There is currently considerable interest in complexes which feature bonding between the group 13 and 15 elements since such compounds offer potential as precursors to III/V compound semiconductors.[1] In previous studies we have reported details of our work on phosphido (R_2P^-) and arsenido (R_2As^-) derivatives of the group 13 elements.[2] We were therefore interested in the analogous amido (R_2N^-) complexes of the heavier group 13 metals for which several examples have been reported.[3] We have now prepared and characterized a number of new amido and amine adduct complexes of gallium and report here details of the synthesis and structures of $[t\text{-}Bu_2Ga(\mu\text{-}NHPh)]_2$ (**1**) and $t\text{-}Bu_3Ga \cdot NH_2Ph$ (**2**) which are among the first structurally characterized primary amido complexes of gallium and the first X-ray structure featuring the $t\text{-}Bu_3Ga$ group.[4] The X-ray structure of **1** suggests the presence of a close N—H···Ga interaction and we were curious to see if such an interaction might exist in the adduct (**2**). The X-ray structure of **2** again indicates the presence of a close N—H···Ga interaction. However the structural data for both compounds were not of sufficient quality to enable the N—H hydrogens to be fully refined isotropically.

RESULTS AND DISCUSSION

Synthesis of the primary amido complex $[t\text{-}Bu_2Ga(\mu\text{-}NHPh)]_2$ (**1**)

Reaction of $t\text{-}Bu_2GaCl$ with one equivalent of LiNHPh in toluene and diethylether (4:1) at −78°C gives high yields of the primary amido complex (**1**). ^1H NMR data for **1** are in accord with the structure determined crystallographically. Thus the t-*Bu*—Ga units appear as a singlet at δ 0.90 and the N—C_6H_5 group as a broad signal located at δ 6.80. The N—H protons were not observed, possibly due to the large quadrupole of nitrogen. The IR spec-

trum contains peaks assigned to the phenyl groups, however, only a very weak peak at 3260.5 cm^{-1} was observed which could be assigned to a ν(N—H) stretch.

X-ray structure of **1**. Molecules of **1** crystallize in the monoclinic space group $P2_1/c$ with two molecules per unit cell. Figure 1 shows the molecular geometry and atom numbering scheme while Fig. 2 illustrates the location of the nitrogen hydrogen atoms. Selected bond lengths and angles are given in Table 2. The structure of **1** consists of dimeric units with a center of inversion and a crystallographically imposed C_2 axis along the Ga···Ga axis. There is a slight distortion in the bonding of the bridging —NHPh groups. The two Ga—N distances are 2.103(9) and 2.018(9) Å. These lengths are somewhat longer than other bridging Ga—N bonds such as those found in $[H_2GaN(CH_2)_2]_3$,[5] [1.97(2) Å]. This difference may be due to the steric influence of the bulky tert-butyl groups. The Ga—C bond lengths are also somewhat lengthened; Ga—C(1), [2.006(9) Å] and Ga—C(5), [2.18(2) Å]. These lengths may be compared to similar values found in the dimeric compound $[Me_2Ga(\mu$-MeN=C(Me)NMe)$]_2$ [Ga—C, 1.991(5) and 2.005(4) Å].[6]

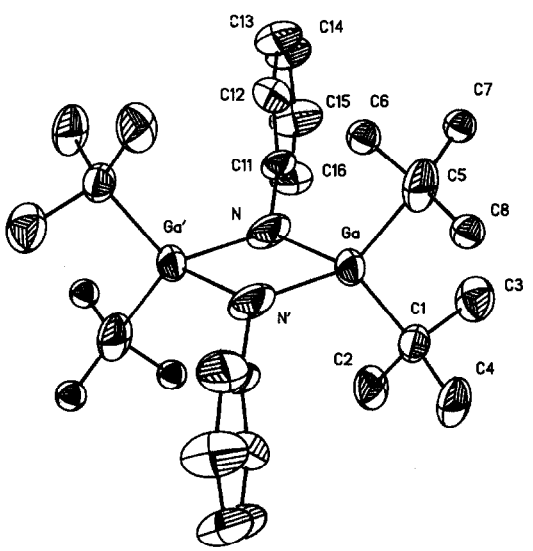

Fig. 1. ORTEP view of (**1**) showing the atom numbering scheme. Hydrogen atoms omitted for clarity.

The nitrogen hydrogen atom was located from difference Fourier maps, but in view of the difficulty of finding one electron between two gallium atoms it was refined with fixed isotropic parameters and allowed to "ride" upon the nitrogen.[7] The location of the hydrogen atom was checked by removal and subsequent location as the largest peak on the final difference map. The hydrogen is symmetrically located 2.037 Å from both gallium atoms. The C(11)—N—H bond angle is acute, 74.5°, demonstrating a close association with the Ga—N plane. The N—H bond length is slightly longer

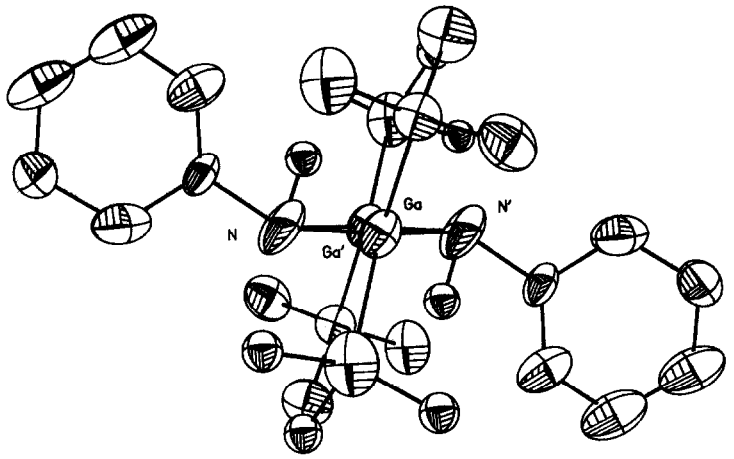

Fig. 2. ORTEP view of (1) showing the location of the nitrogen–hydrogen atoms.

(N—H, 1.105 Å) than the standard length (1.00 Å). Rather than describe this hydrogen as an "agostic" hydride, bonding to empty orbitals on an electron deficient metal atom, it may be more appropriate to describe the interaction as a δ^+–δ^- dipole. In this case the amide proton is attracted to the electron density of the Ga_2N_2 ring; not specifically towards any atom.

Synthesis of the primary amine complex t-Bu_3 Ga · NH_2Ph (2)

Reaction of t-Bu_3Ga with one equivalent of NH_2Ph in toluene at −78°C gives high yields of the primary amine adduct (2). The ^{1}H NMR spectrum of 2 shows a singlet at δ 1.17 (Ga—t-*Bu*) and well resolved peaks at δ 6.5(d), δ 6.8(t), and δ 6.9(t) assigned to N—*Ph*. A broad weak resonance occurs at δ 3.45 for N—*H*. The IR spectrum shows strong peaks at 3347 and 3285 cm^{-1} assigned to ν(N—H).

X-ray structure of (2). Molecules of 2 crystallize in the monoclinic space group, $P2_1/n$ with four molecules per unit cell. The molecular structure of 2 is shown in Fig. 3. Selected bond lengths and angles are given in Table 3. Note that the atoms C(21), Ga, N, and NH(1) are all coplanar with the maximum deviation from the least-squares plane being 0.07 Å for C(21). The Ga—N bond distance of 2.246(9) Å is longer than the corresponding dis-

tance for the adduct of trimethyl gallium with tert-butyl amine which has a value of 2.12(1) Å.[4] This increased length can be partially attributed to steric repulsion between the t-Bu—Ga groups and the phenyl ring. The closest interatomic distance, C(1)—C(3), between these two groups is 3.54(2) Å.

As expected, the configuration of the amine is distorted from the ideal tetrahedral geometry. The C(1)—N—Ga angle of 125.8(8) Å is clearly indicative of steric repulsion between the amine phenyl ring and the t-Bu—Ga groups. Both amine hydrogen atoms were located from difference Fourier maps. However, attempts to refine the hydrogen atoms isotropically led to unrealistic values for the fractional coordinates. Thus, the nitrogen–hydrogen atoms were included in the refinement with fixed isotropic thermal parameters and allowed to "ride" upon the nitrogen. Confirmation of the hydrogen atom locations was achieved by removing these atoms from the refinement and then locating them as the largest two peaks in the final difference map. One of the hydrogen atoms [H(1)] forms an acute angle with the Ga—N bond, H(1)—N—Ga, 87°, while the corresponding H(2)—N—Ga angle is 104°. The N—H(1) distance is correspondingly larger than N—H(2); 1.04 vs 0.92 Å. The Ga···H(1) distance is 2.42 Å which is considerably shorter than the sum of the van der Waals radii for gallium and hydrogen (*ca* 3.1 Å).[8] The other Ga···H(2) distance is 2.63 Å, while the corresponding distances found in the adduct $Me_3Ga \cdot NH_2Bu^t$ are both 2.52 Å.[4]

The IR spectrum of (**2**) displays two strong ν(N—H) stretches at 3347 and 3286 cm^{-1}. There appears to be no particularly low IR active ν(N—H) vibration which may be assigned to a close Ga···H interaction.

Our observation suggests that other derivatives of the heavier group 13 elements may also contain close M···H interactions and further studies are in progress.

EXPERIMENTAL

All reactions were performed under oxygen free nitrogen or under vacuum. Toluene and diethylether were distilled from sodium/benzophenone under nitrogen before use. Aniline was dried over molecular sieves and then distilled from calcium hydride before use. Instruments: IR, Perkin–Elmer, 1330, Digilab FTS-40; NMR, GE QE-300, (^{1}H, 300 MHz). IR spectra were run as Nujol mulls using KBr plates. NMR spectra were recorded in C_6D_6 solution at ambient temperature unless otherwise stated and are in ppm referenced to Me_4Si (δ 0.0, ^{1}H). Melting points were obtained in sealed capillaries under nitrogen (1 atm.) and are uncorrected. t-Bu_3Ga, and t-Bu_2GaCl were prepared as previously described.[9] LiNHPh was prepared *in situ* by the addition of one equivalent of MeLi to NH_2Ph in diethylether at −78°C. The reaction mixture was then allowed to warm to 25°C over the course of 4 h.

Synthesis of (**1**). A solution of LiNHPh (1.33 g, 13.39 mmol) was added dropwise to a solution (−78°C) of t-Bu_2GaCl (2.93 g, 13.35 mmol), prepared *in situ* from the reaction of t-BuLi with $GaCl_3$ in toluene/diethylether (4:1) (50 cm^3) at −78°C. The reaction mixture was stirred (12 h) and allowed to come to room temperature. Volatile materials were removed under vacuum and the residue was extracted with hexane (150 cm^3) and the resulting solution filtered. Reduction in volume of the solution by evaporation under vacuum (10^{-3} Torr) resulted in the immediate formation of **1** as a white micro-crystalline solid. Crystals suitable for X-ray crystallography were grown from a diethylether solution (20 cm^3) cooled to −25°C. For **1**: m.p.

120–123°C, dec. Yield: 2.21 g, 60% based on t-Bu_2GaCl. IR: 3261 w, 1607 m, 1268 m, 1214 m, 1170 m, 1143 m, 991 w, 946 w, 875 m, 857 w, 825 s, 784 m (cm^{-1}). ^1H NMR: δ 6.8 (b, 5H, N—*Ph*), 0.90 (s, 18H, Ga—t-*Bu*).

Synthesis of (**2**). Aniline (NH_2Ph) (0.72 cm^3, 8.30 mmol) was added dropwise to a toluene solution of t-Bu_3Ga (1.00 cm^3, 4.15 mmol) at −78°C. The reaction mixture was stirred (6 h) and allowed to warm to room temperature. The solution was concentrated under vacuum (30 cm^3) and colourless crystals suitable for X-ray crystallography were obtained after several weeks of storage at −30°C. For **2**: m.p. 111–113°C, dec. Yield, 1.04 g based on t-Bu_3Ga. IR: (Nujol mull), 3339 m, 3268 m, 1620 m, 1321 m, 1071 w, 1054 w, 979 w, 929 w, 832 s, 821 m, 755 m, 714 m (cm^{-1}). The N—H stretches do not change significantly in the solid state (KBr disc). ^1H NMR: δ 6.9(t), 6.8(t), 6.5(d) (5H, N—*Ph*), 3.45 (br. s, 2H, N—*H*), 1.17 (s, 27H, Ga—t-*Bu*).

X-RAY EXPERIMENTAL

Details of crystal data and a summary of intensity data collection parameters for **1** and **2** are given in Table 1. Data were collected on an Enraf–Nonius CAD-4 diffractometer at 23±2° using graphite monochromated Mo–K_α radiation. Intensity data were recorded in a manner as described previously.[10] All calculations were performed on a Microvax 3100 computer using the SHELX software package.[11] For each structure the data were corrected for Lorenz and polarization effects.

Compound **1**. Crystals suitable for X-ray diffraction were grown by cooling a diethylether solution to −25°C. Crystals were mounted in thin-walled glass capillaries and sealed under argon. Unit cell parameters were obtained by centering 25 reflections having 2θ values between 20 and 26°. The monoclinic space group $P2_1/c$ was uniquely determined by the systematic absences $h0l$, $l = 2n+1$, $0k0$, $k = 2n+1$. Data were collected in the $+h+k\pm l$ quadrant between 2θ values of 2 and 50°. The reflection intensity standards indicated < 2% decrease in intensity over the course of data collection, and hence no correction was applied. A Ψ scan of four reflections having χ values between 80 and 90° showed a minimum transmission of 80.2% and a maximum transmission of 99.8%. No absorption correction was applied. The structure of **1** was solved by direct methods and successive cycles of difference Fourier maps followed by least-squares refinement. All non-hydrogen atoms were refined anisotropically. The nitrogen–hydrogen atom was located from the final difference map as the largest peak. Attempts to refine the hydrogen separately were unsuccessful and it was included in the refinement with fixed isotropic thermal parameters and allowed to ride upon the nitrogen. All other hydrogen atoms were placed at calculated positions (d_{C-H} = 1.00 Å, H—C—H = 109.5°) and were not refined, rather being constrained to ride upon the appropriate carbon.

Compound **2**. Crystals suitable for X-ray diffraction were grown by cooling a toluene solution to −25°C. The crystals were mounted in thin-walled glass capillaries and sealed under argon. Unit cell parameters were obtained by centering 25 reflections having 2θ values between 22 and 26°. The monoclinic space group $P2_1/n$ was uniquely determined by the systematic absences $h0l$, $h+l = 2n$, $0k0$, $k = 2n+1$. Data were collected in the $+h$, $+k$, $\pm l$ quadrant between 2θ values of 2 and 50°. The intensity standards indicated a < 2% decrease in intensity over the course of data collection, and hence no correction was applied. A Ψ scan of four reflections having χ values between 80 and 90° showed a minimum transmission of 70.0% and a maximum transmission of 98.8%. An empirical absorption correction was applied. The observed structure factors of equivalent reflections were averaged. The gallium atom was found using a Patterson search, and subsequent location of the other non-hydrogen atoms was achieved using difference Fourier maps. The nitrogen hydrogen atoms were located from difference Fourier maps. Attempts to refine these hydrogens led to unrealistic values for the fractional coordinates. Thus these atoms were assigned fixed thermal parameters and then allowed to "ride" upon the nitrogen atom. All other hydrogen atoms were placed at calculated positions (d_{C-H} = 1.00 Å, H—C—H = 109.5°) and were not refined, rather being constrained to ride upon the appropriate carbon.

SYNTHESIS AND CHEMISTRY OF SECONDARY ALKYL IODIDE COMPLEXES OF THE FORMULA $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICHRR')]^+BF_4^-$

ALAIN IGAU and J. A. GLADYSZ*

Department of Chemistry, University of Utah, Salt Lake City, UT 84112, U.S.A.

(*Received* 4 *April* 1991; *accepted* 16 *May* 1991)

Abstract—Reactions of deuterodichloromethane complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ClCD_2Cl)]^+BF_4^-$ with (**a**) isopropyl iodide, (**b**) *sec*-butyl iodide, (**c**) cyclopentyl iodide, and (**d**) cyclohexyl iodide give secondary alkyl iodide complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICHRR')]^+BF_4^-$ (**3a–d**) in good to high NMR yields, depending upon the quantity of alkyl iodide employed. These compounds are much less stable than analogous primary alkyl iodide complexes, but analytically pure **3d** can be isolated from the reaction of $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CH_3)$ and $HBF_4\cdot OEt_2$ in neat cyclohexyl iodide (73%). Complex **3d** decomposes in CD_2Cl_2 to give cyclohexyl fluoride, cyclohexene (74% total) and bridging halide complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]_2X^+BF_4^-$ (X = I, 33%; Cl, 36%). The formation of cyclohexyl fluoride suggests BF_4^- participation in carbon–iodine bond cleavage. Reaction of **3d** and PPh_3 gives the substitution product $[Ph_3PC_6H_{11}]^+BF_4^-$ (24%), cyclohexyl fluoride (24%), cyclohexene (30%) and $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(I)$ (**7**, 95%). An analogous reaction of **3d** and PPN^+Br^- gives cyclohexene (57%) and **7** (99%).

Stable complexes of alkyl halides and transition metals are scarce.[1–5] Since Crabtree prepared the iridium methyl iodide complexes $[(H)_2Ir(PPh_3)_2(ICH_3)_2]^+X^-$ in pure form a decade ago, the vast majority of adducts isolated have been *primary* alkyl halides. Coordinated alkyl halides have been shown to be dramatically activated towards nucleophilic attack.[1,2,4] Thus, useful applications of secondary and tertiary alkyl halide complexes are readily envisioned. Further, when the metal fragment and alkyl halide are both chiral, there is the possibility that one alkyl halide enantiomer might selectively bind ("chiral recognition").

We have previously studied the synthesis, structure and reactivity of the chiral rhenium primary alkyl iodide complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICH_2R)]^+BF_4^-$ in detail.[4] With few exceptions, these compounds are easily isolated in pure form and in good to high yields from reactions of the substitution-labile dichloromethane complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ClCH_2Cl)]^+BF_4^-$ (**1**) and alkyl iodides (3–5 equiv.). We therefore sought to systematically define the scope of analogous secondary and tertiary alkyl iodide complexes that can be generated and/or isolated, and to compare their physical and chemical properties with those of the primary alkyl iodide complexes.

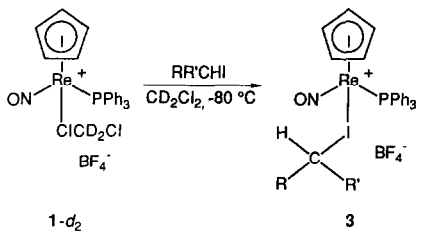
RESULTS

(1) *Synthesis of secondary alkyl iodide complexes*

The methyl complex $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CH_3)$ (**2**)[6] and an internal standard were dissolved in CD_2Cl_2 in an NMR tube and treated with $HBF_4\cdot OEt_2$ at −80°C. The generation of the previously reported deuterodichloromethane complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ClCD_2Cl)]^+BF_4^-$ (**1**-d_2)[5a] was verified by ^1H and ^{31}P NMR (−60°C). The sample was then frozen in liquid nitrogen and treated with 2 equiv. of (**a**) isopropyl iodide, (**b**) *sec*-butyl iodide, (**c**) cyclopentyl iodide and (**d**) cyclohexyl iodide, as shown in Scheme 1. These mixtures were warmed to −40°C in the NMR probe. Secondary alkyl iodide complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICHRR')]^+BF_4^-$ (**3a–d**) formed in 65–75% yields relative to a ^1H NMR resonance of the standard.



Scheme 1. Synthesis of secondary alkyl iodide complexes **3**.

When larger excesses of secondary alkyl iodides were employed, yields of **3a–d** were somewhat greater. However, extensive efforts to isolate pure complexes by this route were unsuccessful. Therefore, **3a–d** were characterized *in situ* by ^{1}H, ^{13}C and ^{31}P NMR spectroscopy, as summarized in Table 1. Properties were similar to those found earlier for primary alkyl iodide complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICH_2R)]^+BF_4^-$.[4] The ICH ^{13}C NMR resonances (47.9–58.3 ppm) showed diagnostic downfield shifts (22–29 ppm)[7] from those of the free alkyl iodides. The *sec*-butyl complex **3b**, which contains two stereocentres, gave two sets of resonances of equal intensity. Thus, the two possible rhenium/carbon configurational diastereomers formed in equal amounts.

Alternative routes to pure samples of **3** were sought. Thus, the methyl complex **2** was dissolved in *neat* cyclohexyl iodide and treated with $HBF_4 \cdot OEt_2$ at −40°C. Workup gave the cyclo-

[a] Recorded at 300 MHz in CD_2Cl_2 at −40°C and referenced to internal $CHDCl_2$ (5.32 ppm). All coupling constants are to ^{1}H and are in Hz.

[b] Recorded at 75 MHz in CD_2Cl_2 at −40°C and referenced to CD_2Cl_2 (53.8 ppm). All couplings are to ^{31}P and are in Hz. Assignments of phenyl carbon resonances were made as described in footnote c of Table 1 in ref. 8.

[c] Recorded at 121 MHz (unlocked) in CD_2Cl_2 at −40°C and referenced to external 85% H_3PO_4.

[d] Two diastereoisomers in a 50 : 50 ratio.

hexyl iodide complex **3d** in a 73% yield as an analytically pure, tan powder. An IR spectrum (CH_2Cl_2, −42°C) showed a ν(NO) at 1707 cm^{-1} (vs). This sample was used for all reactions described below.

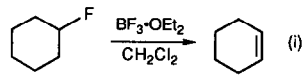
The chlorobenzene complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ClC_6H_5)]^+BF_4^-$ is sometimes superior to **1** as a precursor to complexes of the formula $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(L)]^+BF_4^-$.[5b] Analogous NMR-monitored reactions could not be conducted due to the precipitation of secondary alkyl iodide complexes (**3**) from the chlorobenzene solvent. However, a sample of isopropyl iodide complex **3a** was isolated from a preparative experiment. It was quite pure by ^1H and ^{31}P NMR, but not by microanalysis.

(2) *Thermal and substitution chemistry of cyclohexyl iodide complex* **3d**

A CD_2Cl_2 solution of **3d** and an internal standard was kept at room temperature in an NMR tube. Over the course of 2 days, conversion to two cyclopentadienyl-containing products was observed, as shown in Scheme 2. These were identified, on the basis of ^1H, ^{13}C and ^{31}P NMR spectra, as the previously characterized bridging iodide complex (*RR,SS*)-$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]_2I^+BF_4^-$ (**4**)[9] and bridging chloride complex (*SS,RR*)-$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]_2Cl^+BF_4^-$ (**5**).[5a] Yields were 33% and 36%, respectively, relative to an ^1H NMR resonance of the standard. In separate experiments, **4** and **5** were isolated.

The organic products derived from **3d** were assayed by ^1H NMR and gas chromatography (GLC). A mixture of cyclohexyl fluoride (δ 4.65, CHF) and cyclohexene (δ 5.87, =CH) was formed. No cyclohexyl iodide was detected. With time, the cyclohexyl fluoride diminished as the amount of cyclohexene increased until, at the end of 2 days, only cyclohexene (74%) remained.

An authentic sample of cyclohexyl fluoride was treated with $BF_3 \cdot OEt_2$ in CD_2Cl_2 at room temperature. Clean conversion to cyclohexene occurred over the course of 8 h, as assayed by ^1H NMR and GLC [eq. (1)]. However, cyclohexyl iodide and $BF_3 \cdot OEt_2$ did not react after 24 h under analogous conditions.



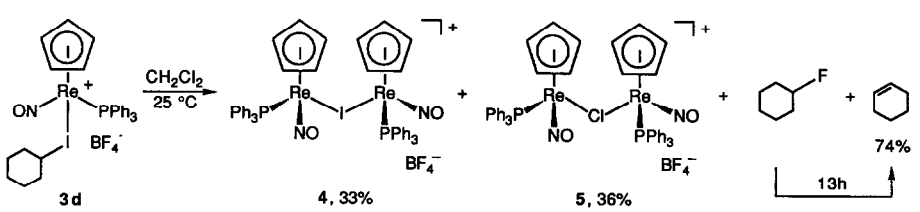
Next, a CD_2Cl_2 solution of **3d** and an internal standard was treated with CH_3CN (1.5 equiv.) at −80°C. The sample was warmed to room temperature. Over the course of 12 h, the acetonitrile complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(NCCH_3)]^+BF_4^-$ (**6**)[5a] formed as the only cyclopentadienyl and PPh_3-containing product, as assayed by ^1H and ^{31}P NMR. The yield was 80% relative to a ^1H NMR resonance of the standard. However, no cyclohexyl iodide was detected by ^1H NMR or GLC, rather, cyclohexene (87%) was the exclusive organic product. Some cyclohexyl fluoride was detected by GLC during the early stages of the reaction, but it subsequently converted to cyclohexene.

(3) *Reactions of cyclohexyl iodide complex* **3d** *and nucleophiles*

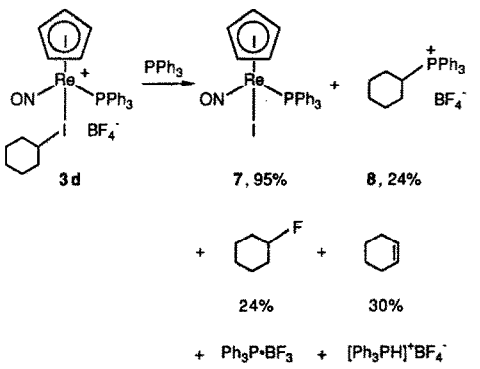
A CD_2Cl_2 solution of **3d** and an internal standard was frozen in liquid nitrogen. PPh_3 (1.4 equiv.) was then added, and the sample was gradually warmed to 0°C. After 8 h, the iodide complex $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(I)$ (**7**)[10] had formed in a 95% yield, as assayed by ^1H and ^{31}P NMR and shown in Scheme 3. However, three major cyclohexyl-derived products were present: the phosphonium salt $[Ph_3PC_6H_{11}]^+BF_4^-$ (**8**, 24%), cyclohexyl fluoride (24%) and cyclohexene (30%). The ratio of cyclohexyl fluoride and cyclohexene did not change significantly with time.

An authentic sample of **8** was prepared from the previously characterized bromide salt $[Ph_3PC_6H_{11}]^+Br^-$,[11] as described in the Experimental. Also, cyclohexyl iodide and PPh_3 (2 equiv.) did not independently react in CH_2Cl_2 at room temperature (24 h). This shows that the cyclohexyl iodide ligand in **3d** is activated towards attack by PPh_3.

Two additional phosphorus-containing products were evident in the ^{31}P NMR spectrum of the **3d**/PPh_3 reaction mixture. These were not quanti-



Scheme 2. Thermal decomposition of cyclohexyl iodide complex **3d**.



Scheme 3. Reaction of cyclohexyl iodide complex **3d** and PPh_3.

fied, but were assigned as $[Ph_3PH]^+BF_4^-$ (4.45 ppm, d, J(PH) 527.0 Hz) and $Ph_3P \cdot BF_3$ (−5.01 ppm, br, s). The large coupling in the former is diagnostic of a phosphonium salt phosphorus–hydrogen bond.[12] Also, the fluorosulphate analogue $[Ph_3PH]^+FSO_3^-$ has been previously shown to give a similar ^{31}P NMR resonance (CCl_4: 5.4 ppm, d, J(PH) 510 Hz).[13] Accordingly, when a CD_2Cl_2 solution of PPh_3 was treated with $HBF_4 \cdot OEt_2$ (0.7 equiv.), a 4.5 ppm doublet was cleanly generated. The Lewis acid/base adduct $Ph_3P \cdot BF_3$ has also been previously characterized.[14] When a CD_2Cl_2 solution of PPh_3 was analogously treated with $BF_3 \cdot OEt_2$, a broad resonance appeared at −5.0 ppm.

Next, a similar reaction was conducted with **3d** and PPN^+Br^-.[15] The mixture was kept at −40°C for 12 h, and then assayed by ^1H and ^{31}P NMR at room temperature. The iodide complex **7** formed in a 99% yield. However, cyclohexene (57%) was the only organic product detected. An aliquot of the mixture was taken when the sample was at −40°C and analysed by GLC. Some cyclohexyl flouride was present.

(4) *Reactions with tertiary alkyl iodides*

A "less bulky", bridgehead tertiary alkyl iodide was sought for scout experiments. Thus, 1-adamantyl iodide (3 equiv.)[16] was reacted with **1**-d_2 in the presence of an internal standard, as described for the secondary alkyl iodides above. Over the course of several hours at −40°C, a multitude of products formed. The major species (*ca* 20%) exhibited plausible NMR resonances for a 1-adamantyl iodide complex (−20°C: ^1H NMR, δ 5.57, s; ^{31}P NMR 12.1 ppm, s). When the sample was warmed to room temperature, bridging halide complexes **4** (δ 5.42, 49%) and **5** (δ 5.41, 40%) formed. The significant yield of bridging iodide complex **4** also suggests that an appreciable amount of the target complex was generated.

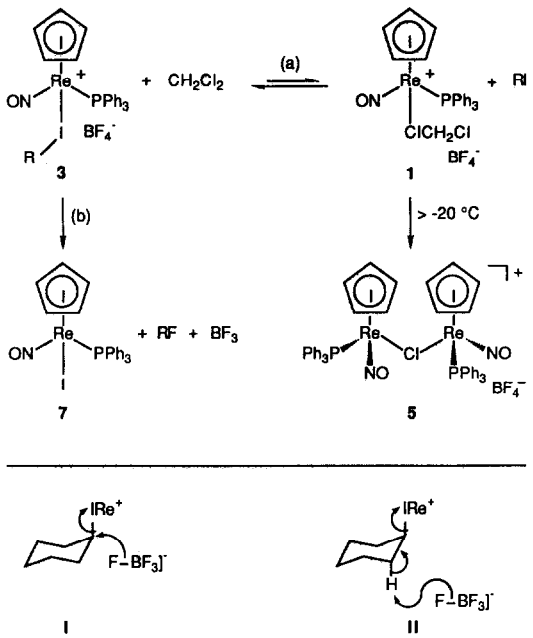
DISCUSSION

We previously reported that isopropyl iodide is about 50% as reactive as methyl iodide, and 67% as reactive as ethyl iodide towards the dichloromethane complex **1** at −41°C.[4a] Thus, secondary alkyl iodides are less nucleophilic than primary alkyl iodides, or poorer Lewis bases in a kinetic sense. This follows logically from their increased bulk. Secondary alkyl iodides are likely poorer Lewis bases in the conventional thermodynamic sense as well. We attempted to demonstrate this by treating cyclohexyl iodide complex **3d** with ethyl iodide (3 equiv.) in CD_2Cl_2 at 0°C. However, the previously characterized[4a] ethyl iodide complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICH_2CH_3)]^+BF_4^-$ was not detected by ^1H or ^{31}P NMR. Rather, the independent decomposition of **3d** occurred.

The isolation of secondary alkyl iodide complexes **3** from preparations involving dichloromethane solvent is in all cases complicated by the formation of the bridging halide complexes $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]_2X^+BF_4^-$. The probable key features of these competing decomposition pathways are sketched in Scheme 4. First, solvolytic displacement of the alkyl iodide ligands in **3** can occur to give dichloromethane complex **1** [step (a)], which rapidly decomposes to the bridging chloride complex **5** above −20°C.[5a] This substitution is likely faster and less endothermic than for the corresponding primary alkyl iodide complexes, accounting for the observed stability trend.

Secondly, carbon–iodine bond cleavage can occur to give the iodide complex **7** [step (b)]. Complex **7** can in turn react with **3** or **1** to give bridging iodide complex **4**.[9] The formation of cyclohexyl fluoride in Scheme 2 suggests that the weakly coordinating[17] BF_4^- anion can participate in the carbon–iodine bond cleavage step, as sketched in **I** (Scheme 4). Alternatively, the carbon–iodine bond might undergo heterolysis, and the carbocation of the resulting intimate "ion pair" could react with BF_4^-. Since some cyclohexene seems to form directly from **3d**, it is also possible that BF_4^- serves as the base in an E2 elimination step, as shown in **II**.

The attack of BF_4^- upon coordinated dichloromethane has been proposed as a key step in the decomposition of **1** to bridging chloride complex **5**.[5a] However, the expected primary product FCH_2Cl could not be conclusively identified in the reaction mixture. Thus, the formation of cyclohexyl



Scheme 4. Some possible decomposition pathways for alkyl iodide complexes **3**.

fluoride from **3d** provides welcome precedent for this step. The anion PF_6^- has been shown to be a poorer fluoride ion donor than BF_4^-.[17] Thus, PF_6^- salts of **3** would likely be somewhat more stable. However, $HPF_6 \cdot OEt_2$, which is required for the formation of the precursor dichloromethane complex, no longer appears to be commercially available in adequate purity.

The mass balance for the organic and inorganic decomposition products of **3d** is only fair. Note that steps **I** and **II** (Scheme 4) give the strong acids BF_3 and HF. These in turn can likely react with many of the primary products. Also, the iodide complex **7** has been shown to undergo a "transalkylation" reaction with dichloromethane complex **1** to give the iodochloromethane complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICH_2Cl)]^+BF_4^-$.[9]

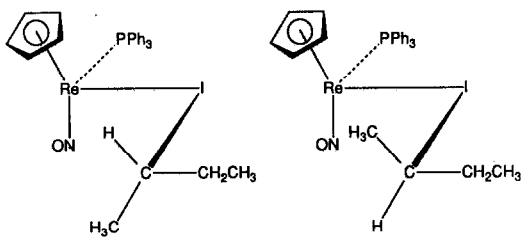
In the reaction of **3d** and PPh_3 (Scheme 3), PPh_3 serves both as a nucleophile (to give phosphonium salt **8**) or a base (to give cyclohexene). Pathways analogous to **I** and **II** (Scheme 4) are likely involved. The formation of comparable amounts of cyclohexyl fluoride and **8** suggests that BF_4^- and PPh_3 attack upon the cyclohexyl iodide ligand is competitive. The BF_3 by-product from the former process subsequently binds to PPh_3, therefore, cyclohexyl fluoride does not convert to cyclohexene as in Scheme 2 and eq. (1). Interestingly, cyclohexyl bromide and PPh_3 react to give the phosphonium salt $[Ph_3PC_6H_{11}]^+Br^-$, without any significant amount of competing elimination.[11]

In contrast to PPh_3, PPN^+Br^- appears to function chiefly as a base towards **3d**. However, the formation of cyclohexene (87%) in the reaction of **3d** and acetonitrile is more surprising. Analogous primary iodide complexes and acetonitrile react to give mainly simple substitution products—acetonitrile complex **6** (82–87%) and free alkyl halides (72–82%).[4a] This suggests a more complex mechanistic sequence, possibly involving the BF_4^- anion, with **3d**.

Crabtree has previously reported the isolation of chiral ruthenium isopropyl iodide and cyclohexyl iodide complexes $[(\eta^5\text{-}C_5H_5)Ru(CO)(PPh_3)(ICHRR)]^+PF_6^-$.[2c] He finds that the former undergoes clean reactions with chloride ions to give isopropyl chloride, and pyridine to give the corresponding pyridinium salt. However, the latter gives only cyclohexene upon reactions with nucleophiles. Cyclohexyl halides are well-known to be more susceptible to elimination reactions than acyclic analogues.

We have previously shown that the methyl iodide complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICH_3)]^+BF_4^-$ exchanges only slowly with CD_3I (15 equiv.) in CD_2Cl_2 at room temperature.[4a] Also, the diastereotopic methyl groups of isopropyl iodide complex **3a** give distinct ^1H and ^{13}C NMR resonances (Table 1). These would be equivalenced by any rapid dissociative process. Thus, the reactions in Scheme 1 are probably under kinetic control.

This is likely relevant to the lack of diastereoselectivity in the formation of *sec*-butyl iodide complex **3b**. Based upon crystal structures of a primary alkyl iodide complex and bridging iodide complex **4**,[4a,9] the diastereomers of **3b** likely adopt the structures **III** and **IV**. In each, the large *C*—I



III (*RS,SR*)
(favored, CH_3 and C_5H_5 *anti*)

IV (*RR,SS*)
(disfavored, CH_3 and C_5H_5 *syn*)

substituent, ethyl, is oriented *anti* to the I—Re bond. We had expected **III** to be more stable due to reduced steric interactions between the cyclopentadienyl ligand and the remaining *C*—I substituents. An analogous consideration accounts for the very high diastereoselectivity in the formation of bridging halide complexes **4** and **5**.[9] Thus, we speculate that significant diastereoselection might be realized under thermodynamically controlled conditions.

In summary, this study has established that secondary alkyl iodide complexes (**3**) can be synthesized and in some cases isolated in pure form. However, they are considerably more labile than analogous primary alkyl iodide complexes. Although the cyclohexyl iodide ligand in **3d** is activated towards nucleophilic attack, competing reactions involving the BF_4^- anion are observed and elimination products usually dominate.

EXPERIMENTAL

General

All reactions were conducted under a dry nitrogen atmosphere. IR spectra were recorded on a Mattson Polaris FT-IR spectrometer. NMR spectra were recorded on Varian XL-300 spectrometers. The following chemical shift standards were used: ^{1}H, residual $CHDCl_2$ (δ 5.32); ^{13}C, CD_2Cl_2 (53.8 ppm); ^{31}P, external 85% H_3PO_4 (0.00 ppm). Mass spectra were obtained on a VG 770 spectrometer. Analytical gas–liquid chromatography (GLC) was conducted on a Hewlett Packard 5890 chromatograph utilizing a capillary column (cross-linked 5% phenyl methyl silicone, 25 m × 0.2 mm × 0.33 mm film) and a 0.6 cm^3 min^{-1} helium flow. Microanalyses were conducted by Atlantic Microlab. Melting points were determined in evacuated capillaries.[18]

Solvents, reagents and standards were utilized as follows: CH_2Cl_2 and CH_3CN, distilled from P_2O_5; hexane, distilled from sodium; methanol, distilled from magnesium; CD_2Cl_2, distilled from CaH_2; $HBF_4 \cdot OEt_2$ (Aldrich), standardized as described previously;[5a] alkyl iodides (Aldrich), filtered through a 3.5 cm alumina column, distilled, and stored at −10°C over copper in the dark; PPh_3 (Aldrich), recrystallized from benzene; Ph_3SiCH_3 (Pfaltz & Bauer), $BF_3 \cdot OEt_2$, and $AgBF_4$ (Aldrich), used as received; cyclohexyl flouride (Pfaltz & Bauer) was assayed by GLC and returned to the vendor unless pure. The salt[15,19] PPN^+Br^- and 1-adamantyl iodide[16] were prepared by literature procedures.

Isolation of $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(IC_6H_{11})]^+ BF_4^-$ (**3d**). A Schlenk flask was charged with $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(CH_3)$ (**2**;[6] 0.339 g, 0.612 mmol), cyclohexyl iodide (3 cm^3), and a stir bar. The mixture was gently warmed to solubilize **2**, and then cooled to −40°C (CH_3CN/dry ice). Then $HBF_4 \cdot OEt_2$ (0.085 cm^3, 0.67 mmol) was added with stirring. The mixture was kept at −40°C for 50 min and then hexane was added. A precipitate formed, which washed with hexane (2 × 3 cm^3) and dried *in vacuo* to give **3d** as a tan powder (0.374 g, 0.447 mmol, 73%), m.p. 100–105°C, dec. Mass spectrum [(+)-FAB (7 kV, Ar, 3-nitrobenzyl alcohol/$CHCl_3$), *m/z* (relative intensity), ^{187}Re]: 754 (M^+, 24%), 671 (M^+-C_6H_{11}, 41%), 544 (M^+-IC_6H_{11}, 57%). Found: C, 41.6; H, 3.8. Calc. for $C_{29}H_{21}BF_4INOPRe$: C, 41.4; H, 3.7%.

Solutions of $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICHRR')]^+ BF_4^-$ (**3**). The following procedure is representative. A 5 mm NMR tube was charged with **2** (0.0453 g, 0.0811 mmol), Ph_3SiCH_3 as a standard (0.0176 g, 0.0641 mmol) and CD_2Cl_2 (0.8 cm^3), and was capped with a septum. The tube was cooled to −80°C, and $HBF_4 \cdot OEt_2$ (0.008 cm^3, 0.073 mmol; 0.85–0.90 equiv.) was added. Next, ^{1}H and ^{31}P NMR spectra were acquired at −60°C, and showed the formation of $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ClCD_2Cl)]^+$ (**1**-d_2) in an 85% yield, based upon limiting $HBF_4 \cdot OEt_2$. The sample was frozen in liquid nitrogen, and isopropyl iodide (0.0124 cm^3, 0.124 mmol, 2 equiv.) was added. The tube was slowly warmed to −60°C. Then ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded (negligible reaction). The sample was kept for 8–10 h at −40°C. Subsequent NMR spectra showed the formation of $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(ICH(CH_3)_2)]^+BF_4^-$ (**3a**, 0.047 mmol relative to the Ph_3SiCH_3 ^{1}H NMR resonance) in a 75% yield based upon **1**-d_2. Table 1 shows the data obtained.

Decomposition of **3d**. A 5 mm NMR tube was charged with **3d** (0.0183 g, 0.0218 mmol), Ph_3SiCH_3 as a standard (0.0123 g, 0.0448 mmol) and CD_2Cl_2 (0.80 cm^3), and was capped with a septum. The tube was kept at room temperature and ^{1}H and ^{31}P NMR spectra were periodically recorded. After 48 h, no **3d** remained. The yields of (*RR,SS*)-$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]_2I^+BF_4^-$ (**4**, 0.0072 mmol, 33%),[9] (*SS,RR*)-$[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)]_2Cl^+BF_4^-$ (**5**, 0.0078 mmol, 36%)[5a] and cyclohexene (0.0083 mmol, 74%) were determined by integration of ^{1}H NMR resonances (C_5H_5, =CH vs Ph_3SiCH_3). The cyclohexene yield was confirmed by GLC. See text for other data.

Reaction of **3d** *and acetonitrile*. A 5 mm NMR tube was charged with **3d** (0.0438 g, 0.0521 mmol), Ph_3SiCH_3 standard (0.0157 g, 0.0599 mmol), and was capped with a septum. The sample was cooled to −80°C, and CD_2Cl_2 (0.8 cm^3) and CH_3CN (0.0040 cm^3, 0.078 mmol) were added via a syringe. The sample was warmed to room temperature, and ^{1}H and ^{31}P NMR spectra were periodically recorded. After 12 h, no **3d** remained. The yields of $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(NCCH_3)]^+BF_4^-$ (**6**, 0.0417 mmol, 80%)[5a] and cyclohexene (0.0453 mmol, 87%) were determined by integration of ^{1}H NMR resonances (C_5H_5, =CH vs Ph_3SiCH_3).

Reaction of **3d** *and* PPh_3. A 5 mm NMR tube was charged with **3d** (0.0366 g, 0.0435 mmol),

Ph_3SiCH_3 as a standard (0.0143 g, 0.0521 mmol), and was capped with a septum. The sample was frozen in liquid nitrogen, CD_2Cl_2 (0.8 cm^3) was added, followed by solid PPh_3 (0.0160 g, 0.0610 mmol). The sample was slowly warmed to 0°C, and ^1H and ^{31}P NMR spectra were periodically recorded. After 8 h, no **3d** remained. The yields of $(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(I)$ (**7**, 0.0413 mmol, 95%),[10] $[Ph_3PC_6H_{11}]^+BF_4^-$ (**8**, 0.0104 mmol, 24%), cyclohexyl fluoride (0.0104 mmol, 24%) and cyclohexene (0.0131 mmol, 30%) were determined by integration of ^1H NMR resonances (C_5H_5, CHX, =CH vs Ph_3SiCH_3). The cyclohexyl fluoride and cyclohexene yields were confirmed by GLC. See text for other data.

Reaction of **3d** *and* PPN^+Br^-. A 5 mm NMR tube was charged with **3d** (0.0244 g, 0.0290 mmol), Ph_3SiCH_3 standard (0.0127 g, 0.0463 mmol), and was capped with a septum. The sample was frozen in liquid nitrogen, CD_2Cl_2 (0.8 cm^3) was added, followed by solid PPN^+Br^- (0.0210 g, 0.0340 mmol). The sample was kept at −40°C for 12 h and then ^1H and ^{31}P NMR spectra were recorded at room temperature. The yields of **7** (0.0287 mmol, 99%) and cyclohexene (0.0281 mmol, 57%) were determined by integration of ^1H NMR resonances (C_5H_5, =CH vs Ph_3SiCH_3). See text for other data.

Preparation of $[Ph_3PC_6H_{11}]^+BF_4^-$ (**8**). A flask was charged with $[Ph_3PC_6H_{11}]^+Br^-$ (0.654 g, 1.54 mmol),[11] $AgBF_4$ (0.352 g, 1.81 mmol), methanol (25 cm^3), and a stir bar. The mixture was stirred for 15 min and was then poured through a 3 cm pad of Celite on a coarse glass frit. The solvent was removed from the filtrate by rotary evaporation. A white microcrystalline powder formed, which was recrystallized from CH_2Cl_2/ether and dried under an oil pump vacuum to give **8** (0.646 g, 1.49 mmol, 94%), m.p. 241°C. IR (cm^{-1}, KBr) ν(BF) 1121 vs, 1054 vs, 996 vs; ^1H NMR (δ, CD_2Cl_2, 25°C) 7.84–7.87 (m, $3C_6H_5$), 3.67 (m, PCH), 2.11 (m, CH_2), 1.83 (m, CH_2), 1.71 (m, CH_2), 1.16 (m, CH_2); $^{13}C\{^1H\}$ NMR (ppm, CD_2Cl_2) 135.2 (d, J(CP) 2.9 Hz, *p*-Ph), 133.8 (d, J(CP) 9.4 Hz, *m*-Ph), 130.7 (d, J(CP) 12.6 Hz, *o*-Ph), 117.3 (d, J(CP) 83.5 Hz, *i*-Ph), 31.0 (d, J(CP) 46.9 Hz, PCH), 26.8 (d, J(CP) 3.0 Hz, $PCCH_2$),[20] 26.0 (d, J(CP) 13.8 Hz, $PCCCH_2$),[20] 25.6 (s, CH_2); $^{31}P\{^1H\}$ (ppm, CD_2Cl_2) 26.7 (s). Found: C, 66.2; H, 6.0. Calc. for $C_{24}H_{28}NF_4P$: C, 66.7; H, 6.1%.

(*Received* 12 *December* 1990; *accepted* 14 *May* 1991)

Abstract—Cu(dibenzo[b,i][1,4,8,11]tetraaza[14]annulene), Cu(dbTAA), Cu(dinaphtho-[b,i][1,4,8,11]tetraaza[14]annulene), Cu(dnTAA), Cu(diphenanthro[b,i][1,4,8,11]tetraaza [14]annulene) and Cu(dpTAA) complexes have been used for synthesizing new conductive materials. Chemical oxidation of the three compounds in acetone slurries by variable amounts of iodine yielded microcrystalline conductive powders with a wide range of stoichiometries. Thermal stability of the oxidized materials was investigated by TGA and DTGA techniques showing a relationship between solid phase stability and iodine content and, together with IR data, suggests the presence of a single phase. Raman spectra show strong scatterings attributable to I_3^- (107 cm^{-1}) and (160 cm^{-1}) I_5^- polyiodides, the latter occurs only in highly iodinated complexes (I/Cu ratio larger than three) and the I_2 presence can be excluded. Electrical conductivity measurements of powder samples of the oxidized compounds exhibit some dependence on the iodine content in the I/Cu ratio range 0–0.9. The temperature response of the conductivity of the oxidized compounds, in the range 70–220 K, is interpretable in terms of an activated formation of carriers. ESR spectra, static magnetic susceptibility and IR data as a function of the I/Cu ratio suggest that the oxidative process involves not only the copper unpaired electron, but also electrons associated with delocalized ligand orbitals on the macrocycle. Large enhancement of the conductivity is shown by Cu(dpTAA)$I_{0.2}$ (1.5 S cm^{-1}) and the temperature dependance of conductivity shows metallic behaviour starting from 200 K.

Partially oxidized metalloorganic complexes with aromatic ligands have provided[1–3] an interesting class of molecular conductors. Partial iodine oxidation of tetraazaannulene complexes of various transition metals promises an interesting class of molecular conductors. As a matter of fact, the role played by the nature of the ligand and the degree of oxidation on their properties has not been systematically investigated. However some studies on metal(II) (M = Ni, Cu, Co, Pd) complexes of the dianionic ligands dibenzo[b,i][1,4,8,11]tetraaza [14]annulene^{2-}, (dbTAA),[1,3–6] 5,7,12,14tetramethyldibenzo [b,i] [1,4,8,11] tetraaza [14] annulene^{2-}, (dbTMTAA)[1,7] and of others, variously substituted dibenzo [b,i] [1,4,8,11] tetraaza [14] annulenes^{2-} [1,3] have been undertaken. Among these, the unsubstituted dbTAA complexes give rise to the most conductive materials and show very promising transport parameters slightly smaller than those of "Molecular metals", like (NiPc)I (Pc = Phthalocyanine).[10,11]

In this paper, as part of a systematic study on

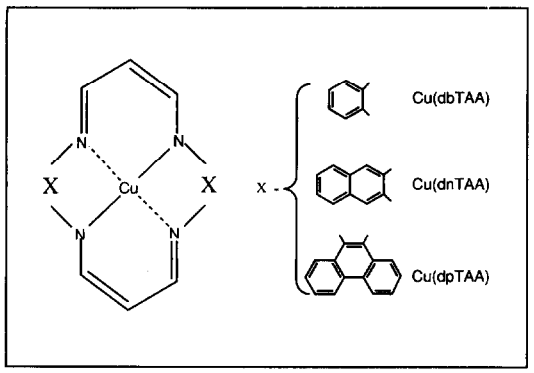

Fig. 1. Scheme of the three complexes.

the properties of these compounds, we present the preparation of the I_2 oxidized compounds of copper(II) with new tetraaza[14]annulene macrocyclic dianionic ligands[12] with larger aromatic moieties, i.e. dinaphtho[b,i][1,4,8,11]tetraaza[14]annulene^{2-} and diphenanthro[b,i][1,4,8,11]tetraaza[14]annulene^{2-} [hereafter $(dnTAA)^{2-}$ and $(dpTAA)^{2-}$, respectively (Fig. 1)]. Our purpose is to gain insight into the influence of the degree of oxidation and the "dimension" of the macrocycle on the solid state conductivity of the material. The results concerning the materials obtained by iodine oxidation of these complexes are discussed in comparison with new data for the analogous copper(II)dibenzo[b,i][1,4,8,11]tetraaza[14]annulene complex, Cu(dbTAA).[12]

EXPERIMENTAL

Reagents

Cu(dnTAA) and Cu(dpTAA) were synthesized following the procedures set up in our laboratory,[12] whereas Cu(dbTAA) was synthesized according to the experimental procedure of Hunziker *et al.* and Wuu *et al.*[3]

Iodination of the copper complexes: procedure. In order to prepare polycrystalline samples of various stoichiometries, finely powdered Cu(dbTAA), Cu(dnTAA) and Cu(dpTAA) in acetone were treated with increasing amounts of iodine dissolved in acetone, in the dark. The reactions were performed by stirring for 18 h at room temperature in a flask stopped with a septum. In a typical experiment Cu(dbTAA) (0.174 g, 0.500 mmol) in 20 cm^3 of acetone was treated with I_2 (0.635 g, 2.500 mmol) dissolved in 15 cm^3 of acetone. The black microcrystalline compound obtained was purified by removing the solvent and the unreacted iodine under a stream of nitrogen. The compound, washed with 5–10 cm^3 of acetone and dried at 40°C and 25 mmHg, was characterized as $Cu(dbTAA)I_{3.3}$.

Physical methods characterization

Spectroscopy. IR spectra were recorded as Nujol mulls with a Perkin–Elmer Model 883 spectrophotometer. Raman spectra were obtained with a Ramanor HG2S spectrometer employing 514.5 nm excitation (250 mW argon ion laser power filtered at 30%). The samples, in glass capillaries, were spun at 3000 rpm. The ESR spectra were recorded with a Bruker 200D spectrometer operating at the X band and equipped with an Aspect 2000 computer for spectra accumulation and magnetic parameter calculation. Susceptibility measurements were carried out by a susceptometer AZTEC-DSM5 operating at 13,500 G equipped with an electromagnet Bruker BE15.

Thermogravimetric analysis. TGA data were obtained by using a B85 Setaram thermal analyser equipped with TGC 85 controller module and a BBC(Goerz Metrawatt) Servogor 120 recorder. Measurements were carried out using a platinum sample boat under a nitrogen atmosphere. A nitrogen flow rate of 50 cm^3 min^{-1} and programmed heating rates of 20°C min^{-1} were employed. Scans were made from room temperature to 600°C. Initial sample mass was nominally 8.0 mg. Iodine contents were directly determined from the thermograms. All the obtained data were in good agreement with the elemental analyses.

Conductivity measurements. Electrical conductivity data by both the linear two-probe and the four-probe van der Pauw[13] methods were obtained. With the linear two-probe technique only room temperature data were acquired. Micropellets, 1 mm in diameter and *ca* 1 mm thick, were introduced in a glass capillary. In the case of van der Pauw measurements sample disks (13-mm diameter, about 0.5-mm thick) were used. The disks were formed using an evacuable die and a Carver press at 12 tons cm^{-2}. Thickness and diameter of samples and probe spacing were determined with the aid of a microscope. Electrical current to the sample was supplied by a Hewlett Packard precision DC current source 6186C. Output DC voltages were detected by Hewlett Packard 3478 A Multimeter. The disks were mounted over zapphire monocrystal, electrical contacts to the samples were made with a palladium paste. The investigated temperature range was between 77 K and room temperature. For measurements at temperatures below room temperature a refrigerator system (Air Product-USA, model LT-3-110) supplied with APD-E

digital indicating temperature controller and equipped with a shroud for conductivity measurements was used. The measurement procedure included: (i) verification of electrical isolation between the sample and mount; (ii) resistance measurements between all four electrodes as a function of current to check for nonohmic behaviour, contact resistance, and sample integrity; and (iii) measurements at zero current to the sample to check for stray voltages. Conductivity data have been collected at least five times on each sample and at least three micropellets with the same I/Cu ratio have been used giving rise to an error of ± 0.05 on $\log \sigma$ (see Table 1).

RESULTS

Iodination chemistry and characterization of the materials

Table 1 reports the most relevant characterization data of iodinated complexes of Cu(dbTAA), Cu(dnTAA) and Cu(dpTAA) prepared according to the outlined procedure. The oxidation afforded black coloured microcrystalline powders for Cu(dbTAA) and Cu(dnTAA), and from red to dark purple powders, depending on iodine content, for Cu(dpTAA). The response of the three complexes to oxidation has been found strongly dependent on the iodine concentration for Cu(dbTAA) and Cu(dnTAA); the iodine uptake reached maximum values for Cu(dbTAA) and Cu(dnTAA) in about 2 h, and in 24 h for Cu(dpTAA); the same general behaviour was also found with iodinating slurries in n-pentane, CH_2Cl_2 or $CHCl_3$; the oxidized compounds were air stable for months, without an appreciable iodine loss. The percentage of iodine reacted is always within 10–50% of the amount used. However, the iodine uptake is not easily predictable and shows large sensitivity to the experimental conditions. Owing to this sensitivity we determined the I/Cu ratio for each sample used by thermogravimetric measurements and elemental analysis (see Table 1) before characterization and physical measurements.

[c] Values reported with estimated errors of ± 0.05.

Thermogravimetric measurements

TGA curves of the three unoxidized complexes are featureless up to 370, 410 and 470°C, respectively. A large weight loss is starting at these temperatures as confirmed by DTGA curves, the shape of which is attributable to sublimation with partial decomposition. The maxima of the differential weight loss lie at 420, 460 and 520°C, respectively. After iodination, the position and the shape of the DTGA curves do not change appreciably at these temperatures. Furthermore the de-iodinated compounds showed the same composition and the same spectroscopic (IR and UV–vis) behaviour as the unoxidized ones. This shows that the iodination process is fully reversible and, likely, does not modify the chemical structure of the complexes.

The iodinated complexes with an iodination degree up to $x = 3$ showed a single step weight loss with sharp and symmetrical DTGA curves centred at 270°C (Cu(dbTAA)I_x and Cu(dnTAA)I_x) and at 180°C (Cu(dpTAA)I_x). Furthermore, Raman spectra show in the range 50–650 cm^{-1} only a strong absorption at 107 cm^{-1} and the superior harmonics at 214, 322 and 438 cm^{-1}, attributable[14,15] to the symmetric stretching mode of I_3^-. These evidences lead to the conclusion that the main iodine species present in the solid phase is I_3^-. Compounds with a higher iodination degree ($x > 3$) showed one more weight loss at 240°C [Cu(dbTAA)I_x and Cu(dnTAA)I_x] and at 150°C [Cu(dpTAA)I_x] attributable to the I_5^- dissociation in I_3^- and I_2, as confirmed by Raman spectroscopy that showed an additional signal at 167 cm^{-1}. This behaviour is similar to that found for some silicon and germanium O-bridged phthalocyanines[14] and Ni(opd)$_2I_x$ [opd = o-phenylendimine][16] complexes although higher thermal stability is displayed by the presently investigated compounds. We exclude the presence of I_2, on the basis of the lack of any Raman band around 207 cm^{-1}, and of I^-, by analogy with previous works[15,17] on iodinated molecular crystals, although this species is undetectable by any of the spectroscopic techniques utilized in this study.

Two trends can be summarized by DTGA: (a) the lower the iodine content the higher the thermal stability of the materials; (b) at comparable x values the DTGA maxima are similar for Cu(dbTAA)I_x and Cu(dnTAA)I_x, both are higher than those found for Cu(dpTAA)I_x by about 100°C.

Electrical conductivity

Conductivity data at room temperature by both the linear two-probe technique on micropellets and van der Pauw's[13] method on pressed discs are in excellent agreement for all the samples. Electrical conductivity data for Cu(dbTAA)I_x, Cu(dnTAA)I_x and Cu(dpTAA)I_x at room temperature are reported in Table 1 and in Fig. 2(b), as a function of the I/Cu ratio determined by DTG. Within the range 0–1 of x, the absolute values of the electrical conductivity at the same x value follow the order Cu(dpTAA)I_x > Cu(dnTAA)I_x > Cu(dbTAA)I_x. The conductivity reaches a pronounced maximum for all the three complexes at a very low x value (0.2). Furthermore Cu(dnTAA) and Cu(dpTAA), also in the unoxidized form, exhibit a not negligible conductive ability. The electrical conductivity, with respect to the unoxidized compounds increases by a factor of 10^8 [Cu(dbTAA)], 10^4 [Cu(dnTAA)] and 10^5 [Cu(dpTAA)]. For x values larger than 0.2 the conductivity drops to nearly constant values for the three oxidized complexes.

This last observation matches with data reported

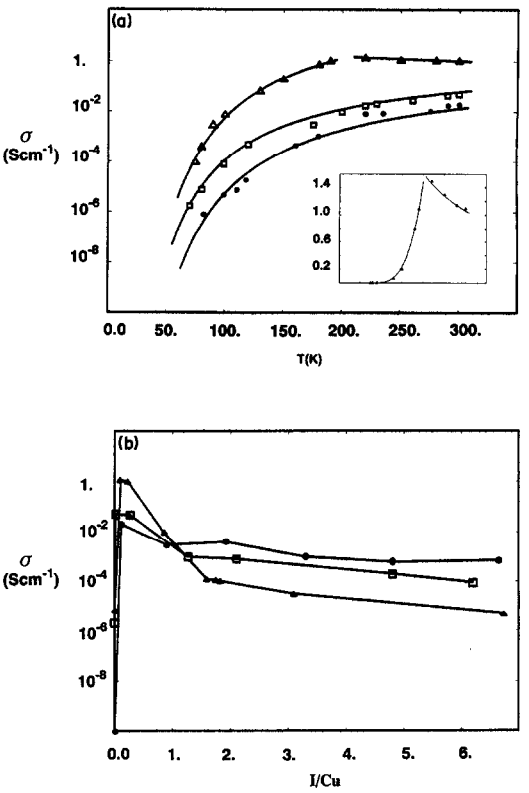

Fig. 2. (a) Temperature dependence of the conductivity. [Plot of log(σ) versus T for Cu(dbTTA)$I_{0.11}$ (●); Cu(dnTAA)$I_{0.10}$ (□), Cu(dpTTA)$I_{0.22}$ (△).] Plot of (σ, T) is reported in the insert for the dpTAA complex in order to point out the different behaviour of the data above and below 200 K. (b) Variation of the conductivity as a function of iodine content. Cu(dbTAA)I_x; Cu(dnTAA)I_x; Cu(dpTAA)I_x. The lines meeting the experimental points are drawn only for eye guide.

for M(dbTAA)I_x powders (M = Cu, Ni, Co, Fe) at x values greater than 0.7, where the conductivity is almost independent of iodination degree. Some authors[3a] have incorrectly concluded that the iodination content does not affect significantly the conductivity of M(dbTAA) oxidized powders, whereas our data point out a strong correlation between iodination extent and electrical conductivity within the range 0–0.9 of x. This correlation parallels that found for $NiPcI_x$ powders,[18] where high conductivity is reached at x values in the range 0.5–1.44.

Although the nature of the correlation between conductivity and degree of iodination might suggest an interpretation based on a percolation model, DTGA results exclude this hypothesis. Moreover IR spectra for all the compounds show a single absorption for the C=N stretching which strongly support the exclusion of the presence of a multiple phase in the iodinated compounds.

The electrical conductivity of $Cu(dbTAA)I_{0.11}$, $Cu(dnTAA)I_{0.10}$ and $Cu(dpTAA)I_{0.22}$ as functions of the temperature is reported in Fig. 2(a). $Cu(dpTAA)I_{0.22}$ shows a "metal like" behaviour ($d\sigma/dt < 0$) between 300 and 220 K, besides near 200 K a semiconducting transition is observed. This trend is clearly shown in the insert of Fig. 2(a). Data between 80 and 200 K are fitted by the following relation valid for activated carrier formation:[19,20]

$$\sigma = AT^{-\alpha}e^{-E_a/2RT} \text{(with } \alpha = 1.02 \text{ and } E_a = 0.21 \text{ eV)}.$$

Moreover the same relation does not fit the data in the whole temperature range, but the data are fitted in the temperature range (200, 300) K by the simple relation $\sigma = AT^{-\alpha}$, where $A = 2.6$ and $\alpha = 1.02$. In the range (80, 220) K both Cu(dbTAA) and Cu(dnTAA) show semiconductive behaviour. The experimental data, in this range, are fitted by the relation $\sigma = A'e^{-E_a/RT}$, where the parameter A' and E_a are 1.08, 0.21 and 1.09, 0.16 for dbTAA and dpTAA complexes, respectively.

A semiconductive behaviour, described by this last equation, is observed in the series $Cu(dbTAA)I_x$, $Cu(dnTAA)I_x$ and $Cu(dpTAA)I_x$, at a higher I/Cu ratio ($x > 5$).

Magnetic susceptibility

The static paramagnetic susceptibility ($\chi^S M$) of $Cu(dbTAA)I_x$, $Cu(dnTAA)_x$ and $Cu(dpTAA)_x$ oxidized complexes have been measured with variable iodine content up to $x = 3$. The results show an analogous trend for the three species and we will discuss here the data obtained for $Cu(dnTAA)I_x$ at x values, 0.26, 1.26 and 2.10. In this species the dominant form of iodine is I_3^- and it is possible to indicate the compounds in the mixed valence form: $[Cu(dnTAA)]^+_{0.09}(I_3^-)_{0.09}$; $[Cu(dnTAA)]^+_{0.42}(I_3^-)_{0.42}$; and $[Cu(dnTAA)]^+_{0.70}(I_3^-)_{0.70}$. The magnetic susceptibility, taking into account the correction for the diamagnetism of the tetraazaannulene ring, of the metal and of the I_3^- polyiodide, are $9.69 \cdot 10^{-4}$, $9.29 \cdot 10^{-4}$ and $9.40 \cdot 10^{-4}$ emu mol^{-1}, respectively. Assuming the same approximation we used[12] for the unoxidized complexes ($1.32 \cdot 10^{-3}$, $1.33 \cdot 10^{-3}$ and $1.28 \cdot 10^{-3}$ emu mol^{-1}, respectively), these values indicate 0.95, 0.46 and 0.46 unpaired electrons for the metallomacrocycle, respectively.

ESR results

The ESR spectra of the oxidized species $Cu(dbTAA)I_x$, increasing the iodine amount, show first a broadening and then a partial resolution of the line; at $x = 0.9$ the spectrum is typical of a copper(II) electron with anisotropic g tensor ($g \approx 2.03$). At higher values of x($x \approx 4$) the spectrum shows another signal centred at $g \approx 2.003$.

This behaviour can be interpreted as due to a progressive decrease of the spin–spin exchange interaction.

Spectra were recorded in the case of $Cu(dnTAA)I_x$ and $Cu(dpTAA)I_x$ at the same oxidation extent where $Cu(dbTAA)I_x$ showed a partially resolved g structure. $Cu(dnTAA)I_x$ exhibited only a slight line broadening ($H \approx 165$ G), but the line shape remained unaltered when compared to the unoxidized sample;[12] at higher oxidation ($x > 6$) the spectrum shows the same behaviour as in $Cu(dbTAA)I_x$.

In the case of $Cu(dpTAA)I_x$ the spectrum shows also the very sharp signal at $g \approx 2.003$ and the copper signal as well; the main difference with respect to the unoxidized sample is the increased linewidth ($H \approx 220$ G) of the signal due to the species in a concentrated environment.

To further check this behaviour and in order to reduce the broadening of the lines we carried out ESR measurements on all three copper complexes, both in the unoxidized and oxidized cases, when diluted (1 : 100 weight ratio) by the corresponding unoxidized nickel complexes.[21]

In all the three unoxidized species, at variance with the case of pure unoxidized samples[12] at low x values, the spectra show two absorptions due to unpaired electrons with different character: one very broad characteristic of copper and a second one at $g \approx 2.003$ whose intensity with respect to

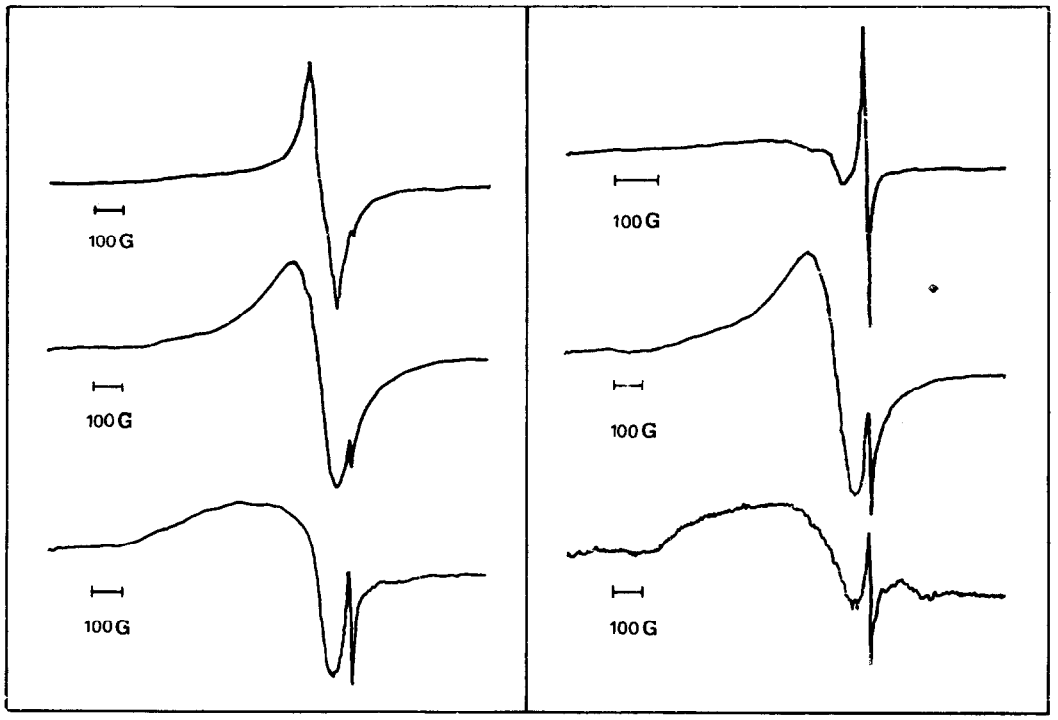

Fig. 3. (a) Room temperature ESR spectra of copper complexes diluted (1 : 100 mg) in the corresponding nickel complexes. Top : Cu(dbTAA) ; field modulation intensity : 2.5 Gpp ; gain : $2.5 \cdot 10^4$; middle : Cu(dnTAA) ; field modulation intensity : 1.25 Gpp ; gain : $8 \cdot 10^4$; bottom : Cu(dpTAA) ; field modulation intensity : 3.2 Gpp ; gain : $1 \cdot 10^5$; central field and scan range as in Fig. 3(b). (b) Room temperature ESR spectra of iodinated copper complexes diluted (1 : 100 mg) in the corresponding unoxidized nickel complexes. Top : $Cu(dbTAA)I_{0.90}$; central field : 3300 G ; scan range : 1000 G ; field modulation intensity : 3.2 Gpp ; gain : $1 \cdot 10^5$; middle : $Cu(dnTAA)I_{0.26}$; field modulation intensity : 3.2 Gpp ; gain : $1 \cdot 10^5$; bottom : $Cu(dpTAA)I_{0.22}$; field modulation intensity : 3.2 Gpp ; gain : $3.2 \cdot 10^5$; the last two spectra were registered at a central field $H = 3200$ G and scan range 1500 G.

the broad band increases from dbTAA to dpTAA complexes.

On oxidation the effects shown in Fig. 3(b) can be summarized : (i) the exchange narrowed signal in Cu(dbTAA) has changed to a broad band with partial resolution in $Cu(dbTAA)I_x$, whereas the line at $g \approx 2.003$ has gained a strong amplitude ; (ii) the central line in Cu(dnTAA) does not undergo significant changes in the shape nor in the width ($H \approx 165$ G) in $Cu(dnTAA)I_x$, whereas the "free-electron" line is slightly increased in amplitude ; and (iii) in the spectrum of $Cu(dpTAA)I_x$ the central absorption is slightly broadened and the line at $g \approx 2.003$ has almost the same amplitude when compared with unoxidized powder.

As a general trend in the diluted Cu(dnTAA) and Cu(dpTAA) systems, oxidation determines only a slight weakening of exchange interaction, whereas in the case of Cu(dbTAA) oxidation is by far more effective. The intensity of the signal at $g \approx 2.003$ increases going from the unoxidized to the oxidized situation ; the change is more evident in the Cu(dbTAA) where also a greater weakening of the exchange interaction is observed.

DISCUSSION

In order to gain a coherent picture of the ESR, magnetic susceptibility, electrical conductivity and IR data, we will follow in the discussion as a guideline two main informations, i.e. the solid state packing of the molecules and the electronic structure of the isolated molecules. Concerning $[Cu(dbTAA)]I_x$ it has been found[22] that the compound with $x = 2.01$ has a structure with planar molecules whose rings stack metal-over-metal with the plane of the rings normal to the stacking axis. Successive rings in the unit cell are staggered by 54°. Chains of I_3^+ lie in the channels between the Cu(dbTAA) stacks as has been found in the case of other dbTAA complexes.[3] It is reasonable to assume that also in the case of Cu(dnTAA) the main packing features are not modified as also indicated by the ESR behaviour of the two systems on oxidation. The

solid state packing suggests that the intermolecular interactions are essentially one-dimensional and limited to the stacking axis. This allows us to give a simple picture of the solid state electronic structure starting from the molecular orbitals of the isolated molecule. The electronic structure[12] of the Cu(dbTAA) complex suggests that the two higher energy bands are those which arise from the b_{1_u} and b_{1_g} orbitals of the isolated molecules; therefore the modifications of the molecular properties following the oxidative processes can be interpreted in terms of symmetry properties and composition of these orbitals. Cu(dnTAA) complex, whose electronic structure was computed following the same theoretical approach of Lelj *et al.*,[12] shows the same ordering of the higher energy occupied levels. In this last case the molecular geometry of the complex was derived from that of Cu(dbTAA)[12] and of naphthalene molecules. Comparison of the susceptivity data with conductivity shows interesting trends. Figure 4 shows the plot of the fraction of electron spin and conductivity data as a function of the I/Cu ratio in the case of Cu(dnTAA); analogous results are found in the case of dbTAA and dpTAA complexes. The correlation between the two properties, although only few points are reported, is fairly clear. Moreover starting from x values near 1.26, both the conductivity and the fraction of free spins remains constant. The trend of the fraction of free spins, which decreases less than expected on the basis of the ionic stoichiometry of the charge-transfer complexes, suggests that a partial removal of electrons from the ligand system is not negligible.

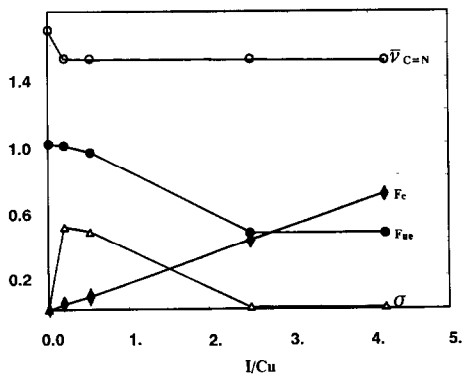

Fig. 4. Plot of the conductivity (σ), fraction of unpaired spin (F_{ue}), wave number of the C=N stretching frequency [$\bar{\nu}$(C=N)] and fraction of positive charge (F_c) in the case of [Cu(dnTAA)]I_x as a function of the I/Cu ratio.

Such a suggestion is further supported by the analysis of the behaviour of the ν(C=N) on increasing the oxidation degree of the system. In fact the oxidation determines a rapid drop of the ν(C=N) which, at x values higher than 1.26, remains constant. This behaviour can be interpreted on the basis of electron density depletion from the C_{aryl}—N bond. At a low I/Cu ratio the electrons are pulled out from the band which arises from the HOMO b_{1_g} level [Fig. 5(b)] with large copper d_{xy}

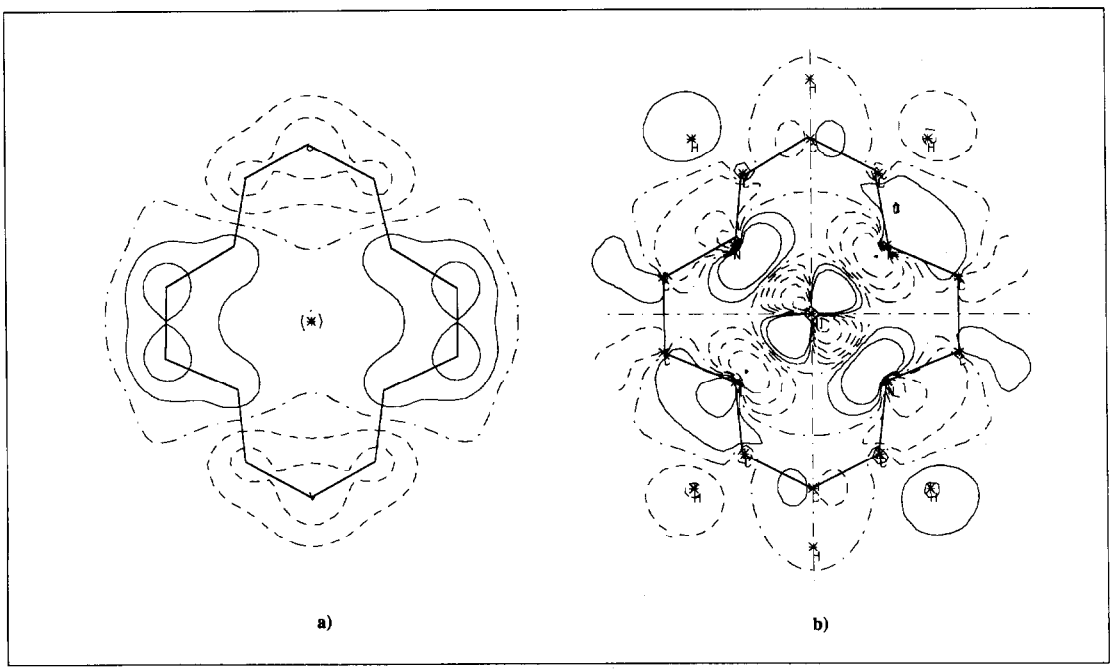

Fig. 5. Contour plot of the b_{1_u} (1.0 a.u. above the molecular plane) (a) and b_{1_g} (in the molecular plane). (b) MOs for Cu(dnTAA) (only the tetraazaannulenic framework is reported). Contour levels: 0, ±0.01, ±0.05, ±0.1, ±0.2, ±0.5 (electron a.u.^{3})$^{1/2}$ (negative: dashed lines; zero: dot-dashed).

character and with a clear metal–nitrogen anti-bonding character.

On the other hand this orbital shows a bonding character between the two mentioned carbon and nitrogen atoms. Ionization from the band which is formed by this orbital induces the reduction of the spin density on the copper atom (then the observed reduction of the static susceptivity) and the reduction of the ν(C=N) as well.

A further increase in the charge (i.e. increasing the I/Cu ratio), obtained at the expense of the b_{1_g} orbital leads to an increased stability of the band formed by HOMO b_{1_g} and to a degeneration with the band formed by SHOMO b_{1_g}. As soon as this last orbital ionizes the π unpaired spin density generated increases the total unpaired spin density on the molecule and then the static magnetic susceptibility is less than expected on the basis of the ionic stoichiometry of the charge-transfer complexes. Moreover the b_{1_u} orbital has π symmetry (with respect to the σ_h plane) mainly localized on the ligand (in the case of the dbTAA and even more in the case of dnTAA) but with a very clear anti-bonding character between the $\text{carbon}_{\text{aryl}}$ and nitrogen atoms [Fig. 5(a)]. Then electron removal from this band increases the strength of the C=N bond against the decrease generated by the ionization of b_{1_g}. This leads to a substantial stabilization of the ν(C=N) value with respect to the modification of the I/Cu ratio.

The above reported ESR spectra, in diluted samples, further suggest that there is a large tendency of the system to be oxidized both on the metal and on the ligand. In fact in all cases, although at different x values, depending on the ligand nature, it is possible to observe a signal at $g \approx 2.003$, characteristic of a "free electron", i.e. an electron mainly localized on the ligand moiety.

The origin of this line might be, in principle, an organic radical (e.g. oxidized free ligand) in the mixture. In the case of the free ligand and phthalocyanine (Pc) metal diamagnetic complexes, this line has been attributed to a radical formed by reversible adsorption of oxygen by Pc.[23] On the other hand, in our case the appearance of this line at very high x values both in the case of Cu(dnTAA) (Fig. 6) and Cu(dbTAA) and its increase, whereas the copper band decreases in the spectra of diluted samples of all the species on increasing the oxidation degree, suggests that the observed phenomenon is indeed dependent on the contemporary oxidation of the metal and ligand in the complex. The interpretation of the nature of the oxidative process can be further strengthened by comparison with the extreme behaviours shown by two already investigated molecular conductors, i.e. CoPcI[24]

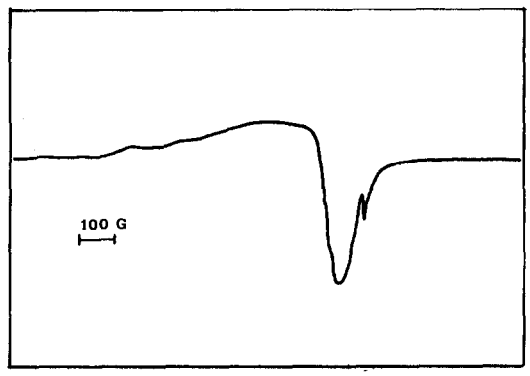

Fig. 6. Room temperature ESR spectra of $\text{Cu(dnTAA)I}_{6.45}$ powder; middle field: 3200 G; scan range 1500 G; field modulation intensity: 1.5 Gpp; gain: $1.6 \cdot 10^{-5}$.

(Pc = phthalocyanine) and CuPcI.[25] In fact, it has been found in CoPcI that oxidation involves only the Co^{2+} paramagnetic centre leading to a totally dz^2 metallic band. The conductivity values are interpreted in terms of relatively short Co—Co distances. The formation of a metallic band is supported by strong coupling phenomena among unpaired electrons, as shown by the calculated number of unpaired electrons for metallomacrocycle which is lower (0.4) than expected for a completely free spin (0.77). On the other hand, recently, the same authors have shown[25] that in CuPcI and in Cu(TATBP)[26] (TATBP = triazatetrabenzoporphyrinato) the oxidative process produces an increase of the number of unpaired electrons for the molecular unit (1.1 against 1.0 of CuPc); this behaviour has been attributed to a fully ring-centred oxidation which leaves intact the Cu^{2+} centres, giving rise to a total susceptibility greater than one spin for the molecular unit. In our complexes the situation seems to be different from the reported cases. In fact a fully metal centred oxidation could not account for the observed trend of conductivity, ν(C=N) and ESR data. Moreover a fully ligand centred oxidation does not match with the decrease of the susceptibility of the oxidized complexes with respect to the unoxidized ones. It is then reasonable to suppose that in our systems the oxidation leads to a removal of electrons from orbitals with large metallic character and from orbitals ligand centred as well.

We can conclude that, as concerns the nature of the carriers, the investigated systems do not differ significantly from NiTAAI_x, CuPcI or NiPcI, which on the other hand exhibit a ligand centred conduction band.

However, unlike CuPcI, the oxidative process in our compounds also strongly affects the metallic

centre, inducing novel magnetic behaviour. This is inferred by the presence of two distinguishable ESR signals that suggest there is no magnetic interaction between carriers and the unpaired electrons of copper centres, at least in the case of dbTAA and dnTAA complexes.

(*Received* 4 *April* 1991; *accepted* 14 *May* 1991)

Abstract—The single crystals of some lanthanide carboxylates are characterized by a lack of inversion symmetry, so they could be used for generation of the second harmonic.[1–5] Single crystals of neodymium and erbium trichloroacetate were synthesized and shown to form the polymeric chain linking dimeric subunits, where the lanthanide ions can occupy different site symmetry positions.

The absorption and luminescence spectra of single crystals of the title compounds were measured at room and liquid helium temperatures; Stark components were determined and analysed in terms of interacting ions. Spectroscopic properties were related to the X-ray crystal data.

Probabilities of *f–f* transitions depending on the orientation of biaxial single crystals were considered.

Two aspects of the spectroscopic studies of lanthanide trichloroacetates seem to be very interesting. First, variation in the atoms (Cl, F, Br) which substitute the H atom of the acetate anion must influence the Ln–O distance, so studies of hypersensitive transition intensity can elucidate the covalent effect in the spectra. Second, broad studies were undertaken to obtain monocrystals of lanthanide carboxylates and their spectroscopic characteristics as part of the search for new materials for nonlinear optics.

Recently we have published the spectroscopic results for dysprosium trichloroacetate single crystals as the first part of the series studies.[7] However the full interpretation of spectroscopic effects was not completed since the crystal structure data were unavailable. The crystal structure data for isomorphic erbium and dysprosium trichloroacetate were reported by Takashi Imai[6] and by Poraj-Koshits.[8] Our data indicate that neodymium single crystals are isomorphous with the above ones, but praseodymium probably deviates from that relation. Moreover the X-ray data show that polymeric chains are formed, linking dimeric subunits with two different site symmetry positions for the Ln^{3+} ions. Lanthanide ions in trichloroacetates are characterized by a lack of inversion symmetry.

In this paper, the results of optical absorption and fluorescence measurements are reported, and the spectroscopic effects are discussed and related to the X-ray data. The existence of short range interactions between ions associated as dimeric pairs is also discussed.

EXPERIMENTAL

Crystals of neodymium and erbium trichloroacetate $Ln(CCl_3COO)_3 \cdot 2H_2O$ were grown from water solutions. The lanthanide trichloroacetates were synthesized by slow reaction between lanthanide oxides and trichloroacetic acid, at controlled pH ($\sim$ 5.4). The crystals obtained in this way were then recrystallized from water solu-

* Author to whom correspondence should be addressed.

tions and grown to the dimensions suitable for spectroscopic measurement. The measured crystal densities are: $\rho_1 = 2.22$ g cm^{-3}, $\rho_2 = 2.34$ g cm^{-3}. Concentration of Ln^{3+} ions in crystals are: $C_1 = 3.33$ M, $C_2 = 3.39$ M, respectively. The dimensions of the crystals ($5 \times 5 \times y$ mm^3, $y_1 = 1.98$, 0.825, 0.578, 0.378 mm $\rightarrow Nd^{3+}$ for different spectral regions, $y_2 = 0.71$ mm $\rightarrow Er^{3+}$) allowed the absorption spectra measurement along the *a*-axis only. Absorption spectra in the region 320–920 nm for Nd^{3+} and 350–1600 nm for Er^{3+} were recorded at 293, 118 and 5 K. Stark components were determined at 5 K. The experimental oscillator strength values were used to calculate the Ω_λ parameters from the Judd relation.[9]

Fluorescence spectra of the neodymium trichloroacetate single crystals were recorded at 4.2 K with a spectrophotometer designed in the laboratory of the Institute of Physics, Polish Academy of Sciences (Warsaw, Poland). The instrument has a GDM 1000 grating monochromator (Carl Zeiss, Jena) with a cooled M 10FD29 photomultiplier tube (Carl Zeiss, Jena). An ILA 120 argon laser (Carl Zeiss, Jena) was used as the excitation source. Fluorescence of Nd^{3+} ions was excited with the 488 and 514 nm lines.

RESULTS AND DISCUSSION

The perspective drawings of the complex around the erbium(1) and erbium(2) atoms, respectively, are shown in Fig. 1;[6] a schematic presentation shows the coordination geometries around the metal atoms as well as the bridging modes in accord with the data of Takashi Imai.[6] In the case of Nd^{3+} single crystals, similar to the Er^{3+} ion[6] (because of the isomorphism of both crystals), two different dimeric subunits exist in the polymeric chain with two different Nd^{3+} ion site symmetry positions. Those two different dimeric subunits are bridged by oxygen atoms of water molecules and two carboxylic bridges of the Ln—O—C—O—Ln type. According to the data of Takashi Imai, in this way three different Ln—Ln distances are observed in the structure. On the other hand the Poraj-Koshits X-ray data indicated the coordination number eight for erbium(1) and seven–nine for erbium(2). Unfortunately in both papers the fitting procedure of coordination polyhedra was not made. Even if we consider the distances, Ln—O, and angles in all possible distorted coordination figures we are not able to find the symmetry centre for metal ions. Such a property of single crystals must be reflected in their spectroscopic properties.

The oscillator strengths for all electronic transitions observed in the absorption spectra at 293, 118 and 5 K are given in Tables 1 and 2. Although the intensity measurement was performed for one crystal orientation (along the *a*-axis in Fig. 2) the mean intensity for two other orientations should not change much. Crystals of trichloroacetate are biaxial, so for that type of single crystal (as was

observed earlier by Lomhein and De Shazer[10–11] and by us[12]) the difference in intensities can vary within the limits of 10%. As regards such a change to the intensity calculations, we can discuss and compare them with those published for other lanthanide carboxylates,[3] especially for single crystals with the same bonding mode of carboxylic group, and with that for the simple acetate $Ln(CH_3COO)_3\cdot3H_2O$.

According to the X-ray data, the substitution of

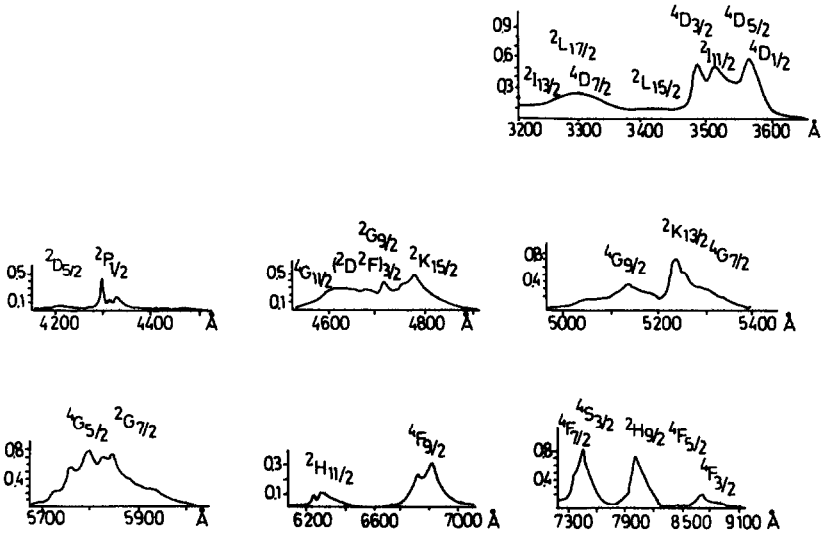

Fig. 2. Absorption spectra of $Nd(CCl_3COO)_3\cdot2H_2O$ crystals at room temperature.

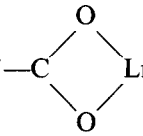
the H atom in the CH_3COO^- anion by one to three F^- ions, as well as by a Cl^- anion leads to the change of structures.[1]

It is also well known that the bonding mode of the carboxylic group in lanthanide acetates changes when the ionic radius is decreased and the Ln—O distance changed (from 2.56 for Ce^{3+} to 2.41 for Er^{3+}). But when we consider the change of ionic radius (from Ce^{3+} to Er^{3+}) we obtain mean values of Ln—O only slightly shorter for erbium. The crystal structure converted from monoclinic $P2_1/b$ to triclinic $P\bar{1}$.[13-14] Aslanov implicated that for the series of acetates the covalency varied, which resulted in coordination of

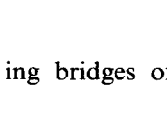


type for the end of the series. As a matter of fact the bonding lengths of such coordination are usually longer than Ln—O—C—O—Ln type.[15]

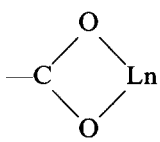
On the other hand, the stability constants of lanthanide acetate decrease from cerium to erbium.[16-17]

Gubanov and Riskov, on the basis of the theoretical calculation, consider the covalent effect in the series of lanthanide oxides and fluoro-oxides.[18] They have found that the density of overlapping of $2p$ oxygen orbitals and f orbitals of the Ln^{3+} ion decreases from neodymium to ytterbium.

The substitution of H atoms in the CH_3COO^- anion by one–three F^- ions, as well as by a Cl^- anion leads to the change of charge distribution on the $XCOO^-$ anion and, consequently, to the structural change. The substitution of H atoms in acetate by three Cl^- anions leads to the change of structure from dimeric for $Er_2(CH_3COO)_6 \cdot 4H_2O$ ($P\bar{1}$ c.n. = 9) to polymeric for $Er_2(CCl_3COO)_6 \cdot 4H_2O$ ($P\bar{1}$ c.n. = 8) and to a drastic change of coordination mode of the carboxyl group (from chelating bridges of



type and chelating



Ln type for the former to simple bridging —Ln—O—C—O—Ln— type for the latter). Coordination number decreased from nine to eight. In consequence the mean bond length decreases (from 2.41 to 2.34 Å) and although the charge distribution and pK_a can suggest the smaller contribution of covalency in trichloroacetates, still the lower coordination number (given by steric effect) leads to a decrease of Ln—O bond lengths. So in consequence we should expect the intensity of hypersensitive transitions to increase as was actually observed

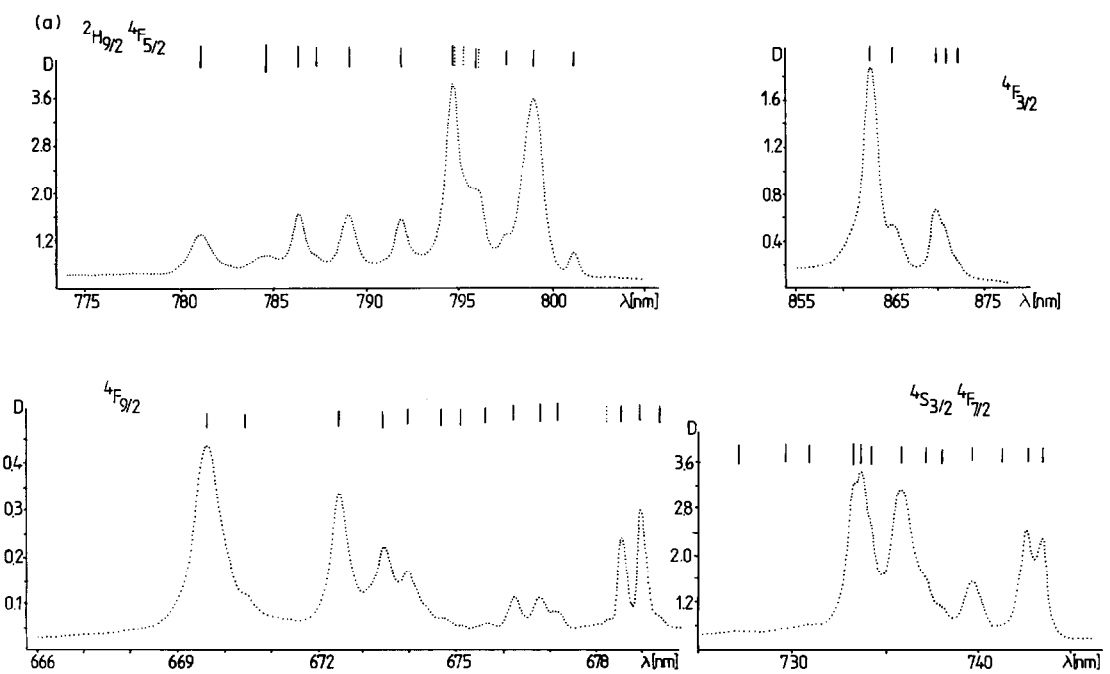


Fig. 3(a).

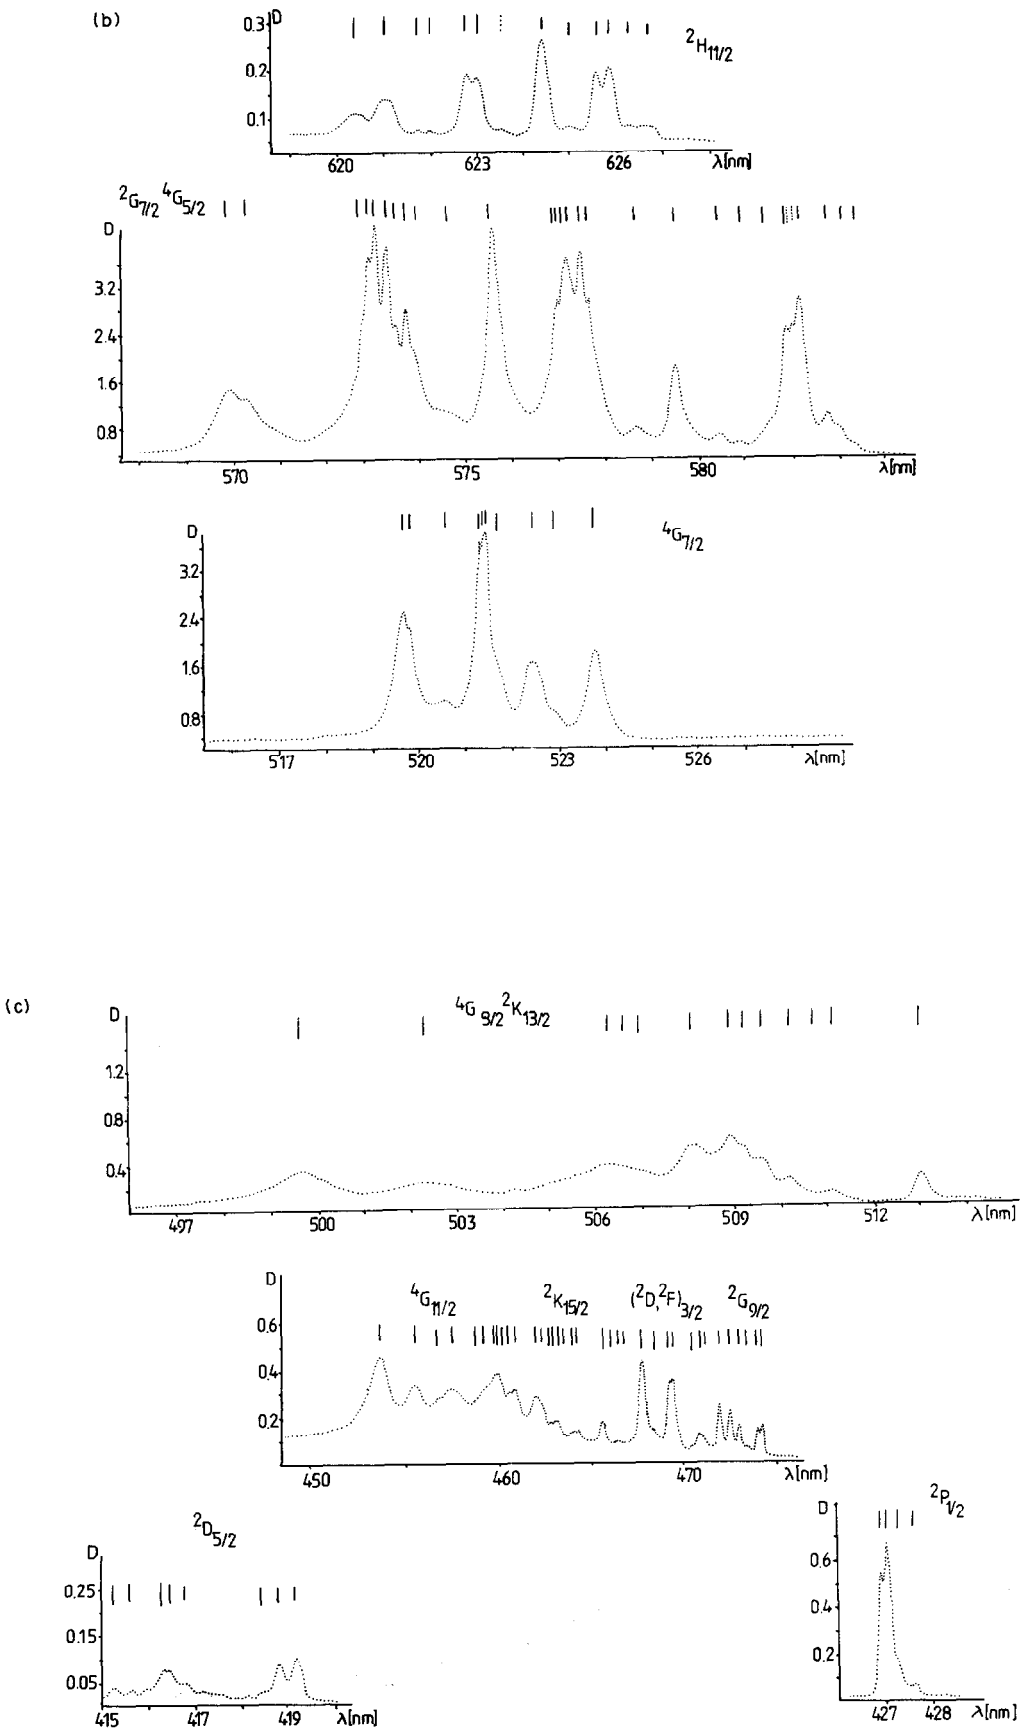

Fig. 3. Absorption spectra of $Nd(CCl_3(COO)_3 \cdot 2H_2O$ crystal at 5 K.

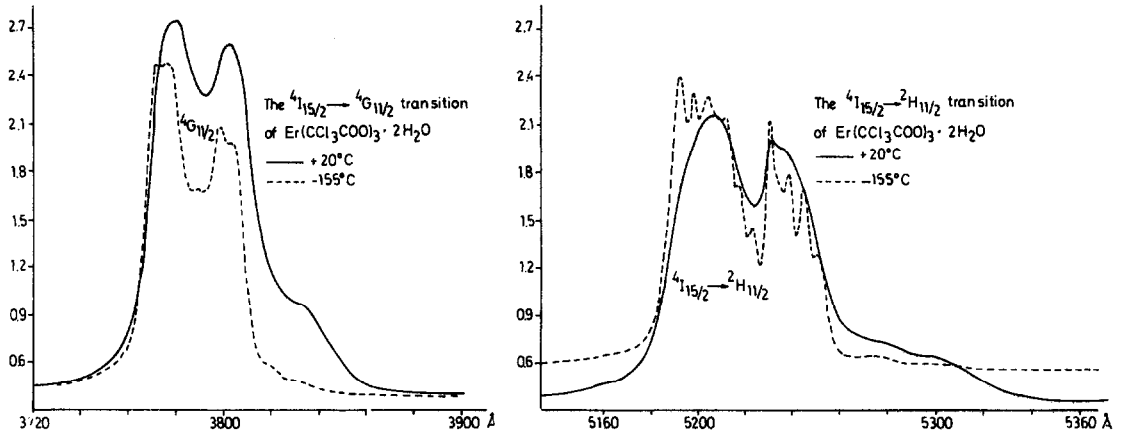

Fig. 4. The hypersensitive transitions of $Er(CCl_3COO)_3 \cdot 2H_2O$ crystals at different temperatures.

(946.84×10^{-8} for erbium acetate to 1444.99×10^{-8} for erbium trichloroacetate) (Figs 2 and 4).[19]

Covalent effect was reported by Henrie *et al.*[20] They consider an increasing basic character of the coordinating ligand (ΣpK_a) resulting in increasing absorption intensity.

If we confront the results of intensity analysis for erbium trichloroacetates and formates (for which the same bonding mode of the carboxyl group appears) and relate them to Ln—O distances, a good direction of intensity change is apparent.[3]

The oscillator strength values at various temperatures are shown in Tables 1 and 2. The drastic decrease of intensity for almost all transitions is obvious. Intensity decays with temperature decrease. It can be given either by change of ground state sublevel population or by vibronic mechanism contribution. If the first effect is involved, the variation of intensity could be almost the same for all transitions. In fact we have observed a different quantity of intensity change, so probably the second mechanism could have taken part also. This last conclusion advocates the shape of absorption bands at 5 K. If we return to the structure data, two Er^{3+} or Nd^{3+} ions occupy two different site symmetry positions, that can implicate the additional Stark components of the second site for a given transition. In fact, however, we have not observed an agree-

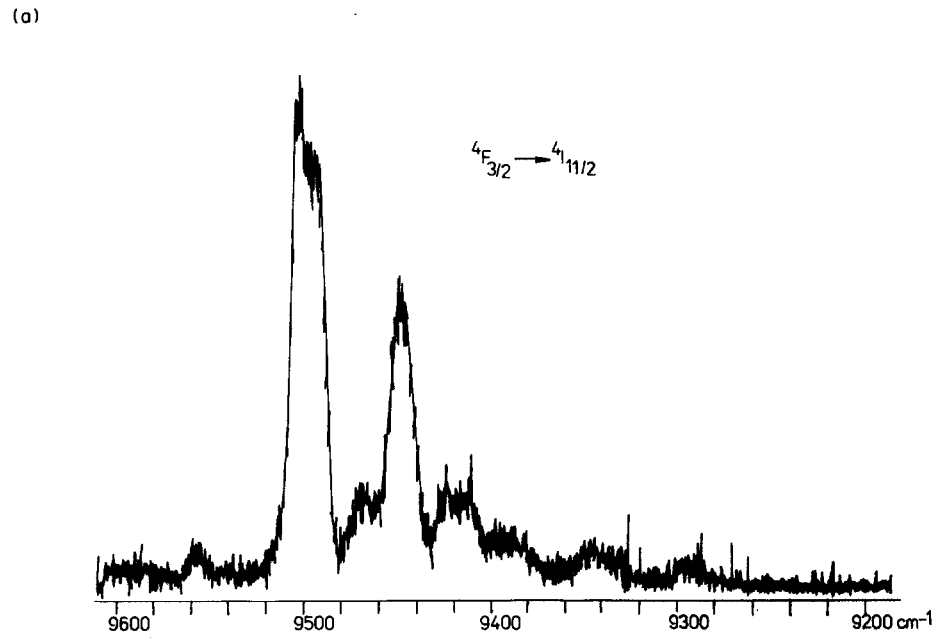

Fig. 5(a).

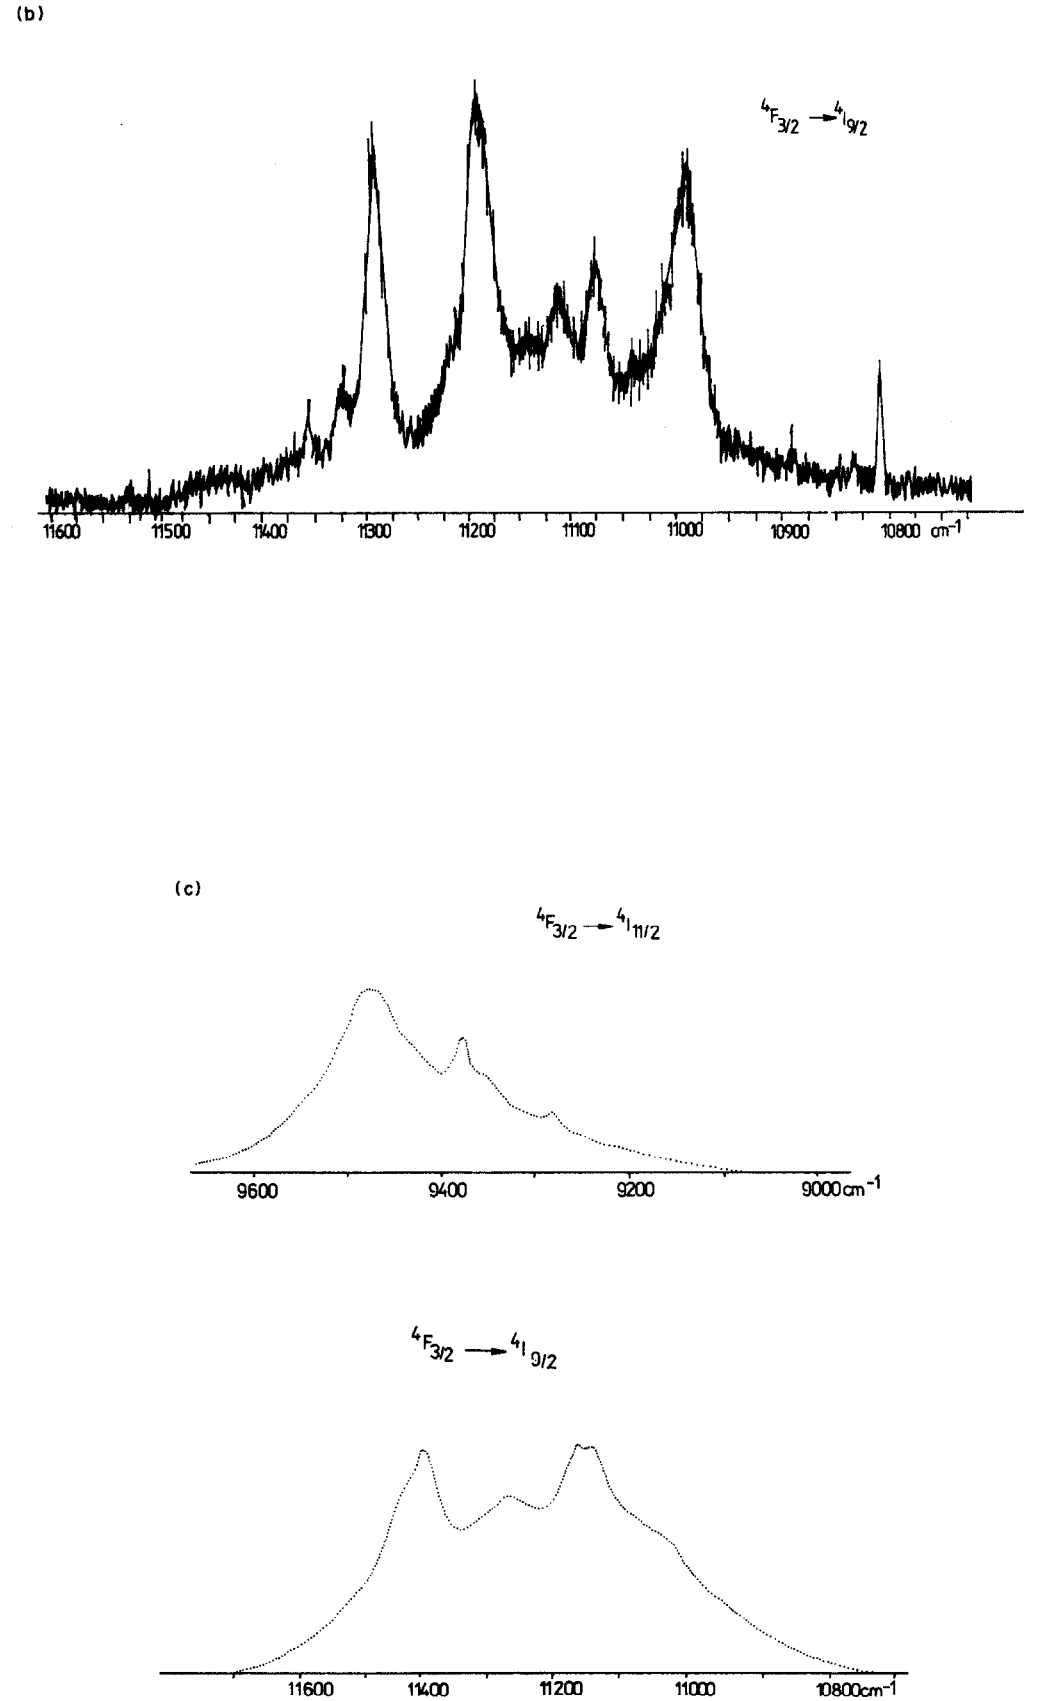

Fig. 5. Luminescence spectra of $Nd(CCl_3COO)_3 \cdot 2H_2O$ crystals. (a) 4.2 K, $\lambda_{exc} = 488$ nm, (b) 4.2 K, $\lambda_{exc} = 488$ nm and (c) 300 K, $\lambda_{exc} = 514$ nm.

ment between the expected and the observed numbers of components. The stronger components are accompanied by the many weak ones. Additional components appeared in almost all transitions which can be given both by vibration and/or by ion-pair interactions. Splitting of $^4I_{9/2} \rightarrow {}^2P_{1/2}$ at 5 K seems to confirm this conclusion. It has been possible due to the mutual perturbation that each ion induces at the site of its neighbour which shifts the energy levels and thus produces satellites of the optical lines (Fig. 3).

Figures 5(a) and (b) show the neodymium trichloroacetate single crystal luminescence spectra at 4.2 K. It was found: 12 Stark components for $^4F_{3/2} \rightarrow {}^4I_{11/2}$; 13 well observed lines and some additional detected as bendings for $^4F_{3/2} \rightarrow {}^4I_{9/2}$ transition. The nature of the additional lines needs further consideration as an effect of vibronic and ion-pair interactions.

Abstract—The redox behaviour of the ligand 1,4-dihydroxy-9,10-anthraquinone (Quinizarine) and its oxidation–reduction products (semiquinones and dianion) has been studied in dimethylsulphoxide, $(CH_3)_2SO$. The combination of Quinizarine in the presence of two equivalents of tetraethylammonium hydroxide (TEAOH) with manganese(II) in a 1 : 2 and 1 : 1 mole ratio forms two complexes. The first one has a stability constant of 9.0×10^{12} M^{-2}, whereas the second one precipitates. On the other hand further oxidation by electrolysis of the solution of Quinizarine in the presence of the two equivalents of TEAOH yields a green solution of the corresponding semiquinone. The combination of this semiquinone with manganese(II) in a 1 : 1 mole ratio forms a violet complex. These complexes and their oxidation reduction products have been characterized by cyclic voltammetry, controlled-potential electrolysis and optical spectroscopy in dimethylsulphoxide solvent. The formation constant for the complex has been evaluated spectrophotometrically and turns out to be 8.9×10^5 M^{-1}. These results may be relevant to the mechanism of the role of manganese in biological systems.

INTRODUCTION

Many manganese complexes have been studied to serve as models for the centre that catalyses the oxidation of water to molecular oxygen in Photosystem II of green-plant photosynthesis.[1–10] A mixed ligand complex in which the manganese atom is bound both to a protein and to another ligand (i.e. a quinone) to facilitate the oxidation of the whole unit has been proposed.[11] Under these conditions the oxidation equivalents would accumulate in this unit to permit the subsequent oxidation of two water molecules to yield hydrogen peroxide and finally molecular oxygen.

The most abundant naturally occuring quinones are paraquinones[12] and among those Quinizarine has the particular feature of having two hydroxy groups in the 1 and 4 positions. Therefore, it can be oxidized to the corresponding *para*-semiquinone which could form a stable complex with manganese, assisted by the 9,10 quinonic system as a second coordinating group. This oxidation process could take place at a more positive potential which would make it more appropriate to develop a model for the active centre of Photosystem II.

In this paper we report the study of the redox chemistry of Quinizarine and the interaction of its different forms with manganese(II).

EXPERIMENTAL

Equipment

A three-electrode potentiostat (Tacussel Model PRT 20-2X potentiostat/galvanostat with Model GSPT wave generator) was used for the cyclic voltammetric and controlled-potential electrolysis experiments.

A current integrator based on operational amplifiers was used as a coulometer in the controlled-potential electrolyses.

Cyclic voltammograms were recorded on a Hewlett–Packard Model 7004 A X-Y recorder.

The electrochemical cell was equipped with a Beckman platinum-inlay working electrode (area 0.23 cm^2), a platinum coil auxiliary electrode, and

* Author to whom correspondence should be addressed.

an Ag/AgCl reference electrode filled with an aqueous tetramethylammonium chloride solution and adjusted to 0.00 V vs SCE.[13] The latter was contained in a Pyrex tube with a soft-glass cracked tip; this electrode was placed inside a Luggin capillary. For controlled potential electrolysis, a platinum-mesh working electrode was employed.

A Beckman Model Acta CV spectrophotometer was used for UV–vis spectrophotometric measurements.

Air-sensitive compounds were handled in a glove bag (Aldrich) under a nitrogen atmosphere and the oxygen content was monitored with a Beckman Model Monitor II Oxygen Analyser.

Reagents

The reagents for the investigation and syntheses included $Mn(ClO_4)_2 \cdot 6H_2O$ (G. Frederick Smith), tetraethylammonium hydroxide (TEAOH) (25% in methanol, Eastman), tetramethylammonium chloride (Aldrich), and tetraethylammonium perchlorate (TEAP) (G. Frederick Smith). The ligand Quinizarine was obtained from Aldrich.

Burdick and Jackson Laboratories "distilled-in-glass" grade solvents were used without further purification for all of the experiments. High purity argon was used to de-aerate solutions.

Because the solvation water of the $Mn(ClO_4)_2 \cdot 6H_2O$ salt interfered with the stoichiometric formation of the complexes under study, $[Mn^{II}(DMU)_6][ClO_4]_2$ (DMU = dimethylurea)[14] was used in all the experiments in which the manganese(II) complexes were formed *in situ*. As a source of manganese(III), $[Mn^{III}(Urea)_6][ClO_4]_3$[15] was used in all the experiments.

RESULTS AND DISCUSSION

The cyclic voltammograms of solutions of Quinizarine in dimethylsulphoxide (DMSO) are illustrated in Fig. 1(a). This ligand presents two reversible couples with reduction peak potentials of -0.58 V vs SCE and -1.14 V vs SCE, and oxidation peak potentials of -0.50 V vs SCE and -1.06 V vs SCE, respectively. Controlled-potential electrolysis after the reduction peaks indicate that one electron has been transferred in each process. Therefore, we can conclude that they correspond to the formation of the semiquinone (species **II**) and the dianion (species **III**) of the ligand as a consequence of the reduction of the quinonic system in the 9 and 10 positions, according to the following half-reactions, eq. (1):

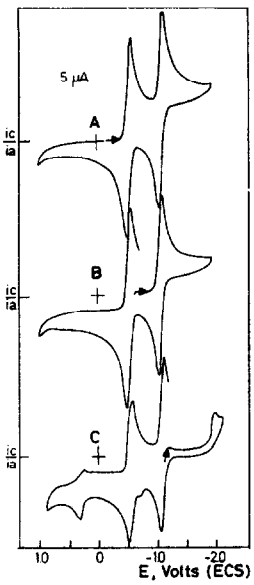

Fig. 1. Cyclic voltammograms in DMSO (TEAP 0.1 M, $v = 0.1$ V s^{-1}) of solutions that are 0.1 mM in Quinizarine [1,4-di(OH)AQ, species **I**] (a); 1.0 mM in semiquinone [1,4-di(OH)SQ$^-$, species **II**] (b); 1.0 mM in dianion [1,4-di(OH)DA^{2-}, species **III**] (c).

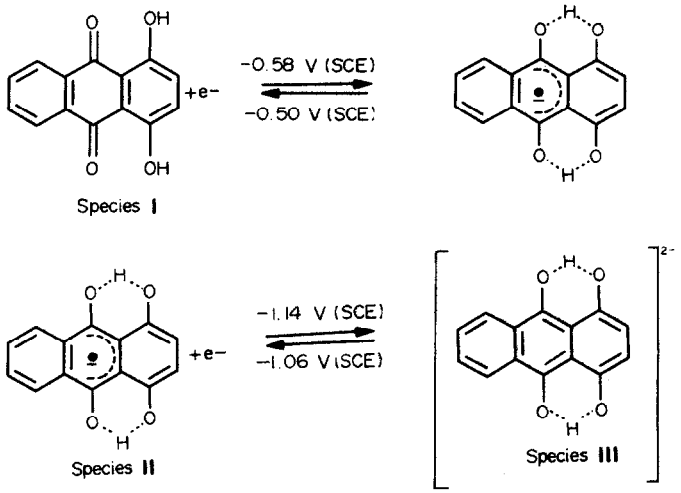

(1)

Quinizarine is yellow–orange in DMSO, whereas the semiquinone **II** is dark brown and the dianion **III** is light brown. Both species **II** and **III** react with molecular oxygen very readily. Figure 1(b) shows the cyclic voltammogram of a solution of the semiquinone **II** generated by controlled-potential electrolysis at −0.78 V vs SCE of a solution of Quinizarine. Figure 1(c) shows the cyclic voltammogram of a solution of the dianion **III** generated by controlled-potential electrolysis at −1.34 V vs SCE of a solution of the semiquinone.

The UV–vis spectrum of Quinizarine [Fig. 2(a)] shows a quinoid electron transfer band at 275 nm (ε = 10,700 M^{-1} cm^{-1}), another quinoid electron transfer band at 325 nm (ε = 3500 M^{-1} cm^{-1}), and an electron transfer band at 470 nm (ε = 8600 M^{-1} cm^{-1}). The last band may involve excitation of the non-bonding electrons of the hydroxy group to the carbonyl anti-bonding orbitals of the quinone.[16] The spectrum of semiquinone [Fig. 2(b)] shows an absorption maximum at 500 nm (ε = 21,100 M^{-1} cm^{-1}) which indicates that in this case the visible peak has shifted bathochromically and its intensity has increased. This effect may be due to the delocalized electrons that produce an aromatic system. Also, it shows a well defined maximum at 390 nm (ε = 6400 M^{-1} cm^{-1}). On the other hand, the dianion **III** shows a very intense absorption maximum at 470 nm (ε = 21,000 M^{-1} cm^{-1}) but it does not show the maximum at 390 nm due to the radical nature of the semiquinone **II** [Fig. 2(c)].

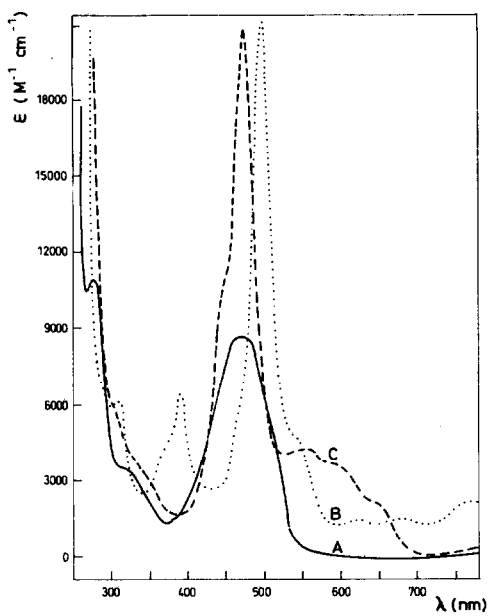

Fig. 2. Absorption spectra, UV–vis, in DMSO of solutions that are 1.0 mM in Quinizarine [1,4-di(OH)AQ, species **I**] (a); 1.0 mM in semiquinone [1,4-di(OH)SQ^{-}, species **II**] (b); 1.0 mM in dianion [1,4-di(OH)DA^{2-}, species **III**] (c).

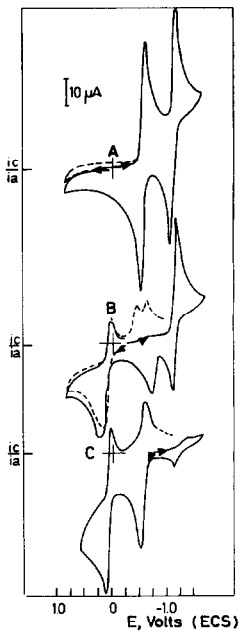

Fig. 3. Cyclic voltammograms in DMSO (TEAP 0.1 M, $v = 0.1$ V s^{-1}) of solutions that are 1.0 mM in Quinizarine [1,4-di(OH)AQ, species **I**] (a); 1.0 mM in Quinizarine and 1.0 mM in TEAOH [1,4-(O^{-},OH)AQ, species **IV**] (b); 1.0 mM in Quinizarine and 2.0 mM in TEAOH [1,4-di(O^{-})AQ, species **V**] (c).

In the presence of one and two equivalents of base the hydroxy protons are neutralized (species **IV** and **V**) and the solutions turn blue. Figures 3 and 4 show the cyclic voltammograms and UV–vis spectra of these compounds.

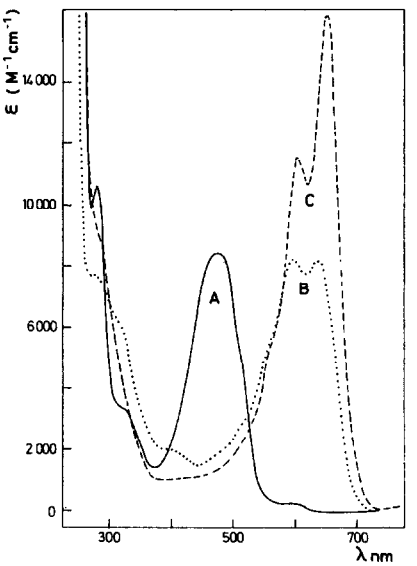

Fig. 4. Absorption spectra, UV–vis, in DMSO of solutions that are 1.0 mM in Quinizarine [1,4-di(OH)AQ, species **I**] (a); 1.0 mM in Quinizarine and 1.0 mM in TEAOH [1,4-(O^{-},OH)AQ, species **IV**] (b); 1.0 mM in Quinizarine and 2.0 mM in TEAOH [1,4-di(O^{-})AQ, species **V**] (c).

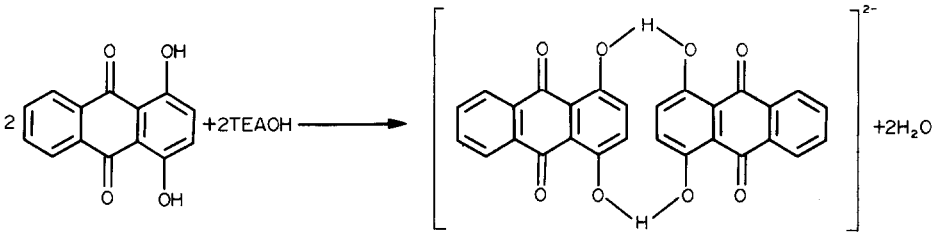
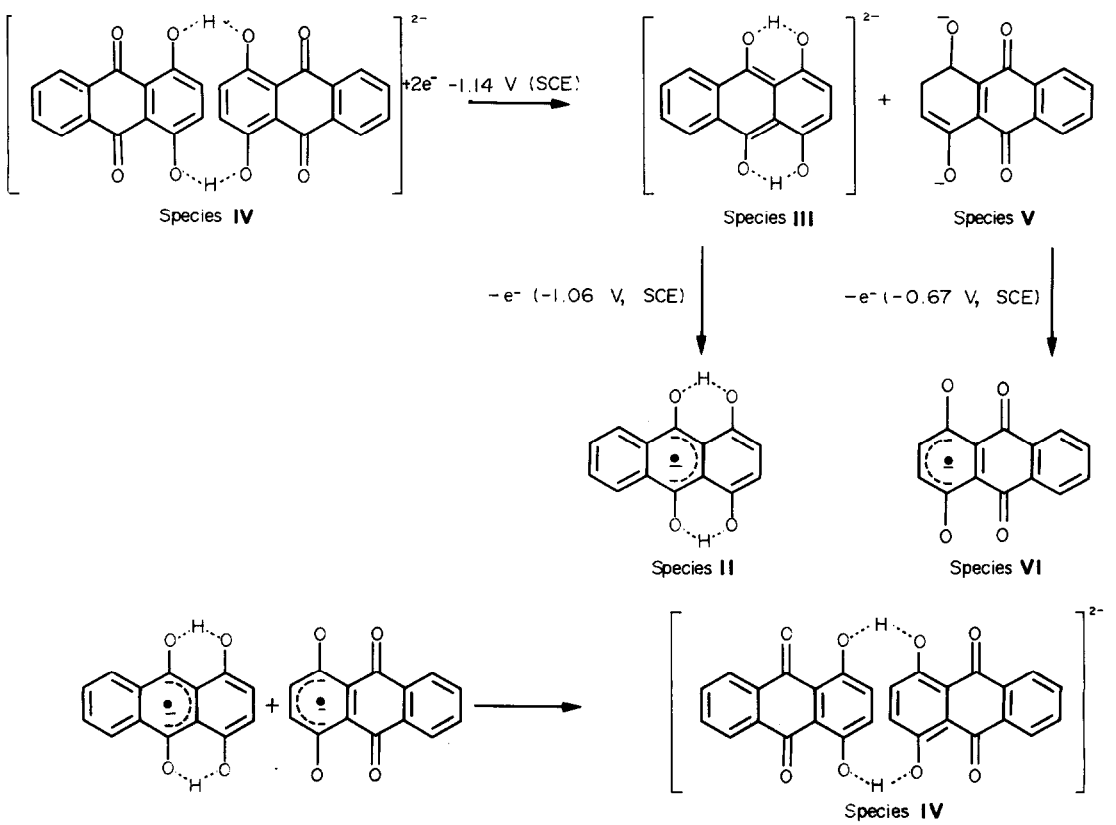
After the addition of one equivalent of base the absorption maxima are: 275 nm ($\varepsilon = 7800\ M^{-1}\ cm^{-1}$), 325 nm ($\varepsilon = 6000\ M^{-1}\ cm^{-1}$), 395 nm ($\varepsilon = 2000\ M^{-1}\ cm^{-1}$), 535 nm ($\varepsilon = 3800\ M^{-1}\ cm^{-1}$), 600 nm ($\varepsilon = 8300\ M^{-1}\ cm^{-1}$) and 640 nm ($\varepsilon = 8300\ M^{-1}\ cm^{-1}$) [Fig. 4(b)]. Upon addition of a second equivalent of base only the absorption maxima at 600 nm ($\varepsilon = 11{,}600\ M^{-1}\ cm^{-1}$) and at 650 nm ($\varepsilon = 16{,}300\ M^{-1}\ cm^{-1}$) show up.



On the basis of our experimental results we have proposed the structure of compound **IV**, because the solution of this species presents absorption maxima at 275 and 325 nm which are characteristic of the protonated quinone (species **I**), and at 600 and 640 nm which are characteristic of the totally deprotonated quinone (species **V**). The cyclic voltammogram of this solution (Fig. 3(b)] presents a reduction peak at −1.14 V vs SCE which involves the transfer of one equivalent of charge, whereas upon reversal of the scan direction two oxidation peaks show up at −0.67 V vs SCE and −1.06 V vs SCE, respectively. Controlled potential electrolysis after these peaks indicate that 0.5 equivalents of charge have been transferred in each case, and the spectra of the solutions obtained after the electrolyses are shown in Fig. 5. Notice that after the reduction of compound **IV** a mixture of protonated dianion (species **III**) and deprotonated dianion (species **V**) is obtained. Species III is characterized by the presence of the maxima at 470 and 560 nm, whereas species **V** can be identified by the maxima at 600 and 650 nm. The oxidation of these two species occur at different potentials: at −1.06 V vs SCE the formation of the protonated semiquinone (species II) is observed whereas at −0.67 V vs SCE the deprotonated semiquinone (species **VI**) corresponding to the oxidation of the 1,4 dihydroxy system, is obtained (the absorption maxima at 390 and 560 nm are not observed). Finally, species **II** and **VI** react to regenerate species **IV**.



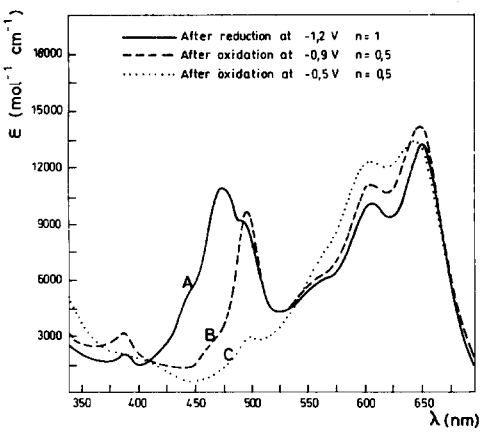


Fig. 5. Absorption spectra, UV–vis, in DMSO of (a) a 1.0 mM solution of Quinizarine and 1.0 mM in TEAOH (species **IV**) after complete electrolysis at −1.34 V vs SCE ($n = 1$), species **III** and **V**; (b) solution A after complete electrolysis at −0.9 V vs SCE ($n = 0.5$), species **II**; (c) solution **B** after complete electrolysis at −0.5 V vs SCE ($n = 0.5$), species **IV**.

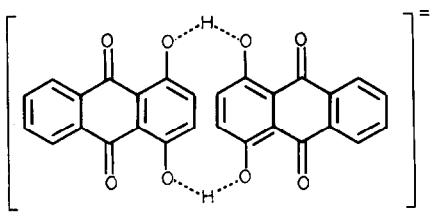
Conductometric titration of a 1 mM solution of Quinizarine in DMSO with a 0.095 M solution of NaOH in methanol gave a first break after the addition of one equivalent of base and then the conductance remained constant until the second equivalent of base was added. From then on an increase of conductance was observed upon addition of an excess of base. This is indicative of the formation of an ion aggregate like species **IV**, which is more conductive than Quinizarine (species **I**).[17-18]

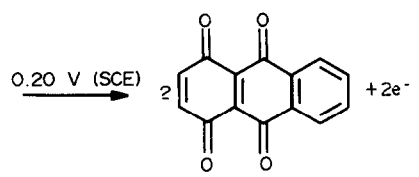
The neutralization of the second proton does not change the conductivity of the solution because the effects of the dissociation of the aggregate and the formation of the dianion compensate. The high conductivity of the aggregate of two monoanions is due to the formation of an ion pair with the titrant cation.

If the titration is done using a solution of tetraethylammonium hydroxide in methanol the conductivity curve breaks are not observed clearly and the conductance values are approximately 20% lower than those obtained when sodium hydroxide is used as the titrant.

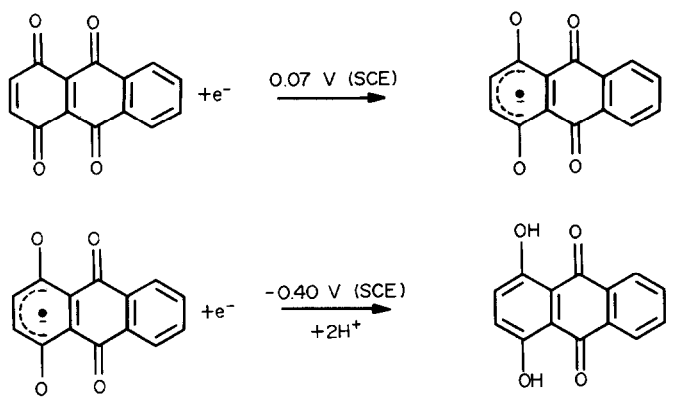
If the initial scan is made in the positive direction one oxidation peak is observed at +0.20 V vs SCE and three reduction peaks at +0.07 V vs SCE, 0.4 V vs SCE, and −0.58 V vs SCE show up. These processes can be represented by the following set of equations:



Species **IV**



Species **VII**

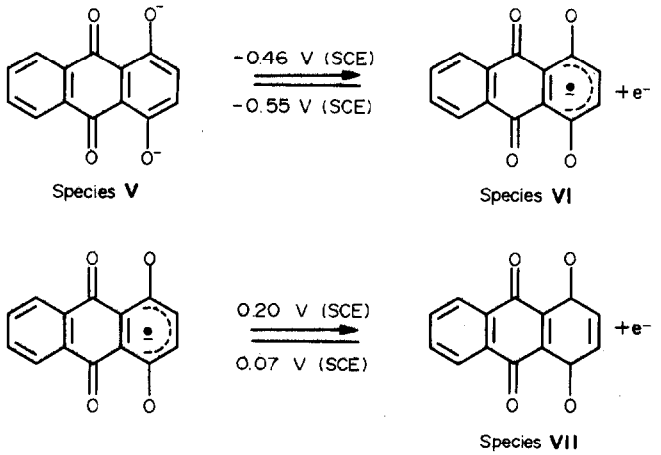


The formation of the diquinonic species **VII** has been verified by controlled-potential electrolysis which indicates that two equivalents of charge are being transferred in this process.

In the presence of two equivalents of base the solution turns blue (species **V**). In this case [Fig. 1(c)] an anodic peak shows up at −0.46 V vs SCE and a second anodic peak at +0.20 V vs SCE is observed. Controlled-potential electrolysis at −0.3 V vs SCE indicates that the first peak corresponds

to a one-electron process that generates a green radical species (species **VI**) produced by the oxidation of the 1,4 dihydroxy system which is then oxidized via another one-electron process to the diquinone **VII**.

The UV–vis spectra of these solutions show absorption maxima at 531 nm ($\varepsilon = 8200\ M^{-1}\ cm^{-1}$), 553 nm ($\varepsilon = 9700\ M^{-1}\ cm^{-1}$) and 606 nm ($\varepsilon = 7850\ M^{-1}\ cm^{-1}$) [Fig. 7(c)].



The direct reaction of the semiquinone **II** generated by controlled potential electrolysis at −0.78 V vs SCE with molecular oxygen generates a blue solution which presents the same spectrum as a solution of deprotonated Quinizarine. The blue species is also generated by a strong base such as superoxide ion (produced by chemical reaction of dioxygen with the semiquinone) which is known to be a powerful Bronsted base in aprotic solvents.[9-20]

$$\text{1,4-di(OH)SQ} + O_2 \longrightarrow \underset{\text{blue}}{\text{1,4-(O}^-\text{,OH)AQ}} + HO_2\cdot$$

In the presence of manganese(II) the protonated Quinizarine or its reduced form (semiquinone) does not form complexes as the cyclic voltammograms and the UV–vis spectra do not change in the presence of the metal ion.

On the other hand in the presence of two equivalents of base the cyclic voltammograms and UV–vis spectra of solutions with different concentrations of manganese(II) (Figs 6 and 7) show that with a 1 : 2 metal-to-ligand mole ratio the presence of free ligand is not observed. The solution is blue–violet. An anodic peak shows up at +0.17 V vs SCE which corresponds to the oxidation of the complex formed to $MnSQ^+$ and SQ^-. These species are finally oxidized to the corresponding diquinonic species at 0.42 V vs SCE, and 0.55 V vs SCE, respectively.

$$\underset{\text{blue–violet}}{MnQ_2^{2-}} \xrightarrow{+0.17\,V} MnSQ^+ + SQ^- + 2e^-$$
$$\downarrow 0.55\,V \qquad \downarrow 0.42\,V$$
$$Mn^{II} + DQ + e^- \qquad DQ + e^-$$

Addition of more Mn^{2+} causes the bis blue–violet complex to react, forming another violet complex with a 1 : 1 stoichiometry [Fig. 7(c)] which precipitates if the concentration is higher than 1 mM. This complex oxidizes at +0.26 vs SCE and +0.55 V vs SCE, whereas the oxidized ligand is reduced at +0.09 V vs SCE. The UV–vis spectra [Fig. 7(d)]

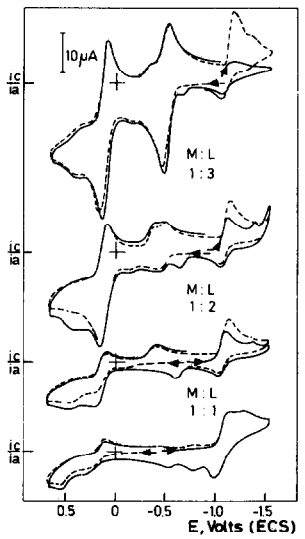


Fig. 6. Cyclic voltammograms in DMSO (TEAP 0.1 M, v = 0.1 V s^{-1}) of (a): a 1.0 mM in Quinizarine and 2.0 mM in TEAOH [1,4-(O⁻,OH)AQ, species **V**]; (b): solution A in the presence of 0.3 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (c): solution A in the presence of 0.5 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (d): solution A in the presence of 1.0 mM $Mn^{II}(DMU)_6(ClO_4)_2$.

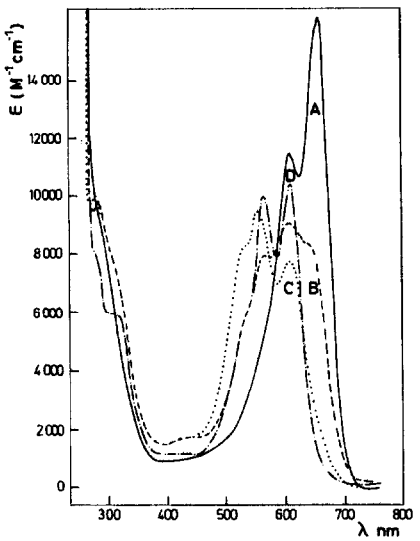

Fig. 7. Absorption spectra UV–vis in DMSO of (a): a 1.0 mM in Quinizarine and 2.0 mM in TEAOH [1,4-(O^-, OH)AQ, species V]; (b): solution A in the presence of 0.3 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (c): solution A in the presence of 0.5 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (d): solution A in the presence of 1.0 mM $Mn^{II}(DMU)_6(ClO_4)_2$.

shows absorption maxima at 569 nm ($\varepsilon = 10{,}000$ M^{-1} cm^{-1}) and 613 nm ($\varepsilon = 10{,}200$ M^{-1} cm^{-1}).

When Quinizarine in the presence of two equivalents of base is oxidized electrochemically at -0.30 V vs SCE it is found that one equivalent of charge is being transferred. Therefore, the semiquinone corresponding to the oxidation of the 1,4 dihydroxy system is obtained. Upon addition of manganese(II) to this green semiquinone a soluble violet complex is formed with a 1.1 stoichiometry. This complex is oxidized at $+0.55$ V vs SCE [Fig. 8(d)] and as a consequence of that it decomposes because after this process the reduction of the diquinone (DQ) is observed at $+0.09$ V vs SCE. This complex presents absorption maxima [Fig. 9(c)] at 520 nm ($\varepsilon = 5000$ M^{-1} cm^{-1}), 555 nm ($\varepsilon = 8200$ M^{-1} cm^{-1}), and 650 nm ($\varepsilon = 9800$ M^{-1} cm^{-1}).

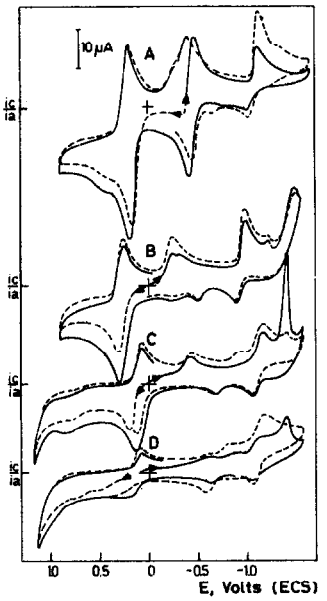

Fig. 8. Cyclic voltammograms in DMSO (TEAP 0.1 M, $v = 0.1$ V s^{-1}) of (a): a 1.0 mM in Quinizarine and 2.0 mM in TEAOH after electrolysis at -0.30 V vs SCE (species VI); (b): solution A in the presence of 0.3 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (c): solution A in the presence of 0.5 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (d): solution A in the presence of 1.0 mM $Mn^{II}(DMU)_6(ClO_4)_2$.

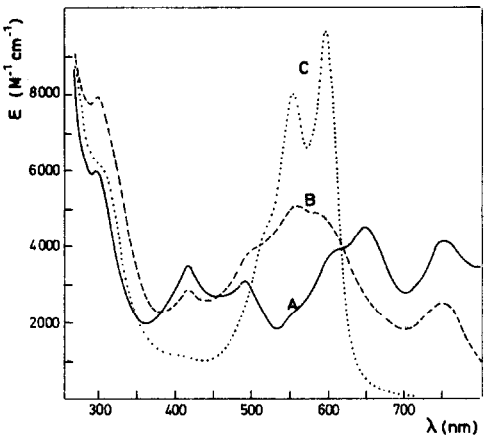

Fig. 9. Absorption spectra UV–vis in DMSO of (a): a 1.0 mM in Quinizarine and 2.0 mM in TEAOH after electrolysis at -0.30 V vs SCE (species VI); (b): solution A in the presence of 0.3 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (c): solution A in the presence of 0.5 mM $Mn^{II}(DMU)_6(ClO_4)_2$; (d): solution A in the presence of 1.0 mM $Mn^{II}(DMU)_6(ClO_4)_2$.

The stability constants of the complexes formed have been evaluated spectrophotometrically. The one corresponding to the $MnSQ^+$ complex has been determined by measuring the absorbance at 750 nm of a solution of the semiquinone produced by controlled-potential electrolysis as the concentration of manganese is increased. This constant turns out to be 8.9×10^5 M^{-1}. In a similar manner the stability constant of the bis complex with quinizarine MnQ_2^{2-} has been evaluated by measuring the absorbance at 660 nm of a solution of the metal as the concentration of ligand is increased. In this case the stability constant is 9.0×10^{12} M^{-2}.

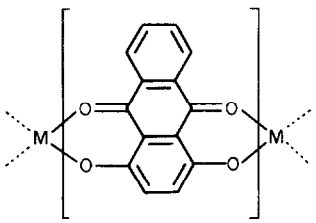
$$Mn^{II} + SQ^{\cdot-} \longleftrightarrow MnSQ^+ \quad Kf = 8.9 \times 10^5\, M^{-1}$$

$$Mn^{II} + 2Q^{2-} \longleftrightarrow MnQ_2^{2-} \quad Kf = 9.0 \times 10^{12}\, M^{-2}$$

In the presence of an excess of manganese(II) a 1:1 complex of manganese with the dianion of

Quinizarine is formed. This complex, being neutral is insoluble in this medium and precipitates, therefore we were not able to determine its stability constant.

Therefore, we can conclude that several complexes are formed between manganese and the different forms of Quinizarine in this medium. The unprotonated ligand, Q^{2-}, forms a 1:1 and a 1:2 complex. The first one is insoluble and probably corresponds to a polymeric structure analogous to those found with copper.[21]



The 1:2 complex is soluble with a stability constant of 9.0×10^{12} M^{-2}. The oxidation of the 1,4 dihydroxy system forms a semiquinone at fairly positive potentials, and this species in the presence of manganese(II) generates a stable complex with a stability constant of 8.9×10^{5} M^{-1}. Probably an intramolecular charge-transfer takes place in this complex, with the metal ion having a manganese(III) character and the semiquinone being reduced to the corresponding dianion. The spectroscopic evidence [Fig. 9(c) compared to Fig. 10(c)] indicates the presence of bound dianion in this complex, which presents the same spectrum as a solution of manganese(III)–dianion (Fig. 10). Consequently, we assume that the manganese atom has a manganese(III) character in this case. This behaviour is analogous to that observed with other ligands such as 3,5-ditertbutyl catechol,[22] Lawsone[23] and Lapachol.[24]

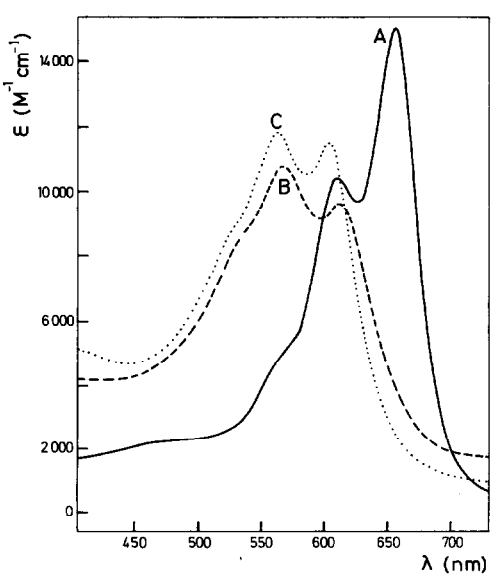


Fig. 10. Absorption spectra UV–vis in DMSO of (a): a 1.0 mM in Quinizarine and 2.0 mM in TEAOH [1,4-(O^-,OH)AQ, species V]; (b): solution A in the presence of 0.5 mM $Mn^{III}(UREA)_6(ClO_4)_3$; (c): solution A in the presence of 1.0 mM $Mn^{III}(UREA)_6(ClO_4)_3$.

Therefore, these results may be relevant for the development of a model system for the active centre of Photosystem II of green-plant photosynthesis. Mixed-ligand complexes of manganese with oxidized Quinizarine and some other ligands that stabilize higher oxidation states of this metal can act as centres that accumulate oxidizing equivalents at a potential positive enough to produce the oxidation of water to molecular oxygen. The study of these mixed ligand complexes is currently in progress in our group.

Abstract—The complexes $LAuCl_3$ [L = 1-phenyl-3,4-dimethylphosphole(DMPP), 1-phenyldibenzophosphole(DBP) and triphenylphosphine], $LAuBr_3$ (L = DBP, Ph_3P) and $LAuClBr_2$ (L = DBP, Ph_3P) were prepared and characterized by physical properties, cyclic voltammetry, far IR, $^{31}P\{^1H\}$ and CP/MAS $^{31}P\{^1H\}$ NMR spectroscopy. Ligand redistribution reactions of the types: $LAuCl + L'AuBr \rightleftharpoons L'AuCl + LAuBr$; $LAuCl_3 + LAuBr_3 \rightleftharpoons LAuCl_nBr_{3-n}$; $LAuCl_3 + L'AuBr_3 \rightleftharpoons LAuCl_nBr_{3-n} + L'AuCl_nBr_{3-n}$; and $LAuCl + L'AuBr_3 \rightleftharpoons LAuBr + L'AuCl + L'AuBr + LAuCl_nBr_{3-n} + L'AuCl_nBr_{3-n}$ all occur rapidly and have been studied by $^{31}P\{^1H\}$ NMR spectroscopy. These reactions all appear to proceed by way of halide-bridged intermediates. The solid state identities of $LAuClBr_2$ were established by a combination of far IR and CP/MAS $^{31}P\{^1H\}$ NMR spectroscopies and single crystal X-ray crystallography for Ph_3PAuBr_2Cl. The R_3PAuBr_2Cl complexes are substitutionally disordered, probably with two-thirds bromine and one-third chlorine in each site. Ph_3PAuBr_2Cl crystallized in the monoclinic space group $P2_1/c$ with $a = 9.086(2)$, $b = 11.410(2)$, $c = 18.734(4)$ Å, $\beta = 95.01°(2)$, and $Z = 4$. The structure was solved by least-squares methods with $R_F = 0.074$ for 1919 unique reflections with $I/\sigma(I) \geqslant 3.0$. The gold atom has nearly regular square-planar coordination with Au—P = 2.314(6) A° and Au—X = 2.399(3), 2.413(3) and 2.415(4) A°.

Solid-state nuclear magnetic resonance spectroscopy is attracting increasing interest in inorganic chemistry.[1] We and others have investigated the utility of CP/MAS $^{31}P\{^1H\}$ NMR spectroscopy for the solid-state characterization of phosphines,[2] phosphine-oxides, -sulphides and -selenides;[3] manganese, molybdenum and tungsten;[4] iron, ruthenium and osmium;[5] rhodium,[6,7] nickel,[8] palla-

dium,[9-11] platinum,[9,10,12,13] copper,[14-25] silver,[26,27] gold,[28,29] cadmium[30] and mercury[31] phosphine complexes. These studies have shown that the ^{31}P chemical shift is very environmentally dependent and provides information concerning the phosphorus and metal site symmetries and the overall geometries of the complexes. The magnitudes of ^{1}J(CuP) and ^{1}J(AgP) allow determination of metal coordination numbers and metal–phosphorus bond distances. For the palladium, platinum, cadmium and mercury complexes, the magnitude of ^{2}J(PP) is a function of the PMP bond angles. Thus, for some complexes their $^{31}P\{^{1}H\}$ CP/MAS spectra can provide details of solid-state structures similar to those available from the more difficult to obtain EXAFS[32,33] measurements.

Gold(III) phosphine complexes of the type R_3PAuX_3 are prepared by oxidative addition of the appropriate halogen, X_2, to the gold(I) complexes R_3PAuX. Previous workers[34-37] have found that when the oxidative additions (reactions 1 and 2) were studied, highly crystalline homogeneous samples were obtained. In each case elemental analyses were consistent with the $R_3PAuXX'_2$ stoichiometries. NMR studies of these substances in solution[36,38] showed that halide redistribution[10] reactions occurred rapidly to produce all six of the possible compounds: R_3PAuCl_3, *cis*- and *trans*-R_3PAuCl_2Br, *cis*- and *trans*-$R_3PAuClBr_2$ and R_3PAuBr_3. These authors discussed the probable solid state identities suggesting that a mixture of R_3PAuCl_3 and R_3PAuBr_3,[37] pure R_3PAuXX_2[34,35] or a mixture of all six species[36] was present in the solid state. They also discussed the mechanism[36,38] of the halide redistribution. We have conducted a thorough study of the complexes of DMPP, DBP (see Struct. 1) and Ph_3P by solution $^{31}P\{^{1}H\}$ and CP/MAS $^{31}P\{^{1}H\}$ NMR, electrochemistry, far IR spectroscopy and X-ray crystallography to obtain a further insight into the solid state identities and ligand redistribution reactions.

$$R_3PAuCl + Br_2 \longrightarrow R_3PAuBr_2Cl \quad (1)$$

$$R_3PAuBr + Cl_2 \longrightarrow R_3PAuBrCl_2 \quad (2)$$

EXPERIMENTAL

(a) *Reagents and physical measurements*

All chemicals were reagent grade and were used as received or synthesized as described below. All solvents, when necessary, were dried by standard procedures and stored over Linde 4 Å molecular sieves. All reactions involving phosphines or phospholes were conducted under a nitrogen atmosphere. R_3PAuX,[29,34] 1-phenyl-3,4-dimethylphosphole[40](DMPP) and 1-phenyldibenzophosphole[41] (DBP) were prepared by literature methods.

Elemental analyses were performed by Galbraith Laboratories, Knoxville, TN. Melting points were determined on a Meltemp apparatus and are uncorrected. IR spectra were recorded on a Perkin–Elmer 1800 FT-IR instrument as polyethylene pellets. The solution $^{31}P\{^{1}H\}$ NMR spectra were recorded at 40.26 MHz on a JEOL FX-100 spectrometer in the FT mode. Typical acquisition conditions were 1 and 5 kHz spectral windows, acquisition times of 4 and 0.8 s, recycle time of 5 s; typically 5 to 10 k transients were collected with proton noise decoupling and 2 Hz line broadening was applied. A JEOL NM 5471 controller was used for temperature control and temperatures were measured with a calibrated platinum resistance thermometer. Chemical shifts were referenced to an external sample of PPh_3 in $CDCl_3$ ($\delta = -6$ ppm) and converted to an 85% H_3PO_4 reference with a positive value being downfield of the respective reference. Cross-polarization magic-angle-spinning (CP/MAS) $^{31}P\{^{1}H\}$ NMR spectra were obtained on a JEOL GX-270 wide bore spectrometer operating at 6.43 T (^{31}P at 109.25 MHz) using a 40 kHz sweep width, recycle delay time of 6 s, and a proton-decoupling field of 10 G. No line broadening was applied. Between 200 and 300 mg of the compound was spun at 4 kHz in Delrin or Kel-F rotors. All the CP/MAS chemical shifts were referenced to an external sample of Ph_3P ($\delta = -6.0$ ppm). The uncertainties in chemical shifts are estimated to be ± 0.5 ppm. Cyclic voltammetry was performed as previously described.[42]

(b) *Syntheses* $LAuCl_3$

The three $LAuCl_3$ (L = DBP, Ph_3P and DMPP) complexes were prepared by the same procedure. The following is exemplary. Chlorine gas was slowly bubbled through a $CHCl_3$ (20 cm^3) solution containing 0.25 g (0.51 mmol) DBPAuCl while the solution was magnetically stirred. The originally colourless solution turned bright yellow within a few seconds. This yellow solution was filtered, the solution volume was reduced to a few cm^3 by rotary evaporation, n-hexane was slowly added and the mixture was cooled to 0°C. The precipitate was isolated by filtration, washed with anhydrous diethyl ether, and vacuum dried to yield 0.24 g (82.8%) of orange crystals, m.p. 119–121°C.

Found: C, 38.5; H, 2.5. Calc. for $C_{18}H_{13}AuCl_3P$: C, 38.4; H, 2.3. Ph_3PAuCl_3,[37] yellow plates (58%), m.p. 179–181°C. DMPP $AuCl_3$, yellow powder (98%), m.p. 121–122°C. All three $LAuCl_3$ (L = DBP, Ph_3P, DMPP) complexes are photochemically and thermally unstable, decomposing even in the absence of light to black solids. The DMPP complex decomposes in 2 weeks and the Ph_3P complex decomposes in approx. 5 weeks.

$LAuBr_3$. The $LAuBr_3$ (L = DBP, Ph_3P) complexes were prepared in the same manner. The following is exemplary. To a solution containing 0.17 g (0.31 mmol) DBPAuBr in 20 cm^3 $CHCl_3$ was added 1.0 cm^3 of 0.34 M Br_2 in $CHCl_3$. The resulting dark red solution was magnetically stirred at ambient temperature for 3 h. The solution was then filtered, the filtrate reduced in volume to a few cm^3 by rotary evaporation, anhydrous diethyl ether was slowly added and the mixture was cooled to 0°C. The precipitate was isolated by filtration, washed with anhydrous diethyl ether, and vacuum dried to yield 0.15 g (68.2%) of burgundy-red crystals, m.p. 121–123°C. Found: C, 30.95; H, 2.17. Calc. for $C_{18}H_{13}AuBr_3P$: C, 31.0; H, 1.9. Ph_3PAuBr_3,[37] brick-red plates (92%) m.p. 149–150°C. Attempted preparation of (DMPP)$AuBr_3$ by the same procedure resulted in the formation of a black oil. The $^{31}P\{^1H\}$ NMR spectrum of this oil suggested the addition of Br_2 to the diene system of DMPP.[40,43]

$LAuClBr_2$. The $LAuClBr_2$ (L = DBP, Ph_3P) complexes were prepared in the same manner as for the $LAuBr_3$ complexes except that the starting material was LAuCl. DBPAuClBr$_2$ (84.2%), burgundy-red crystals, m.p. 128–130°C. Found: C, 32.8; H, 2.1. Calc. for $C_{18}H_{13}AuBr_2ClP$: C, 33.1; H, 2.0%. $Ph_3PAuClBr_2$ (52.1%) burgundy-red crystals, m.p. 162–164°C. Found: C, 32.7; H, 2.5. Calc. for $C_{18}H_{15}AuBr_2Cl$: C, 33.0, H, 2.3%.

(c) *Crystal structure analyses*

A 0.04 × 0.10 × 0.40 mm burgundy-red lath of Ph_3PAuBr_2Cl was selected from among the crystals formed by the reaction of Ph_3PAuCl with Br_2 in $CHCl_2/Et_2O$ in stoichiometric quantities. They were found to be only weakly diffracting. Intensity data were taken with a Nicolet $P2_1$ diffractometer in the θ–2θ mode and were corrected for Lorentz, polarization and absorption effects, the last by the Gaussian method. Systematic absences ($h01$, $1 \neq 2n$; $0k0$, $k \neq 2n$) indicated the $P2_1/c$ space group. The heavy atoms were located by Patterson techniques, and the light atoms were then found on successive Fourier syntheses. The three heavy Au ligand atoms were of equal height in Fourier syntheses, and were treated as Br, which gave satisfactory refinement. Substitution of Br by Cl cannot be excluded, and the relatively high thermal parameters of the Br atoms could be consistent with this [Ueq of Br (*trans* to Br) 0.0727 (10) (mean), of Br (*trans* to P) 0.0846 (15)]. This possibility is not testable by direct refinement because of the correlation of thermal parameters and occupancy; random substitution would be equivalent to 0.83 Br at each site. Anisotropic temperature factors were used for all non-hydrogen atoms. Hydrogen atoms were given fixed isotropic temperature factors, $u = 0.07$ Å^2 and were inserted at calculated positions and not refined. Final refinement was by cascaded least-squares methods [minimizing $\Sigma\omega(Fo-Fc)^2$]. The largest positive and negative peaks on final difference Fourier syntheses were of height (e Å^{-3}) +2 and −4 in the vicinity of the Au atom. A weighting scheme of the form $1/(\sigma^2(F)+gF^2)$ with $g = 0.0026$ was used and shown to be satisfactory by a weight analysis. Three standard reflections monitored every 200 reflections showed no regular changes during data collection. Final $R_F = 0.074$ and $R_{WF} = 0.078$. This rather high final figure is likely to result principally from approximations in measurement of the platy crystal, leading to an imprecise absorption correction, and the weakly diffracting crystals. Computing was with the SHEXTL system[44] on a Data General DG30 computer. Scattering factors were taken from ref. 45. $C_{18}H_{15}AuBr_2Cl$, M = 654.33, monoclinic, $a = 9.086(2)$, $b = 11.410(2)$, $c = 18.734(4)$ Å, $\beta = 95.01(2)°$, $U = 1934.8$ Å^3, space group $P2_1/c$, $Z = 4$, $D_c = 2.25$ g cm^{-3}, burgundy-red plates, μ(Mo–K_α) = 138.1 cm^{-1}, $\lambda = 0.71069$ Å, $F(000) = 1288$.

RESULTS AND DISCUSSION

(1) *Oxidative additions to* R_3PAuX *complexes*

Two-coordinate 14-electron d^{10} LAuX complexes may be expected to readily undergo oxidative addition reactions[46] to form four-coordinate 16-electron d^8 $LAuX_3$ complexes. Neither DBPAuCl nor Ph_3PAuCl react with CH_3I, BrCN, ICN or $ClCH_2CN$. In each case the R_3PAuCl complex was quantitatively recovered. However, the colourless DBPAuCl, Ph_3PAuCl and DMPPAuCl complexes each reacted with Cl_2 in $CHCl_3$ at ambient temperature to give the corresponding yellow LAuCl_3 complexes. All three complexes are photochemically and thermally unstable, eventually decomposing into black solids. The relative rates of decomposition are: $DMPPAuCl_3 > DBPAuCl_3 >$

Ph_3PAuCl_3, which is the order of decreasing ease of oxidation of the respective phosphorus donors. The colourless DBPAuBr and Ph_3PAuBr complexes reacted with Br_2 in $CHCl_3$ at ambient temperature to give the photochemically and thermally stable burgundy-red $DBPAuBr_3$ and Ph_3PAuBr_3 complexes. For DMPPAuBr, Br_2 in $CHCl_3$ not only oxidized gold(I) to gold(III) but also brominated the carbon–carbon double bonds[43] of DMPP leading to a complex mixture of 20 phosphorus containing species as a black oil. The colourless DBPAuI and Ph_3AuI when reacted with I_2 in $CHCl_3$ at ambient temperature formed black oils that gave single $^{31}P\{^1H\}$ NMR chemical shifts in $CDCl_3$ at $\delta = 31.8$ ppm (DBP) and 38.4 ppm (Ph_3P), which are identical[29] to those of DBPAuI and Ph_3PAuI, respectively. This is consistent with the observations that gold(III) complexes are reduced to gold(I) complexes by iodide.[47]

Both DBPAuCl and Ph_3PAuCl reacted with Br_2 in $CHCl_3$ at ambient temperature to form burgundy-red homogeneous appearing crystals of the corresponding $LAuClBr_2$ complexes, whose stoichiometry was evidenced by elemental analyses and these substances have narrow melting point ranges. However, DBPAuI and Ph_3PAuI reacted with Br_2 to form $DBPAuBr_3$ and Ph_3PAuBr_3, respectively, and DBPAuBr and Ph_3PAuBr reacted with Cl_2 to form $DBPAuCl_3$ and Ph_3PAuCl_3, respectively.

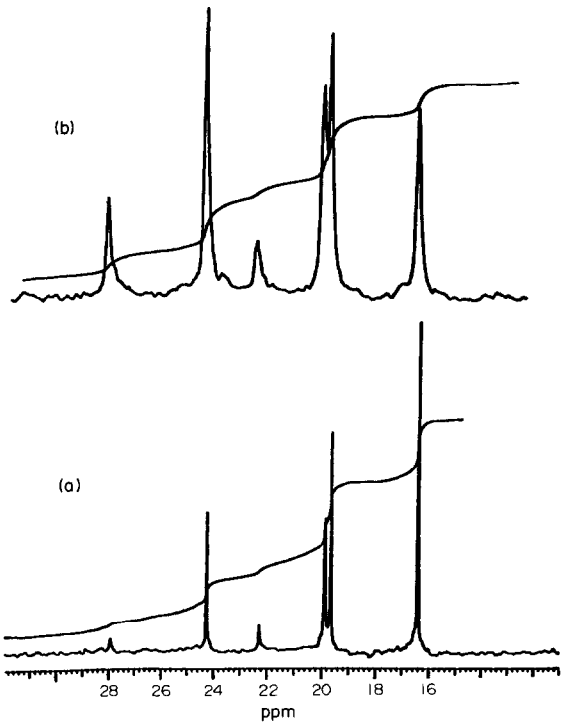

Fig. 1. 40.26 MHz $^{31}P\{^1H\}$ NMR spectra in $CDCl_3$ at 30°C for (a) $DBPAuClBr_2$ and (b) an equimolar mixture of $DBPAuCl_3$ and $DBPAuBr_3$. Assignments as follows: $DBPAuCl_3$ (27.9 ppm), *cis*-$DBPAuCl_2Br$ (24.2 ppm), *trans*-$DBPAuCl_2Br$ (22.3 ppm), *trans*-$DBPAuBr_2Cl$ (19.9 ppm), *cis*-$DBPAuBr_2Cl$ (19.6 ppm), $DBPAuBr_3$ (16.4 ppm).

(2) *Halide redistribution reactions*

Although the elemental analyses and melting point data for the $LAuClBr_2$ complexes would indicate that their solid state identity is as formulated, their $^{31}P\{^1H\}$ NMR spectra in $CDCl_3$ solution at 30°C [Fig. 1(a)] show the presence of more than one species in solution. For both complexes six phosphorus-containing species are present in solution. These species result from halide redistribution[39] reactions of the $LAuClBr_2$ complexes. The $^{31}P\{^1H\}$ NMR resonances are assigned as follows: $DBPAuCl_3$ (27.9 ppm), *cis*-$DBPAuCl_2Br$ (24.2 ppm), *trans*-$DBPAuCl_2Br$ (22.3 ppm), *trans*-$DBPAuBr_2Cl$ (19.9 ppm), *cis*-$DBPAuBr_2Cl$ (19.6 ppm) and $DBPAuBr_3$ (16.4 ppm). These assignments are based upon the chemical shifts of solutions of pure $DBPAuCl_3$ (28.3 ppm) and $DBPAuBr_3$ (16.8 ppm) in $CDCl_3$ at 30°C. We reason that the greater the *trans* influence[47–50] of the halide, the weaker the *trans* Au—P bond and the more upfield the ^{31}P chemical shift. Thus, we expect the ^{31}P chemical shift of *cis*-$DBPAuCl_2Br$ to be upfield of that of $DBPAuCl_3$ but downfield of that of *trans*-$DBPAuCl_2Br$. Also, if the halide redistribution reaction is nearly statistical as is often found for such reactions,[39] then the $DBPAuBr_2Cl$ complexes should be more abundant than the $DBPAuBrCl_2$ complexes and their corresponding ^{31}P resonances should be more intense. The $^{31}P\{^1H\}$ resonances for a $CDCl_3$ solution of Ph_3PAuBr_2Cl at 30°C were similarly assigned: Ph_3PAuCl_3 (42.9 ppm), *cis*-Ph_3PAuCl_2Br (38.3 ppm), *trans*-Ph_3PAuCl_2Br (38.1 ppm), *trans*-Ph_3PAuBr_2Cl (34.8 ppm), *cis*-Ph_3PAuBr_2Cl (33.0 ppm) and Ph_3PAuBr_3 (30.5 ppm).

Heaton and Kelsey[38] similarly observed by ^{31}P NMR spectroscopy that reaction of Cl_2 with Et_3PAuBr in $CHCl_3$ at 25°C resulted in the rapid formation of all six $Et_3PAuCl_nBr_{3-n}$ species but their assignments as to the relative chemical shifts of Et_3PAuCl_2Br and $Et_3PAuClBr_2$ differ from ours. They based their assignments on the systematic trends observed upon *cis*-substitution of chloride by bromide in mixed chloride/bromide platinum(IV) complexes. We believe that our assignments of the relative chemical shifts are more internally consistent than theirs and they are also consistent with the following observation. Figure 1(b) shows the

$^{31}P\{^{1}H\}$ NMR spectrum of a solution prepared from equimolar amounts of $DBPAuCl_3$ and $DBPAuBr_3$ in $CDCl_3$ immediately after mixing at 30°C. The same six species are present in this solution indicating that the halide redistribution reaction is rapid. For a solution of $DBPAuClBr_2$ the Br/Cl ratio is 2 : 1 but in a solution containing equimolar amounts of $DBPAuCl_3$ and $DBPAuBr_3$ the Br/Cl ratio is 1 : 1. Hence, the relative amounts of $DBPAuCl_2Br$ to $DBPAuClBr_2$ species in the latter solution should increase relative to those in the former. The ratio of the integrated intensities of the resonances ascribed to $DBPAuCl_2Br$ complexes to those ascribed to the DBPAu $ClBr_4$ complexes is 0.5 in Fig. 1(a) and 1.0 in Fig. 1(b), consistent with the relative molar ratio of the halides in the two solutions.

(3) *The mechanisms of halide redistribution*

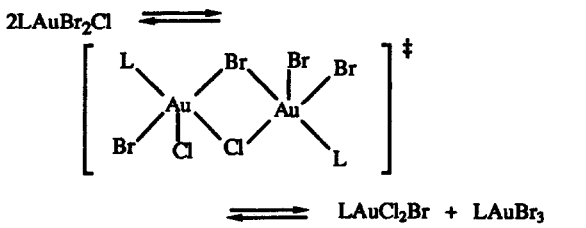
The halide redistributions of $LAuBr_2Cl$ complexes could proceed by two alternative mechanisms: (1) catalysis by LAuCl[36] (reactions 3–6); or (2) simple halide redistribution (reaction 7).

$$LAuCl + Br_2 \longrightarrow LAuClBr_2 \quad (3)$$

$$LAuClBr_2 + LAuCl \longrightarrow LAuCl_2Br + LAuBr \quad (4)$$

$$LAuBr + Br_2 \longrightarrow LAuBr_3 \quad (5)$$

$$LAuCl + LAuCl_2Br \longrightarrow LAuCl_3 + LAuBr \quad (6)$$



(7)

Reactions (3–6), were first suggested by Puddephatt and Thompson[36] on the basis of similarities with platinum(II) catalysed halide redistributions of platinum(IV) complexes. These reactions imply that the $LAuCl_2Br$ and $LAuClBr_2$ complexes are better oxidants than Br_2 or that they react with the gold(I) complexes faster than Br_2. We have therefore examined the electrochemical behaviour of the R_3PAuX and R_3PAuX_3 complexes most of which have not previously been reported.[51]

The redox potentials, determined by cyclic voltammetry in CH_2Cl_2 solution are given in Tables 1 and 2. All cyclic voltammograms were quasi-reversible.[52] As can be seen, the phosphine generally has a smaller effect on the reduction potential of $LAuX_3$ than on the oxidation potential of LAuX. But none of the effects on the redox potentials are very large.

Table 1. Electrochemical properties of some gold(I) complexes

Complex	E_p (V vs Fc^+/Fc)[a] $Au^I \rightarrow Au^{III}$	$Au^I \rightarrow Au^0$	Others
(DBP)AuCl	1.07	[b]	1.27[c]
(DBP)AuBr	1.03	[b]	1.20[c]
$(Ph_3P)AuCl$	1.13	−2.46	
$(Ph_3P)AuBr$	1.14	−2.52	

[a] Measured by cyclic voltammetry ($v = 200$ mV s^{-1}) in CH_2Cl_2 solution at a platinum working electrode, with 0.1 M tetrabutylammonium perchlorate as supporting electrolyte.

[b] Very near the cathodic limit of the solvent/electrolyte/electrode system used.

[c] Oxidation. The current for this process is less than that for the $Au^I \rightarrow Au^{III}$ oxidation. The two values (1.27 and 1.20 V) are close enough so that ligand (DBP) oxidation may be suggested. DPP (Differential Pulse Polarography) results agree very well with CVs.

For the sequence of reactions (3–6) to occur as redox reactions, the potentials for reactions (4) and (6) must be greater than zero. Although the reduction potentials of $LAuClBr_2$ and $LAuCl_2Br$ are not available, we may approximate them by the appropriate weighted averages of the potentials for the $LAuCl_3$ and $LAuB_3$ complexes.[53] Thus, the redox potential for $Ph_3PAuClBr_2 + 2e^- \rightarrow Ph_3P$

Table 2. Electrochemical properties of some gold(III) complexes

Complex	E_p (V vs Fc^+/Fc)[a] $Au^{III} \rightarrow Au^I$	$Au^I \rightarrow Au^0$	Others
$(DBP)AuCl_3$	−0.49	[b]	1.29[c,d]
$(DBP)AuBr_3$	−0.37	[b]	1.17[c,d]
$(Ph_3P)AuCl_3$	−0.49	−2.55	[e]
$(Ph_3P)AuBr_3$	−0.31	−2.54	1.34[c]

[a] Measured by cyclic voltammetry ($v = 200$ mV s^{-1}) in CH_2Cl_2 solution at a platinum working electrode, with 0.1 M tetrabutylammonium perchlorate as supporting electrolyte.

[b] Very near the cathodic limit of the solvent/electrolyte/electrode system used.

[c] Oxidation. The current for this process is less than that for other processes; see ref. 51.

[d] The closeness of these values may indicate DBP oxidation.

[e] Near the anodic limit.

$AuBr + Br^- + Cl^-$ is estimated to be -0.37 V vs Fc/Fc^+ or -0.03 V vs NHE as Fc/Fc^+ is 0.40 vs NHE. The redox potential[54] for $Br_2 + 2e^- \rightleftharpoons 2Br^-$ is 1.087 V. Thus, $Ph_3PAuClBr_2$ is a much poorer oxidant than Br_2. While this argument suggests that the gold(I) catalysed mechanism for halide scrambling is not likely to compete with oxidation by Br_2 it does not necessarily establish that a redox reaction between a gold(I) and a gold (III) species cannot take place. To test the latter possibility, a series of $^{31}P\{^1H\}$ NMR experiments were performed on $CDCl_3$ solutions containing equimolar mixtures of LAuX and $L'AuX_3$. Since the halides on both complexes are the same, no halide redistribution takes place. The $^{31}P\{^1H\}$ NMR spectrum of one such mixture (DBPAuCl plus Ph_3PAuCl_3) is shown in Fig. 2. All four possible species viz Ph_3PAuCl (32.4 ppm), DBPAuCl (24.0 ppm), Ph_3PAuCl_3 (42.8 ppm) and $DBPAuCl_3$ (27.9 ppm) are present in this solution. The same four species were found in the same relative amounts in a solution prepared from equimolar amounts of $DBPAuCl_3$ and Ph_3PAuCl. Similarly, $CDCl_3$ solutions of DBPAuBr plus Ph_3PAuBr_3 and $DBPAuBr_3$ plus Ph_3PAuBr each showed the presence of Ph_3PAuBr (34.5 ppm), Ph_3PAuBr_3 (30.5 ppm), DBPAuBr (26.6 ppm) and $DBPAuBr_3$ (16.3 ppm) in the same relative amounts. These reactions could be the result of phosphine redistribution[39] or of redox reactions. To ascertain if redox reactions are possible, we can crudely estimate[55] the electrochemical potential for one of these reactions. Consider the following half reactions (8 and 9):

$$Ph_3PAuCl_3 + 2e^- \longrightarrow Ph_3PAuCl + 2Cl^- \qquad E^0 = -0.49\,V \quad (8)$$

$$DBPAuCl + 2Cl^- \longrightarrow DBPAuCl_3 + 2e^- \qquad E^0 = +0.49\,V. \quad (9)$$

Thus, for reaction (10) $E^0 \cong 0.0$ V and from

$$Ph_3PAuCl_3 + DBPAuCl \rightleftharpoons DBPAuCl_3 + Ph_3AuCl, \quad (10)$$

$E^0 = -0.0295 \log K_{eq}$, we predict $K_{eq} \cong 1$ and the redox reaction (10) is thermodynamically feasible. Reaction (10) was found to occur rapidly and $K_{eq} = 0.76$, as measured by $^{31}P\{^1H\}$ NMR spectroscopy at 30°C in $CDCl_3$.

This result poses the interesting question as to what would be the products of reactions (11) and (12)?

$$Ph_3PAuCl + Ph_3PAuBr_3 \xrightarrow{?} \quad (11)$$

$$DBPAuBr + Ph_3PAuCl_3 \xrightarrow{?}. \quad (12)$$

In both these cases, halide redistribution as well as a redox reaction are conceptually possible. The results of $^{31}P\{^1H\}$ NMR assessments of these reactions are shown in Figs 3 and 4. As can be seen, complete ligand scrambling occurs in both cases. The assignments given in these figures are based upon comparisons with the ^{31}P chemical shifts of the pure LAuX and $LAuX_3$ complexes and the previous arguments for the $LAuBrCl_2$ and $LAuBr_2Cl$ complexes. The same equilibria were observed to occur for $CDCl_3$ solutions containing equimolar amounts of Ph_3PAuBr plus Ph_3PAuCl_3 and DBP AuCl plus $DBPAuBr_3$.

Since the two possible pathways of halide redistribution (reactions 3–6 or 7) would lead to the same products, both pathways might be operating in the absence of added halogen. This postulation is supported by the results of an additional series of $^{31}P\{^1H\}$ NMR experiments on equimolar mixtures of LAuX and $L'AuX_3'$. One such example was shown in Fig. 4 where complete ligand redis-

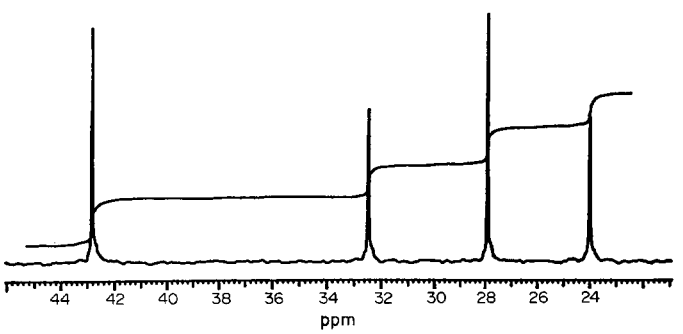


Fig. 2. 40.26 MHz $^{31}P\{^1H\}$ NMR spectrum of an equimolar mixture of DBPAuCl and Ph_3PAuCl_3 in $CDCl_3$ at 30°C. Assignments as follows: Ph_3PAuCl_3 (42.8 ppm), Ph_3PAuCl (32.4 ppm), $DBPAuCl_3$ (27.9 ppm), DBPAuCl (24.0 ppm).

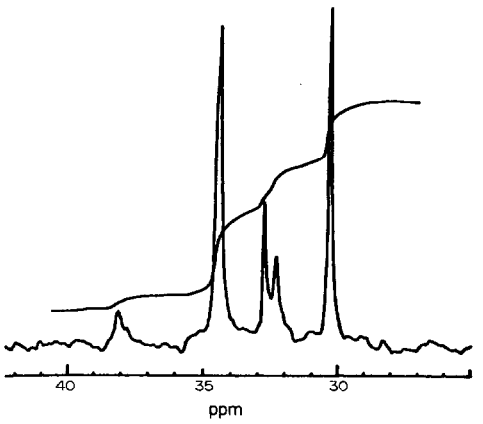

Fig. 3. 40.26 MHz $^{31}P\{^1H\}$ NMR spectrum of an equimolar mixture of Ph_3PAuCl and Ph_3PAuBr_3 in $CDCl_3$ at 30°C. Assignments as follows: *cis*-Ph_3PAuCl_2Br (38.3 ppm), *trans*-Ph_3PAuCl_2Br (37.9 ppm), Ph_3PAuBr (34.5 ppm), *cis*-$Ph_3PAuClBr_2$ (32.9 ppm), Ph_3PAuCl (32.4 ppm), Ph_3PAuBr_3 (30.4 ppm).

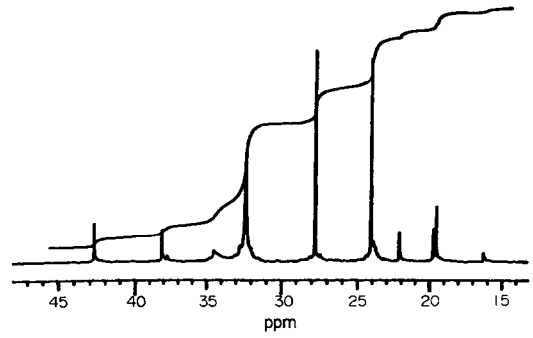

Fig. 4. 40.26 MHz $^{31}P\{^1H\}$ NMR spectrum of an equimolar mixture of DBPAuBr and Ph_3PAuCl_3 in $CDCl_3$ at 30°C. Assignments as follows: Ph_3PAuCl_3 (42.7 ppm), *cis*-Ph_3PAuCl_2Br (38.1 ppm), *trans*-Ph_3PAuCl_2Br (37.8 ppm), Ph_3PAuBr (34.5 ppm), *cis*-$Ph_3PAuClBr_2$ (32.8 ppm), Ph_3PAuCl (32.4 ppm), DBPAuCl$_3$ (27.8 ppm), *cis*-DBPAuCl$_2$Br (24.1 ppm), DBPAuCl (23.9 ppm), *trans*-DBPAuCl$_2$Br (22.1 ppm), *trans*-DBPAuClBr$_2$ (19.5 ppm), *cis*-DBPAuClBr$_2$ (19.5 ppm), DBPAuBr$_3$ (16.2 ppm).

tribution is evident. Ph_3PAuBr plus DBPAuCl$_3$, Ph_3PAuCl plus DBPAuBr$_3$, and DBPAuCl plus Ph_3PAuBr_3 mixtures gave similar results. In each case 12–14 species with the same chemical shifts as given in Fig. 5 and with intensities varying in direct proportion to the varying ligand ratios were observed. In no case were the anticipated 16 resonances observed because of coincidentally equal chemical shifts for some of the species.

Furthermore, complete ligand redistribution was observed for a solution containing an equimolar ratio of Ph_3PAuCl_3 and DBPAuBr$_3$ (Fig. 5). The same species were also found in the same relative amounts for an equimolar mixture of Ph_3PAuBr_3 and DBPAuCl$_3$.

Ligand redistribution also occurs among gold(I) complexes [reaction (13), Fig. 6]. As is evident by the line widths and temperature dependence of this spectrum, the redistributions among gold(I) species are more rapid than those among gold(III) species. Note also that the rate of halide redis-

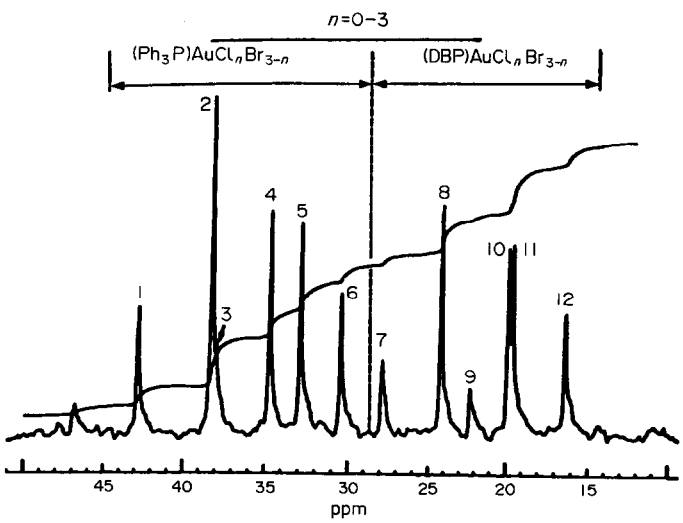

Fig. 5. 40.26 MHz $^{31}P\{^1H\}$ NMR spectrum of an equimolar mixture of Ph_3PAuCl_3 and DBPAuBr$_3$ in $CDCl_3$ at 30°C. Assignments as follows: Ph_3PAuCl_3 (42.9 ppm), *cis*-Ph_3PAuCl_2Br (38.3 ppm), *trans*-Ph_3PAuCl_2Br (38.0 ppm), *trans*-$Ph_3PAuClBr_2$ (34.7 ppm), *cis*-$Ph_3PAuClBr_2$ (32.9 ppm), Ph_3PAuBr_3 (30.5 ppm), DBPAuCl$_3$ (27.9 ppm), *cis*-DBPAuCl$_2$Br (24.3 ppm), *trans*-DBPAuCl$_2$Br (22.3 ppm), *trans*-DBPAuClBr$_2$ (19.9 ppm), *cis*-DBPAuClBr$_2$ (19.6 ppm), DBPAuBr$_3$ (16.5 ppm).

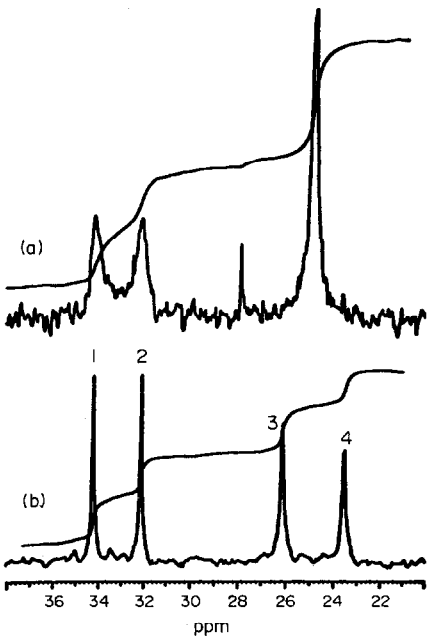

Fig. 6. 40.26 MHz $^{31}P\{^1H\}$ NMR spectra of an equimolar mixture of Ph_3PAuCl and DBPAuBr in $CDCl_3$ at (a) 30°C and (b) −13°C. Assignments as follows: Ph_3P AuBr (34.3 ppm), Ph_3PAuCl (32.2 ppm), DBPAuBr (26.2 ppm), DBPAuCl (23.6 ppm).

tribution is faster for DBPAuX than for Ph_3PAuX species, suggesting that DBP has a greater *trans*-effect than Ph_3P. The same result was observed for an equimolar mixture of Ph_3PAuBr and DBP AuCl.

$$Ph_3PAuCl + DBPAuBr \rightleftharpoons Ph_3PAuBr + DBPAuCl \quad (13)$$

We believe that all of these equilibrium redistribution reactions involve halide-bridged intermediates,[39] similar to that shown in reaction (7). No ionic species such as $[(Ph_3P)(DBP)Au]^+$ or $[(Ph_3P)(DBP)AuX_2]^+$ were ever observed in any of these solutions. Addition of Ph_3P or DBP to solutions containing $LAuX_3$ (L = Ph_3P, DBP; X = Cl, Br) resulted in immediate redox reactions [see eq. (14)]. These results suggest that very little, if any, free Ph_3P or DBP is present during the course of the ligand redistribution reactions. The kinetics and mechanism[56] of the redistribution reactions of pentacoordinate complexes of the type [Au(N ~ N)$(CN)_2$X](N ~ N is a 1,10-phenanthroline; X = Cl, Br) have been described. Anion redistribution of $Ph_3PAuC{\equiv}CPh$ complexes have also been described.[57]

$$Ph_3P + DBPAuCl_3 \longrightarrow Ph_3PCl_2 + DBPAuCl \quad (14)$$

(4) *The solid state identity of* $LAuClBr_2$

The isolated products of the reactions of Ph_3PAuCl and DBPAuCl with Br_2 appear to be homogeneous crystalline substances with narrow melting point ranges and elemental analyses agreeing with the $LAuClBr_2$ composition. However, their $^{31}P\{^1H\}$ NMR spectra in $CDCl_3$ at 30°C show the presence of all six $LAuCl_nBr_{3-n}$ species. Mann and Purdie[34] suggested that only *trans*-$Et_3PAuXX'_2$ is present in the solid state. Williamson and Baird[35] suggested that a mixture of *cis*- and *trans*-LAu $ClBr_2$(L = Ph_3P, Et_3P) is present in the solid state. Puddephatt and Thompson[36] suggested that all six $LAuCl_nBr_{3-n}$ species are present and McAuliffe *et al.*[37] suggested that the solid state products are mixtures of $LAuCl_3$ and $LAuBr_3$ in appropriate proportions. The simplest interpretation of the far IR spectroscopic data (Table 3) is that $LAuBr_3$ and $LAuCl_3$ are present in a 2:1 ratio. This interpretation rests on the fact that the two $LAuClBr_2$ (L = DBP, Ph_3P) complexes show ν(AuCl) and ν(AuBr) vibrations at essentially the same frequencies as those of $LAuCl_3$ and $LAuBr_3$. If the mixed halide species were present in the solid state the ν(AuCl) and ν(AuBr) vibrations for them would be expected to occur at different frequencies, as has been found for HgX_2, HgXX', HgX_2' systems.[58] The CP/MAS $^{31}P\{^1H\}$ NMR spectra (Fig. 7) of the two $LAuClBr_2$ complexes each show two major resonances in a 2:1 intensity ratio (L = Ph_3P, 41.0

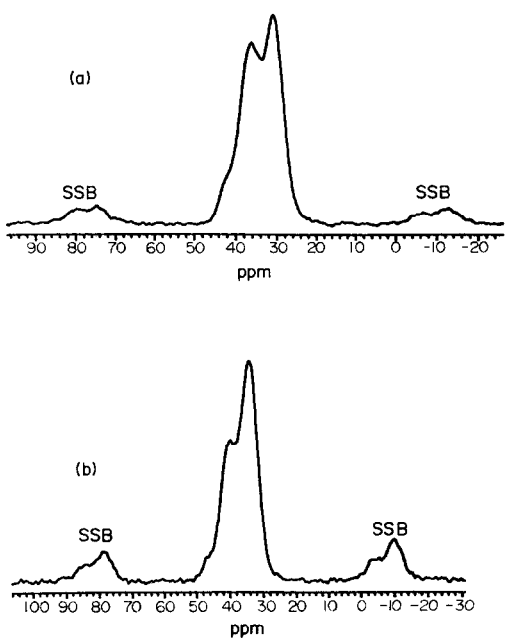

Fig. 7. 109.25 MHz CP/MAS $^{31}P\{^1H\}$ NMR spectra of (a) $DBPAuClBr_2$ and (b) $Ph_3PAuClBr_2$. SSB are spinning sidebands.

Table 3. Gold(III)–halogen stretching frequencies[a] for the $LAuX_3$ and $LAuXX'_2$ complexes[b]

$(Ph_3P)AuClBr_2$	Cl:	366, (347)[d]	310, (313)[d] (301)[e]
	Br:	259, (261)[d] (255)[e]	220, (216)[d]

[a] ν(Au—X) in cm^{-1}.

[b] Recorded as polyethylene pellets.

[c] Refers to the asymmetric (higher energy) as opposed to symmetric (lower energy) stretch of the X—Au—X unit.

[d] From ref. 35, recorded as Nujol mulls mounted between polyethylene discs.

[e] From ref. 37, as Nujol mulls.

and 34.4 ppm; L = DBP, 36.9 and 31.1 ppm). These compare with the CP/MAS $^{31}P\{^1H\}$ NMR spectra of pure Ph_3PAuCl_3 (46.9 ppm), Ph_3PAuBr_3 (36.2 ppm), $DBPAuCl_3$ (42.2 ppm) and $DBPAuBr_3$ (30.5 ppm). Each of these resonances have line widths ($\Delta\nu(1/2)$ ~480 Hz or ~4.4 ppm). We have previously shown that the CP/MAS ^{31}P chemical shift is very environmentally dependent.[9,10,12,29] If $Ph_3PAuCl_nBr_{3-n}$ existed in the solid state with randomly disordered halides, we might expect to see three ^{31}P chemical shifts spanning a range of about 8 ppm. These three resonances would represent Ph_3PAuBr_3 (29.6%), *cis*-Ph_3PAuBr_2Cl (29.6%) plus *trans*-Ph_3PAuBr_2Cl (14.8%) and *cis*-Ph_3AuCl_2Br (14.8%). Given the large CP/MAS line widths together with their lower relative abundances resonances for *trans*-Ph_3PAuCl_2Br (7.4%) and Ph_3PAuCl_3 (3.7%) would probably not be observed (see Fig. 1 for comparison). If only *trans*-Ph_3PAuBr_2Cl was present, only one ^{31}P chemical shift would be observed. Finally, if the solid were a mixture of *cis*- and *trans*-Ph_3PAuBr_2Cl or a mixture of Ph_3PAuCl_3 and Ph_3PAuBr_3, then two resonances should be observed. In the latter case their relative intensities would be 2:1. The observation of three resonances (two major and a minor shoulder) in the CP/MAS ^{31}P NMR spectra (Fig. 7) suggests that these solids probably contain randomly disordered halides.

As further evidence, the X-ray crystal structure of Ph_3PAuBr_2Cl (Fig. 8) was obtained. No inhomogeneity was observable in the crystalline sample. Microscopic observation shows that crystals of Ph_3PAuBr_2Cl are medium-red and those of Ph_3PAuBr_3 are deeper red and that they have different morphologies; they show similar platy morphologies, though the first species gives almost rectangular plates, while crystals of the tribromide are generally diamond-shaped. For Ph_3PAuBr_2Cl the three halides were almost identical in electron density, implying approximately equal substitution of Br by Cl at each site. Bond distances and angles are given in Table 4. Ph_3PAuBr_2Cl is a nearly regular square-planar complex. The two Au—X bonds *trans* to each other [2.399(3) and 2.413(3) Å] are essentially the same length as the Au—X bond *trans* to Ph_3P [2.415(4) Å]. The corresponding distances

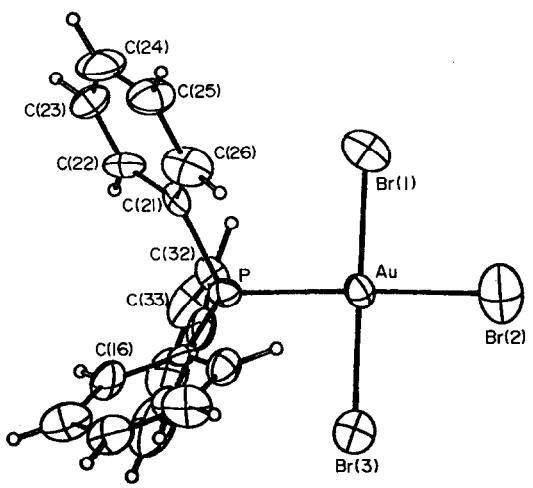

Fig. 8. View of Ph_3PAuBr_2Cl showing the atom labelling scheme; 50% probability ellipsoids. Atoms labelled Br are considered to be substitutionally disordered with approximately 2/3 Br and 1/3 at each site.

Table 4. Selected structural parameters for [$(Ph_3P)AuBr_2Cl$]

Bond lengths (Å)[a]			
Au—Br(1)	2.399(3)	Au—Br(2)	2.415(4)
Au—Br(3)	2.413(3)	Au—P(1)	2.314(6)
P(1)—C(1)	1.794(22)	P(1)—C(21)	1.825(22)
P(1)—C(31)	1.823(26)	Ph: C—C(ave)	1.391(46)
Bond angles (°)			
Br(1)—Au—Br(2)	88.9(1)	Br(1)—Au—Br(3)	177.3(1)
Br(2)—Au—Br(3)	91.1(1)	Br(1)—Au—P(1)	92.6(2)
Br(2)—Au—P(1)	177.2(2)	Br(3)—Au—P(1)	87.3(2)
Au—P(1)—C(11)	112.7(7)	Au—P(1)—C(21)	116.0(7)
C(11)—P(1)—C(21)	102.0(9)	Au—P(1)—C(31)	104.1(8)
C(11)—P(1)—C(31)	111.1(11)	C(21)—P(1)—C(31)	111.1(11)
Ph: C—C—C(ave)	120.0(30)		

[a] Note: the atoms labelled Br are considered to be substitutionally disordered with approximately 2/3 Br and 1/3 Cl at each site.

in Ph_3PAuCl_3[59] [2.273(4), 2.282(4) and 2.347(4) Å] and Et_3PAuBr_3[60] [2.407(1), 2.416(1) and 2.468(1) Å] show that in these complexes the bond *trans* to the phosphine is lengthened because of the high *trans* influence[48–50] of the phosphine. The fact that the Au—X bond *trans* to Ph_3P in Ph_3PAuBr_2Cl is not lengthened to a similar extent suggests greater substitution of Cl for Br in this site, which is consistent with its rather higher apparent thermal parameter.

(*Received* 12 *June* 1991; *accepted* 28 *June* 1991)

Abstract—The title ligand forms stable neutral complexes with gallium and indium and the structure of the latter has been studied by X-ray crystallography.

Kinetically stable complexes of indium and gallium are being examined for use as imaging agents in diagnostic nuclear medicine (^{67}Ga,γ,$t_{1/2}$ = 3.25 days; ^{68}Ga,β^+,$t_{1/2}$ = 68 min; ^{111}In,γ,$t_{1/2}$ = 2.83 days).[1] In order for these complexes to be used *in vivo* they should resist acid (or cation) mediated decomplexation in the pH range 2–8. The synthesis of a set of C- and N-functionalized macrocyclic ligands based on 1,4,7-triazacyclononane triacetic acid that may be attached to tumour-localizing antibodies and rapidly radiolabelled with indium or gallium isotopes has been reported.[2,3] The structures of a hexacoordinate gallium complex of the parent ligand 1,4,7-triazacyclononane triacetate and of its heptacoordinate chloroindium complex have been defined recently.[4,5] A good model for the N-functionalized ligands **2** and **3** is the chiral triacid **1**. The synthesis and preliminary complexation behaviour of this ligand is reported together with the first structural analysis of a hexacoordinate neutral indium complex which has non-crystallographic C_3 symmetry.

Reaction of 1,4,7-triazacyclononane with (*S*)-2-

chloropropanoic acid in the presence of lithium hydroxide yielded the triacid (*R*)-**1** which was purified by chromatography on alumina as its trimethyl ester ($MeOH/H_2SO_4$ followed by HCl/6 M, 18 h, 120°C). The ligand exhibits similar protonation and complexation behaviour to **4** (Table 1).[6]

The ^{67}Ga complex of **1** was prepared (pH 5, 37°C, 15 min) by admixture of **1** and gallium-67 trichloride (as a solution in 150 mM HCl). Analysis by anion exchange HPLC with radiometric detection revealed that 99.2% of the activity was associated with the neutral gallium complex (**1** · Ga) following addition of an excess of DTPA (Hichrom AX300, elutant 0.2 M NH_4OAc/10% MeCN; $t_R = 4.1$ min). The biodistribution of the (**1** · ^{67}Ga) complex in mice was examined and revealed that > 99% of the activity had been excreted after 24 h, consistent with the high *in vivo* stability of the complex. The (**1** · ^{71}Ga) complex may also be observed in 6 M HNO_3 by ^{71}Ga NMR ($\delta_{Ga} = +149$ ppm).

The neutral indium complex [(*R*)-**1** · In], prepared at pH 1 following admixture of equimolar quantities of **1** and aqueous indium trinitrate solution crystallized slowly from solution. The microanalysis suggested that crystallization occurred with one molecule of water. The crystal structure* revealed that the indium was tightly bound by the nitrogen and oxygen donors, with shorter In—O and In—N bond lengths than any reported previously in analyses of indium complexes with tribasic ligands.[5,7-9] The coordination geometry of the indium atom is a distorted trigonal prism in which the angle of distortion from a regular trigonal prism is 20.8°(2) (*cf.* 60° for an octahedral complex). This value is similar to that found for the ferric complex of **4** (25.2°).[10] The indium complex is apparently much less soluble in water (pH 1–8) than (In · **4**) or (Ga · **4**) perhaps due to the less effective solvation of the more lipophilic complex.

*Crystal data for [(*R*)-In · **1**] $C_{15}H_{42}InN_3O_6$, 0.9 (H_2O): $M = 473.4$, cell dimensions $a = 6.679(2)$, $b = 15.551(3)$, $c = 17.361(3)$ Å, $U = 1803.1(7)$ Å^3, $D_c = 1.744$ g cm^{-3}, $Z = 4$, $F(000) = 964$, Mo-K_α radiation ($\lambda = 0.70903$ Å), $\mu = 13.3$ cm^{-1}. Orthorhombic space group $P22_12_1$ uniquely from the systematic absences. Data collected to a maximum 2θ of 54° and corrected for Lorentz, polarization and absorption effects. 2267 independent reflections measured of which the 1973 with $I > 2.5\sigma(I)$ were labelled observed and used in the analysis. The structure was solved by the heavy-atom method and refined by full-matrix least-squares calculations using the NRCVAX[11] programs. All hydrogen atoms were visible in difference maps and were allowed for as riding atoms. The absolute configuration was established unequivocally by the refinement. At convergence, $R = 0.029$, $R_w = 0.025$. Atomic coordinates, full details of molecular dimensions and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

A NEW ROUTE TO THE PHOSPHINE-SUBSTITUTED CLUSTERS $[Os_3(CO)_{11}(PH_3)]$ AND $[HM_3(CO)_{10}(\mu_2\text{-}PH_2)]$ (M = Ru OR Os)

(*Received* 10 *May* 1991; *accepted* 28 *May* 1991)

Abstract—The reaction of $[Ph_4]I$, phosphonium iodide, with the appropriate cluster precursor, e.g. $[Os_3(CO)_{11}(MeCN)]$ or $[M_3(CO)_{10}(MeCN_2)]$ (M = Ru or Os), in the presence of base, BaO, has been shown to be a highly efficient route to the phosphine-substituted clusters $[Os_3(CO)_{11}(PH_3)]$ and the phosphido-bridged cluster $[HM_3(CO)_{10}(\mu_2\text{-}PH_2)]$ (M = Ru or Os).

We have previously reported[1] the synthesis of the phosphine-substituted clusters $[Os_3(CO)_{11}(PH_3)]$ (**2**) and $[Os_3(CO)_{10}(PH_3)_2]$ (**5**) from the direct reaction of $[Os_3(CO)_{11}(MeCN)]$[2] (**1**) or $[Os_3(CO)_{10}(MeCN)_2]$ (**3**) with $[PH_3]$. In a related reaction, the hydrido-cluster $[HRu_3(CO)_{10}(\mu_2\text{-}PH_2)]$ (**7**) has been prepared from $[Ru_3(CO)_{12}]$ and $[PH_3]$. These compounds have been used in the synthesis of higher nuclearity clusters and, in the case of osmium, found to be highly suitable precursors for the formation of the monoanionic hexa-osmium cluster $[Os_6P(CO)_{18}]^-$ containing an interstitial P-atom.[1] Nevertheless, their use has been limited by the potential hazards of $[PH_3]$. In this communication we wish to report a new, highly efficient and safe route to these important precursor materials in which the phosphonium salt $[PH_4]I$ is used as the source of $[PH_3]$.

RESULTS AND DISCUSSION

In a typical reaction the appropriate cluster, e.g. $[Os_3(CO)_{11}(MeCN)]$ (**1**) (120 mg; 0.13 mmol), was treated with $[PH_4]I$ (20 mg; 0.13 mmol) and BaO (140 mg; 0.91 mmol) in CH_2Cl_2 at room temperature for 40 min and then at 40°C for 20 min. After separation by column chromatography on silica, the product, $[Os_3(CO)_{11}(PH_3)]$ (**2**) was isolated in 83% yield and characterized by the usual spectroscopic methods. In addition, a small amount of the iodo-cluster, $[HOs_3(CO)_{10}(\mu_2I)]$, was also obtained. This and other related reactions are illustrated in Scheme 1. In the reaction with $[Os_3(CO)_{10}(MeCN)_2]$ (**3**) the bis-substituted derivative $[Os_3(CO)_{10}(PH_3)_2]$ was the major product. On

Scheme 1.

warming, further reaction occurred and the hydrido-cluster $[HOs_3(CO)_{10}(\mu_2\text{-}PH_2)]$ (**6**) was obtained. However, with the ruthenium analogue $[Ru_3(CO)_{10}(MeCN)_2]$ (**4**) these reactions are rapid and the only identifiable product was the hydrido-cluster $[HRu_3(CO)_{10}(\mu_2\text{-}PH_2)]$ (**7**). Compounds (**3**), (**5**), (**6**) and (**7**) were characterized by elemental analysis, IR and ^1H NMR spectra. These data were fully in accord with those reported earlier.[1]

This relatively easy route to the compounds (**2**), (**6**) and (**7**) has allowed us to carry out a more extensive examination of their chemistry. We find, for example, that compound (**6**) readily undergoes reaction with electrophilic reagents (RX) to produce the phosphorus-substituted products $[HOs_3(CO)_{10}(PHR)]$ [R = Me (**8**); R = CH_2—$CH{=}CH_2$ (**9**)] which are obtained in both the exo- and endo- isomeric forms. The structures of these isomers was initially derived from a comparison of their IR and NMR spectroscopic data with those of the clusters $[HOs_3(CO)_{10}(PHPh)]$ or $[HRu_3(CO)_{10}(PHPh)]$ (**4**), both of which are known to

Table 1. Selected ^1H NMR spectroscopic data

Compound	Chemical shift values (**8**)		
(**6**) ($CDCl_3$)	5.25 (ddd)	4.98 (dd)	−19.90 (dd)
(**7**) ($CDCl_3$)	5.09 (ddd)	4.43 (dd)	−17.45 (dd)
(C_6D_6)	4.47 (ddd)	3.68 (dd)	−17.62 (dd)
(**8a**) ($CDCl_3$) endo	6.16 (ddqd)	1.80 (dd)	−19.48 (dd)
(C_6D_6) endo	5.62 (ddqd)	1.82 (dd)	−19.14 (dd)
(**8b**) ($CDCl_3$) exo	6.43 (ddq)	1.81 (dd)	−19.00 (dd)
(C_6D_6) exo	5.72 (ddq)	1.81 (dd)	−19.20 (dd)
(**9a**) ($CDCl_3$) endo	2.58 (dddd) (CH_2)	5.19–5.29 (m) (=CH_2) 5.89 (dddt) (=CH) 6.05 (ddt) (C_6H_5)	−19.57 (dd)
(**9b**) ($CDCl_3$) exo	3.36 (ddd)	5.20–5.33 (m) 5.85–6.11 (m) 6.25 (ddt)	−19.04 (dd)

possess exo-geometries on the basis of single crystal X-ray structure analysis.[3] From the ^{1}H NMR spectrum the ratio of exo- to endo- products has been found to be *ca* 4 : 1 in the case of compound (**8**) and 7 : 1 in the case of compound (**9**). Cluster (**9**) readily undergoes isomerization and, on starting with a 7 : 1 mixture of exo- and endo-products, conversion to the pure endo-product occurred readily on warming to *ca* 70°C.

The ^{1}H NMR spectra of these products are given in Table 1. Initially they were assigned on the basis of the arguments given above. Further confirmation that our assignment of the exo- and endo-protons was probably correct came from the spectra obtained for samples in benzene-d_6 as a solvent. In this case, as expected, the exo-proton undergoes the more substantial solvent-shift. Furthermore, the endo-proton shows the unexpected larger coupling to the hydrido-ligand [^1J(HP) and ^3J(HH)].

A MONONUCLEAR TERT-BUTYLIMIDO COMPLEX OF NIOBIUM(V). X-RAY CRYSTAL STRUCTURE OF $[Ph_3PCH_2Ph][Nb(NBu^t)Cl_4(py)] \cdot CH_2Cl_2$

WILLIAM CLEGG, R. JOHN ERRINGTON,* DAVID C. R. HOCKLESS and CARL REDSHAW

Department of Chemistry, The University of Newcastle upon Tyne, Newcastle upon Tyne NE1 7RU, U.K.

(*Received* 24 *May* 1991; *accepted* 25 *June* 1991)

Abstract—$NbOCl_3$ reacts with Bu^tNH_2 in the presence of $[Ph_3PCH_2Ph]Cl$ and pyridine in refluxing toluene to give the mononuclear anion $[Nb(NBu^t)Cl_4(py)]^-$, which has been structurally characterized by X-ray crystallography.

Recent interest in organoimido groups as auxiliary ligands for higher oxidation state organometallic chemistry of the early transition metals[1] has stimulated the search for simple synthetic routes to suitable starting materials. The development of molybdenum and tungsten organoimido chemistry has been facilitated by the convenience of the reactions shown in (1) and (2).[2] For the heavier Group 5 elements, the reactions between MX_5 (M = Nb, Ta) and amines, $Me_3SiNHBu^t$ or RNH_2 (R = Et, Pr^i, Bu^t), have been shown to give $[\{M(NBu^t)Cl_3(NH_2Bu^t)\}_2]$ (**1**) or $[\{M(NR)(NHR)Cl_2(NH_2R)\}_2]$ (**2**), respectively, and these can be converted to mononuclear complexes $[M(NR)Cl_3L_2]$ (**3**) or $[M(NR)(NHR)Cl_2L_2]$ (**4**) by treatment with the appropriate ligands.[3] The crystal structure of **2** (M = Ta) has been determined[4] but none of the mononuclear adducts (**3** or **4**) has been characterized crystallographically.

$$WOCl_4 + RNCO \longrightarrow W(NR)Cl_4 + CO_2 \quad (1)$$

$$MoCl_4(thf)_2 + RN_3 \longrightarrow Mo(NR)Cl_4(thf) + N_2 \quad (2)$$

We have been studying the oligomerization of transition metal species $M(X)(Y)Cl_2$ (M = Mo, W; X, Y = O or NR), and have structurally characterized the anions $[W_6O_{14}Cl_{10}]^{2-}$ (**5**), $[W_4(NBu^t)_4O_4Cl_{10}]^{2-}$ (**6**),[5] $[W_3(NBu^t)_3(NPh)_3Cl_7]^-$ (**7**)[6] and $[Mo_2(NBu^t)_4Cl_5]^-$ (**8**).[7] Compound **6** was obtained from the reaction between $WOCl_4$ and Bu^tNH_2 in the presence of Cl^-. In an effort to extend these studies to Group 5 we treated $NbOCl_3$ with Bu^tNH_2 in the presence of $[Ph_3PCH_2Ph]Cl$. The yellow crystalline product obtained has not yet been fully characterized and we have been unable to grow crystals for an X-ray structure analysis, but NMR and IR spectra indicate that it contains terminal NBu^t, μ-O, and coordinated Bu^tNH_2 with diastereotopic hydrogens, which, together with the ^1H NMR inte-

gration, suggest a formula such as $[Ph_3PCH_2Ph][Nb_2(NBu^t)_2(\mu\text{-}O)_2Cl_3(NH_2Bu^t)_2]$.

We repeated the reaction in the presence of pyridine in an attempt to obtain an analogous compound containing pyridine in place of Bu^tNH_2, which we hoped would provide crystals for an X-ray study. Long yellow needles were obtained when the product was recrystallized from CH_2Cl_2/hexane* and the X-ray diffraction study† showed this compound to be the $[Ph_3PCH_2Ph]^+$ salt of a mononuclear tert-butylimido species $[Nb(NBu^t)Cl_4(py)]^-$, an anionic analogue of the adducts (**3**) described by Nielson. The structure of the anion is shown in Fig. 1 and selected bond lengths and angles are given in Table 1.

The anion contains the characteristic features of d^0 transition metal mono-organoimido complexes,[8] although few examples are known for niobium. The distorted octahedral structure with equatorial chlorines displaced away from the multiply-bonded tert-butylimido nitrogen [average Cl—Nb—N(1) = 97°] has a Nb—N_{imido} bond length of 1.731(3) Å, which is similar to that in $[\{Nb(NPh)Cl_2(SMe_2)\}_2(\mu\text{-}Cl)_2]$ [1.733(7) Å][9] but shorter than in other examples of niobium organoimido complexes.[8] The Nb—N_{imido}—C linkage is almost linear, with an angle at N(1) of 176.4(4)°.

Although we have not yet established a mechanism for this transformation of a niobium oxo compound into a tert-butylimido complex, it seems likely that an oxoimido species is formed initially (as in the reaction without pyridine discussed above) which then rearranges to give an insoluble oxo compound and a soluble tert-butylimido complex. We have observed similar redistribution reactions with tungsten oxoimido complexes, where solubility properties seem to determine which products are formed.[10] Further work on this niobium system is in progress.

* Bu^tNH_2 (3.30 cm^3, 31.4 mmol) and pyridine (0.85 cm^3, 10.5 mmol) were added to $NbOCl_3$ (2.25 g, 10.5 mmol) and $[Ph_3PCH_2Ph]Cl$ (4.06 g, 10.4 mmol) in toluene (35 cm^3) and the mixture was heated under reflux for 17 h. After removal of the solvent under reduced pressure, the resulting solid was extracted into CH_2Cl_2 (20 cm^3) and filtered from a white residue. Diffusion of hexane into this solution over several days produced long, yellow needles of $[Ph_3PCH_2Ph][Nb(NBu^t)Cl_4(py)]\cdot CH_2Cl_2$. Satisfactory microanalytical data have been obtained. δ_H (200 MHz, CD_2Cl_2): 1.33 (s, 9H, NC_4H_9), 4.66 [d, 2H, ^2J(PH) 14.2 Hz, PCH_2Ph], 6.8–7.8 (multiplets, 23H, $[Ph_3PCH_2Ph]^+$ and *m*-, *p*-C_5H_5N), 9.29, [d, 2H, ^4J(HH) 4.8 Hz, *o*-C_5H_5N]. $\delta C\{^1H\}$ (50.3 MHz, CD_2Cl_2): 29.5 [s, $NC(Me_3)$], 69.28 (s, $NCMe_3$), 117.37 [d, ^1J(PC) 85.7 Hz, PCH_2Ph], 123.01, 136.79, 151.73, (C_5H_5N), 126.73 [d, J(PC) 8.9 Hz], 128.73 [d, J(PC) 3.7 Hz], 129.04 [d, J(PC) 3.3 Hz], 130.41 [d, J(PC) 12.6 Hz], 131.27 [d, J(PC) 5.5 Hz], 134.15 [d, J(PC) 9.8 Hz], 135.52 [d, J(PC] 2.8 Hz], (Ph_3PCH_2Ph). ν(Nb—Cl) 308, 314 cm^{-1}, s.

† Crystal data for $[Ph_3PCH_2Ph][Nb(NBu^t)Cl_4(py)]\cdot CH_2Cl_2$: $C_{35}H_{38}N_2PCl_6Nb$, Mol. wt = 823.3, monoclinic, a = 11.5933(8), b = 12.0082(8), c = 28.5389(21) Å, β = 100.139(7)°, V = 3911.0 $Å^3$, Z = 4, space group $P2_1/c$; R = 0.0390, R_w = 0.0396 from 3485 unique observed reflections with $3 < 2\theta < 45°$ measured with Mo-K_α radiation (λ = 0.71073 Å) and corrected for absorption. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited as supplementary material with the editor from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

BOOK REVIEW

Gmelin Handbook of Inorganic Chemistry. Pb–Organolead Compounds, Part 2. Published by Gmelin Institute for Inorganic Chemistry of the Max Planck Society for the Advancement of Science. Springer, Berlin, 1990, ISBN 3-540-93606-8, 5 ills, xi+273 pp., 830 g, hard cover DM 1203.

System number 47 of the renowned *Gmelin Handbook of Inorganic Chemistry* comprises the chemistry of lead. In the Organolead series two volumes have appeared, dealing with tetramethyllead and tetraethyllead (TEL), respectively. Both compounds are well known to be effective anti-knock agents in the combustion of gasoline in engines.

In the present book the huge body of literature on TEL has been collected, although not all patent data have been included. The literature has been covered through 1988, but *Chemical Abstracts* has been evaluated through No. 110 of 1989.

The book is divided into clear sections describing the various features of TEL. The first section is a comprehensive enumeration of the many routes that are available for the preparation of TEL, including listings of these in well-organized tables. In the same chapter the analytical techniques for TEL which have been used are described. These deal mainly with the detection of TEL in gasolines, air, natural waters, waste waters, marine sediments and biological samples.

The following chapters list the physical properties of TEL, and a wealth of data is presented, again often in the familiar Gmelin tabular format. The majority of the book is dedicated to a thorough description of the chemical reactions of TEL, starting with its thermally or radiation-induced decomposition. On the whole, the data are very well presented, although the part on the decomposition reactions is somewhat disorderly arranged.

Chapters on the physiological properties, toxicity and environmental impact of TEL are included, which is important in view of the extreme toxicity of TEL. The section on the uses of TEL is largely dedicated to its anti-knock properties, although further applications, such as chemical vapour deposition and vapour phase epitaxy, are also listed.

In conclusion, the book is an excellent summary of the profusion of literature on tetraethyllead. The book clearly reflects the German *Gründlichkeit* and subjects of interest are easily accessible for the reader.

ERRATA

A theoretical study of the linear vs bent geometry for several MX_2 molecules: MgF_2, CaH_2, CaF_2, CeO_2 and $YbCl_2$. R. L. DeKock, M. A. Peterson, L. K. Timmer, E. J. Baerends and P. Vernooijs (*Polyhedron*, Vol. 9, No. 15/16, pp. 1919–1934, 1990).

The equation on p. 1930 for the variation of energy as a function of angle has an error. The third line of this equation represents the dipole–dipole term, and here reference is made to the term in parentheses in that third line. As published, this term reads

$$2+\cos^2\theta-1/(2\cos\theta).$$

This term should read

$$(8/3)-1/(2\cos\theta).$$

For the range of angles considered, the correct equation differs little from the equation used. Hence, there is no change in any of the discussion or Figs 1 and 2.

The authors wish to thank Professor H. Stoll of the Universität Stuttgart for pointing out the correction.

8. CONCLUSION 1990

1. INTRODUCTION

The chemistry of aluminium, one of the most abundant elements in nature, is well-established. However, a study of the alkoxides, β-diketonates and carboxylates reveals interesting and novel features which are briefly presented in this review.

The three classes of compounds included in this review are obviously correlated, as shown by their general formulae.

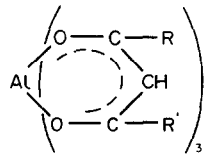
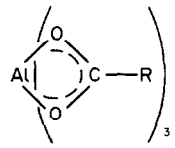
;



and



The polarization of the $Al^{\delta+}$—$O^{\delta-}$—C bond is considerably reduced by the +I inductive effect of the alkyl group in alkoxide derivatives. The donation of lone pair(s) of electrons from the alkoxy group(s) of other alkoxide molecule(s) resulting in the formation of associated/polymeric alkoxide species or from a suitably placed oxygen atom in the chelating β-diketonate ligand would further reduce the polarizability of Al—O bonds. On the other hand, the carbonyl group of the carboxylate ligand(s) would enhance significantly the polarity of the Al—O bond although this would tend to be attenuated by the carboxylate group behaving as a bidentate ligand. This article deals mainly with the attempts made during the past 3–4 decades to utilize the above correlationships in the development of new facets in the chemistry of the latter two classes of compounds of alkoxides.

The electron deficient nature of aluminium is clearly depicted by the formation of not only dimeric aluminium chloride, but also dimeric trialkyls, $[AlR_3]_2$. The extraordinary stability of the first homologue, $[Al(CH_3)_3]_2$, of the latter series illustrates clearly the effect of size (steric factor) of aluminium in addition to its electron deficient character. The alkoxides, β-diketonates and carboxylates of aluminium provide some of the most apt examples, depicting the interplay and delicate balance of electronic and steric effects which are generally the key factors affecting the chemistry of any species. In this direction, the possibility of interaction between vacant *p* orbitals on oxygen in some hindered phenoxide derivatives (Section 2.2.5) with π-acceptor *p* orbitals of monomeric aluminium complexes deserves special mention in addition to alkoxy-bridging associated derivatives referred to above.

2. ALKOXIDES OF ALUMINIUM

In spite of aluminium alkoxides being amongst the most widely studied alkoxides of any element and their extensive applications as catalysts in Meerwein–Ponderoff and Openauer reactions, their chemistry (e.g. even the observed degree of association) was highly confused up to the early 1950s. The extension of the concept of the simple "ageing" phenomenon,[1] well known in the case of aluminium hydroxide (or hydrous oxides) to the alkoxides, and the explanation of the same on the basis of a change from coordination state four to six of aluminium, has opened a new phase in the understanding of aluminium alkoxide chemistry.[2]

2.1. *Synthesis*

Aluminium alkoxides can be synthesized by one of the following methods.

(i) *Reaction of aluminium metal with an alcohol.* In spite of its weakly electropositive character, the reaction of aluminium turnings with alcohols in the presence of catalysts like iodine and/or mercuric chloride[3,4] yields the corresponding aluminium alkoxides.

$$Al + 3ROH \xrightarrow[\text{reflux}]{I_2/HgCl_2} Al(OR)_3 + 3/2H_2\uparrow$$

[R = Et, Pr^i, Bu^t).

The nature of alkyl group affects the reaction considerably, significantly reducing the reactivity of long chain and sterically demanding alcohols. In view of their volatility, the products can be conveniently purified by distillation or sublimation under reduced pressure from the reaction mixture.

In contrast to alcohols, phenols are more reactive, yielding aluminium phenoxides without requiring any catalyst.[5,6]

$$\underset{\text{(excess)}}{Al + 3PhOH} \xrightarrow[\text{reflux}]{} Al(OPh)_3 + 3/2H_2\uparrow.$$

The reactions of metallic aluminium with substituted and higher molecular weight phenols has not been studied in detail and their comparatively slow nature is mentioned in a patent[7] only.

(ii) *Reaction of aluminium chloride with an alcohol in the presence of ammonia.* In view of the facile synthetic route of aluminium alkoxides from metallic aluminium itself, the conventional procedure of preparing metal alkoxides[2] from anhydrous metal chlorides has not been pursued actively, except for a report by Teischner.[8]

$$AlCl_3 + 3ROH + 3NH_3 \longrightarrow Al(OR)_3 + 3NH_4Cl\downarrow.$$

The reactions of aluminium chloride with alcohols do not appear to proceed to completion in the absence of a base. For example, Funk *et al.*[9] reported the formation of a product $AlCl_2(OC_2H_5)\cdot 2AlCl_3\cdot 10(EtOH)$ by the reaction of $AlCl_3$ with ethanol. Mehrotra and Mehrotra[10] on repeating the same reaction in benzene solution, isolated a product having the composition $Al_3Cl_7(OEt)_2\cdot 7EtOH$, which on being heated under reduced pressure is converted to $Al_3Cl_5(OEt)_4\cdot 3EtOH$ (the structure of the corresponding isopropoxide analogue, $Al_3Cl_5(OPr^i)_9$ has been elucidated by Turova and co-workers).[11,12]

As in the case of reaction with the metal, phenols are also more reactive[5] with aluminium chloride.

$$AlCl_3 + 3PhOH \xrightarrow{\text{molten}} Al(OPh)_3 + 3HCl\uparrow$$

$$AlCl_3 + 3PhOMe \xrightarrow{70\text{–}80^\circ C} Al(OPh)_3 + 3MeCl\uparrow.$$

(iii) *Alcoholysis reactions of aluminium alkoxides.* In accord with the common characteristic of almost all main group and early transition metal alkoxides,[2,13] aluminium alkoxides undergo facile alcoholysis reactions.

$$Al(OR)_3 + nR'OH \rightleftharpoons Al(OR')_n(OR)_{3-n} + nROH\uparrow.$$

These alcoholysis reactions can be utilized for the preparation of higher alkoxides from the lower analogues like ethoxide or isopropoxide. The reactions can be driven to completion by fractionating out the lower boiling alcohol azeotropically with benzene (used as solvent). Under these conditions, the reactions can be carried out in any desired stoichiometric ratio, yielding mixed alkoxides of the type $Al(OR')_x(OR)_{3-x}$.[1,14]

Alcoholysis reactions are quite facile, but these are subject to steric factors leading to the formation of mixed products only, e.g. $Al_2(OEt)(OBu^t)_5$, with sterically demanding alcohols.

