertiary alcohols the tris-t-alkoxides $[M(OR)_3]$ were obtained [M = Y, R = CMe_2Pr^i (**4**), $CMeEtPr^i$ (**5**), CEt_3 (**6**); M = La, R = CMe_2Pr^i (**7**), $CMeEtPr^i$ (**8**)] as dimers. The coordinated Bu^tOH in **1** could be replaced by THF or pyridine but not by trimethylamine. The X-ray crystal structure of **3** showed that the La_3 triangle is capped by two μ_3-OBu^t groups with three μ_2-OBu^t bridges as in $[La_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(Bu^tOH)_2]$. The variable temperature NMR data suggest that compounds **1** and **2** have the same structure in solution as compound **3**.

The alkoxides of yttrium and some of the lanthanides have been known for many years,[1–4] but hitherto have not been fully characterized. In recent years the interest in these compounds has been greatly boosted by their applications in ceramics and electronic materials.[5] The need for volatile or soluble (in organic solvents) metallo-organic compounds containing metal—oxygen bonds, which could serve as precursors for the MOCVD or the sol–gel technique has prompted several workers to reinvestigate the older data[6,7] and to search for new compounds.[8,14] The yttrium and lanthanide alkoxides are known to form polymeric structures which are responsible for their low volatility and solubility.[4] Recently it has been shown[6,7] that yttrium, ytterbium and scandium isopropoxides form pentanuclear complexes $[M_5O(OPr^i)_{13}]$ around a five-coordinated (μ_5) oxygen atom. Evans *et al.*[9] attempted the preparation of yttrium t-butoxide from YCl_3 and $NaOBu^t$ or $LiOBu^t$ in THF and obtained products such as $[Y_3(\mu_3\text{-}OCMe_3)(\mu_3\text{-}Cl)(\mu\text{-}OCMe_3)_3(OCMe_3)_4(THF)_2]$ and $[Y_4(\mu_5\text{-}OCMe_3)_2(\mu\text{-}OCMe_3)_4(OCMe_3)_4(\mu\text{-}O)(\mu\text{-}Cl)_2Li_4(\mu\text{-}OCMe_3)_2]_2$. They succeeded in isolating a chlorine-free compound $[La_3(OBu^t)_9(THF)_2]$, although they were unable to solve the crystal structure due to disorder problems. Further work[10] produced more structures of chloro-t-butoxo complexes of yttrium and demonstrated the general complexity of the system and its dependence on small changes in the preparative conditions.

RESULTS AND DISCUSSION

We have prepared the following tris-t-alkoxides of yttrium and lanthanum: $[M_3(OR)_9(ROH)_2]$ [M = Y, R = Bu^t (**1**), Am^t (**2**); M = La, R = Bu^t (**3**)] and $[M(OR)_3]_n$ [M = Y, R = CMe_2Pr^i (**4**), $CMeEtPr^i$ (**5**), CEt_3 (**6**); M = La, R = CMe_2Pr^i (**7**), $CMeEtPr^i$ (**8**)].

We chose the t-alkoxides because the branched OR groups give greatest shielding of the metal atoms thereby decreasing the degree of oligomerization and enhancing the volatility and solubility.

We were also interested in comparing the t-alkoxides with the isopropoxides which we found previously to form the oxo-complexes $[M_5O$

* Authors to whom correspondence should be addressed.

$(OPr^i)_{13}$]. The mechanism of the formation of the oxo-complexes could be either:

(i) by elimination of propene ($MOPr^i \rightarrow MOH + C_3H_6$), or
(ii) by formation of di-isopropyl ether ($2\ MOPr^i \rightarrow M_2O + Pr^i{}_2O$).

Some t-alkoxides (e.g. $Al_2OBu^t{}_6$) are known to undergo β-elimination with formation of an alkene on thermolysis. However, we have found that all of the yttrium and lanthanum t-alkoxides are tris compounds thermally stable at least up to 150°C. Since t-alkoxide groups should eliminate alkenes much more readily than the isopropoxide group this appears to rule out mechanism (i) for the formation of the $[M_5O(OPr^i)_{13}]$ compounds.

Preparations

To preclude the formation of the chloride alkoxides obtained by Evans *et al.*,[9,10] we chose to prepare the t-alkoxides from a chlorine-free starting material. For this purpose we used the reaction of $M\{N(SiMe_3)_2\}_3$ (M = Y or La)[11] with tertiary alcohols in benzene solution:

$$M\{N(SiMe_3)_2\}_3 + 3\ R^tOH \rightarrow [M(OR^t)_3] + 3\ HN(SiMe_3)_2.$$

This approach was recently used by other workers in synthesizing $[Y(OSiPh_3)_3]$,[12] although they were unsuccessful when applying it to the t-butoxide.

The alcohol in at least 30% excess was added to $M\{M(SiMe_3)_2\}_3$ in benzene solution. The mixture was stirred and refluxed for 1 h and the completion of the reaction checked by NMR. The solvents were evaporated *in vacuo* and the residue either sublimed *in vacuo* or crystallized from toluene or pentane. The compounds were characterized by elemental analysis, NMR, IR and mass spectra. An X-ray crystal structure of $[La_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(Bu^tOH)_2]$ was obtained.

All the compounds were obtained as white solids. Compounds **1** and **3** were moderately soluble in organic solvents, while the higher t-alkoxides were very easily soluble in benzene and pentane. Some data on melting points, volatilities and mass spectra of these compounds are presented in Table 1. It is noteworthy that three of these compounds (**1**–**3**) are formulated as $[M_3(OR)_9(ROH)_2]$ with coordinated alcohol, which was identified by IR and NMR spectroscopy. Such complexes are rare in metal alkoxide chemistry[4] since alkoxide bridging is the preferred mode of metal coordination expansion. The coordinated alcohol could be removed by heating (**1**, 60–70°C; **2**, 40–50°C; **3**, 100°C) *in vacuo* with the lanthanum complex (**3**) being the most stable. Therefore, the volatilities observed for these compounds probably relate to the unsolvated tri-t-alkoxides and their melting points are complicated by decomposition caused by loss of coordinated alcohol. The coordinated t-butanol in **1** was readily replaced by THF giving $[Y_3(OBu^t)_9(THF)_2]$ (**9**) which lost THF when heated to 70°C *in vacuo*. Pyridine also displaced the alcohol from **1** but trimethylamine did not. It is noteworthy that Evans *et al.*[9] obtained $[Y_3(OBu^t)_8Cl(THF)_2]$ and showed that the THF could be replaced by pyridine.

None of the higher t-alkoxides (C_6 or C_7) gave complexes with coordinated alcohol, presumably

Table 1.

because of steric hindrance which prevents the metals attaining the octahedral coordination required for the trinuclear species $[M_3(OR)_9(ROH)_2]$. Instead it seems that dimeric compounds $[M_2(OR)_6]$ are formed with tetrahedral metal coordination. Although the volatility data in Table 1 are not very precise it does appear that for both $[M(OCMe_2Pr^i)_3]$ and $[M(OCMeEtPr^i)_3]$ the heavier lanthanum compounds are distinctly more volatile than the corresponding yttrium compounds.

Bradley and Swanwick[13] showed several years ago that in the series $[M(OR^t)_4]$ (M = Ti, Zr, Hf; R = Bu or Am) the volatilities were in the unexpected order Hf > Zr > Ti. This was explained in terms of the mass-entropy effect which becomes apparent when the central metal atom is effectively screened by the bulky ligands and prevented from contributing to intermolecular attractive forces. The rather large difference in volatility between the yttrium and lanthanum compounds suggests that other factors must also be involved. For example the dimeric lanthanum compounds may dissociate more readily to monomers than the yttrium dimers. Nevertheless, the mass spectral data show evidence of gaseous dimeric species for both metals.

Mass spectra

None of the compounds gave parent molecular ions but some important fragment ions were identified by accurate masses as shown in Table 1.

Considering first of all the trinuclear species $[M_3(OR)_9(ROH)_2]$, it is clear that loss of coordinated alcohol has occurred but the presence of trinuclear fragment ions $[Y_3(OBu^t)_8]^+$ (*m/z*, 851), $[Y_3O(OBu^t)_6]^+$ (*m/z*, 721) and $[La_3O_6C_7H_{14}]^+$ (*m/z*, 610.8) suggests that the trimer species $[M_3(OR)_9]$ is present in the vapour state. Although $[Y_3(OBu^t)_9(THF)_2]$ gave no identifiable fragment ions, the pyridine complex gave a peak at 856 corresponding to $[Y_3O_9C_{31}H_{45}N_2]^+$.

For all of the higher t-alkoxides a fragment ion corresponding to $[M_2(OR)_5]^+$ was observed, suggesting that these compounds are dimeric in the vapour state. In addition to the agreement between observed and calculated accurate masses, these species were also confirmed by the presence in the correct proportion of the M+1 ion corresponding to the species containing one ^{13}C atom in place of a ^{12}C atom.

NMR spectra

Variable temperature ^1H and ^{13}C NMR studies were carried out in order to derive structural information on these t-alkoxides in solution. All of the compounds were fluxional and required low temperatures to slow down the exchange between distinguishable alkoxide groups.

The limiting low temperature ^1H NMR spectra of the trinuclear species $[M_3(OR)_9(ROH)_2]$ (**1–3**) were very complex and a knowledge of the molecular structure of the lanthanum compound (**3**) obtained by single crystal X-ray analysis was invaluable in their interpretation. The structure (Fig. 1) shows that in $[La_3(OBu^t)_9(Bu^tOH)_2]$ (**3**) there is a triangle of metal atoms bound by two capping μ_3-OBu^t groups (above and below the triangle) and three bridging μ_2-OBu^t groups. Each metal has two terminal ligands of which two out of six are probably the coordinated alcohols.

The t-butoxides (**1**) and (**3**) exhibit very similar spectra which are detailed in Table 2. At around 230 K, each has five major peaks with intensities in the ratio 2:2:2:1:4, reading from left to right lower field to higher field. Assuming that the two coordinated alcohol molecules are bonded to different metals then one μ_2-OBu^t is unique since the other two will be equivalent. If the two μ_3-OBu^t groups are also equivalent then it follows that the six terminal groups are in a 2:4 ratio corresponding to two alcohols and four alkoxides. Closer inspection of the spectra reveals that there are some significant minor peaks adjacent to some of the major peaks and at low temperature the OH peak for the coordinated alcohol splits into two peaks in a 3:1 ratio. This suggests that more than one structure is present and indeed the molecular structure (Fig. 1) depends on whether the coordinated alcohols are both above (or below) the plane of the M_3 triangle (isomer **A**) or one is above and one below (isomer **B**). The X-ray structure unfortunately does not clearly identify the positions of the alcohol ligands, but it is reasonable to suppose that the OH chemical shifts of isomers **A** and **B** will be slightly different. The unique μ_2-OBu^t resonance at *ca* δ 1.50 is also split into an approximately 2:1 ratio, although the two peaks are not sufficiently resolved to give accurate values of integration. The lowest field peak at *ca* δ 1.80, which is believed to be due to the μ_3-OBu^t groups, also has a small satellite as do the other major peaks, but even at 400 MHz it has not been possible to completely resolve the spectra. At higher temperature (300 K) the spectra simplify to three main peaks in the ratio (left to right from lower field to higher field) 2:3:6 corresponding to $2\times\mu_3$, $3\times\mu_2$ and $6\times$terminal groups due, presumably, to rapid exchange involving the coordinated alcohols and the terminal alkoxide groups. The OH peaks also coalesce into a single peak in the correct proportion to the t-butyl peaks of 2:99

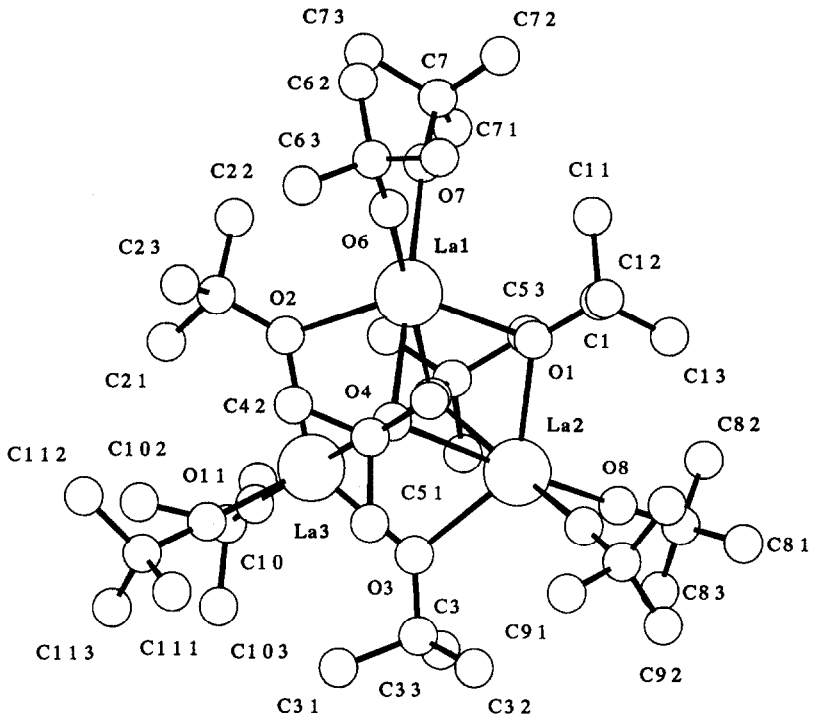

Fig. 1. The molecular structure of $[La_3(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_3(OBu^t)_4(Bu^tOH)_2]$ showing the atom numbering scheme: hydrogen atoms omitted for clarity.

required by the formula. On raising the temperature to *ca* 330 K the three t-butyl peaks all coalesced into a single, broad peak due to exchange of terminal, μ_2-bridging and μ_3-bridging alkoxide groups. Addition of t-butanol (δ 1.15 Bu^t, 2.37 OH) to the yttrium compound (**1**) in toluene (d_8) at 300 K had no effect on the lowest field t-butoxide peak (μ_3-OBu^t), or on the peak at intermediate field (μ_2-OBu^t), but caused a substantial shift from δ 1.43 to 1.26 in the highest field peak (terminal OBu^t groups). This behaviour was taken as further confirmation that the highest field peak was due to the terminal alkoxide groups including the coordinated alcohols. The alcohol OH peak was also shifted to higher field (δ 2.52) as expected showing rapid exchange between free and coordinated alcohol molecules.

The t-amyloxide of yttrium (**2**) gave more complex ^{1}H NMR spectra than the t-butoxide because of the presence of singlets (methyl bonded to the quaternary carbon), triplets (methyl of the ethyl) and quartets (methylene of the ethyl). Nevertheless, the overall pattern was similar to that of the t-butoxides with broad singlets, triplets and quartets at 353 K each giving five resonances at low temperatures (253 K). In the case of the singlets, which were best resolved, the ratios of intensities were 2:2:2:1:4 (from low to high field) exactly as found in the t-butoxides. It is therefore reasonable to conclude that the t-amyloxide has the same trinuclear structure as the t-butoxide.

The ^{13}C NMR spectra of compounds **1–3** showed splitting of peaks similar to that found in the ^{1}H spectra, but were less well resolved and not amenable to quantitative evaluation. The ^{89}Y NMR spectra of **1** and **2** at 310 K showed single peaks at δ 166.8 and 199.1 in C_6D_6. No doubt the fluxional nature of these complexes prevented the resolution into two peaks in the 2:1 ratio required by the structure assuming that the yttrium atoms bonded to one terminal alkoxide and one alcohol would have a slightly different chemical shift from the yttrium bonded to two terminal alkoxides.

The ^{1}H NMR spectrum of **9** at 273 K was rather complex corresponding to the presence of a major species having two broad unresolved peaks at δ 1.78 and 1.35 and a minor species with sharp lines at δ 1.92, 1.72, 1.70, 1.53 and 1.49 in the ratios of 1:3:1:2:1:1, respectively. The peaks due to THF were present at δ 1.43 and 3.59. It appears that more than one species is present but one of them could well have the trinuclear structure of **1** with the t-butanol molecules replaced by THF, analogous to the complex $[Y_3Cl(OBu^t)_8(THF)_2]$ obtained by Evans *et al.*[9]

By careful heating *in vacuo* the coordinated

Table 2. ^{1}H NMR spectra

Compound	Temperature (K)	Chemical shifts[a]

[c] Obtained by removing Bu^tOH from **1** *in vacuo* (see Experimental).
[d] Obtained by removing Am^tOH from **2** *in vacuo*.

t-butanol could be removed from **1** leaving the unsolvated tris-t-butoxide $(Y(OBu^t)_3]_n$, which gave a very broad ^{1}H NMR signal at *ca* δ 1.56 at 297 K. At low temperature (217 K) this was resolved into a complex spectrum of nine peaks (δ 1.80, 1.77, 1.73, 1.69, 1.58, 1.55, 1.49, 1.44 and 1.27) suggesting the presence of polymeric species.

Removal of coordinated t-amyl alcohol from **2** left a solid whose ^{1}H NMR spectrum at 233 K gave five resolved singlets at δ 1.70, 1.63, 1.52, 1.45 and 1.35 in the ratio 2:2:2:1:2, respectively, together with several quartets (δ 2.20, 2.05 and 1.95) and triplets (δ 1.28, 1.22, 1.06, 0.97 and 0.84). Interestingly, the pattern of singlets could be ascribed to trinuclear $[Y_3(\mu_3\text{-}OAm^t)_2(\mu_2\text{-}OAm^t)_3(OAm^t)_4]$, based on the structure in Fig. 1, without the coordinated alcohol molecules. In such a structure the μ_2-ligands would be distinguishable in a 1:2 ratio and the four terminal ligands in a 2:2 ratio. It would seem that the slightly more bulky t-amyloxide groups do not allow the trinuclear cluster to undergo further polymerization resulting in a molecular structure containing one six-coordinate and two five-coordinated yttrium atoms.

The yttrium and lanthanum derivatives of the C_6 t-alcohol dimethylisopropylcarbinol (**4** and **7**)

showed different ^{1}H NMR behaviour compared with the t-butoxides and t-amyloxides. At room temperature, **4** gave a septet (δ 1.63), singlet (δ 1.30) and doublet (δ 1.05) in the correct proportions for the alkyl group. Cooling to 203 K was required to cause splitting to two septets (δ 1.92 and 1.77), two singlets (δ 1.46 and 1.41) and three doublets (δ 1.22, 1.16 and 1.07) which were all broad. The lanthanum analogue (**7**), which also showed only a single alkoxide species at room temperature (δ 1.72 sept., 1.36 sing., 1.03 doub.) gave a more complex spectrum at lower temperatures (233 K) comprising three septets, four singlets and four doublets.

The mass spectra of **4** and **7** gave evidence of dinuclear fragment ions, but the ^{1}H NMR spectra for dimers should give only two alkoxide environments and it may well be that a trinuclear species is present in equilibrium with the dimer. It is noteworthy that for both compounds the signals all moved downfield on cooling. The ^{13}C NMR spectrum of **4** showed no splitting down to 233 K, whereas in **7** splitting into two signals was observed for $C(CH_3)_2$ and $CCH(CH_3)_2$ carbon atoms at 233 K. Interestingly, the ^{89}Y NMR spectrum of **4** gave a single peak at δ 36.8 at very much higher field than the trinuclear compounds **1** and **2**, which contain octahedrally coordinated yttrium. This strongly suggests that in **4** the yttrium is in a lower coordination environment.

The ^{1}H NMR spectrum of **5** gave, at room temperature, two septets, one quartet, two singlets and a multiplet consisting of overlapping triplets and doublets. The ratio of the two septets and two singlets was 2 : 1 in each case, suggesting the presence of a dimer. The spectrum was unchanged on lowering the temperature. The ^{13}C NMR spectrum of **5** showed two unequal signals for the quaternary, CH, CH_2 and CH_3 (ethyl) carbon atoms, but two large (equal) and two small (equal) signals for the CH_3 (isopropyl) carbon atoms. This suggests a dimeric structure in which restricted rotation renders the two methyls of the isopropyl groups non-equivalent. The ^{89}Y NMR signal for **5** was at δ 45.6, which is in the same region as for **4** and also suggests a lower coordination than in **1** and **2**. The ^{1}H NMR spectrum of **8** at room temperature gave a septet, a quartet, a singlet, a triplet and two equal doublets and was unchanged on lowering the temperature. The splitting of the isopropyl methyl doublets suggests non-equivalence as in the yttrium compound (**5**).

The ^{13}C NMR spectrum of **8** also showed one signal for the quaternary, CH, CH_2 and CH_3 (ethyl) carbons, but two (equal) signals for the CH_3 (isopropyl) carbons in agreement with the ^{1}H NMR spectrum.

Finally we mention the ^{1}H NMR spectrum of **6**, which at 353 K gave a quartet (δ 1.54) and a triplet (δ 0.97). At around 303 K the quartet broadens and at 273 K is resolved into two quartets (δ 1.61 and 1.54) in a 2 : 1 ratio. The triplet also broadens and splits into two overlapping triplets (δ 1.04 and 1.00) at 273 K. The ^{13}C NMR spectrum of **6** showed splitting of the quaternary and CH_2 carbon atoms at room temperature, whilst the ^{89}Y spectrum gave one peak at δ 37.5. These data together with the mass spectrum suggest that compound **6** is dimeric with distorted tetrahedral yttrium.

Infrared spectra

Compounds **1–3**, containing coordinated alcohols, have broad bands corresponding to OH-stretching vibrations at 3420, 3439 and 3386 cm^{-1}, respectively. Compound **9** shows one of the characteristic THF bands at 1075 cm^{-1} (cf. 1072 cm^{-1} in free ligand), but the other band at *ca* 913 cm^{-1} is obscured by strong bands due to t-butoxide groups.

X-ray crystal structure of $[La_3(OBu^t)_9(Bu^tOH)_2]$ (**3**)

The molecular structure of **3** was determined by single crystal X-ray diffraction and is shown in Figs 1 and 2. Some bond lengths are listed in Table 3 and bond angles in Table 4. The trinuclear species with the M_3O_{11} metal–oxygen framework has already been described under the NMR section. The presence of two molecules of Bu^tOH in the trinuclear molecule is shown by elemental analysis, IR spectra and ^{1}H NMR spectra, but it was not possible to locate the OH hydrogen atoms in the X-ray structure. It is reasonable to suggest that the coordinated alcohols occupy terminal positions on two of the three lanthanum atoms and their presence might be revealed by longer La—O bond distances compared with the La—OBu^t groups. Looking at the terminal La—O bonds it is noticeable that La(1) has one long (2.604) and one short (2.195 Å) bond suggesting that O(7)C(7)(C71, C72, C73) is one of the alcohol molecules. La(2) is equally bonded to O(8) and O(9) (La—O, 2.304 and 2.308 Å) which must be covalently bonded t-butoxides and therefore La(3) should carry the other alcohol ligand. In fact La(3) is almost equally bonded to O(10) and O(11) (La—O, 2.350 and 2.315 Å) and the difference is barely significant. If the coordinated alcohols are bonded to La(1) and La(3) this would make the μ_2-bridging t-butoxide group O(2)C(2)(C21, 22, 23) slightly different in environment from the other two equivalent μ_2-bridging groups. In fact O(2) forms a symmetrical bridge to La(1) (2.449 Å) and La(3) (2.447 Å), whereas O(3)

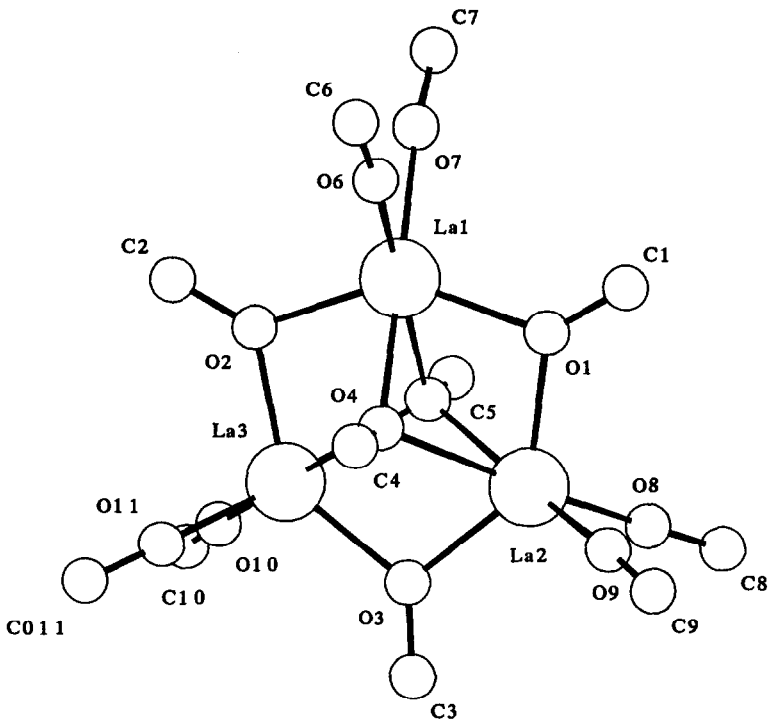

Fig. 2. The structure of the $La_3(OAlk)_{11}$ core. All Bu^t methyls omitted for clarity.

and O(1) form slightly unsymmetrical bridges [La(3)—O(3), 2.417; La(2)—O(3), 2.458; La(1)—O(1), 2.408; and La(2)—O(1), 2.460 Å]. Bearing in mind the uncertainties in these bond distances the data are inconclusive. The presence of coordinated alcohol might be expected to show up in a comparison of La—O—C bond angles. Thus the oxygen atom on a covalently bound alkoxide has two lone pairs of electrons available for π-donation into vacant metal orbitals with a limiting angle of 180° for full π-bonding. The oxygen of a coordinated alcohol has only one lone pair for π-donation leading to an angle nearer to 120°. The data in Table 4 show that three of the terminal groups have LaOC angles very close to 180° (178.9, 178.7 and 177.0), one is 175.1, another is 173.7 and the smallest angle is 167.5°. It is significant that the smallest angle involves La(1)—O(7) which has the longest terminal La—O bond length and was accordingly identified as a coordinated alcohol. The

next smallest angle (173.7°) corresponds to La(3)—O(10), which on bond length considerations could be the other alcohol molecule. It is noteworthy that the LaOC angles in the bridging alkoxides are much smaller (μ_2, 127.0–130.1° and μ_3, 120.8–123.8°). In the absence of any clear cut evidence for the position of the second alcohol, we presume it is disordered, together with an alkoxy group, over sites O(10) and O(11).

All of the lanthanum atoms in **3** are in distorted octahedral coordination with each metal bonded to two terminal, two μ_2-bridging and two μ_3-bridging t-butoxide groups. The μ_3-bridging oxygen atoms cannot be involved in π-donation to the metals and it is significant that they are positioned *trans* to the strongly π-donating terminal oxygen atoms. The overall molecular structure of **3** is similar to that reported for $[Y_3Cl(OBu^t)_8(THF)_2]$ by Evans *et al.*[9] who were unable to remove the final chlorine atom in their synthetic procedure. Further work by Evans *et al.*[10] led to the isolation of $[Y_3Cl(OBu^t)_8(THF)_3][BPh_4]$ which contains the interesting trinuclear cation $[Y_3(\mu_3\text{-}Cl)(\mu_3\text{-}OBu^t)(\mu\text{-}OBu^t)_3(OBu^t)_3(THF)_3]^+$ which also has the same framework structure as **3**.

We believe that in solution compound **1** obtained in this research has the same structure as the lanthanum analogue **3**. Although we have grown a single crystal of **1**, the X-ray crystallographic analysis has so far been thwarted by disorder problems. Work is continuing on the X-ray structure determination for compounds **1** and **4**–**6**. It is interesting to note even the very bulky t-alkoxo groups, $OCMe_2Pr^i$, $OCMeEtPr^i$ and $OCEt_3$, result in the formation of dimeric yttrium and lanthanum trialkoxides. By using the bulky substituted phenoxo

ligand, 2,6-$Bu_2^tC_6H_3O$, Lappert *et al.*[8] have obtained the monomeric $[Y(OC_6H_3Bu_2^t)_3]$ compound which sublimed at 250–255°C/10^{-3} torr and is considerably less volatile than compounds **4–6** reported here. Clearly the gain in volatility expected to result from a monomeric species has been more than compensated for by the lowering in volatility caused by the increased number of atoms in the substituted phenoxo group. Work in progress suggests that enhanced volatility of the metal tris-t-alkoxides will be obtained by substituting CF_3 groups for CH_3 due to the anomalously weak intermolecular forces between fluoroalkyl groups.

EXPERIMENTAL

All operations were carried out under an atmosphere of purified N_2 using vacuum line, glove box and Schlenk-style apparatus. Solvents were dried over and distilled from sodium benzophenone and stored over molecular sieves. Bu^tOH was refluxed over sodium butoxide and distilled. Am^tOH, $Pr^i Me_2COH$, $Pr^iEtMeCOH$ and Et_3COH were dried first over molecular sieves, then the amount required for the reaction was put in excess benzene and finally dried azeotropically. The commercial yttrium and lanthanum chlorides were refluxed in $SOCl_2$ (freshly distilled from linseed oil) for 48 h. The $SOCl_2$ was then evaporated off *in vacuo* and the chlorides heated at 50°C for 20 h to remove residual traces of $SOCl_2$. Hexamethyldisilazane was purchased from Aldrich and dried over molecular sieves. Butyl lithium was used as purchased. The compounds $M\{N(SiMe_3)_2\}_3$ (M = Y or La) were prepared as previously described.[11]

NMR spectra were obtained using Bruker WP80FT, WM250FT and WH400FT spectrometers. Calibration was made using solvent signals from incomplete deuteration and made relative to TMS for ^1H and ^{13}C; ^{89}Y was relative to YCl_3. Mass spectra were obtained using a MS-902 EI mass spectrometer, recorded at 70 eV. IR spectra were obtained as Nujol mulls in the range 4000–200 cm^{-1} using a Perkin–Elmer FT 1720× spectrometer.

Microanalytical data on carbon and hydrogen were obtained from University College, London and from B.M.A.C. The metals were analysed gravimetrically as metal oxides.

Crystallography

Crystal data for **3**: $C_{44}H_{101}O_{11}La_3$, $M = 1223.0$, monoclinic space group $P2_1/a$, $a = 28.163(5)$, $b = 10.987(2)$, $c = 19.974(5)$ Å, $\alpha = \beta = 90$, $\gamma = 99.79°$, $V = 6090.49$ Å^3, $Z = 4$, $D_c = 1.33$ g cm^{-3}, $\mu(Mo\text{-}K_\alpha) = 21.2$ cm^{-1}. Data were collected at room temperature with an Enraf–Nonius CAD4 diffractometer and monochromated Mo-K_α radiation. The data were corrected for Lorentz, polarization and absorption effects. Full-matrix least-squares refinement of 514 parameters gave $R = 0.041$, $R_w = 0.037$ for 4170 unique, observed reflections from 7443 measured. The weighting scheme, $w = [\sigma^2(F_0)+]^{-1}$, gave acceptable agreement analyses. Atomic coordinates, full lists of bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

Preparation of $[Y_3(OBu^t)_9(Bu^tOH)_2]$ (1)

To $Y\{N(SiMe_3)_2\}_3$ (3.1 g) in benzene (85 cm^3) was added Bu^tOH (15 cm^3) and the solution was refluxed for 2 h. Solvent and $(Me_3Si)_2NH$ were then removed by evaporation *in vacuo* and the residue was crystallized from toluene giving white crystals (1.3 g, 67% yield based on yttrium, m.p. 171°C). Found: 25.0; C, 47.6; H, 9.4. Calc. for $[Y_3(OBu^t)_9(Bu^tOH)_2]$: Y, 24.9; C, 49.2; H, 9.5%. ^{13}C NMR ($C_6D_5CD_3$) at 298 K: δ 74.9, 72.2 ($OCMe_3$); 36.3, 34.3 (CH_3); at 233 K: δ 74.9, 72.5, 72.2, 72.1 ($OCMe_3$); 36.5, 36.3, 35.7, 34.0 (CH_3). ^{89}Y NMR (C_6D_6) at 310 K: δ 166.8. IR: 3420br, 1241m, 1207s, 1165m, 983s, 936s, 901s, 877m, 768m, 741w, 530s, 496s, 478s, 391m, 256s, 230w cm^{-1}.

A sample of **1** was heated *in vacuo* at 60–80°C until no more Bu^tOH remained. Found: Y, 2.85. $Y(OBu^t)_3$ requires: Y, 28.8%. Compound **1** appears to sublime at 235°C/10^{-2} torr with decomposition, yielding a white sublimate (47%, m.p. 240°C). Found: C, 39.6; H, 8.1. $Y(OBu^t)_3$ requires: C, 46.8; H, 8.8%.

Preparation of $[Y_3(OAm^t)_9(Am^tOH)_2]$ (2)

A solution of Am^tOH (6 cm^3) in benzene (40 cm^3) was added to a solution of $Y\{N(SiMe_3)_2\}_3$ (6.2 g) in benzene (160 cm^3) and left overnight. After removing solvent, $(Me_3Si)_2NH$ and excess Am^tOH by evaporation *in vacuo* the residue was recrystallized from Am^tOH (2.8 g, 63% based on yttrium, m.p. 84°C). Found: Y, 21.7. $Y_3(OAm^t)_9(Am^tOH)$ requires: Y, 21.7%. ^{13}C NMR (C_6D_6) at 297 K: δ 75.2 ($OCMe_2Et$); 40.7 (CCH_2Me); 31.3 (CCH_3); 11.2 (CCH_2CH_3); at 253 K ($C_6D_5CD_3$): 77.4, 77.0, 74.4 ($OCMe_2Et$); 41.4, 40.7, 39.5 (CCH_2Me); 31.3, 31.2, 29.6 (CCH_3); 12.1, 11.0, 10.8 (CCH_2CH_3). ^{89}Y NMR (C_6D_6) at 310 K: δ 199.1. IR: 3386br, 1360m, 1331w, 1316w, 1287w, 1227m, 1162s, 1151s, 1059m, 1017m, 981s, 949s,

935m, 890s, 878m, 793w, 735m, 534m, 512s, 480m, 464m, 390w, 305w, 242w, 235w, 228s, 225m cm^{-1}.

A sample of **2** was heated *in vacuo* at 70°C until no more Am^tOH remained. The white solid (m.p. 110°C) was analysed for $Y(OAm^t)_3$. Found: Y, 25.8. $Y(OAm^t)_3$ requires: Y, 25.4%. Compound **2** appeared to distil at 150°C/10^{-3} torr with decomposition, giving a glue-like condensate which could not be crystallized.

Preparation of $[La_3(OBu^t)_9(Bu^tOH)_2]$ **(3)**

To a solution of $La\{N(SiMe_3)_2\}_3$ (4.8 g) in benzene (150 cm^3) was added Bu^tOH (5 cm^3) and the solution was refluxed for 1 h and left overnight. After removing volatiles by evaporation *in vacuo*, the residue was crystallized from toluene (3.2 g, 100% based on lanthanum, m.p. 192°C). Found: La, 34.2; C, 42.3; H, 8.6. $[La_3(OBu^t)_9(Bu^tOH)_2]$ requires: La, 34.1; C, 43.2; H, 8.3%. ^{13}C NMR (C_6D_6) at 297 K: δ 73.7, 73.0, 71.6 ($OCMe_3$); 36.2, 35.5, 34.4 (CCH_3); at 253 K ($C_6D_5CD_3$): 73.4, 72.0, 70.8 ($OCMe_3$); 35.0, 34.6, 32.6 (CCH_3). IR: 3439br, 1378s, 1356s, 1349s, 1202s, 1022w, 972s, 936s, 911s, 889m, 826w, 746m, 513s, 488s, 457m, 379m, 353m, 229s, 226s cm^{-1}.

Preparation of $[Y(OCMe_2Pr^i)_3]$ **(4)**

Me_2Pr^iCOH (8 cm^3) in benzene (50 cm^3) was added to a solution of $Y\{N(SiMe_3)_2\}_3$ (8 g) in benzene (200 cm^3) and refluxed for 2 h and left overnight. After removal of the volatiles *in vacuo* the residue was distilled at 170°/10^{-3} torr (5.0 g, 91% based on yttrium, m.p. 161°C). Found: Y, 22.7; C, 53.4; H, 10.5. $Y(OCMe_2Pr^i)_3$ requires: Y, 22.7; C, 55.1; H, 10.0%. The compound dissolves readily in hydrocarbon solvents. ^{13}C NMR (C_6D_6) at 297 K: δ 76.5 ($OCMe_2Pr_i$); 41.2 ($CCHMe_2$); 30.1 (CCH_3); at 233 K ($C_6D_5CD_3$): 76.7, 41.2, 29.6, 19.4. ^{89}Y NMR ($C_6D_5CD_3$) at 310 K: δ 36.8. IR: 1366s, 1353m, 1321w, 1223m, 1175s, 1149s, 1103s, 1051s, 1010s, 947s, 923m, 911m, 869w, 852w, 795w, 714m, 574s, 558w, 532s, 478m, 429m, 378w, 359w, 300w, 254w, cm^{-1}.

Preparation of $[Y(OCMeEtPr^i)_3]$ **(5)**

Compound **5** was obtained from the reaction of $Y\{N(SiMe_3)_2\}_3$ (7 g) and $MeEtPr^iCOH$ (8 cm^3) in benzene, in the same manner as for **4**, as a white solid by sublimation at 170°C/10^{-3} torr (5.0 g, 94% based on yttrium, m.p. 196°C). Found: Y, 20.7; C, 53.8; H, 10.7. $Y(OCMeEtPr^i)_3$ requires: Y, 20.5; C, 58.0; H, 10.4%. Compound **5** dissolves readily in hydrocarbon solvents. ^{13}C NMR (C_6D_6) at 297 K: δ 80.0, 78.2 ($OCMeEtPr^i$); 38.4, 37.0 ($CCHMe_2$); 36.0, 35.3 (CCH_2Me); 26.9, 25.2 (CCH_3); 19.2, 19.0, 18.8, 18.7 ($CCHCH_3$); 10.2, 9.8 (CCH_2CH_3). ^{89}Y NMR ($C_6D_5CD_3$) at 310 K: δ 45.6. IR: 1362s, 1329m, 1313w, 1281w, 1202m, 1169s, 1147s, 1104s, 1063m, 1023s, 994s, 957m, 941s, 908s, 853m, 792w, 724m, 699m, 580m, 563s, 485m, 442m, 393w, 363w, 328w, 281w, cm^{-1}.

Preparation of $[Y(OCEt_3)_3]$ **(6)**

Compound **6** was prepared in the same manner as **4** and **5** from the reaction of $Y\{N(SiMe_3)_2\}_3$ (7 g) and Et_3COH (8 cm^3) in benzene, and the residual white solid was distilled at 225°C/10^{-2} torr (4.0 g, 75% based on yttrium, m.p. 198°C). Found: Y, 20.4; C, 55.8; H, 10.8. $Y(OCEt_3)_3$ requires: Y, 20.5; C, 58.0; H, 10.4%. Compound **6** dissolves readily in hydrocarbon solvents. ^{13}C NMR (C_6D_6) at 297 K: δ 80.2, 78.0 ($OCEt_3$); 33.7, 33.3 (CCH_2CH_3); 9.7 (CH_2CH_3). ^{89}Y NMR at 310 K: δ 47.8 (C_6D_6), 37.5 ($C_6D_5CD_3$). IR: 1344m, 1324m, 1295w, 1277w, 1259w, 1212m, 1158s, 1050s, 996s, 948s, 923m, 851w, 813w, 795w, 762w, 713m, 669w, 578m, 534s, 479m, 456w, 374m, 314w, 283w, cm^{-1}.

Preparation of $[La(OCMe_2Pr^i)_3]$ **(7)**

Pr^iMe_2COH (4.5 cm^3) in benzene (50 cm^3) was added to a solution of $La\{N(SiMe_3)_2\}_3$ (5.86 g) in benzene (150 cm^3), and after refluxing for 2 h was left overnight. After removal of volatiles *in vacuo* the residue was distilled at 135°C/10^{-3} torr (1.75 g, 42% based on lanthanum, m.p. 119°C). Found: La, 31.9. $La(OCMe_2Pr^i)_3$ requires: La, 31.4%. ^{13}C NMR (C_6D_6) at 297 K: δ 77.2 ($OCMe_2Pr^i$); 40.5 ($CCHMe_2$); 28.6 (CCH_3); 19.4 ($CHCH_3$); at 233 K ($C_6D_5CD_3$): δ 29.7, 29.1 (CCH_3); 19.9, 19.4 ($CHCH_3$). IR: 1308w, 1235vw, 1189m, 1169s, 1146s, 1099s, 1061w, 985s, 974s, 945m, 927m, 905m, 858m, 800w, 706w, 552m, 513m, 492m, 437w, 388w, 312w, cm^{-1}.

Preparation of $[La(OCMeEtPr^i)_3]$ **(8)**

Compound **8** was prepared in the same manner as **7** from the reaction of $La\{N(SiMe_3)_2\}_3$ (4.41 g) and $MeEtPr^iCOH$ (4 cm^3) in benzene and the residual white solid was distilled at 150°C/10^{-3} torr (2.1 g, 61% based on lanthanum, m.p. 112°C). Found, La, 29.5; C, 49.8; H, 9.4. $La(OCMeEtPr^i)_3$ requires: La, 28.7; C, 52.1; H, 9.4%. ^{13}C NMR (C_6D_6) at 297 K: δ 79.7 ($OCMeEtPr^i$); 38.6 ($CHMe_2$); 35.5 (CCH_2Me); 26.0 ($OCCH_3$); 19.1, 19.0 ($CHCH_3$); 10.1 (CH_2CH_3). IR: 1361s, 1327w, 1279w, 1259w, 1181s, 1165s, 1147s, 1102s, 1035m,

1007s, 953m, 932s, 911s, 851w, 787w, 715m, 694w, 574m, 557w, 516s, 437w, 416w, 392w, 330w, 233w, cm^{-1}.

Preparation of $[Y_3(OBu^t)_9(THF)_2]$ (**9**)

A sample of **1** was dissolved in THF, refluxed for 1 h and left overnight. After evaporation of the volatiles *in vacuo* the residue was redissolved in THF and compound **9** crystallized out. Found: Y, 24.5; C, 44.9; H, 8.9. $[Y_3(OBu^t)_9(THF)_2]$ requires: Y, 24.9; C, 49.4; H, 9.1%. On heating *in vacuo* at 70°C the THF was pumped off. Compound **9** begins melting at 142°C with decomposition. ^1H NMR ($C_6D_5CD_3$) at 303 K: δ 3.59, 1.88, 1.68, 1.52, 1.46; at 273 K: 3.59 (THF), 1.92, 1.78, 1.72, 1.70, 1.53, 1.52, 1.49, 1.43 (THF). IR: 1354m, 1239m, 1207s, 1075w, 1002s, 985m, 935m, 903m, 876w, 767w, 528m, 497m, 481m, 391w, 256m, 230m, cm^{-1}.

Reaction of **1** *with pyridine*

A sample of **1** was dissolved in pyridine and left overnight. After evaporating off the volatiles *in vacuo* the residue was crystallized from toluene and recrystallized from pentane to give colourless crystals (m.p. 118°C). Found: Y, 26.2; C, 48.3; H, 8.2; N, 2.5. Calc. for $Y_3(OBu^t)_9(C_5H_5N)_2$: Y, 24.6; C, 51.0; H, 8.5; N, 2.6%. ^1H NMR (C_6D_6) at 297 K: δ 9.25, 7.00, 6.81 (multiplets, 2H, 1H, 2H, C_5H_5N); 1.55 (singlet, 28H, $OCCH_3$).

Addition of NMe_3 *to* **1**

(a) Trimethylamine (3.5 cm^3) was condensed at −90°C onto **1** (1.24 g) and allowed to warm to 0°C. After 1 h at 0°C the volatiles were evaporated off *in vacuo* and **1** was recovered unchanged.

(b) NMe_3 (11 cm^3) was condensed onto **1** in toluene (20 cm^3) and allowed to warm to 0°C. After 2 h at 0°C it was kept at −20°C for a further 60 h and the volatiles then evaporated off *in vacuo*. The residue was unchanged (**1**).

Acknowledgements—We thank SERC for support, Mr G. Coumbarides and Mr P. Haycock for NMR spectra, Mr P. Cook for mass spectra and Mr Ian Harding for mounting the single crystal of **3**. We also acknowledge the use of the University of London Intercollegiate Research Service (ULIRS) 400 MHz NMR spectrometer.

CHIRAL NITROGEN LIGANDS IN LATE TRANSITION METAL-CATALYSED ASYMMETRIC SYNTHESIS—I. ADDRESSING THE PROBLEM OF LIGAND LABILITY IN RHODIUM-CATALYSED HYDROSILATIONS

MICHAEL E. WRIGHT* and STEVEN A. SVEJDA

Department of Chemistry and Biochemistry, Utah State University, Logan, UT 84322-0300, U.S.A.

(*Received* 2 *November* 1990; *accepted* 21 *January* 1991)

Abstract—Treatment of 2,6-dichloropyridine with the potassium salt of ephedrine derivatives afforded the new chiral ligands 2-chloro-6-[(1*R*,2*S*)-2-(R_2N)-1-phenylpropanoxy] pyridine [NR_2 = NH_2 (**1a**), NHMe (**1b**), NMe_2 (**1c**)] in good yield. The isomeric and new ligands 2-(X)-[(1*R*,2*S*)-2-amino-1-phenylpropanoxy]pyridine [X = 3-chloro (**2**); X = 5-chloro (**3**); X = 5-trifluoromethyl (**4**)] were also prepared in the study. Combining ligand **1a** with $[(COD)RhCl]_2$ gave rapid addition and the isolable rhodium(I) complex, (COD)[**1a**]RhCl (**5a**). Complex **5a** provided the highest enantioselectivity to date for the asymmetric hydrosilation of acetophenone (30% enantioselectivity, 78% chemical yield) using a nitrogen-based, chiral, bidentate ligand in a stoichiometric fashion. Ligands **1b–c** and 2-[(1*R*,2*S*)-2-amino-1-phenylpropanoxy]pyridine (**1d**) gave low optical yields for the asymmetric hydrosilation of acetophenone. Ligands **2–4** gave enantioselectivity ranging from 10 to 23% (~1.1 : 1, ligand/rhodium) and similar chemical yields as **1a** for the hydrosilation of acetophenone. Employing a 10-fold excess of ligands **2–4** afforded enantioselectivity of 37–42% for the hydrosilation of acetophenone. The success of ligands **1a** and **2–4** as compared with **1d** (4% optical yield) and other bidentate nitrogen-based ligands is attributed to the increased π-acidity of the pyridine ring as a result of the electron-withdrawing substituents.

The asymmetric catalytic hydrogenation[1] and hydrosilation[2] of the carbonyl group is a valuable synthetic method for the synthesis of chiral alcohols.[3] Asymmetric hydrosilation of ketones can be very chemoselective for the carbonyl functional group and thus complements the hydrogenation reaction which shows preferential reactivity towards alkenes. In the early 1970s the research groups of Kumada,[4a] Kagan[4b] and Ojima[4c] and co-workers pioneered the development of the transition metal-catalysed asymmetric hydrosilation of ketones. Continued efforts in the transition metal-catalysed asymmetric hydrosilation for the 1970s focused on the use of chiral phosphorus-based ligands. In 1982, Brunner and co-workers developed rhodium catalysts employing nitrogen-based ligands which showed a significant increase in optical yield relative to all phosphorus ligands developed at that time (Chart 1).[5] A requisite for high enentioselectivity with nitrogen-based ligands has been a large ligand/metal ratio (~5–13).[6] A recently developed chiral terdentate ligand (Chart 1) by Nishiyama and co-workers[7] gave the first significant optical yield (56%) for a nitrogen-based ligand when employed in a stoichiometric fashion. However, for optimum performance the use of excess ligand (4–8, ligand/rhodium) was still necessary and the "assistance" of a Lewis acid (e.g. AgX, X = OSO_2CF_3 and BF_4) was always required. A very attractive feature of nitrogen-based ligands is that the chirality is usually derived from the inexpensive and readily available pool of optically pure amines.

Even with well over 200 chiral bidentate nitrogen-based ligands[8] synthesized in the last decade, not once has the problem of ligand lability been addressed. Instead the issue has been side-stepped by applying Le Chatelier's principle. In the present

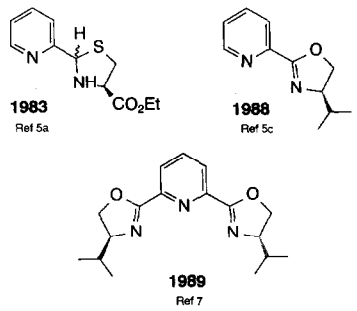

Chart 1.

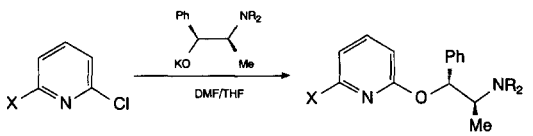
study we demonstrate that there are options to employing excess ligand. By simply tailoring the π-acceptor character of the nitrogen-based ligand it is possible to overcome the necessity of a high ligand/rhodium ratio.

RESULTS AND DISCUSSION

Ligand preparations

We recently developed the efficient synthesis of chiral 6-alkoxy-2-bromopyridines and utilized these materials to prepare a variety of chiral bis(6-alkoxy-2-pyridyl)silane and -methanol ligands.[9] In an analogous manner, treatment of 2,6-dichloro- or 2-chloropyridine with the potassium salt of three ephedrine derivatives afforded compounds **1a–d** [eq. (1)].[10]



(1)

1a, X = Cl, NR_2 = NH_2
1b, X = Cl, NR_2 = NHMe
1c, X = Cl, NR_2 = NMe_2
1d, X = H, NR_2 = NH_2

Ligands **2–4** were also prepared in reasonable yield from the appropriate chloropyridine derivative and the norephedrine potassium alkoxide. The ligands were obtained as light brown oils after flash chromatography on silica gel. In certain cases the ligands were converted to their monohydrochloride salts to obtain analytically pure samples.

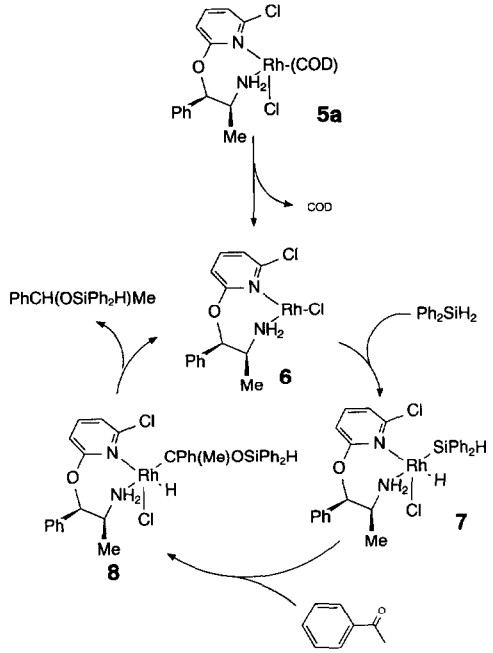
Catalytic applications—hydrosilation of acetophenone

Treatment of **1a** with $[(COD)RhCl]_2$[11] produced the addition product **5a** as an air-stable, light yellow solid. Complex **5a** gave analytical and NMR data consistent with a mononuclear rhodium(I) complex. Complex **5a** was found to efficiently catalyse the hydrosilation of acetophenone in 30% enantioselectivity without the addition of free ligand or a co-factor (Scheme 1,[12] Table 1, entry 1). The significance of this result is amplified in light of that *no other bidentate nitrogen-based ligand has ever afforded higher than a 6% optical yield when used in a stoichiometric fashion.* Notably the *in situ* generation of the catalyst is less efficient than using the preformed rhodium(I) complex **5a** (Table 1, entry 3).



Scheme 1.

Utilization of ligands **1b–c** to generate the catalysts *in situ* afforded much lower optical yields (Table 1, entries 6 and 7). The amine coordination is clearly a requisite to bring the chirality of the ligand in close proximity to the metal centre and also in forming a conformationally rigid ligand environment. The poor results obtained with ligands **1b–c** are likely a consequence of added steric interactions of the N-methyl group(s) in the chelate ring and with substituents on the metal centre.

The integrity of the catalytic system throughout the reaction period is supported by measuring the optical yield of 1-phenylethanol as a function of reaction progress. The relatively constant optical yield ($30 \pm 2\%$) vs reaction progress measured is consistent with the chiral catalytic species remaining intact throughout the entire reaction period. The catalyst stability is limited since at the higher

substrate/catalyst ratio of 400 we obtain a notably lower optical yield.

The low optical yield for ligand **1d** is an intriguing result. On the basis of steric arguments we would anticipate ligand **1d** to chelate stronger than **1a**. To explore the reasons behind the success of ligand **1a** we synthesized ligands **2–4** and evaluated these ligands in the hydrosilation of acetophenone (Table 2). The results clearly demonstrate that the *electron-withdrawing character of the substituent is a key factor*. Substituents in the 5-position produce a trend in optical yield vs the Hammett σ values which suggests that the electron-withdrawing character of the substituent is controlling the ligand's ability to transfer chirality.

It is well known that for low valent transition metals (i.e. Rh^1) d–π backbonding becomes an important factor in the coordination of bipyridine and related ligands.[13] This may indeed be why all the chiral, nitrogen-based, bidentate and even the terdentate ligands suffer lability problems with the soft and low-valent rhodium(I) metal. The rhodium(I) complex can either lose COD (to generate complex **6**) or the nitrogen ligand to generate the *achiral* species **9** (Scheme 2). The latter catalyst will of course carry out the hydrosilation chemistry producing a racemic product. We have measured the relative rate of hydrosilation for $[(COD)RhCl]_2$ against **5a** and found that the former is considerably faster than **5a** ($k_1 \approx 10 \times k_2$). Additional evidence that such an equilibrium is operative is found by increasing the ligand/rhodium ratio and observing not only that the enantioselectivity increased (37–42%), but more importantly, became nearly the

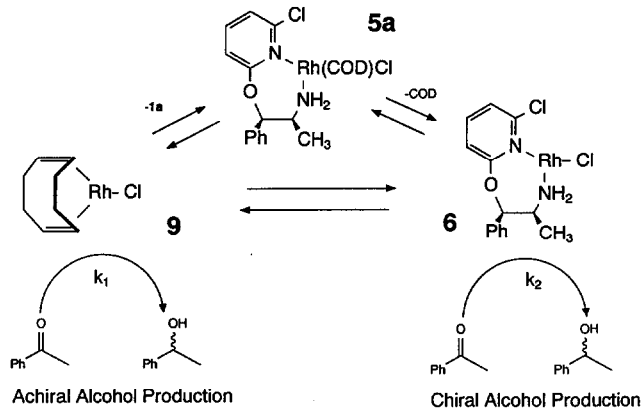

Scheme 2.

same for ligands **2**–**4**. These data would suggest that electronic factors do not affect the optical yield through ligand conformation but rather through controlling the relative concentrations of the active catalysts **6** and **9**.

Molecular modelling of the rhodium catalyst

Molecular mechanics analysis of the proposed catalytic intermediates has been performed using BIOGRAPH (Version 2.0) on an Ardent supercomputing system. We chose to model complex **7** which is the proposed catalytic intermediate responsible for *re* and *si* face selectivity (Fig. 1). Configuration **A** was found to be the lowest energy structure with all other variations being significantly less stable. As suggested by a reviewer we also approached the minimization by supplying a tremendous amount of internal vibrational energy (temperature = 600 K) to the system and then returning to normal (i.e. 273 K). This latter procedure produced conformation **A** as well. On the premise that **A** is responsible for the observed product, then approach of the ketone would be affected by the *axial*-methyl group. The *equatorial*-phenyl group appears to be important for "locking" the ring conformation.

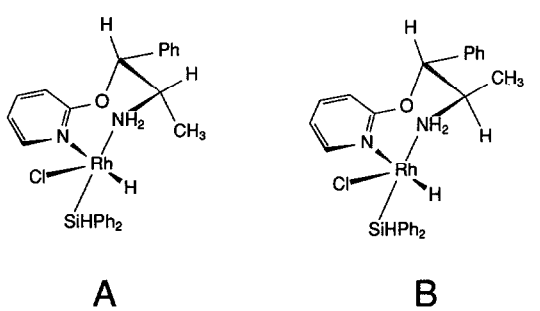

Fig. 1. Drawings illustrating the seven-membered chelate ring for the norephedrine ligands based on molecular mechanics. Structure **A** utilizes the (1*R*,2*S*)-norephedrine ligand and conformation **B** uses the diastereomeric ligand (1*R*,2*R*)-norephedrine.

To test the importance of the *axial*-methyl group in the transmittal of asymmetry we prepared **4(i)**, a diastereoisomer of **4**. As anticipated structure **B** was calculated to be more stable than **A** because both substituents in the chelate ring are equatorial. Utilization of **4(i)** in the hydrosilation of acetophenone gave only a 1% optical yield of 1-phenylethanol even at the high ligand/rhodium ratio of 10 (Table 2). This result confirms the importance of the *axial*-methyl group in the stereochemical outcome of the reaction and suggests a means for modifying and improving ligand performance.

Concluding remarks

Through the synthesis and utilization of a new class of ligands in the rhodium-catalysed hydrosilation of acetophenone we have substantially improved the enantioselectivity for the stoichiometric use of chiral, nitrogen-based, bidentate ligands. The success of our ligands was due to the incorporation of electron-withdrawing groups in the pyridine ring leading to an increase in the π-acidity. This in turn enhanced ligand binding to the soft and low-valent rhodium(I) centre and decreased the concentration of any achiral rhodium catalysts. Modelling of the catalytic systems combined with the synthesis of a diastereomeric analogue provided evidence that the *axial*-methyl group in the chelate ring is crucial for asymmetric induction. Future efforts in our research program will involve the development of chiral nitrogen ligands with a combination of enhanced π-acidity and strong σ-donating capabilities.

EXPERIMENTAL

General

All manipulations of compounds and solvents were carried out by using standard Schlenk techniques. Solvents were degassed and purified by distillation under nitrogen from standard drying agents. Spectroscopic measurements utilized the following instrumentation: ^{1}H NMR, Varian XL 300; ^{13}C NMR, Varian XL 300 (at 75.4 MHz). NMR chemical shifts are reported in δ vs Me_4Si in ^{1}H NMR and assigning the $CDCl_3$ resonance at 77.00 ppm and the DMSO-d_6 resonance at 39.50 ppm in ^{13}C NMR spectra. Optical rotations were measured at ambient temperature (20 ± 1°C) on a Perkin–Elmer 241 polarimeter using the sodium *D*-line. The polarimeter was calibrated using (*R*)-1-phenylethanol (Lancaster Synthesis) by measuring several dichloromethane solutions at concentrations in the range of those prepared from reactions. The (1*R*,2*S*)-(−)-norephedrine, (1*R*,2*R*)-(−)-norpseudoephedrine hydrochloride, (1*R*,2*S*)-(−)-ephedrine, (1*R*,2*S*)-(−)-N-methylephedrine and $[(CO)_2RhCl]_2$ were purchased from Aldrich Chemical Company and used as received. The 2,3-, 2,5- and 2,6-dichloropyridines and 2-chloro-5-trifluoromethylpyridine were purchased from Lancaster Synthesis. The $[(COD)RhCl]_2$ was prepared by the literature method.[11] The acetophenone was distilled from barium oxide and the diphenylsilane was distilled from calcium hydride prior to use and stored under nitrogen. Elemental analyses were performed at Atlantic Microlab Inc., Norcross, Georgia.

Preparation of **1a–d**

Potassium alkoxides were prepared by treatment of the appropriate alcohol with potassium metal in THF for 48 h under reflux. The potassium alkoxide THF solution was transferred by cannulation to a DMF (100 cm^3) solution of 2,6-dichloropyridine (5.92 g, 40 mmol) at 20°C. The mixture was allowed to react for 60 min, then was poured on to water and extracted with ether (2×150 cm^3). The organic layers were combined and washed with brine and then dried over potassium carbonate. Removal of the solvent under reduced pressure afforded compounds **1a–d** in > 82% crude yield. Ligand **1a** was purified by chromatography on silica gel eluting with ethyl acetate/hexanes (1 : 19, v/v) (oil, 50%). Ligand **1b** was purified by chromatography on silica gel eluting with methanol/dichloromethane (1 : 9, v/v) (oil, 46%). Ligand **1c** was flash-columned on alumina (MPLC grade, neutral, non-activated) with ethyl acetate/hexanes (1 : 9, v/v) (oil, 40%).

Hydrosilation of acetophenone

A Schlenk tube was charged with acetophenone (0.6 g, 5 mmol), [(COD)RhCl]$_2$ (12.3 mg, for 100 : 1, substrate/Rh, mol/mol), the appropriate ligand, and dichloromethane (3 cm^3). The mixture was degassed by three consecutive freeze–pump–thaw cycles. A separate Schlenk tube was charged with diphenylsilane (1.3 cm^3, 7 mmol) and dichloromethane (1 cm^3) and degassed as above. The latter solution was cannulated into the acetophenone mixture and allowed to react at 0°C until the carbonyl band in the IR (1685 cm^{-1}) disappeared (~18 h). The mixture was then diluted with acetone (5 cm^3) and 10% hydrochloric acid (10 cm^3) and then stirred vigorously for 2 h. The mixture was extracted with ether and the organic layer dried over potassium carbonate. The ether was removed and the crude product purified by bulb–bulb distillation (fraction from 60–80°C, 0.7 torr, was collected). Contamination by acetophenone in the samples was taken into account and calculated using the ^{1}H NMR spectra for the distilled product. The product was also analysed by preparing the MPTA ester and analysed by high-field ^{1}H NMR according to the literature procedure,[14] and found to be in excellent agreement with the data from optical measurements.

Monitoring the optical yield vs reaction progress

Complex **5a** was formed by adding [(COD)RhCl]$_2$ (82 mg, 0.33 mmol) and **1a** (97 mg, 0.37 mmol) to 30 cm^3 of dichloromethane. The solution was concentrated to 5 cm^3 and ether (100 cm^3) was added. The precipitate was collected and washed several times with ether to remove excess ligand. The solid was redissolved in dichloromethane and degassed Ph_2SiH_2 (8.7 cm^3, 47 mmol) was added. The mixture was allowed to react at ambient temperature for 30 min and then cooled to 0°C. Acetophenone (4.0 g, 33 mmol) was added to the mixture and aliquots (2.5 cm^3) were removed from the reaction vessel at 1 h intervals. The aliquots were transferred to a flask containing an acetone (10 cm^3) and 10% hydrochloric acid (5 cm^3) mixture which had been chilled to 0°C. The product was isolated after work-up by distillation at reduced pressure. Samples of the distilled product (0.100 g) were diluted to 1.00 cm^3 with dichloromethane and their optical rotations measured and enantiomeric excesses calculated.

Molecular mechanics

The proposed catalytic species were modelled using BIOGRAPH (Version 2.0) on an Ardent super-computing facility. The structures were permitted to minimize without any interatomic restrictions and were approached from several different beginning structures to avoid false minima. The metal centre was modelled with ruthenium since Version 2.0 of BIOGRAPH does not contain rhodium. The energies used in the study represent

the total energy of the molecule which is basically a summation of bond, angle, torsion and van der Waals' energies.

ISOLATION OF A SULPHUR-RICH INDIUM POLYSULPHIDE COMPLEX CONTAINING TWO DIFFERENT S_x^{2-} LIGANDS. SYNTHESIS AND STRUCTURE OF $[InS_{10}Br]^{2-}$

SANDEEP DHINGRA and MERCOURI G. KANATZIDIS*

Department of Chemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

(*Received* 15 *November* 1990; *accepted* 21 *January* 1991)

Abstract—The reaction of $InBr_3$ with K_2S_5 (or K_2S_4 and K_2S_6) and Ph_4PBr afforded yellow $(Ph_4P)_2[In(S_4)(S_6)Br]$ (**I**). Complex **I** crystallizes in the monoclinic space group $P2_1/c$ with $a = 14.355(7)$, $b = 17.723(4)$, $c = 20.974(7)$ Å, $\beta = 108.5(1)°$, $V = 5060.6(4)$ Å^3 (at 23°C), $Z = 4$. The $[In(S_4)(S_6)Br]^{2-}$ anion features a trigonal bipyramidal indium centre coordinated by four sulphur atoms and one bromine atom. The latter occupies an axial position. The In^{3+} centre is chelated by two bidentate polysulphide S_4^{2-} and S_6^{2-} ligands. The S_6^{2-} ligand occupies two equatorial positions. The remaining one equatorial and one axial positions are occupied by the S_4^{2-} ligand. The average In—S distance is 2.535(35) Å. The In—Br distance is 2.615(3) Å. Complex **I** shows no absorptions in the UV–vis spectrum. Two strong absorptions at 490 and 457 cm^{-1} in the IR spectrum are attributed to S—S vibrations.

Soluble transition-metal polychalcogenides constitute an important class of compounds with unusual structures and stoichiometries. They are useful as model compounds for sulphided heterogeneous catalysts,[1] metal/sulphur transport agents in geochemistry[2] and precursors to chalcogenide semiconductors.[3] To date, a number of polysulphide, and to a lesser extent, polyselenide and polytelluride complexes with transition metals have been synthesized and structurally characterized.[1–8] In some cases, polysulphides behave differently than their heavier congeners, while in others they behave similarly. It would be important to understand the role of the metal ion in determining similarities and differences in the chemistry of the various polychalcogenide ligands. To date, mostly transition metals have been investigated with respect to coordination to polychalcogenide ligands. On the contrary, the preparation of soluble polychalcogenide compounds containing main-group elements has not been pursued to the same degree. The few existing examples are, $[Bi_2S_{34}]^{4-}$,[9] $[Sn(S_4)_2(S_6)_{0.6}(S_4)_{0.4}]^{2-}$,[10] $[In_2Se_{21}]^{4-}$,[11] $[SnSe_{12}]^{2-}$,[12] $[PbSe_8]^{2-}$[13] and $[M_3Se_{15}]^{3-}$[14] (M = In, Tl). As part of our systematic investigation of polychalcogenide chemistry of the late transition and main group metals[11–14] and in an attempt to prepare the sulphur analogue of the indium–polyselenide $[In_2Se_{21}]^{4-}$ we investigated the corresponding polysulphide chemistry. We have isolated and structurally characterized a new unexpected complex $[InS_{10}Br]^{2-}$, which possesses an unusual structure.

EXPERIMENTAL

All work was carried out in a glove box (Vacuum Atmospheres, Inc.) under a nitrogen atmosphere. Dimethylformamide (DMF) was stored over 4 Å Linde molecular sieves for several days and distilled *in vacuo*. Ether was distilled over sodium (or potassium)/benzophenone under a nitrogen blanket. $InCl_3$ (anhydrous) was purchased from Alpha Products Inc. Satisfactory elemental analyses were obtained. Potassium polysulphides (K_2S_x, $x = 4$–6) were prepared in liquid ammonia from potassium metal and elemental sulphur in the appropriate ratio. The X-ray powder diffraction patterns were recorded either with a standard Debye–Scherrer powder camera mounted on a Phillips Norelco XRG-5000 X-ray generator operating at 40 kV/20

* Author to whom correspondence should be addressed.

mA, or a Phillips XRG-3000 computer controlled powder diffractometer. Ni filtered, Cu radiation was used. Thermal gravimetric analyses were performed on a Cahn TG System 121 under flowing nitrogen. A typical heating rate of 5°C min^{-1} was used. IR spectra were recorded as KBr and CsI pellets on a Nicolet 740 FT–IR spectrometer. Elemental analyses were performed on a JEOL JSM-35C scanning electron microscope equipped with an Energy Dispersive Spectroscopy detector.

Synthesis of **I**

A 20 cm^3 DMF solution of $InBr_3$ (0.200 g, ~0.564 mmol) was added to a 80 cm^3 DMF solution of K_2S_4 (0.117 g, ~0.568 mmol), K_2S_6 (0.153 g, 0.565 mmol) in the presence of Ph_4PBr (0.470 g, 1.121 mmol). The mixture was stirred for ~20 min. Filtration of the pale yellow solution to remove the KBr precipitate, followed by slow addition of *ca* 60 cm^3 of ether, and storage at room temperature for 2 days, afforded 0.41 g of analytically pure, yellow, chunky crystals (61% yield). The synthesis also can be carried out with K_2S_5 (39% yield).

The X-ray diffraction (XRD) powder pattern obtained from this material matches extremely well that calculated from the single crystal coordinates, confirming the purity of the compound. A comparison between the calculated and observed d_{hkl} spacings for this material is shown in Table 1.

X-ray crystallographic studies

The crystallographic data were collected on a Enraf–Nonius diffractometer using an ω–2θ scan

mode and Mo–K_α radiation. The crystals were mounted inside glass capillaries and sealed. Crystal data and details for data collection and refinement are shown in Table 2. The intensities of three check reflections were monitored every 100 reflections and did not show any appreciable decay during the data collection period. An empirical absorption correction was applied to all data based on ψ scans for several reflections. The structure was solved with direct methods using SHELXS-86[15] and was refined with the SDP[16] package of crystallographic programs, using a VAXstation 2000 computer. All non-carbon and non-hydrogen atoms were refined anisotropically. The carbon atoms were refined isotropically. The hydrogen atom positions were calculated and included in the structure factor calculation but were not refined. The final coordinates of all atoms, thermal parameters of all non-hydrogen atoms, tables of least-squares planes and a listing of calculated and observed ($10F_o/10F_c$) structure factors (total of 32 pages) have been deposited with the Director, Cambridge Crystallographic Data Centre. There were no significant residual peaks in the final electron density different map. The XRD powder pattern was calculated using the atom coordinates determined from the single crystal data using the program POWD 10.[17]

RESULTS AND DISCUSSION

Synthesis

Our original aim was to prepare In^{3+}/S_x^{2-} complexes structurally and compositionally analogous to the selenium analogues, $[In_2Se_{21}]^{4-}$[11] and $[In_3Se_{15}]^{3-}$,[14] by reacting $InCl_3$, K_2S_5 and Ph_4PBr in DMF. As it often happens with polychalcogenide ligands, a different complex than anticipated was obtained. The rational preparation of **I** was subsequently carried out by reacting $InBr_3$ with K_2S_5 (or a mixture of K_2S_4 and K_2S_6) in DMF in the presence of Ph_4P^+ according to eq. (1):[18]

$$InBr_3 + 2K_2S_5 + 2Ph_4PBr \longrightarrow (Ph_4P)_2[InS_{10}Br] + 4KBr. \quad (1)$$
$$\textbf{(I)}$$

The UV–vis spectrum of **I** in DMF solution has no characteristic absorption bands (300–800 nm) and features a rising absorbance at higher energies. The absence of an absorption band around 650 nm suggests that the complex does not dissociate in this solvent to form S_x^- radical anions which are responsible for this absorption.[11] In the IR region of the spectrum we observe strong absorptions at 490 and 457 cm^{-1} and a weak absorption at 470 cm^{-1}. These are most likely due to S—S vibrations. A medium intensity absorption is also observed at 352 cm^{-1} which currently is not assigned with certainty.

Thermal gravimetric analysis examination of the thermolysis of **I** under flowing nitrogen shows that the compound begins to lose weight at −335°C. This onset temperature of initial weight loss is shared by other Ph_4P^+ salts of polyselenide complexes. It represents the thermal stability of the Ph_4Ph^+ ion with respect to nucleophilic attack from the S_x^{2-} ligands.[3] The weight loss curve is complicated lacking any well-defined plateaux. At 1000°C, the highest temperature studied, the material continues to lose weight. The grey–black residue obtained contains In, S and P in the 2:2:1 ratio. Its X-ray powder pattern does not show the presence of known In/S, In/P or In/S/P phases.

Description of the structure of **I**

The monoclinic unit cell contains well separated $[InS_{10}Br]^{2-}$ anions and Ph_4P^+ cations. The latter have the usual tetrahedral structure and will not be discussed further. The structure of the $[InS_{10}Br]^{2-}$ anion is shown in Fig. 1. In view of the structure of $[In_2Se_{21}]^{4-}$, and that described here, it appears that five coordination in indium polychalcogenide chem-

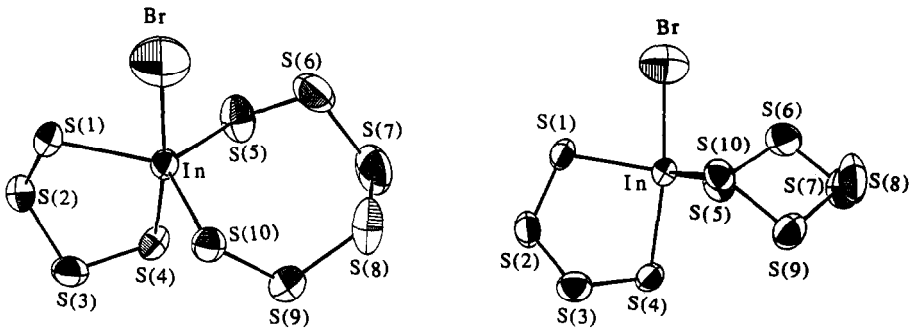

Fig. 1. Two views of the $[In(S_4)(S_6)Br]^{2-}$ anion with labelling scheme, as drawn by ORTEP.

istry is readily accessible. The coordination of indium is best described as a trigonal bipyramid with three equatorial sulphur ligands and two axial (a sulphur and a bromide) ligands. It is somewhat surprising that the bromide ligand occupies an axial site in the molecule since an equatorial position is predicted based on VSEPR arguments. The indium atom is chelated by a S_4^{2-} and a S_6^{2-} ligand. The latter occupies two equatorial positions. The occurrence of S_6^{2-} ligands is rather rare. Another example of a polysulphide complex in which both S_4^{2-} and S_6^{2-} ligands are present is found in $[Sn(S_6)(S_4)_2]^{2-}$.[10] It should be noted, however, that while in the latter complex the S_4^{2-} and S_6^{2-} ligands are disordered about the same crystallographic site, in **I** they are ordered and occupy distinct sites. The average In—S bond distance is 2.535(35) Å. The equatorial In—S bonds are shorter than the axial In—S(4) bond as expected. A listing of selected bond distances and angles for $[InS_{10}Br]^{2-}$ is given in Table 3. The observed S—S bonds are in the normal range of single S—S bond distances reported for other metal polysulphide compounds.[19] It is interesting to note that in the seven-membered InS_6 ring the In, S(5), S(7), S(8) and S(10) atoms lie very close to a plane with S(6) and S(9) positioned, respectively, 1.16 and 1.19 Å above and below it. The same con-

[a] The estimated standard deviations in the mean bond lengths and the mean bond angles are calculated by the equations $\sigma_1 = \{\Sigma_n(l_n - l)^2/n(n-1)\}^{1/2}$. Where l_n is the length (or angle) of the nth bond, l is the mean length (or angle) and n is the number of bonds.

formation has also been observed in the seven-membered HgS_6 ring of the $[Hg(S_6)_2]^{2-}$ complex.[20] The equatorial position of the S_6^{2-} ligand in **I** is rationalized by its ability to provide a wide enough "bite" to span the 4.25 Å needed between equatorial ligands. The smaller S_4^{2-} ligand cannot offer such a large bite (3.7 Å max.) and thus is better stabilized in the fashion in which it is found in $[In(S_4)(S_6)Br]^{2-}$. The position of the S(9) atom in the S_6^{2-} ligand affects the S(4)—In—S(10) angle which becomes 12° larger than the S(4)—In—S(5) angle, suggesting that the S(9) atom exerts a significant steric repulsion on S(4). The flexibility of the S_6^{2-} ligand to tune its "bite" size is evident by the fact that it has now been found to participate in chelating fashion in tetrahedral, trigonal bipyramidal and octahedral coordination. The five-membered InS_4 ring adopts an envelope conformation with S(3) lying 1.1 Å above the In(1)S(2) S(4) plane. To the best of our knowledge, $[In(S_4)(S_6)Br]^{2-}$ is the first molecular example of an In^{3+} polysulphide complex.

The In—Br bond length in $[In(S_4)(S_6)Br]^{2-}$ is 2.615(3) Å, in the correct range for axial binding, five-coordinate indium, being 0.055 Å shorter than the In—Br bond in the six-coordinate $[InBr_6]^{3-}$,[21] and longer than the same bond in the tetrahedral $[InBr_4]^-$.[21] When the bromide is equatorially bound to five-coordinate indium such as in $InBr_3(Me_3AsS)_2$, it forms a shorter In—Br distance in the range of 2.53–2.55 Å.[22] Work is continuing to isolate homoleptic indium polysulphide complexes.

THE MOLECULAR STRUCTURE OF (ALLYL)BIS(METHYLCYCLOPENTADIENYL)NIOBIUM(III)

LINDA K. CHEATHAM, JOHN J. GRAHAM, ALLEN W. APBLETT and ANDREW R. BARRON*

Department of Chemistry and Materials Research Laboratory, Harvard University, Cambridge, MA 02138, U.S.A.

(*Received* 26 *November* 1990; *accepted* 14 *January* 1991)

Abstract—The compound $(\eta^5\text{-}C_5H_4Me)_2Nb(\eta^3\text{-}C_3H_5)$ (**1**) has been prepared and characterized by ^1H, ^{13}C and ^{93}Nb NMR spectroscopy. The molecular structure of **1** has been confirmed by X-ray crystallography and the nature of the bonding between the allyl ligand and the niobium is discussed. Compound **1** crystallizes in the monoclinic space group $P2_1/c$, $a = 6.029(2)$, $b = 7.752(2)$, $c = 26.115(6)$ Å, $\beta = 92.33(2)°$, $V = 1219.5(5)$ Å^3, $Z = 4$, $R = 0.031$, $R_w = 0.050$.

There is a remarkably rich chemistry of bent bis (cyclopentadienyl)transition metal complexes, $(\eta^5\text{-}C_5H_5)_2ML_n$, when $n = 1$–3. Within these complexes the L_n groups are forced, due to the nature of the frontier orbitals, to lie in a common plane perpendicular to the Cp centroid—M—Cp centroid plane. Such an arrangement is indeed observed for $(\eta_5\text{-}C_5H_5)_2NbH_3$.[1] However, derivatives in which the L_n group are constrained from being co-planar such as η^3-allyl pose an interesting question concerning the bonding between the metal and the ligand. Lauher and Hoffman[2] have presented the molecular orbital treatment of $(\eta^5\text{-}C_5H_5)_2M$(allyl) complexes shown in Fig. 1, in which three allyl-to-metal bonding interactions are proposed. Firstly, the lowest filled allyl orbital, *a'*, overlaps with the higher *a'* metal orbital, forming a σ ligand-to-metal bonding interaction. Secondly, the non-bonding *a''* ligand orbital donates into the *a''* metal orbital. In addition, they proposed that significant back-bonding would occur from the lower metal *a'* orbital and the allyl, *a'*, π-antibonding orbital. The two former interactions were also reported from photoelectron spectroscopy studies by Green *et al.*, however, the latter was proposed to be primarily metal lone pair in character.[3]

We have recently reported the preparation of niobium carbide-containing thin films by metal organic chemical vapour deposition, using (allyl) bis(cyclopentadienyl)niobium compounds as single source precursors.[4] As part of this study we have undertaken an X-ray crystallographic structural determination of one of the precursor compounds, $(\eta^5\text{-}C_5H_4Me)_2Nb(\eta^3\text{-}C_3H_5)$ (**1**). The results of which are herein discussed with respect to the theoretical and spectroscopic studies noted above.

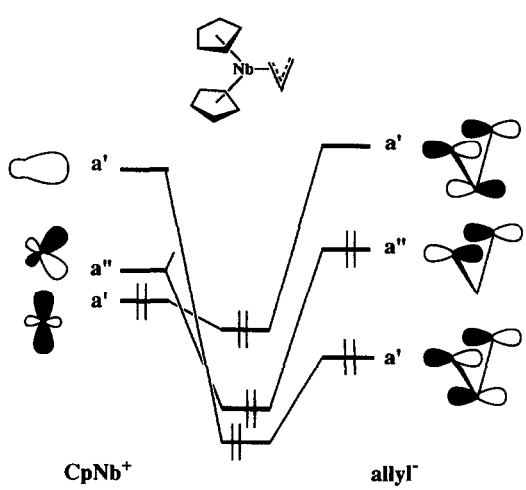

Fig. 1. Orbital interaction diagram for $(\eta^5\text{-}C_5H_5)_2M(\eta^3\text{-}C_3H_5)$.

RESULTS AND DISCUSSION

Treatment of $(\eta^5\text{-}C_5H_4Me)_2NbCl_2$ with two molar equivalents of allyl Grignard in diethyl ether affords the dark green compound $(\eta^5\text{-}C_5H_4Me)_2Nb(\eta^3\text{-}C_3H_5)$ (**1**). Compound **1** is air and moisture sensitive but may be stored under an inert atmosphere at −20°C. The ^1H and ^{13}C NMR spectra (see Experimental) of **1** are consistent with a symmetrically-bound allyl ligand. No exchange is observed between either the exo and endo protons of the allyl group, or the inequivalent methylcyclopentadienyl ligands, even at elevated temperatures (90°C). This indicates that the allyl ligand is non-fluxional.

The molecular structure of **1** has been determined by X-ray crystallography. The crystal structure of **1** consists of discrete molecules separated by van der Waals' contacts. A perspective view of an individual molecule of **1** is shown in Fig. 2, together with the atom numbering scheme. Pertinent bond lengths and bond angles are given in Table 1.

The structural features of **1** are typical of bent sandwich transition metal bis(η^5-cyclopentadienyl) complexes, i.e. the two planar C_5H_4Me groups bend back away from the coordinated η^3-allyl ligand. The angle between the centroids of the two methylcyclopentadienyl ligands [X1—Nb(1)—X2] (134.0°) is within experimental error of the narrow range observed for $(\eta^5\text{-}C_5H_5)_2NbX_2$ complexes [129.3(10)–133.2(3)],[5] but lower than that found for $(\eta^5\text{-}C_5H_5)_2NbH_3$ (141.6°).[1] The C—C distances within the aromatic rings are essentially equivalent, within experimental error, averaging 1.417(4) Å for C(12) to C(16), and 1.421(3) Å for C(22) to C(26). The Nb—C(C_5H_4Me) distances are not equivalent, ranging from 2.368(2) to 2.474(2) Å for C(12) to C(16) and from 2.310(2) to 2.491(3) Å for C(22) to C(26). Similar differences in Nb—C distances were noted for the bis(η^5-cyclopentadienyl)niobium complexes, $(C_5H_5)_2Nb(CS_2)(\eta^1\text{-}C_3H_5)$[5c] and $(C_5H_5)_2NbCl_2$,[5a] in which the Nb—C distances range from 2.37(2) to 2.50(2) Å and 2.33(4) to 2.44(3) Å, respectively.

The allyl ligand is nearly planar, with the C—C distances towards the long end of the range commonly observed for transition-metal allyl systems (1.35–1.45 Å),[6] consistent with the presence of σ-donation from the allyl π-orbital to the metal a'.

Since the allyl hydrogens were located and freely refined, the geometries around the allyl carbons may be readily defined. Whereas C(2) is close to trigonal planar, C(1) and C(2) are in distorted tetrahedral geometries. In addition, the plane of the allyl group is not perpendicular to the plane defined by Nb(2), C(1) and C(3), but is at an angle of 117.6°. These structural features are consistent with a strong bonding interaction betwen the allyl nonbonding orbital and the metal a'' orbital, but little or no back-bonding from the metal to allyl. The latter is therefore in accord with the results obtained from photoelectron spectroscopy[3] which indicates the presence of a metal-centred lone pair. The close structural similarity between **1** and $(\eta^5\text{-}C_5H_5)_2Ti(\eta^3\text{-}C_3H_3\text{-}1,2\text{-}Me_2)$[7] which have d^2 and d^1 metal centres, respectively, is also an indication that metal-to-ligand back donation is negligible.

EXPERIMENTAL

NMR (^1H, ^{13}C and ^{93}Nb) spectra, in C_6D_6, were recorded on Bruker AM-500 and WM-300 spectrometers [δ in parts per million relative to $SiMe_4$ (^1H, ^{13}C external) and $KNbCl_6$ in CH_3CN (^{93}Nb, external)]. The ^1H–^1H connectivity was established by a COSY NMR experiment. Spectra were collected using a standard pulse sequence[8] with a 45° mixing pulse, a 1 s relaxation delay, and a resolution of 4 Hz/pt. The FIDs were not weighted before Fourier transformation and the spectral matrix was symmetrized about the diagonal. The assignment of the methylcyclopentadienyl ligands relative to

the allyl ligand was determined by the observation of NOE enhancement of the signals of the methylcyclopentadienyl ligand closest to the proton attached to the central carbon of the allyl group. In a similar manner, the irradiation of the methyl resonances of the cyclopentadienyl ligands allowed for the assignment of the ring C—*H* resonances. The individual ^1H–^1H coupling constants were determined by the appropriate selective decoupling experiments. The ^{13}C resonances were assigned using a ^1H–^{13}C correlation experiment. Spectra were collected using a standard pulse sequence[9] with a 45° mixing pulse and a 2 s relaxation delay. The FIDs were weighted with a line broadening of 1 Hz prior to transformation. ^1H and ^{13}C NMR assignments are given relative to the atom numbering scheme in Fig. 2. Mass spectra were obtained using a Kratos MS-50L mass spectrometer and associated data system. EI spectra were recorded with an ionization energy of 70 eV at a scan rate of 3 s decade^{-1}. Samples were introduced into the instrument from a direct insertion probe. All manipulations were carried out under argon. Solvents were dried, distilled and degassed before use. The compound $(\eta^5\text{-}C_5H_4Me)_2NbCl_2$ was prepared by an improved modification of previous procedures[10] by the reduction of an ethereal suspension of $NbCl_5$ with ^{i}PrMgBr to give $NbCl_4$. Subsequent reaction with $Na(C_5H_4Me)$ in diethyl ether allowed the isolation of dark brown $(\eta^5\text{-}C_5H_4Me)_2NbCl_2$ in high yield (70–80%). Allyl Grignard, $(C_3H_5)MgBr$, was prepared by literature methods.[11]

$(\eta^5\text{-}C_5H_4Me)_2Nb(\eta^3\text{-}C_3H_5)$ (1)

$(C_3H_5)MgBr$ (23 cm^3, 1.15 M in diethyl ether, 26 mmol) was added dropwise to a stirred suspension of $(\eta^5\text{-}C_5H_4Me)_2NbCl_2$ (4.3 g, 13 mmol) in 100 cm^3 of diethyl ether. The dark green solution was stirred overnight and then the solvent was removed *in vacuo*. The solid was dissolved in 200 cm^3 of pentane, heated at reflux for 1 h, and filtered warm through a medium porosity frit. A green pentane solution was obtained and stored at −20°C under nitrogen. Dark green crystals precipitated upon cooling. Yield: 60–70%.

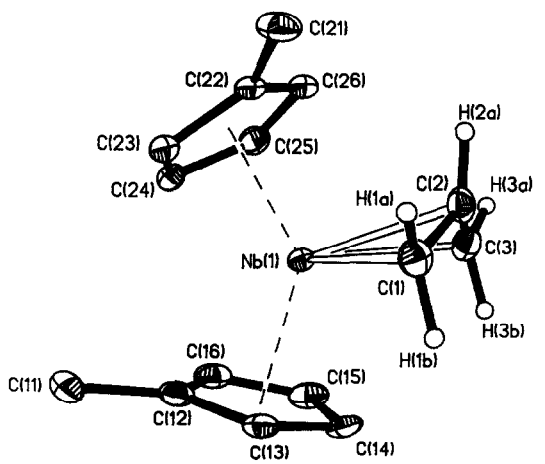

Fig. 2. X-ray crystal structure of **1** showing the numbering scheme. The hydrogen atoms on the methylcyclopentadienyl ligands are omitted for clarity.

INFLUENCE OF LACTAM RING SIZE ON METALLAMACROCYCLE RING TYPE; SYNTHESIS AND CRYSTAL STRUCTURE OF THE HETEROMETALLIC COMPLEX $[Hg_2Er(C_8H_{14}NO)_4(NO_3)_3]_n$

DAVID M. L. GOODGAME,* ARWA M. KHALED and DAVID J. WILLIAMS

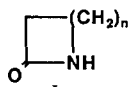
(*Received* 17 *October* 1990; *accepted* 5 *February* 1991)

Abstract—Reaction of 2-azacyclononanone (= LH) with mercury(II) acetate and erbium(III) nitrate in methanol yields the compound $[Hg_2ErL_4(NO_3)_3]_n$ (**1**), which has been characterized by X-ray diffraction. Each erbium atom is eight-coordinate and has two bidentate nitrates and two chelating HgL_2 units bonded to it. The remaining nitrate ion serves to link molecules of **1** to produce polymeric chains. The formation of the eight-membered mercury/erbium-containing rings results in a structure which is radically different from those previously found for the mercury/lanthanide complexes formed by the smaller ring lactams, 2-azacyclobutanone and 2-azacyclopentanone.

In previous work we have demonstrated the remarkable versatility of lactams of general formula **I** to produce polymeric mercury/metal hetero-



I

a; n = 1
b; n = 2
c; n = 6

metallic compounds containing large ring systems incorporating the metal atoms *within the ring framework*. Even with constant lactam ring size (e.g. 2-azacyclopentanone, 2-pyrrolidone, **Ib**) a wide diversity of metallamacrocycle ring sizes and structural types resulted from changes in the metal, M, employed.[1] Also, equally dramatic changes can be induced by reducing the size of the lactam ring to 2-azacyclobutanone[2](β-propiolactam, **Ia**) whilst keeping the metal unchanged. This has prompted us to explore lactams with larger rings, where the small, but potentially significant, changes in the coordination "bite" of the N—C—O lactam unit, coupled with the increased steric influences of the larger alicyclic rings, are likely to result in appreciable modifications to the polymeric structures adopted.

Although the use of larger ring lactams has not proved as amenable as **Ia** and **Ib** to the formation of heterometallic complexes of good crystalline quality—microcrystalline powders or even oils often result—the use of 2-azacyclononanone (**Ic**) has afforded good crystals of the complex $[Hg_2ErL_4(NO_3)_3]_n$ (**1**). X-ray structural studies on **1** show it to have a totally different structure from any of the heterometallic mercury/metal compounds formed by **Ia** or **Ib**.

EXPERIMENTAL

Preparation

Pale pink crystals of **1** separated over 3 days from a methanolic solution of mercury(II) acetate (0.16 g), hydrated erbium(III) nitrate (0.11 g) and **Ic** (0.14 g). Found: C, 28.9; H, 4.2; N, 7.3. Calc. for $C_{32}H_{56}ErHg_2N_7O_{13}$: C, 29.2; H, 4.3; N, 7.5%.

X-ray study

The crystal data are: $C_{32}H_{56}ErHg_2N_7O_{13}$, M_r = 1315.3, monoclinic, a = 12.385(2), b = 17.481(2), c = 19.853(2) Å, β = 106.10(1)°, V = 4130 Å^3, space group $P2_1/c$, Z = 4, D_c = 2.12 g cm^{-3}, Cu radiation, λ = 1.54178 Å, μ(Cu-K_α) = 183 cm^{-1},

* Author to whom correspondence should be addressed.

$F(000) = 2515$. Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans.

A crystal of dimensions $0.03 \times 0.17 \times 0.30$ mm was used. 5004 independent reflections ($2\theta \leqslant 116°$) were measured, of which 4152 had $|F_o| > 3\sigma(|F_o|)$ and were considered observed. The data were corrected for Lorentz and polarization factors; a numerical absorption correction (face-indexed crystal) was applied; maximum and minimum transmission factors, 0.617 and 0.115.

The structure was solved by the heavy atom method. The non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbon atoms. Refinement was by block-cascade full-matrix least-squares to $R = 0.038$, $R_w = 0.034$ [$w^{-1} = \sigma^2(F) + 0.00017F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 1.15 and -0.69 e Å^{-3}, respectively. The mean and maximum shift/error in the final refinement were 0.004 and 0.020, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[3] Selected bond lengths and angles are listed in Table 1.

RESULTS AND DISCUSSION

We observed previously[2,4] that the stoichiometries of the mercury/erbium complexes formed by **Ia** and **Ib** were both of the type $Hg_3Er_2L_6(NO_3)_6$ (where L = the anions of **Ia** and **Ib**), and no compounds of other stoichiometries were obtained on varying the mole ratios of the reactants. In the case of ligand **Ic**, use of the same synthetic method has given a complex of different stoichiometry: $Hg_2ErL_4(NO_3)_3$.

The X-ray analysis shows the erbium atom to be eight-coordinate, adopting a distorted dodecahedral geometry (Fig. 1). The distortion parameters[5] are ϕ_A 26.4°, ϕ_B 101.4° and MA/MB = 1.08. This arrangement may alternatively be visualized as the erbium atom being coordinated axially by two bidentate nitrate groups and equatorially by four oxygen atoms from **Ic** ligands, which, if one regards each nitrate as a single group, produces a distorted octahedral array (Fig.

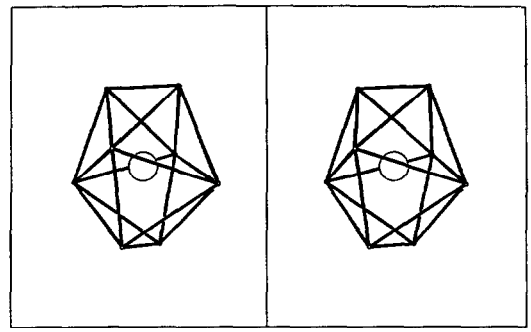


Fig. 1. Stereoscopic view of the dodecahedral arrangement of the oxygen atoms surrounding the erbium atom.

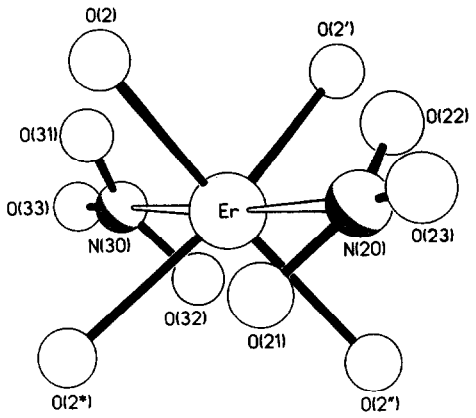

Fig. 2. Coordination geometry about the erbium atom.

2). The overall symmetry approximates to S_4 about the N(20)ErN(30) axis. The nitrate groups are arranged such that O(2), O(31), N(30), O(32) and O(2″) lie in one plane and O(2′), O(22), N(20), O(21) and O(2*) lie in another perpendicular to it. The Er—O bond lengths fall into two groups; those to nitrate oxygen atoms [range 2.413(7)–2.423(6) Å] being *ca* 0.2 Å longer than those to the carbonyl oxygen atoms [range 2.216(7)–2.250(6) Å].

Pairs of **Ic** ligands link via the deprotonated nitrogen atom to crystallographically independent mercury atoms in a nearly linear [Hg(1) 171.3(3)°, Hg(2) 169.8(3)°] arrangement. Each of these HgL_2 units binds to the erbium atom via the exocyclic oxygen atoms forming an eight-membered heterobimetallic ring (Fig. 3) in which only the erbium atom lies significantly out of the ring plane. (There are no significant out-of-plane distortions at any of the four amide nitrogen atoms.) The trans-annular Er...Hg distances are 3.78(1) and 3.83(1) Å to Hg(1) and Hg(2), respectively.

It is noticeable that in this complex the COEr angles are appreciably opened out from an idealized 120° and tend towards linearity (159, 160, 168 and 173°). The largest COM angle we have observed previously in related mercury metal lactam complexes was 156° [for $Hg_2Th(C_4H_6NO)_4(NO_3)_4$],[6] and, in general, the average value lies in the range 135–140°.

Despite the conformational flexibility of the 2-azacyclononanone ring, three of the four have virtually identical conformations (Table 2). Rings B and D (Fig. 3) are the same, C is enantiomeric, but ring A adopts a totally different geometry. A comparison of the conformations of rings A and B, using the amide groups on each ring as a common basis, is shown in Fig. 4.

Compound **1** differs from the related mercury/erbium complexes formed by **Ia** and **Ib** in that only two of the three nitrate anions are bonded to the erbium atom. The remaining nitrate ion does, however, play a key role in the formation of an overall polymeric structure (Fig. 5). It links Hg(1) in one molecular unit to Hg(2) in the next. This is achieved by O(12) binding to both Hg(1) and Hg(2)

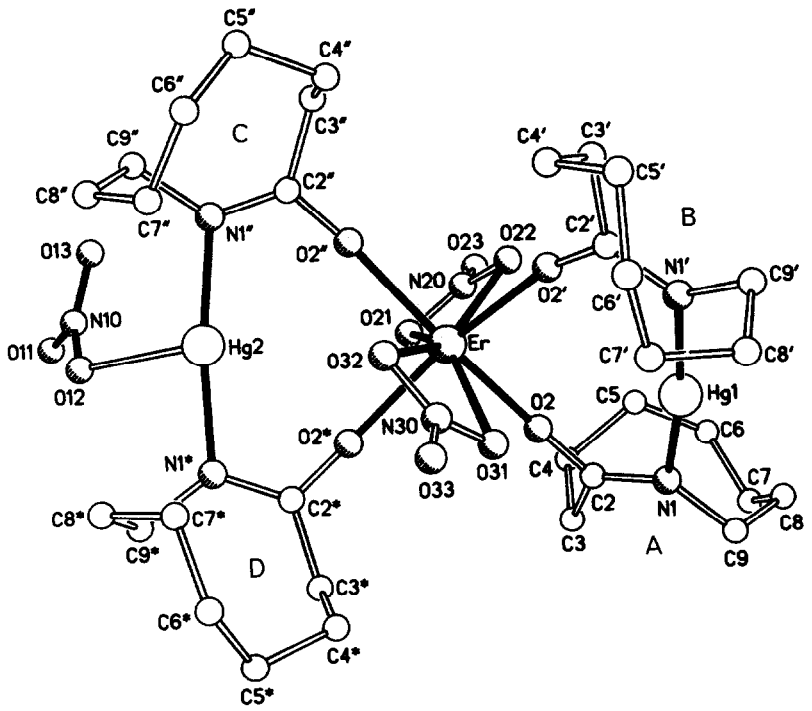

Fig. 3. Perspective view of each $[Hg_2Er(C_8H_{14}NO)_4(NO_3)_3]$ unit, giving the atom numbering.

Table 2. Torsion angles (°)[a] for the 2-azacyclononanone rings in **1**[b]

	A	B	C[c]	D

C(5)—C(6)—C(7)—C(8)	−59	64	57	61
C(6)—C(7)—C(8)—C(9)	98	−76	−70	−79
C(7)—C(8)—C(9)—N(1)	−81	−54	−50	−50

[a] Average ESD *ca* 1°.
[b] Rings A–D are identified in Fig. 3.
[c] Enantiomer of C.

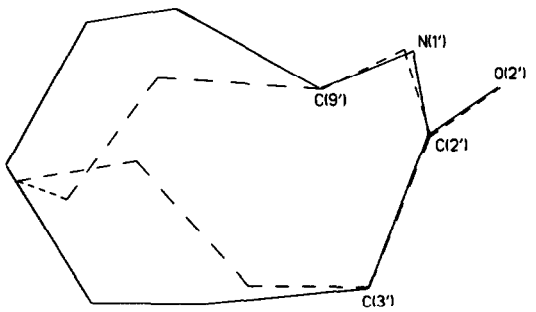

Fig. 4. A comparison of the conformations of rings A and B. Ring A is depicted by broken lines.

[Hg(1)—O(12) 2.75(1) and Hg(2)—O(12) 2.62(1) Å; Hg(1)...Hg(2) 4.5 Å]; O(11) binds to just a single mercury atom, Hg(1) [Hg(1)—O(11) 2.75(1) Å]. In both cases the approach of the nitrate oxygen atoms is virtually orthogonal to the N—Hg—N directions. For Hg(1) the O—Hg—N angles are in the range 91–96° and for Hg(2) they are in the range 84–106°. The direction of the polymer chain is along the crystallographic *b* direction—the chain being made up of screw-related molecules.

Despite the bulk of the alkane rings, the crystal packing is very efficient, with adjacent, centrosymmetrically related polymer chains inter-

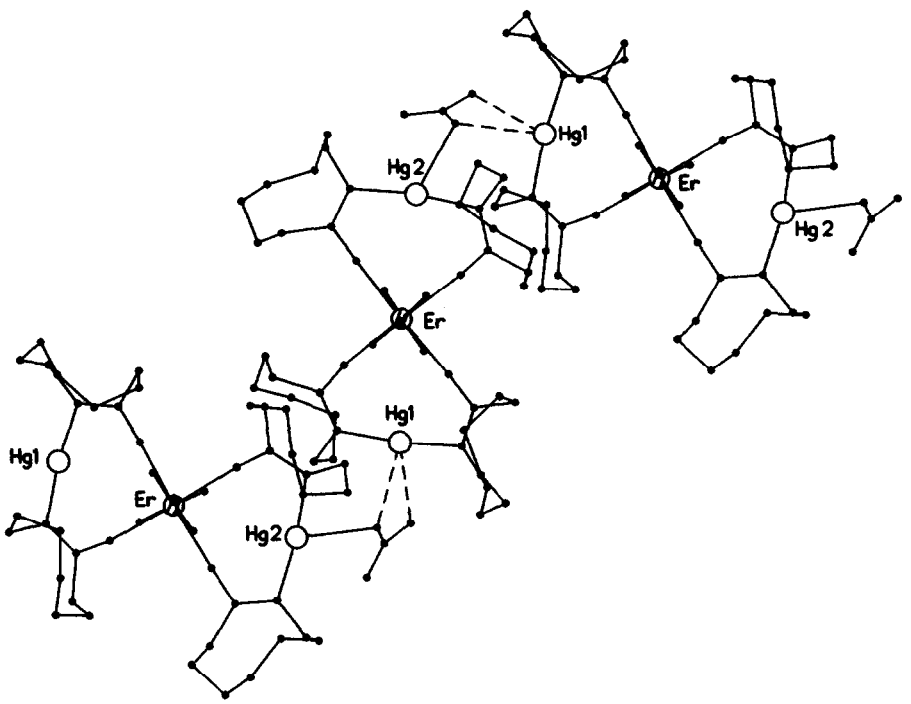

Fig. 5. Part of one of the nitrate-linked polymeric chains of **1**.

leaving with each other. The packing gives rise to short, non-bonded CH...O(NO_3) contacts, e.g. C(3)...O(11) 3.09, C(3″)...O(13) 3.24 Å; in this latter case the H(3A″)...O(13) distance is 2.40 Å and the C—H...O angle, 146°.

It is interesting that the use of the larger ring lactam, **Ic**, produces a structure in which, for the first time for a mercury/lanthanide ion combination, the minimum size (eight-membered) metallamacrocycle is formed. This is in striking contrast to the very large macrocycles (up to 80-membered[1]) previously encountered. The only other eight-membered rings we have found are in the homobimetallic mercury/mercury complex $[Hg_2(C_4H_6NO)_2Cl_2]_n$[1] and the mercury/silver complex $[HgAg(C_4H_6NO)_2(NO_3)]_2$[7] formed by 2-pyrrolidone; in the latter of those two compounds one of the oxygen atoms of the chelating 2-pyrrolidone additionally serves as a bridge between pairs of silver atoms.

(*Received* 23 *October* 1990; *accepted* 5 *February* 1991)

Abstract—The crystal structure of $IPh_2SnCH_2CH_2CO_2Me$: $C_{16}H_{17}IO_2Sn$ (**10**; X = I) has been determined; the tin atom adopts a distorted trigonal bipyramidal geometry, with iodine and the internal carbonyl oxygen in axial sites. The chelated structure of **10** (X = I) [ν(CO) 1684 cm^{-1}] persists in such solvents as dichloromethane, chloroform, tetrahydrofuran and acetonitrile. Pyridine is able to compete with the intramolecular ester coordination in CH_2Cl_2 solution with the formation of unchelated $IPh_2Sn(py)CH_2CH_2CO_2Me$ (**11**) [ν(CO) 1734 cm^{-1}]; the formation constant of **11** is 0.07 ± 0.01 1 mol^{-1} at 25°C.

Ester groups are generally weak donors towards organotin acceptors. However, when sited intramolecularly, for example as in $Cl_2Sn(CH_2CH_2CO_2Me)_2$ (**1**),[1] $Cl_3SnCH_2CH_2CO_2R$ (**2**), (R = Me;[1] R = Pr^i [2]) and $Cl_3SnCH_2CH_2CH_2CO_2Et$ (**3**),[3] they are able to complex strongly to tin centres.[4] Crystal structure determinations[1–3] and spectral data[4–6] for **1–3** and related compounds show that $RO_2C(CH_2)_n$ groups do act as chelating ligands in the solid state. Similar conclusions are obtained in non-coordinating solvents.[2,3] However in coordinating solvents such as MeCN[2,3] or in the presence of nitrogen donors, e.g. pyridine or 2,2′-bipyridine, the coordination by the ester groups, e.g. in **2** and **3**, can be broken.[2,3] From comparison of stability constants, the five-membered chelate ring in **2** is found to be stronger than the six-membered ring in **3**.

The chelating abilities of $RO_2CCH_2CH_2$ and other groups (Me_2NCS_2 and 8-quinolinato) have been compared in appropriate compounds, e.g. $[MeO_2CCH_2CH_2SnCl_{3-n}(S_2CNMe_2)_n]$ (**4**; n = 1–3),[7,8] $[(MeO_2CCH_2CH_2)_2Sn(S_2CNMe_2)_2]$ (**5**)[9] and $[(MeO_2CCH_2CH_2)_2SnCl(8\text{-quinolinate})]$ (**6**):[10] structural studies indicate that the $MeO_2CCH_2CH_2$ group has the weakest chelating ability of these three groups. The sulphido compounds, $[(MeO_2CCH_2CH_2)_2SnS]_3$ (**7**)[11] and $[MeO_2CCH_2CH_2Sn(S)(S_2CNMe_2)]_3$ (**8**),[11] in the solid state, both

* Author to whom correspondence should be addressed.

contain monodentate $RO_2CCH_2CH_2$ units as does $[(RO_2CCH_2CH_2)(Me_2NCS_2)Sn(XCH_2CH_2)_2Y]$ (**9** R = Me, X = S, Y = O; R = Et, X = O, Y = NMe).[12]

The Lewis acidity of organotin halides generally decreases in the sequence: $RSnX_3 > R_2SnX_2 > R_3SnX$. Thus it is anticipated that the tin atom in $XPh_2SnCH_2CH_2CO_2Me$ (**10**) would be a poorer acceptor centre than that in $X_3SnCH_2CH_2CO_2Me$ (X = halide) towards both the internal ester group and external donors. In order to investigate the coordination chemistry of **10**, we have determined the crystal structure of **10** (X = I) and have studied its coordination by donor molecules. We now wish to report our results.

EXPERIMENTAL

The compound $Ph_3SnCH_2CH_2CO_2Me$ (**11**) was prepared from Ph_3SnH and $CH_2{=}CHCO_2Me$ by a published procedure.[13] The reaction of **11** (4.37 g 0.01 mol) and I_2 (2.54 g, 0.01 mol) in CCl_4 (50 ml) gave $IPh_2SnCH_2CH_2CO_2Me$. The reaction residue, after removal of all volatiles, was recrystallized from EtOH to give a solid; melting point 77°C (ref. 13, 76°C). Found: C, 39.3; H, 3.5; I, 26.2. Calc. for $C_{16}H_{17}IO_2Sn$: C, 39.5, H, 3.5; I, 26.1%. ^{119}Sn NMR ($CDCl_3$, 33.35 MHz): δ −92.07 ppm (relative to Me_4Sn).

$Cl_3SnCH_2CH_2CO_2Me$ was a recrystallized sample from a previous study.[6]

Solvents and donor molecules

MeCN was purified by a standard procedure;[14] CH_2Cl_2 and THF were dried over CaH_2 and distilled prior to use. Donor molecules were either redistilled or recrystallized prior to use.

The compound $Cl_2Pt(COD)$ (COD = 1,5-cyclooctadiene) was obtained by a literature procedure.[15]

Formation constants

These were determined from IR data, from the carbonyl region, at 25 ± 1°C in CH_2Cl_2 solution as previously described.[6]

Reaction between **11** *and* $Cl_2Pt(COD)$

Solutions of **11** (0.0437 g, 1 mmol) and $Cl_2Pt(COD)$ (0.0374 g, 1 mmol) in CD_2Cl_2 (total volume 1 cm^3) were mixed and the reaction monitored by ^1H NMR spectroscopy (220 MHz) at 30°C. The successive formations of $ClPh_2SnCH_2CH_2CO_2Me$ and $Cl_2PhSnCH_2CH_2CO_2Me$ were indicated (see Table 1 for ^1H NMR details).

The platinum products—ClPhPt(COD) and $Ph_2Pt(COD)$—were also detected by NMR.

ClPhPt(COD). δ ^1H 2.46 (m, 8H, CH_2), 4.55 (t, 2H, $J^{119}Pt$–^1H 75 Hz, CH), 5.70 (t, 2H, 34 Hz, CH), 6.7–7.4 (m, 5H, phenyl).

$Ph_2Pt(COD)$. δ^1H 2.5 (m, 8H, CH_2), 5.02 (t, 4H, $J^{119}Pt$–^1H, 40 Hz, CH), 6.6–7.5 (m, 10H, phenyl).

Crystal structure determination

Crystal data. $C_{16}H_{17}IO_2Sn$, $M = 486.91$, monoclinic, space group $P2_{1/n}$, $a = 10.073(8)$, $b = 17.721(14)$, $c = 10.427(10)$ Å, $\beta = 112.11(7)°$, $V = 1725(2)$ Å^3, $Z = 4$, $D_c = 1.875$ g cm^{-3}, $D_m = 1.88$ g cm^{-3}, $F(000) = 928$, μ(Mo-K_α) = 3.26 mm^{-1}, $\lambda = 0.71069$ Å, T = room temperature.

Table 1. ^1H NMR spectra (220 MHz) for $Ph_nX_{3-n}SnCH_2CH_2CO_2Me$ in CD_2Cl_2 $\delta(J^{119}Sn$–^1H Hz)

[a] Triplet $J_{H,H}$ 8 Hz.
[b] Multiplets.

Data collection and processing. Colourless crystal, $0.31 \times 0.14 \times 0.25$ mm. The cell dimensions were obtained from setting angles of 14 independent reflections with $2\theta \approx 20°$ on a Nicolet P3 4-circle diffractometer using monochromatic Mo-K_α radiation. 3059 unique intensities were measured with $\theta \leqslant 25°$ as $\theta/2\theta$ scans; 1958 reflections had $F > 5\sigma(F)$. Range of $h\ k\ l$: $0 \leqslant h \leqslant 11$; $0 \leqslant k \leqslant 21$; $-11 \leqslant l \leqslant 11$.

The data were corrected for Lorentz and polarization effects but absorption was ignored. Two reference reflections, monitored periodically, showed no significant variation in intensity.

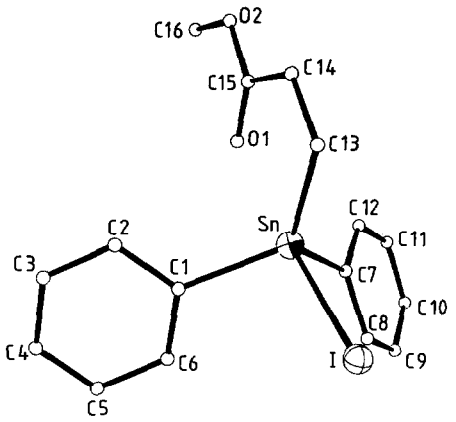

Fig. 1. Molecular structure of **10** (X = I).

Structure analysis and refinement

The structure was determined by the heavy-atom method (Patterson function), which revealed the approximate positions of the tin and iodine atoms. The remaining non-hydrogen atoms were located from successive Fourier difference maps using SHELX 76.[16] The hydrogen atoms were placed in calculated positions and refined relative to their bonded carbons. Full-matrix least squares calculations on F with unit weights and anisotropic thermal parameters for all non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms converged at $R = 0.052$. Atomic scattering factors for carbon, hydrogen, oxygen and tin were taken[16] from SHELX 76. Data for iodine was taken from the *International Tables for X-ray Crystallography*.[17] Final $\Delta\rho_{max} = +0.76$ eÅ^{-3}, $\Delta\rho_{min} = -0.66$ eÅ^{-3}. Molecular geometries were generated by the GX package.[18]

RESULTS AND DISCUSSION

Compound **10** (X = I) was obtained by the reaction of **11** with I_2; this cleavage reaction occurs particularly readily, due to the nucleophilic assistance afforded by the ester group in the rate-determining step. Other reactions of **11** with electrophilic reagents are facile, e.g. even the weakly electrophilic, Me_3SiX, is able to cleave a Ph—Sn bond[19] in **11** to give **10** (X = Cl, Br or I); $Cl_2Pt(COD)$ can cause cleavage of two Ph—Sn bonds to give successively **10** (X = Cl) and $Cl_2PhSnCH_2CH_2CO_2Me$, as shown in this study. ^{1}H NMR spectral data for $Ph_nX_{3-n}SnCH_2CH_2CO_2Me$ compounds are given in Table 1.

Crystal structure of **10** (X = I)

The atomic arrangements are shown in Fig. 1. Bond lengths are given in Table 2 and bond angles in Table 3. Compound **10** (X = I) exists as discrete molecules, containing five-membered chelate rings.

The geometry about tin is that of a distorted trigonal bipyramid, the axial atoms being I [Sn—I 2.811(2) Å] and the carbonyl oxygen [Sn—O 2.55(2) Å] with the valence angle, I—Sn—O, equal to 170.5(3)°. The three carbon units are in equatorial sites [Sn—C = 2.10(2)–2.16(2) Å]: the sum of the C—Sn—C valence angles is 353.8°.

Intramolecular Sn—O distances in other $RO_2(CH_2)_n$—Sn compounds are given in Table 4. It can be seen in Table 3 that the Sn—O distance in **10** (X = I) is comparable with those in **1** (Sn—O 2.52), but is appreciably greater than in **2** [Sn—O 2.337(5)–2.357(5) Å]. The sum of the covalent radii of tin and oxygen is 2.13 Å, while the sum of the van der Waals' radii is 3.70 Å. The Sn—I bond distance is relatively long, cf. the value of 2.764(2) Å in the five-coordinate tin compound,[20] 3-*C*-(IBu_2SnCH_2)-1,2 : 5,6-di-*O*-isopropylidene-α-D-allofuranose, in which the intramolecular Sn—O distance is 2.68(2) Å. Sn—I bond lengths in a number of tetrahedral tin compounds range[21] from 2.69(3) to 2.729(3) Å.

Solution study

Compound **10** (X = I) remains completely chelated in chlorocarbon solvents (CH_2Cl_2 and CCl_4) [ν(CO) 1684 cm^{-1}] as well as in MeCN and THF solutions: the values of ν(CO) for **10** (X = I) in a KBr disc is 1670 cm^{-1}, while ν(CO) for $Ph_3SnCH_2CH_2CO_2Me$ in KBr is 1740 cm^{-1}. Similar findings are obtained for **10** (X = Cl). As can be seen from the ^{1}H NMR spectral data given in Table 1, complexation of the MeO_2C group to tin [in $Ph_nX_{3-n}SnCH_2CH_2CO_2Me$ ($n = 0$, 1 or 2)] results in shifts for δMe and in β-CH_2, from values in $Ph_3SnCH_2CH_2CO_2Me$.

C(6)—C(1)	1.37(3)	C(7)—C(8)	1.39(3)

In CH_2Cl_2 solution, pyridine is able to compete with the intramolecular ester coordination in **10** (X = I) and equilibrium (1) is set up. The value of the formation constant, K_1, at 25°C was calculated to be 0.07 ± 0.01 dm^3 mol^{-1}. Only one pyridine molecule is able to coordinate to **10**. The value of K_1 indicates the difficulty of opening the chelate ring; even in pyridine as solvent, only *ca* 40% has the open structure. One molar equivalents of such donors as 2,2′-bipyridine, acridine and Ph_3P, had no impact on the spectrum of **10** (X = I) in CH_2Cl_2 solution.

ν(CO) 1684 cm^{-1} ν(CO) 1734 cm^{-1}

$K_1 = [(\mathbf{12})] / [(\mathbf{10}, X = I)][py]$

The compound $Cl_3SnCH_2CH_2CO_2Me$ has been previously shown to take part in equilibria with pyridine in CH_2Cl_2 solution (Scheme 1).[6] With $Cl_3SnCH_2CH_2CO_2Me$ **2** (R = Me), both one and two molecules of pyridine could be coordinated; however only on coordination of the second molecule of pyridine is the chelate ring broken.

From comparison of values of K_1 and K_3, it can be seen that the chelate ring in **10** (X = I) is considerably more resistant to opening than in **13**; in other words, the intramolecular ester coordination in **10** (X = I) is surprisingly stronger than that in **13**. The relative strengths of the chelate rings in **10** (X = I) and **2** are also borne out by the effects of MeCN on the opening of the chelates.

Formation constants for 1 : 1 R_3SnCl–py complexes have also been reported:[22,23] values obtained are 1.9 dm^3 mol^{-1} for R = Me in CCl_4 at 27°C (and also in C_6H_6 at 30°C) and 1.1 dm^3 mol^{-1} for R = Ph

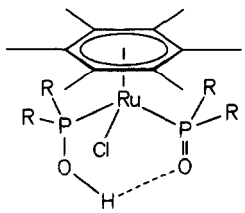
Abstract—The X-ray crystal structure of the heterotrinuclear compound $[Cu\{ClRu[(MeO)_2PO]_2(C_6Me_6)\}_2]\cdot 2CH_2Cl_2$ is described, together with its spectroscopic and electrochemical properties. The copper ion is tetragonally coordinated by four, short copper–oxygen bonds [Cu—O = 1.931(4) and 1.965(4) Å] and two, long Cu—Cl bonds of 2.881(2) Å. The chloride ions bridge directly between the copper and ruthenium, with Ru—Cl = 2.292(2) Å and Ru—Cl—Cu = 93.6(1)°. The other bridging ligands are the $OP(OMe)_2^-$ ligands, which coordinate to copper with oxygen and to ruthenium with phosphorus. The ruthenium coordination is completed by the η^6-C_6Me_6 ligand. The structure of the complex is retained in solutions of CH_2Cl_2 and CH_3CN. Electrochemical studies (CV and DPP) show that both ruthenium(II) ions can be oxidized subsequently at, respectively, 0.69 and 0.87 V. The copper(II) ion is not redox active. The compound has been further characterized by ligand-field spectra and EPR spectra for copper(II). These spectra agree with a tetragonal chromophore CuO_4Cl_2, both for the solid and the (frozen) solution.

Heteronuclear coordination compounds have gained much interest during the last decade,[1] both as synthetic analogues for metalloproteins and as catalytic centres. In the preparation of such heteronuclear species, an asymmetric bridging ligand usually plays a key role.

The coordination chemistry of mono-anionic tridentate ligands is mainly that of the N,N,N-ligands tris(pyrazolyl)borate, $[RB(pz)_3]^-$,[2] and of the O,O,O-ligands $[(C_5H_5)Co\{P(O)R_2\}_3]^-$.[3] Both are 6e-ligands that almost always act as facially coordinating tris-chelating ligands and they are in that respect formally equivalent to the cyclopentadienyl ligands $C_5R_5^-$. The tris(pyrazolyl)borate ligands have a well-developed organometallic chemistry and despite the fact that the O,O,O-ligands $[(C_5H_5)Co\{P(O)R_2\}_3]^-$ are similar to fluoride and oxide[4] (they have electronic properties distinctly different from those of the cyclopentadienyl ligands), they form low-valent transition metal carbonyl complexes as well. Many of them are surprisingly inert. Often they are too unreactive to be valuable catalyst components. In order to control the reactivity of such complexes we designed O,O,X-ligands, where X is a donor centre that coordinates less strongly to metal ions than the P=O oxygen donor centres. Complexes of the type [(ring) metal$\{P(O)R_2\}_2X]^-$ are only useful as the O,O,X-ligands when they themselvers are inert building blocks.



R = OMe

Fig. 1. Schematic drawing of the ligand $L^- = [(C_6Me_6)Ru\{P(O)(OMe)_2\}_2Cl]^-$.

To achieve this we have looked for substitutionally robust d^6 low-spin metal ions protected by a large ring to gain additional inertness. Of the many systems that we have tried, the complexes $[(C_5Me_5)M\{P(O)(OMe)_2\}_2X]^-$ (M = Co, Rh; X = Cl)[5] and $[(C_6Me_6)Ru\{P(O)(OMe)_2\}_2Cl]^-$ (in the following abbreviated as L^-) turned out to be useful as ligands. We have now developed an elegant synthesis of $HL = [(C_6Me_6)Ru\{P(O)(OMe)_2\}\{P(OH)(OMe)_2\}Cl]$, the hydronated form of this O,O,Cl-ligand[6] (see Fig. 1).

In the case of coordination towards copper(II), the ligand has produced a compound[7] analysing as $[Cu\{ClRu[(MeO)_2PO]_2(C_6Me_6)\}_2]$. Preliminary ligand-field spectral data showed a ligand-field maximum at 740 nm, suggesting at least some coordination of the chloride ligand to copper(II) and certainly no CuO_4 chromophore. To find out the details of the structure, a crystal structure determination was performed and solution data were obtained (EPR and electrochemistry).

In this paper we describe the first crystal structure of a compound containing this ligand, thereby forming a heterotrinuclear complex, which proves unequivocally that it can act as a tris-chelating ligand.

EXPERIMENTAL

Starting materials and synthesis

The title compound was synthesized as described before.[6,7] Recrystallization from CH_2Cl_2 provided crystals suitable for diffraction studies.

Physical measurements and analyses

Ligand-field spectra were recorded in the diffuse reflectance mode. Spectra were measured on a Perkin–Elmer 330 instrument equipped with a data station (33,000–5000 cm^{-1}) fitted with a reflectance attachment using MgO as reference material.

IR spectra from 4000 to 200 cm^{-1} were recorded as KBr pellets on a Perkin–Elmer 580 spectrometer. EPR powder spectra were recorded on a Varian E3 instrument (X-band frequencies) using standard conditions. Frozen solution and solution spectra were obtained in CH_2Cl_2 on the same instrument.

Cyclic voltammograms and differential pulse polarograms were obtained in CH_3CN/CH_2Cl_2 solutions, with 0.1 M tetrabutylammonium perchlorate (TBAP) as the electrolyte. The experiments were performed on a EG&G PAR C Model 303 polarograph with an EG&G 384B polarographic analyser. A glassy-carbon electrode was used as working electrode, a platinum wire was used as auxiliary electrode and a saturated calomel electrode (SCE) as reference electrode. The scan rate for the differential pulse polarograms (DPP) was 4 mV s^{-1} and for the cyclic voltammograms (CV) 100 mV s^{-1}.

X-ray structural determination of $[Cu\{ClRu[(MeO)_2PO]_2(C_6Me_6)\}_2]\cdot 2CH_2Cl_2$

A rod-shaped single crystal of $[Cu\{ClRu[(MeO)_2PO]_2(C_6Me_6)\}_2]\cdot 2CH_2Cl_2$ of $0.40\times 0.30\times 0.20$ mm^3 was obtained through slow evaporation of a solution in CH_2Cl_2. Data collection was carried out by an ω–2θ scan on an Enraf–Nonius CAD-4 diffractometer with use of graphite monochromatized MoK_α radiation (λ = 0.71073 Å). Unit-cell parameters and final orientation matrices were determined by least-squares refinement of 25 reflections with $4.93 < \theta < 21.90°$. Details of scan rate and background estimation have been described elsewhere.[8] Standard reflections measured every 5400 s showed no significant changes in intensity. Of the 4717 reflections measured, 4515 were independent of which 3746 were significant [with $I > 2\sigma(I)$]. Intensity data were corrected for Lorentz and polarization effects. No correction for absorption was applied.

Positions of the metal atoms did not follow unequivocally from a three-dimensional Patterson synthesis. The other non-hydrogen positions within the molecule were determined with use of the program MULTAN.[9] Standard refinement revealed the positions of the other non-hydrogen atoms and were refined anisotropically, except for the non-hydrogen atoms of the methylene chloride. Due to the disorder of the methylene chloride the non-hydrogen atoms C(7), Cl(2) and Cl(3) were refined at four positions with 40, 20, 20 and 20% occupancy, and with temperature factors of 5 $Å^2$. Waser constraints were applied for C(7)—Cl(2) [= 1.81(3) Å] and the angle Cl(2)—C(7)—Cl(3) [109(3)°]. Due to the quality of the dataset and the disorder mentioned above, no hydrogen atoms

could be located. Further full-matrix least-squares refinements, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = [\sigma^2(F)]^{-1}$ was terminated when the maximum shift/error was < 0.3. Atomic scattering factors were taken from literature tabulations.[10] Other details of data collection and structure refinement are given in Table 1. Atomic coordinates, anisotropic thermal parameters, less important geometric information and tables of F_o and F_c are given in the supplementary tables.

RESULTS AND DISCUSSION

Structure description

An ORTEP plot of the trinuclear complex is presented in Fig. 2. The cell contains two molecules of CH_2Cl_2 per Ru_2Cu unit. Unfortunately these are rotationally disordered, but could be refined with a few more positions; these have been omitted for clarity. A list of bonding distances is given in Table 2 and relevant bond angle information is given in Table 3.

The centrosymmetric structure consists of a copper ion which is tetragonally coordinated by four, short oxygen contacts [Cu—O = 1.931(4) and 1.965(4) Å] and two, long Cu—Cl contacts of 2.881(2) Å. The chloride ions bridge directly between the copper and ruthenium, with Ru—Cl = 2.292(2) Å and Ru—Cl—Cu = 93.6(1)°. The other bridging ligands are the $OP(OMe)_2^-$

* Related by centre of symmetry.

ligands, which coordinate to copper with oxygen and to ruthenium with phosphorus [Ru—P = 2.263(2) and 2.274(2) Å]. The ruthenium coordination is completed by the η^6-C_6Me_6 ligand, with Ru—C contacts varying from 2.221(6) to 2.307(7) Å. The copper–oxygen distances are significantly shorter than those found in the related $[\{CpCo[P(O)(OEt)_2]_3\}_2Cu]$, where Cu—O contacts of 2.03–2.05 Å (equatorial) and 2.13–2.15 Å (axial) were found.[11] Apparently, the weaker chloride ligands allow the Cu—O contacts to be shorter in the present compound. The molecules $[CuL_2]$ and solvent molecules appear to be packed in the lattice by normal van der Waals' contacts and no unusual phenomena were observed.

Spectral, electrochemical and analytical data

Ligand-field spectral data of the solid compound show a broad doublet with maxima at 13,800 and 10,900 cm^{-1}. According to literature data[12] this band agrees with an elongated, tetragonal chromophore CuO_4Cl_2. In addition, a broad and strong band is observed with a maximum at 26,250 cm^{-1} and a tail into the visible range. This absorption is a MLCT band of the ruthenium centre and causes the light yellow colour of the ligand, L^-, and its metal complexes.

Powder EPR spectra at 300 and 77 K show an axial spectrum, typical for elongated tetragonal symmetry,[12] with parameters $g_\parallel = 2.41(1)$,

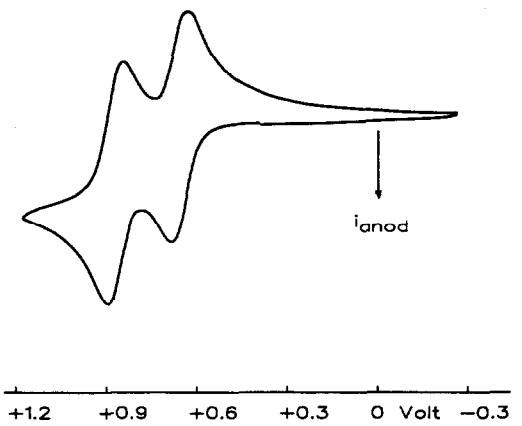

Fig. 3. Cyclic voltammogram of [CuL$_2$] recorded in CH$_2$Cl$_2$; supporting electrolyte NBu$_4$PF$_6$, 50 mV s^{-1}.

$g_\perp = 2.07$ and $A_\parallel = 120(5)$ gauss. The parameters at 77 K have a slightly smaller value for $g_\parallel$ and a slightly larger value for $A_\parallel$, indicative of a somewhat larger degree of tetragonality.[12] A frozen solution in CH$_2$Cl$_2$ shows a spectrum with identical spectral parameters (within experimental error).

Due to the poor solubility of the title complex in CH$_3$CN, electrochemical measurements were performed in a mixture of CH$_3$CN and CH$_2$Cl$_2$ and also in pure CH$_2$Cl$_2$. The cyclic voltammogram exhibits two quasi-reversible oxidation waves at 0.65 V (peak-to-peak separation 70 mV) and 0.86 V (peak-to-peak separation 60 mV) vs SCE, with an approximate intensity ratio of 1:1. Also the differential pulse polarogram reveals the presence of two oxidation processes at 0.69 and 0.90 V, again with an appropriate intensity ratio of 1 : 1 (see Fig. 3). In CH$_3$CN as solvent the ratio deviates from 1 : 1.

The two redox processes of [CuL$_2$] at 0.65 and 0.86 V are tentatively assigned as both being $Ru^{II} \rightarrow Ru^{III}$, with the second oxidation being more difficult as a consequence of the higher charge.[13] To verify the assumption that the copper(II) ion is not redox active in this system, we have measured the cyclic voltammograms of comparable compounds. In [MgL$_2$], two redox processes occur at +0.67 and *ca* 0.83 V (vs SCE). At 0.92 V a further, but only quasi-reversible, oxidation was observed. Furthermore, we have measured the cyclic voltamograms of NaL, [LH$_2$]PF$_6$ and [{(C$_6$Me$_6$)RuCl$_2$}$_2$]. NaL is reversibly oxidized at 0.72 V (peak-to-peak separation 115 mV, 20 mV s^{-1}). [LH$_2$]PF$_6$ is reversibly oxidized at 0.92 V (peak-to-peak separation 80 mV, 100 mV s^{-1}). [{(C$_6$Me$_6$)RuCl$_2$}$_2$] can be oxidized in the presence of extra chloride to give [(C$_6$Me$_6$)RuCl$_3$] at 0.82 V (peak-to-peak separation 80 mV, 200 mV s^{-1}). Thus we can be fairly certain that the redox reactions of [CuL$_2$] are ruthenium centred, without the involvement of copper(II).

The differential pulse polarogram did not reveal the presence of a reversible reduction wave down to −1.5 V. Scanning at more negative potentials leads to decomposition (and deposition) of the compound at the electrodes.

Conclusions

In the present paper the crystal structure and electrochemistry of the copper(II) complex [CuL$_2$] have been described. The results show that L$^-$ (= [(C$_6$Me$_6$)Ru{P(O)(OMe)$_2$}$_2$Cl]$^-$) can indeed act as a tris-chelating agent with an O,O,Cl-donor set; however, the two Cu—Cl bond lengths are quite long. The ligand-field spectrum and the EPR data are in agreement with a very weak ligand field for copper(II). The ruthenium(II) ion in ligand L$^-$ can be oxidized to ruthenium(III). It will be interesting to study how the coordination chemistry and spectroscopic properties of L$^-$ are influenced by the oxidation state of the central metal ion.

A CONVENIENT ROUTE TO LEAD(II) ALKOXIDES

R. C. MEHROTRA,* A. K. RAI and A. JAIN

Chemical Laboratories, University of Rajasthan, Jaipur 302 004, India

(*Received* 14 *November* 1990; *accepted* 18 *February* 1991)

Abstract—A convenient route for synthesis of lead(II) isopropoxide (**I**) by interaction (1 : 2 molar ratio) of PbF_2 with $KOPr^i$ is described. Other alkoxy derivatives can be synthesized by alcoholysis and trans-esterification of **I**.

Following a few earlier publications on bis-aryloxide[1] and oxide–alkoxides,[2,3] there has been a recent spurt of interest in the chemistry of lead(II) alkoxides in view of their potential applications for lead based superconductors,[4,5] as evinced by the synthesis:[6]

$$Pb[N(SiMe_3)_2]+2ROH \longrightarrow 1/n[Pb(OR)_2]_n+2HN(SiMe_3)_2$$

(with R = $HCMe_2$, CMe_3, CMe_2Et, H_2CCH_2OMe, $HCMeCH_2NMe_2$), and structural studies on $[Pb(OBu^t)_2]_3$[6,7] and $[Pb(OCH_2CH_2OMe)_2]_n$.[6]

In view of the above, we now report our work on the quantitative synthesis of $Pb(OPr^i)_2$ by the reaction between anhydrous PbF_2 (freshly prepared from $Pb(NO_3)_2 \cdot nH_2O$ and Na_2F_2 in aqueous medium) and 2 mol of $KOPr^i$ (prepared *in situ* by the interaction of K with Pr^iOH):

$$PbF_2+2KOPr^i \xrightarrow{\text{Benzene}} Pb(OPr^i)_2+2KF\downarrow. \quad \textbf{(I)}$$

Compound **I** is a pale yellow solid, soluble in benzene in which it shows (ebullioscopically) a degree of association between 3.5–4.7, but it tends to polymerize on standing overnight into a deeper yellow solid which becomes sparingly soluble in organic solvents. It forms a mono-adduct with THF, $Pb(OPr^i)_2 \cdot THF$, but not with C_5H_5N.

The freshly prepared $Pb(OPr^i)_2$ is highly reactive and undergoes alcoholysis with some alcohols to yield the corresponding soluble alkoxides, which do not tend to show a similar ageing phenomenon:

$$Pr(OPr^i)_2+nROH \xrightarrow{\text{Benzene}} Pb(OPr^i)_{n-2}(OR)_n+nPr^iOH\uparrow$$

(R = n-Bu, t-Bu and t-Am; n = 1, 2).

The trans-esterification reactions of **I** appear to be more facile:

$$Pb(OPr^i)_2+2CH_3COOEt \xrightarrow[\text{reflux}]{\text{Cyclohexane}} Pb(OEt)_2+2CH_3COOPr^i. \quad \textbf{(II)}$$

Compound **II** was found to be insoluble in common organic solvents, but it is converted to soluble $Pb(OBu^t)_2$ on refluxing (approx. 20 h) under a fractionating column with excess of Bu^tOH in benzene:

$$Pb(OEt)_2+2Bu^tOH \xrightarrow[\text{reflux}]{\text{Benzene}} Pb(OBu^t)_2+2EtOH\uparrow. \quad \textbf{(III)}$$

Compound **III** can also be prepared by the trans-esterification reaction between $Pb(OPr^i)_2$ and CH_3COOBu^t:

$$Pb(OPr^i)_2+2CH_3COOBu^t \xrightarrow[\text{reflux}]{\text{Cyclohexane}} Pb(OBu^t)_2+2CH_3COOPr^i\uparrow.$$

The analysis of lead and alkoxide group(s) in all the products is within experimental (±0.5%) error; as are the estimations of isopropanol/ethanol liberated in the reactions.

$[Pb(OBu^t)_2]_3$ shows a trimeric unit[6,7] in the crystalline form, whereas $[Pb(OCH_2CH_2OMe)_2]_n$, with which $[Pb(OPr^i)_2]_n$ has been shown[6] to be isostructural, exhibits a chain structure. It appears

*Author to whom correspondence should be addressed.

plausible that freshly prepared $Pb(OPr^i)_2$ has structural features similar to those of $Pb(OBu^t)_2$[6,7] and ages into a polymeric form similar to that of $[Pb(OCH_2CH_2OMe)_2]$.[6]

Acknowledgements—Thanks are due to Professor W. E. Buhro and Dr S. C. Goel of Washington University (St. Louis, U.S.A.) for helpful discussions.

CHEMICAL SPECIATION MODELLING AND THERMODYNAMIC DATABASE COMPILATION—I. DATA UNCERTAINTIES

J. R. DUFFIELD,* F. MARSICANO† and D. R. WILLIAMS‡

School of Chemistry and Applied Chemistry, University of Wales College of Cardiff, P.O. Box 912, Cardiff CF1 3TB, U.K.

(*Received* 20 *November* 1990; *accepted* 18 *February* 1991)

Abstract—This article addresses the critical appraisal of thermodynamic data for inclusion in databases for use with computer-based chemical speciation models. The uses of chemical speciation analysis, the need for accurate and applicable thermodynamic data and the uncertainties associated with the modelling of "real-life" processes are considered. Where appropriate, examples are given to illustrate and expand upon individual points.

A comprehensive understanding of the metal–ligand equilibria pertaining to many aqueous environments and fluids including groundwaters, blood plasma, gastro–intestinal juices and food extracts is essential in an ever-increasing number of endeavours. Such equilibria will be of fundamental importance in any area where a knowledge of the chemical form of an element is a prime requirement. Examples of such areas might include research into radioactive waste disposal, assessment of the metal-dependent side-effects of modern pharmaceuticals, the bioavailability of metal ions from foods and the use of metal complexes to suppress bacterial activity.[1–4]

All such studies require detailed analysis of the chemical "speciation" of each metal and ligand present in the system. In this context, speciation is used to denote the chemical form of a given metal ion or ligand with respect to valence state(s), concentrations of complexes and free aquated metal ions in equilibrium with solid precipitates. It is not sufficient only to know the total concentrations.

In most cases, however, due to the very low concentrations coupled with the extremely complicated, and labile, equilibrium processes involved, such systems are inaccessible to direct analytical measurements. One method of overcoming these problems is to model the systems of interest using computer simulation programs and associated databases. These enable the extent of metal–ligand interactions to be quantified as percentages of the total concentrations of any component.

There are a number of computer programs available for the simulation of metal–ligand equilibria in aqueous systems. An abbreviated selection of those used in our laboratories is given in Table 1. Programs such as those listed model the systems in question using the Laws of Mass Action and Mass Balance and thermodynamic formation constants for all of the possible metal–ligand species, in conjunction with defined parameters such as pH, E_h and total metal and total ligand concentrations. Thus, each program solves a series of mass balance relationships expressed in terms of each metal ion and ligand.[1] Clearly, the success of such calculations and their chemical predictions will be critically dependent upon the accuracy of the thermodynamic formation constants of all possible reactions occurring in the system.

The purpose of this series of articles is to review the criteria which should be considered when selecting such thermodynamic data for inclusion in a database from the vast number of sources available (see Part 2), to point out possible deficiencies in existing data and to recommend how these might be remedied.

UNCERTAINTIES ASSOCIATED WITH MODELLING

In any assessment of "real-life" processes made using simulation techniques, there are three major sources of uncertainty. These have been referred to as "modelling", "data" and "completeness" uncertainties as described below.[5]

Modelling uncertainties

These stem from an imperfect understanding of the processes being modelled and/or from numerical approximations used in the mathematical representations of processes.

Data uncertainties

These arise as a result of poor quality and/or applicability of data and parameters used as input to a mathematical model.

Completeness uncertainties

These refer to possible omissions from the model because of lack of knowledge. Random events will fall into this category. In the case of chemical speciation modelling, "completeness uncertainties" will constitute a component of "modelling uncertainties".

The contribution of each type of uncertainty to the overall uncertainty which is intrinsic to a given simulation exercise will vary depending upon the process(es) being modelled.

The total of these three uncertainties associated with a model can be quantified by a combination of uncertainty analysis and exercises in verification and validation. Uncertainty analysis is used to make reliable estimates of the probability that a parameter will have a specific value. It is a subjective approach to the problem of data uncertainty assessment in which the assigned probabilities are expressions of "degrees of belief" that a parameter will have a particular value. The belief is derived

from expert judgement and the concepts adumbrated in this paper are aimed at (i) improving the wisdom of those "experts" who compile databases and (ii) making database users more aware of the origins and possible shortcomings of the individual data.

Verification and validation exercises compare the models and their predictions with experimental results, thereby checking both the mathematics and the input data. These procedures, and especially verification, are also used in "inter-code" comparisons to further assess the success, or otherwise, of calculation procedures.[1]

In principal, completeness uncertainties are unquantifiable, although some allowance can generally be made by extending probability ranges in uncertainty analysis.

In simulations of chemical speciation in dilute aqueous media, the main source of uncertainty is normally due to the quality of the input, specifically that of the formation constants and the composition of their associated complexes. In such purely aqueous phase systems, the physical chemistry theory of metal–ligand interactions and the mathematical models derived therefrom are relatively well understood, i.e. in this instance, mathematical models are more advanced than the associated formation constant databases. Thus, this series addresses the problem of data.

DATA UNCERTAINTIES

Determination of reliable formation constants and solubility products involves a great deal of painstaking experimental work as well as judicious use of whatever graphical and/or computerized numerical methods were available for data analysis at the time at which the work was carried out. Inevitably, values published in the literature will be of varying reliability and it is not uncommon for published values of formation constants for particular metal–ligand systems obtained at various dates by different workers to be in disagreement by a few orders of magnitude.

Factors affecting the quality and reliability of formation constants found in the chemical literature have been considered in various recent publications.[6,7] They are brought together and listed below for convenience and completeness. Where a factor is thought to be particularly important in the present context, it is presented in depth with examples.

Factors affecting the accuracy of formation constants

In the current context, accuracy is used to denote not only the closeness of a given formation constant to its true value, but also the capability of the measured set of formation constants to completely describe the metal–ligand experimental data from which they are derived.

Experimental method. Due regard should be taken of the sensitivity and appropriateness of the method adopted to the type of chemical reaction being investigated. Aspects such as kinetics, solubility and redox properties of the system may be crucial in selection of an appropriate method. A technique which at one time was regarded as suitable for use in the study of a particular system may later be shown to be inadequate. For example, the zinc amalgam electrode was at one stage used for the study of complexes formed in the zinc-cyanide system.[8] Later, it was shown that such electrodes react chemically with cyanide-containing solutions[9] and are, therefore, inappropriate as probes for zinc in such solutions unless special precautions are taken.[10] A faulty experimental method can often be the largest source of error.[6]

Purity of reagents. The presence of impurities in the reagents used, and particularly in the background electrolyte which is present in relatively high concentrations, can lead to unsuspected side reactions and errors in formation constants which are difficult to estimate but often lead to erroneously low values for the constants.

Selection of background electrolyte. By far, the majority of studies of metal–ligand complex formation reactions are now carried out in the presence of a relatively high and constant concentration of a supposedly inert background electrolyte. By this means, activity coefficients of ionic species in solution are held constant and subsequent calculations are greatly simplified. Popular electrolytes for this purpose include KNO_3, $NaClO_4$, KCl and NaCl. In instances where the ligand species has an appreciable basicity, part or all of the cationic component of the background electrolyte may be replaced by the protonated form of the ligand. This lowers the pH of the solutions studied and tends to suppress hydrolysis both of the metal aqua ion and of the complex species formed. If, however, the background electrolyte ions interact significantly and in a specific manner with the system under study, this leads to competing side reactions and usually underestimation of formation constants. Such interactions need not necessarily be of a chemical nature, i.e. they need not involve bond formation, but may involve "outer-sphere" complex formation, i.e. formation of loosely associated ion pairs. If the Fuoss equation[11] is used to estimate values for the logarithm of the equilibrium constant for outer-sphere complex formation log K_{os}, it is found that this quantity depends sensitively on the product of the

charge numbers z_+z_- of the interacting ions, and also on the charge separation a of the ions involved. Thus, for values of a_h ranging between 4.0–8.0 Å, one obtains a variation in the value of log K_{os} as shown in Table 2.

Table 2. The variation of log K_{os} with the product of charge numbers (z_+z_-) and charge separation (a) of interacting ions

	Log K_{os}	
z_+z_-	$a = 4.0$ Å	$a = 8.0$ Å
−1	0.02	0.25
−2	0.76	0.77
−3	1.53	1.29
−4	2.30	1.80
−6	3.85	2.83
−8	5.40	3.86

Thus, even in the absence of chemical interactions, ions from a uni-univalent background electrolyte will associate significantly with reagent ions having charge numbers of 2 or larger and of opposite sign. Since different background electrolytes lead to different values of the charge separation, a, it follows that different uni-univalent background electrolytes which may be quite inert in the chemical sense may, at the same ionic strengths, lead to somewhat differing values of formation constants for a given system. The tabulation above indicates that such a situation may be expected to occur when the charge number of a reagent ion is equal to, or greater than, 3.

This may account at least in part for the effect of background electrolyte on the first protonation constant of polyaminopolycarboxylic acids shown in Table 3,*[12] all determined at an ionic strength of 150 mmol dm^{-3}. As the size of the cation in the background electrolyte is increased in the sequence Na^+, K^+, $(CH_3)_4N^+$, so the corresponding concentration formation constant is seen to increase noticeably. The larger the cation, the larger the corresponding a value for the cation–ligand anion interaction, leading to relative destabilization of the ligand anion and, therefore, increased relative affinity for the hydrogen ion.

Ideally, if the metal–ligand system under investigation has a highly charged metal ion, a background electrolyte containing a large anion should be used. Conversely, if the system involves a highly charged ligand, the background electrolyte should contain a large cation. This will minimize the influence of ionic association effects on measured formation constants. Interesting background electrolytes in this connection are the tetraalkylammonium perchlorates (not all of which have the required solubility properties)[7] and tetrabutylammonium tetrafluoroborate.

Reagent concentrations. These will, of necessity, be reflections of the constraints imposed by the sensitivity of the analytical method used and by the ionic strength changes produced. However, in order to identify all possible equilibria, the metal and ligand concentrations, both absolute and relative, should be varied as widely as possible within the range set by these two limiting factors, as well as by metal ion hydrolysis. It is to be hoped that the concentration ranges used will be reported with the subsequently determined formation constant. The same comments hold true for the variation of pH.

When reviewing data for inclusion in a database reagent concentration ranges will be important indicators, amongst other factors, of the completeness of a proposed set of formation constants for the interaction of a metal ion with a ligand. This is particularly true when concentrations have been specifically chosen so as to focus upon only one major species to the exclusion of minor protonated or hydroxy complexes.

Reagent concentrations are relevant not only to identification of equilibria, but also to the precision of the constants finally obtained. Although it is difficult to generalize on this point, experience in our laboratories has indicated that, for the potentiometric technique, particular care is needed in cell calibration and solution standardization when working solution concentrations are below the millimolar level.

Ionic strength. To achieve the best balance

Table 3. First protonation constants of EDTA and DTPA at 37°C in different background electrolytes (I = 150 mmol dm^{-3})

Background electrolyte	Log β	
	EDTA	DTPA
NaCl	9.120	9.673
KCl	9.844	10.047
$(CH_3)_4N^+Cl^-$	10.074	10.645

* The polyaminopolycarboxylic acids are also known to bind alkali metal ions to a slight extent.[13] Thus, in the present example, the situation will be further complicated by competition between the alkali metal ions and protons for the first protonation site.

between the conflicting requirements of keeping ionic strength constant and covering a sufficiently wide range of reagent concentrations, it would seem that, ideally, solution equilibria should be studied at ionic strengths of at least 1 mol dm^{-3}.[7]

Nevertheless, studies that are carried out with a specific chemical modelling application in view are often carried out at the ionic strength appropriate to that application, viz. 150 mmol dm^{-3} for blood plasma, and 0.7 mol dm^{-3} for sea water. Variations of ionic strength that take place as a result of complex formation should not exceed 1% of the concentration of the background electrolyte, although this restriction can be relaxed a little if the calculation procedures used make allowance for small variations in ionic strength, as is the case in some recently reported computer programs.[14,15]

Computational procedures. These have recently been reviewed in depth.[16] The quality, sophistication and type of optimization procedures used in the calculation of formation constants from the experimental data will have a bearing on their accuracy. It is particularly important that the numerical values and sources of any auxiliary data used (e.g. metal hydrolysis constants, ligand pK_a, pK_w, etc.) should be specified. The use of protonation constants determined by other workers can introduce significant errors since systematic errors are often eliminated when both proton and metal complexes are studied under identical conditions.[17] Another major and often overlooked source of error relates to uncertainties in the set of species or complexes assumed to be present, i.e. uncertainties in the model proposed to account for the experimental data.

Two general strategies have been described for use in tackling the problem of model selection: the Baes and Mesmer approach of using the smallest possible number of species and considering more only if no acceptable fit is found, and the approach of the Sillén school where a number of plausible species is considered and those of low stability rejected. These two approaches often lead to models which differ somewhat, particularly with regard to the proposed minor species but, fortunately, seem to lead to similar conclusions about predominant species.[18] A systematic approach to the sequential introduction of species into an equilibrium model has recently been described by Marsicano *et al.*[19] Whatever method is used, it is most desirable that authors give an indication, with reasons, of possible models that have been rejected during fitting procedures. If, as often happens, two or more models can be proposed that fit the data almost equally well, then the uncertainty limits quoted for the formation constants of complexes common to both models (usually the predominant species) must take account of the unavoidable model uncertainties.

Additional factors affecting the accuracy of solubility products

A wide variety of methods are available for the determination of solubility products of sparingly soluble electrolytes. In principle, any solution property whose value depends upon the extent of dissolution of the sparingly soluble electrolyte can be used. In practice, the most commonly used techniques are EMF measurements (yielding activities or concentrations of uncomplexed ions in solution) or solubility measurements (yielding total or analytical concentrations of both complexed and uncomplexed species in solution).

In this context, for the sparingly soluble solid, M_mL_n, it is important to distinguish between the conventional solubility product,

$$K_s^0 = [M]^m[L]^n$$

(at constant ionic strength/activity coefficients)

and an apparent solubility product,

$$K_s^* = T_M^m T_L^n,$$

which is calculated in terms of analytical (total) concentrations of M and L in solution, with no account taken of any complex formation equilibria involving the species M or L.

The quantity, K_s^*, has little thermodynamic significance and can be expected to have a constant value only if $T_M \approx [M]$ and $T_L \approx [L]$ under conditions in which activity coefficients are held constant and negligible complex formation takes place.

It is evident that reliable values of K_s^0 can only be obtained under conditions in which complex formation in the solution phase is negligible or, alternatively, when the state of knowledge about the solution phase equilibria is sufficiently advanced so that the concentrations of free (uncomplexed) components [M] and [L] can be reliably calculated from values of T_M and T_L determined analytically. This point is illustrated in Table 4, where the solubility product of the sparingly soluble solid $Zn(CN)_2$ is calculated on the basis of various assumptions concerning the presence and nature of the species present in the solution phase. The (analytically determined) solubility[20] of $Zn(CN)_2$ in freshly boiled, triple-distilled water at 25.000 ± 0.02°C is such that the total concentration of zinc in solution is 12.8 ± 1.0 ppm, i.e. $T_{Zn} = 1.96 (\pm 0.15) \times 10^{-4}$ mol dm^{-3} and $T_{CN} = 2T_{Zn} = 3.92(\pm 0.30) \times 10^{-4}$ mol dm^{-3}.

It can be seen that, based on the same exper-

Table 4. Values of the solubility product of sparingly soluble $Zn(CN)_2$ calculated on the basis of various models of the speciation of the aqueous phase

Species allowed for in solution	Literature reference and data of study	Calculated solubility product
Assumption: no complex formation in solution	Pre-1903	3.01×10^{-11}

$Zn_2(OH)^{3+}$, $Zn(CN)_4^-$,	ref. 22	
$Zn(OH)^+$, $Zn(OH)_2$, $Zn(OH)_3^-$		
$Zn(OH)_4^{2-}$, $Zn_2(OH)^{3+}$, $ZnCN^+$	ref. 23 (1972)	1.82×10^{-15}
$Zn(CN)_2$, $Zn(CN)_3^-$, $Zn(CN)_4^{2-}$		
$Zn(OH)^+$, $Zn(OH)_2$, $Zn(OH)_3^-$, $Zn(OH)_4^{2-}$		
$Zn_2(OH)^{3+}$, $Zn(CN)_2$, $Zn(CN)_3^-$	ref. 19 (1987)	3.41×10^{-16}
$Zn(CN)_4^{2-}$, $Zn(CN)_3(OH)^{2-}$, $Zn(CN)_3(OH)_2^{3-}$		
$Zn(CN)_5^{3-}$		

imental data, the solubility product of $Zn(CN)_2(s)$ changes by some five orders of magnitude, depending upon the level of sophistication to which the composition of the solution phase is described. It follows that reported values of solubility products are of rather little value unless all the equilibria existing in the solution phase are adequately accounted for and clearly specified.

Most of the other factors listed previously as affecting the accuracy of formation constants apply equally well to solubility products, with one additional requirement that the solid phase be unambiguously identified, e.g. by X-ray powder diffraction studies.

It is known, for example, that europium oxalate in the presence of sodium ions exists as two solid phases, $2NaEu(oxalate)_2 \cdot 7H_2O$ and $Eu_2(oxalate)_3 \cdot 10H_2O$, with the latter phase being more stable at higher ligand concentrations.[24] Transition between these two phases is slow. Failure to detect changes of this sort will clearly lead to substantial error.

Finally, since solubility equilibrium is usually attained only slowly, adequate tests for equilibrium should be applied, and separation of solid from solution phase, whether done by filtration or centrifugation, should preferably be carried out at the equilibration temperature.

CONCLUSIONS

There is an expanding need for an accurate analysis of the chemical speciation occurring in a wide range of industrial, pharmaceutical and environmental processes.[25] To be successful, such computer-based speciation analyses require a sound understanding of the potential pitfalls generated by uncertainties inherent in the modelling assumptions and in the thermodynamic data used. It is hoped that the discussion of the possible sources of error and the accompanying examples presented in this article will aid experimentalists in the design of their equilibrium measurements and thus increase their relevance for modelling purposes. In addition, the discussion should also assist modellers in their choice of data from the extensive original literature and secondary compilations now available, as will be discussed in Part 2 of this series.

CHEMICAL SPECIATION MODELLING AND THERMODYNAMIC DATABASE COMPILATION—II. DATABASE COMPILATION AND SENSITIVITY ANALYSES

J. R. DUFFIELD,* F. MARSICANO,† M. WATERS and D. R. WILLIAMS‡

School of Chemistry and Applied Chemistry, University of Wales College of Cardiff, P.O. Box 912, Cardiff CF1 3TB, U.K.

(*Received* 20 *November* 1990; *accepted* 18 *February* 1991)

Abstract—The collation of thermodynamic data describing metal–ligand interactions in solution to produce useful, coherent and internally consistent compilations known as thermodynamic databases is discussed. In addition, procedures to update and manipulate equilibrium data in a meaningful and scientifically rigorous way are discussed using an approach known as MASAD (a Multivariate Approach to the Sensitivity Analysis of Data).

The scientific literature from many disciplines abounds with data, of varying degrees of precision and accuracy, describing metal–ligand interactions. The measurement and use of such equilibrium data and the associated uncertainties have already been discussed[1] and recently a book by Martell and Motekaitis has underlined these points.[2] In this paper, we first describe some of the existing compilations of thermodynamic equilibrium data which are available. This description is not exhaustive, however, because the fields of application of the subject are numerous and because interest in the topic, with respect to both measurement and use, spans many disciplines. Therefore, the compilations detailed in the next section have been limited to represent those most readily accessible within the chemistry-based literature, and omission of a compilation from discussion does not imply untoward criticism of that work.

Even taking into account the vast and expanding library of equilibrium data which already exists in compilations, current knowledge of the majority of such systems of potential interest is either inadequate or uncertain, or still awaits investigation. In such situations, a number of approaches can be tried to overcome the problems posed. These include (a) estimation of data from chemical trends and free energy relationships,[3,4] and (b) assessing the robustness of data and models using sensitivity analyses of the type used in modelling radioactive waste disposal scenarios.[5,6] The latter of these two approaches is discussed at some length in this paper.

EXISTING COMPILATIONS OF DATA AND ONGOING CRITICAL ASSESSMENT ACTIVITIES

Various compilations of data covering formation constants of proton–ligand and metal–ligand complexes, as well as solubility products, are available to researchers working in the field of solution equilibria, as well as to prospective users of solution thermodynamic data. Under the auspices of the Commission on Equilibrium Data of the Analytical Chemistry Division of the International Union of Pure and Applied Chemistry (IUPAC), a series of comprehensive but uncritical tabulations of data have appeared in the literature[7–10] covering all data published up to the end of 1973 for organic ligands, and up to the end of 1974 for inorganic ligands. These compilations provide rapid access to the primary literature but no attempt is made to assess the accuracy of published data. The advent of computerization of Chemical Abstracts and the increasing use of computerized literature search facilities

has, to some extent, relieved the pressure for production of updated uncritical data compilations. However, anyone who has used both methods of accessing the primary literature will attest to the continued usefulness, convenience and economy of the uncritical data compilations, and it is hoped that compilers will continue to be willing to devote time and energy to this activity.

The task of producing critical tabulations of protonation and metal–ligand complex formation constants and solubility products is indeed a massive one. The size of the task, and the degree and range of expertise required are such that the task can probably only be adequately tackled on the basis of extended international cooperation.

With regard to protonation/acid dissociation constants, an early critical survey of the literature by Kortüm *et al.*[11] surveyed the literature to the end of 1956. This survey was later extended by Perrin[12,13] and by Sergeant and Dempsey[14] to include literature up to the end of 1970.

For metal–ligand formation constants, an important source of critically selected formation constants available at the present time is a set of volumes published by Martell and Smith between 1974–1977,[15–18] supplemented by further volumes in 1982[19] and 1989.[20] These six volumes cover the literature up to and including 1985. In addition, the IUPAC Commission on Equilibrium Data has, in an editorial capacity, launched an ongoing series of Critical Surveys of Stability Constants of Metal Complexes,[21] which are published initially in the IUPAC official journal, *Pure and Applied Chemistry*, with a view to later binding in a permanent hard-cover form and publication as part of the IUPAC Chemical Data Series.

Some surveys in this series that have appeared to date include formation constants for complexes of EDTA,[22] 1,10-phenanthroline, 2,2′-bipyridyl and related compounds,[23] fluoride,[24] nitrilotriacetate,[25] histidine, phenylalanine, tyrosine, L-DOPA and tryptophan,[26] ethylenediamine,[27] indium[28] and acetylacetonate.[29] In the IUPAC critical surveys, reference is made to all published data, which are then classified into the categories: recommended, tentative, doubtful, or rejected,[21] with full justifications given. Such critical and authoritative surveys, carried out by acknowledged experts in their fields, probably represent the ultimate that can be achieved by way of critical assessment of formation constant data. However, the coverage of each survey is of necessity limited, as is the rate at which such detailed and closely argued surveys can be produced. They, therefore, complement, but in no way supercede or displace, the much wider ranging critical compilations of Martell and Smith. Even the latter ongoing compilation lags behind the primary literature by some 8 years or so. It follows that a user of formation constants, for example, in connection with a chemical modelling application, is likely to construct his initial, or feasibility model (see below) using, say, the Martell and Smith compilations and then, once the really important or critical items of data for the particular application have been identified, the researcher is likely to consult the primary literature to update his information, and to draw his own conclusions about the reliability of that information. At that stage, any IUPAC Critical Survey that may be available and that relates to the systems of interest would be of prime importance.

With regard to solubility products, the uncritical compilations referred to earlier[7–9] are a useful source of data. As pointed out in Part 1 of this series of papers, such values should be read in conjunction with the corresponding formation constants for solution species, and corrected by the prospective user if the situation viz-a-viz the constants for the solution species has changed since the original work was published. Critically selected values can be found in the Martell and Smith compilations.[14–20] In general, the recovery of solubility data from the literature and the selection of the best solubility data for a particular application are held to be frequently so difficult that researchers are often forced to redetermine solubility values for themselves, sometimes rather inexpertly.[30] Since solubility data are required and used by a variety of disciplines, a Solubility Data Project was initiated under the coordination of the Committee on Data for Science and Technology (CODATA) of the International Council on Scientific Unions (ICSU), with contributions envisaged from the various world scientific unions and federations, including IUPAC.

The Solubility Data Project is concerned with preparation of a comprehensive critical compilation involving three board categories of data: solubility of gases in liquids, solubility of liquids in liquids, and solubility of solids in liquids. The entire field was subdivided into 20 series for publication by Pergamon Press.[30] The approach underlying the Solubility Data Project is similar to that of the IUPAC-sponsored Critical Surveys of Stability Constants of Metal Complexes, in that the compilations are prepared by experts in the field, operating according to review procedures established under the direction of topic editors. Surveys that have appeared to data and are of interest in the present context are volumes dealing with the solubility of silver azide, cyanide, cyanamides, cyanate, selenocyanate and thiocyanate,[31] scandium, yttrium, lanthanum and lanthanide nitrates,[32] alka-

line-earth metal halates,[33] copper, silver, gold, zinc, cadmium and mercury oxides and hydroxides,[34] lead sulphates, selenates and tellurates,[35] beryllium, barium, strontium and sodium sulphates,[36] silver chloride,[37] alkali metal and ammonium chlorides,[38] alkali and alkaline-earth oxides and hydroxides,[39] alkali metal and ammonium halates,[40] and copper and silver halates.[41] In addition, various volumes have appeared dealing with the solubility of organic substances and gases in aqueous and other solvents.

It is clear, however, that given the wide range of systems that are potentially of interest to users, and the limited rate at which such surveys can be completed and published, the researcher at the present time is generally still confronted with the need to select critically between values of solubility products appearing in the literature.

Heats or enthalpy changes for ligand protonation and metal–ligand complex formation reactions form an integral part of any thermodynamic database for solution chemical applications because such values (together with partial molar heat capacities if these are available) are used to compute the temperature dependence of the equilibrium constant for the corresponding protonation or complex formation reaction. Critical compilations are available that cover heats of proton ionization reactions reported in the published (refereed) literature through mid-1975,[42] and heats of metal–ligand complex formation reactions through 1973.[43]

CRITERIA FOR SELECTION OF DATA

Many of the criteria that are being applied in the selection of formation constant data for the thermodynamic database used by the authors of this review have been described by Smith and Martell,[14–20] by Beck,[44] and have been applied in practice by authors of Critical Surveys.[22–29] These, together with one or two others, will be summarized briefly below.

Many of the selection criteria stem directly from a consideration of the factors affecting the accuracy of formation constants (dealt with in Part I)[1], and can be summarized as follows:

(a) *The adequacy of the experimental method*

This must be appropriate to the system studied and have survived criticism by later workers.

(b) *The precision of the experimental work*

This can sometimes be gauged by the efforts made at reagent purification, solution standardization and tests for attainment of equilibrium, as well as reproducibility of measurements. Adequate tests for side reactions like oxidation are also desirable.

(c) *The proper choice of medium*

This must be chemically inert towards reactant species.

(d) *Adequate coverage of reagent concentration range, with its implications viz-a-viz ionic strength*

(e) *Adequate level of sophistication of calculation techniques*

This should allow for the effect of all relevant equilibria other than the equilibria studied. Values of all auxiliary data used should be stated and should be reliable.

(f) *Model selection*

Preferably, this should be based on more than simply the prejudices of the authors concerned, and uncertainty limits quoted should in some way reflect uncertainties in the model.

Another class of selection criteria stems from comparisons that can be made between the work of various authors on the same or similar system(s).

First, when several workers are in close agreement on a value for a particular complex, the average of these results is often selected. Values showing considerable scatter could be eliminated.[14–20]

Secondly, a particular difficulty arises when two authors who have studied the same system disagree on the question of what complex species are formed in that system. The disagreement often concerns minor species. The problem of critical selection then becomes a problem, not only of selection of the best value(s), but also one of selection of the best model. It is of paramount importance to ensure that the selected species are not mutually exclusive. It may be that two different sets of species are considered to describe the system equally well and inclusion of complexes and numerical values from both data sets will lead to erroneous results. As a general rule, it is probably safer to accept or reject models (including both species and formation constants) as a whole, rather than to proceed on the assumption that all the complex species reported by both authors have an objective existence. If, however, the two reported studies involved work at very different conditions of reagent concentration, then this rule could be relaxed. It is, for example, well known that polynuclear complexes form to a greater extent at higher metal ion concentrations. In such circumstances, it may be acceptable to "mix models".