Aluminium phenoxide can also be prepared by this interchange technique.[15] The reactions of aluminium alkoxides with hindered phenols have not received much attention and a preliminary investigation[16] indicates the formation of $Al(OBu^t)(OC_6H_3Bu^t_2\text{-}2,6)_2$ with aluminium in the three-coordination state.

(iv) *Transesterification reactions of aluminium alkoxides.* Baker[17] observed that the reaction between aluminium isopropoxide and higher alkyl acetates could be driven in the forward direction by fractionating off the lower boiling isopropyl acetate.

$$Al(OPr^i)_3 + 3CH_3COOR \longrightarrow Al(OR)_3 + 3CH_3COOPr^i\uparrow.$$

Mehrotra and Kapoor[18,19] while extending the above method to the synthesis of alkoxides of other metal (gallium, iron, niobium, tantalium, etc.) reported that with the use of cyclohexane (which forms a lower boiling azeotrope with ethyl or isopropyl acetate) as solvent, the reactions can also be conveniently accomplished in a desired stoichiometric ratio.

$$Al(OR)_3 + xCH_3COOR' \longrightarrow Al(OR)_{3-x}(OR')_x + xCH_3COOR$$

(R = Et or OPr^i; x = 1, 2, 3).

(v) *Reactions of trialkylaluminium with alcohols and phenols.* Trialkylaluminiums, AlR_3, undergo facile substitution reactions with alcohols[20] and phenols[21] yielding products which can be represented as $Al(R)_{3-n}(OR')_n$ and $Al(R)_{3-n}(OAr)_n$ (where R = Me, Et, Bu etc.; R′ = Me, Et, etc.; Ar = C_6H_5 or C_6H_4X etc.; n = 1–3).

Most of the above products are associated in nature.[20,21] Monomeric alkyl phenoxides with hindered phenols have been studied in considerable detail in recent years and their structural and other interesting features are described in Section 2.2.5.

(vi) *Direct electrochemical synthetic techniques.* Notable success has been claimed[22] in the synthesis (including industrial production) of titanium, zirconium, germanium, niobium, tantalum, yttrium, scandium and gallium by electrolysis in conducting admixtures of alcohols with supporting electrolytes such as Bu_4NBr, $Bu_4N \cdot BF_4$ and NaBr using the relevant metal as anode. It may not be out of place to emphasize that the technique has not yet been successful in the case of aluminium, indicating the need for further investigations.

2.2. *Physico-chemical and spectroscopic properties of aluminium alkoxides*

Taking the electronegativity values of aluminium and oxygen as 1.5 and 3.5, respectively, the Al—O bond could be expected, simply on Pauling's formula, to have ~ 50% ionic character. However, most of the aluminium alkoxides show marked covalent behaviour in their solubility in organic solvents and volatility under reduced pressure. The polarization of the $Al^{\delta+}$—$O^{\delta-}$ bond is reduced by the +I inductive effect (Al⇐O—C) of the alkyl group which should increase from primary to secondary to tertiary. The formation of alkoxy bridges of the type: RO(Al)OR(Al); would also tend to operate in the same direction. The action of reducing the electrophilicity of the central aluminium atom by the increased +I as well as steric demands of the more ramified alkyl group would tend to reduce the degree of association and increase the volatility of the isomeric alkoxides of ramified alcohols (cf. Table 1).

It is difficult to sort out the comparative influence of steric and electronic effects but an effort has been made[14] to assess these by synthesizing all the eight isomeric amyloxides of aluminium

Table 1. Boiling points and molecular association of some aluminium alkoxides

Alkoxides	Boiling point °C mm^{-1}	Molecular association in boiling benzene
$Al(OCH_2CH_3)_3$	184.0/0.5	4.1
$Al(OCH_2CH_2CH_3)_3$	232.5/5.0	4.0
$Al(OCHMe_2)_3$	124.0/5.0	4.0
$Al(OCH_2CH_2CH_2CH_3)_3$	270.0/5.0	3.9
Al(OCHMeEt)	172.0/5.0	2.4
$Al(OCMe_3)_3$	160.0/1.0[a]	2.0
$Al(OCH_2CH_2CH_2CH_2CH_3)_3$	255.0/1.0	4.0
$Al(OCH_2CH_2CHMe_2)_3$	195.0/1.0	4.0
$Al(OCH_2CHMeEt_2)_3$	200.0/0.6	4.1
$Al(OCH_2CMe_3)_3$	180.0/8.0	2.07
$Al(OCHEt_2)_3$	165.0/1.0	2.08
$Al(OCHMeCH_2CH_2CH_3)_3$	162.0/0.5	2.06
$Al(OCHMeCHMe_2)_3$	162.0/0.6	1.98
$Al(OCHMe_2)(OMe_2CH_2Me)_2$	154.0/0.5	1.97

[a] Sublimed.

(Table 1). Out of these, the neopentyloxide is of special interest. It is well known that the neopentyl group exhibits the inductive effect of a primary amyl group, but steric factors are similar to the secondary amyl groups due to the close proximity of a tert. butyl group to the primary CH_2 carbon atom. The properties (volatility as well as molecular association of aluminium neopentyloxide) are almost identical to those of three secondary amyloxides (all dimeric) and sharply different from the other three primary amyloxides (all tetrameric) (Table 1).

It may be noted that efforts to synthesize simple tris-tert.-amyloxides, $Al(OAm^t)_3$, were not successful both from the reaction of aluminium metal with the tertiary amyl alcohol as well as from the alcoholysis of aluminium ethoxide or isopropoxide, in which dimeric mixed alkoxides,[14] $[Al(OR)(OAm^t)_2]_2$ (with R = Et, Pr^i), were the end products. It is suggested that it may be possible to synthesize the tris-tert.-amyloxide of aluminium, $Al(OAm^t)_3$, from the reaction of tert. amyl alcohol on trialkylaluminiums, in which case the intermediate bis-amyloxide products should more easily interact with a third molecule of the tertiary alcohol.

2.2.1. *Ageing phenomenon.* With widely conflicting reports from reliable groups of scientists[23–25] on the molecular association of aluminium isopropoxide ranging from two up to 10, the prevailing confusion was resolved by the observation by Mehrotra[1] of the ageing phenomenon of aluminium isopropoxide. It was shown that the vapour density of aluminium isopropoxide shows dimerization up to a high temperature whereas the freshly distilled supercooled liquid aluminium isopropoxide is essentially trimeric. This trimeric form crystallizes in a few days to a tetrameric species $[Al(OPr^i)_3]_4$, which is fairly stable and tends to show further polymerization only on standing for a long time (some months).

Turova *et al.*[26] confirmed the above observation and showed that the molecular complexity, as well as the melting point of aluminium isopropoxide, depends on ageing of the sample (Fig. 1). The phenomenon of the ageing process has also been discussed by other workers.[27–29]

According to these studies, the degree of association in supercooled melts increases over a period of several minutes from 2 to 2.7/2.8 and then gradually, during several weeks, to 4.

The mass spectrometric studies[30,31] also indicate the existence of penta-, hexa- and even hepta-associates in a very low proportion along with trimeric and tetrameric molecules.

2.2.2. *Thermal stability.* Aluminium alkoxides are in general thermally stable under reduced pressure and can be distilled or sublimed in quantitative yields. However, on heating under atmospheric pressure to ~ 350°C, they tend to undergo decomposition with the formation of a mixture of basic oxides, e.g. the decomposition of aluminium ethoxide[32,33] proceeds as follows.

$$2Al(OC_2H_5)_3 \longrightarrow Al_2(OC_2H_5)_4O + (C_2H_5)_2O$$

$$Al_2(OC_2H_5)_4O \longrightarrow 2Al(OC_2H_5)O + (C_2H_5)_2O$$

$$2Al(OC_2H_5)O \longrightarrow Al_2O_3 + (C_2H_5)_2O.$$

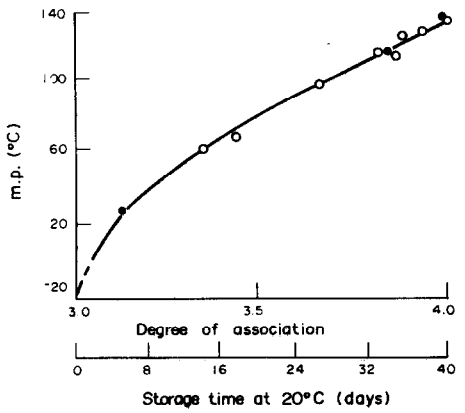


Fig. 1. The dependence of melting point on the degree of association of $Al(OPr^i)_3$: ● data cited by Fieggen and Gerding;[27] ○ data cited by Turova *et al.*[26]

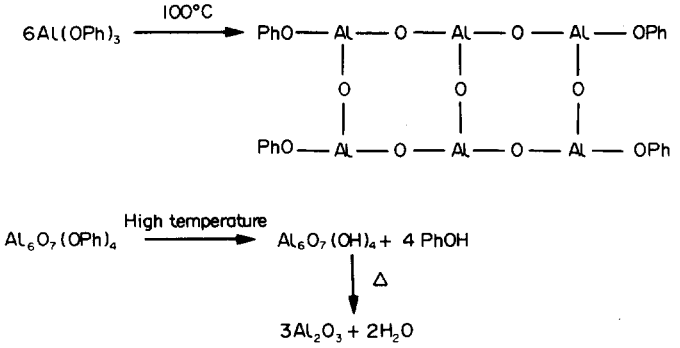
The derivatogram of aluminium isopropoxide showed a three stage decomposition corresponding to the following mechanism.[34]

$$2Al(OPr^i)_3 \xrightarrow{\sim 200^\circ C} Al_2(OPr^i)_2(OH)_4 + 4CH_3CH{=}CH_2$$
$$\downarrow \sim 250^\circ C$$
$$Al_2O_2(OH)_2 + 2Pr^iOH$$
$$\downarrow \sim 330^\circ C$$
$$Al_2O_3 + H_2O.$$

In comparison to alkoxides, the corresponding phenoxides are non-volatile and undergo decomposition with the formation of intermediates like $Ph[OAl(OH)]_4OPh$.[35,36] The D.T.A. studies of aluminium phenoxide show the beginning of decomposition[6] around 100°C with the formation of a residue corresponding in analysis to $Al_6O_7(OPh)_4$ which is later converted to Al_2O_3 at higher temperatures (Scheme 1).



Scheme 1.

2.2.3. *Hydrolysis.* Although aluminium alkoxides like other metal alkoxides are extremely susceptible to hydrolysis, very little work has been carried out in this direction.[37] Alkoxides as well as phenoxides of both metals and metalloids undergo rapid hydrolysis to form basic alkoxides or phenoxides. The nature of the products is dependent on the conditions of hydrolysis. Pfeifer and Flora[35] reported the following order of hydrolytic stability in the mixed butoxy phenoxides of aluminium.

$$Al(OBu)_3 > Al(OPh)(OBu)_2 > Al(OPh)_2(OBu) > Al(OPh)_3.$$

An active interest has arisen in the hydrolysis of aluminium alkoxides used for the preparation of ceramic materials through the solution–sol–gel process, in which alkoxides (either alone or in mixtures) dissolved in organic solvents (generally alcohols) are hydrolysed to give sols. Polycondensation in these sols leads to gel formation which can be sintered into oxide ceramics.[38,39] The hydrolysis of aluminium secondary butoxide in isopropanol has been studied in detail by Chane-Ching and Klein[40] using rheological behaviour and IR spectroscopy.

2.2.4. *Reactions of aluminium alkoxides.* Aluminium alkoxides follow the general characteristics of metal alkoxides in trying to enhance the coordination of the aluminium atom by formation of species with bridging alkoxy groups, rather than by acceptance of lone pairs from donor ligands. In other words, the donor ligands are not generally able to compete thermodynamically with the polymerization process, except in some cases, e.g. formation of species of the type $Al_2(OR)_6(en)$ (where en = ethylenediamine), reported by Bains and Bradley.[41] The recently synthesized monomeric hindered phenoxides of aluminium, $AlMe_x(2,6\text{-}Bu^t, 4\text{-}MeC_6H_2O)_{3-x}$ (where $x = 1$ or 2), form 1 : 1 tetrahedral adducts[42] with PMe_3.

The facile interaction of metal alkoxides with protic reagents in organic solvents in desired stoichiometric ratios has proved to be of great importance in the synthesis of a large number of organic derivatives of aluminium, some of which cannot be prepared by alternative routes. Aluminium isopropoxide which is commercially available has been extensively used for such syntheses. Aluminium isopropoxide reacts with ligands having labile hydrogens in benzene solution, liberating isopropanol, during the course of the reaction, which can be fractionated off azeotropically with

benzene. The fractionation of isopropanol tends to drive the reaction in the forward direction and its estimation by simple chromate oxidation method[43] helps in monitoring the progress of the reaction.

$$Al(OPr^i)_3 + nLOH \xrightarrow{\text{benzene}} Al(OL)_n(OPr^i)_{3-n} + nPr^iOH\uparrow$$

(n = 1, 2 or 3 and LOH = organic ligand).

The versatility of the above synthetic procedure has been demonstrated by the synthesis and characterization of tris- or mixed isopropoxide ligand derivatives of a variety of organic hydroxy ligands, e.g. glycols,[44] catechol,[44] β-diketone,[45,46] β-ketoesters,[45,46] carboxylic acids,[47] fatty acids,[48–50] hydroxy acids,[51] oximes,[52] amidoximes and N-substituted arylbenzimidoximes,[53] unsaturated alkanols,[54] mercapto-carboxylic acids,[55] alkanol amines,[56–58] β-ketoamines,[59] aldamines,[60–62] Schiff bases.[63–74]

Halide alkoxides of aluminium[75–78] have also been synthesized by the reactions of aluminium primary and secondary alkoxides with acyl halides and hydrogen chlorides.

$$Al(OR)_3 + xCH_3COCl \longrightarrow AlCl_x(OR)_{3-x} + xCH_3COOR\uparrow$$

$$Al(OR)_3 + xHCl \longrightarrow AlCl_x(OR)_{3-x} + xROH\uparrow$$

(where R = Et, Pr^i etc.).

The reaction of $Al(OBu^t)_3$ with CH_3COCl has been shown to follow a different route which is represented below in a simplified form.

$$Al(OBu^t)_3 + CH_3COCl \longrightarrow Al(OBu^t)_2Cl + CH_3COOBu^t$$

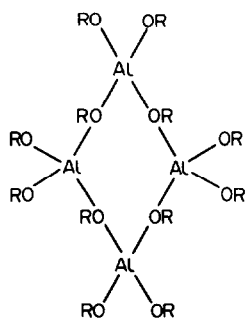
$$Al(OBu^t)_3 + 2CH_3COCl \longrightarrow Al(OBu^t)Cl(OOCCH_3) + CH_3COOBu^t + Bu^tCl$$

$$Al(OBu^t)_3 + 3CH_3COCl \xrightarrow[\text{reflux}]{} Al(OOCCH_3)_3 + 3Bu^tCl.$$

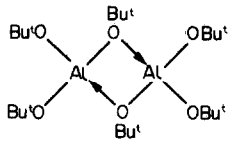
2.2.5. *Structural features.* The IR spectra of aluminium alkoxides $Al(OR)_3$, where R = Et, Pr^n, Pr^i, Bu^n, Bu^{sec} and Am^{sec}, show a number of absorption bands, amongst which those at 1059, 1015, 1033, 1048, 1058, 1070 cm^{-1} were earlier assigned to Al—O—C vibrations.[79,80] On hydrolysis, the intensity of almost all the above bands decreases,[81] but those at ~ 935 cm^{-1} (νAl—O—Al) and ~ 3340 cm^{-1} (νOH), become broader.

On comparing the IR spectrum of aluminium isopropoxide with a number of those of group IV and V metal isopropoxides, Barraclough *et al.*[82] assigned the absorption frequency in the range of 1000 cm^{-1} to νC—O instead of νAl—O—C, as assumed by earlier workers[79,80] and assigned five new absorptions at 699, 678, 610, 566 and 535 cm^{-1} for νAl—O. The presence of such a large number of bands for νAl—O has been ascribed to the polymeric nature of aluminium isopropoxide.

Robinson and Peak[24] in 1935 proposed the following ring structure for tetrameric aluminium alkoxide, $[Al(OR)_3]_4$, formed by sharing two corners each of four AlO_4 tetrahedra.



Aluminium tertiary butoxide which was found to be dimeric in a number of solvents, was assigned[1] the following structure.



The above structure has been confirmed by Bains[83] and Shiner *et al.*[84] from its ^{1}H NMR spectrum, which depicts two distinct signals for terminal and bridging butyl groups in the ratio 2:1, these have been shown to remain unchanged in the temperature range of −14–74°C.

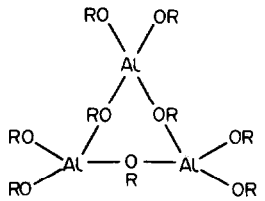
In the reaction of aluminium ethoxide or isopropoxide with tertiary butanol, two moles of ethoxy (isopropoxy) per aluminium atom can be easily replaced. However, under forcing conditions, the ultimate product was found to be $Al_2(OR)(OBu^t)_5$, where R = Et or Pr^i.

The slow nature of the final stage of the above reactions could be explained by assuming[1] an unsymmetrical structure for $Al_2(OR)_2(OBu^t)_4$ products in which the coordination and subsequent reaction could occur on the less sterically hindered aluminium atom on the left being surrounded by two OR and two OBu^t groups only yielding finally the product $Al_2(OR)(OBu^t)_5$, which does not appear to undergo further alcoholysis due to steric factors (Scheme 2).

Scheme 2.

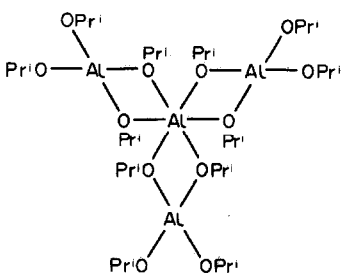
The unsymmetric structure of $Al_2(OPr^i)_2(OBu^t)_4$ has also been confirmed by Bains[83] and Oliver and Worrall[85] from ^{1}H NMR spectral evidence.

The following structure for trimeric $Al(OPr^i)_3$ was supported by the splitting of the methyl signals of the OPr^i groups in the ratio of 1:1:2:2 in its proton NMR spectrum at low temperature, due to terminal and bridging OPr^i groups.[84]



This splitting disappears in the spectrum at room temperature and only a single doublet of the methyl proton is observed.[84] This coalescence of signals may be attributed to a fast exchange of the two types of isopropoxide groups.

Explaining the change in trimeric to tetrameric aluminium isopropoxide on ageing, on the basis of change in coordination number of one of the aluminium atoms from four to six, Bradley[86,87] suggested the following novel structure for $[Al(OPr^i)_3]_4$.



Confirmatory spectral evidence for the above was obtained by PMR spectra, in which three sets of doublets of the methyl proton peaks were observed at 1.70, 1.60, 1.42, 1.33 and 1.33, 1.23 ppm in

the ratio of 1 : 1 : 1 : 1 : 2 : 2.[84,85,88] Shiner *et al.*[84] could observe signals only due to methyl protons but Bradley,[87] Mehrotra and Mehrotra[88] in a 100 MHz PMR spectrum observed two sets of signal for methine protons, having equal intensity, and assigned them to bridging and terminal isopropoxy groups. The splitting in the signal of methyl protons of the isopropoxy group has been attributed to magnetic non-equivalence of two methyls on the same isopropoxy groups.[89] A similar observation had been made earlier by Oliver and co-workers.[90,91]

The appearance of two signals in the ratio 3 : 1 in the ^{27}Al NMR spectrum[92] of aluminium isopropoxide further supports the tetrameric structure proposed earlier and confirms that the molecule contains one central octahedral aluminium surrounded by three isopropoxyaluminate groups.

Earlier X-ray diffraction studies[93] of aluminium alkoxides (methoxide, ethoxide and isopropoxide) supported the tetrameric structure instead of a chain type polymer. The single crystal X-ray structure of aluminium isopropoxide alone appears to have been carried out by Turova *et al.*[26] Aluminium isopropoxide crystallizes out at −30°C in pentane solution with a tetragonal lattice with unit cell dimensions $a = b = 12.595(1)$, $c = 31.823(4)$ Å, $V = 5049(1)$ Å^3, $\rho_{exp} = 1.06$, $\rho_{calcd} = 1.08$, $Z = 16$ and the space group $P4_12_12_1$. These unit cell dimensions are close to those cited by Amma[93] earlier. The crystal structure shown in Fig. 2 has been reported by $[Al(OPr^i)_3]_4$.

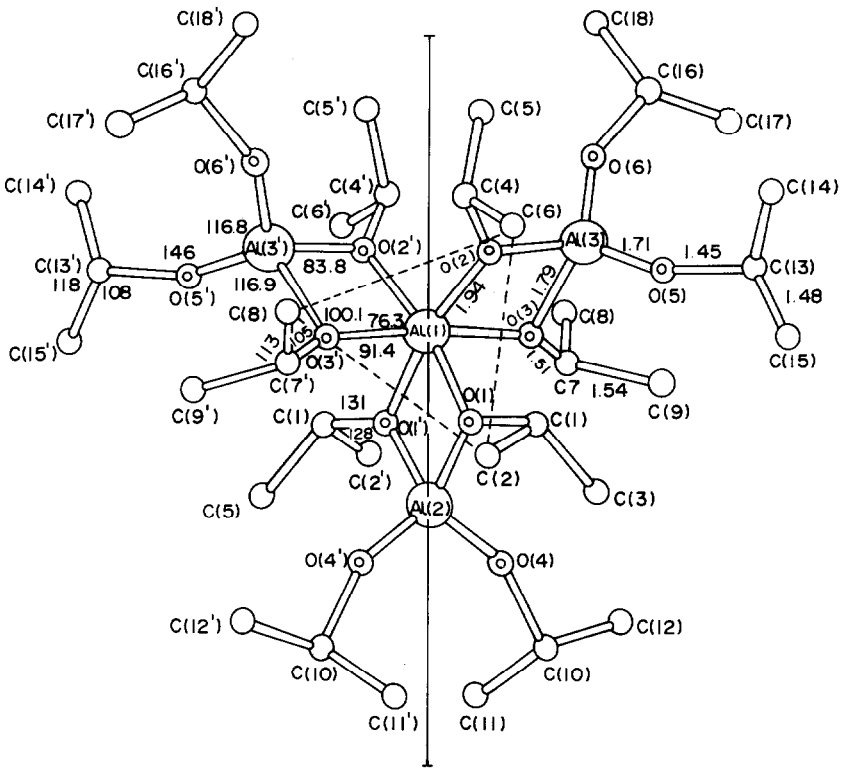


Fig. 2.

2.2.6. *Hindered phenoxide derivatives of aluminium.* Recently (1988), structures of $AlMe(BHT)_2$,[94] $AlMe_2(BHT)PMe_3$[42] and $Me_3NH^+[AlMeCl_2(BHT)]^-$[42] (where BHT = 2,6-di-tert.-butyl-4-methyl phenoxide) have been determined by X-ray crystallography (see Figs 3–5).

The structure of $[AlMe(BHT)_2]$ is planar[94] (bond lengths: Al—O, 1.686 and Al—C, 1.927 Å; bond angles: O—Al—O, 111.9, O—Al—C, 123.6–123.9, Al—O—C, 140.5; 146.8°). As expected, the latter two four-coordinate aluminium derivatives have a distorted tetrahedral geometry[42] with Al—C bond distances of 1.970 and 1.995 Å, respectively; compared to 1.957 Å observed in $Al(CH_3)_3$.[95] This lengthening in Al—C bonds in structures of $[AlMe_2(BHT)PMe_3]$ and $[AlMeCl_2BHT]^-$ is understandable in view of the increase in *p*-character of Al—C bonds on changing from planar to tetrahedral geometry.

Another notable feature of the structures of the latter species is the considerably larger Al—O—C bond angles (164.5–164.0°) than those commonly observed in aluminium alkoxides[26] {cf. Al—O—C

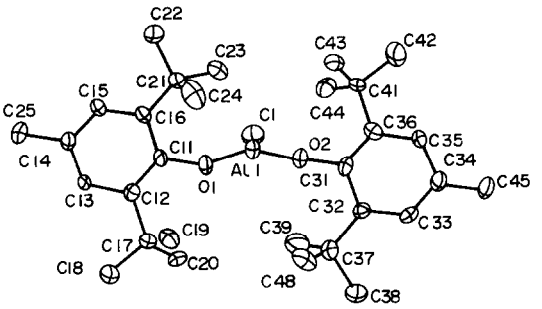

Fig. 3. Crystal structure of $[AlMe(BHT)_2]$.[94]

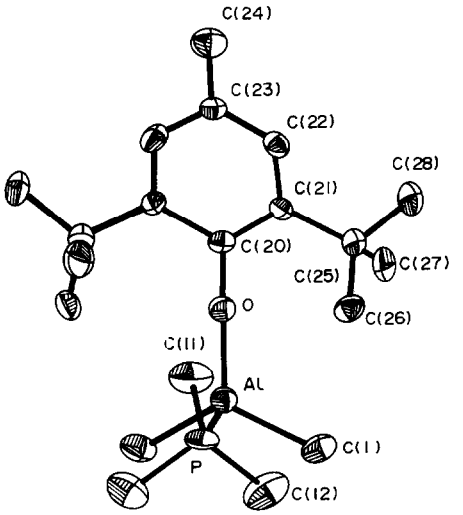

Fig. 4. Crystal structure of $[AlMe_2(BHT)(PMe_3)]$.[42]

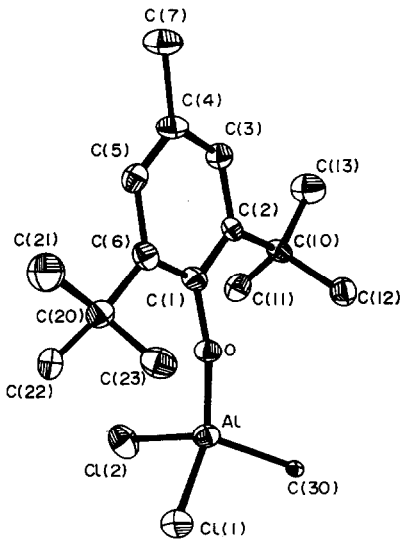

Fig. 5. Crystal structure of the anion $[AlMeCl_2(BHT)]^-$.[42]

for $[Al(OPr^i)_3]_4$, 128.0–135.0°}. In fact this points strongly towards a π interaction between the oxygen *p*-orbitals and the σ anti-bonding orbitals of aluminium derivatives; this conclusion appears to be confirmed by the short Al—O distances of 1.736 and 1.713 Å in the latter two structures, respectively, compared to 1.686 Å in $AlMe(BHT)_2$. However, there appears to be inadequate lengthening in the other Al–ligand bond lengths, a point which deserves further investigation (cf. transition metal derivatives in which *p–d* interaction is quite common).[96]

It is of interest to note that alkylaluminium phenoxides react with Lewis bases[94] (e.g. ethyl toluate) to form four-coordinate derivatives displaying both high activity and stereospecificity in Ziegler–Natta catalytic systems. The reactions of $AlMe_2(BHT)$ and $AlMe(BHT)_2$ with PMe_3 yield mono-phosphine adducts,[42] $AlMe_2(BHT)\cdot PMe_3$ and $AlMe(BHT)_2\cdot PMe_3$. The addition of one equivalent of Me_3NHCl to $AlMe(BHT)_2$ and $AlMe_2(BHT)$ results in the formation of $AlCl(BHT)_2\cdot NMe_3$ and $AlClMe(BHT)\cdot NMe_3$, respectively, whereas addition of two equivalents of Me_3NHCl to $AlMe_2(BHT)$ yields an ionic complex $[Me_3NH][AlCl_2Me(BHT)]$. The molecular structure of methyl toluate adduct, $[AlEt_2(BHT)(MeC_6H_4COOMe)]$, is determined by X-ray crystallography and it is also depicted in Fig. 6.

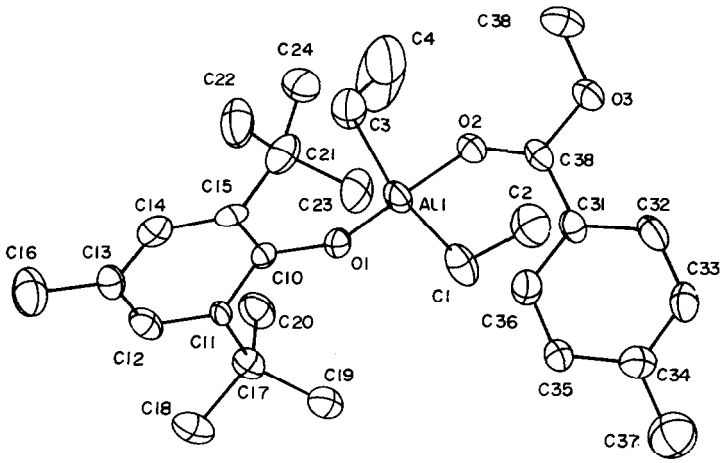

Fig. 6. Crystal structure of $AlEt_2(BHT)(MeO_2CC_6H_4CH_3)$.[94]

3. BI- AND POLY-METALLIC ALKOXIDES CONTAINING ALUMINIUM

Meerwein and Bersin[97] in 1929, using the concept of an acid and base neutralization reaction showed the formation of a species like $K[Al(OPr^i)_4]$ in the titration of potassium isopropoxide and aluminium isopropoxide. In 1952, Albers *et al.*[98] reported the synthesis of $U[Al(OPr^i)_4]_4$ by the following reaction.

$$UCl_4 + 4NaAl(OPr^i)_4 \longrightarrow U[Al(OPr^i)_4]_4 + 4NaCl.$$

Later on another volatile bimetallic compound of uranium, $Al[U(OEt)_6]_3$ was synthesized[99] by the reaction between $Al(OEt)_3$ and $U(OEt)_5$ in the molar ratio 1 : 3.

The existence of ionic species like $[Al(OMe)_4]^-$ was reported by Gut[100] in the titration of aluminium chloride with lithium methoxide in methanol. The formation of similar species has been shown by Mehrotra and co-workers[101] in the titration of aluminium isopropoxide with alkali metal isopropoxides in isopropanol solution. Out of all alkali aluminium isopropoxides, $M[Al(OPr^i)_4]$ (where M = Li, Na and K), only $K[Al(OPr^i)_4]$ was found to be sufficiently soluble in common organic solvents and volatile (with some decomposition). Taking advantage of the solubility of $K[Al(OPr^i)_4]$ species, Mehrotra *et al.*[102–116] have successfully synthesized a number of aluminium containing bimetallic alkoxides by reactions with anhydrous metal chlorides as illustrated by the following equations.

$$MCl_n + nKAl(OPr^i)_4 \xrightarrow[C_6H_6]{Pr^iOH} M[Al(OPr^i)_4]_n + nKCl\downarrow$$

(where M = indium,[102,103] lanthanons,[104-106] tin(IV),[107] tin(II),[108], beryllium,[109] zinc, cadmium, mercury,[110] chromium,[111] iron,[112] manganese,[113] cobalt,[114] nickel[115] and copper[116] etc.).

With pentavalent metals and smaller tetravalent metal atoms like zirconium, all the chlorine atoms are not replaced leading to the formation of heteroleptic products,[117,118] e.g.

$$ZrCl_4 + 2KAl(OPr^i)_4 \longrightarrow ZrCl_2[Al(OPr^i)_4]_2 + 2KCl$$

$$ZrCl_2[Al(OPr^i)_4]_2 + 2KOPr^i \longrightarrow (Pr^iO)_2Zr[Al(OPr^i)_4]_2 + 2KCl.$$

The identity of these products in some cases was established by a fractional distillation of a mixture of alkoxides when the final products indicated in the following equations were distilled out in almost quantitative yields, e.g.

$$Ln(OPr^i)_3 + \underset{\text{(excess)}}{3Al(OPr^i)_3} \longrightarrow Ln[Al(OPr^i)_4]_3 \qquad \text{(Ref. 106, 117)}$$

$$Zr(OPr^i)_4 \cdot Pr^iOH + 2Al(OPr^i)_3 \xrightarrow{Pr^iOH} (Pr^iO)_2Zr[Al(OPr^i)_4]_2 + Pr^iOH \qquad \text{(Ref. 102, 103)}$$

$$Nb(OPr^i)_5 + 2Al(OPr^i)_3 \longrightarrow (Pr^iO)_3Nb[Al(OPr^i)_4]_2$$

$$Nb(OPr^i)_5 + Al(OPr^i)_3 \longrightarrow Nb[Al(OPr^i)_8]$$

$$Ta(OPr^i)_5 + Al(OPr^i)_3 \longrightarrow Ta[Al(OPr^i)_8] \qquad \text{(Ref. 119).}$$

The preparation of similar derivatives, $M[Al(OPr^i)_4]_2$ where M is an alkaline earth metal, e.g. magnesium, calcium, strontium and barium, could finally be effected by the following reaction in which dissolution of the alkaline earth metal appears to be much more facile[120] (may be due to the non-formation of surface layers of insoluble isopropoxides of alkaline earth metals).

$$M + 2Pr^iOH + 2Al(OPr^i)_3 \xrightarrow[Pr^iOH]{HgCl_2} M[Al(OPr^i)_4]_2 + H_2\uparrow$$

(where M = Mg, Ca, Sr, Ba).

Most of these bimetallic alkoxides are volatile under reduced pressure and can be distilled or sublimed. They are soluble in common organic solvents (in which they show generally monomeric behaviour) and thermally stable, but they are hydrolytically unstable.

The bimetallic alkoxides also undergo facile alcoholysis reactions exemplified by the following general equation.

$$M[Al(OPr^i)_4]_n + 4nBuOH \longrightarrow M[Al(OBu)_4]_n + 4nPr^iOH\uparrow.$$

In fact in a number of cases of later "3*d*" metals like nickel, simple alkoxides, $Ni(OR)_2$ do not appear to undergo alcoholysis reaction[117,121] but, even in their cases, the bimetallic alkoxides interchange their alkoxy groups quite readily, following the characteristic feature of alkoxy derivatives of main group and early transition metals. However, this interchange also is subject to steric factors similar to those reported for aluminium isopropoxide, e.g.

$$Ni[Al(OPr^i)_4]_2 + 6Bu^tOH \xrightarrow{\text{facile}} Ni[(\mu\text{-}OPr^i)_2Al(OBu^t)_2]_2 + 4Pr^iOH\uparrow$$

$$Ni[(\mu\text{-}OPr^i)_2Al(OBu^t)_2]_2 + 2Bu^tOH \xrightarrow{\text{slow}} Ni[(\mu\text{-}OPr^i)(\mu\text{-}OBu^t)Al(OBu^t)_2]_2 + 2Pr^iOH\uparrow.$$

Preliminary studies on methanolysis reactions of lanthanon tris-tetraisopropoxyaluminates have shown that initially a transient white insoluble product is formed, but it goes into solution readily from which stable volatile products can be isolated.

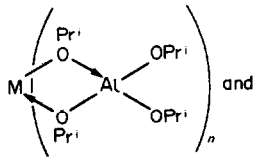
$$Ln[(\mu\text{-}OPr^i)_2Al(OPr^i)_2]_3 + 6MeOH \longrightarrow \underset{\text{insoluble}\downarrow}{Ln[(\mu\text{-}OPr^i)_2Al(OMe)_2]_3} + 6Pr^iOH$$

$$Ln[(\mu\text{-}OMe)_2Al(OPr^i)_2]_3$$

soluble, volatile.

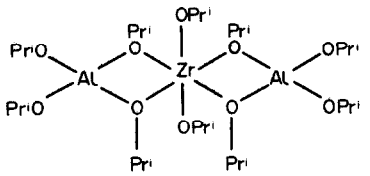
The potential of these bimetallic tetraalkoxyaluminates as precursors for ceramics by the solvent–sol–gel process has been emphasized[31] and has already been exploited for the preparation of spinel[122] from magnesium bis-tetraisopropoxyaluminate. Methanolysis and hydrolysis studies of some bimetallic alkoxides like $Mg[Al(OPr^i)_4]_2$, $Ba[Ti(OPr^i)_5]_2$ and $Ca[Al(OPr^i)_4]_2$ etc., are yielding interesting results[16] showing differences in the reactivity of terminal and bridging isopropoxy groups, followed by mutual interchange of the same.

The structures of these bimetallic tetraisopropoxyaluminates can be easily represented in general as the following.



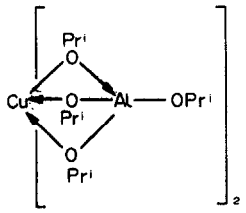
and

(where M = Mg, Ca, Ba, Zn etc.; Fe, Cr, Ga, In, Ln etc.; Th, Sn, Ti etc.; Nb, Ta etc.)



Confirmatory evidence for the plausible structures above has been obtained by IR, ^1H NMR and molecular weight studies and by mass spectroscopic studies of $Ln[Al(OPr^i)_4]_3$,[123] $[Pr^iOBeAl(OPr^i)_4]$,[124] the former show a fragmentation pattern similar to that reported for $[Al(OPr^i)_3]_4$[27] and $La[Al(OPr^i)_4]_3$.[85]

A detailed magnetic and spectroscopic study of tetraisopropoxide aluminates of some 3*d* metals[113–116,125] like iron^{II}, cobalt^{II}, nickel^{II} and copper^{II} showed that for the first two metals, the ligand $[Al(OPr^i)_4]^-$ is bidentate and with copper, it behaves as a tridentate.



In the case of nickel, the ligand appears to be tridentate when R = Et and bidentate when R = Bu^t, for R = OPr^i, there is an equilibrium between the two forms.

The possibility of the synthesis of trimetallic alkoxides arose out of the behaviour of 1 : 1 beryllium tetraisopropoxyaluminate. When the reaction between MCl_2 (where M = Mg, Ba, Zn, Cd, Hg etc.) and $KAl(OPr^i)_4$ was carried out in a 1 : 1 molar ratio, the bis-product $M[Al(OPr^i)_4]_2$ was obtained in all cases except that of $BeCl_2$. This gave $ClBe[Al(OPr^i)_4]$, which could be easily converted into $(Pr^iO)Be[Al(OPr^i)_4]$[109] by reacting with $KOPr^i$ (1 : 1 molar ratio). This product is monomeric when freshly distilled, but dimerizes on standing[126] for a few days into $(Pr^iO)_2Al(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2$.

The species $Pr^iOBeAl(OPr^i)_4$ also reacts with titanium, zirconium, hafnium, niobium and tantalum isopropoxides and yields termetallic isopropoxides.[127]

$$Pr^iOBe[Al(OPr^i)_4] + M(OPr^i)_4 \longrightarrow (Pr^iO)_3M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2$$

$$2Pr^iOBe[Al(OPr^i)_4] + M(OPr^i)_4 \longrightarrow (Pr^iO)_2M[(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2]_2$$

(where M = Ti, Zr and Hf)

$$Pr^iOBe[Al(OPr^i)_4] + M(OPr^i)_5 \longrightarrow (Pr^iO)_4M(\mu\text{-}OPr^i)_2Be(\mu\text{-}OPr^i)_2Al(OPr^i)_2$$

(where M = Nb or Ta).

A number of termetallic isopropoxides containing 3*d* metals have been synthesized by using some stable mixed chloride bimetallic isopropoxides.[128,129]

$$ClM[Al(OPr^i)_4] + K[Ga(OPr^i)_4] \longrightarrow (Pr^iO)_4GaM[Al(OPr^i)_4] + KCl\downarrow$$

$$ClM[Zr_2(OPr^i)_9] + K[Al(OPr^i)_4] \longrightarrow [(Pr^iO)_4Al]M[Zr_2(OPr^i)_9] + KCl\downarrow$$

(where M = Fe^{II}, Co^{II}, Ni^{II} or Cu^{II}).

All these trimetallic alkoxides have been characterized by elemental analyses, molecular weight measurements, spectroscopic and magnetic studies. Almost all are volatile under reduced pressure.

In addition to termetallic alkoxides,[130] tetrametallic alkoxides of trivalent metals like iron have also been isolated.

$$FeCl_3 + K[Zr_2(OPr^i)_9] \longrightarrow Cl_2Fe[Zr_2(OPr^i)_9] + KCl\downarrow$$

$$Cl_2Fe[Zr_2(OPr^i)_9] + K[Al(OPr^i)_4] \longrightarrow ClFe[Al(OPr^i)_4][Zr_2(OPr^i)_9] + KCl\downarrow$$

$$ClFe[Al(OPr^i)_4][Zr_2(OPr^i)_9] + KTa(OPr^i)_6 \longrightarrow (Pr^iO)_6TaFe[Al(OPr^i)_4]Zr_2(OPr^i)_9 + KCl.$$

The synthesis of volatile bi-, ter- and tetra-metallic alkoxides may play an important role in the development of electronic and ceramic materials, particularly in the form of thin films.

The controlled hydrolysis coupled with heat treatment of these polymetallic alkoxides may lead to the formation of mixed metal oxides or oxide hydroxides having potential industrial application.[131–135]

4. ALUMINIUM ALKOXIDES IN SYNTHESES

As early as 1925, the catalytic activity[136,137] of aluminium alkoxides in the reduction of an aldehyde to an alcohol by ethanol was shown.

$$RCHO + CH_3CH_2OH \longrightarrow RCH_2OH + CH_3CHO.$$

Ponndorf[138] in 1926, successfully reduced both aldehydes as well as ketones to the corresponding alcohol by ethanol using aluminium isopropoxide as a catalyst. Aluminium ethoxide was found to be comparatively an inferior catalyst. This reaction is known as the Meerwein–Ponndorf–Verley reaction.

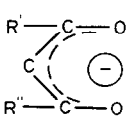
The mechanism for this reaction was developed by Jackman and Macbeth[139] by postulating a cyclic transition state in which hydrogen transfer takes place from the β-C—H bond of an alkoxide to a coordinated aldehyde or ketone.

Nasipuri *et al.*[140,141] used sec.-alkoxy aluminium dichloride, $ROAlCl_2$, prepared *in situ* by the reaction of $LiAl(OR)_4$ with anhydrous aluminium chloride, as a reducing agent for the synthesis of some optically active alcohols from carbonyl compounds, in good yields for the first time. Isobornyloxyaluminium dichloride has been used as catalyst[142] in the reduction of alkyl-methylketones to optically active alcohols.

5. DERIVATIVES OF ALUMINIUM WITH β-DIKETONES AND ALLIED DERIVATIVES

5.1. *Introduction*

The chemistry of β-diketonate derivatives of almost all the transition and main group elements is dominated by the formation of stable chelated derivatives[143,144] with 1,3-diketonate (β-dik) anions.



In spite of a number of other bonding modes, e.g. carbon bonded (with elements like sulphur, selenium, mercury, gold etc.) and both carbon as well as oxygen bonded (with metals like platinum or palladium) derivatives of β-diketones,[143,144] the chemistry of aluminium β-diketonate upto 1960's was limited to oxygen bonded simple chelated tris-derivatives[144–149] only. The reactions of

aluminium alkoxides with β-diketones and β-ketoesters[45] leading to the formation of mono-, bis- and tris-derivatives, $Al(OR)_{3-n}(\beta\text{-dik})_n$ (where $n = 1$–3), have not only provided for the first time facile routes for their synthesis but more recently their characterization by physico-chemical techniques has revealed interesting features of the coordination chemistry of aluminium.[43] It may, however, be pointed out that even in oxygen derivatives, no examples are yet known in which the β-diketonate moiety is bonded to aluminium as a monodentate,[150–151] or a neutral coordinating,[143,150] or bridging[143,152] ligand.

Aluminium tris-β-diketonates were synthesized[153–156] for the first time in 1901–1902 and the first X-ray crystallographic study of aluminium tris-acetylacetonate was carried out by Sirkar[157] in 1926.

5.2. *Synthesis*

The following methods of synthesis have been applied for β-diketonate derivatives of aluminium.

(i) $AlCl_3 + 3\beta\text{-dik-H} \xrightarrow{\text{benzene}} Al(\beta\text{-dik})_3 + 3HCl\uparrow$ (Ref. 158).

(ii) $Al_2(SO_4)_3 + 6\beta\text{-dik-NH}_4 \longrightarrow 2Al(\beta\text{-dik})_3 + 3(NH_4)_2SO_4$ (Ref. 156).

(iii) $\underset{\text{(freshly precipitated)}}{Al(OH)_3} + 3\beta\text{-dik-H} \xrightarrow[\text{reflux}]{\text{benzene+ethanol}} Al(\beta\text{-dik})_3 + 3H_2O$ (Ref. 16).

(iv) Mixed alkoxy β-diketonates have been prepared by the reactions of aluminium ethoxide or isopropoxide with various β-diketones and β-ketoesters in different stoichiometric ratios.[45,46,159–162]

$$Al(OR)_3 + nR'COCH_2COR'' \xrightarrow{\text{benzene}} (RO)_{3-n}Al[OC(R')CHCOR'']_n + nROH\uparrow$$

(where R = Et or Pr^i; R′ = R″ = CH_3; R′ = CH_3, R″ = C_6H_5; R′ = CH_3, R″ = OC_2H_5 etc., and $n = 1$–3).

$$Al(OPr^i)_3 + nRCOCH_2COCO_2Me \xrightarrow{\text{benzene}} (Pr^iO)_{3-n}Al[OC(R)CHCOCOOMe]_n + nPr^iOH\uparrow$$

(where $n = 1$–3; R = C_6H_5, *p*-ClC_6H_4, *p*-FC_6H_4 etc.).

(v) The corresponding tertiary butoxide derivatives have also been prepared by alcohol interchange[45,161,162] reactions of the type.

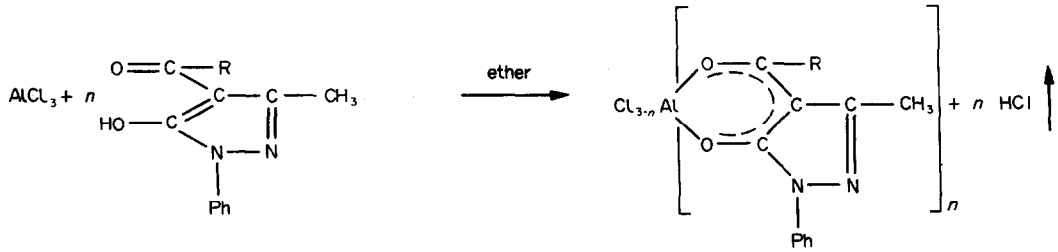
$$Al(OPr^i)_{3-n}(\beta\text{-dik})_n + (3-n)Bu^tOH \xrightarrow{\text{benzene}} Al(OBu^t)_{3-n}(\beta\text{-dik})_n + (3-n)Pr^iOH\uparrow.$$

(vi) Some mixed chloride β-diketone or β-ketoester derivatives[161,162] of aluminium have also been synthesized by the reactions of anhydrous aluminium chloride with corresponding ligands in molar ratio one or two, in dry ether.

$$AlCl_3 + nRCOCH_2COCO_2Me \xrightarrow{\text{ether}} Cl_{3-n}Al[OC(R)CHCOCO_2Me]_n + nHCl\uparrow$$

(where R = *p*-Cl·C_6H_4, *p*-Br-C_6H_4 etc., $n = 1$ or 2)

$$AlCl_3 + n\beta\text{-dik-H} \xrightarrow{\text{ether}} AlCl_{3-n}(\beta\text{-dik})_n + nHCl\uparrow$$



(where $n = 1$ or 2; R = CH_3, C_2H_5, C_6H_5 or *p*-ClC_6H_4 etc.)

(vii) Mixed ligand chelates of the type, $Al(\beta\text{-dik})_n(\beta\text{-dik}')_{3-n}$ (where β-dik and β-dik′ are β-diketonate ligands like acetylacetone, benzoylacetone, hexafluoroacetylacetone etc.) have been synthesized by the following methods.[16,143,163,164]

$$2Al(\beta\text{-dik})_3 + Al(\beta\text{-dik}')_3 \xrightarrow[\text{vacuum}]{\text{heat}} 3Al(\beta\text{-dik})_2(\beta\text{-dik}')$$

$$Al(\beta\text{-dik})_3 + 2Al(\beta\text{-dik}')_3 \xrightarrow[\text{vacuum}]{\text{heat}} 3Al(\beta\text{-dik})(\beta\text{-dik}')_2.$$

The above derivatives can also be synthesized by the following method under much milder conditions.

$$Al(OPr^i)_{3-n}(\beta\text{-dik})_n + 3-n\beta\text{-dik}'\text{-H} \xrightarrow{\text{benzene}} Al(\beta\text{-dik}')_{3-n}(\beta\text{-dik})_n + (3-n)Pr^iOH\uparrow$$

(Ref. 16, 143).

(viii) Mixed ligand complexes of aluminium like $Al(acac)_{3-n}(L)_n$ (where LH is a ligand like 8-hydroxyquinoline) are being synthesized by the following route.[165]

$$Al(OPr^i)_{3-n}(acac)_n + (3-n)LH \longrightarrow Al(acac)_n(L)_{3-n} + (3-n)Pr^iOH\uparrow$$

(where $n = 1$ or 2 and LH = 8-hydroxyquinoline).

(ix) Mixed siloxide β-diketonates of aluminium have been synthesized[46] by the following reactions.

$$Al(OPr^i)_{3-n}(\beta\text{-dik})_n + (3-n)R_3SiOH/R_3SiOOCCH_3 \longrightarrow Al(OSiR_3)_{3-n}(\beta\text{-dik})_n + (3-n)Pr^iOH/CH_3COOPr^i\uparrow$$

(where $n = 1$ or 2; R = CH_3 or C_6H_5)

$$Al(OSiMe_3)_3 + n\beta\text{-dik-H} \longrightarrow Al(OSiMe_3)_{3-n}(\beta\text{-dik})_n + n\text{MeSiOH}$$

(where $n = 1, 2$ or 3).

(x) β-Diketonate and β-ketoester derivatives of a number of aluminium containing bimetallic alkoxides have also been synthesized by the following route.

$$M[(\mu\text{-}OPr^i)_2Al(OPr^i)_2]_n + n\beta\text{-dik-H} \xrightarrow{\text{benzene}} M[(\mu\text{-}OPr^i)_2Al(\beta\text{-dik})(OPr^i)]_n + nPr^iOH\uparrow$$

$$M[(\mu\text{-}OPr^i)_2Al(OPr^i)_2]_n + 2n\beta\text{-dik-H} \xrightarrow{\text{benzene}} M[(\mu\text{-}OPr^i)_2Al(\beta\text{-dik})_2]_n + 2nPr^iOH\uparrow$$

(where $n = 2$, M = Be, Zn, Cd,[109,110] Mg, Ca, Sr, Ba,[2] Mn^{II}, Fe^{II},[149,166] Co^{II},[114] Ni,[115] Cu,[116] Sn^{II}[108] etc.; when $n = 3$, M = Al, Ga, In,[2,149] Cr^{III}[111] etc.).

The occurrence of the initial substitution of terminal isopropoxy groups only has been confirmed by the PMR studies and by the volatilization of the substituted products unchanged.

If the above reactions are extended to the substitution of three isopropoxy groups on aluminium by β-diketonate groups, aluminium tris-β-diketonates are separated out.[106,167]

$$M[(\mu\text{-}OPr^i)_2Al(OPr^i)_2]_n + 3n\beta\text{-dik-H} \longrightarrow M(OPr^i)_n + nAl(\beta\text{-dik})_3 + 3nPr^iOH\uparrow.$$

5.3. *Physico-chemical and structural properties*

Tris-β-diketonate as well as β-ketoester derivatives of aluminium are generally solids, hydrolytically stable and non-volatile. It is now well established that the volatility of metal 1,3-diketonates increases with the substitution of fluorine for hydrogen in the ligand shell.[168–170] Springer *et al.*[171] observed that aluminium tris-fod (1,1,1,2,2,3,3-heptafluoro 7,7-dimethyl-4,6-octanedione) has higher volatility than those of the analogous tris-acetylacetonate or tris-thd(2,2,6,6-tetramethyl-3,5-heptanedione) and only slightly less than that of tris-trifluoroacetylacetone.[169,171] Mixed alkoxy β-diketonates are comparatively more volatile than the corresponding tris-analogues.[45] A comparative thermogravimetric study of β-diketonates of aluminium, gallium and indium revealed that alu-

minium β-diketonates are most volatile.[172] The introduction of an aryl group like phenyl, furyl or thienyl etc. decreases the volatility of the metal chelates.[173]

Aluminium tris-β-diketonates are found to be monomeric[45,161,162] in nature and have an octahedral geometry. The mixed β-diketonate complexes like $Al(\beta\text{-dik})_n(\beta\text{-dik}')_{3-n}$ are optically active. The influence of temperature on optical activity has been studied by NMR. The coalescence temperatures and rate constants for optical inversions for a number of mixed β-diketonate complexes of aluminium have been evaluated.[143,163] Detailed studies have been carried out on the mechanism of such inversion reactions and a number of interesting conclusions involving novel models have been suggested for the same.

The unsymmetrical tris-β-diketone chelates of aluminium are reported to depict *cis*- and *trans*-geometrical isomerism as has been observed in case of a number of other trivalent metal chelates[174–177] also. The NMR (^1H as well as ^{19}F) techniques have been used successfully in differentiating this *cis*- and *trans*-isomerism.

An X-ray study of aluminium tris-(acetylacetonate) derivative[157] was made as early as 1926. This derivative exists in two allotropic modifications,[178] α- and β-forms, having monoclinic and orthorhombic crystal lattice,[179,180] respectively.

Crystal structures for some mixed alkoxide β-diketonate derivatives of aluminium have been reported by Wengrovius *et al.*[46] The crystal structure for $[Al(OPr^i)(Et_2acac)_2]_2$ (Fig. 7) crystallized at −30°C from pentane solution supports our earlier findings[124,161,162] in which we had proposed bonding of two aluminium atoms through isopropoxy bridging.

Aluminium bis-(isopropoxy) acetylacetonate, $Al(OPr^i)_2(acac)$, crystallizes out as a trimer, single crystal X-ray analysis[181] (Fig. 8) of which shows an interesting symmetrical distribution of ligand moieties on the three aluminium atoms, i.e.: (i) two acetylacetonates and two bridging isopropoxides on aluminium (Al2); (ii) one acetylacetonate and four bridging isopropoxide groups on aluminium (Al1); and (iii) four (two bridging and two terminal) isopropoxide groups on aluminium (Al3).

It has been shown that the analogous bis-trimethylsiloxy aluminium acetylacetone is dimeric, $[Al(OSiMe_3)_2(acac)]_2$, and depicts another novel type of unsymmetrical structure[181] (Fig. 9).

In conformity with earlier conclusions on the effect of steric factors on the molecular association of analogous derivatives, it has been further shown that with the substitution of (Me_3SiO-) by (Ph_3SiO-) group, the derivative $[Al(O\text{-}SiPh_3)_2(acac)]$ becomes monomeric tetrahedral structure (Fig. 10).[181]

The above X-ray crystallographic studies of aluminium alkoxide (silyloxide) β-diketonate derivatives reveal that the chemistry and structures of these derivatives are comparatively more complex and the conclusions drawn on the basis of only physico-chemical and spectral data may be misleading

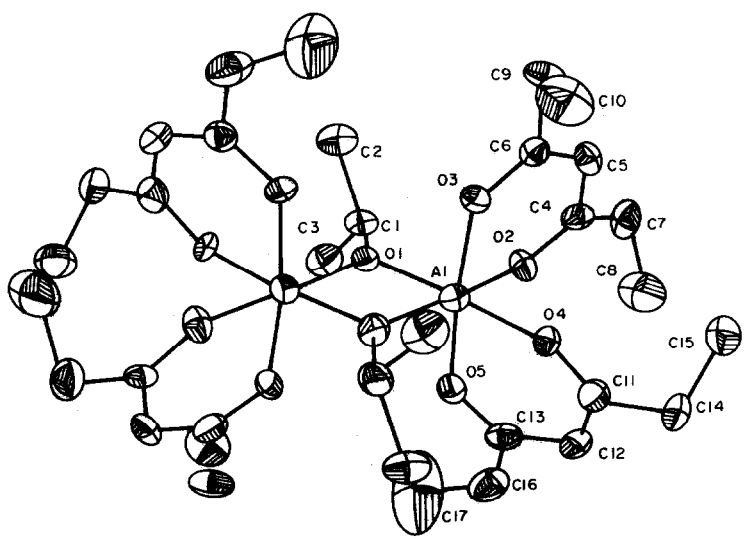


Fig. 7. Crystal structure of $[Al(OPr^i)(Et_2acac)_2]_2$.[46]

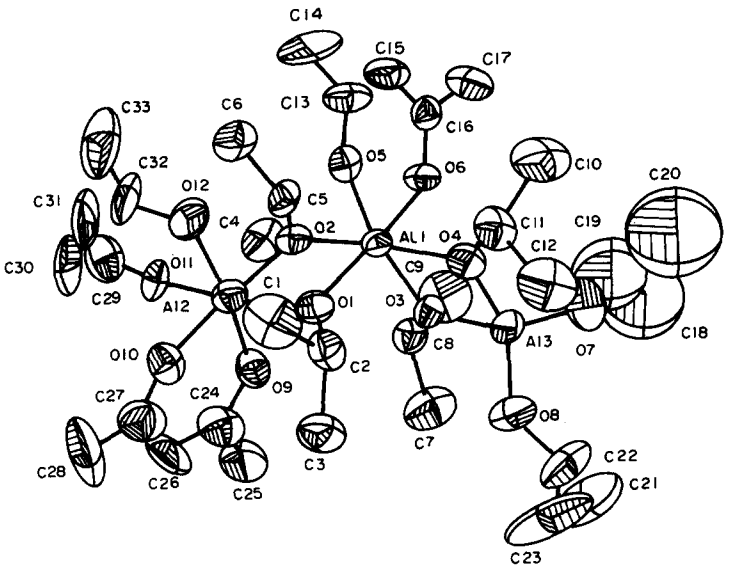

Fig. 8. Crystal structure of $[Al(OPr^i)_2(acac)]_3$.[46]

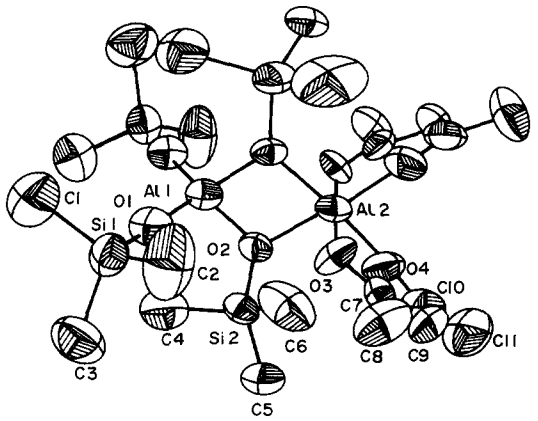

Fig. 9. Crystal structure of $[Al(OSeMe_3)_2(acac)]_2$.[18f]

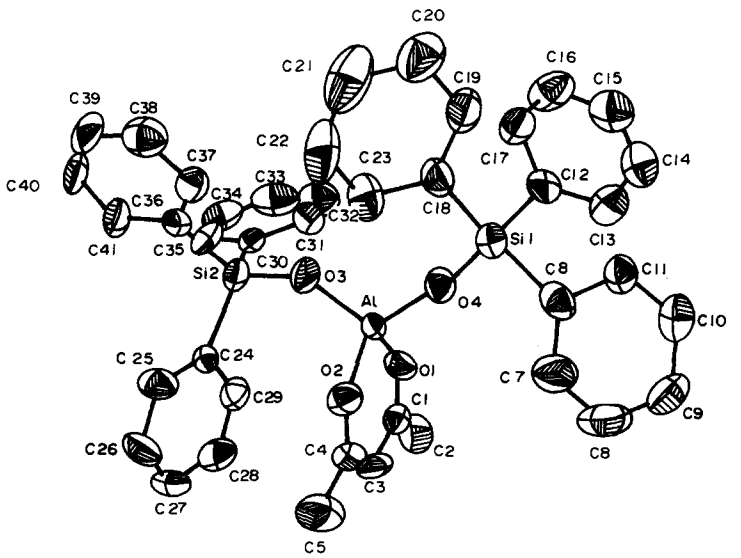

Fig. 10. Crystal structure of $[Al(OSiPh_3)_2(acac)]$.[46]

as the effects of subtle electronic and steric factors on the comparative thermodynamic stability of different possible structures require much more detailed investigations.

6. ALUMINIUM CARBOXYLATES

6.1. *Introduction and historical background*

Aluminium salts of higher fatty acids find commercial applications in several industries[182-185] and are also frequently employed in scientific investigations.[185] In addition to the above and a wide use of aluminium carboxylates in lubrication technology,[182-184] interest in the higher carboxylates (soaps) of aluminium was revived in the 1940s following their use in incendiary Napalm bombs[185(a)] during the Second World War. However, the chemistry, including even the identity of actual derivatives, remained surprisingly obscure.

A review by Gray and Alexander[186] in 1949 cast serious doubts on the very existence of aluminium tri-soaps, arising from numerous failures reported in publications[187-193] from established groups of workers during the decades 1928–1949. Besides reactions in aqueous systems under a variety of conditions, attempts were also made to use aluminium secondary butoxide[186] as a starting material but in all cases, products with the carboxylate : aluminium ratio of only $\leqslant 2$ could be actually isolated.

In fact, the only success claimed in the above direction was that of Glazer *et al.*[194] employing the following route.

$$Al(CH_3)_3 + 3RCOOH \xrightarrow{heat} Al(OOCR)_3 + 3CH_4\uparrow.$$

The main evidence for the formation of aluminium tri-carboxylates in the above reaction was the liberation of 3 moles of methane, but the aluminium analysis of the final tri-carboxylate was far from satisfactory.

Other evidence for the existence of aluminium tri-carboxylates was provided by Lawrence[195] with the observation that 3 moles of alcohol were liberated on heating together aluminium alkoxides with excess fatty acid. Confirming these observations, Gray and Alexander[186] had pointed out that the full amount (3 moles) of alcohol was liberated only at higher temperatures when side-reactions could not be ruled out; they further showed that the analysis of the product(s) obtained after extraction with dioxan in no case showed a carboxylate to aluminium ratio of more than two.

Following his observation[1] that in the alcoholysis reactions of aluminium isopropoxide, two alkoxy groups are replaced with much more facility,[1] Mehrotra[48] carried out the following reaction and confirmed the liberation of 3 moles of isopropanol from a reaction mixture of $Al(OPr^i)_3$ with fatty acids in a 1 : 3 molar ratio, under much milder conditions of azeotropic distillation with benzene.

$$Al(OPr^i)_3 + 3RCOOH \xrightarrow{benzene} Al(OOCR)_3 + 3Pr^iOH\uparrow.$$

Initially received with considerable scepticism the preparation of aluminium tri-soaps by the above route was confirmed by X-ray analysis[196] and IR studies.[197]

The method has since been improved by showing that refluxing of aluminium tert. butoxide with excess fatty acids in benzene solution yielded the tri-soaps[198] without the necessity of any fractionation.

6.2. *Synthesis*

In view of the extreme susceptibility of aluminium derivatives to hydrolysis, non-aqueous media appear to be essential for the preparation of tri-carboxylates, although, hydroxy carboxylates, $Al(OH)_{3-n}(OOCR)_n$ with $n \leqslant 2$ can also be obtained[189-193,199-201] from aqueous solutions. The following methods are therefore available for the preparation of well defined carboxylates of aluminium.

(i) *Reactions of aluminium isopropoxide or ethoxide with carboxylic acids.* Mehrotra[48] in 1953 reported the synthesis of some tri-carboxylates of aluminium viz. laurate, palmitate and stearate, with the corresponding fatty acids.

$$Al(OPr^i)_3 + 3RCOOH \xrightarrow{\text{benzene}} Al(OOCR)_3 + 3Pr^iOH\uparrow$$

(where R = $C_{11}H_{23}$; $C_{15}H_{31}$; $C_{17}H_{35}$).

Later on, a number of aluminium tri-soaps[49] were prepared by interacting aluminium isopropoxide with excess fatty acids in benzene solution and fractionating off the liberated isopropanol azeotropically with benzene.

$$Al(OPr^i)_3 + \underset{\text{(excess)}}{3RCOOH} \xrightarrow{\text{benzene}} Al(OOCR)_3 + 3Pr^iOH\uparrow.$$

The excess fatty acids were removed by repeated crystallization from dry dioxane solution.

Mixed alkoxy carboxylates of aluminium[49] have been synthesized by performing the reactions in molar ratio, 1 : 1 and 1 : 2.

$$Al(OPr^i)_3 + nRCOOH \xrightarrow{\text{benzene}} Al(OPr^i)_{3-n}(OOCR)_n + nPr^iOH\uparrow$$

(where n = 1 or 2).

The lower carboxylates (acetate, propionate and butyrate) of aluminium[47] also were prepared by the following route.

$$Al(OR)_3 + 3\begin{matrix} R'CO \\ \diagdown \\ O \\ \diagup \\ R'CO \end{matrix} \xrightarrow{\text{benzene}} Al(OOCR')_3 + 3R'COOR$$

(where R = Et or Pr^i; R′ = CH_3, C_2H_5 and C_3H_7).

(ii) *Reaction of anhydrous aluminium chloride with acid anhydrides and carboxylic acids.* Anhydrous aluminium trichloride has been reported to react with a mixture of acid anhydride and the corresponding acid yielding the corresponding tri-carboxylates.[202]

$$AlCl_3 + \begin{matrix} RCO \\ \diagdown \\ O \\ \diagup \\ RCO \\ \text{[excess]} \end{matrix} + \underset{\text{[excess]}}{RCOOH} \longrightarrow Al(OOCR)_3 + 3HCl\uparrow$$

(where R = CH_3 and C_2H_5).

These carboxylates are crystallized out from the reaction mixture in quantitative yields. The higher carboxylates of aluminium could not be synthesized from this method.

Aluminium tri-carboxylates as well as chloride carboxylates[203] have been synthesized by refluxing a mixture of anhydrous aluminium chloride and carboxylic acid in benzene solution till the evolution of hydrogen chloride ceased.

$$AlCl_3 + nRCOOH \xrightarrow{\text{benzene}} AlCl_{3-x}(OOCR)_n + nHCl\uparrow$$

(where n = 1, 2, 3 or > 3; R = $C_{11}H_{23}$, $C_{15}H_{31}$, $C_{17}H_{35}$ etc.).

Aluminium chloride carboxylates can also be synthesized by the following alternative route.[49]

$$Al(OPr^i)_{3-n}(OOCR)_n + (3-n)CH_3COCl \xrightarrow{\text{benzene}} Al(Cl)_{3-n}(OOCR)_n + (3-n)CH_3COOPr^i$$

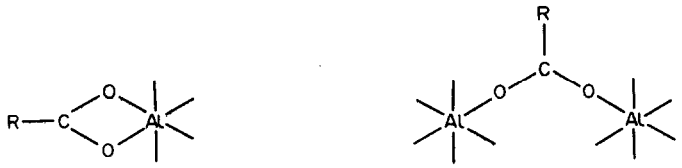
(where n = 1 or 2).

6.3. *Physico-chemical and structural properties*

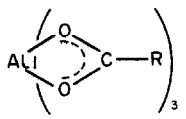
The lower carboxylates of aluminium like acetates, propionates etc. are sparingly soluble in common organic solvents and the solubility increases with increasing hydrocarbon chain length.

The molecular complexity of aluminium tri-carboxylates in non-aqueous solvents has been studied by many workers[197,204,205] and it has been reported that these derivatives are highly associated in solution. However, molecular weight measurement by Rai and Mehrotra[206] have shown that these derivatives do not depict any tendency of association in refluxing solution, i.e. these are monomeric in nature, but even traces of moisture increase the molecular complexity to such an extent as to exceed the limit of its measurement.[198] The reported increase in viscosity[204,205] with increasing hydrolysis also supports the above observation.

On the basis of IR studies of aluminium tri-laurate in dilute and concentrated solutions, Leger *et al.*[197] suggested the presence of both intra- and intermolecularly-coordinated carboxylate groups.



However, Rai and Mehrotra[206] have reported that on refluxing in benzene, the monomeric form is attained by aluminium tri-carboxylates, which may be represented by the following structure.



In contrast to aluminium tri-carboxylates, the corresponding alkoxide and chloride carboxylates are reported to be dimeric[206] and trimeric,[203] respectively.

Aluminium carboxylates are highly susceptible to hydrolysis, which explains the repeated failures of earlier workers[183,186,188,192,205,207] to isolate them in the pure state. Aluminium carboxylates including alkoxide carboxylates are non-volatile in nature. The mixed monoisopropoxide bis-carboxylates of aluminium on heating under reduced pressure yield oxide carboxylates and esters.[208]

$$Al(OPr^i)(OOCR)_2 \xrightarrow[\text{under reduced pressure}]{\text{heat}} AlO(OOCR) + RCOOPr^i\uparrow.$$

These oxide carboxylates exhibit association of the order of 9–10 in benzene solution[208] and may have either a ring or chain structure. These oxide carboxylates have also been prepared by the following alternative route.

$$Al(OPr^i)_2(OOCR) + HOH \xrightarrow[\text{heat}]{\text{benzene}} Al(OPr^i)(OH)(OOCR) + Pr^iOH\uparrow$$

$$Al(OPr^i)(OH)(OOCR) \xrightarrow{\sim 170^\circ C} AlO(OOCR) + Pr^iOH\uparrow.$$

These oxide carboxylates are highly soluble in organic solvents and are hydrolytically more stable.

Aluminium triacetate with a heat of formation of -451.8 Kcal mol^{-1}, gives a basic salt $[Al_3(OH)_2(OOCCH_3)_6]^+$ when subjected to hydrolysis.[209] With liquid ammonia, it forms an adduct at lower temperature and undergoes decomposition at room temperature with evolution of ammonia.[210,211]

Aluminium triacetate undergoes decomposition with the loss of acetic anhydride at about 120–140°C and gets converted to oxyacetate at about 200°C.[211]

$$2Al(OOCCH_3)_3 \xrightarrow{120\text{–}140^\circ} Al_2(OOCCH_3)_4O + \begin{matrix} CH_3CO \\ \diagdown \\ \quad O \\ \diagup \\ CH_3CO \end{matrix}$$

$$Al_2(OOCCH_3)_4O \xrightarrow{\sim 200^\circ C} 2AlO(OOCCH_3) + \begin{matrix} H_3C\text{—}CO \\ \diagdown \\ \quad O. \\ \diagup \\ H_3C\text{—}CO \end{matrix}$$

Themogravimetric studies have shown that higher carboxylates like laurate, palmitate, stearate etc. of aluminium undergo decomposition[212,213] with the formation of ketones at about 200°C. Initially, the decomposition proceeds with the evolution of carbon dioxide, the ketone formed during the course of reaction decomposes above 300°C. The DTG curves for these tri-carboxylates have the same nature but different decomposition temperatures.

$$2Al(OOCR)_3 \xrightarrow{\sim 200^\circ C} Al_2O_3 + 3CO_2 + 3\ \begin{matrix} R \\ \diagdown \\ C{=}O \\ \diagup \\ R \end{matrix}$$

$$\begin{matrix} R \\ \diagdown \\ C{=}O \\ \diagup \\ R \end{matrix} \xrightarrow{> 300^\circ C} CO_2 + H_2O.$$

The alkoxide or chloride soaps undergo two step decomposition. The initial decomposition is due to the hydrolysis from the atmospheric moisture.

$$Al(OPr^i)_2(OOCR) + HOH \xrightarrow{120\text{–}250^\circ} Al(OH)(OPr^i)(OOCR) + Pr^iOH\uparrow$$

$$\downarrow \sim 200^\circ C$$

$$Al_2O_3 + \begin{matrix} R \\ \diagdown \\ C{=}O \\ \diagup \\ R \end{matrix} + CO_2 \xleftarrow{> 300^\circ C} AlO(OOCR) + Pr^iOH\uparrow.$$

$$\downarrow > 300^\circ C$$

$$CO_2 + H_2O$$

The two step decomposition has been observed in the derivatogram of both alkoxide and chloride carboxylates of aluminium.[212,213] The oxide carboxylates, synthesized by the hydrolysis of alkoxide carboxylates also follow a similar pattern as has been observed in the decomposition of alkoxide carboxylates.

7. ALKANOLAMINE DERIVATIVES OF ALUMINIUM

A reference has already been made to the reactions of aluminium alkoxides with alkanolamines.[56,57] Hein and Albert[214] reported the synthesis of alumatrane by heating a mixture of aluminium isopropoxide and triethanolamine.

$$Al(OPr^i)_3 + N(CH_2CH_2OH)_3 \xrightarrow{\text{heat above m.p.}} Al[(OCH_2CH_2)_3N] + 3Pr^iOH\uparrow.$$

Mehrotra and Mehrotra[56] studied these reactions in detail. These reactions can be represented by the following equations.

$$Al(OPr^i)_3 + nNH_2CH_2CH_2OH \xrightarrow{\text{benzene}} Al(OPr^i)_{3-n}(OCH_2CH_2NH_2)_n + nPr^iOH\uparrow$$

(where n = 1, 2 and 3)

$$Al(OPr^i)_3 + HN(CH_2CH_2OH)_2 \xrightarrow{\text{benzene}} Al(OPr^i)[(OCH_2CH_2)_2NH] + 2Pr^iOH\uparrow$$

$$2Al(OPr^i)_3 + 3HN(CH_2CH_2OH)_2 \xrightarrow{\text{benzene}} [HN(CH_2CH_2O)_2]Al$$

$$[O\text{-}CH_2CH_2NHCH_2CH_2O\text{-}]Al[(OCH_2CH_2)_2NH] + 6Pr^iOH\uparrow$$

$$Al(OPr^i)_3 + N(CH_2CH_2OH)_3 \xrightarrow{\text{benzene}} Al[(OCH_2CH_2)_3N] + 3Pr^iOH\uparrow.$$

The progress of all these reactions was followed by estimating the isopropanol liberated and collected in the azeotrope with benzene. It may be interesting to record that only the hydroxy groups of mono- and dialkanolamines appear to be reactive in these replacement reactions, which is in contrast to the observations made in the reactions of germanium[215] and tin[216] alkoxides in which both the amino and hydroxy groups are reactive, leading to a ring compound.

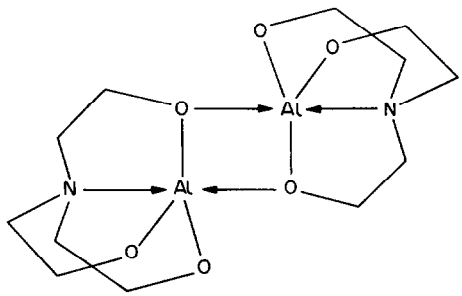
The molecular weight measurements of the derivatives $Al(OPr^i)(OCH_2CH_2)_2NH$, $Al_2[(OCH_2CH_2)_2NH]_3$ and $Al(OCH_2CH_2)_3N$ in refluxing benzene showed that the former two are essentially tetrameric whereas the last one is hexameric (cf. its octameric nature reported[214]).

Recently, the reactions of aluminium isopropoxide with substituted mono-alkanolamines[57] in different molar ratios have been shown to yield compounds of the type $Al(OPr^i)_{3-n}(OXNR_1R_2)_n$ (where R_1 = H, CH_3, C_2H_5; R_2 = H, CH_3, C_2H_5 and X = CH_2—CH_2—, —CH_2—CH_2—CH_2—, —CH_2CHCH_3—, —$C_6H_4CH_2 \cdot CH_2$—; n = 1–3). Most of these derivatives are distillable liquids, which are tetrameric in boiling benzene solution. Structures[57] similar to that of tetrameric aluminium isopropoxide have been suggested for these derivatives.

Triethanolamine has been shown to cleave Al—C bonds in triethylaluminium in toluene or hexane solution to form alumatrane.[217]

$$Al(C_2H_5)_3 + (HOCH_2CH_2)_3N \longrightarrow Al(OCH_2CH_2)_3N + 3C_2H_6\uparrow$$

which was shown by mass spectroscopy[218] to be a dimer in the gaseous phase; the following structure has, therefore, been suggested by Voronkov and Baryshok[219] for this derivative.



An interesting compound $[N(CH_2CH_2O)_3Al_2(CH_3)_3]_2$[220] has been synthesized by the reaction of $AlMe_3$ with triethanolamine, the structure of which is represented below (Fig. 11).

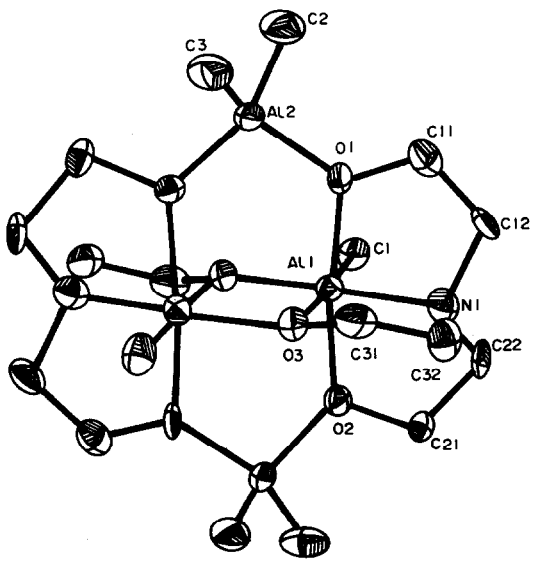


Fig. 11. Crystal structure of $[N(CH_2CH_2O)_3Al_2(CH_3)_3]_2$.[220]

The Al_4O_6 core in the above structure consists of two six-coordinate and two four-coordinate aluminiums and is unlike the one reported previously[221] containing one central octahedral aluminium surrounded by three tetrahedral aluminium isopropoxides. Thus $[N(CH_2CH_2O)_3Al_2(CH_3)_3]_2$ appears to be the first example of a six-coordinate organometallic aluminium derivative.

8. CONCLUSION

The above brief review of the interrelated chemistry of alkoxides, β-diketonates and carboxylates of aluminium indicates that although these derivatives have been known for a long time, they still continue to reveal interesting features. In view of the rapidly growing importance of aluminium oxides in the ceramics industry, the hydrolysis of aluminium alkoxides has been actively pursued[40] during the last few years but further intensive studies on the hydrolytic reactions of aluminium alkoxides including polymetallic derivatives, carboxylates and isomerization studies of β-diketonates are expected to reveal novel features of both academic as well as industrial significance.

The Al—O π-interactions indicated from structural features of recently synthesized hindered phenoxide derivatives of aluminium alkyls are very interesting and should lead to a better understanding of the nature of bonds in such derivatives.

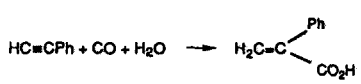
5. CONCLUSIONS 2021

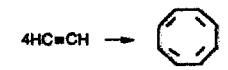
1. INTRODUCTION

Alkynes are versatile building blocks in organic synthesis. They can be used to produce products as diverse as atropic acid [eq. (1)][1] and cyclooctatetraene [eq. (2)].[2] The conversion of alkynes to different organic species is generally assisted by the presence of an appropriate metal or metal



(1)

complex,[3,4] and this is a prime reason for the continuing high level of interest in interactions between alkynes and metal complexes.



(2)

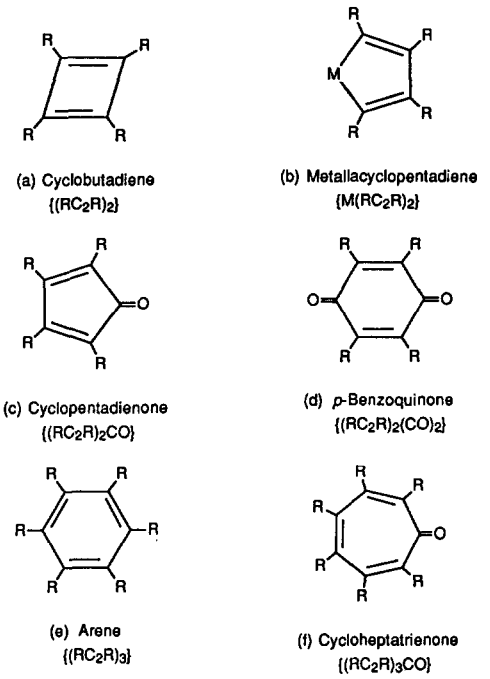


Fig. 1. Examples of cyclic ligands formed by the condensation of alkynes.

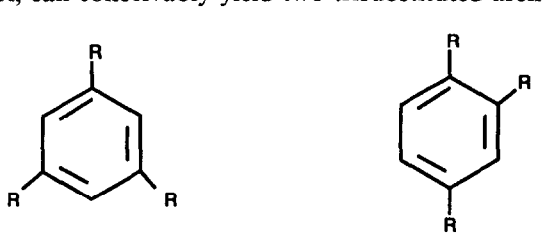
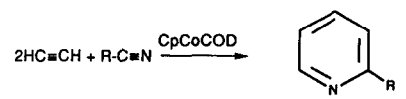
Complexes of almost all the transition metals interact in some way with alkynes. With the early transition metals, individual alkyne ligands often remain intact, even when two or more alkynes are coordinated to the same metal centre.[5] In contrast, reactions between complexes of later transition metals and alkynes frequently result in condensation of the alkyne units to form cyclic and other organic ligands.[6] Some of the many cyclic ligands that have been formed through the cyclic condensation of alkynes are given in Fig. 1, and examples of the formation of most of these ligand types are given in later sections of this report. From the perspective of organic synthesis, it is helpful if the cyclic ligand dissociates from the metal under the prevailing reaction conditions. A particular advantage that alkynes offer in metal catalysed alkyne condensation reactions is the potential to control the substituent positions in the organic product. For example, the cyclotrimerization of a terminal alkyne, HC≡CR, can conceivably yield two trisubstituted arenes, (**1**) and (**2**). However,



(**1**) (**2**)

such reactions catalysed by $Ni(CO)_2(PPh_3)_2$[7] or $Co_2(CO)_8$[7,8] frequently lead to preferential formation of one isomer, the 1,2,4-trisubstituted product (**2**). With the cobalt system this preference has been rationalized by identifying the substituent pattern in the key intermediate, a trisalkynedicobalt complex of formula $Co_2(CO)_4(HC_2R)_3$.[8] Similar intermediates are presumably implicated in the nickel reactions.

Coordinated alkynes are also able to add to other substrates, **X**, with formation of new C–**X** bonds. A representative example of the many reactions of this type is given in eq. (3).[9,10]



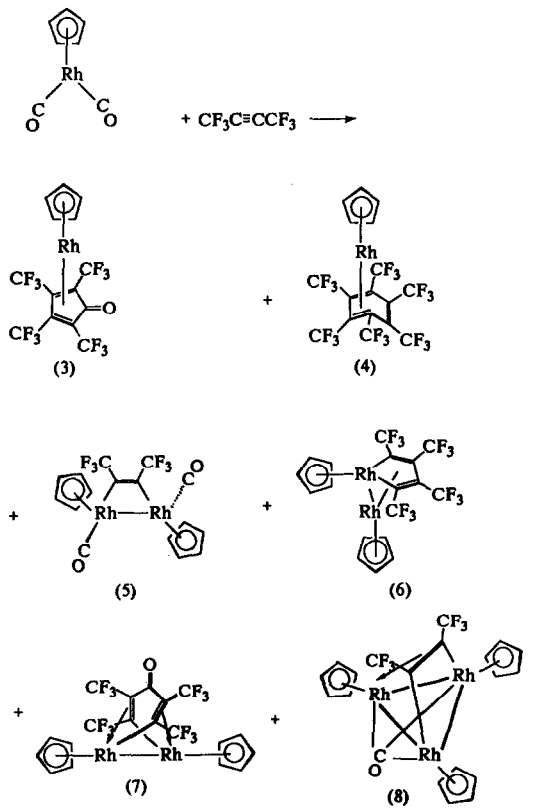
(3)

In extending our knowledge of alkyne transition metal chemistry, considerable attention is currently being directed at the use of di- and poly-nuclear complexes to achieve the chemical modification of alkynes. The well documented studies by Knox[11] and Green *et al.*[12] involving diruthenium and dimolybdenum centres, respectively, and Chisholm *et al.*'s extensive investigations[13] of alkyne complexes of dinuclear tungsten alkoxides, provide just a few examples. Another extremely versatile dinuclear alkyne system is based on the complex $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ which was discovered in our laboratories in the late 1970s. Over the past decade or so, we have investigated the addition of a wide range of substrates to this complex, and we continue to be surprised and stimulated by the results obtained. This report presents an overview of our investigations involving this and related complexes.

2. RHODIUM AND HEXAFLUOROBUT-2-YNE

2.1. *Reaction of* $CpM(CO)_2$ *with alkynes*

During a post-doctoral year with Geoffrey Wilkinson in the early 1960s, I prepared[14] the complexes (**3**) and (**4**) by the thermally initiated reaction of $CpRh(CO)_2$ with hexafluorobut-2-yne, $CF_3C{\equiv}CCF_3$. About 10 years later, some discussion of possible pathways for the cyclic trimerization of alkynes on a single metal site was generated in a departmental seminar at Monash. I persuaded a graduate student to repeat my earlier work, and we designed some further experiments that might throw light on the reaction pathway for formation of (**4**). When the experiment to produce (**3**) plus (**4**) was performed, these compounds were isolated in low yields only. However, a significant amount of a new dinuclear product (**5**) was obtained.[15,16] Further study[16,17] established that a range of products (see Scheme 1) was formed in the reaction system, with the yield of each product being critically dependent on the reaction conditions, particularly the temperature. The dinuclear complex (**5**) was the major product obtained when the reaction was carried out between 100–110°C, but the amounts of (**3**) and (**4**) were substantially greater when the temperature was elevated to 120–125°C.



Scheme 1. Products obtained from the reaction of $CpRh(CO)_2$ with $CF_3C{\equiv}CCF_3$.

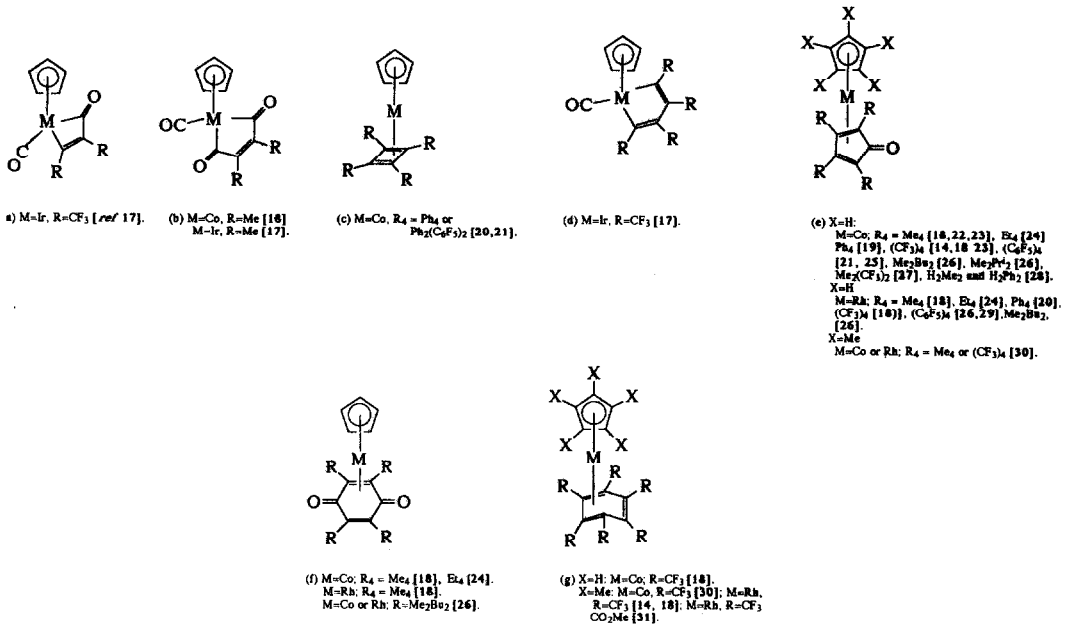


Fig. 2. Examples of mononuclear complexes formed from reactions between $CpM(CO)_2$ or $Cp^*M(CO)_2$ complexes and alkynes. (Reference numbers are given in square brackets.)

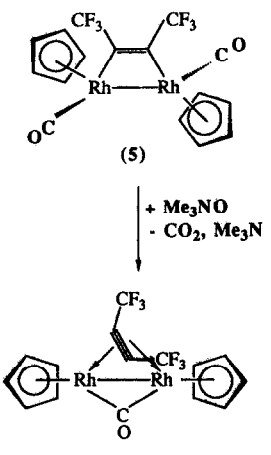
Numerous related reactions between $CpM(CO)_2$ complexes and alkynes have been investigated but generally they give mononuclear complexes such as those displayed in Fig. 2. The formation of dinuclear complexes of the type $Cp_2M_2(CO)_n(\mu\text{-}\eta^1\eta^1\text{-}RC_2R)$ is restricted to just a few systems. At about the same time as our report on $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$, Sakurai and Hayashi showed[32] that the dinuclear monocarbonyl complex $Cp_2Co_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}Me_3SiC_2SiMe_3)$ is formed in the thermally initiated reaction of $CpCo(CO)_2$ with $Me_3SiC{\equiv}CSiMe_3$. Later, we established[33] that the related complex $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}Bu^tC_2Bu^t)$ is produced when $Cp_2Rh_2(CO)_3$ and $Bu^tC{\equiv}CBu^t$ are heated together. However, the corresponding reaction with $Me_3SiC{\equiv}CSiMe_3$ gives mainly a trinuclear complex $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}\eta^1\eta^1\eta^2\text{-}Me_3SiC_2SiMe_3)$. The iridium complex $Cp_2Ir_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ is one of the products obtained from the reaction between $CpIr(CO)_2$ and $CF_3C{\equiv}CCF_3$.[17] (See also Section 2.3.)

When the complex $Cp_2Co_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}Me_3SiC_2SiMe_3)$ was treated with other alkynes,[32] several new complexes were formed. However, the rhodium complex $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}Bu^tC_2Bu^t)$ did not display the same reactivity and seemed completely inert to addition reactions. However, the green colour of the dirhodium complex aroused the interest of Geoff Pain, one of my graduate



Scheme 2. The conversion of $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ to $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$.

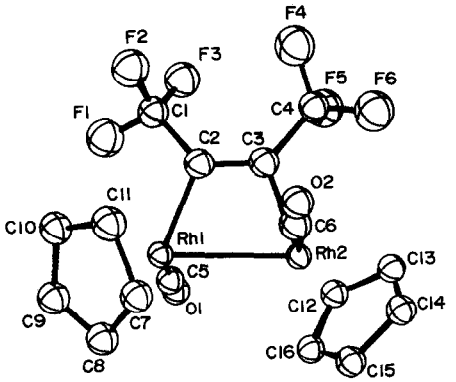


Fig. 3. Molecular structure of $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$.[37] Selected bond distances (Å) and angles (°): Rh(1)—Rh(2), 2.682(1); Rh(1)—C(2), 2.054(10); Rh(2)—C(3), 2.031(10); C(2)—C(3), 1.269(14); C(5)—Rh(1)—Rh(2), 86.6(0.3); C(6)—Rh(2)—Rh(1), 87.2(0.4).

students, and he decided to attempt the conversion of $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ to the corresponding monocarbonyl complex. The reaction worked well when anhydrous Me_3NO was used as a decarbonylation agent (see Scheme 2),[34] with the formation of $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ being signalled by a colour change of the reaction solution from red to green.

2.2. *Synthesis and physical properties of* $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ (5) *and* $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ (9)

Preparation. Subsequent to the above work, we developed a much better route to (**5**) and hence to (**9**). This was based on the initial treatment of $[Rh(CO)_2Cl]_2$ with $CF_3C{\equiv}CCF_3$ which gives an incompletely characterized intermediate of probable formula $[Rh(CO)_2Cl(CF_3C_2CF_3)]_n$, and subsequent reaction of this with TlCp. All stages of the reaction sequence[35,36] are achieved at room temperature, and the overall yield of (**5**) is high. The decarbonylation of (**5**) to (**9**) can then be achieved with Me_3NO as indicated earlier.

Structures. The molecular structures of the two complexes (**5**)[37] and (**9**)[38] were determined from X-ray diffraction data, and these are shown in Figs 3 and 4. This confirmed a very interesting feature of the decarbonylation reaction that had been predicted[34] from spectroscopic data, namely that the bridging alkyne undergoes a 90° rotation when CO is removed. The rotation restores an 18-electron count on each rhodium atom. A rationalization of the electronic requirements for the perpendicular and parallel orientations of the alkyne in these and related complexes has been developed from molecular orbital calculations.[39]

Two further structural features of (**5**) are revealed by spectroscopic studies. Although the two carbonyls are mutually *trans* in the solid state structure, solution IR data indicate that a *cis* isomer also exists. The two isomers can be separated by TLC and are readily distinguished by IR

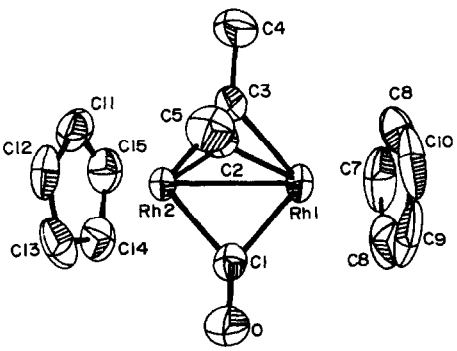

Fig. 4. Molecular structure of $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ (**9**).[38] Selected bond distances (Å): Rh(1)—Rh(2), 2.651(1); Rh(1)—C(2), 2.082(5); Rh(1)—C(3), 2.023(5); Rh(2)—C(2), 2.075(5); Rh(2)—C(3), 2.036(5); C(2)—C(3), 1.363(8).

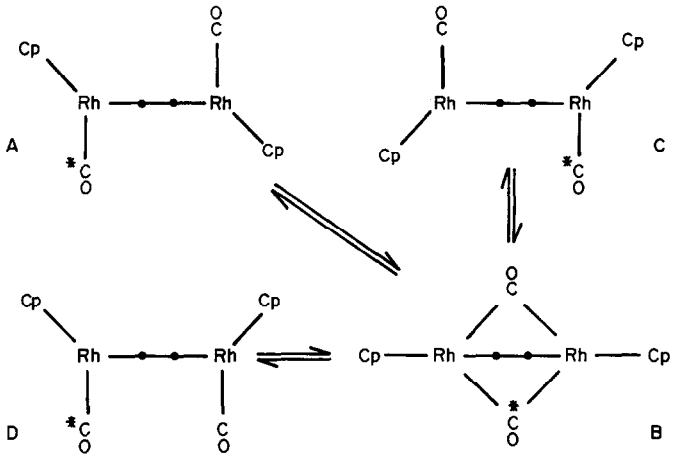

Fig. 5. Proposed pathway for carbonyl site exchange and for *cis* → *trans* isomerization in the complex $(\eta\text{-}C_5H_5)_2Rh_2(CO)_2(CF_3C_2CF_3)$.[40] The molecule is viewed along the  plane, and the CF_3 groups are removed for clarity.

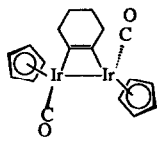
spectroscopy.[40,41] In solution, there is a *cis* to *trans* isomerization, with 50% conversion in 12 h at room temperature. Variable temperature ^{13}C NMR spectroscopy indicates that CO scrambling occurs for the *trans* but it was not detected for the *cis* isomer; a pairwise bridge opening and closing mechanism is invoked[40] (see Fig. 5).

Electrochemistry. A comparison of the electrochemical oxidation and reduction of the two monocarbonyl complexes (**9**) and $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}Bu^tC_2Bu^t)$ has shown[42] that the $CF_3C_2CF_3$ complex is harder to oxidize and easier to reduce than the $Bu^tC_2Bu^t$ complex. However, all of the anionic, cationic and neutral species are kinetically more stable when R = Bu^t rather than CF_3. The stability of the ions is also affected by the solvent used. For example, a very stable cation $[Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}Bu^tC_2Bu^t)]^+$ is produced in dichloromethane, but when oxidation is achieved in acetonitrile, inherently unstable solvated cations are produced. This behaviour indicates that electron transfer catalysis might prove a useful means of generating some chemistry of the normally inert complex $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}Bu^tC_2Bu^t)$. The electrochemical behaviour of (**5**) and (**9**) has also been compared.[43] It is more difficult to reduce and to oxidize the dicarbonyl complex (**5**) than the monocarbonyl species (**9**), and most of the redox products of (**5**) are unstable. The reduction and oxidation pathways are also markedly affected by the orientation of the carbonyls in $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$.

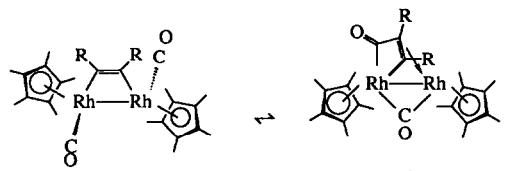
2.3. *Related dinuclear complexes*

We have made numerous attempts to prepare complexes analogous to (**5**) and (**9**), but with metals other than rhodium or alkynes other than hexafluorobut-2-yne. Dinuclear products are rare in reactions of $CpCo(CO)_2$ with alkynes, and we have been unable to form any complexes of the type $Cp_2Co_2(CO)_n(RC_2R')$ except for the previously discussed[32] compound $Cp_2Co_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}Me_3SiC_2SiMe_3)$. Reactions between $CpRh(CO)_2$ and alkynes give a variety of products like those in Scheme 1, but the analogue of (**5**) has been obtained[29] only with $C_6F_5C{\equiv}CC_6F_5$. From the reaction between $CpIr(CO)_2$ and $CF_3C{\equiv}CCF_3$ at 120–160°C, the complex $Cp_2Ir_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ was obtained,[17] both *cis*- and *trans*- isomers being identified. The complex reacts with Me_3NO, but it is a messy reaction system and $Cp_2Ir_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ has not been identified in the reaction products. The related complex $Cp_2Ir_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}C_6F_5C_2C_6F_5)$ is formed[20] when $CpIr(CO)_2$ and $C_6F_5C{\equiv}CC_6F_5$ are heated together, and the μ-phenylene complex (**10**) is obtained from the reaction between $CpIr(CO)_2$ and photo-α-pyrone.[44,45]

An alternative synthetic approach used in attempts to increase the variety of complexes analogous to (**5**) involved modifying the Cp groups. In reactions between $Cp^*_2Rh_2(CO)_2$ and various alkynes $RC{\equiv}CR'$ (R = R' = Et, MeO_2C, CF_3, C_6F_5; R = Ph, R' = Me, MeO_2C or C_6F_5) a range of complexes of formula $Cp^*_2Rh_2(CO)_2(\mu\text{-}RC_2R')$ was formed as the major reaction products.[31,46] The



(10)

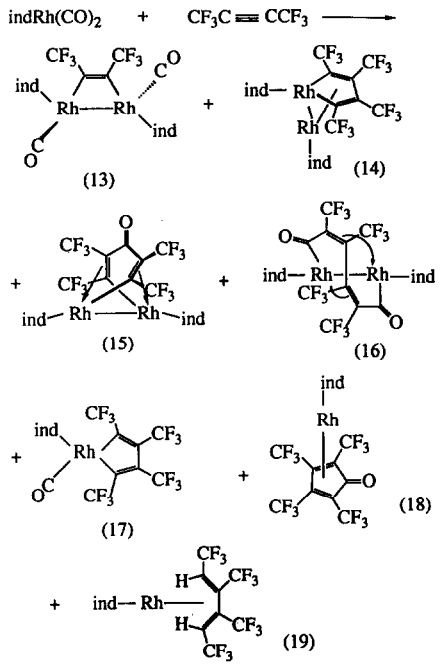


(11) (12)

structures of these complexes vary in an interesting way as the alkyne substituents are changed. The $C_6F_5C_2C_6F_5$ complex exists exclusively in the form (**11**), some others (e.g. PhC_2Ph) adopt only the structure (**12**), and for several of the complexes (e.g. $PhC_2C_6F_5$) (**11**) and (**12**) co-exist. None of these complexes could be decarbonylated with Me_3NO.

The well established "indenyl effect"[47,48] prompted us to extend these investigations to reactions of $indRh(CO)_2$ with $CF_3C{\equiv}CCF_3$ and other alkynes. A rapid reaction did occur under mild conditions[49] with $CF_3C{\equiv}CCF_3$, and the major product was $ind_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ (**13**) with a *trans*-orientation of the carbonyls. Other products formed in this reaction are displayed in Scheme 3. The species (**14**), (**15**) and (**16**) represent new classes of compounds. Treatment of (**13**) with Me_3NO does result in decarbonylation to form $ind_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$. The corresponding reactions of $indRh(CO)_2$ with other alkynes occurred only at elevated temperatures and did not yield complexes analogous to (**13**).

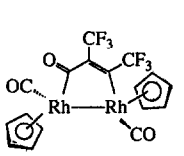
An alternative route to (**5**), which involves a preliminary reaction of the alkyne with $[Rh(CO)_2Cl]_2$ and subsequent treatment of the product with thallium cyclopentadienide, was discussed earlier. Regrettably, attempts[50] to extend this approach to other alkynes led to quite different products. It is interesting, however, that the $\{[Rh(CO)_2Cl]_2 + CF_3C{\equiv}CCF_3 + TlCp\}$ reaction system gives a product of formula $Cp_2Rh_2(CO)_3(\mu\text{-}CF_3C_2CF_3)$ in addition to the *cis*- and *trans*- isomers of $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$. An X-ray diffraction study[51] on crystals of the tricarbonyl complex revealed the structure shown in (**20**). Spectroscopic results indicate that an isomer with two bridging carbonyls exists in solution, and variable temperature ^{13}C NMR data reveal that the carbonyls are



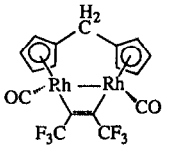
(13) (14) (15) (16) (17) (18) (19)

Scheme 3. Products obtained from the reaction between $indRh(CO)_2$ and $CF_3C{\equiv}CCF_3$ at room temperature. (ind represents η^5-indenyl.)

scrambling rapidly, even at $-100°C$. This complex is readily decarbonylated by treatment with Me_3NO, and both *cis*- and *trans*-isomers of $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ plus the monocarbonyl complex (**9**) are produced.



(20)



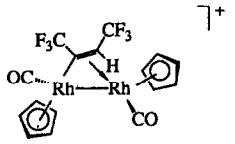
(21)

The bis-cyclopentadienylmethane complex $(CpCH_2Cp)Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ is formed[52] in the related reaction of $[Rh(CO)_2Cl(CF_3C_2CF_3)]_n$ with $TlCpCH_2CpTl$. This complex necessarily has a *cis*-orientation of the two carbonyls (**21**). There is decarbonylation upon treatment with Me_3NO, but the resultant monocarbonyl complex is unstable presumably due to the need for all ligands to be in bridging positions. Although the decarbonylation product cannot be isolated, ligand additions to the *in situ* product have been investigated.

3. REACTIVITY OF THE ALKYNE-DIRHODIUM COMPLEXES

3.1. *Some reactions of* $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ (5)

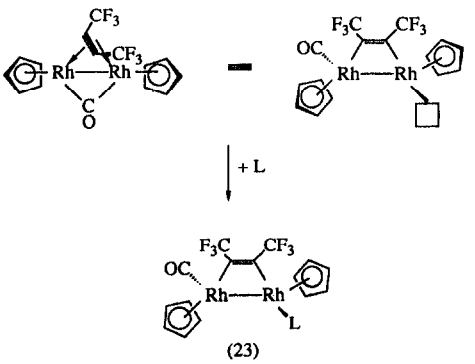
The complex (**5**) is relatively inert, and temperatures exceeding 100°C are needed to initiate substitution reactions. The products formed in these reactions are generally obtained more readily from corresponding reactions with $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ (**9**); these are discussed in the following sections of this report. However, an exceptionally facile reaction does occur when protonic acids are added to (**5**). For example, the cation $[Cp_2Rh_2(CO)_2\{CF_3C_2CF_3\cdot H\}]^+$ is formed when (**9**) is dissolved in concentrated sulphuric acid, and the BF_4^- or PF_6^- salts of the protonated species can be isolated.[40] The spectroscopic properties of the salts indicate that protonation of one of the alkyne carbons has occurred to give (**22**).



(22)

3.2. *Some coordinative additions to* $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ (9)

Although the complex (**9**) is formally coordinatively saturated, it readily adds a variety of substrates under mild conditions. For example, if CO is bubbled through a solution of (**9**), the dicarbonyl complex (**5**) is reformed. This behaviour can be rationalized in terms of an extremely facile interconversion between the perpendicular and parallel bonding modes of the alkyne (see Scheme 4). The addition of numerous other substrates, including $L = PPh_3$, $PMePh_2$, $P(OMe)_3$,



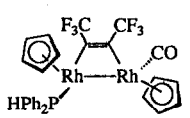
(23)

Scheme 4. A conceptually useful way of rationalizing the high chemical reactivity of (**9**).

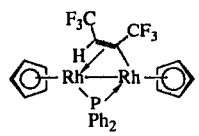
PF_3, $PF_2(NEt_2)$, $AsPh_3$ and CNR (R = Bu^t or 2,6-$Me_2C_6H_3$) can be achieved[53] in a similar manner. It is assumed that CO and L are mutually *trans* in all of these complexes, and this has been confirmed[43] by X-ray crystallography for the complex with L = 2,6-$Me_2C_6H_3NC$. Variable temperature ^{13}C NMR spectroscopy establishes that CO and L exchange rapidly in the complexes (**23**, L = CNR), but this is not possible with the other complexes because the group 15 donor ligands cannot assume a bridging position. The electrochemistry of the complexes (**23**, L = PPh_3 or $CNBu^t$) has been investigated,[43] and the redox behaviour is strongly dependent on the electrode and solvent used. Numerous pathways for rearrangement are indicated after oxidative electron transfer.

The complex $Cp_2Rh_2(CO)\{P(p\text{-tolyl})_3\}(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ has been prepared[50] from (**9**) and tri-*p*-tolylphosphine. The ^1H NMR spectrum of this complex reveals three distinct *para*-tolyl methyl resonances, and this is consistent with restricted rotation about the Rh—P bond. At elevated temperatures, the methyl resonances begin to merge before there is thermal decomposition of the complex. A similar restricted rotation about the Rh—P bond in $Cp^*Rh\{P(p\text{-tolyl})_3\}(C_6F_5)Br$ has been thoroughly studied[54] by variable temperature ^1H NMR spectroscopy.

Treatment of (**9**) with the secondary phosphine PPh_2H gives the addition product $Cp_2Rh_2(CO)(PPh_2H)(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ (**24**).[50] If this complex is left in solution, it undergoes a facile intramolecular H-transfer reaction to yield the bridging alkenyl-phosphido complex (**25**).

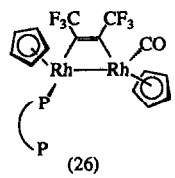


(24)

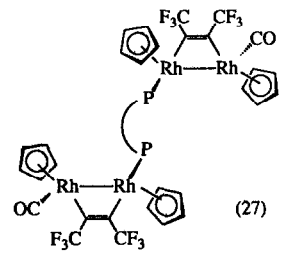


(25)

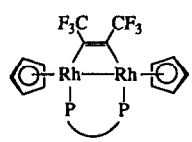
Several bidentate phosphines have been added to (**9**). Dependent upon the mole ratio of reactants, 1 : 1 (**26**) or 1 : 2 (**27**) adducts are obtained.[55] During chromatography, or when left in solution for extended periods, the complex (**26**, P—P = dppm) decarbonylates to form (**28**).



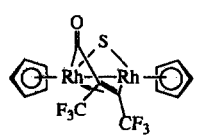
(26)



(27)



(28)



(29)

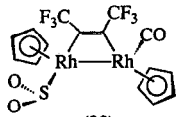
Related complexes have been formed[56] with the phosphinoalkenes $Ph_2P(CH_2)_nCH{=}CH_2$ (n = 1, 2 or 3) and $F_2POCH_2CH{=}CH_2$, and with the phosphinoalkynes $Ph_2P(CH_2)_nC{\equiv}CR$ (R = Me and n = 0, 1, 2; R = H, n = 1). In every case, coordination was from the phosphorus and there was a dangling alkene or alkyne function.

Some group 16 donors have also been coordinated to (**9**), but the adducts are generally less stable than their group 15 counterparts. At −30°C, CS_2 adds to form $Cp_2Rh_2(CO)(CS_2)(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ which decomposes when left in solution to give $Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ and the μ-sulphido complex $Cp_2Rh_2(\mu\text{-}S)(\mu\text{-}CO\cdot CF_3C_2CF_3)$ (**29**). Addition of PPh_3 to the initially

formed adduct results in displacement of the CS_2 and formation of $Cp_2Rh_2(CO)(PPh_3)(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$.

No reaction was observed when (**9**) was treated with CO_2 under a variety of conditions.[57] However, a similar reaction between (**9**) and carbon oxysulphide gave approximately equimolar amounts of the dicarbonyl complex (**5**) and (**29**). The sulphido complex (**29**) is formed more directly from (**9**) and elemental sulphur in solution at room temperature.[57]

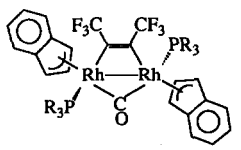
When SO_2 is bubbled into a solution of (**9**), the adduct $Cp_2Rh_2(CO)(SO_2)(CF_3C_2CF_3)$ is obtained.[57] Spectroscopic data on freshly prepared solutions which have been saturated with SO_2 indicate *S*-attachment of the ligand (**30**), but the spectra rapidly become more complex indicating some form of isomerization. In the absence of SO_2, there is reversible dissociation of SO_2 in solution.



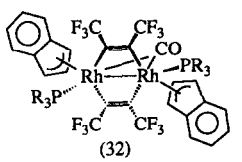
(30)

Weak coordination of dimethylsulphoxide is indicated by a colour change from green to orange–red when (**9**) is dissolved in this solvent. The unsolvated complex is recovered when solvent is removed from the solution. There is no solvation by oxygen-donating solvents such as tetrahydrofuran and acetone, but (**9**) is solvated in solution by acetonitrile.

Not unexpectedly, the indenyl complex $ind_2Rh_2(\mu\text{-CO})(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ displays similar reactivity.[49] The reaction with dppm, for example, occurs rapidly and yields $ind_2Rh_2(\mu\text{-}\eta^1\eta^1\text{-dppm})(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$. There is no evidence for the intermediate formation of $ind_2Rh_2(CO)(\eta^1\text{-dppm})(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$. Knowledge of the indenyl effect prompted us to examine corresponding reactions involving the dicarbonyl complex $ind_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$. With dppm, $ind_2Rh_2(\mu\text{-}\eta^1\eta^1\text{-dppm})(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ was again formed, but addition of the unidentate phosphines PPh_3 or $PMePh_2$ gave unexpected products of formula $(\eta^3\text{-ind})_2Rh_2(PR_3)_2(\mu\text{-CO})(CF_3C_2CF_3)_2$. Possible structures for these complexes are shown in (**31**) and (**32**).



(31)

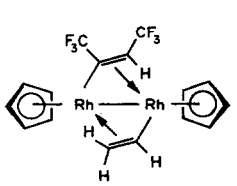


(32)

3.3. C—H *bond activation in reactions with unsaturated hydrocarbons*

Our earliest work on the addition of alkenes to (**9**) was somewhat discouraging. The reactions were slow and not particularly clean. However, a chance discovery that the reactions are greatly accelerated when the reaction solutions are exposed to sunlight opened up an important new area of investigation. In these systems, there is breaking and making of $C(sp^2)$—H bonds with formation of bis-alkenyl complexes. The reaction with ethylene is typical, and gives (**33**) as shown in eq. (4). The ^1H NMR spectrum of (**33**) is given in Fig. 6.

$$Cp_2Rh_2(\mu\text{-CO})(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3) + H_2C{=}CH_2 \xrightarrow[15\text{-}30\ \text{min.}]{\text{sunlight}} Cp_2Rh_2(CO)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3) + \quad (4)$$



(33)

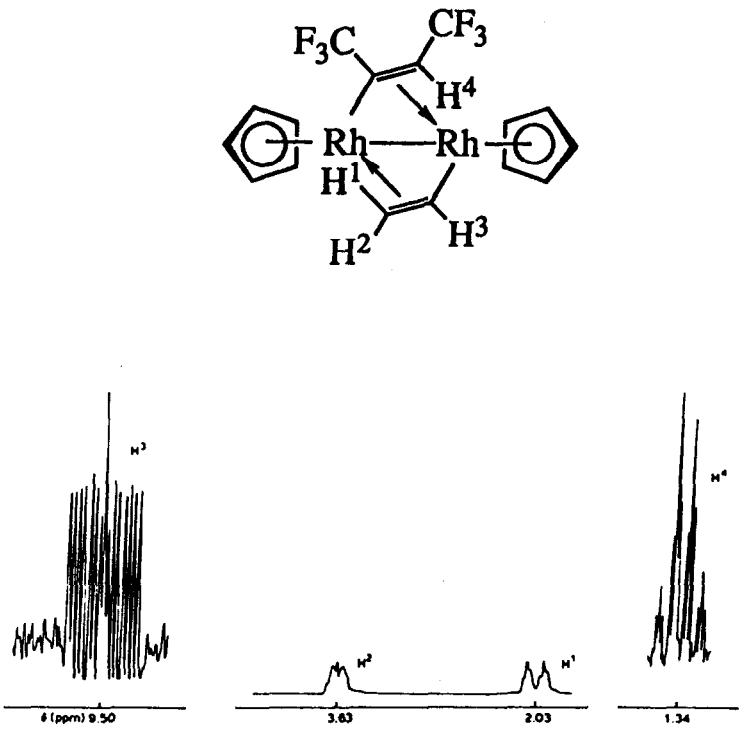


Fig. 6. ^{1}H NMR spectrum of complex (**33**); the resonances for H^3 and H^4 are magnified for clarity.[58]

The spectacular downfield multiplet for H^3 is readily analysed in terms of an ABCXY spin system, and the observed deshielding is diagnostic of a proton in this environment. Related bis-alkenyl complexes are obtained with the acyclic alkenes $H_2C{=}CHR$ (R = Me, Bu^t, Ph, CN), $H_2C{=}CF_2$ and $RHC{=}CHR'$ (R = R′ = Me, Ph, Cl; R = Me, R′ = Et), and the molecular geometries of $Cp_2Rh_2(CH{=}CHCN)\{C(CF_3)C(CF_3)H\}$ (Fig. 7) and $Cp_2Rh_2(CH{=}CF_2)\{C(CF_3)$

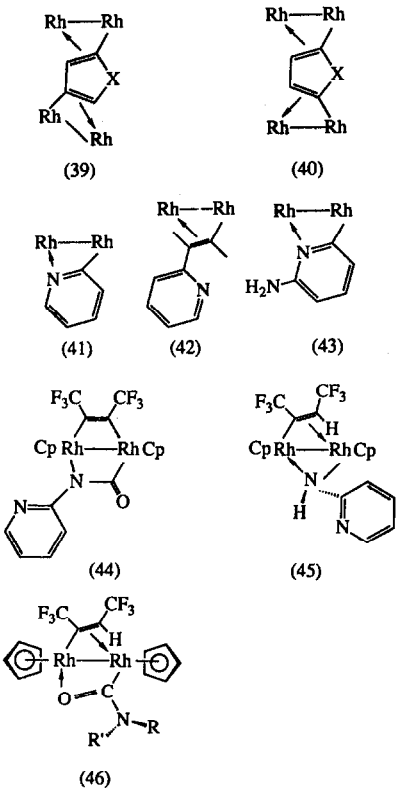
Fig. 7. $C(CF_3)H\}$ (Fig. 8) have been determined[58] from X-ray diffraction data. This establishes that the dihedral angle between the two Rh—Rh—C=C planes is close to 90°.

In the reactions with $H_2C{=}CHR$ and $MeHC{=}CHEt$, some regio-selectivity is evident with a preference for C—H bond cleavage at the least crowded alkene-carbon atom. However, this preference is reversed when the substituent incorporates a Lewis base site. Thus, in the reactions with vinyl acetate and allyl cyanide, all three vinylic C—H bonds can be broken, but there is preference for cleavage of the substituted C—H bonds.[59]

Related reactions occur with cyclic alkenes (cyclooctene, norbornene), acyclic dienes (1,3-butadiene, allene and 1-methyl-1,2-butadiene), cyclic polyenes (1,5-cyclooctadiene, norbornadiene, 1,4- and 1,3-cyclohexadiene, cyclopentadiene, methylcyclopentadiene, cycloheptatriene and cyclooctatetraene) and arenes (benzene, chlorobenzene, toluene, dichlorobenzenes). Figure 9 shows the products obtained[60] for butadiene and illustrates the diversity of C—H bond activations achieved in such systems.

Without exception, the reactions with arenes yielded products in which not one but two C—H bonds were activated. Products of the type $Cp_2Rh_2(\text{arene-H})\{C(CF_3)C(CF_3)H\}$ were never observed; instead all products had the formula $[Cp_2Rh_2\{C(CF_3)C(CF_3)H\}]_2(\text{arene-2H})$. An ORTEP view of the molecular structure of the benzene derivative is presented in Fig. 10. Other interesting twists in the patterns of behaviour were experienced when these investigations were extended to heterocyclic compounds.[61] Furan, thiophene and pyrrole behaved as typical aromatic systems and gave complexes of the type (**39**) and (**40**). When X = O, (**39**) is the major product, but (**40**) predominates when X = S. The reaction with pyridine proceeds differently and gives $Cp_2Rh_2\{C(CF_3)C(CF_3)H\}(\text{py-H})$ of probable structure (**41**). This, and related reactions with substituted pyridines such as the 2-fluoro- and 4-methyl-derivatives are fast, even in the dark. However, the reaction with 2-vinylpyridine requires sunlight and proceeds by activation of a vinylic rather than an aromatic proton to give (**42**). The reaction of (**9**) with 2-aminopyridine was slow in the dark but occurred rapidly in sunlight and gave the three products (**43**), (**44**) and (**45**). The latter two products are formed by activation of N—H rather than C—H bonds. There is N—H bond cleavage in the reactions between (**9**) and allylamine, other primary amines, and $NHMe_2$.[59] These reactions occur in the dark and yield the complexes (**46**) which incorporate a bridging carboxamide group.



3.4. *Cyclic condensation reactions with alkynes*

Dinuclear complexes with bridging metallacyclopentadiene (**6**) or pentadienone (**7**) groups are formed in reactions of $CpRh(CO)_2$ with $CF_3C{\equiv}CCF_3$.[16] The same complexes are obtained when (**5**) is treated with $CF_3C{\equiv}CCF_3$ at elevated temperatures, or under milder conditions from (**9**) and

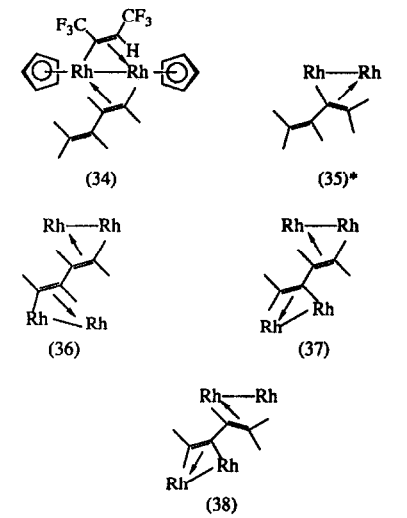


Fig. 9. Products obtained from the sunlight assisted reaction of (**9**) and butadiene. In structural diagrams (**35**) to (**43**), Rh—Rh represents the unit (a):

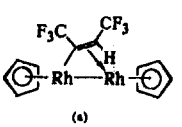

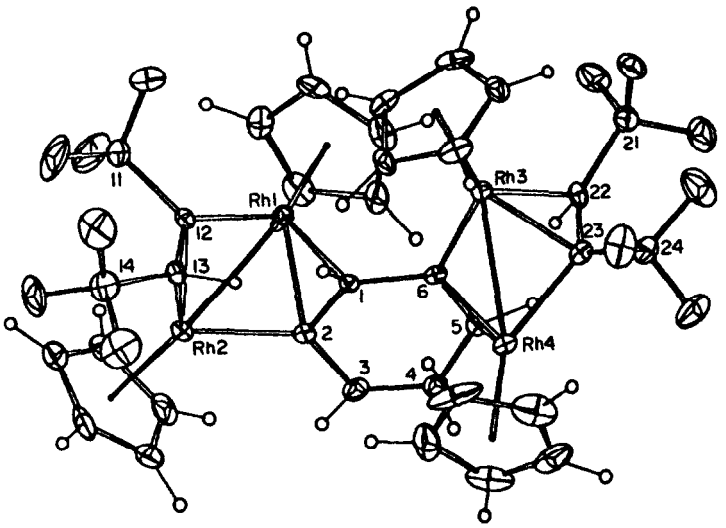

Fig. 10. Molecular structure of the complex $[Cp_2Rh_2\{C(CF_3)C(CF_3)H\}]_2(C_6H_4)$.[60] Selected bond distances (Å): Rh(1)—Rh(2), 2.627(1); Rh(3)—Rh(4), 2.603(1); Rh(1)—C(1), 2.200(7); Rh(1)—C(2), 2.164(7); Rh(1)—C(12), 2.028(8); Rh(2)—C(2), 2.059(10); Rh(2)—C(12), 2.087(8); Rh(2)—C(13), 2.127(8); C(1)—C(2), 1.41(1); C(12)—C(13), 1.415(9).

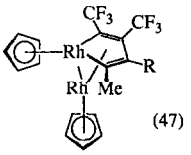
$CF_3C{\equiv}CCF_3$.[33] The metallacyclopentadiene complex $Cp_2Rh_2\{\mu\text{-}\eta^2\eta^4\text{-}C_4(CF_3)_4\}$ exhibits fluxional behaviour (see Scheme 5) when heated in solution.[18] Similar behaviour has been reported for related complexes including $Cp_2Co_2\{\mu\text{-}\eta^2\eta^4\text{-}C_4H_4\}$[62] and $Cp_2Rh_2\{\mu\text{-}\eta^2\eta^4\text{-}C_4Ph_4\}$.[63]

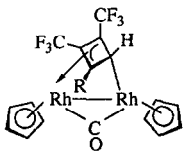
Other alkynes can be added to (**9**) to form related metallacyclopentadiene and pentadienone complexes. The reactions with $PhC{\equiv}CPh$, $MeC{\equiv}CPh$, $Bu^tC{\equiv}CBu^t$, $MeO_2CC{\equiv}CCO_2Me$, $MeC{\equiv}CCO_2Me$ and $MeC{\equiv}CCF_3$ are highly specific and give equal amounts of the metallacyclopentadiene complexes $Cp_2Rh_2\{\mu\text{-}\eta^2\eta^4\text{-}C_4(CF_3)_2RR'\}$ plus the dicarbonyl complex (**5**).[64]

There is high regio-selectivity when the reactions involve unsymmetrical alkynes $MeC{\equiv}CR$, with the regio-isomer (**47**) being formed exclusively. Related reactions with the terminal alkynes $HC{\equiv}CR$ (R = H, CF_3 or Ph) are extremely fast, and lead initially to precipitation of the cyclobutenyl complexes (**48**).[65] In polar organic solvents, these complexes lose CO and convert to the metallacyclopentadiene complexes (**49**).

The cyclobutenyl intermediate (**48**) is formed with other terminal alkynes $HC{\equiv}CR$ (R = Pr, CH_2CO_2Me, $CMe{=}CH_2$, and $CH_2CH_2CH_2C{\equiv}CH$), but pure samples of the complexes could not be isolated due to their high solubility in hydrocarbon solvents and their rapid conversion in solution to (**49**). The conversion to (**49**) always occurs with high regio-selectivity, with the R and H groups located in the 2- and 3-positions, respectively, of the 1-metallacyclopentadiene ring.

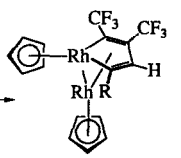


(47)



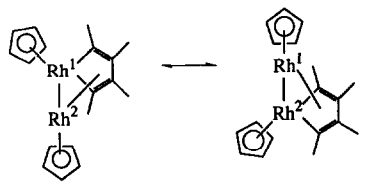
(48)

-CO



(49)

Some other alkynes lead preferentially to formation of the bridging pentadienone complexes (**50**). This occurs for example with $MeC{\equiv}CMe$, $BuC{\equiv}CBu$ and $MeC{\equiv}CR$ (R = Et, Pr^i, Bu^t). The crystal and molecular structure of the complex $Cp_2Rh_2\{\mu\text{-}1,2,5\text{-}\eta : 1,4,5\text{-}\eta\text{-}C_4(CF_3)_2Me_2CO\}$ has

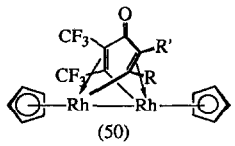


Scheme 5. Ring slippage indicated by the variable temperature NMR spectra of $Cp_2Rh_2\{\mu\text{-}\eta^2,\eta^4\text{-}C_4(CF_3)_4\}$.

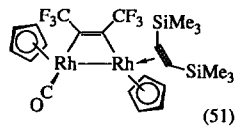
been determined,[66] and this establishes that the bridging ligand is attached symmetrically as shown in Fig. 11.

An analogous structure has been determined[67] for the iron complex $Fe_2(CO)_6\{C_4Me_4CO\}$. Both stereoisomers of (**50**) are isolated from reactions with the unsymmetrical alkynes MeC≡CR.

In the reaction of (**9**) with the alkyne $Me_3SiC{\equiv}CSiMe_3$, a complex was intercepted which has two independent alkyne ligands plus a terminal carbonyl.[33] The proposed structure is shown in (**51**). In refluxing hexane, (**51**) converts to the pentadienone complex (**50**, R = R′ = $SiMe_3$).



(50)



(51)

Some related pentadienone complexes $Cp_2Rh_2\{\mu\text{-}1,2,5\text{-}\eta:1,4,5\text{-}\eta\text{-}C_4R_2R'_2CO\}$ have been obtained by heating $CpRh(CO)_2$ directly with the alkynes MeC≡CR (R = Bu, Pr^i). Three stereoisomers were isolated in each instance.[68] Treatment of $Cp^*Rh(CO)_2$ with MeC≡CMe also gave[30] a small amount of a bridging pentadienone complex $Cp^*_2Rh_2\{\mu\text{-}1,2,5\text{-}\eta:1,4,5\text{-}\eta\text{-}C_4Me_4CO\}$. Some of the complexes $Cp_2Rh_2\{\mu\text{-}1,2,5\text{-}\eta:1,4,5\text{-}\eta\text{-}C_4R_2R'_2CO\}$ have been converted by heating in solution into the mononuclear cyclopentadienone complexes $CpRh\{\eta^4\text{-}C_4R_2R'_2CO\}$.

Since each of the steps depicted in Scheme 6 has been individually verified with certain combinations of M and R, the scheme represents a possible pathway for the formation of mononuclear

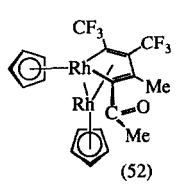
cyclopentadienone complexes from $CpM(CO)_2$ and alkynes. However, alternative possible pathways involving mononuclear intermediates such as $CpM(CO)\{CORC_2R'\}$ and $CpM(RC_2R')\{CORC_2R'\}$ cannot be discounted.

Overall, formation of the pentadienone complexes (**50**) from reactions between (**9**) and $RC{\equiv}CR'$ is favoured only when the substituents R and R′ are alkyl groups. With electron-withdrawing substituents and particularly with polar alkynes, the reaction pathway is directed towards formation of the metallacyclopentadiene complexes $Cp_2Rh_2\{\mu\text{-}\eta^2\eta^4\text{-}C_4(CF_3)_2RR'\}$.

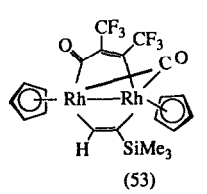
Additional unexpected products were isolated from a number of the above reactions. With $MeC{\equiv}CPr^i$, the complex $Cp_2Rh_2\{C_4(CF_3)_2Me(CMe_2OH)CO\}$ was obtained, and the structure (**52**) was confirmed[64] by X-ray crystallography. The source of this complex was an impurity, $MeC{\equiv}CC(OH)Me_2$, in the commercial sample of $MeC{\equiv}CPr^i$. A dinuclear metallacyclopentadiene complex $Cp_2Rh_2\{\mu\text{-}\eta^2\eta^4\text{-}C_4(CF_3)_2Me(COMe)\}$ was isolated from the reaction with a (as supplied) sample of $MeC{\equiv}CEt$, and again final characterization was achieved only by X-ray crystallography.[64]

Another product isolated from the reaction of (**9**) and $HC{\equiv}CSiMe_3$ was identified spectroscopically as (**53**). It could be isolated in significant yield only when TLC of the reaction solution was performed within a short time ($\leqslant$ 10 min) of mixing the reactants.[65]

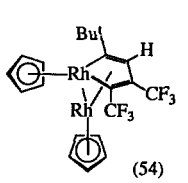
Some of the most extraordinary products were obtained by treatment of (**9**) with $HC{\equiv}CBu^t$.[69] This reaction does give two isomers of the bridging pentadienone complex $Cp_2Rh_2\{\mu\text{-}1,2,5\text{-}\eta\text{:}1,4,5\text{-}\eta\text{-}C_4(CF_3)_2HBu^tCO\}$ and a single isomer of the metalladiene complex $Cp_2Rh_2\{\mu\text{-}\eta^2\eta^4\text{-}C_4(CF_3)_2HBu^t\}$ (**54**). However, the latter product is isolated only when the product mixture is chromatographed on "non-activated" silica supports. With oven-dried supports, two oxygen atoms are transferred to (**54**) to form (**55**) which incorporates an unsaturated keto-ether ligand.



(52)

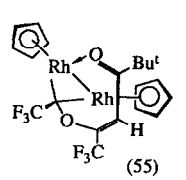


(53)



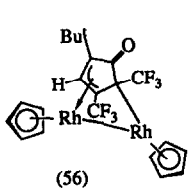
(54)

[SiO2]

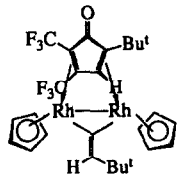


(55)

The molecular structure was established by X-ray crystallography. Two other products isolated from this reaction system could be fully characterized only from X-ray diffraction data. Representations of the molecular structures are given in (**56**) and (**57**).



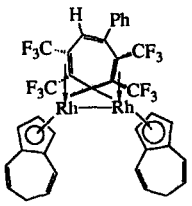
(56)



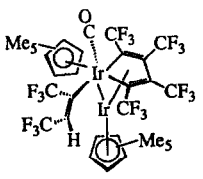
(57)

When the indenyl complex $ind_2Rh_2(\mu\text{-}CO)(\mu\text{-}\eta^2\text{-}CF_3C_2CF_3)$ is treated with $PhC{\equiv}CH$,[49] the complex $ind_2Rh_2\{(CF_3C_2CF_3)_2(PhC_2H)\}$ is formed in addition to $ind_2Rh_2(CO)_2(CF_3C_2CF_3)$. A possible structure for the tris-alkyne complex is shown in (**58**). The analogous reaction with MeC_2Pr^i gives $ind_2Rh_2\{\mu\text{-}1,2,5\text{-}\eta : 1,4,5\text{-}\eta\text{-}C_4(CF_3)_2MePr^iCO\}$ plus the unusual product $ind_2Rh_2\{C_4(CF_3)_2MePr^i(CO_2)\}$. The latter complex has not been structurally characterized. With $Me_3SiC{\equiv}CH$, a pentadienone complex $ind_2Rh_2\{\mu\text{-}1,2,5\text{-}\eta : 1,4,5\text{-}\eta\text{-}C_4(CF_3)_2H(SiMe_3)CO\}$ [**59** ≡ **50** with RR^1 = $(SiMe_3)H$] is the major product.

Another unusual dinuclear product of formula $Cp^*_2Ir_2(CO)_2(CF_3C_2CF_3)_3H$ is formed from $Cp^*Ir(CO)_2$ and $CF_3C{\equiv}CCF_3$ at elevated temperature. It has been characterized crystallographically,[30] and the molecular structure is depicted in (**60**).



(58)

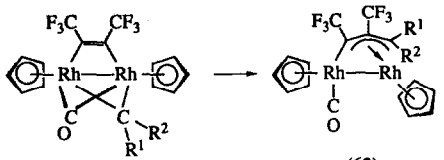


(60)

3.5. *Reactions with diazoalkanes*

The products obtained from reactions of (**9**) with diazoalkanes are influenced markedly by the substituents on $N_2CR^1R^2$. With N_2CH_2,[70] there is a facile elimination of N_2 (Et_2O solution, 0°C) and formation of the μ-alkylidene complex $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}CH_2)(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ (**61**; $R^1 = R^2 = H$). When left in solution, (**61**) converts to $Cp_2Rh_2(CO)\{\mu\text{-}\eta^1\eta^3\text{-}C(CF_3)C(CF_3)CH_2\}$ (**62**; $R^1 = R^2 = H$) by insertion of the methylene group into an alkyne–rhodium bond.

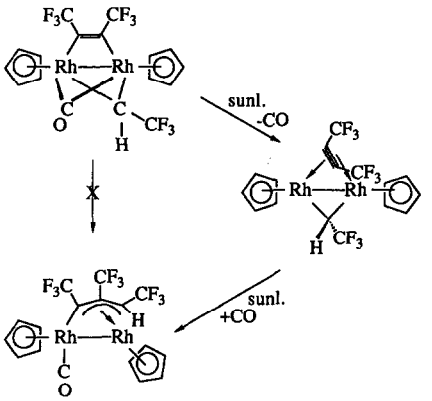
The same reaction sequence occurs with $N_2CH(CO_2Et)$, and NMR monitoring[71] of the conversion of (**61**; $R^1 = H$, $R^2 = CO_2Et$) to (**62**; $R^1 = H$, $R^2 = CO_2Et$) indicates that the alkylidene migration is accompanied by the isomerization (i.e. a twist that interchanges R^1 and R^2) of both (**61**) and (**62**). All four species can co-exist in solution, but the species that finally crystallizes from aged solutions has the configuration with the ester group in the R^1 position. This was determined unequivocally by determination of the crystal and molecular structure.



(61) (62)

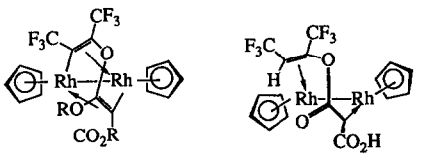
There are analogous alkylidene addition and migration reactions when (**9**) is treated with $N_2CH(SiMe_3)$ or $N_2CH(CH{=}CH_2)$. With these systems, however, the migration reaction is so rapid in solution at 0°C that spectroscopically pure samples of (**61**) could not be obtained. Only one isomer of the η^1,η^3-allyl complexes (**62**) was detected, and this has the substituent *cis* to the CF_3.[71]

Although a μ-alkylidene complex $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}CHCF_3)(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ is formed rapidly in the reaction between N_2CHCF_3 and (**9**), there is no subsequent migration of the alkylidene group, even in refluxing solvents. Further investigation of this system establishes that the migration reaction can be achieved indirectly. The reaction path is shown in Scheme 7.



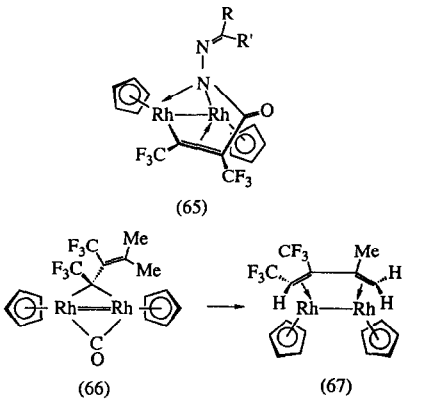
Scheme 7. Indirect pathway for the conversion of $Cp_2Rh_2(\mu\text{-}CO)\{\mu\text{-}CH(CF_3)\}\{\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3\}$ to $Cp_2Rh_2(CO)\{\mu\text{-}\eta^1\eta^3\text{-}C(CF_3)C(CF_3)CH(CF_3)\}$.

A large variety of addition reactions occur with disubstituted diazoalkanes. The diesters $N_2C(CO_2R)_2$ (R = Me, Et, Bu^t) add with loss of N_2 to form the complexes $Cp_2Rh_2(\mu\text{-}CO)\{\mu\text{-}C(CO_2R)_2\}(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ analogous to (**61**). When R = Me or Et, a subsequent migration occurs to give the complexes (**63**; R = Me or Et) in which a new C—O bond has been created. Determination of the crystal and molecular structure[70] of the ethyl ester derivative establishes that the bridging divinyl ether spans the Rh—Rh bond in "flyover" fashion. A migration reaction occurs also when R = Bu^t, but two products have been isolated. One is analogous to (**63**; R = Bu^t), and the other has been spectroscopically characterized[49] as (**64**). Formation of this product has involved hydrolysis of the ester plus migration of $C(CO_2H)_2$ coupled with [H] migration from a carboxylate group to an alkyne carbon.



(63) (64)

In the additions of N_2CRR' (R = R' = Me or Ph; R = Ph, R' = Me or CF_3; R = Me, R' = CF_3) to (**9**), there was retention of N_2 and formation of $Cp_2Rh_2\{\mu\text{-}\eta^1:\eta^2:\eta^2\text{-}C(CF_3)C(CF_3)C(O)NNCRR'\}$. Determination of the crystal and molecular structure[49] of the N_2CMePh derivative established that these complexes incorporate a substituted acetophenone hydrazone ligand (**65**). The reactions with N_2CMe_2 and N_2CMePh gave additional products which were formed by loss of N_2. Spectroscopic data for the complex $Cp_2Rh_2(CO)\{CF_3C_2CF_3\cdot CMe_2\}$ are consistent with the structure (**66**), but the X-ray structure of crystals grown from a solution of this complex revealed a different structure (**67**). The latter complex is formed from (**66**) by a 1,4-

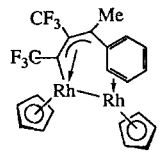


(65)

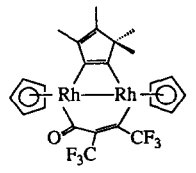
(66) (67)

hydrogen shift which converts the η^1-propenyl ligand to an $\eta^2\eta^2$-butadiene ligand. A CMePh analogue of (66) was obtained from N_2CMePh,[49] but this compound decarbonylated readily, even in the solid state. A possible structure for the decarbonylation product is given in (68).

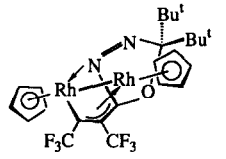
Reaction of (9) with diazocyclopentadiene, $N_2C_5H_4$, gave the novel complex $Cp_2Rh_2\{\mu$-$C(O)C(CF_3)C(CF_3)\}\{\mu$-$\eta^1\eta^1$-$C_5H_4\}$ (69).[49] Formation of this complex involves a 1,2-hydrogen shift within the C_5H_4 unit.



(68)



(69)



(70)

A very unusual [3 + 2] cyclo-addition[72] of the diazoalkane $N_2CBu^t_2$ to the bridging carbonyl in (9) gives the oxadiazoline complex $Cp_2Rh_2\{N{=}N{-}C(Bu^t)_2\text{-}O\text{-}C\text{-}C(CF_3)C(CF_3)\}$ (70). The molecular structure was confirmed by X-ray diffraction and is shown in Fig. 12. The complex (70) undergoes reversible carbonylation to form $Cp_2Rh_2(CO)\{N{=}N{-}C(Bu^t)_2\text{-}O\text{-}C\text{-}C(CF_3)C(CF_3)\}$.

It is not easy to rationalize the diversity of products obtained from the reactions of (9) and diazoalkanes. When there is loss of N_2, it occurs under very mild conditions, and so an intramolecular elimination seems likely. Subtle stereoelectronic effects seem to influence which of the pathways shown in Scheme 8 is followed. Given that the reaction pathway followed with monosubstituted diazoalkanes N_2CHR is invariably to form (d) whereas disubstituted diazoalkanes frequently give (f), it follows that steric effects will often inhibit the formation of a Rh—C bond in the conversion of (c) to (d). When this pathway is blocked, a complex interplay between steric, electronic and thermodynamic effects dictates the nature of the final product.

3.6. *The addition of isocyanide and related ligands*

It was mentioned in Section 3.2 that the isocyanides CNR (R = *t*-Bu or 2,6-$Me_2C_6H_3$) add coordinatively to (9) to form $Cp_2Rh_2(CO)(CNR)(\mu$-$\eta^1\eta^1$-$CF_3C_2CF_3)$. Similar reactions occur with

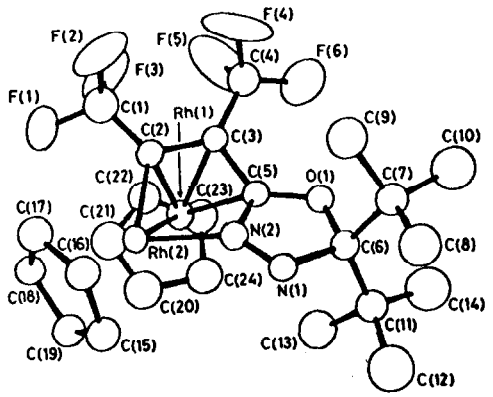


Fig. 12. Molecular structure of complex (70).[72] Selected bond distances (Å): Rh(1)—Rh(2), 2.679(1); Rh(1)—C(2), 2.08(1); Rh(1)—C(3), 2.09(1); Rh(1)—C(5), 2.19(1); Rh(2)—C(2), 2.22(1); Rh(2)—N(2), 2.00(1); C(2)—C(3), 1.43(10); C(3)—C(5), 1.47(1); C(5)—N(2), 1.41(1).

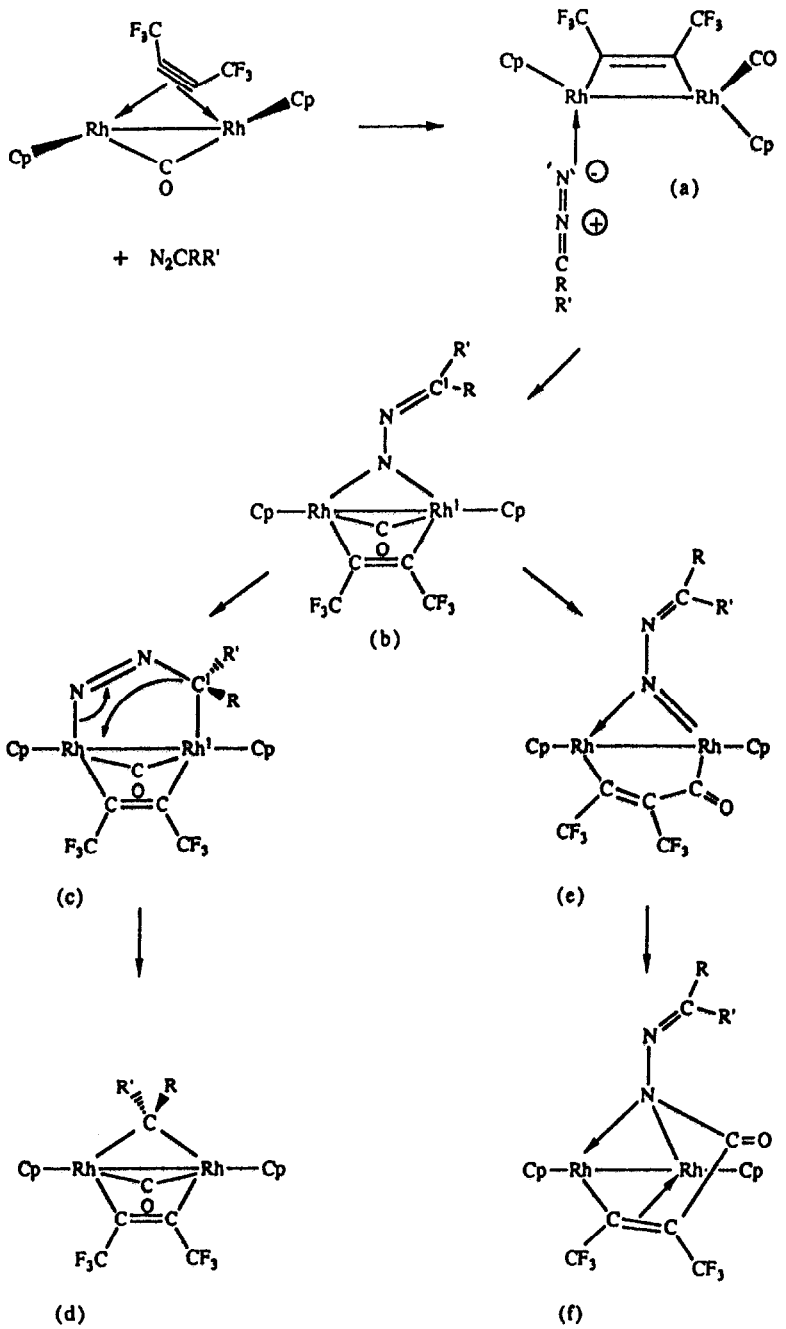
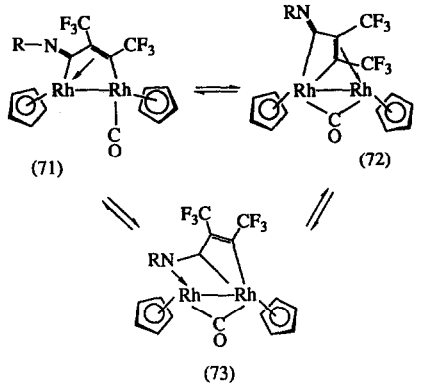


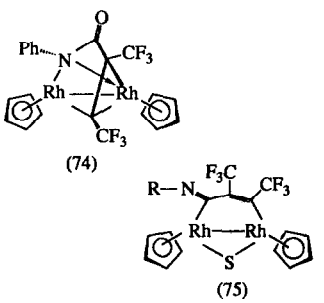
Scheme 8. Alternative pathways in the reactions of diazoalkanes with (**9**).

other isocyanides RNC (R = Et, i-Pr, Cy, Ph, *p*-$MeOC_6H_4$, *p*-$NO_2C_6H_4$) but the products rearrange when left in solution.[73] The rate of rearrangement depends markedly on R and follows the sequence R = Cy, ($t_{1/2}$ = 1740) < i-Pr < Ph < *p*-$MeOC_6H_4$ < *p*-$NO_2C_6H_4$ ($t_{1/2}$ = 1.4 min); it would seem that electronic factors affect the conversion rates. The molecular structure of one of the rearrangement products (R = Et) has been determined by X-ray crystallography. This indicates a terminal carbonyl and a bridging allylimine ligand as shown in (**71**). However, spectroscopic data indicate that when (**71**) is left in solution, it co-exists with two other isomers (**72**) and (**73**). Variable temperature NMR spectroscopy has been used to investigate the rate of interconversion between the three isomers; it is found to be greatest for the aryl systems.

Chemical oxidation of the complexes $Cp_2Rh_2(CO)(CNR)(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ can be achieved with the mild oxidant Me_3NO, and the bridging acrylamide complexes $Cp_2Rh_2\{\mu\text{-}\eta^3\text{-}N(R)C(O)$



$C(CF_3)C(CF_3)$} are formed. The same complexes are obtained upon treatment of (**9**) or (**5**) with isocyanates RNCO (R = Me, t-Bu, *p*-MeC_6H_4). The best preparative method, however, involves addition of nitrene sources N_3R [R = Ph, PhCO, *p*-$MeC_6H_4SO_2$, $(MeO_2C)CH{=}C(CO_2Me)$] to (**9**); these reactions are instantaneous at 0°C.[74,75] In a variation of this method, (**9**) is treated with a carbodiimide RNCNR (R = Pr^i, Cy). This latter reaction yields the isocyanide complexes $Cp_2Rh_2(CO)(CNR)(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ in addition to the appropriate acrylamide complex. The crystal and molecular structure of the complex $Cp_2Rh_2\{CF_3C_2CF_3 \cdot PhNCO\}$ has been determined from single crystal X-ray diffraction data,[74,75] and this reveals the substituted acrylamide ligand as shown in (**74**).



Preliminary investigations of reactions with other heterocumulenes,[76] including isothiocyanates (SCNR), ketenes ($R_2C{=}C{=}O$), thioketenes ($R_2C{=}C{=}S$), ketene–imines ($R_2C{=}C{=}NR'$) and sulphines ($R_2C{=}S{=}O$) have been undertaken. In a number of these reactions, there is evidence for facile ligand fragmentation. For example, the major products obtained from SCNR (R = Me, Et, CH_2Ph, Ph) are formulated as $Cp_2Rh_2(\mu\text{-}S)(CF_3C_2CF_3 \cdot CO)$ and $Cp_2Rh_2(\mu\text{-}S)(CF_3C_2CF_3 \cdot CNR)$ (**75**).

4. THE SYNTHESIS OF CLUSTERS

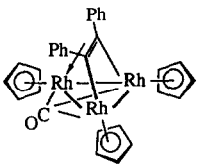
4.1. *The strategy*

The ease of addition of numerous organic substrates to (**9**) extends readily to the addition of metal nucleophiles and other metal complexes. Such reactions occur under mild conditions and thus provide a useful approach to the controlled synthesis of alkyne metal clusters.

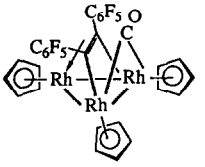
4.2. *Clusters of the type* $Cp_2LRh_2M(CO)_{1\text{ or }3}(CF_3C_2CF_3)$

Our first indication that complexes of this type might be formed readily came from the observation that $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ is a common by-product in reactions of (**9**) with organic substrates. The same complex is formed in 80% yield when (**5**) is treated with $CpRh(CO)_2$. A more direct approach to this and analogous alkyne complexes $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}RC_2R)$ involves reaction of the appropriate alkyne with $CpRh(CO)_2$ or better with $Cp_3Rh_3(CO)_3$.[40] The molecular structures

of two of these complexes prepared in another laboratory were determined[77] from X-ray diffraction data, and two different carbonyl attachments are revealed. When the alkyne is PhC_2Ph, the carbonyl is face-bridging (**76**), but it is edge-bridging (**77**) when $C_6F_5C_2C_6F_5$ is the alkyne. The structures adopted by the $CF_3C_2CF_3$ complex and some related compounds are discussed later.



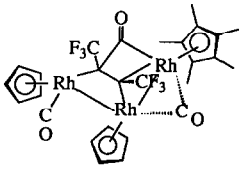
(76)



(77)

In an attempt to gain further insight into the conversion of the binuclear complex (**9**) to the trinuclear complex $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$, the former complex was treated with $CpRh(CO)_2$. This gave some $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ but the tricarbonyl complex $Cp_3Rh_3(CO)_3(\mu\text{-}CF_3C_2CF_3)$ was the major product of this reaction.

Related complexes $Cp_2(\eta\text{-}C_5R_5)Rh_2M(CO)_3(CF_3C_2CF_3)$ are obtained by addition of $(\eta\text{-}C_5R_5)M(CO)_2$ (R = H or Me, M = Co or Rh) to (**9**). The molecular geometry of one of these complexes, $Cp_2Cp^*Rh_3(CO)_3(CF_3C_2CF_3)$, has been established[78] by X-ray diffraction, and there is a V-shaped arrangement of the metal atoms and three different types of carbonyl (**78**). For some of the complexes a second isomer exists but this has not been structurally characterized.



(78)

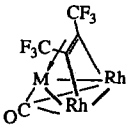
Although $CpIr(CO)_2$ is expected to be more basic than the corresponding Co and Rh compounds, it reacts exceedingly slowly with (**9**) and the yield of $Cp_3Rh_2Ir(CO)_3(\mu\text{-}CF_3C_2CF_3)$ is < 10% after several weeks.[79] When $Cp^*Ir(CO)_2$ was added to (**9**), an interesting contrast in reaction behaviour was observed[79] in that the only heteropolynuclear product obtained was the monocarbonyl complex $Cp_2Cp^*Rh_2Ir(CO)(CF_3C_2CF_3)$. There is a similar anomalous reaction between $indRh(CO)_2$ and (**9**) which gives $Cp_2indRh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$.

The tricarbonyl complexes undergo reversible dissociation in solution at room temperature according to eq. (5):

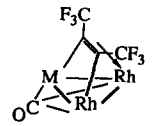
$$Cp_2(C_5R_5)Rh_2M(CO)_3(CF_3C_2CF_3) \rightleftharpoons Cp_2Rh_2(\mu\text{-}CO)(CF_3C_2CF_3) + (C_5R_5)M(CO)_2. \quad (5)$$

The following orders of stability are indicated—R = Me > H; M = Rh > Co (> Ir?). When heated in solution, some of the tricarbonyl complexes undergo partial decarbonylation to give the trinuclear monocarbonyl analogues $Cp_2(C_5R_5)Rh_2M(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$. However, treatment with Me_3NO provides a better way of converting the tricarbonyl to the monocarbonyl analogues. Thus, either directly or by decarbonylation reactions, an extensive range (Table 1) of trinuclear monocarbonyl complexes has been obtained. It was of interest to determine which of the several possible structures was adopted by these complexes.

Spectroscopic data[40] indicate that the two different structural forms co-exist in solution for the complex $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$. The polarity of the solvent affects the proportions of the isomers present, with greater amounts of the edge bridging form being present in more polar solvents. Similar observations apply to $Cp_3Rh_2Co(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ but all three $Cp_2Cp^*Rh_2M(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ complexes adopt the μ_3-CO structure. In all of the Rh_2M-complexes, the alkyne is attached symmetrically (i.e. **79**, not **80**).



(79)



(80)

Table 1. The range of complexes of the type $Cp_2(C_5R_5)Rh_2M(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_5)$

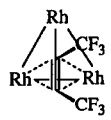
Complex $Cp_2(C_5R_5)Rh_2M(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ R	M	Colour	Carbonyl bonding Mode[a]	Ref.
H	Rh	Purple	face ⇌ edge	40
Me	Rh	Purple–black	face	78
H	Co[b]	Dark green	face ⇌ edge	78
Me	Co	Emerald green	face	78
H	Ir[c]	—		—
Me	Ir	Crimson	face	79
ind	Rh	Green	face ⇌ edge	79

[a] Where isomers exist, the proportions in solution often depend on the polarity of the solvent.
[b] Not fully characterized.
[c] Not prepared.

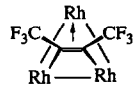
Relatively few reactions of the complexes $Cp_2(C_5R_5)_6Rh_2M(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ have been investigated. Reversible protonation of $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ occurs in protonic acids, and the tetrafluoroborate salt of $[Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)H]^+$ has been isolated.[40] The cationic complex incorporates an edge-bridging carbonyl and probably an edge-bridging hydride ligand. A slow reaction occurs between $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ and $CNBu^t$, and there is cluster fragmentation to produce the new binuclear product $Cp_2Rh_2(CNBu^t)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$.

4.3. *The clusters* $Cp_2(chel)Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$

A related class of trinuclear clusters has been formed by the addition of $(chel)Rh(CO)_2$ complexes to (**9**). Clusters have been prepared[80] with chel = acetylacetonato and other substituted β-diketonates, 8-hydroxyquinolate, N-*para*-tolylsalicyladimine and other Schiff bases. These are 46-electron clusters in contrast to $Cp_3Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ which has a 48-electron count. Although 46-electron alkyne-M_3 complexes normally have a perpendicular attachment of the alkyne (**81**), determination of the molecular structure of the 2,2,6,6-tetramethyl-3,5-heptanedionate (thd) complex $Cp_2(thd)Rh_3(CO)(CF_3C_2CF_3)$ establishes that the hexafluorobut-2-yne adopts a parallel bonding mode (**82**).

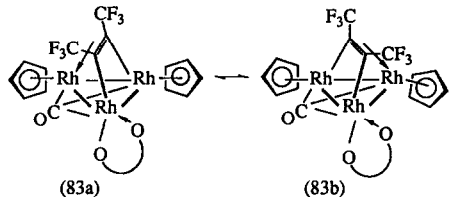


(81)

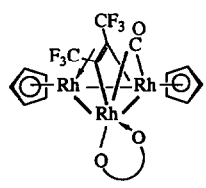


(82)

Spectroscopic results show that two isomers of the $Cp_2(chel)Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ complexes co-exist in acetone solution, with the major isomer (**83**) exhibiting fluxional behaviour. The major and minor isomers are shown in (**83**) and (**84**), respectively; (**83**) corresponds to the solid state structure of the thd complex.

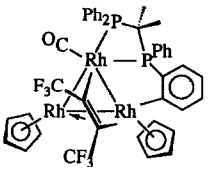


(83a) (83b)

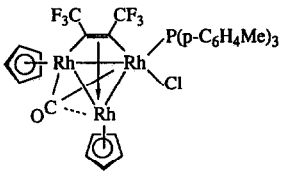


(84)

The clusters $Cp_2(chel)Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ have been subjected to a range of reactions. In the reactions with CO, $CNBu^t$, PhC≡CPh and $PHPh_2$, cluster fragmentation occurs. Examples of the products obtained are $Cp_2Rh_2(CNBu^t)_2(\mu\text{-}\eta^1\eta^1\text{-}CF_3C_2CF_3)$ and $Cp_2Rh_2(\mu\text{-}PPh_2)\{\mu\text{-}\eta^1\eta^2\text{-}CF_3C_2CF_3\cdot H\}$. There is cluster retention in the reactions with SO_2 and tri-*para*-tolylphosphine which give $Cp_2(acac)Rh_3(\mu\text{-}CO)(\mu\text{-}SO_2)(\mu\text{-}CF_3C_2CF_3)$ and $Cp_2(acac)Rh_3(\mu\text{-}CO)\{P(p\text{-tolyl})_3\}(\mu\text{-}CF_3C_2CF_3)$. The reaction with 1,10-phenanthroline gives the cationic cluster $[Cp_2(phen)Rh_3(CO)(CF_3C_2CF_3)]^+$ resulting from chelate ligand exchange. Treatment of $Cp_2(acac)Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ with Me_3SiCl results in removal of the acac ligand, and when this is performed in the presence of other ligands new clusters are formed. Examples include $Cp_2Rh_3(CO)(\mu\text{-}CF_3C_2CF_3)(\mu\text{-dppm-H})$ and $Cp_2Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)\{P(p\text{-tolyl})_3\}Cl$. Proposed structures for these complexes are shown in (**85**) and (**86**).



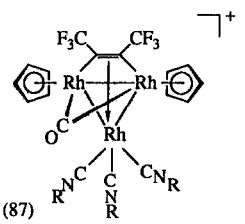
(85)



(86)

4.4. *Cationic clusters* $[Cp_2Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)(CNR)_3]^+$

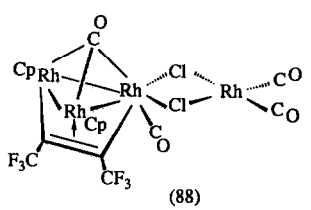
The cationic species $[Rh(CNR)_4]^+PF_6^-$ add to (**9**) with loss of one CNR to form the cationic clusters $[Cp_2Rh_3(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)(CNR)_3]^+PF_6^-$ (R = Pr^i, Bu^t). The symmetrical structure shown in (**87**) has been determined[81] from X-ray diffraction data. This is the minor of the two isomers that co-exist in solution. Although the NMR spectra of (**87**) are not temperature dependent, variable temperature NMR results indicate that the major isomer is fluxional at room temperature. The fluxionality is viewed in terms of a "wind-shield wiper" motion of the alkyne as shown in Scheme 9.



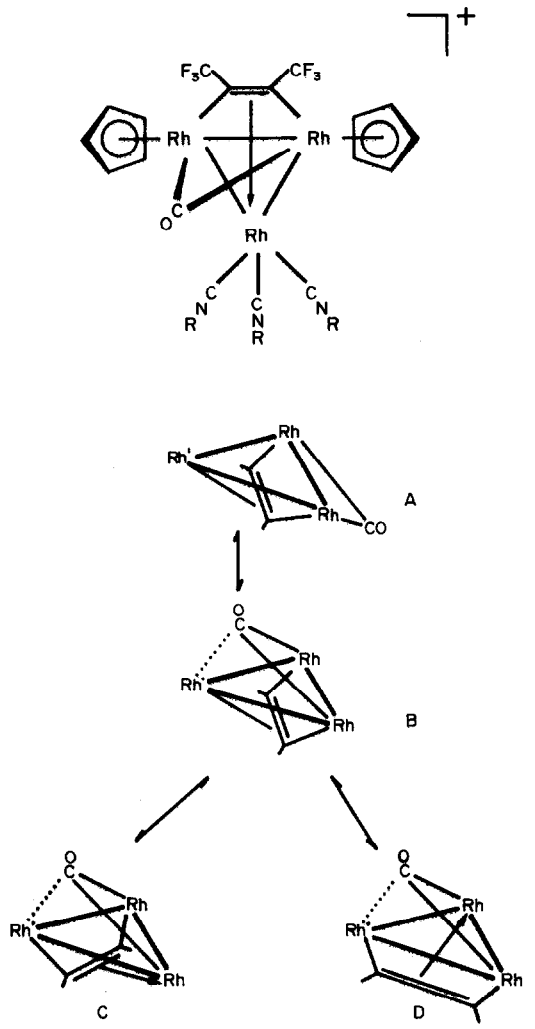
(87)

4.5. *The addition of* $[Rh(CO)_2Cl]_2$ *to* (**9**)

The condensation product $Cp_2Rh_4(CO)_4Cl_2(CF_3C_2CF_3)$ is formed from solutions containing (**9**) and $[Rh(CO)_2Cl]_2$. Crystal structure determination[82] shows that one rhodium of $[Rh(CO)_2Cl]_2$ has added to the Rh—Rh bond of $Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ to give (**88**). In solution, two isomers co-exist and they rapidly interconvert at room temperature.



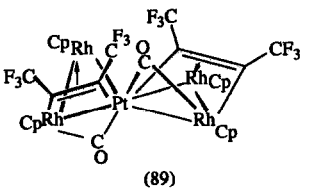
(88)



Scheme 9. Interconversion between isomers of the cationic clusters (**87**).[81]

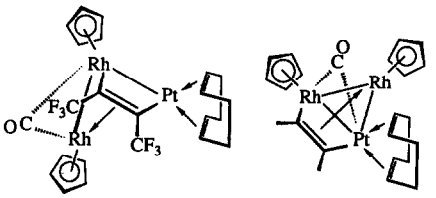
4.6. *Heteronuclear clusters*

Rh_2Pt, Rh_4Pt. Two heteronuclear clusters are obtained[82,83] from the reaction of (**9**) with $Pt(COD)_2$, each being formed by the loss of cyclooctadiene from the Pt^0 complex. With a 1 : 1 ratio of the reactants, the formation of $Cp_2Rh_2Pt(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)(COD)$ is preferred, but substantial amounts of $Cp_4Rh_4Pt(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)$ are obtained when there is an excess of the dirhodium compound in the reaction mixture. The solid state structure of each complex has been established from X-ray diffraction data. In the Rh_4Pt cluster, the Pt is a common apex for two linked Ph_2Pt triangles (**89**).



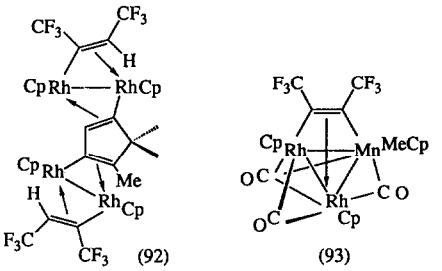
(89)

There is a V-shaped arrangement of the metals in the Rh_2Pt cluster, with one COD remaining on the Pt (**90**). In solution, there is spectroscopic evidence that a second isomer is present, and that it has the structure (**91**). Thus there is facile Rh—Pt bond making and breaking in this system. Variable temperature NMR data indicate fluxional behaviour of the closed cluster.



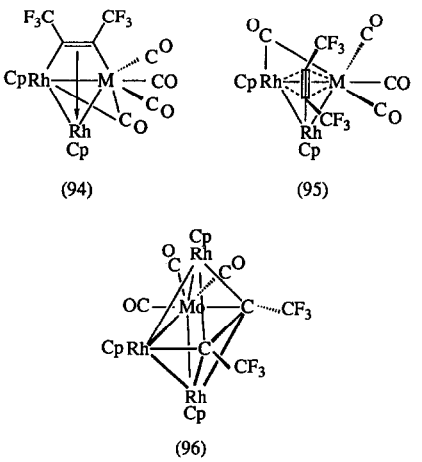
(90) (91)

Rh_2Mn. Numerous products are formed when a solution of $(MeCp)Mn(CO)_3$ and (**9**) is irradiated, or when pre-formed $(MeCp)Mn(CO)_2THF$ is added to (**9**) but only two of the products have been characterized. A ligand transfer reaction gives $(MeCp\text{-}2H)[Cp_2Rh_2(CF_3C_2CF_3 \cdot H)]_2$ (**92**). Interestingly, the isomer obtained in this reaction differs from the four isomers isolated when (**9**) is treated directly with MeCpH (see Section 3.3). The second product is the heteronuclear cluster $Cp_2(MeCp)Rh_2Mn(CO)_3(CF_3C_2CF_3)$ (**93**). Determination of the X-ray crystal structure of this cluster is incomplete because of the apparent need to interchange some of the Mn and Rh atom positions without shifting the MeCp and Cp groups. This problem has not yet been resolved.[84]



(92) (93)

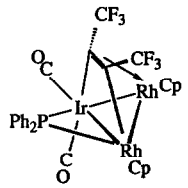
Rh_2Mo, Rh_2W, Rh_3Mo. The 46-electron clusters $Cp_2Rh_2M(CO)_3(\mu\text{-}CO)(CF_3C_2CF_3)$ (M = Mo or W) are formed[85] in the reactions between (**9**) and $Mo(CO)_3(NCMe)_3$ or the W-analogue. Possible structures for these clusters include (**94**) and (**95**), with the latter favoured because it has the perpendicular orientation of the alkyne normally associated with 46-electron alkyne clusters. The molybdenum but not the tungsten system also gives a tetranuclear cluster which is formulated as $Cp_3Rh_3Mo(CO)_4(CF_3C_2CF_3)$. Several structures are possible, but the most likely is (**96**).



(94) (95) (96)

4.7. *Ligand transfer; a limitation in cluster synthesis*

There is scope for preparing various other heteronuclear clusters through extension of this reaction method. We have noted, however, that one limitation in the approach is that ligand transfer sometimes occurs[84,85] in preference to Rh_2—M bond formation. Some examples that illustrates this tendency include the formation of $Cp_2Rh_2(CO)_2(CF_3C_2CF_3)$ by CO transfer from $Mo(CO)_5(NCMe)$, the isolation of both $Cp_2Rh_2(CO)(CNBu^t)(CF_3C_2CF_3)$ and $Cp_2Rh_2(CNBu^t)_2(CF_3C_2CF_3)$



(97)

in the reaction with $Ni(PhC_2Ph)(CNBu^t)_2$, and the transfer of dppm from (dppm-P)$Fe(CO)_4$ to give $Cp_2Rh_2(CO)(dppm)(CF_3C_2CF_3)$.

4.8. *The bridge-assisted formation of clusters*

Two alternative approaches to cluster synthesis based on (**9**) involve prior coordination of a phosphine to the dirhodium complex. One involves complexes of the type $Cp_2Rh_2(CO)(CF_3C_2CF_3)\{Ph_2P(CH_2)_nX\}$ where X = PPh_2, $CH{=}CH_2$, C≡CR etc. The formation of these complexes was discussed in Section 3.2. The dangling functional group is able to coordinate another metal complex. In this way, we have formed several new trimetallic complexes[86] including $Cp_2Rh_2(CO)(CF_3C_2CF_3)(dppe)Cr(CO)_5$, $Cp_2Rh_2(CO)(CF_3C_2CF_3)(Ph_2PCH_2CH_2CH{=}CH_2)\{(MeCp)Mn(CO)_2\}$ and $Cp_2Rh_2(CO)(CF_3C_2CF_3)(Ph_2PCH_2C{\equiv}CMe)\{Co_2(CO)_6\}$. We are currently investigating ways of encouraging Rh_2—M bond formation within the complexes.

There was previous mention of the complex $Cp_2Rh_2(CO)(PPh_2H)(CF_3C_2CF_3)$ (see Section 3.2). The new cluster $Cp_2Rh_2Ir(CO)_2(\mu\text{-}PPh_2)(CF_3C_2CF_3)$ is obtained[85] by treatment of the secondary phosphine complex with n-BuLi and subsequently with $[Ir(COD)Cl]_2$ under a CO atmosphere. The initial reaction presumably gives $Cp_2Rh_2(CO)(PPh_2^-Li^+)(CF_3C_2CF_3)$, and there is elimination of LiCl and replacement of COD by two carbonyls in the subsequent reaction. The structure (**97**) has been established for the Rh_2Ir cluster from X-ray diffraction data. Corresponding reactions with other halo-metal complexes should lead to interesting new phosphido bridged heteronuclear clusters.

5. CONCLUSIONS

The complex (**9**) is a versatile model compound for studying addition reactions, particularly coordinative additions. Reactions generally occur rapidly at or below room temperature. The range of substrates added to (**9**) is considerable and includes phosphines, amines, alkenes, arenes, heterocycles, alkynes, isocyanides, diazoalkanes, azides, heterocumulenes and metal complexes. In many instances, initial coordination of the substrate is followed by further intramolecular reactions to yield new organic ligands. The course of these reactions is very dependent on stereoelectronic influences, and some extremely novel reaction pathways have emerged. In the addition reactions with metal complexes, a range of alkyne metal clusters has been formed and many of these exhibit interesting fluxional effects in solution. Overall, this investigation has revealed a host of novel ligand–metal interactions and many new types of reactions involving the making and/or breaking of C—H, C—C, C—N, C—O, N—H and Rh—M bonds.

Acknowledgements—Many research associates have contributed ideas and their technical skills to various parts of this investigation. Their names appear in the references and I thank all of them for their efforts. I thank the Australian Research Council for financial support and Johnson Matthey Technology Centre for the loan of rhodium trichloride.

(*Received* 3 *May* 1991; *accepted* 4 *June* 1991)

Abstract—The synthesis and electrochemical behaviour of the nickel(II) macrocyclic derivatives [Ni(MC1)L](ClO_4) and [Ni(MC2)L](ClO_4) where MC1 is 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene and MC2 is 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene, and L^- stands for the 1,1-dithio monoanions, dimethyldithiocarbamate (Me_2Dtc^-), diethyldithiocarbamate (Et_2Dtc^-) or pyrrolidindithiocarbamate ($PyDtc^-$), are described. The analytical and spectroscopic data are consistent with a pentacoordinate geometry. Electrochemical studies of these complexes indicate a reversible oxidation process yielding nickel(III) species unstable at room temperature. EPR studies indicate that these short-lived low-spin d^7 nickel(III) species have their unpaired electron in the d_{z^2} orbital.

In previous work,[1] we have reported the first octahedral macrocyclic nickel(II) compounds containing only one 1,1-dithio ligand. These compounds were prepared from $[Ni(DL\text{-}CTH)]^{2+}$ and $[Ni(Cyclam)]^{2+}$ and a 1,1-dithio anionic ligand L^- to yield the corresponding [Ni(N4-macrocycle)L]$^+$ complexes. DL-CTH and Cyclam, are the tetradentate ligands 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane and 1,4,8,11-tetraazacyclotetradecane, respectively, while L^- represents dimethyldithiocarbamate, diethyldithiocarbamate or pyrrolidindithiocarbamate. Similarly, starting with a tridentate macrocyclic ligand together with the same 1,1-dithio ligand L^-, the preparation of the corresponding pentacoordinate [Ni(N3-macrocycle)L]$^+$ derivatives may be envisioned. We report here the synthesis and characterization of two series of such derivatives, [Ni(MC1)L](ClO_4) and [Ni(MC2)L](ClO_4), where MC1 is 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene, MC2 is 2,4,4,9-tetramethyl-1,5,9-triazacyclododec-1-ene, and L^- is dimethyldithiocarbamate (Me_2Dtc^-), diethyldithiocarbamate (Et_2Dtc^-) or pyrrolidindithiocarbamate ($PyDtc^-$). EPR data on the electrogenerated corresponding nickel(III) species are also reported.

EXPERIMENTAL

Synthesis

Bis-(3-aminopropyl)amine, N,N-bis(3-aminopropyl)methylamine, sodium dimethyl dithiocarbamate ($NaMe_2Dtc \cdot 2H_2O$), sodium diethyl dithiocarbamate ($NaEt_2Dtc \cdot 3H_2O$), ammonium pyrrolidindithiocarbamate (NH_4Pydtc) and Ni $(ClO_4)_2 \cdot 6H_2O$ were commercially available and used without further purification. $[Ni(MC1)(OH)]_2(ClO_4)_2$ and $[Ni(MC2)(OH)]_2(ClO_4)_2$ were prepared following the general method of Curtis *et al.*[2]

$HClO_4$ (10%) was added to a continuously stirred water suspension of $[Ni(MC1)(OH)]_2(ClO_4)_2$ or $[Ni(MC2)(OH)]_2(ClO_4)_2$ (1 mmol in 75 cm^3 H_2O) until a neutral solution was obtained. To this solution, an aqueous solution of the appropriate L^- ligand (2 mmol in 50 cm^3 H_2O) was added. A blue–green precipitate was immediately formed and, after 30 min of continuous stirring, the complexes were filtered off, washed with water and air-dried. The average yields were 75%. Elemental analysis data are summarized in Table 1 and are consistent with a $[Ni(MCi)L](ClO_4)$ ($i = 1, 2$) formula.

Physical measurements

IR spectra (4000–200 cm^{-1}) were recorded as KBr pellets with a Perkin–Elmer 1130 IR spectrophotometer. UV–vis spectra (acetonitrile solutions) were recorded with a Shimadzu UV-160 A spectrophotometer (Table 2).

Voltammetric measurements and controlled potential electrolysis were carried out using a DACFAMOV 05-03 computer-controlled instrument with ohmic resistance compensation.[3] Rigorously de-aerated acetonitrile was used as a solvent and $(n\text{-}Bu_4N)PF_6$ (0.1 M) as supporting electrolyte. Solutions were de-aerated again by means of a stream of nitrogen and a nitrogen blanket was maintained above the solutions during the electrochemical experiments. Potentials were referenced using an Ag/AgCl (0.1 M KCl) electrode separated from the bulk of the solutions by a medium porosity fritted disc. The potential for the one-electron oxidation of ferrocene is 420 mV versus the Ag/AgCl (0.1 M KCl) electrode. For the voltammetric measurements, a platinum wire auxiliary electrode was used in conjunction with a platinum disc working electrode (TACUSSEL EDI rotating electrode, area 3.14 mm^2). The voltammetric data are summarized in Table 3. Coulometry was performed at 230 K on a large area platinum electrode at 800 mV. Due to experimental requirements (temperature and atmosphere control), a previously described[4] electrolysis cell allowing combined coulometry–EPR studies was used.

The EPR spectra of the electro-oxidized species in CH_3CN glass were recorded at 100 K on a Bruker ER 200 TT spectrometer, equipped with a Bruker B-NM20 gaussmeter and a EIP 548 microwave frequency counter, operating at X-band frequencies.

RESULTS AND DISCUSSION

The IR spectra of all prepared complexes show a doublet in the 3150–3300 cm^{-1} region assignable to ν(N—H) and a strong sharp band at 1650 cm^{-1} assignable to ν(C—N).[2] Additional bands centred at 1100 (s, broad) and 620 (s) cm^{-1} confirm the presence of the ClO_4^- anion. The dithiocarbamate ν(C—N) stretching band is observed in the range 1510–1530 cm^{-1}, as previously observed in [Ni(N3-macrocycle)L](ClO_4);[1] these values indicate a certain amount of double bond character [ν(C=N) = 1690–1640 cm^{-1}, ν(C—N) = 1350–1250 cm^{-1}].[5] In any case, no bands attributable to water molecules are observed. The electronic spectra of all studied complexes (Table 2) show the first maxima at slightly lower energy than that previously reported[1] for octahedral nickel(II) complexes obtained with similar, but tetradentate, macrocyclic ligands and the same 1,1-dithio ligand, L^-. The other intense bands in the UV region are similar to those observed in the octahedral complexes and can be attributed to charge-transfer bands. We can therefore infer from IR and the elemental analysis data that the [Ni(MC*i*)L](ClO_4) (*i* = 1, 2) complexes studied in this work are pentacoordinate systems.

The cyclic voltammogram of all studied complexes (Fig. 1) shows one oxidation couple in the range studied (0–+2 V). The oxidation potential, $E_{1/2}$, the E_p values and the peak intensity ratio are shown in the Table 3. It is interesting to note that these redox potential values are in the same range (500–600 mV) as those previously reported[1] for the [Ni(N4-macrocycle)L](ClO_4) octahedral complexes. By contrast, in the case of complexes with only one N4-macrocyclic ligand, the Ni^{II}/Ni^{III} redox potential values are significantly higher [$\simeq$ 1 V vs $Ag/AgNO_3$ (0.1 M), i.e. $\simeq$ 1.4 V vs Ag/AgCl (0.1 M KCl)].[6] The values of the peak intensity ratio indicate that the Ni^{II}/Ni^{III} couple is reversible in the case of the [Ni(MC1)L](ClO_4) complexes (I_p^a/I_p^c close to one), but only quasi-reversible in the case of the [Ni(MC2)L](ClO_4) complexes (I_p^a/I_p^c lower than one). This indicates that the complexes with the MC2 ligand are less stable at room temperature than the complexes with the MC1 ligand. Cyclic voltammograms were recorded for various voltage-sweep rates: indeed, the lower the sweep rate, the lower the I_p^a/I_p^c ratio. Using these data, the half-life times of nickel(III) oxidized species have been estimated using the method of Nicholson *et al.*[7] to a few minutes in the case of the [Ni(MC1)L](ClO_4) complexes and to a few seconds in the case of the [Ni(MC2)L](ClO_4) complexes.

Controlled potential electrolysis of acetonitrile solutions of the [Ni(MC*i*)L](ClO_4) complexes were carried out at 800 mV and 230 K. The starting nickel(II) complex solutions are blue–green and turn brown–yellow when oxidized. When these solutions are warmed back to room temperature, decomposition occurs and no EPR signal is observed. Consistent with the sweep-rate dependent cyclic voltammetric data discussed above, the vanishing of the signal is faster in the case of the [Ni(MC2)L](ClO_4) complexes compared to the [Ni(MC1)L](ClO_4) complexes.

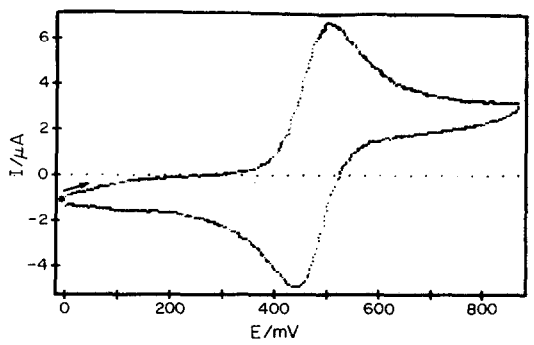

Fig. 1. Cyclic voltammogram of [Ni(MC1)Et_2Dtc](ClO_4). *: starting potential; sweep-rate: 0.1 V s^{-1}; 10^{-3} solution in CH_3CN/(n-Bu_4N)PF_6 (0.1 M); working electrode: platinum rotating disk (area 3.14 mm^2).

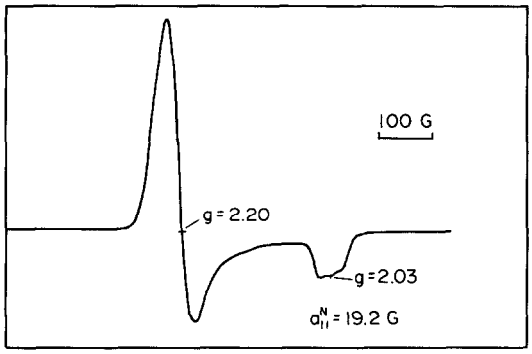

Fig. 2. X-band EPR spectrum (100 K) of [Ni(MC1)$Et_2Dtc]^{2+}$ electrogenerated in CH_3CN at 230 K. (See text for measurement conditions and Table 4 for g and $a_{\parallel}^{N}$ values of the other complexes.)

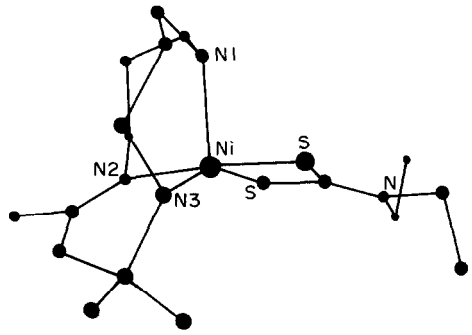

Fig. 3. Proposed penta-coordinate structure for the $[Ni(MC1)Et_2Dtc]^{2+}$ complex cation.

The frozen CH_3CN solution EPR spectra of the product of the electrolysis of the studied nickel(II) complexes confirm that the oxidation process is metal-centred. One typical spectrum, that of [Ni(MC1)Et_2Dtc](ClO_4), is shown in Fig. 2. The spectra consist of axial signals with $g_{\perp}$ and $g_{\parallel}$ values presented in Table 4. Hyperfine splitting (*ca* 20 G) is well-resolved only for $g_{\parallel}$. According to the literature,[6,8,9] such EPR spectra patterns are characteristic of a d^7 system in which the unpaired electron occupies principally the d_{z^2} orbital. The observed hyperfine splitting of the $g_{\parallel}$ feature is due to the interaction with only one nitrogen atom of the N3-macrocyclic ligand ($a_{\parallel}^{N}$ values are given in Table 4). If we assume that the electrogenerated nickel(III) species are also pentacoordinated, this coupling with only one nitrogen atom indicates a square pyramidal geometry with one nitrogen atom in the apical position; in that case, the d_{z^2} orbital is predicted to be lower in energy than the $d_{x^2-y^2}$ orbital.[10] It would be interesting to confirm this structural hypothesis by means of single crystal X-ray diffraction, and work is currently in progress in this direction. Besides, in the present lack of available experimental X-ray structural data of the nickel(II) precursor complexes, the hypothesis of a trigonal bipyramidal geometry with the other position corresponding to the d_{z^2} orbital occupied by one of the sulphur atoms of the 1,1-dithio ligand cannot be ruled out. However, in that case, the d_{z^2} orbital is predicted to be higher in energy than the $d_{x^2-y^2}$ orbital.[10] In the absence of structural data on these complexes, we propose a possible structure for [Ni(MC1)Et_2Dtc](ClO_4) (Fig. 3); this structure was derived and generated from the fractional atomic coordinates of the Et_2Dtc from [Ni(DL-CTH)Et_2Dtc](ClO_4), which structure has been reported,[1] and Ni(MC1) from [Cu(Me_2oxpn)Ni(MC1)](ClO_4), a dinuclear Cu^{II}–Ni^{II} complex we recently structurally characterized[11] (Me_2oxpn is N,N′-bis(2,2′-dimethyl-3-aminopropyl)oxamido).

[Ni(MC2)PyDtc](ClO_4)	2.24	2.03	20.5 G

CONCLUSIONS

The first pentacoordinate 1,1-dithio nickel(II) complexes with one N3-tridentate macrocyclic ligand and one dithiocarbamate ligand have been prepared and characterized by elemental analysis and spectroscopic measurements. These complexes undergo one reversible oxidation process in the 475–575 mV range. Controlled electrochemical oxidation of these complexes give oxidized species, unstable at room temperature, which have been characterized by frozen solution EPR spectroscopy as low-spin d^7 nickel(III) species.

REACTIONS OF NIOBIUM AND TANTALUM CLUSTERS WITH ALIPHATIC ALCOHOLS. SYNTHESIS AND PROPERTIES OF $[M_6X_{12}(ROH)_6]X_2$, M = Nb OR Ta, X = Cl OR Br, R = Me, Et, i-Pr OR i-Bu

(*Received* 10 *May* 1991; *accepted* 28 *May* 1991)

Abstract—The dissolution and subsequent evaporation of the aliphatic alcohol solutions of $[(M_6X^b_{12})(H_2O)_4X^t_2]\cdot 4H_2O$ (M = Nb or Ta, X = Cl or Br; b, bridging; t, terminal) in a vacuum have resulted in complete exchange of the four coordinated water molecules and two terminal halide atoms by aliphatic alcohols forming insoluble, crystalline, diamagnetic clusters of the composition $[M_6X_{12}(ROH)_6]X_2$ (R = CH_3, C_2H_5, i-C_3H_7 and i-C_4H_9). Spectral evidence indicates occupation of all octahedral coordination sites by aliphatic alcohol molecules.

The solubility of the hexanuclear cluster hydrates $[(M_6X_{12})(H_2O)_4X_2]\cdot 4H_2O$ (M = Nb or Ta, X = Cl or Br) in aliphatic alcohols was observed at the time of their discoveries. Chapin[1] measured the molecular weight of $Ta_6Br_{14}\cdot 7H_2O$ (correct $8H_2O$) using the boiling point method in propyl alcohol solution, and showed that the molecules present in this solvent contain Ta_6 units. Forty years later, X-ray diffraction[2] of an ethanolic solution of $M_6Cl_{14}\cdot 7H_2O$ and $Ta_6Br_{14}\cdot 7H_2O$ confirmed this result and revealed the complex cation $[M_6X_{12}]^{2+}$ with the octahedral arrangement of six metal atoms. The position of the absorption bands in the electronic spectra of these systems was found to be solvent dependent.[3,4] Similar results were obtained from potentiometric titrations.[5] More recently it was demonstrated that the solubility of these $[M_6X_{12}]^{2+}$ cluster units in aliphatic alcohols could be the consequence of reactions with solvents.[6] The specific conductivity and pH measurements at 25°C indicated distinct differences in behaviour between $[M_6Cl_{12}]^{2+}$ and $[M_6Br_{12}]^{2+}$ derivatives in alcohol solutions. For the former the specific conductivity was time dependent, whilst for the latter the equilibrium was reached within a few hours. Support for this proposal was also found in the high resolution ^1H NMR spectra of alcoholic solutions.[7] A complex multiplet consisting of 10 resonances was found in the region δ 3.7–3.8 ppm, arising from the CH_3 groups from coordinated CH_3OH molecules present in the mixed-ligand species $[(M_6X_{12})(H_2O)_{6-x}(CH_3OH)_6]^{2+}$, for X = Br, $0 \leqslant x \leqslant 6$, that are formed in methanolic solutions. The complexity of the ^1H NMR spectra for X = Cl is the consequence of competition between Cl^-, H_2O and CH_3OH for the six octahedral coordination sites. Data on the preparation of $[Nb_6Cl_{12}]Cl_4\cdot 3C_2H_5OH$,[8] $[(C_2H_5)_4N]_2[Nb_6Cl_{12}]X_4\cdot 2C_2H_5OH$[9] or $[M_6Cl_{12}](OH)_2\cdot 6H_2O\cdot 2CH_3OH$[10] also exist. Here we describe the synthetic procedure for the preparation of the completely anhydrous, insoluble cluster alcoholates, $[M_6X_{12}(ROH)_6]X_2$, that are formed in aliphatic alcohol solutions after complete displacement of the four coordinated water molecules and two halide atoms from the first coordination sphere of the parent cluster unit.

EXPERIMENTAL

Materials

Methanol, absolute ethanol, i-butanol (all Merck) and i-propanol (BDH) were dried over activated molecular sieves (3 Å). The clusters $[M_6X_{12}]X_2\cdot 8H_2O$, M = Nb or Ta, X = Cl or Br, were prepared using a published procedure.[11] Their

magnetic susceptibility measurements and electronic spectra agreed with those reported previously[12] for $[M_6X_{12}]^{2+}$ units.

Note. Aliphatic alcohol solutions of chloro and to a lesser extent bromo clusters are oxygen sensitive and slowly oxidize first to $[M_6X_{12}]^{3+}$ and then to $[M_6X_{12}]^{4+}$, and all experiments reported here were carried out on the vacuum line and in a dry-box under an oxygen-free nitrogen atmosphere.

Preparation of the clusters

$[M_6Cl_{12}(ROH)_6]Cl_2$, M = Nb *or* Ta, R = Me *or* Et. The clusters $[Nb_6Cl_{12}]Cl_2 \cdot 8H_2O$ (0.6 g, 0.50 mmol) or $[Ta_6Cl_{12}]Cl_2 \cdot 8H_2O$ (0.7 g, 0.405 mmol) in a round bottom flask and methanol (30 cm^3) or ethanol (50 cm^3) were distilled on the vacuum line. The clusters were dissolved in aliphatic alcohols by mixing and stirring the suspensions at room temperature overnight. The solutions were filtered off and evaporated on the vacuum line until dryness by heating the contents of the flask in a water bath at 35°C. Without heating, the clusters were dried on the vacuum line for a further 2 h. The process of distillation of methanol or ethanol on the vacuum line over the substances and its evaporation was repeated two or three more times for methanol or ethanol, respectively. Complete exchange of water molecules by methanol was recognized by the beginning of crystallization of the insoluble clusters $[M_6Cl_{12}(MeOH)_6]Cl_2$. At this point the suspensions were left for a few days to crystallize. Finally, the flasks and their content were transferred to a dry-box and the dark-green precipitates were separated out, washed with methanol and dried over P_4O_{10} under a nitrogen atmosphere.

After repeating the process of evaporation of ethanol cluster solutions in vacuum four times, the complete exchange of water molecules by ethanol was achieved, but the $[M_6Cl_{12}(EtOH)_6]Cl_2$ clusters were still soluble in ethanol. After the last evaporation to dryness the substances were left on the vacuum line to be evaporated overnight. Found: Nb, 45.9; Cl, 40.0; C, 5.9; H, 2.0. $[M_6Br_{12}(MeOH)_6]Br_2$, M = Nb *or* Ta. Clusters $[Nb_6Br_{12}]Br_2 \cdot 8H_2O$ (0.5 g, 0.274 mmol) and $[Ta_6Br_{12}]Br_2 \cdot 8H_2O$ (0.5 g, 0.212 mmol) were dissolved in methanol (20 cm^3) by mixing and warming the suspensions at 30°C. The clear, emerald-green solutions were filtered off (G-4 frit) to the ampoules previously filled with nitrogen, sealed off under nitrogen and left at room temperature for about a week. The dark-green clusters started crystallizing on the walls of the ampoules, were collected on a G-4 frit, washed with methanol in which they were not soluble and dried in evacuated tubes overnight.

Compounds of the same composition were precipitated by the addition of an equal volume of concentrated HBr (free of bromine) to the methanolic solution of $[M_6Br_{12}]Br_2 \cdot 8H_2O$. Found: Nb, 29.8; Br, 59.5; C, 3.8; H, 1.3. Calc. for $[Nb_6Br_{12}(MeOH)_6]Br_2$ (**V**): Nb, 29.8; Br, 59.9; C, 3.8; H, 1.3%. IR data: 3050 m, 1610 w, 1120 m, 998 vs, 578 w, 368 m, 267 s, 242 s. $[M_6Br_{12}(EtOH)_6]Br_2$, M = Nb *or* Ta. To clusters $[Nb_6Br_{12}]Br_2 \cdot 8H_2O$ (0.6 g, 0.329 mmol) or $[Ta_6Br_{12}]Br_2 \cdot 8H_2O$ (0.7 g, 0.298 mmol) in a round bottom flask the ethanol (50 cm^3) was distilled on the vacuum line. In order to dissolve the clusters completely the suspensions were left overnight, then filtered off, evaporated on the vacuum line until dryness and further dried under vacuum for 2 h. The process of distillation of ethanol over the substances and its evaporation on the vacuum line was repeated three more times. Exchange of water molecules by ethanol was complete when the insoluble $[M_6Br_{12}(EtOH)_6]Br_2$ clusters started to crystallize. The suspensions were left at room temperature for 2 days to crystallize. In a dry-box the precipitates were separated out, washed with ethanol and dried over P_4O_{10} in a nitrogen atmosphere. Found: Nb, 28.8; Br, 57.1; C, 6.9; H, 2.0. Calc. for $[Nb_6Br_{12}(EtOH)_6]Br_2$ (**VII**): Nb, 28.5; Br, 57.3; C, 7.4; H, 1.8%. IR data: 3050 w, 1620 w, 1085 m, 1024 s, 870 m, 808 m, 266 m. Found: Ta, 44.1; Br, 46.9; C, 5.6; H, 1.4. Calc. for $[Ta_6Br_{12}(EtOH)_6]Br_2$ (**VIII**): Ta, 43.8; Br, 46.8; C, 5.8; H, 1.5%. IR data: 1150 vw, 1610 w, 1087 w, 1024 s, 875 m, 804 m, 226 vs.

$[M_6X_{12}(i\text{-}ROH)_6]X_2$, M = Nb *or* Ta, X = Cl *or* Br, R = i-Pr *or* i-Bu. Since the starting substances $[M_6X_{12}]X_2 \cdot 8H_2O$ were poorly soluble in i-PrOH

and i-BuOH, the clusters $[M_6X_{12}(i\text{-}ROH)_6]X_2$ were prepared via the intermediate compounds $[M_6X_{12}]X_2 \cdot n\text{EtOH} \cdot (8-n)H_2O$. To the substances $[M_6X_{12}]X_2 \cdot 8H_2O$ (0.6 g) the ethanol (50 cm^3) in a round bottom flask was distilled on a vacuum line as described for $[M_6X_{12}(EtOH)_6]X_2$. After repeated dissolution of the cluster in ethanol and evaporation of the solution to dryness under vacuum to the solid, dried substances $[M_6X_{12}]X_2 \cdot n\text{EtOH} \cdot (8-n)H_2O$ were obtained. The i-PrOH or i-BuOH (50 cm^3) was distilled over the substances on the vacuum line and after dissolution the clear solutions were also evaporated under vacuum. The dissolution of the cluster in i-ROH and its evaporation on the vacuum line was repeated. During this process the slow crystallization of the insoluble $[M_6X_{12}(i\text{-}ROH)_6]X_2$ occurs as a result of the complete exchange of water and ethanol molecules by i-ROH. The suspensions were left to crystallize for 2 more days. Further methods are as described for $[M_6Cl_{12}(EtOH)_6]Cl_2$. Found: Nb, 39.3; Cl, 35.3; C, 15.0; H, 3.4. Calc. for $[Nb_6Cl_{12}(i\text{-}PrOH)_6]Cl_2$ (**IX**): Nb, 39.4; Cl, 36.1; C, 15.3; H, 3.4%. IR data: 3350 w, 3140 w, 1620 w, 1162 m, 1125 w, 1110 m, 1092 vs, 1030 w, 988 w, 950 w, 924 s, 818 s, 345 s, 280 w, 240 w. Found: Nb, 27.7; Br, 55.1; C, 10.0; H, 2.2. Analysis. Niobium or tantalum were determined by the "H-tube" method.[13] The percentage of these metals was also calculated from the amount of M_2O_5 obtained at the end of thermogravimetric decomposition of the alcoholate clusters on the thermobalance. Halogens were determined by potentiometric titrations with standard silver nitrate solution after decomposition of the clusters with KOH and H_2O_2. Carbon and hydrogen were determined by the Rudjer Bošković Institute Microanalytical Service.

Physical measurements. The pH measurements and potentiometric titrations were performed at 25°C with Methrom potentiograph Model E 436. Solid-state IR spectra (4000–180 cm^{-1}) were recorded as Nujol mulls with a Perkin–Elmer Model 580B spectrometer and in methanol solutions with a Perkin–Elmer FTIR 1710 in 0.1 mm KBr cells. Magnetic susceptibility measurements were performed according to Gouy at 22°C for the starting materials and all complexes. Thermogravimetric measurements were carried out on a Cahn RG microanalytical balance in air with a heating rate of 2°C min^{-1}. The X-ray powder diffraction patterns were recorded on a Philips X-ray diffractometer using monochromatized Cu-K_α radiation on powdered samples containing an internal standard[14] of $CaCO_3$, ($R\bar{3}c$, $a = 4.989$, $c = 17.062$.)

RESULTS AND DISCUSSION

$[M_6X_{12}(ROH)_6]X_2$, M = Nb *or* Ta, X = Cl *or* Br, R = Me *or* Et

Crystalline, especially $[M_6Br_{12}(MeOH)_6]Br_2$, diamagnetic substances are the products of the complete exchange of coodinated and lattice water molecules in the starting clusters $[(M_6X_{12})(H_2O)_4X_2] \cdot 4H_2O$ by aliphatic alcohols, methanol or ethanol. Only the bromo clusters $[M_6Br_{12}(MeOH)_6]Br_2$ in this series were simply prepared in two different ways: (1) by leaving the methanolic solution of $[(M_6Br_{12})(H_2O)_4Br_2] \cdot 4H_2O$ in a sealed ampoule under a nitrogen atmosphere for about a week; (2) by acidifying the concentrated solutions of the same clusters by concentrated HBr, the insoluble clusters $[M_6Br_{12}(MeOH)_6]Br_2$ were precipitated out immediately. For the former the beginning of crystallization is concentration- and time-dependent. The synthesis of all of the other alco-

holate clusters was more complicated and was achieved through a long process of subsequent dissolution of the starting eight hydrates in methanol or ethanol, and the evaporation of these solutions *in vacuo* until the insoluble products $[M_6Cl_{12}(MeOH)_6]Cl_2$ and $[M_6Br_{12}(EtOH)_6]Br_2$ were obtained. Only $[M_6Cl_{12}(EtOH)_6]Cl_2$ clusters were found to be soluble in ethanol after complete exchange of water molecules by ethanol.

It was interesting to follow the changes in structure and thermal behaviour of the chloro cluster units upon dissolution in aliphatic alcohols after first and second evaporation *in vacuo* to dryness. For chloro clusters in methanol after the first evaporation *in vacuo* the analytical data were consistent with the substances of the average composition: $Nb_6Cl_{13.98}C_{4.08}H_{22.8}O_{7.86}$ and $Ta_6Cl_{13.98}C_{4.07}H_{23.4}O_{8.01}$, indicating partial exchange of water molecules by methanol. Based on the X-ray powder diffraction patterns new structural arrangements of the cluster units and lower thermal stability (TG measurements) were observed for the mixed ligand alcohol–water clusters as compared to the starting eight hydrates. Also, the solubility in alcohols was considerably higher after the first evaporation than before. After the second evaporation of methanol solutions *in vacuo* only a slight difference in chemical composition was found, yet the insoluble substances $[M_6Cl_{12}(MeOH)_6]Cl_2$ could not be prepared applying one or two evaporations in methanol only, even if the solutions before the first evaporation *in vacuo* were refluxed for several hours. The formation of the insoluble cluster alcoholates was a function of water concentration in alcohol solutions, but also of the process of dissociation of the two halide atoms from the terminal positions. Thus, the conductivity data[6] in methanol or ethanol solution indicated complete dissociation of the two Br^t's from $[(M_6Br^b_{12})(H_2O)_4Br^t_2]\cdot 4H_2O$ within a few hours, while the affinity of the two Cl^t's to be partially coordinated to the cluster units in these solvents was preserved. If ROH solutions were left to be evaporated spontaneously at room temperature without applying vacuum the coordination of ROH molecules to the cluster units failed.

Neither chloro nor bromo derivatives were soluble in polar organic solvents or water, but were soluble in strong oxygen donors like dimethylsulphoxide or N,N′-dimethylformamide. They were sensitive to oxygen and in this respect the bromo derivatives $[M_6Br_{12}(MeOH)_6]Br_2$ were more stable than the chloro derivatives. The process of oxidation to $[M_6X_{12}]^{3+}$ and then to $[M_6X_{12}]^{4+}$ was followed by partial decomposition of some cluster units to hydrated niobium(V) or tantalum(V) oxide. Nicely crystalline (according to the X-ray powder diffraction patterns) derivatives are only obtained with methanol. The analogous $[M_6Cl_{12}(MeOH)_6]Cl_2$ clusters are isostructural, as are $[M_6Br_{12}(MeOH)_6]Br_2$. Neither chloro nor bromo derivatives can be classified in any of the five structural groups[15] previously found within $[M_6X_{12}]^{2+}$ clusters. So far single crystals suitable for the crystal structure determination have not been prepared. The corresponding "*d*" values for $[M_6Br_{12}(MeOH)_6]Br_2$ are measured and listed in Table 1.

IR spectra of all these clusters are very simple and indicate the presence of coordinated alcohol molecules and bridging halides only. The exact position of all absorption bands is given in the Experimental. The strong and unsplit absorption band originating from CO stretchings of coordinated methanol observed at 1000 for **I** and **III** and at 988 cm^{-1} for **V** and **VI** indicates the chemical and structural equivalency among all of the six methanol molecules present. The shift of this absorption band to lower wave numbers in comparison to the position of the same absorption band in liquid[16] methanol (1029 cm^{-1}) indicates strong coordination of the alcohol molecules to the cluster units, reflecting the strong preference of the metal atoms for oxygen-donors in the terminal positions. The position of this band is comparable to that found previously for coordinated methanol molecules.[17] The absence of a strong absorption band in the solid state as well as in the solution IR spectra of these clusters in the 500–350 cm^{-1} region where the MO (oxygen from coordinated methoxo or ethoxo groups) stretching vibrations[18] are expected, suggests that methanol or ethanol are not present as alkoxides. It is interesting that the position of MX_b (b, bridging) vibrations are practically unaffected by the presence of coordinated alcohol molecules in all compounds discussed here as compared to the position of this absorption band in the starting clusters.[19]

$[M_6X_{12}(ROH)_6]X_2$, M = Nb *or* Ta, X = Cl *or* Br, R = i-PrOH *or* i-BuOH

Due to the low solubility of $[(M_6X_{12})(H_2O)_4X_2]\cdot 4H_2O$ in i-PrOH and i-BuOH the synthesis of these alcoholate clusters was only possible via the intermediates $[M_6X_{12}]X_2\cdot n\text{EtOH}\cdot(8-n)H_2O$. The mixed ethanol–water clusters were completely soluble in i-PrOH or i-BuOH and after repeated dissolution and evaporation processes *in vacuo* the isolation of the insoluble $[M_6X_{12}(ROH)_6]X_2$ alcoholate clusters was possible. The i-PrOH deriva-

tives are not isostructural with those of i-BuOH, but the isostructurality was observed within chloro and bromo derivatives of the two series of clusters. Spectral and magnetic properties are relevant to those described for methanol and ethanol derivatives. With the exception of $[M_6Br_{12}(CH_3OH)_6]Br_2$, all of the alcoholate clusters discussed here are slightly moisture-sensitive and if exposed to air a slow transformation to the octahydrates occurs.

CONCLUSION

The large series of alcoholate clusters $[M_6X_{12}(ROH)_6]X_2$ represent a new class of completely

anhydrous cluster species containing the $[M_6X_{12}]^{2+}$ unit. The aliphatic alcohol molecules occupy all available octahedral coordination sites. The crystal structures of these compounds are a function of the particular cluster unit (chloro or bromo) and aliphatic alcohol. In addition to the previously known[10,15] structural groups eight new ones were found within the $[M_6X_{12}]^{2+}$ units. The absence of water molecules makes these clusters suitable as precursors for further reactions with organic and inorganic ligands in non-aqueous solvents. Also, easier oxidation–reduction processes for $[M_6X_{12}]^{n+}$ in solutions are expected in the absence of water molecules.

(*Received* 8 *April* 1991; *accepted* 28 *May* 1991)

Abstract—Aromatic C—H bond activation of various methyl-substituted benzenes by the $Pd(MeCO_2)_2$-SBu^i_2 system have been studied. In the case of *p*-xylene the new and unusual compound $[(SBu^i_2)(2,5\text{-}Me_2C_6H_3)Pd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2Pd(2,5\text{-}Me_2C_6H_3)(SBu^i_2)]$ (**1**) has been isolated. Complex **1** reacts with styrene and carbon monoxide to afford (*E*)-1-(2,5-dimethylphenyl)-2-phenylethene and 2,5-dimethylbenzene carboxylic acid, respectively. It has also been found that coupling products, biaryls, are formed in the reaction between $Pd(MeCO_2)_2$-SBu^i_2 and methyl-substituted benzenes. The isolated arylpalladium(II) complexes and the coupling products have been characterized and identified by means of ^1H NMR, GC-MS, and elemental analysis. On the basis of the isomer distribution of both isolated arylpalladium(II) complexes and the coupling products, the effect of the methyl groups on the benzene nucleus towards aromatic C—H bond activation is discussed.

The activation of arene C—H bonds by transition metals is a subject undergoing current research in organometallic chemistry. There are two main ways to prepare σ-aryl complexes directly from arenes: (1) oxidative addition of arene C—H bonds to coordinatively unsaturated metal complexes which are photochemically[1] or thermally[2] generated, and (2) electrophillic substitution of arenes by metal complexes.[3]

We have recently reported the direct activation of benzene C—H bonds by palladium(II) acetate-dialkyl sulphide systems, whose reactions afforded diphenyltripalladium(II) complexes $[(SR_2)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2PdPh(SR_2)]$.[4] As an extension of this work, activation of aromatic C—H bonds of methyl-substituted benzenes (toluene, xylenes, trimethylbenzenes and 1,2,3,4-tetramethylbenzene) by the palladium(II) acetate-diisobutyl sulphide system has been investigated. This paper gives a detailed description of the above reactions including isolation and detection of the resulting arylpalladium(II) complexes and the coupling products, biaryls.

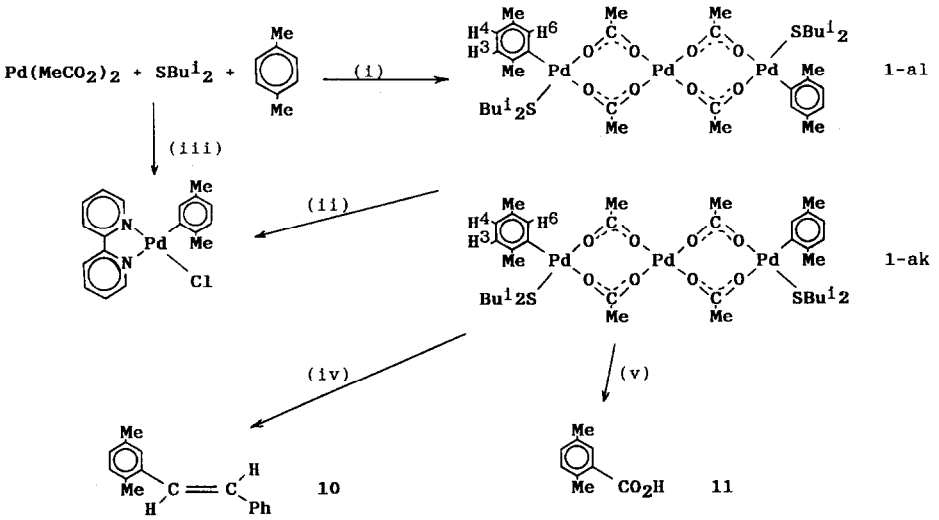
RESULTS AND DISCUSSION

Synthesis of arylpalladium(II) *complexes*

(a) Activation of *p*-xylene and the resulting arylpalladium(II) complex, $[(SBu^i_2)(2,5\text{-}Me_2C_6H_3)Pd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2Pd(2,5\text{-}Me_2C_6H_3)(SBu^i_2)]$ (**1**), and its derivative $[PdCl(2,5\text{-}Me_2C_6H_3)(bipy)]$ (**5**). Using the $Pd(MeCO_2)_2$-SBu^i_2 system, *p*-xylene was directly activated to produce **1**. The ^1H and ^{13}C NMR spectra (see Experimental) closely resembled those of $[(SBu^i_2)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2PdPh(SBu^i_2)]$ which were similarly obtained from heating palladium(II) acetate in benzene in the presence of diisobutyl sulphide.[4] On the basis of these results, elemental analysis, and its reactions (see below), **1** was formulated as the bis(2,5-dimethylphenyl)tripalladium(II) complex $[(SBu^i_2)(2,5\text{-}Me_2C_6H_3)Pd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2Pd(2,5\text{-}Me_2C_6H_3)(SBu^i_2)]$, composed of two geometrical isomers, al and ak (Scheme 1). The structure of **1** proposed here tentatively is shown in Scheme 1. X-ray structural analysis of **1** is in progress but difficulties have been encountered owing to the presence of al and ak isomers.

Complex **1** was treated with bipy and then with



Scheme 1. Reactions of $Pd(MeCO_2)_2$ with *p*-xylene in the presence of SBu^i_2. (i) 90–95°C for 45 min; (ii) bipy, followed by NaCl; (iii) 90–95°C for 45 min, followed by the treatment with bipy and then NaCl; (iv) styrene; and (v) carbon monoxide.

NaCl to afford $[PdCl(2,5\text{-}Me_2C_6H_3)(bipy)]$ (**5**) in 64% yield. This complex was also obtained in 56% yield without isolation of **1**, just by treating the preparative reaction mixture of **1** with bipy and NaCl (Scheme 1). In the ^1H NMR spectrum of **5**, the 5-methyl protons appeared at δ 2.26, while the 2-methyl protons resonated at a comparatively lower field at δ 2.65. Such a deshielding of the methyl resonance *ortho* to the metal atom was found in *trans*-$[Ni(2\text{-}MeC_6H_4)(CCl{=}CCl_2)(PEt_3)_2]$[5] and was ascribed to paramagnetic anisotropy of the metal ion.[5,6]

(b) Activation of other methyl-substituted benzenes and their resulting complexes, [PdCl(aryl)(bipy)] (**2–9**). Diaryltripalladium(II) complexes such as complex **1** could not be isolated by the reactions of the $Pd(MeCO_2)_2$-SBu^i_2 system with corresponding methyl-substituted benzenes except for *p*-xylene, owing mainly to their lower yields. However, by successive treatments with bipy and NaCl after the reactions between the $Pd(MeCO_2)_2$-SBu^i_2 system and the corresponding methyl-substituted benzene, mononuclear aryl-palladium(II) complexes, [PdCl(aryl)(bipy)] (**2–9**), were isolated. Two methods were performed to obtain **2–9** (see Scheme 2), after the activation of the appropriate methyl-substituted benzene by the $Pd(MeCO_2)_2$-SBu^i_2 system: Method A, treatment with bipy followed by NaCl; method B, treatment with NaCl and then with bipy (for further details see Experimental). The results are listed in Table 1 and possible isomers of **2–9** are shown in Fig. 1. It was found that method A afforded a mixture of isomers, while method B yielded only one isomer in which the methyl group is bonded *ortho* to the palladium atom. Previously we have observed that $[(Bu^tSCH_2Bu^t)PhPd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2PdPh(Bu^tSCH_2Bu^t)]$, whose aryl moiety has no methyl group *ortho* to the palladium atom, decomposed during the reaction with LiCl to afford $[PdCl_2(Bu^tSCH_2Bu^t)_2]$ and biphenyl.[4] Enhanced stability of the aryl complexes involving a methyl group in the *ortho* position relative to those containing methyl substituents on *m*- or *p*-positions is mainly due to an increase in metal—carbon bond strength, caused by the d_π–p_π bonding and to an increase in kinetic stability due to the increase in energy difference between the highest occupied and

the lowest unoccupied molecular orbitals.[7] However, in the case of toluene, *o*-xylene and 1,2,3-trimethylbenzene, method A did not produce **2**, **3** or **6** in a pure state.

In the case of the reactions with *m*-xylene, 1,2,4-trimethylbenzene and 1,3,5-trimethylbenzene, there are possibilities to form the arylpalladium(II) complexes, **4c**, **7c** and **8**, respectively, whose aryl moieties contain two methyl groups *ortho* to the central palladium atom. However, they were not obtained;

9	2.75[s, 2-Me]; 2.15, 2.17, 2.20[s, 3-, 4-, 5-Me]; 7.07 [s, 6-H]	9.30[d, ^3J(HH) = 5.4 Hz]

[a] Key: s = singlet, br s = broad singlet, d = doublet, and dd = doublet of doublets. For the numbering of the methyl group and aromatic protons see Fig. 1.

[b] Assigned to 6-H of one pyridyl moiety *trans* to the aryl group. Other protons of the 2,2′-bipyridyl ligand resonated near δ 7.3, 7.6 and 7.9–8.1 as a complex pattern.

only complex **8** was formed in a yield less than 1% and only its ^{1}H NMR spectrum was measured (Table 2).

The ^{1}H NMR spectrum of the arylpalladium(II) complexes derived from *m*-xylene by method A showed three methyl resonances at δ 2.26 (s, 3.3H), 2.27 (s, 1.35H) and 2.66 (s, 1.35H). Considering that the integral values and the lower field shift characteristic of the methyl signal attached *ortho* to the palladium atom (see above), the methyl signals at δ 2.27 and 2.66 were assigned to the non-equivalent methyl groups of isomer **4a**, while the resonance at δ 2.26 was ascribed to the equivalent methyl groups of isomer **4b**. Assignment of the ^{1}H NMR signals of **4a** was confirmed upon measuring the ^{1}H NMR spectrum of the product from method B, which contained isomer **4a** only. The isomer ratio of **4a** : **4b** was calculated as 45 : 55.

In the ^{1}H NMR spectrum of the reaction products of 1,2,4-trimethylbenzene by method A, a pair of signals (ratio 75 : 25) was observed in the arylpalladium moiety (Table 2), judging from the integral values. The ^{1}H-^{1}H COSY spectrum showed correlation between the resonances at δ 6.63 and 7.11, attributable to a weak ^4J(HH) coupling. On the basis of the above results, the minor and major products of the pair were assigned to **7a** and **7b**, respectively.

(c) Reaction of **1** with styrene or carbon monoxide. Complex **1** reacted with styrene in a THF-CH_2Cl_2 mixed solvent to give (*E*)-1-(2,5-dimethylphenyl)-2-phenylethene (**10**) in 90% yield. When carbon monoxide was bubbled through a CH_2Cl_2 solution of **1** and the reaction mixture was treated with sodium hydrogen carbonate, 2,5-dimethylbenzene carboxylic acid (**11**) was obtained in 26% yield. The formation of both **10** and **11** strongly confirmed that **1** contained the 2,5-dimethylphenylpalladium moiety and was formed by direct C—H bond activation of *p*-xylene by the $Pd(MeCO_2)_2$-SBu^i_2 system.

Coupling reaction of methyl-substituted benzenes promoted by the $Pd(MeCO_2)_2$-SBu^i_2 *system**

The fact that palladium(II) acetate promotes or catalyses the coupling reaction of aromatic compounds via the formation of arylpalladium(II) complexes to give biaryls is well-established.[8,9] It has been found that the reaction mixture of the $Pd(MeCO_2)_2$-SBu^i_2 system and methyl-substituted benzenes contained corresponding biaryls. Yields of the coupling products and their isomer distribution are summarized in Table 3.

In the case of 1,3,5-trimethylbenzene, the $Pd(MeCO_2)_2$-SBu^i_2 system gave practically no coupling product. This is consistent with the result reported previously by Itatani and Yoshimoto[9] in the palladium-catalysed coupling of 1,3,5-trimethyl-

* See ref. 4 for the coupling of toluene.

Table 3. Coupling products promoted by the $Pd(MeCO_2)_2$-SBu^i_2 system[a]

	56	 15a(75%)	 15b(25%)	 15c(~0%)
	$\ll 1$[d]	 16a	 16b	 16c
	5	 17(100%)		

[a] Conditions: $Pd(MeCO_2)_2$ (0.050 g, 0.223 mmol), SBu^i_2 (0.022 g, 0.148 mmol) and the corresponding methyl-substituted benzene (12 cm^3).

[b] Yields based on $Pd(MeCO_2)_2$.

[c] Determined by GLC.

[d] Isomer distribution could not be determined owing to its low yield.

benzene. This fact indicated that no C—H bond activation occurred and accordingly, the resulting palladation did not proceed on the benzene carbon between two methyl groups. This seemed to be applicable to the 2-carbon of 1,3-dimethylbenzene (*m*-xylene) and the 3-carbon of 1,2,4-trimethylbenzene; formation of the corresponding coupling products derived from such species were excluded.

In the cases of *o*-xylene, *m*-xylene and 1,2,3-trimethylbenzene, the ^1H NMR spectra of the corresponding isolated coupling products showed the absence of **12c**, **13c** and **15c**. These three compounds would be produced by homocoupling of the corresponding arylpalladium(II) species containing one methyl group *ortho* to the central palladium atom. However, the above arylpalladium(II) species coupled with other species involving no methyl groups around the palladium atom produced **12b**, **13b** and **15b** in moderate yields. On the

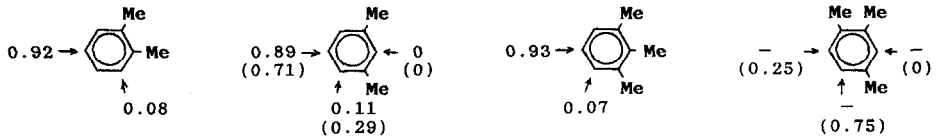

Fig. 2. Relative positional reactivities of methyl-substituted benzenes calculated from the coupling products or from the isolated arylpalladium(II) complexes (shown in parentheses).

contrary, when there is no position to be activated except for the *ortho* position to one methyl group, i.e. *p*-xylene, 1,2,4-trimethylbenzene and 1,2,3,4-tetramethylbenzene, the coupling reaction did occur on these positions to afford **14**, **16** and **17**. However, their yields were generally very low. These results indicated that a C—H bond surrounded by both hydrogen and methyl groups is resistant to activation, owing to steric problems caused by the methyl group.

Relative positional reactivities in each methyl-substituted benzene for C—H bond activation were calculated from the composition of the coupling products formed (Fig. 2). These data suggested that the ease of the C—H bond activation depends considerably on the number of methyl groups around the C—H bond to be activated. Relative positional reactivities were also calculated from the isomer distribution of **4** and **7** (see parentheses in Fig. 2). The value of the 4- or 6-position of *m*-xylene was slightly greater than that of the 5-position, in comparison with the calculated values from the coupling products. This difference might be ascribed to a higher stability of **4a** having an *ortho* methyl group in its aryl moiety (see above). However, in 1,2,4-trimethylbenzene, the 5- and 6-positions are equal in the number of methyl groups around them; reactivity of the 5-position is about three times greater than that of the 6-position. This could be associated with a higher electron density at the 5-position compared with the 6-position: both 5- and 6-positions have one *ortho* methyl group, but in addition the former has another methyl group in the *para* position. On the basis of the arguments presented above, we conclude that the $Pd(MeCO_2)_2$-SBu^i_2 system activates aromatic C—H bonds of methyl-substituted benzenes predominantly at less hindered and more electron-rich positions.

EXPERIMENTAL

All the experiments were performed under nitrogen. Solvents were dried by the usual methods and distilled. Other reagents were used without purification. The NMR spectra were measured on a JEOL JNM GX-270 instrument with $CDCl_3$ as a solvent and reported in δ (ppm) relative to tetramethylsilane. Yields and distribution of the coupling products, biaryls, were analysed with a Shimadzu GC-14A gas chromatograph on a BP-1 (50 m long) capillary column. Coupling products were identified by GC-MS on a Shimadzu GC-MS 9020DF instrument. Melting points were determined on a Yanaco melting point apparatus MP-500D.