Thirdly, when there is poor agreement between published values, and other supporting evidence is lacking, the "track-record" of the authors concerned may influence the selection of values. Other factors being equal, preference may sometimes be given to results of more experienced research groups who have supplied reliable values for other ligands, or who have published other reliable values obtained by the same experimental technique.[14–20]

Fourthly, established trends among similar metal ions and among similar ligands can be useful in deciding between widely differing values.[14–20] The linear free energy relation (LFER) in various forms can be particularly useful here. There are numerous examples in the literature of the use of LFERs to correlate protonation constants of series of structurally related organic acids. Use of the equations of Hammett, Yukawa and Tsuno, Swain and Lumpton, and Pavelich and Taft for this and other purposes have been reviewed recently by Exner and Shorter.[45–47] The use of LFERs for the correlation of formation constants of metal–ligand complexes is less well developed than for ligand protonation but certain quantitative approaches adopted by physical organic chemists in the 1920s only began to be applied to inorganic chemistry in the 1950s.[48] There are various examples in the literature of the use of LFERs to correlate formation constants of pairs of ligands with a series of similar metal ions,[49–52] and also of pairs of metal ions with a series of similar ligands.[49,53–55] The accuracy of these correlations depends, of course, on the degree of similarity of the metal ions or ligands being compared.

Finally, correlation analysis based on two and three term equations of a factor analytic type have had some success in correlating the stabilities of a wide variety of metal ions with certain simple monodentate ligand species.[54,56,57]

Where such correlations are used in deciding between widely differing values, or in assessing whether a single reported value may be worth checking experimentally, they must, as pointed out by Martell and Smith,[15–20] be used cautiously to avoid overlooking real examples of anomalous behaviour.

DATABASE COMPILATION

Once the chemical literature has been accessed and critically reviewed, the resulting thermodynamic data must be collated and then compiled into a database. This latter stage may not be straightforward and probably will involve a number of important scientific and managerial decisions, although these may be constrained by the uses to which the database will be put.

For many uses, in addition to defining a database standard state (e.g. a temperature of 25°C with pure water as the solvent), it may be necessary to define the "master components" whose interactions in solution give rise to the individual complex species. In the majority of cases, this latter consideration will present no real difficulty. Only in the case where different oxidation states of an element can exist is a choice of master component(s) really necessary. Here, two possibilities exist: (a) the individual oxidation states can be the master components for that element, or (b) one oxidation state can be the master component, the other states being defined from that master component using the reduction potentials for the relevant half-cell reactions.

One interesting and potentially very useful approach to the problem of database compilation which endeavours to account for many of the problems posed is currently being researched and put into operation by May and Murray in their Joint Expert Speciation System (JESS) initiative.[58] In this initiative, which is well advanced, it is proposed to provide a computer library of thermodynamic data with utilities allowing update and retrieval of species so that choice of "master component" can be rapidly and easily altered. Furthermore, utilities are provided to enable data to be adjusted to account for changes in temperature (van't Hoff) and in ionic strength (14 ionic strength correction methods have been included). In this way, it is hoped that JESS will provide a user-friendly environment in which databases can be compiled and tailored in a flexible manner as required. It should be noted, however, that the ultimate choice of data used will be the user's responsibility; JESS provides the tools.

As is apparent from much of the above discussion, database compilation is, at present, a time-consuming and often tedious occupation. Whilst the production and use of the best possible thermodynamic database must be the ultimate aim in any chemical speciation modelling exercise, it is often difficult to achieve this task in the short term. In such a situation, database compilation itself may become an iterative process as illustrated in Fig. 1. Here, modelling and compilation combine to help identify and evaluate both the important complex species in a given system and the accuracy and precision of their associated formation constants. Indeed, it is arguable that database compilation should never be divorced from modelling as the two tend to complement each other. This may be particularly important where two data sets exist for a given complex system and where the inclusion of both sets would overestimate the importance of the system. In this case, one possible solution is to use both data sets in a simulation–validation exercise

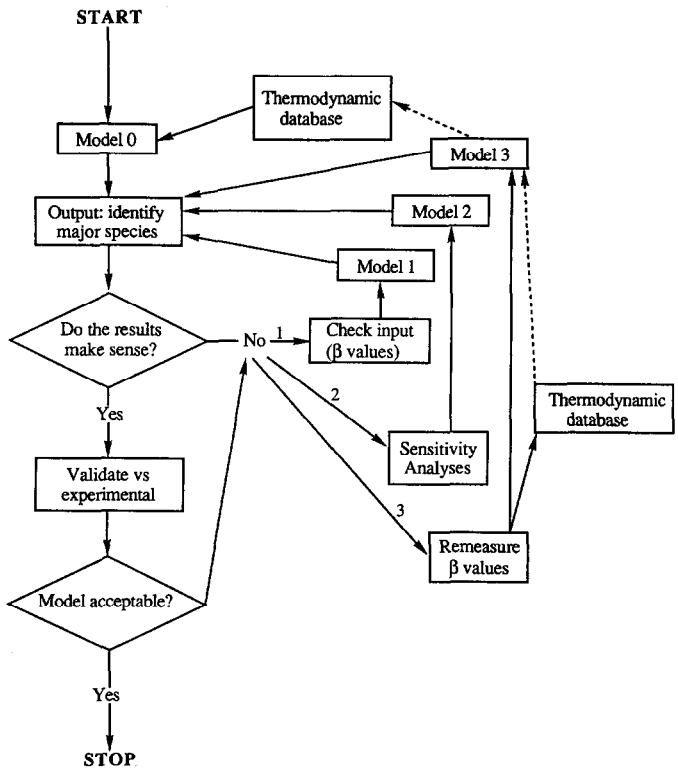

Fig. 1. A flow-diagram showing the interdependence between chemical speciation modelling and the maintenance and improvement of a thermodynamic database. Initially, a feasibility model [model 0] is constructed using the best available input data, i.e. component concentrations, system parameters (pH, E_h) and formation constants. Model 0 is then run and the output examined to identify errors in the input data, particularly with respect to concentrations. From this point on, database maintenance and updating becomes important and is accomplished via an iterative procedure to ensure that predictions made concerning species concentrations are the best possible. This procedure relies to a great extent on the use of sensitivity analyses which allow uncertainties in formation constant data to be identified and so give an indication of metal–ligand systems which may require experimental investigation.

and to choose the data set giving the more accurate predictions. This may be time-consuming and expensive.

Alternatively, the data and model used to simulate the experimental system of interest can be subjected to some form of sensitivity analysis to enable the more important chemical species to be identified and subsequently assessed.

MASAD—A MULTIVARIATE APPROACH TO THE SENSITIVITY ANALYSIS OF DATA

The ultimate aim of the sensitivity analysis of chemical data is to identify the "pivotal" chemical species, changes in whose values lead to significant perturbations in modelling predictions. MASAD has been designed to enable such sensitivity analyses to be automated so that much of the time-intensive analysis of variability of predicted chemical speciation is encompassed within a computer program. The concept is described more fully below.

The concept of sensitivity analysis is familiar in the fields of linear programming[59] and of modelling dynamic systems.[60] However, in the field of chemical speciation modelling, where systems are non-linear and taken to be at equilibrium, neither of the methodologies used in the above disciplines is entirely appropriate.

In the context of chemical speciation modelling, the aim is to determine the sensitivity of the model output to changes in the values of its input parameters, the latter of which are the log β and log K_{sp} values describing the formation of aqueous species and solid phases, respectively. Thus, for any given model some critical output parameter must first be identified, e.g. the solubility of a given element in the system of interest. Overall, MASAD seeks to assess model sensitivity in four main stages:

(i) the input to the chemical model is defined and the critical output parameter identified,
(ii) the model is run and major chemical species determined,
(iii) the model is re-run a number of times with varying log β and log K_{sp} values of important species, and
(iv) the pivotal species identified from a multivariate statistical analysis of the results from (iii).

These stages are described in more detail below.

Once the system of interest has been chosen and the output parameter identified, the system is modelled and the chemical speciation determined. Those complexes considered significant, i.e. which form to $> 0.1\%$ in the initial model, are then selected for inclusion in the sensitivity analysis along with any others which, based upon chemical knowledge, are felt to be questionable.

The next step involves remodelling the system but with simultaneous variation of the significant log β and log K_{sp} values about their base ("accepted") values. If a full factorial design[61,62] was applied to this modelling it would allow the determination of the contributions to the overall sensitivity of the system of all the log β variations and all the interactions between them. This approach would require a great amount of computing time which, for most systems of interest, is unrealistic.

In MASAD, therefore, a probabilistic Monte Carlo approach has been adopted[63] giving a significant saving in resources and time. This reduction in the resource requirement is, of course, at the expense of information describing *all* of the interaction effects.

The method used to obtain the variations in log β values is based upon the random sampling of statistical distributions,[64,65] one per log β value. It is thus necessary to describe which distribution to use and to obtain the relevant parameters for each log β value of interest. As the results obtained from the modelling work will need to be analysed using multivariate analysis to determine both direct and interaction effects, then the statistical tool which would seem to be best able to satisfy the requirements is multiple regression analysis.[66,67] There are non-parametric tools[68,69] available which might be suitable for some of the data analysis but these lack the necessary power to resolve the results into the contributions of each log β and interaction effect.

The use of a parametric tool such as multiple regression requires that the errors associated with the data to be analysed are randomly distributed according to the Gaussian or normal distribution.[70]

Therefore, the Gaussian distribution is employed in the MASAD sampling step. It should be noted, however, that the parameters used by multiple regression do possess a degree of robustness in that they are not affected significantly by slight departures from the Gaussian distribution and the underlying assumption of normality.[71] This latter assumption appears appropriate, especially when the log β values selected for inclusion in a given database are the best unbiased estimates of the true formation constants for the species concerned so that the probability that a formation constant will have a particular value decreases as we move away from the value in the database.

As the Gaussian distribution is employed, each log β value in a database must have a standard deviation assigned to it and this assignment must be based upon some assessment of the quality of the original data. To a certain extent, this is subjective but by employing the ideas promulgated here and in Part I of this series of reviews the authors have developed a five point scale, namely:

(i) very good quality data, vary log $\beta \pm 1.0$ ($\equiv$ SD of 0.5);
(ii) good quality data, vary log $\beta \pm 2.0$ ($\equiv$ SD of 1.0);
(iii) moderate quality data, vary log $\beta \pm 3.0$ ($\equiv$ SD of 1.5);
(iv) poor quality data, vary log $\beta \pm 5.0$ ($\equiv$ SD of 2.5);
(v) species of questionable existence, as for (iv) plus removal from system.

Each log β (describing a chemical species) is assigned a distribution, $N(\log \beta, \text{SD})$, and for each modelling run a random number is obtained from each distribution to represent that log β value in that particular run.

If no quality assessment is possible for a given log β value, a quality class is selected at random from those given above. However, the resource requirement of this approach is significantly higher than is the case when a data quality assessment is available. Furthermore, the resultant output is less reliable. The final stage of MASAD is to analyse the model output to determine the pivotal chemical species, including interactions thereof. As stated above, this is carried out using multiple regression analysis.

CONCLUSIONS

It is apparent that to model aqueous metal–ligand systems and to predict the chemical speciation occurring within such systems, thermodynamic data describing the interactions are

required. The better and the more complete the thermodynamic data used to model the interactions, the greater the certainty with which the predictions can be used and the results believed. Thus, the quality of data (formation constants and solubility products) within the thermodynamic database is crucial and every effort must be made to trace data to source for assessment purposes. Therefore, an "audit trail" for all constants used is a pre-requisite in the management of a thermodynamic database.

Even when such good management techniques are utilized, there will be occasions when uncertainties arise as to the quality and completeness of data concerning metal–ligand interactions. Here, the impact of data uncertainty can be gauged by careful use of sensitivity analyses which will help to indicate whether or not a given species, or set of species, is pivotal in the system of interest. If a species is considered to be pivotal and the associated thermodynamic data is uncertain, the species can then be measured experimentally. In all cases, however, neither the modeller nor the database manager should forget or neglect their chemical knowledge. Individual data points should not be treated in isolation but considered as part of a whole so that chemical trends can be identified and the conformity of relevant data to them assessed. The maxim "garbage in, garbage out" (GIGO) is all too correct in the field of chemical speciation modelling and database users and managers alike must seek to minimize situations where such criticisms can be levelled.

CHEMICAL SPECIATION MODELLING AND THERMODYNAMIC DATABASE COMPILATION—III. MODELLING SOLID FORMATION AND DISSOLUTION

J. R. DUFFIELD,* J. R. JOHNS, F. MARSICANO† and D. R. WILLIAMS‡

School of Chemistry and Applied Chemistry, University of Wales College of Cardiff, P.O. Box 912, Cardiff CF1 3TB, U.K.

(*Received* 20 *November* 1990; *accepted* 18 *February* 1991)

Abstract—Solids may be introduced into speciation using ion activity products and saturation index plots. The compilation of data required for such models is described and the descaling of cooling pipes in an industrial reactor is modelled as an example of how iron oxide dissolution can be maximized with a minimum of corrosion of pipeline and valves.

Previous papers have dealt with the critical appraisal of thermodynamic data for inclusion in databases for use with computer-based chemical speciation models and on-going critical assessment activities.[1,2]

Computer modelling of the precipitation/dissolution of solids in an aqueous medium is usually achieved by the addition of solubility considerations to general aqueous speciation codes since aqueous speciation knowledge is required before dissolution or precipitation can be calculated.

This paper describes the particular problems associated with the selection of formation/dissolution constants for solids, and the interpretation of results from programs using such data.

Factors affecting solubility

The difference between the lattice energy (the energy consumed in separating the ions or molecules of a substance from the crystal lattice) and the hydration energy (the energy released by solvation of ions or molecules), determines the solubility of a solid in water.

Since lattice and hydration energies often vary in a similar manner with change in the chemical variable, for example, increasing with ionic charge and decreasing with ionic size, solubility trends are difficult to predict even qualitatively from a consideration of the difference between these two parameters.

For most ionic solids, the hydration energy is somewhat less than the lattice energy and, thus, the dissolution reaction is generally endothermic, with the result that solubility increases with increase in temperature.

However, for essentially ionic oxides, the oxide ion hydrolyses on dissolution in water and, thus, the dissolution process is exothermic, i.e. solubility decreases with increasing temperature. For some elements (e.g. beryllium and boron), incomplete ionization occurs, and the oxides formed have substantial covalent characters and generally low solubilities.

An equilibrium constant is related to temperature by the expression:

$$K = A \exp(-\Delta H^{\ominus}/RT),$$

where K is the equilibrium constant, T the absolute temperature, and $\Delta H^{\ominus}$ the standard state enthalpy of reaction (assumed constant over small temperature ranges). The constant, A, is also a function of $\Delta H^{\ominus}$ and is assumed to be nearly constant over small temperature ranges.

The effect of temperature on equilibrium constants for the dissolution of solids is much larger than for the formation of aqueous complex species

owing to the generally larger enthalpies associated with dissolution processes. Any modelling work involving solids must, therefore, use equilibrium constants appropriate to the particular temperature considered. Usually, constants at standard temperature are corrected using the van't Hoff equation and reaction enthalpies.

Enthalpies of dissolution are themselves temperature dependent, and the dependence is described by Kirchhoff's law:

$$\left[\frac{\partial \Delta H}{\partial T}\right]_p = \Delta C_p,$$

where ΔC_p is the molar heat capacity change at constant pressure. Very few speciation codes use heat capacities for correcting enthalpies since the effect upon equilibrium constants for solid dissolution is smaller than uncertainties in these parameters.

Since dissolution is an ionic dissociation process, any factors that affect the thermodynamic stability of ions in solution, e.g. ionic strength, will also affect solubility. Ionic strength corrections may be applied in the same way as for aqueous equilibria. Reactions involving the ions formed will also indirectly affect the solubility.

Ion activity products and saturation indices

The solubility product is the inverse of the equilibrium constant for the dissolution reaction of a solid to form ions. For any sparingly soluble salt of the metal ion M^{n+} with the anion X^{m-}, i.e. M_mX_n, the dissolution reaction is:

$$M_mX_n(s) \rightleftharpoons mM^{n+}(aq) + nX^{m-}(aq),$$

and the activity solubility product is given by:

$$K_{sp} = (a_m^{n+})^m \cdot (a_x^{m-})^n = [M^{n+}]^m[X^{m-}]^n \cdot (\gamma_m^{n+})^m \cdot (\gamma_x^{m-})^n,$$

where a = thermodynamic activity and γ = concentration activity coefficient.

The activity of a pure solid is set at unity and need not be included in the expression. The right-hand side is thus the product of $m+n$ concentration (or activity) factors. If the solid is sparingly soluble and the ionic strength of the solution low, the activity coefficients will be near unity, and concentrations can be used rather than activities. Alternatively, if the solid is sparingly soluble and the ionic strength of the solution is constant, but not necessarily low, the activity coefficient factors will have more or less constant values which could be incorporated into the constant, K_{sp}. With this modification to the numerical value of K_{sp}, concentrations rather than activities can once again be used.

The ion activity product (IAP) or activity product, is the product of the activities of the ions produced on dissolution of the solid raised to the power of their stoichiometric coefficients in the balanced reaction equation, i.e. the right-hand side of the solubility product expression. Thus, for the reversible reaction:

$$M_xX_n(s) = mM^{n+}(aq) + nX^{m-}(aq),$$

$$IAP = (a_m^{n+})^m \cdot (a_x^{m-})^n.$$

It is important to note that the IAP differs from K_{sp} in as much as the activities, a_m^{n+} and a_x^{m-}, appearing in the expression for IAP do not necessarily correspond to values at equilibrium but they do correspond to the activities prevailing in a given system which may not be at solubility equilibrium. The saturation index (SI) is defined as the logarithm of the quotient of the ion-activity product to the solubility product, i.e. $SI = \log (IAP/K_{sp})$.

If $SI > 0$ then the solution is supersaturated. Given sufficient time, a precipitate will form and any precipitate present will not dissolve.

If $SI < 0$ then the solution is less than saturated. No precipitate forms and any precipitate present will dissolve.

If $SI = 0$ then the solution is just saturated and no net precipitation or dissolution is expected to occur.

Saturation index plots are a convenient method for representing the propensity of a system for precipitation or dissolution with the need to refer to the actual solubility products involved.

Problems associated with the selection of dissolution constants for databases

Most databases contain a single value for the formation or dissolution constant of a solid, in addition to extra data or a code to correct this value for ionic strength, temperature, etc. Selection of this single value can be problematic for several reasons.

(1) Many values tabulated in compilations are derived from thermodynamic data (such as free energies of formation) rather than direct experimental solubility measurement. Whilst these values can be used in the absence of other data, experimentally determined constants are preferable.

(2) The formation constant may be continuously variable between a lower limit for an amorphous phase or highly hydrated form, and an upper limit for a crystalline phase or less hydrated form, there being no clear delineation between the two. The particular form of solid phase which actually occurs

in a system will depend upon the experimental conditions.

(3) Many solids undergo "ageing" with concurrent stability change as reflected in their formation constants. Ageing can be rapid at elevated temperatures.

(4) The formation constant can be dependent upon the particle size of the precipitate. If the particle size is very small, the surface area per mole becomes sufficiently large to require surface energy to be considered.

(5) Coprecipitation of a foreign ion such as an impurity can alter the stability of the solid. This can occur through:

(a) formation of a solid solution whereby the contaminating ion(s) precipitates with the same lattice structure and similar lattice constants to the solid being considered;
(b) ion entrapment or occlusion whereby foreign ions are trapped during the rapid precipitation occurring in the vicinity. Cation, anion or mixed occlusions can occur, resulting in an impure phase;
(c) adsorption of foreign ions on to the surface of a precipitate. Many precipitates exhibit significant ion-exchange properties.

(6) The accuracy with which a solubility product can be determined depends upon the experimental method and the treatment of the experimental data. Many workers in the past have not taken any account of the complex equilibria between the metal and ligand in solution but, rather, have calculated solubility products from total (analytical) concentrations, giving unreliable constants. Literature reports involving separation of the solid and saturated solution, followed by chemical analysis, often given chronologically decreasing solubility products (decreasing solubility) owing to improvement in the separation (e.g. filtration) technique.

Prediction of solid precipitation

Problems also arise with determining which of several thermodynamically feasible phases will actually form under the conditions being modelled. Furthermore, the particular phase that does, in fact, begin to precipitate may be kinetically controlled and depend upon factors such as:

(1) the concentration of the ions involved in the equilibrium;
(2) the temperature of the solution;
(3) other ions present in solution including impurities;
(4) turbulence;
(5) particle size;
(6) nucleation factors.

Thermodynamic speciation codes can go only as far as indicating phases that might precipitate on the basis of thermodynamic stability. A purely thermodynamic model cannot take into account kinetic effects. Rather, these must be assessed by a skilled professional chemist and used in interpreting such modelling results.

To demonstrate these problems, an example using the iron oxyhydroxide system will be reviewed in the context of aqueous speciation and solid precipitation modelling.

There are a number of iron oxyhydroxide forms reported in the literature. Some occur naturally in geology but can also be synthesized, whilst some are synthetic only. Those relevant to general speciation modelling are described below.

Forms of iron oxyhydroxides

$Fe(OH)_3$. Amorphous ferric hydroxide, an amorphous material which comprises a relatively large proportion of most fresh precipitates and which is formed under conditions of substantial supersaturation with respect to the crystalline oxyhydroxides; it is thermodynamically unstable with respect to both haematite and goethite. An amorphous phase develops by rapid hydrolysis of dissolved ferric species or rapid oxidation and hydrolysis of ferrous iron-rich solutions.

α-Fe_2O_3. Haematite is rarely found as a direct precipitate geologically but slowly crystallizes from amorphous material by dehydration or long term ageing at low temperatures or from short intervals close to 100°C.[3] It may also form to some extent by rapid precipitation at room temperature or from gels around 100°C.[4] The colour is brick red.

γ-Fe_2O_3. Maghemite is rarely found as a direct precipitate but is more usually formed by low temperature oxidation of magnetite, or dehydration of lepidocrocite.[3,5,6] When heated to 200–700°C, it transforms to haematite.[5] It may be produced geologically from other iron oxides by the reducing action of organic matter.[5]

α-FeOOH. Goethite, limonite, precipitates by relatively slow oxidation and hydrolysis of aqueous or solid ferrous iron species.[3,5] Under laboratory conditions, goethite forms most rapidly at pH values higher than 3.5 because the oxidation rate of ferrous iron is extremely slow under more acidic conditions.[3] It also forms by long-term ageing of amorphous material precipitated during hydrolysis

of ferric solutions.[3] Upon dehydration, it forms haematite.[5]

β-FeOOH. Akaganeite is the rarest form under natural conditions,[7,8] The synthetic light brown solid polymorph forms at room temperature by slow hydrolysis of 20–80 mmol dm^{-3} $FeCl_3$ solutions, and it is probable that it only forms from chloride solutions.[3–5,9,10] On heating to 280°C, or boiling in water for 6 days, it transforms to α-Fe_2O_3 (haematite).[9]

γ-FeOOH. Lepidocrocite is dimorphous with goethite. It may be synthesized (indirectly via $Fe_3(OH)_6$)[9] by slow oxidation between pH 4–7 of dilute solutions of ferrous salts or by oxidation of $3Fe_2O_3 \cdot 2FeO$. Usually, its occurrence is accompanied by goethite. Thermally, it dehydrates to form maghemite.[5]

δ-FeOOH. δ-FeOOH is solely synthetic and is obtained by very rapid oxidation of $Fe(OH)_2$. This brown and strongly magnetic material transforms to α-Fe_2O_3 (haematite)[9] on heating above 100°C.

Fe_3O_4. Magnetite is synthesized by oxidation of iron at high temperatures in air by heating Fe_2O_3 in reducing atmospheres, or by precipitation by addition of alkali to solutions of mixed ferrous–ferric ions. It is one of the most abundant oxide minerals in igneous and metamorphic rocks. It frequently occurs as heavy detrital material in sedimentary rocks and it may become concentrated by stream and tidal action to form black magnetite sands.[5] Hydrated Fe_3O_4 (magnetite) rather than hydrated Fe_2O_3 (haematite) is obtained from ferrous hydroxide when the supply of oxygen is limited (e.g. in water at 100°C) and under alkaline conditions.

$FeOOH \cdot nH_2O$. Hydrated haematite and brown haematite are terms used to describe poorly characterized crystalline hydrated oxides whose real identities are not known.[5]

$Fe_2O_3 \cdot 4H_2O$. Crystallized ferric hydroxide may be formed by the slow hydrolysis of ferric ethylate.[11]

$Fe_3(OH)_8$. $Fe_3(OH)_8$ is formed by slow oxidation of $Fe(OH)_2$ under neutral conditions. It forms Fe_3O_4 (magnetite) on heating in water to 100°C. Strong oxidation of the solid forms Fe_3O_4 or γ-Fe_2O_3.[6]

$Fe(OH)_2$. "Ferrous hydroxide" is precipitated as a snow white gel when alkali or ammonia is added to a ferrous solution in the absence of oxygen. It has a green colour if even minute traces of oxygen are present due to iron(III) hydroxide impurities. It immediately oxidizes on contact with oxygen.

The details given above, as well as the relationship between the various oxyhydroxide forms of iron, are summarized in Fig. 1.

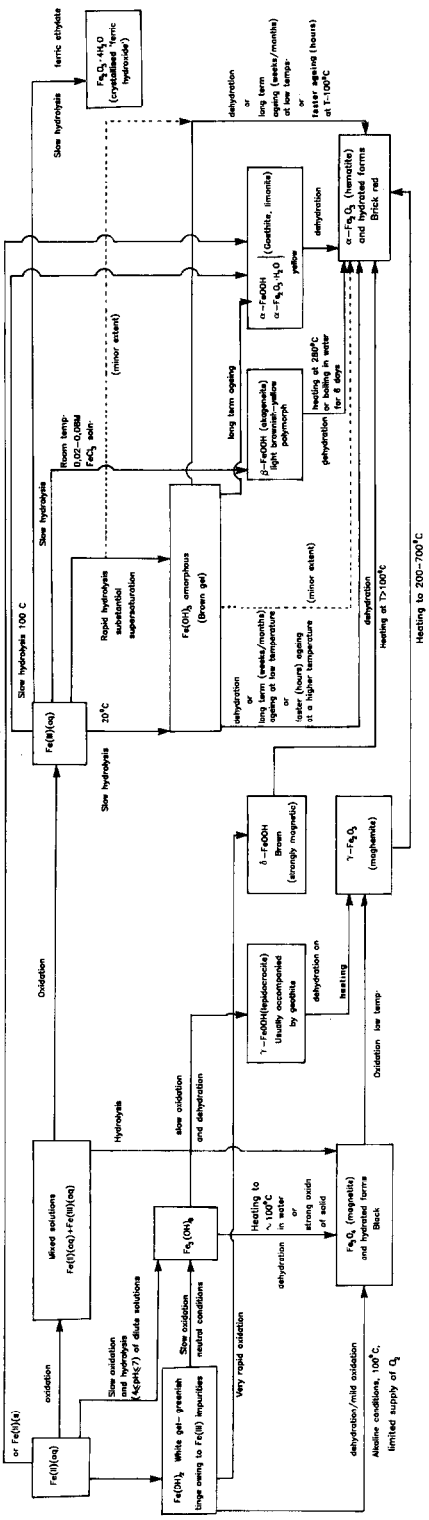

Fig. 1. Relationship between various oxyhydroxide forms of iron that are of interest in the context of aqueous solution modelling.

Redox processes: E_h–*pH relations*

Since iron solids can contain the metal in several oxidation states, the redox potential of the solution needs to be considered carefully when modelling is performed. The interrelationships between all these possible precipitates of iron as a function of redox potential is best shown with an E_h–pH diagram. Figure 2 shows the stability fields for solids and the predominant aqueous species for the Fe–H_2O–O_2 system with 10^{-4} mmol dm^{-3} dissolved iron species (5.6 ppm iron).[3] The procedure for constructing these diagrams can be found in Hem and Cropper[12] and Garrels and Christ.[13]

The boundaries are drawn at equal ion activities. The boundaries between ferric–ferrous aquo iron species and ferric oxyhydroxide solids are drawn for log K_{sp} values of −44 (crystalline solid) and −37.1 (amorphous solid). This difference in log K_{sp} means that at a fixed pH and E_h there can be roughly seven orders of magnitude more dissolved iron in equilibrium with fresh amorphous solid than with well crystallized goethite or haematite. For the E_h and pH values for iron rich aerobic natural waters (pH 5–8, E_h −0.1 to +0.3 V), the system will contain most suspended oxyhydroxides, and lie on the boundary between the regions of stability of the ferrous aquo species and ferric oxyhydroxide solids.

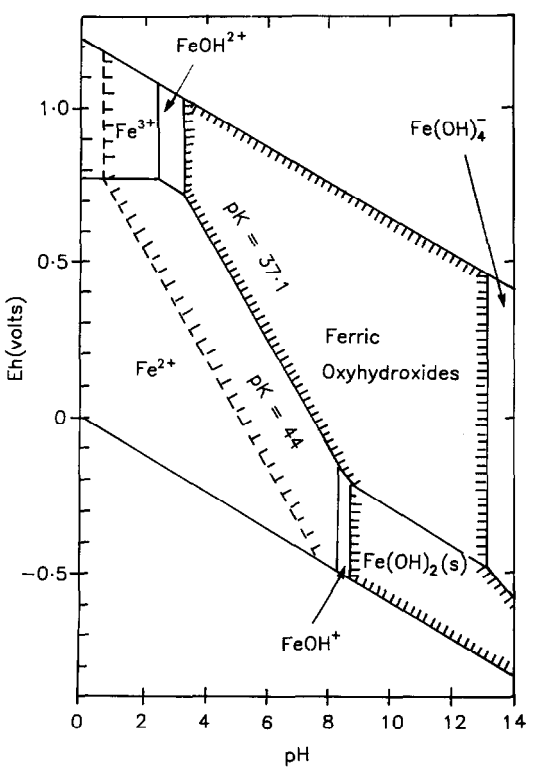

Fig. 2. E_h–pH relations between the predominant aqueous species and iron oxyhydroxides.

General comments

In most cases, the oxyhydroxide first precipitated is amorphous, having been formed under conditions of substantial supersaturation. Early in the precipitation process, poorly crystalline goethite or lepidocrocite may also form. The tendency to form amorphous precipitates increases with the valency of the metal ion.

Many workers refer to this finely divided, disordered precipitate first formed as the "active" form, since it undergoes change with time (ageing) to produce larger and more ordered crystals (the "inactive" form).

The relationship between freshly precipitated amorphous ferric hydroxide and goethite may be written:

$$Fe(OH)_3(\text{amorphous}) = \alpha\text{-FeOOH(crystalline goethite)} + H_2O,$$

and between amorphous ferric hydroxide and haematite is seen to be:

$$2Fe(OH)_3(\text{amorphous}) = \alpha\text{-}Fe_2O_3(\text{crystalline haematite}) + 3H_2O.$$

From free energies of formation,[14,15] the Gibbs free energy for these transformations is found to be −29.18 kJ mol^{-1} (−6.97 kcal mol^{-1}) for goethite and −60.59 kJ mol^{-1} (−14.46 kcal mol^{-1}) for haematite. Thus, with sufficient time, a freshly precipitated ferric hydroxide will transform into the more stable haematite phase.

Oxyhydroxide precipitates are often mixtures of different phases. The apparent thermodynamic stability or the solubility of such mixtures depends mainly on the solubility of the least stable phase present, a phase which is usually amorphous. It must always be remembered, however, that the formation of a particular solid phase may be kinetically controlled owing to slow rates of reaction and may not be observed to occur, even though it is thermodynamically favourable. Another less thermodynamically favourable phase may be observed to form instead. Slow precipitation over long time periods, such as that considered in many geological systems, will favour formation of thermodynamically more stable phases, whereas rapid precipitation, e.g. alkali addition, will favour the kinetic product.

If acid is added to a solution containing precipitated ferric oxyhydroxides, the least stable, more soluble amorphous material may redissolve, leaving behind relatively crystalline particles of lower solubility product.[3]

Oxyhydroxide precipitates usually contain col-

loidal material. Sizes range from molecular $Fe(OH)_3$ to micron sized crystals or crystal aggregates. Both crystalline and amorphous precipitates remain colloidal indefinitely in some solutions. Particle size is probably the major influence on thermodynamic stability of the oxyhydroxides. Other factors include crystallinity, degree of hydration of the precipitate, the presence of impurities, and turbulence.

Thermodynamic relationships

Solution reactions for all the oxyhydroxides can be written in the same form, e.g.

$$Fe(OH)_3(\text{amorphous, s}) \rightleftharpoons Fe^{3+}(aq) + 3OH^-(aq),$$
$$\alpha\text{-}FeOOH(s) + H_2O \rightleftharpoons Fe^{3+}(aq) + 3OH^-(aq),$$
$$1/2\alpha\text{-}Fe_2O_3(s) + 3/2H_2O \rightleftharpoons Fe^{3+}(aq) + 3OH^-(aq).$$

The logarithm of the solubility product expression may be written as:

$$\log K_{sp} = \log[Fe^{3+}][OH^-]^3.$$

Values for log K_{sp} range from -37 for fresh, rapidly precipitated amorphous material to -44 or less for crystalline goethite and haematite.[3]

There is a linear increase in log K_{sp} for oxyhydroxides with decrease in particle size due to surface energy. For equal sized goethite and haematite particles, goethite is more stable when the particle size exceeds 760 Å (0.076 μm) but less stable than haematite at smaller particle sizes. Particle sizes of $\leqslant 100$ Å are common in laboratory solutions and natural waters. Such particles are at least 1.2 and 2.7 log K_{sp} units less stable than well crystallized samples of haematite and goethite, respectively.

Ferric oxyhydroxides precipitated in natural waters are usually mixtures of X-ray amorphous material (does not give an X-ray diffraction pattern) and poorly crystalline goethite (α-FeOOH) and, sometimes, poorly crystalline lepidocrocite. Oxyhydroxides other than these are rarely precipitated from natural waters.

In cases of slight supersaturation of iron solutions with hydroxide ions, nucleation and crystal growth are often slow. The crystalline form may precipitate very slowly and equilibrium is established only very gradually. Under such conditions, short-term measurements of solubility products do not give reliable results.

Solid $Fe(OH)_2$ cannot be formed in air and only forms in solution under reducing conditions. Addition of hydroxide to a ferrous solution in the absence of oxygen yields a fairly crystalline ferrous hydroxide [$Fe(OH)_2$] product. The addition of base to precipitated $Fe(OH)_2$ at high pH gives a material which is easily oxidized at low potential to $Fe(OH)_3$.

The reaction $3Fe(OH)_2(\text{crystalline}) = Fe_3O_4(\text{crystalline}) + H_2(g) + 2H_2O$, has a Gibbs free energy change of -27.3 kJ mol^{-1} (-6.5 kcal mol^{-1}).[14,15] Therefore, $Fe(OH)_2$ is unstable with respect to decomposition into magnetite, water and hydrogen gas. Under a total pressure of 1 atm., a precipitate of ferrous hydroxide should eventually decompose to yield magnetite, and hydrogen would bubble from the system until the conversion was complete.

Solubility can also be represented as a concentration versus pH plot. The solubility of amorphous iron hydroxide as a function of pH is represented in Fig. 3.[16] The hydroxide concentration is determined by the pH, and the plot is of total iron concentration versus pH. The area

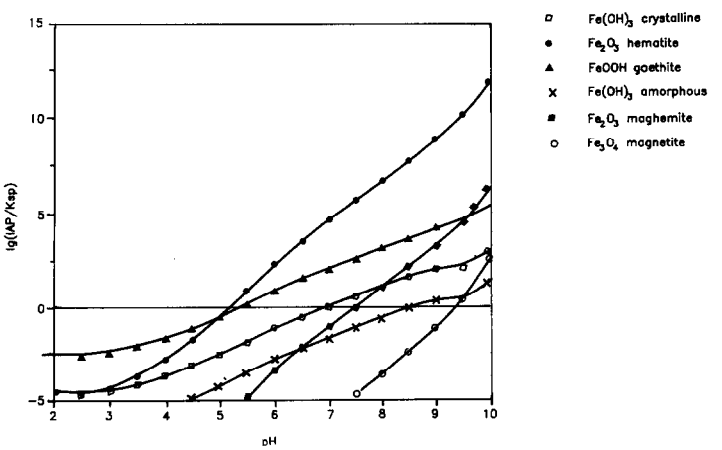

Fig. 3. Solubility of $Fe(OH)_3$(amorphous) depicted on a concentration versus pH plot. A value of -38.7 was used for the solubility product.

above the roughly parabolic hatched envelope represents precipitated amorphous ferric hydroxide (where the ion activity product exceeds the K_{sp} value) while below this the iron is present as a mixture of hydrolysed species. Minimum solubility is observed at a pH of about 8.5. It should be noted that an E_h value was chosen such that all the iron is present as iron(III).

Example of dissolution modelling—descaling a reactor cooling system

The solution used for cleaning the cooling system of a steel reactor was modelled using the PHREEQE code.[17] The oxide corrosion film undergoes dissolution in an acidic aqueous medium (nitric acid added) using EDTA as a chelating agent and with citric acid–ammonium citrate added as a buffer.

Input parameters used for the model were as follows:

Total Fe	20 mmol dm^{-3}
Total EDTA	25 mmol dm^{-3}
Total citric acid	15 mmol dm^{-3}
Total Na^+	50 mmol dm^{-3}
Total NH_4^+	9 mmol dm^{-3}
E_h	0.50 V
Temperature	90°C (363 K).

The system was modelled at pH values between 2–10, fixing the pH by addition of nitric acid or sodium hydroxide as required, in order to maintain the charge balance. The solution was not allowed to equilibrate with solid phases but the saturation indices for solid phases were computed.

Constants

The constants in Table 1 are those from the literature that are believed to be the most reliable at this time. The log K_{sp} values are the logarithms of the solubility products (calculated from the UW* PHREEQE database), in terms of iron(II) or iron(III) as appropriate, and hydroxide ligands. They have been converted into this form so that direct comparison of the numerical values can be made.

The database for PHREEQE, however, uses constants based on water as a master species, and relative to Fe^{2+} as a master species, i.e. the formation constant for hydroxide from water (pK_w) is added to log K_{sp} for each hydroxide ion present in a formula unit of the solid. All Fe^{3+} species include a redox correction of 13.01 for the Fe^{2+}–Fe^{3+} couple for each Fe^{3+} ion present in a formula unit of the solid. Accordingly, they are numerically not directly comparable owing to different oxidation states and numbers of hydroxide ions involved.

The justification for the selection of these particular constants for the UW database will not be discussed here, but are consistent with those of the EIR MINEQL database and the CHEMVAL (Mirage 2 project of EEC) database. Selection was done by expert groups in line with the guidelines proposed by IUPAC.[18]

The formation constants given in Table 2 were used for aqueous iron species.

The iron(II) and iron(III) citrate constants (given at $I = 0$) in Table 3, which were measured at UW, have also been included in the model.

The following iron citrate constants, which have been considered by other workers but which were not consistent with the iron citrate model at UW and were, therefore, not used, were:

$[Fe(OH)_2(Cit)_2]^{4-}$	−4.54
$[FeH(Cit)_2]^{3-}$	13.58
$[FeH(Cit)]^+$	1.28
$[Fe_2(Cit)_2(OH)_2]^{2-}$	−1.61

A plot of saturation index versus pH is shown in Fig. 4 for the iron solids that may, from thermodynamic considerations, possibly precipitate.

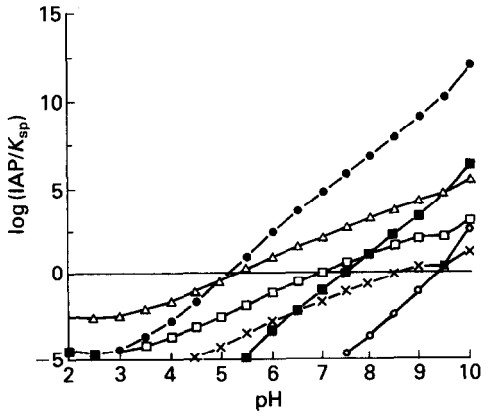

Fig. 4. Saturation index plot for model of reactor cooling system cleaning solution. Key: □, $Fe(OH)_3$ crystalline; ●, Fe_2O_3 haematite; △, FeOOH goethite; ×, $Fe(OH)_3$ amorphous; ■, Fe_2O_3 maghaemite; ○, Fe_3O_4 magnetite.

RESULTS

It may be observed that below a pH value of 5, no solubility products are exceeded, i.e. all saturation indices are less than zero. As the pH increases, the solubility limits for various phases are reached (i.e. the lines cross the horizontal saturation limit line). Of all the solid phases considered, $Fe(OH)_3$ (amorphous) is likely to be the precipitate first formed, on the basis of "real" experimental observations[3] rather than thermodynamic considerations, even though it is not the most thermodynamically stable.

Under the conditions being modelled, maghemite ought not to form since it rarely precipitates directly from aqueous iron solutions but usually forms under reducing conditions from other iron solids.[3,5,6]

Magnetite is unlikely to form since, although the level of oxygen is zero and the temperature high (90°C), the conditions are not sufficiently reducing for any significant concentration of ferrous ions to be present, an experimentally observed requirement for magnetite precipitation.[5]

A small amount of poorly crystalline goethite and/or haematite might be expected to precipitate with the initial amorphous solid formed.[3] Ageing is quite rapid at 90°C, however, so after a period of several hours, transformation to more crystalline $Fe(OH)_3$–haematite–goethite will occur. These phases are more thermodynamically stable and far less soluble than the initially precipitated, more hydrated, amorphous phase. It would be necessary to reduce the pH of the solution to a much lower value than that at which the first precipitate formed in order to redissolve the aged precipitate.

The implications of solid precipitation in a cooling system can be of major importance. Pumps, valves and filters can become blocked and solids can deposit in stagnant areas of low flow, and reduction of the pH to a value sufficient to redissolve the precipitate can cause significant corrosion problems to plant materials. The pH must, therefore, be maintained at a value low enough to allow a good rate of oxide film dissolution, but not low enough for corrosion to become a significant problem, yet not above a pH where solids reprecipitation can occur.

CONCLUSIONS

Solid–solution speciation models which are based upon powerful programs and verified thermodynamic databases permit:

(a) an enhanced understanding of the processes present;

(b) the optimization of desirable effects;
(c) the suppression of undesirable side effects;
(d) the outcome of postulated modifications (e.g. a change of sequestering ligand used) to be assessed.

SYNTHESIS OF NEW SIX-COORDINATE COMPLEXES OF SILICON(IV)

DENNIS F. EVANS* and CHIH Y. WONG

Inorganic Chemistry Laboratories, Imperial College, London SW7 2AY, U.K.

(*Received* 14 *January* 1991; *accepted* 20 *February* 1991)

Abstract—The synthesis of new six-coordinate tris-bidentate complexes of silicon(IV) is reported. Two methods of synthesis have been used, the normal procedure using $SiCl_4$, and a novel method using $Si(OEt)_4$ in the presence of a strong acid. This new route has shown to be preferential for making such compounds in general. The complexes have been characterized by ^1H and ^{29}Si NMR spectrometry in DMSO, elemental analysis and FAB^+ mass spectrometry. Facial and meridional isomerism was normally slow on the NMR time scale and in some cases the rates of isomerism were recorded. Complexes derived from the 3-hydroxypyridin-4-ones were found to be water stable.

Preliminary work on the understanding of the biochemistry of silicon involves an investigation into its aqueous chemistry. Quantitative data for the formation of tris-catecholato silicon(IV) complexes have been previously reported.[1] Since few complexes of silicon are stable in aqueous solution, this present work involves the synthesis of new six-coordinate silicon(IV) complexes in non-aqueous solvents, which are based on a variety of hard bidentate ligands. Several of these ligands, e.g. 1,2-dimethyl-3-hydroxypyridin-4-one and acetohydroxamic acid, have already been shown to chelate efficiently with other hard metal ions, notably with iron(III)[2] and aluminium(III).[3] A new and simple route to these complexes is illustrated below in eq. (1):

$$Si(OEt)_4 + 3LH + HX \rightarrow [SiL_3]^+[X]^- + 4EtOH, \quad (1)$$

where $X^- = CF_3SO_3^-$, HSO_4^-, $CF_3CO_2^-$, Cl^- or the 10-camphor-sulphonate anion. This is found in most cases to be preferable to the normal method used for acac[4] and tropolonato[5] complexes, as shown in eq. (2):

$$SiCl_4 + 3LH \rightarrow [SiL_3]^+[Cl]^- + 3HCl. \quad (2)$$

The complexes have been characterized by ^1H and ^{29}Si NMR spectroscopy, elemental analysis and FAB^+ mass spectrometry.

EXPERIMENTAL

Materials

Silicon tetraethoxide, trifluoromethanesulphonic acid, trifluoroacetic acid, 10-camphorsulphonic acid (camH), maltol (malH), acetohydroxamic acid (aceH), benzohydroxamic acid (benH), 3-hydroxypyridin-2-one (2,3-dihydroxypyridine, dhpH) and 8-hydroxyquinoline-*N*-oxide (hqoH) were obtained commercially from Aldrich and used without further purification. Chrysin (chrH) was obtained from Sigma.

3-Hydroxy-2-methylpyridin-4-one[6] (hmpH), 1,2-dimethyl-3-hydroxypyridin-4-one[7] (dmpH) and 1-ethyl-3-hydroxy-2-methylpyridin-4-one[7] (empH) were prepared by literature methods.

Physical measurements

^1H NMR spectra were recorded on a Jeol GSX270 (270 MHz) spectrometer. $^{29}Si\{^1H\}$ NMR spectra were recorded on a Bruker WM250 (250 MHz) spectrometer. Chemical shifts are quoted relative to internal tetramethylsilane (TMS) for both ^1H and ^{29}Si nuclei. The relaxation reagent, $Cr(acac)_3$, was added (0.08 M) to overcome the

problems associated with the long relaxation times and the negative magnetic moment of the ^{29}Si nucleus. Mass spectra were recorded on a Micromass VG 7070E spectrometer in the FAB^+ mode, with the sample suspended in a *m*-nitrobenzylalcohol matrix.

8-*Hydroxyquinaldine*-N-*oxide* (8-*hydroxy*-2-*methylquinoline*-N-*oxide*, hmqH)

This was prepared by slow addition of *m*-chloroperoxybenzoic acid (27 g, 80–85%, 0.125 mol) in chloroform (150 cm^3) to an ice-cooled and vigorously stirred solution of 8-hydroxyquinaldine (20 g, 0.125 mol) in chloroform (100 cm^3). After 4 h the solution was left to stand at room temperature over a period of 48 h. The *m*-chlorobenzoic acid was subsequently removed by extraction with 0.2 M phosphate buffer (1 : 1 sodium dihydrogen orthophosphate and disodium hydrogen orthophosphate) solution (3×150 cm^3, pH *ca* 7). The chloroform solution was evaporated to dryness and the residue recrystallized from benzene (100 cm^3)/light petroleum (20 cm^3). Yield: 9.9 g, 45%. Found: C, 68.5; H, 5.1; N, 7.5. hmqH requires: C, 68.6; H, 5.2; N, 8.0%. M.p. = 99–101°C.

Preparation of solid hexadentate silicon(IV) complexes

There are two general methods of preparation in accordance with eqs (1) and (2), respectively.

Method 1

$[Si(dmp)_3]^+[CF_3SO_3]^-$. To dmpH (1.00 g, 7.19 mmol) in hot ethanol (10 cm^3), under argon, $Si(OEt)_4$ (0.53 cm^3, 2.40 mmol) was added followed by CF_3SO_3H (0.21 cm^3, 2.40 mmol). The mixture was refluxed for 18 h and precipitated with diethyl ether (5 cm^3). The white solid was filtered under excess argon pressure, and then washed with a little ether (10 cm^3) and dried *in vacuo* at 50°C for 2 days. Yield: 1.26 g, 89%. Found: C, 44.5; H, 4.0; N, 7.1. $[Si(dmp)_3]^+[CF_3SO_3]^-$ requires: C, 44.7; H, 4.1; N, 7.1%. ^1H NMR (270 MHz, DMSO-d_6): δ, 2.35 (3H, m*, CH_3^2), 3.90 (3H, m, CH_3^1), 6.81 (1H, m: d $\{J_{H^5\text{-}H^6} = 6.8$ Hz$\}$, H^5), 8.03 (1H, m: d $\{J_{H^5\text{-}H^6} = 6.8$ Hz$\}$, H^6). H^5 and H^6 were assigned by Nuclear Overhauser Enhancement difference spectroscopy.

Similarly, $[Si(dmp)_3]^+[CF_3CO_2]^-$, $[Si(dmp)_3]^+[HSO_4]^-$ and $[Si(dmp)_3]^+[cam]^-$ were prepared in comparative yields; 80, 65 and 87%, respectively. ^1H NMR showed similar chemical shifts and the bisulphate complex showed the presence of ethanol after drying *in vacuo* at 70°C for several weeks, after which decomposition of the metal complex prevented analytical purity.

$[Si(mal)_3]^+[CF_3SO_3]^-$. This was prepared in 50% yield. Found: C, 40.6; H, 2.4. $[Si(mal)_3]^+[CF_3SO_3]^-$ requires: C, 41.3; H, 2.7%. ^1H NMR (270 MHz, DMSO-d_6): δ, 2.53 (3H, m, CH_3^2), 7.44 (1H, m: d $\{J_{H^5\text{-}H^6} = 4.9$ Hz$\}$, H^5), 8.92 (1H, m: d $\{J_{H^5\text{-}H^6} = 4.9$ Hz$\}$, H^6).

$[Si(dhp)_3]^+[CF_3SO_3]^-$. This was prepared in 75% yield using six-fold the volume of ethanol (60 cm^3) due to the limited solubility of dhpH in hot ethanol. Found: C, 38.1; H, 3.0; N, 8.2. $[Si(dhp)_3]^+[CF_3SO_3]^-$ requires: C, 37.9; H, 2.4; N, 8.3. ^1H NMR (270 MHz, DMSO-d_6): δ, 6.92 (1H, m: t, H^5), 7.25 (1H, m: d, H^4), 7.42 (1H, m: d, H^6).

$[Si(hmp)_3]^+[CF_3SO_3]^-$. This was prepared in 57% yield using four-fold the volume of ethanol (40 cm^3). Found: C, 41.2; H, 3.2; N, 7.5. $[Si(hmp)_3]^+[CF_3SO_3]^-$ requires: C, 41.5; H, 3.3; N, 7.6. ^1H NMR (270 MHz, DMSO-d_6): δ, 2.31 (3H, m, CH_3^2), 6.80 (1H, m: d $\{J_{H^5\text{-}H^6} = 6.3$ Hz$\}$, H^5), 7.86 (1H, m: d $\{J_{H^5\text{-}H^6} = 6.4$ Hz$\}$, H^6).

$[Si(emp)_3]^+[HSO_4]^-$. This was prepared in greater than 90% yield but failed to crystallize with ether, thus the complex was isolated by evaporating the ethanol solution to dryness. ^1H NMR (270 MHz, DMSO-d_6): δ, 1.37 (3H, m: t, CH_3^7), 2.41 (3H, m, CH_3^2), 4.25 (2H, m: quart., CH_2^1), 6.85 (1H, m: d, H^5), 8.08 (1H, m: d, H^6), showed contamination by free ligand.

$[Si(emp)_3]^+[Cl]^-$. This was prepared using a stoichiometric amount of conc. hydrochloric acid (35–38%) as the strong acid. The ethanol solution was evaporated to dryness to leave a pinkish, off-white solid. Yield: 55%. ^1H NMR showed similar chemical shifts as $[Si(emp)_3]^+[HSO_4]^-$, but free ligand resonances were appreciable.

$[Si(ace)_3]^+[CF_3SO_3]^-$. This was prepared by evaporation of solvent to dryness. Yield: 60%. ^1H NMR (270 MHz, DMSO-d_6): δ, 2.05, (3H, s, CH_3), showed contamination by free ligand.

$[Si(hqo)_3]^+[CF_3SO_3]^-$. This was prepared by evaporation of solvent to dryness. Yellow solid, yield: 70%. The ^1H NMR spectrum was too complicated in the aromatic region, however, contamination by free ligand was observed.

$[Si(hmq)_3]^+[CF_3SO_3]^-$. This was prepared by evaporation of solvent to dryness. Yellow–green solid, yield: > 90%. ^1H NMR (270 MHz, DMSO-d_6): δ, 2.20 (3H, s, CH_3^{fac}), 2.35 (3H, m, CH_3^{mer}), showed contamination by free ligand.

* δ shown represent the average values observed; multiplicity caused by facial and meridional isomers. m: d represents multiple doublets.

Method 2

$[Si(dmp)_3]^+[Cl]^-$. To dmpH (1.00 g, 7.19 mmol) in hot chloroform (5 cm^3), under argon, $SiCl_4$ (0.27 cm^3, 2.40 mmol) was added. The mixture was refluxed for 18 h. The solution was evaporated to dryness and the white residue was filtered under excess argon pressure and dried *in vacuo* at 50°C for 2 days. Yield: 1.12 g, 98%. ^1H NMR showed similar chemical shifts to $[Si(dmp)_3]^+[CF_3SO_3]^-$ but the chloroform resonance persisted after drying *in vacuo* at 70°C for several weeks, after which decomposition of metal complex prevented analytical purity.

$[Si(mal)_3]^+[Cl]^-$, $[Si(ben)_3]^+[Cl]^-$, $[Si(hmq)_3]^+[Cl]^-$ and $[Si(chr)_3]^+[Cl]^-$ complexes were prepared as above. The ^1H NMR spectra of $[Si(ben)_3]^+[Cl]^-$ and $[Si(chr)_3]^+[Cl]^-$ were complicated but the formation was confirmed by ^{29}Si NMR and FAB^+ mass spectrometry.

RESULTS AND DISCUSSION

Facial and meridional isomers

For the bidentate ligands studied here, the two oxygen atoms are non-equivalent and thus there is the possibility of meridional and facial isomers, each of which is enantiomeric. In the facial isomer the ligands are equivalent but in the meridional isomer they are all different. The meridional facial (*mer*/*fac*) isomer ratio expected at equilibrium, on a purely statistical basis, is 3 : 1. This is simply the probability expected due to the three possible meridional and one facial isomers. The ratio was observed for complexes derived from a number of the ligands, e.g. malH, hmpH, dmpH and empH.

With the $[Si(dmp)_3]^+$ ion, interconversion of *mer* and *fac* isomers was comparatively slow and partial separation by crystallization could be achieved (Fig. 1). For the $[Si(hmq)_3]^+$ ion, the equilibrium was non-statistical with a *mer*/*fac* ratio of *ca* 1.1 (Fig. 2). Detailed mechanistic studies[8] on similar $M(L—L')_3$ systems reveal the diverse rearrangement mechanisms possible, however, the cause of such large magnetic inequivalence of these isomers was not explained. We attribute the large chemical shift differences to long-range shielding effects, i.e. in the $[Si(hmq)_3]^+$ ion the large magnetic inequivalence is caused by the ring currents produced in the large asymmetric quinaldine ligand. The preference for a particular isomer in solution is rarely observed for $M(L—L')_3$ type complexes. The non-statistical isomer distribution observed may arise from O—Si d_π-p_π interaction. The silicon(IV) cation has empty 3*d* orbitals which are available for d_π donation from the filled p_π orbitals of the oxygen atoms. The higher donor capacity of the oxygen in N → O compared with C—O may be sufficient for the *fac* isomer (with no competing N → O donor orbitals on the same axis) to be stabilized relative to the *mer* isomers (which has one axis with two N → O donor orbitals competing for the same orbitals on the silicon atom).

Rate of meridional and facial isomerism

For the equilibrium: $fac \rightleftharpoons mer$,

$$K = \frac{[mer]}{[fac]} = \frac{k_1}{k_2}.$$

If we can assume first-order kinetics, then it can be deduced that:[9]

$$\log_e \frac{[fac]_0 - [fac]_{eqm}}{[fac]_t - [fac]_{eqm}} = (k_1 + k_2)t.$$

In the $[Si(dmp)_3]^+$ ion where a statistical distribution was observed, we also have $k_1 = 3k_2$. From the 270 MHz ^1H NMR intensity measurements, $k_1 = 2.1 \times 10^{-5}$ s^{-1} ($t_{1/2} = 9.2$ h) and $k_2 = 7.0 \times 10^{-6}\,s^{-1}$ ($t_{1/2} = 27.5$ h) (Fig. 3). Similarly, with the $[Si(hmq)_3]^+$ ion where a non-statistical distribution was observed, we have $k_1 = 1.1\ k_2$, which gives $k_1 = 1.1 \times 10^{-6}$ s^{-1} ($t_{1/2} = 184$ h) and $k_2 = 9.5 \times 10^{-7}\,s^{-1}$ ($t_{1/2} = 202$ h).

It is likely that the large differences in rates are associated with the different chelating ring sizes. This may be deduced from comparisons with the rates observed for tropolonato[10] and acac[11] complexes. The observations can be seen as effects caused by the steric bulk of the larger rings. Within the five-membered chelating rings, there is also the possibility of varying rates according to the stability of the complex. Therefore, the fast rate of isomerism [$k_1 = 1.8 \times 10^{-4}\,s^1$ ($t_{1/2} = 1$ h) and $k_2 = 6 \times 10^{-5}\,s^{-1}$ ($t_{1/2} = 3$ h)] observed for the easily hydrolysed $[Si(hmp)_3]^+$ ion is not unexpected.

^{29}Si NMR

The observed ^{29}Si chemical shifts are given in Table 1. It was shown by Cella *et al.*[12] that six-coordinate complexes of silicon give much more negative values of δ than do complexes in which the silicon is bound to four oxygen atoms only, and this is confirmed in the present work. In addition, for six-coordinate complexes with six-membered chelating rings, the ^{29}Si is much more shielded than in complexes with five-membered chelating rings. Within the five- or six-membered rings there is relatively little change in δ with various ligands. Two

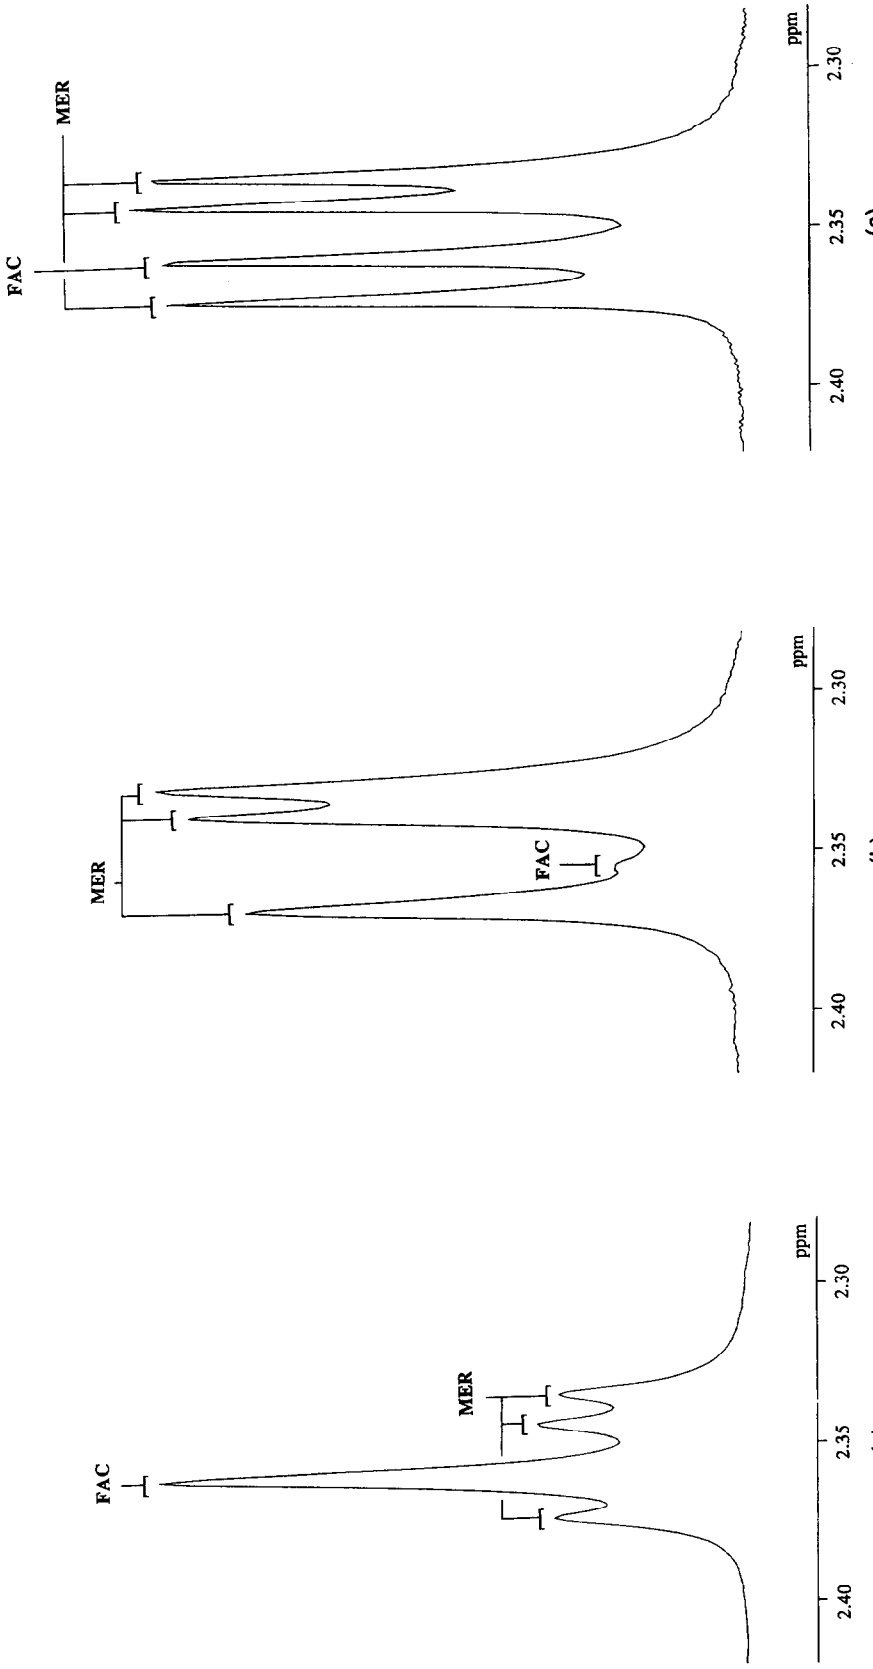

Fig. 1. ^{1}H NMR of 2-Me resonances in $[Si(dmp)_3]^+[Cl]^-$ (270 MHz, DMSO-d_6): (a) recrystallized from chloroform ~ 5 mins after dissolution; (b) recrystallized from ethanol/ether ~ 5 mins after dissolution; (c) solution (a) after 2 days at room temperature.

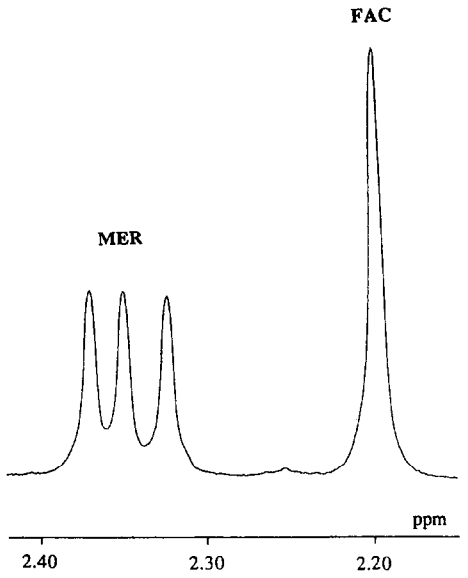

Fig. 2. ^{1}H NMR of 2-Me resonances in $[Si(hmq)_3]^+[CF_3SO_3]^-$ (270 MHz, DMSO-d_6).

^{29}Si resonances are observed for the complexes derived from malH, hqoH and hmqH. One possible explanation for this is the presence of *mer* and *fac* isomers.

Mass spectrometry

Table 2 shows the results of FAB^+ mass spectrometry. In all cases the parent $[SiL_3]^+$ ion is observed. Species corresponding to $[\{SiL_2\}-\{H\}]^+$ and $[SiL_2(OH)]^+$ were observed, the latter species are presumably formed by hydrolysis due to traces of water in the matrix.

CONCLUSIONS

Chelate ring size

The difference in chemical shifts between the five- (^{29}Si, $\delta = -130$ to -150 ppm) and six- (^{29}Si, $\delta = -190$ to -200 ppm) membered chelate rings have been previously reported.[12] Thus, this serves as a method for confirming the formation of six-coordinate silicon(IV) complexes. The important aspects of the ^{29}Si shifts appear to be the *dependence* on chelate ring size and the *independence* of the nature of the coordinating oxygens, overall charge of complex, and the nature of the counter ions. That is, the chemical shifts are dominated by the shielding effects associated with the symmetry around the silicon nucleus. This is in marked contrast to the pentacoordinated and tetracoordinated organosilicon compounds where symmetry is reduced and the nucleus is highly sensitive to the electronic properties of the substituents.[15]

Facial and meridional isomerism

From the above results we also observe a statistical distribution (in DMSO, $t_{1/2} \sim 10^0$–10^1 h) of *fac* and *mer* isomers with the five-membered chelate ring complexes, and non-statistical distribution (in DMSO, $t_{1/2} \sim 10^2$–10^3 h) of *fac* and *mer* isomers with six-membered chelate ring complexes. The difference in rates of isomerization is attributed to steric effects and the difference in isomer dis-

tribution is attributed to the electronic effects of the ligands.

Synthetic considerations

The new method of synthesis [eq. (1)] has proved to be a more convenient, economical and flexible method of preparing six-coordinate tris complexes of silicon. This was demonstrated using dhpH whose solubility is limited in chloroform, thus the complex could not be easily prepared otherwise. It also allows for the possibility of forming complexes with different anions. ^{29}Si NMR and FAB^+ mass spectroscopy provide an easy criterion to confirm formation of these six-coordinate silicon(IV) complexes.

Stability in aqueous media

Equilibrium studies of tris-catecholato silicon(IV) complexes have shown that for dinegative bidentate ligands, formation is favoured in alkaline conditions and electron-withdrawing groups on the ligand.[1]

For the mononegative bidentate ligands we have

$$Si(OH)_4 + 3LH + H^+ \rightleftharpoons SiL_3^+ + 4H_2O.$$

Hence formation of the complexes is favoured at low pH, and by electron-donating groups on the ligand. The only ligands of this type reported in the literature to form silicon(IV) complexes in aqueous solution are tropolones,[5,13] and even here the complexes are almost completely hydrolysed at pH values above *ca* 2.5. The synthesis of $[Si(emp)_3]^+[Cl]^-$ using conc. hydrochloric acid (35–38%) reflects the stability of the complex in aqueous solution. Equilibrium studies of 3-hydroxypyridin-4-ones are currently under investigation but initial results indicate that the complexes are stable at much greater pH values than those derived from tropolones. All other ligands studied here showed complete hydrolysis in acidic solution.

(*Received* 26 *November* 1990; *accepted* 20 *February* 1991)

Abstract—Ruthenium(III) complexes $[Ru(NH_3)_5L](PF_6)_3$ (L = 4-aminopyridine or 4-dimethylaminopyridine) and ruthenium(II) complexes $[Ru(NH_3)_5L](PF_6)_2$ (L = isonicotinamide or pyrazine) form adducts with 18-crown-6 ether in acetonitrile giving a blue shift of the LMCT band for the ruthenium(III) complex, a red shift of the MLCT band for the ruthenium(II) complex and a negative shift of the ruthenium(III)/ruthenium(II) redox potential for all the complexes.

Macrocyclic polyethers (crown ethers) are known to form stable adducts with a variety of transition metal complexes by virtue of multiple hydrogen bonding between the oxygen atoms of the crown ether and protic ligands such as ammonia or water at the primary coordination sphere of the complexes.[1] Such second-sphere coordination may bring about a change in the microenvironment of the metal complexes to modify their physicochemical properties. Microenvironmental change plays vital roles in biological processes.

So far many crown ether adducts of metal complexes have been obtained for inspection of the effects of second-sphere coordination upon the physicochemical properties of the complexes.[2–4] However, no marked changes in electronic spectra and electrochemical properties have been recognized for the aliphatic crown ether adducts, while an adduct formation of hexacyano complexes with polyammonium macrocycles caused a prominent change in the redox potential associated with the metal centre.[5] In this study we have examined electronic spectra and electrochemical properties of ruthenium(III) complexes $[Ru(NH_3)_5L](PF_6)_3$ [L = 4-aminopyridine (ampy) or 4-dimethylaminopyridine (dmapy)] and ruthenium(II) complexes $[Ru(NH_3)_5L](PF_6)_2$ [L = isonicotinamide (isn) or pyrazine (pz)] in the presence of 18-crown-6 ether (18C6) in acetonitrile and found that the second-sphere coordination of 18C6 caused a prominent effect both on electronic spectra and electrochemical properties of the ruthenium complexes.

EXPERIMENTAL

The ruthenium complexes were prepared by the literature methods.[6] Electronic absorption spectra in acetonitrile were recorded on a Hitachi 228 spectrophotometer at 25°C. Cyclic voltammograms in acetonitrile containing n-tetrabutylammonium hexafluorophosphate as the supporting electrolyte were obtained with a three-electrode cell, equipped with a glassy carbon working electrode, a $Ag/AgNO_3$ reference electrode, and a platinum coil as the auxiliary electrode. All measurements were performed in the dark.

RESULTS AND DISCUSSION

Ruthenium(III) complexes $[Ru(NH_3)_5(ampy)](PF_6)_3$ and $[Ru(NH_3)_5(dmapy)](PF_6)_3$ in acetonitrile show the ligand to metal charge-transfer (LMCT) band [transition from the ligand HOMO to the unfilled t_{2g} orbital of ruthenium(III)] at 516 and 598 nm, respectively. On adding 18C6, they shifted to 502 and 576 nm, respectively (see Fig. 1). The intraligand bands found in the region shorter than 300 nm for these ruthenium(III) complexes were practically unaffected by added 18C6, except for only a slight increase in the intensities of the bands.

Ruthenium(II) complexes $[Ru(NH_3)_5(pz)][(PF_6)_2$ and $[Ru(NH_3)_5(isn)](PF_6)_2$ in acetonitrile show the MLCT band [transition from the filled t_{2g} orbital of ruthenium(II) to the ligand LUMO] at 458 and 468 nm, respectively. On adding 18C6 to the solutions the metal to ligand charge-transfer (MLCT) band shifted to 462 and 472 nm, respectively. The intraligand transition bands found in the region shorter than 260 nm for those complexes were little affected by the addition of 18C6.

Such shifts of the LMCT band of the ruthenium(III) complexes and the MLCT band of the ruthenium(II) complexes may be attributed to second-sphere coordination of 18C6 to $[Ru(NH_3)_5L]^{n+}$ ($n = 2, 3$), through ammine-18C6 hydrogen bonding, as demonstrated for other ammine complex/crown ether adducts by the single crystal X-ray method.[2,3,7] It is noteworthy that the LMCT band of the ruthenium(III) complexes shifts toward shorter wavelength, while the MLCT band of the ruthenium(II) complexes shifts toward longer wavelength.

The spectral features observed above can be rationalized as follows. The second-sphere coordination of 18C6 to $[Ru(NH_3)_5L]^{n+}$ ($n = 2, 3$) stabilizes both ruthenium(III) and ruthenium(II) complexes. The ammine–18C6 interaction is expected to be stronger in ruthenium(III) complexes than ruthenium(II) complexes because the ammine proton becomes more acidic when coordinated to higher valent metal ion. Thus, for the ruthenium(III) complexes, the ground state is more stabilized relative to the charge-transfer states and causes a blue shift of the LMCT band, whereas for the ruthenium(II) complexes, the charge-transfer state is more stabilized relative to the ground state and causes a red shift of the MLCT band (Fig. 2).

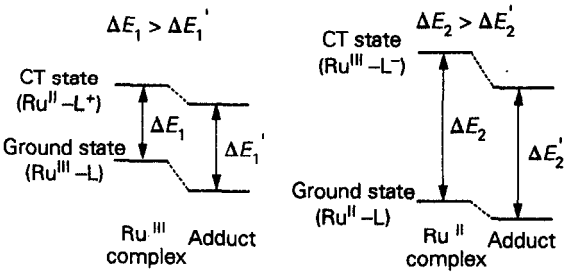

Fig. 2. Schematic energy level diagrams of the ground state and the charge-transfer state for ruthenium(III) and ruthenium(II) complexes and their adducts.

If this is indeed the case, the second-sphere coordination of 18C6 to $[Ru(NH_3)_5L]^{n+}$ ($n = 2, 3$) may also affect the ruthenium(III)/ruthenium(II) redox process. Electrochemical properties of $[Ru(NH_3)_5L]^{n+}$ ($n = 2, 3$) in the absence and presence of 18C6 were investigated by means of cyclic voltammetry. Typical cyclic voltammograms are given in Fig. 3. All the complexes show a

$[Ru(NH_3)_5(pz)](PF_6)_2$	0.225 (60)	0.103 (65)	−122
$[Ru(NH_3)_5(ampy)](PF_6)_3$	−0.125 (60)	−0.255 (60)	−130
$[Ru(NH_3)_5(dmapy)](PF_6)_3$	−0.140 (60)	−0.265 (60)	−125

The $E_{1/2}$ values are taken as the average of the cathodic and anodic peak potentials. The values in parentheses are the peak separations in millivolts.

reversible redox couple attributable to the ruthenium(III)/ruthenium(II) redox process.[8] As seen in Fig. 3, the addition of 18C6 gives rise to a negative shift of the redox couple. The shift was found to be *ca* −130 mV irrespective of the nature of L. The electrochemical results are summarized in Table 1. The electrochemical features observed for the $[Ru(NH_3)_5L]^{n+}$/18C6 system is also compatible with the above discussion; i.e. 18C6 stabilizes the ruthenium(III) complexes more strongly than the ruthenium(II) complexes, so that the half-wave potentials shift cathodically, irrespective of the value of $E_{1/2}$.

The present study demonstrates that the second-sphere coordination of aliphatic crown ethers can significantly affect the spectral and electrochemical properties of ammine complexes. Detailed studies along these lines are in progress.

INTRODUCTION

There has been much recent research activity in the area of organo- and transition metal silicon, germanium and tin chemistry. In particular, there have been a number of reports of the synthesis of discrete, molecular homopolyatomic molecules, as well as, new synthetic routes to oligomers and polymers. The isolation and characterization of Group 14 species with new and unexpected geometries are extending our understanding of structure, bonding and reactivity.

It is the purpose of this Polyhedron Symposium-in-Print to bring together contributions on a variety of different, important aspects of recent developments in homopolyatomic and related silicon, germanium and tin chemistry. Areas that have been covered include new synthetic routes to polysilanes, transition metal substituted Group 14 derivatives, the electronic structure and properties of homo-oligomers and -polymers of the Group 14 elements, the chemistry of transition metal substituted silylenes (silanediyls), and the chemistry of carbene analogues.

I am indebted to the authors for their contributions to this issue, the reviewers for their comments and Ms Sheryl Fellows of Pergamon Press.

SILICON COMPOUNDS WITH STRONG INTRAMOLECULAR STERIC INTERACTIONS—XLIII.* FORMATION AND MOLECULAR STRUCTURES OF TWO ISOMERIC DISILACYCLOBUTANEDIIMINES

MANFRED WEIDENBRUCH,† BRIGITTE BRAND-ROTH, SIEGFRIED POHL and WOLFGANG SAAK

Fachbereich Chemie der Universität Oldenburg, Carl-von-Ossietzky-Strasse 9-11, D-2900 Oldenburg, F.R.G.

Abstract—In the presence of mesityl isocyanide (**7**) or 2,6-diisopropylphenyl isocyanide (**8**), photolysis of hexa-tert-butylcyclotrisilane (**1**) gives dark red crystals of N,N′-dimesityl-2,2,4,4-tetra-tert-butyl-2,4-disilacyclobutane-1,3-diimine (**9**) and violet crystals of N,N′-bis(2,6-diisopropylphenyl)-2,2,4,4-tetra-tert-butyl-2,4-disilacyclobutane-1,3-diimine (**10**), respectively. In the latter case small amounts of the isomeric N,N′-bis(2,6-diisopropylphenyl)-3,3,4,4-tetra-tert-butyl-3,4-disilacyclobutane-1,2-diimine (**11**) are also isolated as green crystals. The X-ray structure analysis of **10** shows that the ring atoms, and the exocyclic nitrogen atoms lie almost exactly in one plane. The two aryl groups are arranged *trans* to each other. The X-ray structure of the ring **11**, however, reveals a folded C_2Si_2 framework with the exocyclic nitrogen atoms being orientated in opposite directions. The aryl groups adopt the *syn*, *anti* conformation.

Despite the great progress made in recent years in the area of unsaturated silicon compounds,[2] stable molecules containing silicon as part of a cumulated double-bond system have not yet been reported.

In 1988, Arrington *et al.*,[3] as well as Pearsell and West,[4] investigated the reactions of silylenes with carbon monoxide in matrices. Reaction of dimethylsilylene was claimed to form a planar silaketene,[3] whereas in the case of the dimesitylsilylene addition product both the electronic spectra and the formation of disilenes on thawing of the matrix indicate that Lewis acid–base adducts of non-planar geometry are formed between the silylene and carbon monoxide.[4] This is corroborated by theoretical calculations[5] which predict an appreciably lower energy of the non-planar form.

Recently, we investigated the photolysis of hexa-tert-butylcyclotrisilane (**1**)[6] in the presence of phenyl isocyanide and isolated ruby-red crystals of N,N′-diphenyl-2,2,4,4-tetra-tert-butylcyclobutane-1,3-diimine (**5**).[7] It is well known that **1**, under photolytic conditions, gives di-tert-butylsilylene (**2**) and tetra-tert-butyldisilene (**3**), both of which can be trapped by various addition reactions.[8] Therefore, we suggested that the reaction is initiated by an addition reaction between **2** and phenyl isocyanide to give a silaketenimine or a Lewis acid–base product of type **4**, which then dimerizes to the isolated **5** (Scheme 1).

To verify that **5** results from dimerization of the suggested silaketenimine and not from a two-fold addition of the phenyl isocyanide to the disilene **3**, we allowed **1** to react with 2,4,6-tri-tert-butylphenyl isocyanide, whose bulky *ortho*-tert-butyl groups should disfavour both cyclodimerization and insertion into the Si—Si bond of a possible disilacyclopropanimine[9] intermediate.

In fact, a monomeric compound consisting of **2** and the aryl isocyanide in a ratio of 1 : 1 was isolated. The spectroscopic data indicated, however, that the expected intermediate of type **4** had rearranged to the trialkylsilyl cyanide **6**.[7]

To determine whether **6** might result from the reaction of **2** with the corresponding isocyanide, or whether it is formed from a precursor of type **5** via a CH activation of the *ortho*-tert-butyl groups, we now have carried out the photolysis of **1** in the presence of mesityl isocyanide (**7**) and of 2,6-diiso-

* For part XLII, see ref. 1.

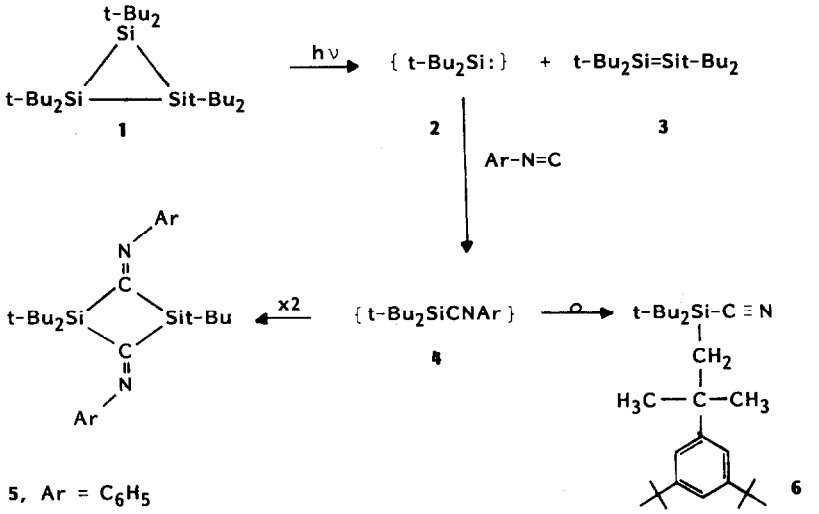


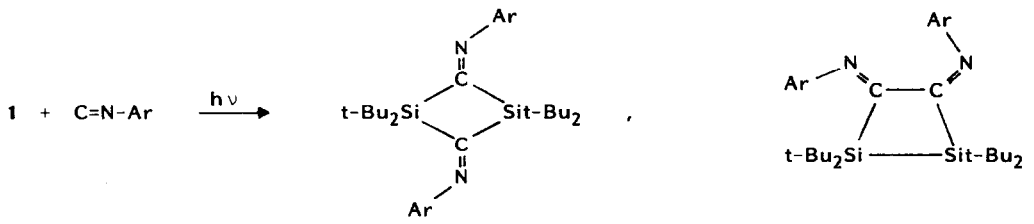
Scheme 1. Suggested mechanism of the addition reactions of aryl isocyanides with photolytically generated di-tert-butylsilylene (**2**).

propylphenyl isocyanide (**8**). These compounds also contain *ortho*-alkyl groups capable of undergoing isomerization reactions (Scheme 2).