Preparation of $[(SBu^i_2)(2,5\text{-}Me_2C_6H_3)Pd(\mu\text{-}MeCO_2)_2Pd(\mu\text{-}MeCO_2)_2Pd(2,5\text{-}Me_2C_6H_3)(SBu^i_2)]$ (**1**)

A suspension of palladium(II) acetate (0.400 g, 1.78 mmol) and SBu^t_2 (0.174 g, 1.19 mmol) was heated in *p*-xylene (20 cm^3) at 90°C for 1 h. Upon cooling, some crystals appeared. After the resulting mixture was concentrated to about 5 cm^3, the precipitated crystals were filtered and washed with hexane to give 0.38 g of **1**. ^1H NMR: δ 0.89 [24H, br, sulphide-CH_3], 1.77 [3H, s, CH_3CO_2], 1.83 [3H, s, CH_3CO_2], 1.86 [3H, s, CH_3CO_2], 1.94 [3H, s, CH_3CO_2], 1.95 [4H, br, sulphide-CH], 2.13 [3H, s, 5-CH_3 of 2,5-xylyl], 2.17 [3H, 5-CH_3 of 2,5-xylyl], 2.83 [8H, br, sulphide-CH_2], 3.02 [6H, s, 2-CH_3 of 2,5-xylyl], 6.64 [2H, d, ^3J(HH) = 7.3 Hz, 3- or 4-H of 2,5-xylyl], 6.75 [2H, d, ^3J(HH) = 7.3 Hz, 3- or 4-H of 2,5-xylyl], 7.51 [1H, s, 6-H of 2,5-xylyl], 7.54 [1H, s, 6-H of 2,5-xylyl]. $^{13}C\{^1H\}$ NMR: δ 20.86 and 20.92 (5-CH_3); 21.61, 21.64, 22.03 and 22.07 (sulphide-CH_3); 23.08, 23.33, 23.47 and 23.57 (acetato-CH_3); 23.89 and 23.92 (2-CH_3), 27.49 and 27.52 (sulphide-CH); 46.29 and 46.32 (sulphide-CH_2); 124.56 (4-C of 2,5-xylyl); 127.34 (3-C of 2,5-xylyl); 132.91 and 133.10 (5-C of 2,5-xylyl); 135.27 and 135.42 (6-C of 2,5-xylyl); 138.51 and 138.67 (2-C of 2,5-xylyl); 140.14 and 140.20 (1-C of 2,5-xylyl); 181.63, 182.07, 183.09 and 183.46 (acetato-CO_2).

Preparation of $[PdCl(2,5\text{-}Me_2C_6H_3)(bipy)]$ (**5**)

(a) Method A: A mixture containing palladium(II) acetate (0.200 g, 0.891 mmol) and SBu^t_2 (0.087 g, 0.594 mmol) was heated in *p*-xylene (20 cm^3) for 1 h. After cooling to room temperature, solid bipy (0.139 g, 0.891 mmol) was added and the mixture was stirred for 3 h. A precipitate appeared which was collected and extracted with $CHCl_3$ (30

cm^3). The $CHCl_3$ extracts were evaporated to dryness and then acetone (10 cm^3) was introduced. After addition of a solution of NaCl (0.260 g, 4.46 mmol) in acetone/water (5 cm^3/2.5 cm^3), the mixture was stirred at room temperature for 1 day and evaporated to dryness. The residue was extracted with $CHCl_3$ to remove the by-product [$PdCl_2$(bipy)] and was chromatographed on a silica gel column (200 mesh, 13 × 1.2 cm) with $CHCl_3$. Complex **5** (0.133 g) was obtained upon the addition of hexane to a yellow fraction. (b) Method C: Solid bipy (0.045 g, 0.286 mmol) was added to a suspension of **1** (0.100 g, 0.0945 mmol) in *p*-xylene (5 cm^3). The resulting mixture was stirred at room temperature for 4 h, and the volatile materials were removed *in vacuo*. The residue in acetone (5 cm^3) was treated with NaCl (0.095 g, 1.63 mmol) in acetone/water (2 cm^3/2 cm^3), and the mixture was stirred at room temperature for 1 day. After evaporating to dryness, the residue was extracted with $CHCl_3$ to remove the by-product [$PdCl_2$(bipy)], and chromatographed on a silica gel column (200 mesh, 11 × 1.2 cm). The yellow fraction which was eluted by $CHCl_3$ was collected and recrystallized from CH_2Cl_2 and hexane to give **5** (0.049 g).

Preparation of the arylpalladium(II) *complexes of the type* [PdCl(aryl)(bipy)] (**2–9**)

Complexes **2–9** were synthesized by two methods A and B. Typical examples are described below:

(a) Method A: A suspension containing $Pd(MeCO_2)_2$ (0.400 g, 1.78 mmol) and SBu^i_2 (0.174 g, 1.19 mmol) in *m*-xylene (20 cm^3) was heated at 90–95°C for 1 h. After the reaction mixture was cooled to ambient temperature, solid bipy (0.278 g, 1.78 mmol) was added and the resulting mixture was stirred for 3 h. Hexane (25 cm^3) was added to the mixture, and the precipitate which appeared was collected. The precipitate was treated with NaCl (0.521 g, 8.91 mmol) in an acetone/water (20/5 cm^3) mixed solvent, and the mixture was stirred for 1 day at room temperature. After the volatile materials were removed *in vacuo*, the residue was extracted with $CHCl_3$ to remove the by-product [$PdCl_2$(bipy)], and was chromatographed on a silica gel column (200 mesh, 22 × 1.2 cm). The yellow fraction which was eluted by $CHCl_3$ was collected and recrystallized from $CHCl_3$–hexane to give a mixture of **4a** and **4b** (0.067 g).

(b) Method B: A suspension containing $Pd(MeCO_2)_2$ (0.400 g, 1.78 mmol) and SBu^i_2 (0.174 g, 1.19 mmol) in *m*-xylene (20 cm^3) was heated at 90–95°C for 1 h. After the volatile materials were removed *in vacuo*, the residue was extracted with acetone (40 cm^3). The extract was treated with NaCl (0.521 g, 8.91 mmol) in water (5 cm^3), and stirred at room temperature for 1 day. The resulting mixture was evaporated to dryness, and extracted with $CHCl_3$ (30 cm^3) to remove the by-product [$PdCl_2$(bipy)]. The $CHCl_3$ extract was then passed through a silica gel column (200 mesh, 27 × 1.2 cm) with $CHCl_3$. The yellow/yellow-orange fraction was treated in benzene (15 cm^3) with bipy (0.278 g, 1.78 mmol) at room temperature for 1 day. The reaction mixture was chromatographed on a silica gel column (200 mesh, 22 × 1.2 cm) with $CHCl_3$ as an eluant. A yellow fraction was obtained and recrystallized from $CHCl_3$–hexane to give **4a** (0.029 g).

Reactions of **1** *with styrene and carbon monoxide*

(a) With styrene: A CH_2Cl_2 solution (15 cm^3) of styrene (0.043 g, 0.416 mmol) was added to a THF solution (10 cm^3) of **1** (0.200 g, 0.189 mmol), and the resulting mixture was stirred for 3 h, whereupon palladium black was precipitated. After the volatile materials were removed *in vacuo*, the residue was chromatographed on a silica gel column (200 mesh, 15 × 1.2 cm). The fraction was eluted with hexane, collected and recrystallized with hexane to give (*E*)-1-(2,5-dimethylphenyl)-2-phenylethene (**10**) (0.071 g, 90%), m.p. 41°C. MS: *m*/*z* 150(M^+). ^{1}H NMR: δ 2.34 and 2.37 [s, Me], 6.9–7.1, 7.2–7.4 and 7.45–7.55 (m, aromatic and olefinic protons). Found: C, 92.3; H, 7.7. Calc. for $C_{16}H_{16}$: C, 92.3; H, 7.7%. (b) With carbon monoxide: At room temperature carbon monoxide was bubbled through a CH_2Cl_2 solution (15 cm^3) of **1** (0.200 g, 0.189 mmol) for 30 min. The reaction mixture containing palladium black was evaporated to dryness and the residue was extracted with ether (20 cm^3). To the ethereal extract saturated sodium hydrogen carbonate in water (15 cm^3) was added, and the aqueous layer was separated and acidified with concentrated HCl. The organic product was extracted with ether (15 cm^3) and the extract was dried over Na_2SO_4. After evaporation of the solvent, the product was recrystallized with hexane to give 2,5-dimethylbenzene carboxylic acid (**11**) (0.015 g, 26%), m.p. 131°C (lit[10] 132°C). MS: *m*/*z* 150(M^+). ^{1}H NMR: δ 2.22 [s, 5-Me], 2.47 [s, 2-Me], 7.02 [s, 3-H], 7.12 [dd, ^3J(HH) = 7.8 Hz, ^4J(HH) = 1.5 Hz, 4-H], 7.74 [d, ^4J(HH) = 1.5 Hz, 6-H]. Found: C, 71.5; H, 6.6. Calc. for $C_9H_{10}O_2$: C, 72.0; H, 6.7%.

Coupling reactions of methyl-substituted benzenes promoted by the $Pd(MeCO_2)_2$-SBu^i_2 *system*

The coupling reactions were performed by the reaction of the $Pd(MeCO_2)_2$ (0.050 g, 0.223 mmol) and SBu^i_2 (0.022 g, 0.148 mmol) system in appro-

priate methyl-substituted benzenes (12 cm^3) at 90°C for 1 h. After cooling, the mixture was analysed by GLC or GC-MS. Yields of corresponding coupling products were determined on GLC using the following calibration curves: bi(*o*-xylyl) for the coupling products of *o*-, *m*-, and *p*-xylene; bi(1,2,3-trimethylphenyl) for 1,2,3- and 1,2,4-trimethylbenzene and 1,2,3,4-tetramethylbenzene. Isomer distributions were determined by comparing the retention times on GLC with corresponding isolated coupling products (see below). Identification of the coupling products **14** and **17** was performed only by GC-MS.

Separation of the coupling products from the reaction mixture

A typical example is shown below. A suspension containing $Pd(MeCO_2)_2$ (1.00 g, 4.45 mmol) and SBu^i_2 (0.434 g, 2.97 mmol) in *o*-xylene (20 cm^3) was heated at 90°C for 1 h. After cooling, the filtered mixture was evaporated to dryness. The residue was chromatographed on a silica gel column (200 mesh, 27 × 1.2 cm), and the fraction was eluted by hexane, collected and evaporated to dryness to give crude bi(*o*-xylyl). This crude product was further purified by preparative TLC (Kieselgel 60 HF) to give 0.20 g [21%, based on the used $Pd(MeCO_2)_2$] of a mixture of **12a** and **12b** (**12a**:**12b** = 12:88, by GLC). GC-MS: *m/z* 210(M^+). Found: C, 91.4; H, 8.6. Calc. for $C_{16}H_{18}$: C, 91.4; H, 8.6%. ^{1}H NMR: **12a**: δ 2.29 and 2.32 [s, 3- and 4-Me], 7.18 [d, ^3J(HH) = 7.8 Hz, 5-H], 7.31 [dd, ^3J(HH) = 7.8 Hz, ^4J(HH) = 1.7 Hz, 6-H], 7.35 [br s, 2-H]; **12b**: only three methyl signals were observed distinctly at δ 2.16, 2.30, and 2.33, and other resonances were obscured due to overlapping.

13: yield 13% [based on $Pd(MeCO_2)_2$] (**13a**:**13b** = 70:30). GC-MS: *m/z* 210(M^+). Found: C, 91.3; H, 8.5. Calc. for $C_{16}H_{18}$: C, 91.4; H, 8.6%. ^{1}H NMR: **13a**: δ 2.37 [s, 3- and 5-Me], 6.97 [br s, 4-H], 7.19 [br s, 2- and 6-H]. **13b**: δ 2.24 [s, 2-Me], 2.35 [s, 4-, 3′- and 5′-Me], 6.92 [br s, 4′-H], 7.02 [br s, 3-H], 7.06 [br d, ^3J(HH) = 7.8 Hz, 5-H], 7.11 [d, ^3J(HH) = 7.8 Hz]; 7.19 [br s, 2′- and 6′-H].

15: yield 23% [based on $Pd(MeCO_2)_2$] (**15a**:**15b** = 95:5). GC-MS: *m/z* 238(M^+). Found: C, 90.7; H, 9.3. Calc. for $C_{18}H_{22}$: C, 90.8; H, 9.2%. ^{1}H NMR: **15a**: δ 2.20 [s, 4-Me], 2.34 [s, 3- and 5-Me], 7.22 [s, 2- and 6-H]. **15b**: only five methyl signals were observed at δ 2.17, 2.22, 2.24, 2.32 and 2.33; other resonances were obscured due to low yield.

Coupling product **16** could not be isolated under the conditions used, and was only detected by GC-MS, *m/z* 238(M^+).

Acknowledgement—The authors are grateful to Professor Mitsuya Shimoda, Department of Food Science and Technology, Faculty of Agriculture, Kyushu University, for GC-MS.

Abstract—The reaction between barium and triethanolamine in toluene/THF affords, after recrystallization in ethanol, the barium alkoxide $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$, which has been characterized by X-ray crystallography. The tetradentate character of the triethanolamine molecule allows the barium atom to be octacoordinated in a monomeric $Ba[(OC_2H_4)(OHC_2H_4)_2N]_2$ unit. However, these units are associated by intermolecular hydrogen-bonding due to the ethanol lattice molecules, thus forming an extensive two-dimensional network. The hydrogen-bonding reduces the volatility of the precursor, but is favourable to the formation of gels by hydrolysis.

Low temperature routes to materials using molecular precursors via sol–gel[1] or MOCVD techniques[2] form an area of considerable interest and technological significance. Barium is involved in many useful dielectric materials based on oxides such as barium titanate or $BaMg_{1/3}Ta_{2/3}O_3$, as well as in the high T_c superconductors.[3] However, while barium alkoxides can be easily obtained via direct attack by alcohols due to the electropositive character of the metal, they remain poorly characterized, and various derivatives, sometimes called "barium extract", have so far been used in the sol–gel process.[4] MOCVD techniques require isolation as well as a better knowledge of the properties of the precursor. Although homoleptic barium alkoxides with classical alkoxo groups have been reported, they appear, once isolated, to display a poor stability with respect to the formation of oxoalkoxides and/or photochemical decomposition.[5] Indeed, the only structurally characterized barium alkoxides —$HBa_5O(OPh)_9(THF)_8$ and $H_3Ba_6O(OBu^t)_{11}(OCEt_2CH_2O)(THF)_3$—are actually penta- or hexanuclear oxo aggregates.[6] Functional alcohols such as triethanolamine are commonly used in the sol–gel process, especially for mixed oxide

materials. This aminoalcohol has, for instance, been used as a means of obtaining superconducting coatings.[7] A $Ti(OR)_4$-triethanolamine product was used as the precursor for the preparation of titanium nitride by pyrolysis.[8] Such potentially polydentate alcohols may also be useful for the stabilization of alkoxides vs oxoalkoxides and/or reduction of the polymerization of metal alkoxides.

We now report the synthesis and molecular structure of $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$, the first structurally characterized barium alkoxide.

EXPERIMENTAL

All manipulations were routinely performed under argon using Schlenk tubes and vacuum line techniques with solvents purified by standard methods. Triethanolamine was dried over molecular sieves. ^1H and ^{13}C NMR and IR spectra were recorded using Bruker AC-200 and IR-FTS 45 spectrometers, respectively. IR spectra were obtained as Nujol mulls. Mass spectra were recorded on a R10-10 Ribermag spectrometer by chemical ionization techniques. Analytical data were obtained from the Centre de Microanalyses du CNRS.

Synthesis of $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$

Bis-triethanolamine barium was obtained by reacting metallic barium (1.57 g, 11 mmol) with triethanolamine (4.92 g, 33 mmol) in a mixture of toluene and THF (60 cm^3, 1:1 in volume). After refluxing for 24 h, all the metal had dissolved and the reaction medium was evaporated. Extraction of the oily residue was performed with ethanol and crystals suitable for X-ray analysis (soluble in acetone or alcohols) were obtained on cooling (3.63 g, 65%). Microanalysis: Found: C, 36.0; H, 7.5; N, 5.4. Calc. for $C_{16}H_{40}O_8N_2Ba$: C, 36.5; H, 7.7; N, 5.3%. IR (Nujol, cm^{-1}): 3130 ν(OH), 1348, 1298, 1261, 1249, 1161, 1107s; 1101, 1084, 1047, 1024 ν(C—O), 974, 903, 878, 730, 580; 540 sh, 490, 395 ν(Ba—O), 274. ^1H NMR (CD_3OD, ppm): 1.22 (t, $J = 7$ Hz), 6H, 2.66 (t, $J = 5.1$ Hz), 12H, 3.66 (q, $J = 7$ Hz), 4H, 3.76 (t, $J = 5.1$ Hz), 12H. $^{13}C\{^1H\}$ NMR (CD_3OD): 18 (CH_3), 58 (OCH_2)(EtOH), 57.8 (NCH_2), 60 (OCH_2). MS (*m/z*, IE): $Ba(OH)(OHC_2H_4)_3N$ (7%), $BaNOC_3H_4$ (25%), BaC_2 (16%), $NC_6H_{12}O_3$ (6%), $NC_4H_{10}O$ (15%), C_2H_4O (100%).

The same product was obtained by reacting the precipitate resulting from the reaction between metallic barium and ethanol with triethanolamine at room temperature.

Crystallographic studies

A crystal suitable for X-ray (grown from crystallization in ethanol) was mounted in a Lindeman capillary and set on a CAD4 Enraf–Nonius diffractometer at room temperature. Accurate unit cell dimensions and crystal orientation matrix were obtained from least-squares refinements of 25 reflections. Two standard reflections were monitored periodically; they showed no change during data collection. Crystallographic data and other pertinent information are summarized in Table 1. Corrections were made for Lorenz, polarization and absorption effects.[9]

Computations were performed using CRYSTALS adapted on a Microvax II.[10] Atomic form factors for neutral Ba, N, O, C and H atoms were obtained from ref. 11. The structure was solved by heavy-atom techniques. The barium atom was located at the origin from unsharpened Patterson. The heavy-atom phasing did not distinguish between the three possible space groups *C*2, *Cm* or *C*2/*m*. In each case, the subsequent F_o syntheses indicated the carbon, nitrogen and oxygen atoms. However, the use of *Cm* or *C*2/*m* implied a disordered model with carbon atoms of the CH_2 groups of the triethanolamine molecule in statistical distribution with respect to the mirror plane. Moreover, *F*-tests showed that the space group should not be centrosymmetric. These results led us to continue refinements in the *C*2 group. Two molecules of ethanol of crystallization were found in a difference synthesis. The two carbon atoms of the ethyl group were statistically distributed between two sites related by a pseudo-two-fold axis. The disordered ethanol molecules were constrained to chemically reasonable dimensions [O—C 1.48(1), C—C 1.52(1), O—C—C 109(1) Å]. All hydrogen atoms, except those in the ethanol (H4) molecules, were found in a difference map. However, only the coordinates of the hydrogen atoms attached to oxygen were refined, but the O—H distances of the triethanolamine ligand were constrained at 1.0 Å with an e.s.d. of 0.1 Å. These hydrogen atoms were given an overall isotropic temperature factor. All other hydrogen atoms were introduced in the refinements as calculated contributors. Their coordinates were recalculated after each cycle, and they were attributed isotropic thermal parameters 20% higher than those of the carbon atoms to which they are attached. Anisotropic temperature factors were introduced for all the non-hydrogen atoms. Least-squares refinements with approximation to the normal matrix were carried out by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where F_o and F_c are the observed and calculated structure factors. The cri-

teria for a satisfactory complete analysis were the ratio of the rms shift to the standard deviation being less than 0.1, and no significant features appearing in the final difference map.

Atomic coordinates and thermal parameters are given as supplementary material.

RESULTS AND DISCUSSION

Bis-triethanolaminato barium was obtained by refluxing metallic barium and triethanolamine with toluene:THF as a solvent, according to eq. (1). Purification was achieved by crystallization in ethanol. Addition of triethanolamine to the insoluble material obtained by reacting barium with ethanol and thus alcoholysis provides another route to $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$

$$Ba + 2N(C_2H_4OH)_3 \xrightarrow{\text{toluene/THF}} [N(C_2H_4O)(C_2H_4OH)_2]_2Ba + H_2 \quad (1)$$

By contrast with other barium alkoxides, this new compound was relatively air stable, suggesting that triethanolamine acts as a polydentate encapsulating ligand. The structure was established by X-ray crystallography. The compound corresponds to an ethanol solvate $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$; the structure of the $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba$ moiety is shown in Fig. 1. Selected bond lengths and angles are listed in Table 2. The barium atom is surrounded by a core of oxygen atoms with Ba—O distances of 2.73(1), 2.753(3) and 2.78(1) Å, corresponding to Ba—O as well as Ba—O(H) bonds. The observed Ba—N distance is 3.009(3) Å. These data are in agreement with the values reported for other barium derivatives in which triethanolamine generally acts as a neutral ligand,[12] the coordination sphere being completed by ligands such as acetates or nitrophenols. The triethanolamine ligand is thus tetradentate, with a transannular Ba—N coordination bond; the clearly pyramidal nitrogen atom (ΣC—N—C

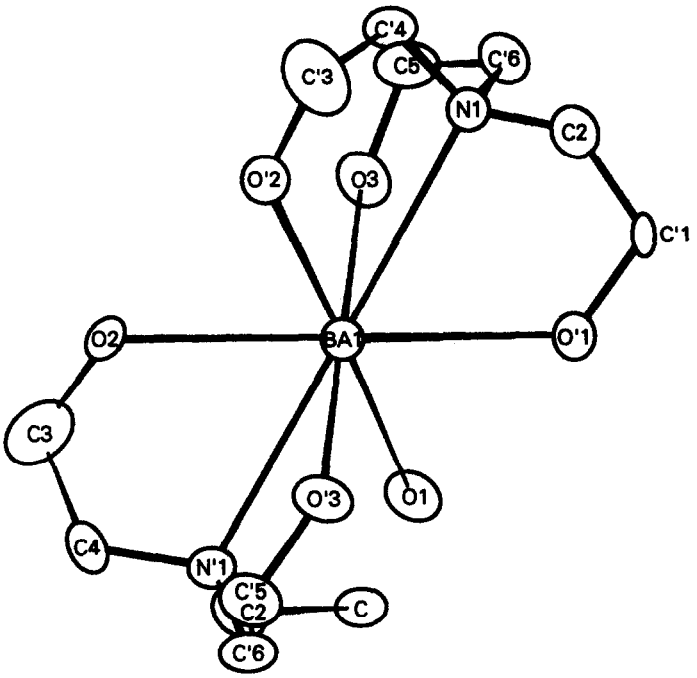

Fig. 1. ORTEP view of the $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba$ moiety of $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$ showing the atom numbering scheme. The hydrogen atoms of the hydroxyl groups could not be located. Atoms labelled ′ are related by a C_2 axis.

[a] Atoms labelled ′ are related by a two-fold axis.

angles = 330.1°) supports this interpretation, the barium atom being octacoordinated. Such a high coordination number is in agreement with the results obtained for other barium–oxygen derivatives where nine- or 10-coordination is common.[12–14]

The range of the Ba—O, Ba—O(H) distance is rather small (2.73–2.78 Å) and the metal–oxygen distances compare well with the sum of the covalent radii (≈ 2.71 Å). The Ba—O—C angles are quite comparable (125.2° av.) probably as a result of the small variation in the Ba—O distances and of the constrained triethanolamine ligand.

All oxygen atoms of the triethanolamine moiety have short contacts (2.54 Å) implying hydrogen bonding with two lattice-ethanol molecules (located ≈ 4.80 Å away from the metal). In fact, intermolecular hydrogen-bonding between the alcohol functionalities both on ethanol and on the coordinated triethanolamine is responsible for the formation of an extensive two-dimensional network, as shown in Fig. 2. The lattice-ethanol molecules build the network and each alcohol is linked via hydrogen-bonding to three different $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba$ molecules, which thus have all their six oxygen centres involved in hydrogen-bonding. This two dimensional network thus spreads out along the *a* and *b* axis, the different layers stack along the *c* axis; there is no interaction between successive layers. The various hydrogen-bonds imply O4(EtOH) is unsymmetrical and nearly linear (161.7–171.2°). The O···H distances are quite short [1.4(1) to 1.74(8) Å], the acidity of the alcohol functionality of the triethanolamine molecule being enhanced by coordination to a very electropositive metal. The shortest interaction is observed between O1 and H4, thus supporting O1 as the alkoxide donor site of the coordinated triethanolamine ligand. The small range in the values of the O···H interactions suggests that the hydroxyl functionality is nearly as potent a donor for hydrogen-bonding as the alkoxide ligand, as observed for instance in $Nb_2Cl_4(OMe)_4(MeOH)_2 \cdot 2MeOH$.[15,16]

Molecular triethanolamine derivatives of various elements have been reported in the literature.[17] They have generally been obtained by exchange reactions starting from alkyls, amides or alkoxides. Reaction (1) seems to be the first example of a synthesis directly from a metal. Solid-state structural information on ethanolamine derivatives is limited to some examples of Group V elements[18] and the aluminum compound $\{[N(C_2H_4O)_3]Al_2Me_3\}_2$.[19] $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$ is, to the best of our knowledge, the first example of a homoleptic metal triethoxyaminate which has been structurally characterized.

$[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$ displays a broad ν(O—H) stretch characteristic of hydrogen-bonding in the IR spectrum at 3130 cm^{-1}. The

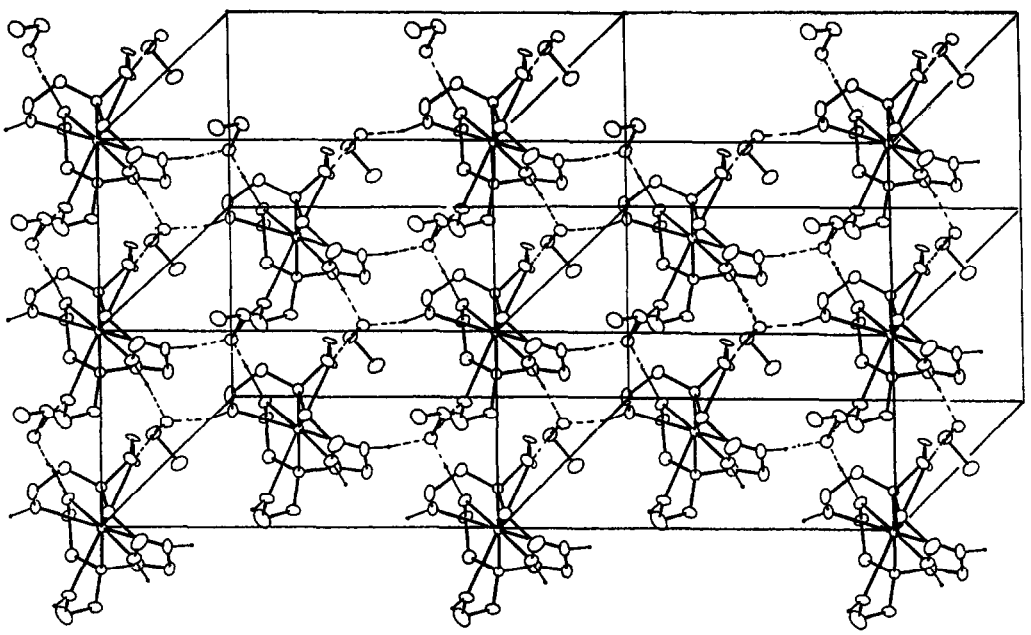

Fig. 2. Projection onto the *a*, *b* plane showing the two-dimensional hydrogen-bonding network of $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$. The representation covers four unit cells; only plan (110) is shown and there are no interactions between plans. Only one position of the ethyl chain of the alcohol has been represented for better clarity.

NMR (^1H and ^{13}C) spectra were obtained in methanol-d_4 solution and the exchange of ethanol by methanol is observed. While most barium alkoxides form precipitates by hydrolysis, $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$ is converted into stable gels by the addition of excess water to its ethanol solutions. The formation of the gel network is probably assisted by hydroden-bonding, as observed in the solid state. $[N(C_2H_4O)(C_2H_4OH)_2]_2Ba \cdot 2EtOH$ is also volatile as shown by mass spectrometry. However, the existence of an extensive two-dimensional network due to hydrogen-bonding requires conditions which are too drastic for MOCVD applications, and the overall properties are more appropriate for spray-pyrolysis.

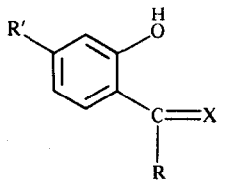
(*Received* 17 *January* 1991; *accepted* 23 *May* 1991)

Abstract—Aqueous ammonia, "paeonol" (2-hydroxo-4-methoxy-acetophenone) and copper(II) salts readily form the neutral bis-iminatocopper(II) complex, a new compound. The solid contains the *trans* isomer, with four-coordinated copper(II). Bis-paeonolatocopper(II) itself exists as a dihydrate and as the anhydrate which is at least dimorphic.

Such *ortho*-substituted phenols as salicylaldehyde (**Ia**; R = R¹ = H; X = O) or acetophenone (**Ib**; R¹ = H; R = CH_3; X = O) are classical chelating agents.[1] Paeonol (**Ic**; R = CH_3, R¹ = OCH_3; X = O, whose trivial name derives from its one-time use in perfumery) is the derivative of acetophenone, substituted by methoxyl at the 4-position.



(I)

Pfeiffer studied[2,3] its chelating properties with several metals, including copper(II). The stoichiometries then reported (denoting paeonol as HP) included: CuP_2, $CuP_2 \cdot C_6H_5NH_2$ and $CuP_2 \cdot$ pyridine.

In preliminary work,[4] some of the detail was not reproduced. We now describe the formation and structure of a new brown product, the bis-complex of the diimine (**Id**, R = CH_3, R¹ = OCH_3, X = NH):

$$Cu^{2+} + 2C_9H_9O_3 \longrightarrow Cu(C_9H_8O_3)_2 + 2H^+$$
$$\downarrow 2NH_3$$
$$Cu(C_9H_{10}NO_2)_2 + 2H_2O.$$

EXPERIMENTAL

Paeonol (2-hydroxy-4-methoxyacetophenone) from Aldrich had, after recrystallization, a m.p. of 51°C. Electronic spectra were recorded with a Perkin–Elmer Lambda 5 spectrophotometer. IR spectra were recorded with a Perkin–Elmer IR 783 spectrophotometer using KBr discs (0.8 mg of compound dispersed in 0.06 g KBr, giving a disc 0.2 mm thick). Magnetic moments were measured with a Gouy balance. Melting points were measured using glass capillaries, and are uncorrected.

Bis-paeonolatocopper(II) was made essentially by the method[2] of Pfeiffer *et al.*, omitting ethanol. The green product had μ_{eff} = 1.7 BM at 13°C (Gouy balance). It was dissolved in the minimum of warm chloroform (spectrosol grade), filtered and kept for 1–2 weeks in an atmosphere of acetone, when crystals formed. The whole process was repeated. Depending upon conditions, three distinct solids

* Authors to whom correspondence should be addressed.

(all green) were obtained. These were square plates of dihydrate (m.p. 260° often with bright luminescence), hexagons (m.p. 245–247°), trigonal prisms or needles (m.p. 254°), or a mixture. Recrystallizing the original solid product from either CH_2Cl_2 or benzene yielded only needles.

IR spectra and analysis showed that the square plates are dihydrated. Found: C, 51.1, 51.2; H, 5.0, 5.4. Calc. for $Cu(C_9H_9O_3)_2 \cdot 2H_2O$: C, 50.3; H, 5.2%. Found (for needles) [mol. mass (mass spec) 394]: C, 54.6; H, 4.68. Calc. for $Cu(C_9H_9O_3)_2$ (mol. mass 393.88): C, 54.9; H, 4.6%. Although the samples were apparently beautifully crystalline, no diffraction spots could be observed. In chloroform, the compound obeyed the Beer–Lambert law, and the derived values for molar extinction coefficients at band maxima are: 647 (ε50) and 550 (ε45) nm. The dihydrate showed IR absorption at (KBr discs, in cm^{-1}) 3480m, 3340sh, 3220sh, 3080sh, 3000w, 2960w, 2940w, 2900sh, 2840w, 1665vw, 1610vs, 1570vs, 1510vs, 1490sh, 1460m, 1430s, 1410sh, 1390s, 1350vw, 1335w, 1260sh, 1250vs, 1220s, 1180m, 1160w, 1140s, 1070s, 1030sh, 1020m, 990m, 970w, 940vw, 870w, 860m, 850m, 790m, 780vw, 750m, 740sh, 660vw, 630sh, 620sh, 610s, 590vw, 500w, 460wm and 390w.

Bis-paeonoliminatocopper(II)

This brown complex (red–purple when crystalline) was prepared by gently heating bis-paeonolatocopper(II) in an excess of concentrated ammonia (sp.gr. 0.88) to complete dissolution. The procedure used in recrystallizing bis-paeonolatocopper(II) was then applied. The ultimate product appeared as homogeneous prismatic needles, m.p. 254°. It showed IR absorptions (KBr discs in cm^{-1}) at 3340m, 3200vw, 3100vw, 3060vw, 3000vw, 2970vw, 2840w, 1600vs, 1525vs, 1500sh, 1480wm, 1450w, 1430s, 1410w, 1365vw, 1350sh, 1330wm, 1280vs, 1260w, 1220vs, 1190vw, 1170s, 1155vs, 1130vw, 1065m, 1040m, 1025s, 990s, 970vw, 915vw, 870vw, 840m, 820s, 770vw, 750w, 725w, 660sh, 645m, 600m, 580sh, 510wm, 460w and 400w. Found [mol. mass (mass spec) 392]: C, 54.5, 54.6; H, 5.2, 5.11; N, 7.0, 7.2. Calc. for $Cu(C_9H_{10}O_2N)_2$ (mol. mass 391.914): C, 55.2; H, 5.1; N, 7.1%.

Unlike bis-paeonolatocopper(II), the visible spectrum of this complex in chloroform revealed only one band at 563 nm. This system obeys the Beer–Lambert law, with $\varepsilon = 78.3$.

The crystals used in the X-ray structural determination were from ethanolic solution: pertinent details of methods are summarized in Table 1 and selected intramolecular bond distances and angles are in Tables 2 and 3. Tables of coordinates of atoms, and of related quantities, and of torsion angles, intramolecular distances and structure factors have been deposited as supplementary results.

DISCUSSION

The properties of the red–brown product strongly suggest that it is a monomeric bis-iminatochelate. It has $\mu_{eff} = 1.76$ BM at 13°, its analyses and molecular ion (m/z 392) agree, and it obeys the Beer–Lambert law with a small extinction coefficient (78). The IR spectrum shows a single sharp absorption at 3340 cm^{-1} (NH). A second major difference from the bis-paeonolatocomplex (which has strong bands at 1610 and 1570 cm^{-1}) is

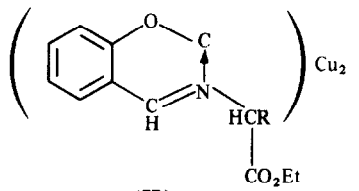
the presence of only one strong band at 1600 cm^{-1}. The red–brown colour is typical[5] of a bis-iminato complex of *o*-hydroxy substituted acetophenones (**I**; R ≠ H). The corresponding salicylaldehyde derivatives (**I**; R = H) are, in general,[5] green.

The single most noteworthy feature of the molecular structure is the proof that this involves a four-coordinated copper(II) ion, doubly chelated by the imine (**Id**) of paeonolate. The environment of the copper ion is closely planar and is almost square. The isomer which is *trans* about the copper(II) ion has crystallized, although this fact need not comment on the equilibrium between geometric isomers in solution. Of all environments for copper(II) ions in crystals, the square and planar is probably the least common.

The formation of the imine from ammonia and the substituted *o*-hydroxyacetophenone is not unexpected.[6] Indeed, one of the earliest observations (150 years ago) of a reaction of a coordinated ligand was for salicylaldehyde (**Ia**) and ammonia. In the presence of nickel(II). Ettling[6a] found this to give the bis complex of the imine (**Id**; R = R' = H; X = NH). However, while complexed salicylaldimines form readily[5b] from salicylaldehydes and ammonia, the corresponding ketimines of the *o*-hydroxyacetophenones do not form nearly so easily.

Such chelated imines are, nevertheless, well enough known. **Id** is also formed in poor and variable yield from the reaction with dioxygen of the complexes of Schiff bases of type (**II**), where the



(**II**)

Schiff base is derived from leucine[7] [R = CH_2 $CH(CH_3)_2$] or from valine[8] [R = $CH(CH_3)_2$]. However, structural studies of imines are rare. The present work seems also to be the first crystallographic study of any derivative of paeonol, though again the composition and properties of its complex compounds with cobalt, such as Co

Table 3. Selected intramolecular angles (°)

(paeonolate)$_3 \cdot CHCl_3$ and salts of [Coen$_2$ (paeonolate)]$^{2+}$ are well-established, as are structures (by diffraction) of complex compounds of copper(II) with the archtypal salicylaldehyde (Hsal), e.g. [Cu(sal)$_2$][9] and [Cu(1,10-phen) (sal)](NO_3).[10]

Finally, the "adduct" of aniline with bis-paeonolatocopper(II) made by Pfeiffer and his students seems likely to be a similar imine complex. Their pyridine adduct may well be more closely akin to the five-coordinated species Cu(acac)$_2 \cdot$ B formed by N-heterocycles (B = pyridine,[11] quinoline[12]) with such copper(II) bis-β-diketonates as bis-2,4-pentane-dionatocopper(II), "copper acetylacetonate".

(*Received* 21 *January* 1991; *accepted* 23 *May* 1991)

Abstract—A new binuclear molybdenum(VI) oxocomplex, ethylenediammonium trioxomolybdate(VI)-μ-oxotrioxoethylenediaminemolybdate(VI), with the formula $(enH_2)[O_3Mo—O—Mo(en)O_3]$ (**1**), has been synthesized. Thermal degradation of the compound to the oxide MoO_3 has been studied by means of thermoanalytical methods. The IR spectrum confirms the presence of the ethylenediammonium cation and the complex anion. The crystal structure of the title compound was determined by X-ray diffraction methods. The crystal contains $[O_3Mo—O—Mo(en)O_3]^{2-}$ anions and ethylenediammonium cations. The molybdenum atoms in the complex anion, show two different coordination geometries which produce a structure formed by a tetrahedral $[MoO_4]$ and an octahedral $[MoO_4N_2]$ sharing an oxygen atom. The ethylenediamine has two functions, it acts as a bidentate ligand and as a cation in the complex salt.

Recently, there has been much interest in the chemistry of oxocomplexes of molybdenum due to their structural similarity to the active sites of certain molybdoenzymes.[1] The biological activity of molybdenum mostly involves the molybdenum(VI) state, the coordination chemistry of which is based to a large extent on oxocomplexes which are of importance for their role in oxidation catalysed by metals.[2] Polydentate ligands have played a key role in the development of modern coordination chemistry and interest in these ligands has been heightened by the realization that they have the potential of providing a controlled coordination sphere to the metal which may mimic the function of the protein in metalloenzymes. On the other hand, the coordination chemistry of polyoxomolybdates complexes containing organic ligands has received considerable attention by virtue of their interest as models for the investigation of the interactions between organic substrates and catalytic metal oxide surfaces in heterogeneous catalysis employing solid molybdenum oxides.[3] They also have relevance in the catalytic photo-oxidation of organic compounds.[4]

In view of this wide interest and as a part of our general research programme on oxocomplexes of molybdenum, vanadium and tungsten with polydentate amines in aqueous solution,[5,6] we report in this paper the preparation, chemical characterization, thermal behaviour and the crystal structure and bonding of a new binuclear molybdenum(VI) oxocomplex with the formula $(enH_2)[O_3Mo—O—Mo(en)O_3]$ (**1**). Interestingly, compound **1** may be classified into two different types of compounds: (a) as a part of the family of

molybdenum(VI) oxocomplexes, and also (b) as a polyoxomolybdate, as it derives from the dimolybdate anion, $[Mo_2O_7]^{2-}$.[7]

Several polymolybdates containing fluoro-,[8] oxygen-[9] and nitrogen-donating ligands[10,11] have been prepared and structurally characterized in the last 10 years. In most of them two sites of the polymolybdate core are occupied only by the ligand L.

EXPERIMENTAL

Molybdenum trioxide and ethylenediamine were purchased from Merck and were used without further purification. Carbon, nitrogen and hydrogen analyses were performed on a Perkin–Elmer 240 C-, H-, N-analyser. Molybdenum was determined thermogravimetrically as MoO_3 after thermal decomposition of the sample in an atmosphere of argon and oxygen. IR spectra were recorded in the 4000–250 cm^{-1} range from KBr dishes on an IR BECKMAN 4240 spectrophotometer. Differential analysis (DTA) and thermogravimetric (TG) analyses were measured simultaneously on a SETARAM TAG 24 S 16 instrument under an argon and oxygen atmosphere with a heating rate of 5°C min^{-1}.

Synthesis of $(enH_2)[O_3Mo—O—Mo(en)O_3]$

Ethylenediammonium trioxomolybdate(VI)-μ-oxotrioxoethylenediaminemolybdate(VI), $(enH_2)[O_3Mo—O—Mo(en)O_3]$ (**1**), was prepared by direct reaction between molybdenum trioxide (1.84 g, 12.8 mmol) and ethylenediamine (2 cm^3, 29.89 mmol) dissolved in distilled water (75 cm^3), by heating and refluxing at 100°C for 5 h, as described in reaction (1). Colourless crystals of **1** suitable for X-ray analysis were obtained by slow evaporation at room temperature. The crystals were filtered off, washed with water, ether and ethanol, and then dried in air. Crystals were found to be stable to air, light and X-ray exposure. Yield 67%. Found: C, 11.2; H, 4.3; N, 13.0; Mo, 44.8. Calc. for $C_4H_{18}Mo_2N_4O_7$: C, 11.3; H, 4.3; N, 13.1; Mo, 45.0%.

$$MoO_3 + C_2H_8N_2(exc) \xrightarrow[H_2O,\,100°C]{pH = 8.7} (enH_2)[O_3Mo—O—Mo(en)O_3]. \quad (1)$$

Crystallographic data collection and structural refinement

Data collection was carried out on an Enraf Nonius CAD4 four circle diffractometer at 295 K with a graphite monochromator and Mo-K_α radiation. A prismatic single crystal with approximate dimensions $0.45 \times 0.40 \times 0.13$ mm was selected and used for intensity measurements. Unit-cell parameters were obtained from a least-squares fitting of the setting angles for 25 reflections in the range $13 < \theta < 16°$. Intensity data were collected using the ω–2θ scanning technique with Miller indices running from 0 to 13 for h, from 0 to 10 for k and from -25 to 25 for l. During data collection, two reference reflections (4 4 0 and 4 2 -10) were monitored after every 100 reflections and every 7200 s to check for drifts in electronics, radiation damage, variations in X-ray tube intensity, crystal stability and counter response. No crystal decay was observed during the data collection process. Data were corrected for Lorentz and polarization effects. Scattering factors for neutral atoms and anomalous dispersion corrections for all non-hydrogen atoms were taken from the *International Tables for X-ray Crystallography* (1974).[12] The position of molybdenum atoms were located on a Patterson map, the remaining non-hydrogen atoms of the structure were located on successive Fourier syntheses. An empirical absorption correction following the DIFABS procedure[13] was applied to data refined with isotropic displacement parameters. Anisotropic refinement was carried out by full-matrix least-squares analysis. A convenient weighting scheme[14] of the type $w = w_1 \times w_2$ with $w_1 = 1/(8.06 - 27.98 \sin\theta/\lambda + 25.96 \sin^2\theta/\lambda)^2$ and $w_2 = k/(a + b|F_o|)^2$ was used to obtain flat dependence in $\langle w\Delta^2 F\rangle$ vs $\langle \sin\theta/\lambda\rangle$ and vs $\langle F_o\rangle$; the coefficients used were $k = 0.55$; $a = 1.14$, $b = 0.00$ for $|F_o| \leqslant 26$; $a = 0.47$, $b = 0.02$ for $26 < |F_o| \leqslant 51$; $a = 0.88$, $b = 0.01$ for $51 < |F_o| \leqslant 67$; $a = -0.98$, $b = 0.04$ for $67 < |F_o| \leqslant 107$; $a = -0.17$, $b = 0.03$ for $|F_o| > 107$. A Fourier difference synthesis revealed the positions of all the hydrogen atoms close to those expected on geometrical grounds and they were kept fixed as isotropic contributors. Most calculations were carried out using the XRAY 76 system[15] running on a Micro VAX II computer. The details of the crystal data are collected in Table 1. Final atomic positional and thermal parameters, together with observed and calculated structure factors, have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Spectroscopic characterization

The IR spectrum of compound **1** shows two peaks at 3390 and 3300 cm^{-1} and they are attribu-

table to N—H stretching vibrations of ammonium groups. There are two strong bands at 3210 and 3140 cm^{-1} due to the $—NH_2$ group of ethylenediamine, shifted towards lower wave numbers by the involvement of the nitrogen atoms of the ligand in coordination.[16] In the 900–810 cm^{-1} region the spectrum displays a complicated pattern of intense bands associated with the symmetric and asymmetric Mo=O stretching vibrations[17] and consistent with the presence of chemically distinct Mo=O moieties. Between 800 and 650 cm^{-1} there is a group of bands which can be assigned to the stretching of the nearly linear Mo—O_b—Mo group.[18]

Thermal analyses

Compound **1** is stable up to approximately 198°C. Its thermal decomposition starts with an endothermic step in the temperature range 198–232°C, corresponding to a mass loss observed in the TG and DTG curves of 6.72%. This first decomposition step is followed by one exothermic process between 232 and 252°C. Both of the two steps are overlapped in the DTG curve. In the DTA curve there are three other exothermic processes in relation with different oxidation processes between 235 and 450°C. A constant weight is achieved above 450°C after losing 32.80% of the original weight. This constant weight indicates that MoO_3 has been formed. This solid product was identified by its X-ray power diffraction pattern and IR spectrum. Thermal decomposition for the whole process can be expressed by reaction (2). It is supposed that unidentified intermediate compounds are oxidized between 198–450°C as shown by reaction (3). Figure 1 shows the thermal decomposition of compound **1**.

$$(enH_2)[O_3Mo—O—Mo(en)O_3] \xrightarrow{\Delta} 2MoO_3 + 2(en) + H_2O \quad (2)$$

$$(en) \xrightarrow{[O]} NO_x + CO_2 + H_2O. \quad (3)$$

X-ray structure determination

The structural analysis reveals that the crystal is composed of discrete complex dianions, $[O_3Mo—O—Mo(en)O_3]^{2-}$, and ethylenediammonium cations, $(enH_2)^{2+}$. The contents of the unit cell and some neighbouring species are shown in Fig. 2, while Fig. 3 shows the structure of the complex dianion and the cation together with the atomic numbering scheme. This kind of associ-

ation has been found in a different complex with composition $(enH_2)[Cr^{III}(en)F_4]Cl$.[19]

The dianion comprises the asymmetric $[O_3Mo(\mu\text{-}O)Mo(L)O_3]$ core, which, to the best of our knowledge, has not been crystallographically characterized previously. The asymmetry gives rise to non-equivalent molybdenum coordination geometries. Molybdenum (**1**) displays a distorted octahedral $[MoO_4N_2]$ coordination through ligation to three terminal oxo groups, to two diamine nitrogen atoms, and to a bridging oxo group. In contrast, molybdenum (**2**) exhibits tetrahedral $[MoO_4]$ coordination via bonding to three terminal oxygen atoms and to the bridging oxo group. Thus, the overall structure of the anion may be viewed as an octahedron and a tetrahedron which are linked together by a bridging oxygen atom vertex. Bond lengths and bond angles in both coordination polyhedra in the anion are listed in Table 2. Although non-equivalent metal sites are not uncommon in binuclear systems of molybdenum(III) and (V), binuclear complexes of molybdenum(VI) usually exhibit symmetrical structures.

The bonding parameters associated with the tetrahedral $[MoO_4]$ unit are unexceptional. However, several other features of the geometry of the $[MoO_4N_2]$ unit merit discussion. In $[MoO_4N_2]$ the Mo=O bond lengths range from 1.747(4) to

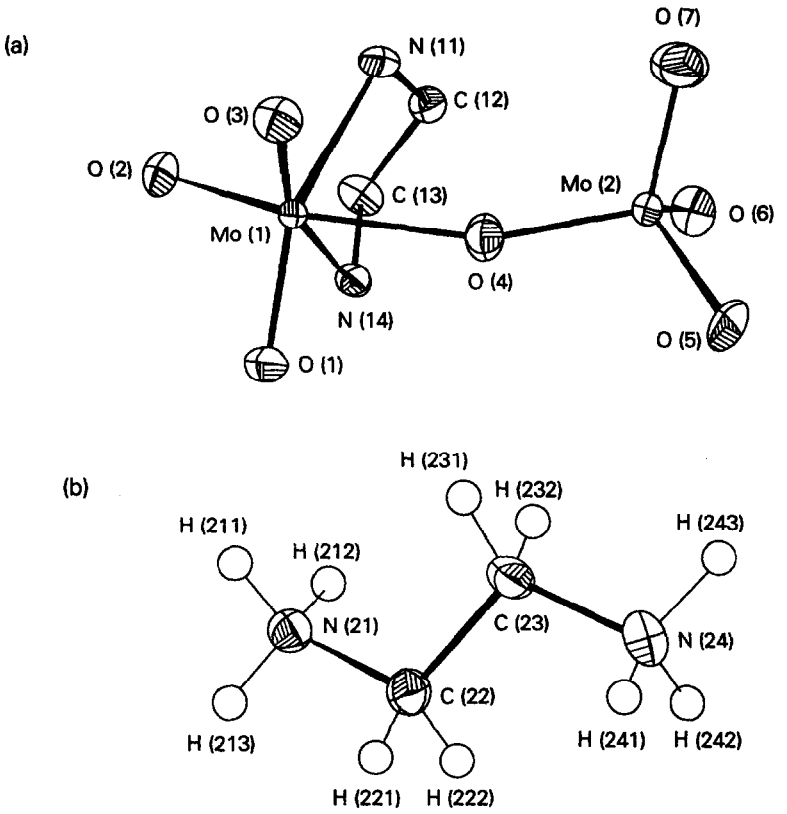

Fig. 3. ORTEP view of the structure of (a) the $[O_3Mo—O—Mo(en)O_3]^{2-}$ anion and (b) the $(enH_2)^{2+}$ cation, showing the atom-labelling scheme.

1.764(4) Å, those in $[MoO_4]$ from 1.737(5) to 1.770(4) Å. These values agree very well with those found in other molybdenum(VI) oxocomplexes[20] or in discrete[7] and polymeric[20,21] dimolybdate anions with molybdenum–oxygen double bonds. The long Mo—N distances [2.317(4) and 2.348(5) Å], in the *trans* positions with respect to the Mo=O bonds, indicate weak interactions, reflecting the absence of a strong electrostatic component to the bonding; a common observation for interactions between molybdenum(VI) and neutral base ligands.[6,18] There is a significant inequality of the bond angles O(2)—Mo(1)—N(11) [84.6(2) Å] and O(4)—Mo(1)—N(11) [76.1(2) Å] involving terminal oxygen atoms and a bridging oxygen atom. This reflects stronger repulsion from the Mo=O bond compared to the Mo—O_b bond. The most significant structural feature of the anion is the presence of non-equivalent molybdenum-bridging oxo distances of 2.129(4) Å for Mo(1)—O(4) and 1.799(4) Å for Mo(2)—O(4), due to the strong influence of the terminal oxo group O(2) and the negligible *trans* influence of terminal oxygen atoms in the distorted tetrahedron $[MoO_4]$. A similar lengthening is shown in polymeric dimolybdate anions which are built by $[MoO_6]$ and $[MoO_4]$ groups linked together by sharing a corner.[20,22] The Mo—O_b—Mo angle is 161.6(3)° and it is indicative of some electronic delocalization which is usually an important factor in the presence of photochemical properties of this type of compound.[23] The distance between the molybdenum atoms of the dianion is 3.8772(4) Å, which is consistent with the absence of Mo—Mo interactions, as expected for a binuclear Mo^{VI}-d^0 complex, and contrasts with the distance of *ca* 2.80 Å observed for oxocomplexes of molybdenum(V), where metal–metal bonding is invoked.[24] The nitrogen atoms are *cis* to each other in the ethylenediamine ligand, giving a gauche configuration [dihedral angle between the N(11)—C(12)—C(13) and N(14)—C(13)—C(12) planes, 54.6(5)°] similar to that observed previously.[25] The ethylenediammonium cation is nearly planar [dihedral angle 178.7(4)°] with *trans* nitrogen atoms. Bond distances and bond angles in the ligand do not significantly differ from those for the cation (Table 2). Nevertheless, N—C and C—C bond distances, and N—C—C bond angles are generally slightly bigger in the ethylenediammonium cation compared to the ethylenediamine ligand.

The crystal packing in this structure is formed by zig-zag parallel chains along the c axis following a sequence ...acac... (where a = anion and c = cation). These chains are placed in two different x levels: $x = 0$ and $x = 1/2$. While the complex anion is nearly situated in the (100) plane, the ethylenediammonium cation is located along the [100] direction. The projection of the crystal structure in the ac plane showing the hydrogen bonding network (N···O) is given in Fig. 4. The crystal structure is stabilized by electrostatic interactions and the presence of an extended hydrogen bond network. Each anion is connected by three $N_a \cdots O$ hydrogen bonds with neighbouring anions from chains at different x levels and the same z level. The ethylenediammonium cation forms $N_c \cdots O$ hydrogen bonds with anions of its own chain and of different chains. The closest approach distances that are suitably orientated to permit hydrogen contacts are listed in Table 3.

It is interesting to note that $N_a \cdots O$ (2.91–2.99 Å) hydrogen bonds between anions are longer than $N_c \cdots O$ (2.73–2.90 Å) hydrogen bonds. In the structure there also are some relatively short $C_c \cdots O$ (3.25–3.47 Å) hydrogen contacts between the oxygen atoms of anions and the carbon atoms of cations. No doubt all the C—H···O contacts cannot be considered as hydrogen bonds, but they do indicate some degree of polarization and the role of this type of interactions in a series of organic and inorganic compounds has also been examined in the literature.[26,27]

(*Received* 22 *October* 1990; *accepted* 23 *May* 1991)

Abstract—The sodium salt of 2-aryltelluroethanol (**1**) (aryl = 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$), which was synthesized by the reaction of $HOCH_2CH_2Cl$ with $ArTe^-Na^+$ (generated *in situ* by borohydride reduction of the appropriate Ar_2Te_2), reacts with $HgCl_2$, $PdCl_2$ and K_2PtCl_4 in 1 : 1 molar ratio resulting in alkoxides of stoichiometry $[MCl(1\text{-}H)_2]_2$. The chelation through tellurium has been supported by proton NMR spectra and in the case of mercury(II) complexes, by ^{13}C NMR spectra also. The presence of ν[M—Cl(bridging)] in the range 200–270 cm^{-1} supports the dimeric formulation for these alkoxides based on chlorine bridges. The ArTe group does not significantly affect the hydrogen bonding pattern of the ethanol. The CH_2 rocking vibrations suggest that **1** exists in the complexes in the *gauche* conformation.

The interest in hybrid organotellurium ligands has been growing since the mid-eighties.[1] Recently, syntheses of several interesting (Te, N) donors[2] and their ligation behaviour have been reported. In the repertoire of (Te, O) ligands there are few compounds as only the ligation of aryltelluroacetic acid[3] and 2-(4-ethoxyphenyltelluro)benzoate[4] has been attempted so far. However, synthetic routes[1d,5] are available for structures **2**–**7**, which may act as (Te, O) donors. Continuing our investigations on hybrid organotellurium ligands, we have synthesized 2-aryltelluroethanols (**1**) and investigated their mercury(II), palladium(II) and platinum(II) alkoxides. The results are reported in the present paper. The alkoxides of palladium(II)[6] and platinum(II)[7] are rare. Recently some chelate stabilized alkoxoplatinum(II) complexes have been synthesized by Pringle *et al.*[8–10] by reacting $Ph_2PCH_2CR_2OH$ (R = H or Me) with a variety of platinum(II) moieties. In the absence of chelate stabilization alkoxides of platinum(II) are extremely moisture-, oxygen- and temperature-sensitive, decomposing to the hydride *via* β-hydrogen elimination or depositing the metal(0). The palladium(II) and platinum(II) alkoxides of **1** have been found to be quite stable and moisture-insensitive, most probably due to the formation of a chelate ring through tellurium. Thus, the present investigations of 2-aryltelluroethanols not only extend to the repertoire of (Te, O) donors but also enlarge the very limited number of examples known of alkoxypalladium(II)/platinum(II) complexes.

ditellurides. Tellurium was estimated by a standard method.[12] The carbon, hydrogen and nitrogen analyses were carried out using a Perkin–Elmer elemental analyser, 240C. The ^1H and $^{13}C\{^1H\}$ NMR spectra in $CDCl_3$ and DMSO-d_6 were recorded at 25°C on a JEOL FX-100 FT-NMR spectrometer at 99.55 and 25 MHz, respectively. IR spectra (of Nujol mulls between CsI windows or KBr/CsI discs) in the range 200–4000 cm^{-1} were recorded on a Nicolet 5DX FT-IR spectrometer. Far-IR spectra (up to 50 cm^{-1}) were recorded in polyethylene on a Perkin–Elmer Far-IR spectrometer, model 1700X. Electronic spectra were recorded on a Hitachi UV–vis spectrometer, model 300.

Synthesis of 2-*aryltelluroethanols* (**1**)

Bis(4-methoxyphenyl) or bis(4-ethoxyphenyl) ditelluride (10 mmol) was dissolved in ethanol (30 cm^3). Sodium borohydride (1 g) dissolved in 1 N NaOH (50 cm^3) was added dropwise to the solution of ditelluride under an oxygen-free dinitrogen atmosphere until it became light yellow. 2-Chloroethanol (1.61 g, 20 mmol) dissolved in ethanol (5 cm^3) was added to this light yellow solution. The mixture was refluxed for 1 h with stirring under a nitrogen atmosphere, cooled and poured into excess water. The aqueous mixture was acidified with dilute acetic acid and extracted using chloroform. The evaporation of chloroform produced a deep yellow liquid. The results of elemental analyses and spectral data are given below.

1a: Analysis. Found: C, 36.6; H, 5.6. Calc. for $C_9H_{12}O_2Te$: C, 38.1; H, 5.6%. NMR (^1H, $CDCl_3$, 25°C): δ 2.20 (bs, OH), 2.88–3.01 (t, 2H, $TeCH_2$), 3.72–3.79 (t, 5H, OCH_2+OCH_3), 6.67–6.76 (d, 2H, ArH *ortho* to Te), 7.61–7.70 (d, 2H, ArH *meta* to Te); ($^{13}C\{^1H\}$, $CDCl_3$, 25°C): δ, 13.3 ($TeCH_2$), 55.3 (OCH_3), 63.0 ($HOCH_2$), 99.6 (C_1), 115.2 (C_3, C_5), 141 (C_2, C_6), 159.8 (C_4).

1b: Analysis. Found: C, 39.2; H, 5.9. Calc. for $C_{10}H_{14}O_2Te$: C, 40.3; H, 6.0%. NMR (^1H, $CDCl_3$, 25°C): δ, 1.30–1.44 (q, 3H, CH_3), 2.89 (bs, OH), 3.69–3.87 (t, 2H, $TeCH_2$), 3.94–4.08 (m, 4H, OCH_2), 6.06–6.79 (d, 2H, ArH *ortho* to Te), 7.59–7.68 (d, 2H, ArH *meta* to Te); ($^{13}C\{^1H\}$, $CDCl_3$, 25°C): δ, 12.9 (CH_3), 14.7 ($TeCH_2$), 58.2 (OCH_2), 63.2 ($HOCH_2$), 99.1 (C_1), 115.6 (C_3, C_5), 140.8 (C_2, C_6), 158.9 (C_4).

Synthesis of mercury(II) *alkoxides of* **1**

1a or **1b** (1 mmol) was dissolved in methanol (20 cm^3). Sodium metal (1 mmol) dissolved in methanol (8–10 cm^3) was added to a solution of **1** and stirred for 30 min. Mercury(II) chloride (1 mmol) dissolved in methanol (5–10 cm^3) was stirred with this mixture for 2 h. The pale yellow precipitate formed was filtered, washed thoroughly with a cold methanol and water (9:1) mixture and dried *in vacuo*. The results of the elemental analyses, m.p.s and spectral data are recorded below.

$[HgCl(\mathbf{1a}\text{-H})]_2$: m.p. 238–40°C (d). Analysis. Found: C, 21.3; H, 3.0; Te, 26.2; Hg, 38.6; Cl, 6.9. Calc. for $C_9H_{11}O_2TeHgCl$: C, 20.8; H, 2.9; Te, 24.6; Hg, 38.6; Cl, 6.8%. NMR (^1H, DMSO-d_6, 25°C): δ, 2.52 (t, 2H, $TeCH_2$), 6.84–6.93 (d, 2H, ArH *ortho* to Te), 7.33–7.41 (d, 2H, ArH *meta* to Te).

$HgCl(\mathbf{1b}\text{-H})]_2$: m.p. 226°C (d). Analysis. Found: C, 23.0; H, 3.1; Te, 24.7; Hg, 36.1; Cl, 6.4. Calc. for $C_{10}H_{13}O_2TeHgCl$: C, 22.5; H, 3.2; Te, 24.0; Hg, 37.6; Cl, 6.7%. NMR (^1H, DMSO-d_6, 25°C): δ, 1.25–1.39 (t, 3H, CH_3), 2.22–2.50 (t, 2H, $TeCH_2$), 6.37–7.14 (d, 2H, ArH *ortho* to Te), 7.62–7.85 (d, 2H, ArH *meta* to Te).

Synthesis of palladium(II) *alkoxides of* **1**

The sodium salt of **1a** or **1b** (0.05 mmol) was prepared as described above and mixed with solid $PdCl_2$ (0.5 mmol). The mixture was stirred for 2 h at room temperature (25°C) in a nitrogen atmosphere. When the $PdCl_2$ dissolved completely, the volume of the mixture was reduced. The precipitate thus formed was filtered, washed with cold methanol and dried *in vacuo*. The results of the elemental analyses, m.p.s and NMR data are given below.

$[PdCl(\mathbf{1a}\text{-H})]_2$: m.p. 98°C (d). Analysis. Found: C, 25.0; H, 3.5; Te, 31.1; Cl, 8.9. Calc. for $C_9H_{11}O_2TePdCl$: C, 25.4; H, 3.5; Te, 31.0; Cl, 8.3%. NMR (^1H, DMSO-d_6, 25°C): δ, 2.08–2.51 (t, 2H, $TeCH_2$), 6.94–7.58 (d, 2H, ArH *ortho* to Te), 7.82–8.38 (d, 2H, *meta* to Te).

$[PdCl(\mathbf{1b}\text{-H})]_2$: m.p. 114°C (d). Analysis. Found: C, 27.0; H, 4.2; Te, 29.8; Cl, 8.0. Calc. for $C_{10}H_{13}O_2TePdCl$: C, 27.4; H, 3.9; Te, 29.1; Cl, 8.1%. NMR (^1H, DMSO-d_6, 25°C): δ, 1.25–1.38 (t, 3H, CH_3), 2.50–2.80 (t, 2H, $TeCH_2$), 6.71–7.08 (d, 2H, ArH *ortho* to Te), 7.58–7.92 (d, 2H, ArH *meta* to Te).

Synthesis of platinum(II) *alkoxides of* **1**

A methanolic solution of the sodium salt of **1a** or **1b** (0.5 mmol) was prepared by the procedure described above and mixed with a solution of K_2PtCl_4 (0.5 mmol) (in approx. 5 cm^3 of water). The mixture was stirred for 3 h until it became reddish-brown and a precipitate started to appear. The vol-

ume of the solution was reduced to half. The resulting precipitate was filtered, thoroughly washed with cold methanol and dried *in vacuo*. The m.p. results of elemental analyses and NMR data are given below.

[PtCl(**1a**-H)]$_2$: m.p. 98°C (d). Analysis. Found: C, 20.6; H, 3.1; Te, 25.1; Cl, 7.0. Calc. for $C_9H_{11}O_2TePtCl$: C, 21.0; H, 2.9; Te, 24.9; Cl, 6.9%. NMR (^{1}H, DMSO-d$_6$, 25°C): δ, 2.38–2.52 (t, 2H, $TeCH_2$), 6.66–6.91 (d, 2H, ArH *ortho* to Te), 7.47–7.62 (d, 2H, ArH *meta* to Te).

[PtCl(**1b**-H)]$_2$: m.p. 132°C (d). Analysis. Found: C, 22.6; H, 3.4; Te, 23.9; Cl, 6.0. Calc. for $C_{10}H_{13}O_2TePtCl$: C, 22.7; H, 3.2; Te, 24.2; Cl, 6.7%. NMR (^{1}H, DMSO-d$_6$, 25°C): δ, 1.25–1.38 (t, 3H, CH_3), 2.50–2.92 (t, 2H, $TeCH_2$), 6.81–7.11 (d, 2H, ArH *ortho* to Te), 7.65–8.01 (d, 2H, ArH *meta* to Te).

The signals of OCH_2, OCH_3 and CH_2O^- protons in the ^{1}H NMR spectra of all the complexes were found to merge with the DMSO signals.

RESULTS AND DISCUSSION

2-Aryltelluroethanols (**1a–b**) and their metal complexes were synthesized by the following reactions.

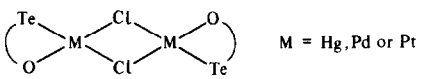
$$HO(CH_2)_2Cl \xrightarrow{ArTe^-Na^+} HO(CH_2)_2TeAr \xrightarrow{Na} NaO(CH_2)_2TeAr \xrightarrow{M(II)} ClM\overline{O(CH_2)_2TeAr_2} \quad (1)$$

(Ar = 4-$MeOC_6H_4$ or 4-$EtOC_6H_4$, M = Hg, Pd or Pt).

The ^{1}H and ^{13}C NMR of **1a** and **1b**, authenticated by elemental analyses, were found to be characteristic. The OH signal in the ^{1}H NMR spectra appears at a position very close to that of ethanol (δ, 2.26 ppm), suggesting that the intermolecular hydrogen bonding of ethanol is not greatly disturbed by substituting its CH_3 group with $ArTeCH_2$. The ν(OH) in the IR spectra occurs as a broad band around 3200 cm^{-1}, which corresponds to the results of the ^{1}H NMR. The regions in the IR spectra generally assigned to the CH_2 rocking mode have bands around 925, 815 and 720 cm^{-1}, which suggest that **1a** and **1b** probably exist in both *trans* and *gauche* forms,[13] at least in the free liquid. Tellurium shields the carbon atoms linked to it and therefore, C_1 and CH_2 protons (even those iinked to OH) appear in ^{13}C NMR upfield.

Mercury(II), palladium(II) and platinum(II) complexes of **1a** and **1b** were found to be fairly air-stable and soluble only in polar solvents like DMSO and DMF, contrary to the ligands which were found to be fairly soluble in $CHCl_3$, CH_3CN, CH_3OH and C_6H_6. All of these complexes are diamagnetic and cannot be synthesized by the direct reaction of metal halides with **1a** or **1b**. The electronic spectra of the alkoxides of palladium and platinum in DMSO exhibit a band around 26 kK, which seems to have major contribution from the $^1A_{1g} \rightarrow {}^1B_{1g}$ transition characteristic of square planar geometry of palladium/platinum.

On comparing the ^{1}H NMR spectra of the ligands **1a** and **1b** with those of the metal alkoxides, taking into account the solvent effect, it appears that the protons of the CH_2Te group undergo deshielding of the order 0.5–1.2 ppm. This probably appears because the negative charge on oxygen is greater in the complexes than in the ligand (**1a** or **1b**), which in turn has an overall shielding effect on the —CH_2CH_2— backbone. The ring protons of **1a** and **1b** exhibit deshielding (0.2–0.8 ppm) on complexation with palladium/platinum(II), which is probably due to the engagement of tellurium in the coordination. The deshielding of protons *ortho* to tellurium also occurs in complexation of **1** with mercury(II) but its magnitude is ~ 0.2 ppm, probably due to the weak nature of the Hg—Te bond relative to the Pd/Pt—Te bond. The dimeric nature of all the complexes is supported by the occurrence of ν[M—Cl(bridging)] vibrations around 200, 270 and 260 cm^{-1} respectively for mercury, palladium and platinum. The absence of ν(OH) in the IR spectra and an OH signal in ^{1}H NMR spectra lends further support that **1** behaves as a uninegative and bidentate ligand in its present complexes. Based on these observations, structure **8** may be proposed for these alkoxides with the presumption that the geometry around mercury is tetrahedral and square planar around palladium/platinum. Since the ν[M—Cl (bridging)] band in the IR spectra of Pd^{II}/Pt^{II} complexes does not exhibit any splitting, it is reasonable to assume they are centrosymmetric. Moreover, ^{1}H NMR spectra of palladium(II) and platinum(II) complexes do not have additional signals, ruling out the possibility that they are mixtures of centrosymmetric *trans* and *cis* isomers (**8**).



(**8**)

The CH_2 rocking vibrations in the IR spectra of all the present complexes appear in the ranges 920–880 and 820–805 cm^{-1}, suggesting that probably the two CH_2 groups of **1a** or **1b** adopt a *gauche* conformation.[8] To further support the ligation of **1** with the three metals through tellurium, com-

parison of ^{13}C NMR spectra of these complexes with those of the ligands was not possible due to inadequate solubility of the former for recording the NMR, except in the case of [HgCl(**1b**-H)]$_2$. The ^{13}C NMR spectrum of this complex exhibits signals[14] at δ 14.4 (CH_3), 24.5 ($TeCH_2$), 58.8 (OCH_2), 63.3 (CH_2O^-), 102.0 (C_1), 115.8 (C_3), 139.2 (C_2) and 159.6 (C_4) ppm. The $TeCH_2$ and C_2 signals appear to be deshielded ($\sim$ 12 and 2.5 ppm, respectively) with respect to the corresponding signals of **1b**, supporting the involvement of tellurium in coordination with at least mercury(II). Attempts to synthesize pure samples of alkoxides of the composition M(**1**-H)$_2$ have not yet succeeded. Similarly we have failed so far in growing crystals of the present alkoxides, suitable for single crystal X-ray work.

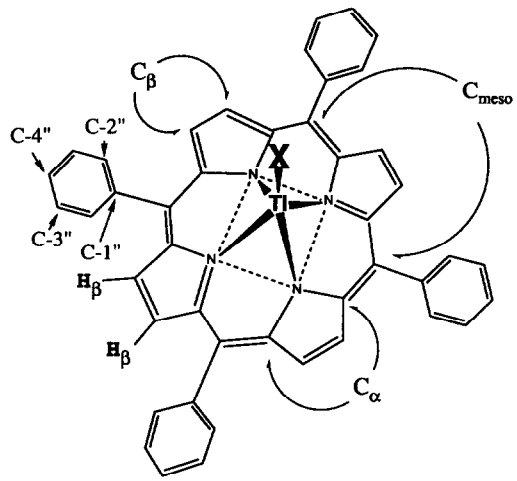
(*Received* 18 *March* 1991; *accepted* 20 *May* 1991)

Abstract—It is shown from the proton resonances spectra of thallium(III) meso-tetraphenylporphyrin acetate that the intermolecular exchange of the acetato group has an activation energy of 4.1 kcal mol^{-1} in CD_2Cl_2. In the slow exchange region, the methyl and carbonyl carbons of the acetato group are observed at 18.8 ppm [with $^3J(Tl—^{13}C)$ coupling constant 280 Hz] and 174.9 ppm [with $^2J(Tl—^{13}C)$ coupling constant 235 Hz], respectively, at −90°C. The phenomenon of the rotation of phenyl groups in the complex from the angle 90–60° relative to the N_4 plane to approximately 0° was identified and examined by using ^{13}C and ^1H NMR spectroscopy at various temperatures.

Thallium(III) meso-tetraphenylporphyrin acetate, Tl(tpp)(OAc), (shown in Fig. 1) is a compound suitable for dynamical NMR studies. It is believed that Tl(tpp)(OAc) has a coordination number of five, rather than six, because the thallium atom is displaced out of the porphyrin plane by about 0.9 Å.[1–4]

In an NMR study of Tl(tpp)(OAc), Abraham *et al.*[5–7] have reported that the methyl protons of the apical acetate ligand were observed as a sharp singlet at $\delta = -0.03$ ppm, with no evidence of coupling of the thallium nuclei with the acetate group. Neither the carbonyl nor methyl signals of the acetate ligand in the ^{13}C NMR spectra was found. However, all other ^{13}C signals in the porphyrin were clearly observed. Hence, they surmised that this effect might be due to the broadening of the ^{13}C signal through an exchange process involving the apical ligand. In the present communication, the proton and ^{13}C NMR spectra of Tl(tpp)(OAc) in solution at low temperatures are examined to confirm the previous inference and to determine the value of the activation energy for the exchange process. Furthermore, an abnormal conformation change at low temperatures has been detected.



where X=OAc

Fig. 1. Structure of the Tl(tpp)(OAc) complex.

On cooling a 0.05 M solution of Tl(tpp)(OAc) in CD_2Cl_2 (Fig. 2), the methyl proton signal, which

* Author to whom correspondence should be addressed.

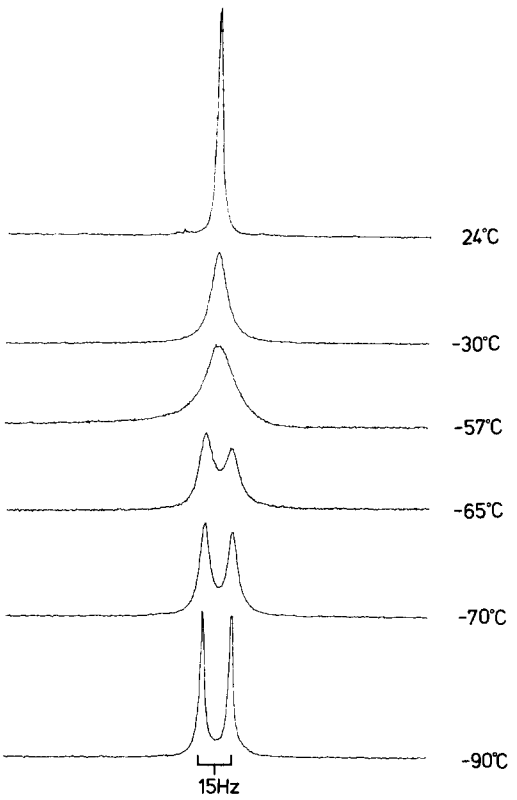


Fig. 2. 300 MHz ^{1}H NMR spectra of the axial acetato protons in Tl(tpp)(OAc) in CD_2Cl_2 at various temperatures.

displays a single peak at room temperature (δ = 0.06 ppm), broadens (temperature of coalescence, T_c −57°C) and finally splits into two peaks with a separation of 14.7 Hz. The process is completely reversible, and the results measured at 300 MHz confirm the separation as a coupling ^4J(Tl—H) rather than a chemical-shift difference. The rate process is treated as a simple two-site exchange rate process and the use of the usual coalescence analysis yields the exchange rate of 32.65 s^{-1} at −57°C, which corresponds to an activation energy (E_a) of 4.1 kcal mol^{-1}.

^{13}C NMR data for Tl(tpp)(OAc) at different temperatures is shown in Table 1. At −90°C (or −75°C), because the intermolecular exchange is extremely slow, methyl and carbonyl carbons of the acetato group are observed at 18.8 ppm [with ^3J(Tl—^{13}C) coupling constant 280 Hz] and 174.9 ppm [with ^2J(Tl—^{13}C) coupling constant 235 Hz], respectively. At 24°C, the rate of intermolecular exchange of the acetato ligand is 352 Hz. The exchange rate is comparable with the coupling frequency of Tl—^{13}C, i.e. 258±23 Hz. In this intermediate exchange region, the signals are broadened beyond detection. Hence, no signal of the axial ^{13}C has been found at 24°C.

The abnormal conformation change due to the rotation of the phenyl group in the complex is also observed from the ^{13}C and ^{1}H NMR spectra at different temperatures. The temperature variation of the c-2″ carbon spectrum of Tl(tpp)(OAc) is shown in Fig. 3 as from a doublet of doublets at 24°C to a triplet at −90°C. This indicates that the dihedral angles between the mean plane of the porphyrin skeleton and the planes of the four phenyl groups vary from a range of 90–60° [3,8] to about 0°. Consequently, the two ortho carbons in the same phenyl group become more equivalent and the inner peaks of doublet of doublets merge together with decreasing temperature. Also, the steric hindrance between the phenyl groups and β-pyrrole increases. It causes the β-pyrrole proton to shift downfield by about 39 Hz from 9.07 ppm at 24°C to 9.20 ppm at −90°C. All other phenyl protons are shifted downfield about 16±5 Hz (shown in Table 2). Furthermore, the chemical shift of C_α (and *c*-1″) shifts upfield about 53 Hz from 150.5 (or 142.4) ppm to 149.8 (or 141.7) ppm (shown in Table 1). Those effects are also evidenced from 2D NOESY at −90°C and 24°C as shown in Figs 4(a) and (b), respectively. Figure 4(a) indicates that there is a strong through space steric interaction between the protons of β-pyrrole and the phenyl protons, while in Fig. 4(b), there is only a weak through space interaction between the protons of β-pyrrole and *ortho* phenyl protons but no signal indicates the interaction between the protons of β-pyrrole and other phenyl protons. All these observations show that, as the temperature decreases, the phenyl groups rotate from the planes at the angle of 90–60°

relative to the N_4 plane to the planes approximately parallel to it.

EXPERIMENTAL

Dynamic NMR spectroscopy

Proton and ^{13}C NMR spectra were recorded on a Varian VXR-300 spectrometer in dichloromethane-d_2, locked on solvent deuterium, and referenced to the residual solvent peak. The temperature of the spectrometer probe was calibrated by the shift difference of methanol resonance in the ^1H NMR spectrum.

Preparation of Tl(tpp)(OAc)

Tl(tpp)(OAc) was prepared as described elsewhere.[5,9] It was dissolved in CD_2Cl_2 to give a concentration of 0.05 M for the NMR measurement.

SYNTHESIS AND CHARACTERIZATION OF *TRANS*-$[Co(NH_3)_4(NH_2CH_3)L]^{3+}$ [L = $(CH_3)_2SO$ OR $(CH_3)_2NCHO$] COMPLEXES

BEATRIZ SIENRA* and ADRIANA MASSAFERRO

Cátedra de Química Inorgánica, Facultad de Química, Av. General Flores 2124, C.C. 1157, Montevideo, Uruguay

(*Received* 19 *February* 1991; *accepted* 5 *April* 1991)

Abstract—*Trans*-$[Co(NH_3)_4(NH_2CH_3)(CH_3)_2SO]^{3+}$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)(CH_3)NCHO]^{3+}$ ions are prepared by Ag^+-induced solvolysis of *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{2+}$ (X = Cl or Br) complexes in dimethylsulphoxide or dimethylformamide. The complexes were characterized by electronic, IR and ^1H magnetic resonance spectroscopy. Both, dimethylsulphoxide and dimethylformamide are bonded through the oxygen atom. The *trans*-complexes obtained are not contaminated with the *cis*-isomers.

Complexes of the type *trans*-$[Co(NH_3)_4(NH_2CH_3)L]$ have been prepared previously with uninegative (L = Cl, Br, ONO_2, NO_2, ONO),[1–3] binegative (L = OCO_2)[4] and neutral (L = OH_2)[4] substituents. In all cases, the methylamine ligand has been introduced in the coordination sphere making use of the strong *trans*-labilizing influence of the sulphito group.[5] It appeared to be useful to prepare some complexes with neutral ligands (other than water) and this paper describes the synthesis of such complexes with dimethylsulphoxide (dmso) and dimethylformamide (dmf). An obvious route, by analogy with the synthesis of the corresponding pentaamines,[6,7] was to heat *trans*-$[Co(NH_3)_4(NH_2CH_3)OH_2](ClO_4)_3$ in dmso or dmf. Nevertheless, following this procedure Balt *et al.*[8] obtained a mixture of *cis*- and *trans*-$[Co(NH_3)_4(^{15}NH_3)dmso]^{3+}$ from the *trans*-$[Co(NH_3)_4(^{15}NH_3)OH_2]^{3+}$ complex. Another possibility was to try substitution of the labile *trans*-$[Co(NH_3)_4(NH_2CH_3)OSO_2CF_3]^{2+}$ ion. However, the *trans*-$[Co(NH_3)_4(^{15}NH_3)OSO_2CF_3]^{2+}$ complex has not been obtained pure (9% *cis* impurity,[9] 13% *cis* impurity).[10] Therefore, we tried the Ag^+-induced solvolysis of *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl]^{2+}$ or *trans*-$[Co(NH_3)_4(NH_2CH_3)Br]^{2+}$ complexes, reactions which were expected to take place with retention of the *trans* configuration.

EXPERIMENTAL

Preparation of trans-$[Co(NH_3)_4(NH_2CH_3)dmso](ClO_4)_3$ *and* trans-$[Co(NH_3)_4(NH_2CH_3)dmso]Br_3$

Solutions of *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ (5 g) in dmso (4 cm^3) and $AgClO_4 \cdot H_2O$ (2.87 g) in dmso (4 cm^3) were mixed and kept at room temperature for *ca* 24 h. The silver chloride precipitate was removed and the filtrate washed with ethanol (25 cm^3). Ether (600 cm^3) was slowly added with vigorous stirring. Upon standing, an oily, red dmso phase settled. The ether phase was decanted off and the oily residue dissolved in 95% ethanol (40 cm^3). The complex was precipitated by the addition of ether (200 cm^3), filtered, washed with ethanol and ether and air dried. The product was recrystallized from water by adding concentrated $HClO_4$ (**CAUTION**) and cooling. The red–violet crystals were collected, washed as before and vacuum dried. Yield 20%.

A saturated solution of the perchlorate salt in water was treated with a concentrated aqueous solution of LiBr and cooled in an ice bath. The product was recrystallized in the same manner.

The complex may be also obtained from *trans*-$[Co(NH_3)_4(NH_2CH_3)Br](ClO_4)_2$, by following the same procedure. The rate of solvolysis of this complex is greater than that of the *trans*-chloro ion.

X	R	λ_{max} (nm)	ε_{max} ($M^{-1}cm^{-1}$)	λ_{max} (nm)	ε_{max} ($M^{-1}cm^{-1}$)	Reference
dmso	H	515	61.3	351	63.7	15
	CH_3	522	64.6	353	67.5	[b]
dmf	H	506	79.4	348	69.2	17
	CH_3	510	78.0	349	71.0	[b]

[a] For R = CH_3, the complexes have the *trans* configuration.
[b] This work.

Preparation of trans-$[Co(NH_3)_4(NH_2CH_3)dmf](ClO_4)_3$

Solutions of *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ (5 g) in dmf (20 cm^3) and $AgClO_4 \cdot H_2O$ (2.87 g) in dmf (4 cm^3) were mixed and kept at room temperature for *ca* 24 h. The silver chloride precipitate was discarded and the filtrate treated with ethanol to precipitate a red–violet solid. After cooling in an ice bath, the crystals were collected, washed with ethanol and ether and air dried. The complex was recrystallized from water by adding concentrated $HClO_4$ and cooling on ice. Yield 30%. Alternatively the compound may be prepared from the *trans*-bromo complex.

Chemicals

The precursor complexes *trans*-$[Co(NH_3)_4(NH_2CH_3)Cl](ClO_4)_2$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)Br](ClO_4)_2$ were prepared by reported methods.[1,2] Other reagents used were AR grade.

Apparatus

UV–vis spectra were recorded on a Shimadzu 210 UV spectrophotometer; IR spectra on a Perkin–Elmer IR 283 instrument; and ^1H NMR spectra were obtained using a Varian T 60 spectrometer.

RESULTS AND DISCUSSION

In this section the *trans*-$[Co(NH_3)_4(NH_2CH_3)L]$ ions are abbreviated as $CoBr^{2+}$, $Co(dmso)^{3+}$, etc.

Both $CoCl^{2+}$ or $CoBr^{2+}$ perchlorates, treated at room temperature with an equivalent amount of $AgClO_4$ in dmso or dmf, produce the corresponding $Co(solvent)^{3+}$ complexes. Therefore, the Ag^+-induced solvolysis reactions take place with stereochemical retention, as expected.

The complexes so obtained and recrystallized, were characterized by elemental analysis* and by their electronic, IR and ^1H magnetic resonance spectra. The latter, especially, gives conclusive evidence of the geometry and purity of the complexes.

The visible absorption maxima of the $Co(dmso)^{3+}$ and $Co(dmf)^{3+}$ ions show a minor shift to longer wavelengths compared with the parent pentaamines (Table 1), in addition to an increase of the molar absorptivity coefficients. These features have been observed in other methylamine complexes[1,2] and were interpreted in terms of a decrease of the crystal-field parameter.[11] Furthermore, the visible spectra of the complexes are indicative of a CoN_5O chromophore, which indicates that dmso and dmf coordinate through the oxygen atom.[7]

The IR spectra of the bromide salt (in KBr and Nujol mull) of both complexes are in good agreement with those reported for the corresponding pentaamines (Table 2). In the $Co(dmso)^{3+}$ complex, the S—O band is identified at 940 cm^{-1}, while in free dmso it appears at 1055 cm^{-1}. Such shifting has been considered as indicating coordination through the oxygen atom.[12] The carbonyl stretching frequency, which appears at 1681 cm^{-1} in free dmf, is shifted to 1650 cm^{-1} in the $Co(dmf)^{3+}$ complex, which indicates that dmf coordinates through the oxygen atom.[13]

The ^1H NMR spectra of both complexes are in agreement with those reported for the corresponding pentaamines (Table 3).[11,14–17] The position of the (NH_3+NH_2) and the *trans*-CH_3 (methylamine) proton resonances are consistent with a CoN_5O coordination entity. In O-bonded *trans*-methylaminetetraamminecobalt(III) complexes, the (NH_3+NH_2) resonance occurs at δ 3.83–3.92 ppm and that of *trans*-CH_3 at δ 1.45–1.63

[b] This work.

ppm.[2–4] Furthermore, the appearance of a doublet for N—CH_3 in the ^1H NMR spectrum of free dmf, has been interpreted as due to restricted rotation about the OC—N< bond, as a result of partial double bonding involving the nitrogen lone pair of electrons.[18,19] The retention of this doublet in the spectrum of the $Co(dmf)^{3+}$ ion implies that such double bonding is retained, prohibiting coordination of the nitrogen atom to the metal.

The ^1H NMR spectra of both complexes also enable the assignment of their absolute configurations. It has been shown[1,2] that the position of the methyl triplet of the methylaminetetraamminecobalt(III) complexes may be employed for this purpose: the *cis* complexes present the methyl resonance at lower field (δ 2 ppm for CoN_5O complexes) than the corresponding *trans* isomers. This allows us to establish the isomeric purity of the compounds obtained, since the spectra show a single methyl triplet, in a position corresponding to a methyl group *trans* to an O-bonded ligand.

Finally, the ^1H NMR spectra confirm the absence of an aqua complex (a possible impurity) because the characteristic sharp Co—OH_2 resonance at δ 5.6 ppm is not present. This method for the detection of the aqua complex impurity is quite sensitive if a high cobalt concentration is used (the perchlorate salts provide the desired solubility).[20]

Acknowledgement—The authors are indebted to Professor E. Umpiérrez for recording the IR spectra and for stimulating discussions.

COMMUNICATION

DISTORTION POTENTIAL FOR MOLECULAR MECHANICS CALCULATION OF PLASTICITY OF COPPER(II) COORDINATION: AN APPROXIMATION

J. SABOLOVIĆ and N. RAOS*

Institute for Medical Research and Occupational Health, University of Zagreb, Ksaverska cesta 2, 41001 Zagreb, Croatia, Yugoslavia

and

Kj. RASMUSSEN

Chemistry Department A, Building 207, The Technical University of Denmark, DK-2800 Lyngby, Denmark

(*Received* 20 *May* 1991; *accepted* 25 *June* 1991)

Abstract—A new, simpler definition is proposed for the distortion coordinate β, defining the empirical potential which was introduced earlier (J. Sabolović and N. Raos, *Polyhedron* 1990, **9**, 1277) in order to reproduce the shapes of distorted coordination polyhedra of tetracoordinated copper(II) complexes. A simpler definition of β, proposed in this communication, facilitates its implementation in the programme for conformational analysis. No significant difference in the structure parameters obtained with the old and the new expression for β was observed. The new function also has a slight advantage in reducing the computational time and accelerating the convergence.

In an attempt to reproduce accurately the shape of (distorted) coordination polyhedra of tetracoordinated copper(II) complexes, we proposed three kinds of models suitable for molecular mechanics calculations: (1) a "dummy" atom model;[1,2] (2) models with distortion potential;[3,4] and (3) a model based on coulombic interactions.[5] Models (2) and (3) reproduced fairly well the planar/tetrahedral distortion as observed in crystal structures of copper(II) bis-chelates with naturally occurring amino acids and their N-alkylated derivatives.[4–6]

In our first paper dealing with the distortion potential,[3] the new potential was defined as:

$$V(\beta) = \tfrac{1}{2}k_\beta(\beta-\beta_0)^2; \qquad (1)$$

where k_β and β_0 (= 180°) are empirical parameters and β is a distortion coordinate defined as an angle between bisectors of two opposite valence angles (Fig. 1).

For the implementation of a new internal coordinate in the existing programme[7,8] it was necessary to define two "dummy" atoms (denoted as Y and Y′, Fig. 1) with the coordinates:

$$x_{iY} = \tfrac{1}{2}(x_{iO}+ax_{iN}) \quad i = 1,2,3; \qquad (2)$$

where x_{iO} and x_{iN} stood for Cartesian coordinates of two (oxygen and nitrogen) atoms in a chelate ring. Variable a was the ratio of Cu—O and Cu—N bond lengths:

$$a = \frac{b_{MO}}{b_{MN}}. \qquad (3)$$

Such an expression for the distortion angle β is rather complicated, especially when calculation of the first and second derivatives of V_β with respect to Cartesian coordinates (necessary for energy minimization) and derivatives of observables with

* Author to whom correspondence should be addressed.

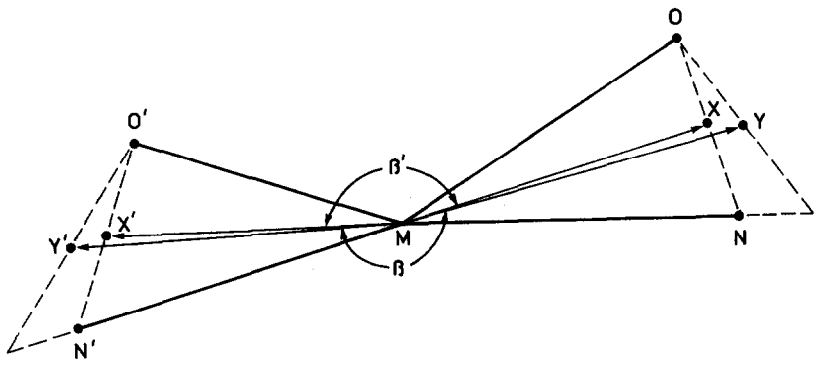

Fig. 1. Definition of distortion angles in tetracoordinated chelates with amino acids. Angle β is defined as an angle Y—M—Y′ and its approximation, distortion angle β' as an angle X—M—X′. M denotes the central atom and X, X′, Y and Y′ are "dummy" atoms needed for construction. The atoms marked with ′ belong to the same chelate ring.

respect to energy function parameters (for optimization of empirical parameters) are needed. Therefore, we investigated a simpler definition of the distortion coordinate (β', Fig. 1) by putting $a = 1$ in eq. (2). The approximation seems to be sound because for copper(II)-aminoacidates, Cu—O and Cu—N bond lengths are virtually constant and $b_{MO} \approx b_{MN}$.

The new function was checked on 12 conformations of bis(N,N-dimethylvalinato)copper (II). The implementation of the new function in the computer programme for conformational analysis produced a reduction, although not an essential one, in computation time (about 1–2% for typical runs with 80 steepest descent and up to 25 Newton–Raphson iterations) and a slightly faster convergence (average 11.1 vs 12.1 Newton–Raphson iterations).

The next test of the validity of the approximate calculation of the distortion angle was to prove if both expressions for the distortion potential yielded comparable results for the most critical internal coordinates (Table 1). The values for the bond lengths around copper for both expressions were virtually identical (mean difference 3.25×10^{-5} Å, $\sigma = 2.49 \cdot 10^{-4}$ Å; for all Cu—O and Cu—N bonds), differing by less than typical experimental error in X-ray analysis. Comparison of the angles yielded slightly higher values (Table 1) which were still in the range of typical experimental error. Also, it has to be noted that no systematic error in any internal coordinate was observed: all mean differences fitted very well in the range of the standard deviations.

From the discussion presented above we can therefore conclude that the new expression for the distortion angle produces essentially the same results and, in addition to being better fitted for implementation in a programme for conformational analysis, it has a slight advantage in reducing the computation time and accelerating the convergence.

Table 1. Comparison of the most critical internal coordinates as calculated with the two functions (the new and the old one) for distortion potential[a]

Internal coordinate	Mean difference (new–old)	Standard deviation	Range
Cu—O	0.0001	0.0003	−0.0005–0.0007
Cu—O′	−0.0001	0.0003	−0.0006–0.0007
Cu—N	0.0001	0.0002	−0.0005–0.0002
Cu—N′	0.0000	0.0002	−0.0005–0.0003
O—Cu—O	−0.124	0.236	−0.623–0.855
N—Cu—N	0.175	0.165	−0.004–0.413
O—Cu—N	0.003	0.008	−0.006–0.022
O′—Cu—N′	0.001	0.008	−0.006–0.020
O′—Cu—N	−0.010	0.031	−0.052–0.043
O—Cu—N′	0.008	0.034	−0.053–0.059

[a] Bond lengths are expressed in Å and angles in degrees. The conformers involved are: 6-6LL, 5-5LL, 2-2LL, 3-3LL, 4-4LL, 1-1LL, 4-6LL, 1-6LL, 3-6LL, 1-4LL, 3-3LL and 4-6DL, according to our notation[9] (L and D denote the ligand configuration). The calculations were performed by using our Model 5.[4]

BOOK REVIEWS

Introduction to Cluster Chemistry. By D. Michael, P. Mingos and David J. Wales. Prentice-Hall, 1990, ISBN 0-413-499049-9 (hardback), xv + 318 pp.

Cluster chemistry has been one of the most spectacular growth areas in the whole inorganic field, aided by advances in synthetic techniques and in particular the mushroom growth in X-ray diffraction studies. Gradually, but less spectacularly, this has been undergirded by a framework describing the bonding in these compounds.

This book provides a timely overview of the whole area of clusters—both metals and non-metals. It is modestly claimed to be an introduction to the area, but in reality is far more than that. Overview, yes, but in no way superficial, as a review of the contents indicate.

The first chapter is a review-length survey of cluster chemistry (71 pp.). It looks at the relationship between metal–metal distance and bond order, and the part played by bridging ligands; bond-enthalpy data; kinetic and steric factors—before launching into a survey of cluster types across the Periodic Table—from Chevrel phases to gold–phosphine clusters, polyhedral boranes to iron–sulphur clusters (does anyone known *why* some ferredoxins have two irons in the cluster, some three and some four?). One valuable feature of the book is the use of information boxes strategically placed in the text; many appear in this chapter summarizing synthetic routes without interrupting the flow of the structural systematization. The book is intended to function as a teaching tool and is amply supplied with questions at the end of this and the other chapters, many of these relating to clusters in the recent literature.

Chapter 2 and succeeding chapters are concerned with the electronic structure of clusters, beginning with an outline of the polyhedral skeletal electron pair theory (PSEPT), but without assuming that the reader already knows the principles of electron-counting. Similarities between non-metal and metal clusters are stressed. Ideas like the isolobal principle and Lipscombe's styx method are touched on in Chapter 2, whilst Chapter 3 traces the Tensor Surface Harmonic Theory (TSH) and its application to clusters, beginning with analogies to the Huckel treatment of polyenes then translating this to spherical functions. The theory is successively applied to σ, π and δ orbitals, first as an outline in Chapter 3 then more fully in succeeding chapters. Thus, Chapter 4 considers clusters like the gold–phosphine systems where radial bonding predominates and σ bonding interactions can be considered in isolation; both types, those with and without interstitial atoms are discussed. MO schemes are set out for various cluster geometries and structures related to the number of valence electrons available. Chapter 5 treats the clusters where the p orbitals are sufficiently low-lying in energy to be involved so that σ and π interactions have to be considered, beginning with boranes and carboranes, but later linking with transition-metal clusters like polynuclear carbonyls. The following chapter looks at skeletal rearrangements. Here, as elsewhere, the book seeks to develop useful analogies, introducing the reader to the principles via the familiar application of the Woodward–Hofmann rules. Chapter 7 turns to bonding in condensed and high-nuclearity clusters, treated mainly by electron-counting (the reader will probably find it useful, here, as elsewhere, to refer to the review by Mingos and May in the recent book, *The Chemistry of Metal Cluster Complexes*). Various clusters are analysed depending on how they are joined together whilst the capping principle is considered and illustrated in terms of Group Theory. Finally, Chapter 8 looks at those clusters where δ orbitals need to be specifically considered, basically those of the early d-block metals where they may be incompletely occupied, and where the less contracted d-orbitals overlap more fully. The book is completed with an index, and there are handy little summaries of the number of electrons associated with common metals and ligands, and of the PSEPT rules on the endpapers.

About the only important cluster not represented is buckminsterfullerene, (growth industry of 1990–1991), though the authors cannot be blamed for not anticipating it! I think that this book will be widely used by researchers, teachers and students. It will interest the synthesist, the structural chemist, the spectroscopist and the theoretician with its encompassing scope. If you have to have one book on clusters, this is surely it.

Bonding and Structure (Structural Principles in Inorganic and Organic Chemistry). By N. W. Alcock. Ellis Horwood, Chichester, 1990, ISBN 0-13-465253-3 (hardback), 0-13-465246-0 (paperback), 321 pp., £16.95.

This book is intended as an undergraduate text. Its style is conceptual rather than extensively mathematical and serves as a very readable introduction to the subject.

The book is made up of three sections. The first two chapters form an introduction, in which the electronegativities of the two atoms in the bond are used to predict bond type, and the techniques giving quantitative information on structure are examined, with emphasis on diffraction methods and EXAFS. Section two, Chapters 3–5, is devoted to metallic, ionic and covalent

It will interest the synthesist, the structural chemist, the spectroscopist and the theoretician with its encompassing scope. If you have to have one book on clusters, this is surely it.

Bonding and Structure (Structural Principles in Inorganic and Organic Chemistry). By N. W. Alcock. Ellis Horwood, Chichester, 1990, ISBN 0-13-465253-3 (hardback), 0-13-465246-0 (paperback), 321 pp., £16.95.

This book is intended as an undergraduate text. Its style is conceptual rather than extensively mathematical and serves as a very readable introduction to the subject.

The book is made up of three sections. The first two chapters form an introduction, in which the electronegativities of the two atoms in the bond are used to predict bond type, and the techniques giving quantitative information on structure are examined, with emphasis on diffraction methods and EXAFS. Section two, Chapters 3–5, is devoted to metallic, ionic and covalent

bonding respectively in their "pure" forms. Metallic structures are analysed in packing of spheres whilst physical properties are related to electronic structure (the Schrödinger equation is given as an appendix). The principal ionic structures are delineated and ionic radii on various scales discussed; binding forces lead into lattice energies, treated qualitatively and quantitatively. Bonding in covalent compounds is discussed in terms of MO theory, starting with simple species like H_2 and H_2^+, then going on to cases like CH_4 and C_2H_2. The VSEPR method is applied to molecular shapes. After a discussion of covalent radii and the factors affecting them, Chapter 5 is concluded with a section on MO schemes for π-bonded systems like N_2, CO and O_2, relating the schemes to PE spectra.

Section three of the book is entitled "Real Bonds and Real Compounds", though it does begin with a chapter on metals(!) that develops the themes already established to trends in the structures of metals and alloys as well as interstitial compounds. Chapter 7, "The Accompaniment of Covalent Bonding", is devoted to van der Waals forces, donor–acceptor bonding (with a valuable classification of donors and acceptors), hydrogen bonding and secondary bonding. Chapter 8 views metal complexes from both the crystal field and MO viewpoints, including CFSE, the spectrochemical series and Jahn–Teller effects. The following chapter begins with an examination of the extent of *d*-orbital involvement in covalent compounds, using various molecules such as the xenon fluorides as vehicles. The boron hydrides and borane anions receive detailed examination and classification into structurally related families and Wade's rules are explained. There is a taste of metal clusters and a rather more extended treatment of delocalized and aromatic systems; a two-page outline of Huckel calculations is appended.

Chapter 10 runs to only 25 pages, but will be of great interest to many readers, as it includes within its compass a range of topical substances—warm superconductors, non-linear optical materials, superionic conductors, ferroelectrics, stabilized zirconia... Chapter 11 contains more important compounds—especially semiconductors. The concept of partial ionic bonding in NaCl and ZnS structures is explored as are layer structures ($CrCl_3$, $CdCl_2$) intercalated compounds and, continuing the theme of layer structures, molecular metals (TTF:TCNQ). The chapter concludes with silicates and modified metals.

The book is completed with tables of covalent, van der Waals, metallic and ionic radii.

This book has many points in its favour. It is very readable and contains much in it that is of use to pre-University students and their teachers as well. Each chapter has a list of useful books and articles for further reading whilst information "boxes" summarizing important concepts are strategically placed throughout the text. Illustrations are clear and liberally used. There are a number of misprints in the text (notably Fig. 7.5); on a personal level, I'd like to have seen a list of structures of all the elements, not just transition metals, and a formula index could have been useful. This text nicely complements existing books like D. W. Smith's *Inorganic Substances*, and D. A. Johnson's *Some Thermodynamic Aspects of Inorganic Chemistry* and will thus be bought by many inorganic chemists and also, I think, many others.

Organometallics in Organic Synthesis 2. Edited by H. Werner and G. Erker. Springer, Berlin, 1989, ISBN 3-540-50531-8, x+322 pp., DM 94.

Readers of the German literature will be aware of the suspicion that their publications are not known as well as in the West as they should. This volume is one of the attempts to rectify this situation! It consists of 17 papers presented at the second of a series of symposia on "Organic Synthesis via Organometallics". The majority of the papers are by Germans, but the international flavour is supplied by contributions from Swiss, Dutch, Austrian, Japanese and American laboratories.

One great advantage of this kind of publication is that it enables one to get an overview of an area of research activity that is not easily obtained by regular perusal of the literature. Different reviewers will choose to highlight different selections of articles; for me, the keynote lecture (G. Wilke) featured useful landmarks, such as Sabatier's discovery of catalytic hydrogenation (1897), as well as some striking syntheses via organo-nickel compounds. Several of the articles featured enantioselective syntheses—that by H. Werner featuring the chiral cyclamen blossom and another plant of traditional use to inorganic chemists (hops) as well as syntheses using chiral phosphine complexes. The recent syntheses and use of di-Grignard reagents in the preparation of metallacyclobutanes and their role in organic synthesis are discussed by F. Bickelhaupt. Some interesting observations on the choice of transition metal alkyls as organic reagents are made by Th. Kauffmann.

Not the least significant point in the collection is the high proportion of the research carried out in inorganic chemistry departments; clearly organic chemistry is too important to be left to organic chemists!

Gmelin Handbook of Inorganic Chemistry. Tungsten. Supplement Volume A3, Physical Properties (continued). 8th edn. Springer, Berlin, 1989, ISBN 3-540-93594-0, xiv+274 pp., DM 1260.

The previous Supplementary Volume, A2, initiated coverage of the physical properties of this element. The present volume extends the properties of bulk tungsten (electronic structure, bonding, lattice dynamics and some crystallographic properties having been dealt with earlier) commencing with deformation properties of both single crystals and polycrystalline specimens. Mechanisms for this are considered at some length, and differences between the two types of specimens noted.

Some interesting observations on the choice of transition metal alkyls as organic reagents are made by Th. Kauffmann.

Not the least significant point in the collection is the high proportion of the research carried out in inorganic chemistry departments; clearly organic chemistry is too important to be left to organic chemists!

Gmelin Handbook of Inorganic Chemistry. Tungsten. Supplement Volume A3, Physical Properties (continued). 8th edn. Springer, Berlin, 1989, ISBN 3-540-93594-0, xiv+274 pp., DM 1260.

The previous Supplementary Volume, A2, initiated coverage of the physical properties of this element. The present volume extends the properties of bulk tungsten (electronic structure, bonding, lattice dynamics and some crystallographic properties having been dealt with earlier) commencing with deformation properties of both single crystals and polycrystalline specimens. Mechanisms for this are considered at some length, and differences between the two types of specimens noted.

Recrystallization is examined, together with the factors affecting the kinetics.

Mechanical properties are next reviewed; successively density, elasticity and anelasticity, plasticity, hardness and ductility. This section of the book involves some 70 pages of text. This is one of the areas in which Gmelin is much more than simply a handbook of inorganic chemistry and would particularly repay study by many engineers and metallurgists.

In the next 40 pages there is a comprehensive account of thermal properties. Tungsten is well known to chemists as the element with the highest melting point; it appears that a value of 3695 K represents the best accepted current value. Other properties critically treated include heat capacity, diffusion, conductance and expansion. A similar amount is given over to electrical properties, particularly conduction. Bulk tungsten is a superconductor below 0.015 K but in thin films superconducting transition temperatures up to 6.1 K have been reported.

The final two sections give an overview of magnetic and optical properties. Here as throughout the book, there is extensive coverage of the Soviet literature, not the least useful feature of the Gmelin system. This particular volume is likely to be more generally useful to scientists from a wide range of disciplines than the more narrowly chemical parts of the Handbook.

The Chemistry of Metal Cluster Complexes. Edited by D. F. Shriver, H. D. Kaesz and R. D. Adams. Verlag Chemie, New York, Weinheim and Cambridge, 1990, ISBN 1-56081-012-2, 439 pp., price not stated.

This important book is the first of a series on the chemistry of organo-metallic clusters. It consists of a balanced collection of reviews by experts in the field, covering bonding, syntheses, reactions of ligands, cluster rearrangements, and catalysis with last, but by no means least, a review of the review literature.

Not the least striking advance in cluster chemistry has been the development of theories to account for the range—undreamed of 25 years ago—of cluster geometries. D. M. P. Mingos and A. S. May survey the classes of cluster compounds; their classification of cluster geometries in order of nuclearity permits some interesting comparisons to be drawn (perhaps a brief introduction to electron counting would make this a little more friendly to the novice). The meat of the chapter lies in the exposition of the Polyhedral Skeletal Electron Pair Theory in its application to clusters. It is pointed out that the "rules" for correlating structures of polyhedra with numbers of electrons are soundly based on large numbers of structures, as well as receiving theoretical justification. The Tensor Surface Harmonic Theory approach is outlined; similarities between isostructural borane and metal cluster fragments leading to the use of isolobal relationships are pointed out. Clusters that do not follow the "rules" are analysed.

The methodology of cluster synthesis is outlined by R. D. Adams. The importance of ligand removal from coordinatively saturated metal compounds as a jumping-off point for cluster synthesis is examined. This can include abstraction of coordinated CO as well as the use of complexes containing labile ligands (e.g. THF)—"lightly stabilized" species that can participate in cluster build-up under mild conditions. Bridge-assisted, metal–metal exchange and other routes are duly considered, along with the more traditional photolytic and (more robust) thermolytic methods. D. J. Darensbourg summarizes substitution reactions in clusters, pointing out the importance of this to an understanding of catalytic processes. He examines examples of the dissociative, associative and interchange pathways, along with different ways in which metal–metal bond dissociation can affect the cluster. The role of isotopic labelling—either metal isotope or ^{13}CO—is discussed.

Cluster-assisted ligand transformations are the subject of G. Lavigne's chapter, pointing out that clusters now offer gentler reaction conditions and a greater degree of control over route. He summarizes ideal conditions—an ideal combination difficult to realise in practice—for a catalytically active cluster. A number of trinuclear clusters are chosen from the iron triad where a range of routes are used to activate the cluster—photochemically or with a suitable nucleophile, for example. Transformations of ligands with a variety of hetero-atoms (P, S, O, and N) as well as of CO and carbon-containing fragments are all considered.

Fluxionality was of course observed first in mononuclear organometallics; here B. F. G. Johnson and A. Rodgers point out that rearrangement of clusters does not just involve ligand positional change but also motion of metal atoms. The normal modes of clusters have to be considered, including librational modes. There is a useful little section for the newcomer on electron counting in clusters and another discussing the relationship between structural studies in the solid state and solution with the timescale of the process. Some case histories [$Fe_3(CO)_{12}$ and $Co_4(CO)_{12}$] are given within the context of isomerization, and a section considers fragmentational routes. Clusters have been considered to be possible models for metal surfaces in heterogeneous catalysis, so that not the least interest in cluster complexes lies in their catalytic potential, explored by W. L. Gladfelter and K. J. Roesselet. In a relatively short chapter, they examine the ability of carbonyl and hydridocarbonyl clusters to catalyse the water–gas shift reaction, olefin hydrogenation, isomerization and hydroformylation, and oxidations. The hydrogenation of CO is a reaction with great industrial appeal—the most promising systems seem to be those running at high temperature and pressure; it is pointed out that under these conditions there is scope for cluster formation, reorganization and breakdown. There would seem to be much scope for the study of activated clusters to permit low-temperature, low-pressure pathways. Much also remains to be done in establishing the

Recrystallization is examined, together with the factors affecting the kinetics.

Mechanical properties are next reviewed; successively density, elasticity and anelasticity, plasticity, hardness and ductility. This section of the book involves some 70 pages of text. This is one of the areas in which Gmelin is much more than simply a handbook of inorganic chemistry and would particularly repay study by many engineers and metallurgists.

In the next 40 pages there is a comprehensive account of thermal properties. Tungsten is well known to chemists as the element with the highest melting point; it appears that a value of 3695 K represents the best accepted current value. Other properties critically treated include heat capacity, diffusion, conductance and expansion. A similar amount is given over to electrical properties, particularly conduction. Bulk tungsten is a superconductor below 0.015 K but in thin films superconducting transition temperatures up to 6.1 K have been reported.

The final two sections give an overview of magnetic and optical properties. Here as throughout the book, there is extensive coverage of the Soviet literature, not the least useful feature of the Gmelin system. This particular volume is likely to be more generally useful to scientists from a wide range of disciplines than the more narrowly chemical parts of the Handbook.

The Chemistry of Metal Cluster Complexes. Edited by D. F. Shriver, H. D. Kaesz and R. D. Adams. Verlag Chemie, New York, Weinheim and Cambridge, 1990, ISBN 1-56081-012-2, 439 pp., price not stated.

This important book is the first of a series on the chemistry of organo-metallic clusters. It consists of a balanced collection of reviews by experts in the field, covering bonding, syntheses, reactions of ligands, cluster rearrangements, and catalysis with last, but by no means least, a review of the review literature.

Not the least striking advance in cluster chemistry has been the development of theories to account for the range—undreamed of 25 years ago—of cluster geometries. D. M. P. Mingos and A. S. May survey the classes of cluster compounds; their classification of cluster geometries in order of nuclearity permits some interesting comparisons to be drawn (perhaps a brief introduction to electron counting would make this a little more friendly to the novice). The meat of the chapter lies in the exposition of the Polyhedral Skeletal Electron Pair Theory in its application to clusters. It is pointed out that the "rules" for correlating structures of polyhedra with numbers of electrons are soundly based on large numbers of structures, as well as receiving theoretical justification. The Tensor Surface Harmonic Theory approach is outlined; similarities between isostructural borane and metal cluster fragments leading to the use of isolobal relationships are pointed out. Clusters that do not follow the "rules" are analysed.

The methodology of cluster synthesis is outlined by R. D. Adams. The importance of ligand removal from coordinatively saturated metal compounds as a jumping-off point for cluster synthesis is examined. This can include abstraction of coordinated CO as well as the use of complexes containing labile ligands (e.g. THF)—"lightly stabilized" species that can participate in cluster build-up under mild conditions. Bridge-assisted, metal–metal exchange and other routes are duly considered, along with the more traditional photolytic and (more robust) thermolytic methods. D. J. Darensbourg summarizes substitution reactions in clusters, pointing out the importance of this to an understanding of catalytic processes. He examines examples of the dissociative, associative and interchange pathways, along with different ways in which metal–metal bond dissociation can affect the cluster. The role of isotopic labelling—either metal isotope or ^{13}CO—is discussed.

Cluster-assisted ligand transformations are the subject of G. Lavigne's chapter, pointing out that clusters now offer gentler reaction conditions and a greater degree of control over route. He summarizes ideal conditions—an ideal combination difficult to realise in practice—for a catalytically active cluster. A number of trinuclear clusters are chosen from the iron triad where a range of routes are used to activate the cluster—photochemically or with a suitable nucleophile, for example. Transformations of ligands with a variety of hetero-atoms (P, S, O, and N) as well as of CO and carbon-containing fragments are all considered.

Fluxionality was of course observed first in mononuclear organometallics; here B. F. G. Johnson and A. Rodgers point out that rearrangement of clusters does not just involve ligand positional change but also motion of metal atoms. The normal modes of clusters have to be considered, including librational modes. There is a useful little section for the newcomer on electron counting in clusters and another discussing the relationship between structural studies in the solid state and solution with the timescale of the process. Some case histories [$Fe_3(CO)_{12}$ and $Co_4(CO)_{12}$] are given within the context of isomerization, and a section considers fragmentational routes. Clusters have been considered to be possible models for metal surfaces in heterogeneous catalysis, so that not the least interest in cluster complexes lies in their catalytic potential, explored by W. L. Gladfelter and K. J. Roesselet. In a relatively short chapter, they examine the ability of carbonyl and hydridocarbonyl clusters to catalyse the water–gas shift reaction, olefin hydrogenation, isomerization and hydroformylation, and oxidations. The hydrogenation of CO is a reaction with great industrial appeal—the most promising systems seem to be those running at high temperature and pressure; it is pointed out that under these conditions there is scope for cluster formation, reorganization and breakdown. There would seem to be much scope for the study of activated clusters to permit low-temperature, low-pressure pathways. Much also remains to be done in establishing the

similarities and differences between mononuclear and cluster systems.

Clusters have spawned a considerable literature, collected together by M. I. Bruce in the final chapter. It has, besides a bibliography of reviews, a handy table of all organometallic cluster syntheses listed in *Inorganic and Organometallic Syntheses* and *Brauer's Handbook*, plus an author index to the reviews.

The book is finished off with both a subject index and an excellent formula index, arranged in order of nuclearity.

There is much in this volume that will result in it being read, and reread, by organometallic and, one hopes, organic chemists.

Ultrasound in Synthesis (Reactivity and Structure: Concepts in Organic Chemistry, Volume 27). Steven V. Ley and Caroline M. R. Low. Springer-Verlag, Berlin, 1989, ISBN 3-540-51023-0, x+133 pp., DM 128.

One of the spin-offs of the age of the instant everything was the application of the microwave oven to chemical synthesis. This slim volume examines a technique that has been around for rather longer, yet is only just starting to be taken seriously.

I fear that the series title will be sufficient to ensure that this volume is read largely by specialists in the chemistry of the element carbon. This would be unfortunate, for whole chapters devoted to organolithium and organomagnesium compounds are of just as much interest to organometallic chemists, let alone that on transition metal carbonyls.

The volume is directed to the synthetic utility of the technique; for this reason there is a long opening section covering practical considerations. Most workers so far have used laboratory cleaning baths, but this book points out the advantages of using ultrasonic probes directly immersed in the reaction vessel. Cells have been developed that allow reactions to be carried out under an inert atmosphere or at moderate pressures. Reaction rates at ambient temperatures can be considerably greater than under reflux without sonic stimulation. It is important to avoid the use of chlorinated solvents as this can mean the release of Cl_2 or HCl. Untrasound liberates OH and H radicals from water, thus producing hydrogen peroxide, so that redox reactions are often encountered in aqueous systems.

Ultrasound considerably shortens the induction time in generating Grignard reagents, probably through removing adsorbed water from the metal surface; very active magnesium hydride can also be made. Potential for one-pot organometallic synthesis is also revealed. A highlight of the lithium chapter is the application to rapid synthesis of lithium diisopropylamide and alkyl- and aryllithiums in high yield in wet technical grade THF! Succeeding chapters treat compounds of other alkali metals and organozinc compounds. The applications to transition metal catalysts have so far been little explored, but a long section reveals many pathways for organic synthesis with iron carbonyls.

A very interesting read; there are many possibilities here for organometallic chemists—the possibility of high yield, rapid syntheses avoiding refluxing, to name but one.

Gmelin Handbook of Inorganic Chemistry. Manganese D7 (Coordination Compounds). Springer-Verlag, 1990, ISBN 3-540-93602-5, DM 1335.

Gmelin coverage of manganese complexes is well-advanced. Since 1979, successive volumes have dealt with complexes of most oxygen- and nitrogen-donor ligands, this volume continuing this coverage with complexes of nitriles and related ligands. Most of it is, however, taken up with complexes of sulphur, selenium and tellurium ligands (mainly the former).

Though less fashionable than the corresponding iron complexes, widely studied as models for the active sites of ferredoxins and other iron–sulphur proteins, manganese forms a wide variety of complexes of these ligands—with both mono- and bidentate ligands, in oxidation states +2, +3 and +4; with "non-innocent" dithiolene ligands, a wider range of formal oxidation states is encountered. Dithiocarbamates and related complexes have been especially studied, the manganese(III)tris complexes undergoing one electron oxidation and reduction to the corresponding cationic manganese(IV) and anionic manganese(II) compounds. Other ligands treated include thioamides and thioureas; for consistency, sulphoxides are dealt with in this volume although they are generally believed to bind to manganese through the oxygen.

As usual with Gmelin, there are clear tabulations of material and a thorough ligand formula index. Much of the literature cited is obscure or inaccessible, making these volumes helpful in these days of cuts in journal subscriptions. It is a measure of the depth of information retrieval that one learns that the manganese(II) complex of saccharin is less sweet than saccharin itself, but leaves a bitter aftertaste in the throat!

Gmelin Handbook of Inorganic Chemistry. Organoiron Compounds, Part B17. Springer-Verlag, 1990, ISBN 3-540-93601-7, DM 1873.

Like Gaul, the Gmelin treatment of the organometallic chemistry of iron falls into three parts. The ferrocene family is in series A, other mononuclear compounds in series B and compounds with more than one iron atom in series C.

Coverage of the compounds with pentahapto ligands bound to iron began in part B11; this volume begins with

similarities and differences between mononuclear and cluster systems.

Clusters have spawned a considerable literature, collected together by M. I. Bruce in the final chapter. Like Gaul, the Gmelin treatment of the organometallic chemistry of iron falls into three parts. The ferrocene family is in series A, other mononuclear compounds in series B and compounds with more than one iron atom in series C.

Coverage of the compounds with pentahapto ligands bound to iron began in part B11; this volume begins with

those compounds where there is additionally an η^2-ligand and two others such as CO, CS, RNC or a carbene. Subsequently, one moves to the $(C_5H_5)Fe$ compounds where the other ligands are allyls (and other trihapto systems), tetra- and pentahapto rings exemplified by the ferrocene analogue $(C_5H_5)Fe(C_5H_4N)$. The volume concludes with acyclic pentadienyls ("open sandwiches") and $(C_5H_5)Fe$ derivatives of pentahapto ligands with six or more ring carbons.

"Gmelin" would be most useful if it were just an aid to literature searching, a kind of catalogue. It is, however, very much more than this, as the literature is carefully sifted. Within families of related compounds, synthetic routes are analysed, and compounds listed with full and clear tabulations of physical properties and spectroscopic data. These tables feature structural formulae of each compound described, so that one is in no doubt, as well as presenting fuller diagrams where the molecular structure has been determined. There are both ligand and formula indexes, so that, all in all, an area containing a bewildering variety of very similar-looking compounds is reduced to order.

The literature is surveyed to the end of 1987, with quite a few references subsequent to that date.

REDUCTION OF WCl_6 BY ALLYLTRIMETHYLSILANE. A CONVENIENT METHOD TO PREPARE $WCl_5(OEt_2)$ AND SOME OTHER DERIVATIVES OF WCl_5

CHRISTINA PERSSON and CARLAXEL ANDERSSON*

Inorganic Chemistry I, Chemical Center, University of Lund,
P.O. Box 124, S 22100 Lund, Sweden

(*Received* 1 *May* 1990; *accepted* 25 *June* 1991)

Abstract—WCl_6 was reacted with excess allyltrimethylsilane in diethyl ether solution at low temperature. The main product in the reaction was shown to be $WCl_5(OEt_2)$ which was isolated as black–green air- and moisture-sensitive crystals. $WCl_5(OEt_2)$ was reacted with different Lewis bases, e.g. pyridine and 9-fluorenone to yield the new compounds WCl_5 (pyridine) and WCl_5(9-fluorenone). The latter most likely being an oxygen bonded complex.

Tungsten is one of the transition metals that can be used as a catalyst for the metathesis of olefins.[1,2] Well-defined tungsten based metathesis catalysts, e.g. isolated tungsten carbene complexes have been developed in recent years.[3–5] An active but poorly defined catalyst can also be prepared *in situ* by reacting WCl_6 with an alkylating co-catalyst, e.g. alkyl-tin, alkyl-lithium or alkyl-alumina reagents.[2] Considerable efforts have been devoted to elucidate the nature of the active catalyst in these latter systems, i.e. to determine the actual oxidation state of the metal and the ligands in the coordination sphere of the metal. The reduction of tungsten(VI) as an important reaction path when alkyl-tin reagents are used as co-catalysts has been demonstrated[6,7] and the reducing properties of $SnBu_4$ have also been used[8] to prepare WCl_5 from WCl_6.

Allyltrimethylsilane has been found to undergo slow self-metathesis and fast cross-metathesis without an added co-catalyst.[9,10] Likewise ring-opening polymerizations have been performed using WCl_6/allyltrimethylsilane as the catalyst system.[11,12]

A mechanism involving metalla-carbene and metalla-cyclobutane complexes is the accepted mechanism of the metathesis reaction.[2] How an initiating metalla-carbene is formed in the system of WCl_6/allyltrimethylsilane is still an unanswered question. Based on the organic products propene and chlorotrimethylsilane, found after reaction of WCl_6 with allyltrimethylsilane, suggestions involving double allylation of tungsten and subsequent α-hydrogen transfer and propene elimination have been put forward as a route to form a carbene.[13,14] As indicated by the other organic products, allylchloride and 1,5-hexadiene, reductive elimination reactions are in this case competing reactions not leading to an active carbene but to reduced tungsten.

In the course of a project aiming at the metathesis of functionalized olefins we have continued the study of allyltrimethylsilane and its reactions with WCl_6 to eventually identify or isolate tungsten-σ-allyl or carbene complexes in the reaction mixture. Based on the observed reduction of tungsten(VI) by tetra-alkyl-tin compounds[6–8] or by cyclic olefins[15,16] we have also considered reduced tungsten as a likely product of the reaction. The work presented here describes the isolation and the identification of $WCl_5(OEt_2)$ and some complexes of tungsten(V).

RESULTS AND DISCUSSION

Reaction between WCl_6 *and allyltrimethylsilane*

The treatment of WCl_6 partly dissolved in diethyl ether at −25°C with excess (4 equiv.) allyltrimethylsilane leads to a colour change in the solution and a dissolution of the undissolved WCl_6.

* Author to whom correspondence should be addressed.

After *ca* 2 h a green precipitate is formed. Continued reaction overnight leads to a dark orange solution and a fluffy green precipitate (**I**). Schlenk filtration to remove the precipitate gives a clear solution. Slow evaporation at low temperature (−30°C) of the ether solvent leads to the deposition of large black–green crystals (**II**) with a metallic lustre. Several crops with the same appearance can be isolated in this way. GC-MS analysis of the organic evaporate reveals the presence of unreacted allyltrimethylsilane together with propene, allylchloride, chlorotrimethylsilane and 1,5-hexadiene. No attempt was made to quantify the relative amount of these products. The relative amount of the green (**I**) and black–green (**II**) materials varies from one experiment to another but in no case does the amount of **I** exceed more than 10% of the total isolated solid material. Both the isolated solids are extremely air- and moisture-sensitive which precludes full spectroscopic characterizations and a precise elemental analysis.

Since direct spectroscopic and analytical methods gave no decisive information on the composition of the solids indirect methods to characterize the major product **II** were sought for. In the search for more stable adducts, reduced tungsten, i.e. tungsten(V) or (IV) was considered as the likely parent compound.

Tungsten(IV) has been isolated as its THF adduct,[17] $WCl_4(THF)_2$, and tungsten(IV) also forms isolable complexes with other Lewis bases, e.g. pyridine[18–20] and bipyridine.[21] Chloro complexes of tungsten(IV), e.g. WCl_6^{2-} are also known.[18] Tungsten(V) forms stable chloro complexes[22] but no simple stable Lewis base adducts besides WCl_5(bipyridine).[8] A brief note[23] describing some benzoic ester derivative is also known.

Complexes with nitrogen donor ligands

Compound **II** dissolves in neat pyridine. An orange solution is thus obtained which within 45 min deposits a small amount of an orange solid. Heating the mixture at reflux results in a dark red solution and more of the orange solid (**III**). After isolation of the solid from the hot solution the elemental anslysis and the IR spectrum reveals that this is the known *trans*-WCl_4(pyridine)$_2$.

Treatment of an etheral solution of **II** with one equiv. of pyridine at room temperature results in immediate darkening of the solution. Within a few minutes stirring a dark green precipitate (**IV**) forms. No definite conclusion as to the formulation of (**IV**) is obtained by elemental analysis.

Comparing the IR spectra of **III** and **IV** disclose similarities, i.e. coordinated pyridine in both substances as demonstrated by the three bands at 444, 683 and 1607 cm^{-1} in the spectrum of **III** and at 440, 680 and 1607 cm^{-1} in the spectrum of **IV**, but also differences in the region of metal halide vibrations. In the spectrum of **III** an intense band at 311 cm^{-1} is present, which is most likely the W—Cl stretch in a *trans*(*D4h*) arrangement of the two chloride ligands, while in the spectrum of **IV** two intense bands at 348 and 322 cm^{-1} are present.

On addition of allyltrimethylsilane (1.3 equiv.) to an ether solution of **II** at room temperature before the addition of pyridine (1 equiv.) a dark solution is obtained. From this solution dark black–green crystals (**V**) separate within minutes. Elemental analysis of this product is in accordance with the formula WCl_5(pyridine).

The IR spectrum of **V** is in many respects similar to the spectra of **III** and **IV**. The bands at 438, 687 and 1607 cm^{-1} showing coordinated pyridine are almost unshifted relative to those of **III** and **IV**. One intense band at 334 cm^{-1}, a shoulder at 350 cm^{-1} and a medium band at 392 cm^{-1} are present in the metal halide stretching region.

If it is considered that pyridine in its reaction with high valent metal ions possesses reducing properties[24,25] as well as complexing properties, the formation of the products **III**, **IV** and **V** can be rationalized. Excess pyridine and heating promotes the reduction to tungsten(IV) as in **III**, while stoichiometric amounts of pyridine at room temperature bring about only partial reduction leading to some kind of mixed tungsten(V)/(IV) product (**IV**) with coordinated pyridine. The isolation of analytically pure WCl_5(pyridine), which is a rare example of tungsten(V) nitrogen-coordinated complex, when allyltrimethylsilane is used as a co-reactant is most likely due to some kind of stabilizing effect of the olefin prohibiting the reduction to tungsten(IV). WCl_5(pyridine) is soluble in solvents such as toluene, benzene and chlorobenzene. In all these solvents red solutions are obtained, but the parent compound cannot be recovered.

As is the case with pyridine, bipyridine reacts with an ether solution of **II** at room temperature to yield a yellow–brown precipitate analysing approximately to a mixture of WCl_5(bipyridine) and WCl_4(bipyridine). This is in accordance with the observation in the case of pyridine and further studies were therefore not pursued. An impure compound of the formula WCl_5(bipyridine) was prepared recently[8] and described as being brick-red.

Chloro-complexes

Compound **II** dissolves in CH_2Cl_2 to produce a clear green solution. On addition of tetra-

phenylarsonium chloride in CH_2Cl_2 a red–brown solution is obtained. Within minutes of stirring a brown solid deposits. Brown crystals (**VI**) are isolated by cooling to −30°C and subsequent filtration. The elemental analysis and the IR spectrum shows that this is the known[22] $[WCl_6][AsPh_4]$. In a similar way the green tetramethylammonium salt is obtained.

The formation of the hexachloro coordinated anion WCl_6^- from (**II**) is strong evidence that (**II**) is a chloro complex of tungsten(V), most likely the ethyl ether adduct $WCl_5(OEt_2)$. A high excess of Cl^- has been observed to induce reduction of metal halides[24] but we are convinced that this is not the case in the present study.

Complexes with oxygen donors

Having reached a likely formulation of (**II**) we found it interesting to try to substitute diethyl ether by other oxygen donors.

On dissolution of **II** in THF by dropwise addition of THF to solid **II** heat is evolved and a yellow suspension is initially obtained. Further addition of THF gives a clear green solution. On continued stirring of this solution at room temperature it gradually changes to finally reach a turquoise colour. By reducing the volume and cooling to −25°C very air-sensitive turquoise crystals of **VII** deposit. The elemental analysis and IR spectrum reveal that this is $WOCl_3(THF)_2$. Precedence for oxygen abstraction reactions from THF can be found[26] although hexamethyldisiloxane seems to be the preferred reagent for this kind of reaction.[8,27] Other oxygen donors react differently. We have studied the reaction of **II** with 9-fluorenone, an example outside the ether class.

Dropwise addition of 9-fluorenone in CH_2Cl_2 into a solution of **II** in the same solvent gives an immediate precipitation of a dark solid. Isolation by filtration gives green–black crystals (**VIII**) which analyse for WCl_5(9-fluorenone). The formation of this compound does not necessarily implicate that 9-fluorenone is a better donor than diethyl ether with respect to tungsten(V). The low solubility of the fluorenone adduct shifts the equilibrium towards the formation of the fluorenone adduct.

All the reactions described and the products isolated in these reactions clearly demonstrate that the parent compound (**II**) must be WCl_5, probably as its diethyl ether solvate. Further proof for this is found in the UV spectrum of **II**. This spectrum shows an absorbance maximum at 298 nm which is in accordance with published data.[28] The reactions carried out also show that care must be taken if adduct formation is used as a method to characterize an unknown compound.

The reaction between WCl_6 and allyltrimethylsilane is in our opinion a convenient entry into tungsten(V) chemistry, easier than the older high temperature methods[29–33] to use. The method is easily applicable for the synthesis of quantities of about 10 g. The solubility of $WCl_5(OEt_2)$ in organic solvents makes this useful as a precursor for other tungsten(V) compounds.

Regarding the actual mechanism by which WCl_5 is formed in the present case, this is still an open question. The results presented here do not allow a distinction between direct reduction and a reaction path involving allylation of WCl_6 and subsequent reductive elimination as suggested in earlier studies. A direct reduction can proceed via chlorine radical transfer from WCl_6 to allyltrimethylsilane resulting in WCl_5, chlorotrimethylsilane and an allyl radical. Further reactions as dimerization of allyl radicals, recombination of allyl and chlorine radicals and hydrogen abstraction from a hydrogen source in the system could equally well, as the indirect reduction, explain the organic products 1,5-hexadiene, allylchloride and propene. The present study reveals, however, no formation of tungsten(IV), which must form in a mono-molecular reductive elimination from tungsten(VI).

EXPERIMENTAL

General procedures and chemicals

All preparations and reactions were carried out under an atmosphere of dried nitrogen or argon using conventional Schlenk techniques. Solvents were dried and stored over activated molecular sieves. Allyltrimethylsilane (Janssen Chimica) was distilled prior to use and stored over activated molecular sieves. Tetraphenylarsoniumchloride (Merck) was dried over Sicapent *in vacuo*. Tetramethylammoniumchloride was dried by vacuum treatment at 50°C for 48 h. 2,2-bypiridine (Merck) was recrystallized from ethanol prior to drying over Sicapent *in vacuo*. Tungsten hexachloride (Janssen Chimica) was purified from the volatile impurities by a continuous nitrogen flow at 120°C. Tungsten was determined gravimetrically as WO_3. Chlorine was determined by Mohr titration. Elemental analyses were done by Mikro Kemi AB, Uppsala, Sweden. IR spectra were recorded on a PE 580B spectrometer or on a Nicolet 20 SXC FT-IR spectrometer as Nujol or Fluorolube mulls between CsI windows or as CsI tablets. UV spectra were recorded in standard Schlenk tubes using a Guided

Wave, Model 260 fibre optic spectrophotometer equipped with an adjustable probe head.

Preparations

(1) *(Diethyl ether)pentachlorotungsten* (**II**). Allyltrimethylsilane (11 cm^3, 69 mmol) was added to a suspension of WCl_6 (6.8 g, 17.1 mmole) in diethyl ether (200 cm^3) at $-25°C$. Upon continuous stirring of the cold mixture WCl_6 gradually dissolved and after 24 h a clear solution and a green precipitate were obtained. The green solid (0.5 g) was separated by Schlenk filtration. Cooling the solution to $-25°C$ and concentration to *ca* 70 cm^3 afforded the first crop (1.9 g) of large black–green crystals. Further concentration to *ca* 20 cm^3 afforded 2.5 g and additional concentration afforded another 0.4 g. Total yield = 4.8 g (64%).

IR: W—Cl 315(s), 351(sh) cm^{-1} and coordinated ether, 1013 and 999 cm^{-1}. Found: Cl, 40.7. Calc.: Cl, 40.7%.

(2) *Bis(pyridine)tetrachlorotungsten* (**III**). **II** (0.45 g, 1 mmol) was dissolved in pyridine (25 cm^3) to give a clear orange solution. After stirring for 45 min at room temperature a small amount of an orange solid was formed. Heating the reaction mixture under reflux for 1.5 h afforded a dark red solution and an orange solid. The solid was isolated by filtering the hot mixture. The solid was washed with 3×5 cm^3 ether and dried *in vacuo*. Isolated yield = 0.20 g.

Found: C, 25.1; H, 2.1; N, 5.8; Cl, 27.7; W, 37.5. $C_{10}H_{10}N_2Cl_4W$ requires: C, 24.8; H, 2.1; N, 5.8; Cl, 29.3; W, 38.0%.

IR: W—Cl 311(s), 330(sh) cm^{-1} and coordinated pyridine, 1607, 683, 444 cm^{-1}.

(3) *(Pyridine)pentachlorotungsten* (**V**). **II** (0.75 g, 1.7 mmol) was dissolved in diethyl ether (30 cm^3) and the solution was filtered to give a clear solution. To this solution 0.36 cm^3 (2.3 mmol) of allyltrimethylsilane was added followed by an addition of 0.16 cm^3 (2 mmol) of pyridine. The solution darkened and dark crystals separated at once. The crystals were collected by filtration and dried *in vacuo*. The crystals were stable in air for a short period.

Found: C, 13.9; H, 1.0; N, 3.2; Cl, 39.0; W, 41.0. $C_5H_5NCl_5W$ requires: C, 13.6; H, 1.1; N, 3.2; Cl, 40.3; W, 41.8%.

IR: W—Cl 334(s), 350(sh), 392(mw) cm^{-1} and coordinated pyridine, 1607, 687 and 438 cm^{-1}.

(4) *Tetraphenylarsonium hexachlorotungstate*(V) (**VI**). Tetraphenylarsoniumchloride (0.8 g, 1.9 mmol) dissolved in CH_2Cl_2 (20 cm^3) was added dropwise to **II** (0.9 g, 2.1 mmol) dissolved in CH_2Cl_2 to give a red solution. After stirring for some minutes a brown solid deposited. Cooling to $-30°C$ and filtration afforded a brown solid (0.6 g). An additional 0.6 g was obtained by addition of CCl_4 (10 cm^3) to the filtrate. The solid can be recrystallized by dissolution in CH_2Cl_2 and precipitated by the addition of CCl_4. Total isolated yield = 1.2 g (81%). M.p. = 255°C (lit.[22] 253–256°C).

Found: C, 36.8; H, 2.5; Cl, 26.3; W, 23.3. $C_{24}H_{20}Cl_6AsW$ requires: C, 36.9; H, 2.6; Cl, 27.3; W, 23.6%.

IR: W—Cl 315(s), 332(sh), 350(m) and 385(w) cm^{-1}.

(5) *Bis(tetrahydrofuran)trichlorooxotungsten* (**VII**). THF (30 cm^3) was added dropwise to solid **II** (0.45 g, 1 mmol). On addition, heat was evolved and an initial yellow suspension was obtained which on further addition gave a green homogeneous solution. Further stirring at room temperature gave a turquoise solution. Reducing the volume to one third of the original volume and cooling to $-25°C$ for 3 days afforded turquoise air-sensitive crystals. These were separated, washed with diethyl ether and dried *in vacuo*.

Found: C, 20.3; H, 3.2; Cl, 23.3. $C_8H_{16}Cl_3OW$ requires: C, 21.3; H, 3.6; Cl, 23.6%.

IR: W—Cl 325(s), 351(m) cm^{-1}; W=O 998(vs), 1003(sh) cm^{-1} and coordinated THF, 1047 cm^{-1}.

(6) *(9-Fluorenone)pentachlorotungsten* (**VIII**). Fluorenone (0.54 g, 3 mmol) dissolved in CH_2Cl_2 (10 cm^3) was added dropwise to a solution of **II** (1.3 g) in CH_2Cl_2 (15 cm^3), whereupon a dark solid deposited. The black–green crystals were separated by filtration and washed repeatedly with diethyl ether before drying *in vacuo*.

Found: C, 29.5; H, 1.6; Cl, 32.5. $C_{12}H_6Cl_5OW$ requires: C, 28.8; H, 1.5; Cl, 32.7%.

IR (Fluorolube): C=O 1550(s,br) cm^{-1}; W—Cl 334(s), 385(m) cm^{-1}.

SYNTHESIS OF A NEW SERIES OF IRON COMPLEXES $Fe(C_5H_5)(CO)(EPh_3)SCOR$, $Fe(Bu^t\text{-}C_5H_4)(CO)(EPh_3)SCOR$ AND $Fe(1,3\text{-}Bu^t\text{-}C_5H_3)(CO)(PPh_3)SCOR$ (E = P, As, Sb) THROUGH PHOTOLYTIC CO-SUBSTITUTION. STUDY OF THE EFFECT OF R, E AND Cp-SUBSTITUENTS ON THE CO-SUBSTITUTION REACTIONS*

IBRAHIM JIBRIL,† MAHMOUD EL-HINNAWI and MOHAMMAD EL-KHATIB

(*Received* 20 *December* 1990; *accepted* 21 *June* 1991)

Abstract—A series of new half-sandwich iron thiocarboxylate derivatives $FeCp'(CO)(EPh_3)SCOR$ [$Cp' = C_5H_5$, $Bu^t\text{-}C_5H_4$, $1,3\text{-}Bu^t\text{-}C_5H_3$; E = P, As, Sb; R = CH_3, $C(CH_3)_3$, C_6H_5, $2\text{-}(O_2N)\text{-}C_6H_4$, $3,5\text{-}(O_2N)_2\text{-}C_6H_3$] has been prepared and characterized through photolytic CO-substitution reactions. The reaction times of these photolytic CO-substitution reactions reveal that these reactions are strongly influenced by the substituents on the Cp ring, R group of the thiocarboxylate moiety and the donor atom E of EPh_3.

The photolytic reactions between the half-sandwich iron complexes $FeCp(CO)_2X$ (X = halides, alkyls, SiR_3, SnR_3, SR) and ER_3 ligands ($E = P$, As, Sb) were commonly applied to prepare the CO-substituted complexes $FeCp(CO)(ER_3)X$. A thermal reaction was also used for the same preparation.[1–10]

The types and yields of the CO-substituted product obtained from any of these reactions are mainly determined by the nature of X and the type of ER_3 ligands. For example, the ionic species $[FeCp(CO)_2ER_3]X$ (X = halide) and the acetyl product $FeCp(CO)(ER_3)COCH_3$ ($X = CH_3$) are among the important products of such reactions.[1–5]

Reactions of $FeCp(CO)_2X$ (X = I, Br) with PMe_3 give $FeCp(CO)(PMe_3)X$, the ionic species $[FeCp(PMe_3)_3]X$ and $[FeCp(CO)_2(PMe_3)]X$ depending on the type of the solvent.[10] Moreover, the irradiation time, the molar ratios of the reactants, the reaction temperature, the nature of the transition metal in the complex and the wavelength range for the UV irradiation are also important factors in determining the type and yield of the different products obtained from a certain reaction.[4,6,11]

The effect of Cp substituents on the rate of thermal CO-substitution reactions has recently been studied on complexes $(C_5H_4X)Rh(CO)_2$ (x = NO_2, CF_3, Cl, H, CH_3 and $N(CH_3)_2$).[12] The study showed that the rate increases as the electron-withdrawing ability of the Cp substituent increases. The effect of electron-donating substituents on the Cp-ring is limited to $(C_5(CH_3)_5)Rh(CO)_2$, which decreases the rate of CO-substitution by 10^{-3} relative to the parent compound but some of this decrease is due to steric factors.[12]

On the other hand, a variety of photochemical deactivation pathways for the mononuclear intermediates $CpFe(CO)X$ have been reported. These include CO dissociation, homolytic or heterolytic metal–X bond cleavage, intramolecular isomerization and interligand rearrangements.[13]

In this study, we carried out the photolytic CO-substitution reactions of a series of new iron dicarbonyl cyclopentadienyl thiocarboxylates, $FeCp(CO)_2SCOR$ where R = CH_3 (**1**), $(CH_3)_3$-C (**2**), C_6H_5 (**3**), $2\text{-}O_2NC_6H_4$ (**4**) and $3,5\text{-}(NO_2)_2C_6H_3$ (**5**)[14,15] with EPh_3 (E = P, As, Sb) in THF at 0°C.

The photolytic CO-substitution reactions with some tert-butyl-substituted cyclopentadienyl derivatives of the iron thiocarboxylate complexes $Fe(Bu^t\text{-}C_5H_4)(CO)_2SCOR$ [R = CH_3 (**6**), C_6H_5 (**7**), $3,5\text{-}(O_2N)_2\text{-}C_6H_3$ (**8**)] and $Fe(1,3\text{-}Bu^t_2\text{-}C_5H_3)(CO)_2SCOR$ [R = CH_3 (**9**), C_6H_5 (**10**), $3,5\text{-}(O_2N)_2\text{-}C_6H_3$ (**11**)][16] are also included in this study.

* Dedicated to the memory of Dr Mahmoud A. El-Hinnawi.

† Author to whom correspondence should be addressed.

The cyclopentadienyl iron thiocarboxylates[1–5] and the tert-butylcyclopentadienyl iron thiocarboxylates[6–8] react with EPh_3 (E = P, As, Sb) to give exclusively the mono-CO-substituted derivatives $Fe(C_5H_5)(CO)(EPh_3)SCOR$ and $Fe(Bu^t\text{-}C_5H_4)(CO)(EPh_3)SCOR$, while the ditert-butylcyclopentadienyl iron thiocarboxylates[9–11] react only with PPh_3 to give the mono-CO-substituted derivatives $Fe(1,3\text{-}Bu^t\text{-}C_5H_3)(CO)(PPh_3)SCOR$ and fail to react with $AsPh_3$ and $SbPh_3$.

EXPERIMENTAL

All reactions and manipulations of chemicals were performed under nitrogen. Solvents were dried and purified by distillation. The thiocarboxylate iron complexes $FeCp(CO)_2SCOR$ (**1–5**), were prepared as described previously.[14,15] The thiocarboxylate derivatives $Fe(Bu^t\text{-}C_5H_4)(CO)_2SCOR$ (**6–8**) and $Fe(1,3\text{-}Bu^t\text{-}C_5H_3)(CO)_2SCOR$ (**9–11**) were prepared as previously reported.[16] A high-pressure mercury lamp (HANAU, 240–600 nm) was used for photolysis. IR spectra were recorded on a Pye–Unicam SP3-100 spectrophotometer. ^1H NMR spectra were recorded on Bruker WP80SY spectrometer with TMS as internal standard. Elemental analyses were performed by M-H-W Laboratories, Phoenix Arizona, U.S.A.

General procedure for the photolytic reaction of $FeCp(CO)_2SCOR$ *with* EPh_3 (E = P, As, Sb)

A THF solution (100 cm^3) of the iron thiocarboxylate complex $FeCp'(CO)_2SCOR$ (usually 1.0 mmol) together with excess (1.5–2.0 mmol) EPh_3 was irradiated at 0°C (ice-bath). The reaction was monitored by IR spectroscopy and irradiation continued until the reaction had gone to completion. This is identified by the disappearance of the two ν(CO) stretching bands in the ranges 2060–2028 and 1998–1980 cm^{-1} that correspond to the two terminal carbonyls in the starting material $FeCp(CO)_2SCOR$, and the appearance of a single ν(CO) stretching band in the range 1954–1915 cm^{-1} that corresponds to the carbonyl group of the CO-substituted products $FeCp'(CO)EPh_3SCOR$.

All reactions gave only the mono-CO-substituted products and no other derivatives were observed. The products were separated by column chromatography (Silica 70–230 mesh). The column was eluted first with 1 : 10 (V/V) ether/n-hexane to isolate the unreacted EPh_3 and then with 1 : 2 (V/V) ether/n-hexane to separate the product. The products were recrystallized from CH_2Cl_2/hexane. The reaction times and the yields are presented in Table 1. Spectroscopic data are presented in Tables 2 and 3. Colours, melting points and elemental analysis are shown in Tables 4 and 5.

RESULTS AND DISCUSSION

The photolytic CO-substitution reactions of the thiocarboxylate compounds **1–11** with excess EPh_3 (E = P, As, Sb) were carried out in THF at 0°C. Cooling was necessary to minimize decomposition and to obtain reasonable reactions rates. The photolytic reactions conducted in this study result exclusively in the formation of the mono-CO-substituted derivatives $FeCp(CO)(EPh_3)SCOR$, $FeCp^*(CO)(EPh_3)SCOR$ and $FeCp^{**}(CO)(PPh_3)$-SCOR [$Cp = \eta^5\text{-}C_5H_5$, $Cp^* = \eta^5\text{-}(Bu^t\text{-}C_5H_4)$, $Cp^{**} =$

The synthesized complexes were characterized by elemental analysis, IR and ^{1}H NMR spectra. The ^{1}H NMR spectra of all complexes (Tables 2 and 3) show the characteristic protons in their expected chemical shift regions. Selected ^{1}H NMR spectra for $Fe(C_5H_5)(CO)(PPh_3)SCO(3,5\text{-}(NO_2)_2C_6H_3$, $Fe(Bu^t\text{-}C_5H_4)(CO)(AsPh_3)SCOCH_3$ and $Fe(Bu^t_2\text{-}C_5H_3)(CO)(PPh_3)SCO(3,5\text{-}NO_2)_2C_6H_3$ are shown in Figs 1, 2 and 3, respectively. Assignment of the protons of the different ligands is based on reported literature.[16]

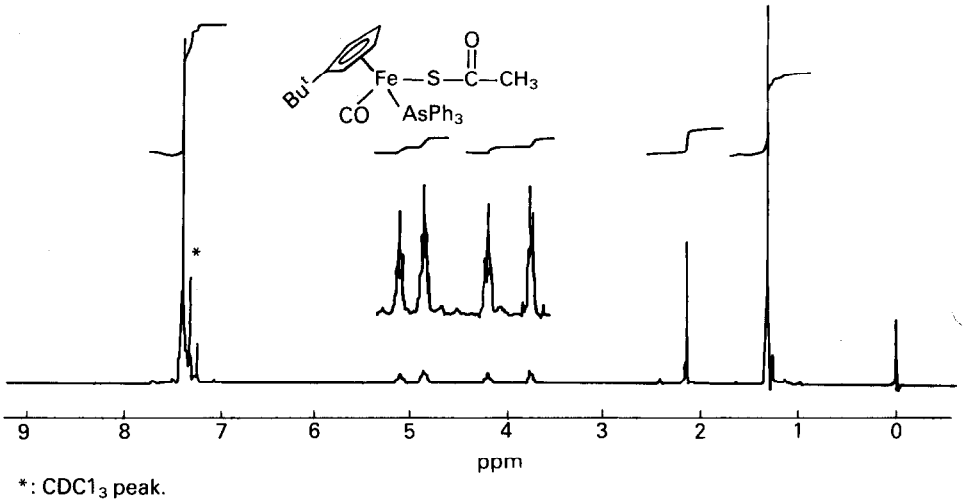
The IR spectra for the CO-substituted complexes are presented in Tables 2 and 3. The spectra of all complexes show one strong terminal CO stretching band and another two bands in the ranges 1525–1610 and 920–950 cm^{-1}, characteristic of the C=O and (C—S) bonds of the S-bonded thiocarboxylate group.[17]

The value of the CO stretching frequency in these complexes is influenced by EPh_3 and the Cp substituents. Thus, ν(CO) for complexes having the same *R* and cyclopentadienyl ligand follows the order $PPh_3 > AsPh_3 > SbPh_3$. This trend is attributed to the increase in the Fe $d\pi$–π^*CO back-donation in going from PPh_3 to $SbPh_3$ because the π-acceptor ability of these ligands is of the order $PPh_3 > AsPh_3 > SbPh_3$.[18] Moreover, ν(CO) for complexes having the same R and EPh_3 follows the order Cp > Cp* > Cp**. This observation could be attributed to the σ-donor strength of the cyclopentadienyl ligand which increases on going from Cp to Cp**. Therefore, alkyl substitution on the Cp ring leads to an increase in the electron density around the iron atom and consequently the Fe $d\pi$–π^*CO back-donation increases.

As mentioned earlier, all the photolytic reactions conducted in this study afforded exclusively the mono-CO-substituted derivatives, FeCp'(CO)(EPh_3)SCOR (Cp' = Cp, Cp*, Cp**). Neither the ionic [FeCp$(CO)_2$-(EPh_3)]SCOR nor the disubstituted [FeCp$(EPh_3)_2$SCOR] products were observed in any of the reactions tried. This could be attributed to the presence of a strong Fe—S bond and to the steric repulsion of the thiocarboxylate moiety with the entering group (EPh_3).

Table 1 shows the product yields and the reaction time data for these photolytic CO-substitution reactions. The reaction time data shows clearly the dependence of these reactions on three major factors, namely, the donor atom E of the reactant EPh_3, the R group of the thiocarboxylate moiety and the substituents on the cyclopentadienyl ligand.

As far as the donor atom E of EPh_3 is concerned, the study shows that the substitution reaction rate follows the order $PPh_3 > AsPh_3 > SbPh_3$. This result is consistent with the previously reported observations.[19] It could be attributed to the nucleophilicity and π-accepting ability of the EPh_3 ligands



*: $CDCl_3$ peak.

Fig. 2. ^1H NMR spectra of $Fe(Bu^t\text{-}C_5H_4)(CO)(AsPh_3)SCOR$.

that are in the order $PPh_3 > AsPh_3 > SbPh_3$.[10]

Considering the effect of the R group of the SCOR moiety, the reaction time data show that the reaction rate follows the order $3,5\text{-}(O_2N)_2\text{-}C_6H_3 > 2\text{-}(O_2N)\text{-}C_6H_4 > CH_3 > C(CH_3) > C_6H_5$. It seems that the reaction time decreases as the electronegativity of R increases, except for C_6H_5. This result could be related to a decrease in the Fe—(CO) bond strength as a result of decreasing the electron density on the sulphur atom and consequently increasing Fe $d\pi$–S $d\pi$ back-donation and decreasing the electron donation from Fe to CO(π^*).[14,15] However, a mechanistic study using additional R groups is certainly necessary to get a clear picture and to come out with reliable conclusions about the effect of R in these reactions.

This study also shows that the tert-butyl substituents on the Cp ring influence the substitution reactions. The reaction time data indicate that the rates of the CO-substitution reactions with PPh_3 follow the order Cp > Cp* > Cp**. Both steric and electronic effects of the tert-butyl groups might be considered in explaining this order.

Finally, the steric effects of the tert-butyl substituents seem to be the most important factor that explains the absence of any product in the reactions of $FeCp^{**}(CO)_2SCOR$ with the bulky $AsPh_3$ and $SbPh_3$ which have a larger cone angle than PPh_3.[17,20]

Abstract—The reduction of $Cl_2Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$ (**1**) with lithium has been investigated. A species with one tin–tin bond, as shown by ^{119}Sn NMR spectroscopy, believed to be $[(\eta^5\text{-}C_5H_5)(CO)_2Fe]ClSn—SnCl[Fe(CO)_2(\eta^5\text{-}C_5H_5)]$ (**2**), is formed as an intermediate. Further reduction results in the formation of $\{:Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}$ (**3**), which has been characterized by spectroscopic and analytical methods and is monomeric in benzene solution, as determined by cryoscopic molecular weight determination. The reactivity of **2** and **3** are discussed.

The synthesis of oligomers of the lower members of the Group 14 elements has been the subject of much study in recent years. Principally, three different synthetic approaches have been utilized to prepare oligomeric organo-germanium and organo-tin species. Linear organo-tin oligomers have been prepared in a stepwise fashion by the reaction of organo-stannyl anions with organo-tin halides.[1] Tin(II) halides have been reacted with Grignard reagents to form, oxidative coupling, a number of interesting spiro-cyclic organo-tin oligomers,[2–4] and the alkali metal-induced reduction of organo-germanium and tin halides has also resulted in the formation of a fascinating series of spiro-cyclic organo-germanium and tin species.[5–8] Other methods have also been used less widely, including thermolysis,[9] photolysis[10,11] and electrochemical reduction reactions.[12,13] We have recently demonstrated that the reduction of transition-metal substituted organo-halo germanes with lithium is an effective route for the formation of Ge—Ge bonds and that the substituent $[Fe(CO)_2(\eta^5\text{-}C_5H_5)]$ is inert to the reaction conditions.[14] However, there are surprisingly few examples of heavy Group 14 oligomers containing transition metal substituents. Pannell and co-workers have studied the synthesis and reactivity of transition-metal substituted organo-silyl compounds for many years[15] and have recently prepared some germanium and tin analogues. Mackay *et al.*[16–18] and Whitmore *et al.*[19] have prepared many examples of Group 14 elements containing transition-metal carbonyl clusters, and Lappert *et al.*[20] have prepared many species containing transition metal–Group 14 element bonds, but few examples contain Group 14–Group 14 elements bonds. We report here our findings on the reductive coupling of the transition-metal substituted halo-stannane, $Cl_2Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$.

EXPERIMENTAL

General procedures

All manipulations were carried out under an atmosphere of dry (4 Å molecular sieves), deoxygenated (MnO) nitrogen.[21] Hydrocarbon solvents were dried and distilled from sodium benzophenone ketyl and stored under nitrogen over molecular sieves. Deuterated NMR solvents were dried over 4 Å molecular sieves and stored under nitrogen. The starting material, $[Fe(CO)_2Cp]_2SnCl_2$, was prepared by the reaction of $SnCl_2$ (Aldrich) with $[Fe(CO)_2Cp]_2$ (Aldrich) using the method of Bonati and Wilkinson.[22] NMR spectra were recorded on a Bruker AC-250 NMR spectrometer. ^1H NMR chemical shifts were referenced to the protio impurity of the deuterated solvent, and ^{13}C NMR chemical shifts were referenced to the central ^{13}C

* Author to whom correspondence should be addressed.

NMR resonance of the deuterated solvent. ^{119}Sn NMR data were referenced to external Me_4Sn using the high frequency = positive sign convention. IR spectra were recorded on a Perkin–Elmer 1620 FTIR spectrometer. Mass spectral data were recorded on a Finnegan mass spectrometer. Elemental analyses were performed by Oneida Research Services.

Syntheses

(1) *Reaction condition A.* $Cl_2Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$ (0.52 g, 0.96 mmol) (**1**) was placed in a 250 cm^3 Schlenk flask and dissolved in 20 cm^3 of THF. An excess of lithium metal was added (15.3 mg, 2.2 mmol) and the mixture stirred at room temperature for 22 h. Immediately after the addition of lithium, the solution changed from orange to deep burgundy–red (3 h) and finally to red–brown after 22 h. During the reaction, samples were removed periodically in order to monitor the reaction by ^{1}H NMR spectroscopy, and the presence of an intermediate **2** was observed. After stirring for 22 h the volatile components were removed *in vacuo* to leave a red–brown residue, which was extracted with 3×20 cm^3 of toluene and filtered. The washings were combined, and the toluene was removed *in vacuo*. The residue was then washed with 4×10 cm^3 of n-pentane, dried *in vacuo* and weighed. The product (**3**) was isolated (0.225 g, 0.48 mmol) in 50% yield.

(2) *Reaction condition B.* A similar reaction was carried out on a larger scale where $Cl_2Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$ (2.00 g, 3.8 mmol) was dissolved in 80 cm^3 of THF in a 250 cm^3 Schlenk flask, and 80 mg (11 mmol) of lithium was added. The mixture was stirred at room temperature for a total of 36 h (when the reaction was complete). The volatile components were removed *in vacuo* to leave a red–brown residue, which was extracted with 4×20 cm^3 of benzene, filtered and the solvent removed *in vacuo* to give a red–brown solid. The product (1.80 g, 3.8 mmol) was obtained in quantitative yield.

Characterization data for **2**: ^{1}H NMR data (23°C, 250 MHz, C_6D_6): 4.66 ppm, s, $J(^{119,117}Sn—^1H) = 7.5$ Hz; (η^5-C_5H_5); ^{13}C NMR (23°C, 62.9 MHz, C_6D_6): 83.6 ppm, s, (η^5-C_5H_5); ^{13}CO was not observed; ^{119}Sn NMR data (23°C, 93.3 MHz, C_6D_6): 689.6 ppm, s, $J(^{119}Sn—^{117}Sn) = 2981$ Hz, 7.4%.

Characterization data for **3**: ^{1}H NMR data (23°C, 250 MHz, C_6D_6): 4.56 ppm, s, $J(^{119,117}Sn—^1H) = 5$ Hz (η^5-C_5H_5); ^{13}C NMR data (23°C, 62.9 MHz, C_6D_6): 84.5 ppm, s (η^5-C_5H_5); 215.5 ppm, s, $J(^{119}Sn—^{13}C) = 95$ Hz, CO; ^{119}Sn NMR data (23°C, 93.3 MHz, C_6D_6): 889.9 ppm, s. No change in line width was observed upon cooling to 183 K, but chemical shift changes were as follows (C_7D_8): 293 K, 887.5 ppm; 243 K, 894.7 ppm; 213 K, 899.5 ppm; 183 K, 904.4 ppm. IR data (KBr disc, cm^{-1}): 2007(s), 1964(s, br), 1915(s), 1429(w), 1413(w), 1001(w), 840(m), 637(m), 574(s), 512(m). Cryoscopic molecular weight determination (C_6H_6): molecular weight was measured at two different concentrations, 0.018 M and 0.033 M. The values were 437 ± 44 and 532 ± 35 Daltons, respectively. The calculated value for $\{Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}$ is 473 Daltons. Each value was determined by three measurements: Mass spectral data (70 eV): 474, M, 3%, $[SnFe_2(CO)_4(\eta^5\text{-}C_5H_5)_2]^+$; 446, M, 5%, $[SnFe_2(CO)_3(\eta^5\text{-}C_5H_5)_2]^+$; 416, M, 10%, $[SnFe_2(CO)_2(\eta^5\text{-}C_5H_5)_2]^+$; 388, M, 5%, $[SnFe_2(CO)(\eta^5\text{-}C_5H_5)_2]^+$; 360, M, 18%, $[SnFe_2(\eta^5\text{-}C_5H_5)_2]^+$; 295, M, 21%, $[SnFe_2(\eta^5\text{-}C_5H_5)]^+$ and/or $Fe_2(CO)_2(\eta^5\text{-}C_5H_5)_2$; 296, M. 8%, $[Fe_2(CO)(\eta^5\text{-}C_5H_5)_2]^+$; 242, M, 5%, $[Fe_2(\eta^5\text{-}C_5H_5)_2]^+$; 186, 100%, $[Fe(\eta^5\text{-}C_5H_5)_2]^+$; 121, 80%, $[Fe(\eta^5\text{-}C_5H_5)]^+$; 91, 63%; 56, 58%, Fe^+. Two other peaks of higher mass were also observed: 650, 12%, M; 509, 18%, M. The letter "M" indicates that more than one peak was found centred around the value of m/z quoted. For a number of these fragments marked "M", the intensity ratio of the peaks corresponded very closely to the isotope ratio expected for the combination $SnFe_2$ (especially $m/z = 474$, 446, 416, and 390). Found: C, 35.9; H, 2.1; N, 0.0. Calc. for $C_{14}H_{10}O_4Fe_2Sn$: C, 35.5; H, 2.1%. Different reaction performed under reaction conditions B; Found: C, 35.84; H, 1.72; N, 0.00%.

(3) *Reaction of 3 with ethyl iodide.* Compound **3** (120 mg) was dissolved in 10 cm^3 of benzene, and 0.7 cm^3 (an excess) of ethyl iodide was added. The mixture was stirred for 30 min, but no change was observed. The volatile components was removed *in vacuo*, and ^{1}H NMR spectroscopy revealed that **3** was recovered unchanged. ^{119}Sn NMR spectroscopy exhibited a resonance at the chemical shift of authentic **3**, which remained a singlet during a gated decoupling experiment.

(4) *Reaction of 3 with pyridine.* The final product (**3**) (0.104 g, 0.2 mmol) was dissolved in 10 cm^3 of toluene, and 3.5 cm^3 (44 mmol, a large excess) of pyridine was added. The solution was stirred at room temperature for 1 h and the volatile components removed *in vacuo*. ^{119}Sn and ^{1}H NMR showed that no pyridine was present and that **3** was recovered unchanged.

(5) *Reaction of a mixture of 2 and 3 with isobutyl magnesium chloride.* $Cl_2Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$ (0.52 g, 0.96 mmol) was dissolved in 50 cm^3 of THF in a 100 ml Schlenk flask and lithium was added (9.6 g). The reaction mixture was monitored by ^{1}H

NMR spectroscopy and allowed to react until all the starting material had been consumed and a mixture of **2** and **3** remained. After 5 h, the ^1H NMR resonance of **1** was barely detectable. At this stage, the volatile components were removed *in vacuo*, and the deep red–brown residue was extracted with 13 cm^3 of toluene, washed with 4 cm^3 of toluene, the washings combined, and the flask placed in the freezer at −10°C. After 30 h, only a very small amount of microcrystalline material was formed. A small portion (3.5 cm^3) of this solution was removed for other experiments. The ratio of **2** : **3** in the remaining 13.5 cm^3 was found to be 28 : 72 by integration of the respective ^1H NMR cyclopentadienyl resonances. To half of this solution was added approximately 0.1 cm^3 of an ether solution of 2 M isobutyl magnesium chloride; a slight excess, assuming **2** contains two chloride substituents per molecule. The mixture was stirred for 1 h at room temperature during which time the solution turned deep red. The volatile components were removed *in vacuo*, and the residue was extracted with three 10 cm^3 portions of toluene extracted with three 10 cm^3 portions of toluene. ^1H NMR spectroscopy of the crude toluene extract showed that **3** was still present, but the cyclopentadienyl resonance of **2** had disappeared and a new resonance at 4.45 ppm was present in approximately the ratio relative to **3** as the original mixture of **2** : **3**.

RESULTS

The reaction of $[(\eta^5\text{-}C_5H_5)(CO)_2Fe]_2SnCl_2$ (**1**) with lithium metal results in the smooth formation of a reactive intermediate (**2**) and a final product (**3**), which analyses correctly as $\{Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}_n$ according to eq. (1). Intermediate **2** is quantitatively converted into **3** by lithium after **1** has been completely consumed.

$$\underset{\mathbf{1}}{[(\eta^5\text{-}C_5H_5)(CO)_2Fe]_2SnCl_2} \xrightarrow{Li} \underset{\mathbf{2}}{[\text{intermediate}]} \xrightarrow{Li} \underset{\mathbf{3}}{\{Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}_n} \quad (1)$$

This reaction is conveniently monitored by ^1H NMR spectroscopy by removing small aliquots of the reaction mixture at various intervals, removing the solvent *in vacuo*, and dissolving the residue in a deuterated solvent (benzene-d_6). Under the reaction conditions A, as described in the Experimental, the reaction of **1** with lithium metal for 3 h results in the formation of a deep burgundy–red solution, and ^1H NMR spectroscopy reveals that three cyclopentadienyl-containing species exist. These three species have ^1H NMR chemical shifts of 4.29, 4.54 and 4.66 ppm in the relative ratios 1 : 8.2 : 6, respectively. The ^1H NMR chemical shift of 4.29 ppm is consistent with the cyclopentadienyl resonance of the starting material (**1**), while 4.54 ppm is observed to be the chemical shift of the cyclopentadienyl resonance of the final product (**3**). All three resonances exhibit coupling to a single type of NMR-active tin nuclei (^{119}Sn: $I = 1/2$, natural abundance = 8.58%; ^{117}Sn: $I = 1/2$, natural abundance = 7.61%) with coupling constants of approximately 5 Hz. After 6 h, the starting material was barely detectable, and the resonances at 4.54 and 4.66 ppm were present in the integrated ratios 1 : 0.6, respectively. As the reaction proceeds further, the resonance at 4.54 ppm grows at the expense of the resonance at 4.66 ppm until, after 22 h, only the cyclopentadienyl resonance at 4.54 ppm is observed. ^{119}Sn NMR spectroscopy of the reaction mixture after 6 h reveals the presence of two ^{119}Sn NMR resonances. One resonance at 892.1 ppm corresponds to the resonance of the final product, while the other resonance occurs at 689.6 ppm and exhibits coupling to ^{117}Sn, where $J(^{119}Sn—^{117}Sn) = 2981$ Hz corresponding to $J(^{119}Sn—^{119}Sn) = 3119$ Hz with an integrated relative intensity that is consistent with the presence of one Sn—Sn bond (see Fig. 1). When the same reaction is carried out under slightly different conditions (Experiment B), the relative concentration of the NMR resonances at 4.66 ppm (^1H NMR) and 689.6 ppm (^{119}Sn NMR) increase, corresponding to intermediate **2**.

Elemental analysis of the final product of reductive coupling (**3**) is consistent with the empirical formula $\{Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}_n$. Cryoscopic molecular weight determinations performed at two different concentrations indicate that **3** is monomeric in benzene solution. Confirmation that the Sn—Fe bond is intact in **3** comes from ^{13}C NMR spectroscopy of the carbonyl ligands in which coupling to both ^{119}Sn and ^{117}Sn is observed where $J(^{119}Sn—^{13}C) = 95$ Hz. In comparison, we have observed that $^2J(^{119}Sn—^{13}C) = 149$ Hz for the carbonyl ligands of **1** (see Fig. 2). The ^1H, ^{13}C and ^{119}Sn NMR spectra of both **2** and **3** are temperature invariant over the range 343–183 K. The IR spectrum of **3** is analogous to that of **1** and $[(\eta^5\text{-}C_5H_5)(CO)_2Fe]_2$. Unfortunately, attempts to isolate the intermediate (**2**) free of either starting material or final product have been unsuccessful. Attempts to monitor this reaction by UV–vis spectroscopy were irreproducible probably as a result of the photolytic lability of these compounds. We did not observe any reaction between **3** and either

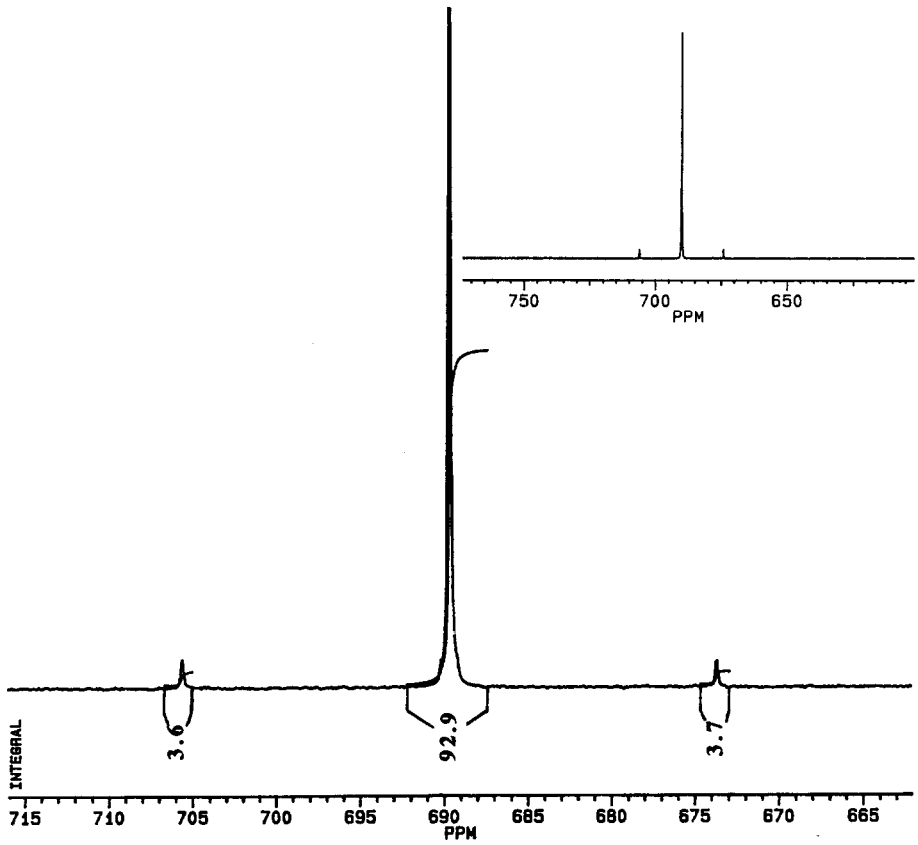

Fig. 1. Proton decoupled ^{119}Sn NMR spectrum of intermediate **2**, showing the ^{117}Sn satellite corresponding to the presence of one tin–tin bond.

ethyl iodide or pyridine under the conditions described in the Experimental. However, **2** reacted with isobutyl magnesium chloride.

DISCUSSION

The goal of this work is to explore the reductive coupling of transition-metal substituted halo-stannanes as a method for the formation of transition-metal substituted oligostannanes. In analogous reactions involving cyclopentadienyldicarbonyl-ferrio-substituted germanium species, we have shown that lithium-induced reductive coupling of Ge—Ge bonds occurs and that the $[Fe(CO)_2Cp]$ moiety is inert to these reaction conditions.[14] A control experiment was conducted according to eq. (2)

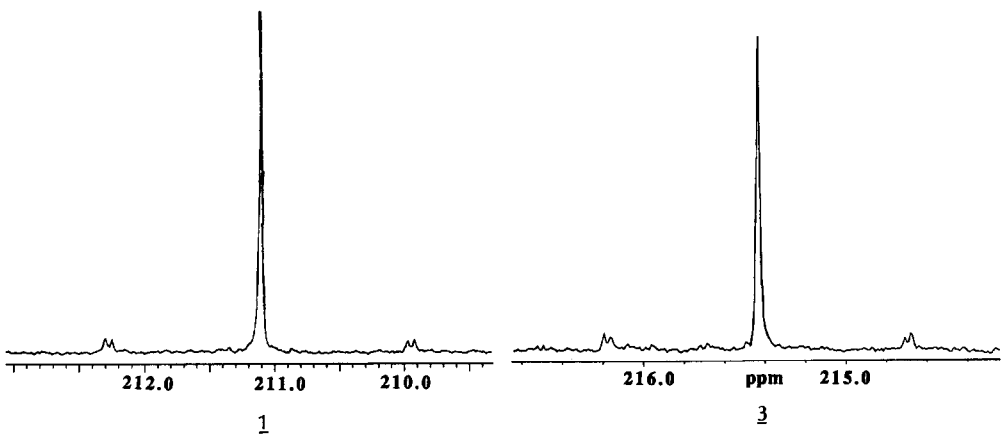

Fig. 2. Proton decoupled ^{13}C NMR spectra of the carbonyl region of **1** and **3**, showing the coupling to ^{117}Sn and ^{119}Sn.

$$[\eta^5\text{-}C_5H_5(CO)_2Fe]R_2GeCl + Li \xrightarrow{THF} 1/2\{[\eta^5\text{-}C_5H_5(CO)_2Fe]R_2Ge\}_2 + LiCl \quad (2)$$

in which the presence of a Ge—Ge bond was conclusively established by single crystal X-ray diffraction. In the present work, the reductive coupling of $Cl_2[SnFe(CO)_2(\eta^5\text{-}C_5H_5)]_2$ appears to follow a different course in which a species containing one tin–tin bond and $[Fe(CO)_2Cp]$ substituents is formed as an intermediate *en route* to isolation of $\{Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}$. We propose that the most likely possibility for the identity of intermediate **2** is 1,2-dichloro-1,1,2,2-tetra(cyclopentadienyldicarbonylferrio)ditin, as shown in eq. (3).

$$\underset{\mathbf{1}}{Cl_2Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2} \xrightarrow{Li} \underset{\mathbf{2}}{[(\eta^5\text{-}C_5H_5)(CO)_2Fe]_2ClSn—ClSn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2} \xrightarrow{Li} \underset{\mathbf{3}}{\{Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}} \quad (3)$$

The fact that **2** contains a tin–tin bond is clearly demonstrated by ^{119} Sn NMR spectroscopy where the tin–tin coupling constant is in the range expected. Unfortunately, since **2** has not been isolated, pure analytical data are not available. However, the presence of Sn—Cl bonds in **2** is consistent with the observations that, in the absence of lithium, solutions containing a mixture of **2** and **3** do not change (in the absence of light) and that **2** reacts with isobutyl magnesium chloride, whereas **3** does not. 1,2-dibromo-1,1,2,2-tetra(pentacarbonylmanganio)ditin has previously been unambiguously characterized[23] as the product of the reaction of $H_2Sn_2[Mn(CO)_5]_2$ with CBr_4.[24] Unfortunately, there are no NMR data available for these species for comparison to **2**.

In the presence of lithium, **2** reacts further to form the heavy metal carbene analogue (**3**) in preference to either an oligomeric tin species or a distannylene. All characterization data for **3** are consistent with the presence of a monomeric heavy carbene analogue, $\{:Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}$, in solution. The possibility that the final product (**3**) exists as an equilibrium mixture of a number of different species is inconsistent with the variable temperature NMR data, where no changes were observed (assuming the rates of exchange are the same order as the NMR time scale). The presence of isocarbonyl–tin bonds was recently observed in similar tin species such as $\{Fe(CO)_3(\mu\text{-}CO)Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}$-(O, Sn), but can be ruled out in the case of **3** as a result of the lack of an IR band in the vicinity of 1866 cm^{-1} in the solid state.[20] Other examples of transition-metal substituted stannylenes have been claimed,[25,26] such as $\{Sn[M(CO)_3(\eta^5\text{-}C_5H_5)]_2\}$, where M = Mo and W, but they have been refuted.[27] However, authentic examples of transition-metal substituted plumbenes have been prepared and unambiguously characterized, such as $\{Pb[Mo(CO)_3(\eta^5\text{-}C_5H_5)]_2\}$.[25] It is worth noting that, in the absence of a Lewis base (such as THF), the bis(metallaplumbene exists as a dimer with isocarbonyl bridges and two types of cyclopentadienyl NMR resonances. Attempts to isolate the base stabilized adduct of **3** $\{:Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2 \cdot py$, were unsuccessful. This is consistent with the observation that **3** is not isocarbonyl bridged in the solid state.

Other examples of $[E(M'L_n)_2]$, where E = a lower Group 14 element, have been prepared and authenticated by single crystal X-ray diffraction, but are best considered as derivatives of Ge^{IV} or Pb^{IV}.[28–33] This chemistry has been extensively reviewed recently.[34–37]

Summary

The reductive coupling of $Cl_2Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2$ with lithium metal in THF solution results in the formation of a species containing one tin–tin bond believed to be $[(\eta^5\text{-}C_5H_5)(CO)_2Fe]Cl\,Sn—SnCl[Fe(CO)_2(\eta^5\text{-}C_5H_5)]$ which, upon further reduction, forms $\{Sn[Fe(CO)_2(\eta^5\text{-}C_5H_5)]_2\}$ rather than transition-metal substituted tin oligomers.

CADMIUM HALIDE COMPLEXES WITH PYRIDINE-N-OXIDE, AND THEIR CRYSTAL STRUCTURES

MARK NIEUWENHUYZEN, WARD T. ROBINSON* and CUTHBERT J. WILKINS*
Chemistry Department, University of Canterbury, Christchurch, New Zealand

(*Received* 4 *March* 1991; *accepted* 18 *June* 1991)

Abstract—Cadmium chloride and bromide form crystalline pyridine-N-oxide (pyo) complexes $[\{(CdCl_2)_3(pyo)_2\}_n]$ (**1**) and an isomorphous pair $[\{CdX_2(pyo)\}_n]$, X = Cl (**2A**), Br (**2B**). X-ray analysis of their structures shows them to have layer lattices arising from removal of a proportion of CdX_2 units from the cadmium halide structures. There is retention of six-coordination through insertion of pyo bridges. The pyo rings overlie the voids created by removal of the cadmium centres. Complexes **2A** and **2B** have the chromium chloride connectivity. The cadmium iodide lattice is more readily degraded and a series of compounds having increasing pyo content is formed; *viz* $[\{CdI_2(pyo)\}_n]$ (**3**) (an already known chain polymer), $[\{(CdI_2)_2(pyo)_3\}_n]$ (**4**), $[\{CdI_2(pyo)_2\}_2]$ (**5**), and $[Cd(pyo)_6]^{2+}$ $[CdI_4]^{2-}$ (**6**). Compound **4** is a chain polymer with mixed iodo- and oxo-bridges, and alternating five- and six-coordinated cadmium centres. Compound **5** is a pyo-bridged dimer with five-coordinate cadmium. In both **4** and **5** pyo plays both bridging and terminal roles. There is a methanolate derivative of **5**, $[\{CdI_2(pyo)_2(MeOH)\}_2]$ (**5A**), with six-coordinate cadmium. The structures show the ease with which cadmium moves between five- and six-coordination, as well as the breaking of the Cd—I bond. In these structures cadmium shows no evidence of any disposition towards the strong digonal bonding characteristic of mercury(II).

Cadmium halides form a wide range of coordination complexes,[1,2] with variety promoted not only by ligand characteristics,[3] but also by the ready variation in coodination number and stereochemistry permitted by the d^{10} configuration of a cadmium centre. With monodentate ligands of low steric demand, e.g. pyridine[4] or formamide,[5] formation of $CdX_2 \cdot L_2$ compounds having linear halogen-bridged chain structures with six-coordinate cadmium are common. There are also a few zigzag or double chain structures formed by $CdCl_2 \cdot L$ derivatives, as with methylurea[6] or water[7] in the monohydrate. In these, there is fusion of a pair of single chains by way of triple bridging provided by half the chlorine atoms. This triple bridging offsets the lower ligand : halide ratio and maintains the six-coordination. If a ligand itself were to have bridging properties there might be other variations.

The high polarity of the N—O bond in pyridine-N-oxide (pyo) means that it has both bridging capacity and the ability to promote ionization[8] through the formation of cations $[M(pyo)_6]^{n+}$. It is known to form cadmium halide derivatives $(CdCl_2)_3(pyo)_2$ (**1**), $CdBr_2(pyo)$ (**2B**) and $CdI_2(pyo)$ (**3**), all with low pyo : halide ratios.[9] The structures of the first two have remained unknown, but the last has been shown to have a polymeric chain structure of yet another type with bridges formed alternately by a pair of iodine atoms and a pair of oxygen atoms.[10] The cadmium is five-coordinate, with terminal linkage to the remaining iodine. With this interesting behaviour there seemed a case for closer examination of the behaviour of pyo towards cadmium halides, and determination of the structures of other derivatives.

It was confirmed first, that compounds **1**, **2B** and $CdCl_2(pyo)$ (**2A**), which is isomorphous with **2B**, are the only crystalline products obtainable from the chloride and bromide under our conditions. The

compounds have layer lattices with ligand bridges, which represent only modifications of the parent CdX_2[11] structure. With cadmium iodide on the other hand, there is more complete degradation of the lattice and increase in the pyo : CdI_2 reactant ratio produces a succession of derivatives **3**, **4**, **5** and **6**, as listed in Table 1. There is a methanolate (**5A**) akin to **5**.

EXPERIMENTAL

Preparations

The compounds were obtained by direct reaction of the halide with pyo in ethanol or methanol. Ligand : halide ratios were varied between equimolecular and 12 : 1, or greater. Methanol provided greater solubility for the parent cadmium halide and faster reaction. It was suitable for the preparation of **1**, **2A**, **2B** and **4**, but ethanol was preferable for **5** and essential for **3** and **6**. Preparation of all cadmium iodide derivatives is, however, prone to complication through the initial appearance of non-equilibrium phases (and some irreproducibility), evidently through lack of requisite nucleation for the equilibrium phases. For recovery, crystals were rinsed with triethoxymethane and dry ether, and dried under a nitrogen stream. Analytical compositions of products are given in Table 2.

$[\{(CdCl_2)_3(pyo)_2\}_n]$ (**1**). With modification of the earlier procedure,[9] pyo (2 mM) in methanol was added to $CdCl_2 \cdot 2.5H_2O$ (2 mM) in boiling methanol (100 cm^3) containing triethoxymethane (4 cm^3). The solution was boiled, filtered, and evaporated to *ca* 40 cm^3. A mass of fine crystals (elongated plates) appeared. Larger single crystals suited to diffractometry were obtained as single or clustered plates by evaporating the mother liquor to half volume and allowing crystallization at *ca* 5°.

$[\{CdCl_2(pyo)\}_n]$ (**2A**). Using a similar procedure, but with the pyo : halide ratios not less than 6 : 1, and boiling for 1 h, analytically pure **2A** separated in finely divided form. Larger crystals were not obtainable, but structural identity with the bromide (**2B**) is shown by powder diffraction data (Table 3).

$[\{CdBr_2(pyo)\}_n]$ (**2B**). The primary product from methanol[9] was finely divided, but recrystallization from dilute solution gave clear (leaf-like) plates, but rather inferior for structure analysis. Variation of reactant ratios did not lead to different products.

$[\{CdI_2(pyo)\}_n]$ (**3**). Clear acicular crystals were obtained from ethanol.[9,10] Use of methanol usually gave **4** and/or **5**, but occasionally large tabular crystals of **3** slowly appeared. The identity of such mor-

phologically different crystals was provided by cell parameters on a broken fragment.

$[\{(CdI_2)_2(pyo)_3\}_n]$ (**4**). This product, usually in admixture with **5**, crystallized from methanol solutions having pyo : CdI_2 in the wide range 1 : 1 to 6 : 1, e.g. pyo (1.5 mM) and CdI_2 (1 mM) in 12 cm^3. The clear crystals were diamond-like with bevelled edges. They were readily distinguished and separated from those of **5** under the microscope. Surprisingly, this product was also obtained (though now in acicular form) from ethanol containing very high pyo : CdI_2 ratios (18 : 1). Its appearance over such varying pyo concentrations shows its crystal nucleation can occur preferentially.

$[\{CdI_2(pyo)_2\}_2]$ (**5**) *and* $[Cd(pyo)_6]^{2+}[CdI_4]^{2-}$ (**6**). Clustered crystals of **5** together with individual prisms suitable for diffraction separated from solutions containing pyo (3 mM) and CdI_2 (0.5 mM) in boiling ethanol (10 cm^3). Dissolution was not complete, but clear crystals separated from the mother liquor.

Crystals of **6** slowly separated when a solution obtained by boiling pyo (5–6 mM) and CdI_2 (0.5 mM) in ethanol (12 cm^3) was allowed to stand.

The methanolate $[\{CdI_2(pyo)_2(MeOH)\}_2]$ (**5A**). Crystallization of this phase from methanol is favoured by reduced temperature, but can be prejudiced by prior crystallization of **5**. Cadmium iodide (0.035 mM) and pyo (7.0 mM, large excess) dissolved in boiling methanol (10 cm^3) gave crystals of **5** at room temperature. However, over a period of 4 weeks there was growth of clear tabular crystals of **5A**. The dry crystals are unstable in air at room temperature, probably due to superficial loss of methanol.

X-ray structure determination. The general procedure was as peviously described.[12] Crystals were held at *ca* 150 K, and ω scans were used. The usual scan speed was 4.88° min^{-1}, over the 2θ range 4–50 or 60°. Details on crystal data, other experimental conditions etc. are given in Table 4. Heavy atoms were located from Patterson maps, and other atoms from difference Fourier syntheses. Hydrogen atoms were introduced at idealized positions, but in **5A**, where the hydrogen atoms appeared, the position of the hydroxylic proton was allowed to refine. The function minimized in the least-squares refinement, with anisotropic thermal parameters, was $\Sigma w(|F_o| - |F_c|)^2$, and reflection weights $w = [\sigma^2|F_o| - g|F_o|^2]^{-1}$. The SHELXTL package[13] was used for data reduction and structure solution.

The more significant bond lengths and angles are listed in Table 5. Additional material available from the Cambridge Crystallographic Data Centre com-

RESULTS AND DISCUSSION

Comments on the structures of individual compounds

The structures show that at the lower pyo : CdX_2 ratios, pyo engages in bridging before terminal bonding develops. This ligand bridging can be by pyo pairs (as in **2**, **3** and **5**) or through mixed bridging with halide (as in **1** and **4**). This compatibility of the O and X atoms for bridging metal centres arises from the ease with which the atoms can accommodate bond angle variations.[12,14] It would also seem to reflect the prior existence in solution of halide-bridged species which can become ligand stabilized.

$[\{(CdCl_2)_3(pyo)_2\}_n]$ (**1**) *and* $[\{CdX_2(pyo)\}_2]$ (**2A**), (**2B**). These layer lattice structures both relate to the "parent" CdX_2 structure,[11] but not directly to one another. In the layer lattice of **1** there are two different octahedral cadmium environments. Cd(1) is linked diametrically to a pair of simple-bridging Cl(2) atoms, a pair of triple-bridging Cl(3) atoms, and a pair of bridging ligands, as in Fig. 1. Coordination around Cd(2) is provided by two Cl(1) atoms, one Cl(2), two Cl(3) and a ligand bridge. The Cl(2)/Cl(3) combination provides bridging to a Cd(1) centre, ligand/Cl(3) to a second Cd(1), and the two equivalent Cl(1)/Cl(3) combinations to two different Cd(2) centres.

In an atom row in the A···A′ direction there are seen to be alternating Cd(1) and Cd(2) centres, but in the adjacent parallel rows the Cd(1) atoms are omitted at the positions marked *. The ligand rings extend across the voids. There are thus twice as many Cd(2) as Cd(1) centres, and the ligand count is two-thirds of the total of cadmium centres. The Cd(1) atoms within each layer are coplanar, with z coordinates 0.5, but the conjunction of simple and triple-bridging causes the Cd(2) atoms to lie alternately 1.82 Å above and below this 002 plane. The complexity of the Cd—Cl bonding accounts for the inadequacy of IR evidence towards indication of the structure.[9]

In **2A**/**2B** the layer structure is more simple. The cadmium atoms all lie in the one plane and their six-coordination is provided by two pairs of bridging halogen atoms and one pair of bridging ligand oxygen atoms. In relation to the CdX_2 structure there is omission of every third cadmium centre (together with two corresponding bridging halogens) along

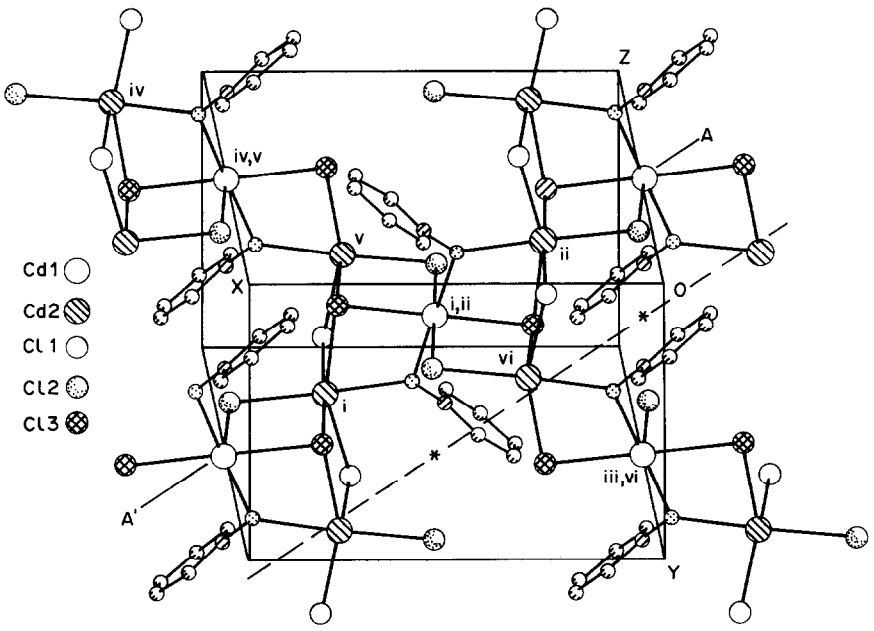

Fig. 1. A single layer for **1** as viewed nearly in the [011] direction. The origin is at the lower rear right of the cell. The z coordinates of Cd(1) atoms are 0.5, but those of alternate Cd(2) are 0.42 and 0.58, respectively. Unoccupied Cd(1) positions (as compared with a $CdCl_2$ lattice) are indicated by *. Symmetry codes shown for cadmium atoms are: (i) x, y, z; (ii) $1-x, 1-y, 1-z$; (iii) $\frac{1}{2}-x, \frac{1}{2}+y, z$; (iv) $\frac{1}{2}+x, \frac{1}{2}-y, 1-z$; (v) $1\frac{1}{2}-x, y-\frac{1}{2}, z$; (vi) $x-\frac{1}{2}, 1\frac{1}{2}-y, 1-z$.

diagonals in the B—B′ direction as seen in Fig. 2. All bridging atoms are thereby reduced to a two-way rather than a triple-bridging role. The "missing" halogen bridges are replaced by ligand oxygen bridges. The connectivity so developed corresponds precisely with that in the chromium trichloride structure.[11b,15] Pairs of pyo rings are disposed above and below the voids arising from cadmium omission, as with **1**. The rings projecting from the layers provide the relatively few approaches (to Br) which are mainly responsible for inter-layer cohesion. Even so, the Br—C(H) inter-layer closest approaches, 3.7(3.0)–3.75(3.1) Å, are slightly longer than the intra-layer approaches, *ca* 3.6(2.8) Å. The weak cohesion would seem to underlie not only the poor crystal development, but also the probability of a small degree of layer misplacement. We have observed that for different crystals the cell parameters c and β are variable. On one crystal the c value, which is determined by inter-layer spacing, was 10.381 Å (cf. 10.309 in Table 4).

It will be noticed that the *trans* disposition of the ligands around Cd(1) in **1** contrasts with the *cis* disposition of the ligand pair in the **2A/2B** structure, the configuration having to meet the demands of bridging in each case. Therefore, while structures **1**, **2A/2B** provide octahedral bonding arrangements which carry increasing ligand content, they do not represent a strictly progressive structural sequence.

$[\{CdI_2(pyo)\}_n]$ (**3**) *and* $[\{CdI_2)_2(pyo)_3\}_n]$ (**4**). As compared with the foregoing polymeric layer structures, the chain structure of **3** indicates, not unexpectedly, that the CdI_2 lattice is more readily degraded than the $CdCl_2/CdBr_2$ lattices. The five-fold cadmium coordination approximating to trigonal bipyramidal (tbp) has received comment.[10]

The chain structure of **4**, Fig. 3, with non-equivalent atoms (oxygen and iodine) paired for bridging contrasts with the equivalent-pair bridging in **3**. The increased ligand content of solutions suited to crystallization of **4** has resulted in the appearance of six-coordinated cadmium centres alternating with five-coordinated along the chain. Iodine and oxygen occupy diametrically opposite positions in the (distorted) octahedron around Cd(1). The Cd(2) environment again approaches tbp, with relatively weak bonding to the ligand oxygen atoms in the apical positions. Going on the chain geometry, it seems to be this tbp bonding influence that underlies the alteration in bridging structure in **4** as compared with **3**.

Within the cell of **4**, the chains lie in the [010] direction. As to be expected, chain packing is determined both by chain conformation and the dis-

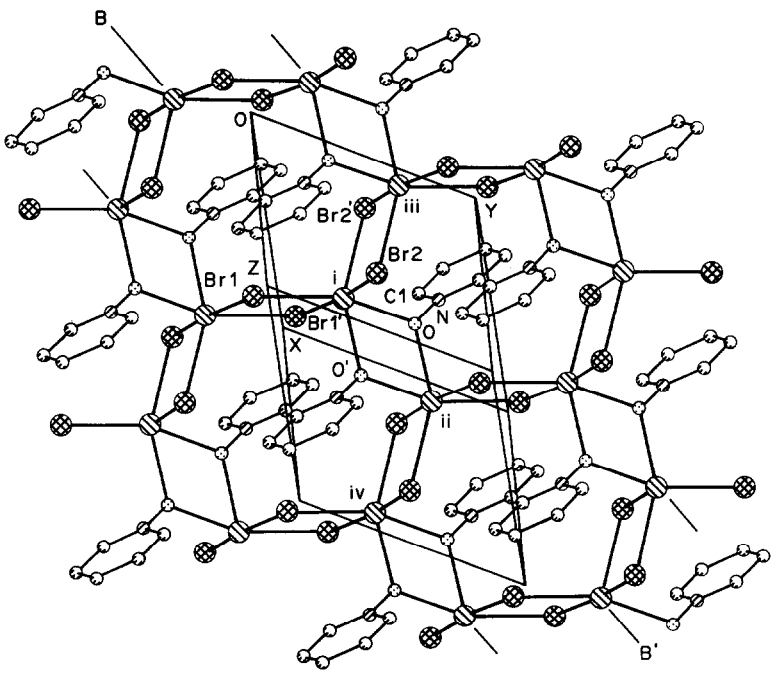

Fig. 2. A single layer of **2** as seen looking towards the [101] direction, with the origin at the top rear left. The disposition of the ligand rings above and below the voids is evident. Symmetry cores for the cadmium centres are: (i) x, y, z; (ii) $1-x, 1-y, 1-z$; (iii) $-x, 1-y, 1-z$; (iv) $x+1, y, z$.

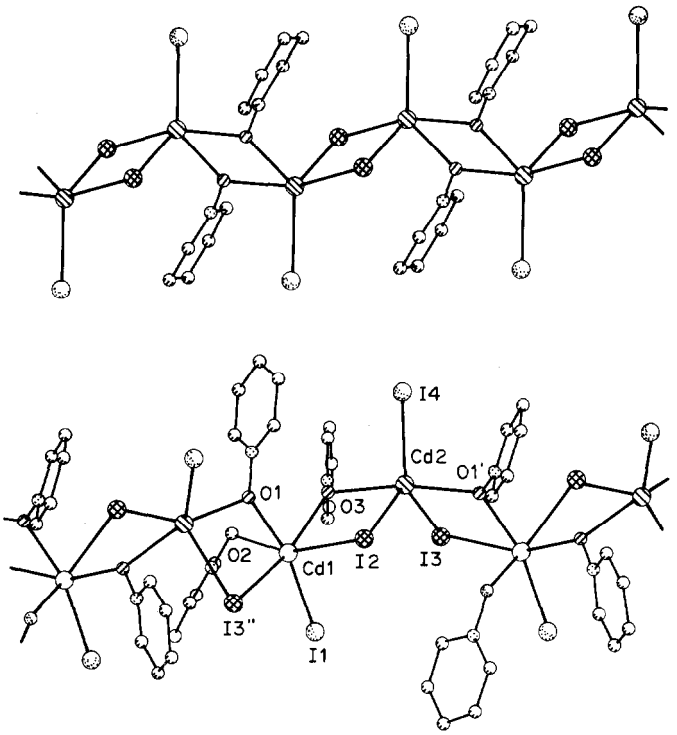

Fig. 3. The chain structures of **3** (upper) and **4** (lower), showing the differing bridging. The structure of **3** is replotted from coordinates given in ref. 10. In **4** there is an alternation of six-coordinate Cd(1) and five-coordinate Cd(2) centres. Bridging oxygen atoms occupy apical positions, and three iodine atoms (two of them bridging) are in equatorial positions around Cd(2). The repeat distance, parallel to the *y* axis of the cell, extends over two asymmetric units.

position of the pyo rings. The shortest inter-chain C—I approaches are 3.8–4.0 Å.

$[\{CdI_2(pyo)_2\}_2]$ (**5**) *and* $[\{CdI_2(pyo)_2(MeOH)\}_2]$ (**5A**). In **5** the coordination is seen to have reverted to five (Fig. 4), although conversion back to the six-coordinate methanolate (**5A**) occurs quite readily. The higher pyo proportion has caused the polymeric chain to break into binuclear molecules. The cadmium environment is still best considered as tbp, even though the O_1—Cd—O_2 angle has fallen to

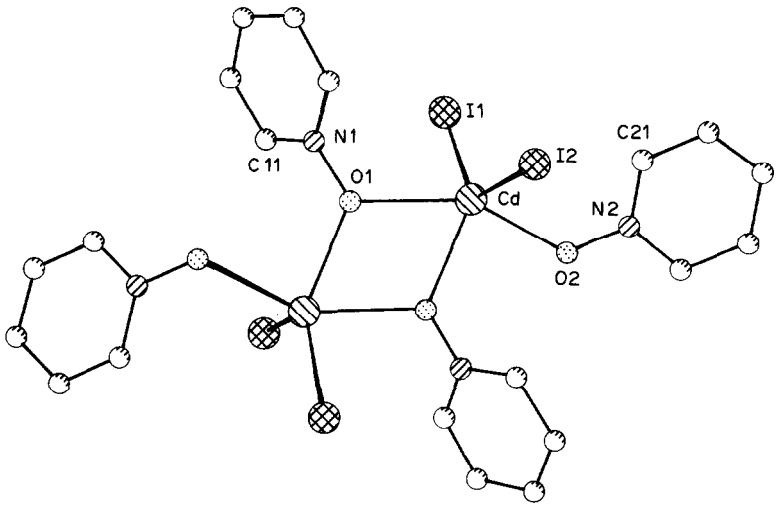

Fig. 4. The centrosymmetric molecule of **5**, with bridging and terminal pyo ligands. With the O(1)—Cd—O(2) angle 152°, O(1) and O(2) lie towards apical positions.

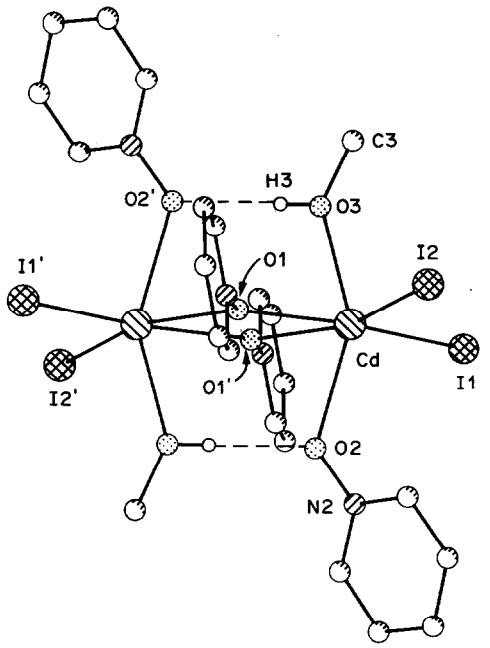

Fig. 5. The centrosymmetric molecule of **5A** with the cadmium centres now in six-coordination through methanol addition. The effect of the hydrogen-bonding on the ligand dispositions is evident.

152°, through the bridging constraint exerted on O(1). The structure of this compound is analogous to that developed by copper(II) halide complexes with pyo.[16]

The structure of **5A** in relation to **5**, with its retention of centrosymmetrical bridging is apparent from Fig. 5. The O(3) and O(2)′ atoms of coordinated methanol and pyo are bent towards each other at 2.715 Å, and hydrogen-bonding which the methanol proton provides between them augments the ligand bridging. This proton position is refined at 0.78 (0.12) Å from O(3), and 0.20 Å from the O(3)—O(2)′ vector. (The displacement is almost parallel to the Cd, Cd′, O(1), O(1)′ meanplane and towards the O(1)′ side.) The O(3)—H(3)—O(2)′ angle of 161° is below the 168° limit which would correspond to e.s.d. values. Thus, there seems to be a real deviation from linearity, probably through constraint from the methanol molecule. The hydrogen-bonding lengthens the O(2)—Cd bond; at 2.387 Å it is longer than the Cd—O(1) and Cd—O(1)′ bridge bonds. The torsion angle between N(2)—O(2) and the I(1)—Cd—I(2) angle bisector is small (4.5° towards I(1)), but that between C(3)—O(3) and the bisector is much larger (32° towards I(1)).

$[Cd(pyo)_6]^{2+}[CdI_4]^{2-}$ (**6**). The cell content is shown in Fig. 6. In the extended structure each iodine makes nearest approaches (I—C, 3.7–4.0 Å; I—H, 3.1–3.4 Å) to rings from four different cations. Through their mutual interaction, both cation and anion are somewhat distorted from regular coordination (see Table 5), although the cation ligands do approach a centrosymmetric array. The Cd—I bond length (2.785 Å av) is slightly longer than the

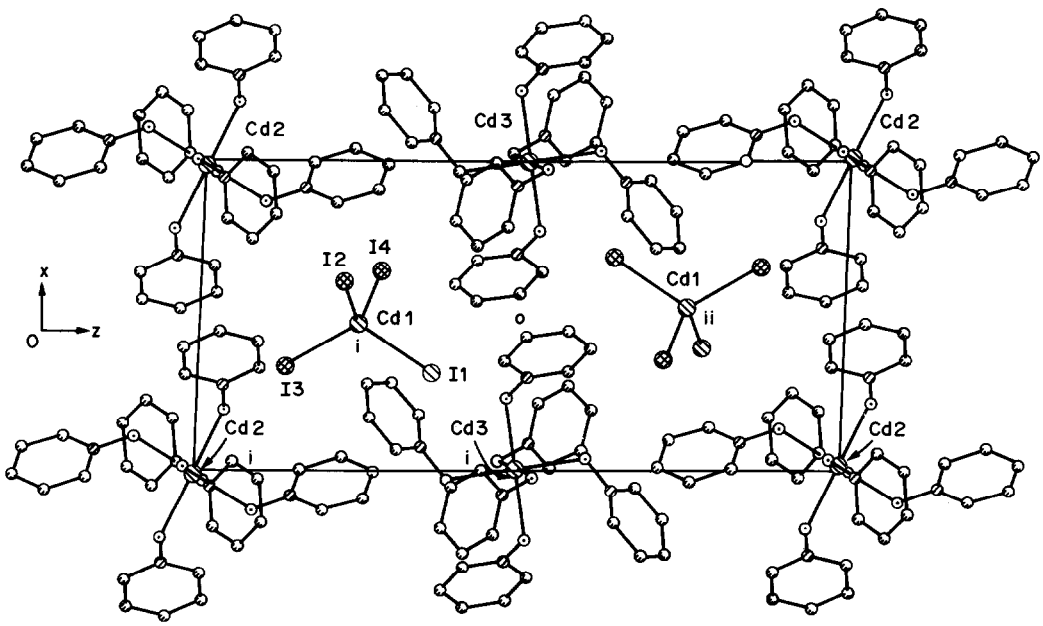

Fig. 6. The triclinic cell of **6** viewed along the *y* axis. Cd(2) and Cd(3) have the *y* coordinate 0.5, while the Cd(1) anion centres (i) and (ii) have $y = 0.0520$ and 0.9480, respectively. Disposition of the ligands about Cd(2) and Cd(3) approximates to centrosymmetric.

terminal Cd—I lengths in neutral five-coordinate structures.

Remarks on cadmium halide behaviour

The formation of these structures is seen as a consequence of the progressive ease of disruption of the Cd—X bonds with the heavier halogens. With the chlorides, the formation of **1** involves relatively small degradation of the $CdCl_2$ lattice. The structure retains some three-way bridging which provides six-coordination for cadmium even with the low pyo : $CdCl_2$ ratio. Excess ligand and a longer reaction time are needed to produce **2A**, where three-way bridging has been eliminated. With $CdBr_2$, on the other hand, no product with triple-bridging could be obtained, and **2B** remained the only product, whether using either higher or lower pyo : $CdBr_2$ ratios.

Cadmium iodide produces no layer lattice deriative, **3** being formed even using the lowest pyo : CdI_2 ratios. The chain structure of **3** occurs as a component of the **2A**/**2B** structure, as can be seen along the top boundary of Fig. 2. Here, in the bromide the chains are linked laterally through equivalent halogen-pair bridges. In place of such inter-chain bridging in the iodide, the halogen remains terminal, with the cadmium in five-coordination.

With the iodide derivatives as a class, there is evidence of greater halide mobility and ease of switching between five- and six-coordination. The lower Cd—I bond strength[17] and larger steric requirement of iodine are relevant—along with the low field of force associated with the large d^{10} cadmium centre. The development of varied bridging modes, and the appearance of non-equilibrium phases which can tip completely the initial course of crystallization are in themselves evidence of halide mobility.[18] The ionic compound **6** comprises the separately known $[Cd(pyo)_6]^{2+}$[19] and $[CdI_4]^{2-}$[1] (Fig. 6). Several factors will control the crystallization of such a compound, but in so far as both breaking and formation of Cd—I bonds are involved, it remains that lattice energy must be impotant in stabilization.

Significance of cadmium bond lengths in tbp and octahedral structures

The structure of **4** permits useful comparison of bond lengths of the octahedral Cd(1) and the tbp Cd(2) (see Table 5). The bridging atoms O(1) and O(3) are linked apically to Cd(2), while the bridging I(1) and I(2) are in equatorial positions, along with the terminal I(4). The Cd(2)—O bonds are longer, while the Cd(2)—I are shorter than their counterparts with Cd(1). This is in line with the normal relationships between tbp and octahedral bond lengths in comparable situations.[20,21] Its particular significance for cadmium lies in confirming the strong distinction between cadmium and mercury(II) coordination. Mercury is characterized by its preference for strong (and relatively short) diagonal bonding at the expense of bonding in other directions.[22] It is evident that cadmium shows no such tendency. This contrast between mercury and cadmium is further emphasized by the very large bond length disparities between $HgCl_2(pyo)$[10] and the present **2B** structure, despite their otherwise matching connectivities.

Acknowledgements—X-ray powder diffractograms were kindly run by Mr John Hastie. We are also indebted to Mr Mark Inder and Ms Jan Wikaira for their varied assistance. Laboratory facilities were provided by the University of Canterbury and through the New Zealand Universities research fund.

Abstract—Treatment of a dichloromethane suspension of [(triphos)CoP_3] [triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane] with CF_3SO_3H affords a compound of formula [(triphos)CoP_3H]$(CF_3SO_3)_2 \cdot (H_5O_2)$. An X-ray crystallographic analysis of the compound has provided evidence for one hydrogen atom bridging a Co—P edge of the CoP_3 core of the metal cation, which crystallizes with one oxonium ion, two $CF_3SO_3^-$ counterions, and one water molecule, all interlinked via a net of hydrogen bonds. The NMR data for the [(triphos)CoP_3H]$^+$ cation suggest that the H^+ electrophilic addition involves both the P_3 group and the metal atom. Additional information on the physical properties of the CoP_3 cluster has been obtained by investigating its electrochemical behaviour and synthesizing the [(triphos)CoP_3]$^+$ cation, containing the radical cluster CoP_3^+, through the oxidation of the parent [(triphos)CoP_3] compound.

The neutral compounds [(triphos)MP_3] [triphos = 1,1,1-tris(diphenylphosphinomethyl)ethane; M = Co, Rh, Ir] which has a pseudotetrahedral core formed by three unsubstituted phosphorus atom and one cobalt group metal, stabilized by the tripod tridentate ligand triphos,[1] exhibit distinct reactivity on the electron rich phosphorus atoms. The heteroatomic polarized MP_3 core interacts with various transition metal fragments through one phosphorus atom,[2] a P—P edge[3] or the P_3 triangular face,[4] depending on the nature of the metal–ligand system provided by the reactant. The reactivity of the above neutral compounds towards various isolobal fragments has recently been considered. The R^+ (R = CH_3,[5] Et[6]) organic groups add to a phosphorus atom of the MP_3 core producing notable distortions in its geometry. The $AuPR_3^+$ fragments upon interaction with a P—P edge of the MP_3 group undergo labilization of the phosphine ligand,[7] with a departure from the behaviour both in solution[8] and toward metal clusters[9] of the gold(I) phosphine halides. Finally, the HgY^+ fragments (Y = Me, Ph) add to a P—P edge in the [(triphos)MP_3] (M = Co, Rh) compounds,[3] producing minor modifications of the core.

It was therefore of interest to examine the reactions of the [(triphos)MP_3] compounds with H^+, which is isolobal with Me^+, Et^+, $AuPR_3^+$ and

* Author to whom correspondence should be addressed.

HgY^+ but presents a smaller steric hindrance. It was also expected that useful complementary information could be obtained by studying the redox properties of the CoP_3 cluster.

EXPERIMENTAL

All reactions and manipulations were performed under an atmosphere of oxygen-free nitrogen. Solvents were freshly distilled under nitrogen from the appropriate drying agents immediately before use. Electronic spectra were obtained using a Perkin–Elmer Lambda 9 spectrometer. Magnetic susceptibilities were measured by the Faraday method with an automated magnetometer DMS-5. The ^{31}P and ^1H NMR spectra were obtained in CD_2Cl_2 using a VARIAN VXR 300 spectrometer operating at 121.4 and 300.1 MHz and are referred to external 85% H_3PO_4 and internal TMS, respectively. The materials and the apparatus used for EPR spectroscopy and electrochemistry have been described elsewhere.[10] The potential values refer to an aqueous calomel electrode (SCE). Analytical data for carbon, hydrogen and cobalt were obtained in the Microanalytical Laboratory of the Department of Chemistry; phosphorus and sulphur elemental analyses were performed by Mykroanalytisches Labor Pascher, Remagen, F.R.G. [(triphos)CoP_3][2] and $[(C_5H_5)_2Fe]PF_6$[11] were prepared as previously described; CF_3SO_3H (Aldrich) was used as supplied. All the compounds were collected on a sintered-glass frit, in a closed system, and washed with benzene and light petroleum (b.p. 40–70°C) in turn before being dried under a stream of nitrogen.

Synthetic procedures

Synthesis of the compounds. [(triphos)CoP_3H]$(CF_3SO_3)_2\cdot(H_5O_2)$. Neat CF_3SO_3H (0.8 mmol) was added to a dichloromethane suspension (40 cm^3) of [(triphos)CoP_3] (0.31 g, 0.4 mmol). Quick dissolution of the solid, with concomitant change in the colour of the solution to orange, was observed. The resulting solution was stirred at 0°C for 2 h. Orange crystals of the compound were obtained by addition of benzene and slow concentration. The compound crystallizes, as found from the X-ray analysis, with water molecules whose amount, mainly assigned in accordance with the results of the structural investigation (see below), well agrees with the elemental analyses (yield 80%). Found: C, 46.6; H, 4.1; Co, 5.3; P, 16.5; S, 5.7. [(triphos)CoP_3H]$(CF_3SO_3)_2\cdot(H_5O_2)$, $C_{43}H_{45}CoF_6O_8P_6S_2$, requires: C, 46.4; H, 4.1; Co, 5.3; P, 16.7; S, 5.8%. ^1H NMR: δ −13.75 (1H, br, $\nu_{1/2}$ 15 Hz), 1.90 (3H, s, CCH_3), 2.70 (6H, s, PCH_2), 7.70 (30H, m, arom. H).

[(triphos)CoP_3]PF_6. Solid $[(C_5H_5)_2Fe]PF_6$ (0.17 g, 0.5 mmol) was added to a dichloromethane suspension (50 cm^3) of [(triphos)CoP_3] (0.39 g, 0.5 mmol). Immediate dissolution of the solid, with concomitant change in colour of the solution to deep red, was observed. The solution was stirred at room temperature for a few minutes and n-hexane (50 cm^3) was added. The resulting solution was concentrated under vacuum at room temperature until a red oil separated. Dark red microcrystals of the compound were obtained on leaving the system overnight (yield 70%). Found: C, 52.9; H, 4.2; Co, 6.1. [(triphos)CoP_3]PF_6, $C_{41}H_{39}CoF_6P_7$, requires: C, 53.4; H, 4.3; Co, 6.4%.

X-ray crystal structure

Diffraction data for [(triphos)CoP_3H]$(CF_3SO_3)_2\cdot(H_5O_2)$. The determination of lattice constants and the intensity data collection were performed using a crystal with dimensions $0.20\times0.30\times0.80$ mm, which was coated with paraffin in order to prevent slow decomposition. An Enraf–Nonius CAD4 diffractometer and Mo-K_α radiation ($\lambda = 0.71069$ Å) were used for all operations, which were performed at room temperature. Lattice constants were determined by least-squares refinement of the angular settings of 22 reflections with $20 \leqslant 2\theta \leqslant 24°$.

Crystal data. $C_{43}H_{45}CoF_6O_8P_6S_2$, $M_r = 1112.73$, monoclinic, $a = 17.968(5)$, $b = 20.823(6)$, $c = 13.326(3)$ Å, $\beta = 103.15(2)°$, $U = 4855(2)$ Å^3, $Z = 4$, $D_c = 1.522$ g cm^{-3}, $F(000) = 2280$, μ(Mo-K_α) = 7.00 cm^{-1}, space group $P2_1/n$.

The intensities of the $\pm h$, $+k$, $+l$ reflections were measured in the range $5 \leqslant 2\theta \leqslant 46°$ in the ω–2θ scan mode with a scan width of $(0.90+0.35\tan\theta)°$ and variable 3–8° min^{-1} scan speed. No crystal decay was observed. Of the total 6750 reflections recorded, 4102 having $I > 3\sigma(I)$ were used for structure determination. Intensity data were corrected for Lorentz and polarization effects and, at isotropic convergence after the structure was solved, they were corrected for absorption by an empirical procedure.[12] The principal computer programs used in the crystallographic calculations are listed in refs 12–14.

Crystal structure determination. The structure was solved by heavy-atom procedures. In the least-squares refinement the function $\Sigma w(|F_o|-|F_c|)^2$ was minimized with final weights $w = [\sigma^2(F_o)+0.0005F_o^2]^{-1}$. The scattering factors for the neutral atoms and the anomalous dispersion correction for cobalt were taken from ref. 15. In

the final refinement the cobalt and phosphorus atoms, as well as all those forming the $CF_3SO_3^-$ anions and the oxygen atoms of the water molecules were assigned anisotropic thermal parameters, whereas the other atoms were refined isotropically. The phenyl groups of the triphos ligand were refined as rigid bodies with idealized geometry. Hydrogen atoms of the triphos ligand were introduced in calculated positions (C—H = 1.00 Å) with temperature factors 20% larger than those of the respective carbon atoms, the methyl group of the ligand being refined as a rigid body, but the hydrogen atoms in the solvate molecules as well as that one considered to be present in the CoP_3 cluster could not be clearly located on ΔF maps and were not introduced in the model. Refinement converged at $R = 0.066$ and $R_w = 0.074$. The highest peaks in the final ΔF map, with heights < 0.7 e Å^{-3} could not be assigned definite meaning. The largest shift/error ratios in the final cycles were < 0.03. Final atomic positional and thermal parameters, bond lengths and angles and F_o/F_c values have been deposited as supplementary material with the Editor, from whom copies are available on request. Atomic coordinates have also been submitted to the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Treatment of a dichloromethane solution of [(triphos)CoP_3] with CF_3SO_3H in stoichiometric ratios ranging from 1 : 1 to 1 : 3, affords after the addition of benzene a compound of the formula [(triphos)CoP_3H]$(CF_3SO_3)_2 \cdot (H_5O_2)$. The best yield is obtained for the 1 : 2 ratio of the reagents, in accordance with the formula of the final compound. This is mildly air-sensitive and soluble in chloroform and dichloromethane. It decomposes quickly, even under nitrogen, in nucleophilic solvents such as acetone, alcohols and ethers, yielding the parent [(triphos)CoP_3]. This behaviour is indicative of a weak interaction between the H^+ and the heteroatomic cluster. Although the synthetic procedures were carried out using dry reagents and solvents, the final compound crystallized invariably with $(H_5O_2)CF_3SO_3$; it is likely that the small amount of water was introduced with the inert gas into the solution.

The structure of the compound, as revealed by the X-ray analysis, is formed by [(triphos)CoP_3H]$^+$ and $H_5O_2^+$ cations, and $CF_3SO_3^-$ anions. A view of the metal cation appears in Fig. 1. Although hydrogen atoms, in particular those in the $H_5O_2^+$ ion or the CoP_3 cluster, could not be safely located, there is convincing structural evidence, as discussed below, of their presence and therefore for the validity of the formula assigned to the compound. In particular, each $H_5O_2^+$ cation forms hydrogen bonds to four anions as in the structures of $(H_5O_2)CF_3SO_3$[16] and $(H_5O_2)_2SO_4$,[17] although the present network of hydrogen bonds, involving a centrosymmetric cluster of two $H_5O_2^+$ and four $CF_3SO_3^-$ ions (Fig. 2), is less extended than the two-[16] or three-dimensional[17] networks existing in the other two structures, probably due to the presence of the large metal cation in the present one. In close agreement with the structures already mentioned, the distance between the oxygen atoms in $H_5O_2^+$ [O(7)···O(8) = 2.43(1) Å] is shorter than the distances [2.53–2.71 Å] formed by the same

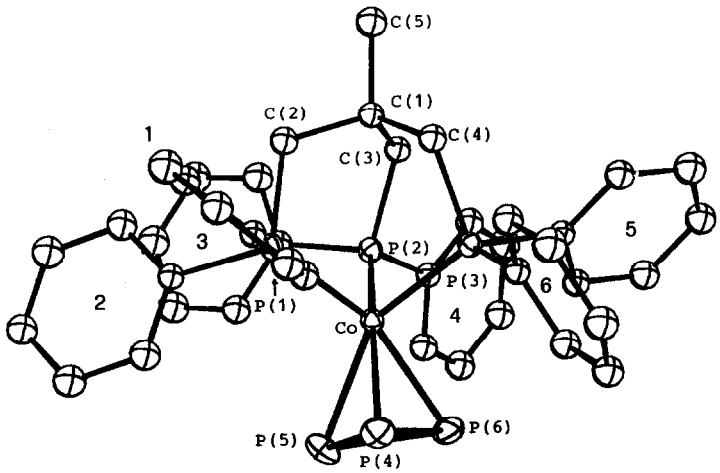

Fig. 1. Perspective view of the [(triphos)CoP_3H]$^+$ cation in the structure of [(triphos)CoP_3H]$(CF_3SO_3)_2 \cdot (H_5O_2)$, with 20% probability ellipsoids. Phenyl groups are numbered but their carbon atoms are not labelled for clarity.

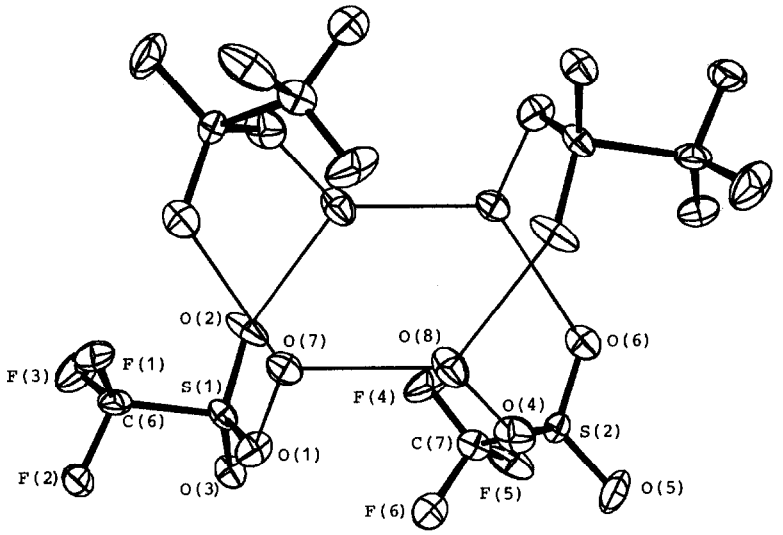

Fig. 2. View of the centrosymmetric cluster formed by two $(H_5O_2)^+$ cations and four $CF_3SO_3^-$ anions in the structure of $[(triphos)CoP_3H](CF_3SO_3)_2 \cdot (H_5O_2)$. Only symmetry-independent atoms are labelled. Hydrogen bond interactions are marked by light lines.

oxygens with those of the anions to which they are hydrogen bonded; moreover, each oxygen atom in $H_5O_2^+$ is pyramidal, with 102–125° angles between the directions to its hydrogen-bonded neighbours. The dimensions of the $CF_3SO_3^-$ anions closely agree with those already reported.[16] The main difference between the geometry of the $[(triphos)CoP_3H]^+$ cation and that of the neutral parent $[(triphos)CoP_3]$ is due to lengthening of a Co—$P(P_3)$ bond from the 2.301(1) Å value, which is identical by symmetry for the three bonds of this type in the parent complex, to 2.396(2) Å (Table 1). The other two Co—$P(P_3)$ distances are only slightly larger (by 0.015 Å, in the mean) in the cation, as are the Co—P(triphos) distances (by 0.027 Å), whereas the dimensions of the P_3 ring are substantially unchanged.