Photolysis of **1** in the presence of **7** resulted in a red solution from which red crystals of the 2,4-disilacyclobutane-1,3-diimine (**9**) were isolated. Upon exposure to the ambient atmosphere, **9** decomposes, both in solution and in the solid state. Only a single set of signals is observed in both the ^{1}H and ^{13}C NMR spectra. This suggests that in solution either the barrier to *cis–trans* inversion at silicon is low, or that **9** has exclusively the *trans* geometry at silicon, as was detected for the phenyl analogue **5** in the solid state.[7]

Co-photolysis of **1** and the sterically more crowded isocyanide **8** yielded a dark green solution from which, upon cooling to −30°C, violet crystals of the four-membered cycle N,N′-bis(2,6-diisopropylphenyl)-2,2,4,4-tetra-tert-butyl-2,4-disilacyclobutane-1,3-diimine (**10**) were isolated. The structure of **10** was confirmed by ^{1}H, ^{13}C NMR and mass spectroscopic analyses and also by an X-ray diffraction study (Fig. 1, Table 1). Compound **10** crystallizes with two independent molecules each lying on a crystallographic inversion centre. The molecular geometry and atom numbering scheme for one of the molecules is illustrated in Fig. 1. Since they have the same basic features, the following discussion will refer to only one of the molecules.

The ring atoms and the exocyclic nitrogen atoms lie almost exactly in one plane. The two aryl groups are arranged *trans* to each other in the solid state. The planes of these aryl groups are strictly parallel to each other. The endocyclic as well as the exocyclic Si—C distances are significantly longer than a standard Si—C single bond length. They are com-



7, Ar = 2,4,6-$(CH_3)_3C_6H_2$ **9**, Ar = 2,4,6-$(CH_3)_3C_6H_2$ **11**, Ar = 2,6-$(i\text{-}C_3H_7)_2C_6H_3$

8, Ar = 2,6-$(i\text{-}C_3H_7)_2C_6H_3$ **10**, Ar = 2,6-$(i\text{-}C_3H_7)_2C_6H_3$

Scheme 2. Photolysis of **1** in the presence of *ortho*-disubstituted aryl isocyanides.

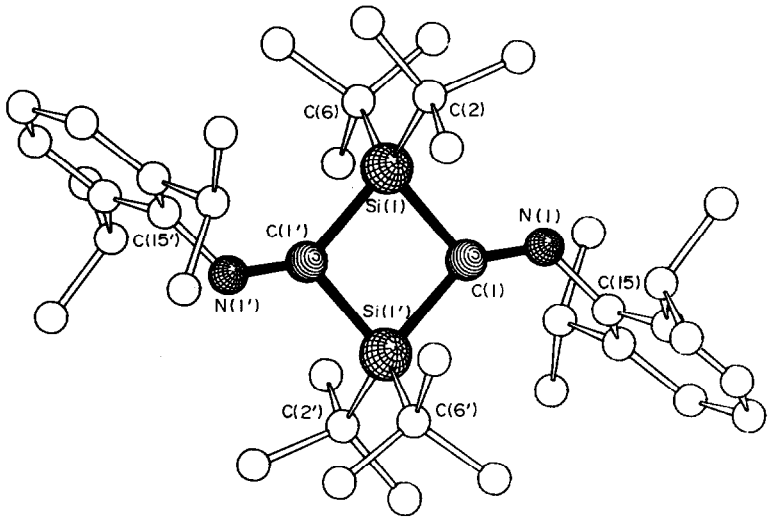


Fig. 1. The molecular structure and atom numbering scheme for crystalline **10** (hydrogen atoms omitted). Only one of the two independent molecules is shown.

parable with the Si—C bond lengths of some sterically crowded 2,4-disilacyclobutanes prepared by Brook and co-workers.[10]

The most striking feature of **10** is its violet colour, which is reflected in the longest wavelength absorption at $\lambda_{max} = 560$ nm. The same absorption lies at 510 nm for a disilacyclopropanimine derivative[9] and at 520 nm for the four-membered ring **5**.[7] The observed red shift of **10** seems to correspond with an increase of ring strain within this series of compounds. This rationalization was recently proposed by West and co-workers[9] in order to explain the bright red colour of the disilacyclopropanimine.[9]

Upon prolonged cooling of the photolysis mixture to −30°C, a minor amount of green crystals was also isolated. The spectroscopic data contribute very little to an elucidation of the structure of these green crystals. The mass spectrum, for example, only shows signals which may be attributed to a disilacyclopropanimine ring system. Therefore, the evidence for the structure of **11** rests ultimately on single-crystal X-ray diffraction data (Fig. 2, Table 2).

The X-ray structure analysis shows that **11** is an isomer of **10** with the imino groups being in the 1,2-position. Contrary to **10**, the Si_2C_2 ring framework is slightly puckered with an interplanar angle of *ca* 26° between the planes formed by the atoms Si(1)—Si(2)—C(1) and Si(2)—C(1)—C(2). The two exocyclic nitrogen atoms are *ca* 0.5 Å above and *ca* −0.65 Å below the mean plane through the ring atoms. The aryl groups adopt a *syn, anti* conformation, with the rings rotated at *ca* 90° against one another. The observed conformation of **11** and the stretching of the Si—Si and Si—C bonds may relieve the sterical strain within this molecule.

These results seem to confirm the mechanism proposed for the formation of **5** and **6** (Scheme 1).

The numbers marked with primes indicate symmetry equivalent atoms.

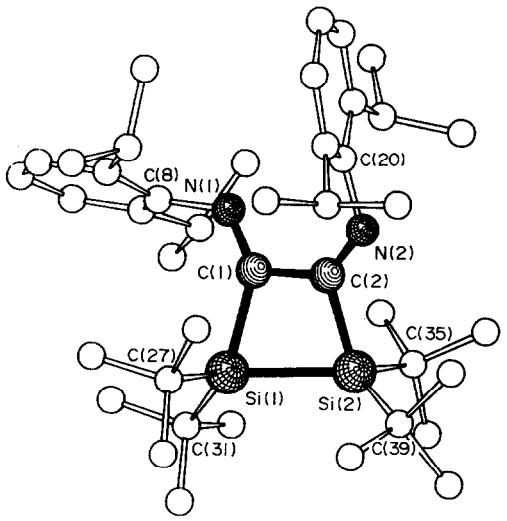

Fig. 2. The molecular structure and atom numbering scheme for crystalline **11** (hydrogen atoms omitted).

Since both **10** and **11** are formed simultaneously in the photolysis reaction, it is possible that they arise from a common intermediate such as a silaketenimine of type **4**. Head-to-tail dimerization then should give the four-membered ring **10**, whereas head-to-head dimerization should yield the isomer **11**. In the absence of trapping reagents some short-lived silaethylenes[13] and silapropadienes[14] bearing bulky substituents also undergo head-to-head dimerizations yielding 3,4-disilacyclobutanes.

Compounds **10** and **11** could also result from reaction of the aryl isocyanide **8** with an intermediate disilacyclopropanimine[9] derivative. However, such insertion reactions of isocyanides into Si—Si single bonds only take place in the presence of a palladium catalyst[15] and should, in this case, be further impaired by the bulky substituents.

EXPERIMENTAL

Materials, measurements and techniques

All reactions were carried out in oven-dried glassware under an atmosphere of dry argon or nitrogen. Photolyses were carried out by using a high pressure mercury lamp (Heraeus TQ 150) which was immersed in the reaction vessel.

The isocyanides **7** and **8** were prepared by the phosgene method[12] from N-(2,4,6-trimethylphenyl)formamide[11] or N-(2,6-diisopropylphenyl) formamide,[11] respectively.

NMR spectra were recorded on a Bruker AM 300 (^{1}H, ^{13}C) or Bruker WP 250 (^{29}Si) spectrometer using deuterated benzene as solvent. IR spectra were recorded on a Beckman 4220 instrument, and mass spectra were recorded by using a Varian-MAT 212 mass spectrometer. UV–vis spectra were recorded on a Shimadzu UV-260 spectrometer. Elemental analyses were performed by Analytische Laboratorien, D-5250 Engelskirchen, F.R.G.

N,N′ - Dimesityl - 2,2,4,4 - tetra - tert - butyl - 2,4 - disilacyclobutane - 1,3 - diimine (**9**)

A solution of **1** (0.436 g, 1.00 mmol) and **7** (0.43 g, 3.00 mmol) in n-hexane (60 cm^3) was photolysed for 5 h. The bright red solution was then cooled to −30°C for several days. After this time red crystals of **9** (0.13 g, 45%), m.p. 224–226°C, had precipitated. ^{1}H NMR : δ 1.19 (s, 36H, t-Bu), 2.13 (s, 6H, *p*-Me), 2.31 (s, 12H, *o*-Me), 6.80 (s, 4H, C_6H_2); ^{13}C NMR : δ 19.75, 20.76, 24.95, 31.42, 124.52, 129.23, 132.61, 156.58, 226.26 (C=N); MS (EI, 70 eV): *m/z* 574 (2, M^+), 429 (36, M^+ − MesNC); IR (KBr): ν(C=N) at 1565(w) and 1550(w) cm^{-1}. N,N'-Bis(2,6-diisopropylphenyl)-2,2,4,4-tetra-tert-butyl-2,4-disilacyclobutane-1,3-diimine (**10**) *and N,N'-bis(2,6-diisopropylphenyl)-3,3,4,4-tetra-tert-butyl-3,4-disilacyclobutane-1,2-diimine* (**11**)

A solution of **1** (0.426 g, 1.00 mmol) and **8** (0.56 g, 3.00 mmol) in petroleum ether, 40–60°C (60 cm^3), was co-photolysed for 1.5 h. The solvent was removed and the residue was recrystallized from n-pentane. The dark green solution was cooled to −30°C for several days. After this time violet crystals of **10** (0.25 g, 76%), m.p. 185°C (decomp.), had precipitated. ^{1}H NMR: δ 1.18 (s, 36H, t-Bu), 1.28 (d, 12H, CH_3), 1.35 (d, 12H, CH_3), 3.37 [sept., 4H, $CH(CH_3)_2$, $J = 6.7$ Hz], 7.05 (t, 2H), 7.15 (d, 4H, $J = 7.7$ Hz); ^{13}C NMR: δ 20.27, 24.22, 25.19, 28.88, 31.42, 122.40, 124.42, 134.73, 156.49, 226.97 (C=N); ^{29}Si NMR: δ 1.68; MS (EI, 70 eV): *m/z* 658 (1, M^+), 471 (15, $M^+ - ArNC$); UV–vis: $\lambda(\varepsilon)$ 226 (25,000), 272 (12,000), 480 (350), 560 (230). Found: C, 76.4; H, 10.6; N, 4.2. Calc. for $C_{42}H_{70}N_2Si_2$: (658.29): C, 75.6; H, 10.7; N, 4.2%.

Upon prolonged cooling to −30°C a minor amount of green crystals of **11** was also isolated. ^{1}H NMR: δ 1.27 (s, 36H), 1.44 (not resolved, 24H, CH_3), 3.11 [not resolved, 4H, $CH(CH_3)_2$], 6.97–7.10 (not resolved, 6H); ^{13}C NMR: δ 24.36, 26.82, 28.76, 31.18, 32.37 (broad), 34.70, 122.20, 123.98, 145.15, 149.86, C=N could not be detected; MS (EI, 70 eV): *m/z* 471 (31, $M^+ - ArNC$); UV–vis: $\lambda(\varepsilon)$ 417, 613 (ε values could not be determined).

X-ray structure analyses of **10** *and* **11**

Slow cooling of the photolysis mixture in petroleum ether to −30°C resulted in crystals of **10** and **11** suitable for X-ray diffraction. In each case, the crystal was mounted in a thin-walled glass capillary. Data collection was performed on a Siemens AED 2 diffractometer using graphite-monochromated Mo-K_α radiation. Significant crystal data and data collection parameters are listed in Table 3.

The structures were solved by direct phase determinations using the SHELX 86 program system

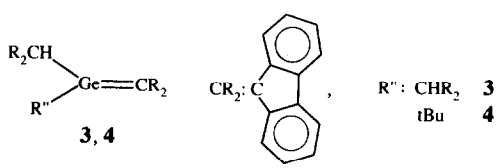
Abstract—Two new stable fluorenylidene germenes **5** and **6** substituted on germanium with two bulky bisyls $[(Me_3Si)_2CH]$ or with a bisyl and a mesityl group have been synthesized by dehydrofluorination of the corresponding fluorogermanes by tert-butyllithium. The ditert-butylfluorenylidene germene **7** could not be obtained by this route, but its lithio precursor **8** can be used as its synthetic equivalent.

Alkenes are among the most important compounds in organic synthesis. Their heavier homologues should also be very useful, both as precursors of potentially interesting new kinds of polymers (such polymers including a Group 14 metal could present new and unexpected mechanical or electrical properties) and in organometallic synthesis. So the study of the compounds M=C (M = Si, Ge, Sn) appears very promising.

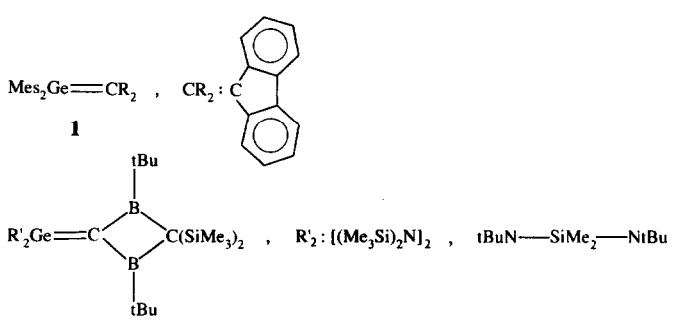
Some years ago, evidence for the formation of transient germenes (M = Ge) was presented by trapping reactions.[1,2] The first examples of stable germenes **1**[3,4] and **2**[5,6] were reported as recently as 1987. Both compounds are stabilized owing to steric (bulky groups on germanium, and to a small extent on carbon) and electronic effects, involving mesomerism between the germanium–carbon double bond and the fluorenylidene group in the case of **1**,[3,4] or delocalization in the free orbital of boron with an ylide type structure in the case of **2**.[5,6]

Very recently we have been able to stabilize two other compounds with a Ge=C double bond, the fluorenylidene germenes **3** and **4**:[7]



3, 4

The great interest of sterically hindered germenes is the stabilization of cycloadduct derivatives which are normally inaccessible. However,



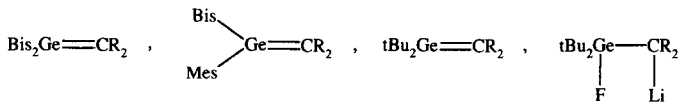
1 **2**

* Authors to whom correspondence should be addressed.

although substituted with two bulky mesityl groups, $Mes_2Ge{=}N{-}N{=}CR'_2$ ($CR'_2 = CR_2$, CPh_2) (obtained by reaction of **1** with diazofluorene or diphenyldiazomethane) could not be stabilized. Very few stable germa-imines have been reported,[9] and their chemical behaviour is not well developed. Also germirane, $Mes_2Ge{-}CH_2{-}CR_2$[10] (obtained from **1** and diazomethane), is unstable but would be of great interest in organometallic synthesis.

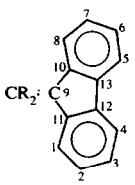
So we thought that such interesting but labile species (as well as germanones, Ge=O, and germathiones, Ge=S, which have been invoked in some reactions from **1**) could be rendered kinetically inert by substituting the germanium starting materials with more sterically demanding ligands.

We report here the synthesis of the new fluorenylidene germenes, substituted on germanium by two very large bis(trimethylsilyl)methyl (bisyl) groups **5**, and with one mesityl and one bisyl on germanium, **6**. In **6** steric hindrance should be intermediate between that observed for **1** and **5**. Moreover, owing to the prochiral germanium, **6** could be useful in mechanistic and stereochemical studies. We report also the attempted synthesis of ditert-butylfluorenylidene germene **7** and the use of the lithio compound **8** as its synthetic equivalent.



5 **6** **7** **8**

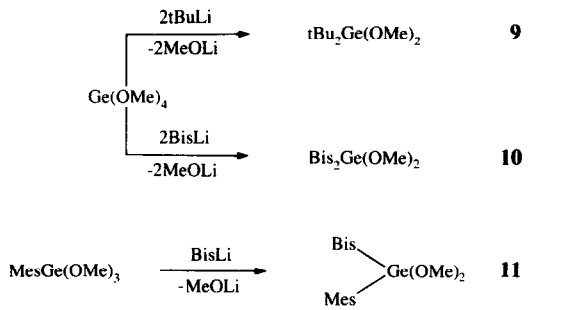
Bis: $(Me_3Si)_2CH$



RESULTS AND DISCUSSION

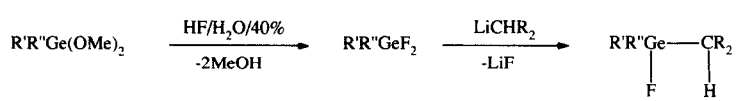
Synthesis of fluorofluorenylgermanes (**15**)–(**17**)

Following our synthesis of germene **1**,[3,4] it appeared that the most convenient route to germenes $R'R''Ge{=}CR_2$ (**5**)–(**7**) would be the dehydrofluorination of fluorogermanes $R'R''Ge(F)CHR_2$ by tert-butyllithium ($R'R'' = tBu_2$, Bis_2, BisMes; CR_2 = fluorenyl). The use of fluorine instead of other halogens eliminates some side reactions, such as direct alkylation of germanium by lithio compounds and lithium–halogen exchange. The first step in the synthesis of **15**–**17** involves the preliminary preparation of dimethoxygermane derivatives **9**–**11**, which are obtained in good yields from tetramethoxygermane[11] and tert-butyllithium or bisyllithium, or from mesityltrimethoxygermane[12] and bisyllithium:



Bis=bisyl: $(Me_3Si)_2CH$

The corresponding difluoro derivatives **12**–**14** are nearly quantitatively obtained by treatment of **9**–**11** with solutions of hydrofluoric acid in water; then addition of fluorenyllithium leads to the fluorofluorenylgermanes **15**–**17**, which are the immediate precursors of germenes **5**–**7**:



R'R'':			
tBu_2	**9**	**12**	**15**
Bis_2	**10**	**13**	**16**
BisMes	**11**	**14**	**17**

Compounds **9–17** could be easily purified by crystallization and exhibit good air and moisture stability, probably because of the large steric hindrance at germanium.

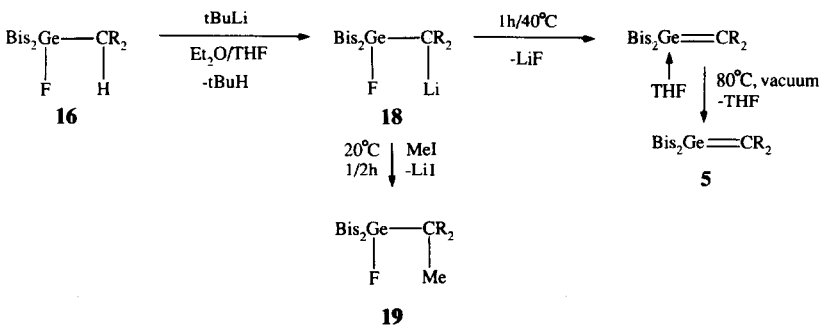
Dibisyl(fluorenylidene)germene (**5**)

The formation of germene **5** is extremely dependent on the experimental conditions. The best yield of **5** is obtained by using a 50:50 mixture of THF/Et_2O as solvent and an excess of tert-butyllithium (1.7 equivalent), required due to the reaction of tert-butyllithium with THF[13] during the lithiation of fluorogermane **16** to afford the lithio compound **18**. Contrary to the species $Mes_2Ge(F)CHR_2$, which on reaction with tert-butyllithium gives the corresponding lithio compound at low temperature, **18** is obtained only after 1 h at room temperature. This low reactivity of **16** compared with its dimesityl analogue could be explained both by steric hindrance and electronic effects.

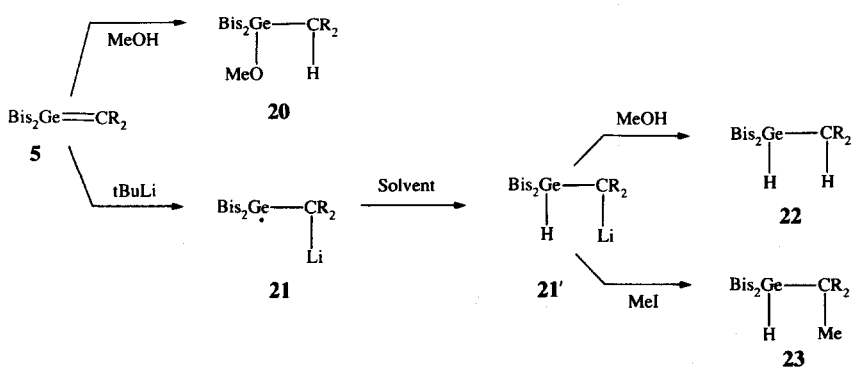
Lithio compound **18** is stable to the reaction conditions and when quenched with methyl iodide affords, nearly quantitatively, the corresponding germane **19** after 1 h at room temperature. Elimination of lithium fluoride produces the expected germene, **5**, only after heating for 1 h at 40°C.

The solutions of germene **5** are highly air and moisture sensitive and they immediately turn from orange to green in the presence of traces of oxygen. Compound **5** can be obtained in pure form and physicochemically characterized by ^1H and ^{13}C NMR. However, it has not been possible to assign with certainty the ^{13}C NMR resonance of the carbon doubly-bonded to germanium. This carbon was expected in the chemical shift region of the fluorenyl carbon atoms and might be small, either because of its long relaxation time or due to quadrupolar coupling with germanium.

The presence of the germanium–carbon double bond is chemically unambiguously proven by addition of MeOH to afford the corresponding methoxygermane **20**, as expected from the polarity $Ge^{\delta+}=C^{\delta-}$ of the double bond. Addition of tert-butyllithium to **5**, followed by quenching with MeOH or methyl iodide, respectively, leads to germanes **22** and **23**. The reaction is best explained by a single-electron transfer mechanism involving the intermediates **21** and **21′**, because it seems that the addition of tert-butyllithium across the double bond is unlikely due to the high steric hindrance on germanium.



Using Et_2O instead of a mixture of THF/Et_2O in the synthesis of **5** from **16**, gives this germene in poor yield (*ca* 20–25%): addition of tert-butyllithium to **16**, in Et_2O, followed by quenching with MeOH, affords **20**, germane **22** and starting



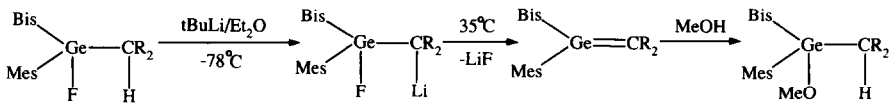
Germene **5** is first obtained complexed with one molecule of THF, but free germene is easily synthesized by heating **5 · THF** at about 80°C *in vacuo*.

material **16**, in about the same ratio. This result can be explained by the slow formation of lithio compound **18**, followed by a rapid elimination of LiF to give germene **5** (in Et_2O, **18** is much less stabilized than in THF). Compound **5** may then react with tert-butyllithium, according to the single-electron transfer mechanism previously described.

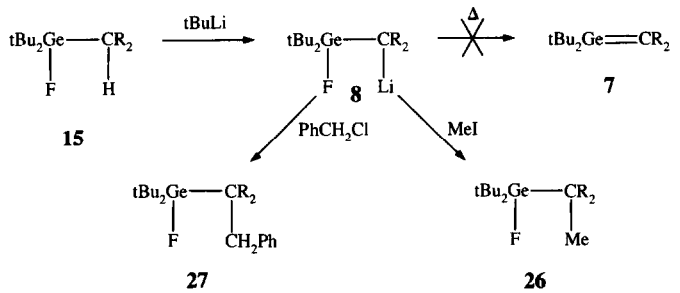
Bisyl(mesityl)fluorenylidenegermene (**6**)

Germene **6** is obtained in a good yield by dehydrofluorination of fluorogermane **17** by tert-butyllithium in Et_2O. Addition of tert-butyllithium was performed at low temperature, and the lithio compound **24** was formed rapidly. Contrary to the case of **18**, THF was not necessary.

Methanolysis immediately after the reaction mixture has reached room temperature affords methoxygermane **25** and starting fluorogermane **17** in the ratio 30:70, indicating only partial elimination of lithium fluoride. The complete elimination occurred only after heating the lithio compound **24** for 0.5 h at 35°C. Under these conditions, addition of MeOH to germene **6** leads quantitatively to formation of **25**:



17 **24** **6** **25**



15 **7** **27** **26**

As for germene **5**, orange solutions of **6** are highly air- and moisture-sensitive, but crystals can be handled in air for short periods. In nitrogen or argon atmosphere, **6**, like **5**, is stable and can be stored for long periods.

Germenes **5** and **6** can be isolated as Et_2O or THF adducts, but also free of complexing solvents. The same phenomenon exists in silicon chemistry: silenes $\rangle Si{=}C\langle$,[14] and sila-imines $\rangle Si{=}N{-}$,[15] have already been isolated as ether or amine adducts, and also as free compounds. This complexation is, of course, due to the polarity of Si=C or Si=N double bonds. In contrast, analogous adducts have never been observed in symmetrical doubly-bonded derivatives such as disilenes,[16] digermenes,[2] distannenes,[17] diphosphenes,[18] or in unsymmetrical sila-,[19] germa-[12,20] or stannaphosphenes,[21] in which the double bond is only slightly polarized and the metal has a weaker electrophilic character.

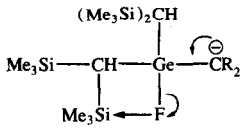
The study of the reactivity of **6** with various unsaturated compounds is now in progress.

Attempted synthesis of ditert-butyl(fluorenylidene) germene (**7**)

Addition of one equivalent of tert-butyllithium to the ditert-butyl(fluoro)fluorenylgermane **15** leads exclusively to the corresponding lithio derivative **8**. Attempts to eliminate lithium fluoride, by using various solvents (Et_2O, THF, pentane) or by thermolysis, were unsuccessful. Formation of **8** is proved by its reaction with methyl iodide or benzyl chloride, leading quantitatively to **26** and **27**:

Therefore, there is a great difference of stability of fluorogermyllithio derivatives, Ge(F)—C(Li), depending on the substituents on germanium: with one or two aryl groups (mesityl,[3] fluorenyl[7]) lithium fluoride is easily eliminated at low temperature, whereas with two alkyl groups such as tert-butyl this elimination did not occur. A rather similar phenomenon has been observed in the synthesis of germaphosphenes, $\rangle Ge{=}P{-}$, in which elimination of lithium fluoride is much easier for Mes_2Ge

(F)P(Li)Ar than for $tBu_2Ge(F)P(Li)Ar$[12] (*ca* −40°C instead of 24 h at room temperature). The easy formation of dibisylgermene **5** from its lithio fluoro precursor **18** could be partly due to the electrophilic assistance of silicon by interaction with fluorine:



However, lithio compound **8** can be considered to some extent as a synthetic equivalent of germene **7**. For example, addition of benzaldehyde to **8** leads to the three derivatives **28**, **29** and **30** which have been obtained in a pure form by fractional crystallization. Formation of **28** and **29** involves the preliminary formation of the four-membered ring germaoxetane **31**, followed by a [4] → [2+2] cycloreversion, and dimerization of the germanone intermediate **32**. The formation of the six-membered ring derivative **30** can be explained by insertion of the germanone **32** into the germanium–oxygen bond of the germaoxetane intermediate **31**. This reaction is additional proof of the initial formation of this heterocycle.

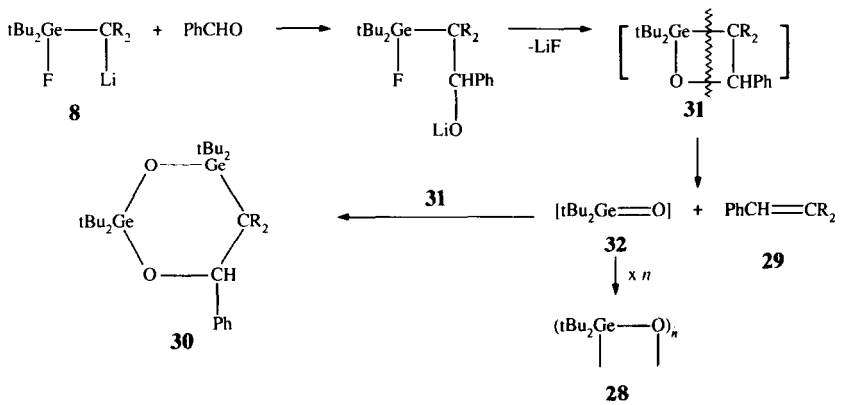
EXPERIMENTAL

General procedures

All the experiments were carried out under argon or nitrogen with flame-dried apparatus. Solvents must be freshly distilled over sodium/benzophenone. ^1H NMR spectra were recorded on a Bruker AC 80 at 80.13 MHz or on a Bruker AM 300 WB at 300.1 MHz; ^{13}C NMR spectra on a Bruker AC 200 at 50.3 MHz (TMS internal standard); and ^{19}F NMR spectra on a Bruker AM 300 WB at 282.4 MHz (CF_3COOH external standard). IR spectra were recorded on a Perkin–Elmer 457 grating spectrometer. Mass spectra were measured on a Nermag R 10 010 spectrometer (EI). Melting points were determined on a Reichert apparatus. Elemental analyses were performed by the "Service de microanalyse de l'Ecole de Chimie", Toulouse (France). Carbon atoms of fluorenyl groups are numbered C_1 to C_{13} according to the scheme shown in the introduction.

Dibisyl(dimethoxy)germane (**10**)

A solution of bis(trimethylsilyl)methyllithium [prepared from bis(trimethylsilyl)bromomethane[22]



CONCLUSION

The germenes **5** and **6** and the lithio derivative **8** described in this paper present a particular interest for the following reasons. Compound **5**, the most hindered germene isolated to date, may stabilize otherwise unstable adducts or low coordination number species. Studies of its chemistry are now in progress. Compound **6** is the first example of germene with a prochiral germanium atom suitable for stereochemical studies at the Ge=C double bond and **8** can be used as a synthetic equivalent of the ditert-butylfluorenylidene germene **7**.

(16.8 g, 70 mmol) and 44 cm^3 of a solution 1.6 M of butyllithium in hexane] in Et_2O (50 cm^3) was added to a solution of tetramethoxygermane (6.6 g, 33.3 mmol) in Et_2O (20 cm^3). After the end of the addition, the reaction mixture was refluxed for 4 h. MeOLi was eliminated by filtration; **10** can be recrystallized in small amounts of pentane at −20°C: 9.19 g (61%); m.p. 55°C. ^1H NMR (C_6D_6): 0.22 (s, 36H, Me_3Si), 1.82 (s, 6H, OMe). ^{13}C NMR ($CDCl_3$): 3.31 (Me_3Si), 12.03 (CHSi), 52.42 (OMe).

Dibisyl(difluoro)germane (**13**)

To a solution of **10** (8.6 g, 18.9 mmol) in Et_2O (100 cm^3) was added a solution of hydrofluoric acid in water (40%, 5.5 g, 50% excess). The reaction was slightly exothermic. The reaction mixture was heated at reflux of Et_2O for 4 h, then the organic layer was extracted with Et_2O and dried overnight over Na_2SO_4. Removal of solvent *in vacuo* led to crude **13** which can be recrystallized from pentane to afford 6.16 g (76%) of white crystals; m.p. 59°C. ^1H NMR (C_6D_6): 0.18 (s, Me_3Si). ^{19}F NMR (C_6D_6): −58.05 (t, $^3J_{HF}$ 18.6 Hz). ^{13}C NMR ($CDCl_3$): 2.42 (Me_3Si), 14.24 (t, $^2J_{CF}$ 8.12 Hz, CHSi).

Dibisyl(fluoro)fluorenylgermane (**16**)

Fluorenyllithium was prepared by addition of a solution 1.6 M of butyllithium in hexane (11.3 cm^3, 18.0 mmol) to a solution of fluorene (3.0 g, 18.0 mmol) in a 50:50 mixture of THF/Et_2O (100 cm^3). The lithio compound was stirred for 1 h at room temperature, then this red solution was slowly added to a solution of **13** (7.75 g, 18.0 mmol) in Et_2O (50 cm^3) at room temperature. The reaction mixture was heated for 8 h at reflux, then filtered through silica (eluent, THF). The volatile components were removed *in vacuo* and crude **16** was recrystallized in pentane to afford 8.08 g (78%) of white crystals; m.p. 339°C. ^1H NMR (C_6D_6): 0.04 (d, $^5J_{HF}$ 0.3 Hz, 18H, Me_3Si), 0.18 (d, $^5J_{HF}$ 0.7 Hz, 18H, Me_3Si), 4.71 (broad s, 1H, CHR_2), 7.25–7.96 (m, 8H, CR_2). ^{19}F NMR ($CDCl_3$): −87.4. ^{13}C NMR ($CDCl_3$): 3.46 (Me_3Si), 4.04 (Me_3Si), 12.27 (d, $^2J_{CF}$ 12.8 Hz, CHSi), 47.73 (d, $^2J_{CF}$ 10.3 Hz, CHR_2), 120.17 (C_4, C_5), 125.87, 126.44, 126.57 (C_1, C_2, C_3, C_6, C_7, C_8), 141.42 (C_{12}, C_{13}), 143.45 (d, $^3J_{CF}$ 1.0 Hz, C_{10}, C_{11}). MS (EI, 70 eV, ^{74}Ge), *m/z*: 557 (M−F, 7), 411 (Bis_2GeF, 3), 393 (Bis_2Ge+1, 1), 165 (R_2CH, 70), 73 (Me_3Si, 100). Found: C, 56.6; H, 8.3. $C_{27}H_{47}FGeSi_4$ requires C, 56.3; H, 8.2.

Dibisylfluorenylgermane (**22**)

To a solution of **16** (2.00 g, 3.5 mmol) in Et_2O (30 cm^3), cooled in a dry ice–acetone, were added 2.7 molar equivalents of tert-butyllithium, 1.7 M in pentane. The reaction mixture was then warmed to room temperature and became an intense red. Addition of an excess of MeOH immediately decolorized the solution. Solvents were removed *in vacuo* and 20 cm^3 of pentane were added; lithium salts were filtered off, and crude **22** was recrystallized from pentane; 1.65 g (85%) of white crystals of **22** were obtained; m.p. 118–119°C. ^1H NMR ($CDCl_3$): −0.21 (d, $^3J_{HH}$ 3.0 Hz, 2H, CHSi), 0.01 (s, 18H, Me_3Si), 0.22 (s, 18H, Me_3Si), 4.52 (s, 1H, CHR_2), 4.75 (t, $^3J_{HH}$ 3.0 Hz, 1H, GeH), 7.18–7.55 (m, 8H, CR_2). ^{13}C NMR ($CDCl_3$): 1.08 (CHSi), 2.95 (Me_3Si), 3.40 (Me_3Si), 42.58 (CHR_2), 119.68 (C_4, C_5), 125.20, 125.59, 126.36 (C_1, C_2, C_3, C_6, C_7, C_8), 140.60 (C_{12}, C_{13}), 146.63 (C_{10}, C_{11}). IR (KBr): ν(Ge—H) 2068 and 2076 cm^{-1}. MS (EI, 70 eV, ^{74}Ge), *m/z*: 557 (M−1, 2), 543 (M−15, 10), 393 (Bis_2GeH, 100), 165 (CHR_2, 25).

Dibisylfluoro(methylfluorenyl)germane (**19**)

To a solution of **16** (0.50 g, 0.87 mmol) in THF (5 cm^3)–Et_2O (5 cm^3) was slowly added 1.7 equivalents of tert-butyllithium 1.7 M in pentane. The reaction mixture, warmed to 0°C, turned gradually yellow. After 1/2 h stirring at 0°C, MeI (0.12 g, 0.87 mmol) was added. After 1 h at room temperature the reaction mixture was practically colourless; LiI was filtrated and solvents were removed *in vacuo*, and crude **19** was crystallized in pentane; 0.44 g of **19** (86%) were obtained; m.p. 112–113°C. ^1H NMR ($CDCl_3$): −0.16 (d, $^5J_{HF}$ 0.6 Hz, 18H, Me_3Si), 0.18 (d, $^5J_{HF}$ 0.9 Hz, 18H, Me_3Si), 1.77 (d, $^4J_{HF}$ 0.6 Hz, 3H, $MeCR_2$), 7.38–7.88 (m, 8H, CR_2). ^{13}C NMR ($CDCl_3$): 3.95 (Me_3Si), 4.31 (d, $^4J_{CF}$ 1.8 Hz, Me_3Si), 14.10 (d, $^2J_{CF}$ 13.1 Hz, $CHSi_2$), 25.40 (d, $^3J_{CF}$ 27 Hz, $MeCR_2$), 52.17 (d, $^2J_{CF}$ 12.6 Hz, CR_2), 120.25 (C_4, C_5), 125.00, 125.05, 126.93 (C_1, C_2, C_3, C_6, C_7, C_8), 140.61, 149.61 (C_{10}, C_{11}, C_{12}, C_{13}).

Dibisyl(fluorenylidene)germene (**5**)

To a solution of **16** (2.0 g, 3.48 mmol) in Et_2O/THF (50:50) (15 cm^3) cooled to −78°C were slowly added 3.48 cm^3 of a 1.7 M solution of tert-butyllithium in pentane (5.92 mmol). The reaction mixture was warmed to room temperature then heated at reflux for 1 h. A slight precipitate of LiF appeared and the reaction mixture turned orange-red. After elimination of LiF by filtration and of the solvents *in vacuo*, crystallization in pentane afforded orange crystals of germene **5** complexed with one mole of THF; the free germene **5** was obtained by heating **5·THF** *in vacuo* at 80°C; 1.53 g of orange crystals (79%) of **5** were obtained; m.p. 149–150°C. **5·THF**, ^1H NMR (CD_2Cl_2): 0.43 (s, 36H, Me_3Si), 1.87 (m, 4H, CH_2), 3.74 (m, 4H, CH_2O), 7.20–7.46 (m, 4H, CR_2), 7.79–8.00 (m, 4H, CR_2). **5**, ^1H NMR (C_6D_6): 0.46 (s, 36H, Me_3Si), 7.27–8.23 (m, 8H, CR_2).

Dibisyl(methylfluorenyl)germane (**23**)

Two molar equivalents of a solution 1.7 M of tert-butyllithium in pentane were added to a solution of **16** (2.00 g, 3.5 mmol) in Et_2O (30 cm^3) cooled to −78°C. The reaction mixture was then warmed to 20°C and became red; on the addition of a two-fold excess of methyl iodide, it turned gradually colourless. After 1 h stirring, solvents were eliminated *in vacuo* and 20 cm^3 of pentane were added to precipitate LiF and LiI. After filtration, cooling of the solution at −20°C gave white crystals of **23**, 1.20 g (60%); m.p. 160–161°C. ^1H ($CDCl_3$): −0.1 (s, 18H, Me_3Si), 0.14 (s, 18H, Me_3Si), 1.79 (s, 3H, MeC), 4.96 (t, $^3J_{HH}$ 1.5 Hz, 1H, GeH), 7.30–7.84 (m, 8H, CR_2). ^{13}C ($CDCl_3$): 3.51 (Me_3Si), 3.72 (Me_3Si), 4.51 (CHSi), 25.48 (*Me*C), 47.94 (*C*R_2), 120.24 (C_4, C_5), 124.13, 126.26, 126.74 (C_1, C_2, C_3, C_6, C_7, C_8), 139.97, 151.63 (C_{10}, C_{11}, C_{12}, C_{13}). IR (KBr): ν(Ge—H) 2056 cm^{-1}. MS (EI, 70 eV, ^{74}Ge), *m/z*: 557 (M−15, 2), 393 (Bis_2GeH, 35), 179 (R_2CMe, 59), 73 (Me_3Si, 100). Found: C, 59.1; H, 9.0. $C_{28}H_{50}GeSi_4$ requires: C, 58.8; H, 8.8.

Dibisyl(methoxy)fluorenylgermane (**20**)

To a solution of **16** (1.0 g, 1.74 mmol) in Et_2O (20 cm^3) and THF (20 cm^3) at −20°C was slowly added a solution of tert-butyllithium 1.7 M in pentane (1.02 cm^3, 1.74 mmol). The reaction mixture immediately turned light yellow and after 1 h was allowed to gradually warm; it turned orange (probably due to the formation of lithio compound). After 1 h at reflux, a three-fold excess of MeOH (0.15 g, 5.20 mmol) was added, to afford a light yellow solution. Solvents were removed *in vacuo* and 30 cm^3 of pentane were added to precipitate MeOLi. Crystallization from pentane afforded white crystals of **2**, 0.83 g (81%); m.p. 105–106°C. ^1H NMR ($CDCl_3$): −0.10 (s, 1H, CHSi), 0.04 (s, 18H, Me_3Si), 0.07 (s, 18H, Me_3Si), 3.74 (s, 3H, MeO), 4.61 (s, 1H, CHR_2), 7.29–7.91 (m, 8H, CR_2). ^{13}C NMR ($CDCl_3$): 1.10 (CHSi), 4.16 (Me_3Si), 4.34 (Me_3Si), 46.23 (*C*HR_2), 53.77 (MeO), 120.04 (C_4, C_5), 125.69, 126.05, 126.34 (C_1, C_2, C_3, C_6, C_7, C_8), 141.31, 144.48 (C_{10}, C_{11}, C_{12}, C_{13}).

Bisyl(mesityl)dimethoxygermane (**11**)

A solution of BisLi [prepared from BisBr (10 g, 41.7 mmol) and a stoichiometric amount of butyllithium 1.6 M in hexane at −78°C] in Et_2O was added to a solution of $MesGe(OMe)_3$ (11.85 g, 41.7 mmol) in pentane (40 cm^3) cooled to −78°C. After the addition the reaction mixture was allowed to warm to room temperature and then refluxed for 4 h. MeOLi was removed by filtration and the solvents were evaporated *in vacuo* leading to nearly pure waxy **11**, which is very soluble in common organic solvents and can be recrystallized from small amounts of pentane to give 17.17 g (91%) of white waxy crystals; m.p. 39°C. ^1H NMR (C_6D_6): 0.15 (s, 1H, CHSi), 0.33 (s, 18H, Me_3Si), 2.14 (s, 3H, *p*-Me), 2.62 (s, 6H, *o*-Me), 3.55 (s, 6H, OMe), 6.77 (s, 2H, arom. Mes). ^{13}C NMR ($CDCl_3$): 2.61 (Me_3Si), 10.50 (CHSi), 21.05 (*p*-Me), 22.73 (*o*-Me), 51.66 (OMe), 129.40 (*m*-C Mes), 131.33 (*ipso*-C Mes), 139.55 (*p*-C Mes), 143.56 (*o*-C Mes). Found: C, 52.6; H, 8.9. $C_{18}H_{36}GeO_2Si_2$ requires: C, 52.3; H, 8.8.

Bisyl(mesityl)difluorogermane (**14**)

A solution of hydrofluoric acid in water (40%, 4.0 g, 50% excess) was added to **11** (5.28 g, 12.8 mmol) in benzene (30 cm^3). The reaction mixture was heated at reflux for 2 h, then the organic layer was extracted with Et_2O and dried over Na_2SO_4. Solvents were removed *in vacuo* and **14** was recrystallized from pentane to afford 3.78 g (76%) of white crystals; m.p. 62–63°C. ^1H NMR (C_6D_6): 0.23 (s, 18H, Me_3Si), 1.99 (s, 3H, *p*-Me), 2.49 (s, 6H, *o*-Me), 6.62 (s, 2H, arom. Mes). ^{19}F NMR (C_6D_6): −61.9 (d, $^3J_{HF}$ 8.2 Hz). ^{13}C NMR ($CDCl_3$): 2.22 (s, Me_3Si), 13.79 (t, $^2J_{CF}$ 8.2 Hz, CH), 21.17 (s, *p*-Me), 23.30 (s, *o*-Me), 129.50 (s, *m*-C Mes), 141.50 (*p*-C Mes), 142.70 (*o*-C Mes). Found: C, 50.1; H, 7.8. $C_{16}H_{30}F_2GeSi_2$ requires: C, 49.4; H, 7.8.

Bisyl(mesityl)fluorenylgermane (**17**)

A solution of fluorenyllithium [prepared from fluorene (3.0 g, 18.0 mmol) and a solution of butyllithium 1.6 M in hexane (11.3 cm^3, 18.0 mmol) in 100 cm^3 of a 50:50 mixture of THF/Et_2O] was slowly added to a solution of **14** (6.99 g, 18.0 mmol) in Et_2O (80 cm^3) at room temperature. The reaction mixture was heated at reflux for 2 h then filtered on silica (eluent, THF). After removal of solvents *in vacuo*, crude **17** was recrystallized from pentane to afford 6.92 g (72%) of white crystals; m.p. 122–123°C. ^1H NMR ($CDCl_3$): 0.01 (s, 9H, Me_3Si), 0.49 (d, $^5J_{HF}$ 0.5 Hz, 9H, Me_3Si), 0.50 (d, $^3J_{HF}$ 21.0 Hz, 1H, CHSi), 1.74 (s, 3H, *p*-Me), 1.98 (d, $^5J_{HF}$ 2.2 Hz, 6H, *o*-Me), 4.73 (d, $^3J_{HF}$ 1.5 Hz, 1H, CH), 6.32 (s, 2H, arom. Mes), 7.00–8.27 (m, 8H, CR_2). ^{19}F NMR ($CDCl_3$): −95.27. ^{13}C NMR ($CDCl_3$): 2.45 (s, Me_3Si), 3.66 (s, Me_3Si), 9.85 (d, $^2J_{CF}$ 15.2 Hz, CHSi), 20.89 (s, *p*-Me), 23.61 (d, $^4J_{CF}$ 6.0 Hz, *o*-

Me), 48.1 (d, $^2J_{CF}$ 11.3 Hz, *C*HR$_2$), 119.62, 120.22, 124.02, 124.75, 124.79, 125.96, 126.38, 126.41, 128.66, 132.32, 132.49 (C_1, C_2, C_3, C_4, C_5, C_6, C_7, C_8 and *m*-C Mes), 132.3 (d, $^2J_{CF}$ 8.0 Hz, *ipso*-C Mes), 138.94, 140.08, 141.47, 142.40, 143.35 (d, 5.0 Hz), 144.33 (C_{10}, C_{11}, C_{12}, C_{13}, *o*-C Mes, *p*-C Mes). MS(EI, 70 eV, ^{74}Ge), *m/z*: 521 (M−15, 2), 371 [BisGe(F)Mes, 63], 165 (R_2CH, 31), 119 (Mes, 11), 159 (Bis, 2). Found: C, 65.5; H, 7.4. $C_{29}H_{39}FGeSi_2$ requires: C, 65.1; H, 7.3.

Bisyl(mesityl)fluorenylidenegermene (**6**)

An equivalent of tert-butyllithium 1.7 M in pentane (2.8 mmol) was added to a solution of **17** (1.50 g, 2.8 mmol) in Et_2O (20 cm^3) cooled to −78°C. (Note: Et_2O must be very carefully dried and deoxygenated and all the apparatus flame-dried *in vacuo*.) The reaction mixture was then allowed to warm to room temperature: it turned gradually yellow, then orange at room temperature, and orange–red on reflux of Et_2O. Approximately 1/2 h of reflux was necessary for the complete formation of germene. LiF was eliminated by centrifugation. Solvents were removed *in vacuo* giving crude germene **6**. Crystallization in pentane gave 0.88 g (61%) of orange crystals of **6**; m.p. 60–61°C. Solutions of **6** are extremely air-sensitive: they turned green when traces of air were added. ^{1}H NMR (CD_2Cl_2): 0.33 (s, 18H, Me_3Si), 0.37 (s, 1H, CHSi), 2.45 (s, 3H, *p*-Me), 2.61 (s, 6H, *o*-Me), 6.96–8.05 (m, 8H, CR_2), 7.14 (s, 2H, arom. Mes).

Bisyl(mesityl)(methoxy)fluorenylgermane (**25**)

An excess of methanol (carefully dried and deoxygenated) was added to a solution of **6** (1.14 g, 2.2 mmol) in Et_2O (10 cm^3). The orange solution of **6** turned immediately colourless. Et_2O and excess of MeOH were eliminated *in vacuo* and crude **25** was recrystallized in pentane to afford 0.91 g (86%) of white crystals; m.p. 134–135°C. ^{1}H NMR ($CDCl_3$): 0.03 (s, 9H, Me_3Si), 0.47 (s, 9H, Me_3Si), 2.06 (s, 6H, *o*-Me), 2.18 (s, 3H, *p*-Me), 3.83 (s, 3H, OMe), 4.85 (s, 1H, CH), 6.59 (s, 2H, arom. Mes), 7.02–8.01 (m, 8H, CR_2). ^{13}C NMR ($CDCl_3$): 2.92 (Me_3Si), 3.83 (Me_3Si), 7.36 (CHSi), 21.00 (*p*-Me), 23.14 (*o*-Me), 44.69 (*C*HR$_2$), 53.10 (OMe), 119.67, 120.19 (C_4, C_5), 124.64, 124.97, 125.69, 125.99, 126.32, 126.44, (C_1, C_2, C_3, C_6, C_7, C_8), 128.65 (*m*-C Mes), 134.52, 138.40, 140.65, 141.70, 143.02, 145.04, 145.07 (C_{10}, C_{11}, C_{12}, C_{13}, *ipso*-C Mes, *o*-C Mes, *p*-C Mes). MS (EI, 70 eV, ^{74}Ge), *m/z*: 547 (M−1, 11), 383 [Bis(Mes)GeOMe, 100], 351 [Bis(Mes)Ge−1, 10], 193 (MesGe, 11), 165 (R_2CH, 53), 119 (Mes, 10), 73 (Me_3Si, 64). Found: C, 66.3; H, 7.9. $C_{30}H_{42}GeOSi_2$ requires: C, 65.8; H, 7.7.

Ditert-butyl(fluoro)fluorenylgermane (**15**)

A solution of fluorenyllithium [prepared as previously described from fluorene (8.67 g, 52.2 mmol) and butyllithium (52.2 mmol) in 120 cm^3 of THF/Et_2O (50:50)] was added to a solution of **12** (11.73 g, 52.2 mmol) in Et_2O (100 cm^3) at room temperature. The orange reaction mixture was heated at reflux for 2 h, then filtered through silica and the solvents were eliminated *in vacuo*. Recrystallization from pentane afforded 13.34 g (69%) of white crystals of **15**; m.p. 90–91°C. ^{1}H NMR ($CDCl_3$): 1.00 (d, $^4J_{HF}$ 1.0 Hz, 18 H, tBu), 4.52 (broad s, 1H, CH), 7.17–8.00 (m, 8H, CR_2). ^{13}C NMR ($CDCl_3$): 28.41 (s, Me), 31.84 (d, $^2J_{CF}$ 8.6 Hz, *C*Me), 41.40 (d, $^2J_{CF}$ 6.8 Hz, CH), 120.11 (C_4 C_5), 125.35, 126.16, 126.48 (C_1, C_2, C_3, C_6, C_7, C_8), 140.93, 143.91 (C_{10}, C_{11}, C_{12}, C_{13}). MS (EI, ^{74}Ge), *m/z*: 372 (M, 15), 315 (M−tBu, 2), 238 (M−2tBu−HF, 15), 207 (tBu_2GeF, 30), 165 (HCR_2, 100). Found: C, 67.5; H, 7.3. $C_{21}H_{27}FGe$ requires: C, 68.0; H, 7.3.

Ditert-butyl(fluoro)(benzylfluorenyl)germane (**27**)

To a solution of **15** (1.0 g, 2.7 mmol) in Et_2O (15 cm^3) cooled to −78°C was added one equivalent of tert-butyllithium 1.7 M in pentane. After warming to room temperature, the reaction mixture turned red. Benzyl chloride (0.34 g, 2.7 mmol) was added to the lithio compound $tBu_2Ge(F)C(Li)R_2$ at room temperature; the solution immediately became light yellow. After 1 h stirring at room temperature, lithium chloride was removed by filtration and then the solvents were removed *in vacuo*. Crude **27** was recrystallized from pentane, affording 1.06 g (85%) of white crystals of **27**; m.p. 157–158°C. ^{1}H ($CDCl_3$): 1.06 (d, $^4J_{HF}$ 1.3 Hz, 18H, tBu), 4.06 (s, 2H, CH_2), 6.41–8.18 (m, 13H, CR_2Ph). ^{13}C ($CDCl_3$): 29.73 (s, Me), 34.44 (d, $^2J_{CF}$ 8.6 Hz, *C*(Me$_3$), 40.69 (s, CH_2), 57.55 (d, $^2J_{CF}$ 8.6 Hz, *C*R$_2$), 120.00 (C_4, C_5), 125.76–136.05 (C_1, C_2, C_3, C_6, C_7, C_8, Ph) 141.20, 146.62 (C_{10}, C_{11}, C_{12}, C_{13}). MS (EI, ^{74}Ge), *m/z*: 462 (M, 2), 328 [tBuGe(F)CR_2CH_2, 1], 257 [Ge(F)CR_2, 13], 207 (tBu_2GeF, 6), 57 (tBu, 100). Found: C, 72.4; H, 7.2. $C_{28}H_{33}FGe$ requires: C, 72.9; H, 7.2.

Ditert-butyl(fluoro)(methylfluorenyl)germane (**26**)

To the lithio compound **8** [prepared from **17** (0.5 g, 1.35 mmol) and one equivalent of tert-butyllithium in Et_2O] was added methyl iodide (0.19 g,

1.35 mmol) in solution in pentane (5 cm^3). After 15 min at room temperature the orange reaction mixture turned yellow; solvents were removed *in vacuo* and 15 cm^3 of pentane were added; LiI was then eliminated by filtration. Crystallization from pentane afforded 0.31 g (48%) of white crystals of **26**; m.p. 87–88°C. ^1H NMR ($CDCl_3$): 0.96 (s, 18H, tBu), 1.53 (s, 3H, CMe), 7.17–8.11 (m, 8H, CR_2).

Reaction of lithio compound **8** *with benzaldehyde*

To a solution of lithio compound **8** [prepared as previously from **15** (1.0 g, 2.7 mmol), one equivalent of tert-butyllithium and Et_2O (15 cm^3) cooled to −78°C] was added a solution of benzaldehyde (0.29 g, 2.7 mmol) in Et_2O (5 cm^3). The reaction mixture turned brown–black, then was warmed to room temperature. During stirring at 20°C for 10 h, it progressively turned yellow. After filtration to remove lithium fluoride, solvents were evaporated *in vacuo*. Pentane (25 cm^3) was added to the crude resulting mixture; cooling to −20°C allowed the crystallization of alkene **29**,[23] which was separated by filtration (0.38 g, 55%). The filtrate contained **28** and **30**, which were separated by fractional crystallization in Et_2O/pentane (50:50). **28** was the first to crystallize. **28**, ^1H NMR ($CDCl_3$): 0.96, 1.21, 1.24 and 1.46 (4s). ^{13}C NMR ($CDCl_3$): 27.43, 27.99 and 31.91. MS (EI, ^{74}Ge), *m/z*: 437 (M − 3tBu, 0.5), 381 (M − 4tBu + H, 1), 367 (M − 4tBu − Me + 2H, 1), 293 (M − $tBu_2Ge{=}O$ − 2tBu + H, 2), 204 ($tBu_2Ge{=}O$, 2), 57 (tBu, 100). **30**, ^1H NMR ($CDCl_3$): −0.04 (s, 9H, tBu), −0.03 (s, 9H, tBu), 0.11 (s, 9H, tBu), 0.12 (s, 9H, tBu), 4.60 (s, 1H, CH), 7.17–7.93 (m, 13H, CR_2 and Ph). ^{13}C NMR ($CDCl_3$): 20.92, 23.43, 24.14 and 28.10 (Me_3C), 60.86 (CH), 62.59 (CR_2), 119.05 to 145.67 (Ph, CR_2).

Abstract—A new base-stabilized silylene (silanediyl) complex (t-BuS)$_2$(HMPA)Si=Fe(CO)$_4$ (**9b**) has been prepared from $Na_2Fe(CO)_4$ and (t-BuS)$_2SiCl_2$ (**2b**) in the presence of HMPA (hexamethylphosphoric triamide). An X-ray structure analysis of **9b** shows the silylene coordinated to the iron atom [Fe—Si = 2.278(1) Å]. The HMPA is bound via its oxygen atom to the unsaturated silicon [O—Si 1.734(2) Å], which adopts a distorted tetrahedral coordination geometry. A comparison of **9b** with the analogous oxo compound (t-BuO)$_2$(HMPA)Si=Fe(CO)$_4$ (**9a**) indicates an almost identical stabilizing effect of the electron-deficient silicon atom in **9b** by π-mesomeric and polarization effects of the t-BuS substituents. The conformation of the substituents found at the silicon atom is reproduced by a force field calculation. A base-free silylene complex (t-BuS)$_2$Si=Fe(CO)$_4$ (**10**) has been observed directly by NMR spectroscopy (^{1}H NMR: δ 1.70, s; ^{29}Si NMR: δ 83.2, s) and was further characterized by a derivatization reaction with HMPA to form **9b**. The HMPA adduct **9b** is a valuable model compound for mechanistic investigations: photolysis of **9b** in the presence of 2,3-dimethylbutadiene as trapping reagent yields 1,4-addition of the silylene to the butadiene. In the absence of any trapping reagents, polysilanes are formed. The experiments provide evidence for a silylene cleavage mechanism.

Interest in organometallic silicon chemistry has considerably increased,[1,2] since the recent discovery of stable coordination compounds with low-valent silicon ligands.[3,4] This refers, in particular, to silylene (silanediyl) complexes (**A**) and their donor adducts (**B**), which are known for the metals iron, ruthenium, chromium and tungsten.[5] Furthermore, cationic silylene complexes (**C**)[4] and cyclic bis-silylene complexes (**D**) have been realized with the compounds Cp*FeSiMe$_2$OMeSi(OMe)Me[6] and CpFeCOSiMe$_2$NH$_2$SiMe$_2$,[7] as well as base adducts of metallasilaallenes (**E**).[8] In a wider sense, the recently isolated complexes of disilaethenes (**F**)[9] and silaethenes (**G**)[10] have also to be considered (Scheme 1).

Base-stabilized silylene complexes are model compounds for extremely reactive, base-free complexes which are proposed as key intermediates in a variety of catalytic reactions. These are, for example, the dehydrogenative coupling of primary silanes to disilanes[11] or the polymerization of silanes by early transition metal catalysts.[12]

A great many research activities have been invested into stable base adducts of silylene (silanediyl) complexes by X-ray structure analysis, NMR and Mössbauer spectroscopy.[1] An X-ray structure study shows important interdependencies between bond lengths, coordination geometry and substituent effects at the silicon atom.[3,5] The bond lengths, as well as the coordination geometry at silicon, are a function of the electronic saturation of silicon, which is given by the respective substituents. Stabilizing substituents induce an elongation of both the metal–silicon and donor–silicon bonds and lead to a stronger distortion of the tetrahedral coor-

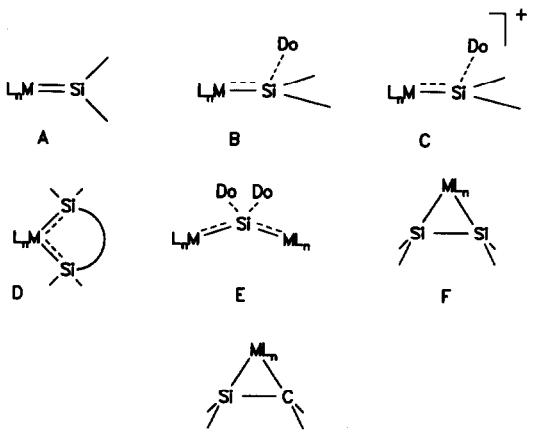


Scheme 1.

dination sphere. Thus, data from X-ray structures are a valuable indicator of the magnitude of the metal–silicon interaction. On the grounds of the extended set of parameters, a fairly good assignment of the effects of particular substituents is possible.[5]

This work describes the effects involved when sulphur is directly bonded to silicon in the coordination compound $(t\text{-BuS})_2(HMPA)Si{=}Fe(CO)_4$ (**9b**). Sulphur, in particular, has been proposed as a stabilizing substituent for low coordinated and low-valent silicon species. Important for the stabilization are π-mesomeric effects, but a strong polarization interaction between sulphur and silicon is also important.[13] Investigations of the stable system $[(i\text{-Pr})_2S]_3Si^+ClO_4^-$ have been reported and are in support of a significant stabilization effect; however, systematic data on sulphur-containing silicon species are still rare.[14] This refers also to the direct observation of silylenes (silanediyls) in a matrix, where exact measurements of the spectroscopic properties of sulphur-substituted silylenes have not been made so far.[14]

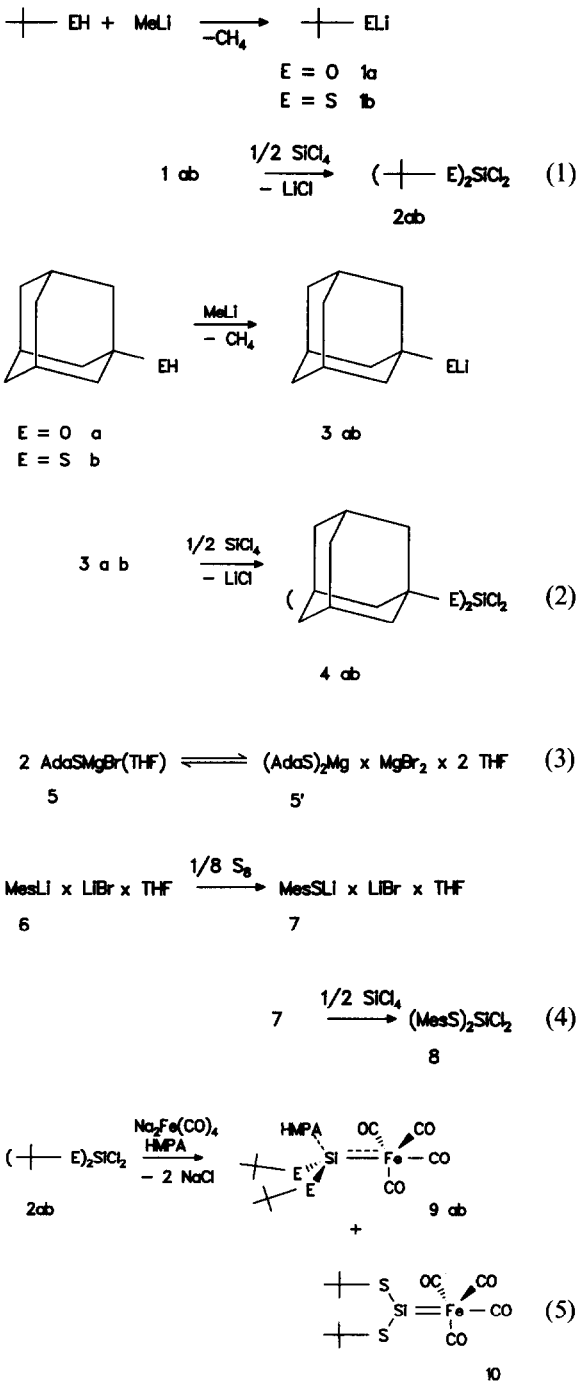
A major reason for this lack of information are the great difficulties involved with the synthesis of silicon compounds due to the inherent kinetic lability of the sulphur–silicon bond, which gives rise to an enhanced nucleophilic displacement of the thio substituents by ligand exchange reactions or hydrolysis.

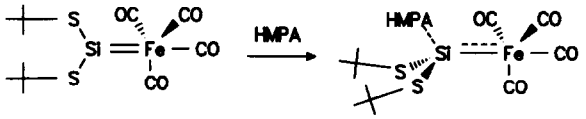
In this article the synthesis of a new silylene coordination compound $(t\text{-BuS})_2(HMPA)Si{=}Fe(CO)_4$ (**9b**) is introduced, together with a crystallographic investigation and a preliminary reactivity study.[15] The given data allow the accurate measurement of the silicon–sulphur interaction and a qualitative assignment of the stabilizing effects which occur.

RESULTS AND DISCUSSION

Synthesis of silylene complexes

A very efficient route to coordination compounds of silylenes is provided via the salt elimination reaction of carbonylate dianions with halosilanes. This reaction is versatile and allows variation of both the metals and the introduced silanes.[3] The required silanes are conveniently synthesized by treatment of the appropriate lithium organyls with $SiCl_4$ at low temperatures.





(6)

The observed selectivities for the dichlorosilanes vary and are highest for bis-t-butylthiodichlorosilane (**2b**). $MesS_2SiCl_2$ (**8**) can be obtained in moderate yields from a reaction of lithium mesitylthiolate (**7**) with silicon tetrachloride; the thiolate **7** is prepared from MesLi + LiBr and sulphur. 1-AdaSMgBr (**5**) forms a Schlenk equilibrium, $\mathbf{5} \rightleftharpoons \mathbf{5}'$, according to eq. (3).

The chlorosilanes, R_2SiCl_2, obtained are purified by fractional crystallization. However, for R = MesS, 1-AdaS, a slow exchange reaction, $2R_2SiCl_2 \rightleftharpoons RSiCl_3 + R_3SiCl$, occurs, which renders further reactions of the halosilanes with metalate anions difficult. The t-butylthio compound $(t\text{-BuS})_2SiCl_2$ (**2b**), purified by preparative gas chromatography, is much better suited for further conversion with $Na_2Fe(CO)_4$ in the presence of HMPA to $(t\text{-BuS})_2(HMPA)Si{=}Fe(CO)_4$ (**9b**) in 30% yield. Compound **9b** is a colourless, crystalline compound, sensitive to air and moisture.

The preparation of $(t\text{-BuO})_2SiCl_2$ (**2a**) and its subsequent reaction to $(t\text{-BuO})_2(HMPA)Si{=}Fe(CO)_4$ (**9a**) have already been described,[3b] but **9a** is included for comparison.

Spectroscopic investigations

All compounds have been fully characterized by NMR and IR spectroscopy (see Experimental). In particular, the ^1H NMR spectrum of **9b** shows characteristic shifts [δ 1.63, s, 18H, t-BuS; δ 2.77, d, $^3J(^{31}P^1H) = 29.0$ Hz, 18H, HMPA]. The ^{29}Si NMR spectrum [δ 74.4, $^2J(^{31}P^{29}Si) = 33.1$ Hz] is also of diagnostic value. The observed IR bands for the ν(CO) stretching vibration are typical for an axial coordination of the silylene ligand (C_{3v}). A comparison of the ν(CO)/cm^{-1} A_1 and E vibrational data and the respective force constants $k_0(^{12}CO)$/Nm^{-1} [For **9a**: ν(CO) 2005(w), 1920(s), 1883(s); $k_0(^{12}CO)$ 1623, 1489, 1432. For **9b**: ν(CO) 1995(w), 1910(s), 1870(s); $k_0(^{12}CO)$ 1607, 1473, 1412] indicates a stronger donor capacity of the coordinated silylene in the sulphur compound **9b**.[16]

The spectroscopic analysis of the reaction mixture [eq. (5)] gives, in addition to **9b**, direct evidence for the presence of a donor-free complex **10** [^1H NMR (C_6D_6): δ 1.70, s, 18H, t-BuS; ^{29}Si NMR: δ 83.2, singlet], with no further impurities present. The ^{29}Si resonance clearly excludes a dimeric species.* According to the intensity distribution of both the ^{29}Si and ^1H NMR signals, **10** is formed in a ratio of 1 : 1.6 (**10**/**9b**). Compound **10** decomposes at -30°C into $[(t\text{-BuS})_2Si]_n$ and $Fe_3(CO)_{11}H^-$ with a half-life time of 12 h.† The polysilane has been isolated. By addition of a 10-fold excess of HMPA, **10** is converted to **9b** quantitatively.‡

Molecular structure of **9b**

An X-ray structure analysis of **9b** (Tables 1 and 2) confirms the proposed molecular structure (Fig. 1). The coordination geometry at the iron centre is trigonal bipyramidal with the silicon ligand occupying an apical coordination site. The Fe—Si bond [2.278(1) Å] in **9b** is short compared with the known Fe—Si single bond distances. The Fe—Si bond lengths of donor-stabilized silylene complexes range from 2.289(2) Å in **9a**[3a] to 2.214(1)/2.221(1) Å in $Cl_2(HMPA)Si{=}Fe(CO)_4$[3c] for acyclic complexes, and 2.207(3)/2.222(3) Å in Cp*Fe(CO)SiMe(OMe)-OMe-SiMe$_2$.[6] A rough estimate of the Fe=Si bond lengths of an uncomplexed double bond on the grounds of covalent radii gives 2.18 Å.[3b]

The coordination sphere of the silicon is completed to a distorted tetrahedron by the addition of a HMPA molecule [Si—O 1.734(2) Å]. The HMPA

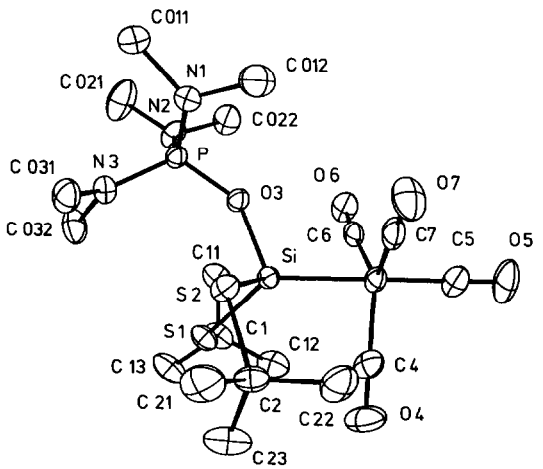


Fig. 1. ORTEP view of **9b**. Displacement ellipsoids at the 50% probability level.

* For $(OC)_4Fe\text{-}SiMe_2\text{-}Fe(CO)_4\text{-}SiMe_2$, ^{29}Si NMR δ 161.0 ppm has been measured, which is typical for metallasilacyclobutanes.

† A dimeric silylene complex would be stable.

‡ This trapping experiment provides further evidence for the presence of a monomeric silylene complex **10**, since the retro-cleavage of a dimeric silylene complex species by a base to a monomeric coordination compound is not known in the literature.

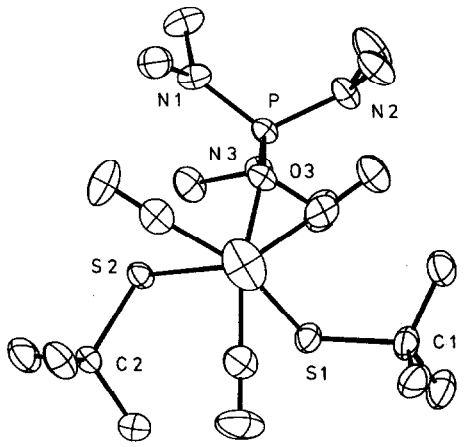

Fig. 2. ORTEP view of **9b** down the Fe—Si axis.

O—Si bond lengths of **9b** and **9a** [Si—O 1.730(3) Å] are identical within the usual three-fold standard deviations. The Si—S distances are relatively short, 2.158(1) and 2.170(1) Å, and indicate a substantial mesomeric π-interaction between the silicon and the sulphur atom, while metal–silicon bond lengths are even shorter due to the more electrophilic silicon atom (π-backbonding).[3c] Thus, a comparison of the Fe—Si bond lengths in **9a** and **9b** allows the conclusion that stabilizing O → Si π-effects are slightly more important in **9a** than S → Si effects are in **9b**. The coordination geometry at the silicon centre shows typical distributions from an ideal tetrahedron, with relatively large bond angles, t-BuS—Si—Fe 123.1(1)/121.3(1)°, and a small angle, t-BuS—Si—S(t-Bu) 98.2(1)°. The sum of the angles between the substituents at silicon, R—Si—R, Fe—Si—R and R—Si—Fe, is virtually the same in **9a** (342.1°) and **9b** (342.6°).

It has been shown that the donor–silicon interaction occurs through the LUMO of the Si=Fe double bond and is strongly influenced by substituent effects.[3c,d] The discussed structural features may be used as a probe for the degree of electronic saturation at silicon and allow a qualitative assignment of the stabilizing effect of sulphur, which is only slightly smaller in **9b** than in the oxo compound **9a**, and substantially greater than in alkyl-substituted silylene complexes.[1]

S(1)—Si—S(2)	98.2(1)	S(2)—Si—O(3)	94.8(1)

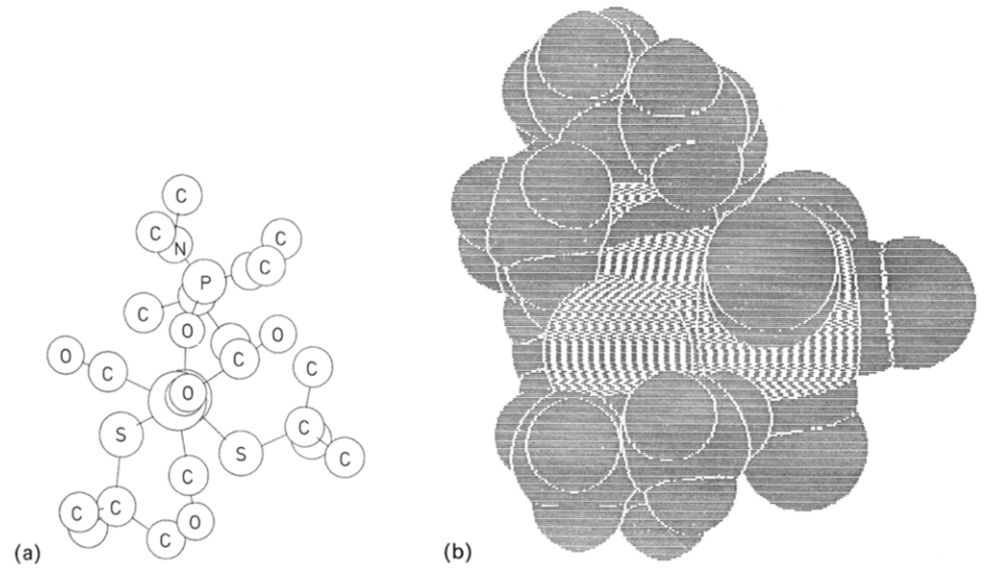

Fig. 3. (a) Projection down the Fe—Si axis of the structure of **9b** obtained by a force field calculation (hydrogen atoms omitted for clarity). (b) View of the van der Waals' surface of **9b** obtained by the force field calculation.

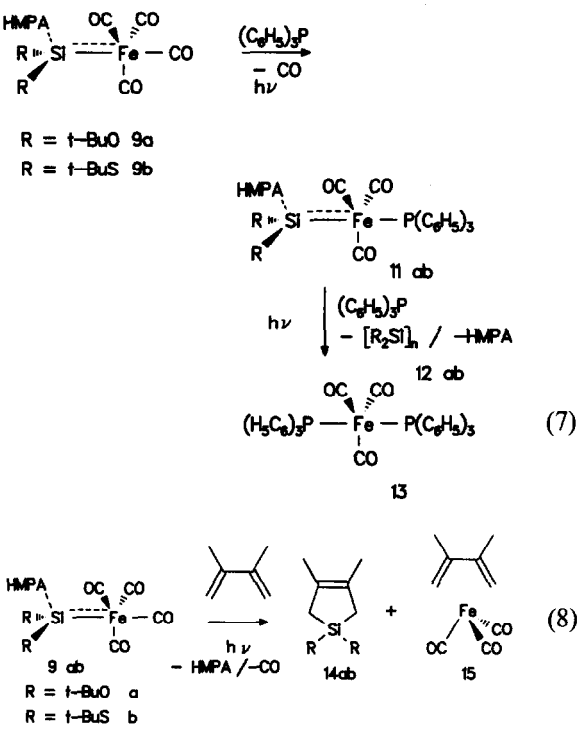
The bond lengths and the coordination geometry at silicon are primarily a result of electronic effects. However, the relative conformation of the organic substituents at the silicon atom represents a minimum of steric interactions. An ORTEP view of the molecule down the Fe—Si bond (Fig. 2) shows that **9b** contains no mirror plane, but the two t-BuS substituents together with HMPA form an asymmetric conformation, which is apparently a minimum of energy. This rotamer is reproduced by a force field calculation.[17] The obtained conformation and van der Waals' surface are depicted in Fig. 3.

Reactions

Previous experiments have shown that coordinated silylenes (with an additional base at silicon) can be activated photochemically or thermally in silylene transfer reactions.[3c]

A reactivity study of **9a,b** provides similar results: photolysis of the complexes $R_2(HMPA)Si{=}Fe(CO)_4$ (R = t-BuO, t-BuS) in the presence of triphenylphosphine leads, after photolytic activation of CO, to the *trans*-phosphine complexes **11a,b**, and subsequently to the displacement of the silylene ligand by a further phosphine to produce the bis-phosphine complex **13**. The liberated silylenes polymerize instantaneously; for **12a**, R = t-BuO, the molecular weight has been determined as 550. $[(t\text{-BuS})_2Si]_n$ (**12b**) is a white, air-sensitive material, soluble in toluene and insoluble in THF. The coordinated HMPA is split off from the silicon during the second step of the photolysis reaction and can be recovered quantitatively.



Trapping experiments of the silylenes with 2,3-dimethylbutadiene have been successful for R = t-BuO and R = t-BuS and yield the products **14a,b** and **15**. The photolysis reaction can be monitored by IR spectroscopy [ν(CO) **9a**: 2005, 1920, 1883 cm^{-1}, ν(CO) **15**: 2045, 1971 cm^{-1}], which shows the disappearance of the ν(CO) bands of **9a** or **9b**

together with a simultaneous increase of the bands of **15**. The reaction follows a (pseudo) first-order rate law. The observed reactivity pattern documents the potential of complexes **9a,b** to react as a silylene source and also provides evidence for a silylene polymerization mechanism. Further experiments concerning the reactivity and spectroscopic properties of [(t-BuS)$_2$Si] are underway.

Summary

The obtained results provide a set of data for both a "donor-free" silylene complex, (t-BuS)$_2$Si=Fe(CO)$_4$ (**10**), and its HMPA adduct, (t-BuS)$_2$(HMPA)Si=Fe(CO)$_4$ (**9b**). An X-ray structure analysis of **9b** allows the estimation of the stabilizing effect of the sulphur substituents at silicon. The bond distances Si—S, Si—Fe, Si—O and the overall coordination geometry at silicon show a substantial stabilization of the electron-deficient silicon by sulphur due to mesomeric π-interaction and polarization effects. The observed effects are slightly smaller than in the oxo compound **9a** and allow the assignment of the following gradation of ligand stabilization capacity: O > S ≫ C. This gradation is consistent with results from ^{29}Si NMR and IR spectroscopy.

^{1}H NMR and ^{29}Si NMR data, as well as trapping experiments with HMPA, give evidence for a labile, "base-free" complex (t-BuS)$_2$Si=Fe(CO)$_4$ (**10**). Both **10** and the HMPA adducts **9a,b** undergo silylene cleavage reactions with subsequent polymerization of the silylenes in solution. This mechanism is supported by trapping experiments of the silylenes with 2,3-dimethylbutadiene.

EXPERIMENTAL

All experiments have been performed in an atmosphere of dry nitrogen or argon, respectively. The solvents were dried by conventional techniques (NaK alloy, P_4O_{10}), and residual water contents were in all cases below 3.5 ppm (detected by Karl Fischer titration). Elemental analyses were carried out at Mikroanalytisches Laboratorium der Technischen Universität München. NMR spectra were obtained on Jeol GX 400 and Jeol FX 270 spectrometers, IR spectra on a Nicolet FT-IR-5DX spectrometer and GC–MS analysis was performed on Hewlett–Packard 5890 A and 5970 B instruments with a column CP SIL 5CB (50 m; 0.32 mm).

Bis(t-butylthio)dichlorosilane, (t-BuS)$_2$SiCl$_2$ (**2b**)

To a solution of t-butylthiol (33.8 cm^3, 0.3 mol) in 100 cm^3 of pentane, n-BuLi (190 cm^3, 0.3 mol) (1.71 M solution in hexane) was added at −40°C. The reaction mixture was stirred for a further 2 h at room temperature. After removal of the solvent *in vacuo*, lithium-t-butylthiolate (27.6 g, 0.287 mol) was isolated as a white solid (96%). Further reaction to the chlorosilane was accomplished by the addition of a solution of the thiolate (27.6 g, 0.287 mol) in 100 cm^3 of THF at −60°C to $SiCl_4$ (16.6 cm^3, 0.144 mol) dissolved in 100 cm^3 of THF. After completion of the addition, the reaction mixture was stirred at room temperature for a further 2 h. The LiCl was removed by filtration and the THF stripped off *in vacuo*. The residual colourless oil was contaminated with LiCl and was therefore purified by vacuum distillation or by prep. GC (retention time: 9.7 min; MS analysis: M^+ = 276.3%). Compound **2b** is a colourless liquid. Yield: 10.6 g (27%); b.p. 90°C/1 mbar. ^{1}H NMR ($CDCl_3$): δ 1.2 (s). ^{29}Si NMR (C_6D_6): δ 4.4.

Bis(1-adamantyloxo)dichlorosilane, (AdaO)$_2$SiCl$_2$ (**4a**) *and bis-(1-adamantylthio)dichlorosilane*, (AdaS)$_2$SiCl$_2$ (**4b**)

To magnesium chips (1.69 g, 69.7 mmol) in 50 cm^3 of ether, 1-AdaBr (15.0 g, 69.7 mmol) dissolved in 100 cm^3 of ether was added dropwise. The Grignard reaction was initiated by external local heating of the mixture. After 30 min, the heat formed is self-sufficient for further reaction. After completion of the halide addition, the mixture was refluxed for 3 h and kept at room temperature for 10 h. Then, sulphur (2.23 g, 69.7 mmol) was added portionwise through a special device and the obtained mixture refluxed for a further 5 h. The slightly cloudy, yellow solution was filtrated and the THF removed *in vacuo*. The brown residue obtained was purified by dissolving it repeatedly in 40 cm^3 of THF and precipitating the product by addition of 40 cm^3 of pentane. Compound **4b** formed as a yellow powder (8.96 g; yield: 48%). ^{1}H NMR (C_6D_6): **4b**, δ 1.5 (m, α-methylene-H): 2.3 (m, β-CH); 3.9 (m, γ-methylene-H).