The above structural data suggest that the added H^+ ion should lie close, in the solid, to the region of a Co—$P(P_3)$ bond. A rationalization for this was sought by performing extended Hückel calculations[18] with the CACAO set of programs.[19] According to the highest overlap population and FMO energy-matching criteria, the Co—P edges of the CoP_3 cluster were better points of attack for H^+ than the P—P edges or the face centres. Moreover, only under the assumption of Co—P activation the experimental trend in bond lengths, essentially consisting in elongation of one Co—P bond, could be anticipated on the basis of the distribution of the overlap population values. In such a position the H^+ ion has similar bonding opportunities to the P_3 group as those available to CH_3^+ in the $[(triphos)Co(MeP_3)]^+$ cation,[5] but it is bound

P(4)—Co—P(6)	55.1(1)		

in addition to the metal atom, forming essentially a Co—H—P three-centre bond; the latter possibility is prevented by steric factors on CH_3^+,[5] which is forced to lie on the opposite side of the P_3 plane with respect to that presumably occupied by the smaller H^+ in the present structure. Bonding within the P_3 group is predicted to be little affected.

The room temperature ^1H NMR spectrum of the compound exhibits the triphos signals with the expected shifts and a high field broad resonance ($\delta = -13.75$) whose intensity and shift are consistent with the presence of one hydride hydrogen atom. Such resonance remains substantially unchanged down to the lowest temperature reached ($-90°C$). The $^{31}P\{^1H\}$ NMR spectrum exhibits two broad and well-separated resonances ($\delta = 28.21$, $\nu_{1/2} = 82$ Hz; $\delta = -296.49$, $\nu_{1/2} = 70$ Hz) having a 1 : 1 intensity ratio. The two resonances, strongly affected by the cobalt quadrupole moment, remain essentially unchanged down to $-90°C$. The lower field signal is assigned to the phosphorus atoms of the triphos ligand and the higher field signal to the unsubstituted phosphorus atoms; the latter signal, which is not affected by proton coupling, occurs at higher field than that found for the parent [(triphos)CoP_3] ($\delta = -276.21$).[20] The high field shift of the P_3 signal in the present compound was unexpected, as such resonance moves considerably downfield on going from the neutral [(triphos)MP_3] (M = Co, Rh, Ir) compounds to the cationic [(triphos)MP_3]BF_4 (M = Ni, Pd, Pt) compounds,[20] which are isoelectronic to [(triphos)MP_3] and to the present derivative. Moreover, it has been observed that also the addition of CH_3^+ to a phosphorus atom of the MP_3 core,[5] or the insertion of the isolobal $AuPR_3^+$ or HgY^+ fragments into one of its P—P edges[3,7] yield low field shifts of the P_3 signal. Finally, a particularly notable low field shift is observed when the addition yields an azide-like P_3 chain.[6] The high field shift exhibited by the unsubstituted phosphorus atoms in the present compound might then be accounted for by an unprecedented type of interaction with the rest of the structure undergone by the P_3 group, such as that suggested above, consisting of a three-centre bond and two "normal" Co—P bonds. In such an arrangement, according to the results of the structural investigation and of the EH calculations, bonding within the P_3 ring is similar to that existing in the parent cluster, but the overall interaction of the ring with the metal centre is smaller than in the CoP_3 case. Finally, hydrogen exchange between the three Co—P bonds and rotation in solution of the P_3H group with respect to the pseudo three-fold axis of the cation may be responsible for the absence of P—H coupling in the spectrum.

Since the H^+ addition should reduce to some extent the availability of electrons to the CoP_3 skeleton, it was considered interesting to study the electrochemical behaviour of [(triphos)CoP_3]. Cyclic voltammetry of [(triphos)CoP_3] in dichloromethane solution shows two successive anodic steps: the first one exhibits features of chemical reversibility (Fig. 3), whereas the second one, lacking any associated response in the reverse scan, is very close to the solvent discharge. Controlled potential coulometry in correspondence to the first oxidation process ($E_w = +0.5$ V) shows that it involves a one-electron molecule. Analysis[10] of the relevant cyclic voltammetry response with scan rate varying from 0.02

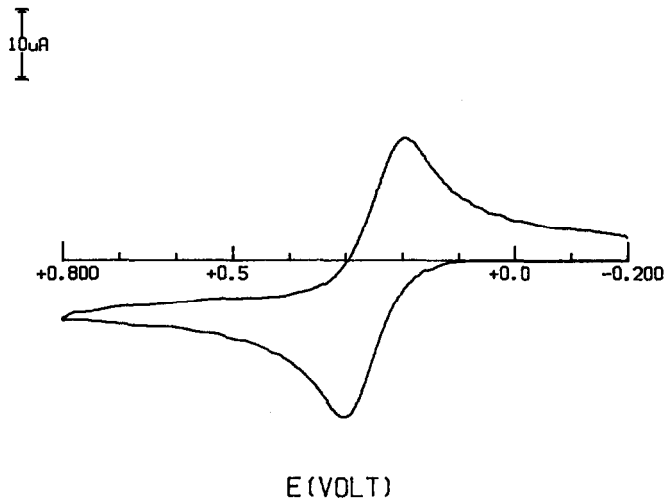

Fig. 3. Cyclic voltammetric response recorded at a platinum electrode in a CH_2Cl_2 solution containing [(triphos)CoP_3] (1.51×10^{-3} mol dm^{-3}) and $[NBu_4]ClO_4$ (0.2 mol dm^{-3}). Scan rate 0.2 V s^{-1}.

to 10.24 V s^{-1} shows that: (i) the peak current ratio i_{pc}/i_{pa} is constantly equal to unity; (ii) the peak-to-peak separation (ΔE_p) progressively increases from 82 to 444 mV; (iii) the current function $i_{pa}v^{-1/2}$ remains substantially constant. On considering that, under the same experimental conditions, the one electron oxidation of ferrocene ($E^{\circ\prime} = +0.45$ V) displays a similar trend in ΔE_p, one can assume that the [(triphos)CoP_3]$^{0/+}$ redox change involves a substantially reversible electron transfer ($E^{\circ\prime} = +0.24$ V). The stability of the electrogenerated monocation [(triphos)CoP_3]$^+$ is not limited to the time scale of cyclic voltammetry (tenths of a second): it is stable also over the longer times of macroelectrolysis, as proved by the relevant cyclic voltammogram, which is complementary to that shown in Fig. 3. The solution turns from yellow to deep red in the course of this process.

The electrogenerated [(triphos)CoP_3]$^+$ was characterized by EPR spectroscopy. The liquid nitrogen ($T = 100$ K) X-band EPR spectrum of the paramagnetic species in dichloromethane solution shows an unresolved anisotropic structure, with axial symmetry [$g_\parallel = 2.228+0.005$, $g_\perp = 2.012+0.005$; $g_{calc} = 1/3(g_\parallel+g_\perp) = 2.084+0.005$]. At 300 K the absorption line splits into a well-resolved hyperfine octuplet (Fig. 4) as a result of the magnetic interaction of the unpaired electron with the cobalt nucleus ($I = 7/2$). The isotropic parameters are $g = 2.086+0.005$ and $a = 27.7+0.5$, in good agreement with the low temperature g value. The spectral parameters are therefore consistent with the metal character of the unpaired electron.

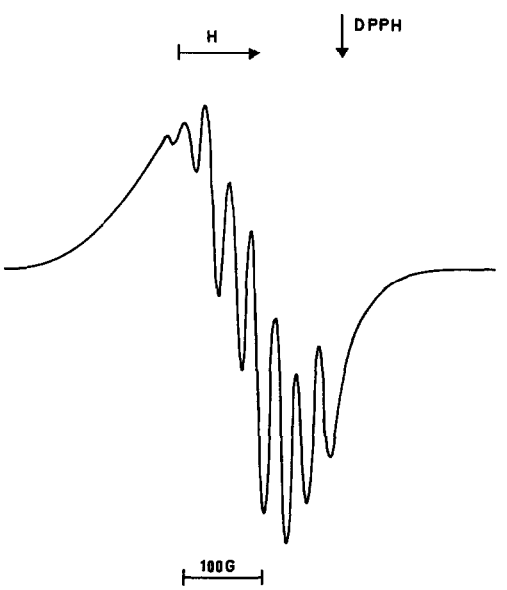

Fig. 4. X-band EPR spectrum recorded at room temperature on a CH_2Cl_2 solution of [(triphos)CoP_3]$^+$.

In view of the electrochemical results the synthesis of a compound containing the CoP_3^+ radical cluster was undertaken. [$(C_5H_5)_2$Fe]PF_6 was chosen as a mild oxidizing agent. When a quantitative amount of [$(C_5H_5)_2$Fe]PF_6 is added to [(triphos)CoP_3] in CH_2Cl_2 a rapid reaction occurs and a dark red microcrystalline compound of formula [(triphos)CoP_3]PF_6 is obtained upon addition of n-hexane. The compound which is stable under nitrogen both in the solid state and in chlorinated solvents solution exhibits a room temperature magnetic moment of 2.2 μ_B. The EPR data for the compound agree with those found for the electrogenerated species. The electronic spectrum of the complex, which exhibits two absorption maxima at 800 and 380 nm and a shoulder at 480 nm, is typical for low spin hexacoordinate cobalt(II).

In conclusion, the data available for the oxidized species suggest that the one-electron oxidation involves removal of one electron from a metal orbital in [(triphos)CoP_3]. Metal orbitals are also involved in the H^+ addition to a definitely larger extent than in any of the previously performed additions to atoms or insertions into P—P bonds of MP_3 clusters.[3,7] However, the amount of charge transferred in the present H^+ addition should be less than that removed by the one-electron oxidation process; moreover, different MOs are likely to be involved in the two processes.

Abstract—The coordination complexes of acrylonitrile, $CH_2{=}CHCN$, methacrylonitrile, $CH_2{=}CMeCN$, and *cis/trans* crotononitrile, $MeCH{=}CHCN$, with a series of metal and metalloid chlorides, MCl_n, where M = Ti^{IV}, Sn^{IV}, B^{III} and Sb^{V}, have been prepared and the coordination is shown to be σ-bonded through the nitrogen "lone pair" to the metal centre. The olefinic protons of the 1:1 complexes of $TiCl_4$ and $SnCl_4$, on coordination, show an upfield shift in the ^1H NMR spectra. Electrical conductivity measurements in nitrobenzene solution show all the addition compounds of $SnCl_4$ and $TiCl_4$ to be non-electrolytes and therefore non-ionic. Consistent with this observation, all of the compounds except for the $SbCl_5$ complex are volatile at room temperature while the 2:1 complexes of $TiCl_4$ with acrylonitrile and methacrylonitrile tend to dissociate in the vapour phase into the 1:1 complex and free ligand. The IR spectra of the complexes have also been studied and in all cases the cyanide stretching frequency increases, showing coordination occurs through the nitrile group.

Addition complexes of nitriles with metallic and organometallic compounds have been known for many years.[1–4] Coordination is normally via the lone pair of electrons on the nitrogen atom and it was observed that on coordination, the IR stretching frequency of the nitrile group always increased. The magnitude of the increase correlated broadly with the strength of the metal–nitrogen bond and clearly reflects strong coupling between the stretching vibrations of the co-linear C≡N and N→M bonds. Acrylonitrile is an interesting nitrile in that, potentially, it is bifunctional and can offer coordination through either the nitrile group or the C=C group, particularly when complexed with transition metals. This gives rise to several possible different structural types and the existence of the three shown in Fig. 1 has been well established.

Other modes of coordination such as via the π-electrons of the nitrile group are also possible, as has been discussed previously.[5]

The coordination chemistry of acrylonitrile has been the subject of recent review,[5] but the coordination chemistry of its methyl derivatives, methacrylonitrile and the isomers of crotononitrile has received relatively little study. The copper(I) derivative $CuBrNCCMe:CH_2$ has been prepared[6] and shown by X-ray diffraction to consist of a chain of bromine-bridged copper atoms in tetrahedral coordination with the other two sites occupied by

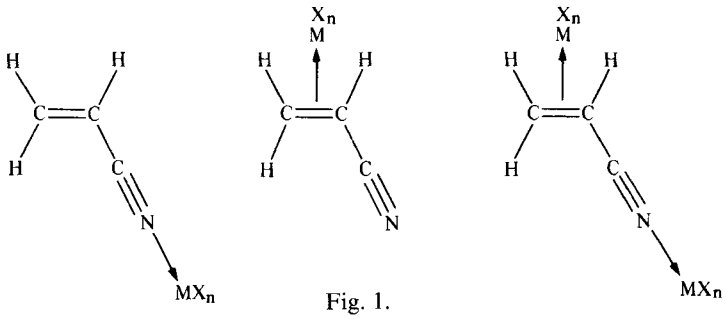

Fig. 1.

methacrylonitrile molecules, σ-bonded through the nitrogen "lone pairs". The π-bonded product analogous to $Cu_2Cl_2(CH_2CHCN)$ was not obtained from the reaction mixture, even with excess methacrylonitrile. Similarly, while bis(acrylonitrile) nickel is a well-characterized compound[7] containing π-bonded olefinic groups, no analogues have been prepared from either methacrylonitrile or crotononitrile.[8] Furthermore, while acrylonitrile itself is known to form stable complexes, anomalous behaviour has been observed[9,10] in its interaction with germanium and silicon tetrachlorides, in which a net repulsion was observed in mixtures of the nitrile and the chloride. The present work was therefore commenced to explore further the coordination chemistry of both methacrylonitrile and crotononitrile for comparison with the coordination chemistry of acrylonitrile itself.

EXPERIMENTAL

Starting materials

Tin tetrachloride, titanium tetrachloride, antimony pentachloride and boron trichloride were obtained commercially and purified by distillation. Acrylonitrile was purified by refluxing with calcium hydride for at least 6 h and then fractionally distilled onto freshly activated 3 Å molecular sieves. This treatment removed the stabilizer, so it was necessary to store the acrylonitrile in the dark to prevent photo-initiated polymerization. Both methacrylonitrile and the mixed isomers of crotononitrile were used without further purification other than standing over freshly activated 3 Å molecular sieves. Nitrobenzene was distilled from P_4O_{10}, and both benzene and pentane were dried over sodium wire. Experimental techniques included the use of a conventional vacuum line, a nitrogen-filled glove box and a dry nitrogen line.

Preparation of metal complexes

Since the methods used for the preparation of the complexes of acrylonitrile and its derivatives are similar, the experiments described below are classified according to the metal chloride used. The term L is used universally to denote acrylonitrile, methacrylonitrile or crotononitrile. Analytical data are given in Table 1.

Preparation of $TiCl_4 \cdot 2L$. Titanium tetrachloride (*ca* 2.5 cm^3) was added by syringe to the ligand (10 cm^3) in a cooled nitrogen-filled flask. A yellow suspension formed which was dissolved in excess ligand by warming with a hair-drier to yield a clear solution. On standing for 15 min and cooling, yellow crystals were deposited from solution which were collected on a filter and washed with cold ligand. The product was dried in a stream of dry nitrogen.

Preparation of $TiCl_4 \cdot L$. Titanium tetrachloride (*ca* 5 cm^3) was added slowly by syringe to a well stirred 1 : 1 stoichiometric solution of the nitrile in benzene (40 cm^3) at room temperature. The solution deposited a yellow microcrystalline solid which was filtered, washed with cold benzene and dried in a stream of nitrogen.

Preparation of $BCl_3 \cdot L$. Boron trichloride (*ca* 5 g) was condensed under reduced pressure into a flask cooled by liquid nitrogen. Pure nitrogen was admitted and dry pentane (30 cm^3) was added by syringe. The mixture was warmed to room temperature to dissolve the boron trichloride uniformly in the pentane. The solution was then cooled in liquid nitrogen and an equivalent molar weight of the ligand was added by syringe. On warming to room temperature, a white solid was obtained which was filtered, washed in dry pentane, and dried in a stream of nitrogen.

Preparation of $SbCl_5 \cdot L$. Antimony pentachloride (*ca* 4 cm^3) was added by syringe to the ligand (10 cm^3) in a flask cooled to liquid nitrogen temperature. On warming to room temperature, a very strongly exothermic reaction occurred, forming a precipitate which was redissolved on warming to obtain a clear yellow solution. On cooling, the solution deposited a white crystalline solid which was recovered by filtration, washed with cold ligand and dried as before.

Preparation of $SnCl_4 \cdot 2L$. Stannic chloride (4

ACN, MCN and CNN represent acrylonitrile, methacrylonitrile and crotononitrile, respectively.

cm^3) was added by syringe to the ligand (20 cm^3) in a flask cooled to −196°C. On warming to room temperature, a white precipitate was formed immediately, which was dissolved by warming. On cooling, white crystals were deposited which were recovered and dried as in the previous example.

RESULTS AND DISCUSSION

Some 15 complexes have been prepared from acrylonitrile and its methyl derivatives, crotononitrile and methacrylonitrile, with the chlorides BCl_3, $TiCl_4$, $SnCl_4$ and $SbCl_5$. Their analytical data (Table 1) are consistent with the formation of 1 : 1 addition complexes, though in the case of $TiCl_4$ and $SnCl_4$, a 2 : 1 stoichiometry can also be obtained. Vapour pressures were measured manometrically at room temperature using a cathetometer. Details are given in Table 2. With the exception of the antimony complex, the adducts are volatile crystalline solids and they are all extremely sensitive to air or moisture. The boron complex had the lowest vapour pressure of the volatile adducts, consistent with the strong Lewis acid properties of boron trichloride, and the tin complex proved to be the least stable of the series, though still contrasting strongly with the silicon and germanium derivatives[9,10] which showed no tendency for complex formation. The 2 : 1 complexes of $TiCl_4$ with acrylonitrile and methacrylonitrile show a tendency to dissociate on heating *in vacuo* to the 1 : 1 complex and free ligand. The methacrylonitrile complex appeared to be more thermally stable than its acrylonitrile analogue as shown by a higher temperature required to effect this dissociation.

Electrical conductivity measurements

While many coordination compounds are simple covalent adducts between donor and acceptor mol-

Table 2. Vapour pressure data for the nitrile–metal chloride addition complexes

Metal complex	Vapour pressure at 20°C (mm Hg) CH_2=CHCN	CH_2=CMeCN	MeCH=CHCN

$TiCl_4$·L	2.52	2.95	3.68
$SnCl_4$·L	3.12	8.31	0.22

ecules, coordination complexes of polychlorometallic compounds have a tendency to form ionic compounds typified by species such as $[L_2MCl_2]^{2+}[MCl_6]^{2-}$ and which, clearly, have a significant electrical conductivity in solution,[11] usually in the range 100–200 Ω^{-1} cm^2 mol^{-1} and 20–30 Ω^{-1} cm^2 mol^{-1} for 1:1 electrolytes. To assess whether the titanium and tin compounds of this study were ionic in nature, the electrical conductivities of the relevant compounds in nitrobenzene solution were measured using a conductivity cell and a PTI-18 digital conductivity meter. All of the conductivities lay in the range 0.8–1.9 Ω^{-1} cm^2 mol^{-1}, showing these complexes to be non-electrolytes and hence simple donor/acceptor adducts.

IR spectra

IR spectra of all the complexes as Nujol mulls were recorded across the frequency range 4000–200 cm^{-1}, using Perkin–Elmer 477 and 577 spectrometers. The assignments of the most diagnostic bands for free acrylonitrile,[12] methacrylonitrile[13] and crotononitrile,[14] together with their coordination complexes are given in Table 3. The shifts in the absorption frequencies of the nitrile bond, the olefinic stretch and the out-of-plane deformation of the olefinic hydrogens upon coordination to the metal centre are also given in Table 2. The importance of these shifts is that they indicate a change in the force constant in the functional group upon coordination, from which the mode of coordination of the ligand can be determined.

All of the adducts show an increase in the nitrile stretching frequency in the range 22–89 cm^{-1}. This indicates strongly that the nitrile group is involved in the coordination. The largest shifts in frequency, which ranged from75–89 cm^{-1}, were observed for the complexes formed by the strongest Lewis acid (and that of lowest molecular mass), boron trichloride which presumably formed the strongest M—N bond. In general, the largest shifts (37–89 cm^{-1}) were also observed for the parent ligand, acrylonitrile. The smallest shifts were observed for methacrylonitrile (22–75 cm^{-1}), possibly for steric rather than electronic reasons and no particular trends were detected for the other metals, or within the 1:1 and 1:2 complexes. The increase in frequency described in this work is in good agreement with other published data[5] on acrylonitrile complexes known to coordinate through the nitrogen where the increase lies in the range 14–61 cm^{-1}.

Stretching frequencies for the C=C bond are also given in Table 3. In each complex, there is a small decrease in the stretching frequency ranging from 3 to 21 cm^{-1}. When acrylonitrile is coordinated via the π-electrons of the C=C group, the stretching frequency of the C—C unit always falls significantly as the new bond order approaches unity. For example,

in bis (acrylonitrile) nickel, a shift of 162 wave numbers from 1608 to 1446 cm^{-1} was observed.[15] Typical shifts lie in the range 106–168 cm^{-1}. It is clear, therefore, that any π-bonding contribution to these complexes is minimal. The twisting $\tau(CH_2)$ and wagging $\omega(CH_2)$ modes, also diagnostic for the mode of coordination of acrylonitrile,[16] were observed in the spectrum of the acrylonitrile derivatives and are listed in Table 4. The shifts are also consistent with coordination via the nitrogen lone pair and the magnitude of the observed splitting confirms boron trichloride to be the strongest Lewis acid of the series under study.

Nuclear magnetic resonance spectra

^1H NMR spectra were recorded on the complexes in benzene solution using a Varian A60/56D spectrometer, operating at 60 Mhz and with tetramethylsilane as the external reference standard. Under normal resolution, the olefinic protons of free acrylonitrile give rise to an ABC-pattern of peaks centred about 6.0 ppm downfield from TMS.[17] Coordination of acrylonitrile through the nitrogen usually results in a small downfield shift of 0.1–0.5 ppm in the resonance from the α-hydrogen, due to the electron-withdrawing effect of the Lewis acid. The effect on the resonance of the β-hydrogen is less well-defined and the shift can be either way.[18] The changes in the ^1H NMR spectrum of acrylonitrile when coordinated to the metal chlorides of this study are summarized in Table 5. A complex pattern of overlapping peaks was obtained for each compound, the centres of which were in the range 4.04–4.83 ppm downfield from TMS. This corresponds to each signal arising from the protons of the vinyl group having been shifted upfield by 0.63–1.49 ppm on coordination to the metal chloride.

In comparison with previous work on nitrogen-bonded acrylonitrile complexes, the magnitudes of the shifts of these compounds are significantly greater and more importantly, are in the opposite direction. Similar upfield shifts, but of a smaller magnitude are also seen in the complexes of methacrylonitrile and crotononitrile, as shown in Tables 6 and 7.

This suggests the presence of some interaction between the C=C π-system and either the metal complex or the metal chloride itself. There is also some evidence for partial dissociation of the nitrile ligand. The 1 : 1 and 2 : 1 complexes of all three nitriles were prepared from stannic chloride and titanium tetrachloride. The upfield shift relative to

the free ligand is always greater for the 1 : 1 complex than for the 1 : 2 complex and this is consistent with a dissociation process, in solution, of the 2 : 1 complex into the 1 : 1 adduct and the free nitrile:

$$MCl_4 \cdot 2L \underset{-Bz}{\overset{+Bz}{\rightleftharpoons}} L + MCl_4 \cdot L \underset{-Bz}{\overset{+Bz}{\rightleftharpoons}} 2L + MCl_4.$$

Such a mixture would then be expected to show the signals arising from the weighted mean of the chemical shifts of the free and complexed ligand. Such a dissociative process also offers a possible explanation for the upfield shift displayed by the nitrile protons on coordination, since the olefinic bond would then be able to interact with any coordinative unsaturation generated by dissociation. It was also observed that the chemical shift of the olefinic protons decreased in the sequence:

$$CH_2{=}CHCN > CH_3CH{=}CHCN \sim CH_2{=}C(CH_3)CN.$$

This reflects the order of stability for the complexes of acrylonitrile and its methyl derivatives with metal halides where it appears that the bulk of the methyl group is sufficient to inhibit the degree of coodination.

COMPLEXES OF RUTHENIUM(II) AND (III) DERIVED FROM O,N-DONOR LIGANDS, AND THEIR EFFICIENCY AS CATALYTIC OXIDANTS FOR ALCOHOLS

AHMED M. EL-HENDAWY

Chemistry Department, Faculty of Science, Damietta, Egypt

(*Received* 1 *May* 1991; *accepted* 4 *June* 1991)

Abstract—The new complexes $[Ru^{II}Cl_2(PPh_3)_2L]$ (L = benzoic hydrazide, bhz; substituted derivatives, R-bhz; R = *p*-Cl, *p*-CH_3, *o*-NH_2 and phenylacetic hydrazide) and $[Ru^{III}X_2(AsPh_3)_2L']$ (L′ = monoanions of 8-hydroxyquinoline, 8-hq; *o*-aminophenol; 2-amino-3-hydroxypyridine; X = Cl or Br) have been isolated. They were characterized by spectroscopic techniques and their redox behaviour was studied by cyclic voltammetry. The ruthenium(III) complexes were found to be more effective catalysts than those of ruthenium(II) for the oxidation of primary alcohols to aldehydes and of secondary alcohols to ketones in the presence of N-methylmorpholine-N-oxide as co-oxidant. Turnovers reached 400 with the catalyst $[Ru^{III}Cl_2(AsPh_3)_2(8\text{-hq})]$.

The interaction of dichlorotris(triphenylphosphine)ruthenium(II) with the sodium salts of various Schiff bases, L, derived from aliphatic dianions and β-diketones or aromatic aldehydes gives the octahedral species *trans*-$[Ru^{II}L_n(PPh_3)_m]$ ($n = 1, 2$; $m = 2$).[1] Pentacoordinated ruthenium(II) complexes have been prepared when isonicotinoyl hydrazone derivatives of β-diketones or salicylaldehyde reacted with $[RuCl_2(PPh_3)_3]$ in the presence of sodium hydride.[2] Recently, we have isolated and characterized $[M^{III}Cl_2(PPh_3)_2L']$ [M = Ru, Os; L′ = O,O-donor ligand(−1)].[3–5] We have been interested in the oxidation chemistry of *trans*-dioxoruthenium(VI) complexes[6–9] and also ruthenium(II) and (III) complexes containing triphenylphosphine.[3,10]

We now report the preparation of the new complexes $[Ru^{II}Cl_2(PPh_3)_2(bhz')]$ [bhz′ = benzoic hydrazide (bhz), $PhCONHNH_2$; substituted benzoic hydrazides, R-$PhCONHNH_2$, where R = *p*-Cl, *p*-CH_3, *o*-NH_2 and phenylacetic hydrazide (phachz), $PhCH_2CONHNH_2$] and $[Ru^{III}X_2(AsPh_3)_2L]$ [L = monoanions of 8-hydroxyquinoline (8-hq), *o*-aminophenol (*o*-amph), 2-amino-3-hydroxypyridine (amhpy); X = Cl or Br]. We also report their spectroscopic and electrochemical behaviour and study the catalytic oxidation of alcohols by such complexes in the presence of N-methylmorpholine-N-oxide (NMO) as co-oxidant.

RESULTS AND DISCUSSION

Reaction of $[RuCl_2(PPh_3)_3]$ with different hydrazide derivatives (bhz′) in refluxing methanol under nitrogen yields yellow precipitates within 0.5–2 h. The ruthenium(III) complexes of 8-hydroxyquinoline, *o*-aminophenol and 2-amino-3-hydroxypyridine were made from $[RuX_3(AsPh_3)_2MeOH]$ (I) (X = Cl, Br) by refluxing methanolic solutions of I with the appropriate ligand for 1–2 h. We have reported previously the synthesis of $[Os^{III}Cl_2(PPh_3)_2L]$ (L = O,O-donor ligand(−1))[4,5] starting with $[OsCl_3(PPh_3)_2MeOH]$. The analytical data (Table 1) indicate that these complexes have the formulae $[Ru^{II}Cl_2(PPh_3)_2(bhz')]$, $[Ru^{III}Cl_2(AsPh_3)_2L]$ (L = 8-hq, *o*-amph, amhpy) and $[Ru^{III}Br_2(AsPh_3)_2(8\text{-hq})]$. The ruthenium(II) hydrazide complexes are air-sensitive since their colour changes on exposure to air, while the other ruthenium(III) complexes are air-stable. All the complexes are only soluble in CH_2Cl_2 and their molar conductivities are very low.

The hydrazide complex $[RuCl_2(PPh_3)_2(bhz')]$ was found to be diamagnetic at room temperature; the other complexes are paramagnetic and their magnetic moments lie in the range 1.65–2.15 BM (Table 2), close to the spin-only value (1.73 BM) for one unpaired electron. This suggests the low-spin $d^5(t_{2g})^5$

configuration for the ruthenium(III) ion in an octahedral environment, as is the case for other ruthenium(III) and osmium(III) complexes.[3-5,11]

The IR spectra of the complexes showed bands due to triphenylphosphine, arsine and coordinated L. Characteristic bands of L are shifted to lower wavenumbers. The strong bands around 1630 and 1600 cm^{-1} observed in the ruthenium(II) complexes of hydrazides are tentatively assigned to the ν(C=O) and $\delta(NH_2)$ vibrations which appear near 1660 and 1600 cm^{-1} in the free hydrazide ligands. This confirms the participation of both the carbonyl oxygen and the amino nitrogen atoms of hydrazide ligands in coordination. The $\delta(NH_2)$ band has been shifted near 1615 cm^{-1} for the complexes $[Ru^{III}Cl_2(AsPh_3)_2L]$ (L = *o*-amph, amhpy). Distinct bands at 1279 and 1274 cm^{-1} were found in the complexes $[RuX_2(AsPh_3)_2(8\text{-hq})]$ (X = Cl, Br), which are consistent with the phenolic ν(C—O) vibration[12,13] which was observed at 1286 cm^{-1} in the free ligands (H8-hq). We could not assign such bands in $[Ru^{III}Cl_2(AsPh_3)_2L]$ (L = *o*-amph, amhpy) due to the presence of ν(C—N) modes in this region. A new band has been found near 425 or 473 cm^{-1} in the complexes which probably arises from the ν(Ru—N) modes as previously assigned for metal–nitrogen vibrations.[14,15] The bands near 320 cm^{-1} are likely to be due to ν(Ru—Cl), similar to those found in $[MCl_2(PPh_3)_2L]$ [M = Ru, Os; L = O,O-donor ligands(−1)].[3-5] A weak band at 260 cm^{-1} was observed for the complex $[RuBr_2(AsPh_3)_2(8\text{-hq})]$ which is probably due to ν(Ru—Br), as found for *trans*-$[RuBr_2(py)_4]$.[7] In the complex $[RuCl_2(AsPh_3)_2(amhpy)]$, no bands were observed for ν(Ru—py) as found with $[RuCl_2(py)_4]$ and $[RuCl_2L_4]$ (L = *o*-aminopyridine) at 294 and 306 cm^{-1}, respectively.[16] This suggests that the coordination of the ligand (amhpy) involves only the amino and hydroxyl groups as with the complex $[RuCl_2(AsPh_3)_2(o\text{-amph})]$. The most important IR bands are listed in Table 1. The air sensitivity of the ruthenium(II) complexes and the deep colours of the ruthenium(III) complexes make them all unsuitable for Raman studies.

Electronic spectra and electron spin resonance

The UV–vis spectra of the ruthenium(II) complexes in de-aerated CH_2Cl_2 solution (Table 1) showed a broad band near 475 nm. This is assigned to metal–ligand charge-transfer transitions, $t_2(Ru) \rightarrow \pi^*(L)$, similar to those found for $[Ru^{II}(bipy)_2A][ClO_4]$ [A = arylazo-oximato ligand(−1)].[17] The band in the region 375–345 nm could arise from $X \rightarrow t_2$ (X = Cl) transitions.[4,18,19] The bands below 300 nm are of the interligand $\pi \rightarrow \pi^*$ type.[5,20] The spectra of ruthenium(III) complexes in CH_2Cl_2 show bands above 550 nm of high intensity, attributed to ligand(π)→metal(d) transitions,[20-23] and the other bands observed (Table 1) are similarly assigned as in the ruthenium(II) complexes above.

The ESR spectra of the solid samples of the ruthenium(III) complexes were carried out at −170°C, cold nitrogen gas was passed over the sample tube for cooling. The spectrum of each complex (Fig. 1 as a representative example) shows three g-values (Table 2) in agreement with a low-symmetry of the ligand field similar to the g-values for *mer*-$[RuCl_3(AsPh_3)_3]$[24] and $[Ru^{III}Cl(Salen)(PPh_3)]$ [H_2Salen = N,N - ethylenebis(Salicylaldimine)].[25] We have recently[4] shown that the complex $[OsCl_2(PPh_3)_2L]$ [L = hexafluoroacetylacetonate ion(−1)] had a similar type of ESR spectrum with C_2 symmetry, so we suggest the structure below for

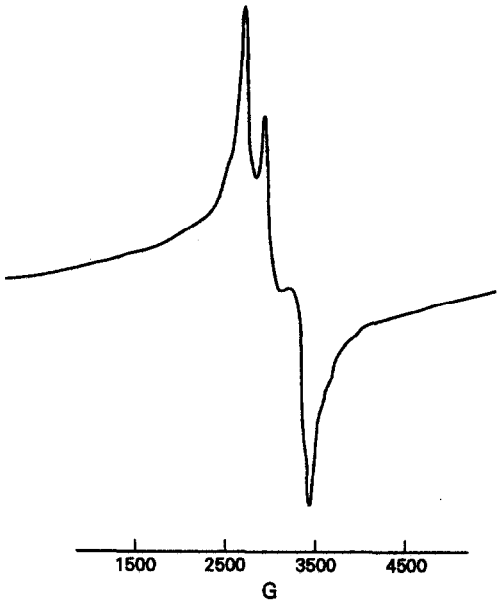

Fig. 1. ESR spectrum of $[RuCl_2(AsPh_3)_2(8\text{-hq})]$.

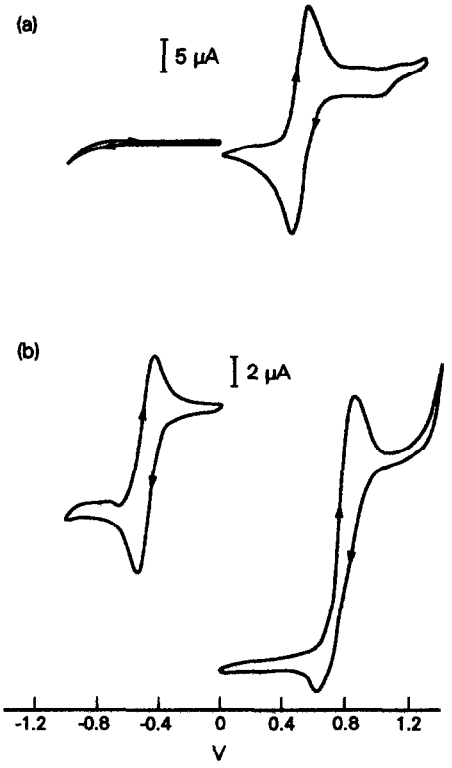

Fig. 2. Cyclic voltammogram in CH_2Cl_2 with 0.1 M $(Bu^n_4N)PF_6$ as supporting electrolyte; volts vs silver electrode: (a) $[RuCl_2(PPh_3)_2(bhz)]$ ($\sim 10^{-3}$ M), scan rate 50 mV s^{-1}; (b) $[RuBr_2(AsPh_3)_2(8\text{-hq})]$ ($\sim 10^{-3}$ M), scan rate 10 mV s^{-1}.

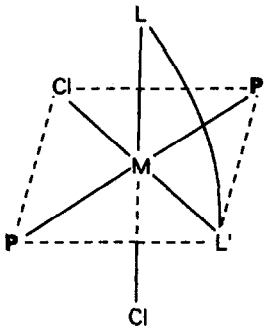
our ruthenium(III) complexes $[RuCl_2(AsPh_3)_2L']$ [L' = O,N-donor ligand(−1)] of C_s symmetry.



[M = Os, P = PPh_3, L–L' = O,O-donor ligand (−1)[4]; M = Ru, P = $AsPh_3$, L–L' = O,N-donor ligand (−1)]

Redox properties

The electrochemical properties of the complexes were investigated by cyclic voltammetry. Voltammetric data vs the silver electrode for 0.1 M $Bu^n_4NPH_6$-CH_2Cl_2 solutions are presented in Table 2. The voltammogram of the hydrazide complexes $[Ru^{II}Cl_2(PPh_3)_2(bhz')]$ reveals only an oxidation wave in each (ΔE = 70–80 mV) which corresponds to a Ru^{II}/Ru^{III} oxidation. The peak separation (ΔE) for each complex is close to that anticipated for a Nernstian one electron process (59 mV);[26] no other peaks could be observed at negative potentials. For $[RuCl_2(PPh_3)_2(bhz)]$, a representative example [Fig. 2(a)] shows only a quasi-reversible one electron oxidation wave, $E_{1/2}$ = +0.50 V, ΔE = 80 mV. The presence of such oxidation waves seems to be typical of ruthenium(II) complexes, e.g. $[Ru^{II}(Salen)(PPh_3)_2]$[27] and $[Ru^{II}(bipy)_2A][ClO_4]$ (HA = arylazo-oxime).[17] The irreversible peak of oxidation found for $[Ru^{II}Cl_2(PPh_3)_2(phachz)]$ was typically observed for $[Ru^{II}Cl_2(HA)]$ at +1.2 V and also explained as being due to a Ru^{II}/Ru^{III} oxidation.[28]

The complexes $[Ru^{III}X_2(AsPh_3)_2(8\text{-hq})]$ (X = Cl, Br) show a pair of cathodic and anodic peaks in each complex [Fig. 2(b)]. The reversible wave at a negative potential (ΔE = 60–70 mV) is presumably assigned to Ru^{III}/Ru^{II} reduction, similar to that found for $[M^{III}Cl_2(PPh_3)_2L]$ [M = Ru, Os; L = O,O-donor ligand(−1)][3,4] and $[Ru^{III}(Salen)(PPh_3)(py)][ClO_4]$.[29] The other couple of peaks at positive potentials have heights double those of the corresponding reduction, ΔE = 170–180 mV. This probably arises from the oxidation of ruthenium(III) to higher oxidation states [e.g. Ru^V], as similarly found for the presence of an irreversible peak at +1.26 V in $[Ru^{III}Cl_2(PPh_3)_2(acac)]$.[4] A small shift to a more negative potential was

observed for the reduction wave of $[RuCl_2(AsPh_3)_2(8\text{-hq})]$ compared with that of the analogous bromo complex, since we expect that the bromo complex is more readily reduced as reported for $[Os^{III}X_2(PPh_3)_2L]$ (X = Cl, Br; HL = 2-hydroxypyridine, 2-hydroxy-6-methylpyridine and picolinic acid).[30] The complexes $[Ru^{III}Cl_2(AsPh_3)_2L']$ (L′ = *o*-amph, amhpy) show an irreversible cathodic peak and a reversible wave of oxidation, corresponding to Ru^{III}/Ru^{II} reduction and Ru^{III}/Ru^{IV} oxidation, respectively.

For scan rates (SR) between 10–100 mV s^{-1}, the ratio $i_p/(SR)^{1/2}$ (i_p = peak current) was constant and the ratio of anodic to cathodic peak current is one, the peak separation being independent of the scan rate. This indicates that the electron transfer is reversible or approaches reversibility and the mass transfer is limited.

Catalytic oxidation

In attempts to find new ruthenium(II) and ruthenium(III) complexes that act as efficient catalysts in the presence of excess NMO for selective oxidation of primary alcohols to aldehydes and secondary alcohols to ketones, we have used the present new complexes for such catalytic oxidation. It has been reported that the complexes $[RuCl_2(PPh_3)_3]$[10] and $Ru^{III}Cl_2(PPh_3)_2(acac)]$[3] (**II**) in the presence of excess NMO are good catalytic oxidants for alcohols with turnovers 50–100. Table 3 summarizes our results for catalytic oxidations by $[Ru^{II}Cl_2(PPh_3)_2(bhz)]$ (**III**) and $[Ru^{III}Cl_2(AsPh_3)_2(8\text{-hq})]$ (**IV**) for alcohols with NMO as the co-oxidant. The oxidations were carried out at room temperature in dichloromethane solution from which water was removed using powdered molecular sieves. There was no detectable oxidation of the alcohols with NMO present only in the absence of a ruthenium complex. Primary alcohols were oxidized to aldehydes and secondary alcohols to ketones with both higher yields and turnovers. The ruthenium(II) catalyst **III** has turnovers (60–80) similar to those obtained by **II**[3] while complex **IV** is far superior to the other catalysts,[3,5,10] achieving turnovers of 400. Both the present catalysts **III** and **IV** are more effective towards oxidation of unsaturated alcohols, e.g. cinnamyl alcohol. The oxidation of cinnamyl alcohol was also carefully carried out using $[RuCl_2(PPh_3)_2(bhz'')]$/NMO [bhz″ = substituted hydrazides; *p*-Cl bhz(**III′**), *p*-Me bhz(**III″**)] instead of **III** under the same conditions; the yield of the aldehyde was 68, 64 and 61% for the catalysts **III′**, **III** and **III″**, respectively. Although the $E_{1/2}$ values of the oxidation waves for the different hydrazide ruthenium(II) complexes are close, it is clear from the oxidation of cinnamyl alcohol that a coordinating hydrazide which contains an electron attracting group (*p*-Cl bhz) increases the rate of oxidation contrary to that obtained with the electron repelling group (*p*-Me bhz). Catalytic oxidation for *p*-methoxybenzyl alcohol by

Table 3. Catalytic oxidation of alcohols by $[RuCl_2(AsPh_3)_2(8\text{-hq})]$/NMO

Alcohol	Product[a]	Time (h)	Yield (%)	Turnover[b]
p-methoxybenzyl	A	2.5	94	400
	A	2	93	80
	A[c]	3[c]	92[c]	105[c]
	(A)	(2.5)	(95)	(200)
piperonyl	A	2.5	83	250
	A	3	79	70
	(A)	(3)	(91)	(200)
cinnamyl	A	4	75	400
	A	2.5	64	70
α-tetralol	K	3	76	400
	K	2	92	65
benzohydrol	K	3	89	200
benzyl	A	3	94	220
	A	2	95	60

Underlined data refer to oxidation by $[RuCl_2(PPh_3)_2(bhz)]$/NMO and those between parentheses are by $[RuCl_2(AsPh_3)_2(o\text{-amph})]$/NMO.

[a] A = corresponding aldehyde, K = corresponding ketones.

[b] Turnover = moles of product/moles of catalyst.

[c] Oxidation carried out under nitrogen.

$[RuCl_2(PPh_3)_2(bhz)]$ was also carried out under nitrogen, and a better yield of the corresponding aldehyde was obtained. This indicates that the oxidations by **III** were not assisted aerobically as are those effected by $[Ru_2^{VI}O_6(py)_4]$,[8] and indeed the optimum condition of oxidation is to perform it under nitrogen since these ruthenium(II) complexes are air-sensitive.

The complex $[Ru^{III}Cl_2(AsPh_3)_2(o\text{-amph})]$(**V**) was also used for oxidation of piperonyl and *p*-methoxybenzyl alcohols; the yield of the corresponding aldehyde (turnovers 200, Table 3) is lower than that given by **IV**. It is of interest to note that the catalyst $[RuCl_2(AsPh_3)_2(8\text{-hq})]$ (**IV**) is more efficient than the other ruthenium(III) complexes (e.g. **V**). This can be concluded from the difference in their electrochemical behaviour at positive potentials, since complex **IV** shows an oxidation wave of current height twice that of complex **V**, as suggested above due to the oxidation of Ru^{III} to higher oxidation states of ruthenium, possibly Ru^{V} and Ru^{III} to Ru^{IV}, respectively. Also, catalyst **IV** is much better than the reported $[RuCl_2(PPh_3)_2acac]$ for the oxidation of alcohols; this probably arises from the appearance of an oxidation wave for **IV** ($\Delta E = 170$ mV) instead of the only anodic peak observed at positive potentials for the acetylacetonate complex **II**. We believe that the presence of such an oxidation wave in **IV** reflects the reason for the more efficient catalysis cycle of oxidation and consequently the higher turnovers given (reached 400).

EXPERIMENTAL

Preparation of complexes

Benzoic acid hydrazide and its substituted derivatives were prepared according to the procedures described earlier.[31]

Preparation of $[Ru^{II}Cl_2(PPh_3)_2(bhz)]$. Complex $[RuCl_2(PPh_3)_3]$[32] (**VI**) (0.48 g, 0.5 mmol) was added under nitrogen to a degassed methanolic solution (10 cm^3) containing benzoic acid hydrazide (0.1 g, 0.75 mmol). The mixture was refluxed on a steam bath where the dark crystals of **VI** dissolved rapidly, followed by the separation of a yellow precipitate. Heating was continued for 0.5 h under nitrogen. The precipitate was filtered off, washed with a little degassed methanol and ether, and dried *in vacuo*.

A similar procedure was used to prepare the other hydrazide complexes in which reflux was continued for 1–2 h. Evaporation of some methanolic solution occurred by passing nitrogen gas through to separate out the products at the end of the reaction.

Preparation of $[Ru^{III}Cl_2(AsPh_3)_2(8\text{-hq})]$. Complex $[RuCl_3(AsPh_3)_2MeOH]$[32] (**I**) was used as a starting material. A solution of **I** (0.21 g, 0.25 mmol) in methanol (100 cm^3) was refluxed, then the ligand (H 8-hq) (0.05 g, 0.35 mmol) added. The mixture was refluxed for 1 h after which time, good yellowish-green microcrystals were obtained, filtered off, washed with methanol and then ether and dried *in vacuo*. The analogous bromo complex was similarly prepared from $[RuBr_3(AsPh_3)_2MeOH]$[32] and reflux continued for 2 h.

The same procedure was used to synthesize the complexes of *o*-aminophenol and 2-amino-3-hydroxypyridine.

Catalytic oxidation by $[RuCl_2(AsPh_3)_2(8\text{-hq})]$ (**IV**)

The oxidation of *p*-methoxybenzyl alcohol is typical. To a solution of *p*-methoxybenzyl alcohol (1 mmol) was added NMO (3 mmol) in CH_2Cl_2 (20 cm^3) and 2.5×10^{-3} mmol of compound **IV**. The solution was stirred for 2.5 h in the presence of 4 Å molecular sieves (0.5 g). The mixture was evaporated to dryness and extracted with ether (2×25 cm^3). The combined ethereal extracts were filtered and evaporated to give *p*-methoxybenzaldehyde which was characterized and quantified as its 2,4-dinitrophenylhydrazone derivative.

The same experiment was carried out using $[RuCl_2(PPh_3)_2(bhz)]$ and $[RuCl_2(AsPh_3)_2(o\text{-amph})]$ in place of **IV**.

IR spectra were measured on a Perkin–Elmer 883 or FT 1720 instrument as liquid paraffin mulls between CsI plates and KBr discs. ESR spectra were recorded with a Varian E-12 spectrometer. The electronic spectra were measured on a Philips PU 8740 UV–vis spectrophotometer or a Varian 634 model. Cyclic voltammetric studies were carried out on a potentiostat/wave generator (Oxford Electrodes) using a platinum working electrode and silver reference electrode in conjunction with a Philips PM 8043 X-Y recorder. Magnetic measurements were made on a Johnson Matthey magnetic susceptibility balance.

FURTHER STUDIES OF $Mo_3(\mu_3\text{-}I)(\mu_3\text{-}H)(\mu\text{-}I)_3I_3L_3$ CLUSTER SPECIES: COMPOUNDS WITH L = PEt_3 AND PPh_3

ALFREDO BURINI, F. ALBERT COTTON* and JOANNA CZUCHAJOWSKA

Department of Chemistry and Laboratory for Molecular Structure and Bonding, Texas A&M University, College Station, TX 77843, U.S.A.

(*Received* 17 *April* 1991; *accepted* 4 *June* 1991)

Abstract—The chemistry leading to the isolation of $Mo_3HI_7L_3$ compounds has been re-examined. Although yields of the species with L = THF could not be improved, crystalline samples of compounds with L = PPh_3 (**1**) and PEt_3 (**2**) have been obtained and characterized by X-ray crystallography and ^1H NMR spectra. The NMR spectra (1,3,3,1 quartets for ^1H) provide conclusive evidence for the presence of the μ_3-H ligand. The principal crystallographic data are: (**1**): orthorhombic space group *Pnma*, $a = 20.726(3)$, $b = 21.704(1)$, $c = 20.05(1)$ Å; $V = 9020$ Å^3; $Z = 4$; d_{calc}, 1.672 g cm^{-3}; $R = 0.0361$, $R_w = 0.0533$ for 423 parameters and 4935 observed data [$F_o^2 > 3\sigma(F_o^2)$]. (**2**): orthorhombic space group *Pbca*, $a = 20.877(8)$, $b = 16.951(5)$, $c = 24.007(4)$ Å; $V = 8495$ Å^3; $Z = 8$; $d_{calc} = 2.508$ g cm^{-3}; $R = 0.0343$, $R_w = 0.0495$ for 296 parameters and 4655 observed data [$F_o^2 > 3\sigma(F_o^2)$]. NMR (^1H in C_6D_6) data: (**1**) $\delta = -5.01$, $^2J(HP) = 36$ Hz; (**2**) $\delta = -2.26$, $^2J(HP) = 39$ Hz.

The preparation and structural characterization of a new type of triangular metal atom cluster species, $Mo_3(\mu_3\text{-}I)(\mu_3\text{-}H)(\mu\text{-}I)_3I_3L_3$ were reported from this laboratory a few years ago.[1] Four compounds, with L = RCN or THF, were structurally characterized by X-ray crystallography. The presence of the μ_3-H atom, which could not be observed in any of the structures, was supported by an NMR signal (−10.3 ppm for the compound with L = PhCN), by the diamagnetism of the compounds and by a molecular orbital calculation. Further studies have now been carried out and are reported here. As will be seen, the present results provide conclusive evidence for the presence of the μ_3-H atom and for its location on the molecular three-fold axis.

EXPERIMENTAL

Materials and methods

All manipulations were carried out under an atmosphere of purified argon using standard Schlenk techniques. The solvents were carefully purified by conventional methods and freshly distilled under dinitrogen prior to use. Chemicals were purchased from the following sources: $Mo(CO)_6$, Aldrich; I_2, Baker; phosphines, Strem. All chemicals were used without further purification. The compounds $Mo(CO)_3(\eta^6\text{-}C_6H_5CH_3)$,[2] $MoI_2(CO)_3(CH_3CN)_2$[3] and $MoI_3(THF)_3$[4] were prepared according to the literature; $Mo_3HI_7(THF)_3$ was prepared according to the literature method[1] or by the procedure reported below. Instruments used were: IR, Perkin-Elmer 783; UV–vis, Cary 17; ^1H NMR, Varian XL-200; ^{31}P NMR, Varian XL-400; elemental analyses were by Galbraith Laboratories, Knoxville, Tennessee.

Preparation of intermediate **A**

This substance was prepared from $Mo(CO)_3(\eta^6\text{-}C_6H_5CH_3)$ by the method described by Cotton and Poli.[1] From 1.50 g of starting material, a yield of 1.60 g of dry **A** was obtained.

Preparation of intermediate **B** *from* $MoI_2(CO)_3(CH_3CN)_2$

Using $MoI_2(CO)_3(CH_3CN)_2$ instead of $Mo_2I_4(CO)_8$, a material which appears to be similar

* Author to whom correspondence should be addressed.

(with CH_3CN ligands instead of THF ligands) to Cotton and Poli's "sample A" was obtained. $MoI_2(CO)_3(CH_3CN)_2$ (0.4 g, 0.77 mmol) was dissolved in benzene (30 cm^3) to afford a brown solution, and this was warmed to reflux temperature. After 2 h a dark brown precipitate was filtered off, washed with benzene and dried *in vacuo*; yield 0.250 g (sample **B**). The IR spectrum (Nujol mull, cm^{-1}) of this compound shows two medium bands at 2308 and 2278 due to coordinated CH_3CN.

Preparation of $Mo_3HI_7(PPh_3)_3$ *from* **A**

Intermediate **A** (0.290 g) was suspended in THF (20 cm^3). Ph_3P (0.200 g, 0.76 mmol) was added and the stirred mixture was warmed to reflux temperature. After 20 h a dark brown solution and a brown precipitate were formed. The brown precipitate, separated by filtration, washed with THF and dried *in vacuo*, did not show any peaks in the IR spectrum; yield 0.150 g. The solution was evaporated to dryness and the oily mixture obtained was washed with hexane. The crude product obtained was extracted with benzene (10 cm^3) and the solution was then filtered through Celite and layered with hexane (30 cm^3). Brown crystals and some brown microcrystalline material were obtained after 3 days. A single crystal from this batch was used for the X-ray analysis. The microcrystalline compound shows the same spectroscopic properties as the larger crystals; yield 30 mg. Found: C, 37.8; H, 2.8. Calc. for $C_{66}H_{58}I_7Mo_3P_3$: C, 37.4; H, 2.8%. ^1H NMR (C_6D_6):[5] δ −5.01 (q, η^3-*H*, ^2J(HP) = 36 Hz), 7.10–8.05 (m, Ar*H*). The UV–vis spectrum in CH_2Cl_2 solution is shown in Fig. 1.

Preparation of $Mo_3HI_7(PPh_3)_3$ *from* **B**

Intermediate **B** (0.250 g) was added to THF (20 cm^3). Most of the solid dissolved to form a dark brown solution. Ph_3P was added and the reaction mixture was warmed to reflux temperature. After about 20 h the reaction mixture was filtered through Celite, and the brown solution obtained was evaporated to dryness. The crude compound was washed with hexane and then extracted with benzene (25 cm^3). The benzene solution was filtered through Celite, concentrated *in vacuo* to about 10 cm^3, and layered with hexane (25 cm^3). A few brown crystals were formed after a few days. These were characterized to be $Mo_3HI_7(Ph_3P)_3$ by their spectroscopic properties.

Reaction between **A** *and* PEt_3

Intermediate **A** (0.200 g) was suspended in THF (20 cm^3), PEt_3 (0.1 cm^3, 0.68 mmol) was added by syringe, and the reaction was stirred at room temperature. After about 3 h most of **A** dissolved giving an emerald green solution and a brown insoluble residue. The reaction was checked by TLC using a silica gel plate and a 1:1 mixture of THF/hexane 1:1 as eluant. The chromatography showed two main spots, a blue one at RF = 0.7 and a yellow one at RF = 0.5. There was no spot corresponding to the spot of a sample of $Mo_3HI_7(PEt_3)_3$ used as a reference. After the reaction mixture was stirred overnight, without any changes being observed, it was evaporated to dryness and the residue extracted with hexane (15 cm^3). The blue solution obtained was concentrated to about 2 cm^3 *in vacuo*. After 2 days at −20°C blue crystals were recovered from the solution. The spectroscopic properties of this sample were in accord with the known compound $Mo_2I_4(PEt_3)_4$.[4] The residue left after extraction with hexane was dissolved in THF (20 cm^3), the solution filtered and layered with hexane (30 cm^3). After a few days yellow crystals were obtained. These were characterized by IR spectroscopy to be $[MoI_4(PEt_3)_2][HPEt_3]$.[4]

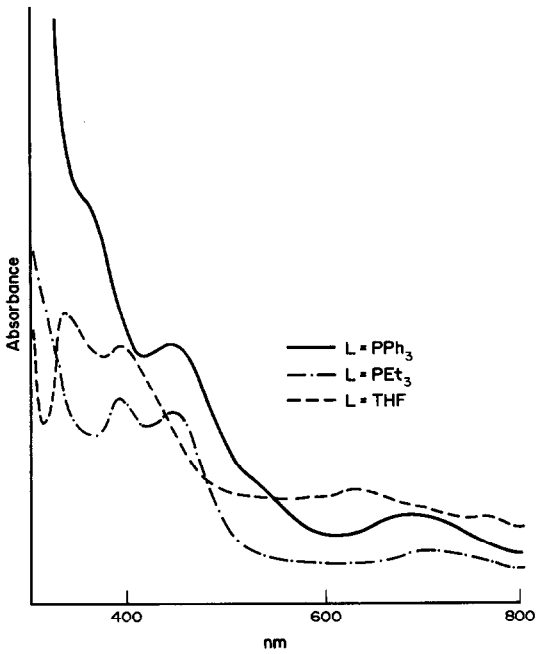

Fig. 1. A comparison of UV–vis spectra for the trinuclear clusters $Mo_3HI_7L_3$ (L = THF, PEt_3, PPh_3). The absorbance is given on an arbitrary scale.

Reaction between **B** *and* PEt_3

Intermediate **B** and PEt_3 were permitted to react as in the procedure described above for the reaction between **A** and PEt_3. Analogous results were obtained.

Preparation of $Mo_3HI_7(THF)_3 \cdot THF$ *from* $MoI_3(THF)_3$

To a suspension of $MoI_3(THF)_3$ (0.50 g, 0.72 mmol) in THF (20 cm^3), toluene (1 cm^3) and $Mo(CO)_6$ (0.024 g, 0.09 mmol) were added. The stirred mixture was warmed to reflux temperature. After 22 h a brown solution and some unreacted starting material were obtained. The solution was filtered through Celite. The presence of the trinuclear cluster $Mo_3HI_7(THF)_3$ was detected by the UV–vis spectrum of the solution. From this solution dark cuboidal crystals were obtained after 2 days. These were found to be $Mo_3HI_7(THF)_3$ by UV–vis spectroscopy and by their reactivity with PEt_3 (see below). Yield: 0.025 g (6%). The mother liquor, checked by UV–vis spectroscopy, showed neither the presence of further $Mo_3HI_7(THF)_3$ nor were there any absorption bonds indicative of $Mo_2I_4(THF)_4$ or other quadruply bonded species.

Preparation of $Mo_3HI_7(PEt_3)_3$

$Mo_3HI_7(THF)_3 \cdot THF$ (20 mg, 6.8 μmol) was suspended in THF (3 cm^3). A small amount of the solid dissolved to afford a green solution. PEt_3 (0.1 cm^3, 0.68 mmol) was added by syringe, and the reaction was stirred at room temperature. All the starting material slowly went into solution and the colour of this turned from green to brown in about 1 h. The reaction mixture was stirred for an additional 2 h, filtered through Celite and concentrated to about 1 cm^3 *in vacuo*. After cooling to -20°C for 1 day dark plate crystals formed. One of the crystals was used for the X-ray analysis. The conversion was almost quantitative. ^1H NMR (C_6D_6):[5] δ -2.26 (q, η^3-*H*, $^2J(HP) = 39$ Hz), 0.92 (dt, C*H*$_3$, $^3J(HP) = 14$ Hz, $^2J(HH) = 7$ Hz), 1.91 (qu, C*H*$_2$, $^2J(HP) = {}^3J(HH) = 7$ Hz). The $^{31}P\{^1H\}$ NMR spectrum was run in a THF solution to which a few drops of C_6D_6 were added. The ^{31}P shift referenced to 85% H_3PO_4 was δ -5.63. The UV–vis spectrum in THF solution is shown in Fig. 1.

X-ray crystallography

The structures of $Mo_3HI_7(PPh_3)_3 \cdot 4C_6H_6 \cdot C_4H_8O$ (**1**) and $Mo_3HI_7(PEt_3)_3 \cdot 2C_4H_8O$ (**2**) were determined by standard procedures for this laboratory.[6] Data collection and reduction were carried out by standard methods with the use of well-established computational procedures.[7] Crystallographic and procedural data for both are summarized in Table 1. Complete tables of crystal positional parameters, further details of data collection and refinement, bond distances, bond angles, anisotropic displacement parameters and structure factors are available as supplementary material.

Compound (**1**)

A dark brown, block-shaped crystal of $Mo_3HI_7(PPh_3)_3 \cdot 4C_6H_6 \cdot C_4H_8O$ was mounted on the tip of a glass fibre using epoxy resin. The reduced cell dimensions indicated that the crystal belonged to the orthorhombic crystal system, and this was verified by axial photography. No correction for decay was necessary. Azimuthal scans of six reflections with Eulerian angle χ near 90° were used as the basis for an empirical absorption correction.[8] After averaging the equivalent reflections there remained 6850 unique data and 4842 reflections with $F_o^2 \geqslant 3\sigma(F_o)^2$. On the basis of systematic absences the space group could be either *Pnma* or $Pn2_1a$. Using *Pnma*, we employed the direct-methods program in SHELXS-86[9] which led to the location of the molybdenum, iodine and phosphorus atoms. The atoms Mo(1), I(1), I(122), I(22), μ_3-H, P(1), C(121), C(124) and H(124) were found to lie on a mirror plane while atoms Mo(2), I(2), I(12) and P(2) lie off the mirror and thus all other atoms are generated by symmetry. After a sequence of alternating least-squares cycles and difference Fourier maps all carbon atoms belonging to the phenyl rings were located, in addition to four molecules of the interstitial solvent benzene and one of THF. Two of the benzene molecules lie on a mirror plane. At this stage most of the atoms were refined anisotropically to give acceptable values of R and R_w. A difference Fourier map now revealed a small amount of electron density above the centre of the Mo_3 unit; this was assigned as a hydrogen atom. Subsequent refinement including the hydrogen atoms in the phenyl groups was carried out using SHELXS-76[10] to give $R = 0.0361$ and $R_w = 0.0533$. The central part and the entire molecule of $Mo_3HI_7(PPh_3)_3$ are shown in Figs 2 and 3, respectively.

Compound (**2**)

A brown–orange, plate crystal of $Mo_3HI_7(PEt_3)_3 \cdot 2C_4H_8O$ was shown to be of good quality by polarized light microscopy. It was mounted on the tip of a glass fibre using Apiezon grease. All procedures for collection and reduction of data are described previously (see Table 1). On the basis of systematic absences the space group was determined to be *Pbca*. The entire molecule was located using the direct-methods program in SHELX-86.[9] The subsequent development of the structure was done by an alternating sequence of least-squares

[c] Quality-of-fit = $[\Sigma w|F_o|-|F_c|^2/(N_{obs}-N_{par})]^{1/2}$.

refinement and difference Fourier maps. Supplementary data has been deposited.*

RESULTS AND DISCUSSION

We have found that the previously described reactions leading to $Mo_3HI_7L_3$ species are reproducible. Unfortunately we have been unable to make substantial improvement in the very small yields of the trinuclear products. We have introduced several hydride sources, $(n\text{-}C_4H_9)_2SnH$, NaH, $NaBH_4$, into the reactions which produce intermediate solutions **A** and **B**, but this has not helped. We have also tried to carry out reaction (1) which, on paper, is perfectly stoichiometric, but it does not go under any known conditions. However, we found an alternative way to prepare $Mo_3HI_7(THF)_3$ (see Experimental) following reaction (2), but the best yield was only 6%.

* *Supplementary material available.* A fully labelled drawing of **1**, tables of positional parameters for **1** and **2**, full tables of anisotropic thermal parameters and molecular dimensions and listings of observed and calculated structure factors (total pages 79).

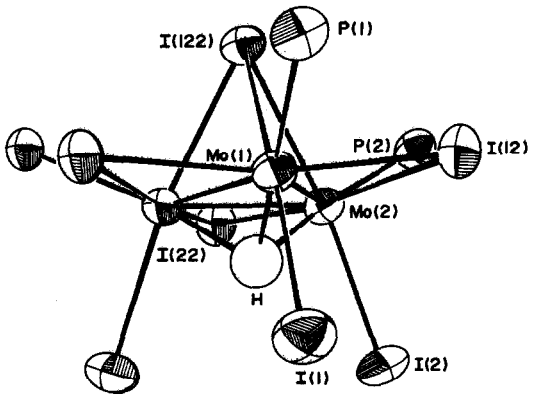

Fig. 2. An ORTEP view of the central core of the trinuclear cluster $Mo_3HI_7(PPh_3)_3$ (**1**). The carbon atoms are omitted for clarity. Atoms are represented by 50% probability ellipsoids.

$$3MoI_2(CO)_3(CH_3CN)_2 + HI(g) \xrightarrow{\text{benzene}} Mo_3HI_7(CH_3CN)_3 + 9CO + 3CH_3CN \quad (1)$$

$$8MoI_3(THF)_3 + Mo(CO)_6 + 3\text{solv-H} \xrightarrow{\text{THF/toluene}} 3Mo_3HI_7(THF)_3 + 6CO + 3\text{solv-I} \quad (2)$$

The presence of $Mo(CO)_6$ in the reaction system is essential since when $MoI_3(THF)_3$ was refluxed alone a brown solution was obtained for which the UV–vis spectrum did not show the cluster species. $Mo_2I_6(THF)_4$ or $Mo_2I_6(THF)_3$, analogous to the corresponding chlorine and bromide compounds,[11] was probably formed. The source of H^- and the fate of the lost iodine are not known; we have suggested in eq. (2) that the solvent plays a role in both these parts of the process, but this is only a speculation. One conclusion that might be drawn from the ineffectiveness of the added hydride is that the slow and limited formation of the products may not be solely restricted by availability of the hydride ligand, but also by the process of forming the Mo_3 cluster itself.

We have found that the compound in which $L = PPh_3$ can be obtained by direct reaction of PPh_3 with the intermediates **A** and **B**. Although this direct approach failed for PEt_3, it was possible to obtain the PEt_3 compound by first isolating $Mo_3HI_7(THF)_3$ and then displacing the THF ligands. This would probably be a fairly general route to the $Mo_3HI_7L_3$ species when L is any ligand other than THF. However, this route will become important only if the preparation of $Mo_3HI_7(THF)_3$ can be substantially improved.

The structures of compounds **1** and **2** are very similar to those previously determined for com-

the μ_3-H atom is expected to be. This is the only structure in which such an observation was made. However, when this was included in the refinement with variable positional parameters it moved somewhat away from the three-fold axis, although it remained in the crystallographic mirror plane.

The most important contribution of the present work is the rigorous demonstration that these clusters contain a hydrogen atom located so that it is coupled equally to all three phosphorus atoms in the $Mo_3HI_7(PR)_3$. The signals for hydride ions in the ^1H NMR spectra of compounds **1** and **2** are located at -5.01 and -2.26 ppm, respectively. These are both 1,3,3,1 quartets and the coupling constants ^2J(H—P) are 36 Hz when L = PPh_3 and 39 Hz when L = PEt_3. The values of ^2J(H—P) are unusually low for PR_3 *trans* to hydrogen; others are known to be in the range 90–180 Hz. This may be due to the low bond order (1/3) of the M—H bonds to the hydride ligand. However, the chemical shifts and the coupling constants are close to those found in the trinuclear iridium clusters $[IrH_2(PCy_3)Py]_3(\mu_3\text{-}H)(BF_4)_2$.[12] The presence of the solvent molecules in the crystal structure of compound **1** was confirmed by ^1H NMR only for two molecules of benzene. The same results were given from the elemental analyses (see Experimental). The absence of one benzene molecule and one THF molecule is due to the fact that the samples used in these cases had been pumped *in vacuo* overnight. The $^{31}P\{^1H\}$ NMR of compound **2** shows a singlet at -5.63 ppm due to the triethyl phosphine ligand in agreement with the presence of three equivalent phosphorus atoms in the trinuclear cluster.

The UV–vis spectra of compounds **1** and **2** are shown in Fig. 4 together with that of $Mo_3HI_7(THF)_3$ in THF solution; they show a blue shift going from L = PR_3 to L = THF with bands at 710, 445, 395 (L = PEt_3), 680, 445, 360 (L = PPh_3), 640, 395 and 340 nm (L = THF).

SYNTHESIS AND CHARACTERIZATION OF SOME BIMETALLIC PLATINUM–RHODIUM COMPLEXES. CRYSTAL STRUCTURE OF $[(PhC{\equiv}C)Pt(\mu\text{-dppm})_2(\mu\text{-}N_2C_3Br_3)Rh(CO)]PF_6$

JEFFREY C. DePRIEST and CLIFTON WOODS*

Department of Chemistry, The University of Tennessee, Knoxville, TN 37996-1600, U.S.A.

(*Received* 4 *February* 1991; *accepted* 4 *June* 1991)

Abstract—The addition of pyrazolate ions to $[ClPt(\sigma,\eta\text{-}C{\equiv}CPh)(\mu\text{-dppm})_2Rh(CO)]PF_6$ (dppm = bis(diphenylphosphino)methane) produces the complexes $[(PhC{\equiv}C)Pt(\mu\text{-Z})(\mu\text{-dppm})_2Rh(CO)]PF_6$ (Z = pyrazolate derivative). The use of the 3-methyl-5-trifluoromethylpyrazolate ion gives a mixture of the two isomers that contain the unsymmetrical pyrazolate ligand in its two possible orientations. The addition of *t*-BuNC to the complexes $[(PhC{\equiv}C)Pt(\mu\text{-Z})(\mu\text{-dppm})_2Rh(CO)]PF_6$ leads to substitution of the CO by *t*-BuNC. The complexes $[(CN)Pt(\mu\text{-Z})(\mu\text{-dppm})_2Rh(CO)]PF_6$ were prepared in a similar manner from $[(CN)_2Pt(\mu\text{-dppm})_2Rh(CO)Cl]$. The dapm analogues $[(CN)Pt(\mu\text{-35mpz})(\mu\text{-dapm})_2Rh(L)]PF_6$ [dapm = (diphenylarsino)(diphenylphosphino)methane; 35mpz = 3,5-dimethylpyrazolate; L = CO, *t*-BuNC] and the complex [*cis*-$ClPt(\mu\text{-35mpz})(\mu\text{-dapm})_2$-*trans*-$Rh(CO)]PF_6$ have also been prepared and characterized. $[(PhC{\equiv}C)Pt(\mu\text{-345Bpz})(\mu\text{-dppm})_2Rh(CO)]PF_6$ (345Bpz = 3,4,5-tribromopyrazolate) crystallizes in the triclinic space group $P\bar{1}$ with $a = 10.351(5)$, $b = 14.707(6)$, $c = 22.445(10)$ Å, $\alpha = 94.78(3)°$, $\beta = 98.56(4)°$, $\gamma = 107.68(3)°$, $V = 3189(2)$ Å^3 and $Z = 2$ at 298 K. The structure was refined to an *R* value of 0.0405 using 8382 unique reflections and 740 parameters. The structure consists of the platinum and rhodium atoms in square planar environments, each with two *trans* phosphorus atoms and a nitrogen atom from the pyrazolate ligand. The fourth ligand coordinated to the platinum atom is a terminal phenylacetylide ion and the fourth ligand coordinated to the rhodium atom is a terminal carbon monoxide.

Bis(diphenylphosphino)methane (dppm) has been a convenient ligand for the construction of binuclear transition-metal complexes. Though complexes of the ligand (diphenylarsino)(diphenylphosphino)methane (dapm) have been much less studied, dapm offers most of the same features as dppm. We have recently investigated several of the chemical, electrochemical and structural aspects of pyrazolato-bridged dirhodium complexes of both of these ligands.[1] In order to gain better insights into factors affecting bonding modes and chemical, electrochemical and structural features of dppm and dapm bimetallic complexes, we have expanded our investigations to include pyrazolato-bridged heterodinuclear transition-metal complexes that contain *trans* dppm and dapm bridging ligands. Herein we describe the synthesis and characterization of several such platinum–rhodium complexes listed in Table 1.

EXPERIMENTAL

Materials

Pyrazole (Hpz), 4-methylpyrazole (H4mpz) and 3,5-dimethylpyrazole (H35mpz) were purchased from Aldrich Chemicals. 4-Bromo-3,5-dimethylpyrazole (H4B35mpz) was obtained from Pfaltz and Bauer and 3,4,5-tribromopyrazole (H345Bpz)[2] and 3-methyl-5-trifluoromethylpyrazole (Hmtmpz) were prepared by a reported procedure.[3] Bis(diphenylphosphino)methane (dppm) was purchased from Strem and phenylacetylene was purchased from Aldrich and both were used without further purification. (Diphenylarsino)(diphenylphosphino)

methane,[4] $Pt(CN)_2(dppm)_2$[5] and $PtCl_2(dapm)_2$[6] were prepared by literature procedures.

Preparation of $[Pt(dppm)_2]Cl_2$

This compound was initially prepared from $PtCl_2(COD)$ and dppm.[7] The following method was used in subsequent preparations. Solutions of dppm (2.5371 g, 6.60 mmol) in 10 cm^3 of CH_2Cl_2 and K_2PtCl_4 (1.1694 g, 2.81 mmol) in distilled water were mixed and refluxed for *ca* 3 h during which time the water layer changed from red to colourless and the CH_2Cl_2 changed from colourless to light green. The CH_2Cl_2 layer was separated from the water layer and the product was precipitated from the CH_2Cl_2 layer as a white powder upon the addition of diethyl ether. The yield was quantitative.

Preparation of $[ClPt(\sigma,\eta\text{-}C{\equiv}CPh)(\mu\text{-dppm})_2Rh(CO)]PF_6$ (**1**)

A modification of the procedure of Hutton *et al.*[8] was used to prepare **1**. To a solution of $Pt(dppm)_2Cl_2$ (1.7569 g, 1.70 mmol) in acetone was added solid $AgC_2H_3O_2$ (0.2834, 1.70 mmol) and phenylacetylene, (0.1529 g, 8.50 mmol). The resulting yellow suspension was stirred in darkness for 2 h, after which an acetone solution of $Rh_2(CO)_4Cl_2$ (0.3300 g, 0.85 mmol) was slowly added dropwise. After the mixture was stirred for 1/2 h, during which time the colour changed from dark yellow to orange, solid NH_4PF_6 (2.7674 g, 17.70 mmol) was added and the mixture was stirred for an additional 10 h. The mixture was filtered and the red filtrate was evaporated to dryness. The product was recrystallized twice from CH_2Cl_2/diethyl ether and dried *in vacuo*. The yield was 80%.

Preparation of $[(PhC{\equiv}C)Pt(\mu\text{-}Z)(\mu\text{-dppm})_2Rh(CO)]PF_6$ (**2**, Z = 35mpz; **3**, Z = 4mpz; **4**, Z = pz; **5**, Z = 4B35mpz; **6**, Z = 345Bpz; **7**, Z = mtmpz)

Method 1. To a solution of **1** (0.300 g, 0.217 mmol) in 40 cm^3 of acetone, a solution prepared by adding 2.72 cm^3 of 0.08 M KOH in methanol to 35mpz (0.0210 g, 0.217 mmol) was added dropwise. After the solution was stirred for 20 min, during which time the colour changed from orange to reddish-orange, it was evaporated to dryness. The product was recrystallized from CH_2Cl_2/diethyl ether. The yellow–orange product was dried *in vacuo*. The yield was 83%.

Method 2 (Z = 35mpz, 4mpz, pz). Solid 35mpz (0.1049 g, 1.085 mmol) was added to an acetone solution of **1** (0.300 g, 0.217 mmol). The solution

was stirred for 1 h, during which time the colour changed from orange to reddish-orange. The solution was evaporated to dryness and the product was recrystallized from CH_2Cl_2/diethyl ether and dried *in vacuo*. The yield was 83%.

Preparation of [(PhC≡C)Pt(μ-Z)(μ-dppm)$_2$Rh(*t*-BuNC)]PF_6 (**8**, Z = 35mpz; **9**, Z = 4B35mpz)

To a stirred solution of **2** (0.125 g, 0.091 mmol) in 40 cm^3 of acetone cooled to 0°C, 0.011 cm^3 (0.100 mmol) of *t*BuNC was added dropwise. The colour changed from orange to red and after the solution was stirred for 20 min, the volume was reduced to 8 cm^3 on a rotary evaporator. The light orange solid that was obtained upon the addition of diethyl ether was recrystallized from acetone/diethyl ether and dried *in vacuo*. The yield was 90%.

Preparation of [(CN)Pt(μ-Z)(μ-dppm)$_2$Rh(CO)]PF_6 (**11**, Z = 35mpz; **12**, Z = 4B35mpz; **13**, Z = 345Bpz)

To a solution of **10** (0.159 g, 0.134 mmol) dissolved in 5 cm^3 of CH_2Cl_2 and 100 cm^3 of acetone, solid NH_4PF_6 (0.044 g, 0.27 mmol) was added and the resulting suspension was stirred for 1 h. A methanol solution of KOH (0.076 g, 0.134 mmol) and 35mpz (0.026 g, 0.27 mmol) was added dropwise and the resulting mixture was stirred for 2 h. The yellow solution was evaporated to dryness and the residue was dissolved in CH_2Cl_2 and filtered. Diethyl ether was added to the filtrate and a light yellow solid was recovered and recrystallized four times from CH_2Cl_2/diethyl ether. The yield was 50%.

Found: C, 48.9; H, 4.1. Calc. for **11** $C_{57}H_{51}F_6N_3OP_5PtRh$: C, 50.3; H, 3.8%.

Preparation of [(CN)Pt(μ-Z)(μ-dppm)$_2$Rh(*t*-BuNC)]PF_6 (**14**, Z = 35mpz; **15**, Z = 4B35mpz)

Compound **11** (0.201 g, 0.150 mmol) was dissolved in 40 cm^3 of freshly distilled CH_2Cl_2 and 40 cm^3 of freshly distilled methanol and cooled to 0°C. After the solution was purged with pre-purified argon, *t*-BuNC (0.0135 g, 0.165 mmol) was added dropwise. The solution changed from orange to dark red and was stirred for 15 min. After the solution was evaporated to dryness, the red solid was recrystallized from degassed acetone/diethyl ether. The yield was 75%.

Found: C, 52.8; H, 4.4. Calc. for **14**, $C_{60}H_{60}F_6N_4P_5PtRh$: C, 51.7; H, 4.3%.

Preparation of [Pt(CN)$_2$(dapm-P)$_2$] (**16**)

$PtCl_2$(dapm-*P*)$_2$ (0.260 g, 0.231 mmol) was dissolved in 10 cm^3 of CH_2Cl_2, after which 50 cm^3 of absolute ethanol was added. To this solution a solution of NaCN (0.0225 g, 0.463 mmol) dissolved in 100 cm^3 of ethanol was added dropwise. The resulting solution was stirred for 15 min and evaporated to *ca* one-third the original volume on a rotary evaporator. The product which precipitated upon the addition of diethyl ether was recrystallized from CH_2Cl_2/diethyl ether. The yield was 87%.

Found: C, 56.4; H, 4.2. Calc. for **16**, $C_{52}H_{44}As_2N_2P_2Pt$: C, 56.6; H, 4.0%.

Preparation of [(CN)$_2$Pt(μ-dapm)$_2$Rh(CO)Cl] (**17**)

To a stirred solution of $Rh_2(CO)_4Cl_2$ (0.0386 g, 0.099 mmol) dissolved in 10 cm^3 of CH_2Cl_2 cooled to 0°C, was added dropwise a solution of **16** (0.219 g, 0.198 mmol) dissolved in 10 cm^3 of CH_2Cl_2. After the solution was stirred for 30 min, it was evaporated to dryness on a rotary evaporator. The orange residue was recrystallized from CH_2Cl_2/diethyl ether and dried *in vacuo*. The yield was 78%.

Found: C, 50.2; H, 3.5. Calc. for **17**, $C_{53}H_{44}As_2ClN_2OP_2PtRh$: C, 50.1; H, 3.5%.

Preparation of [(CN)Pt(μ-5mpz)(μ-dapm)$_2$Rh(CO)]PF_6 (**18**)

The same procedure used to prepare **11** was used to prepare **18** from **17** (0.104 g, 0.082 mmol), NH_4PF_6 (0.0266 g, 0.164 mmol), KOH (0.0046 g, 0.082 mmol) and 35mpz (0.0158 g, 0.082 mmol). The yield was 78%.

Found: C, 46.8; H, 3.7. Calc. for **18**, $C_{57}H_{51}As_2F_6N_3OP_3PtRh$: C, 47.2; H, 3.5%.

Preparation of [(CN)Pt(μ-35mpz)(μ-dapm)$_2$Rh(*t*-BuNC)]PF_6 (**19**)

Compound **19** was prepared from **18** by the same procedure used to prepare **14**. Typical quantities were 119 mg (0.081 mmol) of **18** and 7.44 mg (0.090 mmol) of *t*-BuNC. The yield was 85%.

Found: C, 47.8; H, 4.2. Calc. for **19**, $C_{60}H_{60}As_2F_6N_4P_3PtRh$: C, 48.7; H, 4.0%.

Preparation of [cis-ClPt(μ-35mpz)(μ-dapm)$_2$-trans-Rh(CO)]PF_6 (**21**)

Solid NH_4PF_6 (0.015 g, 0.091 mmol) was added to a solution of **20** (0.117 g, 0.091 mmol) in 10 cm^3 of CH_2Cl_2 and 40 cm^3 of acetone. In a separate flask, 35mpz (0.013 g, 0.14 mmol) and KOH (0.0051 g,

0.090 mmol) were combined and allowed to stand for 5 min. The latter solution was added dropwise to the former mixture and the resulting mixture was stirred for 20 min at 0°C. Stirring was continued while the mixture warmed to room temperature. The solvent was removed via a rotary evaporator and the resulting solid was treated with freshly distilled CH_2Cl_2 and filtered. Anhydrous diethyl ether/hexanes (50/50) was added until precipitation was complete. The product was dried *in vacuo*. The yield was 70%.

Found: C, 46.1; H, 3.8. Calc. for **21**, $C_{56}H_{51}As_2ClF_6N_2OP_3PtRh$: C, 46.1; H, 3.5%.

Physical measurements

^{31}P NMR spectral data were obtained on CH_2Cl_2 solutions with a JEOL FX90Q spectrometer operating at 36.21 MHz. The external reference was 85% H_3PO_4. IR data were obtained on Nujol mulls between polyethylene sheets with the use of a Digilab FTS-20C/V Fourier transform spectrometer. UV–vis data were obtained on CH_2Cl_2 solutions with the use of a Cary 219 spectrophotometer. Spectroscopic data are listed in Table 2. Elemental analyses were performed by Galbraith Laboratories, Knoxville, TN.

Structure determination for [(PhC≡C)Pt(μ-345Bpz)(μ-dppm)$_2$Rh(CO)]PF_6 (**6**)

Crystallographic data are listed in Table 3. Intensity measurements were made on a Siemens R3m/V diffractometer at room temperature. Refined unit-cell parameters were derived by least-squares treatment of diffractometer setting angles of 20 reflec-

tions. The intensities of three check reflections were monitored every 50 reflections and no significant variations in intensities were observed during the data collection. The intensity data were corrected for Lorentz and polarization effects. An empirical absorption correction, based on the φ dependence of the intensities of four reflections with χ *ca* 90° (T_{max} : T_{min} = 0.958 : 0.759), was applied to the intensity data.

The crystal structure was solved by heavy atom (Patterson and difference Fourier) methods.[9] Full-matrix least-squares adjustment of positional and anisotropic temperature factor parameters, with hydrogen atoms included at their calculated position during final iterations, converged to $R = 0.0405$ ($R_w = 0.0464$). The asymmetric unit contains one cation and one-half of two slightly distorted PF_6^- ions. The phosphorus atoms of the PF_6^- ions lie on crystallographic inversion centres, thus resulting in site occupation numbers for P5 and P6 of 0.5. Additional details of data collection and refinement are found in supplementary materials.*

RESULTS AND DISCUSSION

The dppm-bridged complexes **2–6** were synthesized by the addition of the potassium salt of the appropriate pyrazole to **1**. In the cases of the 35mpz, 4mpz and the pz complexes, the pyrazoles can be used directly to obtain the desired product. Hutton *et al.*[8] have shown that **1** contains a phenylacetylide ligand that is σ-bonded to the platinum and weakly π-bonded to the rhodium. The addition of a pyrazolate ion results in the loss of the terminal chloride ion on the platinum and the conversion of PhC≡C$^-$ from weakly bridging to terminal. The pyrazolate ions bridge the two metal atoms to form new unsymmetrical A-frame complexes.

The $^{31}P\{^1H\}$ NMR spectrum of **2** is shown in Fig. 1 and is typical of the spectra of **1–6**. The NMR data are found in Table 2. The bimetallic cations exhibit two ^{31}P resonances. The phosphorus atoms bonded to rhodium (^{103}Rh, 100%, I = 1/2) have chemical shifts in the range 17.4–21.5 ppm and ^1J(Rh—P) values in the range 112–127 Hz. The phosphorus atoms bonded to platinum exhibit chemical shifts in the range 0.58–6.8 ppm and ^1J(Pt—P) values (^{195}Pt, 33.4%, I = 1/2) in the range 2666–2358 Hz.

The ^{195}Pt satellites and the main resonance due to the phosphorus atoms bonded to the non-magnetic platinum atoms appear as virtual triplets. We denote the separation of the outer peaks of the triplets as *N*, following the designation of Shaw *et al.*,[8] where *N* is defined as ^2J(P—P) + ^4J(P—P). The resonances of the phosphorus atoms bonded to rhodium appear as a multiplet which might be described as a pair of virtual triplets with each triplet sandwiched by two weak outer peaks. These outer peaks probably result from weak second-order effects ascribed to the AA′BB′MX spin system.

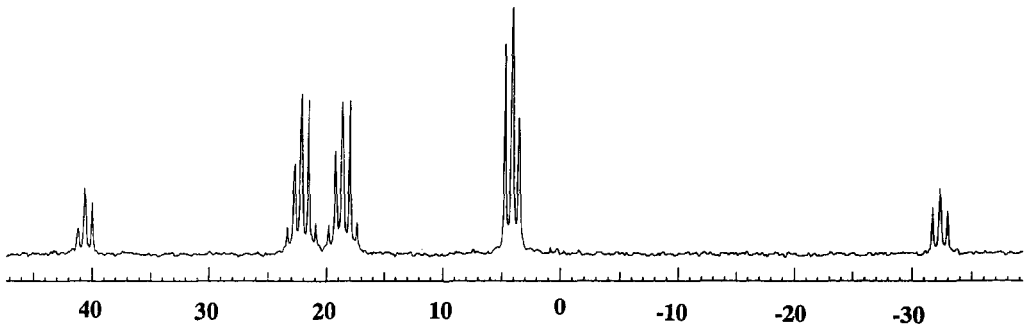

Fig. 1. ^{31}P NMR spectrum of $[(PhC_2)Pt(\mu\text{-}35mpz)(\mu\text{-}dppm)_2Rh(CO)]PF_6$ (**2**).

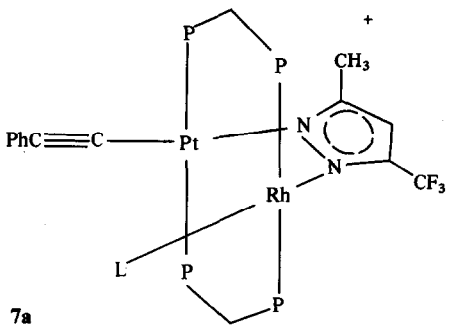
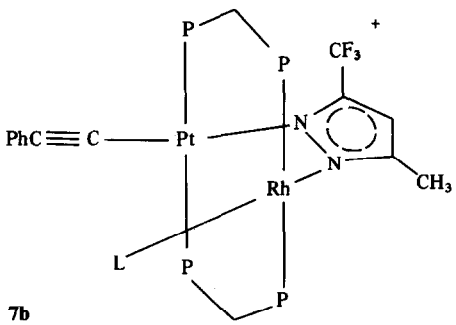
The IR spectra of **2–6** exhibit $\nu(C{\equiv}C)$ values about 85 cm^{-1} higher than that found in **1**. This is consistent with the conversion of the semi-bridging phenylacetylide ligand in **1** to a terminal ligand in **2–6**.

The reaction of the 3-methyl-5-trifluoromethylpyrazolate ion (mtmpz) with **1** gives **7**, whose ^{31}P NMR spectrum is shown in Fig. 2. The spectrum indicates the presence of two products. Since mtmpz is an unsymmetrical ligand, the two donor sites would be expected to exhibit different basicities, possibly resulting in different phosphorus resonances for the isomers **7a** and **7b**. Through induc-



7a



7b

tive effects, the donor nitrogen on the side of the heterocyclic ring with the CF_3 group might be expected to be less basic than the one on the side with CH_3. Perusal of the Pt—P chemical shift and coupling constant data in Table 2 reveals the general trend that J(Pt—P) and δ(Pt—P) decrease as the substituents on the ring become more electronegative. Assuming that this trend holds for the unsymmetrical ligand mtmpz, the platinum-bound phosphorus atom would exhibit lower J and δ values when the nitrogen on the same side of the ring as the CF_3 group is coordinated to the platinum. This analysis leads to the assignment of the minor isomer, with δ(Pt—P) of 1.52 ppm and J(Pt—P) of 2617 Hz, as **7b**, and the dominant isomer as **7a**, with chemical shift and coupling constant values of 3.81 ppm and 2644 Hz, respectively.

The assignment of **7a** and **7b** as the major and minor isomers, respectively, is also consistent with bonding preferences based on hard–soft acid–base (HSAB) principles. The softer platinum should prefer the nitrogen closest to the electron donating substituent, in this case the CH_3 group; thus, based on HSAB theory the dominant isomer is again predicted to be **7a**.

The addition of one equiv of *t*-BuNC to **2** and **5** results in the substitution of CO by *t*-BuNC to give **8** and **9**, respectively. Attempts to prepare the *t*-BuNC complexes of **3**, **4** and **6** resulted in a mixture of complexes that we were unable to separate. The $^{31}P\{^1H\}$ NMR spectra of **8** and **9** are similar to those of **1–6** and the NMR data are found in Table 2.

Treatment of **10** with the appropriate pyrazolate ions leads to complexes **11–13**. The addition of one equiv of *t*-BuNC to **11** and **12** leads to the replacement of CO to give **14** and **15**, respectively. This substitution results in an increase in the metal–phosphorus NMR coupling constants. This effect is attributed to the increase in electron density at the

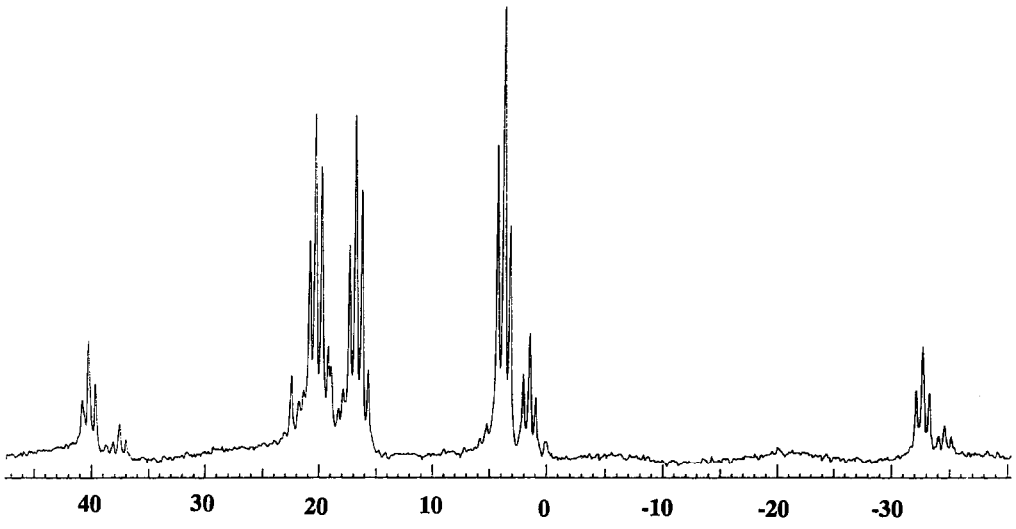


Fig. 2. ^{31}P NMR spectrum of $[(PhC_2)Pt(\mu\text{-mtmpz})(\mu\text{-dppm})_2Rh(CO)]PF_6$ (7).

metal and is consistent with the general observation that one-bond metal–phosphorus coupling constants increase with a decrease in oxidation state of the metal. It is generally accepted that *t*-BuNC is a better σ-donor and poorer π-acceptor than CO, thus placing more electron density on the rhodium and more electron density on the platinum through redistribution of electron density by the ligands.

The ν(CO) values of **11**–**13** show an increase over that of **10**. This can be interpreted as a decrease in the antibonding electron density on the CO and thus, a decrease in the π-backbonding involving the rhodium and CO. The Cl in **10** is acting as a better π-donor than is the pyrazolate ion in **11**–**13**. The replacement of one CN on platinum with the pyrazolate results in a slight decrease in the stretching frequency of the remaining CN ligand. This suggests that the pyrazolate is a slightly poorer π-acceptor than CN.

Dapm complexes

When a solution of *cis*-$Cl_2Pt(dapm\text{-}P)_2$ is treated with NaCN, complex **16**, $(CN)_2Pt(dapm\text{-}P)_2$, is formed. The value of 2324 Hz measured for ^1J(Pt—P) is typical of coupling constants observed for *trans* phosphorus atoms bonded to a platinum atom.[10] The dppm analogue *trans*-$Pt(CN)_2(dppm)_2$ has been shown to be fluxional at 25°C with exchange of bound and unbound phosphorus atoms.[5] Complex **16** does not appear to be fluxional since its ^{31}P NMR resonances are sharp and well defined, features that suggest that the species is not fluxional or that if exchange does occur, it is very rapid at 25°C.

Complex **17** is prepared by reacting 1 equiv of **16** with 1/2 equiv of $Rh_2(\mu\text{-}Cl)_2(CO)_2$. Several isomers are possible for **17**. One isomer has the two phosphorus atoms bound to the platinum and is designated the head-to-head (HH) isomer. The head-to-tail (HT) isomer has a phosphorus atom and an arsenic atom coordinated to platinum. The $^{31}P\{^1H\}$ NMR spectrum clearly indicates that both isomers are present, with the HH isomer being the dominant one. Since **16** was shown by NMR to exist only as the phosphorus-bound HH isomer, dissociation of a dapm ligand must have occurred during the formation of **17** in order for the HT isomer to form. The dissociation of the dapm ligands leads to the possible formation of a second HH isomer of **17** in which the two phosphorus atoms are coordinated to the rhodium atom. However, the ^{31}P NMR spectrum confirms the absence of this isomer.

The addition of 35mpz to **17** produces **18** whose $^{31}P\{^1H\}$ NMR spectrum is similar to that of **17** and also indicates the presence of HH and HT isomers. The isomeric mixture is maintained upon the addition of *t*-BuNC to **18** to form **19**.

Structural characterization of complex **20** indicated that a square planar *trans*-$Rh(CO)ClAs_2$ unit is connected to a *cis*-$PtCl_2P_2$ unit via two dapm bridges such that the two metals are separated by 3.043 Å.[11] Since our investigations indicate that the pyrazolate ions are poorer π-donors than chloride,

we thought that the replacement of a platinum-bound Cl with the pyrazolate ions might favour the arrangement that has the Cl *trans* to the pyrazolate and the phosphorus atoms *trans* to each other. Complex **21** exhibits a $^{31}P\{^{1}H\}$ NMR spectrum that consists of two equally intense doublets with chemical shifts of 7.04 and −0.03 ppm. The chemical shift values and the presence of two sets of satellite doublets due to coupling to ^{195}Pt, indicate that **21** contains two types of platinum-bound phosphorus atoms. These data indicate that the *cis* disposition of phosphorus atoms about the platinum is maintained during the conversion of **20**–**21**.

Several products were shown to result when **20** was refluxed in $CHCl_3$.[10] Among those products was an isomer of **20** that results from the transfer of a Cl from the platinum unit to the rhodium unit. The resulting species has a metal–metal bond, and has the phoshorus atoms bound to the platinum and the arsenic atoms bound to the rhodium in *trans* positions. Because of the bidentate nature of the pyrazolate ions, complex **21** was not expected to undergo the type of thermal isomerization observed for **20** that led to the formation of the metal–metal bond. When **21** was heated in $CHCl_3$ for 2 h, no colour change was observed; however, a single peak at 6.37 ppm accompanied by ^{195}Pt satellites, with a J value of 2598 Hz, did appear in the $^{31}P\{^{1}H\}$ NMR spectrum. The single phosphorus NMR peak and a value of 2598 Hz for ^{1}J(Pt—P) are features that are consistent with the isomer of **21** that is formulated as [*trans*-ClPt(μ-35mpz)(μ-dapm)$_2$-*trans*-Rh(CO)]PF_6, (**22**). Though the conversion of **21** to **22** appeared to be clean, i.e. no other phosphorus-containing species were evident from the NMR, the conversion was not complete, even after heating for at least 12 h. Based on relative intensities, it was estimated that there was about a 20–30% conversion. Attempts to separate the two isomers were unsuccessful.

Structure of [(PhC≡C)Pt(μ-345Bpz)(μ-dppm)$_2$ Rh(CO)]PF_6 (**6**)

As shown in Fig. 3 and revealed by the data listed in Tables 3 and 4, the solid-state structure of **6** consists of a platinum atom and a rhodium atom, Pt(1) and Rh(1), bridged by two transoid dppm ligands and a 3,4,5-tribromopyrazolate anion. The platinum atom is also coordinated to a terminal phenylacetylide ligand and the rhodium is coordinated to a terminal CO. The methylene bridges of the dppm ligands are folded over the 345Bpz bridging ligand. This orientation minimizes the steric interactions of the phenyl groups with the 345Bpz ligand since the phenyl rings on the side with 345Bpz flair outward, thus, creating a more open environment for the bridging 345Bpz ligand. The platinum and rhodium atoms are in approximate square planar environments with the least-squares plane through Rh(1), P(1), P(3), N(1) and C(1) making an angle of 70.8° with the one through Pt(1), P(2), P(4), N(2) and C(4). The Pt—P bond distances and the Rh—P bond distances are essentially the same (Table 4), as are the Pt—N and Rh—N distances. The Pt · · · Rh separation of 3.265 Å suggests that there is no metal–metal bond.[11] Other selected bond distances and angles are found in Table 4.

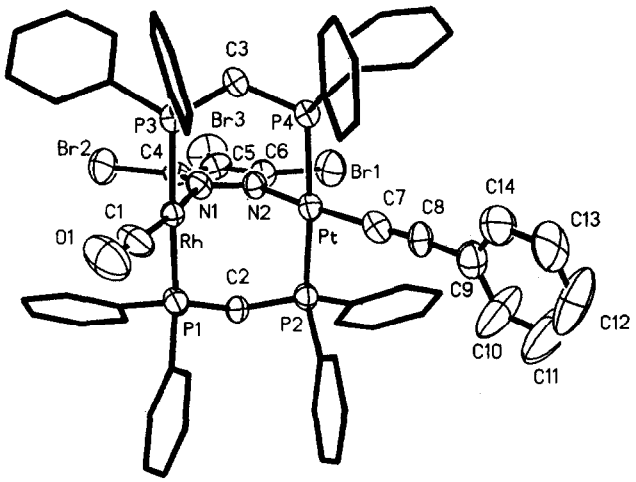

Fig. 3. Structure of [(PhC≡C)Pt(μ-345Bpz)(μ-dppm)$_2$Rh(CO)]$^+$ (cation of **6**) showing 50% thermal ellipsoids (hydrogen atoms and phenyl carbon atoms in dppm are omitted for clarity).

A NOVEL AMINO ACID RACEMIZATION IN VITAMIN B_6-AMINO ACID SCHIFF BASE COPPER COMPLEXES: CRYSTAL STRUCTURES OF AQUO (5′-PHOSPHOPYRIDOXYLIDENE-DL-TYROSINATO) COPPER(II) $3.5H_2O$ AND AQUO (5′-PHOSPHOPYRIDOXYLIDENE-DL-PHENYLALANINATO) COPPER(II) $2.5H_2O$

(*Received* 4 *February* 1991; *accepted* 23 *May* 1991)

Abstract—A novel racemization observed in the Vitamin B_6-amino acid Schiff base complexes, aquo (5′-phosphopyridoxylidene-L-tyrosinato) copper(II) and aquo (5′-phosphopyridoxylidene-L-phenylalaninato) copper(II) is described. The racemization taking place in solution under mild acidic conditions (pH 5–6) was confirmed by CD studies and the products were characterized by single crystal X-ray diffraction. The structures of both complexes show almost parallel orientation of the aromatic side chain and the pyridoxal π-system. The activation of the αC—H group due to the intermolecular π–π interaction is probably the reason for the unusual racemization observed.

Amino acid racemization reactions are of interest in peptide synthesis,[1] geochronology,[2] geothermometry[2] and nutrition.[3] A number of mechanisms have been put forward to explain the diverse nature of these reactions.[2b,4a,5] Neuberger,[5a] in 1948, first proposed that the mechanism involves the removal of the α-hydrogen of the amino acid resulting in the formation of a planar carbanion. Stabilization of this incipient carbanion transition state controls the rate of racemization. This could result from a number of factors[5] that alter the enthalpy and entropy of the transition state, such as inductive and resonance effects, solvation and neighbouring group participation, and steric effects (resulting from both intra- and intermolecular interactions).

Metal complexes of both transition and non-transition metal ions (except nickel[4c]) are known to catalyse racemization.[4c,5d] Metal ions through coordination, can stabilize the intermediate carbanion.[6]

The pyridoxal-amino acid Schiff bases are well known for their catalytic activity in racemization reactions.[7] These studies have received special attention because pyrixodal phosphate-amino acid Schiff bases have been proposed as intermediates in enzymatic racemization reactions.[8] Aromatic amino acids show increased reactivity in these reactions.[9] NMR studies and semi-empirical calculations[9,10] have shown that stabilization of the π-system of the Schiff base due to the π–π interaction with the aromatic ring plays an important role. These studies were done at pH values (*ca* 12.3) which were far from physiological pH. Studies on metal complexes of amino acid Schiff bases have shown that racemization takes place under basic conditions after heating.[11]

Here we report an interesting racemization observed in the copper complexes of pyridoxal phosphate (PLP) with L-tyrosine (I) and L-phenylalanine (II). This study shows that racemization in these systems takes place under acidic conditions, close to physiological pH. The products of racemization were characterized by single crystal X-ray analysis. CD studies show slow racemization in solution.

EXPERIMENTAL

PLP and amino acids were obtained from the Sigma Chemical Company. Methanol (AR grade), $Cu(NO_3)_2 \cdot 3H_2O$ and NaOH were procured from BDH India Limited. The circular dichroism (CD) spectra were recorded in the range 280–470 nm using a J-500A spectropolarimeter attached to a DP-501N data processor.

Preparation of complexes

The Schiff base ligand was first prepared by treating PLP with the corresponding L-amino acid at room temperature. The pH was adjusted to *ca* 4.5 by adding 0.1 M NaOH. The resultant Schiff base was immediately treated with metal salt solution and the final pH was adjusted to *ca* 4.6.

CD spectra

The CD spectra for the complexes were recorded immediately after mixing, after 1, 6, 18 and 23 days. The spectra were also recorded for DL-amino acid Schiff base complexes prepared under identical conditions for comparison.

X-ray structure determination

Details regarding data collection and processing are presented in Table 1. The data were corrected for Lorentz and polarization effects, and for absorption[12] effects for complex **II**.

The structures were solved by conventional Patterson and Fourier techniques and refined by full-matrix least-squares treatment.[13] Hydrogen atoms were located from difference electron density maps.

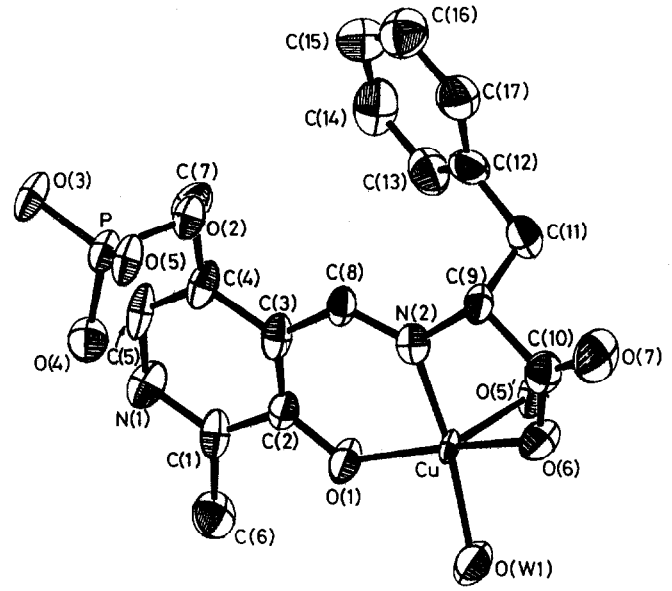

Fig. 2. ORTEP diagram of complex II with thermal ellipsoids at 50% probability, showing the atom-labelling scheme.

RESULTS AND DISCUSSION

The molecular structures of complexes I and II, including atom labelling, are shown in Figs 1 and 2, respectively. The structure of complex I closely resembles that prepared using DL-tyrosine as the starting material.[15]

In the structures of both complexes I and II,* copper(II) has a distorted square-pyramidal geometry. The tetradentate Schiff base exists as a

*This structure was previously solved[16] by photographic methods to a final R factor of 0.145 for 1177 observed reflections, but the coordinates were neither published nor deposited with the Cambridge Data Centre. The low accuracy of the structure is probably due to the reported difficulty of obtaining good single crystals. No experimental details of the synthesis are available. However, we presume that the authors used the DL-compound for their preparation since there is no mention of racemization in the paper.

divalent anion with the phenolate and carboxylate groups deprotonated and the pyridine nitrogen and the phosphate group protonated. The copper ion is coordinated by the Schiff base through the phenolate oxygen O(1), carboxylate oxygen O(6) and imino nitrogen N(2), and the fourth basal donor is a water molecule O(W1). The axial position is occupied by the phosphate oxygen O(5′) from a neighbouring molecule, thus resulting in a one-dimensional polymer. The bond lengths and bond angles (selected values in Table 2) are unexceptional. In both structures centrosymmetrically related molecules run in a zigzag fashion parallel to the *a*-axis. The benzene ring makes dihedral angles of 31.4 and 23.5° with the basal plane, in structures **I** and **II**, respectively. The planarity of the pyridoxal π-system is indicated by the torsion angle 2.0° (**I**) of the aldimine plane H(8)—C(8)—N(2)—C(9) (3.0° in **II**). The molecules are held together in the lattice by hydrogen-bonds and van der Waals interactions.

The crystallization of these complexes in a centrosymmetric space group confirms racemization of the amino acid. Furthermore, the crystals failed to show second harmonic generation when irradiated with a laser beam.

The racemization of amino acids under acidic conditions is unusual, more so for the following reasons. (i) The crystal structures of the copper(II)-salicylaldehyde (a model for PLP) Schiff base complexes of L-phenylalanine[17] and L-tyrosine[18] prepared under acidic conditions do not show racemization. (ii) The copper(II) complexes of these amino acids are also stable to racemization.[19] (iii) The preparation of the reduced Schiff base involving PLP and L-tyrosine carried out under basic conditions[20a] did not result in racemization, as confirmed by X-ray studies.[20b]

It is reported[5b] that environmental factors, as well as structural changes are critical to racemization. Furthermore, as mentioned in the Introduction, π–π interactions may play an important role in these reactions. Therefore, a comparison of X-ray structures of these complexes is of interest. Both complexes showed approximately parallel orientation of the pyridoxal π-system and the aromatic side chain of the amino acid (Fig. 3) [C(8)···C(12) = 3.099, C(8)···C(13) = 3.173, N(2)···C(12) = 3.057 and N(2)···C(13) = 3.403 Å, for complex **I** and 3.046, 3.024, 3.006 and 3.248 Å, respectively, for complex **II**]. A perfect overlapping is probably hindered by the packing effects. This, in conjunction with the NMR results,[9] suggests that a better overlap is possible in solution. The higher temperature factors shown by phenyl ring atoms may be an indication of its mobility. A plausible pathway for the reaction in solution could be given as follows. In the complex, the π–π interaction stabilizes the delocalization in the pyridoxal π-system resulting in the activation of αC—H. This eventually leads to its removal probably by water.[22] The resultant planar carbanion is open to attack by a proton on either side resulting in racemization.

The CD spectra of these complexes were recorded to study the racemization in solution. The spectral changes taking place immediately after mixing are shown in Fig. 4. The CD spectra for the DL-compounds and the L-compounds do not show any

bands after 23 days. The intensity of the peak around 380 nm in Fig. 4 increases with time, indicating the formation of a Schiff base metal complex. Both L-tyrosine and L-phenylalanine showed similar changes. Figure 5 shows the spectra of these complexes after 1, 6 and 18 days. The spectral changes indicate slow racemization. The suggestion of the removal of the proton by water is supported by the fact that complete racemization could be effected in 18 days when water is used as the solvent, whereas a water/methanol mixture showed incomplete racemization for the same period (Figs 5 and 6).

It is reported[11a] for a solution of Cu—PLP—L-phenylalanine complex that racemization is the major reaction at pH *ca* 9.6 and transamination predominates at pH *ca* 5. Since aldimine and ketimine are in equilibrium through transamination some racemization can occur through this equilibrium. However, the isolation of a racemic mixture in good yields (~ 75%) in the present study under acidic conditions is unexpected. The removal of

the DL-complex due to crystallization may be the driving force for the L to D conversion. This is supported by the fact that the isolation of the DL-complex as single crystals could be achieved in 5–6 days, whereas the CD changes do not show that amount of conversion during the same period.

CONCLUSION

This paper describes an unusual racemization under mild acidic conditions observed in two Vitamin B_6/amino acid Schiff base metal complexes. The CD studies show slow racemization for the complexes in solution. The analysis of products by single crystal X-ray analysis confirms the role of intramolecular interactions proposed in amino acid racemization.[5b] These results could be extended to explain the unexpected racemization reactions of amino acids bound to dipeptides and proteins.[23]

Abstract—Investigations on the reaction between $YCl_3 \cdot H_2O$ and phen (1,10-phenanthroline) led to the isolation of the title compound. The synthesis, IR and X-ray structural characterization are described. The crystal contains centrosymmetric binuclear dications $[Y_2(phen)_4(\mu\text{-}OH)_2(H_2O)_4]^{4+}$, uncoordinated chloride anions, two clathrated phen molecules and a disordered methanol molecule. The yttrium ions are eight-coordinated with square antiprismatic geometry to the nitrogen atoms of two phen molecules, to bridging hydroxyl groups and to two water molecules. The $Y \cdots Y^I$ separation in the dimer is 3.651(2) Å.

Among the isolated complexes of Y^{III} and of the lanthanide ions, those with O-donors are significantly more common than those with N-donors. Little is known about the structure of complex species with N-donor bidentate ligands such as 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy), the nature of which has been mainly examined by their solid-state IR spectra.[1–3] They have been reported to contain a lanthanide/ligand stoichiometry ranging from 1 : 1 to 1 : 4, depending on the counter-ion associated with the starting lanthanide compound in the interaction.[2–5]

Our interest in the coordination ability of yttrium(III) towards N-donors led us to examine the interaction of its compounds with phen. From the $YCl_3 \cdot H_2O$/phen system, we obtained the title complex species in crystals suitable for X-ray analysis. Such a system had been found to afford the compound $Y(phen)_2Cl_3 \cdot zH_2O$.[2]

Preliminary results of our study and of the crystallographic characterization of the title complex have been communicated,[6] and herein we report them in detail.

EXPERIMENTAL

Phen monohydrate (Fluka or Merck) was recrystallized from water, while the other reactants and solvents, reagent grade (Stream Chemical, C.

* Author to whom correspondence should be addressed.

Erba, Fluka), were used as received. The analytical data were determined in our laboratory, and the IR spectra of Nujol mulls (CsI plates) were recorded on a Perkin–Elmer model 1430 instrument.

Synthesis of the title compound

$YCl_3 \cdot 6H_2O$ (1 mmol) was added to a stirred methanolic solution of phen $\cdot H_2O$ (6–7 mmol, in *ca* 15 cm^3); the resulting solution was warmed to 50–60°C for *ca* 30 min and then filtered. The filtrate was evaporated under reduced pressure to dryness to give a white sticky residue which was dissolved in methanol (10 cm^3). Me_2CO was then added (*ca* 4 cm^3), and the solution was allowed to stand at room temperature for *ca* 8 days, during which time the product separated in a good crystalline form in *ca* 40% yield. The crystals were washed twice with drops of Me_2CO and allowed to dry to air. Found: C, 56.3; H, 4.3; N, 10.7; Y, 12.0; Cl, 9.4. Calc. for $C_{73}H_{62}N_{12}Y_2Cl_4O_7$: C, 57.0; H, 4.1; N, 10.9; Y, 11.5; Cl, 9.2%. The compound was slowly soluble in methanol, but less so in ethanol; it did not separate from methanol solutions even if very concentrated, and appeared air-stable at room temperature in the solid state.

Crystal data

$C_{73}H_{62}N_{17}O_7Y_2Cl_2$, $Mr = 1539.28$, triclinic $P\bar{1}$ (confirmed by structure determination), $a = 13.970(3)$, $b = 11.398(3)$, $c = 10.818(2)$ Å, $\alpha = 102.07(4)$, $\beta = 94.96(4)$, $\gamma = 86.75(4)°$, $Z = 1$, $V = 1676.8(8)$ $Å^3$, $D_{calc} = 1.49$ Mg m^{-3}, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 18.85 cm^{-1}, $F(000) = 786$, room temperature; final conventional R value is 0.0367 ($R_w = 0.0374$). A pale green–yellow crystal (dimensions $0.20 \times 0.28 \times 0.41$ mm) was used for data collection on a Philips PW1100 automated diffractometer with monochromated Mo-K_α radiation, 2θ scan technique $2\theta_{max} = 52°$. Twenty-five reflections $10 \leqslant \theta \leqslant 14°$ were used for cell dimension refinement. Index ranges measured h −17 to 17, k −13 to 13, l 0 to 13, with two reflections (−2 −3 1 and 2 3 1) measured after every 180 min of X-ray exposure time. There was no significant fluctuation on intensities other than those expected from Poisson statistics. The scan width was 1.20°, scan speed 0.30 s and the total background measuring time was 20 s. The total number of reflections measured was 6963; 4676 reflections having $I \geqslant 3\sigma(I)$, were used in the analysis and corrected for Lorentz and polarization effects and for absorption;[7] no corrections were made for extinction. The structure was solved by using three-dimensional Patterson and Fourier techniques and refined by full-matrix least-squares techniques with anisotropic thermal parameters assigned to all the non-hydrogen atoms (except CH_3OH). Hydrogen atoms were located by difference Fourier maps and refined isotropically. Refinement converged to $R = 0.0367$, $R_w = 0.0374$, $S = 1.27$ weights, $w = 1/[\sigma^2(F_o) + 0.000587(F_o)^2]$, $\Delta/\sigma < 0.04$, residual electron density ± 0.4 e $Å^{-3}$. (Scattering factors were taken from the International Tables for X-Ray Crystallography (1974),[8] with anomalous dispersion terms corrected for Y.) Data processing and computation were carried out using the SHELX 76 program package[9] and molecular illustrations were drawn with ORTEP[10] and PLUTO.[11] Supplementary material (tables of atomic coordinates, atomic vibrations and calculated structure amplitudes) has been deposited with the Editor.

RESULTS AND DISCUSSION

$YCl_3 \cdot 6H_2O$ was allowed to interact with phen under conditions involving salt : ligand molar ratios from 1 : 3 to 1 : 9, reaction solvents such as ethanol or methanol, Me_2CO, THF (tetrahydrofuran), or solvent mixtures, and temperatures from 25 to 60°C. In most cases, the separation of the complex compounds occurred when the reaction was carried out in methanol or ethanol, and Me_2CO or toluene or 2-PrOH was added subsequently. Clear evidence for the formation of another complex species in addition to the title one was obtained by IR spectroscopy. Often, this, as yet, uncharacterized species separated as the first crop of crystals from ethanol–toluene mixtures. The title species was the second crop from those mixtures but it was the main reaction product separating from methanol–Me_2CO.

Isolation of pure samples of the title compound in a good crystalline form occurred when $YCl_3 \cdot 6H_2O$ was allowed to interact with phen at 1 : 6–1 : 7 molar ratios in methanol at *ca* 50°C, with Me_2CO added to the reaction solution.

The solid-state (Nujol mull) IR spectrum of these samples in the 1800–200 cm^{-1} region—where more or less marked alterations of the ligand bands upon coordination can mainly be observed (a)—is shown in Fig. 1, compared to the similar IR spectrum of the free phen monohydrate (b).

As can be seen, the changes from the free ligand consist of multiple splittings, shifts and intensity changes of its bands, but, as known for the phen complexes of alkali and transition metal ions, it is difficult to interpret the spectra satisfactorily in terms of the structure of the complex species, or to relate them to changes in bonding in the ligand. Bands in the 1650–1400 cm^{-1} region (attributed to

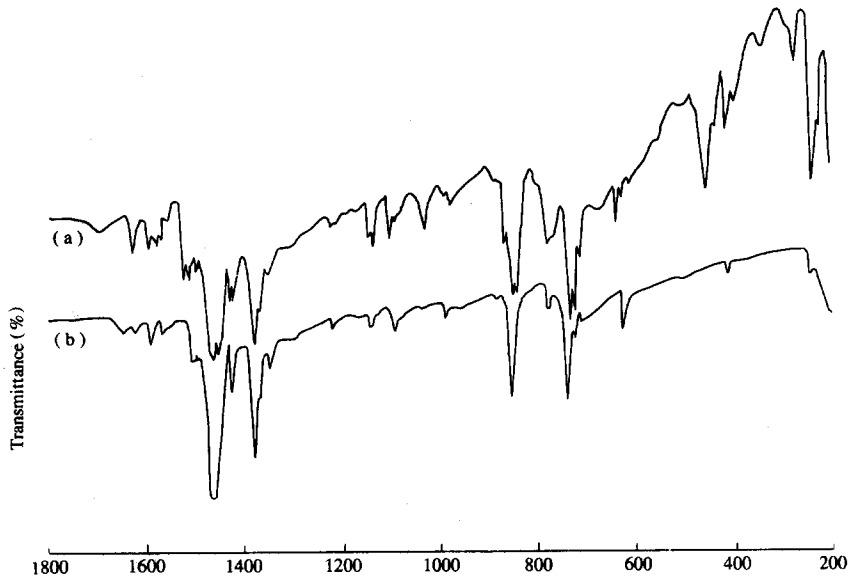

Fig. 1. IR spectra of Nujol mulls: (a) $\{[Y(OH)(H_2O)_2(phen)_2]_2Cl_4 \cdot 2phen\} \cdot MeOH$, and (b) the phen monohydrate.

ring vibrations) undergo splitting and shift to higher frequencies.[1,12,13] Similar shifts occur for bands between 1250 and 1100 cm^{-1}, while those between 1050 and 700 cm^{-1} shift to lower frequencies with splitting of the two strong bands at 850 and 738 cm^{-1} (out-of-plane hydrogen deformation vibrations) and at 852–843 and 732–725 cm^{-1}, respectively. The low-frequency region (650–200 cm^{-1}) appears to be interesting. As is known, ν(MN) (between 400 and 200 cm^{-1}) and other metal-sensitive vibrations may be found in this region.[14] However, besides bands due to coordinated OH ions and water molecules, bands due to the ligand also can be observed (see Fig. 1); those of the free phen at 620, 412 and 240 cm^{-1} shift to higher frequencies. Thus, band assignment for ν(MN) appears difficult; in agreement with another study,[2] the band at 280 cm^{-1} is tentatively assigned to this stretching vibration.

Figure 2 shows the structure of the complex; selected bond distances and angles are summarized in Table 1. Two yttrium(III) ions are bridged by two μ-OH groups; the cation possesses crystallographically required symmetry C_i. Each yttrium ion is eight-coordinate and the coordination geometry is best described as square antiprismatic, but a loss of planarity in the tetrahedral sense of the "squares" indicates that the structure is on the geometric pathway to being dodecahedron. Each of the two squares consists of two phenanthroline nitrogen atoms and two water molecules in one case and of the symmetrically-related hydroxyl oxygens in the second square.

The least-square planes through the "squares" show the following deviations from planarity: first square N(1), N(2), O(2), O(3), −0.060(4), 0.058(4), −0.064(4) and 0.066(4) Å; second square N(21), N(22), O(1), O(11) 0.051(4), −0.053(4), −0.049(3) and 0.048(3) Å, respectively; the dihedral angle between the two best-squares planes is 3.52(9)°. The rotation of one square with respect to the second is about 50°. This relatively regular coordination polyhedron is due to the fact that the only constraint on the polyhedron geometry is due to the coordination of phenanthroline nitrogens as they are at the rigid distances of 2.698(5) Å for N(1)···N(2) and 2.706(5) Å for N(21)···N(22). The two coordination polyhedrons share the hydroxyl edge. Least-squares planes through the phenanthroline ligands indicate distortion from planarity for the two coordinated to the metal in the ranges of −0.104(4)–0.194(5) Å for the N(1)···N(2) ligand and −0.176(5)–0.089(4) Å for the N(21)···N(22) ligand. The third uncoordinated phenanthroline ligand [N(31)···N(32)] is rather flat, with deviations from planarity ranging from −0.051(6) to 0.048(7) Å and with a N(31)···N(32) distance of 2.735(5) Å which is longer with respect to the coordinated ligands. Examination of bond distances in the coordination polyhedron shows that the hydroxyl bridge is rather symmetric: Y—O(1) 2.218(3) Å being not much different from Y—O(1)^{I} 2.233(3) Å (^{I} $-x, -y, -z$); while the Y—O_{water} distances are significantly longer: Y—O(2) 2.357(3) Å and Y—O(3) 2.386(3) Å. These values can be compared to the Y—O_{water} distances

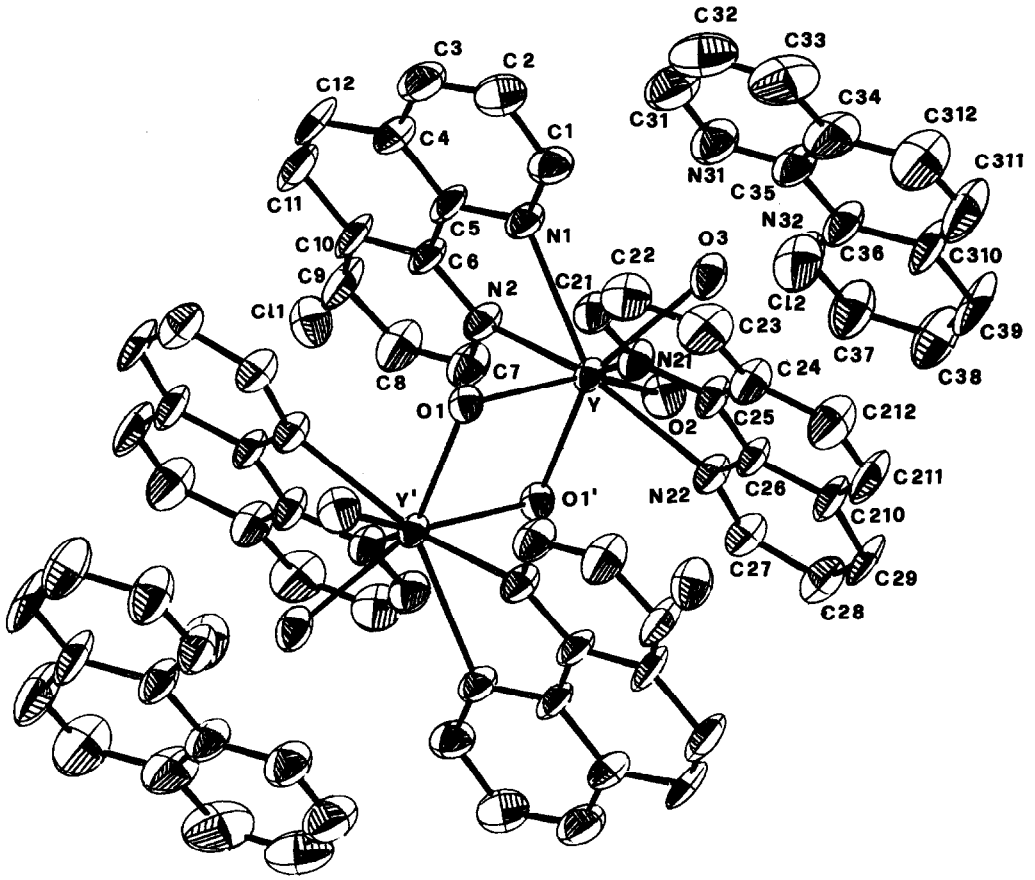

Fig. 2. ORTEP drawing of $\{[Y(OH)(H_2O)_2(phen)_2]_2Cl_4 \cdot 2phen\}$ with the atom numbering system. (Thermal ellipsoids are at 50% probability level.)

varying from 2.327(8) to 2.40(1) Å for the $[Y(OH_2)_7(OHMe)]^{3+}$ complex cation.[15] This significant difference in the yttrium oxygen distances allows us to distinguish between the hydroxyl and the water oxygen. In fact, a short distance has been attributed to the yttrium OH^- distance. This was also confirmed by the localization of one hydrogen on O(1). The yttrium–nitrogen bond distances have values comparable to those found in the hexanitrogen macrocycles, $YMAC(NCS)_3$,[16] $[YMAC(CH_3COO)_2]^+$[17] and $[YMAC(H_2O)(CH_3COO)]^{2+}$,[17] evidencing once more the prevalent electrostatic nature of the bonds to the yttrium ion. Distances where yttrium is enclosed in a macrocycle (which, for this reason, must have dimensions suitable for enclosing the metal ion), are similar to those with chelating ligands such as the phenanthrolines. The $Y\cdots Y^I$ bond distance of 3.651(2) Å seems to exclude any metal···metal interaction.

The crystal packing shown in Fig. 3 is dominated by hydrogen bond interactions. The dimeric cationic units $[Y(phen)_2(H_2O)_2\mu OH]_2^{2+}$, are connected via hydrogen bonding to the chlorine anions and to the two centrosymmetrically-related clathrated phenanthroline. In fact, the $O(3)_{water}$ links $N(32)^{II}$ (^{II} x, y, $1+z$) via hydrogen bonds: O(3)—H(115) 0.90(4) Å, O(3)···$N(32)^{II}$ 2.757(4), H(115)···$N(32)^{II}$ 1.93(5), O(3)—H(115)···$N(32)^{II}$ 153(4)°. The hydroxyl oxygen O(1) is 3.221(4) Å apart from Cl(1), O(1)—H(111) 0.61(4) Å, H(111)···Cl(1) 2.63(4), O(1)—H(111)···Cl(1) 163(4)°; $O(2)_{water}$ at 2.976(3) Å from $Cl(1)^{III}$ (^{III} $-x$, $-y$, $-z-1$) O(2)—H(113) 1.12(5) Å, H(113)···$Cl(1)^{III}$ 1.87(5) Å, O(2)—H(113)···$Cl(1)^{III}$ 169(4)°. Cl(2) makes short contacts with O(2) and O(3) belonging to the coordinated water molecules; the values are 3.018(4) and 3.174(4), respectively.

In addition, as already observed for $[K(phen)_3][Cr_2(CO)_{10}(\mu\text{-}H)]$,[18] coordinated and uncoordinated phen molecules are rather parallel and the angles between the planes of the different phen moieties are $phen_1$–$phen_2$ 12.6(1)°, $phen_2$–$phen_3$ 9.0(1)° and $phen_1$–$phen_3$ 12.5(1)°. The different phens bear several contact distances less than 3.6 Å. In particular, $phen_1$ faces $phen_2^I$ on one side and $phen_1^{IV}$ on the other side (^{IV} $-x$, $1-y$, $-z$), while $phen_2$ is between $phen_3^{II}$ and $phen_1^I$.

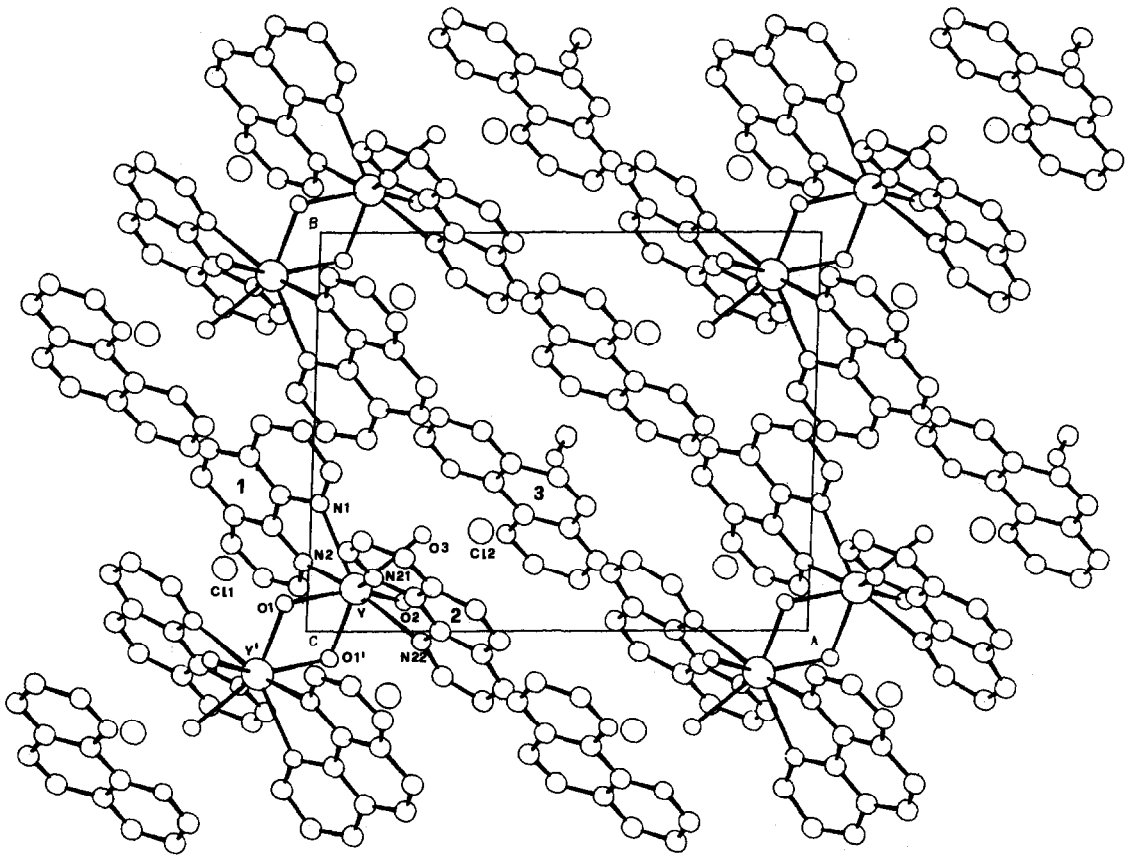

Fig. 3. Cell content viewed down the *c* axis.

Additional short contacts involve $phen_3$ and $phen_3^{V}$ (^{V} $1-x$, $1-y$, $-1-z$). This molecular packing gives rise to columns developing along the [1 1 1] crystallographic direction. These graphitic type interactions, found also in the structure of the free phen,[19] could also be indicative in the case of dipole–dipole interactions among coordinated (in the dimers) and uncoordinated phen molecules.

(*Received* 26 *November* 1990; *accepted* 8 *May* 1991)

Abstract—Copper chromate and dichromate complexes with 2,2′-bipyridyl and 1,10-phenanthroline were synthesized and characterized (UV–vis, IR, FIR, ESR and thermal data). The coordination of the anion in the chromate complexes was proposed from the IR data. The ESR data for the powdered samples reflect both $d_{x^2-y^2}$ and d_{z^2} ground states for the copper ion whereas the glassy solution spectra exhibit only the former. The presence of the chromium(V) ion in the spectra of the complexes dissolved in the water–ethylene glycol mixture is discussed.

Recently, we have reported on the formation of silver(I) chromate complexes with some heterocyclic bases.[1] It was found that in some cases the chromate ion acts as a bidentate ligand forming bridge complexes with the silver ion. The aim of the present paper was to extend this investigation to a new series of copper(II) chromate and dichromate coordination compounds of the type $Cu(HB)_xA$, where HB denotes heterocyclic bases as 2,2′-bipyridine (bpy) and 1,10-phenanthroline (phen) and A represents the CrO_4^{2-} or $Cr_2O_7^{2-}$ ions. Recently, similar compounds have been used in organic syntheses as milder and more efficient reagents than $KMnO_4$ or $K_2Cr_2O_7$.[2–5] Moreover, potent carcinogenic and mutagenic properties of the chromium(VI) ion found in biological systems both *in vivo* and *in vitro*,[6–10] require further detailed studies on the interaction of this ion with various simple and complex cations. Preliminary results on the biological activity of the complexes obtained in this study show that they are less mutagenic than simple alkali metal chromates.[11]

EXPERIMENTAL

Reagent grade chemicals were used in all experiments. Stoichiometries of the solid compounds obtained were established by microanalysis which gave satisfactory results. Complexes of the following formulae have been prepared for the first time: $Cu(bpy)_2CrO_4 \cdot 2H_2O$, $[Cu(bpy)_2]_2CrO_4Cl_2 \cdot 2H_2O$, $[Cu(bpy)_2]_2CrO_4(NO_3)_2 \cdot 4H_2O$, $Cu(phen)_2CrO_4 \cdot 2H_2O$, $Cu(bpy)Cr_2O_7$, $Cu(bpy)_2Cr_2O_7$ and $Cu(phen)_2Cr_2O_7$. Generally, the compounds were formed during the reaction of the methanolic solution of ligand previously mixed with a water solution of K_2CrO_4, and a water solution of the respective copper salt: $CuSO_4$, $CuCl_2$ and $Cu(NO_3)_2$. Dichromate complexes were formed from a mixture of CrO_3 and $CuSO_4$ to which a methanolic solution of ligand was added. The precipitates were washed with water and dried over $CaCl_2$. The chromate complexes were formed as dark green crystals whereas the dichromate complexes were light green powders. The presence of water in the complex molecules was additionally checked by thermal (TG, DTG, DTA) studies. For comparison purposes $CuCrO_4$ was also obtained.

(1) $CuCrO_4$

This compound was prepared[12] by the reaction of $CuSO_4$ (0.2 M) and K_2CrO_4 (0.2 M). The precipitate was allowed to stay overnight in the mother liquid and filtered off.

(2) $Cu(bpy)_2CrO_4 \cdot 2H_2O$

A methanolic solution of 2,2′-bipyridine (50 cm^3, 0.75 M) was added dropwise upon stirring to the same amount of 0.25 M K_2CrO_4 solution. This was mixed with 0.25 M $CuSO_4$ (45 cm^3). The resulting dark green solution was evaporated to approximately 1/3 of its initial volume and left to stand overnight. The obtained crystals were washed and dried (*vide supra*).

(3) $[Cu(bpy)_2]_2CrO_4Cl_2 \cdot 2H_2O$ *and* (4) $[Cu(bpy)_2]_2CrO_4(NO_3)_2 \cdot 4H_2O$

These compounds were prepared as for (2) but using $CuCl_2$ and $Cu(NO_3)_2$ for (3) and (4), respectively.

(5) $Cu(phen)_2CrO_4 \cdot 2H_2O$

Prepared as for (2) but using $CuSO_4$ (40 cm^3, 0.25 M) and a methanolic solution of 1,10-phenanthroline (0.75 M).

(6) $Cu(bpy)Cr_2O_7$

A solution of $CuSO_4$ (100 cm^3, 0.2 M) was added to the solution of CrO_3 (100 cm^3, 0.2 M). The resulting solution was warmed and finally bpy in methanol (100 cm^3, 0.25 M) was added dropwise. The brownish precipitate was formed immediately.

(7) $Cu(bpy)_2Cr_2O_7$

Prepared as for (6) but using only 80 cm^3 of $CuSO_4$ (0.2 M).

(8) $Cu(phen)_2Cr_2O_7$

Prepared as for (6) but using 100 cm^3 of phenanthroline solution (0.25 M).

IR spectra were recorded on a Perkin-Elmer 180 (50–3500 cm^{-1}) spectrophotometer in KBr pellets, Nujol mulls and 1,3-hexachlorobutadiene sandwiched between AgBr plates. FIR spectra were obtained in Nujol mulls sandwiched between polyethylene plates.

UV–vis spectra were recorded on a double beam Hitachi 356 spectrophotometer in the 200–850 nm spectral range in Li_2CO_3 pellets and water, methanol, DMF and formamide solutions and on a Beckmann UV 5240 instrument in the 400–2400 nm spectral range in MgO pellets.

ESR spectra were recorded using a JEOL JES-ME-X band spectrometer with a nuclear magnetometer MJ 110R and microwave frequency meter JES-SH-30X. The ESR spectra were measured for the solutions of the concentration *ca* 1.5×10^{-3} M for the dichromate complexes and *ca* 3.5×10^{-3} for the chromate complexes. In the redox experiments the concentration of all reagents [$K_2Cr_2O_7$, bpy, $Cu(bpy)Cr_2O_7$ and $Cu(ClO_4)_2$] dissolved in the mixture of 40% ethylene glycol and 60% water was the same and equal to 1.25×10^{-3} M.

Thermal analyses (TG, DTG, DTA) were carried out simultaneously on a MOM derivatograph (Budapest Company). The final decomposition products were examined by the X-ray diffraction technique (DRON-2 diffractomter).

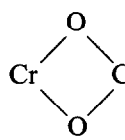
WARNING: Complexes decompose violently on heating.

RESULTS AND DISCUSSION

IR spectra

On coordination as a monodentate $OCrO_3$ ligand the tetrahedral symmetry of the chromate ion can be lowered to C_{3v} whereas in the case of a bidentate O_2CrO_2 coordination it is lowered to C_{2v}.[13] In this study (Table 1) similar to other data,[14,15] we were able to observe all splittings resulting from the symmetry lowering except those of v_4 vibrations which can be explained by their low intensity. The number of bands in the Cr—O stretching frequencies region (800–950 cm^{-1}) and their very strong intensities point to the bidentate chromate coordination in the complexes. The C_{2v} local environment of the chromium ion can be additionally elucidated by the comparison of the Cr—O stretching frequency region of copper chromate and the dichromate complexes of the $Cu(phen)_2A$ type. As they are practically similar and because the dichromate anion (C_{2v}) has less coordination tendency than the chromate ion,[16–18] we conclude that in our case the chromate has indeed the C_{2v} symmetry.

For the assumed O_2CrO_2 coordination, the vibrations associated with the OCrO bridge or



ring can be expected. Unfortunately, the "IR criterion" is not able to distinguish between

Table 1. Band positions (in cm^{-1}) assigned to the Cr—O vibrations in copper(II) chromate complexes

	ν_1	ν_2	ν_3	ν_4	ν_{as}(CuOCr)
$Cu(bpy)_2CrO_4 \cdot 2H_2O$	812	830 855 890	310	360	775
$[Cu(bpy)_2]_2CrO_4Cl_2 \cdot 2H_2O$	815	860 895 940	312	360	770
$[Cu(bpy)_2]_2CrO_4(NO_3)_2 \cdot 4H_2O$	805	830 900 920		370	760
$Cu(phen)_2CrO_4 \cdot 2H_2O$	(810)	(900) 935v.br	304	360	775

these two types of coordination.[19] However, the known crystallographic data for Cu—L—CrO_4 (L—NH_3, OH^-, py)[20,21] and other metal–chromate systems[22–25] show that the chromate ion acts exclusively as a bidentate bridging ligand. In the *ca* 750 cm^{-1} region a strong band is observed which can be assigned to the CrOCu bridge vibration, in accordance with known CrOCr,[26] AgOCr,[1] CoOCr[27] and perhaps accidently, FeOFe ones.[28]

The complexation effect can be also pronounced in the IR spectra *via* copper–nitrogen vibrations (strong bands at 260–310 cm^{-1}) and the absorption in the 1700–1800 cm^{-1} region indicative for the coordination modes of the nitrate group.[29] One single band at 1741 cm^{-1} shows that in the spectrum of **4** the ionic nitrate is present. The coordination of (bpy) and (phen) is observed through splitting and shifting (20–30 cm^{-1}) of the stretching and ring deformation vibrations.

ESR spectra

The ESR spectra of the complexes under study can be divided into three types (Table 2):

(1) Spectra with a line shape characteristic of at least two g values, with $g_\parallel > g_\perp$ [$Cu(bpy)Cr_2O_7$, $Cu(phen)_2CrO_4$, $Cu(phen)_2Cr_2O_7$].

(2) Spectra with a line shape which is the reverse of that of (1), with $g_\parallel < g_\perp$ [$Cu(bpy)_2Cr_2O_7$, $[Cu(bpy)_2]_2CrO_4Cl_2$ and $Cu(bpy)_2CrO_4$].

(3) Spectrum with a broad isotropic line, $[Cu(bpy)_2]_2CrO_4(NO_3)_2$.

Type (1) spectra are consistent with the $d_{x^2-y^2}$ ground state of copper(II) ion with a decreasing

Table 2. Important spectroscopic data for studied complexes. (Wave numbers in cm^{-1}, diffuse reflectance spectra in MgO pellets, the g parameters obtained from ESR spectra for the solid samples, in the parentheses the g values measured at 77K. Crystal water in the formulae has been omitted)

	d–d	ν (Cu—N)	g	
$Cu(bpy)_2CrO_4$	9800sh, 12,500	293, 260	$g_\perp$	2.170 (2.166)
			$g\|\|$	2.072 (2.066)
$[Cu(bpy)_2]_2CrO_4Cl_2$	10,300sh, 13,500	288, 270	$g_\perp$	2.166 (2.166)
			$g_\parallel$	2.035 (2.035)
$[Cu(bpy)_2]_2CrO_4(NO_3)_2$	10,300sh, 13,300	290, 270	g_{av}	2.122
$Cu(phen)_2CrO_4$	10,200sh, 13,300	305, 260	$g_\perp$	2.063 (2.053)
			$g_\parallel$	2.182 (2.174)
$Cu(bpy)Cr_2O_7$	12,700sh, 14,700	282	$g_\perp$	2.064 (2.061)
			$g_\parallel$	2.288 (2.282)
$Cu(bpy)_2Cr_2O_7$	12,900	310, 268	$g_\perp$	2.131 (2.131)
			$g_\parallel$	2.027 (2.027)
$Cu(phen)_2Cr_2O_7$	13,600sh, 15,100	268	$g_\perp$	2.060 (2.056)
			$g_\parallel$	2.111 (2.098)

tetragonal distortion in these three complexes. It should be noted that the spectrum of the complex with one bipyridyl ligand exhibits the greatest anisotropy of the g values suggesting the largest tetragonal distortion being close to the square planar stereochemistry.

The g values of the type (2) spectra suggest the d_{z^2} as the ground state. The observed raising of the g values above 2.00 could be caused by distortion of regular geometry associated with d_{z^2} ground state, i.e. trigonal bipyramidal or *cis*-octahedral or lower symmetries.[30] For the chromate complexes of type (2) this increase is even greater than for the dichromate and can be additionally caused by the exchange coupling between two copper(II) ions bridged with the OCrO grouping.

For $[Cu(bpy)_2]_2CrO_4(NO_3)_2$ (type 3) a broad, isotropic ESR spectrum is observed. The most common reason for this type of line shape is the exchange coupling between copper(II) ions[31] and this is reasonable on the grounds of the bridging ability of the chromate ion.

It has been found[32] that in water–ethylene glycol solutions of $Cubpy_2(ClO_4)_2$ and $Cubpy_2(NO_3)_2$ the ESR spectra in the glasses may be attributed mainly to the 1:1 and 1:3 (Cu:bpy) disproportionation species. Our data (Table 3, Fig. 1) show that: (a) tetragonally distorted copper(II) species ($d_{x^2-y^2}$) are exclusively formed in solution; (b) 1:3 (Cu:bpy) species can be found in the chromate complexes. The nine-line pattern of the superhyperfine splitting of $Cu(bpy)_2CrO_4$ spectrum [Fig. 1(d)] is associated with four nitrogen atoms coordinating in the xy plane. As the coordination of two (bpy) or (phen) molecules in plane seems to be unlikely from steric factors, three bidentate ligands arranged in the *cis*-octahedral stereochemistry may provide four nitrogen atoms to be close to the plane; and (c) mixture of 1:1 and 1:3 species is present in $Cu(bpy)_2Cr_2O_7$ and $Cu(phen)_2Cr_2O_7$ complexes immediately after dissolution of the compound. For $Cu(bpy)Cr_2O_7$, only the 1:1 form has been observed. However, after a few days only the species characteristic of the 1:3 form was found [Fig. 1(c)].

Table 3. ESR parameters for the complexes dissolved in 40% ethylene glycol–60% water solutions at 77 K. In parentheses data for the spectra measured after few days

Complex	$g_\parallel$	$A_\parallel$ (cm^{-1})
$Cu(bpy)_2CrO_4$	2.265	169
$[Cu(bpy)_2]_2CrO_4Cl_2$	2.262	169
$[Cu(bpy)_2]_2CrO_4(NO_3)_2$	2.266	167
$Cu(phen)_2CrO_4$	2.268	168
$Cu(bpy)Cr_2O_7$	2.308	170
	(2.261)	(174)
$Cu(bpy)_2Cr_2O_7$	2.309	172
	2.260	173
$Cu(phen)_2Cr_2O_7$	2.312	167
	2.264	173

The dynamical process (c) connected with the change of the coordination sphere of the cation are characteristic of the dichromate complexes and can be associated with the $Cr_2O_7^{2-}/CrO_4^{2-}$ equilibria (we have observed pH increasing with time).

No such change appears for $Cu(phen)_2SO_4$ which supports the above conclusion.

Apparently, a mode of copper coordination depending upon the chromate or dichromate ion causes the different effects of these anions on the copper(II)–polypyridine equilibria in the water–glycol solutions.

Although various compounds of biological relevance[33] as well as other organic species[34] were studied as reducing agents for chromium(VI), only a few experiments have been done with complexes other than alkali metal chromates and dichromates.[35] The possibility of applying our complexes as mild and selective oxidizers[36] encouraged us to study the interaction of $Cu(bpy)Cr_2O_7$ with ethylene glycol and compare the results with those for $K_2Cr_2O_7$. The additional signals observed at $g = 1.981$ (77 K and room temperature) in a water–ethylene glycol mixture (Fig. 1) can be assigned[37] to chromium(V) complexes formed in the process of glycol oxidation with chromium(VI). Observation of the intensity of ESR signals indicated that in the copper(II) complex, in comparison to potassium chromate, the concentration of chromium(V) is smaller and kinetically less stable. Furthermore, our ESR studies showed that copper(II) ions and (bpy) studied separately, have a diminishing effect on the formation and life time of the chromium(V) species. Further investigation of the oxidation ability of copper(II) chromate and dichromate complexes is in progress.

Electronic spectra

Data on ligand field bands are compiled in Table 2. In general, the tetragonal symmetry, on the basis of ESR data, for the complexes with $d_{x^2-y^2}$ copper(II) ground state can be interpreted by assuming three electronic d–d transitions. The electronic spectra of the chromate complexes exhibit a fairly intense ($\varepsilon \sim 200\ M^{-1}\ cm^{-1}$) broad band at *ca* 13,000 cm^{-1} (requiring a further Gaussian analysis) with a more or less pronounced low energy shoulder at 9000–10,000 cm^{-1}).

Studying the complexes with d_{z^2} copper(II)

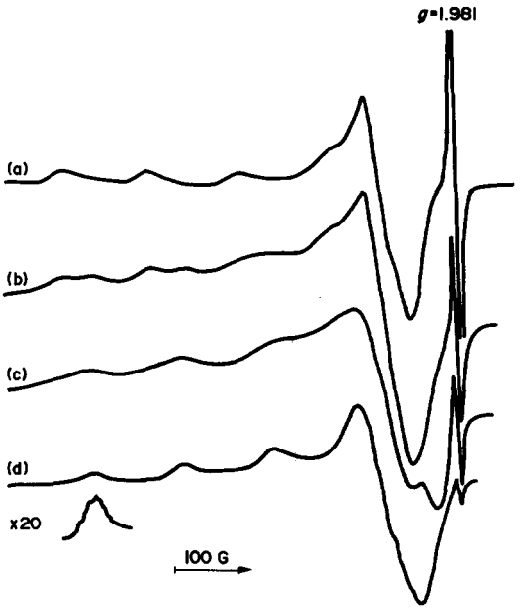


Fig. 1. ESR spectra in 40% ethylene glycol–60% water solutions at 77 K. (a) $Cu(bpy)Cr_2O_7$ freshly dissolved. (b) $Cu(bpy)Cr_2O_7$ after 1 day. (c) $Cu(bpy)Cr_2O_7$ after 2 days. (d) $Cu(bpy)_2CrO_4$. The ESR signals at $g = 1.981$ are due to the chromium(V) species. The decrease of the signals characteristic of chromium(V) from (a) to (c) is observed.

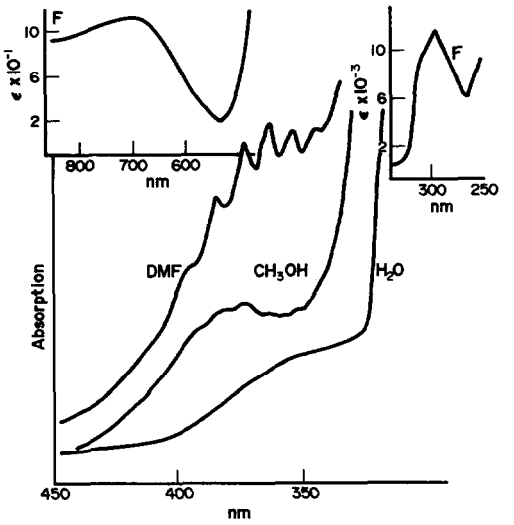

Fig. 2. Electronic spectra of $Cu(bpy)_2CrO_4 \cdot 2H_2O$ in formamide (F), dimethylformamide (DMF), methanol (CH_3OH) and water (H_2O).

ground state, Hathaway and co-workers[38] have found, that the electronic spectra can be used to distinguish between trigonal bipyramidal and *cis*-octahedral coordination modes. The former coordination exhibits one band at *ca* 12 kK whereas the latter is characterized by two bands of approximately equal intensity separated by 3–5 kK. In this case the band maximum at 13 kK with a shoulder at about 3 kK to lower energy may be associated with the *cis*-distorted octahedral geometry.

An intense absorption in the region 350–420 nm (*ca* 28,500–24,000 cm^{-1}) can be seen in the spectra. In this region, the oxygen–chromium CT transitions with characteristic vibrational fine structure attributed to the ν_s(Cr—O) totally symmetric vibrations is observed. The strong disturbance of the structure (Fig. 2) can be explained by the solute–solvent interactions (e.g. hydrogen bonds when formamide or water is used) operating in the systems. The position of the CT bands due to intra-anion transitions for chromate and dichromate anions did not change significantly upon complexation.

Unlike the Cr—O charge transfer transitions, the π–π^* very intense intra-ligand transitions are 200–1000 cm^{-1} bathochromatically shifted upon complexation.

Unfortunately, we were not able to find electronic transitions attributable to the oxo bridge. These bands can be obscured by more intense (e.g. O—Cr CT) electronic bands.

Thermal data

Preliminary results on thermal analysis show that all complexes except $[Cu(bpy)_2]_2CrO_4Cl_2 \cdot 2H_2O$ and $Cu(phen)_2CrO_4 \cdot 2H_2O$ are **explosive** on heating in air. Moreover, $Cu(bpy)Cr_2O_7$ appears to react very violently also in an inert atmosphere. In nitrogen atmosphere the complexes decompose through several stages with the liberation of a non-stoichiometric amount of organic ligand. The final decomposition product in 1000°C was found to be copper(I) metachromite-$CuCrO_2$.

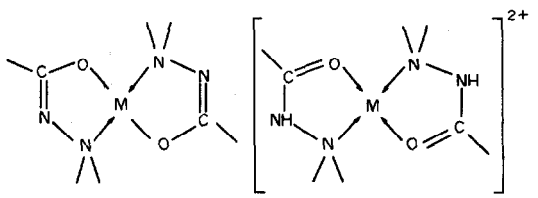
(*Received* 18 *March* 1991; *accepted* 3 *May* 1991)

Abstract—The coordination complexes of acetylferrocene-m-nitrobenzoylhydrazone(HL) with lanthanide elements, LnL_3 (where Ln = lanthanide), have been prepared by the reaction of HL with the metal(III) chlorides in acetonitrile. The data of elemental analyses, IR, UV, NMR, molar conductance, TG and DTA show that the ligand coordinates in the enolic form with a molar ratio of 3 : 1. The complexes are non-electrolytes in DMF, and are more thermostable than their ligands due to the formation of chelate rings.

Metal aroylhydrazones are known to possess biological activity and are potent inhibitors for many enzymatic reactions. The coordination chemistry of aroylhydrazines and related compounds was the subject of extensive studies.[1–6] Acid hydrazones can coordinate to metal ions in (a) the enolic form or (b) the keto form. In general, they coordinate to



(a) (b)

central ions in the keto form when complexing with metal chlorides, nitrates, sulphates and thiocyanates etc.,[1] but in the enolic form with metal acetates in ethanol. In an earlier communication[7] we reported that HL coordinated with yttrium (III) and lanthanide(III) chloride in the keto form. In this paper, these complexes, coordinated in the enolic form, are prepared through the reaction of hydrazone with metal chlorides rather than metal acetates.

EXPERIMENTAL

Methods and materials

Acetylferrocene was prepared according to the method in the literature.[8] The lanthanide chlorides were reagent grade chemicals and m-nitrobenzoylhydrazine was analytical reagent grade. Acetylferrocene-m-nitrobenzoylhydrazone was also prepared according to the literature.[7]

Syntheses of lanthanide chelates

Lanthanide(III) chloride (0.20 mmol) was dissolved in 40 cm^3 of acetonitrile with heating. 20 cm^3 of acetylferrocene-m-nitrobenzoylhydrazone solution (0.80 mmol) in acetonitrile containing 2 cm^3 of triethyl orthoformate were added dropwise into the above solution. The mixture was maintained under reflux for 8 h. The precipitate was separated, filtered on cooling, washed several times with cold acetonitrile and ether and dried to constant weight *in vacuo* to give the pure product, yield > 72%. The physical properties and elemental analyses of these

complexes are listed in Table 1 along with their formulae.

Physical measurements

IR spectra were recorded using a Nicolet 5DX spectrometer using KBr discs in the 400–4000 cm^{-1} region. UV spectra were recorded on a Shimadzu-240 spectrophotometer, using DMF solution in the 200–500 nm region. PMR spectra were obtained on a FT-80A spectrometer using deuterodimethyl sulphoxide as a solvent and TMS as the internal reference. Electrolytic conductance measurements were made with a DDS-IIA molar conductometer and DMF as a solvent at 25°C. Thermal characterization studies were carried out with a Du Pont 1090 thermal analyser in a nitrogen atmosphere.

RESULTS AND DISCUSSION

The complexes of lanthanide elements with acetylferrocene-m-nitrobenzoylhydrazone are amorphous brown powders. These are insoluble in petroleum ether, benzene and water, sparingly soluble in diethyl ether, but soluble in methanol, ethanol, DMF and DMSO. These chelates are hygroscopic. Their elemental analyses show that $LnCl_3$ forms complexes with the loss of chloride ions and that they conform to the formula LnL_3. The reaction solvent acetonitrile promotes the enolization of the ligand.[7]

IR spectra

The important IR frequencies of the ligand and its complexes along with their relative assignments are given in Table 2. The IR spectra of these complexes show significant changes when compared with those of the parent ligand. It can be seen that the bands due to N—H and C=O stretching vibrations and δ(N—H) are not observed in the spectra of these complexes. Instead, new bands are observed around 1607 cm^{-1} and 1246 cm^{-1} which can be assigned to the stretching vibrational modes of conjugate —C=N—N=C—[9] and C—O[10] groups. It is shown that the ligand undergoes enolization in acetonitrile and then reacts with the lanthanide ions to form complexes, accompanied by the release of chloride ions. It is also found that the ν(C=N) band is shifted to a lower frequency by *ca* 20 cm^{-1} while the ν(N—N) band is shifted to a higher frequency by *ca* 27 cm^{-1}. These observations support the coordination through the azomethine nitrogen atom. In addition, the characteristic frequencies of ferrocenyl appear around 3089, 1389, 1102 and 813 cm^{-1}. The bands of m-nitrobenzoyl are observed at 3176, 1597, 1576, 1475 and 713 cm^{-1}.

UV spectra

The UV spectra of the ligand and its complexes in methanol are shown in Fig. 1. It can be seen that

the UV spectra of all the complexes are similar, but they are different from that of the ligand. The band at 298 nm in the ligand is attributed to a band (π–π^* transition) but in the complexes, a bathochromic shift of 30–40 nm is observed. It is possible that the *f*-orbitals of the metal atom and the *p*-orbital of the ligand overlap to form a greater conjugate system after enolizing and complexing. The formation of the greater conjugate system makes the energy level difference between the π and π^* orbitals, i.e. π–π^* transition energy required, decrease. These factors led to the bathochromic shift of the K band in the complexes. The band at *ca* 363 nm is typical of the internal transition of the ligand in the complex and therefore assigned to the —C=N—N=C—O$^-$ fragment of the complex. The ligand and complexes exhibit broad and weak bands around 430 nm, which are due to charge-transfer from iron to either the non-bonding or the anti-bonding orbitals on the cyclopentadienyl rings.[11]

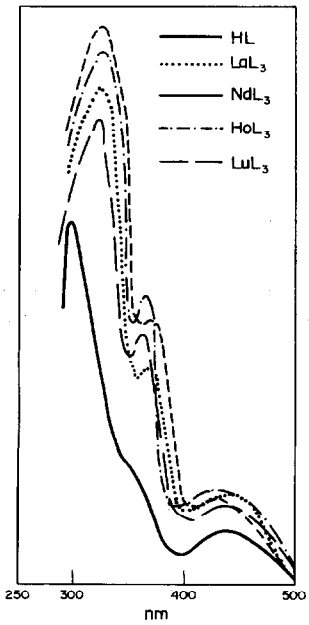

Fig. 1. The UV spectra of the ligand and its complexes.

PMR spectra

The PMR spectra of the ligand and its complexes have been investigated using DMSO as a solvent. Because lanthanides have a tendency to maintain unpaired electron spins, which interact with the nuclei (protons), the H-signals of these complexes are broadened and very weak, except for La^{III} and Lu^{III} complexes. The PMR data of the ligand and two complexes are listed in Table 3. The free ligand exhibits a peak due to the N—H proton at 10.9 ppm, which disappears on deuteration with D_2O. In the spectra of the lanthanide complexes, however, the N—H signal disappears as expected for the enol form. In the spectra of the complexes, the methyl proton suffers some deshielding and gives rise to a signal between 2.45–2.60 ppm, which is shifted downfield by 0.18–0.33 ppm compared to that of the parent ligand. These results indicate that the coordination of the ligand with the lanthanide ions involves the enol form of the ligand.

Table 3. PMR chemical shifts (δ, ppm) of the ligand and some complexes

Compound	CH_3	Ferrocenyl group		C_6H_4	N—H
		Unsubstituted	Substituted

LaL_3	2.45(s)	4.25(s)	4.43, 4.75	7.82–8.74(m)	—
LuL_3	2.60(s)	4.22(s)	4.42, 4.70	7.78–8.80(m)	—

s = singlet, m = multiplet.

Molar conductance

Dissolving the lanthanide complexes in DMF produced a deep brown solution. The molar conductance values (Table 4) of the complexes in DMF lie in the range 17–42 Ω^{-1} cm^2 mol^{-1}. A comparison of these values with those previously reported in the literature[12] shows the non-electrolytic nature of the complexes in DMF.

Thermal analysis

Thermal analyses of the ligand and its complexes show that an explosive decomposition occurs when heated to an appropriate temperature which is due to the presence of the nitro group on phenyl. Hence, the weight loss is difficult to measure accurately. However, TG and DTA measurements of the ligand indicate melting at 186°C and the beginning of decomposition at 190°C, then an **explosive decomposition** at about 243°C. It is interesting to note that the complexes are more thermostable than the ligand. All the complexes decomposed explosively above 327°C.

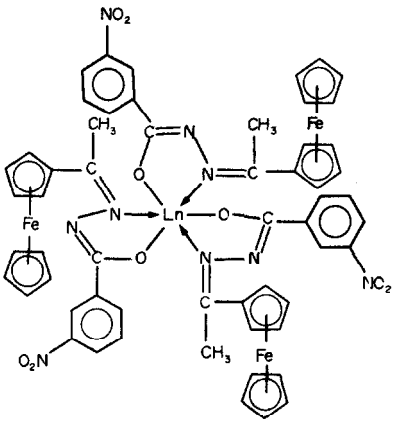

Fig. 2. Proposed structure for the complexes.

XIII	0.97	18
XIV	0.93	25

Conclusions

Acetylferrocene-m-nitrobenzoylhydrazone is a bidentate ligand, three molecules of which coordinate with one molecule of lanthanide(III) chloride through its nitrogen atom in azomethine, and its oxygen atom in the enolic form in acetonitrile, accompanied by the release of three chloride ions; their coordination numbers are equal to six. Therefore, we suggest a plausible structure for our complexes as shown in Fig. 2.

ROLE OF THE LIGANDS IN AFFECTING THE STOICHIOMETRY AND THE RATE OF REACTIONS BETWEEN PLATINUM(IV) AND PLATINUM(II) COMPLEXES

ARNALDO PELOSO

Dipartimento di Chimica Inorganica, Metallorganica ed Analitica, Universita' di Padova, Via Marzolo 1, 35131 Padua, Italy

(*Received* 4 *January* 1991, *accepted* 15 *April* 1991)

Abstract—The stoichiometries and the rates of the reactions between *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$ and $[Pt(en)(N'\text{-}N')]^{2+}$ in the presence of bromide ions have been studied in aqueous solutions (N-N and N′-N′ = en, 1,3-pn, 1,2-pn, meen, dmen, tmen). The platinum(IV) reaction product is either *trans*-$[Pt(en)(N\text{-}N)Br_2]^{2+}$ or *trans*-$[Pt(en)(N'\text{-}N')Br_2]^{2+}$, depending on the bulkiness of N-N and N′-N′. The reaction rates obey a pseudo-first-order rate law with $k_{obs} \approx \{k_c[Br^-]+k_d[Br^-]^2\}[Pt(en)(N'\text{-}N')^{2+}]$. The ligands significantly affect the rates, mainly via their steric hindrance. An increase of the steric hindrance near the platinum(IV) centre only moderately enhances its reactivity towards reduction, whereas a strong lowering of the reactivity of platinum(II) towards oxidation is caused by an increase of the steric hindrance of the ligands coordinated to this atom centre. The quantitative kinetic effect displayed by changes of such ligands either on platinum(IV) or on platinum(II) complexes is also dependent on the particular platinum(II) or platinum(IV) complex used as the standard reducing or oxidizing reagent. An explanation of the observed behaviour is suggested in terms of an atom-transfer redox mechanism.

The rates of inner-sphere redox reactions between platinum(IV) and platinum(II) complexes are known to be affected by non-labile ligands coordinated to the central metal atom.[1-3] However, scarce attention has been so far devoted to establish whether reaction rates are more sensitive to changes of ligands coordinated to platinum(IV) or to platinum(II) complexes.

In order to shed some light on this field, a kinetic investigation has been carried out in aqueous solutions on the reactions between *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$ and $[Pt(en)(N'\text{-}N')]^{2+}$ complexes in the presence of bromide ions [N-N and N′-N′ = ethylenediamine (en), 1,3-propylenediamine (1,3-pn), 1,2-propylenediamine (1,2-pn), N-methylethylenediamine (meen), N,N-dimethylethylenediamine (dmen), N,N,N′,N′-tetramethylethylenediamine (tmen)].

EXPERIMENTAL

Materials

Platinum(II) compounds of the type $[Pt(en)(N\text{-}N)]Cl_2$ were prepared by treating aqueous suspensions of $[Pt(N\text{-}N)Cl_2]$ with a small excess of ethylenediamine and heating at 60–80°C until clear, colourless solutions were obtained. The solutions were evaporated almost to dryness *in vacuo* and the crude material recovered was dissolved in a small portion of either water or methanol. After the addition of charcoal, the resulting solutions were warmed and filtered. Subsequent addition of either acetone or acetonitrile caused the separation of the required products as colourless or very pale yellow flakes or microcrystals (Table 1). Diperchlorates, $[Pt(en)(N\text{-}N)](ClO_4)_2$ (N-N = 1,3-pn, 1,2-pn, meen and dmen), were obtained by treating very concentrated cold aqueous solutions of dichloride analogue with either concentrated perchloric acid or saturated solutions of sodium perchlorate. Platinum(IV) compounds of the type *trans*-$[Pt(en)(N\text{-}N)Cl_2]Cl_2$ were obtained by conventional oxidation of the platinum(II) parents in aqueous solutions with hydrogen peroxide and hydrochloric acid. The solutions were heated on a water-bath for at least 30 min, after which they were evaporated almost to dryness *in vacuo*. The required products were recovered from

the obtained crude materials as described above for platinum(II) complexes.

Reagent grade sodium bromide and perchlorate were dried before use. Doubly-distilled water was used to prepare stock solutions of the reactants.

Reaction products

Spectrophotometric investigations showed that the *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$ complexes examined in this paper react with bromide ions both in the absence and in the presence of added platinum(II) complexes, leading to a reaction product which displays an absorption band with a maximum (λ_{max}) located in the 320–338 nm wavelength range (Table 2), and consistent with the formation of a *trans*-dibromo (ethylenediamine) (diamine) platinum (IV) complex.[4,5] The platinum(IV) reaction product for the reactions carried out in the absence of added platinum(II), as well as in the cases in which platinum(IV) and the added platinum(II) complexes contain the same diamines, is invariably *trans*-$[Pt(en)(N\text{-}N)Br_2]^{2+}$. Such behaviour is rather common for these kinds of reactions.[1,4-6] In the cases investigated here the formation of the named dibromoplatinum(IV) complexes is supported by the verified identity of the value of λ_{max} determined for the exhausted reaction mixtures (Table 2) with that of authentic *trans*-$[Pt(en)(N\text{-}N)Br_2]^{2+}$ complexes [i.e.: 320 (en[4] and 1,2-pn), 321 (1,3-pn), 322 (meen), 327 (dmen) or 338 nm (tmen[5])]. In many cases, two isosbestic points occurred at the correct wavelengths expected for the conversion of the starting dichloroplatinum(IV) complex into the dibromoplatinum(IV) analogue {e.g. (at $[Br^-] = 0.10$ mol dm^{-3}): 281 and 271 (N-N = en), 281 and 275 (1,3-pn), 280 and 272 (1,2-pn), 282 and 273 nm (meen)}. However, the location of these isosbestic points has not been considered as strong evidence for the general identification of the reaction products since they were found to be strongly dependent on the bromide ion concentration (see below). The values of λ_{max} for the exhausted reaction mixtures for reactions between platinum(IV) and platinum(II) complexes containing different diamines allowed to deduce the nature of the reaction product only for the cases reported in Table 2. The exact nature of the platinum(IV) reaction products for the reactions between platinum(IV) and platinum(II) complexes containing only primary diamines or meen could not be established owing to the almost identical values of λ_{max} exhibited by the pair of possible reaction products {i.e. *trans*-$[Pt(en)(N\text{-}N)Br_2]^{2+}$ and *trans*-$[Pt(en)(N'\text{-}N')Br_2]^{2+}$}.

In all the cases in which the reaction products were identified, it was found that the absorbance of the exhausted reaction mixture at a given bromide ion concentration was consistent with quantitative conversion of the starting platinum(IV) complex into the particular dibromoplatinum(IV) complex reported in Table 2. However, it was observed that the absorbance value of an exhausted reaction mixture is higher for a higher bromide ion concentration, even though the wavelength of the absorb-

ance maximum does not change. As a consequence, the location of isosbestic points which accompany the progress of many reactions is dependent on the bromide ion concentration. The observed behaviour is not connected with the occurrence of only incomplete reactions. In fact, addition of sodium bromide to exhausted reaction mixtures was found to cause a sudden increase in the absorbance even at the wavelengths where isosbestic points were observed, which is evidence against the occurrence of an incomplete reaction. On the other hand, such behaviour is a rather common feature for cationic platinum(IV) complexes[5,7] and has not been further investigated.

Kinetics

Stock solutions of the reactants were prepared by weight in aqueous, acidic solutions ($HClO_4$, pH 3.0), an ionic strength of 0.50 mol dm^{-3} being ensured by the addition of the required amount of $NaClO_4$. The reactions were started by mixing appropriate volumes of thermostatted stock solutions of the reactants in 1 cm silica cells maintained in the thermostat-controlled cell compartment of a Lambda 5 UV–vis Perkin–Elmer spectrophotometer. The progress of the reactions was followed by scanning the absorption spectrum of the reacting mixture in the 360–250 nm region at appropriate time intervals. Fast reactions were followed by recording the absorbance against time at a constant wavelength (near 250–260 or 320–340 nm, dependent on both the concentration and type of complexes used). Under kinetic conditions the starting concentration of platinum(IV) complexes was always less than 1×10^{-4} mol dm^{-3} and usually at least 10 times lower than that of the interacting platinum(II) complexes. The concentration ranges explored for platinum(II) complexes and bromide ions are listed in Table 3. It was usually found that the reactions obey a pseudo-first-order rate law for at least two half-lives. Pseudo-first-order rate constants, k_{obs}, were evaluated from the gradient of plots of log $(A_\infty - A_t)$ against time (A_t and A_∞ are the absorbances of the reacting mixture at time t and at the end of the reaction, respectively, at a given wavelength). Some experiments were also performed using comparable concentrations of platinum(IV) and platinum(II) complexes. It was found that a first-order rate law operates even in these cases provided that the platinum(IV) reaction product contains the same diamines as its dichloroplatinum(IV) parent.

Pseudo-first-order rate constants obtained from replicate kinetic runs were usually found to agree to better than 5%. At least 12 kinetic runs were carried out at each temperature explored, using different concentrations of platinum(II) complexes and bromide ions.

RESULTS

The data in Table 3 imply that the reactions studied in this paper display either stoichiometry (1) or (2) dependence on the ligands bonded to the starting platinum(IV) and platinum(II) complexes:

$$trans\text{-}[Pt(en)(N\text{-}N)Cl_2]^{2+} + 2Br^- \xrightarrow{\text{Added } Pt^{II} \text{ complex}} trans\text{-}[Pt(en)(N\text{-}N)Br_2]^{2+} + 2Cl^- \quad (1)$$

$$trans\text{-}[Pt(en)(N\text{-}N)Cl_2]^{2+} + [Pt(en)(N'\text{-}N')]^{2+} + 2Br^- \longrightarrow [Pt(en)(N\text{-}N)]^{2+} + trans\text{-}[Pt(en)(N'\text{-}N')Br_2]^{2+} + 2Cl^- . \quad (2)$$

According to Table 3, stoichiometry (1) is operating for all the reactions between platinum(IV) and platinum(II) complexes containing identical diamines. It must be acknowledged that such stoichiometry is rather common for reactions of this type[1] and, in particular, it has been known for a long time for N-N = en[8] and tmen[5]. Stoichiometry (2) invariably occurs when N-N in *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$ bears a larger number of N-methyl groups than N′-N′ in $[Pt(en)(N'\text{-}N')]^{2+}$ [i.e. (a) N-N = dmen or tmen; N′-N′ = en, 1,3-pn, 1,2-pn, meen; (b) N-N = tmen, N′-N′ = dmen]. Conversely, stoichiometry (1) occurs when the N-N ligand on platinum(IV) contains a lower number of N-methyl groups than N′-N′ on platinum(II) [i.e. (a) N-N = en, 1,3-pn, 1,2-pn, meen; N′-N′ = dmen, tmen; (b) N-N = dmen, N′-N′ = tmen]. Such behaviour for reactions between platinum(IV) and platinum(II) complexes does not appear to have been previously observed, and its occurrence will be rationalized below. The stoichiometry for the reactions between platinum(IV) and platinum(II) complexes containing only primary diamines or meen cannot be inferred from any identification of the platinum(IV) reaction products. Nevertheless, stoichiometry (2) is likely to occur since in the absence of other driving forces the concentration of the starting platinum(II) complex should control the predominating dibromoplatinum(IV) complex which is formed. Under the experimental conditions chosen, the reactions studied obey a pseudo-first-order rate law whose k_{obs}

[a] Estimated errors (from average errors in the rate constants) : ±4 kJ mol^{-1} (ΔH_c^*) and ±12 J K^{-1} mol^{-1} (ΔS_c^*).
[b] At $I = 6.5\times10^{-2}$ mol dm^{-3}: $k_c = 2.33\times10^{1}$ (25°C), 3.75×10^{1} (35°C), 5.34×10^{1} dm^6 mol^{-2} s^{-1} (45°C); $\Delta H_c^* = 30.3$ kJ mol^{-1}; $\Delta S_c^* = -117$ J K^{-1} mol^{-1}.

is shown in relationship (3):

$$-\frac{d[[Pt(en)(N\text{-}N)Cl_2]^{2+}]}{[[Pt(en)(N\text{-}N)Cl_2]^{2+}]\,dt} = k_{obs} = \{k_c[Br^-] + k_d[Br^-]^2\}[[Pt(en)(N'\text{-}N')]^{2+}]. \quad (3)$$

Actually, very small rate terms which are independent of the concentration of either platinum(II) {i.e. $k_a[Br^-]$} or bromide ions {i.e. $k_b[[Pt(en)(N'\text{-}N')]^{2+}]$} could be evidenced in some cases when very low concentrations of platinum(II) or bromide ions were used. However, their contribution to the overall rate was usually within the experimental errors when the reactions were carried out in the presence of added platinum(II) complexes and using not very low bromide ion concentrations. Only in the case of the reactions of *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$ (N-N ≠ tmen)]$^{2+}$ was the k_a rate term always found to be important owing to the poor ability of the named platinum(II) complex to promote the reactions. However, in the evaluation of the k_c and k_d values reported in Table 4, care was taken for the albeit small contribution of the k_a and k_b rate terms. Only activation parameters related to k_c are reported in Table 4, the k_d values being too inaccurate (not better than 5%) to give reliable activation parameters.

DISCUSSION

The results obtained suggest that the reactions occur basically by the well-known atom-transfer redox mechanism (4).[1,2,9,10] In the form depicted by eqs (4a)–(4d) such a mechanism is specifically referred to the reaction path responsible of the k_c rate term, but it can be adjusted to also explain the k_d rate term (see below) (as well as the k_a and k_b rate terms).

$$[Pt(en)(N'\text{-}N')]^{2+} + Br^- \overset{K}{\rightleftharpoons} [Pt(en)(N'\text{-}N')Br]^+ \quad (4a)$$

$$[Pt(en)(N\text{-}N)Cl_2]^{2+} + [Pt(en)(N'\text{-}N')Br]^+ \overset{k_1}{\underset{k_2}{\rightleftharpoons}} [Cl(en)(N\text{-}N)Pt\text{-}Cl\text{-}Pt(en)(N'\text{-}N')Br]^{3+} \quad (4b)$$

$$[Cl(en)(N\text{-}N)Pt\text{-}Cl\text{-}Pt(en)(N'\text{-}N')Br]^{3+} \xrightarrow{k_3} [Pt(en)(N\text{-}N)]^{2+} + Cl^- + [Pt(en)(N'\text{-}N')ClBr]^{2+} \quad (4c)$$

$$[Pt(en)(N'\text{-}N')ClBr]^{2+} + Br^- \xrightarrow{Fast,\ [Pt(en)(N'\text{-}N')]^{2+}} Cl^- + [Pt(en)(N'\text{-}N')Br_2]^{2+}. \quad (4d)$$

The reaction steps depicted here give an account of the reactions displaying stoichiometry (2) as well as of those displaying stoichiometry (1) provided that N-N and N′-N′ are the same. In order to account for stoichiometry (1) of reactions involving platinum(IV) complexes bearing N-N ligands less bulky than N′-N′ coordinated to the starting platinum(II) complex, the subsequent fast reaction (4e) can be confidently suggested to occur:

$$[Pt(en)(N'\text{-}N')Br_2]^{2+} + [Pt(en)(N\text{-}N)]^{2+} \xrightarrow{Fast,\ Br^-} [Pt(en)(N'\text{-}N')]^{2+} + [Pt(en)(N\text{-}N)Br_2]^{2+}. \quad (4e)$$

Some remarks support the reliability of such a proposal. Firstly, data are available[11] which indicate that hindering ligands thermodynamically stabilize platinum(II) over platinum(IV). On this basis only, the occurrence of reaction (4e) is extensively favoured when the N′-N′ ligands are much more hindered than N-N so that *trans*-$[Pt(en)(N\text{-}N)Br_2]^{2+}$ will be the actual product of the overall reaction. Secondly, such a reaction step is expected to be very fast even if the concentration of the $[Pt(en)(N\text{-}N)]^{2+}$ intermediate is very low, if for no other reason than because a bromide ion acts as the bridging atom.[1,2]

Relationship (5) is the rate law expression for reaction mechanism (4) and is fully consistent with that related to the k_c rate term if relationship (6) is accepted:

$$-\frac{d[[Pt(en)(N\text{-}N)Cl_2]^{2+}]}{[[Pt(en)(N\text{-}N)Cl_2]^{2+}]\,dt} = \frac{k_1k_3}{k_2+k_3}K[Pt(en)(N'\text{-}N')]^{2+}][Br^-] \quad (5)$$

$$k_c = \frac{k_1k_3}{k_2+k_3}K \approx \frac{k_1}{k_2}k_3K. \quad (6)^*$$

The second-order dependence on the bromide ions related to the k_d rate term has been previously observed in some cases and ascribed[1] to a reaction path involving a Pt^{IV}, Br^- ion pair in step (4b) instead of *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$. Although such an interpretation is attractive, it should be recalled that second-order dependencies on halide ion concentration have been found many times lately in the oxidation reactions of cationic platinum(II) complexes,[12–14] even when the oxidizing agent is not adequate (e.g. $IrCl_6^{2-}$),[14] to form ion pairs with anions. A reaction path involving a $Pt(en)(N'\text{-}N')Br^+$, Br^- ion pair in (4b) would pro-

* The simplification adopted takes into account the fact that the atom-transfer redox act (k_3 rate term) is likely rate determining.

vide a reason for the occurrence of a second-order dependence of the rate on Br^- and cannot be ruled out in a tentative explanation of the k_d rate term.

An examination of the effect of the ligands on the rates will be restricted to the k_c reaction path.

The data in Table 4 unequivocably indicate that a change of the ligands coordinated to platinum(IV) and/or to platinum(II) has a kinetic effect on the rates of the reactions studied in this paper. However, it is generally found that platinum(IV) or platinum(II) complexes containing only primary diamines react very similarly. Therefore, neither the expansion of the chelate ring (on going from en to 1,3-pn) nor the replacement of a hydrogen atom by a methyl group on the carbon next to the H_2N group (on going from en to 1,2-pn) play an important part in the reactivity of both platinum(IV) towards reduction and platinum(II) towards oxidation. Conversely, the replacement of hydrogen atoms on nitrogen by methyl groups has a definite effect on the rates. Such an effect appears to be qualitatively larger (though in the opposite direction) when N-methyl groups are contained in platinum(II) rather than in platinum(IV) complexes. Moreover, it appears that the observed effect is quantitatively dependent on the particular platinum(II) or platinum(IV) chosen as standard reducing or oxidizing reagent, respectively. Thus, the relative reactivity trends shown in Table 5 are observed at 25°C either for the reductions of platinum(IV) complexes [Table 5(A)] or for the oxidation of platinum(II) complexes [Table 5(B)], as a function of the particular platinum(II) or platinum(IV) complex used as reductant or oxidant, respectively.

A simple explanation of such behaviour is difficult, since a guess of the activation parameters, even once their limited reliability is considered, shows that the reactivity trend found for the reduction of *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$ complexes is largely associated with changes of the enthalpy of activation, whereas changes of the entropy of activation appear to be very important in establishing the reactivity trends for the oxidation of $[Pt(en)(N'\text{-}N')]^{2+}$ complexes, at least when platinum(IV) complexes containing primary diamines are used as oxidizing agents. Many factors may participate in causing the observed trends, in particular solvation changes connected with the replacement of hydrophilic hydrogen groups on nitrogen by hydrophobic methyl groups and changes of steric hindrance caused by the N-methyl groups which are located near the central metal atom. However, many results previously reported in several papers were satisfactorily accounted for by assuming that steric hindrance has a prevailing part in affecting the reactivity of both platinum(IV) complexes towards reduction[3,5,13] and platinum(II) complexes towards oxidation,[3,13,15–18] including platinum(II)[18,19] and platinum(IV)[5] complexes containing en, meen, dmen, and tmen as ligands. On the other hand, the role of steric hindrance in affecting the rates of redox reactions is fully recognized.[20–27] Changes in steric hindrance near the metal atom centres can be reasonably suggested to be responsible for the reactivity trends estab-

Table 5. (A) Relative reactivity for the reduction of *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$

trans-$[Pt(en)(tmen)Cl_2]^{2+}$	1.0	6.9×10^{-1}	1.1×10^{-2}	2.1×10^{-5}

lished in this paper and the following discussion will be centred on this hypothesis.

According to mechanism (4) the experimental rate constant, k_c, is a composite function of [see eq. (6)]: (a) the stability of the five-coordinate platinum(II) adduct, $[Pt(en)(N'\text{-}N')Br]^+$, accounted for by the stability constant K (step 4a), (b) the thermodynamic tendency of the interacting platinum complexes to form the bridged precursor, accounted for by k_1/k_2 (step 4b), and (c) the feasibility of the atom-transfer redox path, accounted for by k_3 (step 4c). A convenient starting point for a discussion is to consider the reactivity trends of platinum(IV) complexes during the reduction by a common platinum(II) complex. The benefit is that in such cases the stability constant of the five-coordinated complex, K, is the same for the entire sequence of reactions, so that observed changes of reactivity should be related only to changes in k_1/k_2 and/or k_3. As far as changes of the diamine in *trans*-$[Pt(en)(N\text{-}N)Cl_2]^{2+}$ are concerned, it can be expected that the formation of the bridged precursor becomes thermodynamically more difficult on increasing the number of N-methyl groups on the diamine, owing to the hampering steric interactions arising between these groups and the ligands bonded to the approaching platinum(II) complex. As far as the k_3 atom-transfer redox step is concerned, it should be recognized that rearrangement of the first coordination sphere (and solvation sphere) of both platinum(IV) and platinum(II) complexes plays a predominant part in the attainment of the transition state configuration of this reaction step. On this basis, it can be reasonably expected that this redox step becomes progressively more favoured on increasing the tendency of platinum(IV) to convert into platinum(II), since a lower rearrangement of the coordination sphere round platinum(IV) will be required [the reducing platinum(II) reactant should play a minor part as it is kept constant]. On the other hand, it should be recalled that (a) increasing steric hindrance near the metal atom stabilizes platinum(II) over platinum(IV)[11] and (b) it is a rather common feature that a redox reaction is kinetically and thermodynamically favoured in the same direction.[10] Therefore, the k_3 term (step 4c) should increase with increasing steric hindrance of N-N in *trans*-$[PtCl_2(en)(N\text{-}N)]^{2+}$. In conclusion, an increase of the steric hindrance near the platinum(IV) centre is expected to cause a decrease of the k_1/k_2 value and an increase of the k_3 term. Experimentally, it is found that the reactivity of platinum(IV) complexes towards reduction by a given platinum(II) complex increases smoothly with the steric hindrance caused by N-N, at least as far as platinum(II) complexes containing non-bulky diamines are considered [however, for platinum(II) complexes containing a very bulky diamine such as tmen the order is somewhat reversed]. Therefore, it can be concluded that in these cases the most commonly observed reactivity trend of platinum(IV) complexes is mainly ascribable to the fact that the positive effect of the driving forces on step (4c) caused by steric hindrance normally exceeds the opposite effect connected with the concomitant destabilization of the bridged precursor. The large important kinetic role played by steric hindrance in the stability of the bridged precursor can be envisaged by comparing the rate constants of the reactions between platinum(IV) and platinum(II) complexes containing identical diamines (e.g. N-N = N'-N' = en, meen, dmen, tmen). In such cases, the atom-transfer redox step (k_3) should scarcely be affected by changes of the ligands since the tendency of platinum(IV) to convert to platinum(II) should be essentially balanced by the opposing tendency of platinum(II) to convert into platinum(IV). On the other hand, the stability constant of the five-coordinated platinum(II), K, should also not change significantly on changing the diamine. Therefore, in the cases above, changes in stability of the bridged precursor, k_1/k_2, should be mostly responsible for any reactivity changes. The relative rates on changing N-N at 25°C are of the order: en (1.0) $\sim$ meen (1.1) $>$ dmen (5.6×10^{-2}) $>$ tmen (3.6×10^{-4}). Therefore, for the above considerations, such a sharp decrease should be ascribed to the destabilizing effect caused by steric hindrance on the bridged intermediate precursor formation. The relative stability of the bridged intermediate is likely to also have a strong part in determining the sequence of reactivity of the series of platinum(II) complexes studied on oxidation by a given platinum(IV) complex. In such cases each of the K, k_1/k_2 and k_3 terms may in principle be affected by changes in the ligands on platinum(II). However, the stability constant of $[Pt(en)(N'\text{-}N')Br]^+$ should not be affected much by changes in the diamine since the steric hindrance should not significantly obstruct the approach of Br^- and even the acceptor ability of platinum(II) should not be affected by changes in ligands of similar basicity. Conversely, the stability of the bridged precursor should decrease by the increasing steric hindrance of the diamine on platinum(II). On the other hand, the atom-transfer redox step should be disfavoured by increasing steric hindrance since (see above) the latter hampers the conversion of platinum(II) to platinum(IV). Therefore, in such cases an increase in steric hindrance near platinum(II) would lead to a decrease of both k_1/k_2 and k_3, thus leading to a decrease in the

experimental rate constant, k_c, which has just been found experimentally.

We can now try to account also for the above-mentioned higher effect displayed by changes in steric hindrance on platinum(II) rather than in platinum(IV) complexes. In fact, when the replaced diamine is linked to platinum(II) both k_1/k_2 and k_3 change in the same direction causing the greatest overall effect, whereas when the replacement is performed on the platinum(IV) complex these terms tend to balance each other, causing the lowest overall effect. Moreover, since a similar dichotomous behaviour should also operate in the contribution of enthalpies and entropies of steps (4b) and (4c) on the experimental enthalpies and entropies of activation, a reasonable justification of the fact that the entropy and enthalpy of activation have a different weight when diamine changes are performed on platinum(IV) rather than on platinum (II) complexes is found.

Finally, it was noticed above that the relative reactivity trends are also dependent on the particular platinum(II) or platinum(IV) complex used as the standard reducing or oxidizing reagent, respectively. This behaviour indicates that the steric hindrances of platinum(IV) and platinum(II) do not behave as mutually independent factors, i.e. they are not additive parameters. This is possibly due to the fact that the Pt^{IV}—Cl—Pt^{II} bridge in the bridged precursors is not symmetric, resembling the cation of Wolfram's red salt in which the Pt^{IV}—Cl bond length is much shorter than that of Pt^{II}—Cl.[28,29] This means that the extent of the interactions between the ligands bonded to platinum(IV) and platinum(II) (and between the ligands and the transferring chloride group) will be dependent on the reciprocal sites where the ligands are located.

(*Received* 17 *October* 1990; *accepted* 5 *April* 1991)

Abstract—The synthetic route, structural features and qualitative results of molecular orbital calculations for 10 cubane-type tetranuclear molybdenum (tungsten) clusters with $S_2P(OC_2H_5)_2$(dtp) as the ligand are summarized. There are two cluster cores, $[Mo_4S_4]$ and $[Mo_4OS_3]$, in the structures of a series of the compounds. Two isomer configurations—α and β—exist for both cubane cores which possess very similar total energies. The difference between the α and β configurations lies only in the coordinating fashion of the dtp ligands to the molybdenum (tungsten) atoms. A characteristic feature of these M—S tetranuclear cluster compounds is that a change in the number of electrons of $\{Mo_4\}$ from 10 to 12 does not affect the fundamental cubane-like molecular configuration. This may be attributed to the effect of symmetry of the cluster structure and the nature of the ligand on the electronic structure of the compounds.

During the past decade, with the exploration of biochemical systems in life processes, the chemistry of cubane-type tetranuclear metal clusters has grown at an enormous rate,[1–5] since the M_4S_4 complexes may act as the active centre in these processes. Our recent research on cubane clusters with dtp ligands [dtp = $S_2P(OC_2H_5)_2$] of $[M_4S_3X(dtp)_6]^n$ (M = Mo or W; X = S or O; $n = 0$ or -1) is summarized here and includes the synthetic route, structural features, as well as the qualitative results of the molecular orbital (MO) calculations for 10 compounds. These clusters are listed as follows:

α-$Mo_4OS_3(\mu$-dtp$)_3$(dtp$)_3$ (1)

α-$Mo_4OS_3(\mu$-dtp$)_3$(dtp$)_3 \cdot 3CH_3CN$ (2)

α-$Mo_4XS_3(\mu$-dtp$)_3$(dtp$)_3$ (3)

(X = S, O; the occupancy factor is about 60% for S)

β-$Mo_4OS_3(\mu$-dtp$)_2$(dtp$)_4$ (4)

β-$Mo_4S_4(\mu$-dtp$)_2$(dtp$)_4$ (5)

β-$Mo_4S_4(\mu$-OAc$)_2$(dtp$)_4$ (6)

β-$Mo_4S_4(\mu$-OAc$)_2$(dtp$)_4 \cdot H$ (7)

β-$Mo_4S_4(\mu$-OAc$)_2$(dtp$)_4 \cdot H \cdot (CH_3)_2CO$ (8)

β-$W_4S_4(\mu$-dtp$)_2$(dtp$)_4$ (9)

α-$W_4S_4(\mu$-dtp$)_3$(dtp$)_3$ (10)

EXPERIMENTAL

The following instruments were used in this work: IR, Perkin–Elmer 577 spectrophotometer, KBr plate; UV–vis absorption, UV-300 Shimadzu recording spectrophotometer, DMSO as the solvent; ^{1}H NMR, VARIAN FT-80A spectrometer; ESR, ER-420 spectrometer, powder specimen; XPS, NP-3G spectrometer (Shenyang Scientific Instrument Factory, Chinese Academy of Sciences),

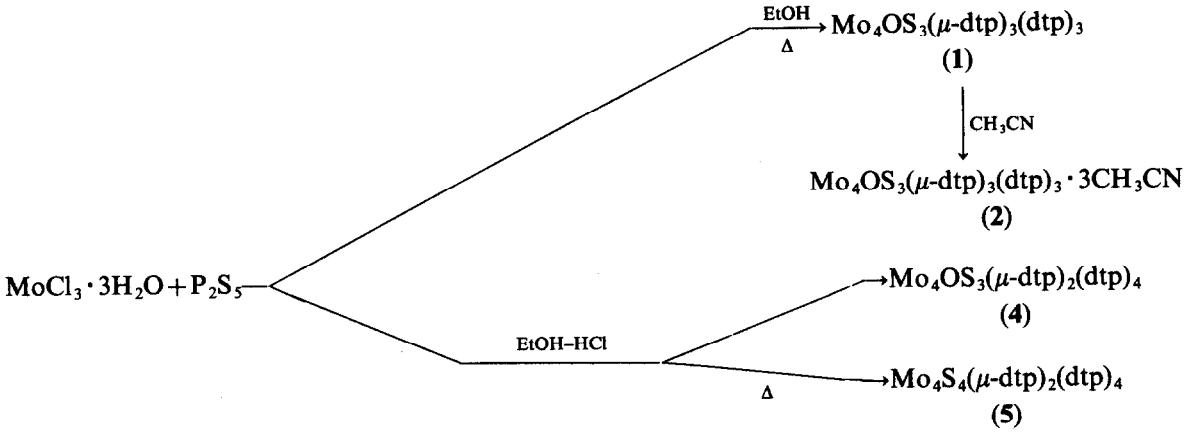
radiation source: Mg-K_α (1253.6 eV), 15 kV, 5 mA; cyclic voltammograms, CV-1b cyclic voltammograph and an X–Y recorder; X-ray crystallography, Enraf–Nonius CAD-4 diffractometer. Other details may be found in the related references.

RESULTS AND DISCUSSION

Synthetic route

The spontaneous self-assembly synthesis from the mononuclear molybdenum (tungsten) compounds

The reactions are as follows:



$$Mo(CO)_6 + MoCl_5 \xrightarrow[\Delta]{EtOH,\ P_2S_5} Mo_4XS_3(\mu\text{-dtp})_3(dtp)_3 \quad (X = 40\%\ O + 60\%\ S) \qquad (3)$$

$$W(CO)_6 + Na_2WO_4 \xrightarrow[\Delta]{EtOH,\ P_2S_5} W_4S_4(\mu\text{-dtp})_2(dtp)_4 \qquad (9)$$

$$K_3W_2Cl_9(aq.) \xrightarrow{\text{Ion exchange}} H_3W_2Cl_9 \xrightarrow{P_2S_5,\ EtOH} W_4S_4(\mu\text{-dtp})_3(dtp)_3. \qquad (10)$$

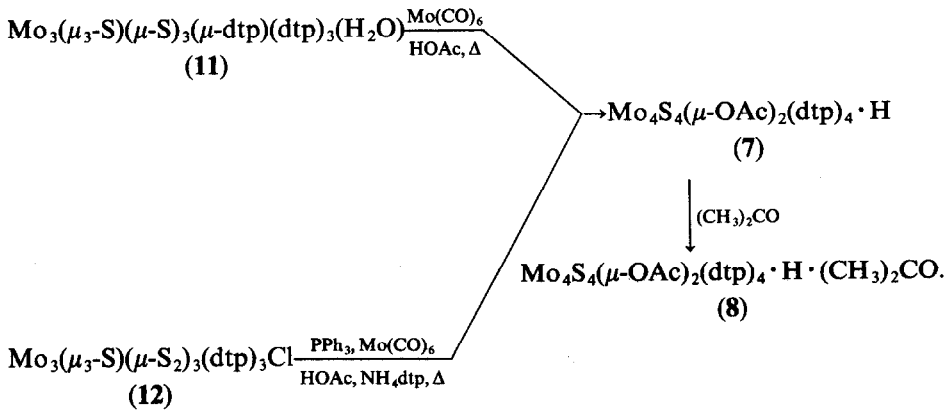
Although the spontaneous self-assembly synthesis is an effective method in the discovery and preparation of new cluster compounds, it has obvious limitations. Firstly, the success of obtaining a new cluster is sometimes only achieved by accident. Secondly, except for compounds **1** and **5**, poor reproducibility and low yields occur in the other synthesis.

The designed syntheses from some polynuclear molybdenum cluster compounds

(1) By direct ligand substitution of a Mo_4 cluster:

$$Mo_4S_4(\mu\text{-dtp})_2(dtp)_4 \xrightarrow{NaOAc} Mo_4S_4(\mu\text{-OAc})_2(dtp)_4$$
(5) (6)

or (2) by a [3 + 1] reaction mode via $[Mo_3S_4]^{4+} + Mo$:



In route (1) it is reasonable to suppose that cluster **6** can be obtained by OAc selective substitution of two bridging dtp from six dtp ligands in cluster **5**, since the OAc^- ligand can only be used as a bridging bidentate ligand in Mo_4 cluster compounds. In route (2), our proposal is (1) the successful synthesis of **6** by a [3 + 1] mode using **11**[26] is dependent on the choice of oxidation state of the added molybdenum cluster. On consideration of **11**, e.g. $[Mo_3S_4]^{4+}$, our attempted synthesis is the reaction of $Mo(CO)_6$ with HOAc to form $Mo_2(OAc)_4$, thereby containing the adduct according to $[Mo_3S_4]^{4+} + Mo^{2+} \rightarrow [Mo_4S_4]^{6+}$ (**6**). (2) When **12**[27] is used as the reactant in a [3 + 1] reaction, the addition of PPh_3 as a desulphurizing reagent changes (μ-S_2) into μ-S; at the same time a dtp ligand is added. The other reaction conditions are similar to those with compound **11**. However, it is shown from the structural analysis that the actual product in the above two reactions is **7**, i.e. $[Mo_4S_4]^{5+}$. One more hydrogen atom is present in **7** than in **6**, which is probably due to the reduction by $Mo(CO)_6$, but the reaction details are not yet clear.

Compared with the spontaneous self-assembly method, this designed synthesis of new cluster compounds from known clusters has the advantages of good reproducibility, high yields and product prediction.

The structural feature

The molecular configuration

The four basic molecular structures of the compounds are shown in Fig. 1. It can be seen that the Mo_4 core displays distorted tetrahedral geometry and contains six Mo—Mo bonds. The μ_3 ligands cap the faces of the Mo_4 tetrahedron (three of which are sulphido atoms and the fourth is a sulphido or oxygen atom) to form the Mo_4XS_3 (M = Mo or W; X = O or S) cubane-type cluster atom. Although many cluster compounds containing the "$[Mo_4S_4]$" core have been reported,[11] the $[Mo_4OS_3]$ core was first discovered by us, and contains the mixed S/O cuboidal Mo_4 species.[28,29]

There are also six dtp bidentate ligands in the

cluster molecule. Their coordination can be divided into two different categories, α and β, according to the time order of discovery. In the cluster molecule of the α-type, three of the dtp groups are terminal ligands where the remaining three are bridging ligands. On the other hand, the β-type has four terminal chelating dtp and two bridging dtp or OAc ligands for molybdenum atoms. The structures of the already known compounds $Mo_4S_4(dtc)_6$ [dtc = $S_2CN(CH_3)_2$][30] and $Mo_4S_4(Et_2PS_2)_6$[31] belong to the β-type, while the α-type was also first discovered in our work.

Our synthetic experiments indicate that in the preparation of "Mo_4" clusters from mononuclear molybdenum compounds by the spontaneous self-assembly method, the $[Mo_4OS_3]^{6+}$ core tends to be the α-type whereas as for $[Mo_4S_4]^{6+}$, the formation of the β-type is favourable.

Important structural data

Table 1 summarizes the main structural data for the 10 compounds obtained by X-ray crystallography.

As shown in Table 1, the crystal structures of compounds **1**, **3** and **10** (all α-type core) belong to the triclinic system. However, the solvated cluster compound **2** has crystallographically imposed C_{3v} symmetry. So far, there are only two examples of cubane-type Mo_4 clusters possessing trigonal symmetry; the other example is $[Mo_4S_4(SCN)_{12}]$ discovered by Cotton.[3]

As for most of the β-type Mo_4 cluster crystals, they belong to the monoclinic or orthorhombic system.

The cubane-type cluster cores $[Mo_4OS_3]$ *and* $[Mo_4S_4]$

Mo—Mo *bond lengths and the volume of the* $[Mo_4]$ *tetrahedron*

In earlier studies on the trinuclear Mo—S cluster compounds, it was found that replacement of μ_3-S by μ_3-O for a pair of μ_3-S and μ_3-O trimolybdenum cluster analogue compounds tends to shorten the Mo—Mo distances. For example, the average Mo—Mo bond lengths of $Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3(dtp)_4 \cdot$Oxazole and $Mo_3(\mu_3\text{-}O)(\mu\text{-}S)_3(dtp)_4 \cdot$Oxazole[32] are 2.760 and 2.638 Å, respectively, with a difference of about 0.12 Å (as shown at the end of Table 2).

On account of our successful preparations of a series of $[Mo_4OS_3]$ and $[Mo_4S_4]$ clusters with dtp as ligands it is thus possible to compare the influence of μ_3-S and μ_3-O on the Mo—Mo bond, not only within the Mo_3 cluster analogue compounds but also within a single Mo_4 framework. The Mo—Mo bond lengths of the representative Mo_4 clusters are listed in Table 2.

Table 2. The Mo—Mo and Mo—μ_3-X bond distances (Å) for six tetranuclear molybdenum clusters

Clusters	Mo—Mo 				Mo—μ_3-S (av.)	Mo—μ_3-O (av.)
α-$Mo_4OS_3(\mu\text{-}dtp)_3(dtp)_3 \cdot 3CH_3CN$ (**2**)	2.831 × 3			2.700 × 3	2.356	2.036
β-$Mo_4OS_3(\mu\text{-}dtp)_2(dtp)_4$ (**4**)	2.821 2.818	2.748 2.758	2.811	2.673	2.344	2.005

β-$Mo_4S_4(\mu\text{-}dtp)_2(dtp)_4$ (**5**)		2.856 × 2 2.865 × 2		2.746 2.808	2.333	
β-$Mo_4S_4(\mu\text{-}OAc)_2(dtp)_4$ (**6**)		2.739 2.748 2.879 × 2		2.665 × 2	2.343	
β-$Mo_4S_4(\mu\text{-}OAc)_2(dtp)_4 \cdot H$ (**7**)		2.772 2.765 2.969 × 2		2.685 2.707	2.354	
$Mo_3(\mu_3\text{-}O)(\mu\text{-}S)_3(dtp)_4 \cdot$oxazole	2.628	2.642	2.644	2.638(av.)		2.027
$Mo_3(\mu_3\text{-}S)(\mu\text{-}S)_3(dtp)_4 \cdot$oxazole	2.752	2.760	2.767	2.760(av.)	2.337	

A comparison of the structural geometry and the Mo—Mo bond lengths of these compounds indicates that both the capping μ_3 ligand and the edge-bridging μ-dtp or μ-OAc ligands are two important factors in affecting the Mo—Mo bond.

Let us first discuss the influence of the bridging bidentate ligand on the Mo—Mo bond distances. In **5**, the average Mo—Mo distance between the two dtp bridged molybdenum atoms is 2.777 Å, whereas that for the four remaining, unbridged Mo—Mo bonds is 2.861 Å (they differ by 0.084 Å). Similarly, in **6**, the μ-OAc bridged Mo—Mo mean value of 2.655 Å is 0.146 Å shorter than the unbridged value of 2.811 Å. It can be seen, therefore, that the presence of bridging dtp or OAc results in the shortening of the Mo—Mo distances, i.e. the Mo—Mo interaction is increased. In addition, the OAc ligand has a stronger effect than the dtp ligand. These effects are very similar to those discussed previously in trinuclear molybdenum clusters.

The influence of μ_3-S and μ_3-O on Mo—Mo bonds in a Mo_4 core is also considered. In **2**, the mean value of three μ_3-O bridged Mo—Mo bonds is 2.831 Å, while that of the other three μ_3-S and μ-dtp bridged Mo—Mo bonds is 2.700 Å (a difference of 0.131 Å). On the other hand, in **4**, the average distance of the two μ_3-S/μ_3-O bridged Mo—Mo bonds is 0.067 Å longer than that of the μ_3-S/μ_3-S bridged molybdenum atoms, whereas that of the μ_3-O and μ-dtp bridged Mo—Mo bond is 0.138 Å longer than that of the μ_3-S and μ-dtp bridged Mo—Mo bond. Thus, it can be seen that in a $[Mo_4]$ core, the μ_3-S/μ_3-O bridged Mo—Mo bonds are always longer than those bridged by μ_3-S/μ_3-S atoms. This result is contrary to that in trinuclear molybdenum clusters, as shown in Table 2.

It is interesting to note that although the μ_3-O bridged Mo—Mo bonds are longer than the μ_3-S bridged bonds in the same molecule, in the $[Mo_4OS_3]$ core, the average value of the six Mo—Mo bond lengths is shorter than in $[Mo_4S_4]$, while the volume of the Mo_4 tetrahedra is still smaller. For instance, in the $[Mo_4OS_3]$ core of **4**, the average Mo—Mo bond is 2.772 Å and the $[Mo_4]$ volume 2.511 $Å^3$, whereas in the $[Mo_4S_4]$ core of **5**, the values are 2.883 and 2.679 $Å^3$, respectively.

Determination of IR and UV spectra

By using clusters **1** and **5** as representatives of $[Mo_4OS_3]$ and $[Mo_4S_4]$ cores, respectively, the measurement of their IR and UV spectra has been carried out. The selected results are as follows: ν(Mo—μ_3-O) (**1**), 590(m) (cm^{-1}); ν(Mo—μ_3-S) (**5**), 440–457(br), 300–360(w) (cm^{-1}). UV–vis absorption: $[Mo_4OS_3]$ (**1**), 240nm(s), 250nm(s), 330nm(br), 420nm(m), 540nm(br); $[Mo_4S_4]$ (**5**), 240nm(s), 350nm(m), 540nm(br), 675nm(w).

In the $[Mo_4OS_3]$ core, splitting of the peaks (240 and 250; 330 and 420) occurs, which correspond to the peaks at 240 and 350 nm in the spectrum of $[Mo_4S_4]$, owing to the lower symmetry caused by the substitution of one μ_3-S ligand by μ_3-O (see Fig. 2).

The number of bonding electrons in Mo_4 *clusters*

As has been mentioned above, when cluster **6** is synthesized by the [3+1] reaction mode, i.e. β-$Mo_4S_4(\mu\text{-}OAc)_2(dtp)_4$, it can be seen from the structural analysis that the resulting product is **7** rather than **6**, i.e. β-$Mo_4S_4(\mu\text{-}OAc)_2(dtp)_4 \cdot H$. Although the position of this hydrogen atom cannot be determined by X-ray crystal structural analysis, it is valid to say that the hydrogen atom does exist based on a variety of spectroscopic data.

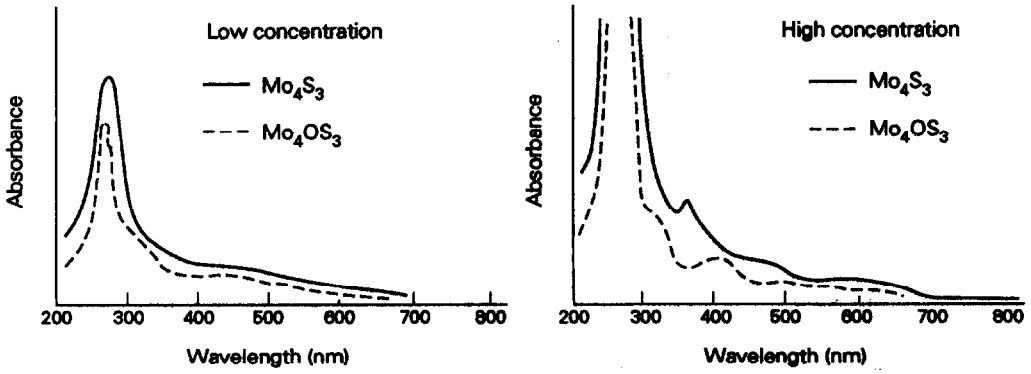

Fig. 2. Comparison of the electronic absorption spectra of $[Mo_4OS_3]^{6+}$ and $[Mo_4S_4]^{6+}$ in DMSO solutions.

Table 3. The Mo—Mo bond distances and number of electrons in [Mo_4]

Compounds	n	Number of electrons in [Mo_4]	Molybdenum oxidation state	Average Mo—Mo bond (Å)
$[Mo_4S_4(edta)_2]^{n-}$	2	10	3.5	2.826
	3	11	3.25	2.807
	4	12	3	2.783
$[Mo_4S_4(\eta\text{-}C_5H_4Pr^i)_4]^{n+}$	2	10	3.5	2.749
	1	11	3.25	2.856
	0	12	3	2.887
$[Mo_4S_4(\mu\text{-}OAc)_2(dtp)_4]^{n-}$	0 (**6**)	10	3.5	2.763
	1 (**7**)	11	3.25	2.811
	1 (**8**)	11	3.25	2.808

The interrelation of Mo—Mo *distances and the number of electrons in* Mo_4

In the two sets of Mo_4 clusters $[Mo_4S_4(\eta\text{-}C_5H_4Pr^i)_4]^{n+}$ ($n = 0, 1, 2$)[33] and $[Mo_4S_4(edta)_2]^{n-}$ ($n = 2, 3, 4$),[34] the Mo—Mo distances vary in a regular way with the number of electrons (10–12) in Mo_4 (see Table 3).

Although the variation of Mo—Mo distances as a function of the number of electrons from 10, 11 to 12 is different, the interrelationship between them is certainly present. As soon as the structural analysis indicates that a difference between the average Mo—Mo bond lengths in clusters **7** and **8** and those in cluster **6** occurs, we are aware that this may be due to the difference in the number of electrons in {Mo_4}. In {Mo_4} of **6**, there are only 10 electrons, while in **7** and **8**, {Mo_4} contains 11 electrons with corresponding total electron numbers of 58 and 59, respectively. Thus it may be deduced that a hydrogen ion must be present in the structures of **7** and **8** to achieve the electroneutrality.

The characterization of ^{1}H *NMR, ESR, XPS and cyclic voltammograms*

In order to further distinguish the differences between **6** and **7** (**8**), ^{1}H NMR, ESR, XPS and cyclic voltammograms were used under the same experimental conditions for the characterization of these compounds.

^{1}H *NMR*. It can be seen from Fig. 3 that an additional hydrogen resonance for **7** appears at 1.75 ppm which then disappears by rapid exchange with deuterium. Thus it may be considered as an active hydrogen in **7**.

ESR. The ESR parameters for **6** and **7** are given in Table 4.

It can be seen from Table 4 that the g factors of **6** and **7** (**8**) are significantly different from each other although they are all paramagnetic. This indicates that the electronic structures of **6** and **7** are also different.

XPS (*X-ray photoelectron spectroscopy*). All the measurements were performed with the Ag(3*d*) lines (373.89 eV, 367.9 eV) as the reference. The resolution is 0.1 eV and the relative binding energies can be measured to an accuracy of 0.05 eV. The electron binding energies of $Mo_3S_4(dtp)_4(H_2O)$ (here Mo is in the +4 oxidation state) are also given for comparison (Table 5).

It can be seen that binding energies of **7** are somewhat less than those of **6** (for $3d_{3/2}$ and $3d_{5/2}$): the oxidation state of molybdenum in **7** is +3.25 which is lower than that of **6**. The number of electrons in {Mo_4} in **6** and **7** is therefore 10 and 11, respectively.

Table 4. The ESR spectral parameters

Specimen	Temperature (K)	g_1	g_2	g_3
$Mo_4S_4(OAc)_2(dtp)_4$ (**6**)	289	2.79	2.29	~ 1.98
	77	2.37	2.14	1.98
$Mo_4S_4(OAc)_2(dtp)_4 \cdot H$ (**7**)	289	2.15	1.97	
	77	2.00	1.95	1.92

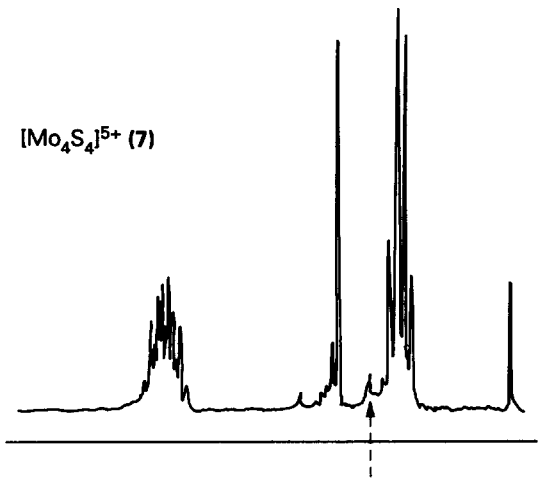

Fig. 3.

Cyclic voltammograms (see Fig. 4). Both the cyclic voltammograms of **7** and **6** have two quasi-reversible waves. The E_p values of **7** are shifted to more positive values than those of **6**, indicating that **7** is more readily reduced than **6**.

To sum up, it can be concluded that the structures of cluster compounds **6** and **7**, prepared by different synthetic routes, are very similar but their Mo—Mo electron numbers are different. This is a common phenomenon in many transition metal–sulphur cubane systems. This means that in this type of cluster molecules, the gain or loss of one or two electrons can still maintain the fundamental molecular configuration. It is also shown that the cubane-like configuration $[Mo_4S_4]$ may act as a reservoir of electrons for redox chemistry. It is on account of the discovery of the property of $[Fe_4S_4]$ ferredoxins as donors or acceptors of electrons in nature that the research on cubane-like metal cluster compounds has attracted great attention and made much progress.

The molecular orbital calculations

In order to elucidate the structural law mentioned above, an analysis of the electronic structure will be provided in this section. A systematic molecular orbital calculation has been carried out using the SCC–EHMO method,[35] developed by Hoffmann *et al.* on several typical clusters (**1**, **4**, **5**, **6** and **7**). The results of these calculations are provided to discuss the following three aspects.

The reason which causes the elongation of the Mo—Mo *bond lengths bridged by the* μ_3-O *atom in the* $[Mo_4OS_3]$ *core*

(1) *The effect of* d–pπ *conjugate interaction.* As is expected from the calculation of the multiple centre *d–p*π bond,[36,37] the OOP (Orbital Overlap Population) between the d_M (non-bonding *d* orbital) and *p*π (S or O lone-pair orbital) makes a significant contribution to the ROP (Reduced Overlap Population) between the metal and bridging atoms in the cluster. The ratio of OOP to ROP for the tetranuclear cluster is about 15–20%. In the α-type $[Mo_4OS_3]$ core (see Fig. 5), owing to the stronger Mo—S—Mo *d–p*π interaction than in Mo—O—Mo, the Mo(1)—S bond length is usually shorter than that of Mo(2)—S, 2.34 and 2.39 Å, respectively. Moreover, more *p*π electrons are transferred to the Mo(1)—S bond. According to the rule of bonding electron-pair repulsive interactions, the

Table 5. The binding energies (eV)

Sample	$3d_{3/2}$	$3d_{5/2}$	Oxidation state of molybdenum
$Mo_3S_4(dtp)_4(H_2O)$	233.65	230.95	+4
$Mo_4S_4(OAc)_2(dtp)_4$ (**6**)	232.21	229.05	+3.5
$Mo_4S_4(OAc)_2(dtp)_4 \cdot H$ (**7**)	232.04	228.84	+3.25

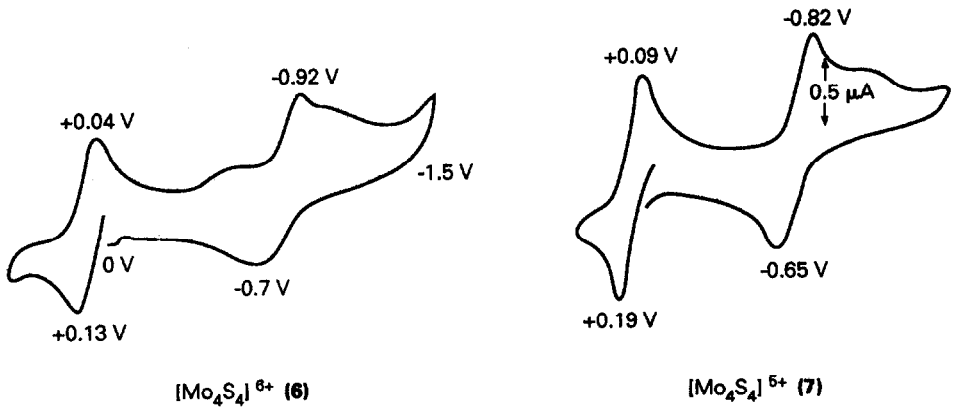

Fig. 4. Cyclic voltammograms (100 mV s^{-1}) of $[Mo_4S_4]^{6+}$ (**6**) and $[Mo_4S_4]^{5+}$ (**7**) (2 mM) in DMF solution containing 0.1 M Bu_4NClO_4 as the supporting electrolyte, peak potential vs SCE.

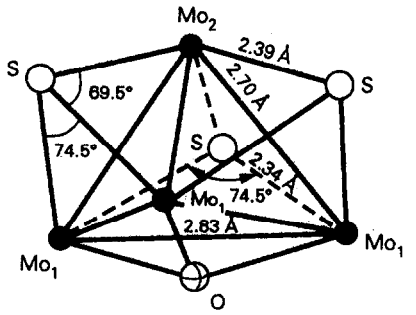

Fig. 5. The structural unit of the α-$[Mo_4OS_3]$ core.

Mo(1)—S—Mo(1) angle (74.5°) is greater than the Mo(2)—S—Mo(1) angle (69.5°). All this is consistent with the results from the X-ray structure analysis. As a consequence, the Mo(1)—Mo(1) bond length is longer than the Mo(1)—Mo(2) bond length.

(2) *The effect of the* μ_3-O *charge.* In general, the greater electronegativity of the oxygen atom increases the Mo—O—Mo bond angle. In the case of $[Mo_4OS_3]$, there is a considerably great negative charge on μ_3-O and therefore the Mo—O—Mo angle is extremely large (see Table 6). Thus, we can see that although the Mo—O bond length is roughly the same as those in other clusters, the charge effect is enough to cause the marked lengthening of the Mo(1)—Mo(1) bonds.

(3) *The pull effect of the bridging* dtp *ligand.* The bridging dtp ligand can actually pull two molybdenum atoms closer together, which results in the shortening of the Mo—Mo bonds.

By comparison, the above two effects (1) and (2) are the dominant factors in the lengthening of the Mo—Mo bond distances (as shown in Table 7). It can be seen from the table that in the β-type $[Mo_4OS_3]$ core, the order of distances is:

$$(\text{Mo—Mo})_{\mu_3\text{-S}+\mu_3\text{-O}+\mu\text{-dtp}} < (\text{Mo—Mo})_{\mu_3\text{-S}+\mu_3\text{-S}}$$
$$2.811\,\text{Å} \qquad 2.753\,\text{Å}$$

$$(\text{Mo—Mo})_{\mu_3\text{-S}+\mu_3\text{-O}+\mu\text{-dtp}} > (\text{Mo—Mo})_{\mu_3\text{-S}+\mu_3\text{-S}+\mu\text{-dtp}}$$
$$2.811\,\text{Å} \qquad 2.673\,\text{Å}.$$

Table 7 also lists the ROP values of various Mo—Mo bonds bridged by different ligands in the α- and β-type $[Mo_4OS_3]$ cores.

Bridge	μ_3-S+μ_3-S +μ-dtp	μ_3-S+μ_3-O	μ_3-S+μ_3-S +μ-dtp	μ_3-S+μ_3-S	μ_3-S+μ_3-O +μ-dtp	μ_3-S+μ_3-O

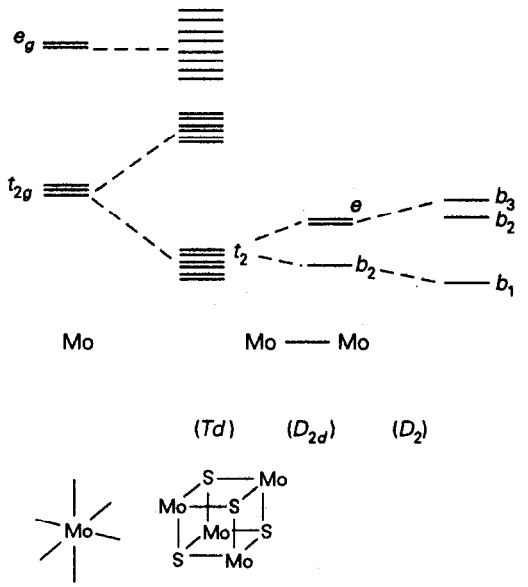

Fig. 6. Qualitative molecular orbital energy level scheme.

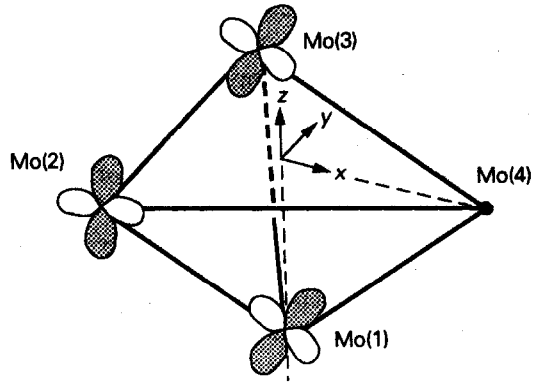

Fig. 7. The weak Mo—Mo π*-antibonding orbital of $[Mo_4S_4(OAc)_2(dtp)_4]^-$.

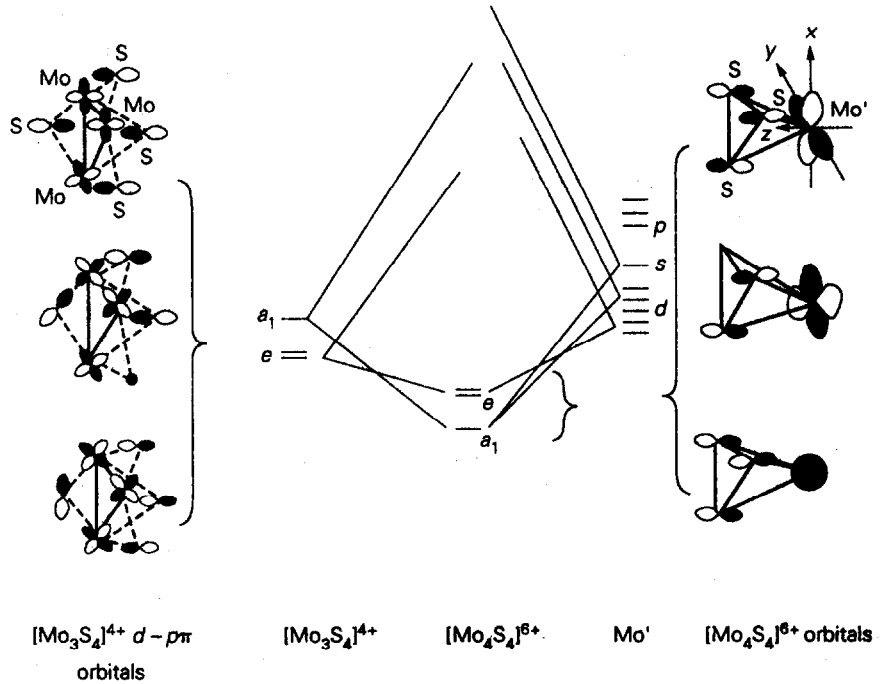

Fig. 8. Correlation diagram showing the interaction of $[Mo_3S_4]^{4+}$ with $Mo(CO)_6$ to form $[Mo_4S_4]^{6+}$.

cluster valence electron (CVE) scheme, 60 electrons will lead to a completely bonded metal tetrahedron in the case of ideal T_d symmetry, of which 12 electrons occupy the six M_4 cluster bonding orbitals, for instance $Mo_4S_4(CN)_{12}$.[2] In many circumstances, however, the $[Mo_4S_4]$ configuration often distorts from T_d to some extent and thus the t_2 orbital (HOMO) of the tetranuclear cluster under T_d symmetry will be split into $e+b_2$ orbitals for D_{2d} symmetry or $b_1+b_2+b_3$ orbitals for D_2 symmetry (as shown in Fig. 6).[38]

It is known from the calculations that the three highest occupied energy levels are -10.26, -10.28 and -10.42 eV, respectively, for $[Mo_4S_4(OAc)_2(dtp)_4]^-$. Since the HOMO is degenerate (having a very small energy difference), both the 10-electron and 11-electron systems may be paramagnetic. Meanwhile, owing to the weak Mo—Mo π^*-antibonding of the HOMO orbital (Mo d_{xy}–d_{xy}, see Fig. 7), the Mo—Mo bond length of **7** (11-electron cluster) is, on the contrary, longer than that of **6** (10-electron cluster). This reason may also explain the difficulty in obtaining the $[Mo_4S_4(\mu\text{-}OAc)_2(dtp)_4]^{2-}$ complex.

The formation mechanism of **7** *by the* [3 + 1] *reaction mode*

It is found from the calculations that it is the σ interaction between the μ_2-S $p\pi$ orbital of $Mo_3S_4(dtp)_4(H_2O)$ and the valence orbitals of $Mo(CO)_6$ that leads to the $[Mo_4S_4]$ cluster, as shown in Fig. 8 (for the sake of convenience in the description, the structure of the $[Mo_4S_4]$ cluster core can be approximately considered as C_{3v} symmetry with Mo′ lying on the z axis, which is perpendicular to the $\{Mo_3\}$ plane).

Clearly, it can be seen that the effect of a multiple centre d–$p\pi$ bond can not only lead to the unusual stability of the $[Mo_3S_4]$ core,[39,40] but speed up the addition reaction as well.

PREPARATION AND SPECTROSCOPIC CHARACTERIZATION OF CAESIUM HEXACHLOROPHOSPHATE

ALAN S. MUIR

Department of Chemistry, Royal Holloway and Bedford New College, Egham Hill, Egham, Surrey TW20 0EX, U.K.

(*Received* 5 *April* 1991; *accepted* 19 *July* 1991)

Abstract—The first alkali-metal hexachlorophosphate, $Cs^+PCl_6^-$, was prepared and characterized by elemental analysis, solid-state ^{31}P NMR, IR and Raman spectroscopies. The thermodynamic stability of alkali-metal hexachlorophosphates is briefly discussed.

The hexafluorophosphate and hexachlorophosphate anions are both well-known and have been characterized as essentially octahedral species by X-ray diffraction[1,2] and a variety of spectroscopic techniques.[3,4] However, the hexabromophosphate anion is unknown, as indeed is the trigonal bipyramidal (molecular) form of PBr_5: this presumably results from steric factors. Mixed chlorofluorophosphate anions have also been reported, as well as a variety of pseudo halogen-substituted anions: ^{31}P and ^{19}F NMR spectroscopy have proved particularly useful in identifying such species in solution.[5–10] Alkali-metal hexafluorophosphates have been known for some time[11] but until now hexachlorophosphates were only known with large polyatomic cations[4,12,13] and *none* of the related alkali-metal salts have been reported. Thermodynamic calculations for the decomposition reactions [eq. (1)] using the Kapustinskii–Yatsimirskii approach have indicated that such species are of borderline stability,[12,13] with values of $\Delta G_R^{\ominus}$ for $K^+PCl_6^-$ and $Cs^+PCl_6^-$ of *ca* -38 and -6 kJ mol^{-1}, respectively.

$$MPCl_6(c) \longrightarrow MCl(c) + PCl_5(c) \quad (M = K, Cs) \qquad (1)$$

EXPERIMENTAL

All manipulations were carried out in an atmosphere of dry nitrogen. Chemicals of the best available commercial grade were used without further purification, although CsCl, RbCl and KCl were dried by warming to *ca* 100°C *in vacuo* for several hours. $Cs^+PCl_6^-$ was prepared typically as follows: hydrogen chloride gas (dried by passage through concentrated H_2SO_4) was condensed onto a mixture of CsCl (2.00 g, 1.20×10^{-2} mol) and $PCl_4^+PCl_6^-$ (2.50 g, 1.19×10^{-2} mol) by immersing the reaction vessel in liquid nitrogen. HCl liquefaction was achieved by warming to *ca* -95°C with a toluene/nitrogen slush-bath and the reaction mixture was agitated for 15 min. The HCl was then permitted to evaporate over $2\frac{1}{2}$ h by controlled warming. The resulting off-white solid was dried by pumping. Chlorine was analysed by potentiometric titration: Found: Cl, 56.3. $CsPCl_6$ requires: Cl, 56.5%.

Raman spectra were recorded using a Coderg PHO spectrometer with excitation at 514.5 nm provided by a Coherent Radiation Argon Ion laser; samples were contained in sealed capillaries. IR spectra were recorded using a Perkin–Elmer 983 spectrometer; CsI plates were used and samples were prepared either as Nujol mulls or as finely-ground solids. Solid-state MAS ^{31}P NMR spectra were recorded using a Bruker MSL 300 spectrometer operating at 121.5 MHz.

RESULTS AND DISCUSSION

The IR and Raman wavenumbers obtained for $Cs^+PCl_6^-$ are presented in Table 1, along with appropriate data for some previously known hex-

Table 1. IR and Raman spectroscopic data (cm^{-1}) for some hexachlorophosphates

Complex	Reference	Modes $\nu_1(A_{1g})$	$\nu_2(E_g)$	$\nu_3(T_{1u})$	$\nu_4(T_{1u})$	$\nu_5(T_{2g})$	$\nu_6(T_{2u})$
$Cs^+PCl_6^-$	Current study	359(s)	268, 277 (m)	440(vs)	286(w)	250, 240 (m)	Inactive

N.R. = not recorded.

achlorophosphates. The agreement is good although there are some small shifts: for an octahedral MX_6^- species three Raman active (A_{1g}, E_g, T_{2g}) and two IR (T_{1u}) modes are predicted and observed. The Raman spectrum is shown in Fig. 1 and some splittings are seen in the degenerate modes: E_g (268 and 277 cm^{-1}) and T_{2g} (250 and 240 cm^{-1}). The IR spectrum recorded as a Nujol mull showed additional bands at 588 and 336 cm^{-1} due to $POCl_3$ impurities arising from sample

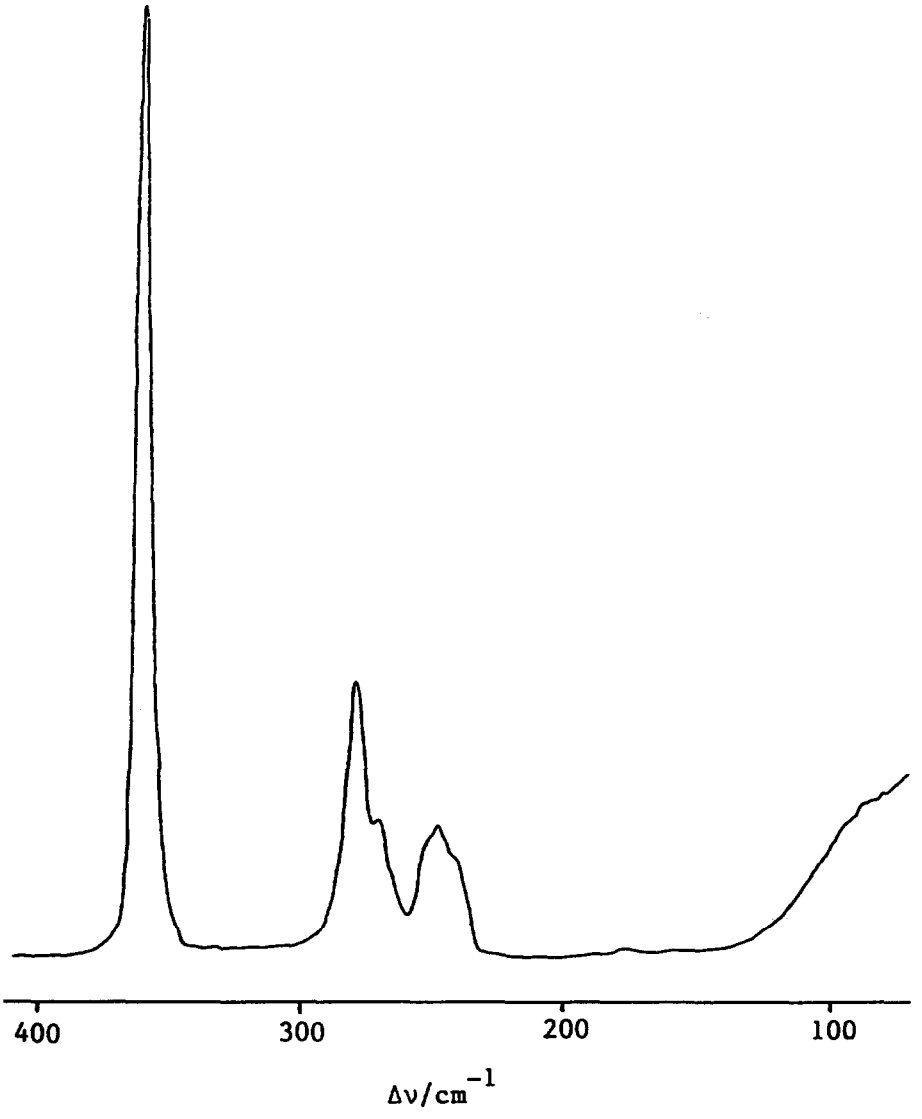

Fig. 1. Raman spectrum of $Cs^+PCl_6^-$.

decomposition, although these did not obscure the PCl_6^- modes at 440 and 286 cm^{-1}. The ^{31}P MAS NMR spectrum of $Cs^+PCl_6^-$ showed a single resonance at −294.7 ppm ($\Delta\nu_{1/2} = 30$ Hz) in accord with previous measurements of hexachlorophosphate salts.[14] The relatively narrow line width is consistent with considerable ionic motion within the system.

When a sample of $Cs^+PCl_6^-$ sealed in a long (6 cm) capillary tube was heated to *ca* 220°C for 1 h in a melting point apparatus, a sublimate was observed at the cool end of the tube: the Raman spectrum of this showed bands at 178, 242, 253, 279, 359, 457 and 656 cm^{-1} indicative of phosphorus pentachloride[15] as confirmed by comparison with the spectrum of an authentic sample of $PCl_4^+PCl_6^-$. No Raman signals were obtained from the residue; thus, the decomposition in Eq. (2) may be predicted.

$$Cs^+PCl_6^-(c) \xrightarrow{\Delta} \underset{\text{residue}}{CsCl(c)} + [PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)] \longrightarrow \underset{\text{sublimate}}{PCl_4^+PCl_6^-(c)} \quad (2)$$

However, all attempts to prepare the analogous $K^+PCl_6^-$ and $Rb^+PCl_6^-$ salts by a similar process involving anhydrous HCl failed, yielding only the starting materials, although a similar reaction between CsF and PCl_2F_3 in acetonitrile at ambient temperature has been shown[6] to yield the salt $Cs^+PCl_4F_2^-$ in admixture with $Cs^+PF_6^-$. This reflects the calculated borderline thermodynamic stability for the alkali-metal hexachlorophosphates and suggests that the stability of $Cs^+PCl_6^-$ derives from kinetic factors. Moreover, on the basis of cation size, the failure to isolate either a potassium or rubidium salt indicates that the title compound is probably unique as a metallic hexachlorophosphate.

Acknowledgements—The author thanks Dr P. N. Gates for helpful discussions and Mr D. Butler (University of London Intercollegiate Research Service) for obtaining the NMR spectra.

SOLVOLYSIS OF THE DIFLUORO(1,10-PHENANTHOLINE)BORONIUM CATION IN DMSO: A ^{11}B AND ^{19}F NMR STUDY

KLAUS R. KOCH* and SUSANNE MADELUNG

Department of Chemistry, University of Cape Town, P. Bag Rondebosch, Cape Town 7700, South Africa

(*Received* 9 *April* 1991; *accepted* 25 *June* 1991)

Abstract—The salts $[LLBF_2]^+BF_4^-$, where LL = 1,10-phenantholine and 2,2′-bipyridine, undergo solvolysis in DMSO solution. The rate of solvolysis of the difluoro(1,10-phenantholine)boronium cation may conveniently be followed by means of ^{11}B and ^{19}F NMR. In contrast, the difluoro(2,2′-bipyridine)boronium cation appears to be rapidly solvolysed on dissolution, highlighting the differences in stabilities of these two boronium cations.

A considerable number of stable cationic boron complexes involving the interaction of monodentate Lewis bases with alkyl- and halogenoboranes have been prepared and characterized.[1–3] The stabilities of these boronium complexes vary greatly depending on the nature of the Lewis base and the substituent on the boron atom.[3] Despite the fact that the first stable cationic chelate boronium complex had been reported in 1906,[4] relatively few complexes involving neutral bi- and polydentate Lewis bases have been reported. Rund *et al.* prepared and characterized a series of complexes of the type $[LLBX_2]^+BX_4$, where $X = F^-$, Cl^- and LL = 1,10-phenantholine, 2,2′-bipyridine.[5] We have had cause to examine the chemistry of similar complexes in solution, and here report the unexpected solvolysis of the difluoro(1,10-phenantholine)boronium cation, $[(phen)BF_2]^+$, in dimethylsulphoxide (DMSO) solution as followed by ^{11}B and ^{19}F NMR.

The complexes $[(phen)BF_2]BF_4$ (**1**) and $[(bipy)BF_2]BF_4$ (**2**) may conveniently be prepared by treatment of a solution of the ligand in anhydrous ether/acetone with the appropriate amount of $(C_2H_5)_2O \cdot BF_3$, at room temperature under dry nitrogen. The salts **1** and **2** precipitate as essentially pure colourless solids and were used without further purification. For **1**: Found: C, 45.4; H, 2.7; N, 9.0. Calc. for $C_{12}H_7N_2B_2F_6$: C, 45.8; H, 2.2; N, 8.9%. For **2**: Found: C, 40.6; H, 2.7; N, 9.5. Calc. for $C_{10}H_8N_2B_2F_6$: C, 41.2; H, 2.8; N, 9.6%.

Examination of the 64.1 MHz ^{11}B NMR spectrum of a freshly prepared solution of **1** in dry DMSO-d_6 shows three resonances: a broad peak at 9.12 ppm, a well defined triplet centred at 2.15 ppm [$J(^{19}F—^{11}B) = 12.5$ Hz], and a sharp single line at 0.75 ppm relative to external $(C_2H_5)_2O \cdot BF_3$. After *ca* 18 min, the broad peak at 9.12 ppm had disappeared and a new resonance at 1.5 ppm appeared. The intensity of the latter resonance grew with the concomitant disappearance of the triplet at 2.15 ppm. After *ca* 19 h, only two resonances at 1.5 and 0.75 ppm were observed; no further changes occurred over a 48 h period. Resolution enhancement of the resonance at 1.5 ppm shows that it has the structure of a poorly resolved quartet, ascribed to $^1J(^{19}F—^{11}B) = 5 \pm 1$ Hz (Fig. 1). The time dependence of the ^{11}B NMR spectrum of **1** is mirrored by the 188.15 MHz ^{19}F spectrum, which initially shows four ^{19}F resonances at −63.35 ppm [unsymmetrical quartet, $J(^{10/11}B—^{19}F) = 12$–14 Hz] and −65.75 ppm (broad, unresolved peak) and two sharp single resonances in the ratio 1:4 at −67.79 and −67.85 ppm, respectively. The resonance at −63.35 ppm disappeared, while the peak at −65.75 ppm grew more intense according to a similar time scale observed in the ^{11}B NMR spectrum. The two resonances at −67.79 and −67.85 ppm did not

* Author to whom correspondence should be addressed.

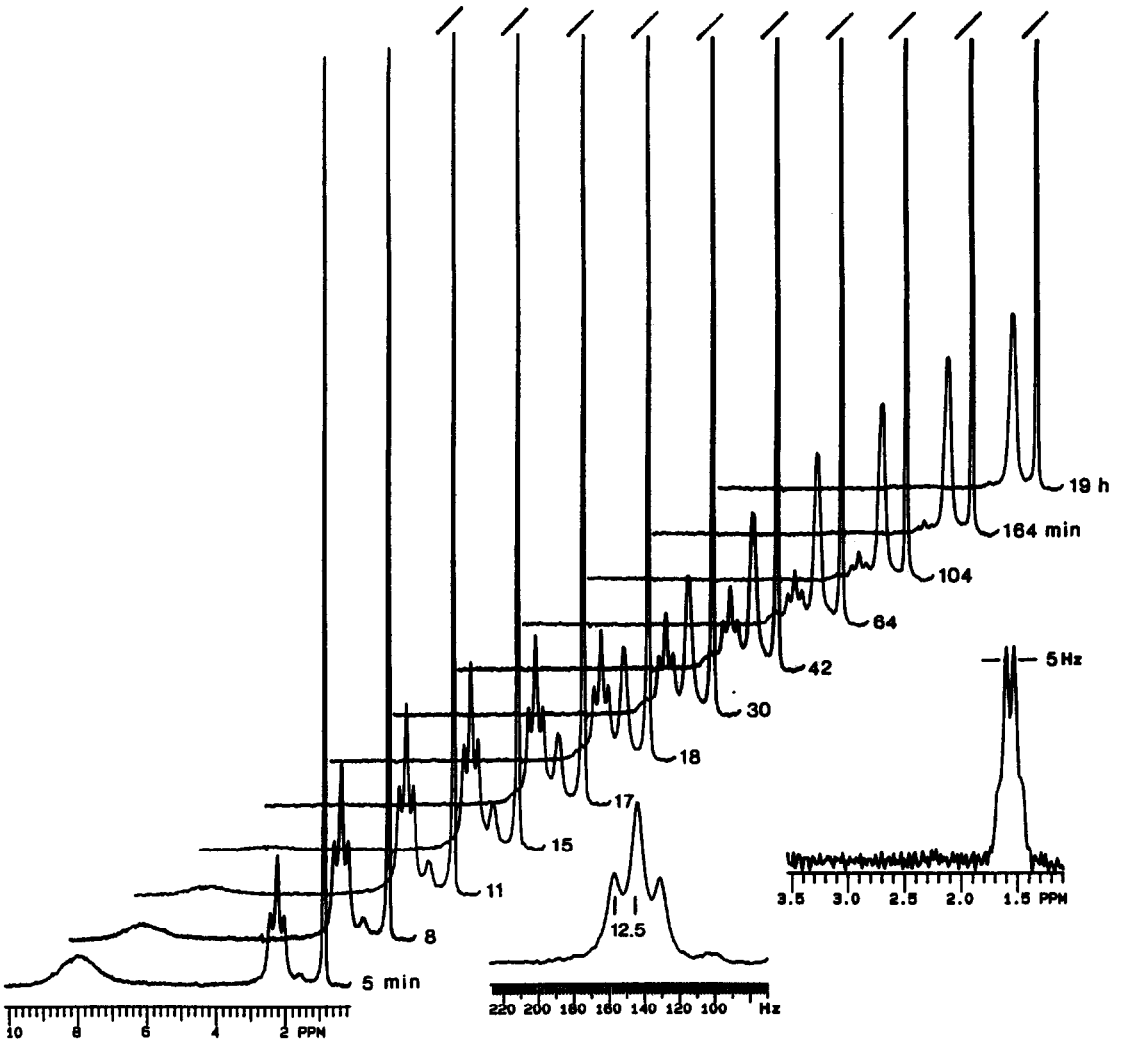

Fig. 1. The ^{11}B NMR spectra of $[(phen)BF_2]\cdot BF_4$ in DMSO-d_6 as a function of time. The resonances at 2.15 and 1.55 ppm are shown in expansion showing resolved $^{19}F—^{11}B$ coupling.

change significantly and may be assigned to the BF_4^- anion, showing the characteristic $^{10}B/^{11}B$ isotope shift of *ca* 0.05 ppm.[6]

By contrast, the ^{11}B and ^{19}F spectra of fresh solutions of **2** did not show a similar time dependence as that observed for **1**. The ^{11}B spectrum obtained is almost identical to that obtained for **1** after 19 h, consisting of a poorly resolved quartet at 1.6 ppm [$^1J(^{19}F—^{11}B) = 4$–5 Hz] and a single resonance at 0.8 ppm. The corresponding ^{19}F spectrum of **2** shows resonances at −65.76 ppm (poorly resolved multiplet) and at −67.78 and −67.84 ppm (ratio 1 : 4).

These spectra clearly show that solvolysis of the boronium *cations* $[(phen)BF_2]^+$ (**3**) and $[(bipy)BF_2]^+$ (**4**) occurs in DMSO-d_6 solution. The rate of solvolysis of **3** is sufficiently slow to be conveniently monitored by means of NMR spectroscopy, whilst for **4** this phenomenon occurs much more rapidly on dissolution of **2**. Based on the analysis of the spectra shown in Fig. 1, we proposed the assignments given in Table 1.

It should be noted that our assignments differ to those of Rund *et al.*[5] These authors reported identical ^{11}B shifts for both **1** and **2**, assigning the resonance at 1.2 ppm to BF_4^- and that at 0.6 ppm to the respective boronium cation. This suggests that solvolysis had already taken its course by the time the ^{11}B NMR spectra was recorded. Moreover, the reported shift values are different to our assignments, despite using the conventional external ^{11}B reference,[7] $(C_2H_5)_2O\cdot BF_3$, as did Rund and coworkers. This discrepancy highlights the importance of proper referencing to avoid confusion. We recorded the ^{11}B and ^{19}F NMR spectra of tetra-*n*-butylammonium tetrafluoroborate in DMSO-d_6,

Table 1.

Species	$\delta(^{11}B)$ (ppm[a])	$^1J(^{19}F—^{11}B)$ (Hz)	$\delta(^{19}F)$[b]
$[(phen)BF_2]^+$	2.15	12.5	−63.35
BF_4^-	0.75	n.r.[c]	−67.79
			−67.85
$BF_3 \cdot DMSO$	1.55	~ 5	−65.35

$[(bipy)BF_2]^+$	Not obs.	—	—
BF_4^-	0.80	n.r.[d]	−67.78
			−67.84
$BF_3 \cdot DMSO$	1.60	~ 5	−65.76

[a] Shifts are relative to external $(C_2H_5)_2O \cdot BF_3$ at 25°C.
[b] Shifts relative to 50% v/v CF_3COOH/D_2O at 25°C.
[c] Species uncertain but could be $[(phen)BF_3]$ in view of the line width of this resonance.
[d] Not resolved, < 1.2 Hz, see ref. 8.

finding a single resonance at 0.73 ppm and −67.93/−67.98 ppm, respectively. Addition of $(C_2H_5)_2O \cdot BF_3$ to some DMSO-d_6 gave a broad signal at 1.47 ppm and −65.71 pm for ^{11}B and ^{19}F, respectively.

In conclusion, we find that the boronium cations **3** and **4** show markedly different stabilities to solvolysis in DMSO-d_6, although in both cases the chelating Lewis base is effectively displaced from the coodination sphere of the boronium cation. We postulate that a highly reactive intermediate $BF_2(DMSO)_2^+$ presumably reacts with BF_4^- to yield the neutral $DMSO \cdot BF_3$ species:

$$[(phen)BF_2]^+ \xrightarrow{DMSO} phen + BF_2(DMSO)_2^+$$

$$BF_2(DMSO)_2^+ + BF_4^- \longrightarrow 2BF_3 \cdot DMSO.$$

The substantial differences in the rates of solvolysis for cations **3** and **4** is an interesting example of the dependence of the stabilities of these boronium cations on subtle differences in the nature of the two chelating ligands involved. Presumably the rigidity of the 1,10-phenantholine as compared to the 2,2′-bipyridine chelate confers added stability to the boronium cation **3**.

Abstract—Blue crystals of $[Cu(NN'dmen)(NO_3)_2]$ (where NN′dmen = N,N′-dimethyl-1,2-ethanediamine) were prepared and its structure was determined by single crystal X-ray crystallography. In this complex both the nitrates are mono-coordinated to the copper in *cis* positions. The IR spectra and magnetic susceptibility are reported.

The combination bands of the ν_1 symmetric stretching mode and the doubly-degenerate in-plane bending mode of nitrate ions, which appear in the 1700–1800 cm^{-1} region in the IR spectra of metallic complexes have been used for structural diagnosis.[1–3] This is very useful for a nitrato complex containing other organic ligands as the IR bands of the common organic ligands are almost absent in this region. An ionic nitrate group gives rise to a relatively strong and sharp combination frequency while the coordinated nitrate groups give two frequencies.[3,4] In the bidentate coordination mode the separation between the two frequencies is wider than that in the monodentate coordinating mode.[4] Single crystal X-ray analysis of $[Cu(N,N'dmen)(NO_3)_2]$ (N,N′dmen = N,N′-dimethyl-1,2-ethanediamine) was undertaken to establish these IR spectral evidences. Moreover, additional knowledge of the structure of the complexes that may exist in solution is of potential importance in understanding the intermediate in the stability studies and in the ligand exchange reactions in solution.

EXPERIMENTAL

High purity N,N′-dimethyl-1,2-ethanediamine was purchased from Fluka AG and used as received. All the other chemicals used were of AR grade.

Preparation of the complex

$Cu(NO_3)_2 \cdot 3H_2O$ (1 mmol) was dissolved in methanol (10 cm^3). Diamine (1 mmol) was then added to the $Cu(NO_3)_2$ solution with stirring. The solution was allowed to evaporate slowly until fine blue crystals formed. Found: C, 17.5; H, 4.6; N, 20.2; Cu, 23.2. Calc. for $C_4H_{12}N_4CuO_6$: C, 17.4; H, 4.4; N, 20.3; Cu, 23.0%. $\mu_{eff} = 1.84$ B.M.; $\lambda_{max} = 592, 701(sh)$ nm.

Physical measurements

The equipment employed for IR spectra (in KBr discs and in Nujol), electronic spectra, elemental analysis and magnetic measurements was the same as described in an earlier report.[1]

Crystal data

$C_4H_{12}N_4CuO_6$, $M_r = 275.7$, tetragonal, space group $P4_12_12$, $a = b = 8.797(2)$, $c = 12.957(3)$ Å, $V = 1002.7(4)$ Å^3, $Z = 4$, (Mo-K_α) = 21.99 cm^{-1}, $D_c = 1.826$ g cm^{-3}, $T = 293$ K.

Data collection, structure solution and refinement

A single crystal ($0.35 \times 0.20 \times 0.15$ mm) was mounted on a glass fibre with epoxy glue. Unit cell dimensions and Laue class were determined from precession photographs. Final cell parameters were obtained by least-squares analyses of the diffractometer angle settings of 25 well-centred reflections having $20 < 2\theta < 35°$. Intensity data were collected on a Hilger–Watt four circle diffractometer (graphite monochromatized Mo-K_α radiation, $\lambda = 0.71073$ Å) using a ω–2θ scan. Of 664 unique data collected up to $2\theta_{max} = 50°$, 438 with $|F_o| > 3\sigma(F_o)$ were considered observed and were used in structure refinement. Intensities of three standard reflections monitored after every 50 measurements during data collection showed no significant change. Data were corrected for Lorentz–polarization factors. An empirical absorption correction[5] was applied using ψ-scan data.

The structure was solved by Patterson and successive Fourier synthesis and refined by full-matrix least-squares using SHELX76[6] with anisotropic thermal parameters for all non-hydrogen atoms, while the hydrogen atoms were kept fixed with isotropic temperature factors in their calculated positions. The final $R[= \Sigma||F_o|-|F_c||/\Sigma|F_o|]$ and $R_w = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ values were 0.030 and 0.031, respectively, using $w^{-1} = \sigma^2(F) + 0.0018|F|^2$. The maximum/minimum peak heights in the final difference Fourier synthesis were 0.48 and -0.31 e Å^{-3}, respectively. Maximum shift/e.s.d. in the final cycle of refinement was 0.005. Neutral atom scattering factors were used.[7] All computations were carried out on Vax cluster system at the University of York, England during the author's (DGA, AKM) stay there.

RESULTS AND DISCUSSION

An ORTEP[8] drawing of the complex showing the atom labelling scheme is shown in Fig. 1. Selected bond lengths and angles are listed in Table 1. The asymmetric unit contained half of the complex with copper lying on a crystallographic two-fold axis. Four major ligand atoms (N(2), N(22), O(1), O(12)) around copper form an approximate square-planar arrangement with one bidentate N,N′-dimethyl-1,2-ethanediamine molecule and two monodentate nitrate ions in a *cis* configuration. Weak coordination of the two symmetry related positions of O(3) [^{1}O(3) at 0.7679, 0.8695, 0.7002 and ^{2}O(3) at 0.8695, 0.7679, 0.2998; Cu—^{1}O(3) = Cu—^{2}O(3) = 2.673(4) Å] completes a distorted octahedron. As expected the IR spectrum, for both the nitrates being coordinated to the metal atom via one oxygen atom, of the complex [Cu(N,N′dmen)(NO$_3$)$_2$] taken in KBr (Fig. 2)

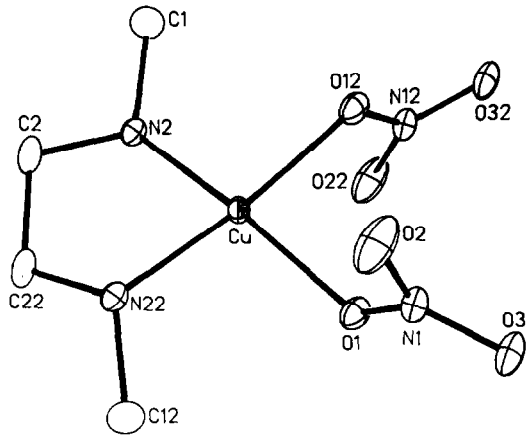

Fig. 1. ORTEP plot of [Cu(N,N′dmen)(NO$_3$)$_2$] with labelling of the non-hydrogen atoms.

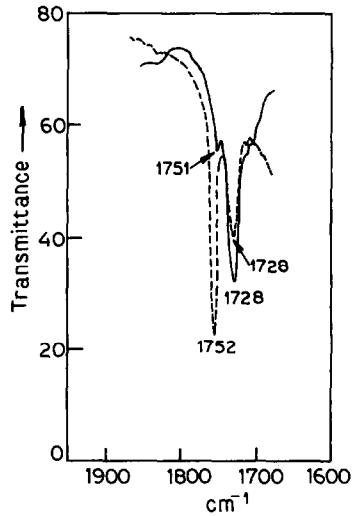

Fig. 2. IR spectra showing the change of band ratio when taken in Nujol (——) and KBr (– – –).

Table 1. Selected bond lengths (Å) and bond angles (°)

Cu—N(2)	2.000(3)	Cu—O(1)	1.993(3)
N(2)—C(1)	1.482(6)	N(2)—C(2)	1.479(6)
N(1)—O(1)	1.293(5)	N(1)—O(2)	1.234(6)
N(1)—O(3)	1.223(5)		
N(2)—Cu—O(1)	165.5(1)	N(2)—Cu—N(22)	86.6(1)
N(2)—Cu—O(12)	95.5(1)	O(1)—Cu—O(12)	86.1(1)
Cu—O(1)—N(1)	119.3(2)	Cu—N(2)—C(1)	119.6(3)
O(1)—N(1)—O(2)	119.2(4)	O(1)—N(1)—O(3)	117.9(4)
O(2)—N(1)—O(3)	122.9(4)		

showed two absorption bands at 1752 and 1728 cm^{-1} with a separation of 24 cm^{-1}. The intensity ratio of the two peaks is reversed when the spectrum is taken in Nujol mulls (Fig. 2). Probably due to exchange of NO_3 ions with Br ions of KBr the IR band which appears at 1752 cm^{-1} overlaps the ionic nitrate band and increases the intensity. The displacements of N(2) and N(22) atoms from the least-squares plane through N(2), N(22), Cu, O(1) and O(12) are $\pm 0.258(4)$ Å, whilst the corresponding values for O(1) and O(12) are $\pm 0.246(4)$ Å, respectively. The nitrate group is essentially planar, the maximum displacement of any atom from the least-squares plane through N(1), O(1), O(2) and O(3) being 0.003(5) Å and almost perpendicular to the plane defined by Cu, N(2), N(22), O(1) and O(12) atoms [the dihedral angle between the two planes is 88.0(2)°]. The distances Cu—O(1) 1.993(3) Å and Cu—N(2) 2.000(3) Å are comparable to those observed in similar systems.[9,10] The magnetic moment of the complex [Cu,(N,N′dmen)$(NO_3)_2$] is 1.84 B.M. at 20°C.

It is to be noted that the structure of the title complex is interesting as both the nitrate ions are coordinated with copper(II) at the *cis* position which is apparently unfavourable due to inter-anionic repulsion.[11]

Acknowledgements—The authors wish to thank Professor J. R. Helliwell, Department of Chemistry, University of Manchester, U.K. for helpful discussions and Mr Suranjan Bhanjachoudhury for the ORTEP plot done at the National Single Crystal Diffractometer Facility, Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Calcutta. We are also grateful to the Department of Physics, University of York, U.K. for allowing two of the authors (DGA, AKM) to use the X-ray diffractometer facility.

Abstract—The reaction of $K_2RuCl_5 \cdot H_2O$ with $(C_5H_4N)P(O)(OEt)_2(L)$ yields the anionic complex $K\{RuCl_2[OP(O)(OEt)(C_5H_4N)]_2\}$ (**4**). One ethyl group of L has been eliminated in an Arbuzov-type reaction. This compound is stable and unreactive (no reaction with imidazole, pyridine, tert-butyl-pyridine, 18-crown-6, PMETA). The reactions of (**4**) with zinc, aluminium or $NaBH_4$ do not lead to reduction of the metal centre but to further dealkylation of L. In contrast, the reactions of L with $MCl_3 \cdot 3H_2O$ produce the new fluxional compounds MCl_3L_2 [M = Ru (**6**), M = Rh (**7**)] containing one bidentate and one monodentate ligand.

Organometallic chemistry of higher oxidation states is attracting increased attention at the present time. Thus, if low oxidation state organometallic chemistry has been extensively studied for the past 20 years,[1] it is only recently that interest has been shown for the reactivity of high oxidation derivatives. Bottomley *et al.* have explored the chemistry of early transition metal oxo-cyclopentadienyl clusters,[2] whereas the discovery by Hermann *et al.* of the complex $(C_5Me_5)ReO_3$ and of its rich reactivity[3] has stimulated a new impetus for the study of such complexes. Attempts to prepare similar ruthenium derivatives in our group have led to new hydrido oxo clusters.[4] However, these compounds are very stable and fairly unreactive which led us to look for new systems containing hard donor ligands.

Recently Taqui Kahn *et al.* described the remarkable reactivity of the ruthenium(III) complex $K[Ru(Hedta)Cl] \cdot 2H_2O$ for reactions as different as hydrogenation, carbonylation and oxidation of hydrocarbons including alkanes.[5]

Furthermore, porphyrin complexes of ruthenium were shown to be able to catalytically oxidize hydrocarbons using molecular oxygen as oxidants.[6] Kläui has used a cobalt complex containing phosphonato groups as a ligand containing oxygen donor groups analogous to cyclopentadienyl. This ligand led to the preparation of both low and high oxidation state derivatives.[7]

In the search for new ligand systems able to accommodate high oxidation state derivatives in the

* Author to whom correspondence should be addressed.

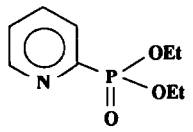

Fig. 1. Structure of the ligand.

chemistry of ruthenium but also to link to medium oxidation state precursors, we considered pyridine phosphonato compounds.[8]

This paper describes our first results with this ligand, namely $P(O)(OEt)_2(C_5H_4N)$ (L; Fig. 1).

RESULTS AND DISCUSSION

The ligand was reacted with two ruthenium complexes: $K_2RuCl_5(H_2O)$ (**1**), since this is a well-defined mononuclear compound,[9] and $RuCl_3 \cdot 3H_2O$ (**2**) as well as $RhCl_3 \cdot 3H_2O$ (**3**).

(1) *Reactions with* $K_2RuCl_5(H_2O)$

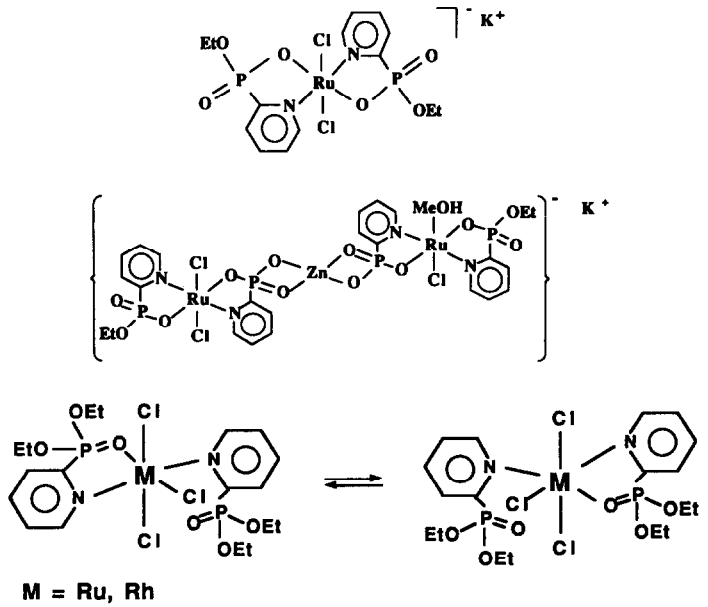
Compound **1** reacts slowly with L in refluxing methanol to give a yellow solution from which a new compound (**4**) is obtained as a yellow powder upon the addition of diethyl ether. Compound **4** is air-stable, soluble in water and polar solvents (methanol, acetone) and is a 1 : 1 conductor in methanol ($\Lambda_M = 80\ \Omega^{-1}\ cm^2\ mol^{-1}$). The ruthenium-containing moiety is most probably anionic since no reaction was observed with $NaBPh_4$ in methanol. However, we equally failed to observe a reaction with $(PPh_4)^+$ probably because of a strong interaction of K^+ with oxygen.

Complex **4** is paramagnetic and shows a magnetic moment of 1.90 μB, in agreement with the presence of one single electron and thus of a d^7 ruthenium(III) configuration. Furthermore, the EPR spectra, whether recorded at room temperature as a powder or at 100 K in CH_2Cl_2, show two signals corresponding to $g_\perp$ at 2.4465 and $g_\parallel$ at 1.9964. This is in agreement with the presence of a C_2 axis.

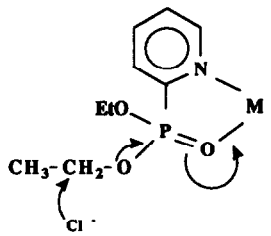
This symmetry of the molecule is confirmed by NMR. Only one peak is observed on the ^{31}P NMR spectrum at δ 2.26 ppm, whereas the ^{13}C NMR spectrum shows the methylene groups of the phosphonate moiety at δ 65 ppm (t, $J(CH) = 161$ Hz), the methyl groups at δ 17 ppm (q, $J(CH) = 140$ Hz) and the pyridine carbons as five broad peaks at δ 156 (d, $J(CH) = 184$ Hz), 145 (s), 141 (d, $J(CH) = 184$ Hz), 130 (d, $J(CH) = 182$ Hz) and129 ppm ($J(CH) = 180$ Hz). The ^1H NMR spectra only show broad peaks near δ 0.9, 1.4, 4.4 and 7.58 ppm.

The IR spectra show as their most salient feature an intense broad band at 1226 cm^{-1} which is attributed to P=O stretching. This is not due to the free ligand [ν(P=O) 1255 cm^{-1}], but a more important shift of this bond would be expected in the case of direct coordination of this functionality to ruthenium. The P—O stretching frequency is observed at 1025 cm^{-1}.

In summary, we propose for **4** the formula $K[RuCl_2\{(C_5H_4N)PO(O)(OEt)\}_2] \cdot MeOH$ (see Scheme 1). This results from the spectroscopic data described above [symmetrical ruthenium(III) structure, equivalence of the phosphorus and carbons,



Scheme 1. Proposed structure for complexes **4**–**7**.



Scheme 2. Proposed mechanism for the dealkylation reaction.

non-coordination of P=O groups] and the conductivity and microanalytical data (C, H, N, P, Cl, O, Ru).

The mechanism for the formation of **4** could involve firstly the substitution of chloride groups by the pyridine phosphonate ligand and then a dealkylation, Arbuzov-type reaction. Such a mechanism has been recently demonstrated during the formation of $[(\eta^5\text{-}C_5H_5)(CO)_2Fe\{P(CO)(NR_2)_n(OR')_{2-n}\}]$ ($n = 1, 2$).[10] Thus, one Cl^- liberated during the substitution could react on one ethyl group of the coordinated pyridine phosphonate ligand to give EtCl and the formation of a sigma Ru—O bond (see Scheme 2).

Reactivity of complex (**4**)

Cation exchange. Since it proved difficult to crystallize complex **4**, cation exchange reactions were attempted with PPh_4Cl and PPNCl. In neither case did a reaction occur. Similarly, no reaction was observed when the crown ether 18-crown-6 or a tridentate amine (PMETA) were added to **4** in methanol. This tends to prove that the potassium cation is strongly associated with the P—O groups of the ligands.

Substitution. In order to render the complex more reactive substitution reactions were attempted with the ligand showing a strong σ-donor character such as imidazole, pyridine and tert-butyl-pyridine. These reactions failed whether carried out in the presence or absence of silver triflate, thus demonstrating the low reactivity of the complex.

Reduction. Reduction reactions were attempted with the hope of leading to neutral and thus more tractable and reactive species. These reactions were attempted with zinc, $Al/HgCl_2$ and $NaBH_4$ in methanol. The reaction occurs rapidly in all three cases to lead to red paramagnetic ruthenium(III) derivatives. Only in the case of zinc was a crystalline material isolated in high yield (**5**). As for **4**, two gyromagnetic constants are observed in EPR ($g_\parallel = 2.225$; $g_\perp = 2.049$). Three ν(P=O) stretches are observed by IR spectroscopy (1261, 1224 and 1165 cm^{-1}) corresponding to three different environments for the phosphonato groups. The ν(P—O) vibration is found at 1025 cm^{-1} as for **4**.

The ^{31}P NMR spectrum shows a broad peak centred at δ 32.9 ppm and the ^1H NMR is broad and similar to that of **4** but reveals the presence of methanol and water in the crystals.

A tentative structure is deduced from microanalysis on eight elements (C, H, N, P, Cl, K, O, Ru) and is shown on Scheme 1. Unfortunately again, the crystals were not found suitable for X-ray analysis. Nevertheless, this result demonstrates the inertness of the ruthenium(III) core in this compound, perhaps because of the lack of a vacant site, and the preferential reactivity of the phosphonato group.

(2) *Reactions of* $C_5H_4NP(O)(OEt)_2(L)$ *with* $MCl_3 \cdot 3H_2O$ (M = Ru, Rh)

Since the lack of reactivity of complex **4** could be attributed to its ligand saturation, anionic character and to the formation of a strong interaction between the potassium cation and the phosphonato ligand, we attempted the preparation of neutral or even possibly cationic derivatives. This chemistry was extended to rhodium which should lead to diamagnetic complexes which are easier to characterize.

Reaction with $RuCl_3 \cdot 3H_2O$. The reaction of $RuCl_3 \cdot 3H_2O$ with two equiv. of L in refluxing methanol yields a yellow solution from which a yellow powder is obtained after the appropriate work-up.

The new complex (**6**) is air-stable, non-conducting in methanol and paramagnetic. Thus, it only shows one broad peak in EPR at $g = 2.3877$, in agreement with a ruthenium(III) formulation.

The IR spectrum shows a very broad band centred at 1160 cm^{-1} and attributed to a coordinated P=O group. A shoulder is visible at 1220 cm^{-1} which could be attributed to a non-coordinated P=O functionality. The P—O stretch is observed as a broad band near 1030 cm^{-1}.

Finally, the ^{31}P NMR spectrum shows two peaks at δ 71.5 and 63.1 ppm, while the ^1H NMR spectrum is broad.

These data together with microanalytical data (C, H, N, Cl) are in agreement with the proposed formulation (see Scheme 1). Some water remains present in the complex and is detected by IR and ^1H NMR. The ruthenium atom remains coordinated to three chloride groups, one bidentate and one monodentate pyridine phosphonate ligand.

It is not entirely clear which end of L coordinates preferentially to ruthenium. IR evidence suggests that it is the pyridine end; furthermore, many pyridine compounds of ruthenium(III) are known.

M = Rh. In order to shed some light on the preceding result, the same reaction was carried out with $RhCl_3 \cdot 3H_2O$. The reaction is similar to that of ruthenium yielding a new complex (**7**) as an air-stable orange powder. The IR spectrum shows, as in (**6**), two bands at 1155 and 1200 cm^{-1} for coordinated and non-coordinated P=O groups.

The ^{31}P NMR spectrum shows at room temperature two broad peaks centred at δ 2.80 and 29.0 ppm. Upon cooling the solution down to 183 K, the peak at δ 2.80 ppm does not move but becomes sharper, whereas the one at δ 29.0 ppm splits into two peaks at δ 28.7 and 30.0 ppm. This result demonstrates a slow exchange between the two pyridine phosphonato ligands at room temperature. The peak near δ 2 ppm is attributed to the non-coordinated phosphonato moiety.

The ^1H NMR spectrum shows two types of ethoxy ligand (methyl groups at δ 1.27 and 1.47 ppm; methylene groups at δ 4.25 and 4.40 ppm). One of these signals is found close to the value in the free ligand (1.43 and 4.31 ppm). Multiplets between δ 7.73 and 9.55 ppm are attributed to the pyridine protons.

As for **6**, the microanalysis of complex **7** favours the formulation $RhCl_3L_2 \cdot 2H_2O$, which is in agreement with the spectroscopic data.

CONCLUSION

We describe in this paper the preparation of new complexes of ruthenium(III) or rhodium(III) of the pyridine diethylphosphonate ligand. This ligand associating a good σ-donor ligand (pyridine) with a good π-donor ligand (phosphonate) could be of great interest for the preparation of new, high oxydation state transition-metal derivatives. We give evidence for the easy dealkylation of the phosphonate in an Arbuzov-type process. The resulting complex is very stable and totally inert. This process is possible because of the existence of free chloride ions in the reaction mixture.

In contrast, complexes **6** and **7** resulting from the reaction of L with $MCl_3 \cdot 3H_2O$ (M = Ru, Rh) are trichlorides for which no evidence for the dissociation of chloride groups have been found.

The reactivity of these new compounds deserves further investigation.

EXPERIMENTAL

General

Microanalyses were performed in the laboratory. All manipulations were carried out under dry argon using standard Schlenk-tube techniques. The solvents were degassed and distilled before use. IR spectra were recorded in the solid state as Nujol mulls or KBr discs on a Perkin–Elmer 983 spectrometer. NMR spectra were recorded on Bruker WH90, WM250 or AC200 spectrometers operating in the Fourier transform mode.

$RuCl_3 \cdot 3H_2O$ and $RhCl_3 \cdot 3H_2O$ were purchased from Johnson Matthey Ltd. $K_2RuCl_5 \cdot H_2O$[9] was prepared according to published procedures. The ligand $(C_5H_4N)P(O)(OEt)_2$ was prepared by a modified literature procedure.[11]

$K[RuCl_2\{(C_5H_4N)PO(O)(OEt)\}_2] \cdot MeOH$ (**4**). Pyridyl-2-diethyl phosphonate (L) (0.23 g, 1.07 mmol) dissolved in absolute ethanol (20 cm^3) was added dropwise to a solution of $K_2RuCl_5 \cdot H_2O$ (0.2 g, 0.53 mmol) in methanol (20 cm^3) for 2 h at room temperature.

The reaction mixture was then refluxed for 48 h yielding a light yellow solution and a very small amount of white precipitate. The filtrate was then concentrated. Addition of diethyl ether caused the precipitation of a light yellow powder which was washed three times with 20 cm^3 positions of diethyl ether and dried *in vacuo*; yield: 63%. Attempts at recrystallization in various solvents were unsuccessful. Found: C, 30.0; H, 3.6; N, 5.2; P, 10.8; Cl, 10.0; O, 19.6; Ru, 17.1. Calc. for $C_{15}H_{22}O_7N_2Cl_2P_2KRu$: C, 29.3; H, 3.6; N, 4.5; P, 10.1; Cl, 11.5; O, 18.2; Ru, 16.4%.

$K[Ru_2Cl_3\{(C_5H_4N)PO(O)(OEt)\}_2\{(C_5H_4N)PO_2(O)\}_2ZnCH_3OH]CH_3OH \cdot H_2O$ (**5**). Excess zinc powder (0.3 g) was added to methanol. The colour of the reaction solution changed rapidly from yellow to red. After 10 min stirring at room temperature, the red solution was then concentrated. Addition of diethyl ether yielded a red precipitate which was washed with three portions of diethyl ether; yield: 85%. Found: C, 26.3; H, 3.3; N, 4.5; P, 9.3; Cl, 8.4; K, 2.5; O, 19.9. Calc. for $C_{26}H_{36}O_{15}N_4Cl_3P_4KZnRu_2$: C, 26.4; H, 3.0; N, 4.7; P, 10.5; Cl, 9.0; K, 3.3; O, 20.3%.

$RuCl_3[(C_5H_4N)P(O)(OEt)_2]_2 \cdot 2H_2O$ (**6**). Pyridyl 2-diethylphosphonate (0.25 g, 1.04 mmol) was added to $RuCl_3 \cdot 3H_2O$ (0.15 g, 0.57 mmol) and refluxed for 24 h yielding a yellow–orange solution. The solution was then evaporated to dryness and washed twice with ether; yield: 80%. Samples for analysis were obtained by redissolution in methanol and reprecipitation using diethyl ether. Found: C, 32.4; H, 5.1; N, 3.5; Cl, 15.0. Calc. for $RuC_{18}H_{32}N_2O_8Cl_3P_2$: C, 32.1; H, 4.7; N, 4.1; Cl, 15.8%.

$RhCl_3[(C_5H_4N)P(O)(OEt)_2]_2 \cdot 2H_2O$ (**7**). As for **6** using $RhCl_3 \cdot 3H_2O$ (0.25 g, 0.98 mmol) pyridil-2-diethylphosphonate (0.41 g, 1.9 mmol), a light orange precipitate was obtained; yield: 80%. Found: C, 31.2; H, 4.0; N, 4.6; Rh, 15.6. Calc. for

$RhC_{18}H_{32}N_2O_8Cl_3P_2$: C, 32.0; H, 4.7; N, 4.1; Rh, 15.2%.

TUNGSTEN(V) DIMERIC COMPLEXES WITH ETHYL XANTHATE

R. LOZANO,† J. ROMAN, F. DE JESUS and E. ALARCON

Departamento de Química Inorgánica y Bioinorgánica, Facultad de Farmacia, Universidad Complutense, 28040 Madrid, Spain

(*Received* 16 *November* 1990; *accepted* 25 *June* 1991)

Abstract—The chemical, spectroscopic and magnetic properties of a number of oxo- and sulphido-bridged tungsten(V) oxo-complexes with ethyl xanthate as a ligand are described. The following formulae are assigned to the complexes: $W_2O_3(LL)_4$, $W_2O_4(LL)_2$, $W_2O_2S_2(LL)_2$, $W_2O_3S(LL)_2$. IR and electronic spectra of these compounds are modified by the introduction of sulphur atoms into the bridge system. The low magnetic moments observed are due either to an interaction through the bridging atoms or to a direct spin–spin interaction, according to a dimer structure with monoxo, dioxo, disulphido and oxo-sulphido bridges. The thermal behaviour has also been studied by differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). The results are discussed on the basis of the structural information available to tungsten complexes.

The relevance to bioinorganic chemistry of molybdenum and tungsten and also to heterogeneous catalysis has been stressed several times in the literature.[1–6]

Although the chemistry of oxo-molybdenum(V) species is dominated by binuclear complexes, curiously, similar binuclear oxo-complexes of tungsten(V) are not known in general. However, we have recently reported the study and characterization of tungsten(V) dimeric complexes with dithiocarbamate and oxine as ligands.[7–11]

The object of the present study has been to obtain binuclear complexes of tungsten(V) with ethyl xanthates as ligands.

The systematic changes upon bridge modification are useful in characterizing the compounds and in clarifying assignments of W—O and W—S bridge stretching frequencies.

These complexes were characterized by IR and electronic spectroscopy, magnetic susceptibility measurements and analytical data. The results obtained permit us to assign the following formulae to the complexes: $W_2O_3(LL)_4$, $W_2O_4(LL)_2$, $W_2O_2S_2(LL)_2$, $W_2O_3S(LL)_2$.

EXPERIMENTAL

(1) *Materials*

$Na_2WO_4 \cdot 2H_2O$ was a Merck commercial product and used as supplied. Potassium ethyl xanthate was prepared by the direct reaction of potassium hydroxide with carbon disulphide and ethanol, and was recrystallized from water: ethanol. The solvents used to prepare and recrystallize the complexes were from Carlo Erba or Merck. The solutions for absorption spectra were prepared using dimethylsulphoxide (DMSO), spectral grade (Merck–Uvasol).

(2) *Analytical procedures*

Elemental analysis were performed on a Perkin–Elmer model 240B elemental analyser.

Tungsten was determined by atomic absorption with a Perkin–Elmer model 430 atomic absorption spectrophotometer, after the complexes had been decomposed with a 1:1 mixture of concentrated nitric and sulphuric acid.

Analytical data are collected in Table 1. Results conform to the proposed formula.

(3) *Methods*

Magnetic susceptibility was determined by the Gouy method at room temperature using a Mettler H-51 AR balance and a type C Newport electromagnet. Molar susceptibilities have been corrected for diamagnetism. Table 1 shows the data.

The IR spectra were measured on a Perkin–Elmer recording spectrophotometer model 283. The samples were run as KBr pellets. Important IR absorption peaks for the compounds are listed in Table 2.

Near UV–vis spectra were measured in the range 220–1000 nm, on a Beckman recording spectrophotometer model 554 using complex solutions in DMSO. The results obtained are given in Table 3.

Thermogravimetric analysis and differential scanning calorimetry were performed between 25 and 600°C on a Mettler TA 3000 system fitted with a Mettler TG-50 thermobalance, and a Mettler DSC-20 differential scanning calorimeter. The scanning rate used was 2°C min^{-1} and samples of *ca* 5 mg were used, so as to render insignificant the temperature non-uniformity within the sample. An aluminium pan was used. Two different atmospheres were used: between 25–400°C a dynamic nitrogen atmosphere, and between 400–600°C a dynamic oxygen atmosphere to allow oxidation to WO_3. The instrument calibration was checked periodically with standard samples of indium (99.99% purity). Several runs were made.

(4) *Preparation of the complexes*

$W_2O_3(S_2COC_2H_5)_4$. $Na_2WO_4 \cdot 2H_2O$ (3.3 g, 10 mmol) was dissolved in 30 cm^3 of water and depolymerized with 2 N NaOH. Another solution of potassium ethyl xanthate (3.25 g, 20 mmol) in 60 cm^3 of water was prepared. A solution of sodium dithionite (1 g) was added, and it was refluxed at 60°C for 15 min, changing from yellow to green. Glacial acetic acid was added dropwise and with vigorous stirring until reaching pH = 5.

A brown solid precipitated which was filtered with heat and *in vacuo* to obtain a brown powder which was then washed with a benzene and petroleum ether mixture and dried over P_4O_{10}. Yield: 63%.

$W_2O_4(S_2COC_2H_5)_2$. A solution of $Na_2WO_4 \cdot$

$2H_2O$ (3.30 g, 10 mmol) dissolved in 40 cm^3 of water was prepared. 2 N NaOH was added until reaching pH 10 and the solution was then heated by boiling for 10 min.

A second solution of potassium ethyl xanthate (1.65 g, 10 mmol) dissolved in 40 cm^3 of water was then prepared. The two solutions were combined and the resulting one was yellow in colour. A solution of sodium dithionite (0.5 g) in water (20 cm^3) was added to it and the resultant solution was refluxed for 10 min, giving a green coloured solution. Lastly, 2 N HCl was added dropwise with continuous stirring until reaching pH 2 whereupon a brownish precipitate was obtained which was washed with a benzene and petroleum ether mixture and dried over P_4O_{10}. Yield: 57%.

$W_2O_2S_2(S_2COC_2H_5)_2$. $Na_2WO_4 \cdot 2H_2O$ (3.3 g, 10 mmol) was dissolved in water (50 cm^3) and a concentrated sodium hydroxide solution was added. The solution was heated by boiling for 10 min to avoid polymerization.

At the same time potassium ethyl xanthate (1.64 g, 10 mmol) was dissolved in water (40 cm^3). This solution was added to the previous one and a new solution of sodium dithionite (1 g) in water (40 cm^3) was added. The resulting solution was refluxed for 10 min, changing colour from yellow to green. Hydrogen sulphide was passed through the resulting solution with simultaneous cooling in a freezing mixture for *ca* 30 min. Glacial acetic acid was added dropwise until reaching pH = 6 and total precipitation then occurred. The solution was filtered and a brownish residue was obtained which was washed repeatedly with a benzene and petroleum ether mixture and dried over P_4O_{10}. Yield: 61%.

$W_2O_3S(S_2COC_2H_5)_2$. A solution of sodium tungstate (3.3 g, 10 mmol) in water (50 cm^3) was prepared, concentrated boiling NaOH (10 cm^3) was

added and HCl (dropwise) until reaching pH = 2. Another solution of sodium dithionite (1 g) in water (40 cm^3) was added to the previous one. The resulting solution was heated gently for 15 min. Once cooled, hydrogen sulphide was then bubbled slowly through the solution for *ca* 60 min changing the solution to a dark brown colour.

Another solution of potassium ethyl xanthate (1.65 g, 10 mmol) in water (40 cm^3) was prepared. The two solutions were combined and refluxed for 15 min. Glacial acetic acid was then added dropwise until reaching pH = 5 and a total precipitation then occurred. The solid obtained was washed with a benzene and petroleum ether mixture and dried over P_4O_{10}. Yield: 63%.

DISCUSSION

According to the results of the analytical, magnetic (Table 1) and spectroscopic data, the synthesized oxocomplexes are dimeric.

(1) *Magnetic properties*

The magnetic moments found for the complexes are low (0.00–0.60 BM). This is probably due to an interaction through the bridged atoms or the possible formation of a direct metal–metal bond.[7-14]

(2) *IR spectra*

The IR spectra show, in all cases, a strong band in the range 932–940 cm^{-1}, which was attributed to the vibration of the symmetric stretching mode of the terminal W=O bond (Table 2).

In the complexes with monoxo-, dioxo- and oxo-sulphido bridges, the bands corresponding to the W—O—W bridge were assigned to 810–820 cm^{-1} and the vibration of the antisymmetric and symmetric stretching modes, of the W—O bridge bond were assigned to the bands between 436–450 cm^{-1}.

Another two bands, which appear in the IR spectra of the complexes with disulphido and oxo-sulphido bridges in the regions 463–471 and 358–372 cm^{-1}, can be attributed to the vibration of the antisymmetric and symmetric stretching mode, respectively, of the W—S bridge bond.

All the complexes studied exhibit two bands in the IR spectra in the 1120–1160 cm^{-1} region, attributable to a W—O—C bond.

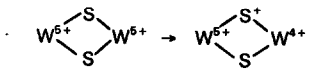
In the IR spectra two vibrational stretching modes for the C—S bond appear, one corresponding to the C=S and the other to the C—S bond, as proved by Cotton *et al.*[15] The band corresponding to the C=S bond is assigned to the 1210–1260 cm^{-1} region while the C—S band appears in the 1050–1080 cm^{-1} region.

(3) *Visible and UV spectra*

The electronic spectra (Table 3) for all the complexes present two bands in the 15,432–15,503 and 16,556–16,611 cm^{-1} regions, which were attributed to *d–d* transitions. The two bands were assigned to $^2B_2 \rightarrow {}^2E(I)$ and $^2B_2 \rightarrow {}^2B_1$ transitions, respectively, for a distorted octahedral structure[16] for the monoxo bridge complexes and for a square-pyramidal structure[17] for the complexes with dioxo-, disulphido- and oxo-sulphido bridges.

In the visible region we can detect two other bands between 21,000 and 23,000 cm^{-1} that were attributed to charge-transfer transitions.

In the complexes with disulphido and oxo-sulphido bridges, another band appears in the visible region at 22,000 cm^{-1} that can be attributed to a charge transfer:

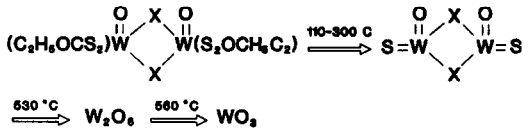


as has been observed in other transition metal complexes with a sulphur bridge.[18,19] The electronic spectra show, in the UV region, three other bands at 30,000, 32,000 and 38,000 cm^{-1}. The electronic spectra of potassium etylxanthate also exhibit three bands at the same wavelength.[20] The differences are not significant. We can attribute these bands to intraligand transitions, $n \rightarrow \pi^*$, $\pi \rightarrow \pi^*$ and $n \rightarrow \sigma^*$, respectively.

(4) *Thermal studies*

The study of the thermal decomposition of tungsten(V) complexes has been made by thermogravimetric and differential scanning calorimetry analysis (Table 4).

The processes observed for the complexes can be schematized as:



Scheme 1.

All the intermediary species have been identified by elemental analysis and IR spectra.

A strong exothermic process was detected between 575 and 600°C for all the compounds without weight loss in the TG curves, which can be attributed to WO_3 formation.

SYNTHESIS AND REACTIONS OF TERT-BUTYLIMIDO COMPLEXES OF RHENIUM. X-RAY CRYSTAL STRUCTURES OF $[(ReNBu^t)_2(OSiMe_3)]_2(\mu\text{-}O)(\mu\text{-}OSiMe_3)(\mu\text{-}O_2CCF_3)$, $Re(NBu^t)_3PPh_2$ AND $[Re(NBu^t)_3(NH_2Bu^t)]O_3SCF_3$

Abstract—The reactions of $Re(NBu^t)_3Cl$ with NaC_5H_5, AgX (X = BF_4, PF_6 and CF_3CO_2) and with $SbCl_5$ lead to the loss of an NBu^t group, and the formation of bis tert-butylimido compounds, respectively, $[Re(NBu^t)_2(\eta^1\text{-}C_5H_5)]_2(\mu\text{-}O)(\mu\text{-}C_5H_4)$, $[(Bu^tN)_2(Cl)Re(\mu\text{-}F)(\mu\text{-}NBu^t)Re(NBu^t)(\mu\text{-}F)]_2X$ (X = BF_4 and PF_6), $[Re(NBu^t)_2]_2(\mu\text{-}OSiMe_3)(\mu\text{-}O_2CCF_3)$ and $[Re(NBu^t)_2Cl_2(MeCN)_2]SbCl_6$. The interaction between $Re_3(NBu^t)_4(O)_5(OSiMe_3)_3$ and AgO_2CCF_3 produces a species, $[Re(NBu^t)_2(OSiMe_3)]_2(\mu\text{-}O)(\mu\text{-}OSiMe_3)(\mu\text{-}O_2CCF_3)$, in which the μ-$OReO_3$ group in the starting material is replaced by μ-O_2CCF_3. Protonation of $Re(NBu^t)_3(NHBu^t)$ by CF_3SO_3H produces the cation $[Re(NBu^t)_3(NH_2Bu^t)]^+$ in which the amine can be replaced by PPh_3. Reactions of $Re(NBu^t)_3X$, where X = Cl or $OSiMe_3$ are replaced by NR_2, PR_2, $NPPh_3$ and $C_4H_3N_2$, are described. Deprotonation of $Re(NBu^t)_3PH(mes)$, mes = $2,4,6\text{-}Me_3C_6H_2$, by Bu^tLi gives the known compound $[Re(NBu^t)_2(\mu\text{-}NBu^t)]_2$ and a new cyclotriphosphane, $(Pmes)_3$.

The structures of compounds listed in the title have been determined by X-ray diffraction. The $[Re(NBu^t)_2(OSiMe_3)]_2(\mu\text{-}O)(\mu\text{-}OSiMe_3)(\mu\text{-}O_2CCF_3)$ structure has crystallographic C_s symmetry with a planar Re_2O_2 ring; Re···Re separation is 3.25 Å. The bridging acetate has a significantly enlarged O—C—O angle of 134°. The $[Re(NBu^t)_3(NH_2Bu^t)]O_3SCF_3$ structure has tetrahedral geometry at rhenium with noticeably differing Re—N distances which correlate to the Re—N—C angles. The $Re(NBu^t)_3PPh_2$ compound has tetrahedral geometry at rhenium and a pyramidal geometry at phosphorus. The Re—P distance is 2.445(2) Å.

In previous papers[1–3] on tris tert-butylimido compounds of rhenium(VII) we have characterized the aryls[1] $Re(NBu^t)_3Ar$, Ar = $2\text{-}MeC_6H_4$, $2,6\text{-}Me_2C_6H_3$ and $2,4,6\text{-}Me_3C_6H_2$(mes) and determined the X-ray crystal structure of the mesityl.[2] The structures of the compounds $Re(NBu^t)_3X$, where X = Cl and $OSiMe_3$, were also determined and the chloride converted to the amido species $Re(NBu^t)_3(NHBu^t)$, which in turn was deprotonated by Bu^nLi to give $Li(tmed)Re(NBu^t)_4$, where tmed = $Me_2NCH_2CH_2NMe_2$.[3] Recently, the arylimido methyl, $Re(NAr)_3CH_3$, where Ar = $2,6\text{-}Pr^iC_6H_3$, was synthesized, as were the compounds $Re(NBu^t)_3R$, where R = Me, Et, σ-C_3H_5 and C≡CPh.[4]

We now describe some unusual reactions of $Re(NBu^t)_3X$, where X = Cl[3] and $OSiMe_3$[5], in which an imido group is removed leading to bis tert-butylimido compounds. Substitution of the siloxide group gives dialkyl- or diarylamido and phosphido species. The amido compound $Re(NBu^t)_3(NHBu^t)$ on protonation gives the cation $[Re(NBu^t)_3(NH_2Bu^t)]^+$ as its trifluoromethane sulphonate.

Analytical and physical data for new compounds are given in Table 1.

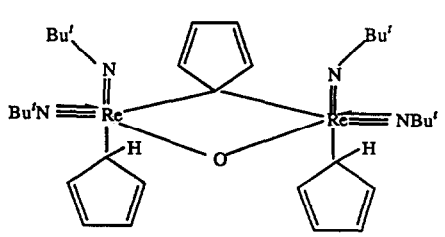
RESULTS AND DISCUSSION

(1) *Reactions leading to bis tert-butylimido compounds*

In attempts to convert $Re(NBu^t)_3(OSiMe_3)$ to the chloride[3] it was observed that interactions with $SOCl_2$ and PCl_3 gave the bis imidotrichloride $Re(NBu^t)_2Cl_3$. We now describe other, different reactions leading to the removal of an NBu^t group.

(a) *Interaction of* $Re(NBu^t)_3Cl$ *and* NaC_5H_5. It was stated by Herrmann *et al.*[4] that all attempts to react $Re(NBu^t)_3(OSiMe_3)$ with C_5H_5M (M = Na, Tl, $SnBu^n_3$) or C_5Me_5M (M = K, MgCl, Li) were unsuccessful. The reaction of $Re(O)_3OSiMe_3$ with C_5H_5Na in THF gives only low yields (*ca* 5%) of $Re(O)_3(\eta^5\text{-}C_5H_5)$, characterized by analysis and spectra.*

The interaction between $Re(NBu^t)_3Cl$ in Et_2O and NaC_5H_5 in THF leads to air-sensitive crystals from hexane of the orange compound **1**, whose X-ray crystal structure has been determined[6] as that shown in Structure I. The bridging $C_5H_4^{2-}$ group

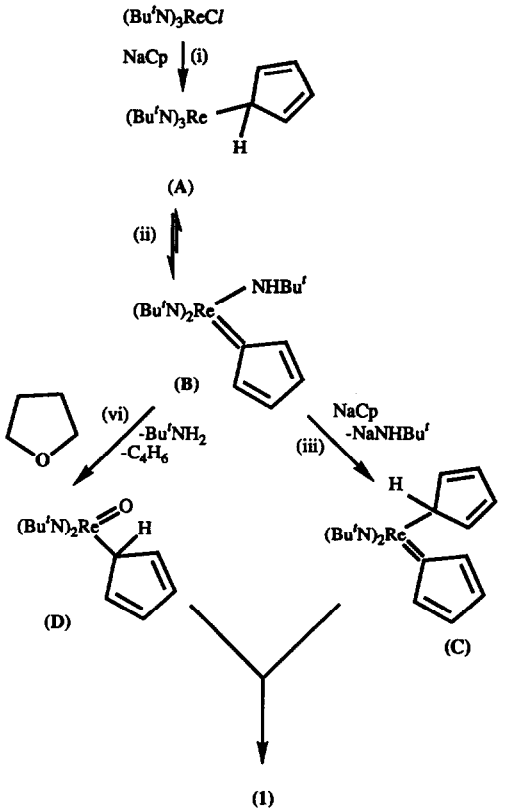


I

* P. G. Edwards and G. Wilkinson, unpublished work, 1979.

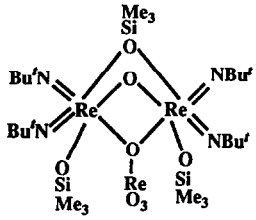
is unique; other types of μ-C_5H_4 moieties are, however, known (see ref. 6). The ^{1}H NMR spectra over a certain temperature range confirmed the fluxionality of the η^1-C_5H_5 groups in **1**, although the slow exchange limit could not be reached at −90°C.

Any mechanism for the synthesis of the compound has to account for the loss of a NBu^t group from each metal atom and for the presence of the bridging oxygen. A possibility is given in Scheme 1 where the first step is the formation of a σ-C_5H_5 compound (**A**). While similar substitution by various Cp nucleophiles in $Re(NBu^t)_3(OSiMe_3)$ has been claimed as impossible on steric and electronic grounds,[4] it is likely that lowered crowding in the chloride compared to the siloxide, coupled with the formation of NaCl rather than $NaOSiMe_3$, can drive the substitution to completion. The intermediate **A** of Scheme 1 could be in a tautomeric equilibrium with the alkylidene **B** from which the tert-butylimido group can be removed by NaCp to give **C** and $NaNHBu^t$. Reaction (iv) competing with (iii) could be a base-initiated (i.e. $NaNHBu^t$) cycloelimination reaction of tetrahydrofuran leading to **D** with the loss of tert-butylamine and butadiene. Interaction of **C** and **D** would then lead to the isolated species with the μ-C_5H_4 group 1.

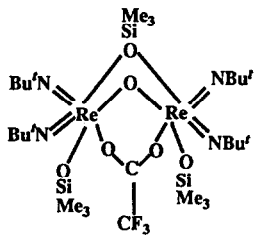


Scheme 1. Possible route to synthesis of compound **1**.

(b) *Interaction of tert-butylimido siloxides with* AgO_2CCF_3. The rhenium siloxides, $[Re(NBu^t)_2(OSiMe_3)]_2(\mu\text{-}OSiMe_3)(\mu\text{-}O)(\mu\text{-}OReO_3)$ (Structure **II**), together with $Re(NBu^t)_3(OSiMe_3)$ were obtained[5] from the interaction between $ReO_3(OSiMe_3)$ and $Bu^tNH(SiMe_3)$, the former on using a deficiency of the amine. The structure of dimer **II** was earlier determined by X-ray diffraction.[7] Another dimer,[2] $Re_2(NBu^t)_3Br(O)(mesityl)(CH_2Me_2C_6H_2O)$ which has μ-O and μ-NBu^t groups, has been characterized crystallographically.



II



III

Although first obtained in low yield by interaction of $Re(NBu^t)_3Cl$ and AgO_2CCF_3, compound **2** was subsequently made by the more rational procedure of the interaction between Nugent's triply-bridged species and silver trifluoroacetate, which leads to substitution of the μ-$OReO_3$ group by μ-O_2CCF_3. The orange crystalline compound **2** was shown by X-ray crystallography to have structure **III**. The structure is shown in Fig. 1; data in Table 2.

The molecule has crystallographic C_s symmetry about a plane bisecting the Re(1)···Re(1′) vector and passing through the bridging μ-O and the O_2CCF_3 and $OSiMe_3$ groups. The geometry at each rhenium atom is distorted octahedral with inter-bond angles in the ranges 73–104° and 151–171°. The angles subtended at rhenium by O(1), O(3) and O(4) are significantly contracted from 90°, whereas those formed by N(1), O(2) and N(2) are noticeably enlarged. The former are a consequence of satisfying the Re···Re separation and ligand bridging constraints and the latter of accommodating the bulky facially-substituted NBu^t and $OSiMe_3$ groups. The strain of bridging between the two rhenium centres by the O_2CCF_3 ligand is reflected in a significant enlargement of the O(4)—C(14)—

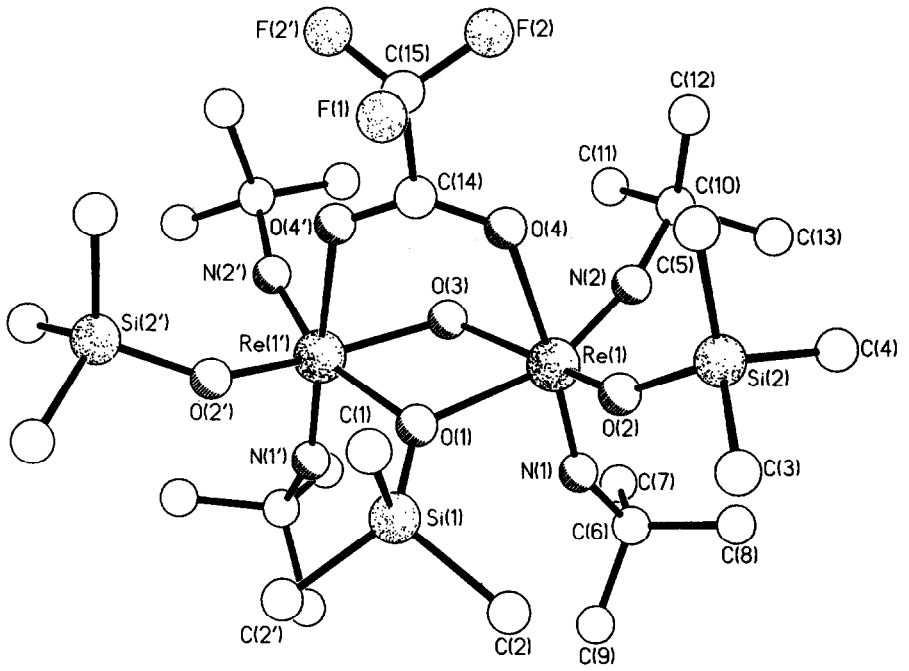


Fig. 1. The structure of $[(Bu^tN)_2(Me_3SiO)Re]_2(\mu\text{-}O)(\mu\text{-}OSiMe_3)(\mu\text{-}O_2CCF_3)$.

O(4′) angle, 134(2)°. With the exception of the Re(1)—O(4) distance [2.32(1) Å], which is significantly longer than that observed for Re—O in e.g. acetates or formates, the remaining Re—O and Re—N distances are normal. The central Re_2O_2 ring is planar to within 0.007 Å and the transannular Re···Re and O···O distances are 3.25 and 2.41 Å, respectively. The angles at N(1) and N(2) are both appreciably bent [152.5(12) and 165.4(13)°, respectively] and consistent with two doubly-bound NBu^t groups. There is marked enlargement of the angle at O(2), 145.3(8)°, compared with that to Si at O(1), 131.0(3)°. These values are virtually identical to those reported for the closely related structure by Nugent and Harlow.[7]

It may be noted that structures **I**, **II** and **III** are

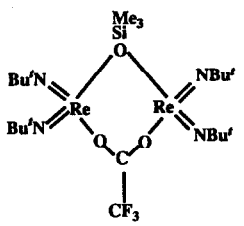
quite similar being bis-imido species with different bridging groups. The IR and NMR spectra are in accord with the structures. Thus, for **2** the ^{1}H NMR data indicate terminal NBu^t groups and both terminal and bridging $OSiMe_3$ groups with the correct intensity ratios, while there is a single ^{19}F resonance for the μ-O_2CF_3 group. The IR spectra show typical bands for the μ-carboxylate and the other groups except that the μ-O frequency is uncertain due to other bands in this region.

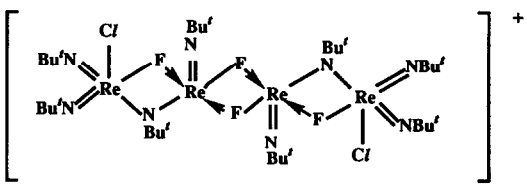
The interaction between $Re(NBu^t)_3(OSiMe_3)$ and silver trifluoroacetate also leads to a bis imido species, presumably by initial electrophilic attack of Ag^+ on a bent imido group; the reaction is evidently complicated and the yield is not quantitative. On the basis of analytical and spectroscopic data, product **3** has structure **IV**; crystals suitable for X-ray study could not be obtained. The compound has rhenium in the V oxidation state corresponding to the loss of an imido group from rhenium(VII). The IR and NMR data are similar to those of **2**.



IV

(c) *Interaction of* $Re(NBu^t)_3Cl$ *with* $AgBF_4$ *and* $AgPF_6$. The interaction between $Re(NBu^t)_3Cl$ and $AgBF_4$ (or $AgPF_6$) is sensitive to the nature of the solvent used and the order of addition of reactants. Crystalline products (**4**, **5**) were obtained only when the reaction was carried out in CH_2Cl_2 and with the addition of the imido compound to the solvent salt in excess.

The salts thus obtained both have a cation with the tetrameric structure shown in Structure V. This structure is based on analytical and spectroscopic data and an incomplete X-ray study[8] of the BF_4^- salt. The latter confirmed the tetrameric structure with the rhenium atoms having distorted square-pyramidal geometry, but the refinement was hindered by disorder problems.



V

As in the reaction of the siloxide with AgO_2CCF_3, reduction occurred since the cation contains rhenium atoms formally in oxidation states IV (inner) and VII (outer). This structure with a linear chain of four metal atoms resembles that of a neutral tert-butylimido(oxo)osmium(VI) compound, $[(Bu^tN)_2Os(\mu\text{-}NBu^t)_2Os(NBu^t)(\mu\text{-}O)]_2$.[9] Since both **4** and **5** are diamagnetic, metal–metal bonding or electron spin coupling via the bridge groups in the cation is evident. The ^{1}H NMR spectrum (CD_2Cl_2) of the cation shows two Bu^tN groups in a 1 : 1 ratio at 25°C, but on cooling there is initial broadening and finally collapse of these peaks at $T_c = -70$°C. Further cooling to −90°C does not allow observation of the slow exchange limit. The data suggest that at higher temperatures the two internal NBu^t and μ-NBu^t groups are exchanging positions very rapidly and the two peaks observed are due to "external" and "internal" imido groups. There is only a single ^{19}F resonance for the bridging fluoride groups at all temperatures.

(d) *Interaction of* $Re(NBu^t)_3Cl$ *and* $SbCl_5$ *in* MeCN. This reaction also leads to the loss of an NBu^t group and the formation of the rhenium(VII) complex $[Re(NBu^t)_2Cl_2(MeCN)_2]SbCl_6$ (**6**). The complex could be formed by chlorination of an NBu^t group by $SbCl_5$, similar to the conversion of $Re(NBu^t)_3(OSiMe_3)$ to $Re(NBu^t)_2Cl_3$ noted above [and to the reaction of Cl_2 with $Cr^{VI}(NBu^t)_2Cl_2$ which leads[10] to $Cr^V(NBu^t)Cl_3$], and possibly Bu^tNCl_2. An alternative route is the following:

$$Re(NBu^t)_3Cl + SbCl_5 \longrightarrow Re(NBu^t)_3{}^+SbCl_6{}^-$$

$$Re(NBu^t)_3{}^+ + SbCl_5 + 2MeCN \longrightarrow [Re(NBu^t)_2Cl_2(MeCN)_2]^+ + Bu^tN{=}SbCl_3.$$

Although $Bu^tN{=}SbCl_3$ is not known it would be similar to $Bu^tN{=}TaCl_3$.

Compound **6** is also available essentially quantitatively by chloride abstraction in refluxing MeCN according to the stoichiometry:

$$Re(NBu^t)_2Cl_3 + 2MeCN + SbCl_5 \longrightarrow [Re(NBu^t)_2Cl_2(MeCN)_2]SbCl_6.$$

The salt crystallizes from MeCN as large, deep orange–red crystals that are soluble in MeCN, THF, CH_2Cl_2 and $CHCl_3$; it is a 1 : 1 electrolyte in MeCN. The IR spectrum shows two stretches for the *cis* nitriles at 2292 and 2319 cm^{-1} that are above the value for free MeCN (2255 cm^{-1}), indicating the absence of M—N π-bonding (which may lower the CN stretching frequency[13]) as can be expected with the high oxidation state of rhenium.

Although an X-ray study confirmed the general features, difficulties in refinement due to disorder

problems preclude detailed discussion. The IR and NMR spectra, which show equivalence of the NBu^t groups, suggest an octahedral structure with *cis*-MeCN and Bu^tN groups and *trans*-chlorines.

Attempts to isolate the triply-coordinated ion $[Re(NBu^t)_3]^+$ have been unsuccessful. The interaction between $Re(NBu^t)_3Cl$ in CH_2Cl_2 and $AlCl_3$ leads to $Re(NBu^t)_2Cl_3$ (cf. above) as the only rhenium-containing product and there is no evidence for $[Re(NBu^t)_3]AlCl_4$. An aluminium-containing product appears to be $[AlCl(NBu^t)]_n$ for which analogues, e.g. $[AlCl(NPr^i)]_6$ are known.[11] The attempted removal of Bu^tNH_2 from the cation $[(Bu^tN)_3Re(NH_2Bu^t)]^+$ by refluxing its salt (described below) in toluene[12] also failed.

(2) *Protonation of* $Re(NBu^t)_3(NHBu^t)$

The interaction of this amide[3] with trifluoromethanesulphonic acid leads to the specific protonation of the amido nitrogen atom and the formation of the cation $[(Re(NBu^t)_3NH_2Bu^t]^+$, which is isolated as the triflate (**7**). The basicity of the amido nitrogen will be greater than that of the imido nitrogens since the lone pairs on the latter are involved in π-bonding $Bu^tN{=}Re$ to a greater extent than is the case for $Bu^tHN{=}Re$. Similar behaviour has been observed for $W(NBu^t)_2(NHBu^t)_2$, where $NHBu^t$ protonation of the amido ligand gives *cis,cis,trans*-$W(NBu^t)_2(\eta^1\text{-}OTf)_2(NH_2Bu^t)_2$.[14] The rhenium compound is a 1 : 1 electrolyte in CH_2Cl_2 or MeCN, although after *ca* 5 min reaction with MeCN begins to occur. The cationic nature contrasts with the structure of the tungsten compound, which has oxygen-bound η^1-triflate groups, possibly due to the reluctance of rhenium(VII) to be five- or six-coordinate when three bulky NBu^t groups are present. The compound is readily hydrolysed by moisture. The IR spectrum of the solid has a band at 1250 cm^{-1} assignable to $CF_3SO_3^-$.[15]

The X-ray crystal structure of the cation is shown in Fig. 2, data is given in Table 3. The geometry at rhenium deviates from tetrahedral with the angles subtended by N(1) and N(2) and by N(3) and N(4), both contracted at 102° whilst the remainder are all slightly enlarged at 113°. There are marked differences in the Re—N bond lengths which range from 1.724(8) Å for N(1) to 1.849(9) Å for N(2). There are concomitant differences in the degree of bending at nitrogen, ranging from 164.6(8)° at N(1) to 139.8(7)° at N(2). In fact, the relationship between Re–N distance and angle at nitrogen is almost linear. The dominance of the scattering by the rhenium atom coupled with the disorder in the F_3CSO_3 anion prevented the location of the NH_2 hydrogen atoms. However, the length of the Re—N(2) bond and the associated angle at nitrogen indicates N(2) as the most likely site for protonation. This conclusion is further strengthened by inspection of the packing of the anion and cation in the crystal (Fig. 3). Here we see that one of the oxygen atoms [O(2)] of the anion is inserted into a cleft between N(2) and N(1) in the cation at a distance of 3.06 Å from N(2).

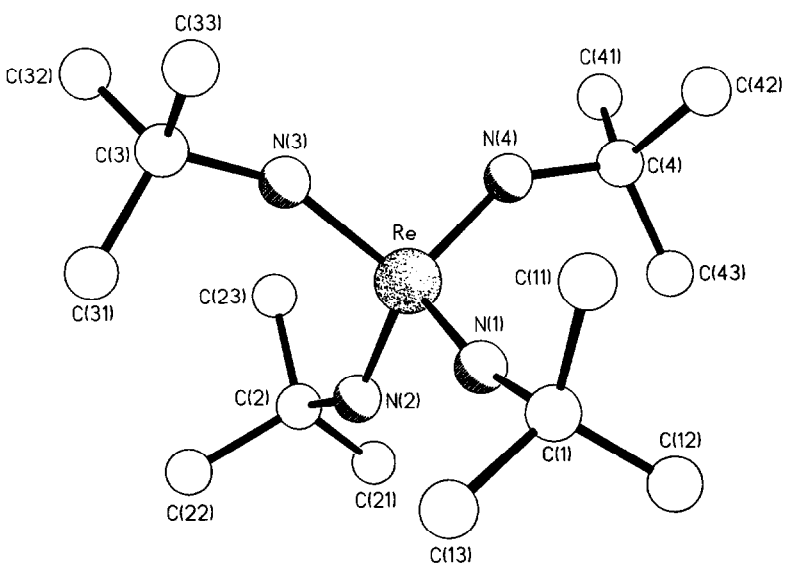


Fig. 2. The structure of the $[Re(NBu^t)_3(NH_2Bu^t)]^+$ ion in the trifluoromethanesulphonate.

Table 3. Bond lengths (Å) and angles (°) for (7) with e.s.d.s in parentheses

Re—N(1)	1.724(8)	Re—N(2)	1.849(9)
Re—N(3)	1.761(10)	Re—N(4)	1.805(10)
N(1)—Re—N(2)	102.2(4)	N(1)—Re—N(3)	113.0(4)
N(2)—Re—N(3)	113.5(5)	N(1)—Re—N(4)	113.2(5)
N(2)—Re—N(4)	113.2(4)	N(3)—Re—N(4)	102.1(5)
Re—N(1)—C(1)	164.6(8)	Re—N(2)—C(2)	139.8(7)
Re—N(3)—C(3)	152.6(8)	Re—N(4)—C(4)	146.0(8)

This is compatible with the formation of a weak cation···anion N—H···O hydrogen bond [the N(1)···O(2) distance is 3.7 Å]; N(3) and N(4) are not approached in this way.

Attempts to substitute the Bu^tNH_2 ligand with various bases such as PMe_3 or PMe_2Ph by reactions in CH_2Cl_2 solution gave mixtures. However, triphenylphosphine gave the salt $[Re(NBu^t)_3(PPh_3)]O_3SCF_3$ (**8**).

Attempts to obtain the hydride $ReH(NBu^t)_3$ by action of NaH or KH on $[Re(NBu^t)_3(NH_2Bu^t)]^+$ in THF gave only the neutral amido complex by deprotonation. Similarly, thermal decompositions of alkyls such as $Re(NBu^t)_3Et$[4] or $Re(NBu^t)_3(O^iPr)$ and treatment of $Re(NBu^t)_3Cl$ with various hydrides, boro- and aluminohydrides also failed, as did the reaction of H_2 in the presence of Et_3N in hexane.

(3) *Substitution reactions of* $Re(NBu^t)_3X$, X = Cl *or* $OSiMe_3$

(a) *Dialkyl- and arylimido compounds.* The interaction of $Re(NBu^t)_3Cl$ and $LiNMe_2$ in Et_2O leads to the dimethylamido complex **9** as a yellow, high-boiling oil. A similar reaction using the siloxide gave a red solution from which no well-defined product could be isolated. However, the siloxide and $LiNPh_2$ react cleanly to give $Re(NBu^t)_3(NPh_2)$ (**10**) as yellow crystals. Both amides are moderately air- and moisture-sensitive. It is of interest that while the oxo analogue $ReO_3[N(mes)_2]$, whose crystal structure was determined, was formed by interaction of $ReO_2(mes)_2$ with nitric oxide via an oxygen transfer to rhenium and a double aryl migration to the nitrogen atom,[16] the reaction of $Re(NBu^t)_2(mes)_2$ with NO gives $[Re(NBu^t)(O)(mes)(\mu\text{-}O)]_2$ and $Bu^tN{=}Nmes$.[2]

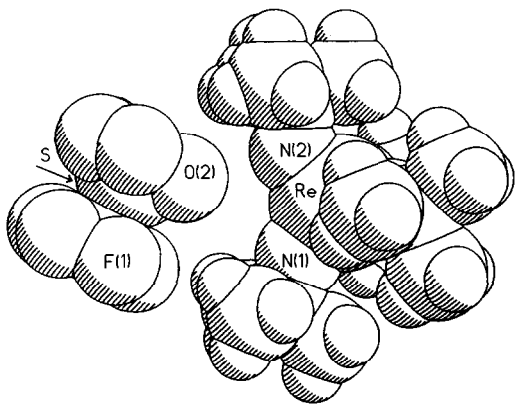

Fig. 3. Space-filling representation of the cation and anion in $[Re(NBu^t)_3(NH_2Bu^t)]SO_3CF_3$.

In the ^1H NMR spectrum of $Re(NBu^t)_3(NPh_2)$ there are two multiplets for the aromatic protons (centred at 7.00 and 7.23 ppm). There is no temperature dependency from −90 to +100°C unlike that found in $ReO_3[N(mesityl)_2]$.[16] For the dimethylamido complex the methyl resonance occurs at 3.35 ppm as a singlet.

(b) *Dialkyl and arylphosphido complexes.* There is a marked difference between the reactivities of $Re(NBu^t)_3X$ (X = Cl or $OSiMe_3$) and those of lithium phosphido reagents. Reaction of the chloride with $LiPPh_2$ gives $[Ph_2P]_2$ as the only identifiable product; this was characterized by its NMR spectrum ($^{31}P\{^1H\}$ = 15.12 ppm in C_6D_6) and m.p. (120°C).[17] $Re(NBu^t)_3(OSiMe_3)$ reacts cleanly with $LiPR_2$ (R = Ph, $SiMe_3$) and LiPH(mes) in Et_2O at −78°C to give the corresponding phosphido complexes: $Re(NBu^t)_3PPh_2$ (**11**), $Re(NBu^t)_3P(SiMe_3)_2$ (**12**) and $Re(NBu^t)_3PH(mes)$ (**13**). The diphenylphosphido complex is obtained as an oil from hexane, but can be crystallized from MeCN as a yellow crystalline solid in *ca* 40% yield. The complexes $Re(NBu^t)_3P(SiMe_3)_2$ and $Re(NBu^t)_3PH(mes)$ are obtained as yellow–orange solids from hexane in yields of *ca* 60 and 45%, respec-

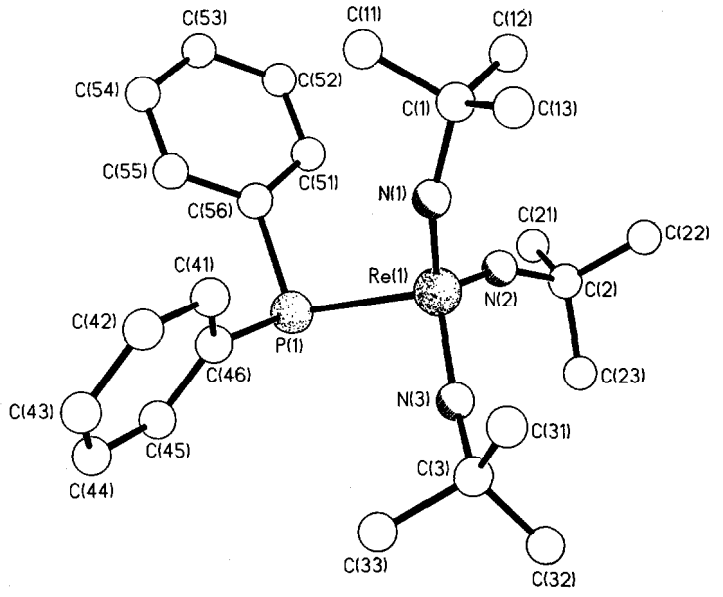

Fig. 4. The structure of $Re(NBu^t)_3(PPh_2)$.

tively. All three compounds have low melting points, are soluble in all common organic solvents, and are moderately air- and moisture-sensitive.

The structure of the diphenylphosphido compound **11** is shown in Fig. 4; data are in Table 4. The compound crystallizes with two crystallographically-independent molecules in the asymmetric unit. Both molecules have nearly identical conformations, the only major difference being in the orientation of one of the tert-butyl groups [C(2)]. The geometry at rhenium is distorted tetrahedral with angles ranging from 99.7(2) to 115.2(3)° in one molecule and from 99.3(3) to 116.2(3)° in the other. The Re—N distances do not differ significantly and are in the range 1.732(7)–1.748(8) Å. The angles at nitrogen reflect an almost equal degree of bending with values between 153.2(6) and 158.7(7)°. It is interesting to note that these values fit the bond length/angle correlation observed above in the $[Re(NBu^t)_3(NH_2Bu^t)]^+$

Table 4. Bond lengths (Å) and angles (°) for (**11**) with e.s.d.s in parentheses

N(2′)—Re(1′)—N(3′)	115.3(3)	N(1′)—Re(1′)—P(1′)	100.8(2)
N(2′)—Re(1′)—P(1′)	107.9(2)	N(3′)—Re(1′)—P(1′)	99.3(3)
Re(1′)—N(1′)—C(1′)	158.7(7)	Re(1′)—N(2′)—C(2′)	153.2(6)
Re(1′)—N(3′)—C(3′)	154.1(7)	Re(1′)—P(1′)—C(46′)	102.6(2)
Re(1′)—P(1′)—C(56′)	104.2(2)	C(46′)—P(1′)—C(56′)	104.4(3)

cation. The two Re—P distances are 2.446(2) and 2.445(2) Å and the angles at phosphorus are all less than tetrahedral ranging between 102.2(3) and 104.6(2)°. The pyramidal geometry at phosphorus is in agreement with the NMR data given below.

Terminal dialkyl or aryl phosphido complexes are relatively rare;[18] for rhenium there is the homoleptic anion,[18c] $[Re(PCy_2)_4]^-$, where Cy = cyclohexyl. The IR and NMR spectra of **11** are in accord with the structure found in the crystal. The ^1H NMR spectrum shows two multiplets (centred at 7.86 and 7.14 ppm) for the aromatic protons and a singlet for the NBu^t protons (at 1.26 ppm); there is no temperature dependency from −90 to +100°C. The ^{31}P NMR spectrum shows a quintet centred at −8.78 ppm, due to the coupling of the four *ortho*-hydrogen nuclei on the phenyl rings with the ^{31}P nucleus (^4J(P—H) = 7 Hz); decoupling the proton resonances gives a sharp singlet at −8.78 ppm. The shifts are in the region characteristic for M—PR_2 single-bonded compounds with pyramidal geometry.[18c]

For $Re(NBu^t)_3P(SiMe_3)_2$, the $SiMe_3$ protons are split into a doublet by the phosphorus nucleus (^3J(P—H) = 4.5 Hz). The $^{31}P\{^1H\}$ NMR spectrum has a singlet at −212.33 ppm. The ^1H NMR spectrum of $Re(NBu^t)_3PH(mes)$ shows a doublet centred at 5.37 ppm for the phosphido proton (^1J(P—H) = 195 Hz). The same coupling constant is observed in the ^{31}P NMR spectrum of the complex where the doublet is centred at −153.1 ppm.

Attempts to deprotonate $Re(NBu^t)_3P(H)(mes)$ (**13**) in the hope of obtaining a phosphinidine[19] species, $[(Bu^tN)_3Re{=}P(mes)]^-$, by interaction with Bu^{t}Li in hexane or MeLi in Et_2O or by refluxing in toluene with Et_3N were unsuccessful. Although deprotonation occurs, other reactions followed and the only rhenium-containing species isolated was the rhenium(VI) dimer $[Re(NBu^t)_2(\mu\text{-}Bu^tN)]_2$, whose structure has been determined.[3] From the reaction of **13** with one equiv. of Bu^{n}Li in hexane the only other product that could be isolated was a colourless, crystalline solid that has been found to be the new cyclophosphane $[P(2,4,6\text{-}Me_3C_6H_2)]_3$.

Cyclophosphanes, $(PR)_n$ (n = 3–6), are known.[20–22] The trimers, with bulky R groups have two of the R groups on one side of the P_3 plane. The $^{31}P\{^1H\}$ spectrum of $(Pmes)_3$ has two singlets at −111.20 and −118.35 ppm in a 2:1 ratio that are in close agreement with values reported for similar compounds.

The mechanism of this reaction leading to the formation of the rhenium(VI) dimer and the cyclophosphane is not clear. The oily, lithium-containing residue has eluded characterization. It is of interest that phosphinidine intermediates have been proposed[22] in the synthesis of metal compounds such as $[(CO)_5Cr]_3(PBu)_3$.

(c) *Phosphiniminato compound.* The interaction between $Re(NBu^t)_3Cl$ and a slight excess of $LiNPPh_3$ in refluxing toluene gives the phosphiniminato complex $Re(NBu^t)_3(N{=}PPh_3)$ (**14**). The resonance form Re—$\ddot{N}$=PPh_3 rather than others such as $Re^-{=}N^+{=}PPh_3$ appears to be the main contributor since the IR band at 1094 cm^{-1} is at the lower limit of the ν(P—N) region (1052–1200 cm^{-1}) for such complexes.[23a] The only other related rhenium(VII) compound is $Re[N(2,6\text{-}^iPr_2C_6H_3)]_3(N{=}PPh_3)$, whose X-ray structure was recently reported: it was made by the interaction between Ph_3PNReO_3 and the aryl isocyanate.[23b]

(d) *Pyrazolate.* The interaction of $Re(NBu^t)_3Cl$ with the sodium salt of pyrazole in THF gives $Re(NBu^t)_3(C_3H_3N_2)$ (**15**). The mass spectrum indicates that the compound is monomeric in the gas phase; the ^1H NMR spectra shows a singlet for the NBu^t protons and an ABC pattern for the $C_3H_3N_2$ protons; the ratio is 9:1 as expected.

EXPERIMENTAL

The general techniques and instruments used have been described.[3,24] All compounds and operations were carried out under purified nitrogen, argon or *in vacuo*. Commercial chemicals were from Aldrich. NMR spectra (250 MHz) are in ppm (δ) in C_6D_6 unless otherwise stated and referenced to Me_4Si (^1H), $CFCl_3$ (^{19}F) and external H_3PO_4 (^{31}P). IR spectra (in cm^{-1}) are in Nujol mulls. Electron impact mass spectra (m/z) show isotropic envelopes for the rhenium-containing ions but only peaks corresponding to those with ^{187}Re (62.5%) are listed.

The compounds $Re(NBu^t)_3(OSiMe_3)$[5] and $Re(NBu^t)_3Cl$[3] were made as described. The previously undescribed tert-butoxide and isopropoxide have been made from the chloride as below.

The reagents $LiNMe_2$, $LiNPh_2$, $LiPPh_2$ and LiP(H)(mes) were prepared by the standard method of interaction of the corresponding amine or phosphine with one equiv. of Bu^{n}Li in hexane at −78°C. $LiP(SiMe_3)_2$ was prepared by the interaction of $P(SiMe_3)_3$ with Bu^{n}Li in THF at −40°C. $LiN{=}PPh_3$ was prepared from $HN{=}PPh_3$[25] and one equiv. of Bu^{n}Li in toluene at −78°C. The sodium salt of pyrazole was made by adding a suspension of NaH in THF to a solution of pyrazole at −78°C; the solution was stirred for 30 min at room temperature, filtered, evaporated and the residue washed with hexane (3 × 30 cm^3).

Tris(tert-butylimido)tert-butoxo)- and -(isopropoxo) rhenium(VII)

To a mixture of $Re(NBu^t)_3Cl$ (0.44 g, 1 mmol) and $KOBu^t$ (0.11 g, 1 mmol) at −20°C was added cold Et_2O (20 cm^3); the yellow solution was allowed to warm and was then stirred for 15 h at ambient temperature. After filtration and removal of the solvent, extraction with hexane (5 cm^3) and cooling gave yellow needles. Yield: 0.34 g, 71%; m.p. 55–56°C. Found: C, 40.7; H, 7.6; N, 9.0%. M.S. 473 (18%), $Re(NBu^t)_3(OBu^t)$; 402 (100%), $Re(NBu^t)_2(OBu^t)$. NMR: ^1H: 1.34 (s, 27H, OBu^t); 1.25 (s, 9H, OBu^t).

The *isopropoxide* was made similarly. Yield: *ca* 82%, b.p. 100–120° at *ca* 0.15 mm Hg. M.S. 457 (M^+), 442 (M—Me); 400 (M—$Me_2C{=}CH_2$); 386 (M—NBu^t). IR: 1220 cm^{-1}, $ReNBu^t$. NMR: ^1H: 1.35 (*s*, 27H, $NCMe_3$); 1.30 (d, 6H, Me_2CH); 450 (sept., ^1H, $CHMe_2$).

Bis[bis(tert-butylimido)(η^1-cyclopentadienyl)rhenium (VII)](μ-oxo)(μ-cyclopentadienylidene) (**1**)

To $ReCl(NBu^t)_3$ (0.45 g, 1 mmol) in Et_2O (20 cm^3) at −78°C was added a THF solution of NaC_5H_5 (1.12 cm^3 of 0.98 M solution, 1.1 mmol) and the mixture was allowed to warm to ambient temperature when the colour changed from orange to brown. After stirring for 1 h the volatiles were removed *in vacuo* and the residue extracted with hexane (3 × 10 cm^3); the orange extracts were concentrated and cooled (−20°C, 12h) to give orange prisms. Yield: 0.065 g, 15%. M.S. 736(1), $Re_2(NBu^t)_4(O)(C_5H_5)$; 458 (45), $Re(NBu^t)_2(C_5H_5)_2$; 443 (100), $Re(NBu^t)(C_5H_5)-CH_3$; 410 (32), $Re(NBu^t)_2(O)(C_5H_5)$. NMR: ^1H (20°C, CD_2Cl_2): 1.35 (s, 18H) and 1.32 (s, 18H) $NCMe_3$; 5.85 (m, 4H, μ-C_5H_4); 6.2 (s, 8H, η^1-C_5H_5).

Bis[bis(tert-butylimido)(trimethylsiloxo)rhenium(VII)] (μ-oxo)-(μ-trimethylsiloxo)(μ-trifluoroacetato) (**2**)

To a suspension of AgO_2CCF_3 (0.11 g, 0.5 mmol) in THF (30 cm^3) at −78°C was added a solution of $Re_3(NBu^t)_4(O)_5(OSiMe_3)_3$[5] (0.45 g, 0.38 mmol) in THF (20 cm^3). After stirring at room temperature (12 h) the solution was evaporated and extracted with hexane (2 × 20 cm^3). Concentration (10 cm^3) and cooling (−20°C) gave yellow crystals, some of X-ray quality. Yield: 0.18 g (44%). IR: 1682 (ν_{asym} OCO); 1454 (ν_{sym} OCO); 1203 (NBu^t). The values of the symmetric and asymmetric carboxylate stretches and the separation $\Delta = 228\ cm^{-1}$ are similar to those in other bridged trifluoroacetates.[26] NMR ($CDCl_3$): ^1H: 1.42 (s, 26H, NBu^t); 0.25 (s, 9H, μ-$OSiMe_3$); 0.13 (s, 18H, $OSiMe_3$). ^{19}F: 57.72 (s).

Bis[bis(tert-butylimido)rhenium(V)](μ-trimethylsiloxo) (μ-trifluoroacetato) (**3**)

To a suspension of AgO_2CCF_3 (0.2 g, 1.27 mmol) in THF (30 cm^3) at −78°C was added a solution of $Re(NBu^t)_3(OSiMe_3)$ (0.5 g, 1.02 mmol) in THF (10 cm^3). After warming and stirring at room temperature for *ca* 18 h, the solution was evaporated *in vacuo* and the residue extracted with hexane (2 × 20 cm^3). Concentration (to 10 cm^3) of the filtered extract and cooling (−20°C) gave a yellow crystalline solid. Yield: 0.57 g, 65%. IR: 1674, 1450 cm^{-1} (asym and sym νOCO, $\Delta = 224\ cm^{-1}$); 1208 (NBu^t). NMR ($CDCl_3$): ^1H: 1.44 (s, 36H, NBu^t); 0.13 (s, 9H, $OSiMe_3$). ^{19}F: 60.18 (s).

Bis[bis(tert-butylimido)chlororhenium(VII)(μ-tert-butylimido)(μ-fluoro)(tert-butylimido)rhenium(IV)(μ-fluoro)]tetrafluoroborate (**4**) *and hexafluorophosphate* (**5**)

To a solution of $AgBF_4$ (0.15 g, 0.76 mmol) or $AgPF_6$ (0.19 g, 0.75 mmol) in CH_2Cl_2 (15 cm^3) was added $Re(NBu^t)_3Cl$ (0.3 g, 0.7 mmol) in CH_2Cl_2 (20 cm^3) when a white precipitate (AgCl) formed immediately. After stirring in the dark for 4 h, the volatiles were removed *in vacuo* and the residue washed with Et_2O (3 × 20 cm^3). Extraction of the residue with CH_2Cl_2 (2 × 10 cm^3) and concentration to 2–3 cm^3, followed by layering with Et_2O gave yellow prisms after *ca* 24 h at room temperature. Yield: *ca* 20%. NMR ($CDCl_3$): ^1H: 1.65 (terminal NBu^t); 1.61 (internal and bridge NBu^t). ^{19}F: BF_4^- salt, −150 (BF_4^-); −126 (μ-F). ^{19}F: PF_6^- salt, −75 (d, J(P—F) = 713 Hz, equatorial F of PF_6^-); −80 (d, J(P—F) = 986 Hz, axial F of PF_6^-); −135 (μ-F).

Bis(tert-butylimido)dichlorobis(acetonitrile)rhenium (VII)hexachloroantimonate(V) (**6**)

To $Re(NBu^t)_3Cl$ (0.4 g, 0.92 mmol) in MeCN (30 cm^3) was added $SbCl_5$ (1 cm^3 of 1 M solution in CH_2Cl_2) and the solution refluxed (*ca* 12 h) and evaporated. The residue was washed with Et_2O (2 × 30 cm^3) and extracted into MeCN (2 × 10 cm^3); concentration and cooling gives bright orange–red crystals. Further crops may be obtained from the supernatant. Overall yield: 0.54 g (72%). Conductivity (MeCN): $\Lambda_M = 111\ \Omega^{-1}\ cm^2\ mol^{-1}$. IR:

2319, 2292 (MeCN); 1200 (NBu^t); 337 vs ($SbCl_6^-$). NMR: ^1H: 1.64 (s, Bu^tN); 2.22 (s, MeCN).

The compound is obtained similarly from stoichiometric amounts of $Re(NBu^t)_2Cl_3$[27] and $SbCl_5$ in MeCN with an essentially quantitative yield.

Tris(tert-butylimido)(tert-butylamine)rhenium(VII) *trifluoromethanesulphonate* (**7**)

To a solution of $Re(NBu^t)_3(NHBu^t)$[3] (0.5 g, 1.05 mmol) in Et_2O (30 cm^3) at −78°C was added dropwise with stirring a pre-cooled solution of CF_3SO_3H (0.1 cm^2, 1.17 mmol in 20 cm^3 Et_2O). The yellow solution was stirred for 1 h and then allowed to warm slowly. The yellow precipitate was collected, washed with Et_2O (2 × 10 cm^3) and crystallized from CH_2Cl_2–Et_2O (1:2) at −20°C as yellow prisms. Yield: 0.29 g, 45%. IR: 3177 (H_2NBu^t); 1250 ($CF_3SO_3^-$); 1210 (NBu^t). NMR ($CDCl_3$): ^1H: 1.45 (s, 27H, NBu^t); 1.39 (s, 9H, H_2NBu^t). ^{19}F: −82.0. Conductivity (CH_2Cl_2): Λ_M = 141 Ω^{-1} cm^2 mol^{-1} (cf. $Bu^n{}_4NPF_6$ under the same conditions, Λ_M = 145 Ω^{-1} cm^2 mol^{-1}.

Tris(tert-butylimido)(triphenylphosphine)rhenium (VII)*trifluoromethanesulphonate* (**8**)

To a solution of the above amine complex (0.2 g, 0.32 mmol) in CH_2Cl_2 (20 cm^3) was added PPh_3 (0.1 g, 0.4 mmol) when the colour changed from yellow to orange. After stirring for 2 h the volatiles were moved *in vacuo* and the residue washed with Et_2O (3 × 30 cm^3) and recrystallized as orange needles from CH_2Cl_2 after addition of Et_2O at −20°C. Yield: 0.14 g, 55%. IR: 1255 (CF_3SO_3); 1210 (NBu^t). NMR ($CDCl_3$): ^1H: 1.25 (s, 27H, NBu^t); 7.3 (m, 15H, PPh_3). $^{31}P\{^1H\}$: 34.83. ^{19}F: −79.0.

Tris(tert-butylimido)(dimethylamido)rhenium(VII) (**9**)

To a solution of $Re(NBu^t)_3Cl$ (0.45 g, 1.03 mmol) in Et_2O (20 cm^3) at −78°C was added a cold suspension of $LiNMe_2$ (0.07 g, 1.4 mmol) in Et_2O (30 cm^3). After warming and stirring at room temperature for 5 h the solution was evaporated and the residue extracted with hexane (2 × 5 cm^3). Evaporation of the extract left a yellow oil which was distilled under high vacuum at *ca* 150°C. Yield: 0.16 g, 35%. M.S. 444 (M); 429 (M—Me); 373 (M—NBu^t). IR: 1211 (NBu^t). NMR: ^1H: 3.35 [s, 6H, $N(Me)_2$], 1.37 (s, 27H, NBu^t).

Tris(tert-butylimido)(diphenylamido)rhenium(VII)(**10**)

As above but using $Re(NBu^t)_3(OSiMe_3)$ (0.42 g, 0.86 mmol) in Et_2O (20 cm^3) and $LiNPh_2$ (0.19 g, 1.10 mmol) in Et_2O (30 cm^3). Concentration of the hexane extract and cooling (−20°C) gave yellow crystals. Yield: 0.26 g, 53%. M.S. 568 (M); 553 (M—Me); 497 (M—Bu^tN). IR: 1200 (NBu^t). NMR: ^1H: 7.00–7.23 (m, 10H, NPh_2); 1.29 (s, 27H, NBu^t).

Tris(tert-butylimido)(diphenylphosphido)rhenium(VII) (**11**)

As above but using $Re(NBu^t)_3(OSiMe_3)$ (0.51 g, 1.04 mmol) in Et_2O (20 cm^3) and $LiPPh_2$ (0.25 g, 1.30 mmol) in Et_2O (30 cm^3). The hexane extracted (30 cm^3) was evaporated and the residue crystallized from MeCN to give an orange–yellow crystalline solid. Yield: 0.24 g, 40%. M.S. 585 (M); 570 (M—Me); 555 (M—2Me); 514 (M—Bu^tN). IR: 1211 (NBu^t). NMR: ^1H: 7.14, 7.86 (m, 10H, PPh_2); 1.26 (s, 27H, NBu^t). ^{31}P: −8.78 [quin. ^4J(P—H) = 7 Hz; coupling to four *o*-H on C_6H_5 rings]. $^{31}P\{^1H\}$: −8.78 (s).

Tris(tert-butylimido)[bis(trimethylsilyl)phosphido]rhenium(VII) (**12**)

As above from $Re(NBu^t)_3(OSiMe_3)$ (0.55 g, 1.13 mmol) in Et_2O (20 cm^3) and $Li[P(SiMe_3)_2]$ (0.26 g, 1.41 mmol) in Et_2O (20 cm^3). Concentration of the hexane extract (20 cm,[3]) and work-up gave a yellow crystalline solid. Yield: 0.28 g, 43%. M.S. 577 (M); 562 (M—Me); 520 (M—Bu^t); 504 (M—$SiMe_3$); 406 (M—3 × Bu^t); 333 (M—3 × Bu^tSiMe_3). IR: 1211 (NBu^t). NMR: ^1H: 1.37 (s, 27H, NBu^t); 0.49 (d, 18H, $SiMe_3$, ^3J(P—H) = 4.5 Hz). $^{31}P\{^1H\}$: −212.33 (s).

Tris(tert-butylimido)(mesitylphosphido)rhenium(VII) (**13**)

As above from $Re(NBu^t)_3(OSiMe_3)$ (0.639 g, 1.29 mmol) but using LiPH(mesityl) (6.25 g, 1.58 mmol). The product is obtained from hexane as yellow crystals. Yield: 60%. M.S. 551 (M); 536 (M—Me); 478 (M—Me, HBu^t); 463 (M—2Me, Bu^t, H); 431 (M—mesityl, H). IR: 2328 (P—H), 1211 (NBu^t). NMR: ^1H: 1.27 (s, 27H, NBu^t); 2.16 (s, 3H, *p*-CH_3); 2.65 (s, 6H, *o*-CH_3); 5.37 [d, 1H, P—H, ^1J(P—H) = 195 Hz]; 6.78 (s, 2H, C_6H_2). $^{31}P\{^1H\}$: −153.16 (s). ^{31}P: −153.1, 155.79 (d, J(P—H) = 195 Hz).

The interaction of stoichiometric amounts of **13**

and Bu^nLi in hexane gave yellow $[(Re(NBu^t)_2(\mu\text{-}NBu^t)]_2$,[3] identified by m.p. and ^1H NMR spectrum, and colourless $(Pmesityl)_3$, which crystallized first, in yields 10–20%. Found: C, 71.5; H, 8.0; P, 20.5. Calc. for $C_{27}H_{33}P_3$: C, 72.0; H, 7.4; P, 20.6%. M.S. 450 (M); 330 (M—mesityl—H); M 302 [M—$(mesP)_2$]. For NMR see text.

Tris(tert-butylimido)(triphenylphosphineiminato)rhenium(VII) (**14**)

To $Re(NBu^t)_3Cl$ (0.38 g, 0.87 mmol) in toluene (20 cm^3) was added $LiN{=}PPh_3$ (0.30 g, 1.06 mmol) in toluene (20 cm^3) and the solution refluxed for 12 h. After evaporation the residue was extracted into hexane (2×30 cm^3) which was filtered, concentrated and cooled to give an orange–brown powder. Recrystallization from Et_2O gave a yellow crystalline solid. Yield: 0.2 g, 33%. M.S. 676 (M); 661 (M—Me); 646 (M—2Me); 605 (M—Bu^t); 400 (M—$NPPh_3$). IR: 1206 (NBu^t). NMR: ^1H: 7.02, 7.44 (m, 15H, Ph); 1.44 (s, 27H, NBu^t). $^{31}P\{^1H\}$: 15.28 (s).

Tris(tert-butylimido)pyrazolatorhenium(VII) (**15**)

To a solution of $Re(NBu^t)_3Cl$ (0.56 g, 1.29 mmol) in THF (20 cm^3) at −78°C was added a cold solution of sodium pyrazolate (from pyrazole and NaH in THF; 0.15 g, 1.67 mmol) in THF (30 cm^3). After warming and stirring at room temperature (18 h) the solution was evaporated and extracted with hexane (2×20 cm^3). Concentration (to 5 cm^3), filtration and cooling (−20°C) gave orange–red crystals. Yield: 0.19 g, 32%. M.S. 464 (M—3H), 449 (M—3H—CH_3); 393 (M—3H—NBu^t). NMR ($CDCl_3$): ^1H: 7.18 (m, 1H, C_4H_3N); 7.59 (m, 1H, C_4H_3N); 5.95 (m, 1H, C_4H_3N); 1.53 (s, 27H, NBu^t).

X-ray crystallography

All three compounds were air-sensitive and were sealed in Lindemann glass capillaries under argon. Crystal data: (**2**) $C_{27}H_{63}F_3N_4O_6Re_2Si_3$, M = 1053.5, monoclinic, a = 9.895(1), b = 22.603(4), c = 10.383(1) Å, β = 109.77(1)°, V = 2185 $Å^3$, space group $P2_1/m$, Z = 2 (the complex has crystallographic C_s symmetry), D_c = 1.60 g cm^{-3}, copper radiation, λ = 1.54178 Å, μ(Cu-K_α) = 115 cm^{-1}, F(000) = 1040. Data were measured on a Nicolet R3m diffractometer with Cu-K_α radiation (graphite monochromator) using ω-scans. A crystal of dimensions $0.03\times0.18\times0.38$ mm was used. 3046 independent reflections ($2\theta \leqslant 116°$) were measured, of which 2252 had $|F_o| > 3\sigma(|F_o|)$, and were considered to be observed. The data were corrected for Lorentz and polarization factors; a numerical absorption correction (face-indexed crystal) was applied; maximum and minimum transmission factors were 0.677 and 0.141. The structure was solved by the heavy-atom method. The non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, U(H) = 0.08, and allowed to ride on their parent carbon atoms. The methyl groups were refined as rigid bodies. Refinement was by full-matrix least-squares to R = 0.064, R_w = 0.058 [$w^{-1} = \sigma^2(F)+0.00050F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 2.32 and −1.87 e $Å^{-3}$, respectively. The mean and maximum shift/errors in the final refinement were 0.000 and 0.000, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system and on an IBM 386 PC using SHELXTL PC.

Crystal data: (**7**) $C_{17}H_{38}F_3N_4O_3ReS$, M = 621.8, monoclinic, a = 15.495(5), b = 11.208(5), c = 16.034(11) Å, β = 105.48(4)°, V = 2684 $Å^3$, space group $P2_1/a$, Z = 4, D_c = 1.54 g cm^{-3}, copper radiation, λ = 1.54178 Å, μ(Cu-K_α) = 96 cm^{-1}, F(000) = 1240. Data were measured as above for a crystal of dimensions $0.17\times0.20\times0.33$ mm. 3625 independent reflections ($2\theta \leqslant 116°$) were measured, of which 2969 had $|F_o| > 3\sigma(|F_o|)$, and were considered to be observed. The data were corrected for Lorentz and polarization factors; an empirical absorption correction (ellipsoidal) based on 309 azimuthal measurements was applied; maximum and minimum transmission factors were 0.367 and 0.206. The structure was solved by the heavy-atom method. The non-hydrogen atoms were refined anisotropically. The triflate ion was disordered about the C—S axis and was refined with two rigid body orientations for both the CF_3 and SO_3 groups. The amine hydrogen atoms could not be located. The positions of the remaining hydrogen atoms were idealized, C—H = 0.96 Å, assigned isotropic thermal parameters, U(H) = $1.2U_{eq}$(C), and allowed to ride on their parent carbon atoms. The methyl groups were refined as rigid bodies. Refinement was by block-cascade full-matrix least-squares to R = 0.046, R_w = 0.045 [$w^{-1} = \sigma^2(F)+0.00054F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 0.75 and −0.61 e $Å^{-3}$, respectively. The mean and maximum shift/error in the final refinement were 0.047 and 0.465, respectively. Computations were carried out as above.

Crystal data: (**11**) $C_{24}H_{37}N_3PRe$, M = 584.8, triclinic, a = 10.430(2), b = 10.319(3), c = 26.227(10) Å, α = 91.23(3), β = 94.23(3), γ = 99.30(2)°, V = 2776 $Å^3$, space group $P\bar{1}$, Z = 4 (2 crystallo-

graphically-independent molecules), $D_c = 1.40$ g cm^{-3}, copper radiation, $\lambda = 1.54178$ Å, μ(Cu-K_α) = 90 cm^{-1}, $F(000) = 1168$. Data were measured as above on a crystal of dimensions $0.17 \times 0.23 \times 0.26$ mm. 7485 independent reflections ($2\theta \leqslant 116°$) were measured, of which 5868 had $|F_o| > 3\sigma(|F_o|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors; a numerical absorption correction (face-indexed crystal) was applied; maximum and minimum transmission factors were 0.352 and 0.105. The structure was solved by the heavy-atom method. The non-hydrogen atoms were refined anisotropically. The phenyl rings together with their hydrogen atoms were refined as idealized rigid bodies. The methyl groups were also refined as idealized rigid bodies with a common refined-free variable isotropic thermal parameter for each tert-butyl group. Refinement was by blocked full-matrix least-squares to $R = 0.043$, $R_w = 0.047$ [$w^{-1} = \sigma^2(F) + 0.00147F^2$]. The maximum and minimum residual electron densities in the final ΔF map were 0.89 and -0.79 e Å^{-3}, respectively. The mean and maximum shift/error in the final refinement were 0.000 and 0.000, respectively. Computations were carried out as above.

(*Received* 24 *April* 1991; *accepted* 20 *June* 1991)

Abstract—The reaction between $CrCl_3(THF)_3$, NaOEt and 2-hydroxyethanethiol ($hetH_2$) gave the complex $(PPh_4)_2Na[Cr_3(het)_6]$ (**1**) as a highly crystalline solid in good yield. Analytical data and structural characterization show the presence also of solvate molecules, one of which is an EtOH group, and another which may be a second EtOH or a H_2O molecule hydrogen-bonded to an Et_2O group; the true formulation is thus **1**·2EtOH or **1**·EtOH·H_2O·Et_2O, or a combination. Complex **1**·EtOH·solvent crystallizes in monoclinic space group $P2_1/n$ with (at −155°C): $a = 23.605(24)$, $b = 17.390(14)$, $c = 17.668(20)$ Å, $\beta = 107.09(4)°$, $Z = 4$ and $V = 6931.98$ Å^3. The structure was solved and refined using 4350 unique data with $F > 3.0\sigma(F)$ collected in the range $6° \leqslant 2\theta \leqslant 45°$. Final values of $R(R_w)$ were 10.98 (10.75)%. The high values of $R(R_w)$ are a consequence of the limited number of strong reflections and the large number of independent atoms arising from the presence of two independent PPh_4^+ cations and two independent anions, both lying on inversion centres. As a result, not all atoms were refined anisotropically; the uncertainty in the identity of the disordered second solvate molecule was also detrimental. The two anions are essentially superimposable. The three chromium(III) atoms are linearly disposed (Cr···Cr, ~2.7 Å) with each Cr_2 pair bridged by oxygen atoms from three het^{2-} groups whose sulphur atoms are terminally ligated. The inversion centre at the central chromium leads to idealized S_6 symmetry with distorted octahedral geometry at each metal. Variable-temperature, solid-state magnetic susceptibility data were collected in the temperature range 2–300 K. The effective magnetic moment, μ_{eff} per Cr_3, decreases from 4.77 μ_B at 299.9 K to 3.71 μ_B at 75.0 K, is then almost constant to 8.0 K and then decreases to 3.16 μ_B at 2.08 K. The data were least-squares fit to the theoretical expression derived for isotropic exchange

interactions between three $S = 3/2$ centres. The fitting parameters were found to be $J = -37.7\ cm^{-1}$, $J' = 0\ cm^{-1}$ and $g = 1.90$, where J refers to interactions between adjacent chromium(III) centres and J' to the interaction between the terminal chromium(III) centres. The metals are thus antiferromagnetically coupled and the complex has an $S = 3/2$ ground state. The structure of the anion of **1** is compared to that found for the $[Cr_3(E_4)_6]^{3-}$ (E = Se, Te) complexes which also possess a linear Cr_3 unit and tetra-atomic chelating ligands.

Over the last few years, we have been involved in developing the thiolate chemistry of the early transition metals. Much of our work to-date has been concentrated on manganese[1] and vanadium,[2] and a variety of species of different nuclearities and oxidation levels have been obtained. Technical advantage has resulted from the use of either chelating or sterically-bulky thiolate ligands to inhibit polymerization and lead to tractable materials. The use of ethane-1,2-dithiolate (edt^{2-}) has been particularly beneficial. With vanadium(III), an unusual tetra-bridged, metal–metal bonded species $[V_2(edt)_4]^{2-}$ results.[2,3] The unusual nature of the vanadium(III) species prompted us to wonder what the product with chromium(III) would be. As reported by others,[3b] chromium(III) forms a complex with the empirical formula $\{(NMe_4)[Cr(edt)]\}_n$ that could not be obtained in a form suitable for crystallography. Our own efforts along these lines with the same anion proved equally fruitless. In the hope of obtaining better crystals, the related chelate 2-hydroxyethanethiol ($hetH_2$)[4] was employed, and the product was successfully characterized as $[Cr_3(het)_6]^{3-}$, suggesting the edt^{2-} complex may be of similar nuclearity and structure. More importantly, however, $[Cr_3(het)_6]^{3-}$ turned out to be the first example of a linear Cr_3^{III} unit, and it has been reported in preliminary form.[5] The prototypical nature of this complex also prompted magnetochemical studies, and the full details of this combined work are described herein.

EXPERIMENTAL

Syntheses

All manipulations were carried out under a dinitrogen atmosphere using standard anaerobic techniques and apparatus. Solvents were degassed by repeated vacuum/nitrogen cycles. Reagents were obtained commercially and used as received except $CrCl_3(THF)_3$, which was prepared as described elsewhere.[6]

Sodium metal (0.50 g, 21.7 mmol) was dissolved in EtOH (80 cm^3) with stirring and 2-hydroxyethanethiol (0.75 cm^3, 10.7 mmol) added by syringe. The septum cap on the flask was then briefly removed under a positive pressure of nitrogen, solid $CrCl_3(THF)_3$ (2.0 g, 5.3 mmol) was added in one portion, and the septum cap replaced and the flask subjected to vacuum/nitrogen cycles to remove any admitted air. The solid slowly dissolved on stirring to give a deep, blue–green solution and a fine white powder of NaCl. After stirring the solution for 2 h at room temperature, solid PPh_4Br (4.5 g, 10.7 mmol) was added as above and the solution stirred for a further 10 min. The solution was filtered and the filtrate allowed to sit undisturbed for 3 days at room temperature. Large dark green, rectangular-shaped crystals were obtained. These were collected by filtration, washed with 1:1 $EtOH/Et_2O$ (3×7 cm^3) and dried *in vacuo*; yield 40–45% based on chromium. The same procedure employing an increased het^{2-} : Cr ratio of 3:1 gave the same product in comparable yield. A sample from a reaction employing the latter ratio provided the crystal employed for the X-ray structural investigation. Found: C, 54.7; H, 5.9; P, 4.4. Calc. for $C_{60}H_{64}O_6P_2S_6NaCr_3 \cdot C_2H_5OH \cdot H_2O$: C, 54.0; H, 5.3; P, 4.5. Calc. for $C_{60}H_{64}O_6P_2S_6NaCr_3 \cdot (C_2H_5OH)_2$: C, 54.6; H, 5.4; P, 4.4. X-ray crystallography and structure solution

Data were collected on a Picker four-circle diffractometer using standard low-temperature facilities; details of the diffractometry, low-temperature facilities and computational procedures employed by the Molecular Structure Centre are available elsewhere.[7] Data collection parameters are summarized in Table 1. A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with monoclinic symmetry and systematic absences corresponding to the unique monoclinic space group $P2_1/n$, an alternate

setting of $P2_1/c$. Following data collection, routine data processing and averaging of equivalent reflections, a set of 9045 unique reflections was obtained, of which 4350 were considered observed based on the $F > 3.0\sigma(F)$ criterion. The structure was solved by a combination of direct methods (MULTAN) and standard Fourier techniques. The asymmetric unit consists of two independent anions, each lying on a centre of inversion, one sodium and two PPh_4^+ cations situated in general positions, one well-behaved EtOH solvate molecule and atoms assigned to a second solvate molecule. Because of the large number of independent atoms and the small number of observed reflections, only the non-hydrogen atoms of the anions, the sodium and the two phosphorus atoms were refined with anisotropic thermal parameters. The PPh_4^+ carbon atoms and the non-hydrogen atoms of the well-behaved EtOH molecule were refined isotropically. At this point, a difference Fourier map was used to identify the second solvate molecule. One peak was a reasonable distance from the sodium for assignment as an oxygen atom, O(54), and it refined well as such. In addition, there were six peaks clustered near O(54), but the closest was at 3.134 Å. These peaks were included as carbon atoms with isotropic thermal parameters in the final refinement cycles. Due to limitations imposed by the number of data and independent atoms, a search for a better fitting model for the poorly-behaved second solvate group(s) was not considered warranted. No hydrogen atoms were included in the final cycles. Final discrepancy indices are included in Table 1. The formula and molecular weight in Table 1 are those for $(PPh_4)_2Na[Cr_3(het)_6]\cdot EtOH\cdot H_2O$, the formulation employing only those atoms in the structure solution which are well-behaved and are at chemically-reasonable distances (*vide infra*).

Other measurements

Variable-temperature magnetic susceptibility data were collected on a Series 800 VTS-50 SQUID susceptometer operating at a magnetic field strength of 10 kG. Diamagnetic corrections were estimated from Pascal's constants for the formula $\mathbf{1}\cdot EtOH\cdot H_2O$ and subtracted from the experimental susceptibility data to obtain the molar paramagnetic susceptibility of the compound. This was then least-squares fit[8] to the appropriate theoretical expression. Solution magnetic moments were obtained in $(CD_3)_2SO$ using the Evans NMR method on a Bruker 300 MHz instrument; a co-axial NMR tube was employed and the frequency separation was measured for the two peaks of the hexamethyldisiloxane internal reference. A diamagnetic correction (Pascal's constants) was employed.

RESULTS AND DISCUSSION

Synthesis and structure

The procedure to complex **1** involves readily-available starting materials and leads to good yields of crystalline product. Treatment of $CrCl_3(THF)_3$ with two or more equiv. of $2Na/hetH_2$ leads to fairly rapid formation of a blue–green solution from which the product slowly crystallizes on addition of a PPh_4^+ salt. Even in the presence of sufficient phosphonium salt, the crystalline material contained one Na^+ cation, which can be rationalized as due to lattice energy effects; the Na^+ is interacting with the anion as will be described below. The formation of a bridged 2:1 ligand:chromium product is a consequence of the preference of the alkoxide oxygens to bridge rather than occupy terminal positions; the formation of non-mononuclear products with het^{2-} has also been observed by us in vanadium(IV) chemistry.[4]

The crystal structure and the analytical data for complex **1** indicate the presence of solvate molecules bound to the Na^+ cation. One molecule is clearly an EtOH, refining well albeit with fairly large thermal parameters. The other molecule is less clear. One atom, O(54), is 2.378 Å from the Na^+, similar to 2.289 Å for the Na—O(EtOH) interaction. Six other peaks, refined as carbon atoms, were also located and one possible interpretation is that these belong to severely disordered ethyl carbons of a second EtOH group. However, none is within 3 Å of O(24) and while this may be an artifact of the model, it is also possible that it is not EtOH. An alternative possibility is that the six peaks are from a disordered Et_2O molecule that is hydrogen-bonded to a H_2O molecule [O(24)]. Based on ana-

lytical data, the formulations **1**·2EtOH and **1**·EtOH·H_2O·Et_2O are both equally acceptable, or indeed a combination of the two.

The structure of the anion is shown in Figs 1 and 2 and selected structural parameters are listed in Table 2. The complex contains two independent anions, each lying on an inversion centre. The two anions are distinguished in Table 2 by the A and B suffixes. Each anion consists of a linear array of three chromium(III) atoms with Cr···Cr separations of 2.677(4) and 2.684(4) Å for anions A and B. Each pair of chromium atoms is bridged by three μ-oxygen atoms from three het^{2-} ligands whose sulphur atoms are terminally ligated. The unit thus consists of three face-sharing octahedra, with the central Cr1 possessing a CrO_6 ligation environment and Cr2 and Cr2′ possessing a CrO_3S_3 environment. The bridges are distinctly asymmetrical, the O—Cr1 distances 1.968(11)–1.989(12) Å being noticeably shorter than O–Cr2 distances, 2.023(13)–2.041(12) Å. All Cr—S distances are essentially identical, 2.023(13)–2.041(12) Å. The inversion centre at Cr1 and the disposition of the chelate rings affords idealized S_6 symmetry to the anions, and a view approximately down the S_6 axis is provided in Fig. 2.

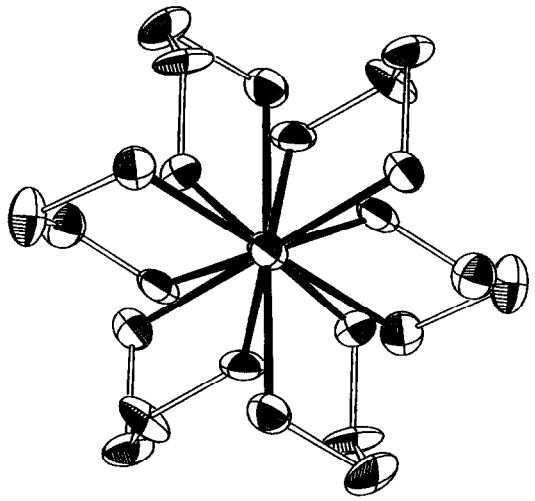

Fig. 2. View of the anion of complex **1** approximately down the Cr_3 axis emphasizing the idealized S_6 symmetry.

The structures of the two independent anions are extremely similar (Table 3) and also extremely similar to that reported for $[Cr_3(E_4)_6]^{3-}$ (E = Se, Te)[9] where E_4^{2-} serves to replace the similarly tetraatomic SCCO backbone of het^{2-} in **1**. The $[Cr_3(E_4)_6]^{3-}$ ions also lie on inversion centres and have idealized S_6 symmetry. Selected structural parameters of **1** and $[Cr_3(E_4)_6]^{3-}$ are compared in Table 3. The major difference is the Cr···Cr separations which are much shorter in **1** (~2.68 Å) than in the chalcogenide-bridged species (>3.2 Å). Note, however, that the Cr1—X_b—Cr_2 angle in the $[Cr_3(E_4)_6]^{3-}$ complexes is slightly *more* acute (~77.5°) than in **1** (~84°) suggesting the increased Cr···Cr separations in the former are merely the consequence of the larger bridging atoms and the correspondingly longer Cr—X_b distances.

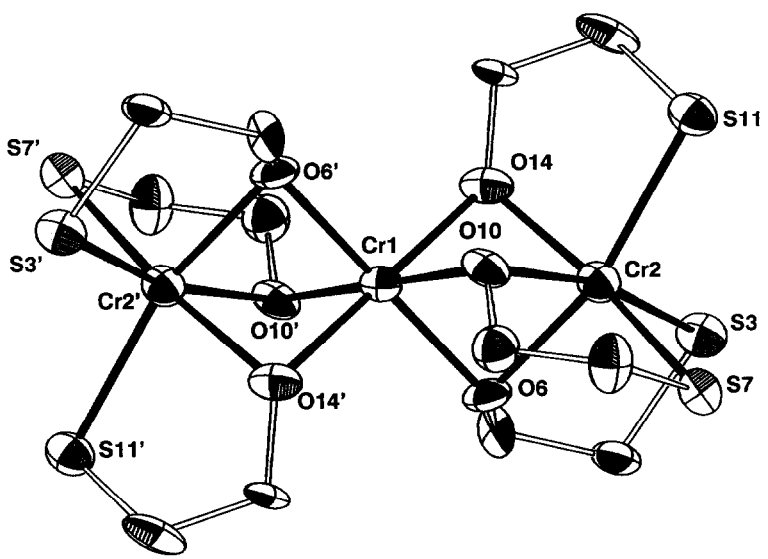

Fig. 1. ORTEP representation of one of the independent anions of complex **1** at the 50% probability level. Primed and unprimed atoms are related by the inversion centre at Cr1. Carbon atoms are numbered consecutively from S to O.

The short Cr···Cr separation (~2.68 Å) in **1** appears to be a consequence of the three RO^- bridges. As noted above, three chalcogenide (Se, Te) bridges give >3 Å separations in trinuclear species, as do the $(\mu\text{-O})(\mu\text{-O}_2\text{CR})_2$ bridges across each chromium pair in the triangular $[Cr_3O(O_2CR)_6]^+$-containing species.[10,11] For dinuclear chromium(III) species, single O^{2-} or OH^- bridges give very long (>3.6 Å) separations and large (135°) Cr—O—Cr angles,[12] whereas two OH^- or OR^- bridges give Cr···Cr separations in the *ca* 2.9–3.1 Å and Cr—O—Cr angles in the *ca* 95–104° range.[13] Only in the complex $[LCr(\mu\text{-OH})_3CrL]^{3+}$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane)[14] are the Cr···Cr separations [2.642(2) Å] and Cr—O—Cr angles [84.1(3)°] comparable to those in **1**. Similarly, short M···M separations are found in $[(NH_3)_3Co(OH)_3$

Table 3. Structural comparisons (Å, deg) between complex **1** and $[Cr_3(E_4)_6]^{3-}$ (E = Se, Te)

Parameter[a,b]	1(A)	1(B)	E = Se	E = Te
Cr···Cr	2.677(4)	2.684(4)	3.207	3.41(1)

Cr2—X_t	2.364	2.360	2.467	2.689
Cr1—X_b—Cr2	83.9	84.2	77.6	77.3

[a] Cr1 and Cr2 labelled as in Fig. 1; for $[Cr_3(E_4)_6]^{3-}$, the central and terminal chromium atoms were originally labelled Cr2 and Cr1, respectively.

[b] Quoted values represent the mean of S_6 symmetry-related parameters: b = bridging, t = terminal, X = O, S, Se or Te.

$Co(NH_3)_3]^{3+}$ [2.565(6) Å][15] and mixed valence $[LFe(OH)_3FeL]^{2+}$ [2.509(6) Å].[16]

The Na^+ cation in **1** is ligated to oxygen atoms O(S1) and O(S4) of the two solvent groups, and is also bound to four sulphur atoms, S7 and S11 of anion A, and S3 and S7 of anion B. The Na···S interactions are in the range 2.842–3.02 Å, typical for Na···S(thiolate) interactions.[17] The Na^+ ion is distorted octahedral and serves to link the two independent anions and give an extended network in the solid state.

One would not expect the Na^+ anion interactions within the solid state to remain intact on dissolution in good donor solvents such as MeCN or DMSO. However, to probe whether the anion maintains its trinuclear nature in solution, a magnetic moment determination in $(CD_3)_2SO$ was performed (Evans method). For a ~1.6 mM solution at 22.6°C, a magnetic moment of 4.68 μ_B per Cr_3 (2.70 μ_B per Cr) was obtained. This is similar to the solid-state value of 4.77 μ_B (*vide infra*) supporting retention of the trinuclear structure in solution. Disruption into mononuclear units would be expected to give 3.87 μ_B per Cr (d^3 spin-only value).

The visible spectrum of complex **1** has been recorded in DMF solution. Two broad bands are observed at wavelengths of 504 and 671 nm with extinction coefficients (ε_M/Cr_3; L mol^{-1} cm^{-1}) of 560 and 505, respectively. These features resemble those expected for isolated chromium(III) ions in near-octahedral fields and may be assigned to the $^4A_{2g} \rightarrow {}^4T_{1g}$ and $^4A_{2g} \rightarrow {}^4T_{2g}$ transitions.[10] Interpretation of the electronic spectra of weakly exchange-coupled metal aggregates in terms of the *d–d* transitions of the individual metal ions has been shown to be an acceptable approximation.[10] Particularly related to the present case are the spectra of trinuclear $Cr_3O(O_2CMe)_6(H_2O)_3^+$; these are also antiferromagnetically coupled (*vide infra*) and display spectra very similar to that of **1**.[10] The two inequivalent types of chromium(III) environments in **1** and the significant lowering of symmetry from octahedral are probably the cause of the broadness in the bands of **1**; the bands representing envelopes of several components. The exchange interactions are almost certainly the origin of the intensity enhancements seen for **1**, the ε_M values being somewhat higher than normally observed for chromium(III).

Magnetic susceptibility studies

Variable-temperature solid-state magnetic susceptibility studies were performed on powdered samples in the temperature range 2–300 K. The formulation $\mathbf{1} \cdot EtOH \cdot H_2O$ was employed in calculating the moles of material employed; use of other formulations as described above affects the values given below only slightly ($\leqslant 1\%$), comparable with the intrinsic experimental and fitting uncertainties. The effective magnetic moment per trinuclear complex, μ_{eff}/Cr_3, decreases from 4.77 μ_B at 299.9 K to 3.71 μ_B at 75.0 K, is then almost constant, decreasing to only 3.54 μ_B at 8.0 K, and then decreases more sharply to 3.16 μ_B at 2.08 K (Fig. 3). The 299.9 K value corresponds to 2.75 μ_B per chromium, significantly less than the spin-only value for a chromium(III) (d^3) centre (3.87 μ_B) and indicating the presence of intramolecular antiferromagnetic exchange interactions. The approximate plateau in the μ_{eff} vs T plot is suggestive of an $S = 3/2$ ground state (spin-only value, 3.87 μ_B/Cr_3).

The general spin-Hamiltonian describing the isotropic exchange interaction for a linear trinuclear complex is given by eq. (1).

$$\hat{H} = -2(J_{12}\hat{S}_1 \cdot \hat{S}_2 + J_{12'}\hat{S}_1 \cdot \hat{S}_{2'} + J_{22'}\hat{S}_2 \cdot \hat{S}_{2'}) \quad (1)$$

The pairwise magnetic exchange interactions

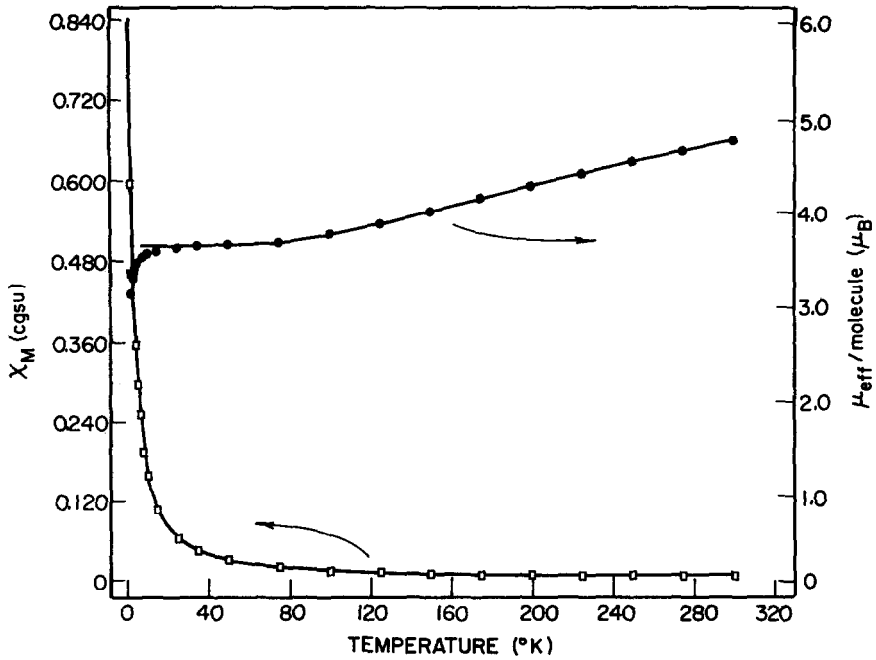

Fig. 3. Plots of the molar paramagnetic susceptibility, χ_M (□), and effective magnetic moment per trinuclear complex, μ_{eff}/Cr_3 (●), vs temperature for a polycrystalline sample of complex **1**·EtOH·H_2O. The solid lines result from a least-square fit of the data to the appropriate theoretical expression. See the text for fitting parameters.

between the central Cr1 and each of the terminal atoms Cr2 and Cr2′ must be identical by symmetry, such that $J_{12} = J_{12'} = J$. The spin-Hamiltonian of eq. (1) can therefore be simplified so that in eq. (2),

$$\hat{H} = -2J(\hat{S}_1 \cdot \hat{S}_2 + \hat{S}_1 \cdot \hat{S}_{2'}) - 2J'(\hat{S}_2 \cdot \hat{S}_{2'}), \quad (2)$$

where $J' = J_{22'}$. For complex **1**, $S_1 = S_2 = S_{2'} = 3/2$. The eigenvalues of the spin-Hamiltonian [eq. (2)] can be determined by using the Kambe vector coupling method[18a] with the coupling scheme $\hat{S}^* = \hat{S}_2 + \hat{S}_{2'}$, and $\hat{S}_T = \hat{S}^* + \hat{S}_1$. The energies of the spin states, which are eigenfunctions of the Hamiltonian in this coupling scheme, are given by eq. (3), where $S = S_1 = S_2 = S_{2'} = 3/2$. The overall degeneracy of this spin system is 64, made up of 12 spin states ranging from $S_T = 1/2$ to 9/2.

$$E = -J[S_T(S_T+1) - S^*(S^*+1) - S(S+1)] - J'[S^*(S^*+1) - 2S(S+1)] \quad (3)$$

A theoretical expression for the molar paramagnetic susceptibility χ_M vs temperature dependence was derived using eq. (3) and the Van Vleck equation;[18b] this expression was employed to fit the experimental χ_M vs T data, and a fit was obtained with $J = -37.7$ cm^{-1}, $J' = 0$ cm^{-1} and $g = 1.90$, with temperature-independent paramagnetism (TIP) held constant at 200×10^{-6} cgsu. No paramagnetic impurity correction term (PAR) was needed. The fit is shown as a solid line in Fig. 3. The zero value of J' is reasonable given the large separation between Cr2 and Cr2′. The ground state with these values of J and J' is a quartet $S_T = 3/2$ state with a doublet $S_T = 1/2$ first excited state and a sextet $S_T = 5/2$ second excited state at ~ 113 cm and ~ 189 cm^{-1} in energy above the $S_T = 3/2$ ground state. The $S_T = 3/2$ ground state is thus fairly isolated from the nearest excited states, and this rationalizes the plateau observed in Fig. 3 in the 8–75 K temperature range, essentially all molecules being in the ground state. The sharp decrease in μ_{eff} below 8.0 K is not predicted by the theoretical model employed (Fig. 3). This low-temperature behaviour may be due to either zero field splitting (ZFS) within the $S_T = 3/2$ ground state or to *intermolecular* antiferromagnetic exchange interactions. ZFS with a positive ZFS parameter D would yield a decrease in the observed value of μ_{eff} as the higher M_S states of the $S_T = 3/2$ manifold become depopulated with decreasing temperature. Alternatively, the Na^+ cation linking the anions (*vide supra*) could be mediating weak inter-anion antiferromagnetic exchange interactions which would again decrease μ_{eff} at very low temperatures. Since these effects, whatever their origin, only manifest them-

selves in the very low temperature region, it was not considered warranted or necessary to pursue a more sophisticated model.

The sign and magnitude of the exchange interactions observed for complex **1** may be compared to those determined for many other di- and trinuclear chromium(III) complexes. In the vast majority of cases, dinuclear Cr_2^{III} complexes have been found to exhibit intramolecular antiferromagnetic exchange interactions with J values in the -0.6 to -55.5 cm^{-1} range.[13] In very few cases have weak ($J = 2.2$ cm^{-1}) ferromagnetic interactions been observed.[19] For triply-bridged Cr_2^{III} species, antiferromagnetic interactions have again been observed; for the $[Cr(\mu\text{-}X)_3Cr]^{3+}$-containing complexes ($X = Cl^-$, Br^-), J values are in the 0 to -8 cm^{-1} range.[20] In contrast, $[LCr(OH)_3CrL]^{3+}$ has a significantly stronger antiferromagnetic exchange interaction ($J = -64$ cm^{-1})[21] consistent with the three shorter Cr—O bonds and better π-bonding oxygen bridges facilitating the super-exchange interaction. For trinuclear systems, antiferromagnetic interactions have been observed in the triangular $[Cr_3(\mu_3\text{-}O)]^{7+}$-containing species with J values in the -9.3 to -19.7 cm^{-1} range.[10] The value of $J = -37.7$ cm^{-1} determined for complex **1** is thus reasonable in both sign and magnitude, the relatively strong nature of the interaction being consistent with the number of bridging oxygen atoms between each Cr_2 pair.

Additional comparison can be made between complex **1** and three other linear Cr_3^{III} species. Two of these $[Cr_3(E_4)_6]^{3-}$ (E = Sc, Tc) were described above; the third is $Cr_3(lig)_2$ (lig = 1,5-diphenyl-1,3,5-pentanetrionato) which has not been structurally characterized but is assumed linear due to ligand restrictions.[22] In all four complexes, exchange interactions between adjacent chromium(III) ions are antiferromagnetic but the J value for complex **1** (-37.7 cm^{-1}) is significantly greater than those for the E = Se (-10.8 cm^{-1}), E = Te (-5.3 cm^{-1}) and lig^{2-} (-6.0 cm^{-1}) complexes. Again, these differences are consistent with the differing nature and number of bridging atoms. Interestingly, only for complex **1** does the least-squares fit give a $J' = 0$ value for interactions between the terminal chromium(III) atoms; for the other complexes J' is in the range $+1.44$ to -1.35 cm^{-1}.

(*Received* 13 *May* 1991; *accepted* 25 *June* 1991)

Abstract—Freshly prepared N,N-dimethyl-furan-2(and 3)-carboselenoamide [abbreviated as H(C-E), or as Hafs and Hbfs, respectively] was cyclopalladated with lithium tetrachloropalladate in methanol giving PdCl(C-E), which reacted with tri-n-butylphosphine (PBu_3) and 4-t-butylpyridine (tbp) to give the adducts PdCl(C-E)(PBu_3) and PdCl(C-E)(tbp), respectively. The iodo analogues were also prepared. Spectroscopic characterization revealed that the furan ring of H(C-E) is cyclopalladated and the selenium atom of the selenoamide group is coordinated to form a five-membered palladaselenaheterocycle. The cyclopalladation of Hbfs occurs exclusively at position 2 of the furan ring. The two selenoamides are cyclorhodated with trichlorobis(tri-n-butylphosphine)rhodium(III) in refluxing toluene to give $RhCl_2$(C-E)$(PBu_3)_2$. The bromo analogues are similarly obtained. Hbfs is similarly cycloruthenated with dichlorotricarbonylruthenium(II) in refluxing 2-methoxyethanol to afford RuCl(bfs)$(CO)_2$, but Hafs is not cycloruthenated under the same conditions. This fact suggests that Hbfs is more reactive towards cyclometallation than Hafs.

Cyclometallated compounds are now recognized as being potentially useful starting materials for organic synthesis and applications to organic synthesis are now becoming a subject of rapidly growing interest.[1] Most of the applications reported concern cyclometallated benzene derivatives and little has been studied regarding such applications of heterocycles, because of a deficiency in the knowledge of cyclometallated heterocycles.[2] This requires investigation for cyclometallation of heterocycles and we have recently been interested in this subject.

An N,N-dimethylthiocarbamoyl group was previously shown to be a good auxiliary substituent which promotes cyclometallation of heterocycles such as furan[3,4] and thiophene.[5] The study is now extended to those heterocycles substituted with a homologous N,N-dimethylselenocarbamoyl group. The cyclometallation with a selenium donor as an auxiliary group is, to the best of our knowledge, the first example. In this paper the results of cyclometallation of N,N-dimethyl-furan-2(and 3)-carboselenoamide (abbreviated as Hafs and Hbfs, respectively) are described and the results of the thiophene derivatives will be separately reported elsewhere. The preliminary report has already appeared.[6]

RESULTS AND DISCUSSION

N,N-dimethyl-furan-2(and 3)-carboselenoamide (Hafs and Hbfs) were obtained by the reaction of the corresponding carboxamides with phenyldichlorophosphine selenide and characterized spectroscopically (Tables 1 and 2).[6] The selenoamides

[a] Only the signals due to Hafs and Hbfs are given in this table. $CDCl_3$ was used as a solvent unless otherwise noted. The signals of $N(CH_3)_2$ are singlets, br = broad, d = doublet, and t = triplet.
[b] The 3-H signal is at 7.19 ppm (dd) (J = 3.5, 0.9 Hz).
[c] Dimethyl sulphoxide-d_6 is used as a solvent.
[d] $^2J(^{31}P—^{77}Se)$.
[e] $J(^1H—^{31}P)$.
[f] Overlapped with other signals.
[g] $^1J(^{31}P—^{103}Rh)$.
[h] The 2-H signal is at 7.72dd (0.9, 1.5).
[i] Accompanied with several weak signals.

[a] Only the signals due to Hafs and Hbfs are given in this table. Solvents are the same as those used for ^1H NMR measurements. Signals for which no coupling constant is given are singlets.

[b] $^1J(^{13}C—^{77}Se)$.

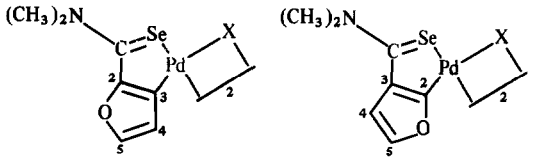
[c] Measured in the presence of tris(acetylacetonato)chromium(III) as a relaxation reagent.

[d] Low concentration prevented identification of signals.

[e] $J(^{13}C—^{103}Rh)$.

[f] $\delta(^{13}C)$ of CO is 191.8, 201.3; 195.1(8.6), 213.2(90.5); 191.7(15.6), 209.8ppm(154.8 Hz) in order of listing.

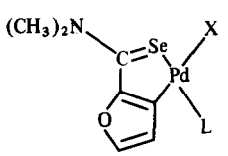
reacted with lithium tetrachloropalladate in methanol to give, PdCl(afs) and PdCl(bfs), respectively, for which we have already proposed structures **I** and **II**.



I **II**

These palladium complexes reacted with tri-n-butylphosphine (PBu_3) and 4-t-butylpyridine (tbp) to give the adducts as shown in Table 3. Metathesis of these complexes with excess lithium iodide in acetone afforded the iodo complexes (Table 3). The IR spectra of these complexes (Table 1) reveal that the selenoamide group is coordinated through a selenium atom:[7] the ν(C—N) bands are in the same region as those of the parents. The appearance of ν(Pd—Cl) is an indication of the coordination of chlorine donors.

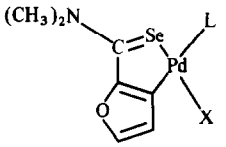
The ^{1}H, ^{13}C{^{1}H} and ^{31}P{^{1}H} NMR spectral results are summarized in Tables 1 and 2. The ^{1}H and ^{13}C spectral patterns essentially resemble those of the parents, suggesting that the cyclopalladated skeletons are retained in these adducts. The ^{1}H and ^{13}C spectral patterns and the ^{31}P chemical shift of PdCl(afs)(PBu_3) are very similar to those of the corresponding thioamide analogue PdCl(aft)(PBu_3) (Haft = N,N-dimethyl-furan-2-carbothioamide) reported previously,[3] to which a *trans*-(C, Cl) arrangement was assigned (cf. structure **III**) (in this



III, *trans*-(C,X)

notation C represents a metallated carbon atom). For the present complex the *trans*-(C, Cl) geometry is further confirmed by the value $^2J(^{31}P—^{77}Se) = 129.9$ Hz, which is in the range reported for a *trans*-(P, Se) arrangement.[8]

The ^{1}H, ^{13}C and ^{31}P NMR spectra of PdI(afs)(PBu_3) reveal that in a $CDCl_3$ solution two isomers exist in a ratio of 57:43 (the ratio is estimated based on the integration intensity of the ^{1}H NMR spectrum). The more abundant isomer shows spectra similar to those of the above mentioned PdCl(afs)(PBu_3), to which a *trans*-(C, X) geometry (**III**) was assigned. The ^{31}P chemical shift of the minor isomer is at a significantly high field to indicate that the phosphorus donor is coordinated *trans* to a carbon donor with a strong *trans* influence[9] which is also consistent with a large J(P—C) value of 3-C (Table 2). A *cis*-(C, X) geometry (structure **IV**) is suited for this; phosphorus and selenium donor



IV, *cis*-(C,X)

atoms are, as a matter of course, in a *cis* relation showing no P—Se coupling. The remarkable downfield shift of the 4-H of the furan ring is also consistent with this arrangement because the 4-H is in proximity to the bulky iodo donor which induces a downfield shift for a nearby proton.[10]

The ^{1}H and ^{13}C NMR spectra of PdCl(afs)(tbp) in $CDCl_3$ solution show the presence of two isomers in the ratio 17:83. The chemical shift of the 4-H of the furan ring is very different between the isomers and very informative (Table 1). In the minor isomer the 4-H is shielded while in the major isomer the 4-H is deshielded relative to that of free Hafs. The difference is explained as follows. In the former case the 4-H is placed in the shielding region of the pyridine ring ligated perpendicularly to the coordination plane; structure **III** (L = tbp; X = Cl) is assigned to this isomer. In the latter case the 4-H deshielding is caused by the nearby located chloro donor[10] in a similar manner as for the above *cis*-(C, I)-PdI(afs)(PBu_3) (structure **IV**: L = tbp; X = Cl). The NMR spectral patterns of PdI(afs)(tbp) are essentially similar to those of the major isomer of PdCl(afs)(tbp) and a *cis*-(C, I) geometry is suitable for this iodo complex. The halogen-dependent chemical shift of 4-H (7.26 ppm for X = Cl and 7.57 ppm for X = I) is consistent with the arrangement where the 4-H is situated near the halogen X.[10]

The ^{1}H and ^{13}C NMR spectra of PdX(bfs)(PBu_3) (X = Cl, I) are similar to those of the parent compound and show the absence of isomerism. The ^{31}P chemical shifts and ^2J(P—Se) values of the two are similar to those of *trans*-(C, X)-PdX(afs)(PBu_3) and structure **V** (X = Cl, I; L = PBu_3) is proposed for the two. For the corresponding thiophene analogue this geometry has been confirmed by X-ray analysis.[11] PdI(bfs)(tbp) exists as a single species but in the case of PdCl(bfs)tbp, two isomers are detected in the ratio 71:29. The structures of these are assumed

Table 3. Yields, m.p.s and analytical results of the complexes

[a] Abbreviations: Hafs = N,N-dimethyl-furan-2-carboselenoamide, Hbfs = N,N-dimethyl-furan-3-carboselenoamide, PBu_3 = tri-n-butylphosphine, tbp = 4-t-butyl-pyridine and etpb = 4-ethyl-2,6,7-trioxa-1-phosphabicyclo[2.2.2]octane.

[b] dec. = decomposition.

based on the ^1H chemical shifts of the tbp ligand: when tbp is coordinated *cis* to a carbon donor the 2-H chemical shift is at a lower field than that when tbp is *trans* to a carbon donor. This relationship has been confirmed for the above mentioned afs complexes as well as the furan and thiophene thioamide analogues reported previously. The 2-H chemical shift of tbp of the major isomer is at 8.80 ppm, while that of the minor one is at 8.61 ppm. The major isomer has a *trans*-(C, Cl) structure (V)

Table 4. Relative abundance[a] of *trans*-(C, X) and *cis*-(C, X) isomers of PdX(C-E)(L) (C-E = aft, bft, afs and bfs)[b]

C-E\L/X	tbp/C	tbp/I	PBu_3/Cl	PBu_3/I
aft	*trans* 18%		*trans* 100%	*trans* 82%
	cis 82%	*cis* 100%		*cis* 18%
bft	*trans* 67%		*trans* 100%	*trans* 100%

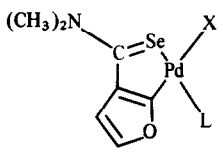
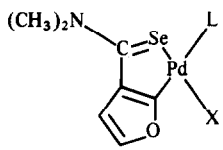
afs	*trans* 17%		*trans* 100%	*trans* 57%
	cis 83%	*cis* 100%		*cis* 43%
bfs	*trans* 71%		*trans* 100%	*trans* 100%
	cis 29%	*cis* 100%		

[a] Relative abundance was estimated based on the integration intensities of the ^1H NMR spectra in $CDCl_3$ solutions at ambient temperature.
[b] C represents a palladated carbon atom.

and the minor is *cis*-(C, Cl) (**VI**). The spectral pat-



V, *trans*-(C,X)

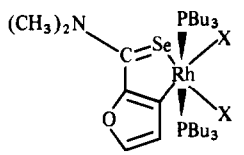


VI, *cis*-(C,X)

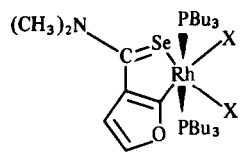
tern of the iodo complex is very similar to that of the minor isomer and a *cis*-(C, I) geometry is suggested for the iodo analogue. The structure of the corresponding thiophene selenoamide derivative has been confirmed by X-ray analysis to have a *cis*-(C, I) geometry.[11]

The isomerism found for these palladium complexes is similar to that for the corresponding thioamide analogues (Table 4) showing that Cl and PBu_3 ligands prefer a *trans*-(C, X) arrangement to a *cis* one, whilst I and tbp ligands prefer *cis*-(C, X) to *trans*-(C, X). A similar preference also exists in the isomerism of cyclopalladated N,N-dimethylferrocenecarbothioamide[12] and N,N-dimethylthiophene-2(and 3)-carbothioamide[5] derivatives. We are now seeking the cause of the isomerism.

The two selenoamides were cyclorhodated with $RhX_3(PBu_3)_2$ in refluxing toluene to form RhX_2(afs)$(PBu_3)_2$ and RhX_2(bfs)$(PBu_3)_2$ (X = Cl, Br). The IR spectra show selenium-coordination of a selenoamide group[7] and the coordination of chlorine donors is apparent from the presence of ν(Rh—Cl) bands (Table 1). The ^{31}P NMR spectra indicate that the two PBu_3 ligands are equivalent and the ^1J(Rh—P) values reveal that the two phosphorus donors are coordinated *trans* to each other. The ^1H and ^{13}C spectral patterns are essentially similar to those of the above palladium complexes except that the ^{13}C signals of the 3-C (afs) and 2-C (bfs) of the furan ring appear as a doublet [^1J(Rh—C)] of triplets [^2J(P—C)] (Table 2). These data are consistent with structures **VII**(afs) and **VIII** (bfs). The thioamide analogue Haft[3] is not cyclo-



VII



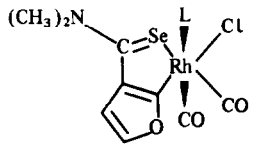
VIII

rhodated with $RhCl_3(PBu_3)_2$ in the same conditions employed here, suggesting that the auxiliary ability of an N,N-dimethyl-selenocarbamoyl group should be superior to that of the corresponding thioamide analogue.

The reactivity of Hafs and Hbfs toward $RuCl_2(CO)_3$ in hot 2-methoxyethanol is very different: Hafs gave only the adduct $RuCl_2$(Hafs)$_2(CO)_2$ while Hbfs was cycloruthenated to afford RuCl(bfs)$(CO)_2$ (Table 3). The former is hardly soluble in common solvents preventing measurement of an NMR spectrum, but the IR spectrum (Nujol mull) reveals selenium coordination of the selenoamide group [ν(C—N) = 1537, 1571 cm^{-1}] and *cis*-coordination of the two CO groups [ν(CO): 1966, 2037 cm^{-1}] as well as the two chlorine donors [ν(Ru—Cl) = 298, 268 cm^{-1}].

The IR spectrum of RuCl(bfs)$(CO)_2$ shows strong ν(CO) bands at 2064, 2049 and 1986br cm^{-1}. The ^1H NMR spectrum of a $CDCl_3$ solution was complicated and that of a dmso-d_6 solution showed

one set of main signals (Table 1), accompanied by several weak signals suggesting the presence of isomers. The complex reacted with phosphorus donors to give the adducts (Table 3). The ^1H and ^{13}C NMR spectra (Tables 1 and 2) are essentially similar to those discussed above to confirm cyclometallation of Hbfs. The large ^2J(P—C) observed for one CO group reveals that the CO and phosphorus donors are coordinated *trans* to each other. The IR spectra of the two show two strong ν(CO) bands [2033, 1962 (PBu_3); 2056, 1996 (etpb)] to suggest *cis*-coordination of the two CO groups. Structure **IX**



IX

(L = PBu_3, etpb) is tentatively proposed but X-ray analysis will be required for confirmation.

EXPERIMENTAL

Measurements

NMR spectra were recorded on Hitachi R-90H (^1H, 90 MHz; ^{13}C, 22.6 MHz; ^{31}P, 36.4 MHz) and Jeol PMX-60 (^1H, 60 MHz) spectrometers. Chemical shifts (δ ppm) were relative to internal tetramethylsilane (^1H, ^{13}C) and to external 85% H_3PO_4 (^{31}P). IR spectra (Nujol mulls) were measured on Jasco IR-A3 and Hitachi EPI-L spectrometers.

Synthesis

Yields, m.p.s, and analytical results are summarized in Table 3.

N,N-Dimethyl-furan-2(and 3) carboselenoamide. The two selenoamides were prepared according to the method reported in the literature.[13] The reaction time employed was 6 h and the two oily amides became an orange solid in the freezer,

PdX(C-E) (X = Cl, Br; C-E = afs, bfs). To a methanol solution (30 cm^3) of lithium tetrachloro (bromo) palladate, prepared *in situ* from palladium(II) chloride (1 mmol) and lithium chloride (2 mmol) (4 mmol of lithium bromide), was added Hafs (Hbfs) (1 mmol) and the mixture was stirred overnight at room temperature. A brown precipitate was collected, washed with methanol and dried in air.

PdCl(afs)(PBu_3). To a suspension of PdCl(afs) (1 mmol) in dichloromethane (30 cm^3) was added PBu_3 (1 mmol) and the mixture was stirred until it became almost clear. To the concentrated solution was added n-hexane in small portions and an initially precipitated brown material was filtered off. Further addition of n-hexane gave a yellow precipitate, which was filtered, washed with n-hexane and dried in air. The iodo analogue was obtained upon metathesis of the chloro complex with excess lithium iodide in acetone. The other palladium complexes were similarly prepared (tbp was used in a two-fold excess and the addition of a few drops of tbp was required in the metathesis reaction with lithium iodide).

RhX_2(C-E)(PBu_3)$_2$ (X = Cl, Br; C-E = afs, bfs). A mixture of $RhX_3(PBu_3)_2$ (1 mmol) and Hafs (Hbfs) (1 mmol) in toluene (30 cm^3) was refluxed with stirring for 6 h and evaporated to dryness under reduced pressure. The residue was dissolved in dichloromethane and the solution was filtered. To the filtrate was added n-hexane and the mixture was then concentrated to a small volume to precipitate yellow crystals, which were collected, washed with n-hexane and dried in air.

$RuCl_2(Hafs)_2(CO)_2$ *and* RuCl(bfs)$(CO)_2$. A mixture of $RuCl_2(CO)_3$ (1 mmol) and Hafs(Hbfs) (1 mmol) in 2-methoxyethanol (30 cm^3) was stirred under reflux for 3 h. Upon cooling the reaction mixture, $RuCl_2(Hafs)_2(CO)_2$ precipitated as a yellow powder, which was collected, washed with ethanol and dried in air. In order to isolate RuCl(bfs)$(CO)_2$, the reaction mixture was evaporated under reduced pressure to near dryness and addition of ethanol to the mixture resulted in the precipitation of a light brown powder, which was similarly treated.

RuCl(bfs)$(CO)_2$(L) (L = PBu_3, etpb). The adducts were prepared in a similar manner as for the above palladium phosphine complexes.

(*Received* 25 *February* 1991; *accepted* 17 *June* 1991)

Abstract—Metathesis reactions were used to prepare dimolybdenum(II,II), diruthenium (II,III) and dicopper(II,II) tetra-μ-carboxylato complexes containing unsaturated aliphatic carboxylate ligands (O_2CR) {R^1 = $HC{=}CH_2$, R^2 = $(CH_3)C{=}CH_2$, R^3 = $H_2CHC{=}CH_2$, R^4 = C_7H_9, R^5 = C_8H_{11}}. The X-ray crystal structure of $[Ru_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4Cl]$ (**9**) shows that there are two independent centrosymmetric Ru_2L_4 dimers in the unit cell, bridged by chlorine atoms to form an infinite polymeric chain. Principal dimensions are Ru—Ru 2.287(1) and 2.290(1) Å, Ru—Cl 2.555(2) and 2.572(2) Å, Ru—Cl—Ru 118.29(7)°. The terminal ethylene ($=CH_2$) and methyl ($-CH_3$) groups of the ligand are mutually disordered. The bicyclo[2.2.1]hept-5-ene-2-carboxylato complexes $[Mo_2(\mu\text{-}O_2CR^4)_4]$ (**3**), $[Ru_2(\mu\text{-}O_2CR^4)_4Cl]$ (**8**) and $[Cu_2(\mu\text{-}O_2CR^4)_4]\cdot 2H_2O$ (**14**) were also synthesized by the Diels–Alder [4+2] cycloaddition reaction of cyclopentadiene with the respective propenoato complexes, $[Mo_2(\mu\text{-}O_2CR^1)_4]\cdot 0.5H_2O$ (**2**), $[Ru_2(\mu\text{-}O_2CR^1)_4Cl]\cdot 2HO_2CR^1$ (**7**) and $[Cu_2(\mu\text{-}O_2CR^1)_4]\cdot 2H_2O$ (**13**). The bicyclo[2.2.1]hept-5-ene-2-methyl-2-carboxylato complex, $[Ru_2(\mu\text{-}O_2CR^5)_4Cl]$ (**10**), was prepared by a similar cycloaddition route from $[Ru_2(\mu\text{-}O_2CR^2)_4Cl]$ (**9**). No Diels–Alder adducts were formed when cyclopentadiene was reacted with $[Mo_2(\mu\text{-}O_2CR^2)_4]\cdot 0.5H_2O$ (**4**), $[Cu_2(\mu\text{-}O_2CR^2)_4]\cdot 2H_2O$, $[Cu_2(\mu\text{-}O_2CR^3)_4]\cdot 2H_2O$ and $[Ru_2(\mu\text{-}O_2CR^3)_4Cl]$ (**11**).

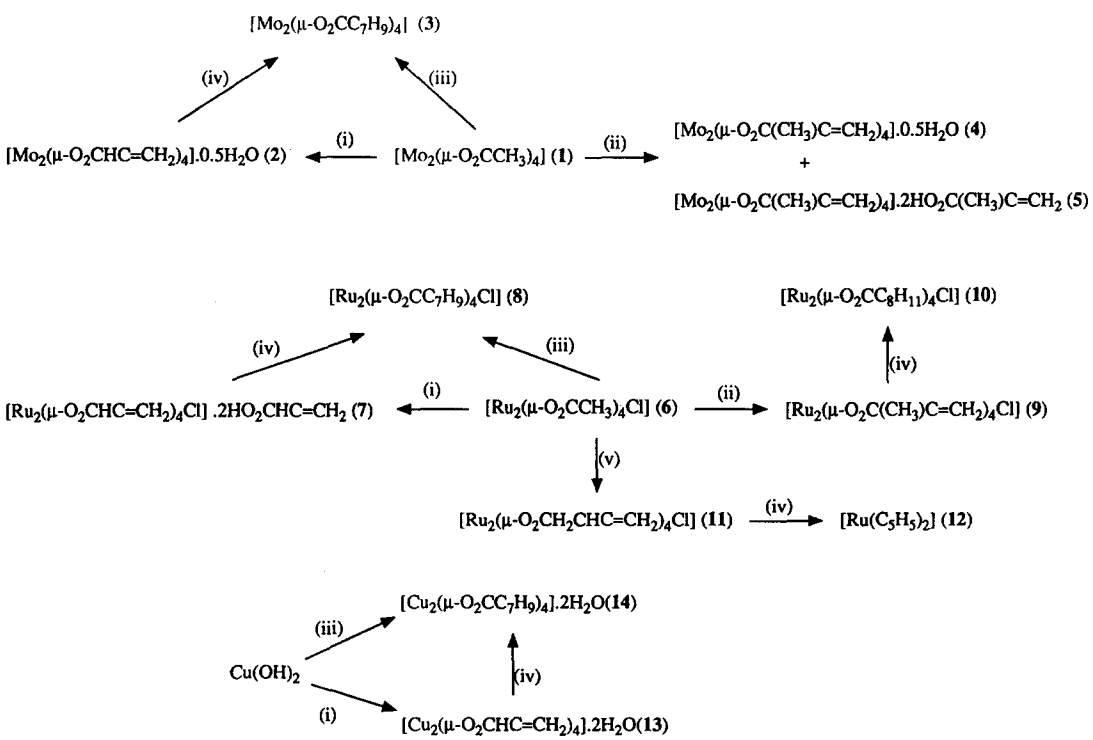
Although much has been written about the chemistry of bimetallic complexes containing saturated alkyl carboxylate bridging ligands[1a,2] relatively little is known about complexes containing the anions of unsaturated aliphatic carboxylic acids. A family of dicopper(II,II) complexes of the general formula $[Cu_2(\mu\text{-}O_2C(H_2C)_nHC{=}CR^1R^2)_4L_x]$ (R^1 = H, CH_3; R^2 = H, CH_3; n = 0, 1, 2, 3; L = heterocyclic nitrogen ligand or PPh_3; x = 0, 2) have been prepared and their magnetic properties studied.[3–6] Mononuclear copper(II) complexes of the formula $[Cu(O_2C(H_2C)_nHC{=}CH_2)_2(py)_2]$ (n = 0, 1, 2) were made by reacting the respective dicopper(II,II) complexes, $[Cu_2(\mu\text{-}O_2C(H_2C)_nHC{=}CH_2)_4$, with pyridine.[3] Resnik and Douglas[7] carried out a polarographic and potentiometric investigation of the effect of the variation of the structural features of unsaturated carboxylic acids (2-butene-1,4-dicarboxylic, 3-butenoic, *trans*-2-butenoic and *cis*-

* Authors to whom correspondence should be addressed.

and *trans*-butenedioic acid) on the stability of complexes formed with Cu^{II}, Cu^{I}, Ag^{I} and Zn^{II}. The crystal structures of the *trans*-2-butenoate complexes $[M_2(\mu\text{-}O_2CHC{=}CH(CH_3))_4(\text{quinoline})_2]$ (M = Cu,[8] Zn[9]) have been described. Mono-, di- and trinuclear cobalt(II) complexes of the formula $[Co_n(O_2C(R^3)C{=}CR^2R^1)_{2n}L_2]$ (R^1 = H, CH_3; R^2 = H, CH_3; R^3 = H, CH_3; L = sterically hindered amine; n = 1, 2, 3) were prepared by reacting $CoCO_3$ with the unsaturated carboxylic acid in the presence of controlled amounts of amine.[10] In addition, homo- and heterotrinuclear *trans*-2-butenoate complexes of the formula $[Zn_3(O_2CHC{=}CH(CH_3))_6L^1{}_2]$[11] and $[MZn_2(O_2CHC{=}CH(CH_3))_6L^2{}_2]$[12] ($L^1$ = quinoline; $L^2 = L^1$, 6-methylquinoline; M = Mn, Co, Ni, Zn, Cd, Mg, Ca, Sr) have also been prepared and structurally characterized. *Trans*-$[Pt(O_2C(H_2C)_n(R)C{=}CH_2)H(\text{tricyclohexylphosphine})_2]$ (R = CH_3, n = 0; R = H, n = 1) complexes have been synthesized by the oxidative addition of 2-methylpropenoic and 3-butenoic acids to $[Pt(cod)_2]$ (cod = 1,5-1,5-cyclooctadiene),[13] and in these complexes the carboxylate ligand is bonded to the metal by only one of its oxygen atoms. Furthermore, Carmona *et al.*[14] have reacted mononuclear ethylene complexes, *trans*-$[M(C_2H_4)_2(PCH_3)_4]$ (M = Mo, W), with carbon dioxide under mild conditions to give binuclear propenoic acid complexes, $[M_2(HO_2CHC{=}CH_2)_2(C_2H_4)_2(PCH_3)_4]$, and the structure of the dimolybdenum complex was determined by X-ray analysis. Chelating 3-butenoate (via the olefin moiety and one carboxyl oxygen) has been inferred in catalytic cycles for rhodium-catalysed C—C coupling of allenes with 3-butenoic acid,[15] and also in the catalysis of C—C bond formation reactions by nickel complexes.[16] Polymeric dimolybdenum(II,II)[17] and monomeric cobalt(III)[18] complexes containing unsaturated dicarboxylate ligands are also known. In this paper we report on the synthesis of a range of new dimolybdenum(II,II) and diruthenium(II,III) complexes containing unsaturated carboxylato ligands, and the structure of the diruthenium complex $[Ru_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4Cl]$ (**9**) is described. In addition, the reactivity of the pendant C=C groups of the new complexes [and analogous dicopper(II,II) complexes] with cyclopentadiene was investigated.

RESULTS AND DISCUSSION

Routes to the bimetallic molybdenum, ruthenium and copper complexes containing unsaturated carboxylato ligands are summarized in Scheme 1, and selected IR data are listed in Table 1. In general,



Scheme 1. (i) $CH_2{=}CHCO_2H$, (ii) $CH_2{=}C(CH_3)CO_2H$, (iii) $C_7H_9CO_2H$, (iv) cyclopentadiene, (v) $CH_2{=}CHCH_2CO_2H$.

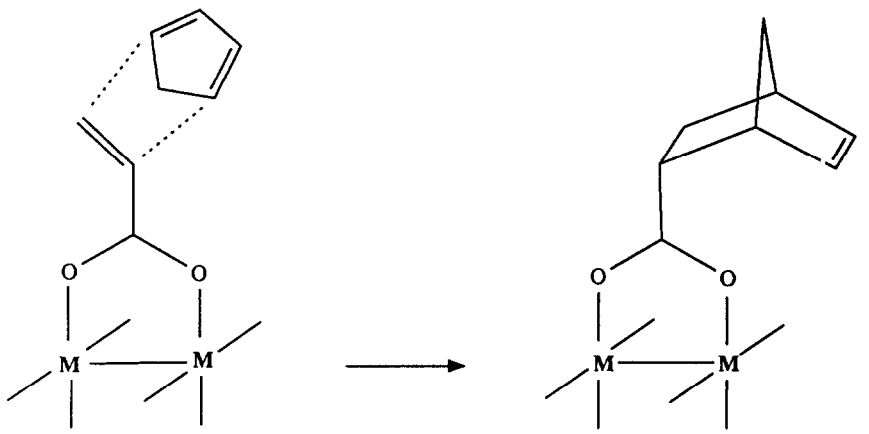
[b] $\nu(OH)_{s,b}$ of acid 2500–3500 cm^{-1}.
[c] $\nu(C{=}O)$ of acid molecules 1690 cm^{-1}.
[d] $\nu(C{=}O)$ of acid molecules 1725 cm^{-1}.
[e] Separate $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ bands were not distinguishable in the broad band centred around this value.

the new unsaturated carboxylato complexes were found to be much more soluble in organic solvents than their saturated precursors. The dimolybdenum(II,II) parent complex (**1**) was treated with a large excess of the incoming unsaturated acid for conversion to the respective tetra-substituted product. In the case of the parent diruthenium(II,III) acetato complex (**6**), two successive metathesis cycles with the incoming unsaturated acid were required to procure complete conversion to the pure tetra-substituted product. The mass spectra of the ruthenium products obtained after only one methathesis cycle showed that the solids were mixtures. In addition to the ion fragment which corresponded to the fully-substituted product ($[Ru_2(\mu\text{-}O_2CR)_4]^+$) {R = unsaturated carboxylate ligand}, fragments attributable to partially-substituted species (e.g. $[Ru_2(\mu\text{-}O_2CCH_3)(\mu\text{-}O_2CR)_3]^+$) were also observed. Mixed-carboxylate product mixtures indicative of incomplete carboxylate exchange have previously been reported for substitution reactions involving diruthenium,[19] dirhodium[20] and dimolybdenum[21,22] complexes. Attempts to prepare the neutral, dimolybdenum tetra-μ-3-butenoate complex $[Mo_2(\mu\text{-}O_2CH_2CHC{=}CH_2)_4]$ by reacting $[Mo_2(\mu\text{-}O_2CR)_4]$ (R = CH_3, C_6H_5) with excess 3-butenoic acid in methanol were unsuccessful, and in each case the only product recovered was a brown, insoluble molybdenum-oxo complex.*

Two methods were used to prepare each of the unsaturated bicyclocarboxylato complexes (**3**), (**8**) and (**14**), with the most direct route being the reaction of *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid ($C_7H_9CO_2H$) with **1**, **6** and copper(II) hydroxide, respectively. The second method involved the reaction of cyclopentadiene (*ca* 20°C) with the respective tetra-μ-propenoato complexes **2**, **7** and **13**. This latter method features four Diels–Alder [4+2] cycloaddition reactions on each molecule of **2**, **7** and **13**, with each of the propenoato ligands behaving as a dienophile (Scheme 2). The diruthenium(II,III) bicyclo[2.2.1]hept-5-ene-2-methyl-2-carboxylato complex (**10**) was also obtained in high yield by the Diels–Alder route (**9** → **10**). Surprisingly, the 2-methylpropenoato molybdenum complex (**4**) and its copper analogue, $[Cu_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4]\cdot 2H_2O$,† both failed to give a Diels–Alder adduct with cyclopentadiene, and essentially unreacted starting complexes were recovered in each case. Whereas the synthesis of complex **10** was accomplished at *ca* 20°C, the usual Diels–Alder method for preparing bicyclo[2.2.1]hept-5-ene-2-methyl-2-carboxylic acid from 2-methylpropenoic acid and cyclopentadiene requires much more forcing conditions (e.g. 2 h at 150°C in a sealed tube[23]). On comparing the reactivities of free 2-methylpropenoic acid and complex **9** towards cyclopentadiene it might be argued that the inductive effect of the Ru_2^{5+} core of **9** enhances the reactivity

* The IR spectrum of the brown solid contained prominent Mo-oxo bands at 740 and 470 cm^{-1} and a broad band in the region 2700–3700 cm^{-1} (O—H and hydrogen-bonding). Analytical data: Found: C, 15.7; H 2.4%.

† This complex was made using the same general procedure outlined in ref. 3 except that freshly prepared copper(II) hydroxide was used instead of basic copper carbonate.



M = Mo, Ru, Cu

Scheme 2.

of the C=C group of the 2-methylpropenoate ligand towards cycloaddition (i.e. activates the dienophiles). Under the same reaction conditions the Mo_2^{4+} core of **4** and the Cu_2^{4+} core of $[Cu_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4]\cdot 2H_2O$ do not appear to have the same activating power as their Ru_2^{5+} analogue. In addition to any beneficial inductive effects that may be operative in the above Diels–Alder reactions there may also be a contribution from the localized "ordered" nature of the complexed dienophiles. Having the four dienophiles bonded to the metal centres via their carboxylate groups confines their movement and effectively compresses them in the same way as the "macroscopic" application of external pressure. As the [4+2] cycloaddition reaction has a negative volume of activation this "ordering" effect should help to raise the ground-state energy of the dienophiles relative to the transition state, thereby lowering the activation energy.[24]

No Diels–Alder adducts were formed on reacting cyclopentadiene (*ca* 20°C) with the 3-butenoate complexes $[Cu_2(\mu\text{-}O_2CH_2CHC{=}CH_2)_4]\cdot 2H_2O$* and **11**. In the latter case ruthenocene (**12**) was isolated from the reaction mixture after prolonged standing. This formation of ruthenocene can be compared to the reaction of $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ with sodium cyclopentadienide to give a molybdenocene dimer containing a bridging fulvalene ligand, $(\eta^5{:}\eta^5\text{-}C_{10}H_8)[(\eta^5\text{-}C_5H_5)MoH]_2$.[25] The apparent lack of reactivity of the copper and ruthenium 3-butenoate complexes towards cycloaddition is not totally surprising since the presence of the methylene group between the olefinic and carboxylate functions of the β,γ-unsaturated 3-butenoate ligand will have a significant deactivating effect on the dienophile. Alder and Windemuth[26] reported that the addition of cyclopentadiene to 3-butenoic acid, to give bicyclo[2.2.1]hept-5-ene-2-acetic acid, was indeed much slower (affected at 170–180°C) than that to propenoic acid. Furthermore, Sallerno *et al.*[27] have recently reported the rhodium-catalysed reaction of 3-butenoic acid with cyclopentadiene to give bicyclo[2.2.1]hept-5-ene-2-acetic acid.

The crystal structure of $[Ru_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4Cl]$ (**9**) consists of two independent centrosymmetric Ru_2L_4 dimers which are linked by a bridging chlorine atom, to form a polymeric chain (Fig. 1). Table 2 lists the principal dimensions. Each ruthenium atom has octahedral coordination with Ru(1)—Ru(1) 2.287(1), Ru(2)—Ru(2) 2.290(1), Ru(1)—Cl 2.555(2), Ru(2)—Cl 2.572(2), Ru—O 2.006(5)–2.026(5), mean 2.018(5) Å, Ru(1)—Ru(1)—Cl 177.99(5), Ru(2)—Ru(2)—Cl 174.28(5) and Ru(1)—Cl—Ru(2) 118.29(7)°. These dimensions are similar to those observed in several other determinations of the type Ru_2L_4Cl (where L is a carboxylate ligand).[1b] Unlike complex **9** there is no disorder in the unsaturated *trans*-2-butenoate ligands in the complexes $[M_2(\mu\text{-}O_2CHC{=}CH(CH_3))_4(\text{quinoline})_2]$ (M = Cu,[8] Zn[9]).

EXPERIMENTAL

Literature methods were used to prepare $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ (**1**),[29] $[Ru_2(\mu\text{-}O_2CCH_3)_4Cl]$ (**6**),[30] $[Cu_2(\mu\text{-}O_2CHC{=}CH_2)_4]\cdot 2H_2O$ (**13**)* and *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid.[31] Reac-

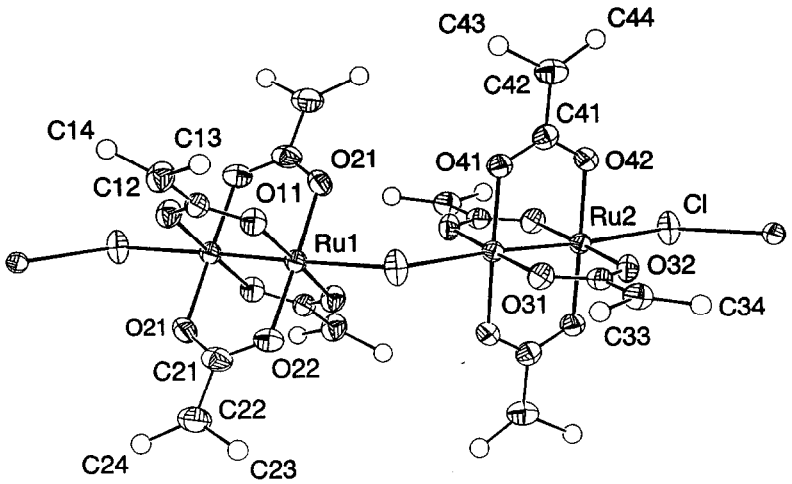

Fig. 1. A view of the $Ru_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4Cl$ polymeric chain with our numbering scheme. The sites of the disordered $=CH_2$ and $-CH_3$ groups are shown as spheres of arbitrary size.[28]

tions were carried out in the air except in the case of the molybdenum complexes which were conducted under nitrogen using standard Schlenk techniques. In general, the molybdenum samples were found to be very air and moisture sensitive. Elemental analyses were performed by the Microanalytical Laboratory, University College Cork, Ireland. IR spectra were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 783 grating spectrometer, and UV–vis spectra were run on a Milton Roy Spectronic 3000 Array. Solid-state, room temperature magnetic susceptibility measurements were made on a Johnson Matthey Magnetic Susceptibility Balance, and mass spectra were obtained using an AEI MS30 instrument equipped with an MSS Data System.

Crystallography

Crystals of **9** suitable for X-ray analysis were obtained by slow evaporation of a methanol solution at ambient temperatures. The crystal chosen was a dark red block of approximate dimensions $0.22 \times 0.12 \times 0.18$ mm.

Crystal data for $C_{16}H_{20}O_8ClRu_2$ (**9**), $M_r = 577.9$, monoclinic, space group $P2_1/a$, $a = 9.062(2)$, $b = 17.815(4)$, $c = 12.792(2)$ Å, $\beta = 92.69(2)°$, $V = 2063(2)$ $Å^3$, $Z = 4$, $D_x = 1.86$ g cm^{-3}, $\mu = 16.0$ cm^{-1}, $F(000) = 1140$, graphite monochromatized λ (Mo-K_α) = 0.71073 Å, $T = 15°C$. 5028 reflections were measured on a CAD4 diffractometer ($2\theta_{max} = 54°$), 4919 were unique and 2871 had $I > 3\sigma(I)$. Lorentz, polarization and empirical absorption corrections were applied. The structure was solved using the Patterson heavy-atom method. All non-hydrogen atoms except the terminal ethylene and methyl carbons were refined anisotropically. The terminal ethylene ($=CH_2$) and methyl ($-CH_3$) groups of the $CH_3{-}C{=}CH_2$ fragment were mutually disordered. This disorder was treated (using the DFIX option in SHELX76)[32] by fixing each of the eight terminal carbon atom positions with site occupancy of 0.5 at 1.34 Å (for ethylene) and site occupancy of 0.5 at 1.50 Å (for methyl) from the relevant C*n*2 carbon (n = 1–4) at appropriate angles. The methyl and ethylene hydrogens were placed geometrically (C—H 0.95 Å) with 0.5 occupancy; the methyl hydrogens were allowed to rotate around the C—C axis, in order to adopt the most favoured conformation. Refinement (with weights derived from coupling statistics) by full-matrix least-squares calculations converged with $R = 0.038$ and $R_w = 0.056$ for the 2871 observed reflections. The final refinement cycle included 332 variable parameters, maximum shift error of 0.01. The final difference map had no chemically significant features. Full details of the analysis are available from the Cambridge Crystallographic Data Centre or from the authors.

$[Mo_2(\mu\text{-}O_2CHC{=}CH_2)_4]\cdot 0.5H_2O$ (**2**)

To a suspension of complex **1** (0.24 g, 0.56 mmol) in dry benzene (15 cm^3) was added propenoic acid (3.0 g, 43.7 mmol). The resulting yellow–brown solution was stirred at room temperature for 4 h during which time the yellow product gradually precipitated. The solid was filtered off, washed with n-hexane and dried *in vacuo*; yield: 0.19 g (70%). Found: C, 29.1; H, 2.6. Calc.: C, 29.5; H, 2.7%. The complex was soluble in all common organic solvents except n-hexane.

The atoms of the disordered $=CH_2$ and $-CH_3$ groups were assigned fixed geometry, C—C 1.34 and 1.50(2) Å, and 120° bond angles.

The roman numerals refer to the following equivalent positions; (I) $-x, -y, -z$ and (II) $= -x, -y, 1-z$.

$[Mo_2(\mu\text{-}O_2CC_7H_9)_4]$ (**3**)

Method (*a*). A mixture of **1** (0.25 g, 0.58 mmol), *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid (1.1 g, 7.9 mmol) and dry methanol (15 cm^3) was stirred at room temperature for 12 h. The volume of the suspension was then reduced to *ca* 5 cm^3 by evaporation under high vacuum (without heating). The yellow product was filtered off, washed with ice-cold methanol and n-hexane, and then dried *in vacuo*. The solid was recrystallized from dry methanol; yield: 0.36 g (84%).

Method (*b*). Complex **2** (0.22 g, 0.45 mmol), cyclopentadiene (2 cm^3) and methanol (15 cm^3) were stirred together at room temperature for 4 days. The product precipitated when the solution was concentrated to low volume (no heating). The solid was recovered as in method (a); yield: 0.17 g

(51%). Found: C, 51.6; H, 4.8. Calc.: C, 51.9; H, 4.9%.

$[Mo_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4]\cdot 0.5H_2O$ (**4**) and $[Mo_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4]\cdot 2(HO_2C(CH_3)C{=}CH_2)$ (**5**)

Complex **1** (0.24 g, 0.56 mmol) and 2-methylpropenoic acid (3.0 g, 35.3 mmol) were stirred together in dry methanol (20 cm^3) at room temperature for 3 h. During the course of the reaction a yellow solid (**4**) precipitated. The solid was filtered off, washed with n-hexane and dried *in vacuo*; yield: 0.26 g, (86%). The remaining yellow–brown filtrate was rotary evaporated at 30°C to *ca* 10 cm^3 and the flask was then sealed under nitrogen. After a short time complex **5** precipitated as yellow microcrystals and these were recovered in the same manner as with complex **4**; yield: 0.04 g (10%). Found: C, 35.5; H, 3.9. Calc.: C, 35.6; H, 3.74. (**5**) C, 41.9; H, 4.7; C, 40.9; H, 4.6%. Both complexes were soluble in all common organic solvents except n-hexane.

Note: complex **5** was also made from **4** as follows. Complex **4** (0.17 g, 0.31 mmol) was added to a mixture comprising 2-methylpropenoic acid (10 cm^3), acetone (5 cm^3) and acetonitrile (5 cm^3). The resulting brown solution was sealed under nitrogen and after 24 h crystals of complex **5** formed. The solid was recovered in the same manner as described above.

$[Ru_2(\mu\text{-}O_2CHC{=}CH_2)_4Cl]\cdot 2(HO_2CHC{=}CH_2)$ (**7**)

Complex **6** (0.95 g, 2.0 mmol) and propenoic acid (5.5 g, 77 mmol) were stirred together in methanol (50 cm^3) at room temperature, and after 72 h all of the solid had dissolved to give a dark brown solution. The solution was rotary evaporated (without heating) to *ca* 5 cm^3 and then ethyl acetate (20 cm^3) was slowly added. The resulting solution was concentrated by rotary evaporation until the brown product just began to precipitate. n-Hexane (30 cm^3) was then slowly added causing a total precipitation of the product. The solid was filtered off, washed several times with diethylether and dried *in vacuo*. The brown solid was then redissolved in a fresh solution of propenoic acid (5.5 g) in methanol (40 cm^3) and the mixture was stirred for a further 72 h. The resulting red–brown solution was rotary evaporated to *ca* 5 cm^3, and the product was reprecipitated using the ethyl acetate/n-hexane method described above; yield: 0.92 g (69%). Found: C, 32.5; H, 2.8; Cl, 4.7. Calc.: C, 32.5; H, 3.0; Cl, 5.3%; m.p. = 257°C (dec); μ_{eff} = 4.0 B.M. per Ru_2; λ_{max} = 435 nm (ε = 623 $dm^3\ mol^{-1}\ cm^{-1}$ in MeOH).

$[Ru_2(\mu\text{-}O_2CC_7H_9)_4Cl]$ (**8**)

All operations were carried out at room temperature.

Method (a). Complex **6** (0.474 g, 1.0 mmol), methanol (40 cm^3) and *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid (2.2 g, 16 mmol) were stirred together for 72 h. This brown solution was then evaporated under high vacuum to give a red–black tar. Ethyl acetate (25 cm^3) was added and the solution then concentrated to *ca* 5 cm^3. Slow addition of n-hexane (*ca* 40 cm^3) induced precipitation of the brown product. The solid was filtered off, washed with n-hexane and dried *in vacuo*. The solid was redissolved in a fresh mixture of methanol (40 cm^3) and *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid (2.2 g, 16 mmol) and allowed to stir for a further 72 h. The solution was again concentrated to a tar and the beige product was recovered using the same ethyl acetate/n-hexane procedure as described above; yield: 0.62 g (79%).

Method (b). Complex **7** (0.3 g, 0.45 mmol), methanol (30 cm^3) and freshly distilled cyclopentadiene (2 cm^3) were stirred together for 20 h. The solution was concentrated to a low volume using high vacuum. Ethyl acetate (20 cm^3) was added and the solution was again concentrated using high vacuum. The resulting dark red tar was stirred thoroughly with n-hexane (40 cm^3). The beige solid which precipitated was filtered off, washed with n-hexane and dried *in vacuo*; yield: 0.34 g (96%). Found: C, 48.3; H, 4.7; Cl, 4.0. Calc.: C, 48.9; H, 4.6; Cl, 4.5%; m.p. = 270°C (dec); μ_{eff} = 4.0 B.M. per Ru_2; λ_{max} = 431 nm (ε = 642 $dm^3\ mol^{-1}\ cm^{-1}$ in MeOH).

$[Ru_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_4Cl]$ (**9**)

The same method was followed as for the preparation of complex **7** using 2-methylpropenoic acid instead of propenoic acid. In addition, 80 cm^3 of methanol was used instead of 40 cm^3. The product formed as a dark brown solid; yield: 0.94 g (81%). Found: C, 33.5; H, 3.8; Cl, 5.8. Calc.: C, 33.2; H, 3.5; Cl, 6.1%; m.p. = 280°C (dec); μ_{eff} = 3.9 B.M. per Ru_2; λ_{max} = 440 nm (ε = 598 $dm^3\ mol^{-1}\ cm^{-1}$ in MeOH). Crystals suitable for X-ray analysis were obtained by slow evaporation of a solution of (**9**) in 10% 2-methylpropenoic acid in methanol.

$[Ru_2(\mu\text{-}O_2CC_8H_{11})_4Cl]$ (**10**)

The same procedure was followed as for the preparation of complex **8** [method (b)] using complex **9** instead of complex **7**. The product was recovered as a dark beige solid; yield: 0.29 g (76%). Found:

C, 49.4; H, 4.9; Cl, 4.2. Calc.: C, 51.3; H, 5.3; Cl, 4.2%; m.p. = 250–280°C (dec); μ_{eff} = 4.0 B.M. per Ru_2; λ_{max} = 428 nm (ε = 620 dm^3 mol^{-1} in MeOH).

$[Ru_2(\mu\text{-}O_2CH_2CHC{=}CH_2)_4Cl]$ (**11**)

The same method was followed as for the preparation of complex **7** using 3-butenoic acid instead of propenoic acid. The product formed as a dark brown solid; yield: 0.80 g (69%). Found: C, 33.2; H, 3.5; Cl, 5.9. Calc.: C, 33.2; H, 3.5; Cl, 6.1%; m.p. = 242°C (dec); μ_{eff} = 3.9 B.M. per Ru_2; λ_{max} = 432 nm (ε = 713 dm^3 mol^{-1} cm^{-1} in MeOH).

$[Ru(C_5H_5)_2]$ (**12**)

Complex **11** (0.11 g, 0.2 mmol) was dissolved in methanol (5 cm^3). Freshly distilled cyclopentadiene (0.5 cm^3) was added and the resulting solution was left to stand for *ca* 3 months. Pale yellow crystals of ruthenocene (**12**) formed in low yield. Found: C, 52.0; H, 4.3. Calc.: C, 51.9; H, 4.3%; m/z = 232 $\{Ru(C_5H_5)_2^+\}$.

$[Cu_2(\mu\text{-}O_2CC_7H_9)_4]\cdot 2H_2O$ (**14**): *Method (a)*

Freshly prepared $Cu(OH)_2$ (0.2 g, 2.1 mmol) was added to a solution of *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid (1.1 g, 8.0 mmol) in methanol (20 cm^3) and the resulting solution was stirred at room temperature for 96 h. Unreacted $Cu(OH)_2$ was removed by filtration and the filtrate was concentrated by rotary evaporation to a blue oil. Ethyl acetate (10 cm^3) was added and the solution was again reduced to a low volume. Diethyl ether (3 cm^3) and n-hexane (3 cm^3) were sequentially added and a pale blue solid (**a**) precipitated. Solid **a** was filtered off, washed with diethylether and dried *in vacuo*; yield: 0.17 g. The original filtrate was stored at *ca* 4°C for 12 h. Over this period a blue complex (**14**) precipitated. The solid was filtered off, washed with diethylether, and allowed to air dry; yield: 0.25 g (33%).

Method (b): Complex **13** (0.2 g, 0.45 mmol) was dissolved in diethylether (100 cm^3) and freshly distilled cyclopentadiene (5 cm^3) was added. The solution was stirred at 20°C for 24 h. Another 5 cm^3 of cyclopentadiene was added and the mixture was stirred for a further 24 h. More cyclopentadiene (5 cm^3) was added and the mixture stirred for another 48 h. A pale blue solid (**b**) was filtered off, washed with diethylether and then dried in air; yield: 0.04 g. The original filtrate was concentrated by rotary evaporation to a blue oil. n-Hexane (5 cm^3) was then added and the mixture stored at 4°C overnight. Complex **14** precipitated and was recovered as outlined in method (a); yield: 0.18 g (56%). Found for (**14**): C, 54.0; H, 5.5. Calc: C, 54.0; H, 5.7%; m.p. = 240°C (dec) (colour change at 120°C); μ_{eff} = 1.9 B.M. per Cu_2 (1.3 B.M. per Cu); λ_{max} = 674 nm (ε = 8900 dm^3 mol^{-1} cm^{-1} in MeCN).

Note: We have not, as yet, been able to establish the identity of the insoluble, paramagnetic, pale blue solids (**a**) and (**b**), and work on this is currently in progress.

SYNTHESIS OF NEW DIMOLYBDENUM(II,II) DI-μ-CARBOXYLATO DICATIONIC AND DIANIONIC COMPLEXES, AND THEIR USE AS POLYMERIZATION CATALYSTS

MALACHY McCANN† and PAULINE GUINAN

Chemistry Department, St. Patrick's College, Maynooth, Co. Kildare, Ireland

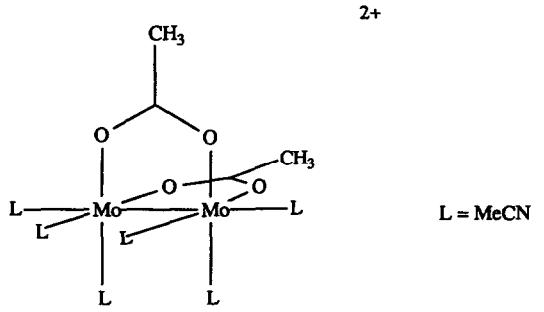
(*Received* 29 *April* 1991; *accepted* 21 *June* 1991)

Abstract—The dicationic complex salt *cis*-$[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_6][BF_4]_2$ (**1**), reacts with an excess of unsaturated carboxylic acid (RCO_2H) to give a family of new dicationic salts, $[Mo_2(\mu\text{-}O_2CR)_2(MeCN)_4][BF_4]_2 \cdot xH_2O$ [R = $HC{=}CH_2$ (**2**), $(CH_3)C{=}CH_2$ (**4**), $H_2CCHC{=}CH_2$ (**6**), $(CH_3)HCH_2CHC{=}CH_2$ (**7**), C_7H_9 (**8**); x = 1 or 2]. Complex **1** also reacts with Et_4NBr to give the dianionic salt $(Et_4N)_2[Mo_2(\mu\text{-}O_2CCH_3)_2Br_4]$ (**9**). Complexes **1**, **4** and **9** catalyse the room temperature polymerization of bicyclo[2.2.1]hept-2-ene. $EtAlCl_2$ was employed as a co-catalyst in these reactions. The dicationic salts **1**, **2** and **4** also catalyse the room temperature polymerization of cyclopentadiene, but the dianionic salt **9** is inactive towards this monomer.

A large number of dimolybdenum(II,II) complexes of the general formula $[Mo_2(\mu\text{-}O_2CR)_4]$ have been made using saturated alkyl and aryl carboxylate ligands.[1] We have recently described the synthesis of a range of Mo_2^{4+}, Cu_2^{4+} and Ru_2^{5+} tetra-μ-carboxylato complexes containing unsaturated alkyl carboxylate ligands, and demonstrated how the pendant C=C functions of the complexed ligands could react with cyclopentadiene to form the respective Diels–Alder cycloaddition adducts.[2] In this paper we describe the synthesis of some dimolybdenum(II,II) dicationic complexes containing two unsaturated carboxylate ligands, and the preparation of a new di-μ-acetato dianionic complex. The use of these complexes as catalysts for the polymerization of bicyclo[2.2.1]hept-2-ene and cyclopentadiene is also reported.

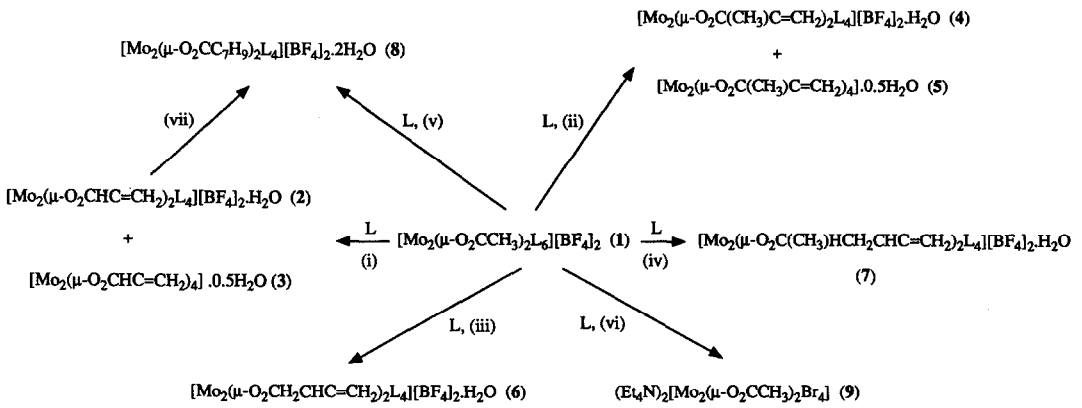
RESULTS AND DISCUSSION

Two different research groups have independently prepared and structurally characterized the red dimolybdenum(II,II) salt *cis*-$[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_6][BF_4]_2$ (**1**), the complex dication having the structure shown below.[3a,b] Earlier, Drago and Telser[3c] reported the synthesis of the closely related salts $[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_4][CF_3SO_3]_2$ and $[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_5][BF_3OH]_2$, which contain four and five MeCN ligands, respectively.



We have employed **1** as the starting material for the preparation of a series of similar dicationic complexes containing two unsaturated carboxylate ligands. Solutions of **1** in MeCN were reacted with an excess of the unsaturated carboxylic acid so as to replace the two acetate ligands with unsaturated carboxylate ligands (Scheme 1). Two successive metathesis cycles were usually required for complete substitution of the acetate by the new carboxylate ligand. The dications of the new salts have the common formula $[Mo_2(\mu\text{-carboxylate})_2(MeCN)_4]^{2+}$, and given that the structural data for

† Author to whom correspondence should be addressed.



Scheme 1. L = MeCN, (i) $CH_2{=}CHCO_2H$, (ii) $CH_2{=}C(CH_3)CO_2H$, (iii) $CH_2{=}CHCH_2CO_2H$, (iv) $CH_2{=}CHCH_2CH(CH_3)CO_2H$, (v) $C_7H_9CO_2H$, (vi) Et_4NBr, (vii) cyclopentadiene.

1 show the four Mo—N (equatorial) distances to be considerably shorter than the two Mo—N (axial) distances,[3a,b] it is reasonable to assume that the four MeCN ligands in the present complexes are bonded equatorially to the bimetallic core.

During the synthesis of the di-μ-propenoato and di-μ-2-methylpropenoato salts **2** and **4** small amounts of the respective neutral tetra-μ-propenoato and tetra-μ-2-methylpropenoato complexes (**3** and **5**) also formed. Pure samples of **3** and **5** have previously been obtained in high yield by reacting $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ with an excess of the respective unsaturated acid.[2] It is interesting to note that when $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ was reacted with the longer chain unsaturated acids 3-butenoic acid and 2-methylpent-4-enoic acid, the tetrasubstituted complexes $[Mo_2(\mu\text{-}O_2CH_2CHC{=}CH_2)_4]$ and $[Mo_2(\mu\text{-}O_2C(CH_3)HCH_2CHC{=}CH_2)_4]$ did not form, and only Mo–oxo complexes were recovered.[4] However, when the same two long-chain unsaturated acids were reacted with salt **1**, the metathesis products **6** and **7** were recovered in high yield and, again, none of the corresponding neutral tetra-μ-carboxylato complexes formed. The di-μ-bicyclo[2.2.1]hept-5-ene-2-carboxylato complex **8** was synthesized by reacting the propenoato complex **2** with a large excess of cyclopentadiene (cpd). Some polycyclopentadiene (pcpd) also formed during the reaction (discussed later). The conversion of **2** to **8** occurs via a Diels–Alder cycloaddition reaction of the type mentioned previously.[2] Complex **8** was also prepared by reacting **1** directly with *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid ($C_7H_9CO_2H$). Finally, when a solution of **1** in MeCN was reacted with Et_4NBr, the red salt **9** formed, which contains the complex dianion $[Mo_2(\mu\text{-}O_2CCH_3)_2Br_4]^{2-}$.

The IR spectra of the new di-μ-carboxylato salts have $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ bands at frequencies consistent with those expected for bridging carboxylates, and a ν(C=C) band was also evident for the complexes (except **8**) containing unsaturated carboxylate ligands (Table 1). Weak bands attributable to the MeCN ligands were present at *ca* 2280 cm^{-1}. In the spectrum of the dianionic complex **9** the acetate $\nu(CO_2)$ bands were at frequencies similar to those found in the spectrum of the structurally characterized diacetate **1**, and a strong ν(Mo—Br) band[5,6] was observed at 268 cm^{-1}.

Although the ^1H NMR spectra of the new salts (Table 1) did show peaks attributable to the different hydrogen atoms of the ligands not much structural information on the complexes was forthcoming due to the complexity of the observed splitting patterns. The spectrum of a DMSO-d_6 solution of the dianionic complex **9** contained two distinct methyl (CH_3CO_2) resonances at 1.93 and 2.00 ppm in a ratio of *ca* 9:1. The presence of two signals suggests that in solution there are two different species present. This type of behaviour was similar to that observed for $CDCl_3$ solutions of the neutral complex $[Mo_2(\mu\text{-}O_2CCH_3)Cl_3(PMe_3)_3]\cdot 0.75THF$.[7] An acetonitrile solution of complex **9** was prepared under anaerobic conditions and its electronic absorption spectrum immediately recorded (Fig. 1, $t = 0$). A single visible peak corresponding to the metal–metal $\delta \rightarrow \delta^*$ transition[1] was present at 540 nm ($\varepsilon \approx 838$ dm^3 mol^{-1} cm^{-1}). This spectrum was similar to that reported for methanol solutions of the closely related dianions $[Mo_2(\mu\text{-}O_3SCH_3)_2Br_4]^{2-}$ ($\lambda_{max} = 522$ nm)[6] and $[Mo_2(\mu\text{-}O_2CCH_3)_2Cl_4]^{2-}$ ($\lambda_{max} = 495$ nm).[9] A solution of **9** was allowed to slowly air-oxidize and the spectrum was recorded at intervals up to $t = 24$ h,

at which time the 540 nm peak had completely disappeared and three new absorption peaks had grown (481, 419 and 382 nm). The disappearance of the 540 nm peak signifies the rupture of the Mo—Mo δ bond.

In conclusion, it is thought that in the solid state the new dicationic complexes are essentially isostructural with **1** [Fig. 2(a)]. It should be mentioned that these complexes could also have a *trans* configuration [Fig. 2(b)]. The dianion, $[Mo_2(\mu\text{-}O_2CCH_3)_2Br_4]^{2-}$, is thought to be structurally similar to the known dianions $[Mo_2(\mu\text{-}O_3SCH_3)_2X_4]^{2-}$ (X = Cl, Br, I)[6] and $[Mo_2(\mu\text{-}O_2CCH_3)_2Cl_4]$.[2-9] The X-ray crystal structure of the latter dianion showed the two acetates to be *trans*. Possible *cis* and *trans* structures for $[Mo_2(\mu\text{-}O_2CCH_3)_2Br_4]^{2-}$ are illustrated in Figs 1(c) and (d).

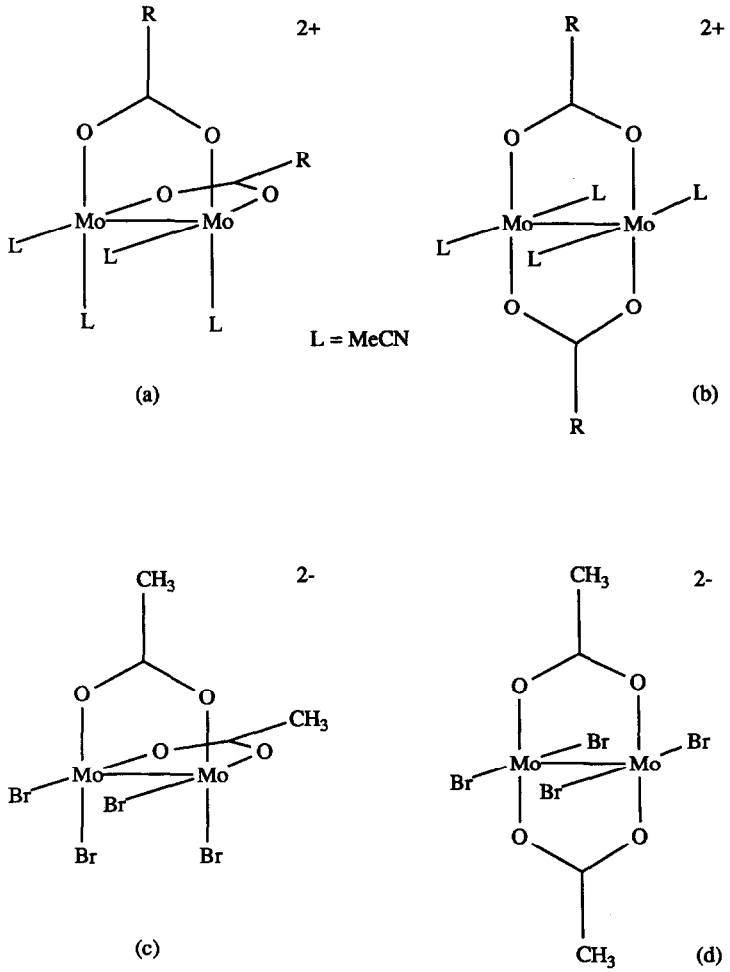

Fig. 2. (a) and (b) Possible structures for the new dications $[Mo_2(\mu\text{-}O_2CR)_2L_4]^{2+}$ [R = HC═CH$_2$ (**2**), (CH$_3$)C═CH$_2$ (**4**), H$_2$CCHC═CH$_2$ (**6**), R = (CH$_3$)HCH$_2$CHC═CH$_2$(**7**), C$_7$H$_9$ (**8**); L = MeCN]. (c) and (d) Possible structures for the dianion, $[Mo_2(\mu\text{-}O_2CCH_3)_2Br_4]^{2-}$.

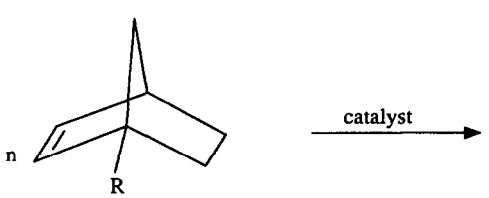
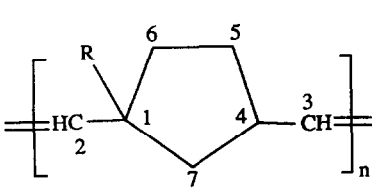
Polymerization catalysis

(1) *Bicyclo*[2.2.1]*hept-2-ene*(*norbornene*). In 1981 Lamotte *et al.*[10] reacted aluminium isopropoxide with $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ to give $[Mo_2(\mu\text{-}O_2CCH_3)_2\{\mu\text{-}(OCH(CH_3)_2)_2Al(OCH(CH_3)_2\}_2]$, the X-ray crystal structure of which showed *trans* acetates and *trans* aluminium isopropoxides. Later, Diefenbach reported that dimolybdenum(II,II) carboxylato complexes in the presence of aluminium, titanium or zirconium alkoxides were good catalysts for the metathesis of alkynes.[11] Furthermore, he prepared and characterized complexes of the type $[Mo_2(O_2CR)_2\{Al(p\text{-}OC_6H_4Cl)_4\}_2]$ [R = CH_3, $C(Me)_3$, CF_3], and subsequently showed that they also catalysed alkyne metathesis reactions. Earlier, we had shown that the neutral and anionic dimolybdenum(II,II) complexes $[Mo_2(\mu\text{-}O_2CR)_4]$ (R = CH_3, CF_3) and $K_4[Mo_2Cl_8]$ are good metathesis catalysts for ring-opening polymerization reactions.[12,13] For example, each of the catalyst/co-catalyst systems $[Mo_2(\mu\text{-}O_2CCH_3)_4]/EtAlCl_2$ and $K_4[Mo_2Cl_8]/EtAlCl_2$ polymerized bicyclo[2.2.1]hept-2-ene and 1-methylbicyclo[2.2.1]hept-2-ene at 20°C, and $[Mo_2(\mu\text{-}O_2CCF_3)_4]$ polymerized the same monomers even in the absence of a co-catalyst.

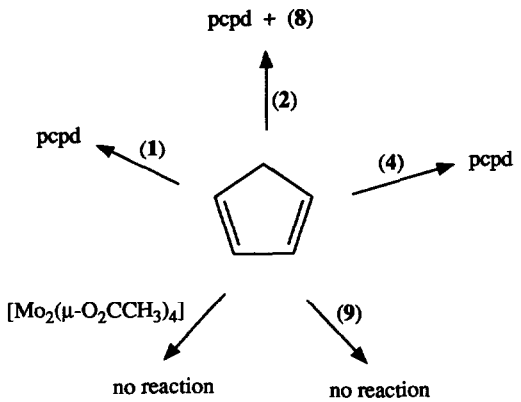
The dicationic complexes **1** and **4** and the dianionic complex **9**, when used in the presence of $EtAlCl_2$ as a co-catalyst, catalysed (0.28 mol % catalyst) the room temperature ring-opening polymerization of bicyclo[2.2.1]hept-2-ene to give poly(1,3-cyclopentylene-vinylene) (pcpv). When the reaction solvent was changed from toluene to acetonitrile no polymerization occurred.[14] From the ^{13}C NMR spectra of the polymers the fraction of double bonds in the polymer chain with *cis* character (σ_c) was calculated.[12,13] The close similarity in



(R = H, Me)



the values of σ_c (*ca* 0.36) found for the three pcpv samples indicates that changing the ligands on the dimolybdenum(II,II) core does not cause a significant change in the stereochemistry of the double bonds in the polymer chain.

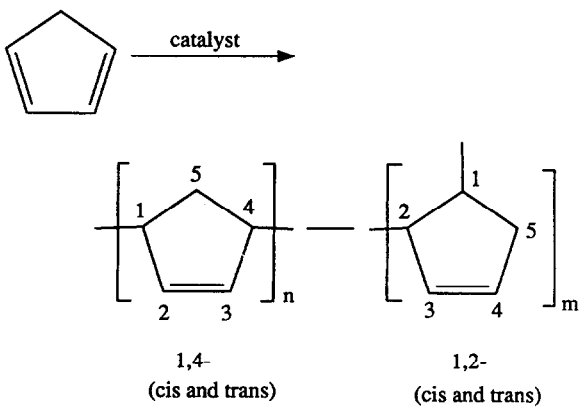


Scheme 2. pcpd = polycyclopentadiene.