Compound **4a** was prepared by deprotonation of 1-adamantol with methyllithium and subsequent conversion to the chlorosilane by $SiCl_4$ (Yield: 62%).

Synthesis of bis(2,4,6-trimethylphenylthio)dichlorosilane [bis(mesitylthio)dichlorosilane], (MesS)$_2$SiCl$_2$ (**8**)

Mesityllithium·LiBr. The synthetic procedure given in ref. 18 was slightly modified. Mesitylbromide (30.1 cm^3, 0.2 mol) was dissolved in 250

cm^3 of diethyl ether. Then, n-BuLi (250 cm^3, 0.4 mol) (1.71 M solution in hexane) was added under vigorous stirring over a period of 1 h. If necessary, the reaction flask was cooled externally by an ice bath. A white precipitate of **6** formed, which increased during a further hour of refluxing of the reaction mixture. The product was isolated by filtration and dried in high vacuum (10^{-3} torr). Yield: 31.8 g (75%).

Lithium mesitylthiolate, LiSMes·THF (**7**). To a solution of MesLi·LiBr (**6**) (31.8 g, 0.2 mol) in 250 cm^3 of THF, S_8 (4.8 g, 150 mmol) was added portionwise over a period of 30 min at −20°C. The sulphur dissolved completely, and the yellow solution which formed was kept at room temperature for a further 3 h. The obtained crude lithium mesitylthiophenolate was purified by derivatization to the thiophenol. Therefore, the THF was first replaced by ether, and subsequently the thiophenolate was converted to the thiol by addition of 0.1 M sulphuric acid at 0°C. The thiophenol was extracted from the water phase with ether. After removal of ether, the thiol was isolated as a yellow oil with a characteristic odour. Yield: 20.4 g (90%); b.p. 106°C. ^{1}H NMR ($CDCl_3$): δ 2.2 (Br, 6H, 3H; *o*-CH_3, *p*-CH_3); 2.8 (s, 1H, SH); 6.7 (s, 2H, aryl-H).

To a solution of mesitylthiophenol (20.4 g, 134 mmol) dissolved in 200 cm^3 of THF, n-BuLi (74 cm^3, 134 mmol) (1.71 M solution in n-hexane) was added. The colour of the solution changed from yellow to orange during the addition. The mixture obtained was then stirred for a further 3 h at room temperature. After removal of the THF *in vacuo*, **7** was isolated in 70% yield (22.7 g).

Bis(2,4,6-*trimethylphenylthio*)*dichlorosilane*, $(MesS)_2SiCl_2$ (**8**)

To a stirred solution of silicon tetrachloride (5.1 cm^3, 45 mmol) in 100 cm^3 of THF, **7** (22.7 g, 93 mmol) dissolved in 100 cm^3 of THF was added at −25°C (3% access of $SiCl_4$), and the reaction mixture turned slightly yellow. After refluxing for a further 6 h, the lithium halides were removed and the solvent stripped off *in vacuo*. The resulting paste was again dissolved in 100 cm^3 of a 3:1 mixture of pentane–ether. After filtration from the residual lithium halides and removal of the solvent, a yellow oil was obtained, which is sensitive to hydrolysis and oxidation. Yield: 12.2 g (70%). ^{29}Si NMR data show the presence of two reaction products in the ratio 4:1 $(MesS)_2SiCl_2/(MesS)_3SiCl$. Compound **8** could not be further enriched by either fractional crystallization or Kugelrohr distillation due to ligand exchange reactions. ^{1}H NMR ($CDCl_3$): **8** δ 2.3 (m, 9H, *o*-CH_3, *p*-CH_3); 6.9 (s, broad, 2H, aryl H). ^{29}Si NMR (C_6D_6): δ 26.7. MS: *m/z* 400 (M^+; 1.7%)

Reaction of **2b** *with* $Na_2[Fe(CO)_4]$ *to form* (t-BuS)$_2$Si=Fe(CO)$_4$ (**9b**) *and* (t-BuS)$_2$(HMPA)Si=Fe(CO)$_4$ (**10**)

To a solution of $Na_2[Fe(CO)_4]$ (3.3 g, 9.6 mmol) in a mixture of 100 cm^3 of THF and 15 cm^3 of HMPA, **2b** (2.7 g, 9.6 mmol) was added at −50°C. The reaction mixture was stirred for 12 h, filtered, and THF and HMPA were subsequently removed at high vacuum (10^{-4} torr). The crude product contained **9b** and **10** in a 1:1.6 ratio. Compound **10** can be converted to **9b** by addition of 2 cm^3 of HMPA. Alternatively, the mixture could be purified by column chromatography on silica gel (2.5 cm diameter, 40 cm height) with a cooled (−15°C) chromatography column. However, **10** decomposed during chromatography into $HFe_3(CO)_{11}^-$ and polysilane **12b**. Analytical data for **9b**: Found (Calc.): C, 38.98 (39.04); H, 6.59 (6.51); N, 7.62 (7.59). IR for **9b** (KBr): 1995 (w), 1910 (s), 1870 (s) [ν(CO) in cm^{-1}]. MS: *m/z* = 553 (M^+; 1.5%). ^{1}H NMR (C_6D_6): δ 1.63 (s, br, 18H), δ 2.77 [d, $^2J(^{31}P^{29}Si)$ = 29.0, 18H]. ^{29}Si NMR (C_6D_6): δ 74.0, **9b**.

^{1}H NMR (C_6D_6): 1.70; ^{29}Si NMR (C_6D_6): δ 83.2, **10**.

Crystal structure analysis of **9b***

Crystal data and a summary of data pertinent to data collection and refinement are colleced in Table 3. Exact cell dimensions were obtained by least-squares refinement of the Bragg angles of 15 selected reflections centred on the diffractometer. Reduced cell calculations did not reveal symmetry higher than orthorhombic. Three standard reflections, measured after every 50 reflections, showed only random intensity fluctuations. Therefore, a correction for crystal decay was not considered necessary, neither was one for absorption. Refinement was carried out with anisotropic displacement parameters. The methyl groups were treated as rigid groups (H atoms with U_{iso} fixed at 0.05 Å^2). To ensure that the chirality of the single crystal under investigation and that of the coordinate set were identical, the inverse coordinate set was also refined.

*A complete list of fractional atomic coordinates including hydrogen atoms and a list of observed and calculated structure factors ($F_o - F_c$) have been deposited together with the manuscript.

[a] $R = \Sigma(||F_o|-|F_c||)/\Sigma|F_o|$.
[b] $Rw = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w F_o^2]^{1/2}$; $w = 1/\sigma^2(F_o)$. Function minimized: $\Sigma w(|F_o|-|F_c|)^2$.

It yielded substantially higher R values, however ($R/R_w = 0.039/0.044$).

Atomic form factors for neutral, isolated atoms were taken from Cromer and Waber,[19] and those for hydrogen were based on the bonded spherical atom model of Stewart *et al.*[20] Corrections for anomalous scattering were applied for all atoms except hydrogen.[21] The programs used included SHELXS-86[22] (structure solution), SHELXS-76[23] (refinement), ORTEP[24] (molecular drawings), as well as locally written routines. All calculations were performed on a VAX 8200.

Molecular modelling of the structure of **9b**

The molecule was optimized by the ALCHEMY minimizer program with $E_{tot} = E_{str} + E_{ang} + E_{tor} + E_{vdw}$. E_{tot} = total energy, $E_{str} = \Sigma_i^N k^d_i/2(d_i - d^0_i)^2$, $d^0_{FeSi} = 2.300$ Å, $k_{FeSi} = 1500$ kcal mol^{-1} Å^2; $E_{ang} = \Sigma_i^N k^\theta_i/2(\theta_i - \theta^0_i)^2$, $\theta_{0FeSiO} = 115°$, $k^\theta_{FeSiO} = 0.03$ kcal mol^{-1} deg^2; $E_{tor} = \Sigma_i^N k_i/2[1 + \sin(\text{per}_i) \times \cos(|\text{per}_i|\omega_i)]$, $\omega_{SiFe^{**}} = 0.1$ kcal mol^{-1} deg^2; $E_{vdw} = \Sigma_i^n[\Sigma_{j>i} E_{ij}(1.0/a^{12}_{ij} - 2.0/a^6_{ij})]$, $E_{FeSi} = 0.200$ kcal mol^{-1}, $a_{Fe} = 3.000$ Å, $a_{Si} = 2.000$ Å. All other parameters were used from the program without modification. A detailed description is given in ref. 5.

Photolysis of complexes **9a** *and* **9b**

The photolysis reaction of **9b** was carried out as described for **9a**.[3d] A solution of **9b** (1.66 g, 3 mmol) and $(C_6H_5)_3P$ (787 mg, 3 mmol) in 100 cm^3 of THF was photolysed at −40°C for 2 h (Hg high pressure lamp). Complex **11a** was isolated quantitatively.

Further irradiation of **11a** at −40°C in the presence

of $(C_6H_5)_3P$ in a 2 : 1 ratio yielded the bisphosphine complex **13** and polysilane, which were separated as described in ref. 3d. ^1H NMR (C_6D_6): **11b** δ 1.7 (s, 18H, t-BuO), 2.5 [d, $^3J(^{31}P^1H)$ = 10.5 Hz, 18H, HMPA], 7.0–7.3 (m, 15H, C_6H_5); **13** δ 7.1 (m, 18H), 7.5–8.0 (m, 12H). ^{31}P NMR (C_6D_6): **11b** δ 87.8; **13** δ 95.2.

Photolysis of **9a,b** *in the presence of* 2,3-*dimethylbutadiene*

Complex **9a** (1.54 g, 3 mmol) together with 2,3-dimethylbutadiene (5.0 g) in 100 cm^3 of THF were photolysed at −40°C. Every 30 min, an aliquot of the reaction mixture (2 cm^3) was taken and concentrated by a factor of 10 in the vacuum (10^{-2} torr). The GC–MS analysis gave two major peaks at retention time 6.2 min, 70% intensity, M = 256 M^+ **14a**: retention time 5.2 min, 20% intensity, M = 222, M^+ **15**. Furthermore, traces of HMPA, M^+ = 179, were present.

No further by-products were observed. Complexes **14a,b** and **15** can be separated by prep. GC. ^1H NMR (C_6D_6): **14a**, δ 1.74, br, 10H, CH_3, CH_2; 1.70, s, 18H, t-BuO; **14b**, δ 1.75, br, 10H, CH_3, CH_2; 1.70, s, 18H, t-BuS.[25] IR (THF): **15**, 2045 (s), 1971 (s) CO.[26]

Acknowledgements—We wish to acknowledge U. Graf and B. Barth (Mikroanalytisches Laboratorium der Technischen Universität München) for carrying out the elemental analysis.

REACTIONS OF THE RUTHENIUM SILYLENE DERIVATIVE $[(\eta^5\text{-}C_5Me_5)(PMe_3)_2RuSiPh_2(NCMe)]BPh_4$ WITH ALCOHOLS, KETONES AND ACETIC ACID

CHENG ZHANG, STEVEN D. GRUMBINE and T. DON TILLEY†

Department of Chemistry, D-006, University of California at San Diego, La Jolla, CA 92093-0506, U.S.A.

Abstract—The cationic ruthenium silylene complex $[Cp^*(PMe_3)_2RuSiPh_2(NCMe)]^+BPh_4^-$ (**1**, $Cp^* = \eta^5\text{-}C_5Me_5$) reacts with alcohols (MeOH, EtOH and ^{t}BuOH) to produce the ruthenium acetonitrile complex $[Cp^*(PMe_3)_2Ru(NCMe)]^+BPh_4^-$ (**2**) and the corresponding alkoxysilanes $HSiPh_2OR$ (R = Me, Et, ^{t}Bu). At low temperature (−60°C), an intermediate (**3**) was observed in the reaction involving ethanol (by ^{1}H NMR spectroscopy). This intermediate gives rise to a RuH hydride signal (δ 11.08), which appears as a triplet ($^2J_{PRuH}$ = 11 Hz). This species may therefore be *cis*-$[Cp^*(PMe_3)_2Ru(H)SiPh_2OEt]BPh_4$, however, the very low $^2J_{PRuH}$ coupling constant suggests a structure involving an η^2-H-$SiPh_2OEt$ ligand. The mechanism of these reactions is suggested to consist of dissociative loss of acetonitrile to produce the base-free silylene complex $[Cp^*(PMe_3)_2Ru{=}SiPh_2]^+$, which adds alcohol across the double bond to form **3**. The observed silane products are then formed via reductive elimination from ruthenium. The enolizable ketones MeCOMe and MeCOPh react with **1** in a similar fashion to give **2** and the silyl enol ethers $HSiPh_2(OCR{=}CH_2)$ (R = Me, Ph). Acetic acid reacts with **1** to afford **2** and $HSiPh_2(OOCMe)$.

Transition metal silylene complexes ($L_nM = SiR_2$) have been implicated in a number of processes involving metal-mediated transfer of silylene groups.[1] In particular, it appears that such species may be key intermediates in metal-catalysed Si—Si bond-forming reactions.[2–6] For example, $(PEt_3)_2PtCl_2$ acts as a catalyst for redistributing the disilanes $RMe_2SiSiMe_2H$ (R = H or Me) to a mixture of oligomers $R(SiMe_2)_nH$ (n = 1–6).[6a] Addition of diphenylacetylene to this reaction mixture resulted in trapping of $SiMe_2$ groups to form $Me_2Si(CPh{=}CPh)_2SiMe_2$. Based on these observations, Yamamoto *et al.* proposed that an intermediate $Pt{=}SiMe_2$ complex was responsible for transfer of silylene groups.[6b] Recently, Zybill *et al.* have shown that the dimethylsilylene derivative $(CO)_4FeSiMe_2$(HMPA) thermally decomposes to $Fe_3(CO)_{12}$ and polysilane of low molecular weight.[7a]

Direct, conclusive evidence for participation of silylene complexes in reaction schemes awaits reactivity studies based on isolated, well-characterized examples. To date only a few transition metal silylene complexes have been reported, and these all display coordination of a Lewis base to the silylene silicon atom.[7–9] Furthermore, very little has been reported regarding reactivity trends for these species. We have described the synthesis and characterization of a cationic ruthenium silylene complex, $[Cp^*(PMe_3)_2Ru{=}SiPh_2(NCMe)]^+BPh_4^- \cdot CH_2Cl_2$ (**1**, $Cp^* = \eta^5\text{-}C_5Me_5$), which is labile in solution and serves as a source of the base-free silylene species $Cp^*(PMe_3)_2Ru{=}SiPh_2^+$.[8b] Here we describe reactivity studies of this complex, which involve transfer of the silylene group to alcohol, ketone and acetic acid substrates.

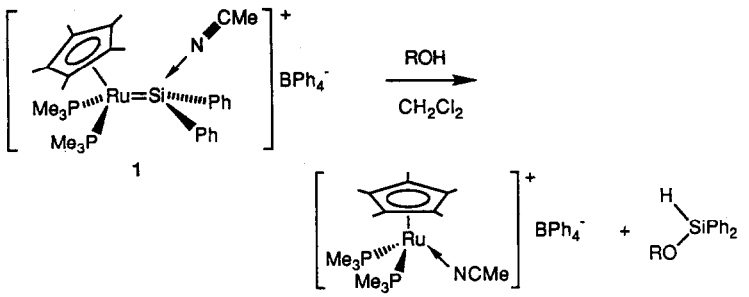
RESULTS AND DISCUSSION

Complex **1** exhibits very limited reactivity toward the aryl silanes $PhSiH_3$, Ph_2SiH_2 and Ph_3SiH. Whereas Ph_2SiH_2 and Ph_3SiH do not react with **1** in dichloromethane over a 3-day period, $PhSiH_3$ reacts slowly with **1** over 1 week to produce a number of unidentified products.

Addition of excess methanol, ethanol or tert-butanol to a dichloromethane solution of **1** results in immediate, quantitative (by ^{1}H NMR spectroscopy) conversion to the ruthenium acetonitrile

† Author to whom correspondence should be addressed.

complex **2** and the corresponding alkoxysilanes $HSiPh_2OR$ [eq. (1), R = Me, Et, or ^tBu].



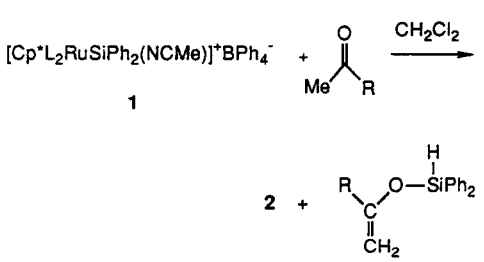
(1)

Ruthenium complex **2** was identified by comparison of ^1H and ^{31}P NMR data with an authentic sample, prepared from $Cp^*(PMe_3)_2RuCl$ and $AgBPh_4$ in acetonitrile.[8b] Spectroscopic characterization of the alkoxysilanes was also facilitated by independent syntheses. These $HSiPh_2OR$ compounds were obtained in high yields by reaction of $HSiPh_2Cl$ with pyridine and the corresponding alcohol in diethyl ether. These reactions are related to the previously reported conversion of **1** and water to **2** and $Ph_2Si(H)OSi(H)Ph_2$.[8b]

Variable temperature ^1H NMR spectroscopy showed that **1** and ethanol react in dichloromethane-d_2 at $-60°C$ to form an intermediate hydride complex **3**. This species exhibits a triplet resonance at δ −11.08 in the ^1H NMR spectrum, characteristic for a ruthenium hydride complex with equivalent coupling to two phosphorous nuclei. However, the $^2J_{PRuH}$ coupling constant appears to be too low (11 Hz) to be due to the silyl-hydrido complex *trans*-$[Cp^*(PMe_3)_2Ru(H)SiPh_2OEt]BPh_4$, since the related alkyl-hydrido complex $[Cp^*(PMe_3)_2Ru(H)Me]BF_4$ has a $^2J_{PRuH}$ coupling constant of 41.8 Hz.[10] The low $^2J_{PRuH}$ coupling constant for **3**, and the equivalence of the phosphine ligands, is consistent with a structure involving an η^2-silane ligand, $[Cp^*(PMe_3)_2Ru(\eta^2\text{-}HSiPh_2OEt)]BPh_4$. Note that the related silyl complexes $Cp^*(PMe_3)Ru(SiR_3)_2H$ [SiR_3 = $Si(OEt)_3$, $SiPh_2Cl$ and $SiMe_2OEt$] also possess low $^2J_{PRuH}$ coupling constants (3 Hz), suggesting the possibility of η^2-$HSiR_3$ ligands.[8b] Other η^2-$HSiR_3$ complexes have been reported,[11] and it has been observed that similar dihydrogen complexes $Cp(L)(L')Ru(\eta^2\text{-}H_2)^+$ are relatively stable species.[12] Unusually small $^2J_{PMH}$ coupling constants for the "hydride" atom(s) of both η^2-H_2 and η^2-$HSiR_3$ complexes have been observed. Note that for $Cp(Me_2PCH_2CH_2PMe_2)RuH_2^+$, $^2J_{PRuH}$ = 31 Hz, whereas for $Cp(Me_2PCH_2CH_2PMe_2)Ru(\eta^2\text{-}H_2)^+$, $^2J_{PRuH}$ = 3.6 Hz.[12c] As the reaction solution is warmed above $-60°C$, intermediate **3** decomposes to **2** and $HSiPh_2OEt$ ($t_{1/2}$ at $-40°C$ = 40 min).

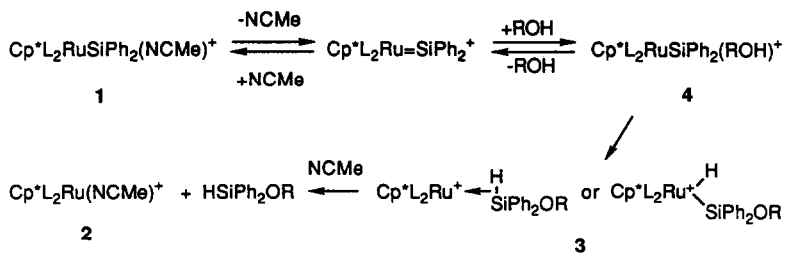
Reactions of **1** with alcohols and ketones (*vide infra*) are severely inhibited by addition of acetonitrile, suggesting that reactions occur via initial loss of acetonitrile from **1**. Indeed we have previously shown that the lability of **1** in solution is due to rapid, dissociative loss of acetonitrile.[8b] The above experimental observations suggest the proposed mechanism shown in Scheme 1. Intermediate **4** was not detected, but it is presumed that coordination of alcohol to the silylene silicon atom precedes Si—H bond formation. Migration of hydrogen may then proceed via transfer to ruthenium, giving the observed $[Cp^*(PMe_3)_2Ru(H)SiPh_2OR]^+$ intermediate complex that decomposes to **2** and $HSiPh_2OR$ by reductive elimination. A kinetic isotope effect, determined by use of a 1 : 1 EtOH/EtOD mixture, was found to be k_H/k_D = 1.0. This negligible isotope effect suggests that a hydrogen migration step is not rate-limiting.

Silylene complex **1** also reacts with enolizable ketones over the course of *ca* 1 h to provide quantitative yields (by ^1H NMR spectroscopy) of **2** and silyl enol ethers [eq. (2), R = Me, Ph].



(2)

Under comparable conditions, no reaction of benzophenone occurred over 12 h. The silyl enol ethers were separated from the reaction mixtures by removal of volatiles under vacuum and extraction with pentane. After filtration, removal of the pentane under reduced pressure afforded the pure silyl enol ethers as colourless oils in high yields. For these reactions, no intermediates could be observed



Scheme 1. (L = PMe_3.)

by variable temperature ^{1}H NMR spectroscopy, but we assume that coordination of substrate to the silylene ligand is a crucial step. In a similar process, reaction of **1** with acetic acid gives **2** and $HSiPh_2(OOCMe)$.

The reactions reported here involve transfer of a silylene fragment ($SiPh_2$) from a metal centre to another molecule. In addition, it is interesting to note that the silicon-containing products are those that would be expected from reactions of alcohols, ketones and carboxylic acids with free silylenes.[13] However, reactions involving the ruthenium silylene derivative **1** appear to be mechanistically distinct, in that the metal centre plays an important role. It is clear that there is much to be learned about reactions of transition metal silylene complexes, and future reports will address additional features of this chemistry.

EXPERIMENTAL

Manipulations were carried out under inert atmospheres of nitrogen or argon using standard Schlenk line and glovebox techniques. Dry, oxygen-free solvents were employed throughout. IR spectra were recorded on a Perkin–Elmer 1330 infrared spectrometer. NMR spectra were recorded on a GE QE-300 instrument at 300 MHz (^{1}H) and 121.5 MHz (^{31}P). Mass spectra were obtained with a Hewlett–Packard 5988-A mass spectrophotometer. Complexes **1**,[8b] **2**[8b] and $Cp^*(PMe_3)_2RuCl$[14] were prepared according to literature procedures.

Reactions of **1** *with protic substrates*

A representative procedure is given for the reaction with methanol. Methanol (4.4×10^{-3} cm^3, 0.108 mmol) was added to a dichloromethane solution (2 cm^3) of **1** (0.100 g, 0.108 mmol). After stirring the solution for 0.5 h, the volatiles were removed under vacuum. The sticky solid was extracted with pentane (5 cm^3) and volatiles were removed from this extract to afford an oily liquid. The remaining solid was shown to be **2** by ^{1}H NMR spectroscopy. The oily liquid was identified as $HSiPh_2(OMe)$ (*ca* 96% pure), by comparison of spectroscopic properties with an independently prepared sample.

Independent syntheses of silanes

These syntheses were accomplished using the reaction of $HSiPh_2Cl$ with pyridine and the appropriate protic reagent. A representative procedure is given for $HSiPh_2OMe$. The silane $HSiPh_2Cl$ (2.0 cm^3, 0.010 mol) and methanol (0.44 cm^3, 0.012 mol) were combined with diethyl ether (40 cm^3) in a flask. Pyridine (1.1 cm^3, 0.012 mol) was then added by syringe, and the resulting solution was stirred for 2 h. The reaction mixture was filtered and the volatiles were removed from the solution containing the product. This afforded an oily liquid which was distilled *in vacuo* (98°C, 0.01 torr) to obtain 2.0 cm^3 of product (85% yield).

PENTAMETHYLDISILYLMETHYL DERIVATIVES OF THE TRANSITION METALS, $LMCH_2SiMe_2SiMe_3$ [LM = $(\eta^5\text{-}C_5R_5)M(CO)_n^-$, M = Fe, W, R = H, Me, $n = 2, 3$; $(\eta^5\text{-}C_9H_7)Fe(CO)_2^-$; $(\eta^5\text{-}C_5H_5)_2MCl^-$, M = Ti, Zr, Hf]*

SNEH SHARMA, RAMESH N. KAPOOR, FRANCISCO CERVANTES-LEE and KEITH H. PANNELL†

Department of Chemistry, The University of Texas at El Paso, El Paso, TX 79968-0513, U.S.A.

Abstract—Pentamethyldisilylmethyl derivatives of the transition metals have been synthesized, $LMCH_2SiMe_2SiMe_3$ [LM = $(\eta^5\text{-}C_5R_5)M(CO)_n^-$, M = Fe, W, R = H, Me, $n = 2$, 3; $(\eta^5\text{-}C_9H_7)Fe(CO)_2^-$; $(\eta^5\text{-}C_5H_5)_2MCl^-$, M = Ti, Zr, Hf]. The cyclopentadienylcarbonyl complexes are photochemically labile with respect to rearrangement to LM-$SiMe_2CH_2SiMe_3$ and are also subject to base-induced migration to the cyclopentadienyl ring to form $(\eta^5\text{-}Me_3SiCH_2SiMe_2C_5H_4)$ derivatives. The titanium, zirconium and hafnium complexes exhibit neither property; the only compound isolated from the photochemical treatment of these complexes being $Me_3SiSiMe_3$. Structural analyses of $(\eta^5\text{-}C_5H_5)W(CO)_3CH_2SiMe_2SiMe_3$ and its phosphine-substituted rearrangement product, $(\eta^5\text{-}C_5H_5)W(CO)_2(PPh_3)SiMe_2CH_2SiMe_3$, are presented.

In a communication published in 1974 we reported that the complex $(\eta^5\text{-}C_5H_5)Fe(CO)_2CH_2SiMe_2SiMe_3$, containing a Si—Si bond, was photochemically labile with respect to rearrangement to a complex containing a direct Fe—Si bond, $(\eta^5\text{-}C_5H_5)Fe(CO)_2SiMe_2CH_2SiMe_3$.[2] Furthermore we observed that when the complex was subjected to base treatment, followed by addition of MeI, a migration of the disilylmethyl group to the cyclopentadienyl ring occurred, during which the group again rearranged to form $(\eta^5\text{-}Me_3SiCH_2SiMe_2C_5H_4)Fe(CO)_2Me$.[3] These two brief communications are the only reports concerning the chemistry of the ligand $Me_3SiSiMe_2CH_2$-. We are presently reinvestigating this area of chemistry, and now report the synthesis, structural characterization and chemical reactivity, of a series of such disilylmethyl complexes of iron, tungsten, titanium, zirconium and hafnium.

RESULTS AND DISCUSSION

The synthesis of the complexes $LMCH_2SiMe_2SiMe_3$ was accomplished via two distinct chemical pathways, outlined in eq. (1) for the cyclopentadienylcarbonyl complexes, and eq. (2) for the group 4 chlorometallocene complexes:

$$[(\eta^5\text{-}C_5R_5)M(CO)_n]^-Na^+ + ClCH_2SiMe_2SiMe_3 \longrightarrow (\eta^5\text{-}C_5R_5)M(CO)_nCH_2SiMe_2SiMe_3 \quad (1)$$

$[(\eta^5\text{-}C_5H_5)M(CO)_n]^- = (\eta^5\text{-}C_5Me_5)Fe(CO)_2$ (IV), $(\eta^5\text{-}C_5H_5)W(CO)_3$ (V)

$$(\eta^5\text{-}C_5H_5)_2MCl_2 + Mg + ClCH_2SiMe_2SiMe_3 \longrightarrow (\eta^5\text{-}C_5H_5)_2M(CH_2SiMe_2SiMe_3)Cl \quad (2)$$

M = Ti (I), Zr (II), Hf (III).

A reaction similar to those described in eq. (1) was performed using $(\eta^5\text{-}C_9H_7)Fe(CO)_2$, the π-indenyl analogue of the $(\eta^5\text{-}C_5H_5)Fe(CO)_2$ (Fp) anion, to produce $(\eta^5\text{-}C_9H_7)Fe(CO)_2CH_2SiMe_2SiMe_3$ (VI). The yields from such direct salt elimination reactions were in the range 50–70%, while whose for the reactions outlined in eq. (2) were more moderate and variable, 7–40%. The complexes IV, V and VI are thermally stable at room temperature, and may also be handled in the air for brief periods of time. The group 4 complexes are very susceptible to decomposition in the presence

*Organometalloidal derivatives of the transition metals—27. For part 26 see ref. 1.

†Author to whom correspondence should be addressed.

of trace amounts of moisture to form $[(\eta^5\text{-}C_5H_5)_2MCl]_2O$. Such behaviour was also reported by Lappert's group for the related monosilylmethyl analogues, $(\eta^5\text{-}C_5H_5)_2MCl(CH_2SiMe_3)$.[4] We were unable to obtain satisfactory analyses on these complexes.

Spectroscopic analysis of the new complexes was performed via the usual techniques, IR, ^1H, ^{13}C and also ^{29}Si NMR. The various data from such investigations are in total accord with the proposed structures, and are recorded in Table 1.

We have performed a single crystal X-ray analysis on **V**, Fig. 1(a). The various bond lengths and angles for the $(\eta^5\text{-}C_5H_5)W(CO)_3^-$ portion of the complex are as expected, and the W—C σ bond length of 2.28 Å is also well within the expected range. The Si—Si bond length of 2.347(4) Å is also in the middle of the published permethylated disilane Si—Si bond lengths. We have previously reported that direct substitution of a transition metal onto a disilane fragment, $(\eta^5\text{-}C_5H_5)Fe(CO)_2$ substituents, causes a pronounced elongation of the Si—Si bond. In the case of complex **V** the effect of the tungsten substituent is essentially muted by the intervening CH_2 group.

We have investigated the chemical properties of the complexes with respect to two main reaction conditions, photochemistry and base treatment, and the results are discussed below.

Photochemistry

The new π-cyclopentadienyl(π-indenyl)carbonyl complexes are readily rearranged when treated with UV light, for example eq. (3):

$$\mathbf{VI} \xrightarrow{h\nu/hexane} (\eta^5\text{-}C_9H_7)Fe(CO)_2SiMe_2CH_2SiMe_3. \quad (3)$$
(VIII)

The new rearranged materials are isolable as stable complexes for the iron systems, but could not be isolated from the reaction with the tungsten complex **V**. In this latter case it was neccessary to perform the photochemical reaction in the presence of triphenylphosphine in order to isolate the corresponding rearranged dicarbonyl(phosphine) complex (**IX**), eq. (4):

$$\mathbf{V} + PPh_3 \xrightarrow{h\nu/hexane} (\eta^5\text{-}C_5H_5)W(CO)_2(PPh_3)SiMe_2CH_2SiMe_3. \quad (4)$$
(IX)

The photochemical rearrangement reactions may be followed by IR spectroscopy, since the metal–carbon complexes exhibit ν(CO) stretching modes at higher frequencies than their metal–silicon bonded counterparts. ^{29}Si NMR is useful for complete characterization. Cleavage of the Si—Si bond transforms the silicon resonances from typical disilane resonances, modified by the transition metal substituent, into a pair of essentially isolated silane fragments. Thus, whereas the two ^{29}Si resonances in **IV** occur at −8.7 ppm (Fe—CH_2*Si*Si) and −20.6 ppm (FeCH_2Si*Si*), the product **VII** resonances are at 42.0 ppm (Fe—*Si*CH_2Si) and 0.4 ppm (Fe—SiCH_2*Si*). As with other iron complexes, the effect

[a] NMR spectra were recorded in C_6D_6, with the exception of **IX** which was recorded in $CDCl_3$. All IR spectra were recorded in n-hexane. Melting points were recorded in open capilliary tubes and are uncorrected.

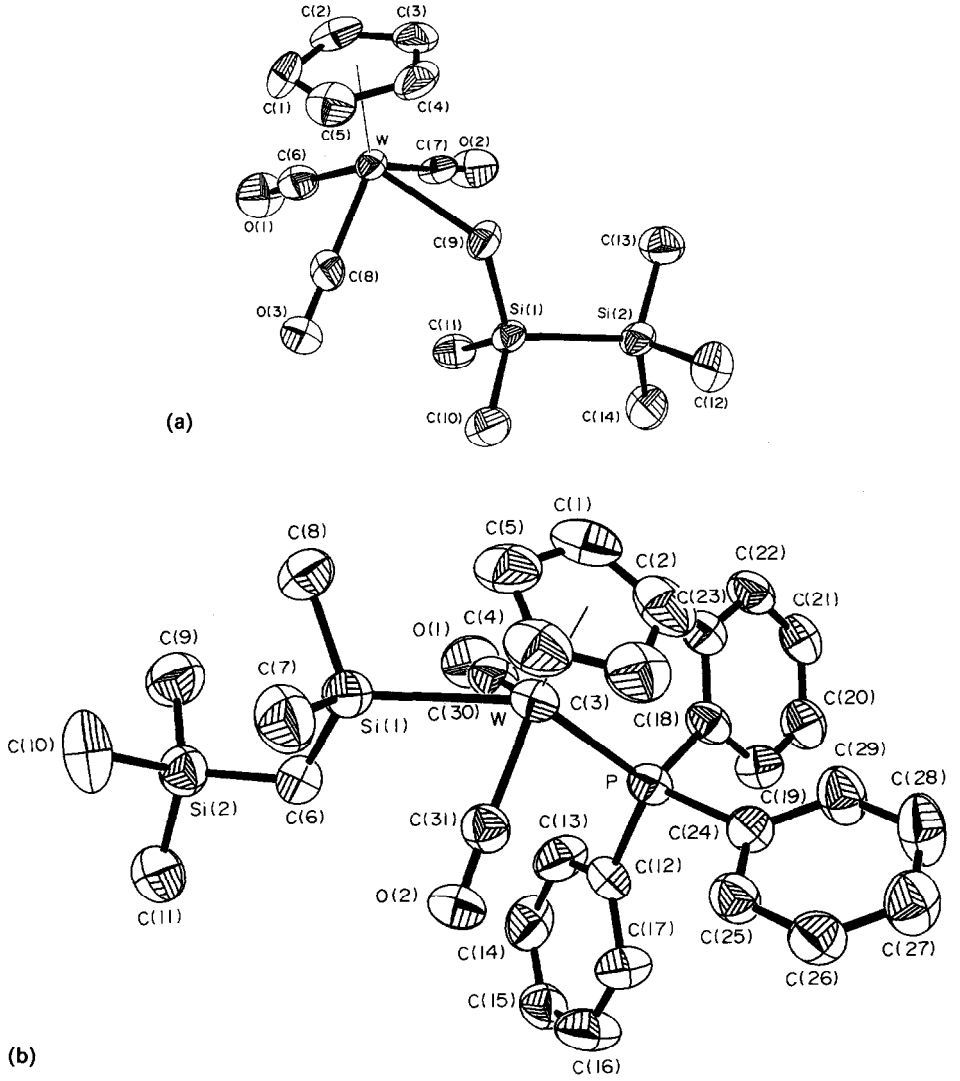

Fig. 1. (a) Structure of $(\eta^5\text{-}C_5H_5)W(CO)_3CH_2SiMe_2SiMe_3$ (V); (b) structure of $(\eta^5\text{-}C_5H_5)W(CO)_2(PPh_3)SiMe_2CH_2SiMe_3$ (IX).

of the transition metal upon the ^{29}Si NMR chemical shift in comparison to the corresponding methyl analogue, i.e. $FeSiR_3$ vs $MeSiR_3$, $\Delta\delta$, is great when the silicon atom is directly attached to the metal, e.g. 49 ppm for $FeSiCH_2SiMe_3$ (VIII) vs $Me_3SiCH_2SiMe_3$, but almost negligible in the case of a silicon atom removed from the iron by three bonds.[5,3] Similar results may be observed for the tungsten complexes, except that the shielding effect created by the tungsten atom upon directly bound silicon atoms is considerably less than that observed in the case of iron complexes.

We have also characterized the rearranged tungsten complex IX by single crystal X-ray structural analysis, Fig. 1(b). The various aspects of the structure are unremarkable, but the structure represents only the third example of the structural characterization of a W—Si bond, and the first in the $(\eta^5\text{-}C_5H_5)W(CO)_n^-$ type system. The W—Si bond length is 2.633(2) Å, significantly longer then those in $(PMe_3)_3IW(H)_2SiMe_3$, 2.389 Å,[6] and $(CO)_4W(\mu\text{-}SiEt_2)_2W(H_2)(CO)_4$, 2.586 Å.[7] The three complexes are very different with respect to the ligands on tungsten, and of course one of the complexes contains a bridging silyl group, thus until a greater series of complexes are available for study the significance of such data is unclear. Selected bond lengths and bond angles are presented in Table 2.

In general the nature of the W—Si bond precludes the ready formation and examination of a large range of complexes of the type $(\eta^5\text{-}C_5H_5W(CO)_3SiR_3$, cf. the large number of complexes of the type $(\eta^5\text{-}C_5H_5)Fe(CO)_2SiR_3$. The rearrangement illustrated here suggests a possible

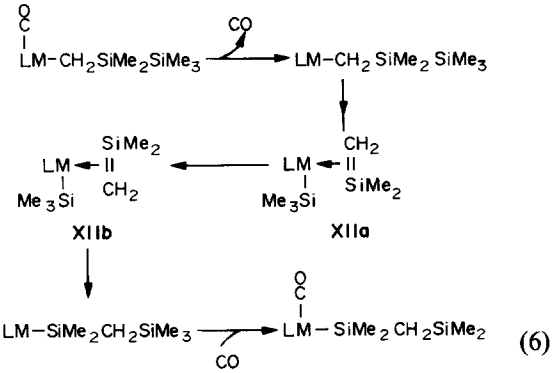
route to stable complexes with a W—Si bond. The rearrangement is related to that initially observed in our laboratories for the complex $(\eta^5\text{-}C_5H_5)Fe(CO)_2CH_2SiMe_2H$,[8] and studied extensively by Wrighton and co-workers for $(\eta^5\text{-}C_5Me_5)Fe(CO)_2CH_2SiMe_2H$ and related tungsten complexes, eq. (5):[9]

$$(\eta^5\text{-}C_5H_5)Fe(CO)_2CH_2SiMe_2H \xrightarrow{h\nu} (\eta^5\text{-}C_5H_5)Fe(CO)_2SiMe_3 \quad (5a)$$

$$(\eta^5\text{-}C_5Me_5)W(CO)_3CH_2SiMe_2H \longrightarrow (\eta^5\text{-}C_5Me_5)W(CO)_3SiMe_3. \quad (5b)$$

Using low temperature matrix isolation spectroscopy, Wrighton and his group confirmed our original suggestion that this reaction proceeded via initial loss of CO, followed by a β-elimination reaction to form a hydrido-metal silene intermediate which rearranged to the observed products upon recombination of CO, or in the presence of other ligands, e.g. PPh_3. We suggest that the mechanism of the disilylmethyl rearrangement reaction is similar to that operating for the $LMCH_2SiMe_2H$ complexes in which an intermediate of type **XII** is formed, eq. (6). This also has the potential for rotation about the metal–silene bond, with recombination to form the observed products upon recoordination of the CO or phosphine ligand.



(6)

We are pursuing a program of chemical modification of the $LMCH_2SiR_2SiR_3$ complexes in the hope of isolating silene intermediates of the type **XII**. It is pertinent that both the Berry and Tilley groups have recently discussed and isolated transition metal silene complexes that can be thought of as models for the system discussed here.[10,11]

As in the case of $FpCH_2SiMe_2H$, the rearrangement observed for the iron complexes $(\eta^5\text{-L})Fe(CO)_2CH_2SiMe_2SiMe_3$ (L = C_5Me_5, C_9H_7) may also be effected thermally. The rates of transformation to the corresponding $(\eta^5\text{-L})FeSiMe_2CH_2SiMe_3$ complexes vary considerably. The π-indenyl complex transforms the fastest, 16 h in refluxing hexane, as might be expected if η^5- to η^3-ring slippage is occurring providing a low-energy route to 16e$^-$ coordinatively-unsaturated intermediates. The ability of the π-indenyl group to activate carbonyl insertion reactions via such η^5–η^3 slippages is well established.[12] The $(\eta^5\text{-}C_5Me_5)$ complex rearranged smoothly after 60 h, but the $(\eta^5\text{-}C_5H_5)$ complex does not yield any significant product after 80 h, exhibiting considerable Fe—C bond cleavage such that the only isolated product was $[(\eta^5\text{-}C_5H_5)Fe(CO)_2]_2$. We are currently investigating the nature of the thermal transformation in the case of the π-indenyl system to note if loss of CO is important.

We have subjected the group 4 chlorometallocene complexes **I**, **II** and **III** to similar photochemical treatment. Monitoring the reaction progress via ^{29}Si NMR, it was apparent that no rearrangements of the type illustrated above occur in this system. After prolonged irradiation in inert hydrocarbon solvents the only identifiable silicon-containing product was $Me_3SiSiMe_3$. This is probably formed via homolytic cleavage of the M—C bond, followed by hydrogen abstraction from the solvent.

Base treatment

Treatment of cyclopentadienylcarbonylmetal complexes of the type $(\eta^5\text{-}C_5H_5)M(CO)_n(L)R$, (M = Fe, Mo, W, Ru, Re, n = 2, 3, R = alkyl, acyl, silyl, germyl, stannyl, plumbyl) with bases such as n-BuLi and LDA at −78°C has been shown to result in deprotonation of the cyclopentadienyl ring to produce a ring-centred anion.[13] This anion is stable in the case of R = alkyl and may be trapped by addition of the appropriate quench, e.g. methyliodide. In the other cases a migration of the R group occurs, sometimes not until elevated temperatures, i.e. 25°C, to produce a metal-centred anion $[(\eta^5\text{-}RC_5H_4)M(CO)_n(L)]^-$ which can also be trapped with appropriate reagents. Treatment of **V** with LDA at low temperature, followed by warming to ambient temperature, led to the formation of the corresponding metal-centred anion as illustrated in eq. (7):

$$(\eta^5\text{-}C_5H_5)W(CO)_3CH_2SiMe_2SiMe_3 \xrightarrow{LDA} [(\eta^5\text{-}LiC_5H_4)W(CO)_3CH_2SiMe_2SiMe_3] \downarrow$$
$$(\eta^5\text{-}SiMe_3CH_2SiMe_2C_5H_4)W(CO)_3Me \xleftarrow{MeI} [(\eta^5\text{-}Me_3SiCH_2SiMe_2C_5H_4)W(CO)_3]^-Li^+. \quad (7)$$
(X)

The migration of the disilylmethyl group occurs with a rearrangement that involves the cleavage of the Si—Si bond and it appears that this is a general type of reaction. The spectroscopic data for the migration product is in accord with the structure. In the case of the rearranged complex **X**, the two ^{29}Si resonances are at −4.2 and 0.1 ppm, respectively. The former resonance is due to the silicon atom directly bonded to the cyclopentadienyl ring, and is typical of such atoms being shifted 3–5 ppm to lower field than the related $MeSiR_3$ compound.[3]

Treatment of the group 4 chlorometallocene-disilylmethyl complexes with LDA did not result in straightforward chemistry and we are still investigating this system.

EXPERIMENTAL

All reactions were performed under nitrogen atmosphere using oxygen-free dry solvents. Titanocene dichloride, zirconocene dichloride and hafnocene dichloride were purchased from Aldrich Chemical Co., Milwaukee, Wisconsin. The pentamethylcyclopentadienylirondicarbonyl dimer was obtained from Strem Chemical Co., Newburyport, Massachusetts, and the indenylirondicarbonyl dimer was prepared by literature procedures.[14] Tungsten hexacarbonyl was purchased from Pressure Chemical Co., Pittsburgh, Pennsylvania, and $Me_5Si_2CH_2Cl$ and $Me_5Si_2CH_2I$ were prepared by literature procedures.[15]

IR spectra were recorded on a Perkin–Elmer 1600 series FT–IR spectrophotometer, and NMR spectra were recorded on an IBM NR/200 FT–NMR spectrometer. All analyses were performed by Galbraith Laboratories Inc, Knoxville, Tennessee.

The syntheses of the new compounds are typified by the examples given below. The analytical and spectral data are given in Table 1.

Synthesis of $(\eta^5\text{-}C_5H_5)_2Ti(CH_2SiMe_2SiMe_3)Cl$ **(I)**

Into a 100-cm^3 side-arm flask, magnesium turnings (0.24 g, 0.01 g atom), titanocene dichloride (2.0 g, 8.0 mmol) and $Me_5Si_2CH_2Cl$ (1.8 g, 10 mmol) were placed in 20 cm^3 of THF. A crystal of iodine was introduced into the reaction mixture which was stirred at room temperature for 2 h. After about 10 min the colour of solution changed to dark red. The solvent was removed *in vacuo* and the dark residue was extracted with a 1 : 1 hexane–methylene chloride mixture. The solution was filtered under nitrogen and subsequent to evaporation of the solvents, a dark red solid was obtained, which on sublimation at 80°C *in vacuo*, yielded 0.22 g (0.6 mmol, 7.5%) of the red, crystalline title complex.

$(\eta^5\text{-}C_5H_5)_2Zr(CH_2SiMe_2SiMe_3)Cl$ **(II)** and $(\eta^5\text{-}C_5H_5)_2Hf(CH_2SiMe_2SiMe_3)Cl$ **(III)** were synthesized in a similar manner, 31 and 35% respective yields, and were purified by recrystallization from hexane.

Synthesis of $(\eta^5\text{-}C_5Me_5)Fe(CO)_2CH_2SiMe_2SiMe_3$ **(IV)**

A 250-cm^3 round-bottomed flask fitted with a septum and a magnetic stirring bar was charged with 40 g of 1% Na/Hg amalgam and 60 cm^3 of THF. To this was added $[(\eta^5\text{-}C_5Me_5)Fe(CO)_2]_2$ (1.5 g, 3.0 mmol). The mixture was stirred for 24 h, at which time IR monitoring indicated that the starting material had been transformed into $[(\eta^5\text{-}C_5Me_5)Fe(CO)_2]^-Na^+$, ν(CO), 1993, 1875, 1860, 1791 and 1755 cm^{-1}. Mercury was removed and the solution was cooled to 0°C, and $ClCH_2Si_2Me_5$ (1.0 g, 5.0 mmol) was added. The solution was stirred for 2 h and the solvent removed *in vacuo*. To the resulting residue was added 60 cm^3 of hexane and the solution was stirred for 1 h and then filtered. The filtrate was concentrated to 5 cm^3 and passed through a silica gel column. A yellow band was formed and eluted with hexane to yield **IV** (1.1 g, 2.4 mmol, 46%) as a yellow solid.

Synthesis of $(\eta^5\text{-}C_5H_5)W(CO)_3CH_2SiMe_2SiMe_3$ **(V)**

A 250-cm^3 side-arm flask was charged with sodium metal (0.30 g, 1.3 g atom) and 60 cm^3 of THF. The sodium suspension in THF was treated with cyclopentadiene (1.5 cm^3, 2.4 mmol) (freshly distilled) in order to react with all the sodium to form a light pink sodium cyclopentadienide solution. The resulting solution was treated with tungsten hexacarbonyl (3.6 g, 10.2 mmol) and the solution heated to reflux for 72 h to form a yellow solution of $[(\eta^5\text{-}C_5H_5)W(CO)_3]^-Na^+$. To this solution was added 5.5 g of $Me_5Si_2CH_2I$ and the solution was refluxed for 18 h. THF was removed and a yellowish-brown liquid was extracted with hexane. Upon concentration to 5 cm^3 and chromatography on a 2 × 25 cm silica gel column with hexane, a yellow band was developed which yielded **V** (2.70 g, 6.1 mmol, 60%).

Photolysis of $(\eta^5\text{-}C_5H_5)_2Ti(CH_2SiMe_2SiMe_3)Cl$ **(I)**

Compound **I** (0.10 g) was dissolved in 1 cm^3 of degassed C_6D_6. This was irradiated for 20 h in a sealed Pyrex NMR tube and monitored by ^{29}Si NMR. The only observable new product was $Me_3SiSiMe_3$.

Photolysis of $(\eta^5\text{-}C_5Me_5)Fe(CO)_2CH_2SiMe_2SiMe_3$ **(IV)**

A solution of the title complex (0.150 g dissolved in 1 cm^3 of degassed C_6D_6) was irradiated for 15 h in a sealed Pyrex NMR tube and monitored by ^{29}Si NMR. After 12 h it was evident that no starting material was present and the irradiation was stopped. The solution was placed directly onto a 2.5×10 cm silica gel column and eluted with hexane. A single yellow band formed, that upon removal and recrystallization from the same solvent yielded **IV** (0.12 g, 80%).

Photolysis of $(\eta^5\text{-}C_5H_5)W(CO)_3CH_2SiMe_2SiMe_3$ **(V)** *with* Ph_3P

A mixture of **V** (0.6 g, 1.25 mmol) and Ph_3P (0.6 g, 2.2 mmol) in 40 cm^3 of hexane, in a quartz tube, was irradiated for 15 h and was monitored by IR spectroscopy. Upon complete removal of the starting material, the solvent was removed and the resulting reddish-orange solid was dissolved in a minimum quantity of methylene chloride and passed through a 2×25 cm silica gel column. An initial yellow–red fraction, eluted with hexane, was collected and after removal of the solvent yielded $(\eta^5\text{-}C_5H_5)W(CO)_2(PPh_3)SiMe_2CH_2SiMe_3$ (0.3 g, 40%). This material was further purified by recrystallization from hexane.

LDA *treatment of* $(\eta^5\text{-}C_5H_5)W(CO)_3CH_2SiMe_2SiMe_3$ **(V)**

To **V** (0.65 g, 1.3 mmol) in 20 cm^3 of THF, in a side-arm flask at 0°C, was added dropwise freshly prepared LDA (4 cm^3, 2.2 mmol). The colour of the solution immediately changed to orange. The solution was stirred for 45 min, at which time the ν(CO) bands of the starting material had been replaced by bands at 1898, 1800, 1778(sh) and 1713 cm^{-1} indicative of a cyclopentadienyltungstentricarbonylate. Addition of excess methyl iodide (2 cm^3), followed by stirring for 10 min, gave ν(CO) absorptions at 2010 and 1914 cm^{-1}. The solvent was removed and an orange compound was extracted with a 1:1 hexane–methylene chloride mixture. This was recrystallized from hexane to yield yellow, crystalline $(\eta^5\text{-}C_5H_4SiMe_2CH_2SiMe_3)W(CO)_3Me$ (0.4 g, 60%).

Structural analysis of $(\eta^5\text{-}C_5H_5)W(CO)_2(PPh_3)SiMe_2CH_2SiMe_3$ **(IX)**

An irregularly shaped crystal, $0.22 \times 0.48 \times 0.50$ mm, was mounted on a glass fibre and covered with epoxy glue. Crystal data were collected at room temperature on a R3m/V Nicolet four-circle diffractometer with graphite monochromated Mo-K_α, $\lambda = 0.71073$ Å, radiation. Unit cell parameters and standard deviations were obtained by a least-squares fit to 25 reflections randomly distributed in reciprocal space and lying in the 2θ range 15–30°. Intensity data were collected in the ω scan mode, with scans from 0.75° below $K_{\alpha 1}$ to 0.75° above $K_{\alpha 2}$, with a variable scan speed of 3–20° min^{-1}. Background counts were taken with a stationary crystal and total background time/scan time of 0.5. Three standard reflections were monitored every 100 reflections and showed no significant decay. The data were corrected for Lorentz and polarization effects and a semi-empirical absorption correction was also applied giving a min/max transmission of 0.020/0.044.

The space group $P2_1/n$ was determined from the systematic absences. The structure was solved by the heavy-atom method and refined by full-matrix least-squares using the SHELXTL-PLUS software package on a Microvax II computer. Selected bond lengths and bond angles are provided in Table 2, and the various collection and refinement data are recorded in Table 3.

Structural analysis of $(\eta^5\text{-}C_5H_5)W(CO)_3CH_2SiMe_2SiMe_3$ **(V)**

A yellow plate of **V**, $0.8 \times 0.4 \times 0.18$ mm, was used for the structural characterization. Three standard reflections were monitored every 100 reflections and used in a profile analysis to allow for approximately 5% of intensity decay during the experiment. The data were corrected for Lorentz and polarization effects and a semi-empirical absorption correction factor was applied giving a min/max transmission ratio of 0.72/0.99. Selected bond lengths and angles are recorded in Table 2, and the various collection and refinement data are recorded in Table 3. Atomic coordinates and equivalent isotropic displacement coefficients for both structures are presented in Table 4.

REACTIVITY OF MOLYBDENUM AND TUNGSTEN DISILENE COMPLEXES

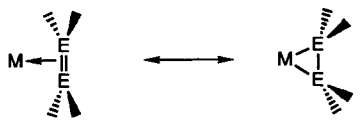
DONALD H. BERRY,† JEAN CHEY, HOWARD S. ZIPIN and PATRICK J. CARROLL

Department of Chemistry and Laboratory for Research on the Structure of Matter, University of Pennsylvania, Philadelphia, PA 19104-6323, U.S.A.

Abstract—The reactions of the η^2-disilene complexes $Cp_2M(\eta^2\text{-}Me_2Si{=}SiMe_2)$ (M = Mo, **1a**; W, **1b**) with a variety of inorganic and organic substrates are reported. Compound **1a** reacts with methanol to yield $Cp_2Mo(SiMe_2H)(SiMe_2OMe)$ (**2**, >80%) and $Cp_2Mo(H)(SiMe_2SiMe_2OMe)$ (**3**, < 20%), products of Si—Si and Mo—Si bond cleavages. Nucleophilic attack by methylenetrimethylphosphorane leads to opening of the $MoSi_2$ ring and yields the disilyl-substituted ylide $Cp_2Mo(H)(SiMe_2SiMe_2CH{=}PMe_3)$ (**4**). Although oxygen atom sources such as O_2, N_2O, epoxides and Ph_3PO do not react cleanly with **1**, reaction with elemental sulphur yields the symmetrical sulphur-atom insertion product cyclo-$Cp_2Mo(SiMe_2SSiMe_2)$ (**5**). In contrast, reaction with triphenylphosphine sulphide principally yields the unsymmetrical insertion product cyclo-$Cp_2Mo(SiMe_2SiMe_2S)$ (**6**). Compounds **5** and **6** have been characterized by X-ray diffraction studies. Insertion into the Si—Si bond of **1a** and **1b** is also observed in reactions with trimethylsilylazide and carbon dioxide, which yield cyclo-$Cp_2Mo(SiMe_2N(TMS)SiMe_2)$ (**7**) and cyclo-$Cp_2W(SiMe_2C(O)OSiMe_2)$ (**10**), respectively. Benzophenone also appears to insert between the two silicon atoms in **1a** to yield a five-membered ring compound, but the instability of this product has precluded a definitive assignment of the structure. The four-membered ring compound cyclo-$Cp_2Mo(SiMe_2)_3$ (**8**) has been identified in the reaction of **1a** with dimethylsilylene, generated by the thermolysis of hexamethylsilacyclopropane. Dimethylsilylene insertion is relatively unselective in non-coordinating solvents such as benzene, and the secondary insertion product cyclo-$Cp_2Mo(SiMe_2)_4$ (**9**) is also produced. However, only **8** is formed in tetrahydrofuran, an observation which can be attributed to the higher selectivity of the intermediate silylene–base adduct formed in the coordinating solvent.

There has been remarkable progress over the last few years in the preparation of transition metal complexes of unsaturated silicon ligands. Stable complexes of disilenes ($R_2Si{=}SiR_2$),[1–3] silenes ($R_2Si{=}CR_2$)[4,5] and silylenes ($=SiR_2$)[6,7] have been isolated and characterized to varying degrees. Although stable free silaolefins have been known for nearly 10 years,[8–11] their high reactivity requires the use of extremely bulky substituents for the preparation of stable species. In contrast, the stabilization afforded by coordination to transition metals has allowed the isolation of relatively unhindered silaolefin complexes.

The bonding of a silaolefin to a metal centre can be expected to be similar to that of an organic olefin, which is best described by the Dewar–Chatt–Duncanson model.[12] In this model synergistic σ and π interactions between the olefin p–π and π^* orbitals and metal orbitals of appropriate symmetry lead to a continuum of possible structures bounded by species containing formal sp^2 and sp^3 centres ("olefin complexes" and "metallacyclopropanes") as shown below.



In accord with this model, structural and spectroscopic evidence suggests that partial double bond character is maintained in the ground state structures of silaolefin complexes.[1–3,5] Reactivity is another measure by which the nature of silaolefin complexes can be gauged. This report describes the

† Author to whom correspondence should be addressed.

reactivity of molybdenum and tungsten disilene complexes towards a variety of inorganic and organic reagents. In many cases analogies can be found between the observed transformations and reactions of three-membered ring silicon compounds such as siliranes and disiliranes. In other instances, however, the chemistry parallels that of free disilenes or metal complexes of organic olefins. For the sake of clarity and convenience, the different classes of reactions have been organized and described in terms of transformations of a MSi_2 ring (e.g. ring-opening and insertion reactions).

The molybdenum and tungsten disilene complexes $Cp_2M(\eta^2\text{-}Me_2Si{=}SiMe_2)$ (M = Mo, **1a**; W, **1b**) can be prepared in multi-gram quantities using the procedures described recently by our group.[1,5] The tungsten analogue has been structurally characterized and exhibits a Si—Si bond length intermediate between single and double bond distances and a relatively small degree of pyramidalization at the silicon atoms. These features are analogous to those found in metal complexes of organic olefins.

In considering the reactivity of these Group 6 disilene complexes it is important to note that although the two extreme bonding limits described above differ in formal oxidation states, both formalisms lead to an $18e^-$ configuration at the metal. Thus it is unlikely that the disilene complexes would undergo nucleophilic processes such as associative ligand substitution or oxidative addition reactions at the saturated metal centre.† The transformations described below are consistent with this expectation and can be most easily analysed in terms of initial interactions between the silicon centres and the substrate.

RESULTS AND DISCUSSION

General comments

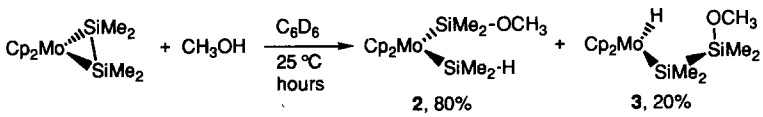
Disilene complexes **1a** and **1b** are stable for prolonged periods of time at 25°C in the solid state or as hydrocarbon solutions. However, their stability in solution at higher temperatures is limited, and benzene solutions decompose with a half-life of *ca* 1 day at 65°C. Non-polar reagents such as H_2 and $HSiMe_3$ were found to be unreactive towards the disilene complexes at 25 and at 65°C. Compound **1** also does not react with donor ligands such as CO, PMe_3 and C_2H_4. This is in contrast to the analogous tungsten *silene* complexes, $Cp_2W(\eta^2\text{-}Me_2Si{=}CH_2)$, which has been found to react readily at 25°C with H_2, H-$SiMe_3$, PMe_3 and C_2H_4 via a reversible "ring-slip" mechanism.[5] This process is apparently not viable for the disilene complexes.

Although most of the reactions are described for either **1a** or **1b**, the reactions of the other analogues were examined in small-scale NMR tube experiments in several cases (MeOH, Ph_3PS, CO_2) and the chemistry of both disilene complexes appears to be comparable.

Reactions which lead to opening of the MSi_2 *ring*

(a) *Methanolysis of* $Cp_2Mo(\eta^2\text{-}Me_2SiSiMe_2)$ (**1a**). Reaction of **1a** with methanol in benzene yields two products (4 : 1) within 18 h at 25°C. The structures of both can be assigned on the basis of the ^1H NMR spectra. The major product exhibits resonances attributable to equivalent Cp ligands, a —$SiMe_2H$ group and a —$SiMe_2OMe$ group, and can be formulated as $Cp_2Mo(SiMe_2H)(SiMe_2OMe)$ (**2**). In contrast, the minor product exhibits resonances for equivalent Cp ligands, a —$SiMe_2SiMe_2OMe$ group and a molybdenum hydride ($\delta - 7.64$, s, 1H) and is assigned as $Cp_2Mo(H)(SiMe_2SiMe_2OMe)$ (**3**).

Thus methanolysis of **1a** proceeds by two net pathways [eq. (1)]: addition of the methanol O—H bond across the Si—Si bond vector (major) and addition across a M—Si bond vector (minor). In both instances a new Si—O bond is formed. At this point it has not been established whether the mixture represents a kinetic or thermodynamic product distribution.



(1)

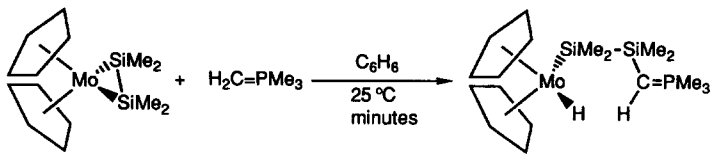
Methanolysis of **1a** could be initiated by nucleophilic attack of methanol or methoxide at silicon. Approach of the oxygen towards the different sides of the $SiMe_2$ plane could then determine whether M—Si or Si—Si bonds are cleaved. Alternatively, proton transfer from methanol to **1a** could lead to the observed products by an initiating electrophilic interaction.

In contrast to the methanolysis of **1a**, Pham and West have recently reported that reaction of the platinum disilene complex $(Et_3P)_2Pt(\eta^2\text{-}Mes_2SiSiMes_2)$ (Mes = 2,4,6-trimethylphenyl) with ethanol yields only the product of Pt—Si bond cleavage, $(Et_3P)_2Pt(H)(SiMes_2SiMes_2OEt)$.[2b] Interestingly, the methanolysis of platinum complexes of less hindered disilenes is reported to yield an uncharac-

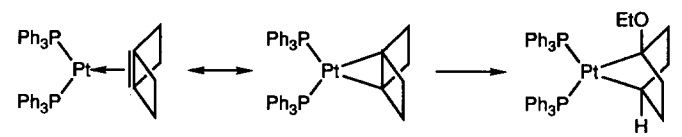
† Note, however, that a degree of unsaturation can be gained by a change in the bonding mode of a Cp ligand. See, for example, ref. 5.

terized mixture containing the products of both Pt—Si and Si—Si bond cleavage.[2b]

Cleavage by alcohols of the Si—Si bond in disilene complexes is reminiscent of the analogous reaction of a disilacyclopropane described by Seyferth and co-workers in 1980.[13] Another interesting parallel can be found in the chemistry of an *organic* olefin complex. In 1974, Wiberg and co-workers described the alcoholysis of the platinum complex of an extremely strained olefin, 2,2,0-bicyclohexene, which yields the product of C—C bond cleavage [eq. (2)].[14] This strained olefin and free disilenes share a common driving force for increased pyramidalization at the olefinic atoms (i.e. greater sp^3-character), which is partially relieved by coordination to a metal centre. Although mechanistic details are not available for either of these Si—Si or C—C bond cleavage reactions, it is clear that Si—Si bond cleavage in **1** is not driven solely by the thermodynamics of Si—O bond formation, or by other factors unique to silicon.



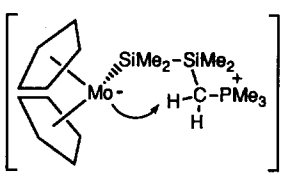
(3)



(2)

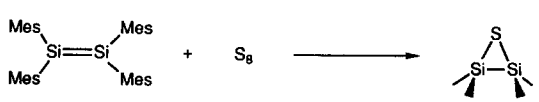
(b) *Reaction of* **1a** *with methylenetrimethylphosphorane.* Reaction of **1a** with methylenetrimethylphosphorane in benzene at 25°C quantitatively yields a single product within 15 min (55% yield after recrystallization). The product has been identified as the unusual disilyl-substituted ylide $Cp_2Mo(H)(SiMe_2SiMe_2CH{=}PMe_3)$ (**4**) on the basis of spectroscopic and analytical data. In addition to the Cp resonance, the ^1H NMR spectrum of **4** exhibits resonances for a PMe_3 group (δ 0.93, d, $J = 6.09$ Hz, 9H), two $SiMe_2$ groups (δ 0.63 and 0.43, 6H each), the ylide proton (δ 0.55, d, $J_{P-H} = 5.0$ Hz, 1H), and the metal hydride (δ −7.77, 1H). The shift of the single resonance observed in the ^{31}P NMR (δ −1.98) is similar to that seen in other silyl-substituted ylides such as $Me_3SiCH{=}PMe_3$ (δ −1.2).[15] In addition, resonances are observed in the ^{29}Si NMR at δ 1.39 (d, $^3J_{Si-P} = 38.9$ Hz) and −17.1 (d, $^2J_{Si-P} = 14.3$ Hz). The chemical shift and J_{P-C} of the upfield resonance compare well with the silicon in $Me_2HSiCH{=}PMe_3$ (δ −27.9, d, $^2J_{Si-P} = 15.8$ Hz)[16] and suggest the resonance at δ −17.1 in **4** is due to the silicon attached to the ylide carbon. Note that the magnitude of three-bond phosphorus couplings are generally larger than two-bond couplings.[17]

Formation of **4** can be reasonably viewed as occurring by initial attack at silicon by the nucleophilic ylide carbon to yield a zwitterionic intermediate containing both cationic phosphonium and anionic molybdenum centres. Proton transfer from the phosphonium methylene to the metal would then yield **4**. Seyferth and co-workers have reported a similar transformation in the reaction of a silacyclopropane with an ylide, and proposed an analogous zwitterionic intermediate.[18]



Net one-atom insertion reactions

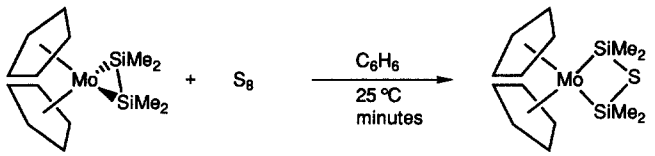
(a) *Reaction of* **1a** *with elemental sulphur.* Free disilenes have been shown to react with chalcogens to produce the corresponding three-membered ring compounds [e.g. eq. (4)].[19] Analogous reactions of the coordinated disilene in **1a** would yield four-membered ring compounds. Although reaction of **1a** with a variety of oxygen-atom sources (O_2, Ph_3PO, propylene oxide) led to extensive decomposition, sulphur-atom sources were found to yield tractable products.



(4)

Treatment of **1a** with elemental sulphur leads to the rapid formation of the symmetrical insertion product, cyclo-$Cp_2Mo(SiMe_2SSiMe_2)$ (**5**), which has been isolated as a red crystalline solid in 54% yield [eq. (5)]. The ^1H NMR spectrum of **2** exhibits

a single resonance due to the Cp ligand and a single resonance due to two $SiMe_2$ groups, consistent with a symmetrical structure. The ^{29}Si NMR spectrum exhibits a single resonance at δ 14.29.



(5)

The structure of **5** was determined by single crystal X-ray diffraction methods. The two unique molecules in the unit cell (**A** and **B**) are shown in Figs 1 and 2. Crystallographic details are summarized in Table 1, and bond distances and angles are listed in Table 2. Structural parameters for the two independent molecules are virtually identical, except for the planarity of the $MoSi_2S$ ring. Each molecule exhibits the pseudo-tetrahedral coordination environment at molybdenum typical for bent metallocenes. The angles subtended at the metals by the Cp ring-centroids in molecules **A** and **B** are 141.2 and 140.9°, and the respective Si—Mo—Si angles are 67.97(6) and 68.83(6)°. The four Mo—Si bond distances measure from 2.550(2) to 2.566(2) Å, in the range expected for typical single bonds.[1] A search of the Cambridge Structural Database found 33 compounds containing a total of 77 Si—S bonds, with a mean distance of 2.134(26) Å. The four Si—S bond lengths in **5** [2.166(3)–2.177(3) Å] are somewhat longer than this mean distance, which can most likely be attributed to the strain of the four-membered ring and the electronic effect of the transition metal on the silicon.

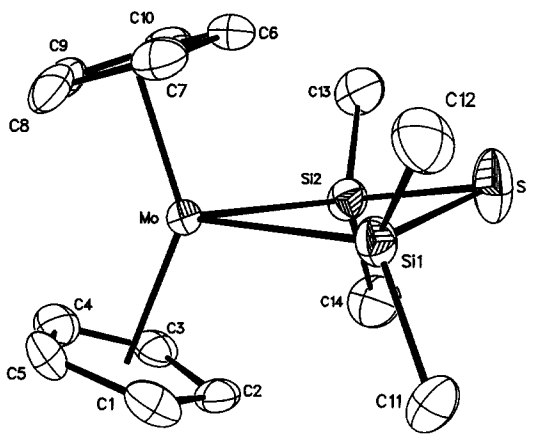


Fig. 1. ORTEP drawing of $Cp_2Mo(SiMe_2SSiMe_2)$ (**5**), molecule **A** showing 30% probability thermal ellipsoids.

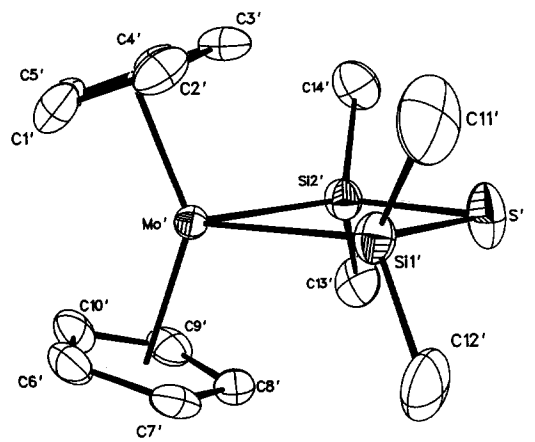

Fig. 2. ORTEP drawing of $Cp_2Mo(SiMe_2SSiMe_2)$ (**5**), molecule **B** showing 30% probability thermal ellipsoids.

The four-membered ring in molecule **B** is essentially planar; the sulphur atom lies only 0.031 Å above the $MoSi_2$ plane and the dihedral angle formed by the $MoSi_2$ and Si_2S planes is only 1.1°. In contrast, the ring in molecule **A** is puckered, with the sulphur atom 0.413 Å above the $MoSi_2$ plane and the corresponding dihedral angle is 14.6°. The conformations of the four-membered rings in molecules **A** and **B** must be very close in energy, and it is likely that crystal packing forces are responsible for the two different geometries. Further evidence for a very soft potential energy surface for distortion of the $MoSi_2S$ ring is found in the thermal ellipsoids of the sulphur atoms, which are elongated perpendicular to the $MoSi_2$ planes in both molecules, and indicate the ease of thermal movement in this direction.

West and Pham have recently reported the structure of a related four-membered ring compound, cyclo-$(Ph_3P)_2Pt(SiMe_2OSiMe_2)$, formed by oxidation of a platinum disilene complex.[2b] This complex exhibits a relatively short trans-annular Si—Si separation of 2.549(2) Å, which has been interpreted in terms of possible cross-ring bonding between the silicon atoms. Typical Si—Si single bond lengths are *ca* 2.34 Å.[20] The trans-annular Si—Si distances in the two molecules of **5** are 2.865 and 2.888 Å, and are long enough to preclude any significant bonding interaction. Short Si—Si contacts are clearly not an inherent feature of MSi_2X rings.

Although the parallel can be made between the

reactions of sulphur with complexed and free disilenes, there are similar analogies with small-ring silicon compounds. Boudjouk and Samaraweera recently reported formation of a silathietane by treatment of the silirane *cyclo*-(t-Bu)$_2$SiCHMeCHMe with elemental sulphur; i.e. net sulphur-atom insertion into the Si—C bond of a three-membered ring.[21] A similar insertion of a sulphur atom into the Si—Si bond of a disilacyclobutane has been reported by Seyferth and co-workers.[22]

(b) *Reaction of* **1a** *with triphenylphosphine sulphide.* In contrast to the reaction with elemental sulphur, reaction of **1a** with triphenylphosphine sulphide in benzene at 25°C (6 days) yields principally the unsymmetrical sulphur-atom insertion product cyclo-$Cp_2Mo(SiMe_2SiMe_2S)$ (**6**), in addition to the symmetrical isomer **5** (*ca* 3 : 1). Recrystallization of the mixture from toluene affords **6** as a pure material (40% yield). The ^{1}H NMR spectrum of **6** exhibits a singlet due to the Cp and two singlets due to inequivalent $SiMe_2$ groups, consistent with the unsymmetrical structure. In addition, resonances at δ 47.0 and −24.5 are observed in the ^{29}Si NMR spectrum.

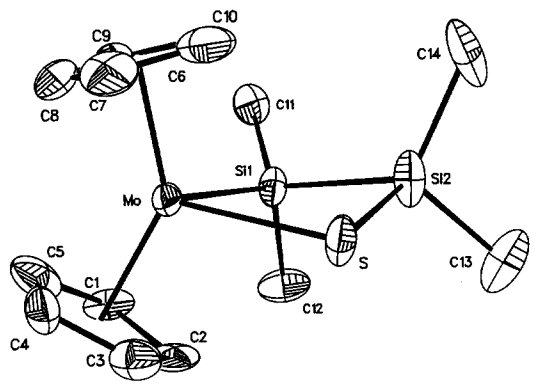

Fig. 3. ORTEP drawing of $Cp_2Mo(SiMe_2SiMe_2S)$ (**6**), showing 30% probability thermal ellipsoids.

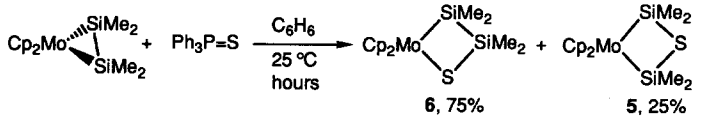
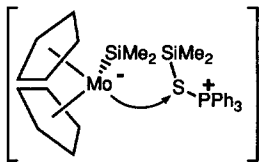
Although well-formed crystals of **6** could be readily grown from a variety of organic solvents, preliminary X-ray diffraction studies indicated that all were twinned. The geometrical relationship of the two interpenetrating unit cells was determined and diffraction data were collected for one of the unit cells (see Experimental). Solution by heavy atom methods and refinement of the data yielded the structure shown in Fig. 3. Crystallographic details are summarized in Table 1. Although the basic structural features should be reliable and all bond parameters are within chemically reasonable ranges (Tables 4 and 5), the twinning complication dictates that the values of the bond lengths and angles be interpreted with some caution.



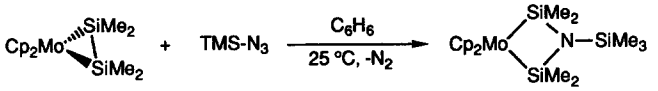
(6)

The structure consists of a puckered four-membered ring and is made up of molybdenum, sulphur and two silicon atoms. As expected on the basis of the spectroscopic data, the sulphur atom is situated between the metal and one of the silicon atoms. The $MoSi_2S$ ring in **6** is non-planar, and Si(2) lies 0.65 Å above the MoSiS plane. The MoSiS and Si_2S planes subtend a dihedral angle of 24.5°.

The formation of **6** may be related to the reaction of **1** with methylenetrimethylphosphorane. Attack at silicon by phosphine sulphide would lead to an analogous zwitterionic intermediate in which proton transfer cannot readily occur. Displacement of triphenylphosphine by the anionic metal centre in the intermediate would then result in ring closure to produce **6**. Consistent with this premise, reaction of **1a** with *triethyl*phosphine sulphide yields a mixture of several products exhibiting upfield resonances characteristic of molybdenum hydrides in the ^{1}H NMR spectrum. These products presumably arise from proton transfer to the metal from the acidic phosphonium alkyl groups in the proposed intermediate, accompanied by decomposition of the resulting sulphur-substituted ylide.

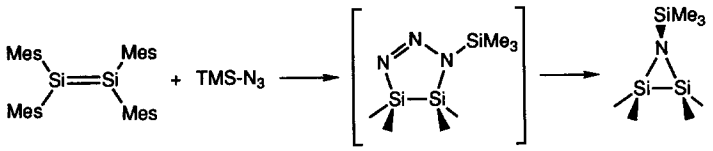


(c) *Reaction of* **1a** *with trimethylsilylazide.* Compound **1a** reacts with trimethylsilylazide in benzene at 25°C to yield the symmetrical nitrogen-atom insertion product, cyclo-$Cp_2Mo(SiMe_2(NSiMe_3)SiMe_2)$ (**7**). Analysis of the reaction mixture by NMR indicates that **7** is produced quantitatively, although the high solubility of the compound resulted in a low isolated yield (29%) following recrystallization. The reaction is complete in less than 1 h, and no intermediates were observed by ^{1}H NMR. The ^{1}H NMR spectrum shows a single resonance due to the Cp ligand and a singlet due to four equivalent silicon methyl groups indicative of a symmetrical structure. In addition, a singlet due to the trimethylsilyl group on the azide is observed. The ^{29}Si NMR spectrum exhibits two singlets at δ 15.63 and −6.21.



(7)

It should be noted that trimethylsilylazide does not decompose to the nitrene under the extremely mild reaction conditions used to prepare **7**, thus a simple nitrene insertion process can be excluded from consideration. West and co-workers, however, have reported that the stable disilene Mes_4Si_2 undergoes 1,3-dipolar additions with a variety of organic azides.[19a] In two instances the initial five-membered ring product is observed prior to formation of the azadisiliranes by N_2 extrusion [eq. (8)].



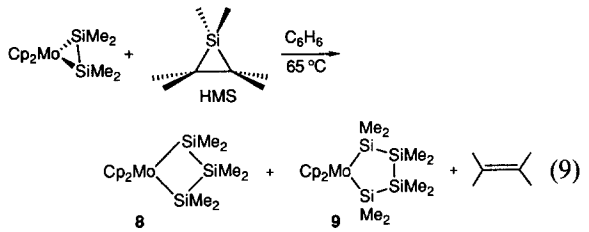
(8)

The facile reaction of **1a** with TMS-N_3 may reflect partial π-character in the coordinated disilene fragment, and could thus involve a formal dipolar addition of the azide.

(d) *Reaction of* **1a** *with hexamethylsilacyclopropane.* Dimethylsilylene has been shown to react readily with a wide variety of substrates. Examples include insertion of dimethylsilylene into silicon and transition metal hydride bonds,[23,24] insertion into Si—C bonds of a silacyclopropane to form a disilacyclobutane,[22] and addition to multiple bonds in organic compounds.[23] However, the harsh thermal or photochemical conditions employed for silylene generation are not suited for studying the reactions of silylenes with most transition metal complexes. However, as reported by Seyferth *et al.*,[25] the thermolysis of hexamethylsilacyclopropane (HMS) generates dimethylsilylene at *ca* 65°C, conditions sufficiently mild to allow examination of the reaction of dimethylsilylene with **1a**.

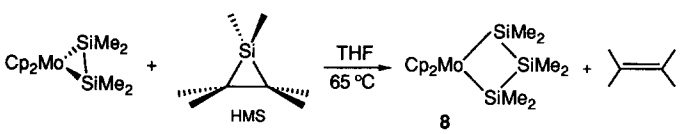
Reaction of **1a** with hexamethylsilacyclopropane in benzene-d_6 at 65°C initially yields the single insertion product, cyclo-$Cp_2Mo(SiMe_2)_3$ (**8**), as shown in eq. (9). The silylene insertion is not particularly selective in benzene solution, and the secondary insertion product, cyclo-$Cp_2Mo(SiMe_2)_4$ (**9**), is also observed before 50% of **1a** has been consumed. In addition, octamethyl-1,2-disilacyclobutane is also formed as a result of competing insertion of dimethylsilylene into HMS.[22] Compound **8** exhibits resonances in the ^{1}H NMR spectrum due to a single Cp ligand and two unequal sets of silicon methyl groups (δ 0.47, 6H and 0.46, 12H). The double insertion product, **9**, shows a similar spectrum,

of equal intensity (δ 0.42, 12H and 0.33, 12H). It has not been established whether silylene insertion occurs into M—Si or Si—Si bonds.



(9)

Previous studies by our group[24] and other workers[26–30] have shown that the selectivity of silylene reactions is greatly enhanced in the presence of Lewis bases. The increased selectivity is attributed to the formation of intermediate base-silylene adducts, which are more discriminating than free dimethylsilylene. Indeed, reaction of **1a** with HMS in the coordinating solvent tetrahydrofuran-d_8 at 65°C yields the single insertion product **8** as the only molybdenum-containing compound.

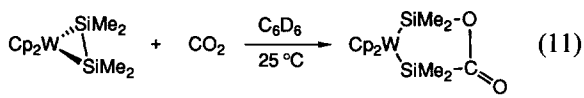


(10)

Net two-atom insertion reactions

(a) *Reaction of* **1a** *with carbon dioxide.* Carbon dioxide generally behaves as a Lewis acid towards transition metal complexes. Typical reactions of carbon dioxide with transition metal complexes involve simple coordination through carbon, or insertion into metal–alkyl or –hydride bonds to produce carboxylates of the general form MO_2CR.[31] Less commonly, metalloesters of the form MCO_2R are produced. Although not as extensively studied, reaction of carbon dioxide with metal silyl complexes yields products derived from initial metalloester (MCO_2SiR_3) formation.[32–35] The latter presumably reflects the favourable thermodynamics of Si—O bond formation, as well as differences in the electronic polarization of M—Si and M—C bonds.