(2) *Cyclopentadiene*. We have recently described how some neutral dimolybdenum(II,II), dicopper(II,II) and diruthenium(II,III) complexes containing four unsaturated carboxylate ligands react with excess cyclopentadiene to give the respective Diels–Alder cycloaddition adducts.[2] No polycyclopentadiene (pcpd) formed during these reactions. The results of reactions of some of the present complex salts with excess cyclopentadiene in acetonitrile at room temperature are outlined in Scheme 2. A 0.09 mol % solution of **4** rapidly catalysed the addition polymerization of cyclopentadiene, with the pcpd precipitating as a white solid (yield: 35%). Unchanged **4** was subsequently recovered from the reaction filtrate. Although **1** also catalysed the formation of pcpd (yield: 8%), it was not as active as **4**. Complex **2** was even less active than **1** and only a very small amount of pcpd was obtained. Furthermore, the Diels–Alder cycloaddition adduct **8** was isolated in high yield from the filtrate of the latter reaction (Scheme 1). The dianionic complex **9** failed to react with cyclopentadiene, and unchanged **9** was recovered. In addition, no pcpd formed when the neutral complex $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ was reacted (either as a suspension in acetonitrile or as a solution in hot methanol) with cyclopentadiene.

Although there are many examples known where non-transition metal Lewis acids have been used as catalysts of the polymerization of cyclopentadiene,[15] there are only a few cases in which transition metal complexes [other than those of titanium(IV)] have been employed,[16] and it is generally thought that all of these catalysts cause the polymerization to proceed via a cationic mechanism.[17–19] Normally, the pcpd obtained from these literature reactions is soluble[20] in $CHCl_3$ and from

their NMR spectra[15,21] it was deduced that these addition polymers contain both 1,4- and 1,2-structural units. Furthermore, it has been shown that the 1,4- and 1,2-content of the polymers is generally dependent on the type of catalyst used, solvent and temperature.[17] Unfortunately, the insolubility of the pcpd obtained using the present complex salts prohibited detailed structural characterization by NMR spectroscopy. However, the IR spectra of these insoluble polymers were identical to those illustrated in the literature[15] for soluble poly-1,4-/1,2-cyclopentadiene.



Assuming that the present polymers are comprised of 1,4- and 1,2-units a possible cationic addition mechanism for their formation can be visualized (Scheme 3). ^1H and ^{13}C NMR studies on complex **1**[3b] have shown that the MeCN ligands are labile, and we have further demonstrated here that they are readily replaced by bromide ions (formation of **9**). Thus, a first step in the polymerization process is likely to be the displacement of one or more MeCN ligands by cyclopentadiene to give species (a). The cyclopentadiene molecule may bond to either one or both (i.e. bridging) molybdenum atoms of the bimetallic core to give the carbocation (**b**), which itself may isomerize to (**c**).[23] Addition of cyclopentadiene molecules to (**b**) and (**c**) will give rise to separate 1,2-pcpd and 1,4-pcpd, respectively. A single polymer molecule containing a mixture of 1,2- and 1,4-units in the chain can form if there is isomerization of either (**b**) or (**c**) during polymerization (Scheme 4).

Given the close similarity in both the structural and electronic properties of the complex dications of salts **1**, **2** and **4** it is difficult to understand the large differences observed in their catalytic activity towards cyclopentadiene. The inactivity of salt **9** is probably attributable to the fact that the dianion $[Mo_2(\mu\text{-}O_2CCH_3)_2Br_4]^{2-}$ can be viewed as a Lewis base and, as such, would effectively repel the electron-rich cyclopentadiene molecule. The neutral complex $[Mo_2(\mu\text{-}O_2CCH_3)_4]$ also failed to catalyse the polymerization of cyclopentadiene, suggesting that it too is not a strong enough Lewis acid for diene activation.

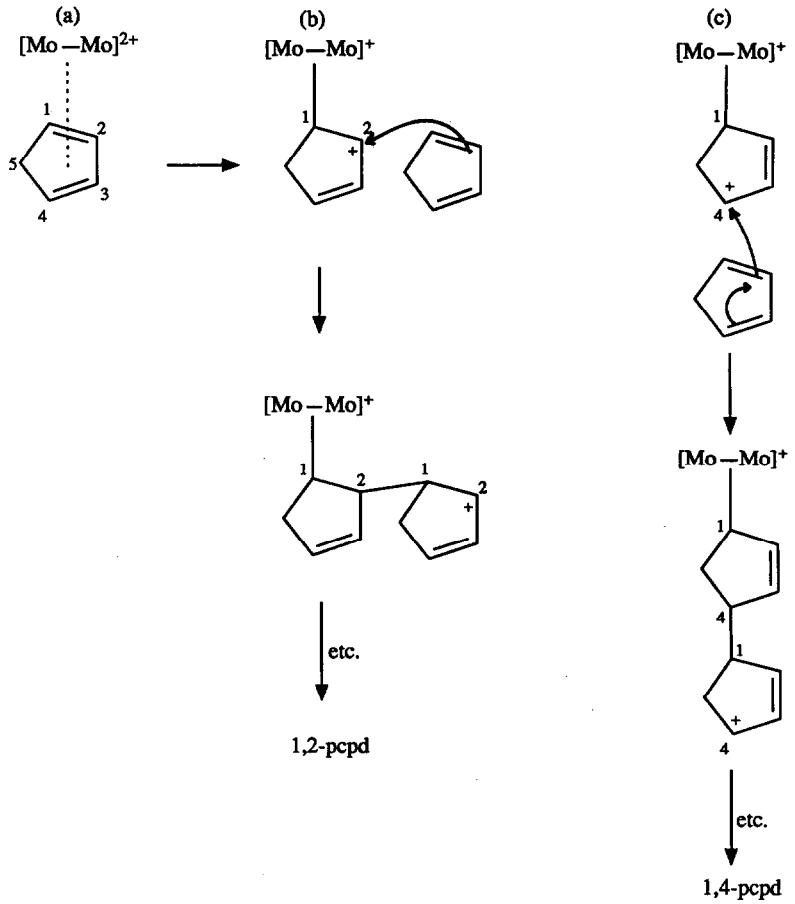
EXPERIMENTAL

All reactions were carried out under nitrogen using dry solvents. Standard Schlenk techniques were employed during the preparation of the molybdenum complexes. Although all of the complex salts were air-sensitive the dicationic salts appeared to be considerably more sensitive than the dianionic salt. Literature methods were used to prepare *cis*-$[Mo_2(\mu\text{-}O_2CCH_3)_2(MeCN)_6][BF_4]_2$ (**1**),[3b] $[Mo_2(\mu\text{-}O_2CCH_3)_4]$[24] and *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid.[25] Ethylaluminiumdichloride was used as a 25% solution in hexane. IR spectra were recorded in the region 4000–200 cm^{-1} on a Perkin–Elmer 783 grating spectrometer, and electronic spectra were run on a Milton Roy Spectronic 3000 Array. ^1H NMR spectra of solutions of the complexes (in $CDCl_3$ or DMSO-d_6, and under nitrogen) and ^{13}C NMR of bicyclo[2.2.1]hept-2-ene polymers (in $CDCl_3$) were recorded using a Bruker AC 80 spectrometer. Elemental analyses were performed by the Microanalytical Laboratory, University College, Cork, Ireland.

$[Mo_2(\mu\text{-}O_2CCH{=}CH_2)_2(MeCN)_4][BF_4]_2 \cdot H_2O$ (**2**) *and* $[Mo_2(\mu\text{-}O_2CHC{=}CH_2)_4] \cdot 0.5H_2O$ (**3**)*

A solution of complex **1** (0.36 g, 0.49 mmol) and propenoic acid (0.5 g, 6.9 mmol) in acetonitrile (20 cm^3) was stirred at room temperature for 12 h, and the resulting light red solution was then reduced under high vacuum (at 20°C) to *ca* 1 cm^3. Addition of toluene (40 cm^3) induced the formation of a dense red oil. The upper yellow liquid was decanted off and fresh toluene (20 cm^3) and acetonitrile (3 cm^3) was added to the red oil. The mixture was stirred vigorously and the crude product **2** eventually precipiated as a red solid. The solid was filtered off, washed with toluene (2 × 20 cm^3) and dried *in vacuo*. The solid was then redissolved in a fresh solution of propenoic acid (0.5 g, 6.9 mmol) in acetonitrile (20 cm^3) and stirred at room temperature for a further 3 h. The red complex was then reprecipitated from the oil form as described above; yield: 0.2 g

* Microanalytical and IR data for complexes **3** and **5** corresponded with that reported in ref. 2 for these complexes.



Scheme 3. [Mo—Mo] = $[Mo_2(\mu\text{-}O_2CR)_2(MeCN)_x]$, R = CH_3,$HC{=}CH_2$, $(CH_3)C{=}CH_2$, $x < 6$.

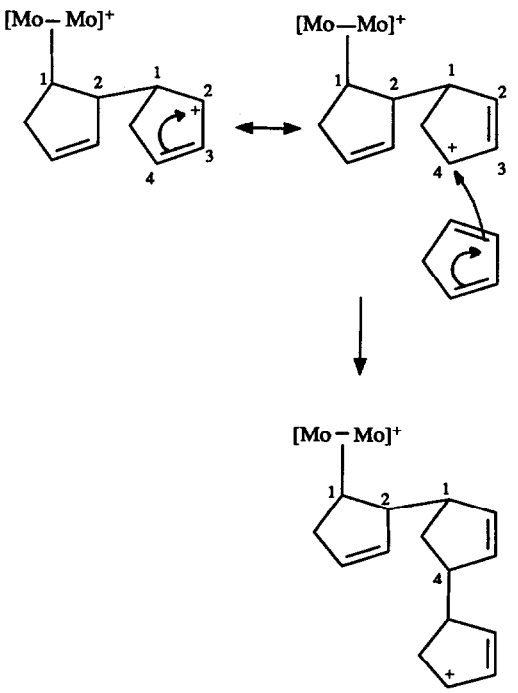
(59%). The combined reaction filtrates (yellow liquid and toluene washings) were concentrated to low volume under high vacuum (at 20°C) and the yellow solid **3** precipitated; yield: 0.05 g (21%). (**2**): Found: C, 24.5; H, 2.8; N, 7.7. Calc.: C, 24.4; H, 2.9; N, 8.1%.

$[Mo_2(\mu\text{-}O_2C(CH_3)C{=}CH_2)_2(MeCN)_4][BF_4]_2 \cdot H_2O$ (**4**) *and* $[Mo_2(\mu\text{-}O_2C(CH_3C{=}CH_2)_4] \cdot 0.5H_2O$ (**5**)*

Using 2-methylpropenoic acid these complexes (red and yellow coloured, respectively) were prepared and recovered by the same method as described for **2** and **3**; yield (**4**): (76%). Found: C, 26.2; H, 3.6; N, 7.9. Calc.: C, 26.8; H, 3.4; N, 7.8%.

$[Mo_2(\mu\text{-}O_2CH_2CHC{=}CH_2)_2(MeCN)_4][BF_4]_2 \cdot H_2O$ (**6**)

Using 3-butenoic acid this red complex was prepared and recovered by the same method as



Scheme 4.

described for **2**; yield: (80%). Found: C, 26.9; H, 3.6; N, 7.4. Calc.: C, 26.8; H, 3.4; N, 7.8%.

$[Mo_2(\mu\text{-}O_2C(CH_3)HCH_2CHC{=}CH_2)_2(MeCN)_4][BF_4]_2 \cdot H_2O$ (**7**)

Using 2-methylpent-4-enoic acid this red complex was prepared and recovered by the same method as described for **2**; yield: (93%). Found: C, 31.3; H, 4.1; N, 7.7. Calc.: C, 31.0; H, 4.2; N, 7.2%.

$[Mo_2(\mu\text{-}O_2CC_7H_9)_2(MeCN)_4][BF_4]_2 \cdot 2H_2O$ (**8**)

Method (a). Using *endo*-bicyclo[2.2.1]hept-5-ene-2-carboxylic acid this red complex was prepared and recovered by the same method as described for **2**; yield: (68%).

Method (b). Complex **2** (0.17 g, 0.25 mmol) and cyclopentadiene (0.4 g, 6.1 mmol) were stirred together in acetonitrile (20 cm^3) at room temperature for 24 h. A small amount of white pcpd solid was filtered off and complex (**8**) was subsequently recovered from the filtrate using the method outlined for the isolation of **2**; yield: 0.14 g (70%). Found: C, 34.3; H, 4.1; N, 7.1. Calc.: C, 34.3; H, 4.1; N, 6.7%.

$(Et_4N)_2[Mo_2(\mu\text{-}O_2CCH_3)_2Br_4]$ (**9**)

To a solution of **1** (0.33 g, 0.45 mmol) in acetonitrile (20 cm^3) was added tetraethylammonium bromide (0.57 g, 2.1 mmol), and this resulted in an immediate red to dark purple colour change. The solution was stirred for 0.5 h and the solvent was then removed using high vacuum. Ethanol (30 cm^3) was added and the resulting suspension was stirred for 1.5 h. The red product was removed by filtration and then resuspended in fresh ethanol (10 cm^3) and stirred for another 10 min. The solid was filtered off, washed with ethanol (3 × 5 cm^3) and then dried *in vacuo*; yield: 0.23 g (57%). Found: C, 26.9; H, 5.4; N, 3.2; Br, 36.2. Calc.: C, 27.0; H, 5.2; N, 3.1; Br, 35.9%. Complex **9** gives an orange solution in MeOH and DMSO, and a purple solution in MeCN.

Polymerization reactions

All polymerization reactions were performed at room temperature and under nitrogen. Typical polymerization procedures are outlined below.

Polymerization of bicyclo[2.2.1]hept-2-ene

Bicyclo[2.2.1]hept-2-ene (0.5 g, 5.3 mmol) was dissolved in dry toluene (1 cm^3) and the dimolybdenum(II,II) salt (0.015 mmol) was added. Ethylaluminiumdichloride solution (0.5 cm^3, 0.33 mmol) was then added and this resulted in rapid polymer formation (as indicated by an increase in solution viscosity). The mixture was then allowed to stand at room temperature for 1 h. Ethanol (*ca* 25 cm^3) was added and the precipitated polymer (pcpv) was washed several times with small volumes of ethanol. The wet solid was then dissolved in chloroform (*ca* 75 cm^3), and the resulting polymer solution was dripped into ethanol (300 cm^3) containing concentrated hydrochloric acid (0.2 cm^3) causing the polymer to reprecipitate as a fine white solid. This solid was filtered off, washed with ethanol and dried *in vacuo* for 1 h at room temperature. A solution of the polymer in $CDCl_3$ was then characterized using ^{13}C NMR spectroscopy. For example, using complex **4** as catalyst, 40 mg of pcpv was obtained. Polymer σ_c values (in parentheses) obtained using the various catalysts were as follows: **1** (0.36), **4** (0.36), **9** (0.35).

Polymerization of cyclopentadiene

A solution of the dimolybdenum(II,II) complex salt (0.036 mmol) and cyclopentadiene (2.6 g, 39.4 mmol) in acetonitrile (5 cm^3) was stirred for 72 h during which time the white pcpd gradually precipitated. The solid was filtered off, washed with acetonitrile and dried *in vacuo*. For example, using complex **4** as catalyst pcpd was formed in 35% yield. The pcpd formed in these reactions was insoluble in all common organic solvents. The polymers discoloured slightly on standing.

(*Received* 17 *April* 1991; *accepted* 18 *June* 1991)

Abstract—The compounds (β-diketonate)Cu(1,5-COD) have been prepared by the reaction between $[(1,5\text{-COD})CuCl]_2$ and Na(β-diketonate) for β-diketonate = hexafluoroacetylacetonate (hfac), trifluoroacetylacetonate (tfac) and acetylacetonate (acac) and 1,5-COD = 1,5-cyclooctadiene. These compounds were characterized spectroscopically and (hfac)Cu(1,5-COD) was characterized, in the solid state, by single-crystal X-ray diffraction. Crystal data: empirical formula, $C_{13}H_{13}CuF_6O_2$; crystal system, monoclinic; space group, $P2_1/c$; $a = 10.011(2)$, $b = 9.777(3)$, $c = 15.658(3)$ Å and $\beta = 107.88(2)°$ and $Z = 4$. The coordination of the copper centre is best described as "3+1" with an asymmetrically coordinated 1,5-COD ligand where the Cu—C(6)═C(7) centroid and Cu—C(10)═C(11) centroid distances are 1.953 and 2.418 Å, respectively. The quantitative disproportionation, according to the equation $2(hfac)Cu(1,5\text{-COD}) \rightarrow Cu + Cu(hfac)_2 + 2(1,5\text{-COD})$ to produce copper metal and volatile by-products, was observed at 200°C.

The chemistry of copper(II) β-diketonate compounds and their Lewis base adducts has been investigated extensively.[1] However, the chemistry of copper(I) β-diketonate compounds has received much less attention. Stable Lewis base adducts of copper(I) β-diketonates with amines,[2] isonitriles,[3] phosphines,[3,4] olefins[5] and carbon monoxide[5] have been prepared, with the general formula (β-diketonate)CuL_n, where $n = 1$ or 2. That the unligated copper(I) acetylacetonate moiety is unstable with respect to disproportionation was quantitatively demonstrated for the ammonia derivative (acetylacetonate)$Cu(NH_3)_{2.5}$.[2]

$$2(acac)Cu(NH_3)_{2.5} \longrightarrow Cu + Cu(acac)_2 + 5NH_3 \quad (1)$$

More recently, it has been shown, qualitatively, that the carbonyl derivative, (hfac)Cu(CO), will evolve carbon monoxide and also undergo a similar disproportionation reaction to produce copper metal and Cu(II)$(hfac)_2$.[5] In principle, this disproportionation reaction could be used as a method to deposit thin films of copper by chemical vapor deposition (CVD) for applications in semicon-

* Authors to whom correspondence should be addressed.

ductor metallization. To take advantage of this reaction for CVD purposes, it is important that the copper-containing precursor be volatile, thermally inert at room temperature and susceptible to thermally-induced disproportionation at elevated temperatures. To avoid impurity contamination in the film, the disproportionation products should be thermally inert at the deposition reaction temperature and volatile so they can be easily removed from the system.

We have recently reported the first evidence for such a thermally-induced disproportionation mechanism during CVD of copper in a series of copper(I) β-diketonate compounds, (β-diketonate)Cu(PMe_3).[6,7] Here we report the synthesis and spectroscopic characterization of the compounds (β-diketonate)Cu(1,5-COD) (where 1,5-COD = 1,5-cyclooctadiene and β-diketonate = hexafluoroacetylacetonate, hfac; trifluoroacetylacetonate, tfac; acetylacetonate, acac),the single-crystal X-ray diffraction structure of (hfac)Cu(1,5-COD) and the quantitative disproportionation of (hfac)Cu(1,5-COD) at elevated temperatures.

EXPERIMENTAL

(1) *Syntheses*

All manipulations were carried out *in vacuo* or under an inert atmosphere using Schlenk techniques as previously described.[8] All β-diketones were purchased from Aldrich Chemical Company, and were stored over 4 Å molecular sieves. The sodium salts of the β-diketones were prepared by a method previously described.[9] 1,5-cyclooctadiene was purchased from Aldrich Chemical company and distilled under nitrogen prior to use and stored over 4 Å molecular sieves.

Elemental analyses were performed by Ms R. Ju at the University of New Mexico, Department of Chemistry. NMR data were recorded on a Bruker AC-250P NMR spectrometer using the protio impurities of the deuterated solvents as references for the ^1H NMR and the ^{13}C resonance of the solvents as reference for ^{13}C NMR spectroscopy. Temperatures were calibrated with either ethylene glycol or methanol. IR data were recorded on a Perkin–Elmer Model 1620 FTIR spectrophotometer. Mass spectra were recorded on a Finnegan GC-mass spectrometer.

The preparation of $[CuCl(1,5\text{-}COD)]_2$ was carried out under reaction conditions different from those described in the literature[10] that are described below. The preparation of (hfac)Cu(1,5-COD) and (tfac)Cu(1,5-COD) compounds was carried out under analogous conditions. The preparation of (hfac)Cu(1,5-COD) is described here in detail as a representative example. The compound (acac)Cu(1,5-COD) was prepared using a similar procedure at lower temperature (−78°C) and could not be isolated, but was identified spectroscopically at low temperature.

(a) *Preparation of* $[CuCl(1,5\text{-}COD)]_2$. A slight excess of 1,5-cyclooctadiene (19.4 g, 0.18 mol, 22 cm^3) was added slowly to a slurry of CuCl (14.8 g, 0.15 mol) in 150 cm^3 of benzene by syringe. When the addition was complete, the solution was stirred in a warm water bath (40°C) for 2 h. Removal of volatile components gave an analytically pure, white powder $[CuCl(1,5\text{-}COD)]_2$ (24.6 g, 79% yield). NMR data: ^1H (C_6D_6, 20°C) δ(ppm) 1.14 (s, br, 8H, CH_2), 5.64 (s, br, 4H, CH). $^{13}C\{^1H\}$ δ(ppm) 28.3 (s, CH_2), 124.2 (s, CH) ppm. IR data (KBr disc, cm^{-1}): 3040(w), 2949(m), 2920(m), 2878(s), 2826(m), 1551(w), 1474(m), 1426(s), 1344(w), 1238(m), 1186(w), 1082(w), 993(w), 957(w), 849(w), 818(m), 744(s), 715(m), 649(m), 480(w), 409(w). Elemental analysis data: Found: C, 46.2; H, 6.0. Calc. for $C_{16}H_{24}Cl_2Cu_2$: C, 46.4; H, 5.8%.

(b) *Preparation of* (hfac)Cu(1,5-COD). The compounds $[CuCl(1,5\text{-}COD)]_2$ (5.20 g, 12.55 mmol) and an excess of Na(hfac) (5.9 g, 25.64 mmol) were placed in a 250 cm^3 Schlenk flask. Addition of 100 cm^3 of Et_2O immediately gave a yellow solution. After 1 h stirring and removal of solvent, a greenish-yellow solid was obtained. Extraction of the product with pentane (150 cm^3) followed by filtration and removal of solvent gave bright yellow crystalline (hfac)Cu(1,5-COD) (6.62 g, 69.5% yield). The compound was sublimed at 65°C under reduced pressure (100 mtorr).

(c) *Spectroscopic data for* (β-diketonate)Cu(1,5-COD) *compounds*:

(hfac)Cu(1,5-COD)

NMR data: ^1H (C_6D_6, 20°C) δ(ppm) 1.80 (s, br, 8H, CH_2 in 1,5-COD), 5.07 (s, br, 4H, CH in 1,5-COD), 6.17 (s, 1H, CH in hfac). $^{13}C\{^1H\}$ δ(ppm) 28.0 (s, CH_2 in 1,5-COD), 89.0 (s, CH in hfac), 115.0 (s, CH in 1,5-COD), 118.5 (q, CF_3 in hfac, J(C—F) = 286.2 Hz), 177.8 ($CF_3C{=}O$ in hfac, J(C—F) = 33.6 Hz). IR data (KBr disc, cm^{-1}): 2953(w), 2892(w), 2842(w), 1637(s), 1593(m), 1553(m), 1526(m), 1483(s), 1432(m), 1345(w), 1259(s), 1210(s), 1142(s), 1097(m), 997(w), 810(w), 796(m), 747(m), 725(w), 671(m), 585(m), 528(w). Mass spectral data (70 eV, m/z): 477, 7%, $[Cu(hfac)_2]^+$; 441, 2%, $[(hfac)Cu_2(1,5\text{-}COD)]^+$;

408, 23%, $[(hfac)Cu(O_2C_2CHCF_3)]^+$; 378, 46%, $[(hfac)Cu(1,5\text{-}COD)]^+$; 339, 23%, $[(hfac)Cu(O_2C_2CH)]^+$; 279, 5%, $[Cu(1,5\text{-}COD)_2]^+$; 201, 51%, $[Cu(O_2C_2CHCF_3)]^+$; 171, 98%, $[Cu(1,5\text{-}COD)]^+$; 117, 26%, $[Cu(C_4H_6)]^+$; 108, 8%, $[1,5\text{-}COD]^+$; 93, 10%, $[C_7H_9]^+$; 80, 35%, $[C_6H_8]^+$; 79, 37%, $[C_6H_7]^+$; 69, 8%, $[CF_3]^+$; 67, 100%, $[C_5H_7]^+$; 63, 35%, $[Cu]^+$; 54, 95%, $[C_4H_6]^+$. Elemental analysis data: Found: C, 41.1; H, 3.48. Calc. for $C_{13}H_{13}O_2F_6Cu$: C, 41.2; H, 3.5%.

(tfac)Cu(1,5-COD)

NMR data: ^1H (C_6D_6, 20°C) δ(ppm) 1.73 (s, 3H, CH_3 in tfac), 1.96 (br, s, 8H, CH_2 in 1,5-COD), 5.11 (br, 2, 4H, CH in 1,5-COD), 5.71 (s, 1H, CH in tfac). $^{13}C\{^1H\}$ δ(ppm) 28.2 (s, CH_2 in 1,5-COD), 29.0 (s, CH_3 in tfac), 94.5 (s, CH in tfac), 112.9 (s, CH in 1,5-COD), 120.0 (q, CF_3 in tfac, J(C—F) = 286 Hz), 171.0 (q, $CF_3C{=}O$ in tfac, J(C—F) = 31.1 Hz), 197.6 (s, $CH_3C{=}O$ in tfac). IR data (KBr disc, cm^{-1}): 2951(w), 2924(w), 2894(w), 2842(w), 1623(s), 1553(m), 1517(m), 1473(m), 1427(m), 1365(s), 1285(s), 1226(s), 1180(s), 1126(s), 941(w), 857(m), 775(s), 742(m), 730(m), 654(w), 600(w), 577(m), 518(w), 419(w). Mass spectral data (70 eV, m/z): 369, 16%, $[Cu(tfac)_2]^+$; 354, 2%, $[(tfac)Cu(O_2C_2CHCF_3)]^+$; 327, 12%, $[(tfac)Cu(OCCH_2CF_3)]^+$; 324, 5%, $[(tfac)Cu(1,5\text{-}COD)]^+$; 300, 14%, $[(tfac)Cu(O_2C_2CHCH_3)]^+$; 285, 2%, $[(tfac)Cu(O_2C_2CH)]^+$; 231, 9%, $[Cu(O_2C_2CHCH_3)_2]^+$; 216, 3%, $[Cu(tfac)]^+$; 201, 2%, $[Cu(O_2C_2CHCF_3)]^+$; 171, 7%, $[Cu(1,5\text{-}COD)]^+$; 147, 19%, $[Cu(O_2C_2CHCH_3)]^+$; 108, 8%, $[1,5\text{-}COD]^+$; 93, 10%, $[C_7H_9]^+$; 80, 30%, $[C_6H_8]^+$; 79, 35%, $[C_6H_7]^+$ 67, 91%, $[C_5H_7]^+$; 54, 100%, $[C_4H_6]^+$. Found: C, 47.4; H, 4.8. Calc. for $C_{13}H_{16}O_2F_3Cu$: C, 48.1; H, 5.0%.

(acac)Cu(1,5-COD)

NMR data ^1H (toluene-d_8, −30°C) δ(ppm) 5.41 (br, s, CH in 1,5-COD), 5.30 (s, CH in acac), 2.11 (br, s, CH_2 in 1,5-COD), 1.95 (s, CH_3 in acac). (−45°C) δ(ppm) 5.43 (br, s, CH in 1,5-COD), 5.31 (s, CH in acac), 2.09 (br, s, CH_2 in 1,5-COD), 1.97 (s, CH_3 in acac). (−60°C) δ(ppm) 5.48 (br, s, CH in 1,5-COD), 5.30 (s, CH in acac), 2.07 (br, s, CH_2 in 1,5-COD), 1.97 (s, CH_3 in acac).

(2) *Thermally induced disproportionation of* (hfac)Cu(1,5-COD)

The thermally-induced decomposition of (hfac)Cu(1,5-COD) was studied in a reactor which consisted of a glass tube, closed at one end with a Kontes tap at the other end. The Kontes tap was attached to a liquid nitrogen cooled U-trap with rubber tubing and the U-trap was attached to a vacuum pump via a Schlenk line. A similar apparatus has been described previously, in detail.[11] A number of thermal decomposition experiments were conducted, and a typical example is described below.

The compound (hfac)Cu(1,5-COD) (370 mg, 0.98 mmol) was placed in the closed end of a glass tube in a nitrogen-filled dry-box and the glass tube attached to the U-trap. The whole apparatus was evacuated (~100 mtorr) and the glass tube placed in two furnaces such that (hfac)Cu(1,5-COD) was heated to 70°C and the remainder of the glass tube was heated to 200°C under dynamic vacuum. The (hfac)Cu(1,5-COD) evaporated from the 70°C zone into the hotter zone where thermal decomposition occurred resulting in copper film formation. After all the (hfac)Cu(1,5-COD) had evaporated, the reaction products were collected and characterized. The compound $Cu(hfac)_2$ was isolated from the cold portion between the hot zone and the U-trap, and 1,5-COD was isolated from the U-trap. The calculated (assuming quantitative disproportionation) and observed amounts of reaction products were as follows: Copper, calc. 30.8 mg, 0.49 mmol; obs. 33.1 mg, 0.52 mmol. $Cu(hfac)_2$: calc. 233.3 mg, 0.49 mmol; obs. 223.8 mg, 0.51 mmol. 1,5-COD: calc. 91.0 mg, 0.98 mmol; obs. 80.0 mg, 0.86 mmol. No isomerization of 1,5-COD was observed.

(3) *Crystallographic data for* (hfac)Cu(1,5-COD)

Yellow crystals of (hfac)Cu(1,5-COD) were grown at low temperature from n-pentane solution. The crystal was mounted in a capillary under a nitrogen atmosphere at 219 K and transferred to a goniostat where it was cooled to 243 K. Crystal data are summarized in Table 1. A total of 2565 independent reflections were measured in the range $2.0 < 2\theta < 50°$ on Siemens R3m/V diffractometer using Mo-K_α(λ = 0.71073 Å) radiation. The data was solved by direct methods using full-matrix least-squares refinement. All hydrogen atoms were visible in a difference Fourier synthesis phased on non-hydrogen parameters. All hydrogens were refined anisotropically with fixed Us set to 1.25 U(equiv.) of parent atoms and non-hydrogen atoms were refined anisotropically in the final cycles. A final difference Fourier map was essentially featureless, with the largest amplitude of 1.70 e $Å^{-3}$. The final agreement factors were $R = 0.0730$ and $R_w = 0.0769$ for 1928 reflections having $F > 3.0\ \sigma(F)$. The relevant bond lengths and angles are presented in Tables 2 and 3, respectively.

Table 1. Summary of crystal data

Empirical formula	$C_{13}H_{13}CuF_6O_2$
Colour of crystal	Pale yellow

RESULTS AND DISCUSSION

The compounds (hfac)Cu(1,5-COD) and (tfac)Cu(1,5-COD) have previously been synthesized by the reaction of 1,5-COD and hfacH with Cu_2O, although no spectroscopic characterization data or reaction yields were reported.[5] In this work, (β-diketonate)Cu(1,5-COD), (β-diketonate) = hfac and tfac were prepared and isolated from the reaction of the corresponding sodium salt of the β-diketone with $[(1,5\text{-COD})CuCl]_2$. The compound (acac)Cu(1,5-COD) was also prepared by this method at −78°C, but it is thermally unstable even at 0°C. This species has been identified in solution by NMR spectroscopy at low temperatures by carrying out the above reaction in a deuterated solvent.

While (tfac)Cu(1,5-COD) has relatively limited thermal stability at room temperature, (hfac)Cu(1,5-COD) exists as a thermally stable, volatile, yellow solid, and is suitable for CVD of copper.[12] This species was characterized further by single-crystal X-ray diffraction at −30°C. Crystal data are presented in Table 1. An ORTEP plot is shown in Fig. 1 together with relevant bond distances and angles in Tables 2 and 3, respectively. Unlike many

examples of copper(I) olefin compounds,[10,13–17] (hfac)Cu(1,5-COD) is monomeric in the solid state with the central copper atom coordinated by the bidentate hfac ligand (O—Cu—O = 93.3(2)°) and the bidentate, but asymmetric 1,5-COD ligand [C(10)—C(11) centroid–Cu—C(6)—C(7) centroid = 86.2°]. The angles and distances within the hfac ligand, and its coordination to copper(I) are similar to other examples of β-diketonate copper(I)

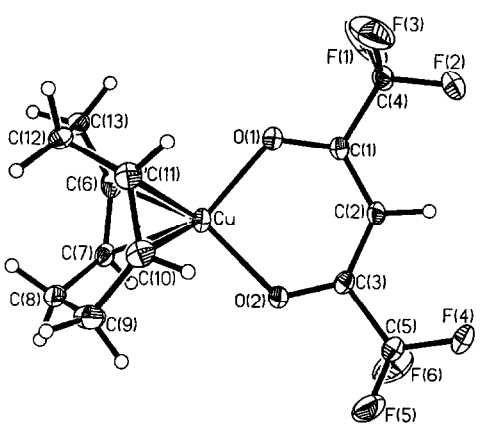

Fig. 1. ORTEP plot of (hfac)Cu(1,5-COD) emphasizing the symmetrical bonding of the hfac ligand to the copper(I) centre.

species we have previously characterized.[3,9,11] The most notable structural feature is the asymmetry in coordination of the 1,5-COD ligand which exhibits Cu—C(6)=C(7) centroid and Cu—C(10)=C(11) centroid distances of 1.953 and 2.418 Å, respectively. This asymmetry is similar to but more pronounced than that previously observed for [(1,5-COD)CuCl]$_2$[10] where the copper double-bond centroid distances were 2.05 and 2.22 Å. Consistent with the copper–carbon bond length asymmetry, C(10)—C(11) is shorter [1.33(1) Å] than C(6)—C(7) [1.37(1) Å]. These C=C bond distances are in the range normally attributed to unactivated, coordinated alkenes. Other angles and distances within the 1,5-COD ligand are as expected. The asymmetry of the 1,5-COD ligand coordination is emphasized in the view shown in Fig. 2 where the copper atom lies 0.267 Å below the O(1), O(2), C(6), C(7) plane. The coordination environment of copper is considerably distorted from tetrahedral and is probably better described as "3+1" coordination. This description emphasizes the observation that one of the double bonds is weakly coordinated to the copper centre which would otherwise possess approximately trigonal planar coordination geometry.

In solution, all three (β-diketonate)Cu(1,5-COD)

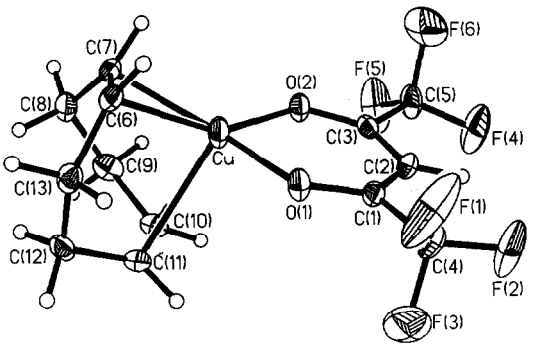

Fig. 2. ORTEP plot of (hfac)Cu(1,5-COD) emphasizing the asymmetry of the coordination of the 1,5-cyclooctadiene ligand to the copper(I) centre.

compounds exhibit one type of olefinic and aliphatic 1,5-COD ^{1}H and ^{13}C NMR resonances, respectively, even at -90°C in toluene-d_8 solutions. This is most surprising for (tfac)Cu(1,5-COD), containing the asymmetric tfac ligand, where two types of vinylic ^{13}C and ^{1}H resonances, respectively, were expected. We observed a similar phenomenon for $[(1,5\text{-COD})CuCl]_2$. This is in contrast to the corresponding rhodium complex $[(1,5\text{-COD})RhCl]_2$ which exhibits three types of 1,5-COD ^{1}H NMR resonances.[18,19] Based on the solid-state structural data we believe that it is most likely that the 1,5-COD ligand is labile and undergoes dynamic rearrangement in solutions of (hfac)Cu(1,5-COD). It is noteworthy that addition of 1,5-COD to a toluene-d_8 solution of (hfac)Cu(1,5-COD) results in rapid exchange between free and coordinated 1,5-COD at room temperature on the ^{1}H NMR time scale. The addition of hfacH to a toluene-d_8 solution of (hfac)Cu(1,5-COD) results in slow exchange with coordinated hfac on the ^{1}H NMR time scale at room temperature. The activation barrier of $\Delta G^{\dagger} = 14.1(+/-0.5)$ kcal mol^{-1} was estimated from the coalescence temperature (308 K) of the methine protons.

Experiments to probe the thermally-induced disproportionation of (hfac)Cu(1,5-COD) have been carried out in which the volatile by-products can be trapped and characterized. A sample of (hfac)Cu(1,5-COD) was heated to 70°C in one end of a glass reactor, with a geometry similar to that previously described,[11] under dynamic vacuum (10^{-2} torr) and evaporated into a hotter zone maintained at 200°C. The compound (hfac)Cu(1,5-COD) completely thermally decomposed under these conditions to yield copper on the hot walls of the reactor, copper(II)$(hfac)_2$ on the cold reactor walls after the hot zone and 1,5-COD in the cold trap.* The compound 1,5-COD was characterized by NMR and mass spectroscopy and $Cu(hfac)_2$ was characterized by mass spectroscopy and elemental analysis. No other products were observed and the disproportionation reaction according to eq. (2) was quantitative by mass balance within the estimated limits of experimental error.

$$2(\text{hfac})\text{Cu}(1,5\text{-COD}) \longrightarrow \text{Cu} + \text{Cu}(\text{hfac})_2 + 2(1,5\text{-COD}) \quad (2)$$

Other reports of disproportionation of copper(I) species have appeared in the literature such as copper(I) aryloxides,[20] but this has recently been disputed.[21]

Further experiments are underway to explore the influence of the copper ligands on the disproportionation reaction and to probe the mechanism of the ligand exchange reactions in this system.

Crystallographic Data. Complete listings of bond distances and bond angles have been deposited with the Editor at Queen Mary College and atomic positional parameters are available from the Director, Cambridge Crystallographic Data Centre.

PREPARATION AND CHARACTERIZATION OF TRIPLY-BRIDGED DINUCLEAR COPPER(II) COMPLEXES CONTAINING THE $[Cu_2(\mu\text{-OH})(\mu\text{-X})(\mu\text{-OAc})]^+$ CORE (X = Cl, Br), AND THE CRYSTAL STRUCTURE OF $[Cu_2(OH)Cl(OAc)(bpy)_2](ClO_4)\cdot H_2O$

(*Received* 12 *March* 1991; *accepted* 18 *June* 1991)

Abstract—Synthetic procedures are described that allow access to complexes containing the cation $[Cu_2(\mu\text{-OH})(\mu\text{-X})(\mu\text{-O}_2\text{CMe})(bpy)_2]^+$ (X = Cl, Br). Reaction mixtures consisting of CuX_2, bpy, OH^-, $MeCO_2^-$ and ClO_4^- ($X = Cl^-$) in $MeOH/H_2O$ give blue solutions from which the products $[Cu_2(OH)Cl(O_2CMe)(bpy)_2](ClO_4)\cdot H_2O$ (**1**) and $[Cu_2(OH)Br(O_2CMe)(bpy)_2]Br\cdot H_2O$ (**4**) can be obtained in good yield. Complex **1** may also be prepared from the known complexes $[Cu_2(OH)(H_2O)(O_2CMe)(bpy)_2](ClO_4)_2$ (**2**) and $Cu_2(OH)_2(bpy)_2(ClO_4)_2$ (**3**). Complex **1** crystallizes in monoclinic space group $P2_1/n$ with (at −175°C) $a = 8.434(1)$, $b = 16.074(2)$, $c = 9.430(1)$ Å, $\beta = 98.09(1)°$, $Z = 2$ and $V = 1265.83$ Å^3. The structure was solved by direct methods (MULTAN) and refined to values of conventional indices $R(R_w)$ of 3.38 (3.54)% using 1499 unique reflections with $F > 2.33\sigma(F)$. The structure of the cation consists of a triply-bridged pair of five-coordinate copper(II) atoms. One of the bridging ligands is a *syn,syn* $\eta^1:\eta^1:\mu_2$ acetate group, the others being the Cl^- and OH^- ions; a terminal bpy molecule completes five-coordination at each metal. The Cu···Cu separation is 2.957(1) Å. The metal coordination geometry is best described as distorted square-pyramidal with the Cl^- ligand occupying the apical site for each metal. The oxygen atom of the water molecule is hydrogen-bonded to the OH^- hydrogen. Recrystallization of **1** from warm water yields **3** in 20% yield; addition of $NaClO_4$ to the solution increases the yield to 40%. Complex **1** in warm water containing one equiv. of $NaClO_4$ and one equiv. of NaOH also gives **3** (yield 73%). The thermal decomposition, room temperature μ_{eff} values, and electronic and IR spectra of **1** and **4** are discussed in terms of the nature of bonding and structure of **1**.

The bridged dinuclear structure $M_2(O_2CR)_4L_2$, first documented in 1953 for copper(II) acetate monohydrate,[1] is ubiquitous in modern coordination chemistry. It is found not only for carboxylates of many transition elements,[2] but also for dimers containing a wide variety of other triatomic bridging ligands.[3] This structural type is associated with a spectrum of metal–metal interactions[4] ranging from no interactions, weak spin-pairing in the copper(II) carboxylates, various orders of metal–metal bonding, to the "super-short" metal–metal bonds. The axial groups are normally monodentate ligands but they may represent inter-dimer association into a polymeric structure[5] or may be absent.[6]

Only a few attempts have been made to incorporate chelating ligands (mainly tridentate), instead of monodentate ones into the $Cu_2(O_2CMe)_4$ structural unit.[7–14] In all cases, dimeric[7–11,13] or polymeric[12,14] complexes with a smaller number of acetate ligands and interesting structural and magnetic characteristics have been obtained. A matter of interest is how much versatility there is in the type of bridging found in copper(II) acetate and whether other small bridging ligands can be incorporated together with acetate bridges in the same complex.

In recent years, we have been investigating the

* On sabbatical leave from the University of Ioannina, Ioannina, Greece.

† Author to whom correspondence should be addressed.

reactions between 3*d* metal carboxylates and N,N- and O,N-bidentate ligands. Most of our efforts have been concentrated in manganese[15] and iron,[16] but we recently extended our efforts to copper and have found that the reactions of $Cu_2(O_2CMe)_4(H_2O)_2$ with chelating 2,2′-bipyridine (bpy) lead to a wide variety of products[17] with bridging units not previously observed in Cu_2^{4+} chemistry. In extending the above work, attempts have been made to prepare a trinuclear complex with the $[Cu_3(\mu_3\text{-}OR)(\mu\text{-}O_2CR')_3]^{2+}$ core, as this structural unit has not yet been identified in copper(II) chemistry.[18] Initial attempts have instead led to interesting dinuclear complexes containing three bridging ligands; the properties of these species are described in this report.

EXPERIMENTAL

Starting materials

All manipulations were performed under aerobic conditions using materials as received; water was distilled in-house. The complex $[Cu_2(OH)(H_2O)(O_2CMe)(bpy)_2](ClO_4)_2$ (**2**) was available from previous work.[17] $Cu_2(OH)_2(bpy)_2(ClO_4)_2$ was prepared as described.[19a] *Caution*: Perchlorate salts are potentially explosive. Although no detonation tendencies have been observed in our work, caution is advised and handling of only small quantities is recommended.

Compound preparation

(1) *Preparation of* $[Cu_2(OH)Cl(O_2CMe)(bpy)_2](ClO_4)\cdot H_2O$ (**1**). *Method A*. To a stirred pale green solution of $CuCl_2$ (0.67 g, 5.0 mmol) in MeOH (25 cm^3) was added bpy (0.78 g, 5.0 mmol) in small portions to give a green precipitate of the known compound $CuCl_2(bpy)$.[19b] This was collected by filtration and dissolved in H_2O (70 cm^3). The resulting blue solution was stirred while an aqueous solution (10 cm^3) containing NaOH (0.07 g, 1.7 mmol), NaO_2CMe (0.41 g, 5.0 mmol) and $NaClO_4$ (0.41 g, 3.3 mmol) was added. The solution soon began to deposit violet–blue microcrystals. The flask was stored at ambient temperature overnight, and the precipitate was collected by filtration, washed with H_2O and Et_2O and dried *in vacuo*; yield, 0.82 g (49% based on available copper). Found: C, 39.4; H, 3.2; N, 8.1; Cl, 10.5. Calc. for $C_{22}H_{22}N_4O_8Cl_2Cu_2$: C, 39.5; H, 3.3; N, 8.4; Cl, 10.6%. IR spectrum (Nujol mull, cm^{-1}): 3450mb, 3365mb, 1601s, 1576m, 1551sb, 1445sh, 1319m, 1312m, 1252m, 1171m, 1157m, 1082vsb, 1055m, 1019m, 978w, 932w, 918w, 897w, 810w, 768vs, 731s, 663m, 650sh, 623s, 545w, 488m, 459m, 417m. Magnetic moment per copper(II) (Faraday method): 2.03 μ_B at 26°C. Solid-state (diffuse reflectance) electronic spectrum: λ_{max}, nm; 340sh, 370, 670, 710sh. Electronic spectrum in MeCN: λ_{max}, nm (ε_M/Cu_2, L mol^{-1} cm^{-1}); 685 (165). Using 0.67 g (5.0 mmol) of $CuCl_2$, 0.78 g (5.0 mmol) of bpy, 0.10 g (2.5 mmol) of NaOH, 0.21 g (2.5 mmol) of NaO_2CMe and 0.31 g (2.5 mmol) of $NaClO_4$, the above synthetic procedure again yielded complex **1**; yield, 1.05 g (63%).

Method B. A slurry of $[Cu_2(OH)(H_2O)(O_2CMe)(bpy)_2](ClO_4)_2$[17] (**2**) (0.25 g, 0.34 mmol) in H_2O (10 cm^3) was treated with solid NaCl (0.04 g, 0.68 mmol). No noticeable colour change occurred. The reaction mixture was stirred for 1 h at 50°C. After cooling to room temperature, the blue solid was collected by filtration, washed with H_2O and Et_2O, and dried *in vacuo*; yield, 0.16 g (70%). The product had IR and electronic spectra identical with those detailed under method A.

Method C. To a slurry of $Cu_2(OH)_2(bpy)_2(ClO_4)_2$[19a] (**3**) (0.67 g, 1.0 mmol) in H_2O (10 cm^3) was added glacial MeCOOH (0.06 cm^3, 1.0 mmol). A noticeable colour change from lavender to blue occurred. To this were added solid NaCl (0.08 g, 1.4 mmol) and MeOH (3 cm^3). The reaction mixture was stirred for 1 h at 40°C. The resulting blue solid was collected by filration, washed with H_2O and Et_2O, and dried *in vacuo*; yield, 0.56 g (84%). The product was identical on spectroscopic examination with **1** prepared by method A.

(2) *Preparation of* $[Cu_2(OH)Br(O_2CMe)(bpy)_2]Br\cdot H_2O$ (**4**). To a stirred dark brown solution of $CuBr_2$ (1.12 g, 5.0 mmol) in MeOH (25 cm^3) was slowly added solid bpy (0.78 g, 5.0 mmol) in small portions to give a pale brown precipitate of $CuBr_2(bpy)$. This was collected by filtration and dissolved in H_2O (105 cm^3). The resulting blue solution was stirred while an aqueous solution (10 cm^3) containing NaOH (0.10 g, 2.5 mmol) and $NaO_2CMe\cdot 3H_2O$ (0.34 g, 2.5 mmol) was added. The dark blue solution was left at ambient temperature. The pale blue, microcrystalline powder that formed was collected by filtration, washed with H_2O and Et_2O (not added to the filtrate) and dried *in vacuo* over silica gel; yield, 0.65 g (38%). Overnight storage of the filtrate at 4°C yielded a second crop of microcrystals of **4**, which were isolated as above; overall yield *ca* 60%. Found: Cu, 18.6; Br, 23.3; H_2O, 2.5. Calc. for $C_{22}H_{22}N_4O_4Br_2Cu_2$: Cu, 18.3; Br, 23.0; H_2O, 2.6%. IR spectrum (KBr pellet, cm^{-1}): 3440mb, 2265sb, 1607m, 1597vs, 1558m, 1487m, 1467m, 1438s, 1430sh, 1319m, 1312m, 1250m, 1169m, 1153m, 1098m, 1069w, 1057w,

1041w, 1022s, 1010s, 942w, 907sh, 890m, 802w, 764vs, 728s, 652w, 575mb, 484mb, 460m, 413m. Magnetic moment per copper(II) (Faraday method): 2.16 μ_B at 23°C. Solid-state (diffuse reflectance) electronic spectrum: λ_{max}, nm: 342, 375, 665, 705sh. Attempts to isolate the ClO_4^- or PF_6^- salt of $[Cu_2(OH)Br(O_2CMe)(bpy)_2]^+$ led to mixtures of $[Cu_2(OH)Br(O_2CMe)(bpy)_2]Br \cdot H_2O$ and $[Cu_2(OH)Br(O_2CMe)(bpy)_2]Y \cdot H_2O$ ($Y = ClO_4$ or PF_6), as deduced from analytical data and IR spectroscopy.

(3) *Conversion of complex* **1** *to complex* **3**

(i) A slurry of complex **1** (0.30 g, 0.45 mmol) in H_2O (20 cm^3) was stirred at 50°C for 45 min. A colour change from blue to lavender occurred. After cooling the mixture to room temperature, the solid was collected by filtration, washed with H_2O and Et_2O, and dried *in vacuo*; yield, 0.06 g (20% based on copper). The identity of the product was deduced by IR spectral comparison with authentic material. An identical procedure but with added $NaClO_4$ (0.06 g, 0.50 mmol) leads to an increased yield of **3**, 0.12 g (40%).

(ii) To a slurry of complex **1** (0.30 g, 0.45 mmol) in H_2O (20 cm^3) was added solid $NaClO_4$ (0.06 g, 0.50 mmol), followed by addition of a solution of NaOH (0.18 g, 0.45 mmol) in H_2O (10 cm^3). An immediate colour change from blue to lavender occurred. The reaction mixture was stirred for 15 min at 50–60°C and the resulting solid was collected by filtration, washed with H_2O and Et_2O, and dried *in vacuo*; yield, 0.22 g (73%). The product had an IR spectrum identical with that of compound **3**.

X-ray crystallographic studies

Crystals suitable for crystallography were grown by careful layering of a green solution of **1** (0.2 g) in DMF (15 cm^3) with Et_2O (25 cm^3) at room temperature. Data were collected on a Picker four-circle diffractometer at −175°C; details of the diffractometry, low-temperature facilities and computational procedures employed by the Molecular Structure Centre are available elsewhere.[20] Data collection parameters are summarized in Table 1.

The structure was solved by a combination of direct methods (MULTAN) and Fourier techniques and refined by full-matrix least-squares. A systematic search of a limited hemisphere of reciprocal space located a set of diffraction maxima with symmetry and systematic absences corresponding to a

monoclinic space group, $P2_1$ or $P2_1/m$. Subsequent solution and refinement of the structure confirmed the centrosymmetric choice, $P2_1/m$. All non-hydrogen atoms were readily located and refined with anisotropic thermal parameters. All hydrogen atoms were clearly visible in a subsequent difference Fourier map; these atoms were included in the final cycles and refined isotropically. The final difference Fourier map was essentially featureless, the largest peak being 0.45 e $Å^{-3}$. The two largest peaks were located in the vicinity of the perchlorate ion. No absorption correction was deemed necessary. Final discrepancy indices R and R_w are included in Table 1.

Physical measurements

IR spectra were recorded as Nujol mulls between CsI plates or KBr discs using a Nicolet 510P Fourier transform spectrometer or a Perkin–Elmer Model 283 spectrophotometer. Solid-state (diffuse reflectance, 890–330 nm) and solution (800–350 nm) electronic spectra were recorded on Varian 634 and Hewlett–Packard 4450A instruments, respectively. Magnetic susceptibilities were measured at room temperature by the Faraday method with a Cahn–Ventron RM-2 balance standardized with HgCo$(SCN)_4$. The molar susceptibilities were corrected for the diamagnetism of the constituent atoms using Pascal's constants. TG/DTG data were obtained with a DuPont R90 instrument equipped with a 951 thermogravimetric analyser in a nitrogen gas flow (50 $cm^3\ min^{-1}$); sample weights of 5–10 mg and heating rates of 1 and 5°C min^{-1} were used.

Analytical procedures

Elemental analyses for **1** were performed at the Microanalytical Laboratory, Department of Chemistry, Manchester University, England. For the bromide determination, samples of **4** were decomposed in 2 M HNO_3; the total bromides were determined potentiometrically with a standard 0.1 M $AgNO_3$ solution, using a Corning–Eel Model 12 potentiometer with calomel and sulphide-selective electrodes.[21] Copper(II) was estimated gravimetrically as copper(II) quinaldate.[22] The amount of water in **4** was determined from the TG pattern.

RESULTS AND DISCUSSION

Syntheses

In our development of Cu^{II}/RCO_2^-/bpy chemistry,[17] we had employed $Cu_2(O_2CMe)_4(H_2O)_2$ and Cu:bpy ratios of 1:1 (a 1:2 ratio is known to produce mononuclear $[Cu(O_2CMe)(bpy)_2]^+$ complexes);[23] all the synthetic methods used led to dinuclear complexes.[17] In extending this chemistry, we considered it of interest to try to prepare trinuclear complexes. These are far less common than are dinuclear copper(II) systems and limited to two structural types,[24] i.e. linear and triangular; they also present interesting structural and magnetic features.[24–30] Recently, we tried to prepare a linear trimer of the formula $Cu_3(O_2CMe)_6(bpy)_2$, like the Mn^{II} analogue,[28] employing a Cu^{II}:bpy ratio of 1.5:1; however, the reaction instead led to $[Cu_2(O_2CMe)_4(bpy)_2]\cdot 2H_2O$ and $[Cu_4(O_2CMe)_4(bpy)_2]_n$.[17] In this work, the influence of added OH^- ($Cu:OH^- = 3:1$) was investigated, wondering whether a product with a $[Cu_3(\mu_3\text{-}OH)(\mu\text{-}O_2CMe)_3]^{2+}$ core might be attainable. An MeOH/H_2O (*ca* 1:3) reaction mixture containing $CuCl_2$. bpy, NaOH, NaO_2CMe and $NaClO_4$ in a 3:3:1:3:2 molar ratio gave a blue solution from which the dinuclear complex **1** was isolated in good yield. The crystal structure of **1** identified the complex to be triply-bridged $[Cu_2(OH)Cl(O_2CMe)(bpy)_2](ClO_4)\cdot H_2O$. Whether Cu_3 species are present in the reaction solution is unclear and difficult to ascertain given the presence of paramagnetism. Nevertheless, as **1** is the first triply-bridged dinuclear copper(II) complex containing three *different* anionic bridging ligands, we decided to pursue the study of this new family of complexes further and a higher yield of **1** was subsequently obtained by changing the $Cu:OH^-$ ratio from 3:1 to 2:1 [eq. (1)].

$$2CuCl_2 + 2bpy + OH^- + MeCO_2^- + ClO_4^- \xrightarrow{MeOH/H_2O} \underset{\mathbf{1}}{[Cu_2(OH)Cl(O_2CMe)(bpy)_2](ClO_4)\cdot H_2O} + 3Cl^- \quad (1)$$

Complex **1** may also be prepared from the complexes $[Cu_2(OH)(H_2O)(O_2CMe)(bpy)_2](ClO_4)_2$ (**2**) and $Cu_2(OH)_2(bpy)_2(ClO_4)_2$ (**3**). Reaction of **2** with an excess of NaCl in H_2O at 50°C gave a clean and high-yield conversion to **1**, emphasizing the lability to substitution of the weakly-bound, bridging aqua group.[17] This reaction is summarized in eq. (2).

$$\underset{\mathbf{2}}{[Cu_2(OH)(H_2O)(O_2CMe)(bpy)_2](ClO_4)_2} + Cl^- \xrightarrow{H_2O} \underset{\mathbf{1}}{[Cu_2(OH)Cl(O_2CMe)(bpy)_2](ClO_4)\cdot H_2O} + ClO_4^- \quad (2)$$

In addition, treatment of **3** with one equiv. of acetic acid in H_2O at 40°C, followed by addition of a slight excess of NaCl led to clean, high-yield

isolation of **1** [eq. (3)], presumably by protonation

$$\underset{\mathbf{3}}{Cu_2(OH)_2(bpy)_2(ClO_4)_2} + MeCO_2H + Cl^- \xrightarrow{H_2O/MeOH} \underset{\mathbf{1}}{[Cu_2(OH)Cl(O_2CMe)(bpy)_2](ClO_4)\cdot H_2O} + ClO_4^- \quad (3)$$

of an OH^- bridge followed by binding of the generated $MeCO_2^-$ and substitution of the bridging aqua ligand by the chloro group. This transformation of **3** to **1** is reversible. Recrystallization of **1** from warm water (~50°C) yielded **3** in 20% yield based on copper; the yield is ClO_4^- limited, however, and addition of $NaClO_4$ to the mixture [eq. (4)] increases the yield of isolated **3**

$$2\underset{\mathbf{1}}{[Cu_2(OH)Cl(O_2CMe)(bpy)_2](ClO_4)\cdot H_2O} + 2NaClO_4 \xrightarrow{H_2O} \underset{\mathbf{3}}{2Cu_2(OH)_2(bpy)_2(ClO_4)_2} + 2MeCO_2H + 2NaCl \quad (4)$$

to 40%. Complex **1** in H_2O containing $NaClO_4$ (one equiv.) and NaOH (one equiv.) also gives **3** (73% isolated yield) at 50–60°C.

The access to $[Cu_2(\mu\text{-}OH)(\mu\text{-}Cl)(\mu\text{-}O_2CMe)]^+$ species from $CuCl_2$ suggested that the reaction system might be capable of extension to other CuX_2 salts (X = halide). The above procedure but with $CuBr_2$ was found to successfully yield the $[Cu_2(\mu\text{-}OH)(\mu\text{-}Br)(\mu\text{-}O_2CMe)]^+$ species in good overall yield [eq. (5)].

$$2CuBr_2 + 2bpy + OH^- + MeCO_2^- \xrightarrow{MeOH/H_2O} \underset{\mathbf{4}}{[Cu_2(OH)Br(O_2CMe)(bpy)_2]Br\cdot H_2O} + 2Br^- \quad (5)$$

Efforts to isolate the ClO_4^- or PF_6^- salt of $[Cu_2(OH)Br(O_2CMe)(bpy)_2]^+$ led to mixtures of **4** and $[Cu_2(OH)Br(O_2CMe)(bpy)_2]Y\cdot H_2O$ ($Y = ClO_4$ or PF_6), due to the low solubility of the bromide salt.

Description of structure

An ORTEP projection of the cation of complex **1** is given in Fig. 1. An ORTEP plot of the inner coordination sphere about the Cu_2 core for the same complex is depicted in Fig. 2. The important structural parameters are listed in Table 2.

The structure of **1** consists of a dinuclear triply-bridged cation lying on a crystallographic mirror plane, a molecule of water of crystallization and a well-separated perchlorate anion; the latter will not be further discussed. The cations are well separated

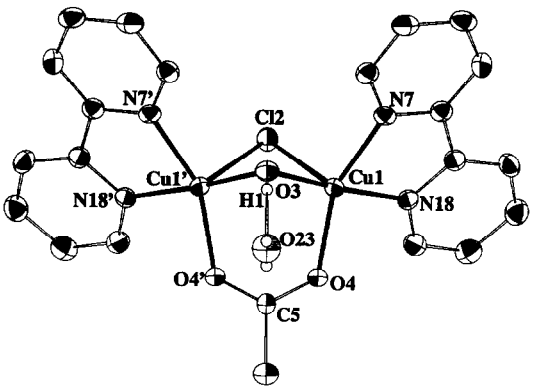

Fig. 1. ORTEP representation of the cation of complex **1** at the 50% probability level. Bipyridine carbon atoms are labelled consecutively from N7. The unlabelled acetate carbon atom is C6. OH^- and H_2O hydrogen atoms are included as spheres of arbitrary size.

from each other. The acetate group is in the familiar bidentate *syn,syn* $\eta^1:\eta^1:\mu_2$-bridging mode; a terminal bpy molecule completes five-coordination at each metal atom. The Cu···Cu separation in **1** is noticeably shorter than in dinuclear triply-bridged copper(II) complexes containing three or two acetato bridges (2.96 vs 3.15–3.40 Å), presumably due to the greater number of mono-atomic bridges.

The metal coordination geometry may be described as distorted square-pyramidal with the chloro ligand occupying the apical position at each metal; this is particularly emphasized by Fig. 2. Analysis of the shape-determining angles using the approach of Addison *et al.*[31] yields a value for trigonality index, τ, of 0.40 for the copper ($\tau = 0$ and 1.09 for square-pyramidal and trigonal bipyramidal geometry, respectively). Thus, the geometry about Cu(1) and Cu(1′) is significantly distorted,

Cu(1)—N(18)	1.998(4)	O(23)···H(1)	2.02(7)
		Angles	
Cu(1)—Cl(2)—Cu(1′)	70.6(1)	N(18)—Cu(1)—O(4)	89.7(1)
Cu(1)—O(3)—Cu(1′)	100.7(2)	N(18)—Cu(1)—O(3)	175.4(2)
Cl(2)—Cu(1)—N(7)	102.8(1)	O(4)—Cu(1)—O(3)	94.2(2)
Cl(2)—Cu(1)—N(18)	96.4(1)	Cu(1)—O(4)—C(5)	127.1(3)
Cl(2)—Cu(1)—O(4)	105.0(1)	Cu(1′)—Cu(1)—Cl(2)	54.7(1)
Cl(2)—Cu(1)—O(3)	85.0(1)	Cu(1′)—Cu(1)—N(18)	144.0(1)
N(7)—Cu(1)—N(18)	80.6(2)	Cu(1′)—Cu(1)—N(7)	123.0(1)
N(7)—Cu(1)—O(4)	151.4(1)	Cu(1)—Cu(1)—O(4)	79.7(1)
N(7)—Cu(1)—O(3)	94.9(2)	O(23)···H(1)—O(3)	171.0(6)

and the four atoms N(7), N(18), O(4) and O(3) defining the basal plane deviate from that plane by an average of 0.22 Å [maximum deviation by N(18), 0.233 Å]; Cu(1) lies 0.245 Å out of the least-squares basal plane towards Cl(2). The dihedral angle between the two CuN_2O_2 planes is 60.6°.

The bond lengths to the bridging hydroxo and acetate oxygens and to the two bpy nitrogen atoms are typical.[17,32] The distance Cu(1)—Cl(2) [2.557(1) Å] and the acute angle Cu(1)—Cl(2)—Cu(1′) [70.6(1)°] are both very similar to those observed in other dinuclear, square-pyramidal copper(II) complexes sharing a common μ_2-Cl^- apex;[33] the bond from the copper to the bridging apical chloro ligand is longer than that to bridging basal chloro ligands (~2.3 Å).[34]

The oxygen atom O(23) of the water molecule hydrogen-bonds to the OH^- hydrogen H(1) [O(3)—H(1), 0.81(7) Å; H(1)···O(23), 2.02(7) Å; O(23)···H(1)—O(3), 171(6)°]. No evidence of inter-cation hydrogen bonds was found.

Complex **1** represents the first structurally characterized example of a triply-bridged, dinuclear copper(II) complex containing three different anionic bridging ligands. Another triply-bridged Cu_2 complex is somewhat structurally related to compound **1** in that it has three different anionic bridging ligands: $[Cu_2(OH)(ClO_4)L]^+$ [35] [L = the monoanion of 2,6-bis(N-(2-pyridylmethyl) formidoyl)-4-methylphenol]; in this complex, however, the third bridging ligand is provided by the aryloxide oxygen of the pentadentate binucleating L.

Some other triply-bridged Cu_2 complexes with three different bridging ligands (two anionic, one neutral) should be mentioned at this point: (i) $[Cu_2(\mu\text{-OH})(\mu\text{-X})LX_2]$ [X = Cl, Br; L = binucleating phthalazine or pyridazine ligands[36] and 2,7-bis(2-pyridyl)-1,8-naphthyridine][33] are also the only other examples of dinuclear copper(II) complexes bridged by both equatorial OH^- and apical X^-. (ii) The MeOH inclusion compound $[Cu_2(\mu\text{-OH})(\mu\text{-}O_2CMe)(L—L)](ClO_4)_2 \cdot MeOH$[37] (L—L = a binucleating tetradentate hexaimidazole ligand) and complex **2**[17] are also the only other examples of Cu_2 complexes bridged by *one* OH^- and *one* $MeCO_2^-$.

The structure of the cation of **1** shows some similarity to that of $[Cu_2(OH)(H_2O)(O_2CMe)(bpy)_2]^{2+}$ [17] (**2**); obviously, the replacement of μ_2-H_2O by μ_2-Cl^- at the common apical position has little structural effect. However, the cations of **2** form infinite chains as a result of hydrogen-bonding interactions with the ClO_4^- counter-ions,[17] while **1** is an isolated dinuclear species with only an intramolecular hydrogen bond.

Thermal decomposition of **1** *and* **4**, *IR and electronic spectroscopy*

The thermal decomposition of **1** and **4** was studied using TG/DTG techniques. We first comment on the dehydration process. The TG curve of **1** shows a one-step, first mass loss between 75 and 100°C, which corresponds exactly to the release of the water content (Found: 2.7. Calc.: 2.7%). The low temperature of H_2O loss shows that this is not coordinated. A TG plateau is present from 105 to 202°C. The anhydrous complex decomposes in four steps, as revealed by the appearance of four DTG maxima, between 205 and 280°C and in a slower process between 280 and 670°C. The absence of TG plateaux during decomposition indicates that stable intermediates are not formed. The final, thermally-

stable residue is CuO (Found 23.4. Calc. 23.8%). The thermal decomposition of **4** is completely analogous.

The room temperature μ_{eff} values of **1** and **4** would appear to exclude strong antiferromagnetic coupling, but it is difficult to rule out weak antiferromagnetic interactions. In fact, both complexes are likely either weakly antiferromagnetically- or ferromagnetically-coupled, due to the "non-complementarity"[38,39] of $MeCO_2^-$ and OH^- orbitals with $d_{x^2-y^2}$ magnetic orbitals. It is interesting to note that all Cu_2^{II} systems bridged by one $R'CO_2^-$ and one RO^- (R = H, alkyl) are known to be weakly antiferromagnetic or ferromagnetic.[17,37-39]

Complexes **1** and **4** possess very similar solid-state electronic spectra, supporting similar structures for their cations. Both exhibit two LMCT transitions[40] in the 375–340 nm range and *d–d* transitions at lower energies. The *d–d* frequencies are fairly typical of distorted square-pyramidal structures.[34,40] The *d–d* spectrum of **1** in dry MeCN is different from the solid-state spectrum, indicating structural changes upon dissolution and/or cation–solvent interactions.

In the IR spectra, complexes **1** and **4** exhibit bands at ~3450 and 3365 cm^{-1}, assigned to $\nu(OH^-)$ and $\nu(H_2O)$, respectively;[41] their broadness and low frequency are both indicative of hydrogen bonding. The $\nu_{as}(COO)$ and $\nu_s(COO)$ bands of **1** and **4** are at 1558–1551 and 1445–1438 cm^{-1}, respectively; the difference Δ [$\Delta = \nu_{as}(COO) - \nu_s(COO)$; 106 cm^{-1} for **1**, 120 cm^{-1} for **2**] is less than that for NaO_2CMe (164 cm^{-1}), as expected for the bidentate bridging mode of carboxylate ligation.[42]

(*Received* 26 *February* 1991; *accepted* 18 *June* 1991)

Abstract—The reactions in diethyl-ether/hexane solutions between aniline and $M_2(OBu^t)_6$ (M = Mo, W) produce $M_2(OBu^t)_4(HNPh)_2(H_2NPh)_2$ in high yield (79–85%) as red–black crystals. The compounds are air-sensitive, soluble in aromatic hydrocarbon solvents, and exhibit dynamic NMR behaviour. The IR spectra show ν(N—H) at 3320 and 3100 cm^{-1}, corresponding to aniline and anilide N—H stretches, respectively. The X-ray crystal structures of $M_2(OBu^t)_4(HNPh)_2(H_2NPh)_2$ are isomorphous for molybdenum and tungsten and reveal eclipsed four-coordinate, essentially planar ends supporting a metal–metal triple bond. Some important bond lengths and angles for $W_2(OBu^t)_4(HNPh)_2(H_2NPh)_2$ ($Mo_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ in parentheses) are as follows (at −169°C and −168°C): M—M 2.3225(8) [2.2538(7)], M—O = 1.93 (1.94) (ave), 1.98 (1.96) (ave), M—N (amide) 1.97 (ave) [1.99 (ave)], M—N (amine) 2.37 Å (ave) [2.36 Å (ave)].

There is now an extensive group of $X_3M{\equiv}MX_3$ compounds where M = Mo and W = X = alkyl (β-H stabilized), NMe_2, OR, SAr′ and SeAr′ (Ar′ = mesityl).[1–4] The $M_2(OR)_6$ complexes are coordinatively unsaturated and depending upon the steric requirements of R may reversibly pick up Lewis bases to form $M_2(OR)_6L_2$ complexes (L = pyridine, amine or tertiary phosphine).[5] The general synthesis of $M_2(OR)_6$ compounds involves the addition of an alcohol to the $M_2(NMe_2)_6$ compound[6] [eq. (1)].

$$M_2(NMe_2)_6 + 6ROH \xrightarrow[\text{hydrocarbon}]{} M_2(OR)_6 + 6HNMe_2 \quad (1)$$

In a number of cases reaction (1) yields dimethylamine adducts $M_2(OR)_6(HNMe_2)_2$ because the equilibrium reaction (2) lies well to the right for the specific combination of R and L, e.g. M = Mo, R = $SiMe_3$, L = $HNMe_2$[7] and M = W, R = Pr^i, CH_2Bu^t, L = $HNMe_2$.[8,9]

$$M_2(OR)_6 + 2L \rightleftharpoons M_2(OR)_6L_2 \quad (2)$$

We describe here reactions involving the addition of aniline to $M_2(OBu^t)_6$ compounds which, contrary to the general reaction shown in eq. (2), proceed to give displacement of tert-butanol and formation of anilide ligands. This provides a rare, and possibly the first example of the replacement of an alkoxide by an amide [eq. (3)].[9]

$$L_nM\text{-}OR + HNR'R'' \longrightarrow L_nM\text{-}NR'R'' + ROH \quad (3)$$

RESULTS AND DISCUSSION

Synthesis

The reactions of excess (> 6 fold) aniline or 3,5 dimethylaniline with $M_2(OBu^t)_6$ (M = Mo, W) in hexane/diethyl-ether solution at room temperature produce red crystals of $M_2(OBu^t)_4(HNPh)_2(H_2NPh)_2$ in high yield (79–85%) [eq. (4)].

$$M_2(OBu^t)_6 + 4H_2NAr \xrightarrow{\text{hexane/ether}} M_2(OBu^t)_4(NHAr)_2(NH_2Ar)_2 + 2HOBu^t \quad (4)$$

(M = Mo, W; Ar = C_6H_5, C_6H_5-3,5-Me_2)

* Author to whom correspondence should be addressed.

The product starts to precipitate from the reaction on standing at room temperature approximately 5 min after mixing the solutions. [Following the reaction by ^{1}H NMR (in benzene-d_6) indicates the formation of HOBu^t but no other intermediate compounds.] The reaction proceeds with less than four equivalents of aniline, though unreacted $M_2(OBu^t)_6$ is obtained with the yields reduced accordingly. No detectable reaction occurs between 2,6-dimethylaniline and $M_2(OBu^t)_6$. Probably steric factors deny access to a potential coordination site in $M_2(OBu^t)_6$.

The $M_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ complexes are air-sensitive in both solution and the solid state, decomposing to brown oils. They have relatively low decomposition points (90–114°C), probably due to the ready loss of the Lewis base aniline ligands. For this reason they are not sublimable without decomposition. The $M_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ complexes are not light sensitive. They are soluble in aromatic hydrocarbon solvents but only sparingly soluble in ethereal or aliphatic solvents.

Spectroscopic characterization

The compounds $M_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ were characterized by IR, microanalysis, ^{1}H NMR, melting points and X-ray crystallography. The IR spectra were run as KBr pressed discs which gave the expected ^{t}BuO and aniline/anilide vibrations. The molybdenum/tungsten analogues of $M_2(OBu^t)_4(NHC_6H_5)_2(NH_2C_6H_5)_2$ have essentially identical spectra. The IR spectra revealed two types of N—H stretching vibrations:[10] $\nu = 3350$ and 3100 cm^{-1}. The higher frequency vibration is attributable to a ν(N—H) of the NH_2 group on the Lewis base aniline ($\nu = 3280$ cm^{-1} for aniline) and the lower frequency due to a ν(N—H) of the anilide ligands.

The ^{1}H NMR spectra of $M_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ are temperature dependent. At very low temperature (−75°C) along with the expected ^{t}BuO$^{\ominus}$ and aniline/anilide aromatic proton resonances there are three singlets at $\delta = 11.85$, 9.40 and 4.75 ppm of equal intensity. These latter resonances are due to the protons on aniline and anilide nitrogens. The peaks at 9.40 and 4.75 ppm can be reasonably assigned to the diastereotopic protons on the aniline nitrogen. One proton is bridging across the M—M core to an adjacent ^{t}BuO$^{\ominus}$ ligand whilst the other proton is pointing away from the M—M multiple bond (see Fig. 1). Presumably the resonance at 9.40 is due to the proton involved in this hydrogen bridge as similar low-field shifts for bridging OH protons have been observed in analogous $M_2(OAr)_4(OBu^t)_2(HOBu^t)_2$ (M = Mo, W; Ar = C_6H_5, C_6H_4-4-Me) complexes.[11] The lower frequency resonance at 4.75 ppm is likely due to the other protons on the aniline. This is further supported by spin saturation transfer experiments at −75°C that reveal the $\delta = 4.75$ and $\delta = 9.40$ ppm resonances are in slow chemical exchange. Irradiation at one resonance causes a > 90% reduction in signal intensity at the other resonance. This is most easily achieved by a slow (on the NMR time-scale) exchange between the two aniline protons, due to O···H hydrogen-bond breakage and rotation about the M—N aniline bond. The peak at $\delta = 11.85$ ppm is unaffected (less than 10% reduction) by these decoupling experiments at low temperature.

The resonance at $\delta = 11.85$ is thus assigned to the anilide protons. It occurs at lower field than the ArNH_2 resonances because it is anisotropically deshielded both by the formal nitrogen–metal multiple bond and its close vicinity to the M—M triple bond.[12]

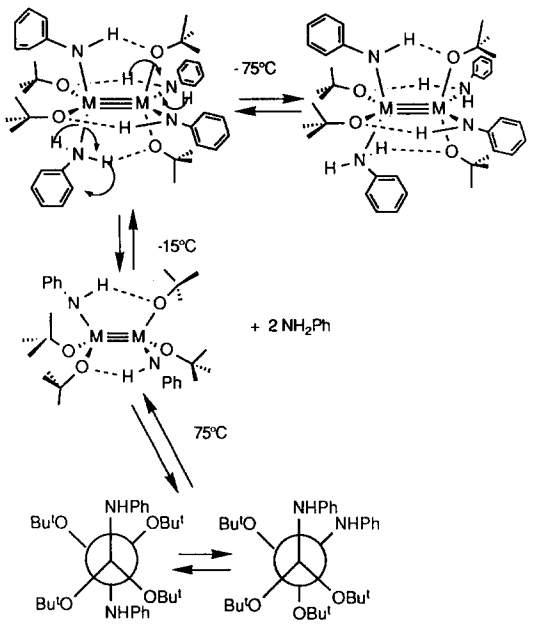
Raising the temperature from −75°C to room temperature alters the ^{1}H NMR spectra of $W_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$. The single peak at $\delta = 11.85$ broadens at −45 to −35°C but sharpens from −15 to 25°C. The peaks at 9.4 and 4.75 ppm are broadened and then lost into the baseline at −35°C and subsequently a peak grows at around 4.6 ppm from −30 to 0°C. This new peak has an integration of four compared to that at 11.85 ppm of two. This implies that it is due to the protons on the aniline ligand which are equivalent above −30°C. In turn this suggests that the aniline ligands are freely dissociated into solution above −30°C as the weighted average of the signal falls at 4.6 ppm rather than at 7.1 ppm, the expected value if a rotation about the M—N bond were making the protons on the aniline equivalent. The aniline nitrogen protons shift to lower frequency with higher temperature such that they occur at $\delta = 3.8$ ppm at 25°C, 3.4 ppm at 65°C and $\delta = 3.2$ ppm at 95°C. Free aniline has for H_2NPh $\delta = 3.2$ ppm. Thus, at 95°C, little aniline is coordinated to the metal. However, in the intermediate regime from 0 to 95°C this resonance is higher than the free value. The aniline is undergoing a fast equilibrium of the type shown in Scheme 1. At high temperatures the equilibrium lies in favour of $W_2(OBu^t)_4(NHPh)_2$ and aniline.

Addition of aniline to an NMR tube of $W_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ in toluene gave at low temperature (−75°C) the resonances at 11.85, 9.40 and 4.75 ppm, as well as that for free aniline at 3.5 ppm (PhNH_2). At room temperature irradiation at the aniline resonance of $\delta = 3.8$ ppm

does not cause any diminishing of the anilide peak at $\delta = 11.8$ ppm, thus indicating that the anilide and aniline N—*H* protons are not undergoing chemical exchange at a measurable rate. At temperatures between 0 and +95°C only one resonance for the H_2NPh protons is observed and the resonance is shifted to higher field upon addition of successive aliquots of aniline, and with increasing temperature indicating that all the aniline in solution spends some time on the dimetallic core.

The anilide N—*H* proton is split into three resonances of unequal intensity on raising the temperature above 0°C. Upon raising the temperature one signal decreases in intensity as the other two increase. At 95°C two peaks of equal intensity are observed at 11.8 and 10.9 ppm. On cooling the sample from 95°C this interconversion is fully reversible such that at 0°C only a peak at 11.85 ppm is observed. This process could be due to a mixture of eclipsed (i.e. N—H···O bonded) and staggered conformers (anti and gauche) of $W_2(NHPh)_2(OBu^t)_4$ with the latter being favoured at high temperatures. At 75°C decoupling of the aniline NH_2 protons at $\delta = 3.5$ ppm does cause a reduction of *ca* 50% in the intensity of the two peaks at $\delta = 11.8$ and 10.9 ppm, thus indicating at higher temperatures the aniline and anilide protons are undergoing a slow exchange.

The variable temperature ^{1}H NMR spectra of $Mo_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ and $W_2(OBu^t)_4(NHC_6H_3Me_2)_2(NH_2C_6H_5)_2$ showed very similar behaviour. The proposed dynamic processes are illustrated in Scheme 1.



Scheme 1.

Crystallographic studies of $M_2(OBu^t)_4(HNPh)_2(H_2NPh)_2$

Crystals suitable for X-ray diffraction were grown from a hexane/ether reaction solution of $M_2(OBu^t)_6$ and aniline at room temperature. The molecular structure of $Mo_2(OBu^t)_4(HNPh)_2(H_2NPh)_2$ is shown in Figs 1 and 2 viewed perpendicular and parallel to the M—M vector, respectively. The selected bond lengths and angles for $M_2(OBu^t)_4(HNPh_2)_2(H_2NPh)_2$ (M = Mo, W) are shown in Table 1 and crystallographic data collection parameters are given in Table 2.

The structures of the molybdenum and tungsten $M_2(OBu^t)_4(HNPh)_2(H_2NPh)_2$ complexes are isomorphous with all bond angles and lengths (within the 3σ criteria) being equivalent apart from M—M = 2.2538(7) Å for M = Mo and 2.3225(8) Å for M = W. These distances are typical for M—M triple bonds uniting four coordinate metal atoms.[5,8]

The $M_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ molecule adopts an eclipsed conformation in the solid state with two essentially square planar ends being joined by a metal–metal triple bond. The eclipsed geometry is sterically unfavourable in dimetallic systems because of non-bonded repulsions between groups on either end of the multiple bond. The observed eclipsed geometry is likely due to the presence of four hydrogen bonds bridging the dinuclear centre. The hydrogens were located in the X-ray analysis for $Mo_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ and were refined isotropically (see Table 3).

The metal–nitrogen distances, 1.98 (ave) and 2.38 Å (ave), clearly indicate two types of coordinated nitrogen ligands. The Lewis base aniline has a weak M—N bond. Indeed this M—N distance, 2.38 Å (ave), is longer than in $W_2(OPr^i)_6py_2$ at 2.26 Å,[5] and is the longest measured first-row Lewis base to metal distance in any $M_2(OR)_6L_2$ complex.[5] The other M—N distance of 1.98 Å (ave) is consistent with a deprotonated aniline. It is only slightly longer than the M—N distances in $M_2(NMe_2)_6$ and $M_2(NMe_2)_4R_2$ complexes [1.94 Å (ave)] and indicates a significant degree of M—N $d\pi$–$p\pi$ bonding.[1]

The M—O distances of 1.95 Å (ave) in $M_2(OBu^t)_4(PhNH)_2(PhNH_2)_2$ are typical of those in other $M_2(OR)_6L_2$ complexes.[5]

The ligands in $M_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ are disposed such that the $^tBuO^{\ominus}$ groups are *trans* to each other on each tungsten. The two O—M—O units are nearly mutually perpendicular to each other. This is probably caused by steric requirements, with the $^tBuO^{\ominus}$ ligands being bulkier than the aniline/anilide ligands. However, this arrangement also maximizes the hydrogen bonding between neighbouring groups across the multiple

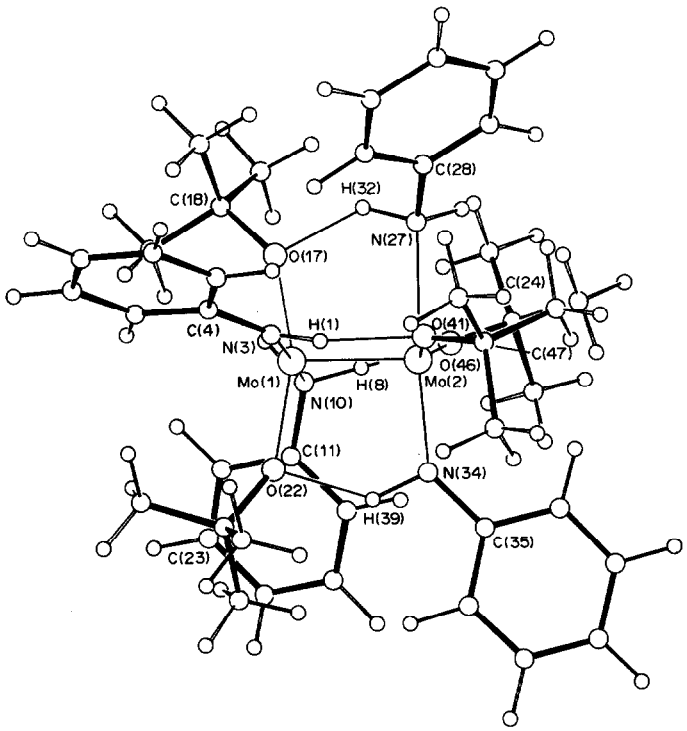


Fig. 1. A ball-and-stick drawing of the $Mo_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ molecule showing the atom number scheme used in the tables and the NH···O hydrogen bonding across the M—M bond.

bond. Interestingly the anilines are on the same side of the molecule. To complement this, the geometry is distorted from the idealized eclipsed geometry with the OBu^t groups being closer to the aniline groups than the anilides at each tungsten centre, resulting in the O—M—O angle of 152.9°.

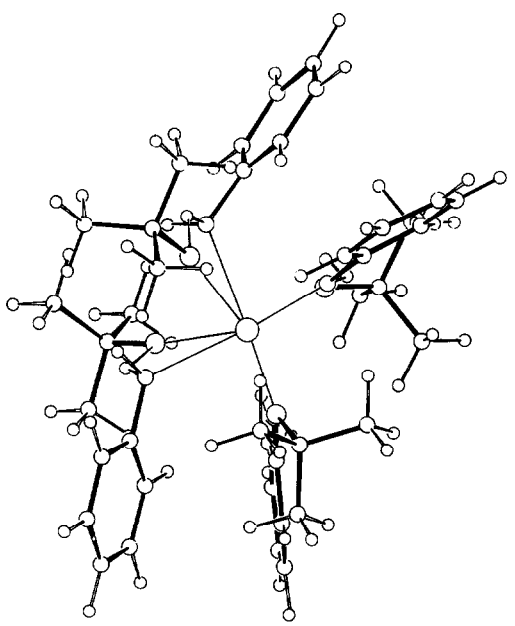

Fig. 2. A view of the $Mo_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$ molecule looking down the M—M bond emphasizing the near eclipsed geometry that results from the hydrogen bonding across the M—M bond.

The non-bonded N···O distances between *syn* groups across the M—M bond range from 2.69 to 2.77 Å. This is indicative of hydrogen bonding.[13] The hydrogens were located in the molybdenum structure and can be inferred for the tungsten analogue because of the isostructural nature of the complexes. The atoms M, M, N and O for the anilides and alkoxide ligands that are involved in hydrogen bonding lie in a plane. As a result of this hydrogen bonding the M—M—O angles (99.3° ave) and the M—M—N angles at 94° (ave) and 91° (ave) for the anilide and aniline nitrogens, respectively, are all smaller than the M—M—N/O angles in $M_2(OR)_6$ and $M_2(NMe_2)_6$ complexes.

Concluding remarks

The aminolysis reaction reported here is a very rare example of reaction (3). Normally the reverse reaction is observed and is driven by the greater strength of the M—OR bond relative to M—NR′R″. Aminolysis does not occur with cyclohexylamine, dimethylamine or methylamine. It appears to be restricted to aniline. This may be a reflection of the pKa of the amine.[14] However, hydrogen bonding is clearly a contributing factor in stabilizing the $M_2(OBu^t)_4(NHAr)_2(NH_2Ar)_2$

molecules relative to say $M_2(OBu^t)_6(NH_2Ar)_2$. Given that reactions of type (3) are equilibria involving proton transfer, it is quite likely that the hydrogen bonding more than compensates for the difference in expected M—OR and M—NHR bond strengths.

EXPERIMENTAL

All reactions were performed under dry nitrogen atmospheres by standard Schlenk techniques. Solvents were dried and deoxygenated by standard methods. ^1H NMR spectra were recorded at 299.60 MHz on a Varian XL 300 in $C_6D_5CD_3$ and are referenced to residual protio toluene at $\delta = 2.09$ ppm. IR spectra were obtained as pressed KBr discs on a Perkin–Elmer 283 spectrophotometer. $M_2(OBu^t)_6$ (M = Mo, W) compounds were prepared according to literature procedures.[15] Aniline and 3,5-dimethylaniline were purchased from Aldrich Chemical Company and were used as supplied. Microanalysis were provided by Oneida Research Services, Whiteboro, New York.

$M_2(OBu^t)_4(NHAr)_2(NH_2Ar)_2$ [M = Mo, Ar = C_6H_5; M = W, Ar = C_6H_5, 3,5-$Me_2C_6H_3$]

The same general procedure was adopted for all compounds, illustrated here for $W_2(OBu^t)_4(HNPh)_2(NH_2Ph)_2$.

To $W_2(OBu^t)_6$ (0.200 g, 0.248 mmol) dissolved in hexane (15 cm^3) at room temperature was added dropwise a solution of aniline (0.140 g, 1.48 mmol) in hexane (5 cm^3)/diethyl-ether (5 cm^3). The solution was allowed to stand at room temperature and after 5 min red crystals were precipitated. After 24 h the filtrate was removed and the red crystals washed with hexane (15 cm^3) and diethyl-ether (5 cm^3) and dried briefly *in vacuo*. Obtained $W_2(OBu^t)_4(HNPh)_2(NH_2Ph)_2$ (0.190 g, 0.185 mmol, 75%).

Found: C, 47.0; H, 6.4; N, 5.5. Calc.: C, 46.6; H, 6.1; N, 5.4%.

Single crystal X-ray studies

General operating procedures and a listing of programs have been reported.[16]

$Mo_2(OBu^t)_4(NH_2Ph)_2(NHPh)_2$. A suitable small single crystal was selected from the bulk sample using inert atmosphere handling techniques. The

crystal was transferred to the goniostat where it was cooled to −169°C for characterization and data collection. A systematic seach of a limited hemisphere of reciprocal space yielded a set of reflections that exhibited monoclinic symmetry (2/*m*). The systematic extinction of *h*0*l* reflections for $h+l = 2n+l$ and of 0*k*0 for $k = 2n+l$ uniquely identified the space group as $P2_1/n$. Data collection was undertaken as detailed in Table 2. A total of 6407 reflections (including space group extinctions and standard reflections) were collected in the given range. Following the usual data reduction and averaging of equivalent reflections a unique set of 5458 reflections was obtained. The *R* value for the averaging was 0.05 for 696 reflections measured more than once. A plot of the four standard reflections measured every 400 reflections showed no significant trends. No correction for absorption was applied ($\mu = 6.3$). Unit cell dimensions were determined for 66 unique reflections having 2θ values between 21 and 31°.

The structure was solved using a combination of direct methods and Fourier techniques. The two molybdenum atoms were located in the initial *E*-map and the remaining non-hydrogen atoms were located in a difference map. Following initial refinement all of the hydrogen atoms associated with the nitrogen atoms were located as well as almost all other hydrogen atoms. All hydrogen atoms were then introduced in idealized positions. Full-matrix least-squares refinement was completed using anisotropic thermal parameters on all non-hydrogen atoms and individual isotropic thermal parameters on the hydrogen atoms. The final *R* value was 0.049 and $R_w(F)$ was 0.045. Reflections having $R < 3.0\sigma(F)$ were given zero weight during the refinement.

The final difference Fourier was essentially featureless, the largest peak being 0.71 e Å^{-3} in the vinicity of C(16).

$W_2(OBu^t)_4(NHPh)_2(NH_2Ph)_2$. A crystal of suitable size was mounted in a nitrogen atmosphere glove bag using silicone grease, and then transferred to a goniostat where it was cooled to −168°C for characterization and data collection. A search of a limited hemisphere of reciprocal space revealed intensities with Laue symmetry and systematic absences consistent with the space group $P2_1/n$, which was later confirmed by the successful solution of the structure. Following complete intensity data collection and correction for absorption, data processing gave a residual of 0.031 for the averaging of 1064 unique intensities which had been measured more than once. Four standards measured every 300 data showed no significant trends.

The structure is isomorphous with the molybdenum complex. It was solved independently using a combination of direct methods (MULTAN-78) and Fourier techniques. The tungsten positions were obtained from an initial *E*-map. The remainder of the non-hydrogen atoms were found in subsequent iterations of least-squares refinement and difference Fourier calculation. Hydrogen atoms were included in calculated positions but were not refined. Hydrogen thermal parameters were fixed at one plus the isotropic thermal parameters of the atom to which it was bonded. The number of hydrogen atoms on each nitrogen was obvious from the W—N distances (1.98 Å for W—NH— and 2.35 Å for W—NH_2—), which was consistent with the earlier work.

In the final cycles of refinement the non-hydrogen atoms were varied with anisotropic thermal parameters to a value of $R(F) = 0.041$. The final difference map was reasonably clean, the largest peak being a tungsten residual of 1.2 e Å^{-3}.

AN ALTERNATIVE MECHANISM FOR THE FORMATION OF THE COBALT(III) MOLYBDATE CATION, $Co(NH_3)_5MoO_4^+$

MICHAEL R. GRACE*† and PETER A. TREGLOAN

Inorganic Chemistry Section, School of Chemistry, University of Melbourne, Parkville, Victoria 3052, Australia

(*Received* 7 *March* 1991; *accepted* 5 *June* 1991)

Abstract—An alternative mechanism is proposed for the formation of $Co(NH_3)_5MoO_4^+$ from $Co(NH_3)_5H_2O^{3+}$ and MoO_4^{2-} in slightly basic solution (pH 7.1–8.0). The observed second-order rate dependence upon $[MoO_4^{2-}]$ may be explained by $HMoO_4^-$ acting as a proton-donating catalyst, in contrast to the previously postulated mechanism involving the formation of dimeric molybdenum(VI) species. An increase in reaction rate was also caused by the addition of other protonated anions (HCO_3^-, $H_2PO_4^-$) to the reaction solution, thus supporting the contention of a general proton-assisted mechanism. No evidence of dimeric molybdenum(VI) was found.

Taylor has reported that the formation of $Co(NH_3)_5MoO_4^+$ from MoO_4^{2-} and $Co(NH_3)_5OH^{2+}$, in the pH range 7.1–8.0, could be conveniently followed using the stopped-flow technique.[1] It was also found that the complexation reaction, given in eq. (1), showed a greater than first-order dependence upon $[MoO_4^{2-}]$.

$$Co(NH_3)_5OH_2^{3+} + MoO_4^{2-} \underset{}{\overset{k_f}{\rightleftharpoons}} Co(NH_3)_5MoO_4^+ + H_2O \quad (1)$$

The forward rate constant, k_f, has four terms, according to eq. (2):

$$k_f = k_a + k_b[H^+] + k_c[MoO_4^{2-}] + k_d[H^+][MoO_4^{2-}]; \quad (2)$$

where: $k_a = 96 \pm 7\ M^{-1}\ s^{-1}$, $k_b = (1.1 \pm 0.2) \times 10^9\ M^{-2}\ s^{-1}$, $k_c = (2.2 \pm 0.2) \times 10^3\ M^{-2}\ s^{-1}$ and $k_d = (1.02 \pm 0.05) \times 10^{11}\ M^{-3}\ s^{-1}$ at 25°C and $\mu = 1.0$ M ($NaClO_4$).

Taylor also noted that the rate of reaction was consistent with substitution at the molybdenum(VI) rather than cleavage of the inert cobalt(III)–oxygen bond. It was suggested that the pathways k_a and k_b correspond to the reaction of $HMoO_4^-$ with $Co(NH_3)_5OH_2^{3+}$ and $Co(NH_3)_5OH^{2+}$, respectively. The second-order $[MoO_4^{2-}]$ dependence for paths k_c and k_d was ascribed to a reaction involving the dimolybdate species $Mo_2O_8^{4-}$, $HMo_2O_8^{3-}$ or $H_2Mo_2O_8^{2-}$, depending upon the active cobalt(III) entity, in order to conform to the observed acid dependence.

The dimolybdate anion, $Mo_2O_7^{2-}$, has been isolated from acetonitrile solution as the $(n\text{-}C_4H_9)_4N^+$ salt, containing corner-shared MoO_4^{2-} tetrahedra.[2] However, $Mo_2O_7^{2-}$ has never been detected in aqueous solution, although a recent study by Cruywagen and Heyns[3] reported evidence of the protonated species $HMo_2O_7^-$ under mildly acidic conditions ($2.3 \leqslant pH \leqslant 6.1$). The discrete dimeric species, $Mo_2O_5(H_2O)_6^{2+}$, has been identified as the major component of molybdate solutions in 2–6 M $HClO_4$ and HNO_3 by ^{95}Mo NMR and Raman spectroscopy.[4] The structure involves two molybdenum(VI) centres bridged by a single oxygen. Two terminal oxygens and three aquo ligands constitute an octahedral environment around each molybdenum ion. However, the existence of an aqueous dimeric molybdenum(VI) species, under normal conditions, must remain tentative since another recent potentiometric study[5] found no molybdate oligomers between monomers and the heptameric series $Mo_7O_{24}H_n^{(6-n)-}$ ($n = 0$, 1, 2 and 3).

The major objective of the present study was to reinvestigate the complexation between MoO_4^{2-}

and $Co(NH_3)_5OH_2^{3+}$ in basic solution, in order to investigate Taylor's postulated reaction between cobalt(III) ions and dimeric molybdenum(VI) species. The presence (or absence) of a term involving dimolybdate in the rate expression could then be used as independent evidence for its existence and assist in the continuing development of the models used to describe molybdenum(VI) speciation in acid solution.

We thought that the second order term in $[MoO_4^{2-}]$ might also arise from $HMoO_4^-$ acting as a general acid catalyst. Consequently, the effect of a range of anions upon the rate of the complexation reaction was also examined.

EXPERIMENTAL

Materials

$[Co(NH_3)_5OH_2](ClO_4)_3$ was prepared by established methods.[6,7] UV–vis spectra were in good agreement with those reported previously.[7,8] $Na_2MoO_4 \cdot 2H_2O$ (May & Baker, LR) was twice recrystallized from base solution (pH $\approx$ 11). Triethylanolamine (Ajax, LR) was distilled *in vacuo*. Na_2HPO_4 (Ajax, AR), $NaHCO_3$ (BDH, Analar), Na_2SO_4 (BDH, Analar) and NaOH (Ajax, AR) were used without further purification. Twice distilled, once deionized water was used throughout

Both equilibrium and kinetic measurements were performed in the presence of 0.1 M triethanolamine in order to buffer the solutions at the required pH and prevent the formation of polymeric molybdenum(VI) species.[1] Solutions were adjusted to the desired pH by addition of either 2 M $HClO_4$ or 2 M NaOH. These solutions showed negligible drift in pH (< 0.05 pH) units) over a period of several months.

The synthesis of $[Co(NH_3)_5MoO_4](ClO_4)$ involved mixing slightly alkaline 0.05 M solutions ($8 \leqslant pH \leqslant 9$) of MoO_4^{2-} and $Co(NH_3)_5OH^{2+}$ at 50–60°C in the presence of *ca* 0.5 M $NaClO_4$. The mixed solution was maintained at this temperature for a further 15 min. The pink solid formed upon cooling was filtered and then washed with ice-cold water, CH_3CH_2OH and then $(CH_3CH_2)_2O$ and dried at 60°C for several hours. The crude complex was recrystallized from a minimum of hot ($\approx$ 80°C) water at pH 8, filtered, washed and dried as above. Yields were typically 30–40%.

The analysis of NH_3 content has been described previously.[9] For $[Co(NH_3)_5MoO_4](ClO_4)$: Found: 20.6. Calc.: 21.1%. The residue after product decomposition was filtered and the molybdenum concentration in the filtrate was determined gravimetrically as $MoO_2(C_9H_6ON)_2$ after complexation with 8-hydroxyquinoline.[10] Found: 23.5. Calc.: 23.8%.

Physical methods

All pH* measurements were performed using a Radiometer GK2401C combined glass electrode, in which the saturated KCl reference solution was replaced with 1 M NaCl to prevent the precipitation of $KClO_4$ at the liquid junction. The electrode was calibrated daily with a series of acid ($HClO_4$, pH 2–3.5, μ = 1.0 M) and base (NaOH, pH 11–12.5, μ = 1.0 M) standards. The slope of the pH vs electrode potential plot was typically 0.059 ± 0.002 V per pH unit.

Absorbance measurements were performed on a Varian Techtron 635D UV–vis spectrophotometer, using a cell block thermostatted to 25.0 ± 0.1°C. Spectra were recorded in a quartz mixing cell (Hellma, 238-QS) which is divided into two equal path-length compartments by a thin wall; a hole at the top of this wall allows mixing of the two reactant solutions. Consequently any absorbance change upon mixing can be directly attributed to chemical reaction.

IR spectra were recorded as KBr discs on a Jasco 302 IR spectrometer. Raman spectra were obtained using a Spex Ramalog 5 Raman spectrometer interfaced with an M6800 microcomputer. During Raman studies of molybdate/phosphate solutions, $NaClO_4$ was added to each solution to maintain an ionic strength of 1.0 M and also provide an intensity calibration for each spectrum [at $\nu_1(ClO_4^-) = 935$ cm^{-1}]. HCl was used to obtain the desired solution pH.

Diffuse reflectance spectra were recorded over the range 340–750 nm on a Beckman DK-2A spectrophotometer ($BaSO_4$ reference). Variable temperature magnetochemical measurements were performed over the range 210–350 K on a thermostatted Gouy balance, calibrated with $Hg[Co(NCS)_4]$. Diamagnetic corrections were applied according to König.[11]

Rate measurements

The formation of $Co(NH_3)_5MoO_4^+$ from MoO_4^{2-} and $Co(NH_3)_5OH_2^{3+}$ was followed spectrophotometrically at 550 nm, using the stopped-flow technique. The cobalt(III) concentration was maintained at 0.0020 M,† whilst $[MoO_4^{2-}]$ was

* The term "pH", used throughout this paper, refers to the quantity $-\log_{10}[H^+]$.

† All concentrations are at the "instant of mixing" = stock concentration/2.

varied between 0.010 and 0.100 M. All rate measurements were made at an ionic strength of 1.0 M ($NaClO_4$) and at 25.0 ± 0.1°C over the pH range 7.1–8.0.

A stopped-flow apparatus, designed and constructed within the Chemistry Department at Melbourne University, was used to perform kinetic experiments with half-lives ranging from 10 ms to several minutes. The molybdate and cobalt(III) reactant solutions were drawn into 2 cm^3 glass, gas-tight drive syringes (Hamilton, 1002-TEFLL) from plastic reserve syringes via three-way taps (Hamilton, No. 86727). A kinetic experiment ("run") was initiated by triggering a solenoid-controlled pneumatic drive, which forced fresh reactant solutions through a Kel-F mixer[12] and into the observation chamber. Up to 20 runs can be recorded before refilling the drive syringes.

The observation cell consists of either: (a) a "straight-through" 2 mm internal diameter quartz tube where the light-beam passes through the tube at a 90° angle, or (b) a "Z-shape" 18 mm path-length chamber in a Kel-F block, enclosed into the brass stopped-flow block by quartz windows. Choice of cell is governed by the magnitude of the absorbance change and the intensity of the transmitted light. Optically dense solutions necessitated using the short path-length tube to ensure adequate signal-to-noise response of the photomultiplier detection system.

The stopped-flow unit is encased in a brass block through which thermostatted water is circulated, allowing temperatures between 7 and 45°C to be maintained to within 0.05°C. A Hewlett Packard 34740A platinum resistance thermometer is inserted into a cavity in the brass casing to enable temperature resolution of 0.01°C. All reactant solutions were thermostatted within the drive syringes for 20 min to ensure thermal equilibration.

A 100 W quartz–halogen lamp, powered by a Hewlett Packard Model 6286A supply, provided the light source for the spectrophotometric detection of reaction progress. A Czerny–Turner design Spex type 1670 Minimate monochromator was used to select the required wavelength. The light source is focussed onto the entrance slit of the monochromator with a quartz lens. An adjustable diaphragm shutter, mounted on the lens, enables the light beam to be blocked between measurements to minimize any photolytic side reactions. The transmitted light from the observation cell is detected by a photomultiplier (RCA type 1P28).

All optical detection components are mounted on an optical rail (Oriel), with the light source, quartz lens, entrance and exit slits of the monochromator and the photomultiplier at the same height as the observation cell of the stopped-flow apparatus.

The difference between the output voltage from the photomultiplier and an adjustable constant voltage source is amplified (Analog Devices AD521J) to maximize the reaction signal change in the range −2.5 to 2.5 V (the bipolar limits of the analogue to digital converter). A passive RC type circuit is used to remove high-frequency noise. The filtered signal is simultaneously displayed by oscilloscope and sampled by the AR11 analogue subsystem of a PDP-11/10-S minicomputer (or an M6802 microcomputer) and stored for subsequent analysis.

Each stopped-flow run consisted of collecting 200 voltage/time data pairs at a specified sampling rate, waiting a predetermined interval and then collecting a further 20 data pairs, representing reaction equilibrium. The sampling rate was usually chosen so that 200 data pairs covered 95% of the total reaction amplitude.

The collection and preliminary analysis of stopped-flow data were performed under the control of the BASIC program RDATA, developed within this laboratory. This program allowed the collection of up to 20 runs for each set of reactant solutions with the capability to maximize the signal-to-noise ratio. Pseudo first-order rate constants for each run and the signal-average could be calculated by either a simple integrated rate expression or by the Guggenheim method.[13]

RESULTS

Characterization of $[Co(NH_3)_5MoO_4](ClO_4)$

IR and Raman spectra were used to ascertain the coordination mode of the molybdate species in $[Co(NH_3)_5MoO_4](ClO_4)$. Table 1 lists the principal observed IR and Raman frequencies for this compound and for $[Co(NH_3)_5MoO_4]Cl$, $[Co(NH_3)_4MoO_4]NO_3$, $[Co(NH_3)_5Cl]MoO_4$ and free MoO_4^{2-}, reported by Coomber and Griffith.[14] Fundamental Raman frequencies for MoO_4^{2-} and ClO_4^-, measured from solid samples of Na_2MoO_4 and $NaClO_4$, are also included.

The ν_1 symmetric stretch of the MoO_4^{2-} moiety can be used to discriminate between alternate modes of coordination. The observed ν_1 frequencies for $[Co(NH_3)_5MoO_4](ClO_4)$, 912 (IR) and 909 cm^{-1} (R), are in excellent agreement with the values cited for $[Co(NH_3)_5MoO_4]Cl$, thus indicating monodentate, inner-sphere coordination to the cobalt(III) ion. Not surprisingly, the frequencies of the perchlorate anion are similar in the cobalt(III) complex and in $NaClO_4$, indicating no significant

interaction between the cobalt(III) and ClO_4^- in the solid.

The UV–vis spectrum of $[Co(NH_3)_5MoO_4](ClO_4)$ was recorded by diffuse reflectance from the solid to avoid complications arising from concurrent rapid aquation to MoO_4^{2-} and $Co(NH_3)_5OH_2^{3+}$ when the complex is dissolved in solution. The spectrum has absorbance maxima at 360 and 525 nm, corresponding to the $^1T_{2g} \leftarrow {}^1A_{1g}(\nu_2)$ and $^1T_{1g} \leftarrow {}^1A_{1g}(\nu_1)$ electronic transitions, respectively.

The effective magnetic moment, μ_{eff}, of $[Co(NH_3)_5MoO_4](ClO_4)$ at 298 K was determined as 0.54 B.M. This value is consistent with a wide variety of low-spin cobalt(III) compounds with moments ranging from 0 to 1 B.M.,[11,16] including the analogous monodentate chromate complex, $[Co(NH_3)_5CrO_4](ClO_4)$, which has a μ_{eff} of 0.62 B.M.[9] As was observed with the chromato species, the non-zero magnetic moment for the d^6 cobalt(III) complex can be explained by temperature-independent paramagnetism, where there is a coupling of the ground and excited states under the influence of the applied magnetic field. This contention is supported by the invariance of the molar susceptibility ($\chi_M = 1.55 \pm 0.05 \times 10^{-9}$ m^3 mol^{-1}) over the temperature range 210–350 K. The molybdate moiety would also most probably be contributing to the observed μ_{eff}, since applying diamagnetic corrections to the uncorrected susceptibilities for Na_2MoO_4 and K_2MoO_4 yield room temperature, magnetic moments of 0.33 and 0.34 B.M., respectively (again arising from temperature-independent paramagnetism).[11]

Equilibrium measurements

As noted by Taylor in his original determination of K_1, the equilibrium constant describing the complexation given in eq. (1), mixing solutions of $Co(NH_3)_5OH_2^{3+}$ and molybdenum(VI) under slightly basic conditions results in a rapid intensification of the purple colour. Figure 1 shows spectra from a mixing cell experiment illustrating the total absorbance change resulting from the complexation reaction. Taylor attributed this absorbance enhancement to the formation of $Co(NH_3)_5MoO_4^+$. This proposal is supported by the close similarity in absorbance maxima between the aqueous spectrum (λ_{max} = 365 and 525 nm) and the diffuse reflectance measurements on $[Co(NH_3)_5MoO_4](ClO_4)$ in this study (λ_{max} = 360 and 525 nm).

The evaluation of K_1 involved analysis of the absorbance changes at 540, 550 and 560 nm (corresponding to the wavelengths of maximum change) using the Benesi–Hildebrand method[17]

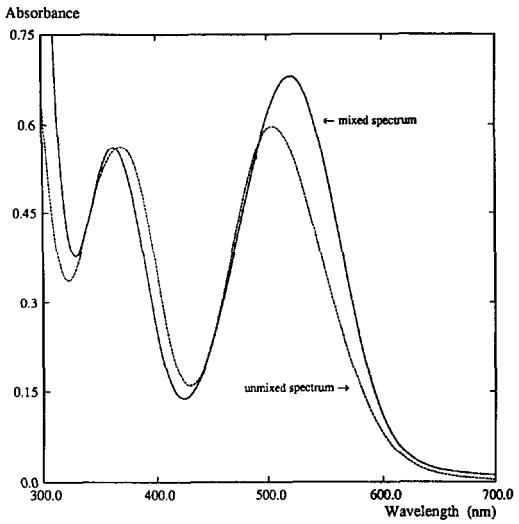

Fig. 1. The effect of complexation upon the UV–vis spectrum of $Co(NH_3)_5OH^{2+}$ and MoO_4^{2-} at 25°C and 1.0 M ionic strength.

with the molybdate concentration in large excess. Calculations were performed according to Taylor and resulted in an average value for K_1 of 960 ± 80 M^{-1} at 25°C and 1.0 M ionic strength (cf. 475 ± 30 M^{-1}).[1]

Kinetic measurements

The acid dependence of the reaction was measured over the pH range 7.1–8.0. Lower pH values and higher molybdate concentrations were avoided to minimize formation of isopolymolybdate species.[18]

All reaction transients were first-order for at least five half-lives. The observed rate constants, k_{obs}, and the relevant reaction conditions are listed in Table 2. Data analysis involved the determination of the forward rate constant, k_f, and its resolution into the four terms given in eq. (2).

Plots of k_f vs $[MoO_4^{2-}]$ were linear at all pH values indicating a second-order dependence upon $[MoO_4^{2-}]$. The slope and intercept terms, shown in Table 3, correspond to the molybdate-dependent and -independent pathways in the forward rate law. Plotting these slope and intercept terms against $[H^+]$ yields the four individual rate constants in Taylor's rate expression.[1] The resultant values for k_a, k_b, k_c and k_d are included in Table 3. The agreement between the two studies is very reasonable if the constants are recalculated using molybdenum(VI) stock concentrations, rather than those at the "instant of mixing".

All measurements were made at 25.0 ± 0.1°C, 1.0 M ionic strength ($NaClO_4$) and with a total cobalt(III) concentration of 0.002 M. Solutions were buffered with 0.1 M triethanolamine. Quoted errors are one standard deviation and are derived from the signal-averaged reaction transient. Concentrations are at the "instant of mixing".

Catalysis of $Co(NH_3)_5MoO_4^+$ *formation*

As mentioned in the introductory remarks, it is possible that the observed second-order dependence upon $[MoO_4^{2-}]$ may be due to general acid catalysis of complex formation, presumably by $HMoO_4^-$. In order to test this hypothesis, various potential catalysts (Na_2HPO_4, $NaHCO_3$ and Na_2SO_4) were added to the molybdate solution prior to the stopped-flow run.

The potential catalyst was mixed with the molybdate solution since SO_4^{2-}, CO_3^{2+} and PO_4^{3-} all form complexes with $Co(NH_3)_5OH^{2+}$ in alkaline

[a] Calculated using stock $[MoO_4^{2-}]$ rather than "instant of mixing" concentrations.

solution.[19] Before assessing the effect of these anions upon the rate of $Co(NH_3)_5MoO_4^+$ formation, some preliminary experiments, designed to determine any direct reaction between these anions and MoO_4^{2-}, were performed. This precaution was deemed essential, since the ability of molybdenum(VI) to form heteropolymolybdate species, including heterophosphates, in acidic solution is well known.[20] Murata and Ikeda have used Raman spectroscopy to follow the formation of the 12-molybdophosphate species, $PMo_{12}O_{40}^{3-}$.[21]

These brief investigations involved quantitatively monitoring the intensity of the Raman ν_1 symmetric stretch of MoO_4^{2-} at 897 cm^{-1}, upon the addition of increasing concentrations of the proposed catalytic species. The formation of any molybdenum(VI)–anion complex would result in a loss of MoO_4^{2-} tetrahedral symmetry and a consequent diminution in the ν_1 peak intensity. In all cases, the concentration of free molybdate was greater than 99% of total molybdenum(VI), even with "catalyst" concentrations in 10-fold excess. A realistic estimate for the accuracy of this technique is $\pm1\%$, thus trace amounts of a molybdo–anion complex would not be detected. Pettersson[22] determined the speciation of molybdophosphates at 25°C over the pH range 3–9. At low pH, the total molybdenum(VI) concentration was comprised almost solely of complex molybdenum-phosphate species, but above pH 7, only MoO_4^{2-} was detected. The combined results of these two studies suggest that the concentration of possible molybdophosphate species at pHs higher than 7.2 would be negligibly small.

(a) *The effect of* SO_4^{2-} *addition.* The effect of SO_4^{2-} upon the rate of $Co(NH_3)_5MoO_4^+$ formation was assessed by adding Na_2SO_4 to a 0.10 M MoO_4^{2-} stock solution prior to mixing with 0.0040 M cobalt(III) at pH 7.54. The results of these experiments are summarized in Table 4(a) and show that SO_4^{2-} has only a marginal effect upon k_{obs}.

(b) *The effect of* HPO_4^{2-} *addition.* In view of the small rate enhancement caused by the addition of sodium sulphate to the reactant system, a preliminary stopped-flow experiment was performed, under identical solution conditions, using 0.025 M Na_2HPO_4. The resultant reaction was too fast for accurate detection using the stopped-flow technique. The concentration of HPO_4^{2-} was then reduced by a factor of 50 and the reaction transient

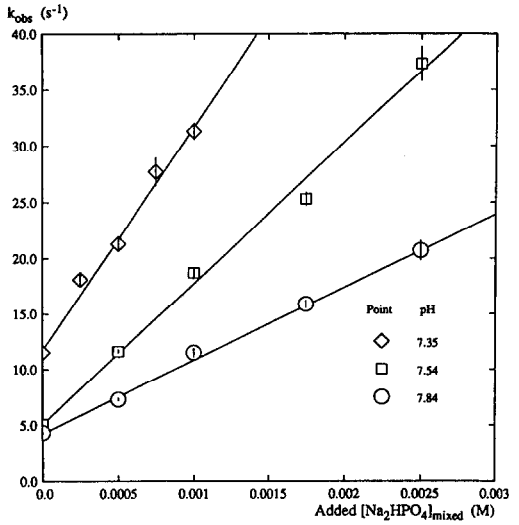

Fig. 2. The effect of pH and total phosphate concentration on the rate of $Co(NH_3)_5OH^{2+}/MoO_4^{2-}$ complexation at 25°C and 1.0 M ionic strength. $[Co^{III}] = 0.0020$ M. $[MoO_4^{2-}] = 0.050$ M.

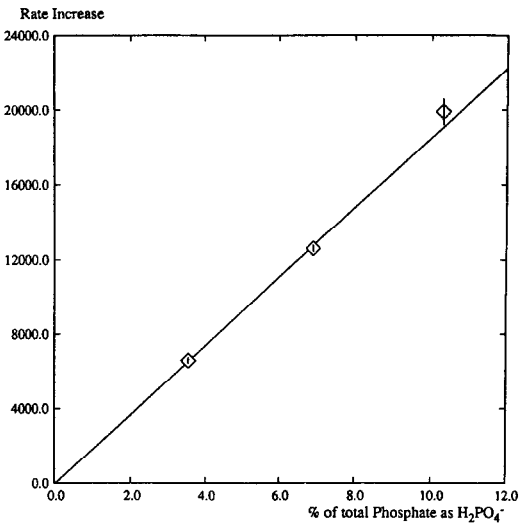

Fig. 3. The catalytic activity of $H_2PO_4^-$ on the rate of $Co(NH_3)_5OH^{2+}/MoO_4^{2}$ complexation at 25°C and 1.0 M ionic strength. $[Co^{III}] = 0.0020$ M. $[MoO_4^{2-}] = 0.050$ M.

showed that even at 5×10^{-4} M, this species doubled the rate of $Co(NH_3)_5MoO_4^+$ formation. Further stopped-flow runs were then conducted to determine the dependence of this rate enhancement upon the concentration of added Na_2HPO_4 and the solution pH. Solution conditions and the observed first-order rate constants for these experiments are listed in Table 4(b).

Figure 2 shows that rate enhancement is linearly dependent upon Na_2HPO_4 at a given pH, but also that the degree of enhancement is acid dependent. The slope of the plot at each pH is a measure of "catalytic activity". The results of the linear analysis of these plots are presented in Table 5.

In the pH range 7–8, phosphate solutions contain both HPO_4^{2-} and $H_2PO_4^-$. The relative proportions of these species are determined by the deprotonation equilibria:

$$H_2PO_4^- \overset{K_a}{\rightleftharpoons} HPO_4^{2-} + H^+.$$

A value of 6.40 ± 0.06 was determined for pK_a at 25.0°C and $\mu = 1.0$ M ($NaClO_4$), by potentiometric titration with NaOH in CO_2-free water, using the automatic titration equipment described elsewhere.[23] This value is in good agreement with the 6.46 ± 0.02 quoted by Smith and Martell under the same conditions.[24]

Figure 3 shows a plot of the catalytic activity vs the percentage of total phosphate as $H_2PO_4^-$. It is apparent from this plot that rate enhancement is linearly dependent upon $[H_2PO_4^-]$ and also, that this species is the only detectable catalyst in solution.

Complications arising from anation reactions between the cobalt(III) and phosphate species in the stopped-flow chamber were not expected since these processes occur by slow cobalt–oxygen bond fission.[25] Hence, $Co(NH_3)_5MoO_4^+$ formation would be essentially complete before any cobalt(III) phosphate complexation occurs.

(c) *The effect of* HCO_3^- *addition.* The addition reaction of CO_2 to $Co(NH_3)_5OH^{2+}$ occurs over the same time frame as the molybdate complexation process[26] and hence poses a potential interference to the desired reaction sequence (due to competition

Table 5. Determination of the pH dependence of Na_2HPO_4 catalytic efficiency on the rate of $Co(NH_3)_5OH_2^{3+}/MoO_4^{2-}$ complexation at 25°C and 1.0 M ionic strength

between MoO_4^{2-} and CO_2 for the cobalt(III) ions). However, the nature of the Co^{III}/MoO_4^{2-} complexation reaction and a careful choice of experimental parameters enables some very informative, semi-quantitative results to be obtained. Taylor found that with $[Mo^{VI}]$ in large excess, the rate of $Co(NH_3)_5MoO_4^+$ formation was independent of $[Co^{III}]$ and observations during preliminary stopped-flow runs in this work indicated that the presence of $NaHCO_3$ had no obvious effect on the reaction transient for this process. The transients were first-order for at least five half-lives and also showed no diminution in absorbance change during reaction upon increased bicarbonate concentration. There was also no indication of a second, first-order transient corresponding to $Co(NH_3)_5CO_3^+$ formation. By limiting the lowest pH solutions to 7.25, the amount of dissolved CO_2 was kept below 5% of the total carbonate concentration and the ratio of MoO_4^{2-} to CO_2 was never less than 2000.

It was found that the presence of $NaHCO_3$ in solution during stopped-flow runs substantially increased the rate of $Co(NH_3)_5MoO_4^+$ formation. Solutions were prepared from CO_2-free water in a nitrogen-filled glove-box. The results of the catalysis experiments are summarized in Table 4(c). The catalytic activity of $NaHCO_3$ was determined in an identical manner to the phosphate system and the linear fit parameters to the k_{obs} vs $[NaHCO_3]$ plots are given in Table 6.

The determination of the active catalytic species is complicated by extensive carbonate speciation and potential reaction with $Co(NH_3)_5OH^{2+}$. Over the pH range studied, CO_3^{2-}, HCO_3^-, H_2CO_3 and dissolved CO_2 are all present in solution. The relationship between these species and the cobalt(III) reaction products is shown in the following equilibrium scheme:

$$H_2O + CO_2 \overset{K_1}{\rightleftharpoons} H_2CO_3 \overset{K_2}{\rightleftharpoons} H^+ + HCO_3^- \overset{K_3}{\rightleftharpoons} H^+ + CO_3^{2-}$$

$$Co(NH_3)_5OH^{2+} \Big\| K_E$$

$$Co(NH_3)_5HCO_3^{2+} \overset{K_H}{\rightleftharpoons} Co(NH_3)_5CO_3^+ + H^+$$

The deprotonation equilibrium involving HCO_3^- and CO_3^{2-} has been well-characterized with a pK_3 value of 9.57 at 25°C and $\mu = 1.0$ M.[24] Dissolved CO_2 and H_2CO_3 are in an equilibrium heavily favouring CO_2, to the extent that the equilibrium constants K_1 and K_2 are normally combined into one apparent pK_{app} for the "deprotonation of CO_2"[26] ($pK_{app} = 6.02$ at 25°C and $\mu = 1.0$ M[24]). A limited amount of work has been done on resolving K_{app} into its K_1 and K_2 components. van Eldik and Palmer report values for these constants of 2.28×10^{-3} and 4.6×10^{-4} M, respectively in 0.5 M NaCl.[27] In the absence of values at 1.0 M $NaClO_4$, these results were used, in combination with K_3, to calculate preliminary carbonate speciation in the molybdate solutions, at the pH values used in this study. The close agreement between the resultant K_{app} value at $\mu = 0.5$ M NaCl[26] and the 1.0 M $NaClO_4$ value indicates that the error introduced by this procedure would be negligible in comparison to the inherent errors in the measurement of the observed rate constants and the effects of cobalt(III)–carbonato complexation. The calculated percentages of total carbonate as H_2CO_3 and HCO_3^- at the "instant of mixing" are included in Table 6.

The plot of catalytic activity against apparent percentage H_2CO_3, shown in Fig. 4, demonstrates that although the doubly protonated species appears to be the major catalyst for the formation of $Co(NH_3)_5MoO_4^+$, the large positive intercept term indicates that another species, most probably HCO_3^-, is also responsible for some rate-enhancing effect. As there is considerable doubt as to the actual concentrations of these species, no further attempt was made to accurately quantify these effects.

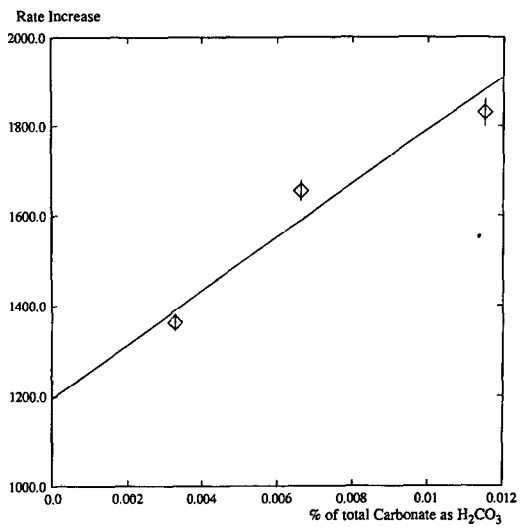

Fig. 4. The catalytic activity of H_2CO_3 on the rate of $Co(NH_3)_5OH^{2+}/MoO_4^{2-}$ complexation at 25°C and 1.0 M ionic strength. $[Co^{III}] = 0.0020$ M. $[MoO_4^{2-}] = 0.050$ M.

DISCUSSION

The reinvestigation of the pH and molybdate dependence for the formation of $Co(NH_3)_5MoO_4^+$, resulted in an expression for the forward rate term which corresponded exactly with that proposed by Taylor[2] [eq. (2)]. After allowing for a plausible difference, by a factor of two, in evaluating the MoO_4^{2-} concentration (stock or "instant of mixing"), the individual second- and third-order rate constants comprising this term were also in good agreement. However, after consideration of the catalytic effect of several protonated anions, an alternative reaction scheme can be proposed to account for the apparent second-order dependence upon $[MoO_4^{2-}]$, observed in both studies. Scheme 1, shown below, involves direct reaction between the cobalt(III) and MoO_4^{2-} species and also requires proton donation from an external "acid catalyst". The resultant rate expression from this scheme also conforms to the observed pH and concentration dependences expressed in eq. (2).

The catalytic species, HA, may be any moiety in solution capable of proton donation to the molybdate to assist in water elimination. In this scheme, the reaction between cobalt(III) and MoO_4^{2-}, observed by Taylor, is catalysed by $HMoO_4^-$ in solution. Although the concentration of $HMoO_4^-$ constitutes less than 0.1% of the total molybdate, it is still present at levels 100–1000 times higher than $[H^+]$. The added catalysts $H_2PO_4^-$, H_2CO_3 and possibly HCO_3^- contribute to the total solution "pool" of proton-donating species.

If the mechanism involves rate-determining proton-transfer and water departure, then the degree of rate enhancement should reflect the acidity of the proton which migrates to the molybdenum(VI) hydroxy group. The slope of the catalytic activity plot is a direct measure of the effectiveness of that species to increase the rate of $Co(NH_3)_5MoO_4^+$ formation. The slope of the plot for H_2CO_3, $(6.0 \pm 0.9) \times 10^4$, is much greater than that for $H_2PO_4^-$, $(1.9 \pm 0.1) \times 10^3$, which can be attributed to the greater acidity of the carbonate species. The slope estimate for H_2CO_3 is a lower limit since no account was taken of the effect of $Co(NH_3)_5CO_3^+$ formation upon carbonate speciation. Clearly, the existence of any correlation between the pK_a of the proton-donating anion and the catalytic efficiency of the species, based only upon two anions, must remain speculative. Further investigation using a wide variety of substitution-inert, proton-donating species may help clarify this situation. It might also be expected that a second-order dependence upon cobalt(III) concentration would be observed with this species in excess over $[MoO_4^{2-}]$. In addition, $Co(NH_3)_5OH_2^{3+}$ would be the likely catalyst due to the greater acidity of the aquo ligand's proton relative to the $Co(NH_3)_5OH^{2+}$ proton. Another advantage of using excess cobalt(III) is that the complications arising from $HMoO_4^-$ catalysis could be minimized.

Path (b) in Scheme 1 involves the initial formation of the protonated complex, $Co(NH_3)_5HMoO_4^{2+}$, followed by rapid deprotonation to $Co(NH_3)_5MoO_4^+$. It has been demonstrated that the incorporation of a $Co(NH_3)_5$ group into the coordination sphere of various oxo anions

(a) $Co(NH_3)_5OH_2^{3+} + MoO_4^{2-} \rightleftharpoons Co(NH_3)_5MoO_4^+ + H_2O$,

(b) $Co(NH_3)_5OH_2^{3+} + HMoO_4^- \rightleftharpoons Co(NH_3)_5MoO_4^+ + H_2O + H^+$,

(c) $Co(NH_3)_5OH^{2+} + MoO_4^{2-} + HA \rightleftharpoons Co(NH_3)_5MoO_4^+ + H_2O + A^-$,

(d) $Co(NH_3)_5OH_2^{3+} + MoO_4^{2-} + HA \rightleftharpoons Co(NH_3)_5MoO_4^+ + H_2O + HA$.

Scheme 1. Various possible reaction paths for the formation of $Co(NH_3)_5MoO_4^+$.

(AsO_4^{3-}, PO_4^{3-}, SeO_3^{3-}, CrO_4^{2-}) dramatically enhances the acidity of any ionizable protons on that anion.[28-31] It is therefore assumed that the pK_a of $Co(NH_3)_5HMoO_4^{2+}$ will be significantly lower than $HMoO_4^-$ itself (3.92 at 25°C and $\mu = 1.0$ M[5]) and consequently, at pH values above 7, the concentration of the protonated product would be negligible.

The almost complete indifference of the reaction rate to added SO_4^{2-} suggests that the catalysis involves proton transfer. It may be argued that the very small dependence of k_{obs} upon increasing sulphate concentration [Table 4(a)] is due to trace amounts of HSO_4^-, but it is equally plausible that this dependence is simply a medium effect resulting from the relatively high concentrations of added Na_2SO_4 (up to 0.1 M). Taylor noted that changing the electrolyte from $NaClO_4$ to $LiClO_4$ caused a marked decrease in k_{obs}. It is interesting to note that the addition of Na_2SO_4 did not retard the complexation reaction as was observed with the formation of Co(tetren)HSO_3^{2+}.[22] This decrease in rate upon addition of SO_4^{2-} was attributed to the formation of unreactive $\{Co(tetren)OH_2^{3+} \cdots SO_4^{2-}\}$ ion pairs.

Unfortunately, definitive assignment of reaction pathways to the terms in the rate expression is impossible due to the inherent proton ambiguities. Paths (a) and (d) in Scheme 1 may be rewritten as reactions involving $Co(NH_3)_5OH^{2+}$ and $HMoO_4^-$, as proposed by Taylor. It is believed that the reaction between Co—OH and $HMoO_4^-$ is more likely than Co—OH_2 and MoO_4^{2-}, since the latter option requires transfer of both protons from the aquo ligand to a molybdenum(VI) oxygen, whereas only one transfer to the molybdenum(VI) hydroxo ligand is necessary from $Co(NH_3)_5OH^{2+}$. Conversely, significant ion-pairing and internal hydrogen-bonding would favour the +3/−2 reaction. Paths (a) and (b) may also be expressed in terms of external proton donation or catalysis as shown below:

(e) $Co(NH_3)_5OH^{2+} + MoO_4^{2-} + H^+ \rightleftharpoons Co(NH_3)_5MoO_4^+ + H_2O$

(f) $Co(NH_3)_5OH_2^{3+} + MoO_4^{2-} + H^+ \rightleftharpoons Co(NH_3)_5MoO_4^+ + H_2O + H^+$.

The attractive feature of this last proposal is that paths (e) and (f) are identical to the general catalysis paths (c) and (d) (except that HA is now specifically H^+) and therefore, only two reactions are required to describe the entire complexation process.

Figure 5 depicts possible transition states for the various pathways proposed for the complexation

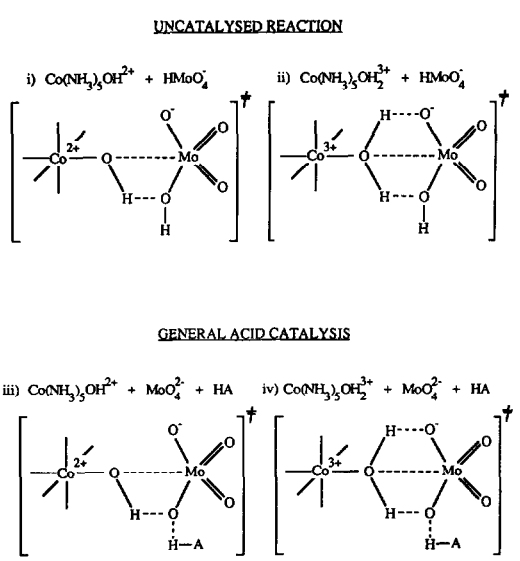

Fig. 5. Proposed transition states for cobalt(III) molybdate complexation.

process. The $HMoO_4^-$ anion has been assigned as the reactive molybdenum(VI) species in the uncatalysed reactions on the basis of the proton-transfer argument discussed above, and also to allow direct comparison with other molybdate substitution processes which are all expressed in terms of this protonated species. The specific proton-catalysed reaction pathways are incorporated into the general acid terms (iii) and (iv), where HA = H^+. The rate constants for the formation of transition states (i)–(iv) are given by:

(i) $k_1 = k_a \times K_H/K_{HM} = 6.6 \times 10^4\ M^{-1}\ s^{-1}$
(ii) $k_2 = k_b/K_{HM} = 1.3 \times 10^6\ M^{-1}\ s^{-1}$
(iii) $k_3 = k_c \times K_H = 2.1 \times 10^{10}\ M^{-3}\ s^{-1}$
(iv) $k_4 = k_d = 3.6 \times 10^{11}\ M^{-3}\ s^{-1}$;

where K_H and K_{HM} are the acidity constants for $Co(NH_3)_5OH_2^{3+}$ (4.79×10^{-7} at 25°C and $\mu = 1.0$ M[10]) and $HMoO_4^-$, respectively.

The rate constants, k_1 and k_2, for the uncatalysed reaction of $HMoO_4^-$ with $Co(NH_3)_5OH^{2+}$ and $Co(NH_3)_5OH_2^{3+}$, respectively, are much lower than for a series of bidentate ligands, shown in Table 7, where the second-order rate constants falls in the range $(0.4\text{–}2.0) \times 10^8\ M^{-1}\ s^{-1}$. These faster reactions have all been attributed to ligand addition processes where the molybdenum(VI) centre expands its coordination to six and Mo—O bond cleavage is unnecessary. Although the reaction of $HMoO_4^-$ with H_2EDTA^{2-} forms an octahedral molybdenum(VI) complex, the slow rate of reaction results from the necessity to break one Mo—O bond.

Table 7. Second-order rate constants for complexation with $HMoO_4^-$ at 25°C[a]

Ligand (L)	Rate constant ($M^{-1}\,s^{-1}$)	Product	Denticity number of L	Reference
$Co(NH_3)_5OH^{2+}$	6.6×10^4	MoO_3L^+	1	This work
$Co(NH_3)_5OH_2^{3+}$	1.3×10^6	MoO_3L^+	1	This work
H_2EDTA^{2-}	2.3×10^5	$MoO_3L_3^{2-}$	3	33
$Oxine^-$	1.5×10^8	$MoO_2(OH)_2L_2^-$	2	34
$(Oxine)SO_3^{2-}$	4.0×10^7	$MoO_2(OH)_2L_2^{2-}$	2	35
$Hcatechol^-$	1.9×10^8	$MoO_2(OH)_2L_2^{2-}$	2	36

[a] Adapted from ref. 1.

A comparison of the rate constants for the two uncatalysed processes (k_1 and k_2), reveals that complexation occurs more quickly with $Co(NH_3)_5OH_2^{3+}$ than the corresponding hydroxo species. The importance of ion-pairing in this reaction scheme was dismissed in the previous study,[1] by analogy with the weak outer-sphere interaction between $Co(NH_3)_6^{3+}$ and MoO_4^{2-}. However, the formation of hydrogen-bonding contacts between the anions $HSeO_3^-$ or $HCrO_4^-$ and $Co(NH_3)_5OH_2^{3+}$ resulted in values for the ion-pairing constant, K_{os}, of between 6 and 8 M^{-1}.[31,37] Even allowing for an order of magnitude difference between K_{os} values for the $+3/-1$ and $+2/-1$ ion-pairs, the intrinsic rate constant for the reaction with the aquo species is still twice that for the cobalt(III) hydroxo ligand. Thus, the effect of increased hydrogen bonding in the transition state and greater proton acidity for reaction with $Co(NH_3)_5OH_2^{3+}$ slightly outweighs the higher nucleophilicity of the hydroxo ligand in $Co(NH_3)_5OH^{2+}$, in determining the more reactive cobalt(III) species towards $HMoO_4^-$.

Even with the absence of supporting activation parameters for this reaction, it still seems reasonable that, in view of the associative nature of the MoO_4^{2-}–oxygen exchange reaction,[38] the extent of bond formation in the complexation transition state outweighs bond breaking. Consequently, changing the nature of the inert cation substituting into the molybdenum coordination sphere should affect the rate of complex formation.

CONCLUSION

Whilst the form of the rate law for the complexation reaction between MoO_4^{2-} and aquo- and hydroxo-pentamminecobalt(III) cations in basic solution is consistent with a previous proposal for the existence of dimeric molybdenum(VI) species, general anion catalysis experiments show that an alternative mechanism is likely. The observed rate of reaction is enhanced by anionic species capable of proton donation to the molybdenum(VI) hydroxo ligand, thereby facilitating water elimination from the transition state. The apparent second-order dependence upon $[MoO_4^{2-}]$ may be explained by the involvement of $HMoO_4^-$ in proton donation. Consequently, this study found no definitive evidence for the formation of molybdenum dimers in slightly basic solution.

Proton ambiguities preclude definitive identification of reactant species in aqueous solution. An investigation into the direct reaction of MoO_4^{2-} with $Co(NH_3)_5OH_2^{3+}$ or $Co(NH_3)_5OH^{2+}$ in an aprotic solvent may prove beneficial in this regard.

(*Received* 7 *February* 1991; *accepted* 23 *May* 1991)

Abstract—Potentiometric and spectroscopic data have shown that the double bond within dehydro-peptides considerably affects their behaviour as ligands relative to their saturated parents, with proton and copper(II) ions.

α,β-Dehydro-amino acids, or by convention Δ-amino acids, are unsaturated analogues of the respective α-amino acids. They exhibit various biological activities and specific structural properties important for many biomolecules.[1–4]

The (*Z*) isomers of Δ-amino acids are much more common than the (*E*) isomers, which were found only for Δ-His and Δ-Ile in a few antibiotics.[2] These structural as well as chemical features which are characteristic for Δ-amino acids should also be critical for their coordination abilities compared to the parent peptides. In this work we present the potentiometric and spectroscopic data for a series of copper(II) complexes with α,β-dehydro-dipeptides and the respective saturated dipeptides.

EXPERIMENTAL

Ligands

α,β-Dehydro-dipeptides were synthesized according to refs 5–8 and Gly-Δ-Leu and Gly-Δ-Phe had the (*Z*) configuration. Gly–Ala and Gly–Phe were obtained from the corresponding protected dipeptides via successive saponification of methyl esters and hydrogenation of the benzyloxycarbonyl groups. Analytical data of the free peptides were in agreement with those from the literature.[9] Gly–Leu came from Fluka. The purities and the exact concentrations of ligands in solution were determined by the Gran method.[10]

Potentiometric studies

The stability constants of the proton and copper(II) complexes of the ligands were determined by pH-metric titrations of 5 cm^3 samples in the pH range 3–10. The concentration of copper(II) chloride stock solution was measured gravimetrically via precipitation of the oxinate. The ligand concentration was 4×10^{-3} mol dm^{-3}, the metal to ligand ratios were 0:1, 1:1, 1:2 or 1:4, and the ionic strength was adjusted to 0.2 mol dm^{-3} (KCl). The titrations were performed with KOH solution of a known concentration (*ca* 0.2 mol dm^{-3}). The pH was measured at 298 ± 0.1 K with a radiometer pHM 64 instrument with a GK2301

* Author to whom correspondence should be addressed.

combined electrode. The electrode system was calibrated by the method described by Irving *et al.*[11] to convert the pH-meter readings to hydrogen ion concentrations. The stability constants $\beta_{pqr} = [M_pA_qH_r]/[M]^p[A]^q[H]^r$ were calculated from the pH-metric titration curves with a PSEQUAD computer program.[12]

Spectroscopic studies

Absorption spectra were recorded on a Beckman UV 5240 spectrophotometer and circular dichroism (CD) spectra on an automatic JASCO J-20 spectropolarimeter. EPR spectra were taken on a RADIOPAN SE/X spectrometer at 120 K and 9.3 GHz. The copper(II) ion concentration in the solutions measured was adjusted to 3×10^{-3} and the metal to ligand ratio of 1 : 3.

RESULTS AND DISCUSSION

Protonation constants (pK values) for the ligands investigated are given in Table 1. There are two protonation steps (*ca* pH 3 and 7–8) which clearly correspond to proton dissociation from the carboxyl and the amino groups, respectively. The appearance of a double bond at the C-terminal α-carbon slightly decreases the basicity of the amino group compared to the relative parent peptides. This may suggest that some electronic density is transferred from the amino nitrogen into the conjugated double bond system of the Δ-residue. The acidity of the carboxyl group increases for Δ-Ala dipeptides and decreases for dipeptides with another Δ-residue. This indicates that the α,β-double bond alone stabilizes the carboxylate anion in the system studied similarly in acrylic acid (pKa 4.26) compared to propionic acid (pKa 4.87). The (*Z*)-side-chain of the Δ-residue exerts a destabilizing effect as with the (*Z*)-substituent in α,β-dehydro-acids.

Gly-Δ-Phe	8.00	3.17	11.17

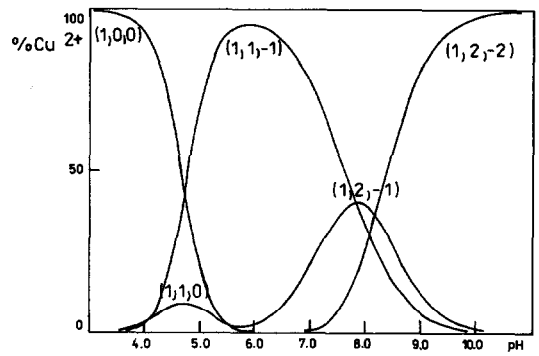

Fig. 1. Concentration distribution curves of the complexes present in the copper(II) Gly-Δ-Leu solution for ligand concentration 4×10^{-3} mol dm^{-3} and 1 : 3 metal to ligand ratio

All investigated dehydro-dipeptides form stable complexes with copper(II) ions and the stability constants (Fig. 1, Table 2) derived from potentiometric titrations could be obtained with a high level of accuracy. The binding modes seem to be the same as in ordinary dipeptides, i.e. the coordination starts at the amino nitrogen and then follows to the amide and the carboxyl groups. This coordination is seen clearly from the spectroscopic data (Table 3).

Copper(II) complexes with X-Δ-Ala

The CD spectra of Phe-Δ-Ala or Val-Δ-Ala complexes exhibit distinct bands characteristic of the amine and amide nitrogen to metal charge transfer transitions indicating the involvement of both nitrogens in the metal ion coordination. Also, ESR and absorption spectra gave good evidence for the species formed (Tables 2 and 3). The species distribution obtained for X-Δ-Ala systems is similar to that for the Gly–Ala system, but the stability constants of complexes with dehydro-peptides are distinctly higher (Table 2). The second deprotonation, i.e. proton dissociation from $CuAH_{-1}$ species occurs around pH 9. The product could be either $CuAH_{-2}$ or CuA_2H_{-2} species. However, the pK value of this process being around 9.2 corresponds precisely to the values obtained for saturated dipeptides for which the hydrolysis (the formation of $CuAH_{-2}$) was proved undoubtedly.[13] Also, in the stability constant calculations the best fit was gained with the $CuAH_{-2}$ complex rather than the CuA_2H_{-2} species. The formation of the former complex at the higher pH range is supported by the absorption spectra which do not change dras-

tically when $CuAH_{-1}$ transforms into $CuAH_{-2}$. The formation of the CuA_2H_{-2} complex with four nitrogens bound to the metal ion should shift the *d–d* transition band to a much higher energy (500–550 nm)[14,15] than that observed for the species discussed, i.e. 620 nm (Table 3). Moreover, only slight variation of the ESR parameters (Table 3) excludes the CuA_2H_{-2} species.[15,16] At very high pH the formation of the latter complex is likely but it is never a dominating species in the solution.

Copper(II) *complexes with Gly-Δ-X ligands*

This group of molecules with X = Leu, Val or Phe, in which a Δ-amino acid residue contains the (*Z*)-side chain, behaves differently than those containing a Δ-Ala residue. There is no pronounced increase in stability of the complexes compared to usual dipeptides (Table 2). However, these ligands give the CuA_2H_{-2} species at pH 7–9 (Fig. 1). The pKs of the formation of the complexes are well below 9.2 (7.4–8.2), excluding the hydrolysis process characteristic of X-Δ-Ala complexes. The parameters of the ESR spectra and the absorption spectra with the *d–d* bands around 500 nm (Table 3) clearly indicate the formation of the four-nitrogen complexes, i.e. the CuA_2H_{-2} species with a $2\times\{NH_2,N^-\}$ coordination mode. The formation of the latter complexes is rather unique for the Gly-Δ-X peptides, although it is possible to observe this kind of species for saturated dipeptides in an extremely high excess of ligand (a 50 : 1 molar ratio). In the latter case the stabilities are about three to five orders lower[17] than those obtained here for Δ-dipeptides. The formation constants collected in Table 2 also indicate the strong impact of the nature of the (*Z*)-side-chain on the stability of the CuA_2H_{-2} species. The weakest complex results from the ligand containing the Δ-Val residue with a methyl group. A slightly stronger complex is formed with Gly-Δ-Leu with an isopropyl group and the strongest one with Gly-Δ-Phe dipeptide with the phenyl side-chain.

CONCLUSIONS

α,β-Dehydro-dipeptides coordinate to cupric ions (similarly to saturated dipeptides) with, however, considerably different stabilities. The stabilities for the X-Δ-Ala complexes are distinctly higher than those of the respective complexes with parent saturated ligands which can derive from the maximal degree of electronic conjugation in the planar $CONH—C(=CH_2)COOH$ moiety.[18–23]

The stabilities of the complexes with the Gly-Δ-X dipeptides (X = Val, Leu and Phe), of which X contains a (*Z*) substituent, are only slightly higher than those of the parent ligands. The formation of the unique CuA_2H_{-2} species is observed. Among the Δ-residues with a (*Z*) substituent, the highest degree of conjugation in the CONH—C=C fragment has been found for Δ-Phe and the lowest for Δ-Val residues.[20] This explains the influence of these side-chains on the stability of the CuA_2H_{-2} complexes.

INVESTIGATIONS INTO THE REACTION OF S_4N_4 WITH $[PPh_4]_2[Pd_2Cl_6]$. THE X-RAY CRYSTAL STRUCTURES OF $[PPh_4]_2[Pd_2(\mu\text{-}S_2N_2)Cl_6]$ AND $[PPh_4][Pd_2(\mu\text{-}S_3N_2)Cl_4]$

(*Received* 14 *January* 1991; *accepted* 23 *May* 1991)

Abstract—S_4N_4 reacts with $[PPh_4]_2[Pd_2Cl_6]$ (**1**) in CH_2Cl_2 to give a mixture of $[PPh_4]_2[Pd_2(\mu\text{-}S_2N_2)Cl_6]$ (**2**) and $[PPh_4]_2[Pd_2(\mu\text{-}S_3N_2)Cl_4]$ (**3**). X-ray crystallography reveals (**2**) to contain neutral S_2N_2 as a bridging ligand whilst (**3**) constitutes only the second example of a complex of the bridging $S_3N_2^{2-}$ ligand.

There is currently great interest in the coordination chemistry of sulphur–nitrogen ligands such as the now well-established $S_2N_2^{2-}$, S_3N^- and $S_2N_3^{3-}$[1] anions as well as rarer species such as $S_3N_2^{2-}$ which has only been observed in two complexes. In $[Pd_2(\mu\text{-}S_3N_2)(S_3N)_2]$ which is prepared in very low yield from the reaction of $PdCl_2$ with S_4N_4 in methanol, the sulphur–nitrogen ligand is symmetrical and bridges the two palladium centres *via* its sulphur atoms.[2] In contrast, the ligand in $[Cp_2Ti(S_3N_2)]$ that is obtained from the reaction of $Cp_2Ti(CO)_2$ with S_4N_4 in thf, is asymmetric (—SSNSN—) and chelate.[3] In addition to complexes of anionic ligands, complexes containing neutral S_2N_2 rings and S_4N_4 cages are also known. The S_2N_2 complexes exhibit bridging coordination through nitrogen in complexes of the type $(S_2N_2)\cdot 2SbCl_5$[4] and $(S_2N_2)\cdot 2CuCl_2$.[5]

Although there have been a wide range of reactions performed on Group 8–10 metal halides, most have made use of polar solvents because of the poor solubility of the metal halides in non-polar solvents. Previous work showed that S_4N_4 reacts with both the binuclear chloro-bridged platinum species $[PtCl_2(PMe_2Ph)]_2$[6] and with the anionic species $[Pt(C_2H_4)Cl_3]^-$[7] (which acts as a source of coordinatively unsaturated $[PtCl_3]^-$) to give platinum(IV) complexes of $S_4N_4^{2-}$. Here we report on the reaction of the binuclear chloro-bridged species $[Pd_2Cl_6]^{2-}$ (present as the tetraphenyl phosphonium salt) with S_4N_4 in CH_2Cl_2. The X-ray structures of the two products are reported.

EXPERIMENTAL

Reactions were performed in an inert atmosphere (nitrogen) using standard Schlenk techniques; $[PPh_4]_2[Pd_2Cl_6]$ (**1**) was prepared by the reaction of $[PPH_4]Cl$ with $Na_2[PdCl_4]$ (1 : 1) in water, followed by recrystallization from CH_2Cl_2/toluene.

In a typical reaction **1** (0.11 g, 0.1 mmol) and S_4N_4 (37 mg, 0.2 mmol) were mixed as solids and then CH_2Cl_2 (50 cm^3) was added with stirring to give a golden brown solution. After a few hours stirring this had changed to a very dark red colour which gradually lightened over the next 48 h. At this point the volume of the solution was reduced to a few cm^3 *in vacuo* and the solution was transferred to a 10 mm diameter tube where it was layered with pentane. Slow diffusion of the pentane for 48 h resulted in the growth of two types of well-formed crystals, dark brown and light orange in colour. These were separated from each other manually; X-ray crystallography revealed the brown compound to be $[PPh_4]_2[Pd_2(\mu\text{-}S_2N_2)Cl_6]$ (**2**) (yield 45 mg, 38%—microanalysis). Found: C, 46.7; H, 3.1; N, 2.2. Calc.: C, 48.2; H, 3.4; N, 2.4%. The orange species was found to be $[PPh_4]_2[Pd_2(\mu\text{-}S_3N_2)Cl_4]$ (**3**) (yield 15 mg, 13%—microanalysis). Found: C, 48.5; H, 3.1; N, 2.3. Calc.: C, 49.8; H, 3.5; N, 2.4%.

Crystal data. $C_{48}H_{40}Cl_4N_2P_2Pd_2S_3$ (**3**), M = 1157.6, monoclinic, $a = 9.634(1)$, $b = 34.973(6)$, $c = 14.664(4)$ Å, $\beta = 98.21(2)°$, $U = 4890$ Å^3, space group $P2_1/c$, $Z = 4$, $D_c = 1.57$ g cm^{-3}. μ(Cu-K_α) = 102 cm^{-1}, $\lambda = 1.54178$ Å, $F(000)$ = 2320.

Data collection and processing for **2** *and* **3**

Nicolet R3m diffractometer, ω-scan method ($2\theta \leqslant 116°$), graphite monochromated Cu-K_α radiation; 3446 and 6603 independent measured reflections, 2987 and 4969 observed [$|F_o| > 3\sigma(|F_o|)$], corrected for Lorentz and polarization factors; empirical absorption correction (ellipsoidal) based on 284 azimuthal scans for **2** and a numerical absorption correction (face indexed crystal) for **3**; the maximum and minimum transmission factors were 0.448 and 0.347 for **2** and 0.588 and 0.236 for **3**.

Structure analysis and refinement

The structures were solved by direct methods and all the non-hydrogen atoms refined anisotropically. In **2** the phenyl groups were refined as rigid bodies. The hydrogen atoms were idealized (C—H = 0.96 Å), assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$, and allowed to ride on their parent carbons. Refinement was by block-cascade full-matrix least squares to $R = 0.048$, 0.057 ($R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$), $R_w = 0.051$, 0.049 ($w^{-1} = \sigma^2(F) + 0.00068F^2$ and $0.00015F^2$) for **2** and **3**, respectively. The maximum and minimum residual electron densities in the final ΔF map for **2** and **3** were 0.74, 0.69 and −0.98, −0.82 e Å^{-3} and the mean and maximum shifts/error in the final refinement cycles were 0.001, 0.004 and 0.004, 0.018, respectively. Computations were carried out on an Eclipse S140 computer using the SHELXTL program system.[8]

RESULTS AND DISCUSSION

When $[PPh_4]_2[Pd_2Cl_6]$ (**1**) is stirred with S_4N_4 in CH_2Cl_2 at room temperature the chloro bridge is disrupted and replaced by a neutral bridging S_2N_2 ligand to give $[PPh_4]_2[Pd_2(\mu\text{-}S_2N_2)Cl_6]$ (**2**) as the initial product. A longer reaction time also leads to further disruption of the Pd—Cl framework giving $[PPh_4]_2[Pd_2(\mu\text{-}S_3N_2)Cl_4]$ (**3**) in addition to **2**. Compound **2** is the first example of an S_2N_2 complex of a group 10 metal, whilst **3** is the first example of a complex of bridging $S_3N_2^{2-}$ to be prepared in reasonable yield (13%). The two complexes are obtained as a mixture of irregular brown crystals (**2**) and well-formed orange needles (**3**). Both types are large enough to allow efficient separation by hand and hence good yields of both complexes can be obtained; similarly both types of crystal were of sufficient quality to allow analysis by X-ray crystallography.

The X-ray structure of **2** (Fig. 1, Table 1) shows that the S_4N_4 cage has been cleaved to give S_2N_2 which is coordinated via both nitrogens, in a centrosymmetric arrangement, to two $PdCl_3^{2-}$ units. The anion is virtually planar with the maximum deviation from planarity for S(1) of 0.06 Å. The geometry of the S_2N_2 ring is not significantly different from that observed in other single crystal studies[1] having transannular S···S and N···N distances of 2.44 and 2.22 Å, respectively. The Pd—Cl distances are in the range 2.282(2)–2.342(2) Å, the shortest being for Pd—Cl *trans* to nitrogen. Interestingly, the Pd—N bond length [1.959(6) Å] is substantially shorter than the values observed for PdS_2N_2 rings in $[Pd(S_2N_2H)(PMe_2Ph)_2]BF_4$[9] [2.031(6) Å] and $Pd(S_2N_2H)(L—L')$ [(L—L') =

acetophenone 2.104(6), N,N-dimethylhydrazone 2.064(6) Å].[10]

An unusual feature of the geometry about palladium in **2** is the significant contraction from 180° of the Cl(1)—Pd—Cl(3) angle [169.4(1)°], the two chlorine atoms being bent towards the sulphur atoms of the S_2N_2 ring. The Cl(1)···S(1′) and Cl(3)···S(1) distances are 3.13 and 2.99 Å, respectively. These distances are substantially less than the sum of the van der Waals radii and coupled with the overall planarity are indicative of an electrostatic interaction between S($\delta+$) and Cl($\delta-$). The associated Cl(1)···Cl(2) and Cl(2)···Cl(3) distances are 3.44 and 3.36 Å, respectively. This type of interaction has also been observed in $(SbCl_5)_2S_2N_2$ (**4**),[4] $(AlCl_3)_2S_2N_2$[11] (**5**) and $[MoCl_4(NSCl)]_2S_2N_2$[12] (**6**). In **4** and **6** the Cl—M—Cl angles are 161, 158.5° (M = Sb, Mo) and 171, 172° for the units which are coplanar and orthogonal respectively, to the S_2N_2 ring. In **4** and **6** the Cl—M—Cl angles are 161 and 158.5° (M = Sb, Mo) for the groups which are coplanar to the S_2N_2 ring, whereas the out-of-plane Cl—M—Cl angles are 171 and 172°. In **4** the Cl···S distance is 3.18 Å. In **5**, which contains distorted pyramidal $AlCl_3$ groups, the shortest intramolecular Cl···S distance is 3.06 Å (the analogous S···Br distance for the bromo compound is 3.15 Å).[13] Clearly, there is a strong attractive interaction between sulphur and the halogen atoms in these systems. We are currently investigating this effect further.

Within the crystal of **2**, the anions form stepped layers (interplanar step separation 0.8 Å) with Cl(3)···Cl(3″) 3.50 Å; there are no other significant intermolecular interactions.

The X-ray structure of **3** (Fig. 2, Table 2) reveals a different cleavage pattern of the S_4N_4 with formation of a bridging $S_3N_2^{2-}$ ligand. This bridges two $PdCl_2^{2-}$ units with coordination through sulphur. The anion has approximate non-crystallographic C_{2v} symmetry and the $Pd_2S_3N_2$ frag-

ment has very similar geometry to that observed in $Pd_2(S_3N_2)(S_3N)_2$ (**6**)[2] with two short and two long S—N bonds and an apical angle at S(2) of 119.4°. The Pd—S distances in **3** [2.266(2)–2.280(2) Å] are significantly shorter than those in (**6**) [2.335(5)–2.354(5) Å], reflecting the difference in the *trans* ligand. The transannular Pd···Pd and S···S distances in **3** are 2.92 and 3.08 Å, respectively. Viewed from the S(1)···S(3) axis the coordination planes are equally inclined from the S_3N_2 plane (119°) and inclined by 121° to each other. There is a noticeable deviation from planarity for both $PdCl_2S_2$ units due to a 4.5° twist of the $PdCl_2$ planes with respect to the PdS_2 planes. There are no significant intermolecular contacts. It is somewhat surprising, in view of the near optimal bite geometry of the $S_3N_2^{2-}$ ligand that so few examples have been reported.

The most prominent features of the IR spectra of **2** and **3** are the bands due to $[PPh_4]^+$, although a number of medium strength vibrations associated with the S—N ligand can be identified in each case. Table 3 compares the IR spectrum of **3** with that of **6** and the related species $Pd(S_3N)_2$ (**7**).[14] The spectrum of **6** is more complex than that of **3** due to the presence of the two S_3N^- ligands; however, comparison with the spectrum of **7** enables the bands due to the latter groups to be identified, namely those at 988, 694 and 514 cm^{-1}. The remaining vibrations, at 1033, 626 and 387 cm^{-1}, compare well with those at 1018, 643 and 387 cm^{-1} in **3** and can be assigned as ν(S—N) and δ(S—N). The low frequency bands in **3**, which are not seen in **6**, can be assigned to Pd—Cl stretches. The IR spectrum of **2** contains medium strength bands at 877, 436, 340 and 282 cm^{-1}; comparison with $(SbCl_5)_2S_2N_2$ and $(SbCl_5)S_2N_2$[15] which show bands at 818/461 and 800/459 cm^{-1}, respectively, indicates that the two high frequency bands are due to S—N vibrations and the others to Pd—Cl stretches.

Abstract—Bis(methylcyclopentadienyl)chloro(α-naphthoyloxy)zirconium, $(CH_3C_5H_4)_2ZrCl(\alpha\text{-}C_{10}H_7COO)$, has been synthesized by the reaction between $(MeCp)_2ZrCl_2$ and equimolar sodium α-naphthoate in toluene at room temperature. The molecular structure of the title complex was determined by X-ray diffraction. The molecules have a five-coordinate bent metallocene structure in which the α-naphthoxyligand is bidentate [Zr—O, 2.317(2), 2.260(2) Å]. The remaining distances are [Zr—Cl, 2.521(1) Å; Zr—C, 480-2, 565 Å; Zr—cent—$CH_3C_5H_4$ 2.217 and 2.230 Å].

Most zirconium metallocene derivatives determined by X-ray diffraction have four-coordinate, 16-electron molecular structures.[1] A limited number of five-coordinate, 18-electron zirconium metallocenes have also been reported.[2–9] More recently, the structures of $Cp_2ZrCl(OOCCH_2CH_2COFc)$,[10] $[Cp_2Zr(\mu\text{-}OCOC_6H_4OCO)]_3$[11] and $[Cp_2Zr(\mu\text{-}OCOC{\equiv}COCO)_n$[12] have been reported, but aromatic carboxyl derivatives of analogous mononuclear zirconium metallocene have not as yet. As part of continuing studies on the substituted cyclopentadienyl titanium group metallocenes,[13] we report here the synthesis and molecular structure of a new five-coordinate, 18-electron complex, $(CH_3C_5H_4)_2ZrCl(C_{10}H_7COO)$.

EXPERIMENTAL

Preparation of $(CH_3C_5H_4)_2ZrCl(\alpha\text{-}C_{10}H_7COO)$

The title complex was prepared by the reaction of equimolar amounts of $(CH_3C_5H_4)_2ZrCl_2$ with anhydrous sodium α-naphthoxyl in toluene for 12 h under nitrogen. The reaction mixture was filtered to remove NaCl. The volume of the filtrate was reduced by vacuum distillation and *n*-hexane was added to crystallize the product. Recrystallization from toluene–hexane solvent afforded colourless crystals; the solid melted at 102–104°C; yield was 84%. Found: C, 60.0; H, 4.5. Calc. for $(CH_3C_5H_4)_2ZrCl(\alpha\text{-}C_{10}H_7COO)$: C, 60.6; H, 4.6%. ^1H NMR (ppm): 2.12(CH_3); 6.08(C_5H_4); 7.40–9.20($C_{10}H_7$). IR(KBr pellets) (cm^{-1}): 3110m, 3060m, 2938w; ν(C—H); 1585s, 1472s, (C=C); 1520s, ν_{asym} OCO; 1450s, ν_{sym} OCO; 1155m, 1038s, 880s, 800s, 780s, δ(C—H).

X-ray structure determination

Cell parameters were determined on a Nicolet R3m/E, four-circle diffractometer with graphite-monochromated Mo-K_α radiation (0.71073 Å) from 19 centred reflections ($3 < 2\theta < 55°$). Details of the crystal parameters along with data collection and structure refinement are summarized in Table 1. Intensity data were corrected for Lorentz and polarization effects but not for absorption.

RESULTS AND DISCUSSION

A perspective view of the molecule $(CH_3C_5H_4)_2ZrCl(\alpha\text{-}C_{10}H_7COO)$, showing the atom-numbering scheme, is displayed in Fig. 1. The important bond distances and bond angles are given in Table 2.

Molecules of the title complex have the bent metallocene geometry, with the zirconium atom attached to a chlorine atom, a bidentate α-naphthoxyl ligand and two symmetrically bound η-$CH_3C_5H_4$ ligands. The zirconium atom has a coordination number of 5, if each η-$CH_3C_5H_4$ group is considered to occupy a single coordination site. The η-$CH_3C_5H_4$ rings are in a staggered conformation, as shown in Fig. 2. Both η-$CH_3C_5H_4$ rings are planar, with displacements of the carbon atom from the mean planes of the ligands being <0.0169 Å (cf. Table 3). The angle between the normals and the planes of the two η-$CH_3C_5H_4$ ligands (126.4°) is slightly smaller than the (centroid $CH_3C_5H_4$)-Zr-(centroid $CH_3C_5H_4$) angle (130.0°), indicating that Zr-(centroid $CH_3C_5H_4$) vectors are not orthogonal to the planes of the η-$CH_3C_5H_4$ ligands. The 10 Zr—C distances are not uniform (2.480–2.565 Å) due to the methyl group on the cyclopentadienyl rings. The values of the Zr—C distances are slightly longer than those of the analogous cyclopentadienyl–zirconium structures.[10] The distances from the zirconium atom to the centroids of the $CH_3C_5H_4$ group rings are 2.217 and 2.230 Å.

Due to crowding in the coordination environment the Zr—Cl bond length [2.521(1) Å] is significantly longer than the distance in four-coordinate zirconocenes[1] (2.441 Å) or in six-coordinate $(MeCp)ZrCl_3(thf)_2$ (2.473–2.493 Å).[14] Compared with the more crowded five-coordinate complexes (cf. Table 4), the Zr—Cl distances in carboxylate derivatives of cyclopentadienyl–zirconium are slightly shorter than those in other derivatives.

$(MeCp)_2ZrCl(C_{10}H_7CO_2)$	0	0	2.260(2)	2.317(2)	2.521(1)	2.22–2.23	130.0	134.8	This work

The naphthoxyl is coordinated to zirconium in a bidentate mode. The Zr—O distances are 2.317 and 2.260 Å, respectively. The Zr—O bond distances are not equal, indicating that the coordinating ability of the two oxygens in the naphthoxyl are different. The C—O bond distances, which are larger than the normal C=O distance (1.22 Å), are also different (C—O1, 1.259 Å; C—O2, 1.269 Å). The Zr—O bond lengths in the title complex are longer than those in $Cp_2ZrCl(OOCCH_2CH_2COFc)$[10] due to steric congestion, but the bond angles Cl—Zr—O, Zr—O—C and O—Zr—O in the two complexes are almost the same.

(*Received* 8 *July* 1991; *accepted* 12 *August* 1991)

Abstract—Laser flash photolysis of the phenyl-substituted digermanoxanes $(Ph_nMe_{3-n}Ge)_2O$ (n = 1–3) results in Ge—O bond homolysis to give germyl radicals and germoxy radicals.

The chemistry of polysiloxanes and polygermanoxanes has recently become of interest because of their importance as electric conductors, photoresistors, liquid crystals and new materials.[1,2] However, the study of polygermanoxanes is very much limited compared with that of polysiloxanes. Herein we describe the first laser flash photolysis studies on aryl-substituted digermanoxanes, $(Ph_nMe_{3-n}Ge)_2O$ (**1–3**, n = 1–3, respectively). The photolysis of phenylated digermanoxanes causes germanium–oxygen bond homolysis to give germyl radicals and germoxy radicals.

Laser flash photolysis (λ = 266 nm, pulse width 5 ns, power 10 mJ pulse^{-1})[3] of **1–3** (10^{-3} M) in cyclohexane at 293 K gave a transient absorption around 360 nm for **1**, and two separated absorptions at both *ca* 320–330 nm and 360 nm for **2** and **3**, as shown in Fig. 1.[4,5] Careful examination of the transient peak of **1** shows that this is composed of two components (λ_{max} = *ca* 320 and 360 nm). The transient peak at *ca* 320 nm arising from **1** cannot be observed apparently because of its much smaller molar coefficient than that of the other transient peak at λ_{max} = 360 nm.[6]

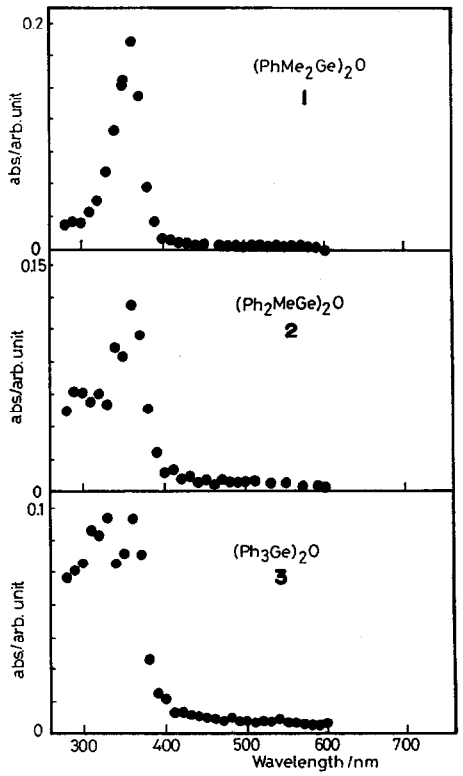

Fig. 1. Transient absorption at 200 ns after photoexcitation of $(Ph_nMe_{3-n}Ge)_2O$ (**1–3**, n = 1–3, respectively) in the degassed cyclohexane solution at 293 K.

* Author to whom correspondence should be addressed.

Table 1. Rate constants for the disappearance of the transients produced by photolysis of the germanoxanes in cyclohexane at 293 K

Compound	λ_{max} (nm)	k/ε (s^{-1} cm)[a]	Rate constant (M^{-1} s^{-1}) O_2	CCl_4	Diene
$(PhMe_2Ge)_2O$	360 nm	6.5×10^{6}[b]	2.3×10^{9}	Not quenched	2.0×10^{9}
(1)	320 nm (s)	9.1×10^{6}[c]	2.0×10^{9}	1.1×10^{8}	—[d]
$(Ph_2MeGe)_2O$	360 nm	1.3×10^{7}[b]	2.2×10^{9}	Not quenched	1.4×10^{9}
(2)	320 nm (s)	8.2×10^{6}[c]	1.2×10^{9}	2.0×10^{8}	—[d]
$(Ph_3Ge)_2O$	360 nm	2.5×10^{7}[b]	2.6×10^{9}	Not quenched	2.0×10^{9}
(3)	330 nm	7.3×10^{6}[c]	1.1×10^{9}	1.2×10^{8}	—[d]

[a] k is the rate constant of second-order decay and ε is the corresponding molar extinction coefficient.
[b] At 370 nm.
[c] At 330 nm.
[d] The absorption is too weak to determine the rate constant.

The transient peaks at shorter wavelength are reasonably assigned to those of the aryl-substituted germyl radicals, $Ph_nMe_{3-n}Ge^{\cdot}$ (n = 1–3), from comparison of spectral characteristics with those of the germyl radicals reported.[4-7] The transient from **1–3** in cyclohexane decayed with second-order kinetics, suggesting the dimerization of germyl radicals to give digermenes. The experimentally determined decay constants of these transients are summarized in Table 1. The assignment of the shorter wavelength transient is futher substantiated by quenching experiments with carbon tetrachloride, oxygen and 2,3-dimethyl-1,3-butadiene. Addition of carbon tetrachloride, an effective radical scavenger,[8] quenched the transient absorption as shown in Table 1.

$$Ph_nMe_{3-n}Ge^{\cdot} + CCl_4 \rightarrow Ph_nMe_{3-n}GeCl + {}^{\cdot}CCl_3$$
$$(n = 1\text{–}3)$$

The quenching rate constants observed agreed with the values reported for the germyl radicals.[4-7] Similarly, oxygen quenched the shorter wavelength very rapidly, as shown in Table 1. The laser flash photolysis of **1–3** in cyclohexane containing oxygen was also performed. The transients at shorter wavelength disappeared, resulting in the build-up of transient peaks at the longer wavelength.

On the other hand, the transient at the longer wavelength in Table 1 may be assigned to that of a germoxy radical by comparing its spectral properties with that generated by laser flash photolysis of germyl-t-butylperoxide ($R_3GeOOBu^t$) and **1–3** in cyclohexane containing oxygen. The photolysis of germyl-t-butylperoxides is well known to give germoxy and t-butoxy radicals.[9]

$$R_3GeOOBu^t \xrightarrow{h\nu} R_3GeO^{\cdot} + {}^{\cdot}OBu^t$$

These transients arising from **1–3** in cyclohexane decayed with second-order kinetics, suggesting the dimerization of germoxy radicals to give digermyl peroxides. The transient from **1–3** in cyclohexane in the presence of a large excess of 2,3-dimethyl-1,3-butadiene and oxygen decayed with pseudo first-order kinetics, and the rate constants obtained are shown in Table 1.

The values of k/ε in Table 1 increase in the order: $Ph_3Ge^{\cdot} < Ph_2MeGe^{\cdot} < PhMe_2Ge^{\cdot}$ for the phenylated germyl radicals, and $PhMe_2GeO^{\cdot} < Ph_2MeGeO^{\cdot} < Ph_3GeO^{\cdot}$ for the phenylated germoxy radicals, respectively. The trend for the germyl radicals may reflect the steric environments around the germanium atom. On the other hand, the trend for the germoxy radicals may be explained by the electronic effect of triorganogermyl groups on the oxygen atom due to the longer Ge—O bond length.

Along with the laser flash photolysis experiments, product studies were carried out by photolysing **1–3** (0.04 M) in cyclohexane with a 110 W low-pressure mercury arc lamp (spiral type) at room temperature for 8–10 h under argon. Unidentified, high molecular weight compounds containing germanium (mol. wt = *ca* 4000) were formed.[10] The cyclohexane solution of **1–3** containing CCl_4 was similarly irradiated for 1 h to give the corresponding chlorogermanes in unexpectedly high yields (168, 200 and 185% for **1**, **2** and **3**, respectively).

$$(Ph_nMe_{3-n}Ge)_2O \xrightarrow{h\nu}$$
$$Ph_nMe_{3-n}Ge^{\cdot} + {}^{\cdot}OGePh_nMe_{3-n}$$
$$2Ph_nMe_{3-n}Ge^{\cdot} \longrightarrow (Ph_nMe_{3-n}Ge)_2$$
$$2Ph_nMe_{3-n}GeO^{\cdot} \longrightarrow (Ph_nMe_{3-n}GeO)_2$$
$$n = 1\text{–}3$$

Scheme 1.

These results are best rationalized by a homolytic scission of the germanium–oxygen bonds of the digermanoxanes **1–3**, as described in Scheme 1. Judging from the yields of the chlorogermanes produced by the photolysis of digermanoxanes **1–3** in cyclohexane containing CCl_4, germyl radicals, which abstract chlorine atoms from CCl_4, may be effectively formed by the photolysis of digermylperoxides.

The bathochromic shift of the observed germoxy radicals relative to that of the corresponding carbon analogue, such as the butoxy radical (λ_{max} = 320 nm), may be explained by a contribution in part by the Ge=O resonance structure as follows:

(*Received* 18 *March* 1991; *accepted* 19 *July* 1991)

Abstract—Mixed-metal cubane-type clusters with Mo_3MS_4 cores (M = Fe, Ni) react with Cu^{2+}: $[Mo_3MS_4(aq)]^{4+} + Cu^{2+} \rightarrow [Mo_3CuS_4(aq)]^{4+} + M^{2+}$, in a new type of reaction involving the replacement of the metal atom in the metal cluster by another metal.

Many ligand substitution reactions of mono- and polynuclear coordination compounds have been reported,[1,2] however, no reports have appeared on metal substitution reactions of metal clusters. Recently we synthesized and characterized mixed-metal cubane-type clusters with Mo_3MS_4 cores (M = Fe, Co, Ni, Cu, Sn, Hg).[3] These reactions can be regarded as reductive additions of metals to the core Mo_3S_4 of the incomplete cubane-type aqua cluster $[Mo_3S_4(H_2O)_9]^{4+}$ (**A**). We report here the reaction of mixed-metal cubane-type clusters $[Mo_3MS_4(H_2O)_{10}]^{4+}$ (M = Fe, Ni) with some divalent and trivalent metal ions.

All procedures were carried out under a dinitrogen atmosphere at room temperature. Six kinds of experiments have been carried out. Experiment 1: reaction of $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ (**B**) with Cu^{2+} ions proceeded as follows. Immediately after $CuCl_2$ was added to **B** (5.75×10^{-4} M in 1 M HCl; $Cu^{2+}/\mathbf{B} = 10$), the characteristic peaks at 464 and 512 nm in the electronic spectrum of **B** grew to give a larger peak at 480 nm, indicating the formation of the $Mo_3CuS_4(aq)^{4+}$ cluster (**C**)[3c] as shown in Fig. 1. Experiment 2: upon the addition of $CuCl_2$ to $[Mo_3NiS_4(H_2O)_{10}]^{4+}$ (**D**; 8.55×10^{-4} M in 1 M HCl; $Cu^{2+}/\mathbf{D} = 10$), the peak at 686 nm in the electronic spectrum of **D** disappeared and the peak at 498 nm shifted towards shorter wavelengths with increasing intensity in 15 h which also indicated the formation of cluster **C** (Fig. 2). Mixing either **B** with Ni^{2+} (Experiment 3: $Ni^{2+}/\mathbf{B} = 10$) or **D** with Fe^{2+}

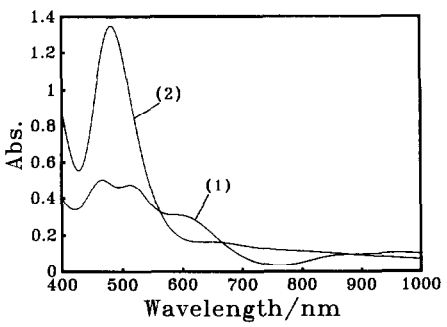

Fig. 1. Spectral change by the reaction of $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ (**B**) with Cu^{2+}. (1) Spectrum containing only **B**. (2) Spectrum taken after 1 min from mixing **B** with Cu^{2+}.

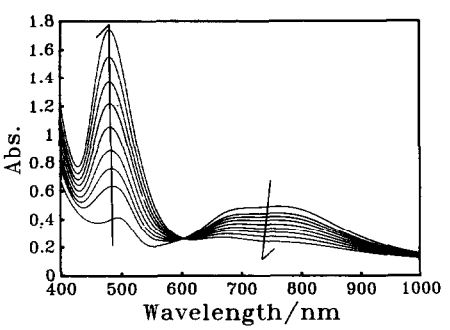

Fig. 2. Spectral changes by the reaction of $[Mo_3NiS_4(H_2O)_{10}]^{4+}$ (**D**) with Cu^{2+}. Spectra taken after 1, 30, 60, 105, 180, 285, 405, 600 and 930 min from mixing **D** with Cu^{2+}. The arrows show the directions of changes of absorbances.

(M = Fe, Ni)

Scheme 1. Reaction of mixed-metal cubane-type clusters $[Mo_3MS_4(H_2O)_{10}]^{4+}$ (M = Fe, Ni) with Cu^{2+}.

(Experiment 4: Fe^{2+}/**D** = 10) resulted in the formation of **A** 3 weeks from mixing, and neither the formation of **D** in the former nor that of **B** in the latter was observed. Mixtures **B** and R^{3+} (Experiment 5: R = Pr, Nd, Sm, Eu, Tb, Dy, Ho) and **D** and R^{3+} (Experiment 6: R = La, Ce, Nd, Eu) were followed spectrophotometrically and column-chromatographically, however, no signs of the formation of clusters with Mo_3RS_4 cores were observed.

The reaction of the mixed-metal cubane-type clusters **B** (or **D**) with Cu^{2+} to give **C** can be shown by Scheme 1. This is the reaction in which one of the metal atoms in the metal cluster is replaced by another metal. The magnitude of the solubility products is of the order: La_2S_3 (10^{-13} M^5) > FeS (10^{-18} M^2) > NiS (10^{-19}–10^{-27} M^2) ≫ CuS (10^{-40} M^2).[4] The results of Experiments 1–6 can be explained by the affinity of metals for bridging sulphurs, which could be expressed by the order Cu—S ≫ Ni—S > Fe—S > R—S.

The aqua cluster **B** is very unstable towards air oxidation[3a] and decomposes to give **A** and Fe^{2+} even under a dinitrogen atmosphere in a couple of weeks,[5] whilst **D** is fairly stable towards air oxidation and the absorption spectrum does not change at all under a dinitrogen atmosphere. The result of Experiment 4 can be explained by the following equilibrium: $\mathbf{D}+Fe^{2+} \rightleftharpoons \mathbf{B}+Ni^{2+}$. The very small amount of **B** thus formed, which cannot be detected spectrophotometrically, decomposes to give **A** and Fe^{2+}. The magnitude of the pseudo first-order rate constants of the substitution reactions ($\mathbf{B}+Cu^{2+}$: $k_{obs} > 1$ s^{-1} at *ca* 25°C; $\mathbf{D}+Cu^{2+}$: $k'_{obs} \approx 5 \times 10^{-5}$ s^{-1} at *ca* 25°C) can also be explained by the difference in affinities of metals for bridging sulphurs.

1. INTRODUCTION

Over the past few decades a large number of sulphur–nitrogen (S—N) compounds have been prepared and structurally characterized.[1] The S—N compounds display a variety of structures ranging from simple amides and imides to ring and cage structures. Many S—N rings and cages are stabilized through extensive π-bonding and the binary S—N cations can be rationalized as being aromatic systems.[2–4] In particular, this was evident from the metallic-like character of the $(SN)_n$ polymer and the fact that it becomes a super-conductor at low temperature.[5] This discovery further stimulated interest in S—N compounds and they have been one of the most active areas of inorganic research.

In view of the rich chemistry of S—N compounds, one might have expected an analogous diversity for their related selenium–nitrogen (Se—N) and tellurium–nitrogen (Te—N) compounds. This, however, has not been realized and until about a decade ago, only relatively few Se—N compounds[6] and even fewer Te—N compounds[7] had been characterized, some of which decompose slowly or even explosively. For example, three inorganic Se—N compounds Se_4N_4,[8] Ag_3SeO_3N[9] and $[K^+]_3[(SeO_2N)_3{}^{3-}]$,[10] which had been structurally characterized, can explode violently. Furthermore, even simple classes of compounds such as amides or imides of selenium and tellurium were, with few exceptions, unknown. It is therefore not surprising that the consensus developed among many chemists that compounds containing Se—N and Te—N bonds were generally unstable.

Probably a significant factor in destabilizing the formation of Se—N and Te—N compounds is the weakening or absence of π-bonding involving the heavier main-group elements. Consequently, it is to be expected that only a few Se—N and even fewer Te—N analogues of the many π-bonded S—N ring systems can exist.

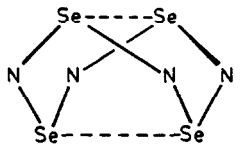
* Author to whom correspondence should be addressed.

However, the "Achilles' heel" in the preparation of new Se—N and Te—N compounds has been the lack of suitable stable precursors, such as S_4N_4 in the preparation of a large number of S—N compounds. Thus, although Wöhler and Espenschied[11] reported in 1869 that Se_4N_4 was more easily prepared than S_4N_4, it also had a much greater tendency to detonate and consequently limits its use in synthesis. The poorly characterized Te_3N_4 and Te_4N_4 are even more explosive.[7] Most Se—N and Te—N compounds which have been reported were synthesized by reacting amines, persilylated amines or lithium amides with chalcogen halides or oxides.

In the last decade an increasing number of Se—N and Te—N compounds have been reported and the detailed structure determined for many of them. Some of these compounds have related S—N partners but the properties of others show interesting differences and often have novel structures. Furthermore, along these developments few new Se—N and Te—N synthetic precursors have been prepared. In light of this recent important progress in inorganic Se—N and Te—N chemistry, we will in this manuscript review the structures of these compounds.

2. EARLY STRUCTURAL INVESTIGATIONS

Only 100 years after its first preparation, a crystalline sample of Se_4N_4 could be prepared by ammonolysis of $SeBr_4$ in liquid ammonia at high temperature and pressure.[12] Subsequent X-ray crystallographic studies showed that the crystals consisted of approximately body-centred cubic packing of cage-like Se_4N_4 molecules (**1**).[8]



1

The average Se—N atomic distances in Se_4N_4 (179 pm) are significantly shorter than Pauling's single bond distance (186 pm),[13] indicating multiple bonding over the eight-membered ring. The relatively long intramolecular Se—Se distances (average 275 pm) complete the cage-like structure of the molecule. The approximately body-centred cubic packing of the Se_4N_4 is believed to be due to relatively short intermolecular parallelogram-type Se···N secondary interactions (296–345 pm; van der Waals Se···N = 350 pm[13]). Undoubtedly, these strong Se···N intermolecular contacts are responsible for the insolubility of Se_4N_4 in all common solvents.

A number of selenamide anions are formed from ammonolysis of SeO_2F_2 or SeO_3 and some of their salts have been isolated.[6,14,15] The detailed structures of Ag_3SeO_3N[9] and $[K^+]_3[(SeO_2N)_3^{3-}]$[10] have been determined. The former compound showed the presence of tetrahedrally-shaped SeO_3N^{3-} anions ($\mathbf{2}^{3-}$) with a very short Se—N distance (167 pm). However, the short Ag—N distances (218 pm) suggested covalent Ag—N bonds.[9] The latter compound contained a relatively flat Se—N six-membered ring, $(SeO_2N)_3^{3-}$ ($\mathbf{3}^{3-}$), in a chair conformation. The average Se—N distance (177 pm) of $\mathbf{3}^{3-}$ and the ring flatness indicated some π-electron delocalization over the ring.

3. SELENIUM–NITROGEN AND TELLURIUM–NITROGEN HETEROCYCLES

3.1. *Five-membered heterocycles*

3.1.1. *Inorganic heterocycles.* One of the first well-characterized inorganic five-membered rings containing a Se—N bond was reported by Gillespie *et al.*[16]

$$S_4N_4 + [Se^{2+}][AsF_6^-]_2 \longrightarrow [(SN_2Se_2)_2^{2+}][AsF_6^-]_2 \quad (1)$$

The two SN_2Se_2-rings form a dimer in the lattice, $[SN_2Se_2]_2^{2+}$($\mathbf{4}_2^{2+}$), with relatively long Se—Se intermolecular bond distances. Passmore *et al.* have recently prepared and structurally characterized the isostructural all-selenium analogue, $[SeN_2Se_2]_2^{2+}$ ($\mathbf{5}_2^{2+}$, Fig. 1), using Se_4N_4 instead of S_4N_4, or by oxidizing Se_4N_4 directly with AsF_5.[17] Furthermore, when Se_4N_4 was treated with excess AsF_5 in SO_2, the AsF_6^- salt of the new $SeN_2Se_2^{2+}$ cation ($\mathbf{6}^{2+}$) could be isolated.[17]

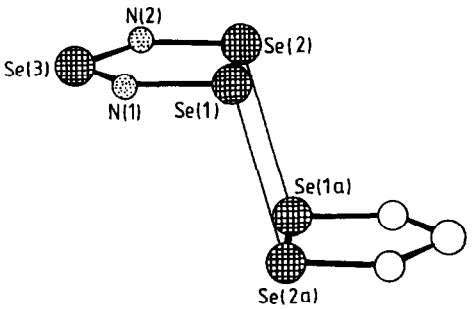

Fig. 1. Crystal structure of $[SeN_2Se_2]_2^{2+}$ ($\mathbf{5}_2^{2+}$).

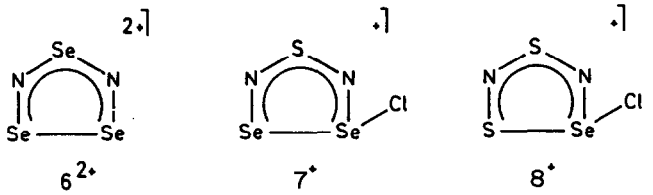
Recently the mixed sulphur/selenium analogues of the $SN_2S_2Cl^+$ cation, $SN_2Se_2Cl^+$ ($\mathbf{7}^+$)[18] and SN_2SSeCl^+ ($\mathbf{8}^+$)[19,20] [eqs (2)–(4)], have been characterized.

$$Se(NSO)_2 \xrightarrow{AsF_5} [\mathbf{4}_2^{2+}][AsF_6^-]_2 \xrightarrow[SO_2]{Cl_2} [SN_2Se_2Cl^+][AsF_6^-] \quad (2)$$

$$Se_2Cl_2 + S_3N_3Cl_3 \xrightarrow{SO_2} S_2N_2SeCl_2 \quad (3)$$

$$Se + [SN^+][AlCl_4^-] \xrightarrow{CH_2Cl_2} [SN_2SSeCl^+][AlCl_4^-] \quad (4)$$

Interestingly, $S_2N_2SeCl_2$ contained both an ionic pair $\mathbf{8}^+Cl^-$ and the neutral $S_2N_2SeCl_2$ molecule in the same lattice.[19] Both ring cations $\mathbf{7}^+$ and $\mathbf{8}^+$ are nearly planar and have the chlorine atoms bonded to selenium.



$\mathbf{6}^{2+}$ $\mathbf{7}^+$ $\mathbf{8}^+$

The relatively short Ch—N (Ch=S/Se) distances in the $\mathbf{4}_2^{2+}$–$\mathbf{8}^+$ cations (Table 1), are consistent with π-electron ring delocalization. However, all the ring Ch—Ch distances correspond to single-bond distances. Perhaps the delocalization system indicated above is more appropriate for these rings rather than a full ring delocalization.

In a search to prepare new low-dimensional conducting materials, Oakley *et al.* have characterized a series of 1,2,3,5-diselenadiazolium cations, $(Ph)CN_2Se_2^+$ ($\mathbf{9}^+$)[21] and p-$C_6H_4(CN_2Se_2)_2^{2+}$ ($\mathbf{10}^{2+}$),[22] by reacting the appropriate persilylated benzamidine with $SeCl_4$ in the presence of a reducing agent, $SbPh_3$ [eq. (5)].

$$\underset{T = SiMe_3}{Ph—C(NT)(NT_2)} + 2(SeCl_4/SbPh_3) \longrightarrow (Ph)CN_2Se_2^+ \quad (5)$$

By metathesis with $NO^+PF_6^-$, the PF_6^- salts could be isolated and their structures determined.[21,22] Like their isovalent analogue $\mathbf{6}^{2+}$, the five-membered rings of $\mathbf{9}^+$ and $\mathbf{10}^{2+}$ are planar and formally have an aromatic 6π-electron system. The Se—Se distances in $\mathbf{9}^+$ and $\mathbf{10}^{2+}$ are significantly shorter than those of $\mathbf{6}^{2+}$, presumably owing to the smaller carbon atoms in the rings.

Complexes $\mathbf{9}^+$ and $\mathbf{10}^{2+}$ can be chemically reduced by $SbPh_3$ to give the formal 7π-electron diselenadiazyl radicals $\mathbf{9}^\circ$ and $\mathbf{10}^{\circ\circ}$.[21,23] Careful purification by sublimation isolated the crystalline materials. Like their isovalent analogues $\mathbf{4}_2^{2+}$ and $\mathbf{5}_2^{2+}$, the radicals form dimers, $\mathbf{9}_2$ and $\mathbf{10}_2$, with

long intermolecular Se—Se distances (Table 2). However, the dimeric CN_2Se_2-rings are in eclipsed configurations ($\mathbf{9}_2$, Fig. 2). Furthermore, a network of Se · · · Se contacts between the dimers, resulting from secondary interactions, was also present in the crystals.

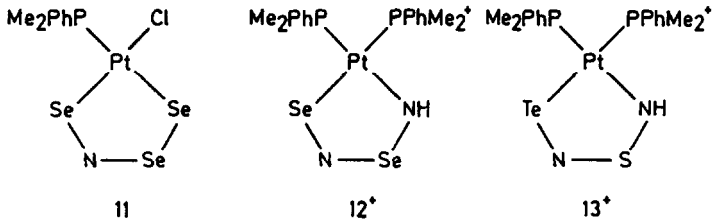
A novel series of five-membered platinum(II) heterocycles (**11**–**13**$^+$) has been prepared and characterized by Woollins and co-workers.[24–27]



Complex **11** was isolated by chromatography of the mixture from the reaction between Se_4N_4 and $PtCl_2(PMe_2Ph)_2$ in $CHCl_3$.[24] [**12**$^+$]Cl^- was, however, isolated after treating the reaction mixture with PMe_2Ph.[25] The BF_4^- salt of **13**$^+$ was prepared by treating $Pt(TeSN_2)(PMe_2Ph)_2$ with HBF_4,[26] which in turn had been isolated from the reaction of $PtCl_2(PMe_2Ph)_2$ with the poorly characterized $Te_3SN_2Cl_2$.[27] The mixed sulphur/selenium analogue of **13**$^+$, $[Pt(SeSN_2H)(PMe_2Ph)_2^+][BF_4^-]$ (**14**$^+$[BF_4^-]), has also been characterized.[28]

The Pt^{II} heterocycles can formally be described as resulting from the coordination of Se_3N^-, $Se_2N_2H^-$ (Fig. 3) and $TeSN_2H^-$ anions to platinum(II).[24–25] Structural analysis revealed the planar nature of the rings and indicated a multiple bond character within the anion fragments (Table 3). This is consistent with the formal 6π-electron system for the anion fragments (or the whole ring). The significant resonance structures illustrating this are given below for **12**$^+$ (Scheme 1).

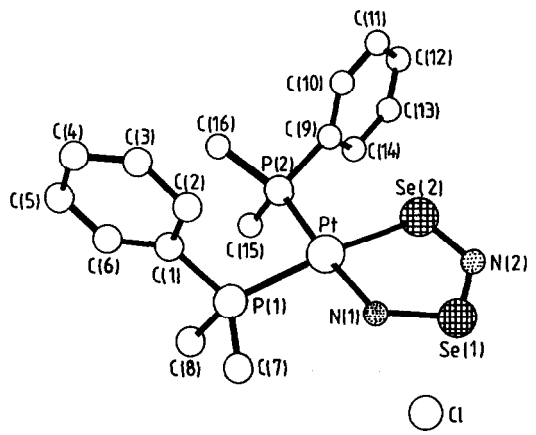


Fig. 3. Molecular structure of $[(PhMe_2P)_2PtSe_2N_2H^+]Cl^-$ (**12**); the hydrogen atoms are omitted for clarity.

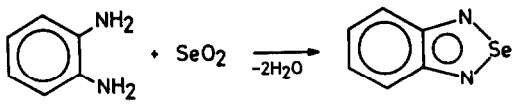
A B C

Scheme 1.

3.1.2. *Organic heterocycles.* Although it is only in the last decade that five-membered Se—N and Te—N inorganic heterocycles have been synthesized, the first five-membered organic Se—N ring was prepared more than 100 years ago by Hinsberg.[29] Hinsberg prepared benzo-1,2,5-selenadiazole (**15**), piazselenol, by simply treating SeO_2 with *o*-diaminobenzene. This reaction is a general synthetic route for other benzo-1,2,5-selenadiazoles and has proved to be an excellent method for analytical determination of selenium.[30] The parent 1,2,5-selenadiazole, $(CH)_2N_2Se$ (**16**), was first prepared about 15 years ago[31,32] and a number of other derivatives have been synthesized.[33]



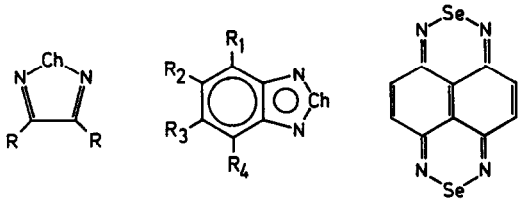
15 (6)

The first organic Te—N heterocycle 1,2,5-telluradiazole, $(CH)_2N_2Te$ (**17**), was synthesized by treating **16** with EtMgBr, followed by the addition of $TeCl_4$ [eq. (7)].[30]

$$(CH)_2N_2Se \xrightarrow[(2)\ TeCl_4]{(1)\ EtMgBr} (CH)_2N_2Te \qquad (7)$$

Compound **17** shows striking stability, being stable in air even when heated on a hot plate![34]

The first preliminary structural investigation of selenadiazole was done on piazselenol.[35] However, it is only in the last decade that the detailed molecular structure has been determined for a number of benzo- and 1,2,5-chalcogenadiazoles (**16–22**),[36–43] as well as the related naphtodiazaselen (**23**).[44]



23

Ch	R

Se	O		19
Se	$C(CN)_2$	N_2Se	20
Se	N_2S	(R_1,R_2)	21
Te			22

The Ch—N distances of these compounds (Table 4) indicate only a small multiple-bond character (single-bond lengths: Se—N 186, Te—N 205 pm).[13] Therefore, the 1,2,5-chalcogenadiazoles, as well as the benzo derivatives, show an increasing importance of resonance structure B in Scheme 2.

[a] Se···O secondary contacts.
[b] Coordination by CN groups.
[c] A six-membered ring.

A B

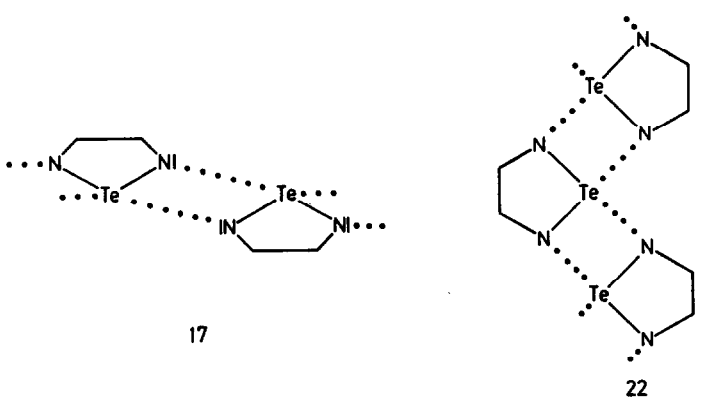
Scheme 2.

Furthermore, the importance of B follows the order Te > Se, consistent with the weakening of π-bonds for the heavier elements.

The high polarity of the Ch—N bonds in these compounds relative, for example, to the related seleno- and tellurophenes, is evident from the physicochemical properties and the presence of short Ch···N intermolecular interactions in their crystals.[34] Thus, intermolecular Ch_2N_2 parallelograms, similar to those in Se_4N_4,[8] are often formed. A higher polymerization of the parallelograms can take place resulting in a planar (**17**) or a ladder-type (**22**) polymer (Scheme 3).

Electrophilic groups such as H^+[38] or $M(CO)_5$ (M = Cr, Mo, W)[45] coordinate to the nitrogen atoms of the 1,2,5-selenadiazole rings. However, reaction with $(Ph_3P)_2Pt(C_2H_4)$ resulted in a Se—N bond insertion to give the near-planar six-membered ring $C_4N_4SePt(PPh_3)_2$ (**24**, Fig. 4).

The benzo-isochalcogenazoles of selenium (**25**) and tellurium (**26**) have been determined.[47] However, the structures of other organic Se—N heterocycles such as 1,2,3-selenadiazole (**27**)[48] and



17 22

Scheme 3.

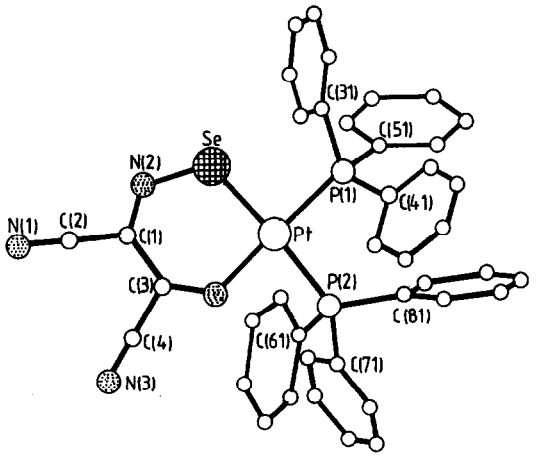


Fig. 4. Molecular structure of $C_4N_4SePt(PPh_3)_2$ (**24**) in the crystal.

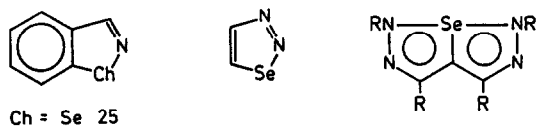
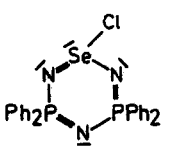
tetraazaselenapentalene (**28**)[49] have not been studied in detail. Organic Se—N heterocycles have previously been reviewed.[50–52]



3.2. *Six-membered heterocycles*

Recently a number of transition-metal cyclometallaphosphazenes have been characterized in our laboratory.[53] The first structurally characterized cycloselenaphosphazene $N(Ph_2P)_2N_2SeCl$ (**29**) was synthesized by reacting $[ClPh_2PNPPh_2Cl^+]Cl^-$ with the thermally unstable $Se(=NSiMe_3)_2$.[54,55]



29

The series resulting from successive replacement of Ph_2P groups with PhC groups $N(PPh_2)(CPh)N_2SeCl$ (**30**)[56] and $N(CPh)_2N_2SeCl$ (**31**)[57] have also been structurally characterized.

The six-membered rings **29–31** are all nearly planar and the rings' short interatomic distances (Table 5) are further consistent with a 6π-electron ring delocalization. However, a more appropriate description of **30** and **31** is to represent them as hybrids of a "normal" π-system and a phosphazene π-system, i.e. replacing Ph_2P with PhC successively fuses Dewar's cyclophosphazene π-electron "islands".[58] The Se—Cl distances in **29–31** are all significantly longer than Pauling's single bond distance (214 pm).

Reduction of **31** gave an eclipsed Se—Se bonded dimer $\mathbf{31}_2$, similar to $\mathbf{9}_2$ and $\mathbf{10}_2$.[57] However, reduction of **30** did not give a Se—Se bonded dimer but two rings linked together by a Se—N bond, $(NPh_2PNPhCNSe)$—$(NSeCPhNPPh_2)$ ($\mathbf{30}_2$).[55] The selenium-bonded ring is analogous to **30** where the chlorine atom has been replaced by the —$NSeCPhNPPh_2$ ring.

Compound **31** was prepared from the six-membered $HN(CPh)_2N_2SeCl_2$ (**32**) ring by careful heating to affect HCl elimination. Structural investigation of **32** showed the ring to have a relatively flat boat-like conformation.[59] However, the Se—N distance (181 pm) indicated a small π-bond character.

Table 5. Bond distances of inorganic Se—N heterocyclic six-membered rings

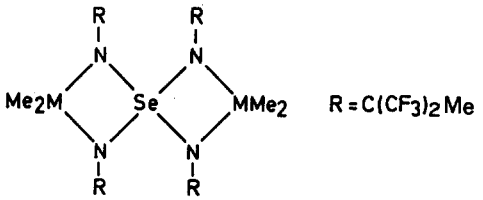
[a] Bonded to a nitrogen atom of a similar ring.

3.3. *Other heterocycles*

Shreeve *et al.* have prepared Si_2N_4Se (**33**) and Sn_2N_4Se (**34**) spiro heterocycles.[60]



However, the detailed molecular structures have not been determined.

Eight-membered and 15-membered Se—N rings, $Se_6(NCMe_3)_2$ (**35**) (Fig. 5) and $Se_9(NCMe_3)_6$ (**36**) (Fig. 6), were isolated from the reaction of $LiN(CMe_3)SiMe_3$ with $SeOCl_2$ or Se_2Cl_2 in a 1 : 1 molar ratio.[61] The rings' Se—N distances (average 184 pm) fall within the range of single-bond lengths. Interestingly, three short intramolecular Se···Se contacts are present in **36**.

The eight-membered $(Ph_2P)_2N_4Se_2Me_2$ ring (**37**) was obtained from the reaction of $Ph_2P(NT)(NT_2)$ (T = $SiMe_3$) with $MeSeCl_3$.[62] The ring has a chair configuration with the SeMe

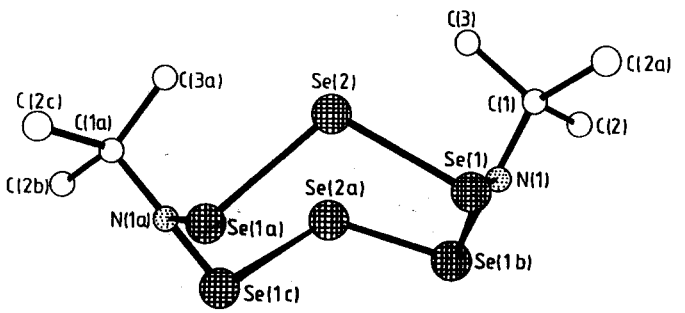


Fig. 5. Molecular structure of the eight-membered ring $Se_6(NCMe_3)_2$ (**35**); the hydrogen atoms are omitted for clarity.

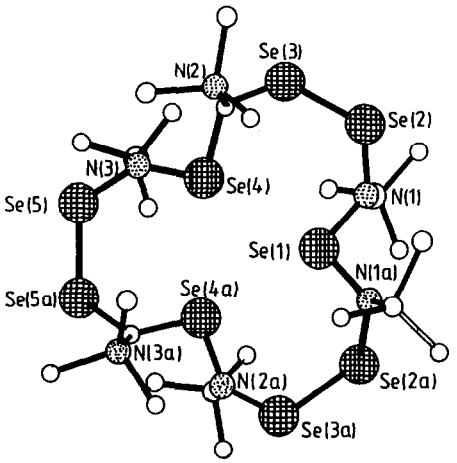

Fig. 6. Molecular structure of the 15-membered Se—N ring (**36**); the hydrogen atoms are omitted.

groups above and below the plane formed by the P_2N_4 atoms (Fig. 7). The ring Se—N bonds are relatively short (178 pm).

A novel cage-like structure, $N[Te(NSN)Cl]_3 \cdot 3DMF$ (**38**) was formed when $TeCl_4$ was treated with $S(=NSiMe_3)_2$ and the product recrystallized from DMF.[63] The unique nitrogen atom is bonded to three tellurium(IV) atoms which in turn are bridged by NSN and Cl groups (Fig. 8). The Te—N distances of 205–207 pm (N) and 202–207 pm (NSN) correspond to single-bond lengths. The overall geometry around tellurium is octahedral with an additional DMF molecule coordinating to the lone-pair side.

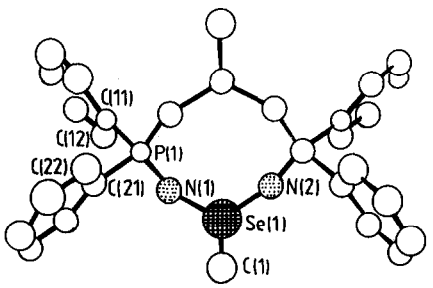

Fig. 7. Molecular structure of the eight-membered ring $(Ph_2P)_2N_4Se_2Me_2$ (**37**) without hydrogen atoms.

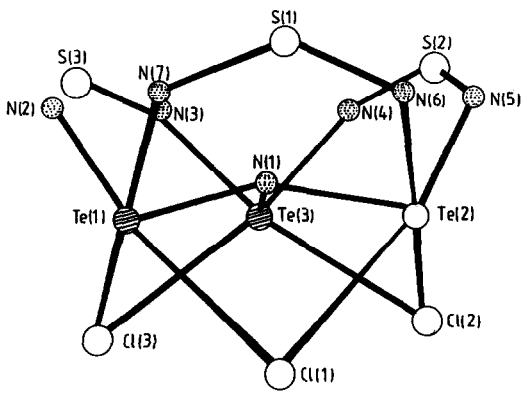

Fig. 8. Molecular structure of $N[Te(NSN)Cl]_3 \cdot 3DMF$ (**38**) without solvent molecules.

4. AMIDE DERIVATIVES OF SELENIUM AND TELLURIUM

4.1. *Amide derivatives of selenium*(IV) *and tellurium*(IV) *chlorides*

Both the mono- and bis-N=PPh_3 substituted derivatives of selenium and tellurium tetrachloride, $(Ph_3PN)ChCl_3$ [Ch = Se (**39**),[64] Te (**40**)[65]] and $(Ph_3PN)_2ChCl_2$ [Ch = Se (**41**),[64] Te (**42**)[66]], can be prepared by reacting $Ph_3PNSiMe_3$ with chalcogen tetrachlorides [eq. (8)].

$$n\,Ph_3PNSiMe_3 + ChCl_4 \longrightarrow (Ph_3PN)_nChCl_{4-n} \quad (8)$$
$$n = 1,2 \qquad Ch = Se, Te$$

The related selenamide $(Me_2S(O)=NPPh_2=N)_2SeCl_2$ (**43**) has also been prepared by a similar reaction.[67]

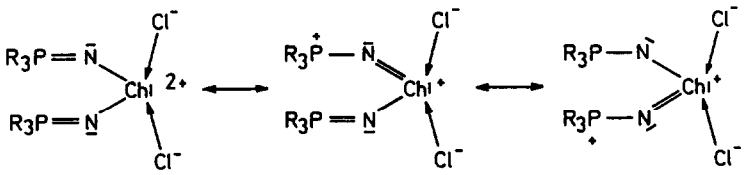
Compounds **41**–**43** all have the same geometry around selenium with the ligand's nitrogen atoms in the equatorial plane and the chlorine atoms in axial positions. However, the Ch—N distances are short, indicating a high multiple-bonding character, but the Ch—Cl bonds are very long (Table 6). Furthermore, contrary to the predictions of the VSEPR rules for AX_4E systems,[68] the chlorine atoms are bent away from the nitrogen atoms.

Table 6. The bond distances (pm) and bond angles (°) of $(AN)_2Ch^{IV}Cl_2$ (Ch = Se/Te)

Compound	A	Ch	Ch—N	Ch—Cl	ClChCl	Ref.
32	CPh[a]	Se	181	241	174	59
41	PPh_3	Se	174	260	150	64
43	PPh_2X[b]	Se	170	265	154	67
42	PPh_3	Te	192	260	163	66

[a] Part of a ring.
[b] X = —$NSO(Me)_2$.

The long Ch—Cl distances suggest very ionic Ch—Cl bonds such that one extreme view of describing **41**–**43** would be a coordination of Cl^- anions to a π-electron stabilized $(R_3PN)_2Ch^{2+}$ cation (Scheme 4).



Scheme 4.

The bending of the $ChCl_2$ fragment would then be a result of the coordination of Cl^- anions to the lone-pair side of the chalcogen atom. This would be consistent with the coordination of anions towards the metal cation lone-pair side observed for a number of other main-group halides.[69]

An alternative rationalization for the ChN_2Cl_2 geometry is to consider the chalcogen atom lone-pair to be more spread out in the equatorial plane to have the multiple Ch—N bonds perpendicular to the ChN_2 plane. The directional character of the multiple Ch—N bond would then repel the Ch—Cl bond pairs away more effectively.

A similar directional repulsion effect of multiple bonds has been invoked to account for the bending of the axial Xe—F bonds of XeO_2F_2 (an AX_4E type system) towards the xenon lone pair.[70] Consistent with this description is the bending of $ChCl_2$ which is much larger for the strong π-donating R_3PN ligands than for weaker π-donors such as, for example, in **32**.

Compound **39** forms chlorine-bridged dimers in the solid state (Fig. 9) with a very short Se—N bond distance (168 pm).[64] The two Se—Cl bridge distances are also very long (263 and 298

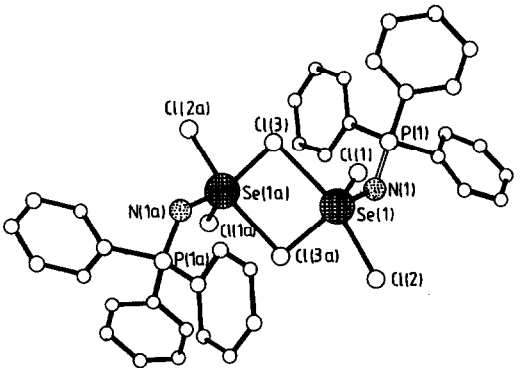


Fig. 9. Molecular structure of the $Ph_3PNSeCl_3$ (**39**) dimer without hydrogen atoms.

pm) and probably very ionic. Thus, the structure of the dimer can be described as ylene (or ylide) pyramidal cations, $SeCl_2(NPPh_3)^+$, coordinated by two Cl^- anions, approximately *trans* to the cation's Se—Cl bonds.

Compound **40** is also present as the dimer in the solid state (Fig. 10) but, unlike **39**, forms a planar four-membered Te_2N_2 ring with short (200 pm) and long (228 pm) Te—N distances.[65] The geometry around the tellurium atom is approximately ψ-octahedral, but with the two chlorine atoms perpendicular to the Te_2N_2 plane bent away from the shorter Te—N bond towards the tellurium lone pair.

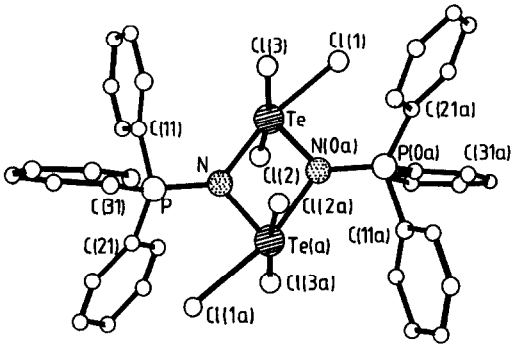

Fig. 10. Molecular structure of the $Ph_3PNTeCl_3$ (**40**) dimer without hydrogen atoms.

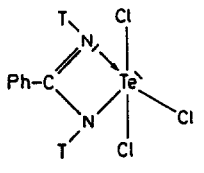
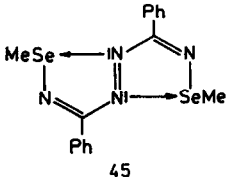
The reaction of $PhC(NT)(NT_2)$ (T = $SiMe_3$) with $TeCl_4$ gave the monomeric $PhC(NT)_2TeCl_3$ (**44**).[71] Compound **44** also has a short Te—N bond (210 pm) and a longer intramolecular Te—N adduct-type bond (219 pm). However, the two Te—N bonds are more equivalent in **44** and the tellurium atom has the expected ψ-octahedral geometry. The reaction of $PhC(NT)(NT_2)$ with $RSeCl_3$ (R = Me, Ph) resulted in an oxidation of the ligand and gave a near-planar diazine (**45**) with two N—Se bonds (181–182 pm).[72] Like **44**, **45** is also stabilized by intramolecular Se—N contacts (265 pm) and formally forms a fused five-membered ring system. Analogous intramolecular donor contacts have been observed in organic seleno-imines.[73,64]



44

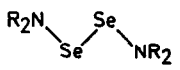


45

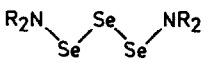
4.2. *Other amide derivatives of selenium and tellurium*

Foss *et al.* have isolated and structurally characterized a series of diaminopolyselanes, $Se_n[N(CH_2)_4O]$ and $Se_4[N(CH_2)_5]$ [n = 2 (**46**), 3 (**47**), 4 (**48**)].[74,76] Compounds **46–48** were formed

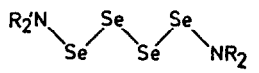
when the amines were heated over selenium powder and PbO_2. They all have a chain-like geometry with Se—N distances (184–185 pm) in the single-bond range.



46

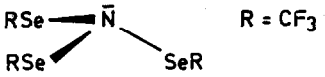


47



48

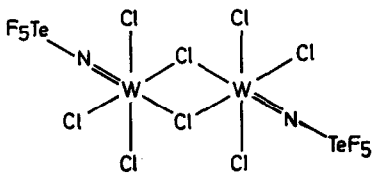
As in **46–48** where nitrogen is bonded to one selenium(II) atom, the **35** and **36** rings are amines with nitrogen bonded to two selenium(II) atoms. An amine with nitrogen bonded to three selenium(II) atoms, $N[SeCF_3]_3$ (**49**), has been characterized from electron diffraction studies.[77] The Se—N distances (184 pm) correspond to a single bond but the Se—N—Se bond angle (119°) is relatively large.



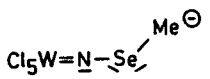
49

Seppelt and co-workers have prepared a large number of H_2NTeF_5 derivatives.[78] Thus, starting from H_2NTeF_5 or $H(SiMe_3)NTeF_5$, compounds with TeF_5 groups bonded to nitrogen containing groups such as N=C=O (**50**), N=S=O (**51**), NCl_2 (**52**), $N{=}SF_2$ (**53**), $N{=}SeF_2$ (**54**), $N{=}PF_3$ (**55**) and $N{=}WCl_4$ (**56**) have been isolated.

Structural analysis showed **56** to be a chlorine-bridged dimer with an almost linear Te—N—W skeleton (Te—N—W 173°, Te—N 198 pm).[78] The Se—N—W skeleton of the recently characterized $Cl_5WNSeMe^-$ (**57**$^-$) anion was likewise near-linear (Se—N—W 174°, Se—N 181 pm).[79] Another metal complex H_2NTeF_5-derivative, $Hg[N(CF_3)TeF_5]_2$ (**58**), had a Te—N distance of 201 pm.[80]



56



57$^-$

The molecular structure of **50** and its selenium analogue, O=C=$NSeF_5$ (**58**), have been determined from electron diffraction studies.[81] The Se—N distance (178 pm) of **58** is 7 pm shorter than Pauling's single bond distance but **50** was found to have a surprisingly short Te—N distance (186 pm).

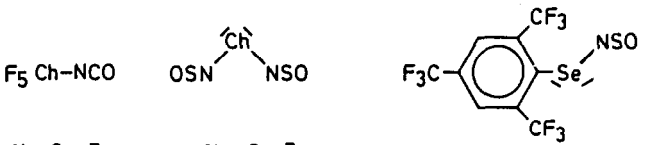
Haas *et al.* have prepared [eqs (9) and (10)] and characterized the bis(sulphinylamido)chalcogens $Ch(N{=}S{=}O)_2$[Ch=Se (**59**), Te (**60**)].[82,83]

$$Se_2Cl_2 + 2Me_3SiNSO \xrightarrow[-2Me_3SiCl,\ 1/8Se_8]{CH_2Cl_2} Se(NSO)_2 \qquad (9)$$

$$(t\text{-}BuMe_2Si)_2Te + 2ClNSO \xrightarrow[-2t\text{-}BuMe_2SiCl]{CH_2Cl_2} Te(NSO)_2 \qquad (10)$$

The Ch—N distances of 183 (selenium) and 204 pm (tellurium) fall within the single-bond range

and the N—Ch—N bond angles are 92° and 87°, respectively. A similar geometry was found for the recently characterized (2,4,6)$(CF_3)_3C_6H_2SeN{=}S{=}O$ (**54**) (Se—N 185 pm, C—Se—N 93°).[84]



Ch = Se, Te — Ch = Se, Te

58, 50 — 59, 60 — 61

$(Me_2N)_2SeO$ (**55**) could be prepared by reacting Me_2NH with $SeOCl_2$ at low temperature [eq. (11)].[85] By standing at room temperature **55** decomposes to give $Se(NMe_2)_2$ (**56**) and oxygen gas [eq. (11)].

$$SeOCl_2 + 4Me_2NH \xrightarrow[-2Me_2NH_2Cl]{-20^\circ C} (Me_2N)_2SeO \xrightarrow[-\frac{1}{2}O_2]{25^\circ C} Se(NMe_2)_2 \qquad (11)$$

However, very few other bisaminochalcogen compounds, $(R_2N)_2Ch$, of selenium and tellurium have been reported. Recently the bis(trimethylsilyl)amide (NT_2) derivatives of selenium and tellurium $Ch(NT_2)_2$ [Ch = Se (**57**)[86,87] Te (**58**)[87]] were prepared in high yields [eqs (12) and (13)].

$$Se_2Cl_2 + LiNT_2 \xrightarrow[-2LiCl,\ 1/8Se_8]{} Se(NT_2)_2 \qquad (12)$$

$$TeCl_4 + 4LiNT_2 \xrightarrow[-4\,LiCl]{} Te(NT_2)_2 \qquad (13)$$

$T = SiMe_3$

In order to prepare **58** and to prevent formation of elemental tellurium, $TeCl_4$ had to be added to four equivalents of $LiNT_2$. It is likely that **58** is formed by a radical mechanism. The tert-butyltrimethylsilylamide ($NTCMe_3$) derivatives $Ch(NT(CMe_3))_2$ [Ch = Se (**59**), Te (**60**)] were prepared by identical procedures.[88]

Low temperature structural analyses of **57**–**60** showed the expected V-shaped geometry of the ChN_2 groups (Fig. 11). However, unlike **57** and **59**, **58** and **60** form dimers in the crystals (Fig. 12) with relatively short Te···Te contact distances [Te···Te 377 (**58**) and 423 pm (**60**); van der Waals Te···Te 420 pm[13]].

In a study of the coordination properties of **58** to metal cations, the AsF_6^- salt of the dark blue tellurium(III) radical cation $Te(NT_2)_2^{\circ+}$ (**61**$^{\circ+}$) was isolated.[81] Radical **61**$^{\circ+}$ was formed when **58** was treated with Ag^+AsF_6 [eq. (14)].

$$Te(NT_2)_2 + Ag^+AsF_6^- \xrightarrow[-Ag^\circ]{CH_2Cl_2} [Te(NT_2)_2{}^{\circ+}][AsF_6^-] \qquad (14)$$

Low temperature structural analysis showed **61**$^{\circ+}$ to be monomeric with two relatively short Te···F interionic contacts (Fig. 13). The short Te—N distances (average 197 pm) of **61**$^{\circ+}$ and the changes

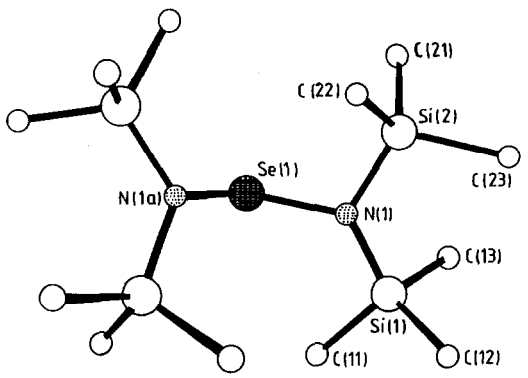


Fig. 11. Molecular structure of $Se[N(SiMe_3)_2]_2$ (**57**) without hydrogen atoms.

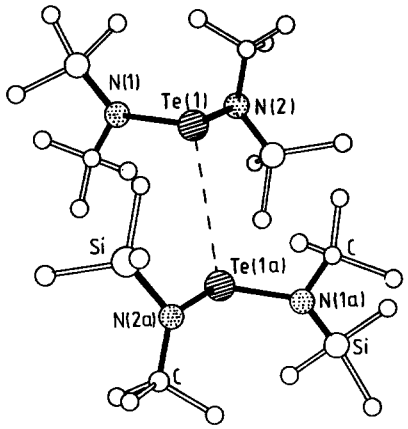

Fig. 12. Molecular structure of the $Te[N(SiMe_3)CMe_3]_2$ (**60**) dimer without hydrogen atoms.

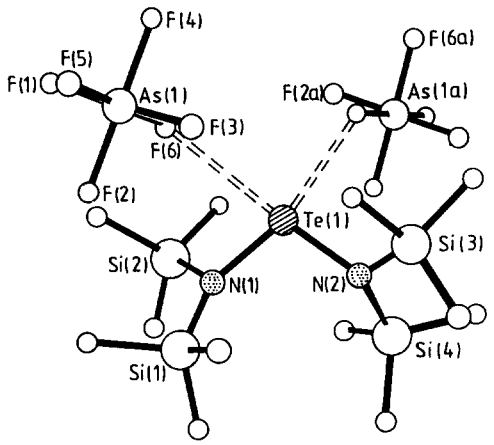

Fig. 13. Crystal structure of $[Te(N(SiMe_3)_2)_2{}^{\circ+}][AsF_6^-]$ (**61**$^{\circ+}$) with Te···F interionic contacts.

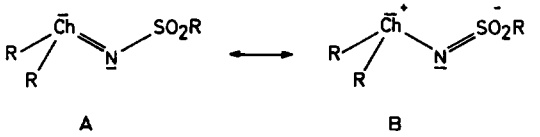
in the NT_2 groups geometries correlate well with the back-bonding model of the ligands' nitrogen atom lone pairs onto the positively charged tellurium atom. ESR solution studies of **61**$^{\circ+}$ indicated that the unpaired electron is localized in a *p*-orbital on tellurium.

5. IMIDE DERIVATIVES OF SELENIUM AND TELLURIUM

A large number of organo-selenimides, $R_2Se{=}NR'$, and a few organo tellurimides, $R_2Te{=}NR'$, are known and have been used for some time in organic synthesis (for a recent review on organo Se—N and Te—N compounds see ref. 52). However, only the detailed structure of $Ph_2Se{=}NSO_2Ph$ (**62**),[90] $(p\text{-}MeC_6H_4)_2Se{=}NSO_2C_6H_4(p\text{-}Me)$ (**63**)[64] and $((p\text{-}MeO)C_6H_4)_2Te{=}NSO_2C_6H_4(p\text{-}Me)$ (**64**)[91] have been determined. The chalcogen atoms in **62–64** are three-coordinated and have the expected pyramidal structure. The structures of the Se—N [182 (**62**) and 179 pm (**63**)] and Te—N (198 pm) compounds **62–64** are best described by the resonance form B. (Scheme 5).

The first binary Te—N cation $Te(N_3)_3{}^+$ (**65**$^+$) has a pyramidal structure with tellurium bonded



Scheme 5.

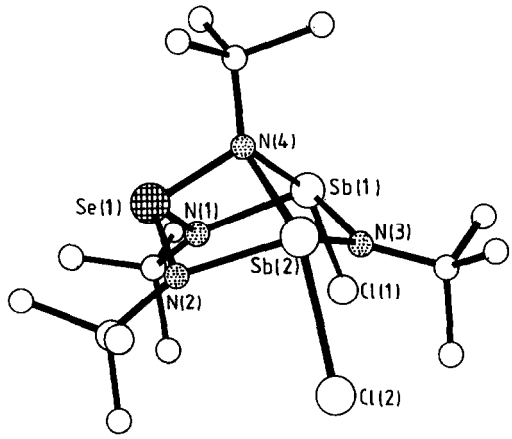


Fig. 14. Molecular structure of $SeSb_2Cl_2(NCMe_3)_4$ (**66**) without hydrogen atoms.

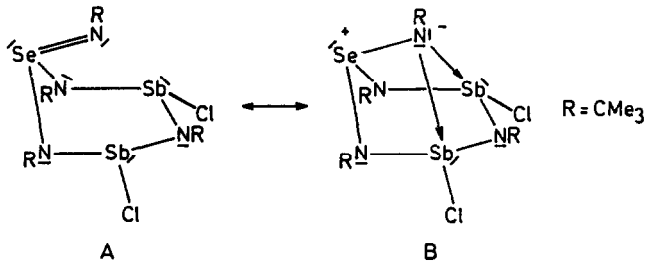

Scheme 6.

to three nearly linear N_3 groups (Te—N 199 pm).[92] Complex 65^+ was found to be analogous to tellurium halide cations, TeX_3^+,[92] so would then correspond to an ylide.

Recently the first all-nitrogen bonded seleniumimide $SeSb_2Cl_2(NCMe_3)_4$ (**66**, Fig. 14) was characterized in our laboratory.[93] Compound **66** consists of a six-membered SeN_2Sb_2N ring with a N—Se bonded non-ring $NCMe_3$ group coordinating further to the antimony atoms. The seleniumimide is thus stabilized by the Sb—N adduct bond as indicated in Scheme 6. The three Se—N distances are nearly equal (179–183 pm) and do not indicate high multiple bonding.

The thermally unstable selenium diimide $Se(=NSiMe_3)_2$ (**67**)[94] was used in the synthesis of **29**. Other selenium diimides such as $Se(=NSO_2C_6H_4(p\text{-}Me))_2$ (**68**)[95] have been used for some time in organic synthesis. However, no structures have been determined.

6. CONCLUSIONS

From the many Se—N and Te—N compounds which have been characterized in the last decade, it is evident that they are not in general unstable but show a relatively rich chemistry. In particular, the introduction of new synthetic precursors such as **57–60** will further stimulate progress in this area. Moreover, the characterization of the novel cages **38** and **66** strongly suggests that Se—N and Te—N compounds can have structures quite different from the known S—N compounds. Due to the low thermal stabilibity of Se—N and Te—N compounds, they might function as precursors for the generation of II/VI semi-conductors at low temperatures.

ETA-6 BONDING OF BENZENE TO POTASSIUM IN $[(C_6H_6)KOSiMe_2Ph]_4$

GARY R. FUENTES, PAUL S. COAN, WILLIAM E. STREIB and KENNETH G. CAULTON*

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 29 *April* 1991; *accepted* 16 *July* 1991)

Abstract—Reaction of KH with $PhMe_2SiOH$ in toluene, followed by recrystallization from benzene, gives $[(C_6H_6)KOSiMe_2Ph]_4$, characterized by elemental analysis, ^1H and ^{29}Si NMR and X-ray diffraction. The molecule is a cubane tetramer of rigorous S_4 symmetry, in which the KO_3 coordination environment is supplemented by η^6-binding of one benzene to each potassium. Crystal data (−169°C): $a = 12.972(2)$, $b = 18.006(2)$ Å, with $Z = 8$ in space group $I\bar{4}$.

There has been considerable recent activity in the field of siloxide (R_3SiO^-) chemistry. Metals have included lanthanides[1] and actinides,[2] transition metals,[3–8] alkaline earths[9] and also alkali metals.[10] The alkali metal chemistry shows the siloxide to be a suitable bridging, as well as terminal ligand, and reveals the common occurrence of the cubane tetramer $[M^I(\mu_3\text{-}OSiR_3)]_4$ structural motif. The curious feature of the cubane structure is that metal coordination number three gives a trigonal pyramidal, rather than the predicted (VSEPR theory) planar structure. It would be anticipated that the pyramidal geometry would leave the metal with enhanced electrophilic character, and the cubane tetramers are in fact found to bind Lewis bases, when these are available. We report here the course of potassium siloxide chemistry when conventional Lewis bases are strictly excluded.

EXPERIMENTAL

Materials and procedures

All manipulations were performed using standard Schlenk techniques either *in vacuo* or in an atmosphere of nitrogen or using a nitrogen-filled glovebox. Solvents used (toluene and benzene) were dried over potassium/benzophenone ketyl. These solvents were distilled under nitrogen and subsequently subjected to freeze–evacuate–thaw cycles prior to use. The reagents KH and Me_2PhSiH were obtained commercially (Aldrich). Potassium hydride was purified by washing repeatedly with hexane, followed by drying *in vacuo*. Dimethylphenyl silane was hydrolysed under buffered conditions to yield the corresponding silanol, $Me_2PhSiOH$,[11] which was then vacuum distilled and subsequently subjected to freeze–evacuate–thaw cycles prior to use.

Physical measurements

^1H and ^{29}Si NMR spectra were recorded on a Nicolet NT360 and a Bruker AM500 (^1H at 361 MHz, ^{29}Si at 99.4 MHz) spectrometer, respectively. These spectra were referenced to $SiMe_4$. Elemental analysis was performed by Oneida Research Services, Inc. Combustion aides were used in an effort to discourage carbide formation.

$[KOSiMe_2Ph]_n$, 1

A 100 cm^3 Schlenk flask was charged with KH (0.74 g, 18.5 mmol) and toluene (15 cm^3). This solution was chilled to 0°C, whereupon $Me_2PhSiOH$ (2 cm^3, 12.3 mmol) in toluene (15 cm^3) was added via cannula. H_2 evolution was observed during the period of addition. After addition of all the $Me_2PhSiOH$, the reaction mixture was allowed to stir for 10 h at

room temperature. After filtration through a 2 cm thick plug of Celite to remove unreacted KH, the solution was concentrated, whereupon a white crystalline solid formed on the sides of the flask. The crystalline solid fractured to a white powder upon removal of all solvent under vacuum. Per cent yield: 89%. ^{1}H NMR (C_6D_6): δ 7.56 (dd, 7.8 Hz, 1.5 Hz, 2H, *ortho*); 7.42 (dd, apparent triplet, 7.8 Hz, 2H, *meta*); 7.29 (tt, 7.3 Hz, 1.5 Hz, 1H, *para*); 2.88 (s, 6H, Me). ^{29}Si NMR (C_6D_6): δ −21.25. Found: C, 50.3; H, 6.1. Calc. for $C_8H_{11}SiOK$: C, 50.5; H, 5.8%.

$[KOSiMe_2Ph]_4 \cdot 4C_6H_6$, 2

A 20 cm^3 Schlenk flask was charged with approximately 0.50 g of $KOSiMe_2Ph$. Approximately 2 cm^3 of benzene was added via cannula. The solution was heated briefly in order to dissolve all of the $KOSiMe_2Ph$. Upon cooling, large colourless crystals precipitated. These were suitable for X-ray analysis.

X-ray structure determination

A crystal of suitable size was cleaved from a large piece of the sample. The crystal was mounted using silicone grease and was transferred to a goniostat where it was cooled to −169°C for characterization and data collection[12] (see Table 1). An initial search of a limited hemisphere of reciprocal space revealed an I-centred tetragonal lattice. Following complete intensity data collection, the Laue symmetry and the lack of any additional systematic absences limited the space group to $I4$, $I\bar{4}$, or $I4/m$. Four standards measured every 300 data showed no significant trends. No correction was made for absorption.

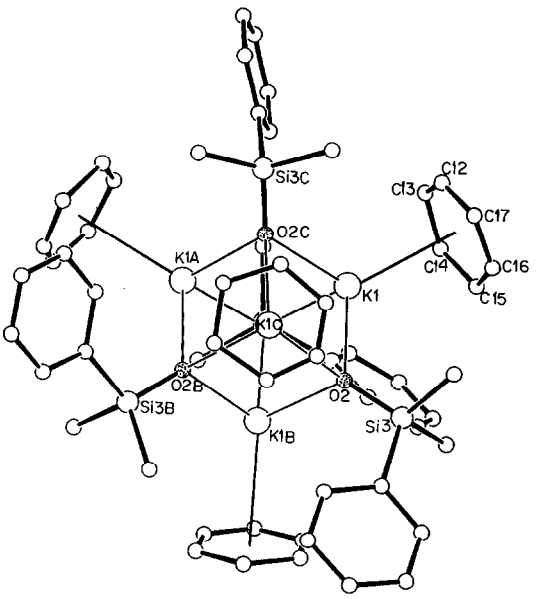

Fig. 1. ORTEP drawing of the non-hydrogen atoms of $[(C_6H_6)KOSiMePh]_4$ showing selected atom labelling. O2A is eclipsed by K1C. Oxygens are stippled.

The structure was solved using a combination of direct methods (MULTAN78) and Fourier techniques when space group $I\bar{4}$ was chosen. The positions of the K, O and Si atoms were obtained from an E-map and the remaining non-hydrogen atoms

were obtained from subsequent iterations of least-squares refinement and difference Fourier calculation. Hydrogen atoms were included in fixed calculated positions with thermal parameters fixed at one plus the isotropic thermal parameter of the carbon to which they were bonded. In the final cycles of least-square refinement, the non-hydrogen atoms were varied with anisotropic thermal parameters. The final difference map was essentially featureless, the largest residual peak being 0.3 e $Å^{-3}$. The results of the structure determination are shown in Tables 2 and 3 and Figs 1 and 2.

RESULTS

Solid-state structures of $[(C_6H_6)KOSiMe_2Ph]_4$

The X-ray diffraction study reveals a tetrameric molecule with a crystallographic S_4 axis (Figs 1 and 2). The rotational conformation about the O—Si bond leaves the $SiMe_2Ph$ group staggered with respect to the OK_3 group. The independent K—O distances within the cube are nearly identical at 2.61 (twice) and 2.62 Å (once), in spite of the pattern of silicon substituents which breaks any rigorous

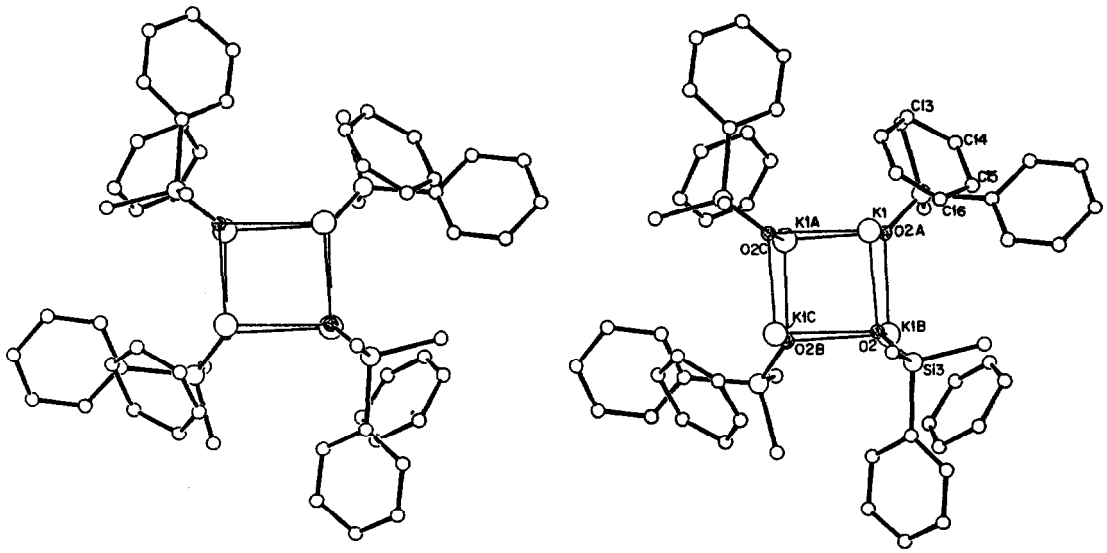

Fig. 2. Stereo ORTEP drawing of the non-hydrogen atoms of $[(C_6H_6)KOSiMe_2Ph]_4$, viewed down the crystallographic S_4 axis. Oxygens are stippled.

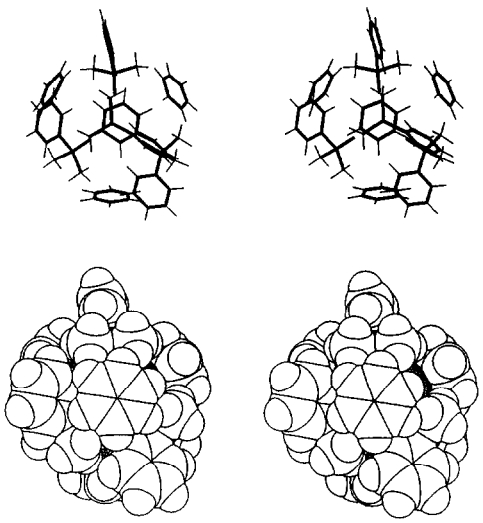

Fig. 3. Stereo stick figure and space-filling drawings of $[(C_6H_6)KOSiMe_2Ph]_4$, with d(C—H) fixed at 1.05 Å. View is perpendicular to the plane of the benzene ring in the foreground.

threefold symmetry. The pattern of placement of these substituents puts the four phenyl rings over a belt of four faces of the cube, leaving two opposite faces unshielded by these phenyl rings. The angles at the corners of the cube (either K or O) are all $90 \pm 2.8°$.

The most interesting revelation of the solid-state structure determination is the occurrence of η^6-binding of one benzene to every potassium. The K—C distances vary by less than 5 esd's and average 3.275 Å.[13] It is evident from a space-filling drawing (Fig. 3) that the tetramer has room to accommodate η^6-binding of benzene because the siloxide bears two small substituents (i.e. methyl). If the siloxide were the more commonly employed $OSiPh_3$, benzene coordination would probably be precluded. It is equally evident from Fig. 3 that ring substituents will weaken the binding of arene to potassium. It is therefore understandable that crystals grown from toluene readily lose solvent and fracture, while those grown from benzene are more stable.

DISCUSSION

This report emphasizes the reality of binding of organic π-electron systems to alkali metals when no better donors are available and when the alkali metal is both sterically accessible and electronically "prepared". The latter term refers here to a three-coordinate potassium which is pyramidal, and thus has more than one hemisphere of its surroundings unoccupied. The present work shows that such binding can occur even in the absence of the back bonding found in transition metal/arene compounds, and also in the absence of Coulomb attraction found in K^+/carbanion compounds. The K—C bond length found here is not much longer than it is in (TMEDA)K(fluorenide)[14] (3.06–3.68 Å). Another relevant comparison material is the potassium/graphite intercalate KC_8, where the K—C distance is 3.06 Å.[15] In $K_8(OSiPh_3)_8(DME)_3$, there is a K—C_{ipso} distance of 3.08 Å.[16] Potassium ion/arene interactions have been reported by the groups of Atwood[17,18] and of Schaverien,[19] and the K—C distances (which range from 3.31 to 3.59 Å) have been reviewed.[19]

We feel that K/arene binding is ubiquitous. Thus, while it has been reported[20] that $K_2[\mu\text{-}N(SiMe_3)_2]_2 \cdot 2$toluene has a bent two-coordinate geometry at potassium (i.e. KN_2), we have calculated the K/toluene distances and find that six K—C (ring) separations range from 3.19 to 3.36 Å. This compound is therefore an unrecognized example of precisely the η^6-benzene binding phenomenon we report in $[(C_6H_6)KOSiMe_2Ph]_4$. A hard Lewis acid like K^+ thus has an affinity even for as soft a donor as an arene π-system. Finally, it bears mention that benzene solutions of alkali metal compounds with low metal coordination numbers are also likely to exhibit this same K/arene binding.

AN ASED–MO CALCULATION OF THE ENERGY LEVELS OF A COPPER(III) COMPLEX: THE (BIS(MALEONITRILEDITHIOLATO)COPPER(III))$^-$ COMPLEX ANION

MUNIME LUNDEEN

Division of Chemistry, Ataturk Egitim Fakultesi, Marmara University, Fikirtepe 81040, Istanbul, Turkey

(*Received* 14 *June* 1991; *accepted* 9 *July* 1991)

Abstract—The molecular orbitals of bis(maleonitriledithiolato)copper(III)$^-$ were calculated by the ASED–MO method. The empty molecular orbital with 25% $3d_{x^2-y^2}$ (Cu) orbital character also has 41% 3*s*, 3*p*, 3*d* (S) and 34% 2*s*, 2*p* (C, N) atomic orbital character. Empty antibonding π_v (S) levels are below this molecular orbital. The HOMO is a π_v (S) level which has 26% $3d_{xz+yz}$ character. An almost pure π_h (S) level is below the HOMO and is followed by the b_{2g} (π^*), π_v (S), π_h (S), b_{4g} (π^*), a_{1g} (σ^*), and b_{3g} (π^*) molecular orbitals. The $\sigma \rightarrow \sigma^*$ transitions from the $\sigma_{C\text{-}S}$ molecular orbitals to the empty molecular orbital with 25% $3d_{x^2-y^2}$ (Cu) atomic orbital contribution in it, which is fully allowed, is calculated to have an average oscillator strength of 1.40.

Copper(III) coordination complexes are not very common. They are expected to have square planar coordination around the copper(III) ion.[1] The crystal and molecular structure of the tetrabutylammonium salt of bis(maleonitriledithiolato) copper(III) complex anion was published by Forrester, Zalkin and Templeton[2] in 1964. We have used the ASED–MO method[3] to calculate the energy levels of this square planar copper(III) complex anion.

PROCEDURE

The ASED–MO method is a semi-empirical method which has given as good results as or better results than HF or CI calculations in the calculation of molecular properties such as equilibrium force constants, k_e, equilibrium bond lengths, R_e, and bond dissociation energies, D_e, of the first-row transition-metal diatomic oxides[3c] and sulphides.[3d] The method produces the overlap integrals, S_{ij}, using analytical approximation to Slater–HF atomic orbitals with atomic orbital exponents which are input. The resonance integrals which are obtained semi-empirically as interaction energies,

$$H_{ij} = -1.125 \cdot (H_{ii}+H_{jj}) \cdot S_{ij} \cdot e^{-0.13R}, \quad (i \neq j)$$

differ from the usual EH approximation in the value of the multiplier of the product of the overlap integral, S_{ij}, between the atoms and the Coulomb energies, H_{nn}, of the atoms, and in having an additional multiplier, $e^{-0.13R}$.[3d] The calculation takes into account repulsions between atoms with their electronic shells around their nuclei by including a term which describes the "bond charge density", which is not symmetric around either nucleus. This term, labelled E_{npf} (potential energy describing the "non-perfectly following" electron density in the bonding region),[3] is approximated by:

$$E_{npf} = \sum_i n_i \cdot e_i^{ab} - \sum_i n_i \cdot e_i^a \cdot \sum_j n_j \cdot e_j^b,$$

where n_i and n_j = the occupation numbers of two-electron orbitals i on atom a and j on atom b, e_i^a and e_j^b = the appropriate Coulomb energies of atoms a and b, e_i^{ab} = the two-body interaction energy, which is calculated by setting the total potential energy, E, at the equilibrium bond distance equal to the sum of a potential energy term, in which the electron density follows the nucleus perfectly, (E_{pf}), and a second term, (E_{npf}), which does not follow the nucleus perfectly. The sum over the i two-electron orbitals is usually taken over the more electronegative atom.[3c,d]

The atomic orbital exponents for the H, C, N and S were obtained from Clementi and Raimondi[4a] and are reported in refs 3a and 5. The 4*s*, 4*p* and double-zeta 3*d* exponents for copper were taken from the work of Richardson *et al.*[4b,c] The exponents for copper are reported in refs 3c and 3d. The valence state ionization energy for the 4*p* atomic orbital of copper is taken as the smallest value for the $4s \rightarrow 4p$ excitation energy in Moore's tables of atomic energy levels.[4d] All other Coulomb energies were taken from Lotz.[4e]

An idealized geometry was used for the complex ion. The sulphur donor atoms were placed along *x* and *y* axes at 2.15 Å bond distances. This bond distance is slightly shorter than the reported average copper(III)–sulphur bond distance of 2.170 Å.[2]

RESULTS AND DISCUSSION

The energy levels of nd^8 square planar complexes have been calculated by Chatt *et al.*,[6] Fenske *et al.*[7] and Gray and Ballhausen.[8] Three LF transitions, two of which may be observed, and several CT transitions are expected.[6-8] If the ligand donor atoms have pi electrons, as in the case of the cyanide ion, an orbitally forbidden CT transition may take place from the occupied $3d_{xy}$ orbital of the metal ion to the lowest energy unoccupied orbital on the ligand with weak intensity.[8] Intense CT transitions are expected from the filled $3d_{z^2}$ and $3d_{xz}$ or $3d_{yz}$ orbitals of the metal ion to the lowest energy unoccupied pi orbitals of the ligands.[8]

The square planar complex anion, bis(maleonitriledithiolato)copper(III)$^-$, has an extended pi system. The four sulphur donor atoms are soft ligands which have large lone-pair electron lobes. Presumably, the square planar copper(III) complex forms so that the lone-pair electrons can participate in the extended pi system. The expected order of the energies of the 3*d* orbitals of the metal ion is $3d_{x^2-y^2} > 3d_{xy} > 3d_{z^2} > 3d_{xz}$, $3d_{yz}$.[8] Because the Coulomb energy of the 3*d* orbital of the copper in the ASED–MO calculation is almost equal to the Coulomb energy of the 3*p* orbital of the sulphur donor (Lotz's[4e] values were used for the Coulomb energies of the orbitals of sulphur), resonance occurs between the atomic orbitals of the metal and the atomic orbitals of the ligand.[3d] The results are shown in Table 1 and require comment.

1. The $3d_{x^2-y^2}$ orbital on the copper which is directed at the sulphur donors is raised in energy above the empty ligand pi orbitals and it is about 2 eV above the highest occupied molecular orbital. The $3d_{x^2-y^2}$ orbital shows significant mixing of the π_v orbitals on the sulphur donors.

2. There are two empty orbitals below the $3d_{x^2-y^2}$ orbital. One of these shows some mixing of the $3d_{yz}$ and $-3d_{xz}$ orbitals of the copper into the π_v orbitals on the sulphur donors. The lower energy empty orbitals are antibonding π_v orbitals on the sulphur donors. These two molecular orbitals are separated by 0.05 eV and are about 0.62 to 0.67 eV above the highest occupied molecular orbital.

3. The highest occupied molecular orbital shows considerable mixing of the $3d_{xz}$ and $3d_{yz}$ orbitals on the copper into the ligand π_v orbitals which have antibonding pi C—S character. This molecular orbital and the filled molecular orbital lying next in energy derive mostly from ligand lone-pair orbitals. In contrast to the highest occupied molecular orbital, the next filled molecular orbital shows no mixing of the 3*d*(Cu) orbitals in it. These two lower-energy filled molecular orbitals appear to be stabilized somewhat by very small coefficients of bonding pi C—N interactions.

4. The order of the energies of the filled 3*d* orbitals on the copper(III) ion is: $3d_{xy} > 3d_{yz-xz} > 3d_{z^2} > 3d_{xz+yz}$. The $3d_{xy}$ orbital has a small amount of sigma overlap with the π_h orbitals on the sulphur donors derived from $3p_y$ atomic orbitals.

5. There are two filled molecular orbitals between the $3d_{xy}$ (Cu) orbital and the $3d_{yz-xz}$ combination of copper orbitals. Of these two molecular orbitals, the lower energy one has some $4p_z$ (Cu) character so that this molecular orbital is a bonding pi Cu—S molecular orbital. The higher energy molecular orbital has no copper atomic orbital character (ignoring very small positive coefficients of the $4p_x$ and $4p_y$ atomic orbitals of the copper). It has bonding pi C—S character (as well as very small amounts of bonding pi C—C and C—N character). It is derived from the π_h orbitals on the sulphur donors.

6. It may be noted that the choice of the *xy*-plane as the equatorial plane about the copper(III) ion with the sulphur donors along the *x*- and *y*-axes in D_{4h} symmetry has led to the construction of two orbitals on the copper, $3d_{xz+yz}$ and $3d_{yz-xz}$, which are not degenerate. The $3d_{yz-xz}$ combination which shows pi overlap with the pi S—C—C system has the higher energy. The lower-energy $3d_{xz+yz}$ orbital has some bonding pi Cu—S character.

7. Just below the 3*d* orbitals of the copper are the π_h orbitals on the sulphur donors which show some bonding sigma Cu—S character. The $3d_{x^2-y^2}$ (Cu) and $-3d_{xy}$, $3d_{z^2}$, $-4s$ atomic orbitals on copper are mixed into these molecular orbitals.

8. The next two molecular orbitals are π_v orbitals on the sulphur donors, one of which has no copper atomic orbital character in it. This orbital, which is at higher energy, has bonding pi C—C—S character. The molecular orbital at lower energy has

$3d_{yz-xz}$ (Cu) character mixed into it. This molecular orbital has some bonding pi C—C—S—Cu character. The molecular orbitals which are bonding sigma C—S orbitals are below the sulphur lone-pair and $3d$ (Cu) orbitals. Mixed into these sigma C—S molecular orbitals are either $3d$ (Cu) or $4p_x$ (Cu), $4p_y$ (Cu) orbitals.

We expect that transitions from the sigma C—S molecular orbitals to the empty $3d_{x^2-y^2}$ (Cu) orbital will be allowed $\sigma \rightarrow \sigma^*$ transitions which have high intensity. These transitions are calculated to be at about 39,840 (I), 44,131 (II), 44,680 (III) and 52,818 (IV) cm^{-1}. The orbital to which these transitions are made has non-zero coefficients of sulphur donor orbitals. Approximate oscillator strengths of the transitions from these sigma C—S molecular orbitals to the empty $3d_{x^2-y^2}$ (Cu) level may be calculated using simplified wavefunctions for the excited state and the initial state. Using the $3p_x$ and $3p_y$ atomic orbitals of the sulphur donors for the ligand wavefunction, ϕ_L, and the $4p_x$ and $4p_y$ atomic orbitals of the copper for the metal wavefunction, ϕ_M, the total wavefunction is taken to be equal to $\Phi = c_M \cdot \phi_M \pm c_L \cdot \phi_L$. The wavefunction for the excited state is taken as the linear combination of the $3d_{x^2-y^2}$ atomic orbital of the copper and the $3s$, $3p_x$, $3p_y$ atomic orbitals of the sulphur donors. The wavefunction for the initial state is for one of the four sigma C—S levels and has coefficients mostly for the ligand $3s$, $3p$ and $3p_y$ orbitals. The sigma carbon–sulphur molecular orbital labelled (I) has a large amount of $3d_{x^2-y^2}$ (Cu) character, the molecular orbital labelled (II) has substantial $4p_x$ (Cu) and $4p_y$ (Cu) character, and the molecular orbital labelled (IV) has substantial $4s$ (Cu) character. The dipole moment integral, D, was evaluated for transitions from each of these levels to the empty $3d_{x^2-y^2}$ (Cu) level (which contains significant contributions from the $3s$, $3p_x$ and $3p_y$ (S) atomic orbitals) using the expression:[9,10]

$$D = \langle \Psi' | \mathbf{R} | \Psi \rangle \approx c' \cdot c \cdot \sum_{\alpha=1}^{4} \left(\sum_{m_l=-1}^{+1} c'_{\alpha_{m_l}} \cdot c_{m_l} \cdot \langle \Phi'_{\alpha_{m_l}} | \mathbf{R} | \phi_{\alpha_{m_l}} \rangle \right),$$

which was set equal to:

$$D = \sum_{\alpha=1}^{\alpha=4} \sum_{m_l=-1}^{+1} c'_{\alpha_{m_l}} \cdot c_{\alpha_{m_l}} \cdot |\mathbf{R}| \cdot \langle \phi'_{\alpha_{m_l}} \cdot \phi_{\alpha_{m_l}} \rangle,$$

where the primed coefficients and wavefunctions apply to the excited state and $|\mathbf{R}|$ is taken as the scalar value, 2.15 Å, which is the copper(III)–sulphur bond length used in the calculations.[2] The theoretical value for the oscillator strength, f(theoretical), is obtained using the formula:

$$f(\text{theoretical}) = 1.085 \times 10^{11} \cdot (\bar{\nu}_{\text{final state}} - \bar{\nu}_{\text{initial state}}) \cdot |D|^2.$$[9]

The values of f(theoretical) which are calculated for electronic transitions from the molecular orbitals labelled levels I, II, III and IV, respectively, to the

$3d_{x^2-y^2}$ (Cu) orbital are 3.486, 2.002, 0.048 and 0.060. Thus, the average value of the oscillator strength for these four transitions is about 1.40.

The energy levels of the bis(maleonitriledithiolato)copper(III)$^-$ complex ion have not been reported previously. Eisenberg, Ibers, Clark and Gray[11] calculated the energy levels of the bis(maleonitriledithiolato)nickel(II)$^{2-}$ complex ion and found the following ordering of the $3d$ (Ni) atomic orbitals: $3d_{xy} > 3d_{x^2-y^2} > 3d_{yz} > 3d_{z^2} > 3d_{xz}$. Aside from the reversal of the positions of the $3d_{x^2-y^2}$ and $3d_{xy}$ atomic orbitals of the nickel(II) ion, which arises from the choice of the x and y axes to bisect the sulphur donor—copper—sulphur donor bonds in the chelate loop, the order given for nickel(II) agrees with the order we give for copper(III). The planar complex anions of Co^{III} and Ni^{III} with the same ligand each have an intense band in the near-IR which is not observed in bis(maleonitriledithiolato)nickel(II)$^{2-}$ and in bis(maleonitriledithiolato)copper(III)$^-$ complex ions.[12] The free maleonitriledithiol ligand has a $\pi_v \rightarrow \pi_v^*$ band at about 29,500 cm^{-1} which is observed at 31,700 cm^{-1} ($\varepsilon = 24{,}000$ cm^{-1}) in the nickel(II) complex ion.[11] This work reports that the π_v orbitals of the sulphur donors appear in the molecular orbitals below the empty $3d_{x^2-y^2}$ (Cu) orbital and, therefore, the transition observed in the free ligand should go to one of these two molecular orbitals which are calculated to be at about 0.673 and 0.621 eV in this ASED–MO calculation. Thus, we assigned the $\pi_v \rightarrow \pi_v^*$ transition of the ligand at 25,604 cm^{-1} and the $\sigma \rightarrow \sigma^*$ transition at 40,000–53,000 cm^{-1}. The latter transitions are fully allowed transitions from the $\sigma_{C\text{-}S}$ molecular orbital to the empty molecular orbital with $3d_{x^2-y^2}$ (Cu) character.

REARRANGEMENTS OF THE UNSATURATED LIGAND 1,1-BIS(DIPHENYLPHOSPHINOMETHYL)ETHENE AND ITS CHALCOGENIDES AND GROUP VI METAL CARBONYL COMPLEXES

JONATHAN L. BOOKHAM*

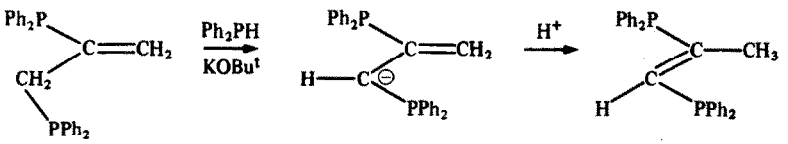
(*Received* 23 *May* 1991; *accepted* 9 *July* 1991)

Abstract—In contrast to the behaviour of other unsaturated organophosphines, treatment of the new ligand $(Ph_2PCH_2)_2C{=}CH_2$ with Ph_2PH in the presence of $KOBu^t$ does not result in addition to the double bond; instead, an allylic rearrangement occurs to give *cis* and *trans* $Ph_2PCH{=}C(CH_3)CH_2PPh_2$ in a 3:7 ratio. In the case of $(Ph_2P(E)CH_2)_2C{=}CH_2$ [E = S, Se] only the *trans* isomer is obtained from this reaction, while under similar conditions $(CO)_4M(Ph_2PCH_2)_2C{=}CH_2$ [M = Cr, Mo, W] yields only a *cis* product in which the two phosphorus atoms remain chelated. The products of these and related reactions are characterized by elemental analysis and ^{13}C and ^{31}P NMR spectroscopy.

The base-catalysed addition of primary and secondary phosphines to activated carbon–carbon multiple bonds is an established route to secondary and tertiary phosphines respectively.[1–5] Activation by one[6] or two (geminally related)[7] Ph_2P groups is of especial interest because the products are then polyphosphines that are important as polydentate ligands, a simple example being $(Ph_2P)_2CHCH_2PPh_2$ which can be formed by the addition of Ph_2PH to $(Ph_2P)_2C{=}CH_2$ as in eq. (1).

(1)



(2)

Furthermore, the activating ability of the Ph_2P group(s) is retained or even enhanced when phosphorus is coordinated to a metal atom or is in a higher oxidation state, as in the $Ph_2P(E)$ [E = O, S, Se] moiety.[8]

It is unclear whether any activating ability is retained when a CH_2 group is inserted between Ph_2P and the multiple bond since there is now also the possibility of an allylic rearrangement (double bond migration) which is normally the favoured pathway, and which would probably proceed via a carbanion intermediate as in eq. (2).

However, when the two phosphorus atoms of the starting olefin are coordinated to the same metal atom, two products are obtained in this reaction—the rearranged olefin with the two coordinated

* Author to whom correspondence should be addressed.

Ph_2P groups mutually *cis* at the double bond, and also the expected triphosphine $Ph_2PCH_2CH(PPh_2)CH_2PPh_2$ with two of its phosphorus atoms coordinated and one free.[9] It is clear then that in this case the double bond is still activated towards addition, but this may be due to the presence of the remaining adjacent Ph_2P group, and in order to test this possibility we have studied the corresponding behaviour of 1,1-bis(diphenylphosphinomethyl)ethene (**1**) and its metal complexes and dichalcogenides. For this system the simple addition reaction would lead to the new ligand $(Ph_2PCH_2)_3CH$.

RESULTS AND DISCUSSION

1 was prepared in *ca* 70% yield by the reaction between the readily available 3-chloro-2-chloromethylprop-1-ene and $NaPPh_2$ in refluxing liquid ammonia. It was isolated as white crystals which can be handled in air but which may be oxidized on prolonged exposure. Microanalytical data and melting points are given in Table 1.

The molecular structure of **1** is confirmed by its ^{31}P and ^{13}C NMR spectra which are summarized in Tables 2–7. The equivalent phosphorus(III) atoms have $\delta(^{31}P) = -18.3$ ppm which may be compared with a value of -16 ppm calculated from group contributions.[10] The carbons of the chemically equivalent CH_2 groups are each part of an AA'X [A,A' = ^{31}P, X = ^{13}C] spin system, but since the coupling $^4J(^{31}P^{31}P)$ is very small their ^{13}C resonances appear as a doublet of doublets at $\delta = 38$ ppm with splittings of 7.3 and 15.3 Hz that correspond very closely to the actual AX and A'X couplings and which are assigned to $^3J(^{31}P—^{13}C)$ and $^1J(^{31}P—^{13}C)$ respectively on the basis of com-

parison with similar molecules. The olefinic CH_2 and C groups are symmetrically related to two phosphorus atoms and their ^{13}C spectra are simple triplets which were assigned by ^{13}C-{^1H} gated decoupling experiments.

1 reacted with elemental sulphur or selenium in refluxing benzene to give the corresponding dichalcogenides (**2**) and (**3**) [see Scheme 1] as air-stable white solids. These have ^{31}P and ^{13}C NMR spectra with the same basic structure as those of **1**, but with changes in the chemical shifts and coupling constants of the magnitudes and in the directions expected[11] to accompany the $P^{III} \rightarrow P^{V}$ transformation, and with ^{77}Se satellites in the ^{31}P spectrum of **3**.

With the group VI metal hexacarbonyls in refluxing diglyme (2,5,8-trioxanonane) **1** gave the corresponding metal tetracarbonyl chelate complexes (**4a–c**) are pale yellow air-stable crystals whose melting points and analytical data are in Table 1. Their ^{31}P chemical shifts correspond well with those calculated using established[12] values of coordination chemical shifts for chromium, molybdenum and tungsten tetracarbonyl complexes with six-membered chelate rings. The values of $\delta(^{95}Mo)$, $^1J(^{95}Mo^{31}P)$, $\delta(^{183}W)$ and $^1J(^{183}W^{31}P)$

also accord with those expected[13] for this type of complex, and the ^{13}C spectra show the presence of axial and equatorial carbonyl groups in a 2 : 2 ratio.

In its reaction with Ph_2PH in the presence of $KOBu^t$ **1** has the potential to undergo either an addition reaction to yield the known triphosphine $(Ph_2PCH_2)_3CH$ or a double bond migration (an allylic rearrangement). In fact, under a range of conditions the result was invariably a mixture of the *cis* and *trans* rearrangement products (**5** and **6**) (see Scheme 1) in a *ca* 3 : 7 ratio. This mixture was a viscous oil from which **5** and **6** could not be obtained in analytically pure forms. However, it was possible to purify them sufficiently to record their individual NMR spectra. The ^{13}P spectrum (see Table 2) of each of these shows an AX spin system with values of $\delta(^{31}P_A)$ and $\delta(^{31}P_X)$ near −15 and −30 ppm as expected[14] for Ph_2PCH_2—R and Ph_2PCH_2=CR_2 fragments respectively, and small values of $J(^{31}P^{31}P)$ as expected for a four-bond coupling. In the ^{13}C spectra (Table 4) the multiplicities were assigned by gated ^{13}C-{^1H} decoupling experiments, and selective ^{13}C-{^{31}P} decoupling experiments were used to assign the various ^{31}P—^{13}C coupling constants. The couplings $^2J(^{31}P_A{}^{13}C_1)$, $^2J(^{31}P_X{}^{13}C_1)$, $^3J(^{31}P_A{}^{13}C_2)$, $^1J(^{31}P_X{}^{13}C_2)$, $^1J(^{31}P_A{}^{13}C_3)$, and $^3J(^{31}P_A{}^{13}C_4)$ can be expected to be substantially independent of the geometry at the double bond and indeed are very similar in **5** and **6**. In contrast $^3J(^{31}PC : C^{13}C)$ is known[15] to be characteristically large when the coupled nuclei are *cis* and small when they are *trans*; the values of 24.4 and 6.5 Hz for this coupling in **5** and **6** respectively therefore lead us confidently to assign to these isomers *cis* and *trans* geometries respectively. This conclusion is supported by the ability of **5** *but not* **6** to form chelate metal complexes (*vide infra*).

The 3 : 7 mixture of **5** and **6** reacted with elemental sulphur or selenium to yield respectively the disulphides **8** and **10** and the diselenides **9** and **11**, the 3 : 7 isomer ratio being retained in the products in each case. In each case the major [i.e. **10** or **11**] isomer was isolated by fractional crystallization as a white air-stable solid (analytical data and melting points in Table 1) and had NMR spectra that confirmed its structure. In particular, the values of $\delta(^{31}P)$ are in the expected regions, and the values of $J(^{31}P$—$^{13}C)$ are *ca* 50 Hz for P^V bound to sp^3-hybridized carbon and *ca* 80 Hz for P^V bound to sp^2-hybridized carbon. It was also possible to obtain most of the NMR parameters of **8** and **9** and these too confirmed the proposed structures. Insufficient is known about the stereochemical dependence of $^3J(^{31}P^VC : C^{13}C)$ to use this coupling to establish the geometry at the double bond, but the nature of the reaction of P^{III} with chalcogen and the retention of the 3 : 7 isomer ratio indicate that no isomerization will have occurred, and that **8** and **9** have the *cis* geometry and **10** and **11** the *trans*.

It was also found that the disulphide **2** reacted with Ph_2PH in the presence of $KOBu^t$ to yield *exclusively* the *trans* isomer **10**. Furthermore, in this reaction no replacement of $Ph_2P(S)$ by Ph_2P occurred, thus confirming that these isomerizations are true allylic rearrangements. Quantitative rearrangement behaviour was also observed when the complexes **4a–4c** were treated with Ph_2PH/$KOBu^t$, the *cis* products **7a–7c** being isolated as air-stable pale yellow crystals (melting points and elemental analyses in Table 1). This is in contrast to the situation found for the *cis* $M(CO)_4$ [M = Cr,

Mo, W] complexes of $Ph_2PC(CH_2PPh_2)=CH_2$ where either addition of a Ph_2P group or rearrangement can occur. The complexes **7a–7c** can also be prepared by the reaction in refluxing diglyme of the 3:7 mixture of **5** and **6** with a 30% equivalent of $M(CO)_6$. This process leaves **6** essentially unaltered and further confirms the assignment of a *cis* geometry to **5**. The use of a larger amount of $M(CO)_6$ again yields **7a–7c**, but in addition di- and polymeric species are formed as a result of coordination by **6** which is unable to form monometallic chelates.

The structures of **7a–7c** are fully confirmed by their NMR spectra (Table 2–6). These show three ^{13}CO resonances with 2:1:1 intensity ratios, arising from two equivalent axial and two inequivalent equatorial carbonyl groups. The ligand backbone ^{13}C resonances are at chemical shift positions close to those found in the corresponding *cis* species **5**, **8** and **9**, and the apparently unaltered values of $^1J(^{31}P^{13}C)$ upon coordination in reality conceal an algebraic increase of *ca* 32 Hz because of a change of sign from −16 Hz in **5** to *ca* +16 Hz in **7a–7c**.

The values of $^2J(^{31}P_A{}^{31}P_X)$ of 41.5, 30.5, and 24.4 Hz for **7a**, **7b** and **7c** respectively are close to those found by Grim[16] as the metal-mediated contributions in unstrained chelate rings for Cr, Mo and W, and thus confirm that any four-bond backbone component can be disregarded.

The overall pattern of these reactions is summarized in Scheme 1 and it is clear that for $(Ph_2P(E)CH_2)_2C=CH_2$ [E = lone pair, S, Se, $M(CO)_4/2$] treatment with Ph_2PH in the presence of $KOBu^t$ leads exclusively to a rearrangement reaction with the double bond migrating to a position closer to one of the Ph_2P groups, and that addition does not occur at room temperature. The stereochemistry of such rearrangements depends upon the relative thermodynamic stability of the products since the *cis* and *trans* isomers share a common intermediate. For E = lone pair the rearrangement is 70% selective for the *trans* product; for E = S, Se it is 100% selective for the *trans* product; and for E = $M(CO)_4/2$ the *cis* product is formed exclusively. This pattern therefore represents the relative stabilities of the (feasible) products and is probably sterically determined—in the last case by necessity, and in the first and second by the moderate and somewhat greater sizes of the Ph_2P and $Ph_2P(E)$ groups respectively.

Finally, it should be noted that all of the products of these rearrangement reactions have a double bond with a single adjacent (and therefore potentially activating) Ph_2P group and yet Ph_2PH does not add to them under our conditions. This we attribute to the presence of relatively bulky sub-

stituents on the olefinic carbon atoms which make attack difficult. In the case of $(Ph_2P)_2C:CHR$ the addition of Ph_2PH becomes substantially slower when R is changed from H to CH_3.[15]

EXPERIMENTAL

NMR spectra were measured on a JEOL FX90 Q multinuclear spectrometer at 2.1 T in CH_2Cl_2 or $CDCl_3$ solutions in 10-mm o.d. spinning tubes. Solvents were dried and deaerated by standard procedures and all manipulations were conducted under an atmosphere of dry dinitrogen or ammonia. For the complexes the procedure used for the chromium congener is given in each case; identical methods were used with molybdenum and tungsten and their proton NMR data are given in that order following the corresponding chromium parameter.

1,1-*Bis(diphenylphosphinomethyl)ethene* (**1**)

Triphenylphosphine (65.5 g, 0.25 mol) in tetrahydrofuran (thf) (200 cm^3) was added over 0.5 h to a stirred solution of sodium (11.5 g, 0.5 mol) in refluxing anhydrous ammonia (1000 cm^3). Solid ammonium bromide (24.5 g, 0.25 mol) was then added over 0.5 h to a give a bright red solution to which 3-chloro-2-chloromethylprop-1-ene (15.6 g, 0.125 mol) in thf (50 cm^3) was added dropwise over 0.75 h. The solution became cream-coloured and after removal of ammonia and thf by evaporation the residue was extracted with diethylether (2×200 cm^3). The combined extracts were dried over anhydrous sodium sulphate and the solvent was removed under vacuum to give a viscous oil. On addition of ethanol (200 cm^3) and storage at $-20°C$ for 24 h a white solid crystallized. Recrystallization of this from methanol (150 cm^3)/dichloromethane (50 cm^3) at $-20°C$ gave the product as colourless crystals in 68% yield. ^1H NMR: ($CDCl_3$) δ(—CH_2—) 3.01 ppm, complex multiplet, 4H; δ(=CH_2) 4.74 ppm, complex multiplet, 2H; $\delta(C_6H_5)$ 7.0–7.5 ppm, complex overlapping multiplets, 20H.

Cis *and* trans-1,3-*bis(diphenylphosphino)*-2-*methylpropene* (**5**, **6**)

To a solution of **1** (10.0 g, 24 mmol) and diphenylphosphine (0.2 g, 1 mmol) in dry thf (50 cm^3) was added potassium tert-butoxide (0.05 g, catalytic amount). The solution was stirred until ^{31}P NMR indicated quantitative conversion into a 3:7 mixture of **5** and **6** (*ca* 2 h) and the solvent was then removed under vacuum. Methanol (50 cm^3) was added to the residue which then yielded a colourless oil upon standing at $-20°C$ for 24 h. After the methanolic mother liquor had been decanted the crude product was dissolved in dichloromethane (20 cm^3) and methanol (80 cm^3) was added to the resulting solution. After standing at $-20°C$ for 24 h the mother liquor was decanted and the oily product was washed with cold methanol (2×200 cm^3) and vacuum dried to give an air-sensitive viscous oil containing the isomers **5** and **6** in a 3:7 ratio. Yield: 88%. Attempts to separate the isomers by fractional distillation were unsuccessful.

^1H NMR: ($CDCl_3$): (**5**); $\delta(CH_3)$ 1.92 ppm, broad singlet, 3H; $\delta(CH_2)$ 3.39 ppm, multiplet, 2H; δ(CH) 5.84 ppm, multiplet, 1H; $\delta(C_6H_5)$ 6.9–7.5 ppm, complex overlapping multiplets, 20H. (**6**); $\delta(CH_3)$ 2.05 ppm, broad singlet, 3H; $\delta(CH_2)$ 2.96 ppm, broad singlet, 2H; δ(CH) 5.64, broad singlet, 1H; $\delta(C_6H_5)$ 6.9–7.5 ppm, complex overlapping multiplets, 20H.

1,1-*Bis(diphenylphosphinomethyl(ethene*-P,P′-*disulphide* (**2**)

A solution of **1** (4.2 g, 10 mmol) in benzene (30 cm^3) containing elemental sulphur (1 g; excess) was stirred at room temperature for 2 h and then refluxed for 0.1 h. After filtration of the cooled solution, methanol (30 cm^3) was added to the filtrate to give a white solid which was recrystallized from methanol (30 cm^3)/dichloromethane (50 cm^3) to give the product as air-stable colourless crystals in 90% yield.

^1H NMR: ($CDCl_3$): δ(—CH_2—) 3.53 ppm, complex multiplet, 4H; δ(=CH_2) 4.64 ppm, complex multiplet, 2H; $\delta(C_6H_5)$ 7.3–7.8 ppm, complex overlapping multiplets, 20H.

1,1-*Bis(diphenylphosphinomethyl(ethene*-P,P′-*diselenide* (**3**)

This compound was prepared in a similar manner to the disulphide **2** using elemental selenium and a reflux period of 2 h. The product was isolated as air-stable colourless crystals in 86% yield.

^1H NMR: ($CDCl_3$): δ(—CH_2—) 3.80 ppm, complex multiplet, 4H; δ(=CH_2) 4.59 ppm, complex multiplet, 2H; $\delta(C_6H_5)$ 6.9–7.9 ppm, complex overlapping multiplets, 20H.

Cis[1,1-*bis(diphenylphosphinomethyl)ethene*-P,P′]*tetracarbonylchromium*(0) (**4a**)

A mixture of hexacarbonylchromium (4.4 g, 20 mmol) and **1** (8.4 g, 20 mmol) in diglyme (50 cm^3) was heated under reflux for 2 h. Methanol (50 cm^3) was added to the cooled and filtered solution to yield a yellow solid which was recrystallized from

methanol (50 cm^3)/dichloromethane (30 cm^3) to give the product as air-stable yellow crystals in 75% yield.

EARLY STAGES OF THE HYDROLYSIS OF CHROMIUM(III) IN AQUEOUS SOLUTION—VIII. KINETICS OF DIMERIZATION OF DEPROTONATED FORMS OF DOUBLY BRIDGED DIMER

MICHAEL R. GRACE and LEONE SPICCIA†

Department of Chemistry, Monash University, Clayton, Victoria 3168, Australia

(*Received* 26 *April* 1991; *accepted* 9 *July* 1991)

Abstract—The dimerization of the doubly bridged hydrolytic dimer of Cr^{III} to give tetramer has been followed in the pH range 3.4–5.0, using a pH stat facility. Acid is liberated as the reaction proceeds and initial rates were estimated from the volume of base added to maintain constant pH with time. The reaction was followed only over the first 8% of dimer conversion to ensure that tetramer was the major product. The pH dependence of k_{obs} has been successfully fitted to an expression which assumes the predominance of three reaction pathways:

$$Cr_2(\mu\text{-}OH)_2(OH)^{3+} + Cr_2(\mu\text{-}OH)_2(OH)^{3+} \longrightarrow \text{tetramer}\quad k_{11} = (2.18 \pm 0.21) \times 10^{-4}\,M^{-1}\,s^{-1};$$

$$Cr_2(\mu\text{-}OH)_2(OH)_2^{2+} + Cr_2(\mu\text{-}OH)_2(OH)^{3+} \longrightarrow \text{tetramer}\quad k_{21} = (5.2 \pm 3.2) \times 10^{-3}\,M^{-1}\,s^{-1};$$

$$Cr_2(\mu\text{-}OH)_2(OH)_2^{2+} + Cr_2(\mu\text{-}OH)_2(OH)_2^{2+} \longrightarrow \text{tetramer}\quad k_{22} = (0.83 \pm 0.08)\,M^{-1}\,s^{-1}.$$

Each deprotonation of dimer affords rate enhancements of 25–160 fold which are in keeping with previous observations for the dimerization of Cr^{3+} and result primarily from labilization of the primary coordination sphere of Cr^{III} on deprotonation of the aquo ligands. The marginally faster overall rate of dimerization of dimer compared with Cr^{3+} is attributed to the greater acidity of dimer and does not result from a greater reactivity of its deprotonated forms.

The conversion of divalent and trivalent metal ions into polynuclear species and, ultimately, polynuclear metal hydroxides involves a complicated sequence of hydrolytic processes. Because these processes occur concurrently, it is often difficult to obtain reliable measurements of discrete polymerization rates. As a consequence, information about the mechanism of these reactions is generally lacking.

In the case of Fe^{3+},[1] measurements of the rate of dimerization of $FeOH^{2+}$ to give $[Fe_2(\mu\text{-}OH)_2]^{4+}$ (eq. 1) have shown that the forward reaction ($k_{11} = 630\ M^{-1}\ s^{-1}$ at 25°C) is faster than the reverse reaction ($k_{-11} = 0.4\ s^{-1}$) for $[FeOH^{2+}] > 0.001$ M. Hence, the equilibrium constant indicates that dimer formation is favoured under these conditions.

$$FeOH^{2+} + FeOH^{2+} \underset{k_{-11}}{\overset{k_{11}}{\rightleftharpoons}} Fe_2(\mu\text{-}OH)_2^{4+}. \quad (1)$$

Furthermore, it has been estimated that formation of dimer from $FeOH^{2+}$ is about 10 orders of magnitude faster than from Fe^{3+}. This is in keeping with the faster rates of substitution observed on deprotonation of Fe^{3+}.[1]

Recent work on the dimerization of Cr^{3+} [2] has shown that several pathways contribute to the reaction rates (eqs 2–4), their relative effect being determined primarily by solution pH.

$$CrOH^{2+} + CrOH^{2+} \longrightarrow \text{dimer} \quad (2)$$

$$CrOH^{2+} + Cr(OH)_2^{+} \longrightarrow \text{dimer} \quad (3)$$

$$Cr(OH)_2^{+} + Cr(OH)_2^{+} \longrightarrow \text{dimer}. \quad (4)$$

The results showed a systematic increase in dimerization rate with degree of deprotonation of the

Cr^{III} aquo ion, consistent with the faster rate of H_2O exchange on $CrOH^{2+}$ compared with Cr^{3+}.[3]

We report here the kinetics of dimerization of the hydrolytic dimer of Cr^{III}, $[Cr_2(\mu\text{-}OH)_2]^{4+}$, to give tetramer (eq. 5) measured over the pH range 3.4–5.0, $T = 298.2$ K and $I = 1.0$ M ($NaClO_4$)

$$Cr_2(\mu\text{-}OH)_2(OH)_r^{(4-r)+} \longrightarrow Cr_4(\mu\text{-}OH)_6(OH)_s^{(6-5)+} + mH^+ \quad (5)$$

using a pH-stat technique. The work is part of a continuing effort aimed at developing a kinetic scheme for the propagation of polymerization in partially neutralized solutions of Cr^{3+}.

EXPERIMENTAL

Materials

$[Cr_2(\mu\text{-}OH)_2(OH_2)_8](CH_3)_3C_6H_2SO_3)_4 \cdot 4H_2O$ was prepared as described in the literature.[4] Dimer solutions in perchlorate media were obtained by reaction of Cr metal with perchloric acid (under nitrogen) to give Cr^{2+} followed by air oxidation to produce dimer, which was subsequently purified by ion-exchange chromatography. Sodium perchlorate and 70% perchloric acid (Merck p.a.) were used as received. Imidazole (Fluka p.a.) was twice recrystallized from ethanol. All aqueous solutions were prepared using deionized, distilled water and those used in pH measurements were also degassed to remove dissolved CO_2.

Instruments and methods

Solution pH values and pH-stat kinetics were measured on a Metrohm 605 pH meter connected to a Metrohm 665 Dosimat autoburette using a Ross combined glass electrode (Orion). The electrode was calibrated against standard $HClO_4$ (pH 2–3, $I = 1.0$ M ($NaClO_4$)) and allowances for differences in ionic mobility were made by applying a Henderson correction. All pH measurements were carried out at $I = 1.0$ M ($NaClO_4$) and a temperature of 298.2 ± 0.1 K, maintained by circulating water through a double-walled reaction vessel from a waterbath fitted with a Haake D8 thermostat and Haake D12 compressor. A slow, continuous flow of N_2 was maintained through the solutions to prevent the absorption of CO_2. Kinetic experiments were conducted with exclusion of light since this has been shown to accelerate the polymerization reactions of Cr^{III}.[2]

The determination of the first two hydrolysis constants of the doubly bridged dimer (K_{D1} and K_{D2}) at $I = 1.0$ M ($NaClO_4$) was performed as described by Stünzi and Marty.[5] The dimer solution was chromatographically purified just prior to measurement and degassed by N_2 before and during the potentiometric titration.

The pH meter and Dosimat were interfaced to a Pericom AT computer through an IEEE interface package (IO tech). This system enabled direct computer acquisition of kinetic data which could then be conveniently analysed using the statistical package SYSTAT.[6]

The chromium content of salts and solutions was determined spectrophotometrically following conversion to CrO_4^{2-}.[5]

Kinetics

The dimer solutions used in kinetic experiments were prepared by either: (i) dissolution of the dimer mesitylene sulphonate in a solution containing 0.01 M $HClO_4$ and sufficient $NaClO_4$ to give $I = 1.0$ M; or (ii) elution of dimer from ion-exchange columns with a 0.01 M $HClO_4$/0.99 M $NaClO_4$ solution since this gave a solution with $I = 1.00(\pm 0.03)$ M. An aliquot of either of these solutions was introduced into the reaction vessel and allowed to reach thermal equilibrium. After electrode stabilization (10 min) a moderately concentrated imidazole solution (0.2 M, $I = 1.0$ M) was added slowly by graduated pipette until the solution pH was close to the desired value. Vigorous stirring was necessary during this addition to avoid localized areas of high pH, which could result in artificially rapid polymerization of the dimer. The computer-controlled titration system was then used to obtain the commencing pH, via addition of more dilute base solution (0.02 M imidazole, $I = 1.0$ M) and to follow the dimerization reaction by measuring the volume of base required to maintain constant pH as a function of time. The reaction was typically followed for 5–8% conversion of dimer.

Product analysis

At the completion of (and sometimes during) data acquisition, aliquots of solutions were taken from the reaction vessel, acidified to pH 2, diluted to $I < 0.1$ M and absorbed onto Sephadex SP C25 ion-exchange columns. The products were then eluted as described by Stünzi and Marty[5] and the chromium content of each fraction determined. For a typical experiment at pH = 3.80, the following product distribution was obtained: dimer, 92.1%; tetramer, 7.3%; higher oligomers, < 0.6%. Analysis of the reaction mixtures as dimerization progressed showed an almost constant amount of higher oligomers (< 0.8%).

RESULTS AND DISCUSSION

In the pH range 3.4–5.0, homogeneous solutions of the Cr^{III} doubly bridged dimer slowly polymerize, initially forming tetramer, followed by further reaction to higher oligomers and the precipitation of polymeric hydroxides. The structure of the dimer (**1**)[7] and the proposed structure of the "open" form of the tetramer (**2**)[5] are shown in Fig. 1. The work presented here concerns only the conversion of dimer into tetramer. Thus, it was important to establish the conditions for following this reaction without interference from subsequent polymerization processes.

The acid dissociation constants of dimer (K_{D1}, K_{D2}) and tetramer (K_{T1}, K_{T2}) can be used to determine whether dimerization releases or consumes protons. The proton balance for the reaction (eq. 5) is given by eq. (6):

$$m = 1 + \frac{s}{2} - r, \tag{6}$$

where

$$r = \frac{\{K_{D1}[H^+]^{-1} + 2K_{D1}K_{D2}[H^+]^{-2}\}}{\{1 + K_{D1}[H^+]^{-1} + K_{D1}K_{D2}[H^+]^{-2}\}} = \frac{[Cr_2(OH)_3^{3+}] + 2[Cr_2(OH)_4^{2+}]}{[\text{dimer}]_T} \tag{7}$$

$$s = \frac{\{K_{T1}[H^+]^{-1} + 2K_{T1}K_{T2}[H^+]^{-2}\}}{\{1 + K_{T1}[H^+]^{-1} + K_{T1}K_{T2}[H^+]^{-2}\}} = \frac{[Cr_4(OH)_7^{5+}] + 2[Cr_4(OH)_8^{4+}]}{[\text{tetramer}]_T}. \tag{8}$$

Values of K_{D1} ($= \{2.14 \pm 0.05\} \times 10^{-4}$ mol dm^{-3}) and K_{D2} ($= \{1.48 \pm 0.07\} \times 10^{-6}$ mol dm^{-3}) used in the calculation of r throughout kinetic analysis were determined as part of this work, while K_{T1} and K_{T2} were taken from ref. 5. Terms involving higher dissociation constants of dimer (K_{D3}, K_{D4}) and tetramer (K_{T3}, K_{T4}, ...) have been neglected as they are expected to make minimal contribution at pH < 5. This is reasonable since the observed difference between the first two dissociation constants of Cr^{III} oligomers of 1–2 pH units[5] is expected to continue for subsequent successive deprotonations of dimer and tetramer. Furthermore, pK_{a3} values for several Cr^{III} amine complexes have been found to be greater than 8.[8]

Although m was found to vary with pH, the values were always positive (Table 1) indicating that the conversion of dimer into tetramer liberates H^+. Thus, reaction could be followed by monitoring the release of H^+ as a function of time.

Product analyses

Product analyses have shown that tetramer is the dominant product formed in the early stages of reaction (< 8% conversion of dimer), although small amounts of higher oligomers (< 0.8%) were found in all reaction mixtures. The proportion of these higher oligomers remained constant throughout each experiment indicating that they were formed at the commencement of the reaction when mildly concentrated base (0.2 M imidazole) is added to rapidly adjust solution pH to the desired value. Regions of relatively high base concentrations (pH > 5) can form for short periods of time which could give rise to multiply deprotonated forms of dimer which, as will be shown later, polymerize at much faster rates than fully protonated dimer and could therefore transform it into polynuclear species. At pH > 5, the "active" dimer hydroxide, $Cr_2(\mu\text{-}OH)_2(OH)_4(OH_2)_4 \cdot xH_2O$, could also form, but as equilibrium pH is established throughout the reaction mixture it would redissolve regenerating deprotonated forms of the dimer. Since substitution is not involved, this process does not lead to polynuclear species.

[a] Defined in eq. (6).
[b] Eq. (12).
[c] Quoted errors are one standard deviation.
[d] Eq. (13).

In summary, product analyses have shown that tetramer is the only significant product formed in the early stages of polymerization of the Cr^{III} hydrolytic dimer. Thus, rate constants can be obtained by the initial rates method successfully used to study the dimerization of Cr^{3+}.[2]

Determination of k_{obs}

The kinetic scheme for conversion of dimer into tetramer is complicated by the presence of several deprotonated forms of the dimer. Over the pH range 3.4–5.0, $Cr_2(OH)_2^{4+}$, $Cr_2(OH)_3^{3+}$ and $Cr_2(OH)_4^{2+}$ are expected to be the dominant species although $Cr_2(OH)_5^{+}$ and $Cr_2(OH)_6$ could also be present albeit in extremely low concentrations. Thus, dimerization may occur through many pathways:

$$Cr_2(OH)_2^{4+} + Cr_2(OH)_2^{4+} \xrightarrow{k_{00}} \text{Tetramer}$$

$$Cr_2(OH)_3^{3+} + Cr_2(OH)_2^{4+} \xrightarrow{k_{10}} \text{Tetramer}$$

$$Cr_2(OH)_4^{2+} + Cr_2(OH)_2^{4+} \xrightarrow{k_{20}} \text{Tetramer}$$

$$Cr_2(OH)_5^{+} + Cr_2(OH)_2^{4+} \xrightarrow{k_{30}} \text{Tetramer}$$

$$Cr_2(OH)_6^{0} + Cr_2(OH)_2^{4+} \xrightarrow{k_{40}} \text{Tetramer}$$

$$Cr_2(OH)_3^{3+} + Cr_2(OH)_3^{3+} \xrightarrow{k_{11}} \text{Tetramer}$$

$$Cr_2(OH)_4^{2+} + Cr_2(OH)_3^{3+} \xrightarrow{k_{21}} \text{Tetramer}$$

$$Cr_2(OH)_5^{+} + Cr_2(OH)_3^{3+} \xrightarrow{k_{31}} \text{Tetramer}$$

$$Cr_2(OH)_6^{0} + Cr_2(OH)_3^{3+} \xrightarrow{k_{41}} \text{Tetramer}$$

$$Cr_2(OH)_4^{2+} + Cr_2(OH)_4^{2+} \xrightarrow{k_{22}} \text{Tetramer}$$

$$Cr_2(OH)_5^{+} + Cr_2(OH)_4^{2+} \xrightarrow{k_{32}} \text{Tetramer}$$

$$Cr_2(OH)_6^{0} + Cr_2(OH)_4^{2+} \xrightarrow{k_{42}} \text{Tetramer}$$

$$Cr_2(OH)_5^{+} + Cr_2(OH)_5^{+} \xrightarrow{k_{33}} \text{Tetramer}$$

$$Cr_2(OH)_6^{0} + Cr_2(OH)_5^{+} \xrightarrow{k_{43}} \text{Tetramer}$$

$$Cr_2(OH)_6^{0} + Cr_2(OH)_6^{0} \xrightarrow{k_{44}} \text{Tetramer.}$$

The rate law which combines all these pathways is given by:

$$-\frac{1}{2}\frac{d[dimer]}{dt} = k_{00}[Cr_2(OH)_2^{4+}]^2 + k_{10}[Cr_2(OH)_3^{3+}][Cr_2(OH)_2^{4+}] + k_{20}[Cr_2(OH)_4^{2+}][Cr_2(OH)_2^{4+}] + \ldots \quad (9)$$

Since the concentrations of all dimeric species present in solution are related by the appropriate acid dissociation constants, this expression may be rewritten as:

$$\frac{-d[dimer]}{dt} = 2k_{obs}[dimer]_T^2,$$

where

$$k_{obs} = (\{k_{00} + k_{10}K_{D1}[H^+]^{-1} + k_{20}K_{D1}K_{D2}[H^+]^{-2} + \ldots\}/\{1 + K_{D1}[H^+]^{-1} + K_{D1}K_{D2}[H^+]^{-2} + K_{D1}K_{D2}K_{D3}[H^+]^{-3} + K_{D1}K_{D2}K_{D3}K_{D4}[H^+]^{-4}\}^2). \quad (10)$$

Measurements of the pK_as of dimer indicate that mono- and doubly-deprotonated dimers are the only conjugate bases of dimer present in significant concentrations in the pH range 3.4–5.0. Hence, the last two terms in the denominator may be neglected.

As the reaction proceeds, the solution volume increases as dilute base is added to maintain constant pH, which is accounted for in the kinetic analysis by incorporating a volume dependent term (eq. 11).

$$\frac{-d[dimer]}{dt} = 2k_{obs}[dimer]_T^2 + [dimer]_T\frac{dV}{(V_0+V)}. \quad (11)$$

In eq. (11), V_0 is the initial volume of the reaction mixture and V is the volume base added at time t. Following the derivation developed for the dimerization of Cr^{3+},[2] the following expression is obtained:

$$k_{obs} = \frac{1}{2t}\left(\frac{V}{[dimer]_0V_0 - \frac{V}{m}([B]+[H^+])}\left\{\frac{[B]+[H^+]}{m[dimer]_0} + 1\right\} + \frac{m}{([B]+[H^+])}\ln\left[1 - \frac{V([B]+[H^+])}{m[dimer]_0V_0}\right]\right), \quad (12)$$

where $[dimer]_0$ is the dimer concentration at $t = 0$, [B] is the base concentration and m is given by eq. (6). If the volume of base consumed is small, this expression simplifies to:

$$V\left[\frac{m[dimer]_0 + [B] + [H^+]}{2m[dimer]_0^2V_0}\right] = k_{obs}t. \quad (13)$$

Consequently, the volume of added base becomes a linear function of time. Plots of V against time were found to be linear for at least the initial 8% conversion of dimer under all experimental con-

ditions. Values of k_{obs} were determined by linear least-squares analysis and are listed in Table 1.

Reaction reversibility

The rate law (eq. 9) assumes that dimerization is irreversible. This aspect requires examination since the interpretation of k_{obs} would be complicated by the existence of back reactions which convert tetramer into dimer. Reaction reversibility may be ascertained from the stability constants of dimer and tetramer. The dimerization reaction may be represented as:

$$\text{dimer} + \text{dimer} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \text{tetramer}. \quad (14)$$

whereupon the rate law becomes:

$$-\frac{d[\text{dimer}]}{2dt} = k_f[\text{dimer}]^2 - k_r[\text{tetramer}]. \quad (15)$$

The equilibrium constant for the reaction is given by:

$$K = \frac{k_f}{k_r} = \frac{[\text{tetramer}]}{[\text{dimer}]^2} = \frac{\{[Cr_4(OH)_6^{6+}] + [Cr_4(OH)_7^{5+}] + [Cr_4(OH)_8^{4+}]\}}{\{[Cr_2(OH)_2^{4+}] + [Cr_2(OH)_3^{3+}] + [Cr_2(OH)_4^{2+}]\}^2} \quad (16)$$

which with the use of the stability constants[5] of dimer ($\beta_{22} = [Cr_2(OH)_2^{4+}][H^+]^2/[Cr^{3+}]^2 = 10^{-5.25}$) and tetramer ($\beta_{46} = [Cr_4(OH)_6^{6+}][H^+]^6/[Cr^{3+}]^4 = 10^{-13.86}$) simplifies to:

$$K = \frac{\beta_{46}\{1 + K_{T1}[H^+]^{-1} + K_{T1}K_{T2}[H^+]^{-2}\}}{\beta_{22}^2[H^+]^2\{1 + K_{D1}[H^+]^{-1} + K_{D1}K_{D2}[H^+]^{-2}\}^2}. \quad (17)$$

Note that the equilibrium constant is pH dependent and that higher pK_as of dimer and tetramer have been ignored as they would have negligible effect in the pH range 3.4–5.0. Mass conservation at constant volume requires that $[\text{dimer}]_0 = [\text{dimer}] + 2[\text{tetramer}]$. It can then be shown that:

$$-\frac{d[\text{dimer}]}{2dt} = k_f\left[[\text{dimer}]^2 - \frac{([\text{dimer}]_0 - [\text{dimer}])}{2K}\right]. \quad (18)$$

Thus, the reaction is effectively irreversible if:

$$\frac{2K[\text{dimer}]^2}{([\text{dimer}]_0 - [\text{dimer}])} \gg 1. \quad (19)$$

Since the reaction was followed for < 8% dimer conversion this condition is met if:

$$R = \frac{2K(0.92)^2[\text{dimer}]_0}{0.08} = 21.2K[\text{dimer}]_0 \gg 1. \quad (20)$$

For the range of pH and [dimer] over which the reaction was followed, the smallest R value of 1800 was obtained at pH = 3.42 and $[\text{dimer}]_0 = 9.5 \times 10^{-3}$ M. Clearly, the back reactions make little contribution to the reaction rate and the observed reaction is essentially irreversible.

Dimerization rate constants

Rearrangement of eq. (10) and collection of all terms with the same power in H^+ gives the following expression for k^*:

$$k^* = k_{obs}\{1 + K_{D1}[H^+]^{-1} + K_{D1}K_{D2}[H^+]^{-2}\}^2 = a_0 + a_1[H^+]^{-1} + a_2[H^+]^{-2} + \cdots + a_8[H^+]^{-8}, \quad (21)$$

where, for example, $a_0 = k_{00}$, $a_1 = k_{10}K_{D1}$, $a_2 = k_{11}K_{D1}^2 + k_{20}K_{D1}K_{D2}$, etc.

As in the previous work on the dimerization of Cr^{3+},[2] the significant terms in $[H^+]^n$ have been identified from a plot of $\log k^*$ against $\log[H^+]$. The plot gives slopes of −2.3, −3.3 and −3.7 at pH = 3.6, 4.0 and 4.8, respectively. These limiting slopes indicate that the important terms in the expression for k^* are those with powers in H^+ of −2, −3 and −4. Integer values were not obtained in this analysis because more than one process will contribute to the overall rate at a particular pH. In the expression for k^*, the corresponding parameters a_2, a_3 and a_4 are in fact composite values, namely $a_2 = k_{11}K_{D1}^2 + k_{20}K_{D1}K_{D2}$, $a_3 = k_{21}K_{D1}^2K_{D2} + k_{30}K_{D1}K_{D2}K_{D3}$ and $a_4 = k_{22}K_{D1}^2K_{D2}^2 + k_{31}K_{D1}^2K_{D2}K_{D3} + k_{40}K_{D1}K_{D2}K_{D3}K_{D4}$. However, it is expected that all pathways where the dimer reactants differ by two or more deprotonations (k_{30}, k_{31}, k_{40}, etc.) will not be significant because: (i) the separations between measured and predicted pK_a values for dimer are such that significant concentration of both species would not be present at the same pH; and (ii) as the reactants approach, rapid proton transfer would occur to the dimer species with the highest degree of deprotonation. Based on these considerations, the expression for k^* was simplified to:

$$k^{\#} = \frac{k^*[H^+]^4}{K_{D1}^2} = k_{11}[H^+]^2 + k_{21}K_{D2}[H^+] + k_{22}K_{D2}^2. \quad (22)$$

Values of $k^{\#}$ are included in Table 1. Weighted† least-squares analysis of the $k^{\#}$ vs $[H^+]$ data gave

† Weighting scheme: $w(i) = 1/\sigma_{k_i}^2{}^{\#}$.

the following rate constants: $k_{11} = (2.18 \pm 0.21) \times 10^{-4}$, $k_{21} = (5.2 \pm 3.2) \times 10^{-3}$, $k_{22} = 0.83 \pm 0.08$ M^{-1} s^{-1}. Attempts were made to fit expressions involving other terms in $[H^+]^n$, but in all cases systematic deviations were found between the calculated and measured values of $k^{\#}$. For example, a model with rate constants k_{10}, k_{11}, k_{21} gave a poor fit at pH > 4.5 while one which allowed only for k_{21} and k_{22} gave a poor fit at pH < 3.8.

Interpretation of dimerization rate constants

The mechanism of conversion of dimer into tetramer is difficult to ascertain for a number of reasons:

(i) Since the reaction was followed for < 8% conversion of dimer, the detection of intermediates which may be present in very low concentrations is extremely difficult. Furthermore, these intermediates may undergo relatively rapid intramolecular processes (e.g. singly bridged dimer, a possible intermediate, is converted into Cr^{3+} at pH < 0 and doubly bridged dimer at pH > 1) which would make their isolation virtually impossible. Chromatographic analysis provided no evidence for the existence of such intermediates.

(ii) Cleavage of tetramer does not produce dimer but rather gives quantitative yields of trimer and monomer.[5] Hence, the often more accessible cleavage reactions provide little insight into the mechanism of tetramer formation.

From the structure of the dimer (**1**) and proposed structure of the "open" tetramer (**2**), plausible reaction mechanisms may be postulated. One such mechanism is given in Scheme 1. This scheme is only intended to represent a reasonable sequence of bond making and breaking stages. The actual order of processes and the specific ligands involved in the formation of the tetramer remain unknown.

Even though the full mechanism of formation is not known, the rate constants can be rationalized by assuming that they reflect the initial dimerization process and not subsequent intramolecular rearrangements to give the most stable form of tetramer. This is reasonable since the interconversion between open (**2**) and closed (**3**) forms of tetramer, depicted in Scheme 1, is much faster ($k = 0.1$–4 s^{-1})[9] than the dimerization rates reported here. During dimerization of Cr^{3+}, conversion of mononuclear Cr^{III} species into singly bridged forms of dimer has been shown to be much slower than subsequent intramolecular ring closure to give doubly bridged dimer. The slower rate of intermolecular dimerization, *cf.* intramolecular processes, probably results from the need to bring the positively charged reactants into close proximity before reaction can occur.

The pH dependence of k_{obs} has been fitted to an expression comprising three rate constants, k_{11}, k_{21} and k_{22}, which represent the following dimerization reactions:

$$Cr_2(\mu\text{-}OH)_2(OH)^{3+} + Cr_2(\mu\text{-}OH)_2(OH)^{3+} \longrightarrow \text{tetramer} \quad k_{11} = (2.18 \pm 0.21) \times 10^{-4}\,M^{-1}\,s^{-1}$$

$$Cr_2(\mu\text{-}OH)_2(OH)_2^{2+} + Cr_2(\mu\text{-}OH)_2(OH)^{3+} \longrightarrow \text{tetramer} \quad k_{21} = (5.2 \pm 3.2) \times 10^{-3}\,M^{-1}\,s^{-1}$$

$$Cr_2(\mu\text{-}OH)_2(OH)_2^{2+} + Cr_2(\mu\text{-}OH)_2(OH)_2^{2+} \longrightarrow \text{tetramer} \quad k_{22} = (0.83 \pm 0.08)\,M^{-1}\,s^{-1}.$$

Substantial rate increases (25- and 160-fold, respectively) accompany each deprotonation of dimer. These rate enhancements are similar to those reported for the dimerization of Cr^{3+}. The rate constants are a combination of the "true" dimerization constants and the ion-pair association constants (K_{IP}) for bringing the positively charged reactants together. Since deprotonation effectively reduces the charge on the reactants, both K_{IP} and the overall rate constants should increase with the degree of deprotonation, as is observed. In addition, deprotonation is known to labilize the aquo ligands in the Cr^{III} coordination sphere and this could also account for the observed rate enhancements. Such accelerations have been observed for the conversion of SBD into DBD,[10] where little variation in ion-pairing constants is anticipated. For example, ring closure within doubly deprotonated SBD, $HOCr\text{-}OH\text{-}CrOH^{3+}$, was found to be 25 times faster than within mono-deprotonated SBD, $Cr\text{-}OH\text{-}CrOH^{4+}$.

In principle, ion-pairing constants can be estimated from the Fuoss and Davies equations and the "true" dimerization rate constants calculated. For the dimerization of Cr^{3+}, such a treatment gives corrected rate constants ($k'_{11} = 0.047$, $k'_{21} = 1.0$ and $k'_{22} = 17$ s^{-1}) which show a constant, *ca* 20-fold increase in rate with each deprotonation. This compares particularly well with the 25-fold rate enhancement reported for ring closure within SBD. However, closer inspection reveals that the corrected dimerization constants are faster than the corresponding ring closure reactions of SBD. This situation probably arises because only electrostatic interactions are considered in the calculation of K_{IP} and it is well known for metal aquo complexes in aqueous solution that H-bonding interactions (both between the metal ions and with the solvent) can have dramatic effects on ion-association. For ex-

Scheme 1. A possible reaction sequence for the formation of tetramer from deprotonated forms of dimer.

ample, the existence of H-bonding in both solution and solid state has been confirmed for several complexes of the type *cis*- and *trans*-$[A_4M(OH_2)(OH)]^{2+}$.[11,12] As the degree of deprotonation increases (i.e. charge decreases) H-bonding between the ions is expected to become more important while interactions with the solvent are expected to weaken. Thus, realistic ion-pairing constants may be much larger than those predicted from the Fuoss–Davies treatment and consequently, the corrected rate constants significantly slower than those estimated above. Given these complications and the fact that the calculation of K_{IP} for interaction between deprotonated forms of dimer would need to account for the non-spherical nature of the ions this treatment was not applied to the current study.

Although k_{obs} for the conversion of dimer into tetramer is larger is 1.3–6 times faster than for the dimerization of Cr^{3+} over the pH range studied, the rate constants for each reaction pathway (k_{11}, etc.) are either equal or greater for the Cr^{3+} case. The faster overall rate of dimerization of dimer can be attributed to the higher acidity of this oligomer, cf. Cr^{3+}. It was anticipated that the presence of bridging OH groups in the dimer, in addition to terminal OH groups, would result in a more labile Cr^{III} coordination sphere than in the case of conjugate of Cr^{3+} which contain only terminal OH groups. However, the reactants are of higher charge

in the case of dimer and this should reduce the ability of the species to come together and undergo dimerization. Knowledge of the rates of other substitution reactions of dimer such as solvent exchange and anation (Cl^-, SCN^-, etc.) would assist in this interpretation. Preliminary kinetic measurements on the sulphate anation of dimer indicate that the singly deprotonated form, $Cr_2(OH)_3^{3+}$, reacts at least an order of magnitude faster than fully protonated $Cr_2(OH)_2^{4+}$.[13]

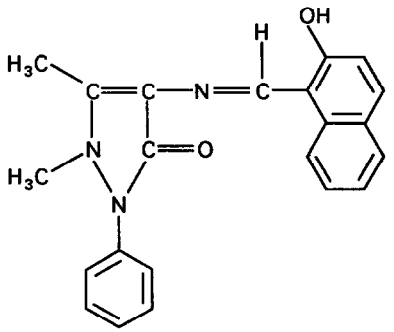
(*Received* 20 *February* 1991; *accepted* 9 *July* 1991)

Abstract—Some complexes of thorium(IV) and dioxouranium(VI) with the Schiff base of 2-hydroxy-1-naphthaldehyde condensed with 4-aminoantipyrine (HNAAP) with the general composition $[ThX_4(HNAAP)_2]$ (X = Cl, Br, NO_3 or NCS), $[ThX_4(HNAAP)_3]$ (X = I or ClO_4), $[UO_2X_2(HNAAP)_2]$ (X = Cl, Br, I, NO_3, NCS or CH_3COO) or $[UO_2(ClO_4)_2(HNAAP)_3]$ have been synthesized and characterized by elemental analyses, conductivity, molecular weight, magnetism and IR spectra. The neutral bidentate ligand coordinates through the azomethine nitrogen and the carbonyl oxygen. IR data also reveal that the perchlorate groups are ionic, the thiocyanate groups are N-bonded while the nitrate groups are bi-covalently bonded. The probable coordination number of Th(IV) is 6, 8 or 12 and of U(VI) is 8 or 10 depending on the nature of anions. Thermal properties are also discussed.

The coordination behaviour of thorium(IV) and dioxouranium(VI) is peculiar because of their inherent capacity to form compounds with coordination numbers of six or higher. The variation in coordination number (6 to 12) observed in the actinide complexes may be attributed to steric factors and electrostatic forces of attaction and repulsion, rather than bond orientation by the well-shielded 5*f*-orbitals of the metal ion.[1–4]

During the last 10 years, there has been considerable interest in the coordination chemistry of Schiff bases with actinide metal ions and a number of publications have appeared in the literature.[5] The ligand derived from condensation of 4-aminoantipyrine with 2-hydroxy-1-naphthaldehyde, i.e. 4-[N-(2-hydroxy-1-naphthalidene)amino]antipyrine (HNAAP) (**I**) is of interest because it is capable of acting as a bidentate or a tridentate ligand depending on whether or not the functional group —OH is involved in coordination. This work reports the isolation and structure elucidation of the complexes of HNAAP with Th^{4+} and UO_2^{2+}.



HNAAP (**I**)

EXPERIMENTAL

Hydrated thorium(IV) nitrate and dioxouranium (VI) nitrate were B.D.H. reagents. Thorium(IV) halides and perchlorates were prepared by established methods.[6,7] The dioxouranium(VI) salts were prepared by an established method.[8] The Schiff base was synthesized as follows. A solution of 1-hydroxy-2-naphthaldehyde (1 mmol) in absolute ethanol (50 cm^3) was mixed with 4-aminoantipyrine (1.1 mmol) in the same solvent and the mixture was refluxed for 2 h. On cooling a yellow crystalline product was separated, which was filtered off and

† Author to whom correspondence should be addressed.

recrystallized in the same solvent. (Yield *ca* 75%; colour—dark yellow; m.p. 201°C.)

Synthesis of the complexes

Crystalline complexes of thorium(IV) and dioxouranium(VI) of the Schiff base were isolated by one of the following methods:

(a) A methanolic solution of the metal salt was added to the Schiff base solution in the same solvent with heating and the reaction mixture was refluxed for 2 h. The solid compound was obtained after partial evaporation under a fan. This was filtered, washed with methanol and dried *in vacuo* over P_4O_{10}.

(b) To a solution of metal salt in ethyl acetate was added the ligand in the same solvent and the reaction mixture was refluxed for 1 h and left overnight at room temperature. The fine crystalline product so obtained, was filtered, washed with ethyl acetate and finally dried *in vacuo* over P_4O_{10}.

(c) To a solution of the metal salt in isopropyl alcohol was added a hot solution of the ligand in the same solvent. In some cases, the desired complex was obtained immediately, but in others it was necessary to reflux the reaction mixture for 1–2 h. On cooling at room temperature the desired solid product was filtered off washed with isopropyl alcohol and dried *in vacuo* over P_4O_{10}.

All the physical measurements and analyses were performed as reported earlier.[8,9]

RESULTS AND DISCUSSION

The interaction of thorium(IV) and dioxouranium(VI) salts with 4-[(*N*-2-hydroxy-1-naphthalidene) amino]-antipyrine (HNAAP) results in the formation of $[ThX_4(HNAAP)_n]$ (X = Cl, Br, NCS or NO_3, $n = 2$; X = I or ClO_4, $n = 3$) and $[UO_2X_2(HNAAP)_n]$ (X = Cl, Br, I, NCS, NO_3 or CH_3COO, $n = 2$; X = ClO_4, $n = 3$). The analytical data are recorded in Tables 1 and 2. All the complexes are quite stable and can be stored for long periods except $[ThI_4(HNAAP)_3]$ which decomposes slowly at room temperature with evolution of iodine vapour. Among the thorium(IV) complexes, the chloro, bromo, nitrato and thiocyanato complexes are non-electrolytes (Tables 1 and 2) in $PhNO_2$, whereas the iodo and perchlorato complexes dissociate in this solvent. The iodo complex appears to be a 1:2, while the perchlorato complex is a 1:4 electrolyte. The uranyl complexes $[UO_2X_2(HNAAP)_2]$ (X = Cl, Br, I, NO_3, NCS or CH_3COO) are all essentially non-electrolytes in $PhNO_2$. The conductance value for the perchlorato complex $[UO_2(HNAAP)_3](ClO_4)_2$ suggests ionic perchlorate groups, the presence of which was further confirmed by the IR spectra. Data on the molecular weights of the complexes in $PhNO_2$ are given in Tables 1 and 2, along with values calculated on the basis of established formula of the complexes. The ground states of uranyl and thorium compounds contain no unpaired electrons, the compounds are therefore weakly diamagnetic as observed by others.[10]

IR spectra and the nature of coordination

The IR spectral band assignments for HNAAP and its complexes are shown in Table 3. The ligand has bands around 3000 cm^{-1} [ν(OH)], at 1640 cm^{-1} [ν(C=O)] and 1590 cm^{-1} [ν(C=N)]. In the com-

plexes, the hydroxyl frequency appears at the same region as in the free ligand. The carbonyl frequency occurs in the 1605–1580 cm^{-1} region and the azomethine frequency in the 1545–1530 cm^{-1} region, indicating that these two groups are involved in bonding. Thus HNAAP in these complexes acts as neutral bidentate ligand. In the far IR region metal–ligand vibrations are tentatively assigned in 410–330 cm^{-1} to ν(M—O) and ν(M—N) modes.[8,9]

The strong ν_3 and ν_4 bands in the spectra of perchlorato complexes occur at 1085 and 620 cm^{-1} respectively, showing the ionic character of the perchlorato groups.[11,12] The ν(C—N) frequency in the actinide thiocyanate complexes lies at *ca* 2020 cm^{-1} and the ν(C—S) frequency falls in the 828–760 cm^{-1} region strongly suggesting N-bonded NCS.[13,14] The ν_3, i.e. δ(NCS) frequency also occurs at *ca* 465 cm^{-1}. The IR spectra of the nitrato complexes show the absence of ν_3 bands at *ca* 1360 cm^{-1} due to ionic nitrate.[15] The bidentate nature of covalent nitrato groups in $Th(NO_3)_4 \cdot 2HNAAP$ has been established by comparing the IR bands at *ca* 1530 (ν_4), 1290 (ν_1), 1030 (ν_2), 808 (ν_6), 740 (ν_3) and 695 (ν_5) cm^{-1} with the spectral bands of $Th(NO_3)_4 \cdot 5H_2O$ at 1520, 1290, 1030, 808, 745 and 715 cm^{-1} respectively.[16,17] In $UO_2(NO_3)_2 \cdot 2HNAAP$ the nitrate groups also seem to be bidentate since the IR frequencies at *ca* 1510 (ν_4), 1280 (ν_1), 1025 (ν_2), 828 (ν_6), 745 (ν_3) and 714 (ν_5) cm^{-1} in this complex due to this group occur almost at the same frequencies as reported earlier.[15,18,19] The complex $[UO_2(CH_3COO)_2(HNAAP)_2]$ is monomeric in nature and the IR data show two bands at 1550 and 1470 cm^{-1} region attributed to ν_{asym}COO and ν_{sym}COO respectively.[20] In this complex the acetate groups are bicovalently bonded.

In all the dioxouranium(VI) complexes, the ν_1 and ν_3 modes of O=U=O are assigned in the ranges 835–825 and 930–925 cm^{-1} respectively[21] (Table 4). Wilson's G–F matrix method[22] was used to determine the stretching and interaction force constants from which the U—O bond distances were calculated following Badger's formula.[23] It is apparent from the calculated data that the U—O bond length decreases with the increase in the value of symmetric stretching frequency (ν_1).[24] A plot of ($\nu_1 + \nu_3$) vs force constants gave a straight line. The U—O bond distances in dioxouranium salts generally range from 1.60 to 1.92 Å depending on the nature of the equatorial ligands.[25] The calculated values of the U—O bond distances in the present complexes are close to 1.73–1.74 Å (Table 4).

Thermal behaviour

The TG and DT curves of thorium(IV) complexes do not show the presence of water molecules either in or out of the coordination sphere. The halo and nitrato complexes decompose endothermically while the perchlorato complexes decompose exothermically[26] with a **slight explosion and evolution of smoke**[26]**—caution.** The TG curves of chloro, bromo and thiocyanato complexes indicate that in the first step, only one mol of ligand has been lost, while at *ca* 475°C, the remaining ligand mole is lost. Finally at *ca* 620°C, oxohalide and oxothiocyanate formation takes place. The thorium(IV) nitrate complexes decompose in the 300–450°C temperature region, losing both ligand molecules. Finally, ThO_2 is obtained as residual mass at *ca* 650°C. The TG curve of $[Th(HNAAP)_3](ClO_4)_4$ shows that the complex starts to decompose at 260°C and continues up to 625°C, after which ThO_2 remains. From the pyrolysis curve it is clear that no stable intermediate perchlorate complex has been formed in this species.

The TG and DT curves of the uranyl(VI) com-

Table 4. Uranyl frequencies (cm^{-1}), force constants and U—O bond distances of dioxouranium(VI) complexes of HNAAP

Complex	ν_1 (cm^{-1})	ν_3 (cm^{-1})	U—O force constant (mdynes $Å^{-1}$)	Force constant due to interaction between bonds (mdynes $Å^{-1}$)	Calc. U—O bond distance (Å)
$[UO_2Cl_2(HNAAP)_2]$	832	925	6.82	−0.29	1.74

$[UO_2(NO_3)_2(HNAAP)_2]$	830	928	6.82	−0.33	1.74
$[UO_2(NCS)_2(HNAAP)_2]$	830	925	6.80	−0.31	1.74
$[UO_2(ClO_4)_2(HNAAP)_3]$	835	930	6.88	−0.31	1.74
$[UO_2(CH_3COO)_2(HNAAP)_2]$	832	930	6.86	−0.33	1.74

plexes clearly indicate the absence of water molecules in the complexes. All the pyrolysis curves behave similarly and show that the decomposition of these complexes have started at 270°C and are completed at *ca* 470°C. The break in the curves in the 270–325°C temperature region indicates that at this stage only 1 mol of ligand has been lost (22–23%) for the halo, nitrato and perchlorato complexes. In the temperature range 430–470°C there is an additional decrease in weight due to loss of all the ligand molecules. The oxide U_3O_8 is formed around 625°C via the formation of UO_3, following which there is no measurable change in weight.[27]

Stereochemistry and the structure of the complexes

The preferred coordination number of thorium(IV) is 6 or 8, but higher coordination numbers have also been observed.[28] In $[Th(HNAAP)_2X_4]$ (X = Cl, Br or NCS) and $[Th(HNAAP)_3I_2]I_2$ the coordination number of Th^{IV} is 8. The conductance, molecular weight and IR data show that in the perchlorate complex, all the four perchlorato groups are present outside the coordination sphere and hence Th^{IV} is six-coordinated in this complex. In $[Th(HNAAP)_2(NO_3)_4]$, the coordination number of Th^{IV} is 12.

In $[UO_2(HNAAP)_2X_2]$ (X = Cl, Br, I or NCS), the coordination number of uranium is 8. In $[UO_2(HNAAP)_3](ClO_4)_2$, both the perchlorato groups are ionic in nature, thus in this complex uranium is octa-coordinated. The IR data of $[UO_2(HNAAP)_2(NO_3)_2]$ and $[UO_2(HNAAP)_2(CH_3COO)_2]$ suggest bidentate nature of nitrate and acetate ligands in these complexes. Thus in these complexes the coordination number of uranium(VI) is 10.

(*Received* 12 *December* 1990; *accepted* 4 *July* 1991)

Abstract—New complexes of the general formulae $[Ln(LH)_2(NCS)_3(H_2O)]$ (Ln = La–Eu), $[Ln(LH)_2(NCS)_3]$ (Ln = Gd–Yb), $[Ln(LH)_3(OClO_3)](ClO_4)_2$ (Ln = La–Gd), $[Ln(LH)_3](ClO_4)_3$ (Ln = Tb–Yb), $[Ln(LH)_2(ONO_2)_2](NO_3)$ (Ln = La–Yb) and $[Ln(LH)(ONO_2)_3]$ (Ln = La, Pr, Nd, Sm, Eu), where LH = N-(2-pyridyl)pyridine-2′-carboxamide, have been isolated. The complexes were characterized by elemental analyses, conductivity measurements, X-ray powder patterns, thermal methods, magnetic susceptibilities and spectroscopic (IR, ^1H NMR, electronic diffuse reflectance and solid state emission *f–f* spectra) studies. All the data are discussed in terms of the nature of the bonding and the possible structural types. The 1:2 and 1:3 complexes appear to be monomeric, while polymeric structures are assigned for the 1:1 nitrato compounds. The LH molecule behaves as a bidentate ligand in the monomeric complexes, bonding through the amide oxygen and N(1′). The amide oxygen and both pyridine residues are coordinated in the 1:1 nitrato complexes.

In recent publications,[1–3] we have reported our efforts towards the preparation and study of lanthanide(III) complexes with amidic ligands, as such complexes have received little attention.[4–10] Our main work to-date has concentrated on the use of ligands which have both amide and carboxylate groups as potential donor sites. With the exception of the monoanion of iso-orotic acid,[3] the neutral amide group of the ligands used remained uncoordinated on complexing with Ln^{III} in aqueous media, despite the fact that this interaction would be stabilized by the formation of stable chelate rings. This is partly because the O_{amide} atom is only weakly basic, and so metal binding is weak, and partly because of competition by the stronger aqua and —COO^- ligands. In agreement with this, when H_2O is driven off by heating then coordination of the amide oxygen does occur; the coordinative unsaturation, after the removal of the coordinated water molecules, leads to the neutral amide group coordination.

In extending the above work, we considered it important to use synthetic conditions and ligands which would favour direct amide coordination. Obvious conditions for our goal were the absence of water from the reaction mixtures and use of weakly coordinating counter-ions, i.e. ClO_4^-. We also felt that the lack of readily ionizable oxygen-based groups, i.e. —OH and —COOH, from the ligands and incorporation of nitrogen-based donor sites might allow access to species with coordinated amide groups. We herein report the results of this effort, the reactions of lanthanide(III) salts with N-(2-pyridyl)pyridine-2′-carboxamide, abbreviated as LH, to give interesting complexes with amide coor-

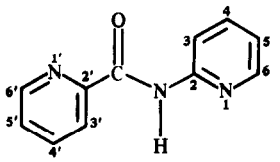
dination.



I, LH

The ligands LH and L^- have been shown[11] to coordinate to transition metal ions in several modes, largely determined by the nature of the metal ion and anion present and preparative conditions.

EXPERIMENTAL

Materials and methods

The salts $LnCl_3 \cdot nH_2O$, $Ln(ClO_4)_3 \cdot nH_2O$ and $Ln(NO_3)_3 \cdot nH_2O$ ($n = 6$, 7) were obtained from Aldrich, Fluka and Ventron. Lanthanide oxides of 99.9% purity were purchased from Johnson Matthey and Co. The anhydrous perchlorates were prepared by slowly heating the hydrates at 1.0 Torr, as suggested by Forsberg and Moeller.[12] Hydrated perchlorates of the lighter lanthanides lost water readily at 200°C without hydrolytic decomposition. With the heavier lanthanides, however, the 250°C temperature required for complete dehydration caused hydrolytic conversion at about half of the hydrated compound to an insoluble product;[12] the anhydrous perchlorate was easily removed by extraction with anhydrous MeCN. Aliquots of solutions of the anhydrous salts in MeCN were analysed by dilution with water and titration with standard 0.01 M EDTA, using xylenol orange as indicator. Anhydrous nitrates were prepared by direct reaction of the oxides with liquid nitrogen (IV) oxide.[12] MeCN and Et_2O were dried by distillation from CaH_2 and Na/benzophenone, respectively. The ligand LH was synthesized as described earlier.[11] Metal, carbon, hydrogen and nitrogen analyses were performed by conventional volumetric and microanalytical methods. The amount of water present in the complexes $[Ln(LH)_2(NCS)_3(H_2O)]$ (Ln = La–Eu) was also confirmed from the TG patterns. **Caution:** Perchlorate salts are potentially explosive. Although no detonation tendencies have been observed with our compounds, caution is advised and handling of only small quantities is recommended. Physicochemical measurements and spectroscopic techniques were carried out by published methods.[13,14]

Complex preparation

For the preparation of the isothiocyanato complexes an ethanolic solution of potassium thiocyanate (6.0 mmol, 15 cm^3), warmed to *ca* 50°C, was slowly added to an ethanolic solution of the appropriate lanthanide(III) chloride hexahydrate (2.0 mmol, 10 cm^3). The resulting mixture was stirred at 50°C for 10 min and then allowed to cool to room temperature, whereupon the precipitated potassium chloride was removed by filtration. The filtrate was mixed with a warm solution of LH (4.0 mmol) in absolute EtOH (15 cm^3) and precipitation occurred over 25–30 min. All precipitates were collected by filtration immediately after 1 h stirring at 50°C, washed with absolute EtOH and Et_2O and dried *in vacuo* over silica gel.

For the preparation of the perchlorate complexes, the anhydrous lanthanide(III) perchlorate (3.0 mmol) was dissolved in MeCN (25 cm^3) in the presence of triethyl*ortho*formate (TEOF, 5 cm^3) as dehydrating agent. The solution so obtained was added to a vigorously stirred, warm solution of LH (9.0 mmol) in MeCN (60 cm^3). Solid product formation was rather rapid (10 min), but completely stoichiometric products and satisfactory yields were obtained after the reaction mixtures were heated under reflux for 1–2 h. The mixtures were filtered while hot and the solids obtained were washed with hot MeCN and *n*-hexane and dried *in vacuo* over P_4O_{10}.

For the preparation of the 1 : 2 nitrate complexes $[Ln(LH)_2(ONO_2)_2](NO_3)$ to 1.0 mmol of the hydrated lanthanide(III) nitrate in 20 cm^3 of warm absolute EtOH was added 10 cm^3 of TEOF and the solution was refluxed overnight. This solution was added slowly to a solution of LH (2.0 mmol) in warm absolute EtOH (15 cm^3). The resulting solution was stirred at 45°C for 2 h. Solid products were deposited during this time, which were collected by filtration, washed copiously with hot absolute EtOH and Et_2O and dried *in vacuo* over P_4O_{10}.

The reactions for the preparation of the 1:1 nitrato complexes $[Ln(LH)(ONO_2)_3]$ (Ln = La, Pr, Nd, Sm, Eu) were carried out under rigorously anhydrous conditions. All manipulations were effected in a gloved box which was flushed constantly with dry nitrogen and which contained anhydrous P_4O_{10} as a desiccant. The complexes were prepared by dissolving 2.0 mmol of the appropriate anydrous nitrate in 10 cm^3 of MeCN and adding a solution of *ca* 1.8 mmol of LH in 20 cm^3 of MeCN. Precipitation of the product occurred immediately. The reaction mixtures were stirred for several hours (exact time not critical) and the solids were collected by filtration, washed with warm MeCN and Et_2O and dried *in vacuo* from 24 to 48 h before evaluation. No preparation of the Ce^{III} complex was attempted. Attempts to obtain complexes with the nitrates of lanthanide elements

heavier than europium resulted in non-stoichiometric solids; only Er^{III} gave repeatedly a solid with the formula $Er(LH)(NO_3)_3$. MeCN, which decomposed when removal of MeCN was attempted.

Efforts to prepare complexes with other stoichiometries were unsuccessful; in most cases the same complexes (those described in Tables 1, 2 and 3) were again isolated.

RESULTS AND DISCUSSION

Physical properties of the complexes

The formulae of the compounds, ligand : metal salt molar ratios used for the preparation of the complexes, yields, colours, molar conductivity values, effective magnetic moments and bonding parameters are given in Tables 1–3. Analytical data are summarized in Table 4. The complexes **40–44** are insoluble in all common organic solvents, while **1–39** are soluble only in DMF and DMSO. Because of the insolubility of the complexes in suitable solvents, we could not grow crystals for single-crystal X-ray structural studies. The Λ_M values of **14–20**, **21–26** and **27–29** in DMSO are in accord with these groups of complexes being formulated as 1 : 2, 1 : 3 and 1 : 1 electrolytes,[15] respectively. The X-ray powder diffraction patterns indicate the formation of six groups of isostructural compounds.

The first group includes the complexes **1–6**, the second the complexes **7–13**, the third the complexes **14–20**, the fourth the complexes **21–26**, the fifth the complexes **27–39** and the sixth group includes the compounds **40–44**. The patterns of the last group show a much smaller number of diffraction lines than for the complexes of the fifth group, suggesting polynuclear arrangements.[16] The room temperature effective magnetic moments of the complexes show little deviation from the Van Vleck theoretical values.

The thermal decomposition of the complexes prepared was studied in the 30–650°C region using TG/DTG, DTA and DSC techniques. The detailed thermal study of the complexes will be described in a subsequent paper.[17] As preliminary results we herein report that: (i) the water molecule present in

[a] Calculated values in parentheses.
[b] No data available.

1–6 is coordinated to the lanthanide ions, (ii) the thermal decomposition of **27–32** occurs in two steps:

$$[Ln(LH)_2(ONO_2)_2][NO_3) \xrightarrow{N_2} \underset{\textbf{27–32}}{} [Ln(LH)(ONO_2)_3] + \uparrow LH \quad (1)$$

40–44, $[Ce(LH)(ONO_2)_3]$

$$[Ln(LH)(ONO_2)_3] \xrightarrow{N_2}$$

Lanthanide(III) oxide + gaseous products (2)

and (iii) the thermal decomposition of some anhydrous isothiocyanato complexes occurs also in two steps, but with a different stoichiometry:

$$2[Ln(LH)_2(NCS)_3] \xrightarrow{N_2} [Ln_2(LH)_3(NCS)_6] + \uparrow LH \quad (3)$$

10–14

$$[Ln_2(LH)_3(NCS)_6] \xrightarrow{N_2}$$

Lanthanide(III) oxide/sulphide(?) + gaseous products (4)

IR spectra

Tables 5 and 6 give diagnostic IR bands; in these tables only selected representative complexes are listed. In the ν(O—H)$_{water}$ region, the spectra of **1–6** show one medium sharp band at 3495–3470 cm^{-1} attributed to the presence of coordinated water.[18]

The IR spectrum of LH shows the characteristic bands of a *trans* secondary, hydrogen-bonded, amide with two chemically non-equivalent 2-pyridyl residues.[11] The absence of large systematic shifts of the ν(N—H) and amide V bands in the spectra of the complexes, in comparison with these bands in LH, confirms the inability of the amide nitrogen to participate in coordination, if non-deprotonated. The amide I band shifts to a lower frequency, while the amide II and III bands shift to higher frequencies; these shifts indicate amide-O coordination.[19]

It is well known that the IR spectra of complexes containing ligands with two pyridine residues may be reliably used as a guide to pyridine coordination and the criteria employed have been adequately discussed.[20–26] The careful study of multiplicity and shifts of mid- and far-IR bands associated with internal modes of vibration of the pyridine rings, can lead to fairly clear structural conclusions. The bands of interest, mostly affected by coordination, are the four ν(C=N) and ν(C=C) bands observed between 1610 and 1410 cm^{-1}, the ring breathing mode near 1000 cm^{1}, an out-of-plane CH deformation near 770 cm^{-1} and the two in-plane and out-of-plane ring deformation bands at *ca* 600 and 400 cm^{-1}, respectively.[20–25] These characteristic bands of the pyridine ring are doubled in the spectrum of LH, due to the presence of two non-equivalent pyridine residues, i.e. C_5H_4NCO— and C_5H_4NNH—. The complexes can be divided into two series on the basis of their IR spectra. The first series complexes (**40–44**) have spectra in which almost all of the key ring bands indicative of metal

$\nu_3(A_1)$[+δ(Py) in-plane]			651sb			
$\nu_5(E)$[+$\nu_4(F_2)$]			628sb			
$\nu_4(F_2)$				630s		
Nitrate bands[a]						
$\nu_1(A_1)$						1577m
$\nu_1(A_1)$[+ring stretch. vibr.]					1505sb	1498s
$\nu_3(E')$					1385sb	
$\nu_4(B_2)$					1292s	1303m, 1293s
$\nu_2(A_1)$					1017s	1015s
$\nu_6(B_1)$					829m	840m, 825m
$\nu_6(B_1)$[+$\nu_2(A_2'')$]					829m	
$\nu_5(B_2)$						723m, 700w
$\nu_5(B_2)$[+$\nu_4(E')$]					707wb	

[a] The $\nu_3(A_1)$ mode of the C_{2v} nitrato groups was not assigned because the region at *ca* 750 cm^{-1} is obscured by strong bands of the coordinated organic ligand.

coordination are doubled. Since these bands are significantly shifted from their positions in the free ligand spectrum (the shift is to higher frequencies for the ν(C=N) and ν(C=C) vibrations, the ring breathing mode and the δ(Py) modes), the implication is that both pyridine-N atoms are coordinated.[20-25] Ring bands of the coordinated ligand in the spectra of the second series complexes (**1–39**) are again doubled, one band being nearly coincident with the corresponding one of the free ligand and the other occurring at a different frequency; these results have been interpreted in terms of the presence of both coordinated and non-coordinated pyridine residues on the same ligand molecule.[20,23-26]

The spectra of **1–13** exhibit the ν(CN), ν(CS) and δ(NCS) modes all in the regions characteristic of terminal N-bonded isothiocyanato groups.[27] In the spectra of **21–26** both the $\nu_3(F_2)$ and $\nu_4(F_2)$ modes of the ClO_4^- group, appearing at *ca* 1090 and 630 cm^{-1}, remain unsplit, showing that the perchlorate groups are present in these complexes only as ionic species.[27] Apart from the T_d ClO_4^- frequencies already observed in the **21–26** series, the spectra of **14–20** show a number of additional anion vibrations, the number and the frequencies of which are indicative of the simultaneous presence of monodentate C_{3v} perchlorato groups.[27,28] In the spectra of **27–39** the frequencies of the bands assigned as vibrational modes of the nitrate groups suggest the simultaneous presence of ionic and coordinated nitrates. The appearance of a strong and broad band at *ca* 1380 cm^{-1} ($\nu_3(E')$) confirms the presence of ionic D_{3h} nitrates.[29] The other vibrational nitrate fundamentals suggest chelating bidentate nitrato groups, as the separation of the two highest frequency bands is large (*ca* 210 cm^{-1}); [27,29] the possibility of bridging nitrato groups is ruled out, because the highest frequency nitrato mode appears below 1550 cm^{-1}.[29] The non-appearance of the $\nu_3(E')$ band in the spectra of **40–44** shows that ionic nitrates are absent. However, these spectra are very complex in the regions of the coordinated nitrate vibrations, and support a complex structure with possible bidentate chelating and bridging nitrato groups being simultaneously involved.[30]

Electronic spectra

The electronic diffuse reflectance spectra of the complexes involve mainly intraligand and *f–f* tran-

sitions. The values of the bonding parameters $\bar{\beta}$(nephelauxetic ratio), δ(Sinha's parameter) and $b^{1/2}$ (covalent factor) of the Pr^{III}, Nd^{III}, Sm^{III}, Ho^{III} and Er^{III} complexes (Tables 1–3), calculated from the solid state *f–f* spectra by standard equations,[31–33] indicate that the interaction between the trivalent lanthanides and the ligands is essentially electrostatic and that there is a very small participation of 4*f* orbitals in bonding.[31–33]

The shape and fine structure of the same *hypersensitive f–f* bands for Nd^{III}, Ho^{III} and Er^{III} have been related to coordination number.[34] For Nd^{III} four transitions are sensitive to coordination environment but one, the $^4I_{9/2} \rightarrow {}^4G_{5/2}$, $^2G_{7/2}$ at about 590 nm, is particularly so. By comparing the spectra of standard Nd^{III} compounds with those of our complexes in the region of the above-mentioned transition, it is concluded that **4** and **30** are eight-coordinated, **17** is seven-coordinated and **42** is nine-coordinated.[34,35] Analogous studies[34,36] for the Ho^{III} (in the region of the *hypersensitive* $^5I_8 \rightarrow {}^5G_6$, $^5F_1$ transition at about 450 nm) and Er^{III} (in the region of the *hypersensitive* $^4I_{15/2} \rightarrow {}^2H_{11/2}$ transition at about 530 nm) complexes demonstrate that **10** and **11** are seven-coordinated, **23** and **24** are six-coordinated, while **36** and **37** are either eight- or seven-coordinated.

The details of the observed low temperature, solid state, fluorescence spectra of the Eu^{III} complexes are given in Table 7. Of primary interest are the transition manifolds, $^5D_0$ to $^7F_0$, $^5D_0$ to $^7F_1$, and $^5D_0$ to $^7F_2$, since these transitions are normally intense and may give vital clues as to the site symmetry around the Eu^{III} ion. Band assignments and the determination of crystal field site symmetries by the examination of Eu^{III} fluorescence band splittings were made by methods described elsewhere.[37,38]

The fluorescence spectrum of **19** shows a single band at 579.5 nm, associated with the $^5D_0 \rightarrow {}^7F_0$ transition. The exhibition of this line is consistent with the following site symmetries:[39] C_n, C_s and $C_{n'v}$ ($n = 2, 3, 4, 6$; $n' = 1, 2, 3, 4, 6$). The magnetic-dipole-allowed $^5D_0 \rightarrow {}^7F_1$ transition consists of two medium components at 590.0 and 592.5 nm. Two intense lines at 612.5 and 616.0 nm and one shoulder at a lower frequency arise from the electric-dipole allowed $^5D_0 \rightarrow {}^7F_2$ transition. The absence of an inversion centre is confirmed by the larger intensities of the transitions to the $J = 2$ and $J = 4$ sublevels, with respect to the intensity of the transition to the $J = 1$ sublevel.[40] The number of transitions to the $J = 0$, 1, 2 and 4 sublevels, appearing in the emission spectrum of **19**, is exactly the same as that theoretically expected in C_{3v} symmetry, where 1, 2, 3 and 5 transitions to $J = 0$, 1, 2 and 4 respectively are allowed.[37,40] Therefore, we believe that the C_{3v}

Table 7. Solid state fluorescence spectra[a,b] (nm) of the Eu^{III} complexes of LH

Assignment	**6**	**19**	**32**	**44**

[a] Obtained at liquid nitrogen temperature by exciting with near-UV radiations.
[b] Emission originates almost totally from the $^5D_0$ excited state (bands associated with $^5D_{1,2} \rightarrow {}^7F_{o,1,2}$ transitions are very weak).
[c] Poorly resolved band.

site symmetry is the most consistent for Eu^{III} in **19**. This site symmetry, together with the physical and other spectral data obtained for this complex (see conclusions), allow us to assign a seven-coordinate structure, corresponding to a capped octahedron.[37,41]

The $^5D_0 \rightarrow {}^7F_0$ transition is allowed in **6** and appears as a medium line at 579.0 nm. The degeneracy of the $^7F_{1,2}$ sublevels is removed and three and four components of the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_2$ transitions, respectively, appear in the relative regions. This spectral pattern suggests C_{2v} site symmetry for Eu^{III} in this compound.[37,40] The $^5D_0 \rightarrow {}^7F_3$ transition appears as a weak broad band and does not show clearly its components, but the $^5D_0 \rightarrow {}^7F_4$ transition exhibits six components between 682.0 and 700.0 nm (in C_{2v} symmetry seven transitions to $J = 4$ are allowed). This site symmetry, together with the other data obtained for **6**, let us assign an eight-coordinate structure, corresponding to a bicapped trigonal prism.[37,41]

Assignment of **32** is slightly more difficult. The $^5D_0 \rightarrow {}^7F_0$ transition at 580.0 nm can be considered as symmetry-forbidden, the spectrum exhibiting a line the intensity of which is clearly less than 0.5% the most intense $^5D_0 \rightarrow {}^7F_2$ transition; this would rule out C_n, C_s and $C_{n'v}$ site symmetries.[38] There are only two well-resolved $^5D_0 \rightarrow {}^7F_1$ features in the 590 nm region with a weak diffuse feature at about 597 nm. The two $^5D_0 \rightarrow {}^7F_2$ features in the 610 nm region have an intensity region of about 2:1. This situation corresponds best to D_{2d} symmetry[38,42] and dodecahedral geometry.[41]

The last compound to be considered is **44**. This compound is weakly fluorescent at room temperature, but fluoresces strongly at 77 K. The emission spectrum of the solid complex shows a weak line at 580.5 nm associated with the $^5D_0 \rightarrow {}^7F_0$ transition. The two $^5D_0 \rightarrow {}^7F_1$ features at about 590 nm have nearly the same intensity. Two lines at 612.5 and 613.5 nm arise from the $^5D_0 \rightarrow {}^7F_2$ transition; their splitting is relatively small and indicates that these two lines originate from an E-component.[43] A strong line at 616.0 nm is also associated with this transition. The above features correspond with what would be expected from C_{4v} symmetry.[38,43] To the physical and other spectral data for **44** let us assign a nine-coordinate structure (see later); we may consider the C_{4v} site symmetry as the one most consistent with the data, corresponding to a mono-capped square antiprism.[41]

^{1}H *NMR spectra*

Table 8 gives the ^{1}H NMR chemical shifts for the free ligand and its diamagnetic La^{III} complexes in DMSO-d_6 (downfield from TMS). The study was based on comparisons with a number of related ligands and complexes,[11,14,19,44–49] on deuterium exchange and on resonance decoupling experiments.

Table 8. ^{1}H NMR (300 MHz) spectral data (δ, ppm) of LH and its diamagnetic La^{III} complexes[a] in DMSO-d_6

Assignment[b]	LH	1	14	27
—CO—NH—	10.40sb	10.44sb	10.43sb	10.37sb

[a] The spectrum of **40** could not be recorded because of its low solubility.

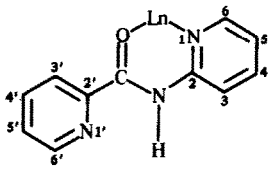
[b] Assignments for individual ring protons were assisted by resonance decoupling studies.

s = singlet; d = doublet; t = triplet; mt = multiplet; b = broad.

The variable-temperature ^{1}H NMR spectrum of LH has been interpreted[11,46–49] in terms of the structure shown in **I** with a *trans* amide group and *trans* pyridine rings. The appearance of the H_3 signal at a considerably low field has been rationalized[11] as the result of long range deshielding by the amide carbonyl group which is *cis* to, and approximately coplanar with, the 2-aminopyridine ring; in **I** the carbonyl group exerts its maximum deshielding effect. The observed conformational preference can be explained by the strong dipole–dipole interactions between the aminopyridine ring and the amide bond;[48,49] this stabilization also hinders rotation about the N_{amide}—C_{ring} bond.

In the spectra of the diamagnetic complexes **1**, **14** and **27**, the amide proton undergoes only a marginal shift to indicate the non-involvement of the amide-N atom in coordination. The signal of the 6′-pyridyl hydrogen shifts downfield compared with that of LH, suggesting that the N(1′) atom of the picolinamide unit is coordinated to La^{III}.[50] The shift observed for the 6-pyridyl hydrogen is insignificant (0.01–0.06 ppm), indicating that the N(1) atom of the aminopyridine unit remains non-coordinated in the complexes. If N(1) coordination had occurred, i.e. coordinating behaviour **II**, the H_3 signal would have shifted to a much higher field because on N(1), O_{amide} chelation LH must have changed its configuration from **I** to **II**;[49] the H_3 atom in **II** is no

longer deshielded by the carbonyl group. The δ value of H_3 is almost unchanged from that in LH, which rules out **II**.



II

From the overall study presented it is concluded that in complexes **1–39** LH behaves as a bidentate chelating N(1′), O_{amide} ligand giving monomeric complexes, while the amide oxygen and both pyridine residues are coordinated in the 1 : 1 nitrato complexes **40–44** yielding polymeric compounds. A coordination number of eight is assigned to **1–6** with the participation of three terminal isothiocyanato ligands and one water molecule in the coordination sphere of Ln^{III}; bicapped trigonal prismatic structures are proposed for these complexes taking into account that **1–5** are isostructural with the Eu^{III} compound (**6**), which has a solid state emission spectrum indicative of this geometry. Physical and spectroscopic data suggest that the complexes **7–13** consist of the coordination entity $[Ln(O_{amide})_2(N(1'))_2(N_{NCS})_3]$; our data do not permit differentiation between pentagonal bipyramidal, capped octahedral, capped trigonal prismatic or trigonal base–tetragonal base structures. Seven-coordination attained by three bidentate LH ligands and one monodentate perchlorato group is assigned to **14–20**; capped octahedral structures are proposed for these complexes bearing in mind that **14–18** and **20** are isostructural with the Eu^{III} compound **19**, which has an emission *f–f* spectrum indicative of this structure. There is little doubt that the compounds **21–26** consist of the six-coordinate $[Ln(O_{amide})_3(N(1'))_3]^{3+}$ coordination sphere and three ionic perchlorates. Physical and spectroscopic data suggest that the complexes **27–39** consist of the coordination entity $[Ln(O_{amide})_2(N(1'))_2(O_{nitrato})_4]^+$ formed by two chelating LH ligands and two bidentate chelating nitrato groups; dodecahedral geometries with a D_{2d} site symmetry for the Ln^{III} ions are assigned to these complexes taking into account that **27–31** and **33–39** are isostructural with $[Eu(LH)_2(ONO_2)_2](NO_3)$ (**32**) which has a solid state emission *f–f* spectrum characteristic of this site symmetry and geometry. Finally, a coordination number of nine and a monocapped square antiprismatic structure with a C_{4v} site symmetry for the metal ion are assigned to the complexes **40–44**, both from physical and spectroscopic data, with bidentate chelating and bridging nitrato groups being simultaneously involved.

The present work demonstrates the utility of amides as coordinating ligands for lanthanide complexes. Our systematic investigation of the Ln^{III}/LH reaction system has confirmed our belief that a variety of amide-coordinated Ln^{III} complexes are capable of existence and that this area may yet prove to be as extensive as that developed for transition metal/amide chemistry.[51] Work in progress at the time of writing is providing neutral, water-soluble, Gd^{III} complexes with chelating amidic ligands, which are currently evaluated as contrast agents for magnetic resonance imaging (MRI).[7] This work will be described in a subsequent report.

Acknowledgements—Some of the spectroscopic material of this work was obtained at the Laboratorium Anorganische Scheikunde, Rijksuniversitair Centrum Antwerpen, Belgium; we wish to thank Prof. H. O. Desseyn for this convenience. We thank Mr P. Kirkos for technical assistance.

SYNTHESIS AND STRUCTURE OF DIMETHOXYETHANE-DICHLORODIOXO-TUNGSTEN(VI)—A HIGHLY SOLUBLE DERIVATIVE OF TUNGSTEN DIOXODICHLORIDE

KLAUS DREISCH, CARLAXEL ANDERSSON* and CLAES STÅLHANDSKE

Department of Inorganic Chemistry, Chemical Center, University of Lund, P.O. Box 124, S 221 00 Lund, Sweden

(*Received* 25 *April* 1991; *accepted* 2 *July* 1991)

Abstract—$WOCl_4$ reacted with hexamethyldisiloxane at room temperature in the presence of ethyleneglycol dimethylether (dme) giving the white crystalline compound, WO_2Cl_2(dme) (80% yield) and its structure was determined by X-ray diffraction. The structure, which is isomorphous with MoO_2Cl_2(dme), is built up of discrete molecules with a distorted octahedral geometry, the tungsten atom coordinates two oxygens in *cis* positions, two dme oxygen atoms and two chlorine atoms.

High oxidation state organometallic chemistry is of great current interest.[1,2] Compounds of this family are active catalysts in the olefin metathesis reaction[3–5] and they serve as model compounds for the active catalyst in the industrially important propylene ammonoxidation reaction.[6] Typical hard donors, e.g. oxo, imido or alkoxy, which can stabilize the high oxidation state of the central atom, are recurrent auxiliary ligands in these complexes. The role of the oxo-ligand as a spectator in metathesis catalysts has been discussed.[7] By reaction with aryl or alkyl isocyanates metal-oxo complexes are conveniently converted into metal-imido complexes.[8]

A recent method to convert metal-chloro complexes to metal-oxo complexes involves the reaction with hexamethyldisiloxane as an oxygen transfer reagent.[9–11] Metal sulphido complexes have also been prepared in a similar way using hexamethyldisilthiane as the transfer reagent.[11] The preparations of different Lewis base adducts $WO_2Cl_2L_2$ have been described[12] and more recent reports include the preparation of the acetonitrile adduct[11] and the bipyridine adduct.[13] The bromo complex WO_2Br_2(bpy) has been successfully alkylated in THF suspension.[14,15] With a soluble adduct of WO_2Cl_2 at hand a more straightforward method than the existing one[16] to prepare the complex Cp*WO_2Cl (Cp* = η^5-permethyl cyclopentadienyl) can be foreseen. In the course of a program directed towards the development of new homogeneous catalysts for the metathesis of functionalized olefins we have considered tungsten–oxo complexes as suitable starting materials for further synthesis. In our search for soluble adducts, $WO_2Cl_2L_2$, compatible with alkylating agents, e.g. alkyl-tin, alkyl-lithium or Grignard reagents we have considered various ethers since ethers, especially dimethoxyethane (dme), have been used as ligands in the preparation of tungsten alkylidene complexes[5] and we present here the synthesis and the crystal structure of WO_2Cl_2(dme).

RESULTS AND DISCUSSION

Preparation of WO_2Cl_2(dme)

Hexamethyl disiloxane reacts with an equimolar amount of $WOCl_4$ suspended in CH_2Cl_2 to give a light yellow solid. The IR spectrum of this solid shows two very strong and broad absorption bands at 853 and 817 cm^{-1} indicative of bridging oxo groups. Additional absorption bands at 1250 and 1000 cm^{-1} which can be assigned[17] to siloxide groups are also present. Based on these IR observations a likely formulation of this intermediate is a highly polymeric tungsten complex, $[W(O)Cl_3(OSiMe_3)]_x$. After addition of excess dme most of the suspended solid is dissolved. The title compound is

* Author to whom correspondence should be addressed.

obtained as white needles from the filtrate by the addition of diethylether and cooling to −30°C.

The dissolution of the initially formed solid on addition of dme indicates the formation of an ether adduct, $[W(O)Cl_3(OSiMe_3)(dme)]$, as the next step in the reaction sequence. Further elimination of $ClSiMe_3$ from this intermediate to give the isolated product is probably facilitated by the presence of the second oxygen atom of the dme ligand in the coordination sphere of the tungsten atom. This method of preparation is essentially the same as that applied in the preparation of $WO_2Cl_2(bpy)$ using the chelating dme ligand instead of bipyridine,[13] with the exception that the bipyridine adduct is insoluble in the reaction mixture. In our hands the preparation of the bipyridine adduct gave the desired compound mixed with varying amounts of $WOCl_3(bpy)$ as indicated by the tungsten oxo vibration $\nu(W{=}O)$ at 972 cm^{-1} in the IR spectrum and by the green colour of the product. This problem is, however, circumvented by letting the reaction between $WOCl_4$ and hexamethyldisiloxane proceed until all the $WOCl_4$ is consumed before bipyridine is added. In the case of dme no reduction of W^{VI} is observed and the isolated product is pure $WO_2Cl_2(dme)$. Alternatively, the reversed reaction order can be used: $WOCl_4$ dissolved in dme/CH_2Cl_2 reacts within half a day with an equimolar amount of hexamethyl disiloxane to give a decolourized solution from which the product can be isolated as given above. The rate of product formation using this method greatly depends on the amount of dme added, decreasing markedly by increasing the dme/$WOCl_4$ ratio. It has been shown[18] that dme reacts with $WOCl_4$ in $CHCl_3$ solution to form an octahedrally coordinated tungsten etherate which reacts further by cleavage of a carbon–oxygen bond to form a tungsten alkoxide complex. Under the reaction conditions given in the Experimental this side reaction is, however, appreciably slower (approx. 3 days) than the chloride/oxide exchange by hexamethyl disiloxane (approx. half a day) and no product from this side reaction is observed.

The two methods presented give products which are indistinguishable by IR or analytical means. The complex prepared is very soluble in donating organic solvents, e.g. thf, dme, dmf and acetonitrile. The solubility of $WO_2Cl_2(dme)$ in CH_2Cl_2 is appreciably high (0.4 M) in contrast to the low solubility in $CHCl_3$. This high solubility is somewhat surprising since the analogous bipyridine complex is virtually insoluble in the same solvents.

$MoO_2Cl_2(dme)$ has been prepared by reaction of solid MoO_2Cl_2 with dme.[19] Attempted preparation of $WO_2Cl_2(dme)$ *via* direct reaction of dme with solid WO_2Cl_2 did not lead to any dissolution of WO_2Cl_2 although the reaction was continued for 5 weeks.

This indicates that the barrier for breaking up the polymeric network of solid WO_2Cl_2 is so high that a direct synthesis is not feasible. The presence of the dme ligand in the coordination sphere of the metal in the step forming the second metal–oxo bond is therefore probably of importance. ^1H and ^{13}C spectra of $WO_2Cl_2(dme)$ in neat thf or acetonitrile show that the dme ligand is labile. The dme ligand is completely substituted in thf while in acetonitrile both the solvated complexes exist in equilibrium, indicating a difference in complex strength for N and O donors. Contrary to the reported[20] lack of reactivity of uncomplexed WO_2Cl_2 with $^tBuNH(SiMe_3)$ we find that WO_2Cl_2(dme) reacts readily with $^tBuNH_2$ and $^tBuNH(SiMe_3)$ to hitherto not fully characterized tungsten amido/imido complexes.[21]

Attempts to exchange the dme ligand in the complex for two thf ligands give a white product with bands at 1040 and 847 cm^{-1} in its IR spectrum as expected for coordinated thf.[22] In addition the presence of a strong broad band at 725 cm^{-1} in the IR spectrum reveals bridging oxo-groups. The analytical data [Found (Calc.) W, 50.3 (51.2); Cl, 19.2 (19.7); C, 13.9 (13.4); H, 2.4 (2.1)%] for this compound are close to the formula $WO_2Cl_2(thf)$ and this formulation is also supported by the bridging oxo group as observed by IR. Whether this oxo bridged structure exists in thf solution or if it is formed as a consequence of a loss of thf during the isolation of the complex is not known. A decreased solubility in thf after the initial isolation indicates that a loss of thf with subsequent formation of oxo bridges might occur.

The structure of $WO_2Cl_2(dme)$

The $WO_2Cl_2(dme)$ molecule with atomic numbering is shown in Fig. 1 and selected bond distances

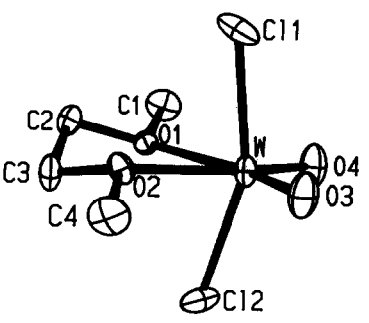

Fig. 1. A perspective view of the $WO_2Cl_2(dme)$ molecule.

Table 1. Selected bond distances (Å) and angles (°) for WCl_2O_3 (dme)

Bond distances (Å)			
W—O(3)	1.69(1)	O(1)—C(1)	1.44(1)
W—O(4)	1.69(1)	O(1)—C(2)	1.46(1)

W—O(2)	2.292(8)	O(2)—C(3)	1.44(1)
W—Cl(1)	2.344(4)	O(2)—C(4)	1.45(2)
W—Cl(2)	2.344(3)		

Bond angles (°)			
O(1)—W—O(2)	70.5(3)	W—O(1)—C(1)	120.5(7)
O(2)—W—O(3)	91.9(4)	W—O(1)—C(2)	117.2(7)
O(3)—W—O(4)	105.1(5)	O(1)—C(2)—C(3)	107.1(9)
O(4)—W—O(1)	92.5(4)	O(2)—C(3)—C(2)	107.4(10)
Cl(1)—W—Cl(2)	157.6(2)	W—O(2)—C(3)	115.2(7)
		W—O(2)—C(4)	119.6(8)

and angles are presented in Table 1. The structure is isomorphous with MoO_2Cl_2(dme).[19] The W^{VI} atom has a distorted octahedral coordination, with the two oxide ions and the two oxygen atoms of the dme ligand forming the equatorial plane and with the chlorine atoms at the apices. The four oxygen atoms are almost coplanar with the tungsten atom in the plane. The oxide ions are *cis* oriented, as also suggested from theoretical calculations,[23] with both W=O bond distances of 1.69(1) Å and an angle O=W=O of 105.1°. The W=O bond distance is close to the mean value of 1.709 Å, recently calculated from other dioxo complexes.[24] The tungsten–oxygen bond distances to the dme ligand are 2.253(7) and 2.292(8) Å, respectively, and the angle O—W—O is 70.5°.

Two chlorine atoms at 2.344(4) Å complete the octahedron around tungsten. Both chlorine atoms are bent towards the dme ligand resulting in a Cl—W—Cl angle of 157.6°. This deviation from linearity is in agreement with extended Hückel calculations[25] on the octahedrally coordinated Mo^{VI} dioxo complex, $H_4MoO_2^{2-}$.

Comparison with the closely related structure, WO_2Cl_2(bpy),[9] shows significantly longer W=O bonds in the bpy derivate (1.745(3), 1.792(2) Å). The bond distance W—Cl and the bond angle Cl—W—Cl are, however, similar in the two compounds.

EXPERIMENTAL

All manipulations were carried out on a vacuum line using standard Schlenk techniques under an atmosphere of dry nitrogen.

$WOCl_4$ was prepared by the method of Gibson,[9] CH_2Cl_2, $O(C_2H_5)_2$ (Merck), $O(SiMe_3)_2$ and ethyleneglycol dimethylether (dme) (Jansen) were distilled and dried using activated molecular sieves (4 Å) before use.

Tungsten analysis was done gravimetrically as WO_3, chloride analysis was done argentometrically according to Mohr's method. Analysis for C, H were done by Ilse Beetz, Mikroanalytishes Laboratorium, Kronach, Germany.

IR spectra (Nujol mulls between CsI plates) were recorded using a Nicolet 20SXC spectrometer. ^1H, ^{13}C NMR spectra in $CDCl_3/CH_2Cl_2$ solution were recorded using a Varian XL 300 spectrometer.

X-ray crystallography

A crystal of the title compound was enclosed in a Lindemann capillary to prevent it from air and moisture. The space group, $P2_1/n$, was uniquely determined from systematic absences. Unit cell parameters were derived from least-squares fit of angular settings of 50 reflexions ($18° < 2\theta < 30°$). The data were corrected for a linear decrease of 17% during the data collection and for Lorentz, polarization and absorption effects, the latter by an empirical method.[26] Some crystal data are collected in Table 2.

The structure was solved by direct methods (MULTAN80), which gave the positions of the tungsten atom and the two chlorine atoms. The remaining non-hydrogen atoms were located from subsequent difference Fourier synthesis. In the final least-squares refinement all non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms of the methylene groups were

Synthesis of WO_2Cl_2(dme)

Method 1. To a suspension of freshly sublimed $WOCl_4$ (6.43 g, 18.8 mmol) in 100 cm^3 CH_2Cl_2 is added $(Me_3Si)_2O$ (3.20 g, 19.8 mmol). The orange crystals are slowly consumed to give a yellow solution. After approximately 1.5 h stirring a light yellow solid precipitates. Ethylene glycol dimethylether (dme) (2.54 g, 28.2 mmol) is added and the reaction mixture is stirred overnight and filtered (G4-frit) to remove the brownish residue which has formed. The clear filtrate is then concentrated at room temperature on the vacuum-line. When pure white crystals begin to precipitate diethylether (100 cm^3) is added. After cooling overnight at −30°C the white crystals formed are collected on a filter, washed once with 20 cm^3 of diethylether and dried *in vacuo*. Yield: 6.11 g, 86%.

Method 2. To a suspension of freshly sublimed $WOCl_4$ (14.24 g, 41.7 mmol) in 170 cm^3 CH_2Cl_2 is added dme (4.88 g, 54.2 mmol). After 5 min stirring $WOCl_4$ is completely dissolved. To the orange solution is added $(Me_3Si)_2O$ (7.10 g, 43.8 mmol) and the reaction mixture is vigorously stirred about 6 h at room temperature. The reaction is completed when the solution is decolourized having only a faint yellowish tint. The clear solution is concentrated on the vacuum-line until white crystals begin to precipitate, 150 cm^3 diethylether is added and the reaction mixture is kept at −30°C for one day. After filtering, the white crystals are washed with diethylether (3×20 cm^3) and dried *in vacuo*. Yield: 12.22 g, 77.8%.

IR data (Nujol, CsI; cm^{-1}): 1279w, 1245w, 1193w, 1155vw, 1108vw, 1078s, 1018vs,br, 976s, 933vs, 862s, 821m, 415w, 402sh, 376vw, 349m, 339m,br, 272w, 257m.

NMR data (300 MHz, 1 : 4 mixture of *d*-chloroform and methylenchloride, 298 K): ^{1}H: 4.09 (s, O-CH_3) and 4.04 (s, CH_2-O), ^{13}C-{^{1}H}: 71.70 (CH_2-O) and 65.45 (O-CH_3). Elemental analysis for $C_4H_{10}Cl_2O_4W$: Found (Required): C, 12.0 (12.7); H, 2.6 (2.7); Cl, 18.9 (18.8); W, 48.7 (48.8)%.

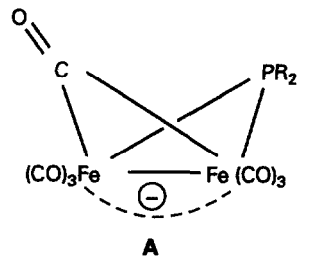
(*Received* 23 *April* 1991; *accepted* 2 *July* 1991)

Abstract—Treatment of $[Ni(CO)_{4-n}(R_2PCl)_n]$ ($n = 1, 2$; R = Bu^t, Cy, Ph) with $Na_2[Fe_2(CO)_8]$ gave, depending on n and R, either the doubly phosphido-bridged complexes $[Fe_2(CO)_6(\mu\text{-PR}_2)_2]$ or the anions $[Fe_2(\mu\text{-CO})(CO)_6(\mu\text{-PR}_2)]^-$. These anions can also be obtained by the reaction of $[Fe(CO)_4(PR_2)]^-$ with either $[Fe_2(CO)_9]$ or $[Fe(CO)_5]$ via the intermediate $[Fe_2(CO)_8(\mu\text{-PR}_2)]^-$. The electronic structure of the anions $[Fe_2(\mu\text{-CO})(CO)_6(\mu\text{-PR}_2)]^-$ has been studied by an EHT calculation which supports their ambident oxygen- or metal-nucleophilicity. The metal-centred nucleophilic reactions of the anion $[Fe_2(\mu\text{-CO})(CO)_6(\mu\text{-PBu}^t_2)]^-$ with H^+ and $[M(PPh_3)]^+$, (M = Cu, Ag, Au), respectively, are described. The new complexes have been characterized by various spectroscopic methods and the structure of $[Fe_2\{\mu\text{-Ag}(PPh_3)\}(\mu\text{-CO})(CO)_6(\mu\text{-PBu}^t_2)]$ has been established by X-ray analysis.

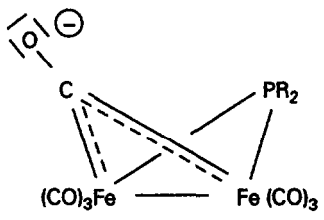
Phosphido-bridged di-iron anions of type $[Fe_2(\mu\text{-CO})(CO)_6(\mu\text{-PR}_2)]^-$ first reported by Osterloh[1] in 1982 (R = Ph), obviously offer a wealth of reactivity. Baker *et al.*[2–4] have recently reported oxidation with $[Fecp_2][BF_4]$ to give a new family of 33e dinuclear radicals $[Fe_2(CO)_7(\mu\text{-PR}_2)]$, which has been extensively investigated by electron spin resonance and molecular orbital studies, ligand substitution reactions as well as structural and electrochemical studies. The same authors described

* Author to whom correspondence should be addressed.

substitution reactions which lead by opening the iron–iron bond to disubstituted di-iron complexes $NEt_4[Fe_2(CO)_6L_2(\mu\text{-}PPh_2)]$ ($L = PPh_3$, PMe_3, $P(OMe)_3$). Photolysis of these complexes results in ligand loss and formation of the substituted anionic complexes $NEt_4[Fe_2(\mu\text{-}CO)(CO)_5L(\mu\text{-}PPh_2)]$ and $NEt_4[Fe_2(\mu\text{-}CO)(CO)_4L_2(\mu\text{-}PPh_2)]$, respectively. We expect these anions to have ambident nucleophilic reactivity as described in structures A and B.



A



B

Osterloh[1] found that the oxygen-based nucleophilic reaction with $[R_3O][BF_4]$ afforded alkoxymethylidine complexes $[Fe_2(CO)_6(\mu\text{-}COR)(\mu\text{-}PPh_2)]$ which isomerized on heating into the acyl complexes $[Fe_2(CO)_6(\mu\text{-}\eta^2\text{-}COR)(\mu\text{-}PPh_2)]$.

In this paper we show that the reaction of chlorophosphane-substituted nickel carbonyl complexes with the di-iron octacarbonyl dianion does not give heteronuclear iron–nickel complexes but gives either $[Fe_2(CO)_6(\mu\text{-}PR_2)_2]$ or $Na[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PR_2)]$. A new synthesis of the di-iron anions $[Fe_2(CO)_7(\mu\text{-}PR_2)]^-$ is presented. The metal-based nucleophilic reactions of the anionic complex $Na[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PBu^t_2)]$ with the electrophilic agents H^+ and $[M(PPh_3)]^+$ (M = Cu, Ag, Au) to yield the hydride complex and the triangular Fe_2M clusters of the coinage metals, respectively, are described. The structure of the Fe_2Ag cluster has been determined by X-ray crystal analysis. In order to come to a better understanding of the bonding properties of the di-iron anions an EHMO calculation on the model anion $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PH_2)]^-$ has been performed.

EXPERIMENTAL

All reactions were performed under oxygen-free argon using conventional Schlenk techniques. Solvents were dried over molecular sieves or over sodium/benzophenone ketyl and distilled under argon prior to use. Melting points were recorded in sealed capillaries under argon and are uncorrected. Starting materials were either commercially available or were prepared according to literature procedures: Bu^t_2PCl,[5] Cy_2PCl,[6] Ph_2PCl,[7] Me_2PCl,[8] $Na_2[Fe_2(CO)_8]$,[9] $Na_2[Fe(CO)_4]\cdot 1.5C_4H_8O_2$,[10] [PPN]Cl,[11] $[\{CuCl(PPh_3)\}_4]$,[12] $[\{AgCl(PPh_3)\}_4]$,[13] $[AuCl(PPh_3)]$.[14]

IR spectra were obtained using an IR 71 of VEB Carl Zeiss Jena. ^1H and ^{31}P NMR spectra were recorded on the Bruker spectrometers WP 200 (^1H at 200.1 MHz, ^{31}P at 81.0 MHz) and AC 80 (^1H at 80.1 MHz, ^{31}P at 32.4 MHz). Chemical shift references are the absolute frequencies of Me_4Si (^1H) and external 85% H_3PO_4(aq)(^{31}P), respectively. Positive shifts are to lower field. The EI mass spectra were obtained with a Hewlett Packard spectrometer 5995 A. FAB MS were obtained with a Finnigan MAT 8430 instrument (Bremen, Germany). Xenon was used for neutral beam production with a beam energy of 8 kV. 3-Nitrobenzylalkohol (NBA) and 2-nitro-*n*-octylether (NOE), respectively, were used as liquid matrix. Mössbauer spectra were recorded at room temperature using a constant acceleration spectrometer with a source of ^{57}Co in rhodium. All isomer shifts are quoted relative to natural iron at room temperature. Absorbers containing less than 10 mg cm^{-2} of natural iron were used for all spectra. The spectra have been fitted to Lorentzian line shapes using an iterative least-squares program. The intensity of the quadrupole doublets were constrained to be equal which is a good assumption for a powdered random sample. The relative proportions of the different components were calculated from peak areas, assuming that all iron species have similar Lamb–Mössbauer factors, which could give rise to an inaccuracy of $\pm 5\%$.

$[Ni(CO)_{4-n}(R_2PCl)_n]$ (**1a–c**, **2a,b**)

These complexes were synthesized according to the procedure used by Ehrl and Vahrencamp[15] for the synthesis of $[Ni(CO)_3(Me_2PCl)]$ by stirring *ca* 10 mmol $[Ni(CO)_4]$ with R_2PCl in the appropriate molar ratio (**1** : 1 : 2 ; **2** : 1 : 1) in diethylether, usually at room temperature in the dark for 1 h (**2**) and 3 h (**1**), respectively. Only the synthesis of **1a** requires refluxing for an additional 4 h after having stirred the mixture for 1 h at room temperature. The CO evolution was monitored by gas volumetric measurements. Subsequently, all volatile materials were removed *in vacuo*, and the residue was dissolved in a minimum quantity of pentane (*ca* 5–10

cm^3). The cold solvent was decanted off, and the white crystals were dried *in vacuo*, keeping them cold and in the dark. The yield is about 80%. Complexes **1** and **2** proved to be fairly unstable both thermally and photolytically and have to be stored below 0°C. $[Ni(CO)_3(Ph_2PCl)]$ appeared too unstable for separation. The analytical and physical data are summarized in Table 1.

Reaction of $[Ni(CO)_2(Bu^t_2PCl)_2]$ (**1a**) *with* $Na_2[Fe_2(CO)_8]$

Complex **1a** (0.48 g, 1 mmol) was added to a suspension of $Na_2[Fe_2(CO)_2]$ (0.38 g, 1 mmol) in 20 cm^3 THF and stirred in the dark at room temperature for 5 h. The deep red–brown mixture was filtered and the solvent was removed *in vacuo*. The sticky residue became microcrystalline by stirring in pentane. After repeated extractions with small amounts of pentane until the solvent remained colourless, the crystals were collected by filtration and dried *in vacuo*. Yield 0.48 g Na[**3a**] (~ 100%). Characterization s. below. The other reactions, summarized in eq. (1), were carried out similarly.

Preparation of Na(K,PPN)[**3a–d**]

(A) An equimolar amount of R_2PCl (0.36 g Bu^t_2PCl, 0.46 g Cy_2PCl, 0.43 g Ph_2PCl, 0.19 g Me_2PCl) was added dropwise to a suspension of 0.69 g (2 mmol) $Na_2[Fe(CO)_4]\cdot 1.5$ dioxane in 30 cm^3 THF, and the mixture was stirred for 2 h. The bright yellow solution changed colour to red–brown after the addition of $[Fe(CO)_5]$ (0.27 cm^3, 2 mmol) or $[Fe_2(CO)_9]$ (0.72 g, 2 mmol), respectively. On stirring for 24 h, the solution was irradiated (Hg lamp) for 5 h. During this time the colour turned deep brown. The reaction mixture was subsequently evaporated to dryness under reduced pressure and the residue suspended in 20 cm^3 pentane, filtered and then washed with an additional 20 cm^3 pentane. After drying *in vacuo* the microcrystalline pyrophoric solids Na(K)[**3a–d**] (yield nearly 100%) were used directly for further reactions, or were dissolved in 10 cm^3 degassed methanol, filtered and the filtrate treated with 1.15 g (2.1 mmol) [PPN]Cl. The resulting crystals of PPN[**3a–d**] were collected by filtration, washed with methanol and dried *in vacuo*.

(B) A solution of 0.72 g (2 mmol) $[Fe_2(CO)_9]$ and an equimolar amount of R_2PH (0.37 g Bu^t_2PH, 0.37 g Ph_2PH) in 30 cm^3 THF were stirred at room temperature for 2 h. The solvent and the $[Fe(CO)_5]$ formed during reaction were removed *in vacuo*, and the residue was redissolved in 30 cm^3 THF. This solution was treated with an excess of KH (*ca* 0.1 g) for 2 h, giving a deep red solution of K[$Fe(CO)_4(PR_2)$] which was filtered and handled after addition of 0.72 g (2 mmol) $[Fe_2(CO)_9]$ as described above. The yields were similar to method A. Complexes Na(K)[**3a–d**] were highly air sensitive in both solid state and solution whereas PPN[**3a–d**] are stable as solids but moderately air sensitive in solution.

Table 1. Analytical and physical data of $[Ni(CO)_{4-n}(R_2PCl)_n]$ (n = 2, **1a–c**; n = 1, **2a,b**)

[a] Calculated figures in parentheses.

These complexes are well soluble in THF and CH_2Cl_2 but not in diethylether and hexane. Analytical and physical data of PPN[**3a–d**] are given in Table 2.

$[Fe_2(CO)_7(H)(\mu\text{-}PBu^t_2)]$ (**4a**)

A solution of $Na[Fe_2(CO)_7(\mu\text{-}PBu^t_2)]$ (**3a**) (0.48 g, 1 mmol) and CH_3COOH (0.12 g, 2 mmol) in *ca* 20 cm^3 THF was rigorously stirred for 30 min. Subsequently, the solvent was removed *in vacuo*, and the residue was three times extracted with 10 cm^3 pentane. The combined extracts were filtered and evaporated *in vacuo* until 5 cm^3 remained. Deep red crystals of **4a** were obtained at −78°C. Further details are given in Table 2.

$[Fe_2(CO)_7(H)(\mu\text{-}PPh_2)]$ (**4c**)

The solution of NEt_4[**3c**] (0.62 g, 1 mmol) and CF_3COOH (0.23 g, 2 mmol) in 30 cm^3 THF was stirred for 3 h. The solvent was removed *in vacuo* and the residue was extracted three times with 10 cm^3 pentane. Evaporation of the filtered pentane extracts gave a deep red oily material (m.p. < −40°C) which was characterized by spectroscopic means.

Air-oxidation of complex **4c**

Dried air was bubbled through a THF solution of **4c** for 1 h. The solution was filtered, and the solvent was removed *in vacuo*. The residue was three times extracted with pentane, and the combined extracts were reduced *in vacuo* to 5 cm^3. $[Fe_2(CO)_6(\mu\text{-}OH)(\mu\text{-}PPh_2)]$ crystallized at −78°C. M.p. 123°C (dec.). IR (hexane, cm^{-1}): 2073 (vs), 2070 (m, sh), 2033 (vs), 2000 (s), 1994 (s), 1984 (s, sh), 1977 (vs). ^1H NMR (CD_2Cl_2): δ −2.16 (d, ^3J(PH) 11.8 Hz, FeH), 7.5 (m, Ph). ^{31}P NMR ($CHCl_3$): δ 121.8 s.

$[Fe_2\{\mu\text{-}M(PPh_3)\}(\mu\text{-}CO)(CO)_6(\mu\text{-}PBu^t_2)]$ (M = Cu, **5**; Ag, **6**; Au, **7**)

The suspension of Na[**3a**] (0.72 g, 1.5 mmol) and $[MCl(PPh_3)]$ (0.36 g (Cu), 0.41 g (Ag), 0.5 g (Au), 1 mmol) in 30 cm^3 THF was stirred at room temperature in the dark for 5 (Cu), 4 (Ag), and 3 (Au) h, respectively. After filtration, the solution was evaporated to dryness, the residue washed with pentane, and repeatedly extracted with small amounts of diethylether until the ether remains nearly colourless. Complexes **5–7** crystallize from these solutions at −30°C. **5** and **6** require purification by repeated recrystallization from pentane/diethylether mixture. For further details and analytical data see Table 2.

X-ray analysis of **6**

Crystal data. $C_{33}H_{33}AgFe_2O_7P_2$, F.W. = 823.1, triclinic, space group $P\bar{1}$, a = 12.714(2), b = 14.667(2), c = 10.121(2) Å, α = 96.79(1), β =

113.14(1), γ = 88.68(1)°, V = 1722.6(4) Å^3, Z = 2, D_{calc} = 1.59 g cm^{-3}, $F(000)$ = 832, λ(Mo-K_α) = 0.71069 Å, μ(Mo-K_α) = 15.2 cm^{-1}.

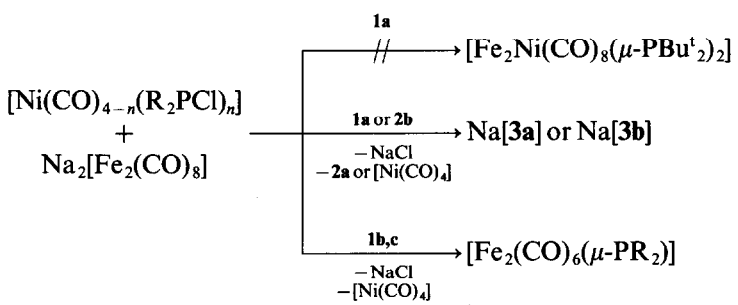
Measurements. A red cubic crystal with approximate dimensions 0.15 × 0.15 × 0.15 mm was mounted in a glass capillary. All measurements were done on a Rigaku AFC6R diffractometer with graphite monochromated Mo-K_α radiation at 296 K. Cell constants and orientation matrix were obtained from a least-squares treatment of the setting angles for 25 reflections in the range 37.8 < 2θ < 43.2°. Intensity data were measured using the ω–2θ scan technique up to 50° in 2θ. A total of 6334 reflections delivered a set of 6036 unique intensity data (R_{int} = 0.039), 4026 of them were considered observed ($I \geq 3.00\sigma(I)$). Lorentz and polarization corrections were applied during the process of data reduction.

Solution and refinement of the structure. The structure was solved by direct methods[16,17] and refined by full-matrix least-squares techniques with anisotropic displacement parameters for the non-H atoms. The displacement parameters of the H-atoms all found in a difference map were refined isotropically. For the refinement 9.17 reflections/parameter were available. The applied weighting scheme was based on counting statistics and included a factor to downweight the intense reflections. The final R was 0.048 (R_w = 0.056). A final difference map had maximum peak heights of 1.11 and −1.31 e Å^{-3}, respectively. The maximum shift/error ratio in the last 1.s. cycle was 0.01. Scattering factors including corrections for anomalous dispersion effects were taken from ref. 18. All calculations were performed using the TEXSAN[19] crystallographic software package of Molecular Structure Corporation. Tables of atomic coordinates and displacement parameters, lists of observed and calculated structure factors as well as a complete list of bond lengths and angles have been deposited with the editor, atomic coordinates also with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis

In an attempt to prepare the electron precise heteronuclear cluster $[Fe_2Ni(CO)_8(\mu\text{-}PBu^t_2)_2]$ by "bridge-assisted" synthesis from $[Ni(CO)_2(Bu^t_2PCl)_2]$ (**1a**) and $Na_2[Fe_2(CO)_8]$ in tetrahydrofurane we unexpectedly obtained the di-iron anion $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PBu^t_2)]^-$ (**3a**) as the sodium salt Na[**3a**]. This result prompted further investigation of the reaction of $[Ni(CO)_{4-n}(R_2PCl)_n]$ (n = 2, **1**; n = 1, **2**) with $Na_2[Fe_2(CO)_8]$. Thus, complexes **1b,c** gave under analogous conditions the well-known neutral bis(phosphido)-bridged di-iron complexes $[Fe_2(CO)_6(\mu\text{-}PR_2)_2]$. On the other hand, treatment of the monosubstituted nickel carbonyl complexes **2** with $Na_2[Fe_2(CO)_8]$ showed no reaction with **2a** and the formation of Na[**3b**] from **2b**, respectively. The reactions discussed are summarized in eq. (1).



(1)

R	Bu^t	Cy	Ph	Me
	a	b	c	d

(throughout this work)

These reactions show (i) distinct differences in the reactivity of $[Ni(CO)_{4-n}(R_2PCl)_n]$ with $Na_2[Fe_2(CO)_8]$ depending on n and R and (ii) that they neither provide heteronuclear FeNi complexes nor a general procedure for the phosphido-bridged di-iron anions **3**.

The mechanism of these reactions remains unknown. However, in summary, one or two ligand exchange steps of R_2PCl for CO occur to give $[Ni(CO)_{5-n}(R_2PCl)_{n-1}]$ and Na[**3**] or $[Fe_2(CO)_6(\mu\text{-}PR_2)_2]$. The latter two products are formed by conversion of R_2PCl into the R_2P^- ligand through

NaCl elimination. The $[Ni(CO)_{5-n}(R_2PCl)_{n-1}]$ by-products were either detected *in situ* by ^{31}P NMR ($n = 2$) or by IR spectroscopy ($n = 1$) as constituents of the volatile material obtained by evacuation of the reaction mixture. $NEt_4[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PPh_2)]$, obviously an anionic complex of type **3**, had already been synthesized by Osterloh[1] in 1982 by treatment of $(NEt_4)_2[Fe_2(CO)_8]$ with Ph_2PCl via $NEt_4[Fe_2(CO)_8(\mu\text{-}PPh_2)]$ as an isolable intermediate. This procedure has later been used by Baker *et al.*[3] for the *in situ* preparation of the di-iron anions **3** with R = Et, Ph, Cy, Bu^t. To our knowledge, the preparation and characterization of these anionic di-iron complexes have not yet been published. This, together with the poor yields of anions **3** [isolated as bis(triphenylphosphane)immonium (PPN^+) salts] we obtained by reacting R_2PCl with $Na_2[Fe_2(CO)_8]$ (PPN[**3a**] 45%, PPN[**3b**] zero %, PPN[**3c**] 10%), lead us to suggest a synthetic method on the basis of the anion $[Fe(CO)_4(PR_2)]^-$ as outlined in eq. (2).

$$\begin{array}{l} Na_2[Fe(CO)_4] + R_2PCl \xrightarrow[-NaCl]{} \\ [Fe(CO)_4(R_2PH)] + KH \xrightarrow[-H_2]{} \end{array} \xrightarrow{THF,\ r.t.,\ 2h} [Fe(CO)_4(PR_2)]^- \qquad (2)$$

$$[Fe(CO)_4(PR_2)]^- \xrightarrow{24\,h;\ +[Fe_2(CO)_9]\ -[Fe(CO)_5],\ \text{or}\ +[Fe(CO)_5],} [Fe_2(CO)_8(\mu\text{-}PR_2)]^- \xrightarrow[-CO]{hv,\ 5h} Na(K)[\mathbf{3a\text{–}d}] \xrightarrow[-Na(K)Cl]{PPNCl} PPN[\mathbf{3a\text{–}d}]$$

The protonation reaction of anionic binuclear complexes and clusters has been frequently employed to produce neutral hydride complexes. Accordingly, complex Na[**3a**] reacts at room temperature in THF with acetic acid to afford crystalline $[Fe_2(\mu\text{-}CO)(CO)_6(H)(\mu\text{-}PBu^t_2)]$ (**4a**) in good yield.

Although the spectroscopic data of complex **4a** (see below) do not allow a decision concerning the coordination mode of the hydride ligand (terminal or bridging) the observed high-field shift for this ligand in the ^1H NMR spectrum gives evidence for a direct iron–hydrogen bond. This result is of interest in the light of the reports on related complexes in the literature. In 1972 Treichel *et al.*[20] reported the synthesis of complexes $[Fe_2(CO)_6(\mu\text{-}H)(\mu\text{-}PR_2)]$ (R = Me, Et, Ph) and one year later found by X-ray analysis of the complex $[Fe_2(CO)_6(\mu\text{-}OH)\{\mu\text{-}P(p\text{-}C_6H_4Me)_2\}]$ that these compounds actually bear a bridging hydroxy ligand.[21] The origin of the oxygen atom remained unknown. Osterloh[1] described, that the reaction of NEt_4[**3c**] with $HBF_4 \cdot OEt_2$ in THF gave the same complex $[Fe_2(CO)_6(\mu\text{-}OH)(\mu\text{-}PPh_2)]$ as reported,[20,21] and noted that the mechanism by which this complex is formed is not known.

These results stimulated further investigation of these complexes. Contrary to the μ-PBu^t_2-bridged anion **3a** the μ-PPh_2-bridged complexes $Na(NEt_4)$ [**3c**] do not react with acetic acid but react readily with CF_3COOH to result under anaerobic conditions a deep red oily material. All attempts to crystallize this compound have failed until now. On the basis of the spectroscopic data, this complex is assigned an analogous constitution $[Fe_2(\mu\text{-}CO)(CO)_6(H)(\mu\text{-}PPh_2)]$ (**4c**) to that of the hydride complex **4a**.

Evidence that the above-mentioned μ-OH bridged complexes were formed by air-oxidation of the hydride complexes in the course of their preparation[1,20] comes from the systematic oxidation of the hydride **4c**. Bubbling dry air through a THF solution of this hydride for 1 h gave orange–red $[Fe_2(CO)_6(\mu\text{-}OH)(\mu\text{-}PPh_2)]$ which was identified by identical IR, ^1H and ^{31}P NMR data with those previously reported.[1,20]

Treatment of the THF solution of Na[**3a**] with the electrophilic complexes $[\{MCl(PPh_3)\}_n]$ (M = Cu, Ag, $n = 4$; M = Au, $n = 1$) yielded the triangular 46e clusters $[Fe_2\{\mu\text{-}M(PPh_3)\}(\mu\text{-}CO)(CO)_6(\mu\text{-}PBu^t_2)]$ (M = Cu, **5**; Ag, **6**; Au, **7**) as deep red–violet crystals. Similar coinage metal clusters have very recently been reported by another group.[22]

Spectroscopy

The new complexes were characterized by elemental analysis (see Experimental) as well as by IR, ^1H, $^{31}P\{^1H\}$ NMR (Table 3), and mass spec-

troscopy. The structure of $[Fe_2\{\mu\text{-}Ag(PPh_3)\}(\mu\text{-}CO)(CO)_6(\mu\text{-}PBu^t_2)]$ (**6**) was determined by X-ray structure determination.

The FAB mass spectra of the anionic complexes PPN[**3a–d**] show in the spectra of the positive ions the $(PPN)^+$ with high abundance (100%). The spectra are nearly matrix-free and display only a few fragments of low abundance (< 10%). In the negative ion mode the characteristic feature of FAB–MS is obtained, i.e. superposition of matrix and sample spectra. The signals of the anions **3a–d** were recorded with a relative abundance in the range of 20–60%. Successive loss of up to three carbonyl ligands is the only degradation process that can be observed. In all cases, for this fragmentation the same course of intensity is displayed, the $(3\text{-}CO)^-$ ion being the most abundant peak. In order to produce this ion it is likely that the bridging carbonyl ligand is being lost to generate a fragment having a formal iron–iron double bond. Ions of the type $(M+3)^-$ and $(M+PPN)^+$, respectively, could not be detected.

Among the ν(CO) bands of complexes PPN [**3a–c**] that near 1720 cm^{-1} indicates a μ-CO ligand. Similar anions with other bridging ligands have been reported recently, and all of them show a band in the $\nu(\mu\text{-CO})$ region.[23] The ^{31}P NMR spectra reveal two signals; one at δ 21.0 for the PPN cations, and the other one at low field indicative of phosphido groups bridging a metal–metal bond.[24–26]

The EI mass spectrum of the hydride complex **4a** shows the molecular peak at $m/z = 454$ followed by a sequence of seven peaks arising from the successive loss of all carbonyl ligands. The remaining fragment ion $HFe_2(PBu^t_2)^+$ ($m/z = 258$) appears with relatively high intensity (8.65%), and fragments further by either loss of Bu^t ($m/z = 57$, base peak) or isobutene $C_4H_8^+$ ($m/z = 56 \triangleq Fe^+$) to leave the fragment ions $HFe_2(PBu^t)^+$ ($m/z = 201$) and $H_2Fe_2(PBu^t)^+$ ($m/z = 202$), respectively. The ^{31}P NMR spectrum displays a singlet at low field again indicating that the phosphido ligand bridges the iron–iron bond. The ^1H NMR spectrum consists of two doublets, one for the protons of the μ-PBu^t_2 ligand and the other one at high field for the hydride ligand. The similarity of the structures of **4a** and **4c** is particularly supported by the signals of the hydride ligands at δ *ca* −10 ppm in the ^1H NMR spectra. For the complex $[Fe_2(CO)_6(\mu\text{-}OH)(\mu\text{-}PPh_2)_2]$ proton signals at δ −2.40 ppm (J(PH) 11.5 Hz)[1] and −2.58 ppm (J(PH) 11.0 Hz),[20] respectively, had been assigned to the μ-OH ligand.

The position of the hydride ligand in complexes **4a,c** could not be elucidated with certainty. Therefore it seemed meaningful to investigate the related coinage metal complexes due to the observation that in almost all clusters where structural comparisons are available the $Au(PPh_3)$ unit occupies a similar position to that of the isolobal hydrido ligand in the related hydrido compound.[27]

The coinage metal clusters **5–7** exhibit a similar band pattern in the ν(CO) region of the IR spectra as do both the starting di-iron anion **3a** and the hydride complex **4a**. Thus five bands appear for terminal CO groups and one for a bridging CO ligand. Due to the positive $M(PPh_3)$ moiety, these bands are shifted to higher wave numbers by about 30 cm^{-1} compared with those of the anionic complex PPN[**3a**]. This could be interpreted in terms of a decrease in the electron density on the iron atoms.

The $^{31}P\{^1H\}$ NMR spectra are as expected, showing one μ-PBu^t_2 environment at low field and one PPh_3 environment. The phosphorus resonance of the PPh_3 ligand coordinated to the M atom appears as a doublet ^3J(PP) for complex **7**, and is split into two double doublets for complex **6** due to both the coupling with ^{109}Ag and ^{107}Ag as well as the ^3J(PP) coupling; for complex **5** this resonance is broad because of the quadrupole moment of the copper nucleus.[28] Accordingly, the signal of the μ-PBu^t_2 ligand appears as a doublet for complexes **5** and **7** ^3J(PP); for complex **6** this resonance appears as a pseudo-triplet due to the superposition of the two double doublets expected from the couplings ^3J(PP) and ^2J(AgP).

The molecular ion of the Fe_2Cu cluster **5** can only be observed in the FAB spectrum of the positive ions. The spectrum is dominated by the matrix and the radical cation $(M)^{+\bullet}$. **5** is detected with less than 5% at m/z 788. Compared with the spectra of complexes **3a–d**, the course of fragmentation is somewhat different. In this case the $(M\text{-}CO)^{+\bullet}$ and the $(M\text{-}3CO)^{+\bullet}$ ions are of very low intensity whereas $(M\text{-}4CO)^{+\bullet}$ provide the base peak in the upper range of the spectrum.

The ^{57}Fe Mössbauer data of compounds PPN[**3a**] and **5–7** are collected in Table 4. The spectra consist of one quadrupole-split doublet corresponding to two equal iron sites which is fully consistent with the crystal structure of the Fe_2Ag cluster **6**. PPN[**3a**] may be thought of as derived from $[Fe_2(CO)_9]$ by replacing two bridging carbonyls by one bridging $Bu^t_2P^-$ ligand. The quadrupole splitting of the anionic complex PPN[**3a**] is roughly three times that observed for $[Fe_2(CO)_9]$ (0.42)[29] but still of the magnitude for a compound with a distorted octahedral environment.[30] A more appropriate description of the coordination sphere around the iron atoms is, ignoring the metal–metal bond, the distorted square pyramid as shown by the X-

ray crystal structure analysis of $NEt_4[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PPh_2)]$.[1] The lower isomeric shift of the anion compared with $[Fe_2(CO)_9]$ (0.16)[29] reflects a higher s-electron density on the iron atoms. This is most likely to be caused by an increased s-electron density through phosphorus-to-iron σ-donation although a decrease in the shielding of the s-electrons by decreasing the $3d$ electron density through increased π-back donations should also be taken into account. On going from the anionic complex PPN[**3a**] to the coinage metal complexes **5–7** an increase of the isomeric shift is observed. This reflects a decrease in the s-electron density which is qualitatively in accord with the 3c–2e bond description of the $Fe_2(\mu\text{-}Ag)$ core as discussed below.

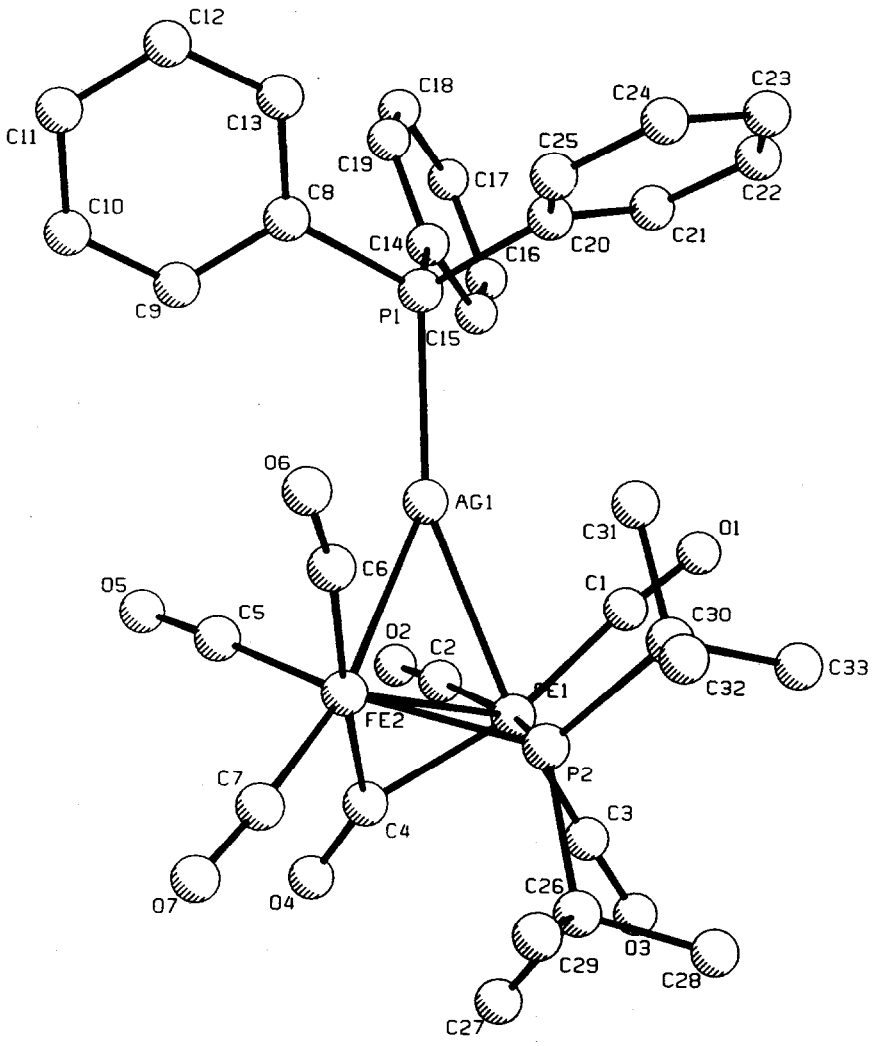

Fig. 1. Molecular structure of **6**.

The structure of $[Fe_2\{\mu\text{-}Ag(PPh_3)\}(\mu\text{-}CO)(CO)_6(\mu\text{-}PBu^t_2)]$ **(6)**

Figure 1 shows the molecular structure of **6** with the atomic numbering scheme. Selected bond lengths and angles are given in Table 5.

The core of the molecule consists of a trinuclear cluster built up of two iron atoms and a silver atom which are positioned at the corners of an almost equilateral triangle. The Fe—Fe bond is double-bridged by both a di-tert.-butylphosphido ligand and a carbonyl group. Besides, the Ag atom is coordinated by a triphenylphosphane ligand and to each iron atom three terminal CO groups are attached. Apart from the organic substituents at the P atoms, the molecule has, in rather good approximation, C_s symmetry with a mirror plane containing atoms Ag, C(4), O(4), P(1) and P(2).

The structure of **6** strongly resembles that of the cation in $[Fe_2(\mu\text{-}Ag)(CO)_6\{\mu\text{-}CHC(NHCH_3)(C_6H_5)\}\mu\text{-}PPh_2)]ClO_4 \cdot C_6H_6 \cdot C_6H_5CH_3$[31] with the only relevant difference that the iron atoms are bridged by a carbonyl group instead of a μ-η^1-alkylidene ligand. Bond lengths in the Fe_2Ag triangles (Ag—Fe(1) = 2.685(1), Ag—Fe(2) = 2.703(1), Fe(1)—Fe(2) = 2.682(1) Å for the cation,[31] for **6** cf. Table 5) are substantially the same and differ by less than 0.03 Å. The Fe—P(2) distances within the phosphido bridge of **6** are about 0.05 Å longer compared with those of the cation and accordingly the Fe(1)—P(2)—Fe(2) angle is more acute by 2.6°. The Ag—P bond length in **6** (2.404(2) Å) is in the range normally observed in silver phosphane complexes (e.g. 2.414(4) Å in $[cp(CO)_2Mo\{\mu\text{-}Ag(PPh_3)\}(\mu\text{-}PPh_2)Mn(CO)_4]$[32]).

The three planes defined by the two iron atoms and one of the corresponding atoms bridging them make the following angles: Fe(1), Fe(2), Ag/Fe(1), Fe(2), P(2) 110.8°, Fe(1), Fe(2), Ag/Fe(1), Fe(2), C(4) 134.5°, Fe(1), Fe(2), Ag/Fe(1), Fe(2), C(4) 114.7°. Surprisingly, the interplanar angle between the planes including the ligator atoms with the most

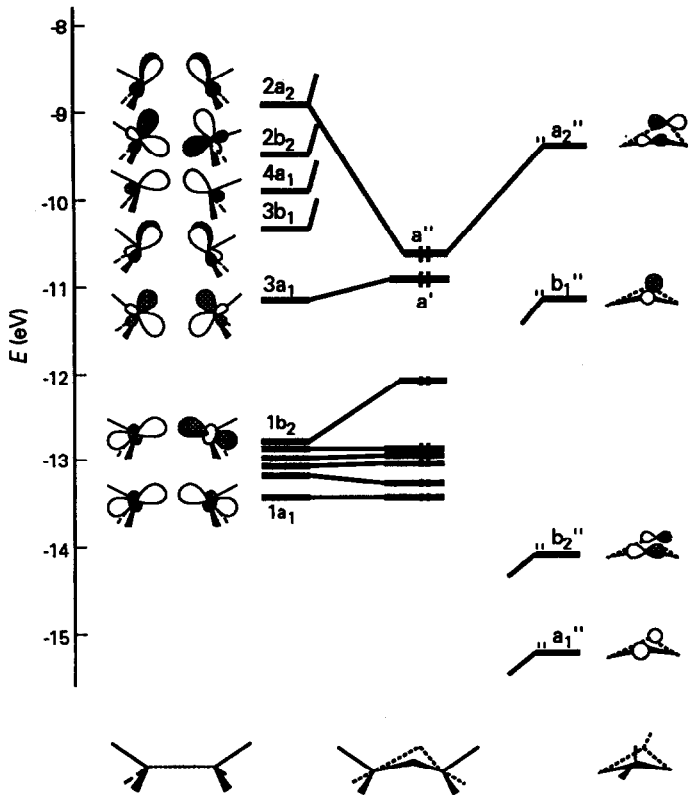

Fig. 2. Molecular orbital diagram of the anion $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PH_2)]^-$ build up from a $Fe_2(CO)_6$ fragment and the two bridging ligands CO and PH_2^-. The orbitals of both fragments have been donated according to the point group C_{2v} to make clear the orbital interactions. The orbitals of the anion itself have been donated according to C_s.

bulky substituents (Ag, P(2)) is the smallest. A comparison between the terminal CO groups and the μ-CO with regard to their bond lengths gives the expected result: the former have longer C—O distances (mean value 1.146(8) Å compared with C(4)—O(4) = 1.191(8) Å) but shorter Fe—C distances.

The six Fe—C—O angles expected to be nearby 180° can be classified into two groups: four with values of about 176° and two (at C(1) and C(7)) with stronger deviations from linearity (about 170°). The latter belong to CO groups in *trans*-position to C(4) and the bend might arise from the influence of the triphenyl-phosphane substituent at the silver atom.

The crystal packing consists of isolated molecules without special intermolecular contacts. Preliminary X-ray investigations of the analogous clusters **5** and **7** gave no indication of isomorphism with **6**.

* Standard parameters were used for the calculations. The geometries for the models match that of the X-ray diffraction studies reported in ref. 1 and in the present paper.

Molecular orbital calculations

The ambident nucleophilic reactivity of the anions $[Fe_2(\mu\text{-}CO)(CO)_6(\mu\text{-}PR_2)]^-$ as described in the resonance formulae A and B should be reflected in the electronic structure of the compound. Therefore, we carried out Extended Hückel molecular orbital calculations[33,34] to examine the sources for this ambivalence.*

Figure 2 shows the molecular orbital diagram of the anion built up from the well-known $Fe_2(CO)_6$ fragment[35] and the two bridging ligands CO and PH_2^-, the latter being a model for the phosphido ligands PR_2^-. The di-iron fragment orbitals $2a_2$, $2b_2$, $4a_1$ and $3b_1$ interact with the symmetric and antisymmetric combinations of the σ and π orbitals of the coordinating atoms to form four metal-bridge bonds. Caused by the different energetic position of the phosphido orbitals and the CO orbitals the symmetric combinations of the ligand orbitals are mainly localized at the phosphorus, whereas the antisymmetric combinations are mainly CO in character. The two highest occupied anion orbitals a'' and a' are schematically shown in Fig. 3. The

Fig. 3. The two highest occupied anion orbitals.

HOMO a'' is the bonding combination between the orbitals $2a_2$ of the di-iron fragment and the π^* orbital of the carbonyl ligand. It represents one of the four metal-bridge bonds. The orbital a' is not influenced by interactions with the bridging ligands. It is considered to indicate the bent Fe—Fe bond in the anion, resembling that described for the $[Fe_2(CO)_6(\mu\text{-}PR_2)_2]$ system.[36,37] Both orbitals a' and a'', can act as donor orbitals towards nucleophiles. Figure 4 represents the metal-based reactivity against a "third bridging ligand" $[M(PR_3)]^+$ with a d^{10}-configurated metal ion M^+ (M = Cu, Ag, Au). The LUMO of $[M(PR_3)]^+$ is a σ-acceptor orbital that interacts with the anion orbital a' to form one additional metal-bridge bond. This description of the bonding within the Fe_2M core of complexes **5–7** is in accordance with the bonding situation in heteronuclear gold-metal clusters containing a μ-bridging $Au(PR_3)$ fragment which is generally said to involve a three-centre two-electron bond between the two metal atoms and the gold atom.[38] Thus, the 46 electron count of these triangular clusters follows from the electron deficiency of this bond.

Although the structure of the hydride complex $[Fe_2(\mu\text{-}CO)(CO)_6(H)(\mu\text{-}PBu^t_2)]$ (**4a**) could not be ascertained, this complex might have a similar molecular and electronic structure as discussed for complexes **5–7** due to the isolobal analogy of H^+ and $[M(PPh_3)]^+$ (M = Cu, Ag, Au).

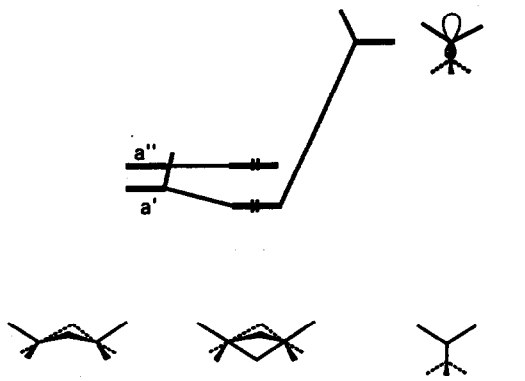

Fig. 4. Schematic plot of the bonding interaction between the anion orbital a' and the LUMO of a bridging $[M(PR_3)]^+$ group (M = Cu, Ag, Au).

The oxygen-based nucleophilicity of anions **3** is understandable by inspecting orbital a'' (Fig. 3). This orbital can be considered to be mainly an oxygen lone pair orbital that is able to donate electronic density from oxygen into the acceptor orbital of e.g. a CR_3^+ group. This is confirmed by the net charges (Mulliken population analysis) of the atoms in the anion model compound: q(Fe) = 0.22, $q(PH_2)$ = 0.02, $q(C_{term})$ = 0.67 (mean value), $q(O_{term})$ = −0.78 (mean value), $q(C_{bridge})$ = 0.20, $q(O_{bridge})$ = −1.03, i.e. the carbonyl bond in the bridging CO is highly polar corresponding to formula **B**.

Abstract—Amine oxide-assisted decarbonylation of $Re_2(CO)_{10}$ in the presence of 1,1′-bis(diphenylphosphino)ferrocene (dppf) produces, under different conditions, $[Re_2(CO)_9]_2$ (μ-dppf) (**1**), $Re_2(CO)_9(\eta^1$-dppf) (**5**) and its oxidation product $Re_2(CO)_9(\eta^1$-dppfO) (**7**). **1** undergoes an oxidative bridge-scission with Me_3NO to give **7**. X-ray crystallographic analysis of **1** and $[Mn_2(CO)_9]_2(\mu$-dppf) (**2**), included for comparison, revealed that the two molecules are isomorphous, each taking the form of an open and "linear" tetranuclear complex supported alternately by M—M bonds and a "half eclipsed" dppf bridge. Complex **7**, which is trimetallic, consists of dppf (mono)oxide coordinated to $[Re_2(CO)_9]$ through the phosphine site. X-ray Photoelectron Spectra revealed the existence of the chemically inequivalent Re and P sites within the same molecule. The chemically distinct Re centres in **1**, **5**, **7** and $Re_2(CO)_9(CH_3CN)$ are differentiable by their Re($4f_{7/2}$) and Re($4f_{5/2}$) binding energies.

Thermal decarbonylation of substituted metal carbonyls is a subject of our recent interest.[1] Phosphine substitution of $Re_2(CO)_{10}$ almost invariably yields $Re_2(CO)_{10-n}(PR_3)_n$ ($n \leqslant 3$)[2] or the intramolecularly bridged $Re_2(CO)_{10-2n}(P—P)_n$ ($n \leqslant 2$)[3] when diphosphines are used. Most of these substitutions were photo-induced and hence competed with the notorious metal—metal bond homolysis. Some of the supposedly dinuclear complexes so formed have in fact been subsequently found to be mononuclear and/or paramagnetic in the form of the hydrido, orthometallated and oxidized products.[4] As a result of our continued efforts to use amine oxide to create different functional metalloligands from the basic metalloligand 1,1′-bis(diphenylphosphino)ferrocene (dppf), we report in this paper that under a mild synthetic condition, a heterometallic complex, $[Re_2(CO)_9]_2(\mu$-dppf) (**1**), was isolated in good yield in the reaction between $Re_2(CO)_{10}$ and dppf. The molecular structure of the analogous $[Mn_2(CO)_9]_2(\mu$-dppf)[5] (**2**) is also included for comparative purpose. These polynuclear complexes though supported by M—M bonds do not have the usual deltahedral structures and hence can only be loosely defined as "open clusters". Whilst the structures of diaxial $Re_2(CO)_8(PMe_2Ph)_2$[6] and a series of $Re_2(CO)_{10-n}(CNR)_n$[7] complexes have been reported, to date there are no X-ray structural data on the analogous Re(0) diphosphine complexes. Most of the structural reports of dppf complexes in the literature have

* Authors to whom correspondence should be addressed.

centred on the ligand in its chelating mode.[8] The present paper, however, emphasizes the bridging nature of the phosphine.

Our isolation of a series of Re complexes with different nuclearities and phosphines in different electronic environments have enabled us to explore the use of X-ray Photoelectron Spectroscopy (XPS) in the study of these Re complexes in their solid state. Though established as a surface technique, XPS has been widely applied as a probe to the chemical and electronic properties of metal complexes. Earlier reports in the applications of XPS in organometallics were devoted mainly to the study of phosphine coordination.[9] Progress however has been inhibited by the general insensitivity of the core binding energies (b.e.s) of phosphorus atoms to different electronic environments.[10] Over the years the effect on metal b.e.s of ligand changes have also attracted considerable attention,[11] including the Re complexes.[9b,12] Reported herein are some of the XPS data which complement the solution results obtained in NMR spectroscopy.

EXPERIMENTAL

General

All reactions were performed under pure dry argon using standard Schlenk techniques. Preparations of $Mn_4(CO)_{18}(dppf)$[5] and $Re(CO)_5Br$[27] were described previously. Reaction of $Re_2(CO)_{10}$ with dppf in thf/CH_3CN mixture led to the isolation of $Re_2(CO)_9(NCCH_3)$ in 52% yield. Preparation of $Re_2(CO)_9(NCCH_3)$ has been reported.[2d,14] Precoated silica plates of layer thickness 0.25 mm were obtained from Merck. The general procedures and instruments used were as described in our earlier reports.[28] The TG and DSC experiments were conducted by use of a Du Pont 9900 thermal analyser under similar conditions as reported.[29] Core level spectra were obtained on a VG ESCA/SIMSLAB MK II spectrometer using Mg–K_α radiation, operating ρn a fixed retardation of 40 and covered the energy regions for all the elements present in the samples. The sample in powder form was sprinkled onto a double-sided Scotch tape mounted onto a standard VG holder. The binding energies were referenced to the hydrocarbon component in the C_{1s} envelope defined at 285.0 eV to compensate for surface charging. The b.e. of each core ionization peak was determined from a symmetric curve fit of the band and is estimated to have an uncertainty of ± 0.2 eV. Sample stoichiometries were checked and confirmed by their core level peak intensities. Deconvolution of the overlapping spectral components were performed on VG softwares. In the simulated spectrum each pair of $Re(4f_{7/2})$ and Re $(4f_{5/2})$ lines is restrained to have an intensity ratio of 4:3 and the spin orbital splitting to be 2.4 ± 0.1 eV. No strenuous effort was made to resolve the P(2*p*) sub-levels. Elemental analyses were performed by the analytical service of this department. The presence of solvate molecules in the sample crystals was confirmed by NMR analysis. The solvent inclusion property of many dppf complexes has been noted in the literature.[30] In reactions in which unreacted dppf ligand was recovered, the experimental yields were calculated based on the ligand consumed.

$Re_4(CO)_{18}(\mu\text{-dppf})\ 0.5\ CH_2Cl_2\ 0.5\ C_6H_{14}$ (1)

A quantity of 35 cm^3 of thf was added to a solution of $Me_3NO \cdot 2H_2O$ (0.051 g, 0.46 mmol) in 1 cm^3 of methanol at room temp. The resultant solution was then slowly transferred into a continuously stirred solution of $Re_2(CO)_{10}$ (0.305 g, 0.47 mmol) in 15 cm^3 of thf, at room temp., via a PTFE transfer tube. The yellow solution so formed was stirred *in vacuo* for 30 min. Two-thirds of the solvent was then removed *in vacuo* and the remaining solution was stirred at room temp. for a further 15 min. Solid dppf (0.128 g, 0.23 mmol) was added and the resultant orange solution was stirred for 50 min under argon. The solvent was removed and the orange solid redissolved in a minimum quantity of CH_2Cl_2 and chromotographed on silica t.l.c. plates. Elution with CH_2Cl_2–hexane (1:4) yielded three orange bands, the second and third of which were converted into the first when left in CH_2Cl_2 solution for 1 week. Recrystallization of the combined extracts from CH_2Cl_2–hexane mixture yielded 0.244 g (59%) of $Re_4(CO)_{18}(\mu\text{-dppf})\ 0.5\ CH_2Cl_2\ 0.5\ C_6H_{14}$ (1). Found: C, 35.2; H, 1.9; P, 3.5. $C_{55.5}H_{36}ClFeO_{18}P_2Re_4$ requires C, 35.3; H, 1.9; P, 3.3%; ν_{max}(CO) 2106m, 2033m, 2000vs, 1970s, 1935vs cm^{-1} ($CHCl_3$); $\delta_H(CDCl_3)$ 7.49–7.36 (m, 20 H, Ph), 5.29 (s, 1H, CH_2Cl_2), 4.36 (t, 4 H, CpH_β), 3.99 (m, 4 H, CpH_α), 1.26 (s(br), 4H, hexane), 0.88 (m, 3 H, hexane); $\delta_P(CDCl_3)$ 5.79 (s).

Complex 1 can be stripped of its occluded solvent by heating the solid at 155°C under argon for 20 min. Found: C, 34.8; H, 1.4; Fe, 3.1. Calc. for $C_{52}H_{28}FeO_{18}P_2Re_4$: C, 34.6; H, 1.6; Fe, 3.1%.

$Re_2(CO)_9(dppf)$ (5)

A quantity of 35 cm^3 of thf was added to a solution of $Me_3NO \cdot 2H_2O$ (0.051 g, 0.46 mmol) in a minimum amount of MeOH at room temp. The resultant solution was slowly transferred into a continuously stirred solution of $Re_2(CO)_{10}$ (0.305 g,

0.47 mmol) in thf (15 cm^3) via a PTFE transfer tube. The yellow solution so formed was stirred *in vacuo* for ½ h, after which two-thirds of the solvent was removed *in vacuo*. The remaining solution was stirred for a further 15 min before it was slowly transferred to a solution of dppf (0.311 g, 0.56 mmol) in thf (12 cm^3). The resultant orange solution was stirred under argon for about 1 h. Half of the solvent was then removed and stirring was continued for 50 min. The solution was evaporated to dryness and the orange residue redissolved in a minimum quantity of CH_2Cl_2 and chromatographed on silica t.l.c. plates. Elution with CH_2Cl_2–hexane (3 : 17) followed by further recrystallization from CH_2Cl_2–MeOH mixture yielded the orange $Re_2(CO)_9$(dppf) (0.254 g, 54%). Found: C, 43.4; H, 2.1; P, 6.1; Fe, 4.4. $C_{43}H_{28}FeO_9P_2Re_2$ requires C, 43.8; H, 2.4; P, 5.3; Fe, 4.7%. ν_{max}(CO) 2106m, 2033m, 1997vs, 1960m, 1935s cm^{-1} ($CHCl_3$); δ_H($CDCl_3$) 7.41–7.35 (m, 10 H, Ph), 7.27–7.15 (m, 10 H, Ph), 4.45 (t, 2 H, coord. CpH_β), 4.19 (t, 2 H, free CpH_β), 4.11 (m, 2 H, coord. CpH_α), 3.83 (q, 2 H, free CpH_α); δ_P($CDCl_3$) 5.65 (s, $P_{coord.}$), −16.96 (s, P_{free}). The yield is very sensitive to experimental conditions and can fluctuate in the range 20–60%. The compound is also invariably contaminated with varying quantities of **1**, from which it is difficult to separate by t.l.c. Unreacted dppf (0.090 g, 0.16 mmol) was also isolated.

$[Re_2(CO)_9(Ph_2P(C_5H_4)Fe(C_5H_4)PMePh_2)]^+I^-$ (6)

MeI (1 cm^3, 16.1 mmol) was added to a diethyl ether suspension (3.5 cm^3) of **5** (0.045 g, 0.038 mmol). The resultant orange solution was stirred for 2½ h at room temp., during which a tan–orange solid gradually precipitated. The residue that remained after removal of the solvent was washed with hexane (3 × 5 cm^3) and characterized to be **6**. (0.049 g, 97%). Ready decomposition of this compound upon isolation precludes an accurate microanalysis; ν_{max}(CO) 2107w, 2040w, 1999vs, 1960m, 1934m cm^{-1} ($CHCl_3$); δ_H($CDCl_3$) 7.71 (m, 5 H, Ph), 7.62 (m, 5 H, Ph), 7.43 (m, 10 H, Ph), 4.93 (t, 2 H, Me-P-CpH_β), 4.56 (q, 2 H, Re-P-CpH_β), 4.36 (q, 2 H, Me-PCpH_α), 4.24 (m, 2 H, Re-P-CpH_α), 3.05 (d, 3H, P-CH_3, $^2J_{P-H}$ 13.2 Hz), δ_P($CDCl_3$), 24.37 (s, H_3C—P), 5.52 (s, Re—P).

$Re_2(CO)_9(Ph_2P(C_5H_4)Fe(C_5H_4)P(O)Ph_2)$ (7)

A quantity of 25 cm^3 of thf was added to a solution of $Me_3NO \cdot 2H_2O$ (0.004 g, 0.036 mmol) in a minimum quantity of MeOH. Solid **1** (0.066 g, 0.035 mmol) was introduced and the resultant solution was refluxed under argon for 7½ h. Two-thirds of the solvent was removed and the remaining solution was refluxed for another 4 h giving a brownish-orange solution together with a little black powdery solid. The solvent was evaporated off and the residue extracted with CH_2Cl_2 and chromatographed on silica t.l.c. plates. Elution by hexane–CH_2Cl_2 (1 : 1) moved only a single orange band of unreacted **1** (0.022 yielded, on recrystallization from CH_2Cl_2/hexane mixture, $[Re_2(CO)_9\{Ph_2P(C_5H_4)Fe(C_5H_4)P(O)Ph_2\}] \cdot H_2O$ (0.014 g, 50% based on **1** consumed). Found: C, 43.0; H, 2.5; P, 5.5; Fe, 4.3. $C_{43}H_{30}FeO_{11}P_2Re_2$ requires C, 42.6; H, 2.5; P, 5.1; Fe, 4.6%; ν_{max} 2106m, 2033m, 1998vs, 1970m, 1936s, (CO)($CHCl_3$) and 1121w (PO) cm^{-1} (KBr); δ_H($CDCl_3$) 7.66–7.35 (m, 20 H, Ph), 4.87 (t, 2 H, O=P—CpH_β), 4.28 (q, 2 H, Re—P—CpH_β), 4.13 (m, 2 H, O=P—CpH_α), 4.05 (q, 2 H, Re—P—CpH_α); δ_P($CDCl_3$) 28.40 (s, O=P), 5.72 (s, Re—P).

Complex **7** could also be obtained from the reaction of $Re_2(CO)_{10}$, dppf and $Me_3NO \cdot 2H_2O$ in 2 : 1 : 2 molar ratio in a single pot in thf, or oxidation of **5** with H_2O_2 in CH_3CN in *ca* 6 and 33% yields respectively.

$Fe(C_5H_4P(O)Ph_2)_2$ 0.5 CH_2Cl_2 (10)

Preparation of this complex has been reported in the literature.[31] The following procedure was preferred for its convenience and higher yield.

30% aqueous H_2O_2 (2 cm^3, 17.65 mmol) was added to a suspension of dppf (0.840 g, 1.52 mmol) in CH_3CN (60 cm^3) at room temp. The resultant orange suspension was stirred for 1½ h at room temp., and evaporated to dryness *in vacuo*. The residual brownish orange solid was recrystallized from EtOH and then from CH_2Cl_2/*n*-hexane to yield tan–orange crystals of **10** (0.640 g, 67%). Found: C, 66.0; H, 4.8; Fe, 8.9. Calc. for $C_{34.5}H_{29}ClFeO_2P_2$: C, 65.8; H, 4.6; Fe, 8.9%; ν_{max}(P=O) 1191vs cm^{-1} (KBr); δ_H($CDCl_3$), 7.61 (m, 4 H, Ph), 7.45 (m, 16 H, Ph), 5.29 (s, 1 H, CH_2Cl_2), 4.71 (q, 4 H, CpH_β), 4.26 (q, 4 H, CpH_α); δ_P($CDCl_3$) 28.27 (s).

$Re(CO)_3$(dppf)Br (11)

Dppf (0.162 g, 0.29 mmol) was added to a solution of $Re(CO)_5Br$ (0.120 g, 0.29 mmol) in acetone (7 cm^3) and thf (10 cm^3) at room temp. The resultant mixture was vigorously stirred as solid $Me_3NO \cdot 2H_2O$ (0.064 g, 0.58 mmol) was added. The orange solution was stirred *in vacuo* for 2 h at room temp. before it was evaporated under vacuum. The product was taken up in CH_2Cl_2 and chromatographed on silica t.l.c. plates. Elution with

CH_2Cl_2/hexane (7:13) followed by recrystallization from CH_2Cl_2/MeOH mixture yielded chrome-yellow crystals of **11** (0.171 g, 65%). Found: C, 49.1; H, 3.1; P, 7.0; Fe, 6.2; Br, 8.7. $C_{37}H_{28}BrFeO_3P_2Re$ requires C, 49.1; H, 3.1; P, 6.8; Fe, 6.2; Br, 8.7%. ν_{max}(CO) 2038s, 1960m, 1902m cm^{-1} ($CHCl_3$); δ_H($CDCl_3$) 7.70 (m, 8 H, Ph), 7.42 (m, 12 H, Ph), 4.95 (m, 2 H, Cp), 4.39 (m, 2 H, Cp), 4.31 (s, 4 H, Cp); δ_P($CDCl_3$) 0.27 (s).

Crystallography

Large orange single crystals of complex $[Re_2(CO)_9]_2(\mu$-dppf)·solvate (**1**) and $[Mn_2(CO)_9]_2(\mu$-dppf)·thf (**2**) were grown from CH_2Cl_2/hexane and thf/EtOH mixtures respectively at 5°C. Single crystals suitable for X-ray diffraction were mounted inside a lithium glass capillary for preliminary characterization and intensity data collection. The crystallographic data and refinement details of **1** and **2** are listed in Table 1. A single crystal of $Re_2(CO)_9(Ph_2P(C_5H_4)P(O)Ph_2)\cdot H_2O$ (**7**) was mounted on top of a glass fibre for preliminary characterization. At this stage one of the cell edges was found to be longer than 35 Å. The diffraction spots would not be well resolved if using Mo–K_α radiation. Hence the intensity data were collected employing Cu–K_α radiation, taking a necessary weak point of high absorption coefficient.

The structures of **1** and **2** were solved by direct methods MULTAN and were found to be isomorphous. The ferrocenyl Fe atom was located along a two-fold axis. Hence only one-half of the molecule is crystallographically independent. The crystal structures were found to have disordered solvate molecules around a crystallographic two-fold axis. For complex **1**, the solvate molecule seemed to be a disordered CH_2Cl_2. Yet as reasonable models of CH_2Cl_2 could not be constructed, C_{41}–C_{44} per acentric unit were refined to cover scattering due to the electron densities in the solvate region. For complex **2**, the electron density distribution conformed to a thf molecule. The molecular drawings of **1** are shown in Fig. 1 whilst **2** is isomorphous to **1**. Final atomic fractional coordinates and selected bond distances and angles for **1** and **2** are listed in Table 2(a) and (b) respectively.

The structure of **7** was solved also by direct methods MULTAN. With $Z = 8$, there are two independent molecules per asymmetric unit. Included in the crystal structure is one hydrate for one $Re_2(CO)_9$(dppfO), linked in a hydrogen bonding system.

All hydrogen atoms were fixed as isotropic μ values in the final cycles of least-squares refinement. The non-hydrogen atoms, except for the hydrate oxygen atoms, were varied anisotropically. The atomic scattering curves of Re, Fe, Mn, P, O, C and H were taken from *International Tables for X-ray Crystallography*, Volume IV. Computations were carried out on a microVAX 3600 with NRCC package.[32]

RESULTS AND DISCUSSION

Synthesis and properties

Reaction between $Re_2(CO)_{10}$ and dppf does not proceed under thermal conditions (refluxing thf). The presence of Me_3NO, however, leads to rapid oxidative decarbonylation of the former thereby facilitating phosphine substitution. The most obvious intermediate for the formation of the title complexes is $M_2(CO)_9(\eta^1$-dppf). Evidence for the Mn complex has recently been obtained. The Re analogue **5** can also be isolated when excess dppf is used. The ^{31}P-NMR of **5** shows a characteristic high field singlet together with the low-field signal assignable to the axial-coordinated phosphine. The nucleophilicity of the pendant phosphine is demonstrated by its ready methylation with CH_3I to give $[Re_2(CO)_9(\eta^1$-$Ph_2P(C_5H_4)Fe(C_5H_4)PMePh_2)]I$ (**6**). Complex **5** can be oxidized by H_2O_2 to give $Re_2(CO)_9(\eta^1$-$Ph_2P(C_5H_4)Fe(C_5H_4)P(O)Ph_2)$ (**7**), which was also isolated as a minor product in a one-pot reaction of $Re_2(CO)_{10}$, dppf and Me_3NO (2:1:2) in thf but best prepared from **1** in its oxidative bridge-scission reaction with Me_3NO in refluxing thf. Such oxygen transfer from an amine oxide to a stable bridging phosphine in preference to a carbonyl carbon was unexpected and unprecedented. This oxygen migratory reaction may possibly be facilitated by a nucleophilic attack of Me_3NO on the coordinate phosphorus site. The ability for the ferrocenyl moiety to dissipate excess charge in the transition state, an idea not dissimilar to that proposed for bridging carbonyls,[13] possibly renders the phosphine phosphorus more electrophilic than the carbonyl carbon. An alternative mechanism which requires the cleavage of the Re—P bond prior to oxygen transfer is deemed to be less likely in view of the inertness of free dppf towards Me_3NO at room temperature, and the kinetic stability of the Re—P bond, as exemplified by the fact that complex **1** is robust even when refluxed with dppf in hexane.

The negligible shift for the ^{31}P NMR signal due to the coordinated phosphorus atom from **5** to **6** and **7** and in fact between **1** and **5** suggests that there is negligible electronic interaction across the dppf backbone in these complexes. The title

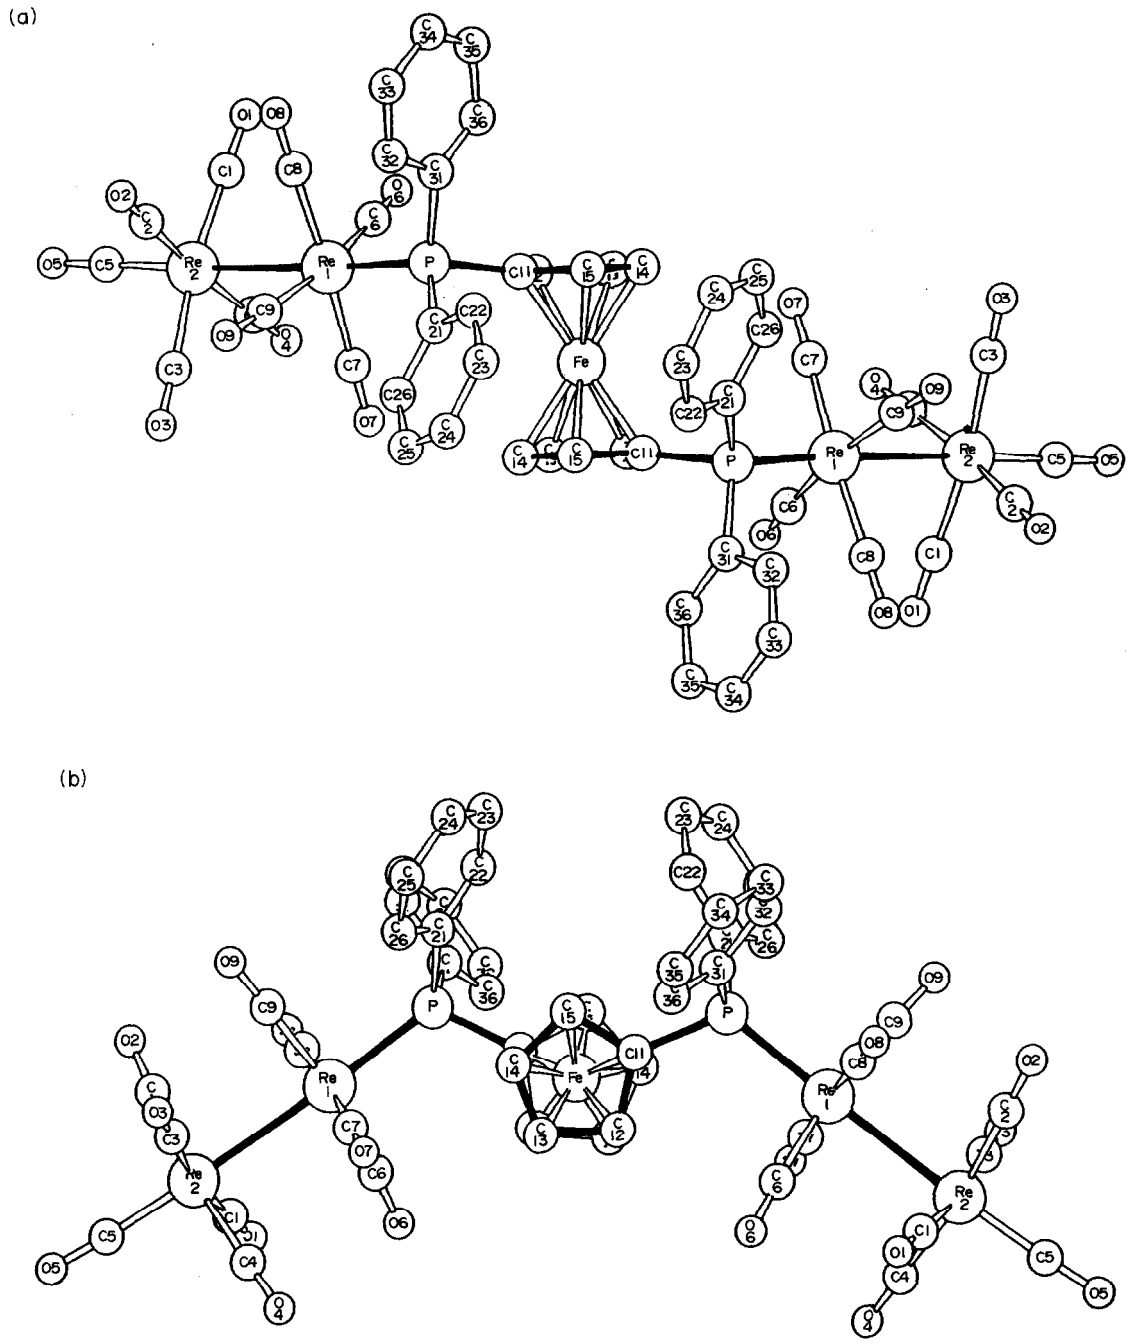

Fig. 1. (a) SCHAKAL plot of $[Re_2(CO)_9]_2(\mu$-dppf) (**1**) (hydrogen atoms omitted for clarity). (b) Top view on the phosphinocyclopentadienyl ring showing its "half-eclipsed" form and the relative orientation of the $[Re_2(CO)_9]$ moieties.

complex **1** is not formed when the preparation is carried out in CH_3CN, in which case $Re_2(CO)_9(CH_3CN)$[2d,14] (**8**) is isolated as the major product. The substitutional inertness of **8** has been documented.[14] The effect of amine oxide in these reactions is particularly significant when one considers the recent photo-induced synthesis of $Mn_2(CO)_8(\mu$-dppf) and $Mn_2(CO)_8Cl_2(\mu$-dppf),[17] neither of which was apparent under our experimental conditions in the synthesis of **2**. Thermogravimetric and Differential Scanning Calorimetric analyses of **1** and **2** revealed their release of trapped solvents at *ca* 154 and 124°C and decomposition of the complexes at *ca* 183 and 182°C respectively. Like the Gp 6 dimeric $M_2(CO)_{10}(\mu$-dppf), both complexes are resistant to further decarbonylation by Me_3NO

[a] The parameter η was checked so that the space group conformed to the correct polarity: 1.00(8).

[b] The solvate molecule is probably disordered CH_2Cl_2 and/or *n*-hexane. As reasonable models of either CH_2Cl_2 or *n*-hexane could not be constructed, C_{41}–C_{44} per asymmetric unit are refined so that contribution of electron densities in the solvate region to the scattering is included.

[c] 0.961, for a parameter in solvate region. 0.008, for $[Re_2(CO)_9]_2$(dppf) parameters.

[d] The highest residual peaks are 1.0–1.2 Å next to Re atoms.

[e] Block-diagonal least-squares reiterations were employed to convergence.

[f] The highest peaks are next to Re atoms at *ca* 1.0–1.1 Å.

at room temperature. No higher substituted products were evident in the preparative reactions of **1** and **2**. The chemical stability of **1** is further demonstrated by its inertness towards S_8 and dppf in refluxing *n*-hexane.

Crystal and molecular structures

In view of the subtleties in the conformational variations of dppf as a ligand, and the lack of structural data for monosubstituted $Re_2(CO)_9(PR_3)$ or its polynuclear analogues in the literature, the X-ray structural analyses for $[Re_2(CO)_9]_2(\mu$-dppf)·solvate (**1**), $[Mn_2(CO)_9]_2(\mu$-dppf)·thf (**2**), and $Re_2(CO)_9(Ph_2P(C_5H_4)Fe(C_5H_4)P(O)Ph_2) \cdot H_2O$ (**7**) were carried out. Single crystals of **1** were obtained from CH_2Cl_2/hexane mixture at 5°C. The crystals of **2** which were suitable for X-ray analysis were grown from thf/EtOH mixture at the same temperature. The molecular structure of **1** is shown in Fig. 1(a). Crystallographic data of **1** and **2** are given in Table 1(a) and (b). Some pertinent molecular data are listed in Tables 2(a) and (b). **2** crystallizes with an occluded thf molecule. ^{1}H NMR spectra of **1** indicates its solvation with hexane and CH_2Cl_2 but the X-ray data only revealed a disordered C_4 entity. The molecules are structurally isomorphous, each consisting of a dppf molecule axially and singly bridging between two $M_2(CO)_9$ moieties with the ferrocenyl iron atom being located on a two-fold axis. These polymetallic complexes are thus supported by two metal—metal bonds and a dppf bridge. The general features of this dppf bridge is similar to that reported earlier for $M_2(CO)_{10}(\mu$-dppf) (M = Cr (**3**), Mo (**4**))[15] with a few notable differences. Whereas the P···Fe···P′ for the Group 6 dimers is virtually linear (Ave. 172.4(3)°), it narrows substantially to 140.56(11)° for **1** and 140.29(6)° for **2**. Accordingly, the P···P′ separation is shortened from an average of 7.068(3) Å in the Cr and Mo dimers to 6.689(4) Å in **1** and 6.697(4) Å in **2**. Related to this M···M shortening is the near-eclipsed ferrocenyl rings in **1** (twist angle = 12.7°) (Fig. 1b) and **2** (12.6°) and near-staggered configuration in **3** and **4** (average angular deviation from the eclipsed configuration is 28.4°).

The title complexes otherwise show normal substituent-induced ring distortions[16] and a displacement of the phosphorus atoms from the plane of the Cp ring, by 0.22(3) Å for **1** and 0.235(13) Å for **2**, away from the iron centre.

Single crystals of **7** were grown from CH_2Cl_2/hexane mixture at 5°C. Two crystallographically independent molecules were located and are shown in Fig. 2. Crystallographic data are given in Table 1(c), and some molecular data summarized in Table 2(c).

Each complex molecule co-crystallizes with a water molecule, which is hydrogen-bonded to the phosphoryl oxygen of the dppfO ligand ($O(1)\cdots O(2) = 2.81(4)$ Å; $O(3)\cdots O(4) = 2.64(7)$ Å). The hydrates are also linked among themselves by hydrogen bonds. The behaviour of free phosphine oxide co-crystallizing with hydrogen-bonding molecules has been documented and elegantly applied to optical resolutions[17] and as crystallizing aids.[18]

Complex **7** consists of a dppfO molecule axially coordinated through the phosphine to a $Re_2(CO)_9$ moiety. The phosphoryl group is pendant with its P atom coplanar with the attached Cp ring. The phosphine P on the other hand is displaced from the Cp plane away from the Fe centre by 0.22(3) Å (0.24(4) Å for the other crystallographically independent molecule) presumably due to the steric bulk of the dimetal entity. The P—O length of 1.432(16) Å (1.494(15) Å) is normal for a P=O bond.[19]

The general structural characteristics of the ferrocenyl and dirhenium nonacarbonyl fragments closely resemble those of **1** and warrant no special mention. Some conformational differences can, however, be noted, e.g. the twist angle of 17.2(15)

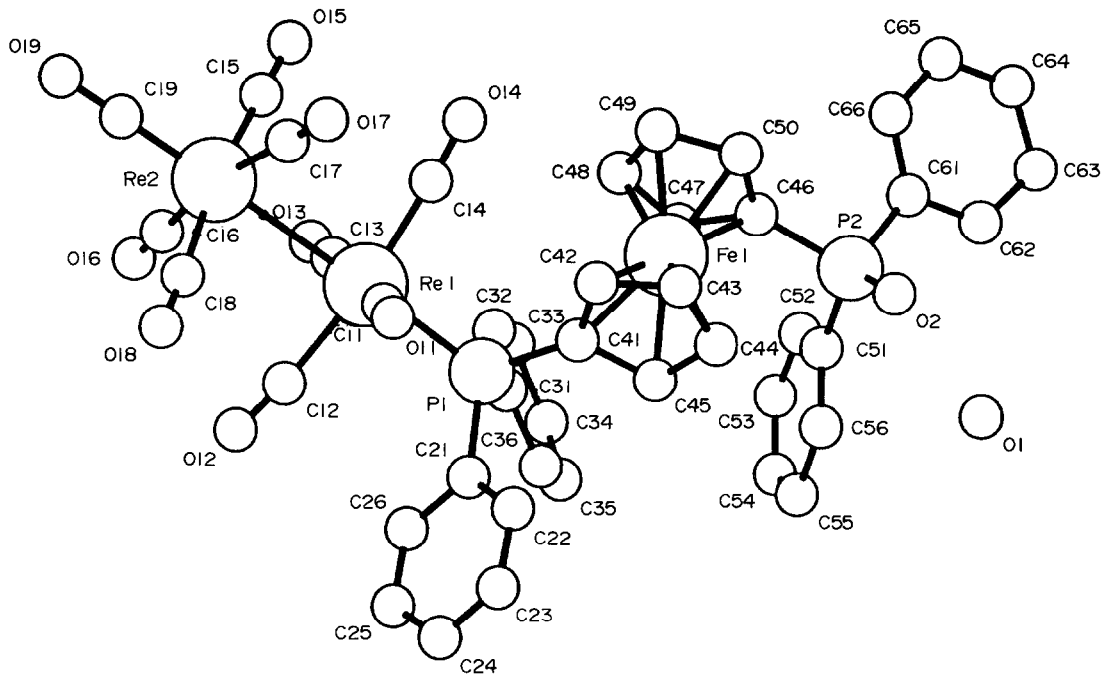

Fig. 2. SCHAKAL plot of $Re_2(CO)_9(dppfO)\cdot H_2O$ (7) (hydrogen atoms omitted for clarity) showing two crystallographically independent molecules.

(20.2(15)°), which orientates the molecule to midway between being idealized eclipsed and staggered. A torsional (C(41)–Cent(1)–Cent(2)–C(46)) twist of 127.0(12)° (122.1(13)°) is also substantially smaller than that found in free dppf[20] and other open-bridged systems[21] including complexes **1**–**4** and consequentially the intramolecular P···P separation (6.369(7) Å (6.342(8) Å) and P···Fe···P angle (133.5(2)° (131.7(2)°) are decreased.

XPS studies

Table 3 summarizes some b.e.s observed in the multinuclear XPS spectra of the compounds studied. Complexes with inequivalent phosphorus atoms generally show a peak broadening of *ca* 0.3 eV in their P(2*p*) spectra. Such broadening, which has been observed in some Gp 6 carbonyls substituted by dppf in a unidentate coordination mode,[22] allows the extraction of a doublet of Gaussian components. A typical P(2*p*) photoelectron spectrum is that of **5** which is shown in Fig. 3. The high energy shift in **5** of 0.9 eV from the dangling site to the coordinated phosphorus reflects the net electron drift P → M upon coordination of the phosphine. Although there is a general consensus[9,9e,10a,10c,10d] that phosphine coordination does not alter the P(2*p*) b.e. because of the counter-balance of σ and π electron drifts, a similar high-energy shift has been reported in a few monophosphine complexes.[23] In these literature cases however, comparisons are made on *different* complexes, the accuracy of which depends on the reliability of the reference peaks.

Just as the b.e.s for free dppf **9**, (131.1(1.8)) and a dangling dppf site in **5** (131.15(1.90)) is virtually

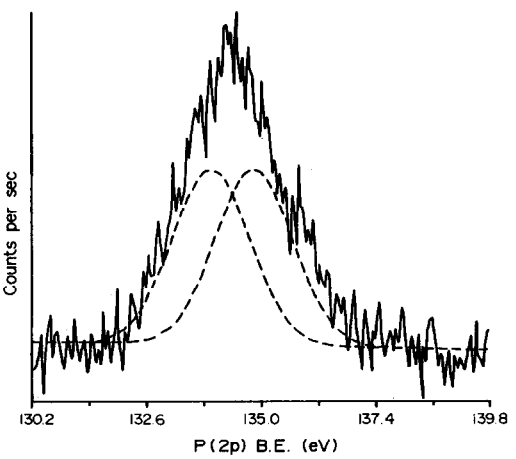

Fig. 3. Experimental (——) and deconvoluted (----) P(2*p*) X-ray Photoelectron Spectra of $Re_2(CO)_9(dppf)$ (**5**) showing the high and low energy bands corresponding to the coordinated and pendant phosphine groups.

[a] Core level binding energies are referenced to hydrocarbon peak at 285.0 eV; full-width half-maximum values given in parentheses; [b] Fe(2$p_{3/2}$); [c] N(1s); [d] Br(3$d_{5/2}$).

indistinguishable, the values for $Fe(C_5H_4P(O)Ph_2)_2$ ($dppfO_2$) (**10**), (132.55(1.95) eV) and the phosphoryl group (132.6(2.00)) are comparable. Midway between these values lie the coordinated phosphines, as shown in **1**, **5** and $Re(CO)_3(dppf)Br$ (**11**). These subtle but significant differences in the P(2*p*) shifts are in full accord with the structural and chemical differences of these systems. The similarity in the P(2*p*) b.e.s of the metal-bound phosphorus in **1**, **5** and **11**, which lie within a narrow range of 0.2 eV, however suggests a rather restricted use in the P(2*p*) core b.e. in the differentiation of the different ligation mode of the phosphine, or the identification of the oxidation state of the metal centre upon which the phosphine is attached. However, comparison of the XPS and ^{31}P NMR shift data revealed a trend showing that the highest b.e. was registered for the most deshielded phosphoryl nucleus and the lowest the most shielded pendant phosphorus. A similar correlation has been recently observed in a Mo–W mixed-metal system in which the ^{31}P NMR shift is related to the metal b.e. though in this case the phosphorus b.e.s are relatively insensitive.[24]

For the nine Re(0) and Re(I) species examined, the Re(4$f_{7/2}$) b.e.s fall in the range of 41.5–43.0 eV, a region generally observed for Re(I)–Re(IV) complexes.[10b,12b,i 2d,12e] The lowest b.e. is found in **1** and **5**, both of which possess a tetracarbonyl rhenium moiety monosubstituted by a phosphine group. Such a relatively low value is expected in view of the zero oxidation state of the metal coupled with the substitution of a π acceptor by a strong σ donor.[25] The high value found in $Re(CO)_5Br$ (**12**), is explained by the strong electron demand on the Re(I) centre by the COs in the pentacarbonyl moiety. Carbonyl substitution in $Re_2(CO)_{10}$ (**13**), invariably leads to a drop in the Re(4*f*) b.e.

A significant feature of the Re(4*f*) spectra of **1**, **5**, **7** and **8** is that, for each, the broad Re(4$f_{7/2}$) peak of FWHM = 2.00–2.05 eV can be deconvoluted into a doublet of equal intensity (FWHM = 1.80–1.90 eV) separated by 0.6–0.7 eV. The equally broad Re(4$f_{5/2}$) peaks can be similarly deconvoluted. Mononuclear, e.g. **11** and **12** and symmetrical dinuclear, e.g. **13** complexes have generally sharper Re(4*f*) bands. A typical spectrum obtained in **1** is illustrated in Fig. 4. The higher energy bands, attributed to the $Re(CO)_5$ fragment, lie within 0.2 eV of the bands from the parent $Re_2(CO)_{10}$ (**13**), This implies that only a marginal increase in electronic charge on the neighbouring metal occurs upon carbonyl substitution on one of the Re atoms. The deconvolution into two Re(4$f_{7/2}$) and two Re(4$f_{5/2}$) peaks provides strong evidence for the existence of two chemically differentiable Re centres with equal statistical distribution in these four tri- and penta-metallic Re complexes.

CONCLUSION

Most of the substitution chemistry of $Re_2(CO)_{10}$ is based on the substitutionally labile $Re(CO)_5$ unit. As demonstrated in this report and some other recent studies,[6,26] the pathway involving homolysis of the Re—Re bond can be bypassed under less stringent experimental conditions. The resultant dirhenium species provides a building block in poly-

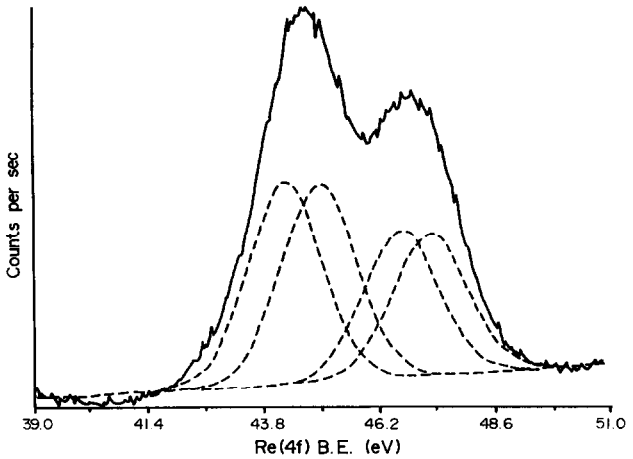

Fig. 4. Experimental (——) and deconvoluted (----) Re(4*f*) X-ray Photoelectron Spectra of $[Re_2(CO)_9]_2(\mu$-dppf) (**1**), showing the two sets of doublets of 1 : 1 intensity.

metallic synthesis. The feasibility of these metal aggregates as synthons to linear clusters and A-frame molecules attracts our current attention.

(*Received* 8 *April* 1991; *accepted* 2 *July* 1991)

Abstract—The title compound of formula $[Cu(terpy)(N_3)]_2(PF_6)_2$ (with terpy = 2,2′:6′,2″-terpyridine) has been synthesized and its crystal structure solved at room temperature by X-ray diffraction methods. The structure consists of $[Cu_2(terpy)_2(N_3)_2]^{2+}$ dimeric cations and non-coordinated hexafluorophosphate anions. The copper(II) ions are five-coordinate linked to three nitrogen atoms of the tridentate terpy ligand and two nitrogen atoms of the azide groups. The geometry of the coordination polyhedron is near to regular square pyramidal. Within the binuclear unit, the copper(II) ions are bridged by two azide groups in an end-on fashion. The Cu—Cu separation is 3.313(2) Å, and the Cu—N—Cu bridging angle is 96.3(3)°.