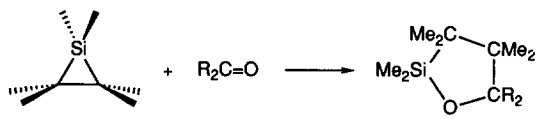
Treatment of **1b** with 1 equiv. of carbon dioxide at 25°C leads to a rapid reaction in which cyclo-$Cp_2W(SiMe_2OC(O)SiMe_2)$ (**10**) is produced in nearly quantitative yield by ^{1}H NMR (72% isolated). Compound **10** is the net result of C=O insertion into the Si—Si bond of the disilene complex. The regiochemistry of the insertion is confirmed by the ^{29}Si NMR spectrum, which exhibits two resonances showing satellites due to the ^{183}W nucleus (δ 50.4, $^1J_{W-Si}$ = 112.7 Hz and δ 15.2, ^1J = 103.9 Hz). The magnitude of these spin–spin couplings clearly indicates both silicon atoms are directly attached to the tungsten centre. The resonance at δ 15.2 can be assigned to the silicon between the metal and the carbonyl carbon by the large ^{13}C coupling observed in a sample prepared with $^{13}CO_2$ ($^1J_{C-Si}$ = 59.6 Hz). In contrast, the silicon resonance at δ 50.4 exhibits a relatively small coupling to the carbonyl ($^2J_{C-Si}$ = 7.2 Hz). The ^{1}H NMR spectrum of the ^{13}C-enriched sample also exhibits spin–spin coupling between the carbonyl carbon and the protons of one $SiMe_2$ group ($^3J_{C-H}$ = 2.0 Hz). The carbonyl is observed in the ^{13}C NMR spectrum as a singlet at δ 197.6, which does not exhibit tungsten satellites. The carbonyl stretching mode is observed as a band at 1675 cm^{-1} in the IR spectrum.



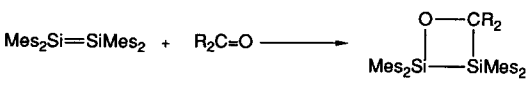
(11)

Although the reaction of carbon dioxide with the disilene complex could be viewed as proceeding by nucleophilic attack at silicon by an oxygen centre, an initial electrophilic interaction would be more consistent with the established reactivity of carbon dioxide.

(b) *Reaction of* **1a** *with benzophenone.* Free disilenes react with aldehydes and ketones to produce disilaoxetanes.[36] Siliranes also react with organic carbonyl compounds, yielding five-membered rings as products.[37] The latter reaction only proceeds readily with α,β-unsaturated ketones and aldehydes.



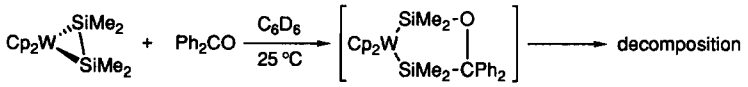
(12)



(13)

Disilene complex **1a** cleanly reacts with 1 equiv. of benzophenone within 1 h at 25°C to yield a single product exhibiting resonances in the ^{1}H NMR spectrum for a single Cp, two $SiMe_2$ groups (δ 0.54, 6H

and 0.59, 6H) and the phenyl groups. Unfortunately, the product is unstable and decomposes within hours to a complex mixture, thwarting all attempts to isolate the adduct. Although the 1 : 1 stoichiometry of the reaction is clear from the ^{1}H NMR, the regiochemistry of the addition is less certain. We favour the regiochemistry shown in eq. (14), in which the carbonyl fragment has been inserted between the Si—Si bond of **1a**, analogous to the carbon dioxide reaction described above.



(14)

Acetone reacts only very slowly with **1a** and yields a complex mixture of products. The observation of resonances characteristic of vinylic protons in the ^{1}H NMR of this mixture suggests that acetone may react as a weak acid (cf. methanol), rather than undergoing an insertion reaction. The greater reactivity of benzophenone relative to acetone towards **1a** may reflect the greater electrophilicity of the carbonyl carbon in benzophenone. Alternatively, the benzophenone insertion may involve an initial electron transfer step to form a benzophenone radical anion, which subsequently attacks a silicon centre in the radical cation of **1a**.

CONCLUSIONS

In summary, although η^2-disilene complexes **1a** and **1b** are coordinatively saturated at the transition metals, reaction is observed with a wide variety of both nucleophilic and electrophilic reagents under extremely mild conditions. The reactions are presumably initiated by interactions with the reactive disilicon moiety. Analogies with the reaction chemistry of both disilenes and three-membered ring compounds can be found for most of the observed reactions of the disilene complexes. However, the preponderance of reactions which lead to cleavage of the Si—Si bond suggests that the three-membered ring analogy will be the most helpful for predicting the outcome of new reactions.

EXPERIMENTAL

General considerations

All manipulations were carried out under dry nitrogen using high vacuum-line or Schlenk techniques or in a Vacuum Atmospheres glovebox. Glassware was oven-dried before use. Petroleum ether (boiling range 35–65°C), tetrahydrofuran (THF), benzene and toluene were freshly distilled from sodium/benzophenone ketyl. IR spectra were measured on a Perkin–Elmer 1430 spectrophotometer. ^{1}H NMR spectra were obtained using IBM-Bruker AC 250 or AM 200 spectrometers. ^{13}C NMR and ^{29}Si experiments were measured using the DEPT or INEPT pulse sequences or gated coupled spectra to obtain coupling constants. Elemental analyses were performed by Desert Analytics (Tucson). High resolution mass spectral analyses were performed on a VG Instruments ZAB-E spectrometer.

Reaction of **1a** *with methanol: formation of* **2** *and* **3**

An NMR tube containing 0.05 cm^3 of methanol, 10 mg of **1a** and 0.5 cm^3 of benzene-d_6 was sealed under vacuum. The reaction was monitored by ^{1}H NMR, which indicated that the reaction was complete after 18 h. ^{1}H NMR of $Cp_2Mo(SiMe_2H)(SiMe_2OMe)$ (**2**): δ 4.7 (m, 1H, Si—*H*), 4.03 (s, 10H, *Cp*), 3.40 (s, 3H, OCH_3), 0.54 (s, 6H, $SiMe_2$), 0.47 (d, J = 1.94 Hz, 6H, $SiMe_2$). ^{1}H NMR of $Cp_2Mo(H)(SiMe_2SiMe_2OMe)$ (**3**): δ 4.22 (s, 10H, *Cp*), 3.38 (s, 3H, OCH_3), 0.30 (s, 6H, $SiMe_2$), 0.28 (s, 6H, $SiMe_2$), −7.64 (s, 1H, Mo*H*).

Synthesis of $Cp_2Mo(H)(SiMe_2SiMe_2CHPMe_3)$ (**4**)

A solution of **1a** (100 mg, 0.29 mmol) and methylenetrimethylphosphorane (3.25 cm^3, 0.29 mmol) in 15 cm^3 of benzene was stirred for 1 h under nitrogen at 25°C. Solvent was removed *in vacuo*, yielding 80 mg (63%) of **4**. Recrystallization from toluene/petroleum ether at −30°C yielded 70 mg (55%). ^{1}H NMR: 4.39 (s, 10H, *Cp*), 0.93 (d, 9H, PMe_3), 0.64 (s, 6H, $SiMe_2$), 0.44 (s, 6H, $SiMe_2$), −0.5 (d, 1H, =C*H*), −7.8 (s, 1H, Mo*H*). ^{31}P NMR: δ −1.98. ^{29}Si NMR (DEPT): δ 1.39 (d, J = 38.86 Hz), −17.13 (d, J = 14.25 Hz). Found: C, 49.80; H, 7.26. Calc. for $C_{18}H_{33}MoPSi_2$: C, 49.98; H, 7.69%.

Synthesis of cyclo-$Cp_2Mo(SiMe_2SiMe_2S)$ (**5**)

A solution of **1a** (197 mg, 0.585 mmol) in 40 cm^3 of toluene was slowly added to S_8 (155 mg, 0.60 mmol) and stirred for 1.5 h under nitrogen. Solvent

was removed *in vacuo* and recrystallization from toluene at −78°C yielded 119 mg (54%) of **5**. ^{1}H NMR: δ 4.02 (s, 10H, *Cp*), 0.70 (s, 12H, Si*Me*$_2$). ^{29}Si NMR (DEPT): δ 14.29. Satisfactory analysis for **5** could not be obtained despite multiple recrystallizations and submissions, possibly as a result of residual sulphur. Found: C, 40.32; H; 5.14. Calc. for $C_{14}H_{22}SSi_2Mo$: C, 44.90; H, 5.92%.

Synthesis of cyclo-$Cp_2Mo(SiMe_2SiMe_2S)$ (**6**)

A solution of **1a** (145 mg, 0.424 mmol) and triphenylphosphine sulphide (125 mg, 0.37 mmol) in 100 cm^3 of benzene was stirred for 6 days at 25°C under nitrogen. Solvent was removed *in vacuo*, yielding a 3:1 mixture of **6** and **5** (^{1}H NMR). Triphenylphosphine and residual triphenylphosphine sulphide were extracted with 100 cm^3 of petroleum ether. Recrystallization of the residue from toluene at −30°C yielded 65 mg (41%) of pure **6**. ^{1}H NMR: δ 4.26 (s, 10H, *Cp*), 0.62 (s, 6H, Si*Me*$_2$), 0.51 (s, 6H, Si*Me*$_2$). ^{29}Si NMR (DEPT): δ 46.96, −24.48. Found: C, 44.79; H, 5.78. Calc. for $C_{14}H_{22}SSi_2Mo$: C, 44.90; H, 5.92%.

Synthesis of cyclo-$Cp_2Mo(SiMe_2N(TMS)SiMe_2)$ (**7**)

A solution of **1a** (140 mg, 0.438 mmol) and azidotrimethylsilane (0.120 cm^3, 0.86 mmol) in 20 cm^3 of benzene was stirred at 25°C for 1 h. Examination of the reaction mixture by ^{1}H NMR indicates that **7** was the only product formed. Solvent was removed *in vacuo* and the product was recrystallized from toluene/hexanes at −35°C to yield 50 mg (29%) of pure **7**. ^{1}H NMR: δ 4.0 (s, 10H, *Cp*), 0.49 (s, 9H, Si*Me*$_3$), 0.30 (s, 6H, Si*Me*$_2$). ^{29}Si NMR (DEPT): 15.63, −6.21. Found: C; 47.79; H, 7.31. Calc. for $C_{17}H_{31}MoSi_3N$: C, 47.55; H, 7.23%.

Reaction of **1a** *with* HMS *in benzene-d*$_6$: *formation of* **8** *and* **9**

To an NMR tube containing **1a** (14 mg, 0.41 mmol) and 0.5 cm^3 of benzene-d$_6$ was added hexamethylsilacyclopropane (0.015 cm^3, *ca* 0.80 mmol). After 20 min at 65°C (15% conversion of **1a**), only cyclo-$Cp_2Mo(SiMe_2)_3$ (**8**) was observed. ^{1}H NMR: δ 0.94 (s, 10H, *Cp*), 0.47 (s, 6H, Si*Me*$_2$), 0.46 (s, 12H, Si*Me*$_2$). With further heating (< 50% conversion of **1a**), formation of cyclo-$Cp_2Mo(SiMe_2)_4$ (**9**) was observed. ^{1}H NMR: δ 3.88 (s, 10H, *Cp*), 0.42 (s, 12H, Si*Me*$_2$), 0.33 (s, 12H, Si*Me*$_2$).

Reaction of **1a** *with* HMS *in tetrahydrofuran-d*$_8$: *formation of* **8**

To an NMR tube containing **1a** (14 mg, 0.41 mmol) and 0.5 cm^3 of tetrahydrofuran-d$_8$, was added hexamethylsilacyclopropane (0.015 cm^3, *ca* 0.80 mmol). Thermolysis at 65°C for 18 h resulted in complete conversion of **1a** and formation of **8** as the only molybdenum-containing product observed.

Synthesis of cyclo-$Cp_2W(SiMe_2OC(O)SiMe_2)$ (**10**)

Carbon dioxide (0.18 mmol) was condensed onto a frozen solution containing **1b** (74 mg, 0.17 mmol) in 15 cm^3 of benzene at −196°C and the mixture allowed to warm to room temperature. A rapid colour change from dark orange to yellow was observed and then solvent was removed *in vacuo*. The solid was extracted with benzene and recrystallized from THF, yielding 59 mg (72%) of **10** as yellow crystals. ^{1}H NMR (C_6D_6): δ 3.75 (s, 10H, *Cp*), 0.50 (s, 6H, Si*Me*$_2$), 0.47 (s, 6H, Si*Me*$_2$). ^{29}Si NMR (DEPT, in THF-d$_8$): δ 50.4 ($^1J_{W-S}$ = 112.7 Hz, *Si*OC), 15.2 ($^1J_{W-Si}$ = 103.9 Hz, *Si*CO). ^{29}Si NMR (**10**-$^{13}CO_2$, DEPT, C_6D_6): δ 50.4 ($^2J_{C-Si}$ = 7.2 Hz), 15.5 ($^1J_{C-Si}$ = 59.6 Hz). ^{13}C NMR (**10**-$^{13}CO_2$, C_6D_6): δ 197.61 (Si*C*O$_2$Si), 76.49 (Cp), 8.66 (Si*Me*$_2$), 4.44 (Si*Me*$_2$). IR (C_6D_6 solution): ν(C=O) = 1675 cm^{-1}. Found: C, 38.01; H, 4.72. Calc. for $C_{15}H_{22}O_2Si_2W$: C, 37.98; H, 4.67%.

Reaction of **1a** *with benzophenone*

The reaction of **1a** (6 mg) and benzophenone (3 mg) in benzene-d$_6$ in an NMR tube was followed by ^{1}H NMR. After 1 h the reaction had reached 90% completion with formation of a single product. ^{1}H NMR: δ 7.0 (m, Ph), 3.84 (s, 10H, *Cp*), 0.54 (s, 6H, Si*Me*$_2$), 0.59 (s, 6H, Si*Me*$_2$). The product is not stable and decomposes within hours at 25°C.

Structure determinations of **5** *and* **6**

General crystallographic procedures. Crystals of suitable size were grown from toluene/hexanes at −35°C, sealed in 0.5-mm thin-walled Pyrex capillaries in the glove box and the capillaries mounted on the diffractometer. Refined cell dimensions and their standard deviations were obtained from least-squares refinement of 25 accurately centred reflections with $2\theta > 25°$. Crystal data are summarized in Table 1.

Diffraction data were collected at 295 K on an Enraf–Nonius four-circle CAD-4 diffractometer employing graphite monochromated Mo-K_α radiation. The intensities of three standard reflections

were measured at intervals of *ca* 80 reflections to check for systematic change during data collection. Data collection is summarized in Table 1. The raw intensities were corrected for Lorentz and polarization effects by using the program BEGIN from the SDP+package.[38]

All calculations were performed on a VAX 11/785 computer using the SDP+software package.[38] The full-matrix least-squares refinement was based on F, and the function minimized was $\Sigma w(|F_o|-|F_c|)^2$. The weights (w) were taken as $4F_o^2/[\sigma(F_o^2)]^2$, where $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes. Atomic scattering factors and complex anomalous dispersion corrections were taken from refs 39–41. Agreement factors are defined as $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_2 = [\Sigma w||F_o|-|F_c||^2/\Sigma w|F_o|^2]^{1/2}$. The goodness-of-fit is defined as GOF $= [\Sigma w(|F_o|-|F_c|)^2/(N_o-N_p)]^{1/2}$, where N_o and N_p are the number of observations and parameters. Final positional and thermal parameters for both structures have been deposited with the Cambridge Crystallographic Data Centre.

Solution and refinement of **5**. A decay correction (18% maximum, 8% average, based on F) was applied to the data. The orthorhombic space group *Pbca* was uniquely determined by the systematic absences. On the basis of the calculated density, 16 molecules (two unique) were expected in the unit cell. The coordinates of two independent molybdenum atoms were obtained by using the program Multan.[38] Analysis of subsequent Fourier maps led to location of the remaining heavy atoms. Refinement using anisotropic Gaussian amplitudes followed by difference Fourier synthesis resulted in the location of most of the Cp hydrogen atoms and at least one hydrogen atom on each methyl group. All remaining hydrogen atoms were placed at idealized locations [D(C—H) = 0.95 Å] using the program HYDRO.[38] Final refinement included anisotropic Gaussian amplitudes for all non-hydrogen atoms and fixed positions and fixed isotropic parameters for the hydrogen atoms. Structure refinement is summarized in Table 1.

Solution and refinement of **6**. A unit cell could not be initially determined from 25 accurately centred reflections. However, approximately half of the reflections fit one monoclinic cell, and the remaining reflections fit a second, related, monoclinic cell, suggestive of a twinned crystal. Approximately 10 well-formed crystals were examined and found to exhibit this twinning, thus data collection was attempted using one of the apparent cells (see Table 1). The molybdenum atom was located from a Patterson map and Fourier methods led to the location of all remaining heavy atoms. Hydrogen atoms were found or placed as described above. Refinement using anisotropic Gaussian amplitudes led to agreement factors of $R_1 = 0.099$, $R_2 = 0.139$ and GOF = 3.983.

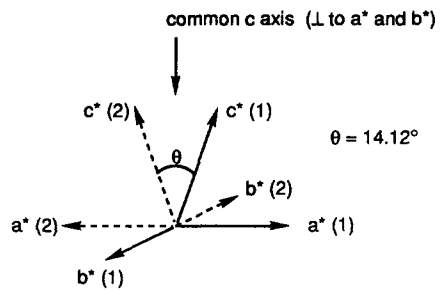


Fig. 4. Relationship of twinned unit cells in crystals of **6**.

The intensities of several reflections were compared in both of the twins and found to be approximately equal, suggesting a *ca* 1 : 1 twin. Analysis of the two twinned unit cells showed the cells were related by a rotation of 180° about a common c axis, resulting in the coincidence of the a^* axis of twin 1 with the $-a^*$ axis of twin 2 and the b^* axis of twin 1 with the $-b^*$ axis of twin 2 (Fig. 4). The c^* axes of the two twins subtend an angle of 14.12°. It was further possible to calculate that reflections for the two cells would be roughly coincident for all reflections in which the l-index is a multiple of *ca* 5 (e.g. $l = 5$, 10, 15, etc). This prediction was confirmed by analysis of the full data set using the program PERFACT, which showed the expected trend of agreement factor as a function of the l-index.† Refinement of the structure excluding reflections with $l = 5$, 10 and 15 led to improved agreement factors $R_1 = 0.077$, $R_2 = 0.118$ and GOF = 3.408. Bond distances and angles did not change significantly in this test refinement (Δ distances < 0.03 Å, Δ angles < 1°). Deconvolution of the coincident data in the full data set was not attempted. As mentioned in the Discussion, it is important to stress that this partial structure determination is included only as a measure of the basic structural features in **6**, and the exact values of the metrical data should be interpreted with caution.

† Maximum overlap of the reciprocal lattices occurs at intervals along c^* corresponding to l-index values which are multiples of slightly greater than 5, hence the intensities of reflections with $l = 6$, 11 and 16 also have contributions from the second twin.

SUBVALENT GROUP 14 METAL COMPOUNDS—XIII.* OXIDATIVE ADDITION REACTIONS OF GERMANIUM AND TIN AMIDES $M(NR_2)_2$ (R = $SiMe_3$, M = Ge OR Sn) WITH SULPHUR, SELENIUM, TELLURIUM OR MeOOCC≡CCOOMe; X-RAY STRUCTURES OF $[Ge(NR_2)_2(\mu\text{-}Te)]_2$ AND $Sn(NR_2)_2CC(OMe)OSn(NR_2)_2CC(OMe)O$†

PETER B. HITCHCOCK, HATAM A. JASIM, MICHAEL F. LAPPERT, WING-POR LEUNG,‡ AUDESH K. RAI and ROSEMARY E. TAYLOR§

School of Chemistry and Molecular Sciences, University of Sussex, Brighton BN1 9QJ, U.K.

Abstract—The germanium and tin divalent amide $M(NR_2)_2$ (R = $SiMe_3$, M = Ge or Sn) readily reacts with a chalcogen (E) or MeOOCC≡CCOOMe to yield the appropriate metal(IV) oxidative addition product $[M(NR_2)_2(\mu\text{-}E)]_n$ (E = S, Se or Te) (**1–6**) or $Sn(NR_2)_2CC(OMe)OSn(NR_2)_2CC(OMe)O$ (**7**), respectively. Each of the compounds **1–7** has been characterized by microanalysis and NMR spectra and two of the compounds $[Ge\{N(SiMe_3)_2\}_2(\mu\text{-}Te)]_2$ (**3**) and **7**, by single crystal X-ray diffraction. Some selected geometric parameters are as follows. **3**: ⟨Ge—N⟩ 1.86(1), ⟨Ge—Te⟩ 2.595(2), ⟨Si—N⟩ 1.76(2) Å; ⟨TeGeTe′⟩ 94.38(6), ⟨GeTeGe′⟩ 85.59(6)°. **7**: (MeO)C—C(OMe) 1.40(2), CC—C(OMe) 1.36(2), MeOCO—Sn 2.125(9), Sn—C 2.07(1), ⟨Sn—N⟩ 2.031(9), ⟨Si—N⟩ 1.75(1) Å. Each of the compounds $Sn(\eta\text{-}C_5H_4R)(NR_2)$ (**8**) and $Sn(\eta\text{-}C_5H_3R_2\text{-}1,3)(NR_2)$ (**9**) was obtained in a mixture with $Sn(NR_2)_2$ and the appropriate bis(cyclopentadienyl)tin(II) compound. ^{119}Sn NMR chemical shifts are reported for compounds **4** and **6–9**.

The majority of papers in this series have dealt with bivalent Group 14 metal molecules $M'X_2$ [M′ = Ge, Sn or Pb; X̄ = a bulky monohapto ligand such as C̄HR_2, N̄R_2, Ō$Ar^{R'}$ or SAr^{Bu^t}: R = $SiMe_3$, $Ar^{R'}$ = $C_6H_2Bu^t_2$-2,6-R′-4 (R′ = H, Me or Bu^t)], which are monomeric in dil. hydrocarbon solution and, except for the dimer $M_2(CHR_2)_4$ (M = Ge or Sn), in the crystal. Such a MX_2 species behaves as a:[1] (i) Lewis base, (ii) Lewis acid or as a substrate for (iii) oxidative addition, (iv) a redox reaction, (v) an insertion reaction, (vi) a metathetical exchange reaction or (vii)[2] a reaction [which may belong to any of classes (i)–(vi)] with a transition metal complex. This paper is principally concerned with some new reactions of type (iii) involving the germanium(II) or tin(II) bis(trimethylsilyl)amide, $M(NR_2)_2$; a minor theme concerns reactions of class (vi) leading to the novel heteroleptic cyclopentadienyltin(II) amides **8** and **9**.

In Part XI, oxidative addition reactions of $M(NR_2)_2$ with various reagents AB to yield the metal(IV) adducts $M(NR_2)_2(A)B$ were described [A—B = R″—Hal (e.g. = Bu^nCl, Bu^tBr or PhI), CH_2Cl—Cl, $CHCl_2$—Cl, CCl_3—Cl, Br—NR_2 or $CF_3C(O)O$—$C(O)CF_3$].[3] Related reactions of $Sn(CHR_2)_2$ have been studied,[3] including those where A—B = H—Cl,[1] H—F or $Bu^tC(O)$—Cl.[3]

Relevant to the present paper are reactions of MX_2 with a chalcogen or those with a conjugated organic compound leading to a cycloadduct.

Treatment of $Sn(CHR_2)_2$ with Me_3NO gave the dimeric tetravalent cyclostannoxane **I**,[4] whereas with a trace of air in the presence of $[Mo\{O(O)CMe\}_2(NCMe)_6][BF_4]$ the stannaozonide **II** was obtained.[5]

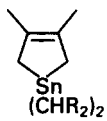
‡ Present address: Chemistry Department, The Chinese University of Hong Kong.

§ née Kelly.

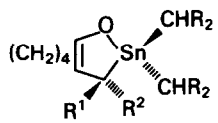
Both these unusual compounds probably owe their stability to the exceptionally sterically demanding bis(trimethylsilyl)methyl substituents at tin; e.g. bulky cyclostannoxanes such as $[SnBu^t_2(\mu\text{-}O)]_3$[4] are generally trimers in contrast to the linear polymer found for the less crowded analogue $[SnPr^i_2(\mu\text{-}S)]_n$.

The carbene-like behaviour of $Sn(CHR_2)_2$ was demonstrated in Part II by its ready transformation into its oxidative cycloadduct **III** with 2,3-

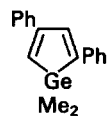


III

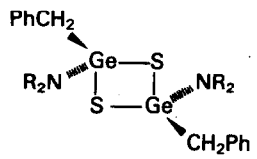
dimethylbuta-1,3-diene.[6] Similar reactions of $Sn(CHR_2)_2$ with a wider series of 1,3-dienes have been examined.[7] That study was extended to other conjugated 4-π-systems such as vinyl ketones or aldehydes, which likewise yielded 1,4-cycloadducts, e.g. **IV** from $OCC(CH_2)_4CCR^1R^2$.[8] The transient $GeMe_2$ has been trapped with various non-functionalized alkynes to give cycloadducts, e.g. **V** from PhC≡CH.[9]



IV



V



VI

The present study of the oxidative addition of the heavier chalcogens to $Ge(NR_2)_2$ was prompted by our earlier discovery of the unusual reaction between $Ge(NR_2)_2$ and $(Me_3Si)_3CSH$ in toluene at *ca* 20°C to give the X-ray characterized compound **VI** [in solution it was a mixture of *cis* (**VI**) and *trans* isomers].[10] Other four-membered ring compounds of the type $[MR'R''(\mu\text{-}E)]_2$ which have been prepared have invariably been obtained from metal(IV) precursors: e.g. the X-ray-authenticated $[GeBu^t_2(\mu\text{-}S)]_2$[11] and $[SnBu^t_2(\mu\text{-}E)]_2$ (E = S, Se or Te)[12] from the appropriate $MBu^t_2Cl_2$ and Na_2E. A similar procedure was employed for the cyclotrimers $[SnR'_2(\mu\text{-}E)]_3$ (R = Me and E = S, Se or Te; or R = Ph and E = S or Te); the crystalline $[SnMe_2(\mu\text{-}Te)]_3$ was found to have a puckered $(SnTe)_3$ skeleton.[13] A "mixed" four-membered ring compound $[Sn(C_6H_2Pr^i_3\text{-}2,4,6)_2]_2(\mu\text{-}O)(\mu\text{-}S)$ has been reported.[14]

A brief mention of some of the synthetic data relating to compounds **1**–**7** was made in ref. 1.

EXPERIMENTAL

Materials, measurements and techniques

The starting germanium(II) and tin(II) bis(trimethylsilyl)amides were prepared as described in Part V.[15] Manipulative procedures for air-sensitive materials were outlined in Part XII.[16] NMR spectra were run on a Bruker WM360 instrument. Colours, melting points, yields and microanalytical data for compounds **1**–**7** are shown in Table 1, while NMR spectroscopic data are given in Table 2. The complexes containing selenium or tellurium (**2**, **3**, **5** and **6**) were stored in the dark.

Synthesis of bis(bistrimethylsilylamido)germanium(IV) sulphide, $1/n[Ge\{N(SiMe_3)_2\}_2(\mu\text{-}S)]_n$ (**1**)

Powdered sulphur (0.1 g, 3.13 mmol) was added to a stirred solution of $Ge[N(SiMe_3)_2]_2$ (1.23 g, 3.13 mmol) in THF (*ca* 50 cm^3). The resultant mixture was a pale orange suspension, which, after 30 min, had become a clear, pale yellow solution. The solution was stirred for 24 h. All volatiles were removed *in vacuo*, leaving a cream solid, which was extracted into n-hexane (*ca* 40 cm^3); the extract was filtered. Cooling the filtrate to *ca* −30°C afforded the white, crystalline *title product* **1** (1.10 g, 75%), which was washed with cold (*ca* −78°C) n-pentane and dried *in vacuo*.

Synthesis of bis(bistrimethylsilylamido)germanium(IV) selenide, $1/n[Ge\{N(SiMe_3)_2\}_2(\mu\text{-}Se)]_n$ (**2**)

Powdered selenium (0.30 g, 3.81 mmol) was added to a stirred solution of $Ge[N(SiMe_3)_2]_2$ (1.50 g, 3.8 mmol) in THF (*ca* 50 cm^3). The initial cloudy, orange–brown suspension cleared rapidly to give a pale yellow solution which was stirred for 24 h. Volatiles were removed *in vacuo*, leaving a pale yellow solid, which was extracted into n-pentane (*ca* 40 cm^3) and the extract was filtered. Cooling of the filtrate to *ca* −30°C produced the white, crystalline *title product* **2** (1.28 g, 71%), which was washed with cold (*ca* −78°C) n-pentane and dried *in vacuo*.

Synthesis of bis(bistrimethylsilylamido)germanium(IV) telluride, $[Ge\{N(SiMe_3)_2\}_2(\mu\text{-}Te)]_2$ (**3**)

Powdered tellurium (0.55 g, 4.29 mmol) was added to a stirred solution of $Ge[N(SiMe_3)_2]_2$ (1.69

Table 1. Colours, melting points, yields and microanalysis results for the complexes 1–7 (R = $SiMe_3$)

Compound	Colour	Yield (%)	Melting point[a] (Boiling point) (°C)	Analysis (%)[b] C	H	N

[a] In sealed capillary tubes under argon and are uncorrected.
[b] Calculated values in parentheses.

g, 4.29 mmol) in THF (*ca* 50 cm^3). The resultant cloudy, grey suspension was stirred for 24 h. There appeared to be some remaining unreacted tellurium powder; the mixture was filtered. Volatiles were removed from the filtrate *in vacuo* to give a bright orange solid, which was extracted into n-pentane (*ca* 40 cm^3), the extract was filtered and the filtrate concentrated (to *ca* 30 cm^3) and cooled to *ca* 0°C. After 24 h, there was no sign of crystallization and so the solution was cooled to *ca* −30°C to afford red crystals of the *title product* **3** (1.43 g, 64%), which were washed with cold (*ca* −78°C) n-pentane and dried *in vacuo*.

Synthesis of bis(bistrimethylsilylamido)tin(IV) *sulphide*, $1/n[Sn\{N(SiMe_3)_2\}_2(\mu\text{-}S)]_n$ (**4**)

Powdered sulphur (0.095 g, 2.98 mmol) was added to a stirred solution of $Sn[N(SiMe_3)_2]_2$ (1.31 g, 2.98 mmol) in THF (*ca* 50 cm^3). The resultant cloudy, orange suspension was stirred for 24 h. The colour had then faded to a pale yellow. The reaction mixture was refluxed (*ca* 65°C) for 2 h, then cooled to room temperature, set aside for 12 h and filtered. Volatiles were removed from the filtrate *in vacuo* to give a pale yellow solid, which was extracted into n-hexane (*ca* 50 cm^3); the filtered extract was concentrated to (*ca* 35 cm^3) and cooled to *ca* −30°C. After 24 h some flaky white solid had appeared; all volatiles were removed *in vacuo* and the solid was redissolved in toluene (*ca* 40 cm^3). The resulting pale yellow suspension was filtered; the filtrate was concentrated to *ca* 30 cm^3 and then cooled to *ca* −30°C to give, as a white powder, the *title product* **4** (0.76 g, 54%), which was washed with cold (*ca* −78°C) n-pentane and dried *in vacuo*.

Synthesis of bis(bistrimethylsilylamido)tin(IV) *selenide*, $1/n[Sn\{N(SiMe_3)_2\}_2(\mu\text{-}Se)]_n$ (**5**)

Powdered selenium (0.34 g, 4.28 mmol) was added to a stirred solution of $Sn[N(SiMe_3)_2]_2$ (1.88 g, 4.28 mmol) in THF (*ca* 50 cm^3). The resultant cloudy, orange–brown suspension was stirred for 24 h, whereafter the mixture was still slightly cloudy but most of the selenium appeared to have reacted. Filtration and removal of volatiles from the filtrate *in vacuo* gave a yellow solid, which was extracted into n-pentane (*ca* 40 cm^3). The extract was filtered, the filtrate concentrated (to *ca* 30 cm^3) and cooled to *ca* −30°C to afford yellow crystals of the *title product* **5** (1.31 g, 59%), which were washed with cold (*ca* −78°C) n-pentane and dried *in vacuo*.

Table 2. ^{1}H, ^{13}C and ^{119}Sn NMR chemical shifts (δ) for complexes **1**–**7** (R = $SiMe_3$) recorded at ambient temperatures at 360.13 MHz (^{1}H), 90.66 MHz (^{13}C) or 134.29 MHz (^{119}Sn) in C_6D_6

Synthesis of bis(bistrimethylsilylamido)tin(IV) *telluride*, $1/n[Sn\{N(SiMe_3)_2\}_2(\mu\text{-}Te)]_n$ (**6**)

Powdered tellurium (0.51 g, 3.98 mmol) was added to a solution of $Sn[N(SiMe_3)_2]_2$ (1.75 g, 3.98 mmol) in THF (*ca* 50 cm^3). The cloudy, orange–brown suspension was stirred for 24 h and filtered. Volatiles were removed from the filtrate *in vacuo* to give an orange–red solid. This solid was extracted into n-pentane (*ca* 50 cm^3); the extract was filtered, the filtrate was concentrated to *ca* 40 cm^3 and cooled to −10°C to afford orange needles of the *title product* **6** (1.20 g, 53%), which were washed with cold (*ca* −78°C) n-pentane and dried *in vacuo*.

Displacement of tellurium from $1/n[Sn\{N(SiMe_3)_2\}_2(\mu\text{-}Te)]_n$ (**6**) *by sulphur*

Powdered sulphur (0.1 g, excess) was added to a stirred solution of **6** (0.17 g, 2.99 mmol) in THF (*ca* 50 cm^3). The cloudy, orange mixture was stirred for 24 h, whereafter the colour of the mixture had lightened to pale orange and a fine, dark grey precipitate had formed. The mixture was filtered; volatiles were removed from the filtrate *in vacuo*, leaving an off-white solid, which was extracted into n-hexane (*ca* 40 cm^3). The filtered extract was cooled to *ca* −30°C to yield after *ca* 24 h the white, microcrystalline $1/n[Sn\{N(SiMe_3)_2\}_2(\mu\text{-}S)]_n$ (**4**) (0.58 g, 41%), identified by comparison with an authentic sample.

Synthesis of $Sn(NR_2)_2CC(OMe)OSn(NR_2)_2CC(OMe)O$ (**7**)

A solution of $Sn[N(SiMe_3)_2]_2$ (2.08 g, 4.75 mmol) in THF at −78°C was added dropwise to a solution of dimethyl acetylenedicarboxylate (0.67 g, 4.75 mmol) in THF. The reaction mixture was allowed to warm to *ca* 25°C. The pale yellow solution gradually changed to deep red over a period of 30 min. After stirring for 2 h, volatiles were removed *in vacuo* and the residue was extracted into n-hexane (*ca* 100 cm^3). The filtered extract was concentrated to *ca* 50 cm^3 and cooled to *ca* −30°C to give deep red crystals of the *title compound* **7** (1.10 g, 48%), which were filtered off and dried *in vacuo*.

Miscellaneous reactions

(i) Attempts were made to make the mixed cyclopentadienyltin(II) amides $Sn(\eta\text{-}C_5H_4R)(NR_2)$ (**8**) and $Sn(\eta\text{-}C_5H_3R_2\text{-}1,3)(NR_2)$ (**9**); each reaction product was a mixture of **8** or **9** and its symmetrical redistribution products the appropriate tin(II) bis(cyclopentadienyl) and $Sn(NR_2)_2$.

Anhydrous tin(II) chloride (5.96 g, 30 mmol) was added to a stirred solution of trimethylsilylcyclopentadienyl-lithium (4.29 g, 30 mmol) in THF (*ca* 70 cm^3). The mixture immediately turned pale brown and a copious precipitate was produced. The mixture was stirred for 24 h to yield a pale yellow supernatant liquid and a brown precipitate. Volatiles were removed *in vacuo*; the residual solid was extracted into n-hexane (*ca* 60 cm^3) and the extract was filtered. [Bis(trimethylsilyl)amido]lithium etherate (7.24 g, 30 mmol) was added to the stirred filtrate. The reaction mixture became orange and more precipitate was produced. The mixture was stirred for 24 h. Volatiles were removed *in vacuo* to leave a sticky, orange solid, which was extracted into n-pentane (*ca* 40 cm^3). Removal of solvent from the filtered extract gave an orange oil, b.p. 112–115°C at 0.01 mbar.

The distillate comprised the *title product* **8** mixed with bis(trimethylsilylcyclopentadienyl)tin(II) and the tin(II) amide. A further distillation under reduced pressure failed to separate these three compounds.

A solution of bis(trimethylsilyl)cyclopentadienyllithium (3.32 g, 15.9 mmol) was added to a stirred solution of anhydrous tin(II) chloride (3.01 g, 15.9 mmol) in THF (*ca* 60 cm^3). Bis(trimethylsilyl) amidolithium etherate (3.83 g, 15.9 mmol) was added in portions to this solution and the mixture was stirred for 24 h. Volatiles were removed *in vacuo*, leaving a sticky, orange–brown solid, which was extracted into n-pentane (*ca* 40 cm^3). Volatiles were removed from the filtered extract *in vacuo* to leave a red oil, b.p. 110–115°C at 0.02 mbar. The distillate comprised the *title product* **9** mixed with bis[bis(trimethylsilyl)cyclopentadienyl]-tin(II) and the tin(II) amide. Despite further distillations, these three compounds were not separated.

Compounds **8** and **9** were identified by their NMR spectra; the ^{119}Sn NMR chemical shifts were particularly decisive; these were measured at ambient temperature at 134.29 MHz in C_6D_6: δ −525.5 for **8** and δ −569.0 for **9**, compared with δ +771.9 for $Sn(NR_2)_2$, δ −2190.3 for $Sn(\eta\text{-}C_5H_4R)_2$ and δ −2203.6 for $Sn(\eta\text{-}C_5H_3R_2\text{-}1,3)_2$.

(ii) Treatment of the orange $Sn(NR_2)_2$ with several MeC≡CCOOMe, PhC≡CCOOEt, EtC≡CEt and PhC≡CH resulted in a colour change (to yellow for PhC≡CH but red for the other alkynes); each mixture proved to be intractable.

X-ray structures of **3** *and* **7**

Crystal and refinement data are summarized in Table 3. X-ray quality crystals of each of compounds **3** and **7** were obtained by recrystallization from n-hexane at −30°C. Intensities for unique reflections with $2 < \theta < 25°$ were measured in the $\theta/2\theta$ mode with a scan width of $\Delta\theta = (0.8 - 0.35 \tan\theta)°$ and a maximum scan time of 1 min. Two standard reflections monitored every hour showed no significant variation. Data were corrected for Lp effects and an empirical correction for absorption based on psi scan measurements was applied to the data for **7**, but not for **3** (the crystal shape was such that a correction would have been small, bearing in mind the reasonably low μ value).

Each structure was solved by location of heavy atoms (Ge, Sn or Te) using the MULTAN program[17] followed by location of remaining non-hydrogen atoms on difference maps; these atoms were refined with anisotropic thermal parameters by full-matrix least-squares. The hydrogen atoms for **3** were held fixed at calculated positions (C—H 1.08 Å) with $B_{iso} = 6.0$ Å^2: those for **7** were omitted

(they were not all located on a difference map). Refinement with a weighting scheme of $w = 1/\sigma^2(F)$ converged at residuals shown in Table 3, when the maximum shift /ESD was less than 0.3. For both **3** and **7**, a final difference map was calculated and showed no solvate molecules or disorder. Programs from the Enraf–Nonius SDP program package were run on a PDP 11/34 computer. Scattering factors for neutral atoms were taken from ref. 18. Tables of atom coordinates and thermal parameters are available from the Cambridge Crystallographic Data Centre. Final structure factors are available from one of the authors (P.B.H.).

RESULTS AND DISCUSSION

The reactions leading to the new compounds $[M(NR_2)_2(\mu\text{-}E)]_n$ (**1–6**) and $Sn(NR_2)_2CC(OMe)OSn(NR_2)_2CC(OMe)O$ (**7**) are summarized in Scheme 1, which also shows that (i) hydrolysis of **7** yields dimethyl succinate and (ii) treatment of $[Sn(NR_2)_2(\mu\text{-}Te)]_n$ (**6**) with sulphur leads via Te^{2-}/S^{2-} exchange to $[Sn(NR_2)_2(\mu\text{-}S)]_n$ (**4**).

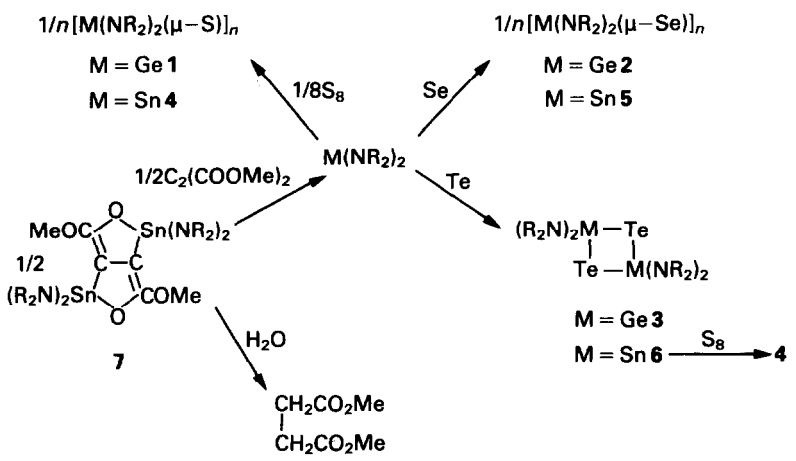
Each of the complexes **1–6** was prepared in a similar fashion by adding the powdered chalcogen to a stirred THF solution of $M(NR_2)_2$. These reactions appeared to be slower for the heavier (a) chalcogens and (b) the Group 14 metal; but all six reactions were complete within 24 h. Each of the complexes **1–6** was readily crystallized from n-pentane.

Although the solution molecular weights of compounds **1–6** were not determined, they are probably dimers; i.e. $n = 2$ in $[M(NR_2)(\mu\text{-}E)]_n$. This assertion is based on (i) their high hydrocarbon solubility (i.e. they are not likely to be linear polymers), (ii) analogy with some of the data cited in the introduction and (iii) the X-ray results on crystalline $[Ge(NR_2)_2(\mu\text{-}Te)]_2$ (**3**), *vide infra*.

At ambient temperature each of the complexes $[M(NR_2)_2(\mu\text{-}S)]_n$ [M = Ge (**1**) or Sn (**4**)] is a white solid, less hydrocarbon-soluble than the appropriate starting metal(II) amide,[15] but with a considerably higher melting point (Table 1). The selenium analogues are white [M = Ge (**2**)] or yellow [M = Sn (**5**)] solids, and each of the tellurium compounds is an orange solid. The colour trends upon increasing the atomic number of the chalcogen are consistent with the colours being due to $n \rightarrow \pi^*$ transitions (involving charge transfer from Ė to a vacant metal-centred *d*-orbital). All have high melting points. The decomposition temperatures at their melting point (Table 1) decreased in the sequence (i) S > Se > Te and (ii) Ge > Sn: these trends follow relative M—E bond strengths. This thermal and particularly photochemical instability was most marked in the case of **6**, which gradually deposited a fine black powder (presumably Te) over the orange crystals after *ca* 24 h exposure to daylight at *ca* 25°C. The selenium analogue **5** showed similar, but less marked, photolability. There was a marked difference in air-sensitivity between the sulphur-containing complexes **1** and **4** and the heavier chalcogenide congeners. The sulphides **1** and **4** were almost air-stable, but the others rapidly decomposed, presumably as a consequence of hydrolysis.

The ^1H, ^{13}C and $^{119}Sn\{^1H\}$ chemical shift data of Table 2 for complexes **1–7** are unexceptional.

The thermal lability of **6** led us to the notion that **6** might be a suitable substrate for reductive elimination into its factors $Sn(NR_2)_2 + Te$. This was put to the test by heating **6** with S_8, whence $[Sn(NR_2)_2(\mu\text{-}S)]_n$ was obtained. Reactions of related metal(IV) tellurides might well offer a general route



Scheme 1.

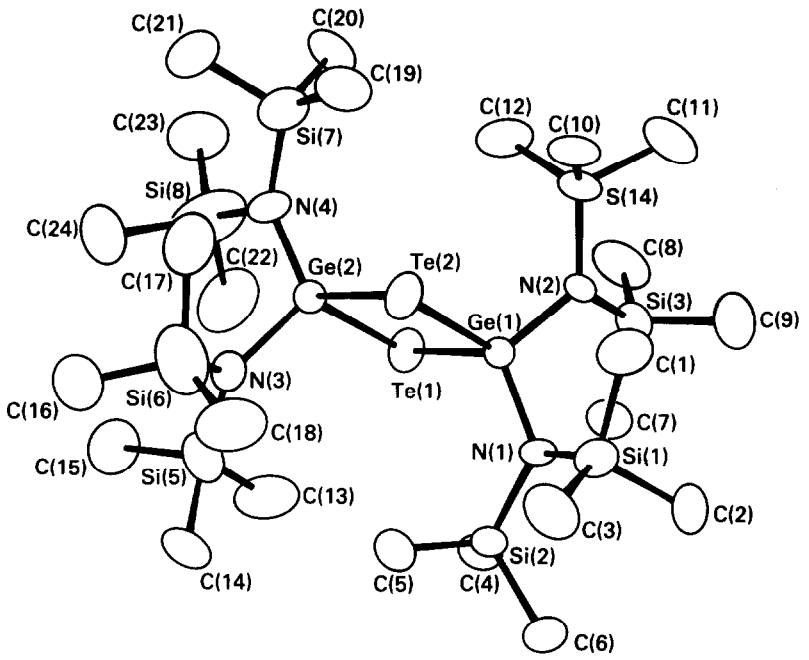


Fig. 1.

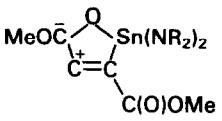
to metal(II) products which, if kinetically labile, may be trapped (e.g. with S_8).

The bicyclic di(stanna)-heterocycle **7** is evidently the product of two successive 1,4-cyclo-additions of $Sn(NR_2)_2$ to dimethyl acetylenedicarboxylate, with **VII** as a possible intermediate. The overall reaction



VII

can also be regarded as an unusual redox process, shown most clearly by including the hydrolysis step [**7** → $(CH_2CO_2Me)_2$] in the reaction scheme. Thus, the oxidation $Sn^{II} \rightarrow Sn^{IV}$ is accompanied by the change in oxidation level of the organic moiety from acetylenic into paraffinic.

The synthesis of the mixed metal(II) compounds $Sn(\eta\text{-}C_5H_4R)(NR_2)$ (**8**) and $Sn(\eta\text{-}C_5H_3R_2\text{-}1,3)(NR_2)$ (**9**) was examined with a view to using them as substrates for oxidative additions, e.g. with a chalcogen. In the event, their preparation was explored (by means only of pilot experiments using ^{119}Sn NMR spectroscopy) from $SnCl_2$ and successively the appropriate lithium cyclopentadienyl and $LiNR_2$, but they were not separated from the symmetrical species $Sn(NR_2)_2$ and the appropriate

tin(II) bis(cyclopentadienyl). The reactions of $Sn(NR_2)_2$ with various non-functionalized alkynes was examined, but the results were inconclusive.

The X-ray structures of crystalline $[Ge(NR_2)_2(\mu\text{-}Te)]_2$ (**3**) and **7**, together with the appropriate numbering scheme, are illustrated in Figs 1 and 2, respectively, while geometric parameters are in Tables 4 (**3**) and 5 (**7**).

Some selected geometric parameters for a number of crystalline, four-membered ring compounds $[MXX'(\mu\text{-}E)]_2$, together with those for crystalline $Ge(NR_2)_2$,[19] are listed in Table 6 in order to put the new data on **3** into context. Each of the $(ME)_2$ rings is planar, with the EME′ angle larger than MEM′ and the MEM′ angle smaller for sulphur than tellurium, but for $[SnBu^t_2(\mu\text{-}E)]_2$ this order is reversed (S > Se > Te).[12] The difference in Ge—E bond lengths between the tellurium (**3**) and sulphur (**VI**) compounds is *ca* 0.35 Å, compared with *ca* 0.32 Å between $[SnBu^t_2(\mu\text{-}Te)]_2$ and the sulphur analogue.[12]

The Ge—N bond lengths in the two germanium(IV) compounds **3** and **VI** might have been anticipated to be similar in magnitude, but shorter than in the germanium(II) precursor, $Ge(NR_2)_2$; the difference in *l*(Ge—N) between the latter and **3**

[a] N—Ge—C.
[b] Monoclinic.
[c] Triclinic.

is in practice rather small. The N—Ge—N′ bond angles in $Ge(NR_2)_2$ and **3** are remarkably similar. The Si—N bond lengths [1.76(1) Å in **3** and **VI** and 1.75(1) Å in $Ge(NR_2)_2$] in these three $Ge(NR_2)_2$ derivatives and in **7**, 1.74(1) Å, are closely similar. In **7** the N—Sn—N angle of 110.5(3)° is slightly wider than in the other three compounds but significantly wider than in crystalline $Sn(NR_2)_2$, 104.7(2)°,[20] while the Sn—N bond length in **7** is slightly shorter than in $Sn(NR_2)_2$, 2.09(1) Å.

The molecular structure of crystalline **7** is entirely consistent with its formulation shown in Scheme 1 as a fused, bicyclic compound having an inversion centre at the mid-point of the C(15)—C(15)′ bond and as mirror plane the planar eight-membered bicyclic skeleton. There is no conjugation in the C=C—C=C fragment as evident from the various C—C bond lengths. The Sn—O bond is significantly longer than in $[Sn(CHR_2)_2(\mu\text{-O})]_2$ (**I**), 1.94(2) Å, or in $[SnR_2(OH)]_2(\mu\text{-O})$, 1.956(1) and 2.032(7) Å (the latter being the Sn—OH).[4]

THE SYNTHESIS, CHARACTERIZATION AND X-RAY STRUCTURE OF *ANTI*-$W_2(GePh_3)_2(NMe_2)_4$

M. H. CHISHOLM,* I. P. PARKIN and J. C. HUFFMAN

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

Abstract—The reaction between $LiGePh_3$ and $W_2Cl_2(NMe_2)_4$ in toluene–THF produces $W_2(GePh_3)_2(NMe_2)_4$ in high yield (69%). The product is air-stable, decomposes at 209°C and is soluble in aromatic hydrocarbon solvents. The ^1H NMR spectrum reveals only an *anti*-isomer with $T_c = 115°C$, $\Delta G^\dagger = 74$ kJ mol^{-1} for amide rotation. The X-ray structure is consistent with the ^1H NMR spectrum and reveals a central *anti*-ethane-like $W_2N_4Ge_2$ core with bond lengths and angles: W≡W = 2.2970(9) Å, W—Ge = 2.625(1) Å, W—N = 1.95(av) Å, W—W—Ge = 95.89(3)°. The compound crystallized in the $P2_1/n$ space group with the cell parameters $a = 19.770(6)$, $b = 11.685(2)$, $c = 9.326(2)$ Å, $\beta = 99.74(1)°$, $Z = 2$, $V = 2123.3$ Å^3, $d_c = 1.802$ g cm^{-3} at −172°C.

There are a number of germanides of the chromium triad, especially for metal centres supported with carbonyl and cyclopentadiene ligands.[1] Despite this very few have been structurally characterized. To our knowledge no dimetallic compounds of this triad containing a metal to germanium bond is known. Previously compounds of the type $M_2(R)_2(NMe_2)_4$ [M = Mo, W; R = Cl, $Si(SiMe_3)_3$, $Sn(SnMe_3)_3$, $SeC_6H_2Me_3$, $SC_6H_2Me_3$, $OCPh_3$] have been synthesized, normally by metathesis reactions involving LiR and the substitutionally labile $M_2Cl_2(NMe_2)_4$ compounds.[2–4] Here we report the reaction of $LiGePh_3$ with $W_2Cl_2(NMe_2)_4$ to produce the first group VI dimetallic germanyl $M_2(GePh_3)_2(NMe_2)_4$. This species could be considered as an example of a heteropolyatomic germanium-containing metal oligomer.

RESULTS AND DISCUSSION

Preparation

Reaction of $W_2Cl_2(NMe_2)_4$ with $LiGePh_3$ proceeds in a toluene–THF solution to produce $W_2(GePh_3)_2(NMe_2)_4$ in high yield (69%), eq. (1):

$$W_2Cl_2(NMe_2)_4 + 2LiGePh_3 \longrightarrow 2LiCl + W_2(GePh_3)_2(NMe_2)_4. \quad (1)$$

The reaction proceeds quite rapidly in that seemingly all the LiCl is immediately precipitated on mixing the reagents. Filtering the solution to remove the LiCl and allowing the filtrate to stand at room temperature yielded orange crystals of $W_2(GePh_3)_2(NMe_2)_4$. These crystals were suitable for an X-ray determination as noted below. The compound is air-stable and soluble in aromatic hydrocarbon solvents (0.2 g/25 cm^3 toluene). It thermally decomposes at 208–209°C but seems relatively inert to hydrolysis either by 6 N HNO_3 or EtOH/KOH (6 N) solutions. These physical properties are probably attributable to the steric shielding provided by the $GePh_3$ ligands, which limits access to the metal centres.

Characterization

$W_2(GePh_3)_2(NMe_2)_4$ had the expected dimethylamide and phenyl ring vibrations in the IR. No assignable M—Ge stretches were seen in the region 4000–200 cm^{-1} [W—Ge = 190 cm^{-1}].[5] The ^1H NMR spectrum of $W_2(GePh_3)_2(NMe_2)_4$ in C_6D_6 is consistent with only the *anti*-rotamer being present in solution. All the dimethylamide ligands are equivalent (related by symmetry elements σ and C_2) but the methyl groups on each dimethylamide ligand are different, being either proximal or distal to the M≡M bond. A difference in chemical shift of 1.55 ppm between these groups is attributable to the diamagnetic anisotropy produced by the M—M triple bond. Variable temperature ^1H NMR spectra in $C_6D_5CD_3$ show extreme broadening at 105°C (Fig. 1) ($\Delta\nu = 465$ Hz) and give an estimated coales-

cence temperature of 115°C at 300 MHz for free rotation about the M—N bond of a dimethylamide ligand. This is amongst the highest T_c values recorded for M—NMe_2 rotation in $M_2R_2(NMe_2)_4$ complexes[2,3] and is consistent with the large steric pressure of the $GePh_3$ ligands. Cooling a sample of $W_2(GePh_3)_2(NMe_2)_4$ to −40°C does not reveal any other dimethylamide environments.

Solid-state molecular structure

The molecular crystal structure of $W_2(GePh_3)_2(NMe_2)_4$ found in the solid state (X-ray) is shown in Fig. 2, looking perpendicular to the W—W vector, and a parallel view is shown in Fig. 3. The structure reveals an "ethane-like" staggered conformation with the $GePh_3$ ligands disposed in

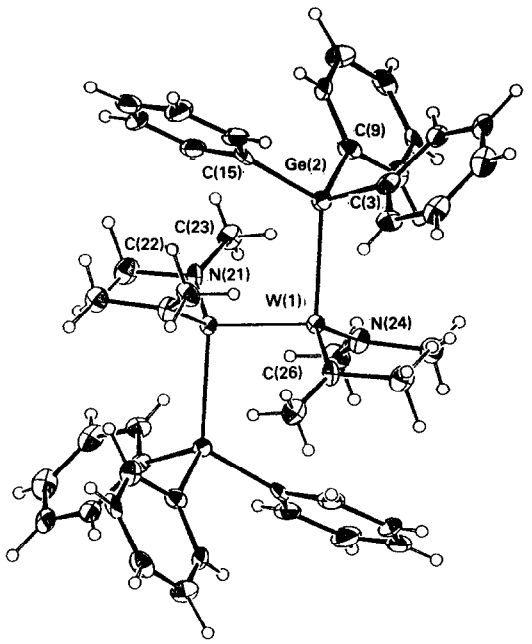

Fig. 2. An ORTEP view of the centrosymmetric $W_2(GePh_3)_2(NMe_2)_4$ giving the atom numbering scheme used in the tables.

an *anti*-configuration. The molecule has a crystallographically imposed centre of inversion.

The W—W distance of 2.2970(9) Å is typical for a W—W triple bond, and considerably shorter than the W—Ge distance of 2.625(1) Å. This later distance is shorter[2] than the corresponding Mo—Sn distance in $Mo_2\{Sn(SnMe_3)_3\}_2(NMe_2)_4$, 2.77 Å, and shorter than the Mo—Si distance in $Mo_2\{Si(SiMe_3)_3\}_2(NMe_2)_4$, 2.67 Å. It is also shorter than the sum of covalent radii of tungsten and germanium. The angles subtended at tungsten reveal the steric pressure of the $GePh_3$ ligand across the M—M bond. Most notable is the enlarged N—W—N angle, 124°, relative to the Ge—W—N angles, 109(av)° (Table 1).

The M—N distance of 1.95(av) Å is consistent with other dimethylamide tungsten distances in $W_2R_2(NMe_2)_4$ complexes, and together with the planarity at nitrogen is indicative of a strong M—N $d\pi$–$p\pi$ interaction.[7]

The observed *anti*-configuration is expected on steric grounds to be more stable than the *gauche* configuration in the presence of the large $GePh_3$ groups. Indeed the large "propeller-like" phenyl rings would seem to preclude the *gauche* conformation even in solution and provide a hydrophobic shield for the NMe_2 ligands. Presumably it is this shielding that makes the compound inert to air, acid and alcoholic alkaline solutions.

EXPERIMENTAL

General procedures and the preparation of $W_2Cl_2(NMe_2)_4$ have been reported.[8]

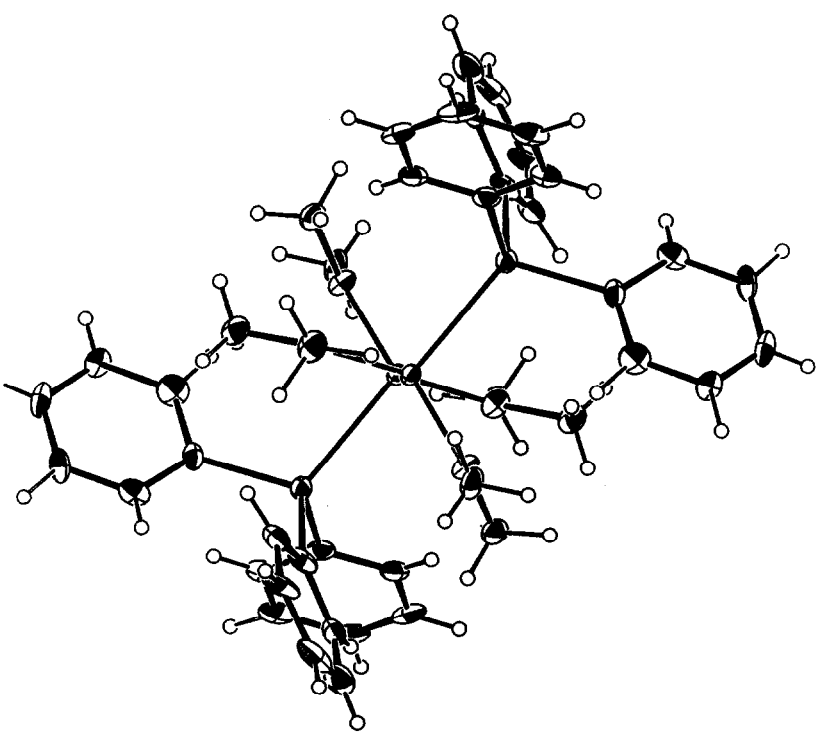

Fig. 3. An ORTEP view of the $W_2(GePh_3)_2(NMe_2)_4$ molecule viewed down the metal–metal bond.

Preparation of $W_2(GePh_3)_2(NMe_2)_4$

Triphenylgermanium chloride (0.500 g, 1.47 mmol) was dissolved in THF (5 cm^3) and added over 10 min to a stirred lithium suspension (0.060 g, 8.6 mmol) in THF (5 cm^3). This mixture was stirred for 5 h to generate a yellow solution and a white precipitate. The $LiGePh_3$ solution was filtered through a fine porosity frit and added to a solution of $W_2Cl_2(NMe_2)_4$ (0.405 g, 0.75 mmol) in toluene (15 cm^3) at room temperature to produce an immediate white precipitate. The reaction solution was allowed to stand for 5 min then filtered through a celite/glass frit. The filtrate was allowed to stand at room temperature for 12 h and deposited orange crystals which were collected by decanting the solvent and washing with hexane (10 cm^3), toluene (10 cm^3) and diethyl ether (10 cm^3). These were suitable for X-ray crystallography as described below. Yield: 0.47 g, 0.40 mmol, 53%. Cooling the filtrate to −20°C produced a further small crop, 0.19 g, 0.16 mmol; combined yield: 69%.

Found: C, 46.3; H, 4.6; N, 4.8. Calc: C, 45.8; H, 4.7; N, 4.7%. The crystals were air-stable for over a week at room temperature and had a decomposition point of 208–209°C. ^1H NMR at room temperature in C_6D_6: δ 7.61 (m, 12H), 7.20 (m, 18H), 3.73 (s, 12H), 2.18 (s, 12H). VT: ^1H NMR $T_c = 115$°C (estimated), $\Delta\nu = 465$ Hz, $\Delta G^\dagger = 74$ kJ mol^{-1} in $C_6D_5CD_3$. IR data (KBr pellet, cm^{-1}): 3040m, 2980m, 2940m, 2845s, 2800m, 2750m, 1560m, 1470m, 1450?, 1435s, 1420vs, 1380w, 1290m, 1250m, 1230s, 1173m, 1150w, 1125m, 1085w, 1070s, 1015s, 985w, 955w, 935vs, 920vs, 840m, 805m, 725vs, 685vs, 655w, 600w, 540m, 460s, 360w, 300s, 290s.

Crystallographic determination

A suitable crystal was located and transferred to the goniostat using standard inert atmosphere handling techniques, employed by the Indiana University Molecular Structure Center, and cooled to −172°C for characterization and data collection.

A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/n$ (alternate setting of $P2_1/c$). Subsequent solution and refinement of the structure confirmed this choice.

Data were collected by using a continuous θ–2θ scan with fixed backgrounds. Data were reduced to a unique set of intensities and associated sigmas in the usual manner. The structure was solved by a combination of direct methods (MULTAN 78) and Fourier techniques. Data were corrected for absorption, based on well-defined crystal faces. All hydrogen atoms were clearly visible in a difference Fourier synthesis phased on the non-hydrogen parameters. All hydrogen atoms were refined (full-matrix least-squares) isotropically and non-hydrogen atoms anisotropically in the final cycles (see Table 2 for crystallographic data).

A final difference Fourier was featureless, with the largest peak being 0.45 e/$Å^3$.

Atomic coordinates have been deposited with the Director, Crystallographic Data Center, Cambridge.

SONOCHEMICAL SYNTHESIS OF 1,1-DIMETHYL-1-GERMACYCLOPENT-3-ENES AND THE EXTRUSION OF DIMETHYLGERMYLENE UPON THEIR PYROLYSIS

DEQING LEI and PETER P. GASPAR*

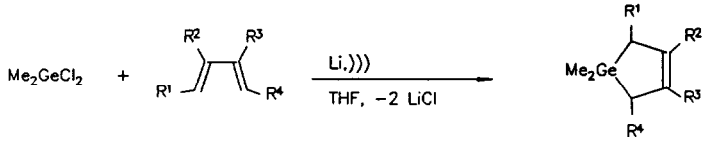
Department of Chemistry, Washington University, St Louis, MO 63130, U.S.A.

Abstract—The ultrasound-promoted reaction of dichlorodimethylgermane with lithium in the presence of substituted 1,3-dienes results in the formation of the corresponding germacyclopent-3-enes in good yields. The gas-phase flow pyrolysis of 1,1,3-trimethyl- and 1,1,3,4-tetramethyl-1-germacyclopent-3-enes leads to the extrusion of dimethylgermylene that has been trapped by addition to 1,3-dienes.

Almost all known silylene reactions are reversible, but carbene reactions usually are not. Extrusion of silylenes from 1-silacyclopent-3-enes is a topic of interest not only because this process is virtually unknown in carbene chemistry, but because study of this process has assisted the elucidation of the mechanisms of silylene–diene addition reactions.[1] While Kolesnikov *et al.* were able to trap dichlorogermylene that was extruded from 1,1-dichloro-1-germacyclopent-3-enes, no dimethylgermylene was captured in the pyrolysis of 1,1-dimethyl-1-germacyclopent-3-ene.[2] We thought it was important to determine whether germylene–diene addition reactions, like those of silylenes, are reversible under flow pyrolysis conditions by preparing 1,1-dialkyl-1-germacyclopent-3-enes and examining their use as a germylene source.[3] Lei and Hampden-Smith have already utilized these findings to generate transition metal substituted germylenes from 1,1-dimetalla-1-germacyclopent-3-enes.[4] Here we report the sonochemical synthesis of a series of 1,1-dimethylgermacyclopenta-3-enes and the extrusion of dimethylgermylene upon their pyrolysis.

RESULTS AND DISCUSSION

Previously, 1,1-dialkyl-1-germacyclopent-3-enes have been synthesized in a two-step sequence by the reaction of alkyl magnesium halides with 1,1-dihalogeno-1-germacyclopent-3-enes, which were obtained from addition of germanium dihalides to suitable 1,3-dienes.[5] We have found that a series of 1,1-dimethyl-1-germacyclopent-3-enes can be prepared by the reaction of dichlorodimethylgermane[6] and lithium metal with the appropriate 1,3-dienes in tetrahydrofuran, promoted by irradiation in an ultrasonic cleaning bath. The reaction was complete within 15–60 min, depending on the diene used. For example, when a solution of 11.5 mmol of dichlorodimethylgermane and excess 2,3-dimethylbutadiene in 30 cm^3 of tetrahydrofuran, together with 0.4 g of lithium metal, was irradiated with ultrasonic waves for 15 min, 1,1,3,4-tetramethyl-1-germacyclopent-3-ene (**1**) was isolated in 54% yield. This series of experiments is summarized below:



(1)

1: $R^1 = R^4 = H, R^2 = R^3 = Me$, 54%

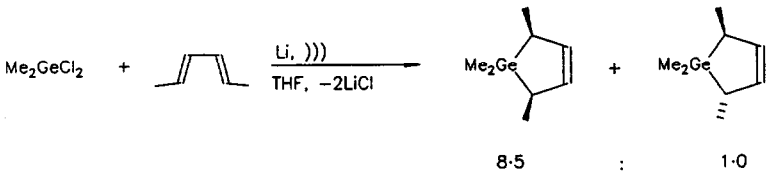
2: $R^1 = R^2 = R^4 = H, R^3 = Me$, 51%

3: $R^2 = R^4 = H, R^1 = R^3 = Me$, 43%

4,5: $R^2 = R^3 = H, R^1 = R^4 = Me$, 15%.

* Author to whom correspondence should be addressed.

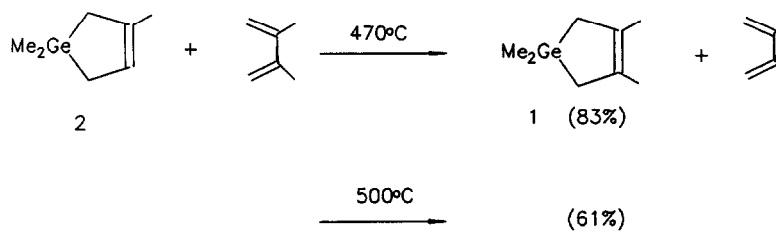
The results shown in eq. (1) suggest that the yields depend on the structure of the 1,3-diene used. The formation of 1,1-dimethyl-1-germacyclopent-3-enes is more facile when there are no substituents on the terminal carbon atoms of 1,3-dienes, i.e. isoprene and 2,3-dimethylbutadiene. The yield of the product decreases dramatically if methyl substituents are present at both termini of the diene π-system. In the reaction of *trans,trans*-2,4-hexadiene (> 99% pure) a mixture of *cis*- and *trans*-1,1,2,5-tetramethyl-1-germacyclopent-3-enes was formed with a *cis*- to *trans*- ratio of 8.5 : 1 [see eq. (2)]. The dominant product stereoisomer retains the geometry of the starting diene.



(2)

These reactions provide a convenient and efficient method to synthesize a variety of 1-germacyclopent-3-enes. It is not suggested that a free germylene is produced by lithium-induced dehalogenation of dichlorodimethylgermane. More likely, "germylenoid" species, $Me_2GeClLi$ or Me_2Ge-LiCl, are involved, analogous to the "silylenoid" species encountered by Boudjouk *et al.*[7] and Pae *et al.*[8] in the analogous dehalogenation of sterically crowed dihalodialkylsilanes $(t\text{-but})_2SiX_2$ and Ad_2SiI_2.

We next studied the gas-phase flow pyrolysis reactions of these germacyclopent-3-enes. We found that the extrusion of dimethylgermylene is an efficient process. When 1,1,3-trimethyl-1-germacyclopent-3-ene (**2**) was subjected to vacuum flow pyrolysis at 470°C, *ca* 2 torr, with contact time *ca* 8 ms, in the presence of a 10-fold excess of 2,3-dimethylbutadiene, the dimethylgermylene adduct, 1,1,3,4-tetramethylgermacyclopent-3-ene (**1**), was obtained in 83% yield based on 44% of the starting material consumed. When the reaction temperature was raised to 500°C, conversion increased to 75% but the yield dropped to 61% :



(3)

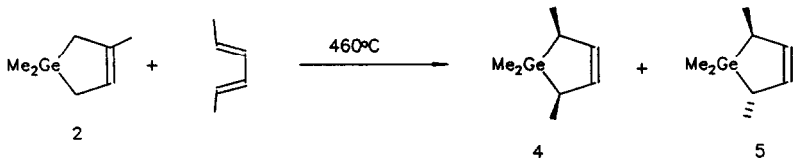
Under the same conditions pyrolysis of 1,1,3,4-tetramethylgermacyclopent-3-ene (**1**) in the presence of a 10-fold excess of isoprene gave 3-methylgermacyclopent-3-ene (**2**) in 71% yield based on the 47% of the starting material converted :

(4)

These results indicate that dimethylgermylene is efficiently generated by extrusion from the germacyclopent-3-enes under relatively mild conditions.

Flow pyrolysis of 1,1,3-trimethyl-1-germacyclopent-3-ene (**2**) in the presence of a 10-fold excess of *trans,trans*-2,4-hexadiene at 460°C gave a mixture of *cis*- and *trans*-1,1,2,5-tetramethyl-1-

germacyclopent-3-enes (**4**) and (**5**) in a combined 15% yield with a 9:1 ratio of *cis*- to *trans*-isomers (35% decomposition of the starting material):



2 4 5 (5)

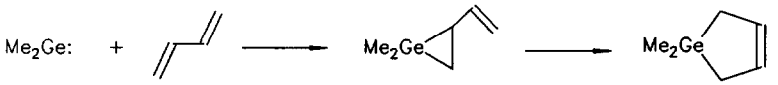
Under the same conditions, the pyrolysis of neat *trans,trans*-2,4-hexadiene, originally greater than 99% pure, indicated that the recovered diene substrate contained 8% of *cis,trans*-2,4-hexadiene and 2% of a mixture of *E*- and *Z*-1,3-hexadienes. Thus the *trans*-isomer might result from addition of dimethylgermylene to *cis,trans*-2,4-hexadiene produced by isomerization of the starting diene under the reaction conditions. These results are therefore not inconsistent with the previously observed stereospecific addition of dimethylgermylene to the 1,3-dienes.[9,10]

CONCLUSION

A series of 1,1-dimethylgermacyclopent-3-enes has been efficiently synthesized by the ultrasound-promoted, lithium-induced dehalogenation of dichlorodimethylgermane in the presence of 1,3-dienes. It has been demonstrated that the 1,1-dimethyl-1-germacyclopent-3-enes are efficient precursors for the thermal generation of dimethylgermylene.

The high temperature addition of germylenes to 1,3-dienes results only in formation of formal 1,4-adducts. However, a stepwise mechanism for addition of silylene to 1,3-dienes has been well established, whose first step is a concerted 1,2-addition followed by competing processes depending on the structure of the key intermediates, *vinylsiliranes*.[1,3] At room temperature, addition of Me_2Ge to a variety of dienes leads to 1:2-adducts, 3,4-dialkyl-1-germacyclopentanes, products whose formation seems to demand the intermediacy of vinylgermiranes.[11] Kinetic studies on Me_2Ge: suggest that at room temperature, 1,2-addition is more rapid than 1,4-addition.[12]

Therefore, one can ask whether the exclusive formation, often in high yield, of formal 1,4-adducts from Me_2Ge: and dienes at high temperatures also involves a vinylgermirane intermediate. Rearrangement of the vinylgermirane to a germacyclopent-3-ene may be sufficiently rapid to account for the stereospecificity that has been observed.[9] The intramolecular rearrangements may be too rapid at high temperatures for reaction with a second diene molecule to occur.



(6)

EXPERIMENTAL

Unless indicated otherwise, all chemicals used were reagent grade and used as supplied. All preparative reactions were carried out under an atmosphere of argon. Tetrahydrofuran solvent was dried over and distilled immediately before use from benzophenone sodium ketyl under a nitrogen atmosphere.

^{1}H NMR spectra were recorded on a Varian XL-300 NMR spectrometer. Combined gas chromatography–mass spectrometry was performed on a Finnigan 3200 instrument operating at an ionization energy of 70 eV. All mass spectra were calibrated internally against perfluoroalkane. Flame ionization detector and thermal conductivity detector instruments were employed for the analytical gas chromatography. A preparative gas chromatograph with dual rhenium tungsten filament TCD detectors was used for separation of the products and for absolute yield determinations on the basis of the amount of the unrecovered precursors, using isomeric compounds as external standards.

Flash vacuum pyrolyses were performed by slowly distilling reactants through a vertical quartz tube (10 mm i.d., 18 cm long) heated by approximately 22 ft of 26 gauge nichrome wire. The nicrome wire was insulated from the quartz tube and the atmosphere with asbestos ribbon. The flow system was evacuated by an oil diffusion pump to *ca* 10^{-5} torr. A gaseous reaction mixture was delivered from a 1-litre reservoir through a ball-type flow meter, and the pressure was measured just upstream from the hot zone by a calibrated thermocouple gauge. The flow system was throttled downstream from the hot zone by a copper plate with a 0.036 in. diameter orifice, and the pyrolysate was condensed in a U-trap immersed in liquid nitrogen. The

temperature was measured at the centre of the hot zone between the outer surface of the tube and the asbestos ribbon by an iron–constantan thermocouple.

1,1,3-*Trimethyl*-1-*germacyclopent*-3-*ene* (**2**)

A mixture of dichlorodimethylgermane (2.0 g, 11.5 mmol), 2-methylbutadiene (1.5 g, 22.1 mmol) and finely cut lithium metal (0.3 g) in 30 cm^3 of THF was sonicated for 30 min under an atmosphere of argon in an ultrasonic cleaning bath (L & R Maxomatic Ultrasonic Generator). The reaction mixture turned light yellowish from what was originally a cloudy suspension, and a white precipitate was formed. The unreacted lithium and precipitate were removed by filtration. The filtrate was distilled at an atmosphere to give 1.4 g of crude product, **2**, which was 72% pure shown by GC (51% yield). The product was further purified by GC (10 ft × 1/4 in. 20% OV-17). ^{1}H NMR (C_6D_6): 0.25 (s, 6H, Ge-Me), 1.34 (bs, 2H, C_5-H), 1.53 (bs, 2H, C_2-H), 1.80 (bs, 3H, C_3-Me), 5.67 (bs, 1H, C_4-H). Mass: 172 (parent), 157 (base). These spectral data are essentially identical to those reported.[3]

1,1,3,4-*Tetramethyl*-1-*germacyclopent*-3-*ene* (**1**)

This was prepared by the procedure described above for germacyclopentene **2**. A mixture of dichlorodimethylgermane (2.0 g, 11.5 mmol), 2,3-dimethylbutadiene (1.9 g, 23.2 mmol) and finely cut lithium metal (0.4 g) in 30 cm^3 of THF was sonicated for 15 min. 1.1 g of germacyclopentene **1** was isolated in 54% yield. ^{1}H NMR (C_6D_6): 0.25 (s, 6H, Ge-Me), 1.56 (bs, 4H, C_2- and C_5-H), 1.76 (bs, 6H, C_3- and C_4-Me). Mass: 186 (parent), 171 (base). These spectral data are consistent with those reported.[3]

1,1,2,4-*Tetramethyl*-1-*germacyclopent*-3-*ene* (**3**)

This was synthesized by the same procedure described for compound **2**. A mixture of dichlorodimethylgermane (1.8 g, 10.3 mmol), 2-methylpentadiene-1,3 (1.7 g, 20.7 mmol) (a mixture of 75% *cis* and 25% *trans*) and lithium (0.3 g) in 20 cm^3 of THF was sonicated for 20 min. 0.8 g of product **3** was isolated in 43% yield. ^{1}H NMR (C_6D_6): 0.19 (s, 3H, Ge-Me), 0.25 (s, 3H, Ge-Me), 1.11 (d, 3H, J = 7.5 Hz, C_2-Me), 1.40 (m, 2H, C_5-H), 1.78 (bs, 3H, C_4-Me), 1.87 (bs, 1H, C_2-H), 5.52 (bs, 1H, C_3-H). Mass: 186 (parent), 171 (base).

1,1,2,5-*Tetramethylgermacyclopent*-3-*enes* (**4**) *and* (**5**)

These were synthesized by the same procedure indicated above for compound **2**. A suspension of *trans,trans*-2,4-hexadiene (1.4 g, 17 mmol), dichlorodimethylgermane (2.9 g) and lithium (0.3 g) was sonicated for 1 h. 0.44 g of products **4** and **5** were isolated in a total of 14% yield. The ratio of *cis*- to *trans*-isomer was 8.5 : 1. ^{1}H NMR (C_6D_6): *cis*-isomer **4**, 0.11 (s, 3H, Ge-Me), 0.22 (s, 3H, Ge-Me), 1.10 (d, 6H, J = 7.8 Hz, C_2- and C_5-Me), 1.78 (q, 2H, J = 7.8 Hz, C_2- and C_5-H), 5.81 (bs, 2H, ole finic H); *trans*-isomer **5**, 0.17 (s, 6H, Ge-Me), the rest of the data are the same as those for its *cis*-isomer **4**. These spectral data are in good agreement with those reported.[9]

Pyrolysis of **1** *in the presence of* 2-*methylbutadiene*

In a typical experiment, a mixture of **1** (47 mg, 0.25 mmol) and a 10-fold excess of 2-methylbutadiene (170 mg, 2.5 mmol) was pyrolysed at 470°C, *ca* 2 torr with residence time *ca* 8 ms. The pyrolysate was separated by GC (10 ft × 1/4 in. 20% OV-17, column temperature at 90°C, He flow rate at 45 cm^3 min^{-1}) to give the starting material in 47% and **2** in 71% yield based on the unrecovered 53% starting material.

Pyrolysis of **2** *in the presence of* 2,3-*dimethylbutadiene*

A gaseous mixture of **2** (69 mg, 0.40 mmol) and a 10-fold excess of 2,3-dimethylbutadiene (328 mg, 4.0 mmol) was passed through the hot zone at 470°C, *ca* 2 torr with residence time *ca* 8 ms. The pyrolysate was separated by gas chromatography (10 ft × 1/4 in. 20% OV-17, column temperature at 90°C and He flow rate at 45 cm^3 min^{-1}). 44% of starting material **2** was recovered. The germylene–diene adduct **1** was isolated in 83% yield based on the unrecovered material **2**. When this reaction was carried out at 500°C, only 25% of starting material **2** was recovered and product **1** was obtained in 61% yield.

Pyrolysis of **2** *in the presence of* trans,trans-2,4-*hexadiene*

A gaseous mixture of **2** (69 mg, 0.40 mmol) and a 10-fold excess of *trans,trans*-2,4-hexadiene (328 mg, 4.0 mmol) was passed through the hot zone at 460°C, *ca* 2 torr with residence time *ca* 8 ms. The pyrolysate was separated by GC (10 ft × 1/4 in. 20%

OV-17, column temperature at 90°C, He flow rate at 50 cm^3 min^{-1}). 65% of **2** was recovered. A mixture of **4** and **5** with a 9:1 ratio of *cis*- to *trans*-isomer was obtained. The ratio of *cis*- to *trans*-isomer was determined by the peak intensity at 0.11 and 0.22 ppm (*cis*-isomer **4**), and 0.17 ppm (*trans*-isomer **5**) in the ^1H NMR spectrum.

ELECTRICAL CONDUCTIVITY OF SOME PERMETHYLPOLYSILANES DOPED WITH ARSENIC PENTAFLUORIDE

A. LOUIS ALLRED* and DONALD A. VAN BEEK JR

Department of Chemistry, Northwestern University, Evanston, IL 60208, U.S.A.

Abstract—Permethylpolysilanes, $Me(SiMe_2)_nMe$ in which n is approximately 48, and long-chain poly(dimethylsilylenes), with or without extensive branching, exhibit electrical conductivity and electron spin resonance when doped with arsenic pentafluoride.

Diverse polymers become conductors when combined with strong electron acceptors or donors, and numerous related observations have been published.[1] Though nearly all of these polymers contain π systems, electrical conductivity in doped, high molecular weight organosilicon polymers and in polysilane, $(SiH_2)_x$, has also been reported.[2,3] Herein we summarize early observations[4] of conductivity in some other polysilane systems which involved either relatively short chains or polysilane branches.