In recent years extensive studies have been directed toward the synthesis and properties of transition metal azide complexes.[1] The interest in the azide anion in coordination chemistry lies, in part, on the marked ability of this pseudohalide to act as a bridging ligand. The azide ligand can bridge two metallic ions either in a symmetrical "end-to-end" fashion or in an "end-on" fashion.[2,3] Among structurally characterized di-μ-azide-bridged complexes of copper, the type "end-on" bridge has been found in the polymeric $[Cu(bpy)(N_3)_2]$[4] (bpy = 2,2′-bipyridine) and dimeric $[Cu_2(N_3)_4(C_{16}H_{34}N_2O_6)(H_2O)]$[5] complexes; while the type "end-to-end" bridge has been reported in the dimeric $[Cu_2(PPh_3)_4(N_3)_2]$ compound.[6] Both kinds of bridging occur in the polymeric copper(II) azide.[7] We are studying some azide-compounds with general formula $[ML_{III}(N_3)_2]$ or $[ML_{III}(N_3)](PF_6)$; where M is Cu or Ni and L_{III} is a tridentate rigid ligand, as 2,2′:6′,2″-terpyridine, pyridine-2-aldehyde 2′-pyridylhydrazone and N-(6-methyl-2-pyridylmethylene)-2-(2-pyridyl) ethylamine.[8–11] In this publication, we present the crystal structure of a new dimeric copper(II) "end-on" azide complex, with formula $[Cu(terpy)(N_3)]_2(PF_6)_2$.

EXPERIMENTAL

Synthesis of $[Cu(terpy)(N_3)](PF_6)$

A warm aqueous solution (20 cm^3) of 0.20 g (0.525 mmol) of $[Cu(terpy)(N_3)_2]$ complex,[8] was treated with a KPF_6-saturated aqueous solution. After stirring a green solid precipitate was obtained. Crystallization of this product from a saturated aqueous solution yielded a few crystals, which were isolated by vacuum filtration and utilized for the X-ray crystal structure determination. The powder pattern of the solid precipitate obtained together with the crystals, shows the existence of other phases, which have vitiated a study of the physical properties. The elemental analysis of the crystals gives the following results: Found: C, 36.4; H, 2.2; N, 17.1. Calc. for $[Cu(C_{15}H_{11}N_3)(N_3)](PF_6)$: C, 36.9; H, 2.3; N, 17.4%.

X-ray data collection and structure determination

A well-formed prismatic crystal with dimensions $0.28 \times 0.10 \times 0.16$ mm was selected for the X-ray study. Preliminary cell dimensions and space group symmetry were obtained from Weissenberg and oscillation photographs. The same crystal was mounted on an Enraf–Nonius CAD-4 diffrac-

tometer equipped with graphite-monochromatized Mo-K_α radiation. Accurate cell constants were determined from least-squares refinement of the setting angles of 25 reflections with $14 \leqslant 2\theta \leqslant 25°$.

Crystal data: $[Cu(C_{15}H_{11}N_3)(N_3)](PF_6)$, $M = 483.9$, $P2_1/n$, $a = 10.149(2)$, $b = 15.593(2)$, $c = 11.694(4)$ Å, $\beta = 103.57(2)°$, $V = 1799(9)$ Å^3, $Z = 4$, $D_m = 1.79(2)$, $D_x = 1.79$ g cm^{-3}, $\lambda(\text{Mo-}K_{\alpha 1}) = 0.7107$ Å, $\mu(\text{Mo-}K_\alpha) = 14.47$ cm^{-1}, $F(000) = 956$, $T = 294$ K. Density was measured by flotation in a chloroform/1,1,2,2-tetrabromoethene mixture.

A total of 7122 reflections were measured ($2\theta \leqslant 50°$; $0 \leqslant h \leqslant 12$; $0 \leqslant k \leqslant 18$; $-13 \leqslant l \leqslant 13$) with the variable-speed $\omega/2\theta$ scan technique. 1902 reflections were considered observed with $I \geqslant 3\sigma(I)$, and used in the determination of the structure. Examination of three standard reflections [(−2−5−2), (−1−4−2), (43−3)] monitored after each 2 h, showed no substantial intensity decay. Lorentz and polarization corrections were applied, but no corrections for absorption. The structure was solved by direct methods with MULTAN 84 system,[12] and refined by full-matrix least-squares, using the SHELX 76 program.[13] The function minimized was $\Sigma w[|F_o| - |F_c|]^2$, where $w = [\sigma^2(F_o) + 0.002907(F_o)^2]^{-1}$. Positions of the hydrogen atoms were computed and refined with an overall isotropic thermal parameters and anisotropy for the remaining atoms. The final R was 0.057 ($R_w = 0.061$) for all observed reflections. At the end of the refinement the maximum peak in the final ΔF map was 0.71 e Å^{-3}. Scattering factors were taken from the *International Tables of X-Ray Crystallography*.[14] All calculations were carried out on a Microvax Computer at the computer centre of the Basque University. The geometric calculations were performed with XANADU[15] and molecular illustrations were drawn with SCHAKAL 88.[16] Further details are presented as Supplementary data, together with atomic coordinates, thermal parameters, bond lengths and angles, mean average planes and structure factors.

RESULTS AND DISCUSSION

Table 1 shows some selected bond distances and angles of the compound. The local copper(II) environment in the dimeric cation is presented in Fig. 1, with the labelling scheme used. Figure 2 shows a stereoscopic view of packing of the molecules in the unit cell.

The structure consists of cationic $[Cu_2(terpy)_2(N_3)_2]^{2+}$ units and non-coordinated hexafluorophosphate anions. The dimeric complex cation is built by two $[Cu(terpy)(N_3)]^+$ units, linked through two azide groups in an end-on fashion, and related by a crystallographic inversion centre.

The geometry of the coordination sphere around the copper(II) ion can be described as distorted square pyramidal. The basal positions are occupied by the three nitrogens of the terpyridine ligand

$i = 1-x, -y, 1-z$.

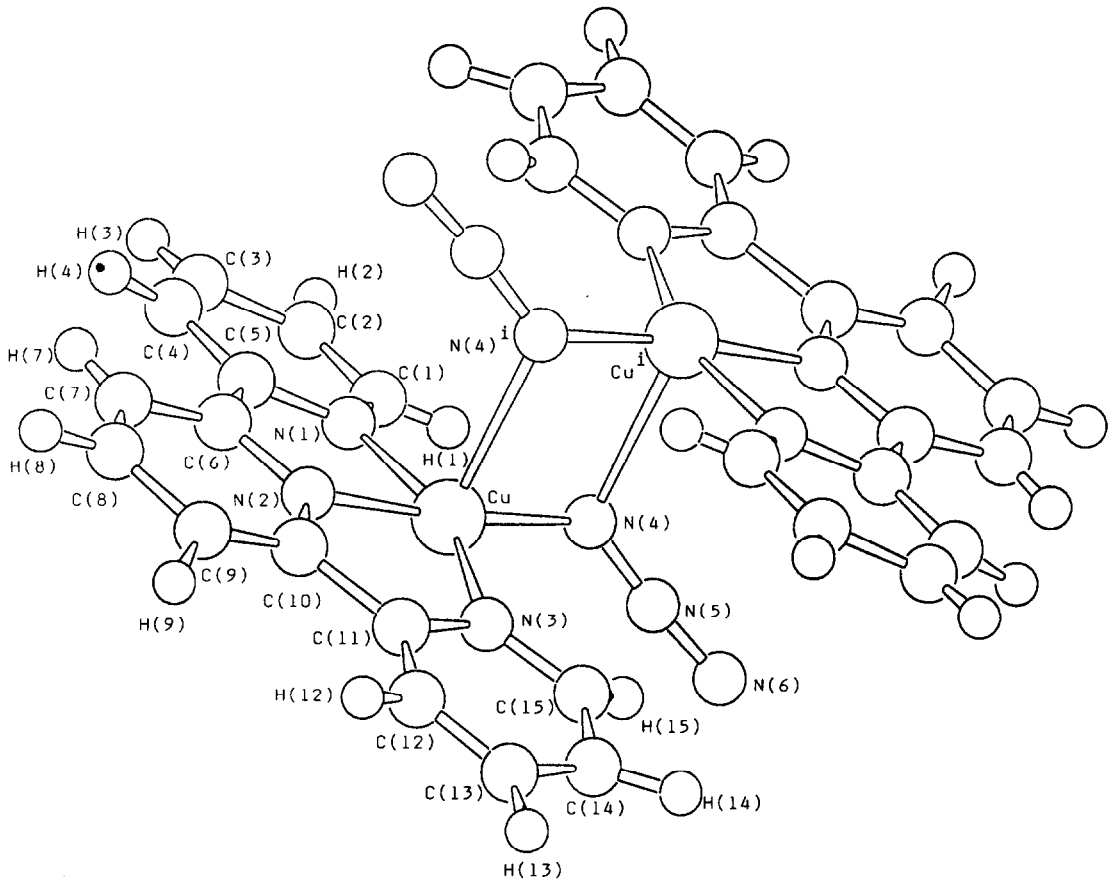

Fig. 1. Molecular structure of the dimeric cation $[Cu_2(C_{15}H_{11}N_3)_2(N_3)_2]^{2+}$.

[Cu—N(1), N(2), N(3); 2.030(8), 1.933(6), 2.005(7) Å, respectively] and one N-azide group [Cu—N(4), 1.954(7) Å]. The apical site is occupied by the other N-azide ligand [Cu—N(4)^i = 2.469(6) Å; $i = 1-x, -y, 1-z$], belonging to the other half of the dimer. The average value of the angles N apical—Cu—N basal is 91(5)°, while the *trans*-basal angles, N(1)—Cu—N(3) and N(2)—Cu—N(4) are 158.5(3) and 173.8(3)°, respectively. The basal atoms are coplanar within ±0.11 Å and the copper(II) ion is practically situated in this mean basal plane (the displacement is 0.03 Å). The departure of these angles from the ideal values of a regular square pyramid is due to the rigid nature of the tridentate ligand. The distortion of the coordination polyhedron from trigonal bipyramid (Δ = 0) towards a regular square pyramid (Δ = 1), has been calculated by quantification of the Muetterties and Guggenberger description.[17,18] The value obtained, Δ = 0.91 (Table 2), is in good agreement with a topology near to regular square pyramidal.

The bridging network Cu_2N_2 is planar due to the

$\Delta = |[(\delta a_1 + \delta a_3 + \delta a_4 + \delta a_6) - 406.0]/182.7| + |[(\delta a_2 + \delta a_5) - 203.0]/248.4| + |[(\delta e_1 + \delta e_2) - 106.2]/187.2| + |(53.1 - \delta e_3)/477.9|$.

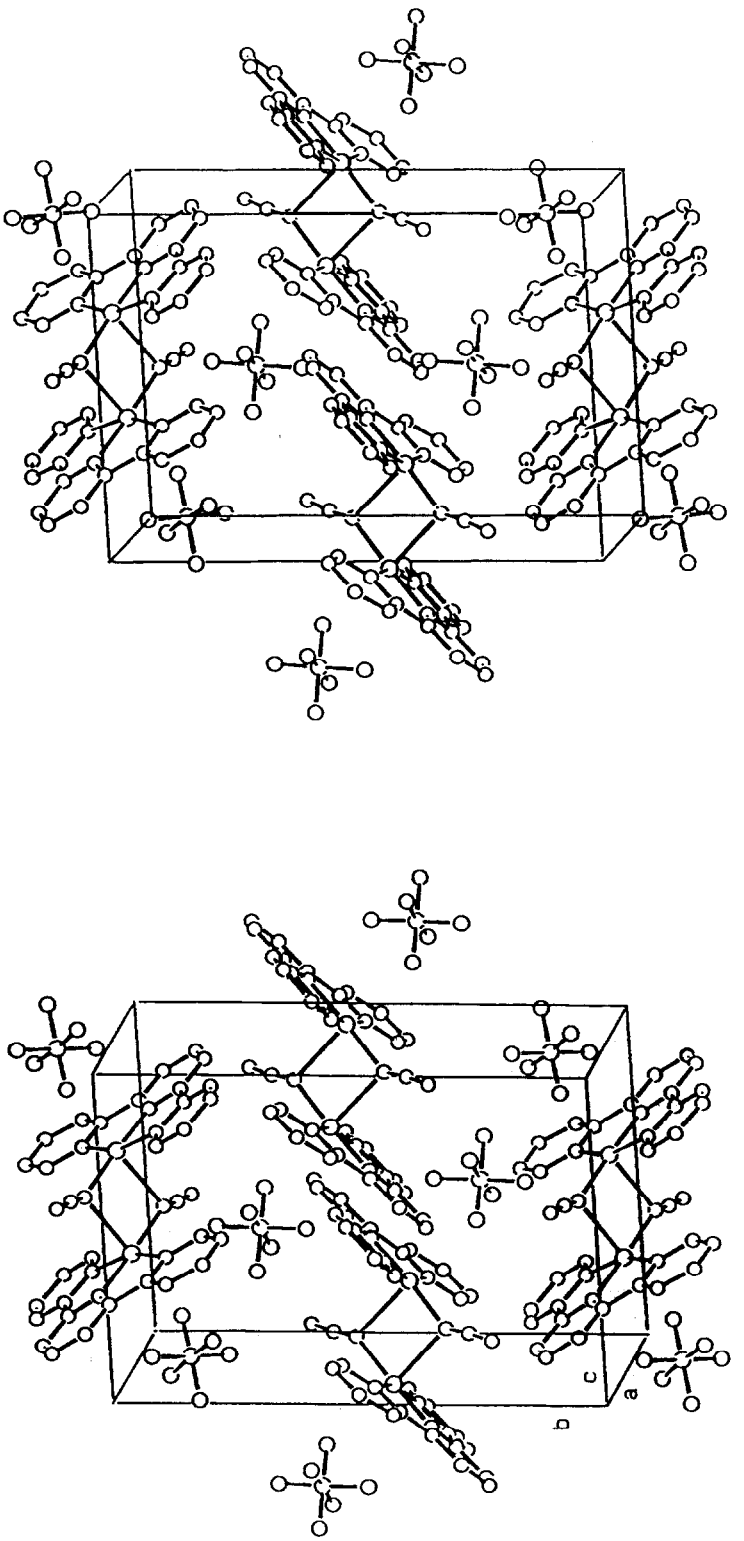

Fig. 2. Stereoscopic view of the molecules in the unit cell.

presence of a crystallographic inversion centre in the dimer. The intradimeric Cu—Cu distance is 3.313(2) Å, and the bridging angle Cu—N(4)—Cu^{i} is equal to 96.3(3)°. The end-on azide group is found to be linear within experimental error [angle N(4)—N(5)—N(6) is 174.5(8)°]. The value for the angle Cu—N(4)—N(5) [129.4(5)°] lies within the expected range for the angle of a trigonally hybridized nitrogen.[19] The N(4)—N(5) and N(5)—N(6) bond lengths are 1.20(1) and 1.15(1) Å, respectively. The values obtained for both bond distances and angles in the tridentate terpy ligand are in good agreement with those given in the literature.[20-22]

(*Received* 21 *March* 1991; *accepted* 2 *July* 1991)

Abstract—The interaction of $[MgCl_2(THF)_2]$ with $[MoCl_3O(THF)_2]$ in 1 : 1 and 1 : 2 ratios in CH_2Cl_2 gave the paramagnetic complexes $[(THF)_3Mg(\mu\text{-}Cl)_3MoCl_2O]$ **I** and $[\{MoCl_4O(THF)\}_2Mg(THF)_4]\cdot CH_2Cl_2$ **II** (THF, tetrahydrofuran). In complex **I**, the molybdenum and magnesium atoms are octahedrally surrounded by three bridging chlorine atoms and terminal oxo-oxygen and two chlorine atoms and by three THF molecules, respectively. Complex **II** consists of Mg^{2+} ions coordinated by four THF molecules and two *trans*-$[MoCl_4O(THF)]^-$ anions coordinated to an Mg atom by oxo O-atoms.

In a previous paper we described the synthesis and properties of the product formed during reaction between $[MgCl_2(THF)_2]$ and $[MoCl_3O(THF)_2]$ in tetrahydrofuran.[1]

$$[MgCl_2(THF)_2]+2[MoCl_3O(THF)_2]\xrightarrow{THF}[Mg(THF)_6][MoCl_4O(THF)]_2 \quad (1)$$

$$2[MgCl_2(THF)_2]+[MoCl_3O(THF)_2]\xrightarrow{THF}[Mg_2(\mu\text{-}Cl)_3(THF)_6][MoCl_4O(THF)] \quad (2)$$

The Mo^{5+} ion is a stronger Lewis acid than Mg^{2+} (reactions 1 and 2) removes chloride ions from $[MgCl_2(THF)_2]$. The formation of $[Mg(THF)_6]^{2+}$, $[Mg_2(\mu\text{-}Cl)_3(THF)_6]^+$, $[MgCl(THF)_5]^+$ and $[MgCl_4]^{2-}$ ions from $[MgCl_2(THF)_2]$ under the influence of transition metal chlorides MCl_n in THF is well documented.[1–4] However, in less polar solvents the formation of the molecular compounds could be expected. Here we describe the results of the study of reaction between $[MgCl_2(THF)_2]$ and $[MoCl_3O(THF)_2]$ in 1 : 1 and 1 : 2 molar ratios in CH_2Cl_2 and the crystal structure of complex $[\{MoCl_4O(THF)\}_2Mg(THF)_4]\cdot CH_2Cl_2$ **II**.

EXPERIMENTAL

Reactions were carried out under dinitrogen using dried solvents and conventional Schlenk apparatus. The complexes $[MoCl_3O(THF)_2]$ and $[MgCl_2(THF)_2]$ were obtained by literature methods.[5,6] ESR spectra were obtained on an SE type X spectrometer, variable temperature (4.2–298 K). Magnetic susceptibility measurements were determined by the Faraday method. IR spectra were obtained using a Perkin–Elmer spectrometer (values in cm^{-1}).

Tris(tetrahydrofuran)magnesium - tri - μ - chloro-oxodichloromolybdenum(V). $[MoCl_3O(THF)_2]$ (1.32 g, 3.64 mmol) was dissolved in 40 cm^3 of CH_2Cl_2 and $[MgCl_2(THF)_2]$ (0.87 g, 3.66 mmol) was suspended in 50 cm^3 of CH_2Cl_2. The solutions were mixed and the stirring was continued until the compounds dissolved. The solution was filtered off and the volume was reduced *in vacuo* to *ca* 50 cm^3. The solution was exposed to slow diffusion of n-hexane. After 24 h green crystals appeared which were filtered off, and washed with n-hexane (3 × 10 cm^3). Yield: 1.5 g, 77.8%. Found: C, 27.1; H, 4.5; Cl, 33.6; Mo, 18.0; Mg, 4.5. $C_{12}H_{24}Cl_5MgMoO_4$ requires: C, 27.2; H, 4.6; Cl, 33.5; Mo, 18.1; Mg, 4.6%; IR ν(Mo=O) 980 (s); other bands: 298 (m), 350 (s), 680 (w), 742 (s), 870 (s), 922 (w), 996 (m), 1020 (vs), 1176 (w), μ_{eff} = 1.6 μ_B (77–298 K), ESR, g = 1.950.

Trans - *bis*[trans - *tetrachloro-oxo(tetrahydrofuran)molybdenio(V)*-O] - *tetrakis(tetrahydrofuran) magnesium dichloromethane.* $[MoCl_3O(THF)_2]$ (3.9 g, 10.8 mmol) was dissolved in 60 cm^3 of CH_2Cl_2 and $[MgCl_2(THF)_2]$ (1.3 g, 5.4 mmol) was sus-

* Author to whom correspondence should be addressed.

pended in 40 cm^3 of CH_2Cl_2. The solutions were mixed and the stirring was continued until the compounds dissolved. The solution was filtered off and the volume was reduced *in vacuo* to *ca* 50 cm^3. After 24 h the green–yellow crystals which were obtained by slow diffusion of *n*-hexane into the solution were filtered off, and washed with *n*-hexane (3×10 cm^3). Yield: 4.6 g, 83.2%. Found: C, 28.8; H, 4.9; Cl, 34.0; Mo, 18.5; Mg, 2.5. $C_{25}H_{50}Cl_{10}MgMo_2O_8$ requires: C, 28.6; H, 4.8; Cl, 33.8; Mo, 18.3; Mg, 2.3%; IR ν(Mo=O) 946 (s), other bands: 278 (m), 316 (m), 354 (vs), 678 (w), 698 (w), 864 (vs), 920 (s), 1018 (vs), 1046 (w), $\mu_{eff} = 2.1$ μ_B (4.2–298 K); ESR, g (1.975, 1.969, 1.906).

The green crystalline compound **II** on heating above 373 K or *in vacuo* (6 h, 10^{-3} hPa) lost CH_2Cl_2 and collapsed to a green–yellow powder. Found: C, 29.8; H, 4.9; Cl, 30.0; Mo, 19.5; Mg, 2.5. $C_{24}H_{48}Cl_8MgMo_2O_8$ requires: C, 29.9; H, 5.0; Cl, 29.4; Mo, 19.9; Mg, 2.5%.

X-ray crystal structure determination

Specimens ($0.5 \times 0.5 \times 1.0$ mm) for **I** and ($0.8 \times 0.8 \times 0.35$ mm) for **II** were cut from larger crystals and sealed in capillaries. For both crystals intensity data were recorded on a Syntex $P2_1$ automated diffractometer using graphite-monochromatized Mo–K_α radiation. Intensities were measured using a 2θ–ω scan technique up to $2\theta = 66°$ and to $2\theta = 52°$ for **I** and **II**, respectively. The intensities of two standard reflections, monitored after every 50 intensity scans, showed no evidence of crystal decay. 2745 [4000] reflections were collected, of which 2069 [3827] [$I > 3\sigma(I)$] were used for the structure analysis for **I** and **II**, respectively. (For **II** only reflections above background were measured.) The data were corrected for background attenuation and polarization effects. For **II** an absorption correction following the DIFABS procedure[7] was applied; minimum and maximum corrections were 0.897 and 1.059, respectively.

Structure determination and refinement

Both structures were solved by direct methods using the SHELXS program.[8] In the case of **I** preliminary Weissenberg photographs showed $P6_3$ or $P6_3/m$ space groups. The non-centrosymmetric space group was assumed, in which Mo and Mg atoms lie on a three-fold axis. This situation is only possible when an oxo O and two terminal Cl atoms bonded to an Mo atom are statistically disordered. Furthermore, because of a so-called structural *trans* effect observed in monooxo complexes[9] the Mo atom also should be slightly disordered around the three-fold axis. This was visible in the large values of B_{11} and B_{22} temperature factors for Mo atoms. Since the positions of O and two terminal Cl atoms are very similar (by symmetry) it was not possible to uniquely distinguish their positions. Therefore no attempt was made to find the detailed crystal structure of this complex. The refinement stopped at $R = 0.07$ for 994 reflections with $I > 3$ (**I**). The principal interatomic distances are: Mg—O 2.03(1), Mg—Cl 2.55(1) and Mg···Mo 3.39(1) Å. In the case of **II** all heavy atoms were found from direct methods and H-atoms were included in geometrically calculated positions with d(C—H) = 1.08 Å. Full-matrix least-squares refinements were carried out on the positional and anisotropic thermal parameters of all the non-hydrogen atoms. Least-squares refinement converted with $R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o| = 0.035$ and $R' = (\Sigma w \Delta F^2 / \Sigma w F_o^2)^{1/2} = 0.0408$; where $w = 1/\sigma^2(F_o)$. Neutral-atom scattering factors were taken from ref. 10. The scattering factors for Mo, Mg, Cl, O and C were corrected for real and imaginary components. A final difference map showed features in the range -0.26 to $+0.32$ eÅ^{-3}. A summary of crystallographic data for compounds **I** and **II** is given in Table 1.

Atomic coordinates, displacement factor coefficients and the list of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis and structure of [$(THF)_3Mg(\mu\text{-}Cl)_3MoCl_2O$]

The interaction of bis(tetrahydrofuran)magnesium dichloride with [$MoCl_3O(THF)_2$] in 1:1 molar ratio in dichloromethane leads to good yields of the green crystalline complex **I** of the above stoichiometry

$$[MoCl_3O(THF)_2] + [MgCl_2(THF)_2] \xrightarrow[CH_2Cl_2]{} \underset{\mathbf{I}}{[(THF)_3Mg(\mu\text{-}Cl)_3MoCl_2O]} + THF. \quad (3)$$

The IR spectrum in Nujol shows the expected bands due to ν(COC) of coordinated THF molecules at 1020 (s) and 870 (s) cm^{-1} and sharp bands at 980 (s) and 350 (s) cm^{-1} due to ν(Mo=O) and ν(Mo—Cl), respectively; by comparison with the $[Mg_2(\mu\text{-}Cl)_3(THF)_6]^+$ cation[1] the peak at 298 cm^{-1} attributed to ν(Mg—O). The crystalline compound **I** is very reactive, undergoing immediate de-

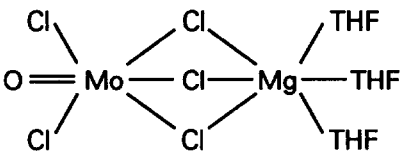
$R(F_o) = 0.035$
$R_w(F_o) = 0.0408$

composition on exposure either to air or moisture but is stable in a closed flask in the solid state and in solution of CH_2Cl_2 under N_2. It is soluble in halogenated solvents, insoluble in hydrocarbons and unstable in THF because the magnesium easily undergoes solvation and the salt $[Mg(THF)_6][MoCl_4O(THF)]_2$ is formed immediately. The compound **I** is paramagnetic, with $\mu_{eff} = 1.6\ \mu_B$ and the ESR spectra in frozen CH_2Cl_2/toluene solution and in the solid state are typical of Mo^{5+} complexes.[1] The molecular structure of **I** was shown by spectroscopic methods to contain molybdenum and magnesium atoms surrounded octahedrally by three bridging Cl atoms and terminal oxo-oxygen and two Cl atoms and three THF molecules, respectively as depicted schematically in Scheme 1.

The course of reactions (1) and (2) in THF is different and the salts $[Mg(THF)_6][MoCl_4O(THF)]_2$ and $[Mg_2(\mu\text{-}Cl)_3(THF)_6][MoCl_4O(THF)]$ are formed. The $[(THF)_3Mg(\mu\text{-}Cl)_3Mg(THF)_3]^+$ cation arises in the reaction:

$$[MgCl_2(THF)_2]+[MgCl(THF)_5]^+ \xrightarrow{THF} [(THF)_3Mg(\mu\text{-}Cl)_3Mg(THF)_3]^+. \quad (4)$$



Scheme I. Schematic structure of the $[(THF)_3Mg(\mu\text{-}Cl)_3MoCl_2O]$ molecule.

This cation is stable only in the solid state and is the component of other salts, e.g. $[Mg_2(\mu\text{-}Cl)_3(THF)_6][TiCl_5(THF)]$[11] or $[Mg_2(\mu\text{-}Cl)_3(THF)_6][MoCl_4O(THF)]$.[1]

Synthesis and structure of $[\{MoCl_4O(THF)\}_2Mg(THF)_4]\cdot CH_2Cl_2$

This compound is readily obtained in high yield by interaction of $[MgCl_2(THF)_2]$ with $[MoCl_3O(THF)_2]$ in a 1 : 2 molar ratio in CH_2Cl_2:

$$2[MoCl_3O(THF)_2]+[MgCl_2(THF)_2] \xrightarrow{CH_2Cl_2} [\{(THF)Cl_4MoO\}_2Mg(THF)_4]\cdot CH_2Cl_2. \quad (5)$$
II

Complex **II** is soluble in halogenated solvents, insoluble in hydrocarbons and unstable in THF. The IR spectrum in Nujol shows stretching modes at 1040 (sh), 1018 (vs), 864 (vs, br) cm^{-1} attributed to ν(COC) and sharp band at 946 cm^{-1} due to ν(Mo=O) which is shifted to lower frequences compared to ν(Mo=O) 980 cm^{-1} found in the $[MoOCl_4(THF)]^-$ anion.[1] The band at 353 (vs) cm^{-1} is assigned to Mo—Cl stretching and at 330 (s) and 278 (m) cm^{-1} to Mg—O vibrations.[1] The stoichiometry of **II** and the shifting of the ν(Mo=O) band to lower frequencies by 34 cm^{-1} in comparison to the $[MoCl_4O(THF)]^-$ ion[1] suggested that the $[MoCl_4O(THF)]^-$ unit was coordinated by solvated magnesium Mg^{2+} and this formation is confirmed by the X-ray study. The structure of the $[\{MoCl_4O(THF)\}_2Mg(THF)_4]$ molecule is in Fig. 1 and some important molecular geometry parameters are given in Table 2. The magnesium atom is octahedrally coordinated by four tetrahydrofuran molecules and two $[MoCl_4O(THF)]^-$ units by O-atoms in *trans* positions. The Mg—O(1,2) bond lengths 2.159(6) and 2.175(5) Å are longer than the respective Mg—O distances of 2.11(1), 2.09(1) Å in $[(ReMe_4O)Mg_2(THF)_4]$[12] and $[\{o\text{-}C_6H_4(CH_2)_2WO\}_2Mg(THF)_4]$.[13] Viewing along the Mo—Mg—Mo axis, the $Mg(THF)_4$ units look like a system of propellers, although each of the THF ligands has a different conformation. The THF molecules containing O(3) and O(4) atoms have

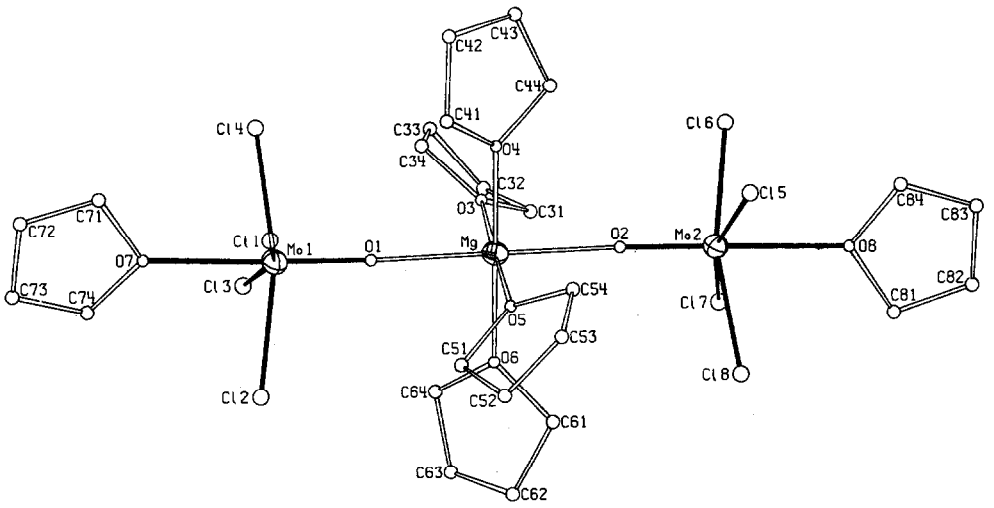


Fig. 1. View of $[\{MoCl_4O(THF)\}_2Mg(THF)_4]$ molecule.

conformations between twist and envelope with asymmetric C(31), C(32) and O(4), C(41) atoms, respectively. The THF molecule with O(6) atom has the twist conformation with C(61) and C(62) atoms moved below and above the plane of the ring, respectively. An envelope conformation is found for THF molecule containing O(5), with atom C(52) displaced from the best plane. The THF ring with atom O(7) is planar and this means that its conformation is an average of different conformations or equivalent ones with mirror symmetry relationships. High temperature factors give additional support for this supposition. The conformation of the tetrahydrofuran molecule with atom O(8) is a distorted envelope. The O(8) atom is deflecting much more as in the typical envelope case.

Complex **II** is paramagnetic with temperature (4.2–298 K) independent μ_{eff} *ca* 2.1 μ_B per two molybdenum centres (the plot of $1/\chi$ against T gives a straight line of slope passing through the origin). The 2.1 μ_B value is too low for two d^1 unpaired electrons of Mo^{5+} (2.83 μ_B), but we do not know

the reason. It is noteworthy that for linear trimetallic complexes where the central metal is diamagnetic antiferromagnetic interactions between the d^1 centres have been observed.[14]

The structure and bond lengths and angles of the $[MoCl_4O(THF)]^-$ units are similar to those found in $[Mg(THF)_6][MoCl_4O(THF)]_2$ and $[Mg_2(\mu\text{-}Cl)_3(THF)_6][MoCl_4O(THF)]$ salts.[1,15,16] Other tetrahydrofuran-solvated magnesium molecular species such as $[(THF)_4Mg(\mu\text{-}Cl)_2FeCl_4]$[17] and $[\{(Me_3P)_3CoN_2\}_2Mg(THF)_4]$[18] are also known.

The adducts of oxo-oxygen molybdenum species like $[MoCl_4O(THF)]^-$ with Lewis acids were unknown. Note, that the $[\{(THF)Cl_4MoO\}_2Mg(THF)_4]$ complex could be obtained only in halogenated solvents because in THF $[Mg(THF)_6][MoCl_4O(THF)]_2$ and $[Mg_2(\mu\text{-}Cl)_3(THF)_6][MoClO_4(THF)]$ compounds are formed (reactions 1 and 2). However, the compounds $[(ReMe_4O)_2Mg(THF)_4]$ and $[\{o\text{-}C_6H_4(CH_2)_2WO\}_2Mg(THF)_4]$ arise in reactions of Grignard reagent or MgR_2 with Re_2O_7 or WCl_4O in tetrahydrofuran.[13,14] Hence it follows that molybdenum oxo-oxygen Mo=O is a weaker base than similar oxo-oxygens of Re=O and W=O because the oxo-oxygen of Mo=O does not form an adduct with Mg^{2+} in THF.

SYNTHESIS, CHARACTERIZATION AND STEREOCHEMISTRY OF BIS(ACETYLACETONATO) DIISOTHIOCYANATO SILANE

SURAJ P. NARULA,* RAVI SHANKAR, BALWANT KAUR and SAJEEV SONI

Department of Chemistry, Panjab University, Chandigarh-160014, India

(*Received* 12 *December* 1990; *accepted* 2 *July* 1991)

Abstract—A hexacoordinated monomeric silicon(IV) complex, $(acac)_2Si(NCS)_2$ [where acac = $(CH_3COCHCOCH_3)^-$] was isolated and characterized by elemental analyses, IR, multinuclei (^1H, ^{13}C and ^{29}Si) NMR spectral data. Initially the complex has the *cis*-structure in solution which changes to an equilibrium mixture (1.8 : 1) of *cis* and *trans* isomers at room temperature in 24 h.

Only a few neutral hexacoordinated complexes of silicon with 1,3-diketonate ligands have been reported[1–4] and their stereochemical lability studied by dynamic NMR spectroscopy and kinetic measurements.[5–9] Amongst the known complexes of the type $(acac)_2SiR_2$, the complexes where R=Cl or Ph, adopt the *trans* structure[3,4] while for R=OAc, it exists in the *trans* form but isomerizes in solution to give an equilibrium mixture of *cis–trans* isomers.[5,6] The heterosubstituted complexes, $(acac)_2SiR'R''$ (where R'=Cl and R''=Me or Ph) exist in non-rigid *cis* form in solution.[7] However, there is no report on the acetylacetonates with other substituents on the silicon atom. Therefore, isolation and characterization of a new homo-substituted bis(acetylacetonato) diisothiocyanato silane, $(acac)_2Si(NCS)_2$ was undertaken and results are reported herein.

EXPERIMENTAL

All operations were carried out under an oxygen-free dry nitrogen atmosphere. Solvents were dried by conventional methods. Silicon tetrachloride (Fluka) was distilled before use.

IR spectra were recorded as Nujol mulls using NaCl/polyethylene optics on a Perkin–Elmer 1430 ratio recording spectrophotometer. ^1H, ^{13}C and ^{29}Si NMR in $CDCl_3$ taking TMS as internal reference were recorded on a Bruker (AM 500) 500 MHz instrument at TIFR (Bombay, India). Elemental analyses of the samples were obtained using a Carlo Erba Strumentazione (Italy) elemental analyser-Model 1106. Mass spectra were recorded on V-G micromass MM 70/70F double focusing spectrometer. Molecular weight of the complex was determined cryoscopically in nitrobenzene.

Preparative methods

Diethoxy/di-n-propoxy diisothiocyanato silanes were prepared by a method already known in literature.[10] The purity of these compounds was checked by elemental analyses, IR, ^1H, ^{13}C and ^{29}Si NMR spectral data.

Preparation of bis(acetylacetonato) diisothiocyanato silane

Acetylacetone (2.0 g, 0.02 mol) in THF was added dropwise to diethoxy/di-*n*-propoxy diisothiocyanato silane (2.34/2.62 g, 0.01 mol) in the same solvent and the mixture was stirred for 15 h at room temperature. The clear solution so obtained was concentrated and n-hexane was added to it. A white solid was precipitated out in each case which was filtered, washed with n-hexane and dried *in vacuo*. The solid was recrystallized in aceto-nitrile/n-hexane mixture. Yield 1.8 g, 53%, m.p. 122–124°C (decomp.). Found: C, 41.8; H, 4.0; N, 8.1; S, 18.4; Si, 7.9. Calc. for $C_{12}H_{14}N_2O_4S_2Si$: C, 42.1; H, 4.1; N, 8.2; S, 18.7; Si, 8.2%. Mol. wt. Found 368; required 342. MS (70 eV): *m/z* (rela-

tive intensity %) 284 (100) [M^+—NCS], 243(9.5) [M^+—acac], 226(25.2) [M^+—2NCS], 59(64.9) $[HNCS]^+$.

RESULTS AND DISCUSSION

Bis(acetylacetonato) diisothiocyanato silane is is obtained from the reaction of dialkoxy diisothiocyanato silane with acetylacetone as,

$$(RO)_2Si(NCS)_2 + 2acacH \xrightarrow{THF} (acac)_2Si(NCS)_2 + 2ROH.$$
$$(R = Et \text{ or } n\text{-}Pr)$$

Elemental analyses and cryoscopically determined molecular weight conform to the above composition. The compound is a white hygroscopic solid, soluble in organic polar solvents. It decomposes on prolonged standing even under inert atmosphere. Mass spectrum of the compound shows no molecular ion $[M]^+$ peak, but the base peak at *m/z* 284 corresponds to the ion [M^+—NCS]. Conductance of its millimolar solution in acetonitrile ($\Lambda_0 = 14.0$ ohm^{-1} cm^2 mol^{-1}) suggests its non-electrolytic nature.

Spectral data

IR spectrum reveals negative spectral shift of ~ 75 cm^{-1} in the ν CO mode (1550 cm^{-1}) of the compound as compared to the free ligand. In metal–acetylacetonates, this change is attributed to the ligand acting as a bidentate monoanion.[1] The ν CN mode at 2110–2100 cm^{-1} has a positive spectral shift ($\sim$20–25 cm^{-1}) relative to the reactants. This may be due to change in phase/predominant N≡C—S$^{\delta-}$ structure[11] in the complex. The ν CS and δ NCS modes at 720 and 460 cm^{-1} respectively are practically unchanged.

The ^{1}H NMR spectrum of the freshly prepared solution of the title compound in $CDCl_3$ reveals two well-resolved signals at 2.2 and2.3 ppm showing non-equivalent methyl groups in the complex. This non-equivalence can be rationalized on the basis of C_{2v} symmetry of the *cis* structure of the molecule. The methyne proton appears as a singlet at 6.0 ppm. However, after 30 min, two additional signals at 2.1 and 5.7 ppm emerge and grow with time reaching a constant concentration after 24 h. These signals integrate protons in the ratio 6:1. This time-dependent change in the spectral pattern may point to the stereochemical lability of the compound in solution. By analogy with the reported δ ^{1}H NMR values of metal acetylacetonates,[12] the signals at 2.1 and 5.7 ppm may be assigned to CH_3 and CH group protons respectively of the *trans* isomer of the compound. The appearance of only one methyl signal is in agreement with D_{2h} symmetry of the *trans* isomer. On the basis of proton integration of various signals in 1-day-old solution, *cis*: *trans* ratio on the equilibrated sample is found to be 1.8:1.

^{13}C NMR data [*cis*: 25.8, 25.7 (CH_3); 102.9 (CH); 193.1, 192.9 (CO) ppm and *trans*, 24.7 (CH_3); 100.6 (CH); 191.9 (CO) ppm] reveal three signals (two for *cis* and one for *trans*) for the methyl and three signals for the carbonyl carbons in the 1-day-old solution of the compound. As expected[9] only a single resonance is observed for each methyne carbon of *cis* and *trans* isomers. Only one signal is observed for the isothiocyanate carbon at 133.5 ppm.

The ^{29}Si NMR spectrum of the *cis* and *trans* mixture in solution exhibits signals at -199.3 and -214.0 ppm. These values are consistent with the six coordinated silicon atoms in both the compounds.[13]

From the above data, it may be concluded that bis(acetylacetonato) diisothiocyanato silane in solution exists initially as the *cis* isomer but is equilibrated to a *cis–trans* mixture (1.8:1) after 24 h. This is a rare observation in the homo-substituted bis(acetylacetonato) silanes.

MIXED LIGAND COMPLEXES OF RUTHENIUM(III)EDTA WITH NUCLEOSIDES

BADAR TAQUI KHAN† and K. ANNAPOORNA

Department of Chemistry, Osmania University, Hyderabad 500 007, India

(*Received* 22 *October* 1990; *accepted* 28 *June* 1991)

Abstract—Mixed ligand complexes of ruthenium(III)edta with nucleosides, adenosine, guanosine, xanthosine, inosine, cytidine and uridine were synthesized and characterized by elemental analysis, IR spectra, electronic spectra, ^{1}H NMR, ESR and by polarography. Based on the above data it is proposed that the purine nucleosides, adenosine, guanosine, xanthosine and inosine coordinate to the metal ion through N_7 and the pyrimidine nucleoside uridine coordinates to the metal ion through N_3, however cytidine forms a chelate coordinating to the metal ion through N_3 and C_2O.

$K[Ru(edta\text{-}H)Cl]\cdot 2H_2O$ is a well-known complex and its mixed ligand complexes with σ-donor and π-acceptor ligands have been widely studied both in solution and solid state.[1–6] In these mixed ligand complexes edta can act as a pentadentate or a tetradentate ligand leaving one or two coordination positions on the metal ion. Nucleosides which are constituents of nucleic acid form many mixed ligand complexes with platinum group metal ions.[7–15] In our earlier studies we have reported mixed ligand complexes of Ru(III)edta with purines and pyrimidines.[5,6] In the present investigation mixed ligand complexes of ruthenium(III)edta with nucleosides were synthesized and characterized by various physicochemical methods.

EXPERIMENTAL

Materials

Hydrated ruthenium trichloride and nucleosides were purchased from Johnson Matthey Company and Sigma Chemical Company (U.S.A.). The disodium salt of ethylenediaminetetraaceticacid was obtained from BDH chemicals. Solvents used were of high purity and distilled before use.

Synthesis

$K[Ru(edta\text{-}H)Cl]\cdot 2H_2O$, complex **1** was prepared by the method of Ezerskaya and Solovykh[16] as modified by Diamantis and Dubrawski.[17] $K_2[RuCl_5(H_2O)]$ was prepared by a modified method of Mercer and Buckley[18] used as the starting material in the above preparation.

Physical measurements

Elemental analysis of complexes were obtained from the Central Drug Research Institute (Lucknow, India). Potassium analysis was done by flame photometry. Conductivity data were measured on a digital conductivity meter No. DI 909. IR and electronic spectra of the complexes were recorded on Shimadzu IR 435 and UV-160 respectively. Far IR spectra were recorded at RSIC IIT Madras. ^{1}H NMR and ^{13}C NMR spectra were recorded on Jeol 500 MHz spectrometer at TIFR Bombay. Electron paramagnetic resonance spectra were recorded on a Bruker ESP 300 X band instrument at CSMCRI, Bhavnagar, on a Princeton Applied Research Electrochemical Instrument equipped with a precision *X–Y* recorder. A PAR 174, polarographic analyser was used to record dc and differential pulse polarograms.

Preparation of complexes

(2) Potassium(ethylenediaminetetraacetato)adenosine ruthenate(III)
(3) Potassium(ethylenediaminetetraacetato)guanosine ruthenate(III)
(4) Potassium(ethylenediaminetetraacetato)xanthosine ruthenate(III)

† Author to whom correspondence should be addressed.

(5) Potassium(ethylenediaminetetraacetato)inosine ruthenate(III)
(6) Potassium(ethylenediaminetetraacetato)cytidine ruthenate(III)
(7) Potassium(ethylenediaminetetraacetato)uridine ruthenate(III) hexahydrate.

Potassium chloroethylenediaminetetraacetatoruthenate(III) (0.4 mM) dissolved in water was added to a hot solution of the ligand (0.4 mM) (adenosine, guanosine, xanthosine, inosine, cytidine, uridine) in water, when the yellow colour of the solution changed to either red (adenosine, guanosine, xanthosine) or deep yellow (inosine, cytidine, uridine). The pH of the solution was between 3 and 4. The solution was refluxed for 12–16 h in an atmosphere of pure nitrogen and the completion of the reaction was checked by TLC which indicated the presence of a single substance. The solution was concentrated to one-fourth of its volume and was precipitated with ethanol/acetone. The complex was filtered, washed with acetone/water mixture, finally with acetone and was then vacuum dried. The complexes are soluble in water.

RESULTS AND DISCUSSION

The analytical and conductivity data of the complexes are presented in Table 1. The conductivity values in DMSO correspond to 1 : 1 electrolytes.[19] The conductivity in water, however, is much higher than that expected for a 1 : 1 electrolyte. The conductivity values in aqueous solution continuously change and attain an equilibrium value after a long time. This is because of the extensive hydrolysis of the complexes in solution around pH 3–4. The equilibrium in solution is complicated and the solution becomes acidic with increase in hydrolysis as tested by pH measurements. The conductivity of complex **1** is also high because of the dissociation of a proton from an uncoordinated carboxylic acid group and hydrolysis of the metal ion.[3]

The IR spectra of the complexes show the N—H and C—H stretching vibrations due to the coordinated ligand in the region 3100–2950 cm^{-1}. In complex **1** K[Ru(edta-H)Cl]·$2H_2O$ a sharp peak at 1720 cm^{-1} and a broad peak at 1650 cm^{-1} shows the presence of uncoordinated and coordinated carboxylate groups of edta respectively. On complexation the peak at 1720 cm^{-1} disappears, indicating the absence of free COOH group in these complexes. In complexes **2**, **3** and **6** a broad peak at 1640 cm^{-1} is due to the overlap of NH_2 deformation modes of the secondary ligand and also due to the coordinated carboxylate group of edta. The $\nu C{=}O$ stretching frequency of coordinated cytidine in complex **6** shifts to a lower frequency by 20 cm^{-1} and is observed at 1680 cm^{-1} indicating that the $\nu C{=}O$ group is involved in coordination to the metal ion. The $\nu C{=}C$ and $\nu C{=}N$ stretching frequencies of the complexes were shifted to a lower frequency by 30–50 cm^{-1} as compared to the frequencies of the nucleosides observed around 1600–1450 cm^{-1}, indicating the involvement of

7	K[Ru(edta)(urd)]·$6H_2O$	29.0 (29.2)	4.7 (4.6)	7.0 (7.2)	5.0 (5.0)	366	27

[a] Calculated values in parentheses.

ring nitrogens in coordination to the metal ion. The νM—N and νM—O stretching frequencies are observed around 500 and 400 cm^{-1} respectively in these complexes indicating that edta coordinates to the metal ion through oxygen and nitrogen.

The electronic spectral absorption bands and their assignments for the complexes are shown in Table 2. The weak bands in the 500–800 nm region observed in some of the complexes are *d–d* transitions of Ru^{III} with some MLCT character.

The NMR spectra were recorded on a high-resolution spectrometer, as the spectra could not be recorded on a low-resolution spectrometer, because of the paramagnetism of Ru^{III}. A representative spectrum is given in Fig. 1. The NMR spectral data of complex **1** are given in Table 3. In complex **1** edta is pentadentate and the sixth position is occupied by a chloride. The ^1H NMR spectrum of complex **2** shows a downfield shift in C_2H and C_8H proton by 0.13 and 0.54 ppm respectively as compared to the ligand. Since the downfield shift in C_8H proton is more than C_2H proton, it is inferred that adenosine coordinates to metal ion through N_7. The $^{13}C[^1H]$ NMR spectrum of complex **2** also supports the coordination of adenosine to the metal ion through N_7. In the ^{13}C NMR of adenosine, the resonances are as follows: $C_2 = 152.85$; $C_4 = 148.97$; $C_5 = 119.28$; $C_6 = 156.02$; $C_8 = 140.05$ and in the complex the resonances are as follows: $C_2 = 152.85$; $C_4 = 149.0$; $C_5 = 120.01$; $C_6 = 156.12$; $C_8 = 142.67$.

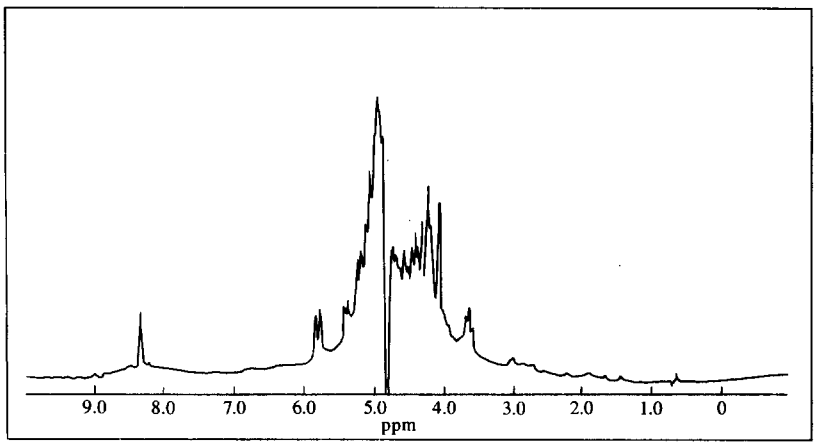

Fig. 1. ^1H NMR spectrum of K[Ru(edta)(xanthosine)].

Since there is a downfield shift in C_8 carbon by 2.62 ppm as compared to resonances in the ligand, the complexation of adenosine to metal ion through N_7 is supported. The ^1H NMR spectra of complexes **3**, **4** and **5** show a downfield shift in C_8H proton by 0.41, 0.30 and 0.88 ppm respectively, indicating that guanosine, xanthosine and inosine coordinate to the metal ion through N_7 in these complexes. The ^1H NMR spectrum of complex **6** shows a downfield shift in C_5H and C_6H protons by 0.77 and 0.56 ppm respectively as compared to the ligand, inferring that cytidine coordinates to the metal ion through N_3 and C_2O. The ^1H NMR spectrum of complex **7** shows a downfield shift in C_5H proton by 0.42 ppm showing that uridine coordinates to the metal ion through N_3. The ribose protons are observed as distinct peaks in the region 2.5 and 6.5 ppm, shown in Table 3 and the edta protons resonate between 3 and 4 ppm.

The electron paramagnetic resonance spectra of the complexes in general show rhombic or isotropic distortions. Complexes **1** and **2** show compressed rhombic distortions with g values 2.37, 2.32 and 1.94; and 2.40, 2.30, 1.99; $g_{av} = 2.23$ respectively. Complexes **3**, **6** and **7** also show rhombic distortions with g values 2.56, 2.30, 1.89, $g_{av} = 2.26$; 2.39, 2.38, 1.94, $g_{av} = 2.21$ and 2.36, 2.26, 2.11, $g_{av} = 2.24$ respectively. Complex **4** shows isotropic distortion with one g value at 2.10.

The electrochemical data of the complexes are given in Table 4. The differential pulse polarogram of complexes show a single peak for the Ru^{3+}/Ru^{2+} couple supporting the formation of 1 : 1 complexes. In these complexes the potentials are more positive as compared to complex **1**, indicating the drift of electron density from metal to the nucleoside ligand, which acts as a weak π-acid. This is further supported by weak MLCT bands around 500 to 800 nm in the electronic spectra of the complexes.

Based on analytical and spectroscopic data, the structures for complexes **2**, **3**, **4** and **5** are shown in Fig. 2, where edta is pentadentate and the ligands coordinate to metal ion through N_7 in these complexes. The structure for complex **6** is shown in Fig. 3, where edta is tetradentate and cytidine acts as a bidentate ligand coordinating to the metal ion

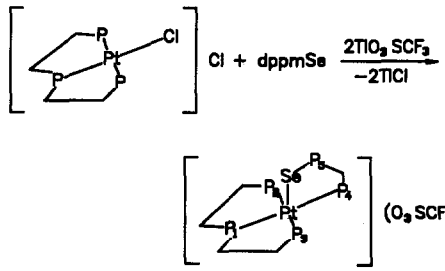
Abstract—The title compounds were generated by the reaction between [$Ptpp_2Cl_2$, dppmE] and TlO_3SCF_3. On the basis of solution ^{31}P, ^{77}Se and ^{195}Pt NMR spectroscopic data, a square-pyramidal structure is proposed with the chalcogen atom in the apical position. In contrast, [Pt(pp_2-P,P′,P″)(dppmO-P)]$(O_3SCF_3)_2$ is four-coordinate. The reaction between $Ptpp_2Cl_2$ and $dppmSe_2$ involves a selenium transfer yielding the *cis* and *trans* isomers of [$PtPhP(CH_2CH_2PPh_2)(CH_2CH_2P(Se)Ph_2$-P,P′)(dppmSe-P,Se)]$(O_3SCF_3)_2$, which are also accessible from [Pt(pp_2-P,P′,P″)(dppmSe-P,Se)]$(O_3SCF_3)_2$ and elemental selenium.

There has been recent interest in platinum(II) coordination complexes with the bidentate mixed Group 15/Group 16 ligands dppmE and $dppmE_2$ (E = O, S, Se) and their anions.[1–5] We report here on the reaction of $Ptpp_2Cl_2$ with dppmE and $dppmE_2$. The former reaction is shown to yield the five-coordinate platinum(II) complexes [Pt(pp_2-P,P′,P″)(dppmE-P,E)]$^{2+}$ (E = S, Se), involving a P_4S or P_4Se donor set.

The vast majority of platinum(II) complexes are square planar, five-coordination is less common. Species of the type $[PtP_4L]^{2+}$ or $[PtP_4X]^+$, i.e. platinum coordinated to four phosphorus donor atoms and one neutral or anionic ligand have been previously reported: $[PtQPCl]^+$ [QP = tris-(*o*-diphenylphosphinophenyl)phosphine], the first compound with a PtP_4Cl core, was reported in 1963.[6] $[Pt(POMe_3)_5]^{2+}$ and $[Pt(PEt_3)_4H]^+$, representing the first complexes involving PtP_5 and PtP_4H cores, were reported in 1973 and 1976.[7–9] Five-coordinate platinum complexes with a PtP_4Hg core have been reported recently.[10]

Reaction of $Ptpp_2Cl_2$ *and* dppmSe

$Ptpp_2Cl_2$[11] reacts with dppmSe[12] and TlO_3SCF_3 according to eq. (1).



1 (1)

Product **1** was isolated as yellow crystals, readily soluble in polar organic solvents. On the basis of solution ^{31}P, ^{77}Se and ^{195}Pt NMR spectroscopic data, the structure of cation **1** is proposed to be

*Author to whom correspondence should be addressed.

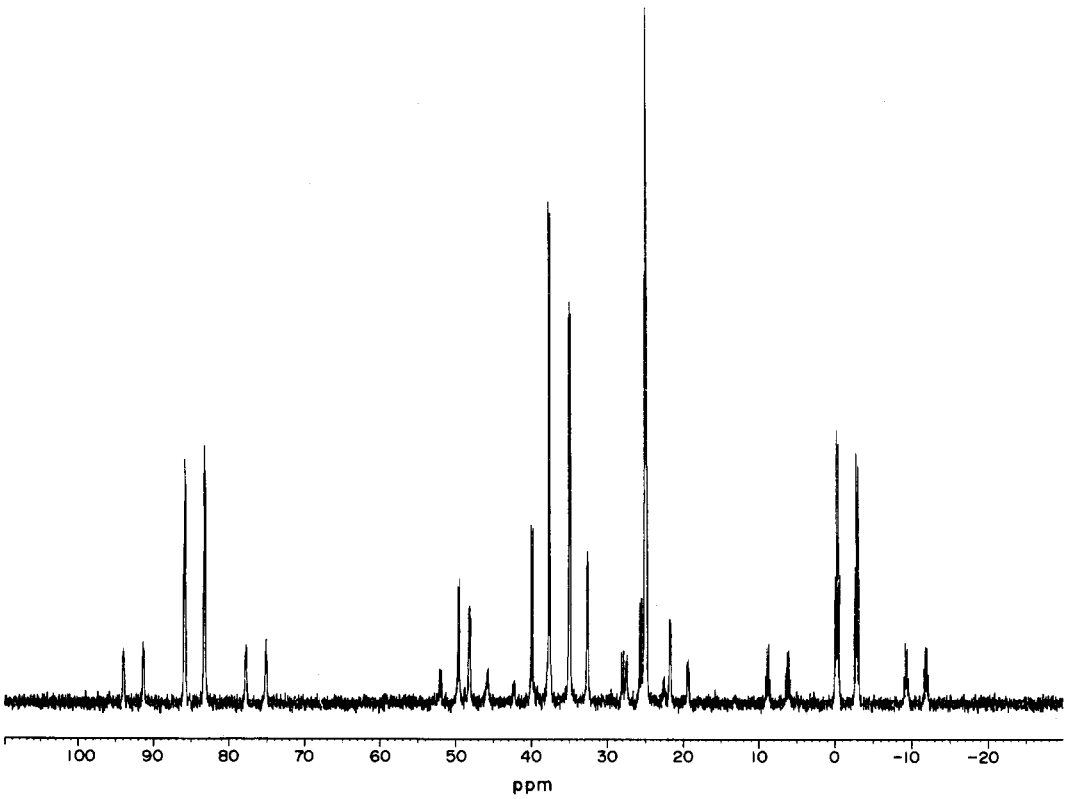


Fig. 1. $^{31}P\{^{1}H\}$ NMR spectrum of **1** (121.4 MHz).

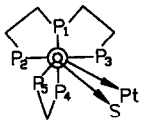
square pyramidal with the selenium atom in an apical position as will be outlined below.

Nuclear magnetic resonance of **1**

^{195}Pt *NMR.* The ^{195}Pt NMR spectrum consists of a dddd signal flanked by ^{77}Se satellites. The Pt—P and Pt—Se coupling constants are in the range of one-bond couplings indicating four phosphorus atoms and one selenium atom coordinated to platinum.

^{31}P *NMR.* The ^{31}P NMR spectrum recorded at 223 K (Fig. 1) shows the presence of five inequivalent phosphorus atoms. The central phosphorus atom of the pp_2 ligand is easily identifiable by its high chemical shift. Its resonance is split by a large two-bond coupling involving the directly bound phosphorus of the dppmSe ligand. A large two-bond coupling is also observed between the terminal phosphorus atoms of the pp_2 ligand. Large $^{2}J(PP)$ couplings indicate the P_1PtP_4 and P_2PtP_3 angles to be near 180°. This requirement is fulfilled in a square pyramidal-like geometry as indicated in eq. (1). The inequivalence of the terminal phosphorus atoms of the pp_2 ligand (Fig. 1) may originate from a twisted conformation of the PtdppmSe chelate ring:* molecular structures of PtdppmS and PtdppmO chelate rings showed the phosphine sulphide and phosphine oxide phosphorus atoms to be out of the coordination plane.[2] An analogous conformation of the PtdppmSe ring would cause inequivalent environments of the terminal phosphorus atoms of the pp_2 ligand. This is sketched below using the positional parameters of a PtdppmS ring.[2] The



inequivalent terminal phosphorus atoms should render the central phosphorus atom of the pp_2 ligand and the platinum centre to be chiral. Despite the two chiral centres only one set of ^{31}P NMR parameters could be resolved, indicating the absence of NMR identification of the stereoisomers according to whether the phenyl group on the central phosphorus of the pp_2 ligand and the selenium atom are mutually *cis* or *trans*. *Cis–trans* isomers

* However, it is unlikely that the barrier to interconversion of the two twisted conformations of the chelate ring will be high enough for this; we thank the referee for pointing this out.

have been reported for some iridium[13] and rhodium[14] complexes of PhP(CH$_2$CH$_2$CH$_2$PCy$_2$)$_2$ (Cy = Cyclohexyl) or ^{t}BuP(CH$_2$CH$_2$CH$_2$PPh$_2$)$_2$, whilst other complexes involving the same metals and ligands only one isomer was observed.

At ambient temperature, the signals of the terminal phosphorus atoms of the pp$_2$ ligand are broadened, indicating a process which interchanges the chemical shifts of these phosphorus atoms.

The phosphine selenide signal is flanked by ^{77}Se satellites. The ^{77}Se—^{31}P coupling (624 Hz) is reduced from that of free dppmSe and this is typical for the coordination of phosphine selenides.[1-3] The chemical shifts of the directly-coordinated phosphorus of dppmSe and the phosphine-selenide phosphorus atom are at −4.0 and 27.5 ppm in comparison with a range of 18.1–24.4 and 32.1–44.1 ppm for other PtdppmSe chelate rings.[1-4] These two parameters were found to depend strongly on the nature of the ligands in the *trans* position in square-planar complexes.[2,4] Since selenium in the apical position has no *trans* ligand, this may account for the anomalous behaviour.

^{77}Se *NMR*. The selenium signal at −371 ppm relative to Me$_2$Se consists of a doublet due to the one bond ^{77}Se—^{31}P coupling and is flanked by ^{195}Pt satellites. The resonance is at lower frequencies in comparison with free dppmSe. By contrast, all selenium shifts of PtdppmSe coordination compounds appear at higher frequencies.[1-3]

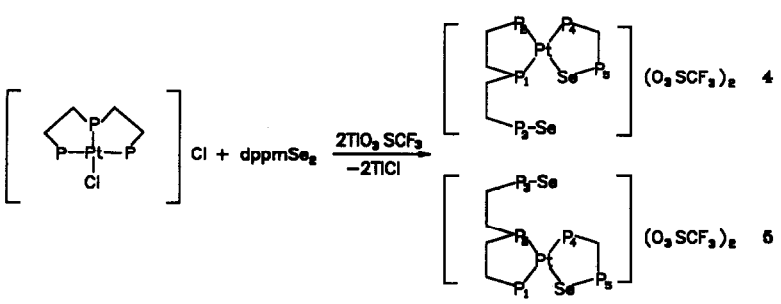
Reactions of Ptpp$_2$Cl$_2$ *with* dppmS *and* dppmO

The yellow complex [Ptpp$_2$dppmS](O$_3$SCF$_3$)$_2$ (**2**) was obtained analogously to eq. (1). The NMR characteristics (Table 1) parallel that of **1** so that a five-coordinate structure [Pt(pp$_2$-P,P′,P″)(dppmS-P,S)](O$_3$SCF$_3$)$_2$ is proposed by analogy. In contrast, [Ptpp$_2$dppmO](O$_3$SCF$_3$)$_2$ (**3**) is colourless and the NMR data (Table 1) provide no evidence for the coordination of oxygen to platinum. This can be rationalized in view of the poorer donor abilities of the hard oxygen in comparison to the soft sulphur and selenium.

Reaction of Ptpp$_2$Cl$_2$ *with* dppmE$_2$ (E = Se, S, O)

The reaction of Ptpp$_2$Cl$_2$, dppmSe$_2$ and TlO$_3$SCF$_3$ was anticipated to result in the coordination of dppmSe$_2$ in a mono- or bidentate manner. Instead, one selenium atom of dppmSe$_2$ is transferred to the pp$_2$ ligand and a mixture of **4** and **5** [eq. (2)] is formed. A similar selenium migration has been observed previously.[4] The same products are obtained upon reaction of **1** with elemental selenium. It is interesting to note that the pp$_2$–selenide ligand present in **4** and **5** does not exist out of the



(2)

platinum coordination sphere: the reaction of pp_2 with 1 meq selenium yields the isomer $Ph(Se)P(CH_2CH_2PPh_2)_2$ according to the higher basicity of the central phosphorus atom.

Complexes **4** and **5** were characterized by ^{31}P NMR spectroscopy (see the Experimental). Complexes **4** and **5** are formed in a ratio of 1:1.3 as estimated by the integration of the ^{31}P NMR spectrum. We were unable to separate **4** and **5**. It is not known if this is due to the similarity of the compounds or to rapid isomerization on the preparative time scale. Down to 233 K, there is no evidence for the coordination of the phosphine selenide to platinum. There is no reaction of $Ptpp_2Cl_2$ and $dppmS_2$ or $dppmO_2$ according to eq. (2).

EXPERIMENTAL

$Ptpp_2Cl_2$ and $dppmE_n$ ($n = 1, 2$; E = O, S, Se) were prepared by published procedures.[11,12] All manipulations were performed under dinitrogen in dried solvents. The NMR spectra were recorded on Bruker WP-80 and AM 300 spectrometers. The chemical analyses were performed by the Institut für Physikalische Chemie der Universität Wien.

$[Ptpp_2(dppmSe)](O_3SCF_3)_2$ (**1**)

A solution of TlO_3SCF_3 (77.8 mg, 0.22 mmol) in methanol (0.3 cm^3) was added dropwise with stirring to $Ptpp_2Cl_2$ (80.1 mg, 0.1 mmol) and dppmSe (46.3 mg, 0.1 mmol) in CH_2Cl_2/MeOH (0.5+0.5 cm^3). After 10 min, the solvent was removed *in vacuo* and the residue was extracted with dichloromethane (1 cm^3) and filtered in order to remove TlCl and excess TlO_3SCF_3. The solvent was removed *in vacuo*. The resulting powder was suspended in methanol and dissolved by dropwise addition of dichloromethane. Slow evaporation yielded yellow crystals of **1**. Found: C, 49.1; H, 3.6. Calc. for $C_{61}H_{55}F_5O_6P_5PtS_2Se$: C, 49.1; H, 3.7%.

$[Ptpp_2(dppmS)](O_3SCF_3)_2$ (**2**)

This was prepared in an analogous method. Found: C, 50.7; H, 3.8. Calc. for $C_{61}H_{55}F_6O_6P_5PtS_3$: C, 50.7; H, 3.8%.

$[Ptpp_2(dppmO)](O_3SCF_3)_2$ (**3**)

This was also prepared analogously. Found: C, 50.4; H, 3.9. Calc. for $C_{61}H_{55}F_6O_7P_5PtS_2 \cdot 0.5CH_2Cl_2$: C, 50.2; H, 3.8%.

$[Pt(PhP)(CH_2CH_2PPh_2)(CH_2CH_2P(Se)Ph_2)(dppmSe)](O_3SCF_3)_2$ (**4**, **5**)

TlO_3SCF_3 (77.8 mg, 0.22 mmol) in CH_3OH (0.1 cm^3) was added to a solution of $Ptpp_2Cl_2$ (80.1 mg, 0.1 mmol) and $dppmSe_2$ (54.2 mg, 0.1 mmol) in CH_2Cl_2/MeOH (0.5+0.5 cm^3). The resulting suspension was stirred for 1 h and filtered to remove precipitated TlCl.

^{31}P NMR data (the labelling scheme is shown in eq. 2): **4**: δP1 57.3, δP2 48.9, δP3 39.7, δP4 27.9, δP5 38.2; J(PtP1) 2311, J(PtP2) 30.48, J(PtP4) 2406; J(P1P2) 6, J(P1P3) 55, J(P1P4) 330, J(P1P5) 35, J(P2P4) 15, J(P2P5) 6, J(P4P5) 48; J(SeP3) 732.

5: δP1 54.7, δP2 46.9, δP3 38.3, δP4 26.0, δP5 35.9; J(PtP1) 2328, J(PtP2) 3038, J(PtP4) 2386; J(P1P2) 6, J(P1P4) 336, J(P1P5) 35, J(P2P3) 43, J(P2P4) 15, J(P2P5) 6, J(P4P5) 48; J(SeP3) 730.

$PhP(Se)(CH_2CH_2PPh_2)_2$

Elemental selenium (7.9 mg, 0.1 mmol) was added to a solution of pp_2 (53.5 mg, 0.1 mmol) in CH_2Cl_2 (0.5 cm^3). The mixture was stirred until a clear solution was obtained.

^{31}P NMR data: δP 42.2, −14.1; J(PP) 42; J(SeP) 727.

A RAPID AND CONVENIENT SYNTHESIS OF TETRAKIS(TRIPHENYLPHOSPHINE)PALLADIUM(0) AND -PLATINUM(0) COMPLEXES BY PHASE-TRANSFER CATALYSIS

MARCELLA IOELE, GIANCARLO ORTAGGI,* MARCO SCARSELLA and GIANCARLO SLEITER*

Centro CNR di Studio sui Meccanismi di Reazione e Dipartimento di Chimica, Università "La Sapienza", P.le Aldo Moro 2, 00185 Roma, Italy

(*Received* 22 *April* 1991; *accepted* 25 *June* 1991)

Abstract—The tetrakis(triphenylphosphine)palladium(0) and -platinum(0) complexes can be prepared with good yields from the corresponding dichlorobis(triphenylphosphine)palladium(II) and platinum(II) complexes using phase-transfer catalysis. A hypothesis on the mechanism is reported.

Tetrakis(triphenylphosphine)palladium(0) (**1**) and -platinum(0) (**2**) are the most commonly used complexes both as starting materials for the preparation of organometallic complexes of these two metals, and for their catalytic effects in many reactions.

For example, **1** is an extremely versatile catalyst for alkene additions and oligomerizations, coupling of organic halides and organometallic carbonylations;[1] **2** catalyses the hydrosilylation of olefins, cleavage of Si—C bonds, carbonylation, hydrogenation and isomerization of olefins.[2]

Although the two complexes are not very stable in the solid state, especially when exposed to air, they are commercially available and may be prepared by several methods, e.g. (a) the action of hydrazine on an alcoholic suspension of bis(triarylphosphine)dihalogenopalladium or -platinum in the presence of an excess of phosphine;[3,4] (b) the action of an excess of triarylphosphine on freshly precipitated palladium oxide;[4] (c) the reaction of an excess of triphenylphosphine with a hot concentrated solution of palladium nitrate;[4] and (d) from chloroplatinate(II), triphenylphosphine and ethanolic potassium hydroxide.[5]

Generally, the two complexes are prepared either by Fitton's modification of the procedure of Malatesta and Angoletta or, more conveniently, by the method of Takahashi.[6]

The method reported by Coulson[7] would presumably be the current one of choice. Now we report a quite general, facile and convenient preparation of **1** and **2** which employs the phase-transfer catalysis, as outlined by the following equations:

$$(Ph_3P)_2MCl_2 + 3Ph_3P + NaOH \xrightarrow[1.5\,M\,NaOH]{THF,\ Bu_4N^+(HSO_4)^-} (Ph_3P)_4M + Ph_3PO + NaCl + HCl$$

M = Pd or Pt.

To a suspension of dichlorobis(triphenylphosphine)palladium(II) (0.17 g, 0.24 mmol) and triphenylphosphine (0.25 g, 0.96 mmol) in peroxide-free THF (10 cm^3) are added 1.5 M NaOH (10 cm^3) and $Bu_4N^+(HSO_4^-)$ (0.01 g) as a phase-transfer catalyst. The mixture is stirred at 25°C for 24 h; then the aqueous layer is removed and the organic yellow phase is evaporated at 40°C *in vacuo*.

The yellow residue is treated with absolute ethanol (5 cm^3), the suspension stirred at 60°C for 20 min, filtered and the solution kept at −15°C for 30 min. Bright-yellow crystals precipitated, that were filtered under argon, washed once with a little cold absolute ethanol (*ca* 1 cm^3) and dried *in vacuo*. Yield: 0.24 g (84%); m.p. 110–115°C (dec.) [lit.[8] m.p. 109–115°C (dec.); lit.[9] m.p. 104–106°C (dec.); lit.[7a] m.p. 116°C (dec.)]. IR, ^1H and ^{13}C NMR spec-

tra were identical to those of a specimen prepared according to Coulson's method and of a commercial sample (Fluka).

The same procedure adopted for the preparation of $(Ph_3P)_4Pt$ gave compound **2** in 87% yield; m.p. 158–160°C (dec.) [lit.[10] m.p. 159–160°C (dec.)] with the spectroscopic properties identical to those of an authentic specimen.

The reaction mechanism probably involves the transport of OH^- ions in the organic phase to form $L_2M(Cl)OH$ by nucleophilic substitution, followed by the rapid substitution of the second chloride by PPh_3 and, according to the general mechanistic scheme, by reductive elimination of a proton and triphenylphosphine oxide.

The triphenylphosphine (in excess) reacts with the coordinatively unsaturated L_2M complex to shift the dissociation equilibrium toward L_4M which precipitates.

(*Received* 18 *February* 1991; *accepted* 25 *June* 1991)

Abstract—A hydrazone ligand (H_2PAPH) derived from pyruvic acid and 4-pyridine carboxylic acid hydrazide and its manganese(II) complex have been synthesized and X-ray diffraction analysis of the complex was carried out. The crystal is monoclinic, space group $P2_1/n$, with unit-cell dimensions $a = 11.252(1)$, $b = 9.828(2)$, $c = 13.708(2)$ Å, $\beta = 66.03(1)°$ and $V = 1385.2$ Å^3, $Z = 4$, $D_c = 2.812$ g cm^{-3}, $F(000) = 1216$, μ(Mo-K_α) = 18.506 cm^{-1}. The structure was solved by the heavy-atom technique from 2417 observed, independent reflections recorded at 293 K and refined to a final $R = 0.028$. The manganese atom has a distorted octahedral coordination with two *trans* water molecules in axial sites and an NO_3 donor set from hydrazone ligands (H_2PAPH) in the equatorial plane. The complex has a polymeric structure. The crystal structure also contains 2.5 water molecules of crystallization, which are involved in a hydrogen-bonding network in the crystal packing. The complex has been also characterized by elemental analysis and IR spectra.

For their chelating capability and pharmacological activity, the chemical properties of hydrazones have received special attention and have been extensively investigated in several research fields.[1–5]

It is well-known that Schiff base complexes with metals have some biological activity, such as anticancer and anti-tumor activity. Because hydrazones are similar to Schiff base chelating agents, we were interested in synthesizing a hydrazone ligand (H_2PAPH) derived from pyruvic acid and 4-pyridine carboxylic acid hydrazine and its complexes with metals to examine their structure, properties and biological activity.

This paper is one of a series on our investigation of metal complexes with H_2PAPH, and describes the synthesis, IR spectra and X-ray crystal structure of manganese(II) complexes with H_2PAPH.

EXPERIMENTAL

Preparations

The hydrazone ligand (H_2PAPH) was prepared by refluxing pyruvic acid (2 g, 23 mmol) and 4-pyridine carboxylic acid hydrazide (3 g, 22 mmol) (1 : 1 molar ratio) in absolute ethanol solution for 6 h. The solution was filtered on cooling and the solid was washed with distilled water and dried *in vacuo* at 80°C. A white powder was obtained; yield, 4.3 g (95%); m.p. 222–3°C. Found: C, 48.1; H, 5.0; N, 18.4. Calc.: C, 48.0; H, 4.9; N, 18.7%.

A saturated $MnSO_4$ solution (1 g) was added to NaOH solution to precipitate $Mn(OH)_2$. The

*Author to whom correspondence should be addressed.

precipitate was filtered and washed with distilled water to separate $MnSO_4$. $Mn(OH)_2$ was then added to a solution of H_2PAPH (0.5 g) in distilled water (30 cm^3). After stirring for 5 h at room temperature, the solution turned yellow (pH = 7). The solution was filtered and the solid was dried *in vacuo* at 80°C (light-yellow powder); yield: 0.5 g (77%). The complex was recrystallized from distilled water to afford orange crystals. Found: C, 35.3; H, 3.6; N, 13.7; Mn, 18.0. Calc.: C, 35.6; H, 3.7; N, 13.5; Mn, 17.5%.

Structure determination

A transparent orange crystal ($0.52 \times 0.37 \times 0.26$ mm) was mounted on an Enraf–Nonius CAD-4 diffractometer. The unit cell was measured by centring 25 reflections ($9 \leqslant \theta \leqslant 16°$) and refined by least-squares. Graphite-monochromated Mo-K_α radiation was used. Intensities were measured with a ω–2θ scan technique (scan width: $0.5+0.35\tan\theta$), θ range: $1 \leqslant \theta \leqslant 26°$ ($h = -13$ to 13; $k = 0$–12; $l = 0$–16). 2765 independent reflections were collected, of which 2417 were considered observed ($I > 3\sigma(I)$). Lorentz and polarization, but no absorption, corrections were made.

The manganese atom was located from a Patterson synthesis and the remaining non-hydrogen atoms from Fourier synthesis. The structure was refined isotropically and the anisotropically by least-squares refinement. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, where $w = 1$. All hydrogen atoms were located from a difference synthesis, and refined with an overall isotropic thermal parameter. The final R factor was 0.028 ($R_w = 0.030$), $(\Delta/\sigma)_{max} = 0.01$ and the final difference-Fourier map showed peaks being less than 0.39 e $Å^{-3}$.

Atomic scattering factors were taken from ref. 6. All calculation were carried out on a PDP 11/44 computer using the SDP package.[7]

RESULTS AND DISCUSSION

Selected interatomic distances and bond angles are in Table 1.

Crystal structure of $[Mn(H_2PAPH)(OH_2)_2]\cdot 2.5H_2O$

Chemical analysis of the manganese(II) complex suggested the formula $Mn(H_2PAPH)(OH_2)_2$. Structure analysis shows that there is one complex unit $Mn(H_2PAPH)(OH_2)_2$ and 2.5 lattice water molecules in the asymmetric unit. The structure of the complex is shown in Fig. 1 and a diagram showing the unit-cell contents is given in Fig. 2.

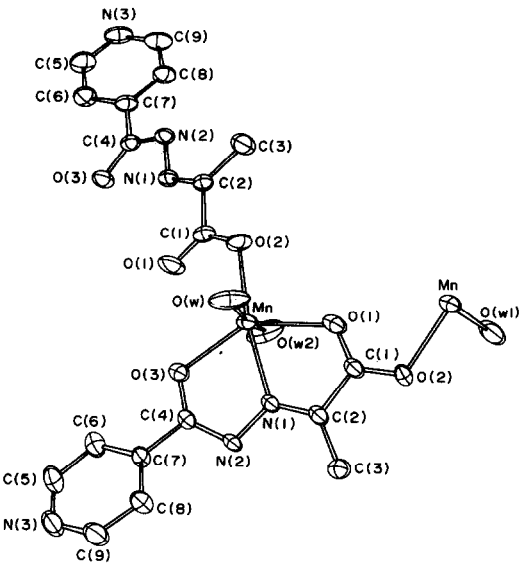

Fig. 1. Structure of the title compound showing the atomic numbering.

The coordination sphere about manganese is a slightly distorted octahedron, with three oxygen atoms and one nitrogen of the H_2PAPH ligands in the equatorial positions and two oxygen atoms of two water molecules occupying axial sites. Valency angles at manganese show significant distortions from an ideal octahedral arrangement. Two of four angles subtended at manganese by adjacent equatorial atoms are smaller than 90°, their range being 70.47(6)–71.06(6)°, while the other two are larger, range 99.61(5)–118.87(6)°. The range of equatorial to axial angles is 84.61(7)–95.75(7)°, and the inter-axial angle is reduced from a theoretical value of 180° to 170.85(6)°.

vii: $-x, 1-y, -z$.

The N(1), O(1), O(2), O(3) and manganese atoms are nearly co-planar with a maximum displacement from the least-square planes of 0.017 Å. With regard to the Mn—O bonds, the three equatorial distances are Mn—O(1) 2.255, Mn—O(2) 2.137 and Mn—O(3) 2.204 Å, while the axial distances are 2.180(2) and 2.217(2) Å. The shortest Mn—O bond is that between the manganese and oxygen atoms of the carboxyl group in the adjacent H_2PAPH ligand. The observed Mn—N(1) bond distance is 2.214(1) Å. Compared with the complexes of other hydrazones with manganese, the mean Mn—O (2.199 Å) and Mn—N (2.214 Å) bond distances of our complex are slightly shorter than those reported in the literature (as shown in Table 2). This is due to the effect of the coordinated oxygen of the carboxyl group.

The carboxyl group in the H_2PAPH ligands cause a polymeric structure, in which two oxygen atoms and one nitrogen coordinated to the manganese(II) atom are from a H_2PAPH ligand while another oxygen is from the carboxyl group of an adjacent H_2PAPH ligand (symmetry code: $1.5-x, y-1/2. 1.5-z$). In other words, two oxygen atoms of the

Complex: **1**, this work; **2**, $Mn(dappc)\cdot 9H_2O$;[2] **3**, $[Mn(H_2dapb)(OH)_2Cl]Cl$;[3] **4**, $[Mn(HL)(OH_2)_2Cl]Cl\cdot H_2O$;[4] **5**, $[Mn(H_2dapb)(CH_3OH)Cl]Cl\cdot H_2O$.[5]

[a] Oxygen donor atom.

[b] Nitrogen donor atom.

carboxyl group in each H_2PAPH ligand bond to two manganese(II) atoms, respectively, resulting in polymer formation. Because two carboxyl oxygens take part in coordination, the bond lengths between carbon and the two carboxyl oxygen atoms are quite close: C(1)—O(1) 1.249(3) and C(1)—O(2) 1.261(3) Å. This is similar to other polymeric structures involving the carboxyl oxygen of manganese complexes.[8,9]

The H_2PAPH ligand and manganese form two five-membered chelate rings. The data in Table 3 show that the five-membered chelate rings are almost in a plane, so the atoms in the chelating rings constitute a conjugated system. Because of conjugation, it appears that the double bonds become longer and single bonds shorter than in the manganese complex with hydrazone reported in the literature. Thus, compared to the manganese(II) complex with hydrazone listed in Table 2, the C(4)—O(3) double bond distance of the title complex is longer than the corresponding C—O bond distances in other manganese(II) hydrazone complexes, and the C(4)—N(2) single bond distance is correspondingly shorter. This shows that the O(3)—C(4)—N(2) group becomes more enolized. The pyridine ring is planar, but this and the two five-membered chelate rings are not co-planar, the dihedral along C(1)—C(4) angle being 26.4° (shown in Table 3).

The molecular packing is dominated by an extensive system of hydrogen bonds between the oxygen and nitrogen atoms of the H_2PAPH ligand and hydrogen atoms of uncoordinated water molecules. Detailed data on hydrogen bonds are summarized in Table 1.

IR spectra—The IR absorption bands which appear at 3451 [ν(N—H)], 1546 [δ(N—H)] and 1286 cm^{-1} [δ(O—H)] in free H_2PAPH disappear in the complex, indicating that the carboxyl oxygen and hydrazide nitrogen atom are coordinated to the metal atom and have lost their hydrogen atoms. The vibration assigned to ν(C—O) of the hydrazide in the complex is at 1307 cm^{-1} instead of ν(C=O) at 1623 cm^{-1} in the free ligand, and the ν(C—N) (at 1452 cm^{-1}) band shifts towards a higher ($\Delta\nu$ 58 cm^{-1}) frequency. It can be attributed to the pres-

SYNTHESES, X-RAY STRUCTURE AND PROPERTIES OF (η^5-CYCLOPENTADIENYL)RUTHENIUM(II) COMPLEXES OF PYRIDYL-2-HYDRAZONE LIGANDS

SISIR K. MANDAL and AKHIL R. CHAKRAVARTY*

Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560 012, India

(*Received* 5 *February* 1991; *accepted* 25 *June* 1991)

Abstract—Complexes of the formulae [(η-Cp)Ru(PPh_3)(η^2-PPH)]Cl and [(η-Cp)Ru(PPh_3)(py)(η^1-PPH)]Cl were prepared by reacting pyridyl-2-phenylhydrazone [PPH, C_5H_4N-2-CH=NNHPh] with (η-Cp)Ru(PPh_3)$_2$Cl and (η-Cp)Ru(PPh_3)(py)Cl, respectively. In these complexes the PPH ligand displays bidentate chelating and unidentate modes of bonding. The molecular structure of [(η-Cp)Ru(PPh_3)(η^2-PPH)](ClO_4)·CH_2Cl_2 was determined by X-ray crystallography. In this complex the metal is bonded to the N-pyridyl and N-imine atoms of the chelating ligand. ^{1}H NMR spectral data suggests that PPH is bonded to ruthenium through the pyridine moiety of the PPH ligand in [(η-Cp)Ru(PPh_3)(py)(η^1-PPH)]Cl.

Recent developments in the chemistry of monocyclopentadienylruthenium(II) complexes containing PPh_3 facial ligand(s) have shown[1–3] that the electron-rich nature of the {(η-Cp)Ru(II)} fragment leads to the formation of a variety of complexes with primarily π-acceptor ligands. The reactivity study of nitrogen-donor ligands with this moiety is largely confined to heterocyclic bases.[4,5] We have investigated the ligational behaviour of the pyridyl-2-phenylhydrazone (PPH, C_5H_4N-2-CH=NNHPh) ligand with (η-Cp)Ru(PPh_3)$_2$Cl (**1**) and (η-Cp)Ru(PPh_3)(py)Cl (**2**). It is observed that while PPH undergoes the chelating mode of bonding on reaction with **1**, it acts as a unidentate ligand when reacted with **2**. Herein, we report the synthesis and properties of two complexes, [(η-Cp)Ru(PPh_3)(η^2-PPH)]Cl (**3**) and [(η-Cp)Ru(PPh_3)(py)(η^1-PPH)]Cl (**4**). Complex **3**, as a perchlorate salt, was characterized by X-ray crystallography.

EXPERIMENTAL

Materials and methods

Dry benzene was used as a solvent. The reactions were carried out under a dinitrogen atmosphere using the Schlenk technique. The precursor complexes (η-Cp)Ru(PPh_3)$_2$Cl and (η-Cp)Ru(PPh_3)(py)Cl were made by following literature procedures.[5,6] The ligand was obtained by reacting pyridine-2-carboxaldehyde (Fluka) and phenylhydrazine (Merck) in ethanol at 0°C. The yellow crystalline PPH thus obtained was washed with cold ethanol and dried *in vacuo* over P_4O_{10}. Elemental analysis was performed on a Heraeus CHN—O rapid elemental analyser. ^{1}H NMR spectra were recorded in $CDCl_3$ on a Bruker WH-270 MHz spectrometer using tetramethylsilane (TMS) as a standard.

Preparation of [(η-Cp)Ru(PPh_3)(η^2-PPH)]Cl (**3**)

A benzene solution (20 cm^3) containing (η-Cp)Ru(PPh_3)$_2$Cl (200 mg, 0.28 mmol) and PPH (200 mg, 0.99 mmol) was heated under reflux for 24 h. On cooling the solution to 25°C, an orange–yellow crystalline precipitate was obtained. The product was filtered, washed with benzene and dried *in vacuo* over P_4O_{10} (yield: 70%). The complex was found to be stable in air and light; m.p. = 165–170°C (decomposition). Found: C, 62.9; H, 4.9; N, 5.9. Calc.: C, 63.6; H, 4.7; N, 6.3%. ^{1}H NMR [δ, ppm, $CDCl_3$]: 4.87 [s, 5H], 6.88 [d, 4H, J = 7 Hz], 7.15–7.58 [m, 20H], 8.86 [d, 1H, J = 6 Hz],

11.40 [s, 1H] (s, singlet; d, doublet; m, complex multiplet; J of H—H).

Preparation of [(η-Cp)Ru(PPh_3)(py)(η^1-PPH)]Cl (**4**)

This complex was prepared following the above procedure using (η-Cp)Ru(PPh_3)(py)Cl as a precursor complex (yield: 70%). Complex **4** has stability similar to **3**; m.p. = 190°C (decomposition). Found: C, 64.1; H, 4.8; N, 7.2. Calc.: C, 64.9; H, 4.9; N, 7.5%. ^{1}H NMR [δ, ppm, $CDCl_3$]: 4.86 [s, 5H], 6.89 [q, 4H, J = 7 Hz], 7.15–8.06 [m, 24H], 8.54 [d, 1H, J = 6 Hz], 8.85 [d, 1H, J = 6 Hz], 11.37 [s, 1H] (q, quintet).

Crystallographic analysis

Complex **3** was converted to a perchlorate salt for crystallization since the chloro analogue did not form crystals suitable for X-ray diffraction. Single crystals of the perchlorate salt of cationic **3** were obtained from a dichloromethane solution of the complex layered with n-hexane in a Schlenk tube under a dinitrogen atmosphere. A reddish coloured prismatic crystal of 0.1 × 0.2 × 0.3 mm dimensions was mounted on a glass fibre using epoxy cement. Unit cell and intensity data were obtained using an Enraf–Nonius CAD4 diffractometer with graphite-monochromatized Mo-K_α radiation following standard procedures. The structure was solved and all non-hydrogen atoms were located by conventional heavy-atom and difference Fourier methods. Refinements were made by the full-matrix least-square procedure. The metal and chlorine atoms, carbon atoms of the Cp ring and all nitrogen atoms were refined anisotropically leaving remaining atoms at the isotropic stage. The convergence was obtained by applying a weighting scheme of the form weight (w) = $1.4387/[\sigma^2(F)+0.000620(F)^2]$. The perchlorate anion was found to be disordered showing a highest peak of 1.24 e Å^{-3} located in the final-difference Fourier map. Other electron densities were < 1.0 e Å^{-3}. All calculations were carried out using a DEC 1090 computer with SHELX[7] programs at the computer centre of the Indian Institute of Science. Complete tables of structure factors, anisotropic thermal parameters and complete lists of bond distances and angles (16 pages) have been deposited with the Editor. Positional parameters and isotropic thermal parameters have been forwarded to the Director of the Cambridge Crystallographic Data Centre.

Crystal data for [(η-Cp)Ru(PPh_3)(η^2-PPH)](ClO_4)·CH_2Cl_2. Formula = $C_{36}H_{33}N_3O_4PCl_3Ru$, M = 873.79, monoclinic, $P2_1$, a = 9.853(2), b = 13.679(3), c = 13.179(2) Å, β = 90.99(2)°, V = 1776.2 Å^3, Z = 2, D_c = 1.63 g cm^{-3}, λ = 0.7107 Å, μ(Mo-K_α) = 6.35 cm^{-1}, $F(000)$ = 818, I = 18°C, 2804 reflections with $I \geqslant 1.5\sigma(I)$, data collection range (2θ) = 4–50°, R = 0.0611, R_w = 0.0614, g = 0.000620, largest shift/e.s.d. = 0.097.

RESULTS AND DISCUSSION

The precursor complexes **1** and **2** were found to react with pyridyl-2-hydrazone (PPH, C_5H_4N-2-CH=NNHPh) to form complexes **3** and **4**, respectively [eqs (1) and (2)]. Characterization of the complexes was done using elemental analytical and ^{1}H NMR spectroscopic techniques.

(η-Cp)Ru(PPh_3)$_2$Cl(**1**) + PPH ⟶ [(η-Cp)Ru(PPh_3)(η^2-PPH)]Cl(**3**) (1)

(η-Cp)Ru(PPh_3)(py)Cl(**2**) + PPH ⟶ [(η-Cp)Ru(PPh_3)(py)(η^1-PPH)]Cl(**4**) (2)

In the ^{1}H NMR spectra of (**3**) and (**4**), the Cp ring protons display a sharp singlet at δ 4.9. The presence of η-Cp, PPh_3 and PPH in a 1:1:1 ratio is observed from the peak integrations of the ^{1}H NMR spectra of **3**. The peak at δ 11.40 could be assigned to the NH proton of the PPH ligand as it undergoes D_2O exchange. The doublet observed at δ 8.86 is assigned to the *ortho*-proton of the pyridine ring in PPH. The spectral pattern in the range δ 7.15–7.58 is complex. A singlet resonance observed at δ 7.58 could be due to the CH proton of the imine group. In **4**, the NH proton appears at δ 11.37. As in **3**, the doublet observed at δ 8.85 could be from the *ortho*-proton of the pyridine moiety in the η^1-PPH ligand. The spectral pattern of **4** in the aromatic region is complex. Peak integrations, however, show a ratio of 5:31 for Cp: other protons in **4**. The spectral features, shown in Fig. 1, are indicative of the presence of both pyridine and η^1-PPH ligands besides one PPh_3 in **4**.

Complex **3** as a perchlorate salt with one CH_2Cl_2 molecule as a solvent of crystallization was structurally characterized by X-ray crystallography. The cationic complex is shown in Fig. 2. Selected bond distances and angles for **3** are given in Table 1. The coordination geometry of ruthenium is essentially octahedral. While one face of the octahedron is occupied by a η^5-Cp ring, the other three facial sites have PPh_3 and a bidentate chelating PPH ligand.

Table 1. Selected bond distances (Å) and bond angles (°) for $[(\eta\text{-Cp})Ru(PPh_3)(\eta^2\text{-PPH})](ClO_4)\cdot CH_2Cl_2$ with e.s.d.s in parentheses

Bond distances (Å)			
Ru—P(1)	2.321(3)	P(1)—C(41)	1.808(8)
Ru—N(1)	2.089(7)	C(1)—C(2)	1.447(12)
Ru—N(2)	2.058(6)	C(2)—C(3)	1.425(12)
Ru—C(1)	2.219(9)	C(3)—C(4)	1.428(13)
Ru—C(2)	2.200(8)	C(4)—C(5)	1.410(12)
Ru—C(3)	2.175(8)	C(1)—C(5)	1.456(13)
Ru—C(4)	2.200(9)	C(10)—N(2)	1.320(10)
Ru—C(5)	2.207(9)	N(2)—N(3)	1.396(9)
P(1)—C(31)	1.833(8)	C(10)—C(15)	1.418(11)
P(1)—C(51)	1.835(8)	C(21)—N(3)	1.443(9)
Bond angles (°)			
P(1)—Ru—N(1)	92.9(2)	C(10)—N(2)—N(3)	120.6(6)
P(1)—Ru—N(2)	89.7(2)	C(21)—N(3)—N(2)	119.8(6)
N(1)—Ru—N(2)	75.9(3)	Ru—P(1)—C(31)	116.3(3)
C(10)—C(15)—N(1)	116.1(7)	Ru—P(1)—C(41)	114.2(3)
C(15)—C(10)—N(2)	114.2(7)	Ru—P(1)—C(51)	115.6(3)

The average Ru—C(η-Cp) distance of *ca* 2.2 Å is similar to that found[1,2,8] in other monocyclopentadienylruthenium(II) complexes. The PPH ligand is bonded through the pyridine and imino nitrogen atoms. The Ru—N(1) distance is found to be marginally longer than the Ru—N(2) distance. This suggests that the Ru—N(py) and Ru—N(imine) bonds are essentially of equal strength.

The isolation of **3** and **4** from two closely related precursor complexes shows that the PPh_3 substitution by the pyridine moiety is the initial step in the former case. This is again evidenced from the fact that both **1** and **2** are unreactive towards benzaldehydephenylhydrazone (PhCH=NNHPh) which has a similar chromophore to that in PPH. The formation of a chelate ring in **3** is facilitated by the removal of a facile PPh_3 ligand of **1**, whilst the imino-nitrogen is unable to form a chelate ring when reacted with **2** since the presence of PPh_3 and py ligands in **2** reduces the electron density on the metal as well as the steric constraints on the coordination geometry.

DECARBOXYLATION IN THE REACTIONS OF $O^{-\cdot}$ WITH METAL CARBONYL COMPLEXES IN THE GAS PHASE

STEVEN L. VanORDEN and STEVEN W. BUCKNER†

Department of Chemistry, University of Arizona, Tucson, AZ 85721, U.S.A.

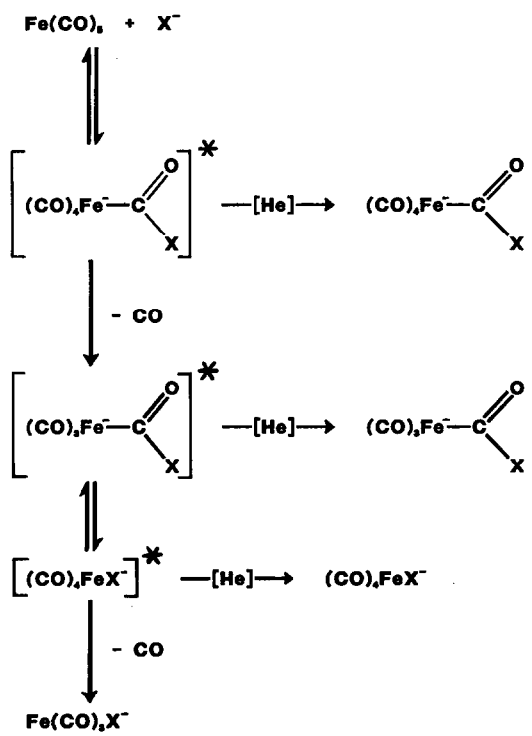
(*Received* 30 *March* 1991; *accepted* 25 *June* 1991)

Abstract—The gas phase reactions of $O^{-\cdot}$ with some first row transition metal complexes have been investigated using Fourier transform ion-cyclotron resonance spectroscopy. $O^{-\cdot}$, generated by dissociative electron capture from N_2O, reacts with $M(CO)_x$ (M = V, Cr, Fe) and manganese(methylcyclopentadienyl)$(CO)_3$ to generate $ML(CO)_{n-1}^-$, exclusively. Thermochemical arguments indicate the products cannot be generated by a simple dissociative electron-transfer mechanism, but must result from loss of CO_2. Although the reactions that generate the metal anion complexes and CO_2 are > 95 kcal mol^{-1} exothermic, the metal carbonyl anion products do not subsequently decompose indicating non-statistical energy disposal in the products. The order of relative rate constants for the reactions of the homoleptic carbonyl complexes [$k^{II}(O^{-\cdot}/V(CO)_6) > k^{II}(O^{-\cdot}/Cr(CO)_6) > k^{II}(O^{-\cdot}/Fe(CO)_5)$] and the product energy disposal results support an addition/elimination mechanism.

Although gas-phase inorganic chemistry has been a very active field during the past two decades,[1,2] there have been relatively few studies on the reactions of negative ions with neutral transition metal complexes. The reactions which have been investigated have mainly focused on nucleophilic addition reactions with carbonyl complexes. Foster and Beauchamp investigated the reactions of F^- and $C_2H_5O^-$ with $Fe(CO)_5$ in an ion-cyclotron resonance spectrometer,[3] and found both anions to react via pathway (1).

$$A^- + Fe(CO)_5 \longrightarrow Fe(CO)_3A^- + 2CO \quad (1)$$

Subsequently, Squires and co-workers have investigated the reactions of varous bare[4] and solvated[5] anions with $Fe(CO)_5$ which proceed via a variety of reaction pathways including electron transfer, direct attachment, hydride abstraction, proton transfer and nucleophilic attachment with the loss of various ligands. The final products obtained in their flowing afterglow reactor are different than those obtained in the low-pressure environment of the ICR spectrometer due to quenching of some reactive intermediates by the helium buffer gas. These intermediates are crucial to understanding the overall nucleophilic activation mechanism, shown in Scheme I. Initially, the nucleophile attacks the carbonyl carbon to form a metal–acyl anionic complex. This activated complex can



Scheme I.

dispose of its excess energy by collision with a neutral molecule as in the high-pressure flow reactor studies, or by the loss of a carbonyl. If the reactive complex loses a carbonyl the unsaturated metal centre forms an M—X bond by migratory deinsertion. In turn, this excited complex can also be quenched by collision with a neutral molecule under high-pressure conditions or decompose by loss of another carbonyl group.

A recent study of nucleophilic activation of metal carbonyl complexes has been directed toward developing an understanding of the homogeneously catalysed water–gas shift reaction (WGSR) and, in particular, the generation of CO_2 in this process.[6] There have been proposals that CO_2 is generated either by decomposition of a carboxylic acid anion $[M(CO)_{x-1}(COOH)^-]$ or the conjugate base metallocarboxylate $[M(CO)_{x-1}(COO)^{2-}]$.[7] The recent gas-phase work investigating this problem has focused on the formation and decomposition of isolated metal carboxylic acid anions.[6] These results have indicated that a large barrier exists to decarboxylation of these species, with decomposition of $Fe(CO)_4(COOH)^-$ occurring exclusively by loss of CO.

In the present work we report on the interactions of the highly reactive anion $O^{-\cdot}$[8] with a variety of neutral metal complexes studied by Fourier transform ion-cyclotron resonance mass spectrometry. The present study was undertaken in an effort to generate gas-phase metallocarboxylates by an addition mechanism similar to Scheme I, and study their decomposition pathways. We observe these gas-phase metallocarboxylates to decompose exclusively via the loss of CO_2. The relationship of metallocarboxylates to the WGSR has been previously discussed.[7,9]

EXPERIMENTAL

All experiments were performed on a Fourier transform ion-cyclotron resonance mass spectrometer recently constructed in our laboratory.[9,10] The trapping cell is a single chamber with dimensions $2.75 \times 1.375 \times 1.375$ in. All reagent gases are admitted into the reaction chamber via Varian variable leak valves. The chamber is pumped by a 6 in. Alcatel diffusion pump backed by an Alcatel rough pump. Pressures are monitored with a Granville–Phillips 271 ionization gauge. Base pressures in the chamber are $\sim 1 \times 10^{-9}$ torr. The magnetic field is supplied by a Varian electromagnet with the field regulated at ~ 0.7 T. The trapping cell and experimental pulse sequences are controlled by a Nicolet FTMS-2000 computer.

Typical reagent gas pressures (nitrogen equivalent) were $\sim 3 \times 10^{-5}$ torr (N_2O) with $\sim 2 \times 10^{-7}$ torr of the metal complex. $O^{-\cdot}$ was generated by N_2O dissociative electron capture, as shown in reaction (2).[11] Electrons were introduced in a 5 ms 3 mA pulse of 8 eV electrons. Stray electrons remaining in the trapping cell after the initial electron beam pulse undergo efficient dissociative electron attachment by the metal carbonyl complexes, [see eq. (3)].[12]

$$N_2O + e^-(8\,eV) \longrightarrow O^{-\cdot} + N_2 \qquad (2)$$

$$e^- + M(CO)_x \longrightarrow M(CO)_{x-1}^- + CO \qquad (3)$$

To verify that the metal containing anion products were due to ion–molecule reactions and not reaction (3), all ions present in the cell were ejected 35 ms after the electron beam pulse. In a delay period (from 20 to 100 ms) after the ejection pulse, no ions were produced. This indicates that 35 ms after the electron beam pulse, no electrons remained in the cell to be attached by the reagent gases. The 35 ms delay was retained in the experimental sequence to eliminate trapped electrons and serve as a thermalization period for the $O^{-\cdot}$ (~ 40 collisions of $O^{-\cdot}$ with neutrals in the ICR cell). Swept double-resonance ejection pulses were used to isolate $O^{-\cdot}$ after the 35 ms formation and cooling periods, and prior to reaction with the metal complex of interest.[13] NO^-, generated by the reaction of $O^{-\cdot}$ with background N_2O, was continuously ejected during the reaction period to prevent direct electron transfer from NO^- (electron affinity = 20 meV) to the metal carbonyl complexes.

For measurement of the relative rate constants for the reactions of $O^{-\cdot}$ with the metal carbonyls it was necessary to determine relative ion gauge sensitivities for the neutral complexes. Obtaining absolute rates for reactions (4)–(6), which would allow determination of absolute ion gauge sensitivities for the metal carbonyls, is not feasible in our instrument due to difficulties in determining absolute ion abundances. However, by simultaneously measuring the relative intensities for $V(CO)_5^-$, $Cr(CO)_5^-$ and $Fe(CO)_4^-$ generated in reactions (4)–(6) and comparing these with the respective literature rate constants of 1.6×10^{-8} cm^3 molecule^{-1} s^{-1}, 2.8×10^{-8} cm^3 molecule^{-1} s^{-1} and 1.1×10^{-8} cm^3 molecule^{-1} s^{-1},[12] it is possible to determine the relative ion gauge sensitivities. For the reactions discussed below the relative rate constants were determined using the uncorrected ion gauge pressure reading and dividing by the relative ion gauge sensitivity.

$$V(CO)_6 + e^- \longrightarrow V(CO)_5^- + CO \qquad (4)$$

$$Cr(CO)_6 + e^- \longrightarrow Cr(CO)_5^- + CO \quad (5)$$

$$Fe(CO)_5 + e^- \longrightarrow Fe(CO)_4^- + CO \quad (6)$$

N_2O was obtained commercially from Matheson. All metal complexes were obtained commercially and used as supplied except for multiple freeze-pump-thaw cycles which were used to remove non-condensible gases.

RESULTS

Under the present low-pressure conditions, $O^{-\cdot}$ reacts with $Fe(CO)_5$, $Cr(CO)_6$, $V(CO)_6$ and $Mn(Me\text{-}Cp)(CO)_3$ (Me-Cp = methylcyclopentadienyl) via pathways (7) and (8), while $O^{-\cdot}$ does not react with ferrocene and cobaltocene. Nucleophilic attack on metallocenes has been observed in solution. Figure 1 shows mass spectra corresponding to reaction (7). The relative rate constants for the reactions of the homoleptic carbonyl complexes are shown in Table 1.

$$O^{-\cdot} + M(CO)_x \longrightarrow M(CO)_{x-1}^- + [CO + O] \quad (7)$$

(M = Fe, Cr, V)

$$Mn(Me\text{-}Cp)(CO)_3 + O^{-\cdot} \longrightarrow Mn(Me\text{-}Cp)(CO)_2^- + [CO + O] \quad (8)$$

The neutral products from reactions (7) and (8) are not detected in the mass spectrum but can be inferred from thermochemical considerations. For $Fe(CO)_5$, dissociative electron attachment is exothermic by 14 ± 10 kcal mol^{-1}.[15] Consideration of the high electron affinity of oxygen[16] makes a simple electron transfer mechanism, as in reaction (9), endothermic by $\sim 20 \pm 10$ kcal mol^{-1}. Reaction (10), which results in the formation of CO_2, is exothermic by 106 ± 10 kcal mol^{-1}. Energetics for reactions (7) and (8) are shown in Table 2 and indicate that CO_2 is generated as the neutral product.[17-20]

$$O^{-\cdot} + Fe(CO)_5 \longrightarrow Fe(CO)_4^- + CO + O \quad \Delta H_{rxn} = 20 \pm 10 \text{ kcal mol}^{-1} \quad (9)$$

Table 2. Energetics for the reaction of $O^{-\cdot}$ with metal complexes[a]

Reaction	ΔH_{rxn} (CO+O as neutral products)	ΔH_{rxn} (CO_2 as neutral product)	D[M(CO)$_{x-2}$CO][17]	CO_2 internal energy	Total product internal energy
$O^{-\cdot}+Fe(CO)_5$	20 ± 12	-106 ± 12[14]	<33	~ 56	$\lesssim 89\pm12$
$O^{-\cdot}+Cr(CO)_6$	19 ± 5	-107 ± 5[18]	$<62, >35$	~ 56	$\lesssim 118\pm12$
$O^{-\cdot}+V(CO)_6$	29 ± 15	-97 ± 15[19]	NA		
$O^{-\cdot}+Mn(Me\text{-}Cp)(CO)_3$	29 ± 15	-97 ± 15[19]	NA		

[a] All energies in kcal mol^{-1}.

$$O^{-\cdot}+Fe(CO)_5 \longrightarrow Fe(CO)_4^- + CO_2$$
$$\Delta H_{rxn} = -106\pm10\,\text{kcal mol}^{-1} \quad (10)$$

The reactions of $O^{-\cdot}$ contrast those of many previously-studied nucleophiles (see Scheme I), since the incoming oxygen atom is lost as part of the neutral product.[4,21] Also, Mn(Me-Cp)(CO)$_3$ reacts with the nucleophiles NH_2^- [$\Delta H_{acid}(NH_3) = 403.6$ kcal mol^{-1}][22] and F^- [$\Delta H_{acid}(HF) = 371.5$ kcal mol^{-1}] via deprotonation with no nucleophilic activation at the carbonyl.[23] However, $O^{-\cdot}$, which has a proton affinity between F^- and NH_2^- [$\Delta H_{acid}(OH^-) = 381$ kcal mol^{-1}], reacts via decarboxylation [reaction (8)] with no proton transfer observed. In contrast to reaction (8), solution studies of the reactions of Mn(Me-Cp)(CO)$_3$ with closed shell anions indicate nucleophilic attack occurs preferentially at the hydrocarbon.[24]

$$Mn(Me\text{-}Cp)(CO)_3 + (F^-, NH_2^-) \longrightarrow Mn(C_6H_6)(CO)_3^- + (HF, NH_3) \quad (11)$$

DISCUSSION

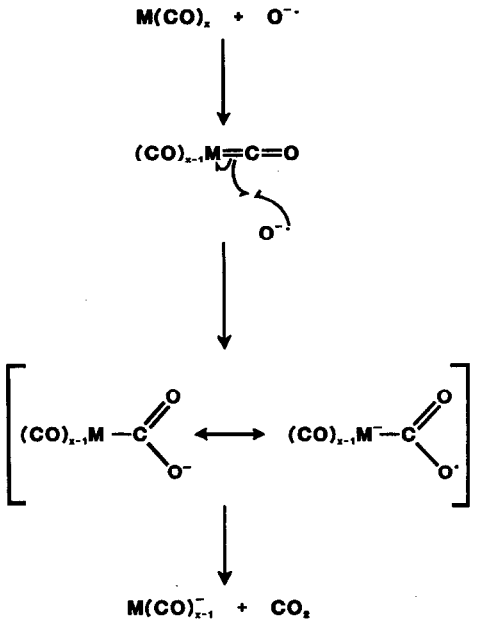
An interesting aspect of the $O^{-\cdot}$ reactions is that the metal carbonyl anion products are not observed to undergo subsequent decomposition, even though the reactions with $O^{-\cdot}$ are more than 95 kcal mol^{-1} exothermic. Recent photo-dissociation studies performed in our laboratory have indicated D(Fe(CO)$_3^-$—CO) $<$ 33 kcal mol^{-1} and 35 kcal mol^{-1} $<$ D(Cr(CO)$_4^-$—CO) $<$ 62 kcal mol^{-1}[18] (see Table 2). The lack of further carbonyl loss from the ionic products generated in reaction (7) indicates the metal carbonyl-anion products are generated with less internal energy than the first metal anion–carbonyl binding energy. Therefore, a large portion of the reaction exothermicity must appear as excitation of CO_2 and/or as relative translational energy of the products. From simple energy randomization considerations the above result is unexpected. For example, in the Cr(CO)$_6$ reaction the product metal carbonyl complex [Cr(CO)$_5^-$] has 27 vibrational modes while the CO_2 has only four vibrational modes. Additionally, the metal complex product has many low-frequency vibrational modes which are not present for CO_2. This will result in a higher density of states for Cr(CO)$_5^-$. Both of these contributions indicate that, based on simple statistical considerations, Cr(CO)$_5^-$ should be generated with a much higher internal excitation than CO_2. Given the high exothermicities for the reactions shown in Table 2 ($> 97\pm15$ kcal mol^{-1}) the metal complexes produced in reactions (7) and (8) would be expected to undergo further decarbonylation.

Similar behaviour has recently been observed by Hack and Rossing in the reaction of triplet oxygen atoms with Cr(CO)$_6$.[25] Interestingly, this reaction also proceeds with the exclusive loss of CO_2, reaction (12). This reaction is quite exothermic [$\Delta H_{rxn}(12) = -90$ kcal mol^{-1}]. The decomposition of Cr(CO)$_5$ only requires 40 kcal mol^{-1}, suggesting that Cr(CO)$_4$ should be generated. However, kinetic evidence suggests the Cr(CO)$_5$ product generated in reaction (12) does not decompose. In their study the only product directly observed in the gas phase was CO_2. Thus, the lack of fragmentation of the nascent Cr(CO)$_5$ was not based on direct observations. The results are, however, consistent with the present results for the reactions of $O^{-\cdot}$ where the metal complexes are not observed to decompose.

$$O(^3P) + Cr(CO)_6 \longrightarrow Cr(CO)_5 + CO_2 \quad (12)$$

There are two reasonable mechanisms which can account for the apparent non-statistical partitioning of exothermicity into the products of reactions (7) and (8). The first is an addition/elimination mechanism. A second mechanism, initiated by electron transfer, is also consistent with the product energy distributions.

Scheme II shows a possible radical addi-

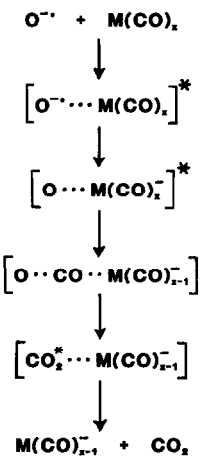


Scheme II.

tion/elimination mechanism for the reaction of $O^{-\cdot}$ with the metal complexes. Previous studies of nucleophilic addition to metal carbonyls have involved closed shell nucleophiles. However, for $O^{-\cdot}$ the highest occupied orbital will contain the unpaired electron, and initial addition involves this orbital. It is likely that the reaction of the radical $O(^3P)$ studied by Hack and Rossing involves this mechanism.[25] The intermediate metallocarboxylate which is generated can decompose via the loss of CO_2. The decomposition involves elimination of a highly bent CO_2 from the complex. Structures for a variety of metallocarboxylate anions and metallocarboxylic acid anions have been obtained and the O—C—O bond angles are generally close to 120°.[7,26] Assuming a bond angle of 120° for the present complexes, the nascent CO_2 would be formed with a *ca* 120° bend, which corresponds to vibrational excitation of the order 56 kcal mol^{-1} in the bending mode.[27,28] Upon decomposition it is likely that the metal carbonyl-anion products will also be generated in a distorted geometry. However, the metal carbonyl anions are highly fluxional with low barriers to isomerization (i.e. square pyramidal to trigonal bipyramidal) and thus, the internal energies associated with the geometric distortions of the carbonyl anion products will be very small.

Given the bond dissociation energies for the metal carbonyl complexes shown in Table 2 along with the observation that the product ions do not undergo loss of CO, less than 62 kcal mol^{-1} must be deposited into the $Cr(CO)_5^-$ product from the energy partitioning to be consistent with our results. Assuming CO_2 contains 56 ± 12 kcal mol^{-1} of vibrational excitation implies a total of $< 118 \pm 12$ kcal mol^{-1} is deposited into internal excitation of the products for the $Cr(CO)_6$ reaction, which is within experimental error of the reaction exothermicity. This is also the case for the $O^{-\cdot}/Fe(CO)_5$ reaction; the sum of the upper limit on the internal excitation of $M(CO)_{x-1}^-$ and the vibrational excitation of CO_2 expected for an addition/elimination mechanism is very close (within experimental error) to the reaction exothermicity. Thus, this mechanism is consistent with the absence of fragmentation of the metal carbonyl-anion products.

An alternative to the addition mechanism involves electron transfer within the nascent ion-induced dipole complex. Recently, many reactions, including ligand switching,[29-31] halogen atom transfer,[32] and small group transfer reactions,[33] have been shown to be initiated by electron transfer in the collision complex. The basic mechanism is shown in Scheme III. After formation of the ion-neutral collision complex, dissociative electron transfer can occur from $O^{-\cdot}$ to the metal carbonyl. As discussed above, direct dissociative electron transfer with the formation of O, CO and $M(CO)_{x-1}^-$ is endothermic. However, the ion-induced dipole complexation energy ($\sim$ 15 kcal mol^{-1}) can facilitate an intermediate electron transfer to generate an $[O \cdots CO \cdots M(CO)_{x-1}^-]$ complex. Within this complex, O and CO can combine to generate $(CO_2)^*$. This produces the complex $[M(CO)_{x-1}^- \cdots (CO_2)^*]$, with the energy localized in the CO_2 moiety. The complex will decompose before full energy redistribution can occur. This mechanism would also result in most of the reaction exothermicity partitioned into vibrational exci-



Scheme III.

tation of CO_2, while $M(CO)_{x-1}^-$ would be generated with little internal excitation, which is consistent with the absence of fragmentation of $M(CO)_{x-1}^-$.

Both of the proposed reaction mechanisms, addition/elimination and electron transfer, are consistent with the available reaction energetics and the observed metal-carbonyl energy disposal and suggest most of the reaction exothermicity will be channelled into CO_2 excitation. Previous studies of electron transfer initiated reactions have observed a correlation between the rate constant for thermal electron attachment for the incoming neutral (in the present study this would correspond to $M(CO)_x$) with the rate constant for the ion–molecule reaction under study.[32] A comparison of the relative rate constants for the metal-carbonyl reactions with the rate for dissociative electron capture by the corresponding metal carbonyl, shown in Table 1, clearly demonstrates that a correlation does not exist, suggesting the electron transfer process is not important for the present reactions. The present results suggest that the gas-phase $M(CO)_x(CO_2)^-$ (M = V, Cr, Fe), generated by nucleophilic addition, decompose preferentially by the loss of CO_2, with no loss of CO observed.

Summary

The reactions of O^- with $V(CO)_6$, $Cr(CO)_6$, $Fe(CO)_5$ and $Mn(Me\text{-}Cp)(CO)_3$ proceed with the production of $M(CO)_{x-1}^-$ and vibrationally excited CO_2. Two mechanisms have been considered for this reaction which account for the apparent non-statistical energy disposal in the reaction products: an addition/elimination mechanism where the CO_2 is generated in a bent configuration, and an intermediate electron-transfer mechanism in which CO_2 is produced by recombination of O and CO within the collision complex. Kinetic data show no correlation with the rate for thermal electron attachment by the metal-carbonyl complex, suggesting the electron transfer mediated process is not operative for these reactions.

Finally, $M(CO)_{x-1}(COO)^-$ (M = V, Cr, Fe) generated in the gas phase by nucleophilic attack, decompose exclusively by decarboxylation. This is in contrast to previous studies of the metallocarboxylic acid anions, $M(CO)_{x-1}(COOH)^-$ which decompose exclusively via decarbonylation, reactions (13).[6]

$$M(CO)_x + OH^- \longrightarrow M(CO)_{x-1}OH^- + CO \quad (13)$$

19. An electron affinity of 52 ± 4 kcal mol^{-1} for $Cr(CO)_5$ is estimated based on data from: L. Sallans, K. R. Lane, R. R. Squires and B. S. Freiser, *J. Am. Chem. Soc.* 1985, **107**, 4379 [$EACr(CO)_5 > 2.3$ eV]; R. N. McDonald and P. L. Schell, *Organometallics* 1988, **7**, 1820 [$EACr(CO)_5 < 2.4 \pm 0.3$ eV]. Combined with $DCr(CO)_5CO = 36.8$ kcal mol^{-1} from: G. P. Smith, *Polyhedron* 1988, **7**, 1605, indicates thermal electron attachment by $Cr(CO)_6$ is 15 ± 5 kcal mol^{-1} exothermic.
20. From the observation of slow dissociation attachment of thermal energy electrons by $V(CO)_6$ and $Mn(Me\text{-}Cp)(CO)_3$ we estimate the following:

$$V(CO)_6 + e^- \longrightarrow V(CO)_5^- + CO$$
$$\Delta H_{rxn} = -5 \pm 15 \text{ kcal mol}^{-1}$$

$$Mn(Me\text{-}Cp)(CP)_3 + e^- \longrightarrow Mn(Me\text{-}Cp)(CO)_2^- + CO$$
$$\Delta H_{rxn} = -5 \pm 15 \text{ kcal mol}^{-1},$$

for use in determination of the $I^{-\cdot}$/metal complex reaction exothermicities.
21. CO_2 loss has recently been reported in the reactions of some metal-carbonyl anions with O_2, see: K. R. Lane, L. Sallans and R. R. Squires, *J. Am. Chem. Soc.* 1984, **106**, 2719; D. L. Bricker and D. H. Russell, *J. Am. Chem. Soc.* 1987, **109**, 3910; and references 14 and 29.
22. Proton affinities were taken from: J. E. Bartmess and R. T. McIver, in *Gas Phase Ion Chemistry* (Edited by M. R. Bowers), Vol. 2, Ch. 11. Academic Press, New York (1979).
23. Cl^- [$\Delta H_{acid}(HCl) = 333$ kcal mol^{-1}] is unreactive with $Mn(Me\text{-}Cp)(CO)_3$ due to its lower proton affinity. Coupling this with reaction (11) can be used to bracket the gas phase acidity of the manganese complex, yielding 333 kcal mol^{-1} < [$\Delta H_{acid}(Mn(Me\text{-}Cp)(CO)_3$] < 372 kcal mol^{-1}. Proton transfer has also recently been observed for $Mn(C_5H_5)(CO)_3$, see: R. R. Squires, in *Gas Phase Inorganic Chemistry* (Edited by D. H. Russell). Plenum Press, New York (1989).

25. W. Hack and A. Rossing, *Chem. Phys. Lett.* 1990, **171**, 547.
26. G. Fachinetti, C. Floriani and P. F. Zanazzi, *J. Am. Chem. Soc.* 1978, **100**, 7405.
27. The internal energy of CO_2 bent at 120° was approximated using the equation:

$$\text{Energy} = 0.5k(\Delta x)^2,$$

where Δx is the displacement of either oxygen atom from the equilibrium position. The force constant k, can be calculated from the frequency of the bending mode 667 cm^{-1} (ν_2). A factor of two was introduced into the reduced mass due to the symmetry of the molecule. This equation places an upper limit on the internal energy of the nascent CO_2. Using a similar approach, an angle of 115° corresponds to 64 kcal mol^{-1} while an angle of 125° corresponds to 47 kcal mol^{-1}. Due to uncertainties in the CO_2 geometry at the transition state and effects due to anharmonicity, limits on product CO_2 internal energy have been set at ± 12 kcal mol^{-1}.
28. Decarboxylation of organic carboxylates in the gas phase had recently been shown to proceed with an activation barrier equal to the reaction endothermicity. This implies CO_2 is produced with little or no vibrational excitation at the CID threshold for the organic molecules. See: S. T. Graul and R. R. Squires, *J. Am. Chem. Soc.* 1990, 112, 2517.

(*Received* 21 *January* 1991; *accepted* 18 *June* 1991)

Abstract—The crystal structure of the title compound has been determined from single crystal X-ray diffraction data. There is little angle strain in the complex which has two carboxylate ions and one alkoxide ion bound to cobalt(III). These conclusions agree with IR, CD and NMR spectral data except that ^1H coupling constants show that the conformation of the malate ligand differs slightly in solid and solution. The three ammonia ligands have different ^1H chemical shifts and different rates of hydrogen exchange in D_2O.

The reaction of the L-malate ion with a tetraamine *cis*-diaquo complex of cobalt(III) at pH 7 gives a crystalline product whose empirical formula is $[Co(NH_3)_3$-L-malate$]\cdot 2H_2O$ (**1**). It is non-ionic, based on conductivity and chemical analysis, suggesting that cobalt binds to a tridentate malate trianion through two carboxylate and one alkoxide oxygen.[1] Such a structure is consistent with the CD spectra in solution and the IR spectra of the solid. There is considerable evidence, based largely on spectroscopic or analytical evidence, for binding of alkoxide ions in complexes of hydroxyacids.[2] For example, mixed bis-phenanthroline-malate complexes of Co^{III}—CO_2^- and —O^- form a five-membered ring with hydrogen bonding of the second carboxylic residue to the alkoxide oxygen.[3] The X-ray diffraction evidence on copper(II)-tartrate complexes demonstrates complexing to the alkoxide oxygen.[4] Some of these complexes are polynuclear and in others the metal is bound to one alkoxide and one carboxylate group. Sugars form ammine complexes with cobalt(III) but binding is by hydroxyl rather than alkoxide groups.[5]

The proposed structure of **1** is reasonable, but unproven; chemical analysis, for example, is consistent with the malate ion acting as a bidentate ligand and with OH^- complexed to cobalt(III). We therefore examined the structure in solution by NMR spectroscopy and in the crystal by X-ray diffraction.

RESULTS AND DISCUSSION

Structure in the crystal

The L-malate trianion is bound to the cobalt atom through O(1A), O(2A) and O(4A) forming five- and six-membered rings; the numbering scheme is shown in Fig. 1. O(4B) of the L-malate ligand is hydrogen bonded to water, $H_2O(9)$, which is hydrogen bonded to the other water molecule, $H_2O(8)$. Hydrogen bonds between water solvates related by the 2_1 axes parallel to the *c* axis result in helical "chains" of molecules along the *c* direction. Hydrogen bonds between water and O(2A) of the L-malate related by the 2_1 axes parallel to the *b* axis result in interactions between the "chains".

Bond lengths and angles between heavy atoms are given in Table 1. (Values in parentheses are the number of standard deviations.) Complete bond distances and angles are included in the Supplementary Material. Bond angles about cobalt are

close to 90°, and those for carbon and oxygen of the malate ligand are close to values typical of tetrahedral and trigonal centres, corresponding to little angle strain in the malate ligand. Figure 1 shows the structure of the complex and Fig. 2 shows it looking down the C(2)—C(3) bond.

Bond lengths of cobalt are *ca* 1.9 and 1.95 Å to oxygen and nitrogen, respectively (Table 1). The malate residue is also relatively unstrained. The bond lengths of cobalt to oxygen and nitrogen are similar to those in L-glutamate bis(ethylenediamine)cobalt(III) perchlorate[8] except that this has a slightly shorter bond of 1.87 Å between the cobalt and alkoxide oxygen. Bonds of cobalt to alkoxide oxygens are shorter than to carboxylate oxygens, pointing to a stronger interaction. Complexes of cobalt(III) with the bidentate malate or tartrate ion typically involve one alkoxide and one carboxylate ligand rather than two carboxylate ligands.[3]

The new results fit earlier evidence[1] that structures are similar in the solid and solution and formation of a complex with a tridentate malate trianion forces chirality on the cobalt centre.

NMR spectra

There are four well-defined ^{13}C signals (^1H decoupled) of the complex at 75.4 and 39.3 ppm corresponding to the methine and methylene carbons, respectively, and two signals of the carboxyl carbon at 179 and 190 ppm.[9] We measured T_1 values for the carboxyl carbons in order to assign the signals, and values are: 2.63 (190 ppm) and 6.41 s (179 ppm). We assume that the carboxyl residue [C(4)] in a six-membered ring (Fig. 1) will have a higher mobility and a higher T_1 than the carboxyl residue [C(2)] in a five-membered ring. On this basis we assign the signal at 190 ppm to C(1) and that at 179 ppm to C(4).

There are two methylene (2.4 and 2.6 ppm) and one methine (3.7 ppm) signals in the ^1H NMR spectrum in D_2O with extensive vicinal and geminal coupling and each set of signals is a doublet of doublets (Fig. 3). The chemical shifts (δ, ppm) and coupling constants (J, Hz) are shown in Scheme 1. We have to consider the assignments of the methylene hydrogens H(3A) and H(3B) on C(3) and their coupling with the methine hydrogen on C(2) (Fig. 3). The view of the crystal structure down the C(2)—C(3) bond (Fig. 2) shows that in the solid methine and methylene hydrogens are in an approximately staggered conformation with dihedral angles of *ca* 60°. This conformation should lead to very similar low vicinal coupling constants between the methine hydrogen and each of the methylene hydrogens,[10] but instead we have very different coupling constants of $J \approx 6$ and 1 Hz (Scheme 1). This result suggests that the complex has slightly different geometries in the crystal and in solution, with a change in the dihedral angles due to rotation about the C(2)—C(3) bond (Fig. 2). Probably the H(2A)—H(3A) dihedral angle decreases from *ca* 60° in the crystal and that for H(2A)—H(3B) correspondingly increases. The coupling constants approximately fit a Karplus

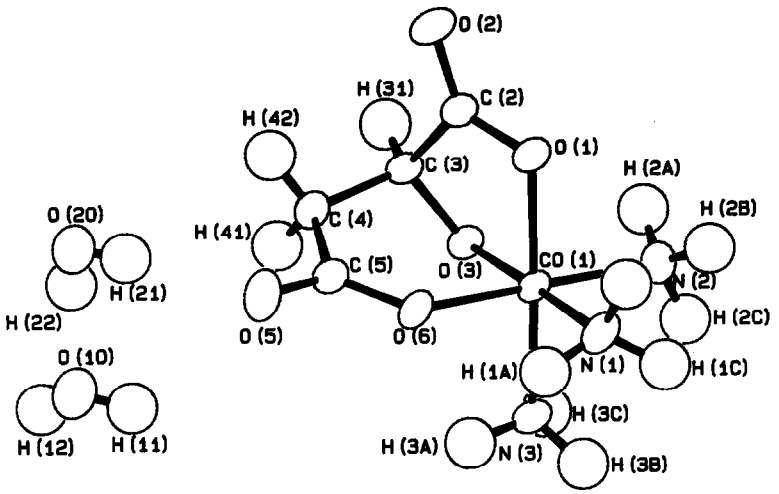

Fig. 1. ORTEP[6] drawing of the structure of $Co(NH_3)_3$(L-malate)·$2H_2O$ (1) showing the atomic numbering scheme;[7] ellipsoids are drawn at 50% probability level.

relation[10] if the H(2A)—H(3A) dihedral angle decreases in solution to 20–30° and that for H(2A)—H(3B) increases to 90–100°. This rotation changes the geometry of the six-membered ring in the complex. An alternative possibility is that rotation reduces the H(2A)—H(3B) dihedral angle (Fig. 2). Inspection of models and molecular mechanics calculations (Experimental) suggests that a decrease in the H(2A)—H(3A) bond angle is preferred (Experimental).

The conformation of the six-membered ring of the malate ligand in the crystal is probably governed in part by hydrogen bonding (Fig. 1 and Supplementary Material). These packing constraints disappear in solution permitting the observed rotation about the C(2)—C(3) bond. In addition, hydrogen bonds to water molecules in the crystal differ from those in solution. Changes in conformation on going from the solid to aqueous solution are understandable, for example, intramolecular hydrogen bonds in hydrogen malate and hydrogen phthalate ion are unsymmetrical in water, but symmetrical in the crystal.[11]

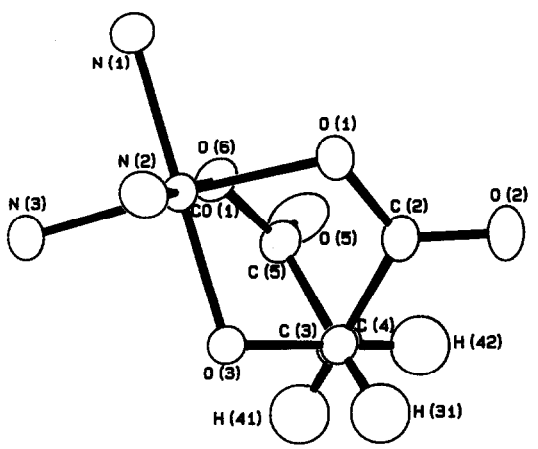

Fig. 2. ORTEP[6] drawing of $Co(NH_3)_3$(L-malate)·$2H_2O$ (1) looking down the C(3)—C(4) bond; ellipsoids drawn at 50% probability level. Solvate waters and ammonia hydrogens have been eliminated for clarity. Atom labels modified with PLOTMD.[7]

Hydrogens of the ammonia ligands give broad, well-separated, signals (Fig. 3). Exchange with D_2O is relatively slow, and different for the three ammonias. The spectra of freshly prepared and 1-day-old solutions are compared in Figs 3A and B. There is little exchange for N—H signals at 3.43 ppm, more for those at 2.91 ppm and extensive exchange for those at 2.76 ppm. There is also line-broadening, in part due to the replacement of NH by ND. Exchange and line-broadening were very evident after 6 days and new signals appeared because of the decomposition of the complex which would generate paramagnetic cobalt(II) and cause line-broadening.

The ^1H coupling constants in the NMR spectrum of L-malate dianion (Scheme 1) fit a conformation with *anti*-carboxylate residues as shown in a Newman projection (**2**).

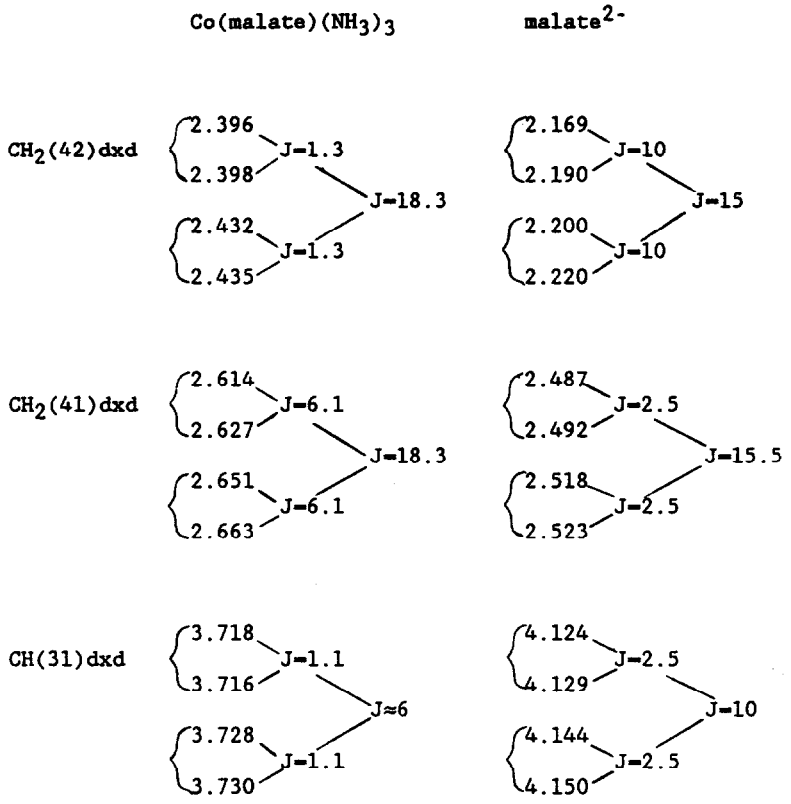
EXPERIMENTAL

Materials

The preparation and characterization of triammine cobalt(III)-L-malate has been described.[1] Single crystals were obtained by slow recrystallization from water.

Crystal data

$Co(NH_3)_3(C_4H_3O_5)\cdot 2H_2O$, $M = 2.77.12$ g mol^{-1}, $D_c = 1.73$ g cm^{-3}, $F(000) = 5.44$, μ(Mo-K_α) = 16.31 cm^{-1}, orthorhombic, $a = 9.6983(3)$, $b = 14.2528(4)$, $c = 7.6901(2)$ Å, $V = 1063(3)$ Å^3, $Z = 4$, space group $P2_12_12_1$ (no. 19), red–violet, crystal dimensions $0.50 \times 0.30 \times 0.25$ mm.



Scheme 1.

Structure determination

Diffraction data were obtained on a Huber four-circle diffractometer automated by Crystal Logic, Inc. (Mo-K_α, $l = 0.71073$ Å, graphite monochromator, room temperature, $2\theta_{max} = 65°$, θ–2θ scan mode). Measurement of the $+h$, $+k$, $+1$ and $-h$, $-k$, -1 quadrants yielded a total of 4452 reflections of which 3994 [$I > 3\sigma(I)$] were used in the refinement. Lorentz, polarization and analytical[12] absorption corrections were applied to the data.

The structure was solved by direct methods (SHELXS)[13] and difference Fourier syntheses. Full-matrix, least-squares refinement was carried out using a locally modified version of the UCLA Crystallographic Computing Package.[14] All least-squares refinements computed the agreement factors R and R_w according to:

$$R = \Sigma||F|F_o| - |F_c||/\Sigma(|F_o|)$$

$$R_w = [\Sigma(\omega(|F_o| - |F_c|)^2)/\Sigma(\omega)|F_o|^2)^{1/2};$$

where F_o is the observed structure factor, F_c is the calculated structure factor, and $\omega = 1/(\sigma(F_o))^2$.

Scattering factors and corrections for anomalous dispersion were taken from the International Tables for X-ray Crystallography.[15] Positions and anisotropic thermal parameters were allowed to vary for all non-hydrogen atoms. Hydrogens were assigned thermal parameters of 0.05 Å^2, those of the solvent water molecules were located in difference maps and their positions allowed to refine; those bonded to nitrogen or carbon were fixed at calculated positions. The final refinement of 148 parameters converged at $R = 0.046$ and $R_w = 0.060$ with EOF = 1.98. The final difference map contained no significant features.

The chiral molecule crystallizes in the enantiomorphic space group $P2_12_12_1$, uniquely determined by the systematic absences: $h00$, $h = 2n+1$; $0k0$, $k = 2n+1$; 001, $1 = 2n+1$. The Friedel pairs were not averaged due to anomalous dispersion effects. Confirmation of the L-malate complex as the correct enantiomer was made by refining the D-malate enantiomer (obtained by coordinate inversion) as described above which converged at $R = 0.057$ and $R_w = 0.078$.

Full details of data collection, atomic coordi-

nates, thermal parameters, full bond length and angle data, and observed and calculated structure factors have been deposited as supplementary material with the Editor, from whom copies are available on request.

NMR spectra

The ^1H and ^{13}C spectra were determined in D_2O at 25°C in a GN500 spectrometer. Freshly made solutions were used except for the examination of NH exchange. The solutions were kept in the dark. We used a 2D ^1H homonuclear shift correlation (COSY) to confirm the ^1H assignments.

There was only one signal of $^{59}Co^{16}$ in D_2O at -2445.5 ppm relative to that of $Co(acac)_3$ in CD_3OD (0 ppm). These measurements were made at 25°C on a GN300 spectrometer.

The ^{13}C T_1 data were obtained by the inversion recovery method[17] on a GN500 spectrometer at 25°C.

Molecular modelling

We used the Chem-X program[18] to model the structure of the complex based on minimization of the free energy. However, the predicted lengths of the Co—O(1A) and Co—O(2A) bonds are respectively longer and shorter by *ca* 0.4 Å than the crystallographic values probably because the program attempts to eliminate strain in the five-membered ring of the complex and does not consider effects of hydrogen bonding to water molecules.

Supplementary material for $Co(NH_3)_3$(L-malate)·$2H_2O$. Table I, complete crystallographic data; Table II, atomic positions; Table III, anisotropic thermal parameters; Table IV, complete bond distances; Table V, complete bond angles; Table VI, hydrogen bonding interactions; Table VII, observed and calculated structure factors.

(*Received* 16 *January* 1991; *accepted* 23 *May* 1991)

Abstract—Synthetic routes to tetraphenylphosphonium salts of $[PtS_x]^{2-}$ are outlined, where $x = 15$ or 18. Generally, $(PPh_4)_2[Pt(S_5)_3]$ is formed most readily.

The compound $[(C_6H_5)_4P]_2[PtS_{15}]$, always solvated, has been obtained by synthesis in acetonitrile (sulphur, triethylamine, H_2S and $[PPh_4]_2[PtCl_6]$) and by metathesis (in DMF) from the known hydrated ammonium compound

$$(NH_4)_2[Pt(S_5)_3]2H_2O + 2[Ph_4P]Br \longrightarrow (Ph_4P)_2[Pt(S_5)_3] \cdot DMF + 2NH_4Br,$$

and from the dismutation (in acetone)

$$3PtS_{17}^{2-} \longrightarrow PtS_{15}^{2-} + 2PtS_{18}^{2-}.$$

X-ray diffraction shows that crystals obtained from DMF and acetone are the solvated salts $[Ph_4P]_2 \cdot [Pt(S_5)_3] \cdot S$, with solvent molecules (S) uncoordinated. In both, the three platinopentathian rings related by a three-fold axis of the anion have the chair conformation. Molecules of the solvent are located between the anion and cation.

Platinum group elements have high affinities for sulphur, manifest in many ways. Heated platinum crucibles commonly embrittle when their contents include sulphur or its compounds. Processes of magmatic concentration often produce[2] a mineralogical association of platinum, palladium and rhodium with sulphides. Platinum metals form stable compounds with ions S_x^{2-}, i.e. sulphides ($x = 1$) and oligosulphides ($2 \leqslant x \leqslant 6$). These include many minerals, such as braggite (PdS), laurite (RuS), cooperite (PtS), bowie-ite (PtIrRhS), sulrhodite (RhS) and erlichmanite (Os, S). New examples exist,[3] like kashinite (Ir, Rh, S), formulated as $(Ir, Rh)_2S_3$.

In the context of geochemistry, of flotation and surface modification of ores and of helping to provide reproducible phases with defined properties, we have been evaluating combinations obtainable from dissolution of heavy metal sulphides in such aqueous systems as yellow ammonium sulphide.

* Authors to whom correspondence should be addressed.

Even recent discussions[4] of the mobility of platinum in aqueous media are in terms of platinum(II) and unidentate S_x^{2-}, whereas the oxidizing power of S_x^{2-} with $x > 4$ and the chelate effect actually combine to make chelated species containing platinum(IV), such as $Pt(S_5)_3^{2-}$, dominant. In much the same way, the early assumption that treatment of compounds of rhodium(III) with stannous salts gave the reduced state rhodium(I) has needed revision, since anions $[Rh(SnCl_3)_nCl_{6-n}]^{3-}$ are isolable.[5]

In addition to the $[PtS_{15}]^{2-}$ ion of Hofmann and Höchtlen,[6] and the remarkable[1k] $[Pt(S_6)_3]^{2-}$ ion, with three seven-membered rings, it was possible to prepare the $[PtS_{17}]^{2-}$ anion (which resolved[1a] spontaneously upon crystallization) as its ammonium salt dihydrate. This finding prompted further investigation of the platinum polysulphide system. We hoped to exercise control over stoichiometry during the synthesis, leading to the selective preparation of $[PtS_x]^{2-}$ ions ($12 \leqslant x \leqslant 21$), wholly inorganic dissymmetric anions.

Most platinum polysulphides have been synthesized from aqueous ammonia. We have in addition studied two other routes. The main solvent now used to prepare polysulphide solutions containing S_x^{2-} of known average x was acetonitrile and the base was NEt_3. We mixed such solutions formed via eq. (1) with an acetonitrile-soluble platinum(IV) compound, according to eq. (2) (where $4 \leqslant x \leqslant 7$).

$$2NEt_3 + H_2S + \frac{(x-1)}{8}S_8 \longrightarrow S_x^{2-} + 2NEt_3H^+ \quad (1)$$

$$(PPh_4)_2[PtCl_6] + 3S_x^{2-} \longrightarrow (PPh_4)_2[Pt(S_x)_3] + 6Cl^- \quad (2)$$

Rauh and associates made polysulphide solutions of a given sulphur chain length by another method.[7] Lithium, or its sulphide, is dissolved in non-aqueous solvents containing sulphur according to equations (3) or (4), respectively:

$$2Li + \frac{x}{8}S_8 \longrightarrow Li_2S_x \quad (3)$$

$$Li_2S + \frac{(x-1)}{8}S_8 \longrightarrow Li_2S_x. \quad (4)$$

Such solutions were also treated with the platinum(IV) salt to give polysulphides.

Our results are given here, with the crystal and molecular structure of the most frequently crystallized product, $(PPh_4)_2[Pt(S_5)_3]$, as two of its many solvates.

EXPERIMENTAL

Electronic spectra were measured with Cary 17, Unicam SP8000 and Perkin–Elmer λ-5 spectrometers, calibrated for wavelength and absorbance with holmium oxide and acidified potassium dichromate, respectively. IR spectra (some are given in Table 1) were recorded, as mulls, using a Perkin–Elmer 783 spectrometer. All solvents were of reagent grade. Acetonitrile was dried at reflux over calcium hydride, ethanol at reflux over magnesium and THF at reflux over sodium/benzophenone or sodium–potassium alloy.

$[PPh_4]_2[PtCl_6]$: $K_2[PtCl_6]$ (1.0 g) was dissolved in hot water (75 cm^3) and a solution of $[PPh_4]Br$ (2.25 g) in hot water (100 cm^3) was slowly added. The resulting orange precipitate was collected by filtration, washed with cold water and dried at 70°C for 12 h. The filtrate, kept cold for 12 h, yielded more orange precipitate which was treated in the same fashion. The total yield was 1.95 g (85%). Found: C, 52.5; H, 3.5. Calc. for $C_{48}H_{40}Cl_6P_2Pt$: C, 53.0; H, 3.7%. Tetraphenylphosphonium bromide was analysed to check the method. Found: C, 65.8; H, 5.3. Calc. for $C_{24}H_{20}BrP$: C, 65.9; H, 5.0%.

Preparation of ditetraphenylphosphonium heptasulphide: $(PPh_4)_2S_7$

Sulphur (265 mg, 1.0 mmol) was added with dry MeCN (50 cm^3), PPh_4Br (1.33 g, 3.2 mmol) and NEt_3 (0.46 cm^3, 3.3 mmol) to a triple-necked flask. The solution was first degassed (nitrogen gas flow) for 5 min, then H_2S (Kipps apparatus) was bubbled through for 30 min, followed by dinitrogen bubbled slowly through for 2 h. The solution was stored cold (refrigerator) over two nights, and red crystals formed. These were collected and washed with ether: yield, 0.33 g. Found: C, 63.9; H, 4.00. Calc. for $C_{48}H_{40}P_2S_7$: C, 63.8; H, 4.5%. The single crystal unit cell parameters were $a = 1105$, $b = 1858$, $c = 1205$ pm, $\alpha = 74.56$, $\beta = 68.97$, $\gamma = 87.73°$ and $V = 2.223$ nm^3. The known cell parameters for $(PPh_4)_2S_7$ arc[9] $a = 1104$, $b = 1859$, $c = 1204$ pm, $\alpha = 74.58$, $\beta = 69.05$, $\gamma = 87.76°$ and $V = 2.220$ nm^3.

Preparation of $(PPh_4)_2[PtS_x]$ (x = 12–21)

The results are collected in Table 2.

The polysulphide solutions were prepared according to eqs (1) and (2).

(1) *Aerobic syntheses.* A typical attempted preparation is described (actually for $(PPh_4)_2[PtS_{12}]$). For PtS_{15}, PtS_{18} and PtS_{21} systems, the absolute amounts of base and $(PPh_4)_2[PtCl_6]$ were varied, keeping the same molar proportions using 100 mg elemental sulphur in each synthesis.

Elemental sulphur (0.100 g, 0.39 mmol) was added, with dried MeCN (50 cm^3) and NEt_3 (0.29 cm^3, 2.09 mmol) to a 100 cm^3 Erlenmeyer flask. H_2S was bubbled through the mixture for 2 min, after which all the sulphur dissolved to give a brownish-red solution. A 25 cm^3 aliquot was added to a solution of $(PPh_4)_2[PtCl_6]$ (0.189 g, 0.17 mmol), in MeCN (20 cm^3). A stopper was placed in the reaction flask and it was left at room temperature.

After 12 h, all the flasks contained some solid. Only the $[PtS_{15}]^{2-}$ system gave reasonable crystals; these were collected by decantation and washed with a little MeCN, then ether (final mass = 75 mg). After a further 6 weeks, more brown solids had separated which did not analyse as pure polysulphide complexes of platinum.

Further experiments were done using different mixed solvents. (i) To sulphur (1.25 g) and NEt_3 (3.0 cm^3) were added dry MeCN (35 cm^3) and dry ethanol (35 cm^3) and H_2S (from a Kipps apparatus) was bubbled through the mixture for 2 min, by which time all the sulphur had dissolved. Some of this solution (5.0 cm^3) was added to a solution of $(PPh_4)_2[PtCl_6]$ (100 mg) in MeCN (20 cm^3). The red crystals which formed after 12 h were separated and washed three times with toluene and ether.

(ii) Experiment (i) was slightly modified: bench reagents were used, and ethanol was replaced by THF. After 12 h, a mixture of sulphur and red polysulphide crystals was isolated. The product was washed well with toluene, then ether.

(2) *Anaerobic synthesis.* Typical preparations, actually for $(Ph_4P)_2[Pt(S_5)_3]$, are described.

(i) In MeCN: (a) dry MeCN (100 cm^3) was added to sulphur (2.04 g) in a triple-necked flask. The mixture was degassed (vacuum line) and oxygen-free NEt_3 (3.4 g) was added. H_2S was slowly bubbled through the mixture which was kept at −10°C (methanol–solid carbon dioxide bath) for 20 min, with continuous stirring, until all the sulphur had dissolved to give a deep red solution. The solution (A) was allowed to warm slowly to room temperature.

A 10 cm^3 aliquot of this solution (A) was added to a deoxygenated (nitrogen bubbler) solution of $(PPh_4)_2[PtCl_6]$ (0.200 g, 0.18 mmol) in MeCN (10 cm^3) and the mixture cooled (refrigerator). After 3 days, the red leafy crystals were separated and washed with ether (yield: 0.232 g, 93%).

The remaining polysulphide solution (A) was kept under nitrogen at room temperature for 13 days, then a 5 cm^3 aliquot was added to $(PPh_4)_2[PtCl_6]$ (0.100 g) in MeCN (10 cm^3). The solution was stored (refrigerator) for 12 h and the resultant red crystals were isolated and washed with THF and ether (yield: 0.110 g, 88%).

(b) Elemental sulphur (0.256 g, 1.0 mmol) was added to a triple-necked flask containing $(PPh_4)Br$ (1.677 g, 4.0 mmol) and NEt_3 (0.404 g, 4.0 mmol) in dry MeCN (50 cm^3). The mixture was cooled to approximately −30°C (methanol–solid carbon dioxide) and degassed (vacuum) three times. H_2S was bubbled through the stirred solution for about 5 s, causing an immediate green colouration, the solution soon becoming red. Further 5 s additions of H_2S were carried out at intervals of 10 min for 1 h, by which time all the sulphur had dissolved to give a red solution. This was stored under nitrogen for 12 h in the refrigerator. Red crystals (200 mg) were filtered off and washed with a little THF and ether.

The "hexa- and heptasulphide" analogues were prepared in a similar fashion, varying the amounts of starting materials according to eq. (1). The small, red spherical crystals obtained for "S_6^{2-}" and the red, acicular crystals filtered from the "S_7^{2-}" preparation were collected as above.

(ii) In mixed solvent: sulphur (2.5 g) was added to premixed THF (35 cm^3), MeCN (35 cm^3) and NEt_3 (6.0 cm^3). The new mixture was degassed and

Table 2. Summary of preparation of polysulphido complexes of platinum from $(PPh_4)_2[PtCl_6]$

Stoichiometry,[a] x, (in $[Pt(S_x)_3]^{2-}$)	Solvent[b]	O_2 free	Method	Yield (% based on Pt)	Microanalysis[c] C	H	S[d]	Comment

[e] H_2S from cylinder except in these two cases, when it was from a Kipps apparatus.
[f] Based on $[PtS_{18}]^{2-}$.

H_2S was slowly bubbled for 25 min until all the sulphur dissolved. Some (4.0 cm^3, 1.12 mmol) of this polysulphide solution (P) was added to a deoxygenated solution of $(PPh_4)_2[PtCl_6]$ (0.200 g, 0.18 mmol) in MeCN (25 cm^3). After standing for 12 h (refrigerator), red crystals (0.21 g, 85%) were isolated and washed with THF and ether.

The remaining polysulphide solution (P) was kept for 5 h under nitrogen at room temperature and the above experiment repeated to yield 0.210 g of similar red crystals (84%) (see Table 2).

(iii) From attempted synthesis of $(PPh_4)_2[PtS_{18}]$: a mixture of sulphur (2.05 g, 8.0 mmol), NEt_3 (3.6 cm^3, 25.6 mmol) and MeCN (100 cm^3) was degassed twice at −5°C (methanol–solid carbon dioxide). H_2S was slowly bubbled for 30 min, during which time the temperature rose to 15°C. (After 5 min bubbling, all the sulphur had dissolved—however a fluffy brown solid formed which re-dissolved upon further addition of H_2S.) (a) The resulting solution (F) was stirred under nitrogen for 2 h and added (10 cm^3) to a solution of $(PPh_4)_2[PtCl_6]$ (0.20 g, 0.185 mmol) in MeCN (5 cm^3). After 12 h in the cold, red crystals, similar in appearance to $(PPh_4)_2[PtS_{15}]$, (0.200 g, 74%—based on $(PPh_4)_2[PtS_{18}]$) were isolated and washed with THF, toluene and ether (see Table 2). (b) The remaining polysulphide solution (F) was degassed three times at −10°C to remove any excess of H_2S, and yellow crystals appeared. H_2S was therefore passed into the mixture until all solids dissolved. 10 cm^3 of this new solution was added to a solution of $(PPh_4)_2[PtCl_6]$ (0.166 g) in MeCN (5 cm^3). After 2 weeks in the refrigerator, yellow–red crystals (X) were separated and washed with ethanol, benzene and ether (yield: 0.208 g, 94%—based on $(PPh_4)_2[PtS_{18}]$). Because of its microanalysis (low carbon, high hydrogen), the substance, X (53 mg) was dissolved in DMF (2 cm^3) and THF (2 cm^3) was added. After 5 days in the refrigerator, 19 mg of red crystals were separated by filtration. Diethyl ether (1 cm^3) was added to the filtrate; after 3 days in the refrigerator, a further 23 mg of red crystals were isolated. (Total yield from recrystallization of X was 42 mg, 80%.)

(3) *Using lithium reagents.* Solutions of lithium sulphides in acetonitrile were made up following eqs (3) and (4) of the text, to give $x \doteq 5$. The polysulphide solutions were added to solutions of $(PPh_4)_2[PtCl_6]$ in acetonitrile. Reaction (4) gave no useful products, whereas path (3) gave a brown-black material. This crude $(PPh_4)_2PtS_x$ (30 mg) was dissolved in DMF (1.0 cm^3). The solution was kept for 3 days in the refrigerator, diethyl ether (1.0 cm^3) was added and after a further 2 days in the refrigerator, red crystals (15 mg) were separated by filtration and washed with ether. Further addition of ether to the filtrate gave only a trace of brown substance.

X-ray analyses of bis(tetraphenylphosphonium) tris(pentasulphido)platinate(IV) *mono solvates*

The crystals of $(PPh_4)_2Pt(S_5)_3$, isolated from the DMF solution of "$(PPh_4)_2PtS_{18}$" and the DMF solution of $(PPh_4)_2PtS_x$ (made from lithium sulphides) were studied by X-ray methods. Crystals from both samples had the same unit cell within experimental error. The intensity data set was collected for a crystal obtained from the lithium sulphide source. The crystal structure of the compound isolated from DMF showed it to be a DMF solvate. During our earlier work,[1k] crystals were isolated from the aged and dismuted acetone solution of $(NH_4)_2PtS_{17}\cdot 2H_2O$. These had almost the same unit cell as those recrystallized from DMF. An intensity data set was also collected for this crystal, isolated from acetone. It has the same molecular structure, according to X-ray measurements, but is an acetone solvate.

Single-crystal measurements were carried out with an Enraf-Nonius CAD4 diffractometer using Mo-K_α radiation. The data obtained were corrected for Lorentz and polarization effects.

Crystal properties for $(PPh_4)_2Pt(S_5)_3\cdot$DMF (**1**): $M_r = 1427.87$; space group $P1$; $a = 1185.3(11)$, $b = 1335.3(7)$, $c = 1930.3(15)$ pm; $\alpha = 95.77(1)°$; $\beta = 93.76(3)°$; $\gamma = 105.64(2)°$; $Z = 2$; $V = 2.913$ nm^3; μ(Mo-K_α) = 30.4 cm^{-1} and $T = 296$ K.

Crystal properties for $(PPh_4)_2Pt(S_5)_3\cdot$acetone (**2**): $M_r = 1412.94$; space group $P1$; $a = 1172.3(11)$, $b = 1337.3(7)$, $c = 1937.4(15)$ pm; $\alpha = 96.03(5)°$; $\beta = 94.57(7)°$; $\gamma = 104.79(6)°$; $Z = 2$; $V = 2.903$ nm^3; μ(Mo-K_α) = 30.5 cm^{-1} and $T = 296$ K.

The intensities of two check reflections of **1** and **2** showed no loss of intensity. Of 8174 independent reflections of **1**, 5422 having $I > 2.5\sigma(I)$ were accepted as observed. Of 6439 independent reflections of **2**, 2907 having $I > 2.5\sigma(I)$ were accepted as observed.

The structures were solved by direct methods, which gave positional parameters for platinum and sulphur atoms. The atomic scattering factors and anomalous dispersion correction factors for heavy atoms were taken from the International Tables.[10] The structure was refined with Pt and P atoms having anisotropic and O, N, C and H atoms isotropic temperature factors, respectively. Phenyl groups were refined as rigid units. An empirical absorption correction was applied. The C—H hydrogen positions were calculated assuming the C—H distances to be 95 pm.

The refinements led to a final $R = 0.048$ ($R_w = 0.051$) for **1** and $R = 0.062$ ($R_w = 0.043$) for **2**. The weighting scheme was based on sigma weights. For both compounds, the largest residual electron densities (1.5 e $Å^{-3}$) were near the sulphur atoms [S(11), S(12), S(13)]. Temperature parameters of the same atoms were also large. Crystallographic calculations were performed with the TEXSAN programs.[11] Figures were drawn with PLUTO[12] and ORTEP[13].

RESULTS AND DISCUSSION

Results of the synthetic work are displayed in Table 2. Orange $(PPh_4)_2[PtCl_6]$ was prepared in good yield (see Experimental) and was soluble in acetonitrile.

Attempts to prepare platinum polysulphides from pure acetonitrile solutions in the presence of oxygen were, on the whole, unsuccessful. However, some crystals of $(PPh_4)_2[PtS_{15}]$ were obtained in low yield (see Table 2).

Reaction of lithium sulphide with sulphur in acetonitrile [eq. (3)] and subsequent addition of $(PPh_4)_2[PtCl_6]$ gave no useful products. However, if lithium sulphide was replaced by lithium [eq. (4)], a brownish-black material was obtained. Analysis showed that this was not pure $(PPh_4)_2[PtS_x]$. However, when this crude substance was recrystallized from DMF (see Experimental), red crystals were obtained which analysed (C, H) for "$(PPh_4)_2[PtS_{17}]$" (see Table 2). Nevertheless, the X-ray structure determination proved this compound in fact to be $(PPh_4)_2[PtS_{15}]\cdot(H_3C)_2NCHO$ with molecules of the solvent DMF occupying gaps in the structure. Dismutation in acetone gave $(PPh_4)_2[Pt(S_5)_3]\cdot$acetone.

Preparation of $(PPh_4)_2[PtS_n]$ *complexes under nitrogen*

When the sulphide solution (stoichiometry "S_5") was prepared in acetonitrile in the absence of dioxygen and added to a deoxygenated solution of $(PPh_4)_2[PtCl_6]$ in the same solvent, a high yield (93%) of $(PPh_4)_2[PtS_{15}]$ resulted (see Table 2). When the polysulphide solution used was stored under nitrogen for 13 days and the experiment repeated, similar leafy, red crystals formed in 88% yield. The crystals made in acetonitrile were not good enough for X-ray work. The compound is insoluble in water and all common solvents except DMSO and DMF; in fact, boiling in concentrated sodium hydroxide causes no dissolution and hence no decomposition. $(PPh_4)_2[PtS_{15}]$ slowly decomposes in DMF: a fresh solution has maximal absorption at 390 nm ($\varepsilon = 10{,}800$ dm^3 mol^{-1} cm^{-1}) and 310 nm ($\varepsilon = 17{,}800$); a solution 3 days old shows considerable broadening of these bands and the apparent extinction coefficients drop to 5530 and 12,430 dm^3 mol^{-1} cm^{-1}, respectively).

Preparation of $(PPh_4)_2S_7$

When $(PPh_4)Br$ was added to a polysulphide solution prepared in dry MeCN ("S_5^{2-}" stoichiometry) in the absence of any metal ion, red crystals formed within 12 h. From preliminary X-ray studies, this compound is the known $(PPh_4)_2S_7$, which Coucouvanis and his colleagues prepared[7] also from MeCN solutions. Microanalyses of compounds prepared as $(PPh_4)_2S_6$ and $(PPh_4)_2S_7$ show these to be different (or decomposed) materials, and whose composition is not understood. The compounds are insoluble in water, diethyl ether, toluene and triethylamine, but dissolve in polar organic solvents to give unstable blue/green solutions, which lose all colour if left at room temperature in air for several minutes. The cause of such blue colours has been much debated,[14] most workers agreeing that it is the S_3^- ion radical which is responsible.

Structures of bis(tetraphenylphosphonium)tris(pentasulphido)platinate(IV) *mono solvates*

The molecular structures of both studied crystals consist of PPh_4^+ cations and $Pt(S_5)_3^{2-}$ anions with the solvent molecules in the holes formed by the ions. The structural parameters of the cation are normal. The S_5^{2-} ligands are coordinated to platinum(IV) ions in a bidentate way, forming three six-membered rings around the platinum ion (Fig. 1). The bonding parameters of the anions in both compounds are very much the same (see Table 3). The Pt—S bond distances are of the same order as in other compounds of the $[Pt(S_5)_3]^{2-}$ anion.[1k,15,16]

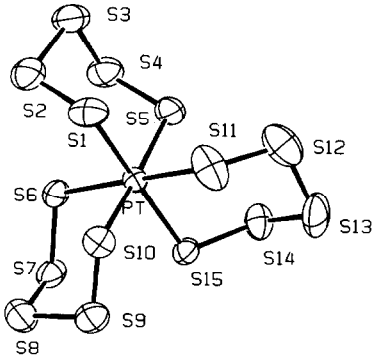

Fig. 1. The structure and labelling of the ion $[Pt(S_5)_3]^{2-}$ in **1** and **2**.

S(10)—Pt—S(15)	91.7(1)	91.6(2)	S(13)—S(14)—S(15)	107.5(2)	108.5(4)
S(11)—Pt—S(15)	90.5(1)	90.6(2)	S(14)—S(15)—Pt	110.6(2)	111.4(3)

The values of the chelate S—Pt—S angles in $Pt(S_5)$ units range from 90.5 to 92.1°. These values are very near to the values[1k] of 90.9–92.8(2)° of the corresponding S—Pt—S angles in the anionic PtS_5 units of $(NH_4)_2[Pt(S_5)_3]\cdot 2H_2O$.

The torsion angles within PtS_5-rings (S = 1–5), (S = 6–10) and (S = 11–15) are in Table 4. They vary from 57.4(5) to 79.9(1)°. The greatest deviations from the normal chair-type six-membered bonding parameters occur in the third chelate ring in **2**. The residual electron densities and high temperature parameters of S(11), S(12) and S(13) suggest that there might be some disorder in this chelate ring. However, none of these sulphur-atoms refined in two positions. The six-membered rings are flexible. The packing forces may induce the ring to have a certain conformation: the presence of the different solvent molecules in the unit cells may be the underlying reason for that. The packing of **1** is shown in Fig. 2.

The bond angles within the chelate rings are all between 91–93°, and rather remarkably, in a structure ostensibly free of strain, the angles made at platinum by opposite sulphur ligand atoms are all between 173–4°. The same feature, apparent departure from linearity (in strain-free compounds of octahedral metal ions) of the angles along the *x*, *y* and *z* axes, is even clearer in the related salt[1k] $(PPh_4)_2[Pt(S_6)_3]$, where these angles are all about 169°. Such apparent deviations from expected linearity in angles at thio-ligated ions are not without precedent (cf. proustite, Ag_3AgS_3 and pyrargite, Ag_3SbS_3, where the bond angles at the two coordinated silver are 165°).

Conclusion

Speciation in polysulphide solutions arises from complicated equilibria sensitive to solvent, to the base used, and to the presence of dioxygen. The particular S_x^{2-} species (i) concentrated in, and (ii) isolated from such complicated solutions by a given metal ion depends markedly on the metal ion and/or cation present and on relative solubilities, e.g.

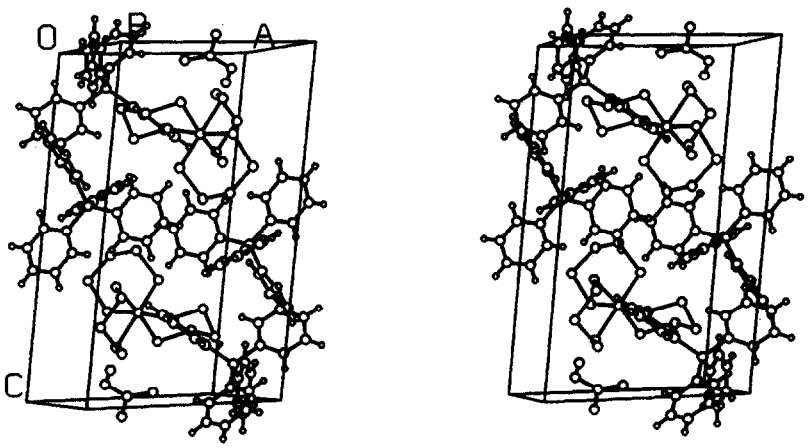

Fig. 2. Views of the packing in **1**.

$[AuS_9]^-$,[17] $[PPh_4]_2S_7$[9] and $[PPh_4]_2[PtS_x]$ ($x = 15$ for most reactions here, employing a wide range of conditions; 17[1c] or 18[1k]). When the combined effect of these factors can be predicted, a whole series of new anions $[MS_x]^{n-}$ or salts C_aS_x (C = cation) could be prepared. The situation is, naturally, further enriched by elements of kinetic control and by the presence of ligands other than oligosulphides. For example, both platinum(II) and platinum(IV) are most readily obtained, homoleptic, with S_5^{2-}: in the presence of phosphines, however, S_4^{2-} is selected (at least in the crystallizing solid), in $[(R_3P)_2PtS_4]$.

COMPLEXES OF LAWSONE WITH URANIUM, MOLYBDENUM, RUTHENIUM AND OSMIUM, AND THEIR USE AS ORGANIC OXIDANTS

AHMED M. EL-HENDAWY

Chemistry Department, Faculty of Science, Damietta, Egypt

(*Received* 8 *March* 1991; *accepted* 3 *May* 1991)

Abstract—The new complexes *trans*-$[UO_2(NQ)_2]$, *cis*-$[MoO_2(NQ)_2]$ and $[M^{III}Cl_2(EPh_3)_2NQ]$ (M = Ru, E = As; M = Os, E = P; HNQ = lawsone, 2-hydroxyl-1,4-naphthoquinone) have been prepared. They were characterized by spectroscopic techniques and investigated by cyclic voltammetry. The complex $[RuCl_2(AsPh_3)_2NQ]$ was found to be a more efficient catalyst than that of the osmium complex for the oxidation of primary alcohols to aldehydes and of secondary alcohols to ketones in the presence of N-methylmorpholine-N-oxide as co-oxidant.

Quinones play an important role in many biological electron-transfer processes, particularly in respiration and photosynthesis.[1] Some of these reactions are catalysed by metal ions such as copper, iron, manganese and molybdenum, although mechanistic aspects of these interactions have not been fully elucidated.[2] During these processes, quinones are reversibly reduced to either semiquinone radical anions or dianionic catechol with concomitant oxidation of the metal ions. Lawsone (HNQ) is the 2-hydroxy-1,4-naphthoquinone pigment found in the leaves of *Lawsonia alba* ("Henna"). Preparation and characterization of its complexes with divalent copper, cobalt, nickel, zinc and lead have been investigated.[3] High-spin ferrous complexes of the type $[Fe^{II}L_2(H_2O)_2]$ (L = anion of lawsone, NQ or its C-3 substituted derivatives, R-NQ; R = CH_3, Cl, I, Br, NO_2) have been studied.[4] More recently[5] the X-ray crystal structure of the complex $[Fe^{II}(NQ)_2(H_2O)_2]$ has been determined, showing that the bound lawsone ligands are in their fully oxidized form and the coordination centres are the C-2 phenolate and the C-1 carbonyl oxygen atoms.

We now report the preparation of the new complexes: *trans*-$[UO_2(NQ)_2]$, *cis*-$[MoO_2(NQ)_2]$ and $[M^{III}Cl_2(EPh_3)_2NQ]$ (M = Ru, E = As; M = Os, E = P). We also report their spectroscopic and electrochemical behaviour and study the catalytic oxidation of alcohols by ruthenium and osmium complexes in the presence of N-methylmorpholine-N-oxide (NMO) as co-oxidant, since $[Ru^{III}Cl_2(PPh_3)_2acac]$ and $[Os^{III}Cl_2(PPh_3)_2SQ]$ (SQ = semiquinone of catechol) have been used previously.[6,7]

RESULTS AND DISCUSSION

Reaction of lawsone with both uranyl acetate $UO_2(CH_3COO)_2 \cdot 2H_2O$ and $MoO_2(acac)_2$ in refluxing ethanol for 2–4 h gives dark reddish-brown and dark brown products, respectively. The ruthenium and osmium complexes were made from $[MCl_3(EPh_3)_2MeOH]$ (M = Ru, E = As; M = Os, E = P) since the complex $[OsCl_3(PPh_3)_2MeOH]$ was reported to be a precursor for the synthesis of $[OsCl_3(PPh_3)_2L]$ (L = O,O-donor ligand (−1) or semiquinone anion).[7,8] Analytical data (Table 1) indicate that these complexes have the formula $[MO_2(NQ)_2]$ (M = U or Mo) and $[M^{III}Cl_2(EPh_3)_2NQ]$ (M = Ru, E = As; M = Os, E = P). Uranium and molybdenum complexes are soluble only in DMSO, but the other complexes are soluble in dichloromethane in which their molar conductivities are very low. The magnetic moment at room temperature, μ_{eff} of the ruthenium and osmium complexes are 1.83 and 2.12 BM, respectively, near the spin-only value corresponding to one unpaired electron, suggesting the low-spin d^5 $(t_{2g})^5$ configuration for the ruthenium(III) or osmium(III)

ion in an octahedral environment. These values are similar to those found for previously reported ruthenium(III) and osmium(III) complexes.[6,8]

Vibrational spectra

The IR spectra of lawsone shows a medium broad band at 3190 cm^{-1} due to the ν(O—H) vibration, as previously mentioned;[4b] this band, as expected, is not observed in the complexes. Raman spectra of the solid of the free ligand display strong bands at 1675 and 1643 cm^{-1} similar to those found in the IR spectra at 1682 and 1640 cm^{-1} attributable to the free carbonyl and the hydrogen-bonded carbonyl.[3,9] In the complexes, both of the two carbonyl vibrations are shifted to lower wavenumbers, as found for lawsonato and substituted lawsonato iron(II) complexes.[4] The hydrogen-bonded carbonyl band in the ligand is more greatly shifted in our complexes and appears in the region 1590–1560 cm^{-1}. This shifted carbonyl band was found to activate the adjacent C=C skeletal in-plane vibration of the conjugated aromatic ring and these activated C=C vibrations can be seen in the region 1570–1540 cm^{-1}, at lower wavenumbers compared with those of the free ligand. The ν(C—O) vibration at 1222 cm^{-1} in lawsone is shifted upwards by *ca* 20–80 cm^{-1} in our complexes due to increase in the bond order.[4b] This confirms the participation of C-1 carbonyl and C-2 hydroxyl in coordination. Raman spectra of $[UO_2(NQ)_2]$ in DMSO contains a strong band at 826 cm^{-1} which is likely to arise from the symmetric stretch of $\nu_s(UO_2)$ of the *trans*-O=U=O moiety, with the strong IR band at 928 cm^{-1} being assigned to $\nu_{as}(UO_2)$. For the molybdenum complex, strong IR bands are found at 920 and 958 cm^{-1}, assigned to asymmetric and symmetric stretches, respectively, of the *cis*-MoO_2 unit as in other complexes of this type.[10–12] The deep colours of the complexes other than the uranyl complex makes them unsuitable for Raman studies. In the ruthenium and osmium complexes, besides the bands representing triphenylphosphine, arsine or coordinated lawsonate anion (NQ), strong bands were observed at 329 and 320 cm^{-1}, likely to be due to ν(Ru—Cl) and ν(Os—Cl) vibrations, respectively, and similar to those observed for $[M^{III}Cl_2(PPh_3)_2L]$ (L = O,O-donor ligand (−1); M = Ru, Os).[6,8] The most important vibrational bands for lawsone and its complexes are listed in Table 1.

^{1}H and ^{13}C NMR spectra

The ^{1}H and ^{13}C shifts are listed and assigned in Table 2; the numbering scheme for the carbon nuclei of lawsone is shown in Fig. 1. It has been

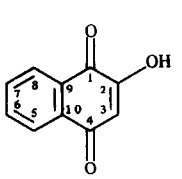

Fig. 1. 2-Hydroxy-1,4-naphthoquinone (HNQ), with atom numbering scheme.

[b] Reference 27.
[c] Reference 18.

reported earlier that in lawsone the hydroxyl signal was not observed,[13] but a broad signal (in $CDCl_3$) at δ 7.42 ppm was seen by others[14] suggesting a dimeric and polymeric association of lawsone. In our hands lawsone in $(CD_3)_2SO$ showed a broad signal at δ 11.63 ppm typical of intramolecular hydrogen bond formation,[15] similar to that found for juglone (5-hydroxy-1,4-naphthoquinone) and plumbagin (2-methyljuglone) at δ 12.3 ppm.[14] The H_3 proton appears as a sharp singlet while the $H_{6,7}$ protons appear as a multiplet. The H_5 and H_8 protons each give a doublet at δ 7.90 and 7.95 ppm, respectively. For the uranium complex $[UO_2(NQ)_2]$, the hydroxyl signal disappeared and there is relatively little difference in the spectral pattern, but a shift to higher field is observed for the H_3 proton although it is only slightly consistent with electron withdrawal by the metal causing decreased electron density in the olefinic double bond; similar effects are observed more in catecholato complexes.[12,16]

The ^{13}C NMR spectrum of the ligand has not been fully and correctly assigned,[17] and on the basis of ^{13}C NMR data of 2-methoxy-1,4-naphthoquinone and other derivatives[18] we could assign the spectra of lawsone and of its uranyl complex as listed in Table 2. The only two resonances to undergo major shifts are C-1 and C-2 (about 10 ppm) to lower field, those nuclei adjacent to oxygen-donor atoms of carbonyl and hydroxyl groups; as observed in the complexes of catechols,[12,16] catecholamine,[10] tropolone[19] and maltol.[20] There is a similar but smaller consequential shift for C-3 and C-9 (see Table 2). We were unable to measure the NMR spectra of the molybdenum complex owing to its low solubility.

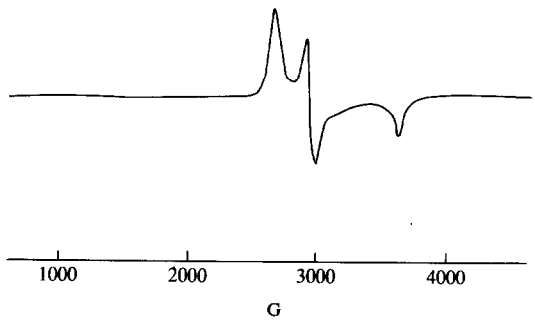

Fig. 2. ESR spectrum of **IV**.

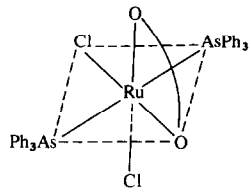
over the sample tube. The spectrum (Fig. 2) shows three g-values in agreement with the low symmetry of the ligand-field with $g_x = 2.49$, $g_y = 2.24$ and $g_z = 1.81$, similar to the g-values for *mer*-$[RuCl_3(AsPh_3)_3]$[25] and $[Ru^{III}(Salen)(PPh_3)Cl]$ [H_2Salen = N,N′-ethylenebis(salicylaldimine)].[26] Recently[8] we have shown that the complex $[OsCl_2(PPh_3)_2L]$ (L = hexafluoroacetylacetonate) (**A**) has a similar type of ESR spectrum, and therefore we suggest structure **B** for our present ruthenium complex of C_2 symmetry, which is similar to that of complex **A**.[8]



(B)

(O—O = NQ)

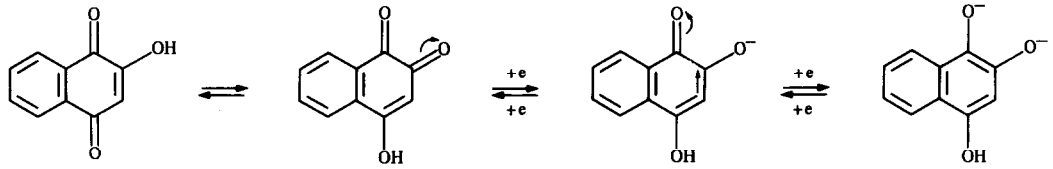
Electronic and ESR spectra

The UV–vis spectra of ruthenium and osmium complexes in dichloromethane solution (Table 2) contained high intensity bands above 500 nm assigned to ligand(π) → metal(d) charge-transfer. The band around 300 nm or the shoulder (in the osmium complex) has been assigned to metal(d) → ligand(π^*) charge-transfer.[21–24] The d–d electronic transition band of lower intensity that has been observed[6] around 600 nm in the complexes $[Ru^{III}Cl_2(PPh_3)_2L]$ [L = O,O-donor ligand (−1)], is therefore expected to receive a large contribution from the intense charge-transfer bands.[4b] The ligand π–π^* transitions occur at 280[7,24] and 254 nm for ruthenium and osmium complexes, respectively.

The ESR spectrum in dichloromethane frozen glasses of the complex $[RuCl_2(AsPh_3)_2NQ]$ (**IV**) (concentration 5×10^{-3} M) was measured at 77 K; cooling was by means of cold nitrogen gas passed

Redox properties

The electrochemical properties of the complexes were investigated by cyclic voltammetric techniques (Table 2). The voltammograms of lawsone, its ruthenium and osmium complexes were recorded on 0.1 M $Bu^n_4NPF_6$–CH_2Cl_2 solutions (potentials vs the Ag electrode). Lawsone exhibits an irreversible cathodic peak, $E_{p,c} = -0.58$ V, and a quasi-reversible wave of reduction, $E_{1/2} = -1.32$ ($\Delta E = 160$ mV), similar to those obtained in 0.1 M $Bu^n_4NClO_4$–DMSO solution.[27] The cathodic peak corresponds to the one-electron reduction of the quinone to the semiquinone anion (**C**), while the reduction wave arises from the conversion of semiquinone to the catecholate dianion (**D**).[4b,28,29] Lawsone can be represented by the tautomeric form of o-quinone (o-Q) which undergoes one-electron reduction to both the **C** and **D** forms shown in Scheme 1.



Scheme 1.

The complex $[UO_2(NQ)_2]$ shows only a quasi-reversible reduction wave, $E_{1/2} = -0.36$ V ($\Delta E =$ 80 mV), and an irreversible reduction peak, $E_{p,c} = -1.45$ V; these could be attributed to reduction of the coordinated lawsone to forms **C** and **D**, respectively. Uranyl acetate under the same conditions does not show any peaks corresponding to reduction or oxidation, nor does the complex $[MoO_2(NQ)_2]$. In the ruthenium complex $[RuCl_2(AsPh_3)_2NQ]$ (**IV**), two redox waves of reduction were found, $E_{1/2} = -0.56$ V ($\Delta E = 80$ mV) and -0.81 V ($\Delta E = 70$ mV), due to *o*-Q/SQ and SQ/Cat reductions, respectively. At positive potentials there is an oxidation wave of similar peak height to those of the reduction waves, arising from a Ru^{III}/Ru^{IV} oxidation. An irreversible anodic oxidation peak is also observed, $E_{p,a} = +1.04$ V, similar to that found for $[RuCl_2(PPh_3)_2acac]$ (**I**),[8] confirming the formation of higher oxidation states of ruthenium other than ruthenium(IV).

For $[OsCl_2(PPh_3)_2NQ]$ (**III**), the voltammogram (Fig. 3) shows three redox waves for reduction and another two for oxidation, each of similar peak height. The peak separation (ΔE) is close to that anticipated for a Nernstian one-electron process (59 mV).[30] The two oxidation waves at positive potentials may presumably be assigned to Os^{III}/Os^{IV} and Os^{IV}/Os^{V} oxidations, since the first redox wave was similarly found for osmium(III) complexes, e.g. $[OsCl_2(PPh_3)_2L]$ [L = O,O-donor ligand (-1)],[7,8] $[OsCl_3(PPh_3)py_2]$[31] and $[Os^{III}X_2(PPh_3)_2L']$ (X = Cl, Br; HL′ = 2-hydroxypyridine and picolinic acid).[32] The first reduction wave, $E_{1/2} = -0.51$ V ($\Delta E = 70$ mV), appears to be similar to those observed for the Os^{III}/Os^{II} reduction of osmium(III) complexes.[8,31,32] The other two reduction waves at more negative potentials are typical of *o*-Q/SQ and SQ/Cat reductions, as in the complexes $[Fe(NQ')_2(H_2O)_2]$ (NQ′ = NQ, R-NQ).[4b] These latter two redox waves are shifted to more negative potentials in the osmium complex than in the ruthenium complex. This reflects a decrease in the acidity of the osmium(II) species (**E**) compared with that of the ruthenium(III) complex (**F**), since the 5*d* electrons in the third-row transition element, osmium, are less tightly held by the nucleus than the 4*d* electrons in its congener, ruthenium, and also the difference in oxidation states of osmium(II) and ruthenium(III). So we expect that **IV** will be more oxidizing than the corresponding osmium complex (because it is more difficult to detach electrons from ruthenium). The formation of species **E** and **F** is shown below.

For scan rates (SR) between 10 and 100 mV s^{-1}, the ratio $i_p/(SR)^{1/2}$ (i_p = peak current) was constant and the ratio of anodic to cathodic peak current is one, the peak separation being independent of the scan rate. This indicates that the electron transfer is reversible or approaches reversibility and that mass transfer is limited. The stabilities of different oxidation states of ruthenium and osmium and coordinated NQ, SQ or Cat in the complexes are reflected by the reversibility of these processes (Scheme 2).

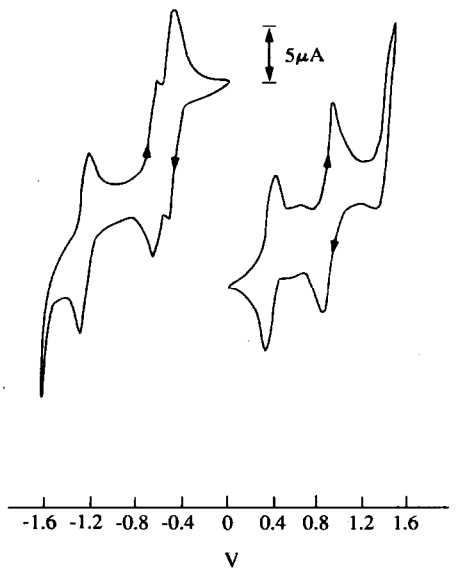


Fig. 3. Cyclic voltammogram in dichloromethane with 0.1 M $(Bu^n_4N)PF_6$ as supporting electrolyte (V vs silver electrode, scan rate 50 mV s^{-1}) for **III** ($\sim 10^{-3}$ M).

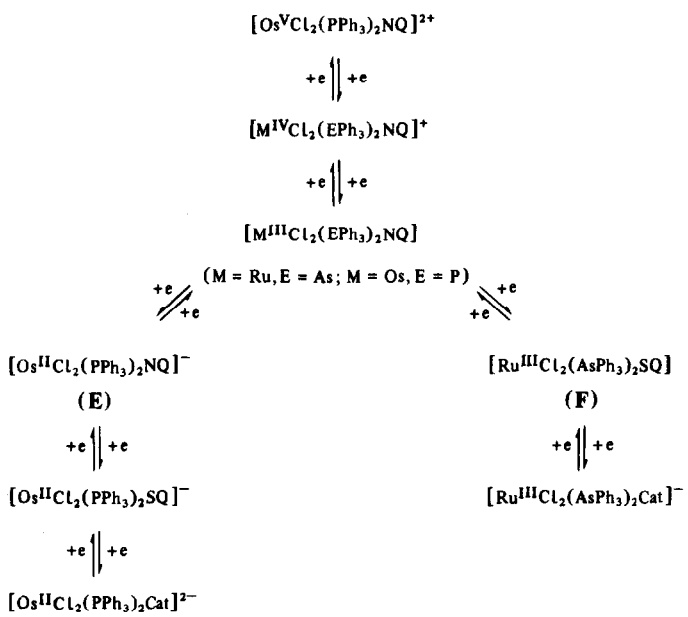

Scheme 2.

Catalytic oxidations

In our continuing work to develop new ruthenium(III) and osmium(III) complexes[6–8] as catalytic oxidants in the presence of excess NMO for selective oxidation of primary alcohols to aldehydes and secondary alcohols to ketones, we used the present, new complexes of ruthenium and osmium for such catalytic oxidation. The complex [Ru^{III}Cl$_2$(PPh$_3$)$_2$acac] (**I**) was found[6] to be a good oxidant for alcohols but the analogous osmium complex[8] showed only weak oxidation of alcohols. In Table 3 we summarize our results for catalytic oxidations by [M^{III}Cl$_2$(EPh$_3$)$_2$NQ] (M = Ru, E = As; M = Os, E = P) in the presence of NMO as the co-oxidant. The oxidations were carried out at room temperature in dichloromethane solution, from which water was removed using powdered molecular sieves. In no case was there detectable oxidation of an alcohol in the presence of NMO but in the absence of a ruthenium or osmium complex. Primary alcohols were oxidized to aldehydes and secondary alcohols to ketones with both higher yields and turnovers, similar to oxidations carried out previously using ruthenium complex **I** and [Os^{III}Cl$_2$(PPh$_3$)$_2$SQ][7] (**II**). In the case of unsaturated alcohols, e.g. cinnamyl alcohol, a lower yield of the corresponding aldehyde was produced by the osmium complex than was given by the ruthenium catalyst. A similar effect was noted for the catalytic oxidation by **II**[7] and by (4-t-But$_4$-pyH)$_2$[RuO$_2$Cl$_4$] in the presence of a greater excess of Et$_4$NCl.[33]

From Table 3 we notice that oxidations by [OsCl$_2$(PPh$_3$)$_2$NQ] (**III**) need more time for completion than oxidations by the ruthenium complex, which is expected as suggested above by the cyclic voltammetric data. Complex **III** can act as a real catalyst for such oxidations since the blue solution of the reaction mixture does not change at all during the reaction time. The osmium complex **III** is much more efficient towards oxidation compared with [OsCl$_2$(PPh$_3$)$_2$acac][8] but is similar to **II**. Also, the ruthenium complex [RuCl$_2$(AsPh$_3$)$_2$NQ] (**IV**) is a better oxidant than **I**. We believe that a possible reason for the efficiency of our present ruthenium and osmium complexes is due to the ability of the coordinated lawsone ligand, NQ, to be reduced to the semiquinone and catechol forms, as shown by the cyclic voltammetric behaviour of these complexes. The catalytic cycle of oxidation is activated by the presence of osmium(III) and ruthenium(III) in the complexes, which are being oxidized, respectively, to osmium(IV), osmium(V) and to ruthenium(IV) and its other higher oxidation states.

EXPERIMENTAL

Preparation of the complexes

Preparation of trans-[UO$_2$(NQ)$_2$]. To a hot solution of uranyl acetate, UO$_2$(CH$_3$COO)$_2$·2H$_2$O (0.42 g, 1 mmol), in ethanol (20 cm^3) was added 2-hydroxy-1,4-naphthoquinone (HNQ) (0.44 g, 2.5

Table 3. Catalytic oxidation of alcohols by $[MCl_2(EPh_3)_2NQ]$ (M = Ru, E = As; M = Os, E = P)/NMO

Alcohol	Product[a]	Time (h)	Yield (%)	Turnovers[b]
p-Methoxybenzyl	A	2	97	80
	A	5	81	100
Benzyl	A	3	87	80
	A	24	95	120
Piperonyl	A	3	94	100
	A	5	79	40
	A	20	91	120
Benzohydrol	K	2	84	50
	K	20	72	40
α-Tetralol	K	2	94	50
	K	24	93	60
Cinnamyl	A	2	91	60
	A	24	39	50

Underlined data refer to oxidation by $[OsCl_2(PPh_3)_2NQ]$/NMO.
[a] A = corresponding aldehyde, K = corresponding ketones.
[b] Turnovers = moles of product/moles of catalyst.

mmol) in ethanol (10 cm^3). The mixture was refluxed for 2 h on a steam bath, when a reddish-brown precipitate separated out, which was washed with hot ethanol and ether, and dried *in vacuo*. A similar procedure was used to prepare *cis*-$[MoO_2(NQ)_2]$ in which $MoO_2(acac)_2$ (prepared by the literature method[34]) replaced $UO_2(CH_3COO)_2 \cdot 2H_2O$ and a deep brown precipitate was obtained after 4 h reflux.

Preparation of $[RuCl_2(AsPh_3)_2NQ]$ (**IV**). The complex $[RuCl_3(AsPh_3)_2MeOH]$ (**V**)[35] was used as the starting material. A solution of **V** (0.21 g, 0.25 mmol) in methanol (100 cm^3) was refluxed, then the ligand (HNQ) (0.07 g, 0.4 mmol) added. The mixture was refluxed for 2 h and a dark solution was obtained, which was evaporated on a steam bath to near dryness. The residue was evaporated with hot methanol, washed carefully with methanol (3×10 cm^3) and then ether, and dried *in vacuo*.

Preparation of $[OsCl_2(PPh_3)_2NQ]$ (**III**). The complex was prepared from $[OsCl_3(PPh_3)_2MeOH]$, which was synthesized as reported previously.[8] A solution of $[OsCl_3(PPh_3)_2MeOH]$ (0.42 g, 0.5 mmol) in methanol (140 cm^3) was refluxed for 30 min on a steam bath until the solution became slightly dark yellow, followed by the addition of the ligand (HNQ) (0.13 g, 0.75 mmol). A reddish, then purple and finally blue solution was obtained, and after continuing reflux for 2 h, nice dark blue microcrystals were precipitated, filtered off, washed with methanol and ether, and dried *in vacuo*.

Catalytic oxidation by $[RuCl_2(AsPh_3)_2NQ]$ (**IV**)

The oxidation of piperonyl alcohol is typical. To a solution of piperonyl alcohol (1 mmol) was added NMO (3 mmol) in dichloromethane (20 cm^3) and 10^{-2} mmol of compound **IV**. The solution was stirred for 3 h in the presence of 4 Å molecular sieves (0.5 g). The mixture was evaporated to dryness and extracted with ether (2×25 cm^3). The combined ethereal extracts were filtered and evaporated to give piperonal, which was characterized and quantified as its 2,4-dinitrophenylhydrazone derivative.

The same experiment was carried out using $[OsCl_2(PPh_2)_2NQ]$ in place of **IV** above. The solution of the reaction mixture maintains its blue coloration and requires more time for completion (as in Table 3).

IR spectra were measured on a Perkin–Elmer 883 or FT 1720 instrument as liquid paraffin mulls between CsI plates and as KBr discs. Raman spectra were measured on a Spex Ramalog 5 instrument with a Coherent Radiation Innova 90 krypton-ion laser with excitation at 5682 Å (yellow), as a spinning disc with a KBr base for the solid sample of lawsone, and excitation at 6471 Å (red) for a DMSO solution of the uranyl complex in a sealed capillary. NMR spectra were measured on a Bruker WM-250 spectrometer. The electronic spectra were measured on a Philips PU 8740 UV–vis spectrophotometer or Varian 634 model. ESR spectra were recorded with a Varian E-12 spectrometer. Cyclic voltammetric

studies were carried out on a potentiostat/wave generator (Oxford Electrodes) using a platinum working electrode and silver reference electrode in conjunction with a Philips PM 8043 X–Y recorder. Magnetic measurements were made on a Johnson Matthey magnetic susceptibility balance.

Acknowledgements—I thank the Royal Society for support, Drs W. P. Griffith and J. F. Gibson for helpful advice, and also Johnson Matthey Ltd for the loan of platinum metals. I thank the University of London Intercollegiate Research Service (ULIRS) for the Raman spectra.

Abstract—The seven-coordinate complex [MoCl($GeCl_3$)$(CO)_2$$(NCMe)_2$($PPh_3$)] reacts with an excess of but-2-yne in CH_2Cl_2 at room temperature to give the six different ligand compound [MoCl($GeCl_3$)(CO)(NCMe)(PPh_3)(η^2-MeC_2Me)] (**1**) in good yield. Solid-state ^{13}C NMR spectroscopy suggests that the but-2-yne ligand is donating four electrons to the molybdenum in **1**. Preliminary studies of the reaction chemistry of **1** with neutral donor ligands are also described.

Many attempts to prepare octahedral complexes with six different monodentate ligands attached have been made with little success. Hitherto, no examples of molybdenum(II) or tungsten(II) complexes of this type have been made. We have been studying the chemistry of the seven-coordinate complexes [$MI_2(CO)_3(NCMe)_2$] (M = Mo or W)[1] with donor ligands[2] and alkynes.[3] In our attempt to potentially increase the number of different ligands attached to the metal, more recently we have been investigating the reactions with donor ligands[4] of the seven-coordinate compound [MoCl($GeCl_3$)$(CO)_3(NCMe)_2$]. This is prepared in high yield by reacting the zero-valent trisacetonitrile compound [$Mo(CO)_3(NCMe)_3$][5] *in situ* with $GeCl_4$. In this communication we report the preparation of the first example of a six different monodentate ligand molybdenum(II) complex [MoCl($GeCl_3$)(CO)(NCMe)(PPh_3)(η^2-MeC_2Me)] (**1**), and describe preliminary reports of its reaction chemistry.

Reaction of [MoCl($GeCl_3$)$(CO)_2$$(NCMe)_2$($PPh_3$)] and a four-fold excess of but-2-yne in CH_2Cl_2 at room temperature affords the dark green complex [MoCl($GeCl_3$)(CO)(NCMe)(PPh_3)(η^2-MeC_2Me)] (**1**) in greater than 70% yield. Complex **1** is particularly sensitive to water, and is also air-sensitive and can only be stored for a few days under nitrogen. It is soluble in polar solvents such as CH_2Cl_2, $CHCl_3$ and acetonitrile, but insoluble in hydrocarbon solvents and diethyl ether. Compound **1** has been fully characterized by elemental analysis (C, H and N), IR, ^1H and solid-state ^{13}C NMR spectroscopy.† Many attempts were made to grow suitable single crystals of **1** for X-ray analysis without success.

The IR spectrum of **1** shows, as expected, a broad single carbonyl band at 1975 cm^{-1}, and a weak asymmetric doublet due to coordinated acetonitrile at $\nu(N{\equiv}C)$ = 2313 and 2286 cm^{-1}. A very weak band at 1684 cm^{-1} due to coordinated but-2-yne is observed, which is at a considerably lower wavenumber compared to uncoordinated but-2-yne suggesting there is considerable back-donation of elec-

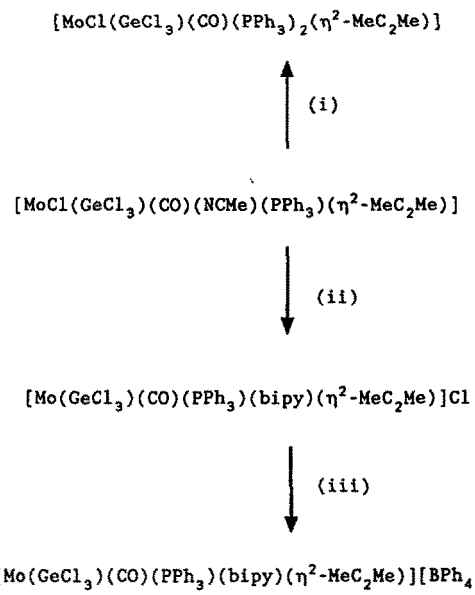
† Selected data for compound (1): Found: C, 43.2; H, 3.5; N, 1.4. $C_{25}H_{24}NOCl_4PGeMo$ requires: C, 43.2; H, 3.5; N, 2.0%. IR ($CHCl_3$) ν(CN) = 2313 (w) and 2286 (w) cm^{-1}; ν(CO) = 1975 (s) cm^{-1}; $\nu(C{\equiv}C)$ = 1684 (w) cm^{-1}. ^1H NMR (25°C) (CD_2Cl_2) 7.4 (m, 15H, Ph-H), 3.0 (vbrs, 6H, ≡C*Me*), 2.35 (s, 3H, NC*Me*) ppm. ^{13}C NMR (25°C, solid) 228.98 (bs, C≡C), 200.86 (bs, C≡O), 131.18 (bm, $CH_3C{\equiv}N$), 23.18 (vbrs, $CH_3C{\equiv}C$), 4.53 (bs. $CH_3C{\equiv}N$).

tron density from filled metal *d* orbitals to empty π^* orbitals on the but-2-yne. The solid-state ^{13}C NMR spectrum shows a broad alkyne carbon (C≡C) resonance at 228.98 ppm which suggests[6] that the but-2-yne ligand is utilizing both of its filled $p\pi$ orbitals and donating four-electrons to the molybdenum. It is difficult to postulate a structure for **1** from the spectroscopic data, and there are at least 30 (15 diastereomers, each one with an enantiomer) possible isomers for this compound. The ^{31}P NMR spectrum ($CDCl_3$, +25°C) of **1** shows a number of resonances, and hence confirms the existence of several different isomers in solution. The ^1H NMR spectrum of **1** from 243–308 K shows a very broad resonance at $\delta = 3.0$ ppm due to the but-2-yne methyl resonances which may again suggest several isomers for this complex.

The reaction chemistry of **1** is diverse, and some reactions with neutral donor ligands are given in Scheme 1. For example, **1** reacts with an equimolar amount of PPh_3 in CH_2Cl_2 at room temperature to afford the dark green acetonitrile displaced product $[MoCl(GeCl_3)(CO)(PPh_3)_2(\eta^2\text{-}MeC_2Me)]$ in good yield. All the new complexes described in Scheme 1 have been characterized by elemental analysis (C, H and N), IR, ^1H, and in selected cases ^{13}C NMR spectroscopy.*

Variable-temperature ^1H NMR studies were carried out on the complex $[MoCl(GeCl_3)(CO)(PPh_3)_2(\eta^2\text{-}MeC_2Me)]$. These studies suggested that the but-2-yne ligand was undergoing rapid propeller-like rotation at room temperature (298 K) (single resonance for the but-2-yne methyl groups at δ = 2.45 ppm), whereas at 228 K two different but-2-yne methyl resonances were observed at $\delta = 2.32$ and 2.40 ppm. Using the equation[7] $\Delta G^{\ddagger} = \pi\Delta\nu h/\sqrt{2}K_BT_C$ ($\Delta\nu = 24.22$ Hz, $T_C = 239$ K), the barrier to but-2-yne rotation of $[MoCl(GeCl_3)(CO)(PPh_3)_2(\eta^2\text{-}MeC_2Me)]$ was calculated to be 50.4 kJ mol^{-1}. This value is typical of other calculated values for dihaloalkyne complexes of molybdenum(II) or tungsten(II) of the type $[MX_2(CO)L_2(\eta^2\text{-}MeC_2Me)]$.[3c-d,8] After many attempts, no suitable single crystals for X-ray crystallography have been grown of the products shown in Scheme 1.



Scheme 1. Reagents: (i) PPh_3 in CH_2Cl_2 at room temperature for 24 h; (ii) bipy in CH_2Cl_2 at room temperature for 1 h; (iii) $Na[BPh_4]$ in NCMe at room temperature for 24 h.

(*Received* 24 *June* 1991; *accepted* 22 *July* 1991)

Abstract—The A-frame complex $[Pd_2Cl_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$, obtained by the reaction between the side-by-side complex $[Pd_2Cl_2(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ (**1**) and dimethyl acetylenedicarboxylate, reacts with silver acetate and silver benzoate to give $[Pd_2(O_2CR)_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]\cdot 3H_2O$ [R = Me (**3**), Ph (**4**)]. Similar reactions with silver salts of (*S*)- and racemic-2-phenylpropionic acid afford $[Pd_2(O_2CHMePh)_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ [(*S*)- (**5**), racemic- (**6**)]. The NMR spectra of **5** and **6** show diastereoisomeric signal splitting, elucidating the presence of the enantiotopic face in **1**.

We[1] have previously reported the synthesis of the side-by-side complex $[Pd_2Cl_2(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ (**1**) and the A-frame complex $[Pd_2Cl_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ (**2**) containing the unsymmetrical bidentate ligand (benzylthiomethyl)diphenylphosphine. In these complexes, two bidentate ligands are coordinated in a head-to-tail fashion. Different from the side-by-side complexes such as $[Pd_2Cl_2(\mu\text{-}Ph_2PCH_2PPh_2)_2]$[2] and $[Pd_2Cl_2(\mu\text{-}Ph_2AsCH_2AsPh_2)_2]$[3] which contain symmetrical bidentate ligands, it has been pointed out that the side-by-side complexes involving unsymmetrical bidentate ligands like **1** or $[Pd_2Cl_2(\mu\text{-}Ph_2PPy)_2]$ have enantiotopic faces if the ligands are coordinated in the head-to-tail mode.[4] Scheme 1 demonstrates the presence of the enantiotopic face in the head-to-tail type of complex which affords chiral A-frames by reaction with a molecule X. We now report the preparation of some dicarboxylato derivatives of **2** and demonstrate by NMR the presence of the enantiotopic face in the side-by-side complex **1**.

RESULTS AND DISCUSSION

Analytical and physical data and NMR spectral data of the complexes obtained in this study are listed in Table 1 and 2, respectively.

Preparation of the dicarboxylato complexes $[Pd_2(O_2CR)_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$

As previously reported,[1] the A-frame complex $[Pd_2Cl_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ (**2**) was easily obtained by the reaction of the side-by-side complex $[Pd_2Cl_2(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ (**1**) with dimethyl acetylenedicarboxylate. Complex **2** reacted with two equivalents of silver acetate to give $[Pd_2(O_2CMe)_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]\cdot 3H_2O$ (**3**). The IR spectrum of **3** exhibited

characteristic bands due to the terminal acetato ligand[5] at 1575 and 1370 cm^{-1}, together with the ν(COO) frequencies of the ester group in the μ-$C_2(CO_2Me)_2$ moiety. As for the ^1H NMR spectrum (in $CDCl_3$), **3** showed a similar spectrum as compared with **2**,[1] except for a new signal at δ 1.55 assignable to the acetatomethyl resonance. These facts suggested that **3** was the diacetato derivative of **2**, but its elemental analysis also suggested the presence of three molecules of water. Actually, the ^1H NMR spectrum in water-free C_6D_6 confirmed that **3** contained three molecules of water. Similarly, **2** reacted with silver benzoate to give $[Pd_2(O_2CPh)_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]\cdot 3H_2O$ (**4**) which also contained three molecules of water. These water molecules might be incorporated between two carboxylato groups by hydrogen bonding. Complexes **3** and **4** did afford good crystals in solution for X-ray structural analysis, but the crystals rapidly became turbid when they were exposed to the air.

It is well established that palladium(II) acetate is a good cyclometallating reagent in comparison with palladium(II) chloride or the palladium(II) chloride–sodium acetate system.[6-8]. In addition, we have found that benzyl sulphide easily reacts with palladium(II) acetate to afford cyclopalladated complexes.[9,10] Complex **3** is a good candidate for the preparation of cyclometallated A-frame complexes as it has both the acetato ligand and benzyl sulphide group. However, **3** could not be converted into a desired cyclometallated complex under the conditions of refluxing in benzene or dioxane.

Silver salts of (*S*)- and racemic-2-phenylpropionic acids also reacted with **2** to produce the bis(2-phenylpropionato) complexes $[Pd_2(O_2CCHMePh)_2\{\mu\text{-}C_2(CO_2Me)_2\}(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ [(*S*)- (**5**), racemic- (**6**)], but in these cases ^1H NMR spectra and elemental analyses showed they contained no water.

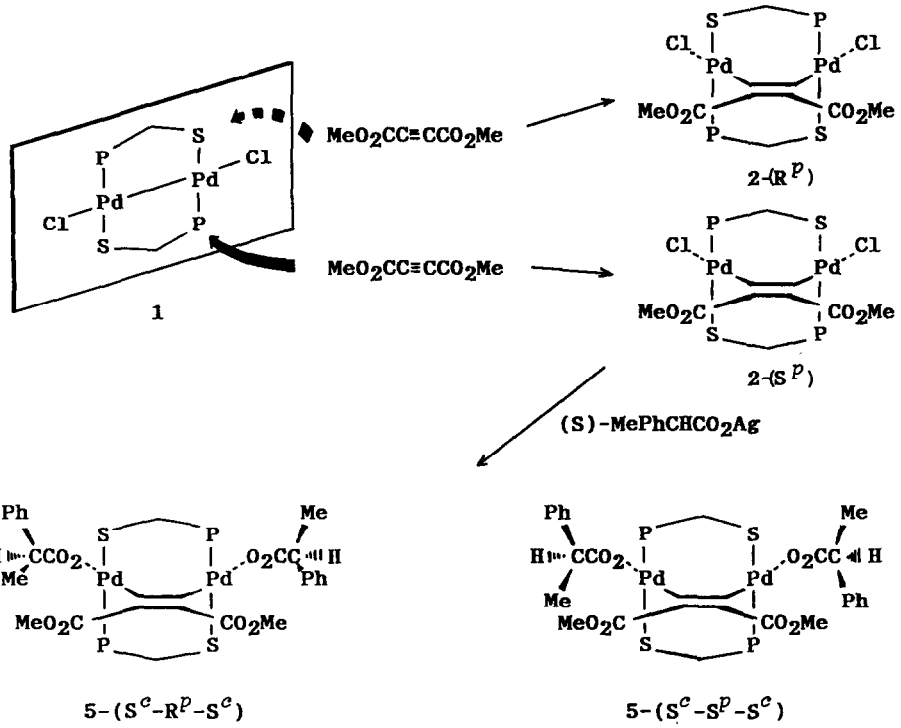
NMR spectroscopic evidence of the presence of an enantiotopic face in the side-by-side complex $[Pd_2Cl_2(\mu\text{-}Ph_2PCH_2SCH_2Ph)_2]$ (**1**)

As shown in Scheme 2, the side-by-side complex **1** has an enantiotopic face and the resulting A-frame complex (**2**) consists of two enantiomers, **2**-(R^p) and **2**-(S^p). In the 400 MHz ^1H NMR spectrum of **5**, two sets of signals with comparable intensities were observed for the resonance of the 2-phenylpropionato ligand (Me: δ 1.07 and 1.18) and the μ-$C_2(CO_2Me)_2$ moiety (MeO: δ 3.05 and 3.08) due to the formation of a mixture of two diastereoisomeric complexes. These two diastereoisomers have the configurations, S^c-R^p-S^c and S^c-S^p-S^c (Scheme 2; superscript c abbreviates the asymmetric carbon atom of the 2-phenylpropionato ligand and superscript p abbreviates the chirality of the plane). The methyl groups of the 2-phenylpropionato ligands as well as the methyl groups of the μ-$C_2(CO_2Me)_2$ moiety in each isomer are equivalent. Moreover, the 162 MHz $^{31}P\{^1H\}$ NMR spectrum of **5** showed two signals at δ 22.06 and 22.23 owing to equivalent phosphorus atoms in each diastereoisomeric complex.



Scheme 2. Enantiotopic face in **1**, two enantiomers of **2** and two diastereoisomeric complexes of **5** derived from the reaction of **2** and silver (*S*)-2-phenylpropionate (superscript c abbreviates asymmetric carbon atom and superscript p abbreviates the plane of chirality).

On the other hand, when racemic silver 2-phenylpropionate is used, the resulting complex (**6**) must be composed of six isomers; S^c-S^p-S^c, R^c-R^p-R^c, R^c-S^p-R^c, S^c-R^p-S^c, R^c-S^p-S^c and R^c-R^p-S^c. In these isomers, three pairs **A**(S^c-S^p-S^c and R^c-R^p-R^c), **B**(R^c-S^p-R^c and S^c-R^p-S^c) and **C**(R^c-S^p-S^c and R^c-R^p-S^c) are enantiomers to each other and are equivalent in NMR spectrometry. The formation probability of pair **C** is twice as much as that of **A** or **B**, as the diastereoisomers having the configurations S^c-S^p-R^c and S^c-R^p-R^c are the same as the isomers R^c-S^p-S^c and R^c-R^p-S^c, respectively, of pair **C**. As for the two phenylpropionatomethyl groups, they are equivalent in pair **A** or **B** but are non-equivalent in pair **C**. Consistent with the above consideration, the observed ^{1}H NMR spectrum of **6** exhibited four methyl signals for the 2-phenylpropionato ligand at δ 1.04, 1.07, 1.19 and 1.20 with equal intensities. Concerning the methyl resonance of the μ-$C_2(CO_2Me)_2$ moiety, three singlets were observed at δ 3.05, 3.06 and 3.08; the signal at δ 3.08 is ascribed to a coincidence of two signals by comparison of intensities. Furthermore, the $^{31}P\{^1H\}$ NMR spectrum of **6** showed four signals at δ 24.85, 22.06, 22.41 and 22.54 due to equivalent phosphorus atoms of each pair **A** and **B**, and two non-equivalent phosphorus atoms of pair **C**.

In conclusion, we report that the enantiotopic face in **1** has been revealed by NMR spectroscopy by comparing its diastereoisomeric derivatives **5** and **6**. The separation of diastereoisomers and their application to asymmetric synthesis are under investigation.

EXPERIMENTAL

General procedures and apparatus were the same as reported in a previous publication from our laboratory.[11] Complex **2** was prepared as described.[1] (*S*)- and racemic-$MePhCHCO_2H$ and silver acetate were commercially available and were used without purification.

Preparations of silver salts of benzoic acid and 2-phenylpropionic acids

These compounds were prepared by a method similar to that of Matthews *et al.*[12] and were obtained as white microcrystals. $PhCO_2Ag$: yield 80%; m.p. 292°C (decomp.). Found: C, 36.4; H, 2.2. $C_7H_5AgO_2$ requires: C, 36.7; H, 2.2%. Racemic-$MePhCHCO_2Ag$: yield 54%; m.p. 245°C (decomp.). Found: C, 41.9; H, 3.5. $C_9H_9AgO_2$

requires: C, 42.1; H, 3.6%. (*S*)-MePhCHCO$_2$Ag: yield 77%; m.p. 247°C (decomp.). Found: C, 42.0; H, 3.5. $C_9H_9AgO_2$ requires: C, 42.1; H, 3.6%. These compounds are almost insoluble in common organic solvents and ^{1}H NMR data could not be obtained.

Synthesis of the dicarboxylato complexes [$Pd_2(O_2CR)_2\{\mu$-$C_2(CO_2Me)_2\}(\mu$-$Ph_2PCH_2SCH_2Ph)_2$] (**3**–**6**)

The preparation of all the dicarboxylato complexes was quite similar and a typical example is shown. (*S*)-MePhCHCO$_2$Ag (0.053 g, 0.206 mmol) was added to a dichloromethane solution (20 cm^3) of **2**, and the mixture was stirred for 1 day at room temperature. The resulting suspension was filtered and evaporated to dryness *in vacuo*. The residue was extracted with ether and diluted with hexane. The mixture was left standing for 1 day in a refrigerator to give **5** as yellow microcrystals (0.036 g, 30%).

Abstract—Solutions of copper(II) halides in propan-2-ol were investigated spectrophotometrically at 25°C and at constant ionic strength. For the chlorides as well as the bromides four mononuclear complexes are present in the solutions and their overall stability constants were calculated as $\log\beta_{CuCl^+} = 5.7$, $\log\beta_{CuCl_2} = 8.6$, $\log\beta_{CuCl_3^-} = 10.2$, $\log\beta_{CuCl_4^{2-}} = 10.6$, and $\log\beta_{CuBr^+} = 6.1$, $\log\beta_{CuBr_2} = 8.4$, $\log\beta_{CuBr_3^-} = 10.2$, $\log\beta_{CuBr_4^{2-}} = 10.7$. Electronic spectra of all the species present in the solution were calculated; the tetrahalogenocuprate CuX_4^{2-} has D_{2d} symmetry.

A comparative study of the thermodynamic stabilities of these complexes in alcohols shows a tendency of stability as an increasing function of number of carbon atoms in the alcohol.

In this paper we present the results of a spectrophotometric study of the copper(II) halide complexes in propan-2-ol with a view to determine the solvent effects on the thermodynamic and spectroscopic properties of these complexes in alcohols. An exhaustive bibliography of copper(II) halogenocomplexes in aqueous as well as in organic solutions has already been reported in our earlier publications,[1,2] we shall therefore limit our bibliographic references to studies carried out in alcoholic medium only.

There are hardly any quantitative studies in alcohols reported in the literature. In one of the earlier works, Kosower *et al.*[3] who observed six absorption bands propose the existence of six bromocomplexes in ethanol. Barnes and Hume[4] have identified the absorption maximum at 625 nm in ethanol as that of the tribromocuprate. Furlani and co-workers have discussed the configurations of the tetrahalogenocuprates as D_{2d} or D_{4h} in different organic solvents.[5,6]

Our results of the studies of these complexes in methanol[1] and ethanol[2] have shown the presence of four mononuclear complexes in both the alcohols. Overall stability constants as well as individual electronic spectra of all species were calculated and the structures in solution of the tetracoordinated complexes were discussed. We now report the results of the copper(II) halide complexes in propan-2-ol. The successive equilibria, the simplified representation of which does not take into account the solvated character of the copper(II) in the inner coordination sphere, $Cu^{2+} + jX^- \rightleftarrows CuX_j^{(j-2)-}$ (X = Cl, Br), were studied at 25°C and at constant ionic strength maintained at 1 mol dm^{-3}. Overall

stability constants, β_j, for the species present were calculated using experimental data of absorption measurements in the UV, vis and the near-IR regions and these parameters in turn were used to calculate the individual electronic spectrum of the species. We do emphasize that β_j are apparent stability constants, calculated in the approximation of no occurrence of ion-pairing of the different species present in the non-aqueous medium.

EXPERIMENTAL

Anhydrous propan-2-ol, Merck p.a., was used. Stock solutions were prepared from $Cu(ClO_4)_2 \cdot 6H_2O$, $LiClO_4$, LiCl, (Fluka) and LiBr (Merck p.a.). Copper solution was titrated against EDTA using murexide as an indicator.[7] Ionic strength was kept constant at 1 mol dm^{-3} with the help of lithium perchlorate. Ligand concentrations were kept higher in order to eliminate the possibilities of formation of plurinuclear complexes on the one hand and favour the formation of highly coordinated complexes such as CuX_4^{2-} on the other hand.

Since copper(II) halide solutions are not very stable, especially the bromide solutions, all measurements were made immediately after the addition of the last reactant. The experimental conditions, in short, were identical to those in studies in methanol and ethanol in order to make a uniform comparison.

RESULTS AND DISCUSSION

Experimental spectra

Figures 1 and 2 represent the experimental spectra of copper(II) chlorides and bromides, respectively.

In the case of chloride solutions the free solvated copper ion seems to have its absorption maximum at *ca* 240 nm. As soon as small quantities of ligand are added an absorption band at 270 nm appears and progressively shifts to 290 nm for $C \geqslant 0.004$ mol dm^{-3}. For ligand concentrations higher than 0.008 mol dm^{-3} a shoulder peak is noticed at *ca* 250 nm, and for still higher concentrations a large band centred at 390 nm is observed along with isobestic points at 264, 308 and 366 nm. In the near-IR region, Cu^{2+} has its characteristic absorption at 800 nm which, as the ligand is added, shifts regularly until 960 nm. For solutions of higher concentrations a large band appears at about 1100 nm.

In the bromide solutions, even at very dilute ligand concentrations, a maximum is observed at 310 nm which for $C > 0.02$ mol dm^{-3} splits in two:

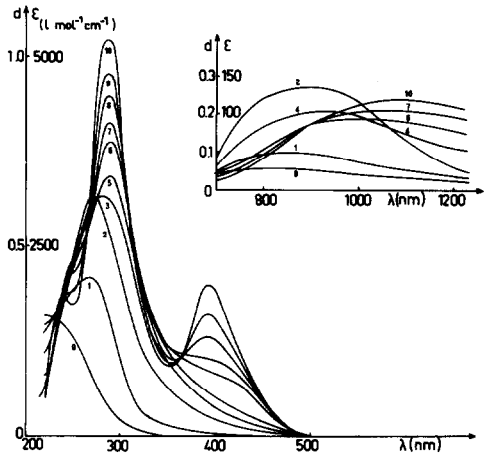

Fig. 1. Absorption spectra of copper(II) in lithium chloride–perchlorate isopropanolic mixtures. $B = 1 \times 10^{-3}$ M, $l = 0.2$ cm (UV–vis), 2 cm (near-IR). Spectra/$[Cl^-]_0$: 0/0; 1/0.001; 2/0.002; 3/0.004; 4/0.008; 5/0.01; 6/0.04; 7/0.08; 8/0.20; 9/0.40; 10/1.0.

one at 280 and the other at 350 nm. The absorption band at 280 nm undergoes a hypsochromic shift to 270 nm. In the vis spectrum there are two large bands at 510 and 640 nm. Finally in the IR region, the absorption maximum of the copper ion at 800 nm is progressively shifted with the addition of bromide ions from 860 to 940 nm in a quite similar way to the chloride system. For $C > 0.08$ mol dm^{-3} this maximum shifts from 940 to 1100 nm, which is probably due to the change in configuration of the tetracoordinated complex.

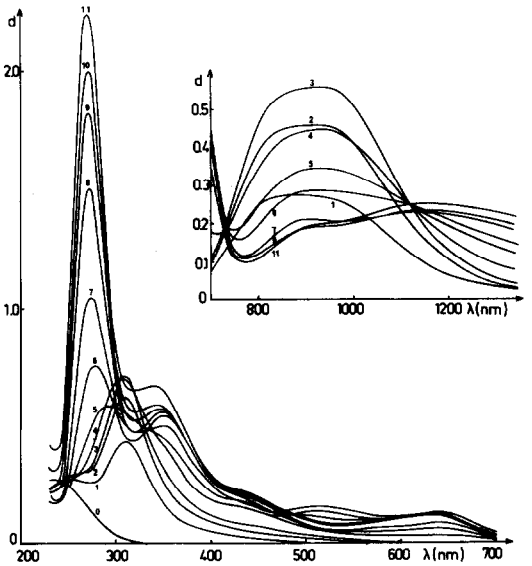

Fig. 2. Absorption spectra of copper(II) in lithium bromide–perchlorate isopropanolic mixtures. $B = 1 \times 10^{-3}$ M; $l = 0.2$ cm (UV–vis), 2 cm (near-IR). Spectra/$[Br^-]_0$: 0/0; 1/0.001; 2/0.002; 3/0.003; 4/0.010; 5/0.02; 6/0.04; 7/0.10; 8/0.20; 9/0.40; 10/0.80; 11/1.0.

Numerical analysis and stability constants

A matrix rank treatment, based on the method of Hugus and El Awady was used to determine the minimum number of absorbing species in the solution.[8] These calculations were carried out on an experimental data set of $N \times L = 400$ absorption measurements for the chlorides (number of wavelength $L = 16$, number of solutions $N = 25$) and 392 measurements ($N = 14$, $L = 28$) for the bromides. The details of the mathematical expressions used for calculations have already been given in our earlier publications.[9,10]

For both the systems, results indicate the presence of at least three complexes. Taking into account these results and the fact that experimental conditions are such that the formation of plurinuclear complexes is negligible, theoretical models for three and four mononuclear complexes, i.e. CuX^+, CuX_2, CuX_3^- and CuX^+, CuX_2, CuX_3^- and CuX_4^{2-}, respectively, were tested and their results summarized in Table 1.

Several initial assumptions are used for the thermodynamic basis of the stability constant of a complex in this kind of non-aqueous solutions:

(1) A stabilization of the ionic environment of the metal is obtained by addition of concentrated electrolytes which do not interfere in the coordination process between metal and ligand. The activity coefficients of the different reacting species will be stabilized in constant ionic strength medium as they are in aqueous solutions. Their values will certainly differ from one non-aqueous medium to another, but it is demonstrated that the ratio of the activity coefficients of the species inherent in superposed equilibria will be constant.

(2) Protic solvents such as propan-2-ol are classified as weakly dissociating solvents having a good ionizing ability according to the dielectric constant values of the pure solvents lying over 20: introducing strong electrolyte mixtures within the medium will certainly, despite constant ionic strength, modify the value of this parameter and consequently the dissociating property of the solvent; but the impact of this variation should be negligible for the solvation energies of the free ions as for the complexes. In such a medium the complexes will be present as ions which is not the case in molecular solvents (acetic acid[11] or tetrahydrofuran[12]) where all the species are ion-pairs or ion-aggregates. The assumption is made that in protic solvents such as propan-2-ol the formation of ion-pairs is not taken into account in the numerical analysis and the calculation of the constants β_j. This condition could only be considered if the association constants and activity coefficients of all species involved in the superposed equilibria are known: but these quantities are impossible to measure simultaneously.

(3) Transferring the ionic strength concept to this non-aqueous medium with the assumption of the activity coefficients stabilization, the interpretation of the superposed equilibria in non-aqueous solutions is possible: it leads to "apparent stability constants" which can be used as "thermodynamic parameters". The zero of the thermodynamic constants of complexation could be obtained through equilibria investigations at different constant ionic strengths and extrapolation to zero ionic strength of the obtained apparent stability constants.

It is seen that in both cases the standard deviation for all measurements in the whole spectrum region, σ_t, is better for models with four than the models with three complexes. Adding to this the fact that

Table 1. Overall stability constants, β_j, for copper(II) chloro- and bromocomplexes for [1, 2, 3] and [1, 2, 3, 4] models

Complexes	β_j	[1, 2, 3]	[1, 2, 3, 4]