EXPERIMENTAL

Coupling of a 1:3 molar ratio of $Cl(SiMe_2)_6Cl$ and $Me(SiMe_2)_6Cl$ with potassium metal gives linear chains, $Me(SiMe_2)_nMe$, where $n = \ldots 42, 48, 54\ldots$. This mixture of products, obtained under conditions similar to those previously[5] used to prepare $Me(SiMe_2)_{18}Me$ and $Me(SiMe_2)_{24}Me$, was treated repeatedly with hot ethanol to remove short permethylpolysilane chains and then Soxhlet-extracted by refluxing carbon tetrachloride for 4 days to leave behind the insoluble polymer. The extracted white, powdery product, amounting to a 53% yield based on total $SiMe_2$, was slightly soluble, 7.0 g dm^{-3}, in 1,2,4-trichlorobenzene at 120°C and was shown by analytical HPLC with a 60 Å size exclusion column to consist of $Me(SiMe_2)_nMe$ oligomers starting at $n = 18$ and approximately centred at $n = 48$.

Two-dimensional and three-dimensional polymers were prepared by coupling with sodium/potassium alloy either $Cl(SiMe_2)_6Cl$ or Me_2SiCl_2 as the monomer, either $MeSiCl_3$ or $SiCl_4$ as the crosslinking agent, and either hexane or tetrahydrofuran as the solvent. The one-dimensional polymer, $(SiMe_2)_x$, was obtained from coupling of Me_2SiCl_2 with sodium/potassium alloy in refluxing hexane. The above preparations involved adding the monomers to the stirred alloy under gentle reflux conditions, refluxing the resulting solution for 24 h, adding Me_3SiCl and refluxing for an additional 24 h to replace any chloro groups remaining in the polymer. Then work-up involved careful hydrolysis, extraction with water and hexane, and Soxhlet-extraction of impurities with ethanol for 24 h. A weak absorption at 1045 cm^{-1} in the IR spectra of the amorphous products indicated the presence of some siloxane linkages. The optimum solvents and molar per cents of crosslinking agents are given in Table 1.

Arsenic pentafluoride was purified by trap-to-trap distillation on a vacuum line until it displayed no IR-detectable impurities. This dopant was added in measured amounts by vacuum line techniques to previously pulverized $Me(SiMe_2)_nMe$ where $\bar{n} = 48$ (**I**), to polymers **II–VI** having the formulae indicated in Table 1, and to dodecamethylcyclohexasilane. Samples **I–VI** became light brown when exposed to AsF_5 at room temperature, but exposure at −78°C gave vivid blue–green products that became light brown upon warming. The doped samples were compressed (320 kg cm^{-2}) into 1.3 cm diameter × 0.1–0.2 cm thick pellets and transferred to a four-probe conductivity apparatus[6] in a dry box. Cooling the stainless steel press with liquid nitrogen facilitated the removal of the pasty $Me(SiMe_2)_nMe \cdot (AsF_5)_{0.17n}$, and satisfactory contact of this material with platinum electrodes was ensured using Electrodag.

RESULTS AND DISCUSSION

$Me(SiMe_2)_nMe$ and all of the higher polymers were found to be electrical insulators ($\sigma < 10^{-10}$ Ω^{-1} cm^{-1} at room temperature) in their undoped states, as expected. Their conductivities increase many orders of magnitude upon being doped with AsF_5. The conductivity of $Me(SiMe_2)_nMe\cdot(AsF_5)_{0.17n}$ ($\bar{n} = 48$) is 1×10^{-5} Ω^{-1} cm^{-1}. Table 1 presents conductivity data for the various doped polymers. The polymers **IV, V** and **VI**, which have extensive branching as indicated in Table 1, relative to polymers **I–III**, had a higher siloxane content, as indicated by IR spectra, absorbed AsF_5 slower, and generally exhibited lower conductivities upon doping. Polymer **III**, when synthesized from a 5:995 mixture of $MeSiCl_3$ and Me_2SiCl_2 and thus having low crosslinking, exhibited conductivity comparable with that of linear polymers. Polymers **III–VI**, with complete linking of silicon in two- and three-dimensional frameworks, were not obtainable by our method of synthesis, and thus siloxane formation upon work-up is expected. The conductivities of both the doped two-dimensional methylpolysilane (**III**), $\sigma = 3\times10^{-5}$, and the linear poly(dimethylsilylene) (**II**), $\sigma = 2\times10^{-6}$, are much lower than those reported[2] for polysilanes having other side chains which facilitate the synthesis of soluble, high molecular weight polymers. The highest conductivities were obtained for polysilanes with silicon-to-AsF_5 ratios of approximately 6 : 1.

Activation energies of 0.6 ± 0.1 eV were calculated using the equation $\sigma_T = \sigma_o \exp(-E_a/kT)$, for conductivities measured at 5 Hz. The a.c. conductivities increased by a factor of approximately two in the frequency range 5–100 Hz. The conductivity of the doped polymers is electronic in nature: two-probe d.c. measurements taken with blocking platinum electrodes and a steady 10 mV potential showed a constant current for long periods. Observed currents were proportional to applied potentials.

Condensing AsF_5 onto $Me(SiMe_2)_nMe$ at or below -78°C led to an intense blue–green colour which bleached above -73°C. Irradiation of a bleached sample at -100°C with a high-pressure mercury–xenon lamp reproduced the blue–green colour, which again disappeared upon warming. Both blue–green samples gave identical ESR spectra with a slightly asymmetric (non-Dysonian) single line having a g-value of 2.005 ± 0.002 and a width of 19 gauss. The g-value and line width were temperature-independent in the -196 to -78°C range and were independent of doping level. The signal intensity decreased slowly at -100°C and decayed with a 4 min half-life at -75°C. Pure **I** did

not exhibit an ESR signal in the temperature range −196 to 0°C or upon irradiation at either −196 or −78°C. Thus, the species which is responsible for both the colour and the ESR signal is not present during the conductivity measurements. Difficulties in preparing pellets and in making electrical contacts at low temperatures precluded making conductivity measurements on the blue–green samples.

The cyclic $(SiMe_2)_6$ absorbed AsF_5 but no blue–green colour was observed at −78°C, and the sample remained white and an insulator ($\sigma < 10^{-10}\ \Omega^{-1}\ cm^{-1}$) at room temperature.

The mechanism of conduction most likely involves migration of positive holes, as proposed earlier for other systems.[1,2,7] Oxidation of the polysilane chains, with hole formation, is consistent with the IR spectra of doped samples having bands at 500, 695 and 720 cm^{-1} attributable[8] to AsF_3 and AsF_6^- but not to Si—F. Oxidative interactions of polysilanes with electron acceptors have been observed.[9,10] The unpaired spin on fully oxidized $(SiMe_2)_6^+$ is found to delocalize on the ring.[10] These polysilanes, in contrast to intensely studied conducting polymers such as $(SN)_x$, polyacetylene and poly(*p*-phenylene), have no significant p_π unsaturation prior to doping. However, the polysilanes should be easily oxidized since the reported oxidation potentials[11] for short-chain permethylpolysilanes are low: 1.33 V (vs saturated calomel electrode) for $Me(SiMe_2)_4Me$, 1.18 V for $Me(SiMe_2)_5Me$ and 1.08 V for $Me(SiMe_2)_6Me$. For photogenerated holes in poly(phenylmethylsilylene) having a molecular weight corresponding to 3750 silicon atoms in the backbone chain, the mobility is $10^{-4}\ cm^2\ V^{-1}\ s^{-1}$ at room temperature in a field of 2×10^5 V cm^{-1} and is thermally activated with an activation energy of 0.24 eV.[7(a)] The relatively high activation energy of −0.6 eV for conductivity in the above systems probably reflects carrier hopping between polymer chains.

The electrical conductivity of these arsenic pentafluoride-doped polysilanes decreases greatly within a few weeks at room temperature, even in the absence of air and light. The thermal, photolytic and chemical instabilities of these systems are formidable obstacles to their applications in devices.

NEW DEVELOPMENTS IN THE CHEMISTRY OF SILICON SELENIDES

PHILIP BOUDJOUK

Department of Chemistry, North Dakota State University, Fargo, ND 58105, U.S.A.

Abstract—The development of a convenient route to selenide anions under conditions that permit the use of organosilicon halides opened the way to a variety of organosilicon selenides. Reactivity studies on these selenide anions as well as our efforts to prepare cyclosilselenanes and subsequent photolysis and thermolysis studies are summarized.

The importance of the chemistry of compounds with silicon–oxygen bonds raises questions about the potential of the relatively virgin field of the sulphur, selenium and tellurium analogues. In attempts to explore this area we found a need for developing improved synthetic procedures for making linear, cyclic and cage silathianes and silselenanes. In this review we summarize our efforts leading to convenient syntheses of silicon chalcogenides with an emphasis on selenium derivatives. Some of these compounds are useful precursors to reactive intermediates containing the silicon–selenium double bond. The results of our work in this area are also discussed.

ANIONS OF SULPHUR, SELENIUM AND TELLURIUM

Sulphur, selenium and tellurium anions react with organic halides to form sulphides, disulphides, selenides, diselenides, tellurides and ditellurides,[1] eqs (1) and (2):

$$2RX + E_2^{2-} \longrightarrow R_2E_2 \quad (1)$$

$$2RX + E^{2-} \longrightarrow R_2E. \quad (2)$$

Historically, the syntheses of sulphur, selenium and tellurium salts of the type M_2Se_n (where M is an alkali metal and $n = 1$ or 2) were limited to liquid ammonia and protic solvents, although Sandman *et al.*[2] have recently produced Na_2Se, Na_2Se_2, K_2Se and K_2Se_2 and their tellurium analogues by the direct reaction of selenium or tellurium powder with sodium or potassium in high boiling, polar, aprotic solvents such as N,N-dimethylformamide (DMF), hexamethylphosphoramide (HMPA) or N-methylpyrrolidinone (NMP), eq. (3):

$$2M + nE \xrightarrow{DMF,\ 110°C,\ 1\ h} M_2E \quad (3)$$

$$M = Na, K;\ E = Se, Te;\ n = 1, 2.$$

Gladysz *et al.* found that lithium triethylborohydride reduced elemental selenium to give Li_2Se or Li_2Se_2 depending on the stoichiometry,[3] eq. (4):

$$2Li(C_2H_5)_3BH + nSe \longrightarrow Li_2Se_n + 2(C_2H_5)_3BH + H_2. \quad (4)$$

$$n = 1, 2$$

Our interest in developing new routes to these anions was first aroused by the report of Degrand and co-workers[4] that a combination of electrochemical reduction and ultrasound was required to generate modest yields of Se_2^{2-}, Se^{2-}, Te_2^{2-} and Te^{2-} in THF, acetonitrile and DMF. Our programme for studying the effects of ultrasonic waves on heterogeneous reactions,[5] as well as our need for a more convenient route to these anions as intermediates for group 14 chalcogenides, provided the motivation to investigate.

To our surprise, we found that simply by adding a catalytic quantity of naphthalene to a slurry of THF, sulphur (selenium, tellurium) and an alkali metal, very high yields of the desired anions are obtained.[6] We were able to produce lithium, sodium and potassium salts of sulphur, selenium and tellurium under very mild conditions. Presumably, the naphthalene forms the naphthalene radical anion which acts as a soluble charge-transfer agent and facilitates reduction. The product is controlled by

Table 1. Reductions of selenium by potassium, sodium and lithium

Reaction	Number	Conditions[a]	Time
$2K + 2Se \longrightarrow K_2Se_2$	1	Reflux	40 min
	2	Ultrasound	85 min
	3	Stir	150 min
$2K + Se \longrightarrow K_2Se$	4	Reflux	55 min
	5	Ultrasound	120 min
	6	Stir	130 min
$2Na + 2Se \longrightarrow Na_2Se_2$	7	Reflux	65 min
	8	Ultrasound	65 min
	9	Stir	135 min
$2Na + Se \longrightarrow Na_2Se$	10	Reflux	80 min
	11	Ultrasound	85 min
	12	Stir	180 min
$2Li + 2Se \longrightarrow Li_2Se_2$	13	Reflux	8 h
	14	Ultrasound	9.5 h
	15	Stir	15 h
$2Li + Se \longrightarrow Li_2Se$	16	Reflux	12 h

[a] All ultrasound and stirring reactions were carried out at 20–25°C except numbers 8 and 9 which were at 35–40°C.

the stoichiometry. Our results for selenium are given in Table 1.

Relative reactivity studies

The *in situ* reduction of selenium by potassium, sodium and lithium in THF produces suspensions of selenide or diselenide salts which were treated with organic bromides. Considerable reactivity differences were observed. For example, diselenides are signifiantly more reactive then selenides for all three cations. However, within the diselenide series, Li_2Se_2 is more reactive than the sodium and potassium analogues, while among the selenides the potassium salt is the most active.

Relative reactivities toward organic bromides in THF:

$$Li_2Se_2 \gg Na_2Se \gg K_2Se_2 \gg K_2Se > Na_2Se > Li_2Se.$$

APPLICATIONS IN THE SYNTHESIS OF SILICON CHALCOGENIDES

Linear systems

We applied this methodology to simple silicon halides to prepare disilathianes and disilselenanes.[7] Of these, hexamethyldisilathiane is particularly important because of its utility in organic synthesis.[8] Prior to our work, the best available procedures called for either hydrogen sulphide[9] or lithium triethylborohydride,[10] both of which have inconvenient aspects in handling and/or work-up. Hexamethyldisilathiane and analogous compounds can now be easily prepared in high yields, eq. (5):

$$S + 2Na \xrightarrow[THF]{\text{naphthalene}} Na_2S \xrightarrow[R = H, Me]{2RMe_2SiCl} \underset{90\text{–}95\%}{RMe_2Si—S—SiMe_2R}. \quad (5)$$

This approach also applies to selenium and tellurium, although the latter produces compounds that are very sensitive to water, oxygen and light.

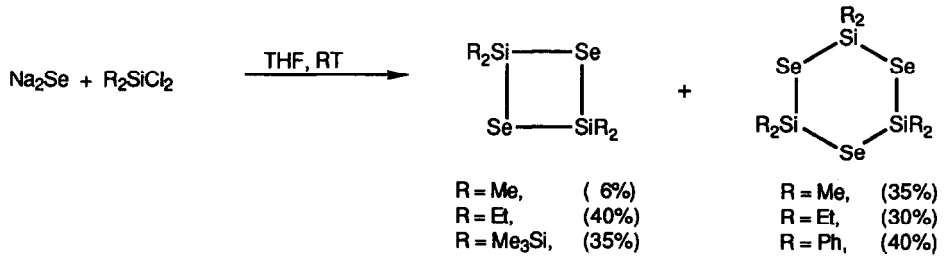
Cyclic and cage systems

When dichlorosilanes are used with sulphur and selenium anions prepared in this fashion, cyclic compounds are obtained, eq. (6):[11,12]

$$M_2E + R_2SiCl_2 \xrightarrow[E = S, Se]{} (R_2SiE)_n. \quad (6)$$

$$n = 2, 3$$

We have been focusing on the cyclosilselananes and found that we could prepare useful quantities of cyclodisilselenanes and cyclotrisilselenanes (Scheme 1). All of these compounds are sensitive to moisture with the exception of the highly hindered $[(Me_3Si)_2SiSe]_2$.

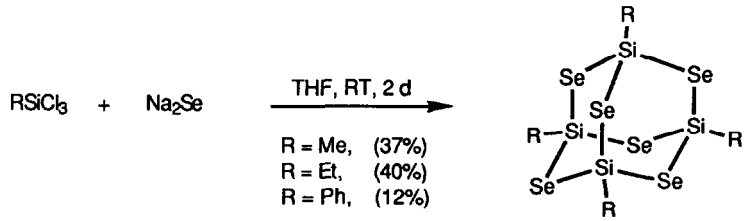


Scheme 1. Synthesis of cyclosilselenanes.

Some physical and spectroscopic properties of cyclosilselenanes
$(Me_2SiSe)_2$: air-sensitive, yellow liquid; decomposes in minutes at 25°C under nitrogen.
$(Me_2SiSe)_3$: air-sensitive, yellow liquid; decomposes in ~ 1 h at 25°C under nitrogen; λ_{254}, $\varepsilon = 1250$.
$(Et_2SiSe)_2$: air-sensitive, yellow liquid; decomposes in ~ 1 h at 25°C under nitrogen.
$(Et_2SiSe)_3$: air-sensitive, yellow liquid; decomposes in ~ 1 h at 25°C under nitrogen; λ_{254}, $\varepsilon = 1100$.
$(Ph_2SiSe)_3$: colourless, crystalline solid; stable for several hours in air.
$[(Me_3Si)_2SiSe)]_2$: light green needles; stable for several days in air.

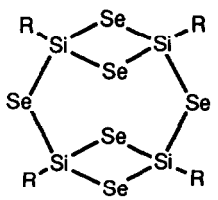
Tricyclo-[3.3.1.1^{3,7}]tetrasilselenanes

There are only two papers describing the synthesis of adamantane-like structures composed of silicon and selenium, $(RSi)_4Se_6$, both of which report very low yields.[13] Using the methodology that led to cyclosilselenanes, but with organotrichlorosilanes rather than dichlorosilanes, we were able to prepare adamantanes in much improved yields [eq. (7)].[14] All three compounds are white, crystalline solids which decompose over the course of a few hours if left in air.



(7)

The structure given in eq. (7) is one of two reasonable isomers from this reaction. The other is the bridged system below:



We used ^{77}Se NMR to discriminate between the two possibilities. The adamantane structure gives only one signal since all six selenium atoms are equivalent. The isomer, on the other hand, has two kinds of selenium atom, one set of four in the four-membered rings and one set of two that bridge these rings and should exhibit two absorptions.

Reactive intermediates

We are interested in investigating the chemistry of reactive species containing multiple bonds between elements of groups 14 and 16. In particular, those of the general formula, $R_2E{=}X$, where E = Si, Ge, Sn and X = O, S, Se, Te. Thus it is necessary to develop convenient high yield routes to these intermediates. For spectral studies it is critical that these routes generate innocuous by-products. Thus "clean" sources of these species is an important goal of our work. Here we discuss the results of our efforts with selenium.

Silaneselones via ring contraction of cyclosilselenanes

Pyrolysis of cyclic compounds of the type $(R_2E{-}X)_n$, $n = 2, 3, 4$, is a well-known route to reactive intermediates of the type $R_2E{=}X$ [eq.

Table 2. Ring contractions of $(Me_2SiSe)_3$ and $(Et_2SiSe)_3$

$$(R_2SiSe)_3 \longrightarrow (R_2SiSe)_2$$

(8)].[15] This approach has been used to generate reactive intermediates for E = C and X = S, Se, such as thiocarbonyl fluoride,[16] thioacetaldehyde and thioacetone,[17] thioformaldehyde[18] and selenoacetaldehyde,[19] as well as for some of the heavier analogues like dimethylsilathione (R = Me, E = Se, X = O)[20,21] and diethylgermathione (R = Et, E = Ge, X = S).[22]

$$(R_2E{-}X)_n \xrightarrow{\Delta} R_2E{=}X \qquad (8)$$

R = alkyl, H, halogen; E = C, Si, Ge; X = O, S, Se.

The first cyclosilselenanes were prepared by Schmidt and Ruf in 1963,[23] but no attempts to generate silaneselones from these compounds, with the exception of our own, have been reported.

$(Me_2SiSe)_3$ and $(Et_2SiSe)_3$ undergo ring contraction, photochemically and thermally, to form $(Me_2SiSe)_2$ and $(Et_2SiSe)_2$, respectively (Table 2). The UV spectra of $(Me_2SiSe)_3$ and $(Et_2SiSe)_3$ show absorbances at 254 nm, while the absorbances of $(Me_2SiSe)_2$ and $(Et_2SiSe)_2$ cut off at 220 nm. Photolysis (Raynonet, 254 nm lamps, hexane) of $(Et_2SiSe)_3$ produces $(Et_2SiSe)_2$ in 90% yield and is the only product observed by gas chromatography (Table 2, entry 5). In a separate experiment, it was shown that $(Et_2SiSe)_2$ is essentially inert to photolysis [254 nm, 48 h, 93% recovery, no evidence of $(Et_2SiSe)_3$]. Photolysis of $(Me_2SiSe)_3$ produces $(Me_2SiSe)_2$ in 68% yield (Table 2, entry 1). Decomposition was observed in the form of discharged elemental selenium in all reactions, photochemical and thermal.

Replacing methyl groups with ethyl groups significantly alters the chemistry of the ring systems. For example, $(Me_2SiSe)_2$ has a $t_{1/2}$ of 60 h at 69°C (refluxing hexane) producing a 22% yield of $(Me_2SiSe)_3$, whereas $(Et_2SiSe)_2$ is stable indefinitely at that temperature and even after 32 h at 250°C, 80% can be recovered [no $(Et_2SiSe)_3$ was detected]. For the six-membered rings, the stabilities are reversed: $(Me_2SiSe)_3$ is stable to 110°C, is only 3% converted to $(Me_2SiSe)_2$ at 150°C, and is less than 50% converted at 225°C even after 94 h (Table 2, entries 1, 6 and 7). The ethyl analogue $(Et_2SiSe)_3$, on the other hand, shows much higher conversion rates to $(Et_2SiSe)_2$, thermally and photochemically (Table 2, entries 2–4). Photolysis of $(Me_2SiSe)_3$ at 254 nm in hexane produces a mixture of $(Me_2SiSe)_2$ and $(Me_2SiSe)_3$ in an 11 : 1 ratio. This mixture was then transferred to a sealed tube and heated to 225°C. After 36 h the ratio changes to about 5.3 : 1, but significant quantities of elemental selenium were also produced.

Thus only for the methyl case does there appear to be an equilibrium between the four- and six-membered rings and then only under thermal conditions. Accurate determination of an equilibrium constant is prevented by the accompanying side reactions. An equilibrium under our photochemical conditions is not possible because $(Me_2SiSe)_2$ and $(Et_2SiSe)_2$ do not absorb at 254 nm.

Ring contraction in the presence of D_3. *Evidence for silaneselones*

Photolysis or thermolysis of $(Me_2SiSe)_3$ [or $(Et_2SiSe)_3$] in the presence of D_3, $(Me_2SiO)_3$, gives $(Me_2SiSe)_2$ and 2,2,4,4,6,6,8,8-octamethyl-1,5,7,3,2,4,6,8-trioxatetrasilselenocane (**3**) [or $(Et_2SiSe)_2$ and 4,4,6,6,8,8-hexamethyl-2,2-diethyl-1,5,7,3,2,4,6,8-trioxatetrasilaselenocane (**4**)], in good yields (Table 3). By analogy to known two atom insertion reactions observed for other $R_2Si{=}X$ species (X = CR_2, NR, O, S),[24] we postulate the inter-

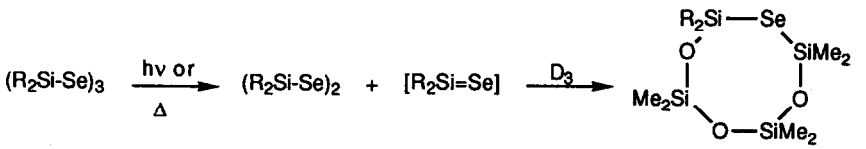
mediacy of silaneselones **1** and **2**, eq. (9):

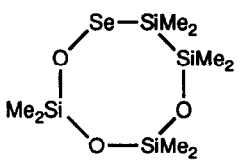


(9)

1, R=Me
2, R=Et

3, R=Me
4, R=Et

The structures of **3** and **4** can be assigned unambiguously on the basis of ^{13}C NMR data. For example, the carbon spectrum of **3** exhibits two singlets at 6.79 and 1.14 ppm, respectively. The alternative structure, **5**, would have at least three absorp-



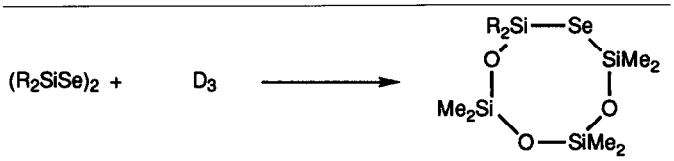
5

tions. The data in Table 3 illustrate important differences in the chemistries of $(Me_2SiSe)_3$ and $(Et_2SiSe)_3$. While $(Me_2SiSe)_3$ is more stable with respect to ring contraction than $(Et_2SiSe)_3$ (Table 1), $(Me_2SiSe)_3$ is a far better source of a silaneselone than is $(Et_2SiSe)_3$.

The experiments with D_3 affect overall silaneselone production. For example, when the ratio of $D_3/(Me_2SiSe)_3$ is 100:1, < 1% of $(Me_2SiSe)_2$ is detected (Experiments 2 and 4). On the other hand, when a $D_3/(Et_2SiSe)_3$ ratio of 100:1 is used, the product mixture contains > 30% $(Et_2SiSe)_2$ (Experiments 7 and 9). While the product distribution may be affected by relative trapping efficiencies, i.e. the smaller dimethylsilaneselone **1** probably reacts faster with D_3 than diethylsilaneselone **2**, the reactivities of the cyclodisilselenanes play a key role because they are sources of silaneselones. When $(Me_2SiSe)_2$ and a 12-fold excess of D_3 is refluxed in hexane for 60 h, no selenocane is observed, but $(Me_2SiSe)_3$ is obtained in 22% yield. This suggests that $(Me_2Si Se)_2$ is a better trap for the silaneselone than D_3, but $(Me_2SiSe)_2$ is approximately 10 times more reactive (Table 4). In these reactions, cyclodisilselenanes are not traps of chemical consequence, since any six-membered ring which is formed should fragment to give silaneselone.

We propose the following pathways for the thermal (> 200°C) reactions of hexaalkylcyclotrisilselanes in the presence of D_3 (Scheme 2). The reaction begins with the extrusion of dialkylsilaneselone

Table 4. Thermolysis of $(R_2SiSe)_2$ with D_3



B C

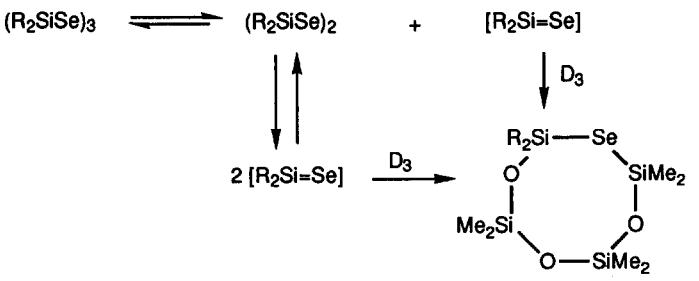
R	D_3/**B** ratio	Conditions	Yield (%) of **C**	Per cent conversion of **B**
Me	12:1	225°C/decane/48 h	70	90
Et	12:1	250°C	5	9

by the cyclotrisilselane. The silaneselone once formed may dimerize, insert into D_3 giving the selenocane or insert into newly formed cyclodisilselenane reforming starting material. We see no evidence of insertion of silaneselone into cyclotrisilselenane to produce cyclotetrasilselenane (in similar experiments with cyclotrisilthianes no cyclotetrasilthianes were observed[20,21]). Cyclodisilselenane formed in the reaction is also capable of extruding silaneselone [e.g. $(Me_2SiSe)_2$ is a more efficient source of silaneselone than $(Me_2SiSe)_3$].

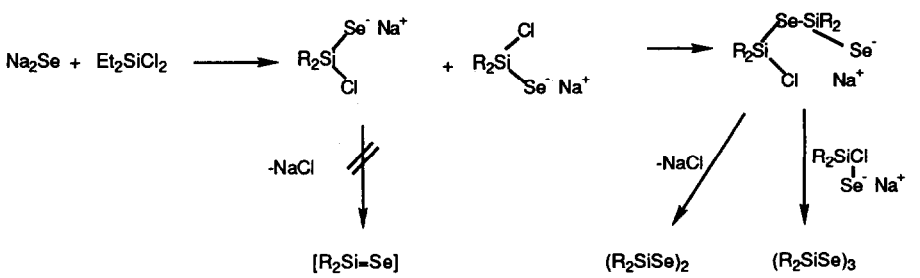
When $(Et_2SiSe)_3$ is photolysed or thermolysed in the presence of triethylsilane, no Si—H insertion is observed. The only observable product is $(Et_2SiSe)_2$ in 90% yield. This indicates that the silaneselone does not readily insert into Si—H bonds under these conditions, and further evidence that silylene formation is not an important pathway in the decomposition of alkylated cyclotrisilselenanes.

No cycloaddition reactions between silaneselones and dienes or alkenes were observed. When $(Et_2SiSe)_3$ is photolysed in a 12-fold excess of cyclohexene, or heated (225°) in a 12-fold excess of anthracene, the only product observed is $(Et_2SiSe)_2$ in approx. 90% yield.

We also investigated the possibility that silaneselones might be intermediates in the synthesis of cyclosilselenanes by treating Et_2SiCl_2 with sodium selenide in the presence of D_3. No selenocanes were detected. This suggests that ring formation occurs primarily through bimolecular reactions involving ionic intermediates (Scheme 3).



Scheme 2.



Scheme 3.

Thermolysis and photolysis of $(Ph_2SiSe)_3$ *and* $[(Me_3Si)_2SiSe]_3$

The photolysis of hexaphenylcyclotrisilselenane in D_3 is more complex than $(Me_2SiSe)_3$ and $(Et_2SiSe)_3$, presumably because the initial photoproducts probably absorb at 254 nm. When a 20 : 1 mixture of D_3 and $(Ph_2SiSe)_3$ was photolysed in methylene chloride at 254 nm for 24 h, six products were detected. Only one could be fully characterized: 4,4,6,6,8,8-hexamethyl-2,2-diphenyl-1,5,7,3,2,4,6,8-trioxatetrasilaselenocane (**6**) which was about 20% of the product mixture and is probably the result of insertion of diphenylsilaneselone, $Ph_2Si{=}Se$, into D_3.

When a decane solution of $(Ph_2SiSe)_3$ was heated to 275°C in a sealed tube for 90 h, only starting material was recovered. However, when a mixture of $(Ph_2SiSe)_3$ and a 20-fold excess of D_3 was heated in decane (275°C, 72 h) $(Ph_2SiSe)_3$ and **6** (30%) were isolated. No tetraphenylcyclodisilselenane was observed. This implies that, at 275°C in the absence of a trap, $(Ph_2SiSe)_3$ is fragmenting to produce tetraphenylcyclodisilselenane and diphenylsilaneselone, but the four-membered ring is either converted back to $(Ph_2SiSe)_3$ or decomposed to the silenselone. We pyrolysed $(Ph_2SiSe)_3$ in the presence of Et_3SiH in an effort to trap diphenylsilylene. We were unable to detect the insertion product, $Et_3Si{-}SiPh_2{-}H$, by GC–MS.

A mixture of tetrakis(trimethylsilyl)cyclodisilselenane and a 12-fold excess of D_3 in decane were heated in a sealed tube at 250°C. After 5 days, analysis of the reaction mixture indicated no volatile products and > 95% recovery of starting material. Photolysis produced similar results.

SUMMARY

Convenient routes to dianions of sulphur and selenium have led to useful syntheses of linear, cyclic and cage silathianes and silselenanes. Ready access to these compounds will lead to a more facile exploration of the chemistry of silicon chalcogenides. Our preliminary studies on cyclosilselenanes has opened the way to the generation of new reactive intermediates containing the silicon–selenium double bond.

Abstract—The general status of catalytic dehydrocoupling as a method for the synthesis of element–element bonds is discussed and evaluated in the context of studies carried out in the authors' and other laboratories. Available thermodynamic data show that dehydrocoupling is favourable for the formation of homopolar bonds between a number of the heavier congeners of the *p*-groups, and heteropolar bonds between first members and lower members of the *p*-groups. Metallocene alkyls and hydrides of group 4 show a particularly high catalytic activity in a number of dehydrocoupling reactions, including Si—H/Si—H, Ge—H/Ge—H, Si—H/O—H, Si—H/N—H and B—H/N—H reactions. The role of some novel silyl intermediates in the dimethyltitanocene- and dimethylzirconocene-catalysed silane coupling reactions is discussed. Current views on the mechanism of these reactions are presented, particularly with respect to the intervention of cyclization reactions and their role in molecular weight limitation.

The formation of element–element (E—E or E—E′) bonds is one of the most fundamental of chemical reactions. In organic chemistry, the existence of innumerable metastable unsaturated compounds, whose multiple bonds are easily opened by electrophilic, nucleophilic or free radical attack, provides a wide range of methods for the formation of C—C and C—E bonds. The few unsaturated compounds of the heavier congeners of the *p*-groups depend for their stability and isolation on the use of sterically demanding substituents which suppress the normal addition reactions that render these types of compounds so useful in organic chemistry.[1–4]

A very general route to the formation of E—E′ bonds is the reaction of a hydride of the more electronegative elements (e.g. N, O and the halogens) with a covalent halide to give the hydrogen halide and the E—E′ bond. The thermodynamics and rates of such reactions can be improved, when necessary, by the addition of a base to scavenge the hydrogen halide.

One of the more important general reactions for the formation of E—E bonds is the Wurtz–Fittig type coupling of element halides by reaction with reactive metals, particularly the metals of group 1. Such reactions have an exceptionally wide application for the formation of E—E bonds, but show little or no selectivity for the synthesis of E—E′ bonds. Many cross-coupling reactions can, however, be carried out in two steps: the preformation of an E-group 1 or group 2 compound, followed by reaction with an E′ halide. There is also voluminous literature on specific cross-coupling reactions using transition metal organometallics and element halides, but this goes far beyond the scope of the present article.

In general, reactions of the kind described above

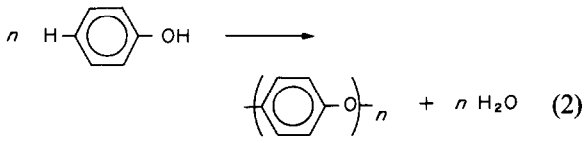
* Author to whom correspondence should be addressed.

present major problems for large scale industrial synthesis. Halide intermediates are relatively expensive and their use generally leads to contaminated salt wastes that are increasingly difficult and costly to dispose of. Batch handling of alkali metals under severe reaction conditions is dangerous and costly. Stoichiometric use of transition metal or main group organometallics is intrinsically costly and always involves difficult by-product recovery and/or disposal problems. Thus, there is considerable incentive to develop alternative syntheses which avoid such problems, while avoiding the introduction of a new set of equally serious problems.

A reaction which is attractive from many points of view is dehydrocoupling, shown in a generalized form in eq. (1):

$$EH + EH \text{ (or } E'H) \longrightarrow E{-}E \text{ (or } E{-}E') + H_2. \quad (1)$$

Such a reaction is appealing since many main group hydrides are in reality, or in principle, easily available at reasonable cost. In addition, the hydrogen by-product is easily recovered. As written, eq. (1) is of little use in the case of the first members of the *p*-groups since the reactions are, for the most part, strongly endothermic under "ambient" conditions. This problem can be, and in some cases has been, overcome by coupling reaction (1) into an exothermic hydrogen-consuming reaction, such as water formation, thus:



(2)

In the present paper we will review recent developments in the application of coordination catalysis to reactions (1) and attempt to interpret some of the results in mechanistic terms.

THE THERMODYNAMICS OF DEHYDROCOUPLING

Although a thorough analysis of the thermodynamics of reactions (1) is still precluded by the relative paucity of data for the bond dissociation energies of the E—H, E—E and E—E′ bonds, some general trends are obvious. Table 1 presents some data for the binary hydrides. From this table it is obvious that the general trend is for reactions (1) to become more exothermic on descending a group. It is also clear that there are many thermodynamically feasible dehydrocoupling reactions.

Although the data in Table 1 are useful to illustrate some general trends, they should be treated with considerable care when attempting to assess the thermodynamic viability of a particular reaction. The E—H energies are average bond energies for the binary hydrides and the E—E energies are for the pure elements. The numbers can be quite different for molecules carrying organic substituents, but unfortunately there is very little data for such cases. An exception to this is the case of silicon, whose industrial importance has encouraged a number of high quality thermodynamic studies.

Table 1. Thermodynamics of dehydrocoupling for some main group hydrides (energies in kJ mol^{-1})[a]

E	D_{E-H}	$D_{E-E \text{ or } E-E'}$	ΔD_R[b]

Si S	320 364	226	+23

[a] Data from ref. 5.

[b] The quantity ΔD_R is the sum of the bond energy changes for the reaction and it is expected to approximate the reaction enthalpy. The values of ΔD_R are based on a value of 435 kJ mol^{-1} for D_{H-H}.

Some data relevant to the dehydrocoupling of silanes is shown in Table 2. From these data two important conclusions may be drawn. In the first place, the dehydrocoupling of silanes is thermodynamically favoured by organic substitution at silicon. Secondly, there is a very large variation in the thermodynamic viability of the reaction, depending on the substitution at silicon. The effect of substitution with silicon is particularly marked, although this must be qualified by the fact that we have no good data on the effect of silicon catenation on the strength of the Si—Si bond. It is also evident that data based on the binary hydrides and the pure elements can be quite misleading.

In conclusion, we draw attention to the fact that the above discussion considers only enthalpic factors. It is not expected that the entropy contributions would be large in a dehydrocoupling reaction, but the high fugacity of hydrogen and its

Table 2. Some bond energies for E—H and E—E bonds (E = C or Si) (energies in kJ mol^{-1})[a]

low solubility could contribute to driving reactions that are thermodynamically marginal. For example, although the data in the tables indicate that the dehydrocoupling of SiH_4 is not thermodynamically favoured, we have in fact observed this reaction in the laboratory.[8]

SOME GENERAL FEATURES OF CATALYTIC DEHYDROCOUPLING OF ORGANOSILANES

A wide range of organometallic complexes has been screened with respect to the catalysis of reaction (1) (E = Si).[9–14] It can be broadly concluded that all compounds so far screened fall into one of two categories. The most common type of activity, and one which seems to occur with virtually any metal complex under approporiate conditions, is a slow stepwise oligomerization which, even in the most promising cases, only leads to low oligomers (n = 2–6). The second category of activity, which up until now is manifest exclusively by some compounds Cp_2MR_2 (M = Ti, Zr, Hf; R = alkyl, H; Cp = η^5-cyclopentadienyl or an alkyl substituted derivative), results in rapid oligomerization to higher oligomers (typically, n = 10–20, but in a few cases to higher values).[15,16] These reactions usually proceed rapidly, even violently, under ambient conditions, while those in the first category normally require the application of heat to achieve reasonable rates. Even some group 4 metallocene complexes exhibit the first rather than the second category of reactivity with primary organosilanes, e.g. bis (indenyl)dimethyltitanium(IV) with phenylsilane, and all group 4 metallocene-catalysed oligomerizations of secondary silanes fall into this category.

The reactivity of organosilanes towards dehydrocoupling is quite sensitive to the nature of the silane. In general, the order of reactivity is 1° > 2° ≫ 3°. Given the thermodynamic values in Table 2, it may be assumed that this order is largely the result of steric constraints. Platinum group complexes are less sensitive to this effect and they commonly couple primary and secondary silanes at comparable rates,[12] but to our knowledge, no effective catalyst for the coupling of tertiary silanes has yet been found.

The group 4 metallocene catalysts are highly sensitive to steric effects. Titanocene derivatives only catalyse the coupling of certain secondary silanes to dimers at an extremely slow rate and even sterically encumbered primary silanes, such as tertbutyl- and cyclohexylsilanes do not oligomerize. Zirconocene-based catalysts are about an order of magnitude more reactive than titanocene analogues[16e] and have been shown to oligomerize some secondary silanes to n = 5 to 6 at higher temperatures and long reaction times.[10]

Catalysts derived from the elements of groups 6–10 also tend to catalyse redistribution of arylsilanes, a serious impediment to the achievement of high polymers.[12,13] Binary carbonyls of manganese, iron and cobalt also catalyse the redistribution of phenylsilane at temperatures where coupling is also catalysed (*ca* 100°C).[17]

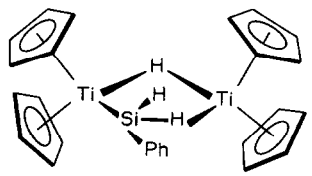
A special feature of the group 4 metallocene catalysts is their exceptional ability to couple 1,2-disubstituted disilanes at a more rapid rate than the analogous monosilanes.[18] As a result of this ability, only small amounts of dimer accumulate during the reaction of phenylsilane. We have shown that dimethyltitanocene (DMT) catalyses the coupling of 1,2-diphenyldisilane to the tetramer and higher, even-numbered oligomers at a faster rate than phenylsilane is polymerized by the same catalyst. Only a small amount of redistribution to the monomer occurs and it seems that the reaction is predominantly one of dehydrocoupling. The greater

reactivity of the disilane may not seem surprising in view of the greater weakness of the SiSi—H bond[7] and the more favourable thermodynamics indicated in Table 2. However, the phenomenon is not general and most other catalyst systems are more effective in the oligomerization of monosilane than of disilane. For example, vanadocene catalyses the dehydrocoupling of primary silanes, but requires temperatures in excess of 100°C to give reasonable rates. The reactions proceed in a stepwise fashion to give first the dimer, then the trimer, etc. In this case, the dimer is less reactive than the monomer and can accumulate up to *ca* 50% of the reaction mixture.[9] Similarly, platinum group catalysts also give high yields of dimer.[12]

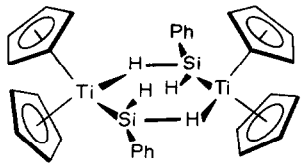
SOME SILYLMETALLOCENE INTERMEDIATES

A number of silyltitanocene(III) and silylzirconocene(IV) complexes have been isolated from reactions of the dimethylmetallocenes with organosilanes. On the basis of NMR and ESR spectroscopies, the products of DMT reactions with silanes are entirely in the form of titanium(III).[16c,19] The only products isolated so far from dimethylzirconocene (DMZ) reactions are zirconium(IV) complexes.[16d,e] There is, however, ample evidence from NMR and ESR spectra that zirconium(III) species are also produced in solution.[16e]

The first complexes isolated from DMT reactions were the silyl-bridged bimetallic species **1** and **2**.[16c]



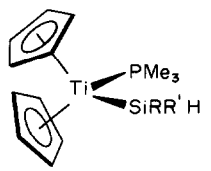
1



2

These complexes can be observed by virtue of their highly characteristic NMR spectra, and in some cases isolated, with all silanes which undergo polymerization. With sterically hindered primary silanes, or secondary silanes, which do not undergo polymerization, there is no evidence for the bimetallic intermediates by NMR, despite the fact that all the titanium is reduced to titanium(III).

More recently we have reported that silyltitanocene species can be trapped with phosphine ligands to give the monomeric complexes **3**.[19] Such complexes can be produced with secondary silyl ligands, thus proving that the main difference between polymerizable and non-polymerizable silanes is their ability to give the dimetallic species **1** and **2**, and not their ability to transform DMT to silyltitanocene(III) species. This should not be taken as indicating that the bimetallic species are necessary to catalytic activity, but rather that steric repulsion may be responsible for both effects.



a: R = Ph, R′ = H

b: R = R′ = Ph

3

An examination of the structural details of complexes **3a** and **3b** reveals: (i) the ligands on the silicon adopt a staggered conformation with respect to the ligands on the titanium, with the Ph and PR_3 groups *trans* to each other [see Fig. 1(a)] and (ii) in the diphenyl complex, one of the Ph—Si—Ti angles (that in a *cis* relation to the phosphorus) is opened up to accommodate the steric repulsion between the phenyl group and the phosphine ligand.[19]

The formation of near planar rings via the Si—H—Ti bridges in complexes **1** and **2** forces the ligands on the silicon into a nearly eclipsed configuration with respect to the ligands on the titanium [see Fig. 1(b)]. Excessive steric repulsion between the extraannular ligands on the silicon and titanium atoms is avoided by the assumption of a very large Ph—Si—Ti angle. The angles for the complexes of interest are listed in Table 3. From these data, it is evident that the monometallic diphenylsilyl complex can form by accommodating steric strain via opening up of one of the Ph—Si—Ti angles. The bimetallic complexes cannot form in this case since even the monophenyl species, for both **1** and **2**, has to open up the Ph—Si—Ti angle because of the near-eclipsed configuration. A second substituent on the silicon would be forced

into unacceptably close interaction with the neighbouring cyclopentadienyl group on the titanium.

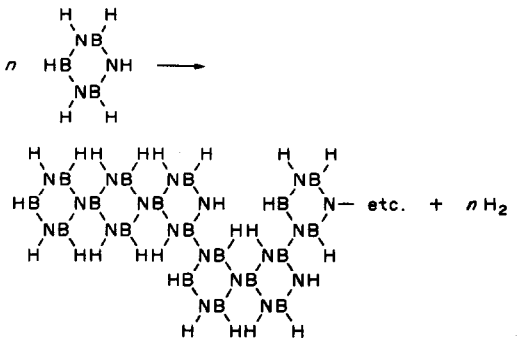
OTHER DEHYDROCOUPLING REACTIONS CATALYSED BY GROUP 4 METALLOCENE DERIVATIVES

Dimethyltitanocene is a very active catalyst for the dehydrocoupling of primary and secondary organogermanes.[20] The reactions are quite complicated and in the case of primary germanes lead to cross-linked gels. Secondary germanes react rapidly, but the products are only low molecular weight oligomers ($n = 4$ and 5). Rather surprisingly, DMZ reacts neither stoichiometrically, nor catalytically, with phenyl- or diphenylgermane. We believe that this lack of reactivity may be due to the fact that equilibrium (3) lies too far to the left in the case of zirconium:

$$Cp_2MMe_2 + RGeH_3 \longrightarrow Cp_2MMe(GeH_2R) + MeH. \quad (3)$$

DMT also is a very potent catalyst for the cross-dehydrocoupling of silanes with —OH and —NH functions. These reactions can be used for synthesis of either simple, or polymeric alkoxy- and aryloxy-silanes, or silazanes.[21]

A quite remarkable case of DMT-catalysed dehydrocoupling was recently discovered by Sneddon *et al.*[22] This reaction involves the dehydrocoupling of borazine to a soluble polymer, whose structure is probably that shown in eq. (4).



(4)

The fact that the polymer remains soluble, even at high conversions, proves that the three BH and the three NH functions on a given ring do not react with equal reactivity. This is probably another manifestation of the rigorous steric constraints operating at the catalytic metallocene centre during the propagation reactions. In the borazine case, formation of a B—N bond between two rings probably prevents reaction of the vicinal NH and BH bonds due to steric hindrance.

THE MECHANISM OF GROUP 4 METALLOCENE-CATALYSED DEHYDROCOUPLING

Although other mechanisms may be operating with other catalysts,[12,13] it now seems likely that all of the group 4 metallocene-catalysed dehydrocoupling reactions described above involve a series of σ-bond metatheses, as described by Tilley and co-workers.[15] Tilley's conclusions were based on a series of observations of stoichiometric metatheses between silicon hydrides and bis(silyl)- and silyl-hydridometallocenes of zirconium and hafnium. In addition, kinetic studies yielded activation parameters and kinetic isotope effects typical of other σ-bond metatheses.

Our earlier reservations on this matter were largely due to the erroneous conclusion that the titanocene-catalysed reaction did not produce small oligomers. More recent results have shown that the failure to observe these oligomers by NMR spectroscopy is due to their being in rapid equilibrium with the catalyst.[18] Carrying out the NMR analysis at low temperature (−40°C), or using GC to analyse for the low oligomers, shows unequivocally that the reaction proceeds by a stepwise build-up and not by a rapid addition polymerization. It has also been shown that 1,2-diphenyldisilane and 1,2,3-triphenyltrisilane both polymerize by a stepwise mechanism to give oligomers with degrees of polymerization of 4, 6, 8, etc., or 6, 9, 12, etc., respectively.[18]

There are only subtle differences between the

polymerization profiles for titanocene- and zirconocene-based catalyst systems, strongly suggesting that the polymerization mechanism is the same for both.[16e] However, major differences are evident in the manner in which the active catalyst is generated for the two cases. We believe, in agreement with Tilley, that the key catalyst species is $Cp_2M(H)SiH_2R$.[15c,23] The differences in the behaviour of DMT and DMZ are mostly due to the different routes, whereby they are transformed to the active catalyst species. In the case of titanium, there is little doubt that the catalyst cycles through the dimetallic complexes **1** and **2**, possibly by way of titanocene. Complex **1** may dissociate directly to give the hydridosilyltitanocene(IV) and titanocene(II), or it may react with silane as shown in eq. (5):

$$Cp_2Ti(\mu\text{-}H)(\mu\text{-}SiH_2R)TiCp_2 + RSiH_3 \longrightarrow 2\,Cp_2Ti(H)(SiH_2R). \quad (5)$$

Although DMZ also gives zirconocene(III) species, which are detectable in silane–DMZ reaction mixtures by ESR and NMR spectroscopies, there is no evidence that these species are important to the polymerization mechanism.[16d] Most of the zirconium is in the form of zirconium(IV) and in the case of reactions of secondary silanes, the stepwise transformation of DMZ to the silylhydride, according to eqs (6) and (7), can be observed by NMR spectroscopy.[16e]

$$Cp_2ZrMe_2 + RR'SiH_2 \longrightarrow Cp_2Zr(SiRR'H)Me + MeH \quad (6)$$

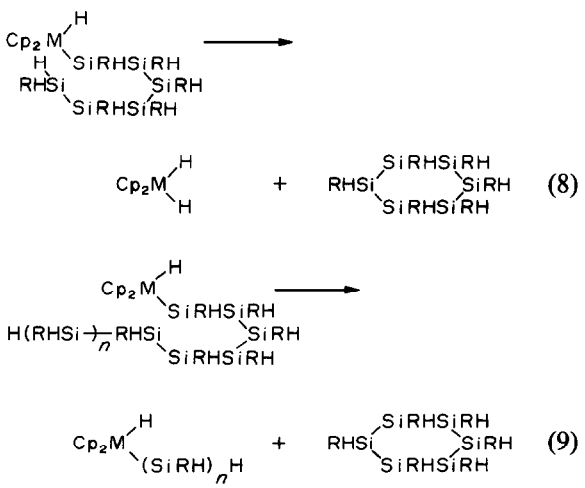
$$2\,Cp_2Zr(SiRR'H)Me \longrightarrow Cp_2Zr(SiRR'H)H + Cp_2Zr(SiRR'Me)Me. \quad (7)$$

Both of these reactions are readily explained as σ-bond metatheses. In reaction (7), the Si—H bond is probably activated towards metatheses by the geminal zirconium atom.

THE PROBLEM OF CYCLIZATION AND DEPOLYMERIZATION

The dehydrocoupling chemistry described above has already provided a number of useful syntheses of compounds containing Si—Si bonds. Whereas the usefulness of the method has so far proved to be very limited for the synthesis of high polymers. The major problem is the occurrence of competing cyclization reactions. Although the di- and trisilanes are both more reactive than the monosilane, the reactivities of higher oligomers fall off rapidly with increasing chain length because of the dilution of the reactive end groups.[18] Cyclic products always form during the chain propagation step, and in certain experimental situations they may be the only products. This is the case under conditions of high dilution with certain monomers (e.g. benzylsilane) and with certain catalyst/monomer combinations [e.g. phenylsilane with 1,2-bis(indenyl)ethanedimethylzirconium(IV)].[24] With neat phenylsilane and either a DMT or DMZ catalyst, linear oligomers dominate until most of the monomer is consumed (*ca* 1 h under the usual experimental conditions). At this point linear oligomers peaking at about 16 silicon atoms are the most abundant species in the reaction product. However, if the reaction mixture is left for much longer periods (several days) a depolymerization occurs, which results in the conversion of linear chains into cyclics.[16e,18]

The formation of cyclic species during chain propagation is most likely the result of an intramolecular metathesis between the distal SiH_2 end group and the M—Si bond at the growing chain end, as shown in eq. (8).[11] This process obviously has a high probability when the silicon chain is about six atoms long. The different propensities for different silanes to form cyclic species are likely due to the steric constraints operating on the intramolecular metathesis, as opposed to intermolecular metathesis. At the present time, we have no data which allow us to choose between the several possible mechanisms for the depolymerization reaction. These include the random cleavage of Si—Si bonds by some reactive intermediate and an intramolecular, back-biting metathesis, as shown in eq. (9):



CONCLUSIONS

Studies of dehydrocoupling reactions catalysed by transition complexes have already yielded a fascinating new family of organosilicon complexes

of transition elements. Studies of the structures of these compounds give some indication of the subtle ways in which stereochemistry can influence the outcome of the reaction. Present systems, while highly interesting from the point of view of formation of E—E and E—E′ bonds, have thus far failed to provide a new route to high molecular weight polysilanes. On the basis of our present understanding of the mechanism, there does not seem to be any intrinsic reason why new catalysts with higher propagation/depropagation ratios cannot be developed. The present results are still sufficiently encouraging to justify a continued search for new catalysts.

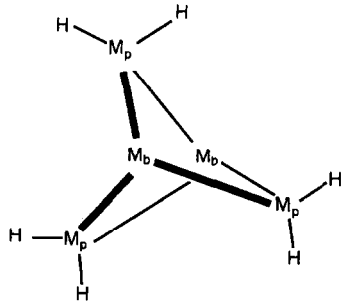
THE STRUCTURE AND BONDING IN GROUP IV [1.1.1]PROPELLANES

MARK S. GORDON,* KIET A. NGUYEN and MARSHALL T. CARROLL†

Department of Chemistry, North Dakota State University, Fargo, ND 58105-5516, U.S.A.

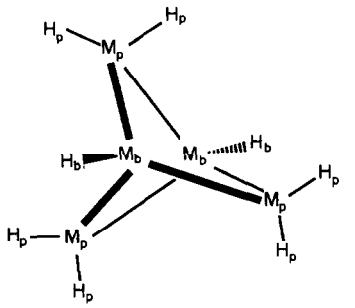
Abstract—The structures of Group IV [1.1.1]propellanes are determined using *ab initio* all-electron and effective core potential methods. The bonding in these systems is examined using the theory of atoms in molecules and localized molecular orbital analysis. Singlet–triplet splittings are also calculated. Comparisons with the corresponding bicyclopentanes are made. The bonding interaction between the two bridgehead atoms decreases upon descending the group. Further, the similarities in the internuclear bridgehead region between the propellanes and bicyclopentanes increase upon descending the group.

In a recent series of papers Sita and co-workers[1] have prepared several intriguing polycyclic tin compounds. One of these species, 2,2,4,4,5,5-hexakis(2,6 - diethylphenyl)pentastanna[1.1.1]propellane (**1**) is particularly interesting, in view of the continuing discussion of the nature of bonding, especially between the bridge atoms, in propellanes.[1–11]



1

According to the X-ray crystal structure of **1** (M = Sn), the distance between the bridgehead (b) atoms, 3.367 Å, is much longer than that between the bridgehead and peripheral (p) atoms, 2.841–2.871 Å. This suggests that the bond connecting the two bridgehead atoms is extremely weak, if it exists at all. Significantly, addition across the b–b bond yields a pentastannabicyclopentane (**2**, M = Sn)



2

whose b–b distance (3.361 Å) differs only slightly from that in the parent [1.1.1]propellane **1** (M = Sn). This reinforces the notion that there is little or no b–b bonding in **1** (M = Sn).

The simplest group IV [1.1.1]propellane, with M = C, has received considerable attention from both experimentalists[12–14] and theoreticians[2,3,7–11,15] in recent years, in an attempt to unravel the nature of the bonding in this compound. In contrast to the case of tin, the b–b bond in the parent [1.1.1]propellane (1.60 Å)[13] is only slightly longer than the b–p bond length in the same compound (1.52 Å) and much shorter than the corresponding b–b distance in **2** with M = C (1.84 Å[16]). These experimental distances suggest that there is much more likely to be a bond connecting the bridgehead atoms in the parent propellane than in its pentastanna analogue.

The numerous theoretical studies of the parent [1.1.1]propellane have recently been reviewed by

Wiberg.[12] A detailed analysis of the bonding in this compound has been presented by Wiberg *et al.*,[2] using the density analysis developed by Bader and co-workers.[15,17,18] These authors emphasize the point that it is essential in analysing molecular structure and bonding to consider the *total* electron density and not just the contributions from a subset of orbitals. Indeed, the density analysis based on a self-consistent field (SCF) calculation with the 6–31G(*d*) basis set[19] reveals a *bond critical point*[15] (that is, a saddle point in the total electron density) connecting the bridgehead atoms. Such a point is indicative of the existence of a bond connecting these atoms and is at variance with the conclusions of earlier analyses,[8,9] based on a subset of the occupied molecular orbitals. Further evidence for the b–b bond is the existence of three *ring critical points*, one for each three-membered ring.

The pentasila analogue of [1.1.1]propellane is unknown experimentally, but has been investigated by Schleyer and Janoschek.[3] Using a two-configuration (TCSCF) wave function and an effective core potential, these authors find a rather long (2.735 Å) b–b bond length and "substantial singlet diradical character". If the latter is defined as twice the square of the coefficient for the excited configuration, the per cent diradical character from the TCSCF wavefunction is 12.5%. This plus a very small natural atomic orbital bond order[20] is taken as an indication that there is only very weak b–b bonding in this compound. Schoeller *et al.* have also predicted a long b–b bond length in the pentasila compound.[6] The ring strain in pentasila[1.1.1]propellane has been investigated by Nagase and Kudo[4a] and Allen and co-workers,[10] both of whom find this species to be less strained than the carbon parent. In a related paper, Nagase *et al.* have suggested that placement of electronegative elements in the peripheral positions should stabilize the b–b interaction in the pentasila compound[4b] and also in the pentagerma compound.[5] To our knowledge, no calculations have been reported to date on pentastanna[1.1.1]propellanes.

In the present paper, we present a systematic analysis of the Group IV [1.1.1]propellanes **1**, with M = C, Si, Ge, Sn, in an attempt to develop a broad understanding of the structure and bonding in these compounds. An ancillary objective of this work is to assess the ability of effective core potentials[21,22] to reproduce the structures and (valence) electron densities predicted by full *ab initio* calculations.

COMPUTATIONAL APPROACH

The electronic structure calculations presented here have been carried out at several levels of theory. Species which are formally closed shell singlets have been investigated with restricted Hartree–Fock (RHF) wavefunctions, within the linear combination of atomic orbitals (LCAO) approximation. Because there is a question with regard to the existence of a b–b bond in species **1**, with M = Si, Ge, Sn, and there is the possibility that significant diradical character exists in these compounds,[3] the propellane structures were also investigated with generalized valence bond[23] wavefunctions. The corresponding triplet states, investigated to obtain a *qualitative* handle on the relative singlet–triplet splittings as a function of M, were studied with unrestricted Hartree–Fock (UHF) wavefunctions.

The fully *ab initio* calculations have been performed with the 3–21G(*d*) basis set,[24] with *d* orbital exponents taken from the original papers. Two different sets of effective core potentials, due to Stevens, Basch and Krauss[21] (SBK) and Wadt and Hay[22] (WH) have also been used to analyse the same set of compounds, using the same *d* orbital exponents as in the full *ab initio* calculations. Geometries were determined using the analytical gradients and algorithms contained in GAMESS.[25] Structures were established as minima by verifying that the hessians (matrices of energy second derivatives) are positive definite. These hessians were constructed from second derivatives obtained analytically (RHF *ab initio*) or from finite differences of the analytically determined gradients.

The nature of the bonding in the compounds of interest have been investigated using the density analysis developed by Bader and co-workers.[15,17,18] Because we have found[26] that spurious behaviour can be obtained in this analysis when heavier elements (such as silicon) are involved and standard basic sets are used, two, rather than one, sets of *d* functions have been used for this analysis. The *d* orbital exponents used for this purpose are 1.12, 0.32 (C), 0.79, 0.1975 (Si), 0.492, 0.123 (Ge), 0.366, 0.0915 (Sn) for the all-electron calculations. For the ECP basis sets the same values are used except 1.6, 0.4 is used for carbon. The density analysis has been discussed in detail elsewhere,[15,17,18] and only a few key points will be repeated here. Bond ($\mathbf{r}_b$), ring ($\mathbf{r}_r$) and cage ($\mathbf{r}_c$) critical points will be of interest in the following discussion. A bond critical point exists between two atoms if there is a "saddle point" in the electron density $\rho(\mathbf{r})$ between the two atoms. At such a point the hessian of the electron density has one positive eigenvalue along the bond axis (λ_3) and two negative eigenvalues (λ_1, λ_2) along the axes orthogonal to the bond axis. The existence of a bond critical point implies the existence of a bond path (path of maximum electron density passing

through r_b), and the two atoms are said to be bonded. The hessian at a ring critical point has two positive and one negative eigenvalues, with the density $\rho(\mathbf{r}_r)$ at the ring critical point being smaller than that at all of the surrounding bond critical points. The hessian at a cage critical point has three positive curvatures and $\rho(\mathbf{r})$ is a local minimum at this point. According to this analysis, a [1.1.1]propellane should have a bond critical point between the two bridgehead atoms if a b–b bond exists, as well as three ring critical points, one on the face of each three-membered ring. The lack of such a bond critical point is evidence that there is no "formal bond" connecting these two atoms.[15,17,18] However, such arguments may not reflect the existence of very flat electron density surfaces.

As an additional tool, the localized molecular orbitals (LMOs) obtained using the prescription of Foster and Boys[27] have been calculated. These LMOs will prove to enhance the Bader analysis outlined above.

RESULTS AND DISCUSSION

Structures

The calculated geometries for the [1.1.1]propellanes and the bicyclopentanes are listed in Tables 1 and 2, respectively. All structures have been predicted at all levels of theory using the SBK effective core potentials. The same is true for the WH ECPs, except that these are not available for carbon. The *ab initio* GVB structures for the germanium and tin compounds and the RHF Sn_5H_8 structure have been omitted in the interest of conservation of

computer time. The ECP structures are generally in quite good agreement with the fully *ab initio* geometries. For carbon, silicon and germanium, the SBK ECP tends to over-estimate bond lengths, the worst case being the Ge_b—Ge_b bond which is over-estimated by 0.1 Å. On the other hand, the WH ECP under-estimates bond lengths to carbon and silicon, but over-estimates those to germanium and tin. In general, the SBK bond lengths are closer to the fully *ab initio* ones. The bond angles predicted by all three methods are quite similar.

Since the GVB wavefunction mixes anti-bonding character into the previously RHF description, it is expected that the GVB bond lengths will be longer than those obtained at the RHF level. This will be particularly true for the M_b—M_b distance, since the highest occupied (HOMO) and lowest unoccupied (LUMO) orbitals correspond to the bonding and antibonding interactions for these atoms. This is indeed seen to be the case in Table 1. For the 3–21G(*d*) structures, the GVB−RHF difference in the M_b—M_b distance is 0.06 and 0.07 Å for carbon and silicon, respectively. The corresponding differences for the SBK ECP are 0.05 and 0.06 Å, respectively, so the trend is well reproduced. In contrast, both ECP methods predict a progressively smaller change in this bond length upon going from RHF to GVB, when M = Si, Ge and Sn. This suggests that as M gets heavier, the bonding interaction between the bridgehead atoms decreases. Further evidence for this conclusion is provided by comparing the predicted b–b distances in M_5H_6 with those in M_5H_8 (Table 2). For M = C, the RHF/3–21G(*d*) b–b distance in bicyclopentane is 0.27 Å longer than the GVB/3–21G(*d*) value for the same distance in [1.1.1]propellane. This considerable difference is expected if one is comparing a bonded to a non-bonded interaction. The SBK ECP comparison is similar. For M = Si, this difference decreases to 0.15 Å [3–21G(*d*)], 0.13 Å (SBK), 0.17 Å (WH). This suggests, as before, that the b–b bonding interaction is smaller for silicon than for carbon. The M_5H_6 vs M_5H_8 b–b distance is even smaller for M = Ge and virtually non-existent for tin. So, the calculated geometries suggest a successively decreasing bonding interaction between the bridgehead atoms as M moves vertically downward in group IV.

As discussed by Schleyer and Janoschek,[3] the loss of bonding interaction between the bridgehead atoms can result in significant diradical character in the propellane species. The calculated GVB coefficients and corresponding natural orbital occupation numbers (NOON) are listed in Table 3. Taking the latter values as a measure of the per cent diradical character, we do find a slight increase

Table 3. GVB–PP coefficients and natural orbital occupation numbers (NOON) for M_5H_6 systems

Systems	Basis set	GVB–PP coefficients HOMO	GVB–PP coefficients LUMO	NOON HOMO	NOON LUMO
C_5H_6	3–21G(*d*)	0.975	−0.223	1.900	0.100
	SBK(*d*)	0.975	−0.223	1.903	0.097
Si_5H_6	3–21G(*d*)	0.964	−0.265	1.860	0.140
	SBK(*d*)	0.964	−0.265	1.860	0.140
	WH(*d*)	0.963	−0.269	1.854	0.146
Ge_5H_6	SBK(*d*)	0.972	−0.233	1.891	0.109
	WH(*d*)	0.968	−0.252	1.873	0.127
Sn_5H_6	SBK(*d*)	0.970	−0.241	1.883	0.117
	WH(*d*)	0.968	−0.250	1.875	0.125

upon going from carbon to silicon. (Note that the calculated value of 14% for silicon is similar to the value of 12.5% found by Schleyer and Janoschek.[3]) However, the per cent diradical character calculated by this measure for M = Ge and Sn is actually lower than that found for Si!

Another approach to this question of diradical character is to investigate the structures and energies of the corresponding triplets, since the triplet states are, by definition, true radicals. The triplet propellane structures are also listed in Table 1. While the difference between the UHF triplet and GVB singlet M_b—M_b distance does decrease as M gets heavier, this difference is still greater than 0.1 Å, even for M = Sn. One would expect the singlet and triplet distances to be the same if the singlet were really a diradical. Similarly, one would expect the triplet to be the ground electronic state in this case. Instead, the triplet is at least 1 eV higher in energy than the singlet, even for M = Sn (Table 4). Further, these splitting values actually are lower limits since the UHF level of theory describes the triplet state better than RHF describes the singlet state. As these observations suggest fairly small diradical character in the ground state [1.1.1]propellanes, it is imperative to examine in detail the characteristics of the electron distributions in these systems.

Analysis of electron density and bonding

While the examination of internuclear distances allows for suggestions as to the strengths of interactions between atoms, shorter internuclear distances do not always imply stronger interactions.[28] A topological analysis of the charge density is a more useful tool to probe the strength and nature of the bonding in these systems.

In general, the electron densities in the valence region generated from ECP wavefunctions (RHF, GVB or UHF) are of the same topological form as the corresponding densities generated from all-electron (AE) wavefunctions (Figs 1–4). Therefore, the two charge distributions have the same number of bond, ring and cage critical points located in approximately the same positions. What is remarkable is that the AE and ECP values of the charge density at these points are very similar (Table 5). For example, differences in the RHF AE and ECP charge densities evaluated at cage critical points do

Table 4. Singlet (RHF)–triplet (UHF) splittings for M_5H_6 systems

[a]See text.

not exceed 0.0061 au. This value is found for Ge_5H_6 in which the geometric differences between AE and ECP are also the largest. In general, valence densities generated from ECP wavefunctions are both qualitatively and quantitatively similar to the corresponding densities generated from AE wavefunctions.

The above observation is encouraging and suggests that a topological analysis of the charge density of large organic, biochemical or transition metal systems determined using ECPs may well yield results which are similar to a corresponding analysis using AE. Since all-electron calculations are often not feasible for these large systems, the usefulness of ECPs becomes readily apparent. Charge distributions calculated from ECP wavefunctions contain the necessary topological features to determine which atoms are bonded to each other, as well as the relative strengths of the interactions.

Though in the vast majority of cases the absence of the core density in the ECP charge distributions does not affect the determination of critical points in the valance region, the bond critical point between M and H (M = Si, Ge, Sn) cannot be located using the ECP wavefunctions. Hydrogen withdraws electrons from M in these cases due to the relative electronegativities of M and H. Since there is no core density on M, there is no maximum at this nuclear position in the charge distribution. Therefore, instead of a saddle point in $\rho(\mathbf{r})$, $\rho(\mathbf{r})$ monotonically increases from the beginning of the valence region of M_p to H (Figs 2–4).

The SBK density has a bond critical point between Si_b and Si_p but WH does not. The WH charge density at the beginning of the valence region is not of sufficient magnitude to cause a saddle to form between Si_b and Si_p. Instead, a non-nuclear local maximum is found and this point is purely an artifact of the WH basis set. For the Sn_bSn_p bond in Sn_5H_8, it is with SBK that this type of critical point is found; WH yields a bond critical point.

We now proceed to analyse bonding in the propellane systems. With the exceptions noted above, the observations made from AE densities are the same as those made from ECP densities. Where possible, we quote AE values; otherwise we use SBK values.

Relief maps of the RHF all-electron total charge distributions in σ_v and σ_h planes for the M_5H_6 and M_5H_8 systems are given in Figs 1–4. Note that the charge density is a maximum only at the nuclear positions. In the σ_v plane, containing the two M_b and one M_p atoms, there are maxima at the two M_b and one M_p nuclei (and also at the H_b nuclei in M_5H_8). In the σ_h plane, containing the three M_p and six H atoms, there are maxima at the three M_p

and six H nuclei. In the σ_v plane there is a saddle point in each charge distribution between each (M_b, M_p) pair. This saddle point has one positive curvature of ρ along the bond axis and two negative curvatures of ρ orthogonal to the bond axis. As noted in the Introduction, such a saddle point is termed a bond critical point. The σ_v plane affords a view of the positive curvature and one of the negative curvatures associated with a (M_b, M_p) pair. The two gradient paths of ρ that originate at the bond critical point and terminate at the M_b and M_p nuclei define the bond path between these atoms. The charge density is a maximum with respect to any lateral displacement along the bond path. For C_5H_6, there is also a bond path between the two bridgehead carbons. The σ_v plane shows the positive and one of the negative curvatures of the C_b—C_b bond, while the σ_h plane shows both negative curvatures. Only for this system is there a bond critical point between the two M_b atoms. In the remaining systems, a cage critical point is found between the two M_b atoms. This kind of critical point is a local minimum and has three positive curvatures: two are displayed in the σ_v plane in M_5H_6 (M = Si, Ge, Sn), and the third curvature (along with one of the positive curvatures also seen in the σ_v plane) is displayed in the σ_h plane.

There are three ring critical points in C_5H_6, one on each three-membered ring face. The σ_v plane shows the two positive curvatures in the ring surface and the σ_h plane shows the negative curvature perpendicular to the ring surface and one of the positive curvatures. There are also three ring critical points in C_5H_8, one associated with each four-membered ring. The arrangement of ring critical points in C_5H_8 is similar to that in the heavier M_5H_6 and M_5H_8 systems (M = Si, Ge, Sn).

Having identified the different types of critical points (points at which the gradient of the charge density, $\nabla\rho$, vanishes), it is now useful to discuss the values of the charge density, ρ, and the Laplacian of the charge density, $\nabla^2\rho$, at these points to gain a better understanding of the bonding and strengths of interaction in the M_5H_6 and M_5H_8 systems.

The M_b and M_p atoms are said to be bonded because a bond critical point, and hence a bond path, exists between them.[15,17,18] For homologous series of molecules, the value of the charge density at this point has been correlated with the bond order and strength of the bond.[2,29–31] These studies have shown that the bond order increases with increasing $\rho(\mathbf{r}_b)$. In the hydrocarbon study, ethane, ethene and ethyne were assigned bond orders of 1, 2 and 3, respectively.[2,29] Since the value of $\rho(\mathbf{r}_b)$ for C_bC_p in C_5H_6 (Table 5) is very close to the analogous value for the CC bond in ethane (Table 6), the C_bC_p bond in propellane may be referred to as a single bond of approximately unit bond order. The $\rho(\mathbf{r}_b)$ value for C_bC_p in C_5H_8 is also close to the ethane value.

The M_bM_p $\rho(\mathbf{r}_b)$ values for M_5H_6 and M_5H_8 (M = Si, Ge, Sn) are slightly smaller than the corresponding M_2H_6 values but never less than 84% of the latter value. These bonds in the propellane and bicyclopentane systems can therefore be referred to as single bonds with bond orders slightly smaller than one.

An analysis of the Laplacian of the charge density, $\nabla^2\rho$, determines the nature of the interaction between bonded atoms.[32,33] If the value of $\nabla^2\rho(\mathbf{r}_b)$ is negative, then a shared or covalent interaction results. If the value is positive, then a closed-shell (e.g. ionic) interaction results. In the M_2H_6 systems, the sign of $\nabla^2\rho(\mathbf{r}_b)$ is negative, implying a covalent interaction. This value becomes less negative as the family is descended, because the charge density to be shared between the heavy atoms is more diffuse

Table 6. bond distances (Å) and bond critical point ($\mathbf{r}_b$) analysis (au) of M_2H_6 systems

System	Wavefunction	M—M Distance	M—M $\rho(\mathbf{r}_b)$	M—M $\nabla^2\rho(\mathbf{r}_b)$	M—H Distance	M—H $\rho(\mathbf{r}_b)$	M—H $\nabla^2\rho(\mathbf{r}_b)$

and because some of this density has been removed by the more electronegative hydrogens. The M_bM_p bonds in the propellanes and bicyclopentanes have negative values for $\nabla^2\rho(\mathbf{r}_b)$ though the magnitudes are slightly smaller than those in the corresponding M_2H_6 systems. The ECP $\nabla^2\rho(\mathbf{r}_b)$ values are not in as good agreement with the corresponding AE values as are the $\rho(\mathbf{r}_b)$ values themselves.

In summary, topological analyses of the M_5H_6 and M_5H_8 charge distributions and comparison with M_2H_6 distributions and distances reveal that the M_bM_p bond is basically a covalent single bond, slightly weaker than the prototype MM bond in M_2H_6.

Using the same analyses as above reveals that the MH bond is a single bond, slightly stronger than the prototype MH bond in M_2H_6. The interaction is a covalent one only for the carbon compounds. In the heavier systems, where the electronegativity of hydrogen substantially exceeds that of silicon, germanium and tin, the interaction is closed-shell (ionic).

A bond path exists between the two bridgehead atoms only in C_5H_6. The ring critical points are in close proximity to the bond critical point (0.096 Å away) and the value of $\rho(\mathbf{r}_r)$ is 97% the value of $\rho(\mathbf{r}_b)$. This means there is a broad bonded maximum in ρ in the interatomic surface (Fig. 1) and a substantial accumulation of charge between the bridgehead nuclei. Wiberg *et al.*[2] have referred to the C_bC_b interaction as a "fat bond" in order to reflect the flat density surface in the bonding region. The value of $\rho(\mathbf{r}_b)$ for the C_bC_b bond in C_5H_6 is 80% of the corresponding value in C_2H_6. The bond order of the C_bC_b bond in C_5H_6 has been calculated to be 0.73.[2]

A similar "fat bond" is not found for C_bC_b in C_5H_8. In fact, a cage critical points exists in the bridgehead region, not a bond critical point. Therefore, a bond path does not connect the M_b nuclei in this (or any of the other) group IV bicyclopentane investigated here. The value of ρ at the cage critical point is only half the value of $\rho(\mathbf{r}_b)$ in C_bC_b of C_5H_6. Figure 1 displays little charge density in the C_bC_b internuclear region of C_5H_8.

As mentioned above, there are three ring critical points in C_5H_8, one associated with each of the three curved four-membered ring surfaces. These ring critical points are in close proximity to the cage critical point (0.054 Å away) and are also very close in ρ values [$\rho(\mathbf{r}_r) = 0.0999$ au; $\rho(\mathbf{r}_c) = 0.0977$ au]. Since the cage critical point is a local minimum in ρ, the ring critical points near it will always be higher in ρ value, even if the difference is very small as it is in this and the other bicyclopentanes.

It is important to recognize that the charge distribution in the bridgehead region of C_5H_8 is different in form from the corresponding region in C_5H_6. In C_5H_8, there is not much charge density in the shallow, flat region between the two bridgehead nuclei, and there is no bond path. In C_5H_6, there is a significant accumulation of charge density and a bond path exists between the two bridgehead nuclei.

The value of $\rho(\mathbf{r}_c)$ in the internuclear bridgehead region in Si_5H_6 is only 48% of the value of $\rho(\mathbf{r}_b)$ in Si_2H_6. This suggests that the interaction between the two silicons is weaker in Si_5H_6 than that in Si_2H_6. The ring critical points in Si_5H_6 are only 0.021 Å from the cage critical point and $\rho(\mathbf{r}_r)$ are only very slightly higher than $\rho(\mathbf{r}_c)$. Thus, a shallow, flat distribution of charge exists between the bridgehead silicons in Si_5H_6 and no bond path is found.

In Si_5H_8, the value of $\rho(\mathbf{r}_c)$ is 61% of the corresponding value in Si_5H_6. The formation of the M_bH_b bonds upon going from M_5H_6 to M_5H_8 removes density from the bridgehead region more than from other regions of the molecule. Though the charge distributions differ quantitatively, qualitatively they have the same topological form. Thus, in the bridgehead region M_5H_6 and M_5H_8 are qualitatively identical in form for M = Si, Ge and Sn (Figs 2–4).

In Ge_5H_6, the value of $\rho(\mathbf{r}_c)$ is 41% the value of $\rho(\mathbf{r}_b)$ in Ge_2H_6. In Ge_5H_8, the value of $\rho(\mathbf{r}_c)$ is 70% of the corresponding value in Ge_5H_6. In Sn_5H_6, the value of $\rho(\mathbf{r}_c)$ is 35% the value of $\rho(\mathbf{r}_b)$ in Sn_2H_6. In Sn_5H_8, the value of $\rho(\mathbf{r}_c)$ is 80% of the corresponding value in Sn_5H_6.

These results lead to the following conclusions: (i) In as much as ρ at the critical point between M_bM_b is a measure of the strength of the M_bM_b interaction (the greater the value of ρ, the stronger the interaction), the M_bM_b interaction in M_5H_6 is weaker than that in M_2H_6, with the interaction becoming progressively weaker as Group IV is descended. (ii) The M_bM_b interaction is weaker in M_5H_8 than in M_5H_6. As the group is descended, the charge distribution in the bridgehead region in M_5H_6 more closely resembles that in M_5H_8, both qualitatively and quantitatively. Thus, the Sn_bSn_b interaction is the weakest of all the interactions.

It has been shown for C_5H_6 that when the C_bC_b distance is increased over the equilibrium distance, the C_bC_b bond critical point eventually coalesces with the three ring critical points and an unstable critical point (possessing one zero curvature) is formed.[2,15] A further infinitesimal increase in the C_bC_b distance yields a cage critical point in the internuclear bridgehead region and three new ring critical points, one associated with each of the newly formed four-membered rings. We have performed this procedure in reverse for the heavier systems. If

we squeeze the two Si_b atoms closer together by 0.20 Å in Si_5H_6 (reducing the M_bM_b distance to 2.494 Å), the three ring critical points coalesce with the cage critical point. Upon a further infinitesimal compression, a bond critical point and three new ring critical points are created, one on the face of each three-membered ring. Thus it takes only 0.20 Å (and a corresponding energy increase of only 1.9 kcal mol^{-1}) to form a bond path between the two Si_b atoms. It should be noted that the remainder of the geometry was not re-optimized upon compression of the bridgehead distance, and so, the energy increase values are upper limits. The value of $\rho(\mathbf{r}_b)$ in the compressed geometry is 0.0590 au and this value is 0.0124 au greater than the cage value in the equilibrium geometry. Still, the value of $\rho(\mathbf{r}_b)$ is 0.0260 au less than the M_bM_p $\rho(\mathbf{r}_b)$ value of 0.0850 au, where the M_bM_p distance = 2.331 Å. Therefore, the shortening of the M_bM_b distance creates a bond path between these atoms although the bond is still weak compared to a normal SiSi bond.

For a similar change in the molecular graph to occur in Ge_5H_6, the bridgehead nuclei must be squeezed together by 0.29 Å. The energy increase is 11.9 kcal mol^{-1}. The value of ρ at the newly created bond critical point is 0.0506 au, 0.0153 au greater than that at the cage critical point in the equilibrium geometry. This newly created bond (of distance 2.593 Å) is weaker than the Ge_bGe_p bond (the Ge_bGe_p distance is 2.449 Å) because $\rho(\mathbf{r}_b)$ in the former is 0.0161 au smaller than the corresponding value in the latter bond.

For a similar change in the molecular graph change to occur in Sn_5H_6, the bridgehead nuclei must be squeezed together by 0.37 Å and the energy increase is 13.2 kcal mol^{-1}. The value of ρ at the newly created bond critical point is 0.0315 au, 0.0104 au greater than the cage critical point in the equilibrium geometry. This newly created bond (of distance 3.092 Å) is weaker than the Sn_bSn_p bond (of distance 2.876 Å) because $\rho(\mathbf{r}_b)$ in the former is smaller than $\rho(\mathbf{r}_b)$ in the latter bond by 0.0190 au.

The ease with which a molecule can change from one structure to another is related to the weakness of the interaction of primary importance in the change.[2,15,34] The equilibrium M_bM_b distances need to decrease by 7, 10 and 11% for the M_bM_b bond path to form (M = Si, Ge, Sn, respectively). The energy needed to bring about this compression increases upon descending Group IV. This supplies further evidence that the Si_bSi_b interaction is stronger than the Ge_bGe_b interaction, which in turn is stronger than the Sn_bSn_b interaction. The two bridgehead silicon atoms are more predisposed to bond path formation than the other heavier systems.

Table 5, in addition to listing the RHF values, also includes the GVB (for singlets) and UHF (for triplets) values. The conclusions made above in the RHF discussion hold for GVB and UHF with one exception. No bond path is found between the C_b atoms in C_5H_6(UHF). The C_bC_b distance is much greater in UHF than RHF (UHF − RHF = 0.28 Å) and the UHF C_bC_b interaction is weaker.

Since the coefficient of the RHF term in the GVB wavefunction is dominant (Table 3), it is useful to inspect localized orbitals.[27] The M_bM_b Boys localized orbital densities are displayed in Fig. 5. The all-electron and effective core potential densities are similar in the valence regions. This observation is further evidence of the success with which ECPs describe valence density. There are two electrons in each of the localized molecular orbitals, and there is a critical point (a maximum) in the orbital density at the M_bM_b midpoint. The values of ρ at this point are 0.1899, 0.0411, 0.0288 and 0.0174 au for M = C, Si, Ge, Sn, respectively. These values are 93, 88, 82 and 82% of the *total* density at the same point for the respective propellanes. Thus, the localization procedure works well to localize the bonding electrons in the bridghead bonding orbital. From the above ρ values and from the contour maps, one sees that there is less density in the M_bM_b bonding region as the family is descended. The amount of density in the localized bridgehead orbital is smallest for Sn_5H_6 owing to the fact that the M_bM_b distance is largest for this system and the effective orbital overlap is smallest.

Though there exists a localized M_bM_b bond orbital in each of the propellane systems, a bond path in the total density exists only in the C_5H_6 case. This is because inclusion of the remaining occupied orbital densities to form the total density creates ring critical points of smaller ρ value than the M_bM_b bond critical point in C_5H_6. However, in the remaining systems, the M_bM_b critical point becomes a cage critical point as the surrounding ring critical points are slightly higher in ρ value. Thus, the existence or lack of a bond critical point and associated bond path as a function of M, especially upon going from carbon to silicon, arises from a subtle difference in the role played by the other LMOs in the M_bM_b region.

Figure 6 displays maps of the singlet RHF minus triplet UHF densities at the RHF geometries for the σ_h plane of the M_5H_6 systems. Going from the triplet to the singlet, the greatest build-up of charge is in the bridgehead bonding region in the vicinity of the M_bM_b critical point. The density differences become increasingly smaller as the group is descended and the M_bM_b bonding interaction descreases. Indeed the difference in the value of $\rho(\mathbf{r}_c)$

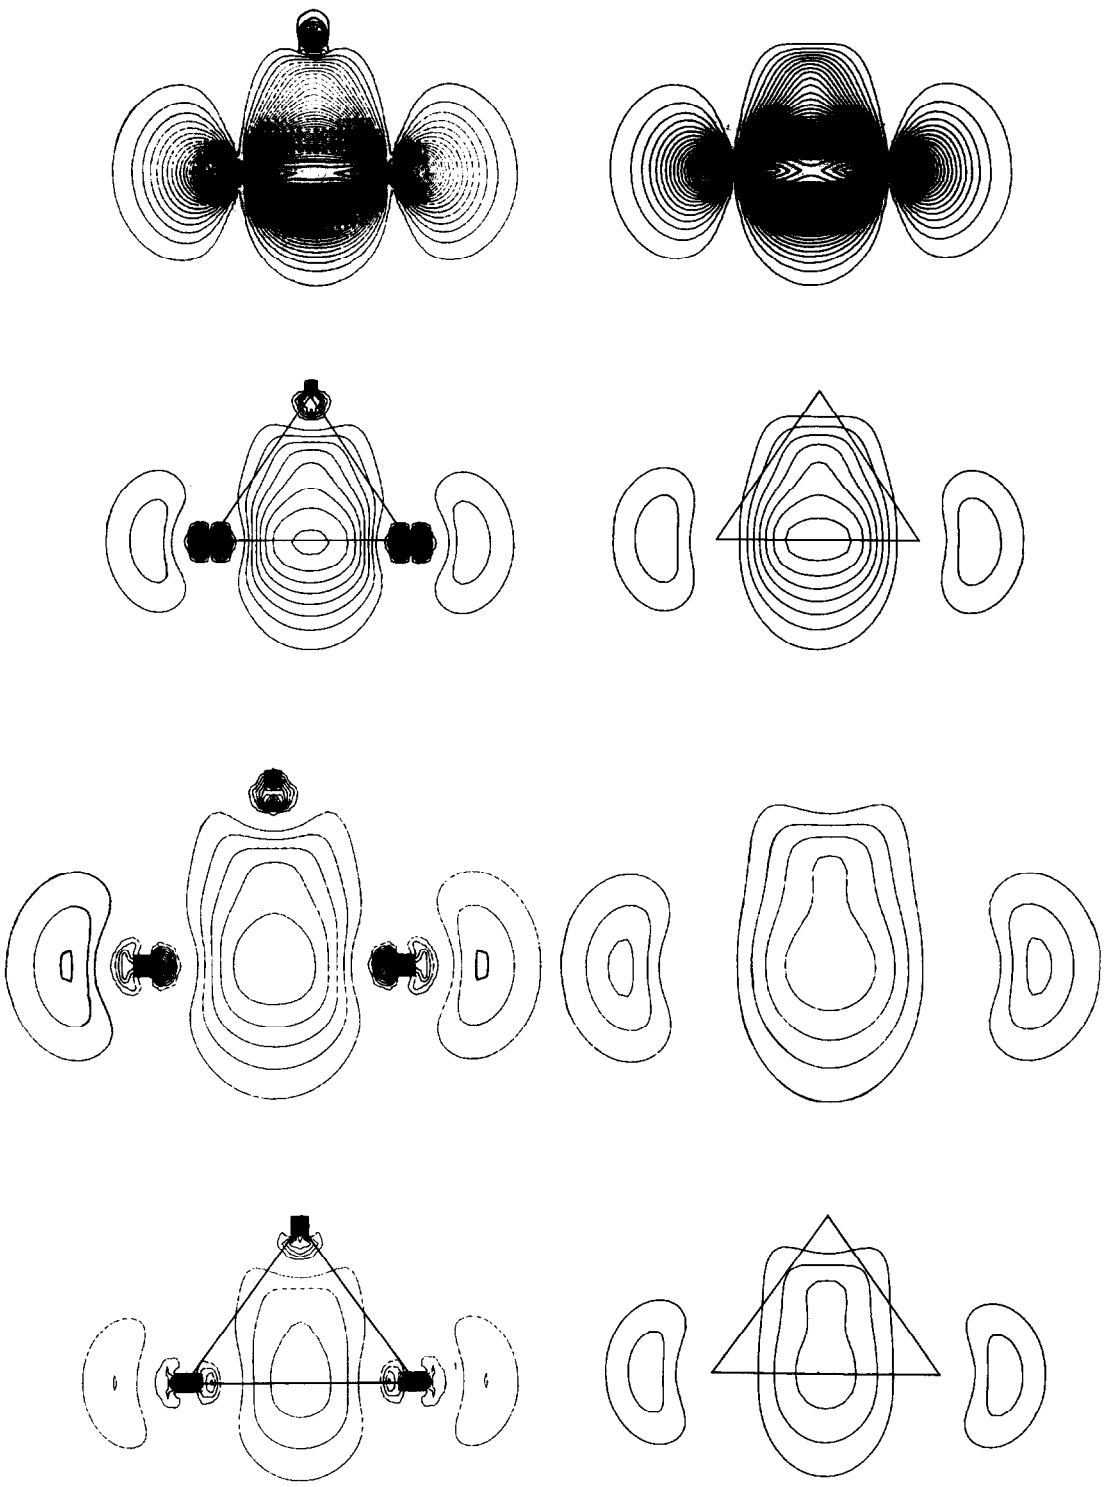

Fig. 5. Contour maps of M_bM_b localized orbital densities in the σ_v plane. The charge distributions for the four maps displayed down the left side of the figure (C_5H_6, Si_5H_6, Ge_5H_6 and Sn_5H_6) are generated from all-electron RHF/3–21G(2*d*)//3–21G(*d*) wavefunctions, while the charge distributions for the corresponding four maps displayed down the right side of the figure are generated from RHF/SBK(2*d*)//RHF/SBK(*d*) wavefunctions.

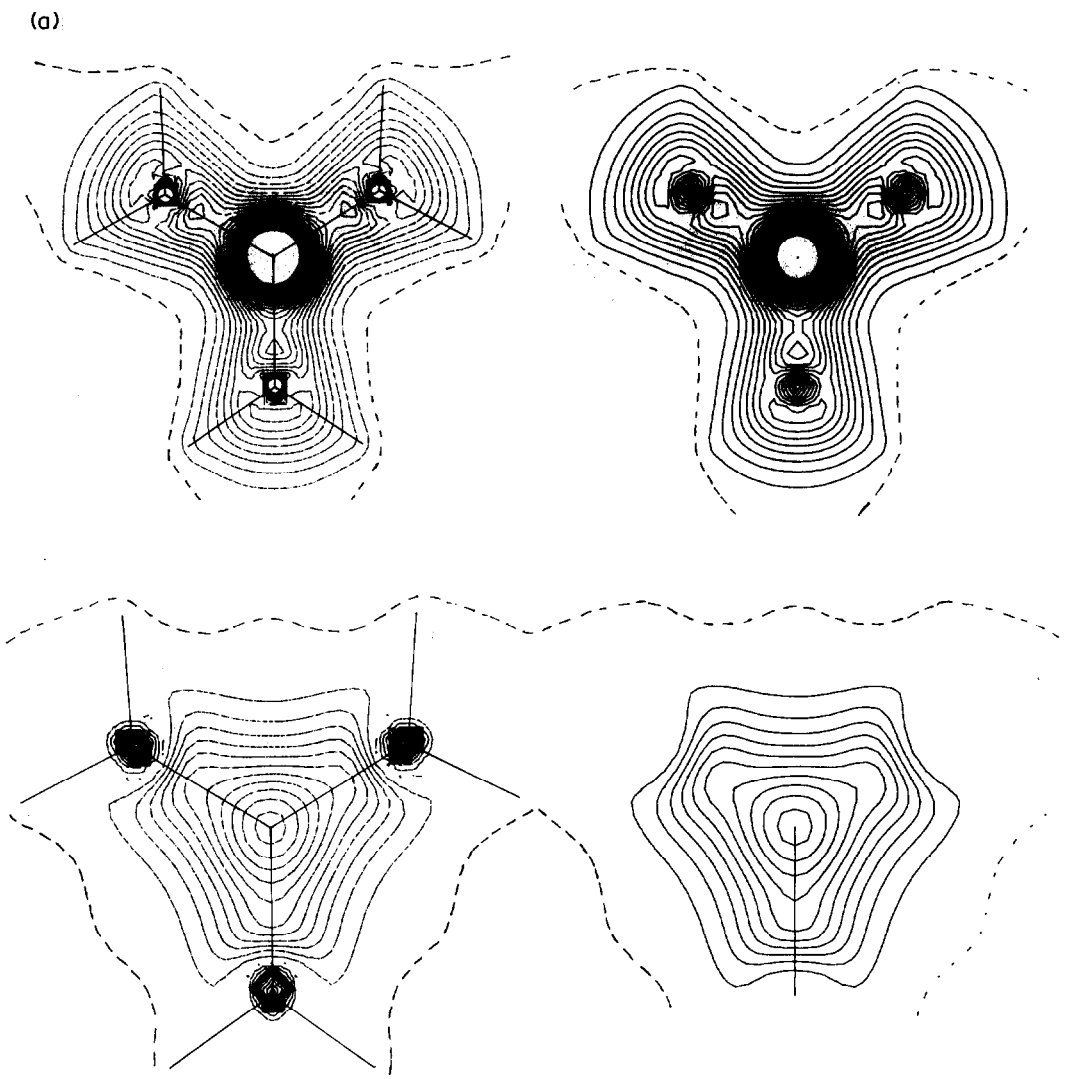

Fig. 6. Contour maps of the RHF minus UHF densities at the RHF geometries for the M_5H_6 σ_h planes. Solid (dashed lines) are positive (negative) values. The largest magnitude contour has a value of ± 0.025 au in all cases. Left-hand side maps are determined by subtracting densities generated using the all-electron 3-21G(2*d*) basic set, while right-hand side maps use the SBK (2*d*) basis set. (a) Top half: C_5H_6; bottom half: Si_5H_6. (b) Top half: Ge_5H_6; bottom half: Sn_5H_6.

between RHF and UHF is smallest in Sn_5H_6, and Sn_5H_6 has the smallest magnitude for the singlet–triplet splitting. In the carbon cases, enough density flows into the singlet system for a bond critical point to form between the bridgehead atoms. In the heavier systems, this is not the case. Note that the same conclusions are reached using either the all-electron or ECP basis set.

CONCLUSIONS

The structures and bonding in [1.1.1]propellanes have been studied in this work. The following points are emphasized:

(i) The bonding interaction between the two bridgehead atoms decreases on descending Group IV so that for tin, there is little difference between Sn_5H_6 and Sn_5H_8 in the M_bM_b region, in agreement with the experimental observations of Sita and co-workers.[1] This statement is supported by geometry comparisons to the corresponding bicyclopentanes and ethanes, by a topological examination of the charge density, by GVB–PP calculations, by singlet–triplet energy and density differences and by localized orbital density analyses.

(ii) Valence electron densities generated from effective core potential basis sets are similar to the corresponding densities generated from all-electron

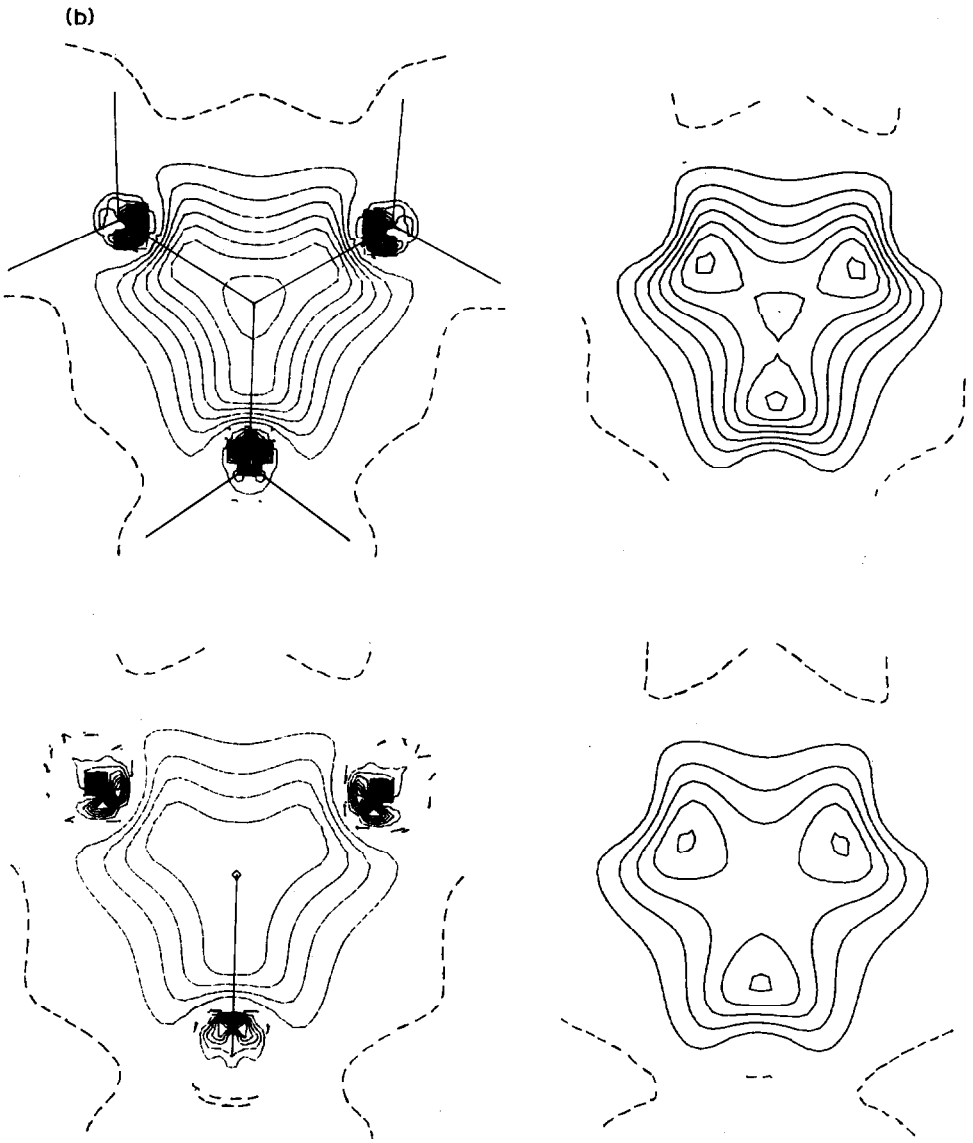

Fig. 6—*continued.*

basis sets. Since these densities are alike, so will be the second derivative density field (the Laplacian). It has been shown that the Laplacian of the charge density field determines the sites of electrophilic and nucleophilic attack and the reactivity of the molecule.[35,36] Therefore, the reactivity of large biochemical and transition metal systems not amenable to all-electron calculations, may well be successfully determined by analysing the Laplacian of the charge density generated from ECP basis sets.

Acknowledgements—The computations described in this work were performed on the North Dakota State University IBM 3090/120E vector computer, obtained, in part, with the aid of a joint study agreement between IBM and NDSU, and on the Cray Y-MP at the San Diego Supercomputer Center. This work was supported in part by a grant from the National Science Foundation (CHE-8911911). We thank Professors Richard Bader, Michael Schmidt, Larry Sita and Keith Laidig for useful discussions, and Dr Walter Stevens for making the SBK ECPs available prior to publication.

SINGLET EXCITATION IN POLYSILANES: *AB INITIO* CALCULATIONS ON OLIGOSILANE MODELS

V. BALAJI and JOSEF MICHL†

Center for Structure and Reactivity, Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX 78712-1167, U.S.A.

Abstract—All-electron SCF–CI calculations with several basis sets have been performed for excited singlet states of the linear oligosilanes Si_nH_{2n+2}, $n = 2$–5, in order to establish their nature as a function of chain length. The results suggest that the lowest $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited state lies below the first $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ state in the shortest few oligosilanes, and that the order of the states changes as the number of silicon atoms in the chain increases. An assignment is proposed for the lowest observed two-photon allowed state of polysilanes. In the gas phase, Rydberg states are expected to dominate the low-energy region of the spectra of oligosilanes shorter than Si_6H_{14}. An increase in the SiSiSi valence angle is computed to lower the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy, and torsion around a central SiSi bond from *trans* towards *cis* geometry is computed to increase it. The effect of alkyl substitution was studied using 2,2-dimethyltrisilane as a model compound. It lowers the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy, primarily by destabilizing the highest σ_{SiSi} orbital by hyperconjugative interaction with the substituents. The results for the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ state are in agreement with simple, qualitative arguments and prior semiempirical calculations.

Polysilanes, $(R_2Si)_n$, high-molecular weight, fully saturated polymers with an all-silicon backbone,[1,2] have remarkable optical properties. These are of considerable importance for the possible use of these materials as photoresists,[3] photoconductors,[4] polymerization initiators,[5] non-linear optical materials,[6] etc., but are as yet poorly understood.

The current theoretical understanding of the spectroscopy of polysilanes relies on a series of semiempirical and *ab initio* calculations on the ground state[7–22] and of semiempirical calculations on electronically excited singlet states[23–31] by a variety of methods. These calculations were performed on model short chains containing no more than 40, and usually only 20 or fewer, silicon atoms. Band theory calculations for infinite chains of perfect translational symmetry have been reported as well.[32–37] We now report results of *ab initio* calculations on vertically excited singlet states of the model systems Si_nH_{2n+2}, $n = 2$–5.

Excited states of polysilanes. Experimental evidence strongly suggests that in room-temperature solutions of poly(di-n-alkylsilane)s the coherence of the lowest-energy electronic excitation extends over no more than two dozen silicon atoms or so.[27,39,40] It has been proposed[25–27,41,42] on the basis of fluorescence depolarization studies and semiempirical calculations that under these conditions the "chromophore length" is conformationally determined. The chromophores were visualized as being approximately planar, all-*trans* chain segments terminated by stronger twists, e.g. *gauche* (*cis*-planar geometry would inhibit delocalization the most), and it was assumed that the polymer backbone contains a fairly wide distribution of segment lengths. If this proposal is correct, the band structure calculations published so far[32–37] are of limited relevance for the interpretation of spectra observed in room-temperature solutions, where these polymers form random coils, and in warm (disordered), neat polymer solids. They would be more pertinent

† Author to whom correspondence should be addressed. Present address: Department of Chemistry and Biochemistry, University of Colorado, Boulder, CO 80309-0215, U.S.A.

to the understanding of the low-temperature solution and ordered solid forms, which have distinctly different conformational structure and optical properties, apparently containing significantly longer chain segments with translational symmetry.

According to this model, the spectra of the disordered polymers, which are of primary interest to us presently, are presumably interpretable as a weighted incoherent sum of contributions from a variety of chromophoric segments differing in length and absorption peak wavelength. On this source of inhomogeneous broadening is superimposed additional broadening due to the fact that each chromophore of a given length can exist in a variety of forms deviating from ideal all-*trans* planarity towards a helical or a more randomly non-planar arrangement, plus the presumably smaller broadening due to a distribution of side-chain geometries and solvent molecule arrangements.

In an alternative view of the high-temperature form of the polymer,[43] the coherence of the excitation is terminated by any of the numerous usual random deviations from perfect symmetry (large number of small twists as in the "worm-like"[44] model, vibrations, zero-point motion, side-chain or backbone conformations, solvent arrangement) without sharp twists in the backbone conformation playing a special role. It has been argued recently[45] that the worm-like model provides a superior description of the low-temperature form of the polymers. It certainly represents a viable possibility for the high-temperature form as well.

There is little doubt of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ nature of the transition to the lowest excited singlet state that is strongly allowed in absorption and emission of all of the forms of the polymers, based on the very high intensity and particularly on the long-axis polarization observed in the stretched solid[25,38,46] and in a streaming solution.[27] Transition assignments that can be excluded for the lowest strongly allowed energy band of the polymers are Rydberg, normally broadened beyond recognition in solution spectra, and $\sigma_{SiSi} \rightarrow \pi^*_{SiC}$, expected to be fairly weak and polarized perpendicular to the chain direction. Transitions to states of these types are undoubtedly present at higher energies. For long, chromophoric segments, such as those presumably present at low temperatures in glasses and in the ordered, neat solid, the question of the interband vs excitonic nature of the excited state arises, but this is not an issue for the relatively short model segments which will be of interest here, since in these the hole and the excited electron are necessarily localized in the same small region of space.

According to some[23] CNDO (however, see ref. 24) and all INDO/S[25-27] calculations, the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ transition is more or less dominated by an electron excitation from the highest σ_{SiSi} to the lowest σ^*_{SiSi} orbital. Note that this does not imply that the σ^*_{SiSi} orbital is the lowest unoccupied molecular orbital (LUMO) and indeed certain calculations,[22,47] as well as the most straightforward interpretation of the very small *s* spin densities observed in the ESR–ENDOR spectra of the radical anions of some cyclic oligosilanes,[48] suggest that the lowest empty orbital of oligosilanes may be of the π^*_{SiC} type, locally antisymmetric to the plane of the silicon backbone. On the other hand, there seems to be general agreement that the highest occupied molecular orbital (HOMO) of polysilanes is of the σ_{SiSi} type, based both on calculations and on photoelectron spectra of model oligosilanes.[8] It is not known to what degree *d* orbitals are needed in the basis set in order to provide an adequate description of the σ and, particularly, the σ^* orbitals. They were not included in the semiempirical calculations reported for excited states.[23-27]

The proposal that excitation coherence length ("chromophore length") in random-coil polysilanes is conformationally determined[25-27,41,42] depends critically on two results of the INDO/S calculations. The first of these is the convergence of the $S_0 \rightarrow S_1$ singlet excitation energy of an all-*trans* or other regular (helical) structures to a finite limit as the silicon chain length increases. There is no doubt that this result is correct in principle and the question is only, at what chain length is the limit reached in practice? The INDO/S method suggests that the excitation energy drops significantly only up to about a dozen silicon atoms in the chain,[25] but it could err in either direction. The simplest way to see that the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy must tend to a finite gap is to note that the vicinal resonance integral from the *n*th silicon atom to the $(n+1)$th silicon atom, $sp^3_{Si(n)} - sp^3_{Si(n+1)}$, is substantially more negative than the geminal one, $sp^3_{Si(n)} - sp^3_{Si(n')}$, so that this linear σ-conjugated system of silicon backbone orbitals exhibits strong resonance integral alternation and is isoelectronic with the π system of a polyene with strong bond length alternation (Fig. 1).

The second critically important INDO/S result on which the proposal depends is the strong increase of the $S_0 \rightarrow S_1$ excitation energy with the twist of one or more bonds away from the *trans* planar geometry towards the *cis* geometry. It is this feature that permits an approximately *gauche* twist to interrupt effective conjugation in the linear chain of interacting σ_{SiSi} bond orbitals. Without this property, there would be no reason to expect a strong twist in the chain, or several such twists, to terminate a chromophore and start another on the other side. The requirement that rotation around

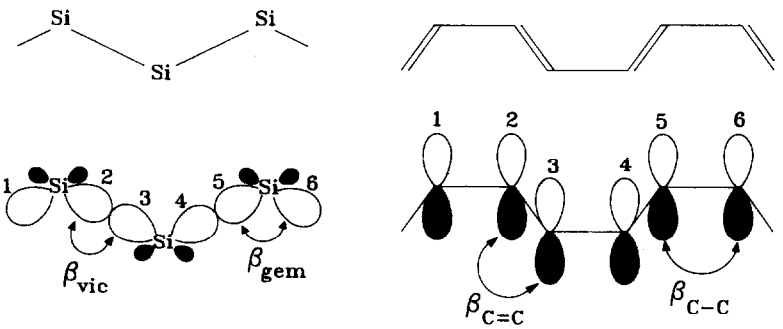

Fig. 1. Basis set orbitals in a σ-conjugated linear chain of interacting silicon sp^3 orbitals in a polysilane (left) and in a π-conjugated linear chain of interacting carbon p orbitals in a polyene with alternating bond lengths (right).

a presumably cylindrically symmetrical σ_{SiSi} bond should affect the degree of σ conjugation may appear counterintuitive at first, but is well grounded in standard theory of *anti*-periplanar through-bond interactions in organic molecules, known to account for numerous experimental observations.[49]

Excited states of oligosilanes. If the segment model for the high-temperature form of polysilanes is correct, an understanding of the electronic states of relatively short oligosilanes will be immediately applicable to the understanding of the optical spectra of the polymers. Even if the worm-like model is correct, one can hope to gain useful insight from an investigation of short oligosilanes, as long as the properties of the shorter oligosilanes can be extrapolated to the long ones.

The present study of a series of simple model segments (Si_nH_{2n+2}) attempts to address at the *ab initio* level several points previously not investigated or examined only at the semiempirical level. It attempts to: (i) verify the nature of the lowest one- and two-photon allowed singlet excitations and the role played by Rydberg and *d* orbitals in their description; (ii) check the sensitivity of the excitation energy to the value of the SiSiSi valence angle; (iii) confirm the proposed effect of chain twisting on the $S_0 \rightarrow S_1$ excitation energy; and (iv) examine the role played by alkyl substitution.

While there is little doubt that the ground state bond lengths in poly(di-n-alkylsilane)s are normal. the valence and particularly the dihedral angles are less sharply defined[2,50] and are sensitive to the nature of the alkyl groups. In this work, we adopt a set of standard model geometries and examine the effect of variation of the angles. We believe this approximation to be adequate for the purpose of examining general trends, but recognize that it contributes to the observed lack of quantitative agreement of the calculated excitation energies with the experimental ones.

It would have been preferable to choose the permethylated oligosilanes [$Si_n(CH_3)_{2n+2}$] and not the parents (Si_nH_{2n+2}) as models for the chromophoric segments in polysilanes, but it was not computationally feasible. As a compromise, we have investigated the unsubstituted parent oligosilanes and explored the effect of methyl substitution in trisilane by performing calculations on 2,2-dimethyltrisilane. *Ab initio* calculations of excitation energies can be presently only carried out for short oligosilane chains if they are to be of credible quality at all, and we have been forced to limit them to disilane (Si_2H_6), trisilane (Si_3H_8), n-tetrasilane (Si_4H_{10}) and n-pentasilane (Si_5H_{12}). Even then, we have only been able to perform them at a level that we consider adequate for the understanding of qualitative features and general trends, but not for quantitative agreement with respect to excitation energies.

METHOD OF CALCULATION

The electronic states of Si_nH_{2n+2}, $n = 2$–5, at standard ground-state geometries were calculated at the level of all-electron SCF followed by configuration interaction (CI). Huzinaga's double-zeta (DZ) basis set[51] was adopted. The effect of silicon *d* orbitals on the nature of the electronic states of silanes was tested by adding *d* functions with an exponent of 0.395 (DZ+d)[52] to the silicon DZ basis. To describe Rydberg orbitals, the silicon DZ basis was augmented with diffuse *s* and *p* functions with exponents of 0.017 and 0.014, respectively (DZ+R).[53]

The configuration list was generated by single and double excitations (CISD) with SCF orbitals as the reference space. The active space in the CISD calculations involved six to 10 highest occupied SCF orbitals and all the virtual SCF orbitals. The

number of configurations thus generated ranged from 20,000 to 50,000.

The following standard bond lengths and bond angles were adopted:[54] SiSi = 2.344 Å, SiH = 1.48 Å, SiC = 1.87 Å, CH = 1.08 Å, ∠SiSiSi = 111.2°, ∠HSiH = 108.0°, ∠CSiC = 109.47° and ∠HCH = 109.0°.

All calculations were performed using a GAMESS[55] program on a Cray X-MP/24 supercomputer at The University of Texas at Austin.

RESULTS AND DISCUSSION

The convention for the axis and orbital labels used in this paper is as follows: (i) The z axis is the long axis of the silicon chain. For structures with all silicon atoms in a single plane, the y axis is the short axis in this plane and the x axis is perpendicular to this plane. (ii) Molecular orbitals that are symmetric with respect to the yz mirror plane containing the silicon atoms are labelled as σ orbitals. Those that are antisymmetric with respect to the yz plane are labelled as π orbitals. Our convention for the σ and π orbitals thus differs from the uncommon convention used in a recent study[22] where even some molecular orbitals that are symmetric with respect to the mirror plane containing the silicon atoms were labelled as π orbitals.

All the electronic states discussed in the following sections are singlet states and the excitation energies correspond to vertical excitations.

*Qualitative molecular orbital bonding model for an all-*trans *polysilane chain*

The extremely simple Sandorfy[56] models C and H provide a natural starting point for a qualitative understanding of the valence and conduction bands in all-*trans* polysilane and of their relation to the delocalized molecular orbitals in all-*trans* oligosilanes (see, for example, ref. 2). In these models, the bonding at each silicon atom centre can be described by using a sp^3 hybrid orbital basis set. Two of the four sp^3 orbitals point towards the in-plane silicon neighbours and the other two point towards the orbitals on the α atoms of the out-of-plane substituents.

In Sandorfy model C, one considers only the silicon backbone orbitals. These can be most easily derived in two steps. First we consider the vicinal interaction between two neighbouring silicon atoms, due primarily to the resonance integral, β_{vic}, between the two strongly overlapping sp^3 orbitals located on these silicon atoms (Fig. 1). It results in the formation of a strongly bonding σ_{SiSi} localized bond orbital and a strongly antibonding σ^*_{SiSi} localized bond orbital. The σ_{SiSi} bond orbital has no interatomic node and the σ^*_{SiSi} bond orbital has one interatomic node across the bond. Second, a weaker geminal resonance integral, β_{gem}, between two sp^3 hybrid orbitals located on the same silicon atom (Fig. 1) couples the σ_{SiSi} localized bond orbitals into delocalized σ_{SiSi} backbone orbitals, and the localized σ^*_{SiSi} bond orbitals into delocalized σ^*_{SiSi} backbone orbitals.

The nodal patterns of the σ_{SiSi} and σ^*_{SiSi} backbone orbitals obtained within this model are shown on the left in Fig. 2. The bonding σ_{SiSi} backbone orbitals have no nodes at SiSi bond midpoints and their relative stability decreases with increasing number of nodes at the silicon atoms. The most stable one has no nodes at the silicon atoms and the least stable one has a node at every silicon atom. The antibonding σ^*_{SiSi} backbone orbitals have nodes at SiSi bond midpoints. Their energy again increases with an increasing number of nodes at the silicon atoms, i.e. the most stable one has no nodes at the silicon atoms and the least stable one has nodes at every silicon atom. In terms of an atomic orbital basis, the least stable σ_{SiSi} backbone orbital contains only $3p_z$ atomic orbitals of silicon and the most stable σ^*_{SiSi} backbone orbital contains only $3s$ and $3p_y$ atomic orbitals of silicon.

In Sandorfy model H, the two sp^3 hybrid orbitals that are not used in the backbone bonding are considered as well. They interact with the orbitals of the substituents (H $1s$ orbitals in the parent polysilane) to form low-energy bonding σ_{SiH} and high-energy antibonding σ^*_{SiH} localized bond orbitals. The former has a larger coefficient on the more electronegative hydrogen, the latter on the less electronegative silicon. Pairwise symmetry adaptation of these bond orbitals with respect to mirror reflection in the silicon backbone yz plane results in the formation of π-symmetry and σ-symmetry bonding and antibonding group orbitals (Figs 2 and 3). The π_{SiH} and π^*_{SiH} group orbitals cannot mix with the previously derived silicon backbone orbitals, which are of σ symmetry. They interact among themselves to yield delocalized bonding π_{SiH} molecular orbitals and antibonding π^*_{SiH} molecular orbitals. Since this interaction occurs primarily through the overlap of $3p_x$ atomic orbitals on silicon, the π^*_{SiH} band is broader than the π_{SiH} band (right-hand side of Fig. 2).

The mixing between the σ_{SiH} group orbitals and the bonding backbone σ_{SiSi} orbitals destabilizes the latter (centre of Fig. 2). The strength of this interaction depends on the energy difference between the interacting orbitals and on the number of nodes. The energy differences between the bonding back-

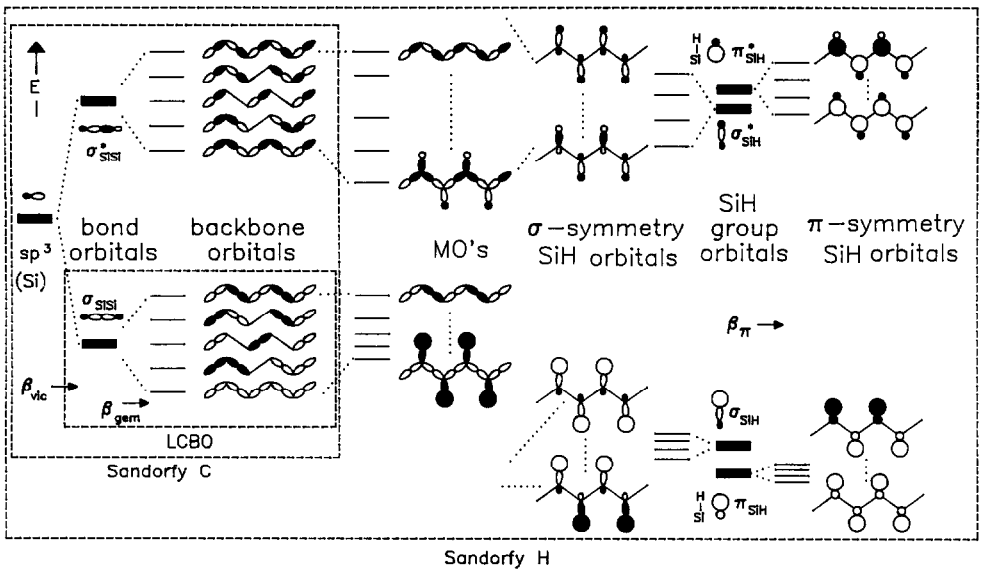

Fig. 2. The construction of σ- and π-symmetry orbitals of a long all-*trans* polysilane chain (schematic).

bone σ_{SiSi} orbitals and the σ_{SiH} group orbitals are large and the coefficients of the latter on the silicon atom small, since silicon is electropositive relative to hydrogen, hence, the interaction is weak. Moreover, at the silicon atom nodal points on the bonding backbone σ_{SiSi} orbitals, the resonance integral between the backbone orbital and the substituent orbital vanishes. For the highest-energy σ_{SiSi} backbone orbitals the interaction is therefore particularly weak and for the HOMO it is absent. Since the most stable σ_{SiSi} backbone orbital is most destabilized and the least stable one is the least affected, the band of σ_{SiSi} backbone orbitals is compressed by the interaction with the σ_{SiH} group orbitals as it forms the final bonding molecular orbitals. We shall continue to refer to these as σ_{SiSi} molecular orbitals for brevity, even though they contain some σ_{SiH} character.

The energy differences between the σ^*_{SiSi} backbone orbitals and the σ^*_{SiH} group orbitals are much smaller (centre of Fig. 2), and the coefficients of the latter on silicon relatively large. Therefore, the σ^*_{SiSi} backbone orbitals are affected more strongly than the σ_{SiSi} backbone orbitals. The most stable σ^*_{SiSi} backbone orbital is stabilized particularly strongly because of the absence of nodal points at the silicon atoms (in the drawing of this orbital in Fig. 4 of ref. 2, analogous to our Fig. 2, the bond-cutting nodes were inadvertently omitted). In general, the σ^*_{SiSi} backbone orbital band is expanded as it forms the final antibonding molecular orbitals. Although the most stable resulting molecular orbitals are mixed heavily with the σ^*_{SiH} orbitals, we shall continue to refer to them as σ^*_{SiSi} molecular orbitals for brevity.

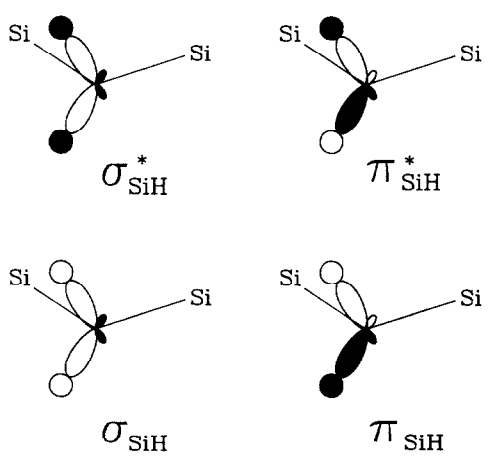

Fig. 3. A schematic drawing of the σ_{SiH}, σ^*_{SiH}, π_{SiH} and π^*_{SiH} group orbitals.

Molecular orbitals and single-reference configuration interaction calculation of excited electronic states (*Table* 1)

The above simple picture for polysilanes of infinite chain length may not be applicable without modification for finite chain oligosilanes because of end effects in the latter. However, we find that the end effects are surprisingly small and that the simple picture provides valuable guidance in the analysis of the results of our *ab initio* calculations. A qualitative picture of the highest few occupied and lowest few

unoccupied computed molecular orbitals is shown in Fig. 4 and agrees quite well with the simple expectations.

Disilane. The ground-state properties of disilane, such as equilibrium geometry, rotational barrier and vibrational spectra have been reasonably well studied by electronic structure methods.[57] However, very little is known about the excited states of this molecule. Experiments[58] and calculations[22,47,57] agree that the equilibrium geometry of disilane corresponds to a staggered conformation, similar to that of ethane. We report here the results of SCF–CISD calculations for staggered (D_{3d}) disilane performed using DZ, DZ+d, DZ+R and DZ+d+R basis sets.

At the SCF level, the HOMO is of a_{1g} symmetry and is the σ_{SiSi} bonding orbital (Fig. 4). The second highest occupied molecular orbital (SHOMO) is of e_g symmetry and is of the π_{SiH} type. The difference in the orbital energies of HOMO and SHOMO is 43 kcal mol^{-1} at the DZ level and increases to 46 kcal mol^{-1} at the DZ+d level. The large energy difference of these σ_{SiSi} and π_{SiH} orbitals, and their opposite ordering compared with ethane, have been noted before by others.[22,47] Koopmans' theorem ionization potential (IP) for the removal of an electron from the HOMO is calculated to be 260 kcal mol^{-1} and 259 kcal mol^{-1} at DZ and DZ+d levels, respectively. These results are in agreement with the *ab initio* calculations reported in the literature.[22,47] CNDO calculations predict the first IP to be about 294 kcal mol^{-1}.[8] The measured first IP is 243 kcal mol^{-1}.[8] More detailed calculations of oligosilanes[19,20] have shown that it is possible to predict their IPs more quantitatively than by Koopmans' approximation. However, this is not of particular relevance to this paper and we shall be content with the 15–20 kcal mol^{-1} overestimation of IPs.

The LUMO is a degenerate π^*_{SiH} orbital of e_u symmetry (Fig. 4). The second lowest unoccupied molecular orbital (SLUMO) is the σ^*_{SiSi} orbital of symmetry a_{2u}, located only 1 kcal mol^{-1} higher in energy than the LUMO at the DZ level and 12 kcal mol^{-1} at the DZ+d level. The ordering of these

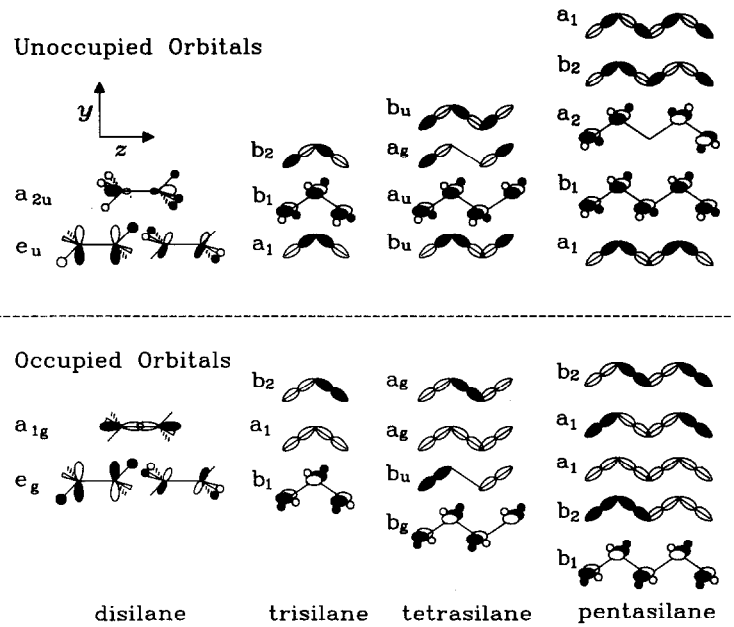

Fig. 4. Schematic representation of the first few highest occupied and lowest unoccupied molecular orbitals in Si_nH_{2n+2} ($n = 2$–5) and their ordering (SCF/DZ).

unoccupied orbitals is consistent with that reported in the literature[22,47] but the energy difference seems to be sensitive to the basis set and/or geometry. The HOMO–LUMO gap is calculated to be 368 and 365 kcal mol^{-1} at DZ and DZ+d levels, respectively. For comparison, an SCF calculation using the 3–21G* basis set predicted 346 kcal mol^{-1} at optimized geometry.[22] The effect of *d* orbitals on the energy of the LUMO σ^*_{SiSi} orbital is more pronounced than their effect on the energies of the σ_{SiSi}, π_{SiH} and π^*_{SiH} orbitals.

At the CISD level, both the DZ and DZ+d basis sets predict the first excited singlet state to be a degenerate $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ state of ^1E_u symmetry, located at about 275 and 280 kcal mol^{-1}, respectively, above the ground state. The lowest $^1A_{2u}$ $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ state lies 298 kcal mol^{-1} above the ground state with the DZ basis set and 310 kcal mol^{-1} above it with a DZ+d basis. Thus, the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation energy increases by only 5 kcal mol^{-1} upon the introduction of *d* orbitals into the basis, while the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy increases by nearly 12 kcal mol^{-1}. This effect is mainly due to the relative destabilization of the σ^*_{SiSi} SCF orbital as discussed above.

The addition of Rydberg functions to the DZ basis produces several low-lying Rydberg transitions at 245–280 kcal mol^{-1}. The lowest Rydberg transition was found to be of the $\sigma_{SiSi} \rightarrow (4s+4p_y)$ type and of $^1A_{1g}$ symmetry. The introduction of *d* orbitals into the basis set (DZ+d+R) again failed to alter the composition of the wavefunctions significantly, but the excitation energy increased by 20 kcal mol^{-1}.

The first five observed excited states have been assigned to Rydberg transitions.[59] The first electronic transition occurs at about 174 kcal mol^{-1} (164 nm). It has been assigned as $\sigma_{SiSi} \rightarrow 4s$ Rydberg, in only qualitative agreement with our results.

The excitation energies calculated for the first few valence excited states at the SCF–CISD level using the DZ basis set are listed in Table 1. A higher-level calculation would certainly be possible for this smallest member of the series, but comparison of the results with those for the longer oligosilanes would then be very unbalanced.

Trisilane. The SCF–CI calculations for trisilane (C_{2v} point group) were carried out using DZ, DZ+d and DZ+R basis sets. In addition, a test calculation where the DZ+d basis set was augmented with a set of *p* polarization functions on all the hydrogen atoms (DZ+dp) was also carried out. Furthermore, a three-configuration MCSCF followed by a three-reference CISD calculation using the MCSCF natural orbitals of the ground state once and those of the first excited state ($\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$) once were performed at the DZ level in order to check the effect of optimizing the orbitals for the excited state.

The SCF ordering of the high-lying occupied orbitals at the DZ level is as follows (Fig. 4): (i) the HOMO is of b_2 symmetry and corresponds to the

least stable σ_{SiSi} bonding molecular orbital, containing mostly $3p_z$ silicon atomic orbitals, (ii) the SHOMO is of a_1 symmetry and 21 kcal mol^{-1} more stable than the HOMO, corresponding to another σ_{SiSi} bonding MO, and contains mostly $3s+3p_y$ silicon and $1s$ hydrogen atomic orbitals, and (iii) the next highest occupied orbital, 50 kcal mol^{-1} lower in the energy than the HOMO, is of b_1 symmetry and is the least stable of the π_{SiH} orbitals. It is composed mostly of $3p_x$ silicon and $1s$ hydrogen atomic orbitals. The orbital ordering and composition remain the same with no significant changes in the orbital energies at the DZ+d and DZ+dp levels. They are in agreement with the earlier *ab initio*[22,47] and CNDO[8] calculations. The first IP based on Koopmans' theorem is calculated to be 250 kcal mol^{-1} compared with the experimental[8] value of 228 kcal mol^{-1}.

All three basis sets agree in the assignment of LUMO, SLUMO and the next lowest unoccupied molecular orbital to a_1, b_1 and b_2 symmetries, respectively (Fig. 4). The a_1 orbital is the most stable σ^*_{SiSi} orbital (mostly Si $3s+3p_y$ and H $1s$). The b_1 orbital is the most stable π^*_{SiH} orbital (mostly Si $3p_x$ and H $1s$), and the b_2 orbital is the σ^*_{SiSi} molecular orbital (mostly Si $3p_z$). For the three basis sets, less than 1 kcal mol^{-1} change is observed in the orbital energy of the low-lying unoccupied a_1 and b_1 orbitals. The b_2 orbital is destabilized by 4 kcal mol^{-1} upon the addition of silicon d orbitals to the basis set and no further change was observed for the DZ+dp basis set.

The ordering and structure of the bonding and antibonding molecular orbitals thus are as expected for an infinite polysilane from the qualitative Sandorfy models C and H even though in such a short chain the end effects ought to be particularly severe. The HOMO–LUMO gap is calculated to be 337, 335 and 335 kcal mol^{-1} at DZ, DZ+d and DZ+dp levels, respectively. Together with the changes in the orbital energies, these numbers indicate that the addition of silicon d functions and/or hydrogen p functions has an even less significant effect on the properties associated with the frontier orbitals of trisilane than is the case for disilane.

At the DZ level, CISD calculations (Table 1) predict the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation to be about 2 kcal mol^{-1} lower in energy than the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation. The addition of d functions reverses the order. In contrast to the situation in disilane, it lowers the energy of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation by 24 kcal mol^{-1} and the energy of the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation by about 27 kcal mol^{-1}. The addition of hydrogen p functions to the DZ+d basis lowers the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation energies by about 8 and 12 kcal mol^{-1}, respectively. The MCSCF–CI calculation described above reduces the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy by about 33 kcal mol^{-1} upon orbital optimization.

The DZ+R basis set predicted a group of Rydberg states located in the range of 210–235 kcal mol^{-1}. The lowest Rydberg transition again is of the $\sigma_{SiSi} \rightarrow (4s+4p_y)$ type and is about 35 kcal mol^{-1} lower than in disilane. The observed energy for the first electronic transition of trisilane is around 153 kcal mol^{-1} (187 nm),[59] 21 kcal mol^{-1} lower in energy than disilane. As in the case of disilane, the three absorption bands that were observed at energies below the first IP of trisilane have been assigned to Rydberg-like transitions,[59] in qualitative agreement with our results.

Trans-*n-tetrasilane*. The SCF–CI calculations were carried out using DZ, DZ+d and DZ+R basis sets, assuming C_{2h} symmetry for the planar *trans* conformation of tetrasilane.

As expected from the qualitative molecular orbital picture, the HOMO of n-tetrasilane is the least stable σ_{SiSi} molecular orbital, with nodes at every silicon atom and no nodes across the bonds (Fig. 4). It is of a_g symmetry. The two other σ_{SiSi} molecular orbitals are a b_u orbital, with one node across the middle SiSi bond, and a totally symmetric a_g orbital with no modes across the SiSi bonds. The qualitative molecular orbital picture based on the Sandorfy C model predicts the a_g orbital with no nodes as the most stable σ_{SiSi} backbone orbital, followed by the b_u orbital with one node and then the a_g HOMO. This indeed is the order of σ_{SiSi} molecular orbitals predicted by CNDO calculations.[8] However, *ab initio* SCF calculations with the DZ, DZ+d or better basis sets[19–22] predict the order of the b_u and the nodeless a_g σ_{SiSi} molecular orbitals to be reversed relative to the σ_{SiSi} backbone orbitals of the Sandorfy C model, so that the resulting SHOMO is of a_g symmetry. This is attributable to the stronger destabilizing interaction of the nodeless a_g backbone orbital with the σ_{SiH} group orbitals (cf. the Sandorfy H model and Fig. 2). The orbital energy differences between the SHOMO a_g and the b_u orbitals are calculated to be only 6 and 2 kcal mol^{-1} at the DZ and DZ+d levels, respectively. The highest bonding π_{SiH} orbital is of b_g symmetry and is much lower in energy, 57 kcal mol^{-1} compared with the HOMO at the DZ level. The first IP (Koopmans' theorem) is calculated to be 241 kcal mol^{-1} at both the DZ and DZ+d levels, compared with the experimental value of 222 kcal mol^{-1}.[8]

The LUMO, calculated at the DZ and DZ+d levels, is a b_u σ^*_{SiSi} molecular orbital. It is a linear combination of the backbone σ^*_{SiSi} orbital and the σ^*_{SiH} orbital, as expected from the Sandorfy H model (Fig. 4). The lowest π^*_{SiH} orbital is of a_u symmetry

and is calculated to be the SLUMO, 19 kcal mol^{-1} above the LUMO at the DZ level. This energy difference is reduced slightly to 17 kcal mol^{-1} at the DZ+d level.

The HOMO–LUMO gap is calculated to be 315 and 314 kcal mol^{-1} at the DZ and DZ+d levels, respectively. The analysis of orbital ordering and the energy differences shows that the silicon *d* functions do not influence the ordering or the orbital energies of the σ_{SiSi} (HOMO), σ^*_{SiSi} (LUMO) and π^*_{SiH} (SLUMO) orbitals. However, for conformational studies the silicon *d* functions may possibly be of some importance.

The DZ basis predicts the first $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ transition to be 9 kcal mol^{-1} lower in energy than the lowest $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation. However, at the DZ+d level, the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy is decreased by 16 kcal mol^{-1} and the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation by 24 kcal mol^{-1}. The net result is that the energy gap between $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation is reduced to about 1 kcal mol^{-1}. The lowest Rydberg excitation occurs at around 203 kcal mol^{-1} and is of the $\sigma_{SiSi} \rightarrow (4s+4p_y+4p_z)$ type.

The experimental UV spectrum of n-tetrasilane in cyclohexane has a broad absorption at 140 kcal mol^{-1} (205 nm).[60] Our calculations indicate that the first excited state is more like a Rydberg state than a valence state. However, Rydberg-like transitions are most likely broadened beyond recognition in the solution spectra, and the observed peak is probably attributable to the calculated $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ transition. A weaker $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ transition is expected to be buried underneath, and our calculations do not permit any reliable statement as to their relative energies.

All-trans-*n-pentasaline*. The SCF–CI calculations were feasible only for the DZ basis set. C_{2v} symmetry was imposed for the all-*trans* conformation.

The highest four occupied orbitals (Fig. 4) are the four σ_{SiSi} orbitals. The energy order of these orbitals predicted by the SCF calculation is b_2, a_1, a_1 (SHOMO) and b_2 (HOMO), in good agreement with earlier calculations.[19,20,22] The occupied π_{SiH} orbitals are below these four orbitals. The highest two are calculated to be 63 (b_1) and 68 (a_2) kcal mol^{-1} lower in energy than the HOMO. The first IP of pentasilane is calculated to be 234 kcal mol^{-1}, compared with the experimental valuc of 216 kcal mol^{-1}.[8]

The σ^*_{SiSi} orbital of a_1 symmetry is predicted by the SCF calculation to be the LUMO. The next higher SLUMO is of π^*_{SiH} character and lies 24 kcal mol^{-1} higher. As expected from the Sandorfy H model, the LUMO shows a considerable silicon 3*s* and σ^*_{SiH} character. The ordering of the unoccupied molecular orbitals at this level of calculation is: a_1 (σ^*_{SiSi} LUMO), b_1 (π^*_{SiH} SLUMO), a_2 (π^*_{SiH}), b_2 (σ^*_{SiSi}), a_1 (σ^*_{SiSi}) and b_2 (σ^*_{SiH}). This ordering is quite different from the ordering obtained from a previous SCF/3-21G* calculation[22] (a_1, a_1, b_1 and b_2). It is possible that the inclusion of silicon *d* functions can alter the ordering of unoccupied molecular orbitals. The HOMO–LUMO gap calculated at the DZ level is 299 kcal mol^{-1}.

The CISD/DZ calculation predicts a $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ $^1B_2$ state described predominantly by the HOMO → LUMO configuration (88%) as the first excited singlet, with an excitation energy of 202 kcal mol^{-1}. Earlier CNDO/2(S+DES CI) calculations[23,24] predict the first excited state to be 124 kcal mol^{-1} above the ground state. However, their HOMO → LUMO configuration contributes only about 50% to the total CI wave function.

A $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ (HOMO → SLUMO) excited state of $^1A_2$ symmetry lies about 16 kcal mol^{-1} higher. Other nearby excited states include a $^1B_1$ state, represented mostly by the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ (HOMO → LUMO+2) configuration, with an excitation energy of 230 kcal mol^{-1}, and a $^1A_1$ state, represented mostly by the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ (SHOMO → LUMO) configuration, with an excitation energy of 232 kcal mol^{-1}. The measured broad first electronic absorption of n-pentasilane in cyclohexane lies at around 133 kcal mol^{-1} (215 nm).[60] As in the case of tetrasilane, this is most likely due to the calculated $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ transition, with a $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ absorption band buried underneath.

Summary. Effect of chain length. Our results for molecular orbitals and their energies have brought no surprises, in that they are essentially fully in line with the simple Sandorfy models, with prior semiempirical and *ab initio* work, and with the known trends in experimental ionization potentials.

More noteworthy are the results for the excited states (Fig. 5), and we are now in position to comment on the nature of the lowest excited singlet state as a function of the number of silicon atoms in a linear oligosilane. The distinctions that need to be made are (i) Rydberg vs valence states and (ii) valence $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ vs $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ states. Another point of interest has been the importance of *d* orbitals for proper description of the valence excited states.

(i) Our results indicate that for disilane, trisilane and tetrasilane, the lowest few Rydberg excitations are of the $4s+4p$ type and are lower in energy than the valence excitations. The trends in the energies of the Rydberg states are expected to parallel the trends in the IPs.[61] Based on the measured first IPs, the Rydberg excitation energy is expected to drop by about 15 kcal mol^{-1} as we go from disilane

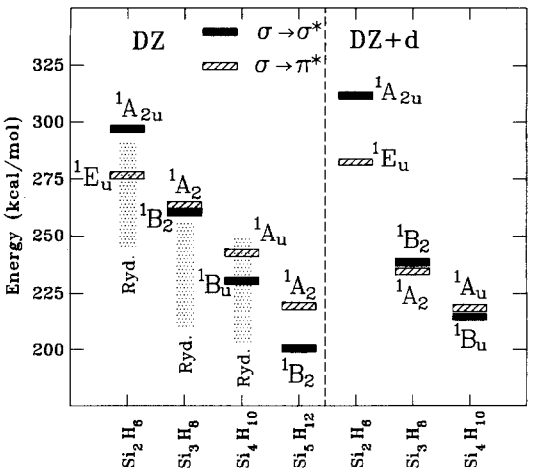

Fig. 5. Energies of the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ singlet excited states in Si_nH_{2n+2} (n = 2–5), obtained from CISD/DZ, CISD/DZ+d, and CISD/DZ+R calculations. See text.

to trisilane and by about 6 kcal mol^{-1} from trisilane to tetrasilane. Our calculated result of 35 kcal mol^{-1} at the SCF–CISD/DZ+R level does not correspond well to the expected value as we go from disilane to trisilane. However, the calculated difference in the lowest Rydberg excitation energy for trisilane and tetrasilane agrees well. The measured first IPs for tetrasilane and pentasilane differ by 6 kcal mol^{-1}.[8] Based on the trends in Rydberg and valence excitation energies, we can estimate that the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation and not Rydberg excitation will be the lowest excitation in n-hexasilane and higher linear oligosilanes. (ii) Perhaps the most important single outcome of our computations is the realization that two types of valence transitions, $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$, compete nearly evenly for the position of lowest energy and that the outcome of the competition is a function of chain length. At the DZ and DZ+d basis set levels, the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy decreases more rapidly than the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation energy as the number of backbone silicon atoms increases. Except in the case of disilane, each of these valence states is quite well described by a single configuration (Table 1). The configurations correspond to excitation from the HOMO (σ_{SiSi}) into the lowest of the σ^*_{SiSi} molecular orbitals or the lowest of the π^*_{SiH} molecular orbitals. The former agrees with the INDO/S description[25–27] and some,[23] but not all,[24] of the CNDO results.

It is clear from Fig. 5 that the lowest valence excited state in a long enough oligosilane will surely be $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$, at least in the all-*trans* conformation. This result is consistent with the previously reported semiempirical and experimental results.[25–27,38,46,62] The trend in the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy as a function of increasing chain length cannot be extrapolated quantitatively to long chains, but is compatible with the convergence limit of about n = 12, suggested by the INDO/S calculations.[25–27] This limit is not known experimentally. The observed excitation energies of polysilane chains $(R_2Si)_n$ continue to decrease up to $n \simeq 100$,[62] but these observations reflect the contributions of a whole distribution of segment lengths, and do not relate to the properties of a single all-*trans* chromophore of a specific length.

At the DZ level, the cross-over point between $\sigma_{SiSi} \rightarrow \pi^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ as the lowest excited singlet appears to be reached at trisilane. Inclusion of polarization *d* orbitals on silicon alters the picture slightly in that it shifts the cross-over point towards tetrasilane. In general, the silicon *d* orbitals play a rather insignificant role. Clearly, we cannot pinpoint the cross-over point, particularly since we have not optimized the geometries. However, it is reasonable to expect that in the shortest oligosilanes, and presumably also in the shortest segments of a disordered polysilane, $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ will be the lowest excited singlet, so that their photophysical properties will be quite different from those normal in longer oligosilanes and longer polymer chain segments. A $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ lowest singlet will have a much smaller oscillator strength and much longer radiative lifetime. This will tend to shift the competition between fluorescence on the one hand and intersystem crossing or photochemical decay on the other in favour of the latter two.

Since the equilibrium geometries of the ground and the excited states undoubtedly differ, the vertical absorption energy and the vertical emission energy plots against n may contain different cross-over points. As the equilibrium geometries of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited states undoubtedly also differ, the lowest excited singlet surface of an oligosilane or polysilane segment of a length characteristic of the cross-over region may contain two distinct minima at comparable energies.

Certain otherwise puzzling experimental observations on polysilanes will indeed be accounted for naturally if the shorter chromophoric segments in a poly(di-n-alkylsilane) chain, absorbing primarily below 300 nm, have a lowest excited singlet state of a much longer radiative lifetime than usual for the longer segments, which absorb primarily at longer wavelengths. The chain abridgement reaction, which proceeds with the expulsion of a R_2Si unit, only proceeds upon irradiation at wavelengths

below 300 nm,[63] and many of the photophysical properties of a series of poly(di-n-alkylsilane)s change abruptly at that same wavelength of irradiation in a fashion compatible with the notion that at shorter wavelengths an essentially non-fluorescent segment is being excited.[64] The present results might account for these anomalies in the behaviour of polysilanes, but it is clearly desirable to first investigate experimentally the short model oligosilanes themselves.

The quantitative agreement between the measured electronic excitation energies in simple oligosilanes[59,60] and the results obtained at the SCF–CISD/DZ level is rather poor. Valence-like excitations in disilane and trisilane are probably higher in energy than their first IPs and are difficult to measure. It is highly likely that we overestimate their energies significantly. The first excitation energies for *trans*-n-tetrasilane and all-*trans*-n-pentasilane are higher than the experimental numbers by 93 and 67 kcal mol^{-1}, respectively. The latter presumably refer to a mixture of conformers. The difference between experimental and calculated excitation energies for *trans*-n-tetrasilane is reduced to 77 kcal mol^{-1} at the SCF–CISD/DZ+d level, but this is still rather high.

Multireference CI calculation of excited electronic states. Although we expect that the lack of quantitative agreement does not play a critical role for the qualitative picture that we are primarily interested in presently, we have attempted to improve the quality of the single reference SCF–CISD results by performing multi-reference CI (MRCI) calculations with the DZ basis set for all four oligosilanes. We have generated 490 reference configurations by exciting eight electrons in the orbital space composed of four highest occupied and three lowest unoccupied SCF orbitals, with an excitation level of four. The CI list included all the single excitations from the reference space to the rest of the unoccupied orbital space (multi-reference first-order CI). The results are shown in Fig. 6. They are qualitatively identical to those of the CISD calculations: in disilane the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation lies below $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$, and the ordering is reversed for the higher oligomers. The vertical excitation energies are lower than those obtained from CISD calculations but still nearly 59 and 51 kcal mol^{-1} above the experimental values for *trans*-n-tetrasilane and all-*trans*-n-pentasilane, respectively. A quantitatively reliable computation of the excitation energies would clearly require the use of optimized geometries, of a larger basis set, optimized excited state orbitals and higher-order CI terms. Some or all of this may be attainable in the near future, particularly with recourse to the pseudopotential approximation.

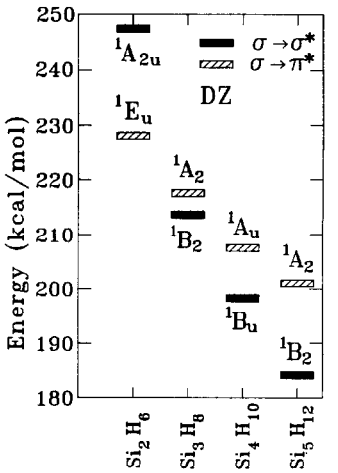

Fig. 6. Energies of the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ singlet excited states in Si_nH_{2n+2} (n = 2–5), obtained from MR–CI/DZ calculations. See text.

A fundamental problem standing in the way of quantitative agreement is the inadequate consistency in the treatment of electron correlation in the oligomers. For a size-consistent quantitative estimation of electron correlation energy in disilane through pentasilane, the minimum number of electrons to be correlated in either a calculation of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ state or a calculation of the $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ state in disilane would be two, in trisilane four, in tetrasilane six and in pentasilane eight. A full CI calculation for the correlation of six and eight electrons over the entire virtual space in tetrasilanes and pentasilanes, respectively, is currently beyond our reach. Further, this type of CI calculation does not include contributions from $\pi_{SiH} \rightarrow \pi^*_{SiH}$ and $\pi_{SiH} \rightarrow \sigma^*_{SiSi}$ excitations, respectively. These will double the electron count for uniform treatment of correlation along the oligosilane series. As a consequence, the current results cannot provide accurate relative energies of the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitations as a function of the silicon chain length. However, since the trends remain the same at all levels of calculation that we have performed (Figs 5 and 6), we believe that they are qualitatively correct.

Remarks on two-photon absorption spectroscopy of polysilanes

Recent investigations[43] of simultaneous two-photon absorption of poly(di-n-hexylsilane) in methylcyclohexane glass and in thin films show a

strongly allowed two-photon absorption band at about 23 kcal mol^{-1} above the lowest strong one-photon absorption band. Two-photon polarization measurements have ruled out the possibility of a final state of $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ character. The absence of any one-photon absorption band at 23 kcal mol^{-1} above the lowest absorption band in the polymer demonstrates that this strongly two-photon allowed state is at best weakly allowed as a one-photon electric dipole excitation. No secure assignment of this two-photon transition has yet been offered.[30,31,43,65]

Our SCF–CISD/DZ calculations for all-*trans* oligosilanes (Table 1) indicate the presence of a higher $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ one-electron excited singlet state of the same symmetry as the ground state (^1A_g for even n, $^1A_1$ for odd n), located 15–30 kcal mol^{-1} above the strongly allowed first excited $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ singlet state (^1B_u when n is even and $^1B_2$ when n is odd). A transition from the ground state to this higher $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ ^1A state is one-photon electric-dipole forbidden for even n and weakly allowed, with short-axis (y) polarization, for odd n, and we propose that this makes this type of state a good candidate for the final state in the observed two-photon transition. In trisilane, tetrasilane and pentasilane, the dominant configuration for this excited state corresponds to the promotion of one electron from the SHOMO (HOMO-2 in tetrasilane) σ_{SiSi} orbital composed of silicon $3s+3p_y$ and hydrogen $1s$ atomic orbitals to the LUMO σ^*_{SiSi} orbital composed mostly of silicon $3s+3p_y$ and hydrogen $1s$ atomic orbitals.

A comparison with linear π-conjugated systems is instructive. In polyenes,[66] the final state for two-photon absorption is a "doubly excited state" with SHOMO → LUMO, HOMO → SLUMO and HOMO^2 → LUMO^2 having roughly equal weights as the dominant configurations. These approximately degenerate configurations are the only three that carry two-photon absorption intensity in the simplest approximation, as they are the only ones obtained from the ground configuration by two successive applications of an "allowed" single-electron promotion (i.e. one that increases the "quantum number", given by the number of nodes in a molecular orbital, by one). The mixing of the three configurations produces three excited ^1A states: 2^1A^-, 1^1A^+ and 3^1A^- in the order of increasing energy (the superscript indicates pseudoparity in the sense of Pariser's[67] alternant pairing). The two $^1A^-$ states are two-photon allowed for a transition from the 1^1A^- ground state, with the two-photon intensity concentrated heavily in the transition to the upper state, 3^1A^-, as a result of balancing contributions from the three contributing configurations. In long polyenes and perhaps already in butadiene, the 2^1A^- state actually lies below the first one-electron excited $^1B^+$ singlet state (HOMO → LUMO). The near degeneracy of the SHOMO → LUMO and HOMO → SLUMO configurations in polyenes is a consequence of their alternant nature (in approximate models, in which alternant symmetry holds exactly, the degeneracy is exact),[67] whereas the closeness of the HOMO^2 → LUMO^2 configuration to the others is "accidental".

At the level of Sandorfy model C, polysilanes are exactly isoconjugate with polyenes and are alternant, too. One might therefore expect that they, too, will have a low-lying doubly excited state of equally mixed "SHOMO" → "LUMO", "HOMO" → "SLUMO" and "HOMO"^{2} → "LUMO"^{2} nature (the orbital labels are placed into quotation marks to indicate that only molecular orbitals of σ^*_{SiSi} nature are counted). Yet, our calculations reveal that the higher $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ state, that we propose as a candidate for the terminal state of strong two-photon absorption, contains only minuscule amounts of "HOMO"^{2} → "LUMO"^{2} and "HOMO" → "SLUMO" configurations and cannot be considered "doubly excited" in the usual sense at all.

Recent CASSCF calculations[28] for trisilane suggest that a vertically doubly excited state with dominant "HOMO"^{2} → "LUMO"^{2} configuration actually exists but lies much higher in energy. It drops rapidly along the chain abridgement reaction coordinate (extrusion of silylene from trisilane), as expected from a Woodward–Hoffmann type correlation diagram.[28,68] Indeed, very recent examination[65] of the successive absorption of two photons by poly(di-n-hexylsilane) revealed not only the two-photon state already discussed above, but also an additional totally symmetrical state at higher energies. This higher state gives rise to an intense $S_1 \rightarrow S_x$ absorption band at energies only a little lower than those of the first intense transition from the ground state, "HOMO" → "LUMO". It is quite plausible that this higher state corresponds to the "HOMO"^{2} → "LUMO"^{2} excitation (^1A_g or $^1A_1$ symmetry). The "HOMO" → "SLUMO" configuration then presumably provides two-photon intensity to one or more yet other transitions at even higher energies. Clearly, judging by our *ab initio* results and the experimental results on simultaneous and successive two-photon absorptions, the oligosilane and polysilane chromophores are not even approximately alternant.

The reason for the loss of alternant symmetry is immediately apparent when one proceeds from the simplest Sandorfy C model to the Sandorfy H model (Figs 2 and 4). Although the energies of the σ_{SiSi} and σ^*_{SiSi} backbone orbitals in themselves still satisfy

the pairing symmetry (identical gaps between "HOMO" and "SHOMO" and between "LUMO" and "SLUMO" and therefore comparable energies for the "HOMO" → "SLUMO" and "SHOMO" → "LUMO" configurations), the interaction of the σ_{SiSi} backbone orbitals with the σ_{SiH} group orbitals has a very different effect than the interaction of the σ^*_{SiSi} backbone orbitals with the σ^*_{Si} group orbitals. As noted above, the resulting band of σ_{SiSi} orbitals is compressed, whereas that of the resulting σ^*_{SiSi} orbitals is expanded. The "HOMO"–"SHOMO" gap is greatly reduced and the "LUMO"–"SLUMO" gap is greatly increased (requiring the introduction of quotation marks, since "SLUMO" is now pushed well above the lowest π^*_{SiH} state or states). As alternant pairing is lost, so is the degeneracy of the "SHOMO" → "LUMO" and "HOMO" → "SLUMO" configurations, and so is their strong mixing. After such uncoupling, the energies of the "SHOMO" → "LUMO", "HOMO"^{2} → "LUMO"^{2} and "HOMO" → "SLUMO" configurations are free to be widely different and their mixing is minimal. One ends up with three two-photon allowed states of comparable intensities at energies not too different from those of the configurations, and all potential for an extremely low-lying "doubly excited" two-photon allowed state is gone.

Inspection of Fig. 2 makes it clear that the root of the problem lies in the lack of mirror-image relation between the σ_{SiH} and σ^*_{SiH} group orbitals and thus is ultimately due to the much higher electronegativity of hydrogen (or carbon), whose 1*s* (or sp^3) orbital dominates the σ_{SiH} (or σ_{SiC}) group orbital, compared with silicon, whose *s*–*p* hybrid orbital dominates the σ^*_{SiH} group orbital. A partial remedy would be to reduce the *s* character of the silicon hybrid orbital used to form the σ_{SiH} and σ^*_{SiH} group orbitals by opening up the SiSiSi valence angle through the use of bulky substituents, but it is unlikely that this effect could be sufficiently large if the lateral substituent remains as electronegative as hydrogen or carbon.

A laterally silylated polysilane of the type $[Si(SiR_3)_2]_n$ ought to have a much better chance at being alternant and exhibiting a more polyene-like, two-photon absorption spectrum. Of course, the stronger resonance integral alternation in the silicon backbone compared with the polyene chain disfavours the "HOMO"^{2} → "LUMO"^{2} configuration energetically relative to "HOMO" → "LUMO", so that even then, the 2^1A state will not be as strikingly low in energy and will not have as much "doubly excited" character. Also, hyperconjugation with the SiR_3 group will introduce additional complications (cf. the following section on alkyl substitution). It would be interesting to see whether lateral substitution with groups less electronegative than silicon, as in $[Si(SnMe_3)_2]_n$, would reverse the situation, making the "HOMO"–"SHOMO" gap larger than the "LUMO"–"SLUMO" gap.

Since the removal of alternant symmetry from the σ_{SiSi} and σ^*_{SiSi} backbone orbitals by interaction with the σ_{SiH} and σ^*_{SiH} group orbitals, respectively, is not at all described by the Sandorfy model C, we believe that the recent attempts to revitalize model C by introduction of electron repulsion at the Pariser–Parr–Pople level[30,31,69] are not likely to provide a correct description of the two-photon states. Although it is possible to manipulate the relative energies of the first one-photon allowed $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation and the first two-photon allowed $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation by adjustment of the β_{gem}/β_{vic} ratio, alternant pairing cannot be removed by this device alone.

Finally, we note that even the Sandorfy H model still neglects some parts of the Hamiltonian that remove alternant pairing, specifically, next-nearest neighbour resonance integrals (β_{13}).

Methyl substitution

Unlike a hydrogen atom, the methyl substituent can interact with the σ_{SiSi} and π_{SiH} orbitals of the silicon backbone of an oligosilane through hyperconjugation. The occupied combined orbitals of the methyl C—H bonds that possess π symmetry with respect to the Si—C bond (not to be confused with π symmetry relative to the plane of the silicon atoms) can act as donors and their unoccupied antibonding counterparts can act as acceptors. The least stable σ_{SiSi} molecular orbital (HOMO) has the right nodal properties (local symmetry) to interact with the methyl donor orbitals (Fig. 7). This interaction should result in a destabilization of the HOMO. The most stable σ^*_{SiSi} molecular orbital, normally the LUMO, has the wrong nodal properties at each silicon to permit interaction with the methyl group orbitals and is not affected. The π^*_{SiH} orbitals of the oligosilane chain can interact both with the occupied and the unoccupied methyl orbitals. The interaction with the donor orbital of the methyl group would destabilize and the interaction with the acceptor orbital of the methyl group would stabilize the antibonding π^*_{SiH} orbital. Semiempirical calculations[33] suggest that the interaction with the unoccupied methyl group orbital is dominant and that the π^*_{SiH} orbital is stabilized.[2] In order to test this simple picture and to examine the influence of methyl orbital interactions on the lowest singlet $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation ener-

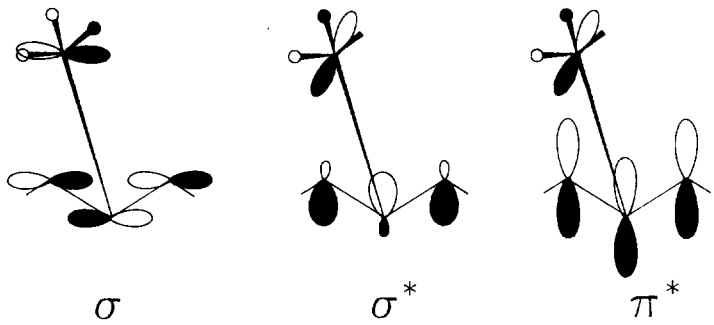

Fig. 7. Schematic representation of the interaction between the local π-symmetry orbitals of a methyl group with the highest σ_{SiSi}, lowest σ^*_{SiSi} and the lowest π^*_{SiC} backbone orbitals of a long all-*trans* polysilane.

gies, we carried out SCF–CI calculations on 2,2-dimethyltrisilane, using the DZ basis set and assuming C_{2v} symmetry.

As in trisilane, the HOMO of 2,2-dimethyltrisilane is the least stable σ_{SiSi} bonding orbital. It has b_2 symmetry and is destabilized relative to the HOMO of trisilane by about 15 kcal mol^{-1}, in accordance with the simple expectations. The experimental IP for 2,2-dimethyltrisilane is not known. However, the measured first IPs for permethylated disilane and tetrasilane are 200 and 184 kcal mol^{-1},[70] respectively. From these numbers, we can guess the IP of permethylated trisilane to be approximately 192 kcal mol^{-1}, which is about 36 kcal mol^{-1} lower than that of parent trisilane. Based on these numbers, it is not unreasonable to expect 15 kcal mol^{-1} reduction of the first IP (destabilization of the HOMO in Koopmans' context) in 2,2-dimethyltrisilane relative to parent trisilane.

The LUMO of 2,2-dimethyltrisilane, which is the most stable of the antibonding σ^*_{SiSi} orbitals, is calculated to be virtually unaffected (destabilized by only 2 kcal mol^{-1} relative to trisilane), again as expected from the simple arguments. The HOMO–LUMO gap in 2,2-dimethyltrisilane is calculated to be 325 kcal mol^{-1}, about 12 kcal mol^{-1} smaller than that of trisilane.

The π^*_{SiH} orbital (SLUMO) of b_1 symmetry is destabilized by 3 kcal mol^{-1} relative to trisilane and shows practically no hyperconjugative interactions. The slight destabilization is most likely due to the larger CSiC angle. Semiempirical calculations[33] suggest that this orbital is stabilized upon methylation, and the reason for the discrepancy is not known.

The $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ (HOMO $\rightarrow$ LUMO) configuration was found to represent well the first excited state of 2,2-dimethyltrisilane, with an excitation energy of about 239 kcal mol^{-1}, reduced by 23 kcal mol^{-1} from that in trisilane. The $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy is about 2 kcal mol^{-1} lower and the SHOMO $\rightarrow$ LUMO $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy about 12 kcal mol^{-1} higher than the lowest $\sigma_{SiSi} \rightarrow \pi^*_{SiC}$ excitation. The experimental UV spectrum of 2,2-dimethyltrisilane is not available and the valence transitions in parent trisilane are not well known, making a comparison with experiment difficult. However, for comparison, the energy for the first electronic excitation of permethylated tetrasilane in isooctane is about 132 kcal mol^{-1} (216 nm)[71] which is red-shifted by 7 kcal mol^{-1} (11 nm) relative to the first transition in n-tetrasilane.[60]

These results show that methyl substitution on the oligosilane chain lowers the HOMO–LUMO gap by hyperconjugative destabilization of the HOMO, causing the $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy in 2,2-dimethyltrisilane to be considerably red-shifted from that in trisilane. The calculated gap between the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and $\sigma_{SiSi} \rightarrow \pi^*_{SiC}$ excited states remains almost unchanged.

Variation of the SiSiSi *valence angle*

Previous calculations on the equilibrium geometry of the parent oligosilanes yielded an equilibrium SiSiSi valence bond angle, θ, of 111.2°.[21,22]

In order to evaluate the effect of θ on the excitation energies, we carried out SCF–CISD/DZ calculations on trisilane and the *trans* conformer of n-tetrasilane as model compounds. The angle θ was varied from 100 to 130°. To accommodate for the changes in the hybridization of the atomic orbitals of the central silicon atoms whose valence angle θ is varied, the HSiH angles were also changed, in the opposite direction. For the two extreme values of θ, 100 and 130°, the corresponding HSiH angles were fixed to be 118 and 88°, respectively, as suggested by MNDO calculations.[72]

The SCF orbital energies of the two highest occupied orbitals and the two lowest unoccupied orbitals of trisilane and *trans*-n-tetrasilane are shown in Fig. 8 as a function of θ, which also provides a schematic representation of the orbitals. The behaviour of these orbitals in both trisilane and *trans*-n-tetra-

silane is similar. In both cases, the ordering of these orbitals does not change as θ is varied from 100 to 130°.

The HOMO σ_{SiSi} orbital (b_2 in trisilane and a_g in *trans*-n-tetrasilane), composed largely of silicon $3p_z$ orbitals, is stabilized as θ is increased, and this is readily understood. At very large values of θ, this orbital is stabilized by the predominantly σ-type positive overlap of the silicon $3p_z$ atomic orbitals at neighbouring silicon atoms. At very small θ, this overlap develops into predominantly π type, its sign changes, and the orbital is destabilized. Significant negative overlap between the $3p_z$ orbitals on the next-nearest neighbour silicon develops as well. The SHOMO σ_{SiSi} orbital (a_1 in trisilane and a_g in *trans*-tetrasilane), composed of the silicon $3s+3p_y$ and hydrogen $1s$ atomic orbitals, is quite insensitive to the changes in the valence angle θ.

The LUMO σ^*_{SiSi} orbital (a_1 in trisilane and b_u in *trans*-n-tetrasilane), composed mostly of silicon $3s+3p_y$ and hydrogen $1s$ atomic orbitals, shows a very strong stabilization as θ is increased. This is mainly due to the decreasing negative overlap of the $3s+3p_y$ atomic orbitals on neighbouring silicon atoms. At the valence angles considered here, the SLUMO is the π^*_{SiH} orbital (b_1 in trisilane and a_u in *trans*-tetrasilane) in both cases. An increase in θ has little effect but the concomitant decrease in the HSiH angle causes a decrease in the overlap between the hydrogen $1s$ and the silicon p_x atomic orbitals and stabilizes the π^*_{SiH} orbital.

The net changes in the HOMO–LUMO and the HOMO–SLUMO gaps as a function of θ are shown in Fig. 9 for the two model compounds. Qualitatively, they suggest that an increase in θ will indeed reduce the first $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ excitation energy and increase the first $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excitation energy slightly.

The calculated energies of the lowest $\sigma_{SiSi} \rightarrow \sigma^*_{SiSi}$ and the lowest $\sigma_{SiSi} \rightarrow \pi^*_{SiH}$ excited states of trisilane and *trans*-n-tetrasilane, obtained as a function of θ by performing single-reference CISD/DZ calculations using an active space of first few highest occupied SCF orbitals (seven in trisilane and five in *trans*-n-tetrasilane) and all the unoccupied SCF orbitals, are given in Fig. 10. The ground state energies of both compounds increase by nearly 5 kcal mol^{-1} as θ is increased to 130° or decreased
